# 1. Introduction

Accessing another's credentials has always been a major goal of hackers or pirates. Typically, pirates would perform phishing or even spear phishing attacks on naïve or unsuspecting targeted individuals. In these attacks, the hacker would send a user a link to some embellished website mimicking a known banking, credit card or other financial site. It would request the unsuspecting user to enter their personal credentials. Once the credentials were entered and transferred to the pirate, the pirate could now perform bank transfers, embezzle money or even take over the victim's account. These attacks were very costly to financial institutions and other highly secure websites, but not highly effective or scaleable. That's because in order to be successful, phishing sites required much intelligence to send the proper link to the appropriate users and even so most users did not take the bait.

In the last five years however, a new more scaleable and effective method of accessing another's credentials has become increasingly popular. This form of piracy, known as credential stuffing, is based on two historical realities:

1. In the past 10 years, thousands of identity databases belonging to large websites, have been breached leading to the identity theft of tens of billions of credentials.
2. Most people reuse the same credentials (username and password) on multiple sites as a convenient way of remembering them.

Given these two facts, new credential stuffing tools were created to enable a set of bots over proxies or VPNs to discover active breached credentials from a set of popular websites. The diagram below illustrates how credential stuffing attacks are performed.

A pirate purchases millions of username/password combinations (combos) extracted from breached websites, and configures a set of bots, proxies, desired websites and scripts describing login navigation details of each of these desired sites. The pirate then inputs all these artifacts into credential stuffing tools. The tool then assigns bots to try all of these combos on each of the popular websites, using navigation instructions within scripts, and connect to them via separate proxies or VPNs. In order to go undetected, different IP addresses are used for each malicious attempt! The tool returns a subset of the list of credentials that are still active on each popular site. This attack is effective because most users tend to employ the same username/password combination across most of their websites.

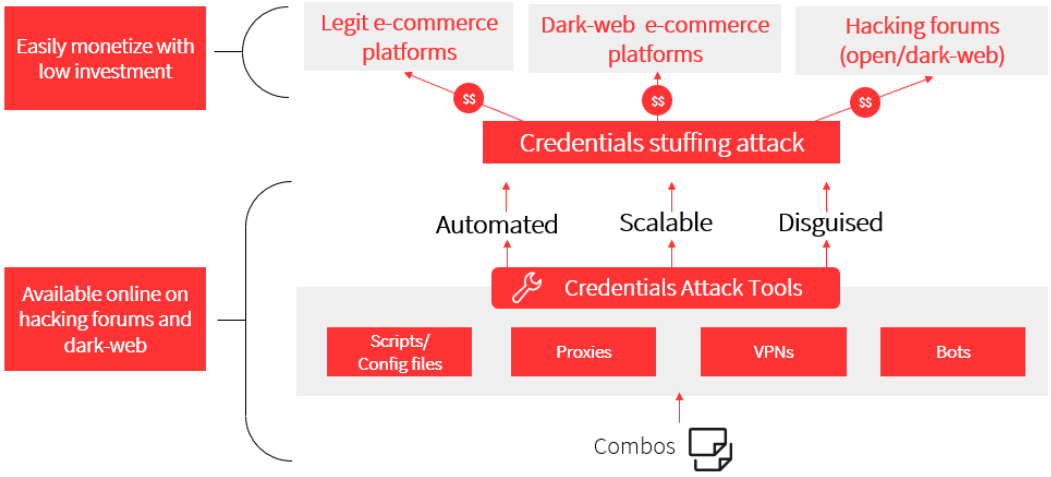

**Figure 1 - Credential Stuffing Attack**

Once any login attempt succeeds, the stolen credentials become marketable and can enable access to another's account. The accounts which are typically accessed via credential stuffing are not only banking sites but also streaming media sites, where the purpose of the attack is not to pilfer money, but to sell access to someone else's account and enable a buyer to enjoy content made available by another's monthly subscription. As a result of these credential stuffing attacks, access to media sites such as streaming video, music, audio book, books etc. are sold over telegram groups, forums, websites on the open Internet and especially the dark web.

Unlike phishing or spear phishing attacks, where the victim realizes the credential theft and resulting fraud fairly early and immediately alerts authorities, credential stuffing attacks on media sites tend to go undetected for a very long time. That's because the pirate or purchaser of the credentials desires to receive a free media service and hence does whatever it takes to remain unnoticed by the real owner.

## 2. The prevalence of fraudulent password usage in media services

Credential stuffing is growing dramatically, especially in media services. According to Forbes, 4.1 billion credentials were breached in the beginning of 2019 alone. The HaveIBeenPwned website has a database of over 10 billion breached credentials. According to Shape Security, between 0.5 and 2% of these credentials will be valid on any targeted website or mobile app.

Between the beginning of May and the end of June this year, Akamai collected data on 8.35 billion credential stuffing attempts across the globe across all industries. They estimate that in Q1, credential stuffing attacks increased by 1,450%, compared with about 200% in 2019 (compared with 2018). One European broadcaster was even hit with peaks of malicious credential stuffing attempts that ranged into the billions. However, as mentioned above, unlike phishing attacks which typically target financial institutions, a good percentage of credential stuffing attacks are focused on media. The graph below by Arkose Labs shows that over 20% of all online traffic to media sites are credential stuffing attacks.

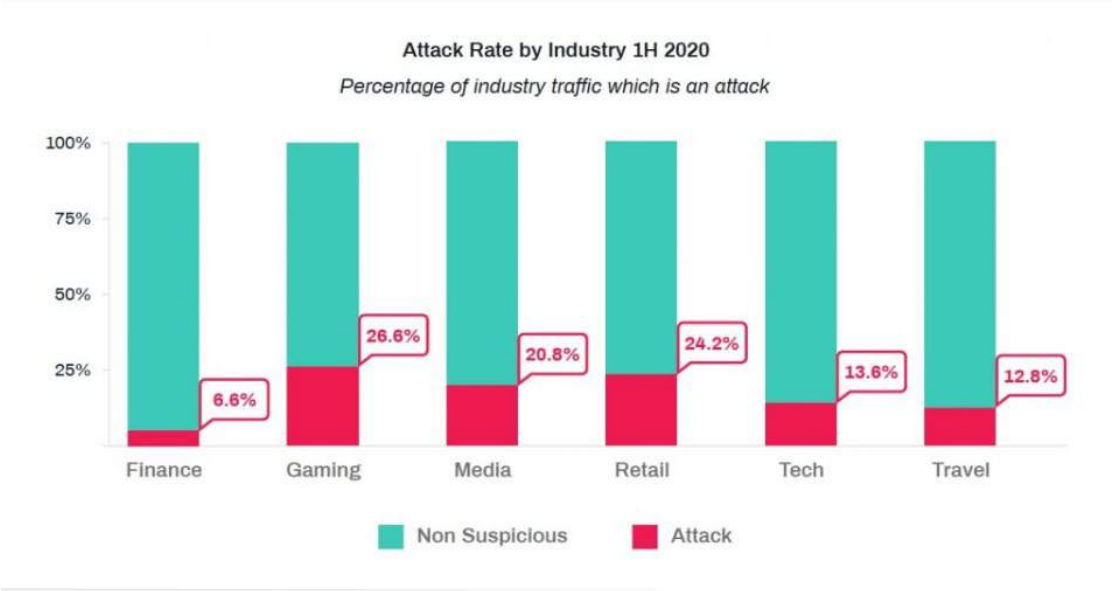

**Figure 2 - Credential Stuffing Attack Rate by Industry**

These attacks against media sites continue to grow significantly. The graph below by Akamai exhibits the steep rise in malicious credential stuffing login attempts against media, exacerbated by the period of COVID-19, where a 300% increase was observed.

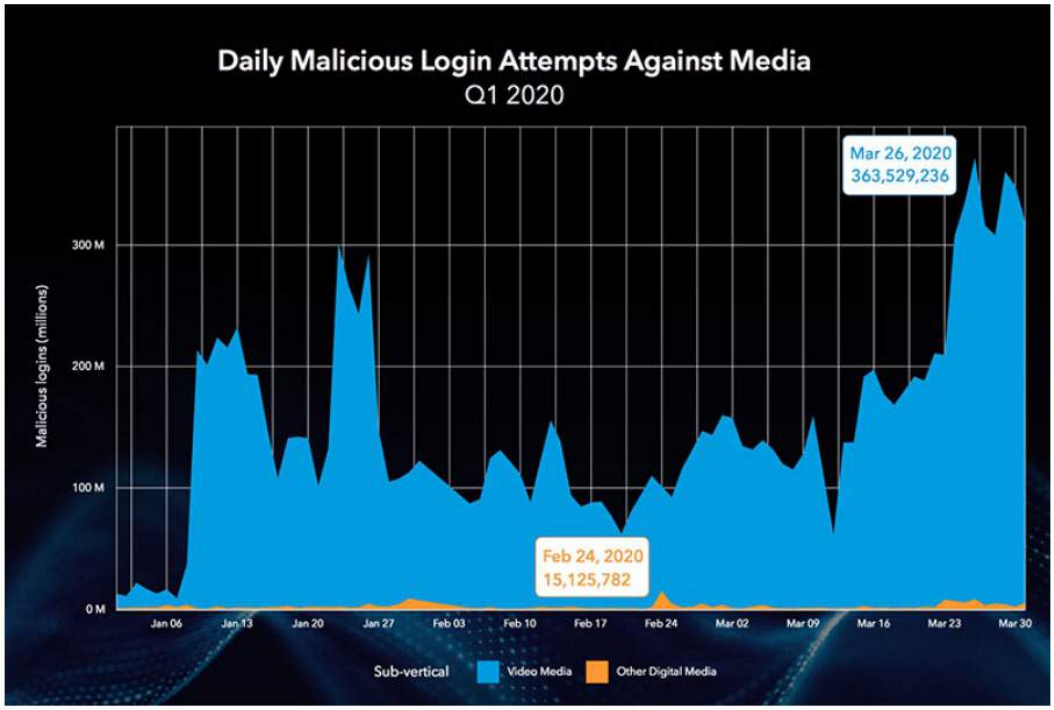

**Figure 3 - Daily Malicious Login Attempts Against media**

But even before COVID-19, between 2018 and 2019 there was a 63% increase in credential stuffing attacks against video media sites as shown by the Akamai graph below.

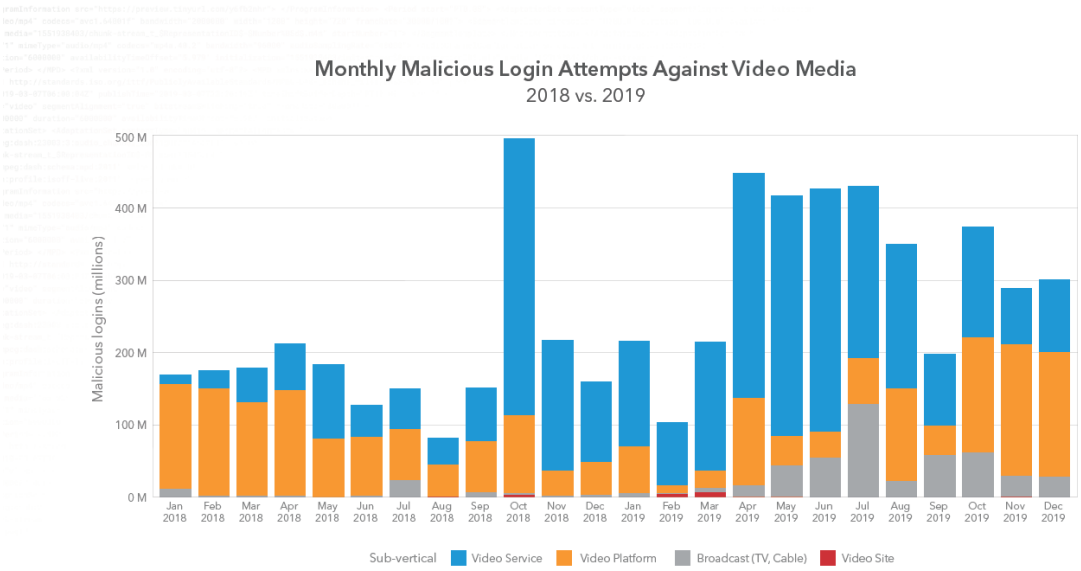

**Figure 4 - Monthly Malicious Login Attemts Against Video Media**

Akamai researchers watching the credential stuffing space in Q1 2020, noted that video media accounts were trading for about $1 to $5 on the criminal market early on. Some packaged offers (those that include multiple services per order) were even being sold for $10 to $45. Toward the end of Q1 2020, those prices fell as the credential stuffing market became flush with new accounts and lists of recycled credentials.

Based on the statistics above, it is clear that the criminal economy is a chained instance, where everything is somehow connected, and no piece of information is without worth. Criminals pre-package compromised accounts, selling them based on interest, location, and volume, and people are willing to pay. This only fuels the criminals' actions and keeps them hyper-focused on evading detection and mitigation.

## 3. Why credential fraud detection is so difficult: Sharing vs Fraud

As mentioned above, credential stuffing discovers marketable credentials that are active on various media sites. These credentials are then typically sold on either the dark web, telegram groups, forums or open Internet websites. Below is an example of a site selling various subscriptions to streaming services for one time payments under $15.

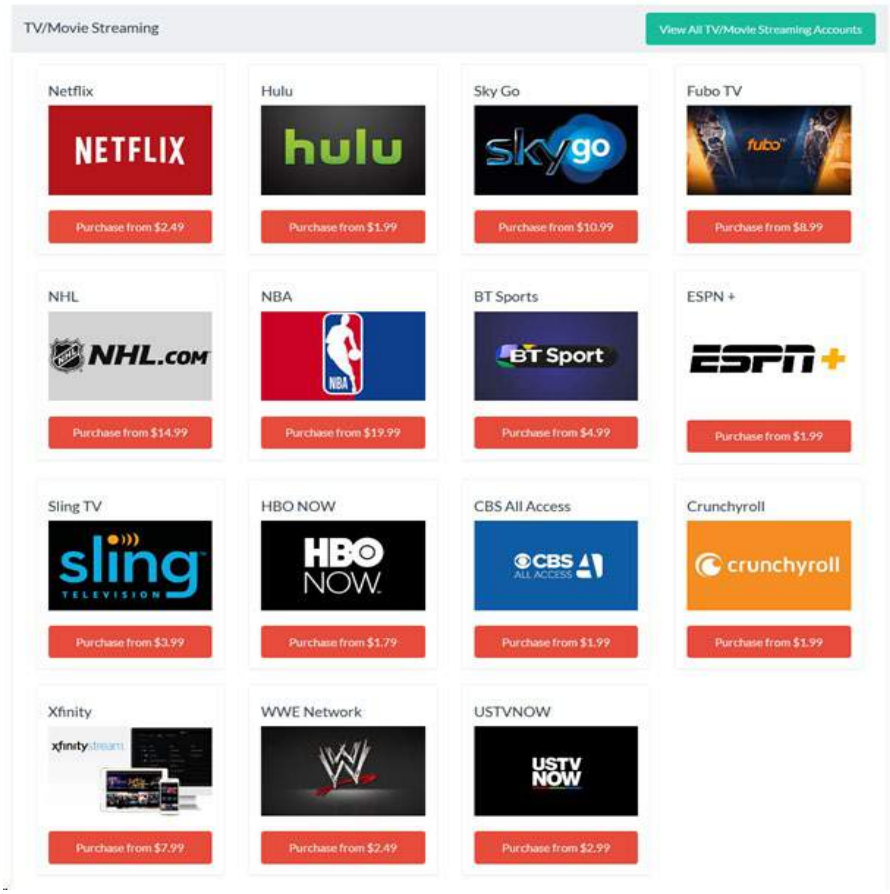

**Figure 5 - Online Sales of Fraudulent Subscription Services**

The motive of those purchasing these credentials is not malicious. They aren't looking to takeover and control the account. Nor are they looking to purchase goods on the account owner's credit card. They simply want to enjoy a popular streaming subscription service for a low one-time cost.

In other words, those who purchase another person's credentials to a popular video media site is unable to find another account owner who is willing to casually share their credentials with them. Hence they need to rely on purchasing the credentials from a stranger in order to receive a free subscription to this media service.

The goal of the user who purchases credentials from a credential stuffing fraudster is to enjoy this service that he purchased for a low one-time fee for as long as possible without being noticed and without the account owner changing his password out of suspicion. Hence, the behavior of the fraudster will by definition mimic that of the sharer, one who benefits from casual sharing, or even the account owner.

Based on this new reality, it becomes challenging by scrutinizing the data alone to differentiate between the account owner and the fraudster and even more difficult to differentiate between the fraudster and the casual sharer. If you scrutinize which devices within any given account constantly view video from out-of-home locations and IP addresses, you cannot distinguish between the fraudster, the person who purchased the fraudulent credentials or the casual sharer.

While most service providers are willing to tolerate some level of casual sharing, the same is not the case when it comes to credential fraud. Given concerns over privacy and other liabilities, detecting the fraudster and differentiating them from the sharer is critical to the well-being of a video service.

Which begs the question: How does one differentiate between casual credential sharing and credential fraud?

## 4. Credential Fraud indicators and Solution Enablement

Synamedia has created a novel solution to detect credential fraud in media services resulting from credential stuffing attacks based on machine learning. In this solution, credentials sold online to any particular media service are purchased by our own intelligence group. The credentials are then used to train a supervised machine learning model to detect a fraudulent account using various indicators. Indicators of fraud in the model are based on some of the following principles:

1. Landscape of how credentials are sold on the various marketplaces and various trends on the frequency of usage of a stolen credential once put up for sale
2. Assumption that there is less correlation between the viewing preferences, behaviors and habits of the fraudster and the account owner versus those of the sharer and the account owner
3. Other anomalous, suspicious and unexpected activity in the account

Once this supervised model is built, it can be applied to locate other, as yet undiscovered fraudulent accounts. Once all fraudulent accounts are classified, a second model is built which can differentiate between the devices of the sharer and account owner and that of the fraudster within each classified fraudulent account. This algorithm is semi-supervised but is based on many of the same indicators described.

Finally, fraudulent devices are graded according to the likelihood that they will perform real malicious activity, such as an online purchase of goods and/or new services in the name the account owner or even an account takeover. The activity diagram describing this algorithm is shown below.

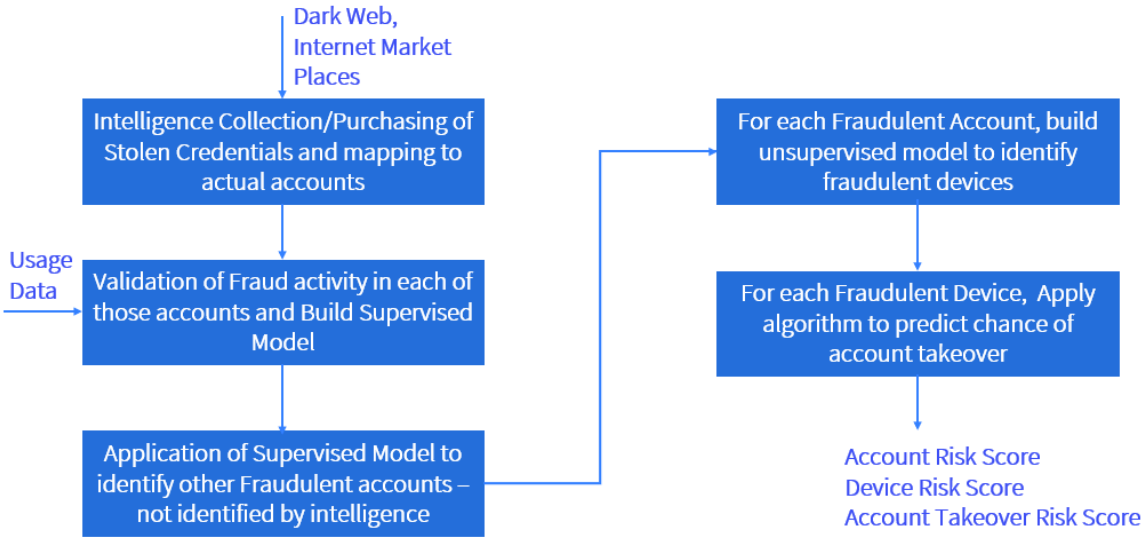

**Figure 6 - Synamedia Anti-Fraud Algorithm**

## 5. Trusted Identity as a Service

By creating such an algorithm, Synamedia provides a service to validate the trusted identity of media accounts and devices within each account. Upon receiving near real-time data streams from a media provider, Synamedia supports an API where it can return:

1. Likelihood that a specific account is fraudulent
2. Likelihood of fraud in each device within that fraudulent account
3. Risk of account takeover or other malicious activity of each fraudulent device in that fraudulent account

An example of this service is shown in the diagram below

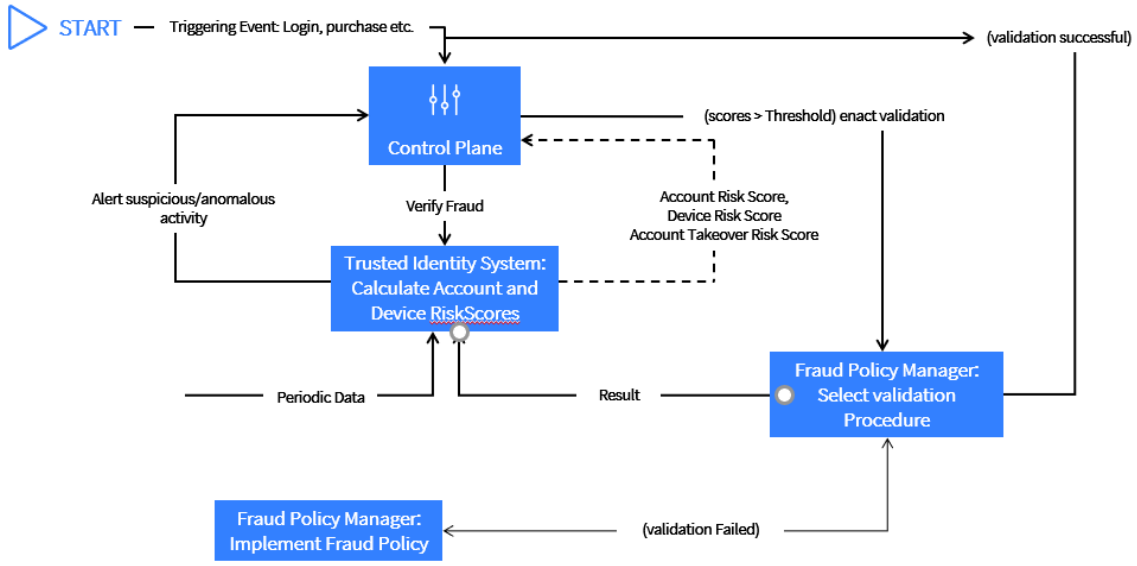

**Figure 7 - Anti-Fraud Detection and Resulting Policy**

This trusted identity service enables a media provider to both perform adaptive authentication and enforce adaptive remediation policies, where the authentication and the resulting policy are compliant to the risk of fraud of every device in every account. As a result, the service provider can create an adaptive policy table as a function of the sensitivity of the trigger (login, TVOD purchase, change of address etc.) which caused the trusted identity API to be called.

Many verification and remediation policies, such as password change and answering security questions, are effective against fraudsters as opposed to sharers because we assume no social connection nor passing of information between the account owner and the fraudster!

An example of an adaptive policy table is shown below.

**Table 1 - Fraud Policy Table**

| Trigger Sensitivity Score | Account Risk Score | Device Risk Score | Account Takeover Risk Score | Fraud Verification Policy | Fraud Remediation Policy if verification Fails | Fraud Remediation Policy if verification Succeeds |
|---|---|---|---|---|---|---|
| <30 | All | ALL | All | None | N/A | N/A |
| >30 <60 | <50 | <30 | N/A | None | N/A | N/A |
| >30 <60 | >50 | <30 | N/A | Provide Password | Suspend Account | Change Password |
| >30 <60 | >50 | >30 | <20 | Answer 1 or more Security Questions | Blacklist Device | Change Password |
| >30 <60 | >50 | >30 | >20 | Biometric / MFA | Suspend Account | Change Password |
| >60 | <50 | <30 | N/A | Provide Password | Suspend Account | Change Password |
| >60 | >50 | <30 | N/A | Answer 1 or more Security Questions | Blacklist Device | Change Password |
| >60 | >50 | >30 | <20 | Answer 1 or more Security Questions | Suspend Account | Change Password |
| >60 | >50 | >30 | >20 | None | Suspend Account and Blacklist Device | Change Password |

# 6. Conclusion

Credential stuffing is a new piracy attack that has become prevalent in the past several years. This is due to the vast increase in the quantity of breached credentials in the marketplace and also based on the fact that few users change their credentials between accounts.

Credential stuffing, as opposed to other credential discovery techniques such as phishing, is prevalent not only on financial sites but also on media sites where the primary objective of the fraudster is to benefit from a low one-time payment to a subscription service. Hence, fraudulent use based on credential stuffing is extremely difficult to detect and disrupt!

Using advanced machine learning techniques, Synamedia has managed to build new fraud detection algorithms that can detect fraudulent usage of devices within accounts based on credential stuffing attacks. The results of this algorithm enable very effective adaptive authentication and remediation techniques to combat those passwords that were stolen and purchased based on credential stuffing!

# 1. Introduction

This paper is a joint effort by members of the SCTE Alternative Energy / Microgrid Working Group. The SCTE Alternative Energy / Microgrid Standards Working Group's (AE/MGWG) charter is to "educate and inform the SCTE community on the applicability and use of alternative energy & microgrid technology in cable operator facilities." This includes: defining operational practices and standards; demonstrating the technology is deployable and manageable for service providers; facilitate communication between service providers, industry partners and other standards organizations; and creating a library of microgrid use cases showing how resiliency can be improved, operational costs reduced, and deployment times decreased through the appropriate application of these technologies.

A microgrid is an electrical system that connects multiple sources and loads that is controllable by the user to allow independent operational choices. Currently, some basic alternative energy and microgrid technology have been deployed throughout the cable industry. However, the industry has not yet taken full advantage of existing, available, and relevant advanced powering technologies. Most existing power systems are not ready to work like advanced microgrids. That said, cable operators can, and should, continue to leverage already deployed technologies and test the new approaches to powering. This paper will attempt to address how microgrid technology has continued to evolve, along with the issues facing the application of future microgrid technologies, to illustrate the benefits of adopting a proactive rather than reactive microgrid implementation strategy.

Today, traditional deployments of energy infrastructure in the cable industry includes Direct Current (DC) power plants and Alternating Current (AC) uninterruptable power systems, long term battery storage, transfer switches and switch gear. It also includes generator sets, renewables and other power sources that have been combined in a traditional manner to provide resiliency and sustainability when grid power is lost. While these are many of the basic elements of a microgrid, they often lack the topology and controls required for full microgrid implementation and performance. However, existing deployments are capable of providing a foundation for transition into a more resilient and functional microgrid architecture.

The fundamental premise behind the deployment of a true microgrid architecture by a cable operator is the increasing opportunity to diversify sources of power and therefore enable a more resilient service offering to customers. This would also allow new capital models and power system topology designs to reduce cost of ownership.

# 2. 10G and the Aging Power Grid

## 2.1. 10G Defined

The cable industry is quickly moving the needle of network service offerings. The collective initiative was announced as 10G at the 2019 CES show in Las Vegas. This collective push to offer a symmetrical 10 gigabit network to subscribers will enable new ideas, businesses, and things not yet imagined coming to life. "The 10G platform is a combination of technologies that will deliver internet speeds 10 times faster than today's networks and 100 times faster than what most consumers currently experience. Not only does 10G provide faster symmetrical speeds, but also lowers latencies, enhanced reliability and better security in a scalable manner."[1] Powering will continue to be an important component to this developing program, and just like the network will evolve, power strategies should evolve as well.

## 2.2. Aging Infrastructure and the Grid

The U.S. electric grid ("the grid") constitutes a vital component of the nation's critical infrastructure and serves as an essential foundation for the American way of life.

America's economy, national security and even the health and safety of our citizens depend on the reliable delivery of electricity. The U.S. electric grid is an engineering marvel, with more than 9,200 electric generating units having more than 1 million megawatts of generating capacity connected to more than 600,000 miles of transmission lines, according to the U.S. Department of Energy, Office of Electricity.

This "grid" feeds consumers through an intricate network of transmission lines, substations, distribution lines, and transformers, as shown in Figure 1.

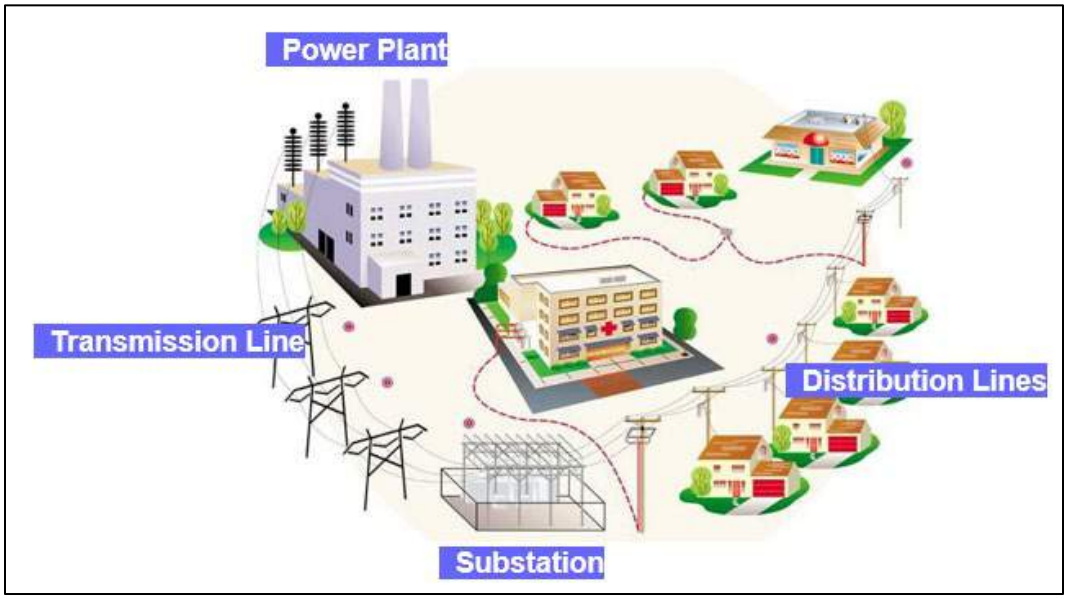

**Figure 1 – Simplified Electrical Grid**

It is generally understood in the industry that the electrical grid is aging. A good assessment is provided by the American Society of Civil Engineer's (ASCE) 2017 Infrastructure Report Card, which described most of the U.S.

energy system as predating the turn of the 20th century, with most transmission and distribution lines at full capacity. These systems were constructed in the 1950s and 1960s with a 50-year life expectancy. The annual number of power outages continue to increase, and the ASCE gave the system a D+, the same rating given to it in the previous three 4-year report card cycles, indicating no changes other than the system continues to age.

As a significant portion of the grid was developed and built half a century ago, it did not include the present-day demand for:

- Higher quality power
- Integration of clean, variable renewable, electric vehicles, and distributed energy technologies
- Remote control and data gathering
- Enabling consumer participation
- Higher security and protection from vandalism, terrorism, and weather

The grid was built to simply deliver power with ease of operation, economically, efficiently, and reliable for the age.

This grid connects numerous utilities which are individually focusing on replacement and upgrade as priority over other issues such as aging workforce, regulatory models, and stagnant growth. Meanwhile, they are developing and improving processes and models to manage their assets more efficiently such as:

- New and innovative testing methods, which help to identify and prioritize old equipment that is most in need of repair and/or replacement
- Cable injection and treatment programs
- Breaker refurbishment and upgrade programs
- Wood pole and tower structure testing, treatment, and replacement

Unfortunately, these programs allow the basic infrastructure to continue to age.

## 2.3. Reliability & Resiliency (eg: Ca. Public Service Power Shutoff (PSPS Program!)

Cable operators are observing compound annual growth rates (CAGR) of 40 – 50% downstream and 20 – 30% upstream driven by streaming video (including 4K content); newer, delay-sensitive gaming applications; and a general increase in consumption. Over the next few years, cable operators will be faced with numerous decisions in order to meet the exponentially growing needs of their customers.

The upcoming implementations of 10G networks, which promise 10X the bandwidth, assure that there will be an increased need for reliable energy to drive these more powerful devices as they are deployed across the network. This increased demand for powering cable plants and networks comes at a time when traditional utilities are grappling with a myriad of issues, including the fact that they have failed to keep up with the increasing need for truly resilient energy across their mostly centralized networks. This can pose another serious challenge that cable operators will need to contend with.

What's more, to contend with existing and up-and-coming competitors, cable operators are also increasing their dependence on reliable and consistent power to service newer offerings that are being driven by the proliferation of Internet of things (IoT) applications, including in-home security systems and other "smart devices." This all increases backhaul requirements and intensifies the demand for resilient and reliable power.

These dynamics are forcing operators to reconsider their investment strategies and the soundness of making longer term capital expenditures to reduce risk, reduce costs and remain competitive. Microgrids may provide a viable strategy, by reducing the dependency on traditional power providers with the possible concurrent benefit of reducing energy-related operating expenses over time. Fortunately, many cable operators have been quietly engaged in building out what could be considered microgrids of sorts. By installing renewables and energy storage systems, operators are adding resiliency and maintaining operations in the event of power failures resulting from disruptions in the power grid. An additional benefit of these hybrid microgrids can also be realized by reducing demand charges and possibly reselling power to utilities under power purchase agreements. Other drivers of the trend to increase independence from traditional providers are the increased intensity, regularity, and length of weather disruptions, and the inability of utilities to easily make enhancements to their generation and distribution capabilities. Issues related to localities objecting to pipeline placement, new power line installations and other regulatory challenges are adding to risks associated with dependency on traditional utility operators. Operators in California have recognized the potential for such grid disruptions and have begun to respond by promoting centers in areas less likely to be impacted. Figure 2 provides a list of electrical infrastructure hazards and associated risks.

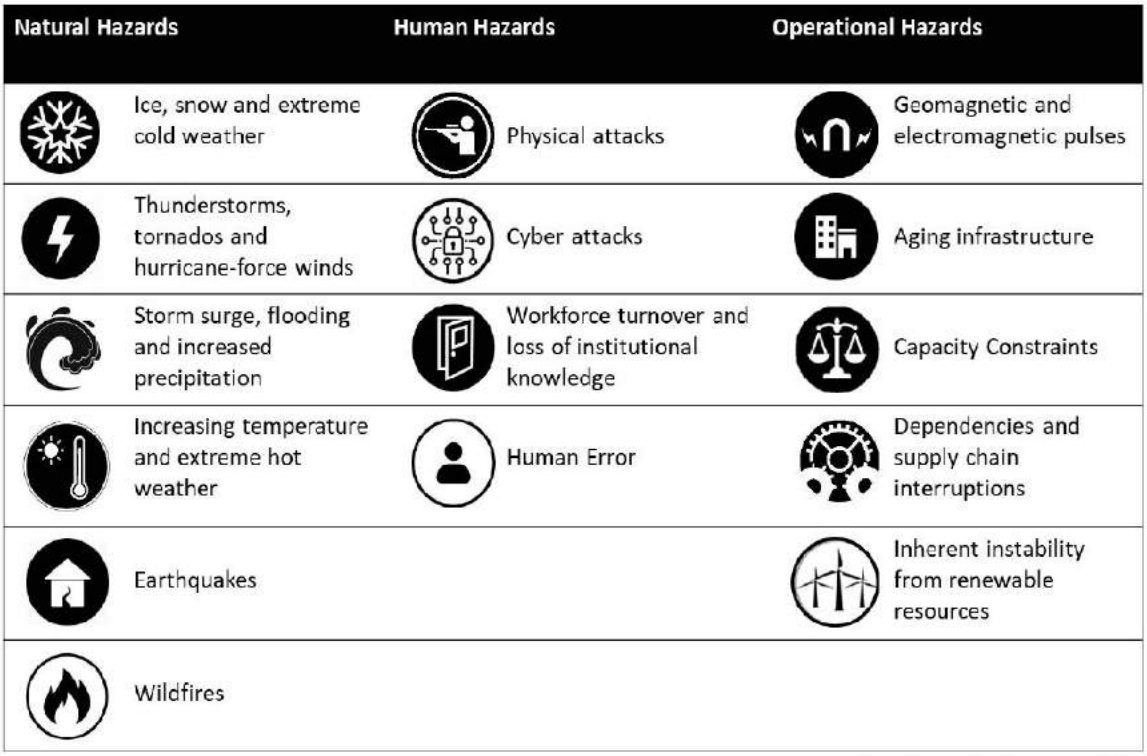

**Figure 2 – Growing Risks to the Electrical Infrastucture**

Growing energy demand is also impacting the existing industry growing risk situation. Despite increased efficiency, the US Energy Administration projects that world energy demand will increase by 28% by 2040. Much of this demand is driven by the increasing digitization of society, data centers, telecommunications systems,

and our households, that continue to require more energy to operate the devices we have become so dependent upon.

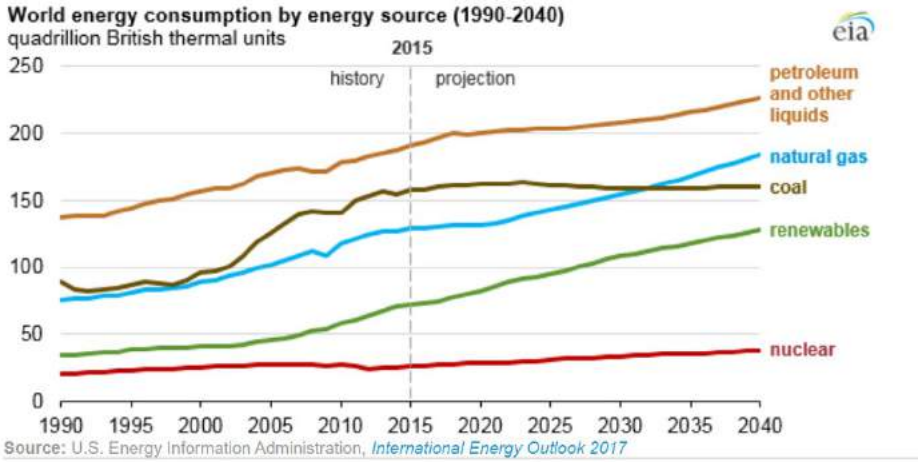

**Figure 3 – World Energy Consumption**

Also compounding the problem is the increased intesnity and frequency of major storms, fires and other natural disasters. Outages of more than 24 hours impact every citizen. Food supply, manufacturers, communications networks, and simple changes to every day routine have consequences beyond financial. Also to be considered are the financial and manpower resources required to respond to such events, the pressure on traditional utilities to modernize generation and distribution networks, and the impact on our communities.

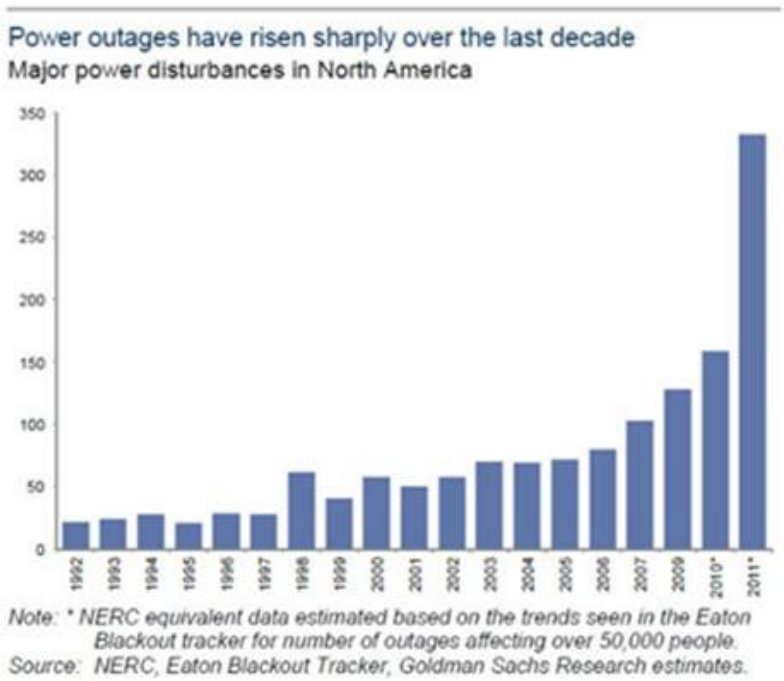

**Figure 4 – North American Power Outages**

The demand for quality, dependable power is also extending beyond primary cable plant and includes the growing demands of peripheral (edge) requirements for power as the technology evolves. Utility costs for these edge sites is also increasing along with the risks of losing utility power. Power fundamentals such as native DC vs. AC supply of energy also adds to the cost and complexity of supporting cable operations. With recent advances in direct current technologies and deployment capabilities DC powered networks can increase system efficiency, particularly as the industry integrates native dc powered renewables and energy storage devices into their power networks.

# 3. Microgrid Defined and the role of alternative energy resources

## 3.1. What is a microgrid?

The SCTE Alternative Energy/Microgrid Standards Working Group (AE/MGWG) developed a definition for microgrids as: "Microgrids may be defined as a localized group of interconnected and managed electricity sources, storage and loads that can be connected with other local microgrids and/or the traditional electrical utility grid (macro grid) but can seamlessly and selectively disconnect from them and function independently as conditions, policies or economics dictate."

## 3.2. Simplified Definition

A more simplified definition of a microgrid can be stated as: A microgrid is an electrical system that connects multiple sources and loads that is controllable by the user to allow independent operational choices.

## 3.3. Distributed Energy Resources (DER)

The United States electric grid is comprised of bulk power generation, distribution, transmission, and consuming entities. The infrastructure enabling just about everything in our modern daily lives has remained largely consistent for close to one hundred years. AC power is generated, moved in higher voltage from generation to substations, and voltage is reduced to feed transmission and then ultimately converted into the low voltage AC power typically used at commercial and residential facilities.

With the advent of solar and what we refer to as "alternate energy" sources, the model of bulk power sources begins to be challenged. The traditional grid model is one of stability, predictability, and regulation to uphold high expectations of availability. To satisfy these expectations of high availability the current system is made up of large central base-load fossil fueled power generation plants and supplemented by addition fossil fueled based peaker plants when demand increases beyond base load capabilities or are needed to supplement when base load system is unavailable. When we plug something into an electrical outlet here in north America, there is no second-guessing power availability. Distributed energy resources can become a viable model to anyone wishing to pursue alternatives to the traditional power grid.

The new challenge of incorporating solar photovoltaic (PV) systems, wind resources, storage (like batteries) raises electrical engineering questions as well as financial market questions. DERs can be defined as: "Distributed energy resources are small, modular, energy generation and storage technologies that provide electric capacity or energy where you need it. DER systems may be either connected to the local electric power grid or isolated from the grid in stand-alone applications. DER technologies include wind turbines, solar/photovoltaics (PV), fuel cells, microturbines, reciprocating engines, combustion turbines, cogeneration, and energy storage systems."[2] Cable operators are in a very good position to evaluate and deploy DERs due to hybrid fiber coax (HFC) communication

network architectures. Critical facilities, people space and even outside plant can be considered for distributed energy adaptation.

There are several use cases that can promote the deployment of a DER for cable operators. These primary cases include lowering grid dependency, becoming less utility grid dependent, and enhancing availability of power. In locations where peak demand charges become very high during seasonal changes (high air-conditioning or heating needs), a local DER such as a grid-tied PV plant can help reduce excess charges. The PV plant can be engineered to match the forecasted spikes in utility grid demands that associate with a higher billing to the cable operator. In 2019, California power providers began to institute public safety power shutdown (PSPS) events. Weather conditions supporting high fire risks have required grid providers to turn off supply in order to lower risks of fire. Communication providers need to become less dependent on the grid to ensure service availability. DERs can help address that need. This approach is naturally related to the third use case of enhancing power availability. NREL conducted a backup power study for cable operators and that report can be found in Reference [3].

Distributed energy resources can play an important role in cable's infrastructure. Determining the strategic adoption can be done following a few steps. First, identify the electrical requirement and/or problem. Are the bills too high? Is power availability becoming unacceptable? Are there renewable energy requirements needed for positive marketing? Does run-time in the absence of grid or traditional generator backup need to be extended? After the applicable question/s is/are identified and answered, the technology can be identified to address the problem. PV has been a reliable go-to; however, each situation will dictate what power generation source would fit best. Second, approach the local utility provider to discuss incentives. If the local power provider has a mandate to lower loads or incorporate renewable power sources, there may be financial awards to help offset DER deployment costs. Third, build out the project plan to commissioning. As with any change to day-to-day operations, a DER implementation requires a solid project plan to ensure successful incorporation into existing network topologies. Finally, document post commission needs, such as maintenance, system milestones and support providers. Cable operator infrastructure requires working with a multi-vendor ecosystem and the DER turn-up can introduce new providers of power service if the existing pool of resources do not specialize in essential power source management. This relationship will be especially important as a DER investment can extend beyond 20 years.

## 3.4. Alternative verses Renewable Energy Resources.

The differences between "alternative energy," "renewable energy," and "clean energy," might not be obvious. Each term is unique and has its own individual definition.

### *3.4.1. Alternative Energy*

Alternative energy refers to sources of usable energy that can replace conventional energy sources (usually, without undesirable side effects). The term "alternative energy" is typically used to refer to sources of energy other than nuclear energy or fossil fuels.

Throughout the course of history, "alternative energy" has referred to different things. There was a time when nuclear energy was considered an alternative to conventional energy and was thus called "alternative energy." The term is ever evolving.

Today, a form of "alternative energy" might also be renewable energy, or clean energy, or both. The terms are often interchangeable, but not the same.

### 3.4.2. Renewable Energy

Renewable energy is any type of energy which comes from renewable natural resources, such as wind, rain, sunlight, geothermal heat, and tides. It is referred to as "renewable" because it does not run out.

People have begun to turn to this type of energy due to the rising oil prices, and the prospect that one day sources of fossil fuels may be depleted. Also, concerns about the adverse effects that our conventional energy sources have on the environment have played a big role in the advancement and adoption of renewable energy sources.

Among the different types of renewable energy, wind power is one which is growing in its use. The number of users who have some form of wind power installed has increased, with the current worldwide capacity being about 100 GW. In addition, the traditional power grid has leveraged commercial wind farms to diversify power sources in environmental correct locations such as the mid-west and parts of Texas.

### 3.4.3. Clean Energy

"Clean energy" is simply any form of energy which is created with clean, harmless, and non-polluting methods. Most renewable energy sources are also clean energy sources, but not all.

One such example is geothermal power. It may be a renewable energy source, but some geothermal energy processes can be harmful to the environment. Therefore, this is not always a clean energy. However, there are also other forms of geothermal energy which are harmless and clean.

Clean energy makes less impact on the environment than our current conventional energy sources do. It creates an insignificant amount of carbon dioxide, and its use can reduce the speed of global warming – or global pollution.[4]

## 3.5. Bringing Alternative Energy Resources Together = Microgrid.

Typical cable industry critical infrastructures (CIs) are constructed with power systems that contain emergency back-up systems, such as fossil fueled generators and lead acid battery-based DC power plants, to ensure system reliability during utility power outage events. A typical system configuration example is shown below in Figure 5.

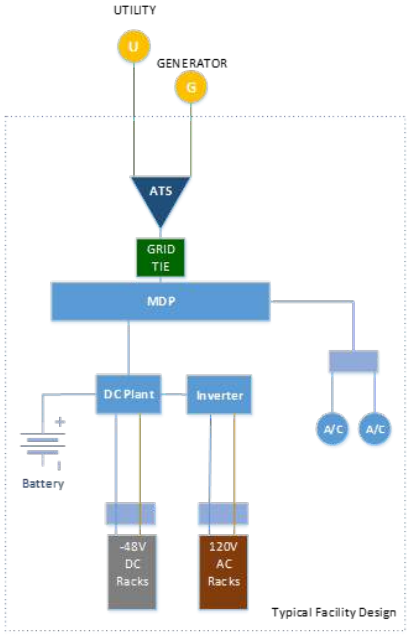

**Figure 5 – Typical System Configuration**

The current state of this infrastructure is characterized with specific technologies characterized by the functions and related adjacent operational functions as described in Table 1.

**Table 1 – Infrastructure Operational Functions**

| Business Function | Technology | Technology Function | Operational Considerations |
|---|---|---|---|
| Primary/Secondary Power Source | Utility Service and Generator | To power the critical load | • Site is dependent upon reliable utility service<br>• Site operates on either utility OR generator<br>• A brief outage is required for generator start-up<br>• Most generators are fossil fuel based<br>• Many sites with dual generators |
| Source Transfer | Automatic Transfer Switch (ATS) | Monitor utility power and controls | • No parallel operation<br>• No closed transition transfers |

| | | | |
|---|---|---|---|
| | | transfer of power source | |
| Power Distribution | • -48v DC/battery plant<br>• Dual bulk feeds to critical loads | Service continuity during transition from utility to generator | • High initial investment with stranded capacity costs<br>• Assorted power distribution configurations<br>• System changes and adds are costly with specialized labor and material which can influence time<br>• Power density varies widely but initial build investment needs to anticipate worse case loads<br>• Inverters can allow for elimination of UPS |
| | Inverter | Critical AC loads through inverter (eliminating UPSs in process) | |
| Stable Operating Environment | HVAC | | • Backed up by generator for power during commercial power outages |

Bringing a variety of power sources together to feed and support a load or multiple loads is a microgrid. The cable industry, to some extent, has a head start in the progression path to microgrids that should be evident from the above. Some examples of microgrid topologies are shown on the following page.

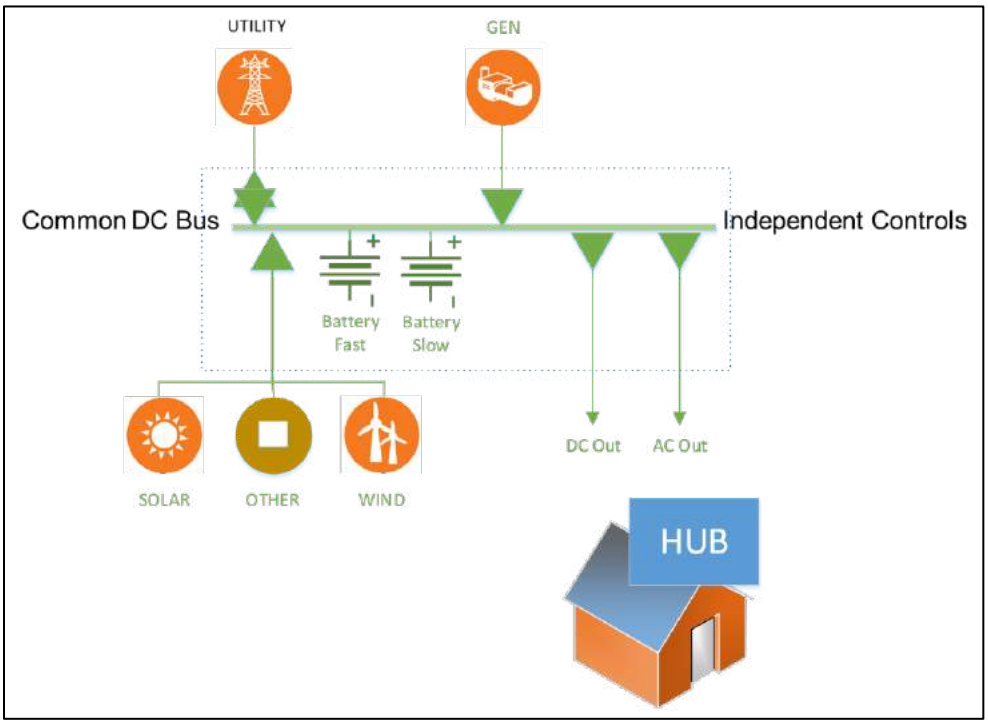

**Figure 6 – Microgrid Topology (1)**

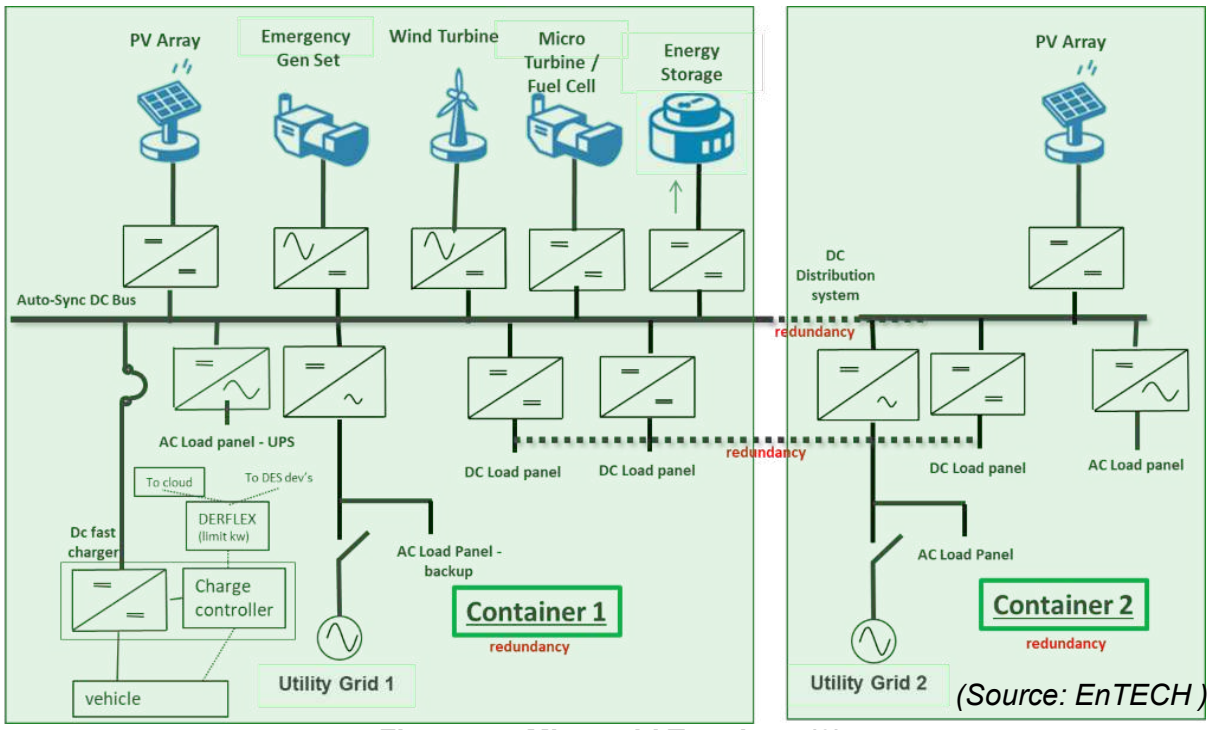

**Figure 7 – Microgrid Topology (2)**

The preceding configurations use a DC power collector bus topology. An example of an AC power configured microgrid is shown in Figure 8 (Source: Schneider Electric).

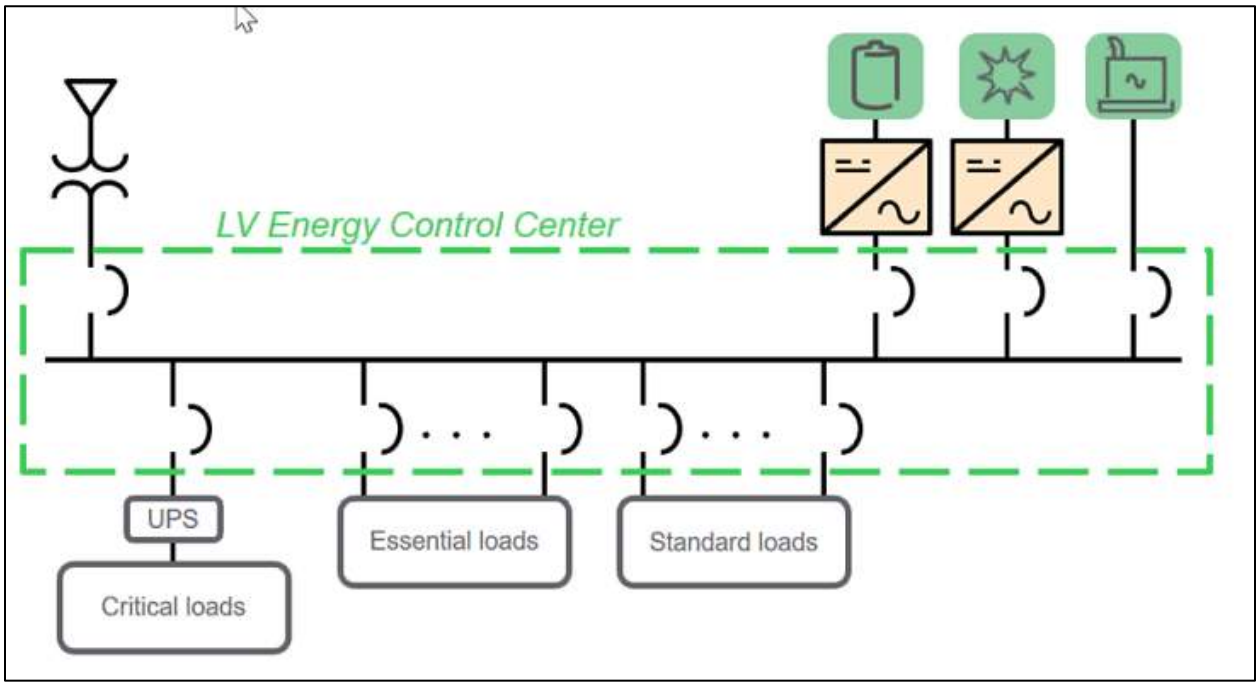

**Figure 8 – Microgrid Topology (3)**

## 3.6. What's In It for the Cable Industry/Cable Operators?

The DOE and other government agencies have been spearheading the definition of microgrids while documenting their value. Now, with the active involvement of two predominant industry organizations - NREL (National Renewable Energy Laboratory) and CableLabs - this should send a clear message that it is time for the cable industry to grab the lead, creating microgrid standards specifically designed for cable operators.

As introduced earlier in the paper, microgrids are very important to the cable industry for several reasons:

1) They provide additional resiliency and reliability in times of unplanned power outages. During severe weather, microgrids can provide the ability to continue providing power to critical facilities.
2) With competitively priced self-generation from renewable and other energy sources, microgrids can provide a hedge to increasing costs of energy for cable operations.
3) Coincident with time-of-use electricity pricing, microgrids can allow cable operators to buy low and sell high for their operational energy needs, as well as the energy needs of their customers.
4) Microgrids provide operational independence from local utilities allowing control and usage of dispatchable power sources independent of local utility performance.

Operational cost containment is an important practice for cable operators, and power is no exception. The idea of purchasing energy at low rates and selling high over a 24-hour period will become increasingly important. Time-of-use rates become pervasive to effectively manage the supply and demand balance of the grid in the presence of increasing renewable energy resources. This is evidenced by the increasing number of cities, states and countries

that have made 100% renewable generation commitments, most notably, the states of California, Hawaii and several others by 2045.

While these economic drivers are valid, other areas of the country with lower electrical costs are justifying microgrids by combining other value propositions with Time-of-use gains. Such benefits include added resiliency, demand shaving, and the utilization and control benefits of higher voltage direct current in a DC-Coupled microgrid.

Basic microgrid technologies are currently deployed within the cable industry, but they are not positioned to best leverage traditional microgrid techniques. The opportunity exists for the industry to take stock of what is changing in their networks, followed by an exploration of how the industry should or can leverage new technologies (including power). As the industry strives to enhance the customer experience, there needs to be a conscious review of how energy use has evolved. As new cable technologies are deployed in the access networks, infrastructure costs to accommodate these changes could end up being fiscally prohibitive in meeting business goals without proper consideration of modular microgrid technology deployments.

The regionalized nature of the cable industry is conducive to microgrid developments. The cable industry could develop microgrids and sell power to/within itself as well as sell power to outside partners. The steadily improving return on investment (ROI) related to microgrid and alternative energy technologies, coupled with regionalized opportunities that exist for the cable industry/cable operators, make a valid argument that there are tangible benefits for microgrid development.

# 4. MicroGrid use cases and drivers for the Cable Industry

## 4.1. Edge Facilities and Outside Plant

It is well documented by SCTE, and as depicted in Figure 9, that the majority of the cable industry's critical infrastructure power footprint is housed within edge facilities and outside plant.

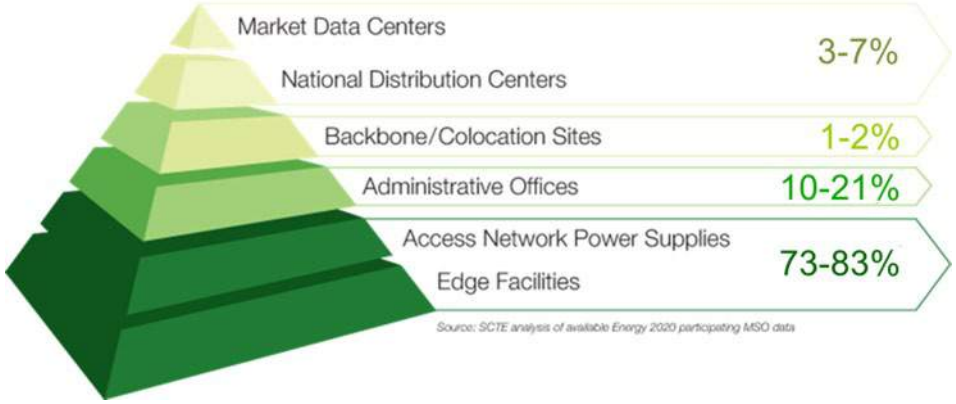

**Figure 9 – Critical Infrastructure Facilities**

**Outside Plant Infrastructure:** Unique to cable and telecom providers is the outside plant and especially the hundreds of thousands of power supplies enabling the hybrid fiber coax network (HFC). Typically, power is provided to the center conductor of the HFC plant via a local power supply. The power supply receives power

from the utility provider typically on the very same pole the cable infrastructure resides. What kind of creative approach could be taken to address the diverse nature of outside plant powering? Self-generation of power in strategic places could be an opportunity for investigation. New innovative power supplies and infrastructure are being investigated and new standards are in process to allow this innovation. New energy storage technologies will also play an important role.

**Edge Facility Infrastructure:** According to ANSI SCTE 226 2015, Class B-D facilities are smaller in nature, support, and design criteria than the larger Class A data center centric facilities. This does not mean that the importance of these infrastructure rich points of presence are small. Evaluation of microgrid deployment options are not easy to determine. Careful examination of each facility should be conducted, and a reusable model built to evaluate the benefit and application of microgrid options at the smaller facilities. The model needs to consider multiple data points such as downtime, cost of power, number of subscribers, and types of subscribers (commercial vs. residential). Network architecture dependencies are important factors when determining microgrid investment. All new infrastructure power solutions must be modular and scalable.

## 4.2. Electric Vehicles (EVs)

The cable industry maintains a fleet of nearly a quarter million vehicles worldwide. In recent years, the industry often encourages technicians to overnight company vehicles at their homes. Continuing to do so will create unique financial opportunities to leverage the industry's broadband infrastructure to manage the charging of cable's future fleet of EVs—and perhaps even private vehicles—across small and large geographic areas.[5]

EVs and hybrid EVs will play an increasingly important role in cable operations. Due to technological advances and continuing declines in battery costs, personal EVs provide fuel savings of nearly $1,000 per year and EVs overall are cheaper than equivalent combustion-engine models for many applications. Deployment of EVs are increasing every year and should be part of microgrid applications and growth. This will help fill the need for increased power reliability and resiliency.

Global decarbonization is driving the further electrification of our world and this will result in increased electricity consumption of 38% by 2050[6]. Electricity is rising in popularity as it is easier to transport, deliver, store, and use. Society's growing dependence on electric power is resulting in an exponential rise in consumption in applications such as data centers and EVs. In and of themselves, EVs are likely to create 20%-30% additional load on the electric grid[6], helping to make the case for the optimization of charging strategies. As such, Time-of-use pricing of electricity is legislated in several states and, along with variable pricing is expected to be pervasive.[7] The departure from fixed electricity rates raises crucial financial questions of 1) when to charge EVs based on varying electricity cost, and 2) how to enable the cable industry to specify methods that monetize the value stack created by managed fleet vehicle charging. As mentioned earlier, cost management of operations for cable operators is important to the business.

## 4.3. Monetizing Optimum Load Shaping and other EV-Based Grid Support Services

Several technologies and market trends are at play that can both negatively and positively affect the cable industry in terms of energy cost. With the increased deployment of EVs, the production, distribution, and use of electricity is rapidly evolving for the charging infrastructure that will be needed, creating critical functionality gaps in managing the grid. EV charging is already stressing grid capacity and affecting the cost of electric power. Yet, when networked and managed in a coordinated fashion, batteries and EVs are proving their ability to provide grid support services such as load shaping, peak reduction, and active power quality management via reactive power and frequency support. Together, grid support services from EVs can create a value stack consisting of reductions in operational costs, maintenance, and new construction of power plants, transmission, and distribution facilities.

If cable operators can reap the rewards of selling power via a microgrid and leverage the collective energy storage across a substantially large EV fleet, the benefits could be substantial. Communications and controls will play an important role in such a scenario.

Since 1882, the grid has operated such that supply from power generators anticipates and follows the demand for electricity. In recent years, the continuing decline in the levelized cost of energy from wind and solar power is such that, in much of the world, construction and operation of new renewable energy sources are less costly than the ongoing operation of existing fossil-fueled power plants. Yet, the demand for electricity is often not coincident in time with the supply from renewables, which themselves are variable and not dispatchable (i.e., not controllable). As such, widespread, pervasive coordination of demand will be valuable in orchestrating electric loads, such as EV charging, to follow the least costly forms of fossil-based and renewable supply.

A growing body of research from several U.S. Department of Energy National Laboratories and throughout industry indicates that load shaping will be increasingly important in reducing the cost of operations in the grid, microgrids, and nanogrids.[8] What is missing are methods to optimally shape load based on the holistic consideration of generation, distribution, and storage. Optimum Load Shaping (OLS) is a newly developed software-based proprietary technology to minimize power generation costs and carbon dioxide emissions that informs electrically powered devices of the forecast times of the lowest cost and cleanest supply. OLS uses an end-to-end generation-to-load algorithm that jointly optimizes supply (part 1) and demand (part 2). Efforts are underway in the SCTE Energy Management Subcommittee, Microgrid Working Group, to propose a standard that will specify the creation of an OLS, its transmission across different networks, and the actions taken by a receiving device, such as an EV or battery charger, that modifies its behavior to minimize differences over time from the OLS.

Forecast Optimum Load Shapes (OLSs) can help monetize the cable industry's future fleet of electric vehicles and facility batteries to provide the critically needed end-to-end, generation-to-load control of the electric power grid. An OLS provides grid control and consists of a set of numbers (e.g. target load for hours 1-24) that forecasts the most efficient electrical supply in grids, microgrids, and nanogrids, so that all stakeholders - generation entities, utilities, distributors, retailers, and consumers—can reduce their electricity costs and carbon emissions.

# 5. The Developing Microgrid Technologies and Industry Trends

As microgrids are developed in greater and greater numbers, microgrid interconnections will also increase. Interconnections will occur directly between adjacent microgrids, but in most cases will be interconnected through the existing electric utility infrastructure. Microgrids and the interconnection of microgrids require new ways to track energy use, power generation by distributed energy resources, and load control in a way that transactions between microgrid owners and operators are being developed. These situations and ongoing engineering developments are what make up the new “Transactive Energy” evolutions as described below.

## 5.1. New term: “Transactive Energy”

The increased use of renewable energy and distributed energy management technologies offers the potential for significant efficiency improvements through market-based transactive exchanges between energy producers and energy consumers.

To enable these sorts of exchanges, however, the modernized grid will require new economic tools and processes. “Transactive energy” is the broad term used to describe this new approach and can be defined as *“a system of*

*economic and control mechanisms that allows the dynamic balance of supply and demand across the entire electrical infrastructure using value as a key operational parameter."*

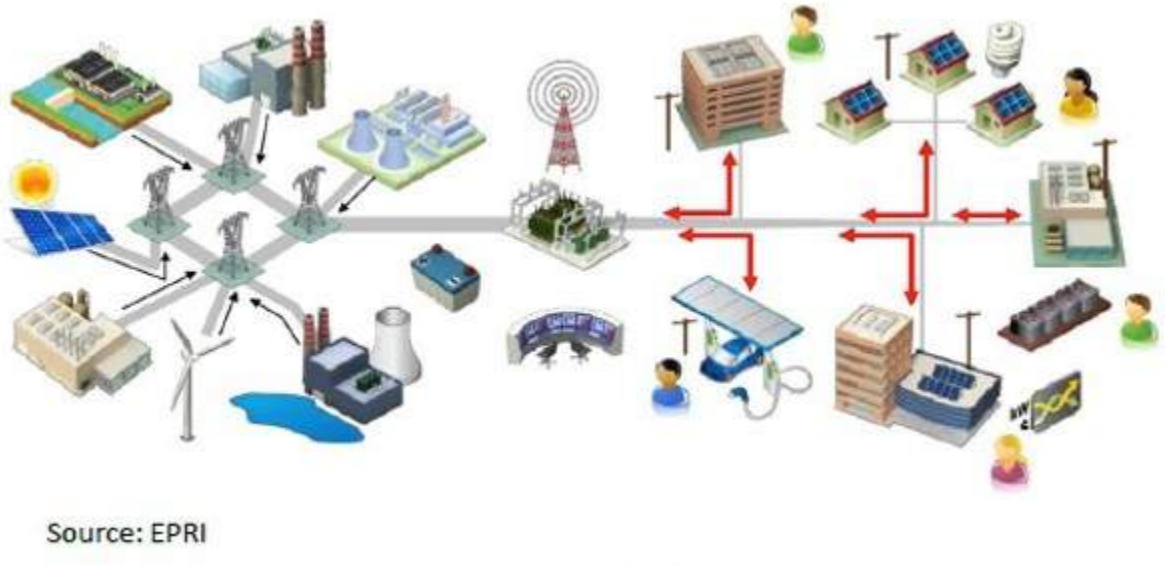

**Figure 10 – Modernized Electrical Grid**

## 5.2. Transactive Energy's Potential Benefits to Consumers

The following list outlines the benefits of moving to a more transactive-based energy model:

- Better utilization of grid assets: Everything from transformers and switches, to vehicle-charging stations and smart meters, can lower costs when optimized, especially during peak demand conditions.
- Greater resilience and reliability: During large storms, a reduced length and frequency of outages
- Greater control over personal energy use: Empowerment of choice and information provided to consumers
- Increased use of renewable energy resources: Gives individual consumers the satisfaction of contributing to larger societal environmental sustainability goals

The growth of a cable operator's business intelligence that is required for this evolution, including the development of artificial intelligence (AI), will evolve into a big data management platform. This platform could make for a new business opportunity for cable operators as well as provide market participation opportunities in various regions of the country.

### 5.3. The Natural Progression Towards Independent Energy Sourcing and Control

Originally driven by economics (cost savings) and social responsibility (energy management), the first step is the installation and application of renewable energy technologies and systems. The next steps are the progression paths to the future with a corporate version of self-actualization (maximizing potential) by participating in the energy market as both a supplier and consumer, with the ability to self-determine the most appropriate energy source based upon real-time availability and needs. The figure below describes the steps in the progression path to the Transactive Energy future

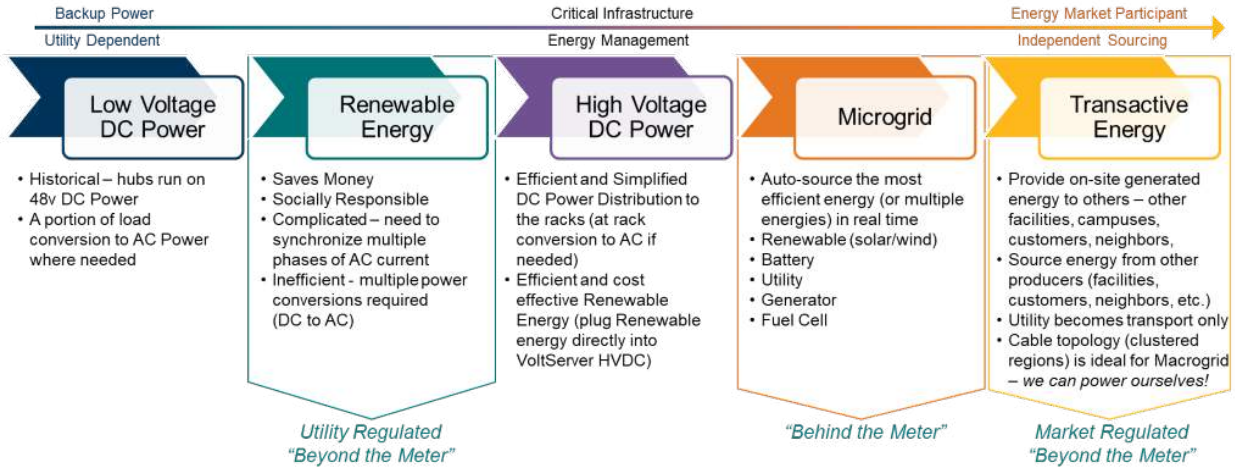

**Figure 11 – Steps to Transactive Energy Market and Critical Infrastructure Resiliancy**

## 6. Conclusion

As the cable industry looks to further standardize on strategic energy concepts like microgrids, opportunity awaits for development, trial and ultimate deployment of microgrid technologies. It has been shown that microgrids are being deployed within many industries and use cases globally. Economics, the rising cost of electricity and the focus on a more sustainable future are the drives for the widescale deployment of solar, wind and other distributed energy resources. New technology large scale energy storage is also becoming more cost effective and is playing a bigger and bigger roll in the new energy future. This paper characterized why it's a sound ideae to fully reap the benefits of multi-source smart power grid scenarios, adhering to cable specific use cases mentioned in the early sections of this paper. Finally, the consensus body represented in the active SCTE working group will pave the way to help accelerate the deployment of robust microgrid solutions. These will enable a foundation of new network ideas, as envisioned and embodied in the announcement of 10G, early in 2019. Microgrids will play a big roll in powering 10G with a summary of use cases, use scenarios and values to the industry in figure below.

# 1. Introduction

With the introduction of DOCSIS® 3.1 technology, profiles and profile management became important to operators who wish to get the most out of their network capacity. With the resiliency advantages of DOCSIS 3.1 technology, network impairments impact service through a loss of capacity but not failure of service until these impairments become severe. Therefore, there is an opportunity to use lost capacity as a way to measure the severity of impairments, and to prioritize proactive network maintenance (PNM) work as well. But with profiles being limited in number on many cable modem termination systems (CMTSs), the theoretical maximum capacity can't always be obtained. So, profiles need to be considered to truly measure the impact of proactive maintenance operations.

In this paper, we present some competing methods for prioritizing PNM work in terms of optimal possible profiles, as well as the measures involved in setting these profiles (RxMER per subcarrier, and bit load). Depending on the conditions of the operator's network and PNM tool capabilities, some solutions will be better than others. So, we will help operators decide an approach that works best for them. The solutions we compare will be offered as workers in our Proactive Operations (ProOps) platform as well, so that anyone interested can conveniently try them for themselves.

Identifying PNM opportunities is one challenge, but prioritizing them is another, and selecting the important problems to work on is yet another. All these steps must be done right for PNM to be effective because repair resources are limited.

Profile management is the practice of optimizing bitrates overall for the cable modems (CMs) on a CMTS; Profile Management Application (PMA) is the name of the application that optimizes profiles, say to maximize overall bit rate across all CMs subject to a limited number of profiles to share.

Operators express that they are reluctant to do proactive maintenance in part because they do not know which problems to address, or which problems will impact service in the future. But the way DOCSIS resiliency mechanisms work, bitrate is sacrificed for service reliability in the face of impairments. So, while one impairment may not itself impact service, a future one will because the impacts pile up until the customer notices. All impairments impact bitrate in some way, be that through codewords that need correction, data that has to be re-sent, or subcarriers that have to be avoided, for examples. This suggests that the impact to bitrate may be a good candidate for prioritizing and selecting important proactive maintenance projects to tackle.

But how do you determine the bitrate impact of impairments? That is where a look at PMA can be informative. For downstream PMA, downstream RxMER per subcarrier is collected and used to determine bit loading, which in turn informs bit load, which informs how the profiles are set. Therefore, there are three potential candidates to consider: RxMER per subcarrier, bit loading, or the profiles assigned.

Therefore, we investigate each of these approaches as methods for assigning PNM work. For some of these methods to work, however, anomaly detection is all but necessary. We also look at possible methods that include anomaly detection using a machine learning approach, and methods that avoid use of an anomaly detector (AD) when possible, for cases where AD is not available. Statistical methods can be used to detect impairments as well; for example, operators and vendors who are members of CableLabs can obtain a copy of Spectra which detects anomalies in spectrum data, including methods that were contributed back by Comcast.

After outlining methods for consideration, we test these methods with an available data set, and compare the merits of the approaches. While we don't have access to operator networks to test the methods in deployment, the comparisons we have made are informative enough to narrow the options down and inform which may be tried first in various situations. We encoded some of the better options into the ProOps platform so we can work with operators to test and tune the methods for their use. These solutions are available to CableLabs member operators for free, and provided in some form to vendors as well.

# 2. Approaches Studied

Next, we introduce the approaches we defined and compared for prioritizing PNM work. Each of these can be updated after information changes, such as the completion of maintenance.

## 2.1. Prioritize by worst profile group without anomaly detection

The target in this method is the worst performing CMs in the worst profile. If your PMA calculation uses anomaly detection within it, then anomaly detection is used indirectly but its information is not directly used in this case.

1. For each CM, calculate its profile from PMA based on the configured number of profiles in its CMTS (Assigned Profile, as is typically done with PMA), and the best profile it could have been assigned with unlimited profiles possible. (Possible Profile is a profile it would be assigned if it were in a cluster of one). Note this is before consideration of impairments that can be removed.
2. Calculate the bit rates (bit loading) these CMs should achieve with these two profiles (BR_AP and BR_PP). [1]
3. Cluster CMs by profile. Given the current PMA approach is to cluster before setting profiles, the clustering comes essentially for free in step 1. Order the clusters by bit rate from lowest to highest so that the worst profile group is selected for consideration first.
4. Start with the profile with the lowest BR_AP; find the CMs in this profile where BR_AP = BR_PP. If none exists, find the CMs with the lowest absolute difference. Call this CM subset CM_Cluster_i for i=1. Assign to this CM subset CM_Cluster_i a severity measure calculated as the difference between BR_AP and the average BR_PP of all CMs sharing the profile but have a higher BR_PP than the group. So, we are assigning to each CM a cluster number and severity number.
5. Remove this CM_Cluster_1 set of CMs from the set of CMs and recalculate the profiles using PMA (returning to step 1 above).
6. Repeat the steps above to find CM_Cluster_2, and repeat again, until all CMs are clustered into CM_Clusters_i for i = 1 to n for an arbitrary n. Note that n will be larger than the number of profiles. The severity will be used to assign importance for maintenance of the CMs in question, and the CM clusters too.

The work is thus clustered. Sum the severities for the CMs in the cluster. The resulting severities are the priorities to sort by for the work.

Note that the number of profiles has to be discovered from a trusted source such as the engineering team. While the CMTS has a maximum number of profiles possible, operations engineering teams can decide to

[1] In a different version, one could calculate the bit rate for each CM if it could be assigned an optimal profile (max bit rate achievable given how the CM was provisioned) (BP_OP). This could also be defined as the target profile based on provisioning targets.

use a smaller number of profiles when implementing. This setting, therefore, will need to be configured in ProOps or your own PNM application environment for each CMTS.

Measuring the severity of CM clusters in this way presents a tradeoff. Clustering by CMs sharing a profile may correlate with geography but maybe not enough to be efficient with truck rolls. And there is not a guarantee that one cause leads to this CM cluster to share a profile. The theory behind this approach is that one or a few related problems are leading to the lowest profile to bring down a group of CMs. If one or two problems are impacting the group, then this approach should highlight the group of CMs experiencing the problem. But if that is not the case, then the clustering may not work as intended.

Due to the nature of profiles, and the small number of profiles to share among all CMs, one change of a CM's performance can cause re-optimization of the mix of profiles; while some CMs get a better performing profile, others can get a worse one. This makes comparison and prioritization difficult.

If a group of CMs is working fine at a low profile due to being at the end of a line, with low RxMER average values, a profile may be selected in this approach which has no addressable issues. Therefore, human intervention will be needed, and perhaps additional rules or checking is needed to remove false positives.

The need for information from experts to inform the profile management, as well as the fact that this method may indicate false positives, suggests it will be difficult to manage.

This method can easily be augmented with anomaly detection. By adding anomaly detection to the calculation, selecting the worst performing CMs, removing the anomalies, and recalculating the profiles to see the impact, the profile information can be used to prioritize proactive work. Using anomaly detection should reduce the expected false positive rate significantly, and make the method worth considering.

## 2.2. Prioritize by worst profile modem without anomaly detection

This method is one which we encoded and will provide comparisons later in this document. This procedure below aligns with our measurement labeled Severity(PMA).

The target in this method is the worst performing CMs over all profiles in terms of their impact on the profile. If your PMA calculation uses anomaly detection within it, then anomaly detection is used indirectly but its information is not directly used in this case.

1. For each CM, calculate its profile from PMA based on the number of profiles possible in its CMTS (Assigned Profile, as is typically done with PMA), and the best profile it could have been assigned with unlimited profiles possible (Possible Profile, a profile it would be assigned if it were in a cluster of one). Note this is before consideration of impairments that can be removed.
2. Calculate the bit rates (bit loading) these CMs should achieve with these two profiles (BR_AP, BR_PP).
3. Cluster CMs by profile. Given the current PMA approach is to cluster before setting profiles, the clustering comes essentially for free in step 1. Order the clusters by bit rate from lowest to highest so that the worst profile group is selected for consideration first.
4. Searching over all profiles, find the CMs where BR_AP = BR_PP (plus or minus a small delta). Or, if none exist, find the CM(s) with the smallest difference in BR_PP-BR_AP. Call this CM subset CM_Cluster_i for i=1. Assign to CM_Cluster_i a severity measure calculated as the difference between BR_AP and the average BR_PP of all CMs sharing the profile but have a higher BR_PP than the group. So, we are assigning to each CM a cluster number and severity number.

 

5. Remove this CM_Cluster_1 set of CMs from the set of CMs and recalculate the profiles using PMA (returning to step 1 above).
6. Repeat the steps above to find CM_Cluster_2, and repeat again, until all CMs are clustered into CM_Clusters_i for i = 1 to n for an arbitrary n. Note that n will be larger than the number of profiles. The severity will be used to assign importance for maintenance of the CMs in question, and the CM clusters too.

The work is thus clustered. Sum the severities for the CMs in the cluster. The resulting severities are the priorities to sort by for the proactive work.

Just as in the previous approach, this approach has the same tradeoff due to the clustering utilizing profiles, and using profile impact as the measure of severity.

Like the previous method, this method can easily be augmented with anomaly detection to allow selection by anomaly that potentially would be removed.

## 2.3. Prioritize by profile bitrate impact using anomaly detection

This method is one which we did not encode for comparison as we expect it to be somewhat like the previous one which we did. However, we think it may be one worth exploring with operators.

The target in this method is the anomalies in the signal, so anomaly detection is explicitly required. But we still use profiles to determine which anomalies to dispatch for.

Assume we have a list of impairments generated for a set of CMs on a given node. Like impairments across CMs, they need to be clustered so that each impairment is associated with a list of CMs that show the impairment, and each CM could be associated with any non-negative number of impairments.

1. For a set of CMs on the same node, and impairments found to appear on the set of CMs, order the impairments found by severity on the CMs and create an association list for each impairment containing the CMs that show the impairment.
2. Find the profiles for each CM on the node using PMA and call these profiles the Assigned Profiles.
3. Take the most severe impairment on the ordered list of impairments, as measured by the amount of impact to RxMER on the subcarriers that it impairs, using a method such as those that follow. Adjust the RxMER per subcarrier for each CM impacted by the impairment as though the impairment was removed (methods like LMS (Cole 1990)), sliding window average or median, EWMA (bi-directional averaged), or FFT-smooth-IFFT methods may be useful here). One reasonable approximation is to assign new RxMER values over affected subcarriers such as the statistical average of the non-affected subcarriers, or a target value for the subcarriers, or for impairments like waves to assign the average of affected subcarriers. Find new profiles for the new set of CMs on the node using the adjusted RxMER per subcarrier.
4. Take the difference in the capacity gains of the newfound profiles and the previously calculated profiles, then assign the delta value as a score to the impairment. Depending on desired approach, cluster the CMs by shared anomaly, profile, or not at all.
5. Update Assigned Profile with the newfound profiles, for all CMs on the node, and repeat the process above (return to step 2) for the next impairment until no more impairments are on the list. All impairments have a severity assigned now.

 

The default is to cluster by impairment found, as that is given in the process. Alternately, we could sum up severities by CM or profile and assign work based on the severities summed.

By using RxMER impact or bit load as the measure of performance, prioritization is straightforward. There are impacts in these measures due to clustering, as profile changes can have the same impact as discussed above, and removal of an impairment can impact more than one CM. But, the measures of RxMER impact (dB or linear) or bit loading are closely linked to network capacity and service bandwidth, so are excellent candidates for prioritizing work. With AD, a focus on the impairment, and therefore the issue to address, reduces the need to cluster. The clustering only helps to measure the impact of the impairment.

Note: A possible adjustment to this method is to take the square of the difference of RxMER values by subcarrier for each CM and sum those square values so that deviations are measured as a squared loss function instead of linear.

## 2.4. Prioritize by bit-loading or RxMER per subcarrier impact using anomaly detection

This method is one which we encoded and will provide comparisons later in this document. We label the measurements for this process as Severity(MER) and Severity(Bitload).

The target in this method is the anomalies in the signal again, so therefore anomaly detection is explicitly required here too. But this time we just use RxMER per subcarrier or the bit loading possible, avoiding explicit use of PMA.

Assume we have a list of impairments generated for a set of CMs on a given node. Like impairments across CMs need to be clustered so that each impairment is associated with a list of CMs that show the impairment, and each CM could be associated with any non-negative number of impairments.

1. For a set of CMs on the same node, and impairments found to appear on the set of CMs, order the impairments found by severity on the CMs and create an association list for each impairment containing the CMs that show the impairment.
2. Find the RxMER per subcarrier for each CM on the node and call these the real values.
3. Take the most severe impairment on the ordered list of impairments, as measured by the amount of impact to RxMER on the subcarriers that it impairs, using a method such as those that follow. Adjust the RxMER per subcarrier for each CM impacted by the impairment as though the impairment was removed (methods like LMS, sliding window average or median, exponentially weighted moving average (EWMA) (bi-directional averaged), or FFT-smooth-IFFT methods may be useful here). Note this is a clustering step as well, resulting in CMs that are clustered around an anomaly. One reasonable approximation is to assign new RxMER values over affected subcarriers that are the average of the non-affected subcarriers, or a target value for the subcarriers, or for impairments like waves to assign the average of affected subcarriers. Call this adjusted RxMER per subcarrier the adjusted values. Apply this step to all impacted CMs in the group.
4. Sum the improvement in bit rate (best possible bit loading) that is gained by removal of the impairment, over all impacted CMs, and assign this result as a score to the impairment. Alternately, one can use the improvement in RxMER per subcarrier values summed over subcarriers.
5. Update the real RxMER values with the adjusted RxMER values for all subcarriers, for all CMs on the node, and repeat the process above (return to step 3 with the updated RxMER per

 

subcarrier values) for the next impairment until no more impairments are on the list. All impairments have a severity assigned now.

The CMs are clustered by anomaly, so that can be used easily by default. Individual CMs can drive the work too, depending on how the user wants to apply the severity and sort for work.

As this method uses AD and measures the impact of the removal of the anomaly, the advantages of the previous method apply here as well.

Note: A possible adjustment to this method is to take the square of the difference of RxMER values by subcarrier for each CM and sum those square values so that deviations are measured as a squared loss function instead of linear.

### 2.5. Prioritize by bit-loading or RxMER per subcarrier without anomaly detection

This method targets poor performing CMs without the use of AD or even PMA or profile information of any kind. It instead goes to the source of profile information, the downstream RxMER per subcarrier values for the CMs involved. We encoded this measurement for comparison later, indicating the measurements as NormalScore(MER) and NormalScore(Bitload).

This simple approach is offered as a method to begin using and developing from. The PMA application is shared in limited ways with vendors, and the CableLabs AD is shared with vendors as an executable only. Not every operator will implement PMA. Such operators are able to make use of this method here too, but some of the methods using PMA and AD are expected to perform better for many operator applications.

1. For a set of CMs on the same node, find the RxMER per subcarrier for each CM on the node, and call these the real values.
2. For each CM, adjust the RxMER per subcarrier for each CM through smoothing (methods like LMS, sliding window average or median, EWMA (bi-directional averaged), or FFT-smooth-IFFT methods may be useful here). One reasonable approximation is to assign new RxMER values over affected subcarriers that are average of the non-affected subcarriers, or a target value for the subcarriers, or for impairments like waves to assign the average of affected subcarriers. Call this adjusted RxMER per subcarrier the adjusted values.
3. Take the sum of the squares or absolute value of the differences in each subcarrier between the real and adjusted RxMER values and call this the severity. A bit loading calculation can be done here as well, and the overall bit loading may be used as the measure instead (inverse of bit load, or difference in bit loading from the real and smoothed RxMER per subcarrier results).
4. Prioritize and sort the CMs by their severities.

GIS information would be needed to cluster work without alternatives such as by anomaly. CM performance may inform that clustering too, as experts have suggested.

## 3. Details, Discussion, and Evaluation

### 3.1. A note on using these results in a PNM framework

To use these approaches as workers in ProOps, and to have a solution that turns data into actionable information, we need to have elements that collect data and calculate statistics (observe), assign priorities and cluster work (orient), sort the clusters and choose which are opportunities (decide) on which to act (act). The elements in these flows sometimes do not follow an order for OODA, but the elements are

represented. Some of the elements which may be separate workers when coded for ProOps, and the roles they may provide, are described next.

- Observe
  - RxMER per subcarrier
  - AD
  - Profile
- Orient
  - RxMER improvement or severity
  - AD severity
  - Profile improvement
  - Anomaly matching
- Decide
  - Severity assignment
  - Sorting results
- Act
  - Dashboard
  - Work list

For an initial configuration, here are the general configuration elements and steps.

- Collect RxMER per subcarrier every 4 hours, and profiles if relevant, then immediately run through any AD, or statistics calculators.
- Calculate any severities or scores needed.
- If the severity calculation did not require clustering yet, then execute on any clustering needed.
- Execute next on any added data to collect for future AD or impairment detection training, etc.
- Calculate any statistics needed based on the clustering, including calculating the cluster severities.
- Sort the clusters or single entities by severity, and calculate any needed data for the dashboard and prioritized work list, which may have a threshold value applied as criteria for inclusion in the work list.
- Present results in a desired file format or data base, along with updating the dashboard.

## 3.2. A note on clustering work by anomalies

As we examine anomalies found in CMs, we will calculate their impact on RxMER per subcarrier or on profiles and assign a value to the CMs where the impairment appears. But in doing this, we want to also combine CMs by impairment in many cases. Combining by profile is done in some methods by default. But working by anomalies may not result in clustered CMs unless the anomalies are compared. An untested approach we suggest is as follows.

1. Cluster anomalies by their features:
   a. For waves, match by cavity wall size first (distance between peaks or troughs), then severity.
   b. For slope, by slope value.
   c. For other impairments, by subcarrier frequency or data ranges.
2. For each cluster, add the net severity scores of the MAC addresses in the clusters; call this the cluster severity.

Several methods may be useful to consider here. For waves, normalize the slope to 0, then take an IFFT to find the frequency values most prominent, and finally correlate the transformed data. Likewise, correlate the untransformed data. Methods to correlate these data include k-means, difference tests like paired-t and Chi-Squared, and some statistical parameter tests such as moment tests.

There are several challenges with comparing anomalies to cluster work, and we leave this work for future consideration. We may start with investigating the IFFT approach with checking for correlation of the transformed and untransformed tests for waves, and use difference tests for frequency bound anomalies (matched by anomaly type or not).

## 3.3. What to monitor

Several statistics may be worth monitoring including the following.

- Table of CMs by severity, ordered by severity
- Table of CMs by hours in the top worst (configurable) by net severity
- Plot of clusters by number of CMs in the cluster and severity
- Plot of the top worst (configurable) CMs or clusters by severity, over time
- Overall node health score by severity total

## 3.4. Training data for anomaly detection

Training on new data of the AD needs a human supervisor to be involved to label samples or make corrections. Labeling samples means manually adding labels to the new samples. We can also use the AD to perform detection on the new samples, and the human supervisor makes corrections to the localization and classification results. Even if the prediction seems precise enough, small corrections are still necessary to make the labels even more precise. This work is needed because the feed forward neural networks are deterministic in terms of making predictions on the same input data. If we use the same data with the label that's generated by the AD itself for training, it's only reinforcing the model to what it has learned and not helping the model to learn from the new samples.

Each type of spectrum data will use a separate training process to train a separate model using labeled datasets, because different spectrum data may reflect impairments differently. Also using separate models can help stabilize the model and improve efficiency and accuracy.

## 3.5. Bit loading

Bit loading is handled differently depending on whether the solution is based on PMA or AD (including non-AD RxMER calculations).

With PMA, the bit loading gain is represented by the J value. PMA calculates profiles, then calculates a relative capacity gain by using dynamic profiles over 256-QAM flat profiles as the J value. The J value can be used to find an overall channel capacity gain in bit load. By calculating a set of modulation profiles, making an adjustment to the data, then calculating a new set of profiles, the differences in total bit loading can be compared. But realize that by looking at profiles and making changes based on those, the gain in bit loading depends on the other CMs on the impacted channels, so making a change to a CM or one or more channels impacts multiple CMs, and potentially more than one profile, so an overall impact has to be considered.

With AD, anomalies are first detected by the AD. As we know their type and frequency range from the AD, we first calculate the average bit loading from the average MER value from all subcarriers, then calculate the difference between subcarrier (within the anomaly range) bit loading values and the average bit loading. So, for each anomaly we have a total bit loading loss calculated. These scores can be weighted by anomaly types and added together. This is how we calculate the bit loading in these approaches using AD; RxMER-based bit loading calculations are similar.

## 3.6. Measuring performance

Because these methods have a few very different methods for measuring severity, it is difficult to compare the performance of some of these approaches. Likewise, combining these methods is possible but a weighting scheme for that might need to be developed. Further, there really are two ways to think about the operational performance of these approaches: the alignment of severity to actual problems in service and plant, and the alignment of severity to financially responsible repair work. The methods informing these severity measures are separately comparable by their ability to collect valuable information to support manual troubleshooting and repair. In addition, the calculation time required (performance) of the methods is a consideration too.

For the methods we encoded, we can provide computational performance comparisons. But without field studies to compare effectiveness, we can't provide any useful guidance on the performance of one approach over another in terms of the effectiveness of the work performed as a result. We can, however, provide a comparison of the information that each approach provides to the technicians, and our risk assessment of which methods should most closely align with effective work. We leave operational performance comparisons to the operators, and we look forward to working with any operator willing to work with us to optimize these methods.

## 3.7. Comparison of measurements

We applied several of our methods to a large data set of RxMER per subcarrier values and calculated the output measurements of each. Where we could apply different measurements to the same CM, we did so; the results are plotted in the figures that follow.

In these figures, when referring to bit load (labeled Bitload) and RxMER (labeled as MER), severity score and normal score are different ways to calculate similar statistics, and thus potentially used in the same way.

- **Severity score** is the sum of separate anomaly scores (calculated against the sample average in this case), so these two severity scores are from the AD involved methods.
- Alternately, the **normal score** calculation doesn't include AD. It only calculates the "area" below the sliding median across the sample. These normal scores are therefore a measure of variability. We can use them as a severity measure like severity score.

However, both severity and normal scores are from the perspective of the single CM.

Alternately, the channel score is the sum of all CM scores on the same channel; the optimal total capacity of the channel with a certain number of profiles and other constraints can be estimated using profiles generated by PMA, so is the important measure for PMA consideration. In the figures below, we refer to channel score as Severity(PMA).

Note that Severity(Bitload) would be equivalent to Severity(PMA) if there were unlimited profiles (or as many or more profiles as CMs, so that each CM can have its perfectly matched profile).

See Figure 1 for the relationship between Severity(MER) and NormalScore(MER). Note all scores are positive, and we see a cone shape relationship. While the two approaches correlate, this graph does suggest that one measure will prioritize work differently than the other. The top few for one measure are different than the top few for the other.

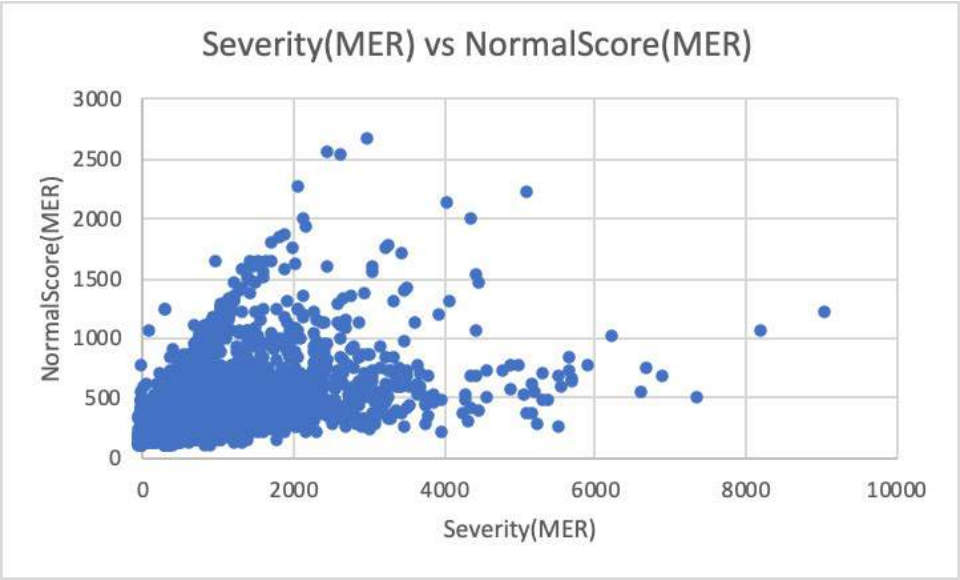

**Figure 1 - Severity versus normal score from RxMER**

Figure 2 shows the same comparison between severity and normal score, but for bit loading. Again, all measurements are positive. But there are several observations that score differently on one measure with little change in the other. Again, taking the top opportunities with one measure and the top for the other measure may not have any overlap, or very few. The two approaches will suggest different work to consider.

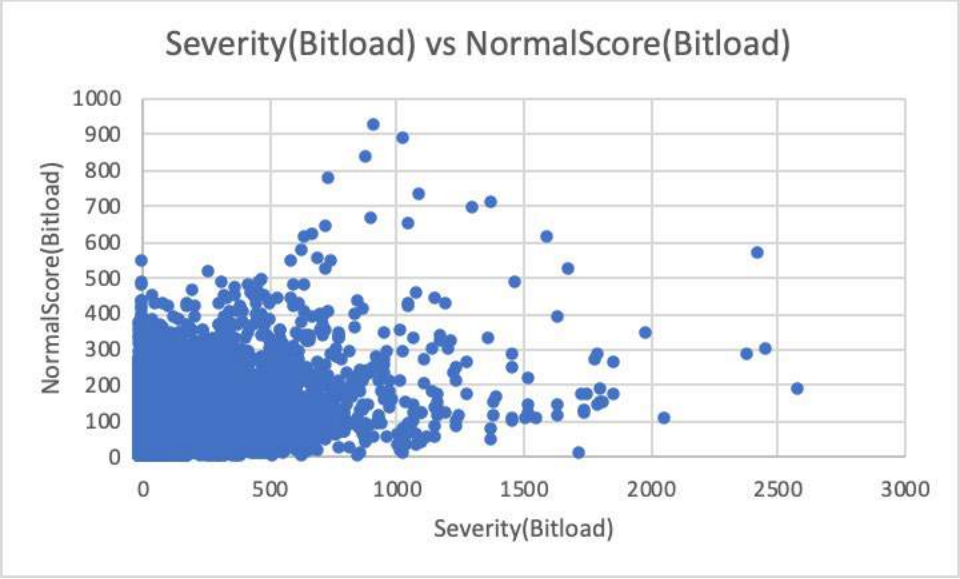

**Figure 2 - Severity versus normal score from bit load**

Figure 3 compares the severity measures of MER and bit load. Notice a high degree of correlation. This graph suggests that using either measurement is sufficient. And due to the way that bit loading is calculated, this relationship is expected.

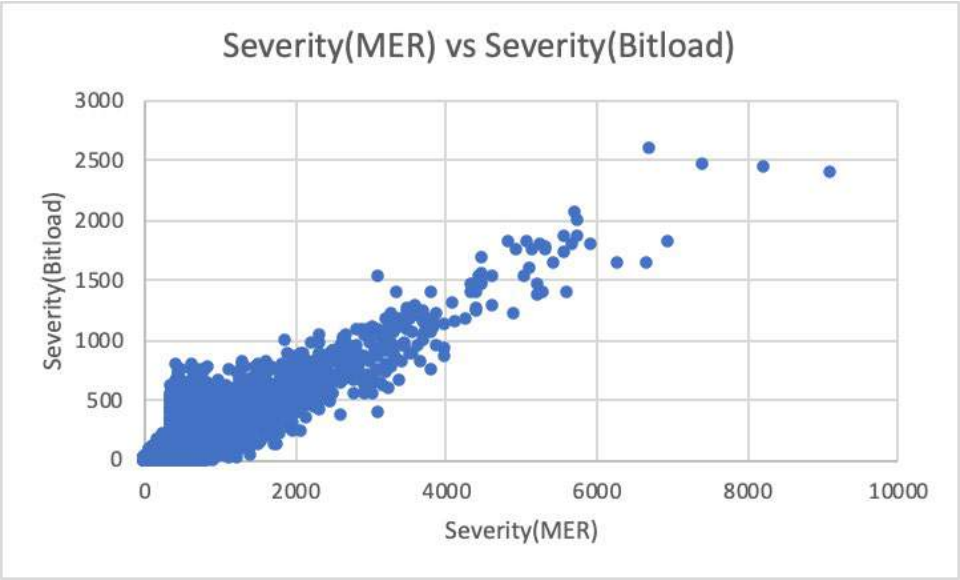

**Figure 3 - Severity from RxMER value versus severity from bit loading value**

With profile management added to consideration, we can calculate the severity of the PMA measurement and compare it to the other severity measurements. Figure 4 shows the MER severity compared to the PMA severity. As expected, there are clusters where addressing the problem may have negative impact on the overall profile, and those do have smaller MER severity. Certainly, if removing an impairment will result in a net overall lower performance from PMA, that might not be work you want to prioritize (there are other conditions that may change that decision, and there may be different approaches to PMA that avoid the conflict, as we discuss later).

However, note that at least for this set of data, those with negative impact after considering profiles are less severe. Therefore, if we use RxMER per subcarrier to prioritize PNM work, the risk may be low of having a negative or small impact after considering profiles. It may be sufficient just to check the profile impact when in doubt, if using RxMER per subcarrier as the basis for selecting proactive work.

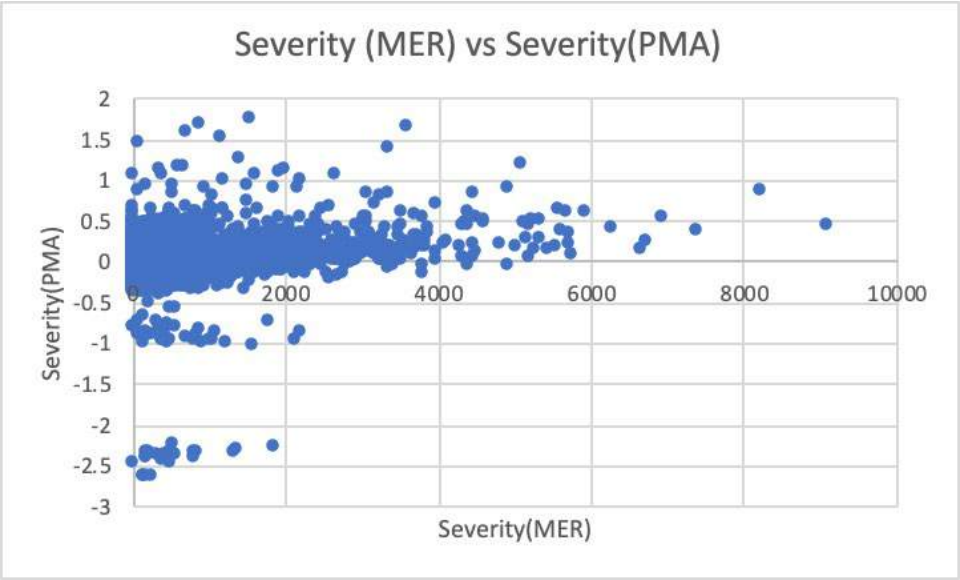

**Figure 4 - Severity from RxMER value versus severity from PMA value**

Figure 5 compares severity of bit loading and PMA. Like Figure 4, we see the same relationship and the conclusions are the same, as expected.

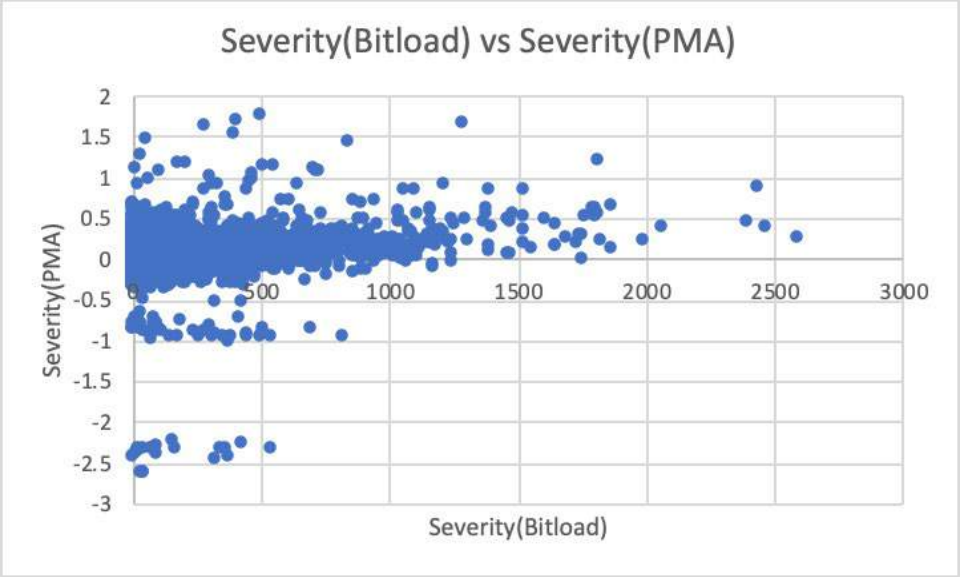

**Figure 5 - Severity from bit loading versus severity from PMA value**

Figure 6 relates the normal scores of MER and bit loading. Like Figure 3, we see a strong correlation. But this time there is a large number of high normal scores for bit loading that have small MER normal scores. This suggests that, without the ability to find impairments in an automated fashion, there is good reason to look at both measurements and perhaps look deeper to determine which is best. But this is also another reason for using an AD.

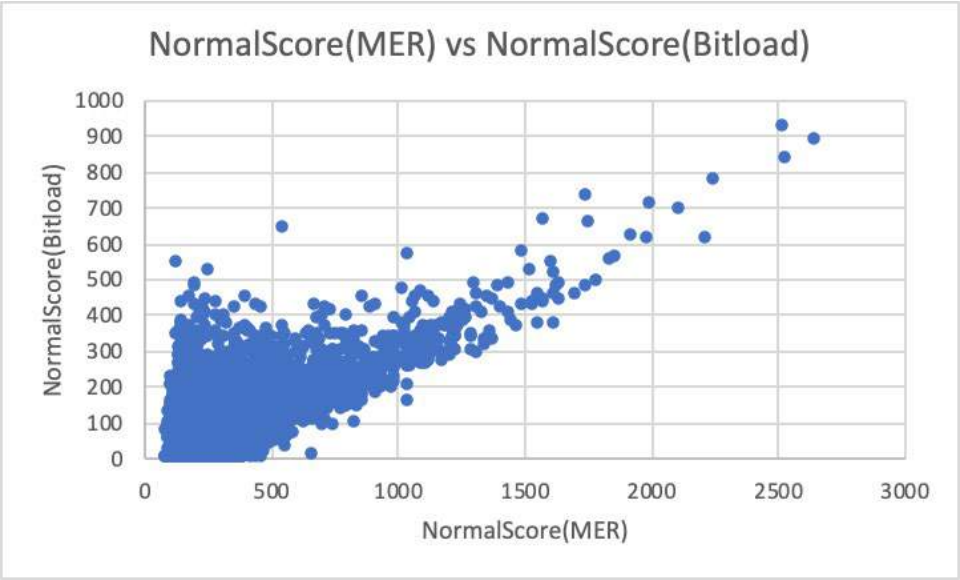

**Figure 6 - Normal score from RxMER value versus normal score from bit loading value**

Figure 4 and Figure 5 suggest looking at severity for MER and bit loading for only positive PMA severity. Figure 7 shows the conditional relationship, and it strongly resembles Figure 3. This result suggests that the dynamics of PMA cannot be well predicted by just looking at improvements in MER or bit loading, so some consideration of profile impact is warranted for selecting PNM work.

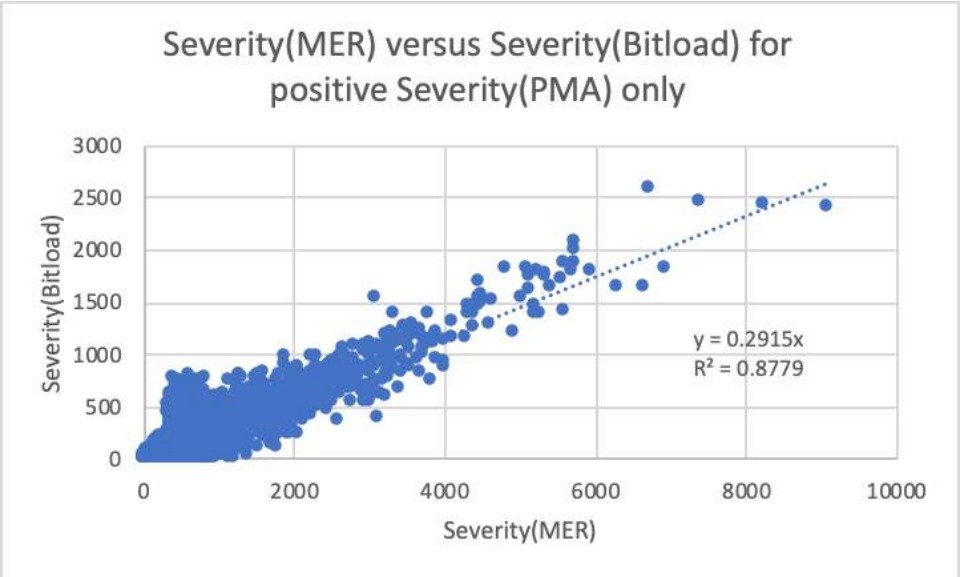

**Figure 7 - Severity for RxMER value versus bit loading for CM that score a positive PMA severity**

Next, we want to look at individual anomaly types to see if some types of anomalies exhibit different relationships. If we find that some anomaly types appear to score generally higher, or have different relationships with profiles, then we may want to treat them differently. But as we see in the figures that follow, there seems to be no difference in these relationships by anomaly type.

Figure 8 through Figure 13 are repeats of Figure 1 through Figure 6 respectively, but for only LTE anomalies. Note the patterns are respectively very similar, leading to the same conclusions for just LTE anomalies.

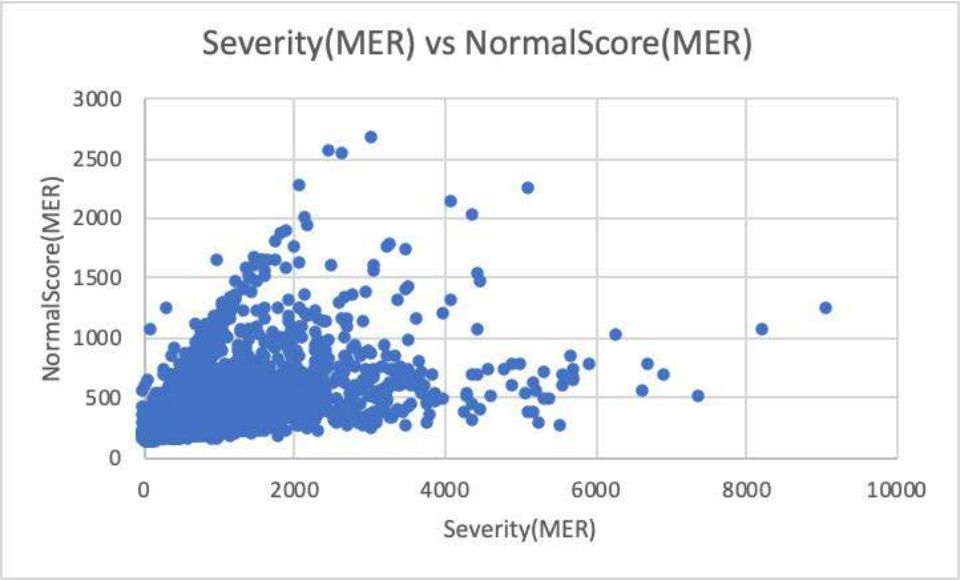

**Figure 8 - Severity versus normal score from RxMER for LTE ingress impairments**

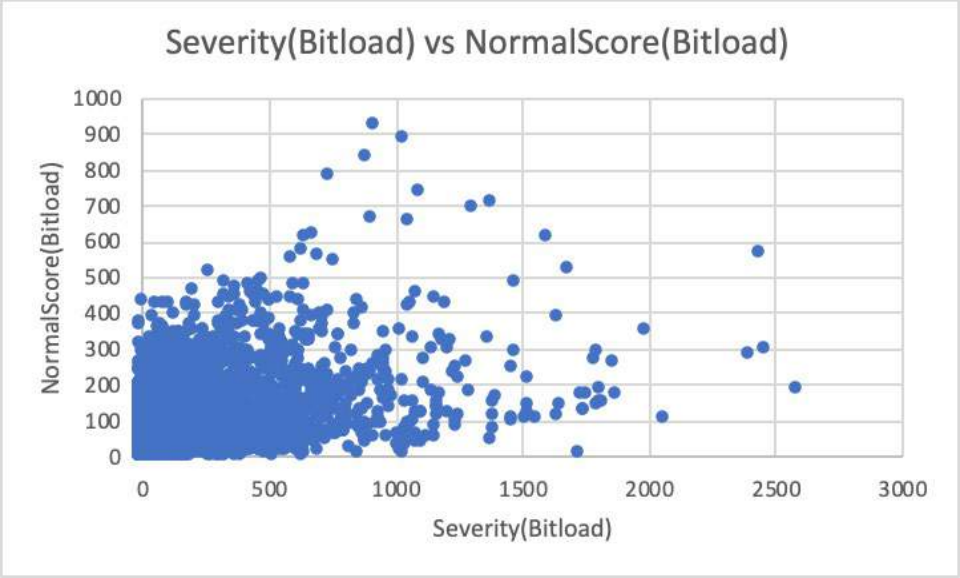

**Figure 9 - Severity versus normal score from bit load for LTE ingress impairments**

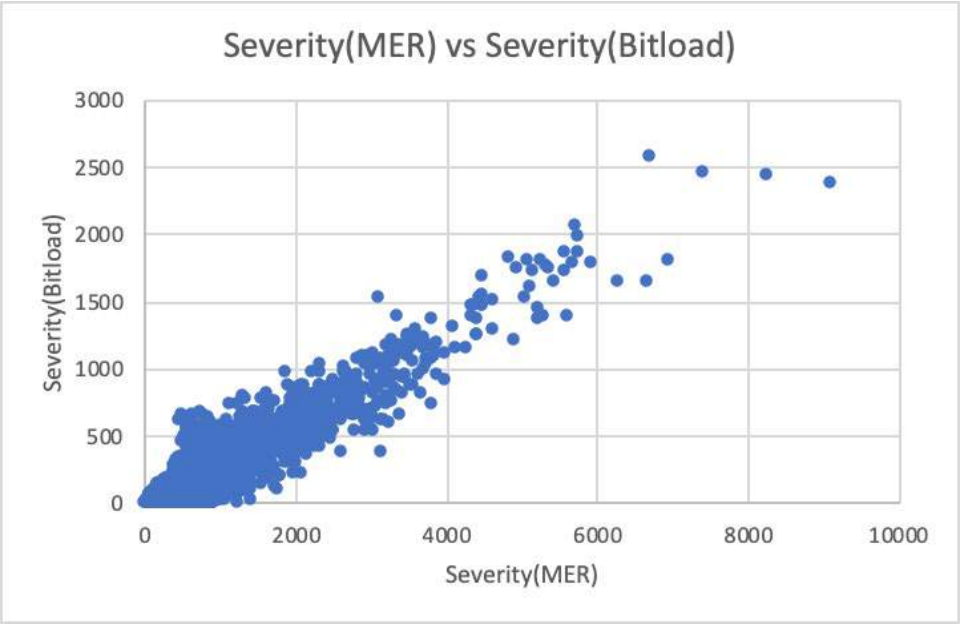

**Figure 10 - Severity from RxMER value versus severity from bit loading value for LTE ingress impairments**

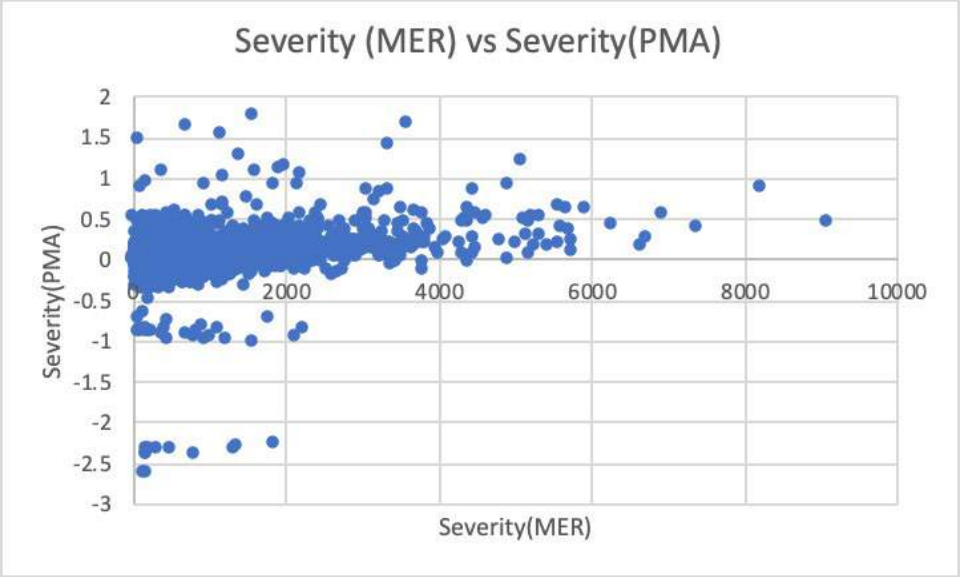

**Figure 11 - Severity from RxMER value versus severity from PMA value for LTE ingress impairments**

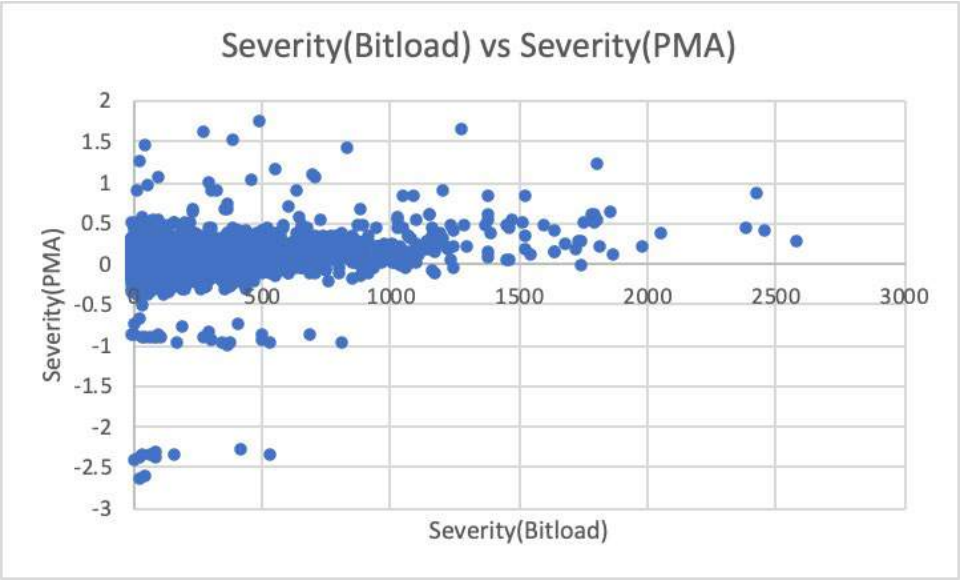

**Figure 12 - Severity from bit loading versus severity from PMA value for LTE ingress impairments**

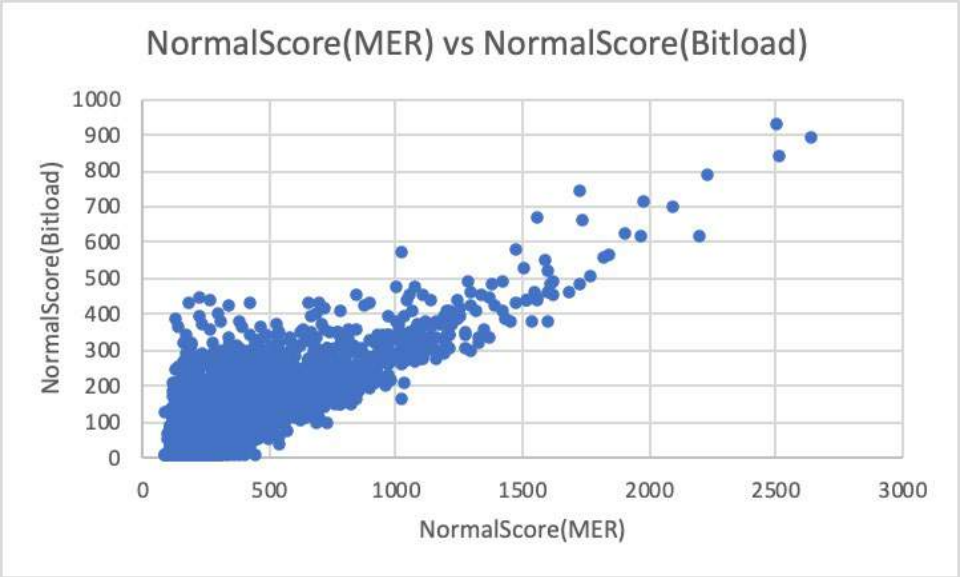

**Figure 13 - Normal score from RxMER value versus normal score from bit loading value for LTE ingress impairments**

With five separate impairment types to identify, and several modems showing multiple impairment types, showing all graph combinations would fill several pages with little value. Therefore, we are showing a few sample graphs for other single impairments, and for those modems with multiple impairments in Figure 14 through Figure 18, which follow.

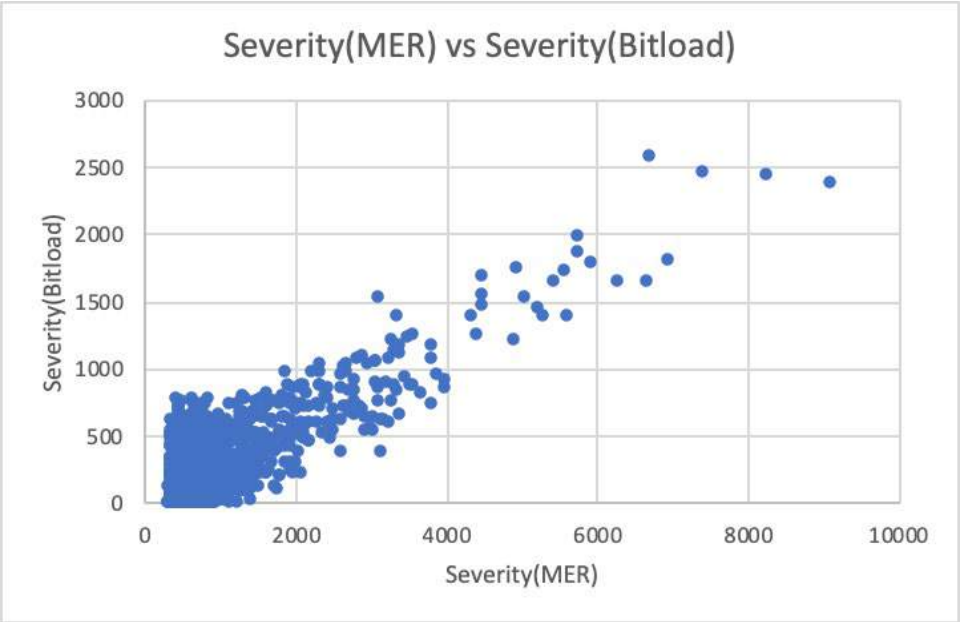

**Figure 14 - Severity from RxMER value versus severity from bit loading value for wave impairments**

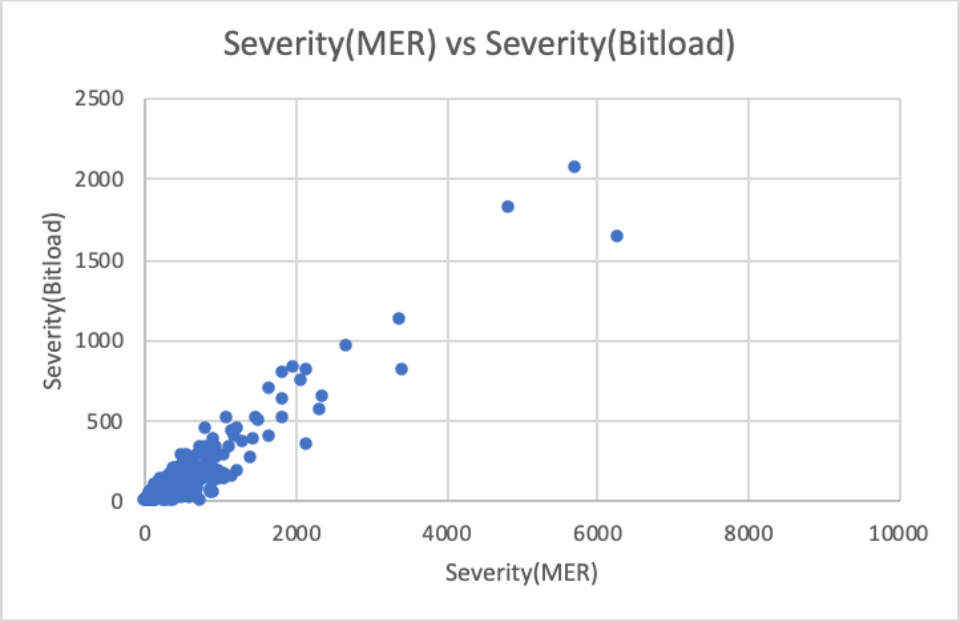

**Figure 15 - Severity from RxMER value versus severity from bit loading value for rolloff impairments**

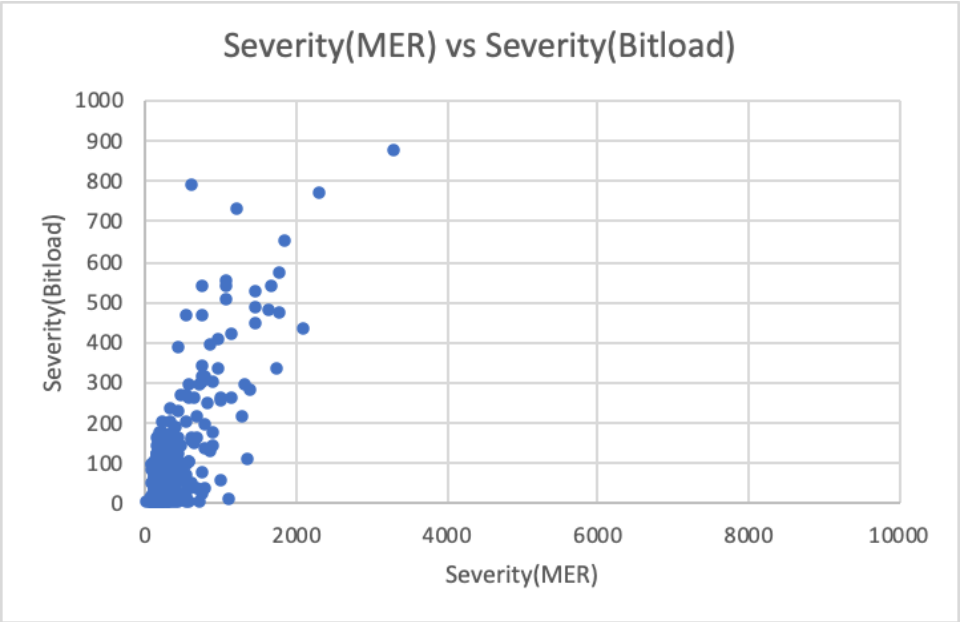

**Figure 16 - Severity from RxMER value versus severity from bit loading value for suckout impairments**

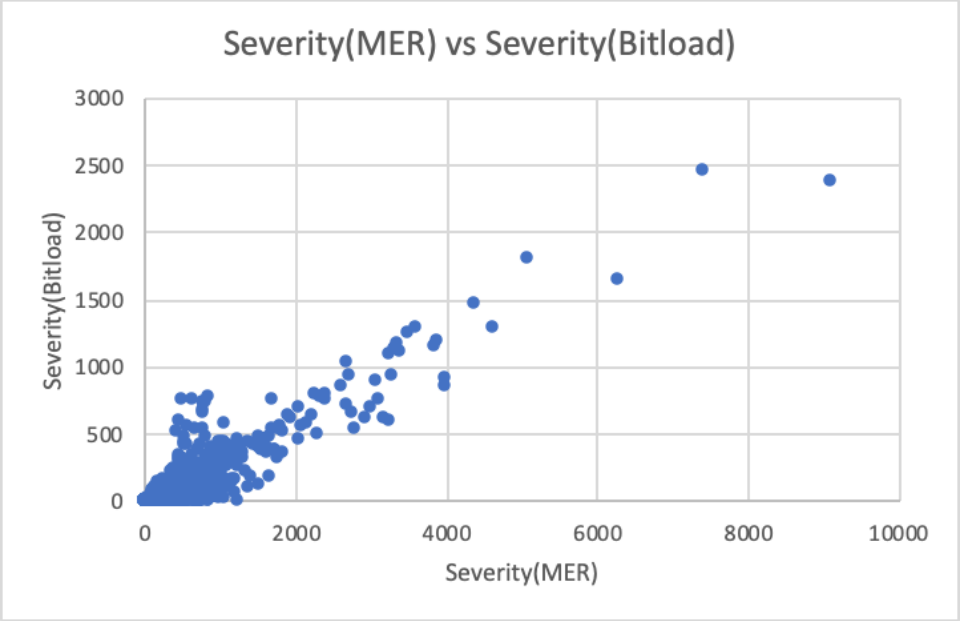

**Figure 17 - Severity from RxMER value versus severity from bit loading value for spike impairments**

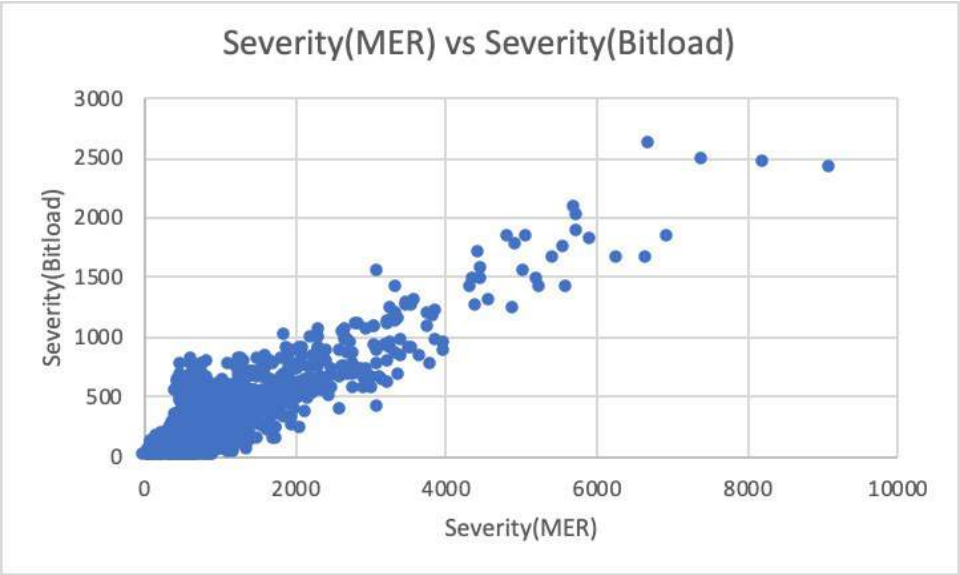

**Figure 18 - Severity from RxMER value versus severity from bit loading value for modems reporting multiple impairment types**

These plots suggest a few important results which inform maintenance decisions.

A reliable method for identifying anomalies in an automated way is important. Without analyzing the tradeoffs between statistical methods and machine learning techniques for this problem, we only suggest operators use anomalies to identify the opportunities to address because they are indications of cable plant problems.

Further, we suggest using either RxMER per subcarrier or bit loading as a measurement basis, with a measurement of the difference in either as a way to prioritize work. Equally, a plant quality measurement could be used if it is a comparison between the actual performance and intended performance.

Profile management must be considered when selecting proactive maintenance work. Looking at the provided figures, it is conceivable that only the most impactful impairments are addressed, and those appear to have positive impact on overall profiles. But not all PNM activities will yield positive net profile impact, so some consideration should be given here. We explore this issue a bit more next.

## 3.8. Manual simulation of proactive maintenance impacts

As an exercise to further demonstrate these relationships, we next conduct a manual simulation of maintenance performed on a set of modems. We select a sample of modem data from the larger data set which generated the figures previously discussed. We then select the most significant impairment on a measure of performance, remove the identified impairment from the RxMER per subcarrier data of all modems where it appears by a mathematical adjustment, recalculate profiles and measurements, then repeat a few times. We then report the results of this experiment in a few forms.

While many of the methods we outline in this paper are CM or CM cluster centric, this approach demonstrates using two of the methods as a measurement but in an impairment centric maintenance approach, which we believe is an operationally effective way to perform PNM. The impact on profiles however is examined here too, as we can already see it should be considered for an overall network service impact perspective.

In the comparison done here, the method of section 2.2 is augmented to be an anomaly driven version of using Severity(Profile) as the measure, and this is compared to the method of section 2.4 where we prioritize by bit load impact from correcting the impairment (Severity(Bitload)). Therefore, looking at the difference should show something about the impact of profiles on the simulations.

We make one large assumption in this analysis worth mentioning: we are identifying anomalies in multiple CMs and correlating anomalies so that we presumably remove one anomaly from multiple CMs where it appears. Therefore, the assumption is that the anomaly is indeed one anomaly appearing in multiple CMs, whereas it may not be the same anomaly but rather more than one that coincidentally appear the same in the RxMER per subcarrier data. While the strength of this assumption is related to our ability to accurately cluster by anomaly, the use is comparative in this simulation so should not bias the results greatly. The intent is to see the impact of profiles on PNM selection, and it should still show that impact.

For this simulation comparison, we selected a set of 526 CMs on the same section of plant. Figure 19 shows the RxMER per subcarrier data of all these CMs overlaid on the same plot. Notice related impairments are indicated.

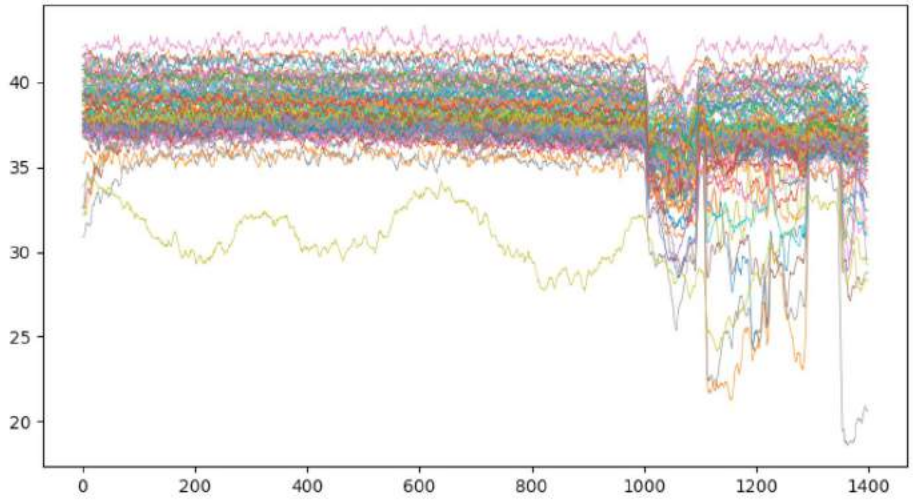

**Figure 19 - 526 CMs on a common channel, many experiencing impairments that appear related**

The simulation results are shown in Figure 20 and Figure 21, as well as Table 1 and Table 2. Figure 20 is a graph of the total bit load for the set of CMs at each iteration, where an iteration is the mathematical removal of an impairment from the RxMER values, with the impairment selected by the two compared methods: Severity(Bitload) and Severity(Profile). Note that for the first few impairments, there is little difference in the methods. In fact, seeing the detailed results in the two tables, the first three impairments selected by the two methods are the same. After about seven iterations, there is little difference in the two approaches. These results suggest that either approach may be sufficient for selecting PNM work. But more data and simulations would be needed to prove this hypothesis.

Looking at Figure 21, we see that the profile management results, as indicated by J value, vary more. Thus, at least for the selected PMA used here, there is impact on PNM selection and the impact of PNM on service. Of course, this impact is not likely detectable by customers or even applications in many cases, but it may be in extreme cases.

This result suggests that the profile management approach implemented should be made robust to PNM activities. Fortunately, this is easy: if each CM's RxMER is the same or improved after PNM, and a recalculation of profiles yields a solution that is further from the objective, then keep the existing profile solution set, and consider recalculating until a better solution is found. As many PMA are heuristics, you can always change the order of inputs and get a different answer. As profile calculation is fast, and profiles are often kept for long periods of time, there is little reason not to calculate several solutions and select the best according to operations and business objectives.

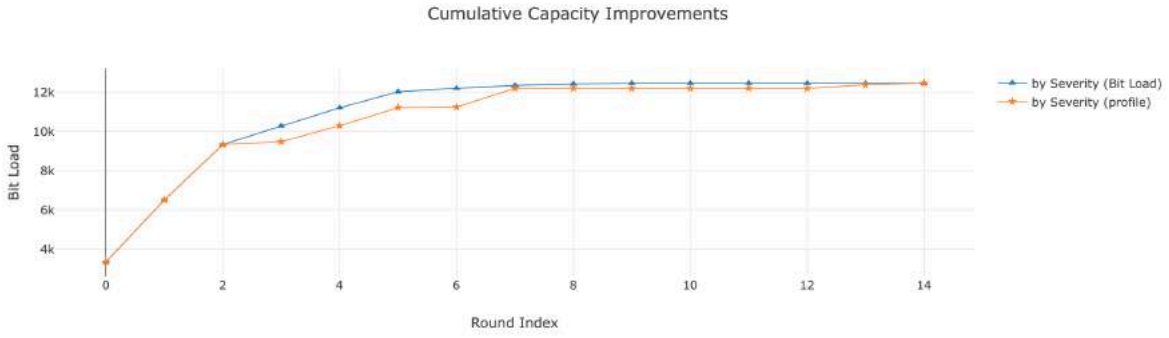

**Figure 20 - Cumulative bit load improvements over multiple rounds of impairment removal for both methods**

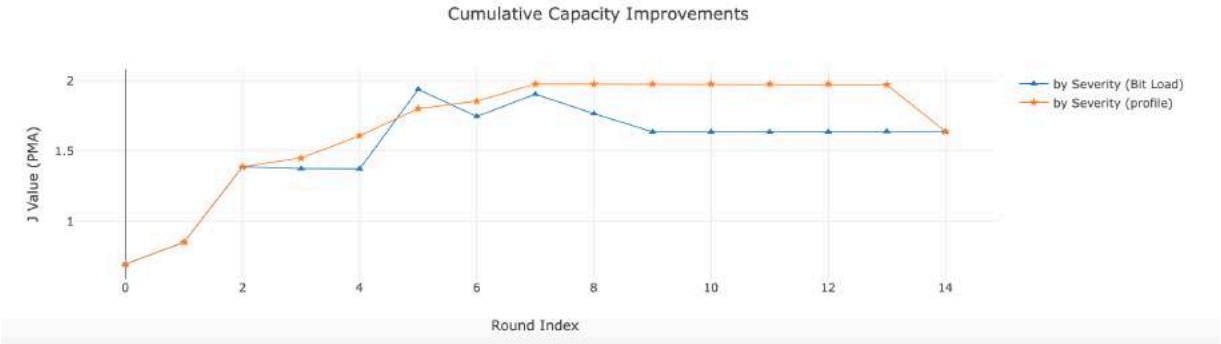

**Figure 21 - Cumulative J value (PMA) improvements over multiple rounds of impairment removal for both methods**

**Table 1- Results prioritized by bit load (Severity(Bitload))**

| Round | Anomaly | Location (Subcarrier ID) | Num CMs | Severity (Profile) | Severity (Bit load) | Num CMs (Better Profile) | Num CMs (Worse Profile) |
|---|---|---|---|---|---|---|---|

## 4. Conclusion and Future Work

Profile management has a clear influence on the impact to service that results from PNM. Therefore, some consideration of profiles is important when selecting proactive work to do. It is advisable that operators at least look at the impact on profiles when determining whether to conduct PNM, and it is likely a factor in prioritizing proactive work.

Anomaly-driven PNM, finding and eliminating anomalies, appears to be the most popular approach that operators take for their PNM; but modem-driven PNM is an option to consider for some, as the data that most informs PNM comes from the CMs. Likewise, profile-driven PNM is an option to consider as well. But ultimately, each of these factors needs to be considered in some way in deciding which PNM work to take on.

Though this paper does not compare all options, an examination of the options presented here does suggest that impairment-driven identification of maintenance opportunities is a very good approach, that problem severity can be measured by impact on CMs, and that it is necessary and complimentary to PNM decision making to consider the impact on profiles when determining the capacity impact on the network for selecting maintenance. Said differently—find anomalies, investigate their impact on customers'

service, estimate the impact due to profiles and on network impact expected from the work, and use these pieces of information to prioritize and select PNM opportunities. It may at times be best to let profiles drive PNM maintenance decisions, in fact.

Seeing that some network repairs can have negative impact on profiles, it suggests more work on profiles is warranted too. It may be simple enough to set a rule that says, if all CMs improve, then the recalculation of profiles can only result in a net benefit, or a benefit to each CM, or another appropriate rule, before consideration of replacing profiles. In other words, do not harm first. Alternately, it may be useful to develop algorithms that set profiles to be robust against these changes. Likewise, it may be worth investigating different objectives when setting profiles altogether.

Further computer simulations of various PNM selection criteria are warranted by this work. The two limited simulations we ran suggest that very significant PNM opportunities can have significant impact on network capacity, whereas smaller ones may not. Further, there are several measures that can be used to select PNM opportunities, and they may all be sufficient for many operations, though that should be checked with further simulation and field experiments. The limited simulations we ran also suggest that profiles recalculated after plant improvements may not always improve capacity for everyone or overall, but that can be easily addressed in software or in operations decisions.

At least, consider this work as a roadmap for analyzing PNM strategies for operations. The graphical comparisons are simple to do with your own data, and running simulations of various approaches can be very informative. Extending this work into cost analysis may be the necessary step to procure funding for operational improvements.

Our best hope is to work with operators to test some of these approaches and determine which are the most cost effective to operations and impactful to service overall. Selecting proactive work requires identifying the opportunity, measuring it, estimating the benefit of addressing it, and then executing on those opportunities with the most promise. Therefore, the best measure of success is to determine the cost and benefit of the work being done, then adjust the opportunity selection process to optimize the program on those measures. The field work that has to be done is to determine which of the approaches outlined in this paper, or alternative approaches, are best suited to optimize the maintenance program. Looking at the conclusions that follow, we already have a good idea where to start. Fortunately, for well-equipped or unequipped operators alike, CableLabs has ProOps encoded and ready to assist.

Certainly, there remains a lot of confirmation work with operators before all this can be applied optimally to operations. While identifying the anomalies and measuring their significance to service are important steps, the PNM work to remove the anomalies has to be done to measure cost and impact, so that both can be modeled better for more accurate and operator-specific decision making.

## List of Tables

 

# 1. Introduction

In the last decade, home network architectures have become more complicated due to advances in wireless technology, and the explosion of different types of wirelessly connected devices such as Internet-of-Thing (IoT) devices, cell phones, tablets, laptops, gaming devices, etc. In fact, the U.S. smart home market is expected to show a compound annual growth rate of 16.9%, reaching 46.6B by 2024 [1]. In this home network architecture, some cable Multiple System Operators (MSOs) deploy a two-box solution for both residential and Small and Medium-size Business (SMB) customers where one box is an access CPE device (i.e., cable modem or an ONU), and the second box is a wireless router. Cable operators typically have limited information about the access CPE device's health status, and no information about the customer's home network, including what type of clients are connected to the home network, and their bandwidth usage vs. time. Such home network health and traffic information would be very useful to the Cable operators in order to enhance their customers' experience by optimizing the customer's home network traffic, prevent potential field issues, and be able to introduce new services such as customer's home network management and security. Furthermore, some Cable operators have already begun the transition towards cloud-based management of wireless routers and other devices, which is not supported by the currently field-deployed access CPE devices.

In this paper, the challenges with the current home network architecture are first explained. Then, the proposed home network architecture with an agile software stack on the access CPE device is discussed. This includes the agile software stack and components with the cloud-based management of the access CPE device to enable streaming of all the telemetry data. Third, the streaming telemetry data path, including the components and operation of the cable MSO's Streaming and Analytics platform are explained. Fourth, the organized hierarchical Grafana dashboard design with all of the different types of streamed data telemetry, including home network traffic metrics, D3.1 eMTA health metrics, DOCSIS RF info, event alarm and notifications is explained. A comparison between the OpenWrt-based streaming telemetry method in the paper and other streaming telemetry methods is then reviewed. Finally, the benefits to Cable operators using the OpenWrt-based streaming data telemetry method for access CPE devices are summarized.

# 2. Home Network Architecture

Cable MSOs' common customer home network is a two-box solution, consisting of a D3.1 eMTA device, which is connected to an HFC network via a coaxial cable on the WAN port, and connected to a Wi-Fi router on the LAN port via an Ethernet cable as shown in Figure 1 configuration A. For a Fiber-To-The-Home (FTTH) deployment, the access CPE device is an Optical Network Unit (ONU) connected to a Passive Optical Network (PON). A Wi-Fi router with a number of Wi-Fi APs or multiple Wi-Fi routers are typically used in larger homes for wireless mesh connectivity, resulting in improved data throughputs for all of the wirelessly connected devices in the home network. The software stack on the D3.1 eMTA device is monolithic, customized for each Silicon and OEM vendor, and does not provide any metrics about the health of the access CPE device and the wirelessly connected clients. The D3.1 eMTA monolithic software stack results in long and costly validation testing cycles before the new firmware that meets the Cable operator's requirements can be deployed. Furthermore, Cable operators are moving toward a cloud-based infrastructure for both command/control and streaming telemetry, which the current access CPE device's monolithic software architecture does not accommodate.

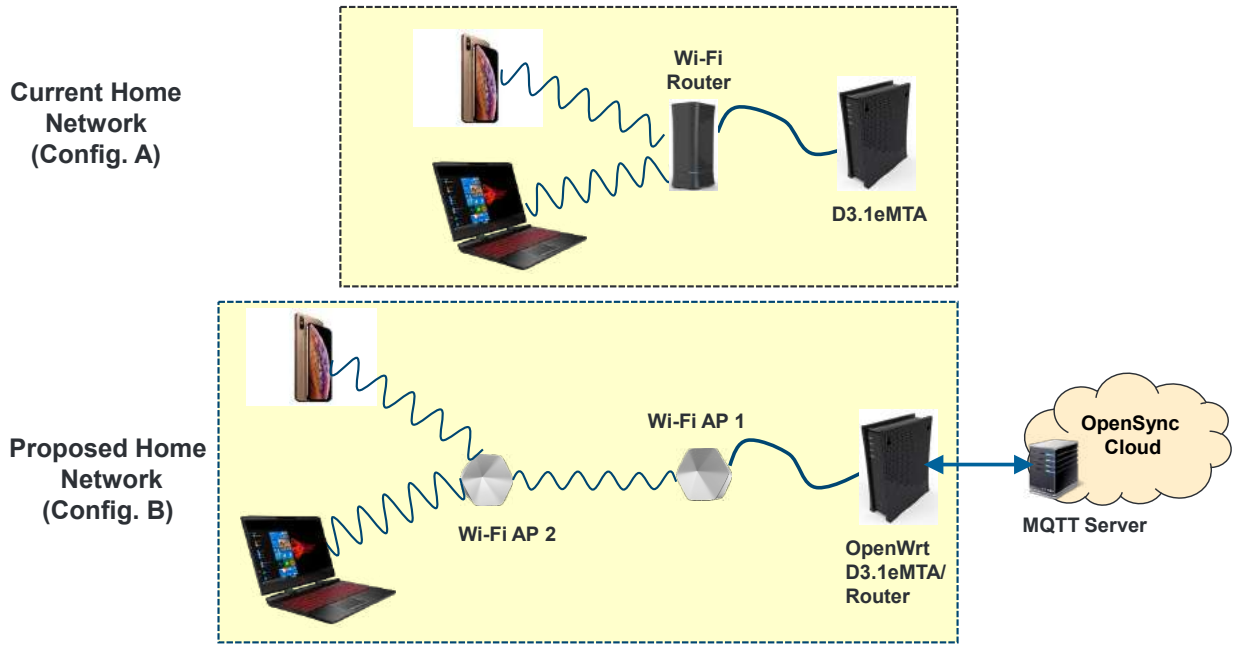

**Figure 1: Current and Proposed Home Network Architecture Diagrams (Configurations A and B)**

## 3. Access CPE OpenWrt Software Architecture

OpenWrt is an open-source project for embedded Operating System (OS) based on Linux. It was selected since it is highly-flexible open-source OS with a large ecosystem of vendors and developers that enable cable MSOs to rapidly develop new features and plugins that can also be containerized [2]. One of the key built-in benefits of OpenWrt OS is a full carrier-gradeIPv4/IPv6 routing functionality on the access CPE device with no need to redesign the hardware. Moving the routing functionality from the connected Wi-Fi router to the access CPE device enables cost optimization by using a generic Wi-Fi AP as the second box, and focusing the AP performance on the wireless connectivity in the home network.

To address the challenge explained above, an agile OpenWrt-based software stack was developed as a Proof of Concept (PoC) using D3.1 eMTA device operating in a home network architecture as shown in Figure 1 configuration B. The agile OpenWrt software stack is integrated with an OpenSync™ layer, a Silicon vendor Software Development Kit (SDK), and the Message Queue Telemetry Transport (MQTT) server architecture as shown in Figure 2. In addition, the CM and voice firmware was loaded on the access CPE device.

MQTT is a lightweight Machine to-Machine (M2M) transport communications protocol [3]. The D3.1 eMTA streams the telemetry data statistics to the Grafana dashboard via the MQTT server that is hosted in the OpenSync™ cloud, which forwards the data to the cable MSO's Streaming and Analytics platform. MQTT supports various authentications and data security mechanisms (using a script to generate security certificates). The Grafana tool was selected since it is a multi-platform open-source analytics and interactive visualization web application that users can customize to create complex monitoring dashboards [4].

The OpenSync™ cloud is composed of a Network Operations Center (NOC) and OpenSync™ controller for managing a network of OpenSync™-enabled devices. Cable operators can establish their own

OpenSync™ cloud by obtaining an OpenSync™ source-code license. The OpenSync™ cloud provides operator-friendly services, including:

- Device and firmware management
- Inventory and billing system
- Network performance control
- Onboarding and provisioning of field-deployed devices
- Telemetry reporting and data analytics
- Network operations, and customer support.

The NOC in the OpenSync™ cloud translates and communicates management commands in a single Wi-Fi AP network and in mesh multi-AP Wi-Fi network via Open vSwitch Database (OVSDB) distributed database commands. The OpenSync™ controller utilizes the OVS implementation and OpenFlow protocol for networking, and MQTT protocol for receiving state and telemetry data from OpenSync™-enabled devices. Specifically, the OpenSync™ controller provides the necessary command and control services such as:

- Network Status
- IP Address (displayed)
- Network Mask
- DHCP Status
- Parental Control
- Speed Test initiation and results
- Reset and Reboot device

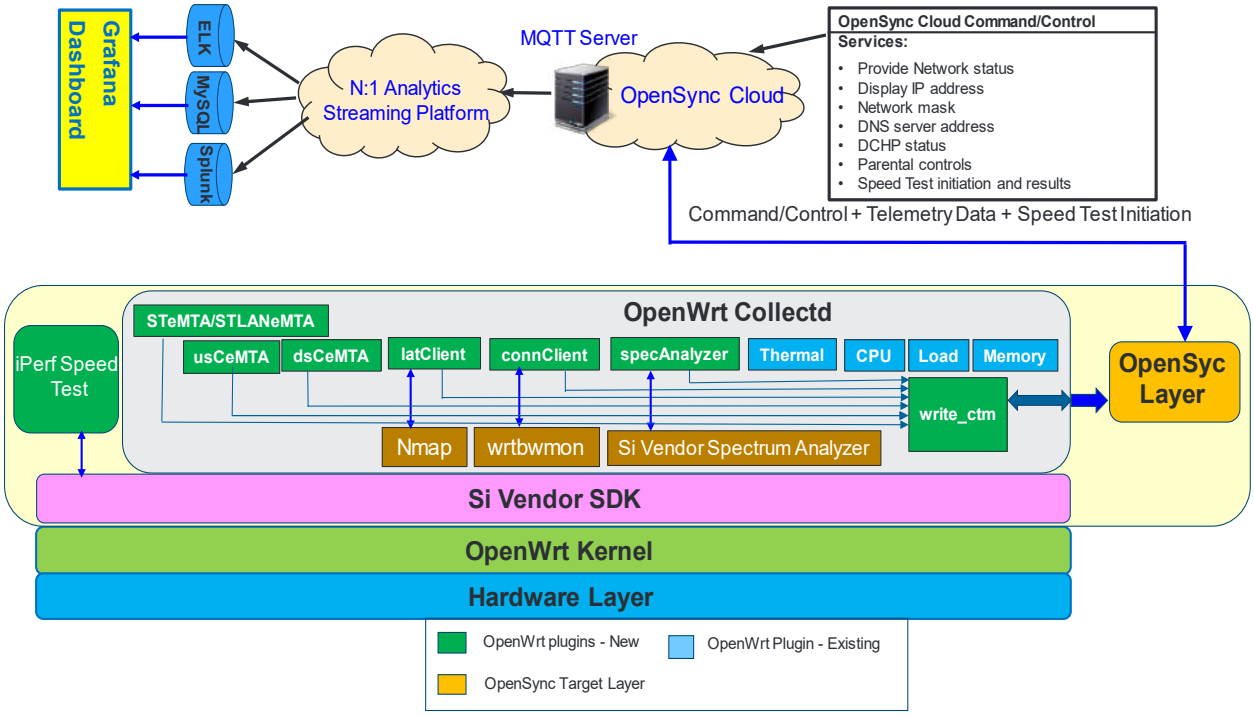

**Figure 2: OpenWrt Integrated with OpenSync™ Software Architecture**

In this software architecture a smart remote agent based on an OpenWrt data collector open-source software component called collectd was used as shown in Figure 2 [5]. The collectd component gathers metrics from various sources, e.g. the operating system, applications, log-files and external devices, and stores this information or makes it available over the network. Those statistics can be used to monitor systems, find performance bottlenecks (i.e. *performance analysis*) and predict future system load (i.e. *capacity planning*). The collectd component, which offers a variety of Plugins (software programs), is used to collect different types of telemetry data from a few Wi-Fi routers. The collectd component's default reporting time interval is 30 seconds, but other configurable time intervals can be selected. New capabilities and functionality (green-colored boxes in Figure 2) were added to the collectd software components. For example, the smart remote agent can be used to run a specific test such as measure the IPv4/IPv6 DOCSIS round-trip latency as explained below using the eMTALat plugin, read the collected measurement data, and streamed the data to the service operator's streaming and analytics platform. The blue-colored boxes are existing supported OpenWrt Collectd plugins that are utilized in this architecture. The collectd software components are integrated with the Silicon vendor's SDK and with the supported OpenWrt OS. It should be pointed out that other custom plugins and shell scripts can be developed, and the listed plugins below are just a sample framework.

**Green-coded collectd plugins descriptions:**

1. **usCeMTA:** Software plugin to pull all the DOCSIS upstream channel information used by the D3.1 eMTA (RF level, channel frequency, etc.).
2. **dsCeMTA:** Software plugin to pull all the DOCSIS downstream channel information used by the D3.1 eMTA (RF level, channel frequency, etc.).
3. **latClient:** Software plugin that measures and reports the round-trip latency from the D3.1 eMTA to each of the wirelessly connected devices in the home network based on their IP address or MAC address as shown in Figure 1.
4. **connClient:** Software plugin that measures and reports the number of transmitted and received packets from each of the wirelessly connected devices in the home network.
5. **specAnalyzer:** Software plugin to obtain the RF downstream and upstream spectrum of the Access CPE device.
6. **eMTALat:** Software plugin that measures and reports the minimum, maximum, and average round-trip DOCSIS latency between the D3.1 eMTA and the connected CMTS. First, it initiates a trace-route command to get CMTS IPv4 and IPv6 addresses. Then, it starts ICMP request and reply commands to measure the DOCSIS latency between CM and CMTS and stores the test results in separate files for IPv4 andIPv6. The eMTALat plugin reads results from these files and send them to write_ctm plugin, which in turn sends the measured DOCSIS latency results to the OpenSync™ layer's SM (not shown in Figure 1).

**Wrtbwmon:**

wrtbwmon is a small and basic shell script designed to run on Linux powered routers (OpenWRT, DD-WRT, Tomato, and other routers where shell access is available). It provides per user bandwidth monitoring capabilities and generates usage reports [6].

**Nmap**:

Network Mapper or Nmap is a free and open source utility for network discovery and security auditing [7]. Many systems and network administrators also find it useful for tasks such as network inventory, managing service upgrade schedules, and monitoring host or service uptime. Nmap uses raw IP packets in novel ways to determine what hosts are available on the network, what services (application name and version) those hosts are offering, what operating systems (and OS versions) they are running, what type of packet filters/firewalls are in use, and dozens of other characteristics (nmap.org).

**write_ctm collectd Plugin:**
The **collectd** service calls its collection plugins over a configurable time period. The collectd daemon collects various statistics from the device for aggregation and forwarding to a desired destination. The write_ctm plugin aggregates the stats, converts them to Protobuf format, and sends the collected telemetry data to the OpenSync™ STATS Manager (SM), which in turns forwards the collected telemetry data to the OpenSync™ Queue Manager (QM). The OpenSync™ QM sends the collected telemetry data to the cable MSO's Streaming and Analytics platform via the MQTT server. It should be pointed out that collectd plugin can also send string-formatted event notification based on system defined threshold levels. The write_ctm plugin registers its write API to collectd, and fetches data from the existing plugins on the expiration of every time period. No changes are needed to the existing plugins.

The blue-coded collectd plugins (Thermal, CPU, Load, Memory) are standard open-source collectd plugins that were added to the list of collectd plugins as shown in Figure 2.

# 4. Access CPE OpenSync™ Software Architecture

Figure 3 shows the key OpenSync™ software architecture components integrated with OpenWrt software, and the connectivity to the OpenSync™ cloud [8]. OpenSync™ is a cloud-agnostic open-source software that consists of many managers running as separate processes and performing their specific set of tasks. The software code of the Diagnostics Manager (DM) and STATS Manager (SM) was updated for streaming the collected telemetry data and other test results such as the iPerf speed test results via the OpenSync™ cloud. Table 1 summarizes the OpenSync™ manager functionality and their status. Some of the managers listed are required for basic operation, while the other listed managers are optional, depending on the desired functionality.

**Table 1: Summary of OpenSync™ Managers' Functionality and Status**

| Manager Name | Manager Functionality | Manager Status |
|---|---|---|
| Diagnostics Manager (DM) | Responsible for spawning the rest of the OpenSync™ managers and optionally monitoring them. It controls starting, stopping, restarting of the OpenSync™ managers, and monitoring the reboot status of the OVSDB. The iPerf speed test software was developed and integrated into the DM such that the speed test can be initiated from the OpenSync™ NOC, and the DS/US speed test results are sent to Grafana dashboard. | Required for basic operation |
| Connection Manager (CM) | Responsible for establishing the backhaul connection and keeping connectivity to the cloud. | Required for basic operation |
| Network Manager (NM) | Responsible for managing all network related configuration and network status reporting. | Required for basic system network configuration |

| | | |
|---|---|---|
| Wireless Manager | Not applicable to access CPE devices. Used in Wi-Fi routers to read and updated their configuration and state tables. | Required for basic system network configuration |
| Queue Manager (QM) | Responsible for aggregating reports from different OpenSync™ Managers | Optional |
| Statistics Manager (SM) | Responsible for processing all requested wired and wireless statistics and sending results to the cloud. The configuration is done through OVSDB while MQTT is used for the data plane. All the telemetry health metrics mentioned below are collected by write_ctm component as shown in Figure 2, and are transmitted to the SM, which forwards all the collected telemetry data to the QM as shown in Figure 3. | Optional |
| OpenFlow Manager (OM) | If the OpenVSwitch is used on the device, then the OM is responsible for managing packet flow rules. | Optional |
| Log Manager (LM) | Responsible for collecting and uploading logs and system information upon the Cloud request (log pull) and for handling log severity setting for running modules. | Optional |
| Platform Manager (PM) | Responsible for covering specific platform features which can't be covered by other managers such as synchronization between device GUI and cloud, and cloud-managed device parental control. | Optional |

## 4.1. iPerf Speed Test

The iPerf speed test is initiated from the OpenSync™ Network Operations Center (NOC). Submitting a speed test request from the NOC sends a message via Openflow to the access CPE device, and the speed test request is detected on the device by the speed test handler in the OpenSync™ DM. The speed test handler calls a script on the device that in turn invokes an iPerf3 speed test with a pre-defined set of arguments. The speed test is run once to collect the upstream test results, and once again to collect the downstream results. The speed test results from each test are saved to files on the Access CPE device. The STeMTA collectd plugin processes the speed test results from the files and delivers them to the MQTT server, as described in the STeMTA Plugin section. The ability to initiate the iPerf speed test from the OpenSync™ NOC and review the collected speed test results would be very helpful to the Cable operators' call center to quickly address customers' issues.

### *4.1.1. STeMTA Plugin:*

A new speed test plugin, which is called STeMTA, was added to collectd. The STeMTA plugin calls an iPerf speedtest script to initiate the iPerf speed test on WAN port of the D3.1 eMTA. Once an iPerf speed test is completed, then the script writes the downstream and upstream speed test results to iPerf download and upload result files. The STeMTA plugin reads results from these two files and sends them to the write_ctm plugin, which in turn sends the measured speed test results to the OpenSync™ SM.

### 4.1.2. *STLANeMTA Plugin:*

A new Speed Test plugin, which is called STLANeMTA, was added to collectd. The STLANeMTA plugin calls iPerf LAN speedtest script to initiate the iPerf speed-test on LAN port of the D3.1 eMTA. Once iPerf speed-test is completed, the script writes the downstream and upstream speed test results to an output file. The STLANeMTA plugin reads results from this file and sends to them to the write_ctm plugin, which in turn sends the measured speed test results to OpenSync™ SM.

### 4.1.3. *Cloud Security*

The software architecture also includes several cloud-connectivity security features. The D3.1 eMTA uses OpenSync™ device certificates to authenticate and connect to the OpenSync™ cloud, and to connect to the MQTT server in order to stream the collected telemetry data to the Cable operator's Streaming and Analytics platform. In addition, a shell script in the device is used to monitor all Secure Shell (SSH) and TELNET connections to the D3.1 eMTA, which are reported to the Grafana dashboard.

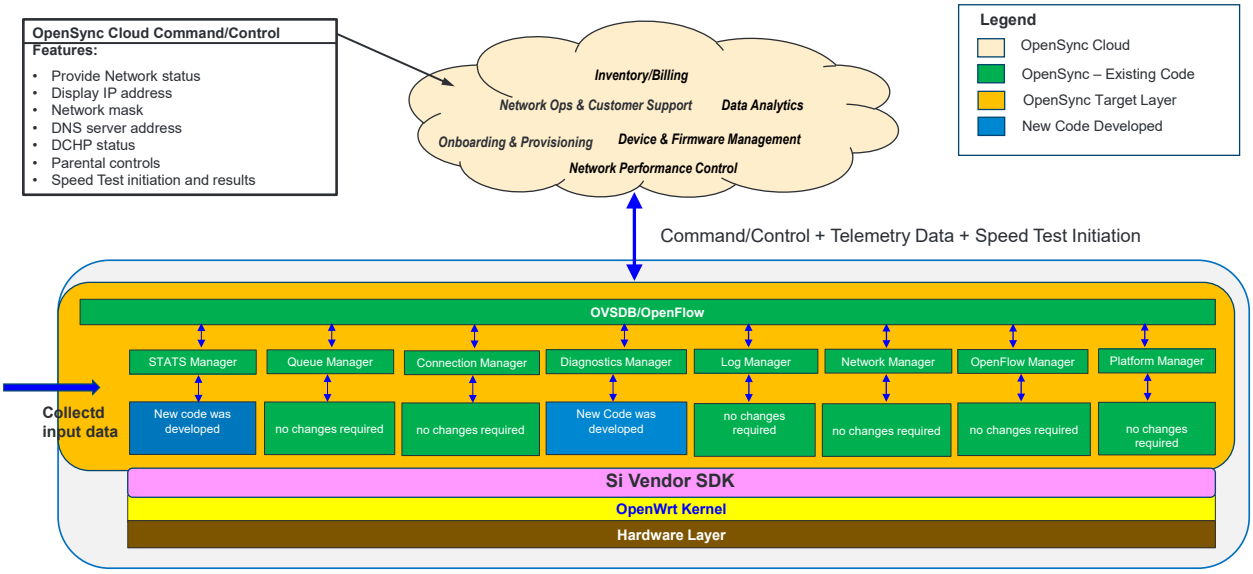

**Figure 3: OpenSync™ Software Architecture with the Connectivity to the OpenSync™ Cloud**

## 5. Streaming Telemetry Data Path

Figure 4 shows the telemetry data path (current implementation) from the OpenWrt D3.1 eMTA to the Grafana dashboard via the cable MSO's Streaming and Analytics platform. The collected telemetry data is streamed in Protobuf format to the MQTT server hosted on the OpenSync™ cloud, and then to the cable MSO's Streaming and Analytics platform.

Cable MSO's future network architecture separates the control plane and the data plane as intelligence is no longer resident on hardware devices but rather on the network's software driven controllers where network analytic models can act on traffic behaviors, services flows, and configuration state to predict and

respond in near real-time to the networks changing demands. The network architecture's data plane includes the Cog platform, Data Distribution Bus (DDB), and Data Governance platform. The Cog platform is a data engineering platform that builds enriched data sets called Analytics Data Sets (ADSs), which is represented by the First Normal Form (1NF). These ADSs are distributed across the operator's network, and are used for data modeling and Machine Learning (ML). The DDB, which is shown in Figure 4, is the initial point of data ingestion driven by Apache Kafka [9]. The DDB is also the initial system, where all data is classified as a data asset. The Data Governance platform provides the framework for decisions and accountabilities within the corporate structures to manage and protect the data assets [10]. Any raw data that is not governed as dictated by the data governance standards is transformed for compliance with the standards. As the Cable operators are moving their network's control plane to the cloud, their data plane is maintained in various edge locations deeper into the network, or in this case, the customer's home.

The D3.1 eMTA telemetry data in Protobuf format is ingested by the Kafka Connector source for MQTT, which is part of the data plane of the cable MSO's Streaming and Analytics platform as shown in Figure 4. The Kafka Brokers received the converted telemetry data from Protobuf to Apache Avro™ format, and transmit the telemetry data to the Kafka Connector Sinks [11]. The telemetry data is ingested by different data analytic tools, depending on the type of data. For example, Elasticsearch (ELK) tool ingests time-series data, while MySQL tool ingests relational data before the telemetry data is displayed on the customized Grafana dashboard.

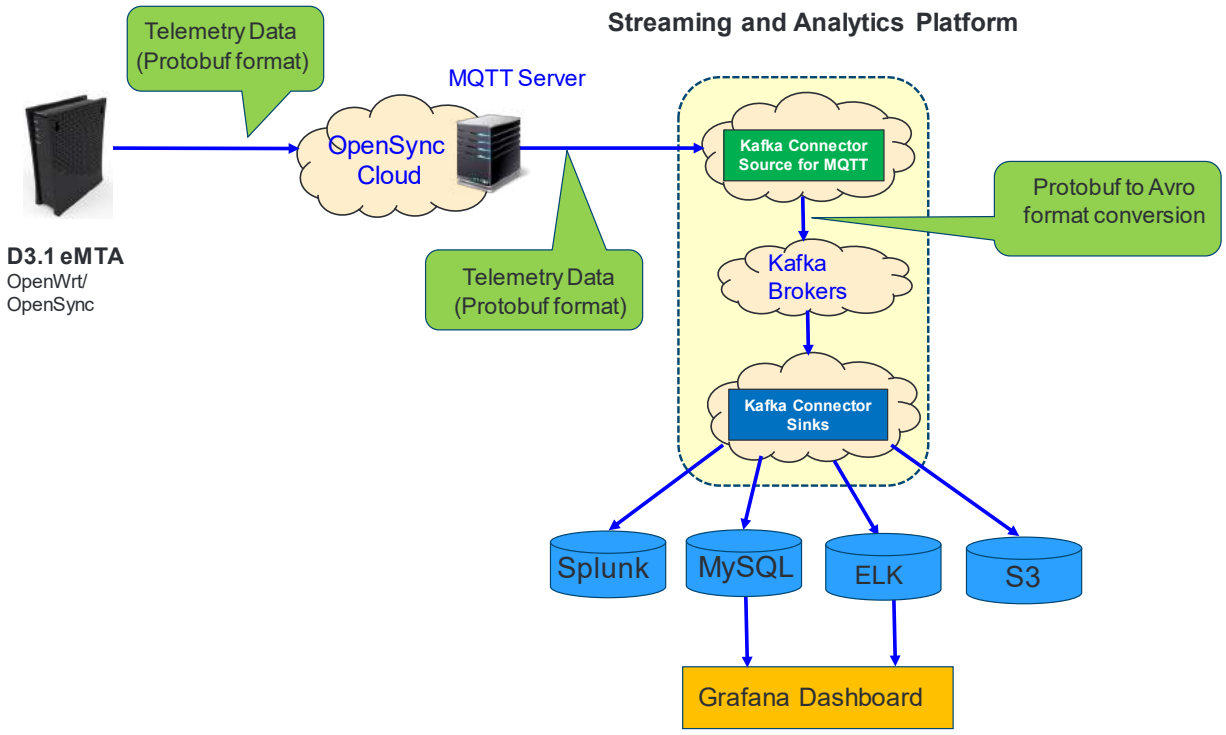

**Figure 4: Telemetry Data Path from the Access CPE Device to the Grafana Dashboard**

# 6. Grafana Dashboard Design

The design goal for the customized Grafana dashboard is to concisely present all the different types of telemetry data to the Cable operator's care agent, and to focus the agent attention to any reported failures and unhealthy device metrics. Figure 5 shows, for example, the organized hierarchical color-coded Grafana dashboard with the key components, level 1 health metrics, and their operational status based on pre-determined threshold levels. In addition, the geographical map of the customer location is shown along with reported data telemetry results. The organized Grafana dashboard includes the following information:

A. D3.1 eMTA Router system information such as:
   - CPU utilization (%) in a given time period
   - Free system memory (%) in a given time period
   - System load (%) in a given time period
   - Networking information such as IP address, network mask, DHCP status, etc.
   - Instantaneous and average system temperature in a given time period
   - Average, minimum, and maximum round-trip IPv4 and IPv6 latency in a selected period of time to the CMTS

B. Home network traffic from all the wirelessly connected devices via the Pods or Access Points:
   - IPv4/IPv6 of the wirelessly connected client in home network
   - Number of transmitted and received packets for each device
   - IPv4/IPv6 round-trip latency between the D3.1 eMTA and each of the connected clients

C. Cable modem Downstream/Upstream channel information, including:
   - Downstream channel information (i.e., channel ID, channel type, lock status, channel bonding status, received power level, SNR/MER, channel center frequency, channel width, modulation profile, etc.) – see Figure 9.
   - Upstream channel information (i.e., channel ID, Transmit power level, channel center frequency, channel width, channel bonding status, etc.)

D. RF downstream and upstream spectrum information – downstream/upstream RF signal power (dBmV) vs. frequency (MHz).

E. Downstream/Upstream speed test results on the WAN port (i.e., iPerf server in the cable MSO's cloud) and the LAN port (i.e., between iPerf server running on D3.1 eMTA and the connected home network's client).

F. Security notifications and alarms information, including:
   - Security notifications: for example, if someone is trying to temper with the Access CPE via unauthorized access to the device's management and control GUI via SSH. In this case, the color-coded green status of the security notifications and alarms dashboard component would change to either a color-coded orange or red, indicating an increased security risk.
   - Collected metrics alarms where one or more red thresholds were violated. For example, if the temperature of the device is significantly elevated, and the device is about shut-down or go into energy saving mode.

G. Customer location map, providing the cable MSO's care agent information where the customer is located within the cable MSO's service area footprint.

H. Voice health metrics, including:
   - Phone line number
   - phone status (on/off hook)
   - phone line IPv4 and IPv6 addresses

- Voice call start time, end time, call duration, call failed
- phone line registration status

I. External Battery Backup Unit (EBBU) metrics, including:
   - Manufacturer identity, HW model number, software agent version, battery status
   - EBBU output voltage, and estimated remaining charge capacity,
   - Alarm description (On battery, Low battery, Depleted battery, EBBU shutdown in pending, EBBU shutdown is eminent)

J. Access CPE device information, including:
   - Cable modem (CM) HW version, SW version, MAC address, serial number
   - IPv4 address and IPv6 address
   - CM system uptime
   - CM security status/type
   - CM connectivity state status/type

K. Access CPE device reboot information, including:
   - Last device reboot event time, date, and count
   - Last device reboot description

L. IPv4/IPv6 DOCSIS round-trip latency, including:
   - IPv4 and IPv6 minimum, average, and maximum round-trip latency to the connected CMTS in a given period of time

M. Device event logs, including any device configuration events, DHCP warnings, DOCSIS events, etc.

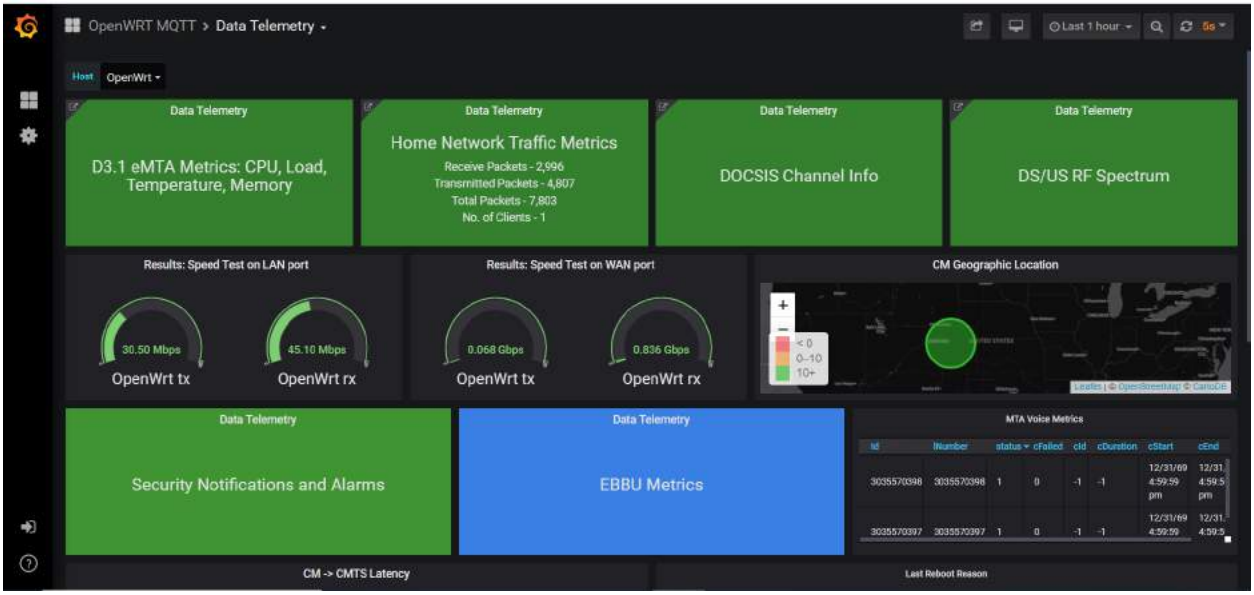

**Figure 5:Hierarchical Color-Coded Grafana Dashboard with the Key Telemetry Components**

Level 2 telemetry data shows the status of each of the reported health metrics in a given period of time. Figure 6, for example, shows the reported status of the D3.1 system parameter, including system load (%), CPU utilization (%), system temperature (°C), and free memory in the last hour. Each of these reported metrics has a different set of threshold levels to indicate its healthy status. For example, a healthy CPU utilization is below 75%, and it is color-coded green, while unhealthy CPU utilization is above 85%, and it

is color-coded red. CPU utilization between 75% up to 85% is color-coded orange. If all the level 2 D3.1 system parameters are healthy, then the D3.1 eMTA system component (level 1) turns green.

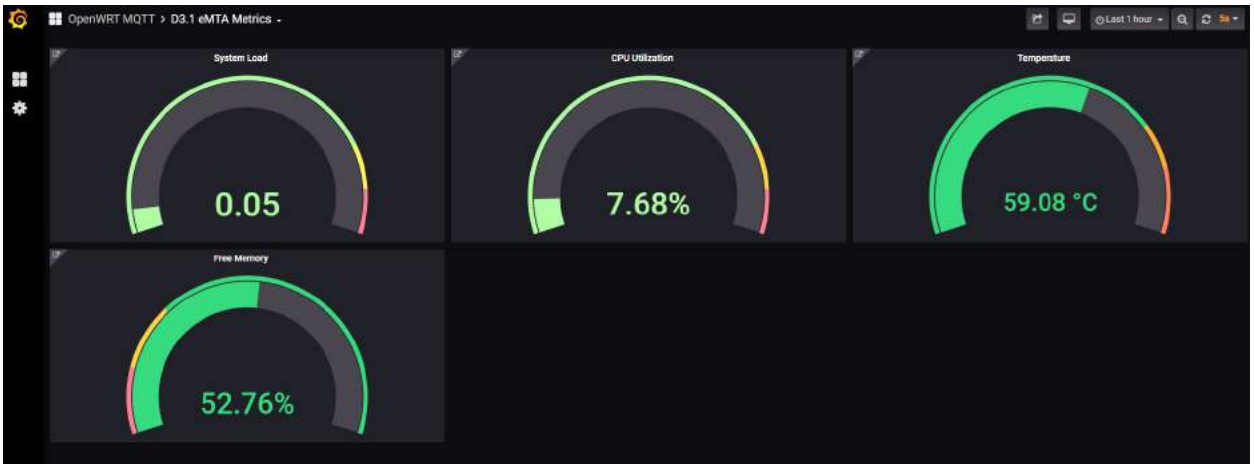

**Figure 6: Reported Status Level 2 Access CPE Metrics in the Last Hour**

Level 3 telemetry data shows the time behavior of each of the selected metrics in any given time frame. This type of telemetry reporting can be important when deeper insight into the reported metrics is needed to diagnose an issue or abnormal behavior of the D3.1 eMTA device. Figure 6 shows, for example, the reported level 3 telemetry data the time behavior of the CPU utilization reported in the last hour. The CPU utilization data is collected based on a selected time interval, which is 5 seconds in this example. The CPU utilization in this example is low, and varied between about 2.5% to 22.5%. Note that the average system load and CPU utilization are two different things. The system load is a measurement of how many tasks are waiting in a kernel run queue (not just CPU time but also disk activity) over the selected time period. The CPU utilization is a measure of how busy the CPU is during the selected time period.

This type of telemetry data is particularly useful since ML models can be executed on the selected customer data based on the collected historical data to determine if the current reported issue previously occurred, when it occurred, and provide suggested guidelines to the cable MSO's care agent how to mitigate this issue, particularly if this issue previously observed with other customers.

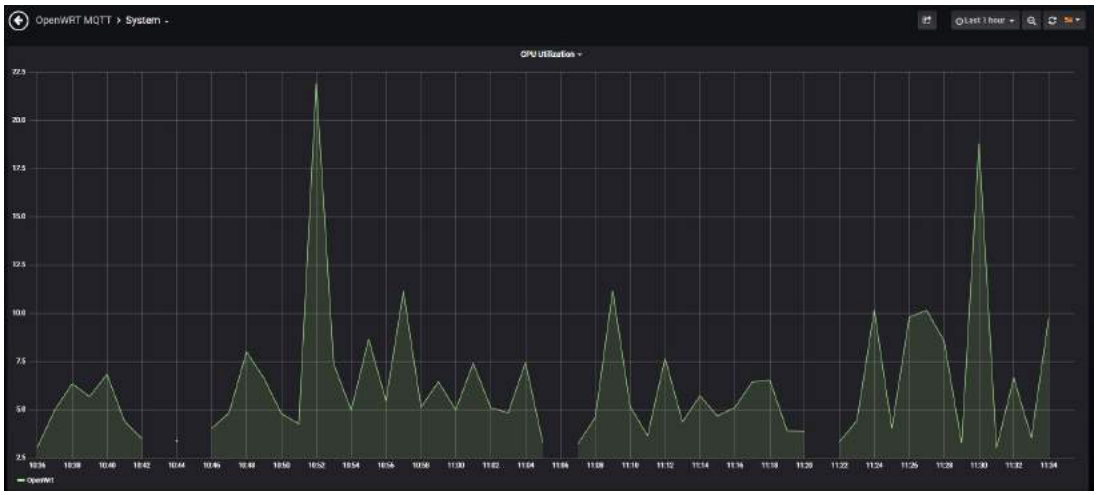

**Figure 7: CPU Utilization of Access CPE vs. Time (Level 3) Reported in the Last Hour**

One of the challenges for the operator's care agent is to gain visibility into the customer's home network (Figure 1) for network optimization and debugging field issues. This challenge is met by having the access CPE device function as a router, and connected to a Wi-Fi AP via Ethernet cable. Figure 8 shows, for example, the home network traffic parameters (level 2), including the number of transmitted and received packets by each wirelessly connected client in the home network based on their IP address or MAC address reported in the last hour. Instead of using the connected client's IP address or MAC address, the actual client's identification can be displayed on the Grafana dashboard with the integration of a device fingerprinting agent such as a Cujo Artificial Intelligence (AI) agent [12]. The client identification includes device name, device vendor, device model number, device type, device OS, etc. This can be a very useful feature for customers trying to diagnose their home network traffic. For example, customers can identify if there is a specific client that consumes most of the bandwidth in the home network, and/or make changes to their home network configuration.

In addition, the average round-trip latency between the D3.1 eMTA and each of the wirelessly connected client in the last hour is reported. Level 3 home network traffic data can be obtained by selecting a specific client in the home network based on their IP address. For example, the number of transmitted and/or received packets vs. time by the selected client over the selected time interval can be displayed on the Grafana dashboard.

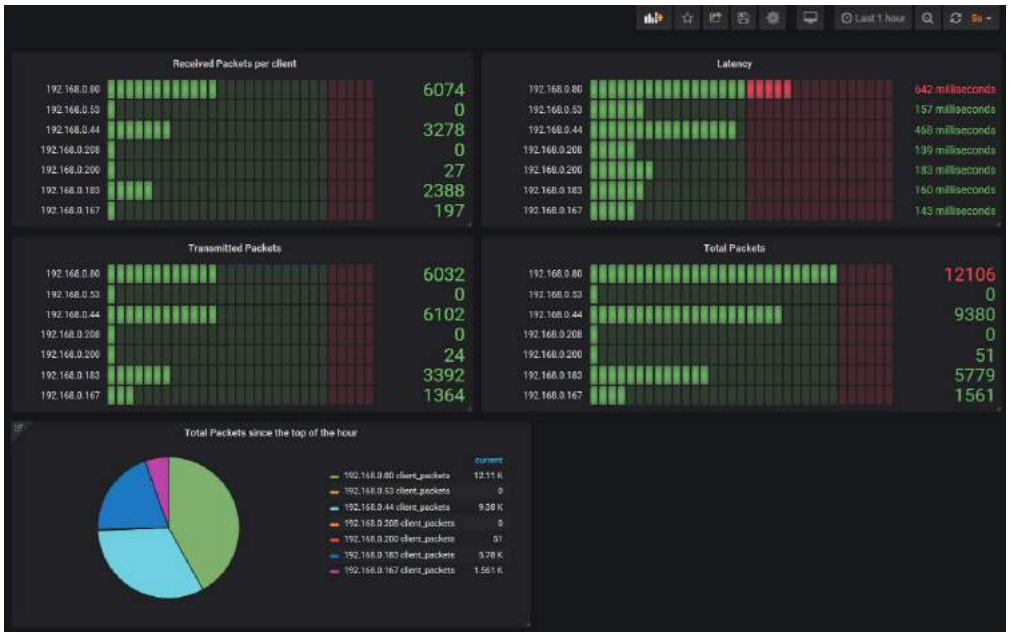

**Figure 8: Home Network Traffic Parameters for All the Wirelessly Connected Client in the Home Network**

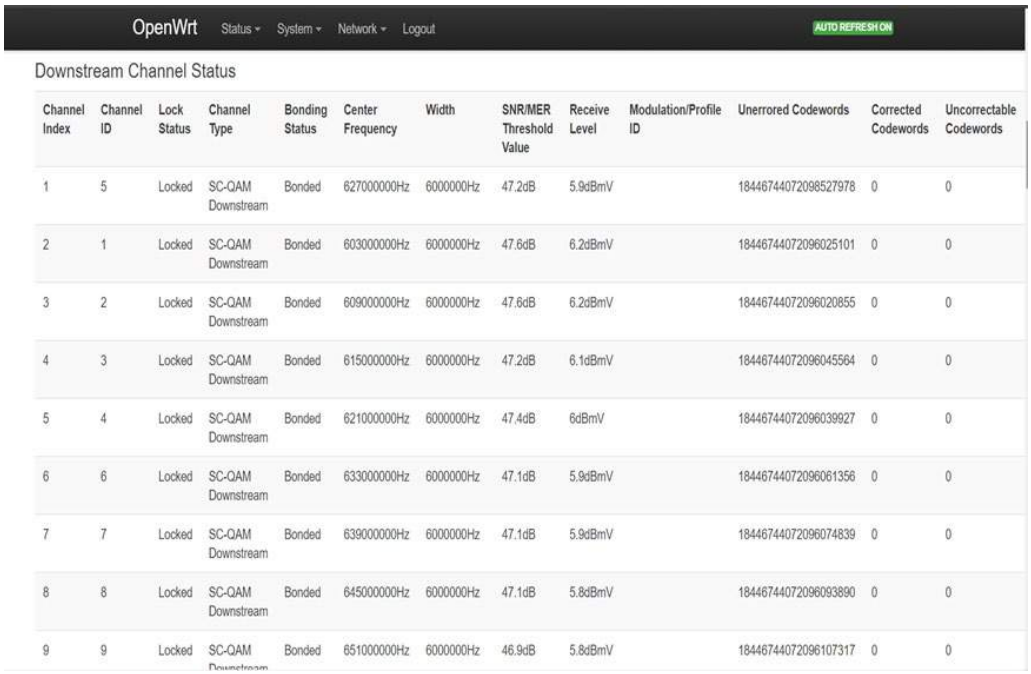
Monitoring the DOCSIS channel information is also important to ensure robust operation of the CM at the customer location. Figure 9 shows, for example, the downstream DOCSIS channel information status, including the channel lock status, channel type, channel bonding status, channel center frequency, channel width, SNR threshold, and received power level, unerrored codewords, number of corrected codewords and uncorrectable codewords. Having access to such monitored historical data with ML models can significantly help to identify troubled CMs in the field compared with other CMs connected to the same CMTS.



| Channel Index | Channel ID | Lock Status | Channel Type | Bonding Status | Center Frequency | Width | SNR/MER Threshold Value | Receive Level | Modulation/Profile ID | Unerrored Codewords | Corrected Codewords | Uncorrectable Codewords |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 1 | 5 | Locked | SC-QAM Downstream | Bonded | 627000000Hz | 6000000Hz | 47.2dB | 5.9dBmV | | 18446744072098527978 | 0 | 0 |
| 2 | 1 | Locked | SC-QAM Downstream | Bonded | 603000000Hz | 6000000Hz | 47.6dB | 6.2dBmV | | 18446744072096025101 | 0 | 0 |
| 3 | 2 | Locked | SC-QAM Downstream | Bonded | 609000000Hz | 6000000Hz | 47.6dB | 6.2dBmV | | 18446744072096020855 | 0 | 0 |
| 4 | 3 | Locked | SC-QAM Downstream | Bonded | 615000000Hz | 6000000Hz | 47.2dB | 6.1dBmV | | 18446744072096045564 | 0 | 0 |
| 5 | 4 | Locked | SC-QAM Downstream | Bonded | 621000000Hz | 6000000Hz | 47.4dB | 6dBmV | | 18446744072096039927 | 0 | 0 |
| 6 | 6 | Locked | SC-QAM Downstream | Bonded | 633000000Hz | 6000000Hz | 47.1dB | 5.9dBmV | | 18446744072096061356 | 0 | 0 |
| 7 | 7 | Locked | SC-QAM Downstream | Bonded | 639000000Hz | 6000000Hz | 47.1dB | 5.9dBmV | | 18446744072096074839 | 0 | 0 |
| 8 | 8 | Locked | SC-QAM Downstream | Bonded | 645000000Hz | 6000000Hz | 47.1dB | 5.8dBmV | | 18446744072096093890 | 0 | 0 |
| 9 | 9 | Locked | SC-QAM Downstream | Bonded | 651000000Hz | 6000000Hz | 46.9dB | 5.8dBmV | | 18446744072096107317 | 0 | 0 |

**Figure 9: Downstream DOCSIS Channel Information Status**

# 7. Comparison with Other Streaming Telemetry Methods

There are other streaming telemetry data methods for access CPE devices. One of the streaming methods is based on the Internet Protocol Detail Record Streaming Protocol (IPDR/SP). The Cable Modem Termination System (CMTS) is using the IPDR/SP via CableLabs-defined schemas to collect customer data usage via billing records from specific service flows used by the CMs and export them to IPDR Collectors [13]. IPDR/SP utilizes the concept of templates in order to eliminate the transmission of redundant information such as field identifiers and typing information on a per data record basis.

Specifically, IPDR/SP Subscriber Account Management Interface Specification (SAMIS) Type 1 schema is probably the most common IPDR schema in use by the cable MSOs. SAMIS Type 1 uniquely identifies the specific CM attributes and service flow's attributes serviced by the CM. Currently, these billing records are collected every 15 minutes by the CMTS, which forward the collected records to the IPDR Collectors hosted in the regional data centers before the data is ingested by the cable MSO's Streaming and Analytics platform. Expanding the CMTS usage of the IPDR/SP to collect all of the various performance and health metrics, alarms, and notifications from each field-deployed CM would overburden each CMTS with huge amounts of data. To estimate the magnitude of this issue, it is assumed that each CM streams ≈ 62.5MB telemetry data every 24 hours based on the current implementation, and each CMTS is connected to ≈ 20k CMs. Consequently, each CMTS would receive about 1.25TB of telemetry data every 24 hours. Thus, this approach is burdensome since the CMTS do not process or make decisions on the enormous amount of collected telemetry data. Furthermore, new IPDR schemas for non-DOCSIS parameters such as voice metrics would need to be defined, standardized, and integrated with the access CPE firmware.

Model-Driven Telemetry (MDT) is another modern method for continuously streaming operational data from network devices such as the access CPE using a push model. Applications need to subscribe to a set of the access CPE device's Yet Another Next Generation (YANG) data models over standard protocols,

and push the collected telemetry data from the device when a change has occurred. MDT is not new to the cable industry as several Cable operators have already implemented and deployed MDT data collection and monitoring systems in their network [14]. Implementing MDT on access CPE devices requires the development a new software layer and components for YANG data models. In addition, a common set of standard Application Programming Interfaces (APIs) need to be defined for integration with an OpenWrt-based access CPE software stack. Furthermore, no detailed telemetry comparison analysis of performance vs. cost has been done to justify such an MDT-based development effort by the Cable operators.

In contrast, the OpenWrt and OpenSync™-based streaming telemetry method uses an agile lightweight and efficient smart agent based on an open-source code with customized plugins using the Silicon vendor's APIs. The proposed approach is to segregate the telemetry data such that all customer's billing records continue to be provided using the IPDR/SP, while all of the other access CPE device's performance and health metrics are directly transmitted to the cable MSO's Streaming and Analytics platform via the OpenSync™ cloud. Consequently, the CMTSs are not overburdened with huge amounts telemetry data.

# 8. Conclusion

In this paper, an agile OpenWrt software stack integrated with OpenSync™ layer and Silicon vendor SDK with carrier-grade IPv4/IPv6 routing functionality was developed on a common existing access CPE hardware. The connectivity of this access CPE device to the OpenSync™ cloud provides a standardized command and control method for networking services as well as operator-friendly services such as onboarding and provisioning on field-deployed devices, device firmware management, network operations and customer support, billing and inventory support. A smart remote agent was developed and integrated with the OpenWrt software stack that enables the access CPE device to stream various types of telemetry data to the cable MSO's Streaming and Analytics platform via the MQTT server hosted on the OpenSync™ cloud for analysis, and displays the collected data on a hierarchical color-coded Grafana dashboard. The streaming telemetry data consists of a wide variety of information, including:

- Access CPE system information
- CM device information
- Home network traffic information from all the wirelessly connected clients
- DS/US DOCSIS channel information
- DS/US RF spectrum output
- Event and alarms information for the collected metrics
- Speed test results on both the WAN and LAN ports
- Voice metrics information
- EBBU status information

Comparison with other streaming telemetry methods such as IPDR/SP and MDT reveal various challenges with the implementation of these methods. For example, expanding the IPDR/SP usage by the CMTS to collect all of the various performance and health metrics, alarms, and notifications would overburden each CMTS with huge amounts of data that it does not process or make decisions on is not an attractive approach. Implementing MDT on access CPE devices requires the development a new software layer and components for YANG data models without clear benefits.

Finally, as shown in this paper, the adoption of an OpenWrt-based streaming telemetry offers clear benefits to Cable operators. First, it enables cloud-based management of the access CPE devices and direct streaming of the telemetry data to the cable MSO's Streaming and Analytics platform via the OpenSync™ cloud without overburdening the CMTS. Second, the availability of the telemetry data to the operator's

care agent is likely to enhance customer satisfaction by reducing the number of truck rolls as field issues are resolved more quickly. Third, collaborations among different Cable operators will enable the industry to standardize the OpenWrt-based software architecture with the streaming telemetry across different types of CPE hardware platforms. Furthermore, the standardized agile software stack is expected to accelerate the development and deployment of new revenue-generating services.

# 1. Introduction

The plethora of new technologies and alternatives has made the task of HFC network migration more challenging than ever! The MSOs are faced with difficult decisions as their strategy executives and HFC network architects try to navigate the future of their HFC networks. The difficulty comes from identifying potential market challenges and addressing those challenges using the right technology in a timely and cost-effective manner.

DOCSIS 4.0 offers various technologies that will enable the delivery of 10 Gbps DS peak rates and 5 Gbps US peak rates. Utilizing the right technology at the right time will be instrumental for the success of the MSOs. This paper attempts to provide the list of available tools in the network migration toolkit and proposes a time-aware methodology for using these tools to yield a cost-effective migration strategy that meets customers traffic demand and addresses competition.

This paper is organized as follows: Section 2 introduces the latest traffic engineering trends and potential COVID-19 impact. Various network migration tools are described in Section 3. Section 4 discusses the decision interactions between some of the migration tools like traditional FDD, FDX & dynamic soft-FDD, and ESD. Time-aware decision process is discussed in Section 5. Section 6 provides an example migration strategy that uses various migration tools. Finally, the paper is concluded in Section 7.

# 2. Latest Traffic Engineering Trends & Potential COVID-19 Effect

Figure 1 and Figure 2 show the latest busy-hour average subscriber consumption rate (Tavg) for the DS & US directions, respectively, collected from multiple MSOs. These trends, which were captured in the beginning of 2020 and before the COVID-19 pandemic effect has spread, show that Tavg averaged across various MSOs yielded 2.36 Mbps for the DS and 164 kbps for the US. Additionally, the 2020 statistics show that the 3-year DS Tavg CAGR had dropped from 34% to 30% and the US Tavg CAGR had slightly dropped from 22% to 21%.

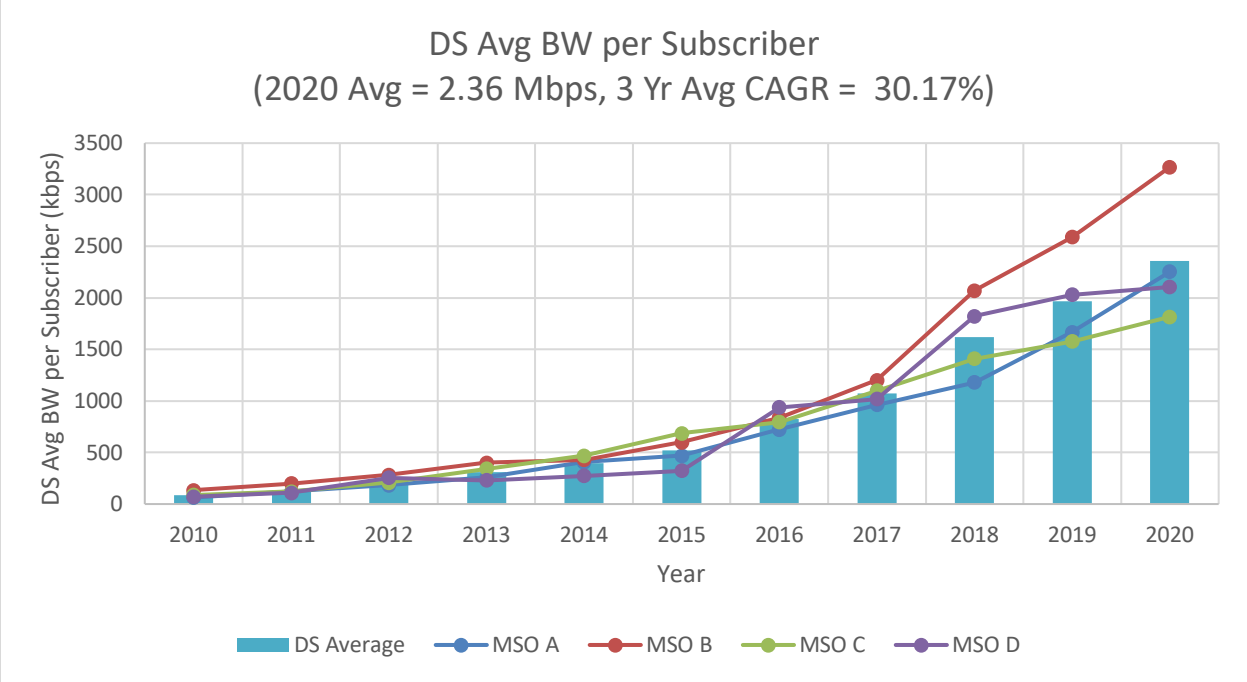

**Figure 1 - DS Tavg latest statistics before COVID-19**

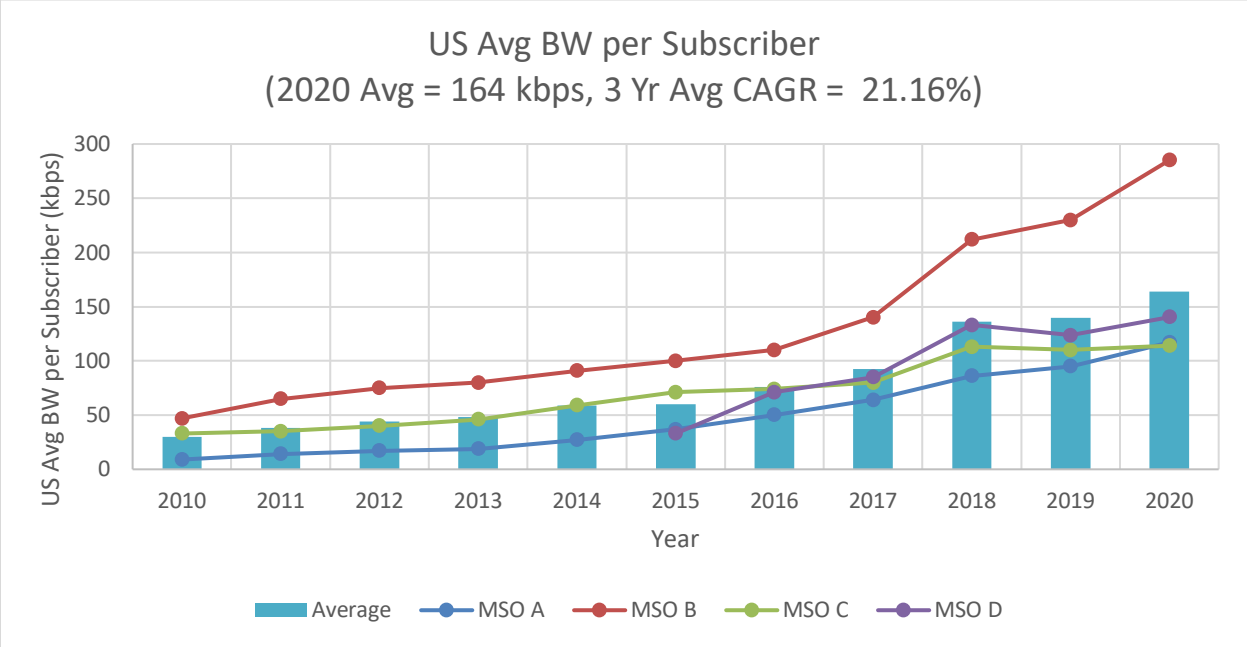

**Figure 2 - US Tavg latest statistics before COVID-19**

At the outset of the COVID-19 pandemic, the DS and US consumption increased significantly as countries, states, and cities enforced a lockdown to control the disease. With many people at home and the

lack of outside activities, increased network consumption was in the form of video streaming, working-from-home, virtual video gatherings, gaming, etc. The increase in the US utilization was about 35% and the increase in the DS utilization was 20%. As some countries, states, and cities started to reduce the limits of the lockdown, the consumption (relative to pre-COVID numbers) has decreased recently (as of July 4, 2020) and currently shows an increase of about 22% for the US and 14% for the DS [NCTA-COVID-19-Tracker-2020]. The US & DS will not likely go back to the original levels because of the "new normal" after COVID-19, where many people will likely continue to work from home. It is probably reasonable to assume that the US will settle to 18% (half of 35%) and the DS will settle to 10% (half of 20%). Therefore, our traffic engineering assumptions for the analyses provided later in this paper assume an US Tavg of 190 kbps (instead of 164 kbps) for 2020 and a DS Tavg of 2.6 Mbps (instead of 2.36 Mbps) for 2020. Note that these percentages represent one-time jump in Tavg due to COVID-19 and are independent from the CAGR percentages discussed in the beginning of this section ,which represent the annual growth in Tavg.

# 3. Network Migration Tools

This section briefly describes the available tools in the network migration toolbox. These tools can be used to gradually and concurrently migrate along an optimal migration path that extends the useful life-span of today' HFC network while gradually transforming it into the desired end goal as a FTTH network.

## 3.1. Selective Subscriber Migration

Selective subscriber migration refers to the concept of performing HFC surgical operations, whereby customers demanding very high peak rates are moved to a different platform, such as an overlay FTTH network running a specific flavor of PON. This concept, which was explained in detail in [Spring-Forum-Migration-2016], avoids the need to upgrade the whole network in order to meet the abnormal service levels associated with very small penetration rates. For instance, if only a select number of residential or business customers request symmetrical 10 Gbps service, while the rest of customers are happy with sub 1 Gbps service, then it makes sense to move those few customers to 10G PON (e.g., XGS-PON or 10G-EPON) as opposed to overhauling the whole HFC network. This tool can be used to constrain the goal of HFC network migration to address rates offered by EPON or GPON but not with 10G PON competition. Using this constraint in the decision process will yield an optimal cost-effective competitive migration strategy.

## 3.2. Node Splits and Node Segmentations

Node splits and node segmentations provide another powerful tool within the HFC network migration toolkit. They can help reduce the number of subscribers per SG, which will lead to less congestion and therefore the ability to support higher peak service rates for a longer time. Recall that the total capacity required by a SG that has Nsub subscribers, each consuming an average busy hour rate of Tavg, and requesting a peak rate service of Tmax, is given by the following formula, where K is a QoE coefficient that is recommended to be between 1-1.2 to provide good QoE:

$$\text{Required SG Capacity} = Nsub*Tavg + K*Tmax$$

Note that with fixed available capacity, reducing the number of subscribers using a node split will reduce the first term of the above equation, which will enable supporting higher Tmax (within the second term) using the fixed available capacity.

## 3.3. Digital Video, Switched Digital Video & IPTV

The use of analog video channels comes at a price because they do not use the spectrum very inefficiently. Moving video from analog to digital channels will enable better utilization of the scarce spectrum via more efficient encoding schemes of the digital content. Adding SDV capabilities that only transmit video streams when being viewed can also help reduce spectrum utilization for video services. As time goes on, reducing the number of digital video channels and migrating to IPTV video (which uses more spectrally-efficient DOCSIS 3.1 channels) will provide yet another level of efficient usage of spectrum.

## 3.4. Split Upgrade

There are multiple US split options supported by the DOCSIS3.1 specifications: sub-split (5-42 MHz in NA and 5-65 MHz in Europe), Mid-split (5-85 MHz), and High-split (5-204 MHz). Supporting US peak rates up to 400 Mbps will require moving from sub-split to mid-split. On the other hand, supporting US peak rates in excess of 1 Gbps will require a move to a high-split architecture.

DOCSIS 4.0 specifications add other ultra-split options with US limits up to 300 MHz, 396 MHz, 492 MHz, and 684 MHz. These splits can be used in a fixed or dynamic manner as will be explained later in this paper.

## 3.5. Full Duplex DOCSIS

FDX is a technology that is designed to allow the US & DS traffic to share the same spectrum simultaneously. The FDX technology was thoroughly explained in [SCTE-Tec-Soft-FDD-2019]. It is optimized for DAA N+0 network architecture. MSOs who find it expensive to migrate their networks to N+0 will likely need other alternatives. One of those alternatives is to use FDX amplifiers. However, those amplifiers will cause the problem of Interference Group elongation [SCTE-Tec-Soft-FDD-2019], where most of the subscribers become a member of the same interference group (i.e., interfering with each other); therefore true FDX operation in N+x networks may not be feasible.

## 3.6. Dynamic Soft-FDD

In the previous section, the challenge of running FDX in N+x (x>0) networks was described. A potential solution for that problem is to run the system in Dynamic Soft-FDD mode [SCTE-Tec-Soft-FDD-2019], where the split is changed dynamically to match the traffic demand and hence offering the same benefits as FDX, but with typically larger Interference Groups. In a nutshell, Dynamic Soft-FDD is viewed as the tool that enables FDX operation in cascaded networks. Dynamic Soft-FDD is based on the same modem silicon as FDX and can help avoid replacing taps and passives beyond 1.2 GHz. However, more complex amplifiers will be needed, which may put a limit on the maximum cascade depth that can be supported with Dynamic Soft-FDD. Additionally, operating the Dynamic Soft-FDD plant could be challenging for some MSOs.

### 3.7. Extended Spectrum DOCSIS

Another tool in the network migration toolbox is ESD, where the DS spectrum is allowed to go beyond 1.2 GHz. DOCSIS 4.0 introduced requirements for 1.8 GHz operation in equipment whose housing supports 3 GHz spectrum. The ESD technology was described in detail in [SCTE-Tec-Soft-FDD-2019] [Spring-Forum-ESD-2016]. While the ESD technology requires changing taps and amplifiers, it works in an FDD mode just like today's networks. The ESD amplifier design can also be challenging due to the high gain requirements needed for operation at high frequencies, where attenuation is significant. Additionally, it should be noted that the limited TCP can be a potential issue with very long plants but not so much with short or medium plants, which make the majority of current HFC networks. Those challenges and potential solutions were discussed in [SCTE-Tec-Soft-FDD-2019].

### 3.8. Active Taps

As the networks get deeper in fiber deployment, they may eventually get to N+0. Before pulling fiber any deeper, the concept of active taps could be beneficial as taps are transformed into small active devices that support relatively small gain values. This enables continued use of the hardlines with higher modulation orders at higher frequencies, which will yield additional capacities [ANGA-Cable-Migration-2019] [SCTE-Tec-Soft-FDD-2019].

### 3.9. Fiber To The Tap

FTTT is a natural late-stage step to take before pulling fiber to the home, whether active taps were used or not as an intermediate step. FTTT enables the use of existing drop cables that can support frequencies up to 25+ GHz, which translates to data rates of more than 200 Gbps [Spring-Forum-ESD-2016]. In fact, when FTTT is used, the coaxial cable network becomes a point-to-point network which will enable ESD operation to be used in combination with FDX operation (without undergoing the current complexities of FDX that are faced with the current multi-point-to-single-point HFC networks).

## 4. Interactions of Traditional FDD, FDX & Dynamic Soft-FDD, and ESD

It can be confusing to think of multiple interrelated tools at the same time. In order to address this challenge, a decision tree was developed for N+x networks as shown in Figure 3. Observe that the decision tree considers multiple interrelated network migration tools including traditional FDD with DOCSIS 3.0 splits, DOCSIS 3.1/DOCSIS4.0 split change, Dynamic Soft-FDD, and ESD. In this context, recall that Dynamic Soft-FDD is the FDX flavor for N+x networks.

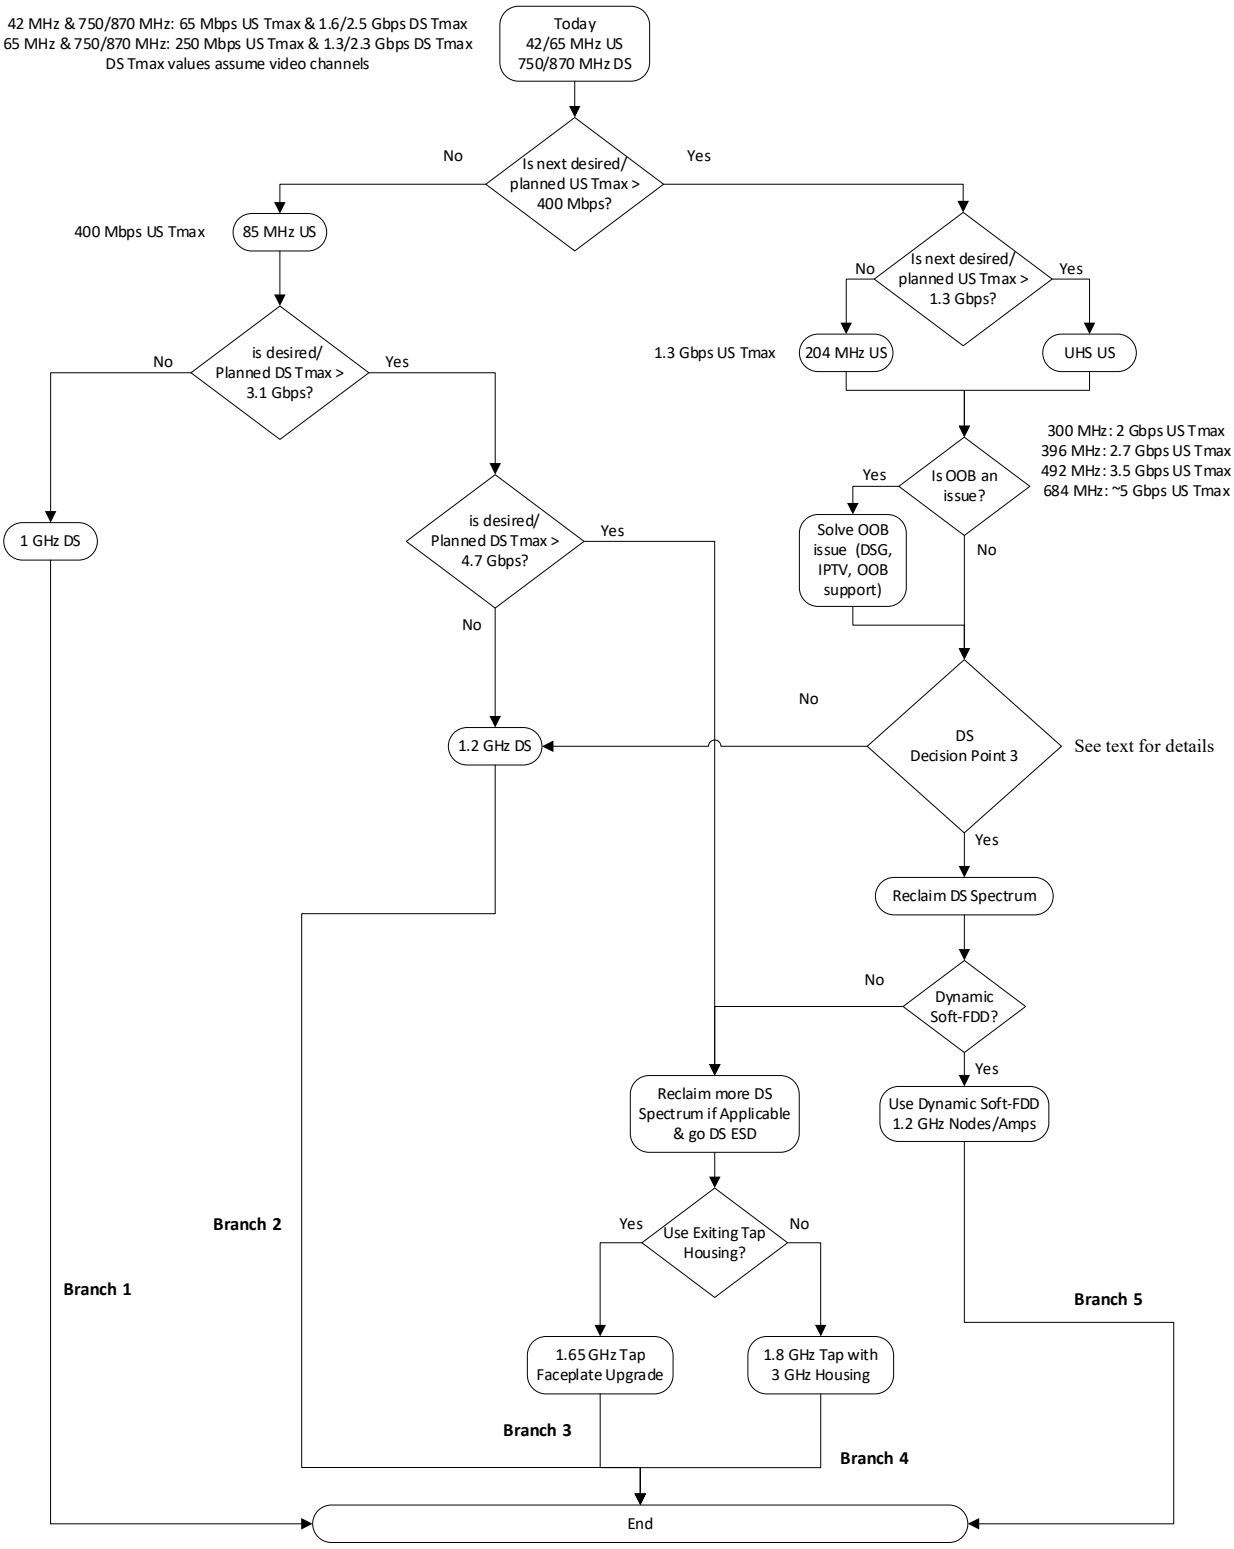

**Figure 3 - Decision tree combining multiple interrelated network migration tools: traditional FDD with DOCSIS 3.0 splits, DOCSIS 3.1/DOCSIS4.0 split change, Dynamic Soft-FDD, and ESD**

The ‘DS Decision Point 3’ in Figure 3 contains a list of decision questions, depending on the chosen US split, as follows:

Case (Split)
- Case A: 204 MHz Split
  - is desired/Planned DS Tmax > 3.6 Gbps?
- Case B: 300 MHz Split
  - is desired/Planned DS Tmax > 2.7 Gbps?
- Case C: 396 MHz Split
  - is desired/Planned DS Tmax > 1.7 Gbps?
- Case D: 492 MHz Split
  - is desired/Planned DS Tmax > 900 Mbps?
- Case E: 684 MHz Split
  - is desired/Planned DS Tmax > 0 Gbps?

It can be observed from the above decision point case statement that 1.2 GHz systems cannot support DS Tmax values more than 900 Mbps if the US split is 492 MHz or higher. Note that the 1.65 GHz Tap faceplate upgrade option refers to reusing existing taps housings by only replacing the faceplate with a new faceplate that supports higher frequencies, which can help in reducing the labor costs.

The assumptions that were used to calculate the Tmax numbers in the decision tree are as follows:

- **Traffic Engineering**
  - K = 1
  - Nsub = 250
  - US Tavg = 0.19 Mbps (0.164 Mbps with added step increase of 18% due to COVID-19)
  - DS Tavg = 2.6 Mbps (2.36 Mbps with added step increase of 10% due to COVID-19)
- **US**
  - # of 6.4 MHz SC-QAM channels = 4
  - SC-QAM spectral efficiency = 4.15 bps/Hz
  - OFDMA spectral efficiency = 7.5 bps/Hz
  - US spectrum start frequency = 15 MHz
- **DS**
  - # of 6 MHz SC-QAM channels = 20
  - SC-QAM spectral efficiency = 6.33 bps/Hz
  - OFDM spectral efficiency = 7.8 bps/Hz
  - Video: 66 Digital channels

Clearly, it should be noted that similar decision trees can easily be created for a different set of assumptions.

Note that analyses used in developing the decision tree assumed a SG size of 250 subscribers and 66 digital video channels, which can be argued to be good representative values of today’s HFC networks. Table 1 provides the Tmax values that can be supported over today’s HFC networks assuming no modifications. On the other hand, Table 2 provides the Tmax values that can be supported over a modified network using the different migration branches that were illustrated in Figure 3, which are:

1. Branch 1: 85 MHz US with 1 GHz DS
2. Branch 2: 1.2 GHz DS (with different US splits)
3. Branch 3: 1.6 GHz DS using tap faceplate upgrade (~ESD with different US splits)
4. Branch 4: 1.8 GHz DS using new ESD taps (ESD with different US splits)

5. Branch 5: 1.2 GHz Dynamic Soft-FDD

**Table 1 - US & DS Tmax values that can be supported with today's networks (different configurations)**

| US Split (MHz) | Top of DS Spectrum (MHz) | US Tmax (Mbps) | DS Tmax (Gbps) |
|---|---|---|---|
| 42 | 750 | 60 | 1.5 |
| 42 | 870 | 60 | 2.5 |
| 42 | 1002 | 60 | 3.5 |
| 65 | 750 | 250 | 1.3 |
| 65 | 870 | 250 | 2.2 |
| 65 | 1002 | 250 | 3.2 |

**Table 2 - US & DS Tmax values that can be supported via different migration paths (with Digital video)**

| US Split (MHz) | US Tmax (Gbps) | DS Start Frequency (MHz) | Branch 1 FDD 1.0 GHz DS Tmax (Gbps) | Branch 2 FDD 1.2 GHz DS Tmax (Gbps) | Branch 3 FDD 1.65 GHz DS Tmax (Gbps) | Branch 4 FDD 1.8 GHz DS Tmax (Gbps) | Branch 5 Dyn. Soft-FDD 1.2 GHz DS Tmax (Gbps) |
|---|---|---|---|---|---|---|---|
| 85 | 0.4 | 108 | 3.1 | 4.7 | NA | NA | 4.7 |
| 204 | 1.3 | 258 | NA | 3.6 | 6.9 | 8.1 | 4.7 |
| 300 | 2.0 | 372 | NA | 2.7 | 6.1 | 7.2 | 4.7 |
| 396 | 2.7 | 492 | NA | 1.7 | 5.1 | 6.2 | 4.7 |
| 492 | 3.5 | 606 | NA | 0.9 | 4.2 | 5.4 | 4.7 |
| 684 | 5.0 | 834 | NA | 0 | 2.5 | 3.6 | 4.7 |

It should be noted that the above decision tree must be used along with other tools like selective subscriber migration, node splits, migrating to IPTV, etc. This wholistic approach to the decision-making process yields an optimal migration path from complexity and cost point views. In particular, the table above contains technology options that are either costly or not available today, which should be taken into consideration as the MSOs plan a stepping-stone migration process.

## 5. Time-Aware Decision Making

A key missing aspect from the decision tree and the other tools described in the previous section is the time dimension of the decision. Specifically, the busy hour per subscriber consumption rate (i.e., Tavg) continues to grow as time goes on, which in turn reduces the Tmax values that can be supported given a particular network architecture. Also, the SG size (Nsub) decreases as more node splits are undertaken, which leads to higher Tmax values. However, these two terms are multiplied by each other in the QoE formula so the net effect may not be obvious unless simulations are performed. Another aspect that changes with time is the migration of digital video channels to IPTV which leads to more efficient video delivery and that yields support for higher Tmax values. This section introduces the time-awareness aspect into the decision process.

In order to take the above time-affected tools into consideration, the analysis in this section uses the latest traffic CAGR numbers presented in section 2 (i.e., US CAGR of 21% and DS CAGR of 30%). Also, the impact of node splits over time is studied by analyzing the effect of moving to smaller SG sizes (i.e., reducing the SG size from 250 to 125 and then to 64). Finally, moving video delivery from 66 digital channels to IPTV is also simulated to understand the effect of this move on the life of the network. Finally, multiple curves are illustrated to show the impact of changing the US split and moving the DS top end to 1.65 GHz or 1.8 GHz.

The Time-aware simulation assumptions are as follows:

- **Traffic Engineering**
  - K = 1
  - Nsub = 250 subscribers (Penetration ratio of data subscribers 50%)
  - US Tavg = 0.19 Mbps (0.164 Mbps with added step increase of 18% due to COVID-19) in 2020
  - US CAGR = 21%
  - DS Tavg = 2.6 Mbps (2.36 Mbps with added step increase of 10% due to COVID-19) in 2020
  - DS CAGR = 30%
- **US**
  - # of 6.4 MHz SC-QAM channels = 4
  - SC-QAM spectral efficiency = 4.15 bps/Hz
  - OFDMA spectral efficiency = 7.5 bps/Hz
  - US spectrum start frequency = 15 MHz
- **DS**
  - # of 6 MHz SC-QAM channels = 20
  - SC-QAM spectral efficiency = 6.33 bps/Hz
  - OFDM spectral efficiency = 7.8 bps/Hz
  - Video options: 66 Digital channels, or IPTV
- **IPTV Video**
  - Penetration ratio of video subscribers = 30%
  - Unicast only
  - HD MPEG4 bit rate = 5 Mbps
  - UHD/4K bit rate = 17 Mbps

- 90% HD / 10% UHD mix
- 5% VOD

The results of the analyses are shown in Figure 4 - Figure 9. The first three figures assume digital video channels and study the effect of node splits by varying the SG size from 250, to 125, and finally to 64. Similarly, the last three figures change the SG size but assuming IPTV video delivery instead of digital video channels.

Understanding how to interpret the curves can be best illustrated using an example. For instance, in Figure 4, curves with no markers show the highest peak service rate (Tmax) that can be supported in the US direction for different US split options. On the other hand, curves with markers indicate the highest DS Tmax that can be supported for different configurations (particular US split combined with DS spectrum limit).

Let's assume that the MSO would like to offer symmetrical 1 Gbps service, it can be seen from the Figure 4 that high-split (i.e., 204 MHz US split) can support US Tmax of 1 Gbps until about 2031 – this can be observed from the non-marker gray curve that corresponds to 'US Tmax: 204 MHz US Split'. Using the same approach, it can be seen that a 204 MHz US with 1.2 GHz DS system can offer a DS Tmax value of 1 Gbps beyond 2026 – this can be observed from the circle-marker dark blue curve that corresponds to 'DS Tmax: 204 MHz Split with 1.2 GHz DS'.

The effect of a node split that divides the SG size in half (from 250 to 125), can be observed in Figure 5, where it can be seen that high-split can offer US Tmax of 1 Gbps to about 2034 and high-split 1.2 GHz DS system can offer a DS Tmax value of 1 Gbps about 2029. Also, observe how a move to IPTV can further extend the lifespan of the network. For example, for a SG of 125, a move to IPTV will enable a high-split network with 1.2 GHz DS to support DS Tmax value of 1 Gbps to about 2031 as can be observed in Figure 8.

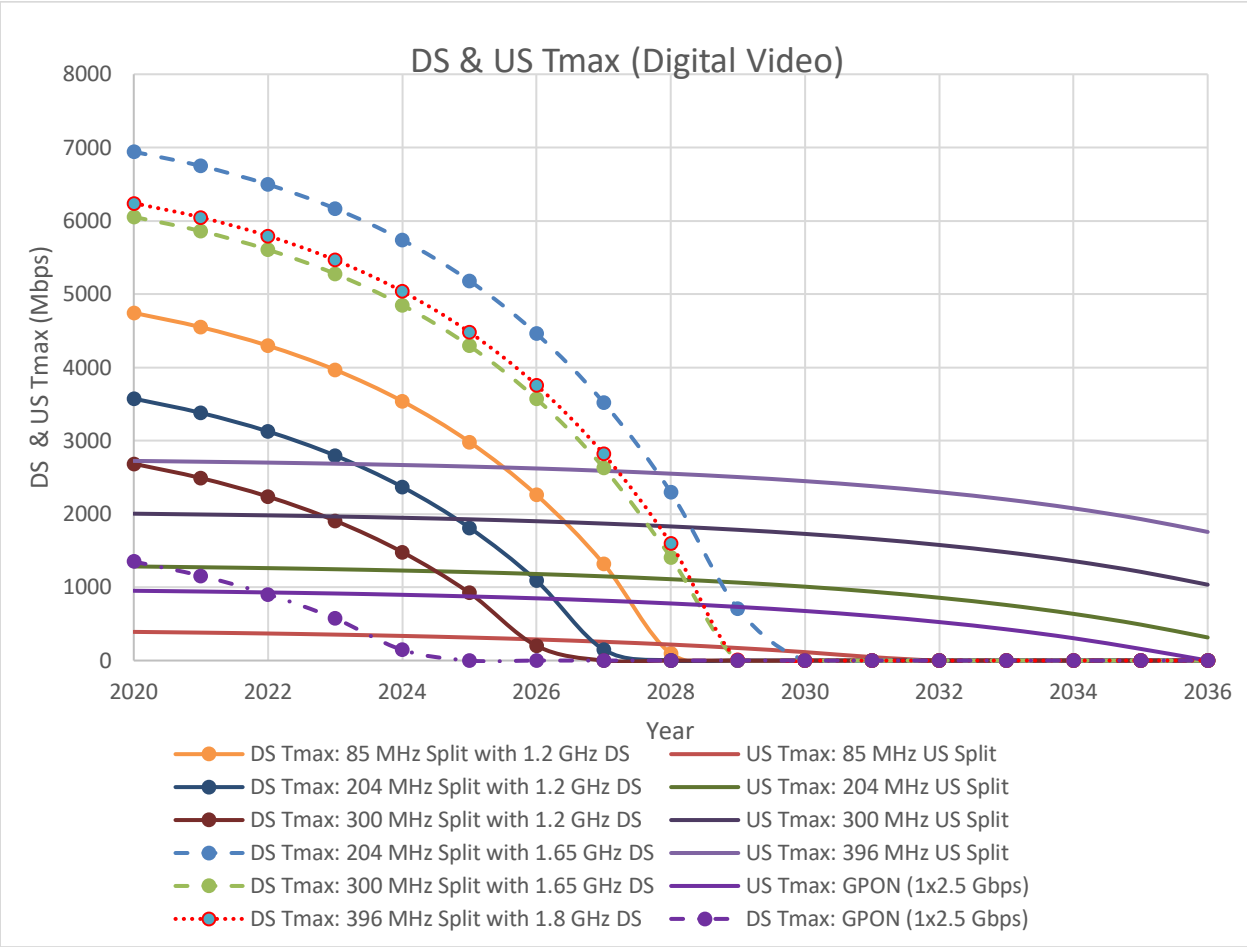

**Figure 4 - US & DS Tmax values that can be offered over time for various split options and DS spectrum sizes. (SG size = 250, 66 Digital video channels)**

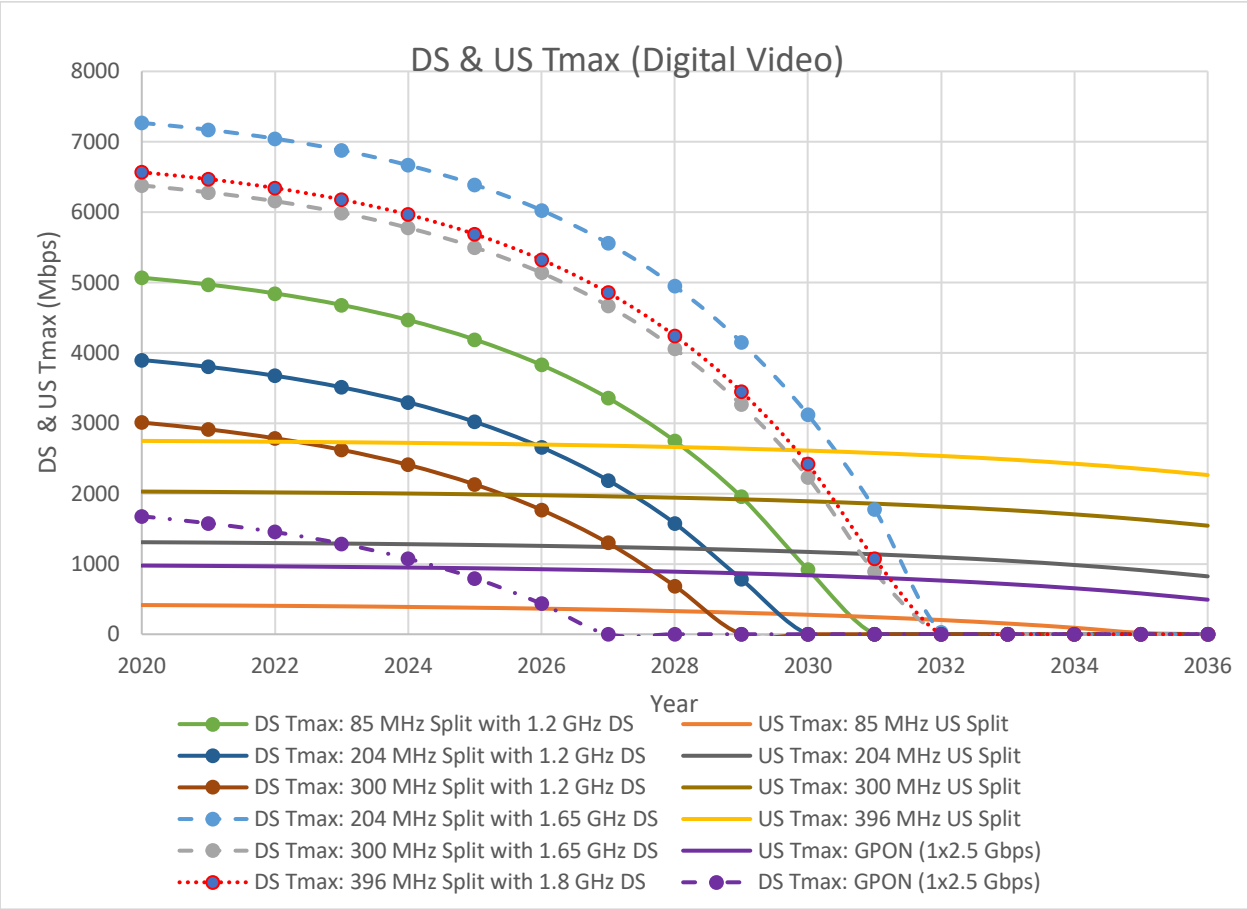

**Figure 5 - US & DS Tmax values that can be offered over time for various split options and DS spectrum sizes. (SG size = 125, 66 Digital video channels)**

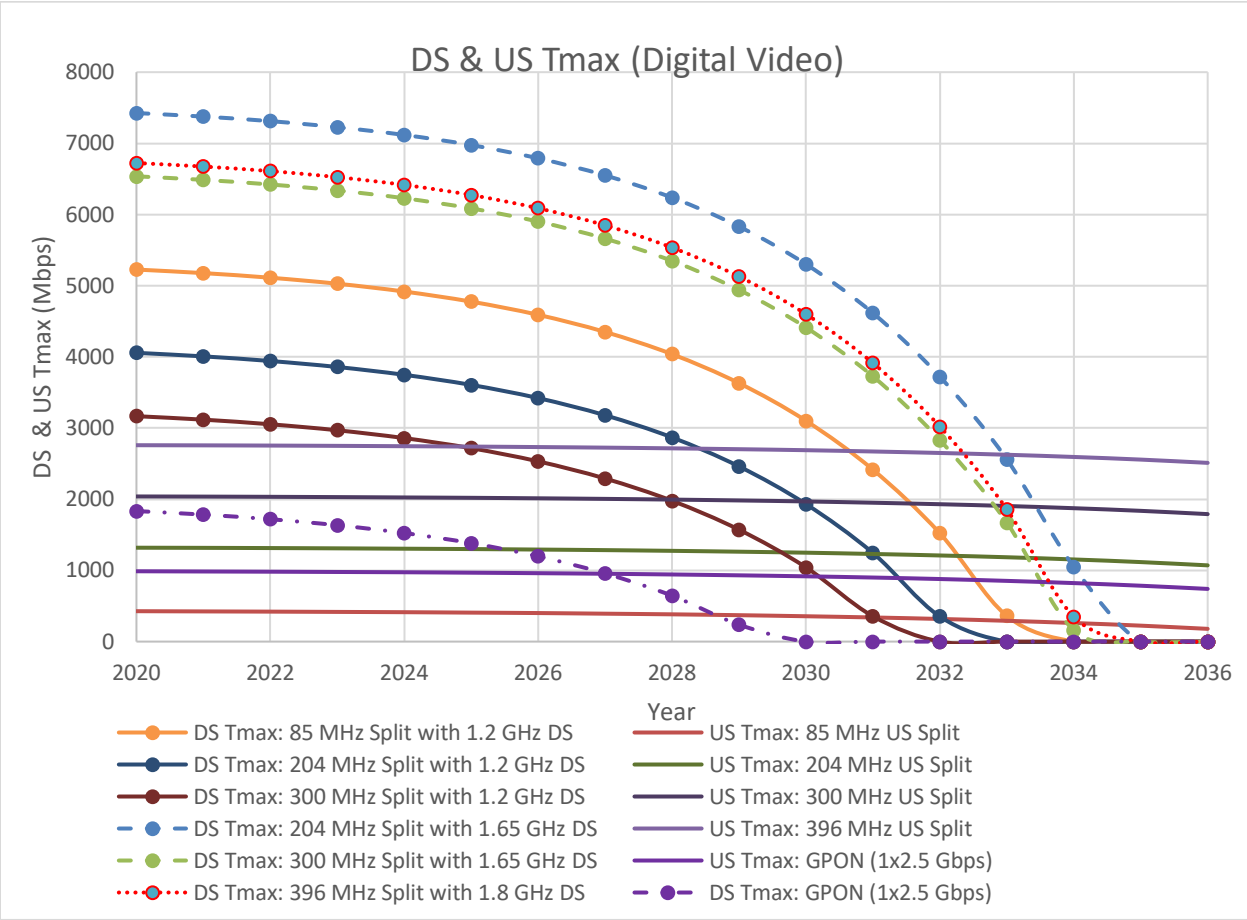

**Figure 6 - US & DS Tmax values that can be offered over time for various split options and DS spectrum sizes. (SG size = 64, 66 Digital video channels)**

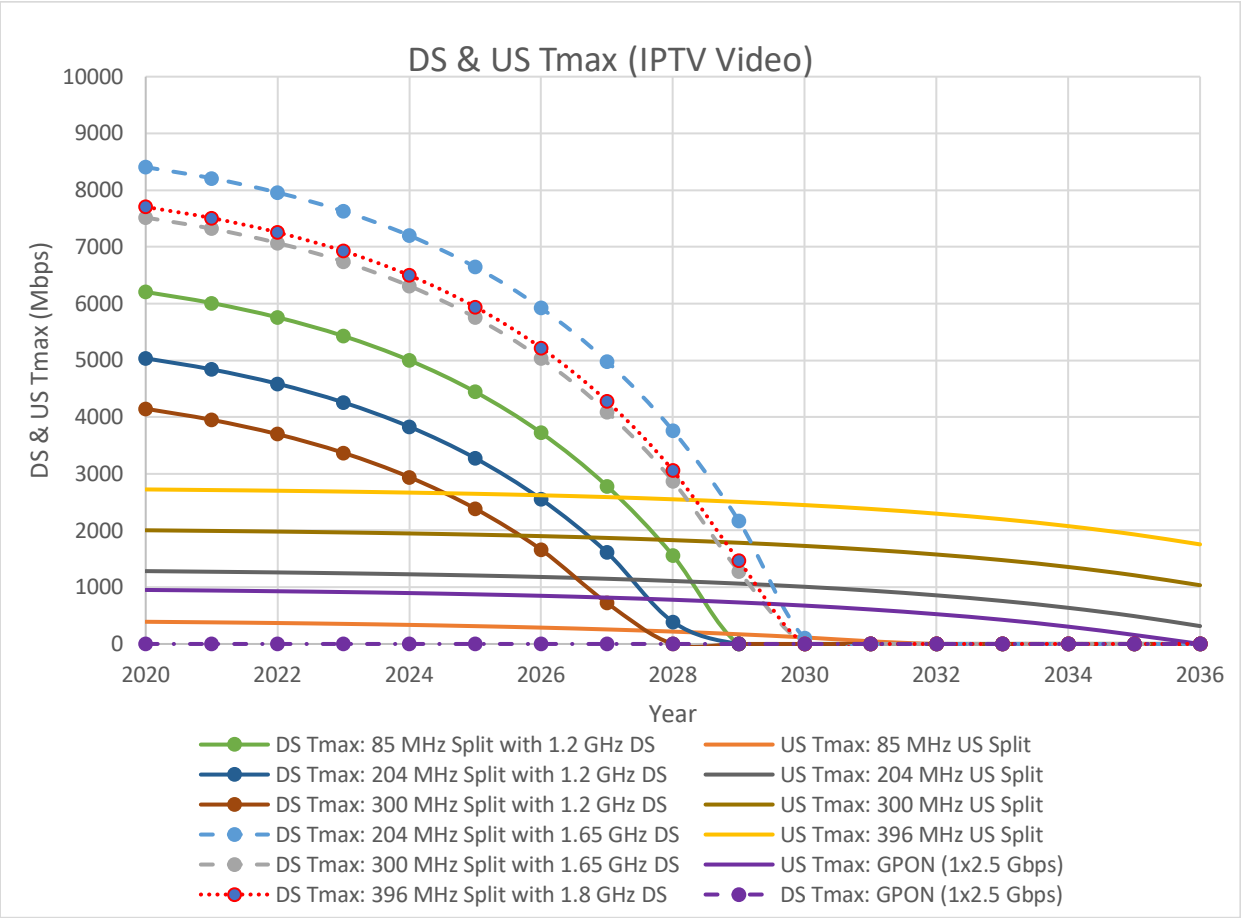

**Figure 7 - US & DS Tmax values that can be offered over time for various split options and DS spectrum sizes. (SG size = 250, IPTV video channels)**

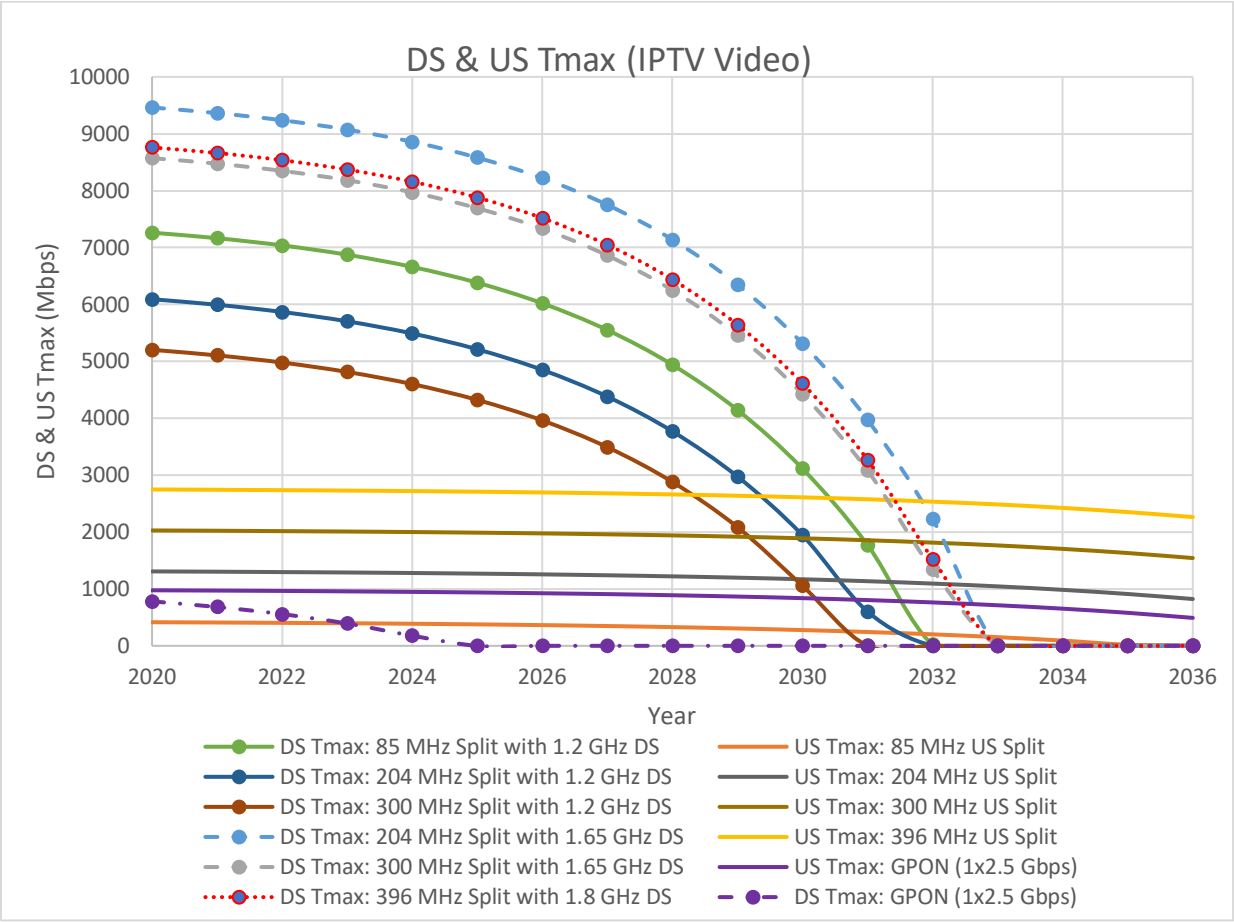

**Figure 8 - US & DS Tmax values that can be offered over time for various split options and DS spectrum sizes. (SG size = 125, IPTV video channels)**

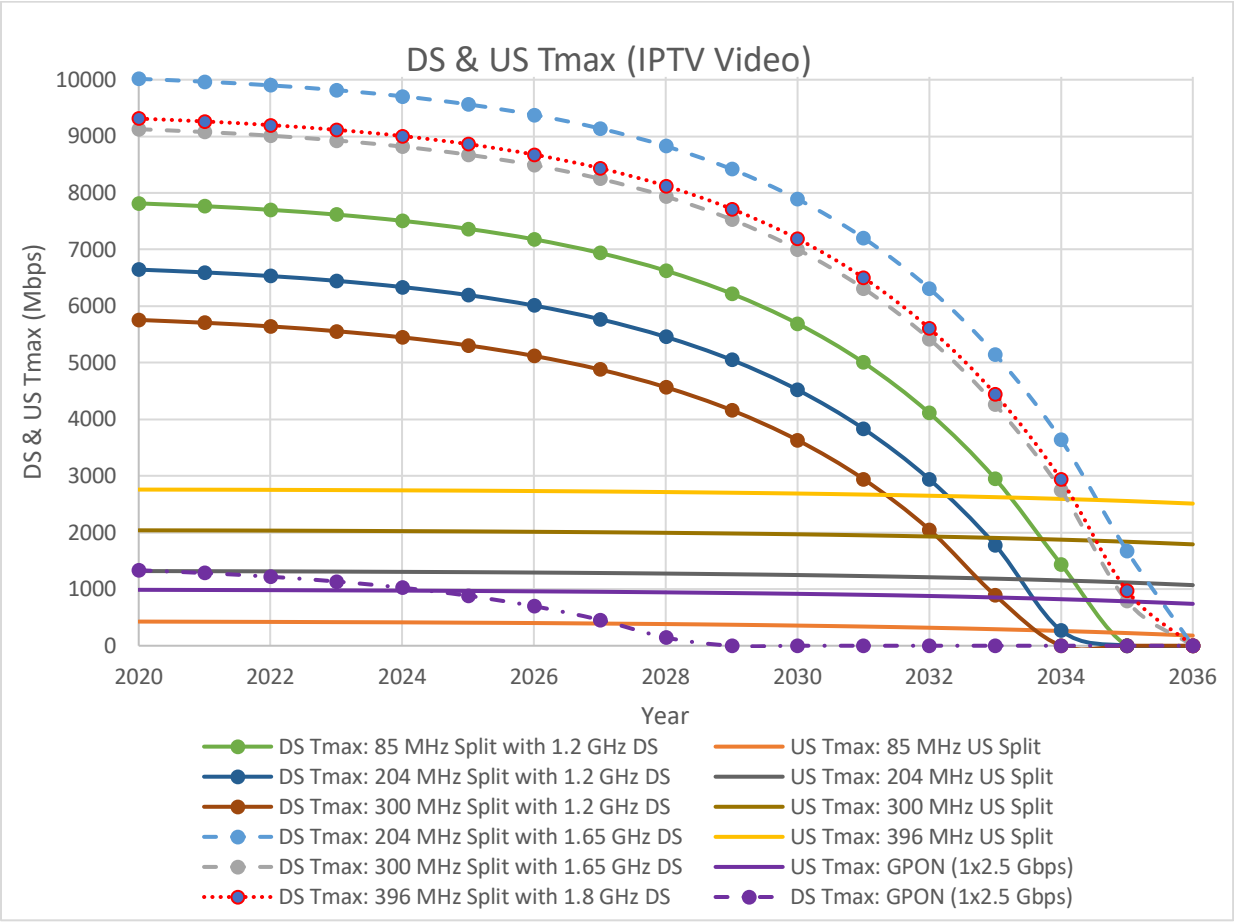

**Figure 9 - US & DS Tmax values that can be offered over time for various split options and DS spectrum sizes. (SG size = 64, IPTV video channels)**

Observe that the above figures do not propose a specific set of US or DS Tmax values that the MSOs should offer. An MSO with envisioned support for a particular Tmax value (depending on their specific demand and competition) can use the curves to estimate the lifespan of their network given that envisioned Tmax value.

Besides indicating the Tmax capabilities resulting from US split changes, node splits, DS spectrum size changes, and video delivery strategy changes, the above family of curves can also be used concurrently with other tools like the selective subscriber migration tool. For example, looking at Figure 4 which assumes digital video and SG size of 250 subscribers, it can be noticed that high-split with 1.2 GHz DS network cannot support DS Tmax values of 5 Gbps. However, if selective subscriber migration is used, where the few subscribers requiring 5 Gbps service are moved to another platform (like 10G PON over FTTH), then the rest of the subscribers on the network will need less demanding DS Tmax values like, say 1 Gbps, and therefore the same network with no modification will be able to support a DS service rate of 1 Gbps to 256 subscribers until 2026.

Finally, it should be noted that Figure 4 - Figure 9 include Tmax curves that can be supported using the 1x2.5Gbps GPON platform. For the digital video scenarios, it is assumed that video is transported via a

separate wavelength and therefore all of the GPON capacity is available for data. On the other hand, the IPTV scenarios assume that IP video traffic is sent over the PON technology along with data and therefore both video and data share the total available capacity, which leads to reduced Tmax values. It can be seen from Figure 4 - Figure 9 that HFC networks can compete very well against GPON using the available migration tools. This observation can lead us to argue that it is wise to limit the competition scope of HFC networks to only compete against EPON/GPON and use selective subscriber migration for customers who require service rates that are comparable to those offered by 10G PON, when the percentage of subscriber requiring those rates is small. This can be a smart move that yields a cost-effective migration strategy, where HFC networks can live for a long life while meeting the demand and addressing non 10G PON competition.

Finally, it should be noted that all of the curves in Figure 4 - Figure 9 will stretch to the right if the CAGR percentages drop.

# 6. Example Network Migration Strategy

As mentioned earlier, there are many tools available to help the MSOs with their HFC network migration exercise. Some of the near-term tools are:

- Enable more DOCSIS 3.1 OFDMA for the US
- Enable more DOCSIS 3.1 OFDM for the DS
- Node split/segmentation
- Enabling Switched Digital Video
- Increasing Video Compression
- Video BW reclamation by moving to IPTV
- Increasing the US split
- Increasing the DS spectral range
- Selective subscriber migration

An optimal network migration strategy is obtained by applying a comprehensive decision process that considers all the available tools concurrently. The process is repeated every time a decision is to be made. In particular, the optimal decision changes as time moves on. This paper listed various tools that can be used concurrently along with a proposed decision tree and family of time-aware curves to help make the right decision when a migration step is needed.

Based on the above, an example migration strategy is given below:

1. Reframe the goal as ‘constrained’ network migration **{Selective Subscriber Migration}**
    a. The result of constraining the process is avoiding the costs associated with unnecessary ‘network-wide’ upgrades when only a small percentage of the subscribers demand a service requiring such an upgrade. This is accomplished using the Selective Subscriber Migration tool, where a constraint is put on the maximum data rate that should to be supported using the HFC network. Any peak rate exceeding this maximum is to be offered using another platform like PON over FTTH. An example of a chosen max rate to be supported on the HFC network can be 2.5 Gbps. Rates beyond 2.5 Gbps are not carried by the HFC network. That is, HFC is to compete with EPON/GPON but not 10G PON, when the percentage of subscribers requiring rates in excess of 2.5 Gbps is very small. The result is moving the small percentage of subscribers with demand for very high peak rates to a different platform, which in turn relieves the pressure from the existing network and therefore elongating the life of the network by allowing it to serve

the remaining 'normal' subscribers without massive upgrades. Note that when the MSO decides to offer a particular service that requires an upgrade to the majority of their subscribers, then a network-wide upgrade will be appropriate and justifiable.

b. The next steps in this migration strategy example assume network-wide upgrades, where all super subscribers have already been moved to a different platform.

2. Continue reducing the SG size **{Node splits}**
    a. Node splits and node segmentation will help in reducing the SG size, which will reduce the overall busy hour BW requirements and therefore elongate the life of existing networks.
3. Move to 204 MHz US with 1.2 GHz DS **{High-split/1.2 GHz DS network architecture}**
    a. With DOCSIS 3.1, 204 MHz US enables the offering of 1+ Gbps US peak rates. 1.2 GHz DS adds additional spectrum to accommodate the increased DS traffic demand.
    b. Assuming no node split (i.e., SG size of 250 subscribers), high-split with 1.2 GHz DS can offer symmetrical 1 Gbps until at least 2026 (DS limited). With two nodes splits (i.e., SG of 64 subscribers), the same architecture can offer 1 Gbps symmetrical service until 2031/2032.
4. Continue Reclaiming video BW **{Move video to IPTV}**
    a. Moving video to IPTV can further elongate the life of a high-split 1.2 GHz DS HFC network (with SG size of 64 subs) by two years. That is, it can offer symmetrical 1 Gbps service until 2033/2034.
5. Further Increase the US & DS throughputs **{Move to either ESD or Dynamic Soft-FDD}**
    a. DOCSIS 4.0 ESD specifications enables the US to go up to 684 MHz and the DS to go up to 1.8 GHz. This will yield US and DS peak rates of 5 Gbps and 10 Gbps, respectively. ESD is a fixed-split FDD operation that is easy to manage but it requires the replacement of taps and amplifiers. Amplifiers may be challenged with high gain requirements to accommodate the increased attenuation at higher frequencies. As mentioned earlier, limited TCP values may not a major issue for short and medium HFC plants.
    b. Dynamic Soft-FDD is the FDX flavor for N+x networks. It enables the US to go up to 684 MHz and the DS to continue to be at 1.2 GHz, where the US & DS time-share the 108-684 MHz spectrum. This will yield US and DS peak rates of 5 Gbps and 10 Gbps, respectively. While Dynamic Soft-FDD does not require tap replacements, its operation may be a little more challenging than ESD. Also, due to the potential complexity of the amplifiers, it may only work for small cascades although it has the advantage of using the same FDX CPE silicon.
    c. While ESD & Dynamic Soft-FDD are equivalent from capacities point view, the decision to go one direction versus the other has major implications to the network architecture and its operation.
6. **Active Taps**
    a. Taking the fiber deeper in the network beyond N+0 can be done in stages. In particular, the MSO can choose to maximize the use of existing hardlines by using active taps, which are small active amplification devices, to enable signal delivery at high frequencies over hardlines.
7. **FTTT**
    a. Whether active taps were used or not, before going FTTH, it is beneficial to visit this step to maximize the life of HFC networks by using the existing drop cables that can go beyond 25 GHz. In fact, with FTTT architecture, the HFC network becomes a point-to-point network with only the drop cable between subscriber and the network. This can enable FDX, ESD, or combination of the two.

8. **FTTH**
    a. The desired end goal of HFC networks is to extend the fiber to the home.

## 7. Conclusions

There are many tools available in the network migration toolbox which will enable the HFC networks to support their customers well into the 2030 decade. These tools include selective subscriber migration, node splits, moving video to IPTV, upgrading the US split, increasing the DS spectrum, dynamic Soft-FDD, active taps, FTTT, and FTTH.

After utilizing the selective subscriber migration concept to constrain the network migration process, the article proposed a decision tree combined with a time-aware decision process to yield an optimal network migration strategy. It was found that the combination of light/medium touch options like moving the US split 204 MHz with 1.2 GHz DS & nodes splits/segmentations can extend the life of the HFC network to 2030 if the desired DS Tmax is 2 Gbps or less. Deploying IPTV will further extend the life of HFC networks. Moreover, this article also showed that Dynamic-Soft-FDD & ESD can both increase the life-span of HFC networks. In the ESD case, going with US splits higher than 396 MHz when the DS is limited to 1.8 GHz is not optimal.

# 1. Introduction

The broadband industry has been relying on public-key cryptography (PKC) to provide secure and strong authentication across its networks and devices. In particular, the DOCSIS standard [Doc31, Doc40] uses X.509 [Itu509] certificates to verify that a device is a legitimate entity that is authorized to join the network—for example, a cable modem or a Remote PHY (R-PHY) node [Rphy1]. The choice of using digital certificates and public-key infrastructures (PKIs) to protect DOCSIS identities has resulted in a scalable and easy-to-deploy key management system for the entire industry.

Although the DOCSIS PKI has been a success story over the past 20 years (it is one of the largest PKIs ever deployed worldwide), things are changing rapidly on both the security side and the broadband industry side.

On the security side, new advancements in traditional and non-traditional computing are threatening our ability to use traditional public-key and key-exchange (KEX) algorithms. On the network infrastructure side, new zero-trust architectures are being designed that require software and hardware entities to securely authenticate to each other (and encrypt traffic) in a distributed environment.

This paper describes our proposal for a backward-compatible quantum-resistant trust infrastructure (or PKI) for the broadband industry. Specifically, our work focuses on the practical aspects of deploying a quantum-resistant trust infrastructure by leveraging our idea—namely, the composite cryptography mechanism [Com20].

The paper is organized as follows: Section 2 provides a description of the quantum threat for the various parts of a PKI; Section 3 describes the composite crypto solution and its two building blocks (i.e., `CompositeKey` and `CompositeSignature`); Section 4 describes how to practically deploy composite crypto in PKIs; Section 5 provides considerations surrounding the use of secure elements and hardware security modules (HSMs); and Section 6 describes a deployment proposal for securing the DOCSIS PKI. Finally, Section 7 provides our conclusions and envisioned future work.

# 2. Trust Infrastructures and the Quantum Threat

Deploying real security is difficult, and security engineers rely on basic cryptographic primitives to make sure protocols operate as intended and data is accessed only by authorized entities. Deploying real security is even more difficult when uncertainty around the efficacy of your basic tools is at risk. Unfortunately, we are living in a period of great cryptographic "uncertainty," where the advancements in both traditional and quantum computing pose serious threats that may impact the possibility to provide secure access and data privacy not only for the broadband industry, but across the Internet.

Recently, advancements in quantum computing suggest that the possibility to break PKC might be closer than initially thought. Specifically, the work of Craig Gidney and Martin Ekerå [GE19] improves the efficiency of quantum computers to perform code-breaking calculations, thus reducing the required resources by orders of magnitude. For example, in 2015, researchers estimated that a billion quantum bits or qubits (aka q-bits) would be required to factor 2048-bit keys due to the need to use noise-reduction codes that require significant extra qubits themselves. With the recent advancement from Gidney and Ekerå, the number of required qubits is reduced to only 20 million.

Another example of the fast-paced rhythm of innovation occurring in the quantum space is the fact that researchers have already moved away from studying qubits to building quantum logic gates. Many

 

experts theorize that at the current speed of innovation, we will have a quantum computer within 20 years—a very short period of time in the cryptography space.

The takeaway message is alarming for all of us: Governments, military and security organizations, banks, medical facilities and everybody else will have no options to secure their data against powerful quantum computers.

The situation is even more alarming when considering that there are no complete or general solutions today that allow for securing all aspects of a PKI—not just signatures or certificates. In particular, regardless of the specific standard or technology used in a PKI (e.g., X.509, PGP), no deployments currently cover the possibility of using multiple algorithms in a combined fashion to further secure the infrastructure in case one or more algorithms are deemed compromised. Our approach addresses this limitation by leveraging a recursive construct for both public-key signatures and keys that can be applied to every aspect of the PKI lifecycle management.

On the quantum-safe cryptography standardization front, things are moving forward as NIST recently announced the beginning of Round 3 in its selection of a quantum-resistant cryptography standard that began few years ago [Nist20].

Because the new standard will specify one or more quantum-resistant algorithms for digital signatures, public-key encryption and key generation, the selection of finalists comprises various classes of algorithms and mathematical properties. In particular, of the original 69 proposals submitted for Round 1, only 26 made it to Round 2. For Round 3, only 8 candidates were selected. Four of the candidate crypto-systems provide public-key encryption, while the remaining four are digital signatures schemes.

The selected key encapsulation mechanisms (KEMs) that provide public-key encryption are:

- **Classic McEliece.** This KEM is the result of a merger between the Classic McEliece and NTS-KEM. This work is a code-based KEM based on the original cryptosystem from 1978. The cryptosystem has never gained much interest in the cryptographic community; however, its resistance to Shor's algorithm makes it a good candidate for post-quantum standardization. Classic McEliece, which uses the binary Goppa code, comes with very large public keys but the smallest ciphertext of any other solution. Although this performance profile might not be the best fit for the general protocols we use over the Internet today, its stable specifications combined with a long history of cryptoanalysis make it an appealing choice for some applications.

- **CRYSTALS-Kyber.** This algorithm is based on the presumed hardness of the module learning with errors (MLWE) problem. The scheme has excellent all-around performance for most applications. It also enables relatively straightforward adjustment of the performance-versus-security tradeoff by varying module rank and noise parameters. NIST regards this scheme as one of the most promising KEMs for standardization.

- **NTRU**. This is a structured lattice-based KEM that has an established adoption history because variations of this KEM have already been standardized by IEEE [Ntru09] and ANSI [Ntru10] organizations. Although NTRU has a small performance gap in comparison with Kyber and SABER, its longer history was an important factor in NIST's decision because of less risk of unexpected intellectual property claims. An important characteristic of NTRU is the fact that it relies on a different problem than MLWE; thus, it provides diversity in the set of structured lattice-based KEMs for the finalists.

 

- **SABER.** This KEM is based on a variation of MLWE—namely, the Module Learning With Rounding (MLWR), in which rounding from one modulus to a smaller second one replaces the addition of small errors. In general, SABER provides good performance for general-purpose applications. One of the areas that NIST encourages more research on is side-channel analysis for the non-Number Theoretic Transform (non-NTT) style of multiplication that is unique to SABER. Together with NTRU and Kyber, SABER is one of the most promising KEMs selected for Round 3.

For digital signatures, the following are considered as finalists:

- **CRYSTALS-Dilithium.** This is a lattice-based signature scheme that relies on the MLWE hardness and the module short integer solution (MSIS). One of the advantages of CRYSTALS-Dilithium over its main competitor, Falcon, is the simpler implementation due to the use of the same modulus and ring for all parameter sets and samples. Overall, Dilithium has a good balance in terms of key and signature sizes and performs well for key generation, signing and verification, making it one of the strongest candidates for standardization as it performs well in real-world experiments.

- **Falcon.** The Falcon signature scheme is lattice-based and uses the "hash and sign" paradigm. Although this scheme is more complex to implement than Dilithium, it offers the smallest public key and signature sizes. From a key generation point of view, Falcon is slower than other candidates, but the overall strong performance makes it a good fit for existing Internet protocols and applications.

- **Rainbow.** This scheme is very different from the previous two. Rainbow is a multivariate signature scheme with an unbalanced oil and vinegar (UOV) construct. Rainbow provides fast signing and verification, along with very short signatures. The downside of this scheme is the extremely large public key sizes. Some issues with the security claims and the fact that NIST prefers algorithms with royalty free licensing put this algorithm at the bottom of the list.

- **GeMSS.** This is the second multivariate signature scheme that uses the "big field" paradigm. Although it offers the smallest signatures of any other schemes and provides a fast verification algorithm, the large size of public keys is the limiting factor for adoption, especially in low-end devices where signing can be very slow. Also, the large size of public keys makes it impractical when used with TLS or SSH without protocol changes. This algorithm is still in consideration, in case developments in Round 3 show the Rainbow scheme to not be suitable for standardization.

NIST also selected eight alternative algorithms whose evaluation will continue after the first selection for the standard. These eight alternative algorithms either might need more time to mature or are tailored to more specific applications. For example, the Sphinx+ scheme is considered very secure but also very conservative in its design. Because this translates into higher bandwidth and slower performance than the selected primary candidates, Sphinx+ is being considered only as a backup option for standardization. The review process for Round 4 will continue after Round 3 ends, and eventually some of these alternative algorithms could become part of the standard at a later date. The status of the NIST selection process is available in the NIST Internal Report 8309 [NISTIR].

## 2.1. PKI Building Blocks

To convey which parts of a trust infrastructure will be affected by the use of quantum computing, we provide a classification of algorithms or "building blocks" that are used to protect both authentication and user data and show how they might be impacted by the quantum threat.

Specifically, when it comes to the various types of building blocks, we shall differentiate between public-key algorithms for authentication (e.g., RSA, ECDSA), KEX algorithms (e.g., Diffie-Hellman, Elliptic-Curves Diffie-Hellman), hashing algorithms (e.g., SHA-256, SHA-3) and encryption algorithms (e.g., AES).

**Public-Key Algorithms.** Public-key algorithms are primarily used to authenticate (and sometimes encrypt) data. Algorithms like RSA or ECDSA are the most common when used in conjunction with X.509 digital certificates. The main difference between RSA and ECDSA, besides the underlying mathematical properties, is in the size of the cryptographic overhead (or bandwidth) and key-generation complexity. In particular, when compared through the performance lens, ECDSA has a clear advantage, especially when deployed in small or computationally limited devices. When compared through the security lens, though, further considerations are due. One interesting feature of RSA is its ability to use different key lengths without changing the algorithm. This allows, for example, RSA cryptosystems to increase the size of the public/private keypair to adjust to increased security risks due to advancements in computing and crypto research. ECDSA, instead, does not support this feature: Once the curve is selected (e.g., NIST's Secp256r1 curve), the key size cannot be changed, and to increase the security of the system, new curves (e.g., NIST's Secp521r1 curve) must be supported (even for validation only).

**Key-Exchange Algorithms.** This class of algorithms has been recently revamped because of the effort, in the TLS space, to deploy perfect forward secrecy (PFS). Specifically, the use of finite-field Diffie-Hellman (DH) and Elliptic-Curve Diffie-Hellman (ECDH) has been required by the latest TLS specifications [RFC 8446] to overcome the security limitations of the RSA-based KEX mechanism and decouple authentications from key exchanges. KEX algorithms are at the core of protocols like TLS to securely derive the encryption keys used after the negotiation phase.

**Hashing Algorithms.** This class of algorithms is at the core of the authentication process in modern PKIs. In fact, to authenticate any type of data (e.g., a certificate or simply a document), the data must be "summarized" to make the signing process efficient and more generic (i.e., providing the same operational approach when working with different algorithms). Because of this, breaking the properties of the hashing algorithms can be quite devastating for a public-key cryptosystem.

**Encryption Algorithms.** When it comes to securing data from unauthorized access, encryption algorithms provide the necessary building blocks via the use of securely exchanged (via the authentication process) encryption keys. The ability to successfully attack these algorithms can bypass any authentication process used during the transfer of encryption keys and therefore grant an attacker direct access to the data.

In the rest of this section, we provide a summary of the threats for each class of algorithms and how (and if) the quantum threat is significant in that space.

## 2.2. Modern Cryptography and the Quantum Threat

### *2.2.1. Public-Key Cryptography*

When it comes to public-key algorithms such as RSA or ECDSA, the threat of quantum computers being able to "guess" (factor large numbers or solve the discrete logarithm problem) private keys is comparable for both cryptosystems. In fact, PKC uses mathematical algorithms to generate complex keys, thus making the code to reverse-engineer the private component from the public one statistically very hard. Different public-key systems can use different algorithms, as long as they are based on mathematical problems that are easy to put into place but difficult to reverse-engineer. For instance, any computer can multiply two extremely large prime numbers, but factoring the result is nearly impossible—at least, it would be for a classical machine. Although only few classes of algorithms (so far) have been identified to be more performant on quantum computers, factoring large numbers is one of them. Specifically, Shor's quantum factorization algorithm could be easily used to break this type of cryptosystem.

The optimization that is possible on a quantum computer is due to the fact that it should be able to use the properties of quantum mechanics (e.g., entanglement) to probe for patterns within a huge number without having to examine every digit in that number. Because cracking both RSA and EC ciphers actually involves finding patterns in huge numbers, quantum computers can perform the inverse operation at practically the same speed as the forward one. For example, while on a conventional computer, finding a pattern for an EC cipher would take $2^{N/2}$ steps—where N is the number of bits in the key. On a quantum computer, the number of steps would be in the order of only N/2!

RSA, ECC and DH are examples of cryptosystems that will not be secure against an adversary with access to a quantum computer.

### *2.2.2. Hashing Algorithms*

Hashing algorithms give us a chance to breathe a little easier. As explained in the previous section, some problems with a special structure (e.g., factorization for RSA, discrete log for EC) typically fall in the category of problems for which quantum computers can reduce the task to finding the period of some function, which is surprisingly not difficult to solve on a quantum computer.

However, for unstructured problems, quantum computers seem to provide "only" some non-trivial quadratic speedup, via the use of Grover's algorithm [Gro96]. Simply put, this indicates that a hash function with 256 bits of security today would still have 128 bits of security in a post–quantum computing era.

### *2.2.3. Encryption Algorithms*

Symmetric encryption, and more specifically AES-256, is believed to be quantum-resistant. Quantum computers are not expected to be able to reduce the attack time enough to be effective if the key sizes are large enough. Also in this case, the speedup from Grover's algorithm allows quantum computers to perform exhaustive searches in the square root of the classical time, rendering classical attacks more expensive than generic ones in most cases. To achieve 128 bits of security in a post–quantum computing scenario (equivalent to AES-128 today), primitives providing 128 bits of security (e.g., AES) need to have a key length of at least 256 bits. In other words, the speedup in the quantum exhausting search provided by Grover's algorithm is the main reason why the current recommendations for encryption with post–quantum computing security mandate for AES [Dr99] with a 256-bit key.

If you are using AES in your systems in 2020, you should favor AES-256 over AES-128. This is true for software environments, but it is especially important when chipsets and hardware deployment is involved; to make sure these devices can take you over the "quantum hump," support for AES-256 is required [Aes16, Aes20].

Ultimately, as with the hashing algorithms case, modern symmetric encryption algorithms are not affected as badly by quantum computing as public-key ones as long as we deploy larger keys (e.g., AES-256).

### 2.3. Algorithm Agility to the Rescue

Algorithm agility is at the core of best practices when it comes to cryptosystems today. Algorithm agility refers to the possibility of substituting cryptographic algorithms (and associated data structures) as needed, without having to change protocol messages or main data structures.

Fortunately, the X.509 standard, used across the Internet and in the broadband industry, provides the possibility to extend the generic data structure to integrate new algorithm-dependent ones in order to identify public keys and signatures. Technically, this is achieved by coupling the crypto data structures with an algorithm identifier that can correctly validate and process the associated data structure(s) across different types of objects used in PKIs (e.g., X.509 certificates, Online Certificate Status Protocol [OCSP] responses, Certificate Revocation Lists [CRLs]).

For example, look at how public keys are encoded in X.509 certificates:

```
AlgorithmIdentifier  ::=  SEQUENCE  {
        algorithm            OBJECT IDENTIFIER,
        parameters           ANY DEFINED BY algorithm OPTIONAL  }

SubjectPublicKeyInfo  ::=  SEQUENCE  {
        algorithm            AlgorithmIdentifier,
        subjectPublicKey     BIT STRING  }
```

Here, `SubjectPublicKeyInfo` comprises an `AlgorithmIdentifier` that identifies the cryptographic algorithm and associated parameters, as well as a `subjectPublicKey`, which is a `BIT STRING` [RFC 5280]. The value of `subjectPublicKey` is the Distinguishing Encoding Rule (DER) encoding of the public-key structure as defined for the specific algorithm used.

For example, Section 2.3.1 of [RFC 3279] defines the contents of `SubjectPublicKeyInfo` and how to encode the `RSAPublicKey` structure whose DER representation is to be used for the value of `subjectPublicKey`.

Our solution leverages the algorithm agility feature and defines a new algorithm identifier that encodes, recursively, a set of one or more `subjectPublicKey` data structures to encode multiple keys with different algorithms, as discussed in the next section.

## 3. A Composite Crypto-Based Solution

The cable industry, as well as the larger Internet community, is faced with the very difficult task of addressing the quantum threat early in order to continue to securely authenticate network devices and users by switching to different algorithms when needed. On top of that, the broadband industry faces the additional challenge of handling this future transition while relying on fielded devices (e.g., CMs, R-PHY/R-MACPHY nodes) that might be expensive to replace or update.

Although the selection for standard post-quantum algorithms has not been finalized yet, we have been actively looking at how to deploy such algorithms for the broadband industry when they become available. In particular, we looked at how to protect the integrity of the most vulnerable parts of our DOCSIS trust infrastructure first (from a quantum-threat perspective)—that is, the root and intermediate CA. We focused on these assets first because they are valuable targets that would allow for an attacker to generate new valid entities for the ecosystem. Once the integrity of the upper levels of the hierarchy are secured, devices can be updated to support the deployed post-quantum algorithm(s) via Secure Software Download (SSD) or other mechanisms.

What we found in our research is that we could use the same algorithm agility feature that is built into modern PKIs to support the use of multiple keys for every aspect of the PKI lifecycle; from certificates to revocation lists, everything supports our new paradigm. In other words, our work enables the use of classic algorithms like RSA or ECDSA alongside new ones. This allows for a gradual transition to new algorithms without losing backward compatibility for devices that cannot be updated with the new algorithms. Figure 1 provides an intuitive representation of the composite crypto when used in X.509 certificates.

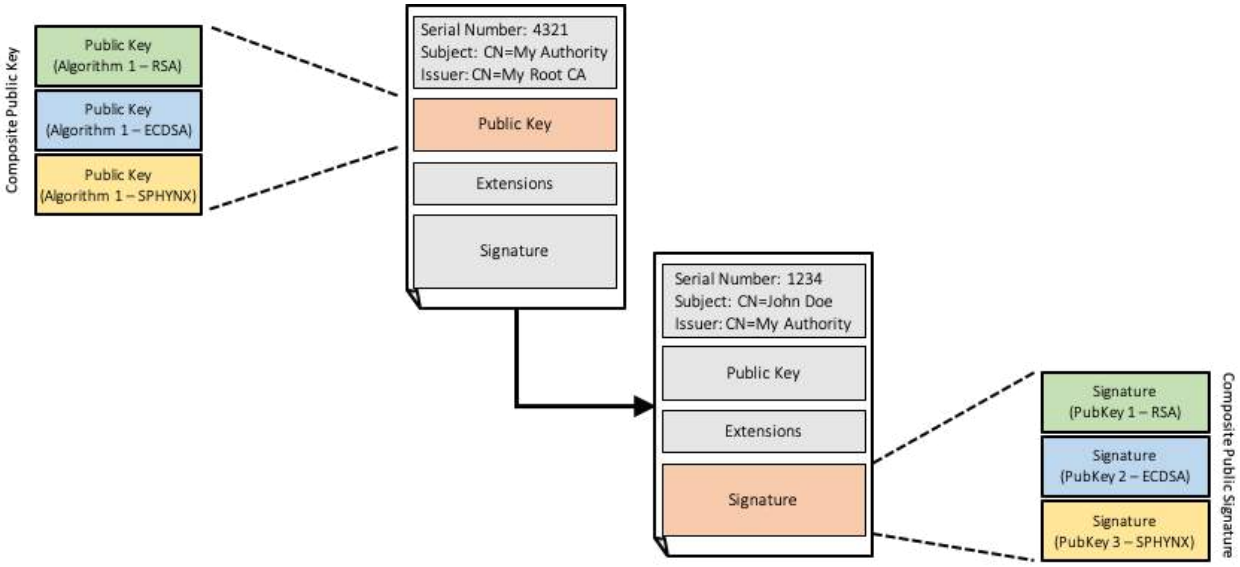

**Figure 1 - Example of Composite Crypto Usage in X.509 Certificates**

It is interesting to notice how our invention can be used at any time when there is either (a) the need to transition to a new protocol without establishing a completely separated infrastructure or (b) uncertainty related to the security of an algorithm over an extended period of time. For example, the solution described in this paper could be used to transition from less efficient cryptosystems (e.g., RSA) to more efficient ones (e.g., ECDSA) or to provide signatures with different hashing algorithms.

### 3.1. A New Paradigm: CompositeKeys and CompositeSignatures

As suggested earlier, to address our problem we relied on our initial considerations about algorithm agility to provide a simple and backward-compatible solution. In particular, we defined a new algorithm identifier and associated encoding that uses standard substructures to encapsulate multiple keys or multiple signatures in PKI data structures and authentication data.

The new type of public keys and signatures—namely, `CompositeKeys` and `CompositeSignatures`, respectively—provide the building blocks we were looking for: backward-compatible encoding for both signatures and public keys that allows for multiple keys and algorithms to be used to secure X.509 objects and produce generic signatures. By mixing classic and post-quantum algorithms, not only can all aspects of a PKI be protected today, but clients supporting at least one of the combined algorithms will be able to operate in the environment.

For example, to trust the authentication of data, relying parties might decide to verify one, some or all of the signatures depending on the ability of the relying party to support any of the algorithms used for keys and signatures.

### *3.1.1. Composed Public Keys and X.509 Certificates*

The technical aspects of our work are simple. We first defined a new value for the `algorithm` field within the `AlgorithmIdentifier` used in the `SubjectPublicKeyInfo` of a `tbsCertificate` structure of a X.509 certificate:

```
compositeKeys OBJECT IDENTIFIER ::= {iso(1) identified-organization(3) dod(6)
                        internet(1) private(4) enterprise(1) OpenCA(18227) 10 }
```

When this value is used for the algorithm identifier, it means that the value encoded in the associated public key field (e.g., the `subjectPublicKey` field) contains multiple public keys and associated parameters. The parameters field of the `AlgorithmIdentifier` itself shall be set to `NULL` in this case as there are no specific parameters associated with the composite key – the recursive nature of the data structure allows us to delegate the parameters to the individual keys definitions.

To encode the different keys, we use a sequence of `SubjectPublicKeyInfo` objects. Each of these objects encodes the specific algorithm identifier for the specific key with its parameters and value. The final sequence is then encoded as the DER representation of the sequence of keys.

We also define the `CompositePublicKeyInfo` as a `SEQUENCE OF SubjectPublicKeyInfo` where each `SubjectPublicKeyInfo` carries the information of one public key. The ASN.1 definition of the `CompositePublicKeyInfo` is as follows:

```
CompositeSubjectPublicKeyInfo ::=  SEQUENCE (1..MAX) OF SubjectPublicKeyInfo
```

where the `SubjectPublicKeyInfo` within the `CompositeSubjectPublicKeyInfo` must not use `compositeKeys` as an algorithm identifier to prevent multiple levels of recursion.

For example, to add two separate public keys in an X.509 certificate via composite crypto, the encoding would be as follows:

```
aCompositeSubjectPublicKeyInfo  = SEQUENCE { keyInfoOne, keyInfoTwo };
  -- The main structure, a sequence of two subjectPublicKeyInfo

keyInfoOne.algorithm.algorithm  = rsaEncryption;
keyInfoOne.algorithm.parameters = NULL;
keyInfoOne.subjectPublicKey     = RSAPublicKey;
  -- The keyInfoOne provides the definition for the first key (RSA)

keyInfoTwo.algorithm.algorithm  = id-ecPublicKey;
keyInfoTwo.algorithm.parameters = EcpkParameters;
```

 

```
keyInfoTwo.subjectPublicKey     = ECPoint;
  -- The keyInfoTwo provides the definition for the second key (ECDSA)

aCertificate.tbsCertificate.subjectPublicKeyInfo.algorithm.algorithm = compositeKey;
aCertificate.tbsCertificate.subjectPublicKeyInfo.algorithm.params = NULL;
aCertificate.tbsCertificate.subjectPublicKeyInfo.subjectPublicKey =
                                                    DER(aCompositeSubjectPublicKeyInfo);
```

where `aCompositeSubjectPublicKeyInfo` is the sequence of two `subjectPublicKeyInfo` (i.e., `keyInfoOne` and `keyInfoTwo`). The DER representation of the `aCompositeSubjectPublicKey-Info` is then stored in the `subjectPublicKey` field of the `subjectPublicKeyInfo` of the `tbsCertificate`.

### *3.1.2. Composite Signatures and X.509 Certificates*

When it comes to signatures in X.509 certificates and their validation, we used a similar approach. We first defined a new algorithm identifier for `compositeSignatures` and then defined the specific data structures for the composite algorithm.

Specifically, when a `compositeSignatures` schema is used to encode multiple signatures at once, the value for the algorithm identifier associated with the signature is defined as follows:

```
compositeSignatures OBJECT IDENTIFIER ::= {iso(1) identified-organization(3)
                dod(6) internet(1) private(4) enterprise(1) OpenCA(18227) 11 }
```

When the `compositeSignatures` identifier is used, the corresponding value encoded in the `signatureValue` field contains multiple signatures and associated parameters encoded as the DER representation of a `CompositeSignatureValue` that is a `SEQUENCE OF SignatureInfo`. Each `SignatureInfo` carries the information about one of the signatures applied to the certificate. The definition of the `CompositeSignaturesValue` is as follows:

```
  CompositeSignaturesValue  ::=  SEQUENCE (1..MAX) OF CompositeSignatureInfo
```

For example, to encode signatures made with two separate keys (one RSA key and one EC key), the encoding would be as follows:

```
aCompositeSignatureInfo         = { sigInfoOne, sigInfoTwo };
  -- The main structure, a sequence of two SignatureInfo

sigInfoOne.algorithm.algorithm  = rsaEncryption;
sigInfoOne.algorithm.parameters = NULL;
sigInfoOne.subjectPublicKey     = <RSA Signature Value>;
  -- The sigInfoOne provides the definition for the first signature (RSA)

sigInfoTwo.algorithm.algorithm  = id-ecPublicKey;
sigInfoTwo.algorithm.parameters = EcpkParameters;
sigInfoTwo.subjectPublicKey     = <ECDSA Signature Value>;
  -- The sigInfoTwo provides the definition for the second signature (ECDSA)

aCertificate.signatureAlgorithm.algorithm.algorithm = compositeSignatures;
aCertificate.signatureAlgorithm.algorithm.params    = NULL;
aCertificate.signatureValue = DER(aCompositeSignatureInfo);
  -- The final encoding of multiple signatures in a certificate
```

 

where the aCompositeSignatureInfo structure contains the sequence of the two SignatureInfo (i.e., sigInfoOne and sigInfoTwo). The DER representation of the aCompositeSignatureInfo is then used for the signatureValue field of the certificate structure.

### 3.1.3. Generating Composite Signatures

To generate composite signatures, the signer shall generate each signature independently by using each of the keys present in the signer's CompositePublicKeyInfo in the same order they appear. Specifically, the signer shall use the first key to generate the first signature, the second key to generate the second signature, and so on. The signer shall generate one signature for each key in the key set.

For example, if the CompositeSubjectKeyInfo has three public keys ($K_1$, $K_2$ and $K_3$) of types RSA, EC and DSA, respectively, the signing party shall generate the first signature by using $K_1$, the second signature by using $K_2$, and the last signature by using $K_3$.

### 3.1.4. Verifying Composite Signatures and Time-Dependent Validation Policies Deployment

To be able to verify composite signatures, a relying party shall verify each of the applied signatures independently. Also in this case, the relying party shall verify the signature by using the corresponding public key in the signer's certificate in order—that is, the order of the signatures within the CompositeSignature shall respect the order of the keys in the CompositePublicKeyInfo in the certificate.

For example, if the certificate has a CompositeSubjectPublicKeyInfo that contains three keys ($K_1$, $K_2$ and $K_3$) of types RSA, EC and DSA, respectively, the relying party shall verify the first signature in the composite signature by using $K_1$, the second signature by using $K_2$, and the last signature by using $K_3$.

One important aspect of our invention is that it can be combined with the possibility of applying validation policies that can be changed over time or remain static.

In a static configuration, for example, the relying party might set its policy not to evaluate the correctness of signatures if they do not support any of the used (or specific) algorithms, or otherwise refuse to trust the signed data entirely, even if it is not able to verify just one of the composite signature's elements.

In a time-dependent policy, relying parties could instead use the quantum threat risk level to set the threshold for the policy change. Imagine, for example, an infrastructure in which both RSA and ECDSA algorithms are used via CompositeKeys encoded in the root and intermediate CA certificates. Also imagine that the RSA algorithm is set to retire because deemed not secure in 10 years (e.g., the used key sizes for the infrastructure are not considered secure anymore). In addition, assume that ECDSA will still be considered secure for the application (e.g., larger keys can be deployed here because of better performances). A validation policy could allow relying parties to validate composite signatures by using only the RSA algorithm for the next 10 years. After that, the policy might mandate relying parties to validate signatures by using all algorithms to make sure the stronger one(s) is validated too.

In the post-quantum scenario, this translates to a very similar approach.

Specifically, although static policies might be more appropriate for those relying parties or devices whose crypto cannot be updated (see the next section), more dynamic ones could be deployed when the validation of new algorithms can be added to the device. In this case, up to a certain security risk level

 

(e.g., until practical deployment of quantum computers is achieved), relying parties and devices could still be allowed to use just the traditional algorithms for validation and enable the new ones when the risk level for the involved stakeholders goes over the acceptable threshold (and support for it is successfully deployed).

#### *3.1.5. Use of Composite Crypto for Backward Compatibility*

The same solution can be used when deploying a new infrastructure where participants in the ecosystems might not be able to update their security parameters. In this case, composite crypto structures can be used to deploy trust infrastructures where new and old algorithms coexist in the `CompositeKeys` and `CompositeSignatures` of certificates. The deployment of superseded algorithms along with new ones allows relying parties that cannot update their cryptographic suites (e.g., devices that are already in the field) to participate in the same infrastructure while still allowing other relying parties to use stronger validation algorithms.

In other words, composite crypto can be used to keep using old algorithms to accommodate for older, already-in-the-field devices that might have hardware constraints (e.g., they have a secure element that cannot be replaced) without compromising the overall security of the infrastructure. The stronger keys/algorithms will be used by more capable devices (e.g., P-521 or quantum-resistant algorithms).

# 4. A Complete Solution: From Requests to Revocation

Although other solutions have been tried to provide support for adding multiple keys or algorithms to certificates by adding new types of extensions, no other solution actually tackles all the aspects of the PKI lifecycle. Specifically, no other solution is available that addresses not only the authentication of certificates but also the authentication of certificate requests and revocation objects. In this section, we take a look at the applicability of our solution to these aspects that are central to the correct behavior of PKIs.

## 4.1. Requesting Composite Certificates

In PKIs, the [PKCS10] standard is commonly used when it comes to requesting certificates. Many standard (and non-standard) protocols use it as the core building block for their own certificate request messages. Examples of this can be found in Certificate Management over CMS (CMC) [RFC 5272, RFC 5273] and in the Automated Certificate Management Environment (ACME) [RFC 8555].

Fortunately, our work is compatible with the PKCS#10 format.

In particular, to authenticate PKCS#10 requests with composite crypto, the `signatureAlgorithm`'s algorithm identifier in the `CertificationRequest` structure can be set to carry the `compositeSignatures` value, and the `parameters` one can be set to `NULL`.

The `signature` field is the one that carries the DER representation of `CompositeSignatures` and contains all the signatures generated with the `compositeKeys` associated with the identity that is requesting a certificate. The signatures are calculated, as usual, over the DER representation of the `certificationRequestInfo` field of the `CertificationRequest`.

### 4.2. Use of Composite Signatures in CRLs

CRLs are the oldest form of revocation for X.509 certificates [RFC 5280, RFC 5759, RFC 6818]. Their structure was inspired by credit-card number blacklists and are used to convey the list of serial numbers of certificates that have been revoked (together with an optional reason code). Because this list is often signed by the issuing CA (or a designated signer), we need to make sure that this list is securely authenticated, even in a post-quantum threat scenario.

Our approach seamlessly works with CRLs too.

As with the case of X.509 certificates, the `signatureAlgorithm` field in the `CertificateList` structure can be set to carry the `compositeSignatures` value, and the `parameters` field can be set to `NULL`. The `signature` field of the `CertificateList` can be set to carry the DER representation of the `CompositeSignaturesValue`.

Also, in this case, there is no change in how the signatures are generated because the individual signatures are calculated over the DER representation of the `tbsCertList`, as usual.

### 4.3. Use of Composite Signatures in OCSP Requests and Responses

OCSP requests and responses have signature fields that can be leveraged with composite signatures to address the quantum threat without requiring any protocol changes.

To authenticate OCSP requests, the `signatureAlgorithm` algorithm identifier in the `Signature` structure of the `OCSPRequest` can be set to `compositeSignatures`, and the `parameters` field can be set to `NULL`. The corresponding `signature` field of the `Signature` structure can then hold the DER representation of the `CompositeSignature` value itself. The signatures are calculated, as usual, over the DER representation of the `tbsRequest` in the `OCSPRequest` structure.

For OCSP responses, the `BasicOCSPResponse` structure provides, together with the `tbsResponseData` and the `signatureAlgorithm` ones, the needed fields to host composite signatures. Specifically, the `signatureAlgorithm` algorithm identifier in the `BasicOCSPResponse` structure can be set to `compositeSignatures`, and the `parameters` field can be set to `NULL`. The corresponding `signature` field can be set to hold DER representation of the `CompositeSignaturesValue`. Also in this case, the individual signatures can be calculated and encoded, as usual, over the DER representation of the `tbsResponseData` field of the `BasicOCSPResponse`.

## 5. Composite Cryptography and Hardware Integration

Modern cryptography relies on two main principles: making algorithms public and moving all security properties to the secrecy of keys. That is why one of the pillars of modern cryptography is keeping your secrets ... secret! This is true not only for shared secrets but also for private keys.

To help with the security of keys, best practices commonly require the use of HSMs or secure elements in our devices to make sure that (a) private key computations safely happen on a dedicated processor and (b) their value cannot be extracted by a remote party.

From this point of view, the quantum threat not only poses a risk from a security perspective, but it also requires hardware updates to provide the same security properties that we have enjoyed for decades.

 

Although quantum-resistant algorithms must be run in software until support for them is provided via secure hardware implementations, the composite cryptography solution itself is fully compatible with existing hardware and security modules. This is because the processing of the individual keys and signatures still relies on the same primitives; therefore, no changes are required for composite crypto integration, as long as the algorithm is supported by the crypto accelerator. Similarily, current standard interfaces to crypto hardware, like PKCS#11 [PKCS11] and supporting libraries, do not require any changes for the same reasons. This is extremely important for preserving backward compatibility with deployed HSMs, which are usually large and very expensive pieces of equipment used mostly to secure operating CA keys.

This means that all investments that Certificate Service Providers (CSPs) made in purchasing and maintaining their HSMs are not impacted, as no changes are needed to leverage composite crypto. For example, existing root and intermediate CAs can add new keys to their own certificate and have their new request signed by using composite crypto today. This allows current infrastructures to add new algorithms and still be able to leverage the security (and certifications) of today's crypto hardware (e.g., FIPS 140-2).

Summarizing, composite crypto can be used today with existing certified hardware components, thus allowing the transition from, for example, RSA to ECDSA without the need for new hardware or certifications. Support for new algorithms is still required for deploying quantum-safe crypto.

# 6. Deploying a Backward-Compatible, Quantum-Safe DOCSIS PKI

So far, the DOCSIS ecosystem has deployed two different infrastructures throughout its lifetime. The first one, today referred to as "legacy PKI," was deployed 20 years ago and provides its services for DOCSIS 1.1–3.0 devices. Because this infrastructure is set to expire soon, it was reasonable to focus our efforts on the newer infrastructure.

The second deployed infrastructure, or "new PKI," was introduced to update the security parameters for the whole broadband industry and provides its services to secure not only DOCSIS 3.1–4.0 devices but also other entities associated with the existing and upcoming distributed architectures (e.g., R-PHY or CCap Core). Because this infrastructure is not going to sunset anytime soon, our work has been focused on defining the deployment strategy for securing this second "new" infrastructure across the "quantum-threat hump."

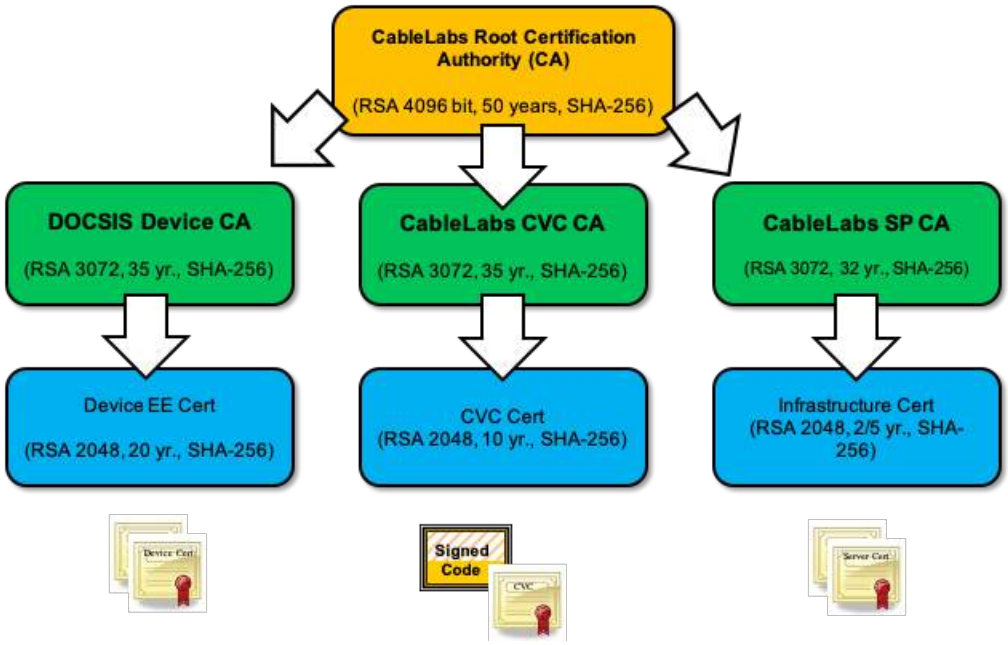

**Figure 2 - The DOCSIS "New PKI" Hierarchy**

Figure 2 depicts the "new PKI" structure that comprises a three-tier hierarchy with an offline root CA that issues a second level of intermediate CAs. These CAs issue only end-entity certificates and have assigned operational scopes (e.g., device certificates vs. code-signing certificates) that limit their liability in case of compromise. All participating entities in the infrastructure use the RSA algorithm for their keys.

Currently, our work is focused on setting up a test infrastructure that uses composite keys and signatures to secure the core part of the infrastructure (i.e., the root CA and the intermediate CAs) against the quantum threat and, at the same time, provide the possibility to leverage algorithms other than RSA for increased efficiency.

The envisioned test infrastructure mimics the current "new PKI" hierarchy and uses, for the core of the hierarchy (i.e., root and intermediate CAs), three separate public keys: the current RSA key, a new ECDSA key and a new Post-Quantum-Algorithm (PQA) one. Device or end-entity certificates are issued with a single algorithm that can be either RSA, ECDSA or the PQA, depending on the entity or device capabilities. Network or server-side identities are issued with composite crypto keys comprising all the deployed algorithms to support all classes of devices (i.e., classic and post-quantum).

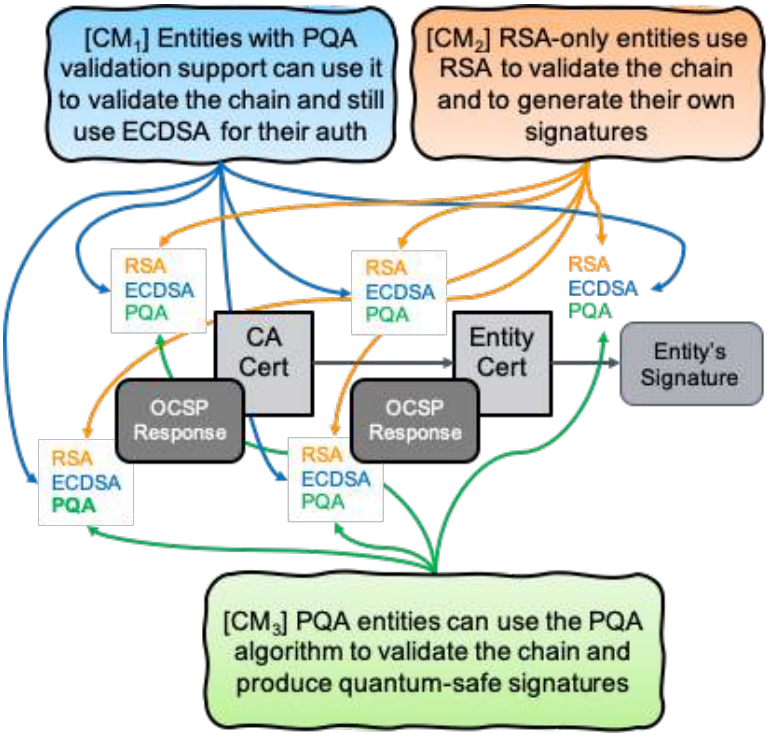

**Figure 3 - Validation Scenario Showing Multiple Entities with Different Capabilities**

Figure 3 provides a validation scenario in which three devices with different capabilities are authenticating themselves with credentials from the quantum-safe PKI. In this scenario, $CM_1$ is capable of only working with ECDSA P-256 keys but can validate PQA signatures and public keys, $CM_2$ is capable of only working with RSA keys, and $CM_3$ fully supports PQA (not only validation but also signing and key management) and can also validate RSA and ECDSA.

On the client side, $CM_1$ can benefit from using either classic or quantum-safe crypto and still authenticate itself by using classic crypto (ECDSA). $CM_2$, instead, is a constrained device and can only use RSA; without any further update, this class of devices cannot be securely authenticated under the quantum-threat model (see the next section for proposed mitigations to address this use case). $CM_3$ is a newer device that fully supports the selected PQA and therefore uses that algorithm to both validate the network credentials and generate its own authentication traces. In case $CM_3$ also supports classic cryptography, RSA or ECDSA validation algorithms can still be used before quantum-based attacks become practical.

On the network side, the CMTS must support all the algorithms supported by the entire population of deployed devices—both for validation and authentication. To be able to authenticate $CM_1$, the CMTS must support ECDSA. To be able to authenticate $CM_2$, instead, the CMTS has to support RSA. Ultimately, authenticating $CM_3$ requires the CMTS to support the PQA. On the authentication side, to allow devices that might support only one of the deployed algorithms to be able validate the network credentials (e.g., in Baseline Privacy Plus Interface [BPI+] V2), the CMTS must support all of the used algorithms in its composite key. This allows the use of RSA, ECDSA and PQA on the various classes of devices without the need of separate identities or infrastructures.

In the rest of this section, we provide an overview of the proposed approaches for tackling the quantum threat when deploying full PQA-based solutions is not an option—for example, because of limitations in fielded devices.

## 6.1. Deploying Post-Quantum Solutions for RSA-Only Capable Devices

One of the most challenging issues when it comes to cryptography is to include devices with different capabilities, and some of these devices might not be upgradeable. This can be due to software limitations (e.g., firmware or applications cannot be securely updated) or hardware limitations (e.g., crypto accelerators or secure elements).

Although composite cryptography cannot be used to secure non-quantum-safe authentications against the quantum threat by itself, in case entities and devices do not to support any post-quantum algorithm, we identified a solution that can be used to extend the lifetime of deployed devices for the broadband industry.

### *6.1.1. Fielded Devices and Authentications*

To consider securing fielded devices that cannot be updated to support PQAs, we looked at their current capabilities. We researched which classes of quantum-safe algorithms are available and how can we leverage them, given today's hardware constraints, to provide quantum-safe authentications.

What we found is that especially for constrained devices, the only option at our disposal is the use of pre-shared keys (PSKs) to allow for post-quantum safe authentications for the various identified use cases. We looked at the limitations and how to tackle them when planning for the transitioning. In this scenario, the post-quantum PSK (PQP) is used to generate quantum-safe signatures and, in some cases, to also provide a "second factor" of authentication for the certificate chain when no PQA support is available.

To generate quantum-safe signatures, devices can start using the PSK with their device private keys (e.g., RSA keys) to produce quantum-safe authentication data; the classic cryptography provides the identity information, along with the proof of possession of the classic private key, while the PQP provides the security of the message via a symmetric signature. Combining the PSK with the authentication process can be done in different ways. A hash-based key derivation function (HKDF) [RFC 5869] can be used with the PQP to derive a message-specific key that is then used with an HMAC function to authenticate the messages.

In BPI+ Version 2[1], because of the use of the Cryptographic Message Syntax (CMS) [RFC 5652], combining PSKs with DOCSIS authentication could also be used to provide key encapsulation capabilities for delivering authorization keys via a quantum-safe mechanism [RFC 8696]. For previous versions of DOCSIS, or where BPI+ V2 is not supported because direct RSA encryption of the authorization key is used, additional changes to the protocol messages might also be required.

Let's now take a look at two different scenarios and how to address their limitations. The first use case assumes that private keys, certificates and crypto capabilities cannot be updated—in this case, we rely on traditional crypto to perform the needed setup operations securely before the quantum threat is real. To remove the requirement for time-safe deployment, a second proposal is introduced that looks at devices whose private keys cannot be updated, but their support for composite crypto and quantum-safe KEX algorithm can (e.g., via SSD).

[1] The new version of BPI+ was recently introduced in the DOCSIS 4.0 specifications to introduce several improvements to the authorization process, such as mutual authentication and perfect forward secrecy.

#### 6.1.1.1. Immutable Devices and Quantum-Safe Traditional Authentications

In this scenario, we look at entities and devices whose support for new algorithms cannot be updated—not even for validation-only operations (i.e., no support for private keys or signing). Because of these restrictions, our proposal is to leverage traditional cryptography to distribute per-device PSKs that can be leveraged for post-quantum authentications.

Specifically, our proposal is to enhance the DOCSIS protocol to introduce the possibility to securely transfer (or derive) a common PSK between the operator's network and the device being authenticated (i.e., the cable modem or the R-PHY node). Once the PQP is securely delivered to the device, this secret can stay dormant until needed for generating quantum-safe signatures. This PSK can be deployed as part of the initial registration of devices to the network, or it could be initiated at any time as long as the PQP is transferred securely.

One very important aspect of the solution is to make sure not only that the session parameters are properly authenticated via the quantum-safe signature, but that the certificate chain is protected against modifications by including it into the original signature. Assuming the PSK is secure, the relying party (e.g., the CCap Core or the CMTS) can trust both the signature and identity of the device because of the security of the PQP.

The big limitation here is related to the security of the PSK. Because the PSK has to be transferred or derived by using traditional cryptography, an attacker could potentially pre-record the device's traffic and then—when access to a quantum computer is obtained—get access to the PQP by breaking the classic KEX algorithm. The attacker would then be able to impersonate any device, even when using the PQP when generating signatures. Although a more secure solution is provided in the next section, operators can make things difficult for a malicious attacker who is pre-recording DOCSIS traffic to analyze and decrypt it at a later time.

Indeed, operators can deploy keys at random intervals or use procedures for combining new and old values (and/or replace them) at random times. An attacker would require knowledge of the whole history of the device connectivity to be able to attack its PQP.

#### 6.1.1.2. Partially Upgradeable Devices and Quantum-Safe Traditional Authentications

When entities and devices can be updated to support new algorithms, but their private keys cannot (e.g., they are tied to secure elements that cannot be updated), more secure options can be adopted for transferring the PSK. We think that this upgrade path might be the most common for the broadband industry given that the possibility to provide secure software updates is built into the DOCSIS protocol since its inception.

In this scenario, we assume that devices have been updated to support composite crypto and a quantum-safe KEX algorithm, but they cannot update their own private keys. We also assume that the root and the intermediate CAs have been deployed with a PQA algorithm alongside traditional ones.

To protect the PQP against a possible all-powerful adversary that can break the traditional cryptography, we share the PQP by using a quantum-safe KEX algorithm. The use of a quantum-safe KEX algorithm guarantees that an adversary would not be able to have access to the PQP, even when pre-recording encrypted sessions. The use of traditional cryptography still provides the needed secure identity validation to make sure the PQP is shared across the right entities. Also, in this case, when generating authentication

 

data, we need to protect the certificate chain because the link between the intermediate CAs and the end-entity certificate is not yet protected via a PQA.

When the entity's certificate can be updated and signed by using a PQA (i.e., the CA signs a new certificate for the entity that includes the original "traditional" key of the entity only, and it is signed using all the keys in the CA's composite certificate), the need to sign the certificate chain with the PSK can be relaxed. In fact, because the links from the root to the end entity is already secured by the use of a PQA, no additional use of the PSK to protect the device's or CAs' identities is needed.

# 7. Conclusion

In this paper, we have examined the quantum threat, the current status of post-quantum cryptography and the associated standardization efforts. We also describe how the quantum threat will affect the various classes of algorithms we use today within the broadband industry.

The core of this paper provided a description of our novel approach based on composite cryptography, and how it can be used to address the quantum threat. Specifically, we provided the technical description of the composite cryptography building blocks (`CompositeKeys` and `CompositeSignatures`) and showed how to integrate them in every aspect of modern trust infrastructures and associated services (e.g., certificates, CRLs, OCSP). We then explored our proposal for a quantum-resistant and backward-compatible DOCSIS PKI and the use of PSKs to secure entities and devices that will not have access to quantum-resistant cryptography.

Our future efforts will be aimed at working on open source tools and test environments. The quantum-safe test services deployment will be paramount for security experts and researchers to experiment with combining different quantum-resistant algorithms and study their interactions with our protocols. The selection of the protocols and their parameters will pave the road to quantum-resistant DOCSIS implementations and deployment.

Ultimately, the takeaway message from our work is that the quantum threat is closer that many people think, and we need to be already preparing our infrastructures and protocols for the upcoming revolution. Not only quantum computers will become more capable of handling more complex problems; the advancements in quantum-based algorithms put everybody's security and privacy at risk.

Although the deadline for planning to address this new class of threats is fast approaching, our work shows how the broadband industry can already start to address them today and lead the transition to quantum-safe cryptography to be able to continue to protect users' privacy and securely deliver top-quality services.

# Live Single-Stream HDR Production for HDR and SDR Cable Distribution

## What Happens When "Post Production" Is Real-Time

prepared for SCTE•ISBE by

**Chris Seeger**
Director, Advanced Content Production

## List of Figures

# 1. Introduction

Developing video content for the extended dynamic range and color depth in high dynamic range (HDR) and wide color gamut (WCG) now common in consumer displays isn't necessarily new: the first functional 4K/HDR televisions came out in 2016, and popular over-the-top (OTT) video platforms have routinely produced content in HDR since then. However; it is far, far more difficult to shoot and deliver HDR content for live linear workflows than it is for most file-based post produced approaches. That's because in live HDR production environments, handling graphical placements, color correction, and luminance normalization across what is usually a mix of SDR (standard dynamic range, which is essentially contemporary HDTV) and HDR cameras must be done on-the-fly and in real-time.

Also, differences in system colorimetry exist within the primary HDR systems, specifically Hybrid Log-Gamma (HLG) and Perceptual Quantizers (PQ), and took us some time to understand. A functional workflow for live delivery requires multiple levels of conversion for various signals throughout the infrastructure - like graphics, video playback, SDR and native HDR cameras. This three-part paper will explore 1) conversion and perceptual measurement for HDR and SDR; 2) how HDR production workflows are orchestrated for live content, and 3) how those live linear workflows are distributed – a topic likely of most interest to the cable television industry.

In addition, the paper will illuminate the research and collaborative processes necessary to build a functional, single-stream HDR-SDR workflow, at each stage of the pipeline, without compromising the artistic intent or quality of the distribution paths for either the HDR or the primary (and revenue-generating) SDR. In-depth research of color conversions will be discussed and explored, such as the specialized techniques described in the International Telecommunications Union – Radiocommunications Sector's (ITU-R) Recommendation BT.2124. Production layouts will be explored and described, so that readers gain a deeper understanding of decisions made in the baseband (serial digital interface(SDI) and IP – Internet protocol), file-based conversions/transcodes, and orchestration layers.

# 2. Content Conversion and Perceptual Measurement

Content conversion and perceptual measurement matters because of the vast differences in a scene you see with your own eyes, and that same scene captured by a camera and displayed on a screen. In real life, we see these bright and colorful scenes – but when we capture and move the image through to legacy TV's, some of the highlights and light levels get muted. That's because a traditional TV can was designed to display 100 nits (a "nit" is a measure of brightness, roughly equivalent to the light of one candle per square meter). Figure 1 shows a simulated scene represented in both HDR (lower image) and SDR.

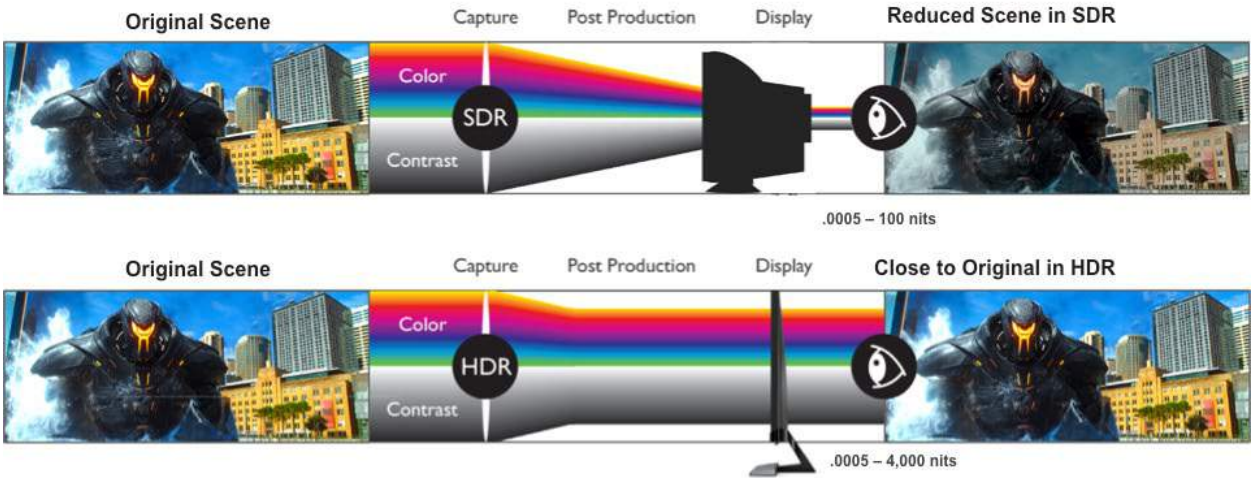

**Figure 1 - How Do We See Light and Color? (© Universal Pictures from PacRim)**

The interplay between cameras, display screens and brightness dates back to the early days of analog cathode ray tune (CRT), which could achieve only a relatively marginal level of brightness, measured at approximately 100 nits. Compare this against today's HDR TVs (and some smartphones) – which can be as bright as 4,000 nits; and SDR TVs, which is to say "traditional HDTVs," that can scale the peak white to a maximum of around 400 nits (note that a recommendation that is in development would make it around 200nits so it matches reference/graphics white in HDR). As time went on, and digital techniques replaced analog, cameras advanced to the point of being able to record a much wider dynamic range – meaning more detail to describe a larger range of luminance, from dark to bright, and a far richer span of colors that is closer to what the human visual system is capable of. HDR(High Dynamic Range) gives you substantially better highlights (the twinkly stuff), and WCG(Wide Color Gamut) gives you redder reds, bluer blues, blacker blacks.

HDR got a better foothold, commercially, within the medical imaging community, which required a method to see in a highly detailed and reliable way. As it turned out, the HDR images were so vivid, and so much closer to the workings of the human visual system (which we'll get to next), that it began to be developed for consumers. In today's consumer electronics marketplace, it's getting harder to find a television that doesn't include HDR, than one that does.

Dolby Laboratories (Dolby), in particular, focused on a system of quantization that could standardize the way HDR content is displayed, known in the industry as "PQ," for perceptual quantization. In essence, PQ adds more bits to areas where the human visual system can see more detail and fewer bits where we see less detail. The thought is, if we can't see the detail, why store more detail. Additionally, PQ decided to use an absolute mapping which associates a specific code value with a luminance level.

If history is our guide, a proposed video standard isn't really a technology story unless a competing standard is vying for consideration. Which, in the case of HDR video, is HLG, co-developed by the British Broadcasting Corporation (BBC) and Nippon Hoso Kyokai (NHK – also known as the Japan

Broadcasting Corporation). Unlike PQ, HLG deliberately has some aspects of backwards compatibility to SDR(SDR, which is to say "HDTV" that uses traditional gamma mapped signals) when used with wide color gamut or ITU-R Recommendation BT.2020. Backward compatibility does not exist with older legacy displays that use the narrower color space in HDTV (ITU-R Recommendation BT.709). It works by defining a nonlinear transfer function, known as an electro-optical transfer function (EOTF), in which the lower half of the signal values use a gamma curve, and the upper half use a logarithmic curve.

SDR and HLG are relative systems that scale the entire image from a lower luminance level to a higher luminance value (the dynamic range doesn't change only the luminance level). SDR was designed as a 100 nit system and we scale it to 200-400 nits for consumer delivery.

HLG was originally designed as a 1000 nit system and was adapted with a newer algorithm (ITU-R Recommendation BT.2100) in order to scale to other luminance levels without hue shifts. Scaling shifts shadows, midtones and highlights which can be an important consideration when distributing a signal to consumer displays that are getting brighter and brighter. Scaling does not increase the dynamic range (it's like turning the volume up in audio).

The differences between the absolute (PQ) and relative (HLG) HDR systems are important to remember when we get to the distribution section of this document.

Our work producing and distributing HDR content began after a test run with the 2015 Independence Day fireworks in New York city, and then in earnest with the opening ceremonies for the 2016 Olympic Games, in Rio de Janeiro, Brazil. Since then, Comcast/NBCUniversal produced and distributed HDR video for the 2018 PyeongChang Winter Olympics; the 2018 and 2019 Notre Dame football season; the 2018 men's Federation Internationale de Football (FIFA) games; and, earlier this year, Chicago Blackhawks hockey games. We learn something new every time we venture into an HDR/WCG event, and in particular these learnings tend to focus on ways in which to optimize content conversions, and avoid unnecessary duplications. The aim is a live production that "produces once, outputs twice:" Once in native HDR; once in converted SDR. This is no small feat. The rest of this paper will explain why.

## 2.1. How the Human Visual System Sees Light and Color

If the ultimate goal of video production is to faithfully reproduce what the eye sees, then a rudimentary understanding of the human visual system (HVS) is useful. The basics: the human eye takes in light, which is processed primarily by cone cells, which are sensitive to certain wavelengths – long, medium and short. Our rod cells are sensitive to dark scenes, and thus aren't as involved in the processes of, say, watching television. Rod cells are more numerous than cone cells, but are less important, perceptually, during normal lighting conditions.

Figure 2 illustrates how the HVS processes information. Incoming light is captured by the three photo receptors (cones) in the eye, which have peak sensitivities in the Long, Medium and Short wavelengths, designated "L," "M" and "S." Linear light is converted into a non-linear signal response, to mimic the adaptive cone response of the HVS. Notice the different ratio of L/M to S wavelengths.

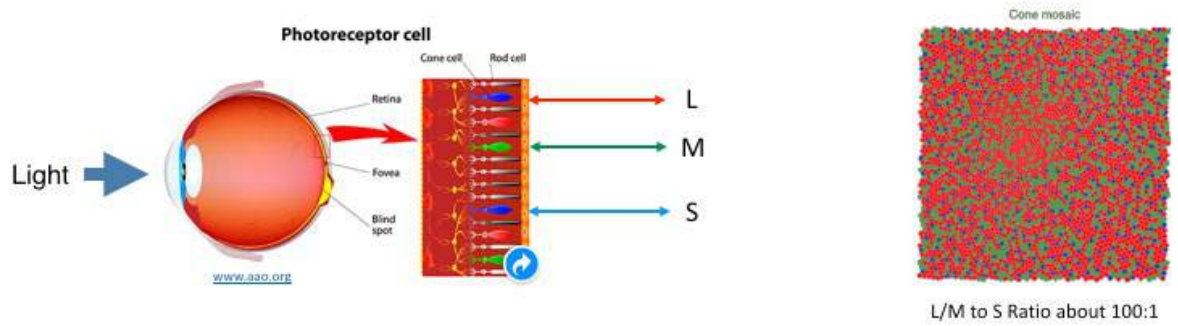

**Figure 2 - The Human Visual System and Color**

Not only that, but the HVS is adaptive, so, the responses can change, and those changes must be taken into account, especially when considering a much wider dynamic range.

Figure 3 illustrates static versus dynamic adjustments to light levels. Adapting to darker environments – like attempting to see objects in the night sky, after being in a lit room – can take as long a 30 minutes; in brighter environments, it can take five to 10 minutes for the eyes to adapt. In general, the HVS can see about 12 simultaneous stops; "stops" are a scaled measure of dynamic range. But! The HVS can operate within a 24-stop range, by doing a number of things, like scanning up and down in different brightness ranges, then adapting(perceptual) while adjusting the human pupil (physical), which when dilated, allows us to see darker detail, but loses brighter detail. Pupil contraction allows us to see detail in brighter objects, but sacrifices darker detail.

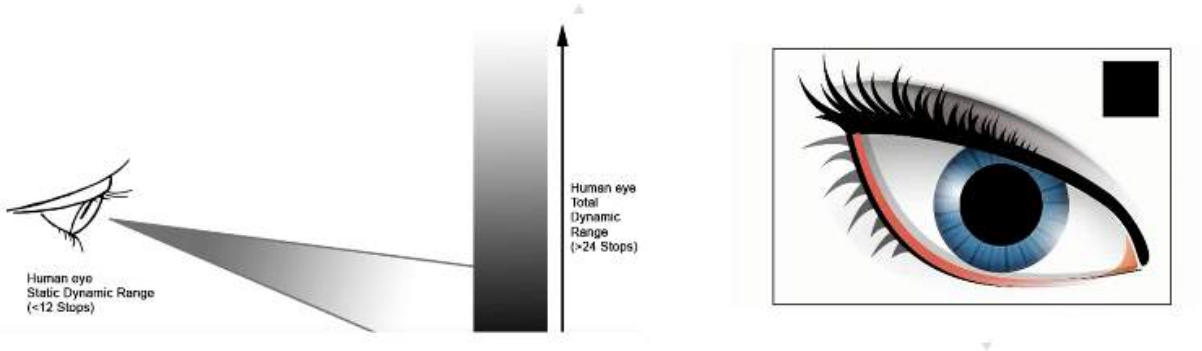

**Figure 3 - Static versus Dynamic Adjustments to Light Levels**

Because of adaptive factors (some of which aren't mentioned), the HVS is relative. It plays tricks on you!

Allow me to prove it to you:

In Figure 4, the stripe in the middle of the image appears brighter on the left side than the right – but it's not. As you scan from left to right on Figure 4, the images will appear to change – but they are not. It's merely your brain, adapting.At any moment in time, the HVS is juggling a complex mixture of perception, adaptation, sensitivity, acuity, and "day vs. night" variables. As content producers, it's important to pay attention to these variables, so as to provide consistent content to our viewers.

**Figure 4 - The Human Visual System is Relative**

Then there's the matter of how the Human Visual System interprets color and contrast, and how many different ways the brain can see things.

For instance:

- The "Hunt Effect," simulated in the upper portion of Figure 5, illustrates how color saturation appears to increase – but the only thing that actually increased was the luminance/brightness.
- The "Stevens Effect," does something similar with contrast, in that it appears to increase with brighter light.
- The "Bartleson-Breneman Effect," investigates how display image contrast increases with the luminance of surround lighting.
- The "Helmholtz-Kohlrausch," shows that where there is a saturated and a neutral color of the same luminance, the saturated color may appear brighter. This is another example of how saturation plays a role in perceived brightness, which will change with the viewing environment.
- The Perkinje Effect (illustrated in the lower image in Figure 5) describes the tendency for the peak luminance sensitivity of the eye to shift toward the blue end of the color spectrum at low illumination levels as part of dark adaptation. In consequence, reds will appear darker relative to other colors as light levels decrease

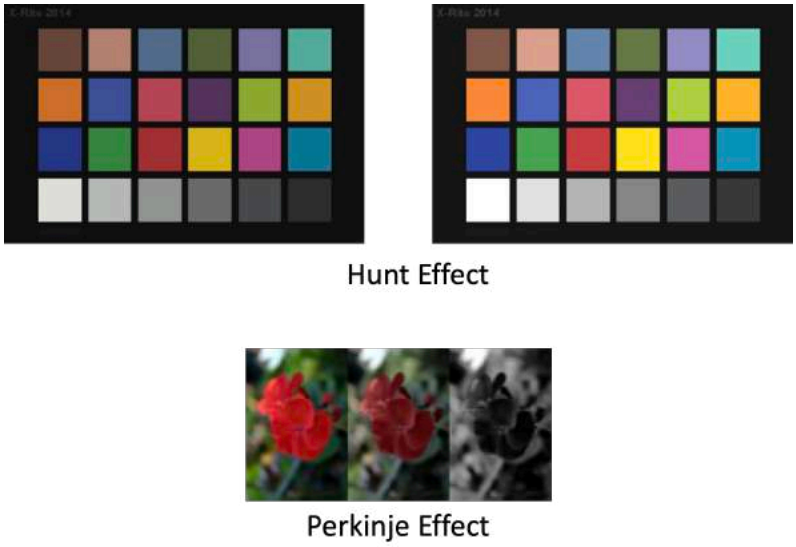

**Figure 5 - Color Appearance and HDR Production**

Because of the vast increases in luminance that come with HDR technologies, a significant issue to resolve is overall viewing comfort. Simply put, with HDR, as objects of certain colors get larger, they can become uncomfortably bright to view. The ITU-R produced standards for all levels – but they don't include object size, color and temporal elements. As a result, small, twinkly images can be really beautiful, but large, bright objects can quickly become offensively bright.

This requires broadcasters and video content producers to purposefully shade material by observing additional elements mentioned earlier (object size, color and duration on-screen). Eventually, my hope is that "color loudness" rules will be established, just as there are for audio. Although out of scope for this paper, we recently filed a preliminary patent with some concepts which we believe will help to develop a "comfort metric" for HDR measurement tools.

Figure 6 is a bit of "eye-candy" to expose other strange perceptual elements. In the image, nothing is moving, but the blue dots appear to be moving. It illustrates the impact of drastically different contrast levels, which essentially make our brains freak out.

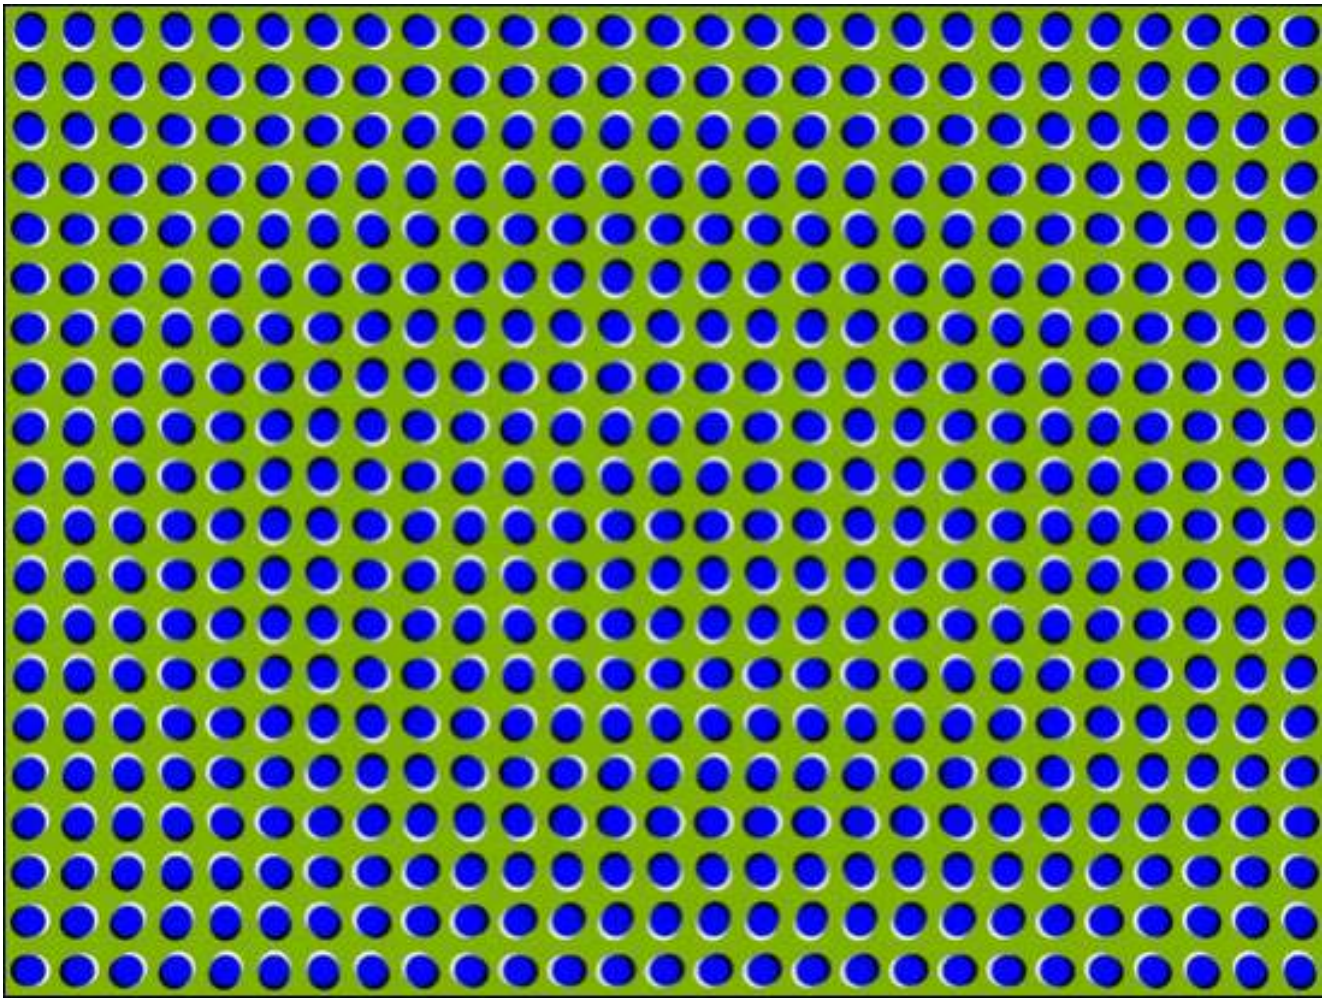

**Figure 6 - Nothing in This Image is Actually Moving**

## 2.2. SINGLE-STREAM HDR AND SDR PRODUCTION

Figure 7 takes us directly into the deep waters for content producers. It depicts the inner workings of a video control facility, as well as a control room, based on ITU-R Report BT.2408. In essence, we mapped out all of the pieces of the live HDR puzzle, necessarily including cameras, displays, the video switcher, graphics, distribution outputs, and how a typical HDR production would be laid out. Few (if any) broadcasters have budgets to support a full complement of HDR cameras; generally speaking, the HDR cams are used for "important capture," while the extant suite of SDR cameras are put to use in, say, helicopter shots or those less vital to the overall imagery. Over time, all the camera's will be capable of HDR.

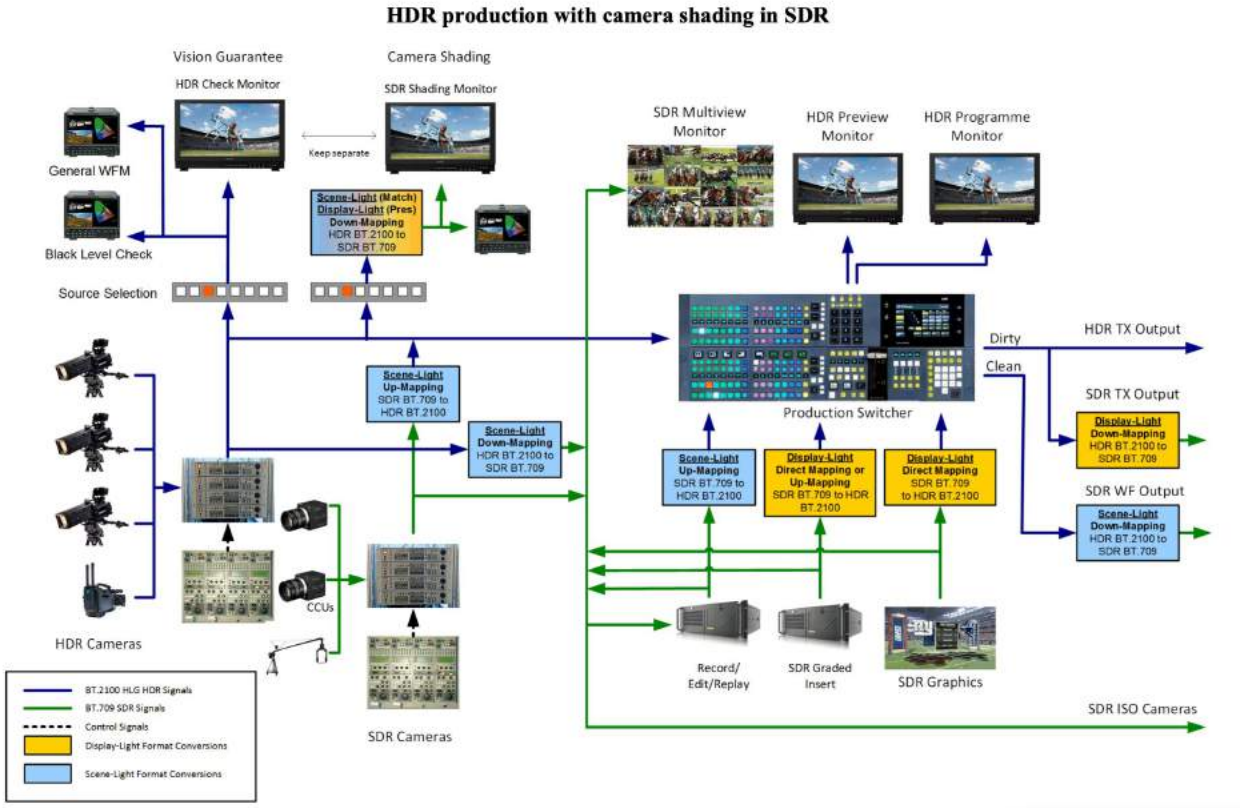

**Figure 7 - Single-Stream HDR and SDR Production (ITU-R Report BT.2408)**

### *2.2.1. Video Control*

The video control area includes both HDR and SDR cameras, managed by a "shader" – essentially a "golden eye" for color and light – who matches the outputs of both camera types before they go on air. All sources need to be converted to the same HDR system before they enter the production, therefore, SDR sources are converted by "direct-mapping" or "up-mapping," to HDR, using specific look-up tables (LUT). Specific LUTs are used and are chosen dependent on each production. If, for instance, the production uses S-log3 versus HLG there will be a different LUT set. Also, some productions prefer a different mapping of light levels requiring a different set of LUTs. The primary goal for the design of any LUT-set is to preserve artistic intent on the HDR and SDR sides of the output.

In HLG productions, two types of conversion must be applied. One is called "Scene Light Conversion," which gets applied to older SDR camera's in order to match them with native HLG's "natural look", and the other is "Display Light Conversion." which get's applied to all other inputs and outputs (HLG to SDR).

Scene Light Conversion applies the source video's inverse-OETF (optical-to-electrical transfer function) to generate scene light prior to conversion, using the output OETF (to HLG, SDR or PQ) as the video

signal. In essence, it converts the SDR signal, with its color balance, and rebalances the colors in order to better match with a native HLG camera. HLG-BT.2100 cameras produce what has been labeled as the "Natural Look". Some markets set their camera's to output what has been labeled the "Traditional Look" which restores a similar color balance and saturation compared to SDR or PQ. This could complicate media exchange in the future.

SDR-to-HLG Display light conversion (DLC) applies a the SDR EOTF prior to the conversion to HLG, in order which converts the source to displayed light which properly preserves the artistic intent (color balance) of the source. SDR-to-HLG scene-light conversion will desaturate images while HLG-to-SDR scene-light conversion would oversaturate images because the variable luma-gamma in HLG will not have been applied.

Predictive LUTs are also an important video control room component, so that HDR to SDR conversion can be previewed, such that we know exactly what the SDR output feed to legacy distribution will look like, before it goes to air.

### *2.2.1. Control Room*

In the control room, depicted in the right box of Figure 7, a multi-viewer screen is used by the director and technical director, to examine all camera outputs and select which shot to use. A LUT can be used here which will output the HDR feed into the SDR multi-viewer compilation. The control room is also where slow motion replays, SDR graphics, and HLG replays are composited in the video switcher, all while preserving the color balance of the source. Those elements are direct-mapped using Display Light Conversion (DLC). Native HDR playback and HLG replays do not require upconversion, and feed directly into the video switcher.

The switcher outputs directly to a native HDR distribution feed, which then goes to the transmission system; the signal will also be transmitted in SDR to our legacy broadcast network. Legacy SDR output from the HDR production requires a DLC (HDR-to-SDR), which reduces the dynamic range but maintains the color balance and therefore as much of the original artistic intent in the HDR production as possible. We have found that mapping HLG-75% to SDR-95% and then constructing a subjective knee which preserves additional highlights from HLG between SDR 95% and 109%. An HLG "pre-compression" knee applies compression natively in HLG from 90%-109% and then applies an additional knee which "post-compresses" HLG 75%-109% to SDR 95%-109%. This process creates substantially more compression in upper end of the HLG curve beyond SDR "legal range" and preserves additional highlights within SDR "legal range."

## 2.3. Hybrid Log-Gamma

HLG works by capturing scene light, then sending it through an OETF. The resul is a curve, representing the scene's light level, that determines the quantization of the light levels into certain bits or code values. The scene light signal is what gets carried to the display, via SDI, IP or file for video distribution. Inside the receiving display, assuming it is HLG-equipped, several things happen: it applies an inverse-OETF, to reverse what was done in the camera, then an OETF is applied using gamma-to-luma only (not R,G,B - red, green, blue), so that it can scale the luminance of the images depending on the display's peak

brightness capabilities. A 1,000 nit display will use one overall system gamma value, while a 2,000 nit version will use another, and that gamma value will scale only the light level, separate from the color. Perceptual effects like the Hunt Effect are important to remember when varying luminance and still require more study to understand what their impact might be. Variables like the perceptual effects are part of why we convert to PQ for distribution.

## 2.4. HLG from camera to display

HLG signals, from camera to display, apply a variable luma gamma in the display, which is determined by the display's peak brightness capability. By contrast, SDR and PQ apply gamma to R, G & B. This difference in gamma application for HLG produces a non-linear difference in chromaticity, relative to SDR or PQ.

The offshoot of this rather difficult process is that the signal looks desaturated compared to what we're used to in SDR. In some countries, that desaturated look is considered "less colorful," even though more accurate to the scene. The desaturated version is commonly known as a "natural look," whereas a "traditional look" re-saturates the images. As a direct result, HDR cameras carry two HLG settings – one for the natural look, the other for the traditional look. Deciding and/or converting between the two "looks" adds an additional level of complexity in broadcast workflows. A "Mild" setting is provided in some camera settings. It achieves a setting in between natural and traditional.

## 2.5. Color Conversion and objective color accuracy measurements

At this point, we know that we have to convert between SDR, HLG, or PQ. For the live-linear realtime conversions we commonly use 3D LUTs with a minimum size of 33 points and recommend a high quality interpolation method. 3D LUTS allow our file-based conversion workflows to match our baseband hardware conversions (live and post production conversions will match). Newer conversion methods are becoming available that allow for purely mathematical transforms. Purely mathematical transforms perform much less interpolation than LUTs and may become preferred over time.

In the early days of our HDR journey, we made subjective measurements for every LUT and every piece of new conversion hardware – we'd put the video in (test patterns and actual video), then examine the conversion vs the original side-by-side on a displays, and on a scope. It was a fairly inaccurate way of looking at very complex things like light and color. We found ourselves needing an objective measure that could make critical measurements. The ITU adopted metric created by Dolby (BT.2124) for objective color volume measurement. ITU-R BT.2124 uses a "color difference metric, called Delta-E ITP which measures the color volume difference (Delta) of one normalized sampled color volume (HLG, PQ and SDR) and another. ITP is a derivative of ICtCp which applys a small conversion to Ct (Ct/2). I and Cp remain the same.

ICtCp was designed to use key aspects of the HVS, in three steps, illustrated in Figure 8.

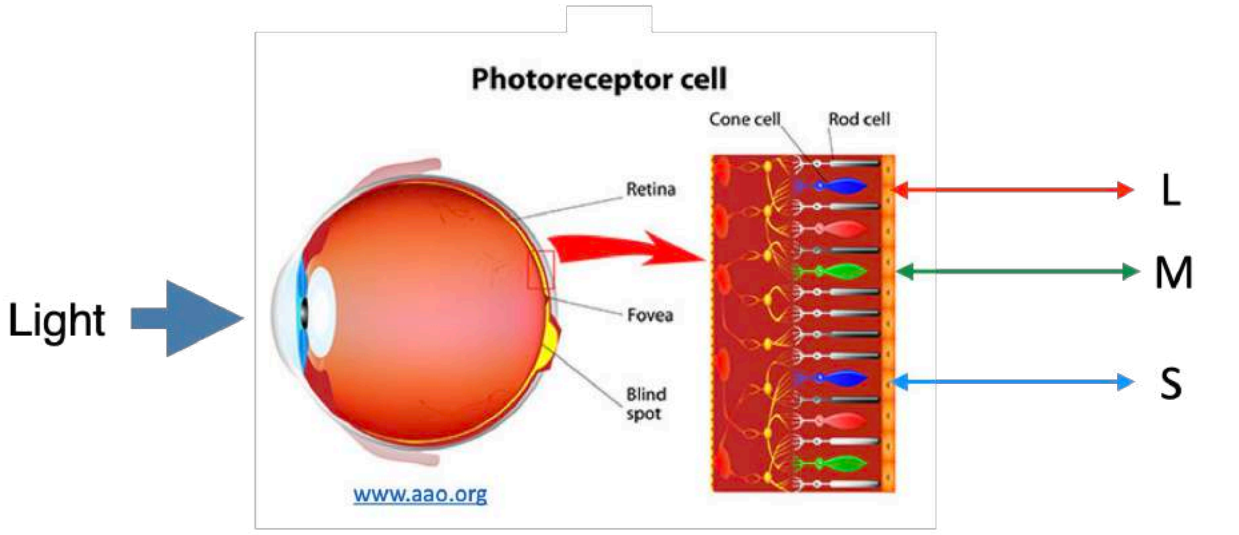

**Figure 8 - Objective Color Accuracy Measurement**

First, incoming light is captured by the three photo receptors (cones) in the eye, that have the previously discussed peak sensitivities in the Long, Medium and Short wavelengths. Next, the linear light is converted into a non-linear signal response, to mimic the adaptive cone response of the HVS. It is ICtCP's ability to algorithmically mimic the HVS that allows us to measure the perceptual appearance. It's not perfect, but it goes a long way to mimic how our eyes and brains translate color and light.

It's worth noting that this was important enough for us to build a plug-in to perform this measurement, using mathematical formula's contributed by Dolby and other recommendations from Philips. Normalizing all signals into ICtCp-PQ-BT.2020 (one large color volume container) enables us to make a single plot for comparisons of conversion accuracy between all current SDR-HDR-WCG systems.

First, after normalizing the signals, the T/P (color) components of ITP can be plotted on an X-Y axis to check for hue shifts throughout the LUTs conversions points.

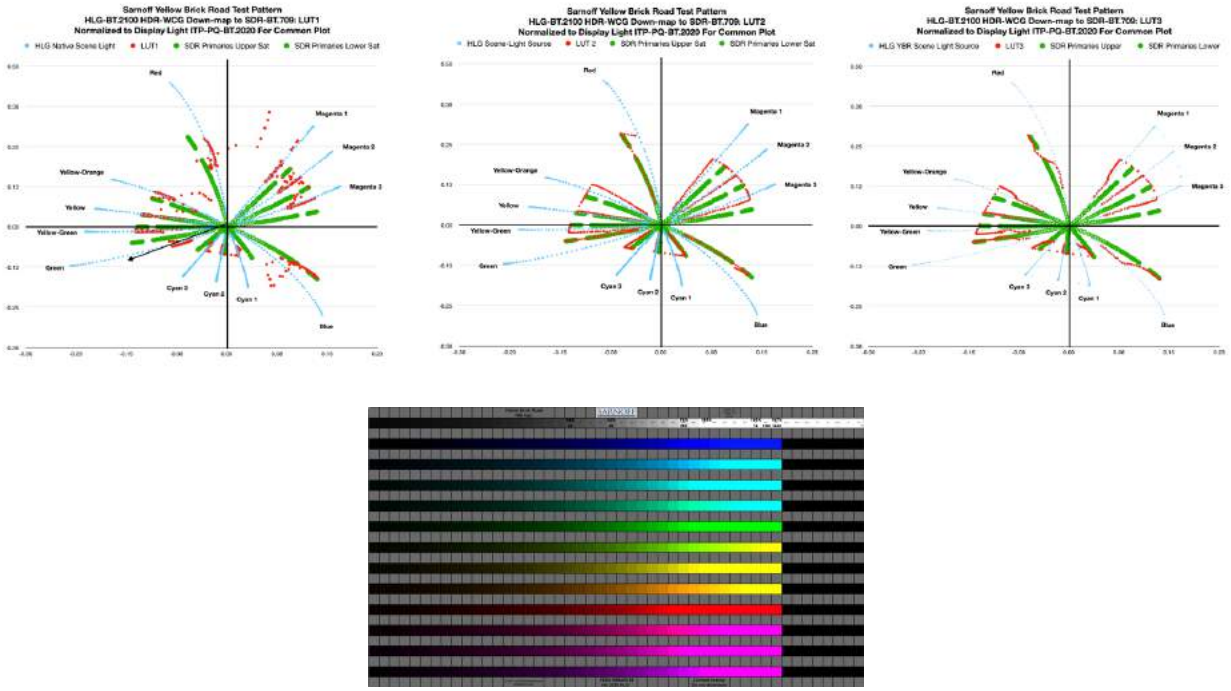

**Figure 9 - LUT Conversion (devices & software): Sarnoff(SRI) "Yellow Brick Road" Pattern**

Figure 9 compares three LUTs, with 576 sample points, to test up/down mapping and round-trips for color accuracy using the T/P components of ITP. All three samples are measuring the same pattern – a compilation of 576 color chips, to ascertain the ramp up in primary colors, and also the accuracy of compound colors (magenta, yellow, cyan, etc). In each sample, the blue dots represent the original(following BT.2020 primaries), the red dots represent the conversion, and. The green lines show the measurement of the SDR color primaries (BT.709) , because we want to know if the conversion is tracking the BT.2020 or BT.709 primaries so we can understand the conversion strategies.

LUT 1, on the far left, shows a conversion following the ITU-R Report BT.709 primaries for RGB for the majority of the mappings, but is extremely inaccurate with shadows and has less color detail. LUT 2, in the middle, shows excellent linear tracking of a conversion from ITU-R Recommendation BT.2020 to follow the BT.709 primaries. LUT 3, on the right, is a conversion that reproduces the BT.2020 colors within the BT.709 color triangle until the saturation/luma gets too high, then it slews toward the BT.709 primaries.

Of the three, the left-most conversion (LUT 1) is the worst of the bunch; the middle (LUT 2) is very good, and the far right is somewhat more subjective, if only because of the inevitable light and color tradeoffs that occur when converting from a larger to a smaller container (from HDR to SDR; BT.2020 to BT.709).

Figure 10 is an example of Delta-E ITP measurements for a conversion from SDR to HLG. Delta-E ITP provides a simple metric representing the difference of intensity and color between one image and another. An major benefit to the Delta-E ITP algorithm is that any unit measured above a "1" is considered a "Just Noticeable Difference," or JND. This means that humans are able to discern a difference between two object's light or color, if it measures above a 1. When calculated one against the other with the Delta-E ITP algorithm, it gives us a reliable indicator of noticeable differences, indicating accuracy issues with color and light  conversions between HLG, PQ and SDR.

| ITP Difference Original vs LUT Converters | |
|---|---|
| Colorchecker CSM Suite HLG 709 colors in 2020 | Display Referred SDR->HLG |
| | ΔE-ITP |
| dark skin | 0.6107 |
| light skin | 0.4276 |
| blue sky | 0.5727 |
| foliage | 0.4997 |

| bluish green | 0.3500 |
| orange | 0.9263 |
| purplish blue | 0.4047 |
| moderate red | 0.8893 |
| purple | 0.3227 |
| yellow green | 0.5079 |
| orange yellow | 0.5393 |
| blue | 0.4771 |
| green | 0.5339 |
| red | 0.7252 |
| yellow | 0.3631 |
| magenta | 0.7047 |
| cyan | 0.3159 |
| white | 0.2364 |
| Gray 2 | 0.2208 |
| Gray 3 | 0.2589 |
| Gray 4 | 0.2547 |
| Gray 5 | 0.2193 |
| Gray 6 | 0.1750 |

**Figure 10 - LUT Conversion: Delta-E ITP (SDR-to-HDR) Using Sarnoff(SRI) Color Checker 2014**

Since implementing the original color metrics workflow, we've also added the ability to plot our SDR, PQ, HLG sources normalized into CIE1976 u'v' in order to examine absolute chromaticity based on recommendations from Philips in ITU.

## 3. Single-Stream HDR-SDR Production

The bulk of our experience in producing live content in HDR is, perhaps predictably, sports. As mentioned previously, our HDR/WCG adventures began in earnest with the 2016 Olympic Games, in Rio de Janeiro, Brazil. Subsequent HDR productions included the 2018 PyeongChang Winter Olympics; the 2018 and 2019 Notre Dame football season; the 2018 men's FIFA games; and, earlier this year, Chicago Blackhawks hockey games. Producing live content in HDR, while preserving and/or converting live feeds for SDR broadcasts, involves a blend of baseband and file-based workflows and overall orchestration.

Specifically, three different tone maps are used to manage overall brightness, for scene light, HDR display light, and SDR display light. Live HDR cameras feed into the switcher are output in native HDR. Legacy SDR camera's are up-mapped using Scene-Light so that the SDR color balance matches HLG. Other legacy pre-produced content and graphics from SDR are direct-mapped using Display-Light on the fly to preserve artistic intent.

File movement is challenging, from an orchestration perspective. Files need to be moved efficiently, converted, and transcoded and then blended with the live, native feeds.

Consistently shading HDR content is another significant component of live productions, to set levels, color balance and obviate uncomfortable light levels. Through the ITU-R, broadcasters have established recommendations for a reference white / graphics white level, at 203 nits (75% HLG; 58% PQ in narrow range.) Reference white acts as an "HDR anchor point" for all other focal points like skin tones, grass, and other images, to prevent HDR brightness levels from going too high -- while reserving enough space for highlights up to 1,000 nits for some HLG material (1,000 nits is an established normalization point for HLG to PQ conversions). Many non-HDR consumer TVs scale SDR to approximately the same peak white brightness level as the HDR anchor point (reference white at 203 nits).

For right now, most HDR productions use SDR graphics which mean they don't have to change their workflow. The SDR-to-HDR conversion LUT handles the mapping of graphics into HDR. By establishing an anchor point, HDR graphics producers could build elements and know where to map them – when looking at a scope, they can reference those known white levels. This reference white level is extremely important to making the production consistent, especially for live material. Again, the over-riding goal is to ensure that the colors and light levels delivered are consistent and aren't so uncomfortably bright as to be garish.

Figures 10 and 11 illustrate the concept of HDR shading, with no highlights (Figure 10) and highlights (Figure 11.) Highlights (like the sky in Figure 11) are typically a small part of the content. In Figure 10, an average scene from a game correlates on the scope image to roughly a 75% level, which indicates that the levels are set well. In Figure 11, a segment of the sky is in the shot, which immediately skews the corresponding scope level above 75%. Some of the scene reaches 100%, which is equivalent to 1,000 nits. The CIE1931 (an earlier version of the chromaticity measure for color gamut devised by the Commission Internationale de L'Eclairage) in Figure 10+11 maps the visible chromaticity range and shows how the current image occupies a specific color space. It is the colorful plot in the bottom middle of the scope screen capture. The plot for BT.2020 WCG imagery shows the picture information well inside the BT.709 triangle. The circle on both figures is a vector scope, which helps identify standard color targets which color bars should fall into.

HLG images are normalized to 1,000 nits as per ITU-R Recommendations during conversion to PQ so that when the signal is distributed, displays of all brightness levels will match the original intent and not be uncomfortable. Using this normalization level means that PQ's absolute mapping will preserve brightness levels at their originally-created levels seen by the production shader.

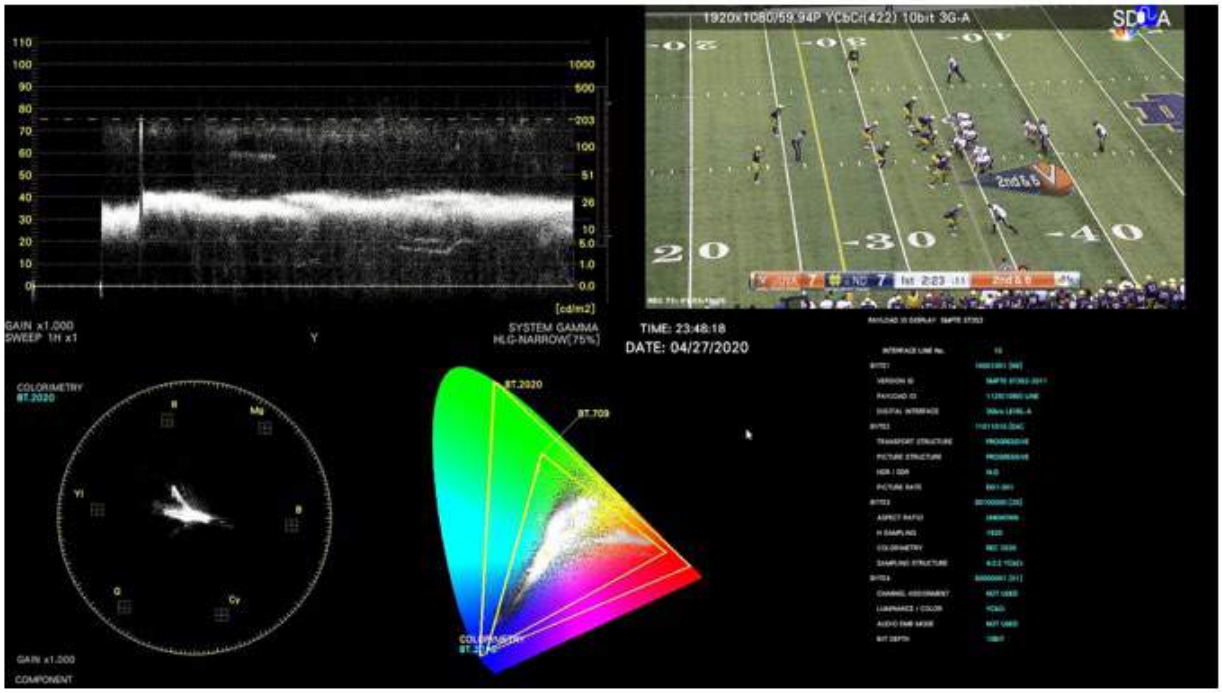

**Figure 11 -: Examples of Shading: No Highlights**

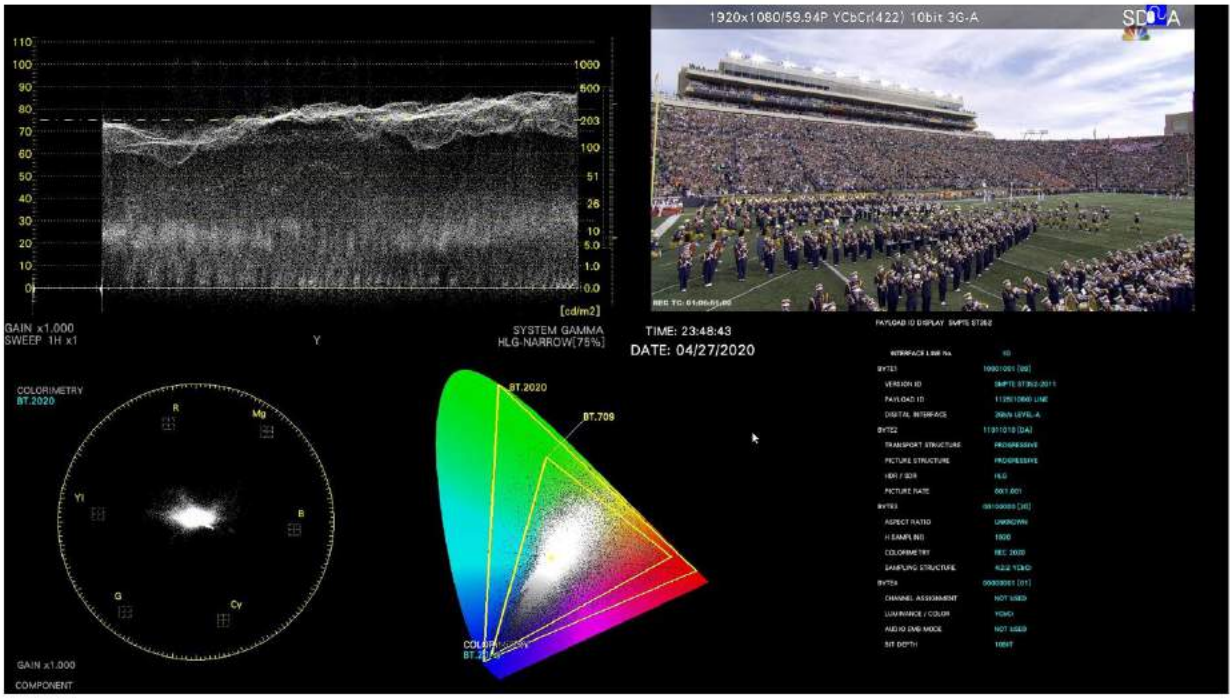

**Figure 12 - Examples of Shading: Highlights**

# 4. HDR/SDR Single-Stream Distribution

Figure 14 illustrates a simplified, single-stream HDR workflow for distribution. At the network origination point, all the production sources – SDR sources are de-interlaced, tone-mapped, scaled and color space converted. Since NBCU is agnostic to the HDR production format, native HDR formats (HLG or camera logs like S-log3) are converted to the final distribution format, PQ and resolution-scaled if necessary. Any third-party, native HDR content is also readied for transmission.

The process of cross-conversion from HLG to PQ has been defined in ITU-R Report BT.2390 (Figure 12) and produces an mathematically transparent conversion. It specifies a normalized peak white at 1,000 nit using an HLG system gamma of 1.2. Since HLG has a smaller color volume compared to PQ, we typically allow overshoots up to 109% for HLG (9% above peak-white) during conversion.

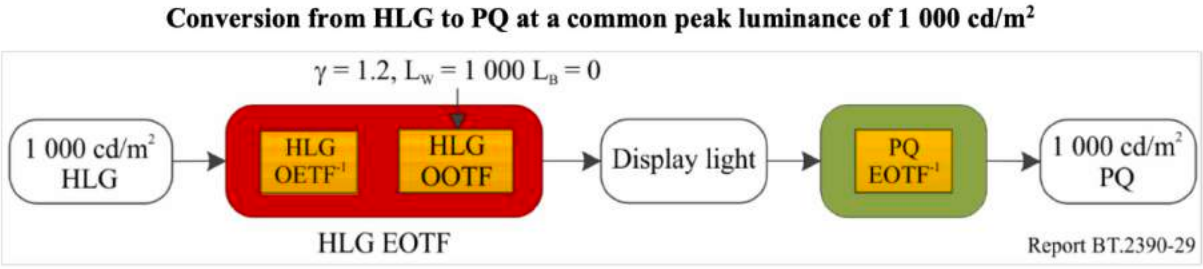

**Figure 13 - This conversion produces a PQ image which is visually identical to HLG**

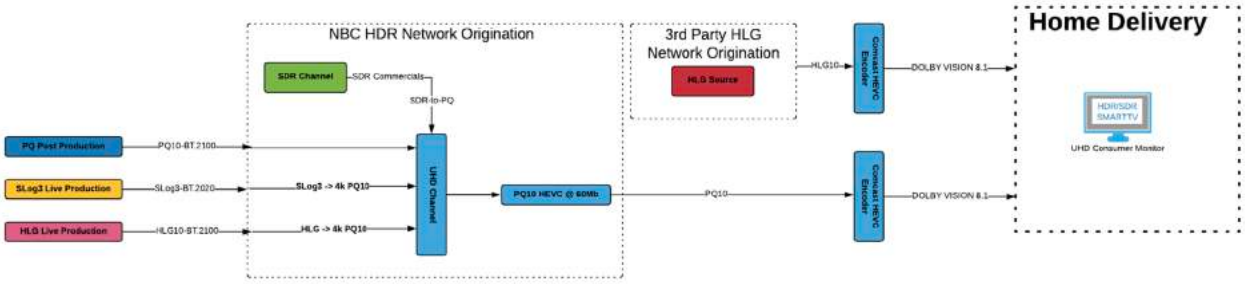

**Figure 14 - A simplied view of the NBCU/Comcast production through distribution in PQ**

The final distribution includes:

- Event production video: Converted from HLG/Slog3 to PQ
- Commercials: Converted from SDR to PQ
- Audio is encoded externally as Dolby ATMOS immersive audio and then embedded in the video prior to the HEVC encoder.
- Video is encoded using high efficiency video coding (HEVC) at 60-80 Mbps
- Mezzanine encode is transmitted to distribution partners (cable, satellite, and IP/OTT.).

NBCUniversal and Comcast use PQ for linear distribution because, for starters, it is the most common HDR system in-market: it's in every HDR display TV, and supported in OTT streamers like AppleTV and Roku; and, OTT providers like Netflix use it. It's used in PQ10, HDR10, HDR10+ (in each case, the "10" represents 10 bits, not the 8-bit transmissions of SDR). It can use static or dynamic color volume mapping (as mentioned earlier), which improves tone-mapping to displays with different brightness capabilities. Its conversions from other HDR formats are transparent, and normalized conversion from SDR to PQ preserves the original artistic intent.

Comcast is able to take NBCU's higher contribution rate HEVC video and re-encode it to a lower distribution rate while also adding Dolby Vision dynamic metadata to the HEVC stream. The Dolby Vision metadata provides scene or frame-based dynamic tone-mapping which provides benefits when the consumer display has different capabilities compared to the source. As televisions peak brightness

capabilities improve, the content producers may choose to improve the content as well but initially not all of the more affordable consumer displays will support the superior capabilities. Using dynamic metadata can improve tone-mapping from content to display which much of the consumer ecosystem can benefit from.

An additional benefit of mapping an HLG production to PQ for distribution is that we can take advantage of PQ's support of static or dynamic metadata for improved tone-mapping on less expensive displays that don't support luminance at or above 1,000nits. Finally, many HLG consumer displays clip above nominal video levels (100 IRE), but we can preserve levels above HLG-100IRE during the conversion because PQ supports up to 10,000nits(10x that of HLG). The IRE unit is used in the measurement of composite video signals.

In live-linear broadcast distribution, PQ, with proper shading, means that as displays get brighter, the images will remain at the original brightness unless the consumer manually changes settings. The original artistic intent is preserved and does not suffer from some other perceptual effects referenced in section 2.1 (Hunt, Stevens, etc.). Since some cinema or pre-produced content are currently shaded at levels up to 4,000 nits, relative systems like HLG, could be restrictive as displays improve. In short, for live-linear distribution, PQ's absolute mapping, combined with the productions white level anchor point, make beautiful imagery and preserves artistic intent all the way from the production to the consumers HDR display.

# 5. Conclusion

Producing and delivering HDR content for live linear workflows, like sports, is considerably more complex than it is for most file-based, VOD-styled approaches, which have post production resources that simply don't exist for live, on-the-fly material. Live productions must handle graphics, color correction, and luminance normalization in real-time, across what is usually a mix of SDR (which is essentially contemporary HDTV) and HDR cameras.

This paper details differences in system colorimetry which exist within the primary HDR systems, and specifically HLG) and PQ. It describes functional workflows for live delivery, including what are multiple levels of conversion for various signals throughout the infrastructure -- like graphics, video playback, SDR and native HDR cameras.

It has covered how format conversion and perceptual measurement work for HDR and SDR productions, how HDR production workflows are orchestrated for live content, and how those live linear workflows are distributed in PQ. Most contemporary broadcasters and cable providers are following a similar, if not identical, path: Producing in HLG or other camera-logs and distributing in PQ.

This paper also explained what it takes to build a functional, single-stream HDR-SDR workflow, at each stage of the pipeline, without compromising the artistic intent or quality of the distribution paths for either the HDR or the primary SDR feeds. In-depth research of color conversions were discussed and explored, as well as production layouts.

Finally, distribution requirements, delivery infrastructure and technical specifications were described and explored. In particular, we described why production environments tend to prefer to use the HLG transfer function, while distribution functions favor PQ.

## List of Figures

# Introduction

Virtualization delivers efficiencies and creates new capabilities, while expanding the network cloud and blurring boundaries at the network edge. In the initial wave of virtualized functions and appliances, demonstrating that software-based infrastructure could be as robust as its hardware equivalent has been a paramount concern. Recent developments in data plane acceleration technologies, including SmartNICs, are playing an important role in meeting and exceeding performance requirements. Going forward, as services expand to meet opportunities, especially in the evolving network edge, the challenge will be to narrow the gap between performance and manageability. A Next-Gen Cloud model promises to minimize those trade-offs.

# 1. Business and Technology Drivers

## 1.1. Demand for Services

For change or evolution in a network to occur, there needs to be a business reason. A prerequisite for any change is demand for services. There also needs to be technology that can make the delivery of those services more valuable and profitable. But in regard to revenue generation, the cable industry is in a relatively strong position.

Demand for high-speed data remains strong. Since March 2020, subscribers have especially taken advantage of the upstream capabilities of DOCSIS networks. The industry's flexible content delivery networks (CDNs) are an attractive platform for businesses seeking to deliver automated and targeted advertising. Cable's telephony business has declined, as have all landline offerings, but the industry's MVNO business is up. There is also a growing opportunity to work with mobile operators on backhaul, mid-haul and fronthaul (Xhaul), as smaller cells proliferate in the 5G/LTE-A transition. MSOs continue to build their business services portfolio, both in the SMB market and beyond.

## 1.2. Edge Computing/IoT Opportunities

Among those existing services, perhaps the work being done in CDNs (manifest manipulation, formatting, encryption, etc.) is the leading example of computing at the network edge today. But at the intersection of wireless, consumer and B2B, new applications involving mobile and IoT devices that need similar services are emerging across numerous verticals. A few examples include:

- Cloud gaming – A billion-dollar industry that has grown during the pandemic, cloud gaming benefits from low latency associated with edge-computing; in effect, it "needs an edge."[1]
- Surveillance, mapping – Distributed network sensors from security cameras, drones and IoT devices drive massive volumes of traffic across constrained wireless networks; one opportunity is for more integrated and AI-driven management.[2]
- Health care – From medical-grade wearables to RFID tags in hospital inventories, IoT is playing a key role in today's increasing digital healthcare system; it needs secure, robust connectivity.
- Smart cities – Municipalities aiming to deploy outdoor Industrial (I)IoT systems that connect remote sensors to network servers could leverage vast HFC networks.[3] From automated traffic lights to self-driving vehicles, what's needed is very low latency and very high reliability.
- Augmented reality – Related to gaming, AR applications are also playing a role in business and industrial settings; like other examples, it could benefit from low-latency and AI.

Cable executives see potential in several of these and other categories. But according to a survey conducted by Broadband Success Partners, they face obstacles, including a lack of operational support for

monetization and the existing network itself. When asked what is most needed to make edge computing happen, they have one leading answer: “Network infrastructure (physical and virtual) that is programmable and provides network performance information.”[4]

### 1.3. Technology Evolves, Virtualizes

The industry’s technology leaders have adeptly exploited the capabilities of the HFC plant with iterative versions of DOCSIS, while anticipating areas of growth, such as the need to meet demands on the upstream or low-latency requirements for Xhaul and other emerging services.[5][6]

Some MSOs have also begun to adopt cloud computing and virtualization, seizing opportunities for efficiency, innovation, lower OpEx, automation, improved management, elasticity and scale. The use cases involve program guides/UIs, CPE devices, CDN and most notably the CMTS/CCAP. In new cases following the distributed access architecture (DAA), the virtualized (v)CMTS is not only disaggregated, but its core software is loaded onto x86 servers and compute power deployed on remote PHY devices (RPDs) in the last mile.

The DAA initiative was driven less by new market opportunities than the need to manage costs, especially those involving power and headend/hub real estate. The goal has been to grow without launching a massive rebuild or upgrade cycle; in other words, to keep cost per bits stable while meeting escalating demand and maintaining stringent service performance requirements.

At the same time, the vCMTS has opportunities at the network edge. Here, again, the industry is being proactive.[7] One relevant trend is the move away from scale-out homogenous servers using x86 CPUs only, to scale-out heterogenous services that include x86 CPUs, as well as graphics processing units (GPUs), field-programmable gate arrays (FPGAs), and other elements.[8]

As usual, prospects arrive with additional challenges. Delivering services over virtualized and software-driven infrastructure within tight performance and cost parameters is no small feat. But there are other requirements to consider, such as agility, network scalability, security, operational support, product lifecycle and overall management capability.

## 2. The Virtualization Story

### 2.1. IT Legacy

Network virtualization is far from a new technology. The idea of a virtual machine (VM) goes back at least to the mid-1970s.[9] Two decades later, in the tech boom of the late 1990s, the time was right to focus on software that acted like a real computer with an OS, separate from underlying hardware. The first product of VMware, founded in that era, was a hosted hypervisor, which enabled users to set up and maintain VMs on a single physical machine.

This market primarily focused on IT, on business-critical applications such as data base systems and Web applications. The emergence of the Network Functions Virtualization (NFV) initiative in 2012 shifted attention to areas such as routing, firewalls and load balancing, all workloads requiring much higher packet rates and much lower packet loss rates. In the case of VMware, these requirements led to a “re-architecture” of the entire networking stack, from the virtualized network interface controller (vNIC) emulation to virtual switching in the device driver.[10] As it happens, there were ongoing industry initiatives collaboration to support such efforts.

### 2.2. DPDK and Fast Packet Processing

The Data Plane Development Kit (DPDK), founded in 2010 by Intel, became an important resource. Made available under an open source license, DPDK was created to be a "vendor-neutral software platform for enabling fast packet processing, upon which users can build and run data plane applications."[11] The open source community at DPDK.org launched in 2013, and the initiative went under Linux Foundation management in 2017. Alternatives to DPDK are available; according to software development community StackShare, they include Beats, Riemann, LibreNMS, PRTG and Nagios XI .

For its part, the DPDK and its resources, which include libraries and drivers to implement network functions in commodity servers with commodity NICs, have driven industry-wide data-plane efficiencies. Partly inspired by DPDK techniques, VMware built and released an initial enhanced networking stack (ENS) that delivered a packet forwarding rate, in 64-byte packets, with 4 times greater efficiency, while maintaining a packet loss rate of less than 0.001 percent. Since then, performance has continued to improve.

### 2.3. Architectural Considerations

Other developments impacted the landscape. At the OS-level, virtualization enabled the delivery of resource-efficient software in packages called containers, which are associated with a release by Docker in 2013. Soon thereafter came an open-source container orchestration system known as Kubernetes, designed by Google and now maintained by the Cloud Native Computing Foundation (CNCF). While often pitted against each other, these approaches can all coexist. The latest VMware platform, for instance, allows using any combination of VMs and containers.

At the system level, disaggregated functions mean that control, data and management planes can be deployed across a distributed topology. Where to place what, however, follows basic rules. Because of inherent low latency and advances in processing, edge clouds offer performance advantages for data plane-intensive workloads; while control and management plane components (to the extent that they figure within a virtualized infrastructure) can be centralized with regional and global scope.

One example is distributing compute and virtualization via Flexible MAC Architecture (FMA), a CableLabs initiative. FMA provides the flexibility to place the MAC or compute portion of the CCAP anywhere from the DataCenter to Headend/Hub or in the outside cable plant. The FMA enables placement of the MAC of such a data-plane intensive workload closer to the Edge to address low-latency applications like AR/VR, gaming, or autonomous vehicles and centralize other functions like control and management plane. Such a flexible edge computing model enables smooth integration with wireless.

## 3. MSO Options

### 3.1. Legacy Appliance-based

The cable industry has several options regarding virtualization. Whether involving routers, CDNs, firewalls, CMTS/CCAP or other equipment, MSOs can expand their infrastructure as needed via standard appliance-based solutions. This largely status-quo approach, even with disaggregation, poses continued challenges to scaling and incurs operational costs and complexities.

### 3.2. Virtualization – Evolved on Bare Metal

Virtualizing on bare metal, i.e. on a single-tenant physical server, can deliver certain benefits, including performance and resource utilization; although challenges remain across a number of areas, including scalability, data persistence, networking, security, and management/operations.

### 3.3. Native on Hypervisor

This second road to virtualization enables a unified, converged architecture, with the benefits of higher availability, densification, scale, multi-tenancy and greater manageability. This "Next-Gen Cloud" approach also enables greater agility. Both virtualization approaches entail breaking with legacy models and acquiring new areas of expertise.

## 4. Next Gen Cloud

To expand upon the third option above, the Next-Gen Cloud, let's consider its platform architecture, benefits and values.

### 4.1. Next-Gen Architecture

The Next-Gen Cloud schematically rests upon a standard Network Functions Virtualization Infrastructure (NFVI) and Cloud-Native Network Functions (CNF) infrastructure. (See Figure 1.) Above that is the Virtualized Infrastructure Management (VIM) layer, which enables handling containers and related infrastructure "as a service" (IaaS, CaaS). The Virtualization layer provides resource abstraction for computing, networking, and storage and gives the same experience across VMs and containers.

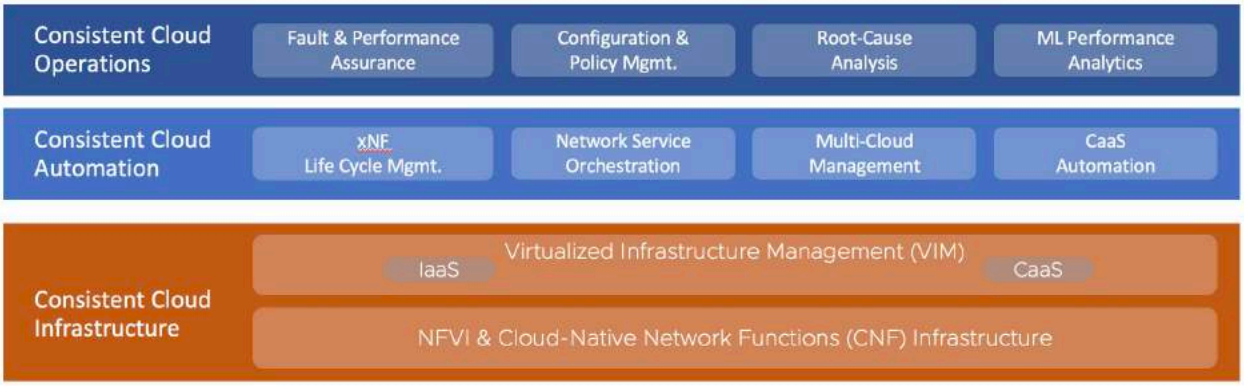

**Figure 1 – Next-Gen Cloud Architecture**

Cloud automation and operations reside above the infrastructure. Cloud Automation provides multi-layer automation for consistent operations across any network from the core to the edge to the access. Cloud automation enables smooth management and orchestration of the infrastructure layer and automates network functions' placement and lifecycle management over VM- and container-based infrastructure. Cloud Operations provides real-time assurance designed to simplify your network operations through holistic monitoring and performance management, providing comprehensive visibility and automation. Cloud operations in a virtual environment can integrate with existing NetOps tools and data, but they also enable cloud-native ways of fulfilling functions in the areas of fault and performance assurance, configuration and policy management, root-cause analysis (RCA), and machine-learning (ML) analytics.

None of these technologies work without revenue generation and/or positive ROI. Conceptually, at the top of the stack lie a wide range of monetization opportunities; and embedded within the stack are tremendous cost savings and management efficiencies.

## 4.2. Next-Gen Benefits

The benefits of this approach derive from the interplay of the platform's capabilities and performance in these areas:

Scalability – Orchestration enables elastic scaling of cable workloads, while consistent dimensioning and improved hardware utilization reduces space and power required in headend and hubs. The platform brings uniformity while maintaining security, networking and monitoring requirements.

Operational Efficiency – Having a common platform enables deployment and management of multiple Kubernetes clusters, along with VMs. Sophisticated software, which leads to fully automated services, compares favorably to an inefficient and complicated manual process of managing physical storage devices and using SNMP for monitoring to the NOC. It also provides a consistent experience with a simplified life-cycle management.

Faster Time to Market – This kind of platform allows MSOs to respond quickly to emerging edge compute and other opportunities through an extensive, multi-vendor partner ecosystem, as well as integrated service blueprinting, deployment, monitoring and management.

Workforce Efficiency – Remote deployment and high-performance, self-healing capabilities can reduce truck rolls and the need for on-site service technicians, whether in the access plant, hubs, headends or data centers.

Reduced TCO – Lower CapEx results from increased throughput and performance; reduced OpEx, from software-driven infrastructure and service assurance.

Safe and Easy Convergence – Consistent infrastructure, automation and operations enable easy convergence, with reduced risk of misconfiguration; hybrid VM and container-based applications feature advanced networking and security features.

## 4.3. Next-Gen Capabilities

Agility. With a hypervisor, a new bare-metal server can connect to the container domain in minutes. That agility is one of the reasons that major public cloud providers use hypervisors to run their container services. Such agility and scalability work because the hypervisor de-couples and abstracts software from the hardware. The Next-Gen Cloud delivers over-subscription capability, improving utilization of the underlying hardware. This compares favorably to the standard practice of racking and stacking, re-segmenting the network and then testing that the segmentation was correct.

Networking. The Next-Gen Cloud implements a single underlay network on VMs to provide end-to-end connectivity and management for both containers and traditional applications. A single underlay network makes it easier to connect containerized applications to traditional, non-containerized components like databases; simplifies network management with centralized policies and advanced security; and enables selecting the overlay network and the service mesh that works best for containerized applications.

Security. Containers and hardware virtualization not only can, but very frequently do coexist and actually enhance each other's capabilities. VMs provide strong isolation, OS automation and an ecosystem

of solutions. They enable secure and efficient running of containerized applications in production. Containers being run on hypervisors can take advantage of security innovations, including micro-segmentation, which enables security architects to apply security controls and deliver services at the individual workload level.

Manageability. A comprehensive, flexible platform allows you to deploy and manage multiple Kubernetes clusters as well as to manage, patch and upgrade the container host OS. All these capabilities empower you to run traditional and containerized workloads on a common infrastructure, while ensuring optimal performance and preventing interference between workloads.

Performance. Empowered by vSwitch and Workload Acceleration functions, the Next-Gen cloud's hypervisor can provide more efficient overall workload performance for containers than Linux systems running on physical hardware. The platform uses advanced scheduling algorithms that enable employing modern DPDK packet processing, allocating CPU cycles for efficient networking, and faster packet processing to optimize all workloads. The Next-Gen cloud also employs hardware offloading techniques to dedicate all the compute for workloads and can leverage SmartNIC for infrastructure computing.

# 5. Data Plane Acceleration

## 5.1. Performance and Tradeoffs

To look more closely into performance, let's first set the stage. Workloads in service provider solutions involve the control and signaling plane, the data plane, and the management plane. A network element (NE) traditionally was built to handle control and data plane functions in one box, with its own element management system (EMS). With the arrival of SDN, the data and control planes began to separate. Then with NFV, multiple functions within each NE were broken into multiple VNFs, providing service providers with choice, enabling best-of-breed solutions with more software-based control.

Of the three workloads, those on the data plane need to meet the most stringent requirements. (When the data plane is lost, the subscriber notices.) These demands led to the development of software accelerators that put applications needing fast packet processing in the 'fastpath' of a compute host. Management and low-priority applications could go via 'slowpath.' Yet the arrival of virtualization made it difficult to attain expected performance levels, because the hardware used was based upon commercial off-the-shelf (COTS) servers.

To be sure, virtualization correctly done continued to have significant benefits, primarily: those derived from the secure pooling of networking resources across multiple hardware units. A virtualization layer with a virtual distributed switch that spans multiple hosts (servers) can live-migrate workloads and efficiently distribute resources on demand. To gain performance, service providers used two techniques: single root I/O virtualization (SR-IOV), a concept introduced by Intel that allows for bypassing the virtualization layer when it relates to the data path; and DirectPath I/O, which allows for direct access to a physical NIC.

These techniques enabled faster packet processing but came at the expense of not being able to use a wide range of critical features, all provided by the best-in-class virtual infrastructure. Applications built for these pass-through mechanisms also faced security and cloud-ready challenges. Another technique that gained popularity was CPU pinning, which led to locked-in hardware, driving up CapEx and OpEx costs.

Among the tools enabled by the DPDK initiative was a software library that helped enhance performance by allowing for optimized packet allocation across DRAM channels. The principle being that allocation of memory from local nodes and cache-alignment of objects can lead to superior performance. The upshot

 

of these developments was an accelerated vSwitch, now a key to the Next-Gen Cloud model, which overcomes the drawbacks of SR-IO and DirectPath I/O and obviates the need for other techniques, such as CPU pinning.

## 5.2. Two Data-Plane Acceleration Options

With that background, we can now consider two data-plane acceleration approaches, both involving PCIe NIC devices. The first involves offloading with a standard Performance NIC; and the second, doing so with SmartNIC. Both cases use an x86 host server and the accelerated vSwitch, which supports two configuration modes: Standard, for use with any management or control-plane application; and Enhanced, for use with data-plane intensive applications. In the first approach, the vSwitch is running on the hypervisor, and in the second, it has been offloaded onto the SmartNIC and can leverage separate embedded NIC cores. (See Figure 2 and Figure 3.)

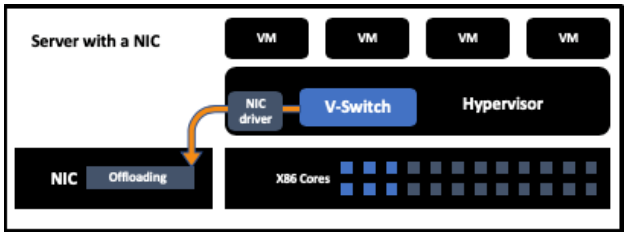

**Figure 2 – Performance NIC Architecture**

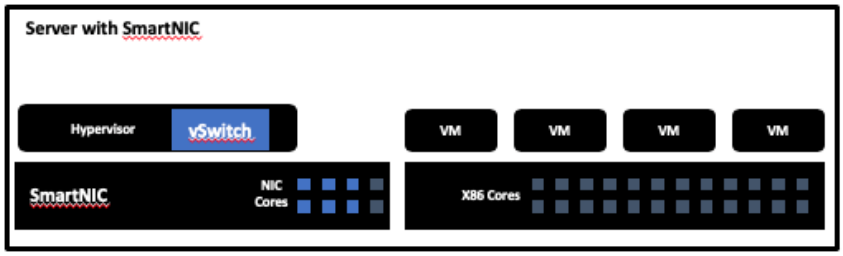

**Figure 3 – SmartNIC Architecture**

### *5.2.1. Acceleration with Performance NIC*

Operators have several ways to boost performance, not only in the software realm. We will point out five areas. (See Figure 4.) Let's begin with decisions involving hardware elements:

(1) NIC choice – To meet 10G requirements, first choose Performance NICs with TCP Segmentation Offload (TSO) and Checksum Offload (CSUM) capabilities, as well as overlay support.

(2) CPU Choice – Devote a high number of cores for workloads and find the right balance between CPU speed, core count and wattage requirements.

(3) Server architecture – Increased performance is a function of the NUMA balance, choice of the right PCIe and server architecture. Another key consideration is server immutability, in which servers are never modified after being deployed.

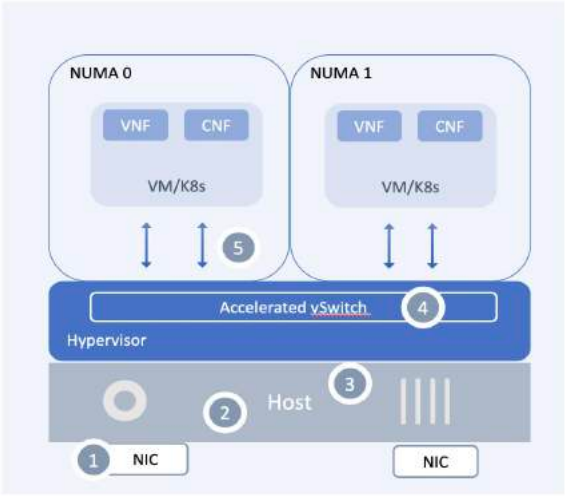

**Figure 4 – Acceleration with Performance NIC**

With the right mix of hardware, performance can be further enhanced through strategic choices in software implementation (enabled by Next-Gen cloud):

(4) vSwitch Acceleration – Based on Intel DPDK principles, an accelerated vSwitch provides very high throughput, low latency, low jitter, near zero-packet loss, characteristics that are essential to run data plane-intensive workloads, whether at the Core, the Edge or the Access. The accelerated vSwitch achieves higher packet performance by freeing the network to work on any server or modern NIC; dedicating CPU cycles for networking; and deploying faster switching with flow cache, lockless datapath and faster packet processing (SSE). The vSwitch forwards traffic between components running on the transport node (between VMs/VNFs or between containers) or between internal components and the physical network.

(5) Workload acceleration – Other options include using an accelerated vNIC, dedicating (pinned and isolated) vCPUs; topology awareness, and Huge Pages support.

Powered by the accelerated vSwitch and an accelerated workload with the right combination of NIC, CPU and server hardware, this approach can handle the various workloads in use today. VNFs in all types of form factors – whether VMs, containers, or micro services – can run on this kind of enhanced solution. Being agnostic to the application, the vSwitch provides operators with the 'freedom of choice' to pick any VNF that would meet the solution needs.

### *5.2.2. Performance NIC Test Results*

Tests of Performance NICs, which can flag latency- and jitter-sensitive applications and choose selective vCPU pinning, generated results well within acceptable parameters. In a traffic stream starting and terminating with Spirent TestCenter software, with latency that included both transmission delay introduced in forward and reverse paths as well as software processing times, the average latency contributed by virtualization functions amounted to less than 30 microseconds; for jitter, less than 10 microseconds. Both are negligible amounts. When testing throughput of varying packet sizes, the actual throughput approximated the line rate, with a representative bundle of video-heavy packets generating a speed of 3.98 Mpps and 4.5 Mpps, respectively, for 3- and 4-core implementations.

### 5.2.3. SmartNIC

There is a growing consensus that CPU cores are such a precious commodity that they should never do network, storage, or hypervisor housekeeping work, but rather focus on core computation. That means network offloads and storage offloads need to be mainstream in the coming years, creating an even more asymmetric and heterogeneous processing environment than many are envisioning down the road. Throwing more and more compute at the problem is unsustainable. The goal is to iterate fast, but I/O processing is unable to keep pace with compute processing. SmartNICs enable offloading all or most of a virtual switching stack or a large chunk of a distributed storage stack.

A SmartNIC is a high-performance NIC, equipped with general-purpose compute cores capable of running an OS and general-purpose applications and workloads. It is both a NIC, with flow-match hardware capabilities, and a mini server. In architectural terms, its purpose is to move server management to SmartNIC cores and offload the entire vSwitch/hypervisor. As a result, the host x86 remains dedicated to workloads, increasing its efficiency. The host x86 can run either a VM/container or a bare-metal.

One of the big reasons to use a SmartNIC is not only to save CPU resources, but to scale in different ways, for instance by saving power and space. Offloading the heavy compute enables an operator to free up the CPU for others things, such as multi-access edge computing (MEC) in 5G. Another key to a full CPU offload is the potential to implement policy and priorities straight on the input, without having to use the OS at all, which makes for a powerful story.

Other benefits include a clear-cut between infrastructure and application, air-gap security, cost management, application acceleration (e.g. security, load balancers, etc.). In organizational terms, the SmartNIC clearly splits ownership and enables multi-tenancy. (See Figure 5.) SmartNICs are positioned to handle workloads that are scaling to meet 10G requirements.

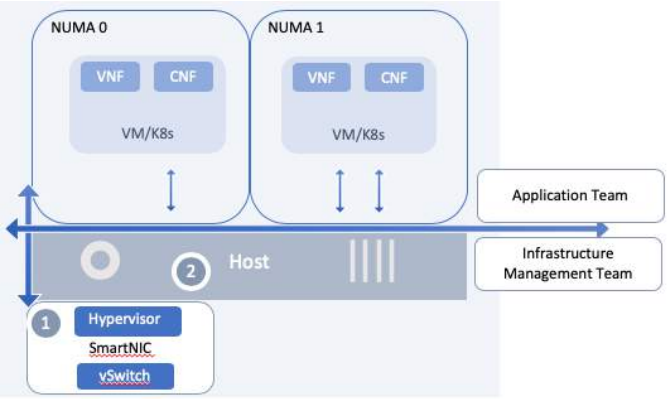

**Figure 5 – Acceleration with SmartNIC**

Because SmartNICs come equipped with onboard local persistent storage, a large amount of DDR RAM, multi-level caches, PCIe root complex, virtualized device functions and I/O capabilities, they have significant potential for use cases that extend beyond network acceleration and vSwitch offloads. Those cases could include but are not limited to management plane offload and virtual device acceleration.

## 6. Next-Gen Cloud Reference Architecture

The reference architecture for Next-Gen Cloud includes five tiers: from physical infrastructure to VM and container-based platforms to resource orchestration to cloud automation to solutions. (See Figure 6.) On

the solutions tier, the vCMTS is only one of many, which also include L2/L3 solutions, SD-WAN and various video-centric services. Being extensible to emerging solutions and business models is one of the most compelling attributes of the Next-Gen Cloud.

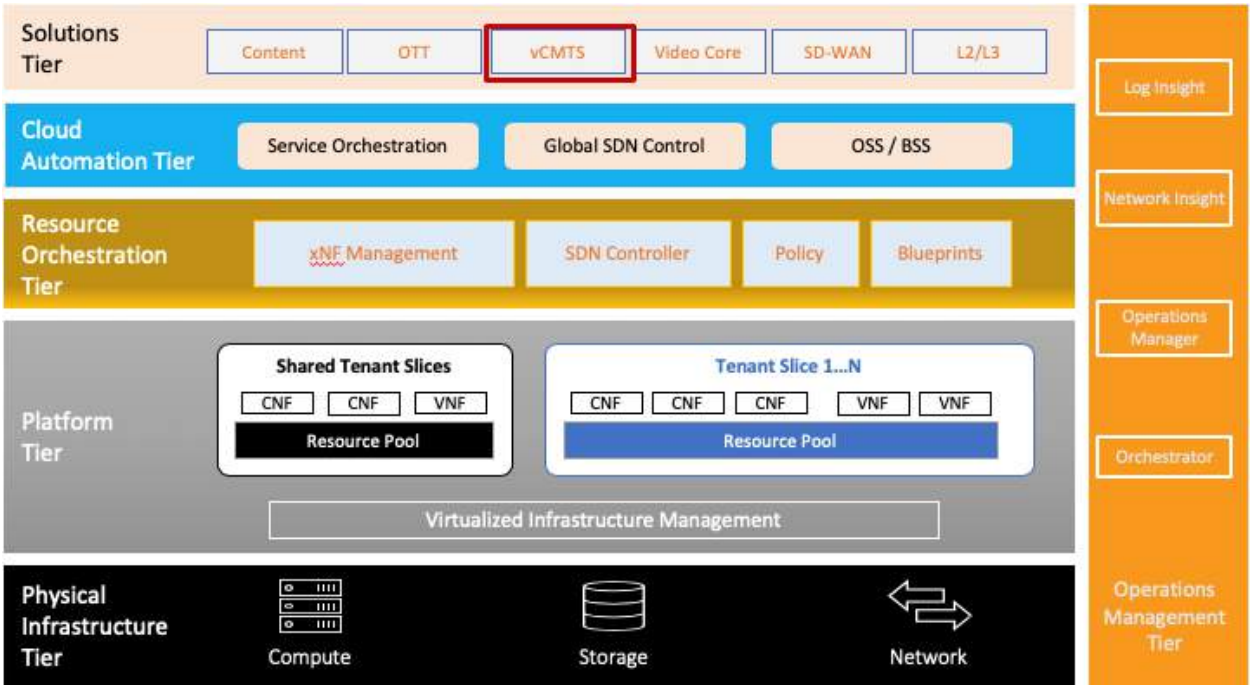

**Figure 6 – Next-Gen Cloud Reference Architecture**

Moving from that top tier down the stack, we note that it features centralized control and management, including embedded automation and optimization. Its highly flexible infrastructure as code (IAC) model is characterized by a heterogenous runtime with Network Function and Resource Isolation. Finally, it rests upon commodity hardware and storage and leverages vertically integrated

## 7. vCMTS Use Case

Compared to the mobile industry, where NFV has proved to be effective in 4G LTE production deployments and has become the basis for building 5G networks across extensive footprints, virtualization in the cable industry has taken a more gradual and piecemeal approach. The initial deployments of the vCMTS occurred after MSOs assessed different approaches to DAA and enhancements to DOCSIS. It is beyond our scope to assess those ongoing rollouts, but it is noteworthy that one summary practical lessons from a DAA deployment with a vCMTS last expressed concerns at the operational and management layer, in particular the need for tools.[12]

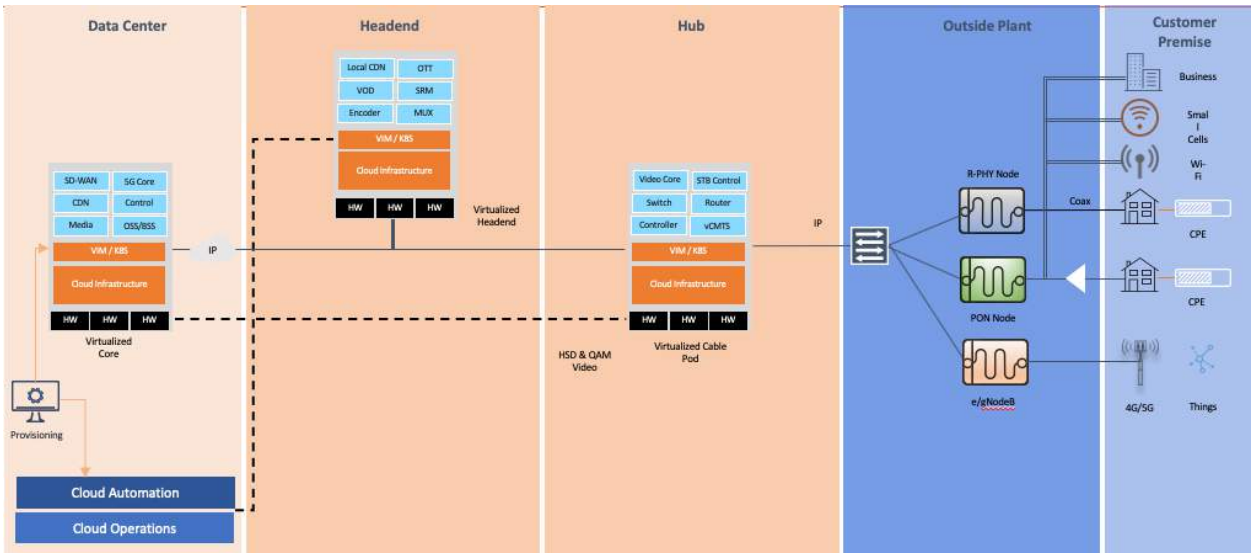

**Figure 7 – Scale and Convergence in Next-Gen Cable Cloud**

If manageability is an issue with the current vCMTS model, in which the R-PHY node is the only element in the outside plant, will it not become more so if and when MSOs deploy virtualized PON nodes and eNodeB devices? (See Figure 7.) Moreover, in addition to services delivered to residential CPE endpoints, those involving enterprises, small cells, Wi-Fi, 4G/5G and the proliferating number of edge compute business cases also need to be managed. Conducting efficient root-cause analysis over a network with no centralized control and integrated operations management is just one challenge we could mention.

On the other hand, with Next-Gen Cloud model, there is ongoing innovation in management, automation and OSS. Virtualization changes the way we can set up, handle faults, share resources, and more.

## Conclusion

Growing demand for connectivity, compute and storage at the network edge is an exciting prospect for MSOs shifting to a distributed and virtualized network infrastructure model. Advanced data plane acceleration that can drive high performance over software-based infrastructure is also an encouraging development. Less exciting is the prospect of building more operational siloes to handle a growing menu of use cases and services, which defeats one of the fundamental reasons for the drive toward virtualization in the first place: "the principle that it is no longer necessary to solve for the platform and runtime layer below network applications in a different and particular way for each additional application – with all of the attracted cost, complexity, and operational management overhead that differentiation implies."[13]

# Table of Contents

# 1. Introduction

Saturation of traditional markets is forcing ISPs to evaluate new strategies to drive revenues while continuing to deliver a superb user experience and improve returns on capital. Differentiating service offerings is critical to achieving these goals. Commodity connectivity doesn't always motivate subscribers to stay with a service or offer any incentive to pay more for it. Subscriber-facing services that enhance loyalty and increase "stickiness" can help.

Providing managed services and moving up the stack can find a receptive audience amongst business customers. Properly targeted value-add subscriber services can increase ARPU and differentiation and improve retention. But mitigating the costs of this specialty care will drive the use of more efficient, deployment solutions. One of the challenges delivering subscriber services is controlling costs to maintain margins in a world where specialized staff to oversee service deployment and operation are costly and difficult to find. Cloud services deserve consideration to reconcile these conflicting objectives

Cloud services can help contain costs and improve service agility (time to market). They've become mainstream for enterprises, but ISP service enablement in the cloud is a different proposition than typical enterprise IT applications. This paper will offer perspectives from the developer of a cloud service that enables ISPs to deliver security protections for businesses.

# 2. On the Path to Cloud

Starting in early 2013 a team at Nominum (acquired by Akamai in 2017) started down the path of building a cloud-based security service offering for ISPs. The security service consisted of DNS resolvers and a platform that supported functions such as gathering data, distributing policies, and supporting a portal. As with most development projects there was an evolution with several early, admittedly highly tactical, initial steps.

The first effort was to deploy the software components using the services of a public cloud provider. It was activated at a security conference to provide production DNS resolution (rDNS) services on an open network. Integration of dynamic threat intelligence identified devices with bot infections and there was a portal available for attendees to check their status.

Learnings from this pre-proof of concept led to deployments to support customer pilots of the security service. At the time, getting pilots running at ISPs involved lengthy engagements to get equipment and technician/administrator time in labs. Running these early solutions in the public cloud bypassed this time and materials bottleneck and permitted a faster time to market metric.

Some of the pilots in the public cloud were opened up to run limited production network traffic, so the next logical step was to run more scaled production workloads. The first foray was to support a customer who needed a network protection service immediately but had to contend with a 90 day window to procure and provision hardware in their network to support it. Successful execution of this service in the cloud provided validation and the process of formalizing the service began. All of the early experiments yielded useful insights that fed specifications for development teams ongoing work. Migrating functions to the cloud not only yielded efficiency from the network provider, it also removed the need for the IT team to procure, install and manage the servers and apps attendant to those functions.

## 3. Service Considerations

The first step for the product and development teams was agreeing on the parameters of the "service". The following sections highlight the primary service considerations.

## 4. Data Plane versus Control Plane

Security is about examining network traffic to determine whether it is malicious or legitimate.

Approaches that operate in the data plane implement inline packet inspection to evaluate traffic. In the past it was possible to get visibility into most of the traffic on a network, but the predominance of encryption has introduced significant limitations. Inspecting packet traffic at line speeds has always been a costly operation, and inspecting encrypted traffic adds even more costs and operational overhead.

DNS filtering is an alternative that operates in the control plane. Incoming subscriber queries can be matched against dynamic threat intelligence provisioned in resolvers, and policies can be applied to manage unwanted traffic. The team recognized attractive scaling capabilities since there is no need for pervasive filtering of network traffic (and decryption) and it can be layered on infrastructure already deployed and managed. Threat coverage can be expanded by selectively forwarding suspicious traffic (typically domain names that point to both malicious and legitimate web resources) to proxies for further inspection. Experience has shown this is a small percentage of traffic, usually around 2%.

An obvious question given the emergence of DNS encryption standards is whether they make DNS traffic opaque to network operators. The new standards, DNS over TLS (DoT) and DNS over HTTPS (DoH) define encrypted transport for queries between stub resolvers implemented in client devices, and resolvers deployed by network operators (ISPs, MNOs, enterprises, Wi-Fi, etc.). Operators of resolvers using encrypted transports still see queries in the clear and services provided by the resolver function as they would with unencrypted transport.

## 5. Subscriber Experience

A subscriber's Internet experience is closely tied to latency. In this case DNS resolution is an important part of the solution and the network architecture called for resolvers situated at the network edge as close to subscribers as possible to minimize transit delay. They were dimensioned to align expected subscriber densities with resolver performance (queries per second) to rightsized capacity.

Experience with resolution infrastructure at more than 100 large ISPs worldwide for nearly 20 years showed in today's fixed networks (2020) a subscriber account can generate 10,000 queries per day. Growth has averaged about 20% per year. This provided metrics for sizing subscriber demands on resolvers, and along with a best practice targeting QPS performance at 50% CPU capacity to minimize latency under load, and 5X headroom for growth yielded necessary resolver capacity.

Services that can be customized have more potential to actively engage customers and provide an incentive to remain loyal since they've made an investment in configuring the service to meet their unique requirements. A natural extension of filtering to prevent malicious activity is customer defined filters to block unwanted content for families (parental controls) or businesses (Acceptable Use Policies).

A portal user interface is the subscribers window into their household security posture and another contributor to satisfaction with the service and thus value. Key words for the UI team were "rich, relevant, simple, comprehensible". Menus define web filters and integrated device management capabilities

simplify configuration of user/device specific profiles through device discovery, registration, and pairing functions. Reports display Internet usage and security threats deterred. Scaling, especially with personalization, introduced complexity in the portal infrastructure. Underlying cloud services had to support secure access to millions of unique portal instances, as well as distribution of policy/preferences in near real-time to instantiate subscriber preferences, and collection of data to populate displays for each subscriber.

## 6. Security and Privacy

The team recognized concerns about security have been an inhibitor for adoption of cloud services and designed layers of defenses to protect the different components of the service. Portals for both administrative functions controlled by the ISP (discussed below), and subscriber-facing functions are protected with each providers Identity and Access Management system. A Web Application Firewall (WAF) protects server and user side APIs (discussed below). Perimeter defenses add another layer of protection.

Privacy is a dominant issue virtually everywhere in the world today and especially in developed countries. Privacy regulations in many parts of the world such as the EU General Data Protection Regulations (GDPR) define frameworks for the permissible collection and management of personal data. Security services and similar services like content filtering are subject to privacy regulations and the development team established several overriding principles followed in the design of the system:

- Only data that is necessary to operate the service, and provide reports covering its operation to subscribers, is processed. Data is not retained longer than necessary for any purpose.
- Data is pseudonymized where possible (e.g. subscriber IPs) in ways that render it impossible/impractical for a 3rd party to compromise subscriber privacy.
- Subscribers can guide processing of their personal data by expressing their preferences in an online portal. They can see the results of filtering (processing) at any time.

Additional data governance considerations motivated the definition of data processing and retention policies. Software built into the components of the service encrypts data in motion. AWS Elastic Block Storage (EBS) encrypts data at rest so the whole partition is encrypted. Further, data in many cases data had to be stored and processed in the country where it was collected (data residency) so in-region cloud services are used. Providers access to all of their data at all times on a real time basis was built into the system. A function was also added that allows providers to zero out their data on demand.

End user requests about their data are currently handled by customer Service Representatives (CSRs) and forwarded to support channels. Data is also available in the system for provider operations teams to integrate with in-house systems to automate this function.

## 7. Integration into Provider Systems

Cloud services simplify deployment of ISP services by off-loading functions that providers would otherwise have to install and maintain in their networks. Integration with provider systems is still required to:

- Provision Subscriber identifiers, typically within an abstract subscriber ID that’s not tied to an identifier that might change (like an IP address or MAC address) and that does not reveal Personally Identifiable Information (PII)

 

- Make policy changes requested by subscribers through a customer service representative (CSR) or self-service by the subscriber too
- Manage IP address updates in real time through RADIUS messages or DHCP logs. This is necessary due to the decision to allow subscribers to configure their unique content filtering preferences. Their policies have to follow them through address changes.
- Support SSO to allow for integration with subscriber and applications portals for CSR (these portals are described below
- Connect to data collection and management systems. There's considerable built in flexibility to stream protocol and service logs to a central repository to support internal data collection and reporting functions for:
    - Customer support
    - Service adoption
    - Service utilization
- Enable functions required by BSS such as reporting on service adoption

## 8. Cloud Considerations

In early 2017 the initial cloud release was ready for production networks. At a high level there were 4 major components to the service to support in the cloud: DNS resolution, data transport, policy management, and subscriber and operator interfaces. Teams first explored how to scale the service in the cloud for daily usage patterns and peak events while accommodating growth in demand. Established metrics for the resolution component, discussed above, were extrapolated to build out the other components of the system.

Given the criticality of availability/reliability with respect to user experience a decision was made to deploy a single stack for each provider, versus taking advantage of potential gains from multi-tenancy (although these were never really measured so it's not clear they exist for this kind of service). Isolation has numerous positive implications, one customer can't take down the service, performance is more predictable, there's less data/privacy exposure and data can be repatriated. For resilience the service is deployed in fully redundant stacks in two different public cloud regions. A single region or service will not create an outage.

A Service Level Agreement tracks average availability on a monthly basis from telemetry data available through administrative service interfaces. Service credits are calculated when outages exceed an availability baseline.

The service was also designed so providers could deploy some components in their own networks in a hybrid configuration, or deploy the whole stack.

## 9. APIs

Early production deployments of the cloud service quickly highlighted features and functions that were necessary and not yet implemented. APIs rose to the top as essential. Provisioning interfaces were needed to integrate with provider operational processes and systems. Two provisioning APIs were created, one an abstraction and one low level. AWS APIs were a source of inspiration and insights for the development teams and used as the model for their efforts. Providers should hold all their cloud service vendors to a similarly high bar!

One of the provisioning APIs powered the subscriber portal so providers can build customized, purpose-built portals and match the user interface look and feel to other portals subscribers have access to. This API was beneficial from a vendor perspective as well since it reduced the burden developing differentiated features requested by individual customers.

The ability to provision subscribers/services was also exposed in this API - objects that represent subscribers and the services they have could be created. Portal authentication integrates with AAA such as RADIUS, LDAP can use SSO. A third API was created for IP to subscriber mapping using dhcp log scraping, radius accounting message ingestion or a REST API.

Several requirements were established for APIs

Proper documentation - Use swagger to generate docs in its standard format. Offer pdf docs with integration examples.

- Versioning. Enable critically important backwards compatibility for integrations.
- Simple API calls. Make heavy use of abstraction to minimize complexity.
- Read (GET) calls. Verify subscribers are properly provisioned in scaled, high throughput installations.

## 10. Customer Support and Operations

Customer support functions typically take advantage of APIs for subscriber provisioning and IP tracking, supplemented with logging information gathered by the service. A portal was designed to allow CSRs to look up subscribers, and their configuration (IP addresses, policies) as well as when they last generated traffic with the service. A pre-built portal was created, and APIs can be used to create a custom portal.

Another portal was created to provide global reports on the service such as Top infections, Top blocks, and service adoption. This reporting data can also be integrated with BSS or other custom interfaces used by a provider. Access to both portals is controlled with RBAC and can be integrated with an external directory such as LDAP.

## 11. Summary

Value-add subscriber services are becoming more strategic as ISPs look for new ways to grow revenues. Controlling costs for service enablement is essential, and reducing time to market is increasingly mandated, even as it’s harder to find and retain specialized staff, and rigid processes to deploy new functions raise costs and inhibit agility.

Widespread availability of higher broadband speeds to both enterprises and residential customers has greatly facilitated the feasibility of control or data plane, cloud-based services. When typical customer locations have access to 100Mbps of bandwidth or greater, even with conventional latency the performance is high enough to allow remote and cloud compute as part of routine communications.

For these reasons cloud services deserve consideration to reconcile these conflicting objectives. They’ve become mainstream for enterprises, but ISP service enablement in the cloud is a different proposition than typical enterprise IT applications.

Product and development teams at Akamai created a cloud based security service designed to make it easy for ISPs to target customers with a new offer. Focus and 20 years’ experience drove design considerations to:

 

- Enable the best possible subscriber experience, minimizing latency, providing a high degree of customization, and effective security with “just works” simplicity
- Build scale, availability and resilience into cloud-based components that support the service
- Ensure security and respect for privacy for the service itself, staff who operate it, and subscribers who use it
- Integrate with provider systems to automate provisioning, support monitoring, and collect data for business systems and to meet regulatory requirements

## List of Figures

# 1. Introduction

Encrypting DNS traffic has been a focus of the IETF for several years, and in late 2018 two standards were formalized for use between clients (stub resolvers) and resolvers[1]: DNS over TLS and DNS over HTTPS. Numerous implementations have appeared, and DNS encryption has become a visible topic in industry media.

It's a testament to the original design that the way the DNS operates has remained largely unchanged for more than 30 years since the protocol was originally specified. Stub resolvers on clients (typically configured from a local network with a protocol like DHCP) send queries to a caching resolver which, in turn, talks to authoritative DNS servers that provide answers to queries.

DNS encryption changes the transport protocols and, due to some design choices, opens up the possibility of significant changes in the way client devices behave. This paper discusses these changes and their potential impact on service providers. It also offers guidance about how to address encrypted DNS deployments, summarized below:

- Communicate about privacy and security practices so subscribers are aware of how their service is protected and privacy is preserved
- Implement Best Practices for DNS resolution to ensure services are performant, resilient, and always available
- Understand the new DNS encryption protocols and how they can be deployed, and participate in formulation of standards to ensure they can be scaled and operationalized
- Consider additional services that protect subscribers and further enhance their privacy by preventing loss of personal data

# 2. DNS Encryption Protocols

The DNS over TLS protocol (DoT) is specified in IETF RFC 7858. DNS over TLS uses port 853 rather than port 53 originally specified for DNS. Currently available client implementations of DoT are summarized in a table below. It's important to point out stub resolvers on user devices can also connect to "over the top" public DNS services rather than an in-network resolver provisioned by a network operator[2]. Because it uses a dedicated port, it is easy to detect DoT in network traffic, a useful characteristic for network operators and security teams.

[1] Details of the motivations for developing these new protocols can be found on the Akamai Blog: Architectural paths for evolving the DNS

[2] Public DNS resolvers have been available for many years but the advent of DNS encryption creates the perception they are more private and secure, and integration into client software makes them more accessible.

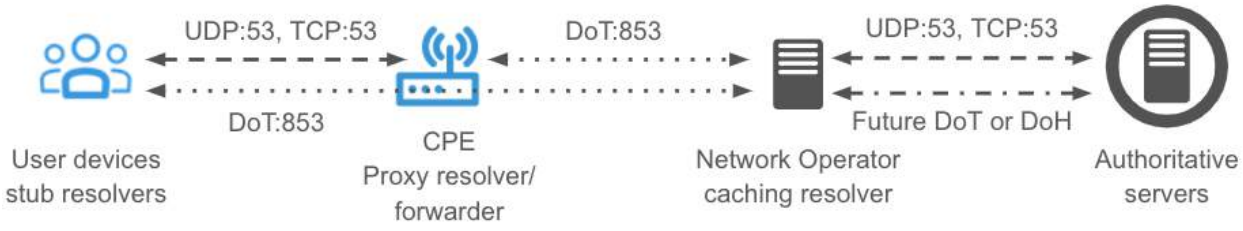

**Figure 1 – DNS over TLS defines encrypted transport between stub resolvers and resolvers using TLS**

The DNS over HTTPS protocol (DoH) is specified in IETF RFC 8484. DoH uses the same port, 443, as HTTPS. Currently available client implementations of DoH are summarized in a table below. As with DoT, user devices can connect to "over the top" public DNS services. Because it uses the same port as HTTPS, it's impossible to identify DoH in standard web traffic, which raises obvious security and operational concerns. Perhaps also obvious but worth stating, operators of DoH resolvers still see queries in the clear, regardless of the encrypted transport and services provided by the resolver function as they would with unencrypted transport.

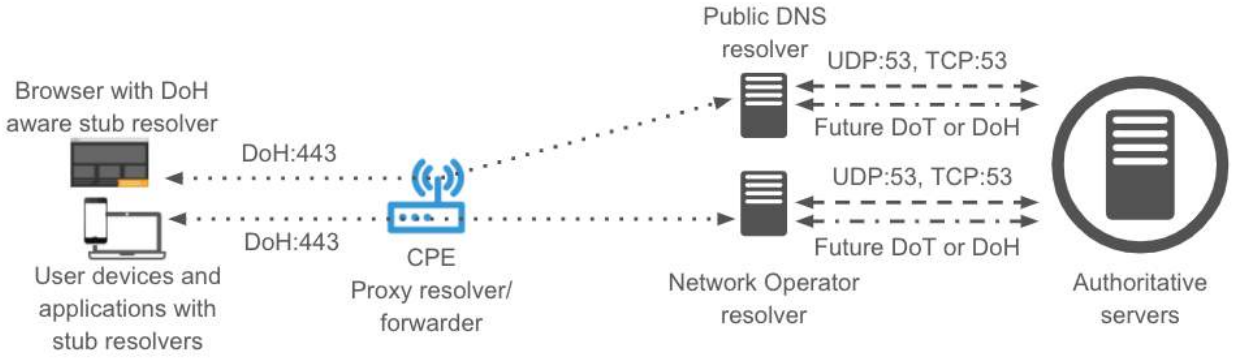

**Figure 2 – DNS over HTTPS defines encrypted transport between stub resolvers and resolvers using HTTPS**

## 3. DNS Encryption and ISPs

DNS encryption is intended to protect users from unwanted eavesdropping of DNS traffic by a third party on the path between the user and the resolver they're connected to. Most provider networks are highly secure, and it's challenging for adversaries to infiltrate them and intercept traffic. Providers in many parts of the world are also subject to data privacy regulations and/or have contractually agreed Terms of Service that spell out how they use and protect customer data.

This clouds the DNS encryption value proposition for providers. It's hard to make a business case that secure networks with defensible data protection processes and policies benefit from a layer of encryption that adds cost and complexity.

But service providers are still motivated to understand these new protocols because they may fundamentally change the way subscribers perceive DNS, and client implementations may make it easier for users to bypass provider DNS and connect to public DNS resolution services like Google and several others.

On the positive side, providers have the potential to create value added services that take advantage of DNS encryption. Technology solutions can be developed that keep business and consumer subscribers connected to encrypted DNS resolvers offered by their provider when they're off that provider's network, visiting an untrusted Wi-Fi hotspot for instance. In these cases, since their traffic is transiting untrusted networks, encryption is useful.

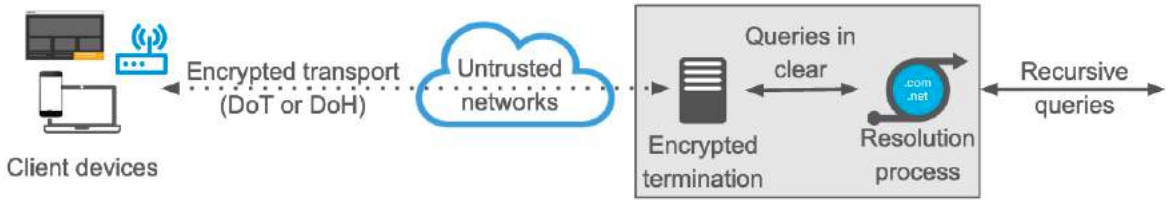

**Figure 3 – Encrypted transport termination with query processing in the clear**

Queries are de-encrypted at the transport layer and presented in the clear for resolution. As encryption between client and resolver is terminated at the providers DoH/DoT service, the DNS service can be equipped with threat intelligence and policies that identify malicious or unwanted domain names to enable security (blocking phishing and malware for subscribers) or content filtering (parental controls for families) to add more value. Integrated offers can also be created with a unified subscriber experience across both a providers network and other networks a subscriber traverses.

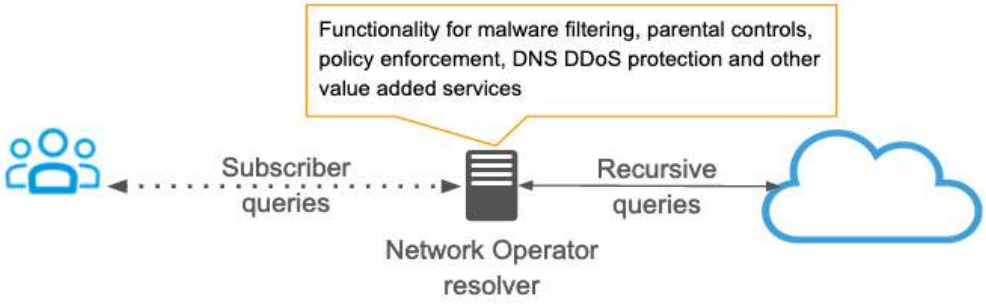

**Figure 4 – Resolvers can be equipped with threat intelligence and policy to enable security and other services**

## 4. DNS Encryption Client Implementations

Numerous client implementations of DoT and DoH are tabulated below. The client ecosystem continues to progress at rapid pace, with a broad representation of DNS Encryption capable operating systems, browsers, applications and CPEs existing today. It is expected that configuration mechanisms and awareness of local network conditions, as detailed below, will continue to evolve with ongoing standardization efforts.

**Client Feature Summary as of Q3 2020**

| | DoT | DoH | Existing Configuration Mechanisms | Awareness of local network conditions |
|---|---|---|---|---|
| **Operating Systems** | | | | |
| Android 9+ | | | Same Provider Auto Upgrade or user specified on OS config | Auto upgrade to same DNS provider, fallback to unencrypted |
| Apple iOS 14 | | | Configurable by Apps or user specified on OS/system config | Enterprise policy awareness. Fail open when auto-discovery in use. Resolver configuration specified by App is optional fallback to system specified encrypted DNS resolver |
| Apple MacOS 11 | | | Configurable by Apps or user specified on OS/system config | As above |
| Windows 10 | | | Limited Same Provider Auto Upgrade or user specified on OS/system config | User specified (Unencrypted only, encrypted only, encrypted preferred with unencrypted allowed) |
| **Browsers** | | | | |
| Firefox | | | Geo Specific Opt-Out + explicitly configured | Canary domain. Fallback to system specified DNS. Enterprise policy, safe search, parental controls detection |
| Chrome | | | Limited Same Provider Auto Upgrade + explicitly configured | Auto upgrade to same DNS provider, fallback to unencrypted. Enterprise policy, parental controls detection |
| Chromium variants | | | Limited Same Provider Auto Upgrade + explicitly configured | As above |
| **Mobile Apps** | | | | |
| 1.1.1.1 | | | Manually enabled, restricted to 1.1.1.1 service | User specified App exclusion |
| Intra | | | Manually enabled | User specified App exclusion |

| | | | | |
|---|---|---|---|---|
| Quad9 Connect | | | Manually enabled, restricted to 9.9.9.9 service | User specific list of domains to send to system resolver |
| **CPE** | | | | |
| FritzBox | | | Manually enabled | User specified (DoT servers, fallback behavior) |
| Turris | | | Manually enabled | User specified (DoT servers) |
| OpenWRT | | | Manually enabled | User specified (DoT/DoH servers) |

Additional details of current client implementations can be found in the appendix at the end of this paper.

## 5. Provider Impact of DNS Encryption Clients

As can be seen from the descriptions above, there's currently considerable diversity in client behavior because standards only define how to use secure transport for DNS. Standards aren't yet defined for clients to discover encrypted resolvers, understand local network conditions, and establish and maintain a connection.

Today end users need to take some action in order to enable DNS encryption - navigate to a configuration interface and accept defaults and/or enter information or load an app. There are also differences in how clients fall back to DNS over port 53 if a connection to an encrypted resolver can't be established or fails. And there's no agreed upon method to acknowledge or detect local network conditions, such as the presence of a VPN, an enterprise network, or DNS filtering that might be subverted by the choice of an alternative resolver.

These are critical limitations for service providers. Manual configuration by users is completely incompatible with operation at scale. Default configurations that favor public DNS resolvers bypass provider DNS. Ignoring local network conditions can subvert security and services like parental controls.

As of July 2020, a wide range of possible solutions to these problems have been proposed in the IETF. They can be broadly categorized as: informational drafts describing the current state of the problem, proposals to use existing network technologies like DHCP or Radius to upgrade to secure transport, methods to add functions to the DNS itself, and overlay solutions.

One of the drafts is currently being tested with the Firefox browser and DoH resolvers deployed by Comcast[3]. In simplified terms, it tests for the presence of DNS policy (e.g., security, parental controls) using a "canary" domain that signals its presence and then queries for a special name to get the address of an encrypted resolver provisioned on the local network. If the query fails, then additional logic can be implemented to select an alternative DoH resolver. This mechanism is currently being tested in Firefox with DoH resolvers deployed by Comcast.

[3] https://www.ietf.org/id/draft-rescorla-doh-cdisco-00.html

To influence the way clients discover resolvers, the ISP/MNO community needs to be active in the IETF and contribute to relevant RFCs. This will ensure standards deliver the same “just works” experience users have today and are compatible with operational systems.

## 6. Operational Impact of DNS Encryption

Privacy is a highly visible issue almost everywhere in the world and, if subscribers perceive encrypted DNS is “better,” providers may be motivated to deploy it across their resolution infrastructure, particularly if subscribers start to migrate toward public DNS services.

Providers need to consider underlying details of client implementations because they’ll impact operation and scaling of DNS resolution infrastructure. The shift to TCP-based, secure, transport is a major change from almost exclusively UDP-based transport today. To maximize network efficiency, resolvers will have to support today’s TCP and UDP as well as multiple transport-level authentication and encryption options going forward. Dedicated equipment for TLS termination (like load balancers) increases costs and operational burden. It also adds complexity to troubleshooting efforts with separate interfaces for transport layer problems and DNS resolution itself. Different operational teams need to be coordinated to resolve issues.

Resolver performance will be heavily driven by client side implementations, and there’s little consistency at present. Connection set up overhead must be understood and resolvers need to be tuned for TCP based services in addition to UDP based services. Session reuse (reusing established sessions for multiple queries) must be evaluated as well since it can have a large impact on performance. Advancements in modern server hardware allow for comparable scaling of TLS termination negating the need for specialized appliance based solutions. Failure conditions and resultant bursts of connection setup requests also need to be factored into dimensioning decisions.

Traffic types will shift as client implementations change. Monitoring and comparing Do53, DoT and DoH workloads on an ongoing basis will allow operations teams to make educated capacity planning decisions. Insights into these factors can be found in a presentation at the DNS-OARC conference held in February 2020: DNS Encryption Operational Experience and Insights.

Because it runs over HTTPS, the advent of DoH introduced the possibility of tighter integration with applications, and DoH implementations have been released in browsers. Any app could choose to implement DoH and it is also supported in several public or "over the top" DNS resolution services. The combination of these two developments has important implications for ISPs (and other network operators) and the people who use their networks.

Migrating DNS resolution to applications is a significant change. In the past, applications running on devices relied on a stub resolver implemented as part of the devices operating system which typically query resolvers provisioned by the operator of the network a device is connected to.[4]

[4] Most operating systems also allow users to manually configure DNS settings to point to a resolver that will take precedence over a resolver configured by the local network.

Fragmentation of DNS resolution among applications raises a number of concerns. One of the most obvious is the risk of substantially complicating troubleshooting when connectivity problems arise. As can be seen from the table and appendix there is currently considerable diversity in client implementations. Individual applications could choose different resolvers and have different methods for exposing that choice to the user (or not expose it at all). They could also have different philosophies about respecting local DNS filtering policies on a network.

Additional considerations may apply when a provider offers resolution services to their enterprise customers. Businesses are potentially exposed when workers use public DNS services, knowingly or not, because sensitive internal domain names could be leaked to external sources. Internal enterprise applications also will not work properly since internal names will not resolve on public resolvers. Enterprises or provider partners may need to make provisions to block access to public DNS services to prevent these problems.

Providers may need to adjust services that use DNS filtering for parental controls or security protections to account for the presence of client implementations that may choose public DNS services. For example as discussed previously some client implementations attempt to check for the presence of DNS filtering by querying for a special canary domain name. In order to ensure their filtering services are preferred by these clients providers will need to provision canary names and respond to the queries properly. In the future there may be other methods that will have to be accommodated.

It appears as though the threat landscape will evolve as well, as attackers explore whether an encrypted DNS path offers advantages.[5] In the past it was easy to monitor DNS traffic but encrypting the transport with DoH complicates the picture since DNS queries look no different than massive volumes of HTTPS traffic traversing a network.

One possible solution is to break the bootstrapping mechanism expoits use. DoH stub resolvers have to query special hostnames to obtain the IP addresses of DNS resolution services before they can establish a connection. The stub has to use the default resolver in the operating system on the device where it resides in order to accomplish this, which is usually configured by the local network (such as a provider network). Security vendors can track host names of malicious third party DoH resolvers so access to them can be blocked.

Regardless of whether DNS encryption is deployed, the presence of public alternatives amplifies provider incentives to ensure their DNS resolution services are robust and performant. Resolvers are the glue that connects subscribers to their fixed and mobile broadband services. If operators of public DNS services succeed in persuading subscribers to use their resolvers, they will play a significant role in controlling the user experience. DNS is central to virtually every internet transaction, even simple web page loads can send tens of queries. This means performance and latency of public DNS resolvers can have a direct impact on how a user perceives their internet access. Although relatively rare, there may also be cases where a resolver is unable to resolve a name and users get an error message that a resource is unavailable.

When public DNS services operate slowly or fail, as has happened several times in the past, subscribers may associate the problem with their service provider because they may not understand the role DNS plays or may not remember they switched their DNS settings! Providers may need to bear support costs during 3rd party outages and deal with unhappy customers.

[5] https://www.sans.org/reading-room/whitepapers/dns/needle-haystack-detecting-dns-https-usage-39160

A blog post referenced in the bibliography offers design and deployment guidance to help providers establish their resolvers as the preferred choice.

## 7. Summary Action Plan

DNS encryption has been highly visible in industry media for more than 2 years; there are many client implementations available including those from major OS, browser, mobile app and CPE vendors and several scaled public DNS resolution services exist that support it. Whether deploying it or not, providers need to be aware of the landscape and prepared to respond by:

- Communicating about privacy and security practices including network protections that block intruders, DNS data usage and retention policies, and other privacy enhancing measures in place.
- Implementing Best Practices for DNS resolution whether or not DNS encryption is supported to ensure provider resolvers are better than OTT alternatives - more responsive, reliable, resilient, & secure.
- Considering value added services that protect subscribers by deterring phishing, bots and malware that invade privacy and steal valuable personal data. Motivate subscribers to personalize their service - so they're less likely to leave.
- Contributing to relevant standards to ensure DNS encryption implementations deliver the same "just works" experience users have today, and are compatible with operational systems.

# Appendix: DoT and DoH Client Implementations

As of August 2020, implementations will continue to expand and evolve.

## DoT

### Operating systems

Google Android - first with support for a DoT client in 2018. After configuration by the user (it's not a default yet) it acts as the DNS client for the device, just like the DNS over port 53 client.

Apple iOS 14 and MacOS 11 - Introduced at 2020 developer conference. There is currently no way to configure DoH/DoT from the network. Users can configure an encrypted default resolver for all apps on the system. App developers can configure an encrypted resolver independent of the system, and allow users to opt-in or configure their own encrypted resolver. DoH and DoT are context-aware, when a VPN app or corporate network is detected they will not override configured settings. Developers can also write "rules" to enable encrypted DNS in certain situations or contexts. Enterprise administrators will be able to use Mobile Device Management to configure or override encrypted DNS settings. Plans call for warning users if network providers block encrypted DNS.
https://www.zdnet.com/article/apple-adds-support-for-encrypted-dns-doh-and-dot/

### Mobile Apps

1.1.1.1 - a special purpose app released by Cloudflare in 2019 acts as the default stub resolver for a device. It connects to Cloudflare's 1.1.1.1 public DNS service using DoT or DoH.

Quad 9 Connect - a special purpose app for Android and iOS released by Quad 9 in 2019 acts as the default stub resolver for a device. It connects to Quad 9s public DNS service using DoT. Quad 9 is a nonprofit founded by IBM, Packet Clearinghouse, and the Global Cyber Alliance.

### CPE

FritzBox, Turris, and OpenWRT implementations proxy client requests coming in from port 53 over a secure port 853 to a resolver.

## DoH

### Operating Systems

Apple iOS 14 and MacOS 11 - as above for DoT

Microsoft Windows 10 - a testable version of DoH was released in May 2020 aimed at power users. Users configure Windows to use DoH and then need to separately add encrypted resolvers from Google, Cloudflare, or Quad 9 through the Control Panel or Settings.
https://techcommunity.microsoft.com/t5/networking-blog/windows-insiders-can-now-test-dns-over-https/ba-p/1381282
Microsoft plans to release additional features in their 21H1 update to include more accessible system wide configuration functionality
https://www.howtogeek.com/685996/whats-new-in-windows-10s-21h1-update-coming-spring-2021/

### Browsers

Mozilla - early entrant with experimental Firefox release supporting DoH in June 2018. Currently Firefox falls back from DoH to operating system defaults for DNS when heuristics detect an enterprise DNS configuration or DNS-based parental controls. One of the heuristics is the use of a canary domain, a special domain name implemented by a network operator Firefox can query that signals the use of DNS filtering on a network.
https://support.mozilla.org/en-US/kb/firefox-dns-over-https
In 2018 they released requirements for Trusted Recursive Resolvers (TRR) organizations must meet if they want their DoH services accessible in Firefox.
https://wiki.mozilla.org/Security/DOH-resolver-policy

Chrome - early entrant with experimental Chrome release in July 2019 . Chrome preserves the user experience by doing Same Provider Auto Upgrade (auto-upgrading when the existing DNS provider supports DoH). It will also allow manual config of a 3rd party DoH resolver.
https://www.chromium.org/developers/dns-over-https
https://blog.chromium.org/2020/09/a-safer-and-more-private-browsing.html

For completeness Bromite, Brave, Edge, Opera, and Vivaldi all take advantage of DoH features built into Chromium. Their network characteristics are like Chrome.

### Mobile Apps

Intra - a special purpose app released by Google's Jigsaw technology incubator in 2019 acts as the default stub resolver for a device. It connects to Google Public DNS using DoH.
https://getintra.org/#!/

1.1.1.1 - as above for DoT.

**Title** **Page Number**

 

# 1. Introduction

In a cable plant, it is essential to manage upstream spectrum and mitigate the impact of interferences, especially for lower spectrum bands that are susceptible to various types of noise ingress. The introduction of OFDMA in DOCSIS 3.1 (D3.1) with different bit-loadings at different minislots provides the benefits of enhanced capacity, as well as all flexibility in managing the spectrum usage. Yet surprisingly, not many MSOs have taken full advantage of DOCSIS 3.1 capabilities. Part of the reason is, accompanying the enhancements in capacity and flexibility, comes the complexity in computation, as we have to deal with finer granularity in both detecting the noise levels and reacting to them fast enough.

D3.1 provides an OFDMA profile, which defines, among other properties, a bit-loading pattern that could be adopted by a group of cable modems (CMs). Further, a Profile Management Application (PMA) utilizes the power of offline servers to tackle the computation complexity. A PMA server may take performance measurements on an OFDMA channel for a considerably long time in order to calculate OFDMA profiles. However, in a typical cable plant, especially in its lower band, we may observe many random bursts of noise that vary in time, frequency and power amplitude, and such noise might come and go swiftly. Figure 1 below gives a snapshot of upstream interference in an HFC network. Therefore, using PMA alone is not enough. As upstream interference is naturally observed at the CMTS, it makes sense to augment PMA with a CMTS-based solution that adapts quickly to interference levels measured locally.

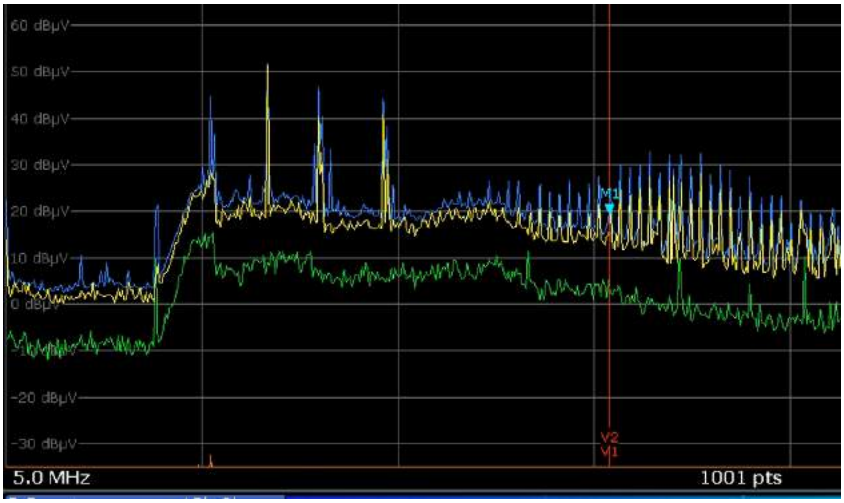

**Figure 1 A Snapshot of Upstream Interferences in an HFC Network**

This paper presents a novel approach that uses various OFDMA profiles with different bit-loading configurations to generate a dynamic profile. We consider upstream impairment with a duty cycle of one or a few seconds, and target a CMTS-based adaptive solution that yields optimal throughput across all CMs. To achieve the objective, we measure upstream channel impairments at a per-minislot level through constantly monitoring the receptions at the CMTS burst receiver. Based on the results, we could dynamically upgrade or downgrade IUCs. The decisions to upgrade or downgrade IUCs are considered for each individual minislot, and can take place locally and automatically without notifying the affected modems.

This approach is referred to as “Dynamic IUC” in the rest of the paper. The generated dynamic profile is referred to as “Dynamic scheduling IUC”, or “DS-IUC” in short.

This approach could be combined with any existing profile management mechanisms. For example, an operator could manually configure 2 OFDMA profiles on an OFDMA channel, or alternatively, a PMA server could elect 2 such profiles based on its calculation. The CMTS could then utilize these 2 profiles, plus NULL bit-loading as a special case, to generate a DS-IUC, thus providing a 3-tier adaptation for each minislot, at an interval much shorter than that of the PMA updates.

# 2. Background

OFDMA transmission as introduced in D3.1 utilizes different bit-loadings at different subcarriers in the same upstream channel, so that it can adapt to different noise conditions at these subcarriers. D3.1 introduces multiple OFDMA Upstream Data Profiles (OUDPs) on an OFDMA channel, each of which defines a bit-loading pattern that could be adopted by a group of CMs at a certain time period. In particular, an OUDP includes the following information:

- An IUC number (5, 6, 9, 10, 11, 12, or 13)
- Bit-loading and pilot pattern for each minislot or consecutive minislots in order. The bit-loading number ranges from 0 (no transmission) to 12 (4096-QAM)

Per D3.1 MULPI ([1]), the content of these profiles is communicated to CMs through UCD messages. The assignment of one or two such profiles to a CM is using TCC in either registration response or DBC messages. The standard limits that a maximum of two profiles of a channel could be assigned to a CM at any given time.

For terminology, as this document considers data transmission on OFDMA channels for the most part, therefore without mentioning explicitly, we may simply use “OFDMA profile”, “data profile” or even “profile” to replace the full term of “OFDMA Upstream Data Profile”. We also use it interchangeably with “data IUC” or “IUC” without ambiguity.

## 2.1. Performance Measurement

There exist multiple mechanisms to measure the performance of an upstream channel, including:

- Active and Quiet Probe (see [3]). For this purpose the CMTS may schedule one or more OFDMA symbols and sends a P-MAP. In case of an Active Probe, the CMTS uses a SID assigned to an active CM, and measures RxMER of the CM at the time specified by the P-MAP. The active probe symbol for this capture normally includes all non-excluded subcarriers across the OFDMA channel. In case of a Quiet Probe, the CMTS uses an Idle SID in the P-MAP. It requires all subcarriers, including excluded ones, to be probed. Quiet probes could be used as a baseline to generate initial upstream profiles before modems come online. On the other hand, Active Probes could be scheduled periodically for each active CM in order to generate more accurate upstream profiles over time.
- MER and FEC measurement associated with data receptions. The CMTS burst receiver may provide the following information for each received burst:
    - MER
    - FEC correctable codeword count
    - FEC uncorrectable codeword count
    - Total codeword count

  With the codeword counts the CMTS could subsequently calculate FEC correctable rate (i.e., cFEC) and FEC uncorrectable rate (i.e., uFEC).

- OUDP Test (see [1]). D3.1 includes a mechanism to test an OUDP profile currently in use by providing grants with a special OUDP Test SID to the testing CM. The CM will transmit using a specific payload pattern and the CMTS could subsequently count the FEC and CRC errors in addition to measuring the MER. The OUDP Test SID has to be assigned to the CM in advance.

In this paper, we assume the above performance measurement mechanisms are available as a prerequisite. On top of that, we introduce a novel method that derives performance metrics per-minislot and per CM group, in real-time and with no or minimum overhead in bandwidth utilization.

### 2.2. OFDMA Profile Management

The specifications in reference [4] provide operators a way to statically configure a set of OFDMA profiles on an OFDMA channel. With such a configuration, a CMTS could locally decide which profiles to be assigned to which CMs and at what time.

Reference [2] describes an architecture using an external Profile Management Application (PMA) server. The PMA server constantly monitors the upstream spectrum, by initiating RxMER measurement for upstream subcarriers (using quiet or active probes), or triggering "OUDP Test", both through the CMTS. The PMA could also utilize information from other tests, such as upstream captures from a PNM server, as well as historical information obtained on the plant. With such information, the PMA server is able to evaluate the current upstream channel's performance and generate a set of profiles for the channel. Meanwhile, the PMA server may also designate one or two of these profiles to each CM on this channel. Reference [2] defines an API for this operation.

The above mechanisms require assignments or re-assignments of IUCs to CMs, or modification of IUC content over time. Note that there are only a limited number of IUCs that can be supported on an OFDMA channel. Besides, only one or two IUCs on this channel can be assigned to each CM at any given time. One of them is typically the lowest bit-loading IUC (IUC 13) that is required for pre-registration. Therefore, the mechanisms above require the CMTS to communicate with the corresponding CMs constantly using UCD and/or DBC messages. This imposes a limitation as for how fast the profile management functions could run, and how soon the CMTS system could adapt to channel impairment. An operator may define a time interval, which determines how often to re-evaluate the current profiles and potentially modify or re-assign these profiles to CMs.

In this paper, we assume that a profile management mechanism such as stated above is available as a prerequisite, so that at any given time, each CM will be assigned with a high profile and a low profile, denoted as IUC H and IUC L respectively. We loosely define the interval of profile modification or re-assignment as "profile management interval". On top of that, we introduce a novel method that dynamically upgrades or downgrades IUCs on an OFDMA channel, at per-minislot granularity and in reaction to real-time noise much faster than the "profile-management-interval".

## 3. Per-Minislot Measurements

Assume the CMTS burst receiver is able to collect FEC correctable count, FEC uncorrectable count, total word count and MER for each received burst (see 2.1). When FEC errors are detected with the received burst and the burst size is more than a minislot, it is impossible to determine which minislot has contributed to the impairment due to the effect of interleaving. In order to obtain these metrics on per minislot granularity, we designate some minislots in each OFDMA frame to be used for one-minislot grants, with a pre-defined percentage and with their positions rotate in each frame. See Figure 2 for an illustration. In this way each minislot will be scanned over time with the same frequency. For example, if we designate 1% of the minislots in an OFDMA frame to be used for single minislot grants, it takes 100

 

frames to scan through every minislot. Depending on the frame size (6 – 36 symbols) and Cyclic Prefix (CP) values, there could be ~1000 - ~8000 frames in a second. If for example there are 3000 frames in a second, any particular minislot will be scanned 30 times in a second, including single-minislot grants at this location assigned to any CM group.

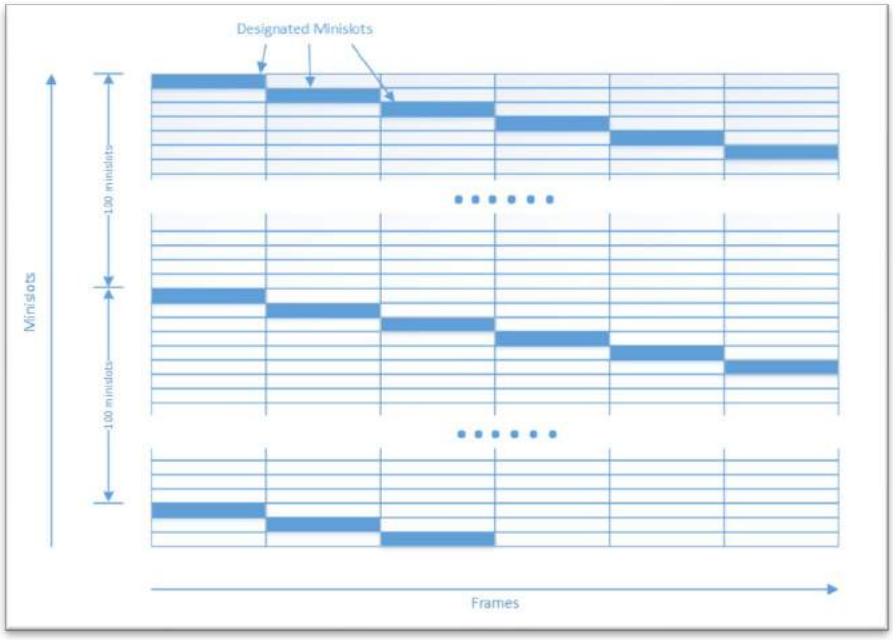

**Figure 2 Designated Minislots For Single-Minislot Measurements**

At the time of MAP generation, the upstream scheduler allocates grants for CM requests per the normal operation. If a grant hits one of the designated minislot location, this grant will be fragmented, and the next grant will occupy a single minislot. Then, only performance metrics of these single minislot bursts are taken into consideration, and the rest are discarded for this measurement. To be specific, when the single minislot burst is received by the CMTS, it will be measured and the performance metrics will be counted toward the group which the transmitting CM belongs to.

## 3.1. OUDP Test

There're several scenarios where OUDP Test could be useful, including the following:

- A CM group could possibly drop its bit-loading to NULL in some minislots, due to severe interference experienced at these minislots (see Section 4). In this case the scheduler avoids scheduling any grant for either data or ranging requests, therefore there is no subsequent measurement available on these minislots based on active data. The CMTS then has to explicitly poll these minislots using OUDP Tests, in order to determine whether the interference condition has changed.
- When there are unused minislots in an OFDMA frame, the CMTS could utilize these minislots to test the performance of any CM group of its choice, again using OUDP Tests.

# 4. Dynamic IUC

Assume with one or more of the "profile management" mechanisms as described in 2.2, a CM is assigned with a high profile and a low profile, denoted as IUC H and IUC L respectively. Then, in a time interval much smaller than the "profile management interval", the CMTS might switch between IUC H, IUC L, plus NULL bit-loading as a special case. Such dynamic switches could be determined for each individual minislot, and could occur locally without communicating to the CM through MMM messages.

In particular, the CMTS upstream scheduler periodically generates a "Dynamic Scheduling IUC (DS-IUC)", which adopts IUC H, or IUC L, or NULL, on a minislot-by-minislot basis. In other words, the bit-loading value at a minislot could assume bit-loading_<IUC H, minislot>, or bit-loading_<IUC L, minislot>, or 0. The scheduler could possibly encode different data IEs of the same CM with different IUC numbers if these IEs fall into different minislots in a MAP.

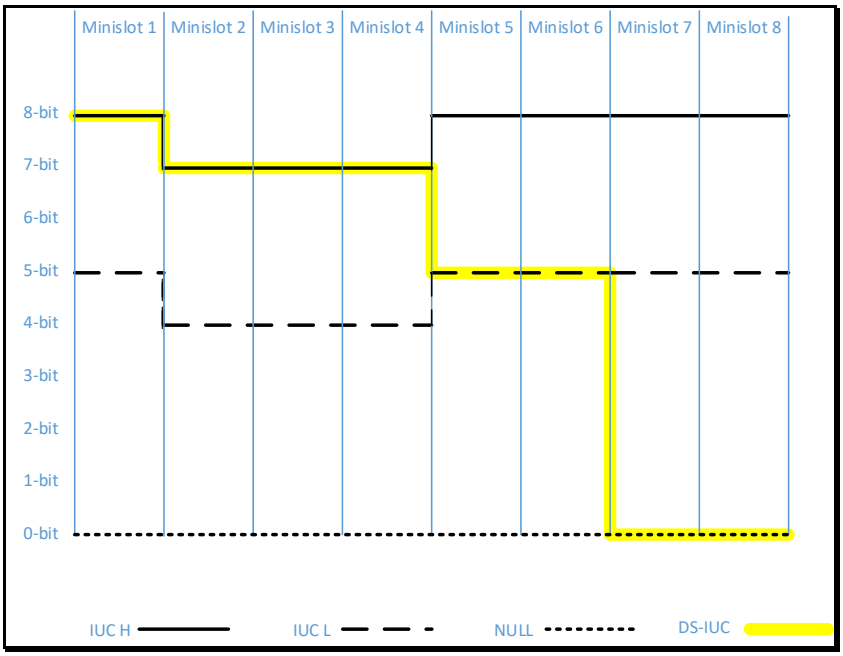

**Figure 3 Dynamic Scheduling IUC**

An example of DS-IUC (partial) is illustrated in Figure 3. In this example, IUC H is defined as follows:

{minislot 1: 8-bit QAM},{minislot 2-4: 7-bit QAM}, {minislot 5-8: 8-bit QAM}, …

IUC L is defined as:

{minislot 1: 5-bit QAM}, {minislot 2-4: 4-bit QAM}, {minislot 5-8: 5-bit QAM}, …

The DS-IUC adopts IUC H in minislot 1 – 4, but adopts IUC L in minislot 5 and 6, and again adopts NULL bit-loading in minislot 7 - 8. Therefore the DS-IUC is defined as:

{minislot 1: 8-bit QAM}, {minislot 2-4: 7-bit QAM}, {minislot 5-6: 5-bit QAM}, {minislot 7-8: 0-bit QAM}, …

The collection of IUC H, IUC L and NULL provides a 3-tier option for dynamic adaptation to noise conditions to a certain extent without involving the CM, and such adaptation may be different on different sub-bands. The creation and modification of DS-IUC is performed periodically. This period is referred to as “dynamic scheduling interval”, which should be much smaller than the “profile management interval”. For example, the dynamic scheduling interval can be chosen from sub-second to multiple seconds while the profile management interval can be chosen from sub-minute to multiple minutes or even hours.

## 5. Experimental Results

To demonstrate the effects of Dynamic IUC, we ran an experiment in the lab with a D3.1 CMTS from Casa Systems and a D3.1 CM from Technicolor. An OFDMA channel is configured with the frequency span of 5 – 85 MHz and with K = 18 symbols per OFDMA frame. 5 distinct Data IUCs are configured and allocated to the OFDMA channel, namely IUC 9 – IUC 13.

When the CM is online, two data IUCs, namely IUC 9 and IUC 13, are assigned to the CM based on assessment of the current condition. Here IUC 9 is the “IUC H” and IUC 13 is the “IUC L”: IUC 9 has a constant bit-loading of 1024-QAM across all minislots, and IUC 13 has a constant bit-loading of 64-QAM across all minislots. Between the two IUCs assigned to the CM, the scheduler starts with IUC H for unicast data transmission until there’s an issue.

Profile management interval is configured as 1000 seconds, which means for every 1000 seconds, the system could possibly update the assignment of IUC H and/or IUC L to the CM. This operation is skipped in our experiment. On the other hand, the dynamic scheduling interval is configured as 5 seconds, which means for every 5 seconds, the scheduler possibly switches among IUC H, IUC L and NULL for each minislot and each CM group, based on per-minislot performance measurements of the current 5-second interval.

Figure 4 depicts a snapshot of the OFDMA channel (partial) when there is no noise. In the figure, a) and b) reflect cMER and uMER respectively, c) is the plot of MER, and d) displays the calculated DS-IUC. At this point DS-IUC is the same as IUC 9 across all minislots. As we can see, using IUC 9 the per-minislot cFEC and uFEC are both 0, and the per-minislot MER stays between 43.1- 47.7dB. These results show IUC 9 is working appropriately across the whole channel, therefore DS-IUC is unchanged, i.e., it stays the same as IUC 9.

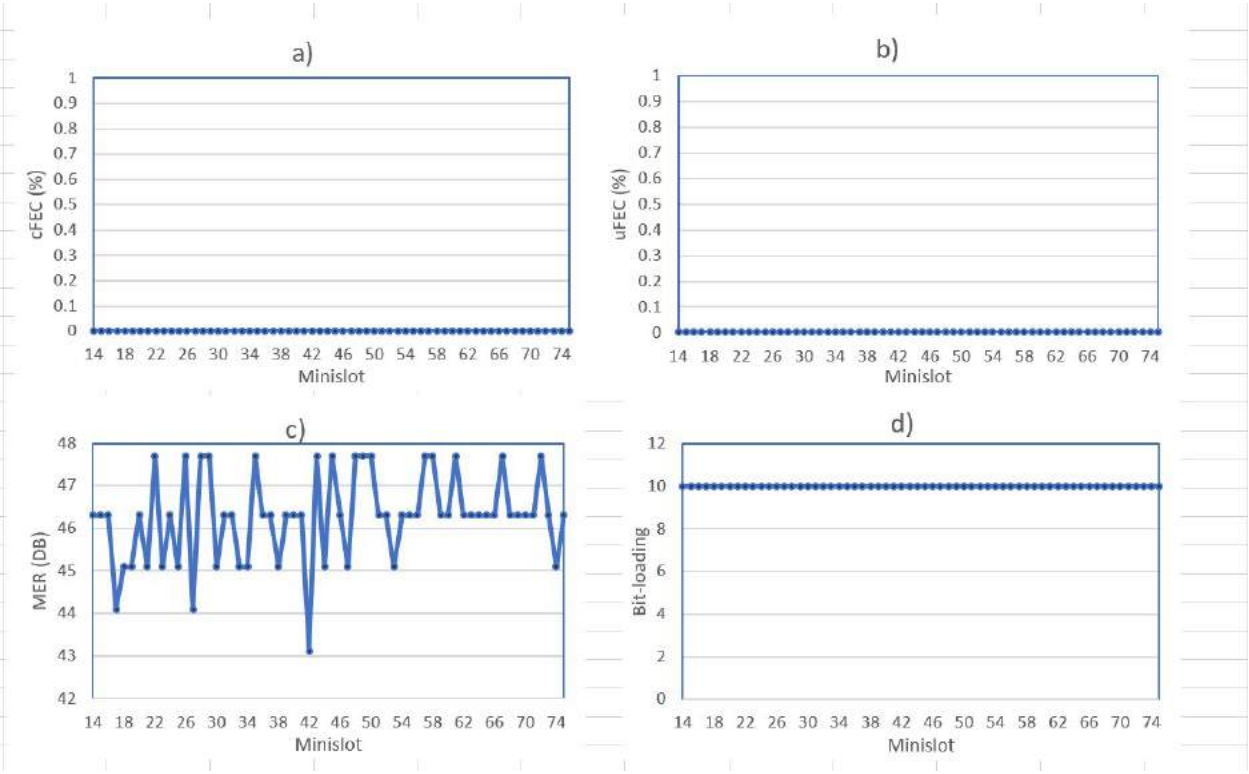

**Figure 4 Per-Minislot Measurements and DS-IUC Without Noise**

We then introduce some noise using a signal generator. The generated signal is a sharp tone centered at 25Mhz with a FM of 1Mhz. It is injected into the upstream port with a 2-way combiner. Figure 5 depicts a snapshot of the OFDMA channel (partial) roughly 5 seconds after the noise is injected. Again a) and b) reflect cMER and uMER respectively, c) is the plot of MER, and d) displays the calculated DS-IUC. As we can see, at this point the MER drops below 42.3dB within minislot [30 – 68], and drops below 26.7dB within minislot [46 – 53]. This forces a degradation in bit-loadings. As a result, the scheduler adopts IUC 13 for impaired regions within minislot [30 – 45] and within minislot [54 – 68]. It further adopts NULL bit-loading for a severely impaired region within minislot [46 – 53]. The rest of regions is little affected and so IUC 9 is kept unchanged.

Note the diagrams in Figure 5 illustrate measurements after the adapted DS-IUC is calculated and take into effect, which comprises IUC 9, IUC 13 and NULL at unimpaired, impaired, and severely impaired regions respectively. In the impaired regions, since modulation is reduced to IUC 13, uFEC and cFEC become 0 once again. In the severely impaired region however, as NULL bit-loading is adopted, there's no data permitted for transmission. The CMTS needs to schedule one-minislot grants for OUDP Tests, using IUC 13. Diagrams in a) and b) of Figure 5 show that the cFEC and uFEC values obtained with such OUDP Test frames are still significantly high at the severely impaired region, and so the DS-IUC stays at NULL in this region.

When the noise is removed, the per-minislot FEC and MER metrics would change accordingly to what were before. Then, with less than 5 seconds delay, the scheduler adjusts DS-IUC to adopt IUC 9 once again across all minislots. The diagrams at this moment are almost identical to those in Figure 4 and are omitted here.

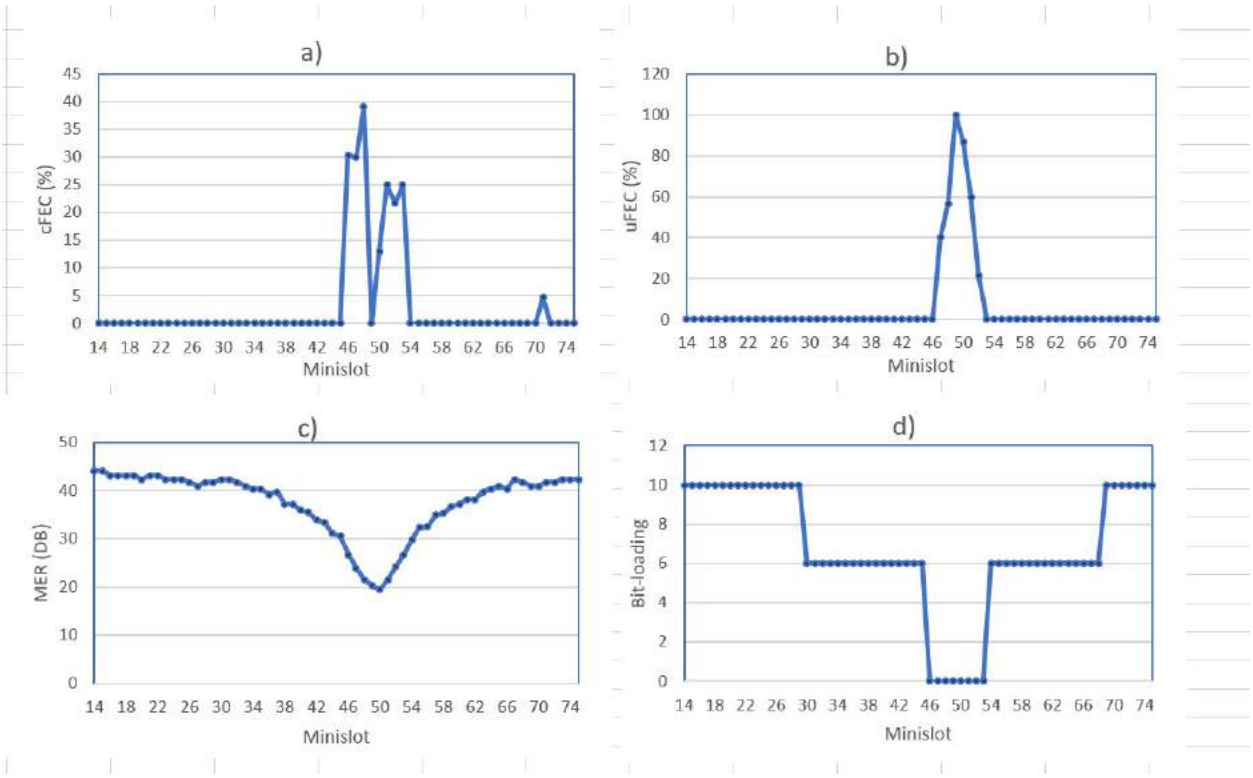

**Figure 5 Per-Minislot Measurements and DS-IUC with Noise**

# 6. Miscellaneous Notes

A few notes regarding Dynamic IUC are worth mentioning here, as detailed in the following.

## 6.1. Dynamic Ranging Zone

Besides utilizing the per minislot performance metrics to facilitate data transmissions, the CMTS could also use the same to direct range requests. For example, the CMTS could choose a default ranging zone to start with. Once cable modems come online and the per-minislot performance metrics are collected, if the CMTS determines that the original ranging zone is too noisy, it could optionally select a new region with the highest MER. It then moves the initial ranging and/or fine ranging zone to the selected region, i.e., the ranging IEs would contain IUC 3 or IUC 4, and contain minislots from within that region.

## 6.2. Partitioning CMs to CM Groups

In the previous sections we loosely refer to the term “CM group”. It is further explained in this subsection, as follows. We assume that all CMs utilizing an upstream channel could be partitioned into a limited number of groups, with each group observing the same pattern of impairment at almost all times. Different group behaviors could reflect different D3.1 CM types, or different segments of the cable plant, etc.

The methods and rules to partition CMs into CM groups depend on deployment scenarios and implementation specifics. In an extreme case, if the number of CMs is manageable and the resources (memory, cpu cycle) are sufficient, we could designate each CM as a CM group.

In another extreme case, if all CMs on the upstream channel behave uniformly across all minislots and at all times, they could be categorized as in the same CM group. Due to the "funnel effect" of upstream noises, this model could work for lots of scenarios. For example, it could work when the only source of interference is ingress noise.

With CMs on an OFDMA channel partitioned into CM groups, we could obtain FEC and MER statistics on a per CM group basis. We could also define DS-IUCs on a per CM group basis, as described in the previous sections.

The exact mechanism for how to partition CMs into CM groups could be a topic for further studies.

### 6.3. Single-Minislot Approximation

Special care must be given when a single minislot is not sufficient for a grant. This could happen if the combination of bit-loading and frame size is too small for the smallest LDPC codeword. In that case a smallest multi-minislot grant to fit the LDPC codeword could be scheduled, which covers the minislot being examined plus one or more neighboring minislots. The performance metrics of this minislot will be estimated based on what is measured with the multi-minislot burst. The exact mechanism as for how to obtain the estimation of the single minislot performance metrics could be a topic for further studies.

## 7. Conclusion

The solution of "Dynamic IUC" presented in this paper starts with selectively scheduling one-minislot grants for either active data or OUDP Test data, and measures channel impairments at a per-minislot granularity using data received at the burst receiver. Based on the above, the CMTS leverages the two OFDMA data profiles, namely IUC H and IUC L, that were previously assigned to a group of CMs, plus NULL bit-loading as a special case, in order to produce a DS-IUC with a 3-tier adaptation. The decision to choose the tier is made for each individual minislot and each CM group. Additionally, the decision takes place locally without notifying the affected CMs. Finally, it can take place immediately, i.e., one or a few seconds after onset/offset of an impairment.

Dynamic IUC could be combined with any existing profile management mechanisms, such as PMA. For example, one could use PMA to elect IUC H and IUC L for a group of CMs, and use Dynamic IUC to leverage the elected IUCs and provide a 3-tier adaptation. In this way the system is able to handle both long-term and short-term impairments, resulting in an optimal upstream throughput across all CMs.

## List of Figures

 

 

 

# 1. Introduction

One of the most versatile pieces of test equipment available to the cable industry is the spectrum analyzer. Spectrum analyzers, which are instruments that display signals in the frequency domain (see ***Figure 1***) have for decades been used for headend, hub site, and outside plant maintenance and troubleshooting. However, spectrum analyzers have historically been expensive and not typically available to field personnel; usually not particularly portable; and in some cases, complicated to use.

That said, wouldn't it be nice to have a spectrum analyzer in every cable subscriber's home? What if those in-home spectrum analyzers could be remotely accessed so that technicians didn't have to go to each home to use them? Even better, what if that in-home spectrum analyzer capability already existed and was widely deployed?

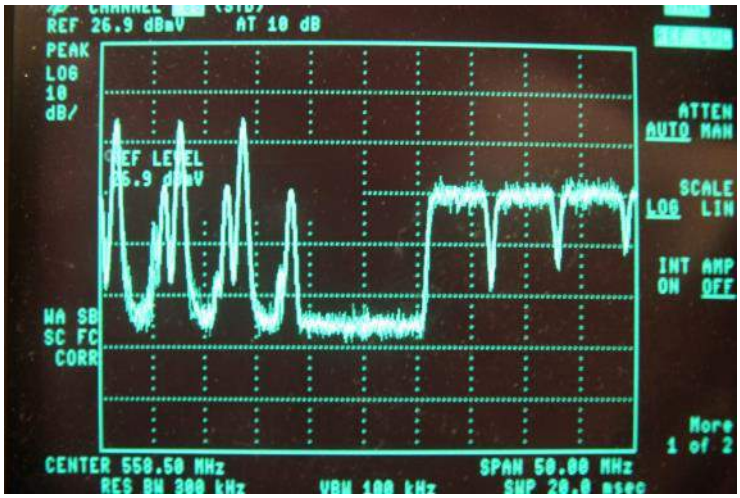

**Figure 1. Spectrum analyzer screen shot showing analog TV signals on the left side and digital signals on the right side. The vertical axis is amplitude, and the horizontal axis is frequency.**

Let's answer those three questions in reverse order, starting with the last one first: In-home spectrum analyzer capability does exist and has for several years. Those in-home spectrum analyzers can be remotely accessed, using simple network management protocol (SNMP) or similar. And while not in every cable subscriber's home, they are in a sizeable percentage of homes with Data-Over-Cable Service Interface Specifications (DOCSIS®) customer premises equipment (CPE).

That in-home spectrum analyzer capability is known as full band capture (FBC) and is a cable modem spectrum analysis feature available in DOCSIS 3.0 and 3.1 cable modems. Cable modem spectrum analysis functionality was first defined in version I20 of the DOCSIS 3.0 Operations Support System Interface Specification (CM-SP-OSSIv3.0-I20-121113) back in November 2012.[1] See [Ref. 1].[2]

Figure 2 shows an example of an FBC display of the downstream in a cable network. The data was captured remotely from an FBC-capable DOCSIS modem in the home of one of the authors, showing a problem-free downstream spectrum. The vertical axis is amplitude (dBmV), the horizontal axis is frequency in MHz, and the resolution bandwidth (RBW) is 117 kHz.

[1] The DOCSIS 3.0 specifications were first published in 2006, and the first DOCSIS 3.0 cable modems were certified by CableLabs in 2008.

[2] References are in the bibliography near the end of the document.

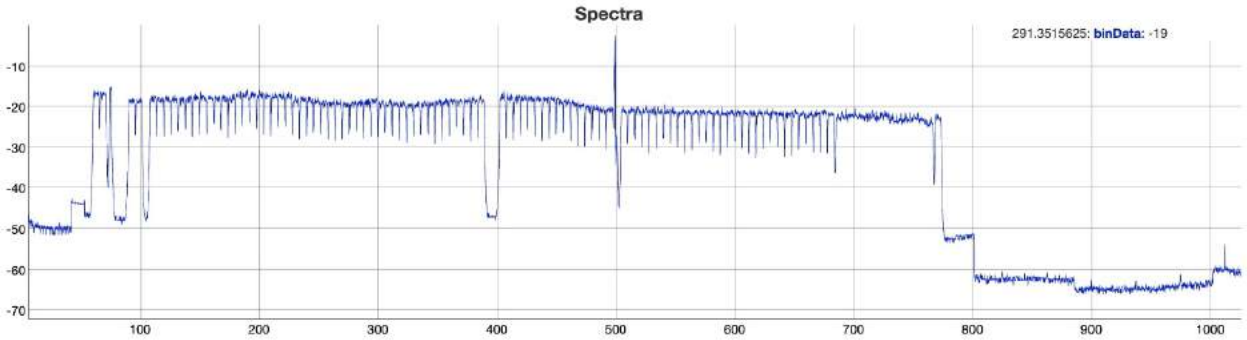

**Figure 2. FBC screen shot of a cable network's downstream spectrum from a DOCSIS modem in the home of one of the authors (courtesy of Comcast).**

Figure 3 shows another example of an FBC display of the downstream spectrum in a cable network. The display was captured remotely from an FBC-capable DOCSIS modem in a cable subscriber's home, and shows a suckout (notch) in the vicinity of 625 MHz that would otherwise have been difficult to identify without having a technician on-site. As before, the vertical axis is amplitude (dBmV), the horizontal axis is frequency in MHz, and the RBW is 117 kHz.

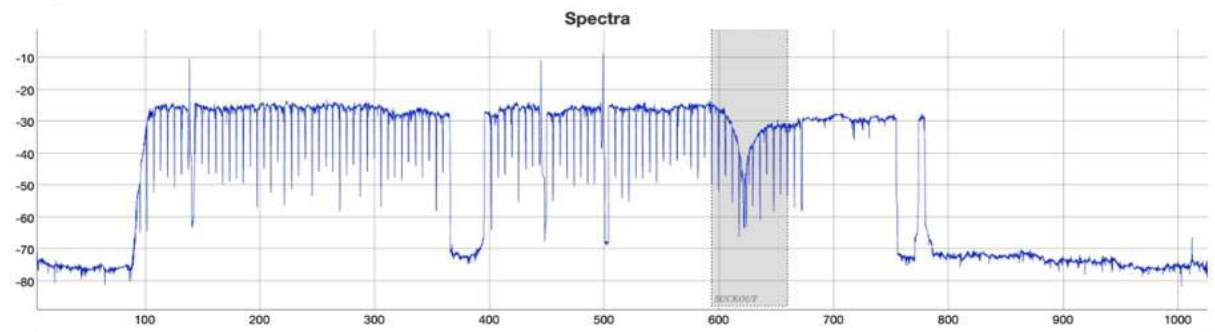

**Figure 3. FBC screen shot of a cable network's downstream spectrum. This display shows a suckout (notch) at about 625 MHz (courtesy of Broadcom).**

Some operators have been using FBC successfully as part of their proactive network maintenance (PNM) programs. But many operators have not taken advantage of FBC, perhaps because they don't know about it, or don't know how to use it. Whatever the reason, FBC is a powerful tool that is supported in most DOCSIS 3.0 and all DOCSIS 3.1 cable modems.

This paper highlights the benefits of FBC; provides an overview of how FBC works; shows several examples of the types of impairments that can be identified using FBC, along with some use cases demonstrating how cable operators use FBC to troubleshoot specific problems; and explains how to retrieve and display spectral data from modems (example Python code to retrieve and plot FBC data can be found in the Appendix). Also included is a discussion about using FBC for displaying upstream spectral data – especially noise – a capability supported in some cable modem implementations. Finally, the paper provides guidance and findings about how to transform the visual spectrum data into actionable decisions, including opportunities for automation, and operational expenditure savings.

## 2. FBC Benefits

As mentioned previously, FBC is being used by several cable operators as part of PNM programs, both in standalone tools and in third party PNM tools. FBC enables operators to have spectrum analysis capabilities wherever FBC-capable DOCSIS 3.0 and 3.1 cable modems have been deployed.
Is FBC really like having a spectrum analyzer in subscribers' homes? **Figure** 4 and **Figure** 5 show a lab setup comparing the screen shot from an FBC-equipped cable modem with a screen shot from a Keysight spectrum analyzer. Single carrier quadrature amplitude modulation (SC-QAM) signals are located at the low end of the spectrum starting at 261 MHz. Two orthogonal frequency division multiplexing (OFDM) signals are located between about 408 MHz to 600 MHz and 608 MHz to 800 MHz respectively. A continuous wave (CW) carrier is present at 303 MHz. A filter created a deep notch at about 337 MHz, and a 5 MHz to 750 MHz bandpass filter rolled off the higher OFDM signal about 25 dB from 750 MHz to 800 MHz.

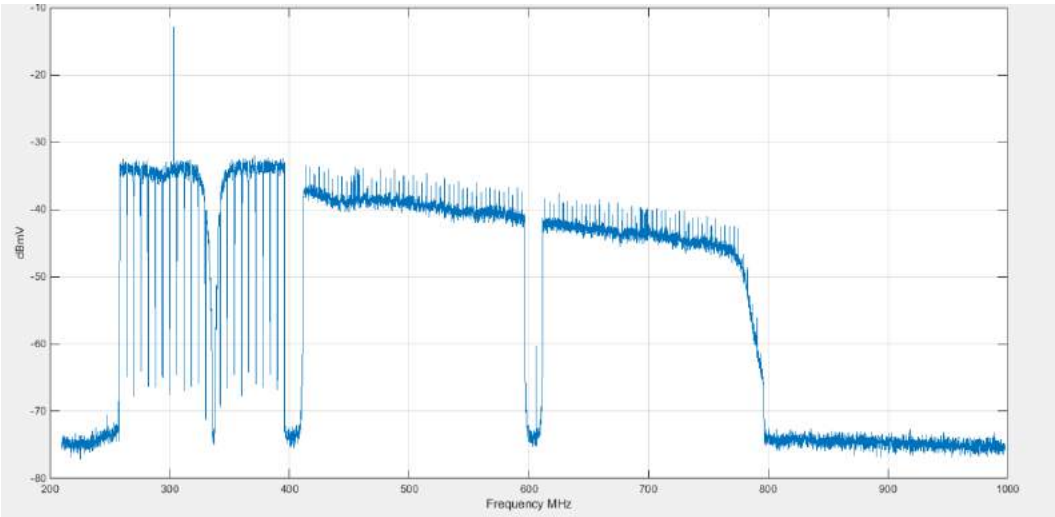

**Figure 4. FBC from modem in lab setup (see text). Courtesy of CableLabs.**

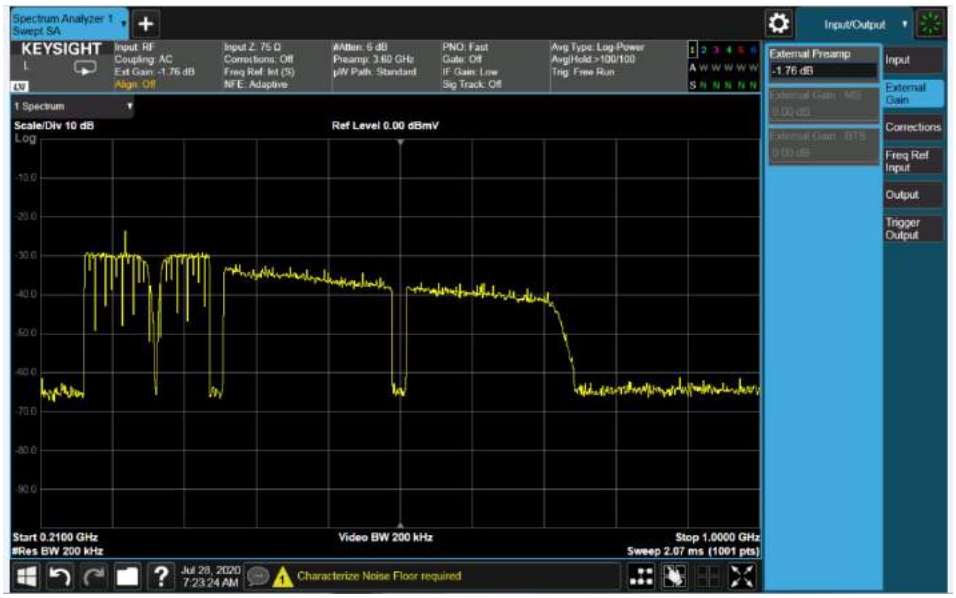

**Figure 5. Spectrum analyzer display of the same RF spectrum in Figure 4 (courtesy of CableLabs).**

FBC allows operators to obtain remote spectrum captures at the subscriber premises without having to take an expensive spectrum analyzer into the field; without requiring access into subscribers' homes; and without having to roll a truck to identify problems! Key benefits of FBC include significant operational advantages, not to mention operational cost savings.

With a substantial number of FBC-capable DOCSIS cable modems already deployed, these devices have gathered critical mass and are now in a large percentage of subscribers' homes. As such, operators can use FBC to identify individual drop problems, and correlate RF spectrum signatures from neighboring modems to troubleshoot and locate distribution network problems affecting groups of modems.

The width of the FBC spectrum – the full downstream spectrum (and sometimes also the upstream spectrum, depending on modem implementation) – allows operators to detect very short micro-reflections not visible when just a single channel is analyzed through adaptive equalization or pre-equalization. FBC has enabled verification of channel RF level alignment – for instance, incorrect narrowcast injection signal levels – and the detection of ingress. Correlation of FBC signatures before and after actives enables the detection of nonlinear problems in amplifiers. And much, much more. **Figure** 6 shows examples of some of the impairments that can be identified using FBC. Additional examples are included later in this paper.

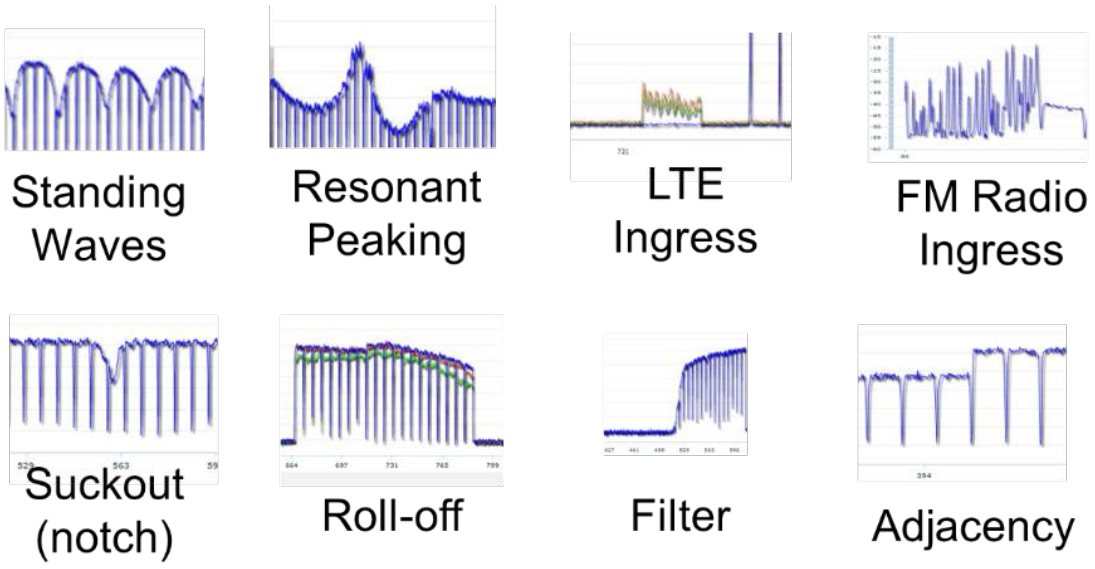

**Figure 6. Examples of some impairments found using FBC (courtesy of Comcast).**

Clearly, having the equivalent of a spectrum analyzer in every home that has an FBC-capable modem provides powerful troubleshooting and maintenance capabilities. That said, it is simply not practical for cable operators to manually look at every modem's FBC spectrum data. What to do? Automated spectrum signature analysis and impairment detection are available to scale the analysis to the millions of modems deployed with FBC functionality, and are discussed later in Section 8. All of this can be done remotely!

## 3. A Closer Look at Impairment Categories

Impairments to an FBC's spectrum can be broken into two classes or categories: things that are added to the FBC that should not be there, and downstream signals that have been modified from their original unimpaired state. Fortunately, most downstream SC-QAM and OFDM signals appear to have a relatively static noise-like appearance to a spectrum analyzer, but this is not true for upstream signals.

Energy that is added includes:

- Random noise from plant nonlinear distortion or from too-low RF levels.
- Wideband ingressors such as LTE signals and UHF TV broadcast signals, entering the network via shielding problems in the hardline distribution network or subscriber drop (including inside the home).
- Narrowband signals like broadcast FM radio and amateur radio transmissions, entering the network via shielding problems in the hardline distribution network or subscriber drop (including inside the home).
- House wiring noise. House wiring noise can enter the cable plant through defective coaxial cable shielding, which is unfortunately pervasive. [Ref. 2] estimates that 12% to 20% of houses have defective cable shielding and can pass noise from house electrical wiring to the cable plant. House wiring noise is harder to detect and measure because it is often intermittent, usually impulsive in nature, and concentrated in the upstream band, which is visible only with cable modem FBC hardware that has an upstream view capability. Such modems are already deployed in the field (more on this later),
- FBC measurement artifacts, such as an elevated noise floor and spurious signals. These generally are relatively small and easy to identify.

Things that modify the waveform include:

- Adjacency – One example is incorrect narrowcast RF signal levels compared to the rest of the downstream spectrum.
- Filter – Indicates the presence of a filter (e.g., a high-speed data-only filter).
- Non-periodic waves – A response impairment that occurs in the presence of distributed impedance mismatches that can be caused by, for example, water in the coaxial cable.
- Resonant peaking – Usually caused by a loose module, circuit board, poor grounding, etc., in an active or passive device.
- Rolloff – Low-end rolloff is usually caused by a loose center conductor seizure screw or similar. Higher-frequency rolloff is caused by water, or damaged cable or equipment.
- Standing waves – Periodic scalloped sinusoidal or sinusoidal-like amplitude ripple in the frequency response is created by discrete impedance mismatches.
- Suckout – Notch in the frequency response affecting one or more channels, caused by loose modules, module covers, printed circuit boards, poor grounding, and similar problems inside of active or passive device housings. Can also be caused by repetitive, regularly spaced impedance discontinuities in coaxial cable.
- Tilt – Some upward or downward tilt is normal, but excessive downward tilt is indicative of a problem.

Because a cable operator may have many millions of cable modems in its plant, and because the artifacts can be dynamic, as mentioned previously software exists that can automatically detect and report on both added and modified impairments. The power of human eyes and brains is assisted greatly by sophisticated PNM software algorithms processing thousands of FBC responses in batch mode.

Several examples of FBC spectrum displays showing a variety of impairments are included in Section 5.

# 4. How FBC Works

## 4.1. General Operation

FBC is a feature that uses low-cost discrete Fourier transform (DFT) and fast Fourier transform (FFT)-based technology to support spectrum analyzer-like functionality in many DOCSIS 3.0 and all DOCSIS 3.1 cable modems.

As mentioned earlier, FBC spectrum data can be accessed remotely using SNMP or similar, allowing a cable operator to see where various impairments might be problematic from the perspective of the modems and without the need to be on-site at the subscriber premises.

Spectrum analyzers are instruments used to measure the frequency content of an input signal. This is also what DFT does. Multiplying the input signal by what is called a DFT matrix measures the correlation of that input signal with each row in the DFT matrix, and each row is a sine/cosine of a particular frequency. Thus, each output bin represents the power of the input signal at that frequency with a complex value which corresponds to the amplitude and phase of that frequency component within the input signal.

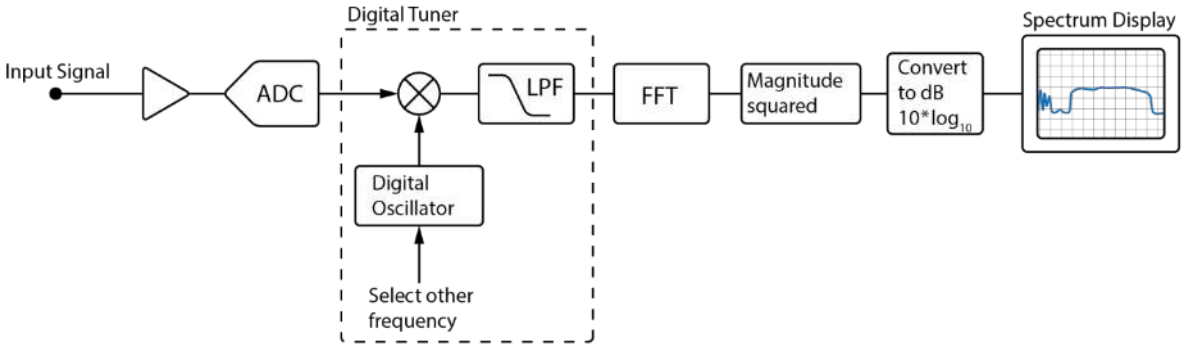

**Figure 7. Digital spectrum analyzer block diagram (see text).**

**Figure 7** shows a block diagram of a digital spectrum analyzer which could reside in a cable modem. The input signal enters at the left of the diagram; this signal is the full upstream or downstream band of the cable plant. An analog front end (represented by a small triangle in the figure) amplifies the signal and provides RF gain control. A high-speed analog-to-digital converter (ADC) provides digital samples of the signal. A digital tuner, consisting of a digital oscillator and lowpass filter, selects the desired analysis band around a specified center frequency. The signal from the selected band is applied to the FFT, which multiplies the signal by the DFT matrix. Each bin of the FFT output comprises a complex value consisting of two numbers, real (I) and imaginary (Q), giving the correlation of the input signal with the particular frequency corresponding to a single row of the DFT matrix. Typically, a spectrum analyzer is only concerned with the magnitude, not the phase, of the FFT output. So, the power (magnitude-squared) of each bin is computed, that is, $I^2 + Q^2$ for each bin. If spectrum smoothing is to be applied, the previously-described process is repeated with a fresh set of data from the same band, and the power values from several captures are averaged at each bin location. The smoothed bins are converted to decibels by taking $10*\log_{10}$ of each bin power value. The decibel values, one for each frequency bin, are displayed as the spectrum of the input signal.

If the entire band is able to be processed as a single analysis band, the tuner shown in ***Figure 7*** is not necessary. However, if the band is being analyzed in segments, then the tuner is used to step through a sequence of analysis segments of the full band, and the individual spectrum segments are spliced together to produce the overall wideband spectrum.

## 4.2. FBC Controls

The cable modem FBC feature is defined by the CmSpectrumAnalysis management information base (MIB) object in the CableLabs DOCSIS 3.1 CM OSSI specification [Ref. 3]. The CmSpectrumAnalysisCtrlCmd MIB provides a set of attributes which are used to configure and enable a spectrum capture. The cable modem spectrum capture is performed over a set of spectral segments where the segment width is defined by the SegmentFrequencySpan and the entire capture is defined by the FirstSegmentCenterFrequency, LastSegmentCenterFrequency and NumBinsPerSegment. WindowFunction allows selection from an assortment of windows. The RBW is a function of the NumBinsPerSegment but is scaled by an amount related to the WindowFunction in use for the capture; the reported RBW (units of Hz) is used to multiply an input signal or noise flat power spectral density (PSD, or dBmV per Hz) to yield the power (dBmV) measured in each bin: Flat PSD (dBmV/Hz) times RBW (Hz) equals bin power (dBmV). The frequency-resolving capability of the window, which is similar to the frequency span of its passband, is different than the RBW, and is described by the EquivalentNoiseBandwidth MIB object. This object is a unitless number relating the ratio of the window

 

frequency span divided by the FFT bin spacing. At least one vendor has scaled the application of the window function such that the RBW is always equal to the bin spacing, but the frequency-resolving capability is still described by the EquivalentNoiseBandwidth MIB object. An averaging feature, NumberOfAverages, is available for the FBC which uses the leaky integrator method. The averaging feature is very useful in that the averaging is performed by the cable modem software prior to making the data available. The data for a particular capture can be retrieved using the CmSpectrumAnalysisMeas object or by using the Bulk Data CM Spectrum Analysis File uploaded via TFTP. Additional details are discussed in Section 6.

The CableLabs specification has no requirements with respect to the accuracy of the spectrum analysis feature. However, the measurement inherits accuracy from the cable modem requirement to report the power per 6 MHz in any downstream channel with an accuracy of ±3 dB. The amplitude data which is made available as just described uses 16 bit two's complement notation in units of hundredths dBmV per bin.

## 5. FBC Examples

This section includes several examples of FBC screen shots from operating cable networks. The examples highlight some of the more common impairments that can be identified using FBC. In systems where FBC is being used, technicians' comment that the spectrum analyzer-like displays are very intuitive and easy to interpret. Use case examples with more detailed information about the problems observed are included, too.

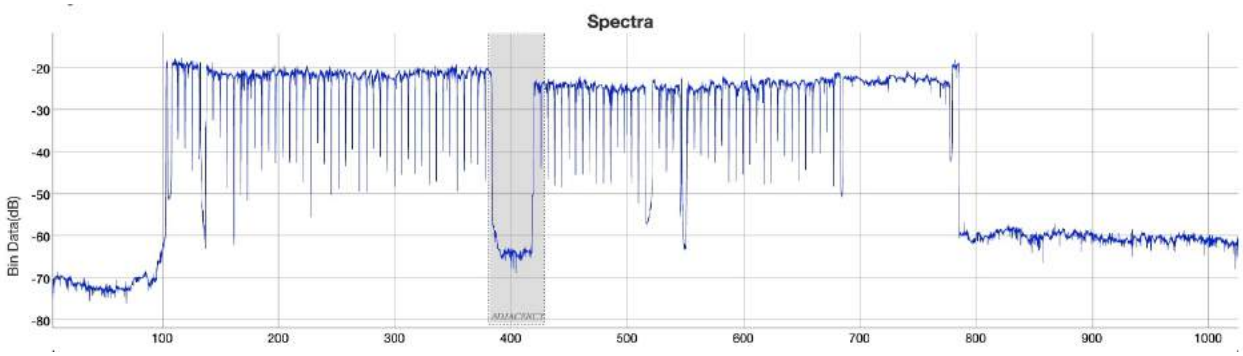

**Figure 8. Adjacency – While the spectrum is relatively flat, note that signals below 400 MHz are a few dB higher in amplitude than signals above 400 MHz. This suggests incorrect RF level adjustment in the headend or hub site (courtesy of Comcast).**

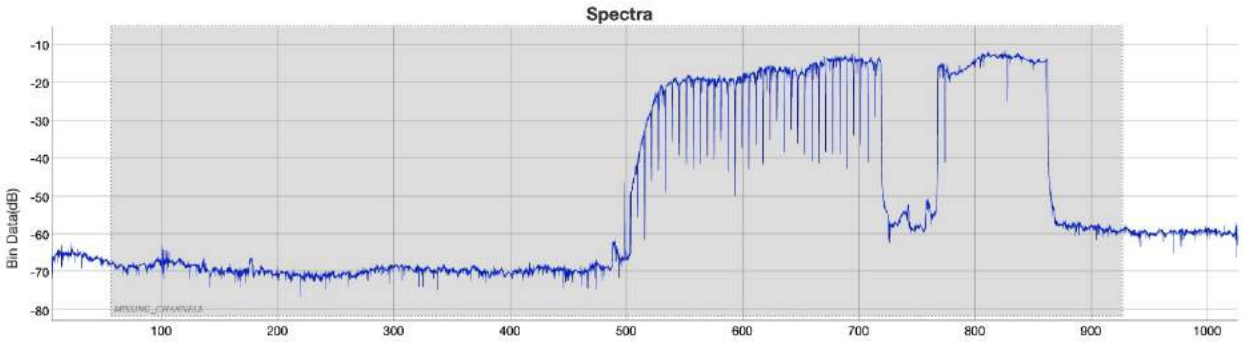

**Figure 9. Filter – Indicates the presence of a filter in the subscriber drop (courtesy of Comcast).**

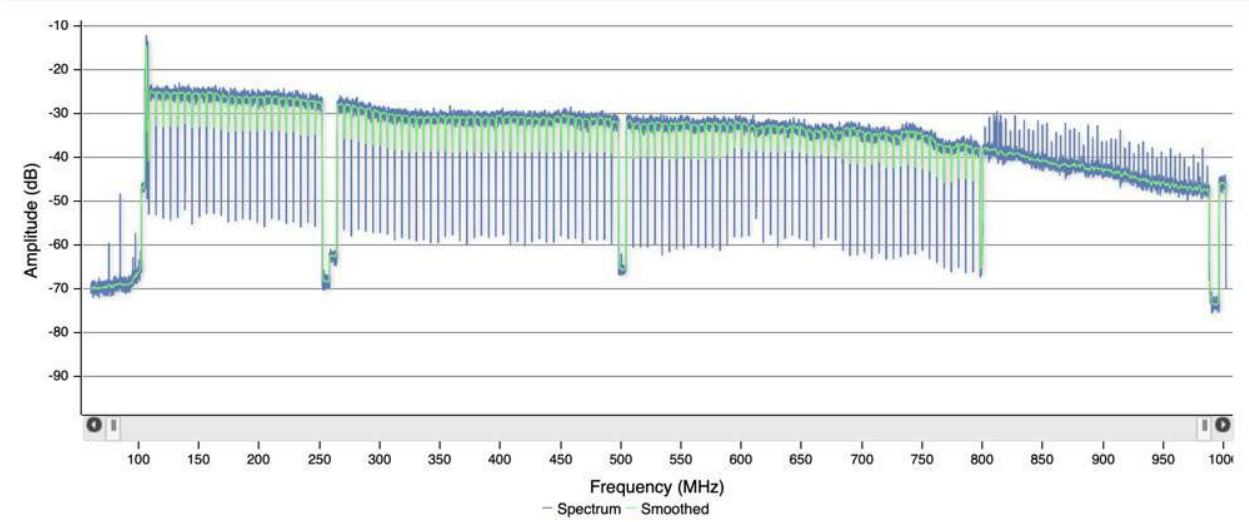

**Figure 10. Negative tilt – Typical response at or near ends-of-line locations, but excessive negative tilt could indicate a problem. Note presence of what appears to be FM broadcast band ingress at the left end of the display (courtesy of Akleza).**

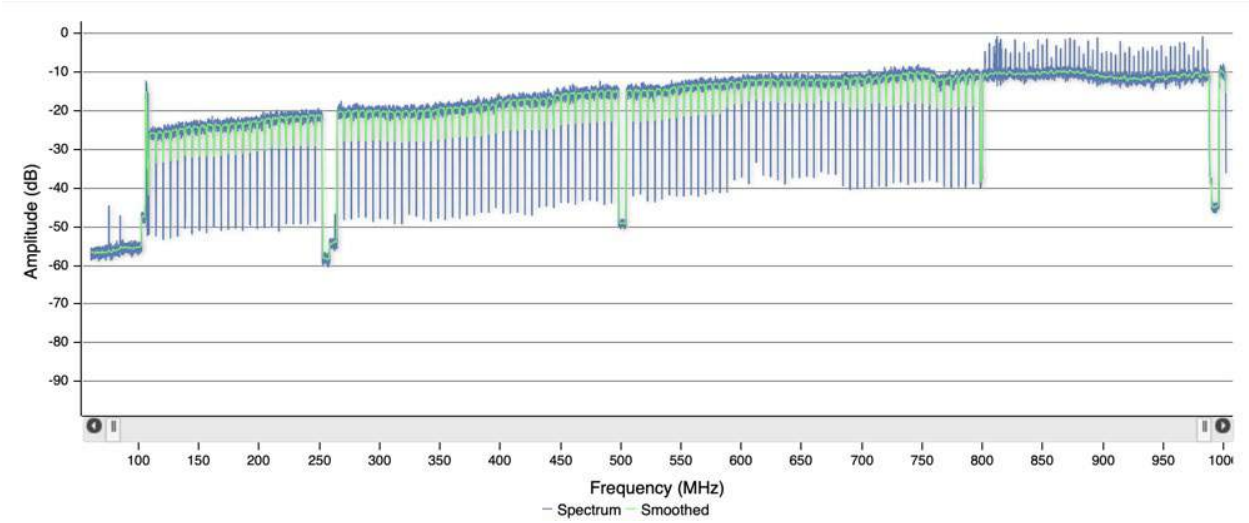

**Figure 11. Positive tilt – Typical response at or near the output of nodes and amplifiers. Note presence of what appears to be FM broadcast band ingress at the left end of the display (courtesy of Akleza).**

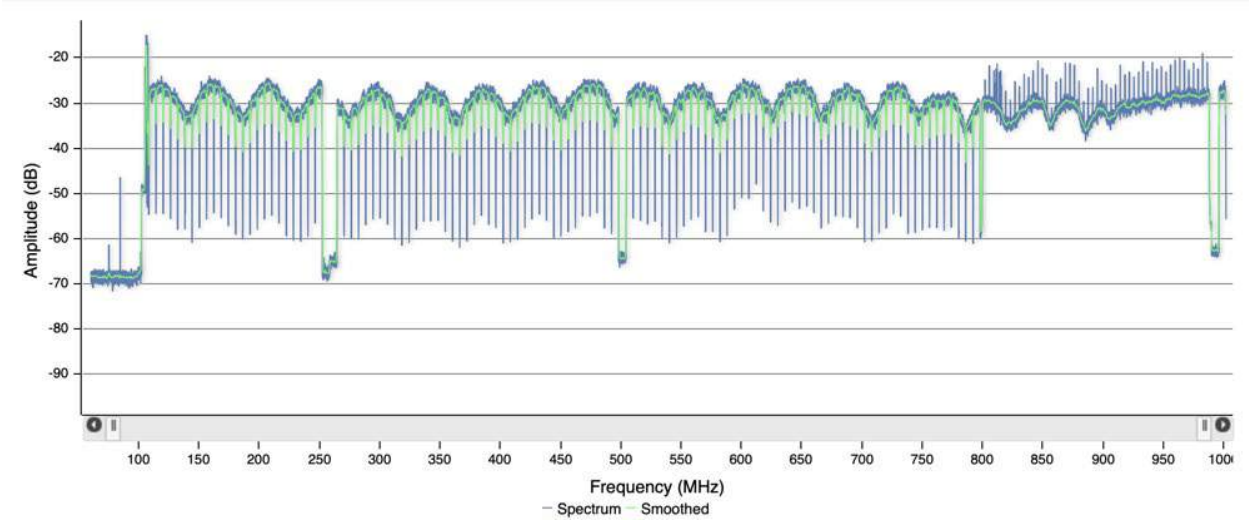

**Figure 12. Standing wave – Classic example of scalloped sinusoidal wave shape in the response, caused by an impedance mismatch (courtesy of Akleza).**

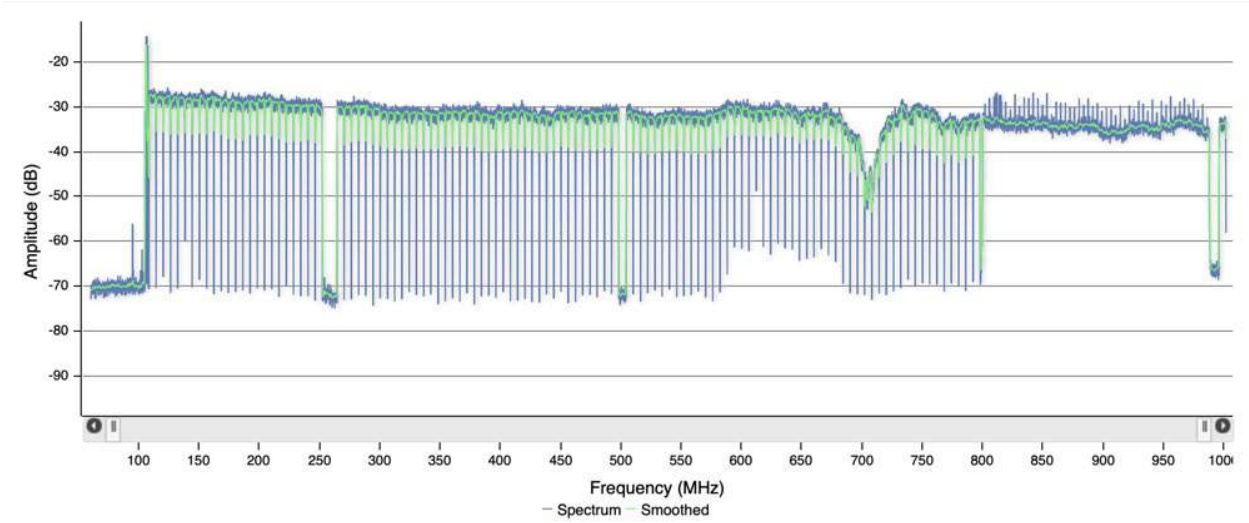

**Figure 13. Suckout – Notch in the response, centered just above 700 MHz (courtesy of Akleza).**

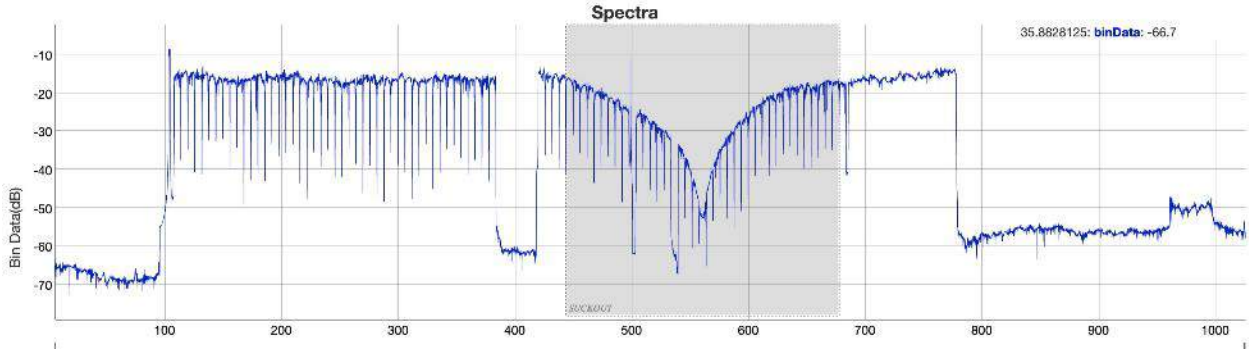

**Figure 14. Suckout - A severe example, centered between 500 MHz and 600 MHz (courtesy of Comcast).**

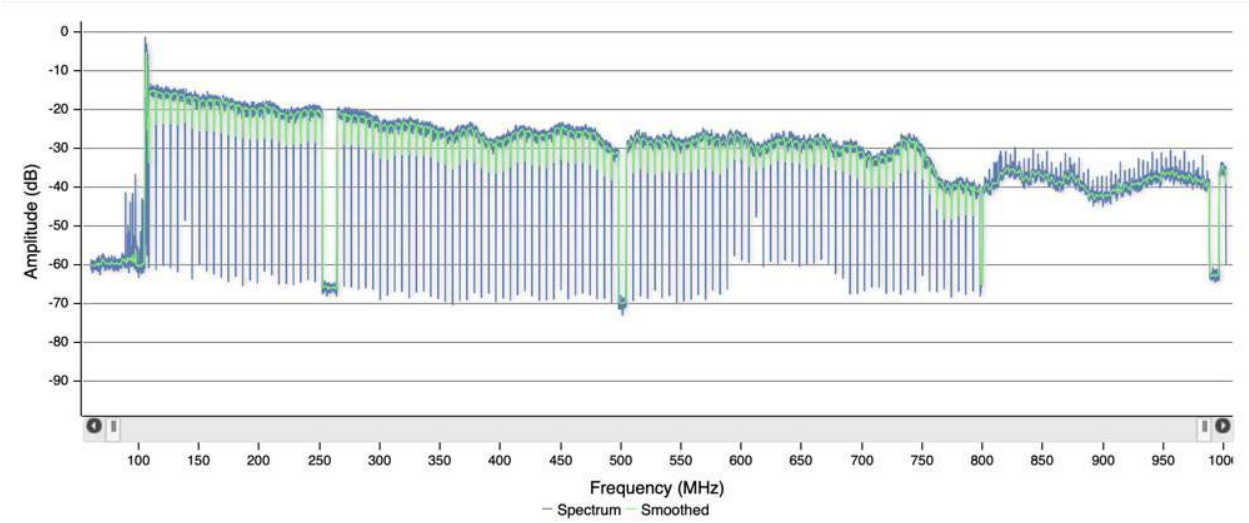

**Figure 15. Water damage - Non-periodic wave shape in the response and higher attenuation at higher frequencies, typical of water damage in a subscriber drop (courtesy of Akleza).**

The next four figures show resonant peaking varying over a four-day period. An important note: Should a varying response problem such as resonant peaking occur in the vicinity of the cable network's AGC pilot, amplifier operation will be affected and signal levels will vary, too. Tracking down what is often an intermittent problem like this is usually difficult, but FBC can be a valuable tool to help quickly identify and locate the source.

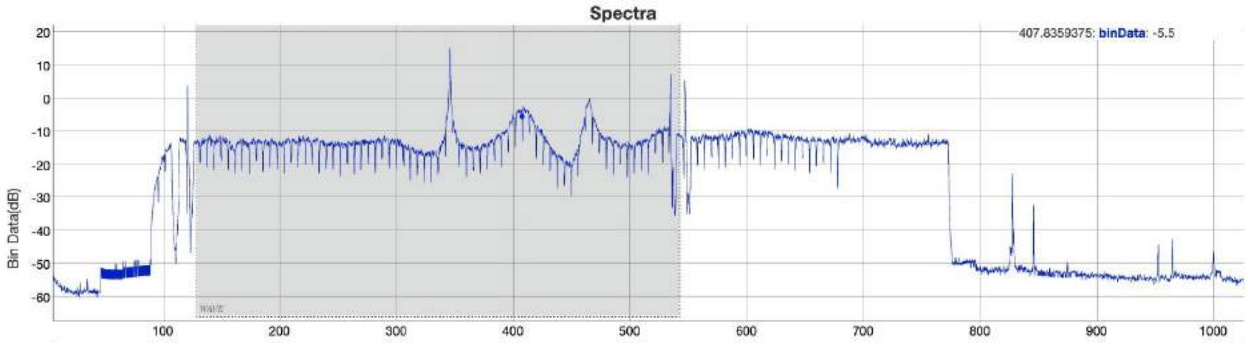

**Figure 16. Resonant peaking – Day 1 FBC spectrum (courtesy of Comcast).**

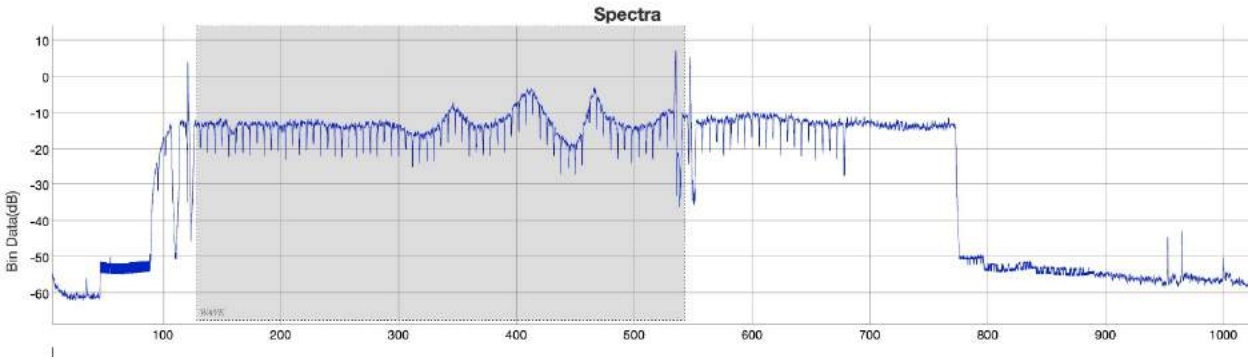

**Figure 17. Resonant peaking - Day 2 FBC spectrum, same modem as previous figure (courtesy of Comcast).**

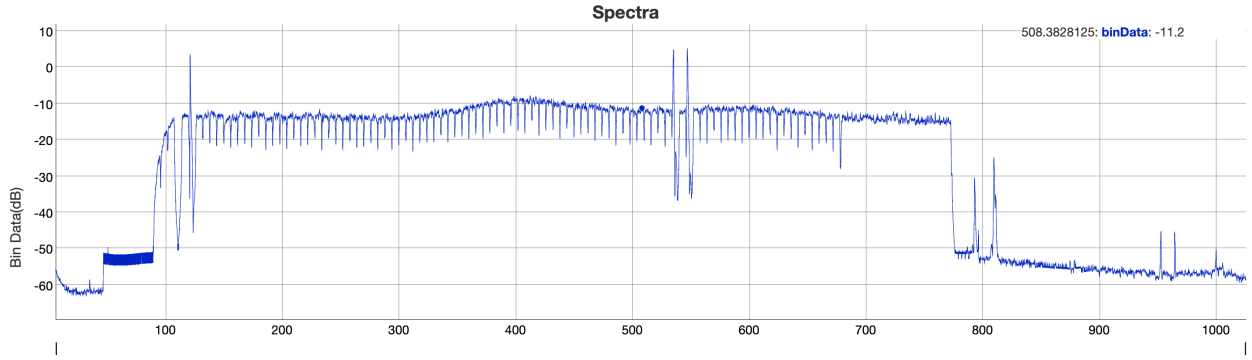

**Figure 18. Resonant peaking – Day 3 FBC spectrum, same modem as previous two figures. Note that the problem seems to have disappeared (courtesy of Comcast).**

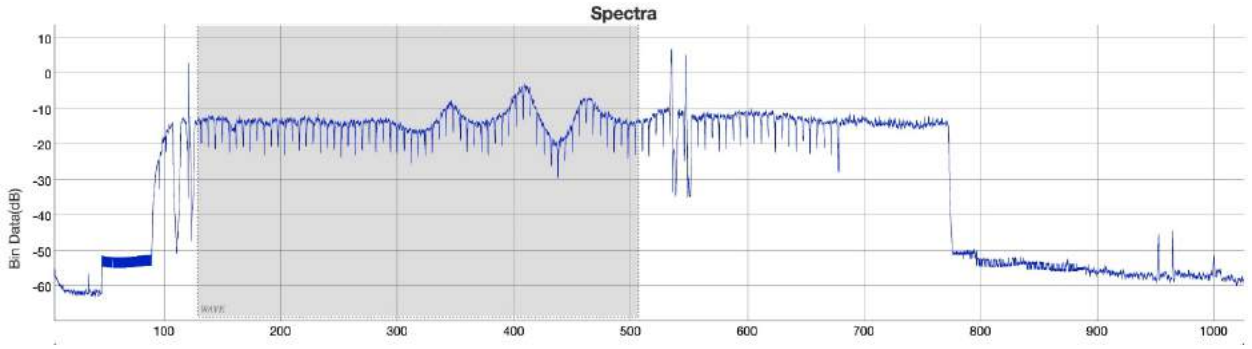

**Figure 19. Resonant peaking - Day 4 FBC spectrum, same modem as previous three figures. The response problem has returned (courtesy of Comcast).**

## 5.1. FBC Use Cases

The following examples include additional details related to the use of FBC to troubleshoot problems.

### *5.1.1. Water damaged drop*

FBC was used to identify an individual subscriber drop that had water damage, specifically by the unique signature in the displayed frequency response. As ***Figure 20*** shows, the response has a non-periodic wave shape, and attenuation increases dramatically at higher frequencies. Remote polling of the modem showed that most of the downstream SC-QAM signals had poor performance, as shown in ***Figure 21***. The upstream was relatively unaffected.

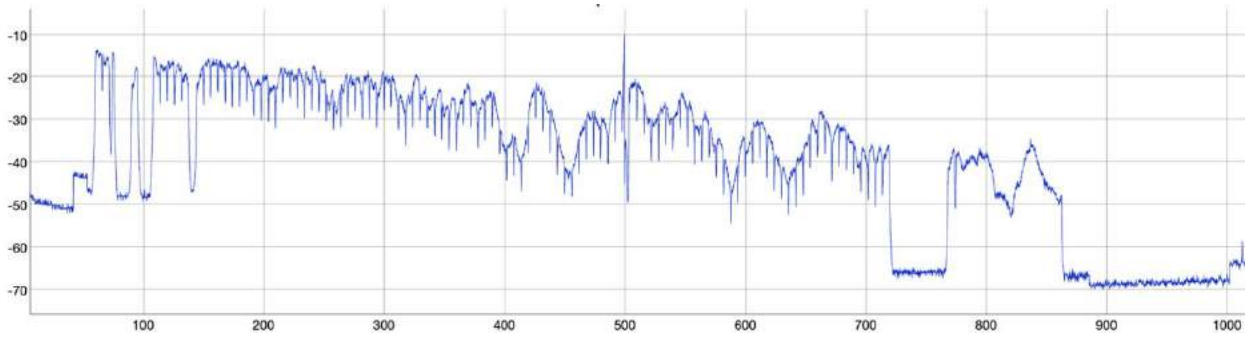

**Figure 20. Water damage before repair. Note the non-periodic wave shape in the FBC response and the higher attenuation at higher frequencies. This particular example occurred when abrasion damaged the cable's jacket, allowing water to enter the cable (see text). Courtesy of Comcast.**

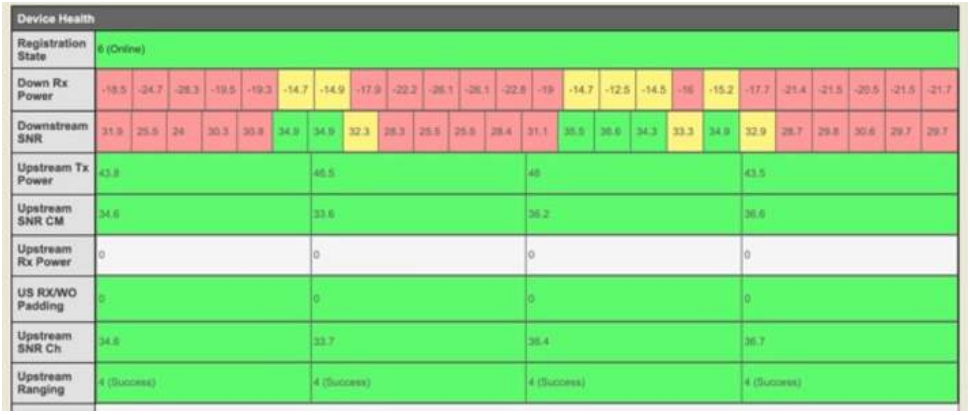

**Figure 21. Most of the downstream SC-QAM signals have low signal level and degraded RxMER, indicated in red shaded boxes. The upstream was relatively unaffected (courtesy of Comcast).**

Technicians went to the subscriber location and were able to find and fix the problem without having to enter the premises. ***Figure 22*** shows the coax jacket, which had been damaged by abrasion from the electrical service drop. The damaged coax jacket allowed water to enter the cable and travel inside of the cable all the way to the ground block. ***Figure 23*** shows water coming out of the connector at the ground block end of the drop.

**Figure 22. Damaged coax jacket where water was able to enter the cable.**

**Figure 23. Water coming out of the end of the connector at the ground block.**

The fix was to replace the subscriber drop from the tap to the ground block. ***Figure 24*** shows the FBC screen shot after the new drop was installed, and ***Figure 25*** the post-repair SC-QAM performance.

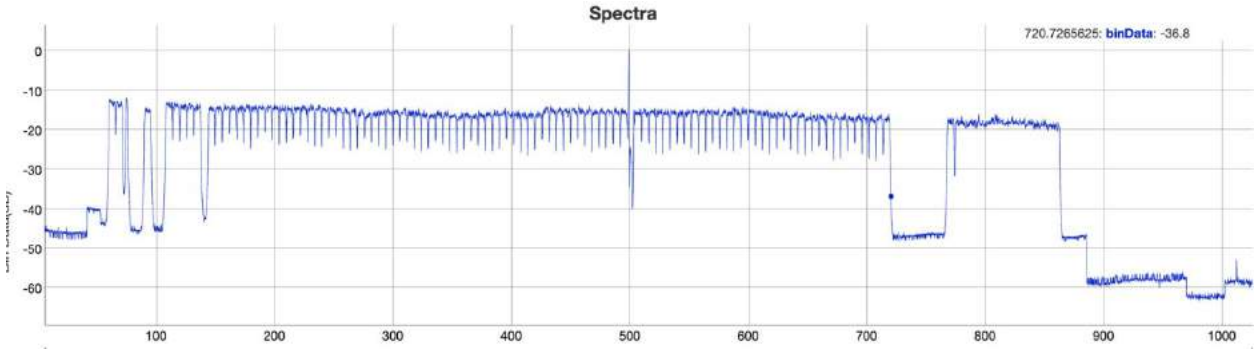

**Figure 24. FBC response after drop cable was replaced from the tap to the ground block (courtesy of Comcast).**

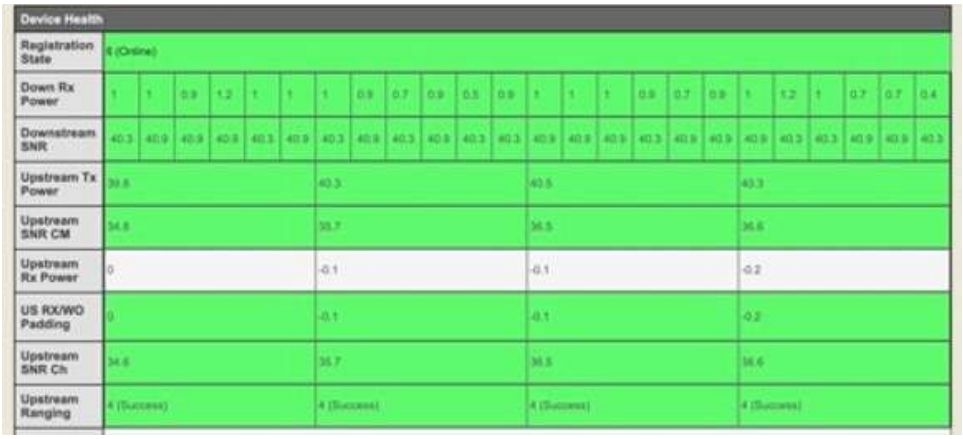

**Figure 25. Signal performance after the drop was replaced (courtesy of Comcast).**

Additional discussion about water-soaked cable can be found in Section 7.4.

### *5.1.2. Localizing a problem to a specific drop*

A problem was detected at Subscriber A: The OFDM modulation profile was limited to 64-QAM, but was expected to be 2048-QAM or better.

The OFDM signal in this 860 MHz HFC network is from 774 MHz to 864 MHz, with an exclusion band configured – 790 MHz to 820 MHz – to avoid ingress from the European 800 MHz 4G/LTE band.

Using the cable modem's built-in FBC function (port 8080), strong ingress was detected at all 5G and LTE frequencies in the area, as shown in ***Figure 26***.

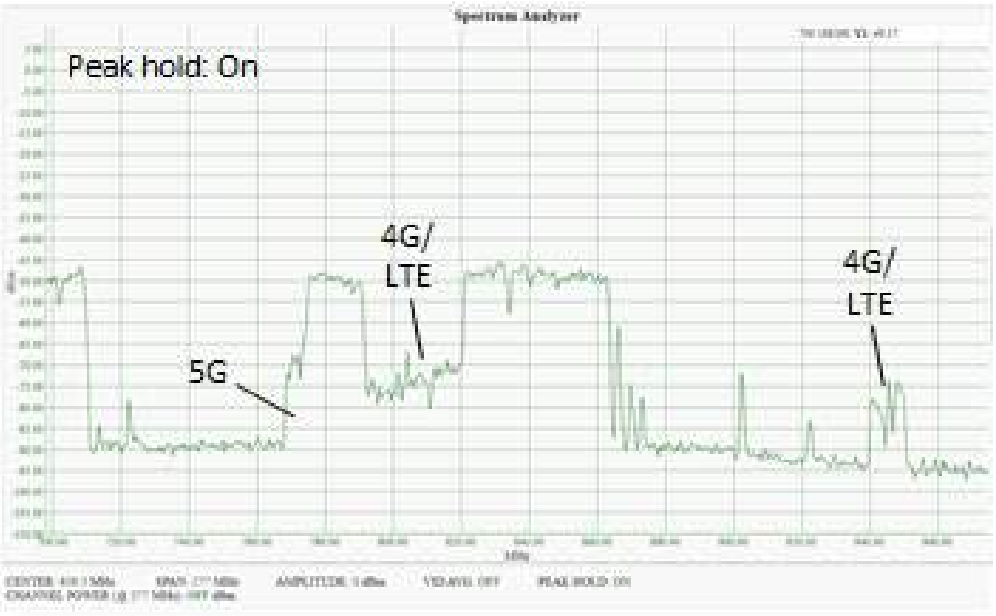

**Figure 26. Subscriber A's FBC showing 4G/LTE and 5G ingress (courtesy of Telia Norge).**

Looking up the neighboring address (Subscriber B) and using FBC in that cable modem (***Figure 27***), no ingress is to be seen.

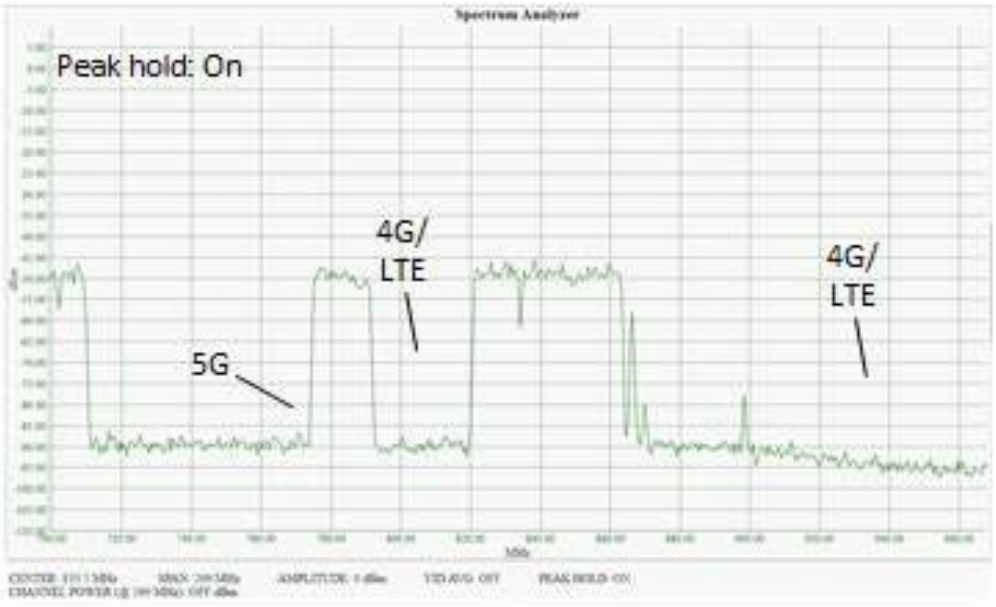

**Figure 27. Subscriber B's FBC, showing no 4G/LTE or 5G ingress (courtesy of Telia Norge).**

It can now easily be determined that the root cause of the problem is related to the drop cable and/or house internal network at Subscriber A's premises.

Checking the location of nearby base stations (***Figure 28***), it turns out that Subscriber A is located approximately 420 meters (~1380 feet) from a cell site that is operating on the 700, 800 and 900 MHz bands.

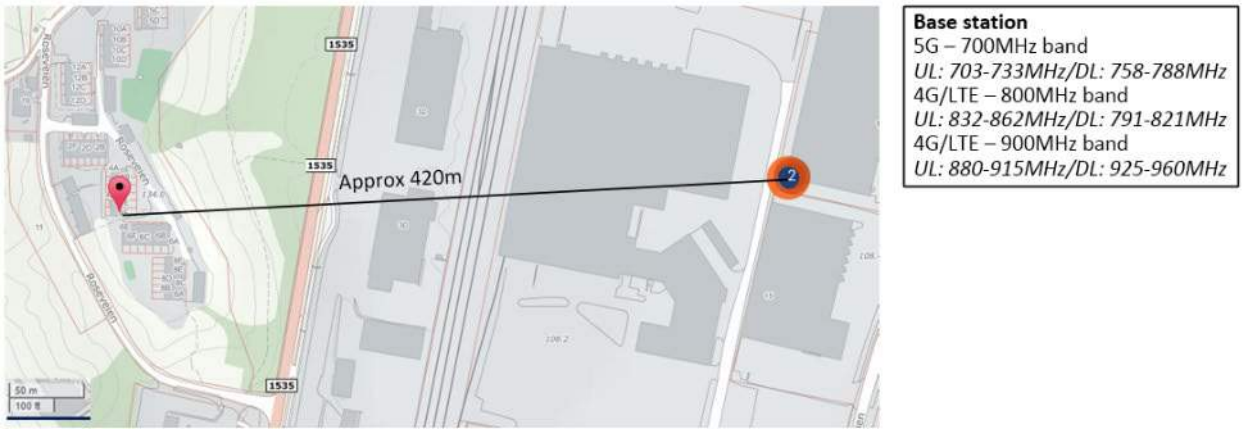

**Figure 28. Location of cell site near the affected subscriber drop.**

### *5.1.3. FBC Analysis and Fault Location Example*

In this example a standing wave was detected that impacting a large part of a node's service area. This problem could clearly be seen in the FBC plots as shown in the traces on the right-hand side of ***Figure 29*** and was impacting all subscribers downstream of amplifier [1]. Modems that were being fed by a different distribution leg of upstream amplifier [2] did not show the impairment as can be seen in the FBC plot on the left. This analysis immediately isolates the problem to output connections coming from amplifier [1], the trunk output of amplifier [2] connecting to amplifier [1], or a cable fault between the two amplifiers.

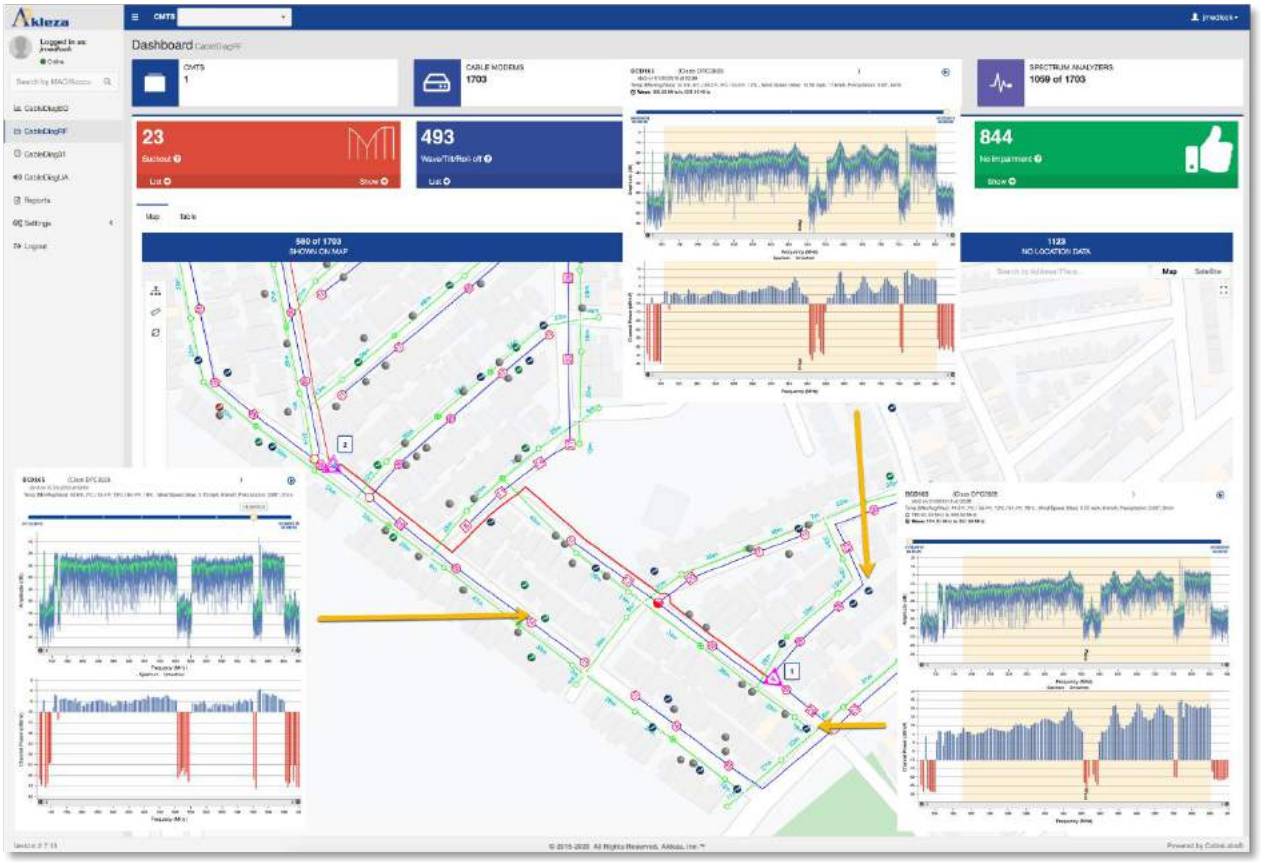

**Figure 29. Example of using FBC to isolate a standing wave fault (courtesy of Akleza).**

The technicians first checked amplifier [1] and its output connections. When the amplifier was opened, water poured out indicating a problem with the enclosure seal. Additionally, the internals of the amplifier showed corrosion as can be seen in ***Figure 30***.

 

**Figure 30. Amplifier [1] containing water and showing corrosion (courtesy of Akleza).**

Given the amount of damage to the amplifier, it was replaced, and the cable modems rescanned. This did not correct the problem indicating that the fault causing the standing wave was upstream of amplifier [1]. A field meter attached to the input side of the amplifier was used to verify this analysis and showed the problem could be seen in the signal coming in from upstream amplifier [2] (***Figure 31***).

The fault must therefore be with upstream amplifier [2] or its trunk output as it was already determined that the fault could not be seen on either of the amplifier's auxilliary distribution outputs.

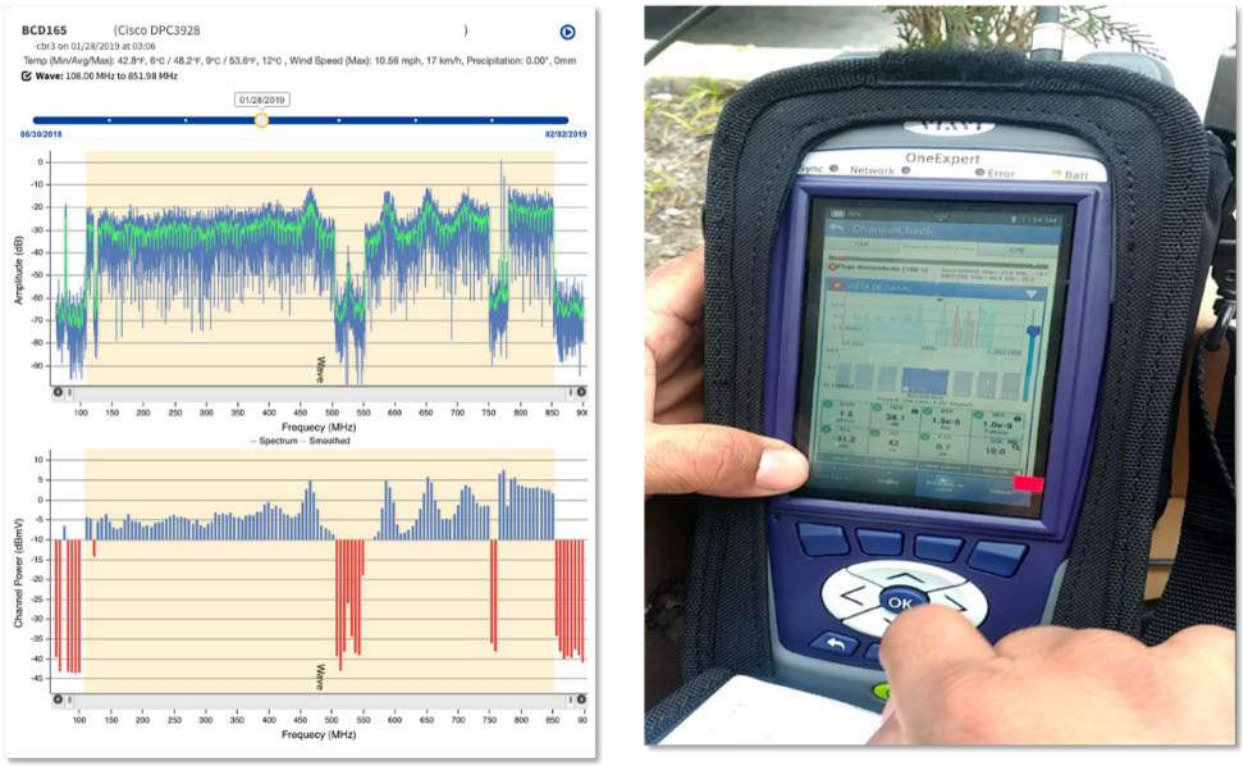

**Figure 31. Fault still visible after replacement of amplifier [1] (courtesy of Akleza).**

Verifying the signal at the output test port for the trunk connection did not show any standing wave meaning that the problem had to be with the output connector itself or the cable. When the output connection was inspected it was noticed that the connector showed signs of corrosion as well as the center conductor being cut too short, and therefore not making good contact internally (***Figure 32***). Corrorision and badly installed connectors are common causes of impedance mismatches in the cable plant and can cause standing wave spectrum faults.

**Figure 32. Amplifier [2] with corroded connector (courtesy of Akleza).**

Once the output connector was replaced, the cable modems were rescanned and showed that the standing wave fault had been fixed. ***Figure 33*** shows the resulting FBC plot from one of the cable modems after the fault was corrected.

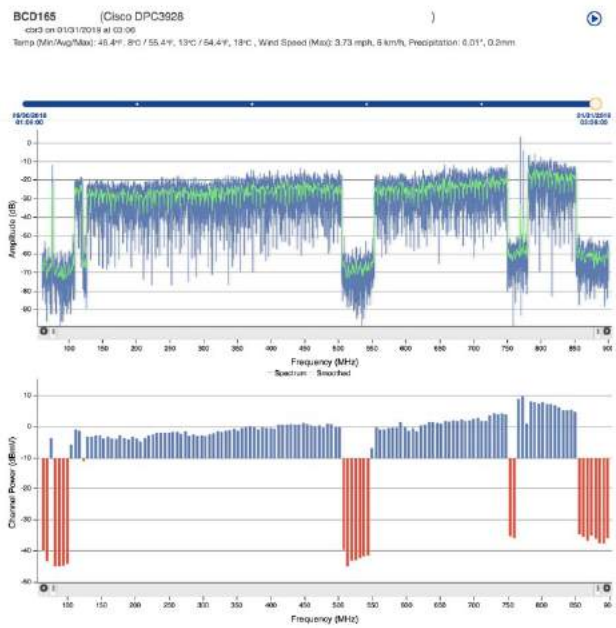

**Figure 33. FBC trace after faulty connector replaced (courtesy of Akleza).**

This example shows how analyzing FBC data collected remotely from cable modems within the network can quickly be used to identify customer service faults and quickly triangulate the fault location based on the FBC response from multiple devices.

# 6. How to retrieve and Display FBC Data

## 6.1. FBC Data Collection

In DOCSIS 3.0 the configuration and collection of FBC data uses SNMP requests to a cable modem supporting FBC. The PNM Best Practices: HFC Networks (DOCSIS 3.0) guide [Ref. 4] describes the high-level functionality while the SNMP MIB objects are defined in the DOCS-IF3-MIB.[3]

DOCSIS 3.1 introduced a new set of requirements on the cable modem related to the collection and reporting of PNM data as described in Section 9 of the DOCSIS 3.1 Physical Layer Specification [Ref. 5], and in PNM Best Practices Primer: HFC Networks (DOCSIS® 3.1) [Ref. 8]. DOCSIS 3.1 also introduced a new bulk-data transfer mechanism that uses the trivial file transfer protocol (TFTP) to upload PNM data to a destination TFTP server. Configuration of the PNM test execution, file storage, and TFTP destination use SNMP as defined in [Ref. 3] and CCAP Operations Support System Interface (OSSI) Specifications [Ref. 6].

While the DOCSIS 3.1 bulk-data transfer mechanism supports the collection of FBC data, this is only supported by DOCSIS 3.1 cable modems. The DOCSIS 3.0 SNMP-only mechanism is, however, supported by both DOCSIS 3.0 and 3.1 modems and functionally provides the same capability so can be used as a single method across both cable modem types. This section covers the use of the DOCSIS 3.0 SNMP configuration and retrieval mechanism. For more information on the DOCSIS 3.1 bulk-data transfer mechanism refer to [Ref. 3] and the DOCS-PNM-MIB.

Commercial FBC data collection, analysis, and display products are generally available in the market from PNM vendors. The following information is provided on how to configure, retrieve, and plot FBC data for those looking to experiment with and understand what is possible with that data. Because capturing spectrum information requires SNMP read/write access to the cable modems, access using a locally attached workstation is unlikely. Typically, an FBC solution is deployed within the cable operator's operations or back office organization and must deal with a number of elements including security and data storage. A high resolution, full downstream spectrum capture can generate 200 kB to 300 kB of data that is streamed back from the cable modem. Deploying a system-wide solution therefore requires careful engineering as well as suitable resources to handle the data collection and storage requirements.

In the provided examples the freely available Net-SNMP tools are used which can be installed on most operating systems. For specific instructions on installing and using Net-SNMP for a particular platform visit the Net-SNMP website at www.net-snmp.org. Any SNMP community string or IP addresses included in this paper are simply examples and should be updated to match your own environment. Some Python-based scripts have also been provided to assist in the collection and display of the FBC data. These are provided purely for informational purposes and should not be considered production-level code. **Figure** 34 shows the DOCS-IF3-MIB objects that will be used to configure and retrieve the FBC data from the cable modem.

[3] The CableLabs MIB repository is here: http://mibs.cablelabs.com/MIBs/DOCSIS/

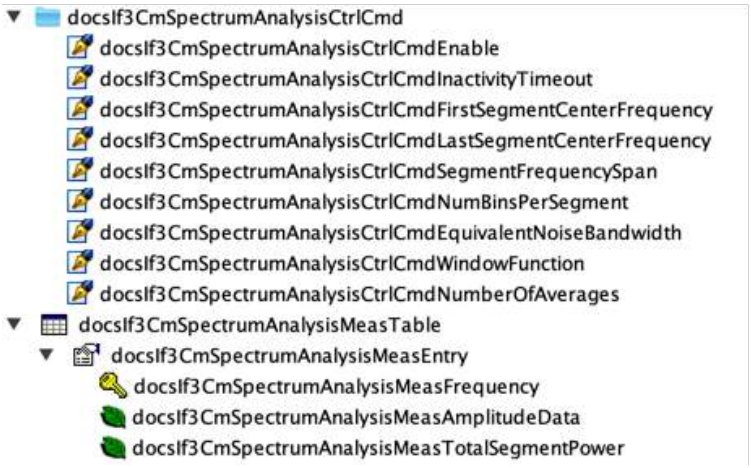

**Figure 34. IF3-MIB spectrum capture objects**

While in general all DOCSIS 3.0 and 3.1 cable modems should be capable of spectrum capture, some early DOCSIS 3.0 cable modems running older versions of firmware may not support the capability. In order to first determine if a cable modem supports FBC, a simple SNMP read operation on the docsIf3CmSpectrumAnalysisCtrlCmdEnable object can be performed. If the device supports FBC, this object will return a value, while a device that does not support the function will return an SNMP No Such Object error meaning that the cable modem firmware does not support the DOCS-IF3-MIB FBC objects.

This example shows a response from a cable modem that supports FBC.

```
$ snmpget -v2c -c public 10.60.0.7 docsIf3CmSpectrumAnalysisCtrlCmdEnable.0
DOCS-IF3-MIB::docsIf3CmSpectrumAnalysisCtrlCmdEnable.0 = INTEGER: false(2)
```

This example shows the response from a cable modem that does not support FBC.

```
$ snmpget -v2c -c public 10.60.0.17 docsIf3CmSpectrumAnalysisCtrlCmdEnable.0
DOCS-IF3-MIB::docsIf3CmSpectrumAnalysisCtrlCmdEnable.0 = No Such Object available on this agent at this OID
```

Instructing the cable modem to collect FBC data and then retrieving the data is a two-step process. First the `docsIf3CmSpectrumAnalysisCtrlCmd` objects need to be set to values describing the data capture you want, and then the results are read from the `docsIf3CmSpectrumAnalysisMeasTable`. Again, depending upon the vintage of the cable modem and the functionality supported by its firmware, not all configurations may be possible.

To understand the configuration of the spectrum capture, you first need to consider how much of the spectrum you want to capture, and the resolution of the captured data. Between the start (`docsIf3CmSpectrumAnalysisCtrlCmdFirstSegmentCenterFrequency`) and end (`docsIf3CmSpectrumAnalysisCtrlCmdLastSegmentCenterFrequency`) points of the desired spectrum capture, you define the width of a segment (`docsIf3CmSpectrumAnalysisCtrlCmdSegmentFrequencySpan`) and then how many samples or bins (`docsIf3CmSpectrumAnalysisCtrlCmdNumBinsPerSegment`) you want measured within that segment. The configuration of these parameter defines how much data is going to be collected and needs to be read back from the cable modem. The greater the number of bins the higher the spectral resolution, however, this will generate more data that must be retrieved.

For example, if you request a capture of the full downstream spectrum, from, say, 54 MHz to 1002 MHz, using a segment frequency span of 6 MHz, and 256 bins per segment, you would generate 40,192 data points at a resolution of 23 kHz per point. Reduce the number of bins to 64, and you would now only

 

have 10,048 data points with a resolution of 94 kHz per point. Depending upon how you intend to use the data and the resources available to capture and store the data, you can adjust these configuration parameters accordingly.

To initiate a spectrum capture, you first must set the configuration parameters and the enable flag. **Figure** 35 shows how to configure a high resolution full downstream data collection as just described.

```
$ snmpset -v2c -c public 10.30.0.12 \
docsIf3CmSpectrumAnalysisCtrlCmdFirstSegmentCenterFrequency.0 u 57000000 \
docsIf3CmSpectrumAnalysisCtrlCmdLastSegmentCenterFrequency.0 u 999000000 \
docsIf3CmSpectrumAnalysisCtrlCmdSegmentFrequencySpan.0 u 6000000 \
docsIf3CmSpectrumAnalysisCtrlCmdNumBinsPerSegment.0 u 256 \
docsIf3CmSpectrumAnalysisCtrlCmdEnable.0 i 1
```

**Figure 35. Configuration example for high resolution downstream data collection.**

The command in **Figure** 35 sets the span width to 6 MHz, the start center frequency to 57 MHz, and the end center frequency to 999 MHz. Setting the enable value to true (1) signals the cable modem to start its spectrum capture. Using the 6 MHz span width additionally allows the spans to be aligned to standard channel frequencies whose power is also measured during the spectrum capture.

With the spectrum capture now enabled, the spectrum data can be retrieved by doing a snmpwalk of the `docsIf31CmSpectrumAnalysisMeasAmplitudeData`. This will return an SNMP table row for each frequency span as shown in **Figure** 36.

```
$ snmpwalk -v2c -c public 10.30.0.12 docsIf3CmSpectrumAnalysisMeasAmplitudeData
DOCS-IF3-MIB::docsIf3CmSpectrumAnalysisMeasAmplitudeData.57000000 = Hex-STRING:

E5 7A E2 41
```

**Figure 36. Returned SNMP table row for each frequency span.**

The first 20 bytes of each rows data consists of five integers (4 bytes) as follows:

```
 4 bytes: CenterFreq
          The center frequency of the span.
  4 bytes: FreqSpan
          The width in Hz of the span.
  4 bytes: NumberOfBins
          The number of data points or bins that compose the
          spectral data. The leftmost bin corresponds to the
          lower band edge, the rightmost bin corresponds to the
          upper band edge, and the middle bin center is aligned
          with the center frequency of the analysis span.
  4 bytes: BinSpacing
          The frequency separation between adjacent bin
```

```
                centers. It is derived from the frequency span and
                the number of bins or data points.
                The bin spacing is computed as:

                  BinSpacing = FrequencySpan/(NumberOfBins - 1)

                The larger the number of bins the finer the resolution.
        4 bytes: ResolutionBW
                The resolution bandwidth or equivalent noise
                bandwidth of each bin. If spectral windowing is used
                (based on vendor implementation), the bin spacing and
                resolution bandwidth would not generally be the same.
```

Each remaining two-byte data pair represents a bin amplitude in units of 0.01 dB. The bin amplitude data is in two's complement format so must be translated into a decimal value. There are a number of ways to convert two's complement data to decimal, but to simplify, we first convert from hexadecimal to decimal. Then, if the value is greater than 32767, it represents a negative number so we subtract 65535; otherwise, use the initially converted value. Divide the result by 100 to get the amplitude bin in dB. For example:

```
E6D6 in decimal is 59094
As 59094 > 32767 then bin value = 59094 – 65535 = -6441
Bin Amplitude in dB = -6441 / 100 = -64.41 dB
```

Using the example data above, the first row would decode as:

```
center frequency: 0365C040 = 57000000 Hz
frequency span: 005B8D80 = 6000000 Hz
number of bins: 00000100 = 256
bin spacing: 00005B8D: 23437 Hz
resolution bandwidth: 00005B8D = 23437 Hz
Bin 0: E6D6 = -64.41 dB
Bin 1: E6EA = -64.21 dB
Bin 2: E69D = -64.98 dB
:
Bin 255: EC1C = -50.91 dB
```

Given the center frequency, the number of bins, and the bin spacing, the frequency of each bin can be calculated

```
Frequency = center frequency – (number of bins / 2 * bin spacing) + (bin number *
bin spacing)
```

Using this formula, the frequency for the above example bins would be:

```
Bin 0: 54000064 Hz
Bin 1: 54023501 Hz
Bin 2: 54046938 Hz
:
Bin 255: 59976499 Hz
```

After decoding each of the `docsIf3CmSpectrumAnalysisMeasAmplitudeData` rows into their frequency and bin amplitude parts, you now have a list of frequencies and amplitudes that can be plotted to show the FBC spectrum.

In order to simplify the retrieval, decoding, the Appendix contains Python code listings of scripts that can be used to collect and display FBC data. The output of the getFbcData.py script is a comma separated values (CSV) file containing frequency and amplitude columns. This file can be directly imported into Excel and a chart created. **Figure** 37 shows an example Microsoft Excel chart using this imported data.

 

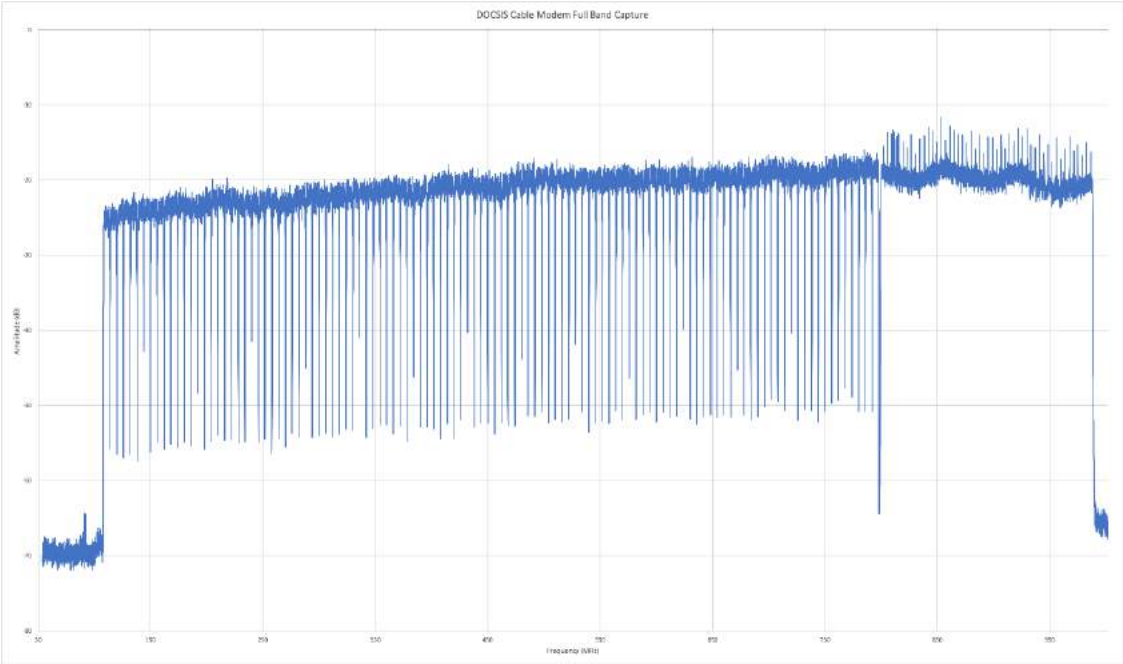

**Figure 37. FBC plot using Microsoft Excel (courtesy of Akleza).**

The Python script showFbcData.py reads a previously saved FBC CSV file and displays a plot using the Python Plotly package. **Figure** 38 shows the same FBC data displayed using this script.

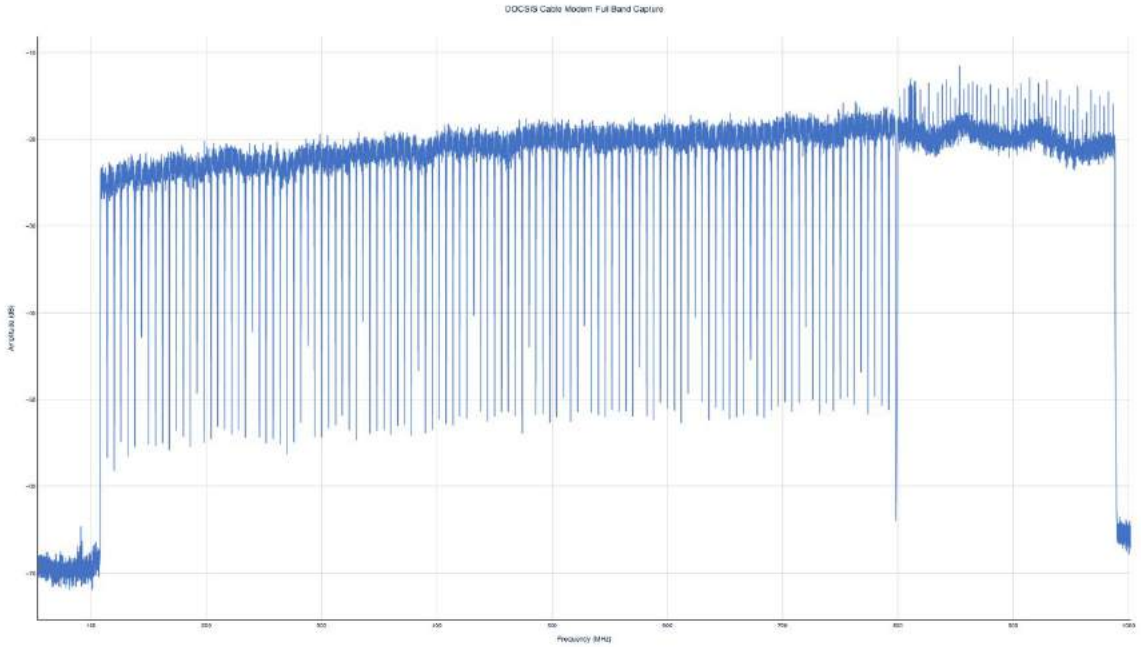

**Figure 38. FBC plot generated using example Python scripts (courtesy of Akleza).**

As shown in **Figure** 34 there are a number of configuration parameters that can be used to control the extents and resolution of the FBC function on the cable modem. Configuration parameters are also

available to control the spectral windowing function and the number of captures to be averaged during the spectrum capture.

The DOCS-PNM-MIB defines a number of windowing filters to smooth out spectral leakage problems in the underlying capture mechanism. While a number of window functions are specified, not all cable modem implementations support all of them but most do support the Hanning window which is commonly used by setting the `docsIf3CmSpectrumAnalysisCtrlCmdWindowFunction` to `hann(1)`.

Averaging is an important configuration option to help in smoothing the instantaneous capture of the underlying ADC within the FBC process. For example, **Figure** 39 shows the result of a capture with no averaging performed.

```
$ snmpset -v2c -c public 10.30.0.8 \
docsIf3CmSpectrumAnalysisCtrlCmdFirstSegmentCenterFrequency.0 u 57000000 \
docsIf3CmSpectrumAnalysisCtrlCmdLastSegmentCenterFrequency.0 u 999000000 \
docsIf3CmSpectrumAnalysisCtrlCmdSegmentFrequencySpan.0 u 6000000 \
docsIf3CmSpectrumAnalysisCtrlCmdNumBinsPerSegment.0 u 256 \
docsIf3CmSpectrumAnalysisCtrlCmdWindowFunction.0 i 1 \
docsIf3CmSpectrumAnalysisCtrlCmdNumberOfAverages.0 u 1 \
docsIf3CmSpectrumAnalysisCtrlCmdEnable.0 i 1
```

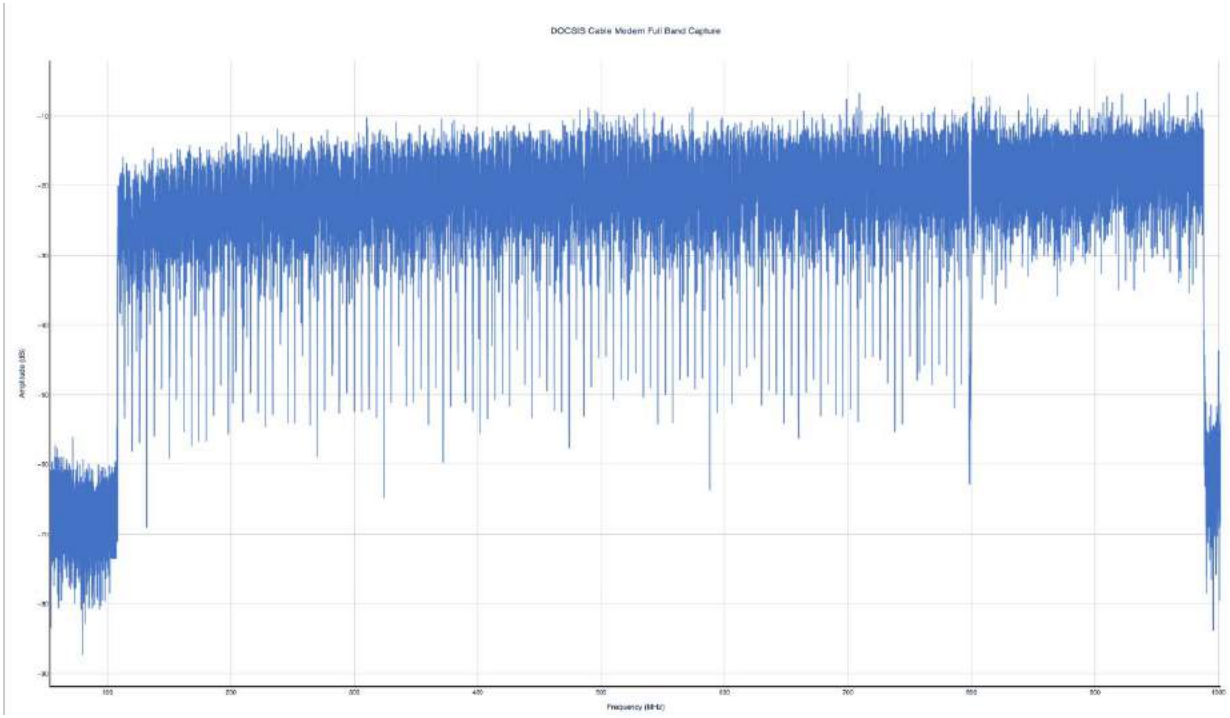

**Figure 39. FBC plot with no averaging (courtesy of Akleza).**

**Figure** 40 shows a capture where the `docsIf3CmSpectrumAnalysisCtrlCmdNumberOfAverages` was set to 32. Now you can more clearly see details such as the pilots and PLC in the OFDM channel which are lost in **Figure** 39.

```
$ snmpset -v2c -c public 10.30.0.8 \
docsIf3CmSpectrumAnalysisCtrlCmdFirstSegmentCenterFrequency.0 u 57000000 \
docsIf3CmSpectrumAnalysisCtrlCmdLastSegmentCenterFrequency.0 u 999000000 \
docsIf3CmSpectrumAnalysisCtrlCmdSegmentFrequencySpan.0 u 6000000 \
docsIf3CmSpectrumAnalysisCtrlCmdNumBinsPerSegment.0 u 256 \
docsIf3CmSpectrumAnalysisCtrlCmdWindowFunction.0 i 1 \
docsIf3CmSpectrumAnalysisCtrlCmdNumberOfAverages.0 u 32 \
docsIf3CmSpectrumAnalysisCtrlCmdEnable.0 i 1
```

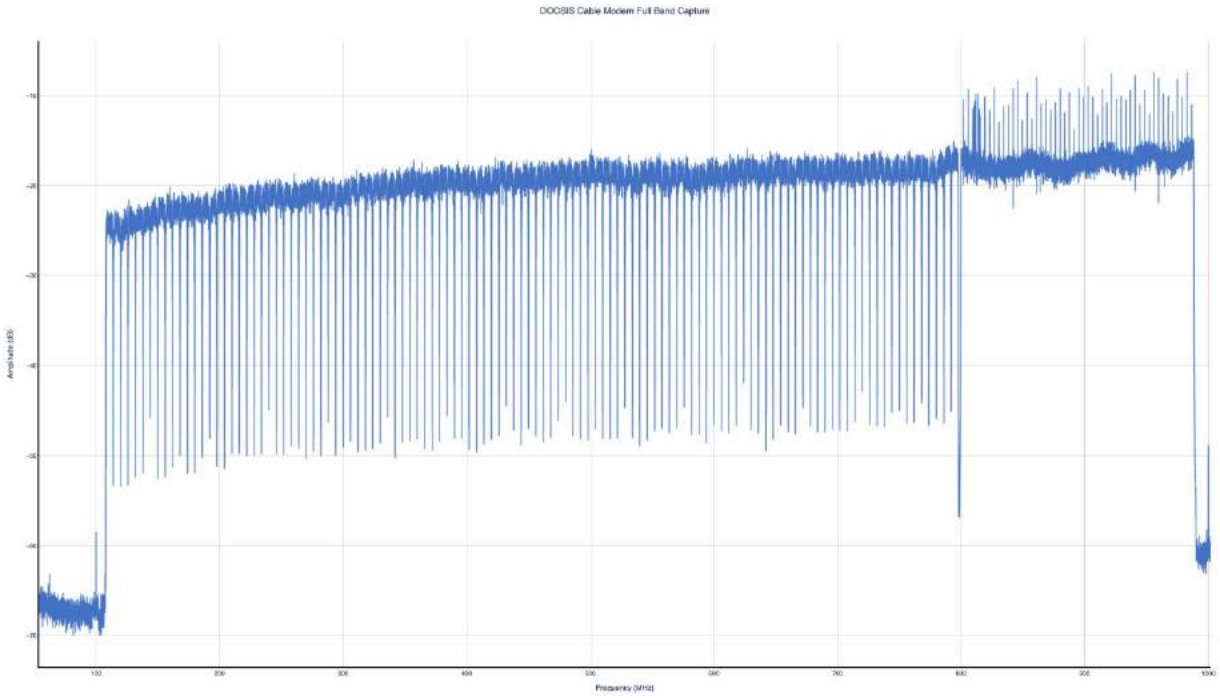

**Figure 40. FBC plot with 32 averages (courtesy of Akleza).**

Unfortunately, older cable modems do not fully support averaging, some supporting a smaller number of averages, and some none at all. In these cases, the initial set of the `docsIf3CmSpectrumAnalysisCtrlCmdNumberOfAverages` object will fail with an SNMP error as follows:

```
Reason: inconsistentValue (The set value is illegal or unsupported in some way)
Failed object: DOCS-IF3-MIB::docsIf3CmSpectrumAnalysisCtrlCmdNumberOfAverages.0
```

When this occurs the polling application will have to make multiple requests to retrieve a number of samples and then implement a running average over these samples.

With both averaging and collection of high-resolution captures, significant detail can be seen. **Figure** 41 shows the same capture as above but zoomed into see the detail of the SC-QAM signals and the start of the OFDM signal with its pilots and PLC.

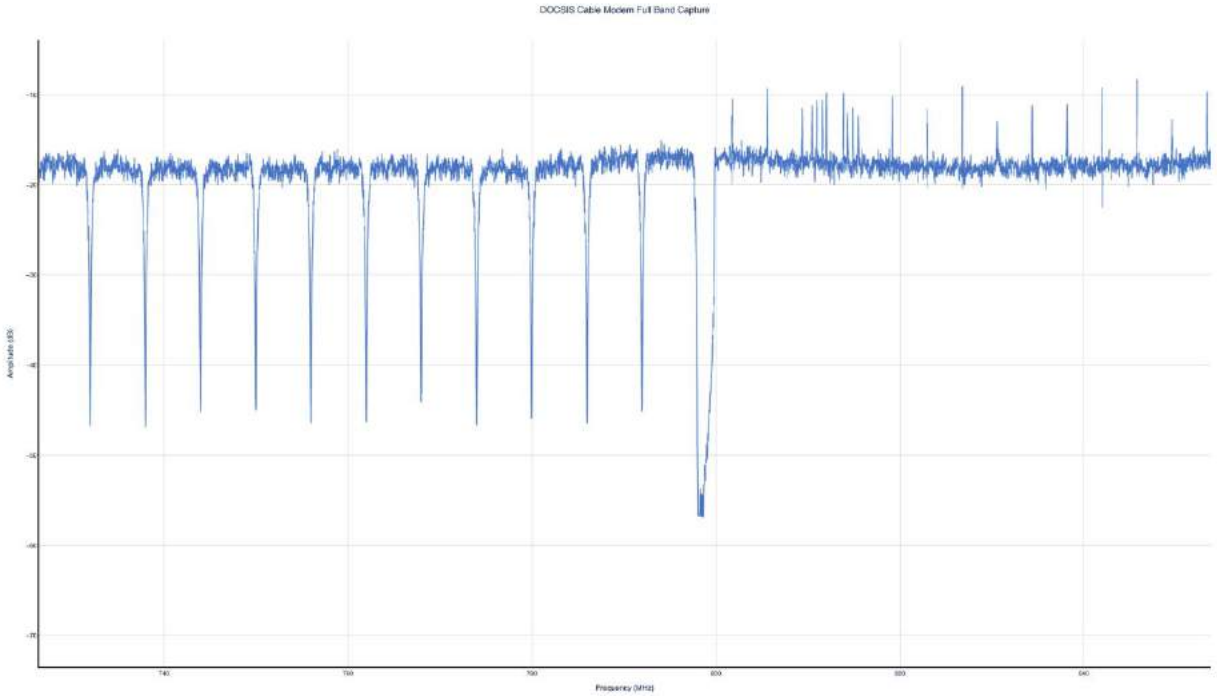

**Figure 41. Zoomed view of high resolution and averaged FBC (courtesy of Akleza).**

 

# 7. Advanced FBC Applications

## 7.1. Estimating Distances with High Accuracy

Because of a large potential bandwidth associated with an FBC spectrum, the ripples or waves in the magnitude plot can be analyzed to produce very accurate distance estimates. A signal captured in a narrow band can only produce inaccurate distance measurements. One method that has been developed in the CableLabs PNM Working Group is to process spectral data with an inverse discrete Fourier transform, using the FBC response for real coefficients and all zeroes for the imaginary coefficients. If a broadband signal is transformed, this method produces a highly accurate time response, and a magnitude response with decent and predictable results.

It is useful to examine exactly how delayed signals arrive at the cable modem or time domain reflectometer (TDR), and how and where they can be observed using, for example, high impedance probes. **Figure** 42 has two diagrams showing how reflections are generated on a cable line, one with a single reflection and one with two reflections. The cable lines are blue and X marks the locations of impedance mismatches R, RA, and RB. Each impedance mismatch in this example causes a 20% reflection ($S_{11} = S_{22} = 0.2$). The horizontal lines are signals going downstream to the right and diagonal lines are signals going upstream to the left. The strength of the signals in volts for each cable segment is labeled in red and the coax is assumed to have no cable loss. The TDR impulse response plot is shown on the left, and an FBC impulse response received downstream is shown on the right. Upstream and downstream responses can also be observed by high impedance probes, placed as illustrated.

For the single reflection case, a 20% signal is reflected back from point R and is observed at probe 1, but no delayed copy of the signal appears downstream (probe 2). However, probe 2 does observe that the downstream signal is weaker than it should have been (0.8 instead of 1.0). In other words, FBC on a cable modem is effectively blind to a single reflection caused by a single impedance mismatch.

For the two-reflection case, signals bounce back and forth between reflection points RA and RB infinitely, although generally only the first few recursions can be observed before the signal is too weak to be seen. A ripple in the frequency domain is equivalent to one or more impulses in the time domain. Thus, when a ripple in the frequency domain is observed, you know you have an echo tunnel (distance between RA and RB), but you don't know the locations of the start point or stop point. However, you can determine an exact length from an exact time delay obtained by an inverse Fourier transform. **Figure** 43 shows water damage that created one end of an echo tunnel, and the other end of the tunnel was caused by a seizure screw not being tightened on a terminator.

Additional information about reflection types can be found in [Ref. 7].

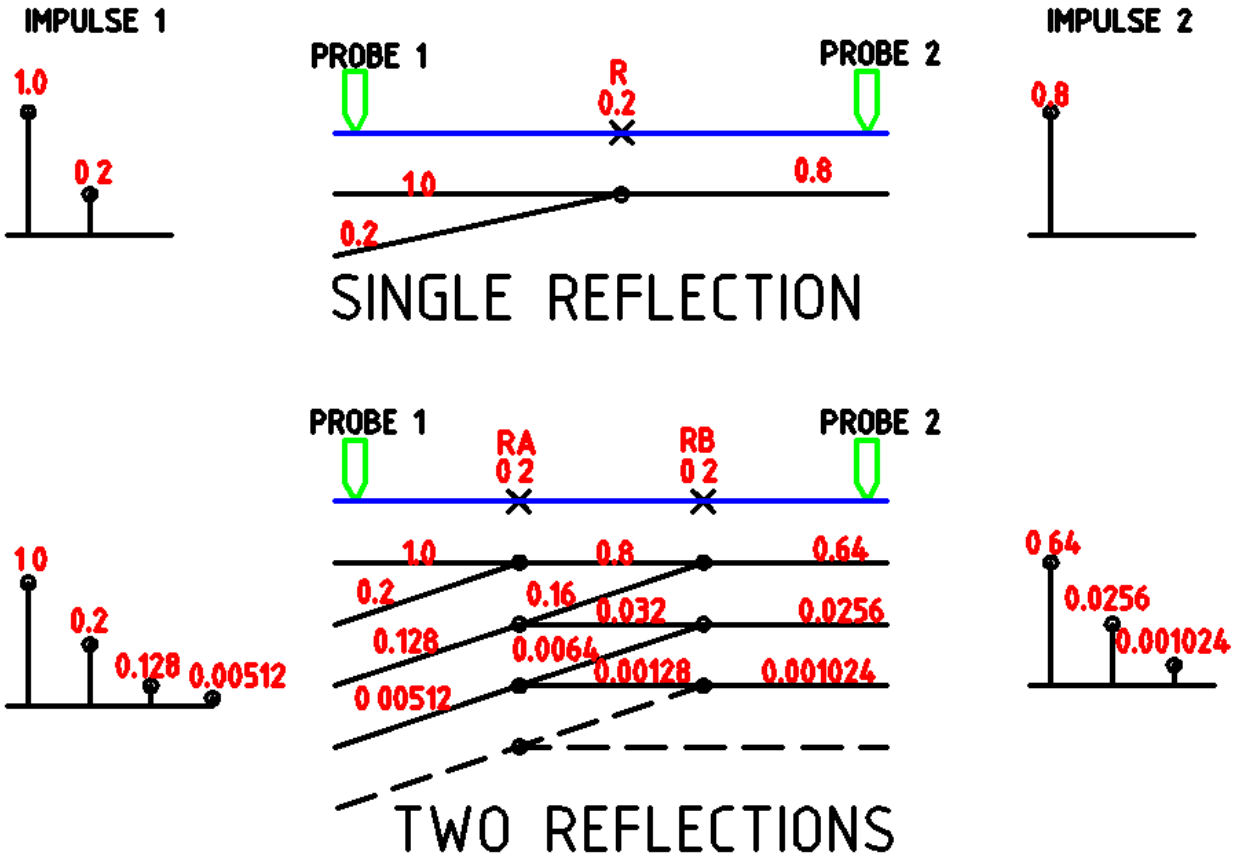

**Figure 42. Diagrams showing what is observed at two points on a cable line for the one- and two-reflection cases. The inpulse responses on the right can be observed by the FBC and the inpulse responses can be observed by an active or passive TDR.**

**Figure 43. Damaged hardline coax that was at one end of an echo tunnel; the other end was a loose seizure screw on a chassis terminator installed in an end-of-line tap. Further**

**complicating things: The damaged cable was submersed in water. Courtesy of CableLabs.**

## 7.2. Drop Cable Testing

A simple test that can be done on drop cable to verify that it is working well is to disconnect one end, say at the ground block, and test the drop cable from the tap with a TDR. The TDR impulse response should reveal the open drop cable with only a few dB of attenuation associated with the drop cable. Any other response indicates a bad drop cable. This method can be performed with a conventional metallic TDR or with a passive TDR.[4]

## 7.3. Using FBC to View Upstream Noise

The FBC's tuning range includes the upstream band. The upstream band is of interest to capture for much the same reasons as the downstream band; just as impairments add energy that interferes with reception of downstream signals (see Section 3), energy can be added that interferes with the reception of upstream signals. Assume that somewhere in the drop or house wiring is a shield break that allows electrical noise traveling on the outside of the coax to gain entry to the coax wiring. Once the noise gains entry, it travels in both directions – toward the CPE and toward the headend or hub – the latter where it can cause interference to other upstream signals at the CMTS receiver. The same interference can be detected by terminal equipment located in the home, identifying the home where the ingress entered the cable plant.

How strongly the ingress enters the plant, compared to the upstream transmission, will determine the ingress-to-signal ratio at the upstream receiver. Also, where the ingress enters the plant, in terms of insertion loss to-and-from the cable modem, will determine how the ingress-to-signal ratio will appear at the F-connector of the cable modem. Even if there are no filters or active components in the path between the ingress point and the cable modem, the ingress-to-signal ratio will be lower at the cable modem F-connector than at the CMTS upstream receiver, and will be lower by at least twice the insertion loss of the path from the cable modem to the ingress point.

An additional consideration is that upstream signals can have levels in the range of +17 dBmV/1.6 MHz to +53 dBmV/1.6 MHz, generally; for comparison, downstream signal levels can be in the range of -10 dBmV to +15 dBmV per 6 MHz channel. In some cases the cable modem's transmitted upstream energy can be significantly greater than it is receiving in the downstream. To be useful in locating ingress it will generally be necessary to capture upstream ingress when upstream transmissions are not occurring at the same frequency. This is because often an impairing ingress has smaller PSD than the transmitted signal, at the cable modem, and will be obscured by the cable modem's own transmission if it is occurring at the same frequency as the ingress.

Capturing the upstream spectrum at the F-connector of the cable modem can help provide insight into troubleshooting, and lead to fixing the cause of the ingress. Since the ingress-to-signal ratio is generally already lower at the cable modem than at the upstream receiver, it is desired to capture the upstream spectrum without the stopband loss that would occur on the high-frequency port of a cable modem's

[4] Water damaged cable may not show up well unless the TDR has test energy in the UHF spectrum, which can usually be achieved by choosing a very narrow pulse width.

 

internal diplex filter. Details of how this is facilitated in some cable modem implementations are beyond the scope of this paper.

### 7.4. Using FBC to Find Water-Soaked Coaxial Cable

**Figure** 44 is a frequency response of a coaxial cable that has water inside the jacket. It can be compared to **Figure** 45 which is caused by a standing wave created by a pair of separated impedance mismatches. Operational experience has shown that this water characteristic is a highly reliable indicator of the presence of water in coax, most typically in drop cable. But water responses have also been observed in hardline coax. If a coaxial cable is tested with a TDR in wide bandwidth mode (narrow pulse width), a nearby region of water damage can be localized. It has been observed to correct itself when the coax either dries out or the water inside is frozen hard, although its characteristic reappears when the frozen water thaws. Water gets inside the coax at abrasion points, hairline cracks, kinks, or at connectors. The rough non-periodic spectral response is caused by the non-uniform saturation of water-versus-distance over a section of the coaxial cable. Generally, a second characteristic accompanies the rough spectral response: higher attenuation at high downstream frequencies, as much as 15 dB to 25 dB (or more!). Upstream attenuation is typically only a few dB, but the high downstream attenuation often results in greatly reduced throughput and customer dissatisfaction. The adaptive equalizer in the cable modem can tolerate the rough spectral response, but loss of signal level results in data errors.

Relatively simple software currently exists to detect both types of impairments by their rapid variation of amplitude versus frequency, but these simple algorithms cannot distinguish water damage from standing waves.

A DSP algorithm is being developed where a spectral response is filtered, flattened and interpolated to remove high-level responses such as AGC pilot signals, and low responses such as vacant spectrum. Finally, an inverse Fourier transform produces an impulse response which is examined for dispersion. One or two narrow lines indicate a standing wave, and a dispersed time response indicates water. The dispersion can be enhanced by performing an autocorrelation function on the time response, improving detection. Another revealing characteristic is large spectral down-tilt caused by water attenuation. **Figure** 44 shows a response with water in time and frequency and **Figure** 45 shows the same data for a standing wave.

One simple method to measure dispersion is to measure the impulse response coefficients relative to the DC term, remove the two largest coefficients, and then remeasure the coefficients. A small drop after coefficient removal indicates a dispersed water response and a large drop indicates a large standing wave response. Another method is to take the ratio of the peak-to-average of the time coefficients, where a large peak-to-average indicates a standing wave, and a smaller peak-to-average ratio indicates a non-periodic water-caused wave. Note that it is possible for a cable to suffer both water and standing wave impairments at the same time. Likewise, it is possible for a cable to have a second standing wave frequency present.

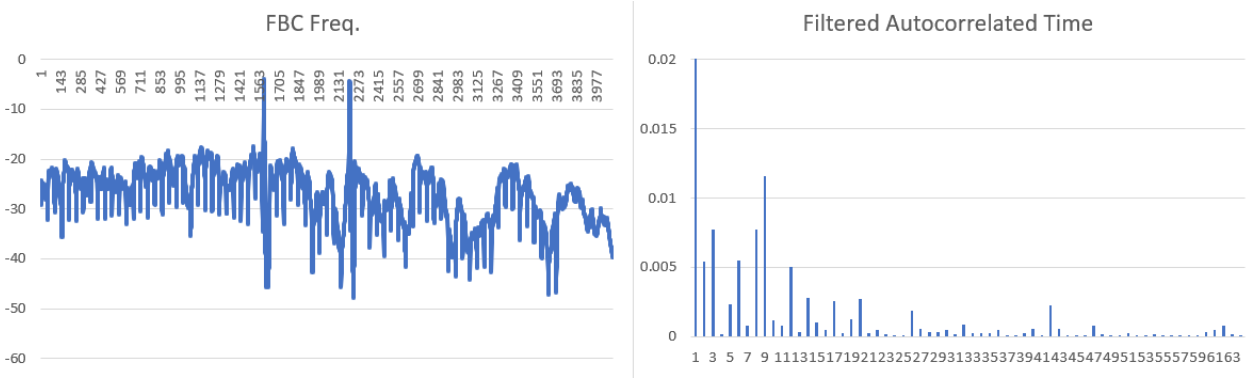

**Figure 44. Water-soaked coax, FBC plot on left and impulse response on right. The impulse response is highly dispersed.**

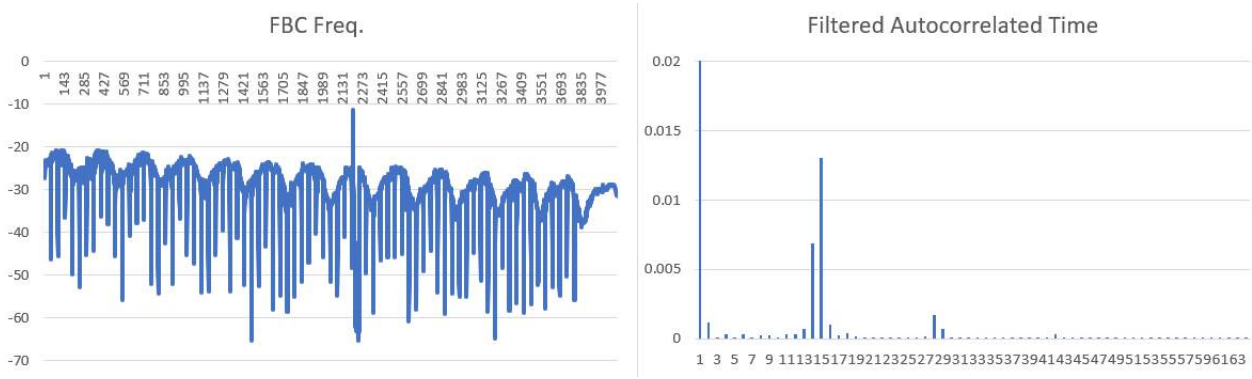

**Figure 45. Coax with standing wave response. FBC plot is on left and impulse response is on right. The impulse response is not dispersed.**

## 8. Impairment Detection

Detecting impairments from spectrum analysis data is simple but time consuming to do manually. Fortunately, there are methods that can assist with this problem. Three practical categories for addressing this problem effectively include:

- Simple magnitude and statistical methods followed up with manual inspection,
- Mathematical and statistical models to recognize impairments followed up with manual inspection, and
- Machine learning approaches that find and classify impairments, for either direct action or followed up with manual inspection.

Only operators will have numbers to compare between these methods, and so far we have not found any data being shared. We expect, however, that the first two methods will generally be slower than the third, based on a comparison of methods developed by CableLabs; and we expect that false positives and false negatives will decrease moving down this list. Further, because the purpose is to address the impairments, eventually someone will manually validate the results, before or during dispatch.

However, it is important to mention that automating the first inspection of spectrum data can reduce the bulk of manual labor necessary. The speed of automated inspection may not be a critical factor, but rather the ability to do a reliable first inspection will save a large amount of manual work.

For example, consider 1000 results. If there are 10 impairments in 1000 samples, a manual process has to look at all 1000 samples to find them. An automated process might have 50% false positives and 10% false negatives, so might report 18 impairments. After looking at these 18 results manually, which is far faster than looking at 1000, nine impairments may be found. The net result is finding nine impairments by looking at 18 for a 50% efficiency, compared to finding 10 impairments by looking at 1000 for a 1% efficiency. While not all impairments are found due to the false negative rate, the efficiency is profound.

For some time, there have been DOCSIS® 3.0 anomaly detection methods available in the CableLabs Common Code Collection (C3). This method is a rule-based method that finds anomalies, identifies their types, and finds the frequencies they impact, all using rules, statistics, and traditional methods. CableLabs created a prototype which Comcast implemented and improved on, and that version is available for use by operators.

For DOCSIS 3.1, CableLabs offers ProOps as a platform for operators to test PNM methods, which includes a statistical method as well as the potential for a machine learning-based anomaly detection method. The latter is used for RxMER data today, but we are confident that it can be trained to work with spectrum data if operators wish to try this.

## 8.1. Impairment detection and automation

Automating FBC impairment analysis helps present the data in ways that are easy to understand and drive business decisions. Anomaly detection and classification algorithms are available through CableLabs or built into commercially available PNM tools. These algorithms detect and categorize the severity of the impairments at each FBC-capable cable modem in the network. In addition to the detection and severity categorization, the automation tools typically provide statistics and a list of modems with similar impairments grouped by geographic areas. This gives insight into the area of the HFC network that is of interest and has the potential to impact the customer experience of many subscribers.

For example, detected impairments are typically color coded by severity. Yellow for minor (less likely to be impacting) and red for major (more likely to be impacting). This enables the automation tool to assign a status of “red” to a modem that has one or more impairments identified, meeting the criteria for “red.” Subsequently it is easy to count and calculate the percentage of modems with a “red” status, either overall or by impairment. Combine the impairment severity information with HFC network topology information, and the automation tool will guide an engineer or network analyst to the HFC segment with the most issues identified.

The impairment algorithms use the FBC spectrum data, based on the bins, and calculate the power levels to represent the 6 MHz channels when required. The following is a brief description of the available impairment algorithms and their behavior:

**Tilt** – The condition where signal levels vary in a linear manner as the frequency increases. The variation can be low to high (positive tilt) or high to low (negative tilt); refer back to Figure 11 and Figure 10 respectively. The parameters of the detection can be adjusted, but typically tilt is identified when the power variation is calculated to be 15 dB or more. The algorithm will also calculate a severity number between 0 and 100, with 0 being the least severe and 100 being the most severe. In this way, the severity can be broken down into yellow or red. An example configuration would be yellow for severity number between 0 and 80, and red severity for 80 to 100.

**Adjacency** – Identifies a group of channels with median amplitude values several dB higher than other channels in that part of the spectrum, likely caused by incorrect narrowcast injection levels; refer back to Figure 8. The algorithm calculates the median amplitude within the 6 MHz channel and triggers an impairment detection when the adjacent median amplitude differs (typically by 3 dB to 14 dB). An example severity range would be yellow ≤ 50 and red > 50.

**Standing waves** – Algorithm automation calculates changes in the median amplitude to determine when the signal includes amplitude ripple (standing waves); refer back to Figure 12. The algorithm can account for the natural tilt of the spectrum. Severity is calculated based on the difference between the min and max power level in the detected wave range. Example severity levels are yellow ≤ 7.5 dB and red > 7.5 dB.

**Notch (suckout)** – Algorithm detects when amplitude differences and high tilt are present in groups of channels; refer back to Figure 13 and Figure 14. Severity is based on the amplitude depth of the notch.

**Rolloff** – Can automatically detect non-flat loss of signal level at or near the upper end of the RF spectrum. The algorithm uses a rolling median and calculates severity by steepness of the roll-off amplitude over 4 dB.

**Resonant peak** – The algorithm detects areas of the spectrum where the amplitude maximum is higher than the average of the surrounding frequencies; refer back to Figures 16, 17, 18, and 19. Severity is determined by the difference between the maximum and the average amplitudes. Sample severity threshold is yellow at ≤ 7 dB and red > 7 dB.

# 9. Conclusion

Many DOCSIS 3.0 cable modems – and all DOCSIS 3.1 cable modems – support full band capture capability. FBC gives cable operators the equivalent of a spectrum analyzer in every home in which an FBC-capable modem has been installed. FBC spectral displays can show impairments such as ingress, frequency response problems, the presence of filters, incorrect narrowcast versus broadcast signal levels, and much more. Furthermore, those spectral displays are intuitive and easy to understand. A key benefit is that many problems can be identified remotely without the need to first roll a truck.

Some cable operators use FBC for plant maintenance and troubleshooting, and some operators and third-party vendors have incorporated FBC in their PNM tools. Yet many cable operators do not take advantage of FBC – technology that already exists in their networks – or are unaware of its capabilities.

The industry has been given a valuable and powerful tool for plant maintenance, and software exists to integrate FBC with operational practices. The opex is out there, waiting to be saved!

# 12. Appendix

The following Python code is provided as a demonstration of how to retrieve and plot FBC data from a cable modem.

The script getFbcData.py should be called after a capture is initiated on a modem by setting the `docsIf3CmSpectrumAnalysisCtrlCmdEnable` object to true. The results are saved into the specified CSV file that can then be imported into a spreadsheet application such as Excel or be used by the showFbcData.py script.

## Introduction

In 2019, Comcast developed a Profile Management Application (PMA) system for generating and transacting D3.1 downstream (DS) profiles tailored to the conditions of each Orthogonal Frequency Division Multiplexed (OFDM) channel in its network. The approach, machine learning algorithms and system architecture were described in a previous SCTE technical paper [1]. The initial plan for this follow-up paper was to focus on Comcast's PMA deployment journey, the success of which is evidenced by thousands of Cable Modem Termination Systems (CMTSs) managed by the PMA, yielding greater than 20 Tbps of added downstream (DS) capacity to the network.

With the onset of the COVID-19 crisis, some of that focus shifted, in lockstep with the shift of the U.S. and worldwide workforce from office to home. Figure 1 shows the 32% increase in upstream (US) traffic, post-COVID, and the shift in peak times for DS traffic from 9:00 PM to 7:30 PM, and from 9:00 PM to 8:00 AM & 6:00 PM for US traffic. Figure 2 shows the bandwidth demand growth, around time of the COVID crisis (Spring of 2020), for US traffic (black curve) and DS traffic (sky blue curve). With work-from-home traffic increasing on the network, and because of the earlier implementation of the PMA, the DS capacity was available, and the network was able to easily scale to the significantly increased demand.

The US is a different story. As a fraction of the total available spectrum, and even as it is being industrially widened from sub-split to high-split configurations, the fact remains that US capacity is a more difficult challenge. Commencing with shelter-at-home requirements, US traffic grew sharply, seemingly overnight. Comcast has publicly shared data on the increases in traffic scale since COVID started [2-4], along with transparency about the level of investment and technological attention that prepared us for "Black Swan" scenarios like a pandemic. This enabled more effective management of the additional traffic growth delivered over the Data Over Cable Service Interface Specification (DOCSIS) broadband network [5]. As this paper will ultimately show, by adding an upstream PMA focus to the existing PMA suite, we were able to boost upstream capacity by 36%, from 86 Mbps to 117 Mbps.

Given these extraordinary circumstances, with the COVID crisis in full swing, and with the shift in internet usage, we refocused this paper to share our accelerated efforts in developing and deploying PMA for the US using DOCSIS 3.0 technology. Fortunately, the technology that was brought to bear on the challenges of US capacity was already under development. The effort was shaped by the early concepts found in CableLabs member publications from the late '90s [6] into the early 2000s. Combined with state-of-the-art methods, including scaled cloud-based compute, and machine learning techniques such as Reinforcement Learning (RL), we were able to ensure system stability and optimize the network bandwidth as spectral conditions and demand changed.

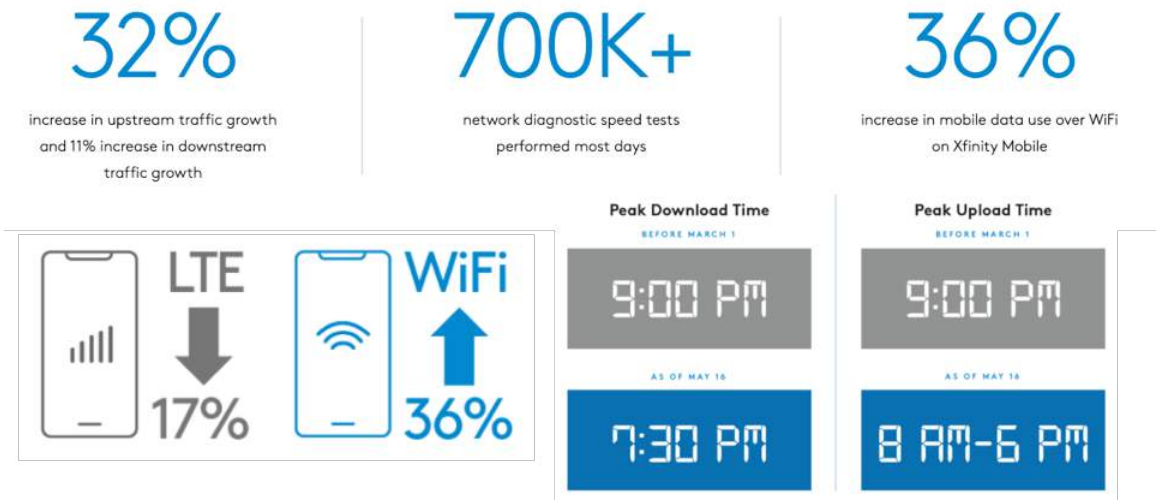

**Figure 1 - COVID network impact on traffic peak times.**

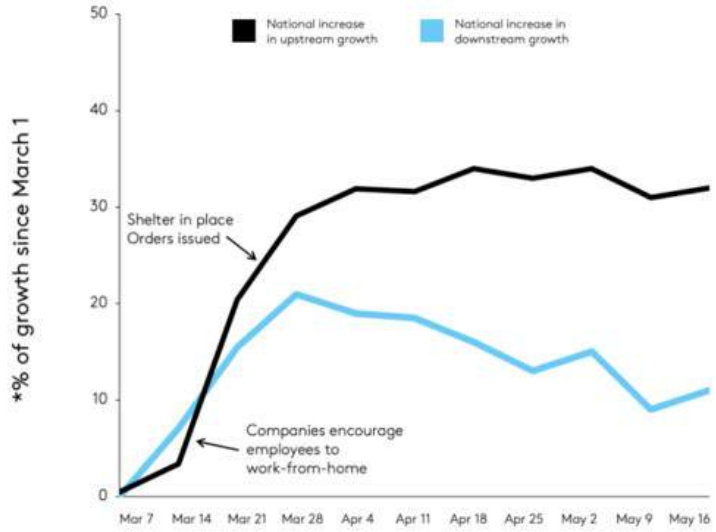

**Figure 2 - COVID network impact on bandwidth demand.**

Note that at the start of 2020, the US D3.0 profile management was under development as part of a holistic capacity management and long-range access network architecture plan, along with other efforts, such as passive hybrid fiber-coax (HFC) with deeper fiber, virtualized CMTS with remote PHY nodes, and spectrum augmentations, such as high-split and FDX. The D3.0 US PMA effort was initially targeted at optimizing the upstream spectrum, in conjunction with the deployment of additional US channels. The additional US channels were located in parts of the spectrum that would be difficult to manage without an autonomous modulation profile optimization system, given known and persistent levels of ingress. The D3.0 US profile management was also intended for those network segments without fiber deep and spectrum upgrades, to help offset the timing risks related to developing and deploying new technology by deferring or eliminating investment in legacy technologies.

The paper is organized as follows: Section 1 recaps our 2019 Expo paper by providing an overview the PMA system and its algorithms and describing the current state of the DS algorithm. Section 2 presents analyses and dashboards created to track system performance & health. Section 3 presents our vision for

how the PMA system is expected to evolve in the future. Section 4 is dedicated to describing the US PMA system. Section 5 concludes with the lessons learned from the PMA deployment journey.

## 1. Overview of System and Algorithms

The PMA system architecture and DS algorithms have been described at length in the previous SCTE technical paper [1] A brief recap and description of the prior work is included here for professional context. The PMA system is composed of four separate components, shown in Figure 3: Data Collector, Data Storage, Analytics Engine, and Configuration Manager.

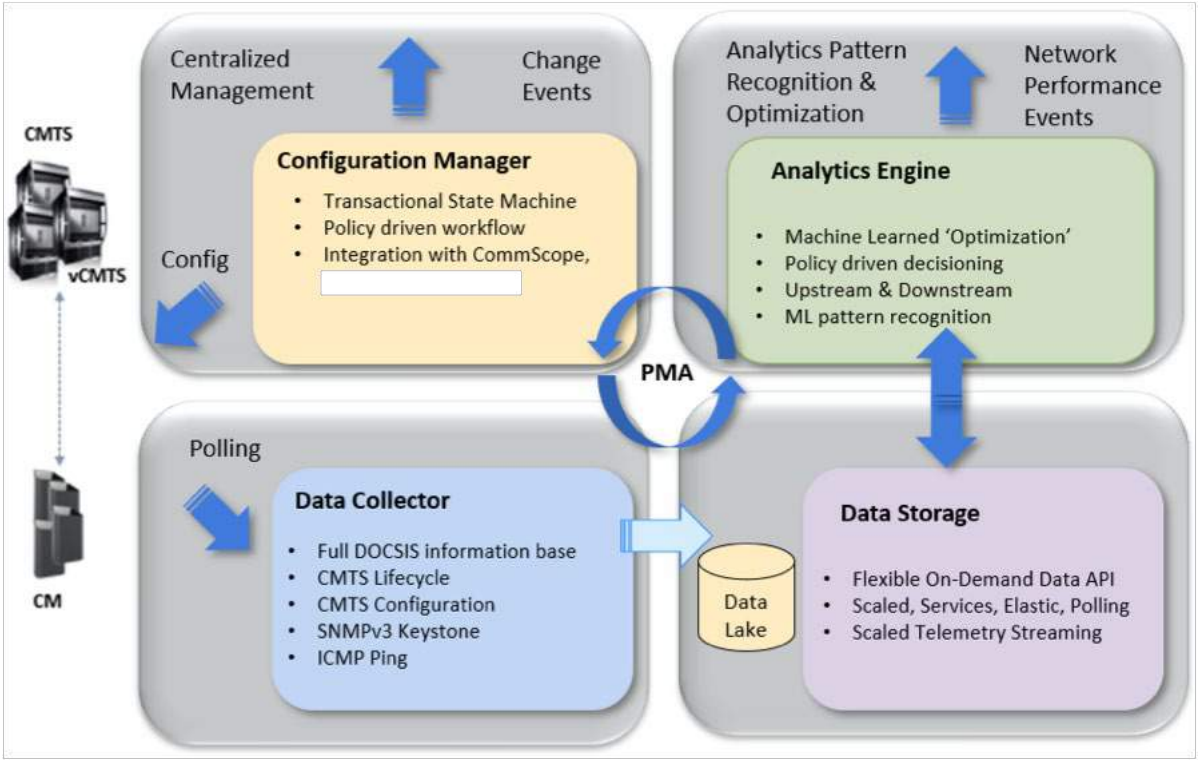

**Figure 3. The PMA System Architecture.**

The Data Collector is responsible for collecting telemetry data from CMTSs and gateway devices. The data is polled at different frequencies that range from every 5 min to hourly, and was designed to constitute a "comprehensive poller," enabling applications beyond the scope of PMA. From a PMA perspective, the data needed to support the construction of OFDM profiles falls into the following categories:

- **Network topology**: Establishes linkage between device, OFDM channel, and CMTS.
- **Configuration model**: Provides characteristics of the OFDM channel, e.g. number of subcarriers, subcarrier width, frequency range, position of exclusion bands, etc.
- **CMTS type**: Provides make, model, hardware & software versions of a given CMTS.

- **Telemetry**: Retrieves Modulation Error Ratio (MER), Forward Error Correction (FEC), signal, and traffic measurements from devices, and channel utilization measurements from CMTSs. This category constitutes the largest bulk of the data, given that MER spectra are measured at a per-device OFDM subcarrier resolution, with 4096 data points for each MER sample for each device.

The Data Storage is primarily comprised of a public cloud-based data lake, where the polled data listed above land in raw (unprocessed) form.

The Analytics Engine (AE) is a machine learning pipeline that uses the data to construct OFDM profiles suitable for use by the devices in the network—given spectral conditions measured over certain time windows. At its core, constructing profiles is a type of optimization problem in which the stated objective is to maximize channel capacity and minimize codeword error rates, subject to certain constraints. Thus, the problem contains an inherent trade-off between improving robustness and increasing network capacity, since reducing error rates is achieved by opting for lower modulation levels, at the expense of reduced channel capacity.

The constraints are dictated by the CMTS hardware and software versions, as different CMTSs support different numbers of profiles per OFDM channel. Within the construct of a profile, they may also support different numbers of modulation exception zones (segments), as well as imposing additional constraints on the attributes of a segment (e.g. segment width).

Algorithmically, the AE uses hierarchical clustering—a type of unsupervised machine learning algorithm—to group together devices that share common noise characteristics and assign them a common modulation profile. Additional smoothing algorithms are applied post-clustering, to reshape the segments according to given constraints. In the current version of the algorithm, the clustering objective function is designed to maximize capacity around a statistical decision boundary.

FEC rates are considered, indirectly, by imposing additional constraints on the mapping from MER values to modulation levels (e.g. a MER value > 27 dB supports 256-QAM at maximum). As an example, the plot in Figure 4 shows MER measurements alongside the constructed profiles on a dual *y*-axis plot. Since spectral conditions vary over time, multiple MER samples are captured over a time window dictated by AE policy. For each panel (device) we show 3 curves characteristic of the variation in MER: the max level (dark gray curve), the min level (light gray curve), and the $10^{th}$ percentile (red curve). Also, per policy, it is the $10^{th}$ percentile that is fed to the algorithm as conservatively representative of the device's MER state. The constructed profiles are overlaid on the plots and follow the scale of the right *y*-axis. In this specific example, the CMTS allows 4 profiles per OFDM channel, 4 segments per profile, and a segment width that is a multiple of 1 MHz. Profiles 1-3 are overlaid in yellow, blue, and green colors, respectively on the devices that are assigned to each of the 3 profiles. Profile 0 (not shown) is the control profile and is set to a flat 256-QAM by AE policy. Note that the impairments shown are generated in the lab and applied to select devices. Because of the CMTS-imposed limitation of 4 exception zones (segments), the algorithm overcompensates for the V-shaped impairment exhibited in the MER spectra of device #5.

Lastly, the Configuration Manager (CM) is responsible for transacting profiles generated by the AE. The output from the AE defines profiles according to a standardized intermediate JSON format that is agnostic to the CMTS make and model. The CM converts the output to commands that are specific to the CMTS. The CM is also responsible for validating the profiles, deciding on whether to reject or accept the AE recommendations, scheduling the transacting of the profiles according to a policy that defines allowed maintenance dates/times, and performing pre- to post-transaction checks to confirm that the configuration was successfully applied.

 

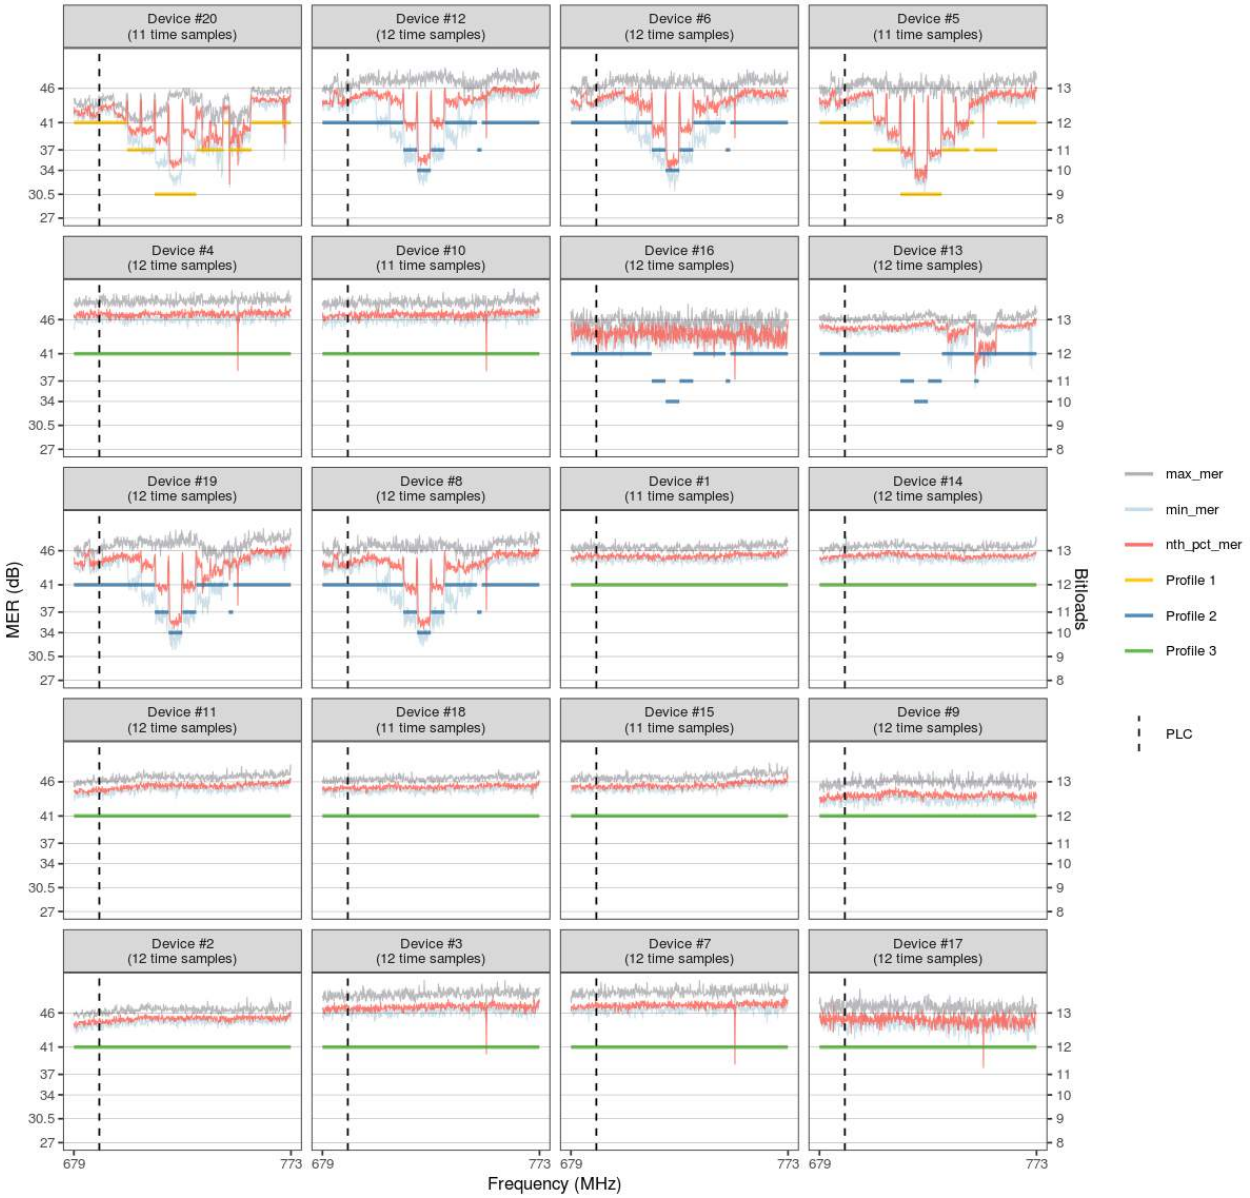

**Figure 4. Example of PMA profiles constructed for a set of 20 devices.**

## 2. Network Visibility

A prerequisite to deploying PMA was achieving a high level of visibility into the network, in order to respond to issues that may arise as deployment ramps up. Thus, this requirement opened a path to an independent effort on dashboarding and automated notifications. While the PMA's Data Collector is exhaustive in the breadth of data it collects, the focus of this effort was to provide insight and visibility into metrics that are PMA-related or perceived to be PMA-related. We start by introducing the basic design criteria for the PMA dashboards:

- The overall health of the PMA system is to be monitored through a common "home view" that constitutes an entry point to all other dashboards.

- One must be able to drill down from the “home view” to an “OFDM channel” detailed view.
- All dashboards must display near-real time information (limited by the Data Collector’s polling frequencies).
- Dashboards must be informative in the operational sense, i.e. highlighting issues and allowing operations to take appropriate actions to remediate.

## 2.1. Home level view

**Figure 5. Screenshot of the DS PMA home view dashboard.**

Given the design criteria, we next introduce some of the key metrics displayed on the home view dashboard shown in Figure 5. The home view aggregates all metrics by division—the highest-level organizational structure within Comcast’s network. This view is meant as a first entry point to monitor the health of the PMA system. The “Lowest 100 Ranked Interfaces” table brings to attention interfaces (OFDM channels) that are low performing, from a PMA perspective and, thus require further investigation. Clicking on an interface name opens the interface-level dashboard with additional details.

Note that names of divisions and interfaces shown in the dashboard screen capture were anonymized. The metrics shown on the home view are:

- **Point-in-time Metrics**: Latest metrics on health and performance of the system that include:
    - **Capacity gain** (34.3% for Division A in Figure 5): The capacity gain attributable to PMA as measured relative to a 256-QAM baseline. Note that the capacity metric represents an instantaneous value calculated from the actual traffic distribution across different OFDM profiles as captured from telemetry in 100s of thousands of service groups across the network.

    - **Raw gain** (6020 Gbps for Division A in Figure 5): Same metric as above but calculated in units of absolute Gbps.

    - **Number of CMTSs** (587 for Division A in Figure 5): Number of CMTSs managed by the PMA system at the time of this snapshot.

    - **Traffic on Profile 0** (2.1% for Division A in Figure 5): Since Profile 0 is configured as 256-QAM or 64-QAM by policy, ideally no devices would use Profile 0. Thus, this metric is indicative of a combination of the health of the system and the freshness of the configured profiles. If spectral conditions degrade and data profiles are not updated in a timely manner, more traffic will flow on Profile 0.

    - **CM success rate** (91.0% for Division A in Figure 5): Percent of CMTSs that were successfully configured with updated profiles during the last configuration window, which is set by policy.

    - **Excluded modems** (0.8% for Division A in Figure 5): Percent of devices with severe impairments that were excluded from the clustering algorithm. The rationale for device exclusion is to avoid wasting a customized profile on severely impaired devices that require field work to effectively mitigate. The current criteria for excluding a device requires that the mean modulation that a device supports is less than the profile 0 capacity (256-QAM or 64-QAM).

- **Lowest 100 ranked interfaces**: The aggregate measures described above may conceal severe issues affecting only a small number of OFDM channels. Hence, this table ranks the 100 channels that require most attention. The ranking is based on a combination of metrics that include traffic on Profile 0, number of devices experiencing OFDM partial service issues, and total number of devices on the channel. In addition, this table provides an entry to detailed interface-level dashboard by clicking on the channel name.

- **Traffic distribution**: This is a time series showing the distribution of traffic across profiles aggregated for all OFDM channels in the topology context. The capture shows that >90% of traffic flows through Profile 3—the highest capacity profile. It also reveals some cyclical behavior with increased traffic on Profile 2 during peak usage times. Note that PMA configures profiles based on device clustering according to the MER characteristics. Even though the PMA assumes that each device should be assigned a specific profile, the ultimate assignment of profiles is left to the CMTS, according to its internal profile selection function as a policy. The fact that most of the traffic flows on Profile 3 indicates that the mapping between MER values and modulation levels is conservative. Section 3 discusses capturing additional capacity gain by

adjusting the AE policy thresholds.

- **Age of profiles**: A distribution of profile age shows that most interfaces were updated within the last day (column labeled 0 days). This view allows monitoring profiles that may become stale. The current update frequency is daily. However, the AE will recommend profile updates only if there was a change in the spectral conditions that warrants updating the existing profile. Hence, it is expected that the age distribution will show profiles that are older than 0 days.

## 2.2. Interface level view

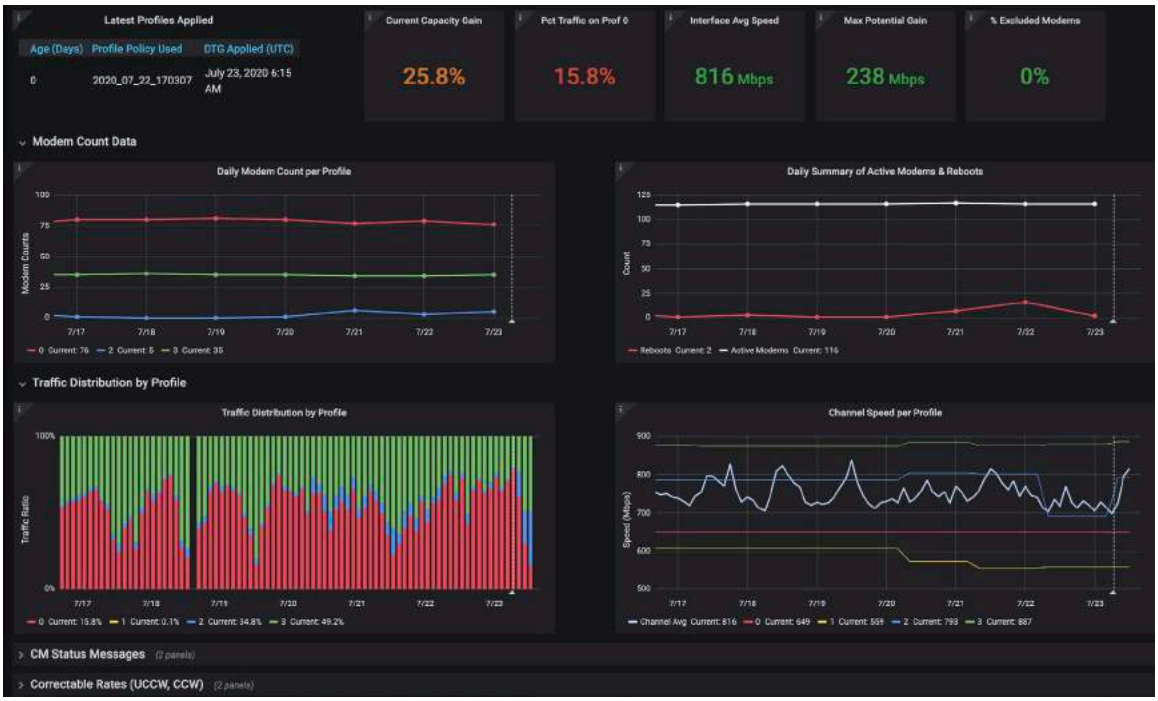

**Figure 6. Interface level view dashboard for DS PMA.**

The interface (OFDM channel) level dashboard offers a highly detailed view of the network dynamics occurring on that interface. A screenshot of the interface dashboard is shown in Figure 6. It shows point-in-time metrics as well as time series metrics covering various dimensions. This view shows device counts and reboots, traffic distribution, and channel speed as function of time. Other views including the CM status message statistics and error rates are "collapsed in" (not shown in screen capture) for conciseness. The view contains several sections covering the following areas:

- **Point-in-time metrics**: These are similar to the home-level view of point-in-time metrics but aggregated at the interface-level.

- **Modem counts data**: Counts of devices by profile, total device count and count of device reboots.

- **Traffic distribution**: Traffic distribution across profiles and the speed of each profile.

- **Modem CM-Status Messages**: Breakdown of D3.1 CM-status messages reported by devices related to the health of the OFDM channel.

- **FEC error rates**: Time history of the correctable and uncorrected codeword error rates.

- **Traffic volume data**: Time history of traffic volume (unicast octets) as reported both by CMTS and devices.

Note that similar dashboards were developed for the US PMA. Select views of these are shown in Section 4.

### 2.3. Notifications

Because networks tend to degrade over time from an impairment perspective, if not maintained, we developed methods to reduce the impact of the network on the customer experience. In addition to the operational views described above, impairment detection algorithms are provided as a core part of the architecture. Notifications from these are delivered across a messaging bus to other Comcast OSS tools, to ensure that technicians are dispatched to the right hubs, network segments and homes to remediate issues. The following data are provided as part of the notifications, to assist with event prioritization and triangulation:

- Interface details such as Physical Link Channel (PLC) location, start/end frequencies, total number of impacted cable modem counts.
- List of impacted cable modems with severity of impairments.
- Interface impairment ranking at the national, divisional, and regional levels.
- Reference to the API for historical data stored in the data lake related to the event.
- Reference for the API to enable fix agents to collect real-time on demand data, to confirm that the issue is still present, and to assist in isolation and to confirm mitigation.
- Other data sources to enrich the event, such as the mobile wireless carriers that overlap with the OFDM channel.

Notifications for severely impacted interfaces are also sent via email to divisional engineering and operations teams. Additional details, such as device/interface RxMER images, are posted to internal collaboration platforms. Note that another Comcast-authored SCTE paper describes the pattern detection associated with these notifications [7].

## 3. Next Generation Algorithms

The current PMA algorithm predicts a ~30% increase in network capacity, relative to a flat 256-QAM baseline, on average. Figure 5 shows that the capacity gain as measured from real-time traffic is around ~35%. This gap between predicted gain and realized gain is due to the internal profile selection function of the CMTS, based on CM-STATUS messages. The internal profile selection effect is clearly visible in the traffic distribution by profile shown in Figure 5, in which more than 90% of the traffic is observed to flow through Profile 3—the highest capacity profile. The logic for internal profile selection function varies across vendors, but the general idea is the same: the CMTS regularly sends test codewords to devices on all configured profiles and determines, based on the encountered errors, the highest capacity profile a device is capable of using. The CM responds with CM-STATUS messages descriptive of that specific device's perspective on the performance. These messages are further processed through proprietary selection algorithms with controls for the operator to optimize. The fact that most devices are able to use a higher capacity profile than recommended by the PMA algorithm indicates that the

thresholds adopted for converting MER to modulation (shown in Table 1) are somewhat conservative. This added resiliency against errors is a known feature of the low density parity check (LDPC) error correction algorithm. While quantifying the LDPC benefit is not straightforward, prior studies suggest that it provides an additional 3-6 dB improvement over Reed Solomon—its D3.0 counterpart [8] Next, we discuss how to take advantage of the superior performance of the LDPC to capture additional capacity gain.

**Table 1 - Minimum MER values that support the corresponding modulation from DOCSIS 3.1 specification.**

| MER Threshold (dB) | Modulation efficiency |
|---|---|
| 0 | 0 |
| 9 | 2 |
| 15 | 4 |
| 21 | 6 |
| 24 | 7 |
| 27 | 8 |
| 30.5 | 9 |
| 34 | 10 |
| 37 | 11 |
| 41 | 12 |

The PMA pipeline offers several algorithmic tuning knobs that are configured by policy. One such knob is a global offset in dB applied to the thresholds listed in Table 1. We experimented with the knob by relaxing the threshold for 2 production CMTSs, while tracking key performance metrics against a control CMTS group within the same site. The results of the experiment shown in Figure 7 reveal that an additional 10% increase in capacity is garnered by relaxing the thresholds by 3 dB, without introducing a negative impact on the codeword error rates. In all panels, the control group is shown in red and the experiment group in light blue. The first 3 vertical dashed lines correspond to the points in time at which the thresholds were adjusted by 1, 2, and 3 dB respectively. For the 4$^{th}$ vertical dashed line, the adjustment was maintained at 3 dB (i.e. no change over previous state). The top left panel in Figure 7 shows the capacity of the experiment group increased per adjustment, with a total increase of ~10% at 3 dB. The top right panel shows the traffic on Profile 0 (256-QAM) shows similar levels across the 2 groups, indicating that shifting the thresholds is not causing data profiles to become unusable by devices. The bottom left panel shows the correctable error rates increased for the experiment group following the first adjustment by 1 dB. The bottom right panel shows the uncorrectable error rates reveal no trend related to the adjustments (notice that the uptick towards the end of timeline was experienced by both experiment and control groups).

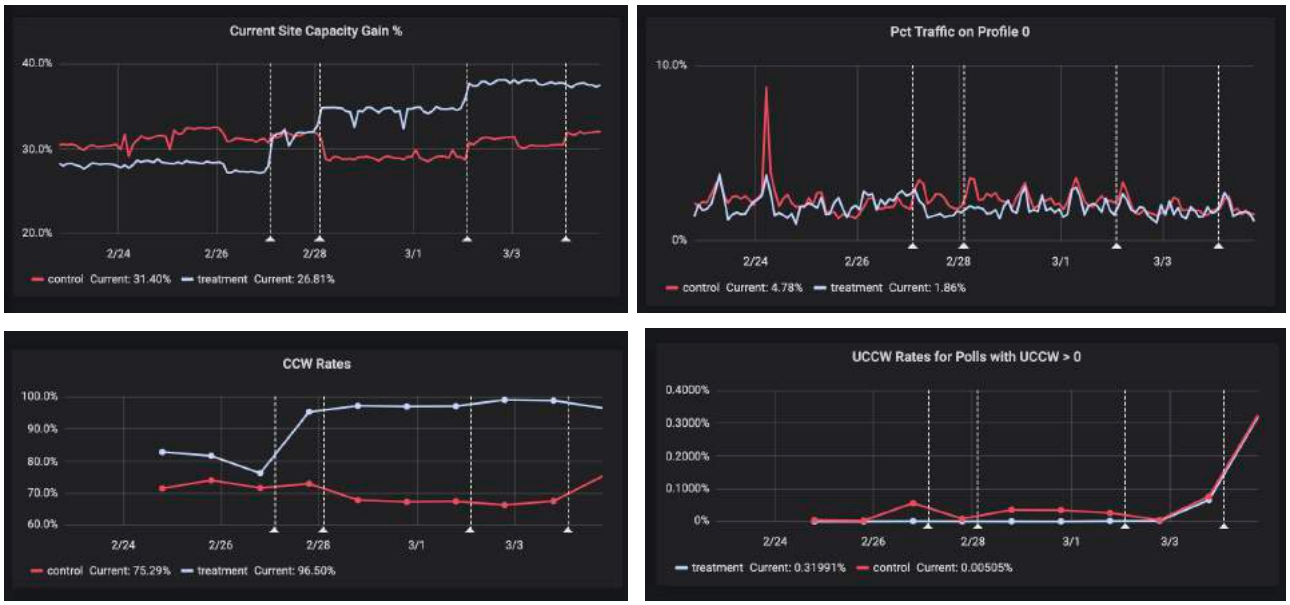

**Figure 7 - Key results from the experiment in which modulation mapping thresholds were relaxed.**

While the results shown in Figure 7 are encouraging and point to the possibility of capturing additional gains by tweaking the global policy, we opted not to adopt such strategy for optimizing capacity gains. The main motivation is the fact that plant conditions vary across the network. A one-threshold-fits-all policy may mask problems in areas were impairments exist and where certain population of devices may benefit from some added robustness (even moving the threshold in the opposite direction, to scarify capacity for robustness). Hence, our current effort focuses on developing a Machine Learning (ML) control system that offers much greater flexibility in configuring the profiles, including adjusting the modulation thresholds down to within a specific profile exception zone (segment). Other policy attributes may similarly be modified, such as the statistical aggregations used across time and frequency, before and after clustering of modems.

One methodology that shows promise in this realm is reinforcement learning (RL). In RL, the ML agent "learns" an optimal policy by interacting with the environment. The outcome is akin to allowing the agent to dynamically modify the MER mapping thresholds, or other policy attributes, per OFDM channel-profile-exception zone (segment) and based on feedback in the form of the FEC error rates encountered by devices. We are currently in the midst building a RL solution for US PMA. As will be shown in Section 4, US PMA has a limited action space, compared to DS PMA, and therefore it offers an opportunity to experiment with and refine the solution with the expectation that these methods will be subsequently adapted to be used for DS PMA and D3.1 US OFDMA PMA.

# 4. Upstream DOCSIS 3.0 Profile Management

## 4.1. Overview

The goal for the D3.0 US PMA solution was to add enough US capacity to allow at least 1 year of bandwidth demand growth, based on forecasted Compound Annual Growth Rates (CAGR), without having to segment nodes using legacy technology. Our engineering models calculate capacity based on MAC layer data rates, net of all physical layer and time-based overhead. Based on these models and progress to-date, using both D3.0 upstream PMA and adding the 5$^{th}$ & 6$^{th}$ channels, we have increased the

upstream MAC layer data rate capacity from approximately 86 Mbps to approximately 117 Mbps, an increase of 36%, exceeding a year's worth of upstream growth even if COVID traffic levels remain as described in Figures 1 & 2.

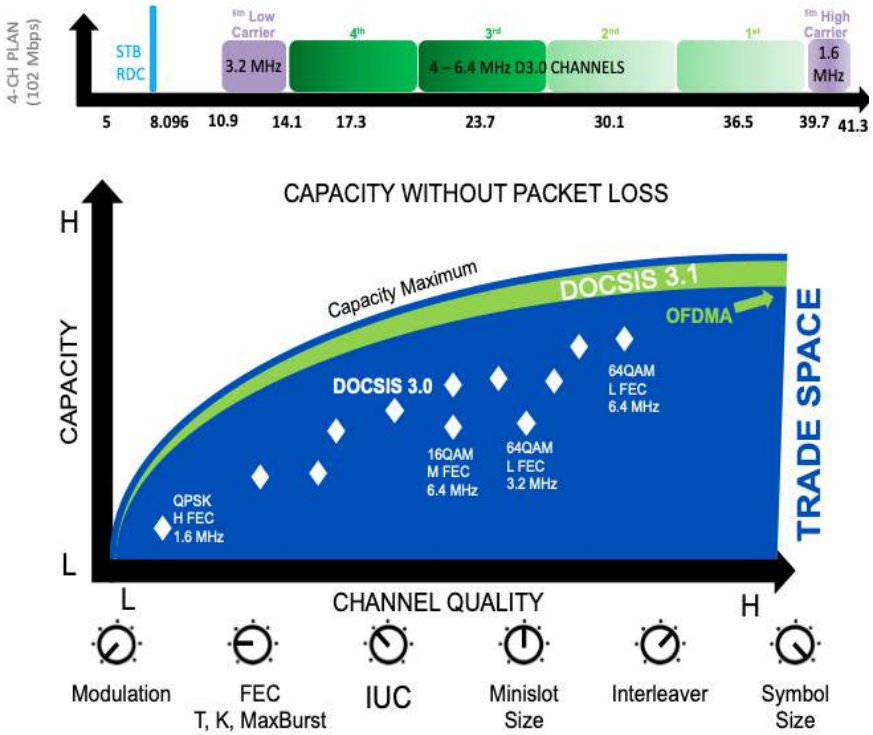

**Figure 8 - Schematic demonstrating how upstream Profile Management would enable additional capacity in legacy low split HFC.**

The profile management optimization process uses all the different knobs available in the upstream channel and modulation profile configuration to increase capacity, where channel quality allows it (see Figure 8). The top panel shows the addition of the 5th and 6th upstream channels; together, these are responsible for increasing capacity by approximately 15%. We are migrating to a standard channel plan across our sub-split nodes that enables a channel width of 3.2 MHz for the 5th US channel and 1.6 MHz for the 6th US, where both represent SC-QAM channels. Figure 8's bottom panel is a schematic highlighting the tradeoff between increasing capacity and increasing robustness. US PMA configures the knobs shown in the schematic to achieve the right balance. These tuning knobs are responsible for additional 20% capacity across all channels, above the robust defaults in use across the network in Q1 2020. Also, when needed, the solution can increase Forward Error Correction (FEC) and use more robust modulation to mitigate potential customer experience issues attributable to noise and ingress. These configuration updates are all done autonomously on the production network today. However, when the COVID-induced increase in upstream traffic began, the US automated execution flows had not been completed. Specifically, the configuration manager (CM) features were still under development.

As the capacity impact became apparent, the development team came together to work closely with the field operations and engineering teams, to calculate and statically configure more efficient modulation profiles with AE. The intent was to provide capacity relief and prove out the benefits of optimization algorithms on the production network, while simultaneously accelerating the development of the closed-

loop autonomous system. The initial static deployments based on the profiles calculated by the AE, as the shelter-at-home orders peaked – more so in markets saturated with high-tech corporations -- had a significant positive effect on capacity. One example of an extreme upstream congestion case is shown in Figure 9. The top plot shows octet utilization for 4 channels, and the bottom plot the minislot and octet utilization of one of the optimized channels. Profile upgrades were done on the 1st and 2nd channels but not the 3rd and 4th channels. Consequently, approximately 10% more peak data is seen going through network with the initial efficient profiles. In this example, the minislot utilization and the octet utilization were at the maximum level for extended periods of time. When the static, more efficient profiles were applied to the 2 higher spectrum channels, the capacity was increased by 17% relative to the capacity of the two lower spectrum channels, which were not modified until the fully autonomous CM was available. Additionally, for the same level of minislot utilization, 10% more Mbps (octet utilization) were able to be sent by customers through the network than were previously transmittable. Correspondingly, the minutes of time at maximum utilization per day were subsequently reduced. Adding additional channels to further augment capacity on top of this example, along with other techniques, enabled a very quick response to and resolution of capacity hotspots.

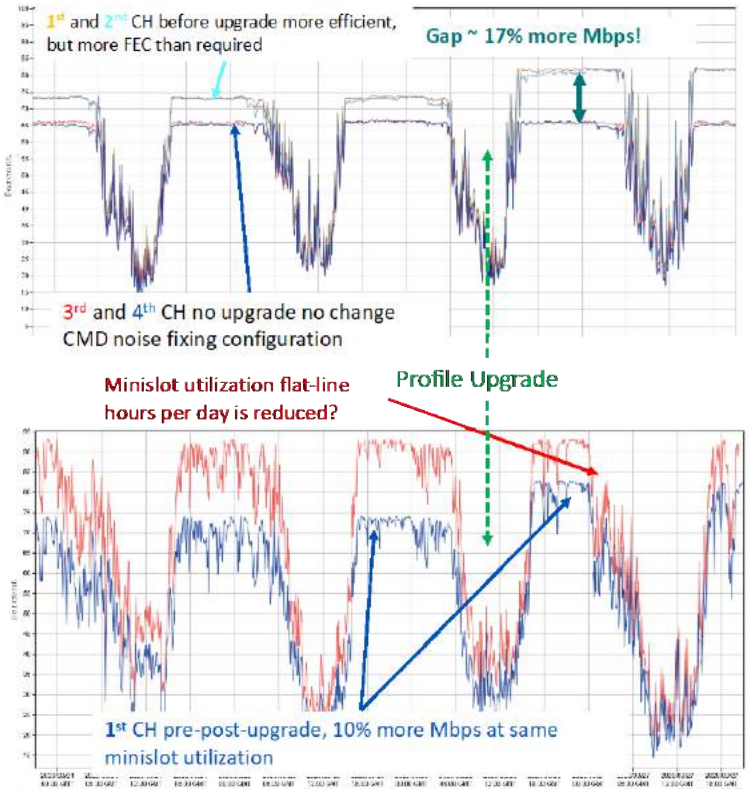

**Figure 9. Peak COVID High Utilization Example.**

Figure 10 shows an example of one of the operational dashboard's tracking system performance for the upstream PMA solution. Notice the activity in the profile distribution plots (identifiable by the colored bars around 7/18). This activity corresponds to the early stages of introducing a new CMTS, because the control system requires a few update cycles before converging to steady-state, at which time which most channels operate at the highest capacity profile (profile index 251). For reference, as additional CMTSs are added to the system, they are initialized to start on static, very robust profiles. These robust profiles are intended to combat a common transient noise source on the network in the lower 2 spectrum channels.

Additionally, and as noted earlier, a very robust but efficient modulation profile had also been statically deployed on the upper two spectrum channels, as described in the 2018 SCTE paper [9]. After accelerating the CM development and moving through trial and deployment, the automated system was turned on. It iterated through a set of modulation profiles, in small, low risk increments, and based on the channel's quality metrics. The metrics include correctable and uncorrectable codeword errors, signal-to-noise-ratio (SNR), partial service statistics, and minislot utilization. Over a period of approximately 24 hours, the modulation profiles were modified until they reached a steady-state based on the set control system strategy. The result is approximately 98% of the upstream channels are running effectively, without codeword errors, and around 2% are running on a profile addressing US noise sources such as transient switching power. The 21.2% capacity gain shown on the dashboard for these CMTSs is consistent across our network, approximately doubling the capacity gains of the example shown in Figure 9. The upshot is that the system autonomously optimizes all upstream channels, not just those in the higher quality spectrum.

**Figure 10 - US Dashboard example for a HUB of 5 new CMTSs managed by the US D3.0 PMA solution.**

In addition to other key performance indicators, such as system settling time, capacity gain and error rates, there is the profile stability rate. Also shown on the dashboard is a distribution of how often an upstream channel has a profile update, highlighting remarkable network stability. In total, 98% of US channels require a profile update less than 1 time per week; 99% of US channels require a profile update less than 3 times a week; and < 0.5% of channels require profile updates more than once per day.

This stability also highlights the promise of D3.1 OFDMA profile management as the modem population grows, or the upstream spectrum available allows us to achieve the benefits of OFDMA. The authors plan to provide a future update on the OFDMA algorithm under development in 2020. What's exciting so far is that network quality is superior to that required for the best D3.0 capacities, and the profile management system will be able to take advantage of the higher order modulations available with D3.1.

## 4.2. How D3.0 US PMA works

The PMA system, as described previously, was extended to implement US D3.0 PMA functionality. The capacity is increased (or decreased) in small steps, while errors are fixed proportionally or predictively, either by increasing robustness or detecting transient noise indicators. When network issues are detected, operations staff is notified of network issues to drive remediation, ensuring maximum capacity is sustained and yielding operational savings. This is a "business as usual" step that happens regardless of whether the customer experience is being degraded due to packet loss.

The modulation profile capacities shown in the Figure 11 are based on compatible upstream channel configurations and channel widths. Similar templates exist for the narrower 3.2 MHz and 1.6 MHz channels. Figure 11 summarizes a subset of modulation profile attributes that must be set compatibly with the US channel attributes and other aspects, such as codeword size, preamble length, guard time, and

interleaver settings. For example: profile 251 uses a 97 bytes payload and a 2 bytes parity for the short data grant, a 247 bytes payload and a 4 bytes parity for the long data grant, and designates the cutoff between short and long data grants to be 5 minislots in length (the burst size). The station maintenance and unsolicited grant service interval usage code (UGS IUCs) are similarly optimized to achieve the efficient use of minislots and required robustness. Each template consists of 25 profiles, constructed to comprehensively sample the parameter space, along the modulation and FEC regime dimensions. For example, profile 251 exhibits the highest modulation (256-QAM) and least robust profile (meaning the profile with the lowest FEC overhead.)

**Figure 11 - The profile configuration template for 6.4 MHz-wide channel.**

Figure 12 describes how the whole PMA system came together. In the top schematic, theoretical models for noise are shown, as well as measured MER and traffic data that informs the construction of the US profiles. The bottom left schematic shows the result, which is a profile matrix configuration that spans a wide range of operating conditions. On the bottom right, system response is shown, in terms of error rates along with a defined policy that informs the selection of a suitable profile. This iterative process continues indefinitely as network conditions change. Note that the current profile update cycle is once every 6 hours. This value is configurable through policy and we are currently conducting A/B testing on a small subset of the CMTSs to discern if a higher update frequency (~hourly) further improves performance. In more detail:

- Models were developed for different transient and white noise channel models for each of the profiles.
- The range of network metrics were analyzed across the different spectrum locations, coming from over 50M+ DOCSIS devices, to understand the range of performance expected on the production network.
- Distribution of traffic packet and concatenated burst data was obtained to fine tune the codeword efficiency calculations.
- This data was fed into models of profile design, resulting in a set of static modulation profiles that cover a wide range of operating conditions and capacity yields.
- These profiles were tested in an automated lab system that automatically configures the profile on the upstream channel and injects the additive white Gaussian noise AWGN or transient noise, at increasing intensity, in increments of a fraction of a dB. Simultaneously, the system measures the CMTS upstream metrics for SNR and metrics related to codewords and traffic generators. The lab results were then compared to the theoretical models and matched to within +/- 1 dB. These lab and modeling results were then used to set the profile management application policy.
- The analytics engine, based on these models, analyzes the network data in real time. Based on statistics across time samples, and driven by policy, it selects the correct modulation profile for the current conditions. A policy, for example, could limit the operation to a subset of the matrix of profiles, such as limiting the low spectrum 6th channel to only operate in lower modulation transient noise profiles, or constraining the higher spectrum channels to only operate in the top 2 rows of the matrix, depending on channel minislot utilization levels.
- The analytics engine then closes the loop by continuing to measure network performance. It adjusts the modulation profiles as required, and based on network performance statistics intended to keep the errors at a healthy level, also based on policy.
- This closed loop control system is modifiable using Reinforcement Learning (see Section 4.4).

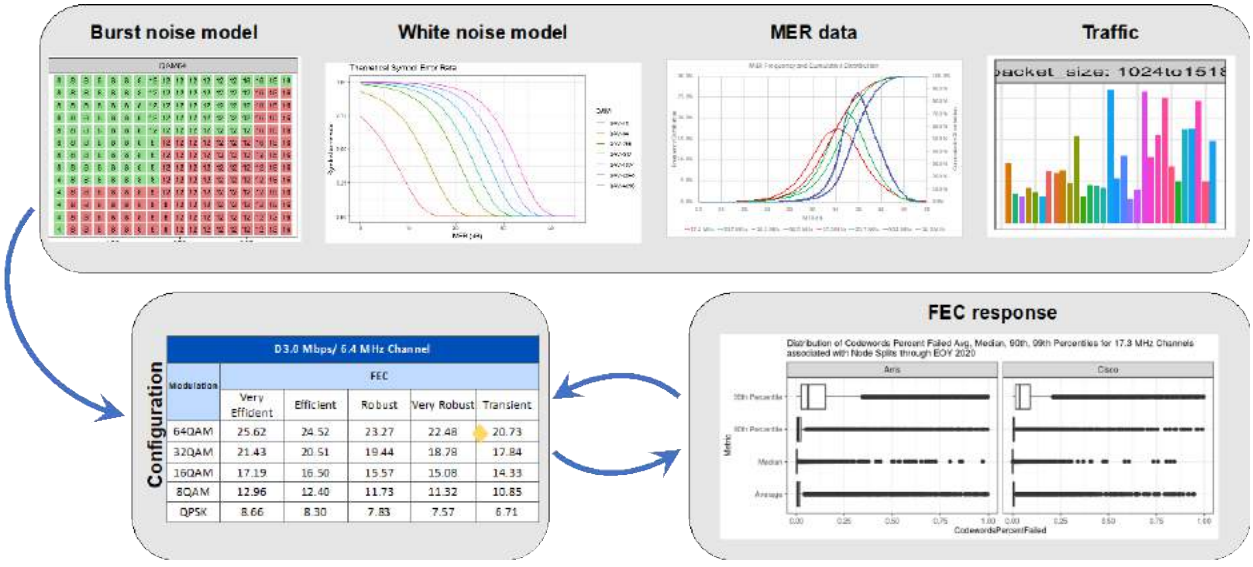

**Figure 12 - D3.0 PMA System Comes Together.**

## 4.3. Why D3.0 US Optimization increase network capacity?

The core idea behind the US profiles is based on changing the FEC configuration to play the trade-off between increasing codeword packing efficiency and increasing robustness against noise (be it white

noise or high frequency transient noise). The concept is illustrated in Figure 13, which shows an illustration of the anatomy of a FEC codeword for a range of modulation profiles. In this example, moving from the transient to the very efficient profile would allow transmitting the same packet while leaving sufficient time for two additional DNS requests to a website (such as "www.ieee.org") that otherwise would have been occupied by un-necessary physical layer and time overhead. The codeword includes a preamble at the beginning, a guard interval at the end, and portions for data (payload) and parity bytes in between. The lengths of all of these components are defined as part of an US profile configuration. In addition, D3.0 allows the definition of different FEC configurations for different traffic packet types (short data grants, long data grants, and voice.) This is where the problem becomes an optimization problem: Knowledge of traffic and noise patterns can inform proper profile configuration, to achieve high packing efficiency (defined as data payload length/codeword length), while maintaining error rates at an acceptable level. Rather than constructing the "right" profile for each US interface, we created a global template of 32 profiles covering a range of operating regimes and QAM modulations (a subset of which is shown in Figure 11 for 6.4 MHz wide channels). Notice how varying the packing efficiency is achieved by changing the FEC configuration: the long data grant for profile 251 (the most efficient 64-QAM profile) has a payload length of 247 bytes and a parity length of 4 bytes, while profile 271 (designed to deal with transient noise) has a payload length of 121 bytes and a parity length of 16 bytes. Consequently, profile 251 has a speed that is approximately 20% larger than profile 271. Note that the values stated above are not arbitrary. They were designed in consideration of the actual traffic packet size distribution on the network, and the type of transient noise typically experienced due to DC power supplies (the so-called common mode disturbance (CMD) noise described in Ref. 7).

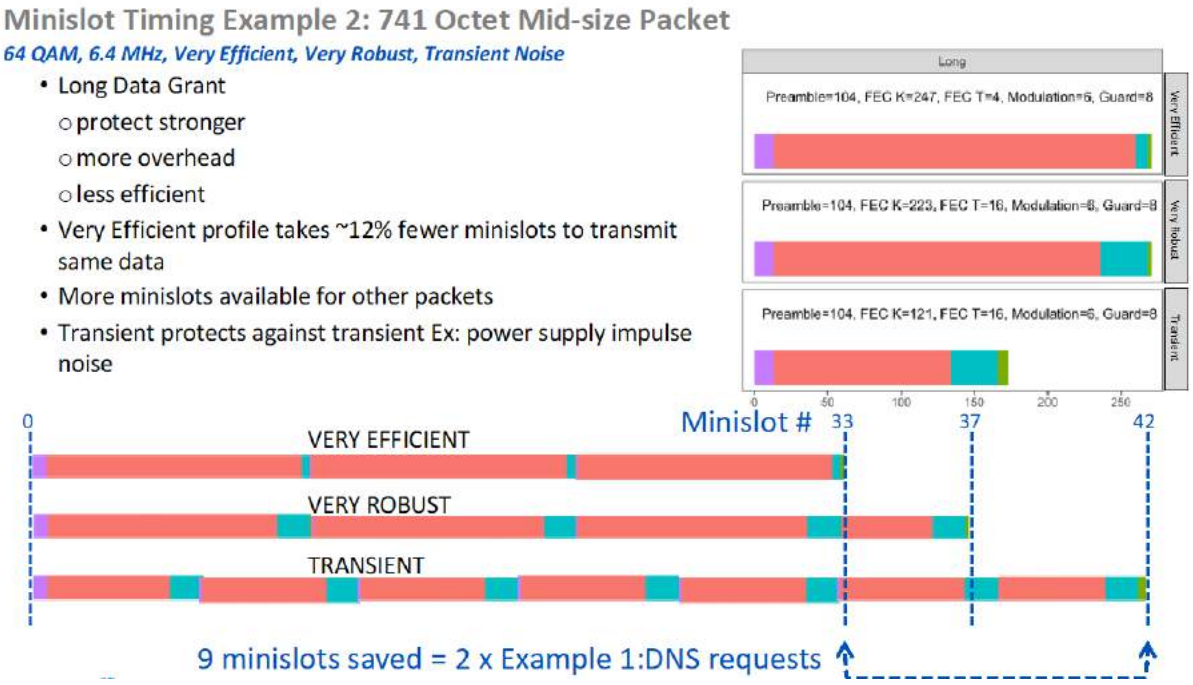

**Figure 13 - Anatomy of a FEC codeword showing example of different codeword configurations for the D3.0 US long data grant.**

### 4.4. The Reinforcement Learning approach to US PMA

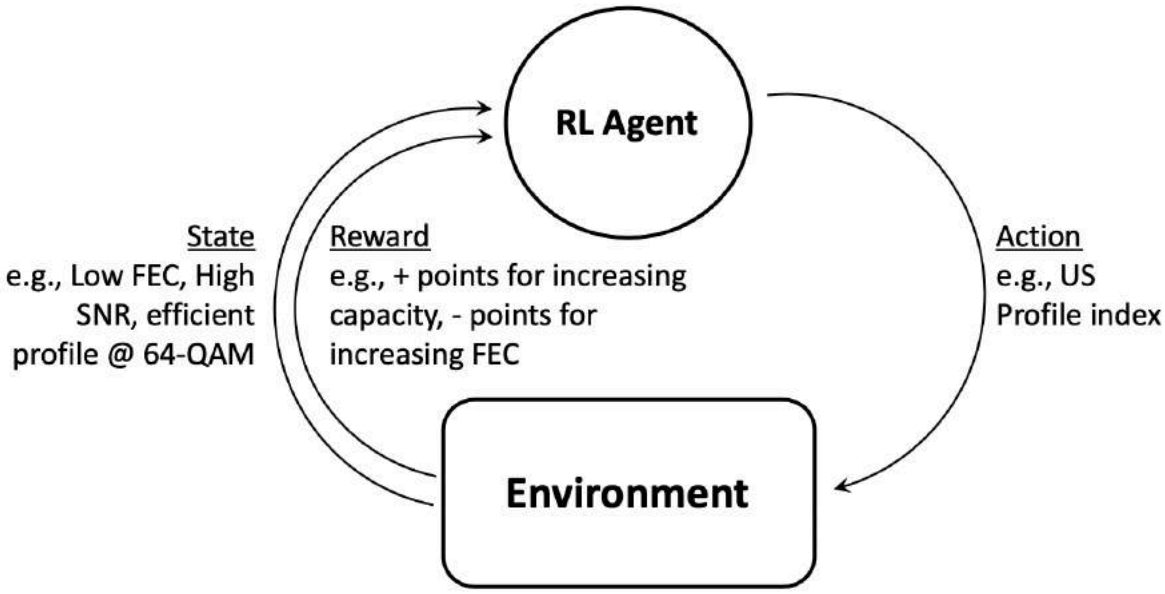

**Figure 14 - Schematic of the Reinforcement Learning system for US PMA.**

The general scheme for the Reinforcement Learning (RL) problem is shown in Figure 14. The goal of the agent, as it interacts with the environment, is to learn an optimal policy that maps states into actions. In the context of upstream PMA, states represent channel telemetry and configuration, while actions represent the upstream profile choice. The ideas behind RL are based on decades-old concepts in control theory and dynamic programming. What is unique to RL is the concept of learning from "trial and error." That is, the agent will at times purposely select a random, non-optimal action in order to continue exploration of the environment. This is useful for two reasons: (1) The number of states, in combination with possible actions, is too vast to sample in a systematic way. (2) Even with sufficient knowledge of the dynamics of the environment at a given point in time, the environment is typically non-stationary. Changes in these dynamics warrant that the agent maintains a level of exploration over time. Our first attempt at representing the US PMA control problem as an RL problem included defining the following components:

- **States**: FEC error rates, traffic volume, and device SNR aggregated to the channel level are discretized by binning the continuous variables according to some given thresholds (e.g. uncorrectable error rate > 1% is High, <1% but >0.1% is Medium, and <0.1% is Low). The profile modulation (QPSK to 64-QAM) and profile type (most efficient to most robust) are discrete to begin with. The resulting state space includes ~6,000 states.

- **Actions**: We limit the agent's actions to changing the profile level by +/-3 steps (in either direction, i.e. upgrading or downgrading by *n* steps), maintaining the same state, or transitioning in or out of the special profile designed for transient noise. Thus, the total number of possible actions is 9.

- **Rewards**: These are scalar values allocated to the agent following each action taken. They are designed to incentivize the agent to maximize returns in the long run. Rewards proportional to the change in profile level are awarded (e.g. upgrading the profile by 3 steps incurs a reward of +3). However, experiencing an uncorrectable error rate above 1% incurs a reward of -10, as this is deemed to be negatively impactful to

the customer experience.

- **Policy**: The policy is a mapping from states to actions—i.e. it represents the decision process. The agent starts with an initial policy that resembles the fixed rule-based approach in the live production PMA pipeline. Example: if FEC rates are below a certain required threshold and the SNR level is above another required threshold, then the channel is reconfigured with a profile that is one step higher than the current one.

With the above in place, the goal of the agent is to discover and maintain an optimal policy. This is done by maintaining a degree of exploration. Typically, the agent would select a random action 1% of the time and the optimal action 99% of the time, under what is known as the epsilon-greedy policy (with epsilon=0.01). Initially, there will be a subset of channels running on a randomized profile between update cycles (currently 6 hours). The risk of causing an adverse effect is mitigated by the fact that the action space limits the magnitude if the upgrade to 3 steps. Furthermore, as more states are explored and convergence to an optimal policy is achieved, the amount of exploration could be dialed down to below 1%. Within the core RL algorithm, as new state-action pairs get explored, the agent collects its rewards based on changes in the environment (perceived through the state) and updates a table representing the long run return for each combination of state-action. This table can be trivially converted into a "most optimal" policy at the time. The update process itself is founded in theory relating to Markov Decision Processes (MDP). These are a special type of processes in which the current state is sufficient to describe all the preceding history of the process. Modeling the RL problem as an MDP allows the use of a host of sampling-based approaches to efficiently update the state-action values. In addition, MDP theory predicts convergence to an optimum policy, given a stationary environment and sufficient number of update iterations. Our current efforts are focused on implementing the RL algorithm and testing it on a small subset of production CMTSs, in order to assess how well it performs against the existing static policy.

## 5. Conclusion

As of this writing, Comcast is currently optimizing capacity across thousands of CMTSs and hundreds of thousands of OFDM and D3.0 upstream channels for more than 50 million DOCSIS gateways and cable modems. The system processes tens of terabytes of data and performs approximately 500,000 recommendations and transactions per day to optimize the upstream and downstream channels. To date, this has yielded capacity improvements of more than 30% in the downstream (towards customers) direction, and of approximately 20% in the upstream direction (from customers.)

To achieve scale and very high levels of reliability, PMA was developed as a serverless, elastic, cloud-native solution—taking advantage of distributed compute, storage, and network options. One of the primary design patterns was to allow for component independence: loose coupling with strong interoperability to promote feature velocity and a high cadence of delivery. Adopting these basic principles enabled each of the functional components and sub-components to have independent, automated, and continuous integration and deployment trains. This allowed for system updates to scale to business needs, often being updated seamlessly and in parallel several times a day.

There are real opportunities to capture additional efficiencies from invested capital in the network. Along this journey we learned a couple things:

- *Keep it simple: It matters to scale.* Network capacity is a complex environment. Modern access networks are complicated; DOCSIS technology is complicated; CPE devices are complicated and required many firmware updates. CMTS solutions are heterogenous and required many new features to be developed. The number of devices and variety of devices are complicated; their

 

different firmware versions, also complicated. Complex systems often exhibit emergent and unexpected behavior and require special consideration when building to scale. Best to keep it as simple as possible (advice perhaps easier said than done!)

- *Leverage the cloud.* The benefits of the cloud are real, and public cloud is an accelerator. Leveraging public cloud resources allows you to focus resources on key problems. It allows you to reliably reach scale, at a velocity that meets business demands.
- *Keep learning through iterative builds.* For best results, build on platforms that can be updated seamlessly and constantly tested. We could not have anticipated all the conditions that we encountered and benefited greatly from a team and culture that was built on iterative learning.
- *Be data-driven by measuring what matters.* Along the entire journey, from early analysis to production dashboards and quality metrics, trusting the data and developing a data-driven strategy allowed us to match practice to theory and build confidence. Being data driven will drive you toward success.

# 1. Introduction

Customer Experience, Telco, Machine Learning, Automation… all sounds a bit dry, no? If not, this should help shed light on a specific use case, but also provide details and lessoned learned while building the solution. If so, read on to perhaps find some surprising details. Many are aware of the impact from Machine Learning but may not be aware just how many portions of the enterprise it is now altering -- or the magnitude of those changes.

With building an ML platform in mind, specifically to improve and automate the customer experience, this paper will illustrate how we accomplished this. It will also detail lessons learned and insights not only on the data itself, but on the architecture and thinking behind it.

Another focus is the challenges and differences of scaling and maintaining the Machine Learning components of the architecture. The highlight here is that while Proactive Network Management (PNM) [1] has laid out a number of excellent methods on how to collect and analyze network telemetry from CPE and other headend equipment, it has not covered the aspects of what to do or how to handle the data with respect to utilizing ML models.

This paper will begin with the Customer Experience use case, and work from that point through to the end solution. A number of open source technologies are referenced as possible implementations for components. Other components can certainly be used.

The desire to share this information stems from the fact that some of these solutions are not easy. They require not only multiple resources to develop the front-end user interface, but the back-end platform as well. After the ML models have been trained, the task of building the platform, scaling, testing specific tools and gluing everything together is still rather manual and prone to performance and optimization challenges. With those things in mind, the details throughout this paper should aid the reader in determining directions to go when considering, building and scaling such a system.

# 2. History

Telemetry collection and polling have been widely covered in the industry with both positives and negatives. The positives almost always outweigh the negatives, in terms of providing the ability to determine outages quickly, gain insights on which partitions and elements in the network require maintenance and many other useful applications. Using telemetry with machine learning is also fairly old, just not commonly referred to as “machine learning”. Take adaptive equalization in digital communications as an example. The parallels are many between parts of adaptive equalization and how machine learning algorithms work. Or, take the DOCSIS upstream pre-equalization process as another example. For each burst of data in a transmission, the preamble is used just like a training set for a supervised ML algorithm, but for the CMTS’s upstream adaptive equalizer. Likewise for the downstream, with a blind-equalizer -- it is the same as an unsupervised ML algorithm. Overall, there are inputs, derived coefficients and an optimization problem – which is to minimize the mean square error of the outputs.

Applying ML algorithms to other telemetry angles is simply considering different shapes. With polling or collection systems, gathering telemetry from CPE, headend or data center equipment, and funneling that into distributed computing environments to do essentially the same thing the CMTS was doing with adaptive equalization, is a larger scale scenario with potentially more complex models. This method of analyzing telemetry is just the next evolution, after analyzing telemetry for outages or full spectrum data

for various distortions -- but now using more complicated methods such as ML models to tease out new artifacts and correlations in determining network health.

# 3. Customer Experience as it relates to ML

What is customer experience? According to customer experience futurist Blake Morgan, it "really boils down to the perception the customer has of your brand" [2]. In the use case laid out, it is the perception of the self-service customer experience.

## 3.1. Use Case

The outcome of the project is to automate simple common customer service questions and return immediately useful feedback or solutions to the posited issue or question. The goal here was two-fold: one, to improve the customer experience by knowing their issue before they do and if possible remedy it, and two, to reduce the number of calls to customer service.

When left open-ended, the outcome is intractable, given the large problem scope of all possible issues customers may face while going through all the various customer service avenues available to them. Therefore the scope and requirements of the outcome were reduced to answer a few basic questions, then continue to build out the capability to handle more queries from there. These initial questions were:

- Is there an issue with my internet service?
- Is there an issue with my video service?
- I have a billing or account inquiry?

All of the problems require use of machine learning. The first two require telemetry data and additional machine learning as well. For the third question, the goal was to handle simple questions initially, such as "why is my bill different than last month?" or "how much does my TV package cost?" and has since been expanded to handle more questions.

With the goals and outcome clearly defined, the solution required thinking on how to accomplish this, given the large number of telemetry and other data sources available.

# 4. Telemetry

The breadth of telemetry for most telecommunications companies and network operators is vast. Data comes from a number of sources which generally are customer devices, headend or data center equipment or public devices. Customer devices or CPE (Customer Premises Equipment) are usually comprised of cable modems, Wi-Fi Access points, cable boxes and the ever growing list of IoT devices. Central locations such as the headend, Point of Presence (POP) and data centers tend to be the geographic source for equipment such as CMTSs, access networks, video sources and more.

The correlation between our initial questions and data sources were fairly straightforward:

- Internet service problem: telemetry from the cable modems and CMTSs
- Video service problem: errors from our Video Backend Service (VBS)
- Billing / account inquiry: billing data system

During the exploration of datasets, a single dataset was found that provided attributes for both the internet and video service questions, which was errors from the OS that runs on both cable modems and STBs.

The informational and error messages from devices built on the Reference Design Kit (RDK) [3] turned out to be very valuable, as both the Set-top Box (STB) and Cable Modem (CM) use the same transmission medium from the premise to the headend or hub site.

## 4.1. Attributes

Telemetry from the RDK consists of a number of attributes useful to determine if there are issues from the CM side, STB side or both. It contains general information about the CPE:

- CPU utilization
- Memory utilization
- System load
- Wi-Fi signal strength
- Etc.

Perhaps the most useful data from RDK, however, are error codes and counts. These errors relate to dropped packets, firmware errors, signal errors, etc. The specific attributes which were the most impactful as part of the machine learning model were "rf_error_erouter_ip_loss", "rf_error_ipv6pingfailed", and "rebootreason=unknown". These attributes increase the accuracy of the models in determining whether or not the issue is related to internet service / high speed data (HSD).

While the RDK telemetry provided beneficial information for both HSD and video, the VBS data provided the majority of telemetry needed to determine if the customer issue was video-related. The VBS data contains such telemetry as:

- User interactions with their TV via the remote
- Errors displayed on-screen to the customer
- Errors with satisfying a request to the customer
- Etc.

For the billing questions, having data about the customer billing history, specific elements on the bill and differences between those elements over time provided the majority of features needed to satisfy the initial use-case.

## 4.2. Usefullness

In "Observing home wireless experience through wifi APs" [14], it was shown that many in-home Wi-Fi markers were able to characterize wireless experience. In our work, the definition of telemetry includes error and system logs produced by RDK, which is unique to our use case compared to the literature. We will detail a few examples in this section to give the reader a picture of their utility.

The telemetry includes readings of Wi-Fi signal strength (known as RSSI, for Received Signal Strength Indicator) and channel utilization. RSSI is a negative value (-100,0) and a value below –80 is considered poor signal strength. Therefore, it is clear that this telemetry feature can be useful in identifying devices that have an impacted customer experience. Likewise, channel utilization data can indicate when a given Wi-Fi channel frequency is saturated from too many devices or too much traffic. High utilization is an indication that one may need to change the Wi-Fi channel the router is using for signal transmission.

The RDK logs are another source of events which may impact a customer's service. For example, if a reboot occurs, there are multiple keys that indicate the event has taken place, and in some cases, why the reboot occurred. Unscheduled reboots are generally strong indicators of a customer experience issue.

Moreover, there are system logs when processes on the box restart, which can also impact service, depending on the process. (Such processes are programs running on the thin version of Linux on the gateways). There are other markers like “system_uptime”, which gives the time since a last reboot, and “rf_error_ipv6pingfailed”, which indicates a count of pings to a fixed IPv6 server address that have failed since the last log. In total, there are over 750 unique keys which appear in RDK and more are added over each release.

# 5. Platform

## 5.1. General Architecture

All of the features learned from exploratory data analysis need to be processed, parsed and transformed so they can be passed into the model. During offline training of the model, the researchers perform these tasks but usually at smaller scales. Or, if full-scale, it usually doesn’t run constantly. Also in the research environments, the lack of introspection, scaling (depending on the researchers’ environment), monitoring and alerting is unacceptable for running a supported product. These are among the goals of an ML platform.

The basic components of the platform, in order of data flow, are:

- Data producer
- Raw data consumer
- Feature engineering
- Model invocation
- Inference storage or action

This typically involves one or more teams and one or more platforms to handle the data. It is common for the platform responsible for polling or collecting data from the CPE to be handled by one team, while a different team is responsible for the ML platform.

When greatly simplified, data collection can be boiled down as seen in Figure 1. Here, some process (usually many parallel processes) is responsible for connecting or listening to the CPE and other devices to collect, format and aggregate telemetry. JSON is typically used for data formatting, though other formats are becoming more common, such as Protocol Buffers and Apache Arrow objects. After the data is formatted, the telemetry collection system will publish the messages to a message bus for consumption from other teams within the organization. For our systems, we use Apache Kafka, as it is stable and scales well.

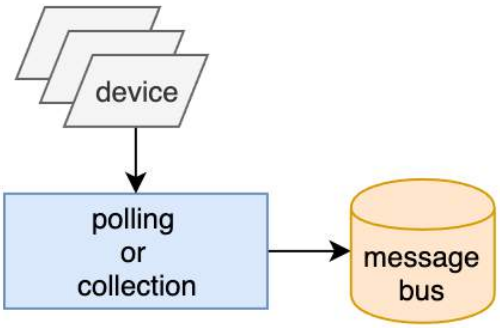

**Figure 1 - Telemetry collection flow**

Once the data has been published to the message bus, it is decoupled from the data collection platform and available to be used by the ML platform. A simple flow for processing the telemetry events from the message bus is detailed in Figure 2. Here a message bus consumer process will listen to the stream for new messages. Next the message will be parsed, and various transformation and/or normalization steps will be performed on the data to prepare the dataset to be passed into the ML model. Before or after parsing and feature engineering, it is common to store features into a database so they can be later retrieved. This is useful when building aggregate feature sets (such as time windows, feature enrichment, etc.) so the model may be passed a richer and potentially more useful set of features. Once the features are ready, the model is invoked, which produces an inference or prediction. This output is then handled by possibly storing that in another database, distributed filesystem or even published to another message bus to do something with that model output.

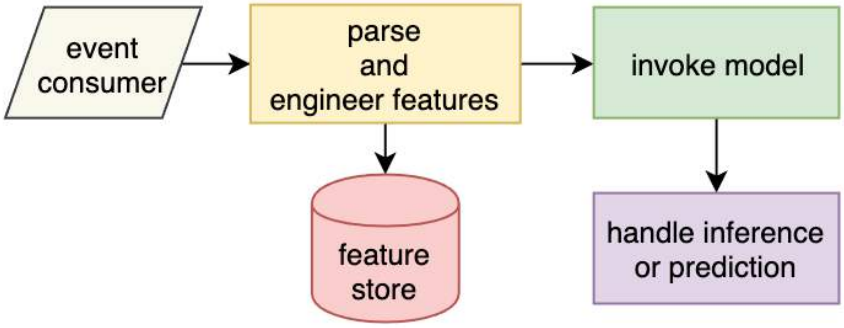

**Figure 2 - Feature engineering and model invocation flow**

While these two systems are usually logically separated and loosely coupled, thanks to the message bus architecture, they do need to combine as shown in Figure 3. Here the full picture is seen with both the telemetry collection platform and the machine learning platform receiving telemetry.

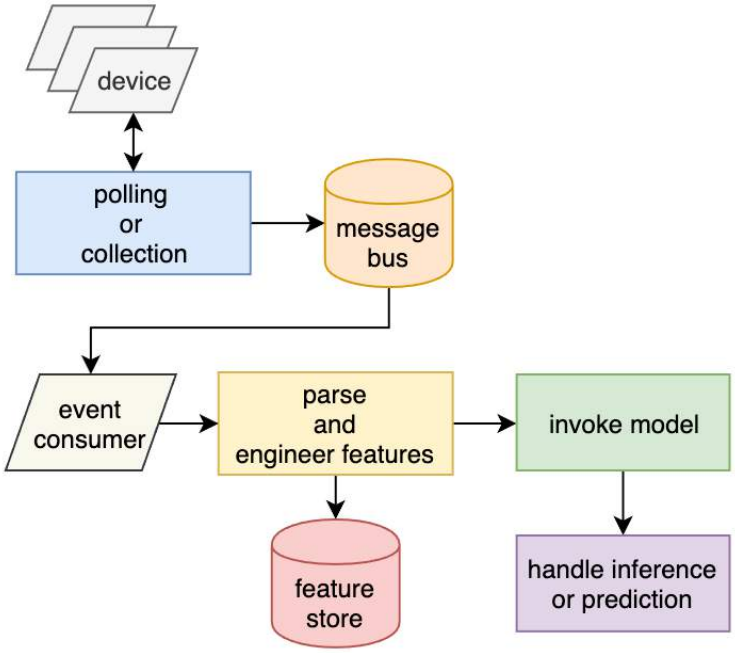

**Figure 3 - End-to-end telemetry and ML processing flow**

## 5.2. Implementation

### *5.2.1. Technology choice*

The end architecture contains the same components and flow as shown in Figure 3, but there are differences in how those components look after scaling and with specific technology choices. For the flexibility to run programs of any type, Docker was chosen to contain some of these complex applications. For scalability, a container orchestration layer is required to dynamically scale resources to match the needs of the incoming telemetry – in our case, Kubernetes was chosen here. For a scalable message bus, the choice was Kafka, as previously mentioned. Depending on the rate of operations and type of data in the features, a range of database technologies and types can satisfy that requirement. For example, if you have relational data, a more traditional SQL database such as MySQL or PostgreSQL might be chosen. For a NoSQL database, perhaps Apache Cassandra or MongoDB. For a NoSQL cache layer, CouchDB, Redis, or if SQL, then MemSQL. This is by no means a comprehensive list of database technologies but do represent a few options to investigate, should you have a specific set of requirements for your feature store. For our solution, Redis was chosen primarily for performance reasons and data retention. The research team determined that the largest useful window of data was 24 hours and older historical data beyond that was less impactful. It is also relatively quick to repopulate, as well, in the case of catastrophic cluster issues.

Kubeflow was chosen for model serving not only because it works well with Kubernetes but contains a number of require features as well. More specifically, a sub-component of Kubeflow called Seldon Core was chosen due to its flexible inference graphs, monitoring and A/B testing capabilities. Finally, Python is the language of choice for deploying models due to the fact that the models will require little or no code changes to be deployed. Also, many Python specific packages such as NumPy are very performant and don't have great equivalents in other languages. This also allows the model owner or team less familiar with production operations to maintain and re-deploy their model as needed. Other scientific languages, such as R, have far less library and performance support for writing and running general components.

### *5.2.2. Architectural differences*

The differences between our general architecture in Figure 3 change when we consider Kafka and Kubernetes. Starting with Kafka, it is important to understand a bit about how Kafka works so that we can scale appropriately. Without getting too deep into Kafka's architecture, there are three basic components: the topic (which consumers and producers use), the broker (a node in the Kafka cluster that handles topics) and partitions (a sharded piece of the topic). When we have high volume topics, those usually need to be partitioned out so we can scale throughput horizontally. In Figure 4, the telemetry polling architecture would publish messages to a specific Kafka topic with $b_n$ brokers and $P_m$ partitions.

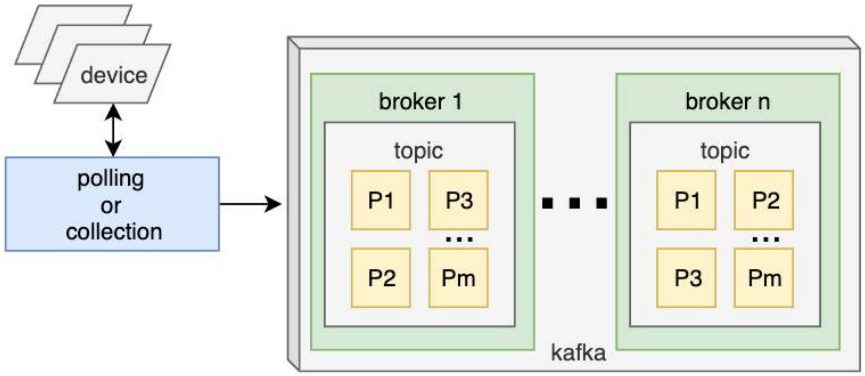

**Figure 4 – Message bus parallelism**

To calculate $n$ and $m$, the volume and message size need to be determined. For this example X,Y and Z are just example features. Actual features used in the system are Signal-to-Noise Ratio (SNR), RSSI and others. Take the following row as an example:

**Table 1 – Sample telemetry**

| MAC address | Customer ID | X | Y | Z |
|---|---|---|---|---|
| aa:bb:cc:dd:ee:fa | 123456780 | 2.156 | True | 3 |
| aa:bb:cc:dd:ee:fb | 123456781 | 3.211 | False | 7 |

If each of these records were represented as individual messages, then they might look like this in JSON.

```
{"mac":"aa:bb:cc:dd:ee:fa", "customerid": "123456780", "x": 2.156, "y": true, "z": 3}
```

However, the data is usually far from optimal, introducing additional parsing overhead or unnecessary extra data. Such as an unnecessary element as shown below "pollresult" or perhaps elements represented as strings instead of their actual datatype.

```
{"pollresult":

      {"mac":"aa:bb:cc:dd:ee:fa", "customerid": "123456780", "x": "2.156", "y":
"True", "z": 3}}
```

### *5.2.3. Message bus performance*

Using this less than perfect data, we can now calculate the volume and size of the messages to determine the correct number of brokers and partitions for the Kafka topic. Using our system as a more realistic example for the message size, the mean message size of 1.4 kilobytes is used. Assuming there are ten million devices being polled every minute and the JSON is raw (uncompressed) on average 1.4kB, and the message above, the throughput would be $\frac{1e7*1400}{1000^2} * \frac{1}{60} = 233.\overline{3}$/MBs. Using 50MB/s per broker as a rule from Dropbox's Kafka Throughput limit post [9], rounding up we would require 5 brokers at 50MB/s each, giving us a reasonable 250MB/s throughput. To determine the number of partitions, multiply the number of brokers by 10, which yields 5 brokers with a single topic of 50 partitions. Of course, this is just an example, and situations are different based on hardware type, network throughput and many other factors.

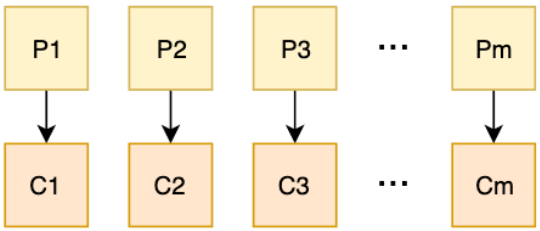

**Figure 5 – Message bus consumer scale matching**

The reason partition counts per topic are important relates to the performance gain of matching consumer processes or as a multiple of the number of partitions. Here, with 50 partitions, you may need to scale the message bus consumers as shown in Table 2.

**Table 2 – Message bus consumer scaling**

| Consumer count | Multiple | Comment |
|---|---|---|
| 5 | 10 | If message processing is very fast, single consumer may be able to handle multiple partitions each. |
| 25 | 2 | Many more consumers handling partitions. If message processing is more computationally intensive, each consumer might only handle two partitions. |
| 50 | 1 | A single consumer per partition is required if the code is not only parsing, but performing some action or invoking a ML model inline as shown in Figure 5. |

Final thoughts on consumers and messaging or streaming systems: There are many combinations of great open source projects which can be used instead of writing the consumer logic manually. For example, systems like Apache Flink and Apache Beam, as well as offerings from the various cloud providers, can perform many of the functions described here.

### *5.2.4. Container orchestration*

Once the number of consumers has been determined, a scalable, fault-tolerant environment is needed to run the consumers and models. The flexibility of the runtime environment is crucial to operating and maintaining ML models and pipelines, which made Kubernetes and Docker a natural choice. Kubernetes also allows elastic horizontal scaling, to scale up for spikes and scale down for dips in processing.

Zooming in on the general architecture in Figure 3, the message consumption and feature handling, as well as the model invocation components -- all translate to Kubernetes pods. Once the engineer or researcher creates the model, it is pushed to a container repository, then pulled down in Kubernetes to run and monitor, as shown in Figure 6, until there is a change. Kubernetes can scale up and down by adding and removing replicas of a particular pod corresponding to the addition and removal of worker nodes.

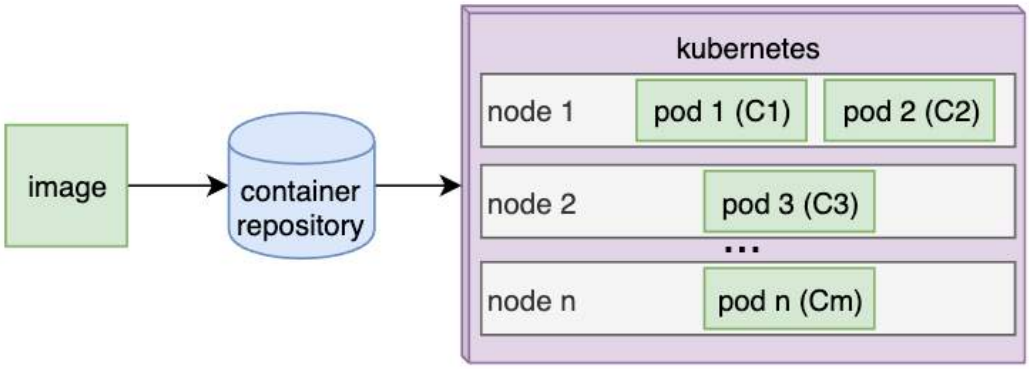

**Figure 6 – Container parallelism**

A benefit of Kubernetes is that pods of any type can be run together on the same cluster. If the consumer pods for example are written in Java, and the model code is written in Python, then both can run simultaneously on the same worker nodes, thanks to Docker, and shown in Figure 7.

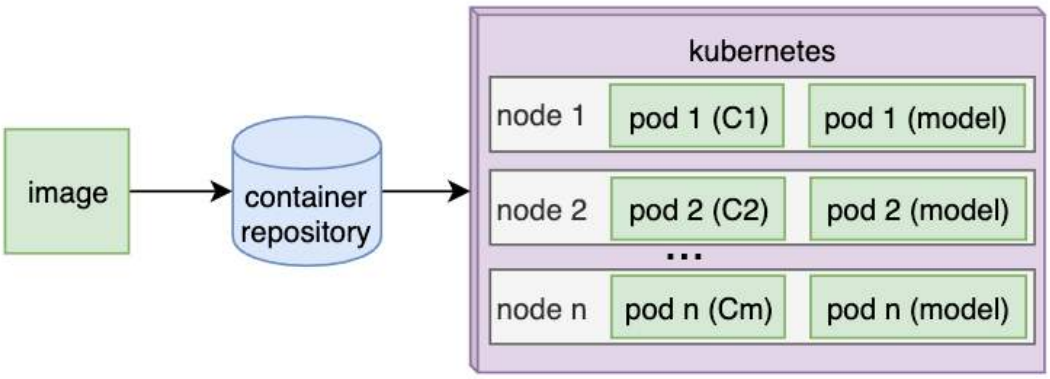

**Figure 7 – Container isolation**

## 5.3. Feature engineering performance and guidelines

Just before the model can be invoked, the raw features from the polling architecture require parsing and some manipulation specific to the ML model. Many types of manipulations exist, such as min-max normalization and standardization. For specific ML domains such as Natural Language Processing (NLP) or Deep Neural Networks (DNN), the data may need to be tokenized or one-hot encoded. Three of these normalizations are common, so it is necessary to look at them with the corresponding features and how those features get changed.

### *5.3.1. Min-Max normalization*

To rescale features between 0 and 1, the formula is $x' = \frac{x - \min(x)}{\max(x) - \min(x)}$. However, this requires that the maximum and minimum values of the features are available. Many systems may only contain partial feature sets from which the minimum and maximum value cannot be derived. Note that the term "feature set" is just a series or list of features, and order may be important. Also common is to scale features to a particular range $[a, b]$. For this, the formula is slightly different $x' = a + \frac{(x - \min(x))(b - a)}{\max(x) - \min(x)}$. If the features

require these normalizations, the minimum and maximum may be provided, or the telemetry will need to be collected for an acceptable period of time to derive acceptable values.

### *5.3.2. Sum or counts*

Adding or counting features for a particular time window or sample is a common normalization. However, the computational complexity when performing feature engineering at scale here can be deceiving – especially when referring back to the example of ten million devices polled every minute. Take a hypothetical situation where the desired prediction is a usage pattern spike given two features, bytes in and bytes out. Assume that research has found 30 minute windows to be optimal for predicting if there will be a spike. The total feature size for all devices would be $1e7 * 30 = 300e6$ or 300 million. If the features were simply a MAC address, bytes in, bytes out, and timestamp, the JSON representation might look like

```
{"mac": "aa:bb:cc:dd:ee:fa", "bytesin": 1287630, "bytesout": 58360, "timestamp":
"2020-07-01 02:31:05"}
```

The feature set size for all ten million MAC addresses would be $\frac{\sim 103\ bytes}{1024^2} * 10e6\ devices * 30\ minutes$. While this is only ~29.3GB worth of features which is relatively small, the compute time may be large. Consider another example: Python code as pseudo-code. There are a number of details left out, such as actual timestamp calculation, and data structure details:

```
# iterate through current polled messages from the kafka topic for each device

for features in current_features_from_kafka:

  # get history

  history = get_history_for_mac(features['mac'])

  history.append(features)

  # iterate through history

  summed_features = {'bytesin': 0, 'bytesout': 0}

  for history_features in history:

    # expire old items

    if history_features['timestamp'] > thirty_minutes_ago:

      # iterate through features
```

```
    summed_features['bytesin'] += history_features['bytesin']

    summed_features['bytesout'] += history_features['bytesout']
```

Say there are 50,000 messages from Kafka, each having 30 minutes of history, with the computational complexity of $O(n^2)$ (where $n$ is the number of steps), which results in $50000 * 30 = 1{,}500{,}000$ iterations. If all ten million are polled every minute, that is 300 million iterations per minute. All of this requires more replicas to scale or, some simple tuning of the algorithm. If the math is commutative, it can be parallelized out of order, and for a simple count, it is. However, here the values may contain negatives, which means it is non-commutative and must be executed in order, serially. However, these can certainly be parallelized as the only requirement is that each device needs its feature sets to be computed in order. By changing the algorithm to remove iterating through the entire history set for each new message, we can reduce the second loop from 30 iterations to just two operations when storing the summed features as well in a database. There are obviously a few more steps here, such as the back and forth from the database and type conversion (if necessary), but it can all add up -- which can, in some cases, dramatically increase costs. With the improvement, for the 50,000 messages from Kafka we're now only doing 50,000 iterations instead of 1,500,000 and a time complexity of $O(n)$.

```
# iterate through current polled messages from the kafka topic for each device

for features in current_features_from_kafka:

  # get history from feature store

  history = get_history_for_mac(features['mac'])

  summed_features = get_summed_features_for_mac(features['mac'])

  # remove the first (oldest) and decrement from summed_features

  oldest_history = get_expired_feature_from_history(history)

  summed_features['bytesin'] -= oldest_history['bytesin']

  summed_features['bytesout'] -= oldest_history['bytesout']

  # add the current features

  summed_features['bytesin'] += features['bytesin']

  summed_features['bytesout'] += features['bytesout']
```

Said another way, we can look at it as a sum of series, where those series may contain negatives. Let $n$ equal the number of historical feature sets for the series $a$, and $m$ equal the number of features within each historical feature set $a_i$. The total sum $S_m$ is the series of all historical feature sets:

$$S_m = \sum_{i=0}^{n-1} \sum_{j=0}^{m-1} a_{ij}$$

Now let $c$ equal the current message being processed with $p$ features. Then the historical features sum the current features:

$$S_m = \sum_{k=0}^{p-1} S_k + c_k$$

If the previous sum of the historical feature sets is known, then let $h$ equal that series, and the original operation can be rewritten more efficiently as a single sum. This does not take into account the subtraction or decrementing of historical feature sets that expired from the desired time window (30 minutes for this example):

$$S_m = \sum_{k=0}^{p-1} h_k + c_k$$

Keep in mind that this assumes the series and elements are the same between series. In real-world data, the elements for each piece of telemetry may be different, resulting in sparse data structures which require different thinking to process efficiently.

### 5.3.3. Mean

The mean here is a bit more complicated because without iterating through the entire history an actual mean $\frac{1}{n}\sum_{i=1}^{n} a_i$ can't be derived. To get around this and get a "good enough" mean, we turn to a simple moving average, so we don't have to iterate through the entire historical time window of features. With a simple moving average $\frac{1}{n}\sum_{i=0}^{n-1} p_{M-i}$ is used as we have the historical features in the database and the code is similar to the sum example.

### 5.3.4. Other operations

For operations such as standard deviation, minimum or maximum values are more complicated to process given a single value. There are potential ways to calculate these things given more values, such as minimum or maximum, if you know the top or bottom 5 for a particular feature. This requires keeping those lists and can be cumbersome -- which may defeat the purpose of computational efficiencies, unless the historical time window or number of messages therein is large.

# 6. Model Serving

The last component of the system is the model, and how it gets exposed to users or other parts of the organization. This is perhaps the most straightforward piece of the system, not considering what happens to the output (prediction or inference) from the model. The simplicity comes from a project called Seldon Core which allows almost any type of ML model to be invoked with Python and served from Kubernetes. In Figure 7, not only is the model potentially running alongside the feature engineering on the same node, but in separate containers, it is also able to scale horizontally by simply changing the number of replicas. This can also be performed automatically with elastic scaling. All the major cloud providers support some kind of model serving and each has their own benefits and drawbacks depending on the situation. Running your own Kubernetes allows you to also run Prometheus or tie it into an existing monitoring solution within the organization, such as to leverage metrics and alarming for the operations support side of these platforms.

## 6.1. Requirements

Given the large number of components in the model, a system which supported core requirements such as multi-armed bandits, A/B testing and advanced inference graphs was required. Seldon Core was chosen as it satisfied all of these requirements and integrated well with Kubernetes and production monitoring systems. Seldon can support a user-defined inference graph, which allows custom configuration and combinations of models and components. It also allows for percentages of traffic to be handled by each, thus allowing for more complicated implementations such as A/B testing. As part of the user request flow to the model, it was important to ensure that customer HTTP sessions are sticky to a particular A/B model. In order to accomplish this, a custom Seldon router, which takes a seed value can be written to route requests to the same components in the inference graph depending on values in the payload (such as a customer identifier.

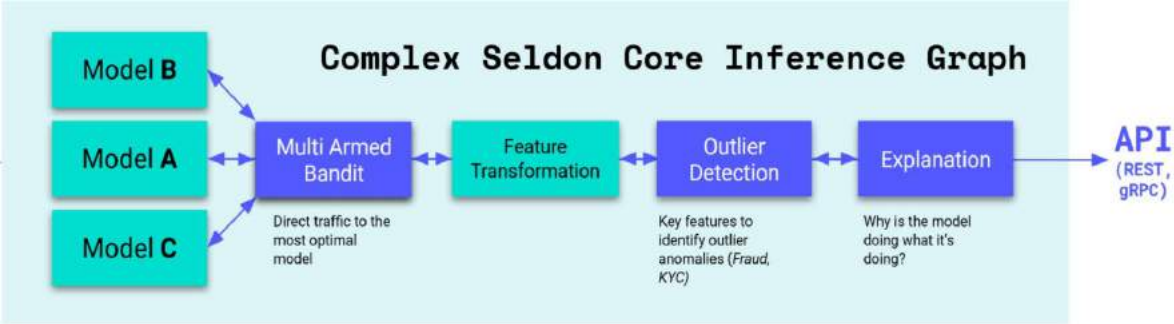

**Figure 8 – Inference graph example**

## 6.2. End-to-end flow

While the entire flow is shown in Figure 3, there is a critical piece missing. Figure 9 depicts the end-to-end flow, including customer interaction with the system to request predictions from the model.

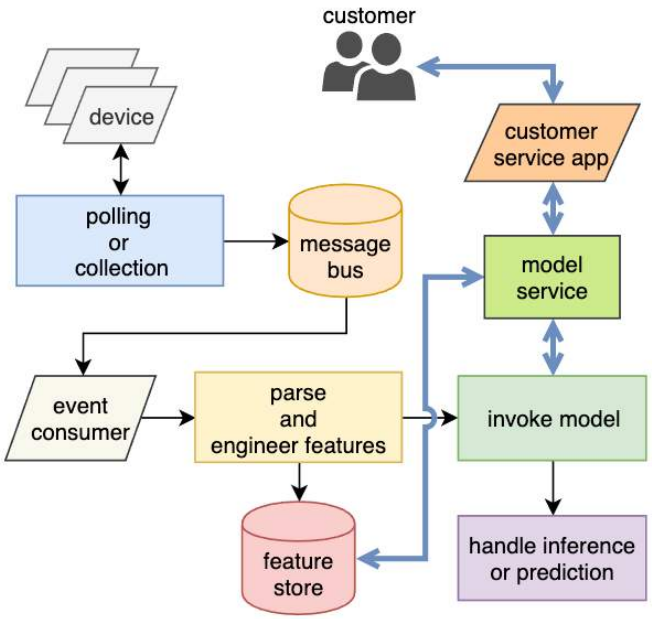

**Figure 9 – End-to-end platform flow**

In the second flow with the thick blue lines, the customer interacts with the customer service application on their device or web browser. This invokes the model service and returns the prediction back to the application, then the user, about whether or not it believes they are experiencing an issue based on the telemetry and output from the application. If there is an issue, it attempts to specify a recommended fix action, or, as a last resort, refer the customer to customer service. This system has been successful at handling millions of customer requests quickly and accurately, improving the customer experience.

## 7. Scale

In our customer experience ML platform, we're generally handling 100k+ messages per second and executing 300-500k+ operations per second to our Redis clusters. As previously mentioned, this is accomplished with horizontal scaling from Kubernetes. In many of our platforms, we're handling more than just the RDK datasets, as our models require engineered features from many varying datasets to produce the unique outputs to improve the customer experience.

Our Kubernetes clusters generally run with 10 or more nodes at 16 CPU cores per node and 128GB RAM. The Redis cluster nodes have far fewer CPU cores (4) as the Redis process is single-threaded, yet they have much more memory, generally 256GB RAM. Our Redis nodes as well as the Kafka broker nodes have secondary 1TB drives for disk-based persistence, replication and retention.

## 8. Model

Our goal is to prompt a user to troubleshoot one of their services in order to increase engagement and troubleshooting inside the chat bot. Thus, our data is generated based on both customer feedback and the decision to show a prompt to a user. In this way, the model will impact the data generating process, which is different from standard classification or regression use cases, where the data generation is assumed to

be independent of the model's output. For example, in image classification, if a model incorrectly labels a picture of a cat as a dog, there is no impact to the ground-truth label—that the photo is of a cat. In our case, we will have feedback based on the action we select, but we have no information on if the model took a different action. Our problem can be formalized in the framework of contextual bandits.

Contextual bandits algorithms extend the traditional multi-armed bandits problems by giving the agent a state to aid in decision making. Each data point can be thought of as a "round" of a game, where the state is the features of the model ("agent/policy") , the action is chosen by the agent, and the reward is the label. Contextual bandits problems are a special case of Reinforcement Learning, where the length of a round is 1. The goal of the agent is the learn to play the game in order to maximize the expected reward when following the agent's action recommendations.

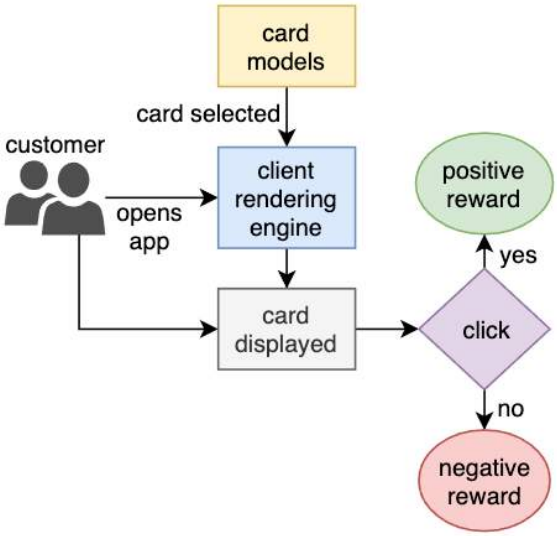

**Figure 10 – Model flow**

One drawback to reinforcement learning and contextual bandits in industry is that the algorithms are traditionally trained online. In the case of reinforcement learning, agents typically have access to a simulator of the environment (i.e. a game) and they learn as they play (c.f. "Playing Atari with Deep Reinforcement Learning" [17]). For contextual bandits algorithms, they often need to be deployed into production and learn as they serve customers [15], [16]. This is because the data distribution changes as the agent learns, as the agent will select new actions based on new information. This is different from the static training set found in classic supervised learning. Because of this, a suite of theoretical techniques has been developed to evaluate and train agents offline, namely "off-policy" techniques [18], [19]. Off-policy techniques have been employed in a variety of industrial applications successfully, including [20], [21]. This approach utilizes data from a production logging policy with sufficient randomization for training and evaluation of offline policies.

One of the large benefits of off-policy evaluation is the ability to estimate the true online performance of a contextual bandits model without deploying it into an A/B test. This allows the researcher to rapidly prototype many candidate models and choose the best model for an A/B test which impacts customers.

With that said, our model is a linear model which predicts the reward for each action (prompt) that we may show the user given the state, i.e. telemetry features defined above. After predicting the expected

 

reward for each action, we take the action with the highest reward and output that action to the production system. We train the model using various off-policy approaches [22] and select the model which performs the best on the off-policy evaluations of our metrics for production. Crafting reward functions is an art more than a science, and generally are designed by experts to maximize not only the business metric of interest but also downstream metrics. In our case, our reward function is a proxy for the click-through rate of the prompt, where we have a negative reward if a card was shown and not clicked. We scaled reward functions to be between [-1,1], as it makes the training process more stable through smaller gradient updates.

All analysis was done in Jupyter Notebooks, including training. Models were defined and trained using Keras, a popular abstraction of neural network operations that sits on top of libraries like Tensorflow. In production, the model is invoked to select a card for the user upon application start.

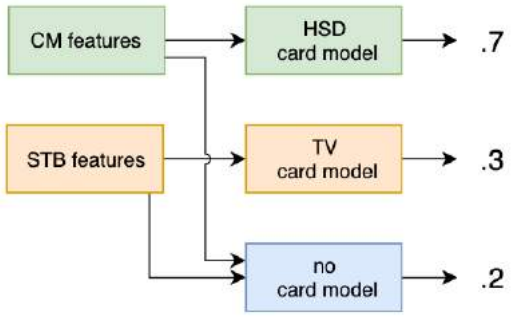

**Figure 11 – Model architecture**

## 8.1. Feature Engineering

The telemetry we utilize comes in several forms: snapshots of physical characteristics of the Wi-Fi signal; device performance indicators usually expressed as a percent; and application logs which count the occurrences of different system messages, including error codes. We pass each of these types of features through a different pipeline to create appropriate features. All of our features are aggregations over window of time *t,* where *it* depends on the feature type.

For continuous features, we utilize statistical aggregations over the time window. Many of the continuous features are related to devices connected to the gateway, and so we will have multiple devices for a given customer. We take an aggregation of statistics calculated on each device as our final feature. For example, consider the RSSI: we calculate the mean, median, the standard deviation, and other statistics for each device, and then we aggregate these statistics again for a single value for each customer account. Time aggregations are used so that the model has is able to learn a sense of what's "normal" and can identify deviations from those norms. More significant deviations could imply impact to a customer.

For count valued features, we base our approach on common natural language processing (NLP) techniques. The counts of the more common errors/logs over a time window can indicate the intensity of a problem, and the existence of rare keys can indicate a complete service impairment. Thus, common NLP techniques are applicable to our use case and provide a framework for creating features (embeddings) from which a model may learn. Each error code or system message indicator is treated as a "word" and

passes this context to our feature pipeline as a “bag of words”. The data is then transformed via a pre-trained TF-IDF pipeline before using it in the model.

Our feature processing pipelines use classes from sci-kit learn. For example, all features are normalized before training using preprocessing classes. Continuous features are standardized and (sparse) count features are scaled by their maximum absolute value. In addition, the TF-IDF embeddings are implemented using the corresponding classes found in scikit-learn for this purpose.

## 9. Results

By utilizing the machine learning model, we achieved a 40% improvement in customer engagement, as measured by the abandon rate of sessions (when a customer opens the application and leaves without clicking or asking a question). This was measured through an A/B test where all customers selected to get a card were split into two groups: the treatment group who were shown the card and a control group where we held back the card. This business impact was accompanied by a measurable increase (~42%) in the click-through rate of cards when compared to simple card display rules based on telemetry cutoffs. This improvement was calculated by comparing each approach to a baseline over their respective time periods in production to control for temporal differences. The final number is the relative difference between the two statistics after controlling for the baseline.

Using the general architecture depicted in Figure 8, with simple horizontal scaling, the platform can process very large amounts of incoming telemetry data. When converted to feature sets, the production systems are handling 100k transformations per second. This is using feature windows that vary between 6 and 24 hours based on the dataset and requirements for the model. This scaling is nearly seamless if the code is written with good microservice design principles in mind, and the ease of increasing replicas for an application is handled. Kubernetes also supports elastic scaling based on certain metrics, which is useful for processing spikes or bursts in traffic.

Scale aside, researchers and ML engineers have the ability to deploy models and feature pipelines as needed. This reduces code rewrite from POC or research code to production code as the production systems support many languages, ML model types and complex pipelines. Additionally, troubleshooting and operations (MLOps) is greatly aided by Prometheus integration with thresholding from Grafana and other tools to ensure problematic components are dealt with quickly. System availability is high due to the redundant nature of Kubernetes and requiring all components have a minimum of two replicas and dual components when they lie in the critical path.

## 10. Looking Ahead

These sorts of open source platforms and architectures are simply the beginning of a sweeping change coming to not only telecommunications, but every other industry. Big telcos certainly have an advantage now, given the vast datasets being collected now or in the future. While the physical properties of components and systems are well understood, there is always room to identify new correlations in failure or impairment types. With new hardware, more optical components and higher speeds -- and the fact that connectivity is so vital to everyone -- this shift to self-identifying and self-healing networks will become more critical. While ML models are not specifically required for every problem, the collection and analysis platforms are, because the data is required to work towards more data-driven decision making. Also, in the future, the platform output itself will be fed through various anomaly detection model types to determine if system performance has deviated sufficiently to warrant human interaction. Platform failures and other behaviors can be modeled to increase self-healing, predictive scaling (as opposed to reactive) and automated root-cause analysis -- down to the specific component.

These platforms will need to adapt in the coming years, to leverage FPGA or GPU hardware to handle increasingly more complex analysis and ML workflows. Many companies are already seeing the benefits from GPU, though TPUs and other hardware will be available to further drive down these large costs.

## 11. Conclusion

Again, the core problem here is that customer service and many other applications may require ML to make a measurable impact in customer experience. As we have shown, not only were many open source technologies instrumental in building the solution, they were not the only important pieces. These systems may need to scale which will require deep dives into some of the core components that get executed many times over, and those should be optimized as much as possible. While choosing Python (the same language as is common for research) initially proved troublesome, performance has increased dramatically and new avenues to optimize these functions, such as GPU offload have come a long way.

When thinking about the model, effort is required to determine if ML is necessary at all and how it can make a positive impact on the problem. For this problem, a contextual bandits approach was chosen but that does not mean is it the correct solution for other similar problems.

By now, after reviewing the problem, solution and challenges to solving this problem at large scale, it is hoped that this information is not only helpful but the start of a change in thinking about how problems will be solved going forward into the next decade. ML is not beginning but continuing to alter many parts of our organizations and this will only accelerate. The information presented here may be somewhat specific to telco telemetry data, but in fact it can be applied to most any similar dataset.

Our customers are the core of what we do and drive us to strive to do better in terms of not only providing services but help when those services become impaired. This solution and others not only aids in our graceful and accurate handling of these, but the hope is for all of us to continue to think about these problems from the customers perspective.

# Table of Contents

## List of Figures

# 1. Introduction

From a Wi-Fi perspective, Christmas arrived in March of this year with the FCC greenlighting LPI exploit of the entirety of the 6 GHz band, to a fixed PSD of 5 dBm/MHz – and this, without the complication of implementing an AFC (Automated Frequency Controller) system to dynamically allocate EIRP vs channel masks for devices. A perhaps unappreciated corollary is that only the Wi-Fi 6 MAC and beyond are permitted to be utilized by devices contending for the 1.2 GHz worth of spectrum, which will promote much more deterministic and efficient wireless delivery metrics. AFC -- and access to additional EIRP footprint --, have been kicked down the road for the time being; in the meantime, SPs have the opportunity to pursue a glut of new bandwidth opportunity with a still-significant indoor radiation footprint.

Preliminary coverage performance of 6E (Wi-Fi 6 @ 6 GHz) reference platforms will be presented in this paper, along with recommendations on initial leverage of the spectrum which should produce better bitrate and latency coverage of a dwelling – along with plug-and-play upgrades to extant home networks which minimize user installation headaches. There is a brief section outlining opportunities for early creep-in of features formally scheduled for Wi-Fi 7 and some additional test data (unfortunately limited by transmit chain noise fidelity) hinting at the benefits of raising the PSD to 8 dBm/MHz. Finally, there is a closing section which anticipates the adoption curve for various aspects of the scheduling functions which are due to sit just above the Wi-Fi 6 MAC, along with an analysis of some of the tradeoffs which are beginning to emerge as the radio, FEM and filter vendors balance time-to-market against both MAC accessibility for tuning performance and analog circuit challenges on the RF chain front.

# 2. Testing the 6E Proposition for Home Indoor Deployment

Two particular bitrate reach propositions begged initial testing: a) how far can you space 4x4 trunk endpoints in a “typical” home setting given 5 dBm/Mhz PSD and 160 MHz of channel BW at 6 GHz?; and b) given the likely configuration of clients as 2x2 devices, what is the equivalent “throw” for bitrate coverage between a 4x4 AP and 2x2 client in such a setting? For that matter, how do these “service reach” numbers compare to 5 GHz performance (at higher PSD, lower BW and with airtime contention losses due mainly to heterogeneous MAC accesses to the same medium)?

## 2.1. Wi-Fi Test House

We were fortunate to have available a 3-level, 5000 sq ft class Wi-Fi test house and pre-production reference platforms (capable of Wi-Fi 6 operation in both the 5 and 6 GHz bands) from two vendors to provide test telemetry which we could compare to analytical expectations. The three floors of the test house floorplan are shown below:

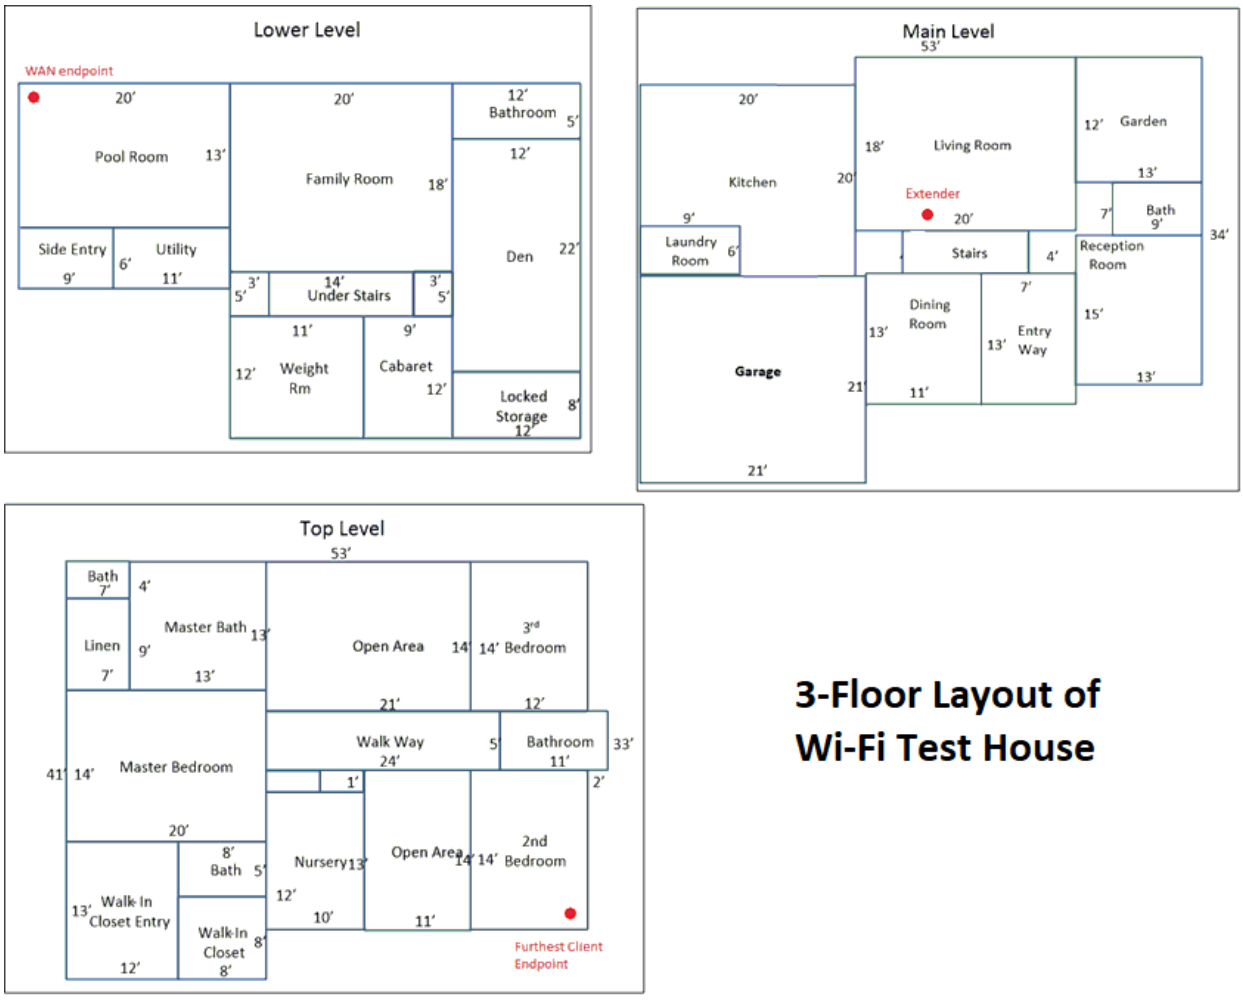

**Figure 1 - Commscope Wi-Fi house Floorplan**

Note the test endpoint placements, chosen to produce challenging pathlosses which could provide inference for more modest layouts as well (the average US home being ~ 2700 sq ft; average apartment in the vicinity of 1000 sq ft). Expectations were that proper extension of a 4x4 6E trunk from WAN insertion at the lower level pool room to approximate midpoint of the test house would allow us to paint 2x2 client TCP bitrate coverage everywhere in the home to between 1 and 2 Gbps (presuming leverage of 160 MHz channel BW and a PSD of 5 dBm/Mhz).

## 2.2. Analytical Expectations

The basis for the confidence in coverage stems from raw UDP throughput analysis. The case of 4 spatial stream leverage of varying channel BW's for a symmetric 6E link (versus accumulating path losses) is shown below:

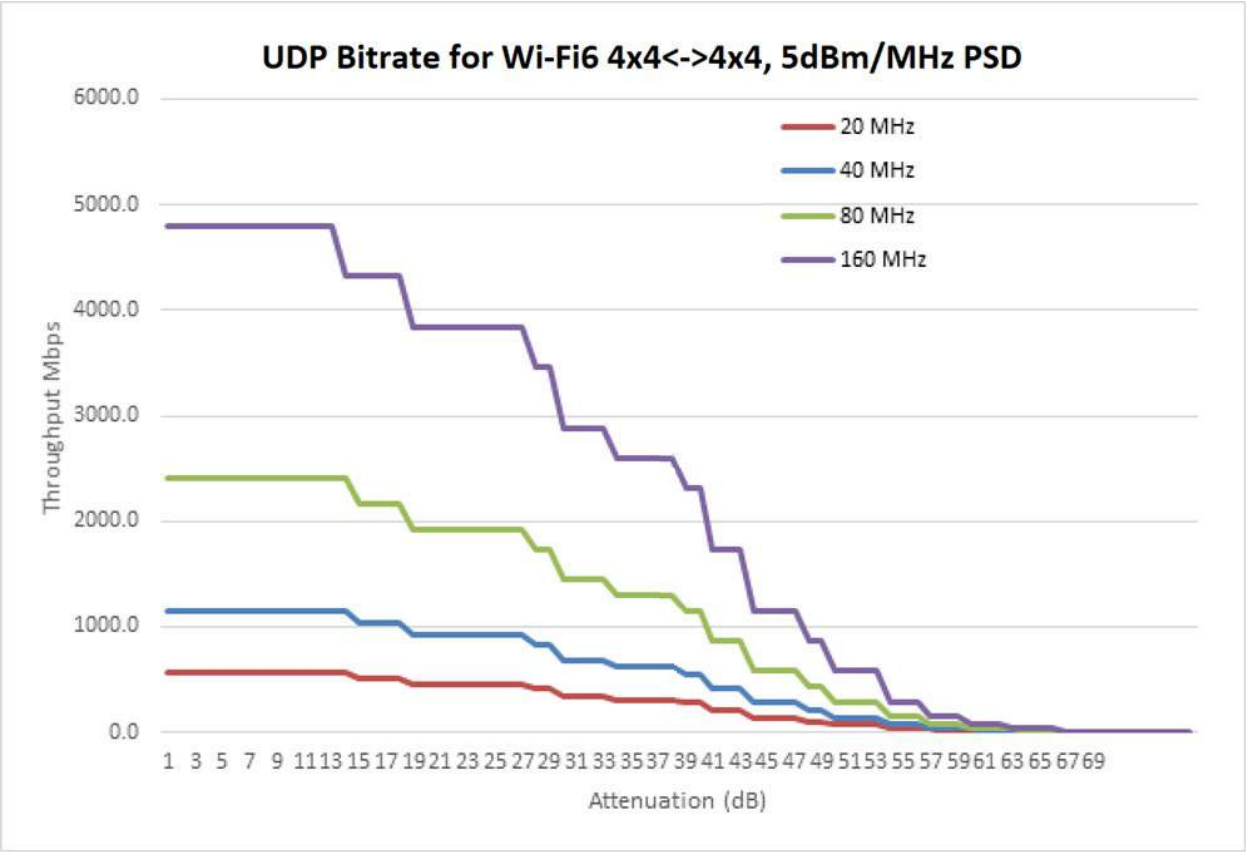

**Figure 2 - UDP Bitrate Curves @ 5 dBm/MHz**

Note that the abscissa lays out losses past 1 meter off of the antennae. It is also noteworthy that the general shape of the MCS breaks (bitrate steps) is exactly mirrored across all BW – this is due to EIRP being metered exactly as a function of occupied BW (fixed PSD). In terms of actual link performance, these UDP asymptotes will be reduced by TCP overheads (typically 10-20%, depending on packet parameters) and will also be subject to implementation losses (systemic, as analog RF chain fidelity issues – principally noise and filter shape; and circumstantial, as spatial stream compromises – polarization and element diversity losses).

With respect to asymmetrical 6E link performance, a similar UDP bitrate waterfall can be estimated for the case of a 4x4 AP linking with a 2x2 client:

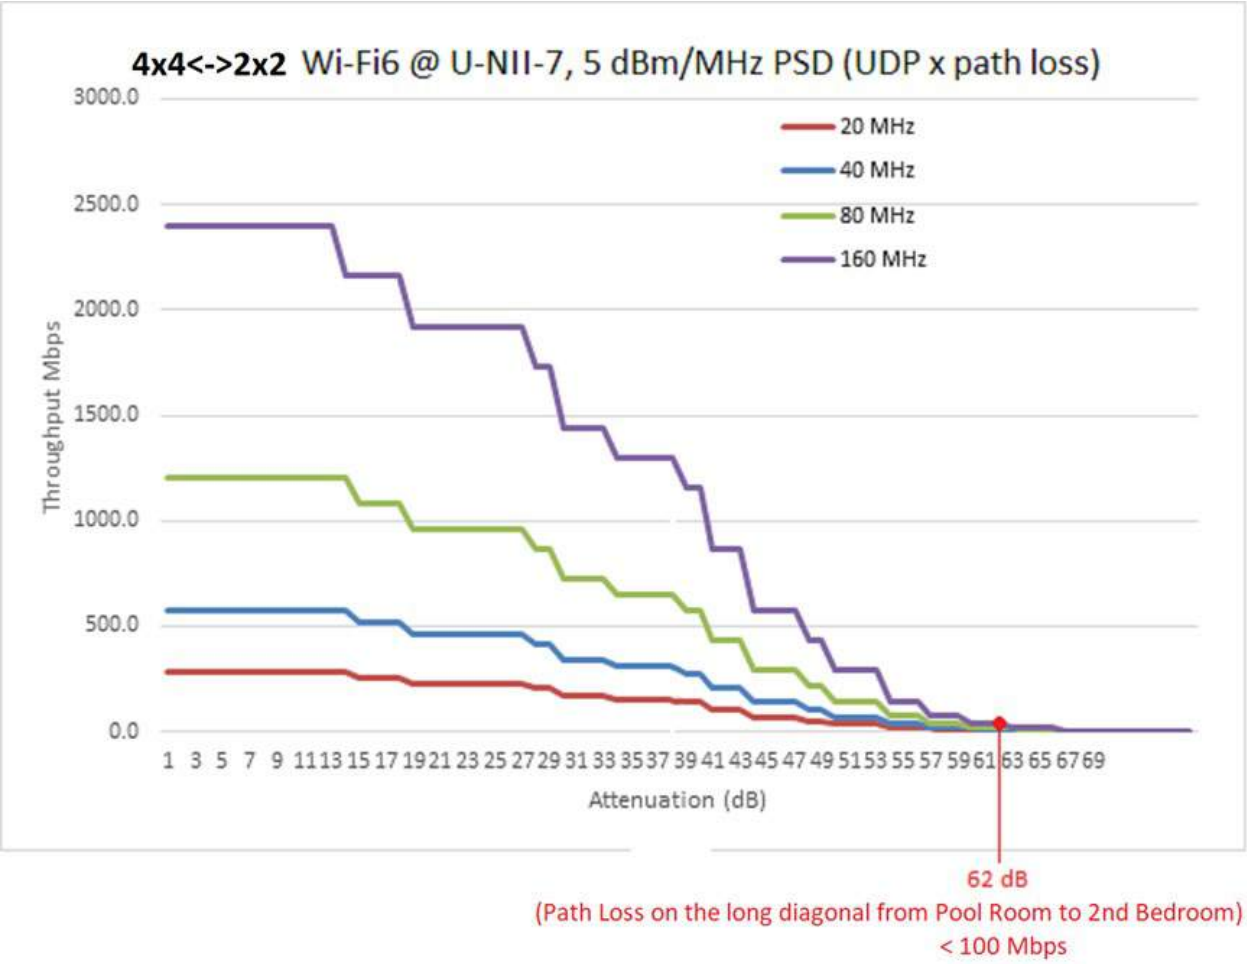

**Figure 3 - AP to Client UDP Bitrates**

Note the callout on pathloss @ 62 dB: this is the estimated LOS transit loss from the Wi-Fi house pool room up to the furthest potential client location in the upper floor 2nd bedroom. The budgetary accounting includes FSPL and multiple drywall and floor transitions ( the former measured at 4.5 dB per wall and the latter, 9 dB per floor – in the 6 GHz band).

Using this single-vector predictor for pathloss, the following heatmap for bitrate support (as 4x4 AP linking to 2x2 client at 160 MHz BW, 5dBm/MHz PSD) by room is produced:

**Figure 4 - Bitrate "heat map" for Wi-Fi house from AP in Pool Room**

The three floorplans stack one above the other, so as anecdotal experience indicates, as you move along a 3D diagonal from the WAN insertion point in the pool room lower level and progress towards the far 2nd bedroom on the top level, the predicted bitrate support "cools". The analysis suggests that the challenge of supporting > 1 Gbps in a large home from a single 6E GW device located at the WAN connection point (typically against one wall in a lower level) would not be possible. In particular, user endpoint uses in upper floor bedrooms appear underserved.

This layout challenge begs for link extension. If a spatial midpoint were chosen in the home, one would expect to be able to paint better coverage at the home extremes via reduction in the worst-case pathlosses posed. Graphically, the placement of a 6E extender at home midpoint (mid-level living room chosen for the Wi-Fi house) produces the following improved link parameters:

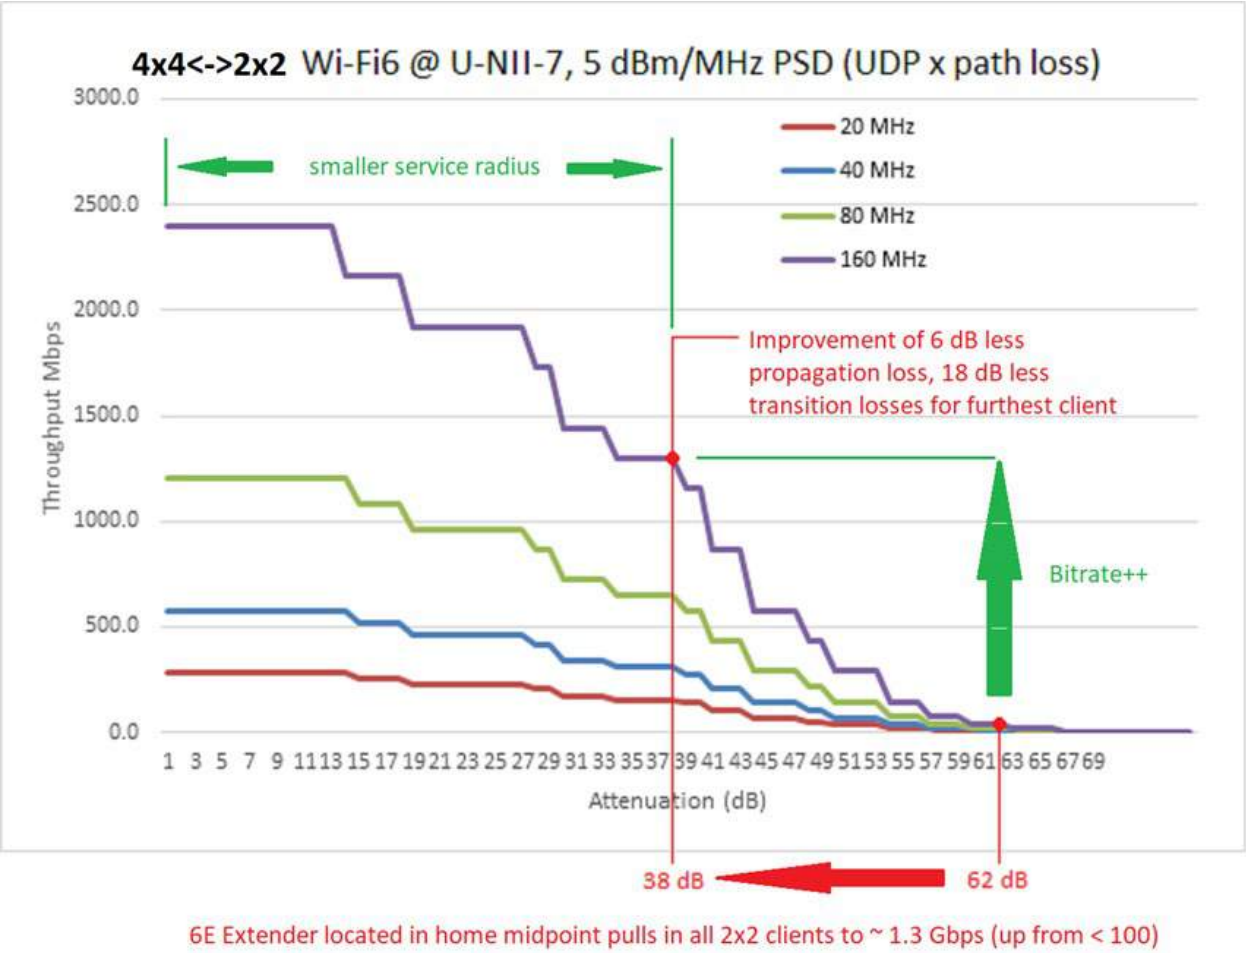

**Figure 5 - Improvement in Whole House Path Losses with Midpoint AP**

The modeling suggests we can have our > 1 Gbps large home by 6E extension at home midpoint with leverage of the 5 dBm/MHz PSD and 160 MHz channel BW. Here's what the modified heat map produces:

**Figure 6 - Wi-Fi House Bitrate Heat Map from Midpoint AP**

If the extender is multiband (a sensible enough proposition, given the foregone conclusion of legacy clients) then we can also predict coverage at 5 GHz, using a Wi-Fi 6 MAC on a 4x4 AP capable of 1W EIRP at 80 MHz BW (but restricted to 65% airtime access due to contention):

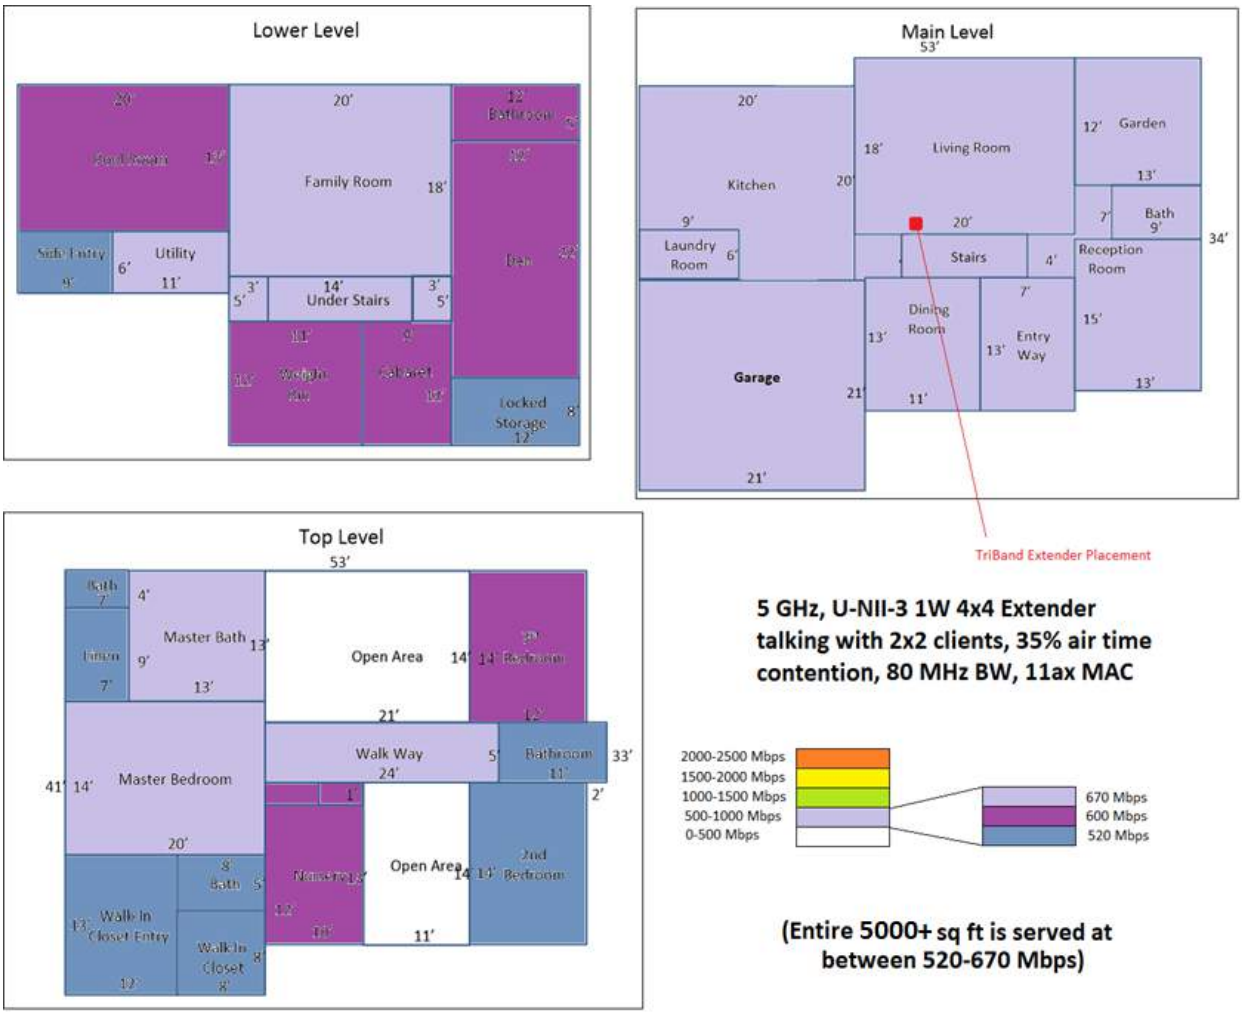

**Figure 7 - Wi-Fi House Heat Map for 5 MHz, Wi-Fi 6 from Midpoint AP**

Whole-home coverage for these clients from the extender is decent (~ ½ Gbps class) and more homogeneously distributed (due to the higher radiating power and most bitrate losses accumulating due to airtime contention). To put the impact of contention at 5 GHz (which will NOT present itself at 6 GHz due to OFDMA scheduling of a fully Wi-Fi 6 compliant, client population), note the following waterfall chart which predicts Wi-Fi 6 MAC performance in identical BW and spatial streams in the 5 and 6 GHz bands (and this, with the 5 GHz band operating at a much healthier power level):

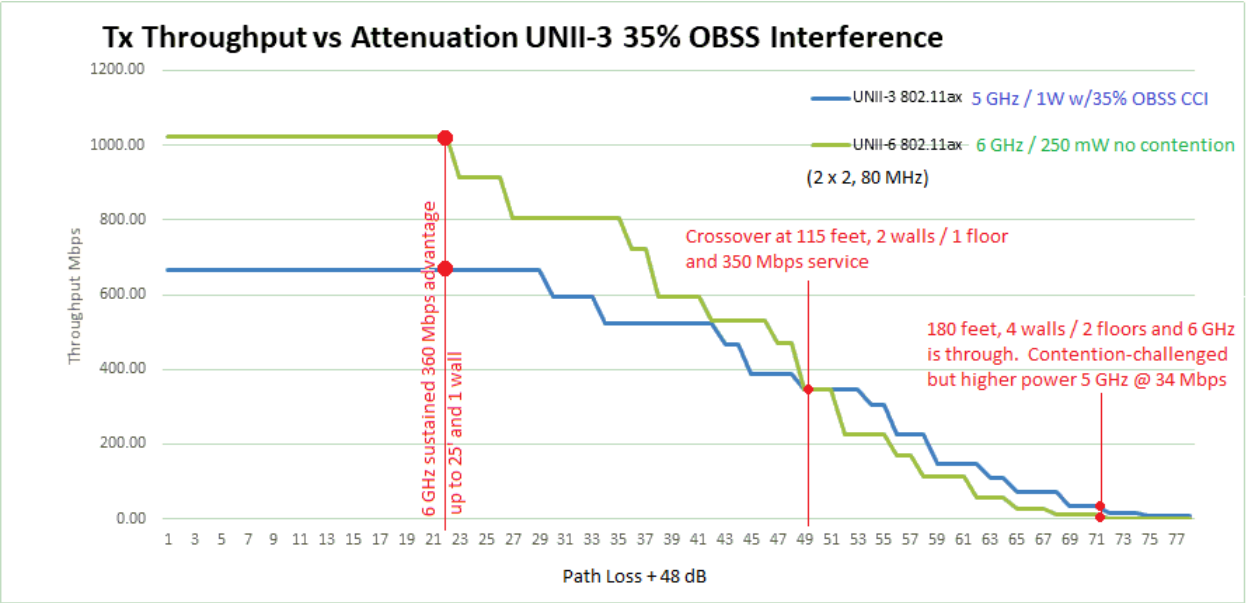

**Figure 8 - Impact of Contention at 5 GHz**

These results beg some questions on extender band profile, spatial stream assignment and RF chain management (including antennae multiplexing, perhaps) for proper future-proofing of client band and MAC migration; we will tend to that in a later section.

## 2.3. Measurements and Reconciliation

Multiple days of testing were conducted at the Wi-Fi house to vet performances of the alternate vendor candidates and tune device alignments for repeatable data-taking in the various 6E use cases. The summary results for these follows:

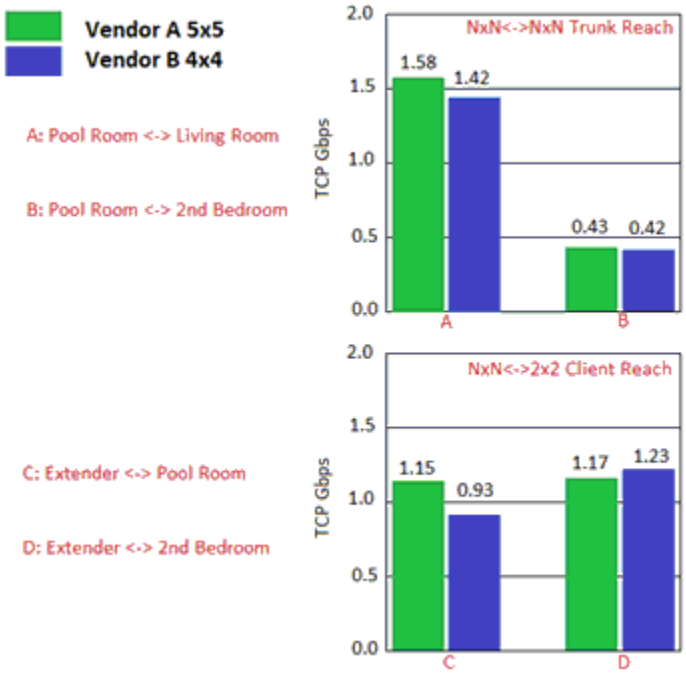

**Figure 9 - Measured Bitrates Throughout Wi-Fi House**

The key takeaways here are that: 1) a NxN < - > NxN bookended trunk link from WAN insertion point in the basement to midpoint of the home could sustain an ~ 1.5 Gbps TCP bitrate; 2) worst-case link throughput for NxN < - > NxN just cleared 400 Mbps for the long diagonal reach from WAN to 2nd bedroom client (MUCH better than the single-vector analysis predicted); and 3) 2x2 client link service from an NxN AP in the home midpoint (living room, mid-floor) was sustainable everywhere to ~ 1 Gbps. A secondary observation is that, in the client link data, the implementation loss looks quite small (< 10% off of target expectations once UDP has been discounted for TCP overhead) – but in the full trunk bookend case, where one might expect double the spatial stream efficiency to show, an average multiplier of 1.44 (instead of 2) was obtained (~ 25% implementation loss). This points to the general observation that full spatial diversity is easier to obtain in the oversampled case than when one relies on full orthogonal recovery from all antennae in an N:N setting. (Losses due to antenna element blanking, insufficient packaging diversity and polarization mismatches are harder to mask).

There was an additional lurking issue which only became more pronounced when we attempted to vet the benefit of a PSD boost from 5 dBm/MHz up to 8 dBm/MHz. Additional detail on this is captured in subsequent sections.

## 2.4. Implications for 6E Product Planning

Two new product opportunities seem to immediately exist in bringing 6E CPE to market which do not rely on simultaneous emergence of clients (the “chicken and egg” marketing conundrum when new band exploits appear). The first such opportunity would be a tri-band Wi-Fi 6 AP (2.4/5/6 GHz) as a “ready for Wi-Fi 6” play for consumers looking to upgrade or create a home wireless network. This anticipation play has as its rationale the ability to mount a Wi-Fi 6 MAC in all bands and so both continue to serve legacy clients (in whatever native MAC they utilize) and provide improved connectivity for both new multiband Wi-Fi 6 clients and specific new 6E devices as these emerge in the market. The second device

would appear to be a bridging device (Ethernet to 6E) which could be applied against several "touchless" home wireless network upgrades. Some use case examples follow.

A key marketing opportunity lies in the superior latency and contention-free performance of 6E. Not mentioned in prior sections but potentially holding the key for particular service mounts at 6 GHz is the notion that, until the rather prodigious link capacities of 160 MHz channel operation in the band are reached (and scheduling onset occurs in the AP), link latency easily outperforms that encountered in either of the 5 GHz bands or 2.4 GHz (as in: a sub-millisec asymptote – essentially the time required to rasterize the arriving data against all available RU's and dispatch it). Viewed this way, 6 GHz may be thought of as virtual wireline (which need not be pulled, obviously).

Applications particularly sensitive to latency include networked twitch games – the bulk of which are presently connected in the home wirelessly (by a factor of roughly 7:3 versus Ethernet). Moving these gaming systems (and PCs) to the low-latency 6 GHz band can be done by simply upgrading a GW AP with a 6 GHz radio (Tethered Ethernet dongle as the migratory – as in "no new AP" -- option) and doing the same for the gaming system or PC. Service reach to several hundred Mbps for even just two spatial streams seems guaranteed by our testing, regardless of where in the home lies the gaming device; and there would be no intervening alternate band/MAC backhaul to impress nondeterministic latency on the otherwise bridged link. Yes, not the cheapest solution – but as pointed out previously, no pulling of Ethernet either – and simple plug-in, "touchless" remediation of a perceived problem is always valid market rationale.

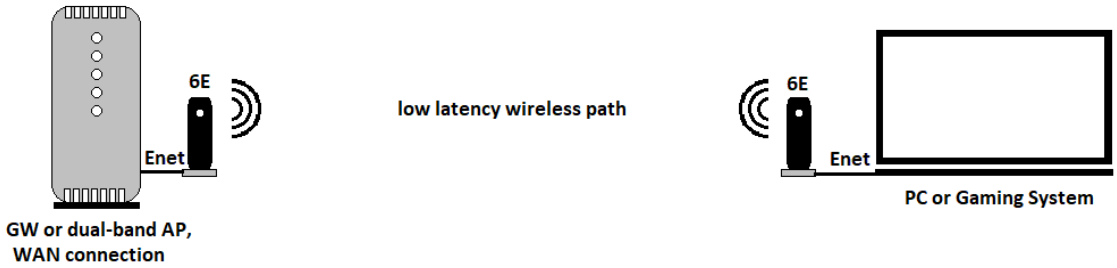

**Figure 10 - 6E Wireless Link for Gaming**

Another bookend 6E solution which need not wait on the emergence of explicit 6 GHz clients is the trunk backbone alluded to in the document's prior sections (for those cases when floorplan service footprint overwhelms a location-marginalized single GW). Using 6E to extend a virtual WAN connection to the middle of the home – on first deployment being only responsible for trunk traffic haul between endpoints and leaving the entirety of client support to the 2.4 and 5 GHz bands – would greatly improve whole home coverage and eliminate Wi-Fi dead zones by collapsing the 2.4/5 GHz service radii to all clients (thus permitting higher sustained MCS and throughput for each of the links). As the client palette shifts over time, the load balancing of the trunk could move in concert – perhaps offloading unprioritized trunk traffic to 5 GHz as replacement clients migrate to the 6 GHz band. As with the gaming latency solution, the fix could involve a simple tethered 6E radio augmentation to existing GW and extender – or in the case of a single dual-band AP serving an entire dwelling, adding what amounts to a tri-band extender (2.4/5/6 GHz) to the home midpoint and plugging in 6E capability for the original dual-band AP.

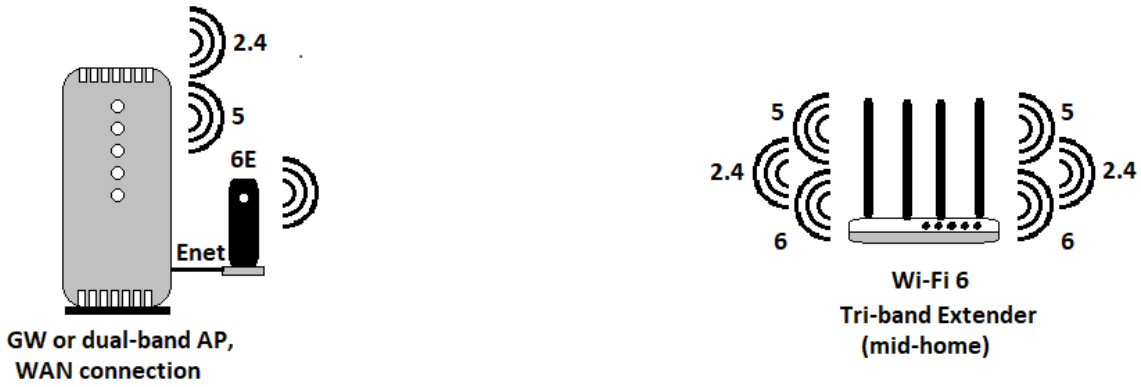

**Figure 11 - 6E Upgrade to Existing Dual-band AP at WAN**

This segues into the notion of adaptable AP resource allocation – specifically with respect to analog circuit elements and antenna farm exploits. The multiplexing options lay out nicely if one allows for broadband-matched antennae and potentially, FEMs. Different price points will determine base multiband capability, but a specific example might drive home the point. Presuming that 2.4/5 GHz FEMs can be stretched to both 2.4/5 and 2.4/6 GHz devices (the built-in diplexers bifurcating the 2.4 from the other, common, band support), we already have the BAW/SAW devices which delineate the 2.4, 5 and 6 GHz bands (so-called "coexistence filters") and so can consider our switching options. Hypothesizing an adaptable 8-chain AP leads to this, among other, possible implementations:

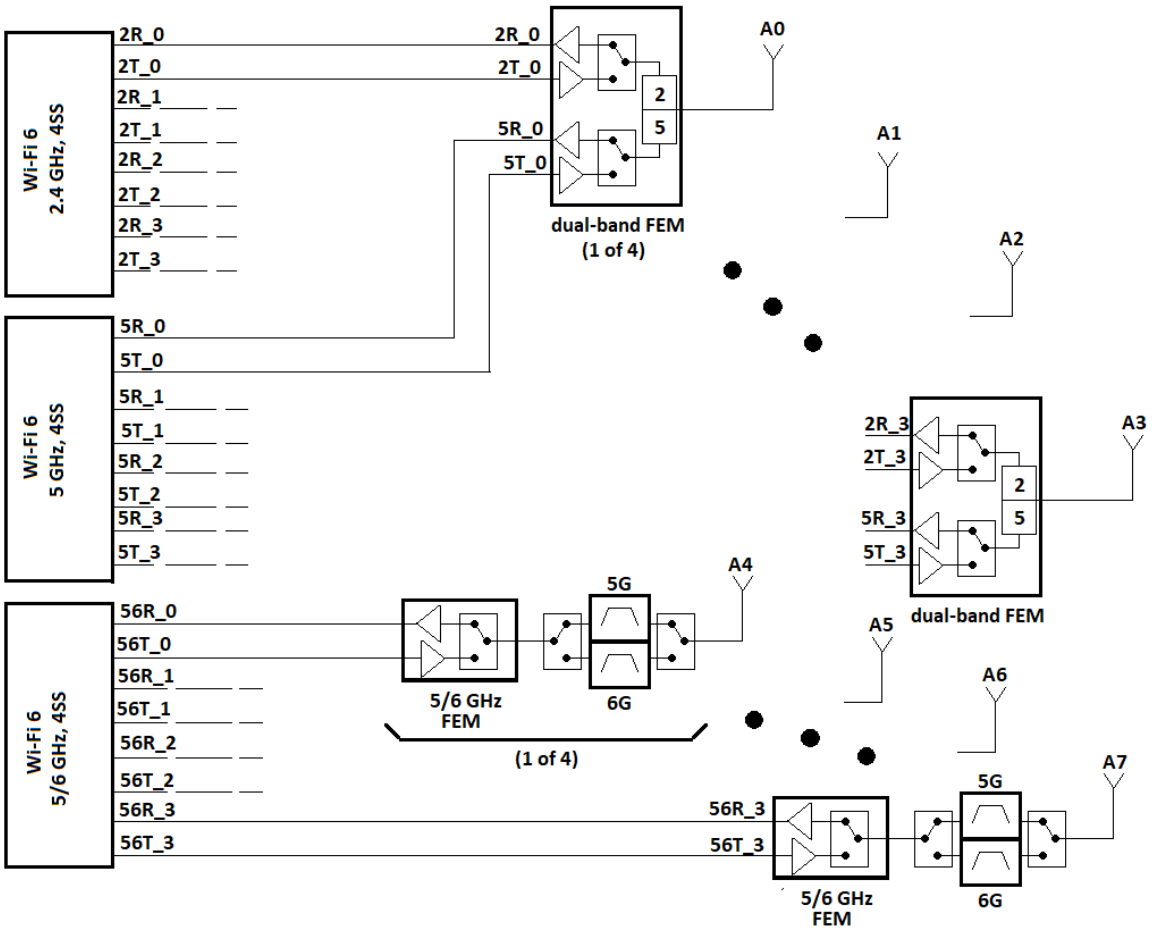

**Figure 12 - Reconfigurable Multiband AP**

This diagram describes the potential of multiband FEMs and configurable 5/6 GHz radio chips to implement an AP with reconfigurable band coverage – as might be advantageous when addressing the desire to first upgrade MAC capability in the lower bands before switching on actual 6E support for new client devices (as they come available). And while not evident in radio vendor planning at this stage, it is not inconceivable that configurable Wi-Fi 6 radios for 2.4/5/6 GHz appear some day (along with supporting infrastructure like wideband FEMs and triplexers). Clearly, every home's traffic profiles will be at least slightly different, so to the extent that band and spatial stream flexibility can be designed in, such adaptability improves market edge.

A quick sidebar is in order. As a more philosophical discussion, the exploit of the 2.4 GHz ISM band for Wi-Fi might be ripe for reconsideration given the advent of the many, unfortunately disparate, IoT radio mesh exploits which target that same spectrum (Zigbee, Thread, BLE). Coordinated exploit of the band by the many interested parties is a bit brute force and clumsy at this stage and perhaps a graceful exit (or at minimum, an explicit band-sharing FDM solution) may be the future play for 802.11. The flip side of the coin may also show forth: IoT applications normally relegated to other radio technologies may find new homes in Wi-Fi 6 narrowband assignment. To the extent that constrained end devices could host a Wi-Fi 6 stack, this bears watching.

It is important to bookmark one additional item in regards to this: the potential for early adoption of 320 MHz channels in the 6 GHz band (3 such ought to be available in North America). Assuming RF chain fidelity can match the offering, the PHY bitrate asymptote for a 2x2, 320 MHz link would be 4.8 Gbps. Adoption of this very broadband channel capability might provide sufficient rationale (and capacity insurance) to park initial 6E AP capability at 2 RF chains. This greatly simplifies the multiplexing overhead in our hypothetical early adoption 6E AP, since the 6 GHz chain connects can be fixed at 2. If we also presume that 2.4 GHz AP coverage for the whole home is adequately served by our WAN entry point location, a lower cost alternative for Wi-Fi 6 extension might take on the following form:

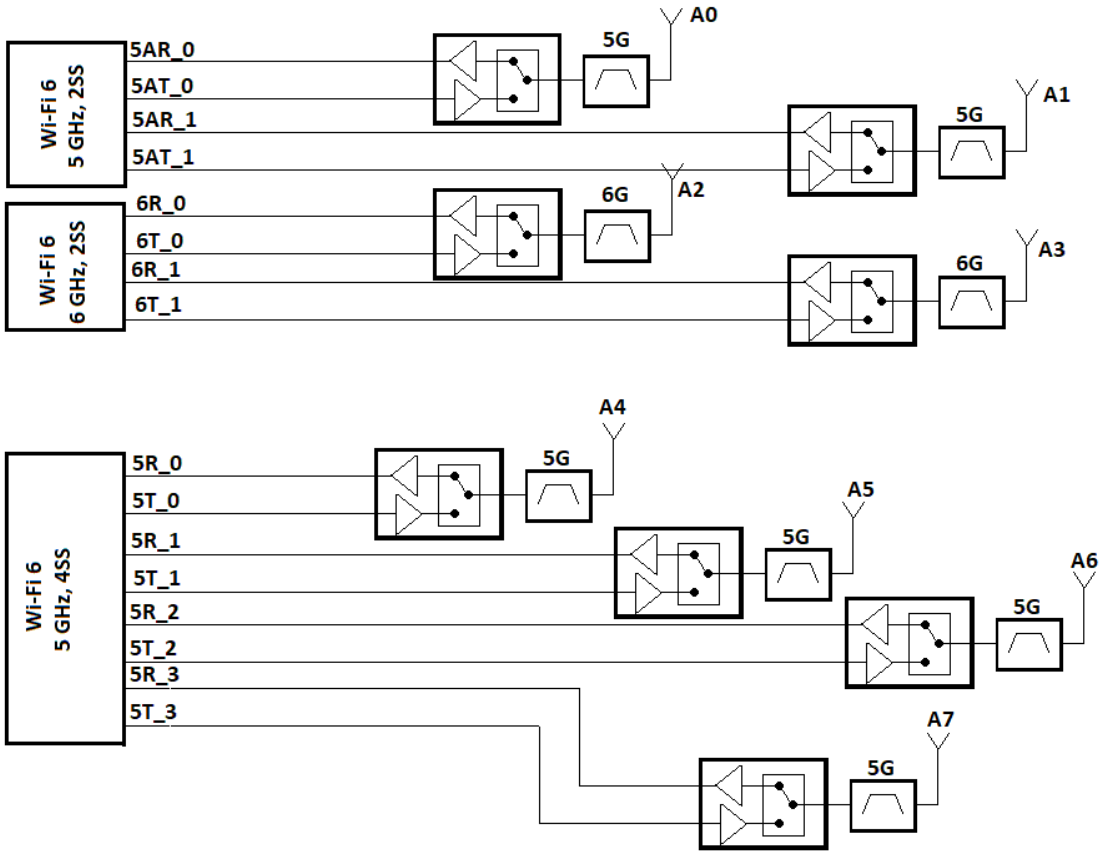

**Figure 13 - Mux-less Alternative for Midpoint AP**

Note that this type of extender commits itself only to the upper bands (assuming whole-home 2.4 GHz coverage from the WAN insertion point would be adequate) and avoids the multiplexing costs of our prior example. At issue is the degree of future-proofing offered by a 2-chain 6E (potentially 320 MHz BW) capability; if deemed adequate, this makes for a less complex and cheaper solution. The premise is that you have one, four-chain "heavy lift" capability at your choice of 5 GHz bands (for trunk hauling, say) and one lightweight assistant for proximate distance clients in that same band. The 6E capability, though spatially constrained, has a very flexible application capability (especially given the initial paucity of 6E clients and the prospect of neatly commanding all significant data exchanges from the AP itself).

At this point, it seems incumbent to also point out that the broad swath of uncontended 6 GHz BW avails itself of a notion which outlived its usefulness in the lower bands due to issues with airtime oversubscription and heterogeneous MAC accesses: the repeater. Simply put, one could mount a 6 GHz

repeater as an AP mid-home and orchestrate air time on that single 6E radio for what would function as front- and backhaul between otherwise farflung and bitrate-lean clients. Such an arrangement could be implemented in straightforward fashion with an AC-plugged "wall wart" and might represent the means by which either distant clusters of 6E clients – or a bit-hungry single 6E service mount in a detached shed or garage – gets its high bitrate and low latency connection to the home edge WAN located an appreciable distance away. Prior instantiations of the repeater function required explicit diplexing of the repeat trunk, essentially replicating air time losses on an additional channel. While merely inconvenient and problematic in the 5 GHz band, such implementation at the grossly oversubscribed 2.4 GHz band meant such attempts were all but doomed. 6E's expansive spectrum would allow many of these private "repeat" meshes to co-exist without extracting a penalty on the "main" channel.

# 3. Coming Attractions

The ink on the March FCC announcement laying out the access to a new chunk of spectrum for Wi-Fi has not even dried and there are already three areas of bitrate service growth which are garnering attention. Two of these are related to scaling features planned for Wi-Fi 7 (320 MHz channel BW and 4096-QAM) – and the other has to do with unlicensed spectrum proponents wishing to migrate to a slightly higher PSD (8 dBm/MHz vs the present 5). All of these should yield opportunities for link improvement but there is also a clear benefit hierarchy to the proportional improvements one might expect. These are covered in decreasing magnitude of impact in the following sections.

## 3.1. 320 MHz Channel Bandwidth

By far the most attractive of the features-in-waiting is the ability to accommodate 320 MHz channel BW. The scale benefit here is obvious: double the maximum bandwidth and you will potentially yield double the supported bitrate. As alluded to in a prior section, this also gives us the option of considering fewer spatial leverages for the capability, since the raw capacity of even a single stream (2.4 Gbps – at admittedly very short service throws) dwarfs performance of 4x4 Wi-Fi systems in the lower bands.

But 320 MHz brings its own challenges as well: due to achievable filter Q's and proximate band signaling, there are likely only 3 such channels available across all of the 6 GHz spectrum (and perhaps only 1 in Europe). And the very aperture of these large channels make them susceptible to rogue or OBSS interferers – which coupled to the dynamic range requirements for dense QAM constellation leverages, could make exploiting the capability a difficult proposition "in the wild" (especially with respect to forced concentrations of disparate SSIDs – as happens in MDUs. In short, it is a very worthy feature to have, but perhaps not fully leverageable in all AP deployments.

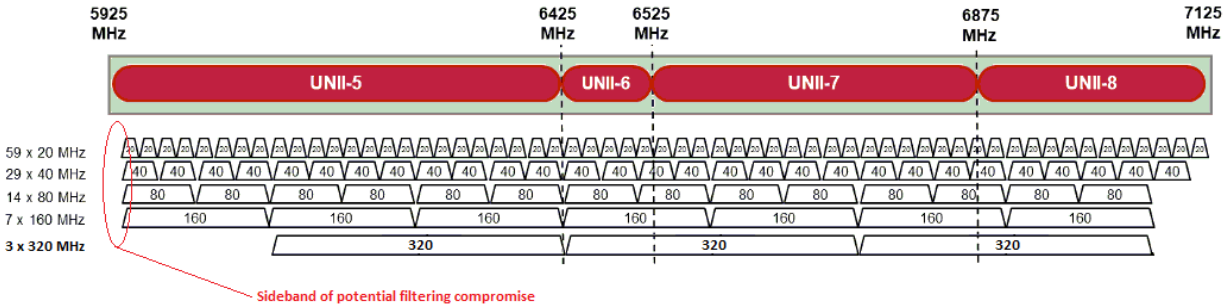

**Figure 14 - 6 GHz Wi-Fi Spectrum (with 320 MHz channels)**

### 3.2. 8 dBm/MHz PSD

We have already shown fairly decent whole home coverage at the FCC's original setting for LPI services (5 dBm/MHz). Pushing up the PSD does exactly what the bitrate waterfall curves suggest: you potentially can establish a link MCS higher by a step (or two) and reap the scaled bitrate benefit for doing so. The following 5 dBm/MHz chart (for 4x4 6E) indicates potential benefit (at 160 MHz BW) at one particular path loss operating point:

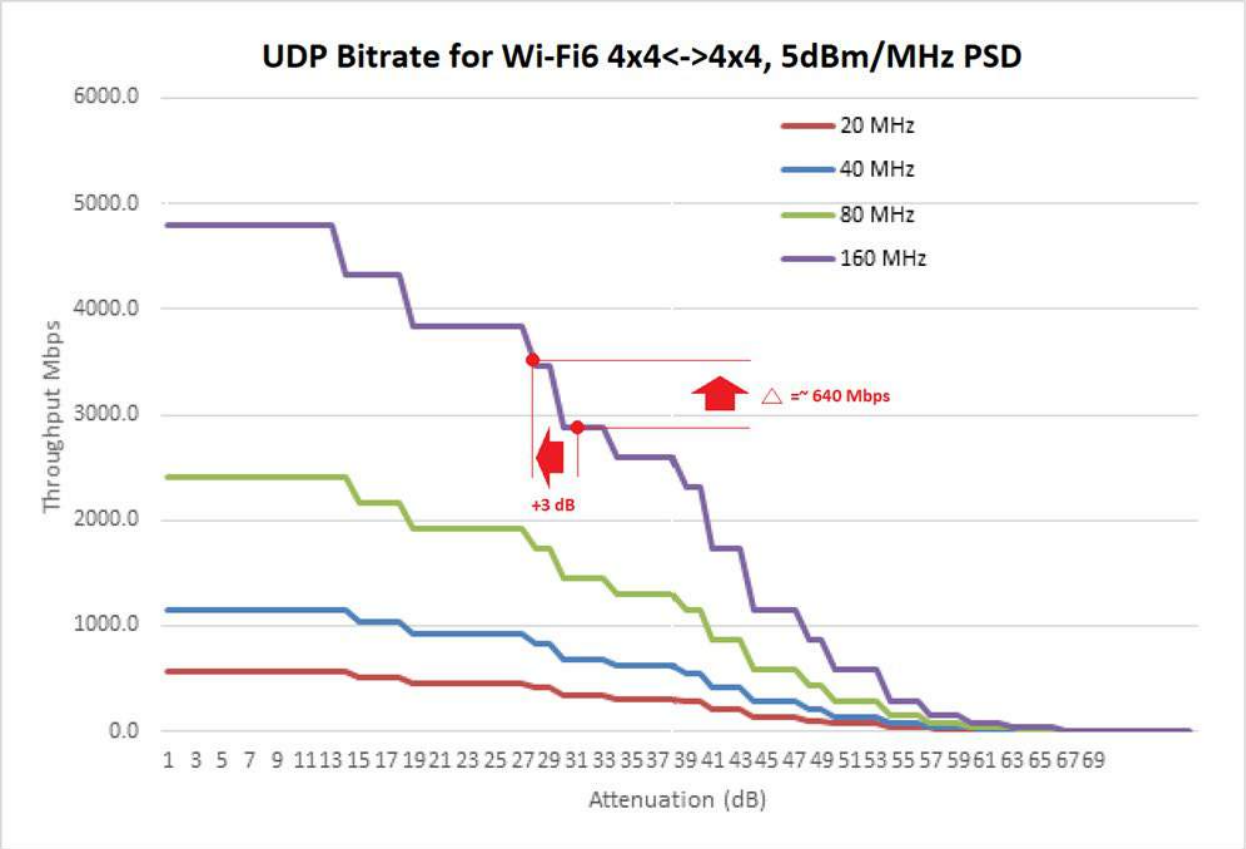

**Figure 15 - Effect of Increasing PSD to 8 dBm/MHz**

If we then take our original heat map and recalculate the room-by-room reach at 8 dBm/MHz, we get the following comparative results (5 dBm/MHz on the left and 8 dBm/MHz on the right):

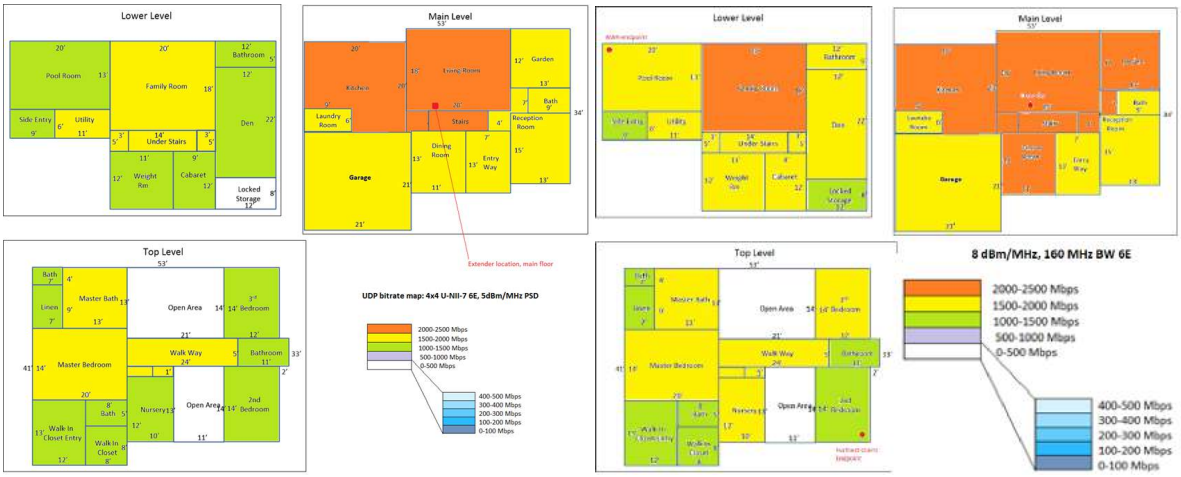

**Figure 16 - Comparitive Reach to Clients from Mid-Home AP @ 5, 8 dBm/MHz**

Note the expanded reaches for the 2 Gbps+ and 1.5 Gbps+ regions for the higher PSD setting.

An attempt was made to test this analytical promise but the effort required upgaining antennae on a vendor-suppliied reference platform (the standard 2 dBi elements and RF PA chain maxed out at an EIRP of 27 dBm, 3 shy of that necessary to validate 8 dBm/MHz at 160 MHz BW). Since we wanted to explore max impact (as opposed to doing a scaled test at lower BW), the decision was made to upgain the antennae elements to buy the necessary EIRP. The exercise produced mixed results, however. As it happened, receiver-commanded power back-offs at any path loss much less than full span of the Wi-Fi house meant the transmit side could not reach the desired EIRP. The fundamental culprit appeared to be PA fidelity (excessive noise); for the lone case where we could validate the bitrate improvement, the benefit for the 3 dB extra PSD showed as ~ 32%:

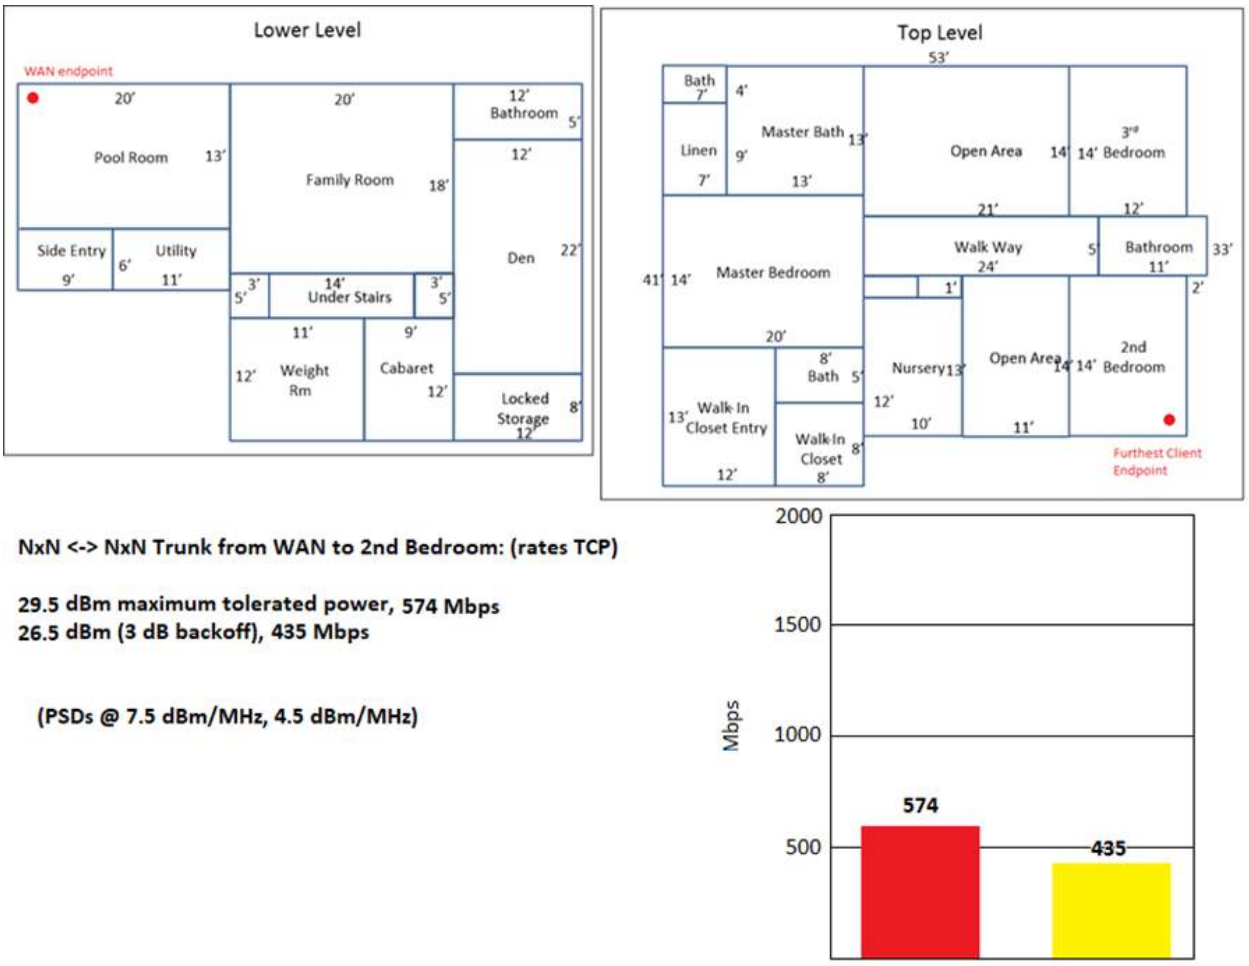

**Figure 17 - Measured Bitrate Improvement at 8 dBm/MHz (vs 5)**

### 3.3. 4096-QAM

Ranking last in terms of desirable upticks to signaling bitrate is 4096-QAM – not that such spectral efficiency is not laudable but that, relative to 1024-QAM, it places extreme implementation pressures on the analog circuit goodness of hosting implementations for perhaps not a great operational reward (in terms of signal throw). The fundamental benefit boils down to a 20% improved spectral efficiency given the raw symbol length of 12 bits versus 1024's 10. You might react with "Hey, gain is gain – so why not?"

But the rub is that, to deliver such a dense constellation, the link needs to stand up an SNR which approaches 40 dB. If you attempt to do that for a 160 MHz channel, the napkin math is striking: only signals above ~ -50 dBm need apply. This pretty much reserves the use of 4096-QAM to same-room-only (relative to the AP) and multi-spatial stream implementations -- and even at that, clock phase noise and transmitter chain fidelity need to be pristine (so as not to pre-emptively rob SNR and reduce the already constrained service radius). The spectrum efficiency is remarkable (9 bps/Hz for ¾ rate coding) – but the exploit aperture makes this feature a bit of a unicorn.

# 4. 6E Air Time Considerations

The Wi-Fi 6 MAC contains five particularly noteworthy framing aspects (Trigger Frames, Block Acks, Buffer Status polling, TWT and MU-OFDMA) which streamline wireless community accesses to the medium. Applied to a wide channel BW, these AP-managed on-air exchanges can mimic data arrival heuristics to an impressive bitrate threshold before queueing techniques (as for differential service data priorities) need be invoked and introduce something other than simple dispatch latencies to the delivery time for the packets involved. Air time access in general will move between variable-width data exchange windows (scaled via the amount of data to be moved in order to empty buffers) and framed exchanges whose duration defines a maximum performance latency target for prioritized traffic. In all cases, there is algorithmic art performed which seeks to exploit the rectangular capacity posed by RU's x frame time. And all this need be exhausted before resort of a second AP radio (channel) to overlay an FDM option to the proceedings should be considered to alleviate single channel exhaustion.

The general scheduling opportunity in Wi-Fi 6 decomposes along two fronts: the scheme for mapping RU's in the OFDMA matrix to fit the AP's client demands and the fairness doctrine applied to whatever queueing scheme is adopted to stage data for dispatch.

## 4.1. AP Framing

A high-altitude summary of the framing structure for 6E communications – which is commanded exclusively by the AP, is in order. Essentially, Trigger Frames are used by the AP to coordinate single user, multi-user and upstream PDUs on the channel in question. The ability to coordinate multi-user exchanges via OFDMA mapping is also critical to the higher efficiencies in Wi-Fi 6, since simultaneous access to the channel can be synchronized across all clients. (Mu-MIMO offers another exploitable axis – spatial diversity -- but though this is specified, Wi-Fi MAC implementations to date have eschewed this as overwrought).

In addition to the data transfers, status details and general housekeeping can be coordinated through triggered responses for the multi-user environment as well. Simple Block Acks to close out TCP requirements fall into this category. In addition, by soliciting Buffer Status Reports from clients, the AP has access to a key metric for determining scheduled queue servicing priorities based upon its knowledge of its own queues, all the client queues and target scavenging bitrates represented by the applied MCS @ RU profile assigned to each particular client. With this knowledge, any of the proportionately fair (PF) scheduling algorithms (M-LWDF or EXP-PF -- common to LTE and WiMAX OFDMA networks) may be employed to serve clients should brute-force FIFO rasterization of the outbound (or inbound) data start to produce framed exchanges that approach the maximum targeted frame size for the given channel bandwidth (scheduler onset). A reasonable bound for this might be something on the order of 5 msec or so.

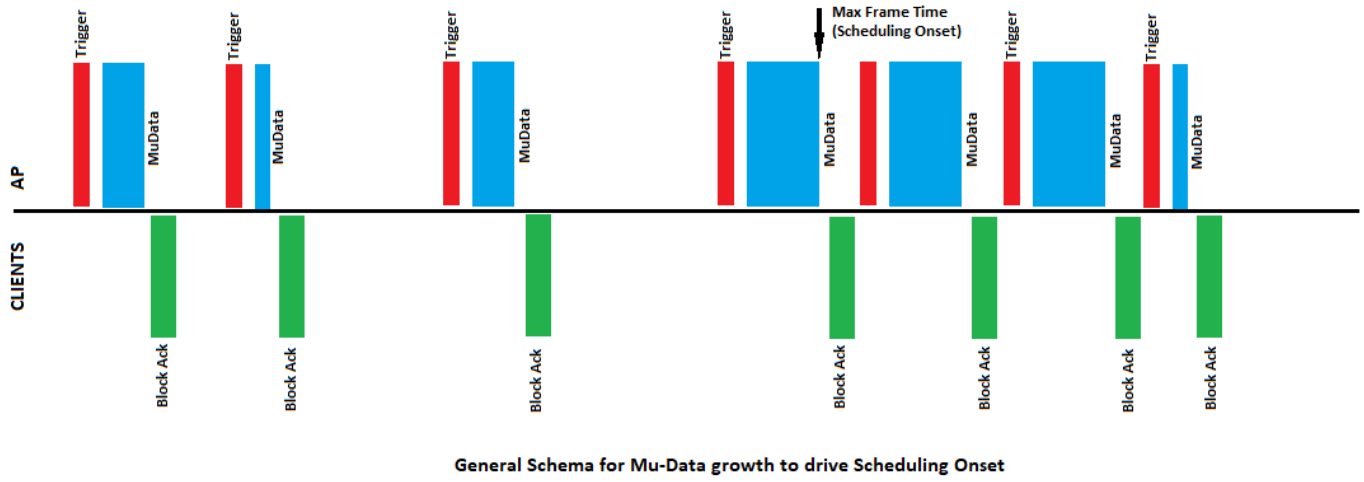

**Figure 18 - Mu-PPDU Behavior at Scheduling Onset**

## 4.2. The Single Radio Extender (Repeater) Dynamic

In one of our analytical cases, we describe the deployment of an extender AP to provide a mid-home anchor point to virtually extend the home WAN attachment to a more convenient radiating point for balanced support of 6E clients. This scenario does introduce an air time complexity for the trunk link, summarized by the realization that the single channel capacity calculation necessarily involves both the 4x4 hauling trunk and multiple 2x2 client links. Both of these capacities impinge on the single channel air time, with clients attached to the extender essentially consuming two blocks of air time (to/from the midpoint, with repeated to/from the WAN endpoint for backhaul/fronthaul) and with clients associated with the WAN side only accounting for single transfers each. The air time hit is not necessarily double for the extender clients, however, since the trunk capacity is defined by 4 spatial streams @ the MCS for the trunk and the client impact is essentially 2 spatial streams at a different extender/client link MCS (might be higher or lower than the trunk MCS and depends on client distance from the extender). The key is that the higher the sustained MCS to the clients can be made, the less demand on airtime to service them; and the overriding goal is air time efficiency (clients / frame).

## 4.3. The Rectangular Mapping Challenge

Because LTE and WiMAX have already tilted these windmills, there is a glut of prior art describing different schemes for assigning RU's to client service needs in very demanding capacity scenarios (typical client counts going into the hundreds). (Refer to the reference section.) Such is not likely to materialize for 6E home networks for the forseeable future and there is value in simplifying some of the more elaborate schemes from those mobile networks to suit the more limited scale of home meshes (to cost benefit, or marginalization of firmware complexity). To put it more bluntly, SU data packaging – even if concatenated for several (few) users, looks to be the dominant initial scheduling tactic for 6E's emergence. This involves simply rasterizing the outbound data over full exploit of the channel BW available (as RU's) until buffer exhaustion – and repeating the behavior for other clients when such data intermittently arrives. Multiple simultaneous browser sessions describe this type of scenario.

However, once streaming applications get mounted (especially in tandem), MU data dispatch dominates and actual stepped rectangular fitment begins to be necessary. In broad strokes, data bound for dispatch to multiple clients can be represented as a strip of symbols – such symbols he result of the achievable MCS on its own link. This strip, taken as a rectangle of area 1, can be applied in raster fashion across

whatever span of RU's is considered fair. In those other networks, there can be many clients, each with different rectangular blocks to move – so the technique is to triage the blocks, from largest to smallest, and fit them in a fixed size frame (symbol times x RU's) so that a minimal number of gapped or unused RU's occurs. (The problem is NP-complete, so a perfect or even optimum footprint is never guaranteed, but comparative performances can at least be evaluated for "consistent fit excellence"). Note that the problem is usually bound by a maximum RU assignment limit per client.

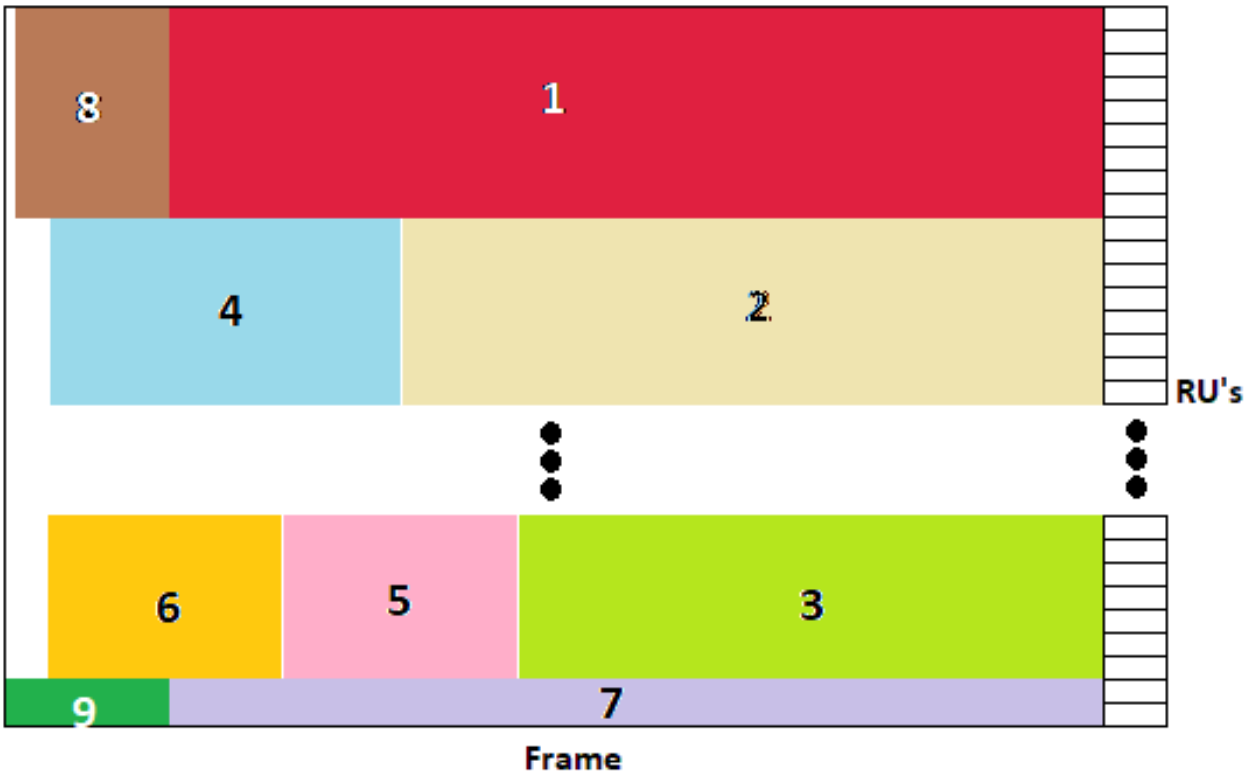

**Figure 19 - Fixed Frame Mapping via Progressive Largest Area**

In home 6E networks, the lower overlaid client count makes this more of a factorization problem. If you presume you are going to burst to perhaps 4 simultaneous clients, each of a different block size, you will likely want to rank-order the blocks with the area as a weighting factor. The sum of these weighting factors should map into the RU-span (BW) of the channel in question. By taking the area weights to assign the available RU's, you essentially get the 4 rasterized areas to be roughly the same lengh – which minimizes lost transmit opportunity and packs the burst as tightly as can be done. (Note that RU minimum grouping size will distort this somewhat.)

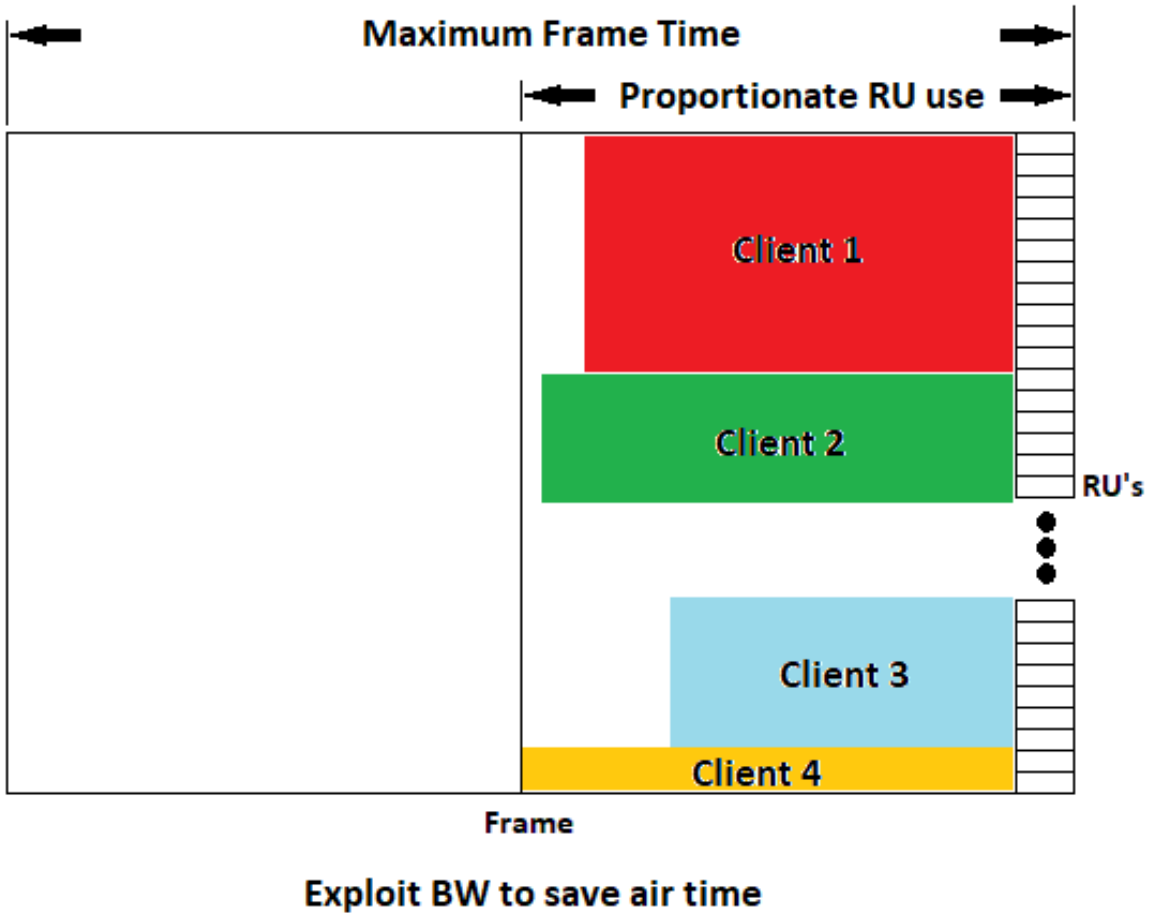

**Figure 20 - Home 6E Network Proportionally Fair Mapping of Mu Data**

## 4.4. Queues, Priority and Fairness

It is becoming painfully evident that radio vendors will be reserving details of the rectangular mapping algorithm – along with frame sizing – for themselves to implement, leaving little tuning capability for users aside from QoS designation. The number of QoS levels will define the number of queues allowed (plus at least one shunt lane for pre-emptive priority – TWT -- or retransmissions). In LTE space, a typical algorithmic first resort is a move to two queues: "real-time" and "non-real-time" to be able to express a priority for traffic where latency and jitter are less tolerated (typically media streams). This simple bifurcation usually sees a reservation for somewhere between half and three-quarters of the link capacity for real-time consideration, with the balance (and the unused reserved) available for non-real-time traffic. This is likely to find its way into 6E networks – and stacks on top of the rectangular filling exercise above in the following way: instead of just one queue sourcing the blocks of data to be transferred, there are two or more (all but the last with a reserved area). The fitment problem is simply stepwise executed on successive priorities. First, all the top priority blocks get mapped against that reserved area, from largest area to smallest. If space is left over after priority traffic exhaustion, this is reclaimed for priority 2 (plus its own reserve). Priority 2 is mapped in similar fashion and whatever residual is left is used to accommodate the last priority. This exercise is truncated if the maximum framing area is reached before buffer exhaustion. In all cases, buffers are appropriately FIFO-shuffled (and the next frame is queued).

## 5. Conclusion

Wi-Fi's gifted new spectrum – with a MAC ante which sheds 20 years of multi-epoch, stacked and somewhat organic growth, is a shot of adrenaline for wireless indoor networks. The healthy LPI EIRP footprint of 5 dBm/MHz (without the complexity of seeking AFC database permissions and perhaps with more level yet to come) looks to provide Gbps+ coverage and low-millisec signaling latency to even large floorplan American homes. Additional coverage insurance may come by way of additional channel BW in the not-too-distant future. With the Covid-19 pressures to WAN infrastructure apparently driving a new technology tranche there, the opportunity to craft even more demanding wireless home applications stand to be vastly improved. Certainly, media-infused experiences which immerse the user will be easier to mount – and with a much more robust signaling conduit to support IoT devices, expectations for next-generation remote applications – particularly security, telemedicine and aging-in- place, go up as well.

Eventually, there will be enough client demand that scheduled air time at 6 GHz will become a necessity – but this eventuality may still be several years away, given the multiple Gbps of capacity represented by diverse spatial exploit of the channel BWs involved. In the interim, lessons from OFDMA scheduling of LTE and WiMAX systems (802.16e) – which have been around for over 10 years -- may find themselves represented in 6E networks. The deferred onset of need for efficient scheduling algorithms means relatively boilerplate commutating exercises (weighted round robin) with perhaps only a single premium queueing structure (two total queues) might provide all the fair access consideration required for early generation 6E home network scheduling agents.

# 1. Introduction

The industry's latest technology displacement comes in the form of new system architectures. Shifting service provider networks from analog optics to pure digital optics creates a distributed access architecture (DAA). The fiber network now known as a converged interconnect network (CIN) allows for many advantages for future features and performance.

These advantages include features like low-latency functionality for gaming and Mobile (5G) backhaul, better performance to optimize DOCSIS 3.1 for more capacity/speed, and software features for operational simplicity and support.

High speed access via cable or telco has been a long battle that benefits the consumer in the end in the form of competition for better services and/or pricing. The cable industry has re-invented itself many times over with DOCSIS now with version 3.1 deployed and D4.0 on the horizon. We can easily offer > 1 Gbps DS and potentially 100 Mbps or higher US speeds.

The latest "trick up their sleeves" is a new architecture to exploit this even further. By displacing the modulation/demodulation functionality (the physical layer - PHY) remotely, cable operators can offer better reliability, higher quality and in essence, higher speeds.

So, the question, "why R-PHY or DAA in General", will be addressed to provide answers to questions the attendees may not have even known to ask. We look at Remote PHY technology and implementation concerns for CMTS platforms along with benefits of DAA. A new phase is occurring now for outside plant upgrades that convert analog optics to digital optics. There are lessons learned and best practices to make this transition easier, less cumbersome with less customer-generated support cases.

# 2. Background

Current remote phy devices (RPD) come in node module or shelf designs and support the DOCSIS 3.1 spectrum requirements. The downstream (DS) upper bandedge is 1.218 GHz with an upstream (US) upper bandedge of 204 MHz. The DS lower bandedge will be dictated by the diplex filter and could be hardware or software controlled. Typical US/DS splits will be 42/54, 85/105 (this may actually be 102 to satisfy legacy out-of-band (OOB) settop box DS signaling around 104 MHz), and 204/258 MHz.

DOCSIS 4.0 full duplex (FDX) allows the spectrum band between 108 and 684 MHz to have US and DS overlap, but only for non-primary DS OFDM with US OFDMA signals. D4.0 frequency domain division (FDD), previously known as Extended Spectrum DOCSIS (ESD), is associated with a DS bandedge extension to 1.8 GHz. This also increases US to 684 MHz with an 834 MHz DS start. The US options come in 96 MHz blocks from the D3.1 204 MHz bandedge, but recently one block edge was removed from the specification; 588 MHz.

The physical layer devices (RF signals) from the CMTS will be remotely located from the headend (HE) to the field, whether in a node or some type of shelf design. Also, the fiber will be converted from analog to digital causing all HE signals needing to be created at the remote location. These devices must now generate multiple simultaneous DS signals such as:

- CW carriers for:
  - Leakage test signals for Arcom, Effigis, Comsonics, and Trilithic/Viavi typically at 138 MHz and 612 MHz. Four total carriers where most vendors use two. Trilithic may use three.
  - AGC pilots and alignment tones. Ability for placement on the visual carrier frequency and levels ~6 dB > SC-QAMs.
- DOCSIS SC-QAMs (1.1, 2.0, 3.0) & D3.1 OFDM (multiple 192 MHz blocks)
- MPEG and DVB video
  - Out-of-band (OOB) signaling for legacy STB; 55-1 = Motorola; 55-2 = SA/Cisco

Upstream signals must now be demodulated in this remote location and the US RF spectrum remotely viewed in some fashion. RPDs and D3.1 CMs on the market today support:

- 8 SC-QAMs (ATDMA/TDMA)
- 2 OFDMA 96 MHz blocks

## 3. Deployment Scenarios

Figure 1 below depicts a typical legacy analog deployment for hybrid fiber/coax (HFC) networks. I-CCAP stands for integrated converged cable access platform where all the RF signals are integrated in the CMTS. Converged means the CMTS can provide DOCSIS and MPEG-2 video signals providing much more savings in the reduction or elimination of video edge-qams.

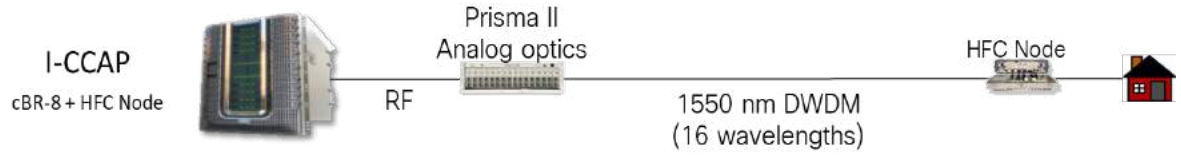

**Figure 1 - Typical Analog Deployment**

Figure 2 below represents the conversion of a legacy analog HFC plant into a distributed access architecture (DAA) and specifically converting the analog optics into pure digital optics.

**Figure 2 - Digital Fiber (DAA) Node Deployment**

Figure 3 below shows another scenario where a DAA can be implemented. This could be a hub site consolidation or even a small HE merged into an existing bigger HE. Digital optics affords us the distance and performance advantages to do this. This scenario shows a hybrid approach where analog HFC is still present, but an entire hub or HE has been eliminated and replaced with signals generated farther away.

**Figure 3 - DAA Shelf Deployment**

A fourth idea would be RF port or service group (SG) expansion in the HE. If a current CMTS chassis has 56 DS RF connectors, that in essence is 56 SGs. If a node split or addition is planned, then adding an entire new CMTS is tough to justify, more rack space, power, cost, HVAC, etc. Another option could be to covert one of the RF cards to a digital card and attach via fiber to a few RPD shelves creating more SGs and RF connectors.

## 4. Remote PHY High Level Benefits

There are many benefits to migrating to digital fiber, but we'll start with some high-level ones first.

R-PHY solves power and real estate problems associated with scale and growth. We can scale out vs scaling up. R-PHY moves spectrum creation from the hub to a node and turns a node into mini-hub. Spectrum represents 100% of services delivered and now this spectrum allocation is targeted closer to the customers. All RF coax, combining and splitting is replaced with fiber, switching and routing.

R-PHY changes HFC from analog fiber to digital fiber and into a 10/100 Gbps Ethernet. The CCAP core can move out of a hub to the headend and turn the hub into an Ethernet switching complex and/or allow hub site consolidation. This enables sharing of commercial and residential plants and provides lower power per SG in the hub. The plant can now become a full- service IP network with simpler fiber design rules and lower plant maintenance costs.

Digital optics also have lower optics costs (10G), more SGs per wavelength and more wavelengths per fiber; 40 vs 16 for analog.

All the core assets such as Video, CMTS, EQAM can be virtualized and allows a cloud-native networking approach and true virtualization.

## 5. Digital Optics Benefits

There are a plethora of specific digital fiber benefits and the focus of this presentation and paper.

Analog fiber is typically referred to as the "Achilles' Heel" of HFC. Link distance (budget) dictates the optical link performance and usually the entire end-to-end performance. Digital fiber provides much better modulation error ratio (MER), which in turn allows higher D3.1 modulation schemes to be applied with higher speeds.

One of the biggest pitfalls of analog fiber is overdriving the laser also known as clipping. US laser clipping is one fallout of this and well known because of the nature of US noise funneling and ingress in the lower spectrum. DS laser clipping is also a concern when we start adding

more channels, more D3.1 OFDM spectrum, emergency alert system (EAS) kicks in, and ingress as well. When we convert to digital fiber, all this concern goes away. There is no laser clipping! Granted, we still need to be aware of analog to digital (A/D) compression, but it's much less systematic than analog laser clipping.

One of the driving forces for capacity is the US and the limited spectrum (typically 42 MHz in North America) we have to allocate for DOCSIS channels. D3.1 supports a 204 MHz upper US bandedge and many systems are looking at this. With the level of US laser clipping we get with 42, 65, or 85 MHz systems, 204 MHz could be a non-starter. Supporting an US of 204 MHz and higher will most likely require digital fiber, in one form or another.

Another great benefit of digital fiber is much longer distances are supported. DOCSIS originally stated .8 msec of delay, which equates to ~100 miles (160 km) of fiber from CMTS to CM. This is possible with EDFA optical amplification, but at the expense of more delay and a performance hit. D3.1 actually dropped the delay to .4 msec or 50 miles end-to-end since almost 99% of fiber nodes are within that realistic distance. Digital fiber transmissions do not degrade in performance like analog (intensity modulated light). It is in essence on/off; 1/0. It's much easier to regenerate a 1! These signals are sent in time vs frequency. More capacity for analog means more spectrum. More capacity for digital means more time/faster links. It's not unfathomable to envision digital links across the country and networks evolving into data/server farms centrally located and feeding remote phy devices across the country thousands of kilometers away. This helps consolidate real estate (hubs).

Another very big advantage/benefit that is often overlooked is cost per wavelength. Digital fiber allows dense wavelength division multiplexing (DWDM) of 40 wavelengths vs only 16 for analog.

**Note**: This all assumes analog video is retired or some type of overlay is used, which isn't optimum either. Also, US RF testing and spectrum analysis are now required at the RPD, so any test equipment in the HE that requires RF input will be obsolete unless upgraded.

## 6. Power and Space Savings

A huge benefit of a converged platform along with digital fiber is power and space savings. Converging DOCIS with video delivery through the same chassis can save lots of power and rack space from video e-qam removal. Removing analog video and migrating to digital fiber eliminates the analog optic transport saving power and rack space as well. Coax goes away, RF combining, and splitting is removed, but optical splitting/combining needs to happen. Some rack space saved is needed now for switches, routers, and possibly timing servers.

Typically, two 13 RU CMTS chassis can be collapsed into one chassis. Less CMTSs = less:

- Power
- HVAC
- Rack space

Below is a Cisco command to view power requirements for different components.

- `cmts#show environment power`
  `==============================`

```
R0          FRU Power      709 W
2           FRU Power      390 W   <<< Regular RF linecard with RF PIC
9           FRU Power      150 W   <<< RPHY specific linecard
9/1         FRU Power       18 W   <<< DPIC with 8 SFP+ (SR)
```

The linecard in slot 2 is a regular integrated linecard that provides 8 DS RF connectors for 8 SGs and uses 390 W. The linecard in slot 9 has the US and DS phy modules removed to support remote-phy and lists 150 W. The RF physical interface card (PIC) must be exchanged with a digital PIC which could have up to 8 optical transceivers. That PIC adds 18 W for a total savings of 390-(150+18) = 222 W. A typical fully loaded chassis with 56 SGs drops from ~5 kW to 4 kW.

**Note**: Even though the PHY is removed, it still has to be accounted for since the service provider pays for outside plant powering. This Phy is moved to the node causing an increase from ~120 W to 160 W.

If Video is incorporated for a converged solution, there will be much more power and rack savings!

## 7. The Power of Digital and IP

Another benefit of digital fiber is the conundrum we face with splitting/combining with RF. We cannot combine multiple RF upstream legs without interfering and adding noise/ingress. Node splits equal more SGs, which equals more RF connections equaling more CMTSs. This means more RF cabling, rack space, and powering besides cost. Figure 4 below shows a typical analog deployment with the CMTS feeding US and DS independent connections to analog fiber optic transport.

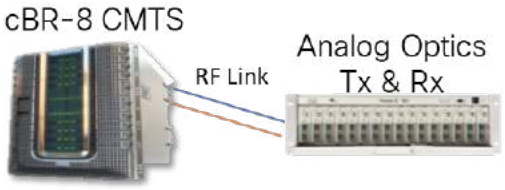

**Figure 4 - Typical Analog HFC Deployment**

Figure 5 depicts what happens when we do node splits and must add more CMTS chassis to accommodate the extra US connections from the added optical receivers. One could combine the US Rx outputs and share on an existing CMTS US port, but that's like taking 2 steps forward and 1 step back. Why combine noise and ingress?

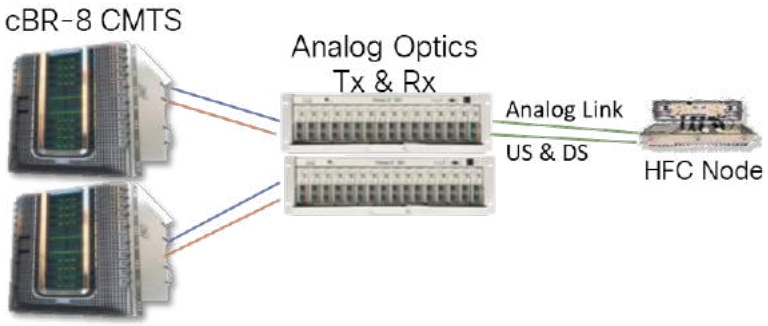

**Figure 5 - Node Splitting in RF Domain**

Figure 6 below depicts replacing analog optics with digital optics and removing the analog Tx and Rx equipment. Digital optics allows splitting/combining in the time domain with faster digital links. RF does not allow that. If more SGs are needed, they can be deployed in the field without worry of how many RF connections are left on a CMTS in the HE.

**Figure 6 - Digital Combining/Splitting**

## 8. Automation and Operational Support

In a large scale RPD deployment, automation is a must. There will be dozens of steps per RPD with anywhere from 50 to 500 RPDs per CMTS core and 100s of cores in typical network or region. There exist some key steps for RPD deployment automation.

1. Initial RPD discovery
2. RPD to MAC resources mapping
3. Config generation and application to CMTS
4. RPD deployment validation
5. Ongoing health monitoring

DAA is the first, critical step in the path to virtualization**.** Each step works, has value, and is a good investment.

1. Integrated CCAP
2. R-PHY with physical core and physical orchestration
3. vCCAP stand-alone core and R-PHY shelf or node
4. vCCAP in the data center
5. vCCAP with full orchestration
6. vCCAP core with containers and micro-services

## 9. "Real Life" Testing and Results

DAA with digital fiber links can traverse much longer distances than analog fiber. To prove that a CM could properly connect and provide HSD along with video services, we put together the design shown in Figure 7 below. This was the control test with very short distance.

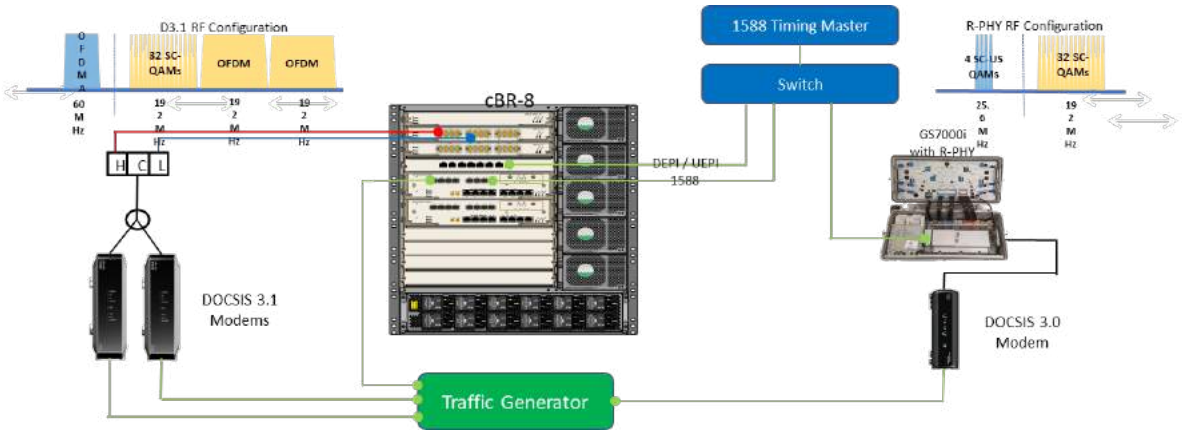

**Figure 7 - Lab Testing Diagram**

The "real life" distance testing consisted of connecting a CMTS core in RTP, NC with an RPD in Lawrenceville, GA. This is depicted in Figure 8 below. The distance is ~ 350 miles (565 km) at least "as the crow flies".

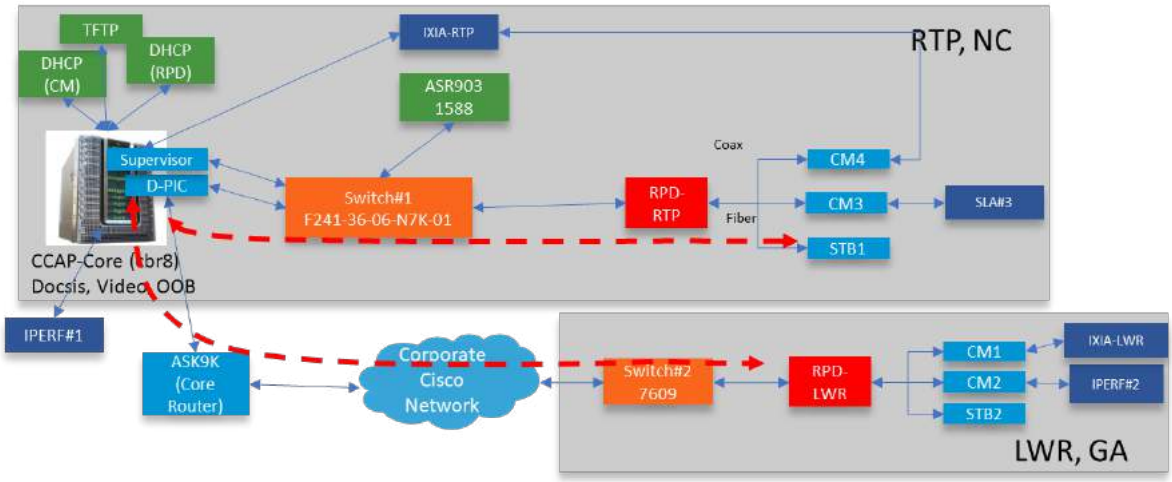

**Figure 8 - Real Network Distance Testing Diagram**

Running some numbers for velocity of propagation of fiber along with speed of light in a vacuum, we can surmise 2000 km of fiber = ~ 10 ms. This means our fiber distance and delay should only be ~ 3 ms. After some troubleshooting and configuration changes, some observations and major points were made.

- Roundtrip time delay between our CMTS in RTP and the RPD in LWC was 18 ms (avg).

- To our surprise the corporate network required 13 hops to get to our end location. We quickly determined that router and switch delay could be very high, unstable, and unpredictable!

- Using a Linux box for traffic testing required our MTU packet set to 1434 bytes. The MTU across the IT link was set to 1500.
  - When BPI+ was enabled for security, the MTU on Unix boxes changed to 1428 in order to accommodate the extra bytes used in the DOCSIS Extended Header.

- Precision timing protocol (PTP) is used from proper timing between all the components. Stability and reliability are of utmost importance. Properly designing this part of the equation is critical.

- Certain devices in between the CMTS and RPD may require, or be set for, an MTU of 2000 B. Depending on the RPD vendor or firmware, it may be necessary to turn DEPI fragmentation off:
  - `cable depi fragment off`

- Because our distance was > 100 miles and more specifically, > 500 υs of delay, we had to activate DEPI Latency Measurement (DLM) to properly get the CIN delay added to the Map Advance. If not properly set, the RPD may be fine, but CMs will lose station maintenance and drop offline or not register at all. It is suggested to use DLM with the `measure-only` syntax to track stability of the measurements and if >500 υs, remove the `measure-only` option.
  - ```
    cmts(config)#cable rpd xxx
         (config-rpd)#core-interface Tex/1/x
         (config-rpd-core)#network-delay dlm 1 "measure-only"
    ```

- Because US scheduling is still done at the CMTS for an R-PHY solution, the US request/grant cycle from the DOCSIS protocol can experience delay/latency and affect per-CM US speed. D3.0 with mtc-mode and continuous concatenation and fragmentation (CCF) can get around this. The concern is for D1.x and D2.0 CMs if trying to offer > 5 Mbps on the US over such long distances. You could even have a D3.0 CM register in D2.0 mode (US and/or DS) with the same consequences. One option around this is activating a Cisco proprietary feature known as DOCSIS Predictive Scheduler (DPS).
  - ```
    cmts(config-if)#cab upstream ?
         dps    docsis predictive scheduling on one mac-domain
    ```

  This feature can even help "speed up" US acks that are required for DS OTT ABR video such as Netflix and Hulu TV.

- Another potential cause for concern with Remote-PHY is the CIN traffic. This part of the network (digital fiber) must not be over utilized or oversubscribed. Traffic engineering is critical and proper quality of service given to critical signaling. Also, what if the CIN is a Metro-Ethernet link not owned by the service provider? All the overhead is being billed with no return on investment. Even if the CIN is owned, overhead is a concern for traffic engineering of the CIN. Some of this overhead traffic is created by DS Map traffic, DS video, NDF/NDR and US triggered spectrum captures.

- SC-QAM primary DSs contain MAPs (500/sec) and that will be related to how many are primary and how many USs are in the mac domain. The mac domain could be a 1x2 architecture causing more USs.
  - **Note**: If no data traffic is present during testing, the MAPs are inflated since SC-QAM is MPEG-2 encapsulated leading to 188 B MAPs. Once DOCSIS traffic fills in the 188 B frames, MAPs are closer to 100 B. Also, of note, OFDM primary is not MPEG encapsulated, so 100 B for MAPs is a good number to use. MAPs in DEPI cause UEPI as well, so the CIN MAP overhead will be slightly increased.

Here is an example of potential CIN overhead for a 10Gig link based on a typical deployment.

- 500 Maps/s*100 B/Map*8b/B*8 USs/SG*(24 DSs+1 UEPI)*2 RPDs = 160 Mbps.

It's possible to get this down to 52 Mbps by implementing D3.1 OFDMA US and removing some US SC-QAM chs along with decreasing the DS primary from 24 to 12.

DOCSIS rate is 38.8 Mbps for 256-QAM Annex B since all layer 1 overhead (FEC and Trellis coding) is done at the phy, so not transferred on the CIN. A raw rate of 42.88 is wrong to use for CIN calculations. That 38.8 may include MAPs as well and will be calculated separately below. The CMTS reports 37.5 Mbps, but actual user-rate is closer to 36 Mbps after subtracting MAPs. One could use 37.5 for the CIN calculation, but 38.8 is probably safer. This is close to 50 Mbps for Annex A Euro-DOCSIS.

Video needs 38.8 Mbps and VoD sends null bytes even if no one is watching. So that traffic has to be accounted for always.

The Map overhead will be worse with 1 ms Maps for LLD, more USs and primary DSs, and multiple RPDs per CIN link. Another overlooked aspect is in European markets that are required, or plan, to keep transmitting FM radio over their cable plant. NDF mode 7 is specified for the digitization of the whole FM band and then sent through the CIN link causing 512 Mbps of overhead! This could be a great time to remove this carriage. We also need to be concerned with US Triggered Spectrum Captures (UTSC) as each could be 50 Mbps. Gathering this information from many RPDs, many ports and continuously could have dire consequences.

## 10. Future Gazing

"Those who do not learn history are doomed to repeat it". So, how did we get here? DAA can be many variants such as Remote-PHY, Remote MAC-PHY, Remote Distributed CMTS, Flexible Mac Architecture (FMA) all using a CMTS core (hardware) or virtual /cloud using servers.

There were concerns with Remote MAC-PHY because of cost, complexity, and power requirements. The cable industry settled on a max wattage of 160 W for the node. More complexity in the field (remote) and in many devices brings a level of unease and unknown.

Remote-PHY gained traction and came first because it was simple. There's something to be said for the "KISS" principle. With complex components in a central location and the PHY in field,

it is a simplified design with less chance of issues in the field. Even firmware/software upgrades, bug fixes, and feature additions are easier and more stable.

Knowing that the first iteration of analog to digital migration would probably be a simple node lid changeout with no respacing and 95% of node upgrades would be much less than 50 miles, meant no concern for latency. It's really business as usual (BAU).

With that said, one benefit we listed was hub consolidation, which leads to CIN > 100 miles. Now latency is a concern and it will be necessary to address. This is why we have DLM, DPS and low latency DOCSIS (LLD) as part of the Cablelabs' specification. Part of LLD is the implementation of proactive grant service (PGS) which will provide lower latency for applications that require it like gaming or 5G mobile backhaul. There is even a spec called R-PHY 2.0 that allows for US scheduling in the R-PHY device. So, it is not a full Remote MAC-PHY, but a variant of it.

All this finally brings us to what lies ahead; US scheduling in the RPD explained in the R-PHY 2.0 specification for LLR. Because MAPs are generated in the RPD and the CM US Request and DS Grant are processed in the RPD, there is no CIN contribution to latency. Only the RF portion will contribute and that is typically < 1 mile of coax. This is better for gaming, quicker ping responses and faster US acks for better/smoother DS TCP, which could be OTT ABR video like Netflix and Hulu TV. This also means that DLM would not be needed.

In addition to less latency, LLR also affords us little to no MAP traffic overhead on the CIN. Having MAPs and the US scheduling in the RPD eliminates reliance on PTP sensitivity or PTP issues in general. These PTP issues could be self-induced, 3rd party devices, link redundancy failovers, etc. Granted, we would still need PTP for Mobile Xhaul and other features, but simple DOCSIS CM stability, station maintenance and T3/T4 timers would be solid.

A few other positives being investigated; possibly implement the US Scheduler in existing deployed RPD hardware with no additional power draw and maybe faster RPD reboots ☺

## 11. Don't Forget/Neglect the "Little Things"

I would be remiss to not mention the little things that are forgotten or neglected. Always start with Layer 1 (Physical Layer) when troubleshooting and validating connectivity. Just because we are using digital transmissions doesn't mean there aren't requirements for optical power Tx and Rx. We must verify correct fiber (single mode vs multimode) and SFPs. Care must be taken to not crisscross the Tx and Rx. Singe mode(yellow jacket) vs multi-mode (orange or blue) is usually easy to identify by color.

SFPs come in different Tx/Rx power. Short reach (SR) are specified for 20 km, while long reach (LR) and ZR are used for 40 & 80 km, respectively. Using ZR SFP optics on a multimode short distance fiber jumper is not going to work properly if at all. Using optical attenuators may be a work-around, but it's still not suggested.

**Note**: The different values are really based on the Rx sensitivity and the Tx are all the same around 3 dBm. The distance quoted is also based on pure link budget, but in reality, you will lose power from connections, splitters, splices, etc.

Other fiber optic concerns are the actual connections. Does it require LC or SC connectors (node vs optical switch vs RPD, etc.)? Don't forget the patch panels and bulk adapters. Are they angled or flat connections (UPC vs APC)? These are also color coded as black/red for flat and green for angled. Even if a bulk adapter is green, don't assume the connector on the other side of the patch panel is green (angled) as well. Talking about patch panels, how do we justify the cost of many breakout fiber connections with short jumpers and the associated cost of all those SFPs? Here's where copper/10G twinax has been tried or better yet, active optical cable (AOC). Know your options. In regard to breaking out a 100G link to multiple 10G links, QSFPs are available. Newer technology may provide 25G or 40G.

One of the benefits of digital fiber explained earlier was the capability to support DWDM of 40 wavelengths of light vs 16 for analog. This is made possible by optimizing different wavelengths defined in the ITU specification. We must make sure the proper ITU is matched up as a Tx/Rx pair if hard-set, but newer technology may allow adjustable; manual or automatic, at a cost of course.

We may be moving RF out of the HE and getting rid of coax and splitters/combiners, but at a price. We will be replacing RF combining/splitting with routing and switching and fiber connections.

The CIN must be symmetrical for the DS and US (Tx and Rx) which could also be a concern when designing redundancy. An Ethernet ring translates to two different length redundant paths making the RPD DLM and Map Advance adjustment/update critical. The CIN design could also incorporate daisy-chaining to take advantage of a 10G link but only needing maybe 3G at each RPD.

## 12. Conclusion & Summary

Upgrading or migrating from analog fiber to digital fiber should be an easy sell, but many variables must be taken into consideration in addition to cost. If we look at Remote-PHY in particular, let's separate facts from fiction.

- It's simple and it works
- N+0 **not** required
- Minimum components in RPD yields:
  - Best cost
  - Lowest node and plant power
  - Max SG density for given power budget
  - Best availability
- Same consistent approach for DOCSIS, Video, & OOB
- DAA needed for:
  - US expansion to 204 MHz & beyond
  - Virtualization
  - FDX
- MAC and Scheduler can be scaled as needed since they are central
- Much better visibility of node with RPD vs old transponder technology/nothing
- DOCSIS & video traffic encrypted on fiber

- Centralized software
- Security: CMTS software kept in secure location
- Interoperability
  - Supported by multiple silicon vendors
  - OpenRPD Forum

Remote-PHY can be trialed in targeted areas and doesn't require a complete overhaul of the plant. A great business case could be made for multiple dwelling units (MDU). This could be digital fiber to the MDU with a 1RU RPD shelf feeding the existing HFC plant of the MDU as shown in Figure 9 below. Maybe LLR could be exploited as well for low latency applications.

The shelf can run on 110 Vac or -48 Vdc, so no need for a special quasi-square wave outside plant powering required for a node solution. This could provide 3-6 SGs and provide DRFI DS output levels. The US and DS are independent with support for 204 MHz US and 1.2 GHz DS. Each SG (US and DS pair) could feed a riser with no concern for temperature effects on US attenuation. We could take this a step further and implement Technetix diplexer-less booster amps to "future-proof" the US split. When D4.0 CPE become available, we could upgrade the RPD to higher splits without the need for a plant upgrade assuming taps and passives are specified out to 1.8 GHz.

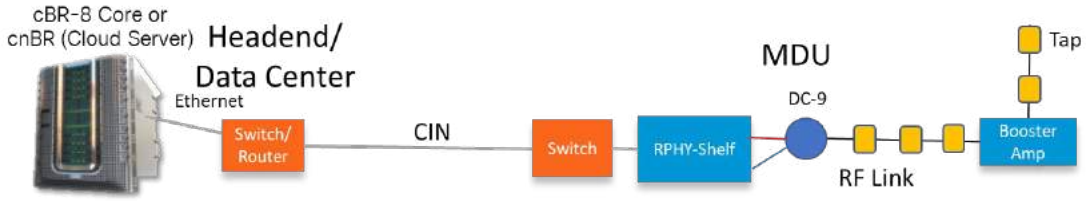

**Figure 9 - DAA for MDU Business Case**

Converting analog fiber to digital with all its benefits is a foregone conclusion. Whether that is FTTH with EPON/GPON or DAA with R-PHY, MAC-PHY or some variant, depends on other variables such as cost, time to implement, and comfort level. Either way, the benefits of digital fiber are indisputable and the way of the future.

# Guide to Managing Cable Network Traffic Congestion

## Addressing Capacity and Congestion with Cable Modem Termination System (CMTS) "Tweaks"

A Technical Paper prepared for SCTE•ISBE by

**John J. Downey**
Sr. CMTS Technical Leader
Cisco Systems

# Table of Contents

**Title** **Page Number**

## List of Figures

**Title** **Page Number**

## 1. Introduction

With unprecedented demand on local broadband networks, operators are under pressure to prepare for congestion and capacity issues before they happen. During the Spring of 2020, most systems experienced the equivalent of one year's growth in 2-3 weeks. The industry "weathered this storm", but we must be prepared for continued demand. Some suggestions will be given to help alleviate and mitigate congestion now and also provide ideas on how to address capacity concerns into the future on cable operator DOCSIS plants.

## 2. Top Seven Steps

1. Decreasing subscribers per service group (SG) is one of the most obvious choices, but it can be achieved in a multitude of ways.
    - ✓ Increase the amount of SGs and add more licensing/channels.
    - ✓ Decrease service groups (SG) down to one fiber node (FN).
    - ✓ Utilize upstream (US) segmentation. Maybe the node supports multiple downstream (DS) optical receivers and US transmitters or the US utilizes baseband digital reverse (BDR) and can be converted from 1 to 2 US segments.
    - ✓ The last option would be a physical node split, but if utilizing distributed access architectures (DAA) like Remote-PHY, possibly a 1x1 RPD can be replaced with a 2x2 or some other variant.
2. Verifying no **uncorrectable** Forward Error Correction (Uncorr FEC) and "clean" plant should be part of everyone's proactive maintenance plans, but sometimes relegated to the bottom of the list.
    - ✓ Uncorr FEC is basically dropped packets. Regardless of modulation error ratio (MER), signal-to-noise ratio (SNR), carrier-to-noise ratio (CNR), correctable FEC (fixed packets); Uncorr FEC is the most important to your end-customer.
    - ✓ **Note**: Uncorr FEC is not only caused bad plant issues. It could be from bad timing (time offsets and MAP Advance), poor port-to-port isolation leading to signal "bleed-over", modulation profile settings, and a myriad of other contributors.
3. Increasing capacity without physical node splits or SG changes may be the first goal and can be achieved with a few ideas.
    - ✓ Use the highest US and DS modulation along with the largest channel widths as possible. This may have no cost increase since licensing may be based on channel only and not the rate/speed.
    - ✓ Utilize DOCSIS 3.1 where possible. ***Note**: More speed does not necessarily mean less latency! D3.1 US may exhibit even more latency with ping tests.

- This brings up an all too familiar question, “How many D3.1 CPE are needed to justify exchanging ATDMA chs for OFDMA spectrum?” Is it 10%, 25%, 50%, even higher? If 10% of your users are using 85% of your capacity, they either have D3.1 CMs already or you could identify those “heavy users” with subscriber traffic management (STM) and then give them a D3.1 CM. Assuming it’s not that bad and 10% use 50% of your US, that could be the justification to drop 2 ATDMA chs and use that spectrum for more efficient D3.1 OFDMA. There are some advantages to dropping from 4 to 2 ATDMA chs. D3.0 CMs get back 3 dB more max Tx power and less DS overhead in the form of MAPs. Two ATDMA chs give 54 Mbps aggregate US speed and one could offer a 20 Mbps service and lower. All other US offerings >20 Mbps would use D3.1.

✓ Allocate more spectrum for high speed data (HSD) services. This may entail using spectrum once thought to be questionable such as: roll-off, known ingress areas like CB, LTE, Aeronautic band, and the very low end of the US spectrum. DS may require you to “steal” from video spectrum. Analog video reclamation should be an easy sell but converting MPEG-2 video to MPEG-4, over the top (OTT) video is the ultimate endgame and takes more consideration and planning.

✓ Utilize/exploit “Powerboost”™. More speed could translate to “actual” vs “perceived”. Powerboost is a term/feature (name trademarked by Comcast) used for faster speeds that can affect perceived speed (DS & US). A command may need to be configured on the CMTS for DS Powerboost activation along with a very large DS Max Burst setting, like 50 MB in the cm file.

✓ Figure 1 below depicts an example of a D3.1 CM with 510 Mbps max rate, 600 Mbps peak rate, and 70 MB DS max burst. This can achieve approximately 6 seconds of Powerboost.

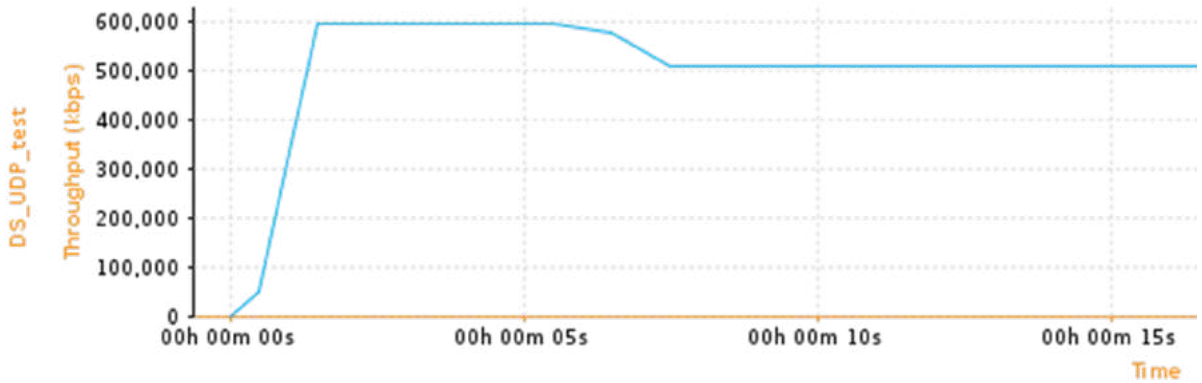

**Figure 1 – DS Powerboost Example**

- **Note:** DOCSIS 3.0 CMs support a TLV for per-CM Peak Rates.
- Utilize to alleviate typical 10% over-provisioning, which is usually done to negate differences between layer 2 & 3 speed reporting.

- Can exploit US Max Traffic Burst for US "Powerboost" as well. US Powerboost may help alleviate perception of lower speed. This can also be exploited to apply a peak-rate and less over-provisioning, which is typically done today at 10% just to "ring the bell".
- The "jury is still out" whether this can negatively affect OTT video and other adaptive bit rate (ABR) applications with buffer loading.

✓ An US Powerboost can be achieved as well. If for example we wanted to provide a 500x50 Mbps offering, most would typically set for 550x55 Mbps. Instead, we could use Powerboost to allow: 500x50 max rate, 550x60 peak rate, and 50x10 MB DS/US max burst. This should provide ~ 8 secs of US and DS Powerboost.

4. Eliminate Overhead
   - ✓ More USs in a MAC domain creates more DS MAP overhead at ~.4 Mbps per US. Increasing US channel size and eliminating too many US channels will help. Another way to get less US channels per MAC domain would be to create more MAC domains. This can be achieved easily when the SG consists of two fiber nodes (FNs).
   - ✓ Also, moving to every 4th DS as Primary could save 54 Mbps per 24-ch DS bonding group (BG). The trade-off is less aggregate capacity for D2.0 CMs.
   - ✓ Remove "stale" service flows. Some inactive VoIP flows may not be torn down according to their T8 timer and can be done automatically with the CMTS command, `cable service flow activity-timeout 300`. Add this CMTS global command so flows with no activity > 300 seconds (5 minutes) are torn down if the CM/eMTA does not do it automatically.
   - ✓ Understand WIFI, VPN, etc. encapsulation overhead along with potential "bottlenecks".
   - ✓ US acks are used for DS TCP flows. D3.0 & 3.1 CMs support and have ack suppression on by default helping to alleviate US acks. For very fast DS TCP flows (i.e. 1 Gbps), this helps alleviate US overhead from the acks required (typically 20 Mbps decreases to ~7 Mbps). The pitfall to this is each ack is now more important and ack suppression is not very active or efficient when the DS flow is slow (IE < 10 Mbps). So, having many OTT video sessions simultaneous across one CM may not benefit from ack suppression since each flow is 3-10 Mbps.
5. Control Abusers and Denial of Service (DoS) Attacks
   - ✓ Cloning – DMIC, BPI+, "Hotlist".
     - The CMTS can control the same mac address on a chassis and identify potential cloned devices. It can also control CPE "appearing" behind multiple CMs, but it has not visibility across multiple chassis. Some

external devices may have this visibility like the DHCP server and better suited for cloning identification.

- If a cloned device is identified, you can disable CM ranging and registration by implementing the Cisco "hotlist" command.

```
(config)#cab privacy hotlist ?
   cm            Add cm hotlist
   manufacturer  Add manufacturer hotlist

(config)#cab privacy hotlist cm ?
   H.H.H         CM mac address H.H.H
```

- **Note**: The CM could still be ranging "all the time", but it will not even show init(r1) on the CMTS. Some could argue that it's better to let it register and give it a cm file with network access disabled.

✓ Over-Use/Abuse
- Deep Packet Inspection (DPI) can be used to at least identify "heavy" users.
- Subscriber Traffic Management (STM) takes rate limiting and monitoring down to the least common denominator, which is bytes. There is no bias towards ports, applications, etc. It solely looks at total bytes over a certain time frame and can dynamically drop the CM's QoS to a lower rate for a given time period.

✓ Arp Attacks, IGMP Joins?
- Arp Filters, Access Lists (ACLs), subscriber-based rate limiting (SBRL).

✓ Expiring Certificates
- Allow/Deny Lists. Cablelabs' certifications are expiring by end of 2020 and some CM certifications could render it unusable.

6. Optimize CMTS Efficiency
   ✓ Load Balancing
   ✓ D3.1 Graceful Profile Management & US/DS Resiliency/Partial Mode

7. Implement Cache Servers
   ✓ **Note**: Netflix, YouTube and other OTT video providers may drop video quality to save bandwidth and/or temporarily halt 4K video offerings.
   ✓ Allowing a new gaming version of Fortnight or Call of Duty to be stored on a cache server closer to your end-users mitigates WAN traffic and overload.

## 3. CMTS & Cable Interface Suggestions

- **CM Insertion Interval** - CM ranging opportunities
  ✓ `(config-if)#cab insertion-interval auto 120 1000` or (`60 480`)

- ✓ The Cisco scheduler has dedicated time every 60 ms for initial maintenance (IM). The number of CMs online and traffic utilization will automatically make the insertion interval change between those two numbers. Verify with the show controller command:
  - `cbr8#sh contr c1/0/2 upstream | in Insertion`
    `Ranging Insertion Interval automatic (120 ms)`
    `Ranging Insertion Interval automatic (120 ms)`
    `Ranging Insertion Interval automatic (120 ms)`
    `Ranging Insertion Interval automatic (120 ms)`
    `Ranging Insertion Interval automatic (120 ms)`
- ✓ **Note**: The value reported could be an average between a changing insertion interval and report a value that is not an increment of 60 as one would expect.
- ✓ It may be worth experimenting with this Insertion Interval. The cBR-8 defaults are 120 1000, but we have had success in the past with the old uBR10K defaults of 60 480. We have also used "fixed" settings (lowest of 100 ms and highest of 2000 ms) to address maintenance windows. The lower number creates more opportunities for CM registration at the expense of user traffic capacity.
- ✓ A new CM will start ranging typically around 6 to 9 dBmV in 3 dB steps until the CMTS "sees" it, which is about -20 dBmV at the CMTS. Once the CMTS "sees" it, the CM will report inti(r1) as they are doing initial maintenance (IM). This is contention time and CMs will back-off when, and if, they collide. Explained below.
- ✓ **Note**: The CM should quickly go from broadcast IM to unicast station maintenance (SM) for final ranging and report init(r2). This does not have to be in 3 dB steps anymore.

- **US Range & Data Backoff & Init Technique** - Used to minimize collisions in the US
  - ✓ `cable upstream x range-backoff 3 6`
    - This can be experimented with in case CMs collide at init(r1) and have to back-off. The code allows a CM to back-off randomly between 2^0 (1) to 2^3 (8) insertion intervals (above command) for first collision. Second time collision, randomly back-off between 2^3 (8) and 2^6 (64) insertion opportunities.
    - In the case of a CMTS reboot, the insertion interval would be the lowest of every 120 msec and a bunch of CMs would be in inti(r1). Assuming collisions are happening, they would back-off randomly that first time between 1-8 opportunities, this means between 1*120 and 8*120 = a back-off anywhere from 120 msec to .96 sec.
    - **Tip:** Look for CMs stuck in init(r1) as they could cause issues by "eating up" limited IM opportunities and cause high Uncorr FEC counters.
  - ✓ `cable upstream x data-backoff 3 5`

- This is for contention Request collision back-off. The good thing about faster US service flow speeds, is usually after an initial contention Request, the subsequent bandwidth (BW) Requests end up being "piggybacked" within the actual data traffic and no more possibility of collisions. We have seen good results lately in some markets using values of 4 and 6.

**Side Note**: More US utilization coupled with applications not using unsolicited grant service (UGS) such as Vonage, Skype, Zoom, Wi-Fi calling and other BE VoIP, will increase the probability of Request collisions. This could also be exacerbated by DS OTT video and its TCP acks that must be sent on the US.

I suspect customers with audio-only will have more contention requests since video would increase the US throughput requirements and piggybacking should occur more often.

**Warning**: These collisions could lead to laser clipping and dropped packets. This is not the case for distributed access architectures (DAA) like remote-PHY since the fiber link is digital and there would be no laser clipping.

The following Cisco CMTS commands can be used to verify BW Requests whether they are contention or piggybacked. It cannot tell when contention requests actually contend/collide. The first one is intended for a specific CM. Refer to your CMTS vendor for similar commands.

```
cbr8#sh int cx/y/z sid n count ver | inc BW
BWReqs {Cont,Pigg,RPoll,Other} : 8306, 3243, 0, 0
```

This second command will show per US.

```
cbr8#sh contr cx/y/z up n | in Request|Bytes
Bandwidth Requests = 2776290
Piggyback Requests = 1077964
Invalid BW Requests= 195
Bytes Requested = 256264277
Bytes Granted = 1626995783
```

If for example 500 homes were in a SG/FN and 10% are doing some sort of teleconferencing and 40% of them are doing audio-only and half of them actually have collisions. This gives 500*.1*.4*.5 = 10 potential request collisions. 10*log(10) = a 10-dB potential power spike. To add power perfectly, signals need to be the same frequency, amplitude, and phase. At the US laser input, signals will be the same freq and power, but phase is based on timing/distance. CMs have time offsets to keep tight timing alignment, so phase could be aligned as well.

**TIP**: A trait of laser clipping is "seeing" artifacts like second and third order harmonics above the diplex filter region. One way to prove a signal is an artifact is to turn off the original, "real" signal or watch a spectrogram view, which is time in the Z axis. If artifacts disappear the same time signal below 42 MHz disappears or fluctuates, then it's a high probability that it's a harmonic or by-product of inter-mixing of signals (heterodyning). Keep in mind that sometime DS signals leak on the US, so it's actually ingress and not a harmonic. Also look below 5 MHz

and make sure AM or HAM radio is not getting into your node. It's been seen in the past where a node using a special port for power insertion wasn't as efficient as believed for RF choking. Installing a power inserter on an RF leg solved the issue.

Other power spikes could be CMs coming online and ranging. A CM on a low value tap will normally only need to transmit maybe 35 dBmV and if it ranges it could go as high as 57 dBmV. Utilizing flexible solution taps (FST) with built-in EQs helps alleviate this since CMs all transmit between 40-50 dBmV and will not have a large range to ramp up.

**Warning**: There could also be a concern with CMs in the "hotlist" as they will still range. Whether this exacerbates the issue is unknow since they never show init(r1), but they're ramping up on every UCD and trying all day long!

- ✓ `cable upstream ranging-init-technique 2`
  - This cable interface command helps US ranging for D3.0 mtc-mode (US bonding) by eliminating contention ranging on the other USs in the US BG once the first US has ranged. The default is technique 1, which means contention IM. Tech 2 is unicast, so basically SM ranging. There have been issues with some CMs with tech 2 in 3.18 code, but tech 3 or 4 could be tried as well. It also helps with RFoG systems and also for D3.0 DS load balance (LB).

- **Throttle CM Ranging**
  - ✓ `[no] cable throttle-modem init-rate <1-1000> holdoff-time <5-100> flush-rate <100-1000>`
    - Suggested values; 32 CM/s; 45 sec; 300 CM/s
  - ✓ `show cable throttle-modem`
  - ✓ `cable up rate-limit-bwreq exempted-priority <priority>`

- **Prioritize Pre-registration Traffic**
  - ✓ `(config)#cable qos pre-registration us-priority [0-7]`
    - Default of 0, with a suggestion of 6 or 7. During CM registration, a CM first goes through init(r1), which is contention-based ranging. Once the CMTS "hears" it, it goes to init(r2), which is unicast ranging to fine tune the levels and add Pre-EQ. Once these physical layers are complete, the CM state will report int(rc) and it can now be "docsis pinged". The next state is dhcp (init(d)) and the CM must now use actual data transmissions that compete with other CM transmissions. If the dhcp discover is small, the CM could use a short grant and its associated modulation, otherwise it will use a long grant with its modulation. If other CM transmissions are higher than priority 0 and lots of US utilization, then this init(d) state may never have any opportunities to be fulfilled, so set it much higher than 0!
  - ✓ DS – "`cable service flow priority`" (EDCS-1524683). Contact Cisco TAC and/or CX for more information.

- ✓ **Note**: Setting all BE flows > priority 0 can lead to issues.

- **US Max Power Issues**
  - ✓ `cable upstream n power-adjust continue 6`
    - Helps CMs exceeding Max Tx power to stay online.
    - **Note**: A max transmit CM will be commanded to change level every 15-20 seconds during its SM, optimally only once. Some CMs have been observed to go into the fast polling mode (every second) for 5-10 times before moving on. This is a good reason to make sure < 5% of your CMs with a Rx marking of **!** are in this state.
    - By increasing the "continue" command to 6 dB, the CM will be permitted to stay online if the CMTS receive level is between -6 dBmV and 0 dBmV. If the level is above -1, you won't see a "!". If the level is below -6 dBmV, the CM will go offline. For systems that still have high-value taps (29 & 26 dB), this helps keep the CM online, but will produce CMs with different CNRs & MERs.
    - **Warning**: Allowing a large `power-adjust continue` to be configured can lead to CMs having a large range to overcome isolation and potentially appear on US ports where they should not! It could also allow CMs located off low value taps to range very high and create intermittent laser clipping.
    - **Note**: If the level of noise on the US is enough to distort the US level being received by the CMTS, then the CM and CMTS will go into "`power-adjust noise`" averaging mode. A "*****" will be displayed next to the receive level in the `show cable modem` command. When this occurs, CMs are polled using a one second interval. By default, the percentage of "noisy" ranging responses that cause a CM to enter "`cable upstream n power-adjust noise`" mode is 30%. This percentage may be increased to alleviate excessive power level adjustments in the presence of noise.
    - The following command can be used to identify CMs in max Tx power, max time offset and noise averaging mode.

```
cbr8#scm | in \*|!|MAC|State
MAC Address   IP    I/F     MAC          Prim RxPwr Timing
              Add           State        Sid (dBmV) Offset
38c8.5cb6.63ca -- C2/0/2/U1 online(pt)   15   !0.00  1209
38c8.5c09.42c0 -- C2/0/1/UB w-online(pt) 1    -1.00  !6104
6477.7d90.4368 -- C2/0/7/UB w-online(pt) 12   *0.50   1532
```

  - ✓ `cable upstream max-channel-power-offset 6`
    - The above command helps D3.0 & D3.1 CMs select the best US BG. When a D3.0 CM registers, it does so on a single channel, a reference channel, and relays its Tx level back to the CMTS. The CMTS can determine if that level will be adequate for multi-ch bonding. The "`power-adjust continue`" range is **NOT** used for this decision.

- **Note**: Cisco has a feature that will drop from 4-ch to 2-ch (if configured) and finally single-ch mtc-mode. This depends on the Tx level supported plus it adds in the `max-channel-power-offset` calculations. This command has a default of 3 dB, but a value of 6 is recommended. If that level is not adequate for all options, then the CM resets itself. Example; CM ranges on US0 and reports 55 dBmV, CMTS wants to do 4-ch bonding and determines that 64-QAM for 4-ch US bonding has a max output of 51 dBmV + 3 max-ch-offset = 54, so CM drops to 2-ch BG, if configured.

✓ Stick with the double minislot from default like we suggest and never quadruple it. If so, more "time on the wire" will be wasted. Dropping it to the default minislot of 1 when using 6.4 MHz ch width will not save anything and could affect US concatenation and per-CM US speed.

✓ `cable upstream balance-scheduling`

- The US scheduler tends to allocate more minislots in the first US in the US BG if not using this command. This is not "bad" but can affect D2.0 CM US load balancing. This command is not on by default, but highly suggested to implement. Another option would be to assign US0 to your highest, "best" US frequency and the last US in the BG to the lowest, "worst" US frequency.
- **Warning**: Do not use this command for RFoG (DPON) environments.

✓ `cable upstream qos fairness`

- Implement the qos fairness cable interface command to help fairly share between D3.0 and D3.1 CMs so one doesn't "starve out" the other. It's not on by default and we have seen D3.1 allocated more speed at the expense of D3.0 CMs. The command doesn't change the cross-bonding functionality. D3.1 CMs still prefer 3.1 spectrum before utilizing 2.0/3.0 spectrum (chs).

# 4. VoIP & Service Tiers

## 4.1. Call Signaling Insurance

✓ Utilize non real-time polling service (nRTPS) for call signaling. This allocates non-contention request opportunities to guarantee call signaling during high US congestion. The beauty of nRTPS is it allows contention requests, if available, along with non-contention requests, while RTPS is non-contention only. It also allows a priority to be configured for the flow associated with the nRTPS request. Keep in mind that this flow will use another SID.

✓ This would be a good time to re-evaluate the modulation profile used for the A-UGS burst since much more traffic could be created by eMTAs. Using a more robust modulation vs the A-Long burst may not be in our best interest anymore and cause undesirable wastage of time on the wire.

### 4.2. Service Tiers

- ✓ When adding faster service tiers, be sure to delete the old, slower ones. Many people forget to delete obsolete tiers when they migrate to higher tiers.
- ✓ **Warning**: The slow-to-fast ratio should not be more than 1:1000. If it is, the slower rate could constrain the faster rate!
- ✓ Make sure DS call signaling flows utilize an LLQ flow by making sure they use a non-zero max latency value. Then these slow flows will not affect the ratio limit.
- ✓ Look at all the flows forwarded on a Wideband or Integrated interface and verify the highest rate and the lowest rate do not exceed a 1000:1 ratio.
  - Example: if offering a 1 Gbps speed, then the lowest offering should be 1 Mbps and higher.
  - It's also not a good idea to use a minimum guarantee rate for any flows (US or DS). Dynamic QoS flows like UGS are fine.

## 5. Going Forward and Planning for the Next Inevitable Event

- Implement a subscriber-based subscription model for quick activation of more channels/capacity.
- Have segmentable nodes for future segmentation and quick activation.
- Implement DAA for better performance, complementary to D3.1, and a pathway to Cloud.
- When available, implement D4.0 Low Latency DOCSIS (LLD) features.
  - ✓ One of those features is Proactive Grant Service (PGS).
  - ✓ Cisco has its own feature called DOCSIS Predictive Scheduler (DPS).
    - `(config-if)#cab upstream dps`
    - Helps US latency in long CIN delay DAA, lowers latency for DS TCP.
    - **Note**: Intel/TI Puma 5 CMs don't seem to benefit.

# Table of Contents

## List of Figures

# 1. Introduction

2020 has been a landmark year for the human race. Never before has the human race been equipped with the technical capability to be able to handle dissecting data as well as innovation in finding cures and prevention to something like the coronavirus strains that now threaten the fabric of how we behave as a society. We are all locked in our homes and trusted areas of interaction with our fellow humans. No sector of the human race has been more affected by the pandemic than the elderly population. The virus itself affects those with compromised or weaker immune systems more often than not. This not only brings our elderly population into the most vulnerable group but also now making elderly care homes possibly the most likely place to catch and spread a virus and contagion.

Even before our pandemic times, it was clear that Aging in Place (AIP) was a key area for new opportunities for Cable Operators to tap into. It's not only a huge improvement change for elderly lives but also a new source of high margin revenue for the Cable Operators. Lockdown at home has given everyone a taste of what it is like spending more time in your home and in particular the role of connectivity in our digital work and social lives. One could almost claim that the foundation pillar of AIP is connectivity. Thus making it obvious that the Service Provider is in a unique position to open up the floodgates on a new defacto model for living out your life in your own home.

Now is the time for Cable Operators to go beyond the triple play and quadruple-play and add high-value connectivity-based services for the AIP cycle of the connected home life. The following sections of this paper will take the reader through the opportunity and some of the key tenets of a Cable Operator led AIP solution. It will also hopefully open up discussion on the key decision points and also the inertia elements for the operator to pivot into this space. This paper will focus specifically on AIP at home rather than in dedicated living communities which can share a lot of the technology and approaches similar to normal residential housing AIP. It will also highlight the simple approach to AIP with the simple tenets of:

- Technology assist for aging in place
- Connectivity
- Communication
- Data Analytics

With a practical focus on the simple assists for Aging in Place, the Cable Operator can do well in the high-value service that will emerge to keep people at home longer.

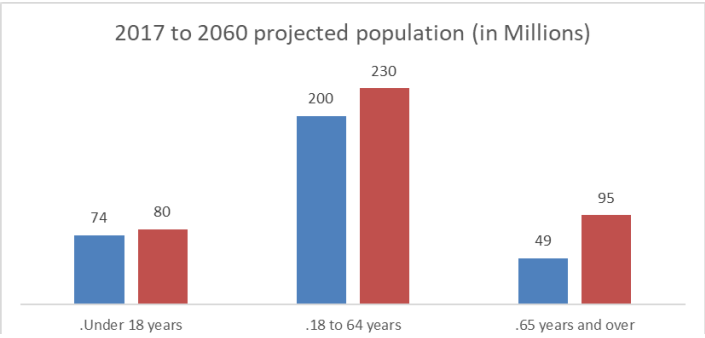

**Figure 1 US Census 2017 - 2060 population projection**

# 2. Understanding the Aging in Place market opportunity

US aging population percentage is growing. Based on[1] the US Census, as shown in Figure 1, the aging population that is above 65 years old, is nearly going to double from 49M in 2017 to 95M in 2060. This is attributed to the reduction in mortality rate. This growing elderly population is going to significantly increase healthcare and in general, their lifestyle-related spending.

[1] United States Census Bureau, *2017 National Population Projections Tables: Main Series*, available here

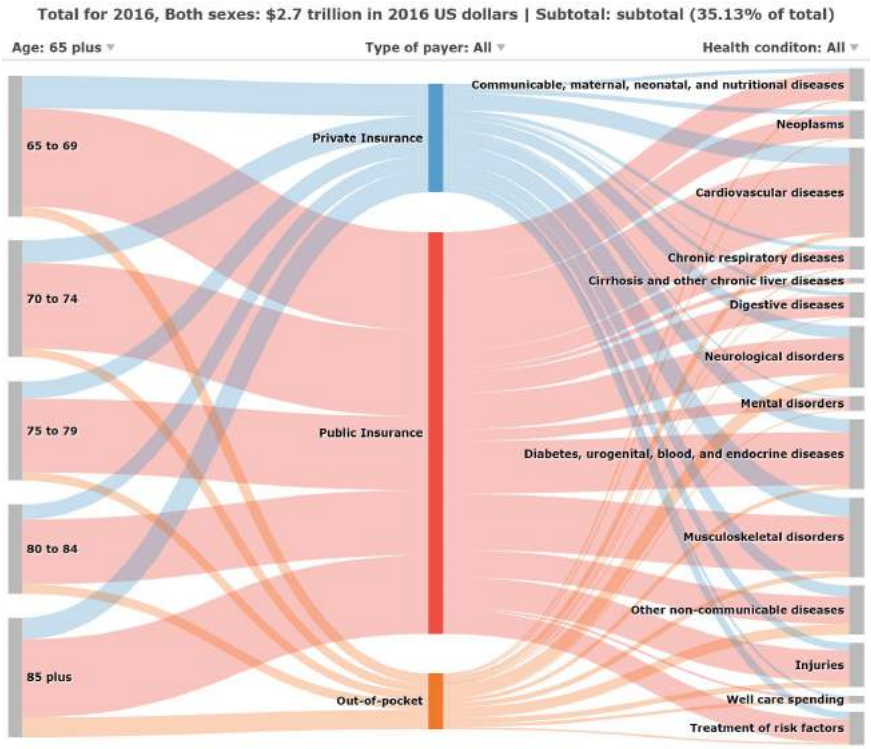

**Figure 2 2016 healthcare spend from elderly based on their insurance and condition**

As shown in Figure 2 from VizHub[2] Out of $2.7Trillion spent on healthcare in 2016 in the US, ~35% is spent on the above 65 years age group. This amounts to ~$1Trillion on the needs of an aging population. Based on the yearly healthcare cost allocation from National Health Accounts[3] the overall healthcare spending reached $3.6Trillion in 2018. If the same trend continues, by the year 2028, the US will be spending ~$1.6T on the elderly population (as presented in the insert *2018 & 2028 US Healthcare Spend and Highlevel AIP Opportunity*). This is the basic spend on the elderly with the status quo of support. Through innovations, different industries are trying to address the needs of the elderly. Some of these healthcare spendings can be used for their lifestyle changes that potentially can reduce the overall cost.

The aging population will be more technical savvy ➔ Open to newer business models

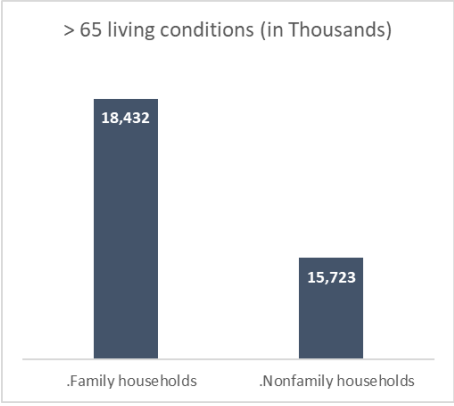

**Figure 3 2019 elderly living by census.gov**

The 65-year-old today entering their AIP journey is more technically savvy and has lived most of their life with the Internet (introduced 30 years back), laptops (30 yrs.), smartphones (13 yrs.), and devices such as Alexa (6 yrs.). So, the 65-year-old today is in reasonable shape to leverage and drive technology themselves for their AIP independence. The 85-year-old today in their AIP journey has probably struggled in their use of technology having missed the key events above as part of their working and earlier life. The tech-savviness along with the serious inclinations to staying independent, as shown in Figure 3, 42.1% amounting to 14.4M[4] households (Not including elders couples that are living alone themself) in the US fall into this target market. Historically the homes are growing at 1.013 times year over year. This will lead to roughly 16M homes passed by 2028. This is expected to grow to ~30M by 2060. Like any solution a

[2] *Tracking personal health care spending in the US | Viz Hub*, availabe here

[4] United States Census Bureau, *The Older Population in the United States: 2019*, available here

connectivity and technological-based solution to help people remain in their homes as long as possible targets the majority of people who follow the pyramid sections, as shown in Figure 4, below where the person can remain in their home with technical support even to the point where they need regular help from external sources and even if they need full-time nursing care. For issues of the mind and brain and Chronic health conditions, these typically have to be handled in

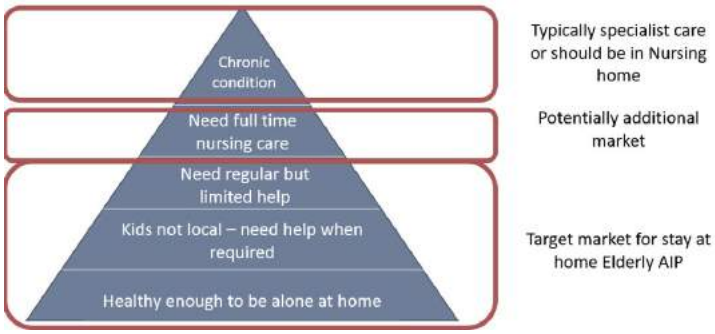

**Figure 4 Targeted elderly population who prefer to age in place**

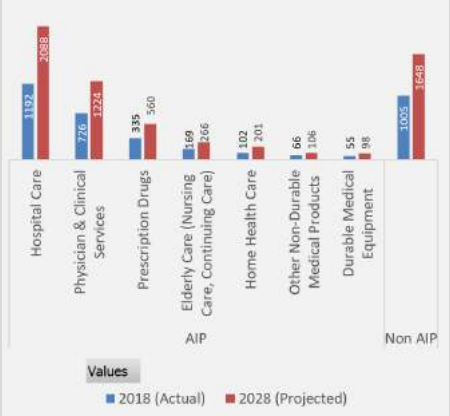
Nursing homes or specialized assisted living communities with onside medical resources.

For this Market research analysis we can make some coarse assumptions to develop a best-case opportunity size, as follows:

> Assuming in 2020 ~25% of those 65+ living on their own currently need the help of technology (such as for their self-care, Independent living, and Ambulatory problems) to improve quality of life and the ability to remain at home, the target customer base would be ~14M people. By 2060 this will reach ~24M. 25% of the 14M can immediately benefit from technology assist solutions.
>
> In 2020 about 8% of the population on a Cable Operators network are over 65 and of this about 25% are living on their own. So a *hypothetical operator with 2M subscribers* has an addressable market of 160K subs above 65 of which 45K are living on their own, which will increase to 75K by 2060. This group will be the most motivated to adopt based on the price points compared to the assisted living options.

**2018 & 2028 US Healthcare Spend and Highlevel AIP Opportunity**



NHE[3] provides a detailed breakdown of healthcare actual send of $3.65T in 2018 and a projected spend of $6.2T by 2028, as presented above (numbers are in billions). Out of this overall spend $2.6T in 2018 and $4.5T can be addressed by the initiatives that are part of the Aging In Place initiatives. Note that this opportunity sizing includes all age groups. If we assume 35% of this is spent on the elderly (as shown in Figure 2), it would be approximately $1T in 2018 growing up to $1.6T by 2028.

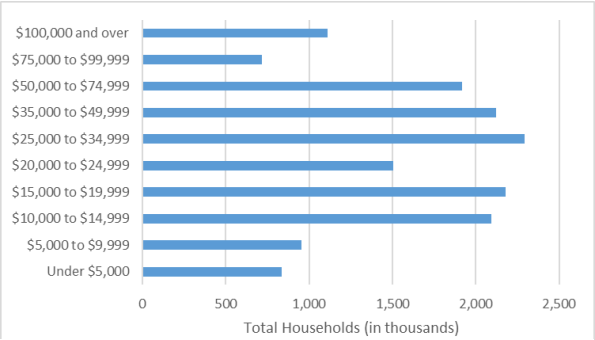


**Figure 5 Yearly income, in 2018, of Aging in Place individuals**

Now let us see if we can figure out some potential indicators as to how much people are willing to pay, should pay, or can pay for AIP based technology solutions. As shown in Figure 5, the non-family households (representative of the Aging in Place individuals) income is skewed towards less than $50K per year[4]. People age 80 and over who live alone had a median income of $22K in 2018 compared to $52K for married couples.

One out of five older adults have income from earnings. In 2018, the median income of the four-fifths of people age 65 and older who are fully retired was $20,440. The amounts were similar among all older age groups. The monthly income, with no earnings, is about $1,700 so you will see that all of the monthly costs of care are more than the earnings of a lot of the US senior citizens. 2017 Social Security Bulletin[5] report that roughly half of the aged population live in households that receive at least 50 percent of total family income from Social Security and about one-quarter of the aged live in households that receive at least 90 percent of family income from Social Security. In 2018, the yearly average assisted living cost[6] is $45K ranging from $36K minimum in South Carolina to $72K in Delaware. Nursing home costs run from average in 2019 annually of $89K for a semi-private room to $100K for a private room. Things have increased since 2016 and are still increasing as the aging population competes for Nursing Home beds and are on track for 2028 to be $120K for a semi-private

**Figure 6 2019 US monthly median cost of elderly care solutions**

nursing home room to $135K for a private room. As usual, things vary by state from the highest Alaska at $29K for a private room to the lowest Oklahoma at $5K per month. The 2019 Monthly median cost for care in each of the categories of In Homecare, Community and Assisted Living, and Nursing home care are presented in Figure 6. These numbers don't show the additional costs for memory care or for severe disabilities which are much more expensive. Traditional home health care aides assist seniors with daily activities of living, light housekeeping, offer medication reminders, and serve as companions. Their wages average $20.50 per hour, $164 per day, $5K per month, and $59K annually. *It is this cost and service that we are targeting for technology assist care to minimize the number of hours, days of in-home services, or aides to help.* Skilled nursing care typically involves services similar to home health aides, but providers are trained and certified nurses or therapists who are able to offer additional care such as medication administration, wound and injury care, and various types of therapy. Skilled care averages $220 daily, $6.6K monthly, and approximately $79K per year. *We also want to try and use technology to*

[5] *The Importance of Social Security Benefits to the Income of the Aged Population*, available here
[6] *Nursing Home Costs*, available here

*minimize the visits and hours spent in the home of the home health aides and other medical support.* GoInvo[7] estimated in 2019 that ~$252B of $3.5T total healthcare costs are spent in Home Health Care and Nursing Care. Compare this with the combined revenue of all US Cable Companies of $83B in 2018.

A couple of other discussion points to consider when understanding the Aging in Place dilemma. In particular the role of family careers for both elderly and in particular single elderly parents. Some of the key premises of *aging in place business opportunities with technology solutions are to enable the parent's children and relatives to provide a more effective caring solution* for not only their parent(s) but themselves. The problem of children caring for their parents is a complex one and has many parameters from

- different cultural views of living with parents
- the stress and business of the lives with their own kids – not having enough time for their parents
- the hassle factor of looking after their parents vs it being a vocation to do it
- the guilt of kids not doing enough for their parents
- the guilt on parents having to rely on their kids for support
- the economics for care – if the parent(s) can't afford, can the kids pay for the Help services
- Proximity and closeness of the kids or family members to the Aging in Place parent(s)

[7] GoInvo, *Where your health dollars go*, available here

And lots of other factors that many readers will be familiar with the 2020 AARP report[8] provides a very

**A note on taxation and Medicare coverage for Aing in Place**

In most cases out of pocket nursing home costs are generally tax deductible under itemized medical expenses. If yourself, your parent, spouse or another legitimate dependent is in nursing care primarily for medical care, then expenses related to medical care, lodging and meals are deductible. However, seniors in nursing homes for personal reasons rather than medical, will only be allowed to deduct costs associated with actual medical care, but not meals and boarding costs. Medicare will cover skilled nursing care expenses in very specific situations and is not designed to pay for nursing home or custodial care costs long term. One such situation is when a senior has been hospitalized and released, but still requires a bit of specialized care. Medicare will help pay for short terms stays in nursing homes if they:

- Were admitted to the hospital for a minimum of three days as an inpatient
- Have been admitted to a Medicare certified facility within 30 days of the hospital stay
- Need skilled care like physical therapy, speech therapy, and other types of rehabilitation

Those who meet all of these conditions under original Medicare will qualify for assistance as follows:

- Up to 20 days of nursing care is 100% covered by Medicare
- After day 21 and up to day 100, patients will pay a co-pay that averages $170.50.
- After 100 days, all Medicare coverage ends and all payments are the patient's responsibility.

Medicaid Coverage for Nursing Home Care.This coverage assists individuals with many types of medical care including doctors visits, hospital stays and long-term care services such as those received in a skilled nursing facility. Often, this program covers 100% of these costs, but there may be co-payments for certain beneficiaries. For those who qualify for Medicaid, this is the best choice for nursing care coverage. Your Home does not count against Medicaid if someone else is living there or its less thant $595,000 (or $893,000 in some states). Medicaid may put a lien on your house to cover expenses on your death.

detailed analysis of the impacts on the extended family due to elderly caregiving. They found that more than 1 in 5 Americans (21.3 percent) are caregivers, having provided care to an adult or child with special needs at some time in the past 12 months. As shown in Figure 7, This totals an estimated 53.0 million adults in the United States, up from the estimated 43.5 million caregivers in 2015. When looking at caregivers for adults only, the prevalence of caregiving has risen from 16.6 percent in 2015 to 19.2 percent in 2020. They also highlight "*Unpaid caregiving is increasing in prevalence and the U.S. population continues to age and live longer with more complex and chronic conditions. Caregivers feel the push and pull of providing care on their time, their financial well-being, their health, their family, their work, and their own personal well-being. They may find themselves in need of information, resources, benefits, or programs—but these things are often difficult to find or access, or too expensive to afford. Unpaid caregivers are serving as a core piece of the health and long-term services and supports (LTSS) systems, as well as the main source for long-term care for adults living at home and in the community.*"

-

[8] AARP, *Caregiving in the US*, available here

| | 2020 Prevalence | Estimated Number of U.S. Adults Who Are Caregivers | 2015 Prevalence | Estimated Number of U.S. Adults Who Are Caregivers |
|---|---|---|---|---|
| Overall | 21.3%* | 53.0 million | 18.2% | 43.5 million |
| Caregivers of recipients ages 0–17* | 5.7%* | 14.1 million | 4.3% | 10.2 million |
| Caregivers of recipients ages 18+ | 19.2% | 47.9 million | 16.6% | 39.8 million |
| Caregivers of recipients ages 18–49 | 2.5%* | 6.1 million | 2.3% | 5.6 million |
| Caregivers of recipients ages 50+ | 16.8% | 41.8 million | 14.3% | 34.2 million |

** Significantly higher than in 2015.*

**Figure 7 Prevalnce of caregiving by age of recepient, 2020 compared to 2015 from AARP**

As shown in Figure 8, family caregivers[8] spend ~24 hours per week on their loved ones while 21% of caregivers are providing 41+ hours of care. The solution potential is to appeal to these family caregivers to give them the tools to have a more balanced life themselves and be able to use technology to be able to decrease the amount of active time that they spend with the parent(s) they are providing care.

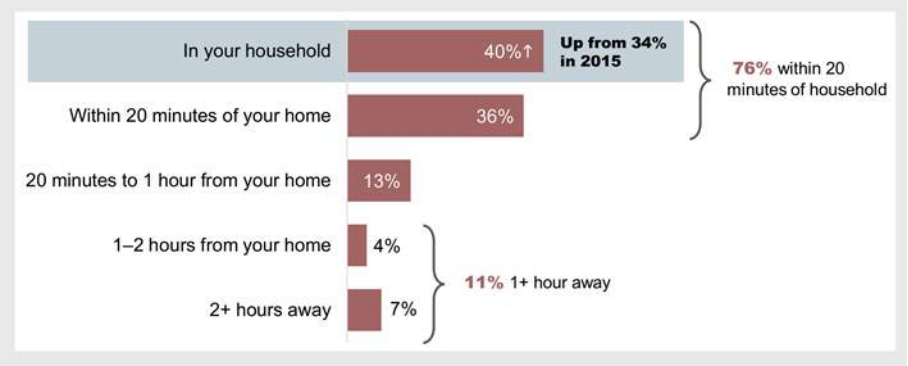

**Figure 8 Average number of hours per week spent by caregivers (from AARP)**

AARP analysis[8] also identified that, as shown in Figure 9, ~76% of the caregivers are within 20 mins from the care recipient and ~11% of them are more than an hour away. This also provides a good case for the monitoring solutions that can be offered for the AIP population.

**Figure 9 Caregiver distance from Care Recipient (from AARP)**

As shown in Figure 7, an estimated 40M Americans are providing care for older members of their family. These family careers often have severe impacts[8] on their own careers, finances, and ability to also save for their retirement and healthcare. *The technology solutions suggested here in this paper would offer many of these careers more time and the use of technology to be more efficient with their face to face time with their elder parents and in many cases remain remote for their parents for a lot longer in the Aging in place lifecycle.* Some of the aging population needs are well articulated in the National Science and

Technology Council report[9] as extracted into the insert *"Emerging technologies to support an aging population"* below.

**Emerging technologies to support an aging population**

This report identifies a range of emerging technologies that have significant potential to assist older adults, and it is offered as a guide for both public and private sector research and development (R&D) *to improve the quality of life, enhance individual choice, reduce caregiver stress, and cut healthcare costs*. The Task Force identified six primary functional capabilities as being critical to individuals who wish to maintain their independence as they age and for which technology may have a positive impact.

**1.Key Activities of Independent Living.** Living independently requires the ability to perform of a range of activities that impact our daily lives. Many of these activities can be assisted through technology, including those that support good nutrition, hygiene, and medication management.

**2.Cognition.** Cognitive changes are common during aging, with increasing prevalence at older ages—varying in severity and impact. These changes can affect the ability to live independently as well as personal safety. Technology holds the promise to help older adults monitor changes in their cognition, provide mental training to reduce the impact of these changes, and create systems that assist individuals and families to maintain financial security.

**3.Communication and Social Connectivity.** Older adults may face communication challenges as the result of hearing loss, social isolation, and loneliness, especially in economically distressed and rural communities. Technology can improve hearing and strengthen connections to larger communities.

**4.Personal Mobility.** Mobility is a key factor in successful aging. To live independently, an individual must have the ability to comfortably and safely move around the home and throughout the larger community. Technology can assist older adults in staying mobile and able to safely perform key activities necessary for day-to-day life as well as interact with their communities.

**5.Transportation.** True independence requires mobility outside of the home and neighborhood. Transportation needs and limitations are dictated to an extent by the changes to individual physical and cognitive abilities that come with age. While some older adults remain completely independent and continue to drive without assistance, others may be able to drive but require vehicle modification and/or advanced technologies to assist them while operating a vehicle. New technologies could also help older adults more safely and easily use public transportation.

**6.Access to Healthcare.** Access to healthcare plays a critical role in helping older adults stay active and independent as they age. Activities and strategies that support the maintenance of function and independence with age are multifaceted. Alignment and coordination of these efforts through technology can increase the effectiveness and efficiency of these services.

In the process of identifying primary capabilities and focus areas in which technological advances can have a positive impact in enabling older adults to age in place, several areas emerged that are associated with a number of technological solutions and were therefore not specific to individual R&D recommendations. These areas are included in the final section of the report, **Cross-Cutting Themes**.

[9] Committee on Technology of the National Science and Technology Council, *Emerging technologies to support an aging population,* March 2019, available here.

As shown above, significant work is in progress to address the aging population needs and one of the top priorities is to provide this to reduce the overall healthcare costs. It is also intuitively understood that aging in place will provide significant cost savings. Note that these costs are not all related to healthcare alone, as explained in the insert *"Emerging technologies to support an aging population"*. Some of the technological areas aging population require assistance is highlighted in Figure 10. Although this gives the depth and breadth of the needs for the aging population, the stepping stone for this is an **AIP Home**. The rest of the paper we focus on this application noting that the opportunity for the Cable operators is a lot more than what is covered in this paper.

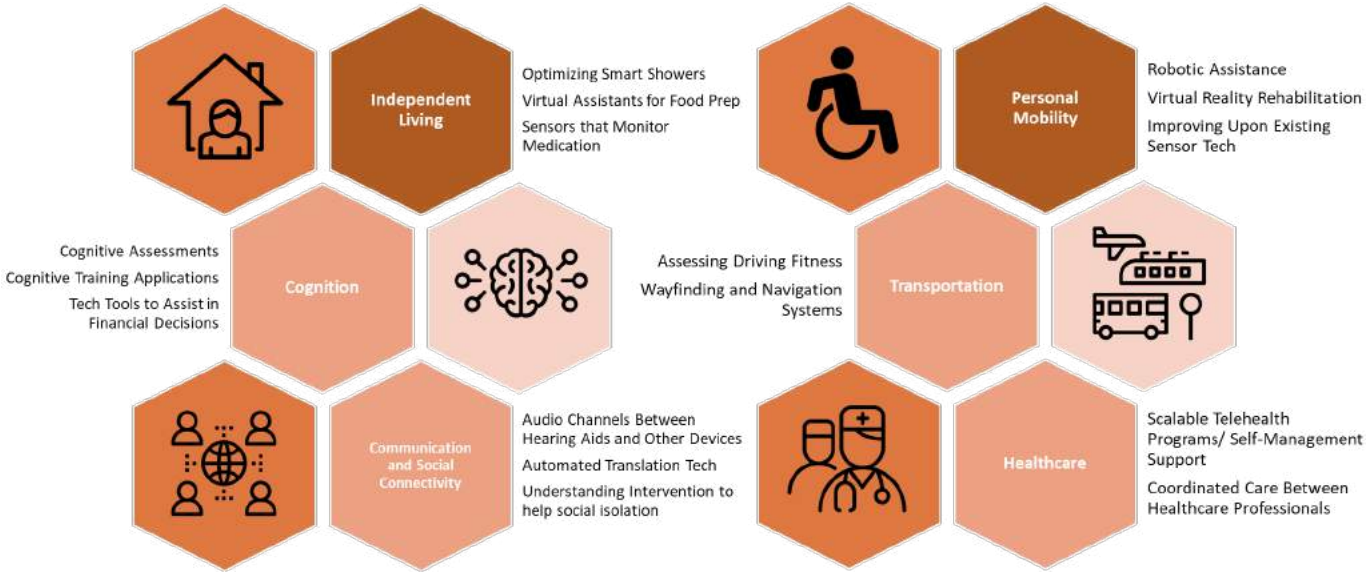

**Figure 10 Some of the example technological soutions required for the aging population**

As a first step to the business case, let us understand the current costs or payments by the elderly population. Then analyze this against the target population who can adapt to the elderly-friendly smart homes. In later sections, we analyze some of the solutions, as low hanging fruits, that Cable operators can offer to reduce the health care costs and its potential revenue opportunities.

Figure 6 provides the cost of the elderly population in different stages of support. The following discussion will outline different opportunities for the Cable operators -

- Provide a preventative/pre-emptive technology solution to the 55M maximum elderly homes
- Out of which 3.5M homes that can potentially use the solutions now with specific packages
    - This opportunity is going to grow to ~6M by 2050 based on population growth estimates
- Offer the technical solutions to reduce the human support for in-home care support costs
- Offer solutions to prolong the need for Assisted Living through different technical solutions
- Offer solutions to enable in-home nursing through technologies rather than Nursing Homes

Before we leave the business case roll up it is also important to consider the cost of insurance typically paid for the Aging in Place journey of your life. Fidelity Insurance[10] estimates that the average US Citizen is going to need $285K to cover the costs of Health in retirement. Annuity.org[11] shows that an 85-year-

[10] Fidelity Insurance, *How to plan for rising health care costs,* August 2020, available here
[11] Annuity.org, *Health care costs in retirement,* 2019 survey, available here

old couple in 2039 is likely to be spending $34K on their Health Care costs not inclusive of Long Term Care specific costs.

There are many healthcare costs related to technical challenges that can be addressed in an *AIP home*. Note that healthcare is only a small portion of the AIP needs (as highlighted in the *Emerging technologies support for AIP insert*). For example, technology can help with,

- Maintaining contact with family and neighbors to avoid loneliness and depression
- Minimizing the likelihood of accidents and issues in the home
- Getting to someone quickly when falls or other medical issues happen
- (Possibly) Following doctors' orders on diet and medication

A simple representation of some of the technology services that could be implemented to curtail physiological, medical issues as well as improve help time and quality of life for those with deterioration in being able to look after themselves. Figure 11 shows some of the technological services that can be offered to the aging in place population.

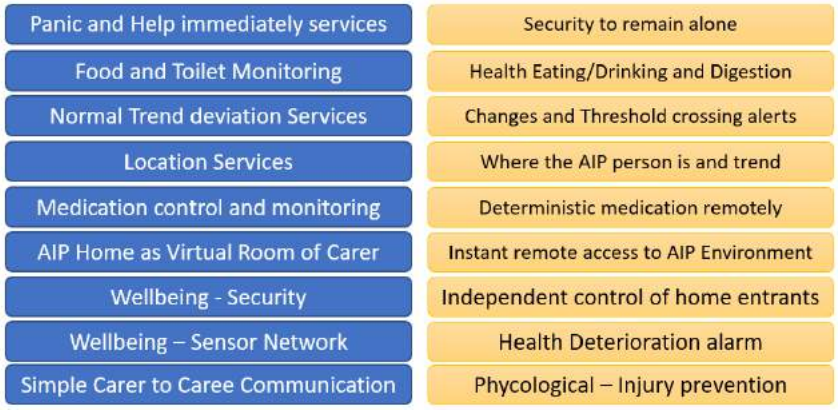

**Figure 11 Simple technology solutions that can assist aging in place**

HIPAA considerations: Medical information is protected by HIPAA[12] (Health Insurance Portability and Accountability Act) Patient Health Information (PHI) handling rules. It is important to stress that the Cable Operator offers service to an *AIP Home* and the person is **NOT** to be a medical service provider. ~~-or potentially not even to perform the functions of a Care Portal (Where any telemetry from the AIP Home is stored).~~ It is worth exploring this more as one of the main questions in the business case for Aging in Place - the liability and responsibility of Cable operators in *AIP Home* service. The collection of telemetry from the Aging in Place home that collates to provide services to the AIP person is the activity we are targeting for the Cable Operator opportunity. The information in the telemetry can be wide-ranging from –

- Non-PHI related AIP application activities - watching TV, motion derived from Wi-Fi detection
- PHI related information like the collection of BLE based health sensors - thermometers, pulse oximeters, blood pressure cuff
- Not so certain PHI information which on its own is not medical information but can be used to derive health issues and is not subject to HIPAA PHI on its own
    - the collection of other sensors BLE, ZigBee, Wi-Fi, Z-wave, others that perform other detection sensory functions (room presence, door open/close, fridge open/close, pillbox opened/closed)
    - the use of cameras for visible monitoring and internal home transparency to approved carers

[12] HHS.gov, *Guidance Regarding Methods for De-identification of Protected Health Information in Accordance with the Health Insurance Portability and Accountability Act (HIPAA) Privacy Rule*, Nov 2012, available here

    - the use of audio devices to detect cries for help
    - the use of panic buttons for emergency help solutions
- Highly PHI associated information such as the specialist internet-connected home medical equipment ranging from pill dispensers to chronic illness support like cloud-controlled and monitored dialysis machines.

These all have varying degrees of issues with privacy, reliability, a consequence of correctness. It is envisaged that most Cable Operators will not provide the AIP care portal solution (for the purposes of this paper's scope – think of it as the interim database of the parametric information collected from the AIP home to perform the AIP service. This database and API interfaces are subject to the rules of privacy for both home and medical (if recorded) information). As shown in Figure 12, the cable operator can use two simple mapping models.

(Model 1) Cable Operator provides **only** a connectivity solution and a set of cloud services to the AIP solution and AIP care portal – forwarding AIP telemetry in a pass-through model to Healthcare Delivery Organizations (HDO's). The client solutions in the AIP solution set are typically supplied by the AIP portal company and in many ways are anonymized to the Cable Operator who may only provide a certain hub and display and audiovisual help services – driven by API's that can be accessed by the AIP solution provider. This access to this cloud, App, and API services can be a 'charge for' service – particularly gaining access to Operator provided device resources in the home. HIPAA compliance is a wide-ranging area which we will outline briefly later in the paper but this solution offering works to abstract the Cable Operator as much as possible from any HIPAA compliance requirements. With the increase in privacy requirements for every Cable Operator and consumer engagement, Cable Operators are already becoming familiar with the security and privacy of data and have implemented solutions themselves and with vendors like CommScope and others to ensure compliance to privacy and security. In this architecture, the Cable Operator provides a business service to

- AIP Care Portal companies who make the compliant linkages to AIP homes and the AIP resources that need to help them like Care Companies and Medical support
- Collects a fee from - AIP person or carers, selected Care Company service provider – allowing them access IoT Hubs, Displays, another home telemetry including voice and audio services.

(Model 2) An argument could be made that the Cable Operator could actually perform the Care Portal function explicitly as an extension of its own Home telemetry databases. The Cable Operator already performs smart home and IoT functions and many of these functions overlap with the same schemes for AIP solutions where some of the IoT devices are recording health information. The Cable Operator can provide the necessary security, privacy, and anonymization features to the northbound AIP resources including medical analysis services. In this scenario, the Cable Operator could expand its Smart Home or Security services to cover some of the functions of response to AIP issues and response requirements. The Cable Company could also partner with AIP solution providers to give them access to their Care Portal solution as part of their service. The Cable Operator would take a percentage of the direct to AIP person service charges for the use of its Aging in Place Care Portal and in-home devices and telemetry services.

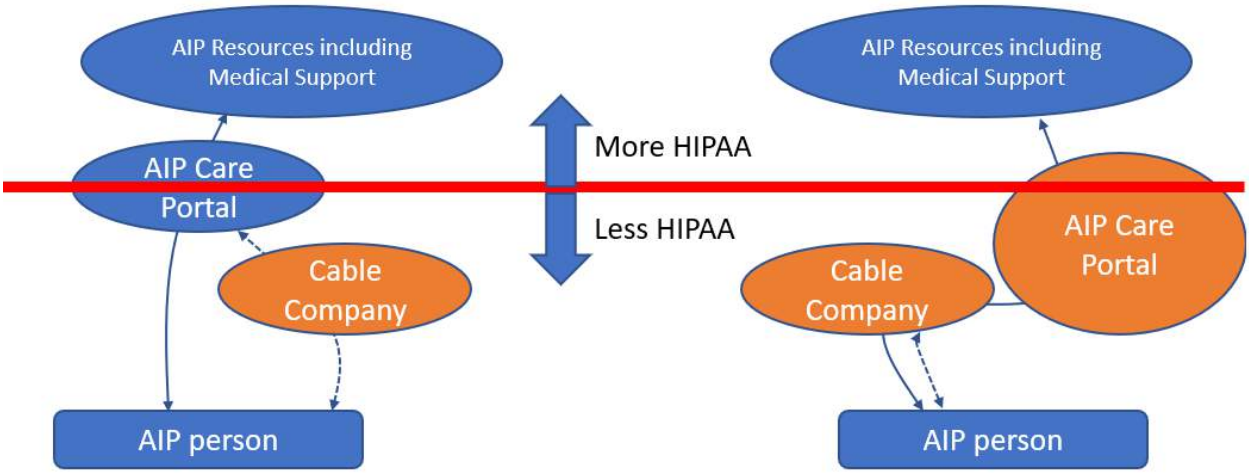

**Figure 12 The two potential solution architectures for AIP services from Cable Operator**

Expanding on the issues around liability and having now introduced the HIPAA and PHI words let us spend a few minutes and discuss some of the key areas that typically come up when discussing Health over Cable solutions

- Medical Liability when offering services that can be tagged as pulling health or medical information from the home or devices
- Offering emergency alert solutions like panic buttons and not fulfilling SLA with consumers on the reliability of emergency alert solutions.

As stated earlier – the goal of the Cable Operator Aging in Place solution is to pick the solution set to **minimize** any interpretation or prognosis of medical data and to align an AIP solution more with the Home Security offerings of the Cable Operator – where the key issues are reliability of connection to the cloud – and the ability to hand off the telemetry information to the Security service provider and call-out services.

HIPAA (Health Insurance Portability and Accountability Act) is a broad-ranging Act but the key element of it for AIP solutions is to adhere to the HIPAA privacy regulations and provide the defined protection and confidential handling of health information. The National Institute of Standards and Technology (NIST) and the National Cybersecurity Center of Excellence (NCCoE) have been defining standards to make sure that medical devices cannot be compromised, and privacy standards are maintained. There is a new term used on the Internet of Medical Things (IoMT). There are probably two basic levels of worry of exposure

- Informational leaks about the individual's medical conditions, health status, changes in health etc.
- Unauthorized, incorrect, or illegal changes in any medical parameters or status that can inadvertently affect the person or are illegal. This particularly applies to any AIP solutions that have changes made in the conditions in the home like
    - Changes in recommendations for medication dosage via reminders or other technology assists
    - Changes in chemical mixes in sophisticated medical devices like infusion pump based delivery systems.

To reemphasize, the cable operator approach to Aging in Place solutions will be to provide the best possible solution to minimize exposure to the deeper medical elements which will typically be offered by partnered solution and the key thing for the Cable Operator solution will be to leverage

- Devices and Hubs to connect to overlaid AIP devices
- Provide reliability of connectivity service
- Provide an AIP Consumer Experience in its own Consumer Experience across its ownership of devices like a TV screen
- Leverage its non-PHI telemetry to create economic telemetry streams when correlated with AIP devices strengthens the Cable Operator value in the AIP value chain

A typical reference architecture for Aging in Place and intervention Telemedicine is shown Figure 13.

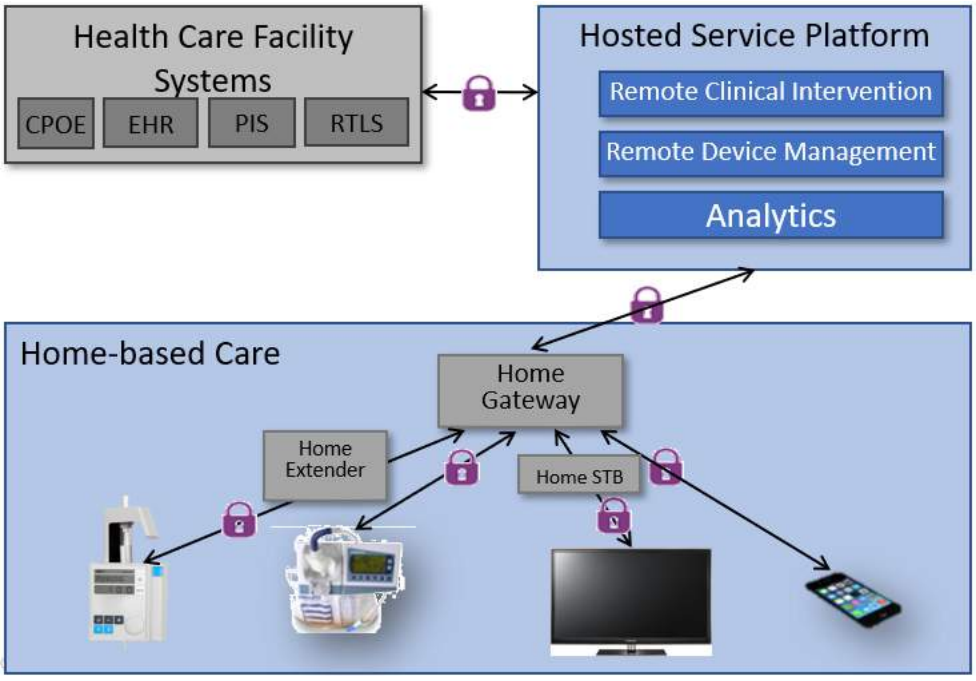

**Figure 13 Potential 3-way solution set for Aging in Place and Medical intervention**

A more detailed but simple illustration of the AIP value process for the Cable Operator architecture in AIP is illustrated in Figure 14. Whatever path the Cable Operator goes in the value chain of Aging in Place they are positioned well to be able to offer the service or partnered services through their

- Ability to market services into the 65+ bracket homes they provide broadband and video services
- Ability to market to the kids and caregivers of an elderly parent(s) who are also in their network
- Potentially also collaborate with each other on AIP services across different partnered Operator Networks. This is the case where the AIP home is in for example Mediacom's network and the Kids and Carers are remote on a Comcast network.

It is this ability to market, fulfil and support the service as well as the integration of the solution into the Connectivity and Video offering (detailed later) that drives a strong case for the Cable Operator to insert in the value chain of Aging in Place.

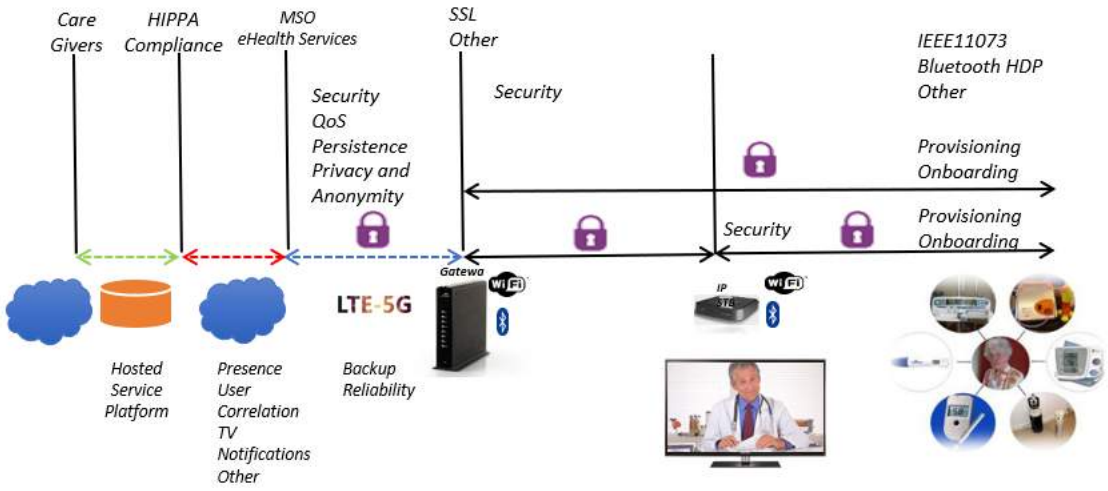

**Figure 14 Key Elements of the Connectivity Solutions for Cable Operators in AIP value chain**

## 3. Connectivity a major element of the Aging in Place solution

Now, let's start to develop the pillars for the Technology solution and Connectivity solution offerings that the Cable Operator can offer to the Aging in Place home on its network.

The key is using the broadband connectivity provided by the Cable Operator to form the basis of the AIP solution. As shown in Figure 15, the 65+ group is one of the demographics with the lowest internet connections and in 2020 it is ~80% of the population. As part of technology based AIP solutions, there will need to be some new additional connections and the new costs introduced for broadband services. Cable Companies should consider some new reduced rate services for these initial connect applications to onboard the AIP home and then grow the value of the connectivity with the payers of the home connection.

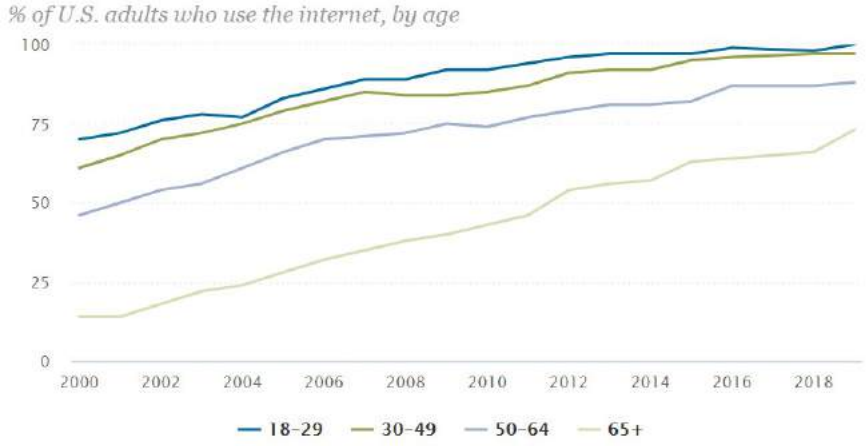

**Figure 15 US - 2000-2019 Adults connected to the Internet by age**

One additional point of note is that there are many people who are for connection to elderly people using technology tools themselves for communication and in some cases do-it-yourself monitoring and even more advanced health-based monitoring solutions. These solutions typically comprise of – video conferencing capable phones (Apple Facetime, Google Duo) for visual contact, smart speakers (Alexa Dot and Show, Facebook portal, Google mini, Google Next Hub), solutions like Alexa Drop-In – which allows an incoming call to be answered without the user having to pick up, emergency alert pendants, cameras,

some sensors for movement etc. But typically they are not going beyond this small subset of solutions into more complex and linked monitoring and activity promoting solutions.

However, it should serve to highlight the basic importance of connectivity. To create that connection from remote carer to AIP person and to make the visibility into their current status something that can be checked by simply looking at an application on your phone. This is key also to the business proposition of Aging in Place. To be able to

- Make the carer infrastructure remain remote from the house as long as possible
- Only have the carers in the AIP persons home when they desire or is necessary or scheduled
- Minimize the carer travel cost and optimize the efficiency of the time they spend face to face
- Allow multiple carers to share the burden of care with technology to help them all see the daily life metrics of the Aging in place person and spread the response amongst more than one individual for different activities (Remote carers can take a watch on cameras placed in AIP persons home or monitor alerts to alleviate this burden from carers)
- Allow the AIP person to remain in control of their own care needs through initiating help
- Become independent and remove burden that an AIP person may cause on their family
- Spend wisely by the AIP person or their family carers in covering any AIP costs. This sometimes translates to not spending money on even Internet connectivity for the elderly and certainly slower to invest in technology solutions and Do-It-yourself plans.

The last point 'spend wisely' is an interesting part of the AIP journey and especially when a decline in ability is slow but steady. Our elderly from 65 onwards, are a generation where saving for 'a rainy day' has always been in their minds as well as trying to also leave their kids something to improve their lives. Additionally, when small issues around ease of mobility or getting more chairs bound to creep in, there is not an immediate tendency to start spending money to get help a few times a day to move to different parts of the house. Indeed many or all AIP persons tend to soldier on at tasks that were once simple like dressing in the morning but have gotten much harder due to arthritis or other ailments – and don't think to look for a morning help service until they reach absolute inability to do the task. People and the Elderly with limited and finite resources will not spend money for help until its usually past the time they needed it. *It is this fear of opening the dwindling bank account or running up debts that many times inhibits an AIP person from using $20 per hour to help resources to enable them to keep quality of life and continue to function well in their homes. This can be one of the biggest drivers of creating a Cable Operator connectivity led Aging in Place solution that provides elements that always show the cost efficiencies and return on living at home longer.*

The Figure 16 below illustrates a typical three phase potential decline in the Aging in place process. For most people, the journey starts where you remain independent even if afflicted with some health and mobility issues. Most of the solutions for technical support of AIP rely on sound mind and diseases of the mind while they can be still supported with technology often and most of the time involves rely on heavy personal contacts of carers.

As you can see in this very simplified approach to Aging in Place – the first phase of reasonable health is the 'monitoring phase'. In this phase, connectivity is used to provide remote access for carers to the health of the AIP person and their daily status. *One of the key elements of a Cable Operator Aging in Place offers is to promote the on-ramp of this stage process to the 65-year old that probably feels they don't need this phase of monitoring until it is required which is sometimes too late for the avoidance of issues.* We will discuss some on-ramp options for Cable Operators later in this section– particularly with the monitoring service tied to existing devices the AIP person has in the home for access to internet and video services.

 

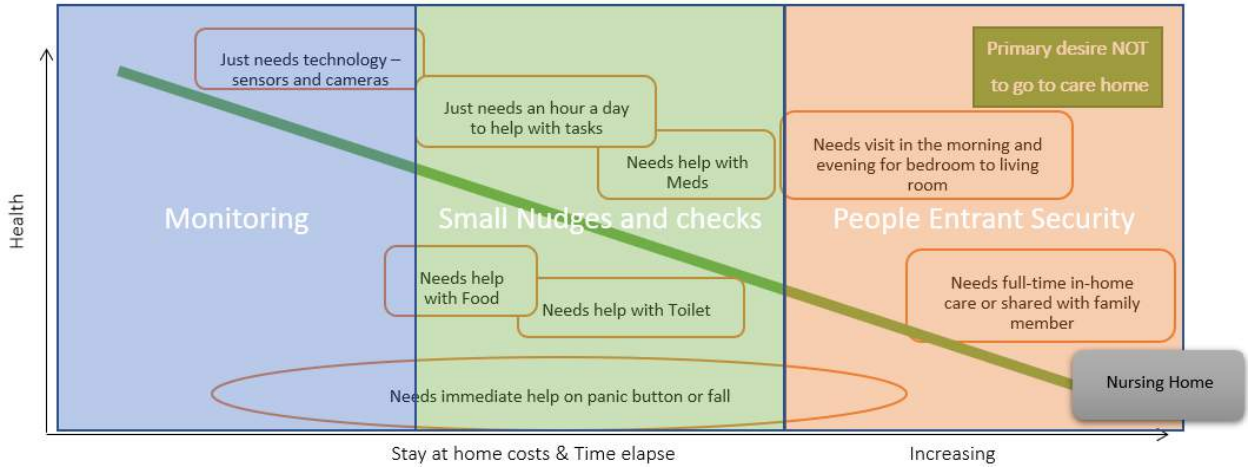

**Figure 16 The Simple Phases of Aging in Place decline**

Monitoring needs to be clarified before we progress. Monitoring, as shown in Figure 17, has usually two aspects when discussed with Aging in Place solutions

- Family carers monitor a parent or parents who are starting to decline a little or through a period where they have to take medication for improvements – *the focus for Cable Operator solution is probably to define a package and market to this audience.*
- Professional monitoring where any home readings go directly to a Care Portal for professional review with an intermediary (doctor or care company) – *this can be done with business development functions directly to the AIP companies in the area.*

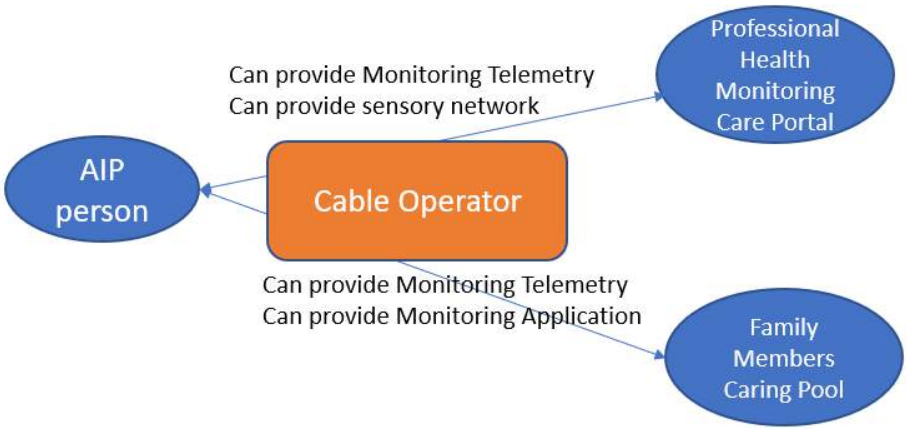

**Figure 17 Cable Operator Connectivity can provide the basis for Monitoring Services**

There is an opportunity for the Cable Operator to really own the first and to partner with companies who provide the second option. During this monitoring phase – the focus for a connectivity solution is to be simple. There is a simple hierarchy of monitoring all of which can be offered at different prices and levels of sophistication. The first is the availability of the connection catering to different requirements of reliability and price points.

- High Available connection to the home – typically with a Cable/DOCSIS/Wi-Fi first and backup with LTE or 5G NR (which can be pay as you use basis to make it more cost-effective)

- Leveraging the general DOCSIS broadband connection for the majority of all monitoring solutions and typically of high availability. *Solutions can be added to the Cable Operators' own monitoring of their network to immediately alert any AIP monitoring solutions when the DOCSIS network has dropped – allowing the carers to use other methods of contact (direct calls to LTE/5G based phones or get someone to the AIP person).*
- Leveraging the existing device ecosystem in the home to create a convergent solution offering across the Broadband and Video services which offer reuse opportunities for Aging in Place.
- Leverage the increase in deployment of Smart Speaker assistants that support both Audio and Visual feedback and output.
- Leveraging the increase in deployed IoT radios, in particular, BLE which is becoming the key remote control interface to Set Top Box and Smart Media Devices.
- In particular the key use of the connected Smart Media Device as the connected Hub of Aging in Place services.

Bringing back the connectivity architecture, as shown in Figure 14, the key elements of the connectivity chain, ensuring security on the link, ensuring persistence of data sending, ensuring privacy and anonymity, and ensuring simple onboarding and provisioning of AIP devices/services. All based around the key devices of broadband GW and Wi-Fi, and Smart Media Device (with inclusive BLE and Far-Field Voice and Speaker technology).

Much of the AIP service can be served with this simple and for the most part – a normal home device and connectivity ecosystem. *This is key to the Cable Operator business case in that the investment in AIP capital expenditure is aligned with the general capital expenditure for the new Cable Home inclusive of IoT, Smart Assistants, and the migration of the STB to the Smart Media device.* The SMD will be explored in more detail in the next section of the paper as it is the key device and hub to offer the AIP Cable Operator service. The key areas of transparency in the home and ability to capitalize on both the standard Broadband and Video devices are issued and the general IoT devices supplied as part of smart home and security applications. There is a natural sensory network now emerging in the home – with (i) Wi-Fi (ii) BLE (iii) other IoT radios like Zigbee and Zwave (iv) Voice input – that can provide the foundational pillars of Cable Operators Aging in Place hub and interface to partner AIP services.

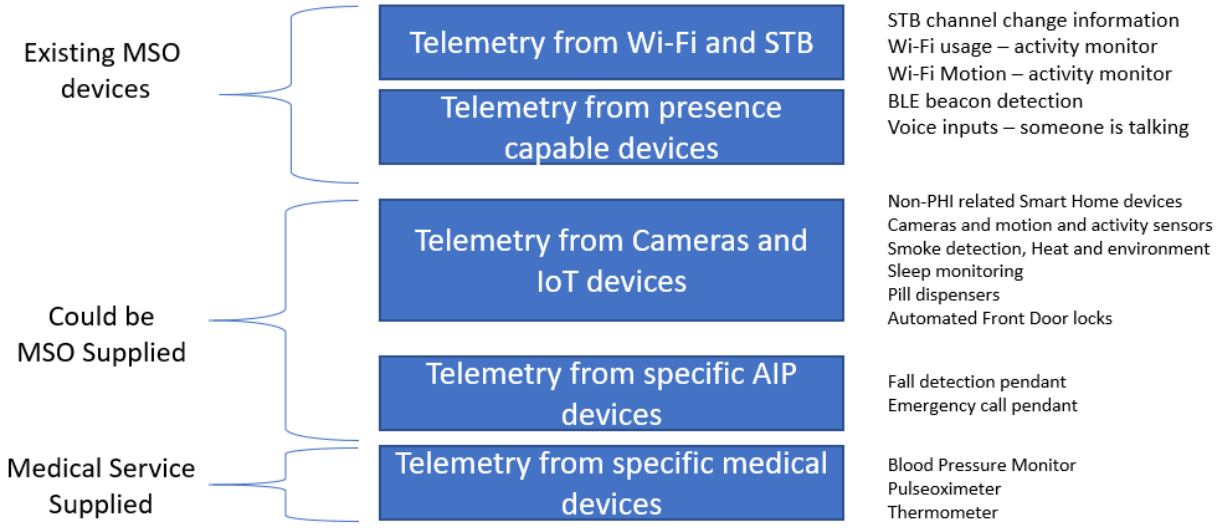

**Figure 18 The five classes of device types that make up the AIP telemetry solution**

Probably the most important connectivity and monitoring feature is just the ability to easily contact the AIP home remotely but with the following problems that a better solution than just calling them on the phone has to offer

*i.* **Video Chat** is always better than just voice for better and more personal interaction as well as the psychological benefits of more intimacy. Additional regular video views of the AIP person helps to do visual checks from carers. *Video transparency of the AIP home is probably the #1 fundamental connectivity feature and it alone could be improved to form a basic package to the AIP home*

a. As Elderly people age – the ability to use the Tablet and Smart Phone can diminish. Phones can get lost and require mobility to find them. The use of static Video Conferencing solutions is a key part of the communication reliability to the AIP home. Cable Operator provided Video Conferencing solutions are an important part of the AIP solution. One of the key functions of the evolution of STB to Smart Media device is to support Video Conferencing on a TV – the primary screen that most elderly's spend a large portion of their day and is present in the rooms they occupy most. The TV itself also has the advantage of size and accessibility features for hard of sight and hearing. Even the humble TV remote can also be a more friendly interface device than a complex smartphone.

ii. **Use of Voice as an input to the Aging in Place solution**. The advent of Smart Assistant technology has now found a home as part of the Aging in Place solution. Providing a cheap way to have whole-home coverage of a smart speaker and communication solution but most importantly as a way to be able to offer remote intercom support easily. Being able to reliably contact Mam or Dad when they have mobility issues and always be able to connect with them is key to the immediacy of monitoring – feeling that your parent(s) are in the next room and simple check upon them with an intercom solution. Today Alexa Smart Assistants for example offer a drop-in capability where a carer can immediately drop into an AIP home with Alexa's drop-in enabled and the incoming voice or video call is automatically answered by the AIP Alexa device. This is an enormous advantage in the process of communication with elderly AIP persons with more and more of their time spent in one or 2 sitting locations during each day. Removes the issues with regular phones and smartphones

a. Always powered in Smart Speaker – so no battery rundown of mobile phone
b. Permanently located in the room and always available – DECT and Cordless phones getting lost
c. Does not require the AIP person to get up to find or answer the phone
d. Offers the ability to also do simple remote doctor visitations using quality video conferencing camera and audio. No issues with poor microphones or covered microphone muffled voice
e. Can use audio-only smart assistants in modesty rooms like bedroom and toilet. Can be a simple emergency solution for toilets to provide immediate audio linkage when required or allow fallen AIP person to call for help as augment to a pendant solution.

**iii.** **Use of Cameras in the AIP person's home.** The use of Cameras in the home to allow remote visual monitoring of the AIP home is a key part of the ability for someone who is usually on their own and does not have a daily person call and spends days on their own. Cameras can be seen as too invasive for many people to have in their home watching their every move but when confronted with the choice of (i) paying for home help (ii) burdening your kids and carers to call often and spend more time checking up on you (iii) not wanting to use other sensors in the home – the camera can be the best option for the AIP person to remain at home for as long as possible.

a. The key to the camera solution is to use them in the context of the AIP lifecycle and in particular when people have limited movement and ambulatory problems. When AIP persons are constrained to living in their house 24x7 and do not drive or only leave the house when family members take them out they usually get constrained to spending most of their time in 3 rooms in the house. With some mobility, they spend their times typically in 3 rooms – in kitchen for meals and variation of time spent in the room, in living room typically in front of

 

the TV and for change of location to kitchen, bedroom. The kitchen and Living room with camera additions give huge telemetry and contact with AIP to allow the longest periods of no visits to the AIP person or minimize the simple checkup time spent. When the AIP person's mobility is compromised they become essential to allow someone to remain in their home. They can even afford someone to spend all their time in a bed with the comfort of immediate access to their wellbeing and contact by remote carers and nursing staff.

b. The key to the camera is to also offer
    i. Motion and the new person in House triggers – as Carers and Kids cannot spend all day looking at Mom or Dad in their home
    ii. Fall detection – improvements in AI is now making this possible
    iii. Facial detection – improvements in the technology now make it capable to recognize regular visitors and carers vs new entrants to the home
    iv. Health checking by Camera – High-resolution IR capable cameras allow the ability to detect pulse rate, potential high and low blood pressure, changes in walking gait and other medical insights
c. Also offer fire and other detections (my not be as good as dedicated sensors for smoke or fire)
d. Offer with inbuilt speakers and mic – an alternative to connect if the primary phone or smart assistant connection is not working. Many cameras now have mic and speakers built in to be able to communicate briefly into the room.

Monitoring forms the most important phase of any Aging in place solution. One key question is will 65+-year-olds or their carers see and understand the value of having or providing an AIP monitoring solution. An effort will need to be put into marketing the solution values and the importance of early adoption and not the usual 'wait for something to happen' before doing something about it. The other element of monitoring is to provide a simple converged solution that is packaged like a typical MSO service where it's simple and integrated into the existing offering. The competition for an MSO monitoring solution is the Do it yourself process – so the integrated offering in the typical broadband, video, and mobile solutions of MSO will be the key driver to adoption.

The Figure 19 below shows the simple effect of the five simple MSO supplied or leveraged devices and sensory information to provide the single most important, simplest, and most effective service of AIP – the decision for carer or kids to visit their AIP parent. While visiting Mom or Dad can be a vocation for many carers and as we showed in earlier sections that 65.7% of kids are close to their parents and about 10% are very far so need remote monitoring. But as we have also shown even when carers and kids are close to parents it is a huge stress on their own lives and their time. *This monitoring solution offers as much potential to those kids as the far away remote kids – to provide as much care time as they can without having to visit because of worry of falls or other 'absent' information from their parent's home.* Philosophically it is a balance between their life and their parent's life and the heavy burden of guilt vs a nursing vocation drive. What this technology solution offering does is to provide the balance that seems to work with

- 100% reliable remote communication to Mom or Dad – avoid that huge frustration of not being able to contact home and worry
- Simple video triggers throughout the day – allowing an easy email or app scan to see AIP person is in good form and up and about
- Periodicity of function changes – AIP – especially when confined to house or room for much of the time gets to be very deterministic in events from the home (TV habits, motion habits, sensor value consistency) and these simple snippet updates give a fast 10-second 'everything's ok' view to the carer

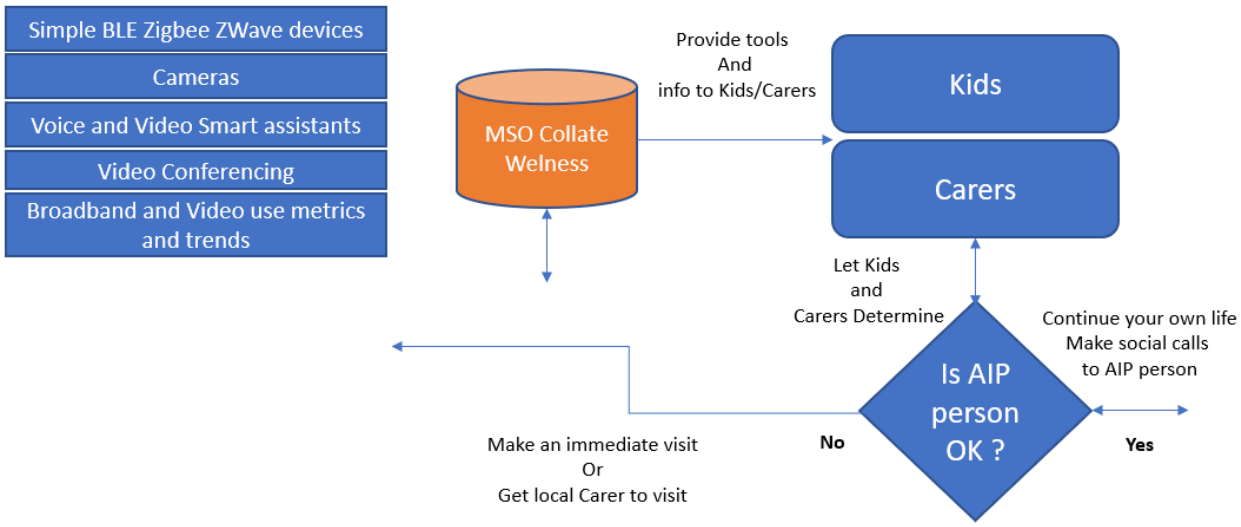

**Figure 19 The simple monitoring flow diagram for AIP**

The second phase in the AIP timeline solution is the 'Small Nudges and Checks' stage where the AIP solution gets more proactive in its engagement with the home. The areas that a proactive attempt at helping the AIP process in this stage are

- Reminders and Notifications: Medicine and medication reminders, doctors' appointments, scheduled visits to the home, bill pay reminders etc.
- Nudges and Checks: Take readings from any supplied IoMT devices like blood pressure or thermometers. Often the condition of not doing doctor visits is that the AIP person has to take their own readings continually. Automated locking of doors by adding smart locks to the doors. Leverage of Camera-based smart DoorBells, Automated turning on and off lights, Heating and Cooling use/on/off nudges and reminders, Food ordering nudges based on access to food order information, Pushed information from their carers and children – display on TV

Solutions already exist for these types of notifications and reminders but are usually SmartPhone driven and in recent times there have been extensions to smart assistants to also set up important reminders. The issue is a typical one that is also found in IoT generally in that it is

- Not fully understood by the population and demographic of 65+ AIP person and often not even by their Kids or Carers that these tools exist
- Still relatively complex for the majority of people
- Disaggregated and not consolidated in a simple Consumer Experience

For notifications and reminders, the Cable Operator has a better solution potential than the SmartPhone applications and that is the leverage of the TV as the main portal interface for all AIP communications. The ability to be able to access this large-screen format to affect these Aging in Place applications removes much of the inertia of the 3 issues above.

- Cable Operator provided a portal solution that can mix in AIP notifications, Video Conferencing in the same CX solution for the lean-back video experience
    - Can leverage the directions of the 2 most popular middleware solutions on STB/SMD to add services and applications
        - AndroidTV and App Store and other AndroidTV services

        - RDK V and the evolving improvements in the Downloadable Application Container solutions for both STB/SMD and Broadband devices
- Made simpler to work in lean-back mode utilizing simplest input devices
    - Aging in place adapted remote controls for ease of use. In some cases, it can be a large button remote for hard of sight elderlies
    - Use of Far-Field voice to provide input to the services and replies
    - Larger Font displays through the accessibility feature available in RDK and AndroidTV for sight-impaired AIP persons
    - Higher Audio playback for hard of hearing AIP Persons
- Even the control of the AIP persons STB/SMD by the remote Carer or family member to get the right channel or program is a well-traveled issue that many have seen when they are caring remotely for their parent(s)

Perhaps the most important nudge of all is the reminder for taking medication which in itself the feature dwarfs all others as the largest payback for the AIP process. Many AIP persons forget their medication or take it incorrectly. One simple scheme is to couple the notification of medication schedule with the TV experience and uses it to prompt for medication or taking readings from supplied IoMT devices. The TV screen and its engagement with AIP persons is a key opportunity to be able to provide all AIP services on the 65" palette that is the TV.

The last simple role the Cable Operator can play in the Aging in Place solution is the ability to help in the entrance and tracking of people into the AIP home. This is one of the key issues of the AIP process especially when there is a lack of mobility and hearing and the process of answering the door is both a difficult process and also opens security issues. Even when using solutions like food delivery when the AIP person is no longer driving on leaving the home un-aided the ability to answer the door can be the main inertia to the person staying on their own. So, a simple addition of a smart front door lock and camera solution tied to the Cable Operator solution and allowing

- Visibility of who is at the door – not only to AIP person but also to their carer or kids
    - On the TV screen and the smartphone app for both the AIP person and Carer/Kids
- Ability to open the door from the TV remote, voice or smartphone application – both for the AIP person themselves and the remote Carer/Kids
- Logging of open and close door events including thorough checking of the locking process of the door after people have left. Potential separate camera verification.

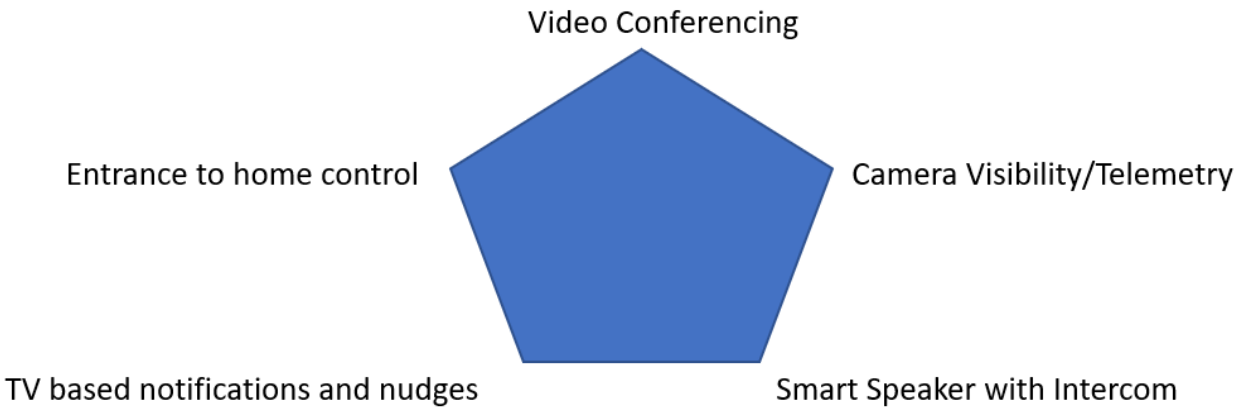

**Figure 20 The 5 key tenets of simple AIP solution set for Cable Operators**

With these 5 simple features, as shown in Figure 20, integrated into the Cable Operators current offerings and devices, there is a high probability of covering the key features that are required to provide the tools to the AIP person(s) to be able to control their own lives, reduce the burden on their Carer and Family circle and provide the realtime transparency to the home so that any event that happens that threatens their health is responded to immediately – either through direct voice and video access to the home or the dispatch of someone close to the home. This solution works really well for local carers and family members to keep their time optimized for f2f visits and removes much of the guilt of family members who are not close to their AIP parents by being able to cost-effectively direct local resources to help only when required or in a normal deterministic schedule.

The cost of these solution elements is also very low from both a capital investment perspective for both the Cable Operator and the Aging in Place home.

For the Cable Operator, the cost elements overlap a lot with the capital investment for the broadband and video and phone experience and the main constituents are

- Broadband Gateway with Wi-Fi – the **amortized cost for Broadband Service sale**
- Smart Media Device – **amortized cost with Video entertainment experience**
- Smart Phone Device – **amortized cost with Mobile service if offered by Cable Operator**
    - All AIP App elements can be downloaded on a third-party device
    - AIP person and their Kids/Carers also download and use Apps as part of service
- Operator supplied
    - Camera(s)– Prices can range from $25 to $900 depending on solution quality
        - Camera additions to Smart Media Device for lean back Video conferencing
        - Camera additions to other non-SMD locations
    - Additional in-room audio smart assistants – Prices can range from $55 to $180 depending on the configuration
    - Smart Door Bell including camera – prices can range from $120 to $300 depending on configurations
    - Smart Lock for Door – prices can range from $150 to $300
    - Optional LTE/5G backup devices for Broadband services
- Cloud storage and transaction costs for device telemetry and cloud to cloud partner and Care Portal engagements
- Additional Technician costs for installation of AIP additional devices in particular Front Door solutions of Doorbell and Camera
    - There is the scope that these can be done as Self Install Kits given the reasonable simplicity of Doorbell and Lock installs
    - Internal Camera installs can all be self-install for AIP or Family members to do

# 4. The Cable Operators solution play for Aging in Place

This section along with Appendix A, will define the recommended AIP Home architecture and the role the Cable Operator can play to provide a valuable service to this market where the price of staying at home as long as possible can sometimes be not even defined in monetary terms. Finding the balance of

(i) Existing CAPEX spend and OPEX spend on install and support for Broadband Video and Mobile services

(ii) Adding in additional elements to the existing Broadband Video and Mobile devices to support the AIP market and to abstract this for maximizing the almost 9% of your network

and 55M people in the US that can avail of the service. Sharing this CAPEX investment is key to the business proposition

(iii) Looking at the extension of Aging in Place investment and it's additional overlap to the Telemedicine business for **EVERY** customer on your network. Aging in Place solution and Telemedicine services have a lot of overlap with investment and partnership opportunities

(iv) What the Operator provides vs Care Companies, Insurance Companies, Health Providers and Government support agencies for improving aging life and reducing the cost of out of home care

(v) Providing client devices that add to the support of Aging in place but minimize the medical nature of the offered AIP service. Leveraging a Smart Home and Security solution to also support key non-medical Aging in place services

(vi) Leveraging existing Cloud services to create the Cloud to Cloud telemetry connections to specialist Aging in Place partner solutions.

(vii) Leveraging the change in services architecture paradigm of moving away from locked Operator services on Broadband and Video devices to one where containerized service can be added to the connectivity network to effect new services through the devices and endpoints in the home.

Figure 21 illustrates the key eleven elements of the Cable Operators solution for *AIP Home*. These solutions focus on the simple non-medical elements that make Aging in Place work with the virtual access to the home by carers and family. It also allows the Cable Operator to partner with AIP partner companies offering resources and services to the AIP process ranging from - home help services, food and meal preparation services, medical services, insurance services, specialist care services, etc.

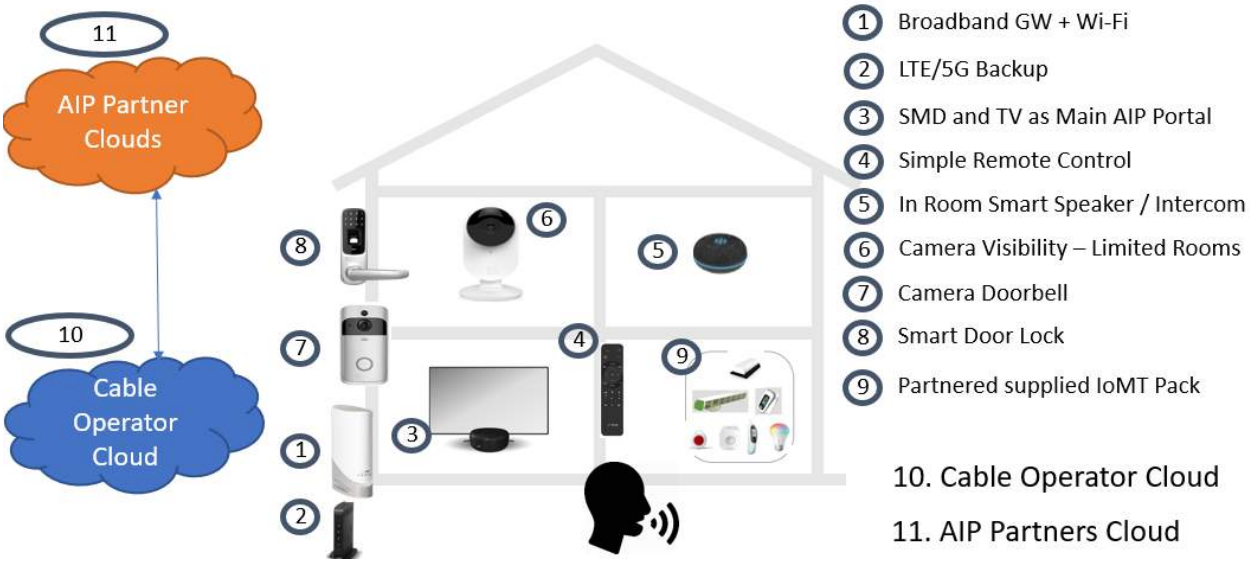

**Figure 21 Eleven key service offerings from a Cable Operator to support AIP Home**

A detailed discussion on these eleven services, their needs, the opportunity, the cost (CapEx and OpEx) implications, and the application extensions (such as telemetry) are provided in the Appendix.

## 5. Business case with estimates of tiered service prices

Before putting together the business case for the AIP solution proposition for a Cable Operator, let us look at some assumptions –

- The average life expectancy in the US is 78.6[13] years in 2020 and it is trending up: The likelihood of people dying or leaving their home is part and parcel of the AIP business case process. When you are selling solutions and investing CAPEX in the 65+ customer base you have a much higher probability of any invested capital or install costs for recurring revenue that may not reach their full potential. The life expectancy of 78.6[13] for the US population determines your strategy. Figure 22 the probability of dying at different ages. This gives an idea of how the aging population and their supporting team think about different investments to the *AIP Home*. So, for risk mitigation, it probably drives a balance of getting some upfront capital investment costs for any solutions offered and a recurring revenue opportunity.

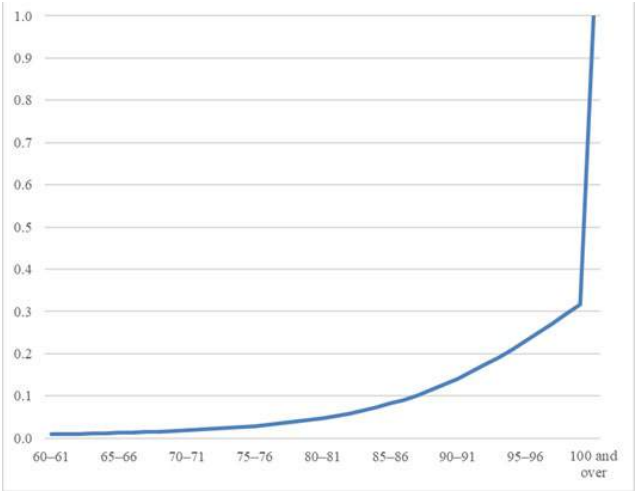

**Figure 22 Probability of dying between X and X+1 years**

- The financial stability for the aging population from a Lifetime Income[14] point of view is essential for the future *AIP Home*: Increasing life expectancy and lack of proper financial planning will severely impact the lifestyle of the aging population. Supporting such financial services and also bundling the technical solutions to meet with the *AIP Home* is essential for the wide-scale adoption of the services that we discussed in this paper.
- The fragility of the aging population forces innovative and expeditious services: Injury like a broken hip (300,000 seniors break a hip in the US each year of which 70% of them are women) forces the aging population, especially *AIP Homes,* to adapt to their conditions. Studies have shown[15] that the mortality rate of a broken hip over 65 years of age doubles over 12 years after the broken hip. In usual care, the reported 1-year mortality after sustaining a hip fracture has been estimated to be 14% to 58%. The relative risk of mortality in the elderly patient population increases by 4% per year. The first year after a hip fracture appears to be the most critical time.

The above elements reinforce that AIP investment should be either (i) some upfront cost for CAPEX and monthly lease fee for equipment and service (ii) buy out option of the equipment with a monthly fee for service. The affordability of the technology assists in remaining at home is somewhere between

- Pay anything to remain at home and reduce the burden on kids and remain independent
- The average income of the 65+ age group who are not working is $1,700 per month
- The average cost of Home Health Care of $4,000 per month deducting what Medicaid offers to support for Home Care[16] such as, home and environmental accessibility modifications (alterations such as wheelchair ramps, walk-in bathtubs, stair-lifts, and environmental aids for lighting), medical equipment, and supplies, Personal Emergency Response Services (PERS) are electronic monitoring or call and respond services that enable persons to live alone or to spend portions of their day without direct supervision. There are four different categories of programs within Medicaid that offer funding that can be used to pay for electronic safety monitoring for the

[13]NVSS, *National Vital Statistics Reports*, June 2019, available here
[14] American Academy if Actuaries, Risky business: Living longer withour income for life, June 2013, available here
[15] Geriatric Orthopedic Suegery and Rehabilitation, *The 1-Year Mortality of Patients Treated in a Hip Fracture Program for Elders*, Sept 2010, available here
[16] Paying for senior care, *Medicaid's home care benefits: Eligibility, waivers and application information*, August 2020, available here

elderly (therefore for PERS / medical alert services) (Medicaid Waivers, Consumer Directed Services, Medicaid State Plan – Personal Care Attendant, Money Follows the Person. There are also non-Medicaid sources of financial assistance for PERS devices[17]. Some of them are provided in the table below.

- There is also a high probability that Family Members will also help out with the costs for technology-based AIP solution. They have the greatest to gain by minimizing their face to face visits to their parents to when they want to go versus having to constantly check if their AIP parent is ok. They may also be able to continue to claim the carers allowance themselves while using the technology packs to make their visit times much more efficient.

| Service Type | Description | Cost |
|---|---|---|
| Basic Service | Wearable pendant to a call center for emergency response | $25 - $50 / month |
| Mid Range | Pendant / watch with automated fall detection, call center, emergency response, family notification | $30 - $60 / month |
| High End | Wearable device, multiple in-home sensors, two-way communication, online reporting, emergency response, multi-party notification and add-ons | $500 - $1000 startup and $50 - $100 / month |

The current costs for these PERS services are defined above. The AIP solution being proposed in this paper does cover the PERS safety monitoring requirement and extends beyond this with other functions that really cover the stay at home independence inertia items like Door Ingress and Egress. The ability for both the camera and the drop in audio and video services as well as additional features in the remote control unit – all improve the ability to do PERS.

**A note on AIP technology adoption**

Age related issues *don't really respect the socio-economic demographic*. While more money in retirement can help you pay to stay healthier – a serious fall levels everyone. Other degenerative diseases also drive same decline no matter how much money you have.

For technology based assist solutions there is a belief that the *adoption* of this type of service will start in families that have that *bit more money and are already tech-savvy* having seen the benefit of consumer IoT devices and smart assistants. In fact many of these families may try and help their AIP parent(s) with Do it Yourself Technology solutions. We would like to think however, that these proposed AIP technology solutions can find their way to the poorest demographics as they may have the largest impact in keeping these seniors in the own home and out of the stressful work of assisted living, day care and other hugely expensive burdens.

Its also hoped that *the Medicare and Medicaid services can also look to these technology solutions* as driving large savings in their premium payouts and extend PERS and other coverage items to include the suggested device sets indicated in this paper. Why is a DOCSIS GW , WiFi AP , Extender or IoT hub not a potential insurance subsidized device given roles in preventing injury and providing reliable immediate triggers when threshold of sensor readings are breached and doors are opened. More work needs to be done to move more of the technology assists in the home for AIP into subsidies from insurance companies.

[17] Paying for senior care, *Medical Alerts & Personal Emergency Response Services Costs*, May 2020, available here

We believe, as highlighted in the insert "*A note on AIP technology adoption*," this market opportunity will take off for the Cable operators. Let us look at the business case for the Cable Operator in Aging in Place. For the purposes of this paper, to make it simple, let's assume

- Margins on the proposed services below are even better than Broadband margins
- Because of the lower survivability rate in this age group (65 and above), we have to reduce risk on Capex and Opex investment
    - So, most models will be upfront installation cost with recurring lease cost on device
    - The AIP services as a Software Service will be licensed as yearly maintenance costs for the additional software updates and improvements
    - Some higher initial onboarding costs for third party OTT AIP service providers – the assumption being that a limited number of partners per region or state will be used
- The services below do not include the cost of basic triple-play services and the device lease costs.

So the following analysis outlines 5 simple illustrative AIP Packs. The potential revenue opportunities are highlighted in the table below.

| AIP Service Offering Costs | Install cost | Upfront cost | Leasing cost/mo. | Purchase cost |
|---|---|---|---|---|
| **(1) Family communications pack** | | | | |
| SMD + Video conference | $50 | $200 | $10 | $500 |
| Additional SMD + VC | $50 | $200 | $10 | $500 |
| **(2) Wholw home family communication adder** | | | | |
| In room smart audio assistant + IoT | | | $8 | $99 |
| Two pack - in room smart audio assistant + IoT | | | $14 | $180 |
| **(3) Entrance and egress security kit** | | | | |
| Smart doorbell | $60 | | | $150 |
| Smart doorlock | $120 | | | $250 |
| Smart doorbell + doorlock pack | $150 | | | $325 |
| **(4) Camera** | | | | |
| 1080P only single camera | $50 | | $7 | $120 |
| Two pack 1080P only cameras | $75 | | $12 | $225 |
| 4K single camera | $50 | | $12 | $200 |
| Two pack 4K cameras | $75 | | $20 | $390 |
| **(5) AIP for IoT pack** | | | | |
| Motion sensors | $100 | $100 | $4 | |
| Smoke and fire detection | | | | |
| Kitchen sensors | | | | |
| Toilet flush sensor | | | | |
| **(6) Skills support** | | | | |
| (1) + linkage to TV and TV notification | | | $15 | |
| (2) + linkage to TV, remote, voice system | | | $20 | |
| (5) solution software | | | $20 | |
| AIP care portal connect service (Care portal to add services to devices installed) | | $250 | $50 | |

(1) Family Communications Pack: This service focuses on a simple large-screen video conferencing integrated into the TV experience. Features include - Smart Media Device and Camera bundle, Smart Phone App for Family and Carer Givers, Features like TV pause when a call, Family members can leave notifications on the TV screen, etc. This package can be for one room or more than one with additional service and equipment lease. It offers options for complete buy out of the device vs lease cost.

(2) Whole-Home Family Communications Adder: This service adds Audio only Smart Assistant adders to additional 'modesty' rooms.

(3) Entrance and Egress security kit: This service includes, Smart Doorbell and Smart Lock combination for TV controlled secure visitor ingress and egress to the home. Note that the installation costs are higher in particular for the Door lock.

(4) Cameras: Add 1080p and 4k camera options added to the SMD camera solutions. These can be placed in other rooms or on outside locations for TV-based security assessment

(5) AIP IoT pack (for non-medical devices): This service focuses on non-medical related IoT packs on giving the Family and Carer simple daily life functions transparency. These devices include - room motion sensors, sleep sensors, toilet flush, kitchen sensors (fridge, microwave, and hob/oven usage), in room location, smoke heat gas detection, etc.

All of these are tied to the Family and Carer Giver app and are displayed on a TV. These skill packs are charged additionally to the device costs/leasing costs and will have constant innovation on them as well as requiring cloud resources that will cost on an annual basis.

| Sample pack contents | Upfront cost | Purchase cost | Per Month | Take rate | PM Revenue | PY Revenue |
|---|---|---|---|---|---|---|
| (1) | $200 | | $25 | 10% | $3 | $30 |
| (1) + (3) | $200 | $675 | $45 | 20% | $9 | $108 |
| (1) + (3) + Two pack 1080P (4) + (5) | $300 | $825 | $81 | 25% | $20 | $243 |
| (1) + (2) + (3) + Two pack 4K (4) + (5) | $300 | $925 | $103 | 30% | $31 | $371 |
| Above + AIP Care portal | $250 | | $133 | 15% | $20 | $239 |
| | | | | | **$83** | **$991** |

How will this then roll out to the AIP population with different requirements depends on privacy, different budget levels, etc. The above simple table outlines 5 configurations of the above packs from a simple one SMD VC communications pack to a premium most of the services selected in more than one room pack. These range in price per month from $25 to $133 per month. A Take rate estimate of the 5 packs is shown in the above table with Pack 4 is the most popular at a 30% take rate. Using this trivial simple take rate – the average cost per month is about $83 per AIP home. Note there is also upfront payments additional to this per month price as well in our proposed model.

This is in line with research data and PERS costs shown above (this solution goes beyond basic PERS features) that show AIP persons or their family willing to pay at $50-$99 per month to remain as independent as possible at home.

| Target market (yearly revenue projections) | Market size | Take rate | Revenue (Billions) |
|---|---|---|---|
| AIP Homes (Total market for 65+) | 56,000,000 | 3% | $1.67 |
| | | 30% | $16.65 |
| | | 50% | $27.75 |
| Elderly on their own need help | 3,750,000 | 3% | $.11 |
| | | 30% | $1.12 |
| | | 50% | $1.86 |
| > 65 households in 2M subs | 170,000 | 3% | $.01 |
| | | 30% | $.05 |
| | | 50% | $.08 |
| Elderly on their own needing help in 2M subs | 45,000 | 3% | $.00 |
| | | 30% | $.01 |
| | | 50% | $.02 |

As a final step to give a quick feel for the overall opportunity for revenue let's look at a very simple model of 3%, 30% and 50% take rates of the 2021 AIP population across

- The entire 56M AIP Homes base
- The smaller subset of Elderly on their own already needing ambulatory and other help – 3.75M
- And a simple hypothetical 2M subscriber MSO for their revenue return

As you can see below it could be a $28Bn per year market if 50% of homes over 65 had such a Cable Operator supplied solution. Even with those needing help now at 50% penetration, it's a $1.9Bn per year revenue opportunity. For a 2M subscriber Operator with 50% of their 65yr+ homes taking a solution – it's an $84M per year opportunity. And if only 50% of the AIP people already requiring help take it – it is a $23M per year opportunity.

Of course, there are other elements that can be further considered, such as -

- Additional Broadband and Video services for new subs or upgrades to existing ones
- Stickiness – AIP person is likely to never leave Operator as Broadband and Video Provider

- Stickiness – their family and carers may also switch to the Broadband and Video services of their AIP parents if they see the additional value. And there could be family packs offered at some overall discount as a new tier of service
  Additionally, AIP services that go beyond that are only technological specific

# 6. Conclusions

As Cable Operators enter the next decade between 2020 and 2030 there are a number of key trends correlating to allow them to add new high-value revenue opportunities. As Operators move to the 'quad-play' of Voice Video Data and Mobile – there is another level of Service that is emerging in the Aging in Place and Telemedicine space. This area offers high value per month returns to the Cable Operator and potentially $82 per month revenue from 9%+ of its subscriber base. With the advancement in IoT devices, Far-Field Voice and Smart Assistants, and in particular the evolution of the STB to the Smart Media Device a Cable Operator has a device arsenal that can be re-purposed and in some cases double-dipped to Aging in Place revenue opportunity. By choosing a simple path based on connectivity, SMD, home communication, home ingress, and egress, and home telemetry solution and extending to partner with specialist AIP companies the Cable Operator can provide a longer time at home for many of their Elderly and aging customers. Not only is it a profitable solution direction but a hugely worthwhile solution space that can improve the lives of up to 55M people in the US but also bed in a new digital home solution that will also grow to improve Telemedicine and other home services.

# Appendix A: Some solutions operators can offer for AIP Homes

| Service offering | Opportunity information | Additional AIP needs |
|---|---|---|
| Broadband GW and Wi-Fi: Fundamental components that can be primary internet services to 20% of the *AIP Homes* that do not have an internet connection. | 20% of the AIP Homes<br><br>CapEx is absorbed in operator spend.<br><br>No additional OpEx. | Option to use the connectivity telemetry and data from the home and apply it to AIP trend analysis. Simple ML-based trending of internet usage (no use – alert carers), health and status of connected devices, changes in numbers of connected devices, new devices present in the home. |
| LTE/5G backup: The solution to resolve an outage on the HFC network is to supply a backup LTE/5G solution that can switch over reasonably fast and support the WAN internet connectivity for all the in-home AIP services and communication. This can be charged on a per-use basis to minimize the cost of LTE and also to make it easier for those AIP families to purchase the service when worried about the cable network dropping. | For those families looking for beyond 5x9's reliability of connectivity to an AIP place home.<br><br>No additional CapEx<br><br>Requires OpEx through additional training and installation from a technician (could be self-install) and support costs and training. | Needs additional support for the health and provisioning of the LTE device as well as a solution to be able to reliably swap access support from Cable to LTE and back again. No real specific AIP elements are required. |
| SMD and TV as the main AIP portal: The STB is on a new evolution trajectory to move from being just a traditional decoder to being an in-room device that can open up the 65" TV as the portal for many services including AIP. The device itself and the location of TV's in the AIP home – correlates with the two main rooms that the AIP person spends most of their time outside of the bedroom. Typically these rooms are (i) kitchen and (ii) living room – which as mobility decreases in AIP lifetime the AIP person spends more time sitting and in front of the TV. This makes the SMD the idea device to become the AIP command | As the Cable Operator moves from humble STB to the Smart Media Device solution and brings in new Smart Media devices – they can enable an AIP service to the device easily with the addition only of a Video Conferencing camera as an additional service over their regular | The opportunity to be able to leverage the SMD Portal to both the TV pixels and speaker audio to be able to connect AIP resources to the AIP person. |

| Service offering | Opportunity information | Additional AIP needs |
|---|---|---|
| console for both the AIP person and their carers to connect and communicate to minimize the burden of face to face visits and care. With the use of Videoconferencing, it also makes it much easier to have immediate and frustration-free discussions with parents to improve their psychological well-being. | next-generation TV experience evolution.<br><br>Potentially Cable Operator can absorb Smart Media devices in its evolution to IP Video over Wi-Fi CapEx and adds more Far Fied voice and visual smart assistant support.<br><br>Requires additional training and support for the SMD and AIP services. | |
| Simple remote control: As we age our ability to use and work with devices that can be lost or misplaced, are hard to see, have small buttons, have complex button presses, etc. These can be a source of massive frustration as well as potentially stop the ability to accept incoming calls or simply change the channel to watch a favorite program. Changing the design of the remote control to be *AIP Home* friendly such as be less easy to lose or slip down the side of the chair, have bigger and fewer buttons, support push to talk voice to enable services and smart functions, have a remote from home initiated 'find me' beep or noise function to locate it.<br><br>The remote can also be repurposed to be a pendant remote control that can also provide emergency alert services. Idea's for this service include: Adding accelerometer and **gyrometer** support to the remote to detect falls and rapid movements – with an automated call out to Carer or Family member, Red button press to engage carers or specialized call out services, etc. | Opportunity to create a differentiated – fit for function – AIP friendly remote control device.<br><br>This would be a separate SKU of remote for AIP purposes.<br><br>Requires additional training and support costs. | Needs additional support for the services added to the remote – particularly if its IP addressable and supports the 'find me' and emergency alert services. |
| In-room speaker/intercom: To complete the coverage of the *AIP Home* transparency and visibility for Carers it is important to add additional communication devices to the 'modesty' rooms in the home like a bedroom and possibly toilet. This completes the formula of being able to constantly contact the person and also afford them the potential to constantly contact their carers or family as they move around rooms. The addition of an audio-only smart assistant will complete the | The opportunity here is to introduce general whole-home voice and audio for the general population but to also drive this for an AIP specific application. The operator supplied Smart Assistant solutions | Needs additional support for the IoT and Voice/Audio data models to support management and provisioning of the device. AIP applications can be applied to the device |

| Service offering | Opportunity information | Additional AIP needs |
|---|---|---|
| transparency coverage of the home and make the *AIP Home* very much a virtual extension of the carers and families home – with a minimum burden and maximum return.<br><br>The Operator can also affect another level of security and privacy over these audio listening devices and also include easier point to point access to designated only listeners or call endpoints – typically just the AIP carers and family members.<br><br>The device can also offer additional IoT radios to also engage with non-BLE solutions added to the home for smart IoT or even non-BLE IoMT solutions. | have additional advantages for home use.<br><br>Absorbed in normal Cable Operator Capex spend : Potentially. The addition of Far-Field Smart Speaker based solutions as an augment to the SMD Visual Smart assistant is an architecture that has merit for creating a new whole-home platform for new services including Aging in Place services.<br><br>Requires additional training and installation from technicians (could be self-install) and support costs and training. | – but typically will be cloud hosted and leverage skills frameworks that have already been integrated for regular consumer services. |
| <u>Camera solutions for room visibility in defined areas</u>: Cameras in the home cause lots of discussion about invasion of personal privacy. However when confronted with having to -leave the home for Assisted living or Nursing home, add more burden to family and carers with more visits to *AIP home,* increased cost in home health care, worry about being on one's own so outdoor camera solutions can give peace of mind, these concerns will lessen. The addition of Cameras to the *AIP home* – is a much more palatable and acceptable solution to the AIP person when it adds this value.<br><br>Cameras in the home for AIP should be allocated in the following 'modesty' fashion - they should only be added to rooms like Kitchen and Living Room , they can be combined in those rooms as both constantly viewing devices and video conference solutions – especially when combined with SMD and TV, they have additional role to provide a view of front door to the TV and Smart Phone for automated visitor access to the home, their telemetry can be also used for other AI based and AIP and Telemedicine services using video to extract meaningful home insights | New class of device and service that has multiple roles across the general customer services but a specific relevance to Aging in Place services.<br><br>New chargeable device as part of AIP or Security initiatives. Additionally, options for charging for recording or AI services on the data as part of menu of services on video telemetry.<br><br>Requires additional training and install from technician (could be self install) and support costs and training. | Video and Audio recording services as well as events like motion , person and other finer grained AI derived services. AIP applications can be built on the Video services and solutions that can analyze heart rates, changes in walking gait, falling as well as fire , smoke or other solutions can be overlaid on the data collected. |

| Service offering | Opportunity information | Additional AIP needs |
|---|---|---|
| For the Carer and Family cameras - provide more value to them than the AIP person and so are their main vehicle to establish wellbeing of AIP person, provide a fast way to track the activities of the day like eating and drinking and visual verification of taking medicine, provide a way to approve ingress to the home for visitors remotely with confidence – a scheduled visit or repair service etc., provide emailed or Instant Message event triggers with captured frame or video snippet for activity in the room – making it easy to verify the key events of the day of (Up and going, in the relevant rooms, moving, time based changes of rooms, visitors etc.)<br><br>The Operator can supply these cameras solution as part of Video Conferencing service on SMD as well as extra cameras for Door and other rooms as part of their service. Camera solutions scale outside the AIP opportunity to other home peace of mind security services and in particular of infrequently occupied second home monitoring services. The device can also offer additional microphones and speakers to also support camera based intercom features. The Camera should also support IR and Nightvision modes to be able to support visibility through 24 hour period. Cameras will also trigger alerts at any fire's starting in the home as motion events. | | |
| Camera doorbell: One of the limiting factors of Aging in place that is solvable with technology is automated entrance to the home for visitors and also answering the door to strangers when desired. This is a particularly important feature when mobility has reduced of a single Aging in Place person. Allowing delivery of food with trusted people as well as scheduled maintenance or health workers using a secure automated door solution is a key part of elongating the stay at home battle of aging in place. Adding a Camera doorbell provides this capability and can uniquely be tied to the STB and SMD by the Cable Operator to allow someone who spends their time in a chair or bed to also control entrance to the home. | Opportunity : New class of device and service that has multiple roles across the general customer services but a specific relevance to Aging in Place services.<br><br>Absorbed in normal Cable Operator Capex spend : New chargeable device as part of AIP or Security initiatives. Additionally, options for charging for recording or AI services on the data as part of menu of services on video telemetry. | Video and Audio recording services as well as increasing ability to do facial recognition on the door bell camera. Logs of entrance and egress to the home as well as being able to deal with unwelcome people at the front door. Gives also an additional level of security as people don't loiter when they know they are on cameras. |

| Service offering | Opportunity information | Additional AIP needs |
|---|---|---|
| | Additional Opex costs : Yes – requires additional training and install from technician (could be self-install) and support costs and training. | |
| Smart door lock: Works in conjunction with the Smart Doorbell to provide a good secure automated solution to grant secure access to approved visitors. With key elements of aging in place being - food delivery, health worker visits, ambulance visits to take you to scheduled doctor visits, amazon or online services delivery etc.<br><br>The ability to automatically open the door by the AIP person or even remotely by the Carer and Family can be a huge help in remaining independent in AIP timeline.<br><br>There are additional devices that can be fitted to the door to make sure it closes when opened as well as the door lock telemetry for close to ensure highest security levels on the door closure process. | New class of device and service that has multiple roles across the general customer services but a specific relevance to Aging in Place services.<br><br>New chargeable device as part of AIP or Security initiatives..<br><br>Requires additional training and install from technician (could be self-install) and support costs and training. | For security purposes the application of software solutions to ensure the door is properly closed and the door/open close correlated to the doorbell telemetry ensures complete visibility to the door access solutions. |
| Partner supplied IoMT pack: There is a place for the Cable Operator in the medical devices that can be required in the Aging in Place journeys. Typically, they will be supplied by specialized Health Care Companies, Insurance companies, Specialist Aging in Place solution providers and in many cases come pre-provisioned for immediate send of information to a care portal database. The Cable Operator can add value to this service by - providing the IoT hub elements to connect the IoMT devices (Typically BLE but also offering Wi-Fi and ZigBee and ZWave onboarding, doing BLE to IP conversion from the device, supporting reliable first time pairing of the devices to the IoT hub and connection to the cloud etc.), displaying the status and onboarding and results of the devices integrated into the both (The SMD visual display on the TV, any Operator supplied Smart App, integrating the IoMT devices into the Cable Operators TV Consumer experience, Adding audio playback of the recorded values for sight challenged AIP | Partnership opportunity with specialist monitoring and Aging in Place care companies. Cable Operator provides the Hub function to the IoMT device pack issued by the partner monitoring company. Cable Operator takes a fee for the onboarding service and integration into SMD visual path for notifications and other services.<br><br>An OTT service that can be added to the Cable Operators service architecture for other services like their own IoT | The solution should probably be offered as Virtual Network Function added to the Cable Operators network and together with containerized application solutions added to the Broadband and Video Service delivery system – offer the Cable Operator the option of being able to partner with specialist Caring Services and Resources. It is not expected that the |

| Service offering | Opportunity information | Additional AIP needs |
|---|---|---|
| person(s)), adding additional security and redundancy via the addition of LTE/5G WAN backup.<br><br>Opening up cloud to cloud interfaces between the Connectivity path and the Medical Cloud to provide secure reliable integration with the home User experience. This is typically done by - Cloud to Cloud interface definitions, containerized applications that can be added to the SMD and IoT hubs to gather IoMT information, providing logging solutions to ensure trace back of readings and frequency. | services and even Wi-Fi management. Additional effort required if Cable Operator provides more features in the connection of IoMT to the specialist Aging in Place providers cloud.<br><br>No additional or at least very minimal as part of the next phase of addition of containerized services into the Cable Operators Broadband and Video and Smart Solutions. | Cable Operator does anything with any data from the IoMT devices except to provide tools to ensure they have onboarded and remain connected as well as other alerts for any outages or unscheduled disconnects. |
| Cable operator cloud: As mentioned in earlier sections – the expected solution for Cable Operators AIP business is to provide additional cloud support to the (1) Cameras and Smart Assistant based services – offering additional access to these devices directly to AIP person(s) and carers and family. There can be opportunities to also allow specialist AIP companies to access cameras with permissions from family and AIP persion(s). These services can be provided cloud to cloud (2) Doorbell and Smart Lock solutions as extensions of any Smart Home or Security solutions offered by the Cable Operator. The Cable Operator providing the automated entrance service to the AIP person is a cloud hosted application and needs additional services to ensure closure and alerts to AIP family and carers if closure contact is not made. The specific IoMT pack is not typically controlled by the Cable Operator and is typically a pass through service that the Operator will offer to the AIP either through partnered solutions or potentially to designated solution offerings recommended by the family or AIP themselves. The definition of the interfaces to these third party IoMT monitoring and care portal companies has no specific standard at the moment but there are several potential solution architectures for this that could provide some future telemetry and information sharing from Cable Operator domains to AIP resource domains. For now the simple mechanism is to send all the IoMT information through the Cable Network to the defined cloud endpoint after VNF and | | |

| Service offering | Opportunity information | Additional AIP needs |
|---|---|---|
| Containerized applications for AIP Resources are installed in the Cable Operators Service Delivery Platform. | | |
| AIP partner clouds and cable operator interfaces: This area demarcates the non-Medical and Medical elements of Aging in Place. In the paper we have outlined the value areas that the Cable Operator can add from its own cloud to home AIP services. However there is another important opportunity that can be also added to the Cable Operators services to the AIP home. The specialist Care Companies, Medical Resources and other Aging in Place resources can connect either - Directly through the operators network to the devices, Support some potential for Cloud to Cloud integration for Operator supplied value add services to the medical or other AIP OTT services<br><br>This offers the potential to be able to – (1) Onboard with Operator supplied Hub devices (for its own AIP and general Home IoT and Smart Home services) rather than additional hub. New Software Delivery schemes unlock the possibility for a containerized AIP medical app to be added to support Aging in Place medical device packs and other internet connected services above the basic ones supplied by the operator. (2) Offer additional Operator pulled telemetry and even Machine Learning to the AIP resource cloud service (potentially driving some standardization of data sharing) and combine this information for a better overall service from the specialist AIP service provider<br><br>This is a more complex proposition for the Cable Operator as there are many AIP specialist companies, and they differ regionally throughout the US. In most cases the AIP resource company is recommended by - Doctor/Hospital, Rehab center, Day Care center, Health Insurance Provider.<br><br>Or researched by Family member or AIP for the Home Help or monitoring solutions.<br><br>But the potential does exist to be able to onboard and integrate with these solutions typically via - software architectures to allow downloadable services in Operator supplied devices, cloud to Cloud integration | | |

| Service offering | Opportunity information | Additional AIP needs |
|---|---|---|
| and definition of interfaces to share data and information.<br><br>More research and 'analysis needs to be done in this area of interfacing with Aging in Place medical and other specialist services.<br><br>Data exchange and the privacy of data will also need to be expanded and is outside the scope of this paper. While there is the HIPAA and PHI specifications to govern access to sensitive medical data generally all data from the AIP person and home will start to become more privacy focused – particularly when simple sensor information combined with medical devices can be merged in an overall view of AIP persons health levels. There has already been a new act created in California – the California Consumer Privacy Act – CCPA which is similar in many ways to the trend in Europe with the General Data Protection Regulation being put in place to define rules around consumer privacy in a digital world.<br><br>Before going onto the next section we will also mention that there are many other additional sensors that could be added to ensure more safety and peace of mind visibility in the home. These include but are not limited to - motion sensors, smoke and fire detection, sleep sensors, toilet flush sensors, fridge open sensors, door open sensors etc.<br><br>These can be added as required to the Cable Operator Aging in Place pack and the telemetry added into the flow for the Carers and Family members to interpret. These devices can provide safety and security features as well as general indications of healthy hygiene practices for the AIP person. Declines in the normal levels of feeding, toilet frequency and sleep can be used to pre-empt medical issues and get earlier family and doctor interventions. These statistics can also be combined with supplied medical devices telemetry to get a clear picture of overall health and aid prognosis by Doctors. | | |

# Why Are Cable Operators A Natural Fit To Support Telehealth

# An Inter-Industry Perspective

A Technical Paper prepared for SCTE•ISBE by

# Table of Contents

## List of Figures

# 1. Abstract

Cable and healthcare industries are crossing paths at many places including in the area of Telehealth. This paper explores how mutually beneficial collaborations can be created between the two industries.

In the process we evaluate different building blocks of Telehealth. A case will be made for the cable operators supporting some of these building blocks. We will provide a quick survey of some of the publicly known Telehealth inter-industry collaborations. We will analyze different stakeholders in the Telehealth ecosystem and their needs.

We are going to highlight the low hanging fruits in this collaboration where Cable operators can begin. And finally provide a preliminary recommendation on how cable operators to venture into a mutually beneficial opportunity.

# 2. Evolution of Telehealth and challenges

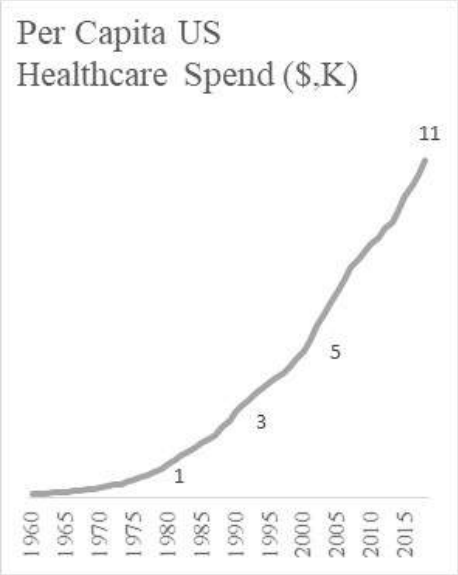

**Figure 1 - US healthcare spend 1960-2018**

Healthcare expenses are skyrocketing in United States [1]. Per Capita national expenditure rose from $146 in 1960 to $11,160 in 2018 (refer to Figure 1) at a rate of 4.6%. It is expected to rise at a yearly rate of 5.4% from 2019 – 2028 (refer to [2]).

In the market, there are many healthcare and technology initiatives to reduce wastage, reduce cost and increase productivity [3]. As will be discussed later in the document, many inefficiencies can be addressed by Telehealth initiatives. With this brief motivation, we will discuss the background of Telehealth and its promises in detail in the rest of the section.

Although, this is not a primer on healthcare definitions, it is essential to understand tele terms that are often confused by non-healthcare professionals. Telehealth and Telemedicine are defined by HIMSS as [4] – Telehealth: *A broad variety of technologies and tactics to deliver virtual medical, health, and education services. A collection of means to enhance care and education delivery. This term encompasses the concept of "telemedicine," which refers to traditional clinical diagnosis and monitoring delivered by technology. The term "telehealth" covers a wide range of diagnosis, management, education, and other related healthcare fields including but not limited to dentistry, counseling, physical and occupational therapy, home health, chronic disease monitoring and management, and consumer and professional education.* Figure 2 gives a high-level summary of the above terminology and different types of Telehealth services offered. For a bit more discussion and relevant references from Telecom operators' point of view refer to [5]. In this paper we focus only on Telehealth aspects of the telecom and healthcare inter industry puzzle.

Telehealth [6], in a nutshell,

- Addresses lack of access to quality care specifically in the remote communities
- Reduces provider burnout in unnecessary activities such as traveling between facilities

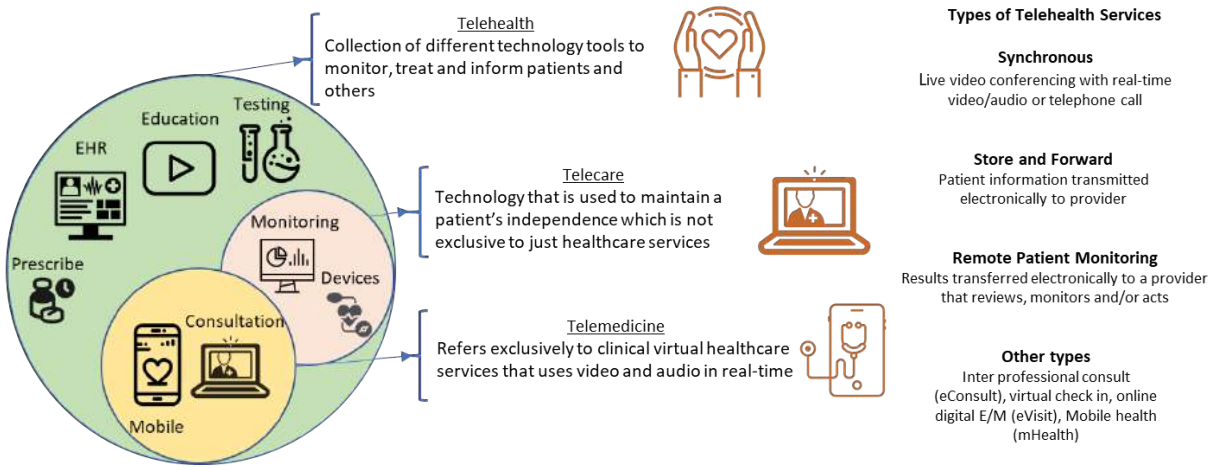

**Figure 2 - Types of Telehealth and relation between Telehealth, Telemedicine and Telecare**

- Assists with care gaps in chronic disease management with different patient's providers
- Increases and manages hospital staff utilization through effective capacity management
- Controls the escalating costs the providers are caught in the fee schedules and no-shows

The question is, if Telehealth is solving inefficiencies in the healthcare industry, why is it not taking off? There are some significant technological, policy and perception issues that need to be addressed for Telehealth to be widely adopted. These are briefly mentioned in the insert – "Telehealth Challenges."

**Telehealth Challenges**

Telehealth is envisioned in 1960s. Why did it not take off yet, if the healthcare industry unanimously agrees to its benefits? We have three roadblocks **Error! Reference source not found.** -

*Payment:* Payment codes are not available for many Telehealth services yet

*Policy:* Federal and state healthcare agencies have different policies that restricts the adoption of Telehealth

*Proof of Quality:* Healthcare professionals must prove that the quality of care provided by Telehealth matches non-Telehealth

These barriers are, atleast temporarily, lifted due to COVID-19. Radipidly in the last few months Medicare, who is the largest government sponsored health insurance, relaxed their restrictions around the communication mechanisms, payment restrictions etc. [8], [9], [10]. The Telehealth community has gained their long deserved recognition in a hurry. Telehealth solutions or services adoption has surged from roughly 54 percent in 2014 to 85 percent in 2019, indicating a higher level of acceptance and desire for telehealth solutions and services [11]. We will need to wait and see if these policies and payment structures will be continued after the COVID-19 scare subsides. A generic agreement in the healthcare community is that we will not go back to the pre-COVID status, but will also not have the same level of policy and payment relaxation.

Even before the COVID situation itself, there had been significant tailwinds that are driving the innovation and adoption in the Telehealth industry [12]. These tailwinds are mainly around expanded funding availability, increased adoption, proven results, disruptive acquisitions [13], availability of 5G and 10G [14] networks.

Telehealth focus has been catching attention from different industries. Firms are trying to solve a portion of the problems. For example, there are over 300 companies claim that they are addressing Telehealth needs [12]. This early adoption stage of the Telehealth industry is heavily fragmented due excitement in the market. In addition, the government agencies, such as The U.S. Department of Health and Human Services (HHS), are trying to control these disruptions in an orderly fashion through relevant Telehealth success metrics [15]. Such a ripe innovation grounds are becoming more and more favorable to the Cable Industry, as we will discuss in the next few sections. The question will be more on what strategy an operator needs to employ when addressing Telehealth needs rather than if they should enter this market.

## 3. High level stakeholder needs

As shown in Figure 3, Telehealth ecosystem has many stakeholders. Of course, it begins with the *patient* and their *family members* that are involved in the decision making of a healthcare visit. If the patient needs additional care, such as taking care of an elderly person, the *care giver* will also need to be part of the ecosystem.

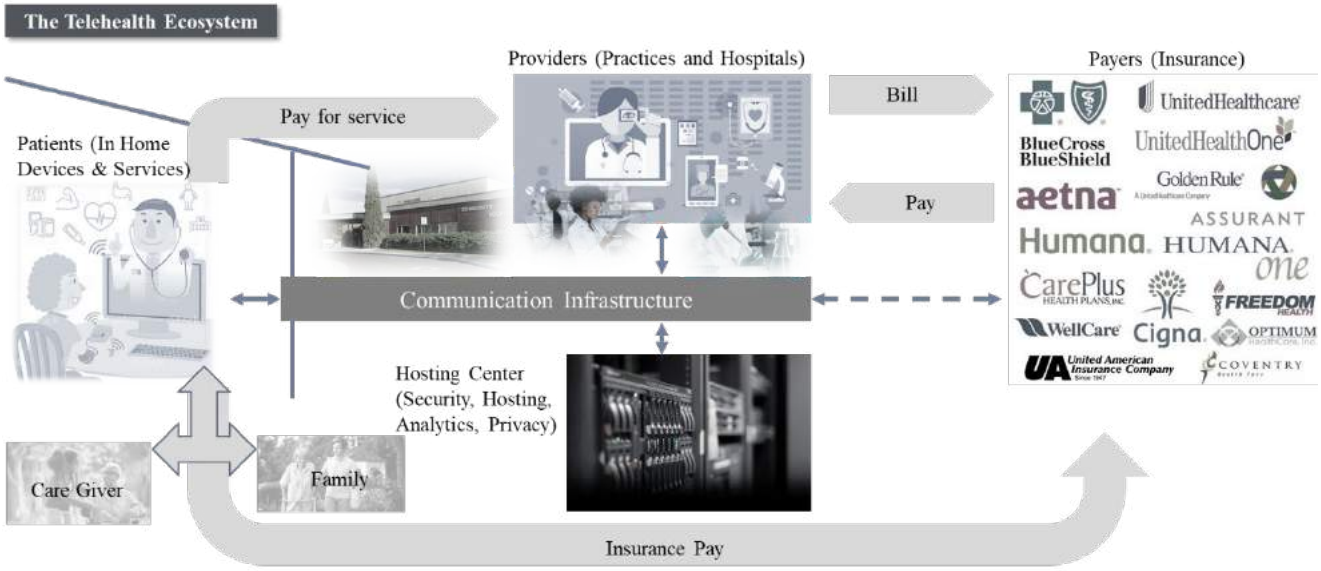

**Figure 3 - The Telehealth ecosystem consists of patient, provider and payer side partners**

The patient interacts with the *provider(s)* (Doctors, Physician Assistants, CNP, etc.) for guidance and treatment. Note, that there could be multiple providers as part of their treatment. In addition, the provider ecosystem includes their *satellite* or *community hospitals* (such as the VA Telehealth services [16]), *pharmacies, labs,* and/or *imaging group*. The providers and the patients interact with the *payers* (the public or private insurance companies) for billing and getting paid for the services. In addition, the *state and federal policy makers* (not shown in the figures) sets the guidance to the whole ecosystem. Note, in case of Telehealth, all these interactions are happening on the infrastructure provided by the *operators*. Before diving too deep into the details, lets understand the goals of Telehealth. The policy makers, who are the gate keepers for the Telehealth services, are interested in understanding the efficacy of the Telehealth services in the following dimensions [15] –

- **Access to care:** Access to information for patient, family, care team, and caregiver
- **Financial impact:** Cost to patient, family, caregiver team, society, and the health system
- **Experience:** Patient, family caregiver, care team member, and community experience

- **Effectiveness:** System, clinical, operational, and technical effectiveness

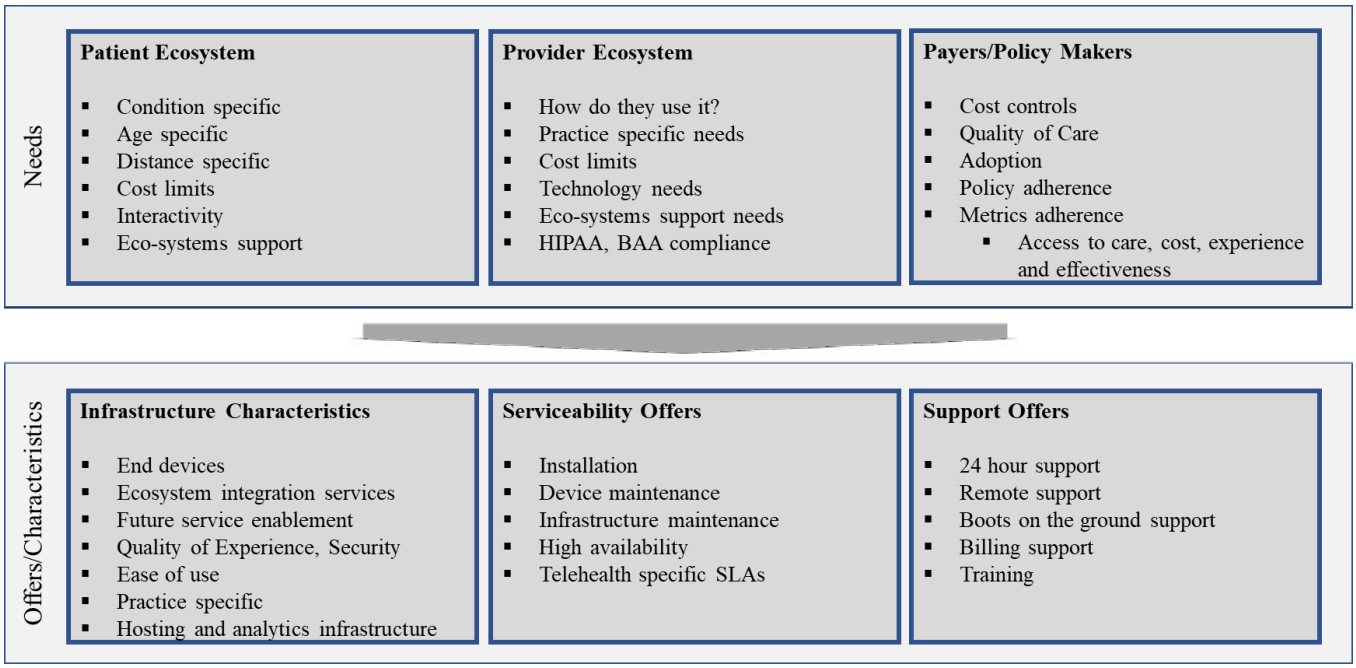

**Figure 4 - High level needs and offer alignment of a Telehealth ecosystem**

Not going too much into the details, we would like to highlight some of the Telehealth needs as shown in Figure 4. These needs can be classified into patient ecosystem needs, provider ecosystem needs, payer needs and policy maker guidance. These needs are self-explanatory and aligns with the Telehealth metrics. To meet the needs of the Telehealth environment, in addition to the most important aspect of the health care involvement, the supporting solution characteristics can be classified into the infrastructure characteristics, the serviceability offers, and the support offers. These are essential to turn a fragmented Telehealth offer into a manageable solution. In the following sections we will build a case on how cable operators can, with their current capabilities, become the Telehealth environment managers.

## 4. Building blocks of Telehealth Environment

The Telehealth environment can be offered as a B2C (Business to Consumer), B2B, and B2B2C business models. As a preliminary step towards offering the Telehealth environment, the Cable operators should investigate which business model they would enter with to ensure success in this highly fragmented healthcare market. Cable operators have a unique relationship with customers through their broadband services. But keep in mind, healthcare is a more emotional and demanding (from service agreements point of view) service. If you are selling to the Telehealth environment through providers and their satellite offices, we need to first consider what are their incentives. These incentives can be identified through the Telehealth metrics identified before. The other more attractive model is to reach consumer through healthcare establishments. There have been multiple studies performed showing this as a valid approach for entering into the Telehealth environment. Many operators have created their healthcare IT initiatives ([17], [18], [19], [20]) to get their feet wet in this inter-industry activity. Lately we have seen the Telco and Cable operators are turning their head to the more profitable Telehealth initiatives (Refer to [22], [23], [24]).

The best way to understand the building blocks of the Telehealth solution is by looking at the day in the life of a patient. As shown in Figure 2, Telehealth offers are classified into Synchronous, Store and Forward, Remote Patient Monitoring and Other categories (Tele-education, metrics gathering, analytics, mHelath, eHealth etc.). These are elaborated in Figure 5 from a patient's point of view to gain more insights into the Telehealth service offerings.

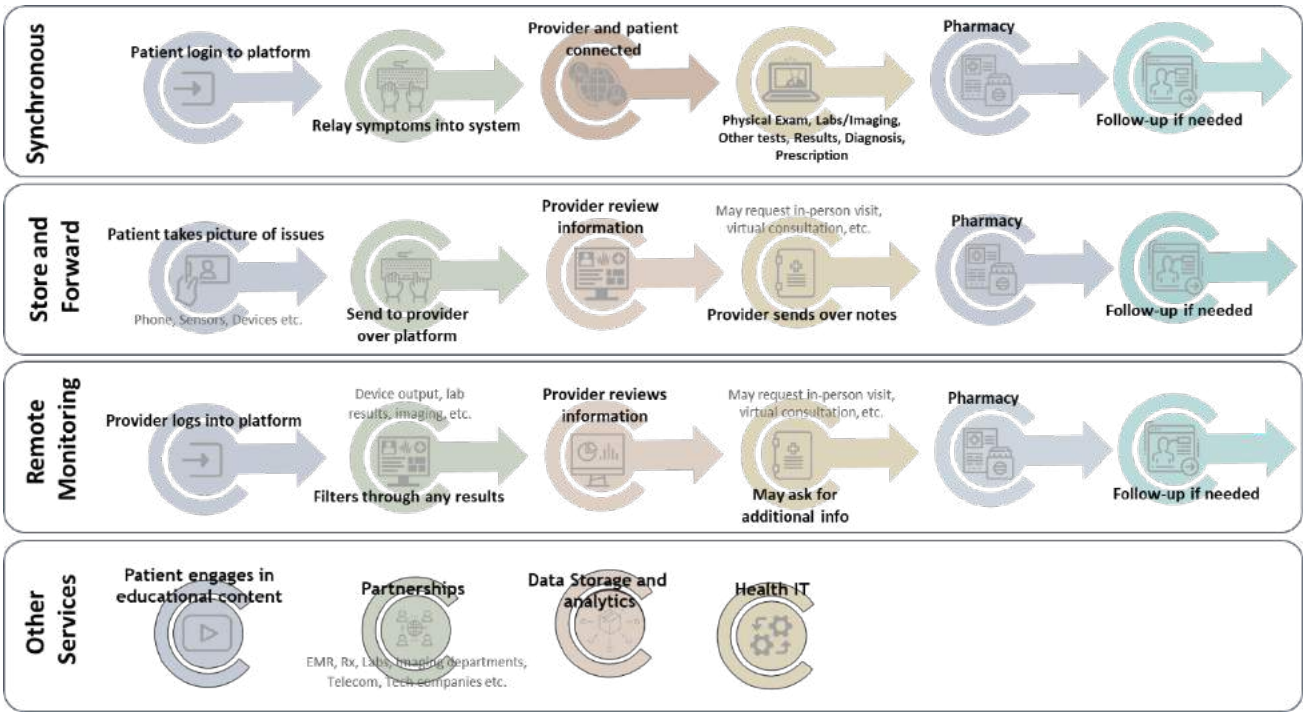

**Figure 5 - Day in the life of a patient in different Telehealth scenarios**

Telehealth is a rapidly evolving industry. The question is how can Cable operators get onto this fast moving train? Looking at the Telehealth environment, as shown in Figure 5, from Cable Operators point of view, one can identify three sets of building blocks as below:

- Patient environment support
    - Communication platform
    - (Future) Consumer oriented unified communications
    - (Future) Device Integration of current and future in home care devices
    - (Future) Usability and accessibility
    - (Future) Supporting team integration
    - (Future) Installation services
    - (Future) Support services
    - (Future) Training support
    - (Future) Build homes to meet future needs
- Provider environment support
    - Communication platform
    - Infrastructure support
    - Unified communications

    - Secure infrastructure
    - (Future) Integrating the provider ecosystem partners
    - (Future) Patient monitoring infrastructure
    - (Future) Integrate with store and forward components
    - (Future) Increased installation and services relationships
    - (Future) Training and education support
    - (Future) Telehealth related ML algorithms
- Policy and payer environment support
    - (Future) Telehealth metrics tracking
    - (Future) Telehealth ML algorithms for problem centric analysis
    - (Future) Policy organizational support

Once we understand the business model and the building blocks of services to be offered in the Telehealth environment, we need to address the incentives to get the right priorities for the stakeholders. This process will refine the roadmap of Telehealth environment execution by the cable operators.

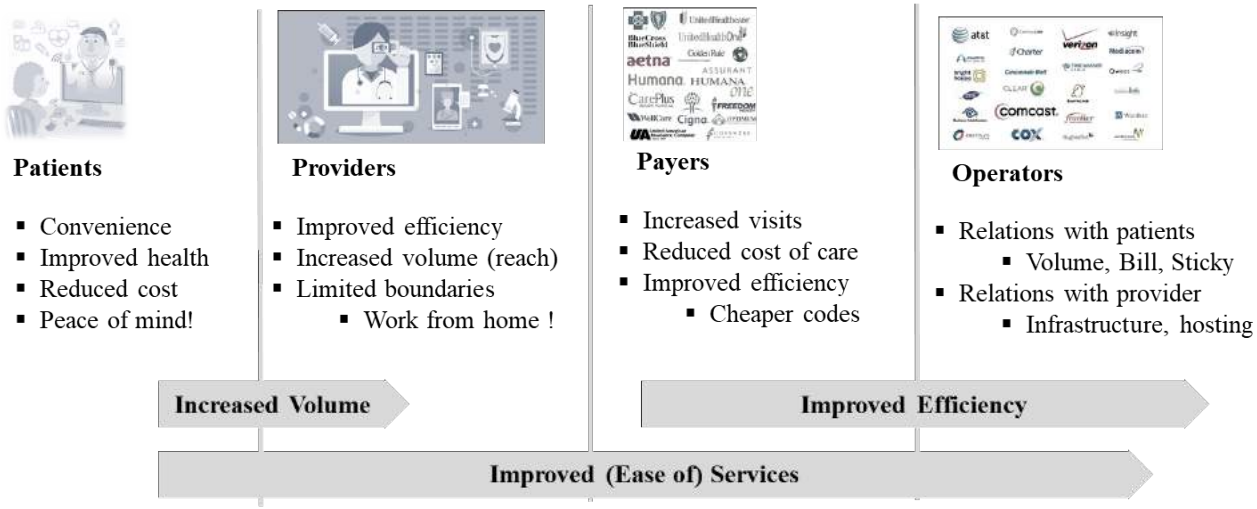

**Figure 6 - Telehealth environment incentivized for different ecosystem players**

Figure 6 provides a quick capture of different incentives in the Telehealth environment. When the cable operators are creating their solutions, we recommend elaborating their offering in a framework, such as above, to address the incentives of different stakeholders in the environment. In the following section we evaluate such a framework to create high level recommendations and a roadmap for the cable operators.

## 5. Cable Operator supported Telehealth recommendations

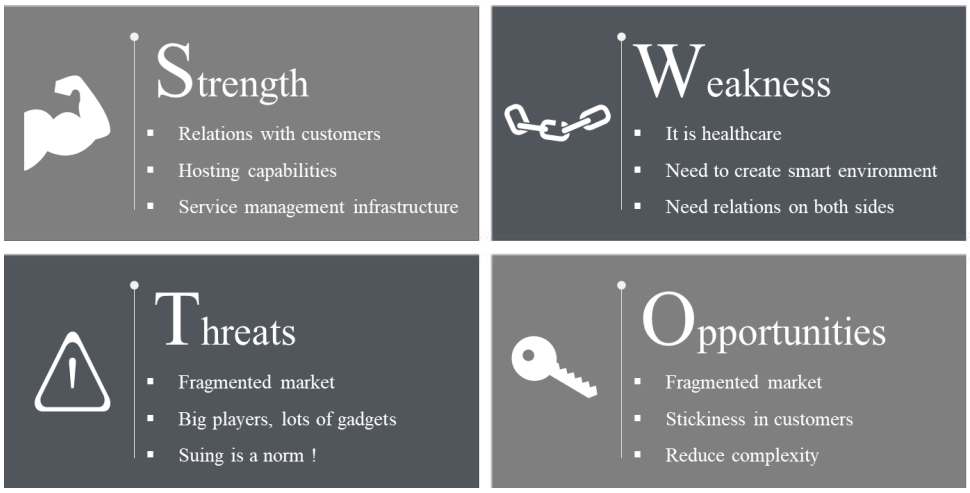

**Figure 7 - Cable operator high level SWOT analysis**

Figure 7 shows the top differentiators that a cable operator can use to their advantage in this rapidly evolving Telehealth industry, and the risks they need to overcome. To become a formidable player in this inter-industry activity they need to create a razor sharp strategy enhancing their strengths to meet healthcare needs, fostering targeted relations, and offering aggressive enhanced services with commitment.

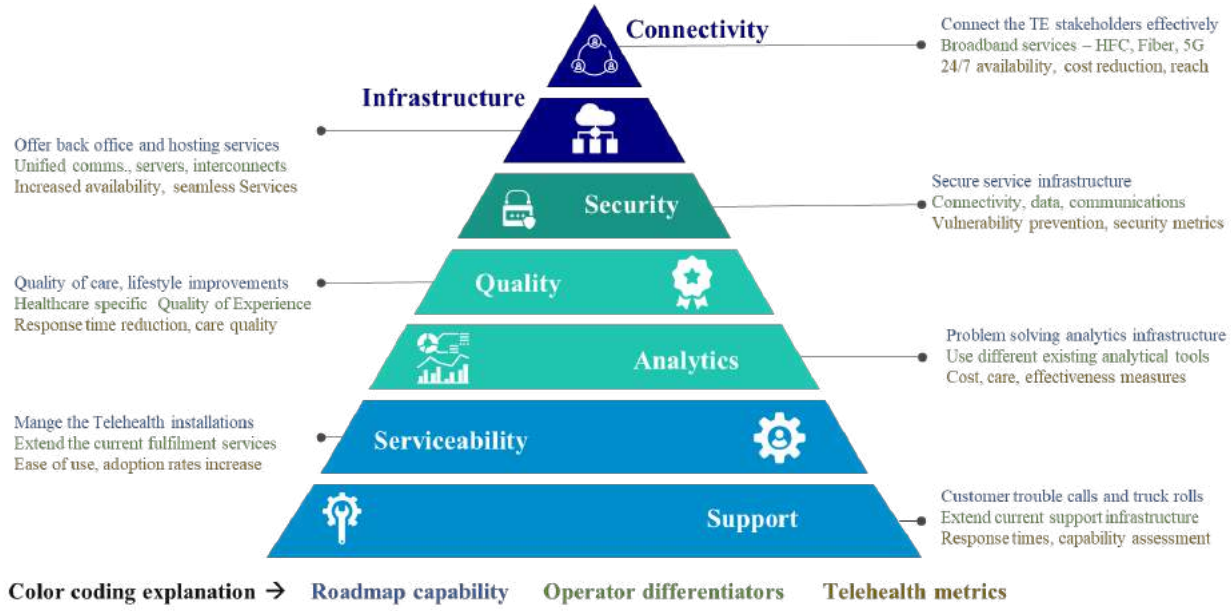

**Figure 8 - A potential roadmap prioritization for executing Telehealth solutions by the cable operators**

Bringing all the concepts, metrics, and capabilities together, in Figure 8, we propose a potential roadmap for the Cable Operators to successfully offer a Telehealth environment.

1. Offer your existing capabilities to healthcare industry:
    a. We propose the operators to play to their strength to start with. This include the *ubiquity of reach and relations* through **connectivity**. It is observed that the biggest challenge for the Telehealth customers is still the broadband connectivity. This is certainly understandable in the rural areas. Even in the urban and suburban areas, this seem to be one of the main concerns. The lowest hanging fruit for the cable operators is to bundle these connectivity services in the healthcare language to address the customer needs. The wireline services such as HFC and Fiber based solutions, along with the wireline services with the future 5G etc., can solve these basic needs. Some of the metrics the healthcare industry understand related to connectivity are the *24/7 availability*, *cost reduction through efficient use of time and increased reach of the patients*.
    b. Extend the existing **service oriented infrastructure** to meet the healthcare needs. These include the managed back office and hosting services – specifically focused on the supporting the above mentioned communication relations. This includes services such as Unified communication services. Assist the healthcare providers in hosting their important data (such as EMR data, patient specific data, billing information etc.) and a portfolio of seamless interconnection (between the stakeholders) services. These services can be measured through the *availability and seamless access* metrics.
    c. Offer a state-of-the-art **secure platform**. The healthcare industry is longing for the day-to-day security infrastructure that the cable operators offer for connectivity, data, and communications. Working with their security infrastructure, the providers by solving the security related issues will be welcome by the healthcare industry. Such an infrastructure's effectiveness can be measured through *vulnerability prevention and other security metrics*.
2. Adopt your capabilities to the healthcare needs:
    a. Adopt the service **quality metrics** that the cable operators are using to monitoring to the healthcare services. Develop healthcare specific quality of care and lifestyle improving service – like what we call the Quality of Experience metrics for the services we offer for the triple play services. Metrics such as *response time improvements, cost reduction, quality of care improvements* etc. need to be measured on the data that is mined for these healthcare services. This increases the adoption of the Telehealth services and hence the Cable Operator supported healthcare services.
    b. Use your **service oriented analytical platform** to assist the complex healthcare issues. Put the complex digital infrastructure that Cable Operators have developed to solve Telehealth related problems. These metrics will be in cost of care reduction, quality of care improvements, Telehealth effectiveness etc. This, in our opinion, is a simple redirection of the analytical infrastructure to the healthcare industry.
3. Increase the capabilities of the operators to meet the future needs of the healthcare industry:
    a. Develop **Telehealth installation services** as a first step to turn the Telehealth as a standard portfolio service. Extend the fulfilment PPTs (people, processes, and tools) to offer the Telehealth installation services. Implement different fulfillment learning that you have, such as self-service and assisted service combinations, to make the customer's life easy when deploying these services. Measure your stakeholders and your successes through metrics such as *ease of use and adoption increase*.
    b. Offer **Telehealth support services** to turn the fragmented market to your advantage. Use your customer's support infrastructure through care centers, truck rolls to address their healthcare needs. This comes at the expense of mobilizing your support organizations to gain healthcare expertise. The size of the Telehealth opportunity foreshadows the complexities reshaping your service organization. The reward for the operators is significant enough that this is a necessary step to gain the full control of your inter-

industry opportunities. Success can be measured by *response time, and problem solving capability assessment* metrics.

In addition to the step-by-step Telehealth services, the Cable Operators have to make the appropriate decisions to develop a go-to-market strategy either through partnerships, building some of the solutions, or by applying the BOT (build, operate and transfer) model. For such a solution they need a clear roadmap for execution, deciding which market they are after: B2B, B2C or B2B2C. For additional information reach out to the authors.

# 1. Introduction

Modern software applications are composed of several inner connected modules enabling various features. Today's complex business and market-driven environment constantly pushes the edge to deliver software application faster than ever. Developers are battling with delivery deadlines that are not driven by the complexity of software offerings rather by the go-to-market motivations. As a result, insecure code has become a leading security risk and, increasingly, the leading business risk as well. It's irresponsible at every level to ignore this risk while doubling-down on anti-virus solutions and firewalls — neither of which protects applications [1].

It is important to have holistic view to software protection that provide check points and resolutions throughout the development cycle. It is also equally critical to empower the developers with technologies and methods to be able to automatically identify and detect certain types of attacks. There are commercial software security tools that transform cryptographic credentials so that they cannot be easily extracted. Other tools can make software reverse engineering very hard by sensing a debugger and transforming the binary code logic such that it looks unintelligible even with a debugger attached.

Dynamic Executable Verification (DEV) as described in this paper, provides low-impact dynamic integrity protection to applications that is compatible with standard code signing and verification methods. Further we discuss a system architecture where components of the Dynamic Executable Verification are placed into a secure cloud-based service which can only be configured by an authorized security administrator. To set the context, we discuss secure boot, tampering attacks and methods to perform static and dynamic analyses. Then we dive into details of DEV techniques that aim to ensure that software cannot be tampered with either statically or dynamically, without detection. The cloud aspect of the DEV makes it even easier for developers as the burden of configuring security tools is moved into a cloud service and the risk of releasing an application with lower than intended security is reduced. We will then present a couple of application use cases before concluding the paper.

# 2. Secure Boot Example and Limitations

Secure boot implies that each successive stage of software is authenticated – including BIOS or first-stage boot code, successive boot stage, Operating System kernel and all of the applications that execute on top of the OS. Authentication of each of the software layers is repeated every time that a system is re-initialized or rebooted. The very first set of instructions executed by a device after a reboot (first stage boot) may be protected in hardware as read-only (e.g., in ROM or a locked sector or flash) and may not need to be authenticated (since it cannot be changed).

Secure boot prevents physical tampering attacks that include opening up a device and re-flashing all of the software with unauthorized code that has not been digitally signed by an authorized party. If any piece of software is missing a digital signature or if its digital signature is invalid, the device will not boot – or at least that piece of software will fail to execute.

That's quite distinct from secure software download where a software image is authenticated once prior to being persistently installed in the device, into flash or a hard drive. Following a successful secure software download, that software is no longer validated even after a device reboots. A fully secured device would typically include both: secure software download for secure software updates and secure boot to prevent physical tampering with the device.

There are many different ways to achieve secure boot, but one example is illustrated in the figure below:

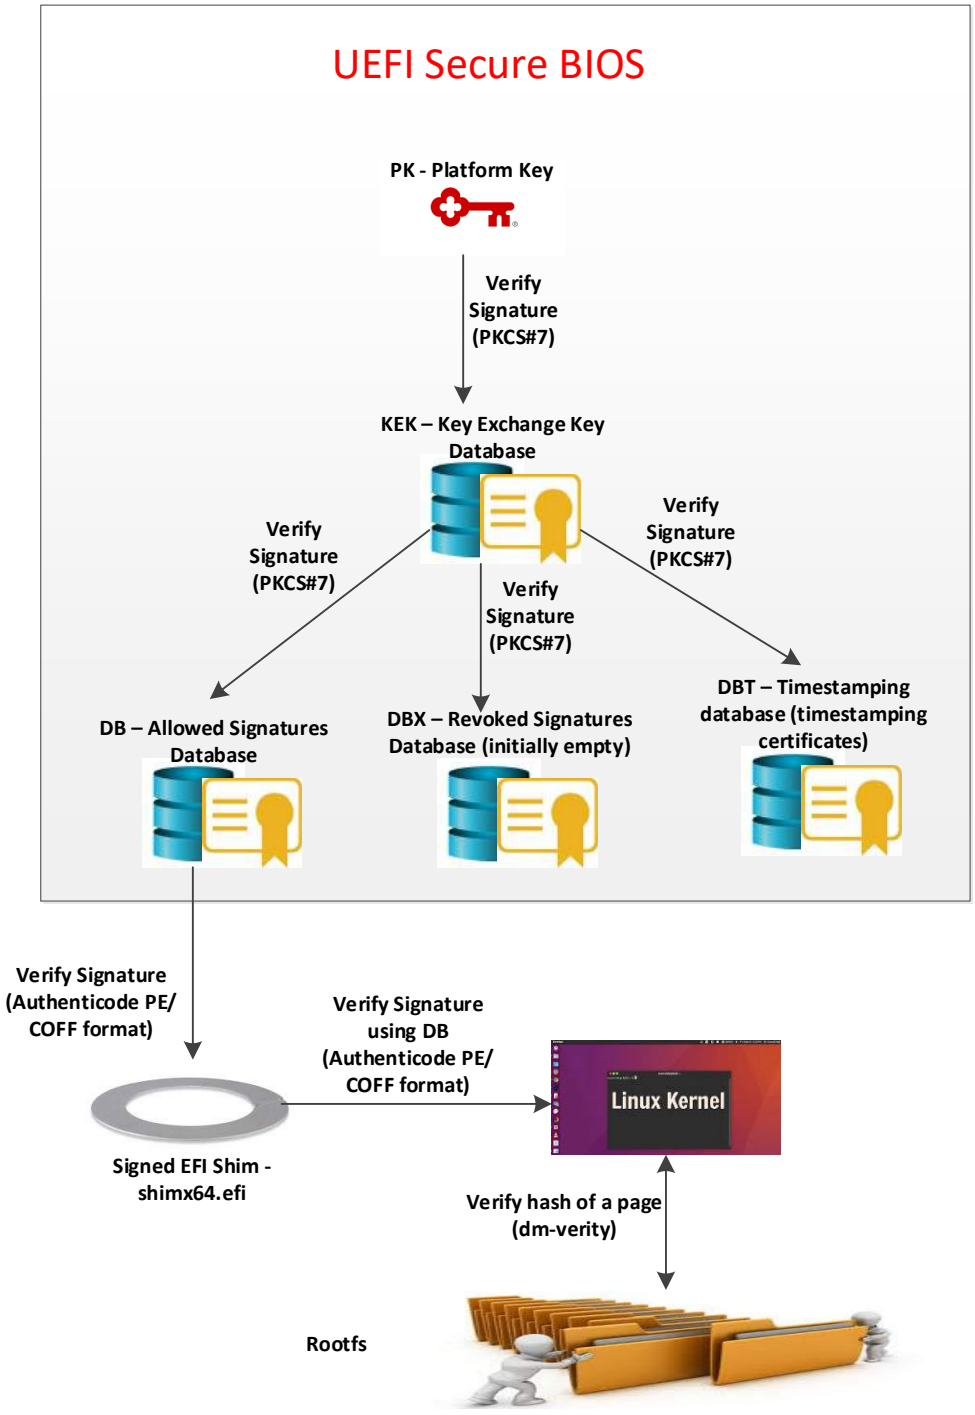

**Figure 1 - Example of Linux Secure Boot**

In this example, a standard UEFI BIOS that is now commonly available in Windows and Linux PCs as well as embedded devices has UEFI security turned on. It is assumed that UEFI BIOS is HW-protected and cannot be easily modified.[1] The figure shows the standard UEFI key/certificate hierarchy where the top-level Platform Key is used to verify the KEK (Key Exchange Key) which in turn is used to authenticate:

- DB (Allowed Signatures Database) that may for example contain a list of certificates that are permitted to validate a PKCS#7 signature.
- DBX (Revoked Signatures Database) may contain a list of code signatures that are on a prohibited list (e.g., due to security vulnerabilities in the corresponding code)
- DBT (Timestamping Database) – a list of certificates that may be used to validate signed timestamps, utilized to establish when a particular code release was signed. Timestamps may be utilized to reject an older version of the code with an earlier timestamp.

In this example, EFI Shim is first validated by a certificate inside DB and then launched and executed by the BIOS. EFI Shim in turn validates a signature on the Linux kernel (also using a certificate inside the DB) which is subsequently allowed to execute.

This is what is sometimes referred to as UEFI secure boot, but it is incomplete since none of the application code is authenticated and may be easily replaced by an adversary. One way to complete a Linux secure boot (as illustrated above) would be to:

- Place all applications, scripts and executables into a read-only file system such as a Linux rootfs.
- Configure the Linux kernel such that it contains a table of hashes of each page of the rootfs file system, using a facility called dm-verity [2]. Every time that a rootfs page is brought into RAM, its hash is validated. Any tampering to any of the code stored in rootfs will be eventually detected when the corresponding page is brought into RAM and it no longer matches the original hash of that page.

Such secure boot design can be achieved on some devices with custom firmware such as digital set-tops but in some cases, it is not possible to isolate all the executable code into a single read-only file system. Some devices by design have both executable code and data files stored within the same file system, some pages need to be dynamically changed and therefore page-level authentication techniques such as dm-verity do not apply.

In those cases, one cannot rely on secure boot to validate all of the binary code, especially application code, that may need to execute on a particular device. Techniques described in sections 6 and 7 of this paper provide alternative means to validate the more security-sensitive application code – even in the environments where full or even partial secure boot is not available.

## 3. Software Based Secure Boot Example

This next example of a software-based secure boot is simplified and has less software boot stage than you would normally see, but it illustrates how a software-based secure boot may be applied:

[1] Security guidelines for secure UEFI BIOS are provided in NIST SP 800-147

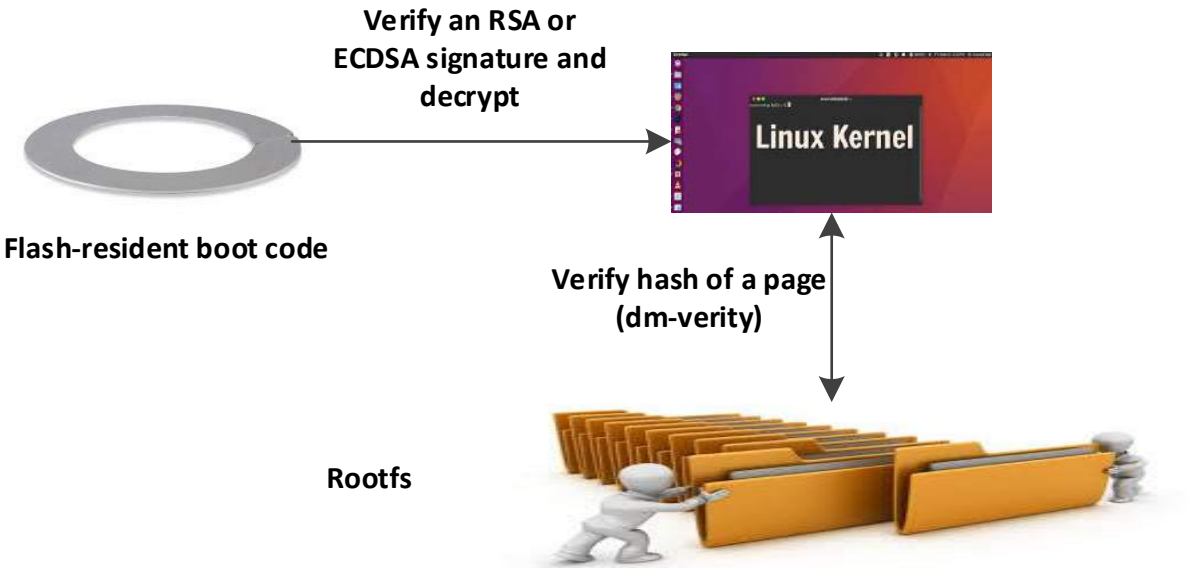

**Figure 2 – Software Based Secure Boot Example**

This device is relying on authenticity of the flash-resident boot code to verify integrity of the Linux kernel which in turn utilizes dm-verity to authenticate all the application code which is isolated in a read-only rootfs file system. This software boot architecture can provide secure boot only if we can be assured that the flash-resident boot code cannot be modified (e.g., by skipping a signature check on the Linux kernel).

Techniques presented in sections 6 and 7 of this paper may be utilized to prevent unauthorized modifications to the flash-resident boot code. Furthermore, this flash-resident boot code may be hiding a decryption key for the Linux Kernel using white box techniques to transform a cryptographic key. An attacker would have a hard time making changes to a self-validating version of the flash-resident boot code. However, replacing it completely would mean that the Linux kernel cannot be decrypted and extracting the decryption key for the Linux kernel is also made hard by white box techniques [3].

# 4. Static vs dynamic analyses

## 4.1. Static and dynamic analyses concept

Static and dynamic analyses of a software program are essential ways to discover software security vulnerabilities. They are both important elements of software security analyses and if done correctly, could expose cases that are more costly to resolve once the software is released to market. According to Wikipedia, "Static program analysis is the analysis of computer software that is performed without actually executing programs, in contrast with dynamic analysis, which is analysis performed on programs while they are executing." [4]

Static analysis requires a good knowledge of software architecture and its internal structures of the software application. It is certainly the more thorough approach and may also prove more cost-efficient with the ability to detect bugs at an early phase of the software development life cycle. It goes deep into the software providing peace of mind that each and every line of source code has been thoroughly

 

inspected. It potentially can examine all possible execution path without running the program [5]. In a more sophisticated cases, static analysis can be performed on the binary version of the software revealing valuable information about all branches of the code.

Dynamic analysis, on the other hand, is capable of exposing a subtle flaw or vulnerability too complicated for static analysis alone to reveal [6]. It can generate real-time results of execution paths and provides valuable information to security analysts about the software behavior in the runtime environment. In the dynamic analysis, a set of canned input data are typically being supplied to analyze the behavior and expected outputs/results. If done in the controlled and configured settings, it can expose valuable security vulnerabilities in the runtime.

Static and dynamic analyses are only effective if they become part of the software development cycle and performed on every release. This requires certain security policies and practices to be in place per each software release iterations. Policies and practices are evaluated during the design phase from a security point of view. Then static analysis is performed by each developer per each development cycle to identify any leaking security holes. The process continues into the application execution phase where dynamic analysis is conducted in the runtime [3].

As part of this iterative process, developers and security engineers review the analysis report and come up with appropriate recommendations for the development team to consider. The process has to account for a systematic way to feed back the analyses results to the development team and make it a routine practice to adopt. The recommended changes will then be funneled thru the cycle as any other software features or bugs. This systematic and comprehensive process is essential part of any successful static and dynamic analyses practice.

## 4.2. Static and dynamic analysis tools

The quality and coverage of the analysis dependent on the sophistication of the analysis tools. It varies from those that only consider the behavior of individual source code statements and declarations, to those that include the complete source code of a program in their analysis. Tool can be deployed at unit level, system level or integration level. For a complete list of tools targeting various types of software applications refer to [7] and [8].

A comprehensive evaluation of analysis tool is beyond the scope of this paper. However, it is worth to mention the following criteria in choosing analysis tools:

**Table 1 Static and dynamic analysis tools**

| Criteria | Description |
|---|---|
| Programming language | C/C++; Java; Perl; Python, etc. |
| Complexity of the code and inner logics | Code implementing mathematic, crypto and other complex algorithms |
| Input/output data media | Ways input and output data flow in and out of the application |
| Transport, network and communication mechanisms | TCP/IP, HTTP, etc. |
| Targeted Operating Systems | Linux, eLinux, Windows, Mac, etc. |
| Build environment | Host machine and cross compilers |
| Deployment platforms | Devices, servers, browsers, etc. |
| Virtual machines and containers | JVM, Docker, etc. |
| Obfuscation tools | Source code level or binary obfuscation |
| Configuration scripts | Settings and deployment scripts |
| Error handling and logging mechanisms | How errors and logs are exposed |
| Tool reporting capabilities | Reports and results of the analysis tool |

# 5. Tampering Attacks and Threats

A consumer electronic device faces two types of general threats:

1) Outsider attacks performed by an attacker on the Internet or a public WiFi network. The attacker is for example able to scan the network for vulnerable devices containing outdated versions of the OS, web server, web browser or other commonly utilized applications which have not been recently patched.

   Once such a vulnerable device is found, at attacker is able to place her own attack software on that device. Attack software may be utilized to:
   - Compromise user's privacy – search user's system for passwords, credit card numbers and other private user information. Even if your own PC and electronic devices are well-protected, your private information may be stolen from one of many online banks, storefronts or other websites where your personal information is exposed. There are numerous and frequent examples of large-scale breaches, including Facebook [9], Yahoo [10], Google [11] and many-many more. And you are not always in control of protecting your personal electronic devices as security flaws may be exploited for a considerable period of time until the security flaw is discovered and patched by the manufacturer. [12]
   - Steal user's computing resources for attacker's own use such as Bitcoin mining (called Cryptojacking). User's device will appear to be very slow while much of its memory and CPU resources are utilized by this attacker [13].
   - Launch a distributed denial of service attack (after compromising many vulnerable devices) onto popular Internet services or storefronts – for political motives, a personal vendetta or just to create chaos on the Internet. Examples of such attacks that were carried out against GitHub, independent media sites in Hong Kong, CloudFlare security provider and content delivery network, Spamhaus anti-spam service and U.S. banks [14].

   Frequent patching of the OS and applications in the devices that you own and setting up perimeter security with firewalls and IP address filtering (including restricting ports and services) would provide a significant deterrent at least against direct attacks against you or your enterprise.

2) Insider attacks performed by a subscriber against electronic devices that are owned or leased by the subscriber – in order to rip off digital content, including making illegal copies of movies, songs and games after stripping off or disabling DRM protection.

   Additional insider attacks may be performed by disgruntled or dishonest employees, contractors or vendors. Such attacks are generally mitigated with authorization techniques – each person has restricted access only to the computing resources, applications and digital information that are required for that person to perform his or her job.

The focus of this paper is on advanced techniques for protecting software applications against tampering attacks during execution in runtime. Section 6 describes techniques to make software tamper-resistant independent of underlaying platform-related code signing protection and without requiring any HW security capabilities on the device where it executes. Section 7 goes further to protect key security parameters that are utilized in the generation of tamper-resistant code on a cloud server with restricted access. Developers are able to utilize a cloud service for creating self-verifying tamper-resistant code without direct access to security-sensitive parameters.

# 6. Dynamic executable verification design and concept

Any software application is potentially vulnerable to *tampering attacks* aimed at defeating their security measures [15] [16] [17]. Tampering attacks are a particularly low effort way to achieve license circumvention and software piracy. In particular buffer-overflow and hooking attacks are common dynamic tampering attacks that regular code-signing methods cannot detect or prevent. The last line of defense (and in many cases the only line of defense) is for applications to be capable of strongly defending their intellectual property and secrets against any such attacks. The goal of integrity protection is to increase the level of effort and complexity of such attacks.

We begin with a brief survey of integrity protection mechanisms in common use. We then describe a novel construction of dynamic executable verification.

## 6.1. Related work

In this section we briefly survey the methods of integrity protection in common usage:

### *6.1.1. Static code signing*

The majority of integrity protection methods in commercial use are targeted at preventing *static tampering attacks,* which involve unauthorized modifications to a program's binary code prior to execution:

- Apple code signing [18].
- Microsoft code signing [19].

 

#### 6.1.1.1. Drawbacks of static code signing

Code signing and verification methods do not detect *dynamic* modifications made to the executable code at runtime, such as with *buffer overrun attacks* [20].

### 6.1.2. Self-checking

Horne et al. [16] and Chang and Atallah [21] present self-checking techniques, in which a program repeatedly checks itself to verify that it has not been modified. These techniques consist of the dynamic (or runtime computation) of a cryptographic hash or a checksum of the instructions in an identified section of code, which is compared with a precomputed hash or checksum value at various points during program execution. Detected tampering will then trigger a response mechanism; such as a silent-failure-mode.

#### 6.1.2.1. Drawbacks of self-checking

While such methods reliably detect unanticipated changes in the executable code at runtime, it is relatively easy for an attacker to identify the verification routine due to the atypical nature of the operation; since most applications do not read their own code sections [22].

Once detected, these schemes can usually be defeated with simple conditional logic modifications [21] or via hardware attacks [23]; and more recently by *virtual machine debugging attacks* [24], where the address ranges in a program's code section may be translated to an unchanged static image of the code so that any hash or checksum values are always computed correctly despite modifications to the underlying program code.

### 6.1.3. Just-in-time code decryption

Aucsmith [15] and Wang et al. [25] utilize the notion of self-modifying, self-decrypting code, where any tampering with the encrypted image will result in the decryption of "garbage" instructions, which leads to a catastrophic runtime failure.

#### 6.1.3.1. Drawbacks of just-in-time code decryption

Several constructions using variations of this technique have been proposed and implemented [26] [27] [28] with varying results; however the widespread adoption of memory protection standards such as PAE/NX/SSE2 [29], and more recently, Intel's MPX [30] with support in mainstream operating systems and toolchains [31], limit this method to legacy and non-standard implementations. For example, since version 18.x of the Microsoft CL compiler/linker, the specification of a writeable attribute on executable code sections is ignored at both compile and in link time.

### 6.1.4. Oblivious hashing

Chen et al. [17] proposed a technique called *oblivious hashing*, where the idea is to hash an execution trace of a code section. The main goal is to blend the hashing code seamlessly with the code block, making it locally indistinguishable. An oblivious hash is *active* in the sense that the code to be protected must run (or be simulated) in order for the hash to be produced. An oblivious hash also depends on an exact path through a program, as determined by the program's inputs.

#### 6.1.4.1. Drawbacks of oblivious hashing

Since an oblivious hash depends on a specific control-flow pathway in the executing program, this technique has limited applicability to specialist algorithms with simple linear control-flows. Additionally, since the computation of the oblivious hash is independent of other instructions being executed, tampering attacks that do not affect the internal control-flow of the program, such as *hooking attacks* [32], will remain undetected by this method.

### 6.1.5. Post-link executable modification

Many approaches involve the modification of executable code post-linking, so as to inject code or data elements used for the purposes of runtime verification, such as hashes or checksums.

#### 6.1.5.1. Drawbacks of post-link executable modification

- Incompatibility with standard code-signing and verification methods.
- Limited toolchain compatibility due to possible conflicts with compile-time or link-time optimizations.
- Conflict with technologies that modify binaries post-linking, such as Apple's *application thinning* [33].
- Potential dependency on external third-party tools to finalize binary representations.

### 6.1.6. Other (intractable) approaches

Some methods, such as self-modifying code [34], appear in commercial usage without tractable security descriptions.

#### 6.1.6.1. Drawbacks of intractable approaches

If the security properties of these methods cannot be objectively assessed, they are unlikely to pass a strict security audit.

## 6.2. Goals for integrity protection

We state the goals of integrity protection that we wish to satisfy with our construction.

1. Increase the cost of static and dynamic tampering attacks
    - Based on tractable principles that can be validated by a security auditor.
    - Resistant to real-word attacks.
    - Based on sound cryptographic principles.
2. Lightweight
    - Low performance overhead.
    - Small memory footprint.
3. Tunable
    - Fine-tunable percentage and locations of automatically generated integrity protection code.
    - Full manual control of integrity protection targets and the locations of verification code.
    - Automatic or custom detection responses.
4. Compatibility with standard code-signing

- Compatibility with standard code-signing and verification methods.

5. No frozen/finalized binaries
    - Frozen/finalized binary representations are not required.
6. Support a diverse range of use-cases
    - "Easy mode" where minimizing impact to existing processes is the primary motivation.
    - "Normal mode" for typical use-cases with reasonable expectations of security.
    - "Secure mode" for implementations where security is the primary motivation.
7. Future-proofed formats
    - Use of formats that provide future-proofing against changes to key sizes and cryptographic schemes, such as X.509.
8. Broad platform compatibility
9. Broad toolchain compatibility

## 6.3. Dynamic Executable Verification

In this section we describe a Dynamic Executable Verification (DEV) construction and its security properties.

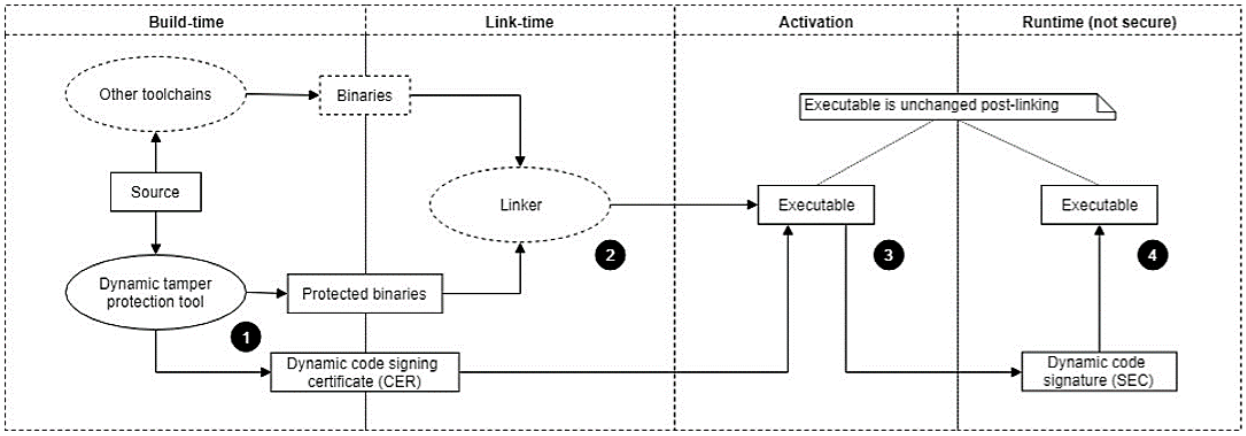

**Figure 3 Dynamic executable verification generic use-case**

1. Dynamic executable verification is added to an application at build-time to protect against tampering before and during runtime.
    - The tamper protection tool generates protected binaries along with a dynamic code signing certificate (CER).
    - The tamper detection code in the protected binaries is stealthy, diverse and spread throughout the application to mitigate discovery and circumvention of the tamper protection mechanics.
    - Unlike a static code signing certificate, the CER allows signing of dynamic code blocks within an executable to activate dynamic executable verification of that application.
2. Linking is done by a standard linker, which may incorporate unprotected binaries built by other toolchains.
3. Activation of dynamic executable verification is achieved by the executable using the CER to self-sign. This should be done in a secure environment to prevent the certificate from being leaked.

- If the certificate is valid and matches the protected portions of the executable, it generates a dynamic code signature (SEC) to be deployed along with the executable to the runtime environment.
- The executable is unchanged post-linking. This ensures maximum compatibility with sandboxed runtimes and traditional code-signing methods.

4. A runtime failure mode will be triggered if the executable or the SEC has been tampered with in any way before or during execution.

## 6.4. Construction

DEV protection is applied to a program (denoted by the symbol *P*) during compilation by the Dynamic tamper protection toolchain, resulting in a protected program (denoted by the symbol *P'*).

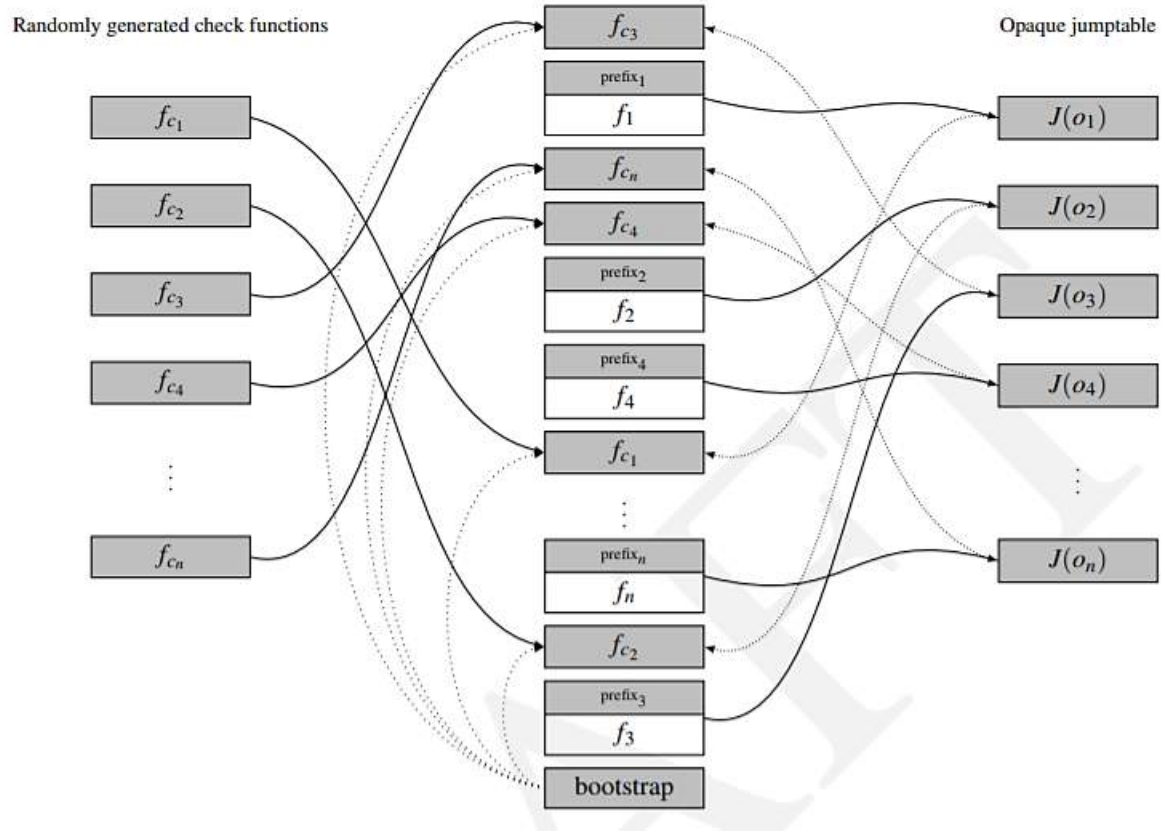

**Figure 4 The DEV module injects random function prefixes (middle), check functions (left), an opaque jumptable (right), and a bootstrap (bottom) into the protected binary at build-time.**

### *6.4.1. Random function prefixes*

As depicted in Figure 4:

1. For each function/method *f* in the input program *P*, a random 16 byte function prefix $f_{\text{prefix}}$ is prepended to *f* during compilation, using a standard LLVM operation [35]. We have verified that this method is compatible with all target platforms and toolchains; and with compiler and link-time optimizations.

2. LLVM ensures that the function prefix is aligned to the function's entry point, so that the injected checking code starts from the *prefix* address (typically flagged as an innocuous *data* section) rather than the actual address of the function *f*. This is designed to evade detection by automated and manual analysis techniques to identify self-referential tamper detection code [22].
3. At only 16 bytes per function, the use of a random function prefix is lightweight in terms of footprint, and has negligible impact on performance.

### 6.4.2. Randomly generated check functions

As depicted in Figure 4:

One or more check functions $f_c$ (denoting the check function $c$ of $f$) are randomly generated and injected at random locations in the protected binary $P'$

### 6.4.3. Opaque jumptable

As depicted in Figure 4:

1. The relationship between the calling function $f$, and check function $f_c$ is obfuscated via the use of an opaque jumptable $J$.
2. For each randomly generated opaque identifier $o \in O$, the opaque jumptable computes the mapping $J(o) = f_c$ so as to conceal the relationship between the calling function $f$ and the checking function.
3. Each checking function $f_c$ references the prefix $f_{prefix}$ of $f$ rather than $f$ itself, thus avoiding any direct reference to calling function $f$ from the checking function $f_c$.
4. For added security, the mapping $J(o)$ may be implemented as a complex Boolean expression based on a reduction to a known hard problem, such as 3-CNF-SAT [36].

### 6.4.4. Bootstrap

As depicted in Figure 4:

1. If the signature (.sec) data does not exist, and if a valid X.509 certificate is passed to the bootstrap, then the bootstrap will *activate* DEV protection by calling each checking function $f_c \in P'$ (via the opaque jump table $J$) to generate the secure signature data.
2. Activation is carried out one-time per implementation instance.
3. Post activation, the bootstrap reads the .sec data into memory for use during runtime verification.

## 6.5. Runtime verification

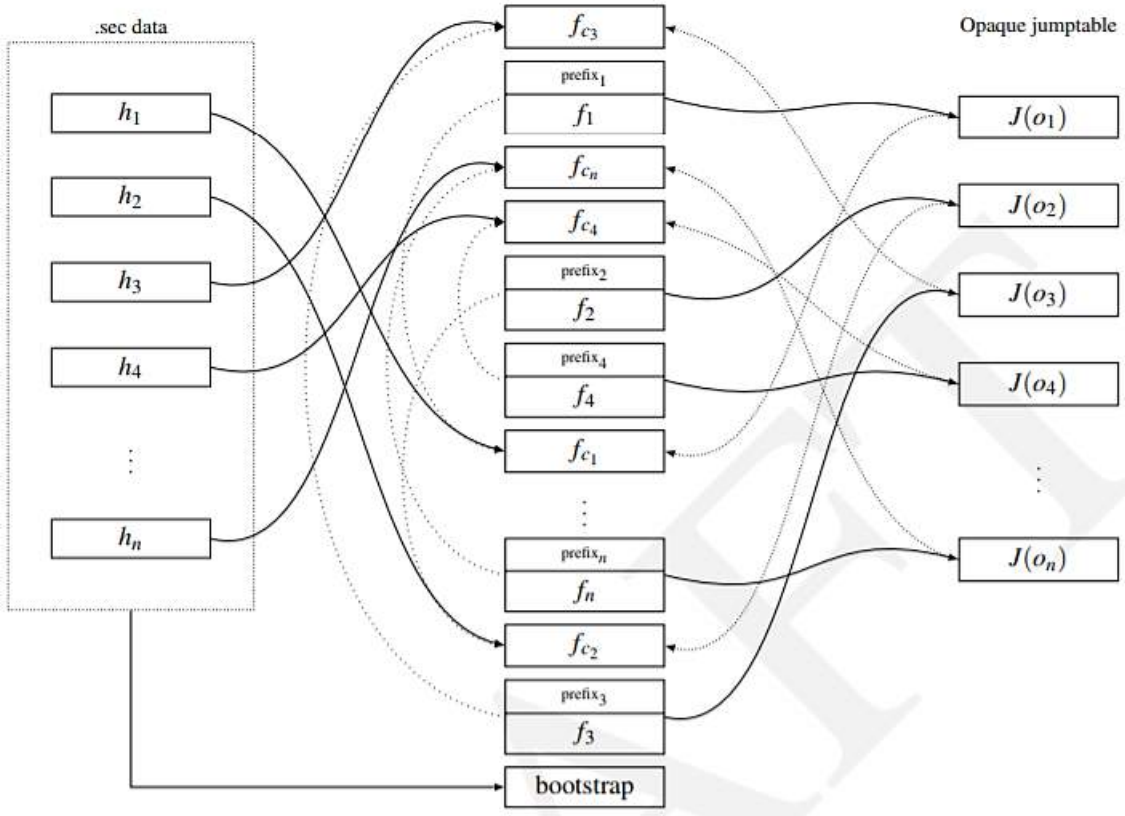

**Figure 5 Dynamic executable verification happens during runtime execution, where each checker function is called according to the mapping defined in the opaque jumptable.**

1. After DEV protection has been activated, the .sec data is used at runtime to enforce DEV integrity protection on all specified functions and methods.
2. Detected tampering with the executable or .sec data will result in a failure mode.
   - By default, the failure response should initiate a delayed system crash that is difficult for an attacker to track back to the detection code.
   - This failure mode may be overridden with a custom callback function by specifying the

## 6.6. Security

We have identified two primary security modes that can be utilized in conjunction with the activation method to achieve variable levels of security vs implementation overhead.

### *6.6.1. Mode 1*

In mode 1, DEV protection is activated on the *first run* of the protected executable program. DEV protection does not modify this executable at any time. During activation, the DEV bootstrap validates the supplied DEV X.509 certificate (.cer) data. If valid, secure signature (.sec) data is generated, which is used by the executable to enforce integrity protection at runtime.

### 6.6.2. Mode 2

In mode 2, DEV protection is activated by a *setup executable*, which is separate from the runtime executable. DEV protection does not modify either executable at any time. During activation, the DEV bootstrap validates the supplied DEV X.509 certificate (.cer) data. If valid, secure signature (.sec) data is generated, which is used by the runtime executable to enforce integrity protection.

| Security level | Mode | Activation | Runtime |
|---|---|---|---|
| Highest | 2 | Trusted | Untrusted |
| High | 1 | Trusted | Untrusted |
| Medium | 1 | Privileged | Untrusted |
| Low | 1 | Untrusted | Untrusted |

**Table 2 A range of security levels are attainable under different use-cases.**

1. Activation in a trusted environment coupled with the splitting of activation vs runtime (in mode 2) provides the highest security level.
2. For high security applications in mode 1, DEV activation should be carried out in a trusted setting, so that the X.509 certificate remains confidential.
3. A medium security level is attainable with mode 1 if DEV activation is carried out in a factory setting or in a privileged runtime mode.
4. A low security profile is obtained in mode 1 if DEV protection is activated *on-the-fly* when the application is first executed at runtime.

# 7. Cloud-based architecture for dynamic executable verification

We present a cloud-based dynamic executable verification architecture to strengthen the overall security properties of DEV. In particular this will offer improved security of the dynamic code signing certificate (CER).

- The cloud service will only permit dynamic code signing request from authorized parties for authorized applications.
- The cloud service consists of two scenarios:
    1. Cloud virtual machine-based activation
    2. Local activation utilizing cloud-based code signing
- This service will be able to interact with other cloud-based security services to offer detailed reporting, metrics, and security alerts.
    - Detailed tamper protection coverage.
    - Activation failures.
    - Runtime metrics.
- Cloud-based dynamic code signing cannot be carried out by developers without cloud credentials or with insufficient permissions.

- A correctly defined permissions structure will ensure that only parties with the appropriate credentials can request dynamic signing for production deployment and that signing will only be permitted for applications built with valid developer credentials.
- There is no path to input manually generated CERs from non-cloud tamper protection tools into the cloud-based dynamic code signing. This is by design to prevent unauthorized developers from signing executables for production deployment.

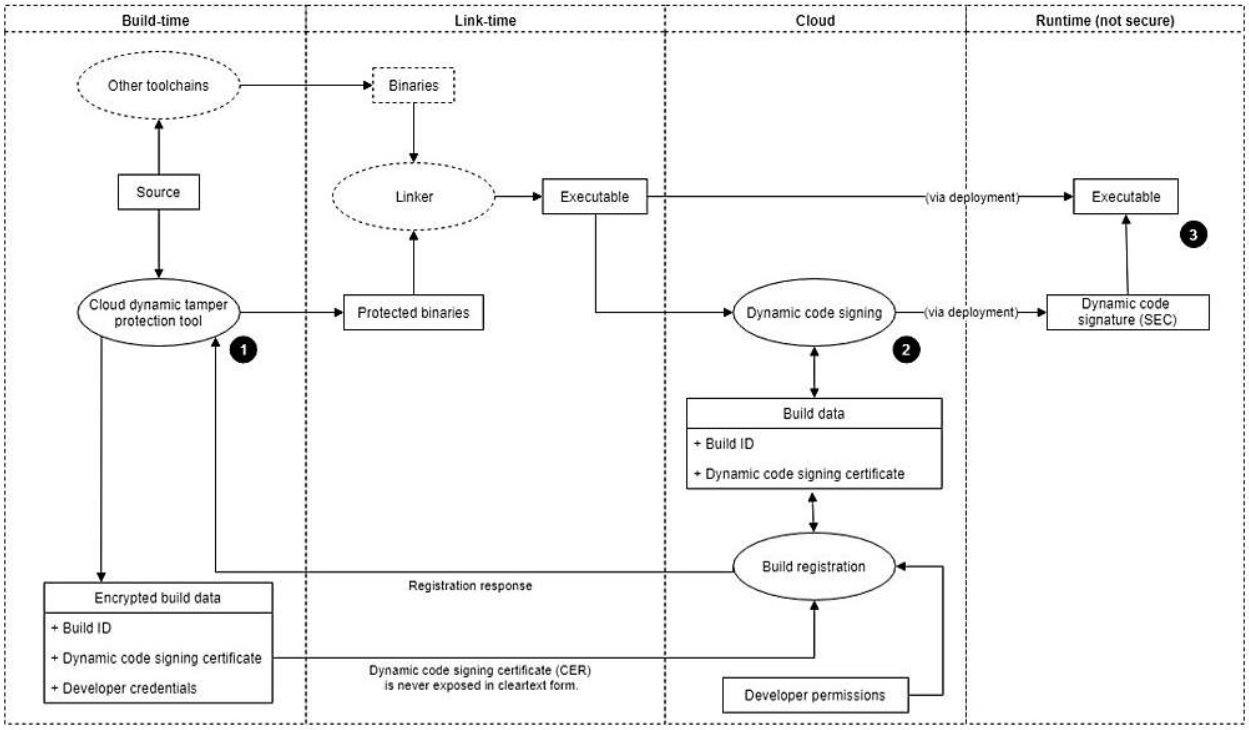

**Figure 6 Cloud-based dynamic executable verification**

1. At build-time, the cloud dynamic executable verification tool sends a unique Build ID and dynamic code signing certificate (CER) securely to the build registration cloud endpoint as depicted in Figure 6.
    - Cloud endpoint authenticates user's credentials before accepting the Build ID and CER over an encrypted link(e.g. using user name/password, digital certificate, one-time password, etc.).
    - Build registration will send a failure response if the request is not authentic or the developer credentials are not authorized for dynamic code signing.
    - Failure responses will abort the tamper protection tool with an error condition.
2. At activation time, the executable is securely sent to a dynamic code signing endpoint post-linking.
    - An authenticated connection to this endpoint is assumed to exist.
    - Cloud service runs executable in a secure VM to obtain a dynamic code signature (SEC).
    - If the executable is invalid, the dynamic code signing fails, or if the developer permissions associated with the Build ID are insufficient, the endpoint will abort with an error condition.
    - Otherwise, the endpoint returns the SEC for runtime deployment.

- Note that the dynamic code signing cloud endpoint does not accept a CER as input, thus preventing non-cloud protected executables from being signed.

3. A failure mode will be triggered if the executable or the SEC has been tampered with in any way before or during execution at runtime.
    - Note that the executable remains unchanged post-linking.

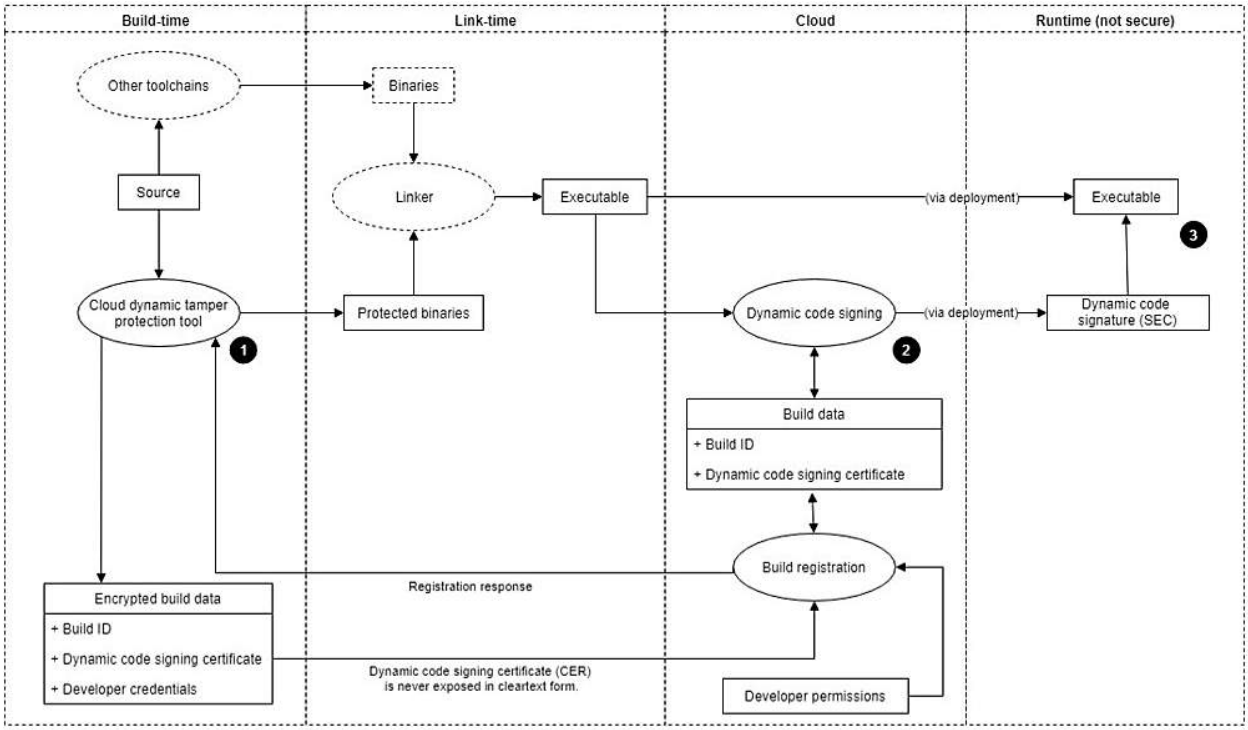

**Figure 7 Cloud-based dynamic executable verification (no cloud VM)**

1. In this scenario, the customer must set up a secure runtime environment to carry out the following.
    - Run a linked executable to generate a Dynamic Code Signing Request (DCSR).
    - Send the DCSR to the dynamic code signing cloud endpoint (via an authenticated connection).
2. The dynamic code signing cloud endpoint evaluates the DCSR.
    - An authenticated connection to this endpoint is assumed to exist.
    - If the request is not authentic, the DCSR is invalid or the developer permissions associated with the Build ID are insufficient, the endpoint will abort with an error condition.
    - Otherwise the endpoint returns a dynamic code signature (SEC) for runtime deployment.
    - As with the base scenario, the executable remains unchanged post-linking.
    - Note that the dynamic code signing cloud endpoint does not accept a CER as input, thus preventing non-cloud protected executables from being signed.

# 8. Application use cases

Dynamic executable verification discussed in this paper opens a great potential with a lot of oversights to designers/developers in protecting their applications. This technology provides ability to delivery software application with self-contained protection against tempering attacks without depending on the targeted platform security offerings. The ability to sign a portion of your software binary and dynamically verifying it in the runtime is applicable to any software application. A wide range of applications can utilize such techniques in their security software development practices and immediately obtain visibility into their application protection. Here we highlight a couple of these use cases.

## 8.1. Browser-based application

Browser-based application is a piece of software running in the browser context. It usually comes in a form of extension (i.e. Chrome) or plug-in (i.e. Edge) or even natively compiled binary (i.e. web assembly in Firefox). As a result, its live time and resource capabilities are limited to the browser session and prone to its attacks. Dynamic executable verification provides independent detection of browser session attacks to the application running in that context no matter which browser is hosting the application.

## 8.2. Container-based server application

As containers become more widespread and acceptable way of deploying server applications, more and more companies are migrating their application to utilize such environment. That of course comes with its own security risk and again dependency on the container provider. As a result, the application security relies on the security of underlaying container technology. Dynamic executable verification provides independent detection of attacks leaking out of hosting containers to applications. This provides a peace of mind to companies virtualizing their application to cloud.

## 8.3. DRM application

DRM agents or libraries hosted in an application can be subject for tampering attacks to lift and later user credentials and authorizations. Dynamic executable verification with cloud-based feature can actively detect and provide visibility to these types of attacks. It gives device/platform independent integrity protection and verification to strengthen the very core features of DRM applications.

# 9. Conclusion

In this paper, we discussed a software protection technology that can fill in the gap in securing applications without any dependencies on the targeted platform. Dynamic executable verification with cloud-based addition helps security engineers and developers to detect tempering threats throughout the code (as needed) in the runtime and take appropriate measures to remedy against them. This enables companies to deploy iterative security analysis processes with independent verifications in their software development practices, utilizing feedback received from attack surface analysis in runtime. There are all kinds of applications in various domains with different use cases that can benefit from this technology and take advantage of its features immediately. CommScope has deployed Dynamic executable verification technique in several products including DRM agents already and in the process of using cloud-based variation in near future.

# Table of Contents

## List of Figures

# 1. Introduction

There is a limit to how many bits can be sent down an optical fiber. This limit, known as the 'Shannon Limit' is defined as the maximum rate at which data can be sent over a medium with zero errors. Technologies such as coherent optics allow operators to get closer to this theoretical limit. However, moving forward, the gains in spectral efficiency that will be achieved with future generations of coherent technology are diminishing. This will require alternative approaches and ideas to deal with network scalability challenges. Using updated designs, next generation hardware, and software tools, network operators will be able to extend the life of their networks as well as deploy new networks more quickly, efficiently, and accurately. Using these ideas, operators can start reducing the slope of their spectral usage curve while at the same time, deploying new photonic networks with higher efficiency.

# 2. Preface

It is estimated that global internet traffic will grow 3.7-fold from 2017 to 2022. Globally, IP traffic (alone) has also grown three-fold in the same period. This reflects a compound annual growth rate (CAGR) of 30% and 26% respectively[1]. Drivers for this tremendous growth include Video (IP, Internet, VoD), gaming, mobile devices, social media, and the Internet of things. Additionally, the average residential bandwidth speed has more than doubled from 24 Mbps to almost 50 Mbps. Consumers now regularly achieve 100+ Mbps download speeds with "standard" cable internet service.

Looking into the future, will these tremendous growth rates continue? And what are the drivers? The answer to the continued growth question is "yes". The drivers will be new and expanded offerings that will continue to drive the need for bandwidth such as medical imaging, tele-medicine, virtual reality and gaming, cloud storage, and of course this new necessity of "working from home". These new drivers, as well as the old ones, will continue to drive demand for the internet and fuel the growth of optical networks.

How much bandwidth will be needed? While this is certainly a "loaded" question, let us consider some simple math that could provide some direction for thought. The C-band, or conventional band, covers the fiber spectrum from 1530 nm to 1565 nm and is approximately 4800 Ghz wide. That might be forty-eight 100 Ghz spaced channels or that might be ninety-six, 50 Ghz spaced channels. If we consider ninety-six 50 Ghz spaced, 35 GBaud, 100 Gbps channels as a "full spectrum system", how many of these "full spectrum systems" are required if we project a 25% CAGR into the future for the next 11 years?

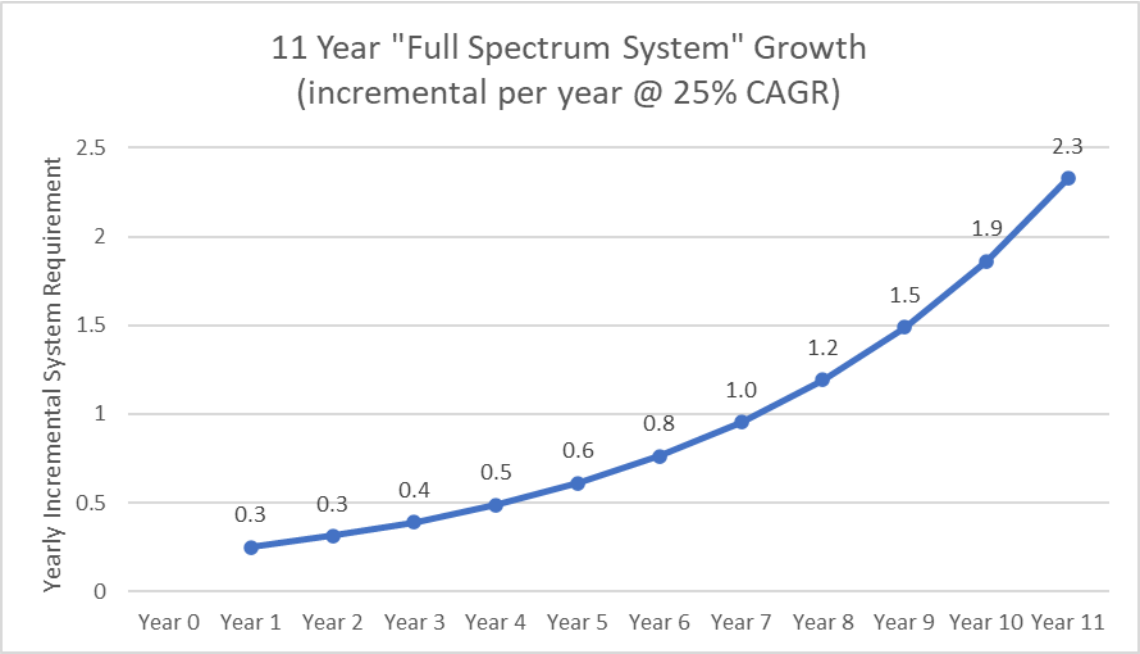

**Figure 1: 11 Year 'Full Spectrum System" Growth**

This graph shows that using a compound annual growth rate of 25% per year, an operator using a photonic layer capable of ninety-six 100 Gbps channels will, by year 7 have to deploy and enable a new, full spectrum, photonic system with EVERY subsequent year. When the provider hits year 11, the growth rate exceeds TWO new, full spectrum systems every year.

So, how are operators to keep up with this growth? This paper has been written to suggest strategies that might be used by multiple-system operators (MSOs) to efficiently scale their networks and support more capacity with fewer incremental systems/fiber pairs (and network resources), and improve efficiencies for their customer as well as for their shareholders.

# 3. Network Design

## 3.1. Migration from Older Technologies

Older generation photonic networks are typically based on 100 Ghz or 50 Ghz ITU grid and use passive, fixed grid filters to provide optical channel access. These older systems are reaching capacity based on the limited spectral efficiency of this generation of photonics and transponders. The first opportunity that operators could use to slow their system deployment curve is to upgrade an older, fixed grid network to a newer, flexible grid photonic system.

Much of today's newer photonic equipment is still backward compatible with the older, fixed grid standards. This would allow, for example, flexible grid WSS hardware to provide a direct replacement for older fixed grid WSS hardware in the existing fixed grid network. This equipment compatibility would permit network operators to upgrade high use portions of their existing fixed grid system, using the current fiber pair, to newer, flex grid capable wavelength selectable switch (WSS) hardware. Additionally, flex grid capable colorless channel mux/demuxes would also be installed with the new flex grid WSS modules. Once the flex grid capable photonics are in place, flex grid functionality could be "enabled". Operators could then utilize the full functionality of flex grid. This fixed to flex upgrade does

come with challenges such as migration maintenance windows, specific channel pass-through rules, and operational differences between the fixed and flex grid portions of the network. However, if specific portions of the fixed grid network are bandwidth limited, this type of flexible grid upgrade is an option available that could increase the spectral efficiency by as much as 350% on the new flex grid portion of the network.

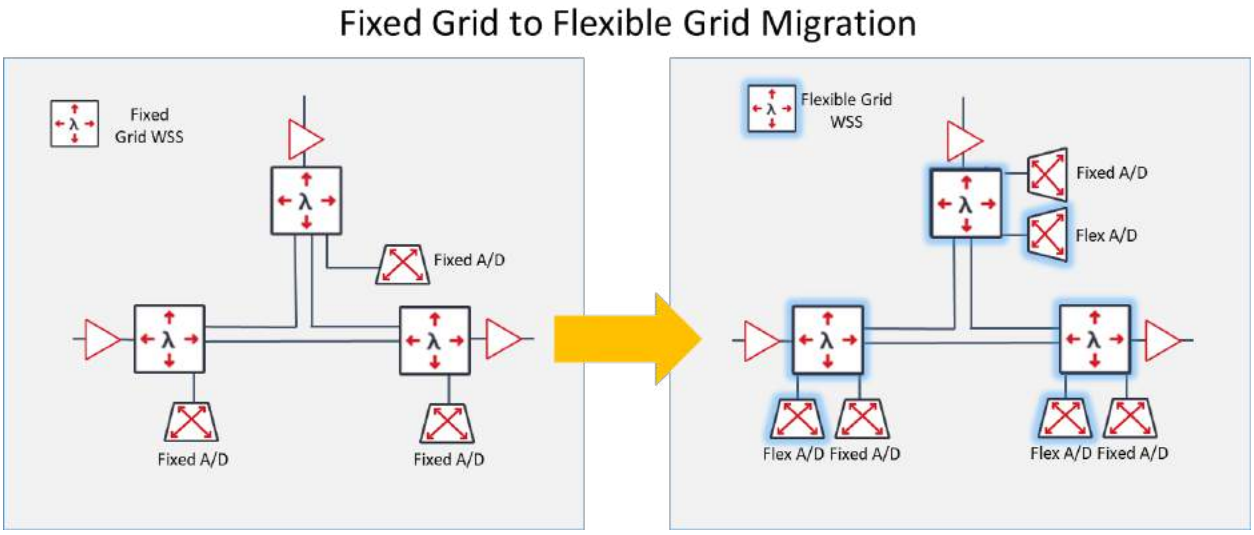

**Figure 2: Fixed Grid to Flexible Grid Migration**

With proper network planning during the fixed to flex migration, the spectrum can also be "de-fragged". The de-frag would allow for the efficient continued use of the operator's current transponders while also allocating space for the use of next generation, larger bandwidth transponders. This upgrade enhancement will delay network exhaust because of the higher spectral capacity of the next generation hardware while continuing to utilize existing transponder assets that the operator has already purchased.

## 3.2. Express Overlay Networks

Many current MSO networks were built as "one size fits all" networks. The one size fits all network must provide all transport functions including Core-to-Core, Core-to-Region, and Region-to-Region connectivity. These different functional traffic flows cause the network to grow at different rates. When highly used portions of the network grow faster than other portions, bandwidth bottlenecks can occur.

Single use, express overlay networks is another strategy available to MSOs that could provide targeted relief and extend the life of the original network. In the portions of the network where bandwidth bottlenecks are starting to occur, an express overlay photonic network could be added that would address the highest functional contributor to the bandwidth. As an example, if there is a bandwidth bottleneck in a Core-to-Core corridor, a new, purpose-built Core-to-Core express overlay network could be added. This does two things. First, the original Core-to-Core traffic would be migrated to this new network path. This migration of bandwidth from the original to the new express overlay system would free up spectrum on the original network for additional Region-to-Core and Region-to-Region traffic. This extends the original network's "time until full". Second, the new path could be built using new technologies (flexible grid, next generation transponders) that would then increase the spectral efficiency of the new path helping to slow even further the need for additional photonic systems.

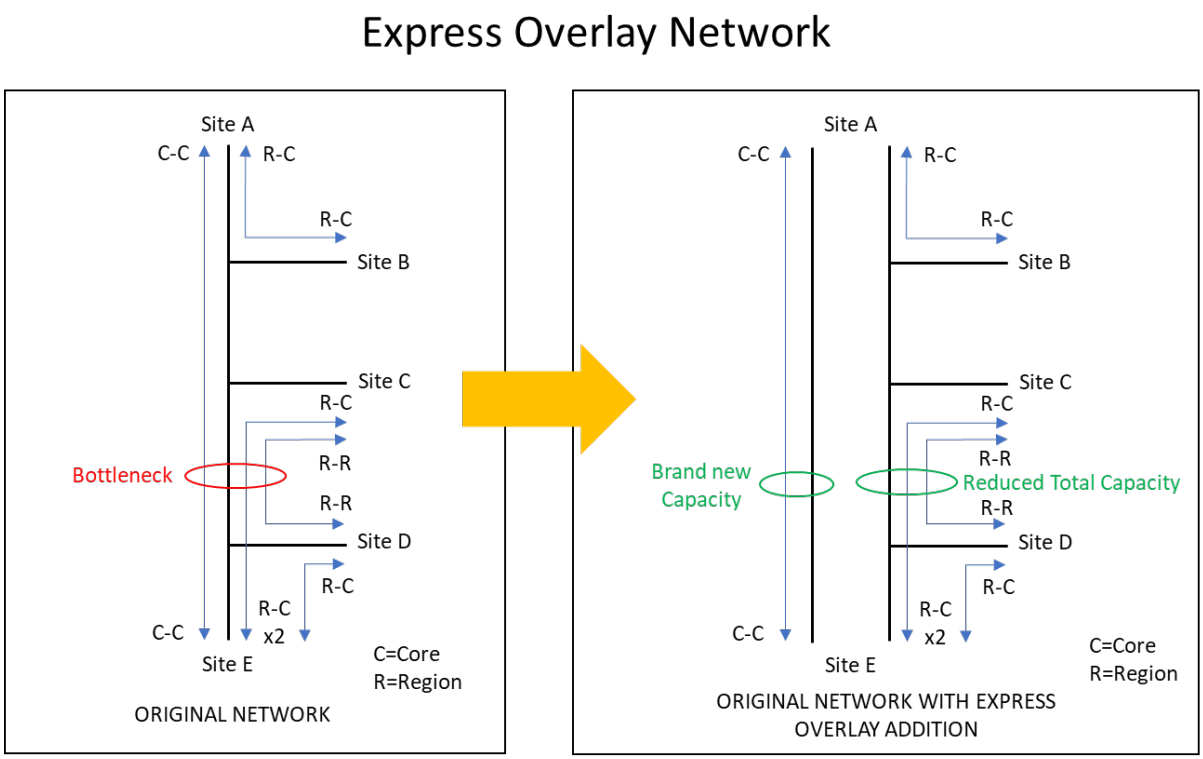

**Figure 3: Express Overlay Network**

## 4. New Hardware

In addition to network design strategies, there is a new generation of photonic equipment that can dramatically increase spectral efficiency and thus increase the time required between network builds. This new hardware includes higher baud, coherent modem technology that creates higher bandwidth channels to optimize reach and eliminate regeneration. Flexible grid photonics facilitate the efficient transport of higher baud transponders and ultimately increase the spectral density of the fiber and lower the cost per bit. L-Band photonics that enable the L-Band spectrum adjacent to the C-band allow for doubling the capacity of the fiber, increasing the return on investment of fiber assets and delaying new fiber builds.

### 4.1. Higher Baud, Higher Bandwidth Transponders

Using today's newest optical transponders, operators can make transponder selections that exactly fit their network transport needs. "I have a short link, and I need maximum fiber capacity." Or, "I have a long link and I don't want any regeneration." And, "I want to optimize my spectral efficiency." Today's newest generation optical transponders can provide a solution for all of these needs.

With the ability to select coherent optic technology with baud ranging from 35 GBaud up to 95 GBaud, spectral efficiency can be optimized for the given photonic layer topology. Today's transponders use probabilistic constellation shaping which creates the ability to select optical transponder line rates from 100 Gbps to 800 Gbps to optimize the capacity relative to available margin. The new transponders also use enhanced forward error correction (FEC) and other sophisticated algorithms that ultimately permit longer reach of the photonic signal.

These next generation transponder features allow network operators the ability to independently select the baud and line rate to maximize the spectral usage across a desired path. As an example, for shorter reach paths an operator would be able to create an 800 Gbps link while using a symbol rate of approximately 90 Gbaud. Then, provision a second transponder pair to create a non-regenerated 400 Gbps line using 95 GBaud on a path that goes from Miami to Seattle. Finally, a third transponder pair could be used to "dial in" the optimal bit rate to satisfy any specific route in-between. This degree of transponder flexibility is creating a new paradigm in how photonic networks can optimize their spectral use.

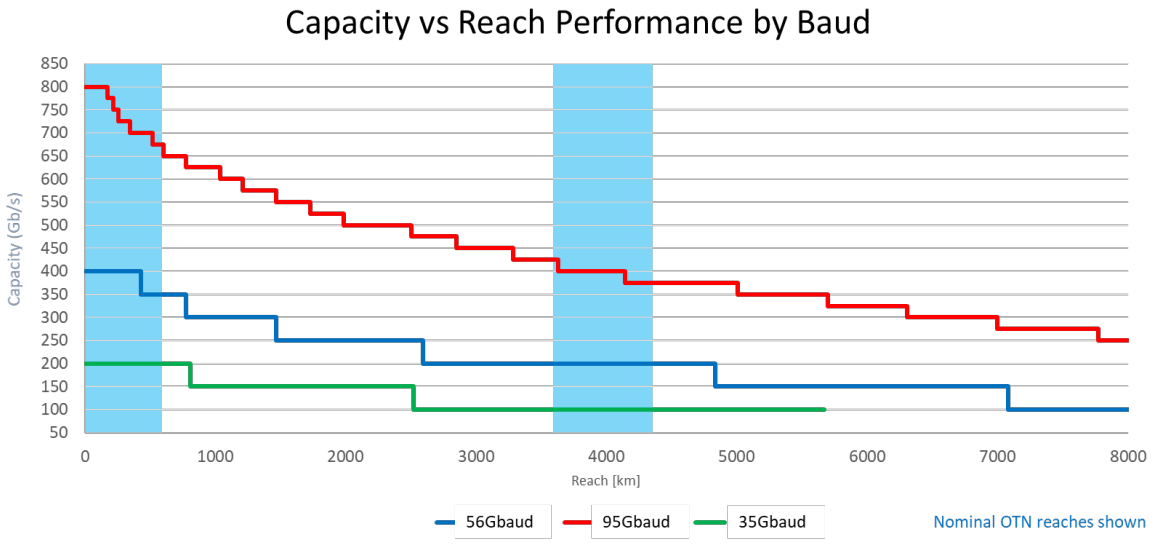

**Figure 4: Capacity vs. Reach Performance by Baud**

## 4.2. Flexible Grid Photonics

Older generation optical networks are based on 100 Ghz or 50 Ghz spaced photonic systems. These older, gridded networks can offer forty-eight or ninety-six fixed grid optical channels within the total 4800 Ghz C-Band spectrum. This fixed grid spacing is based on the ITU standard and has been the norm for most photonic systems for over 20 years. These older systems use passive, ITU grid filters to provide wavelength ingress/egress. Second and third generation optical transponders running at 35 GBaud typically require 37.5 Ghz of optical spectrum which fit perfectly into these ITU gridded filters. This version of the network has served the industry well for years.

As next generation transponders become available, they bring with them the need for larger per channel spectrum. This larger channel spectrum requirement exceeds that which is available on these ITU gridded filters. Flexible grid photonics offer bandwidth "chunks" as small as 6.25 Ghz. The flexible use of these 6.25 Ghz chunks as well as a WSS based mux/demux for wavelength ingress/egress, permits more granular utilization of spectrum needed for the desired network transmission characteristics.

With flexible grid photonics and the ability to change the baud and bit rate of each specific transmitter, network operators can optimize the use of the spectrum. In the situation where the operator provisioned an 800 Gbps channel using a symbol rate of 90 GBaud, this configuration would provide as many as 48 (x800 Gbps) channels which is a total bandwidth of 38.4 Tbps on the fiber pair for a short reach path in the C-Band. If the L-Band is in place, that number is doubled. In the example of a path that crosses the United States running at 400 Gbps and 95 GBaud, this configuration would provide as much as 33.6 Tbps (42x400 Gbps channels) transported coast to coast without any O-E-O regeneration.

Flexible grid photonics add another level of adjustability to the new optical network. With the ability to specify the guard band appropriate for the link design, operators can engineer their photonic deployments with the highest spectral efficiency available for their specific network. For example, on shorter photonic paths, packing multiple network media channels into a single media channel allows for a reduced guard band size which permits the channels within the media channel to occupy less spectrum. This ultimately allows more channels to be placed in the total spectrum. This guard band reduction is another way that flex grid photonics improve spectral efficiency.

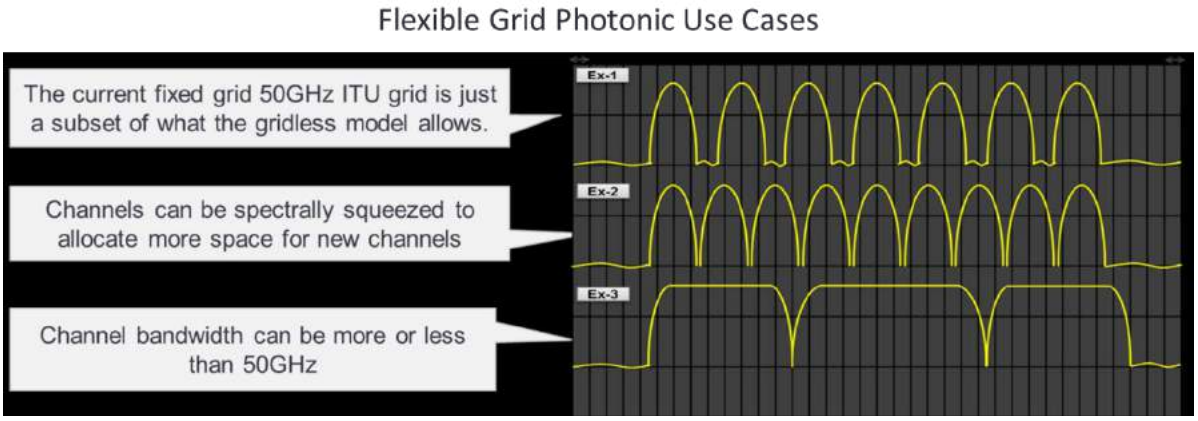

**Figure 5: Flexible Grid Photonic Use Cases**

## 4.3. L-Band Capability

As the incremental gains in spectral efficiency progressively diminish with each new generation of coherent technology, expanding the photonic layer into the L-band is becoming an increasingly popular option for scaling networks. The L-Band, long band, or extended band is the wavelength band immediately next to the C-Band. The L-Band covers the spectrum from 1565 nm to 1625 nm. For years, the L-Band has held the promise of extending the usable spectrum for operators. Unfortunately, first generation L-Band hardware never commercially delivered the additional L-Band capacity due to usability issues and deployment/upgrade complexities.

First generation L-Band deployments required splitter/couplers to provide fiber access to the L-Band equipment that was to be added later. These splitter/couplers used valuable span margin ultimately reducing much needed receiver optical signal to noise ratio (OSNR) on early generation transponders.

Additionally, when the L-Band is added to the C-Band in an active network, the L-Band can experience optical amplification at the expense of the C-Band due to stimulated raman scattering (SRS). So, when the L-Band is finally added to the C-Band fiber, the C-Band could experience a reduction in optical power. This reduction in C-Band total power has a potential impact to the OSNR of those in-service C-Band channels, especially when the C-Band spectrum is full. This link performance challenge is made harder by different fiber types, span losses, raman configurations, and channel powers in the network. As a result, the link engineering for the L-Band addition can be quite complicated.

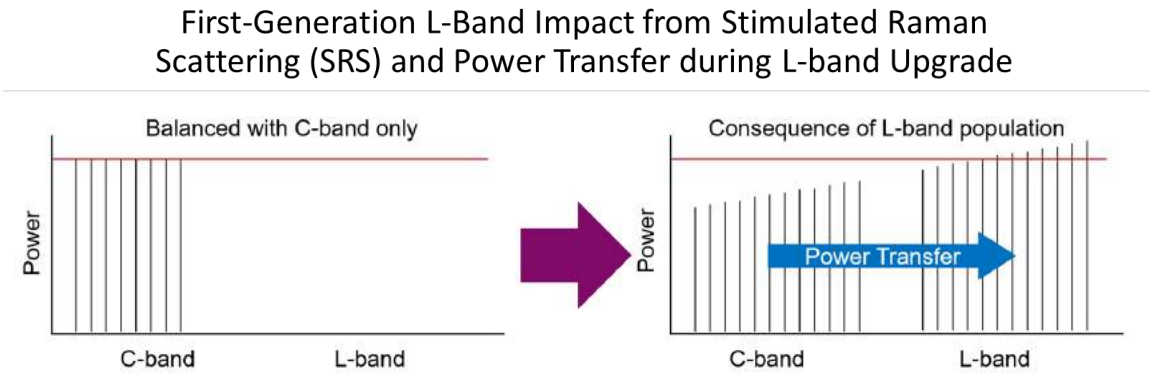

**Figure 6: First Generation L-Band Impact from Stimulated Raman Scattering (SRS) and Power Transfer during L-Band Upgrade**

Finally, the first-generation L-Band upgrade challenge was further complicated by the fact that none of the L-band hardware had been added day one. This meant that every site in the network had to be visited to add the needed L-Band equipment. On larger networks, a visit to every site could be very costly and time consuming.

Next generation C&L band equipment includes the day one deployment of both C&L band optimized/ready hardware. These new photonic systems include C&L band amplified spontaneous emission (ASE) that provides "full power" to the entire C&L band spectrum from day one. As working channels are added to the C&L system, the ASE for that spectrum is replaced by the new channel, keeping the total power constant. This means that once the new C&L photonic system has been engineered and turned up, no additional link engineering or optimization is required. The operator can count on stable, predictable performance across the lifetime of the system, regardless of the channel count.

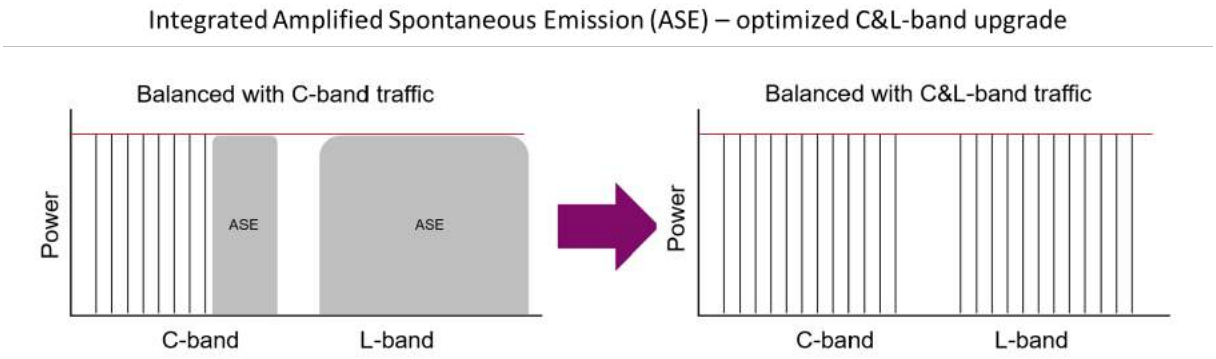

**Figure 7: Integrated Amplified Spontaneous Emission (ASE) – Optimized C&L-Band Upgrade**

From a deployment perspective, all intermediate sites (line amplifier and dynamic gain equipment (DGE)) would include full C&L band capable equipment day one. The "terminals" would include the C-Band WSS and C-Band amplifiers as well as both C&L band ASE hardware. Using this configuration, the C-Band can be fully populated with transponders from day one while the L-Band (with ASE) is idle. Then, when capacity demands require upgrade to L-Band, only the terminal sites are visited where the L-Band WSS and amplifier hardware is added. Since the intermediate line amplifier and DGE sites are deployed

full C&L band day one, these sites do not require any additional visits or work. All the limitations of the first-generation L-Band have been addressed and corrected with these new C&L band photonic systems.

An additional benefit of having all the C&L line amplifiers and DGEs already deployed is L-Band upgrade velocity. Since the L-Band upgrades only require a visit to the terminal sites, these upgrades can happen in a very rapid manner.

### 4.4. Additional Fiber Diagnostics

Today's new photonic systems also include "onboard" fiber diagnostic equipment. Every new photonic element (terminals, line amps, and DGEs) now includes an integrated optical time domain reflectometer (OTDR) that can measure fiber length, fiber loss, reflective events, and chromatic dispersion. Additionally, with the support of the built in ASE, the non-linear properties of the fiber can also be evaluated in real time. These enhanced fiber characterization capabilities will make photonic layer turn ups more accurate and provide the NMS with in-service, real time fiber information permitting a host of improvements in network operations and maximizing network capacity.

## 5. Software and Automation

Software and automation continue to increase its role in our lives, from an alarm clock on our smart phones to automated control of our home thermostat. Likewise, software and automation are becoming more critical to the efficient operations of network operators as well. The following are next generation uses of software and automation that will become essential to operators' ability to work efficiently.

### 5.1. Software – From Planning to Operating

Telecom operators have always struggled with software. There were different software platforms for every vendors' equipment. There was an Element Management System (EMS) for each different network element. There were Network Management Systems (NMS) for every platform. These different systems typically did not communicate with each other and as a result, interoperability between different vendors' EMS/NMS systems and the equipment under those systems was difficult to affect. These systems were basically good at one thing . . . managing their specific equipment and the signals going through them.

Today's next generation NMS systems take a much more holistic approach. These new NMSs are designed with "open" in mind. North and sound bound interfaces allow operators to utilize single system orchestration across multi-vendor domains. Additionally, these systems are no longer just for operations, alarms, management, and provisioning. Next generation network management systems have been architected to additionally provide support for the entire network life cycle from planning to deployment to operations to optimization.

### 5.2. Planning Equals Deployment

In the past, planning was considered a necessary evil. There were never any good planning tools. So, everyone "had a spreadsheet". When design and planning are completed offline, the probability of the plan and the network becoming out of sync is very high.

The next generation NMS has integrated the planning function into the NMS. Now, design and planning can be done on the NMS itself. Those designs and plans are stored on the NMS which assures that there is complete agreement between the designs and the network. When new planning is needed, the network is the starting point for the new plan and all previously created designs are considered in the new plan. As plans are implemented and become deployed in the network, the NMS is aware of these adds. The

 

ability of the NMS to be the gatekeeper is especially helpful in companies with large planning groups. The synchronization between planned and deployed keeps everyone on the same page thus reducing waste from duplicate, overlapping, or incompatible designs.

## 5.3. Zero Touch Provisioning

Once a new design has been created, how is that design processed into deployed and operational equipment? In the past, the design was probably transferred to a spreadsheet and a drawing was made which was then handed off to the deployment team who re-typed the provisioning data from the spreadsheet into the new equipment. This method was inefficient and potentially inaccurate with many manual operations required.

In today's environment where NMS planning has been completed, the NMS planned design is converted into a group of Zero Touch Provisioning (ZTP) files by that same NMS. The NMS sends the necessary ZTP files to a designated FTP server. After physical installation and power-up of the equipment is complete (including the connection of fiber), the installer provides the equipment with an IP address and the location of the FTP server. The new network element retrieves its boot file and commissioning file and then self-installs the commissioning information. Once the ZTP process is complete, the element reboots and is fully functional and ready for use.

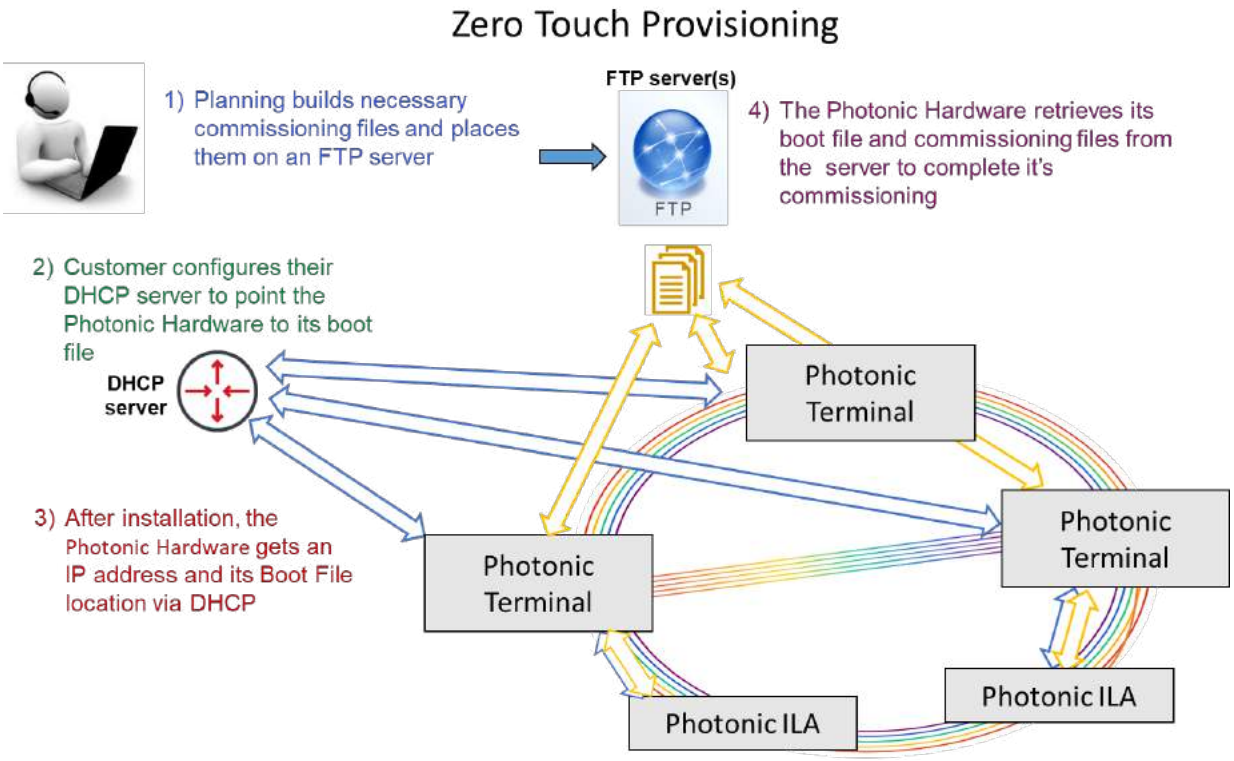

**Figure 8: Zero Touch Provisioning**

Another aspect of photonic ZTP is the ability of the amplifiers to self-characterize the fiber to which they are connected. The onboard OTDR provides advanced Fiber Characterization (FC) to thoroughly characterize the fiber plant connected to each amplifier. This FC information is provided back to the NMS. Using the configuration tools built into the NMS, optimized amplifier provisioning information can be calculated and provided back to the photonic hardware on a span-by-span basis to achieve the best

possible performance. This software based, photonic optimization results in the highest possible spectral efficiency for that fiber path.

Finally, post turn up, these same fiber characterization tools allow operators to monitor their fiber plant to preemptively respond to issues and provide detailed information to isolate those issues when they arise.

Since the ZTP information delivered to each network element has been validated by the NMS, it is highly accurate. The accuracy of this information will reduce the overall time required to turn up new network elements. When bandwidth demands require operators to deploy a full photonic system every year, ZTP will be essential to accomplishing this deployment in an accurate, timely manner.

## 5.4. Margin Mining

On older fixed grid photonic systems, it was difficult to determine available transponder Rx OSNR margin. In some cases, error corrections could be counted and compared to pre-FEC numbers. Then, using complicated math, operators were able to confirm that their transponder channels were running within acceptable margins. However, even when these calculations were available, there was limited ability to change the characteristics or performance of those channels.

Today, advance software features coupled with next generation photonics and newer baud and bit-rate adjustable transponders provide many optimization options to network operators. One of these newer software implementations is margin mining.

Next generation photonics can provide enhanced operational information including fiber loss, dispersion, fiber types, span counts, BER, and SNR margin. Additionally, next generation transponders can change both the baud and bit rates to maximize performance. Using these parameters, the NMS can now identify available margin and quantify that margin for use in the network. Margin mining can be used to identify this available margin and increase a transponder's bit rate improving the throughput on the link. Margin mining could also be used to reduce the guard band between channels while using the current baud and bit rate. In both cases, there is an increase to spectral efficiency which will result in longer system longevity.

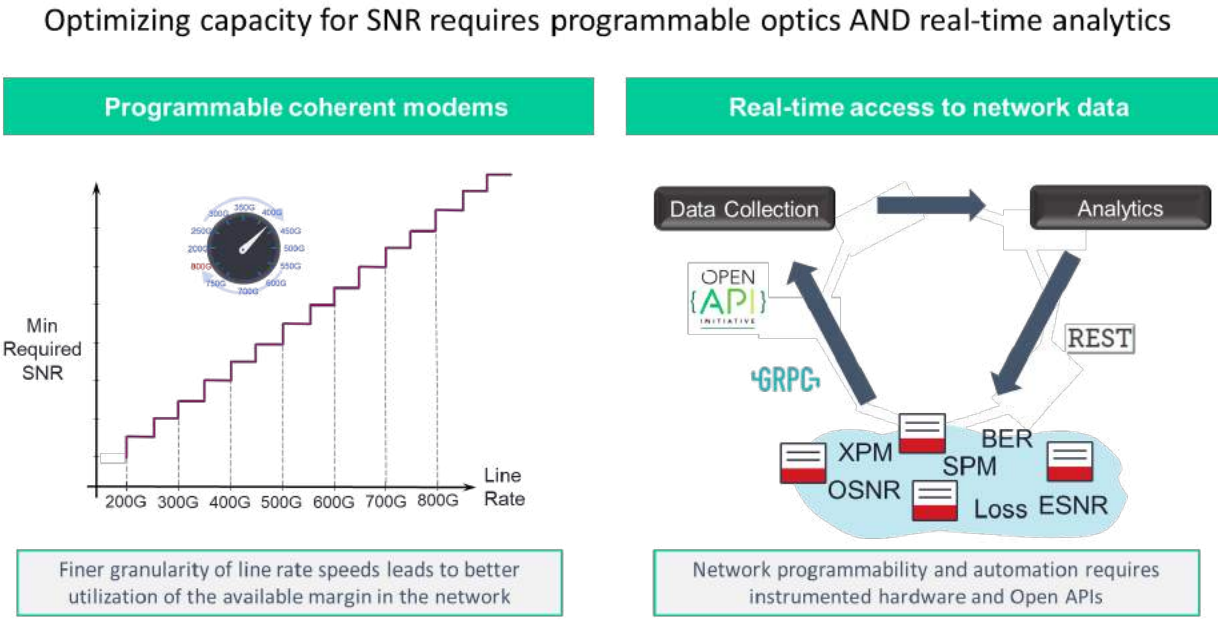

**Figure 9: Optimizing capacity for SNR requires programmable optics AND real-time analytics**

## 6. Conclusion

There is a limit to how many bits can be sent down an optical fiber. This limit, known as the 'Shannon Limit' is defined as the maximum rate at which data can be sent over a medium with zero errors. Technologies such as coherent optics allow operators to get closer to this theoretical limit. However, moving forward, the gains in spectral efficiency that will be achieved with future generations of coherent technology are diminishing. This will require alternative approaches and ideas to deal with network scalability challenges. Using updated designs, next generation hardware, and software tools, network operators will be able to extend the life of their networks as well as deploy new networks more quickly, efficiently, and accurately. Using these ideas, operators can start reducing the slope of their spectral usage curve while at the same time, deploying new photonic networks with higher efficiency.

# 1. Introduction – Connected Devices

The Internet of Things (IoT) is radically changing the way businesses operate and people interact. Billions of devices, sensors, and chips—many of them simple, everyday objects—can communicate with us and each other. Hospitals can monitor and regulate pacemakers at long distance, factories can automatically address production line issues, and hotels can adjust temperature and lighting based on a guest's preferences.

The IoT is changing the nature of products and equipment, as well as customers' expectations of their partners and suppliers. Consumers are pressing for greater accountability and better outcomes from manufacturers for the products and services they provide. As more devices connect the user experience directly back to the manufacturer, it creates expectations that the manufacturer is aware a problem is occurring, and potentially even before it occurs. Organizations like John Deere used to "simply" provide equipment to farmers, yet these farmers are now expecting John Deere to help them use the equipment more effectively. These rapidly changing expectations create both opportunities and challenges. Michael Porter and James Heppelmann summarized it well in The Harvard Business Review:

> *Once composed solely of mechanical and electrical parts, products have become complex systems that combine hardware, sensors, data storage, microprocessors, software, and connectivity in myriad ways. These "smart, connected products"—made possible by vast improvements in processing power and device miniaturization and by the network benefits of ubiquitous wireless connectivity—have unleashed a new era of competition. (How Smart, Connected Products are Transforming Competition, 2014)*

## 1.1. Connected Devices, Analytics, and Cognitive Computing

IoT is not just about connecting devices. It is a critical first step, but ultimately an enabling one for what follows. An IoT of billions of devices and sensors is pointless unless it effectively utilizes the flow of information. Most of the data generated from these devices will never be used as it simply cannot be understood in time to act. As described in a recent McKinsey Global Institute report:

> *Currently, most IoT data are not used. For example, on an oil rig that has 30,000 sensors, only 1 percent of the data are examined. That's because this information is used mostly to detect and control anomalies—not for optimization and prediction, which provide the greatest value. (The Value of Digitizing the Physical World, 2015)*

IoT is about the creation of new insights by analyzing the data that the connected devices generate. First movers are already shifting focus to make sense of the data as it is generated and leverage it for higher value functions. Companies are adopting analytics solutions to process the data for diagnosing problems, predicting outages before they occur, and prescribing solutions.

This use of analytics is also having an impact on existing sensor placements as well their modus operandi – including new sensors or relocating sensors for the purpose of predictive analytics. Classic use of

 

sensors have been to ensure proper operation and quality control. Connected device capabilities now include lifecycle reliability characteristics monitoring – prevent catastrophic failures and extend the useful life thus reducing total cost of operations (TCO).

However, traditional analytics have limitations when it comes to identifying relationships among unstructured data, such as equipment manuals, work orders, and service history. This is where cognitive computing comes into play.

Cognitive augmented intelligence infuses thinking into objects, systems, and process. It provides new opportunities to ingest and analyze data, including unstructured data. Through cognitive capabilities, systems can continuously learn, interpret, and respond. Advanced cognitive systems can communicate via natural language… see, listen and learn.

Cognitive computing and traditional analytics are two sides of the same coin and both are required to achieve business results:

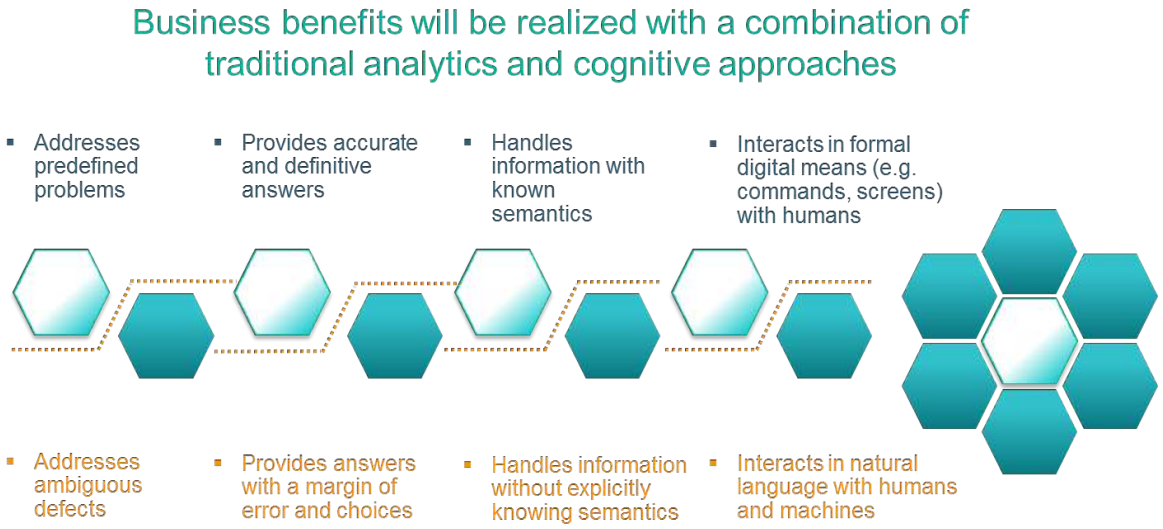

**Figure 1 – Business Benefits will be realized with a combination of traditional analytics and cognitive approaches**

The combination of IoT with cognitive capabilities opens new avenues for clients to boost operational performance, enhance customer experience, and lead industry transformation:

- Work smarter by providing employees cognitive insights from a company's collective knowledge of information
- Give equipment and devices the power to reason and learn, and the ability to interact naturally with people
- Facilitate expedient repair of broken or faulty equipment via a cognitive assistant

## 1.2. Connected Devices and People

Capitalizing on the IoT will further accelerate the shift to what we call Digital Operations. Digital Operations can be defined as a deliberate strategy of transforming businesses through analytics-led, Internet of Things enabled, business and operating models focused on predictive decision making and optimized efficiency.

Few organizations, however, believe they are ready for that scale of change. IBM's Institute for Business Value (IBV) has documented C-level concerns that the pace and breadth of change are beyond their current people's ability to address them. Capitalizing on the IoT will require organizations to rethink how their process engineering integrates IoT services into manufacturing and delivery. Additional data science and quantitative analysis skills, which are already in short supply, will be required to make smart use of the pending flood of IoT generated information streams. Further, IBV research determined that organizations are not sufficiently building the people resources required to address changes resulting from IoT.

Any IoT solution must consider the implications on the organization's people or it will ultimately be limiting and ineffective. Both data and people are essential linchpins in a holistic IoT solution because of the requirement for the right information, processed the right way, driving the right actions by machines and humans. Simply put – the best data in the world will not help unless people can put it to effective use. Since cost and talent issues prevent "throwing people at it", the effectiveness of the employee needs to be raised to collectively become a smarter organization. We are not implying the replacement of humans by machines, but cognitive systems communicating insights that expand the boundaries of what can be known and acted on. IoT will continue to change the nature of how machines and humans work together.

By its very nature, the IoT is a connected web of interdependencies. An effective IoT strategy requires addressing both data and human challenges to succeed. Aggregating these elements brings true business value.

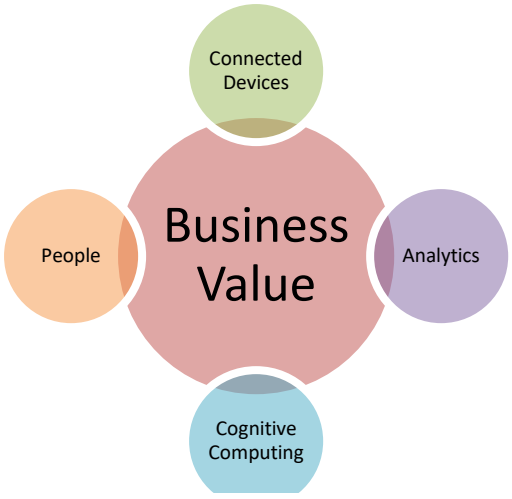

**Figure 2 – Connected Devices + Analytics + Cognitive Computing + People brings Business Value**

## 2. Maintaining Equipment

By nature, the equipment management ecosystem has had its own current set of challenges before the IoT. As the interdependencies and complexity of operations has increased (whether in an Industrial, Commercial, Mobile, or Consumer-based setting) over the last 2+ decades with advancing control technologies, it has created a new set of challenges:

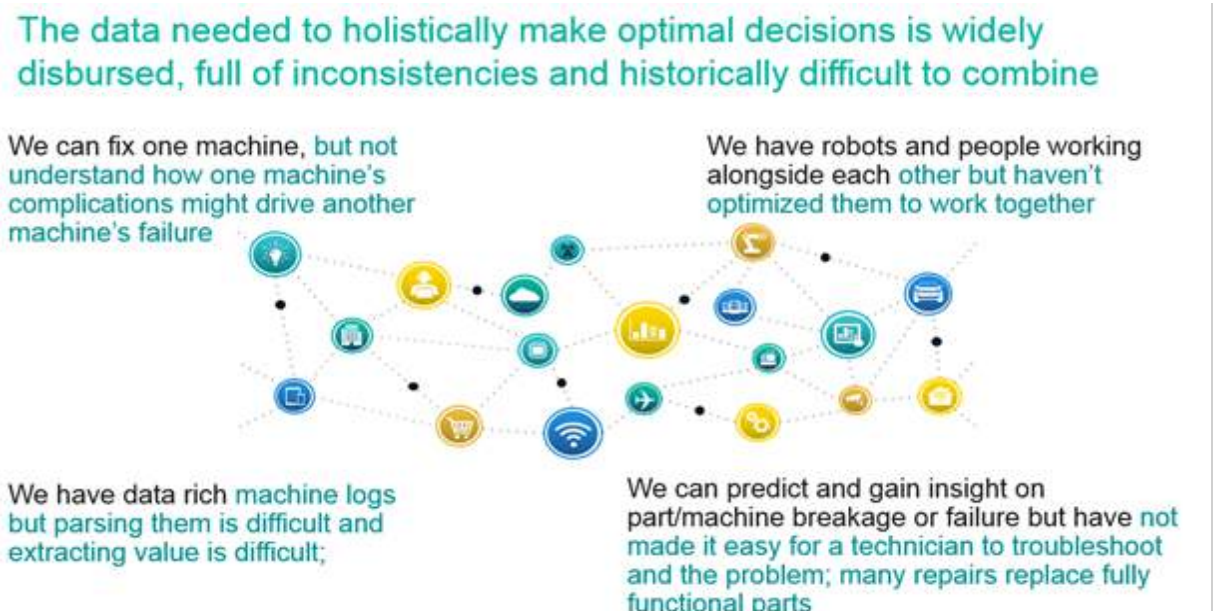

**Figure 3 – The data needed to holistically make optimal decisions is widely disbursed, full of inconsistencies and historically difficult to combine**

**connect** to equipment, **predict** equipment or system failures before they occur, facilitate **repair**, and **optimize** their operations.

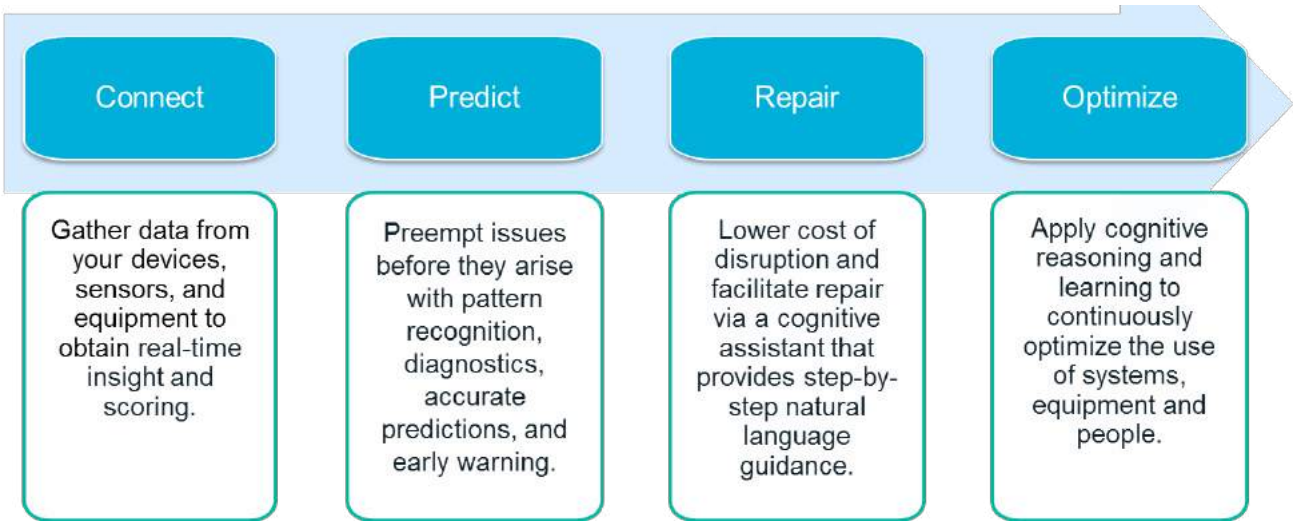

**Figure 4 – Connect → Predict → Repair → Optimize**

## 2.1. Connect

For multiple decades, electronic sensors have been a staple in the manufacturing industry, in transportation, in consumer products, in utilities and across all other industries. Availability and accessibility to that data has been done in the form of many disparate systems, databases and solutions. The IoT platform enables quick connection of devices, sensors and data and infuses intelligence into applications and services. The Predict and Optimize pillars are big consumers of both realtime and historic data, and the intravenous access provided by the IoT platform is transforming equipment management.

The IoT platform leverages AI to enable real-time insights, natural language processing, machine learning, and video/image/audio analytics. The AI takes the data inputs from connected devices and other sources to uncover patterns and insights previously unattainable. It recommends and implements actions such as safety controls, energy management, and quality assurance.

Key elements include communications with multiple protocols, analytics tools, device data storage, application development environment, data protection, and integration with third party devices and platforms. This approach utilizes the data received from connected devices to feed real-time data into the Predict pillar.

## 2.2. Predict

Suggesting the obvious, identifying and solving problems before they occur is less expensive and prevents operational disruption.

Work with multiple data sources to generate models targeted at predicting asset failure or quality issues so your organization can avoid costly downtime and reduce maintenance costs. Predictive analytics can detect even minor anomalies and failure patterns to determine the assets and operational processes that are at the greatest risk of problems or failure. This early identification of potential concerns helps you deploy limited resources more cost effectively, maximize equipment uptime and enhance quality and supply chain processes, ultimately improving customer satisfaction.

This approach utilizes analytics to:

- Provide predictive indicators of pending asset failures
- Quickly identify primary variables as part of root cause analysis
- Minimize product quality and reliability issues via early warning indicators
- Optimize spare-parts inventory and help to normalize an unpredictable supply chain
- Provide advance indicators of warranty claims to increase customer satisfaction
- Enhance sales and operations planning to reduce operations costs

It is the output generated from predictive analytics that becomes the input to the Repair pillar to initiate human action as needed.

## 2.3. Repair

As the IoT transforms customer expectations and competitive pressures, demands on the people working within those industries also increases. This further stresses the human side of product and service delivery and creates problems moving to a digital operations model.

At a field engagement level, the flood of data creates additional challenges for effective service delivery. Field Technicians are often overwhelmed with information from a variety of internal and external data sources.

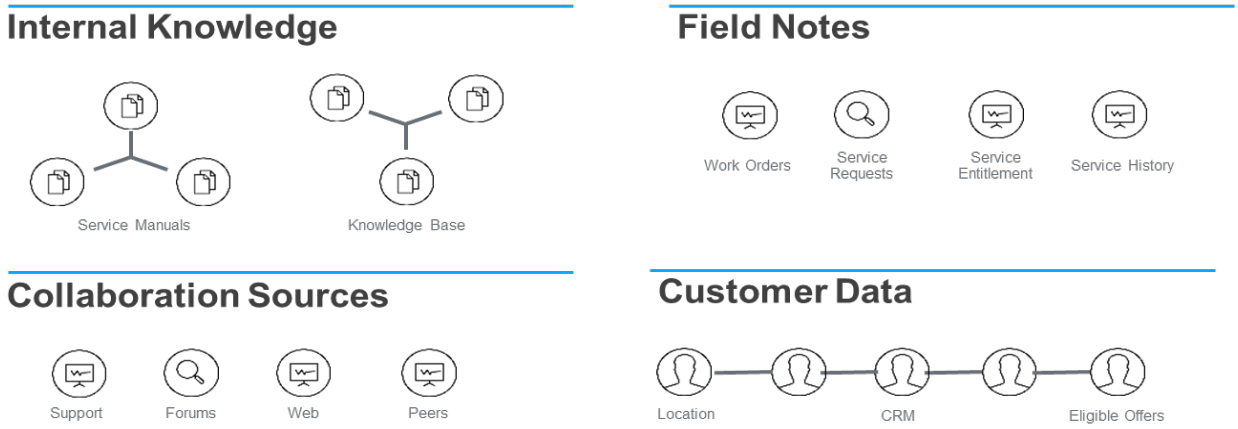

**Figure 5 – Organization of knowledge sources**

As machinery and equipment evolves in the IoT era and becomes more complex, the requisite skills and knowledge to repair the systems also increases. Often, there is a lack of effective methods to diagnose and resolve issues quickly out in the field. This impacts company operations and customer satisfaction and potentially drives poor use of parts and resources.

To solve these challenges, companies are leveraging AI as a cognitive advisor for field service technicians. AI ingests various forms of information related to the equipment and repair of it; service manuals, knowledge base, service history, support information, forums, client information, etc. AI learns from this information to develop the best of course of action for repairing the equipment. When an outage or breakage occurs, the technicians can engage AI directly over a simple interface including diagnosis and chat, connecting to current internal systems for specific data. The technician can communicate with AI in natural language to obtain help in diagnosing the problem and step-by-step repair instructions. AI can continue to support the field technician if there are questions or additional information needed as they work on the repair. Field technicians can interact with AI conventionally via a keyboard, or as useful, verbally via Speech-to-Text. AI understands the context that the field technician is asking and can down-select the likely materials and interactions from the Connect and Predict parts of the process that initiated the Repair cycle.

Based on the flexible nature of an IoT Platform building blocks, the solution can be adapted to meet specific business needs. For example, AI could use visual recognition to help identify the type of equipment and the nature of the problem to further expedite repair.

This approach utilizes AI to:

- Ensure problems are fixed correctly the first time – First time to fix metric
- Decrease repair costs by lowering time spent on repair – Mean time to repair (MTTR)

- Optimize training by providing a cognitive tool for teaching – helping to address the aging workforce challenge faced by many industries
- Drive incremental revenue by creating new services opportunities
- Improve customer satisfaction

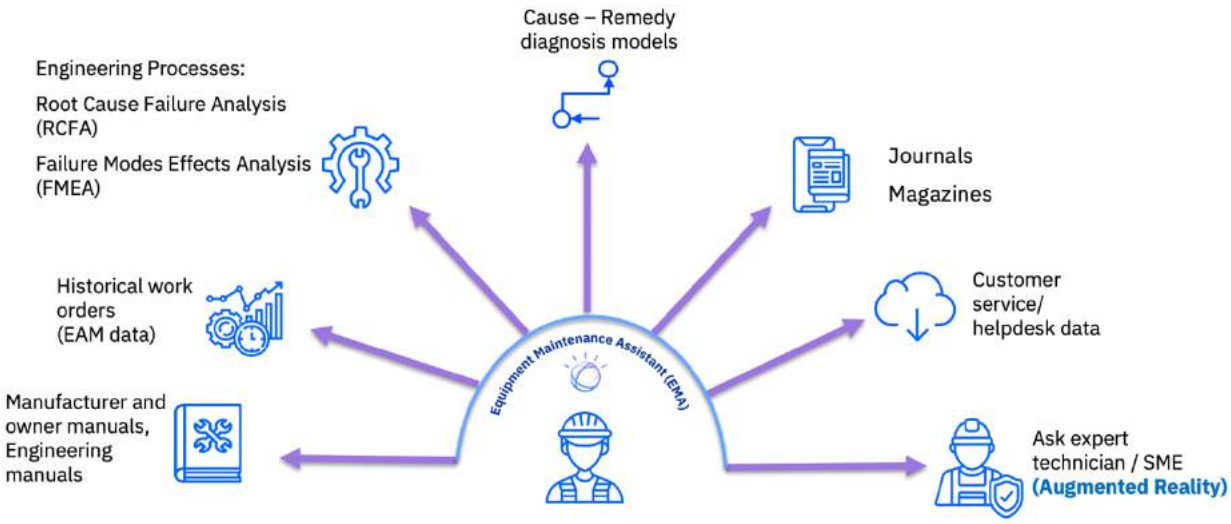

**Figure 6 – Operationalization of AI technology through natural language queries (NLQ), troubleshooting diagnosis and augmented reality (AR)**

## 2.4. Optimize

This is defined as the Optimize step as an approach that systematically improves outcomes through continual closed-loop learning. Closed-loop learning means that the recommendations are compared to actual outcomes after the actions have been performed. Learning from predictions, while not as widespread as it should be, is not in itself new but this approach addresses a key gap in the process. While this approach learns consistently with machine learning approaches, it also actively learns from the human activity side of the IoT. More specifically, this approach learns from how humans interact with the predictive analytics predictions and how the work was successfully accomplished to both improve the statistical modeling to predict the future and how subsequent engagements provide better context to the people actually doing the work.

Optimize applies cognitive computing and analytics to provide closed-loop learning based on outcomes to constantly improve the usage of systems, equipment, and people. It requires a consultative approach to determine specific areas in the process that could be optimized. There is no "one-size-fits-all" approach and the technology is based on the use case and desired outcome.

Following are some of the areas that we are currently working with clients to optimize their use of machinery and equipment:

- Identify correlations in separate defects among interdependent clusters of systems to improve repair efficiency
- Enhance first-time-fix effectiveness by predicting other components that may fail due to the repair
- Improve cognitive learning based on the outcomes of previous repair jobs for a selected asset or similar repair jobs on like assets
- Leverage machine learning and AI's visual recognition to evaluate manufacturing performance and make recommendations to alter parameters to improve the process

## 3. High level Architecture

As described above, this approach consists of four pillars; Connect, Predict, Repair, Optimize. The modular approach provides opportunity for a phased approach. However, the value from the aggregation and integration of the parts exceeds the sum of the individual components. Following is a sample architecture connecting these four areas into one solution.

### 3.1. Technical Architecture

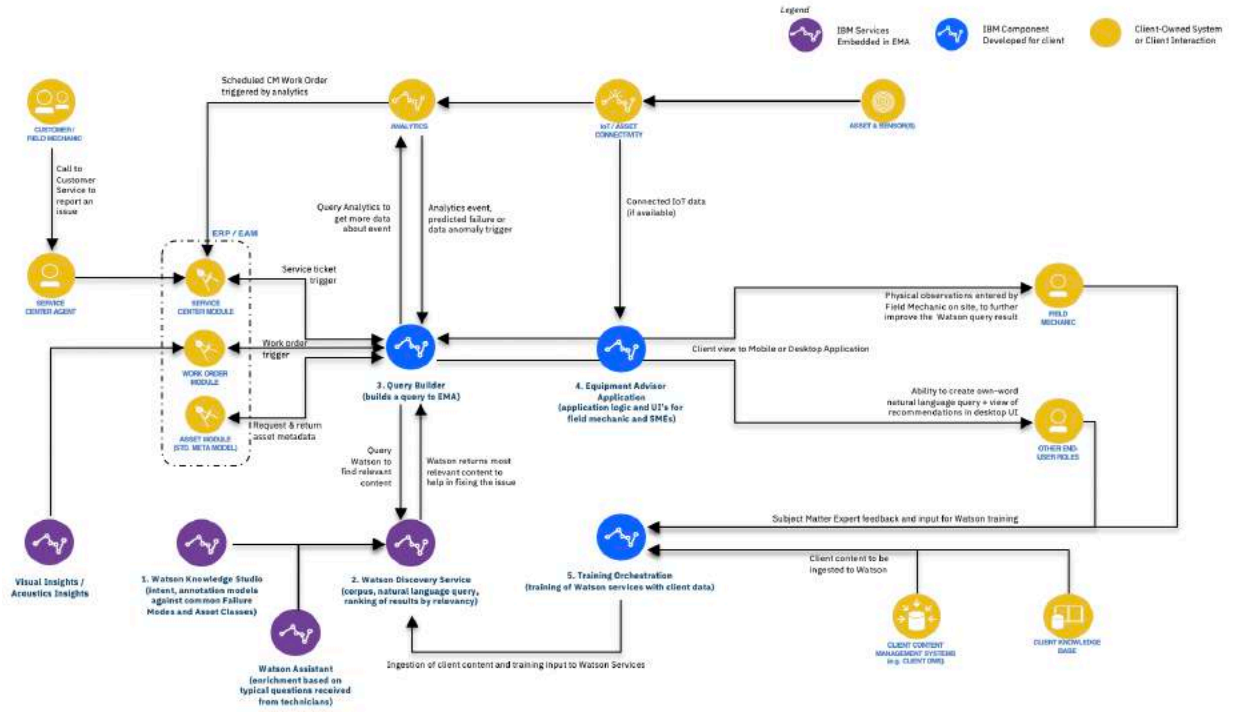

**Figure 7 – High-level architecture**

In this example, sensors connected to the equipment provide real-time updates to monitor the activity. Predictive analytics are used to evaluate the operational health of the equipment and provide early warnings of trouble. Machine learning continuously sweeps for non-obvious patterns. AI can ingest information from structured and unstructured sources to more quickly identify the issue. Visual cues are provided to display early warnings and if necessary, a repair request is initiated. The field technician leverages AI to obtain step-by-step instructions on the repair using natural language processing and conversation. AI continues to learn and develop a corpus of information through the process which provides continuous improvement.

# 1. Abstract

Academics, strategy pundits and entrepreneurs like to talk about the transformative power of artificial intelligence (AI) and the need to accelerate implementations. (AI has been called the “new electricity.”[1]) But service provider operations teams tend to tell a different and more nuanced story. While no one disputes the long-term potential of these technologies, what’s becoming clear is that the complexity of advanced AI, such as neural networking, is difficult to fit into their current paradigms.

The pragmatic way to adopt these technologies is to define a clear use case, start with what you already have, and layer on these technologies in such a way that operations teams can augment existing architectures. A phased approach allows room to focus on learning and enhancing rather than replacing existing network operations (NetOps) practices, including root cause analysis, in order to evaluate costs and benefits. Key to this process is focusing on a better-together approach to provide evidence-based demonstration of value. In this paper, we will introduce neural networking, explain why it is a good fit for today’s networks, and provide use cases from our experience in deploying these technologies in 5G and cable environments. It is more than possible to experiment with this technology, while evolving, rather than reinventing existing skillsets and processes.

# 2. Introduction

A method of problem solving that moves beyond reactive to proactive management, root cause analysis (RCA) has long been a goal of effective NetOps. As cable networks have become increasingly complex, with service delivery stitched across access networks, optical fabric, IP/MPLS backbones and, increasingly, cloud infrastructure, NetOps has evolved accordingly. In a NetOps 2.0 world, RCA has not only become an expected feature, it has needed to become smarter and more effective.

Implementing a proactive and predictive RCA in complex service provider clouds that span networks comprising more than a million devices is no trivial challenge. How do you determine the network radius of "problem spaces” that are compounded in extent by multi-tenancy, network traffic paths, and physical and logical L2/L3 connections? Neural networking-based algorithmic approaches, using non-deterministic and probabilistic models and automated computation, are one promising approach to this challenge. Employed to multi-tiered problem spaces with temporal and spatial aspects, this brand of AI technology is highly effective at executing RCA on top of non-deterministic anomaly detection, all within context.

The prerequisites are network and service discovery, along with a platform for data collection, streaming and processing. When properly set up and implemented over physical and virtual infrastructure, neural networking can drive improved RCA and its positive business effects across multiple use cases. On the other hand, if inadequately understood or lacking in data, neural networks can exceed their limits or result in less control. As with any AI or machine learning (ML)-driven initiative, upfront knowledge is key.

# 3. Background

## 3.1. NetOps, PNM and RCA

There are many aspects to NetOps, from the physical Network Operations Center (NOC) itself to the personnel who work there to the policies employed to the technologies used in managing, monitoring and control any number of discrete or interrelated networks. A common term used in the cable industry used for optimizing NetOps is proactive network maintenance (PNM). As a part of a special initiative covering wired, Wi-Fi and optical technologies, CableLabs has encouraged careful thinking about PNM,

 

emphasizing the benefits of proactive management.[2] The point of any such exercise, of course, is a higher level of customer service.[3]

The RCA approach to problem solving falls into that broad category of proactive measures, in that it seeks to uncover the underlying cause of faults or incidents affecting network performance; and because the failure to address that cause is likely results in recurring issues. By isolating the fundamental fault associated with a multiplicity of issues, RCA leads to a reduction in immediate number of alarms, as well as a lower number over time. RCA does not by itself remediate problems, but feeds into a process of corrective and preventative action.

## 3.2. Service Provider Clouds

A typical domain for applying the tools of PNM is the cable access plant, for instance DOCSIS-related problems that occur on that part of the network spanning the CMTS or CCAP device and the related modem at the customer premise. Yet with virtualization, that network now extends beyond the physical plant into cloud infrastructure.

The distributed access architecture (DAA) initiative remains one of the industry's most prominent use cases related to virtualization. Being transformed from purpose-built hardware into software enables a cable operator to run the CCAP in a data center on a private cloud. Other possible cases for MSO virtualization include VOD, network PVR, 5G and Multi-access Edge Computing (MEC).[4] These cases increasingly cross industry lines, many applications all requiring high-performance, low-latency networks. The expansion of these networks has placed a tax on traditional NetOps. MSOs have expressed frustration with monolithic management tools, and delight in those that deliver cross-domain results.[5] An extensive physical and cloud environment makes it difficult to rely on siloed legacy tools with manual processes and scripts. (See Figure 1.)

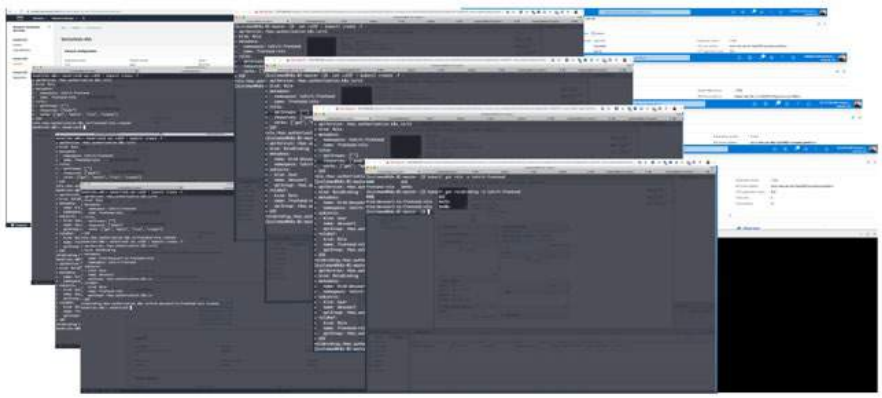

**Figure 1 – Multiple Screens Manual Processes**

## 3.3. Neural Networking

In that context, it is fair to ask whether networks can survive without AI. The real question today, however, is what kind of AI or ML serves best. Neural networking is worth considering. It may appear to be a recent addition to this category, but its genesis goes back decades. Building upon theories of biological neural network, i.e. the brain, the seminal paper on artificial neural networks appeared in

1943.[7] By the late 1990s, engineers were looking at possible applications in manufacturing.[8] Driven in part by innovative big-data ingest and storage capabilities, neural networking in recent years has achieved tremendous progress in areas such as natural language processing and image recognition.

In the cable and telecommunications arenas, other kinds of AI and ML have taken the lead. One example is a trial that involved "operational analytics (OA) and machine intelligence (MI)" to predict service impairments in near real-time, which used Support Vector Machine (SVM) classification, spectral clustering, tree-based taxonomy and related tools.[9] Like these uses of advanced data analytics, neural networks can very well approximate the non-deterministic, stochastic nature of various network scenarios.

Neural networking is typically supervised, i.e. it requires setting up and training a data model. A key characteristic is that these networks involve layers of input, hidden and output neural nodes, each connected to others, with certain weighed coefficients. Besides feed-forward networks, there are other kinds of deep-learning models, including recursive neural networks (RNN) and convolutional neural networks (CNN), etc. But neural networking can be unsupervised as well, especially when no labeled data is available. The system tries to find patterns and form clusters in a meaningful way. It involves mapping the continuous random variables to discrete representations, while neural networks are capable of achieving that through their ability to converge.

# 4. Are Neural Networks a Good Fit?

## 4.1. Modern Network Characteristics

There are a number of reasons for servicer providers of all stripes to consider the applicability neural networking for key NetOps problems, such as RCA. One overriding reason is that for many, networks are simply not what they were only a few years ago. Nor have they reached an endpoint. Monitoring and analytic tools and platforms simply need to keep pace with advancing network technologies. that now increasingly bear these characteristics:

### *4.1.1. Complex*

A conventional approach to network monitoring and management has involved applying simple thresholds to classifying physical layer HFC performance within normal and abnormal parameters. That remains an effective way to trigger alarms, but insufficient when the goal is to isolate underlying problems affecting services that touch heterogenous networks, each of which may have its own siloed data arranged in unique formats. Assessing and weighing multiple inputs, and becoming even smarter over time, is possible with the computational power and adaptability of a neural network.

### *4.1.2. Dynamic*

The disaggregation of once-unified equipment, such as the CMTS or CCAP device, into core and remote elements, is an indication of not only growing network complexity but also accelerated change. The addition of remote PHY devices (RPDs) entails new configurations and adjusted topology adjustments, while a virtualized CMTS core now depends upon cloud infrastructure that may rapidly scale up and down. Edge wireless, IoT devices and even CPE contribute more unknowns to the mix. Neural networks are adept at handling dynamic change.

#### 4.1.3. Data-rich

The sheer volume and variety of data emanating from today's networks is one of the biggest drivers in the search for new approaches. Only a few years ago, network data mean SNMP queries that delivered a limited amount of information every fifteen minutes, and of that very little was useful. MSOs had tools that could handle those challenges. The data challenges now facing many MSOs are beyond their scope. Neural networks actually work better with inputs provided by big data analytics.

#### 4.1.4. Real-time

Exacting performance in areas such as latency matter to many end customers, whether the scenario is cell backhaul or internet gaming. Data about those services matters, too. But even if MSOs were able to staff their NOCs with the sharpest analysts, the rate at which performance data arrives and the need to process them with utmost speed is beyond human capabilities. Manual review of Syslogs and support cases do not scale, and status-quo analytic tools fall short. To respond to network behavior real-time, service providers need certain automatic ML-based mechanisms, and neural networking is a very good ML model.

### 4.2. No Free Lunch

Neural networking is not the only advanced AI and ML-based analytic tool available. For supervised classification problems, there are some commonly used ML algorithms, such as SVM, decision tree, logistic regression, etc. For decision tree, rigidness of the model is the common problem which easily leads to over-fitting. Although they can be trained to be accurate, once given new data, they may jump to wrong conclusions. That could happen through creating tree branches that follow certain order of precedence. Ensemble methods, however, can alleviate this problem.

SVM performs data separation either linearly or non-linearly, which highly relies on the choice of kernel function. It makes a model difficult to scale well to a large dataset. While logistic regression tends to underperform when there are multiple or non-linear decision boundaries, it is not flexible enough to naturally capture more complex relationships. Neural networking is more flexible as it has the capability to approximate almost any scenario accurately by adjusting hidden layers and hidden nodes.

A common criticism of neural networks is that they operate like black boxes. While a decision tree is relatively easy to understand, it is hard to explain how a neural network arrives a particular conclusion. Neutral networks do well with large amounts of data, which makes them a good fit for advanced communications networks; but the converse applies, they do less well in scenarios that are data-deprived. Computationally powerful, they can also require more time to train than traditional ML algorithms, which can increase their cost. Likewise, operating them requires some expertise in data science.

Shortchanging knowledge and taking a set-it-and-forget-it approach can be tempting but dangerous. A single-engine propeller aircraft can be operated and maintained manually; whereas a commercial jet airliner requires NetOps 2.0-level systems and procedures. Yet when pilots are unable to override these systems and are unprepared for edge cases that may arise, they cede too much control to the automation that was designed to optimize flight operations.[10]

A similar charge could be leveled against a neural network, which generally speaking is a "non-convex optimization problem," especially when the activation function is non-linear. (Since weights are permutable across layers there are multiple solutions for any minima.) Sometimes, domain knowledge is needed to make sounding judgements when selecting reasonable ML tuning parameters. The takeaway is that it is important, whether building one of these platforms yourself or working with a partner, to understand the technology's potential benefits, its operating characteristics and its limits.

# 5. Existing Frameworks

How do existing service assurance platforms handle RCA? A crucial prerequisite of any framework is data collection, streaming processing and data modeling. As for RCA more directly, one currently effective approach is to rely on multi-dimensional matrices of deterministic models that create 'signatures' related to symptoms and problems. The idea is to correlate events and alarms with known patterns and signatures to identify where the root of the problem lies. Other best practices include continuous self-updating; adapting to dynamic workloads, network configurations and inventory; and integrating with orchestration tools for auto-remediation and incident management for support workflows.

What status quo platforms typically do not yet have is a continuous flow of anomaly detection, leading to RCA for the anomaly, and finally providing prescription for the problem. A non-deterministic, neural networking engine can extend while enhancing other effective techniques for anomaly detection, RCA and problem prescription. The neural networking ML utilizes streaming processing output, although the training can be done off-line. Then streaming processing engine picks up ML result, through multi-stages to generate real-time results in an automated fashion. This paper focuses on RCA, while the problem prescription is out of scope.

Below is an example of flow using neural networking in radio access network (RAN) throughout the whole data analytics process. (See Figure 2.)

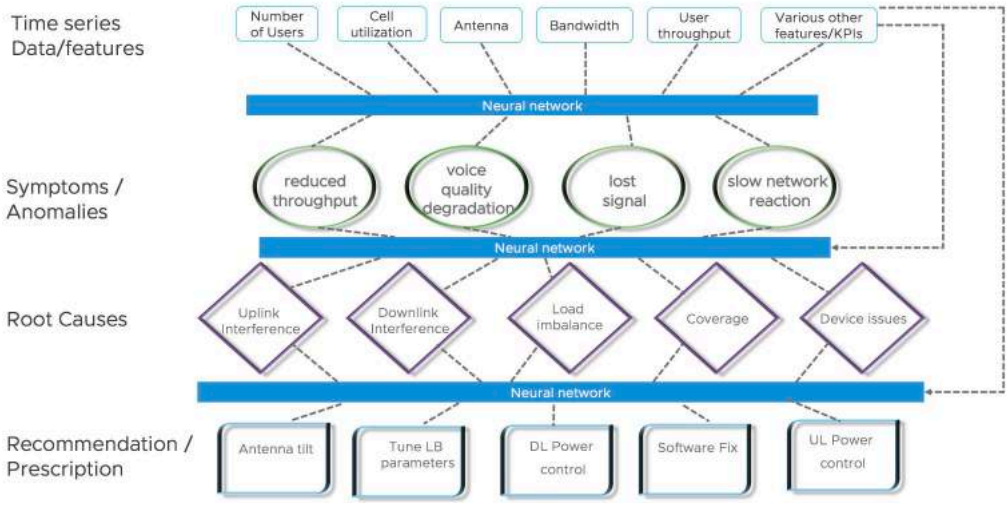

**Figure 2 – Continuous ML Flow**

# 6. Use Case Scenarios

## 6.1. Anomaly Detection, RCA

Neural networking works well for anomaly detection, which is both a powerful technique and a prime use case. The detection of anomalies, or statistical outliers, is applicable in complex, on-prem/off-prem and dynamic environments where operators are interested in long-term trends, aberrations such as spikes, and cross-correlation with other inputs. In the case of having no global formula to define anomaly, neural networking is able to learn the network performance down to the subscriber level over a long-enough period of time and determine the anomaly. All of that information can help drive effective RCA, which

could also be considered a use case. Anomaly detection can be supervised, unsupervised or semi-supervised, depending upon the use of a training data set. Like RCA, it figures in several other use-case scenarios.

## 6.2. Performance Management

To track the delivery of any number of services across a large subscriber base, a service provider today needs to receive concurrent data feeds from a massive number of network elements, correlate those with user session data, and then calculate real-time key performance indictors (KPIs). The big data platform enables an operator to achieve those tasks. Neural networking is built on top of the platform to combine the KPIs with application-specific inputs and policies to deliver network visibility, anomaly detection, and real-time predictive network intelligence.

## 6.3. Fault Management and Configuration Management

A fault management system must have a comprehensive picture of the network topology, which is related to configuration management. There are thousands of ways can a network fail, go sideways or skip a beat. Hardware failure, connectivity loss, and power outages are some types of network faults. Let's consider one, the misconfiguration of a network device, such as an RPD. Anomaly detection might first indicate that subscriber data throughout is not matching up with other session-level parameters. A system equipped with neural networks for anomaly detection might detect conditions where average user throughput dropped below a certain level, while the channel utilization was abnormally high, and DOCSIS sub-carrier utilization low. Identifying the condition and the underlying cause then enables a recommendation for device reconfiguration.

Another example is a cellular tower fault. Each cell has neighbors, and if one cell is in trouble, then the user traffic is distributed to the neighbor cells, at which point the neighbor cells will show an abnormal increase of traffic amount and maybe congestion. Some network faults directly impact or even block service delivery. Neural networking can certainly help network fault management to detect/predict fault and further diagnose the source and type of the fault. The subsequent action is to automatically trigger fault correction, or to at least prevent incidents from happening in the future.

## 6.4. Predictive Maintenance

In its early forms, neural networking was seen as a way to help monitor manufacturing processes, predict failures and schedule maintenance on aging equipment. It likewise applies to telecommunication and IT network equipment, which can experience transient or permanent hardware or software malfunction. One concern involving new proliferating IoT endpoints is battery life.[11] Neural networking could assist in managing this and other aspects of IoT, including the detection of missing data transmission and related RCA, either as part of an MSO's own network or a managed service to businesses.

## 6.5. Security and Fraud

In the area of intrusion detection, network security experts have combined anomaly detection models with various deep neural networking structures.[12] Models could detect strong login behavior, too many DNS requests or frequent changing of temporary IP or ID during a session. Operators themselves are motivated to prevent telecommunications fraud on their own networks and to deliver high-value managed security services to other businesses. To detect fraud, the data covers several domains, such as network usage in multiple types of networks, financial, personal information, location information, etc. Fraudsters are good at frequently changing their behavior to match the 'normal' pattern of the network to circumvent the security rules, which increases the level of difficulty for fraud detection. In addition to detecting

 

identity theft and fraudulent activity, network operations intelligence has also had to track the location and time of fraud. The data-mining capability of neural networking has made it a candidate for providing better information to MSOs about unsanctioned use of telecom networks, whether for financial gain, abuse of services, ghosting, tampering, cloning or other fraud.[13]

# 7. General Neural Networking Approach

A neural network-based service assurance recognizes that the world has changed. Service-related data once arrived slowly and with limited utility. Then services became IP-centric, and it was economically and technically feasible to ingest and store exponentially more data than before. Applying neural networking for anomaly detection, RCA and other uses entails completing a sequence of tasks: data collection (and network discovery), data processing, data modeling and follow-up adjustments. (See Figure 3.)

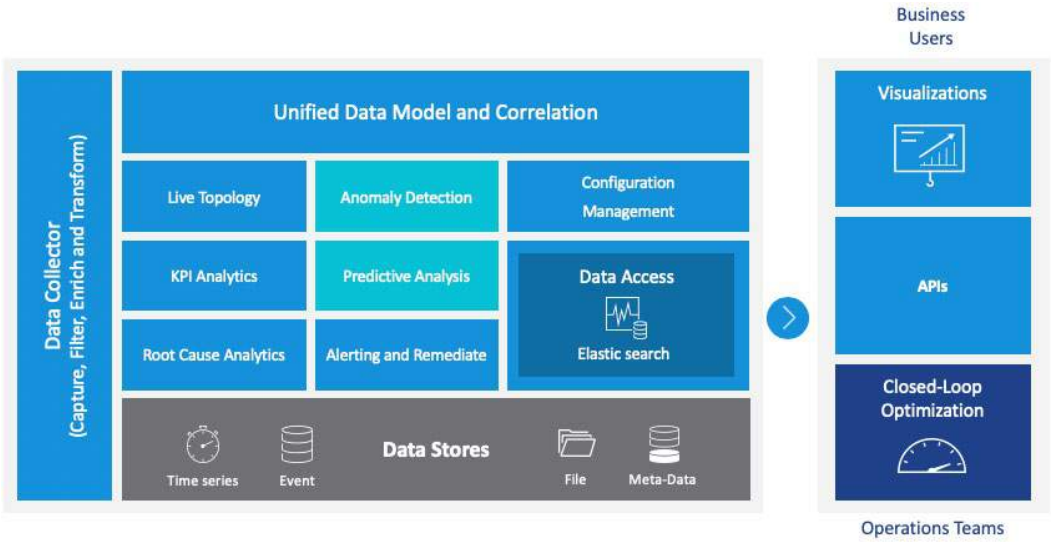

**Figure 3 – Data Analytics Model**

## 7.1. Data Collection

This task involves collecting fault and performance metrics for each network component at the user level. There are traces, events as performance metrics. The fields include start and end-time on each of 1000s of pieces of equipment, user ID, traffic type (voice/video/data) IP address and location, throughput, traffic volume, etc. For security and fraud use cases, typically call detail records (CDR) and network management system (NMS) logs are needed. CDR and logs have subscriber-level call details and activity records in a certain period, i.e., once a month. Network devices could use various industry standard data collection methods, such as SNMP, REST, NEP, etc., for streaming data sources. The time stamp is important for model training and prediction. Data collectors may span multiple vendors, with their own implementations and formats, as well across network silos. What generally appears in the NetConf standard are configuration files, counters and information about the state of the device.

## 7.2. Data Processing Pipeline

After setting up the collectors, the next step is to set up real-time streaming and processing of the time-stamped data into a data pipeline and connecting to a database. The process of data joining can be a

challenge in the streaming domain, with SQL joins being especially slow and difficult. Yet standard big-data and schema-agnostic database formats have helped smooth the preparation phase. Related tasks include filtering, sanitizing the data, as well as running network topology discovery to associate data with device location. There is a Kafka bus to connect various big-data components in the pipeline. Those components exchange data/information through the Kafka bus. Some big data frameworks are Apache Spark, Twitter Heron, Apache Flink, etc.

A common way of storing the processed data is to ingest data via Kafka into a data lake, which will be used for neural networking model training. The streaming processing engine is equipped with a ML module. The module can get the ML model result and uses streaming data to generate prediction results, such as anomaly detection or RCA.

Below is one example of streaming data processing pipeline including neural networking model training engine. (See Figure 4.) Note that data lake is not the only way to store the data; there are other ways which do not require a data lake, such as tiered storage in Kafka. Also, some neural networking ML use cases do not require the results to be fed back to real-time streaming processing engine; they can certainly run separately.

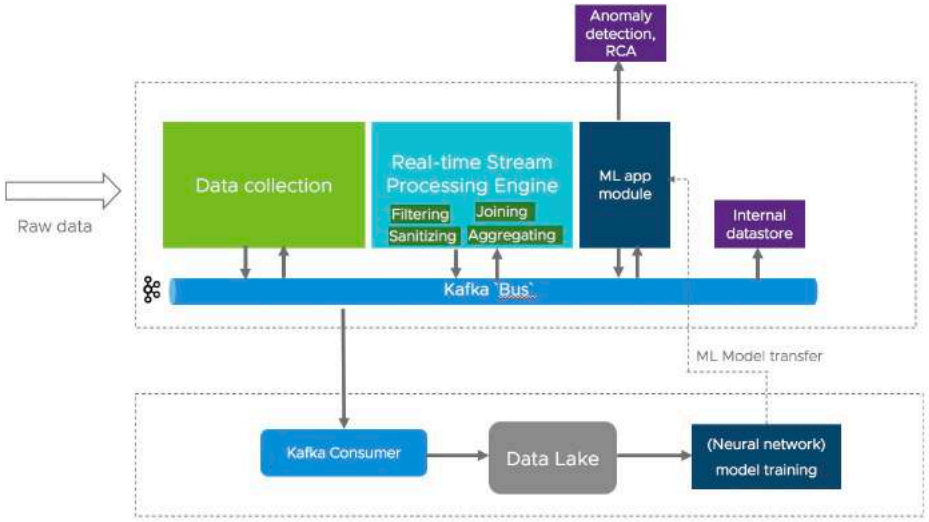

**Figure 4 – An Example of Streaming Processing Data Pipeline**

## 7.3. Further Adjustment

Other data management techniques may be required. During data preparation, in the case of missing data, average or default data may be inserted, or the fields could be ignored. Several approaches can be taken in the case of data skewness, such as oversampling, or synthetic minority oversampling technique (SMOTE) to compensate for an imbalance within the set. Neural networks tend to make better predictions when trained on balanced data.

## 7.4. Data Modeling

Correlating chosen KPIs (containing time stamp, user ID, traffic type, etc.) with different network components is important to establishing an end-to-end view. A critical part of building a model is identifying features, which correspond to parameters or counters in events. These could be throughput, signal strength, transmit power, or whichever ones best align with the use case in question. All of those

features are associated with a single time stamp that represents training data that are fed into the model. Data scientists can optimize the model's "fit" by adjusting the weights and layers of the middle nodes, which may have distinctive properties of their own, such as the ability to do "convolutional" math or look back across the network in a "recursive" manner. If so engineered, the model will deliver outcomes that determine a root cause or detect anomalies. (See Figure 5.) There are various ML framework libraries to draw upon, including TensorFlow, Theano, Deeplearning4j, Keras, sklearn, etc.

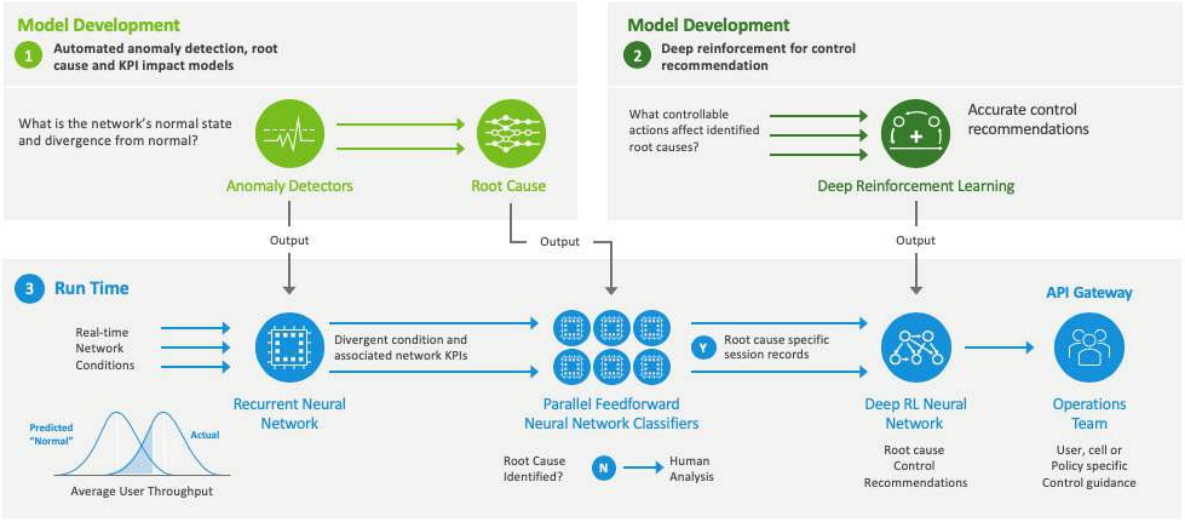

**Figure 5 – Data Model Development**

## 7.5. Continuous Learning

The model training is a continuous process. We should proactively compare ML predicted result with ground truth and then adjust the model if necessary. A separate effort can be placed on continuously enhancing the model, and then feedback the new model in the subsequent data analytics flow. (See Figure 6.)

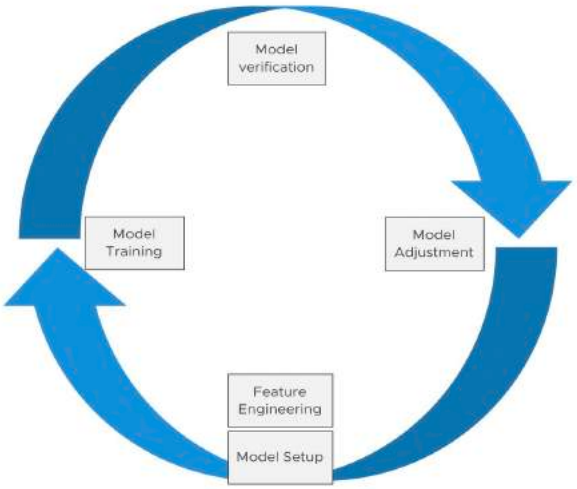

**Figure 6 – Continuous Training Cycle**

## 7.6. Model Management

After a neural networking ML model is delivered, the following criteria need to be evaluated:

- ML performance, which can be evaluated by comparing the prediction result with ground truth and quantified by mathematical formula.
- What features are used? Can the feature list be changed?
- Are the training data generalized enough?
- How much training data is enough?
- Is there any over-fitting or under-fitting?
- What are the optimal hyper parameters? Are they generalized or specific to particular scenarios?
- Is human input needed? For example, sometimes human help is needed for training data labeling, or domain knowledge is needed to customize the ML prediction result.

The above considerations should be taken into the model management. Further actions like model versioning, customization, refinement, profile, performance recording, dependency should be incorporated when deploying models:

- Model versioning: If a model is only suitable for old data, a version is used to avoid using the wrong model on new data.
- Model customization: ML models are normally consistent across deployments but can be customized to take into account market-specific conditions. For example, different hyper-parameter lists, or values are used for different markets (due to different RF bands, geographical situation or other factors); different feature lists or weights for different markets or clusters, etc. Another case is that network performance should follow some theoretical rule, but sometimes an AI/ML-driven prediction lands outside of the reasonable boundary; in which case human customization or adjustment is needed.
- Model profile: Certain mechanisms to prevent over-fitting, under-fitting, and ML software framework can be recorded for evaluating ML model performance.
- Model performance: This helps determine how good a model is. It can be evaluated in various ways, such as, F1-score, area under the curve (AUC), receiver operating characteristics (ROC) curve, learning curve, R2-score for regression algorithm, etc. Also the learning curve can help determine how much training-set data are needed or are sufficient.
- Model dependency: When new or novel patterns are detected, the associated event stream can be used as labeled data by domain experts (which suggests human input) for re-training of models using supervised learning. This human-input dependency can be incorporated into model-training software.

## 7.7. Model Optimization and Automation

Machine learning helps realize a big portion of network operations automation. But the ML model itself can also be optimized and automated. In the case of neural networking, the model performance heavily relies upon the hyper parameters, including the number of hidden layers, the number of nodes in each hidden layer, the learning rate, etc. In a production environment, it is crucial to automate the process of selecting optimum tuning parameters. Bayesian optimization appears to be an efficient choice, as it not only helps find the vector of hyper parameters that result in a neural network with the lowest error, but also reduces considerably the time spent on model tuning. There are other optimization tools or ML libraries available, as well.

# 8. Other Limitations

As mentioned earlier, while neural networking thrives on large amounts of data, in some cases there may not be enough. Challenges surrounding data joining have also been noted. Mistakes on a key or value could result in the time stamp being off, which would make it difficult to correlate data belonging to the same user session. One solution is to set a slightly wider time range. Finally, there are always going to be false positives and false negatives. The tradeoff between precision and recall cannot be avoided. In setting up the model and use case, operators should take note of the use case and consider any false positives.

# 9. Best Practices for Adoption of Neural Networking

Experience across the wider service provider industry has revealed an effective way to approach this powerful and challenging technology. If you are motivated to successfully adopt neural networking for RCA, consider the following key principles:

## 9.1. Start Where You Are

Allow yourself room to experiment. Consider a data-driven before/after business case that can be used to showcase progress and share learnings. We recommend starting with one of the use cases mentioned above, perhaps anomaly detection, being applicable in many scenarios.

## 9.2. Layer on New Capabilities, Stitched Together at a Workflow-level

Early adopters are thrilled to discover that neural networking can deliver insights that were previously impossible to obtain. Yet the difficulty in explaining how it works can hinder practical and actionable impact. By framing the technology as an augmentation, on a second screen or a dashboard with all anomalies detected by neural networking tagged as an overlay, operations teams can get started with the technology in a way that stages risks and provides ample room for learning and evolving, both in terms of testing and tuning the models, but also to mitigate false positives while the models are being developed.

## 9.3. Collaborate, Internally and Externally

Given the rate at which these technologies are evolving, and the centrality of model definition and evolution, it pays to collaborate with other teams both internally and externally. In our examples here, many of the models applicable to any network scenario were developed initially for 5G interference scenarios but are equally applicable to DOCSIS environments and LLX deployments. Look for ways to collaborate across silos and share insights.

## 9.4. Be Metrics-driven: Use Testing to Show Impact over Time

Neural networking is not a reinvention as much as an evolution, and in to demonstrate value and prioritize investments in these technologies, vanguard teams who are seeing the most success with implementations have taken “show me” approaches to proving value. The most straightforward way is to define a clear use case and employ A/B testing to demonstrate the value with before-and-after metrics. Prioritize future steps accordingly.

### 9.5. Avail Yourself of Expertise When You Need It

Because of the learning curve and pitfalls of developing, training, evolving, and explaining neural networking models, having access to the right level of expertise is crucial in getting these programs off the ground. It can be time-consuming to identify domain experts who are adept at translating the data science principles into the context of RCA. Plan ahead.

# Table of Contents

## List of Figures

## List of Tables

# 1. Introduction

According to Harbor Research and analysis by Fujitsu, the Smart City market will reach $5.6B in North America by 2025.

Cities own hundreds of departments that are using software targeted to their functions. These datasets are generally local to the organization. In addition, real-time access to digital representation of city's physical assets are rare.

Using the CBRS-band (Citizens Band Radio Service), cable companies can build private networks for cities to bring together disparate systems and make it economically feasible to digitize and access physical assets in real-time. Visibility to data from multiple systems will provide insight to improve operational efficiencies, provide better experiences for citizens, and improve environmental impact.

In this paper, we will discuss the lessons learned from our private network deployment and Parking Occupancy App that was deployed by City of Dublin. We will also discuss the positive unintended consequences of the private network and App during COVID-19 outbreak.

# 2. Smart City Market in North America

$ Millions

## 3. Why is Digital Transformation Important to Cities?

Digital representation of cities' assets such as parking spaces, roads, utilities and fuel consumption is important to the cities because it provides citizens with better experiences, reduces the carbon foot print, improves emergency response, and reduces operational cost.

Historical data based on the digital representation of assets and processes help cities better understand their operations, predict the future, and improve decision making and planning processes.

Software virtualization, low cost sensors, cameras, GPUs, and most importantly the shared spectrum have enabled this digital transformation to be economically feasible.

## 4. Parking Occupancy App

*Customer Problem*

Multiple congested parking lots and lack of parking management impact local businesses

*Solution*

Private network and edge computing with video surveillance and analytics

**Figure 2- Smart Parking, City of Dublin**

**Figure 3- Darby Street Lot**

## 5. Dublin Architecture

The physical connectivity in the City of Dublin included, Radios, BBU (Base Band Unit), cameras, and CPEs (Customer Premise Equipment). Radios and BBU were installed on a utility Pole at the parking lot. The cameras and CPEs were installed on the city light poles around the parking lot.

Application software used the whilebox servers that provide network functionality. The Video-Analytics software ran on the MEC (Multi-access Edge Compute) node. IoT-framework and application software ran on the Core.

**Figure 4- Dublin Architecutre**

## 6. Why CBRS?

Many critical Enterprise applications that require low-latency, high bandwidth, or a massive number of connections cannot be solved using Wifi (Unlicensed Spectrum) or are economically infeasible to address through public networks (licensed Spectrum).

FCC opened CBRS (Citizen's Broadband Radio Service) which operates at 3.5 GHz band and allows 80 mHz of spectrum to be shared. CBRS is not unlicensed spectrum like Wifi, and it is not licensed spectrum that is controlled by the service providers. It is a new concept where the spectrum is shared in a 3 layer model. When an incumbent is not fully utilizing the spectrum, the Authorize Access Users can jump in and use the spectrum. SAS (Spectrum Access Sharing) is provided through 3rd party vendors (Google, Commscope, SONY, ...) that control access.

Cable companies can provide access points that are CBRS-enabled and enter the wireless market to provide Private Networks or Neutral hosts services to enterprises and cities.

Source: commscope

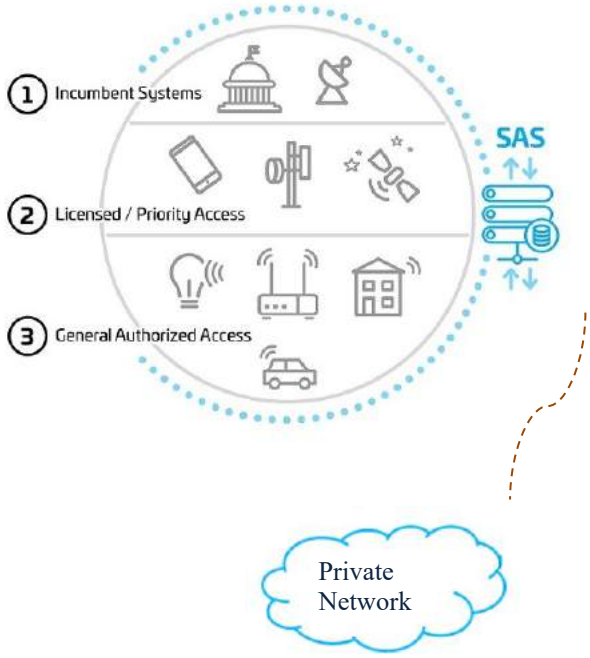

**Figure 5- CBRS Architecture**

## 7. Lesson #1 – Deployment

- Permitting and inspection takes time
- Installation can be expensive
- MEC connectivity should be planned early
- Cameras are not UE's (today)
- Appearance Matters - Customer facing eqpt must look professional and SW must be intuitive

## 8. Lesson #2 – It is all about data

- Automatic data collection is important
- Site access statistics can alert hacks/security attempts
- Data must be simplified through Graphs/Charts in order to facilitate quick path from "data to decision"
- Open APIs are a must
- Access to real-time images/video streams is important

## 9. Lesson #3 – Environmental challenges

- **Rain & Snow** – Rain drops and snow flakes can attach to the camera and cover portion of the view. This will effect the accuracy of the Video-Analytics
- **Trees & Leaves** – As spring roles around, the leaves on the trees may obscure portion of the camera view.
- **Storms and high wind** – Camera attachments must be highly secure to avoid camera movement during a storm, if the cameras move, adjustment must be made to correct field of view.
- **Sunset/Dusk** – Visibilty of the camera view is effected by the change of lighting during sunset.
- **Length of the attachment poles** – If cameras are attached to short poles, the visibility is reduced and more cameras will be required.

## 10. COVID-19 - Compliance

Although the goal of the project was to better understand the parking congestion, the project allowed City of Dublin staff to remotely monitor compliance to COVID-19 “Stay at Home” orders.

Remote access to the city resources can save lives by eliminating the need for city staff to physically come close to the public.

**Figure 6 - COVID-19 Compliance**

## 11. Conclusion

Private Networks enable deployment of additional Apps. Now that the Dublin Private Network is in place, we can add our COVID-19 based applications (Smart Distancing and Smart Masks) over the air to the network servers to enable additional compliance measurements.

The low cost of CBRS allows cable companies to enter the wireless market by building private networks for enterprises and cities. Once the network is in place, the white box servers that provide network function virtualization can be re-used to run additional application software and therefore, allow cable companies to provide Apps that provide digital twins of Cities' assets.

## List of Figures

## 1. Introduction

Cable companies are positioned to enable remote monitoring of patient data through connected medical devices. The remote needs of customers due to Coronavirus highlighted the need to offer healthcare services outside of traditional brick and mortar medical facilities. Existing solutions that enable the wireless transfer of data from connected medical devices suffer from numerous shortcomings that limit the adoption of this technology.

The predominant means of wireless connectivity for in-home medical devices is Bluetooth Low Energy. Most manufacturers require the use of a smartphone and a proprietary application to transmit vitals measurements from healthcare devices. This places a heavy burden on a patient's ability to purchase a smartphone and then have the technology savvy to download an application and connect with the healthcare devices. These proprietary applications also lead to data siloes and inconsistent security practices. To overcome this limitation some device manufacturers and service providers resort to using expensive cellular radios and data plans. As a result of these steep barriers many of the most vulnerable patients are unable to participate in the use of this technology.

There is a better way. IoT radios, such as Bluetooth Low Energy (BLE), should be included in traditional Ethernet and Wi-Fi routers. These common access points are a natural bridge between Personal Area Networks (PAN) that are used for most constrained IoT devices' wireless communication and traditional IP based Local Area Networks (LAN) and Wide Area Networks (WAN). This should be combined with a flexible software platform that can provide interfaces for IoT device provisioning, command and control, and telemetry transport.

Utilizing this approach to fulfill remote patient monitoring use cases would enable devices to be onboarded with little or no user intervention. It would also ensure that sensitive healthcare measurements can be sent directly to secure whitelisted endpoints. As administrators of the platform, Cable companies can implement industry standard security practices and provide advanced monitoring and troubleshooting services. This solution removes the technological barriers to entry, improves connection reliability, and can be provided at a much cheaper price point than using cellular.

This paper describes a prototype of a router-based remote patient monitoring system which will be much more effective than the current approaches. It introduces OpenSync, a cloud-agnostic open-source software for the delivery, curation, and management of services for the modern home and the IoT extensions that need to be added to it. It describes the enhancements that must be made to the router and its software stack, as well as what cable companies can do as an industry to enable this new line of business.

## 2. What is Remote Patient Monitoring (RPM)

Remote Patient Monitoring (RPM) is a new technology in the rapidly evolving world of digital healthcare delivery. RPM allows for the collection of patient data outside of traditional brick and mortar healthcare facilities. The ability to regularly take readings of vitals and other physiological measurements enables healthcare professionals to provide custom tailored

treatments and intervene more quickly if patients are not progressing as expected. There are other uses as well: consumers can track their own wellbeing, research and analytic companies can collect anonymized data to improve overall healthcare and design new therapies.

RPM has been enabled by the continual miniaturization of electronics and by the evolution of IoT. Most connected medical devices are battery operated, constrained devices. They typically use Bluetooth Low Energy for wireless communications but sometimes come with cellular or Wi-Fi radios. Most of the devices specialize in taking a single medical measurement and generally attempt to transmit the value as soon as it is available. Examples of RPM devices include connected blood pressure cuffs, pulse oximeters, scales, thermometers, glucometers, and more.

A diverse set of stakeholders is required for RPM to achieve general acceptance and provide value to users. The major stakeholders in the space are patients, doctors, device manufacturers, electronic medical records providers, insurers, patient engagement companies, healthcare exchanges, and many more. Each stakeholder has different interests and responsibilities. These competing factors often lead to data being siloed with a single entity causing patients to get less value from the technology. Coordinating access to medical data and ensuring proper authorization can become very complex. Cable companies can play the coordination role.

## 3. Why Should Cable Operators Care

Currently there exists no standard for transporting data from connected medical devices to backend systems in the cloud where the data can be used and stored. Cable companies are well positioned to influence the creation of standards and be the connectivity bridge. Cable already has a presence in nearly every home across the country and provides connectivity for millions of connected devices. The next evolution of this connectivity should be to connected medical devices that use personal area networks.

The potential benefits to Cable companies are vast. Cable companies stand to enhance the relationship with their customers and improve their overall reputation by being the guardians to sensitive health information. Internet and advanced wireless connectivity packages can be made stickier since they play a vital role in directly ensuring our customer's wellness. There also exists new lines of revenue through the direct administration of remote patient monitoring services or through partnerships with healthcare systems and providers. This technology also presents an opportunity to engage in the wider smart home industry.

## 4. Current Implementations and Their Shortcomings

Remote patient monitoring requires the transfer of sensitive data from medical devices to the internet. To facilitate this data transfer two general approaches have been adopted. The first and most common approach is to use a smartphone as a hub and the second approach is to equip medical devices with cellular radios. Each carries its own shortcomings that limit the adoption of this technology.

The smartphone as a hub approach works by utilizing the Bluetooth radio that is ubiquitous in smartphones today. The smartphone acts as a central device and is able to connect to nearby BLE medical devices. Once connected to the medical device the smartphone is able to retrieve readings from the device and send them to the cloud or store them locally. Generally the process of connecting to the device and retrieving measurements is done through a proprietary application provided by the device manufacturer.

The smartphone as a hub approach suffers from a few shortcomings. The first is that it requires users to have a smartphone. Patients are also required to download proprietary applications, turn on Bluetooth, create accounts, adjust permissions and settings, and perform a range of other tasks that may not be simple for many of the most needy. The proprietary nature of the application required to interact with the device often leads to data siloes. Having medical devices from different manufacturers also generally requires separate applications.

To overcome these limitations the second approach of using cellular radios has been adopted. This approach generally places cellular radios directly in connected medical devices. Rather than requiring a hub to enable the transfer of data to the cloud the device can directly transfer the data itself. While this approach eases the technological burden on patients it increases the cost of connected medical devices and requires expensive recurring data plans. It also increases the complexity of the device and leaves the security implementation completely at the discretion of the device manufacturer.

## 5. A Better Connectivity Solution

An ideal connectivity solution for remote patient monitoring must retain the cost effectiveness of inexpensive Bluetooth radios while minimizing the technical role a user must play. It should provide the patient the ability to authorize access to their medical data but otherwise be transparent to them. The nuance involved in connecting the medical device to a network, controlling the device, and ultimately transmitting readings to the cloud should be automated. The user interface for patients to interact with their medical data should be completely decoupled from the application that transfers data from device to cloud. All device provisioning and association with a particular user should be done by backend systems that require little or no patient involvement.

To have the widest adoption the software should be open source and the router components should be hardware agnostic. An open source solution would allow every connectivity provider and medical device manufacturer to deploy the solution. A hardware agnostic platform would allow components to be cost competitively sourced and limit the leverage of any given vendor. This helps drive down the total bill of materials and avoid procurement obstacles.

## 6. Why Use a Router

The router is a natural replacement for the use of a smartphone as a hub and its always on nature provides many additional advantages for the collection and transfer of medical data. The router is a relatively inexpensive and common piece of equipment for most households. It currently serves to connect ethernet and Wi-Fi capable devices to the internet. With addition of IoT radios the

router can also be a bridge to connected medical devices and facilitate the transfer of data to the cloud.

Using a router to provide access to the internet for connected medical devices provides an inexpensive connectivity option. This also ensures that existing BLE medical devices can participate. Routers can be centrally and remotely administrated. The always-on access point lends itself nicely to regular collection of connectivity diagnostics. Remote administration can assist in troubleshooting malfunctioning equipment.

## 7. Why Use the OpenSync Platform

Equipping routers with additional IoT radios is only part of the solution. In addition to the necessary hardware to communicate with connected medical devices a software platform to interact with the devices is also required. Such a platform must be capable of being remotely managed, have a secure pipeline to facilitate telemetry, and be capable of being run on routers. In addition, the software must be deployed to millions of routers and bulletproof.

OpenSync is a software platform that meets the requirements to enable remote patient monitoring. It has baked in support for JSON RPC, a synchronized bi-directional database, and MQTT. These components make the platform extremely flexible, extensible, reliable, and secure. OpenSync and all of its components are open source. It can be run on OpenWRT, RDK, and other Linux based operating systems. OpenSync has also been thoroughly vetted and underpins the routing platforms of a number of major companies.

## 8. BLE Telemetry

To facilitate the transmission of data from a connected medical device, some means of uniquely identifying the device and some means of communicating with the device are required. In the majority of RPM devices, the means of communication is Bluetooth Low Energy and the device can be uniquely identified by its MAC address. Additional pieces of information that are required for the BLE protocol are the GATT service UUID that is broadcast in advertisement packets, and GATT characteristic UUID(s) that stores the device's value(s) of interest. Additional information is helpful but not necessarily required.

All BLE transactions begin with a device advertising itself. Information included in the advertisement packet is the MAC address of the device and usually a GATT service UUID. The service UUID can effectively be used to determine what type of device is advertising while the MAC address can be used to uniquely identify the exact instance of the device type. Any scanning devices that hear this advertisement can then issue a connect request to the remote device if they are interested in interacting with it. Upon establishment of the connection the central device can then issue commands to the peripheral device. These commands can assist in learning more about the capabilities of the device, reading values from the peripheral, writing values to the peripheral, or enabling notifications.

In a remote patient monitoring use case a typical transaction begins with a device turning on when a user engages it. This could be a user stepping on a scale, pressing a button on a blood pressure cuff, or placing a pulse oximeter on their finger tip. The device begins taking a measurement and when the first reading becomes available the device begins advertising itself. Nearby devices that are listening for these advertisements can issue a connection request in response. When the listening device connects it enables notifications on the medical device and the medical device then transmits values as they become available. This could be a stream of values as is the case with a pulse oximeter or a single value as is the case with a weight scale. When the medical device is done taking its measurement or otherwise disengaged by the user it disconnects from the listening device and goes to sleep. Transactions can grow more complicated when adding in authorization or bonding but this is the basis for the transfer of readings from a connected medical device to an internet connected device.

## 9. Proof of Concept

To prove the viability of RPM on a router and through OpenSync, the Emerging Technology team at Charter Communications designed and implemented a proof of concept. The design used a Raspberry Pi to act as a router and added a Silicon Labs Bluetooth capable radio via USB. The main software component is a custom build of OpenSync with extensions for IoT. These extensions included schema updates, a Bluetooth Low Energy hardware abstraction layer (HAL), a centralized RPM manager, and specialized plugins to assist the manager application. Supporting software components included a RESTful API, MQTT to Kafka connector, WebSocket server and a simple user interface.

The system works by allowing applications to issue commands in response to events generated by the Bluetooth Low Energy hardware abstraction layer or by updates made to configuration tables in the synchronized database. The BLE events that were exposed for the proof of concept include: advertisement packet received, connection established, service discovered, characteristic discovered, notifications enabled, and new value received. The BLE commands that were exposed include: enable scanning, connect to device, discover services, discover characteristics, and enable notifications. This simple set of commands and events allowed for interactions with four different types of medical devices. They include a blood pressure cuff, pulse oximeter, scale, and thermometer. Each device was made by a different manufacturer.

Every device interaction begins with provisioning a specific medical device to a customer account through the RESTful API. The RESTful API exposes resources that are capable of performing database transactions. These database transactions are then replicated down to the Raspberry Pi via the magic of OpenSync. The information needed for provisioning the specific device is it's MAC address, the UUID of the GATT service it advertises, and the UUID of the GATT characteristic that stores the value of interest.

When the RPM manager code running on the Raspberry Pi detects the provisioning of a new device it enables scanning through the BLE HAL. The HAL then begins to pass received advertisement packets up to the RPM manager code. If the manager finds an advertisement packet with a matching MAC address it then issues a connect request to the device.

Upon successful connection the manager then begins a process of attribute discovery on the device. If one of the discovered attributes happens to match the UUID of the GATT characteristic value of interest, the manager issues an enable notifications command. The device will then begin transmitting measurements to the Raspberry Pi as they become available. When a new value is received the manager code takes the raw bytes and transmits them to the cloud via MQTT. Once in the cloud the data is then able to be ingested by any stakeholders that have authorized access.

The main steps for getting data off the medical device can be broken down into three basic processes. The first process is establishing a connection between the medical device and router. The second process is discovering the attributes that the device exposes if this is not already known. The third process is enabling notifications and receiving values of interest. Below are sequence diagrams depicting the main processes that take place.

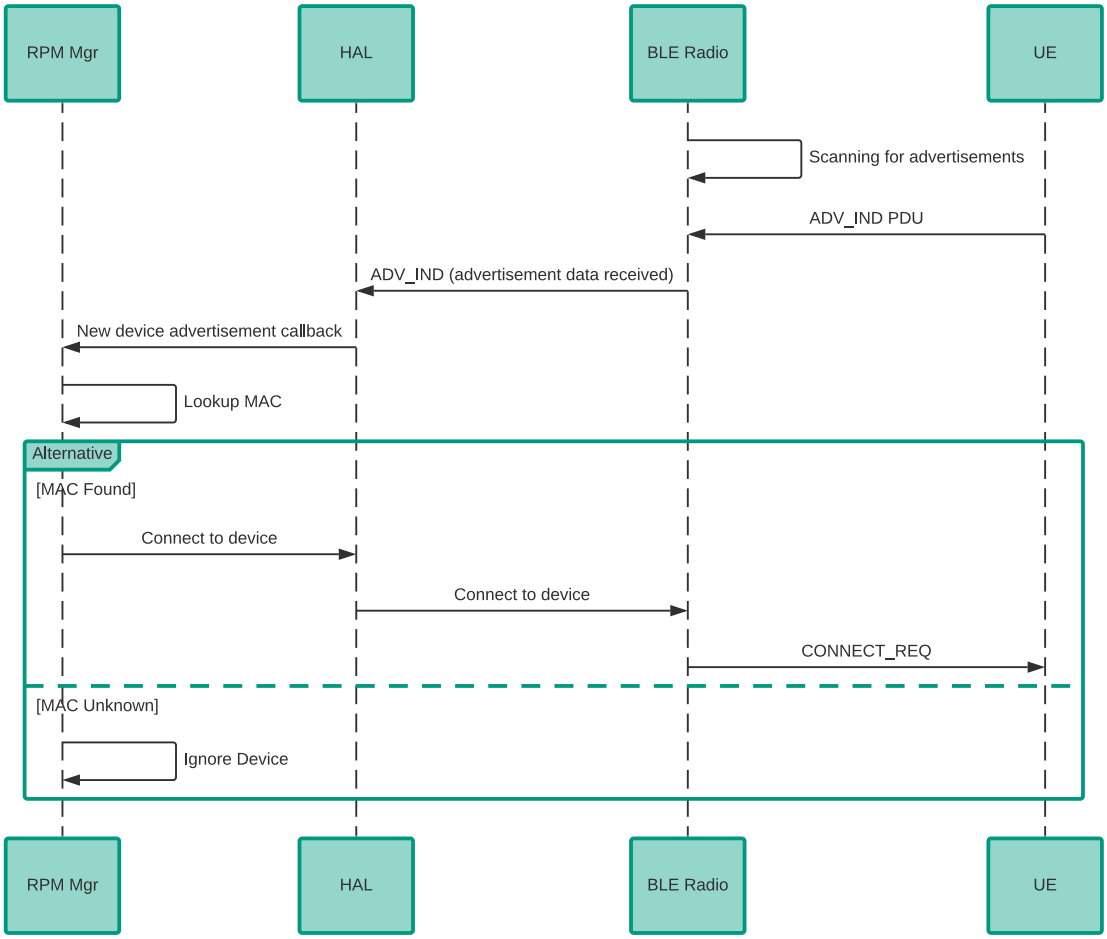

**Figure 1 – Device Discovery and Connection**

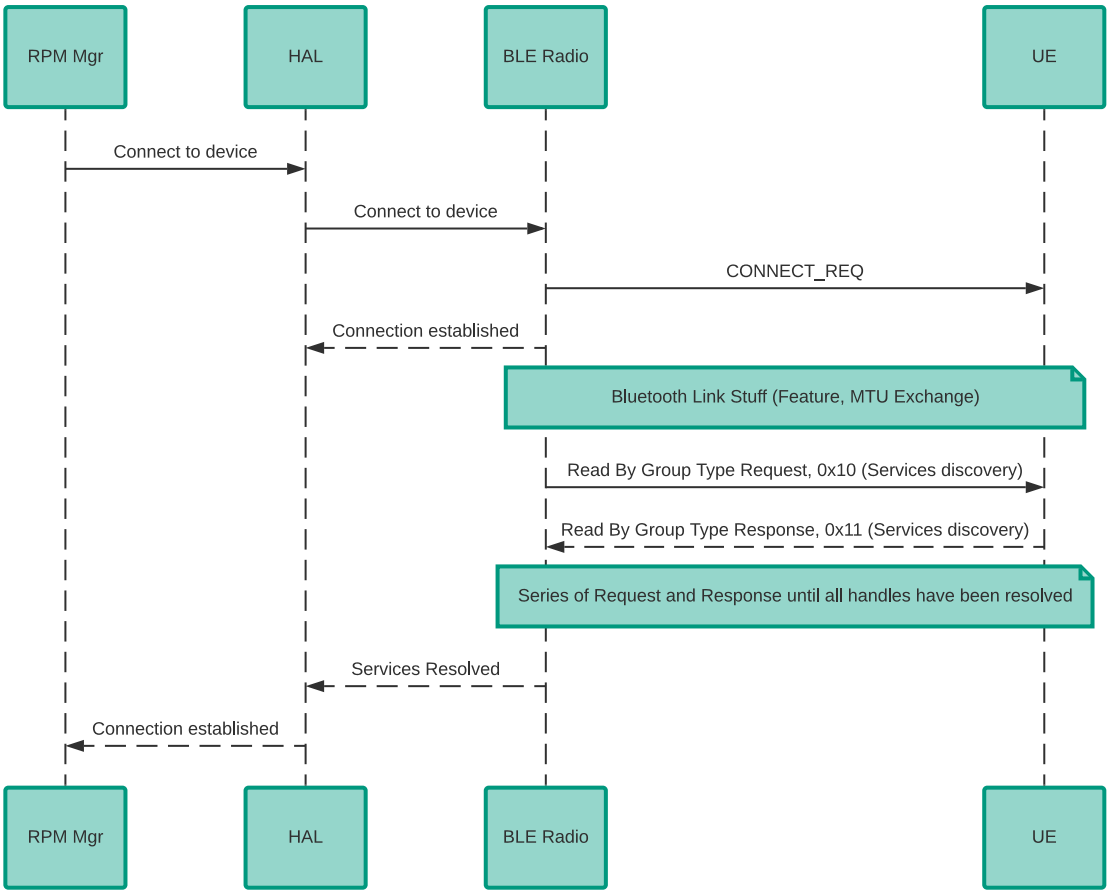

**Figure 2 – Device Connection and Attribute Discovery**

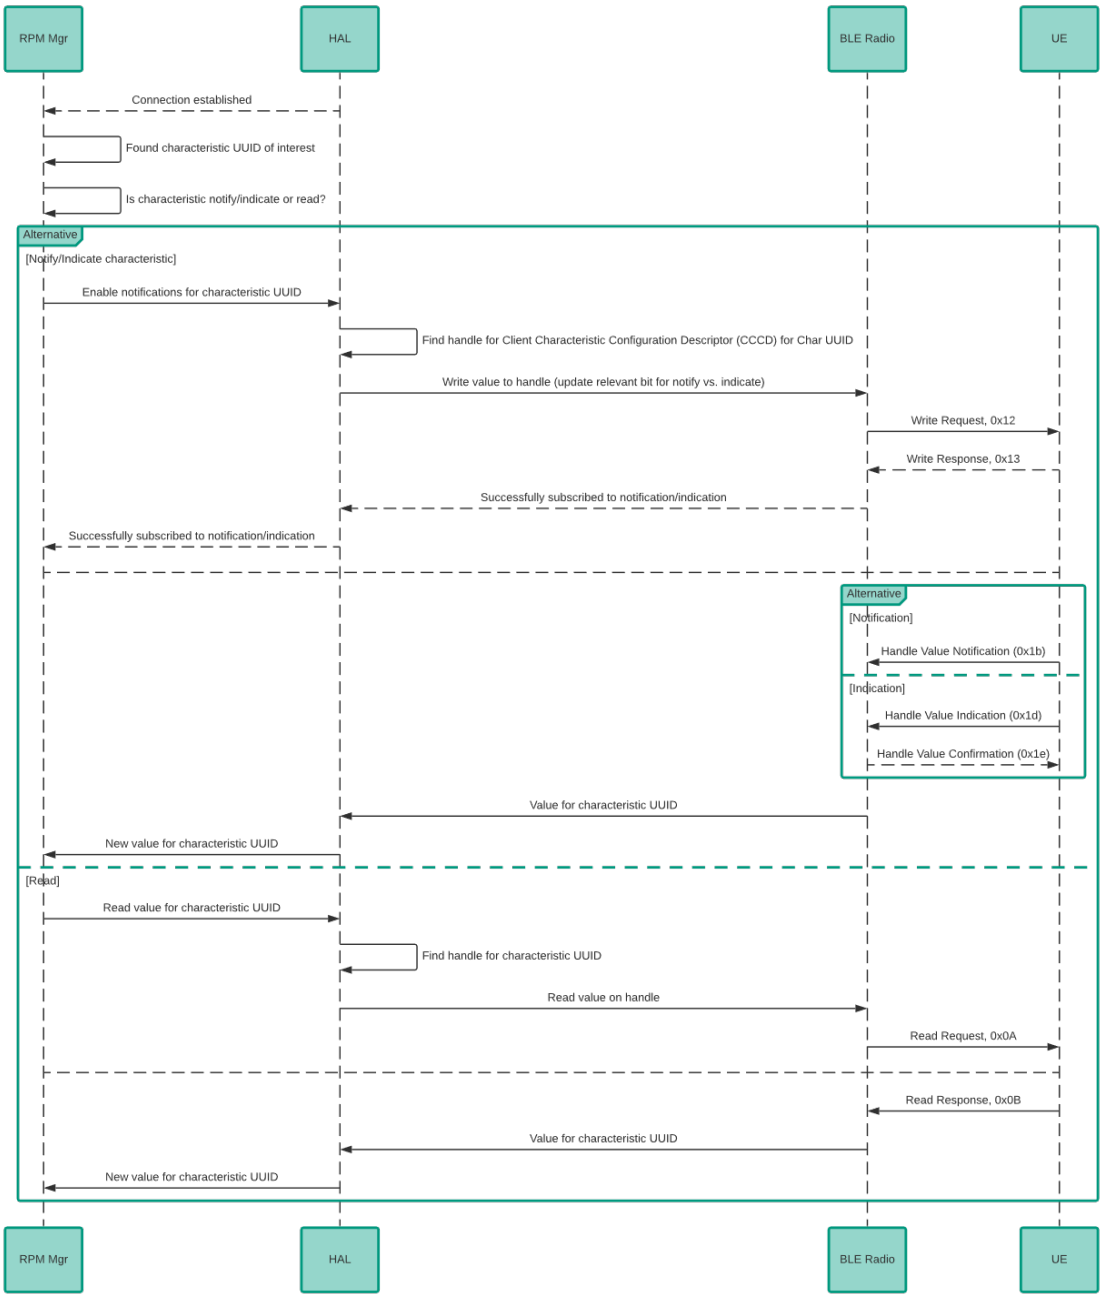

**Figure 3 – Data Transfer**

## 10. Areas Requiring Additional Work

The RPM proof of concept demonstrated the bare minimum required to facilitate the transfer of data from connected medical devices. The above outlined approach does not address security. Utilizing the outlined components, security can be centrally administered, data can be guaranteed to be encrypted while in transit from the router to the cloud, and additional best practice security standards can be employed.

In addition to work done around security, a more robust set of interfaces to provision devices and ingest data should be designed. The simple user interface created for the proof of concept allowed for manual provisioning of devices to a single customer account and the ability to view measurements in real time. A more effective interface would allow the process of device provisioning and data access to be automated at the point of sale or when prescribed by a doctor. It should allow the customer to elect where their data should be transferred and should require consent for all third party access.

While the proof of concept shows that a router can be used for remote patient monitoring, it has not been tested with day to day use. Potential areas that can improve performance would be bonding with devices and maintaining device information such as mappings from a GATT UUID to an attribute handle. Additional systems can also be created to track battery levels, device connectivity history, and RSSI values.

## 11. Potential Concerns with the Outlined Approach

The approach outlined above will work well for the majority of remote patient monitoring use cases. However, it suffers from two potential concerns. The first concerns placement of the router and signal range of the protocol. Bluetooth low energy has a range of 100 meters but in practical usage this is generally closer to 25 to 50 meters. In large homes or MDUs with lots of interference, the router may not be situated in an ideal location to accommodate these restrictions. In such situations placing IoT radios in Wi-Fi mesh access points would be an excellent approach. These can be small devices that create Personal Area Networks with a Wi-Fi data backhaul to the main router. In addition to providing extended IoT coverage they can also improve general Wi-Fi coverage.

The second concern relates to specific use cases requiring real time transmission of readings taken outside of a user's home. In this situation cable operators may be able to use a smartphone to serve as a hub for gathering and transmitting measurements with a companion app that complements the in home service. As Cable companies venture more into the mobile space this becomes a practical approach.

## 12. Conclusion

Remote patient monitoring is an emergent technology in the delivery of healthcare that holds great potential. To fully capitalize on this potential a better platform for the transfer of data from connected medical devices is needed. The benefits of the approach described in this paper are more reliable connectivity, stricter security, cost efficacy, decoupling of data acquisition and data interaction, and an improved user experience. Cable companies are in a strong position to

leverage existing and enhanced infrastructure to support RPM technology. The rewards for implementing an RPM platform will be increased customer loyalty, new potential streams of revenue, and an opening to play a larger role in the broader smart home space. If Cable companies work together to create an open source standard many device manufacturers and RPM service providers will welcome the opportunity to use it.

# Introduction

Full-duplex DOCSIS has been encountering a continuous uphill battle to double the channel capacity through resource sharing of uplink and downlink channels. As the downstream and upstream are delivered via the same spectrum at the same time, co-channel interference in the form of internal coupling, micro-reflections or echoes becomes a formidable challenge. To ensure the proper operations of full-duplex DOCSIS, echo cancellation is an urgently needed technique. Typically, it involves analog cancellation to lower the power level of the major echoes below the analog-to-digital converter (ADC) dynamic range, while digital cancellation is followed to remove the residual echoes ensuring a sufficient modulation error ratio (MER).

Many conventional echo cancellers are realized via a subtraction scheme, which implies the receiver is operating linearly. However, this limits the transceiver operation margin and the achievable MER. As the power of the desired and the echo signal increase, the receiver front-end may be driven away from its linear operation range and introduce nonlinear impairments. The crosstalk among the echoes and the desired upstream signals would degrade the echo cancellation performance. Thus, a simple subtraction-based cancellation is no longer sufficient.

In this paper, we propose a deep neural network (DNN) based method to simultaneously cancel the echoes and recover the upstream signal. Both the received signal and the known downstream signal will be fed into the DNN processer, and the DNN output is the recovered upstream signal. The DNN is an efficient method to mitigate nonlinearities because of the implemented nonlinear activation function at each hidden layer. After proper initial training, the DNN-based canceller can achieve an excellent upstream signal recovery and outperform the conventional digital cancellation schemes. Moreover, the on-demand dynamic training can be performed implicitly without impacting the regular DOCSIS system operation. This novel approach would dramatically improve the recovered upstream signal quality and increase the capacity of the DOCSIS. This paper is organized as follows. Section 1 reviews the background of echo cancellation in full-duplex (FDX) DOCSIS and the conventional methods' limitation. Section 2 introduces the concept of deep learning and the principles of DNN to realize echo cancellation. Section 3 demonstrates a proof-of-concept experiment and results analysis of DNN based echo canceller.

# Content

## 1. Echo Cancellation in FDX DOCSIS

In the current cable access network, frequency division duplex (FDD) is implemented to provide various services to the cable subscribers. With FDD, the available cable spectrum is divided into non-overlapping parts for downstream and upstream, respectively. Different frequency splits have been defined including low split, mid split and high split. However, even with 5 MHz -204 MHz available spectrum of high split for upstream traffic from the cable modem (CM) to cable modem termination system (CMTS), it's still not sufficient to accommodate the exploding growth of bandwidth demanding services like AR/VR gaming, high-resolution video streaming. Besides, the high split also reduces the available spectrum to downstream traffic. To address the limited spectrum of cables and increase the spectrum usage efficiency, FDX was firstly introduced as DOCSIS 3.1 Full Duplex and latterly rebranded as part of DOCSIS 4.0 [1]. Unlike the frequency division multiplexing (FDM), the downstream spectrum could be reused by the upstream traffic without sacrificing the downstream bandwidth. In theory, the FDX DOCSIS allows overlapping spectrum between downstream and upstream traffic. Considering the 1.8 GHz full spectrum of the cable plant, the coax network bandwidth could potentially be doubled to 3.6 GHz. Though the appealing advantages of FDX DOCSIS, it suffers from various implementation challenges. One of the

most significant challenge is the self-interference from the CMTS (Remote-PHY, RPD node) transmitter to its receiver. The system impairment due to self-interference is severe in FDX as the upstream and downstream share the same frequency spectrum, which cause co-channel interference. The self-interference arises from the internal coupling as well as the echoes in the forms of micro-reflections due to impedance mismatch at the taps as shown in Figure1.

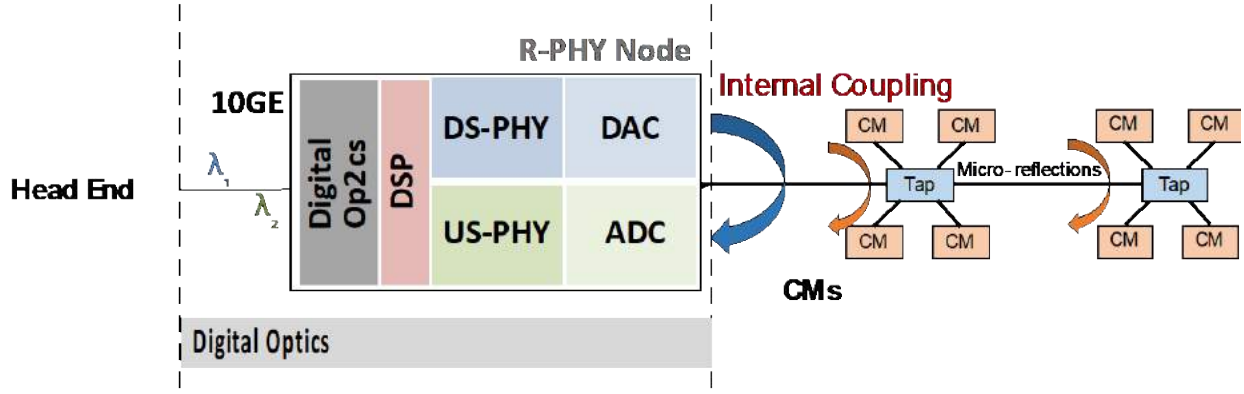

**Figure 1 – Illustration of Self-Interference in FDX DOCSIS.**

Since the downstream signal has a much larger power compared with the upstream signal, the received upstream signal will be overwhelmed in the spectrum if there's no sufficient isolation. As the interfering down-stream (DS) signal is in-band, it cannot be directly removed by a radio frequency (RF) filter. Therefore, echo cancellation is necessary at the RPD-equipped node to cancel the self-interference and realize the FDX transmission in the cable network. It's typically assumed that N+0 network topology is necessary to support FDX DOCSIS as bidirectional FDX amplifier is associated with dramatic design implications [2]. N+0 topology imposes all passive RF components which can support bi-directional analog RF transmission based on Lorentz reciprocity theorem. Such that the FDX operation is possible without the expensive replacement on the already deployed cables and taps.

The conventional echo cancellation techniques in FDX DOCSIS split into two process, namely, Analog cancellation and digital cancellation. The logistics behind the split is to accommodate the limited dynamic range of the ADC at the node receiver. The power level of the reflections in the FDX spectrum can be more than 15 dB higher comparing to the desired upstream signal [2]. Applying analog cancellation before receiving by the node receiver can significantly relieve the saturation effect of ADC and improve the effective MER for the upstream signal detection. Figure 2 shows the typical setup and process for echo cancellation in FDX DOCSIS. The analog echo canceller takes a copy of the downstream signal and tunes its phase and magnitude to create a canceling signal with the same amplitude but with 180-degree phase difference. As the actual echo signals are from various sources and different locations, the multiple echo paths with different amplitude and phase are tracked and estimated in the digital domain and then converted into analog domain for cancellation using a DAC. After the analog cancellation is performed, digital cancellation is followed to further suppress the echoes using tracked/computed echo cancellation coefficients. The conventional echo canceller assumes that the self-interference (SI) can be removed by subtraction. However, this assumption doesn't hold true when there's nonlinearity at the receiver of the RPD. In realistic FDX implementation, an echo cancellation method which can mitigate the nonlinear impairments is necessary.

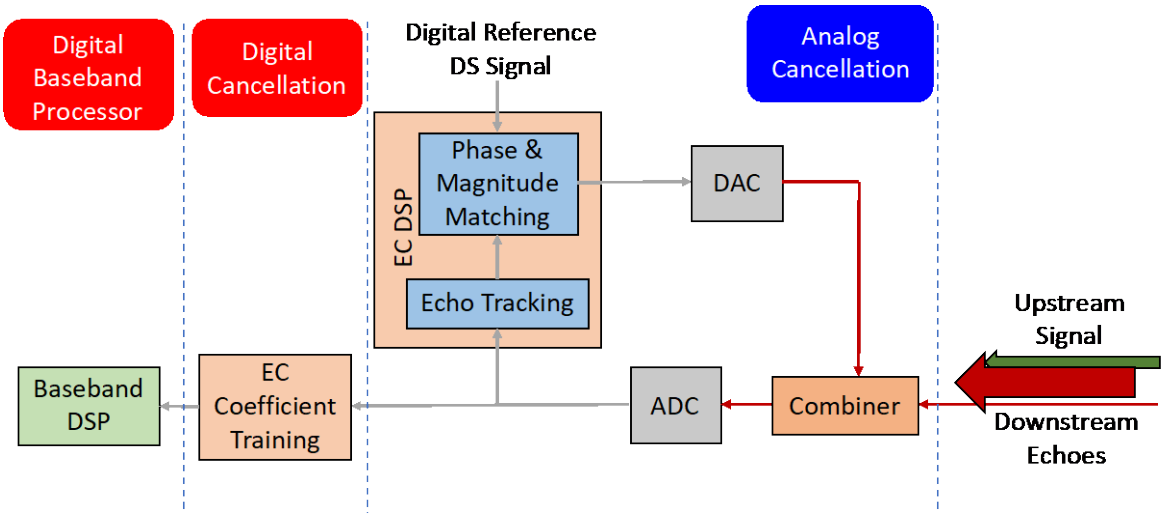

**Figure 2 – Conventional Echo Canceller Structure and Process.**

## 2. Deep Learning Recap and DNN-based Echo Canceller Principles

Deep learning has attracted tremendous interest from research and industry implementation. It is a sub-field of machine learning and it's based on artificial neural network with representation learning including supervised, semi-supervised and unsupervised. Deep learning performs excellently in image/video recognition, natural language processing and gaming. Beyond those conventional applications, deep learning also shows promising capability in dealing with challenges in wired/wireless communication, like multi-level signal recovery and adjacent channel interference mitigation [3-4]. Moreover, due to the booming development of neural network training algorithm, the training efficiency is significantly improved, while transfer learning can further reduce the required training time when there are any dynamic effects. Once the neural network is properly trained, the DNN inference is fast with low complexity as only simple matrix multiplications are required. Besides, the DNN can be implemented using general hardware like GPU, which provides the DNN with high scalability and low implementation cost.

To solve the aforementioned challenges in echo cancellation, we design and implement a DNN-based echo canceller to eliminate the nonlinear echo and the nonlinear crosstalk at the receiver jointly. The echo canceller will be implemented at the RPD. Here, we take the received signal and the known SI signal as the input to the DNN, while the output of the DNN is the recovered upstream signal of interest. The proposed DNN structure and parameters are shown in Figure 3, which consists of 3 hidden layers with 64, 32, and 16, respectively. The input layer has 41 neurons like the taps of a non-casual filter, while the output has 1 neuron representing the recovered signal-of-interests (SOI). The nonlinear rectified linear unit (ReLU) activation function is used at each hidden layer. In this case, the mapping between the received signal to SOI is not by subtraction of SI anymore. The nonlinear correlations between SI and SOI and the nonlinear distortion on the SI signals are also eliminated by the DNN after learning the sophisticated mapping. Besides, the DNN canceller realize the simultaneous echo cancellation and SOI recovery, greatly simplify the conventional two-step process.

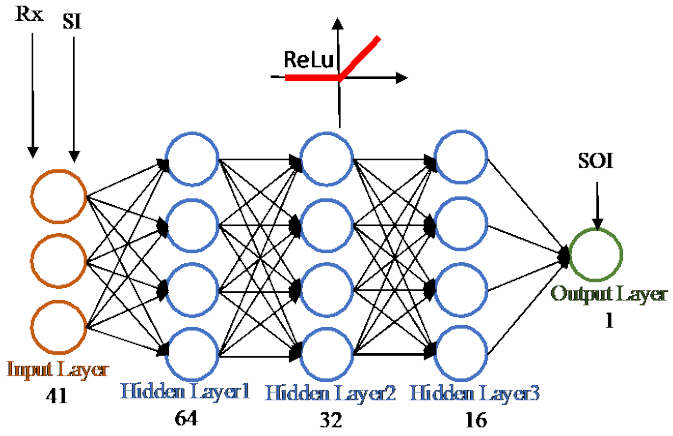

**Figure 3 – Structure and parameters of proposed DNN echo canceller.**

Another benefit of the DNN canceller is its minimal impact on regular service during its training process. As shown in Figure 4, due to the limited modeling capability, the conventional digital signal processor (DSP) needs to be built in a block structure. The echo information is firstly estimated and removed from the received uplink signal with echo. After the echo canceller, a baseband DSP is conducted to recover the SOI subsequently. It is worth note that to obtain the accurate echo information, an additional training period is required in the conventional DSP fashion. In other words, certain time slots are preserved for DS signal transmission only, in such period, the upstream (US) signal is halted, and the DS training signal occupies all the available RE, resulting in a low channel utilization. On the other hand, the proposed DNN based decoder can break the DSP block structure. Most importantly, aided by the sophisticated DNN decoder, the dedicated training period can be removed which allows an implicit training without impacting system operation. Therefore, full-duplex transmission can be achieved all the time.

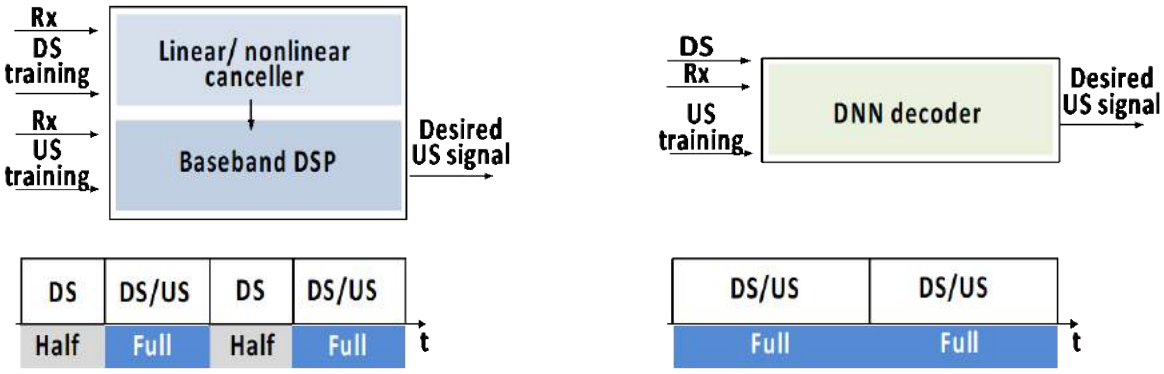

**Figure 4 – Comparison of DSP structure and time domain data management. (a) linear and nonlinear cancellers (b) DNN decoder.**

## 3. Experimental Setup and Results Analysis

The experimental setup of the orthogonal frequency division multiplex-based (OFDM) full-duplex transmission system is illustrated in Figure 5. A 16-GSa/s arbitrary waveform generator (AWG) is employed to generate the downlink echo and the desired uplink signal. To evaluate the impairment due to

the interference power from the reflected echo, a 10-dB attenuator cascaded by a 35-dB gain amplifier are applied to boost the downlink signal. Echo signal and the desired signal are combined via a power combiner before entering a 10 GSa/s real-time scope (RTS). Both echo and uplink signal are offline encoded and decoded via Matlab. The typical OFDM processing is employed. The FFT size is 2048 and the subcarrier spacing is set as 1.92 MHz. The bandwidth of echo is fixed as 990MHz and the desired uplink signal bandwidth under tested are 90, 450, and 990 MHz, respectively. The downstream transmitted power is ranging from -10 to -18 dBm before the power amplifier.

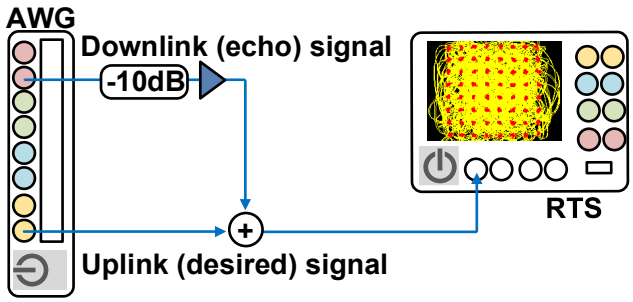

**Figure 5 – Experimental setup of the OFDM-based full-duplex transmission system.**

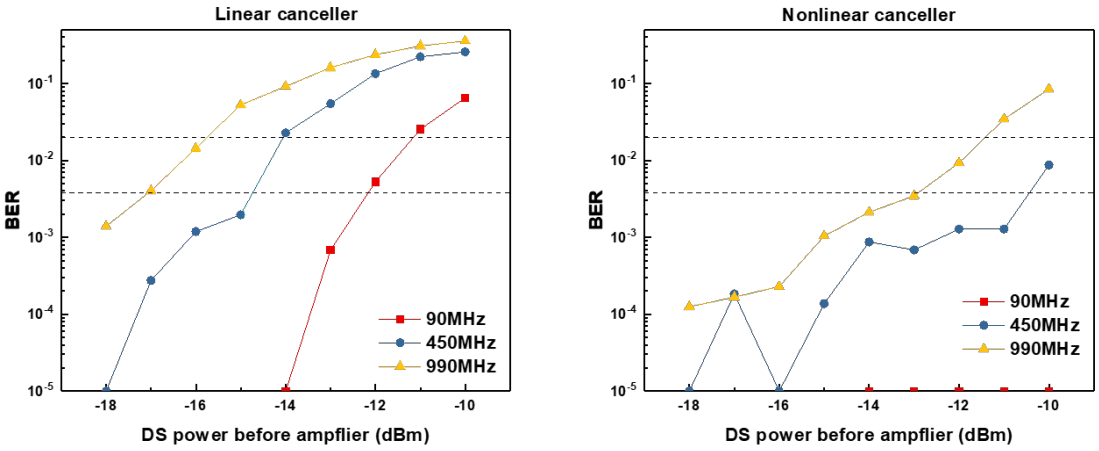

**Figure 6 – BER performance versus interference with (a) linear (b) nonlinear cancellers.**

As one can note that in Figure 6, the received BER performance is getting worse as the bandwidth of uplink increasing. This can be understood since the output Vpp of the desired signal, i.e., uplink, is fixed by the AWG as 1 V. Thus, as the bandwidth increasing, the per subcarrier SNR is decreased. Meanwhile, the BER is getting worse when the DS power increasing because the echo impairment is also increasing for the uplink signals in this case. On the other hand, the BER performance with nonlinear canceller, i.e., Volterra equalizer, always outperforms the linear canceller, i.e., minimum mean square error (MMSE), at the cost of a much higher DSP complexity. In the case of 90-MHz US, the BER of nonlinear canceller performs irrelevant to the power of echo interference.

The DNN decoding is a data driven processing. In this demonstration, the received signal is decoupled as training set, validation set and test set. Each set of data occupies one third of the received signal. The training set is firstly used to train the optimal weights and bias of the DNN, and the validation set is employed to validate the behavior of the DNN model. The DNN model we designed has one input layer,

three hidden layers, and one output layer. Activation function is $ReLu(x)$ and the loss function is MSE. Optimizer employed in this experiment is Adamax which can ensure a faster and better convergence. After modeling, the test set would be processed by the trained DNN; while the training set result is also presented as a benchmark. It is worth to remind that DNN can cancel the SI and recover the SOI simultaneously, which enables full-duplex transmission.

As shown in Figure 7, the DNN decoding performance of 90 MHz US is similar to the nonlinear canceller. In this case, the DS information is not needed and thus all the RE can be fully utilized for the full-duplex operation. However, the performance of DNN drops quickly as the bandwidth increasing to 450MHz. DNN only outperforms the linear canceler in the strong interference range of DS power over -15 dBm, in such range, both DNN and linear canceler cannot achieve the FEC threshold requirement even with 20% overhand. This performance degradation may be caused by the insufficient vertical resolution of the received signal, since the peak to average power ratio (PAPR) increase proportional to the active subcarrier number. To circumvent this restriction, a straightforward method is reducing the active subcarrier number at the cost of reducing the bandwidth.

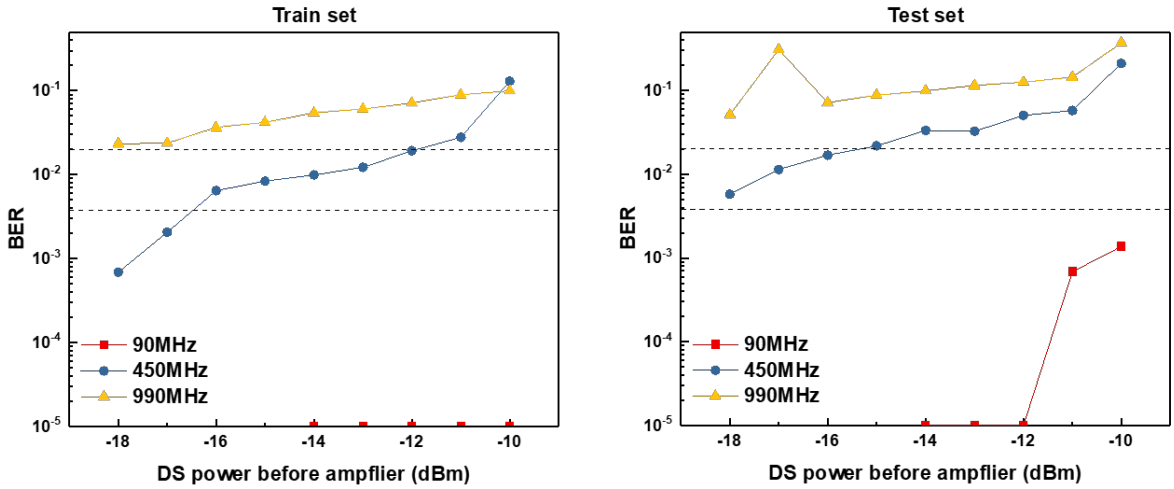

**Figure 7 – BER performance verse interference with DNN decoder (a) train set (b) test set.**

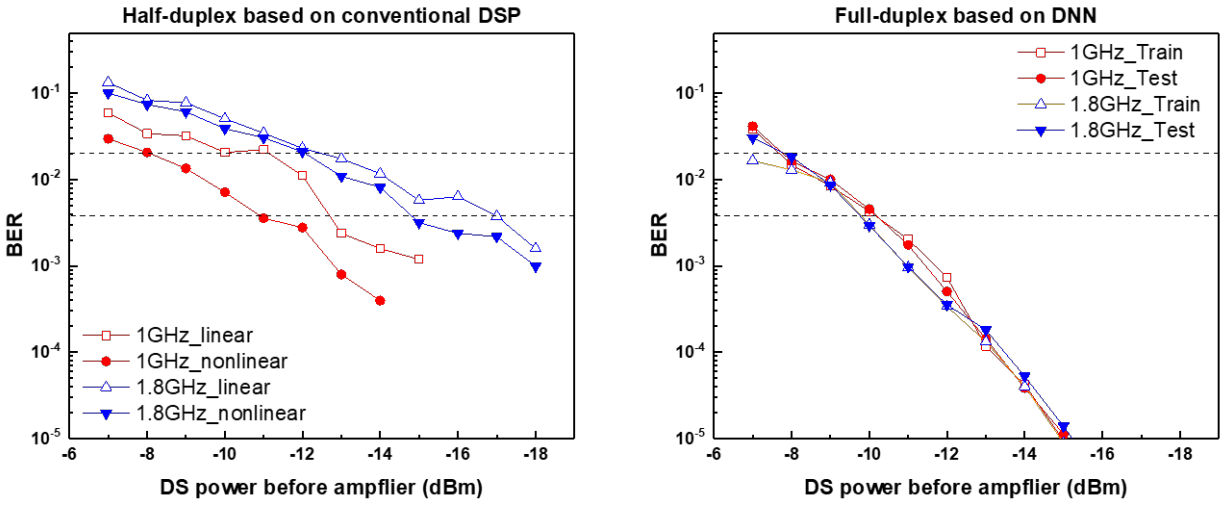

**Figure 8 – Wideband echo canceller BER performance (a) conventional DSPs (b) DNN.**

To get the better DNN performance and keep the transmission bandwidth, we can reduce the fast Fourier transform (FFT) size and active subcarrier number as well as increase the subcarrier spacing. Bandwidth under tested are 1GHz and 1.8GHz to comply with the DOCSIS 4.0 requirement. The active subcarrier number are 32 and 58, respectively. With the new settings, the US and echo have the same bandwidth for the FDX operation. the DNN canceller outperforms the conventional linear and non-linear DSPs in both scenarios as shown in Figure 8. The test set data performance is close to the training set, which implies no overfitting issue in the DNN process. The received performance is not sensitive to the bandwidth increment.

# Conclusion

As cable access network service providers evolve toward N+0 architecture and FDX DOCSIS for higher capacity, the echo cancellation technique becomes a core enabler to ensure reliable and high-performance services. The DNN-based echo canceler offers a future-proofing solution for cable operators to satisfy the exponentially growing bandwidth demand without dramatic infrastructure change.

In this paper, we explain the working principles of the proposed DNN canceller and conduct a proof-of-concept experiment to verify its performance in SOI recovery comparing with Volterra-based nonlinear canceler and conventional linear canceler. Better BER performance is observed at any measured DS transmission power for both 1 GHz and 1.8 GHz bandwidth cases. The results show the DNN canceller is robust for different configurations and working conditions of the coaxial cable network. This means that the cable operators may effectively support FDX operation over the whole available DOCSIS 4.0 spectrum without significant update on the physical infrastructure.

# 1. Introduction

Cable network bandwidth demands are growing exponentially as video becomes ubiquitous, Internet of Thing (IoT) devices proliferate, and new high bandwidth wired, and wireless Access technologies come online. Gartner estimates 90 percent of the data generated by the massive number of Internet-connected devices is sent to regional data centers for processing,[1] further stressing network infrastructure and increasing average response times for everyone.

That said, there is an incredible opportunity for broadband connectivity providers and those offering over-the-top (OTT) applications and Services to help make sense of and take action on the data coming from cars, cameras, factories, enterprises, and homes, and to do so in a timely manner. In fact, whole new categories of Services have been dreamed up, requiring ultra-low latency (i.e., augmented/virtual reality (AR/VR)), enhanced data privacy (i.e., medical records), or bandwidth optimization (i.e., video surveillance).

Figure 1 shows a range of industries and application segments that will benefit from these new network and compute capabilities if they can be delivered in a cost-effective manner.

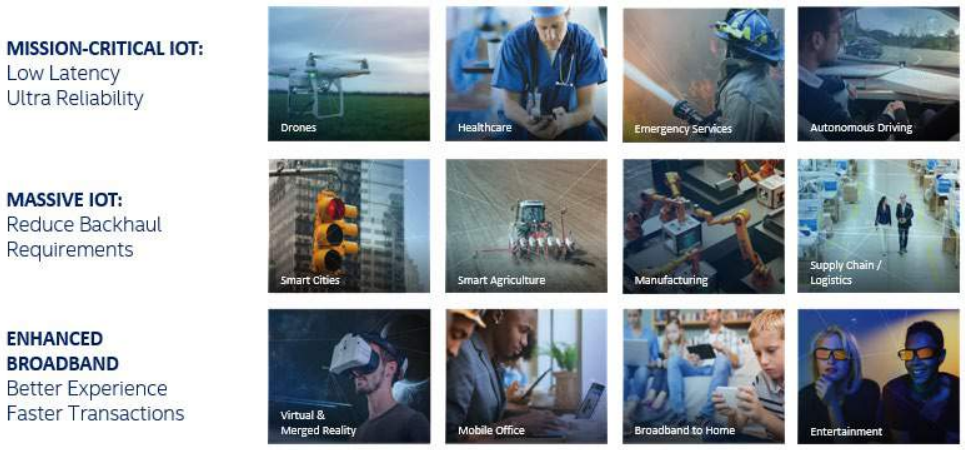

**Figure 1 - Requirements on the Network for New Services**

For many networks, the latencies and other key performance indicators (KPIs) for specific Services within these segments, as shown in Figure 2, will require smart upgrades across the network infrastructure to:

- Reduce end-to-end latency by an order of magnitude
- Allow data to be processed closer to where it is generated, and
- Provide a coordinated deployment and management system to keep costs in line with revenue

[1] Gartner, "Edge computing promises near real-time insights and facilitates localized actions."; https://www.gartner.com/smarterwithgartner/what-Edge-computing-means-for-infrastructure-and-operations-leaders

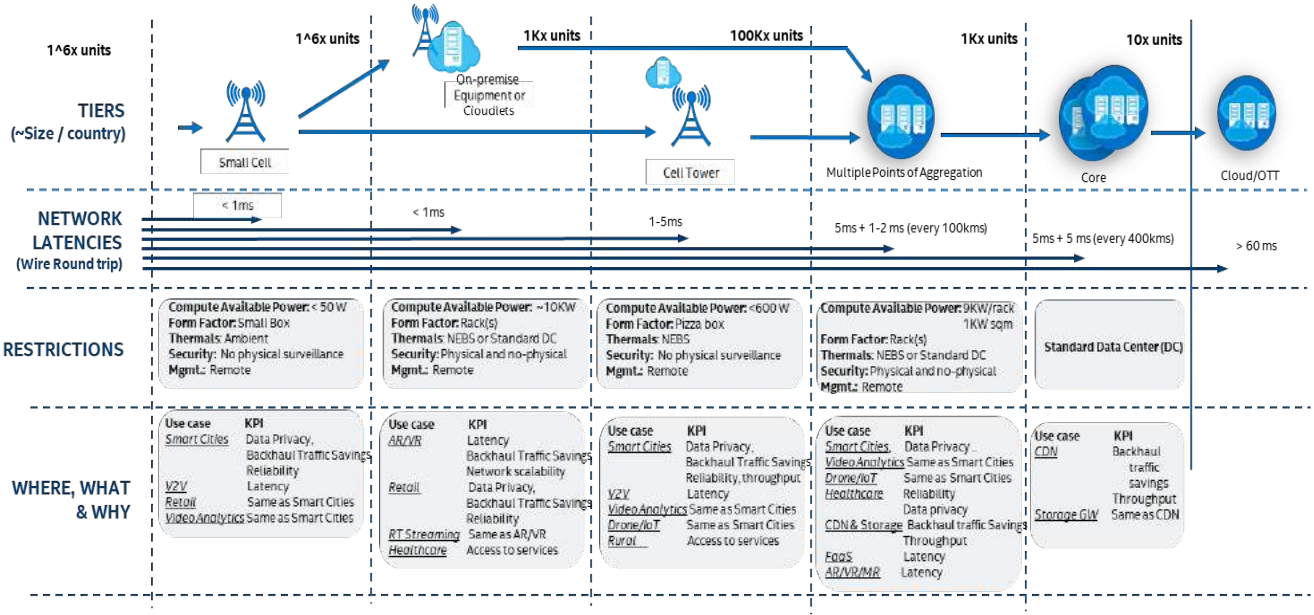

**Figure 2 - Use Cases and Associated KPIs**

Looking at the topology of the network, "The Edge" makes for an interesting and obvious place to manifest key infrastructure because it is physically closer to end users. The reality is there are multiple places that could be considered the Edge, and they all can exist in the same network. Figure 3 shows that at the top level, the Edge can be split into an On-Premises Edge and a Network Edge. The next section will go deeper into defining both deployment models, what types of Services are best provided by one model compared to the other, and other considerations to deliver maximum flexibility and return on investment (ROI).

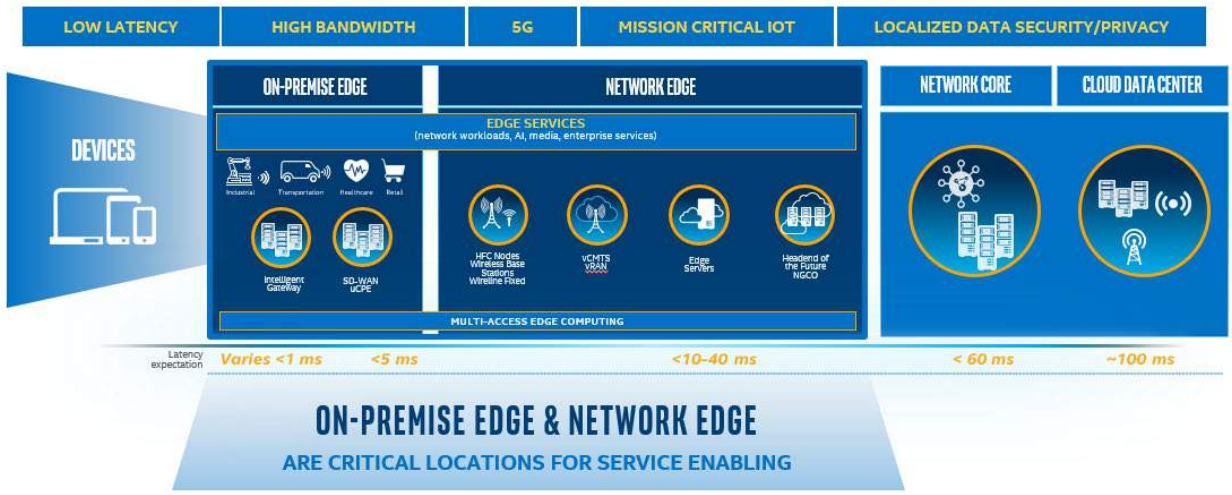

**Figure 3 - Logical Parts of the Communication Service Provider Network**

Figuring out where network infrastructure may be hosted is only part of the battle. This paper will continue on to discuss considerations for designing and buying Edge platforms, as in the actual hardware and software that will run the network, how functions are split across different equipment, and who owns the functions, users, and traffic.

In a single-Access or single-Service world, it is easy to line up bespoke solutions that include appliances and custom management interfaces. Perhaps the finances work out for two or three solutions set up in parallel. But to scale Edge infrastructure and maximize resources and operational efforts, a common platform (or at least common building blocks) that addresses all Access technologies and Service deployments will make the most sense. To this end, this paper introduces the idea of a Converged Edge Architecture, comprised of commercial off-the-shelf (COTS) equipment and standard software frameworks and interfaces that can be used to develop any number of specific solutions. This approach reduces complexity and time-to-market and allows for common orchestration across any Edge location. Converged Edge Architecture does not define a single platform, but rather is a common framework that will deliver the right Edge platform for the functional needs and environmental constraints of a given location in the network.

There are many reasons the cloud is moving to the Edge, including network optimization through virtualization and data locality, cost savings through white box platforms and automation, and new monetization opportunities through the introduction of new Services and business relationships. This paper primarily focuses on the last category – opportunities and considerations around implementing Services – though topics like virtualization and automation will be referenced as they underlie modern network architecture and implementation.

In fact, recent headlines[2] have shown that some communications service providers (CoSPs) and cloud service providers (CSPs) are already implementing Services at the Edge and selling them commercially. This paper should serve as further encouragement and also as a guide to show there are many considerations to creating an effective and scalable Edge that supports both multiple Access technologies and the latest Services, hosted by the CoSPs, CSPs, and companies with OTT offerings. It is the right time for multiple system operators (MSOs) to plan their new Edge(s), as it can be done in conjunction with the ongoing march towards a Distributed Access Architecture and a virtualization environment in its many forms.

By asking the right questions and knowing some of the key architectural options discussed in this paper, network operators – and MSOs in particular – will be in a better position to realize the value of their existing infrastructure and improve customer experience in an increasingly Edge-focused world.

## 2. Edge Deployment Models

Figure 4 breaks down the taxonomy of Edge platforms and locations beyond the top-level of an On-Premises or a Network Edge. The On-Premises Edge, or "On-Prem Edge," can be broken down into platforms/locations for smart sensors, intelligent gateways, and intelligent Edge servers, with generally increasing complexity, power, and capability as one moves left to right. Similarly, the Network Edge contains platforms and locations at the Access Edge, near Edge, and data center Edge.

Note that some networks may not manifest all these categories because the physical real estate to host certain equipment might not exist, locations and functions may have been consolidated onto fewer

[2] Fierce Wireless, "Verizon, AWS bring 5G MEC to Boston, Bay Area"; https://www.fiercewireless.com/operators/verizon-aws-bring-5g-mec-to-boston-bay-area

platforms, or some functions may not be implemented for one reason or another. Conversely, the network operator does not have to necessarily choose On-Prem Edge types or Network Edge types exclusively, as they each have their own pros and cons with respect to achieving different types of technical and business goals.

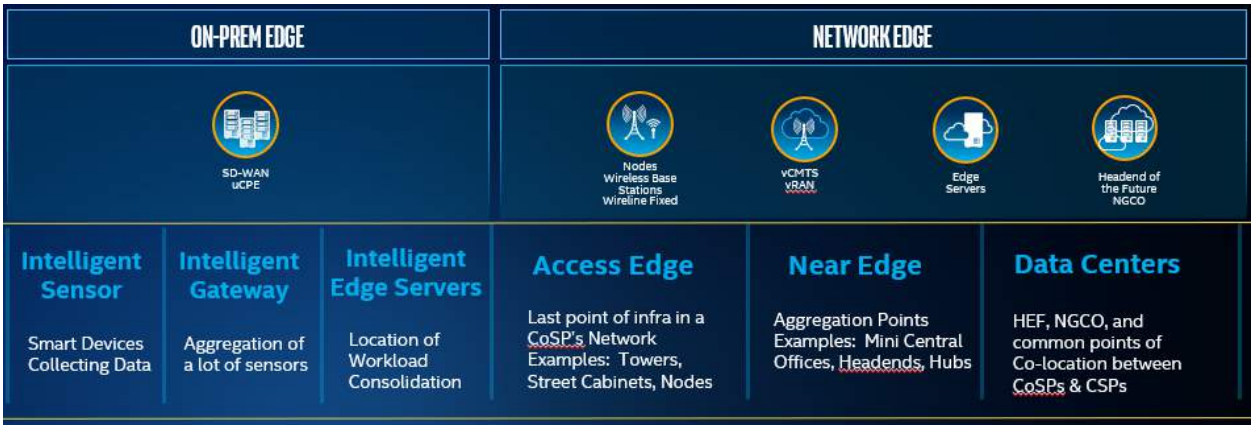

**Figure 4 - Edge Locations and Terminology**

The following sections cover these deployment models in turn.

## 2.1. On-Premise Edge

Figure 5 shows an On-Prem Edge-type deployment model. Here, there is a controller for Services that is located at some centralized place in the network and manages functions and Services that ultimately run on an Edge platform, like a universal customer-premises equipment (uCPE). Non-real-time functions such as controllers and Service management will usually reside in the most cost-effective place, which is typically deep in the network at a regional data center or even in a public cloud. That said, the controller may absolutely be deployed at another Network Edge location, like a Headend or Hub, to comply with legal requirements, or perhaps to satisfy operator or customer requirements for full data locality.

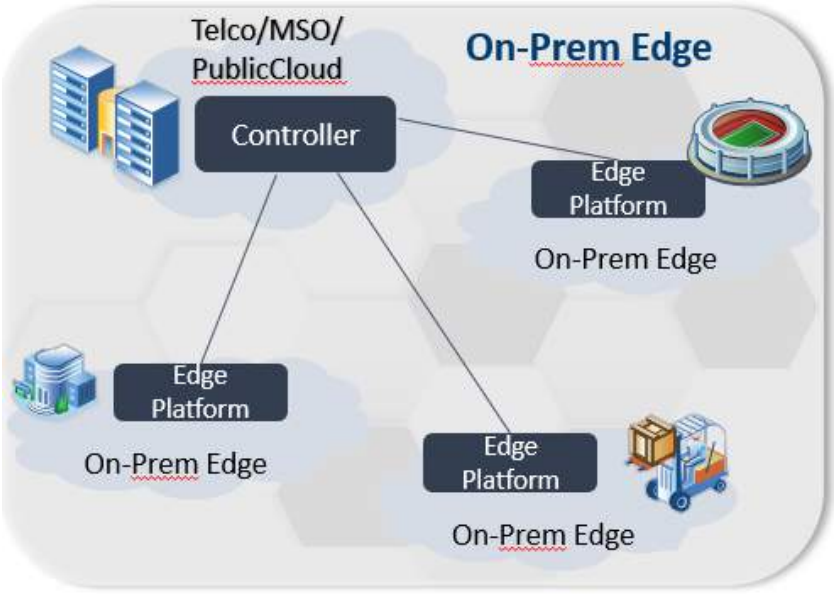

**Figure 5 - View of an On-Premise Edge Deployment**

Growing at a triple-digit rate in recent years,[3] SD-WAN solutions are generally offered through an On-Prem model, serving various applications for stadiums, farms, industrial IoT, and the like. True to its name, the main distinguishing factor for the On-Prem model is it includes a flexible platform at the customer premises that can run dynamic, real-time workloads locally. These workloads can be virtual network functions (VNFs) or Services.

While this paper focuses more about the requirements and options in the Network Edge, the platform choices for On-Prem are comprehended in the Converged Edge Architecture framework introduced in Section 5.

## 2.2. Network Edge

Figure 6 shows a Network Edge-type deployment model. In this case, there is also a controller – or more likely, a set of controllers – within the CoSP hierarchy to control network function virtualization infrastructure, multiple VNFs, and/or Services hosted directly by the operator or its partners. These controllers will orchestrate and manage such functions to run on Edge platforms located generally at Nodes, Hubs, Headends, point-of-presence server locations, or central offices. As in the On-Prem model, the controllers could exist anywhere "upstream" from Edge platforms in the network; it is likely that they will run from a regional data center, private cloud, or at a CSP.

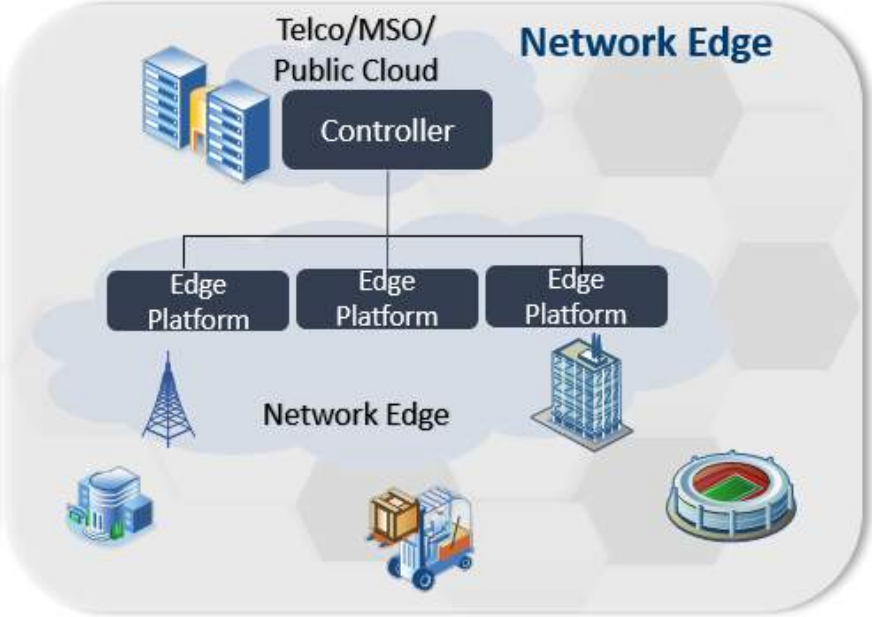

**Figure 6 - View of a Network Edge Deployment**

This infrastructure will support broadband Access, perhaps more than one type, as well as host Services that can be delivered by operators themselves, CSPs, or third parties. Given all these possibilities, the Edge platforms in Figure 5 are not necessarily a single server or appliance but can manifest as a collection of equipment at a location, providing a set of APIs upstream to controllers and other functions, and downstream to users. In short, Edge platforms may involve more than one piece of hardware or more than one physical location.

To make the most of a Network Edge deployment and to keep costs down as the number of Access types and Services increases, it will be key to find as much common ground as possible between the different hardware elements and to provide a homogeneous software layer for management. These are some of the main goals of the Converged Edge Architecture effort covered later.

Many of the platform-as-a-service products that have been announced[3] by various CoSPs, CSPs, Edge compute specialists, and real estate management companies (i.e., towers) are based on a Network Edge deployment model. Behind the scenes, there are a variety of ways these parties can organize themselves and their resources to make their own Edge products. They will ask themselves – what network functions and Services should we offer (and who should own these products), where should the equipment exist, who should own the customers, how should revenue be divided, and so forth. The answers to these questions have both business and technical repercussions, and for the latter, will affect how the Edge platforms/locations can be architected. The next section describes several Network Edge platform architectures emerging in the marketplace and the associated advantages and disadvantages from the network operator's perspective.

# 3. Network Edge Platform Architectures

The On-Prem network deployment model has its own implementation challenges, but at a high level, network functions and Services will run on a uCPE at the customer premise with a software controller running deeper in the network on COTS servers and managing those Services.

As discussed earlier, the Network Edge case has many options for splitting up functions across different network locations and deciding who will own those functions and equipment (i.e., some may be owned by a CoSP, CSP, or a third-party). The CoSP Edge architect will have to consider which Services the network operator would like to host, where equipment (and its capabilities) can be deployed, how to split network functions (i.e., controllers versus data plane), and who is going to own which parts of the solution in order to come up with a comprehensive Edge platform architecture.

There are several divergent approaches emerging in the market. Each approach allows for different types of business arrangements (i.e., how is revenue paid and split up) and will require different technical arrangements to be made between the partners involved.

1. CoSP + CSP Colocation
2. CoSP Led
3. CSP Led
4. CoSP Aggregator

The following sub-sections will review what it takes to implement each one of these business arrangements, along with the main driving forces for a CoSP to pursue one over the over.

## 3.1. CoSP + CSP Co-location

Currently, the most popular, or at least the most talked about, architecture for a Network Edge deployment is for a CSP to co-locate equipment to deliver their Services at Edge locations owned by the CSP. Figure 7 shows the logical view of how this would work. Presumably, the locations being “shared” by the CoSP and CSP would have latency advantages over what the CSP could promise on their own, with the CoSP having physical real estate very close to end users.

A CSP could then charge a premium when offering a content delivery network (CDN), a video analytic engine, or a generic platform-as-a-service with tighter and better guarantees around latency or data locality than the same Services being deployed at a regional data center or at their own site.

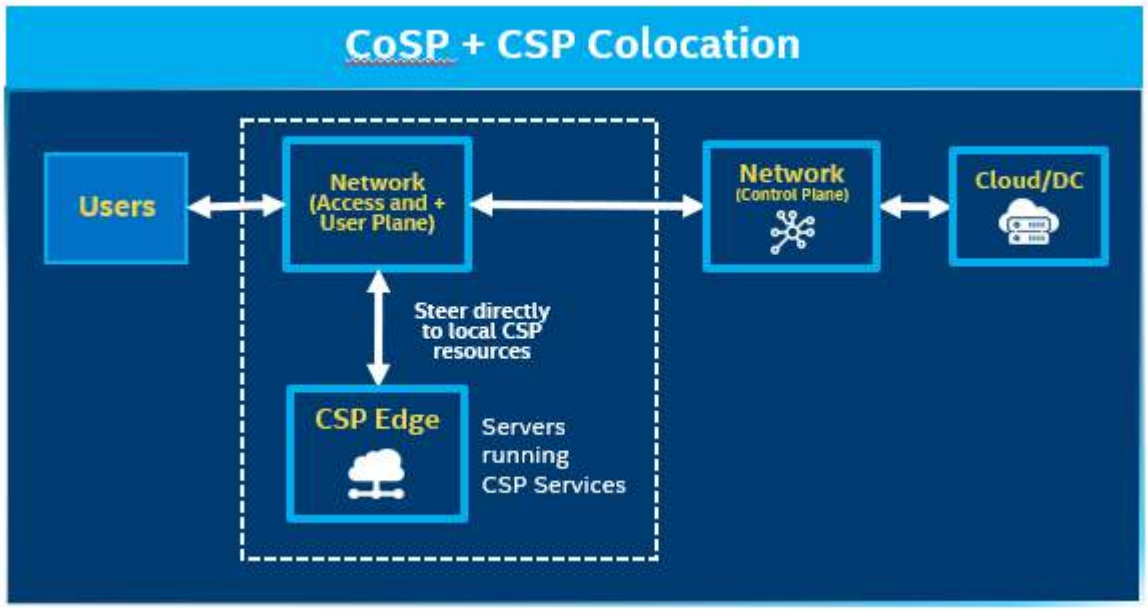

**Figure 7 - Communications Service Provider and Cloud Service Provider Co-location**

The most straightforward benefit for the CoSP is it gets some sort of "rent" or revenue share from the CSP. More interesting for business development is that these partners can engage in joint marketing to advertise the CSP is offering Services over the Access medium owned by the CoSP that would not available through other means – a "better together" story. There may also be practical reasons to enter into this type of agreement as the CoSP may not have the expertise or desire to develop and manage whatever Services are being provided by the CSP.

From the CoSP perspective, the downside is that it does not have direct control on how co-located Services are monetized, and, further, would not have access to the user information or traffic telemetry for secondary opportunities for data monetization. In addition, there may be some inadvertent CoSP/CSP lock-, or at least constrain the relationship to one CSP at a time if the CoSP location is not set up to easily host and secure multiple parties.

For this model, the "Edge platform" is made up of two subsets of equipment hosted at the same Headend, Hub, or Node: one owned by the CoSP providing the network connectivity and the other owned by the CSP providing the Services. The CoSP and the CSP would select their individual equipment based on their own experiences and needs.

Note that the CoSP could also become a customer of the CSP and have them host new Services on their behalf, so this arrangement does not preclude the CoSP trying their hand at offering Services. It's just that the Cloud/Service infrastructure is being provided by CSP and getting paid for it. In this case, though, perhaps the co-location aspect of this arrangement would even allow knowledge transfer of Cloud technologies to the CoSP?

### 3.2. CoSP Led + CoSP/CSP Services

The second most common architecture is for the CoSP to own the Edge platform altogether, hosting CSP Services on it on behalf of the CSP. In this case, the CoSP must develop an API, allowing CSPs to access resources at advantageous Edge locations. With this architecture, the CoSP owns the execution and delivery of the Services to the customer. Figure 8 shows the logical diagram of the platform.

From the CoSP perspective, there is more complexity and internal expertise needed, as they need to develop and maintain their own commercial platform-as-a-service. CoSPs do not have ownership of the Services themselves but would be able to monetize the management of the Edge locations and equipment.

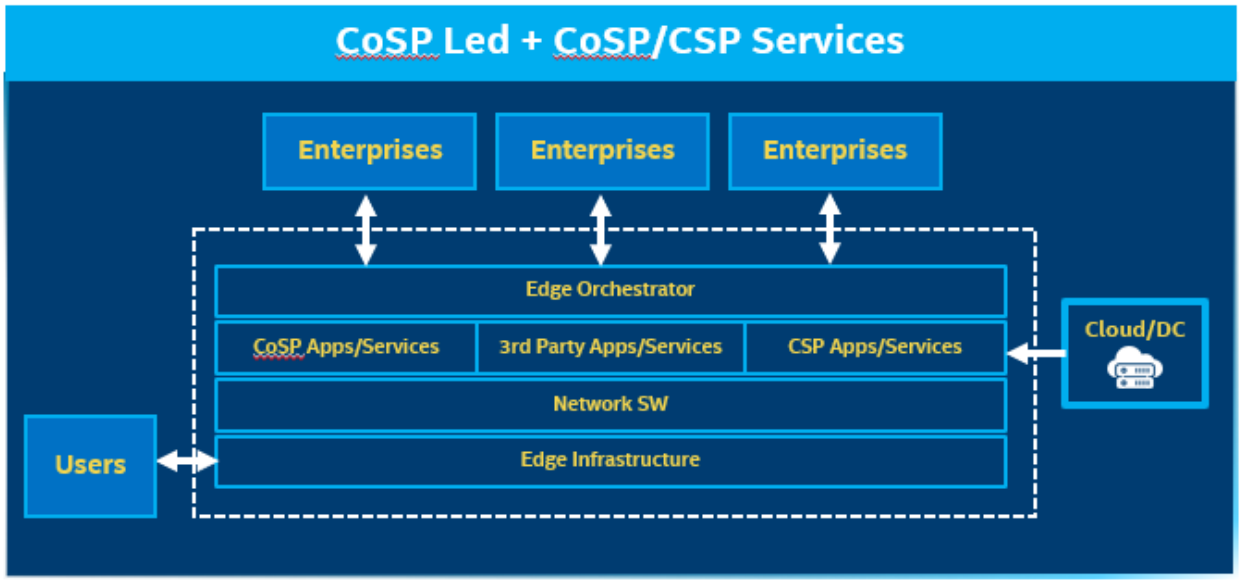

**Figure 8 - Communications Service Provider-Led Edge Deployment**

The additional benefits for the CoSP is it does not have to deal with the logistics of hosting another company's equipment in their buildings, and it has a unified interface to sell its Edge platform to any number of CSPs or third parties. Developing this model also implies the CoSP invested in internal resources that understand cloud technologies, which is generally a good thing as more elements of the network are virtualized.

For this model, the Edge platform is wholly specified and managed by the CoSP. There can still be multiple types of equipment involved in the final implementation, but a single owner is more likely to host all the different functions and Services on a common set of hardware in order to get better economies of scale for both the capital costs and for the ongoing costs towards the workforce. High performance VNFs running on COTS servers and new options for programmable switches are making it easier to reduce the number of specialized appliances in the network, as described in more detail in the next section.

### 3.3. CSP Led

The last two models to be presented may be less prevalent, but nonetheless fit certain niches. In the CSP-led model shown in Figure 9, the CSP owns the Edge locations and platforms. This assumes the CSP has real estate close enough to users to distinguish their Service offerings from those coming from the general cloud. In this case, the CSP uses a CoSP for last mile connectively, but otherwise owns all aspects of the Service delivery and management.

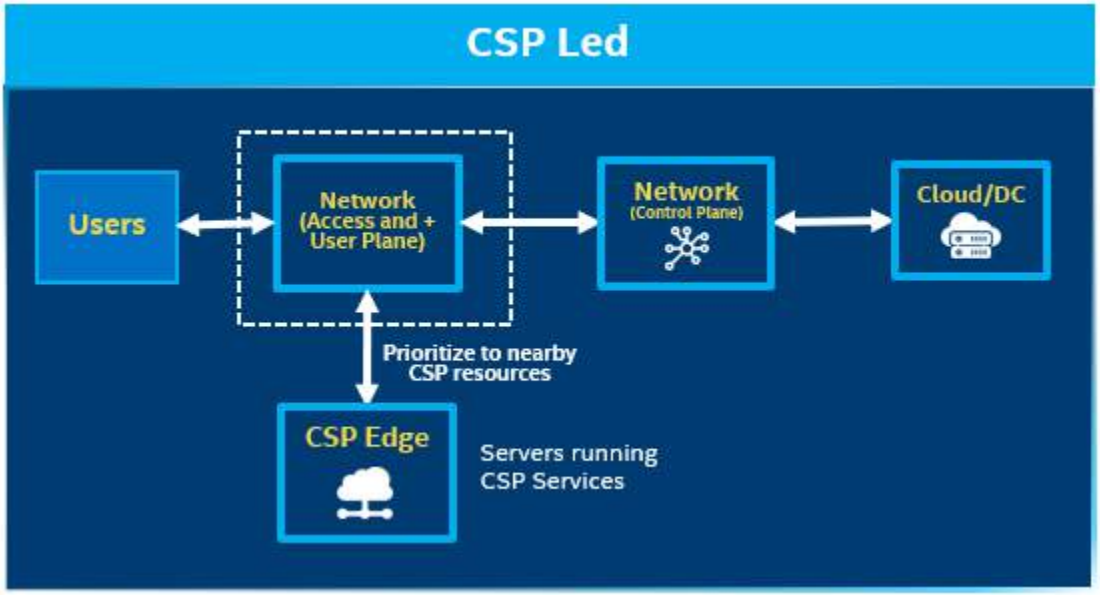

**Figure 9 - Communications Service Provider-Led Edge Deployment**

For the CoSP, this model may just be construed as a high-end business as usual arrangement, where a CSP or any other customer is paying for a broadband offering, albeit one with low or ultra-low latency guarantees. That said, CoSPs are finding that partnerships with CSPs focused on Edge-specific infrastructure (i.e. that have developed, or can develop, many points of presence near last-mile CoSP locations) may actually make for a convenient alternative to the CoSP + CSP Co-location option insofar that a similar "better together" story can be created but without the added logistics and coordination of sharing the same physical space and Headend or Hub management[4].

In this model, the CoSP and CSP platforms can be developed and deployed relatively independently if the connection between the two networks can minimize latency to an absolute minimum.

So, the CoSP's Network Edge platform is whatever the CoSP wants to use for its most advanced Access and broadband offerings and should follow the best practices of the industry (i.e. generally moving to DAA and virtualization-based solutions). Similarly, the Network Edge platform of the CSP will be optimized for the products and Services they are offering and generally will be a common software management infrastructure hosted on COTS servers and switches – typical for any CSP.

[4] Robuck, "Cox targets the Edge for the next evolution of network performance and security", https://www.fiercetelecom.com/telecom/cox-targets-Edge-for-next-evolution-network-performance-and-security

Like the CoSP/CSP Co-location model, the CoSP could also become a customer of the CSP, hosting new Services on their behalf.

### 3.4. CoSP/CSP Aggregator

This last model is one in which a third-party aggregates connectivity and Service options from a variety of CoSPs and/or CSPs and offers a common API to other service providers. In this case, the aggregator owns its own real estate, buys connectivity from one or more CoSPs, contracts with CSPs for Services, and perhaps even offers its own Edge Services. The result is an aggregated Edge offering.[5] Figure 10 shows how such an aggregator can develop its own platform or Service API that then plugs into the offerings of partner companies for execution and delivery.

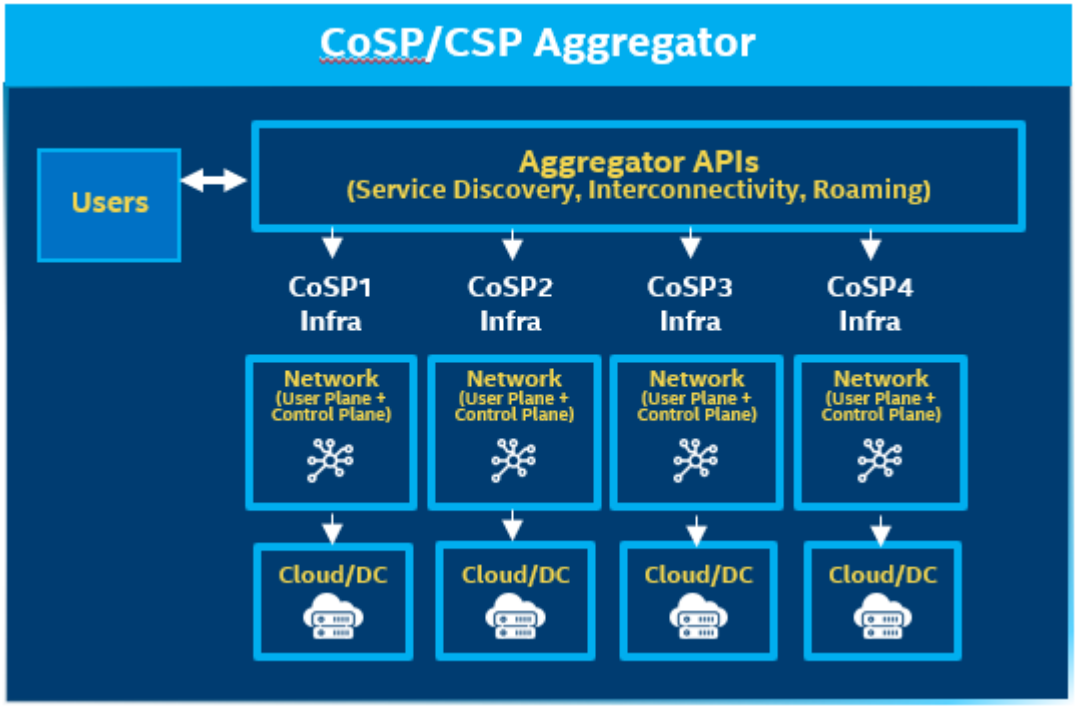

**Figure 10 - Communications Service Provider Aggregator-Led Edge Deployment**

CoSPs could monetize this arrangement in multiple ways. If they are just selling broadband connectivity, then this basically is the same as the CSP model. Alternatively, they could move up the food chain and offer their own platform-as-a-service, as described in the CoSP-led approach mentioned previously.

For the aggregator, the Access and broadband connectivity from CoSPs, and therefore the Services coming from CSPs, is ideally via an Ethernet/IP network. In this case, the Edge platform architects do not have to worry about the disparate requirements (and sometimes baggage) of physical Access technologies and therefore it is easier to choose COTS hardware – servers and switches – for the reasons mentioned in previous sections.

# 4. Mapping to Real Estate

This paper has discussed both Edge deployment models and Edge platform architectures as logical entities, but in real life, the equipment, software, and operations to manifest these things need to live in physical locations in the MSO network. This section maps the theoretical to the empirical world and discusses the competitive advantages cable networks may have compared to Access technologies.

CableLabs recently described typical MSO network locations and how their characteristics could apply to Edge deployments.[6] Figure 11 shows how the following locations are connected and how far they are from end users:

- Cloud
- Regional Data Centers
- Headend/Hub
- Aggregation Nodes
- Child Nodes
- Customer Premises
- Cell Sites

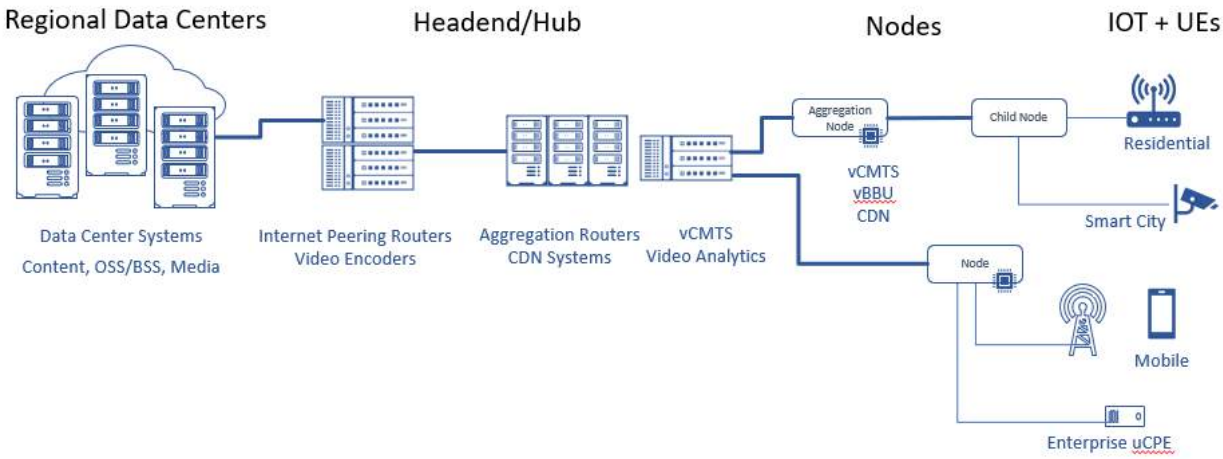

**Figure 11 - Type of locations in the MSO Network**

On-prem or Network Edge locations have associated benefits and constraints. On the benefits side, the closer one gets to the IoT devices and users, the lower the latency, the higher the data locality, and the lower bandwidth required upstream in the network. On the constraints side, the closer one gets to the IoT devices and users, the less power, the less environmental control, and the more costly it is to deploy and service equipment.

The benefits for On-Prem or Network Edge are straightforward to understand – "closer is better" for latency and data locality. The following discusses the constraints for the different types of host equipment that can be hosted.

[6] Levensalor, Stuart, "The Modular, Virtualized Edge for the Cable Access Network", https://community.cablelabs.com/wiki/plugins/servlet/cablelabs/alfresco/download?id=2c46cef2-af44-47be-bdd4-98a948cbc60d

The left side of Figure 12 shows a large, multi-story, regional data center (e.g., central office or CO) or large Headend, serving tens or hundreds of thousands of users, and for the most part, the set up can use typical data center approaches. Moving to the right along this continuum towards the users, the environmental constraints increase, the compute capacity goes down, and the deployment and management of equipment is more costly.

**Figure 12 - Network Edge Location Characteristics**

CoSPs need to decide if they want all the above locations to be "available" for their Edge. That is, will a given location and the equipment therein not only have the right level of physical connectivity in both directions, but will they also have an ability to run network functions or enterprise software? Further, how much of this hardware and software can be brought into a centralized management domain?

In the ideal cloud-extended-to-the-Edge vision, every location is part of a large pool of flexible, distributed, compute, storage, and networking resources and functions; Services can be set to run where they are needed to satisfy technical and business needs at the lowest possible cost. This is easiest when all the hardware is common, and the software has similar resource needs – as in data center and CSP locations. However, the further out one gets from the regional data centers, the more likely software workloads have higher data plane needs, lower latency requirements, and traditionally, have been served by specialized appliances. These types of devices will be part of an Edge plan for many operators, noting that fixed-function devices raise the TCO, and by definition, limit the flexibility of the solution.

As discussed earlier, the move to Distributed Access Architecture (DAA), virtualization, the power of general-purpose compute via COTS servers, and the growing market for programmable switches will reduce the need for such legacy solutions. Certainly, many Edge platforms residing in regional data centers, Headends, and Hubs will be based on COTS servers and switches.

Regarding the locations in the outside plant, it may not have been possible from a technical or economic standpoint to have flexible compute resources at the Nodes or smaller huts and cabinets in the past, but this is changing. Operators still need to do their homework to understand what is possible based on their

existing infrastructure and what types of businesses they want to pursue in the future, but the expanded availability of NEBS-compliant servers and industry innovations, like the SCTE Generic Access Platform (GAP), will bring down the cost of putting small-form-factor servers at these types of locations.

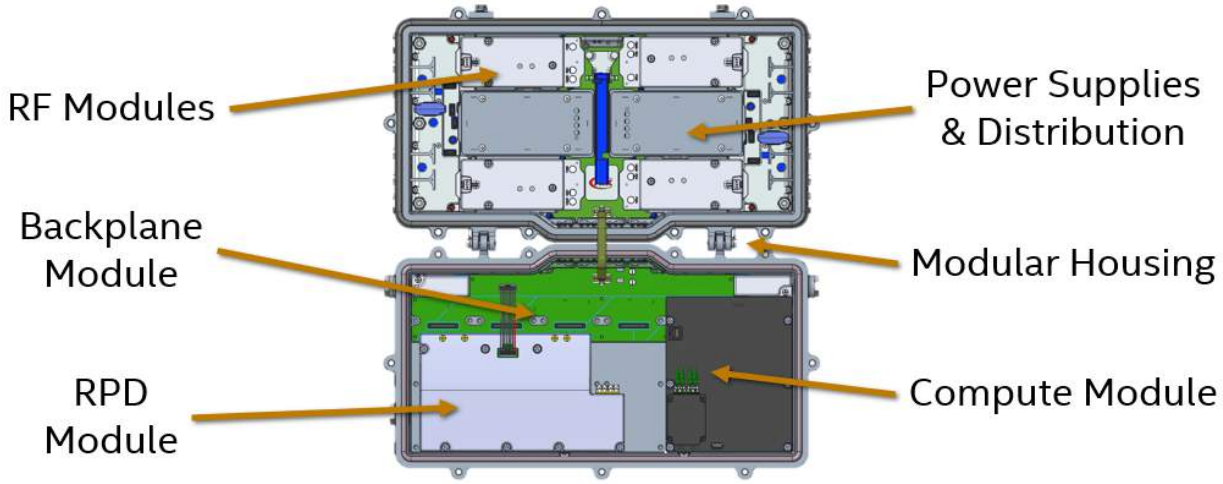

**Figure 13 - Generic Access Platform with Compute Module**

Figure 13 shows an example of a GAP-compliant Node in which the form factor, the electrical and logical connectivity, and module management are standardized, such that a vendor can provide the same types of compute, storage, and network capabilities found in a data center. The scale might be different – in the hybrid fiber-coaxial (HFC) case, the Node may serve only a couple of service groups – but the architecture and the way its resources can appear to the larger management infrastructure of the network operator are very much the same.

What developments like GAP mean is that it is now possible, from both technical and business perspectives, to distribute flexible resources to all parts of the network. For the cable MSO with a lot of unique real estate and right of way investments, this is a powerful competitive advantage.

## 5. A Converged Edge Architecture

Once an Edge architect has determined which locations can support Edge platforms, there is still the choice of which equipment and software to deploy to execute the desired On-Prem or Network Edge models and the subsequent business arrangements discussed earlier. If a CoSP seeks to cost-effectively develop and scale more than one Access technology and Service infrastructure for the Edge, there must be some common platform to run everything.

The idea of minimizing the number of platforms comes under the banner of "convergence." CableLabs identified a Converged Network Architecture Framework that defines the different types of convergence that apply to the 10G network:

- Access Convergence
- Transport Convergence
- Platform Convergence
- Core Convergence
- Operations Convergence

The "platform" or Edge platform that has been discussed in this paper is a concept that, in the ideal case, spans across all these domains. That is, how does one design Network Edge equipment and software infrastructure to enable a seamless user experience across all Access types, have a limited set of common hardware, take the best elements of the cloud world, consolidate management of Services, and ease operations with telemetry and automation? On top of that, the platform needs to be a carrier-class solution, computationally lightweight and efficient, high performance, and have facilities for optimized life cycle management.

In the past, it was not possible to set up a common hardware and software infrastructure to meet the needs of all areas of a network, support multiple Access technologies, and offer multiple Services in more than one domain. Figure 14 shows how technical solutions associated with various business owners were set up in silos, and thus they were developed, deployed, and managed independently. In this scenario, each solution is bespoke, and in a world where only one or two solutions was needed at a time, it was enough and still cost-effective to develop such independent systems and institutional expertise.

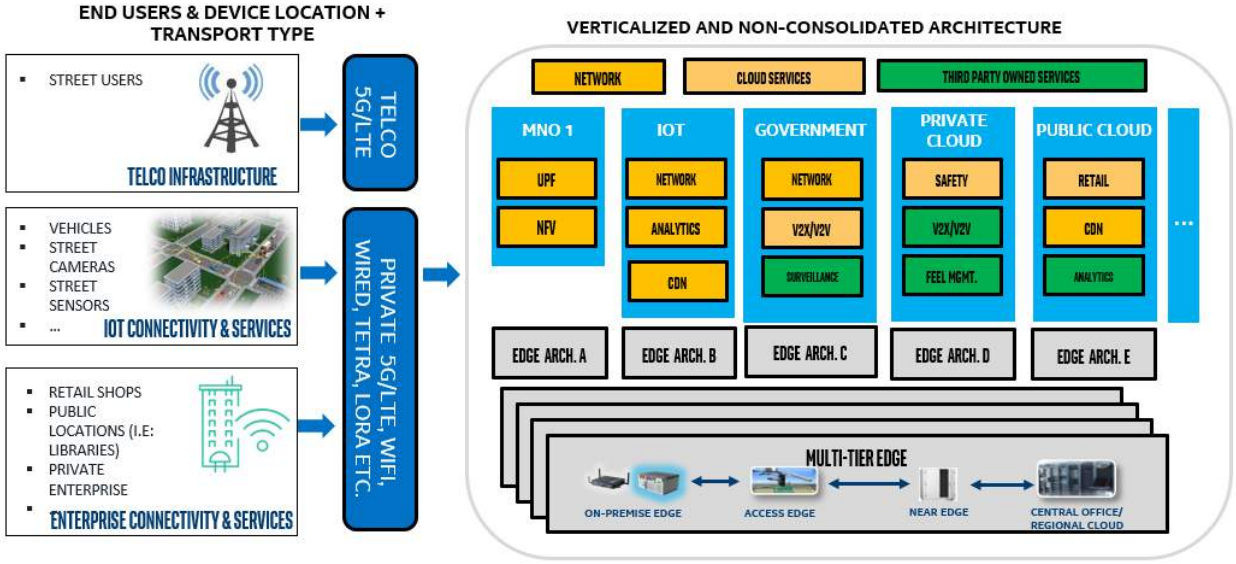

**Figure 14 - Access and Service Infrastructure in Silos**

However, the future 10G network needs to accommodate many wired and wireless Access technologies, and a host of new Services; and consequently, the old way of architecting networks is not going to work from economic or operational perspectives. What ameliorates this challenge is the rise of virtualization, containerization, and cloudification, new standards for power management, telemetry, and slicing the network for different Service tiers, and the resulting ability to converge a multitude of workloads on the same COTS equipment (i.e., standards-based servers and switches). But there still needs to be a

framework or a set of building blocks to put everything together in a way that scales across all the locations in the network, from the large data centers to the Nodes.

There are already several industry efforts towards software platforms at the Edge, including OpenNESS, CNTT Edge, Project Adrenaline, OpenVINO, and Open Visual Cloud. Some of these efforts have a relatively broad scope, for example, to move software infrastructure for the cloud to what is presumed to be a scaled-down platform for the Edge. Other efforts focus only on addressing the needs of specific domains (i.e., visual processing). However, to really touch on all aspects of convergence, there needs to be a view and a framework that can aid both hardware and software design using scalable building blocks so solutions can be deployed in any part of the Edge network.

With that in mind, researchers at Intel, led by Francesc Guim, Principal Engineer, and Timothy Verrall, Senior Principal Engineer, for the Intel Edge Architecture Group,[7] have been contributing to the development of a framework called the Converged Edge Architecture. The objective of this effort is to unify and converge Access, IoT, and other workloads on standards-based hardware and software. This Converged Edge Architecture is not a specific piece of hardware or software, but rather it is a set of building blocks to create a "Plug and Play" Edge platform that is relevant to the specific requirements of CoSPs for any location and for any set of functions.

The base of the Converged Edge Architecture framework assumes the hardware can be constructed using components that provide common features important for Edge deployments across the full range of performance needs and power constraints found in an operator's network. For an Edge platform, these base features need to include easy and performant virtualization, large software support across many vertical domains, extendibility though accelerators, strong security capabilities, and moving forward, functions for real-time machine learning algorithms. Silicon supporting x86 architecture satisfy all these criteria today, but in the future, other options may emerge.

Possible hardware configurations for a Converged Edge Architecture-based solution are:

- Headend: a rack of x86-based 1RU or 2RU servers with a programmable top of rack switch
- Node: a small form factor x86 server for a standardized GAP enclosure
- Outdoor uCPE: a small form factor x86 server in a custom ruggedized enclosure

In all these cases, a common software management infrastructure identifies the compute, storage, and networking capabilities and connectivity of each location and orchestrates Access functions and Services according to defined service level agreements. Figure 15 shows the high-level design for Converged Edge Architecture software infrastructure. It consists of a sub-infrastructure to host the data plane functions for Access technologies, sub-infrastructure to host Services, a transport/switching infrastructure to move data from hardware (e.g., NICs) to the dataplane or Services or between the dataplane and any of the Services, and an infrastructure for coordinated deployment, orchestration, and management of all elements therein.

[7] Francesc Guim, Principal Engineer, Timothy Verrall, Senior Principal Engineer Intel Edge Architecture Group, 2020.

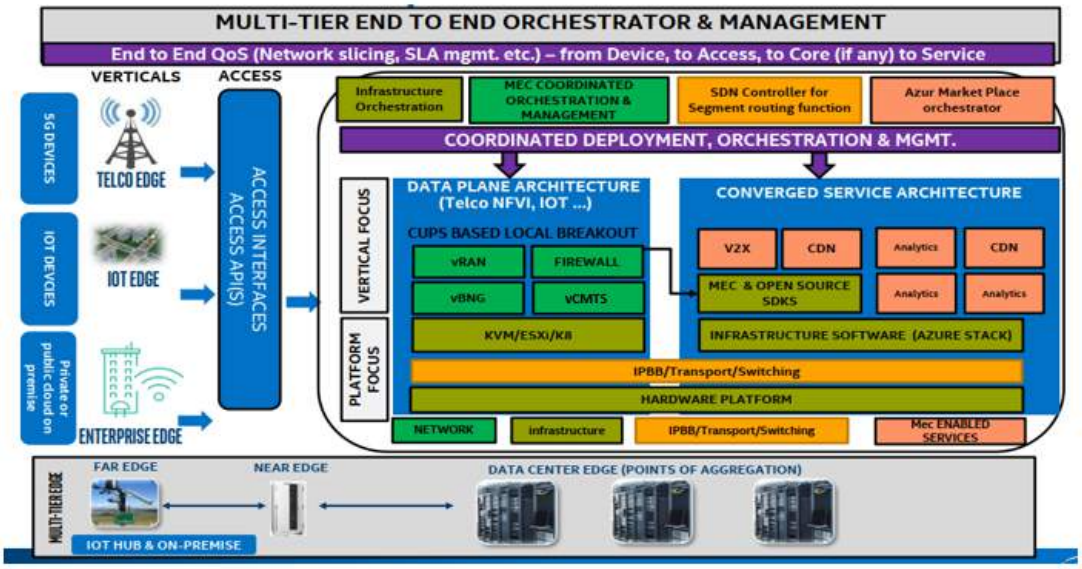

**Figure 15 - Converged Edge Architecture**

Figure 16 shows the next level down of granularity for types of software components the Converged Edge Architecture framework considers within the previously mentioned sub-infrastructures. Also shown is a sampling of candidate options from the market, including some of the familiar names in the industry. A solution would include at least one option from each row, though it would be common to include multiple elements. For example, a Smart Cities platform may have both Wi-Fi and HFC Access technologies, supported along with two or more frameworks to perform local video analytics and execute action plans.

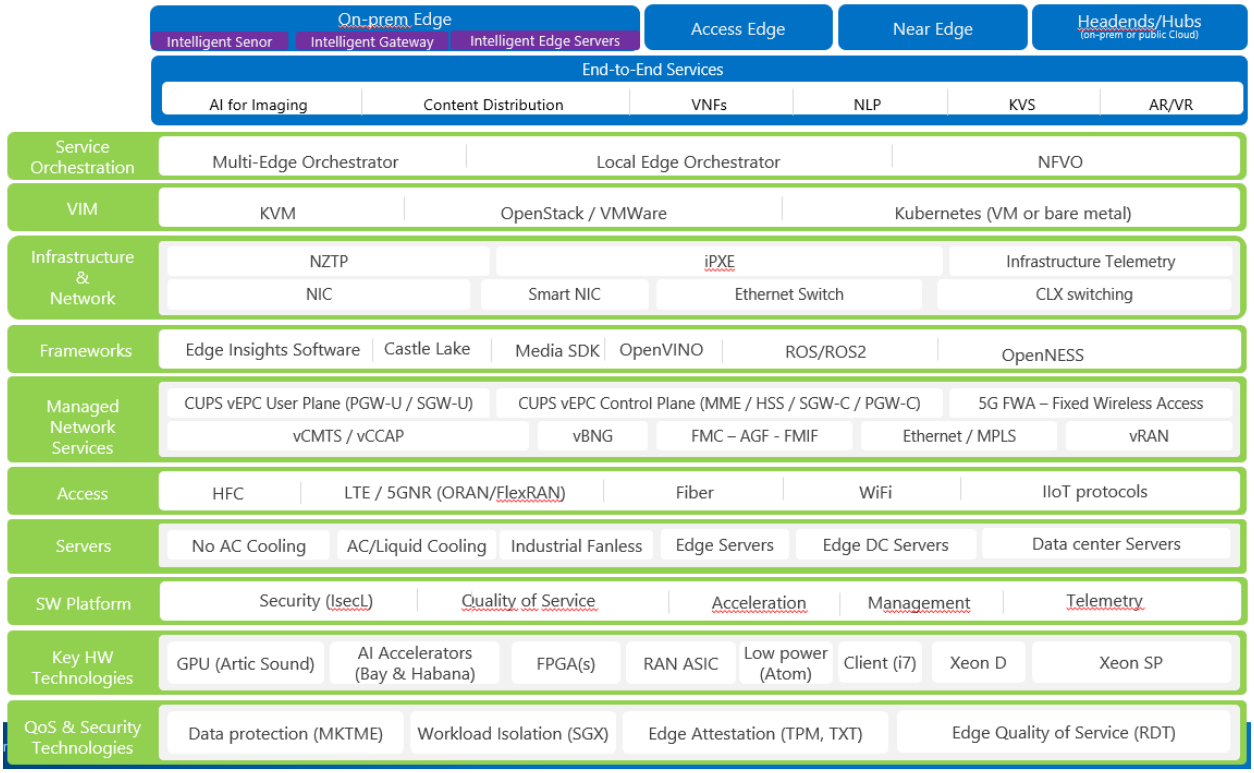

**Figure 16 - Mix and Match for an Edge Platform**

Work on Converged Edge Architecture continues as real-life solutions for the IoT and Network Edge solutions are developed, new hardware and software elements are deployed, and lessons are learned in real-world conditions.[8] The goal is to provide a framework or template that can be used by OEMs, ODMs, TEMs, and ISVs to develop scalable, flexible, Edge platform solutions for wherever they may be needed across the Edge.

# 6. Considerations for Designing an Edge

The MSO network of the 10G era is Multi-Access, allows next-gen Services in a wide range of performance tiers, and has the flexibility to deploy capabilities where they are needed in the network to deliver on business goals. Some of these new Services require lower latencies or tighter controls around data sovereignty, which leads us to look at the capabilities of facilities closest to the end users – infrastructure collectively known as "the Edge".

## 6.1. A Summary of the Options

This Edge, of course, is not necessarily constrained to being one location, one platform, or one type of business arrangement. At the top level, an operator can plan for an On Prem Edge or Network Edge – or both. The On Prem Edge implies that equipment at the customer site, like a uCPE, will run one or more Services locally while being managed and controlled centrally in the network. The Network Edge is

[8] "Converged Edge Reference Architecture (CERA) for On-Premise/Outdoor", https://builders.intel.com/docs/networkbuilders/converged-edge-reference-architecture-cera-for-on-premise-outdoor.pdf

based on hosting Access and Services from equipment owned and operated by the CoSP, partner CSPs, or other 3rd parties in various arrangements of a Network Edge platform architecture:

- CoSP + CSP Co-location
- CoSP Led + CoSP/CSP Services
- CSP Led
- CoSP/CSP Aggregator

The platform architecture for each of these is made of a limited set of hardware (i.e. if virtualization and programmable components are involved) and software infrastructure to manage different elements of the Edge solution as well as the interface(s) to outside network elements. The details are in an earlier section, but the difference between the architecture types really boils down to the questions of:

- Who owns the real estate?
- Who owns the physical equipment?
- Who owns the software infrastructure(s)?
- Who owns the data/customer?

Generally speaking, ownership gives more opportunity for monetization, but it also means the owning organization needs more institutional knowledge in the domain at hand to make sure the technology delivers the desired results.

The MSO network, with years of developing and deploying an HFC plant, is in a unique position to "own the real estate", that is, where to host Edge Platform equipment to provide the best latency and data locality profiles for new Services. In fact, intelligence and compute capabilities are coming to all places in the network – even to Nodes and other locations in the outside plant. Along these lines, the MSO/CoSP also has the expertise to design and deploy whatever Access elements required for the Edge solutions, although partnerships may be involved when new Access technologies, like a 5G wireless Service, are added to the network.

Where it gets more interesting – and where there is a lot of innovation/experimentation happening – is in answering the rest of the questions as they relate to providing Services. It seems the default behavior would be to bring in a CSP or 3rd party to host and manage their own Services over the last mile broadband connection being provided by the CoSP. This is simply because the Cloud technologies used in this case might be outside of the core competencies of the CoSP, so partnering with a CSP is the most straightforward way to monetize the aforementioned real estate advantages.

In the CoSP + CSP Co-location model, the CSP physically houses their equipment in the same location as the Edge location of the CoSP, be it a Headend, Hub, or Node. The CSP Led model is similar, except that the CSP equipment resides in a point of presence near-to, but outside, of the CoSP Edge location. In these cases, the CSP and/or 3rd parties making use of CSP resources "own the physical equipment… software infrastructure… data" and therefore the customers for the Services being sold. They could even host Services that the CoSP wants to provide like localized SD-WAN offerings for small and medium businesses.

CoSP's wanting to follow the CoSP Led + CoSP/CSP Services model and offer their own Edge infrastructure to host Services – i.e. to own the equipment and software infrastructure – will have to develop or hire their own expertise in Cloud technologies. This might seem like a difficult and far-out proposition to those used to single function appliances in their network, but as Access workloads get virtualized (ex. vCCAP, vBNG, vRAN, etc.) the technologies to manage and deploy both Access and

Services are starting to converge. The final alternative is to leave it to an aggregator with a local point of presence host the equipment and software infrastructure and sell broadband and, potentially, Services through them (along with perhaps similar offerings from competitors).

Again, a key competitive advantage for the MSO is that it has invested in and has rights of way for Edge-friendly locations to host Edge platforms for either itself or for a CSP. Even though these locations range in physical space available, the amount of power that can be delivered, and other environmental constraints, with virtualization, telemetric capabilities, facilities for remote security, and software infrastructure for managing such distributed computing elements, it is possible to consolidate the number of platforms into the minimum possible. Less disparate architectures and technological domains means a better total cost of ownership across the network.

To this end, the Converged Edge Architecture project is an effort to help OEMs, ODMs, TEMs, and ISVs mix and match common COTS hardware and open source software elements through a common framework to construct a scalable and flexible platform that matches the performance, lifecycle, and form factor requirements for any Edge location. Commercial examples of industrial On-Prem, 5G vRAN, and other solutions that made use of the Converged Edge Architecture framework are starting to emerge and providing the industry with proof points of the benefit leveraging standards, COTS hardware, and reference software architectures for faster time to market and lower total costs of ownership.

## 6.2. Asking the Right Questions

Admittedly, it will take more than a checklist to consider all the options above and architect an Edge or Edges in a given network. But a few key decisions that will drive the planning and architecture are:

- What type of Services do you want to offer and what requirements do they have on the network?
- What business models / partnerships do you want to support – who owns what?
- Where are you willing to deploy equipment / functions / infrastructure?
- What equipment and software infrastructure can be consolidated across the network?
- Who is going to own the various parts of the Edge solution in the organization?

The last question about organizational ownership may be the hardest as “the Edge” crosses what were typically separate domains – multiple Access technologies, Enterprise Services, Data Center and Cloud resources, etc. But it is because of this breadth that it is clear the Edge is important for MSOs to grow their businesses; whatever options are chosen. If fact, while difficult, thinking about a grand Edge strategy may be the chance for an operator to re-think existing silos, align on the latest technological innovations, and be a distinguishing factor against the competition.

All that said, practical realities to leverage existing systems, skillsets, and business relationships will make this an iterative process. That is, it is good to develop the ultimate end-state for your network and the organizations supporting it, but you may have to accomplish the transformation in stages. For example, would implementing a CSP Led model first allow you to get into the market and show the value of your CoSP Edge locations while you start developing Cloud expertise internally and drive the Ecosystem to be able to consolidate Access and Services later onto the same servers and switches?

Regardless of the path, the time is now to get started on this journey! MSOs can leverage their unique infrastructure and real-estate investments to provide improved network visibility, performance, control, flexibility, and agility with a distributed compute architecture all the way to the Edge – wherever it may be!

# Abbreviations

| | |

# 1. Introduction

My most used quote for 2020 so far can be summed up in one of my Bubbie's (Yiddish for grandmother) favorite sayings, which is as follows: *Der Mentsh tracht un Gott lacht.* Which is roughly translated as "Man plans and God laughs".

Despite our plan of intents, plan of records, short-range plans, and long-range plans, the World was caught by surprise with the current events impacting us. We have seen our carefully laid plans cast aside as we have all scrambled to meet user demands resulting from mass isolation to curb the spread of an unseen enemy. For many of us we have experienced 18-24 months of utilization growth in a 3-month window from March to June 2020. Thankfully we are fortunate to have deployed spare capacity and use a data transmission protocol that has handled the new demands very well.

With ubiquitous stay-at-home orders being issued throughout the world in the March and April timeframe, a new era and social experiment had begun. It has created conditions that had never before been witnessed on the planet in the modern era; it would stress many areas of society, including medical resources, human relations, business operations, educational institutions, entertainment and sports, politics and elections, food distribution, travel, supply chains, and much more.

There has been and will be much written about causes and effects of the current World condition. In this paper we will examine learnings we have gathered so far during this unparalleled journey focusing on the cable network and DOCSIS technology in particular.

# 2. Background

A key segment of society that was undoubtedly surprised and, in some cases, strained by these rapid changes was the high-speed data broadband infrastructure that makes up an important portion of the Internet. With more people staying at home and working at home than ever before, the COVID-19 pandemic introduced rapid and profound changes to the high-speed data infrastructure.

In the DOCSIS networks operated by MSOs, these changes were felt almost instantaneously in both the upstream and downstream data paths within HFC plants. It is accurate to state that no traffic engineers within the Cable Industry (or any Industry for that matter) had ever anticipated the potential need for stressful traffic engineering models simulating bandwidth consumptions that might result from the arrival of a worldwide epidemic that would drive a majority of the subscriber base into their homes for 24 hours a day and for many months at a time.

The surprising and unexpected arrival of these incredible conditions created an intense traffic load, and this load could have easily overloaded the DOCSIS network and rendered the infrastructure (and the Internet) useless at a time when "work-at-home" and the ability to connect to others on-line became a necessity for society.

However, the DOCSIS infrastructure and the Internet held up quite well to these unexpected stresses. Granted, there were some growing pains and problematic issues that required emergency actions for correction, but many of these issues were rapidly resolved with CMTS/CM configuration changes and/or channel augmentations. The Cable Industry was able to successfully respond to this sudden onslaught of traffic. But the issues that were encountered by this sudden bandwidth surge were likely exposing an Achilles Heel that will need to be addressed in the near future.

## 3. Traffic Engineering Model

It may be instructive to explore some typical traffic engineering models that may have been being used by MSOs in February 2020 prior to the arrival of the COVID-19 pandemic. Within these models, the authors will make use of a "QoE-based Traffic Engineering Formula" defined in [1], which is given by:

$$\text{Required Bandwidth Capacity} = N_{sub} * T_{avg} + K * T_{max} \quad (1)$$

where:

- $N_{sub}$ is the number of subscribers in the Service Group
- $T_{avg}$ is the Average Bandwidth Consumption of a single subscriber (during the busy hour)
- $T_{max}$ is the maximum Bandwidth offered in the Service Level Agreements
- K is the QoE coefficient, which is a value typically between 0.8 and 1.5 (larger values yield better Quality of Experience); K=1.2 is the value used in this paper.

Let us consider a "typical" HFC network in February of 2020 that might have been architected for a $N_{sub}$=250-subscriber Service Group with the following assumptions:

- Downstream $T_{max}$ = 1000 Mbps
- Downstream $T_{avg}$ = 2.5 Mbps
- Downstream $T_{avg}$ CAGR of 26%
- Upstream $T_{max}$ = 30 Mbps
- Upstream $T_{avg}$ = 0.175 Mbps
- Upstream $T_{avg}$ CAGR of 26%

Using these assumptions, the following Traffic Engineering rules are observed:

- "Typical" High-Speed Data Downstream Traffic Engineering in February of 2020
    - 32 x 6 MHz 256QAM SC-QAM Channels @ 36 Mbps per channel
        - 32*(36 Mbps) = 1152 Mbps Capacity
    - 1 x 192 MHz 1024QAM OFDM Channel @ usable spectral efficiency of 10 bps/Hz
        - (192 MHz)*(10 bps/Hz) = 1920 Mbps Capacity
    - Total Downstream Bandwidth Capacity

        - 1152 Mbps + 1920 Mbps = 3072 Mbps
    - Busy-hour Downstream Average Bandwidth Consumption per Subscriber = 2.5 Mbps
    - Number of Subscribers in a Typical Service Group = 250 Subscribers
    - Average Busy-hour Downstream Bandwidth Consumption ($T_{avg}$) in a Typical Service Group
        - 250*(2.5 Mbps) = 625 Mbps
    - "Headroom" Downstream Bandwidth (to support traffic bursts) in a Typical Service Group
        - 3072 Mbps – 625 Mbps = 2447 Mbps
    - Maximum Supportable Downstream SLA Throughput ($T_{max}$) calculated using the "QoE-based Traffic Engineering formula with a K of 1.2" = Headroom/K = 2447 Mbps/1.2 = 2040 Mbps
    - Maximum Downstream Life-span of existing HFC Plant (without changes) using the "QoE-based Traffic Engineering formula with a K of 1.2 and Downstream $T_{avg}$ CAGR of 26%" and $T_{max}$ of 1000 Mbps"
        - log[(3072 Mbps-1.2*1000 Mbps)/625 Mbps]/log[1.26] = 4.75 years
- "Typical" High-Speed Data Upstream Traffic Engineering in February of 2020
    - 3 x 6.4 MHz 64QAM ATDMA Channels @ 25 Mbps per channel
        - 3*(25 Mbps) = 75 Mbps Capacity
    - 1 x 3.2 MHz 64QAM ATDMA Channels @ 12.5 Mbps per channel
    - 1 x 9.6 MHz OFDMA Channels @ usable spectral efficiency of 8 bps/Hz
        - (9.6 MHz)*(8 bps/Hz) = 76.8 Mbps Capacity
    - Total Upstream Bandwidth Capacity
        - 75 Mbps + 12.5 Mbps + 76.8 Mbps = 164.3 Mbps
    - Busy-hour Upstream Average Bandwidth Consumption per Subscriber = 0.175 Mbps
    - Number of Subscribers in a Typical Service Group = 250 Subscribers
    - Average Busy-hour Upstream Bandwidth Consumption ($T_{avg}$) in a Typical Service Group
        - 250*(0.175 Mbps) = 43.75 Mbps
    - "Headroom" Upstream Bandwidth (to support traffic bursts) in a Typical Service Group

- 164.3 Mbps – 43.75 Mbps = 120.55 Mbps

- Maximum Supportable Upstream SLA Throughput ($T_{max}$) calculated using the "QoE-based Traffic Engineering formula with a K of 1.2"
  - Headroom/K = 120.55 Mbps/1.2 = 100 Mbps
- Maximum Upstream Life-span of existing HFC Plant (without changes) using the "QoE-based Traffic Engineering formula with a K of 1.2 and Upstream $T_{avg}$ CAGR of 26%" and $T_{max}$ of 30 Mbps"
  - log[(164.3 Mbps-1.2*30 Mbps)/43.75Mbps]/ log[1.26] = 4.6 years

Note: The illustrative numbers above do not represent any particular MSO. Different MSOs will have different Traffic Engineering numbers and different Bandwidth Capacity numbers than those shown above.

As can be seen in the example scenarios above, this "typical" MSO in February would have had enough "headroom" in their Downstream Bandwidth Capacity to permit them to operate for another 4.75 years prior to having to consider any type of plant modifications to accommodate the expected Downstream $T_{avg}$ Bandwidth growth rate (resulting from a predicted 26% CAGR that might have existed in February). In addition, this "typical" MSO in February would also have had enough headroom in their Upstream Bandwidth Capacity to permit them to operate for another 4.5 years prior to having to consider any plant modifications to accommodate the expected Upstream $T_{avg}$ Bandwidth growth rate (resulting from a predicted 26% CAGR that might have existed in February). These lifespans are shown by the Bandwidth Requirements curves in Figure 1 and Figure 2 which are based on the QoE-based Traffic Engineering formula of Eq. (1) above.

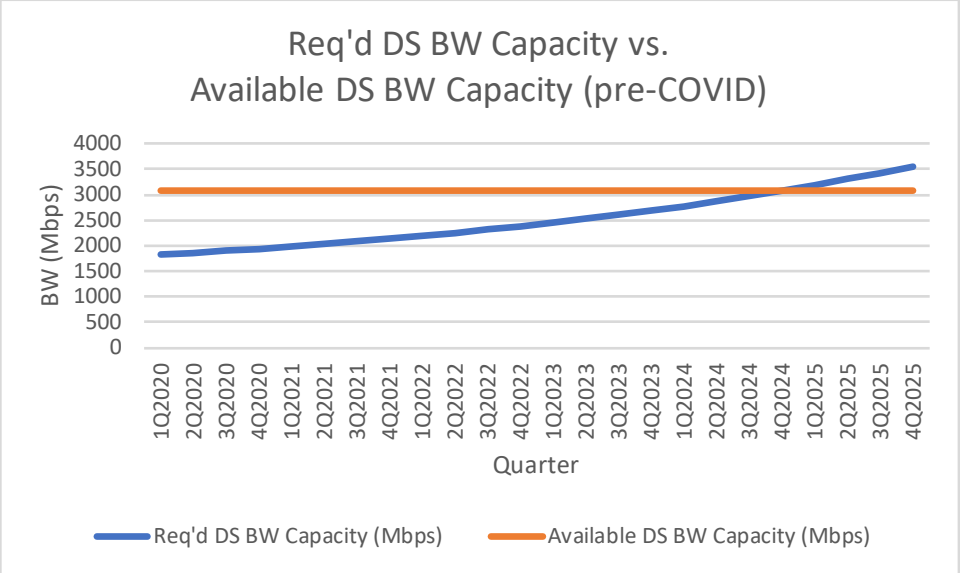

**Figure 1 - Required Downstream Bandwidth Capacity vs. Time for "Typical MSO" (pre-COVID-19)**

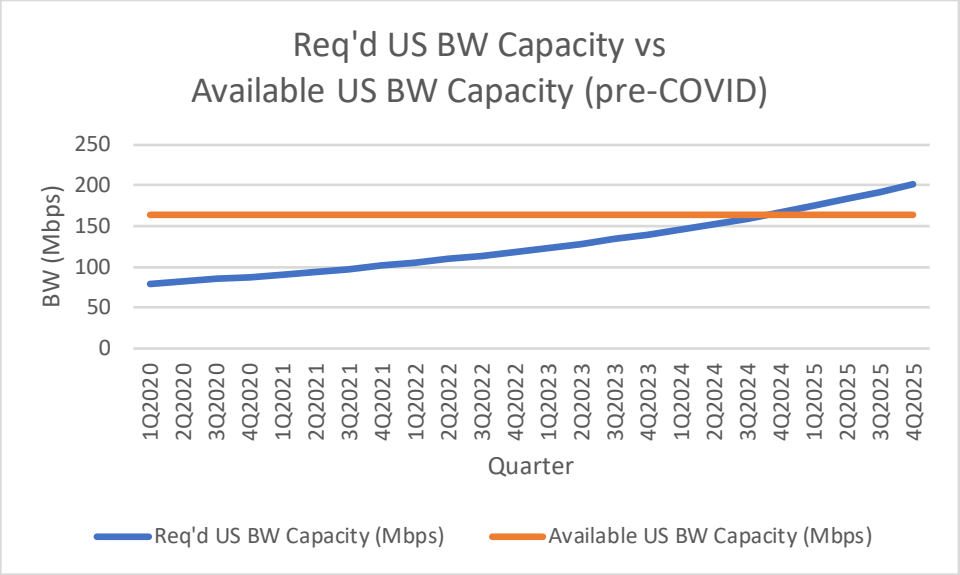

**Figure 2 - Required Upstream Bandwidth Capacity vs. Time for "Typical MSO" (pre-COVID-19)**

Even without COVID-19, this "typical" MSO would have likely "run out of gas" in their Upstream during the fourth quarter of 2024, and it would have forced the subscribers to live with sub-standard QoE for a while or it would have forced the MSO to utilize one of several options to modify their plant to extend the capacity and life-span of their DOCSIS Upstream services. Many of those possible options for expanding the Available Bandwidth Capacity will be outlined in sections below.

Now let us consider the profound bandwidth usage changes that occurred in the mid-to-late March timeframe in most MSOs and let us explore their impact on the curves and DOCSIS lifespans of Figure 1 and Figure 2.

The bandwidth activities of post-COVID-19 "stay-at-home" subscribers are very different from the activities of subscribers prior to the arrival of COVID-19; in both the upstream and downstream direction, and during the day and at night. In a matter of a few days while "stay-at-home" was becoming the norm, the bandwidth demands increased more rapidly than ever seen before.

Reported Downstream Bandwidth consumption ($T_{avg}$) during the evening busy-hour timeframe increased by 12-25% at different MSOs. Upstream Bandwidth consumption ($T_{avg}$) during the evening busy-hour timeframe increased by 20-50% at different MSOs. Most of this night-time bandwidth growth was driven by a combination of more video streaming, video-conference work meetings, social networking traffic, and gaming traffic (both playing and viewing). In the Upstream, it also included an increase in TCP ACKs associated with the Downstream packets.

Reported Downstream Bandwidth consumption ($T_{avg}$) during the mid-day timeframe increased by 26-86% at different MSOs and reported Upstream Bandwidth consumption ($T_{avg}$) during the mid-day timeframe increased by 30-150% at different MSOs. Most of this day-time bandwidth growth was driven by a combination of video-conference work meetings, videoconferencing for remote education, social networking traffic, and gaming traffic (both playing and viewing). In the Upstream, it also included an increase in TCP ACKs associated with the Downstream packets.

Examples changes with US operators from the NCTA web page are shown in Figure 3 and Figure 4.

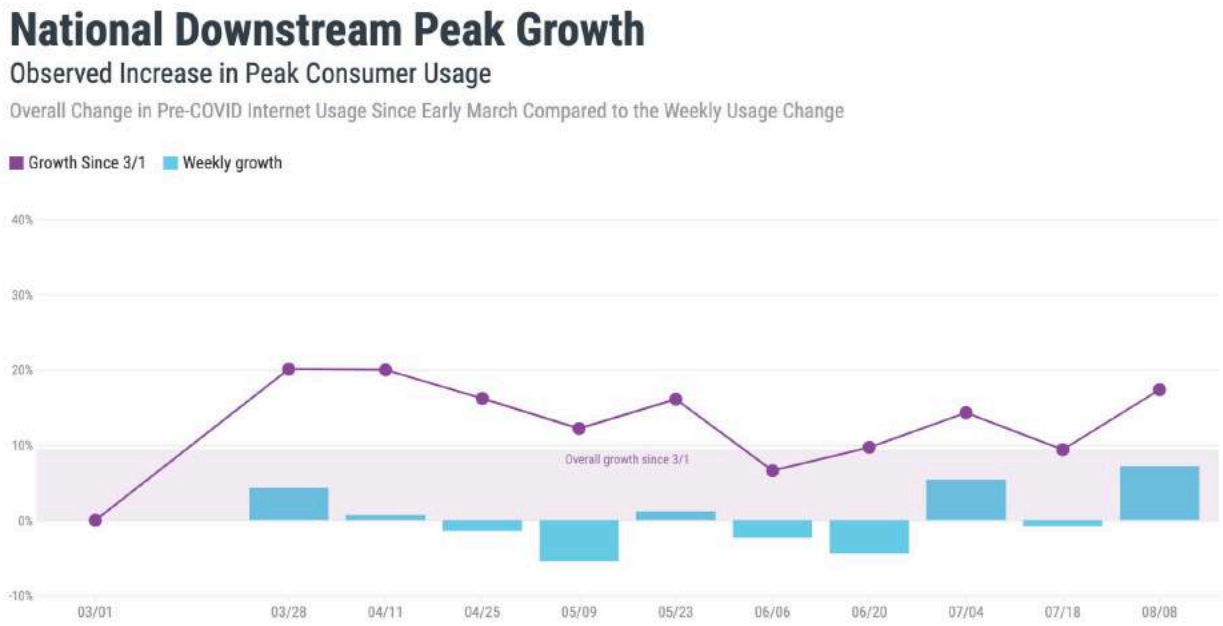

**Figure 3 – Example Downstream Bandwidth Changes as "Stay-At-Home" was Rolled Out**

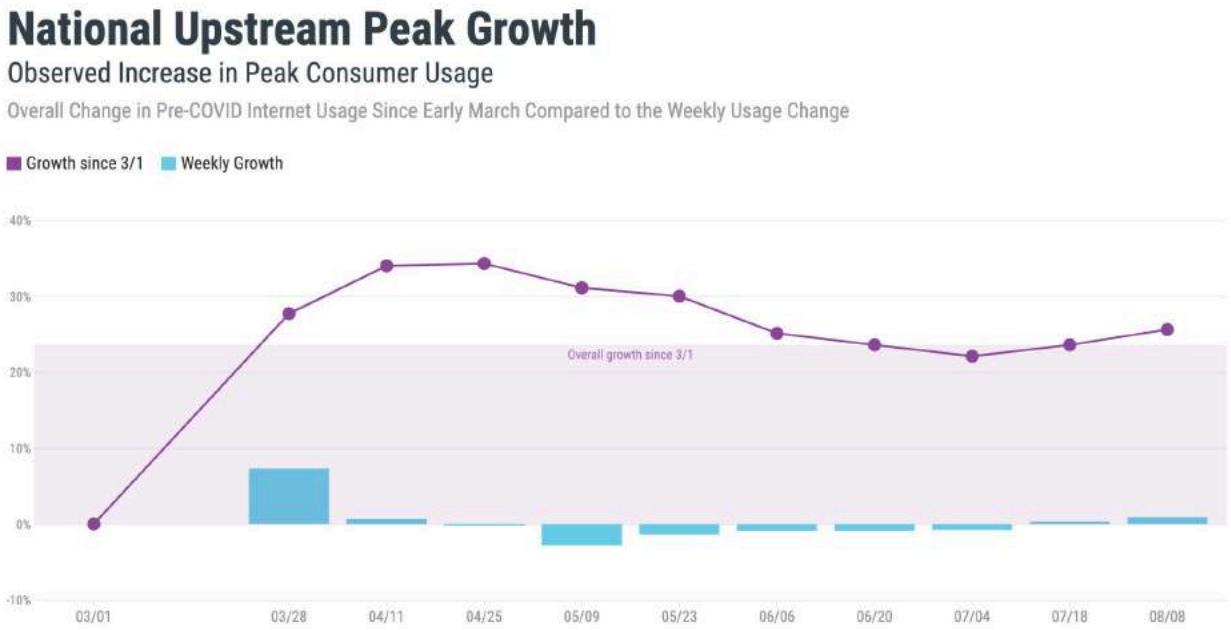

**Figure 4 – Example Upstream Bandwidth Changes as "Stay-At-Home" was Rolled Out**

In the figures above, the busy-hour bandwidth (at night) still exceeds the mid-day bandwidth, so the busy-hour bandwidth characteristics will still stress the DOCSIS system and define the ultimate Bandwidth Capacity Requirements (as they did in the past prior to COVID-19).

For our "typical" MSO scenario (post-COVID-19), let us assume that they experienced the following $T_{avg}$ BW growth spurts on their networks when "stay-at-home" rules were initiated:

- Downstream $T_{avg}$ Bandwidth step function increase in 2Q2020 = 25%
- Upstream $T_{avg}$ Bandwidth step function increase in 2Q2020 = 50%

It is assumed (and hoped) that there will come a time in different localities when "stay-at-home" orders will begin to be relaxed. At that point in time, it is expected that some workers will begin to return to work at the office. However, the success of the "work-at-home" model during 2020 may push many companies to consider allowing more of their employees to continue working at home even after the "stay-at-home" orders are relaxed. We will create models for our "typical" MSO which assume that 25% of the "stay-at-home" workers will return to the office in 3Q'2020 and another 25% of the "stay-at-home" workers will return to the office in 1Q'2021. Note: These percentages may be accomplished by rotating different employees into the office at different times to reduce the density of employees in the office and reduce the likelihood of COVID-19 transmissions).

After the two phases of employees returning to work, we are assuming that 50% of the "stay-at-home" workers will continue to work at home moving into the future. As a result, it will leave the Bandwidth requirements higher in the long-term; even after COVID-19 has returned the world back to the "new normal." These "new normal" Bandwidth requirements will thus be higher than they would have been had COVID-19 never existed.

The resultant modified Bandwidth Requirements curves (post-COVID-19) are shown in Figure 5 and Figure 6. Within these figures, we have assumed that the network conditions have not changed (other than the step functions resulting from COVID-19).

We are still assuming an $N_{sub}$=250-subscriber Service Group with the following assumptions:

- Downstream $T_{max}$ = 1000 Mbps
- Downstream $T_{avg}$ = 2.5 Mbps
- Downstream $T_{avg}$ CAGR of 26%
- Upstream $T_{max}$ = 30 Mbps
- Upstream $T_{avg}$ = 0.175 Mbps
- Upstream $T_{avg}$ CAGR of 26%

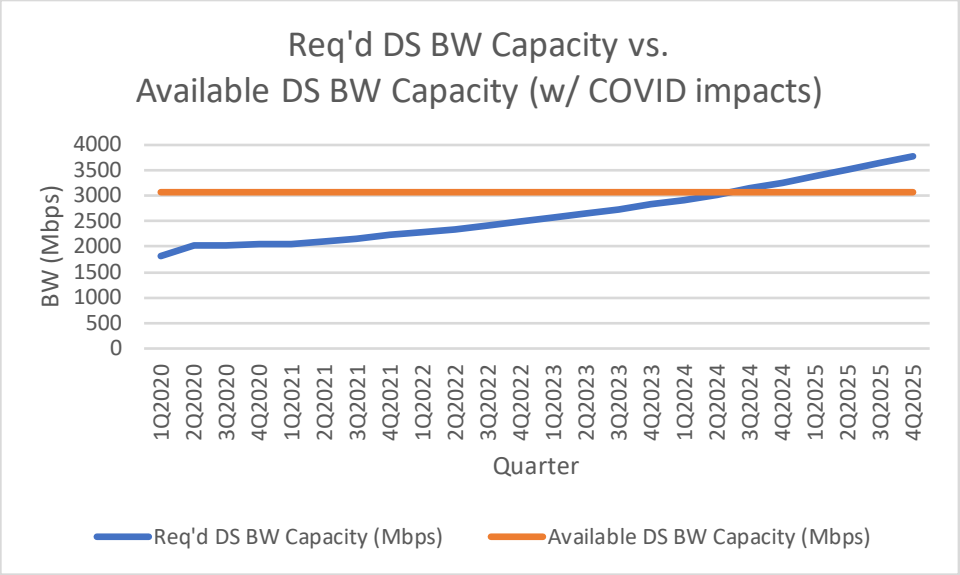

**Figure 5 – Required Downstream Bandwidth Capacity vs. Time for "Typical MSO" (post-COVID-19)**

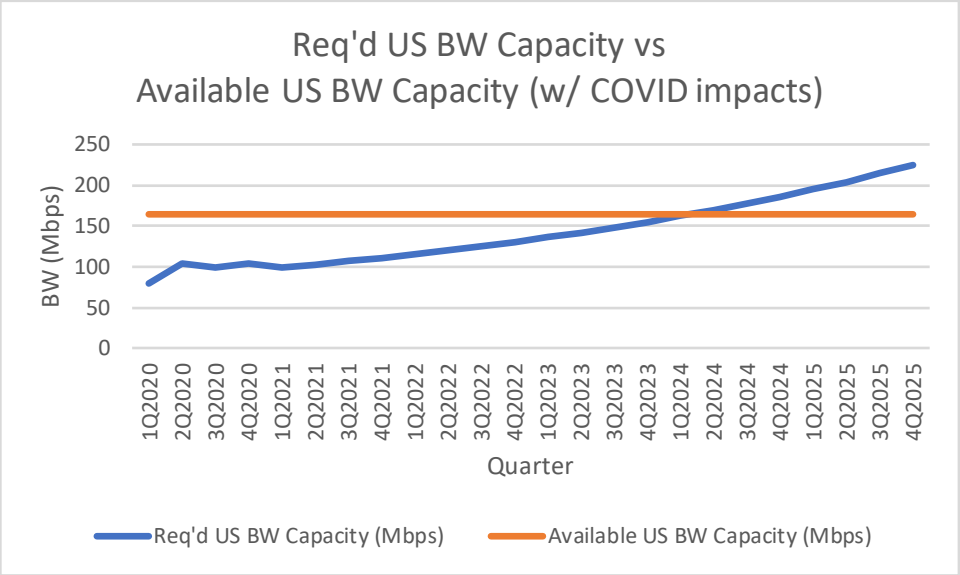

**Figure 6 – Required Upstream Bandwidth Capacity vs. Time for "Typical MSO" (post-COVID-19)**

Comparing both Figure 1 to Figure 5 and Figure 2 to Figure 6, it is clear that COVID-19 may play a large role in DOCSIS network evolution going forward. It may force MSOs to make network transitions sooner than they had originally planned - even if the Downstream $T_{avg}$ CAGRs and Upstream $T_{avg}$ CAGRs do not increase. The large bandwidth "step function" up resulting from "stay-at-home" actions and the smaller bandwidth "step functions" down resulting from limited "return-to-work" actions leads to these transitions.

It can be seen in Figure 5 that the impact of the COVID-19 step functions would force Downstream network modifications for this "typical" MSO to occur in 2Q2024 instead of 4Q2024. And it can be seen in Figure 6 that the impact of the COVID-19 step functions would force Upstream networks modification for this "typical" MSO to occur in 2Q2024 instead of 4Q2024

This "typical" MSO may not represent the situations at all MSOs. Many MSOs have smaller Service Groups with less than 250 subscribers. And many MSOs also have allotted more Bandwidth Capacity to DOCSIS networks. For example, European MSOs typically have 65 MHz of spectrum dedicated to the Upstream, which gives them much more Upstream Bandwidth Capacity and a longer lifespan on their Upstream. And some MSOs throughout the world have already begun to transition to 85 MHz Mid-Splits. As a result of this additional "headroom" (in the form of extra Bandwidth Capacity), many of these MSOs were able to easily absorb the bandwidth surge that occurred during the "stay-at-home" orders, and they therefore saw little or no problems on their Upstream DOCSIS systems when COVID-19 hit.

## 4. Early Learnings

DOCSIS technology has handled the dramatic increase in usage very well. Both work-at-home and schooling-at-home created a large step-function in demand where operators have seen 18 months of growth in the first 3 months of isolation. In fact, with the effort to flatten the curve everything became focused in the home including work, school, entertainment, gaming, and new areas including exercise, tele-health, remote-library (book) access, video calls, etc. Just about everything migrated to the home broadband connection.

Why did DOCSIS broadband hold up so well? Starting from the ground up, the coaxial cable used for DOCSIS broadband is a superior medium from which more capacity keeps being mined. Coaxial cable supports much higher speeds than the twisted pairs used for telephone DSL service and even early fiber optic point-to-multipoint protocols. Starting with the DOCSIS 3.1 specifications in 2016, the coaxial cable supported higher speeds than a fiber optic network running GPON technology (gigabit passive optical network). The recent DOCSIS 4.0 specifications position cable-based broadband to rival 10 gigabit PON technologies using the existing coaxial cables in place today. This bandwidth can be realized in that at one point the coaxial cable carried hundreds of cable TV channels, which over the past decade have been migrated to broadband and entertainment migrating to IPTV.

Beyond the cable, DOCSIS technology has been optimized for orderly traffic flow. It has evolved to become a point-to-multipoint network that supports large amounts of capacity; and the network efficiently schedules the use of that capacity among users to meet service demand and provide quality of experience. The work first started in 1996 with collaboration among suppliers and operators to unify cable broadband technologies. Back then there were over a dozen proprietary systems which created a fragmented market and more importantly prohibited the retail availability of cable modems. The original goal was to unify around a single specification that brought together best-of-breed technologies. Without going into details, though very interesting, the effort was successful.

A huge benefit to unifying around a single set of specifications was getting the supplier community to focus their efforts on making DOCSIS technology the best-in-class service it has become today. The technical details include the physical layer (PHY), the media access control (MAC) layer, the security layer (SEC), operating system support (OSSI), and more. Over the next 20 years the innovations continued including advancements in silicon for better digital signal processing allowing even higher speeds and larger capacity to be realized.

The result is coupling an outstanding medium, i.e. coaxial cable, and very focused technology development to create the DOCSIS cable broadband as we know it today, with gigabit services possible anywhere there is a cable system. The DOCSIS 4.0 specifications support multigigabit symmetric service which will be the service offerings of this decade as that technology becomes available.

Both capacity and usage are instrumented in the DOCSIS network. There is a deep knowledge of how the network is performing both from a capacity and performance perspective on a day-to-day basis. The goal is to stay ahead of growth and the DOCSIS network has multiple levers to pull to increase capacity. Operators are always increasing capacity by one of two methods: adding more spectrum or segmenting the network so available spectrum is applied to fewer users.

The focus of DOCSIS 4.0 technology is increasing upstream capacity to as much as 6 Gbps. The operator has flexible options for upstream capacity, and along the way the downstream can be increased to as much as 10 Gbps.

Speaking to the upstream in North America, the vast majority of the coaxial cable is operated with a low-split (42 MHz) and typically has less capacity than the downstream. Low-split is a hold-over from the days of analog television channels and cable-ready TV sets (both of which are rapidly going the way of the do-do bird, if not already there). Low-split allowed the old Channel 2 to be carried on the coaxial cable starting at 54 MHz. The old analog Channel 2 has generally been replaced by digital TV carriers and IPTV, so the reasons for low-split are becoming few and far between.

DOCSIS equipment is very resilient, and for low-split operation it would encourage operators to experiment with these recommendations to get more upstream capacity. Next we discuss some strategies.

Removing large guard-band between carriers as it is not needed. The DOCSIS specifications are written such that RF channels can be directly adjacent to each other. In discussions with operators during the time of COVID-19, we have seen situations where the upstream DOCSIS carriers have large guard-bands between them as shown in Figure 7 below.

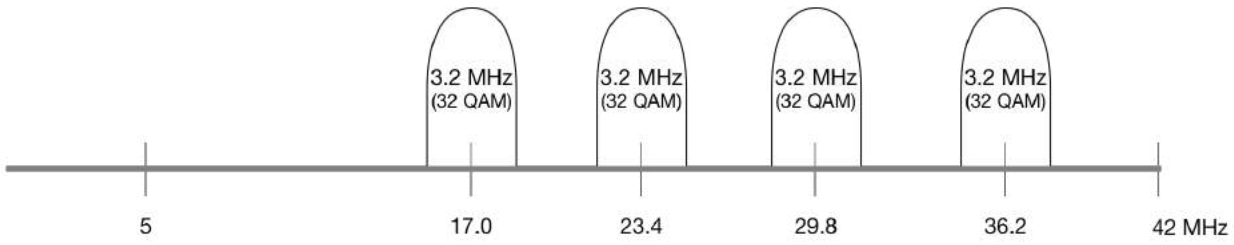

**Figure 7 – Large Guard Bands Between Upstream Channels**

These spaces between any DOCSIS carriers (upstream or downstream) have been found to not be needed; the carriers may be directly adjacent to each other on each side with minimal guard-band. There is a potential to use as little as 100 KHz spacing between ATDMA carriers. However, as you place a carrier near the roll-off starting at 42 MHz it is best to leave around a 500 KHz guard-band from 41.5 MHz to 42 MHz to avoid non-linearities related to amplifier cascades.

Increasing modulation order to 64 QAM for the legacy upstream DOCSIS carriers. The DOCSIS QAM technology is quite resilient, and the recommendation is to increase carriers to 64 QAM modulation, widen the carriers to use available spectrum, and remove the guard-band between the carriers. As shown in Figure 8 below, the moves should be done stepwise to confirm proper operation.

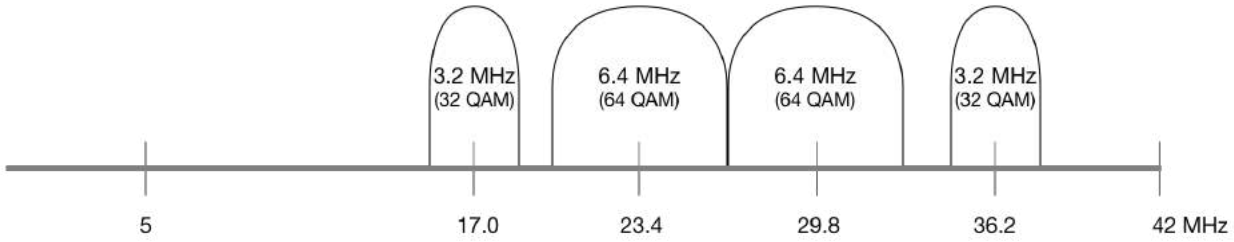

**Figure 8 – Increasing Channel Width To Increase Upstream Capacity**

Figure 9 shows using all available spectrum, which could include widening all upstream carriers and abutting those carriers.

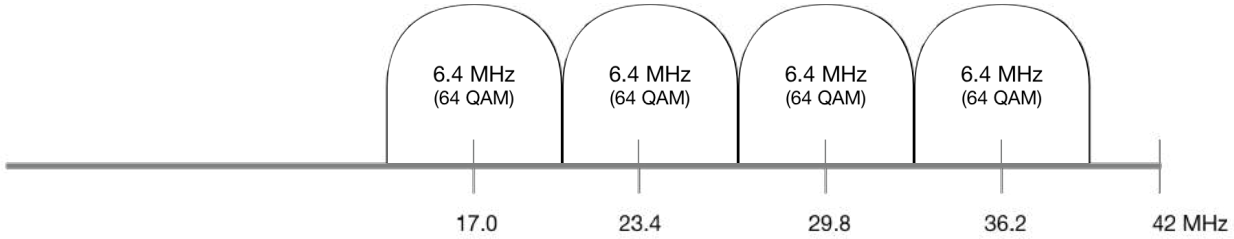

**Figure 9 – Maximizing Upstream Capacity With Wide Upstream Channels and Small Guard Bands**

As an additional step, try one or more additional carriers, up high or down low as shown in Figure 10. Operators have been successful at adding new carriers, which is a testament to maintaining the plant more diligently over the last decade. The DOCSIS technology has many options for optimizing channel layout and is not the same as even a decade ago. The digital transceivers have increased in sensitivity and capabilities to enable optionality not thought of even 5 years ago.

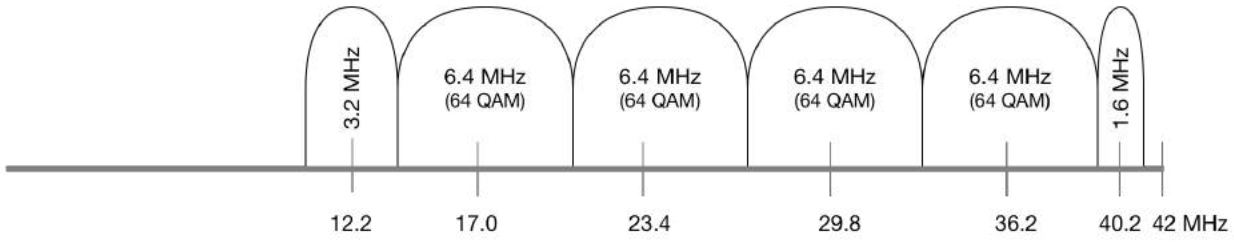

**Figure 10 – Adding Additional Upstream Channels**

Homes passed decreased which lowers the effect of noise funneling at low frequencies. Cascades have shortened which lessens the impact of group delay close to the diplex filter cut-off frequency. Operators have been successfully running narrow carriers (typically with lower order modulation) both down to 10 MHz and closer to the diplex filter.

Next steps include:

- Allocating more spectrum to DOCSIS broadband, specifically in the upstream which has implications on the downstream
- Migrating to DOCSIS 3.1 technology that includes OFDMA in the upstream and new modulation orders up to 1024 QAM (Theoretically may be up to 4096 QAM)

The DOCSIS 3.1 specifications define three upstream spectrum options that include a top end of the spectrum at 1,218 MHz and are in use around the world, as shown in Figure 11

- Euro-split (65 MHz)
- Mid-split (85 MHz)
- High-split (204 MHz)

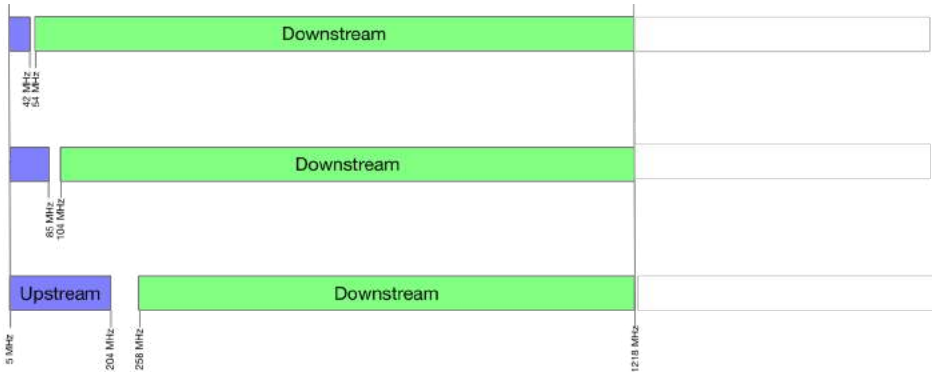

**Figure 11 – DOCSIS 3.1 Upstream Spectrum Options**

The DOCSIS 4.0 specifications include additional upstream spectrum options:

- 204 MHz
- 300 MHz
- 396 MHz
- 492 MHz
- 684 MHz

And the DOCSIS 4.0 specification includes operating the coax up to 1794 MHz, as shown in Figure 12.

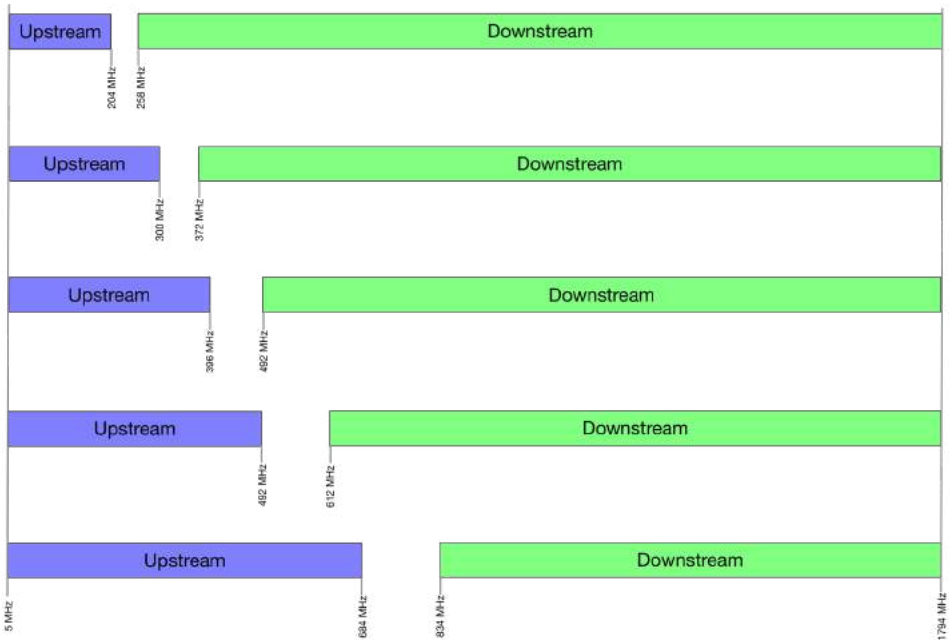

**Figure 12 – DOCSIS 4.0 Upstream Spectrum Options**

Table 1 shows a comparison of the upstream capacities for these different upstream spectrum options shown in Figure 11 and Figure 12.

**Table 1 – Upstream Capacity Comparison**

| Upstream Frequency (MHz) | Increase in Spectrum | Aggregate Upstream Capacity |
|---|---|---|
| 42 | Not applicable | 100 Mbps |
| 85 | 102% | 400 Mbps |
| 204 | 385% | 1.4 Gbps |
| 300 | 614% | 2.3 Gbps |
| 396 | 842% | 3.1 Gbps |
| 492 | 1,071% | 4.0 Gbps |
| 684 | 1,528% | 5.7 Gbps |

The capacities above include 4 upstream SC-QAM channels and filling the rest of available spectrum with OFDMA channels (primarily 1024 QAM though your numbers may vary).

There are many options, but operators first have to wrap their heads around allocating more spectrum to the upstream. Which also may mean moving the top end of the downstream to allow for maintaining legacy video and data as increasing the return without changing the forward means less available forward spectrum.

## 5. More Upstream Means a Few Technology Changes

OFDMA technology, which includes high order modulations up to 1024 QAM technology, which is double the bit density of current upstream 64 QAM technology (10 bits per second per Hz as compared to 6 bits per second per Hz).

The nature of most internet network traffic has changed a lot over the past few decades. Many of the network protocols (at Layer 4 and higher) have become much more intelligent and more adaptive to network congestion. These algorithm use information on network packet loss and network packet delay to determine optimal throughputs that vary as a function of time. These algorithms (for the most part) tend to be very accommodating, backing off their traffic rates at the source whenever congestion is suspected anywhere within their traffic's path through the network. This is true of all of the Layer 4 TCP variants (ex: BIC, CUBIC) that have been developed and deployed in recent history. It is also true of the higher-layer protocols that throttle traffic for UDP-based applications (ex: QUIC). IP Video transport has evolved to now utilize many Adaptive Bit-Rate techniques at higher protocol layer to change the video resolution and the required video bandwidth capacity in response to network congestion. These types of adaptive bandwidth management techniques can be found in both MSO-managed IP video delivery services and OTT IP video delivery services. They can also be found in the video-conferencing solutions (ex: WebEx, Zoom, and Teams) that have become extremely popular for use by work-at-home employees. It was (in part) the ability of these protocols to throttle down their bandwidth usage during times of congestion that helped permit MSOs to survive the sudden bandwidth surge that occurred when the COVID-19 lock-downs first began. That throttling capability, coupled with the innovative scheduling algorithms in DOCSIS CMTSs, ensured that most users could get adequate QoE even in the presence of an incredibly high traffic load generated by their neighbors.

MSOs have taken great steps to increase the reliability of the cable broadband network. With the move to work-at home, network reliability takes front seat. No one wants network issues when on web calls most of the day, or students participating in classes from home. As part of its long-standing proactive network maintenance (PNM) project, CableLabs® has been developing technology and best practices to increase the reliability of the cable network. The SCTE took this effort up in 2017 by creating a PNM working group within its standards program, specifically in the Network Operations Subcommittee (NOS). PNM for the HFC network has taken advantage of the intelligence available in cable network elements such as the CMTS and CM, as well as plant information to determine type, severity, and location of an impairment. The goal is to proactively correct issues before customers are even aware of them. By sifting through huge amounts of data collected from the network, information can be turned into actionable intelligence to increase the reliability of the network and provide a better experience to cable broadband subscribers.

## 6. Current Activities

As operators became aware of the mass isolation policies and the resulting bandwidth impact on the access network, we needed to respond rapidly. In many cases there was sufficient latent capacity in the network to handle the initial load, particularly in the downstream; but upstream challenges required fast decisions. We are accustomed to a long-term planning cycle of projecting node actions. These actions may include combinations of adding channels for capacity, node segmentation, or physical node splits, and they oftentimes demand forecasting of the bandwidth capacity requirements 6-18 months into the future. As a result of sheltering-in-place, we saw our 18-month forecast occur in a few weeks.

We were fortunate with how resilient the DOCSIS protocol has become, but it does not alleviate the reality of needing to increase spectrum for both upstream and downstream as we progress into the future.

This experience implies that each operator needs to make some difficult decisions quickly. Now that the DOCSIS 4.0 specifications are complete and silicon is being developed for both Extended-Spectrum and Full-Duplex DOCSIS technologies, cable operators need to decide which path to follow. Not necessarily today, but in the near future, as decisions need to be made regarding changing the outside plant to support either direction. Some of those changes may require years of small plant modifications to ultimately support the bandwidth demands of the future.

What we learned from COVID-19 can fill volumes; but the key learning seems to be that even a blind mouse can find a piece of cheese at times. We were very fortunate for the brilliant men and women who developed the DOCSIS infrastructure, as the inherent resiliency of the protocol and products, coupled with the work done in the cable outside plant itself, enabled us to weather the initial storm of a pandemic. However, it is not the time to rest; we need to prepare and prepare rapidly for the next potential event on the horizon.

## 7. Longer-Term Activities

The negative experiences suffered by some MSOs during the COVID-19 bandwidth surge is a harbinger of things to come in the future if MSOs do not continually upgrade their networks to accommodate the ever-growing traffic demands. While Downstream $T_{avg}$ CAGRs may have slowed from 50% to ~26% in recent years, there is still yearly bandwidth growth occurring in both the Downstream and Upstream directions. In addition, there has clearly been some un-planned bandwidth growth resulting from COVID-19 stay-at-home actions.

Competitive threats from 5G and PON providers may also someday force bandwidth wars, and that struggle will undoubtedly lead to a need for much higher bandwidth offerings within subscriber Service Level Agreements. There will likely come a day when the $T_{max}$ of 1 Gbps within the Service Level Agreement of today is replaced by a 2 Gbps (or higher) $T_{max}$ Service Level Agreement in the future. As we have learned in the past, a higher $T_{max}$ means a higher $T_{avg}$. And increases in either or both of those parameters will produce a need for higher Bandwidth Capacities.

To provide adequate Bandwidth Capacity to support these higher $T_{avg}$ and $T_{max}$ bandwidths, MSOs are already looking at new technologies for the future. These technologies include the tried-and-true action of running with a Fiber Deeper architecture. Whenever permissible, MSOs will likely pull fiber closer to the home as the years pass to reduce customer counts per node. This effectively reduces the $N_{sub}$ value within Service Groups, and it also moves the MSOs closer to their end-game technology, which is possibly a Fiber-To-The-Premise or wireless delivery solution.

As a step towards the 10G Initiative of the future, MSOs are also likely to begin deploying the newly defined DOCSIS 4.0 technologies by the middle of the 2020 decade. This may include Full-Duplex DOCSIS (FDX) technologies (with 1.2 GHz Downstreams and up to 684 MHz Upstreams) or Extended Spectrum DOCSIS (ESD) technologies (with 1.8 GHz Downstreams and up to 684 MHz Upstreams). It is quite possible that many MSOs will find a need to utilize only 300-492 MHz of that available Upstream spectrum (which offers ~2.1-3.6 Gbps of Upstream bandwidth capacity).

MSOs are likely to deploy these DOCSIS 4.0 technologies even before they enable them, because they typically want to deploy gear that will last deep into the future. For many MSOs, DOCSIS 4.0 technologies are planned for use well into the 2030's, so the desire to have the equipment in the field for 10-20 years requires that they begin planning for DOCSIS 4.0 equipment deployments as soon as possible. This also means preparing the outside plant by deploying equipment that can support the spectrum required for the same time period. As an example, if an MSO expects that 10 Gbps SLAs

requiring DOCSIS 4.0 technology are required to be enabled by 2032, and if it requires eight years of diligent plant upgrades to permit ubiquitous enablement of DOCSIS 4.0 technology, then DOCSIS 4.0 field deployments in the outside plant would clearly have to begin by 2024.

Since many of these network technologies will be deployed in DAA environments (both Remote PHY and Remote MACPHY), a critical element of those networks is the Converged Interconnection Network (CIN) that provides Ethernet connectivity from the head-end to the node. Today, CIN networks tend to be limited to 10 Gbps Ethernet optics. A Fiber Node supporting two 10 Gbps Service Groups would obviously require more than 10 Gbps of Ethernet capacity. Thus, as bandwidth capacities of DOCSIS 4.0 deployments rise in the future, it is probable that there will be a move to 25 or 50 Gbps Ethernet Optics within the next decade.

If daisy-chaining of nodes becomes popular or if future architectures employ an Ethernet hub near the nodes, then MSOs may also find value in using the newly defined Coherent Optic technologies. These technologies will provide very high bandwidth capacities (>500 Gbps) at a very low cost for the relatively short-hop fiber runs between head-ends and hubs/nodes.

# 8. Conclusion

There were some great learnings that to date have come out of COVID-19 shelter-in-place orders:

1. You can never have too much fiber or spectrum in your network
2. Leverage existing technologies as long as you can, but not longer
3. Not every node is created equal
4. There is an established order to things, but sometimes it can get mixed up

And most importantly…

5. Serendipity and hope are not a business plan

We were very fortunate as an industry that all of the hard work that went into DOCSIS specifications, silicon, and products, over the past 24 years has shown that the capabilities of the DOCSIS ecosystem are what enabled the cable broadband industry to lead the way providing incredible service during a pandemic. As leaders of the cable industry it is incumbent on us to prepare the way for those that will follow in our footsteps, as we have followed in the footsteps of those that came before us. We must therefore create a series of technologies that will allow cable to continue exceeding the demands of our customers for the next 50+ years.

This implies planning, committing to, and supporting those who are working on and developing these new technologies. Keeping our focus on what our customers need today and in the future will lead each of us to make the right decisions for our companies; this means not getting led down a path that may look shiny today but will tarnish rapidly as the reality of long-tail and support costs kick in.

Now is the time to analyze where our companies and customers are heading, plan for our network transformations, develop resources towards executing our plans, and commit to our vendors for our directional choices. Like anything else in cable, these things take time and now is that time to begin.

In conclusion, we need to **act now**, **be bold**, and **stay true** to our individual directions.

# 1. Introduction

During its lifetime, a device may need to be updated for a variety of reasons. New network access mechanisms or new types of applications and services may be introduced. This can mean that new device digital identities will need to be installed in already deployed devices to enable such new use cases. Examples of new digital identities include new DRM or conditional access credentials for new sources of content, IoT device certificates, credentials for a new copy protection interface such as DTCPv1, DTCPv2, HDCP 1.x, HDCP 2.x, etc.

Provisioning of credentials into devices already connected to the Internet and deployed to individual subscriber homes cannot rely on network or perimeter security. Even when devices are in an enterprise network or in a network operator's domain, it is still prudent to deploy "defense in depth" by providing end-to-end authentication and encryption all the way to the target device, in addition to any perimeter security such as firewalls, IP address filtering and port mapping. Each device and credentials provisioning server need a well-secured root of trust, delivery of credentials should be secured end-to-end and protected against a variety of network-based attacks.

A provisioning system handling different types of credentials has to support a variety of authorization models for different network operators and content providers. Different authorization interfaces are utilized to validate that a legitimate authorized device is being provisioned and that it belongs to a legitimate subscriber authorized for new credentials.

A credentials provisioning system may require a high degree of scalability for large populations of subscribers of premium content or for IoT appliances. Millions of devices may need to be provisioned with new credentials in a relatively short period of time. The worst-case scalability scenario is probably when a DRM or conditional access system is compromised, and every subscriber requires a new set of credentials within a short time period.

This paper describes an architecture of the CommScope credentials provisioning system called Online PKI Update System (OPUS) that has evolved over 10+ years in order to handle a variety of operator-specific and DRM-specific requirements with reliability, flexibility and scalability in mind.

## 1.1. OPUS System Overview

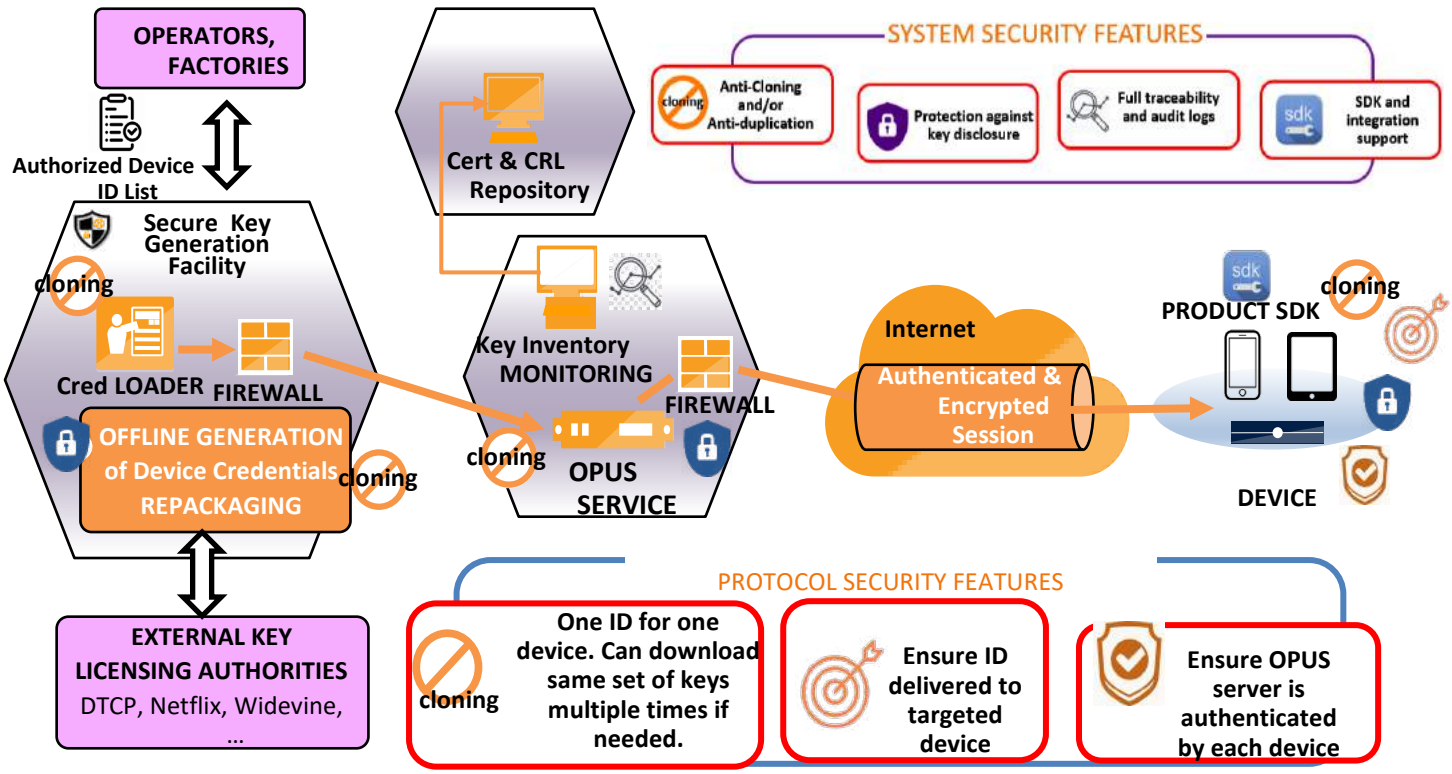

**Figure 1 - OPUS System Overview**

The OPUS service is accessible by provisioning clients via the Internet. It is protected from malicious attacks by means of a firewall, use of cryptographic specialized hardware, frequent security scanning and patching and other generally recommended security practices. The OPUS service consists of a cluster of frontend machines that are Internet facing to receive and pre-process provisioning requests. Sensitive and secure operations are performed by the backend servers, where the secure database and hardware security modules (HSMs) are located. Additional firewall is installed between the Frontend and Backend to provide additional protection. A hardware-based load balancer is utilized to distribute the workload among the cluster of frontend/backend machine pairs. Device credentials are generated and packaged in an offline secure key generation facility to provide end-to-end security from generation or re-packaging to final consumption on the target device.

There are in general two categories of credentials. In the first category, the credentials are generated locally in the secure key generation facility. It is commonly recommended to generate secret/private keys inside the device itself. However, the quality of a random number generator is highly variable across various device categories and developers that are not skilled in security could utilize a poor random number source such as C functions rand() and srand(). Even Linux random number source from /dev/random and /dev/urandom are not considered to be a high-quality random number source and may not be adequate for cryptographic use. Therefore we chose to generate cryptographic material with an HSM inside the secure Key Generation Facility so as to guarantee a sufficient degree of randomness for device credentials. The generated credentials are secured in both the offline Key Generation Facility and

during the transport to the OPUS server and end device so that the risk of compromise prior to the credentials reaching a target device is minimal.

In the second category, the credentials are provided by external parties. The key generation facility in that case only re-packages the credentials to the correct format and applies additional encryption. In some cases, key generation or re-packaging may be based on an authorized device ID list provided by third party such as the Network Operators or Factories. Credentials generated or re-packaged are loaded to the OPUS server through a Credentials Loader application.

The OPUS system utilizes a proprietary request and response message protocol to communicate with provisioning clients. The protocol was evolved over time to provide:

- Flexibility of provisioning any type of device credentials, including but not limited to X.509 device certificates.
- Support for a variety of authorization models some of which that occurred in practice are described in this paper.
- Session security at the application layer with low performance overhead, not requiring additional session setup using a protocol such as TLS or IPsec. Especially considering that each session with an individual device is very short-lived, just for delivery of a single set of device credentials.
- Seamless integration with load balancers, simplified since there is no session setup (OPUS server is stateless)
- Flexibility in terms of adding new cryptographic algorithms

To simplify the integration process, typically an OPUS SDK is built by the CommScope OPUS team and provided to a client device software team. The OPUS SDK handles all the OPUS related processing, including cryptographic operations. This SDK allows fast and easy integration with client teams utilizing the OPUS service and at the same time ensures that the security features on the client side are implemented as designed.

The OPUS solution provides many features crucial to a credential provisioning system, including anti-cloning, strong key protection, reporting, and easy integration. The system is configurable to safely allow the same credential to be downloaded multiple times by the same device in the legitimate cases where the credential on the device may be lost or corrupted. Typically, this is allowed only when that credential can be securely bound to a specific device as was the case in a couple of use cases described in this paper.

In terms of key protection, end-to-end encryption is used in most cases such that device keys are encrypted from generation/re-packaging and decrypted only at the final device. Unique per-device encryption is utilized whenever it is available. In the cases where global encryption is applied to the delivery of device credentials, additional session-based encryption is added by the OPUS server to mitigate the risks of cloning.

Reporting is another important aspect in provisioning. OPUS system maintains logs from key generation/packaging to the actual provisioning transactions, allowing usage reports to be created that may be needed by Network Operators. The logs are crucial for troubleshooting and debugging issues associated with the device credentials provisioning. There is an inventory monitoring service in the system which can generate key inventory reports. When key inventory drops below a preset threshold, a trigger will be created so that responsible parties will be alerted, and more data will be generated or externally acquired and repackaged accordingly.

The OPUS system provides a flexible and scalable solution for secure identity provisioning for devices in the field. In the following, many actual use cases will be discussed in more detail.

# 2. Existing OPUS Use Cases

## 2.1. Provisioning of Credentials based on Operator and Model Authorization

The following is a common use of OPUS for field provisioning of DRM keys into deployed digital set-tops and other secure video rendering devices. Each deployed device has been provisioned with a factory-installed unique credential. Most common type of credential in use is an X.509 device certificate chain, issued by either the network operator or device manufacturer.

Netflix credentials in particular require that an operator signs a business agreement with Netflix and opens a corresponding device account for a specific device model and region. An example of this process is documented here: https://openconnect.netflix.com/en/#what-is-open-connect. This process sometimes takes much longer than anticipated and is completed after a particular device model is already in mass production. Therefore, it becomes necessary to provide a secure field provisioning interface to download unique per-device Netflix keys online.[1]

Another common use case is provisioning of Widevine DRM and Attestation Keys into Android and Android TV devices.[2] These Android credentials require for a device vendor to set up a per-model account with Google and when Widevine keys are utilized in conjunction with a Netflix service, then separate accounts for each network operator are also required.

Yet another use case when DRM keys may be provisioned into device following their manufacture is an introduction of a brand-new DRM or copy protection system. DTCP version 2 was introduced in 2017[3] and adds a higher level of content protection which requires a Trusted Execution Environment inside each device and makes use of larger key sizes and stronger cryptographic algorithms than what is defined in DTCP version 1. DTCP version 2 is more suitable for protection of premium 4K and HDR content than DTCP version 1. By the year 2017, there was already a population of secure digital set-top boxes and digital TVs with a sufficient level of HW security and these devices are capable of supporting DTCPv2 and protecting the streaming of 4K and HDR content from a digital set-top box to a digital TV or between server and client set-top boxes. Again, this is a use case for OPUS to update qualified devices with the corresponding DTCPv2 keys.

The following sequence diagram demonstrates the use of OPUS for provisioning of new DRM credentials into each device:

[1] Linux-based and Windows-based Netflix clients are based on Microsoft PlayReady DRM https://www.lightreading.com/cable-video/netflix-taps-playready-as-primary-drm/d/d-id/677491 but still require additional Netflix-specific device keys provisioned into each device. PlayReady DRM keys do not require per-operator Netflix accounts and can be provisioned in the factory ahead of time.
[2] See https://developers.google.com/android-partner/guide/keybox and https://developer.android.com/training/articles/security-key-attestation.
[3] See https://www.dtcp.com/dtcp.aspx

**Figure 2 – Provisioning of Credentials Based on Operator and Model Authorization**

The above sequence of credentials provisioning steps are as follows:

1. Network operator optionally provides a list of devices requiring an upgrade and new DRM credentials. If this list is incomplete, then this whole sequence may need to be iterated multiple times.

   In majority of cases the operator did not require this list and all devices of a particular model and belonging to a particular operator were allowed to upgrade. But there were some cases when the operator wanted us to upgrade only specific devices based on their list of device identifiers. A device identifier here could be a SOC ID, MAC Address or a Serial Number.

   New types of device identifiers may be supported in the future on a case-by-case basis. Most of the time a new type of device identifier can be supported with no software changes to the OPUS system. A device identifier which is a function of a device certificate (e.g., hash or fingerprint of the device certificate) may be introduced in the future as an OPUS enhancement.

2. Generate the new sets of device credentials (e.g., issue X.509 certificates). Or in other cases which we had to commonly support – obtain and then re-package and re-encrypt 3rd party DRM credentials e.g., Netflix, Google Widevine or Google Attestation Keys. This may require a SOC-specific format that can be later processed by the chip inside the trusted execution environment (TEE).

3. Encryption may utilize either a global HW key known to the SOC TEE environment or unique per-SOC encryption whenever the SOC ID is known in advance. Decryption is often required to occur inside a TEE on the SOC, especially when the new DRM is expected to handle 4K or HDR high value content.

   When the SOC ID is known, it may be utilized to either derive a unique per-SOC key from a global HW key and SOC ID, or utilized to look up a unique One Time Programmable (OTP) key for that SOC in some internal or external database. For CommScope's past utilization of OPUS – we had to handle all of these use cases.

4. Load the generated new DRM credentials onto the OPUS server which is accessible online by devices that are being upgraded. Device credentials were generated in an offline air-gapped facility and so this transfer may be done by a human operator with removable media.

5. At some point prior to a new device model starting to submit requests to OPUS, an OPUS administrator must obtain and install the device root CA and device sub-CA that will be trusted by the OPUS server for submitting requests for device credentials. There can be multiple trusted CA certificate chains configured for the same (operator ID, credentials type) combination since a particular operator may have several different device models with different factory-installed device certificates from different issuers that all require the same new credentials to be downloaded in the field.

   This process needs to be repeated for each new credential type – even if it is the same device model requesting a new credential. For more flexible authorization rules, an operator could require the same device model to utilize a different certificate chain for downloading a different type of device credential. There shouldn't be a limit on the number of CAs installed on the OPUS server, covering any number of authorized device models and types of credentials.

Besides configuring the list of trusted CA certificates, there are other miscellaneous configuration parameters that should be set for each credential type. For example, the type of the key agreement algorithm (e.g., Diffie-Hellman or Elliptic Curve Diffie-Hellman), key size or Elliptic Curve ID, etc.

This step is required for all use cases but for simplicity is not shown on subsequent diagrams.

6. A project manager, possibly a member of customer's operations team, is given a go ahead that the new credentials are now ready to be downloaded.

7. The project manager coordinates a device update to prepare devices for a new credentials download. In this example, device update involves an authenticated software update where the new software has the logic to connect to the OPUS server and request the new credentials (in step 8 below). Well ahead of this step CommScope builds an OPUS client SDK for each different device platform to make it easier to complete this software update.

   In other cases, devices may already have the latest software capable of connecting to the OPUS server but were waiting for some sort of a trigger such as e.g., a TR-069 configuration message. It is not advisable to wait until the end user tries to access content requiring the new DRM and then begin the credentials download – to avoid any potential delays that are visible to the user.

   Section 3 on scalability shows that OPUS is really a cluster of servers capable of very large throughput, but still – there is a lot of unpredictability in the Internet performance and it is best to install DRM credentials in advance of the need to use them.

8. If the software update is required and has not yet taken place, the software is downloaded, verified and installed during this step.

   A software update is required under a variety of circumstances such as:
   - A credentials update was not anticipated during the initial device manufacturing and the corresponding interface to the OPUS server was not implemented at that time.
   - Operator's device authorization mechanisms for new credential updates were not defined at the time of device production or had undergone some changes since then.
   - A field update for new credentials was anticipated prior to manufacture, but a strategic decision was made to accelerate device production schedule and defer the interface to download credentials to a future software update.
   - Any software in the device that is related to the new credentials incurs a per-device license fee and is therefore deferred to a software update and only for specific end users that subscribe to a specific service.

   But in some cases a device may already have the right software to interface to OPUS and this step could be replaced with a trigger message to begin a credentials' download.

   Typically, after the software update is validated and installed, the device will reboot, and restart and it may undergo secure boot (not shown on the figure).

9. Device submits a request for new DRM credentials. This request must be authenticated, and we normally rely on factory-installed certificate and private key for that purpose. This device should have implemented secure boot such that all software running in the device is authenticated. It is also recommended to utilize a TEE for this purpose.

Over the years, we had to handle some exceptions where for example a device with no public key credentials was being upgraded with a DRM application that requires a unique device certificate. Sometimes a device has credentials that are by contract restricted to protect only a specific interface (e.g., DTCP-IP or HDCP copy protection or credentials for a specific DRM) and so still – there were no device credentials available to authenticate a request to OPUS.

Under those circumstances, a software update to a device (in steps 6 & 7) included a software-protected signing key which can be mathematically encoded using whitebox techniques and a software protected decryption key which can also be whitebox-encoded. Here, a device signs the request with its software protected signing key if a more secure option is not available. And associated device certificate issued to the corresponding public key is also attached.

This message includes a unique device identifier as a separate parameter and may also be included in the device certificate attached to the request. Device identifier is validated against the authorized device ID list (see the next step).

This request also includes a key agreement public key of the device in order to establish a one-time session encryption key – in addition to encryption that already occurred offline in step 3. The device generates its key agreement public/private keypair and the public key is included in this request message.

Typical key agreement algorithms include Diffie-Hellman (DH) and Elliptic Curve Diffie-Hellman (ECDH). OPUS protocol is configurable and allows for introduction of new key agreement algorithms as needed.

10. Here, the request is authenticated by checking certificate chain and signature of the requesting device. Authorization is also verified using multiple configurable options:
    - Check if Operator ID in the request is authorized for this type of credential
    - Check if a particular device model is authorized for this type of a credential
    - Check if this specific device has its ID in the authorized device ID list
    - Check a CRL to make sure that the factory-installed certificate is not revoked. There may be multiple CRLs, but OPUS will check a specific CRL corresponding to the End Device's certificate in the request. Not all device certificates include a crlDistributionPoint extension so the server may need to be configured with the corresponding URL manually.

11. After all authentication and authorization checks passed, the OPUS server will either look up a new device credential based on the authorized device ID, or if allowed by configuration, find the next unbound globally encrypted credential.

    The server will generate its own key agreement keypair and include its public key in the response that it is preparing. It will also generate a one-time session key based on server's key agreement private key and the client device's key agreement public key in the request message. This session key is utilized to add an extra layer of encryption, preventing the reuse of the same encrypted credentials in any other OPUS session.

    In the case that encryption in step 3 was done with a unique device key, the reuse or copying of those encrypted credentials in another device is already prevented and this extra layer of session key encryption may be skipped for improved performance and scalability.

12. The OPUS server adds its own signature and certificate chain and sends back a reply containing the server's key agreement public key and the encrypted device credentials.

13. Device receives the response, validates OPUS server's signature and certificate chain and then proceeds to decrypt, validate and install its new credentials. These new credentials should be decrypted inside a secure TEE environment and then re-encrypted using a device unique key to bind these new credentials to the specific device.

## 2.2. Provisioning Credentials Based on Proof of Subscription

Pay TV subscribers may lease or purchase a local DVR that will record subscriber's favorite digital content and this content can later be streamed to subscriber's secondary rendering devices, including additional client set-top boxes, mobile phones and tablets. This subscriber may want to watch content recorded on the main DVR on her tablet connected over a local Wi-Fi network while in a different part of the house from where the DVR is located. Alternatively, a subscriber would like to receive live or pre-recorded content directly to her tablet, cellphone or laptop via a content distribution network while traveling, away from home.

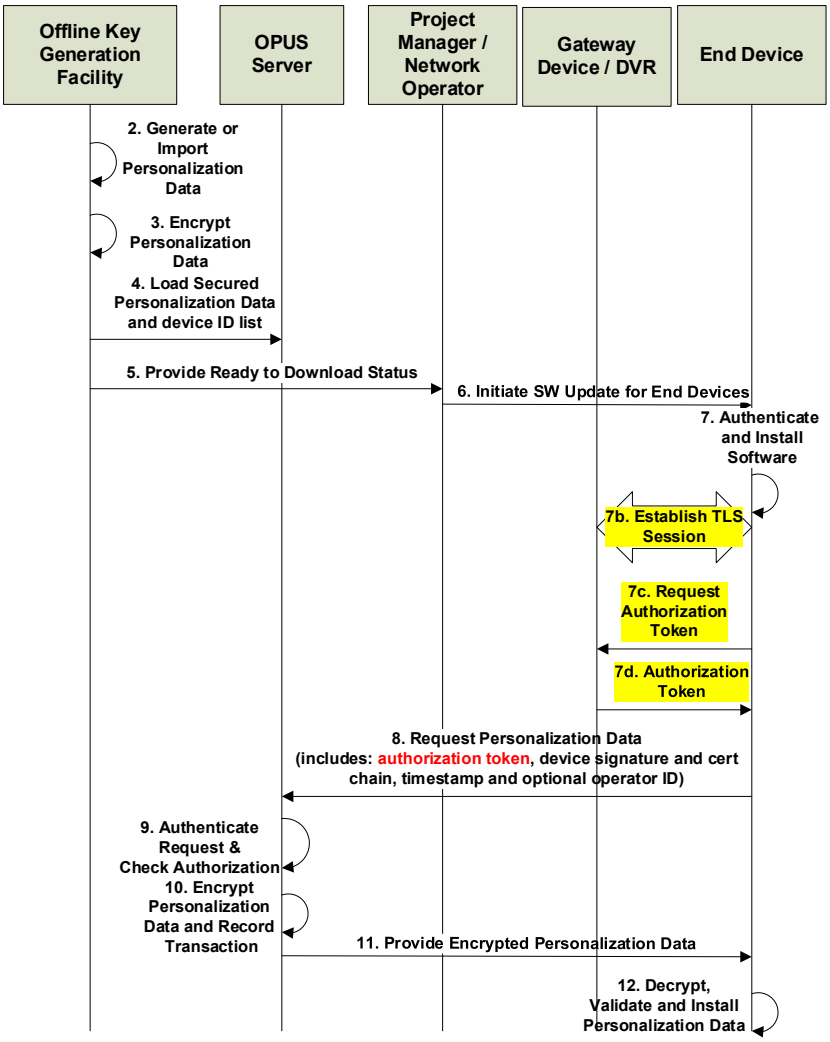

**Figure 3 – Provisioning of Credentials Based on Proof of Subscription**

The above sequence of credentials provisioning steps is similar to the sequence described in section 2.1 with the following differences associated with device authorization:

- Optional step 1 where an authorized device ID list is provided by the operator is not there.

- A subscriber leases a DVR from an operator and pays for an additional service that allows this subscriber to obtain DVR content or even content direct from the operator's content distribution network on some small number of additional personal devices authorized by the operator, including mobile phones, tablets, PCs, etc.

- To prove that this subscriber has a DVR and is authorized for additional content streaming or download services to a personal device, steps 7b, 7c and 7d were added:

- 7b: establish a 2-way authenticated TLS session. The end device and DVR both have pre-installed certificates that can be used for this purpose. DVR would typically be the TLS server and end device is the client.
- 7c: Device requests an authorization token
- 7d: DVR checks subscriber authorization for content sharing with additional devices and if authorized, signs and returns the authorization token. DVR is separately configured by the operator to enable this service.
    - Authorization step in the DVR may include checking the limit on the number of end devices or the DVR may have its own authorized device ID list received from the operator to make sure that this end device is authorized.

Some examples of additional credentials provisioned into the end device include DTCP-IP, X.509 device certificate, Netflix or Widevine. (Netflix and Widevine DRM are typically utilized to secure content delivery direct from the content provider or the network operator but not from the DVR.)

## 2.3. Provisioning of New Credentials with Offline Matching Existing Device ID

In some cases a network operator may decide to switch to a new Digital Rights Management system that requires new device credentials such as for example device X.509 certificate chain and private keys. Other DRM systems require their own proprietary DRM credentials in a proprietary format that may need to be installed after devices are already manufactured. In other cases, the operator completes their business agreements with a DRM provider after devices already start shipping and so are shipped lacking the necessary DRM credentials.

An operator may require that such a DRM upgrade is done for a specific set of devices and device IDs that are registered in their network and provides the manufacturer with an authorized device ID list requiring such an upgrade. A device identifier attached to the new device credentials may be for example a MAC Address and it may be included as an X.509 certificate subject name attribute as was the case in the CommScope's experience. Another example of provided device identifiers is a list of SOC identifiers which may be used to encrypt each new DRM credential with a SOC-specific symmetric key.

One way to address these use cases is to process an authorized device ID list in a secure offline facility where we have access to all the factory-provisioned device certificates. For each device ID in the authorized list we look up the original factory-provisioned device certificate and use the included public key to encrypt the newly generated DRM credentials of that device. The X.509 certificate that is part of the new credentials is signed in an offline facility using a Certificate Authority approved by the DRM provider and the device ID in the authorized list is included in the new certificate. Encryption is unique to a specific device and is end-to-end, providing a very high level of security. Clear device credentials are not exposed anywhere outside of the secure offline facility and the device itself.

Alternatively, a SOC ID may be used to look up or derive a SOC-specific and hardware-protected symmetric key and utilized to encrypt the newly generated device credentials. In this case, encryption will still be unique to a specific device and is end-to-end, providing the same high level of security.

CommScope has utilized the deployed OPUS system to perform such device upgrades for multiple (4+) operators which made a decision to switch their whole network from Digital Rights Management System #1 to Digital Rights Management System #2 or in other cases concluded their DRM agreements after devices were already manufactured and delivered to that operator. In each case, the DRM upgrade was successfully completed according to plan.

The following diagram focuses on a use case where each new credential is an X.509 certificate and private keys are encrypted using a public key from a factory-installed certificate:

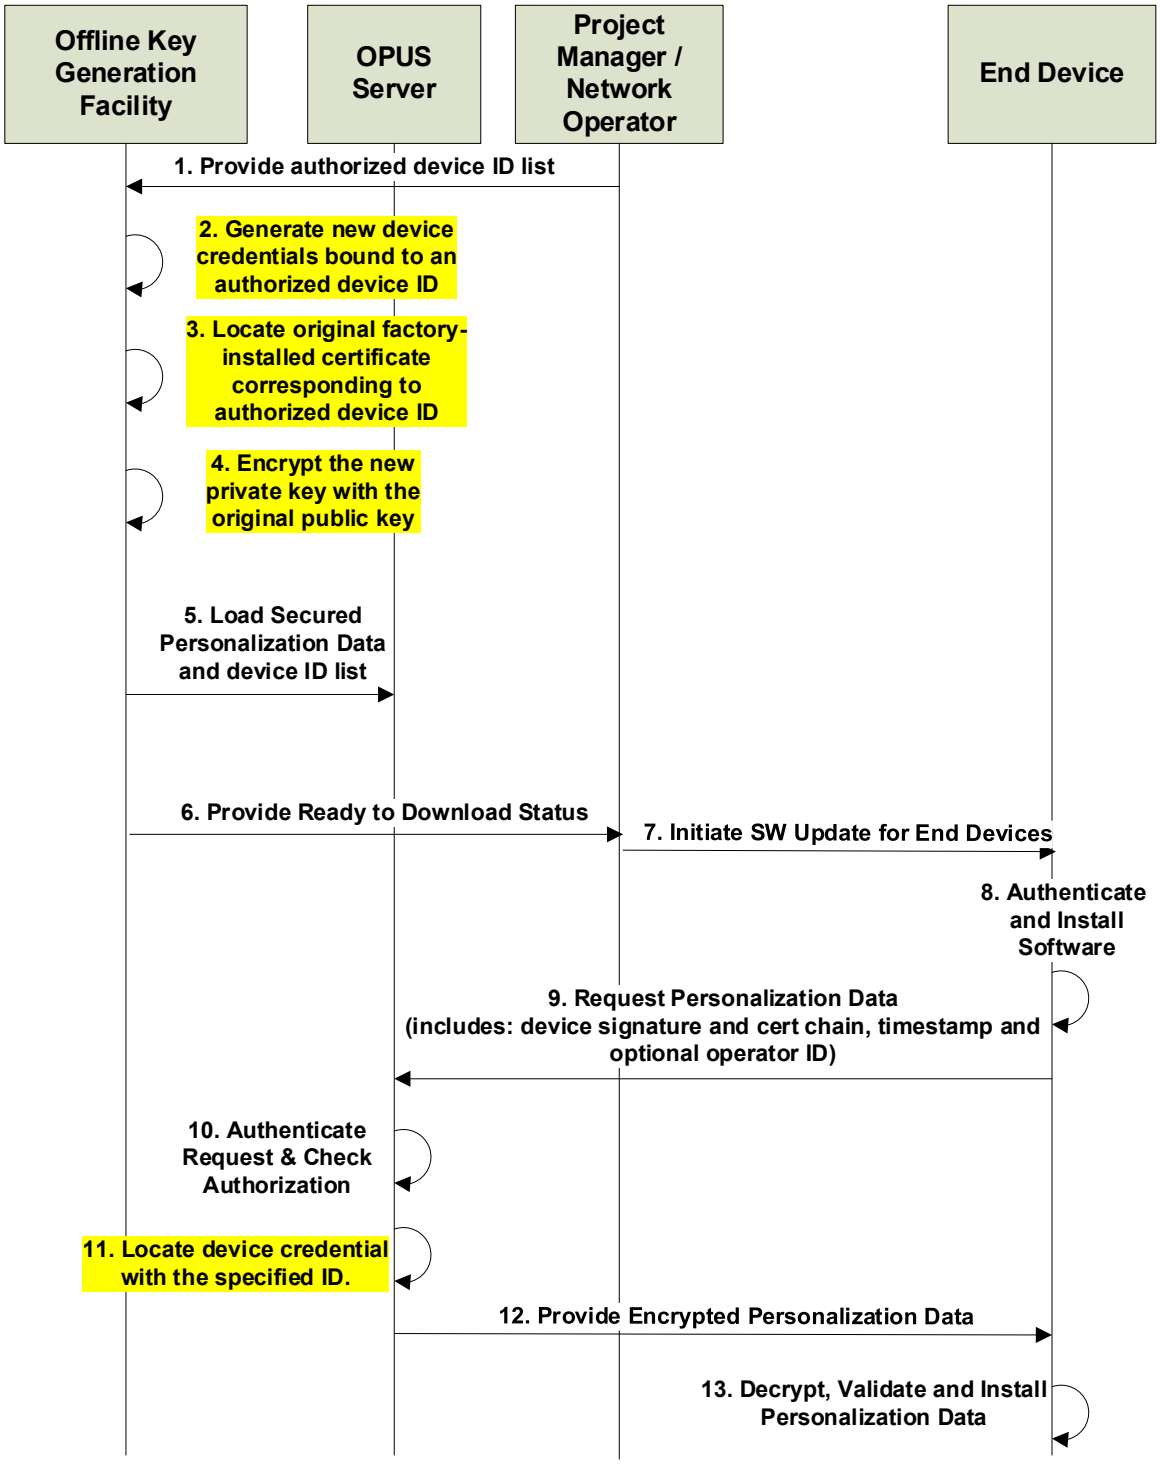

**Figure 4: Provisioning of Credentials Matching Existing Device ID**

1. Network operator provides a list of authorized device identifiers such as MAC Addresses that are required to be present in the new device certificates.

2. Generate the new device credentials consisting of a public/private keypair and a device certificate chain. The newly generated device certificate includes one of the authorized device identifiers on the list. Certificate is signed using a Certificate Authority that is authorized for use with the new DRM system.

3. Locate the original factory-installed certificate in an offline database. The original certificate may contain the same device identifier. If the original certificate contains a different identifier, then the authorized device ID list provided in step #1 needs to include pairs of (factory-cert-device-ID, new-cert-device-ID) for each device. That way, factory-cert-device-ID can be used to locate the original factory-installed device certificate. Private key corresponding to that factory-installed certificate is not needed.

4. A public key is extracted from the factory-installed certificate and utilized to encrypt the new private key, generated as part of the new device credentials for the new DRM. If RSA public keys are utilized, due to size limitations the RSA public key is utilized to indirectly "wrap" the larger RSA private key structure. A standard RSA wrapping mechanism is specified in [5].

5. Uniquely encrypted device credentials for each ID in the authorized device ID list are loaded to the OPUS server. Encryption was performed in an offline facility and therefore this step requires manual action such as transfer of the keys on removable media. Authorized device ID can be implicit – each authorized device ID is included in one of the uploaded device credentials.

6. A project manager, possibly a member of customer's operations team, is given a go ahead that the new credentials are now ready to be downloaded.

7. The project manager coordinates a device update to prepare devices for a new credentials download. This may be done via an authenticated software update to the end device. (See a more detailed description on step #6 in section 2.1.)

8. If device received a software update needed for the DRM credentials update in step #7, then the software update is authenticated in this step prior to installation.

9. The device submits a request for new credentials to the OPUS server. In this use case, the device includes the new device ID that it requires in the new credential and the request is signed using the factory-installed device certificate and private key.

10. The OPUS server verifies the signature and certificate chain of the request. Some authorization may be performed here, such as verifying the network operator's ID in the request to make sure the operator is authorized for this DRM update.

11. Locate the new device credentials matching the device ID in the request. This provides additional implicit authorization – devices that did not have their device ID included in the list provided during step #1 will not have their certificate loaded on the OPUS server. Either that means that device is not authorized for the DRM upgrade – or the operator simply missed providing the identifier of this device.

12. The encrypted device credentials located on the OPUS server are returned to the device in this step. It isn't necessary to apply additional session-based encryption here since the new credentials are encrypted for a specific target device. But the message is signed and anti-replay protection may be needed in the absence of a key agreement protocol such as DH or ECDH.

13. Device receives, verifies and installs its new credentials. Decryption and re-encryption are likely required in order to store the new DRM credentials using DRM-specific encryption. But in some cases it may be sufficient to save the encrypted private key in the exact format as it was received.

In practice, it turned out that it was very hard for operators provide a complete authorized device ID list in step #1 for all devices that required the DRM upgrade. Some devices may have their device identifier modified in repair. Or the operator may be missing some identifiers of newly shipped devices for which they have not yet received a shipping notice. In our practice, this is an iterative process and for each operator we received the authorized device ID list in 5-10 parts and so this whole process was repeated 5-10 times per operator.

One way to handle this upgrade is to have the OPUS server keep track of errors of requested device IDs that were not found in its list, deliver this list of missing IDs to the operator which would then determine if those are legitimate devices that were missed during the previous DRM upgrade iterations. And then repeat the whole process with the previously missing device IDs.

OPUS system has also been utilized in very similar use cases as the above with a few variations, where:

- The new DRM credentials are in a DRM-proprietary format and may not include X.509 device certificates
- Authorized device ID list consists of SOC IDs and DRM credentials are encrypted with a SOC-specific symmetric key instead of a public key from a factory-installed certificate

The sequence of entity interactions looks the same as in the above diagram with minor variations in the type of device identifiers and encryption that was deployed.

## 2.4. Provisioning of New Credentials with Offline Matching Existing Device ID for Wireless Devices

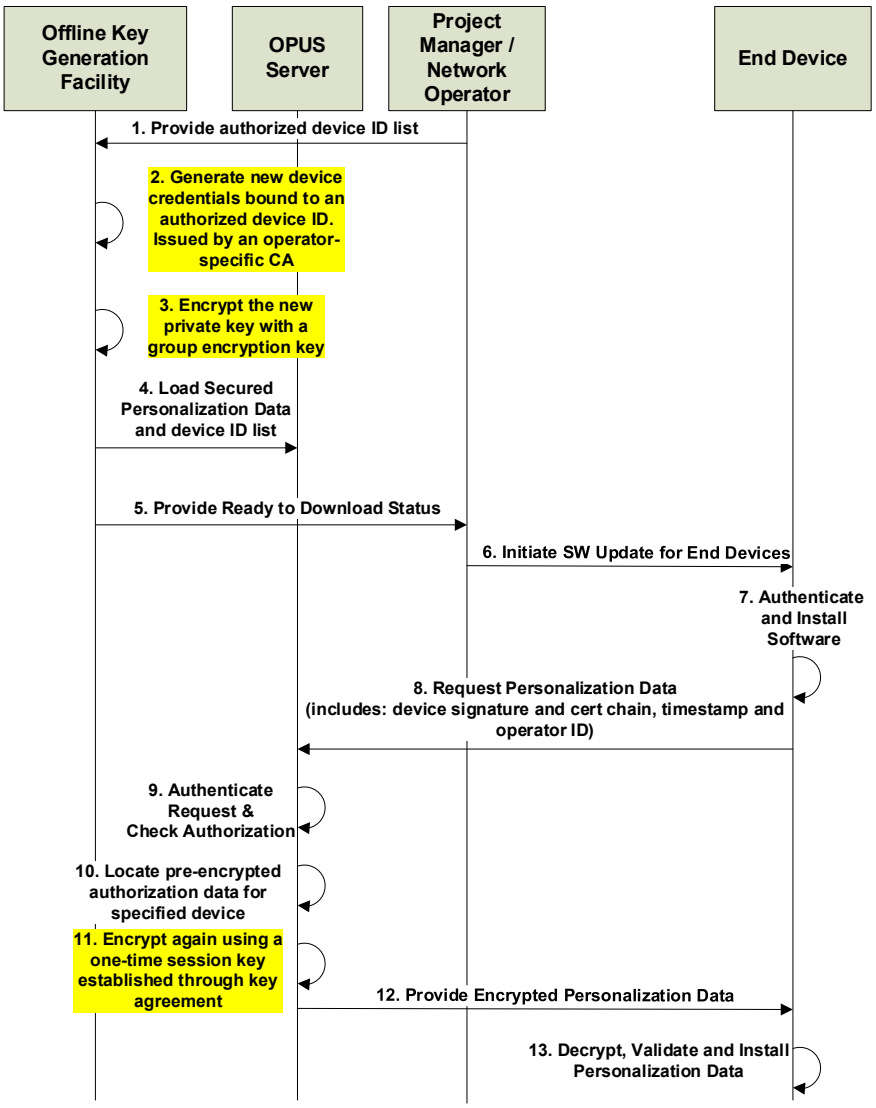
In some cases, a wireless network device such as a router, base station, radio point or radio point controller requires an X.509 device certificate that is utilized in a lower layer protocol security such as for Thread, IKE/IKEv2/IPsec or MACsec. In those cases, it is common to require a device identifier such as the MAC Address to be present in those certificates. Such certificates can be installed in the factory, except when an operator wants to install their own credentials that chain to an operator-specific Root CA.

A device manufacturer may not know network operator's identity prior to manufacture or equipment may change ownership between different operators when a portion of operator's network is sold to a new operator. Such use cases can also be addressed with OPUS providing field provisioning of new device credentials in a very similar manner as the use case described in section 2.3, but with some simplifications.

Encryption in the offline facility is done with a group key which doesn't require locating the original factory-installed certificate. Instead, the OPUS server performs a key agreement protocol to generate a unique session key for an extra layer of encryption thus preventing cloning attacks and reuse of the same encrypted credentials in multiple devices.

The use case below was in practice considered for a wireless network device upgrade, although the same OPUS profile can be applied to field provisioning of any kind of new credentials – when each new credential is targeted to a specific device and a list of the corresponding device identifiers is known in advance. It has some similarity to the use case describe in section 2.3, except that here the OPUS operator may not have access to the factory-provisioned device credentials.

This is illustrated in the following diagram:



The above sequence of credentials provisioning steps is described in more details below:

1. Project Manager or Network Operator provides an authorized device ID list (list of device identifiers for devices requiring new credentials). Each such list is associated with a specific Network Operator, used to determine which CA is used to issue the corresponding device certificates. In practice, this step is iterated periodically. For example, the project manager sends a list for all new devices shipped within a pre-determined time period.

2. Generate the new sets of device credentials (e.g. X.509 certificates) with the device identifiers provided in the list. The CA used to issue the certificates may be specific to the Network Operator.

3. Encrypt each of the device private keys using a group/model-specific symmetric key or a key derived from such a key.

4. Load the authorized device ID list and new credentials onto the OPUS server. The new credentials are identified by a Personalization Type ID that is specific to the type of credential and Network Operator combination. Since the credentials were generated in an offline air-gapped facility, data loading may be performed by a human operator using removable media.

5. The Project Manager or Network Operator is notified that the credentials have been loaded and therefore ready to be consumed by the devices on the list.

6. This step describes the process of the Project Manager or Network Operator triggering the software update to the device for requesting the new credential. This step is the same or similar to step 6 in the section 2.1.

7. In this step, the device verifies and installs the software update necessary to interface to the OPUS server, if it has not been done yet.

8. Similar to the previous use cases, the device submits a request to the OPUS server for new credential, identified by a Personalization Data Type ID. Since the new private key to be provisioned is globally encrypted, a unique session key will be created by the server (in a later step) to mitigate the risk of cloning. Therefore the device generates a key agreement key pair for the request and includes the key agreement public key in the request. In addition, the device also includes an Operator ID for additional validation by the server. The request includes a device signature and a factory-installed certificate.

9. Upon receiving the provisioning request from a device, the OPUS server verifies the signature on the device using the attached device certificate extracted from the request. The server makes sure that the device certificate used is chained to a pre-configured CA for that Personalization Data Type ID. Next, the server extracts the Device ID from the device certificate and verifies if it is on the authorized device ID list. The server would reject the request if any of the verification steps fail.

10. Next, the OPUS server looks up the credential pre-generated for that particular device, based on the Device ID. The credential includes the new device certificate and globally encrypted private key.

11. Since the private key is encrypted globally, OPUS server applies another layer of encryption on top of it using a session key derived from the key agreement algorithm. To do this, the OPUS server extracts the key agreement public key from the request, and generates its own key agreement key pair.

12. The OPUS server sends a response to the device including the new credential (the new device certificate and corresponding private key, which is now double encrypted with the session key), and the server's key agreement public key, needed for the device to derive the same one-time session key. The server also signs the response using its server certificate.

13. After receiving the response, the device verifies the signature of the message using the provided server certificate. The device also makes sure the server certificate chains to a trusted CA embedded in the provisioning software installed earlier. The device then derives the one-time session key using the provided server key agreement public key and its own private key. The device then removes both layers of encryption over the private key, utilizing the one-time session key and then the global encryption key. At this point the device may perform further validation to make sure the certificate is properly formatted and chained to the expected Root CA certificate. It also makes sure the private key and certificate match each other. After all the validation, the device can proceed to store the new credentials.

    To avoid cloning, the private key must be stored encrypted using a unique key tied to the device rather than using a global key. The device derives such a unique key from a global key and a device or SOC identifier. Or a unique device key may have already been provisioned (e.g. into secure OTP memory). The device uniquely encrypts the new private key and saves it into persistent storage along with the associated device certificate.

This use case has the security advantage that the signing CA is hosted in the offline key generation facility and not on OPUS. However, a drawback is that system response time may not satisfy the operational requirements imposed by the Network Operator. After the authorized device ID list is provided to the offline key generation facility, there will be a lead time for the new credentials to be available for a device to download. In some cases, Network Operator may impose a short turnaround time, say, one day, which may not be satisfied easily with the many steps (some manual) for this process. The next use case can be used in such scenarios.

## 2.5. Provisioning of New Credentials with Online Matching Existing Device ID

The approach for wireless device credentials provisioning that is described in section 2.4 was seriously considered but as it turned out – after an operator submits a new order for wireless devices, the new certificates have to be made available almost immediately. While it is a more secure approach in section 2.4 where none of the Certificate Authorities are operated online, it did not meet the practical performance constraints.

Therefore, in practice we addressed this use case with a different system architecture that enables the OPUS server to issue new operator-specific certificates. The OPUS server is sufficiently hardened where the certificate issuer's private key is protected in the HSM at all times and device private keys do not need to be exposed on the server. The OPUS server is also sufficiently hardened and is protected behind a firewall.

Just as in the previous section, this use case is not limited only to the wireless device credentials, although in practice that's where it was applied.

This use case is illustrated in the diagram below:

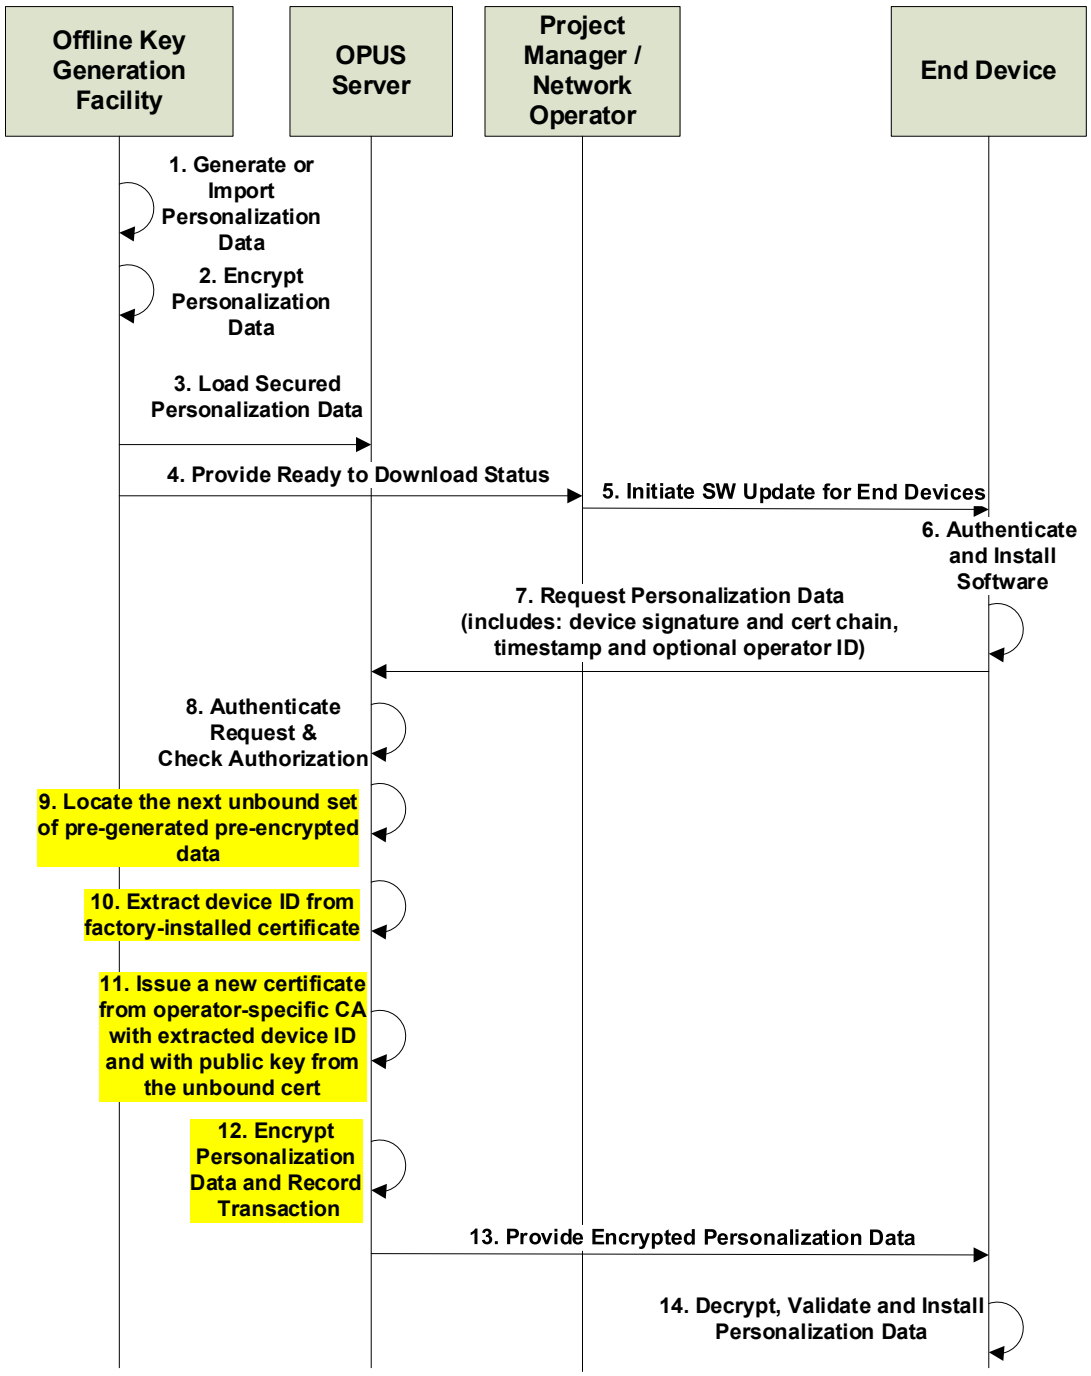


**Figure 5 – Provisioning of Credentials Online Matching Existing Device ID**

The above sequence of credentials provisioning steps is explained in the following:

1. A set of device credentials, called the Origin Credentials, are pre-generated in the offline key generation facility. Each record of Origin Credential includes a device private key and a corresponding Origin Certificate issued using an identifier that is not the final device identifier.

This is because the list of authorized device IDs is not yet known at this point. The generation may be triggered by production volume estimation provided by a Project Manager.

2. The device private key is encrypted just as in Section 2.4, using a group/model-specific symmetric key or a key derived from such a key. This allows the device private keys to be pre-encrypted end-to-end from generation to the device. The OPUS server does not need to have access to the clear device private key and therefore the exposure of the device private keys is minimized.

3. The Origin Credentials are loaded to the OPUS server. These credentials are identified by a Personalization Type ID that is specific to the type of credential but not necessarily specific to the Network Operator. Note that at this point, the credentials are not yet bound to a specific device.

4. The Project Manager or Network Operator is notified that the credentials have been loaded, and provisioning can proceed.

5. This step describes the process of the Project Manager or Network Operator triggering the software update to the device for requesting the new credential. This step is the same or similar to step 6 in the section 2.1.

6. In this step, the device verifies and installs the software update necessary to interface to the OPUS server, if it has not been done yet.

7. In this step, the device submits a request to the OPUS server similar to step 8 of section 2.4. Again, since the device private key is globally encrypted, a one-time session key will be used to add an additional layer of encryption. Note also that in this use case, the request must include the Operator ID, which will be used by the server to determine which CA to use for issuing the final certificate.

8. Upon receiving the request, the OPUS server authenticates the request and checks for authorization, similar to the previous case. However, as an authorized device ID list is not utilized here, the OPUS server only verifies that the factory-provisioned device certificate in the request is issued by a trusted CA pre-configured for this specific Personalization Data Type and for the specified Operator ID.

9. OPUS server retrieves the next available unbound set of Origin Credentials, which includes an Origin Certificate and a corresponding globally-encrypted device private key.

10. OPUS server then extracts the device ID from the factory-installed certificate in the request. This device ID will be used in the final certificate.

11. OPUS server issues a final certificate for the device. The final certificate has the extracted device ID in the subject name, and the public key extracted from the Origin Certificate. The final certificate is signed by the OPUS server using a CA determined by the Operator ID provided in the request. This final certificate is now bound to the device. For additional security, the CA private keys are protected in an HSM and therefore never exposed in the clear on the server. Additionally, an operator-specific certificate template may be selected based on an Operator ID. For example, certificate validity period and some subjectName attributes may be determined by an operator-specific template.

12. In this step, the server derives a one-time session key to encrypt the globally-encrypted device private key. This is the same as in the previous use case. The session key can be derived inside the HSM as well to minimize its exposure.

13. The final credential is then sent to the device.

14. The device decrypts, validates, and installs the credentials the same way as in the previous use case.

In practice, this is the selected method utilized by OPUS to provision operator-specific credentials into wireless devices. While still maintaining end-to-end encryption of private keys from the offline key generation facility all the way to the target device, this method enables real-time provisioning of the device credentials and doesn't depend on manual pre-processing and installation of an authorized device ID list.

# 3. Scalability and Benchmark Results

With a cluster of 2 front end/back end OPUS server pairs, when key agreement is not required (when unique-per device encryption is applied end-to-end), the observed throughput is 30 million transactions per day. The load balancer allows OPUS to increase scalability if necessary and multiple OPUS clusters with their own load balancers may be deployed for different operators or different types of device credentials. The observed performance included hardware acceleration for RSA signatures provided by a hardware security module (in addition to the signing private key protection)

Key agreement protocols such as DH or ECDH may require additional OPUS server pairs to maintain the same level of scalability. This is highly variable depending on the computing power, hardware-based crypto acceleration and a choice of the key agreement algorithm. According to [6], software implementations for ECDH utilizing NIST P256 curve are 3 times faster than 2048-bit classic Diffie-Hellman. ECDH utilizing Curve25519 gains a performance improvement of another factor of 3 over the NIST P256 curve.

For the OPUS design, security of device credentials is the highest priority since additional layers of encryption or larger key sizes can always be offset by additional pairs of FE/BE servers which can be shared across multiple types of device credentials and operators.

# 4. Future Work

The use case described in section 2.5 provides a lot of flexibility to network operators to provision a device with their own credentials that utilize an operator-specific CA and an operator-specific certificate template. However, that use case requires a device to store a new private key that is downloaded into the device from the OPUS server. And that may not be possible for devices that utilize secure OTP memory to store a private key which cannot be modified following manufacture.

For such future use cases, the OPUS server may issue a new operator-specific certificate for the same public key that is part of a certificate installed at manufacture time and corresponds to a device private key that is burned into fuses and is not updateable. Allowing multiple simultaneously valid certificates for the same public key is not a recommended security practice and in this case we should revoke the previously issued certificate right before issuing a new operator-specific certificate.

Another way to address the limited storage for private keys in the OTP security fuses would be to derive a public/private keypair during device startup from a seed value that is locked in OTP. This can be easily done with the Elliptic Curve crypto system where a private key is a random value and is much more difficult with RSA. With this approach, each new operator-specific certificate can be issued to a new public key derived based on the new operator ID and it will not be necessary to revoke a previous certificate unless it was compromised.

Additional OPUS system flexibility will be addressed with future enhancements, including for example:

- Improving algorithm agility through the following means:
    - OPUS request will include a list of client-supported algorithms and the OPUS server will select the algorithms from that list to protect the corresponding response containing new credentials.
    - In the case that OPUS server finds client's selection of algorithms inadequate, a client will be automatically redirected to a software update with additional/stronger algorithms. After the client has been upgraded, it will retry.
- Introduction of additional types of device identifiers such as for example a certificate fingerprint

# 5. Conclusion

Today's consumers may own or lease a wide variety of digital entertainment devices all capable of receiving DRM-protected digital content. Different network operators and over the top content services are protected with a variety of DRM systems and a new use case for a particular device model may not be apparent until after those devices are manufactured and delivered to end consumers.

In order to provide maximum entertainment value to consumers, it becomes necessary to provision their devices that are already installed in their home with new DRM credentials. This can be both a daunting scalability challenge and a security concern.

There are many other types of devices such as routers, wireless network access points, radio points and radio point controllers that have similar needs to obtain new cryptographic device credentials after each such device has already been fielded. Such devices may reside in consumer's home network, a private enterprise network or in the network provider's infrastructure. And they may require different types of credentials to be field downloaded.

Furthermore, a credentials provisioning system has to be constantly revised in order to support new use cases involving new authorization models that may be specific to a network operator or to a new industry. This paper demonstrates that a single field provisioning system can be designed with sufficient flexibility and scalability to address such challenges and to handle many use cases.

# Abbreviations and Definitions

| | |
|---|---|
| AES | Advanced Encryption Standard |
| BE | back end (server) |
| CA | Certificate Authority |
| DH | Diffie-Hellman |
| DRM | digital rights management |
| DTCP | Digital Transmission Content Protection |
| DVR | digital video recorder |
| FE | front end (server) |
| ECDH | elliptic curve Diffie-Hellman |
| HDCP | High-Bandwidth Digital Content Protection |
| HDR | high dynamic range (high quality video content format supported by Ultra HD TVs) |
| HSM | hardware security module |
| IETF | Internet Engineering Task Force |
| IoT | Internet of things |
| IPsec | Internet Protocol Security |
| ITU-T | International Telecommunication Union Telecommunication Standardization Sector |
| MAC | media access control |
| MACsec | media access control security (specified by the IEEE 802.1AE-2006 standard) |
| OPUS | Online PKI Update Service |
| Origin Credential | Device credential generated in the factory which requires at least partial transformation and replacement on the OPUS server prior to being provisioned into a target device. |
| OTP | one time programmable |
| PKI | public key infrastructure |
| RFC | request for comments (an IETF standards document) |
| RSA | Rivest-Shamir-Adleman (public key cryptosystem) |
| SDK | software development kit |
| SOC | system on a chip |
| SSL | Secure Sockets Layer |
| Sub-CA | subordinate certificate authority |
| TEE | trusted execution environment (e.g., ARM TrustZone, or a separate security processor/co-processor with its own memory space) |
| TLS | Transport Layer Security (IETF-standardized successor to SSL) |
| X.509 | Standardized format for digital public key certificates. It is published as an ITU-T standard and has a corresponding IETF standard, RFC 5280. |

# 1. Introduction

Digital Access Architecture (DAA) is driving the transformation in next-generation cable-access networks. In contrast, the effective integration of legacy video services and automation deployments can be a daunting, and an often-overlooked task. DAA technology is continually evolving, and these issues apply to many operators facing similar challenges. Creating a solid foundation and adopting DAA technology in stages allows for a scalable video architecture and a *one-touch* approach to deployment, thereby avoiding expensive upgrade costs to customers and infrastructure.

This whitepaper explores Shaw's operational and technical complexities of integrating legacy video into a DAA network and presents the best practices and lessons learned from this undertaking. A robust discussion around functional and automation transformations are covered to prepare operators for large-scale Remote PHY Device (RPD) deployment, modification, and monitoring in an evolving network ecosystem.

# 2. Drivers for Legacy Video Integration into DAA

Shaw believes that DAA is the path forward in upgrading to a robust, resilient, high performance, future-proof, hybrid fibre-coaxial (HFC) network. However, a large install base of legacy customer premise equipment (CPE) exists and needs to be considered. Shaw set out to create an architecture that fully supports in-place capabilities of legacy CPE while still being able to embrace a move to DAA, allowing for upgrading to DAA infrastructure without the added cost of CPE replacement. Furthermore, due to the realities of hub site to node combining, a non-trivial amount of power and space is being expended to the end of manual radio frequency (RF) combining. The ability to reduce entire racks of connected gear to a handful of 1RU switches and dense wavelength division multiplexing (DWDM) hardware could offer significant power, space, and cooling savings. As a result, reducing the requirements for real estate, possibly being able to house an entire hub site in a small fibre cabinet.

While initially researching architectures for legacy Video DAA, we endeavoured to utilize a solution that could re-use as much of the original legacy acquisition, encryption, and out-of-band (OOB) communication hardware. Leveraging as much virtual and Commercial Off-the-Shelf (COTS) hardware as possible to minimize vendor lock-in and maximize flexibility in the event of changing use requirements. Another significant consideration was compatibility with chosen RPHY nodes that were being tested and decided on by other teams. Taking all of these considerations into account, we built the architecture described in this paper.

The evolution of DAA infrastructure has allowed Shaw to utilize the spectrum more efficiently. It has already reduced combining losses at the plant level for installed RPDs by 6dB downstream and 3dB upstream. We have launched our first RPD-only hub site with no video RF combining. Once networking was present on-site, Shaw was able to turn this hub site up and achieve full RPD functionality in a matter of hours, due to the reduced RF combining.

## 3. Principal and Auxiliary Core Overview

When creating the initial architecture, the legacy video architecture was approached with the following three principles:

- Scalability
- Compatibility with current legacy systems
- Difficulty of automation

Having a separate auxiliary core in each region for legacy video services behind a principal core is the solution that most closely meets Shaw's current and future video needs. The auxiliary core is a secondary GCP controller core tasked explicitly with handling video RF and channel map configurations after handoff from principal core. The principal core is a dedicated GCP controller that handles initial configuration and handoff to auxiliary cores as well as all DOCSIS frequency configuration and control. This design's substantial benefit is the Cable Modem Termination System (CMTS), and video can be scaled separately depending on customer and business requirements. In the future, because of the modular architecture, the video auxiliary core can be eliminated once the transition to Internet Protocol television (IPTV) is complete with no impact to the principal core, aside from the removal of a few global settings on the CMTS. The video auxiliary core is lightweight, scalable, and relatively cost-effective compared to utilizing a CMTS video core in each region and affords a more finely tuned automation schema.

## 4. Current State of Legacy Video (Pre-DAA)

Using a headend/hub site architecture has various components distributed across the network. Most of the video components and RF combining happens in hub site facilities, which may have space and power limitations. Linear broadcast services are processed in core sites, i.e., a headend, and then combined in hub sites with narrowcast Video on Demand (VOD) and DOCSIS services to produce the full RF line up. Scaling activities and node splits can increase complexity when combining occurs in the hub site, potentially forcing the need for additional hardware.

An example of Shaw's original legacy hub site architecture is displayed in the following diagram:

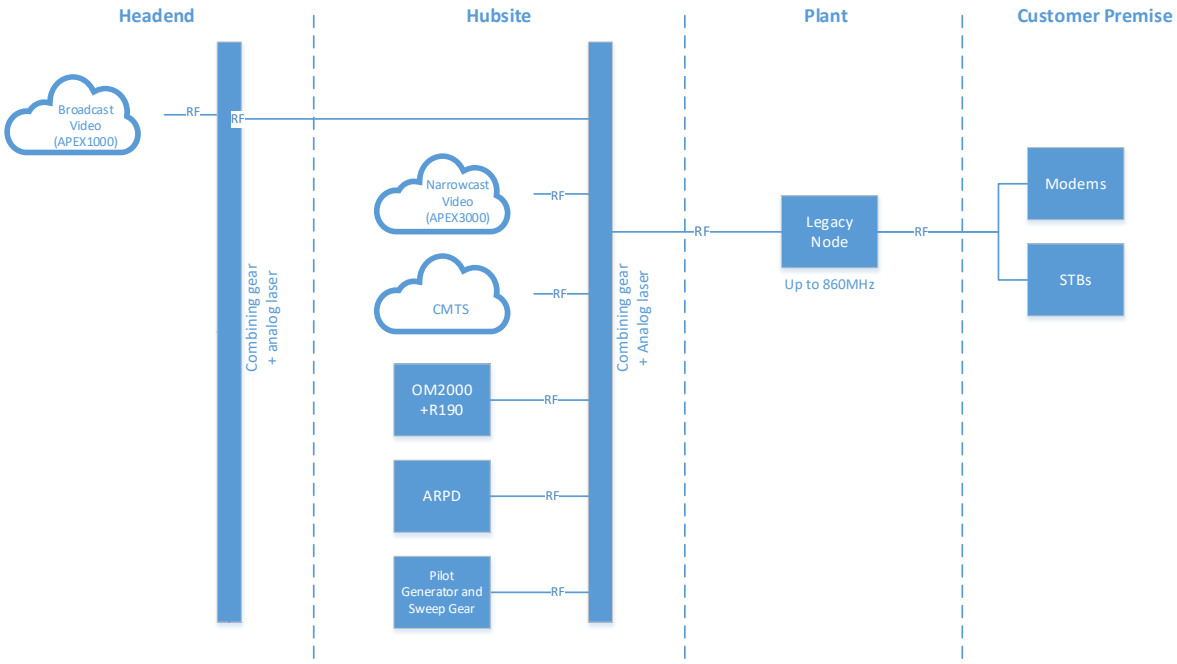

**Figure 1 Legacy Hub Site Video Architecture**

With this engineering, linear video is acquired at various signal acquisition facilities (SAF) and made available to video multiplexers—Digital Content Managers (DCMs) and edge Quadrature Amplitude Modulation (QAM) CommScope APEX1000s. Here it is distributed on Shaw's video wide area network (WAN) over an internet protocol (IP) multicast format.

Once multiplexed into Multi-Program Transport Streams (MPTS), edge QAMs in the headend subscribe to these video multicasts and modulate the signals to video QAM carriers over RF. This broadcast RF spectrum leaving the headend is then transported to attached hub sites, where the broadcast video gets combined with local narrowcast services (VOD), and put on the plant.

# 5. DAA Technology and Components

The DAA video core infrastructure is responsible for the aggregation and encryption of video services, and the configuration of all video, OOB, and SCTE-55 communication for DAA RPDs. In collaboration with CommScope, it was possible to lay a solid foundation for a genuinely scalable DAA video architecture that creates a reliable infrastructure for rapid expansion without incurring technical debt.

Considering the long-term goal of DAA and that DAA requires the same interactive components of a legacy node (RADD [Remote Addressable Danis/DLS Downloader], OM [Out-of-Band Modulator], ARPD [Advanced Return Path Demodulator], etc.), it was decided not to create net-new. Instead, Shaw opted to utilize existing equipment already in the hub site and leverage it in the DAA solution. Each net-new and replacement DAA video node is attached to an already existing and functioning analog node or hub site in a logical manner, therefore, enabling seamless and transparent migration from analog nodes to DAA nodes in the event of a node swap or split, providing the same valued customer experience across the entire footprint.

Housing the non-legacy component of DAA in the data centre, it is possible to reduce a hub site footprint to as small as a single Converged Interconnect Network (CIN) leaf router.

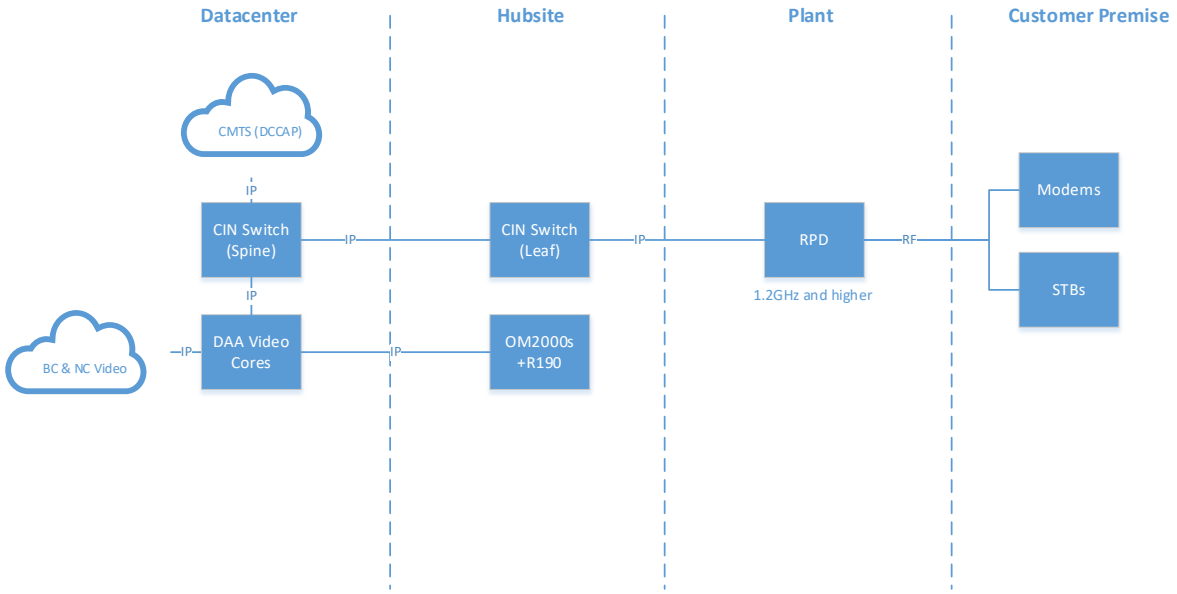

**Figure 2 DAA Data Flow**

## 5.1. VUE Solution

The Video Unified Edge (VUE) provides the network and RF information between the video sources and the RPDs. It is a highly independent scalable solution designed to replace the legacy headend video gear functioning as an auxiliary core for Shaw's DAA environment. VUE is a containerized application which can be used in both bare-metal and virtualized environments.

The following servers establish the VUE:

- Two video platform server (VPS) systems operating on separate virtual machines:
  - VUE Docker repo (VPS#1), and
  - VUE platform services (VPS#2)
- VUE application servers (pipe servers), which operate on bare metal chassis

The two VUE platform servers share the functions of managing and maintaining the VUE environment. VPS#1 deploys and controls the entire VUE OS/Docker solution and performs upgrades and maintenance. VPS#2 is responsible for the Generic Configuration Protocol (GCP) communication to the RPD through the Auxiliary Core Control Plane (ACCP) sub-system, which is in a dedicated Docker container. Because this system communicates directly with RPDs, this sub-system requires connectivity to the CIN in addition to a connection to our management network.

VUE application servers (VUE pipe servers) are responsible for the creation of Downstream External PHY Interface (DEPI) and Upstream External PHY Interface (UEPI) streams. These streams carry interactive and video MPTS multicast traffic to the RPD. In Shaw's infrastructure, each pipe on the VUE pipe server is in its own Docker container and carries a single 38.8Mbit MPTS.

Internal communication between all CommScope VUE servers (applications server and VUE platform servers) use either Secure Shell (SSH) or Application Program Interface (API) over our Operations Administration Maintenance and Provisioning (OAMP) network.

The following image displays the rack elevations for the DAA infrastructure. Each network encryptor (NE) blade on an APEX 3000-NE can output approximately 6.5G of traffic, allowing Shaw to build 42 service groups per VOD COR – a VUE pipe server designated for narrowcast, at four Annex B MPTS per service group. Annex B is a cable standard that modulates a MPEG-TS input into a QAM-256 output. Each service group is assigned four VOD carriers and four RPD nodes initially. This number can be scaled up and down to dynamically meet fluctuating capacity demands utilizing our back office and automation tools.

Each DAA rack with seven VOD pipe servers can feed 1176 DAA nodes with no physical combining involved. With the second rack added, a total of 3,528 nodes can be fed.

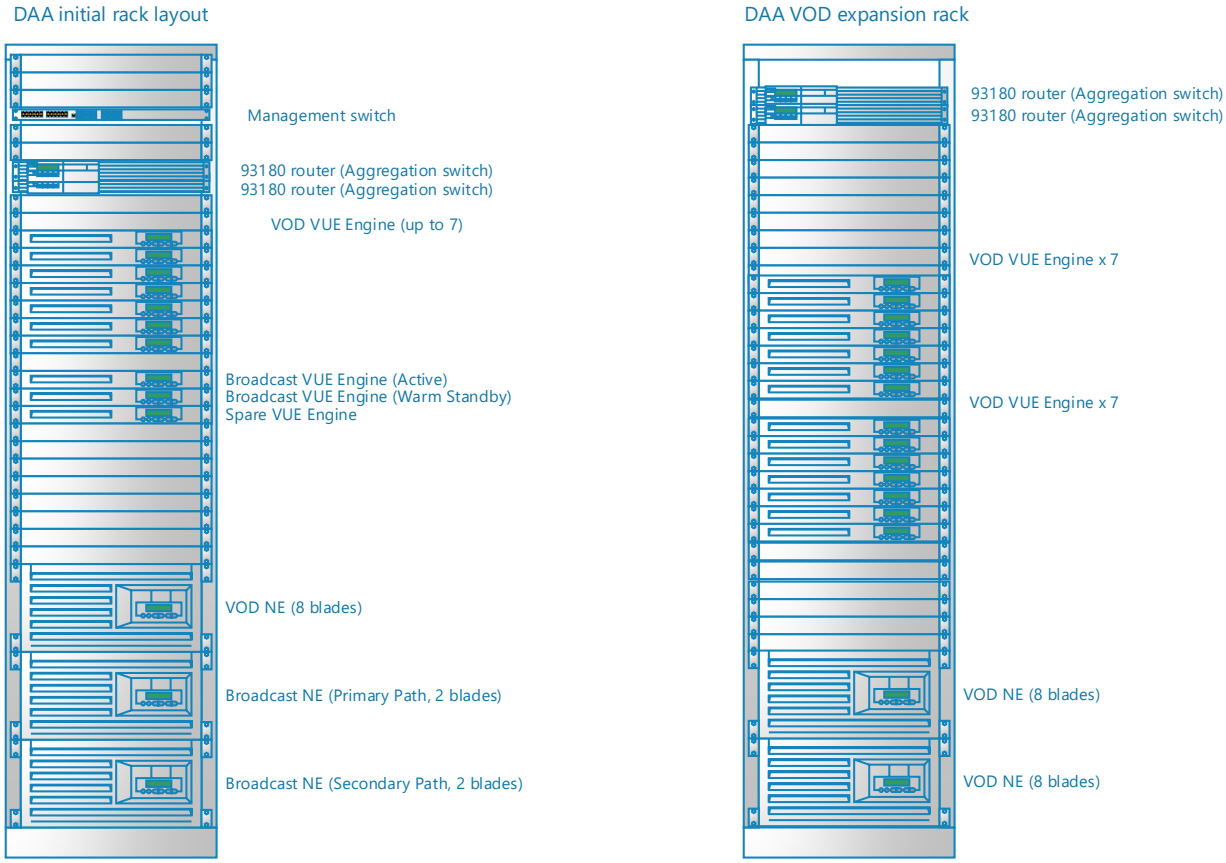

**Figure 3 Shaw DAA Rack Layout**

## 5.2. APEX 3000-NE

The APEX 3000-NE device is a high-density network encryptor capable of supporting and ingesting 12,288 unique program identifications (PIDs); up to 4096 multicast streams. It can support Single Program Transport Streams (SPTS) for VOD and MPTS for broadcast services. The APEX 3000-NE egresses encrypted traffic on the same physical port that it ingests unencrypted traffic, allowing for a denser installation requiring fewer physical switchports.

Features:

- Eight blades configured in an N+1 model
- 12 total 10GigE interfaces where four interfaces are the back up for the first eight interfaces
- Redundant host modules
- Redundant power supplies
- Support for User Datagram Protocol (UDP) port mapped VOD and includes support for Real Time Streaming Protocol (RTSP) provisioned VOD services
- Performs broadcast and SDV encryption
- Supports PSI generation and message insertion
- Support for SCTE-52 encryption for broadcast and VOD through Common Tier Encryption (CTE)

## 5.3. Video Topology Manager

The Video Topology Manager (VTM) is a software-defined management solution that configures and manages the video configurations in DAA. Service groups with specific settings are created in VTM for each of the video services offered and then assigned to applicable RPDs. Additionally, VTM interfaces with the Digital Addressable Controller (DAC) and receives all channel information for the region. This related information defines service group information for the RPDs configured by the regional ACCP sub-system.

A single instance of VTM can administer the entire DAA topology. Aside from using VTM to automate, this solution can also build serving groups and modify channel maps. In the future, there will be an option to use VTM as a dashboard that enables granular troubleshooting on a per RPD basis country wide.

## 5.4. Legacy SCTE55-1 Interactive Signaling

### *5.4.1. Virtual ARPD*

For interactive traffic, the Advanced Return Path Demodulator (ARPD) functionality is on the RPD. RF streams are demodulated and encapsulated using the Remote Upstream External PHY Interface (R-UEPI) standard and routed to the broadcast application server (VUE pipe server). The application server identifies the upstream traffic by the Layer Two Tunnelling Protocol (L2TP) *sessionID* and *varpdSourceid*, then routes this data to the correct port on a legacy Network Controller (NC-1500). Each Virtual Advanced Return Path Demodulator (vARPD) – one per hub site, is its own logical entity in the DAC. It is configured identically to a physical ARPD on both the legacy Network Controller and the DAC.

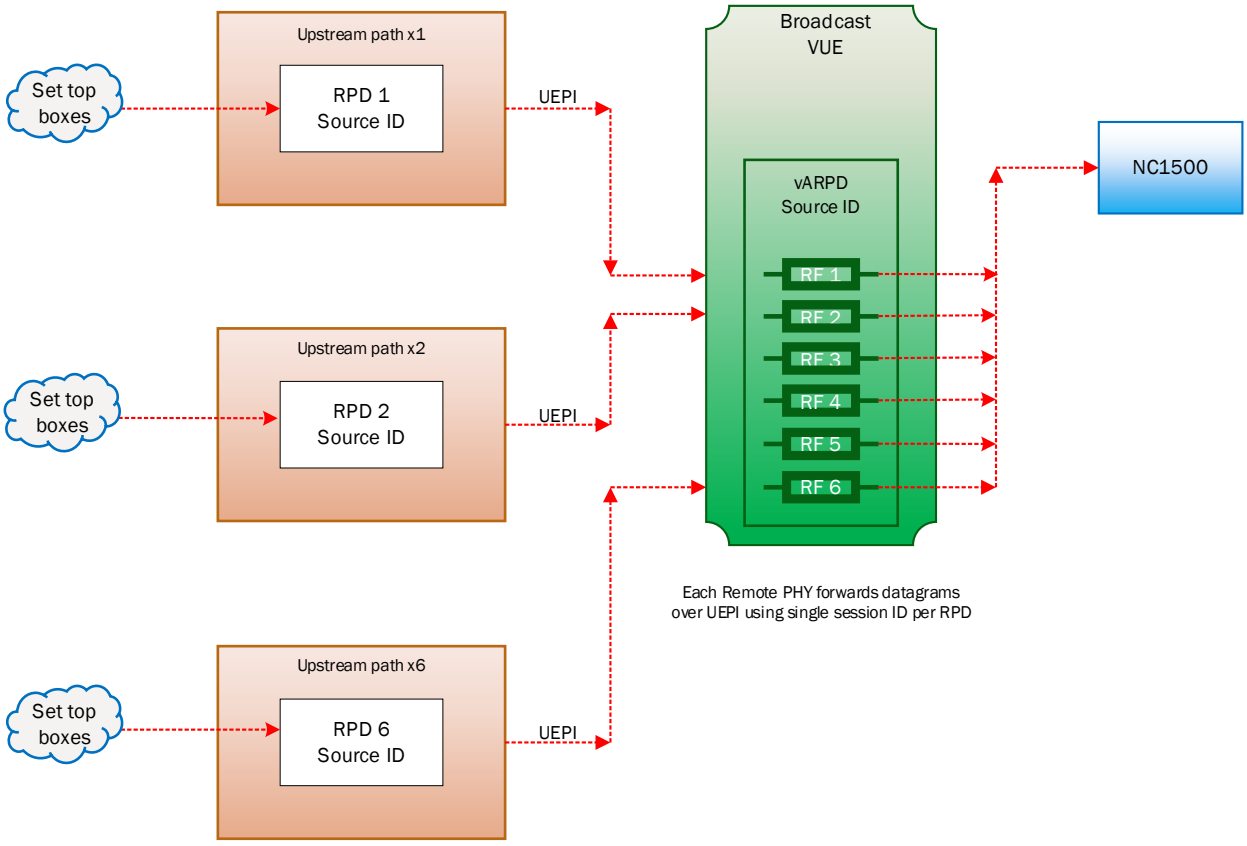

**Figure 4 RPD and vARPD Relationships**

### *5.4.2. Out-of-Band Modulator*

Downstream OOB data is still handled by an existing OM2000 located in each hub site. The out-of-band modulator (OM) sends forward data streams containing guide data, code modules, channel map information, Emergency Alert System (EAS) messaging, DAC messaging, and app network data.

On the legacy OM2000, an IP interface is enabled pointing at the VUE application server (VUE pipe server) over the OAMP network. The OM2000 communicates with the VUE application server utilizing unicast UDP IPv4 traffic. The OM2000 packs seven, 188-byte MPEG packets into a single 1,500-byte packet and forwards to the VUE pipe server's IPv4 OAMP interface on a unique port. Each hub site OM's communication port was configured in an exclusive range per DAA region. For example, the UDP port range 4000-4100 is the Calgary region and port 4001 is specified for a particular hub site within that region and is not re-used; keeping the ports separate provides teams to discover and identify problems quickly.

### 5.4.3. NC1500

The NC1500 is a network controller that functions the same as it does in the legacy network; it works as both a DHCP server and a router which assigns IP addresses and routes upstream messages between nodes and RADDs. To complete configuration, the NC requires an IP address for each vARPD; therefore a virtual IP address is created and reserved in the Internet Protocol Access Management (IPAM) system and inserted into the NC configuration. The vARPD IP is a placeholder and not reachable on Shaw's OAMP network, so ping checks to these IP's will fail from the NC1500. Other upstream connectivity tests such as DAC refreshes are utilized instead of ping checks to verify return path functionality during troubleshooting.

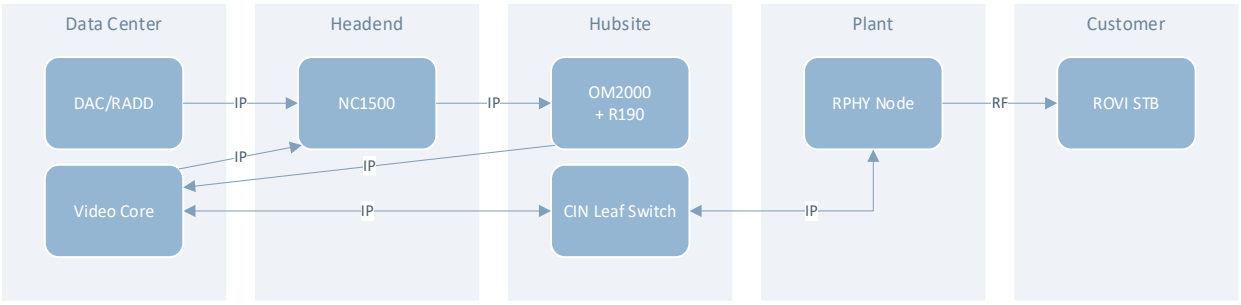

**Figure 5 DAA Interactive Network (Physical Locations)**

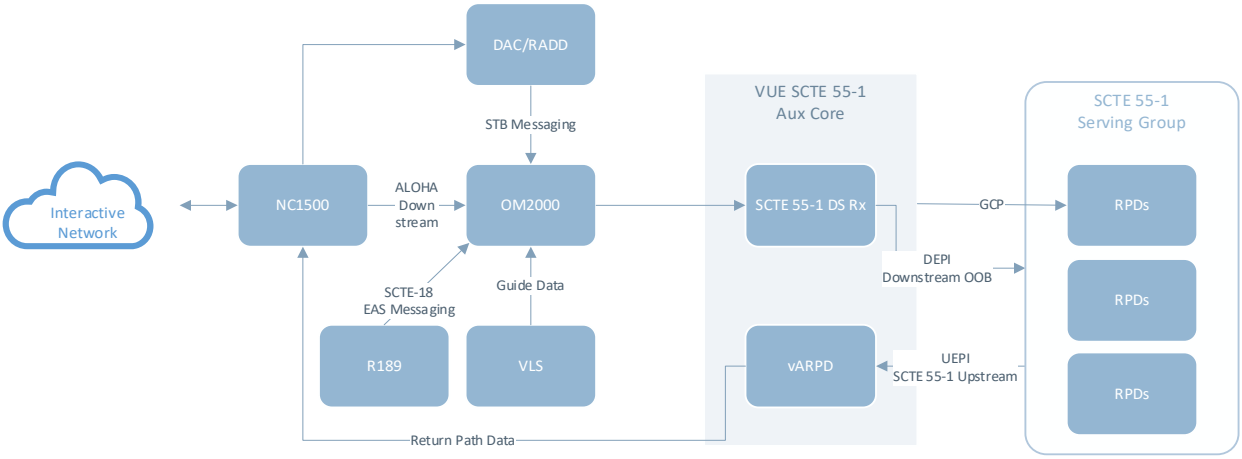

**Figure 6 DAA Work Flow**

## 5.5. DSG SCTE55-1 Interactive Signaling

For the DOCSIS set-top gateway (DSG) boxes, new DAA Converged Cable Access Platform (CCAP) cores have been deployed for their provisioning and control traffic. Targeting these tunnels is done at the Media Access Control (MAC) level and are configured using the existing Conditional Access (CA1 and CA2) and EAS SCTE-18 multicast streams the legacy DSG boxes already use.

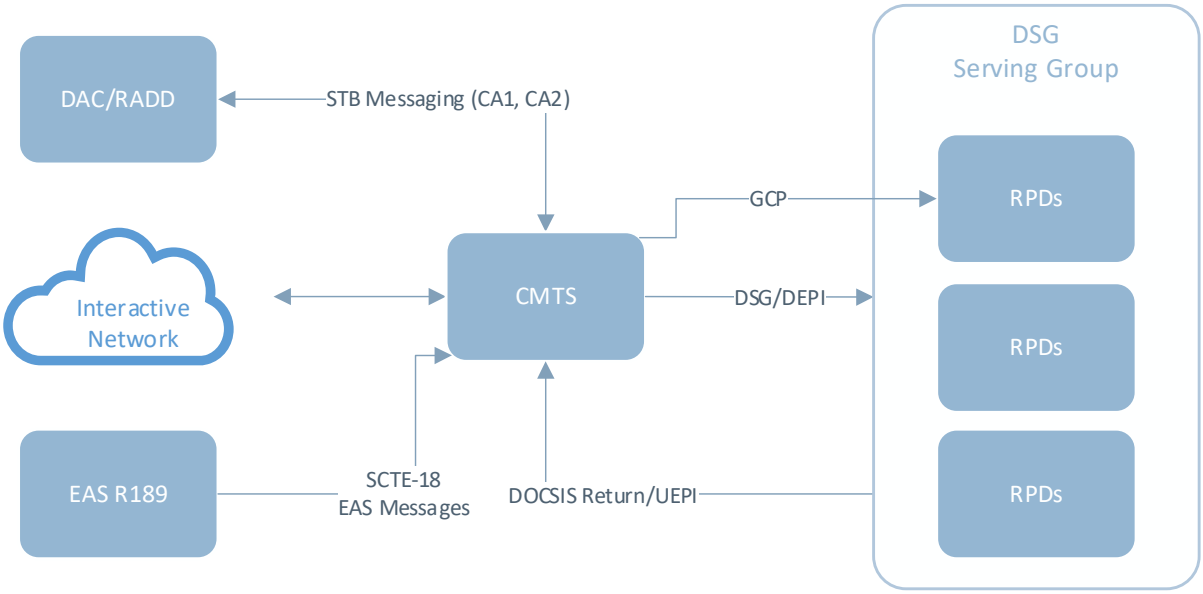

**Figure 7 DSG Interactive and Data Flow Traffic**

## 5.6. Converged Interconnect Network

CIN is a critical network that provides a redundant, highly available, scalable, and agile network solution for DAA and other Shaw services.

The CIN network leverages a spine-leaf architecture enabling a scalable DAA delivery. The spine (deployed in headend/data centres) typically has 100G interfaces and aims to maximize the fibre segments' throughput. The leaf is deployed to hub sites and aggregates traffic for multiple RPDs. All traffic carried on the CIN network is IPv6.

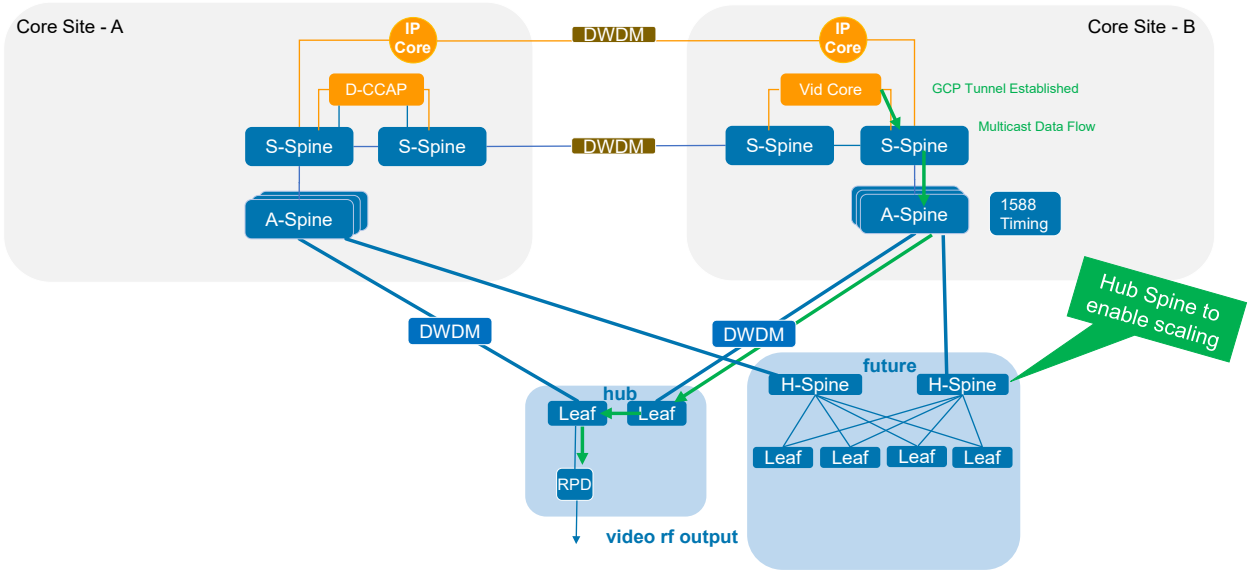

**Figure 8 CIN Network**

## 5.7. Timing

Shaw's DAA architecture utilizes the Precision Time Protocol (PTP), also referred to as IEEE-1588. The PTP protocol provides a method to synchronize all the devices connected to the CIN. PTP minimizes network jitter and synchronizes packet delivery across the CIN network. This is important because in current architectures, the DEPI pipes and RPDs have minimal jitter buffer. The principal core, the pipe servers, the RPDs, and any additional auxiliary cores are configured and synced to a PTP server. As with all other traffic on the CIN network, PTP is utilizing IPv6 addressing.

In Shaw's DAA design, the PTP master clock chassis syncs to the Global Positioning System (GPS) using a roof-mounted antenna, which synchronizes the two clocks deployed in each DAA region. These clocks are configured hot/hot to achieve necessary resiliency.

Currently, PTP clocks have a maximum allowance of 500 clients per clock or 1,000 clients per master clock chassis. In the future, Shaw will be transitioning to a boundary clock architecture where each RPD is assigned a more local boundary clock that syncs back to the PTP master chassis and presents itself as a PTP peer. This boundary clock architecture will allow Shaw to grow exponentially without utilizing dozens of PTP master clocks.

## 5.8. Remote PHY Device

The Remote PHY Devices (RPDs) replace traditional HFC nodes and assume the functionality of the edge QAMs in today's architecture. They have a network interface fed by fibre northbound, and RF interfaces southbound towards customer premises. The initiation sequence is described in the automation section 14. RPD Provisioning and Activation Process Through Automation.

# 6. DAA Monitoring Solution

To achieve an accurate monitoring solution, it was deemed necessary to install probes as close to the edge as possible. This accomplished two goals – end-to-end network verification and quality assurance for customer video feeds. There are probes in each region, with multiple probes in our largest region Vancouver. The probes installed in hub sites are on the same leaf routers that the RPDs are and acquire the same DEPI encapsulated multicast. The probes decapsulate multicast DEPI and then analyze the MPEG streams utilizing industry-standard methods. Shaw can currently monitor the entire broadcast channel lineup at multiple sites in real-time and trap any errors to a central dashboard. If bandwidth and licensing are concerns, narrowcast and OOB streams can be verified on an on-demand basis.

Because of DAAs regional and multicast architecture, the number of probes required can be minimized yet still maintain a high level of confidence in video quality to customers. An incumbent vendor has already integrated into the operational team's dashboard solution, so new probe outputs were added directly into an existing view. The Operations team required no further training on the monitoring solution because the probes present video quality metrics identical to the legacy MPEG probes.

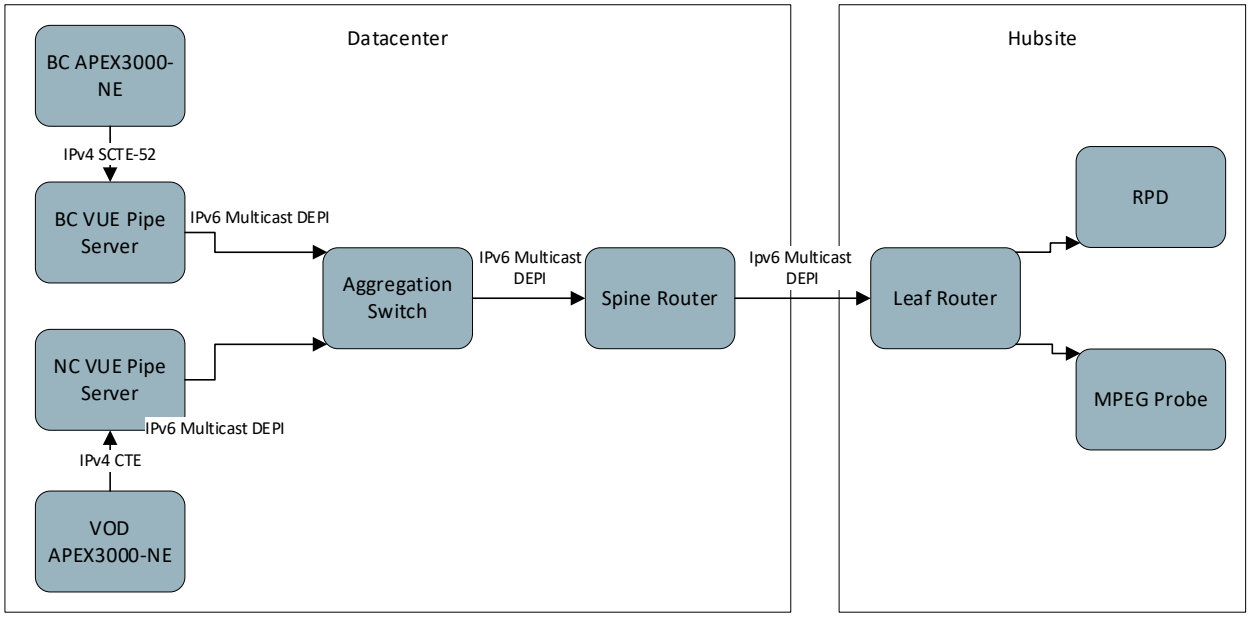

**Figure 9 DAA Monitoring Architecture**

# 7. Video and VOD Encryption

Shaw's conditional access system, the CommScope DAC, was initially configured to encrypt video services using DigiCipher II (DCII) – a CommScope proprietary encryption standard. As part of the DAA/auxiliary core project, Shaw migrated from this proprietary standard to the more open and industry-accepted alternative SCTE-52 (DVS-042). The conversion to SCTE-52 has allowed Shaw to deploy headend devices made by vendors who are not capable of licensing or using the CommScope DCII scheme.

As a sub-category of this process, all the VOD devices in production were converted to the new SCTE-52 encryption schema.

# 8. Video Broadcast Acquisition Architecture

Within Shaw, broadcast video delivery, encoding, multiplexing, and transport over the video backbone network have not changed for the DAA video solution. Instead of edge QAMs doing the encryption in the headend/data centres, video streams are encrypted by an APEX3000-NE. The NE is a product offered by CommScope based on the APEX3000 hardware with a bulk network encryptor license. Once the NE license is applied, it disables the RF ports on the chassis, receives the transport streams over IP, encrypts, and outputs over IP.

Two APEX 3000-NEs were installed at each DAA region to provide full chassis redundancy. Currently, the APEX 3000-NE cannot switch between streams. Therefore, it is impossible to utilize a single APEX 3000-NE for both primary (red) and backup (blue) broadcast video paths. Each APEX 3000-NE is connected to the primary and secondary video network. Both APEX 3000-NEs have two interfaces connected to an aggregation switch to provide link redundancy. Encrypted data streams from the APEX 3000-NEs are aggregated by the VUE pipe server, which evaluates the quality of incoming streams utilizing TR 101 290 and packet counters—in turn, selecting the best copy. The pipe server encapsulates the encrypted MPEG streams into DEPI (L2TP) tunnels.

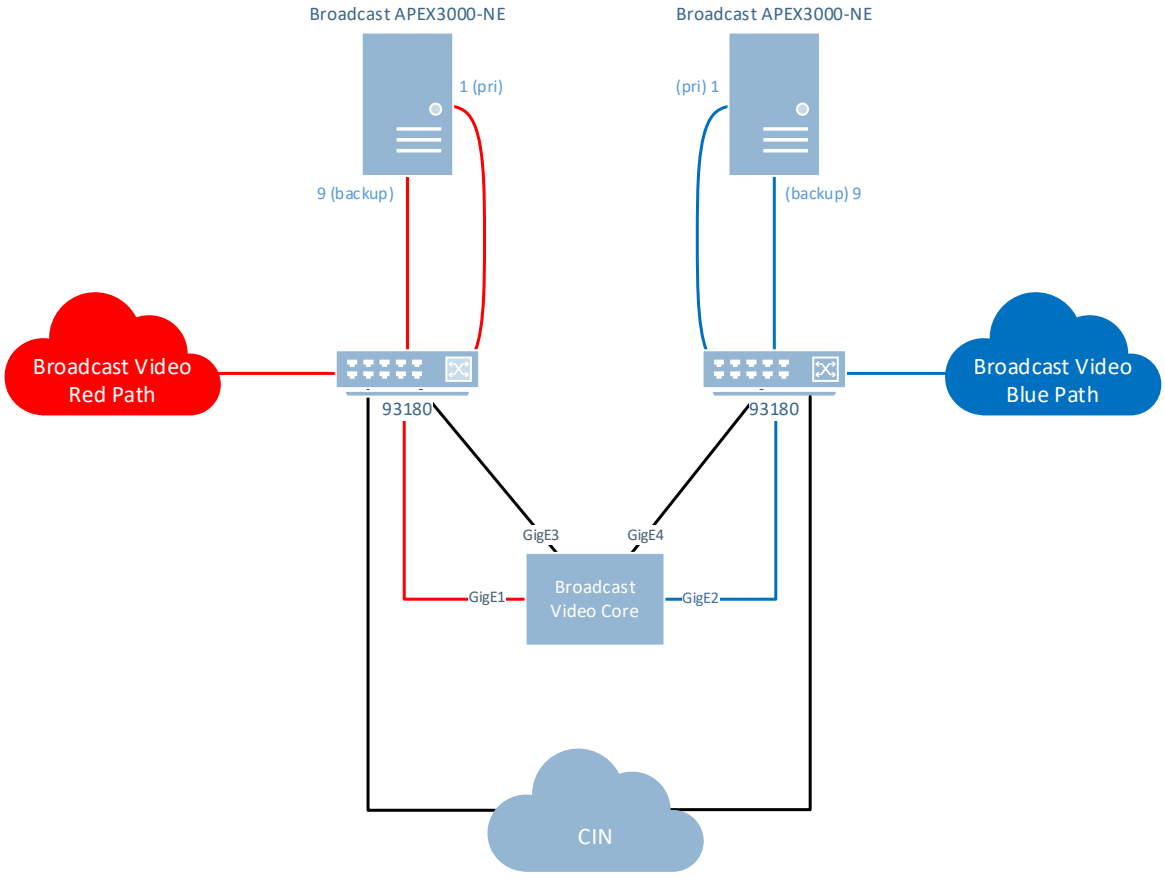

**Figure 10 Broadcast APEX 3000-NE Data Centre Network Configuration**

# 9. Narrowcast Architecture

Video-on-Demand (VOD) is delivered using previously existing VOD pumps that are now consolidated and centralized in the data centres in the three main regions – Calgary, Edmonton, and Vancouver. Shaw's narrowcast architecture is based on UDP mappings, whereby each RF QAM carrier is assigned a UDP port that has 21 programs (PIDs) attached to it. Program numbers 1-10 are for standard content, while programs 12 -21 are for adult content.

Currently, each QAM carrier has a unique Transport Stream Identifier (TSID) tied to it, and program 11 on each of the UDP ports is reserved for a Barker Channel embedded with TSID. This PID has been reserved in the VUE core and is automatically assigned to any port on the output UDP mappings.

A region unique TSID exists for every VOD carrier, on every VOD service group. When a VOD session begins, VOD back office (referred to as Edge Resource Manager (ERM)) maps the customer to a VOD encryptor, and calculates the next available UDP port. ERM then initiates a stream from the video server (VOD pump) to the VOD encryptor and VUE. The VOD back-office forces the STB to tune to the carrier and MPEG number mapped to the UDP port. If there is a TSID mismatch, ERM will attempt to tear down this first session and regenerate it to the correct location. This is referred to as TSID auto-correction. TSID auto-correction occurs if there is a billing system or VOD back-office configuration issue, or a physical wiring issue in the hub site. ERM is responsible for monitoring the bandwidth of the devices to ensure a VOD session can be established.

VOD encryption is also handled by APEX 3000-NE devices configured for full encryption. Each STB is authorized and entitled for VOD through our billing systems, the APEX3000-NE contains this package. Encryption is SCTE-52 and key distribution happens via the controller (DAC). The redundancy features for the APEX 3000 NE do not change from its legacy predecessor APEX 3000. No chassis redundancy has been implemented for VOD in DAA, as this mirrors currently existing VOD infrastructure on the legacy network.

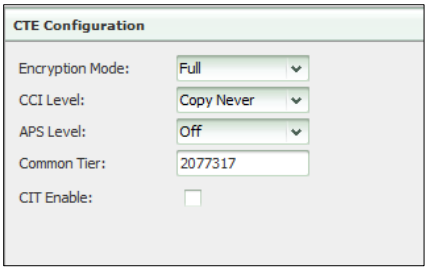

**Figure 11 NE GUI Showing VOD Encryption**

In the DAA architecture, each blade on the APEX 3000-NE is a one-to-one mapping with a VOD COR. Service groups in DAA are software-defined, and VOD sessions are streamed out over multicast. All RPD's under one single service group will subscribe to the same multicast.

A total of four interfaces are required, two each on the NE blade and VOD COR, respectively. To standardize and simplify our operations, all the four IPs selected are in the same IPv4 subnet. The output of the VOD COR propagates through the CIN network:

- Traffic interface on NE
- Virtual interface on NE
- Traffic interface on VOD COR
- Virtual interface on VOD COR

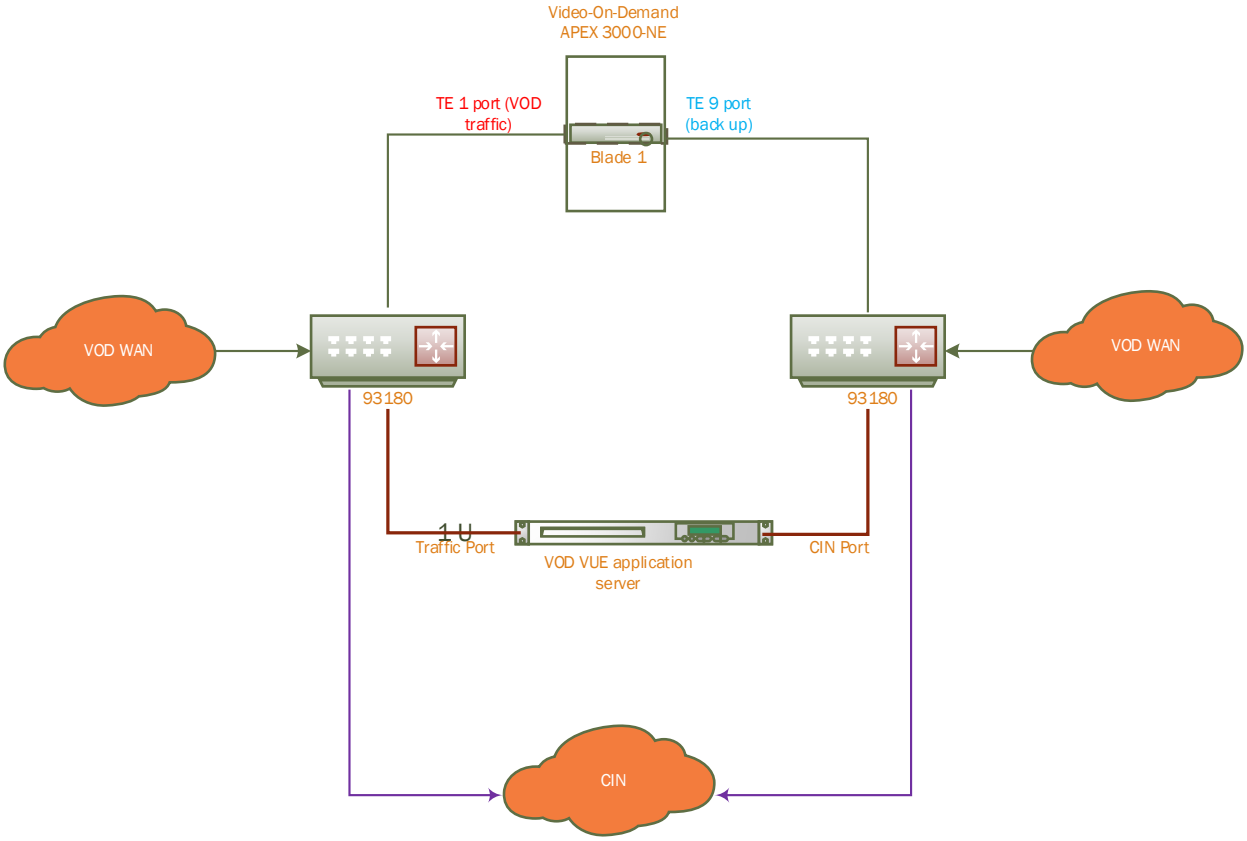

**Figure 12 Narrowcast Architecture of the APEX 3000-NE Blade and VUE Configuration**

# 10. IPv6 Addessing Standards

During the architecture process, it was decided to utilize strictly IPv6 for all addressing. This provided us with the room to logically and sustainably address RPD, cores, and pipe servers in a manner that would enable us to keep them logically separate from a regional and city perspective while also allowing for ample room for addressing. We feel that because of the number of addresses at our disposal, having separate hextets for cities and regions ease troubleshooting in the case of problems and allow the ability to be very specific when configuring network routing, assisting with keeping our network secure.

When choosing multicast addresses, a similar schema was used. Easily identifiable addresses outline OOB, local broadcast, system broadcast, and VOD just by looking at the address, while still giving us ample room to expand to as many different types of multicast as required—with no addressing space constraints.

# 11. Multicast, DEPI, and SessionID Relationships with Physical Frequencies on the RPD

RPDs assign physical frequencies directly based on the L2TP *sessionID* that DEPI tunnels deliver. In a broadcast video scenario, MPTS sessions are muxed into a DEPI (L2TP) tunnel and given the *sessionID* that points to the physical frequency that the MPTS is reconstituted onto. In our solution, *sessionID* is calculated as shown below:

```
session ID = baseMulticastSessionId + freqInMHz / 2
```

In our infrastructure, the *baseMulticastSessionId* is 0x80002000 in hex, or the integer 2147491840.

The following example calculation is utilized to determine the *sessionID* for 195 MHz in the main ACCP configuration file:

```
"channelType": "DsScQam",
"frequency": 195000000,
"multicastIp": "ff35:c531::daa:8123:1",
"tsId": 0,
"modulationType": "Qam256",
"interleaverDepth": "I128-J4",
"powerAdjust": 0
```

**freqInMHz** – 195

**sessionID** – 195 / 2 = 97

**chanObj.sessionID** – 2147491840 + 97 = 2147491937 or 0x80002061 in hex

The RPD receives the L2TP *sessionID* and reconstitutes it to 195 MHz on the plant.

Shaw has approximately 48 broadcast MPTS, and current RPD specifications only allow for 16 multicast streams. To streamline and facilitate a common architecture in all the DAA fed regions, Shaw has opted to create two unique broadcast service groups, each assigned a new multicast IPv6 address. These service groups are referred to as system and local. The system service group carries the channels common across the region, while the local service group carries channels specific to the city fed by the remote PHY nodes.

Future utilization of simultaneous substitution (simsub) content may be required (currently part of the local lineup), into a different multicast group. This schema remains within the RPDs 16 multicast session limit and allows for growth in the future.

## 12. Regional Video Realities and Solutions

Unfortunately, the method in which Shaw rolled out plant infrastructure via acquisitions and net-new builds did not adhere to any physical frequency standard regarding the transport stream to the Electronic Industries Alliance (EIA) channel. Physical frequencies are created on the RPD; therefore, the two solutions that came forth were to either significantly increase the broadcast auxiliary core hardware and network capacity or align all the hub sites to a single physical frequency/MPTS map.

Currently, Shaw is working on aligning system transport streams (TS)/physical channels across all regional markets. Once standardization is achieved, Shaw can carry non-simsub channels using a single multicast stream, utilizing one or more secondary MPTS DEPI feeds for any simsub and local content on a per-market basis. This process will save substantial traffic across the CIN network, and a non-trivial amount of server chassis as the bulk of our video traffic is not simsub.

Due to the distance and jitter limitations of DEPI, smaller micro-cores were designed to feed smaller regional sites that are otherwise outside of the regional pipe server footprint. As long as a hub site has routes to the RED/BLUE video WAN, a single APEX-3000 NE with four raptor blades can be utilized, and three initial VUE pipe servers to feed DEPI narrowcast and broadcast to customers supplied in that remote market. This maintains GCP signalling from the regional data centres as GCP is not latency and jitter sensitive, thereby alleviating any distance concerns for DEPI video. This also reduces traffic heading across the backbone between markets and services surrounding areas with DAA without building an entirely new full-scale DAA core.

## 13. Shaw Automation Strategy

Manually provisioning video services is time-consuming, error-prone, and a repetitive process. Shaw designed the DAA provisioning system with many small, discrete systems to handle specific tasks, rather than large systems that perform many tasks. This is a significant change from many of our past designs. Each domain (e.g. video, CCAP, CIN, DHCP) manages their provisioning components, and these systems primarily use HTTP/Representational State Transfer (REST) and SOAP as a means of communication.

Video automation has fulfilled the long-term objectives to:

1. Deploy data-and-software-driven automation to support legacy video services via RPDs.
2. Enable Shaw to deploy RPDs rapidly to meet our capacity needs to continue to offer excellent service to our customers.
3. Provide a framework that can be used to automate other CCAP components as part of any node change.

Shaw uses an in-house video automation system named VADR (Video Activation of DAA RPDs). VADR is a new system that handles the video provisioning and de-provisioning requests from Service Director (SD). Additionally, VADR supports a VOD dashboard, that assigns and re-allocates VOD service groups dynamically for RPD's depending upon their usage and the total number of nodes attached to them.

Due to the nature of DAA, multiple tools had to be either created or adapted to be functional in an RPD environment. Presently, VADR interacts with the following systems in the Shaw network to provision a node successfully. Each of these systems is either net-new or are modified to function with VADR:

- Service Director (SD)
- Resource Inventory (RI)
- VOD Central Database (CDB)
- Video Topology Manager (VTM)

## 13.1. Service Director

Service Director (SD) is a system that performs provisioning and de-provisioning of the Remote PHY Devices (RPDs). It interfaces with multiple network elements and Operations Support Systems (OSS) to complete the provisioning and de-provisioning processes.

The following two items are the OSS network elements that SD interacts with to extract information and passes to the VADR for RPD provisioning.

- **Asset Inventory System (ERP)**: This system provides the SD with the MAC address, serial numbers, and other RPD device-related information. SD uses the REST interface to query the ERP database for RPD parameters.
- **Resource Inventory (RI)**: Details the CIN, RPDs provisioned, and other information such as IPv6 prefixes on the network.

SD interacts with multiple network provisioning elements, using the OSS components mentioned above to activate the RPD:

- **BEANS** – Automated provisioning system used to configure distributed CCAP (D-CCAP).
- **CIN (NETCONF)** – Protocol used to interact with leaf routers (hub sites), aggregation spines (headends), and super spines (data centres).
- **DHCP/FLEXO** – Automation tool used to assign IPv6 addresses to the RPDs. The SD interacts with FLEXO using the REST interface.
- **VADR/VUE** – Composes the RPDs for video configuration by receiving the provisioning and de-provisioning requests from the SD. Interaction with VADR is enabled utilizing REST calls.

The following diagram displays the SD DAA interactive map showing its interaction with multiple OSS and network elements:

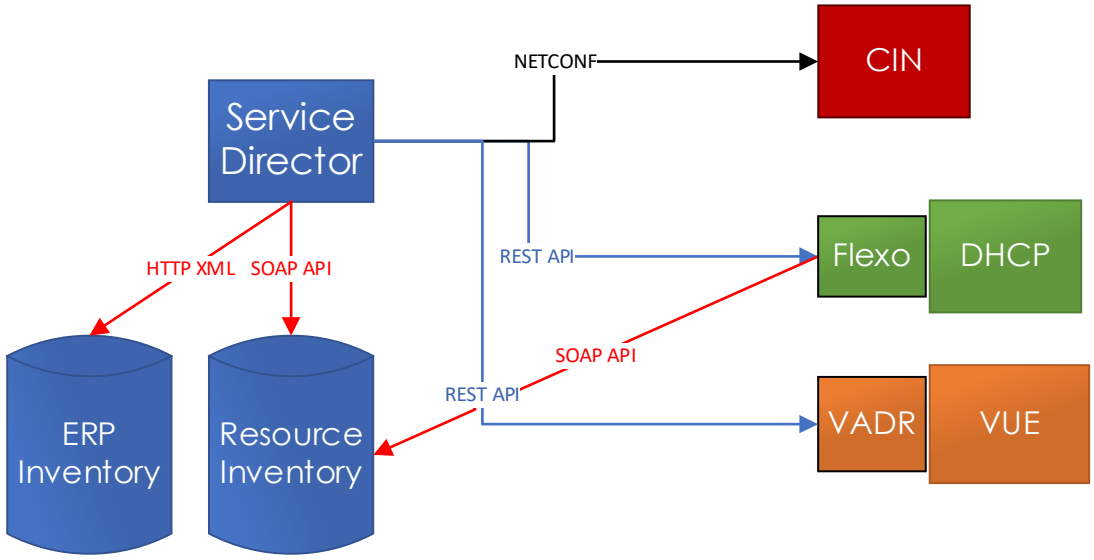

**Figure 13 SD DAA Interactive Map**

## 13.2. Resource Inventory

Resource Inventory (RI) provides information about the broadcast and OOB service groups. Currently, in RI, each region is classified as a Regional Video Centre (RVC), which encompasses the region's global configurations. Each hub site under these RVC's is assigned a local and OOB service group depending upon the simsub requirements for the hub site. In Shaw's case, due to the possibility that a hub site may have a different local serving group configuration, we have enabled RI to overwrite RVC configurations with hub site configurations if a hub site configuration exists. Otherwise, the RVC configuration is passed to the RPD.

As Shaw improves the automation processes further, RI will be configured to be the source of truth for VOD COR and APEX 3000-NE configurations for VADR.

## 13.3. VOD Central Database

The VOD Central Database (CDB) is one of the critical elements of the ERM infrastructure that assigns the RPDs to a specific VOD service group and its associated multicast based on the information received from VADR. It is the central location that keeps track of and assigns return paths to each new RPD that is activated in the field.

The VOD CDB is also responsible for creating and adding VOD APEX 3000-NE blades into the VOD database tables and its correlating VOD COR.

### 13.4. Automating the Video Topology Manager

VTM is a control plane and RPD configuration system that presents a standardized API into the VUE infrastructure. Shaw uses VTM to create and modify broadcast and narrowcast serving groups, administer RPDs, and monitor and modify regional VUE solutions.

VADR communicates with VTM to configure RPDs for video. VADR collects and interprets data from SD, RI, and VOD CDB then proceeds to set configurations utilizing the VTM API. During configuration, VADR adds the RPD with the proper MAC address and relevant serving group information into VTM. VTM then takes this information and configures the VUE ACCP server itself. This allows for a highly flexible and scalable single configuration endpoint allowing for ease of troubleshooting and administration over multiple regions and a large amount of RPDs.

## 14. RPD Provisioning and Activation Process Through Automation

Due to Shaw's efforts with automation and RI, once the hub site parameters are configured into the RI and CDB systems, the bulk of RPD configuration happens seamlessly at activation.

The following steps describe an RPD node turnup:

1. A technician arrives at a location and begins wiring the node physically.
2. The technician provides the MAC address of the RPD to the implementation team.
3. The Implementation team kicks off the SD provisioning process, which bridges each of the following services, provisioning and activating the RPD on the fly:
    - BEANS configures the principal core
    - SDs NETCONF service provisions the CIN devices
    - VADR sets the auxiliary video core via VTM
4. At this point, the RPD is considered provisioned. On completion of the physical wiring, the technician can power up the RPD.

When an RPD is first connected and powered up, it receives IP addressing information and the address of the principal core through Dynamic Host Control Protocol (DHCP). Once the communication with D-CCAP is initiated, it will receive the following configuration data from the device:

- A command to enable its PTP service.
- Network information on how to locate a PTP server.
- DEPI/UEPI and RF information (frequency, modulation, etc.), for the enablement of DOCSIS carriers.
- The address(es) of auxiliary core(s).

One of the auxiliary cores is the VUE auxiliary core. The RPD will send a startup-notification containing the RPDs MAC address to the auxiliary core, which will send the video DEPI and UEPI configuration for the RPD based upon the configuration the ACCP controller received from VTM. After the initial setup is complete, then the RPD will attempt sync with the PTP server.

The ACCP controller (VUE controller) requests a PTP sync status from the RPD after configuring all the channels and pseudowires. Once the RPD notifies VUE that PTP sync status is true, VUE then activates the previously configured channels by setting RF Mute to *Disable*, and the Admin state to *Up*. After activating all channels, VUE sets the RPD state to *Operational*. If the RPD has not yet achieved PTP sync, the channels being configured are set up in an RF Mute state, and the Admin state is set to *Down*.

If the VTM later updates channels on the RPD, the RPD has achieved PTP sync, and has been made operational, VUE will set up these channels with all of the configuration parameters; RF Mute state to *False*, and Admin state to *Up*, all at the same time.

Once the PTP sync message is successfully forwarded to the auxiliary core, all configured video RF channels are unmuted.

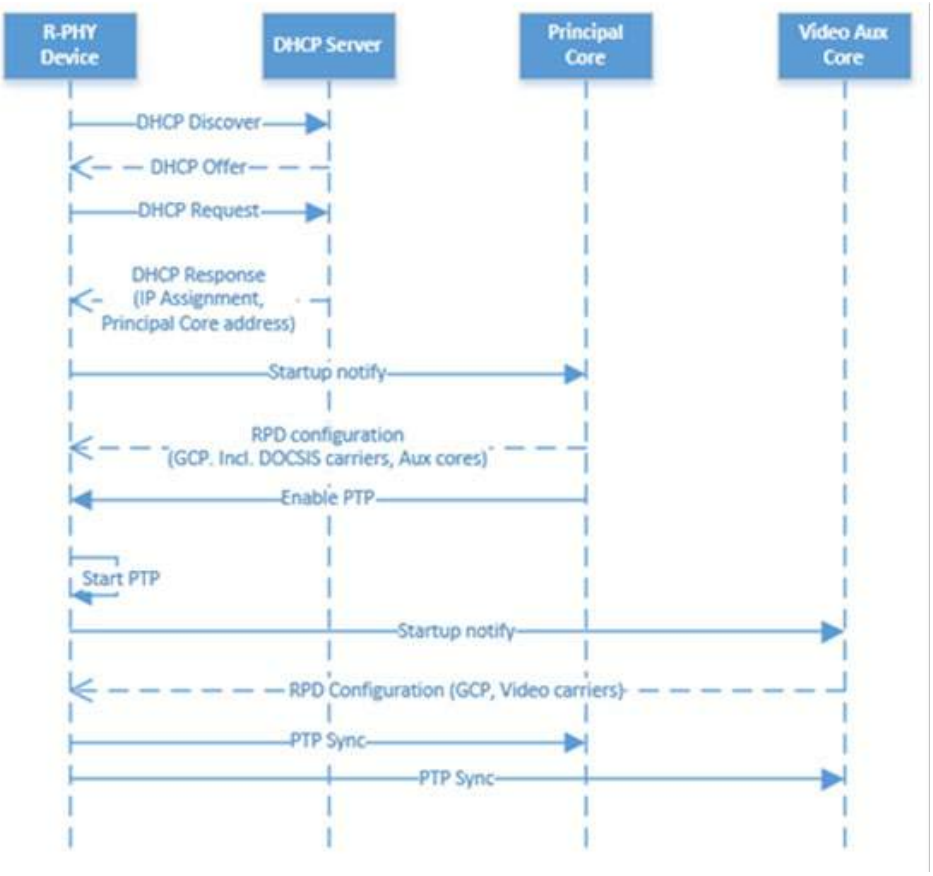

**Figure 14 Activation Sequence Diagram During the RPD Activation Process**

# 15. Lessons Learned

Architecting and integrating DAA with legacy video is a challenging task, and as an organization, many lessons were learned in architecting this solution.

During the architecture planning process, it was decided to utilize IPv6 for all RPD addressing. This enabled efficient use of the address space for RPD's, CIN network, and auxiliary core on a per region and hub site level while also allowing ample room for scaling out our DAA infrastructure. The sheer amount of IPv6 addresses has empowered us to have separate hextets for our regional video cores, which ease and assist with troubleshooting our network during outages. With the flexibility that IPv6 multicast addressing offers us, we decided to choose an addressing scheme that quickly identifies our out of band (SCTE-55), local, system and VOD service groups just by looking at the addresses.

We underestimated the bandwidth and multicast requirements required to service a footprint that had hundreds of unique TS/EIA frequency variants between each of our markets. Even though our channel maps reflected the same virtual channels between respective markets, this did not necessarily mean that the virtual channels resided on the same physical frequency. To be as economical as possible, we decided to align all of our TS/EIA schemas region-wide, in each region. This cut down on the duplicate multicast and the number of servers required to serve the duplicate multicast to separate markets, where the only difference is what EIA frequency the service resides on.

Early in our design phase, we came across specific markets built in a way that made sense at the time; however, as business needs or the market changed, the design and buildout of the market did not keep up. In these markets, specifically, there were conditional access requirements that differed in conditions to adjacent cities to roll out DAA video to the market. For these use cases, we had to either move the entire city between DACs or add a net-new set of DAA video pipe servers just for that city to adhere to our architectural requirements for DAA. As we advance, we take a much more holistic approach to conditional access architectures and how they interplay both now and in the future. Early in the project, the idea was that DAA should use a net-new DAC. In hindsight, it would have cost a little more, but as DAA technology improves, it may have proven to be more elegant.

Due to our sizeable footprint and the long distances between regional pipe servers and some of our more distant markets, we were outside the nominal range for DEPI. What we came up with, instead of having to create and license net new regions for smaller centers, was to create a "mini region," which would include pipe servers, but rely on the larger regional data centers for GCP command and control, as well as encryption. To facilitate this, we choose a central location for these pipe servers with a good network and a properly hardened datacentre facility and utilize a single "mini region" to feed as many small markets as possible. An excellent example of this would be our interior BC region, which has a large number of low population towns nearby, and good fibre availability, yet too much distance from a DEPI perspective to backhaul video from a fully-fledged datacentre.

From an automation perspective, early on in the project, we realized that our resource inventory system was inadequate to support our DAA initiative fully. Next was months of design and decision meetings, culminating in a multi-phased rollout to achieve full compatibility with automation tool requirements. Two of the major obstacles we had were the initial implementation of IPv6 addressing into our resource inventory system and specifying serving group, out-of-band, and VOD configurations to our automation system in a granular, sustainable, and information-complete way. As we advance with RI, we now put as much information as we have available in as specific and granular a format as possible, even if we are not currently using all the data. There may come a time when we may need to automate against it.

These are some of the more valuable lessons that we have learned while designing and implementing this solution, and we continue to learn and grow from our work in this technology daily. With features being added all the time, our architecture continues to shift and mature. The final lesson we have learned from this endeavour is to design the architecture to be modular.  This avoids rip-and-replace, and duplicate efforts wherever possible.

## 16. Conclusion

As Shaw continues to embrace next-generation technologies, we feel our architecture is adaptable and scalable enough to maintain pace with any future considerations. Because of our automation efforts, we can run two legacy video infrastructures side-by-side with minimal impact, and no new resource requirements for operational teams. As we move towards an IP-only video solution, we can systematically and remotely free up plant spectrum for CMTS, until finally completing our transition to all-IP. Our auxiliary core legacy video architecture is an essential tool in enabling Shaw's network evolution going forward.

# 1. Introduction

As the industry explores providing higher bandwidth services, leveraging the Data-Over-Cable Service Interface Specification (DOCSIS) 4.0 and look at evolving legacy DOCSIS 3.1, operators are planning to move to 204 MHz split and higher return band splits. In order to meet the existing plant leakage regulatory requirements and ensure that operations are not interfering with licensed over the air signals, operators need to evolve how they measure and monitor cable plants for signal leakage.

This paper will discuss the options which are available to operators, balanced by what is technically possible based on the products available today and the roadmaps for the future. Two methodologies will be explored in this paper. The first method examined will be the use of the traditional downstream transmission of signals through the plant and the options that exist within the preservation of this existing form of transmission. The second method discussed will use the cable modem to generate specific signals to characterize leaks and transmitting them back through the plant.

For context, the paper will present potential deployment scenarios and the associated impact to the existing leakage programs that are being run in the industry and how these options can impact the requirements around the legacy set top box Out-of-Band (OOB) control telemetry.

With an open discussion and alignment about ways to solve these problems and a commitment from industry to build scalable and affordable solutions into future technologies, the industry can move forward and continue to meet regulatory requirements seamlessly.

# 2. Setting the Stage

Moving to high split is a transformative network change which entails various technical and operational challenges as operators upgrade the relevant plant components. However, operators are up to this challenge because increased upstream will enable them to offer higher speed tiers and unlock additional revenue potential.

Around the world, cable companies operate in different regulatory environments. However, their foundational principals are quickly converging onto a similar framework, and the OOB requirement is agnostic to regulatory requirements. When it comes to high split, every operator is expected to reach the same end state, though different regulatory environments may impact the “how.” In addition, each company will have a unique set of business requirements, plant upgrade roadmaps and test equipment configurations that will dictate the optimal path forward.

There are two fundamental designs for the plant transmission and maintenance of leakage signals. The first is the existing paradigm is the generation of the signals in the hubsite. The second is an approach being developed around having the signals generated in the customer premises.

Operators will likely go through a transitionary period where they move to provide higher upstream services, while balancing business and regulatory requirements. A conceptual, roadmap-based approach is required as operators move toward the “end state” for signal leakage detection within the aeronautical band. Throughout the discussion below there will be some simplifications made in both the graphical representation of the concepts, and the descriptions of the solutions therein. These simplifications are made to make the options accessible and clear for the reader, while not removing any of the logical or conceptual challenges that are described within the solutions.

The shift in spectrum is depicted in Figure 1 below.

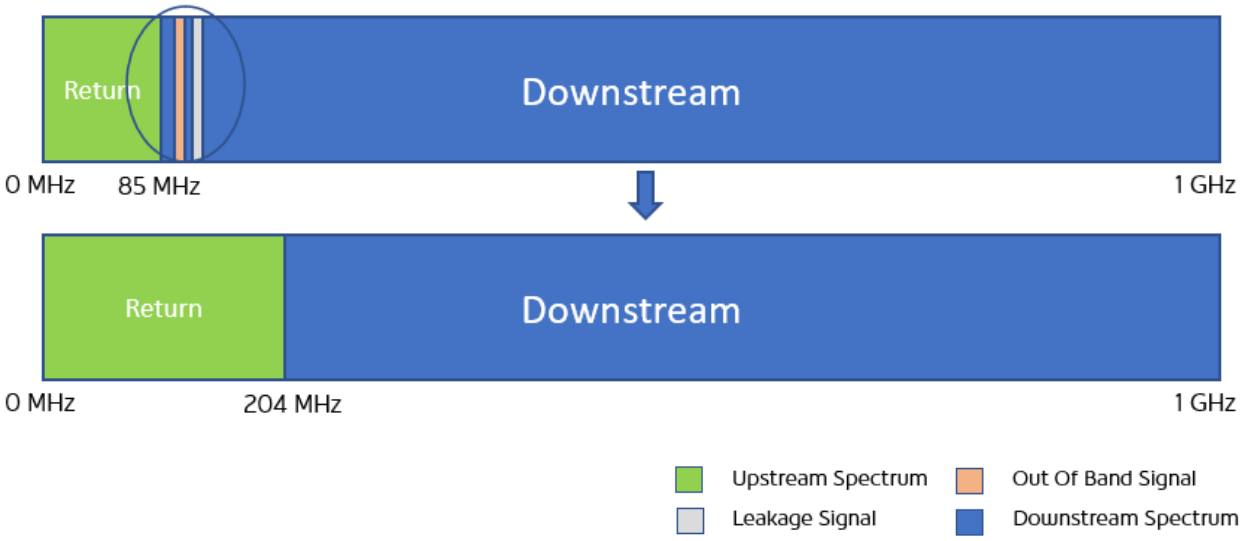

**Figure 1 - Transition from 85 MHz to 204 MHz**

Due to the fundamental properties of signal transmission in the access network and customer premises, any signal trying to traverse through the access network plant in a direction opposite to the allocated spectrum (i.e. upstream signals on the downstream or vice-versa) may cause interference. These signals will also be blocked when they encounter a diplex filter in an active or passive piece of equipment. There are some creative solutions around using these features of the plant to the operator's advantage which will be explored throughout this paper.

The other consideration operators will need to address throughout this transition is their oversubscription rate, which can be described as the percentage of available capacity being offered to each customer over and above the capacity required for each customer to achieve their maximum data rate simultaneously. Upstream capacity complicates the calculation when compared to the downstream oversubscription rate because large portions of upstream traffic are in bursts and latency sensitive. The in-depth considerations of these implications will not be addressed in this paper, where the focus will remain on the transmission of different telemetry signals.

## 3. Methodology

Throughout this section, we will cover the direction of transmission of the signals through the plant. There will be the existing downstream transmission of the signals from the hubsite to the customer premises and then that existing paradigm will be inverted and the transmission of these leakage signals will be generated in the customer premises and back towards the hubsite.

There are two main types of leakage signals that will be referenced throughout the course of this paper. The first signal is a dual sideband suppressed carrier (DSB-SC) signal. This is demonstrated conceptually below and was the next step of leakage signals after switching from analog video carriers. Today this is

generated by two carrier waves (CW) that have a specific frequency offset and amplitude relative to the regular downstream transmissions on the plant.

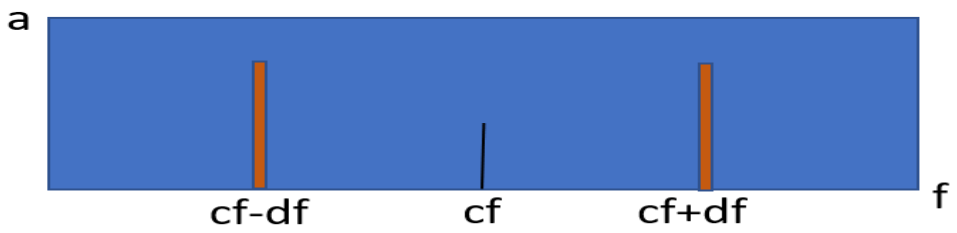

**Figure 2 - DSB-SC Signal Block Diagram**

The second type is contained within the DOCSIS 3.1 specification, specifically the utilization of pilot carriers that exist within orthogonal frequency-division multiple access (OFDMA) known as OFDM upstream data profile (OUDP)

Tables of calculations that follow are based on the following assumptions:

- Single carrier quadrature amplitude modulated (SC-QAM) channels are 6 MHz wide with a capacity of 25 Mbps
- OFDMA channels are 1024-QAM with an expected bit rate of 8 bits/sec/Hz

These numbers and assumptions are approximations based on information available today.

## 3.1. Transmission Downstream

There are two methods that leverage existing downstream transmission signals. These methods have compromises made in terms of spectral efficiency for the newly available upstream and require a complex amplifier design that is expected to result in a higher cost for this equipment. This is balanced by two main benefits, both of which are centered around the retention of existing leakage detection test equipment and video technology platforms. The intent of this is not to provide a cost analysis but to succinctly lay out the options that exist if an operator wishes to preserve these legacy signals.

The first primary benefit is the retention of the existing leakage program that is currently being used by the operator. Depending on the size and scale of the operator and their operations, outfitting the field teams with new leakage equipment may prove to be a large undertaking from a capital standpoint. Additionally, as an industry, there is an increasing focus on the operational cost of technology changes and any time there is a change to equipment, practices, and methodology there is the introduction of an operational cost that will also need to be captured.

The second primary benefit is preserving any relevant downstream signals, specifically OOB. The removal of the OOB signal is not an option for many operators, as the number of set tops boxes that rely on only this signal and cannot use other telemetry is in the millions in many cases.

### 3.1.1. Notching Out Spectrum

When looking at keeping the existing legacy signals intact, the first thing considered was preserving a portion of the existing downstream spectrum by using notch filters for the switch to a 204 MHz return, known as high split, as pictured in Figure 3.

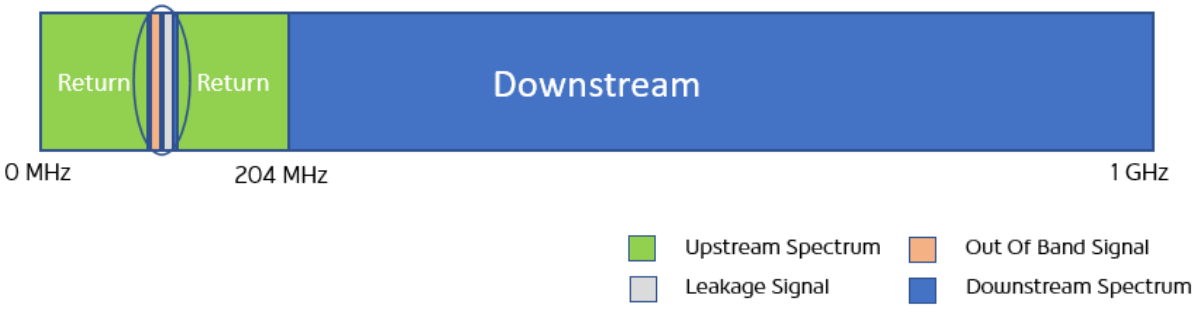

**Figure 3 - Conceptual Spectrum Notch**

Sacrificing any portion of the newly increased upstream spectrum, especially as operators look to reap the benefits of the newly opened return band in terms of both congestion relief and providing higher upstream tiers to customers, may seem counterproductive at first glance.

The cost of creating this notch in the upstream and sacrificing the return spectrum should be understood contextually in terms of what it means from a capacity perspective for the operator, what it means for speed tiers and potential to help capacity to help relieve congestion. The capacity calculated itself is not sufficient for determining the true costs of this spectrum sacrifice to a specific operator.

To determine the size of the notch required in the spectrum to preserve the downstream transmission of legacy signals, it is important to keep in mind that the OOB signal has some room to move within the downstream spectrum. The leakage signal may also have some room to move within the aeronautical band depending on the regulatory environment of the operator. Placing these signals are close together as possible will minimize the size of the notch required and keep the available capacity as high as possible given these constraints.

The table below details three potential notch-width scenarios based on manufacturing technology available today, and what can be reasonably expected for spectrum required to preserve the signals. A thinner notch would allow for the preservation of the OOB signal, while a wider notch could accommodate both the OOB and the leakage signals. For the purposes of this calculation, it is assumed that there would be six 6.4 MHz wide SC-QAM channels and the remaining of the spectrum would be utilized by OFDMA.

**Table 1 – Calculated Available Upstream Capacity based on Notch Width**

| Notch Width | Available Spectrum | SC-QAM Spectrum | OFDMA Spectrum | Projected Capacity |
|---|---|---|---|---|
| 20 MHz | 5-105 & 125-204 MHz | 5-55 MHz | 55-105 & 125-204 MHz | 1182 Mbps |
| 30 MHz | 5-105 & 135-204 MHz | 5-55 MHz | 55-105 & 135-204 MHz | 1102 Mbps |
| 40 MHz | 5-100 & 140-204 MHz | 5-55 MHz | 55-105 & 140-204 MHz | 1062 Mbps |

There is another consideration for notch filters in longer cascades known as Group Delay. Group Delay is caused by a multitude of issues, which are relatively known, understood, and compensated for in deployments today. The introduction of a notch filter will create the same characteristics around the upper and lower bounds of this filter that cause group delay in upstream transmission. It is expected that an operator will end up with group delay issues on either side of notch filters in longer cascades in addition to the other group delay issue that are expected for the channel bounded by the high split filter. The spectrum that can expect to see group delay issues arise in is highlighted in Figure 4.

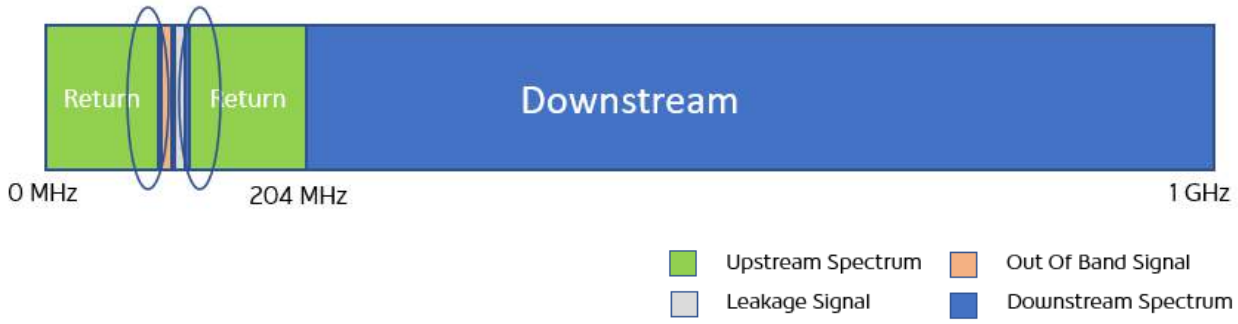

**Figure 4 - Additional Group Delay Locations**

There are not currently any deployments of this solution currently available for study and evaluation, so any discussion around this expected loss in modulation for the OFDMA channels that border this filter will be based on existing upstream deployments and understanding of OFDMA. It is difficult to say whether the OFDMA channel is so robust that it can overcome the majority of the impairments introduced from group delay, or if it will degrade the whole channel to a point that leaving a small exclusion band is preferable. An in-depth analysis of the optimal size of the notch filters and exclusion channels requires future investigation and is beyond the scope of this paper.

### *3.1.2. Up-Conversion*

The second method of downstream transmission that will be discussed will be referred to as up-conversion. This concept is based on the idea of transmitting the signals which are required higher in the spectrum than where they are needed, in what would still be downstream. Once the signal reaches an active device in the plant, it will be transposed from the higher frequency and inserted as a downstream transmission in the return band on each output legs of that active. Once the signal is inserted into the return band, it begins to traverse that span of coaxial cable in a direction opposite to the other signals on that cable. It would be bound by the diplexers in the plant, where the signal would effectively be discarded since it would be trying to traverse the filter in the wrong direction. These leakage detections and OOB signals would then be regenerated on the other side of the active equipment.

For this Up-Conversion, there is additional complexity created in the amplifiers and downstream spectrum plan when compared to adding a notch filter, but up-conversion could be a more efficient use of the available return spectrum. There is also the option to handle the OOB and leakage signals differently in this deployment. The OOB will still have to be generated in the head-end or hubsite and transmitted through the plant since it is a signal that requires specific intelligence and transmission characteristics. The leakage tones however may be generated at each amplifier, or at the node, as required. This is due to the fact that although the signal is very specific, it does not require a two-way communication path or any acknowledgements from the equipment receiving the signal. The option to transmit the OOB in the downstream and convert the leakage signals as required in actives, may prove to be advantageous in the manufacturing of the actives, tuning or deployment. However, the benefits are not measurable at this time.

This is conceptually depicted in Figure 5.

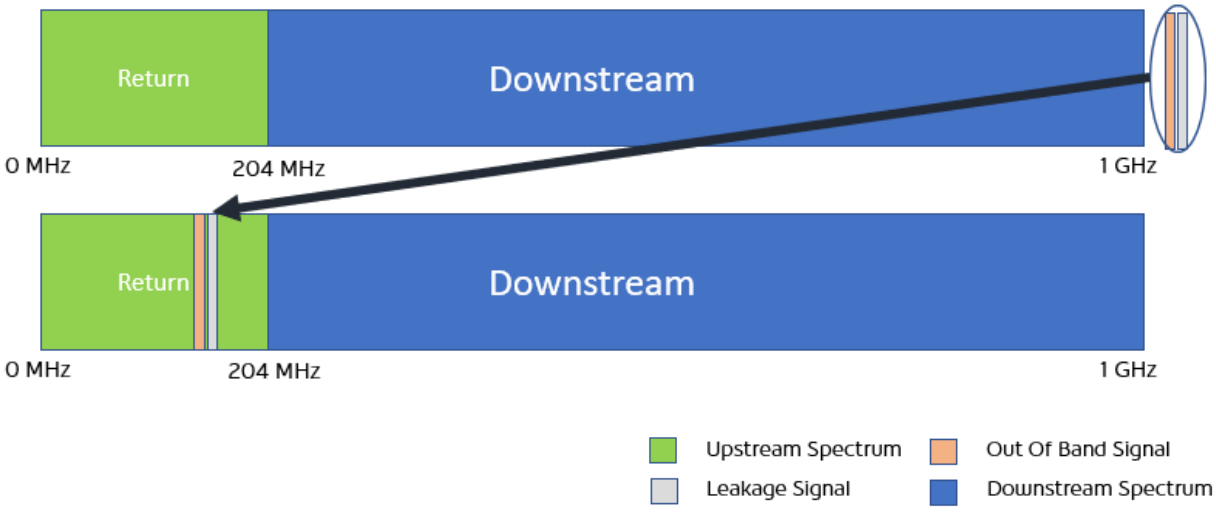

**Figure 5 - Up-Conversion**

The inclusion of these signals on the return band does come with a reduced return spectrum available for transmission at the customer premises. To the modem in the home, these incoming signals will be blocked by the diplex filter within the modem and not cause interference. The spectrum that these signals are arriving into the modem on however will be occupied, and therefore unavailable for the modem to use in upstream transmission. The specific placement of these signals will likely vary in every cable operator deployment due to various interpretations of the optimal spectrum plan, manufacturer guidance and other debate, but the fact remains that there will be a small area of upstream spectrum that the modem should not be allowed to transmit on due to the fact that there will be existing signals there. This is illustrated in Figure 5.

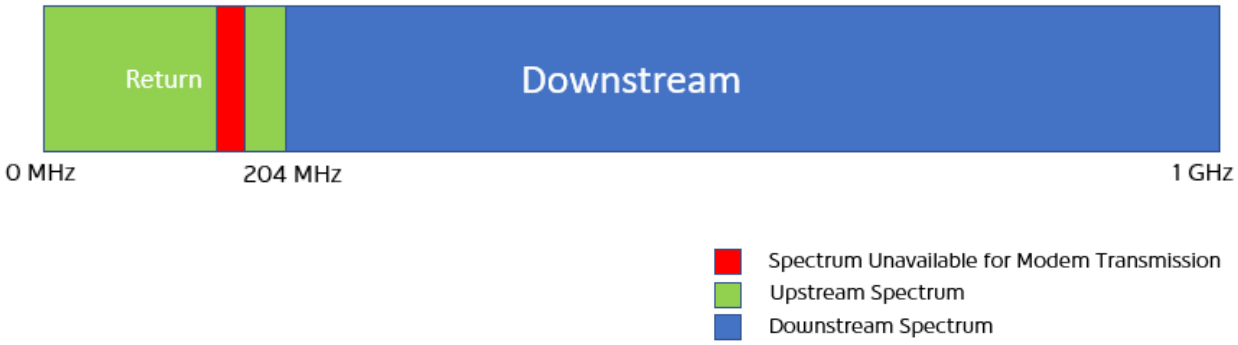

**Figure 6 - Spectrum Available For Modem Transmission**

The size of the notch in Figure 6 is not to scale and is provided for illustrative purposes only. The amount of unavailable spectrum will vary depending on how the signals are placed and layered into the spectrum. The calculation provided in Table 2 could be considered a conservative estimate of what would be available for upstream capacity.

The group delay issue reappears in the up-conversion deployment due to the fact that it will still require a filter on the output leg of the amplifier to insert the leakage and OOB signals without further interference or ingress. The placement and function of the filter would be only on the output of the amplifier, and not the input which would lead to approximately half the group delay impact of the notch filter.

**Table 2 – Capacity for Modem in Up-Conversion Plant**

| Available Upstream Spectrum | SC-QAM Spectrum | OFDMA Spectrum | Projected Speed |
|---|---|---|---|
| 5-105 & 115-204 MHz | 5-55 MHz | 55-105 & 115-204 MHz | 1262 Mbps |

This allows for a more efficient usage of the upstream spectrum than the notch method and largely avoids the issues introduced by group delay. This comes at a cost of increased complexity in both sides of the spectrum deployment due to the specific configuration required for the modem, the likely requirement of a very specific upstream channel plan and finding space for the signals to be transmitted in the downstream.

## 3.2. Transmission Upstream

Leveraging the modem to generate the required leakage signals would allow for the signal to be created in every area of the plant, where there is live signal. These methods provide what is required for the leakage signal generation and having it created by the modems themselves ensures that they are in every portion of the plant that is transmitting in that spectrum. Conceptually, this is essentially turning the transmission of these signals around, where before they were going from the hub site to the customer, now they will go from the customer into the network.

While discussing the solution based around the modem transmit leakage signals, the plant being modeled is one that has removed the OOB requirement for the set top boxes. The reason for the removal of the OOB signal is not a technical requirement of the solution and it is possible to maintain the downstream transmission of this signal in the following scenarios. The reason for OOB from the discussion for the

upstream transmission scenarios are twofold. The first is that the methods of preserving the signal have been covered above, since it will need to remain a downstream signal that has a two-way communication to the hub site. The second is that removal of this signal before inverting the leakage model is programmatically aligned with the tradeoffs considered in the transmission methods, as well as conceptually aligned with transforming the plant in a manner that is easy to understand.

The measurement of these signals is in the same portion of spectrum that is currently measured and meets existing regulatory requirements in the aeronautical band without adding great complexity to the rest of the plant. Figure 6 is a high-level diagram of how this would look, with the new transmission area of the modem depicted in purple.

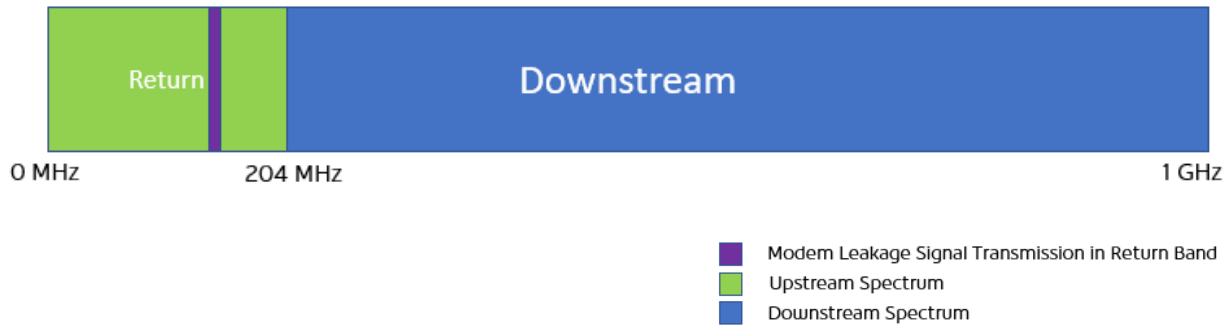

**Figure 7 - Conceptual Modem Transmission**

Initial findings from silicon manufacturers centered around having the modem transmit the required signals have led to the assumption that there will be minute-to-negligible sacrifices in the upstream, allowing the full spectrum to be provided as capacity as pictures in Table 2. The distribution of spectrum between SC-QAM and OFDMA channels has remained due to the fact there will be previous generations of DOCSIS in the plant for a long time to come.

**Table 3 – Full Upstream Available**

| Available Upstream Spectrum | SC-QAM Spectrum | OFDMA Spectrum | Projected Capacity |
|---|---|---|---|
| 5-204 MHz | 5-55 MHz | 55-204 MHz | 1342 Mbps |

The deployment of this solution has a caveat that comes from the following scenario. The Operator has taken node ABCD and upgraded it to 204 MHz. At this moment, all the existing modems, or at least the majority, only support 42/85 MHz split, and the operator may be out of compliance with a regulatory body. This is a challenge every operator will have to resolve. One suggested path involves ensuring that there is a modem installed, either in the customer premises or an environmentally hardened cabinet, that is transmitting the leakage signal back through the plant from the last tap in every run. This modem cannot distribute the required signal to all the other drops on the tap run due to the nature of coaxial distribution plant, specifically around port-to-port isolation between taps. The lack of leakage signal on every drop without a 204 MHz return modem is not immediately a problem. This is because if there are no 204 MHz return modems in an area, there is no transmission within that band that will need to be measured. The 42/85 MHz modems will continue to function as normal, and not transmit within those restricted bands. As the homes on the node become populated with 204 MHz modems that can transmit in the areas that require monitoring, those modems will be transmitting the required aeronautical band leakage signals for detection.

### 3.2.1 Generation of Carrier Waves from Cable Modem

The first option examined for the inversion of signal generation will be using the Cable Modem to generate the CW tones at spacing (refer to Figure 1 for an illustrative example) and power for the existing leakage equipment to detect. The immediate advantage in this method are clear, the cable modem can effectively generate the same signal that the leakage detection equipment has been detecting before, and at very low cost in terms of upstream spectral usage.

Using the chipset to generate the two CW tones does count towards the maximum number of channels available on the tuner. The chipset that was examined for the purpose of this analysis was the Intel Puma 7. This chipset has eight SC-QAM channels available on the tuner, which would be reduced to six available channels while having these two additional tones allocated for leakage detection. This means that there would be a limitation to the number of SC-QAM channels that could be run, and the remainder would need to be OFDMA. It is not considered to be a material cost because most operators do not run more than six SC-QAM channels today. Once the spectrum is expanded, it is much more spectrally efficient to add OFDMA channels instead of further SC-QAM channels.

During testing of this methodology where the modem chipset generates these narrow and powerful tones, some harmonic signals have been observed. The behavior of the CW tone generation and resulting side effects are detailed in Table 4.

**Table 4 – SC-QAM CW Harmonics**

| CW Center Frequency | CW Signal Strength | Harmonic Location | Harmonic Strength |
|---|---|---|---|
| 85 MHz | 34 dBmV | 215 MHz | -38 dBmV |
| 108 MHz | 33 dBmV | 192 MHz | 4 dBmV |
| 137 MHz | 31 dBmV | 163 MHz | 23 dBmV |

The creation of these harmonics may require additional regulatory, specification or investigation considerations that are beyond the scope of this paper.

### 3.2.2 Utilizing Cable Modem Pilots

The DOCSIS 3.1 standard includes protocols within OFDMA that can be used as pilots for leakage detection in the inverted leakage detection paradigm. There is a feature known as the OFDM upstream data profile (OUDP) that utilizes very specific pilot signals and although they are designed for a different purpose, there is the potential to leverage these pilot signals for leakage detection. Through optimized cable modem termination system (CMTS) scheduling, an operator may be able to remove any encumbrances to the spectrum entirely and allow a fully open return spectrum free from any notches, areas unavailable to transmit, or destructive interference.

The utilization of an existing carrier or protocol which does not add additional costs or limitations to the access network would be a huge benefit to any leakage program. Leakage has evolved from requiring whole channels, to potentially fitting in between SC-QAMs. The end goal is to use existing signals, transmitted without a penalty in bandwidth, to meet regulatory and plant hardening requirements.

There are three main areas to consider when it comes to using OUDP for leakage detection:

- The DOCSIS side requires creation of a CMTS scheduling scheme to minimize the cost to the access network. The evolution of the cable modem transmission profiles to the point where the OUDP pilot signals represent a consistent and distinct signal to be measured and profiled are still in the exploratory stages. The framework exists within the DOCSIS standards to support this initiative.
- From the test equipment perspective, measurement of these new pilot signals will be a technical challenge for equipment manufacturers. This is a new type of signal being generated, and it will have different propagation and measurement characteristics. At minimum, this will require firmware upgrades. For existing leakage test equipment, a hardware upgrade may be necessary.
- After the technical challenges are resolved on how the signal will be generated, scheduled and measured in the field, there will need to be extensive testing around the signal equivalency to existing leakage systems to ensure regulatory compliance.

# 4. Conclusion

This paper examined four solutions for leakage and OOB issues which occur in high-split and the considerations for each of these options. There are advantages and disadvantages to each, and the opportunity for other permutations of these solutions is still possible. Table 5 summarizes the proposed solutions and the main factors that have been discussed.

**Table 5 – Summary of Options**

| Proposed Solution | Available Capacity | OOB Removal Required | Replace Test Equipment |
|---|---|---|---|
| Notch | 1062 Mbps (min) | No | No |
| Up-Conversion | 1262 Mbps | No | No |
| Modem CW | 1342 Mbps | Yes* | No |
| Modem OFDMA Pilot | 1342 Mbps | Yes* | Yes |

*If OOB is left on the plant, it is still possible to move to these solutions. The capacity available will closely resemble the in the “Up-Conversion” solution.

The industry needs to align on the optimal milestones in the roadmap for evolving leakage detection. This will drive the development of solutions, as well as testing and detection of these new signals and configurations.

Once operators align on one solution, the industry will be better equipped to advocate for their needs with both regulators and suppliers. This will allow for manufacturing efficiencies and lower maintenance and upgrading costs for plants.

The size and scale constraints that come with a physical cable plant drive the need for a thoughtful, balanced approach to change. This can be a delicate act with regulatory requirements, operational requirements, business demands and technology changes. Evolution of leakage detection methods must happen concurrently with the evolution of the cable plant; it cannot be treated like an afterthought.

Creating an open and transparent dialogue around the move to high-split creates an excellent opportunity for operators to transition smoothly to high-split and continue to increase their offerings to customers, especially at a time when upstream is becoming more important than ever.

**Title** **Page Number**

# 1. Introduction

The gaming industry continues to grow, eclipsing the movie entertainment industry in revenues. In 2019, the digital video game market garnered $120.1 billion (SuperData, 2020), while the worldwide box office earned $42.5 billion (Comscore, 2020). In a 2018 survey, it was estimated that more than 23 million Canadians played video games (The Entertainment Software Association of Canada, 2018). This means more than 60% of Canadians could be considered gamers. Gamers are demanding higher speeds and lower latencies from their providers to achieve competitive and enjoyable multiplayer gaming experiences. These customers are choosing their service provider on either real - or perceived - advantages that the network technologies offered by providers. Additionally, real time applications such as voice and video conferencing require low latency and jitter to perform with high reliability and quality. While it is impossible for any single service provider to control end to end latency of internet traffic beyond their own network, there are steps that can be taken to achieve the lowest possible latency. Multiple Service Operators (MSOs) are constantly developing and deploying the latest technologies and strategies to improve latency and jitter on their networks.

ISPs advertise technologies that reduce latency, and third party measurements that indicate lower latency than competitors. For example, TELUS, a Canadian telco ISP, has a website dedicated to explaining latency and claiming thatFibre To The Home (FTTH) is better for gaming.

**Figure 1 – Sample ISP Gaming/Latency Website (TELUS, 2020)**

Speed test sites also are starting to show latency scores as another tool for measuring ISP quality (Speedtest.net / Ookla, DSLReports speedtest, and bing.com's speedtest to name a few).

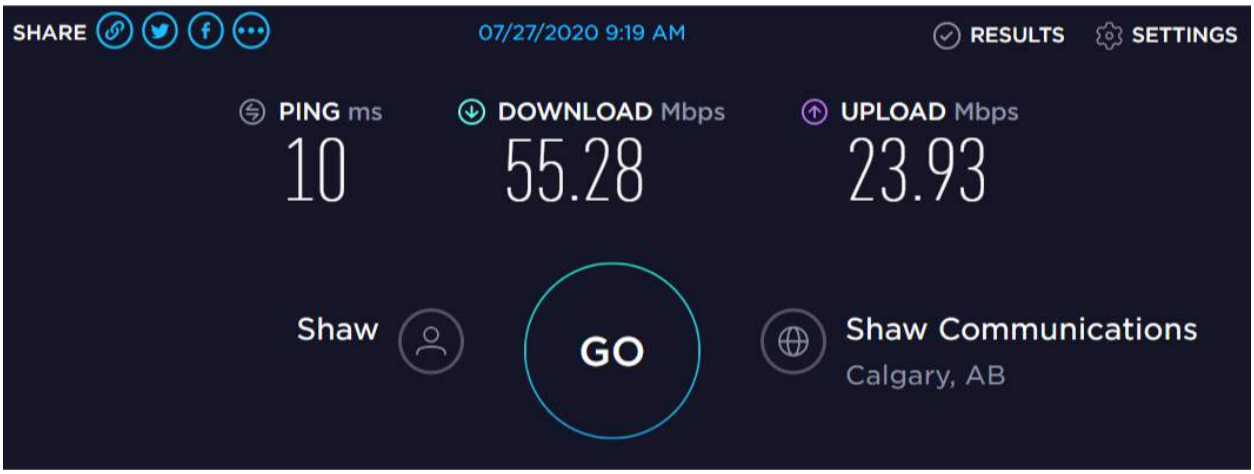

**Figure 2 – Speedtest.net's Result Page Showing Latency Result (Ookla, 2020)**

League of Legends publishes ISP connectivity scores based on latency, jitter and packetloss. Their North American site for this is located at https://lagreport.na.leagueoflegends.com/en/ (Figure 3 – League of Legends' Lag Report) and shows not only your current provider's score, but a "leaderboard" of providers in your area (Figure 4 – League of Legends' ISP Leaderboard for Calgary, AB), and many games have in-game displays of latency statistics.

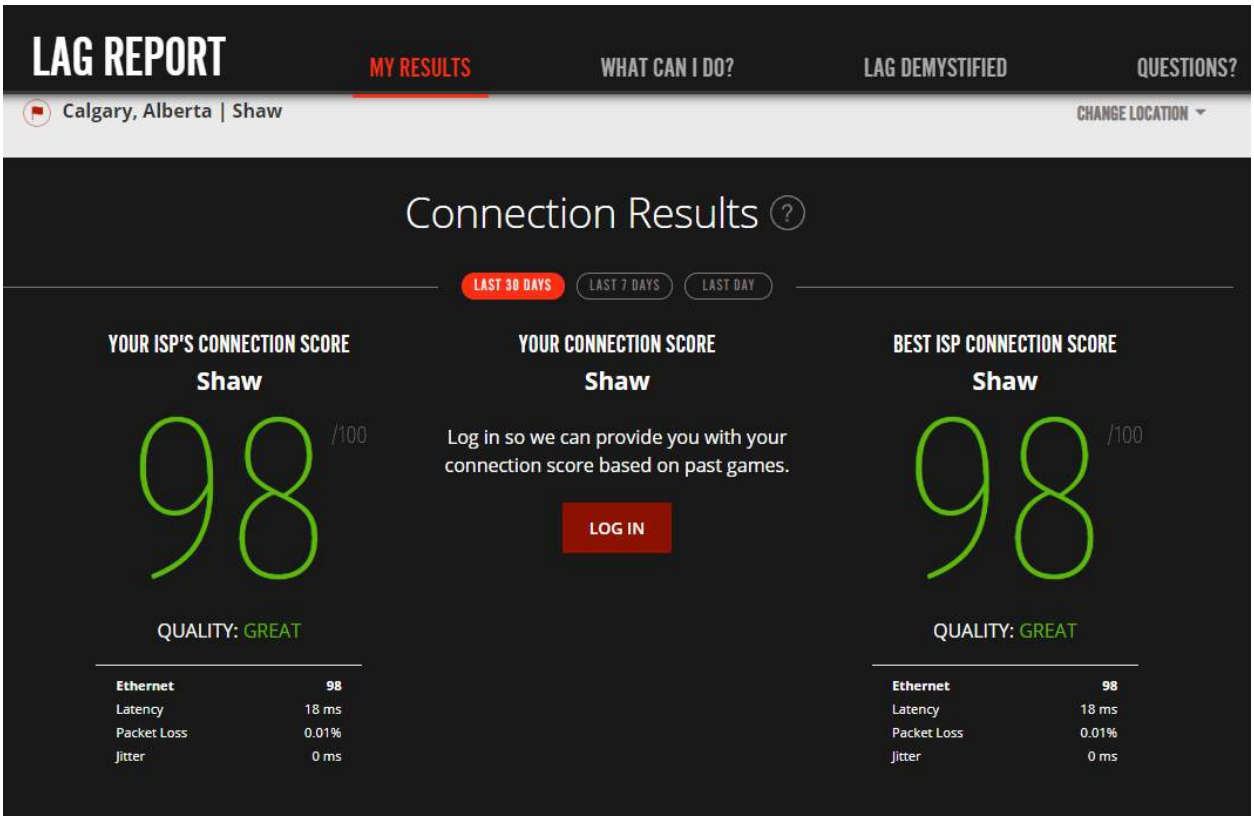

**Figure 3 – League of Legends' Lag Report (Riot Games, 2020)**

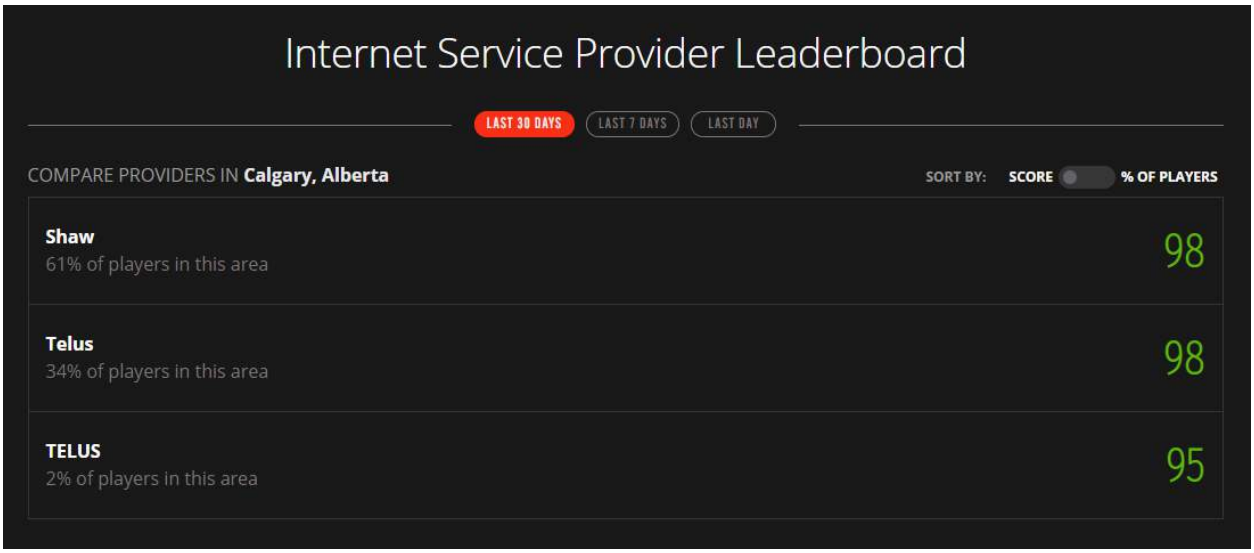

**Figure 4 – League of Legends' ISP Leaderboard for Calgary, AB (Riot Games, 2020)**

Gamers are very interested in latency and jitter because of its impact on targeting and player location within the game – which can mean the difference between winning and losing. Jitter, which is often unpedictable, can be especially challenging for game servers to compensate for.

While average latency is the amount of time (on average) a packet takes to traverse the network, it is measureable and relatively stable (on average). Jitter is the difference in latency between different packets and is the variability of latency. The more variability, the harder it is for a game to be accurate and consistent between players.

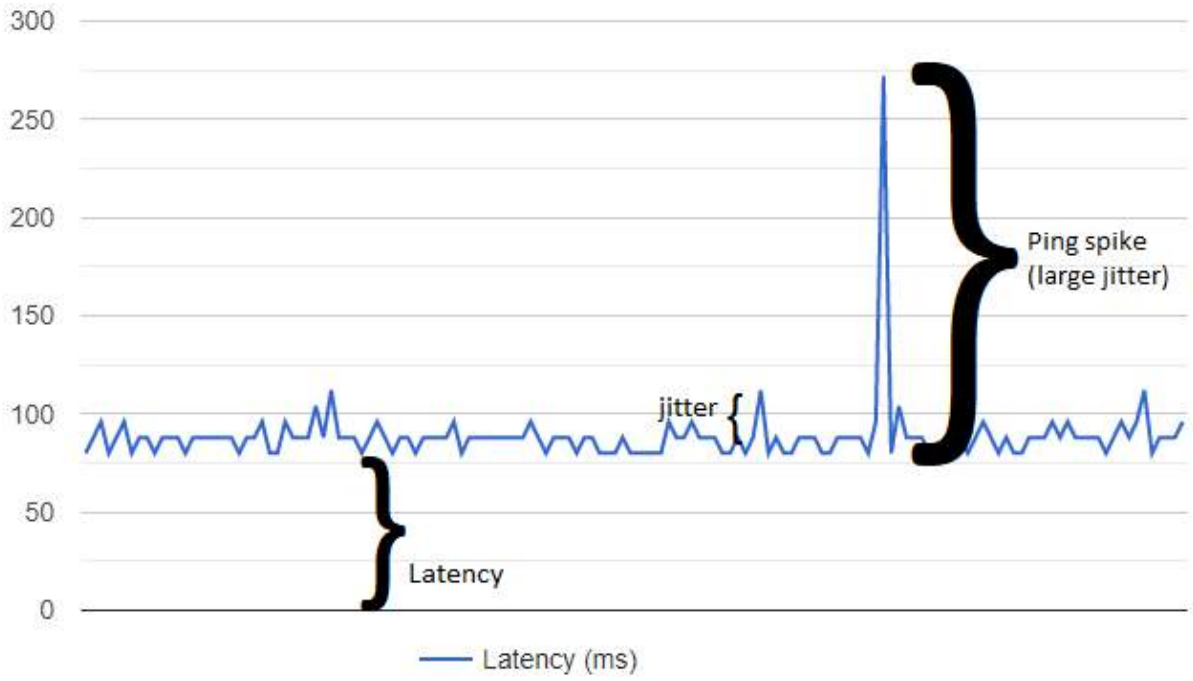

**Figure 5 – Average Latency And Jitter**

This paper will discuss current and future methods that help improve latency and jitter at several points in the network: in the home, in the Data Over Cable Service Interface Specification (DOCSIS) network, and in the core ISP network. Technologies such as WiFi 6 Orthogonal Frequency-Division Multiple Access (OFDMA), CableLabs' Dual Channel WiFi, Low Latency DOCSIS (LLD) and routing optimizations will be discussed. We will show the level of improvement available at each part of the network, and the perceived and actual performance gains that can be expected, as well as the promise of LLD in the DOCSIS network.

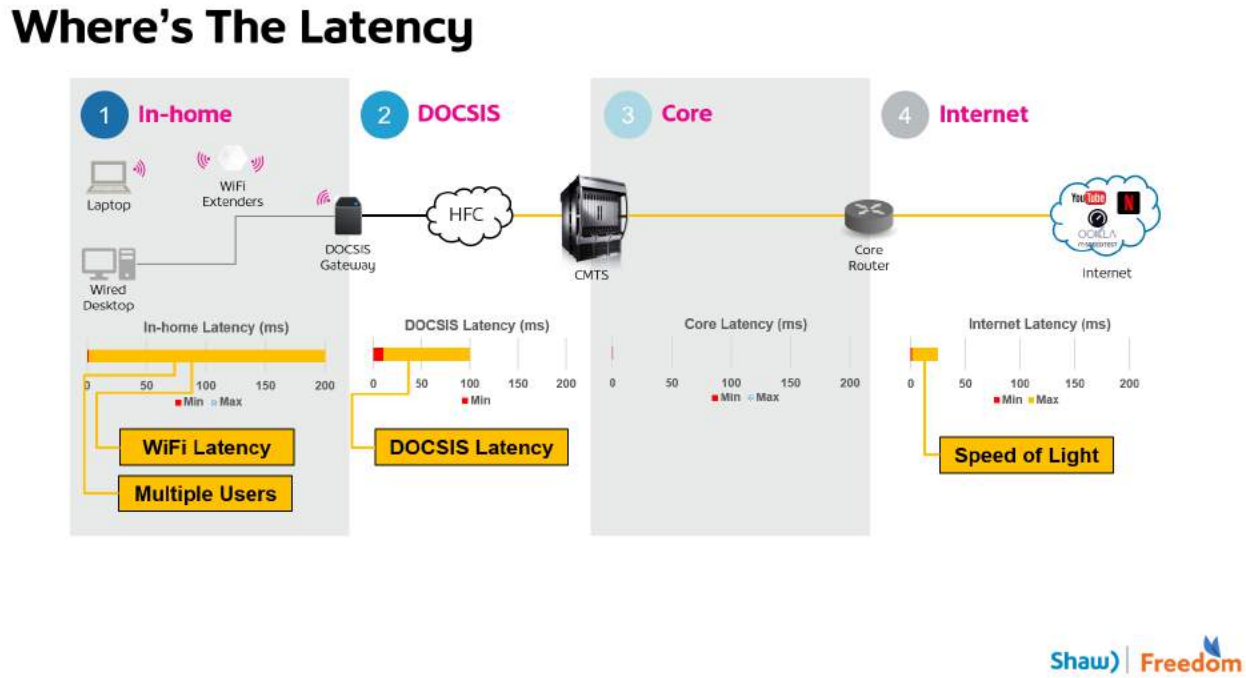

**Figure 6 – Where's the Latency?**

We will discuss three of the main areas shown in Figure 5; In-Home, the DOCSIS network, and the Core network, discussing some currently-available methods for reducing latency in these areas. Then, this paper will look at some technologies coming in the near future for each of these areas.

## 2. Current Methods For Improving Latency and/or Jitter

### 2.1. In-Home Technologies

Latency in the home is usually caused by WiFi usage. When wired, most home networks perform in the millisecond range, and quite frequently under a millisecond of latency is added traversing the home network. Over WiFi, conditions can vary wildly in different locations within the home, sometimes even in the same location. Yet customers continue to use WiFi as a primary method for connecting devices due to ease of use and the lack physical wiring in the home.

### 2.1.1. WiFi Multimedia

WiFi Multimedia (WMM) is a WiFi specification that was built to prioritize voice and video traffic over best effort internet traffic and also allows to de-prioritize background, non-latency sensitive traffic. When congestion happens WMM can ensure prioritized traffic will continue to get the bandwidth it requires. This also means it spends less time in the queue, avoiding latency and jitter penalties. We have seen applications such as Zoom employ WMM in the wild today, ensuring video calls perform well even in hostile WiFi environments. However, this is all at the cost of applications and traffic that don't use WMM, as their traffic will be penalized in WiFi congestion/contention scenarios. Any router supporting 802.11n or later should also have WMM enabled by default.

### 2.1.2. Summary

For applications that utilize WMM, and during congestion, the improvement can be tens to hundreds of milliseconds, as non-WMM WiFi queues can be quite large.

## 2.2. Access Network – DOCSIS

Technologies that can be employed in today's DOCSIS network include enabling Active Queue Management (AQM), adding orthogonal frequency-division multiplexing (OFDM) for DOCSIS 3.1 modems, and reducing DOCSIS Upstream Bandwidth Allocation Map (MAP) message intervals to 1ms or less. For the following tests, the test suite used defines jitter as IP Packet Delay Variation (IPDV) and is the average of all differences between each packet sent.

### 2.2.1. OFDM

Adding even a relatively small OFDM channel (64MHz) can allow for a small (0.5ms) end to end latency improvement. Based on Shaw's testing to date, this improvement doesn't seem to vary much with the size of the OFDM channel; it is only a function of whether the OFDM channel is present (and operational) or not.

**Table 1 – Latency And Jitter In Relation To OFDM Channel Presence And Size**

| OFDM size (MHz) | Average Latency (ms) | Average Jitter (ms) |
|---|---|---|
| 0 (not configured) | 9.62627 | 2.19518 |
| 64 | 8.93366 | 2.22067 |
| 192 | 8.93708 | 2.21159 |

### 2.2.2. MAP Intervals

The MAP messages control when modems can request bandwidth, and also tells modems when they can transmit the data they have. Reducing the time between these messages can have an impact on latency as it gives more opportunities for modems to request bandwidth. Reducing the MAP interval to 1 ms or less is a requirement of LLD, but it is also something that is tunable today on some CCAP hardware.

Based on Shaw's testing to date, moving to < 1 ms MAP intervals can lower average latency a further 0.2ms, however it negatively impacts jitter by about about 0.2 ms as well.

**Table 2 – Latency And Jitter when MAP Interval Is Changed**

| MAP Interval (ms) | Average Latency (ms) | Average Jitter (ms) |
|---|---|---|
| 3.2 | 10.06525 | 1.93527 |
| 0.8 | 9.86053 | 2.20513 |

### *2.2.3. Upstream AQM*

Active Queue Management helps protect any network queue (wherever it is enabled) from ping spikes and latency due to network queuing. Commonly referred to as "buffer bloat", this problem occurs when a bottleneck on the network receives data faster than it can send it out; it causes network latency to climb. Some of these queues can hold a large amount of data, allowing them to hold packets for very long times; sometimes into the range of multiple seconds. AQM uses the TCP mechanism of dropping packets to slow down TCP streams and actively monitors the time packets are spending in the queue. DOCSIS cable modems utilize the DOCSIS PIE algorithm to determine which packets are required to be dropped. Figure 7 shows the improvement with AQM enabled vs. disabled. As mentioned, since TCP dropping is the mechanism used to improve latency, when the upstream is congested with pure UDP traffic, the improvement is negligible. However, in a mixed or pure TCP traffic scenario, the latency can be improved dramatically, as seen in Table 3.

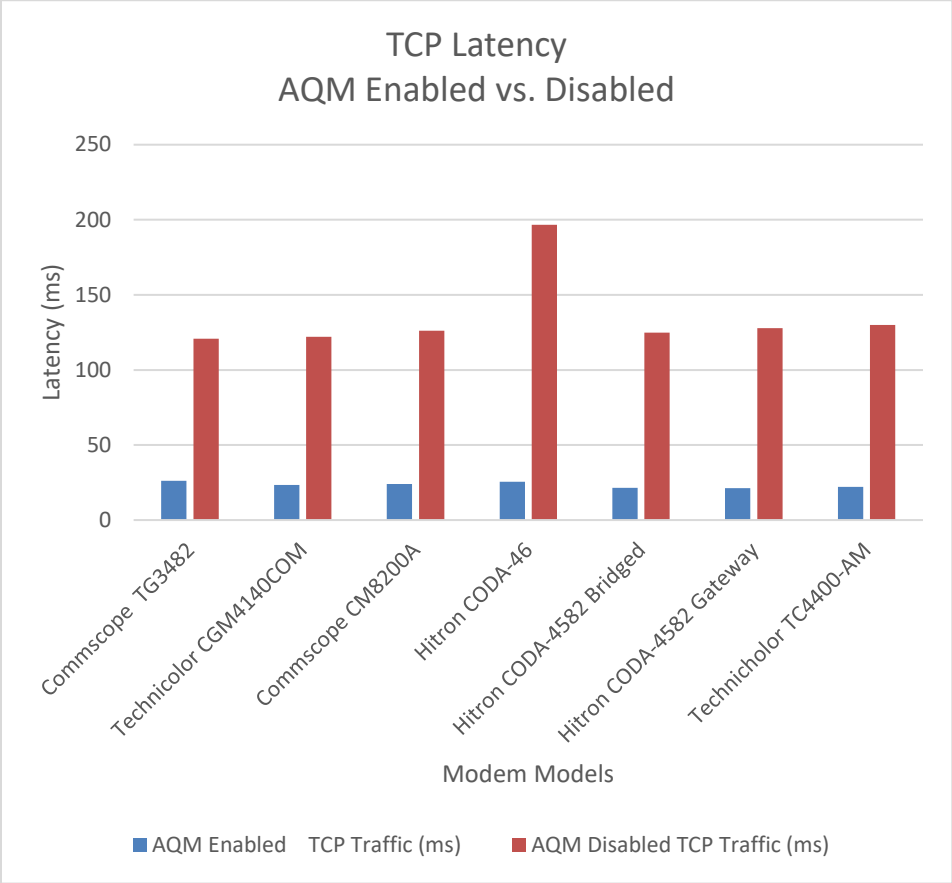

**Figure 7 – TCP Latency When AQM Is Enabled Or Disabled**

**Table 3 – Latency When AQM Is Enabled/Disabled**

| | Commscope TG3482 | Technicolor CGM4140COM | Commscope CM8200A | Hitron CODA-46 | Hitron CODA-4582 Bridged | Hitron CODA-4582 Gateway | Technicholor TC4400-AM |
|---|---|---|---|---|---|---|---|
| **AQM Enabled UDP Traffic (ms)** | 154.1 | 181.0 | 174.6 | 168.3 | 421.1 | 8.5 | 172.9 |
| **AQM Disabled UDP Traffic (ms)** | 201.8 | 216.2 | 213.2 | 194.1 | 22212.7 | 14.7 | 209.0 |
| **AQM Enabled TCP Traffic (ms)** | 26.2 | 23.3 | 24.0 | 25.6 | 21.5 | 21.3 | 22.2 |
| **AQM Disabled TCP Traffic (ms)** | 120.8 | 122.0 | 126.1 | 196.6 | 124.8 | 127.9 | 129.9 |

### *2.2.4. Downstream AQM*

One of our CCAP vendors implements the Weighted Random Early Detection (WRED) AQM algorithm for downstream traffic. However, by default, it is turned off, so when customers saturate their downstream service flows with downstream traffic, latency increases due to bufferbloat on the service flow. We configure our downstream to use the WRED AQM with a minimum threshold of 40 ms, a maximum threshold of 60 ms, and drop probability of 50%. Figure 8 shows the difference in latency over a short (about 1 minute) download between WRED being enabled and disabled.

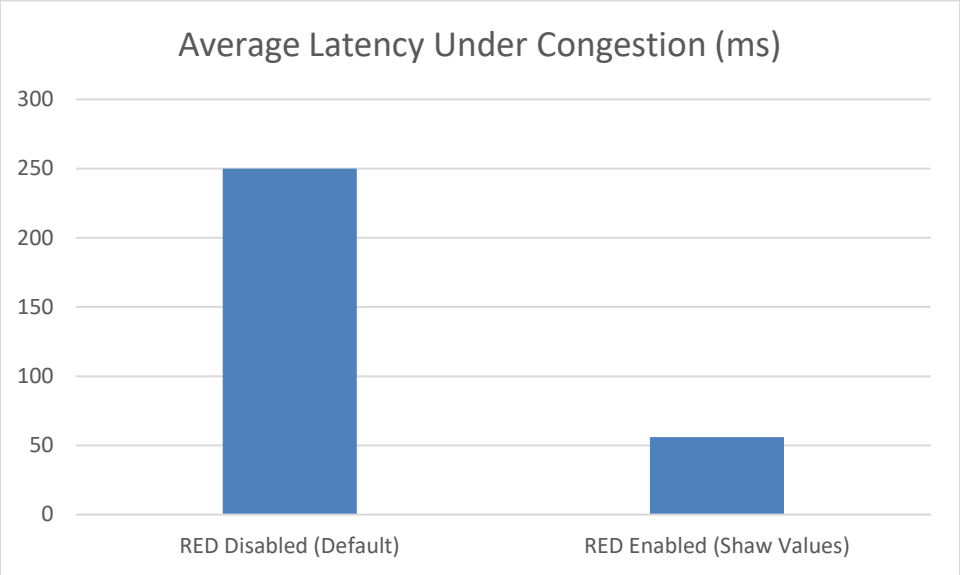

**Figure 8 – Average Latency Under Congestion**

### *2.2.5. Extra UDP Traffic*

As more traffic bandwidth is injected through a set of service flows, latency and jitter appear to start to at first increase, and then decrease for a final improvement of over 3.5ms in latency, and over 1.6ms in jitter. This experiment added a second 75Mb/s UDP stream, and compared to the results to cases where no extra data streams were added.

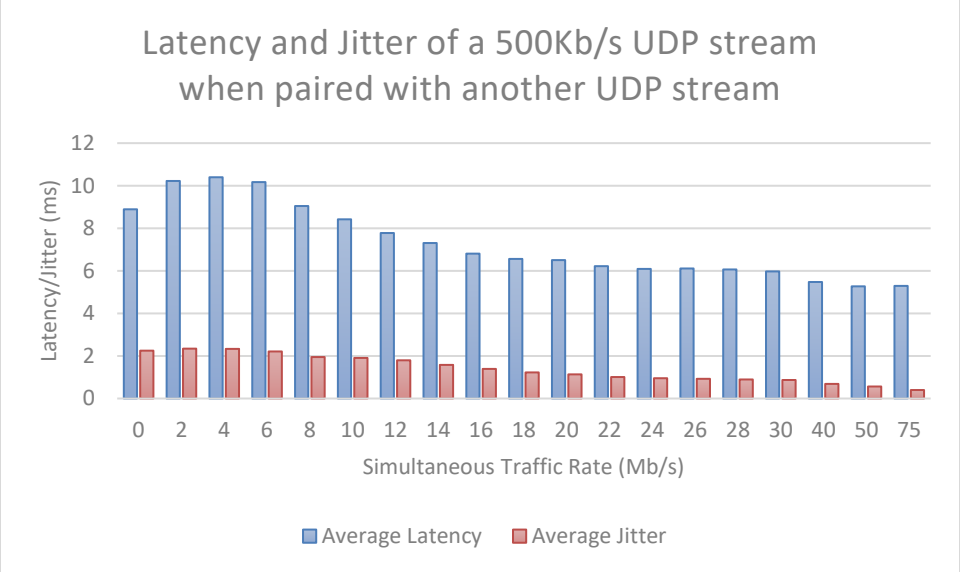

**Figure 9 – Latency And Jitter In The Presence Of A Second UDP Stream**

This is clearly not practical for a production deployment, as it locks up a lot of upstream bandwidth. It may also just be an artifact of the scheduler used by the specific CCAP chassis used in this test, but is nonethless interesting for its results in lowering both latency and improving jitter.

#### *2.2.6. Summary*

Utilizing DOCSIS 3.1 channels (OFDM) and reducing map intervals to 1 ms or less can bring latency down by about 0.7 ms combined, at the cost of some jitter (increase of an average jitter of about 0.2 ms). Adding AQM can also ensure that latency does not grow unreasonably due to congestion, and it can also save over 100 ms of latency during congested periods.

### 2.3. Core Network

#### *2.3.1. Route and Metric Tuning*

This method can have a significant impact on latency. Results can have a greater than 10 ms improvement over non-optimal routes. Mapping is done by using ICMP to find the latencies of different routes between different paths through the network. An example is shown in Figure 10.

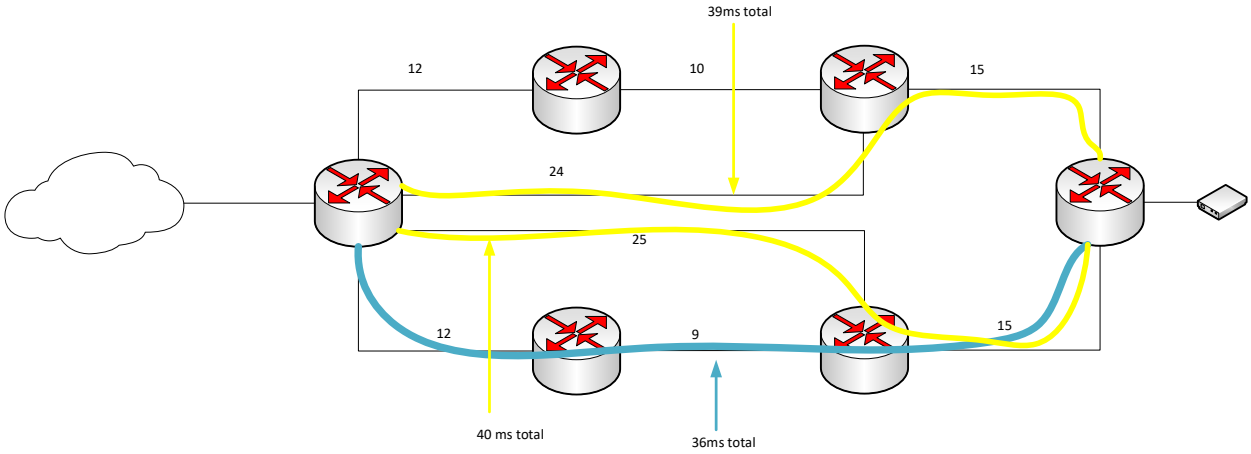

**Figure 10 – Latency Of Multiple Paths Through A Network**

The yellow path represents the network paths when no metric tuning has been done, and all links are equal cost. In this case, there are two paths. Depending on the load balancing algorithm the first router on the right uses, or could use one or the other path (39 or 40 ms), or could load balance packets between them for a single session resulting in a 1 ms jitter on the path.

When metrics are tuned to take the latency of each link into account, the resulting path is the blue path, giving the customer 36 ms of latency to traverse the network to the peer/transit point, and no jitter.

### *2.3.1. Disabling ECMP For Peering and Transit Links (Latency Stability)*

Border Gateway Protocol (BGP) will sometimes advertise equal costs for multiple peering or transit points for a given network. In this case, latencies can vary wildly from session to session as traffic moves between these different peering or transit links. End users would complain that latency was “good” on one day, but was “bad” on another day as their gaming session would change the exit point from our network.

In Figure 11, with Equal Cost Multipath (ECMP) enabled, a customer could reach a server through two network paths in the local network, if BGP had the same metric at each edge router. If the total Return Trip Time (RTT) for the yellow path is noticeably different than the green path, the customer will notice that for different gaming sessions to this server, he could see different latencies. Allowing the IGP metrics from metric tuning to be the tiebreaker for routing means that the network path (in this case) would always be the green path due to the lower latency internally. Depending on the latency to the server outside the network, the total RTT could actually be higher through the green path, but the latency being stable across sessions was more acceptable to customers, even if it was higher for specific servers.

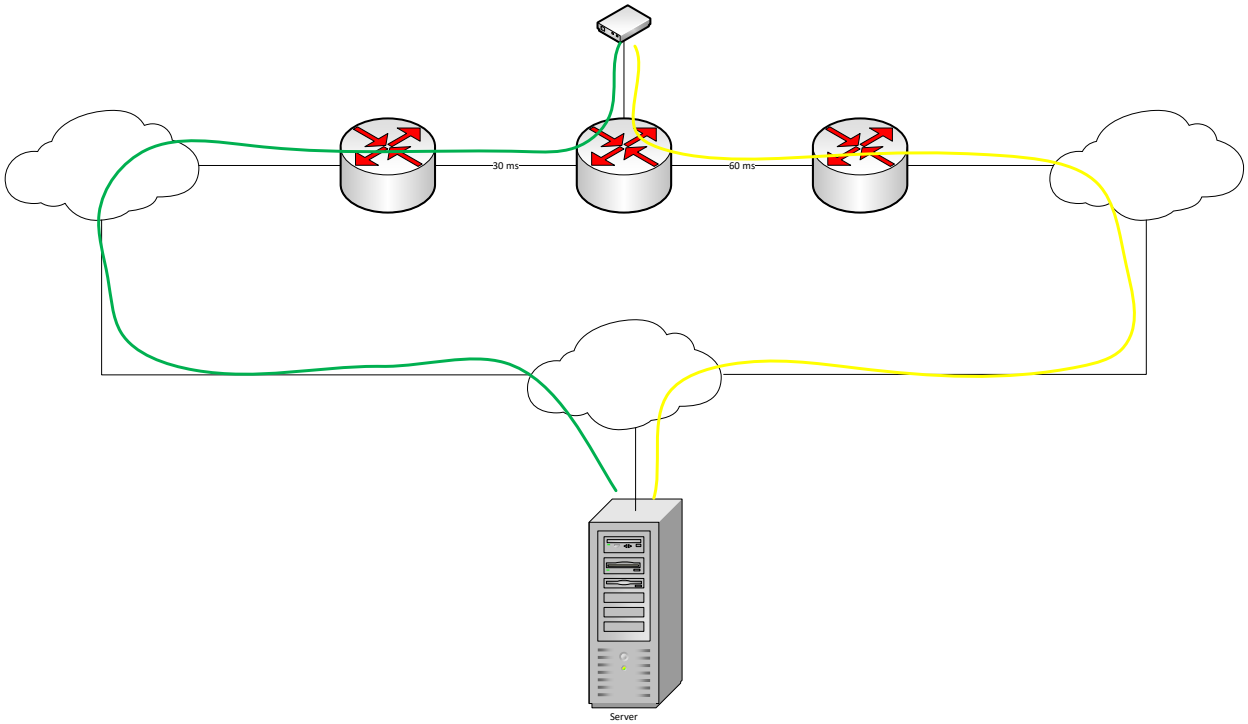

**Figure 11 – Network Exit Points**

#### *2.3.2. Summary*

These methods in the Core Network can improve latencies from 1 to 50 ms or more, depending on size and complexity of the network.

# 3. Upcoming Technologies And Methods For Improving Latency And Jitter

## 3.1. In-Home Technologies

WiFi 6 includes Orthogonal Frequency-Division Multiple Access (OFDMA). This feature improves bandwidth sharing with large numbers of clients to prevent clients talking over each other, thereby reducing latency and jitter in busier networks. In order to take advantage of OFDMA, however, all clients must be WiFi 6 enabled with OFDMA capability.

Dual Channel WiFi[tm] is a technology developed by CableLabs to provide a separate (or multiple separate) downstream channels in combination with a "legacy" channel. This allows large downloads, and streaming to be shunted to this separate channel, keeping the legacy channel open for upstream and legacy clients, reducing latency and jitter by reducing contention and congestion when clients are requesting large amounts of traffic.

## 3.2. Access Network – DOCSIS

### *3.2.1. Low Latency DOCSIS*

The two technologies in LLD that will contribute the most to latency and jitter improvements are dual-queue and the Proactive Grant Service (PGS). LLD AQM will also ensure that latency is held down during congestion and Coupled AQM will ensure that bandwidth is available to both the low latency queue as well as the classic queue during congestion

#### *3.2.1.1. Dual-Queue*

Dual-queue provides a separate set of DOCSIS service flows, so time sensitive traffic doesn't have to compete with non time sensitive traffic within a single queue. This means that even when there is a large amount of traffic on the legacy service flow, it will not affect the queuing behaviour of the low latency service flow.

Dual-queue also allows the DOCSIS scheduler to schedule latency sensitive traffic differently to provide low latency and low jitter.

So, why don't we have all traffic low latency? Queuing delays are actually caused by some applications sending traffic in a manner that results in a build up of packets in the network. The biggest source of this type of traffic is any application that uses TCP today. Those applications need the network to provide a deep buffer to absorb bursts of traffic, and don't perform well if the network has shallow buffers. But games and latency sensitive applications typically deal with small packet loss better than latency variation, and large buffers allow for large variation or spikes in latency, as well as large latency if the buffers are kept full for a long time. Having small buffers just for latency sensitive applications will ensure packets are not held for too long. The dual-queue feature of Low Latency DOCSIS equipment gives both types of traffic the appropriate buffer for their needs: a shallow buffer for Low Latency traffic, and a deep buffer for Classic traffic.

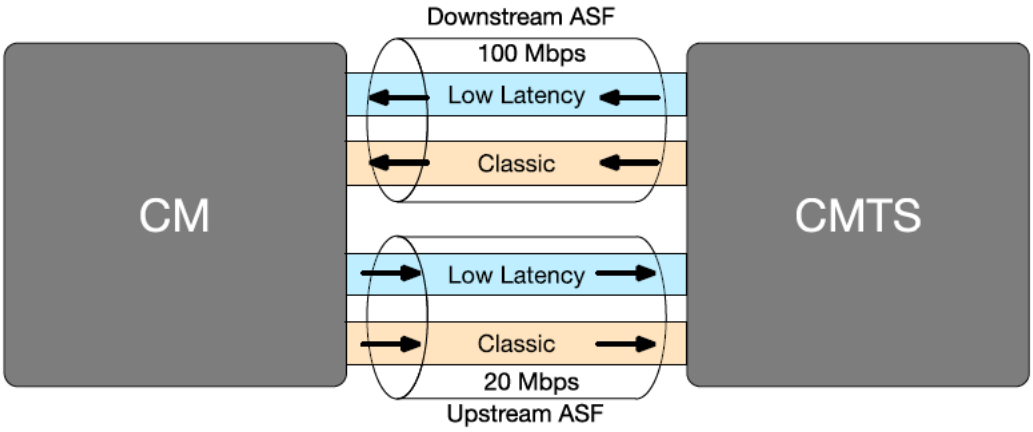

**Figure 12 – Dual Queue Service Flows (White, Sundaresan, & Briscoe, 2019)**

This does mean that we will need to differentiate the traffic via some means. We do have access to DOCSIS packet classifiers, but these would be hard to manage as it would require classification of every type of traffic and every different game to be put into the low-latency service flow. LLD will use several

methods to classify traffic into the low latency service flow; a Differentiated Services (DiffServ) value or Explicit Congestion Notification (ECN). CableLabs has proposed a DiffServ value of 0x2A be defined as Non-Queue-Building (NQB), and LLD would use this value, as well as ECN values. As ECN is supported, Low-Latency Low-Loss Scalable throughput (L4S) will also be supported for applications that need both high bandwidth and low latency. CableLabs has been working with game developers to inform them how to mark their packets through gaming conferences and through the website pingspikeskill.com.

#### *3.2.1.2. Proactive Grant Service*

Proactive Grant Service (PGS) is a new DOCSIS upstream scheduling service included in LLD. PGS is like the Unsolicited Grant Service (UGS) used primarly for voice services, but where UGS is very static with the size of packets and the number of grants given, PGS is much more dynamic, allowing for different size packets and different amounts of bandwidth. PGS helps reduce the grant-delay cycle inherent in the DOCSIS protocol (Figure 13 – DOCSIS Grant Delay Cycle).

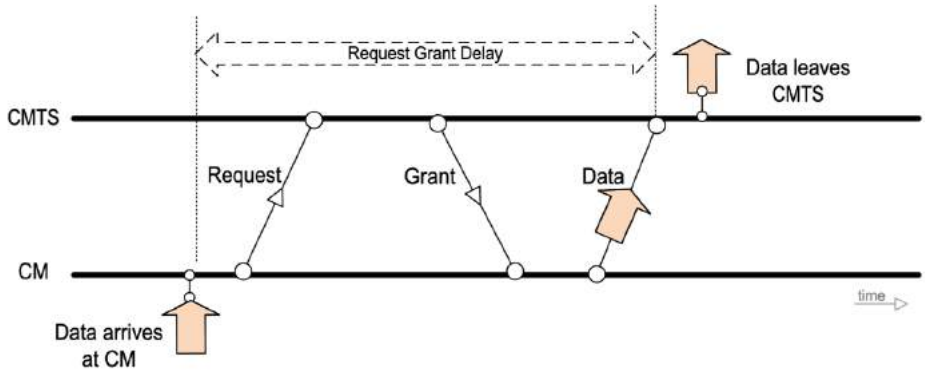

**Figure 13 – DOCSIS Grant Delay Cycle (White, Sundaresan, & Briscoe, 2019)**

As the name indicates, PGS proactively tries to predict and give grants for the modem to transmit data based on past behaviour, so that the modem doesn't have to request the grants (effectively removing the grant delay cycle latency); but the downside is that if the modem doesn't have any data to transmit, that bandwidth is now wasted.

#### *3.2.1.3. Upstream Scheduling Improvements*

Typically it takes more time than a single MAP interval to process a request for bandwidth, so reducing the MAP interval alone does not provide a huge boost to latency reduction. If the turnaround for processing the request can be reduced along with the MAP interval reduction, this should allow for a good reduction of latency and jitter even without PGS.

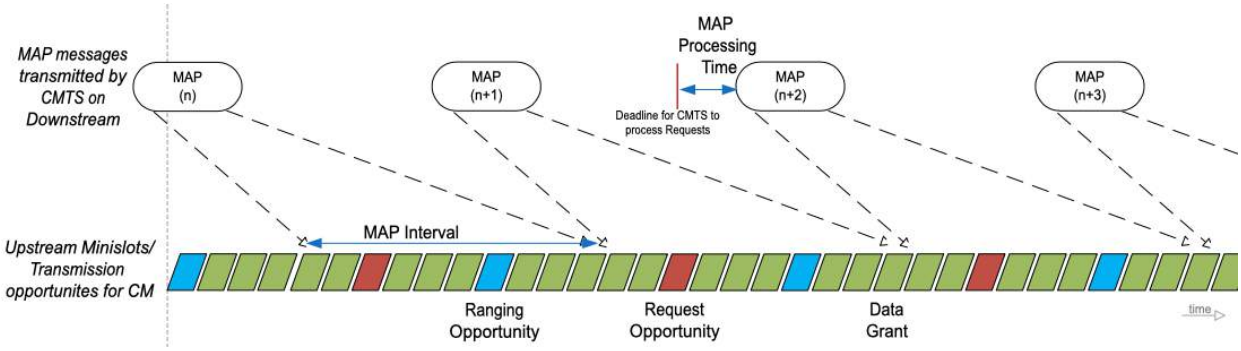

**Figure 14 – MAP Interval and MAP Processing Time (White, Sundaresan, & Briscoe, 2019)**

#### *3.2.1.4. Coupled AQM*

Coupled AQM ensures that there is shared bandwidth for both the low latency service flow and the classic service flow within the aggregate service flow during times of queuing. The total bandwidth consumed by the coupled service flows is limited by the AQM configuration settings. This feature ensures that the low latency service flow does not starve out the classic service flow under this condition, and aims to ensure that classic TCP sessions and future L4S TCP sessions all receive a fair bandwidth allocation.

#### *3.2.1.5. Summary*

Total potential improvements with LLD will run in the range of 5-10 ms of latency (more in cases with congestion/queuing), as LLD can deliver DOCSIS latency of ~1ms (White, Sundaresan, & Briscoe, 2019) and jitter will most certainly be improved as well with both PGS and upstream scheduling improvements. This will significantly close the "latency gap" that last mile fibre products use in their marketing, even though 5-10 ms may seem like a small improvement overall.

### 3.3. Core Network

Currently the optimization of routing configurations for specific destinations is very manual and labour intensive, and it has only been done a handful of times when teams have the cycles to perform the required tuning. Going forward we are considering launching a project to keep these up to date and ensure they don't cause problems as our network evolves and changes. We are also looking at enabling partial automation for these optimisations, but that is further in the future.

CIN networks can add another level of complexity to these calculations especially for more remote sites due to the diverse path requirements and distances involved. Even within a single metropolitan area, fiber paths and switching delays can contribute to a slight difference in latency between paths. Paying attention to the different latencies between each path will continue to be an ongoing process.

Cloud Gaming, Augmented Reality (AR) and Virtual Reality (VR) applications will start to require lower latency, and since the networks between users and where servers are hosted can make up a large portion of the latency budget, edge computing or edge cloud, where servers are moved into ISP facilities, or very close to them, can also play a part in the ability for an ISP to lower latency for their customers.

# 4. Conclusion

Carefully focusing on the parts of the network over which you have control provides ample opportunity for reducing inefficiencies. Enabling AQM and having devices and applications that utlise WMM can yield many latency benefits. In addition, wiring as many devices as possible in the home can help keep latency down in times of congestion. Enabling DOCSIS 3.1 downstream channels (OFDM) and reducing upstream MAP intervals to 1 millisecond or less can bring DOCSIS access latency down a small but measureable amount. Finally, ensuring your core network is optimized for latency via continual measuring and adjusting of IGP metrics can give you an edge over even FTTH.

Some technologies look impressive, but need to be framed within their use case. For example, AQM, WMM, WiFi6 OFDMA, and Dual Channel WiFi all perform impressively during congestion or on busy networks, but during normal operations may not yield much improvement for latency or jitter. That doesn't mean they aren't important, as even home networks can have short bursts of extreme traffic or a large number of devices requiring network resources at the same time. Some of the technologies may seem like they don't contribute much to a lower RTT on the network, such as 1 ms MAP Intervals, OFDM, or even LLD, but these can lower the difference of latencies seen between FTTH and DOCSIS, and in the case of LLD even eliminate that difference altogether.

In the future WiFi 6 within the home will further hold latency down as more and more devices are added to home networks. LLD may bring latency down to as low as 1 ms in the access network. Further optimisations on the Core network can ensure latency on a DOCSIS network is as low as even the best FTTH network.

Figure 15 below shows the rough amount of latency that can be shaved off the RTT with each technology or optimization. Some are additive, some (such as LDD, which includes MAP Intervals and AQM) includes other technologies listed. Some may seem small, but work under most conditions (MAP Intervals/OFDM) while others (marked with asterisks) seem like large gains, but only work under some conditions (AQM). LLD has technologies that will improve both areas, as seen with its two entries. These will all work together to improve latency and jitter on the network keeping latency sensitive applications and gamers satisfied and happy.

# 1. Introduction

As data trends and usage increase, operators are looking for methods to increase the capacity of the network. This is especially the case with upstream. During the COVID-19 pandemic, the need to increase the return-band spectrum bandwidth and throughput became evident. The graph below demonstrates this increase in usage:

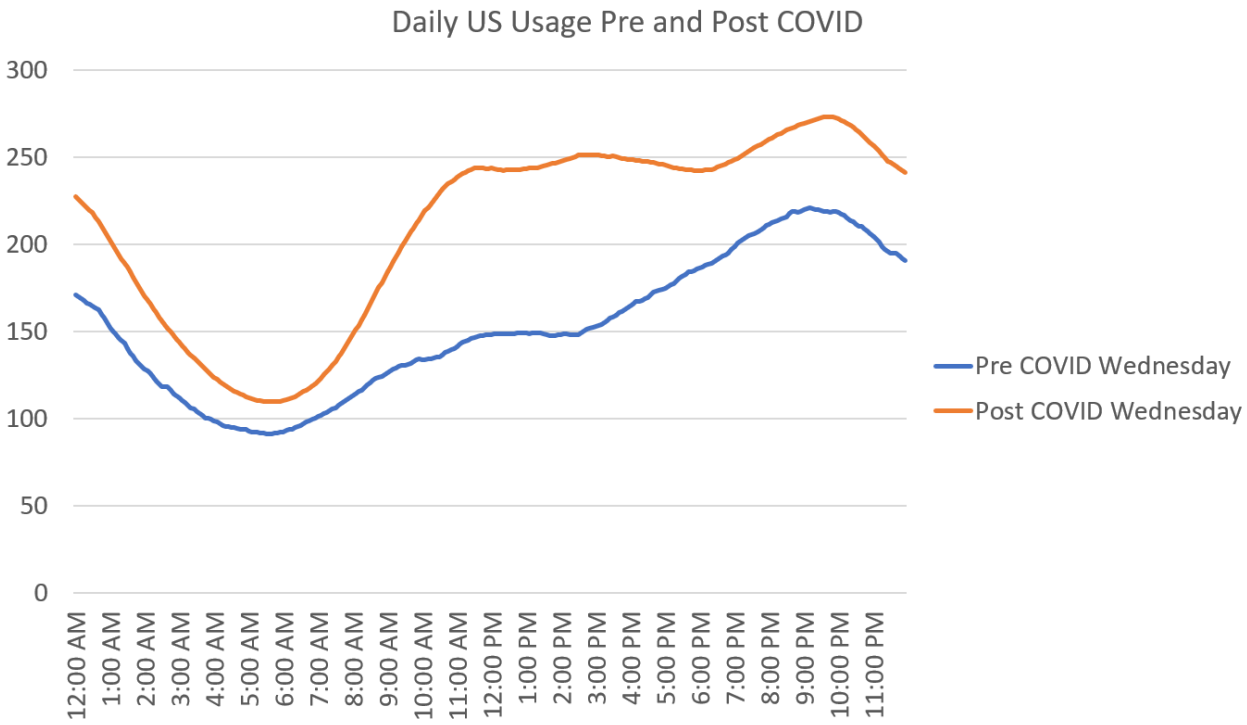

**Figure 1 – Upstream Data Trends Pre and Post COVID-19**

As a part of upgrading the outside plant (OSP) to 1.8 GHz extended spectrum DOCSIS (ESD) and beyond, to achieve 10 Gbps and more, many operators face the costly prospect of amplifier re-spacing. Given how costly and labour intensive plant re-spacing can be, innovating ideas to overcome this challenge are highly encouraged.

MSOs have traditionally relied on high gain amplifiers to overcome coaxial loss in the access architecture. Traditional amplifiers have served this purpose well, providing 50-60 dBmV of gain, however, they can be power hungry, drawing 60-80 watts each. They can also introduce unwanted distortions in the spectrum, decreasing the signal quality and essentially lowering the achievable throughput in the network.

Distributed gain architecture involves deploying smaller and lower gain amplifiers in selective areas of the network, in conjunction or instead of high gain amplifiers. These amplifiers have a much lower power draw in comparison traditional amplifiers, which can drastically decrease the draw from the existing power supplies, leaving more room for other technologies to be deployed in the access network.

Due to the simplicity of these amplifiers, being single stage with a fixed gain and tilt, they can also be deployed in conjunction with traditional amplifiers. This can boost the end-of-line performance in areas

that the span loss of the plant cannot be overcome with the available total composite power (TCP) of the traditional amplifiers.

This paper will provide an elaborate study and comparison between a traditional N+2 plant, N+2 plant with booster amplification, and a fully distributed gain versions of the same plant models. An end-of-line performance and power analysis will be provided for each scenario.

# 2. Technological and Operational Challenges with Extended Spectrum DOCSIS

Prior to the analysis, we must first discuss the challenges that operators face when considering upgrading their access networks to ESD.

In 'traditional' plant, being 750 MHz or even 1 GHz, most MSOs expect 4kQAM to be achievable by each orthogonal frequency division multiplexing (OFDM) carrier deployed, however, the same is not true for 1.8 GHz and beyond. One of the primary reasons for this would be the current spacing that the outside plant is designed to.

## 2.1. Plant Spacing and Drop-In Upgrades

Most OSP architectures are designed to 550 MHz and 'stretched' to 1 GHz. As a result, most of the radio frequency (RF) power in plant actives, including nodes and amplifiers, has been utilized to overcome the existing span losses. Span loss is defined as the total insertion loss of all the elements in a hybrid-fibre-coax (HFC) span, measured in dB. This includes all the plant passives such as taps, splitters and couplers. Although the span losses today are manageable with the current amplifier gains, they will certainly become a major point of concern when the spectrum is expanded to higher frequencies. As an example, a span loss of 35 dB at 1 GHz in a traditional plant equates to 49 dB at 1.8 GHz.

Plant re-spacing is always an option, however it can be extremely costly and, as a result, operators will rely on the expanded power of amplifier gain chips to overcome span losses.

## 2.2. Total Composite Power (TCP)

It is generally understood that 1.8 GHz amplifier chips will have ~75 dBmV of total composite power (TCP) available. With that in mind, not all of this power is available for use. As an example, the figure below demonstrates the trade-off between modulation error ratio (MER) and TCP utilized:

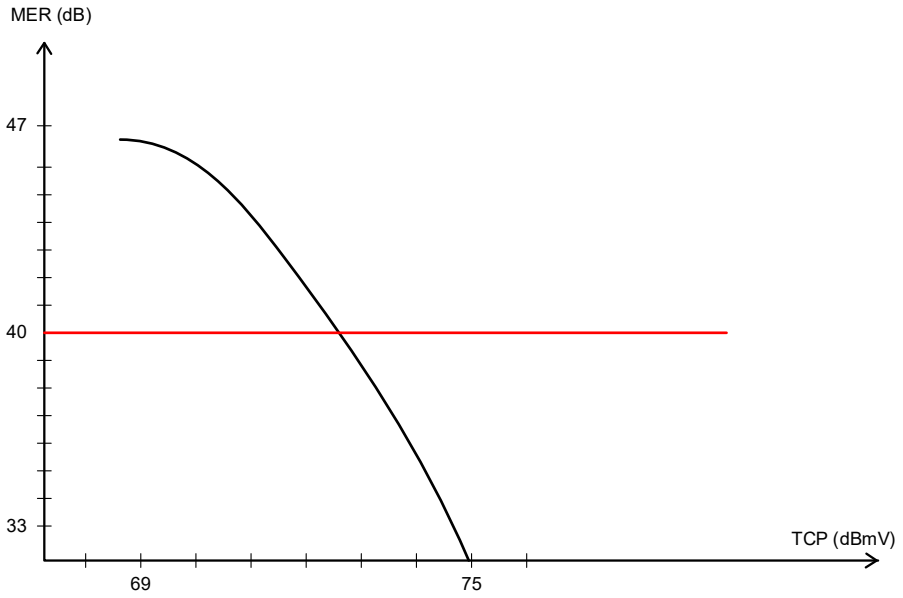

**Figure 2 – TCP vs. MER**

As a general rule of thumb, 3 dB of back-off is needed to achieve 40+ dB MER, which is typically what operators aim for. Along with that, the internal loss of the active device has to be accounted for, which is usually 2 dB. To summarize, there is a total of 70 dBmV of power to be utilized at the port of each active device. This can be a concern for operators given that 65-68 dBmV of TCP has already been allocated to overcome the span losses in the 'traditional' plant.

## 2.3. Taps

Taps and passives can be another point of concerns when upgrading the OSP to 1.8 GHz. Traditionally, most operators have relied on face-plate upgrades to expand the spectrum range of plant taps and passives. This is generally accepted as a faster and more cost-effective method to upgrade the available bandwidth of taps.

Unfortunately, this might not be the case with 1.8 GHz upgrades. A face-plate upgrade of the current 1 GHz taps can potentially expand the bandwidth to approximately 1.6 GHz. It should also be noted that this is a best effort.

This can be a concern given the uncertainty of the maximum available bandwidth in the plant. As a result, it is generally accepted that taps and passives have to be swapped out for 1.8 GHz version. Given that the entire housing of the tap has to be swapped out as a part of this effort, most of the taps being developed will have housings that can support up to 3 GHz with future face-plate upgrades, future proofing the plant for 3 GHz upgrades.

# 3. Cascaded Plant Design Challenges

HFC architectures can be divided into two categories:

- Passive plant (N+0): where no amplifiers are used after the node
- Cascaded plant (N+X): where amplifiers are used to boost the signal multiple times to the end-of-line

When designing an N+0 plant, the main point of concern is the output performance of the node. Assuming that we are operating in a distributed access architecture (DAA) plant, the primary drivers for the plant quality would be the MER of the DAA device. Since no amplifiers are used to boost the signal, no noise or distortion is added to the primary signal being generated by the DAA device.

On the contrary, when designing an N+X plant, the following can be of concern:

- Amplifier noise contribution
- Amplifier distortion contribution

**Note**: In order to calculate the overall system carrier to noise ratio (C/N) a starting C/N has to be assumed. Due to the continued development in this area, no starting C/N has been assumed from the RF source (RPD or RMD). Instead, the cascaded amplifier network's contribution to the system C/N has been calculated in this paper. Once a starting C/N is determined at the output of the node, the overall system C/N can be calculated.

## 3.1. Noise

Designing a cascaded system for optimal carrier to noise is always a big priority for an operator. One of the biggest contributors in system design is the receive power (Rx Power) at the amplifier, given that it is one of the primary drivers for the overall system C/N.

The equation below calculates the C/N of a single amplifier:

$$C/N\,(dB) = \; C_i(dBmV) + 57.4 - NF(dB)$$

Where:

- $C_i$: input signal
- $NF$: Noise figure of the amplifier

Note: the number 57.4 is the thermal noise power in dBmV for 6 MHz QAM carriers.

The equation above shows the significance of the Rx power versus noise figure of the amplifier, in overall system design.

The overall system C/N for amplifiers operating at different output levels can be derived from the following equation:

$$C/N_{total}\,(dB) = \; -10log\left\{10^{\frac{-C/N1}{10}} + \; 10^{\frac{-C/N2}{10}} + \cdots + \; 10^{\frac{-C/Nn}{10}}\right\}$$

Where, $C/N_x$ is the carrier to noise of each amplifier calculated independently.

When cascading identical amplifiers operating at the same output level, the following approximation is typically used:

$$C/N_{total}\,(dB) = C/N_x - 10log_n$$

Where:

- $C/N_x$: the carrier to noise of a single amplifier
- $n$: the number of identical amplifiers in cascade.

## 3.2. Distortion

The buildup of distortions in a cascaded plant is less predictable than noise. Knowing that almost all carriers deployed in the spectrum in the future will be digital, the distortion products can be summed into carrier to intermodulation noise (CIN), which will increase the noise level that should be considered in the system C/N. Due to lack of availability of data in this realm, CIN was not considered in this paper but it is something that needs to be studied extensively, discussed in section 12.

Since distributed gain amplifiers have very low distortion characteristics, due to the low gain and simplicity of these amplifiers, and the fact that distortions for traditional amplifiers are highly unpredictable, composite second order distortion (CSO), composite triple beat (CTB) and subsequently CIN have been nullified in the calculations for end-of-line performance.

## 3.3. Designing a Noise-Limited System

For optimal performance, operators design systems that are unity gain. This means that the loss between two amplifiers is equal to the gain of each amplifier. If the loss is less than the gain, output power needs to be increased and as a result, distortions will accumulate. In contrast, if the loss is greater than the gain, then the input power will be too low to the input of the amplifier, degrading the C/N of the system.

Due to the difficulties that come with designing a system that is both noise and distortion limited, removing one of those parameters will be optimal. Given that noise performance of amplifiers is far more straight-forward in comparison to distortion, designing a noise-limited system is an attractive idea.

Since distortions are highly dependent on output power TCP, designing a noise-limited system can be achieved by reducing the output power out of the node/amplifiers and making sure the signal is received at the next amplifier at a high enough level for acceptable C/N in spite of the amplifier's noise figure (NF).

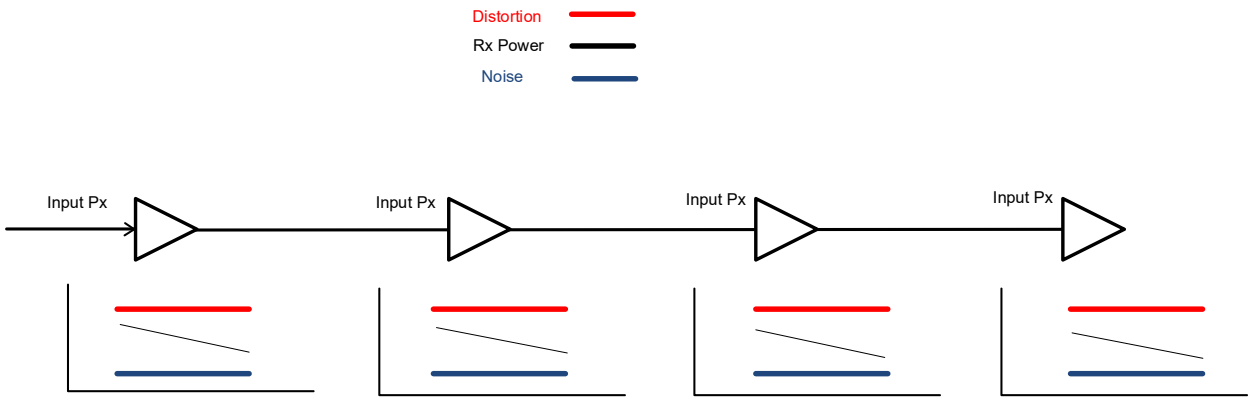

**Figure 3 – Signal Level Balanced Between Noise and Distortion**

# 4. Plant Models

In order to encompass most of the HFC architectures deployed, the below plant models and assumptions were considered for this analysis.

Note: Trunk spans are defined as spans that are untapped. Distribution spans are tapped. Both trunk and distribution span losses include all other passive elements' insertion losses, such as splitters and couplers.

Assumptions:

- Modem:
  - Point of entry (PoE) device
- Drop:
  - Cable: RG6
  - Length: 150 feet
- Number of taps in each span:
  - 5
- Distribution span losses at 1GHz:
  - Typical plant: 35 dB
  - Stretched plant: 37 dB
- Trunk span losses at 1 GHz:
  - Typical plant: 32 dB
  - Stretched plant: 35 dB

The figure below summarizes the parameters above:

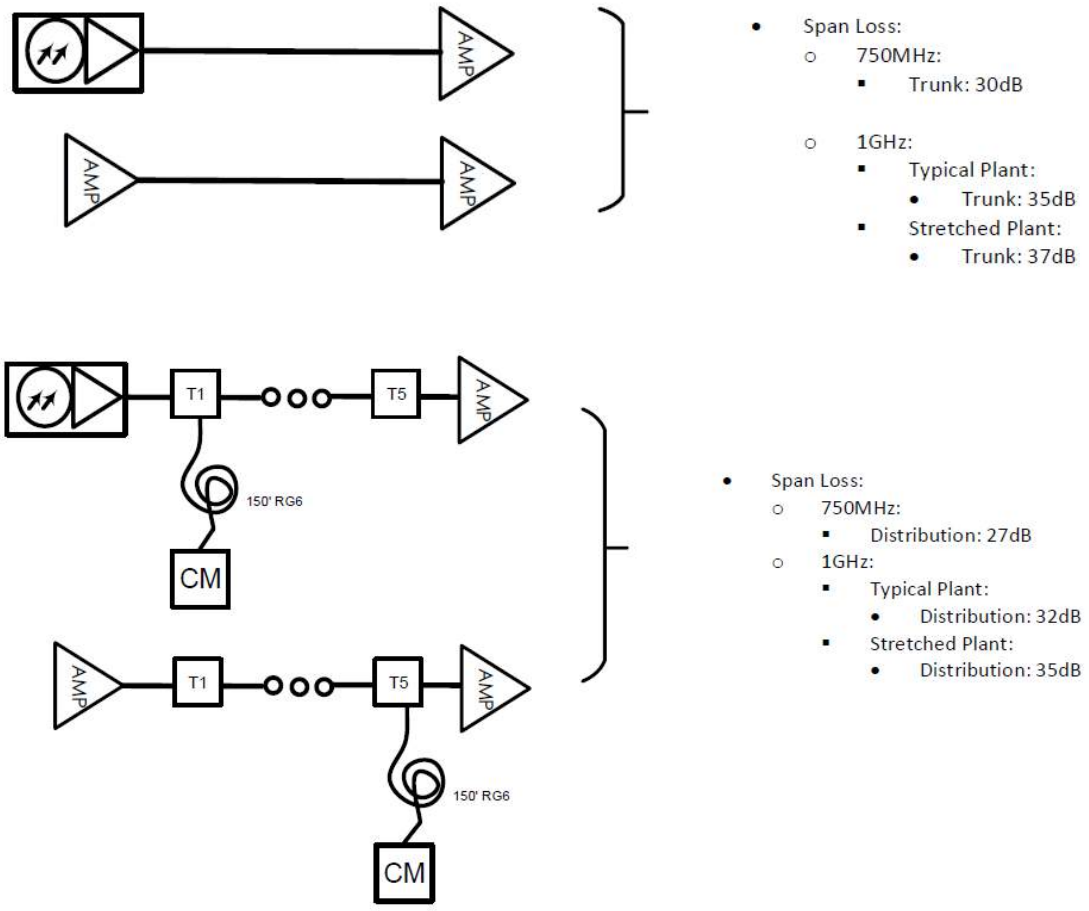

**Figure 4 – Plant Models**

Taking the span loss parameters above into consideration, the following plant models have been created for the analysis.

Note that the area of focus for this paper is in the last two spans of the N+2 plant, where the amplifiers are installed. The first span, between the node and the first amplifier has not been analyzed for performance. Instead the focus is on the input to the first amplifier since that will be the baseline for the system C/N.

Throughout this paper, each plant type will be referred to by its respective distance:

- **135' plant**: 135 feet between each plant element
- **190' plant**: 190 feet between each plant element
- **204' plant**: 204 feet between each plant element

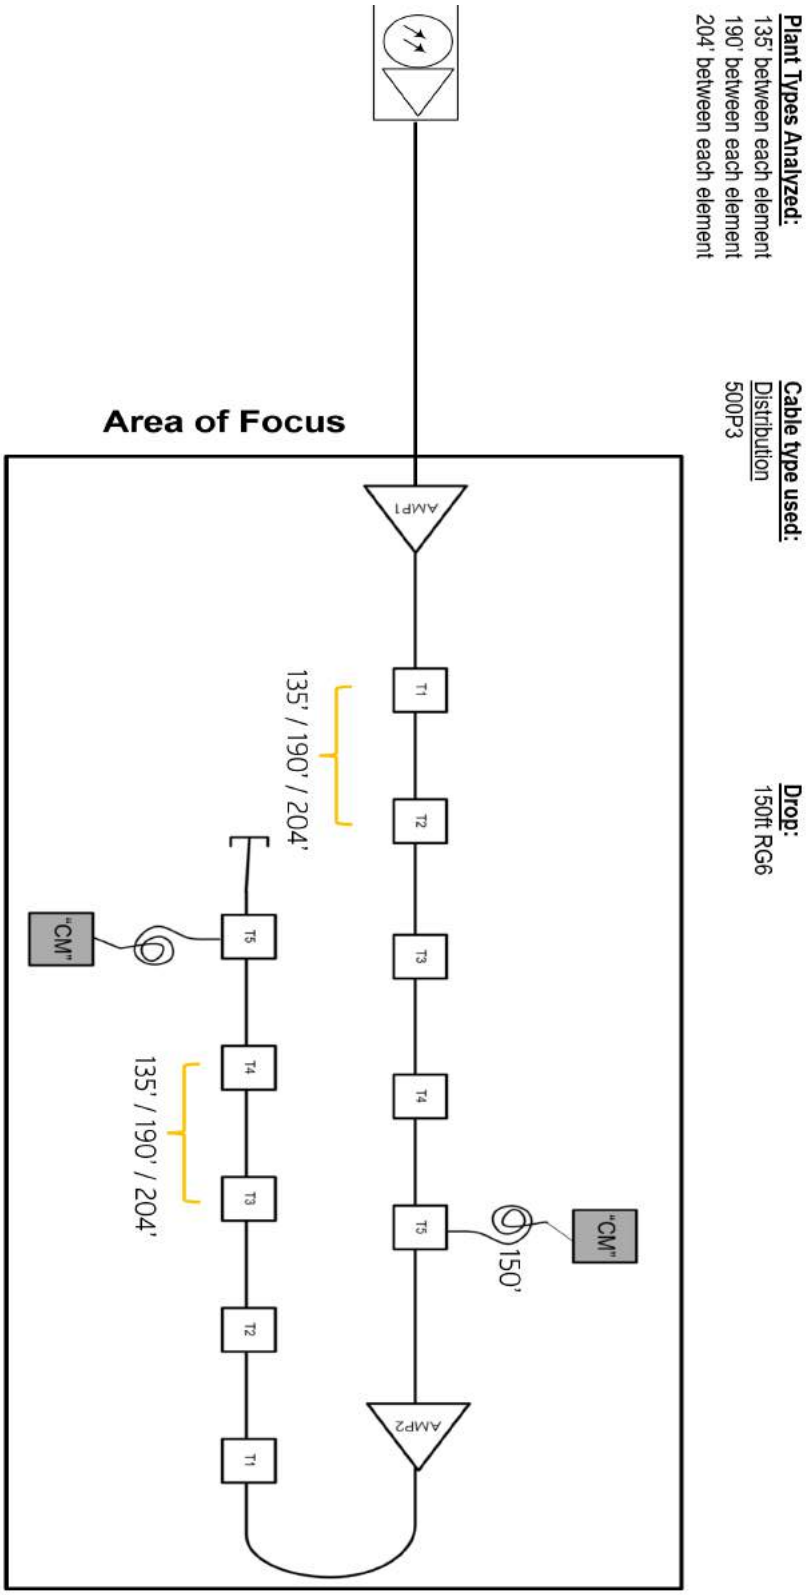

**Figure 5 – Analyzed Plant Types**

### 4.1. Traditional Node and Amplifier Outputs

Assuming 70 dBmV of TCP is available at the port of each active device, the following two options can be considered for extending the spectrum to 1.8 GHz:

1. Change the output tilt in a way to make it more 'flat'
2. Introduce a step-down at a certain frequency, typically 1 GHz

Given the sensitivity of 'legacy' devices in the plant to RF level fluctuations, option 1 is typically avoided. Instead option 2 is typically considered by most operators in traditional plant design.

With that in mind, along with knowing that the majority of TCP is allocated on the higher portion of the spectrum (in this case 1.8 GHz), the following power spectral density (PSD) outputs have been assumed for traditional node and amplifier outputs:

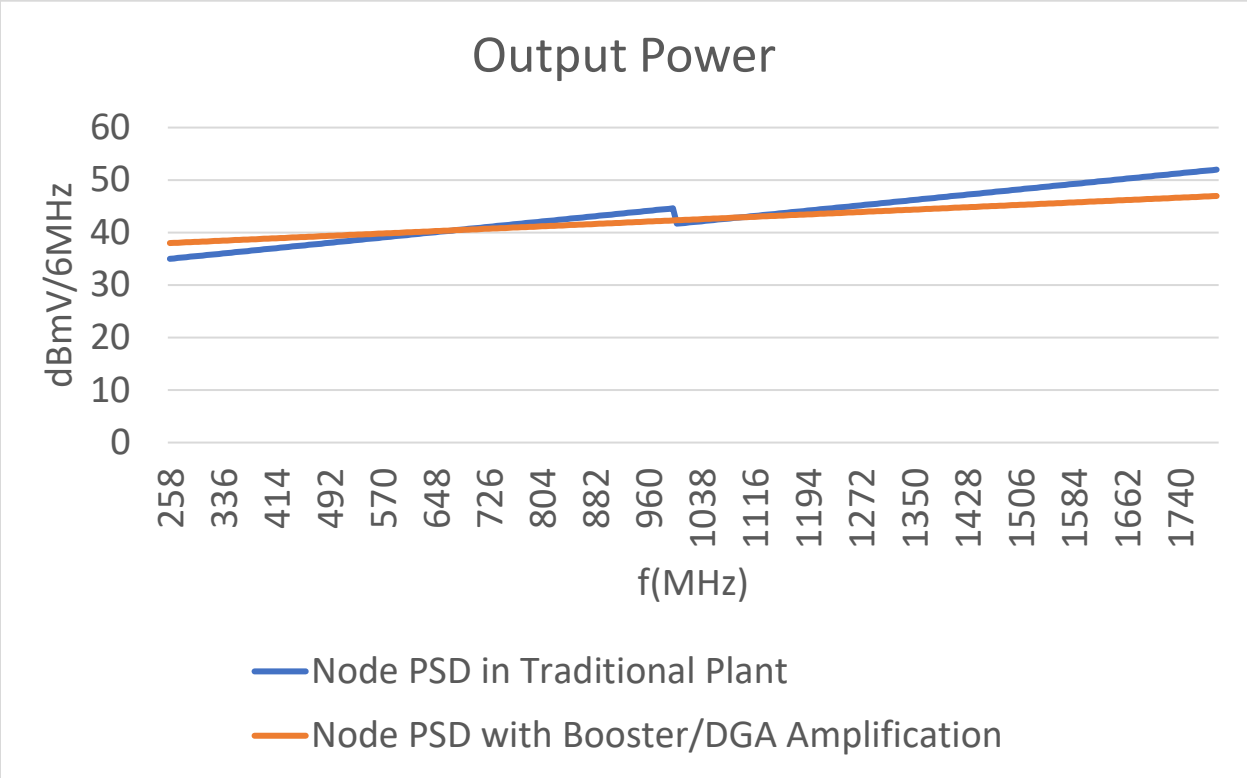

**Figure 6 – Node and Amplifier Output PSD**

It can be seen from the figure above that distributed gain architecture (DGA) PSD does not have any step-downs throughout the spectrum, due to the addition of DGA amplifiers along the distribution path.

The raised levels from 258 MHz to 650 MHz should be mentioned in light of the comment above regarding legacy devices. Given that the low end of the spectrum has been raised by only 2.5 dB, the potential impact of this on legacy devices along the distribution path has been deemed insignificant.

## 4.2. Traditional Node and Amplifier Noise Figure (NF)

Depending on the type of amplifier deployed in the OSP and their respective internal splitting, the DS NF of traditional nodes and amplifiers can vary anywhere between 8 dB – 12 dB. In order to set a baseline for system C/N calculations, the following NF has been assumed:

**Table 1 – Node and Amplifier NF**

| | |
|---|---|
| **Node & Amplifier NF @ Device Port for DS** | 11 dB |

## 4.3. Modem (MDM) Transmit Power:

The following table has been referenced in the DOCSIS 4.0 specification for modem transmit power (Tx)

**Table 2 – MDM Tx Power/1.6 MHz**

| Upstream Centre Frequency | 108 MHz | 684 MHz | Spectral tilt (dB) |
|---|---|---|---|
| **Upstream Reference PSD (dBmV/1.6MHz)** | 33 | 43 | 10 |

Converting the numbers above from 1.6 MHz reference PSD to 6.4 MHz equivalent numbers, the modem Tx power can be graphed as:

**Table 3 – MDM Tx Power/6.4 MHz**

| Upstream Centre Frequency | 108 MHz | 684 MHz | Spectral tilt (dB) |
|---|---|---|---|
| **Upstream Reference PSD (dBmV/6.4MHz)** | 39 | 49 | 10 |

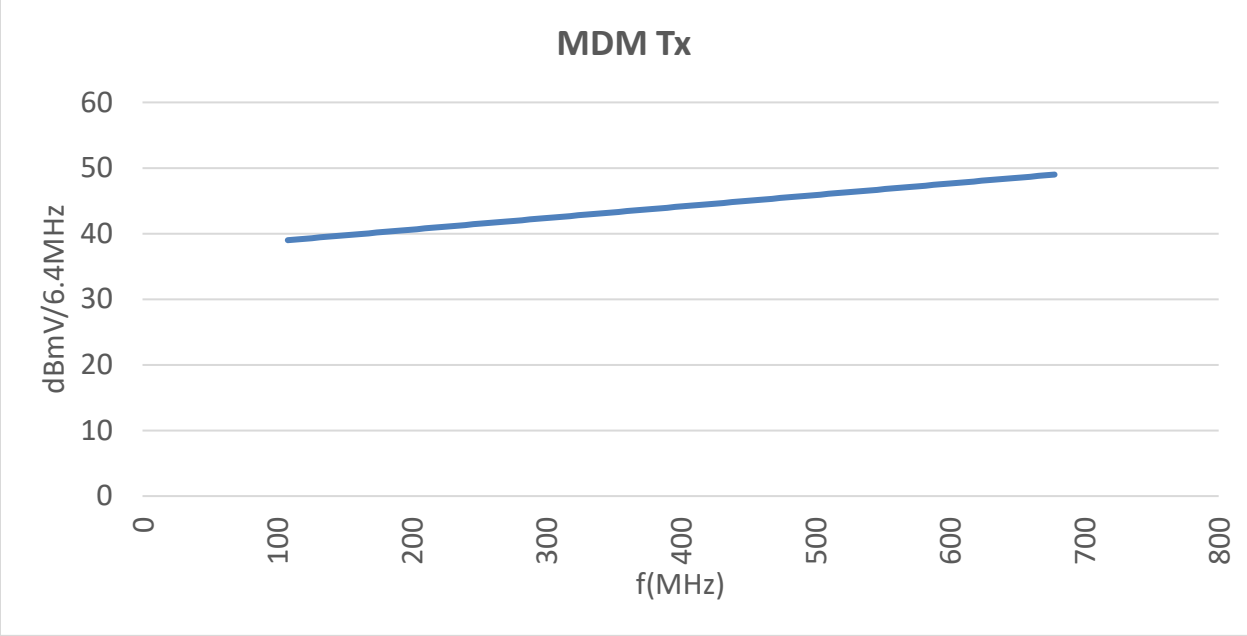

**Figure 7 – MDM Ouput Power PSD**

## 4.4. Modulation Order vs. Power and C/N

In order to have a baseline for achievable modulation orders throughout the distribution plant, the below table from the DOCSIS 4.0 PHY specification has been utilized.

Note: although DOCSIS 4.0 modems are able to receive and demodulate signals as low as 16QAM with 16 dB of C/N and -30 dBmV/6 MHz, no values below 256QAM has been considered in this paper since modulation orders lower than 256QAM are typically deemed unacceptable by operators.

**Table 4 – MDM Tx Power/6.4 MHz**

| Constellation | C/N (dB) | Rx Power/6 MHz (dBmV) |
|---|---|---|
| 4kQAM | 44 | -6 |
| 2kQAM | 40 | -9 |
| 1kQAM | 36 | -12 |
| 512QAM | 33 | -15 |
| 256QAM | 30 | -18 |

# 5. DGA Amplifier Considerations

In order to implement booster or DGA amplifiers, a baseline for upstream (US) and downstream (DS) gains needs to be set. Given that these amplifiers are single stage with a fixed output, the output performance of the device is highly dependent on the input levels for upstream and downstream. This is defined by noise power ratio (NPR) for the US and carrier to interference noise ratio (CINR), as a function of input TCP.

For the designs carried out in this paper, due to lack of availability on the parameters mentioned above, instead only the US and DS amplifier's noise figure (NF) has been considered in the overall system performance considerations. The NF of booster/DGA amplifiers have been shown in the table below:

**Table 5 – DGA Amplifier DS and US NF**

| | |
|---|---|
| **DGA/Booster Amplifier NF @ Device Port for US and DS** | 15 dB |

## 5.1. DS Gain

The following figure has been assumed for the DGA amplifier DS gain:

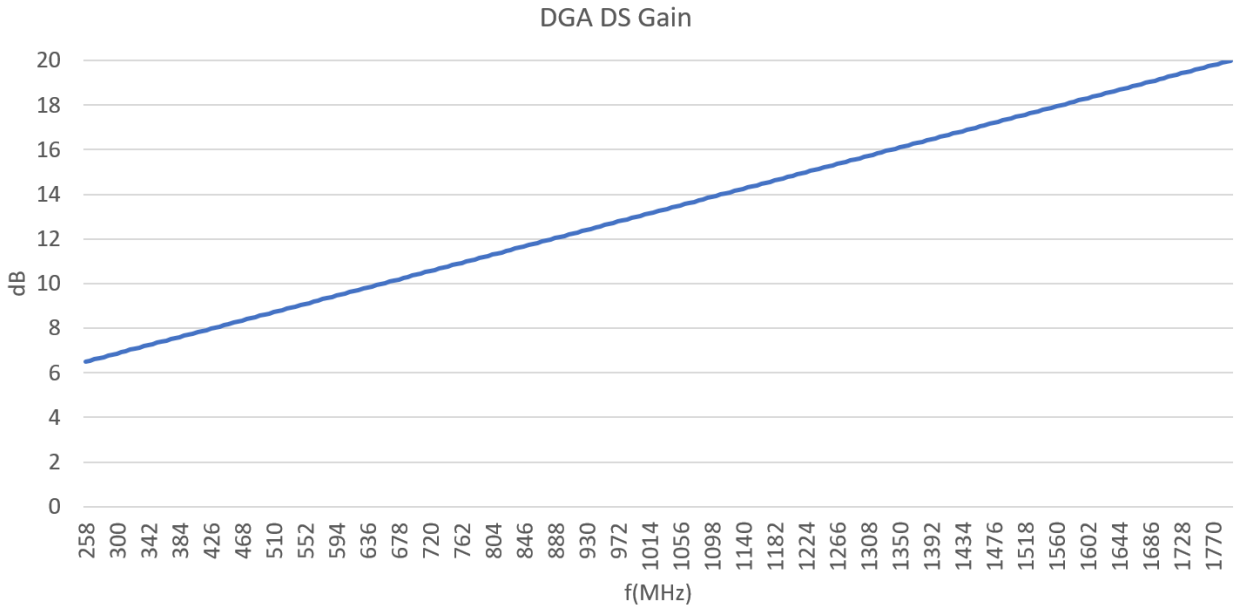

**Figure 8 – DGA Amplifier DS Gain**

## 5.2. US Gain

The following figure has been assumed for the DGA amplifier US gain:

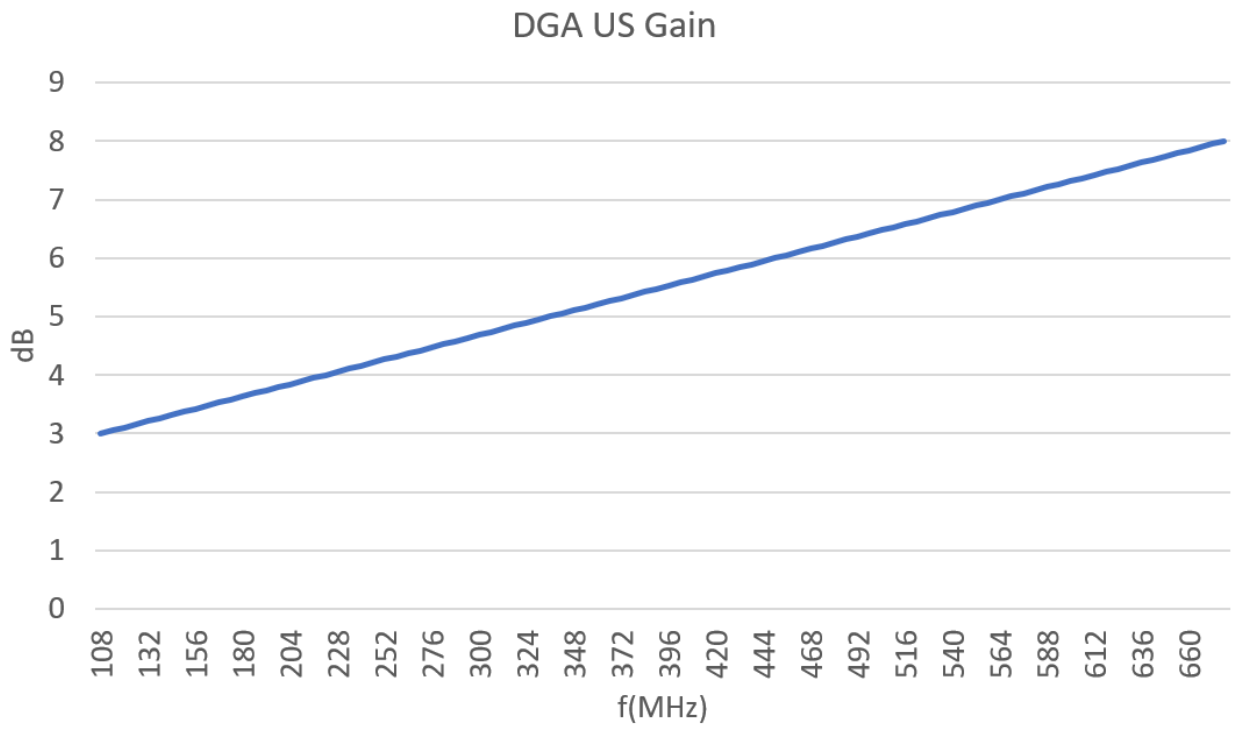

**Figure 9 – DGA Amplifier US Gain**

# 6. Traditional Plant DS Results

The performance results in this section are used as a baseline for comparison. Before discussing the modem receive levels in each plant type, the amplifier contributions to system C/N for each scenario is calculated below.

**135' Plant C/N:**

Applying the 'traditional PSD' node and amplifier output in section 4.1 to the 135' plant model will result in the following Rx Power at the port of amplifiers:

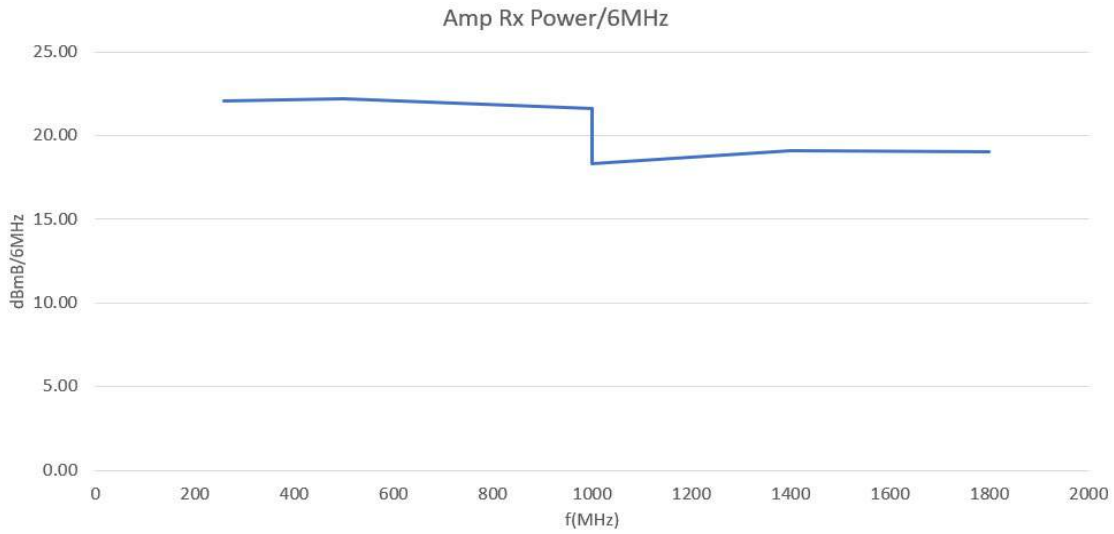

**Figure 10 – 135' Amplifer Rx Power @ Amp. Port**

From the figure above the C/N contribution of the amplifiers at 1 GHz and 1.8 GHz can be calculated:

**Table 6 – 135' Tradtitional Amplifier Contributions to System CNR**

| | |
|---|---|
| **N+2 CNR @ 1 GHZ** | 58.7 dB |
| **N+2 CNR @ 1.8 GHz** | 59.4 dB |

**190' Plant C/N:**

Applying the 'traditional PSD' node and amplifier output in section 4.1 to the 190' plant model will result in the following Rx Power at the port of amplifiers:

**Figure 11 – 190' Amplifer Rx Power @ Amp. Port**

From the figure above, the C/N contribution of the amplifiers at 1GHz and 1.8GHz can be calculated:

**Table 7 – 190' Traditional Amplifier Contributions to Ststem CNR**

| | |
|---|---|
| **N+2 CNR @ 1 GHZ** | 51.7 dB |
| **N+2 CNR @ 1.8 GHz** | 48.4 dB |

**204 Plant C/N:**

Applying the 'traditional PSD' node and amplifier output in section 4.1 to the 204' plant model will result in the following Rx Power at the port of amplifiers:

**Figure 12 – 204' Amplifer Rx Power @ Amp. Port**

From the figure above the C/N contribution of the amplifiers at 1GHz and 1.8GHz can be calculated:

**Table 8 – 204' Traditional Amplifier Contributions to System CNR**

| | |
|---|---|
| **N+2 CNR @ 1 GHZ** | 50 dB |
| **N+2 CNR @ 1.8 GHz** | 45.6 dB |

**Observation:** From the results in Table 7 and 8, we can observe that although the input Rx power into the traditional amplifiers are below 11 dBmV/6 MHz, all the C/N's are above the minimum required for 4kQAM. This is an optimistic assumption for 190' and 204' plant as the distribution network's contribution the system C/N is very close to the numbers in Table 4. As noted in section 3.1, the starting C/N from the node plays a big role in the overall system C/N.

Knowing this and applying the 'traditional PSD' node and amplifier output discussed in section 4.1 to the plant models in section 4.0, will result in the modem receive levels (MDM Rx) below.

**Note:** as discussed in section 4, all the drops lengths throughout this paper are 150 feet of RG6 which can be considered a worst-case scenario.

## 6.1. 135’ Plant MDM Rx Powers

The Rx power levels /6 MHz for each modem along the distribution line for the 135’ plant has been demonstrated below:

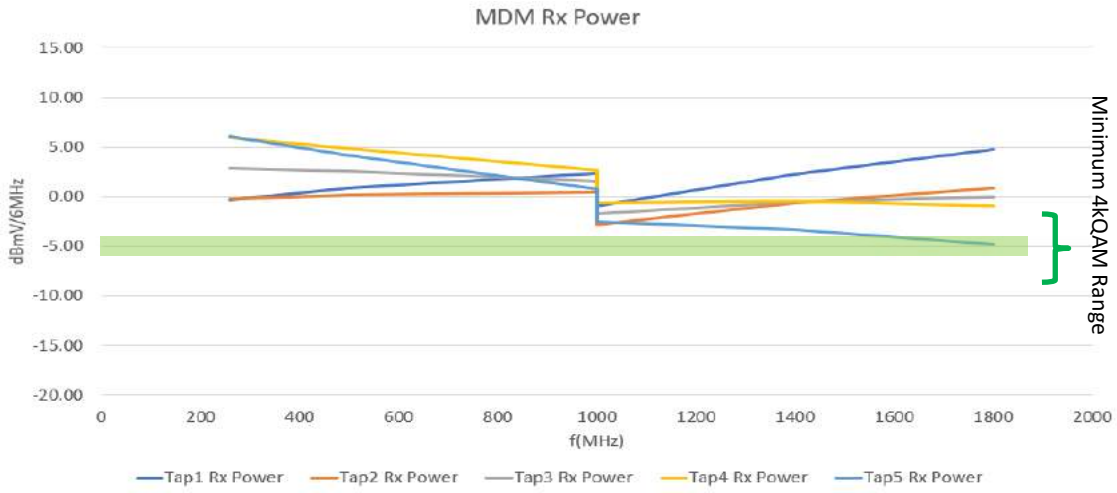

**Figure 13 – 135’ Span 1 MDM Rx Power/6 MHz**

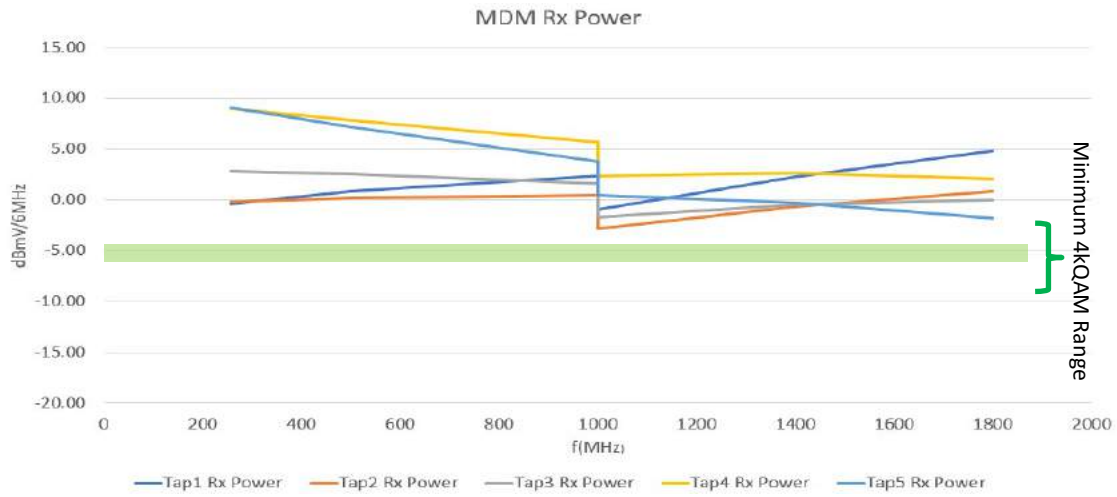

**Figure 14 – 135’ Span 2 MDM Rx Power/6 MHz**

## 6.2. 190’ Plant MDM Rx Powers

The Rx power levels /6 MHz for each modem along the distribution line for the 190’ plant has been demonstrated below:

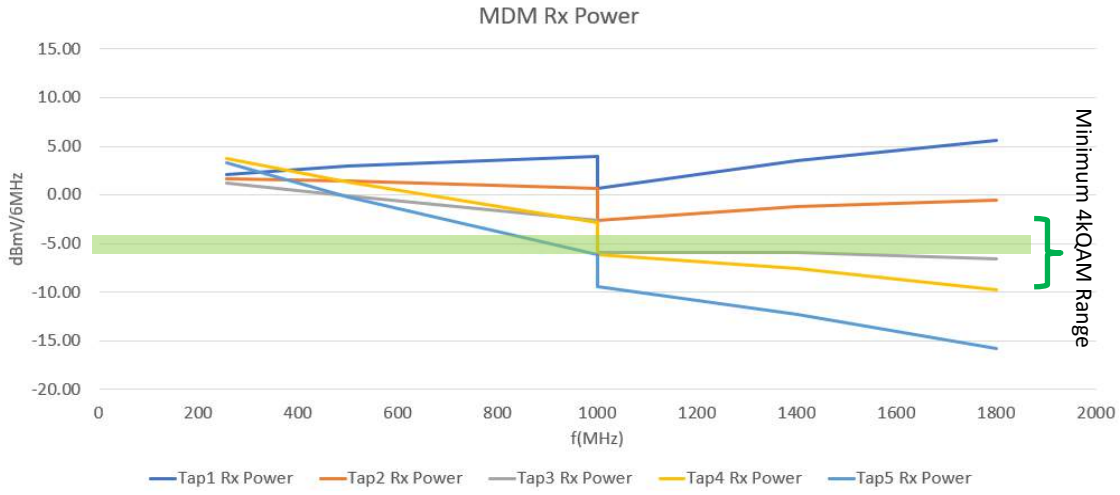

**Figure 15 – 190’ Span 1 MDM Rx Power/6 MHz**

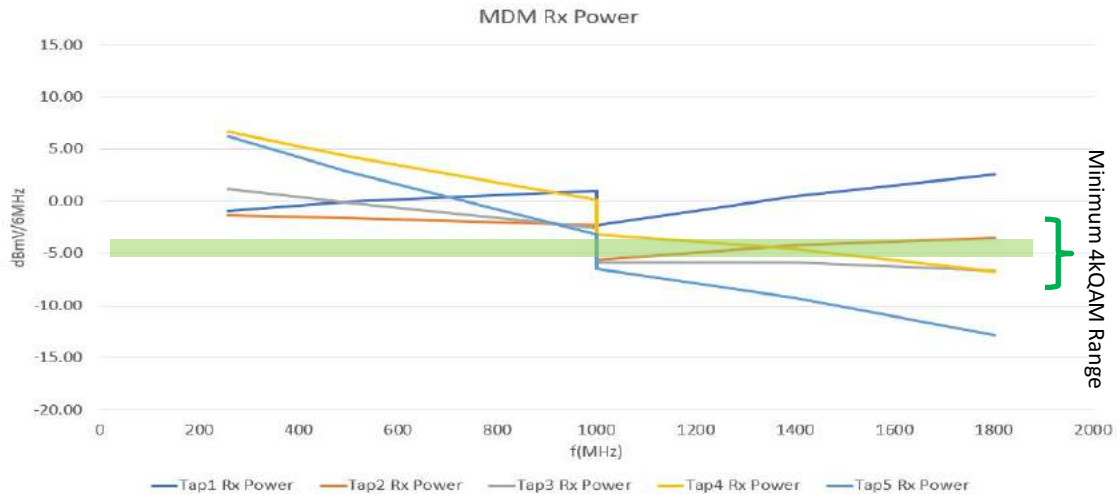

**Figure 16 – 190’ Span 2 MDM Rx Power/6 MHz**

## 6.3. 204’ Plant MDM Rx Powers

The Rx power levels /6 MHz for each modem along the distribution line for the 204’ plant has been demonstrated below:

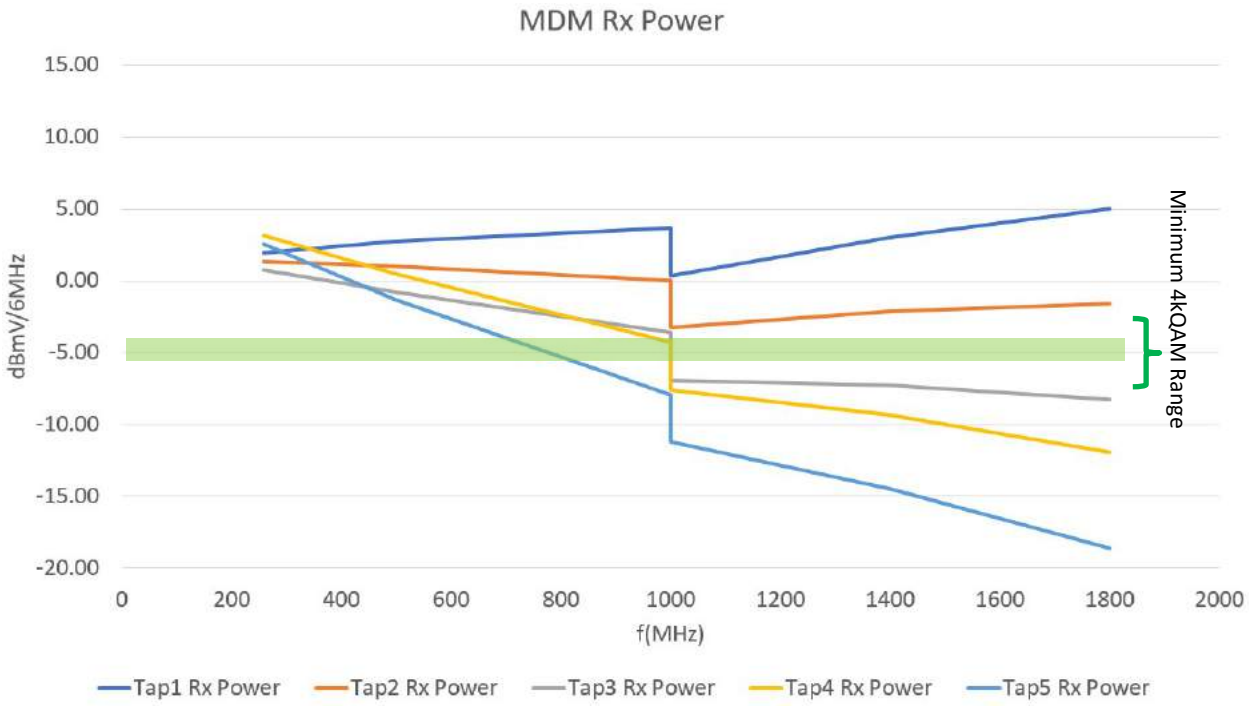

**Figure 17 – 204’ Span 1 MDM Rx Power/6 MHz**

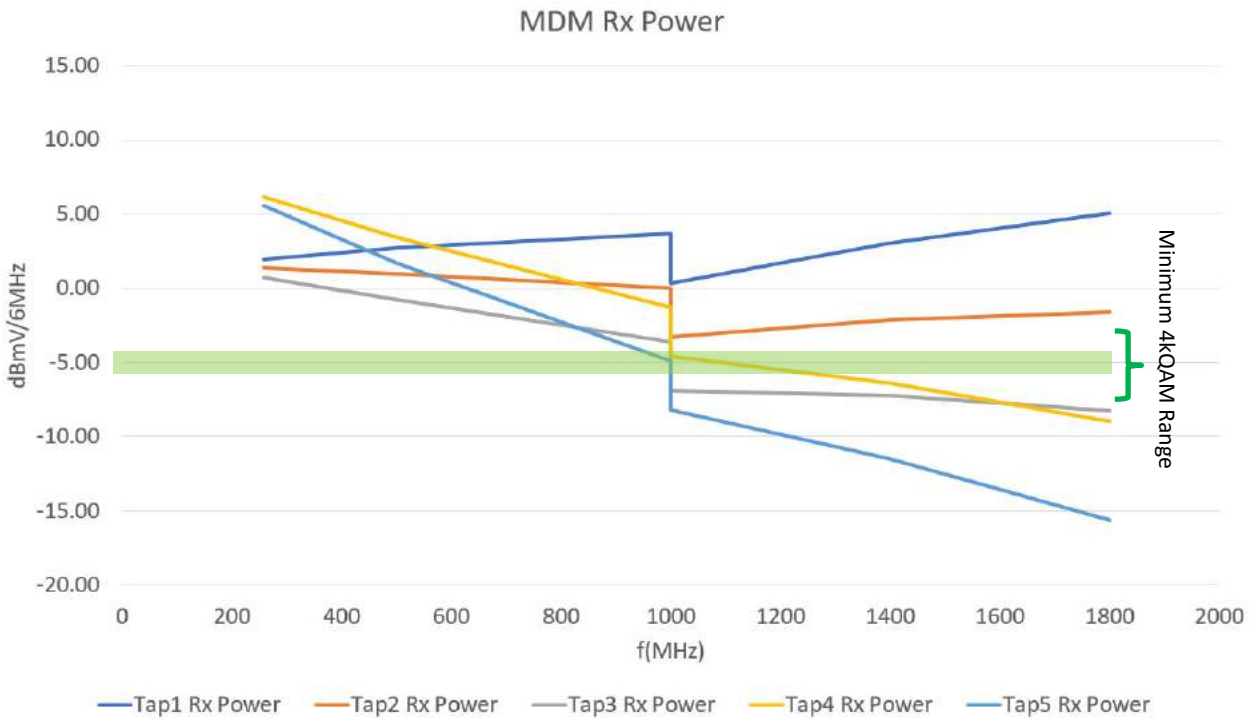

**Figure 18 – 204' Span 2 MDM Rx Power/6 MHz**

**Observation:** in the 135' plant, all the modems are capable of receiving 4kQAM with traditional amplifiers only. On the contrary, it can be seen than 190' and 204' plant models struggle with achieving 4kQAM throughout the distribution network. It should also be emphasized that all of the analysis above was done using 150 feet of RG6 as the drops throughout the distribution plant. Reducing this length will improve the Rx levels at each MDM, improving the MER and achievable modulation order.

## 7. Booster Amplifcation DS Results

Based on the results demonstrated in the previous section, the 190' and 204' plant models struggle with achieving 4kQAM throughout the distribution network. These plant models could be prime candidates for adding booster amplifiers mid-span to not only increase the Rx power at each traditional amplifier input, but also to boost the MDM Rx levels in each span. Given that 135' plant is capable of achieving 4kQAM (Figures 13 and 14), no booster amplification has been considered for this plant model.

As discussed in section 4.1 and given the new additional mid-span gain from the DGA/booster amplifier, the need for a step downs in the output PSD is eliminated. This new output PSD results in a 2.5 dB lower TCP (69.8 dBmV vs. 67.3 dBmV), which can subsequently improve the output C/N of the node. As previously covered in section 3 this has not been considered in overall system C/N calculations.

**Note:** Based on the early prototype form factors of DGA/booster amplifiers, the final version of the product should approximately be the equal to the size of a mainline splitter. This can have immense benefits when it comes to ease of installation and access. In other words, as long as pedestals (PEDs) are installed for tap locations, an assumption has been made that DGA/booster amplifiers will fit in existing PEDs.

## 7.1. 190’ and 204’ Plant Design with Booster Amplifiers

The following design has been considered for the 190’ and 204’ plant types, with booster amplification mid-span:

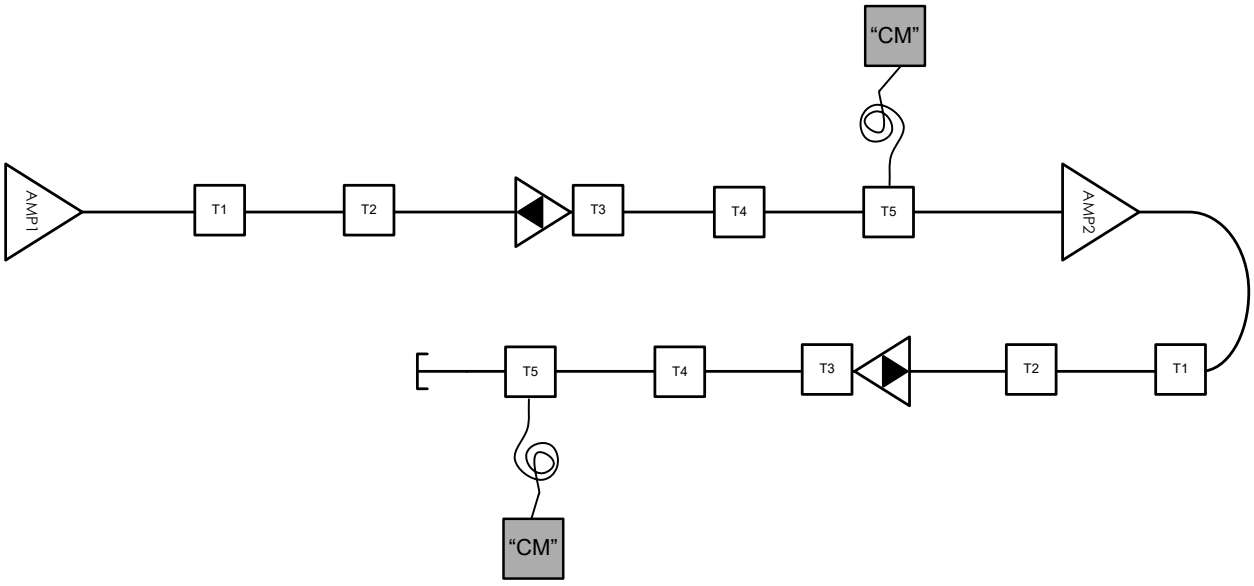

**Figure 19 – 190’ and 204’ Plant with Mid-Span Booster Amplification**

In this new design with the added gain mid-span, the tap values after the booster amplifier must be increased to ensure reasonable Rx power at the modem. This will further improve the end-of-line Rx power because higher value taps have lower insertion loss values throughout the spectrum.

Additionally, as discussed in section 4, given the added 20 dB of gain at 1.8 GHz, there is no need for any step down at 1 GHz. DGA gain from Figure 8 has been applied to the node and amplifier outputs.

As a result, the new traditional amplifier Rx levels have been demonstrated below:

## 190’ Plant Traditional Amplifier Rx Power with Booster Amplification:

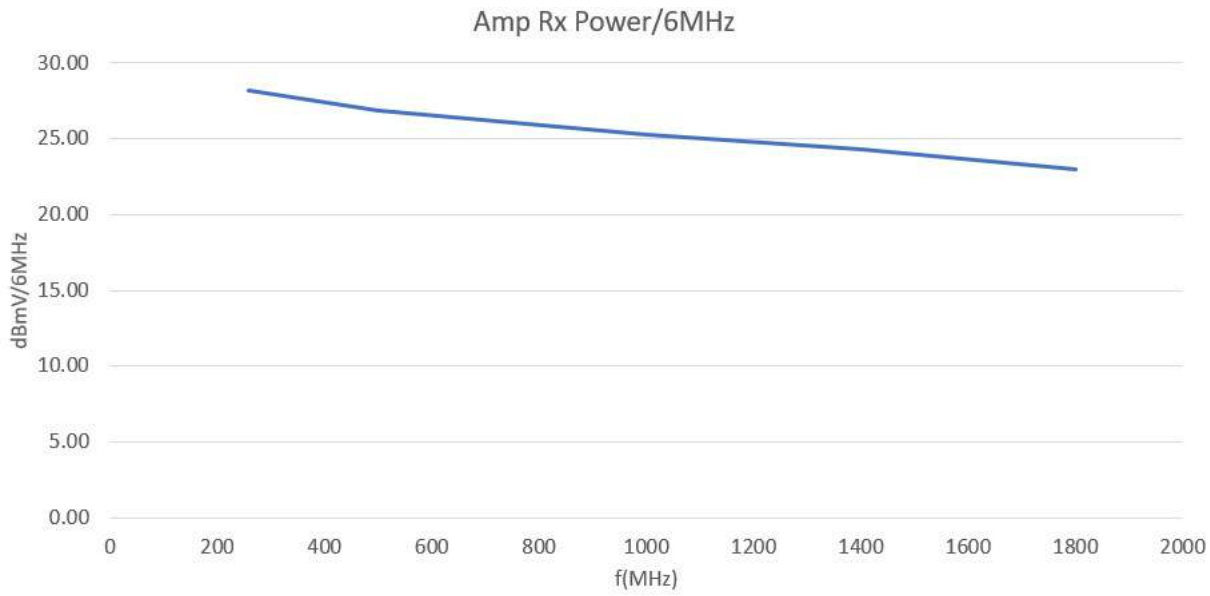

**Figure 20 – 190’ Amplifier Rx Power @ Port with Booster Amplification**

## 204’ Plant Traditional Amplifier Rx Power with Booster Amplification:

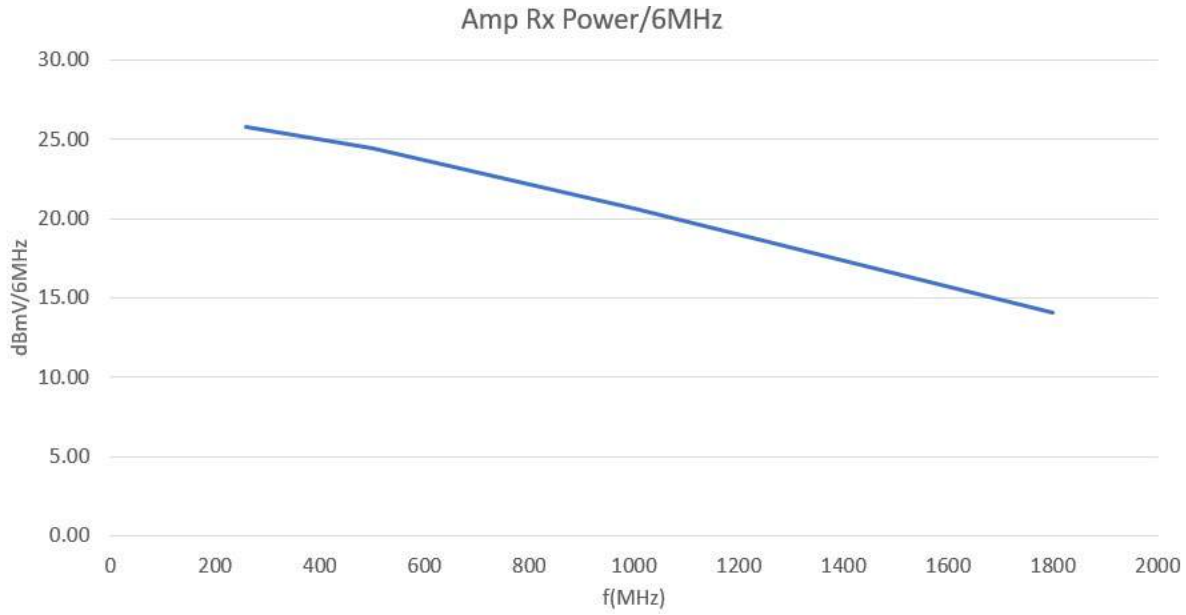

**Figure 21 – 204’ Amplifier Rx Power @ Port with Booster Amplification**

A point of concern would be adding two additional amplifiers, essentially taking the current N+2 design to N+4. The overall contributions of the amplifiers to the system C/N can be calculated for each case, demonstrated in the table below:

**Table 9 – Amplifier Contributions to System C/N**

| | 190' Plant | 204' Plant |
|---|---|---|
| **Amplifier Contributions to C/N @1 GHz** | 61.8 dB | 58.9 dB |
| **Amplifier Contributions to C/N @1.8 GHz** | 58.7 dB | 53 dB |

An assumption can be made that the limiting factor in achieving each modulation order is the Rx power at the modem. Keeping that in mind, the figures below demonstrate MDM Rx power at each tap, with the addition of booster amplification mid-span:

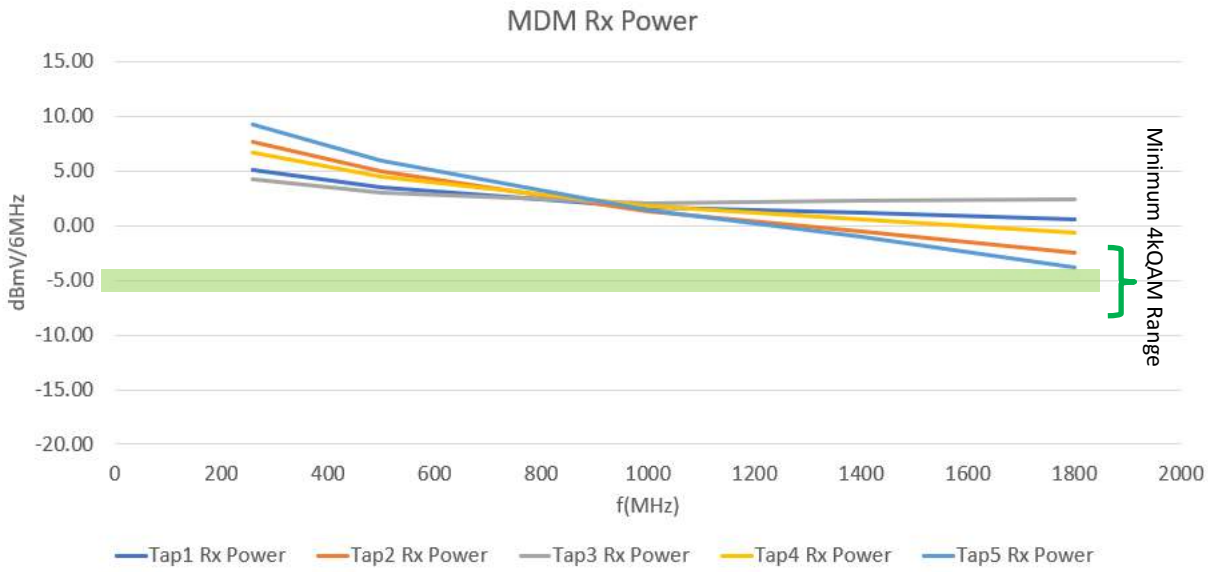

**Figure 22 – 190' Span 1&2 MDM Rx Power/6MHz**

It can be observed that all the taps along the distribution line are now well above the 4kQAM threshold.

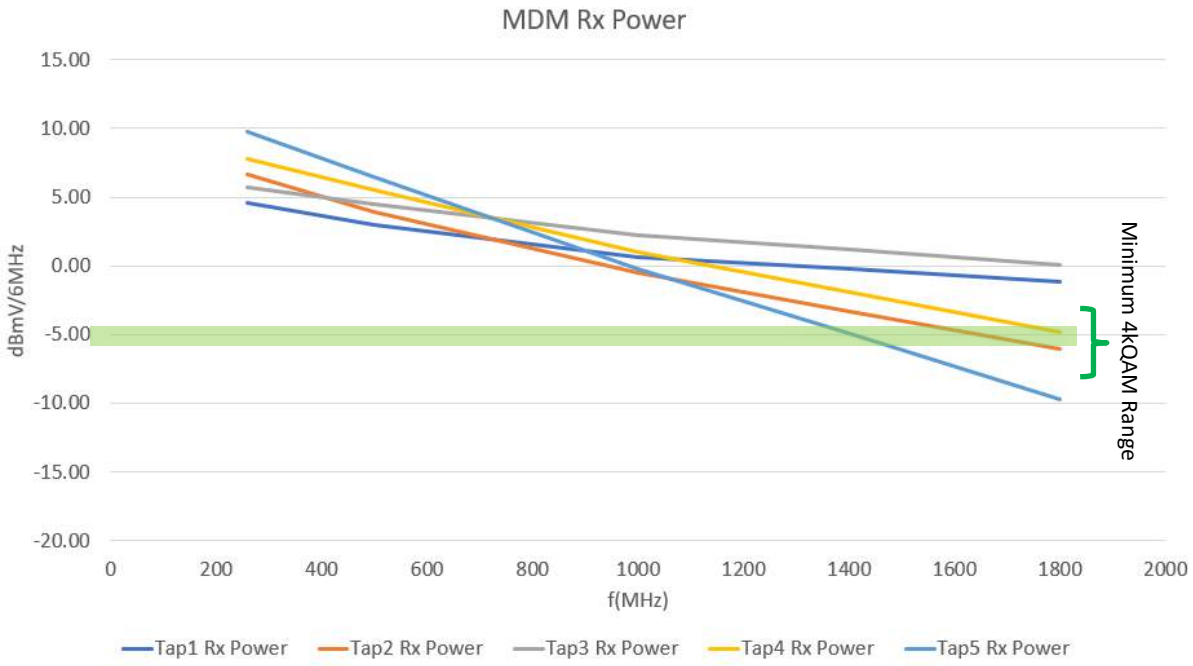

**Figure 23 – 204' Span 1&2 MDM Rx Power/6MHz**

Aside from ~200 MHz of Tap 5, it can be observed that all the taps along the distribution line are now above the 4kQAM threshold.

### 7.2. Booster Amplification Observations

Mid-span booster amplification seems to provide a viable option to increase the system C/N and subsequently, the overall system achievable modulation order. This is also assuming that the booster and DGA amplifiers have very low distortion characteristics, where they can be considered negligible.

## 8. DGA Design and DS Results

DGA design can be described as distributing the gain of traditional amplifiers along the path. This can potentially have the following benefits:

- Enhancing end-of-line performance
- Fully moving away from distortions and intermodulations and, as a result, achieving a noise-limited system
- Eliminating the need for having any step downs in node or amplifier output
- Reducing the output power of the node, resulting in improvement of the output MER
- Reduced power draw (covered in section 10)

Additionally, as discussed in section 7, the form factor of the DGA amplifiers are roughly the size of a mainline splitter. Assuming there are PED locations available for taps, DGA amplifiers should fit before or after the taps, depending on the design.

From an OSP design perspective, DGA can seem strange in comparison to designing a traditional plant. As demonstrated in sections 8.1, 8.2 and 8.3, the 'mid-span' tap values can vary anywhere from 17 to 20 dB taps, depending on where the DGA amplifier has been installed. This can present design challenges

for operators as new design methodologies have to be crafted in order to optimize plant performance. This will be discussed further in section 12.

DGA designs might also seem counter intuitive to the concept of cascade reduction. As demonstrated in the following sections, the cascade length of the studied N+2 plants can increase up to 8. This cascade length can vary by approximately 2 amplifiers for each case analyzed, depending on the end-of-line performance expectations by the operator. For the purpose of this study, all plant types have been designed to achieve 4kQAM.

An important note to keep in mind is that the designs shown here are moving away from a unity gain design since no pads or equalizers were considered in this analysis. With traditional amplifiers, this can cause concern as distortions can accumulate quite rapidly when a system is not designed with unity gain in mind. Theoretically speaking, given the extremely low distortion characteristics of DGA amplifiers, it has been assumed that distortions will not result in degradation of signal quality at the end-of-line. This needs to be verified in the future as more products are available in this realm.

In the below sections, the performance of each plant type when converted to DGA, has been discussed.

## 8.1. 135' Plant Design and DS Results

The following design has been considered for 135' plant:

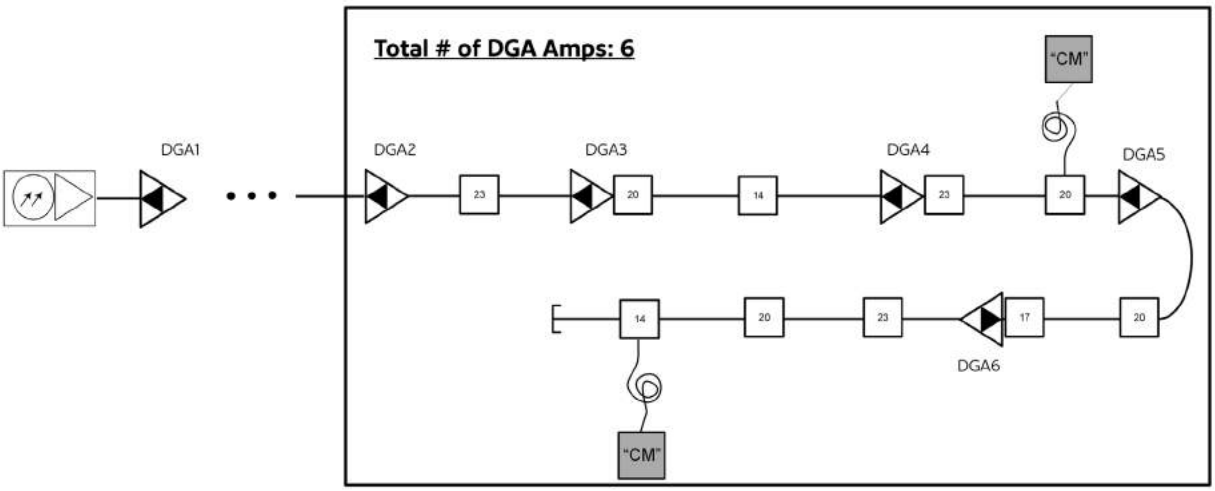

**Figure 24 – 135' DGA Conversion**

**Note:** in order to have a baseline, spans 1 and 2 have been kept the same in comparison to the 'traditional' plant spans.

As it can be seen, a previously N+2 plant has been converted to N+6. Although this might seem concerning at first, the Rx power at each DGA amplifier along with the amplifier contributions to the system C/N has been shown below:

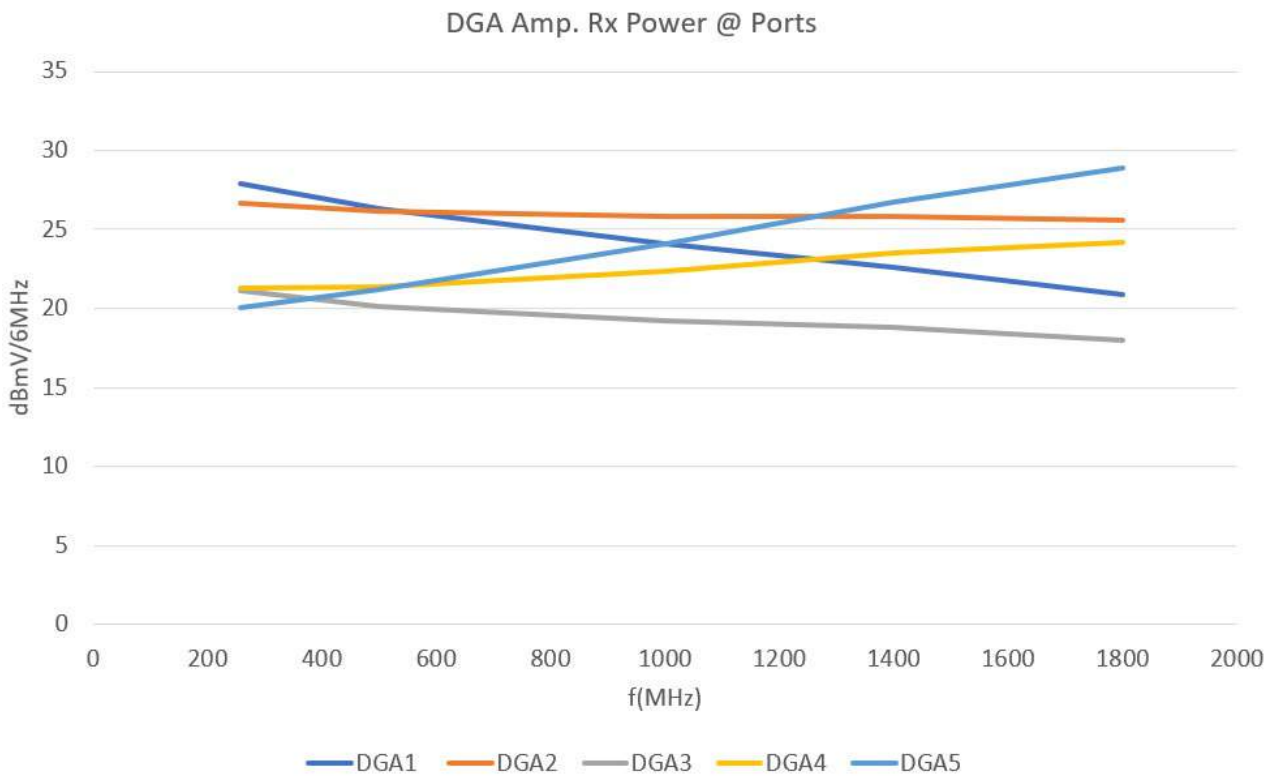

**Figure 25 – 135' Plant DGA Amplifiers' Rx Power @ Ports**

From the figure above, calculating the overall amplifier contributions to system C/N will result in the following:

**Table 10 – 135' DGA Amplifier Contributions to System C/N**

| | **135' Plant** |
|---|---|
| **System C/N @1 GHz** | 61.8 dB |
| **System C/N @1.8 GHz** | 58.7 dB |

Knowing the above, it can be assumed that the limiting factor for plant performance would be the Rx power at the modems. The figures below demonstrate Rx power at each tap's modem location for each span:

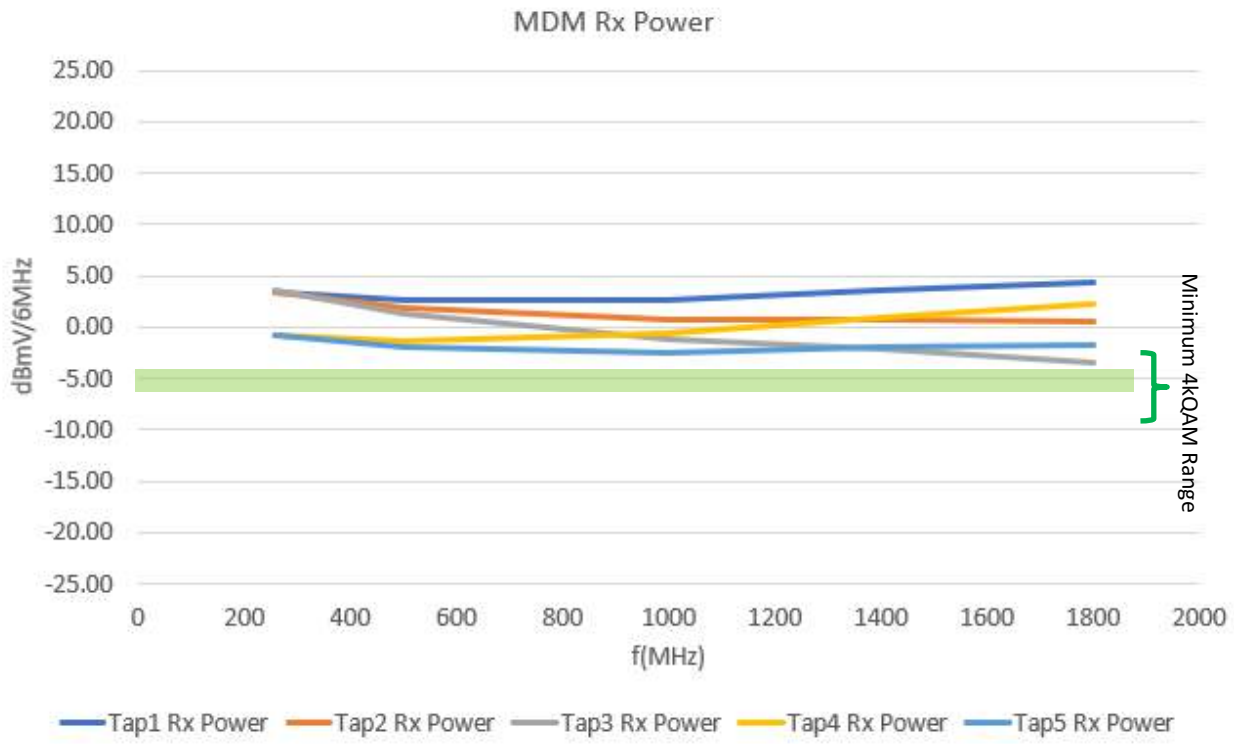

**Figure 26 – DGA 135' Span 1 MDM Rx Power/6MHz**

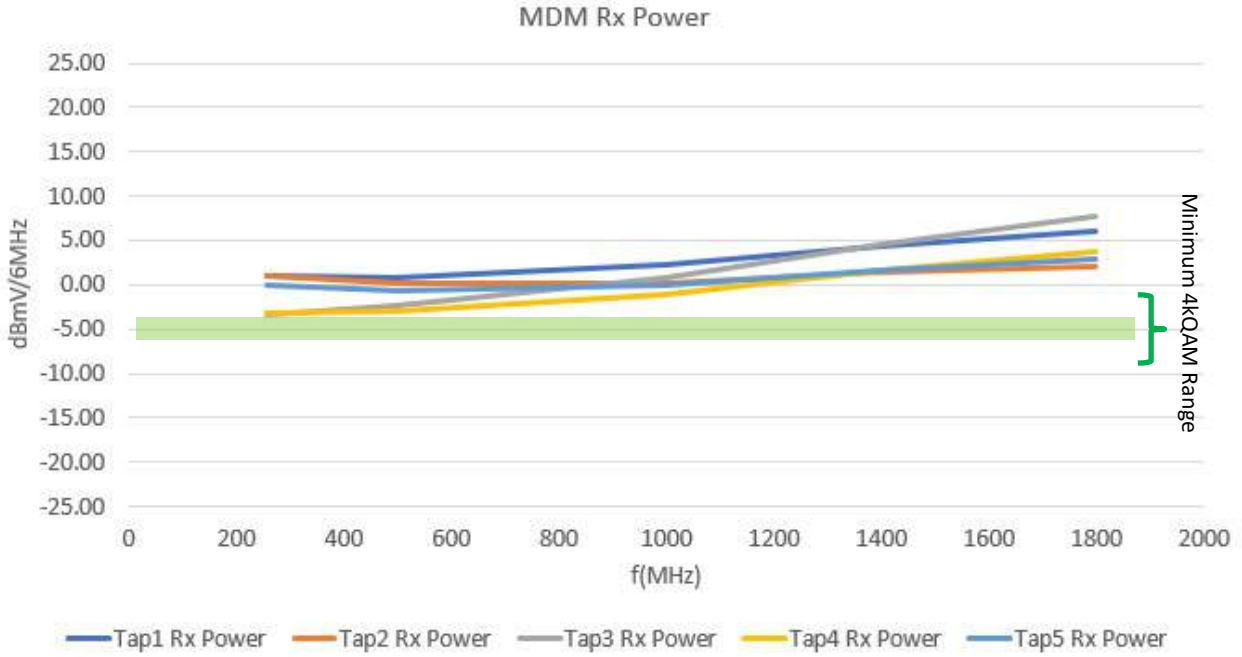

**Figure 27 – DGA 135' Span 2 MDM Rx Power/6MHz**

Although the 135' plant does not seem to benefit from DGA from an achievable modulation order perspective, it will benefit from the power reductions properties of DGA. This will be further discussed in section 10.

## 8.2. 190’ Plant Design and DS Results

The following design has been considered for 190’ plant:

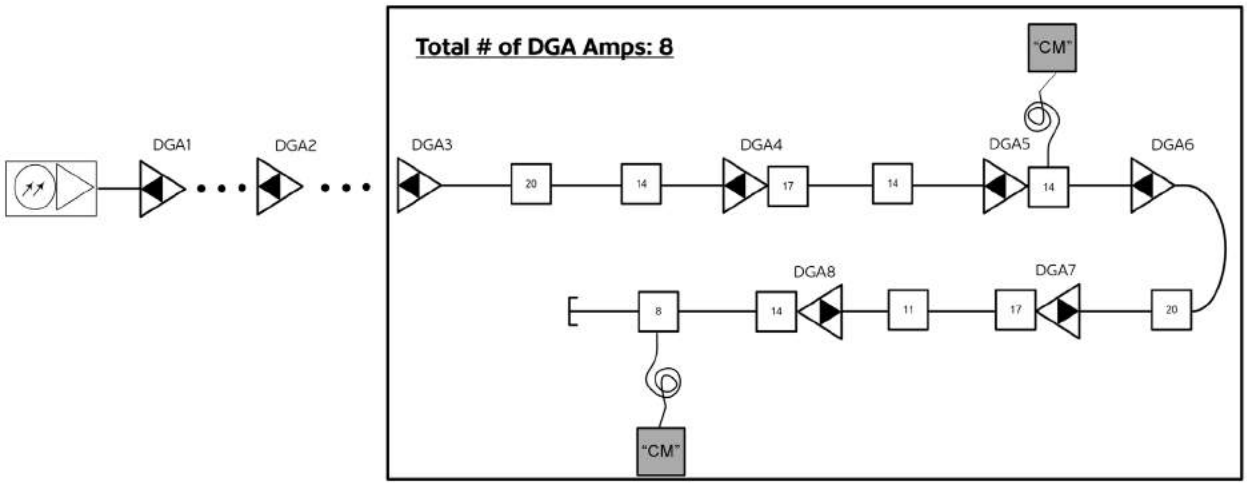

**Figure 28 – 190’ DGA Conversion**

The previous N+2 plant has been converted to N+8. The Rx power at each DGA amplifier has been shown below:

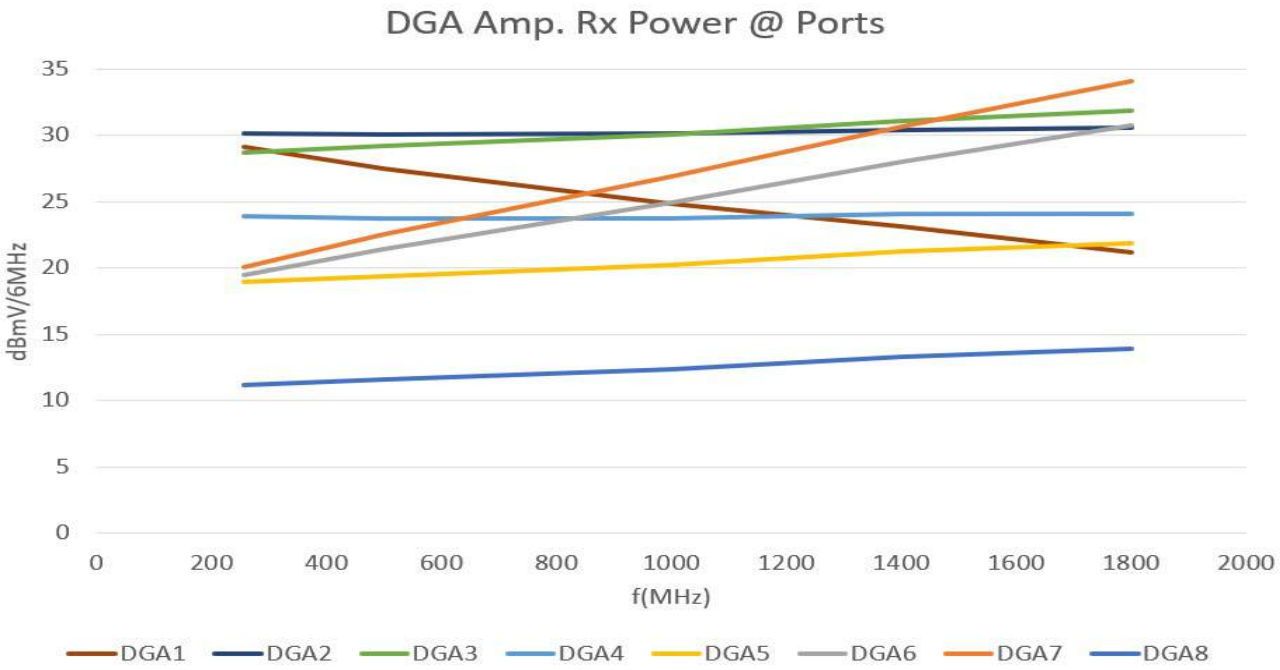

**Figure 29 – 190’ Plant DGA Amplifiers’ Rx Power @ Ports**

From the figure above, calculating the overall amplifier contributions to system C/N will result in the following:

**Table 11 – 190' DGA Amplifier Contributions to System C/N**

| | 190' Plant |
|---|---|
| **Amplifier Contributions to CNR @1 GHz** | 54 dB |
| **Amplifier Contributions to CNR @1.8 GHz** | 54.5 dB |

It can be seen that the overall system C/N can remain high, despite the fact that 8 amplifiers have been designed in cascade.

With that in mind, the modem Rx power still seems to be the limiting factor in the achievable modulation order. The figures below demonstrate Rx power at modems in each tap location:

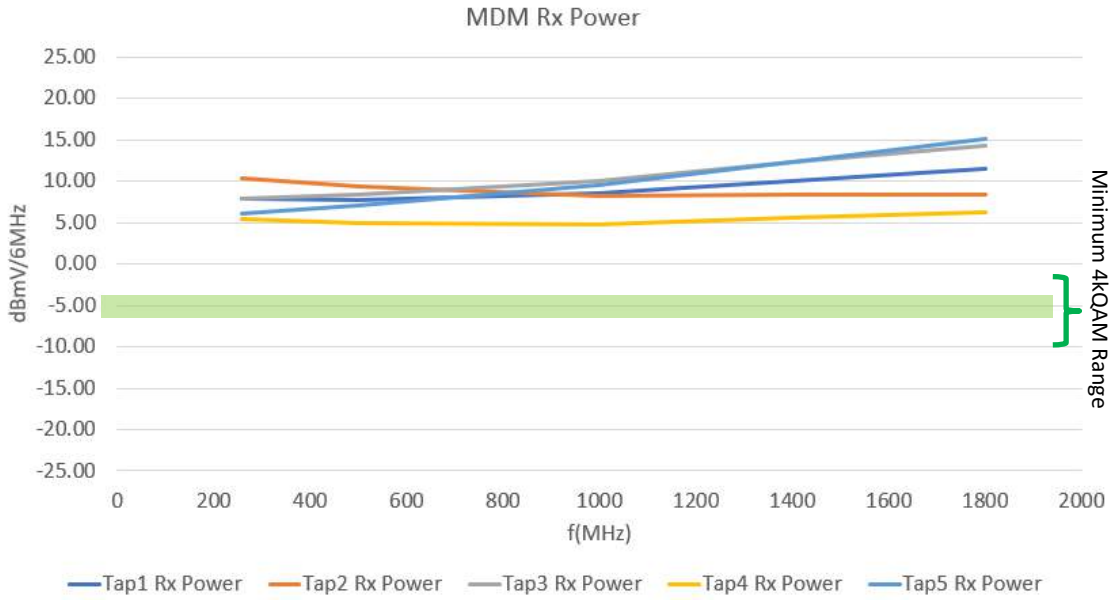

**Figure 30 – DGA 190' Span 1 MDM Rx Power/6 MHz**

**Figure 31 – DGA 190' Span 2 MDM Rx Power/6 MHz**

It can be observed that all the Rx powers throughout the distribution plant are well above the minimum 4kQAM threshold.

## 8.3. 204' Plant Design and DS Results

The following design has been considered for 204' plant:

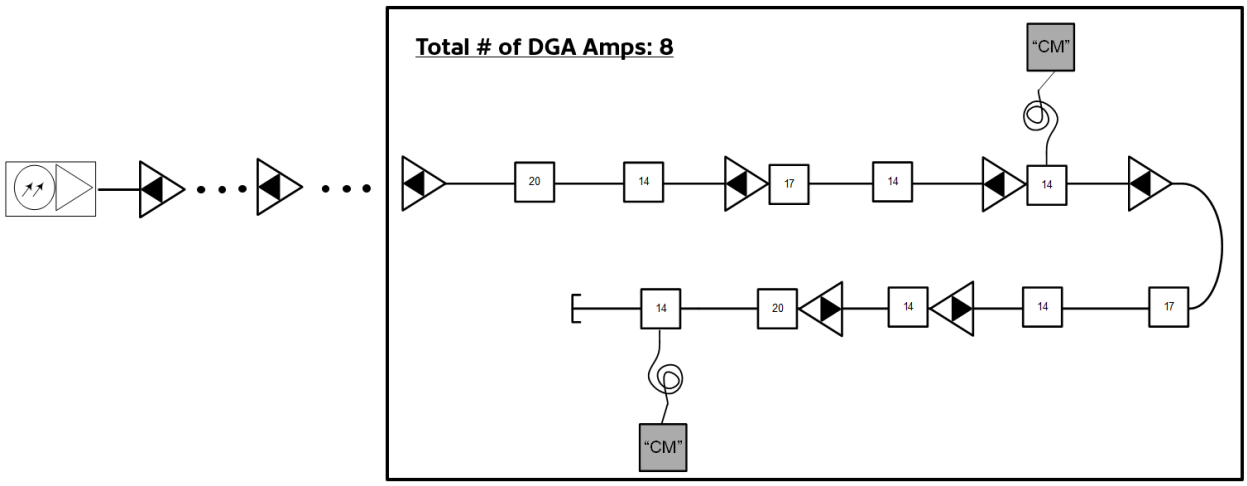

**Figure 32 – 204' DGA Conversion**

The previous N+2 plant has been converted to N+8. The Rx power at each DGA amplifier has been shown below:

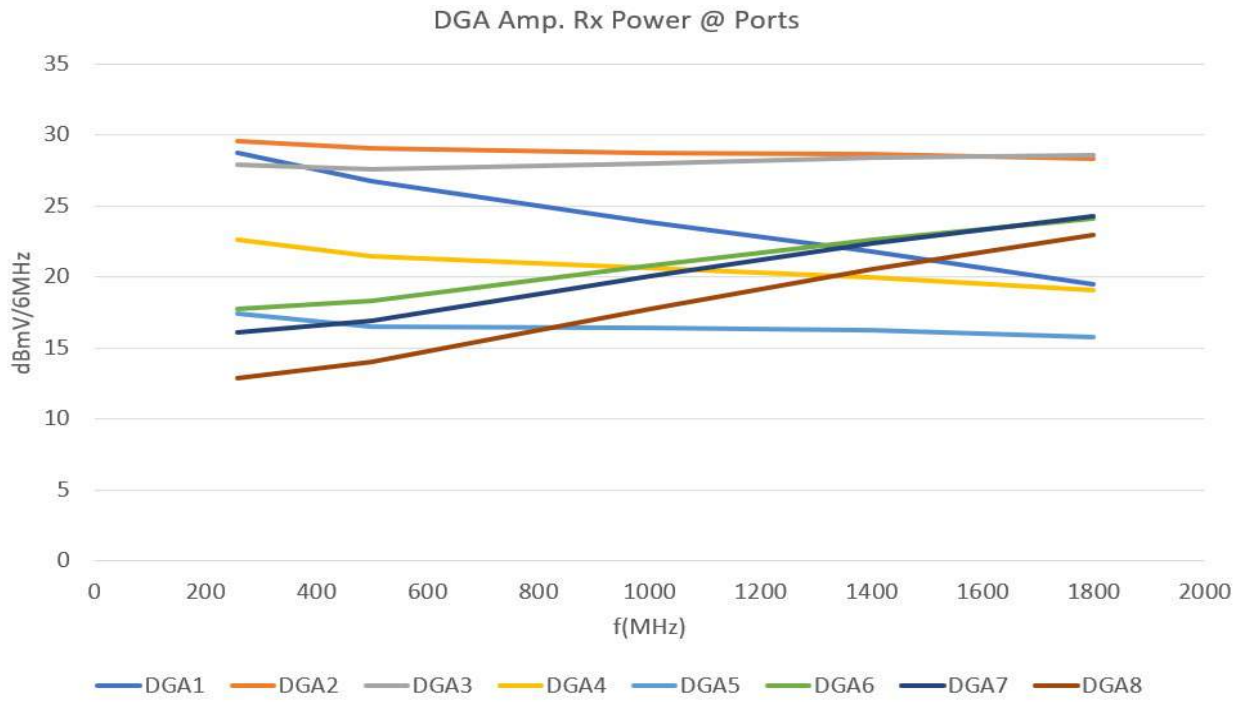

**Figure 33 – 204' Plant DGA Amplifiers' Rx Power @ Ports**

From the figure above, calculating the overall amplifier contributions to system C/N will result in the following:

**Table 12 – 204' DGA Amplifier Contributions to System C/N**

| | **204' Plant** |
|---|---|
| **System CNR @1 GHz** | 54.2 dB |
| **System CNR @1.8 GHz** | 53.5 dB |

It can be seen that the overall system C/N remains high, despite the fact that 8 amplifiers have been designed in cascade.

With this in mind, the modem Rx power still seems to be the limiting factor in the achievable modulation order. The figures below demonstrate Rx power at modems in each tap location:

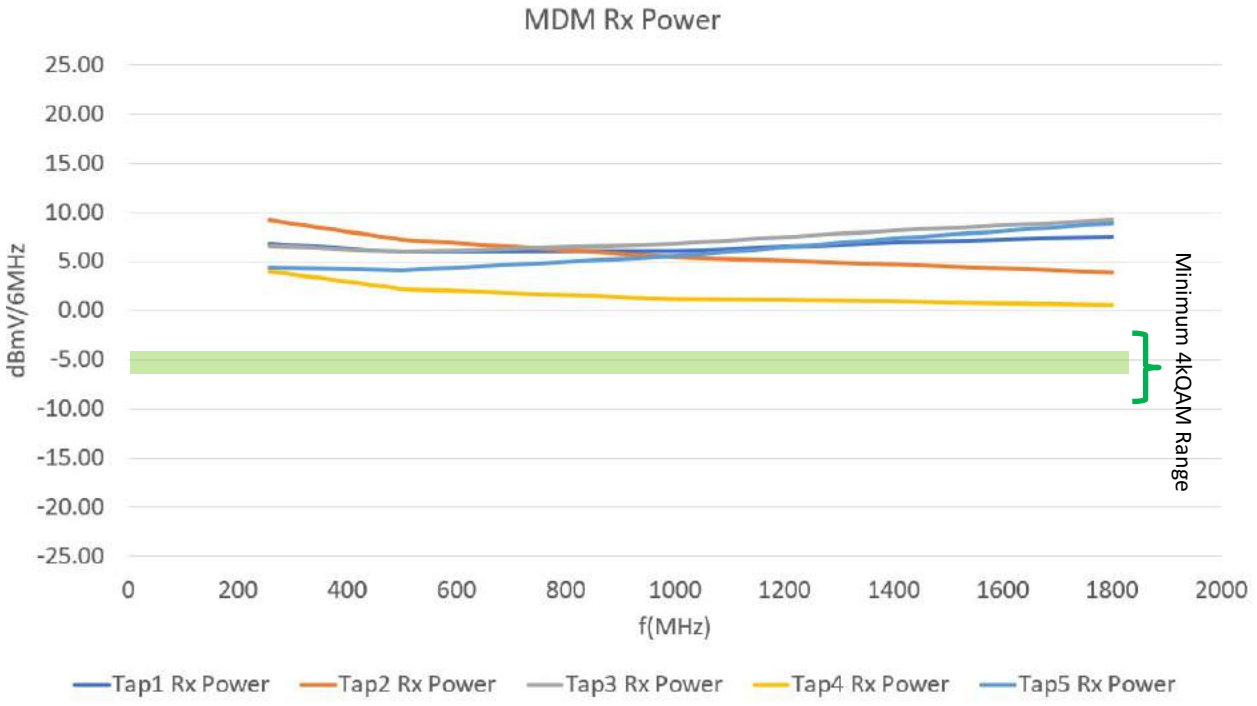

**Figure 34 – DGA 204' Span 1 MDM Rx Power/6 MHz**

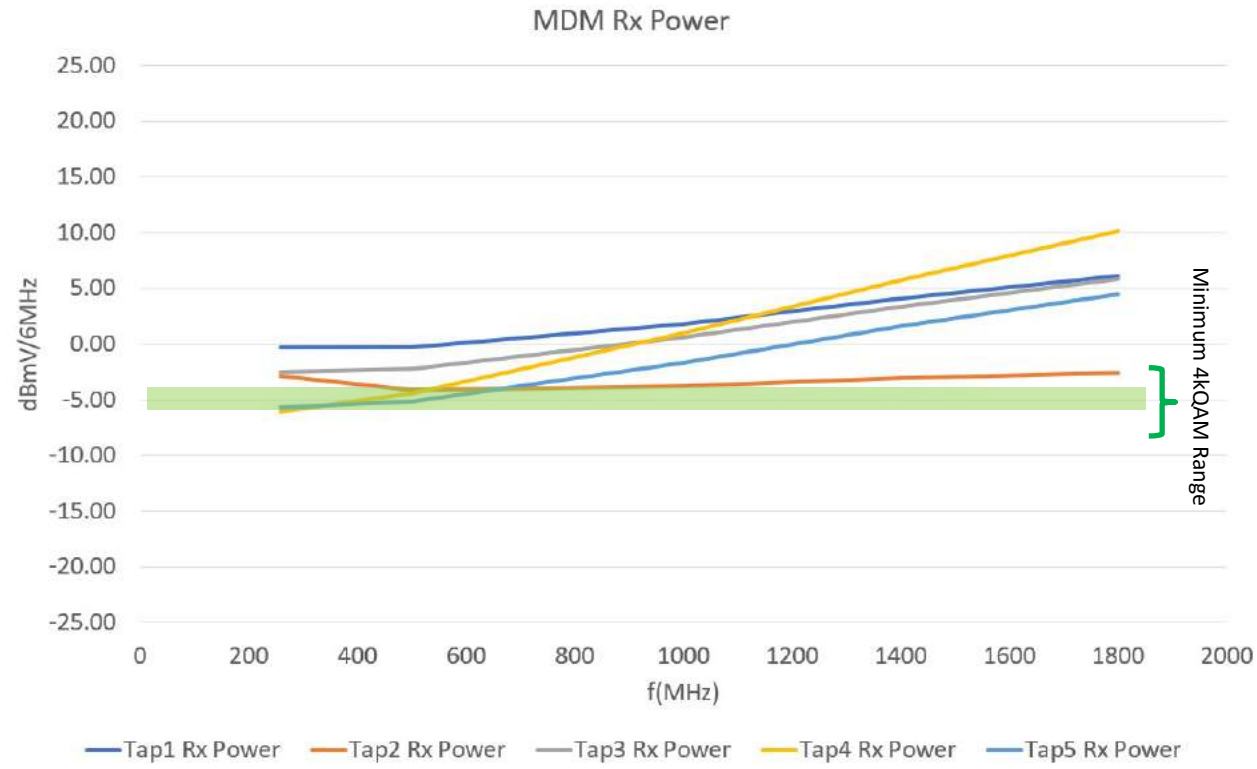

**Figure 35 – DGA 204' Span 2 MDM Rx Power/6 MHz**

It can be observed that all the Rx powers throughout the distribution plant are above the minimum 4kQAM threshold.

### 8.4. DGA DS Design Observations

DGA appears to provide a high system C/N and end-of-line performance in each of the plant models analyzed. This is most visible in the 190' and 204' plant models analyzed. It can be observed that although the cascade length in the analyzed plant models were increased from +2 to +8, the achievable modulation orders were increased by roughly 2-3 orders of magnitude.

## 9. Upstream Analysis and Considerations

Given the complexity of US analysis in a system and due to noise funneling from amplifiers and modems, this paper has focused on the potential points of concern in a DGA plant, especially regarding 204' plant, given that it is the longest plant type analyzed.

It should be noted that no closed loop gain control has been considered in this analysis. It is assumed that all the modems in the distribution will be transmitting at maximum power in accordance to Figure 7, to determine any shortcomings in the upstream network.

Assuming that the modems sitting at each location will be transmitting with their maximum capability in the return path in accordance to Figure 32, the following Rx powers/6.4 MHz can be expected at the port of each DGA amplifier:

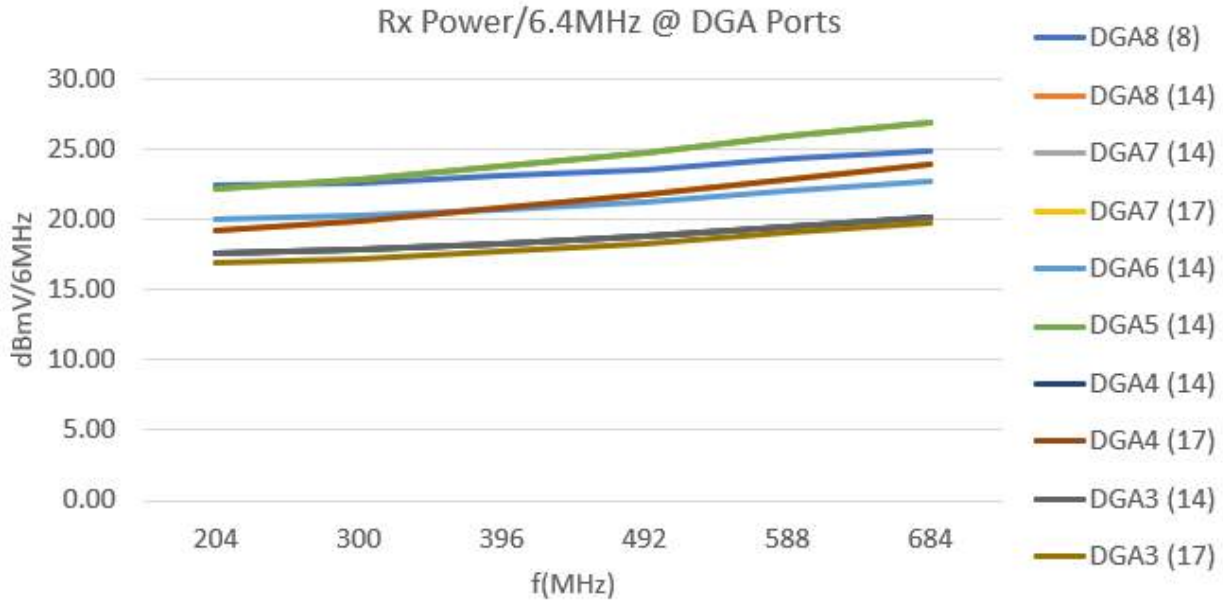

**Figure 36 – 204' Plant Return Path DGA Amplifiers' Rx Power @ Ports**

**Note**: In order to simplify the figure above, only data from tap values in parenthesis have been shown. These are modems that are subject to the highest amount of loss in the distribution plant. Furthermore, since the focus area of the analysis for this paper is in the distribution plant (DGA3-DGA8), no data from DGA1 and 2 have been shown in the figure above.

Although all the Rx power levels at the ports of each DGA amplifier seems sufficiently high, the primary point of concern is the return signal being subject high attenuations from long coaxial spans and higher insertion losses from low value taps. Assuming DGA amplifiers' return gain in Figure 9, the following Rx powers/6.4 MHz can be expected at the port of the node, in the 204' plant model:

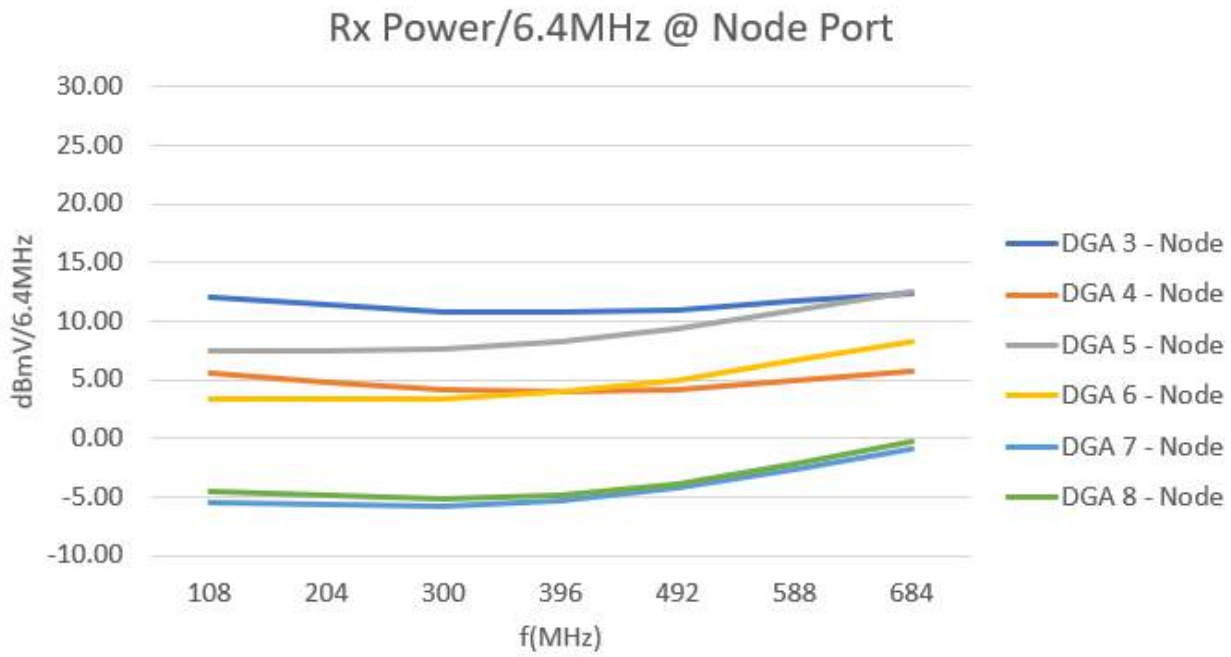

**Figure 37 – 204' Plant Return Path Node Rx Power @ Port**

Given that the focus area of analysis for this paper is in the distribution portion of the plant (from DGA3 to DGA8), DGA1 and 2 have not been included in the figure above.

The figure above can raise concerns with regards to system performance in the US. This is especially the case because modems in DGA7 and 8 spans are the lowest common denominator, setting the limit for overall system performance in the return path.

The return path gain of DGA amplifiers is not the only point of concern. Given the DS DGA design in 204' plant, many 14 and 17 taps were used to ensure high DS Rx power levels at the MDM. Although this can improve the DS Rx power levels at MDM locations and subsequently increase the system's achievable modulation order in the DS, it will make the US performance suffer. For comparison, based on the tap data available today, typically 23 taps have 1.2-1.4 dB of loss in the legacy band. The same band will have 2 dB higher insertion loss in lower value taps such as 14 and 17 dB taps.

To show the significance of high insertion loss values from low value taps on the return path network, it can be assumed that higher value taps were used throughout the distribution network.

**Note:** In practice, this can be considered unrealistic in OSP designs, since increasing the tap values results in lower DS Rx power at the MDMs. This assumption is made simply to quantify the impact that low value taps can have in the overall system performance.

Assuming a lower insertion loss of 1.5 dB for the distribution taps, DGA8's new Rx Power at the node has been shown in comparison to Figure 37:

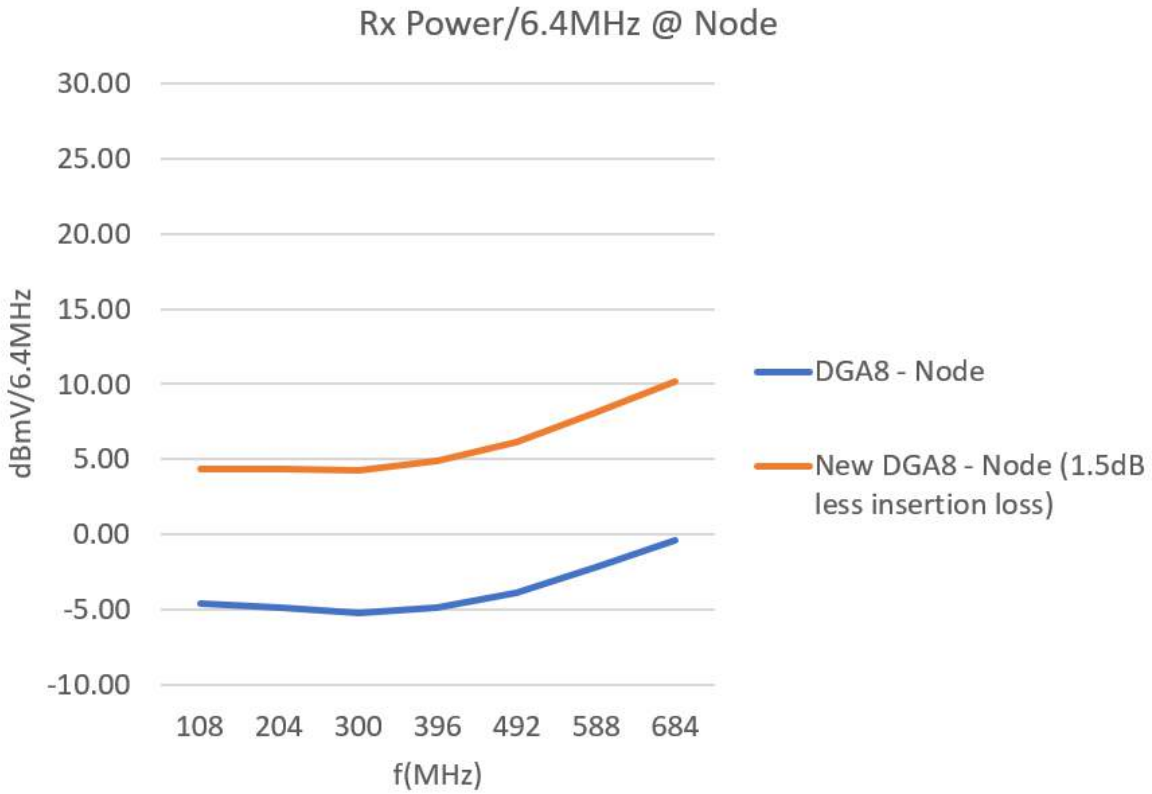

**Figure 38 – Last Span DGA-to-Node Level Comparison – 2dB Insertion Loss Taps vs. Regular Taps**

Although 1.5 dB of insertion loss may seem insignificant in traditional plant design, it makes a drastic difference in DGA. This is because in traditional HFC design, one or two low value taps may be installed in each distribution span. As shown in section 8.2 and 8.3, the number of low value taps can vary from 5-8 when converting a traditional N+2 environment.

In order to overcome the challenges in the US, two proposals are made in the following sections.

## 9.1. Higher MDM Transmit Levels in Lower US Splits

Knowing that the DOCSIS 4.0 MDM transmit channel set (TCS) will have 64.5 dBmV of TCP available and assuming that operators may not go to 684 MHz in the US, given the DS upper limit of 1.8 MHz, the 'unused' TCP from the upper frequencies in the return band can be re-allocated to the lower bands. This can result in an 'up-lift' of the transmit PSD of the MDM, which is demonstrated in the figure below:

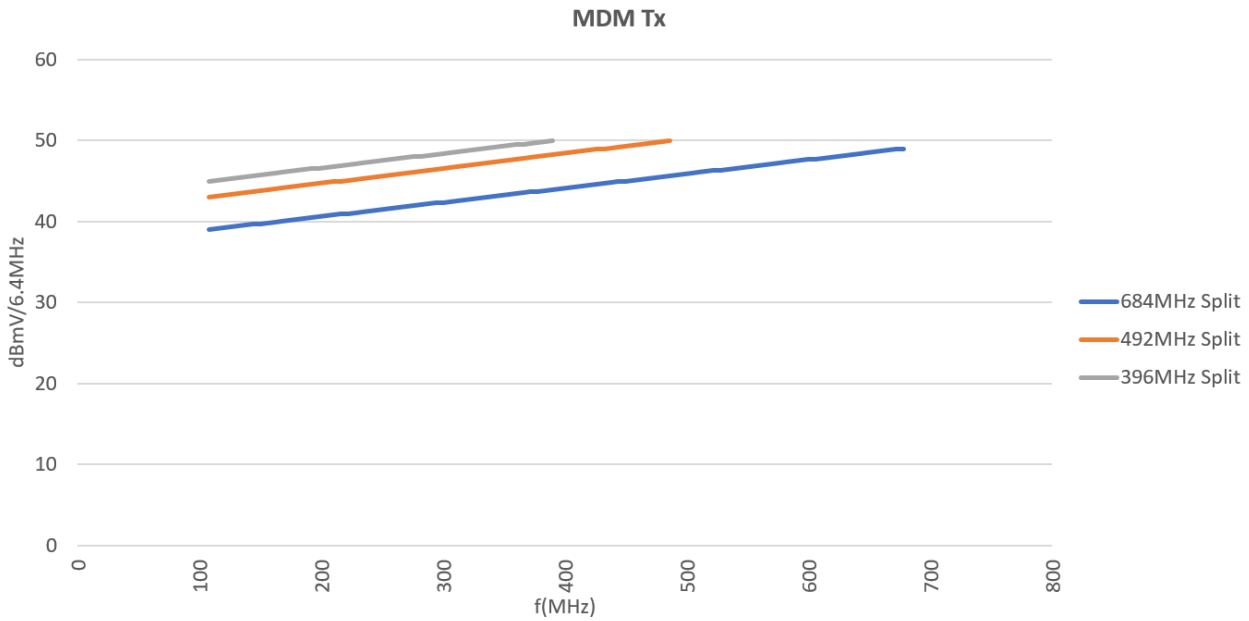

**Figure 39 – Raised MDM Output Power PSD in Various Splits**

Increasing the transmit PSD may raise concerns regarding spurious emissions and fidelity requirements in accordance to the DOCSIS 4.0 specifications. This needs to be studied more extensively to ensure adherence to said specifications.

With that in mind, let us assume a 396 MHz split. Applying the 6 dB additional available power to DGA8 in Figure 37 will result in the following US Rx power at the port of the node:

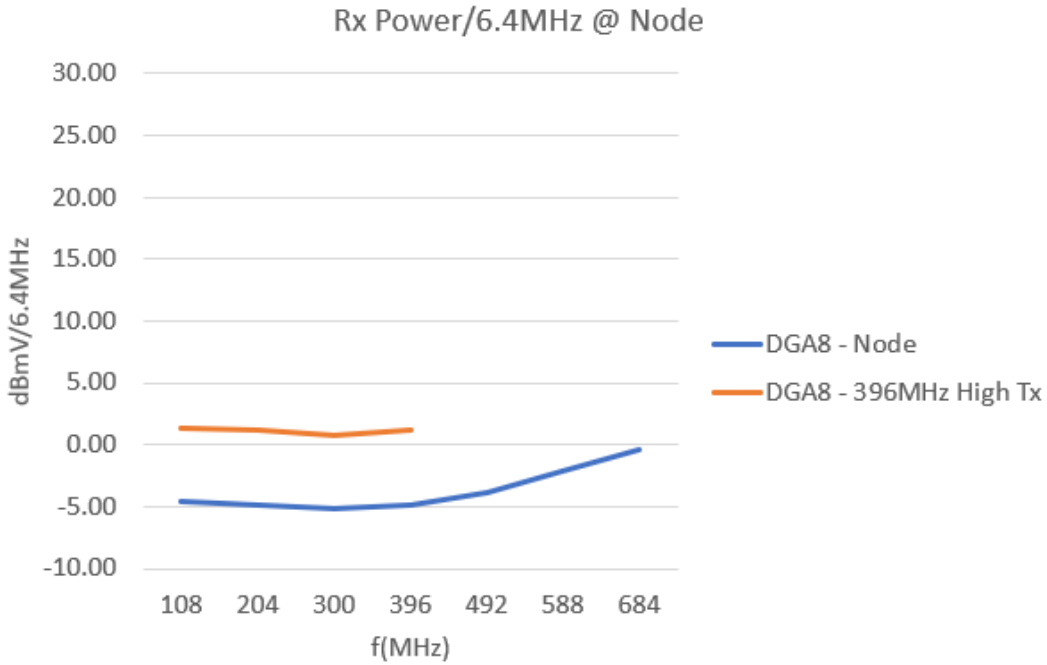

**Figure 40 – Last Span DGA-to-Node Level Comparison – Raised MDM PSD**

It is visible that re-allocating the power from the unused 396 MHz - 684 MHz to the active 5 MHz to 396 MHz can approximately result in a 6 dB increase in US Rx power at the node without increasing the modem's TCP.

## 9.2. Higher Return Gain in DGA Amplifiers:

Let us assume the gain of the DGA return amplifier is increased by 2 dB at 108 MHz and by 1 dB at 684 MHz, resulting in the following figure:

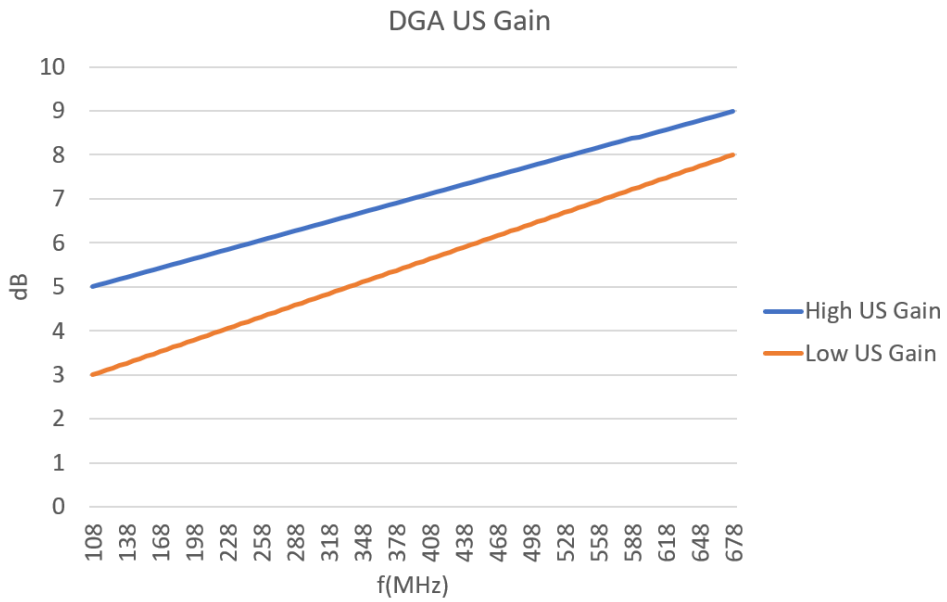

**Figure 41 – High vs. Low Gain DGA Return Amplifier**

DGA8's new US Rx power at the node with the newly assumed gain has been demonstrated in the figure below:

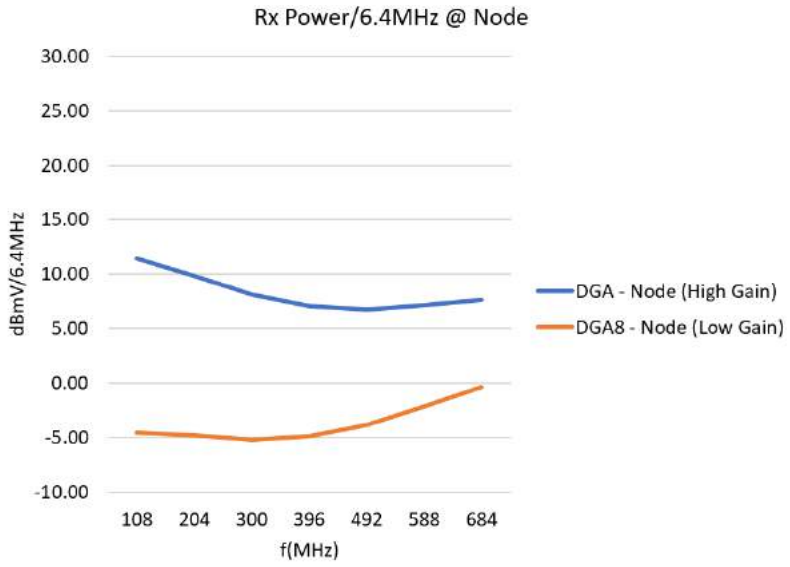

**Figure 42 – Last Span DGA-to-Node Level Comparison – High Gain vs. Low Gain Return DGA Amplifier**

## 10. Power Draw

One of the most attractive concepts of DGA is reduced power draw in the OSP. Traditional plant design can be quite power hungry with 150 watt nodes, and amplifiers that draw anywhere from 30 to 60 watts.

Power supplies themselves can be quite challenging to deploy, given the reduced amount of available real estate for installing them. Due to this, the current power supplies installed in the OSP are expected to support the future technologies deployed by operators, which may seem very challenging

DGA can reduce the power consumption in the OSP drastically in comparison to traditional designs. In order to quantify this in the plant models analyzed in this paper, the following has been assumed:

- N+2 plant
- 4 outputs from each node
- 150 watt node
- 40 watt line extenders
- 7 watt DGA amplifier

The following table demonstrates the potential power saving in an N+2 plant.:

**Table 13 – Power Draw Comparisons**

| Traditional | Booster | DGA 135' | DGA 204&190' |
|---|---|---|---|
| 460 Watts | 515 Watts | 320Watts | 375Watts |
| | ⬆ 10% | ⬇ 30% | ⬇ 20% |

Although the power draw in the booster amplification case has increased by 10%, it was demonstrated in section 7 that the performance at the end-of-line can increase by 2-3 orders of modulation. This is also assuming that future amplifiers will not be able to adjust power consumption based on their output power and utilized TCP.

It can be seen that DGA saves 20-30%, depending on the plant model. This is dependent on the number of DGA amplifiers used in each span to overcome the existing span losses.

This reduction in power draw from existing power supplies presents countless opportunities for operators to deploy other technologies in the access network, such as DAA, small cell and 5G.

# 11. Plant Reliability

Here we compare the availability of a traditional cable plant with the new distributed gain amplifier (DGA) system.

We assume that the failure modes of traditional amplifiers and DGAs are comparable, and one does not impact any more customers or impact any customers differently than the other. For example, customers on a branch are not impacted by the failure of an amplifier on another branch, and generally only the customers downstream of a failed amplifier are impacted by the failure of an amplifier.

Therefore, we can model these systems as simple series systems of replaceable components.

Further, we will define the components of each system as amplifiers and non-amplifiers.

The variables n_tamp and n_dga are respectively the number of traditional amplifiers and DGAs in the comparable systems

Given the systems are equivalent except for the number and type of amplifiers, we can define the availability of each of these systems as follows, for an arbitrary customer of the systems.

Traditional system availability: $A\_tsys = A\_line * A\_tamp^{n\_tamp}$

DGA system availability: $A\_dgasys = A\_line * A\_dga^{n\_dga}$

A_line is the availability of the line system, everything but the amplifiers, which is the same in both architectures. A_tsys is the traditional system amplifier availability component, a series of amplifiers each with availability A_tamp. A_dgasys is the availability of the series of DGAs in the system, each with availability A_dga.

Now we compare the two systems. We want the new system to be at least as good as the old, so we have the constraint

$$A\_dgasys \geq A\_tsys$$

Or

$$A\_line * A\_dga^{n\_dga} \geq A\_line * A\_tamp^{n\_tamp}$$

So

$$A\_dga^{n\_dga} \geq A\_tamp^{n\_tamp}$$

Given that the number of amps in either system is an integer, and n_dga = n_tamp + n for some integer n greater than 0, we can rewrite the previous equation as

$$A\_dga^{n\_tamp+n} \geq A\_tamp^{n\_tamp}$$

And then taking the n_tamp + n root of both sides, with acknowledgement that the variables are bounded positive, and the availabilities are between 0 and 1, we get

$$A\_dga \geq A\_tamp^{n\_tamp / (n\_tamp + n)}$$

We refer later to this above equation as the amplifier relation. Considering the architectures analyzed:

If n_tamp = 2, n = 6, n_tamp/(n_tamp+n) = 0.25

If n_tamp= 2, n = 5, n_tamp/(n_tamp+n) = 0.29

If n_tamp = 2, n = 4, n_tamp/(n_tamp+n) = 0.33

The tighter constraint is 0.25, and so a goal to reach is

$$A\_dga \geq A\_tamp^{0.25}$$

But most plant designs will only use 6 DGAs so the more common constraint will be

$$A\_dga \geq A\_tamp^{0.33}$$

If the probability that the above two equations are each true is greater than 50%, then odds are the new architecture will perform better on average in a large sample.

Now let's look at some comparisons based on amp availability values.

We can assume reasonably that A_tamp ranges from 0.999 to 0.99999 given service performance; with some data collection we can narrow it down further, and even find estimates based on use conditions, environment, etc. But based on this broad range of estimates, setting the inequality in the amplifier relation equation to an equality to see the worst case for the DGAs, we find that A_dga relates to A_tamp as in the figures below. We show results as dots for two deployments: 6 DGAs and 8 DGAs. The line of equality is added as a solid line for reference. The first graph shows availability in linear scale, while the second shows unavailability (1-availability) in log scale (U_dga and U_tamp respectively).

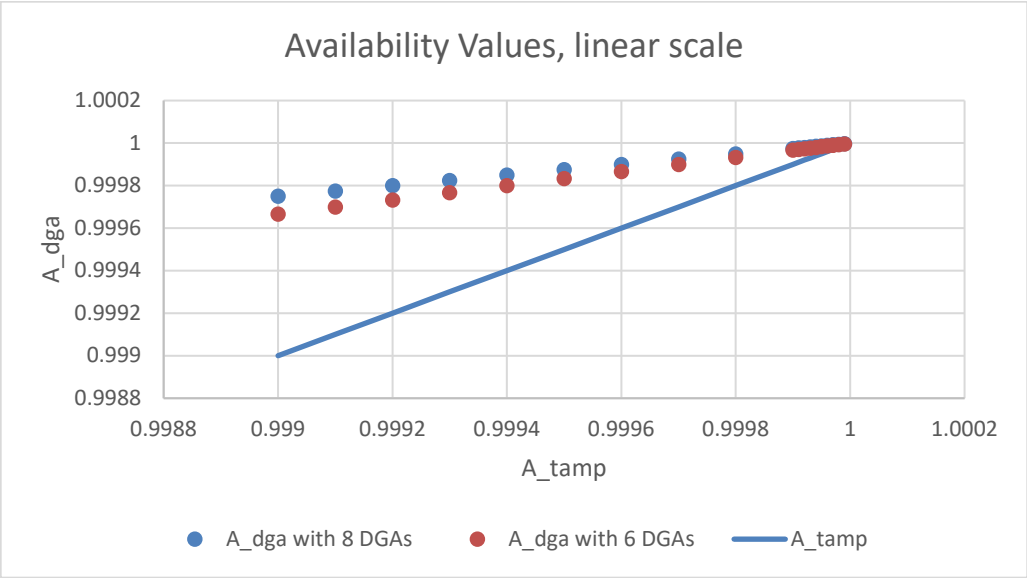

**Figure 43 – DGA Availability**

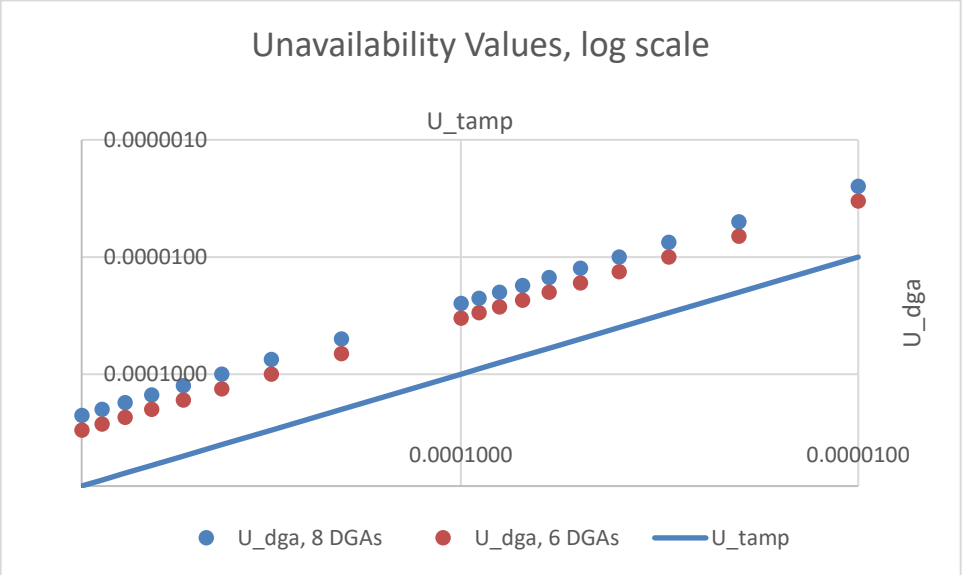

**Figure 44 – DGA Un-availability**

**Table 4 – Unavailability Comparison for DGAs for Two Example Architectures versus Traditional Amplifiers**

| U_dga, 8 DGAs | U_dga, 6 DGAs | U_tamp | %diff, 8 DGAs | %diff, 6 DGAs |
|---|---|---|---|---|
| 0.0002501 | 0.0003334 | 0.0010000 | 74.991% | 66.656% |
| 0.0002251 | 0.0003001 | 0.0009000 | 74.992% | 66.657% |
| 0.0002001 | 0.0002667 | 0.0008000 | 74.992% | 66.658% |

From Figure 43, it appears that the DGAs need to have a much higher availability than the traditional amplifiers. But looking at Figure 44, from an unavailability (downtime) perspective, the difference is not unlikely to be achieved. Table 4 shows the values used to plot Figure 44. The percent difference in unavailability (%diff) is calculated as (U_tamp – U_dga)/U_tamp.

For comparative perspective, the DGA needs to have about 75% less unavailability than the traditional amplifier over its useful life if 8 are used. But if just 6 are used, then just 67% less unavailability is needed. Think of this percentage of unavailability as a reduction in downtime overall. While a ¾ reduction in downtime might seem aggressive, these DGAs are much simpler, with newer components, so have a chance to beat that mark if designed for reliability. Recall that in most cases only 6 DGAs are needed, so most cases need just a 2/3 reduction.

An additional consideration too is that, if DGAs have significantly higher availability, it is not likely because they are significantly more repairable, but rather because their rate of occurrence of failures over the same lifetime of the original amplifiers is much lower. This means DGAs are likely to have much longer useful lifetimes, and therefore may further reduce lifetime costs for providing service. However, highly accelerated life testing should be conducted to verify this assertion, and to provide evidence of the seemingly aggressive availability and reliability targets.

Note that the same equations describe the relationships for reliability as well as availability, as these are series systems. But as this is a repairable system, availability is the measure that makes more sense for the system. Fortunately, the system availability is an important contributing factor to the service availability which is important for customer experience. Reliability of the service from a user experience may be important as well.

## 12. Future Considerations

This section summarizes and discusses the points of concern that were brought up in the previous sections of this paper.

## 12.1. Unity Gain, Distortions and Cascade Limits

One of the primary assumptions of this paper was that DGA amplifiers' distortions accumulate less quickly than the current amplifiers deployed by operators. This is primarily due to the simplicity and the low gain characteristics of these amplifiers, being single stage, with a fixed gain and tilt.

As mentioned in section 3.3, unity gain has been one of the primary design focuses for OSP in the past. Operators have adjusted their networks by adjusting node and amplifier outputs to balance both noise and distortions. Moving away from unity gain can raise concerns, especially regarding distortions. Knowing that almost all carriers deployed in the spectrum in the future will be digital, the distortion products can be summed into CIN, which can be translated to increase in noise level that should be considered in the system C/N. Due to lack of availability of data in this realm, this was not considered in this paper but it is something that needs to be studied extensively.

This subject needs to be studied further in the future when more products are available in this realm, to ensure that CIN products will not decrease the overall signal quality.

It should be noted that unity gain design can theoretically be achieved with DGA, assuming adjustments can be made in DGA amplifiers. This can also increase the number of DGA amplifiers needed in comparison to a non-unity gain design. It is worth noting that unity gain designs with DGA should be easier to achieve in green-field, in comparison to drop-in upgrades in brown-field applications. This can be achieved by simply balancing span losses and gain of DGA amplifiers, as currently done in traditional plant design.

The increased number of DGA amplifiers itself can raise concerns as well. Afterall, operators have been reducing cascades by pushing fibre deeper into the distribution plant. As demonstrated in section 8, when converting an N+2 plant, the number of DGA amplifiers can vary anywhere from 6-8, when designing for optimal performance (4kQAM).

When discussing the potential maximum number of DGA amplifiers in cascade, it requires a fine balance between the available spectrum, system C/N and distortions (CIN). The figure below, extracted from Broadband Cable Access Networks by David Lafarge and James Farmer, demonstrates this perfectly:

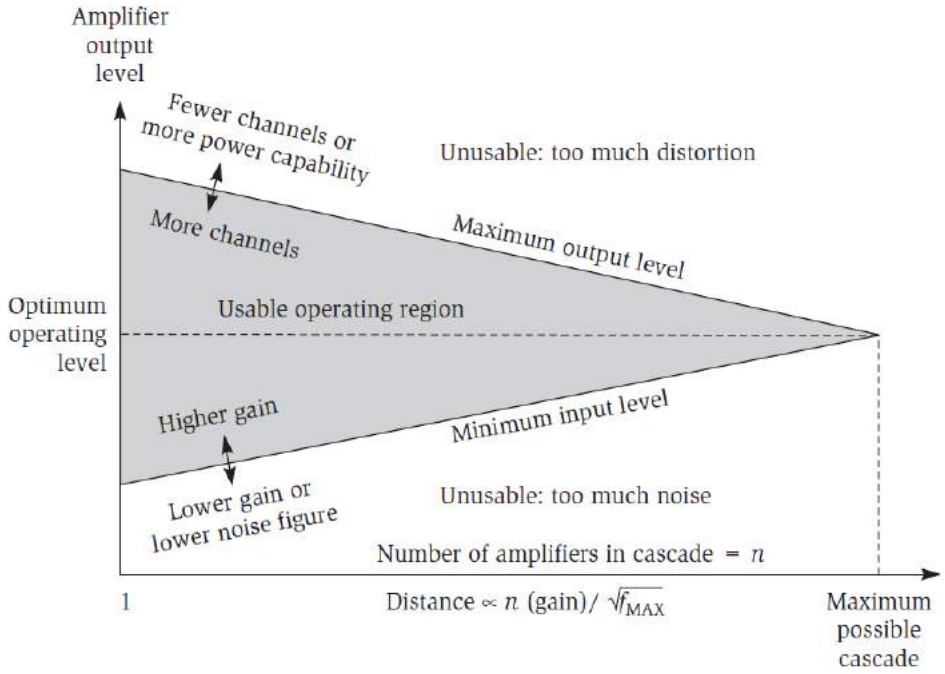

**Figure 45 – Relationship between Cascade, Noise and Distortion**

## 12.2. US Gain and Performance

As discussed in section 9, the US system performance can be a major point of concern, especially in longer span (higher span-loss) plant types. This is due to the increase amount of loss that the signal is subjected to. The higher loss is due to the longer coaxial distances along with higher insertion losses in low value taps.

The following proposals were made in sections 9.1 and 9.2:

- Raised output PSD's at the MDM
- Increased return gain in DGA amplifiers

The two proposals have to be studied individually and in combination to determine the feasibility of them being implemented by the vendor community.

## 12.3. Design Standards

DGA presents a major shift in how access networks are designed. Given that OSP designs have remained more or less the same in the previous decades, such a drastic shift in design could be a multi-year endeavor.

A slower and incremental implementation of DGA is something to be considered. As MSO's reduce cascade lengths in the OSP while pushing fibre deeper, booster amplifiers can be implemented in sections of the plant that struggle with the current spacing, especially when upgrading the available spectrum to 1.8 GHz. This can also help with not having to potentially deploy DGA in N+3 or N+4 architectures. This may result in 15+ amplifier cascades which can present difficulties regarding plant maintenance and performance in the future.

### 12.4. 3 GHz

DGA presents exciting insights into what access architecture and designs could look like when contemplating 3 GHz spectrum expansions. In 2019, a paper was published under the title “Blueprint for 3 GHz, 25 Gbps DOCSIS” by John T Chapman, Hang Jin, Thushara Hewavithana and Rainer Hillermeier, which covers this topic in great detail. As MSO’s reduce cascades and reach passive networks (N+0) in the future, DGA can be the answer to achieving 3GHz of available spectrum and 25 Gbps.

## 13. Conclusion

This paper discussed how booster amplification and DGA implementations can improve performance in the analyzed plant models. A comparison for overall system performance and C/N contributions from amplifiers were discussed between a traditional N+2 plant models, N+2 models with the introduction of booster amplifiers mid-span, and DGA converted versions of them.

From a downstream performance perspective, it was observed that the analyzed plant models in a DGA system can achieve much higher orders of modulation in comparison to the traditional plant model. This is despite increasing the cascade length from +2 to +6 or +8, depending on the spacing. This was especially visible in longer plant models that have been ‘stretched’ to their current spacing limits.

It was also demonstrated that DGA can substantially reduce the power draw in the OSP, leaving headroom for future technologies to be deployed in the access network. This is one of the most attractive points of a DGA system, given the current limitations and challenges that operators face regarding plant powering.

Furthermore, the form-factor of the DGA amplifiers alleviate a number of concerns regarding available real estate for installing traditional amplifiers and PEDs. High gain amplifiers require large PEDs to accommodate their large form-factors, along with cooling requirements. DGA amplifiers’ form-factors are more comparable to main-line splitters, making them extremely convenient for installation in the OSP. They can be installed in almost any existing PED in the access network.

It was also demonstrated that a DGA plant can be as reliable as a traditional one, despite the increase in the number of amplifiers in a distribution run.

As attractive as the items mentioned above may be, DGA can be seen as a major shift in how access networks are designed. Various challenges were also discussed throughout this paper that require more in-depth research. Upstream gain and performance of a DGA system, maximum cascade length and unity gain designs are some of the points of concern.

Although this concept is in its infancy, it does seem to offer extremely attractive solutions to some of the major challenges that operators may face when upgrading their networks to 1.8 GHz and beyond. It would be worth the effort to analyze the challenges identified, to ensure they can be alleviated.

# 1. Introduction

Achievable data rates in the fixed access network keep increasing. While passive optical networks (PON) move to 25 or 50 Gbit/s with IEEE 802.3ca [1] and MGfast [2] targets 10 Gbit/s aggregated point-to-point rate over twisted pair, it is time to evaluate HFC technology as a successor for 10 Gbit/s capable DOCSIS, using full duplex or 1.8 GHz bandwidth [4].

Figure 1 compares the data rate trends for different access technologies. DSL, as a point-to-point technology is at lower rates, but with a higher growth rate. While DOCSIS and PON, both shared medium technologies, follow a similar trend with lower growth rate of the aggregated rate, which is compensated by reducing the number of subscribers sharing the bandwidth as an additional measure.

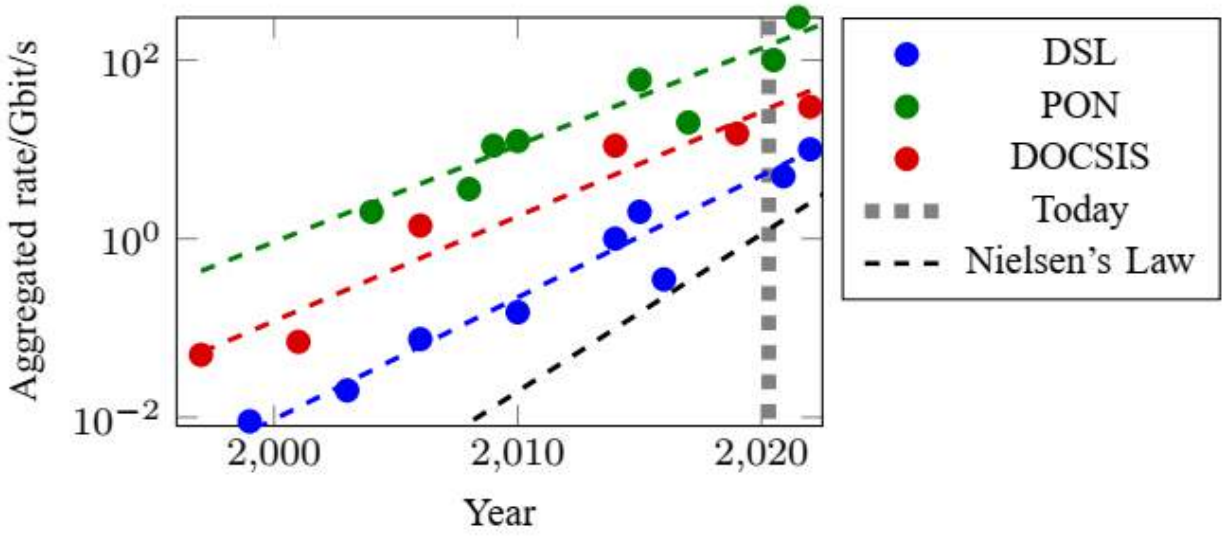

**Figure 1 – Agrregate rates of different access network topologies by standard introduction year**

From Figure 1, aggregated data rates around 30 Gbit/s are a competitive choice for a future DOCSIS generation, which is herein called extended spectrum DOCSIS (ESD). This will allow 20-25 Gbit/s downstream (DS) and 5-10 Gbit/s upstream (US) rates, which is comparable to a single 25G PON wavelength service that is shown in [5] to serve future access network requirements. Following the arguments of [6], this will allow for 10 Gbit/s services and cover the bandwidth growth predicted by Nielsen's law [7].

The cable industry has recognized ESD as a viable path to extend competitiveness of DOCSIS network at a fraction of cost compared to fiber deployments going forward. Under the 10G DOCSIS initiative, 1.8 GHz frequency division duplexing (FDD) DOCSIS and 1.2 GHz full duplex DOCSIS options have been included in DOCSIS 4.0 as two possible ways of getting to 10 Gbit/s node throughput, enabling low single digit Gbit/s services. We can consider 1.8 GHz FDD to be an intermediate step to get to the 3 GHz ESD and 10 Gbit/s services. In this paper, we will focus more on 1.8 GHz ESD when describing algorithms and evaluating performance results. Nonetheless we will maintain the forward compatibility of our algorithms for a future 3 GHz ESD solution.

One of the key enablers of ESD is the advancement of power amplifier (PA) technology that can support multi GHz transmit signal. However, total composite power (TCP) of these PAs does not scale with the

increased spectrum beyond 1218 MHz. Therefore, the ESD communication system is limited in its transmit power. Optimal allocation of available transmit power and appropriate bit-loading (profile definition) is needed to get the maximum capacity out of the network.

In this paper, we outline a framework for closed loop optimization of the capacity of ESD systems subjected to the TCP constraint mentioned above. Cable modems provide the node with channel estimate and signal to noise ratio estimate data and the intelligent node uses this data to calculate the optimal power allocation and bit-loading for the downstream. This can be made part of the profile management application running on a virtual Cable Modem Termination System (vCMTS). We have shown that combining careful allocation of channels, closed loop optimization of transmit power, and adaptive bit-loading achieves considerable gains in data rate and reduction in TCP for network topologies currently present in MSO networks.

# 2. Technological and Operational Challenges with Extended Sepctrum DOCSIS

As MSO's expand their spectrums to 1.8 GHz and beyond, the expectation for the achievable modulation order at the top end of the spectrum is reduced. In traditional plant, being 750 MHz or even 1 GHz, most MSOs expect 4096 QAM to be achievable by each orthogonal frequency division multiplexing (OFDM) block deployed there. But the same is not true for 1.8 GHz and beyond. There are many reasons why that is the case but the primary one would be the current spacing that outside plant (OSP) is designed to. Due to this, any method to increase the achievable throughput in the network is highly sought after.

This section explores the technological and operational challenges of upgrading the plant to 1.8 GHz.

## 2.1. Plant Spacing and Drop-In Upgrades

Most OSP architectures are designed to 750 MHz and 'stretched' to 1 GHz. As a result, most of the RF power in plant actives, including nodes and amplifiers, has been utilized to overcome the existing span losses. Span loss is defined as the total insertion loss of all the elements in an HFC span, measured in dB. This includes all the plant passives such as splitters and couplers. Although the span losses today are manageable with the current amplifier gains, they will certainly become a major point of concern when the spectrum is expanded to higher frequencies. As an example, a span loss of 35 dB in a traditional 1 GHz plant equates to 49 dB in 1.8 GHz.

Although plant re-spacing is always an option, it can be extremely costly and as a result, operators will rely on the expanded power of amplifier gain chips to overcome span losses.

## 2.2. Total Composite Power (TCP)

It is generally understood that the 1.8 GHz amplifiers will have ~75 dBmV of total composite power (TCP) available, which is roughly the same power available in current 1.2 GHz devices. With that been said, not all of this power is available for use. As an example, Figure 2 demonstrates the trade-off between Modulation Error Ratio (MER) and TCP utilized.

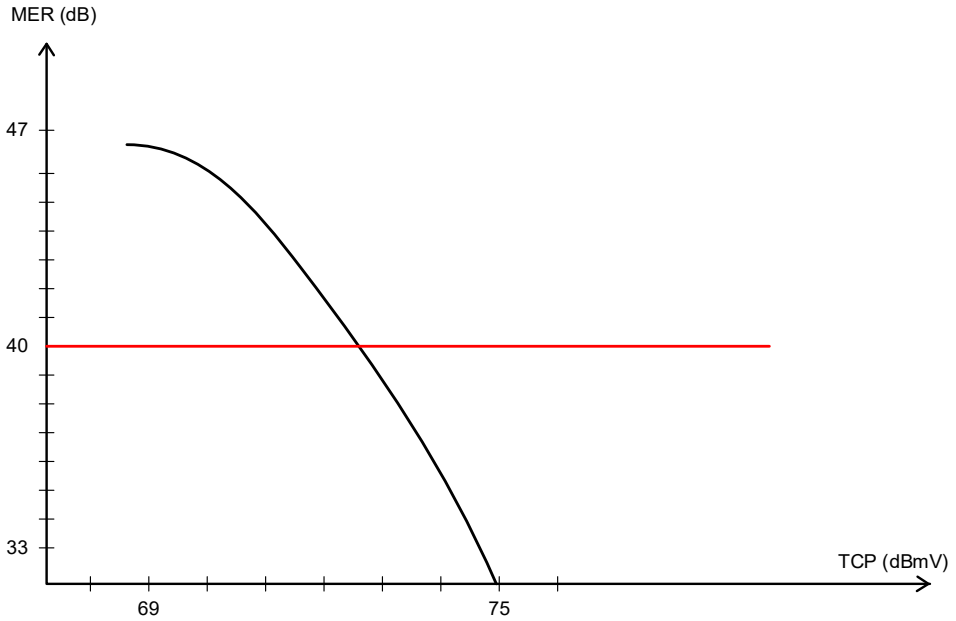

**Figure 2 – Amplifier Nonlinear Distortion**

As a general rule of thumb, 3 dB of back-off is needed to achieve 40 dB+ MER, which is typically what operators aim for. Along with that, the internal loss of the active device has to be accounted for, which is typically 2 dB. To summarize, there is a total of 70 dBmV of power to be utilized at the port of each active device. This can be a concern for operators given that 65-68 dBmV of TCP has already been allocated to overcome the span losses in the 'traditional' plant.

## 2.3. Passive Network Updates – Taps and Other Connectors

Taps and passives can be another point of concern when upgrading the OSP to 1.8 GHz. Traditionally, most operators have relied on face-plate upgrades to expand the spectrum range of plant taps and passives. This is generally accepted as a faster and more cost-effective method to upgrade the available bandwidth of taps.

Unfortunately, this might not be the case with 1.8 GHz upgrades. Based on the research and the information released by the vendor community, a face-plate upgrade of the current 1 GHz taps can potentially expand the bandwidth to ~1.6 GHz. it should also be noted that this is a best effort.

This can be a concern given the uncertainty of the maximum available bandwidth in the plant. As a result, it is generally accepted that taps and passives have to be swapped out for 1.8 GHz version. Given that the entire housing of the tap has to be swapped out as a part of this effort, most of the taps being developed will have housings that can support up to 3 GHz with future face-plate upgrades, future proofing the plant for 3 GHz upgrades.

## 2.4. Plant Model

In order to encompass most of the hybrid-fiber-coax (HFC) architectures deployed, the following plant models and assumptions were considered for this analysis.

Note: Trunk spans are defined as spans that are untapped. Distribution spans are tapped. Both trunk and distribution span losses include all other passive elements' insertion losses, such as splitters and couplers.

Assumptions:

- Modem:
  - Point of entry (PoE) device
- Drop:
  - Cable: RG6
  - Length: 150 feet
- Number of taps in each span:
  - 5
- Distribution span losses at 1 GHz:
  - Typical plant: 35 dB
  - Stretched plant: 37 dB
- Trunk span losses at 1 GHz:
  - Typical plant: 32 dB
  - Stretched plant: 35 dB

Figure 3 and Figure 4 summarize the parameters above.

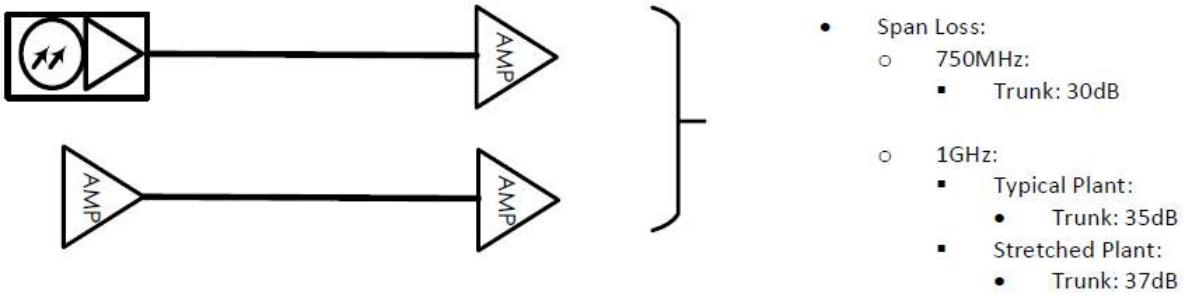

**Figure 3 – Trunk Span Losses**

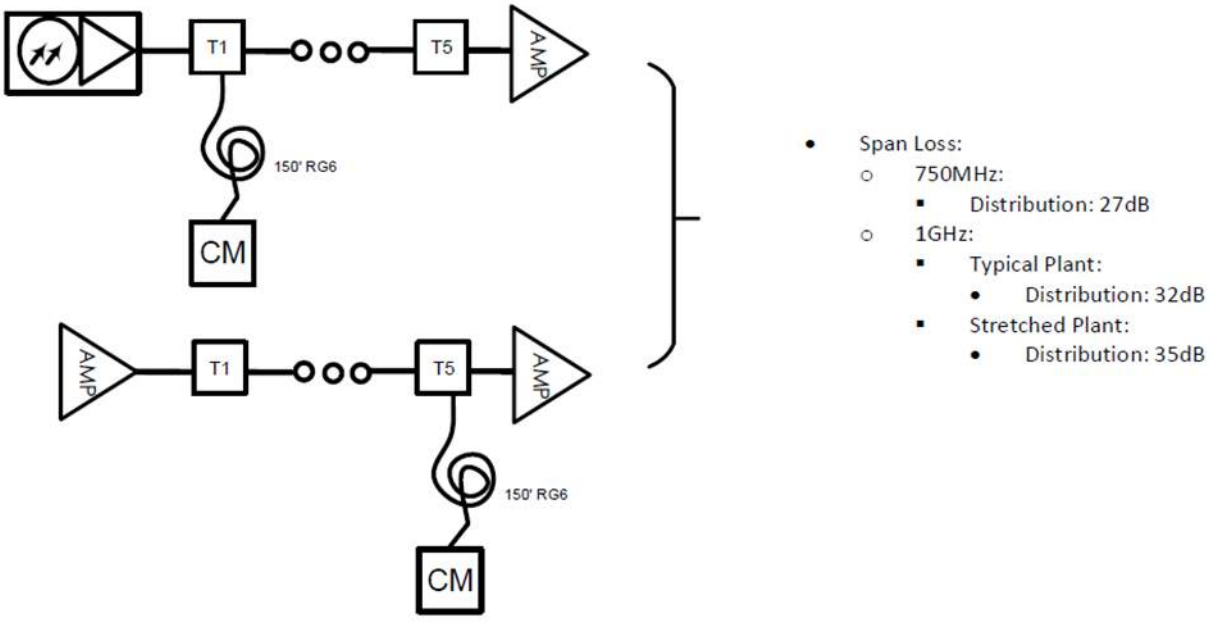

**Figure 4 – Distribution Span Losses**

### *2.4.1. N+0 vs N+X*

HFC plant can be divided into two categories: passive and cascaded.

- Passive plant (N+0): where no amplifiers are used after the node
- Cascaded plant (N+X): where amplifiers are used to boost the signal multiple times to the end-of-line

When designing an N+0 plant, the main point of concern is the output power of the node. Assuming that we are operating in a distributed access architecture (DAA) plant, the primary drivers for the plant quality would be the modulation error ration (MER) of the DAA device. Since no amplifiers are used to boost the signal, no noise or distortion is added to the primary signal being generated by the DAA device.

On the contrary, when designing a cascaded plant, the following can be a concern:

- Amplifier noise contribution
- Amplifier distortion contribution

### *2.4.2. Noise*

Designing a cascaded system for optimal carrier to noise is always a big priority for an operator. One of the biggest contributors in system design is the receive power (Rx Power) at the amplifier, given that it is one of the primary drivers for the overall system carrier to noise (C/N).

The equation below calculates the C/N of an amplifier:

$$C/N\,(dB) = \; C_i(dBmV) + 57.4 - NF(dB) \qquad (1)$$

Where:

- $C_i$: input signal

- $NF$: Noise figure of the amplifier

Note: the number 57.4 is the noise power for QAM carriers. This value will vary marginally depending on the temperature.

Equation (1) shows the significance of the Rx power versus noise figure of the amplifier, in overall system design.

The overall system C/N can be derived from the following equation:

$$C/N_{total}\,(dB) = -10log\left\{10^{\frac{-C/N1}{10}} + 10^{\frac{-C/N2}{10}} + \cdots + 10^{\frac{-C/Nn}{10}}\right\} \quad (2)$$

Where $C/N_x$ is the carrier to noise of each amplifier calculated independently.

When cascading identical amplifiers, the following approximation is typically used:

$$C/N_{total}\,(dB) = C/N_x - 10log_n \quad (3)$$

Where:

- $C/N_x$: the carrier to noise of a single amplifier
- $n$: the number of identical amplifiers in cascade.

### 2.4.3. Distortion

The build-up of distortions in a cascaded plant are less predictable than noise. The following equation can be used to estimate the carrier to composite triple beat (C/CTB) and carrier to composite second order distortion (C/CSO):

$$C/CTB_{total}\,(dB) = C/CTB_x - 20log_n \quad (4)$$

$$C/CSO_{total}\,(dB) = C/CSO_x - 10log_n \quad (5)$$

Where:

- $C/CTB_x$: the distortion of a single amplifier
- $C/CSO_x$: the distortion of a single amplifier
- $n$: number of identical amplifiers in cascade

### 2.4.4. Designing a Noise-Limited System

For optimal performance, operators design systems that are unity gain. This means that the loss between two amplifiers is equal to the gain of each amplifier. If the loss is less than the gain, the distortions with accumulate. Whereas if the loss is greater than the gain then the input power will be less than the desired amount, degrading the system C/N.

Due to the difficulties that come with designing a system that is both noise and distortion limited, removing one of those parameters will be optimal. Given that noise performance of amplifiers is far more straight-forward in comparison to distortion, designing a noise-limited system is a very attractive idea.

Since distortions are highly dependent on output power, designing a noise-limited system can be achieved by reducing the output power out of the node/amplifiers and making sure the signal level received at the next amplifier is high enough, based on equation 1. Figure 5 demonstrates balancing the signal level against noise and distortion in a system design.

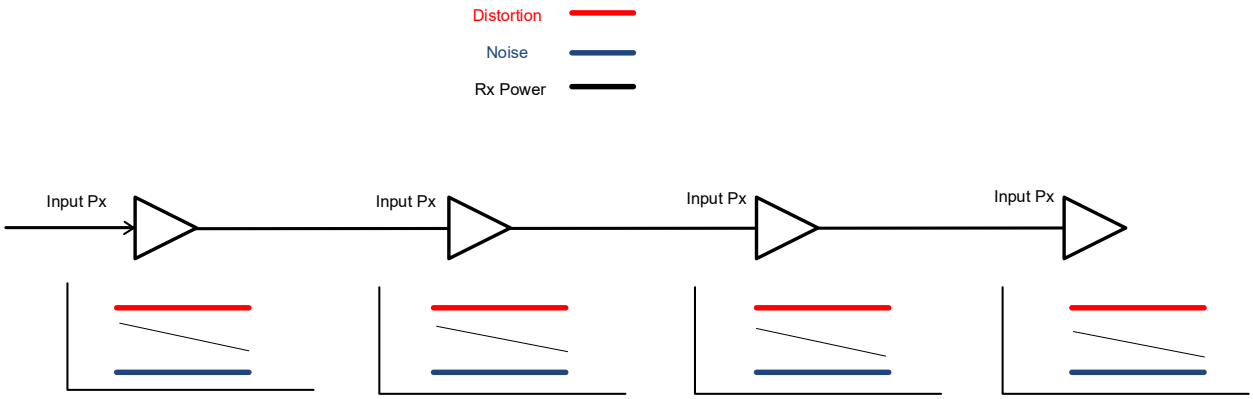

**Figure 5 – Signal Level Balanced Between Noise and Distortion**

## 2.5. Typical Plant Topologies

In this paper we focus on Node + 0 (Figure 6) and Node + 4 (Figure 7) networks as the basis for performance evaluation.

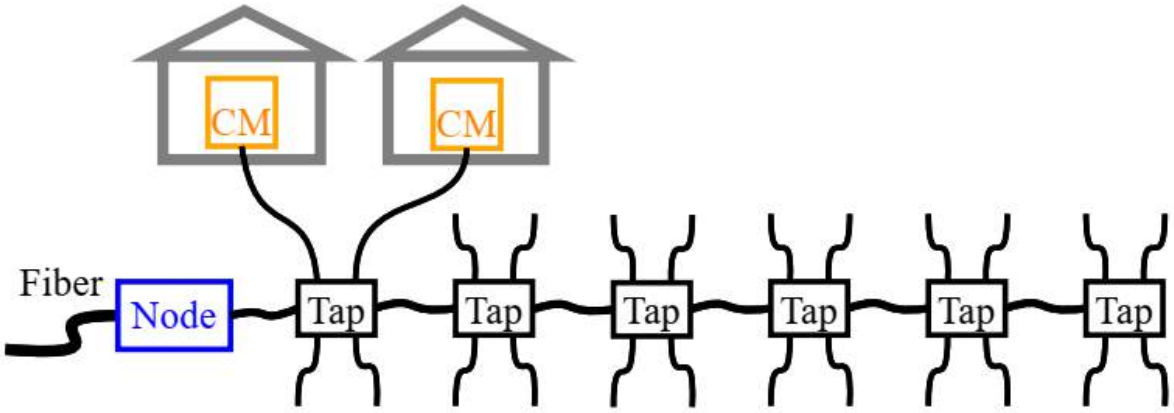

**Figure 6 – Node + 0 Passive HFC Plant Topology**

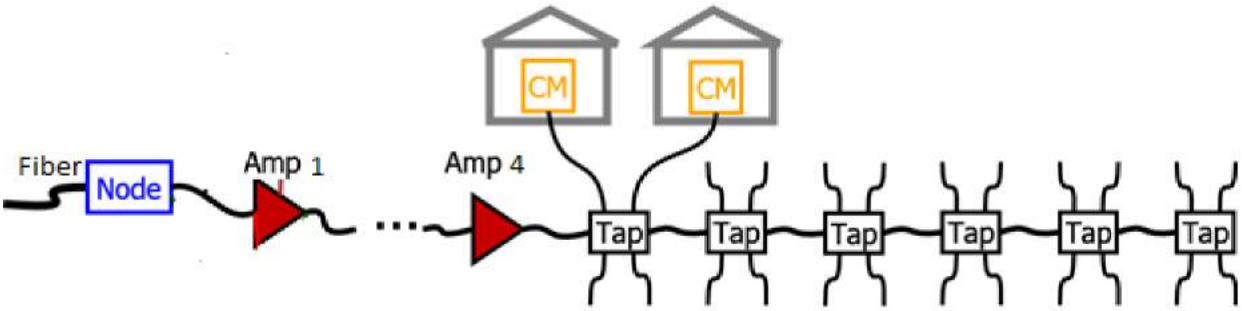

**Figure 7 – Node + 4 Cascade Plant Topology**

This plant topology has 5 amps total in cascade, the node amp and the 4 network amps. The network is built with a cascade of 4 trunk spans and single distribution span as described in section 2.4.

### 2.6. Problem Definition

As described before, the ESD communication system is limited in its transmit power. Optimal allocation of available transmit power and appropriate bit-loading (profile definition) is needed to get the maximum data rate out of the network. In this paper, we outline a framework for closed loop optimization of the throughput of ESD system subjected to TCP constraint mentioned above. We will show that combining careful allocation of channels, closed loop optimization of transmit power, and adaptive bit-loading achieves considerable gains in data rate and reduction in TCP for network topologies currently present in MSO networks.

## 3. Theoretical Framework for Closed Loop Throughput Optimization

In this section, we present the theoretical framework for optimizing the available transmit power for throughput of the cable network. We start off with the simpler case of Node + 0 passive network and then extend the theory to cover general case of Node + X, X>0, networks.

### 3.1. Node + 0 Network

The capacity evaluation for the extended spectrum HFC network requires knowledge of the channel characteristics and capacity limiting factors. The capacity limiting factor in the transmitter is amplifier distortion. At the receiver, additive white Gaussian noise and receiver distortion due to analog-to-digital conversion limits capacity. HFC transmission schemes such as DOCSIS 4.0 [4] use OFDM modulation, where the channel is partitioned into K narrowband subcarriers k = 1, . . . ,K with a subcarrier spacing Δf. Those orthogonal channels are coupled only by nonlinear distortion or a sum power constraint. The transmit power per carrier x(k) as well as the information rate per carrier b(k) can be adjusted per carrier. The data rates for a given signal-to-noise ratio SNR(k) on carrier k is given by

$$R = \eta \Delta f \sum_{k=1}^{K} \min\left(\log_2\left(1 + \frac{SNR^{(k)}}{\Gamma}\right), b_{\max}\right). \quad (6)$$

where limitations of modulation and coding are considered in terms of an SNR gap to capacity Γ [12] as well as with a limit $b_{max}$ to the number of bits transmitted per carrier and channel use. The OFDM system requires overhead for the cyclic extension to guarantee orthogonal channels, which is considered

in an efficiency factor η. Using η = 1, Γ = 1 and $b_{max} \rightarrow \infty$ gives the capacity without coding and modulation limitations.

Capacity, C, and achievable rate, R, are evaluated with respect to power constraints where the simplest case is a sum power constraint [13]. For practical systems, additional per-carrier constraints are considered, as shown in [14], Sec. 3.1.6. For this case, achievable rate, R, and capacity C for the case of Γ = 1, is the solution to

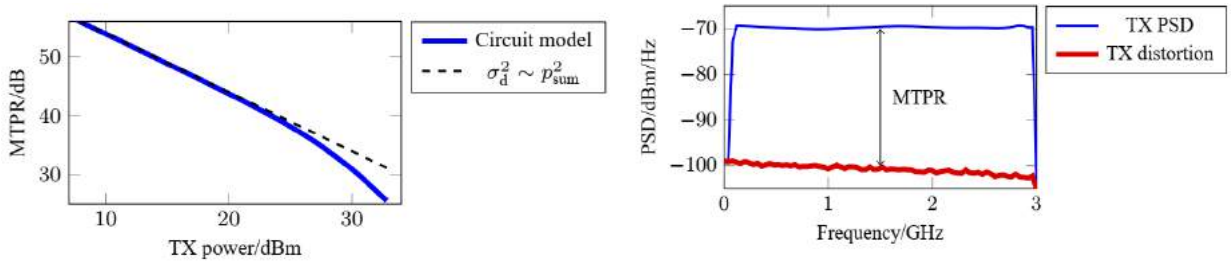
$$\begin{aligned} R_l = & \max_{x_l^{(k)}} \sum_k \log_2 \left( 1 + \frac{|H_l^{(k)}|^2 x^{(k)}}{\Gamma \sigma_l^{(k),2}} \right) \\ & \text{s.t.} \sum_k x^{(k)} \leq p_{\max} \\ & \text{s.t. } 0 \leq x^{(k)} \leq p_{\text{mask}}^{(k)} \end{aligned} \tag{7}$$

where $H_l^{(k)}$ is the channel coefficient on carrier k (attenuation, phase) between node and cable modem (CM) l and $\sigma_l^{(k).2}$ is the additive white Gaussian noise variance on carrier k for CM l.

The power constraints are formulated as a sum power limit $p_{max}$ and a spectral mask constraint $p_{mask}^{(k)}$. Limitations of the modulation alphabet size to $b_{max}$ are incorporated into the spectral mask constraint, using $p_{mask}^{(k)} = {\Gamma(2^{b_{max}} - 1)\sigma^{(k),2}}/{|H^{(k)}|^2}$. The solution to Eq. (7) is obtained by a modified water-filling algorithm as described in [14], chapter 3.1.6. Other algorithms to solve Eq. (7) have been published in [15],[17].

The sum power limit, $\sum x^{(k)} \leq p_{max}$, in Eq. (7) can be seen as a simplified model for the behavior of real transmit amplifier, where the SNR and thus the data rate is limited by distortion increasing with increasing transmit power. Transmit amplifier distortion can be seen as a transmit power dependent noise source with variance $\sigma_d^2$. It is characterized in measurement and simulation by a missing tone power ratio (MTPR). MTPR is the ratio between signal power and distortion power, as shown in Figure 8 (b). It is determined as the signal level on one OFDM carrier which is transmitted with zero power while the others are transmitted at the desired level ($MTPR^{(k)} = {x^{(k)}}/{\sigma_d^2}$). In the following discussion, the cable modem index l is skipped without loss of generality.

Figure 8 (a) shows the increase of nonlinear distortion $\sigma_d^2$ in a 3 GHz amplifier circuit model. The MTPR decreases with increasing transmit power, $p_{sum} = \sum_{k=1}^{K} x^{(k)}$. In frequency domain, as shown in Figure 8 –(b), distortion is approximately flat.



(a) (b)

**Figure 8 – Distortion evaluation from amplifier circuit model**

The dependency between distortion variance $\sigma_d^2$ is and signal power $p_{\text{sum}}(x^{(k)})$ can be described by $\sigma_d^2 = \delta \left(p_{\text{sum}}(x^{(k)})\right)^{\alpha}$. For the amplifier shown in Figure 8 (a), the constants are δ = −64 dB and α = 2. Following the argumentation of [9] a lower bound for the capacity of the nonlinear copper channel is derived.

Introducing distortion in the SNR per carrier gives the term

$$SNR^{(k)} = \frac{|H^{(k)}|^2 x^{(k)}}{\sigma^2 + \delta^{(k)} \left(p_{\text{sum}}(x^{(k)})\right)^{\alpha}} \tag{8}$$

where the distortion variance is $\sigma_d^{(k),2} = \delta^{(k)} \left(p_{\text{sum}}(x^{(k)})\right)^{\alpha}$, assuming white distortion. This gives the rate R (or capacity C with Γ = 1) according to

$$R = \max_{x^{(k)}} \sum_k \log_2 \left(1 + \frac{|H^{(k)}|^2 x^{(k)}}{\Gamma \left(\sigma^2 + \delta^{(k)} \left(p_{\text{sum}}(x^{(k)})\right)^{\alpha}\right)}\right)$$
$$\text{s.t. } 0 \leq x^{(k)} \leq p_{\text{mask}}^{(k)} \tag{9}$$

The derivative $\frac{\partial R}{\partial x^{(k)}}$ is given by

$$\frac{\partial R}{\partial x^{(k)}} = \frac{\left|H^{(k)}\right|^2}{\left(\sigma^2 + \delta_k \left(p_{\text{sum}}(x^{(k)})\right)^{\alpha}\right)(\Gamma + SNR_k)} - \sum_{d=1}^{K} \frac{\left|H^{(d)}\right|^2 x^{(d)} \alpha \delta^{(d)} \left(p_{\text{sum}}(x^{(k)})\right)^{\alpha-1}}{\left(\sigma^2 + \delta^{(d)} \left(p_{\text{sum}}(x^{(k)})\right)^{\alpha}\right)^2 (\Gamma + SNR^{(d)})} \tag{10}$$

and $\partial R / \partial x^{(k)} = 0$ must hold for the optimal power allocation for all carriers with $0 < x^{(k)} < p_{\text{mask}}^{(k)}$. The optimal power allocation can be found, e.g., by a projected gradient method with a step size ρ as given by

$$x_{t+1}^{(k)} = \min\left(\max\left(x_t^{(k)} + \rho\frac{\partial R}{\partial x^{(k)}}, 0\right), p_{\text{mask}}^{(k)}\right) \tag{11}$$

It can be shown [17] that the solution to equation (10) takes the following form,

$$\frac{1}{\mu} = \sum_{d=1}^{K} \frac{\left|H^{(d)}\right|^2 x^{(d)} \alpha\delta^{(d)} \left(p_{sum}(x^{(k)})\right)^{\alpha-1}}{\left(\sigma^2 + \delta^{(d)}\left(p_{sum}(x^{(k)})\right)^{\alpha}\right)^2 \left(\Gamma + SNR^{(d)}\right)} \tag{12}$$

The dependency between $\mu$ and $p_{sum}$ is given by,

$$\frac{1}{\mu} = \frac{1}{|I_{\text{fill}}|}\left(p_{sum} + \sum_{k\epsilon I_{\text{fill}}} \frac{\Gamma\sigma_{nd}^{(k),2}}{\left|H^{(k)}\right|^2} - \sum_{k\epsilon I_{mask}} p_{mask}^{(k)}\right) \tag{13}$$

Where $I_{mask}$ is the set of subcarriers for spectral mask constraint is active and $I_{fill}$ is the set of subcarriers with power allocation to meet water-fill level, and $|I_{\text{fill}}|$ denotes cardinality (number of elements) of the set $|I_{\text{fill}}|$.

Hence the transmit power per subcarrier is given by,

$$x^{(k)} = \begin{cases} \frac{1}{\mu} - \frac{\Gamma\sigma_{nd}^{(k),2}}{\left|H^{(d)}\right|^2} & \text{for } k\epsilon I_{\text{fill}} \\ 0 & \text{for } k\epsilon I_0 \\ p_{mask}^{(k)} & \text{otherwise} \end{cases} \tag{14}$$

Where $I_0$ is the set of subcarriers where positiveness constraint given in equation (7) is active and therefore no power is allocated.

To implement the optimization scheme, the distortion parameters, δ and α must be known from an amplifier characterization. During operation, the noise conditions must be known from an SNR measurement. The algorithm performs multiple water-filling steps. As the optimization can be done by software in background during operation of the link, there is no issue with computation time.

### 3.2. Extention to Node + X, X > 0, Networks

The algorithm described in section 3.1 assumes a single source of transmitter distortion at the node and a single receiver noise source at each CM, as it is reflected in the SNR in Eq. (8). In case of a Node + X topology with multiple intermediate amplifiers, each intermediate amplifier represents an additional source of distortion and each amplifier input experiences additive receiver noise.

Still, it can be shown that under a certain assumption, the optimization framework of section 3.1 can be applied to the Node + X case, too. The precondition for the spectrum optimization to be applied is that the attenuation and down-tilt of the cable section, given by the transfer function $H_{span}^{(k)}$ , is compensated by

amplifier stage $H_{amp}^{(k)}$ at the end of the cable section, such that the power level and spectral shape of the transmit signal is the same at each intermediate amplifier $H_{span}^{(k)}$ $H_{amp}^{(k)} = 1$, as shown in Figure 9.

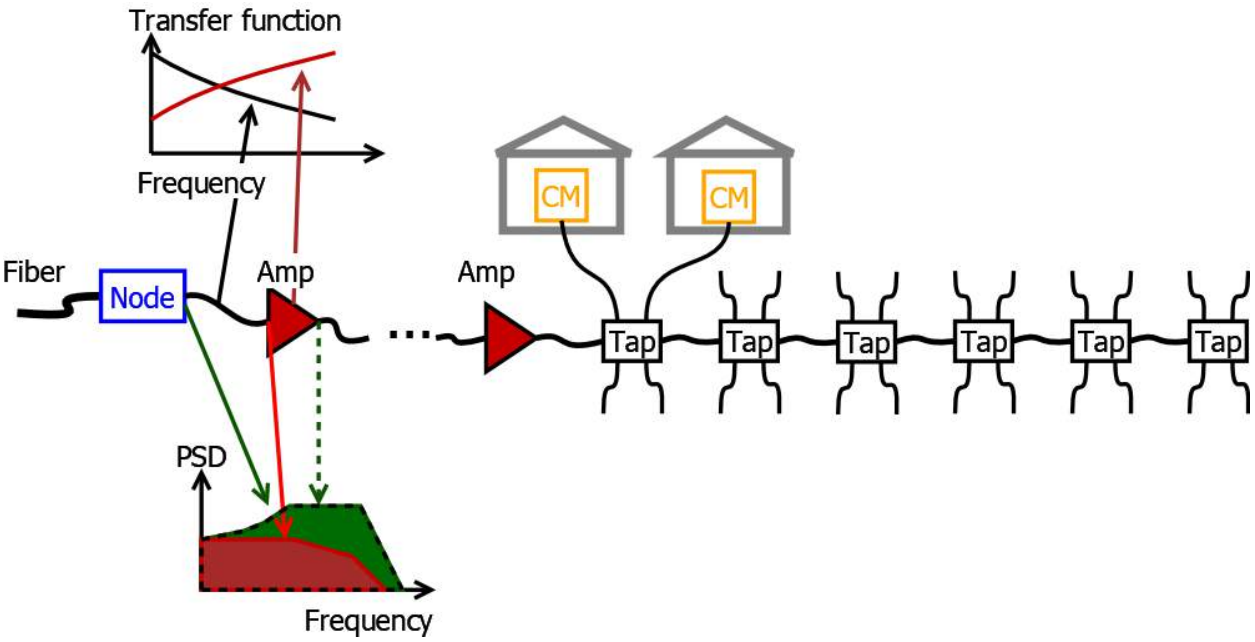


**Figure 9 – Node+X topology with Power Spectrum Optimization**

Mathematically, the transmit power per carrier k, $x^{(k)}$ is (approximately) the same at node output and the amplifier outputs , $x^{(k)} \approx x_{amp,1}^{(k)} \approx \ldots \approx x_{amp,n}^{(k)} \; \forall \, k = 1, \ldots, K$ . With this condition satisfied, all the amplifier distortion of N amplifiers can be combined into one distortion $(N+1)\,\delta^{(k)}\left(p_{sum}(x^{(k)})\right)$.

The receiver noise of the amplifiers, assuming $\sigma_{amp}^2 \ll \left|H_{span}^{(k),}\right|^2 x^{(k)}$ for all the used frequencies, can be handled as additive noise. The receiver noise of the amplifiers is summed up, referred to the CM receiver and added to the CM receiver noise $\sigma^2$ which gives the overall additive noise term to be $N\,\sigma_{amp}^2 \left|H_{amp}^{(k)}\right|^2 \left|H^{(k)}\right|^2 + \sigma^2$.

Accordingly, the algorithm of section 3.1 remains as is while performing the following substitutions

Receiver noise: $\sigma^2$ ➔ $N\,\sigma_{amp}^2 \left|H_{amp}^{(k)}\right|^2 \left|H^{(k)}\right|^2 + \sigma^2$

Transmitter distortion: $\delta^{(k)}\left(p_{sum}(x^{(k)})\right)$ ➔ $(N+1)\,\delta^{(k)}\left(p_{sum}(x^{(k)})\right)$

Compared to the Node + 0 architecture, transmitter distortion optimization is even more relevant in the Node + X architecture, as there is a higher distortion level present due to the distortion of multiple amplifiers adding up. It may also be beneficial to drive the TCP of individual amps down as much as possible to lower individual nonlinear distortion contributions from amps. We will look at strategies on achieving this objective in this in this paper.

### 3.3. Algorithm Description

The above framework leads to an iterative throughput optimization algorithm described below.

**Initialization Step:** Initialize the TCP, $P_{sum}(0)$, to the target maximum power level. Index 0 refers to initial value

Following that, the following steps are performed in an iterative loop, until the $P_{sum}(n)$ converges to a steady value. $|P_{sum}(n) - P_{sum}(n+1)| < Threshold$

**Iterative Step 1:** Apply water-filling described in [14] with the current $P_{sum}$ to discover,

- $I_0$ = The set of subcarrier that get no power allocation
- $I_{\text{fill}}$ = The set of subcarriers that gets power allocation to water-fill level
- $I_{\text{mask}}$ = The set of subcarrier that gets power allocated to $p_{mask}^{(k)}$ level. For these subcarrier $p_{mask}^{(k)}$ level is hit before reaching water-fill level and therefore no additional power is wasted to reach water-filling level

**Iterative Step 2:** Based on subcarrier sets information from previous step and Equation (14), calculate the power allocation per subcarrier, $x^{(k)}$.

**Iterative Step 3:** Calculate water-filling level, $\frac{1}{\mu}$, using equation (12)

**Iterative Step 4:** Update the TCP, $P_{sum}(n+1)$, from equation (13)

**Exit Criteria:** If $|P_{sum}(n) - P_{sum}(n+1)| < Threshold$ then stop iteration. Otherwise go back to Iterative Step 1.

Pseudo code for the algorithm is given below.

**Table 1 – Optimization algorithm summary**

| | |
|---|---|
| Initialization | $P_{sum}(0)$ = max allowed TCP |
| Iteration | Identify the sets $I_0$, $I_{\text{fill}}$, and $I_{\text{mask}}$ (water-filling, [14])<br>Update $x^{(k)}$ using Eq. (14)<br>Calculate $\mu$ from Eq. (12) with updated $x^{(k)}$<br>Update $P_{sum}(n+1)$ from μ, using Eq. (13) |
| Exit Criteria | $\lvert P_{sum}(n) - P_{sum}(n+1)\rvert < Threshold$ |

## 4. System Level Solution for Closed Loop Optimization

In order to apply the closed loop optimization algorithm developed above in a practical system, we first need to consider the impact of channel allocation. Channel allocation and power optimization together form our overall closed loop solution. We consider two power allocation strategies; Full spectrum allocated to each CM, and channel stacking or staggered channel allocation.

## 4.1. Full Spectrum allocated to each CM

Consider the mid-split US/DS partitioning with all the CMs allowed to use DS OFDM channels anywhere in the spectrum from 108 MHz to 1794 MHz. In this case, power allocation is optimized considering channel frequency response and noise of all channels for a CM connected to a particular tap. Given that each channel is potentially shared between all CMs in the node, we have to carefully select the CM that we target the optimization algorithm for (i.e. what channel frequency response and noise responses to use in the algorithm). Going for the worst-case CM (farther away from node) or the best-case CM (closer to node) may not lead to overall node throughput optimization. A CM that represents median or overage behavior, in terms of received signal quality, would lead to better results. Once the downstream power is optimized, DOCSIS has other tools, such as the profiles, to fine tune the throughput for CMs with different received signal quality.

## 4.2. Channel Stacking

In this case, based on the observation that the cable channel has higher losses at higher frequencies, we allocate the lower frequency channels to far away CMs and higher frequency channels to close in CMs. It will be shown later that this allows us to reduce the TCP of node and amps significantly, opening up potential other benefits in overall network architecture.

## 4.3. Implementation Considerations

Closed loop algorithm implementation considerations are described in this section. The aim is, as much as possible, to work within the current DOCSIS 4.0 standard provisions to implement the algorithm described in previous section. We also highlight aspects of the standard that can be improved to better facilitate the closed loop throughput optimization.

The algorithm described in section 3.3 requires per subcarrier channel frequency response estimates and total noise estimates from the CMs to derive the optimal power allocation. DOCSIS 3.1 and 4.0 provide following proactive network maintenance (PNM) features to help gather this information from the CM:

- Downstream Channel Estimate Coefficients: CMTS can command CM to send Channel Estimate coefficients to CMTS (section 9.3.4 of [3], [4]).
- Downstream Receive Modulation Error Ratio (RxMER) Per Subcarrier: CMTS can command CM to send MER estimates to CM (section 9.3.6 of [3], [4])

Noise power per subcarrier can also be derived from the above information.

Once the optimal power allocation solution is found, the CMTS needs to shape the downstream transmit spectrum accordingly. The DOCSIS 4.0 spec [4] has provisions for the node to shape the transmit RF spectrum under the following constraints:

- Apply a uniform up tilt (i.e. same gradient across all entire spectrum) to the transmit spectrum so that more power is allocated to higher frequencies.
- Introduce multiple step downs/ups to maintain total composite power bound (sum step downs < 10 dB)
- Spectrum discontinuities, step down/up, are only allowed in OFDM channel boundaries

Figure 10 shows an example power allocation instance allowed by the spec viewed at interface C – before the uniform tilt and power amplification (PA).

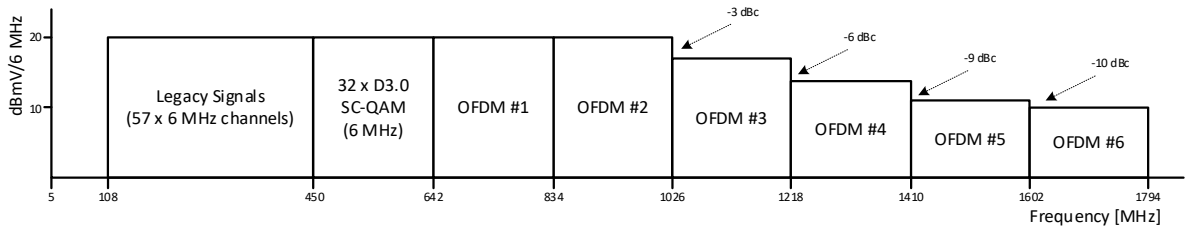

**Figure 10 – Downstream Transmit Power allocation as seen from Node Interface C**

At interface D (node output port), post tilt application and PA, the above spectrum appears with a uniform up tilt while keeping the same step-downs seen in Figure 10.

One key area where the spec could be amended is to allow for more flexible spectrum shapes with possible flat power spectral density (PSD) at high frequencies at interface D. This means removing the condition of uniform tilt across the entire spectrum mentioned above. This will allow for more accurate implementation of some of the transmit PSD optimization scenarios described later in this document. However, we should weigh the benefits of doing so against potential complications to the node and amp architectures as well as the operation of the network.

We can bring in a machine learning approaches to incorporate various other aspects of the system in the overall solution, such as:

- Take into account the individual CM throughput usage over time in channel allocation
- Overall node-wide throughput usage over time
- Service agreement data for individual CMs
- Prior knowledge of network topology

A profile management application (PMA) can also be used in conjunction with the items mentioned above to increase the overall performance in the distribution plant. By enabling dynamic bit-loading and profiles assigned to each service group, the overall plant throughput and stability of the plant will increase.

## 4.4. Create Headroom in Power Budget for Soft Flexible MAC Architecture

In this section, we briefly address an added benefit of potential TCP reduction by closed loop optimization in creating room in the overall network power budget for a soft flexible MAC architecture (FMA) solutions. Currently the node power budget is very tight already with remote PHY device (RPD) solutions. With a node power budget ranging from 160 W to 180 W for North America, the RPD and the RF power amplifiers are already using up most of this power. For example, for 85% power delivery efficiency, power left over for other potential uses are roughly 16 W and 33 W for a 2x2 node with 4 legs for overall 160 W and 180 W power budgets respectively. A large chunk of the power is taken up by the 4 PAs, which are assumed to be at 71 dBmV TCP at the node output port.

For FMA solutions, especially remote MAC device (RMD), where MAC functionality is also distributed to the node in addition to PHY, the above excess power is not sufficient for a fully software based solution using general purpose compute, let along having additional headroom for future edge computing applications. This forces a solution which is either based on ASIC/FPGA or/and a CPU with limited compute (to fit within available power budget).

If we can lower the TCP by just 2 dB, to 69 dBmV, this increases the available power for FMA and edge compute to 28 W to 45 W. As shown in section 5, with the additional power saving achievable with closed loop optimization combined with channel stacking, it is possible to reduce the TCP by as much as 6 dB for1.8 GHz ESD. Even for 1.2 GHz DOCSIS, we can explore channel stacking with power optimization to get some reduction in power consumption. This opens the possibility of a soft MAC architecture and also leaves enough headroom for other future edge compute applications.

# 5. Simulation Results and Discussion

Rate results for different network topologies, channel allocation strategies and power allocation strategies are given in this section. Node + 0 and Node + 4 network topologies are considered. Allowing all CMs to access the entire downstream spectrum vs channel stacking is also considered. In terms of power allocation, three different allocation strategies are compared:

- Tilted TX PSD to receive flat RX spectrum at CM.
- Flat TX PSD as implied by conventional water filling solution.
- Optimal power allocation based on the algorithm described in this paper.

We explore both the mid and high split plant scenarios:

- Mid-split: DS starts at 108 MHz
- High-split: DS starts at 258 MHz

## 5.1. Full Optimization for Node + 0 and Node + 4

In this section, we explore the optimization of transmit PSD for capacity without any other constraints imposed by operational considerations. This is partly an academic exercise to gain insight into the properties of the power allocation algorithm

### *5.1.1. Node + 0 Network, Mid-Split*

Figure 11 shows the throughput for CMs connected to different taps for the three different power allocation strategies.

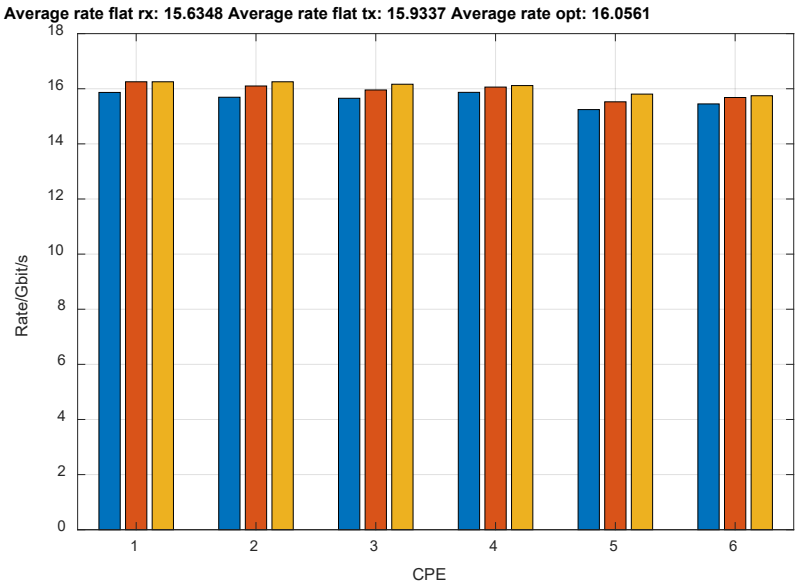

**Figure 11 – Rate for flat RX (blue), flat TX (red) and optimal (yellow) power allocation**

Throughput gain from using the optimal algorithm is limited in this case.

### *5.1.2. Node + 4 Network, Mid-Split*

The same three power allocation strategies described in section 5 are used here. It is assumed that the distribution cable sections have 35 dB attenuation at 1 GHz. The Node + 4 network is constructed with four straight trunk cable sections with amplifiers followed by a cable section.

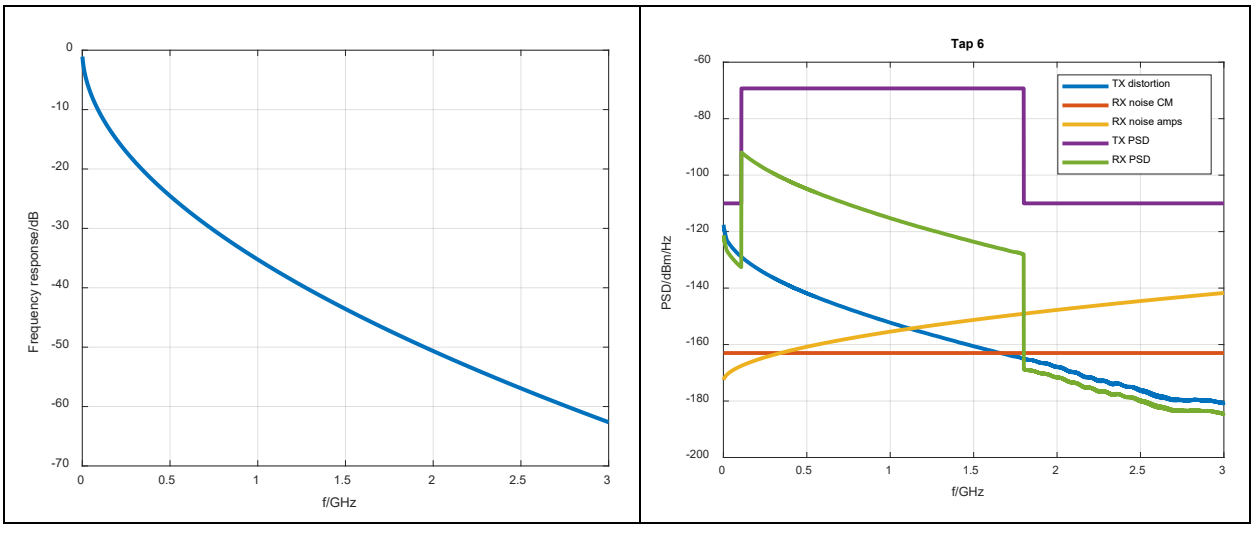

**Figure 12 – Attenuation of the cable sections (left) and signal and noise PSDs at the last Tap (right)**

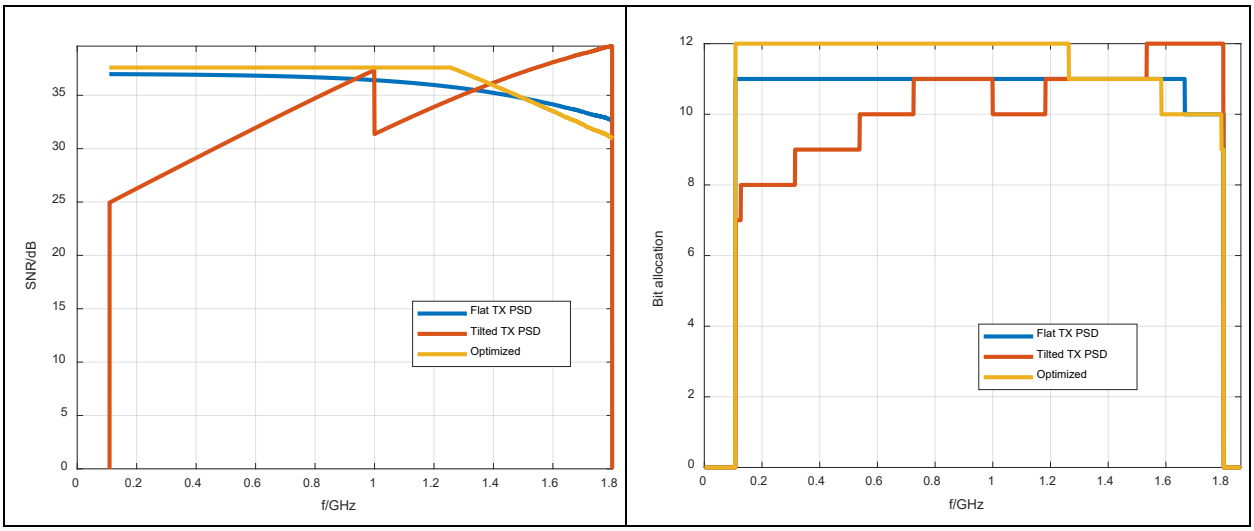

**Figure 13 – Node + 4 mid split SNR at Tap 3 (left) and bit allocation at Tap 3 (right)**

The distortion of all 5 transmit amplifiers (CMTS and 4 amplifiers) is the same. Each amplifier compensates the channel attenuation and tilt of preceding cable segment completely (segment unity gain) such that the transmit spectrum is the same at each stage. For the noise figure of the amplifiers, 2 amplifiers with 5 dB and 2 amplifiers with 10 dB are assumed. Additional 3 dB of losses in the receiver is assumed (account for losses in passive connectors, diplexers, etc).

Figure 14 shows the throughput for CMs connected to different taps for the 3 power allocation strategies. Up to 10% Rate improvement is achieved with the optimal power allocation.

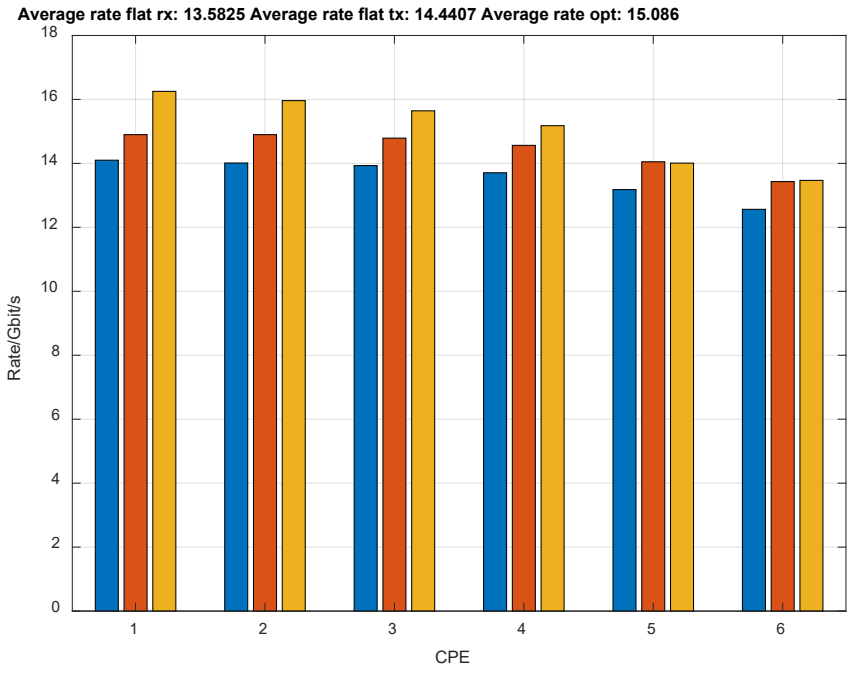

**Figure 14 – Node + 4 mid-split Data rates for tilted TX- flat RX PSD (blue), flat TX PSD (red), and optimized PSD (yellow)**

Figure 15 shows transmit power spectrum for the 3 power allocation schemes (left) and TCP when optimizing throughput for a certain tap (right). In case of tilted TX PSD and flat TX PSD, the transmit power spectrum and TCP don't depend on the tap. When optimizing throughput for long taps (5, 6), the optimal spectrum shape is flat, while optimizing for short taps (1) gives a tilt for all frequencies as an optimal shape. When optimizing for the medium taps (2-4), the optimal spectrum shape has a tilt at low frequencies followed by flat region at high frequencies. The tilt at low frequencies indicates that the performance at these frequencies are nonlinear distortion dominated. On the other hand, at high frequencies the dominance of thermal noise (i.e. signal is more attenuated and hence closer to thermal noise floor) makes the flat spectrum optimal (classic water-filling comes into play). TCP graphs shows the TCP at node when optimized for tap number given in x-axis.

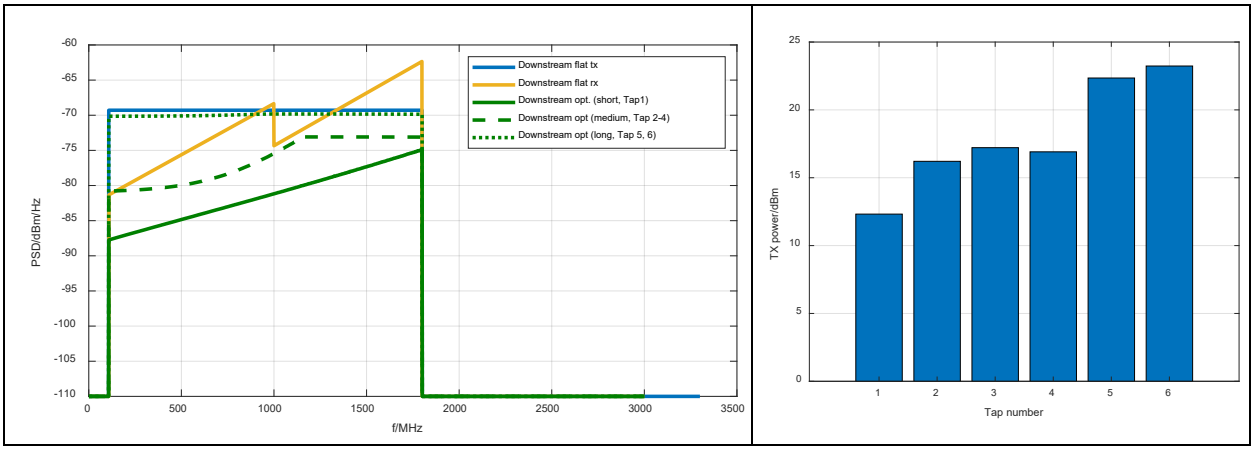

**Figure 15 – Node + 4 mid-split Transmit PSDs and TCPs for different allocation schemes**

TCP requirement is dominated by the far away CMs, requiring the full 71 dBmV (22.25 dBm) of power.

### *5.1.3. Node + 0 Network, High-Split*

We've repeated the test for high split note to get the following rate and TCP results. TCP requirement is dominated by far away CMs demands.

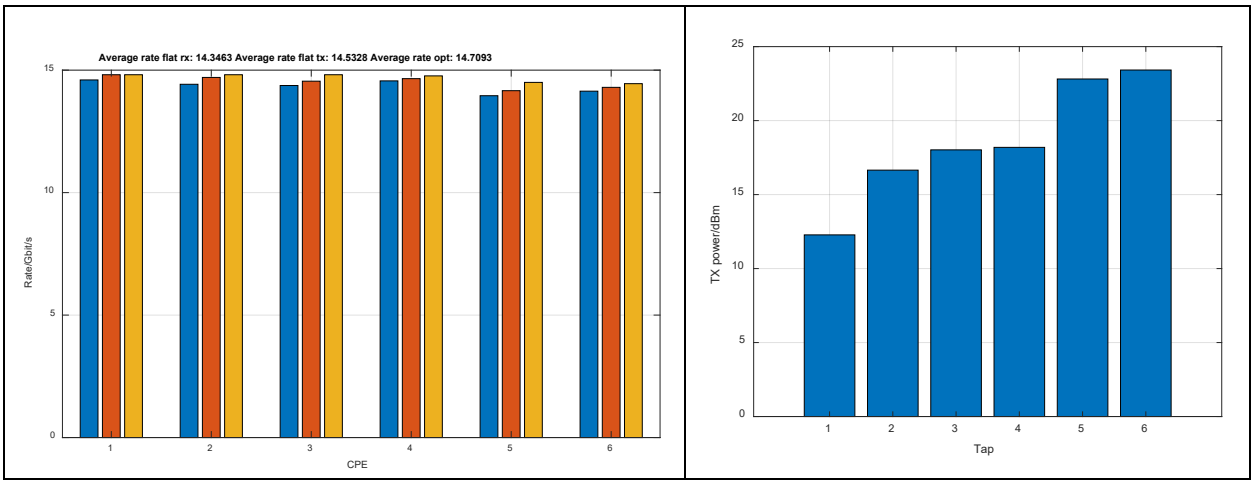

**Figure 16 – Node + 0 high-split Data rates for flat RX (blue), flat TX (red), and optimized (yellow) and corresponding TCP**

Optimal PSDs are shown in Figure 17. Although we can maintain a uniform tilt in spectrum for the close in and medium range CMs, long range CMs forces a flat spectrum at high frequencies.

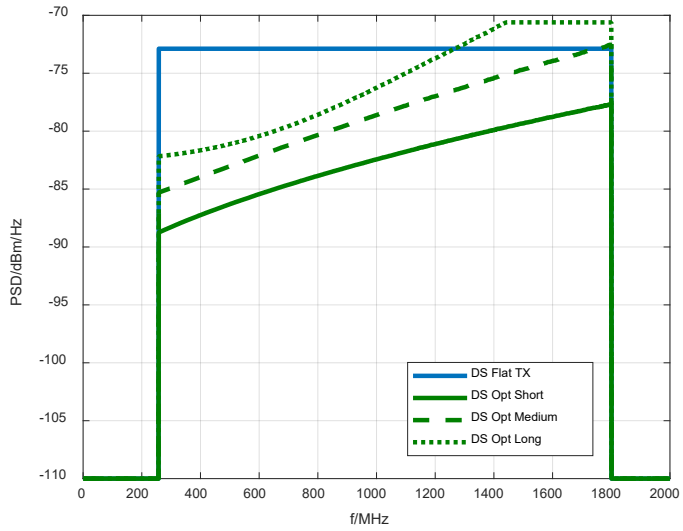

**Figure 17 – Node + 0 high-split Transmit PSDs for different allocation schemes**

### *5.1.4. Node + 4 Network High-Split*

Up to 10% rate improvement achieved with optimal power allocation as show in Figure 18 (left).

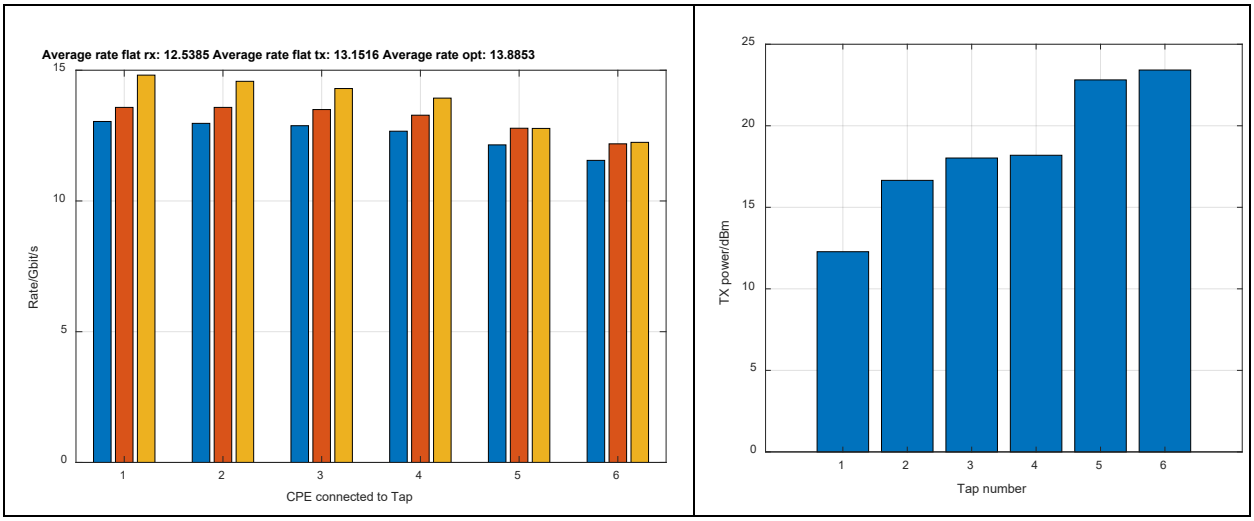

**Figure 18 – Node + 4 high-split Data rates for flat RX (blue), flat TX (red) and optimized (yellow) and the corresponding TCP**

Power allocation across frequency for the 3 allocation schemes is shown in Figure 19.

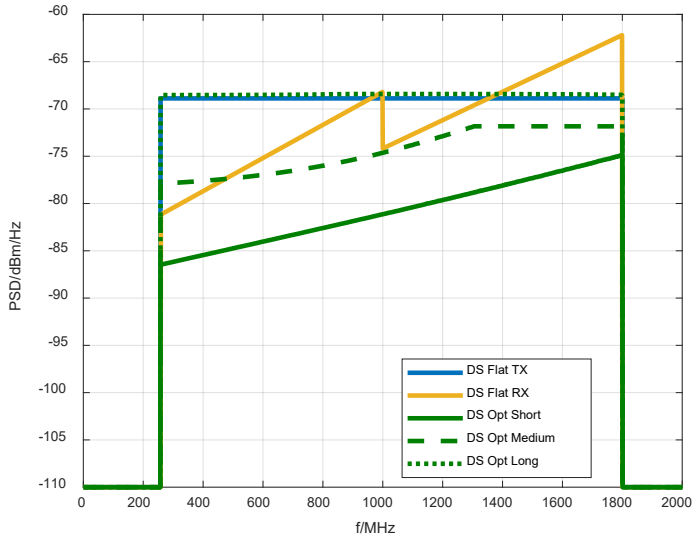

**Figure 19 – Node + 4 high-split Transmit PSDs for different allocation schemes**

## 5.2. With Staggered Channel Allocation – Channel Stacking

In these tests, we exploit the property of the cable channel that it has higher losses at higher frequencies. To minimize the impact of higher losses in higher frequencies, we allocate these higher frequency channels to close in CMs and lower frequency channels to far away CMs. Consider to hypothetical channel allocation (non-DOCSIS) shown in Figure 20. The channel estimate for each allocated channel is used in the optimization algorithm.

| Modem Channel | 1-4 (Tap 1) | 5-8 (Tap 2) | 9-12 (Tap 3) | 13-16 (Tap 4) | 17-20 (Tap 5) | 21-24 (Tap 6) |
|---|---|---|---|---|---|---|
| 1 | | | | | | |
| 2 | | | | | | |
| 3 | | | | | | |
| 4 | | | | | | |
| 5 | | | | | | |
| 6 | | | | | | |
| 7 | | | | | | |
| 8 | | | | | | |
| 9 | | | | | | |

**Figure 20 – Channel to CM allocation for PSD optmization**

Figure 21 shows PSD for the above channel allocation scheme. A significant reduction is TCP (up to 6 dB) is achieved through this channel allocation scheme without losing any throughput.

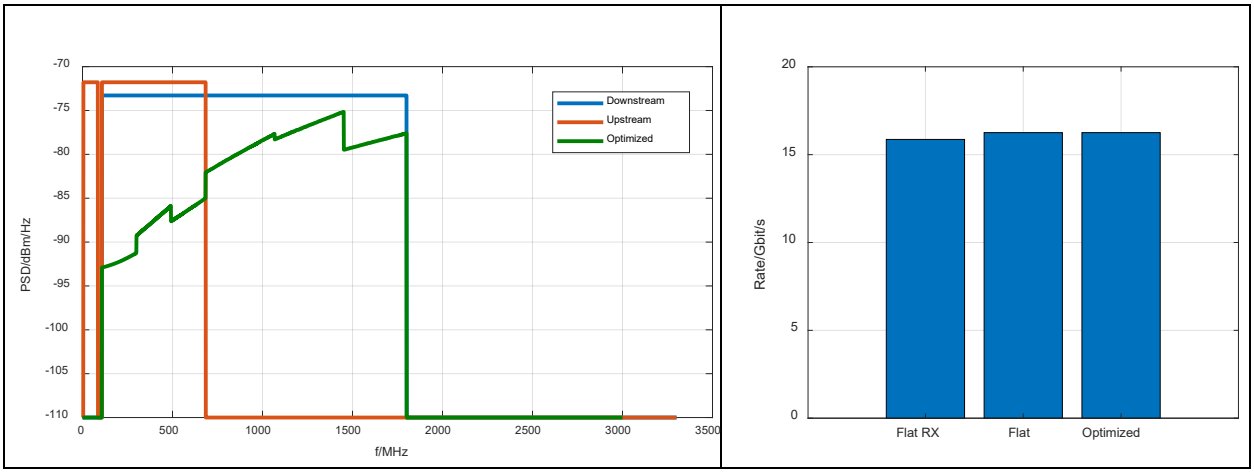

**Figure 21 – Power allocation vs Data rates**

However, this is not quite a practical allocation scheme. In practice we would allocate set of channels to a group of CMs and take advantage of statistical multiplexing to improve the utility of the spectrum.

Figure 22 shows a practical channel allocation scheme where channels allocated to long range CMs are indicated in green and channels allocated to short range CMs are indicate in yellow. Within each channel set, the CM corresponding to the channel estimate used in the optimization algorithm is indicated in dashed lines.

| Modem Channel | 1-4 (Tap 1) | 5-8 (Tap 2) | 9-12 (Tap 3) | 13-16 (Tap 4) | 17-20 (Tap 5) | 21-24 (Tap 6) |
|---|---|---|---|---|---|---|
| 1 | | | | | | |
| 2 | | | | | | |
| 3 | | | | | | |
| 4 | | | | | | |
| 5 | | | | | | |
| 6 | | | | | | |
| 7 | | | | | | |
| 8 | | | | | | |
| 9 | | | | | | |

**Figure 22 – Channel stacking for two service groups**

Note that each CM is allocated 5 OFDM channels, which will allow us to maintain 10 Gbit/s for the service group (SG).

SG A:

- CMs in Taps 1 to 3.
- Allocated channels 5 to 9

SG B:

- CMs in Taps 4 to 6
- Allocated channels 1 to 5

This channel allocation enables what we call 10G DOCSIS and it will appear like a node-split in the sense that we are supporting two 10G SGs using available spectrum.

By optimizing the power allocation for each channel to match at least one of the taps in each SG, we are optimizing the average throughput of each SG (assuming each user has roughly the same probability of using each channel).

The alternative scheme shown in Figure 23 uses the same channel allocation, but the channel frequency responses used in the optimization algorithm is taken from the medium range CM within each SG. This is the default channel allocation method used in following tests unless mentioned otherwise.

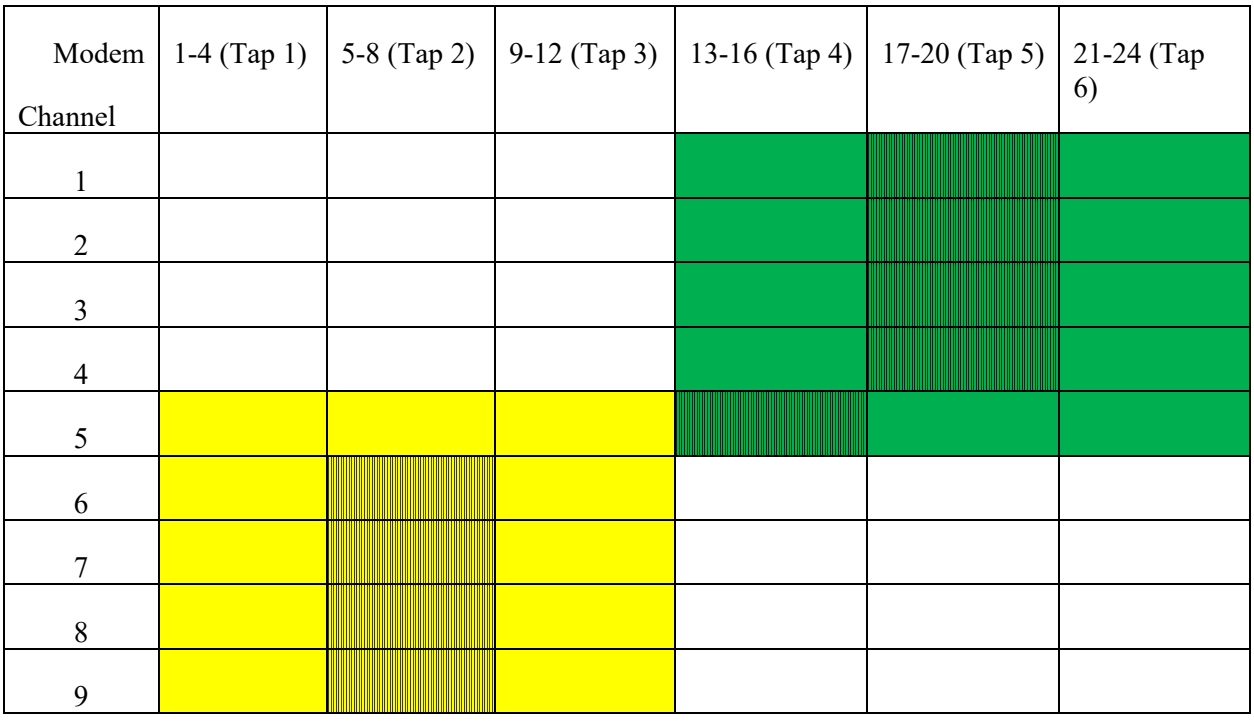

**Figure 23 – Default channel stacking scheme for two service groups**

In practice, with additional information, we could make more data driven approach to allocating channels and deciding which tap/CM channel estimate we use for optimization.

### 5.2.1. Node + 0 Network Mid-Split

Figure 24 shows the optimal PSD and resulting data rates for the channel allocation scheme given in Figure 23 for Node + 0 Network.

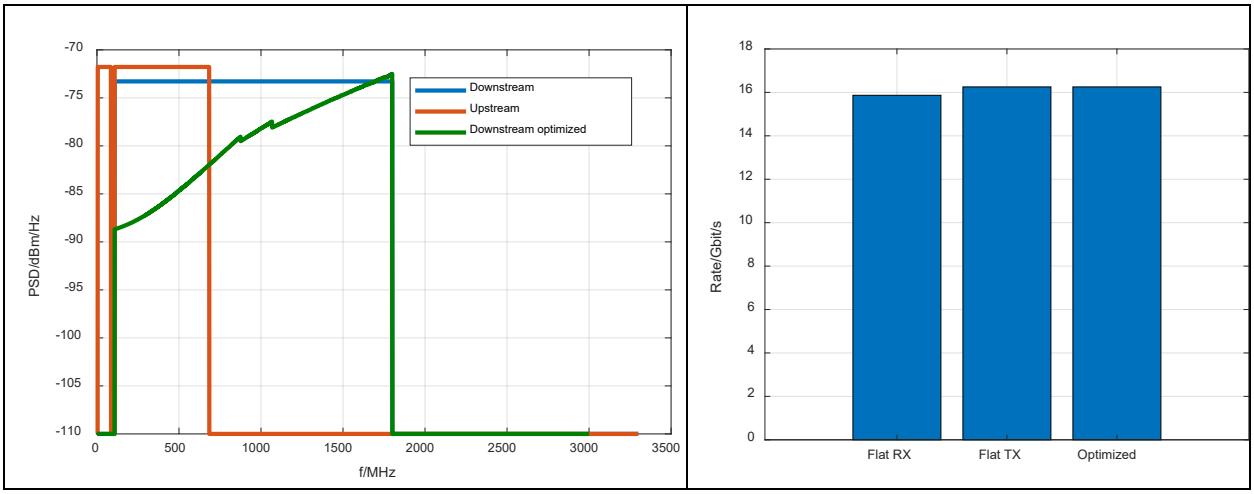

**Figure 24 – Node + 0 mid-split Power allocation and Rate for channel stacking**

Note that the TCP has reduced by nearly 6 dB compared to assigning all the channels to each CM. Furthermore, the overall rate is higher compared to allocating all channels to each CM.

### 5.2.2. Node + 4 Network Mid-Split

Channel allocation based power optimization results for Node + 4 mid-split case is shown in Figure 25. As in Node + 0 case, we are making significant savings in TCP. In addition, the optimal power allocation gives 10-15% increase in the throughput compared to non-optimal power allocation schemes.

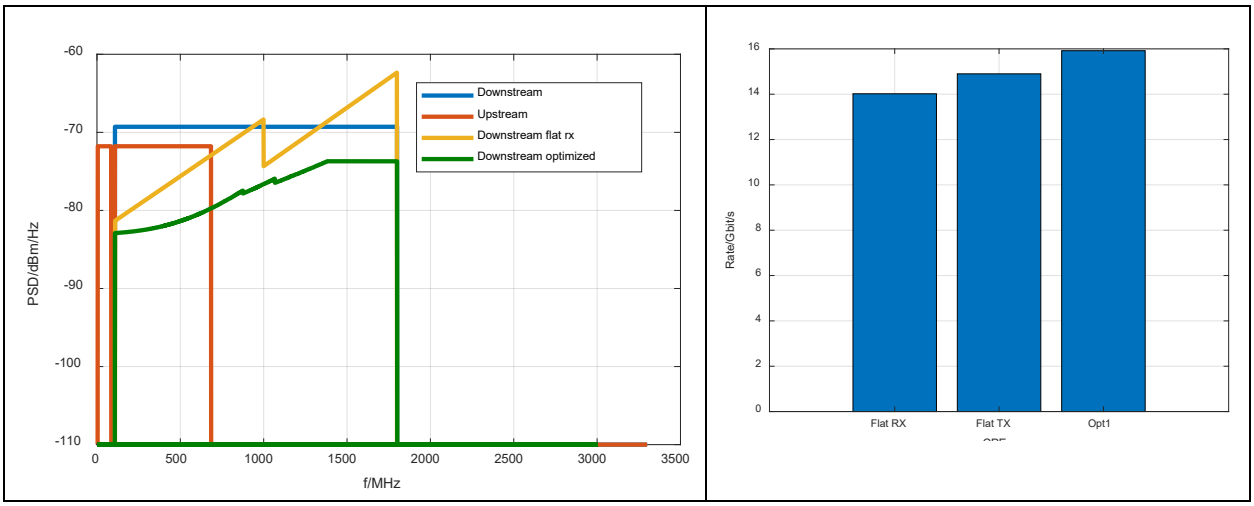

**Figure 25 – Node + 4 mid-split power allocation and Rate for channel stacking**

### 5.2.3. Node + 0 Network High-Split

Channel allocation based power optimization results for Node + 0 high-split case is shown in Figure 26. As with Node + 0 mid-split cases, we are making significant savings in TCP while not losing any throughput.

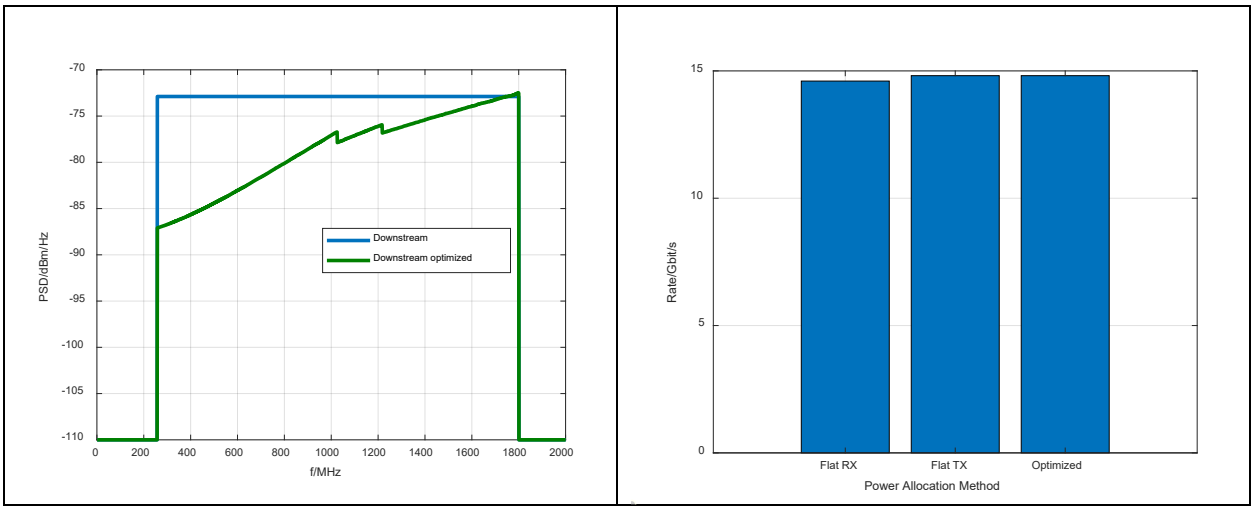

**Figure 26 – Node + 0 high-split power allocation and Rate for channel stacking**

The optimized TX TCP is 6 dB below the TX power used for flat TX and flat RX.

### 5.2.4. Node + 4 Network High-Split

Channel allocation based power optimization results for Node + 4 high-split case is shown in Figure 27. As in Node + 4 mid-split case, we are making significant savings in TCP, and at the same time improving the throughput by 10-15%.

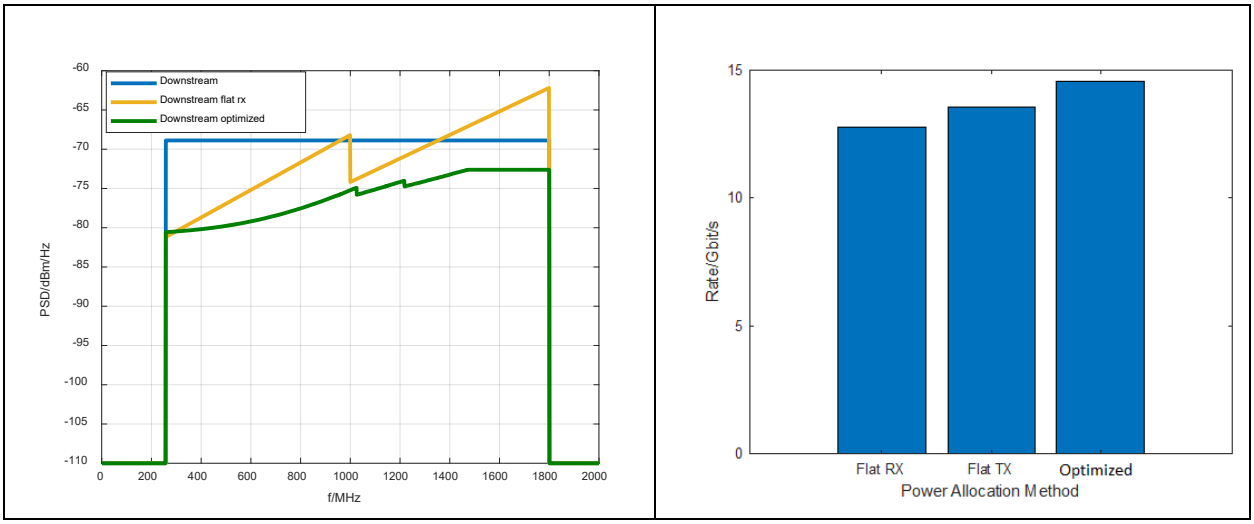

**Figure 27 – Node + 4 high-split power allocation and Rate for channel stacking**

## 6. Conclusion and Future Work

This paper shows that there are significant benefits to be gained from careful allocation of channels to the CMs and optimization of available limited transmit power in a ESD system.

For a given channel allocation, considerable throughput gain, in order of 10%, is achievable with closed-loop power optimization. Furthermore, carefully combining the channel allocation and optimal power distribution can significantly reduce the required TCP for the node and the network amps.

The additional headroom created in transmit power budget can be exercised to improve the range of the network. On the other hand, savings made to overall node power consumption budget can enable more flexible fiber deep deployment options, such as soft FMA and edge compute.

The above benefits are applicable to network topologies across the board, be it passive Node + 0, fiber deep, or conventional Node + X.

Further work is needed to quantify the effect of relaxing some of the network design principles, such as unity gain.

# 1. Introduction

The telecommunications industry is well underway to moving to virtualizing network functions, and the cable industry is no exception. This paper focuses on providing understanding of virtualized solutions and technology, by analyzing design aspects, capacity planning and architecture evolutions of a CCAP virtual function.

Initially, different virtualization technologies such as virtual machines vs containers are compared, together with continuous integration and deployment as a key element for the required agility to deploy new services and network functions. It is important to mention how the evolution to a distributed computing model and particularly how Mobile Edge Computing (MEC) and network slicing will shape future networks.

Next, a network architecture design is presented focusing on the evolution to separate control and user planes and the impact on network traffic, how they align with distributed access architectures in two flavors, Remote PHY and Remote MAC PHY, and how the vCCAP function could split in two new logical functions in the near future.

Lastly, a set of conclusions is presented to help cable operators better understand the requirements, design options and tradeoffs of vCCAP and DAA deployments in general for the next two to three years and how this decision will impact on the deployment of other related VNFs such as BNG (Broadband Network Gateway) or an EPC (Evolved Packet Core).

# 2. Virtualization

## 2.1. Virtualization Introduction

Generally speaking, Virtualization is defined as running one or multiple instances of a computer system on a layer which is abstracted from the hardware. Each abstracted instance is called a virtual instance. Over the year's virtualization evolved from being just a way of running more than one operating system on a desktop computer at the same time, at the expense of noticeable performance degradation to now being a ubiquitous technology in the server world.

Virtualization offered the ability to run different operating systems, and multiple instances of each. This concept allowed a large system to be split into multiple smaller ones, and hence where now a server could be used to run multiple applications or services while allowing each of them to run completely isolated of the other like it was running in its own dedicated server (Morabito, Cozzolino, Ding, Beijar, & Ott, 2018) - Figure 1.

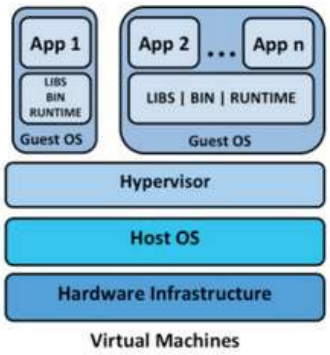

**Figure 1 – Virtual Machines**

## 2.2. The Hypervisor

As seen in Figure 1, in order to run multiple virtual machines in physical hardware, a software component is required. This software component is called a hypervisor, a program which takes care of allocating the available resources to each of the virtual machines. Any program run under the hypervisor should exhibit an effect identical with that demonstrated if the program had been run on the original machine directly (Popek & Goldberg, 1974). There are two types of hypervisors as seen in Figure 2. Type one hypervisors are operating systems themselves and run the guest virtual machines directly. Type two hypervisors need to run on a pre-installed operating system and run as application that can be stopped or started.

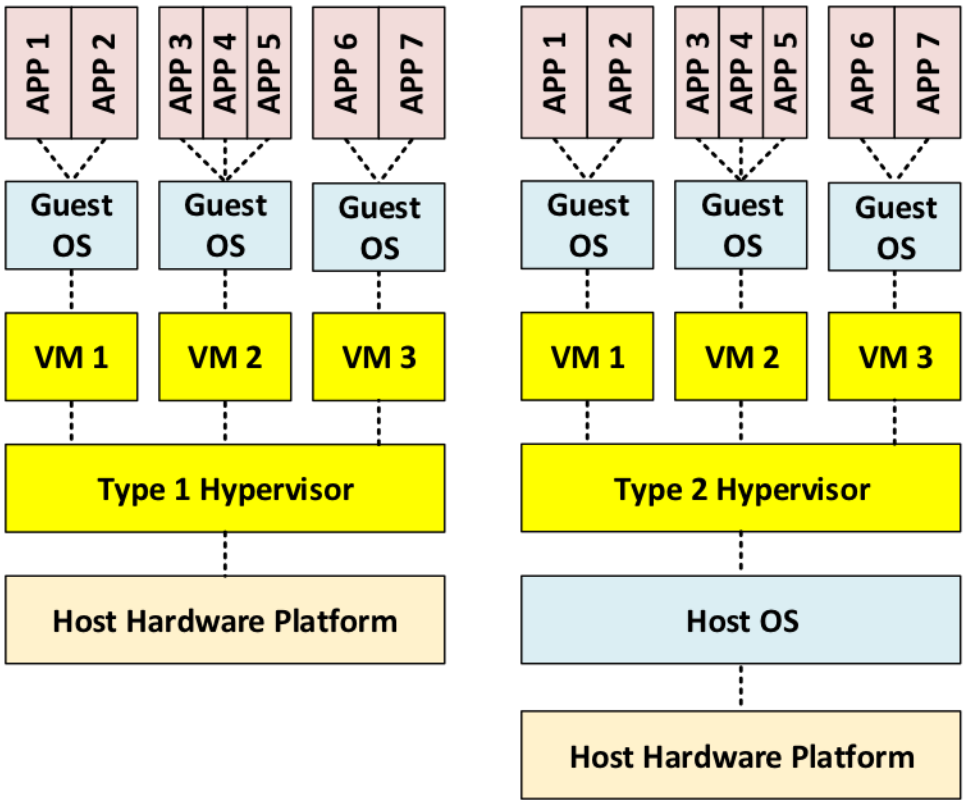

**Figure 2 - Hypervisor Types**

Some examples of commercial and open source hypervisors are listed in Table 1.

**Table 1 - Hypervisor Examples**

| Type 1 | Type 2 |
|---|---|
| VMware ESX and ESXi | VMware Workstation |
| Microsoft Hyper-V | Oracle VM VirtualBox |
| Citrix XenServer (Xen Based) | Red Hat Enterprise Virtualization (kvm Based) |
| Oracle VM (Xen Based) | |

### 2.3. Virtual Machines

A virtual machine is a term that dates back to 1974 and is defined as an efficient and isolated duplicate of a real machine, where a piece of software provides an environment which is essentially identical to the original machine and programs can run with only minor decreases in speed (Popek & Goldberg, 1974). Virtual machines or guests can have access to the resources available on the host system. The host system can provide computing power, memory, disk space and access to the network interface cards. In the early days of x86 virtualization, hypervisors needed to fully emulate the behavior of the virtual machine including the CPU instruction set, causing a big overhead of computing power and significantly affecting performance of the whole

virtualized system. In 2006, Intel and AMD introduced hardware implemented virtualization extensions (VT and SVM) which allowed the hypervisors to directly access the CPU instructions thus making x86 virtualization possible in terms of performance (Adams & Agesen, 2006). Depending on the expected quality of service, sometimes those resources could or could not be oversubscribed.

### 2.4. Network Function Virtualization

In 2013 ETSI coined the term Network Function Virtualization (NFV). At that time telecommunications operators' networks were populated with a large and increasing variety of proprietary hardware appliances. Launching a new service required even more hardware and the space and power requirements to integrate those boxes was becoming a real challenge. At the same time energy costs were increasing and also hardware obsolescence cycles were becoming shorter, increasing CAPEX costs (European Telecommunications Standards Institute, 2012). At the same time off-the-shelf server computing power was increasing with the costs of those servers being reduced.
Network Functions Virtualization's goal is to address these problems by providing standardization to the virtualization technology in order to consolidate different network equipment types into industry standard off the shelves servers, switches and storage (European Telecommunications Standards Institute, 2012) as seen in Figure 3.

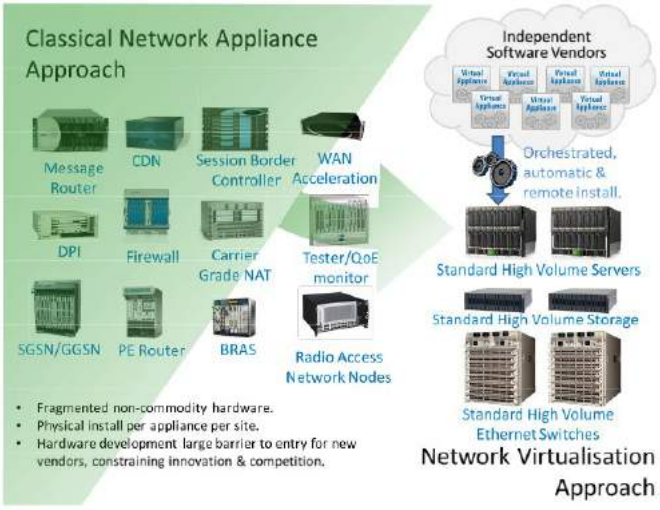

**Figure 3 - Network Function Virtualization examples**

### 2.5. Management and Orchestration

Network function virtualization (NFV) changes how networks are managed. Hundreds of network functions running on a server farm can easily make operations very complex. For that reason the European Telecommunications Standards Institute (ETSI) started in 2013, an effort to define the framework shown in Figure 4 for NFV management from the initial set-up, to day-to-day operations, which is called NFV MANO (Management and Network Orchestration). This is the framework for the management and orchestration of all resources in a data center for virtualized functions, those resources include: compute, networking, storage, and virtual

machines (VM) as seen in Figure 5. The main goal of MANO is to allow flexible on-boarding. (European Telecommunications Standards Institute, 2012)

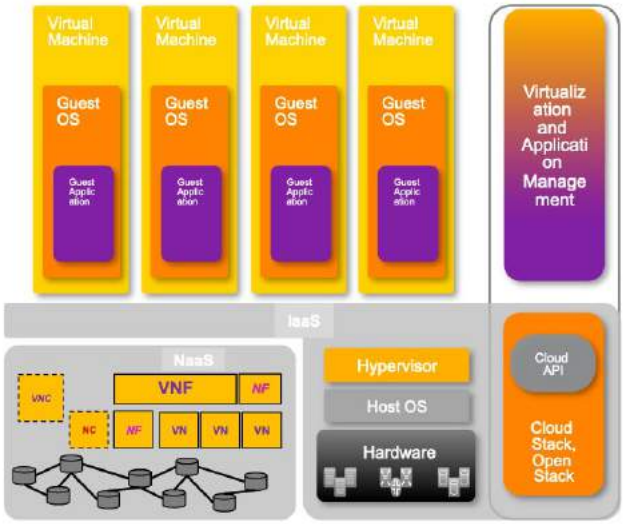

**Figure 4 - NFV Paradigm**

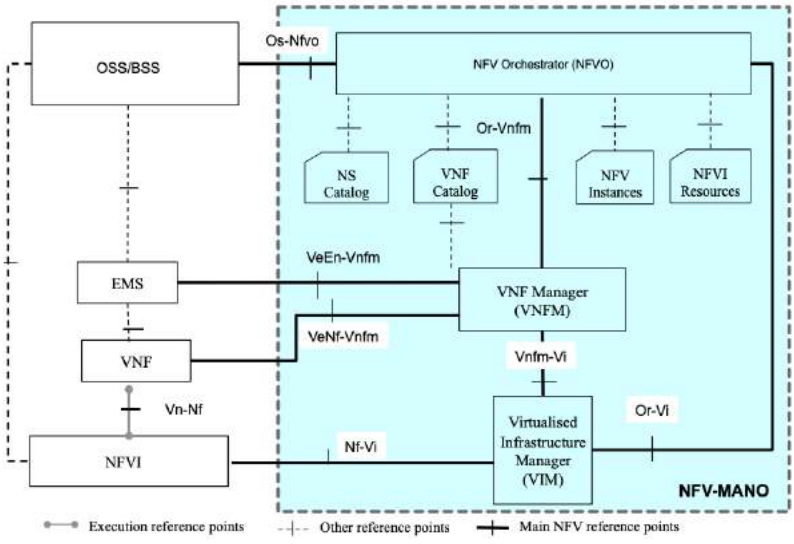

**Figure 5 - NFV MANO Framework**

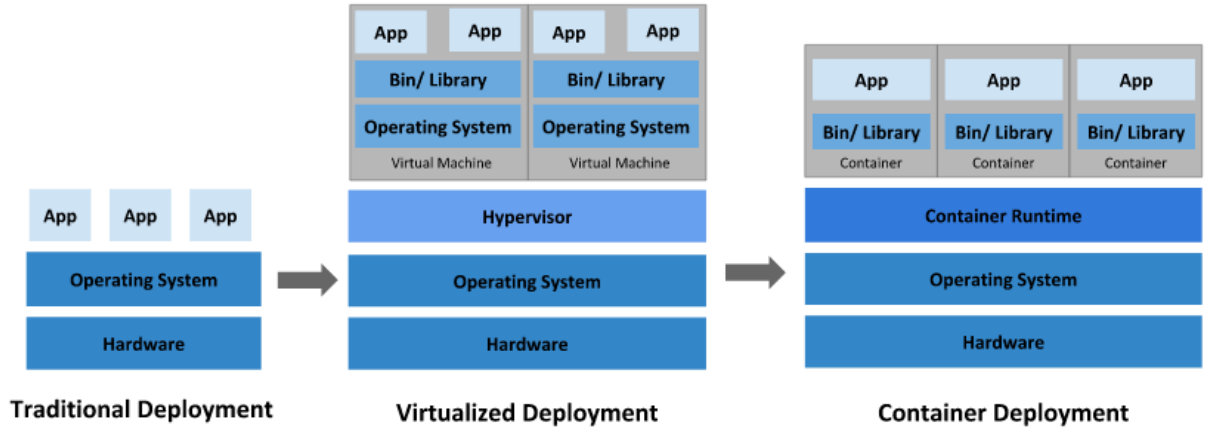
## 3. Containers

As VMs were deployed, organizations started to run applications on separate virtual machines in order to dedicate their own resources (CPU, memory, storage). However, each application had to have a separate operating system running in each virtual machine.

At scale virtual machines may take up a lot of system resources, and a base operating system installation may take several gigabytes of storage. For example, running a single webserver on a virtual machine may require several gigabytes of operating system and libraries, while the application itself only takes a few megabytes of storage and memory. Multiply that by a big number of webservers and other applications, and the overhead of virtualization becomes very noticeable.

At the same time, with the wide adoption of Linux as an operating system, and a big share of network applications using it as its underlying platform, an interesting idea was born: Why can't applications share the same operating system and be virtualized at the operating system level instead of at the hardware level?

A container is an isolated environment from the operating system host that runs an application by virtualizing it. This allows it to create multiple application workloads on a single OS instance. The kernel of the host operating system provides the required components for running the different functions of an application, separated into containers as shown in Figure 6. Containers run isolated tasks from each other, and an application cannot harm the host machine nor come in conflict with other apps running in other containers. (Simic, 2019)



Retrieved from: https://kubernetes.io/docs/concepts/overview/what-is-kubernetes/

**Figure 6 - Containers Architecture**

Docker is the most common container engine now in the market, however there are several other options for container engines shown in Table 2.

**Table 2 - Container Engines**

| Windows Server Containers |

## 3.1 – Containers and Microservices

Applications are easy to develop using a monolithic approach, but as the size of the application and its user base grows it becomes very complex to scale up. Monolithic applications can have up to hundreds of different services tightly coupled, which makes it very complex for different development teams to handle their coordination. This is the reason why most of the software industry is moving to a new paradigm, known as microservice architecture (Yu, Silveira, & Sundaram, 2016).

In a microservice approach, an application consists of several services, each independent of the other. Each service does a specific function which is developed and deployed independently from the others. Services transfer data or information to other services using a standardized communication protocol as seen in Figure 7.

Some of the benefits of microservices are easier automated testing, flexible deployment models and increased overall resiliency; however all this comes at the expense of careful planning of the architecture and increased R&D investment, mainly given to the following factors:

1) Since everything is an independent service, careful handling of requests traveling between the modules is required. This generates the need of designing in advance the APIs that the microservices will use to communicate between them its maintenance across version changes.
2) Testing a microservices based application can be complex. In a monolithic approach, the application just needs to be launched and validate its connectivity with the underlying services such as database or webserver. With microservices, each service needs to be confirmed to be working properly in advance before integration testing of all the microservices as an application can occur.

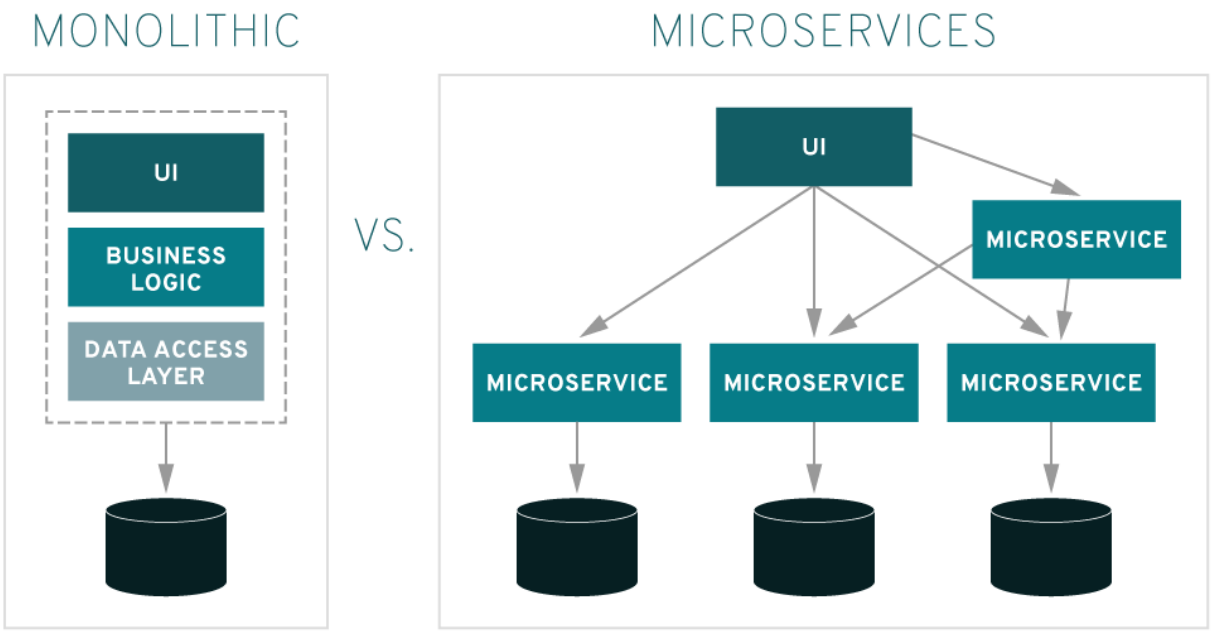

**Figure 7 - Monolitic vs Microservices Architectures**

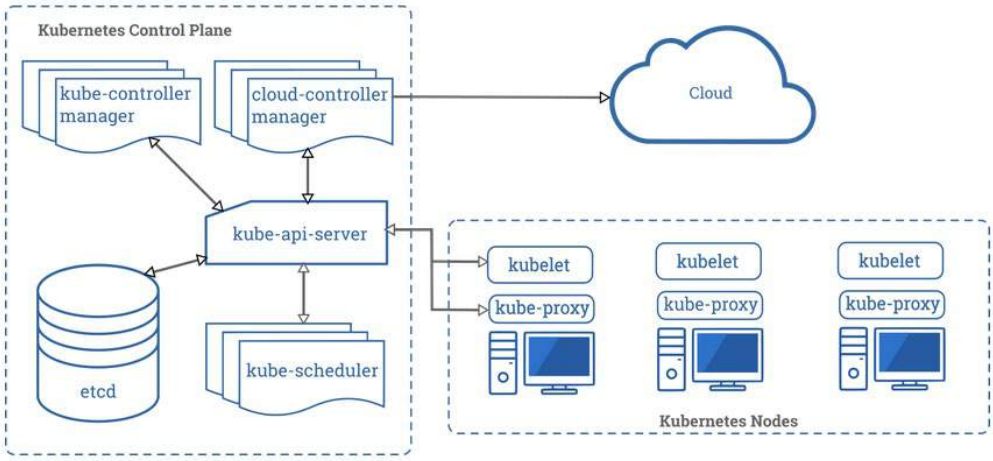
As has been shown before, a container is just a way of deploying and running a program or process isolated from others sharing a common operating system. One could have one big monolithic application running as a container and in the other side there could be a big number of microservices running on a bare operating system. However, in the real world these independent approaches have been very complementary, as containers are the portable code envelope and big applications could be decomposed into many microservices that can be independently deployed.
DevOps processes are the pillar of modern applications, and support running multiple parts of applications independently in different microservices, with much greater control over their life cycles.

## 3.2 – Containers Orchestration

Container orchestration is the process of automating the deployment, management and scaling of containers. As mentioned before, service providers will need to deploy hundreds or thousands of containers and for that reason an automation process for container orchestration is required. Container orchestration can help to deploy the same application across multiple environments and microservices in those containers and make it easier to orchestrate different types of services such as storage, networking, and security. (Redhat, n.d.)

There are several orchestration tools for managing containers at scale together with its lifecycle management. The most popular is called Kubernetes, however Docker Swarm, and Apache Mesos are also well-known orchestration tools.

Kubernetes is an open source orchestration tool that was developed by Google. Kubernetes orchestration allows the deployment of applications that are supported by multiple containers, running those containers in clusters of servers and verifying their health and scale-in or scale-out as required by capacity demands. In general, Kubernetes eliminates most of the manual processes associated with deploying complex containerized applications. The Kubernetes architecture is presented in Figure 8.



Retrieved from: https://kubernetes.io/docs/concepts/overview/what-is-kubernetes/

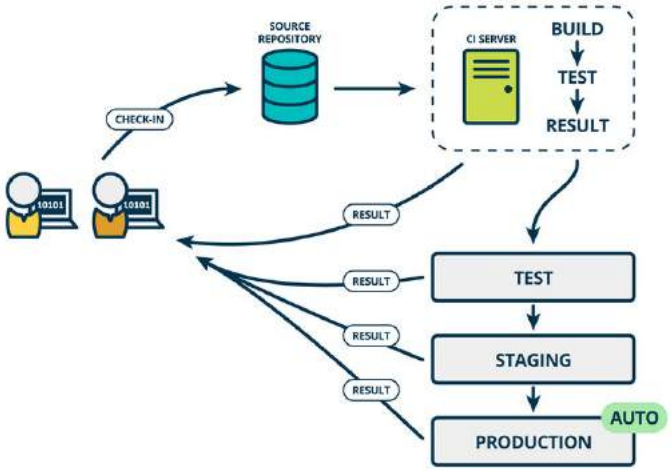
**Figure 8 - Kubernetes Architecture**

## 3.3 – Continuous Integration/Continuous Deployment

Continuous software engineering is an area which refers to the development, deployment and feedback from software and customers in a very rapid cycle (Fitzgerald & Stol, 2017). The continuous software engineering process can be split into two main areas

Continuous Integration (CI) is a widely established development practice in the software industry where teams integrate and merge development code very frequently, for example multiple times per day. CI allows software developers to have shorter release cycles and improve software quality (Fitzgerald & Stol, 2017). Many of the processes involved in CI are automated.

Continuous Deployment (CD) is a practice that goes a step further and automatically and continuously deploys the application to a production environment as seen in Figure 9. That environment can be within the same company or with an external customer. In the latter case, Continuous Delivery (CDE) may apply, where the application is only delivered but not automatically turned into production and requires some manual intervention before being deployed.



Retrieved from: https://www.mindtheproduct.com/what-the-hell-are-ci-cd-and-devops-a-cheatsheet-for-the-rest-of-us/

**Figure 9 - CI/CD Process**

Two common software tools for this process are GIT as the source code repository, and Jenkins as the CI Server. Jenkins builds the application from the code repository, automatically tests, and delivers the containers to a container repository.

# 4. The Clouds

## 4.1. Private Cloud

According to the National Institute of Standards and Technology (NIST), a private cloud is defined as infrastructure which is provisioned for exclusive use by a single organization comprising multiple consumers (e.g., business units). It may be owned, managed, and operated by the organization, a third party, or some combination of them, and it may exist on or off premises (National Institute of Standards and Technology , 2011).

The main advantage of a private cloud is that resources are not shared. A private cloud is best for businesses with dynamic needs that require direct control over their computing resources, in general to meet security or regulatory requirements.

Private clouds also have a few disadvantages as increased automation and user self-service can bring added complexity. These technologies require teams to rearchitect data centers and use extra management tools and can result in increased staff and capital expenditures to acquire the infrastructure to support it.

When a private cloud is properly architected and implemented, the organization can benefit from self-service and scalability, and the ability to launch or optimize computing resources on demand. In Table 3 there is a list of the main private cloud platforms in the market. It is important to mention that Openstack-based platforms are provided by several mainstream vendors.

**Table 3 - Private Cloud Platforms**

| |
|---|
| Openstack |

| VMware vCloud |
|---|

## 4.2. Public Cloud

According to the National Institute of Standards and Technology (NIST), a public cloud is the cloud infrastructure that is provisioned for open use by the general public. It may be owned, managed, and operated by a business, academic, or government organization, or some combination of them. (National Institute of Standards and Technology , 2011)
From a service provider standpoint, a public cloud is a platform in which a third-party service provider makes available computing resources which can be software applications, virtual machines (VMs) and complete enterprise-grade infrastructures over the public Internet. This public cloud service provider owns the data centers where customers' services run. Service providers take care of all the infrastructure maintenance and provide connectivity access to applications and data. (IBM, 2020)
There are four main models of cloud services as shown in Table 4 together with examples of cloud providers for each. Each cloud service model has a different management complexity compared to the other, as shown in Figure 10.

**Table 4 - Cloud Service Models**

| | |
|---|---|
| Software as a Service (SaaS) | Google Apps, Dropbox, Salesforce, Cisco, Concur, GoToMeeting, Slack |
| Platform as a Service (PaaS) | Google App Engine, Force.com, Redhat Openshift |
| Infrastructure as a Service (IaaS) | Amazon Web Services (AWS), Microsoft Azure, Google Compute Engine, Rackspace |
| Metal as a Service (MaaS) | Amazon Web Services Bare Metal, Microsoft Azure Bare Metal Servers, Google Bare Metal |

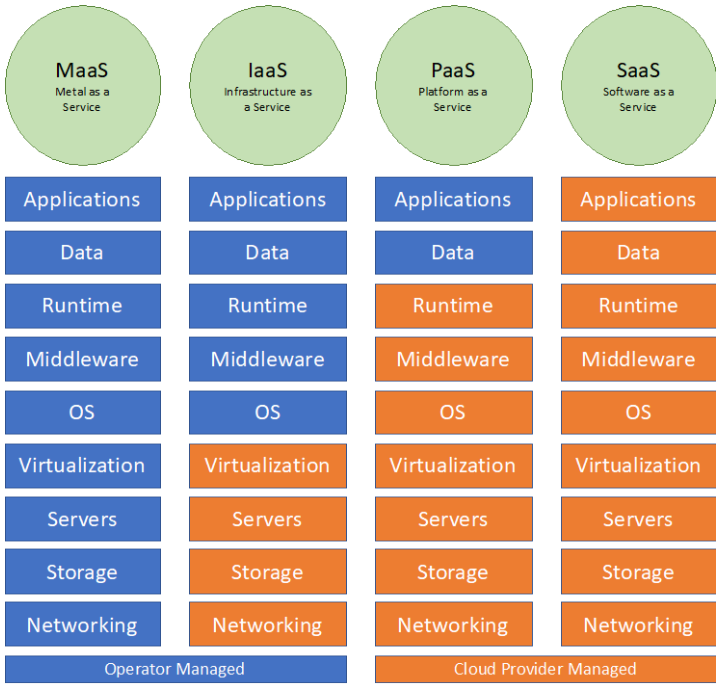


**Figure 10 - Cloud Services Models**

### 4.3. Hybrid Cloud

According to the National Institute of Standards and Technology (NIST), a hybrid cloud infrastructure is a composition of two or more distinct cloud infrastructures (private, community, or public) that remain unique entities, but are bound together by standardized or proprietary technology that enables data and application portability (e.g., cloud bursting for load balancing between clouds) (National Institute of Standards and Technology , 2011).

### 4.4. Platform as a Services (PaaS)

There are several common core microservices which could be shared in either a private or public cloud, without having to replicate them in each application. It may be desirable that service providers have them as a shared PaaS services. Some of them are listed below.

- **Message Queue**. Responsible for delivering messages from one service instance to another. The message queue will support different messaging patterns including request/response, broadcast, pub/sub model.
- **Session Database**. Responsible for storing session state in a common place, which enables stateless processing.
- **Service Discovery**. Responsible for service registration, service heath monitoring and service state notification. Note some platforms like Kubernetes provide built-in service discovery.
- **Configuration store**. Responsible for maintaining persistent configuration for the containers. The service configuration will be modeled as a tree structure. Each micro service will have its own subtree

- **Logging**. Responsible to collect logs from all micro-service instances. This service provides a single access point to view the logs.
- **Analytic and Visualization**. Responsible for providing in-depth knowledge of the platform status and presents the result in an easy-to-understand graphical form.
- **Management API**. Responsible for providing RESTAPI/CLI to configure the platform and provide service statistics or session information.

An example implementation of such architecture is shown in Figure 11 with a list of some of the most common software packages for them listed in Table 5.

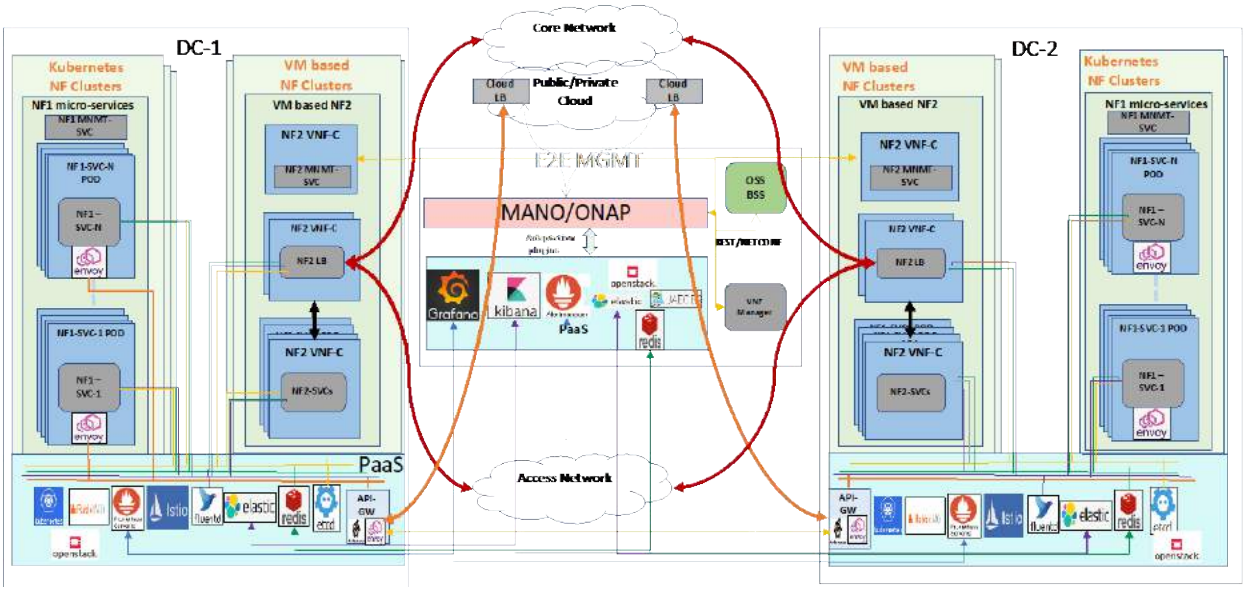

**Figure 11 - Cloud Native Hybrid Architecture**

| Calico/Multus | Container Networking |

# 5. Virtualizing the CCAP

## 5.1. Control and User Plane Separation (CUPS)

Cable Operators have historically used CMTS as Edge equipment which has several functions like per-subscriber session, policy enforcement and data forwarding in the same box. With the advent of Control Plane User Plane Separation (CUPS), CMTS functions could be decomposed and disaggregated such that the User Plane Function (UPF) could be deployed in a distributed manner, and the Control Plane Function (CPF) could be deployed in a centralized manner depending on the level of scale and aggregation needed. (Asati & Bernstein, 2019)
The deployment of new services, such as 4K video, IoT, etc., and increasing numbers of home broadband service users present some new challenges for broadband routers such as:

- Low resource utilization: The traditional CCAP acts as both a gateway for user access authentication and an IP network's Layer 3 edge. The nature of the tightly coupled control plane and forwarding plane makes it difficult to achieve the optimum performance of either of the planes.
- Complex management and maintenance: Due to the large numbers of traditional CCAP instances a network must have, each device must be configured one at a time when deploying global service policies. As the network expands and new services are introduced, this deployment mode will cease to be feasible as it is unable to manage services effectively and rectify faults rapidly. (Hu, et al., 2018)

To address these challenges, a cloud based BNG with CU separation conception is defined in (Broadband Forum, 2018) however the same idea is applicable to a CCAP box. The main idea of Control-Plane and User-Plane separation is to extract and centralize the user management functions of multiple CCAP devices, forming a unified and centralized control plane (CP). The traditional router's Control Plane and Forwarding Plane are both preserved on CCAP devices in the form of a user plane (UP). Note that the CU separation concept has also be introduced in the 3GPP 5G architecture. (3GPP, 2018)

## 5.2. Virtual CCAP Core and Remote PHY

As mentioned in the previous section, the paradigm of separating control and user planes brings significant benefits to the table. Traditional integrated CCAP boxes running on dedicated hardware were not able to benefit from the approach where control plane, user plane and physical modulation were part of the same hardware box. However, with the adoption of Distributed Access Architectures the paradigm has shifted so that the modulation function has moved to the RPD and now the CCAP core may be an IP-in/IP-out only box. This shift brought the possibility of moving CCAP software functions from dedicated hardware onto commercial off-the-shelves (COTS) servers and generated the term virtual CCAP as seen in Figure 12

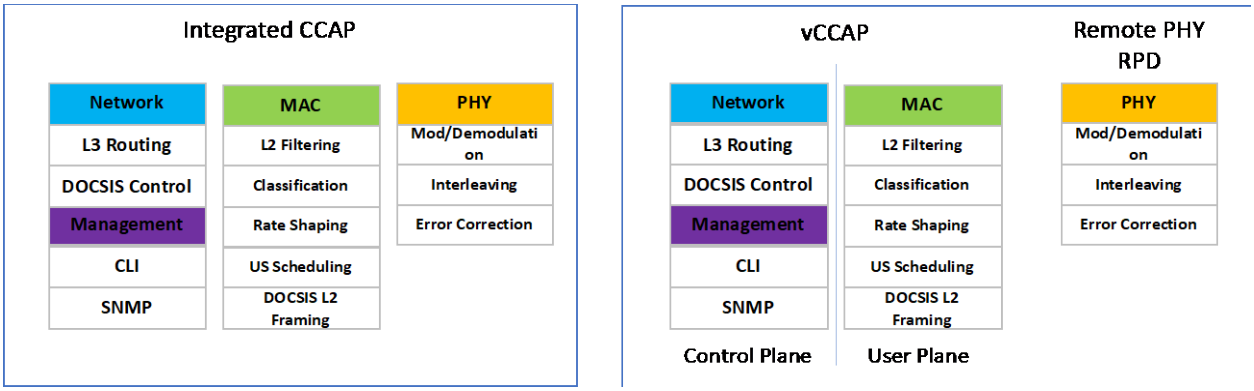

**Figure 12 - Integrated CCAP vs virtual CCAP Functions**

Two conclusions can also be drawn from Figure 12:

a) The CCAP's different software components can be grouped to exploit the benefits of microservices which were analyzed in section 2
b) At the same time, it also makes sense to separate the control and user plane functions, as there is an advantage of potentially being able to put them in separate locations.

The above points support using containers for the vCCAP user plane and control plane functions. Now one could think that a user plane container can be the equivalent of integrated CCAP MAC card which typically serves 6 to 8 HFC serving groups, but in reality, that constraint does not exist anymore. A user plane container can serve a single serving group as seen in Figure 13; and at the same time scale to manage multiple user plane functions.

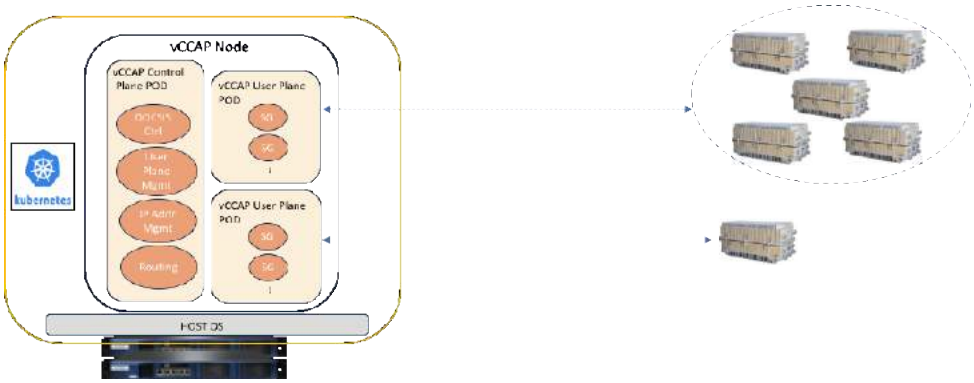

**Figure 13 - vCCAP Node to Container Mapping**

No matter how many serving groups per container one decides to use, it is evident that the quantity of containers will be significant, so as analyzed in section 2, a container orchestration engine would be also mandatory in order to manage the growing number of containers. However the benefits of container orchestration are not only related to the onboarding of the containers but also how they can handle dynamic scale-in and scale-out of containers based on server utilization or network traffic, or even on redundancy management in the case of software or hardware failures.

As an example, architecture, a container farm is shown in Figure 14 using Kubernetes as the container orchestrator. Kubernetes relies on control-plane and worker nodes; the control-planes take care of the onboarding, deployment and monitoring of the groups containers or PODs which are dynamically deployed in the worker nodes on multiple datacenters on the operator's network.

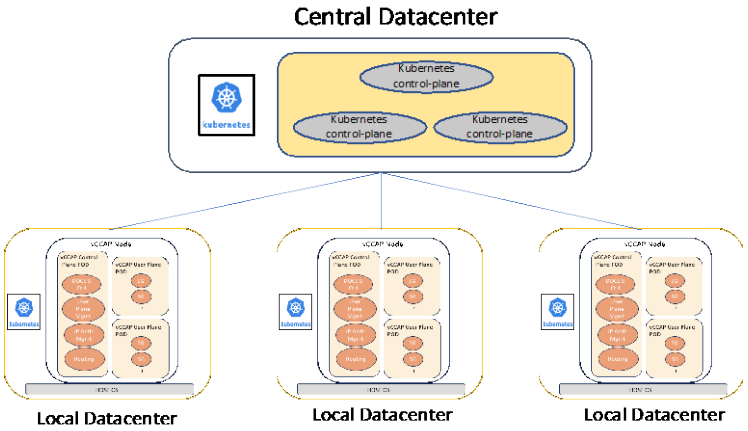

**Figure 14 - vCCAP Kubernetes Managed Architecture**

As mentioned before, Kubernetes can monitor health status of the running pods. In the example in Figure 15, if it detects a failure on the hardware or software of a user plane pod, it can switch its operation to a redundant POD.

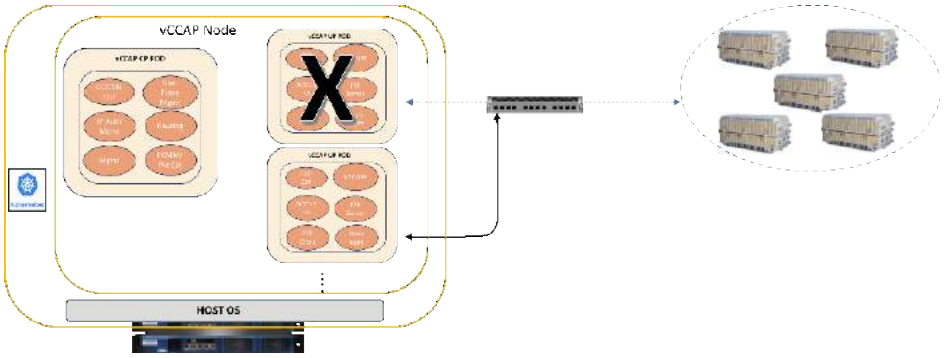

**Figure 15 - vCCAP Container Based Redundancy**

Perhaps one of the most important advantages of deploying virtualized CCAP is the flexibility to support different types of architectures, going from a totally distributed model where the computing power can be in the hubsites (which can be repurposed as data centers) to a totally centralized model where the computing power is a main datacenter, to any combination in-between. Figure 16.

Each model has its advantages and disadvantages depending on space availability, bandwidth consumption and server usage efficiency, however having the ability to mix them and use the most efficient model for each case is one of the key highlights of vCCAP. This is known as a Hybrid model.

| Centralized vCCAP | Distributed vCCAP |
|---|---|
|  |  |

**Figure 16 - vCCAP Deployments Models**

### 5.3. Multi-access Edge Computing (MEC)

Multi-access edge computing (MEC) is a cloud environment located at the edge of the network, in close proximity to end users and coupled with the service provider's network infrastructure. Even before 5G is rolled out, current fixed and mobile networks can already enable support for these challenging use cases by using MEC technology. MEC is able to offer low latency and high bandwidth, and, in addition allows services to be deployed in different industrial premises such as road infrastructure, airports, and factories, bringing computing power where it is needed

most. MEC is a key enabler for low latency IoT technology and having this computing power on a node in the network can provide a big number of extra benefits apart of the network function virtualization (Porambage, Okwuibe, Liyanage, Taleb, & Ylianttila, 2018). ETSI Industry Specification Group MEC were the pioneers in creating a standardized computing platform for mobile networks applying network edge related use cases. (Giust, et al., 2018)

### 5.4. Virtual MAC Manager and Remote MAC/PHY

The Remote MAC-PHY technology moves both the DOCSIS MAC and PHY layers down to the Remote/Fiber Node. The link between the Headend and the node is essentially a Layer 2 connection using Ethernet (Cable Television Laboratories, Inc, 2015). This new device is called the Remote MAC Device (RMD), where this device can be integrated with a Remote PHY Device (RPD) as in Figure 17 or both functions can be in different devices as in Figure 18.

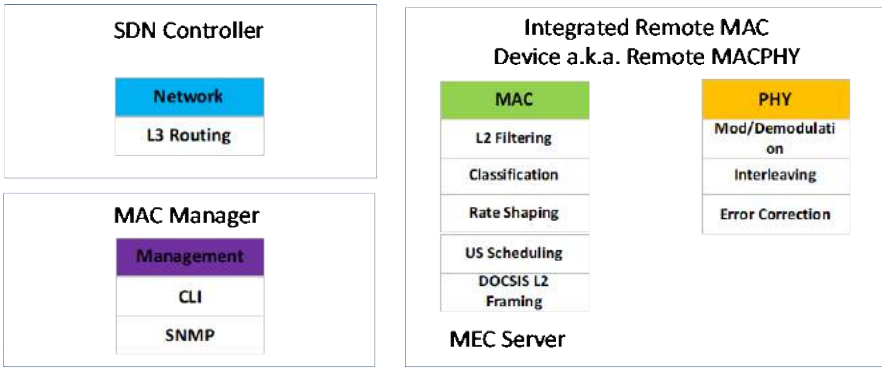

**Figure 17 - Integrated Remote MAC-PHY Device**

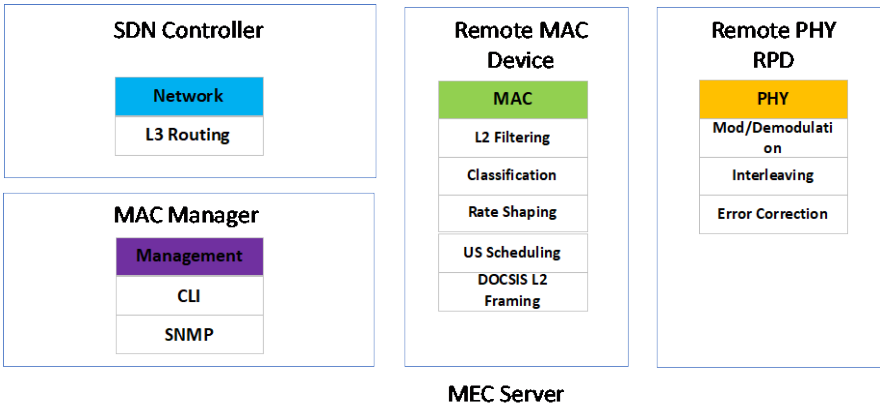

**Figure 18 - Decoupled Remote MAC - Remote PHY Devices**

It is particularly relevant to highlight that as mentioned in section 5.2, the MAC function is the user plane of a virtual CCAP, which could be run as a container in a cloud native platform. So, in this architecture the Remote MAC Device doesn't need to be more than a Multi-access Edge

Computing server running on a hardened node enclosure, which is automatically managed by container orchestration engine such a Kubernetes.
At this stage the only remnant of the CMTS is the MAC manager which is a centralized software function which provides management access such as command line interface and monitoring data of the CCAP network function running on the remote devices.

## 6. Future and Convergent Core Functions

Cable Operators can use this technology shift to embrace Fixed Mobile Convergence (FMC) by putting edge network functions at the hub sites which will become virtualization datacenters. As mentioned before, CUPS could enable a common user plane function for cable access, FTTH access and mobile access distributed, while the control plane could be located in centralized datacenters. This is aligned with the decomposed vCCAP and RPHY trend that the industry is following (Asati & Bernstein, 2019). Virtual BNGs and 5G Virtual EPCs can run in the shared cloud environment providing a high level of optimization and integration.

In Figure 19, a potential evolution path for core access networks is presented, where the virtualization of the core and densification of the access will be the first step towards a real Fixed and mobile converged network.

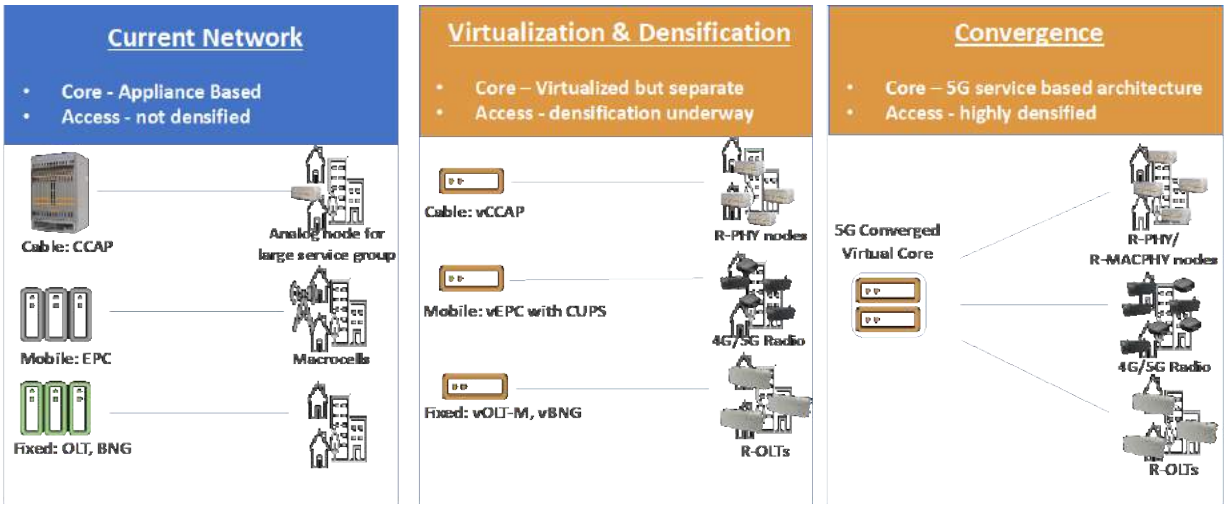

**Figure 19 - Fixed Mobile Convergence Evolution**

## 7. Conclusion

This paper described the state of current virtualization and containerization technologies, discussing benefits and disadvantages applied to cloud technologies. A review of virtual and private cloud was done with a focus on the implementation of virtual network functions and how a continuous integration and deployment approach will help in making networks more agile and flexible.
Next, an architecture proposal was presented for deploying a virtual CCAP network function leveraging the benefits of cloud native platforms together with the benefits of control and user

plane separation. A brief discussion of Multi Access edge computing aligned with the transition path to Flexible MAC Architectures and remote MAC-PHY was shown.

Lastly, a vision for future Fixed Mobile Convergence is presented with the evolution through virtualization of the network functions and densification of the access network.

As a final conclusion: HFC networks need to evolve into adopting the benefits provided by virtualization, containerization and cloud technologies. As reviewed during the paper, those technologies provide not only big improvements in efficient usage of the infrastructure but more importantly bring the ability to deploy new services in a quick and agile manner, something that will be a key factor for cable operators to continue its success in the new world of Fixed Mobile Converged networks.

# 1. Introduction

As bandwidth capacity continues to grow for existing hybrid fibre coax (HFC), so does the flexibility to utilize new technologies within HFC networks. Establishing practices which support new technology platforms, while fully employing the large investment in the HFC plant is important. As the coaxial cable is capable for shorter distances of carrying high bit rate traffic, MSOs generally implement a fiber deeper approach, where node splits allow fiber penetration further into the network, and closer to the customer. Often, an N+0 approach is considered, which has no active devices on the "last mile" coax between the optical node and the customer premises. However, cost considerations often require compromises, and in many cases, an N+1 (one amplifier between node and customer) or even N+2 approach is implemented — still a vast improvement over the historical N+4 or higher architectures.

HFC networks traditionally terminate node traffic on cable modem termination systems (CMTSs). Integration of CMTSs with other transport functions in the head-end and hub has driven implementation of the converged cable access platform (CCAP). CCAP combines the functions of the CMTS and the edge quadrature amplitude modulators (QAMs), allowing digital data processing prior to analog conversion for transport on the access network. Although CCAP itself drove more power and space efficient HFC edge network solutions, in a fiber deep architecture, the number of nodes will increase significantly, and with it, the requirement for additional CCAP hardware in the hub. This, in turn requires additional space, power and cooling in the facility.

In the distributed access architecture (DAA), the constraints on the headend are ameliorated since the physical and media access control (PHY and MAC) can be placed further in the access network (e.g. directly with the optical node). There are multiple implementation possibilities for DAA. Currently, the most popular and only fully CableLabs specified approach is Remote PHY, where the CCAP PHY layer is moved to the node, while the MAC layer continues to reside in the hub. The facility improvements in terms of space, power and cooling are moderate, as the CMTSs are not being eliminated.

Other possible implementations of DAA are Remote MAC/PHY and Remote CCAP. Here, both physical and MAC layers are moved to the node. Many functions can be virtualized and this in turn can lead to a drastic reduction of facility space, power and cooling requirements.

In 2019, as an integral part of evolving the network to 10G, Shaw began the process of introducing DAA into its network. As with other MSOs, the key driver of this effort was to move CCAP PHY processing from the hub to the node, replacing RF optics with metro ethernet (metroE) optics. The chosen strategy evolved DAA into the network in a controlled manner, implementing DAA in greenfield nodes and node splits, but not proactively in existing brownfield. As this was a different approach to DAA implementation, the company wished to better understand how a migration to DAA in this manner would affect energy usage across their footprint.

In conjunction with Shaw, Saras Energy Consulting worked to assess the energy use impact of the company’s approach to DAA across its footprint. The workplan focused on the following investigative objectives:

- Establish a hypothesis about the impact of DAA on facility and outside plant (OSP) energy environments, based on the DAA design and implementation plan as per Shaw standard.

- Collect and analyze any relevant DAA architecture, equipment, and deployment data to model energy usage over time across the Shaw footprint.
- Use the model to prove and/or adjust the hypothesis and answer critical energy usage related questions.
- Utilizing the analysis, work with Shaw to draw conclusions with respect to the energy usage profile related to the Shaw DAA deployment plan.
- Analyze OSP powering capacity and architecture, specifically related to the ability of the power architecture to accommodate DAA evolution, as well as additional IoT, small-cell and other non-HFC connectivity alternatives.

To evaluate DAA impact on the network, the team first developed a model detailing energy usage for the business as usual (BAU) network architecture. It should be noted that the term BAU is used in this paper to refer specifically to Shaw's traditional plant build as currently defined. The team then developed a DAA model, based on Shaw's specific DAA implementation process, to compare against BAU. Conclusions were then drawn from the modeling work.

## 2. Business as Usual Network

The business as usual network has been built and developed over time in a manner consistent with MSO practice. The diagram below provides a view of the BAU network

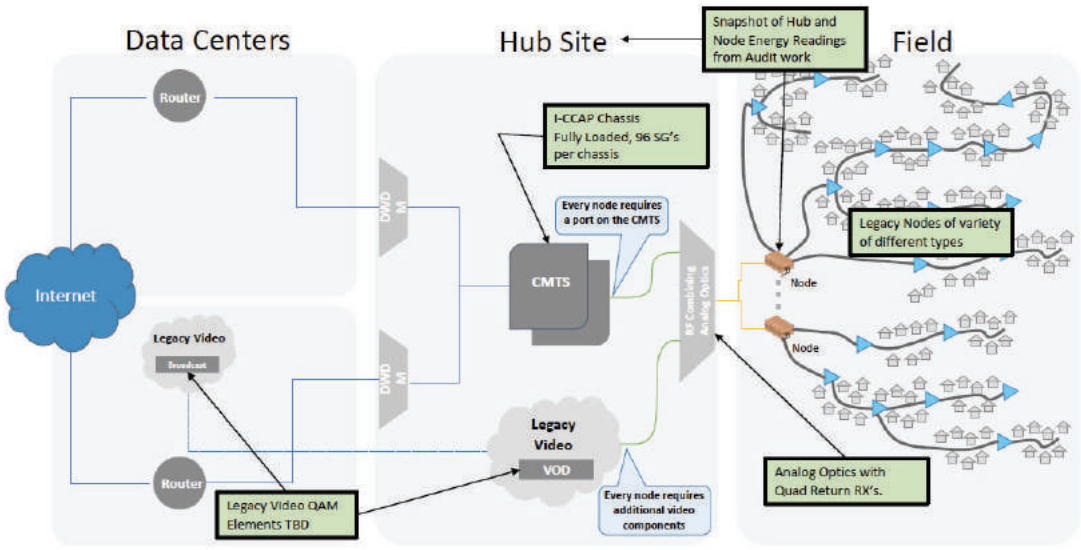

**Figure - 1 Business as Usual Network Deployment**

Shaw implements a tiered facility structure, with the top tier data center/core facilities located in key regions served and connected by a national mesh ring network. From the regional core sites, rings are used to connect to hub edge facilities in the region. Hub/edge facilities support a load of approximately 50,000 homes passed (HP) with capacity to go to 80,000 HP. The HFC distribution network stars out from the hub/edge facility. In the facility, the company connects nodes to an

integrated CCAP (I-CCAP) device, with standard RF optical devices and connectivity infrastructure in place to support the forward and return bandwidth to/from the nodes.

With respect to Shaw's HFC infrastructure, it is N + X, with current attention to reduce or maintain node size and cascade lengths. Congestion relief in the downstream is achieved by node-splitting, where the node is physically divided to create two nodes, adding an additional optical path to the head-end, effectively doubling the dedicated downstream capacity to the same area. Upstream congestion relief is via a combination of node splits and conversion to a higher return path bandwidth of 85 MHz, techniques which increase dedicated upstream capacity for the area being served.

The company is committed to evolving fiber deep over time, with the ultimate goal of moving towards DOCSIS 4.0 in preparation for a 10G future. Evolution to N + 2 architecture is the first step to that future [1]. In support of this, greenfield plant and any brownfield upgrades are built to N + 2.

## 3. Approach to DAA

As noted in the introduction, an important part of Shaw's evolution to 10G is implementation of DAA in its network. DAA itself is a cable industry initiative, spearheaded by CableLabs, and forms a key part of the cable industry's drive to 10G in the future. Network benefits related to DAA implementation include:

**Network Efficiency**

- Increased network capacity
- Better end-of-line signal quality, higher modulation rates, higher bitrates
- Better spectral efficiency, more wavelengths per fiber

**Operational Efficiency**

- Reduced headend power, space and cooling requirements
- Hub consolidation
- Simplified Hub Architecture by leveraging digital optics (eliminates RF combining)

**Enabling Convergence**

- Extends IP network into the field
- Ability to leverage common IP Network for multi-tenant applications
- Alignment with FTTx build-out
- Required steppingstone to Virtual CCAP (vCCAP), 10G and the Edge Cloud

A high-level view of the Shaw approach to DAA implementation is shown in Figure 2 below.

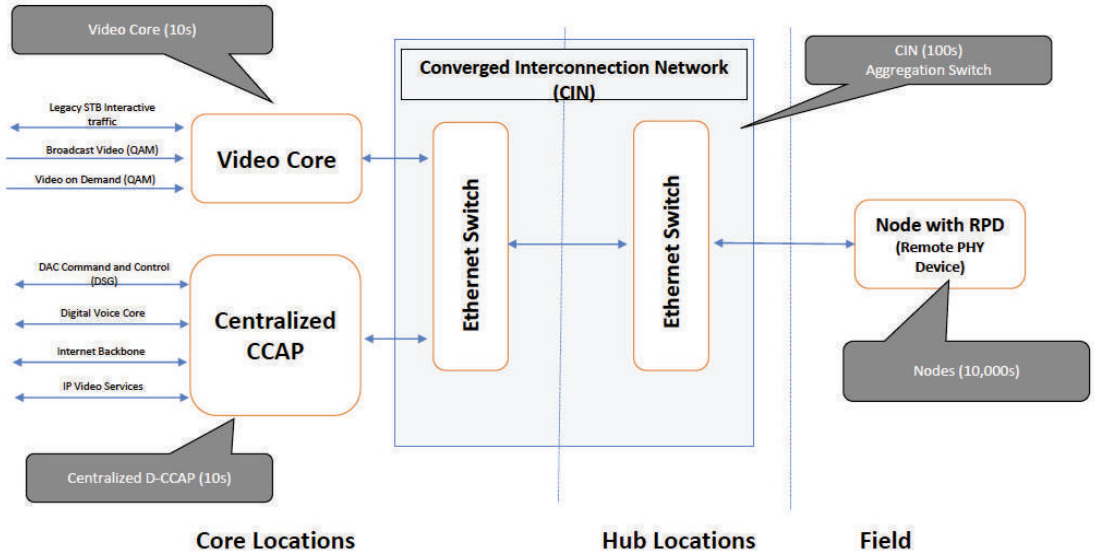

**Figure 2 Shaw DAA Implementation**

Key elements of the DAA infrastructure as defined by CableLabs in [4] and to be deployed by Shaw include:

- **Remote Phy Node (RPD):** The RPD is a device located in the node in the network which implements the Remote-PHY specification to provide conversion from digital Ethernet transport to analog RF transport.
- **Converged Interconnection Network (CIN):** The network (generally gigabit Ethernet) that connects a CCAP Core to an RPD.
- **CCAP Core:** A CCAP device that uses MHAv2 protocols to interconnect to an RPD. This device could be a DOCSIS Core, Video Core, OOB Core, RPD Controller (or a combination of these roles). Distributed CCAP (D-CCAP) is the implementation of CCAP Core the Shaw network uses and is used to represent the CCAP core function in this paper.

## 4. DAA Transition

Although Shaw's overall approach to DAA is consistent with that of CableLabs and the industry, a full DAA implementation will be controlled and measured. DAA will be implemented to meet node growth related to greenfield build and node-splits, as well as very selectively in existing brownfield upgrades. To support this evolutionary approach, initially a D-CCAP core and its associated CIN devices are to be placed in Shaw regional core sites. The infrastructure will be used to support the initial DAA node requirement for any hubs served from that core. D-CCAP and CIN network will grow with DAA node need, with D-CCAP chassis' and CIN leaf switches ultimately evolving outward to the hub sites as and when demand in DAA nodes dictates.

With respect to the nodes, Shaw's transition strategy will not entail pro-actively changing existing brownfield nodes to DAA with limited exceptions. Instead, DAA transition will cap legacy node

placement as much as practicable, and use DAA nodes for new greenfield builds, as well as node growth related to node splits. Key attributes of this approach include:

- Focuses on building greenfield plant primarily with DAA nodes.
- In brownfield, implements node splits to relieve congestion primarily in the following manner:
    - Existing node split and new node created with node split will be DAA nodes in the field.
    - Both nodes from the node split will be placed in D-CCAP chassis on 10 Gbps connection via CIN.
    - Existing coax network beyond the nodes stays consistent with traditional HFC node split practices. This is not a change to existing coaxial distribution plant other than to use DAA nodes vs. traditional nodes in the field.

Once a node split has been completed and the new nodes connected to the DAA infrastructure, transition reaches completion with removal of any elements of the BAU I-CCAP infrastructure that has been taken out of service. But as this is an evolutionary process, this happens only after all in-service elements on the legacy devices are completely transitioned to D-CCAP and CIN network:

- I-CCAP chassis removal does not occur until all nodes are removed from the chassis. As the geography of where node splits occur is relatively random and based on many factors, this may be a few years away, given the spread of I-CCAP devices in the network and average number of ports in use on those devices.
- RF transmitters and receivers will be removed and powered down as and when all nodes connected to the chassis have been moved to the CIN. This may happen more quickly, potentially in the first few years after node split, as the number of nodes per chassis is smaller.

At this point, it is not Shaw's intent to actively work to re-arrange BAU node connections to vacate I-CCAP chassis' and/or RF optic modules as utilization on them lessens, but to let natural attrition determine when devices are vacated and can be removed.

Figure -3 below shows detail of Shaw DAA strategy.

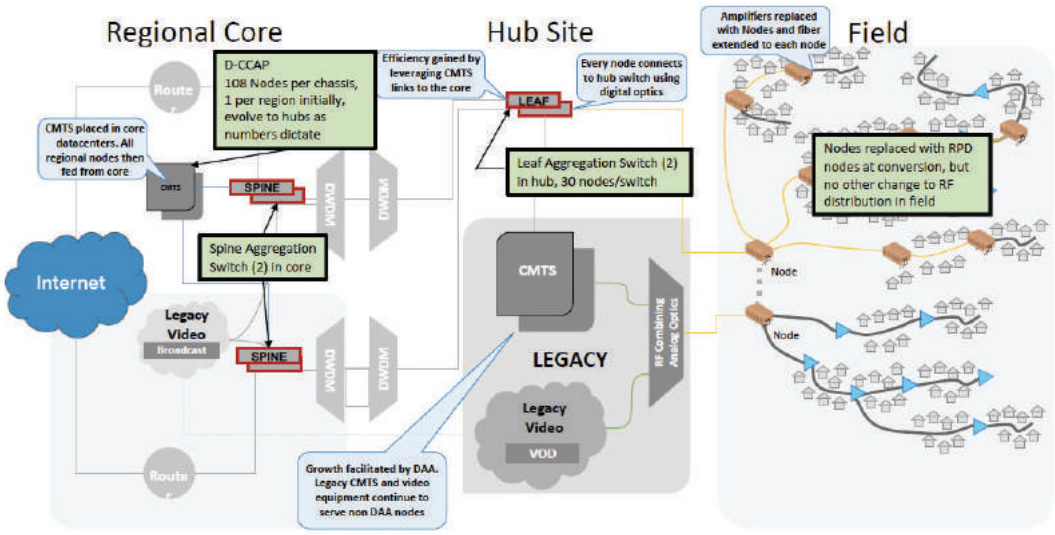

**Figure -3 Shaw DAA Implementation**

To summarize, with this approach, legacy I-CCAP infrastructure is largely capped in the footprint. The DAA infrastructure operates in parallel to the legacy I-CCAP and RF infrastructure, taking on all growth in nodes due to either greenfield build and/or node splitting. Legacy BAU I-CCAP equipment and supporting RF infrastructure is vacated over time by attrition, with equipment removed as and when service is no longer provided on it.

## 5. Modeling Energy Usage

As with other operators, Shaw's BAU networks grows energy usage year-over-year, due partly to continued growth in greenfield network homes passed, as well as increases in bits transported due to subscriber consumption related to internet use, streaming, etc. Greenfield growth drives additional nodes and actives in the field, along with the associated CMTS and RF optical components to support them. Increasing usage by subscribers creates node splits, along with the CMTS, RF optics, and new nodes required to support them. As subscribers' appetite for data consumption does not appear to be slowing, space as well as energy constraints in existing edge facilities are moving operators towards solutions which solve and/or mitigate these challenges. Evolution to DAA is driven by the needs of the cable operators like Shaw to solve the future space and energy usage problems growth of the BAU network creates if it continues at current pace.

Although in the past, work had been done on energy usage comparing BAU vs. the ***full*** implementation of DAA in a facility footprint [5], energy usage comparing BAU to a more evolutionary approach to DAA such as the one used by Shaw has not been modelled and/or analyzed. The following two sections of this paper detail this modeling, as well as results from the modeling work.

### 5.1. Initial Energy Usage Hypothesis

After initial review of Shaw's BAU scenario and DAA implementation plan detailed above, it was hypothesized that during the transition period from BAU to DAA, initially total energy usage would increase in comparison to BAU, before ultimately decreasing over time. This was due to three key reasons:

- Initially DAA D-CCAP, switch, and router equipment is added in core and hub sites to facilitate DAA, duplicating BAU network resources servicing nodes today.
- Removal of I-CCAP equipment will not occur until an individual chassis is completely vacated. This could take years.
- The DAA nodes in OSP are higher power devices than the BAU nodes they replace.

Figure -4 shows initial high-level modeling of percentage change to BAU associated with DAA implementation and transition done to form the initial hypothesis.

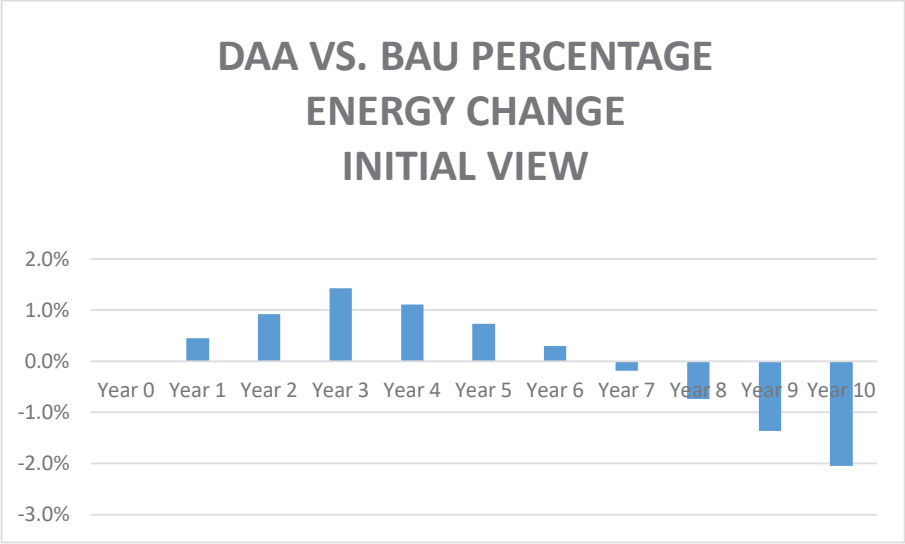

**Figure -4 DAA vs. BAU Percentage Energy Change Initial Hypothesis Modeling**

The initial high-level modeling represented in Figure 5-1 supported this hypothesis, showing an increase in energy usage in the early years related to deploying DAA in this manner. Ultimately, over time as DAA predominates and more BAU equipment is removed, DAA power does reduce, and go lower than BAU. That high-level modeling indicated timing of the cross-over point for DAA producing lower overall energy usage than BAU was a function of how fast DAA was implemented in the network, as well as how quickly I-CCAP infrastructure was removed from the network.

## 5.2. Energy Model Assumptions and Structure

To validate the initial hypothesis, a more detailed model was created. The detailed model starts with a base model for energy use in the BAU network. Layered on top of the BAU base is a model detailing changes related to implementing DAA in the plant, incorporating the Shaw transition assumptions. This allows comparison of BAU vs. DAA specific to the company approach. The base BAU model as

well as the DAA overlay use company supplied and industry data, as well as current company practices for developing and growing the network.

Model Year 0 was specifically designed to align with Shaw current plant and energy information garnered from energy audit work performed in 2018. Key elements included:

- **Network footprint volume:** Used Shaw overall plant data in 2018 for HP, nodes, etc. as a starting point for the base BAU model.

- **OSP power per node:** Calculated OSP power per node using OSP PS data from audit performed in 2018 on calendar year 2017 data, combined with total node numbers from the plant data.

- **Hub/Facility power per node**: Calculated hub facility power per node using data from a sample of stand-alone hubs with known number of nodes connected.

From this data, total OSP and facility power across the Shaw footprint was calculated for Year 0, specifically matching audit data.

Moving in time from Year 0, the model changes homes passed and number of nodes year-on-year into the future using key drivers related to greenfield expansion and node splits. These include:

- **Greenfield expansion**: 1% increase in HP per year. This assumption is based on typical industry data for greenfield in developed markets. This was used to drive node growth due to greenfield build in the model.

- **Percentage node splits in year due to TB growth**: 5% of nodes from previous year. This was based originally on industry data, although a sample of Shaw data supported this assumption as reasonable. This was used to drive node growth in the model due to node splits.

The node growth resulting from the above drivers changes year-by-year energy usage in OSP and hub power based on the following key assumptions:

- **Facility equipment power:** RF optics power, CMTS chassis power, etc. as provided by Shaw for specific devices used in the company network. These numbers were used to calculate energy use changes in critical facilities for node growth related to plant extension and node splits in the year.

- **CMTS chassis utilization**: Model assumes one node per port per Shaw current practice, and 66% port utilization based on experience/industry norms. CMTS chassis' in the model grew as a function of node growth in combination with this utilization assumption.

- **Facility PUE**: Facility PUE was assumed to be 2.0, based generally on conservative industry norm. This is needed in the model as it drives changes for non-equipment energy (i.e. HVAC, lights, etc.) in facilities.

- **Brownfield node power:** Model uses per node power calculated from 2017 PS audit through-out the model.

 

- **BAU greenfield node power:** As greenfield nodes target N + 2, in theory they will be smaller than the brownfield assumption around node size and power. As such, greenfield node power is assumed to have W/HP consistent with a brownfield node.

- **BAU node split power**: After a node split, total power for the sum of the two split nodes is incremented by the power difference between the new node and the amp it is assumed to be swapped for.

For the DAA model, many of the base assumptions were similar to BAU. As with BAU, DAA model uses Shaw overall plant HP, nodes, etc. to model a Year 0 starting point similar to BAU today. Key growth drivers around greenfield growth percentage, node split percentage, PUE, and chassis utilization year-on-year are the same, as well.

The DAA model differs largely due to implementation and transition assumptions. Implementation drives changes to per node energy usage in the following ways:

- **OSP power per node:** DAA power per node is adjusted by the increment in power associated with replacement of the standard node with a DAA node.

- **Hub/Facility power per node**: Facility power is adjusted using DAA equipment elements instead of legacy equipment for the added nodes.

The DAA model itself is driven by the Shaw transition strategy. Key elements include:

- **DAA nodes only deployed in greenfield plant**: All plant extension greenfield nodes will be DAA nodes and therefore connected to D-CCAP chassis.

- **Node Splits:**

    - Existing node and the new node created from a split will be DAA nodes in the field.

    - Both nodes from the node split will be placed in D-CCAP chassis on 10 Gbps connection via CIN.

    - Existing node being split will be removed from I-CCAP chassis.

    - RF Optics connected to existing node will be disconnected.

- **Legacy I-CCAP**: I-CCAP infrastructure is capped – all node "adds" due to greenfield build and/or node splits become DAA and are placed on D-CCAP chassis.

- **BAU I-CCAP and RF Optics removal**: These items are removed but only after all BAU services are completely transitioned. Following assumptions are made in the model made for removal timing:

    - RF Optics removed in the same year I-CCAP node is moved to D-CCAP as part of node split.

    - Full I-CCAP chassis' are removed three years after initial node moved to D-CCAP (i.e. starting year 4 in the model).

- **Evolutionary Strategy**: Strategy does not include targeting hubs and/or CMTS chassis/RF optics for complete conversion, and/or potential transfer of nodes to BAU ports to clear equipment for removal.

# 6. Findings from Modeling

Modelling work focused on a ten-year view of energy usage for each of the two options. Ten years was chosen because it is far enough in the future to see trends, but not beyond the point where the assumptions made could still seem applicable. Output was generated with respect to OSP plant energy usage, hub/facility energy usage, and combined usage, across the whole Shaw footprint. Data and analysis from that work is contained in this section.

## 6.1. BAU

BAU modeling shows future growth in energy usage in the footprint as assumed new greenfield build and node splits drive additional nodes. Figure -5 below shows the changes year-on-year.

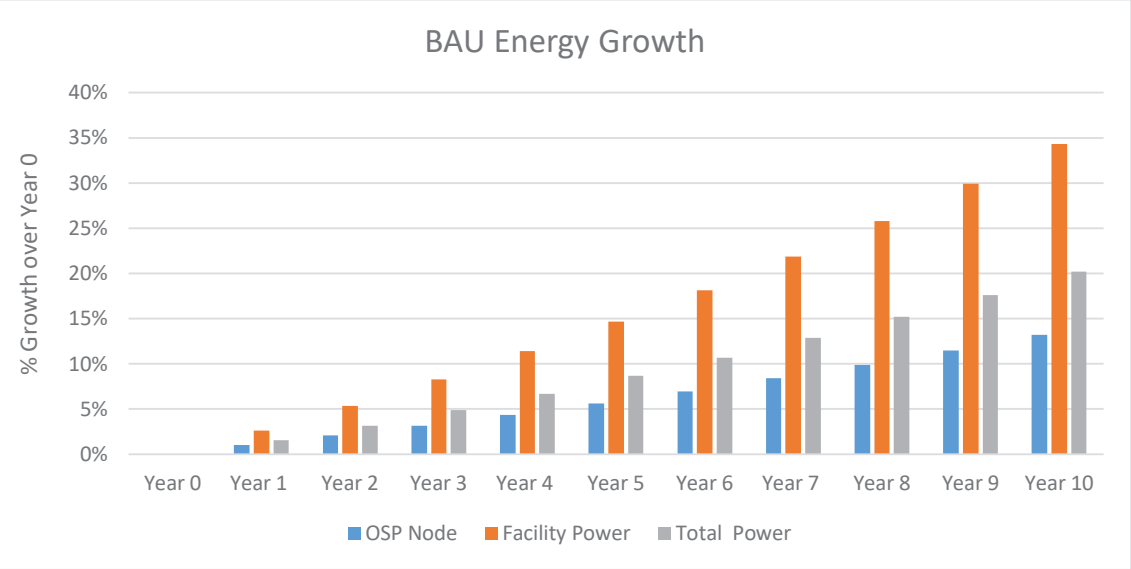

**Figure -5 BAU Energy Growth**

BAU OSP growth in the overall footprint is driven by a combination of greenfield expansion, as well as growth due to node split. Key impacting items associated with this were:

- Additional 1% of greenfield plant built in the footprint. This was the primary driver of BAU OSP energy use growth.
- The slightly smaller per node power specifically on the new greenfield nodes as at N + 2 they are smaller and require fewer active elements to be powered.
- The slightly higher power in split nodes due to swap of an amp with a node.

With respect to the individual components, OSP energy grows at a compound annual growth rate (CAGR) of 1.2%, making it 13% higher in Year 10 in comparison to Year 0.

Facility/Hub power grows at a much higher CAGR of 3.0% over 10 years. This is driven almost entirely by the addition of I-CCAP chassis', RF optics and infrastructure needed to support added greenfield nodes, as well as the nodes added via node splits. In comparison to Year 0, Year 10 usage is 34% higher in BAU.

Combining the effects of OSP and facility/hub growth, overall energy growth for BAU implementation had an energy usage CAGR of 1.9%. In comparison to Year 0, Year 10 usage is 20% higher. This combined view forms the basis of the BAU situation for comparison to DAA.

## 6.2. DAA

DAA modeling shows future growth in energy usage as well. As with BAU, new greenfield build and node splits drive this, tempered by the DAA transition drivers. Figure -6 below shows the changes year-on-year.

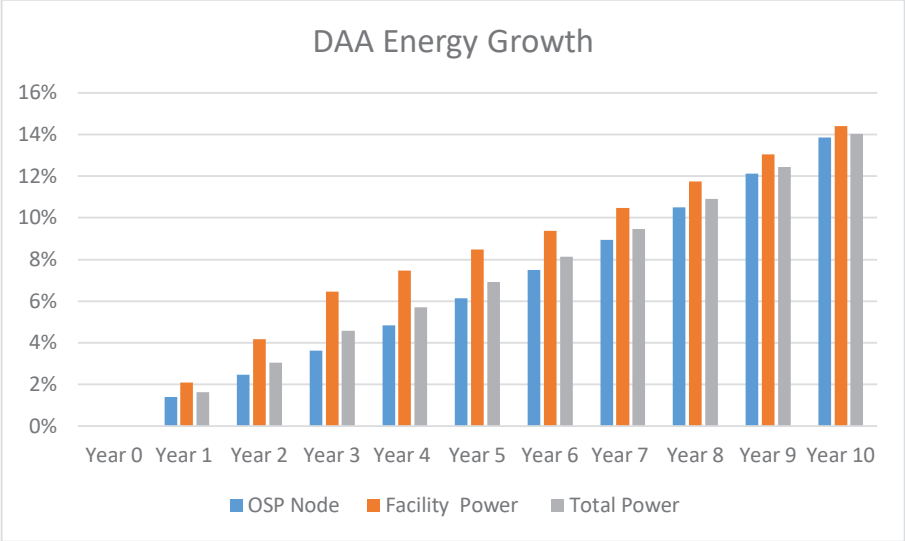

**Figure -6 DAA Energy Growth**

In relation to the individual components, DAA OSP energy is impacted largely by the same key drivers as BAU. Energy usage CAGR is 1.3% over the ten-year period, making energy usage 14% higher after 10 years. Both figures are slightly higher than BAU due to the swap out of legacy nodes with higher powered DAA nodes.

Facility/hub power growth undergoes much more meaningful changes from DAA implementation. Usage per year is higher in early years (2.1% - 2.2% per year), due to the addition of D-CCAP infrastructure coupled with the delay in removing legacy equipment related to DAA transition strategy, particularly the I-CCAP chassis' equipment. Starting in Year 4, the model begins the process of eliminating legacy I-CCAP chassis', and DAA growth approximately halves. The combination of removing I-CCAP chassis' from the network, and taking up port growth from Year 1 with lower power D-CCAP chassis', works to minimize yearly growth from that time to the 1.0% per year range.

As such, the facility energy use CAGR is 1.4%, with overall growth over the ten-year period slightly above 14%, both much lower than BAU.

The combined effect of the DAA transition strategy yields an energy use CAGR over 10 years of 1.3%, driving growth for the combination of OSP and facility to be 14% higher in Year 10, both lower than BAU. Even with the migratory approach, ultimately the swapping out of I-CCAP for D-CCAP, and swapping RF optics for CIN components, overcomes the added energy for DAA nodes in the OSP, leading to lower energy usage in comparison to BAU. Using the Shaw DAA transition strategy, energy usage will increase in future due to growth in plant and continued node splits – but DAA works to lessen that growth in future in comparison to BAU.

After modelling the Shaw DAA transition strategy, questions arose around how this might compare to energy usage for a complete conversion of a facility/hub to DAA in Year 1, as the company was contemplating this for a hub due to reasons related to an existing facility,. Although previously published work [5] on this topic was written from a more generic perspective, modelling of the Shaw specific use case for implementing DAA immediately in a hub provided some guidance.

Using energy audit data, along with homes passed, node and I-CCAP chassis data for facilities in the Calgary area, year one full DAA was modelled. The model used the following assumptions, yielding the following results

- **OSP DAA immediate implementation:** To calculate this, it was assumed all nodes within each of the hubs were swapped with DAA nodes. This drove a 4% increase in OSP power, solely related to the immediate swap out of lower powered existing nodes with higher powered DAA nodes.

- **Hub/facility DAA immediate implementation:** To calculate this, all I-CCAP chassis' in the hubs were swapped for D-CCAP. Additionally, all optical transmitters and receivers were eliminated, replaced with a CIN network to which the DAA nodes were connected. This resulted in a 42% decrease in hub/facility power, primarily due to the I-CCAP for D-CCAP platform swap.

- **Overall DAA immediate implementation:** The combination of these two effects drives a 5% decrease in overall energy usage. This relatively modest overall percentage reduction is a function of the heavy weighting towards OSP energy in the sample areas, which at ~80% is the majority of the total energy usage. Even though energy savings in the facilities for this approach would be meaningful, because of the large OSP component, they have a more limited impact on overall energy usage.

It should be noted that although not specifically a part of the work, high level estimation was that in addition to the significant savings in facility energy, fully implemented DAA would reduce space to somewhere between a third to a half of what it was pre-DAA.

Although meaningful energy and space savings would be achieved with immediate conversion to DAA in a facility, it is unlikely the savings associated with that change would offset the capital required to accelerate DAA implementation on its own. In special cases, lease challenges and/or space/energy limitations might necessitate such a change. The ability to use an all DAA implementation to meet a particular building and/or facility challenge is an important tool an operator can use. Although there are real benefits in energy and space savings in comparison to BAU to a full DAA implementation on Day 1, other rationale beyond those savings would be required to justify such a conversion.

### 6.3. DAA vs. BAU

Figure -7 compares year-on-year percentage difference in energy use change between BAU and DAA.

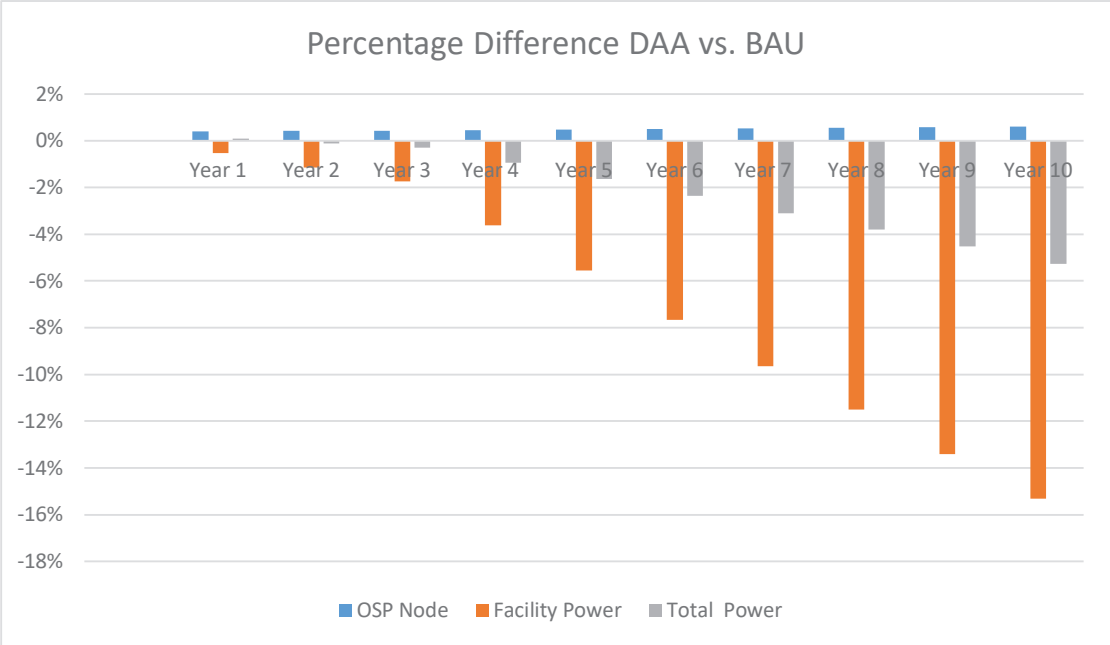

**Figure -7 Percentage Difference DAA vs. BAU**

This comparison of DAA energy growth to BAU energy growth shows the Shaw DAA transition strategy, even with its evolutionary approach, delivers energy usage reduction against BAU over time. Overall energy usage stays roughly the same in the early years, with the small decrease in facility energy offset by a slight increase in the much larger OSP component. This changes in the later years, as ultimately removal of I-CCAP components over time accelerate the energy usage reductions of DAA versus BAU.

Learnings from the modeling and subsequent analysis associated with it include:

**Early years impact of dual DAA and BAU infrastructure:** Section 5.1 hypothesized DAA energy use would increase in the early years with placement of dual DAA and legacy infrastructure for a period of time, reducing in comparison to BAU after I-CCAP removal started. In fact, the model showed the impact of this was negligible. Analysis indicated capping the placement of much higher power I-CCAP devices, and adding new capacity needs on newer, lower power D-CCAP devices in the DAA model, mitigated the added power of the dual infrastructure. A learning from this work was that the key to avoiding an early-year increase in energy usage related to this strategy is to cap I-CCAP and put all node growth in facilities on D-CCAP infrastructure.

**Timing and size of DAA reduction – I-CCAP removal assumption:** As expected, the size and timing of the DAA reduction varies with the assumption as to when I-CCAP chassis' would start to be

removed. From a modeling perspective, earlier removal improves DAA in comparison to BAU, later removal lessens the energy improvement of DAA. The assumption of beginning the removal of chassis' in Year 4 equal to the number of ports vacated in Year 1 is an estimate trying to approximate when the nature of node split locations would fully vacate I-CCAP resource over time. If a more exact estimate of this is required, future work could look at adding depth to this part of the modelling based on real world experience, as well as producing quantitative analysis as to impact of varying I-CCAP removal starting point assumption in the model.

**Timing and size of DAA reduction – improvement via consolidation:** As noted in section 5.2, the DAA transition strategy does not include targeting lowly utilized equipment chassis' for complete conversion, to clear for removal. In fact, the timing and size of the DAA savings would be improved with a strategy for setting a minimum utilization point after which legacy architecture would be consolidated. Because a nominal spend would be required to accomplish consolidation, scheduling should be done strategically to minimize costs. One would not want to see this DAA implementation strategy lead to the continued use of a number of rarely-utilized I-CCAP and RF optic chassis' for a long period of time.

**Facility/hub space savings**: Although this work focused on energy usage, it should be noted DAA would lessen space requirements in the facility/hub locations. The DAA transition strategy slow-rolls the I-CCAP to D-CCAP evolution, so space savings will be evolutionary in much the same way energy usage evolves. Although conversion from I-CCAP to D-CCAP platforms yields minimal space savings for the chassis' themselves, elimination of RF optics, as well as the associated RF combining equipment over time, would free up significant space in the facility. The high-level estimate was that, with fully implemented DAA, facility space would be in the order of half to a third of the space used today. Future work specifically related to space would be recommended to better understand and quantify this.

**Future of vCMTS:** DAA and D-CCAP are both part of Shaw's network evolution strategy. Additionally, Shaw is evaluating the potential to evolve the D-CCAP architecture to vCMTS as and when that evolution makes sense. vCMTS holds the promise of housing the CMTS functionality in more space and power efficient white-box storage and server devices, potentially further improving energy and space efficiency in facility/hub devices. Future work to assess energy impact of vCMTS would be recommended as and when evolution to the platform is being planned.

## 7. Outside Plant Power Network Capacity Analysis

As noted in Section 2, Shaw BAU OSP network is standard HFC with ~N+X architecture with plans to maintain or reduce node sizes and cascades lengths. Consistent with HFC deployment norms, the company has implemented a distributed power infrastructure in the OSP to power nodes and active devices in the HFC network. In addition to the nodes and actives, the OSP power infrastructure also supports additional non-HFC devices e.g. small cell, Wi-Fi AP's, etc.

As a part of network evolution of taking fiber deeper, the company intends to use existing power supplies and power supply locations as much as possible. In addition to accommodating network evolution, the company expects the current OSP power infrastructure to be capable of incorporating more of the additional loads related to non-HFC equipment in the future. To date, Shaw has connected in the range of 10,000 Wi-Fi AP's to the coax network, and as an MNO, have connected 4G LTE small cells and are anticipating connecting 5G, both as noted in [3]. The table below outlines the approximate power draw for different types of devices which may be connected to the power network.

**Table -1 Non-HFC Device Typical Power**

| Device | Power Consumption (per device) | Quantity per Site | Total Power/Site | Range |
|---|---|---|---|---|
| **Small Cell** | 60-180W per device, | 1-3 | 60 - 500W 300W-320W/site typical | ~250M (3.5GHz CBRS) |
| **Wi-Fi AP** | 15-35W | 1 | 25W | ~200M (2.4GHz) |
| **IoT** | 60W | 1 | 60W | 2-4Km |
| **Gateway** | Modem (15W-20W) + Load | 1 | 80W – 140W | For Cameras, etc. - depends on device under load |

Source: Industry Data

To better assess the ability of the OSP power infrastructure to support these goals, as well as understand spare capacity in the power network, the energy audit work performed on the OSP power supplies was used to analyze utilization of the power infrastructure.

The audit found that Shaw's OSP PS population totaled a little over 20,000, of which 95%+ were analyzed as a part of the audit work. With respect to voltage, data indicated ~75% of the PS's were 90V with the vast majority of remaining PS's at 60V, yielding an average plant voltage of 83V. Status monitoring data yielded an average current of 5.8A. Both the 90V/60V split, as well as the ~6A average current, are typical of MSO peer operators [2].

Power supply output voltage and current as acquired via the status monitoring system was used to analyze the PS network. Load investigations were based on Volt-Amperes (VA) calculations from this data, since the output power factor is not known. Key findings from the data included:

- Average output VA across the footprint is 482 VA. This is the average usage for each of the PS's in the network.
- Average capacity for the mix of PS's in the power supply universe is 1286 VA. This implies primarily 15A PS's in the network, with some mix of smaller and larger variants.

This leaves on average ~800VA available across the footprint. As noted in [2], given the majority of the PS's in the footprint are 15A capacity, good practice dictates power supplies target to run close to 80% of load, or with 3A available. This would equate to a minimum spare capacity requirement for standard network of ~250 VA. At an average of 800 VA available capacity, the power supply network appears to have more than enough headroom for future growth.

While averages provide important data, distribution of the count of power supplies around the average can provide operators a more informed view. Distribution of the power supply count by available VA is as shown in Figure -8 below.

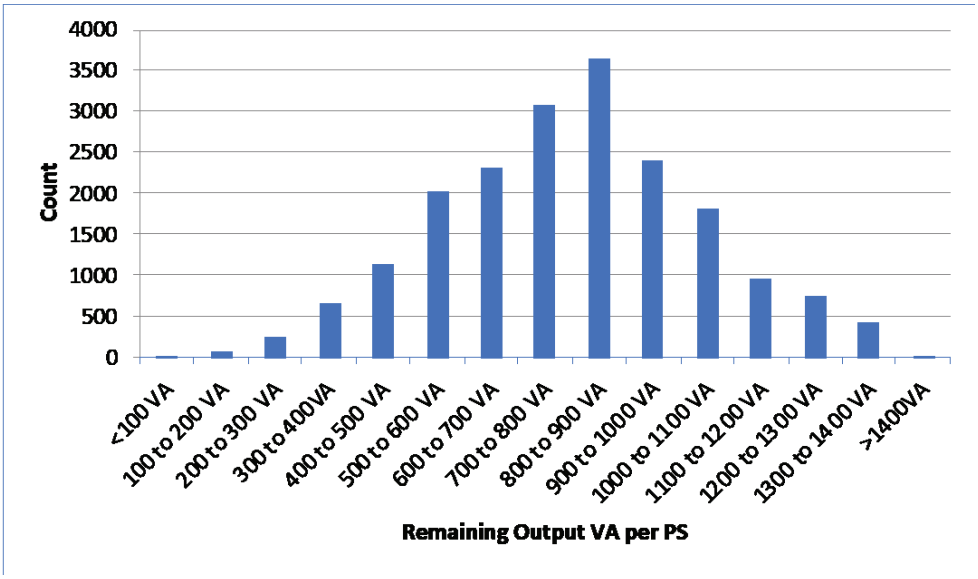

**Figure -8 PS Distribution of Remaining Output VA**

As demonstrated above, the vast majority of power supplies have in excess of 200 – 300 VA of capability minimum as headroom recommended. Figure -9 re-structures the data above with respect to the percentage of power supplies in each category.

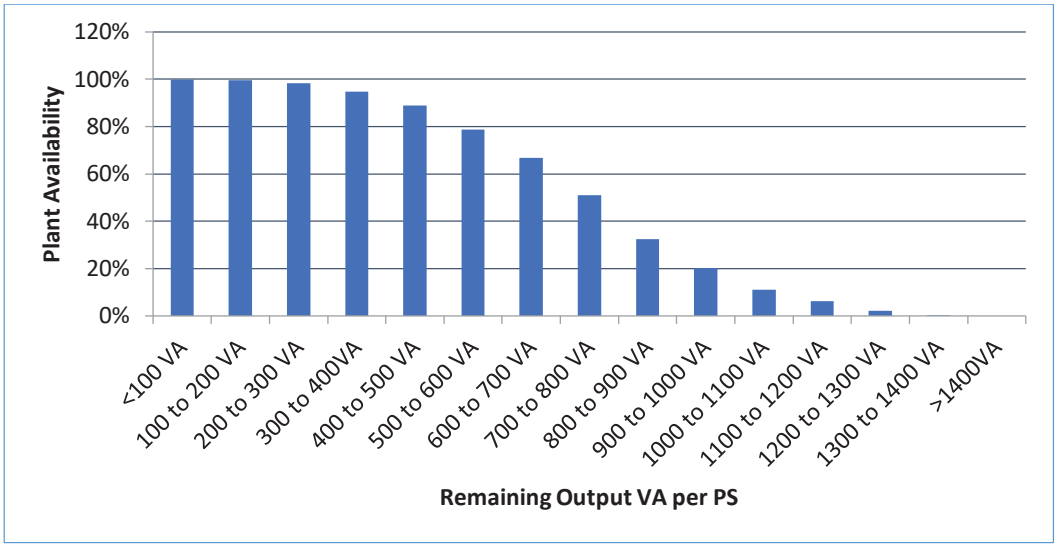

**Figure -9 Distribution PS Remaining Output VA %'s**

Key takeaways from this analysis include:

- 95%+ Power Supplies have minimum recommended headroom of 250 VA.
- 95% of Power Supplies have 300 – 400 VA or more, providing minimum headroom plus some added capacity for almost all PS's.

- 67% of Power Supplies have 600 – 700 VA or more, leaving minimum 350 VA over recommended minimum for additional loads.

- Average 800 VA of available capacity implies on average 550 VA over recommended minimum for additional loads.

Although the addition of DAA and continued node splits as Shaw evolves to N + 2 architecture will have an effect on reducing headroom, as noted above, it is the company's intent to manage any additional power needs related to network evolution and the addition of non-HFC elements from the existing power supply capacity. This analysis concludes that Shaw's OSP power architecture generally has the capacity to continue supporting the evolution of the HFC network, as well as additional small cell, IoT and gateway devices into the future.

## 8. Conclusion

The journey to 10G will push Shaw's network to evolve. Implementing DAA will be a key element of the network of the future. To properly balance timing and cost with needs and benefits, the company has chosen an evolutionary strategy for DAA implementation. This strategy will embed DAA into the network in a controlled manner, focusing implementation in greenfield nodes, as well as using DAA nodes in node splits at first, and proactively implementing DAA in existing brownfield only in very limited cases.

Even though it is an evolutionary approach, the Shaw DAA migration still provides energy savings over time in comparison to BAU implementation. Modeling work performed on the company's DAA implementation vs. BAU showed the following:

- DAA OSP energy slightly higher than BAU at 14% vs. 13% cumulative ten-year growth, due primarily to higher powered DAA nodes replacing existing nodes.

- DAA facility energy decreasing to 14% cumulative ten-year growth vs. 34% for BAU, due primarily to swap of I-CCAP with D-CCAP, as well as swapping RF optical devices with CIN elements. This is where the savings of the DAA transition are.

- DAA overall increases energy 14% vs. 20% cumulative ten-year growth for BAU. The Shaw evolutionary approach to DAA implementation slows but does not eliminate BAU infrastructure energy growth.

Capping I-CCAP growth and moving node growth to the lower energy DAA platform mitigates the initial power increase of dual D-CCAP and I-CCAP infrastructures. Real energy reduction in comparison to BAU begins when I-CCAP infrastructure is fully vacated and removed from facilities. Timing is impacted by speed of DAA evolution – if the process is accelerated, energy usage benefits will accelerate, and if it is slowed, energy usage savings will similarly slow. Energy usage reduction speed is also impacted by any actions that drive a less random, more geographically targeted DAA implementation. The faster I-CCAP and RF optical equipment can be fully vacated and eliminated, as opposed to lingering in service at low utilization, the faster energy usage benefits will accrue.

The benefits of immediate conversion to DAA were examined. Modeling from Calgary data indicated immediately converting a hub geography to DAA reduces facility power significantly (~42%), but overall impact is more modest (-5%). This is largely due to a large proportion of total energy (~80%) was OSP energy in the sample areas used – other areas where OSP energy was a more typical 70/30

split would see greater benefit. The small OSP increase also played a minor role. Although facility improvement in both energy usage and space reduction would be meaningful in an immediate transition of a hub to DAA, on their own it would be assumed they would not justify the cost. Full DAA implementation in a hub geography, however, could be a useful tool for solving specific space and power challenges, should they arise.

Finally, energy audit data was used to examine headroom in the OSP power infrastructure to handle DAA evolution, as well as additional non-HFC devices intended to be connected to the power infrastructure in the future. The data showed:

- Average headroom adequate to support evolution to DAA and fiber deeper, as well as multiple additional devices.
- ~2/3rds of nodes have headroom for even the largest anticipated single load device to be added and still maintain minimum headroom.
- 97%+ nodes have minimum headroom in place (20% capacity).

Although each case needs to be examined on its own merit, in general, the Shaw OSP power infrastructure has ample headroom to accommodate DAA evolution and the addition of non-HFC elements to the power infrastructure.

# 1. Introduction

Upgrading current hybrid fiber coax (HFC) networks to extended spectrum (ES) introduces many challenges for operators, equipment providers, and component vendors. Historically upgrades have been accommodated by utilizing improved component performance to develop actives that drop into existing network locations. A drop-in strategy means minimal downtime and reduced labor costs.

Given the familiarity of this strategy it's natural to look at upgrading current actives for ES by leaning on newer component technologies to reduce costs while realizing the goals of increased bidirectional bandwidth. The extension to 1794 MHz might be difficult enough to force a departure from the standard architectures by adding additional active elements at key places in the network. However, before we get to that point the question remains: how far can newer component technology take us?

Major goals for an ES upgrade center around reusing as much of the existing active installations as possible. Ideally, system power supply capacity should not be exceeded, and active upgrading should consist of replacing old equipment trays with new ones without changing locations or re-splicing cables. To not disturb operating levels to existing customers, current output levels are maintained. Any additional energy located in upper bands must be facilitated through the use of newer, more efficient amplifier components powered from the same or lower DC power as today.

Historically, the cable industry has struggled to employ a sufficient workforce during major upgrade cycles. While client-side silicon capable of meeting the full DOCSIS 4.0 requirements may be a way off, it would be advantageous to have ES capable actives soon that are both legacy friendly and easily switched to an ES configuration. ES capable actives can then be deployed as soon as they are ready which will help smooth demand on the workforce when the new modems are ready.

The ES upgrade challenge is like increasing the link budget of a legacy communication system, much of which has been based on older component technology. The incremental losses at 1794 MHz, particularly for customers in unfavorable tap locations with lesser-grade coaxial cable served off long drops can be substantial. Rolling back the quadrature amplitude modulation (QAM) rates for these customers works counter to the purpose of the upgrade. The transmit (Tx) performance from the network active cascade and the receive (Rx) performance at the point of entry (PoE) are key parameters available to offset the detrimental effects of increased losses. In most cases today, components operating in the field provide lower levels of Tx and Rx performance compared to what is readily achievable in a new generation of components using technologies that now serve key locations in wireless networks.

Other improvements and optimizations outside the scope of this paper provide additional performance margin. Low density parity check (LDPC) codes provide distinct advantages over existing Reed Solomon error correction. Similarly, there has been much study about how to best allocate an amplifier's total composite power (TCP) capability by offsetting and adjusting the upper spectrum to 1794 MHz to best fit the physical plant realities.

This paper focuses on how Tx and Rx performance at key locations in the network may be improved to smooth the path for the emerging ES upgrade. In particular, the design methodology for a new set of components targeting optimum Tx power under a fixed DC budget for an ES line extender (LE) is presented. We propose a multiple-stage integrated-circuit-based design approach to optimize overall performance. Likewise, achievable Rx performance is shown as an opportunity for point of entry (PoE) devices.

## 2. The Importance of Bias

Class A amplifiers have served the cable industry well. They provide a good combination of bandwidth and linearity necessary to handle legacy analog TV encoding. Fortunately, networks have been upgraded over time to maintain the high level of linearity needed for analog signals, which serendipitously makes them excellent candidates for handling high level QAM signals in the high bandwidth digital era.

Of course, the downside of Class A stages is their poor efficiency. Achieving high linearity takes a lot of DC bias. Amplifier crash point, the RF output power level where modulation error ratio (MER) rapidly falls as input drive is increased, is likewise dominated by biasing considerations. Although methods of linearization, such as digital pre-distortion (DPD) and legacy analog pre-distortion can provide worthwhile benefit, ultimately crash levels and the ability to increase Tx TCP levels are still constrained by bias. Once a transistor runs out of voltage or current as it traverses along its load line it is no longer capable of reliably carrying information.

It follows then that to maximize the Tx TCP performance attention should be focused on how to optimally allocate bias in the cascading component stages. Higher TCP levels are usually within reach, as demonstrated in recent fiber deep output stages, but at cost of additional DC power that probably eclipses the available legacy power of a high percentage of the networks operating today.

There are any number of ways to adjust bias conditions in Class A amplifiers. The most common and obvious involves adjusting the quiescent current of the stages within a design. However, as equipment vendors seek to differentiate their offerings, it's worthwhile to note that an additional level of efficiency is available by incorporating the supply voltage as part of the design optimization. On this point many vendors have been inflexible on supply voltage and consequently left performance on the table to their competitive disadvantage.

Table 1 highlights the costs and benefits of a few examples of bias control schemes. As ES amplifiers emerge, greater thought can be given to the benefits of incorporating a network management system (NMS) as part of an intelligent network. The techniques below are not mutually exclusive and may be combined to innovate equipment designs. Here the term "bias" is inclusive of both voltage and current being applied to an amplifier component.

**Table 1 – Examples of Bias Control Schemes**

| Technique | Description | Advantages | Disadvantages |
|---|---|---|---|
| Factory / Field Bias Set | Adjust once and forget | Low cost | Inflexible |
| Active Bias Control | Localized control loop | Minimizes variations unit-unit and over temperature | Minor cost adder |
| Remote Bias Adjustment | NMS monitoring and control | Configurable to network differences | Added cost |
| Automatic Bias with Static RF Level | Servo based on required or NMS controlled RF level | Ease of deployment and optimized efficiency | Added cost |

| Technique | Description | Advantages | Disadvantages |
|---|---|---|---|
| Envelope Tracking | Dynamically adjust based on derived signal envelope | Significant improvement in efficiency | Must know envelope condition and have means to suitably adjust bias conditions, cost of added circuitry |
| Active Linearization | Dynamically adjust based on full spectrum of input signal | Significant improvement in efficiency | Requires much higher speed device processes |

# 3. Introduction to Design of an ES Line Extender

## 3.1. Legacy 2-stage Line Extenders

To help with the bias optimization process for ES line extenders, we considered the interaction of gain, corresponding RF output level, and bias expenditure of a hypothetical LE design. For a given RF input level the amount of gain in a stage is intimately connected with its RF output level requirement. We considered how we could develop a family of amplifier components that would optimize cascaded LE performance while fitting within the legacy power available in today's line extenders. By carefully distributing the amount of gain and bias in intermediate stages we sought to maximize bias available for the final Doubler stage, thereby hoping to maximize the Tx TCP and MER budget.

Of course, line extenders have additional loss elements in the RF path, such as diplexers, automatic gain control (AGC) circuits, directional couplers, and tilt equalizers. Since one goal is to maintain legacy levels in an ES deployment the amount of tilt needed considerably rises. Because most of the tilt is accomplished with passive circuits the cascaded gain must be increased. In addition, the location of this tilt loss must be carefully considered since it places added burden on both the cascaded noise figure and distortion performance of the line extender.

As a starting point, consider a simplified downstream LE block diagram in Figure 1. Two stages of amplification are commonly used in most line extenders today. Depending on how RF output level control is implemented, downstream LE gain for a 1002 MHz design ranges from 39 to 33 dB. An input "Push-Pull" and an output "Doubler" combine to provide approximately 48 dB of amplification. Interstage losses account for the difference between total LE gain and gain provided by these amplifier components.

Cascaded tilt in the range of 8 to 18 dB are commonly configured by applying appropriate tilt modules. Locating most of the tilt directly at the input will deteriorate overall MER performance through thermal noise mechanisms. However, distortion contributions to MER performance will be minimized since each stage operates with a high input tilt. Conversely, locating most tilt between gain stages leads to MER degradation from the driver amplifier since it must drive a higher RF level through the tilt loss.

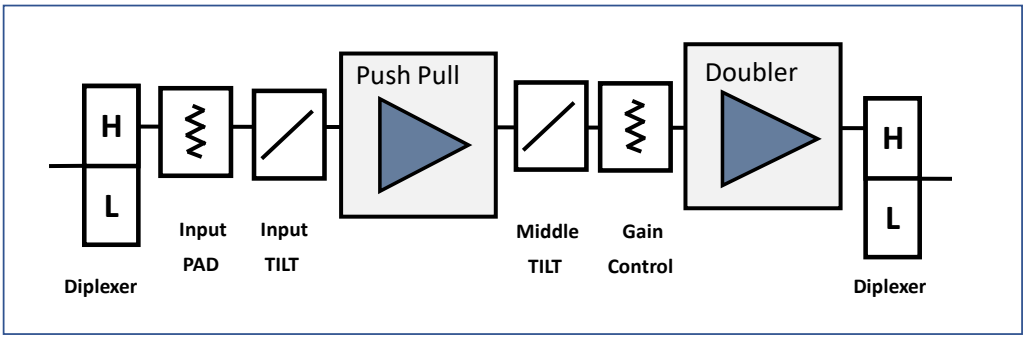

**Figure 1 – Simplified Downstream Line Extender**

To overcome the additional plant loss in an ES buildout, LE gain must be increased by as much as 16 dB compared to legacy 1002 MHz line extenders. Operating tilts will naturally increase to around 22 to 26 dB, meaning that thermal noise contributors to MER degradation will be more difficult to manage. Add to this the desire to carry high levels of QAM in longer RF cascades such as N+4 or N+6, and the problem of where to locate the additional gain and tilt becomes non-trivial.

## 3.2. Gain Limitations in Single Stage Amplifier Components

Most gain stages in cable networks use the familiar cascode topology in a push-pull configuration. Figure 2 shows the familiar single stage cascode topology. We consider a cascode a single stage amplifier since feedback is wrapped around both transistors in the configuration. A combination of series (RS) and shunt feedback (RF) is used to set impedances and manage gain flatness. Due to limitations in intrinsic transistor transconductance and bandwidth, gains of single-stage 1800 MHz amplifiers max out around 23 dB. However, in our testing a slightly lower gain 21.5 dB version has shown superior efficiency performance.

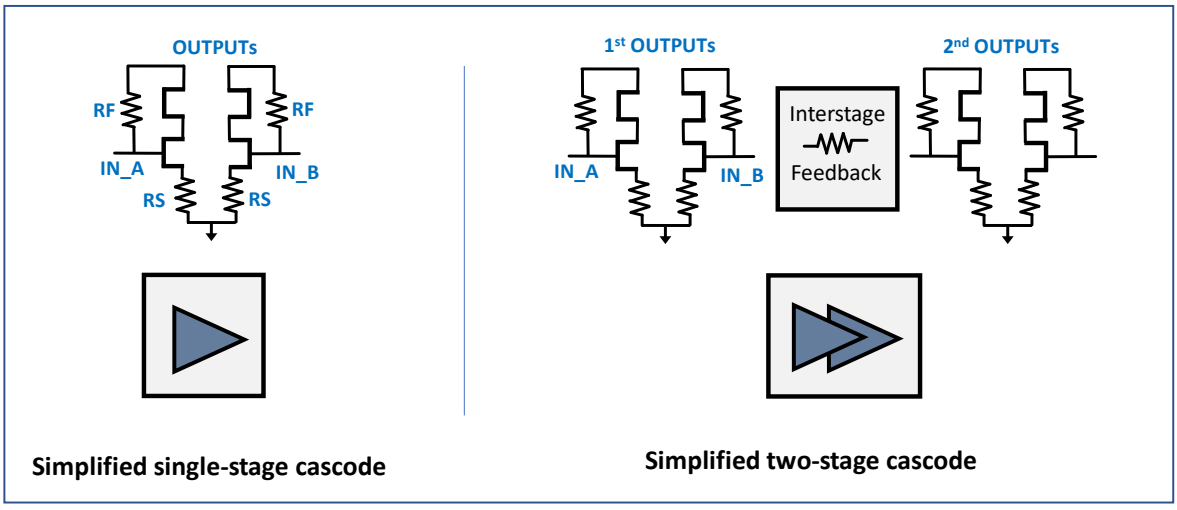

**Figure 2 – Single and Two-Stage Cascode Amplifier Component Topologies**

For intermediate level designs using simple baluns on the input and output, practical gains are closer to 19 dB per stage. These devices commonly take a reduced 5 V to 8 V supply voltage and output a suitable level to power moderate amounts of attenuation and tilt leading to the output Doubler stage. Because these designs have lower power consumption, they can be fabricated on a single die leading to more

consistent performance. If standard baluns are used for unbalanced-to-balanced conversions designers can achieve good impedance consistency using little board space. Standard GaAs processes are commercially available to fabricate these circuits leading to acceptable overall cost.

### 3.3. Two Stage Design for Additional Gain and Negative Feedback

Figure 2 also shows a two-stage cascaded cascode amplifier component concept. The additional stage provides a boost in available gain useful in any number of additional series or shunt on-die feedback arrangements. This provides the integrated circuit designer freedom in setting impedance over a wide range of gain levels. It's possible to design a two-stage integrated circuit where fabricating a range of gains is just a matter of changing on-die resistor values. Practical gains for this two-stage approach range from 22 dB to 30 dB.

An example of a single-die two-stage 25 dB gain design with moderate interstage feedback is shown in Figure 3. The high degree of feedback provides consistent performance over temperature and fabrication process variations. Gain stability over temperature for the 25 dB prototype inclusive of input and output baluns is shown below. Bias current variation over temperature was +/- 1.5%. Data was taken from a heat sink temperature of -30 deg C, 25 deg C, and 100 deg C.

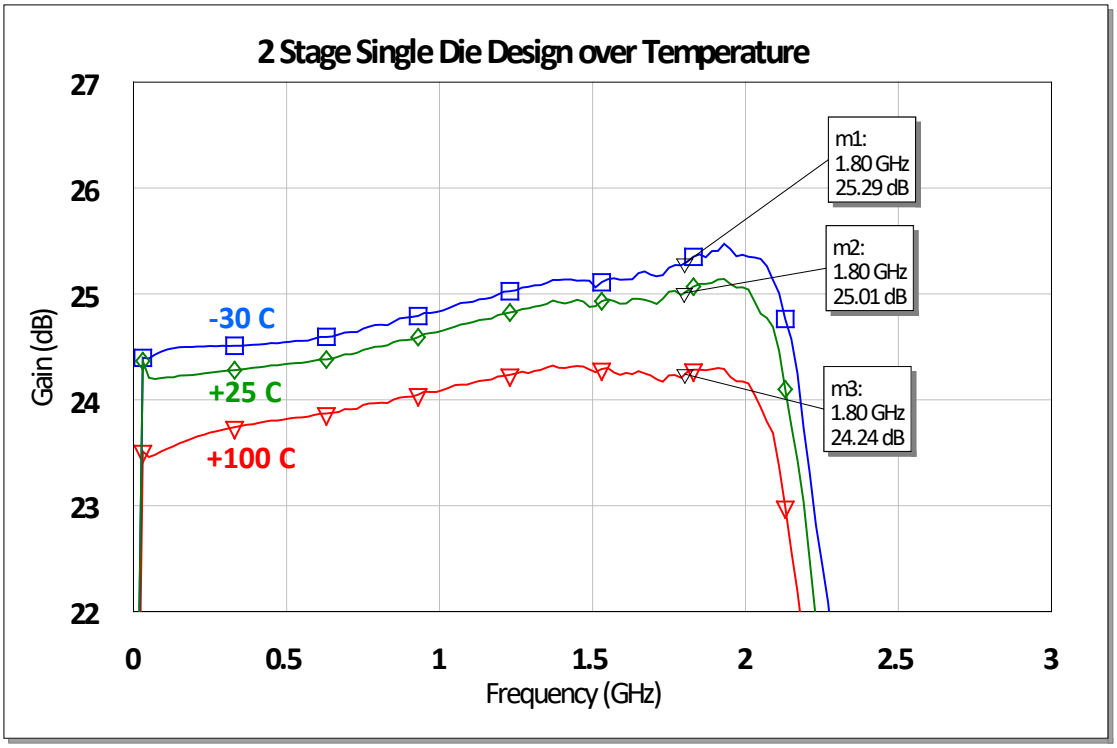

**Figure 3 – Two-Stage Gain over Temperature**

### 3.4. Common Packaging, Pin Definitions, and Application Artwork

In many cases developers of equipment need flexibility to adjust their designs with different gains and power levels to serve the wide range of operator requirements. In the past component vendors relied on the SOT115 package to offer different gain levels to the market. By leveraging this approach, we can

design single stage and two stage integrated circuits with a common application circuit and layout. A bill of materials (BOM) change is all that is needed to adjust gain and DC power consumption levels.

For example, an industry standard 5mm x 5mm QFN package with an exposed backside paddle can be used to package a family of intermediate level amplifier components, with gains ranging from as low as 12 dB through 30 dB. With good thermal precautions, power consumptions of up to 4 W can be managed easily, although as will be seen later our initial integrated-circuit designs consumed between 1.7 W and 3.0 W.

## 3.5. Options for Higher Gain in Line Extender Design

With available gain levels from components in mind, a few options for implementing higher gain can be considered. The question becomes how to optimally achieve the higher gain with additional stages in a modified LE block diagram while holding to the power envelope. A few options are shown in Figure 4.

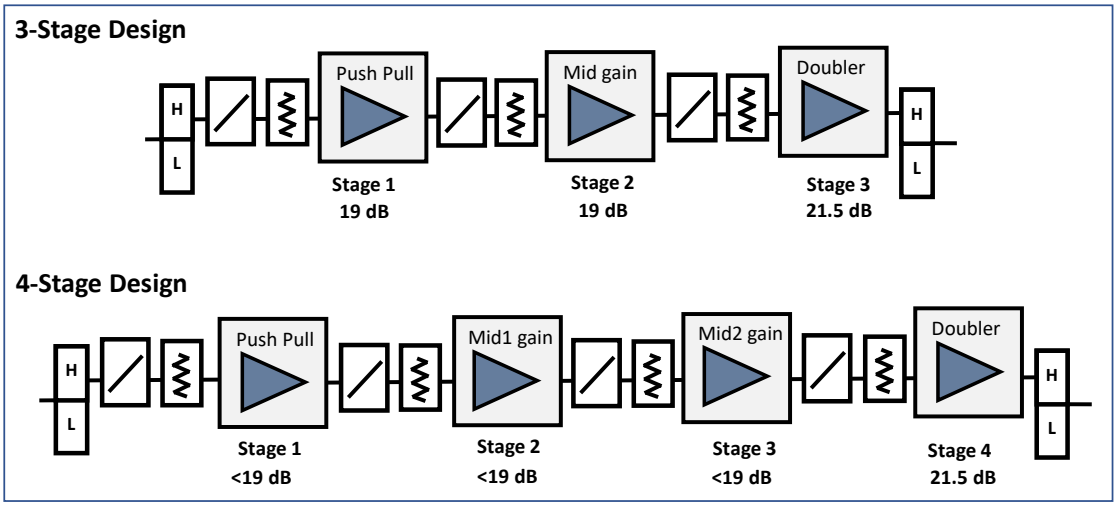

**Figure 4 – Options for Increasing Downstream ES Gain**

A 3-stage design utilizes push-pull and mid-gain stages operating from the lower supply rail which provide up to 19 dB of gain. Tilt and gain control can be accomplished in any number of ways with variable loss circuits to optimize dynamic range. An output Doubler provides up to 21.5 dB of gain. Although simple enough, the 3-stage design will struggle to provide enough gain to serve the entire range of LE gains operators need to drive a wide range of physical plants currently in service.

A 4-stage extension provides good gain, allowing design margin to locate interstage attenuation and tilt networks for best station performance. However, the added cost of the 4$^{th}$ stage is a disadvantage considering the anticipated cost pressures on LE upgrade modules.

An alternative is found in a 4-stage design, implemented in 3 amplifier components, termed a 3a stage design in Figure 5. Here the middle stage is a single die design encompassing 2 cascode stages with feedback wrapped within the 2 cascode stages.

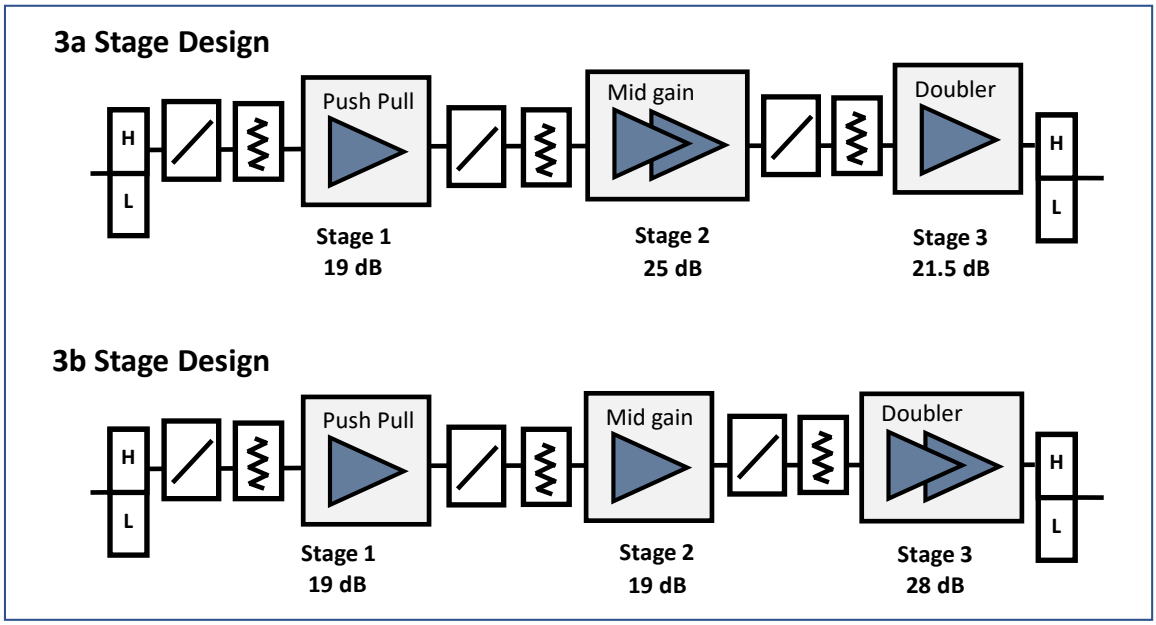

**Figure 5 – High Gain 3-Stage Design Options**

### 3.6. Variable Attenuators

Gain adjustment can be performed using variable attenuator circuits around the various stages. Since gain of the line extender can shift from unit to unit and over temperature, variable attenuation is commonly used to adjust for these changes. Maintaining a flat frequency response and consistent return loss over a moderate range of attenuation is of primary importance to reduce cascaded frequency response ripple. Unfortunately, in attenuator design there is often a tradeoff between impedance consistency over attenuation, attenuation range, and minimum attenuation. Traditional approaches have considerable insertion loss while newer designs have less. Because there are a wide range of implementations used by equipment vendors it behooves manufacturers of amplifier components to provide a wide range of gains in a common package and footprint to provide equipment designers the flexibility necessary to reach their goals.

## 4. Empirical Modeling Work on Early Devices

Given the interplay between gain, bias consumption, and output level capability, we sought to construct a measurement-based representation of early prototype 1800 MHz capable devices for use in LE system simulations. We fabricated standard cascode topology push-pull amplifiers on a single gallium arsenide (GaAs) pseudomorphic high electron mobility transistor (pHEMT) die with series and shunt feedback resistors chosen to achieve close to the high end of realizable gain comfortably beyond 1800 MHz. Single-stage and two-stage designs were fabricated. With a single-stage 19 dB gain intermediate level stage as a starting point, we characterized the relationship between bias current and voltage, MER, output TCP level, and various tilts. Our test source exercised 384 to 1794 MHz with a 6 dB offset above 1026 MHz

Tilt, voltage, and current were exercised extensively to produce a comprehensive data set for these devices. We then developed an interpolative software model for this device which could be used for

continuous simulation of gain and linearity within the bias and tilt space of the original data set. The data collection was thorough enough that the model very closely matches actual device performance. Figure 6 shows an example of output from the device model over a range of bias and output conditions.

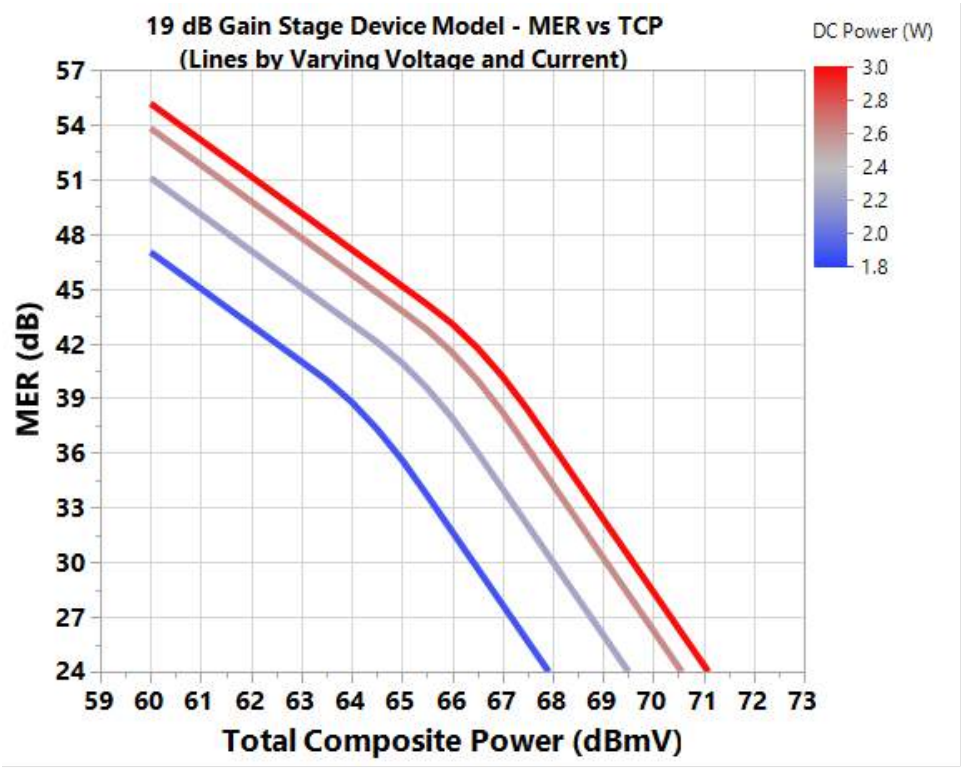

**Figure 6 – MER Modeling Example**

We also fabricated early devices for building output Doubler stages. We intentionally kept the question of supply voltage(s) open, knowing that this choice has major ramifications on overall TCP performance and efficiency outcomes. While historically a 24 V rail has been a strict requirement on Doubler output stage designs, the evolution of device technology has opened possibilities for improved Doubler performance using non-24 V rails. Recent 34 V Doublers serving the higher TCP Fiber Deep architecture are one example of what can be achieved with a wider design window. Furthermore, we assumed that the optimum LE TCP efficiency would come from two distinct supply rails – a higher voltage rail for the output Doubler and a lower rail for all other actives in the LE, including upstream gain.

Using the same approach as the 19 dB gain stage, we characterized the 21.5 dB gain Doubler stage and developed a model for use in system simulations.

# 5. Optimizing Gain, Bias, Tilt, and AGC Allocations

## 5.1. Cascade Simulator Concept

Equipped with models for extended spectrum active devices, we set out to develop a model for a complete LE. The intent was to determine the guiding principles for choosing the optimal topology for an LE, including the distribution of gain, tilt, biasing, and placement of any AGC element(s) or other lossy elements. This would both inform the development of a more comprehensive portfolio of extended spectrum active devices and allow us to provide data-supported recommendations for LE layout and

design. In order to extend our active device models into a full LE simulator, we had to develop several additional elements. First, simple passive element models (diplexers, equalizers, plug-in attenuators, and variable attenuators) were developed. Second, bounding conditions and assumptions on passive elements for LE design had to be determined. Lastly, a tool capable of cascading the system had to be developed to work with these models. In order to operate with the non-standard device models, we had developed for the active devices, we chose to create a custom cascade simulator for this purpose.

Starting from a defined un-tilted input and a perfect SNR, the simulation tool operates on an arbitrary topology of LE passive and active elements, cascading MER, noise, and signal in the downstream path. The cascade technique assumes that the MER can be treated as equivalent to uncorrelated noise power for the purposes of cascading. We found this relationship can be practically demonstrated on a test bench. This model does not consider BER; however, the output levels of the active devices in a typical line extender should keep bit errors from becoming a concern for purposes of these simulations. Further, the use of higher modulation orders in OFDM carriers in DOCSIS 3.1 / 4.0 deployments results in BER which is highly correlated to MER and generally not a function of device crash behavior.

We largely focused on simulations of 3-stage topologies, as it quickly became apparent that by leveraging higher gain intermediate stages as outlined above, four active stages should not be necessary except perhaps in the most extreme high-gain, high-loss cases. Even with higher gain early stages, two-stage designs are impractical for all but the highest gain actives and lowest gain requirements for LE modules.

Except where otherwise noted, most simulations were performed for an overall LE gain window of 40-50 dB with the following constraints and assumptions:

- 70 dBmV total composite power at LE output
- > 45 dB MER performance of full LE
- 26 dB output tilt from 54-1794 MHz (24 dB passive tilt, 2 dB from active components)
- 0 dB input tilt
- 2.5 dB loss at both input and output for diplex filters and other passive elements
- 5 dB (or alternatively 3 dB) minimum insertion loss for a well-matched variable attenuator circuit
- Variable attenuator nominally set 6 dB above minimum to accommodate up to 5 dB gain loss for extreme temperature excursions (+1 dB for safety)
- 1.5 dB minimum insertion loss for equalizer/tilt modules
- ~18.5 W total DC power for downstream amplifiers

## 5.2. Optimizing Variable Attenuator Placement

The first question that we addressed was how to distribute attenuation – namely the placement of variable attenuator(s) as part of an AGC scheme. These could in theory be placed anywhere in the chain, but the practical locations would be between the first and second stage, between the second and third stage, or both with the attenuation split in some manner. The simulation was conclusive on this point – as long as other components are chosen and located properly, the optimal choice is to place any variable attenuation between stages 1 and 2. This keeps the output of the second stage from being overtaxed, and any noise floor concerns are better alleviated by moving a portion of the tilt after the second stage instead of shifting attenuation. This also lowers the overall gain requirement from the actives by a reasonable amount (compared to a split attenuator design). Consider Figure 7, which shows three optimized topologies for a 45 dB gain line extender, with the attenuation distributed as outlined above. Note also that the “Evenly Split” configuration additionally requires several dB more gain from the actives.

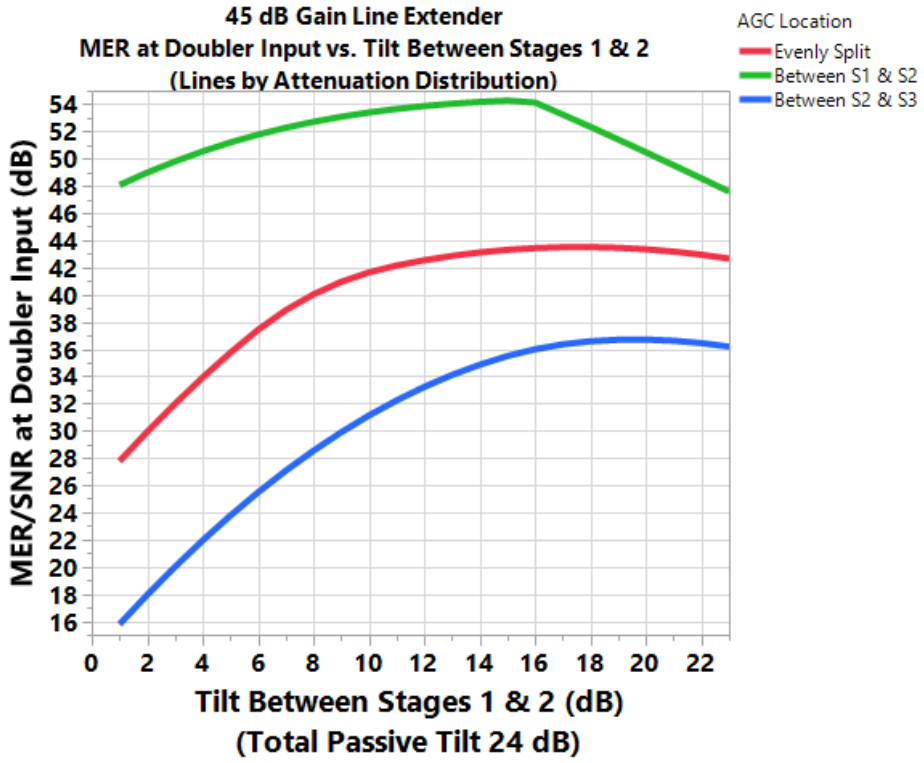

**Figure 7 – Effects of Attenuation Distribution**

This result fits with expectations: regardless of the distribution of attenuation, the output from the first stage remains the same. The only device linearity concern that can be addressed is the second stage's output power requirement. Optimally 100% of the attenuation and loss would be between stage 1 and stage 2 for this reason, but noise-related effects preclude this, so we seek to strike a balance by placing all of the attenuation and the "right" amount of tilt between stage 1 and stage 2.

We found that a useful metric for comparing various configurations was to look at plots of the MER/SNR coming in to the Doubler versus the amount of tilt placed between stage 1 and stage 2. The remainder of tilt is then implied to be between stage 2 and stage 3. Removing the Doubler linearity from the equation (though not its gain, since that informs the gain required from the rest of the chain) allows for the contributions of the various configurations to be more easily distinguished. Plotting MER against the tilt allocation provides a useful way to consider two related dimensions of the problem at once.

## 5.3. Optimizing Gain and Tilt Placement

We were now able to investigate questions about optimal gain and tilt distribution in the LE. Consider Figure 8, which shows a variety of possible gain and tilt distributions, grouped into colors based on which of the first two stages has higher gain. . Two Doubler gain scenarios are considered. One scenario uses a Doubler gain of 21.5 dB and a second uses 28 dB gain. For each Doubler gain scenario we consider the effect of allocating the remaining required gain to the 1st and 2nd stages and use the tilt allocation between stages as the driving variable in the analysis.

The first and most apparent result is the observation that very high Doubler gain is ideal from a linearity perspective. A Doubler with 28 dB gain would enable the rest of the LE to be built with low gain stages without fear of non-linear contributions from the intermediate stage, even with low bias on that

component. With a 28 dB gain Doubler the remaining gain can be evenly split between 1st and 2nd stages, resulting in the blue plot in Figure 8.

Unfortunately, when designing within the legacy DC envelope for line extenders, process limitations constrain the gain to the low 20s. With a reasonable increase in bias voltage and current for the Doubler stage it would be possible to produce a 28 dB gain output stage with similar linearity to existing 12-14 W, 21.5 dB gain designs. That is generally outside the scope of this paper, but it bears consideration for situations where such a design change is possible.

Considering the scenario where the Doubler gain is 21.5 dB, the analysis shows best MER performance with the 2nd stage gain greater than the 1st stage. The various curves account for different levels of gain allocations between the 1st and 2nd stages. Regardless of the split it's favorable to have more gain in the 2nd stage with tilts evenly split between stages, resulting in MER into the Doubler above 53 dB. Placing too much gain in the 1st stage leads to distortion contributions from the 1st stage.

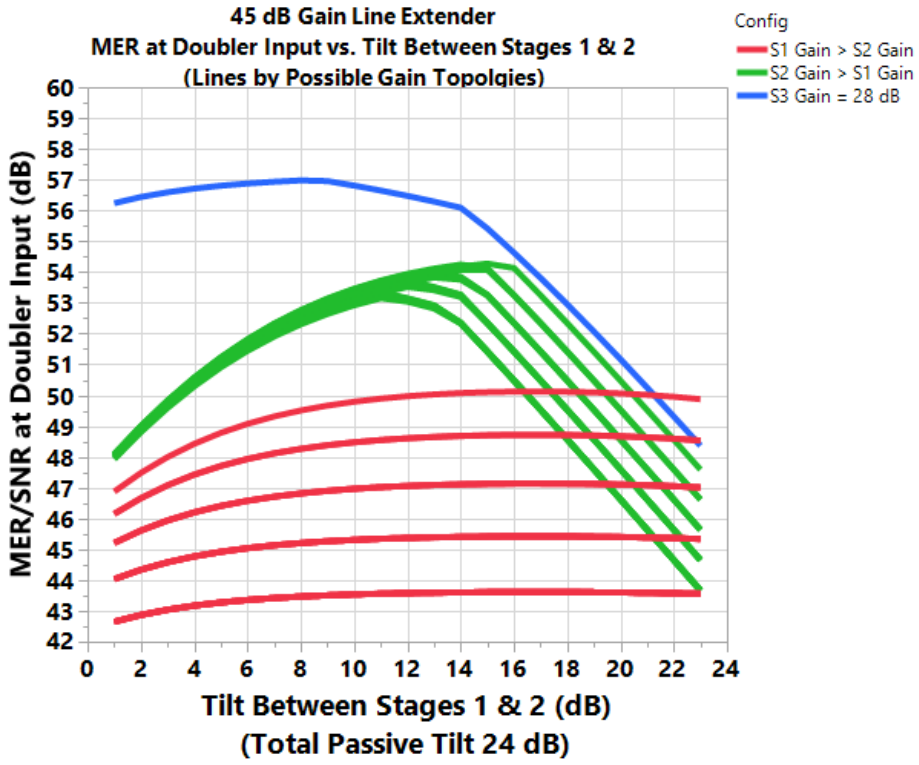

**Figure 8 – Example Gain/Tilt Topologies**

Starting from the known capabilities of the output Doubler, the ideal tilt split and gain of the first two stages can be solved simultaneously. Not surprisingly, given the number of factors which can contribute to degrading the SNR in the line extender, there is no simple set of linear equations which can be derived to produce the correct answer for all conditions. Further, such an answer would remain only a guideline as there are not enough varied active or passive elements available for actual design.

While a direct invocation of the simulation would be necessary to find the exact optimal topology for a given design target, there are two simplified approaches which both give reasonable approximations of optimum LE performance for LE gains in the range of 40-50 dB, given output TCP/tilt and passive loss criteria roughly similar to those outlined above. All gains are at 1.8 GHz:

1) Hold the gain of the second stage (~25 dB) and tilt split (~14/10) constant and allow stage 1 gain to vary
2) Hold the gain of the first stage constant (~19 dB) and allow stage 2 gain and tilt split to vary:

In general, the second approach proves to be more practical. It broadens the window for optimally splitting the tilt and for getting the correct gain. What this implies is that when the device gain varies due to temperature and the attenuator needs to be adjusted to compensate, the shift in performance as the arrangement of gain and tilt becomes "non-optimal" will be minimized. To demonstrate this, consider Figure 9 which shows an estimation of amplifier gain (and passive loss) shifting as a function of increasing or decreasing temperature, and the result of adjusting the attenuator to maintain 45 dB overall LE gain. The gains in this example are 19 dB for stage 1, 25 dB for stage 2, and 21.5 dB for stage 3.

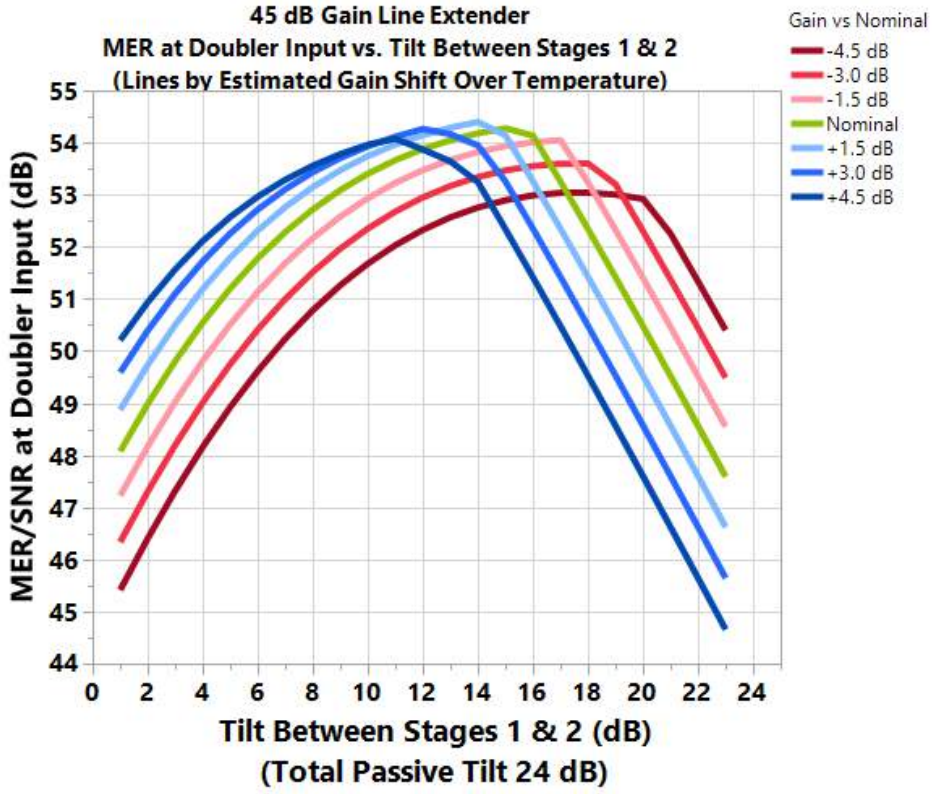

**Figure 9 – Attenuator Compensating for Gain Shifts due to Thermals**

## 5.4. Optimizing Bias Allocation

All the data so far presume some typical biasing for the components in question. Ideally, the overall DC budget for the downstream section of the LE will provide as much DC power as possible to the output Doubler while keeping the first two stages operating at just above the level where they would contribute meaningfully to the overall output SNR. To look at this, we'll consider the second method outlined previously, where stage 1 gain is held constant and stage 2 gain and tilt split are varied. Under these conditions, can any bias be borrowed for the Doubler?

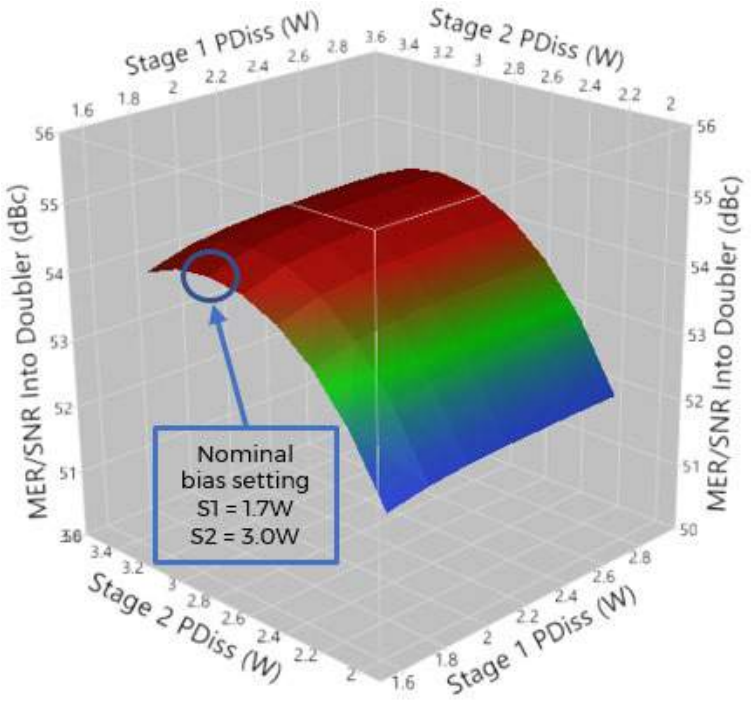

**Figure 10 – SNR Into Doubler as a Function of Stage 1 and Stage 2 Power Dissipation**

Simulation of optimal gain and tilt distribution for a 45 dB gain LE over stage 1 and stage 2 bias can be seen in Figure 10. With the modeled components, it would be possible to extract ~1 W from the second stage bias and transfer it to the Doubler, presuming that a change of incoming SNR to the Doubler from ~54 dB to ~52 dB would not negatively impact output performance. In our model, increasing the Doubler bias by 1 W was break even with the decreased incoming SNR to that stage, because the Doubler was already running at an optimized bias condition.

Optimizing the bias allocations within a given DC budget can be a sensitive process and would be best performed on prototype boards to directly observe the crossover point where improvement in Doubler linearity no longer overcomes degradation in earlier stage linearity.

It's worth noting that in theory, the bias and gain configurations could be simultaneously optimized to produce a slightly more favorable result. The devices were nominally biased well already, and the model would need to be significantly more precise throughout to benefit from such a small optimization.

## 5.5. Other Effects

There are a few other effects which can alter the model that are worth mentioning, the first of which is noise figure. The influence of noise figure for the input device is understood, and while it's relatively small, it grows larger as the overall LE gain increases or if too much tilt is placed after the first stage amplifier. For example, an optimally constructed 48 dB overall gain LE will see a ~0.5 dB change in MER coming into the Doubler for a 1 dB change in stage 1 noise figure. When considering a 42 dB gain LE, the change is only ~0.2 dB. More surprising is the fact that the second stage noise figure should also not be ignored. In this case the discrepancy between low and high gain LEs is more stark – at 42 dB overall gain, the effect of stage 2 NF is less than 0.05 dB, while at 48 dB overall gain, the effect is roughly 0.5 dB MER per 1 dB NF. This occurs because the optimal distribution of tilt and attenuation

pushes the input signal to the second stage as low as possible to avoid non-linearities behavior in that stage.

One last effect worth mentioning is that of the minimum insertion loss of the variable attenuator. We have made a very conservative assumption that this would be around 5 dB, but it is certainly possible with careful design to craft an attenuator with lower insertion loss (IL). In doing simulations with a minimum IL of 3 dB, we found that while it is overall a more favorable configuration, it does not provide as much benefit as one might expect. Less attenuation required between the first two stages allows for more tilt to be placed before the second stage and enables the use of a lower gain input stage (or a lower gain second stage, although this approach is less beneficial per our analysis). Excepting some fringe cases, we found that the overall MER improvement into the Doubler from a 2 dB change in attenuator minimum loss was on average about 1 dB. A lower IL for the attenuator does enable more design flexibility, provided it remains well-behaved through its full attenuation range and is useful for incrementally improving linearity.

## 5.6. Simulation Summary

In the end, it's impossible to provide hard and fast rules for overcoming all the challenges that designing a line extender entails. However, some guidelines have been provided for managing the interrelated set of variables that must be considered. We hope that these will prove useful in the design of line extenders for 1.8 GHz going forward. The simulations helped us identify the concept of developing a family of interchangeable downstream amplifier components.

## 5.7. Resulting LE Performance

Using the measurement-based models we considered overall cascaded performance as a function of the tilt spilt using the previously described parameters. The results are shown in Figure 11. Variable attenuation is placed between stage 1 and stage 2. Gains for stage 1, stage 2, and stage 3 are 19.0 dB, 25.0 dB, and 21.5 dB respectively. Coaxial port output TCP is set to 70.0 dBmV and downstream consumption in amplifier components is limited to 18.5 W. Upstream amplifier component prototypes capable of 40 dB gain and 69 dBmV TCP from 108 MHz through 684 MHz consumed 3.5 W. This brings the combined DC consumption to 22 W. The results show relatively consistent MER performance > 45 dB with the best option being an even splitting of the passive tilt.

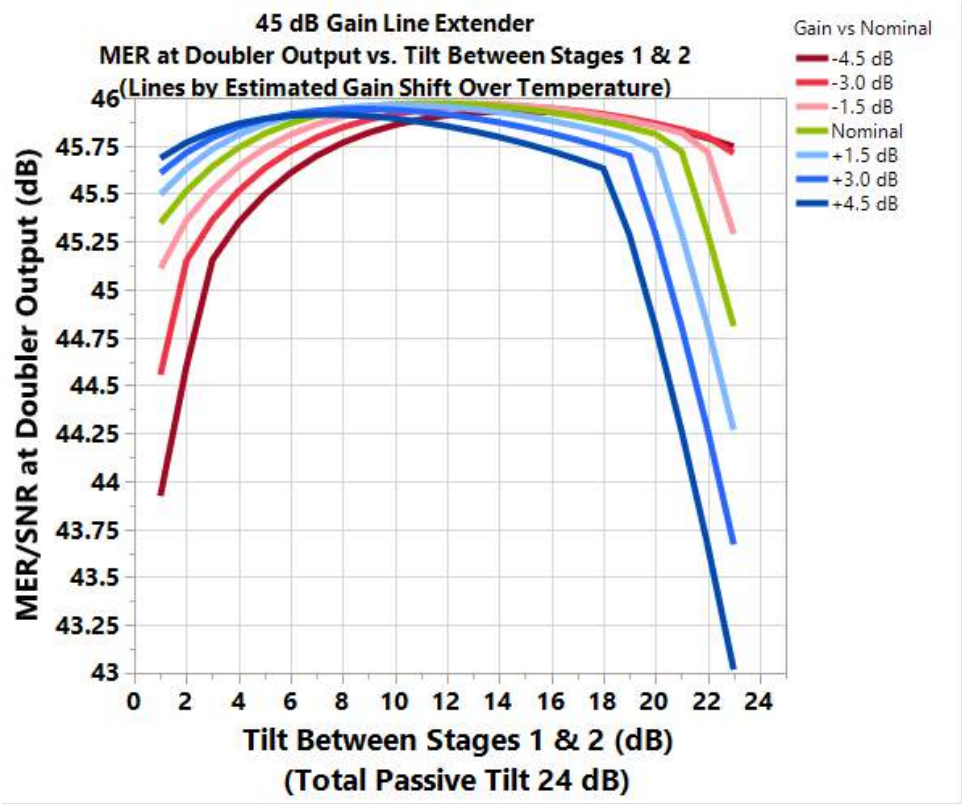

**Figure 11 – Modeled MER Performance of 45 dB Line Extender**

### 5.8. Higher Output Levels

Although the focus has been on staying within the existing LE power budget, it is feasible to increase the Tx TCP from the Doubler by adjusting the design and biasing scheme. Prototype Doublers have shown ability to output > 77 dBmV TCP but require near the maximum SOT115 power dissipation of 18 Watts. Getting higher output levels would best be approached with a new packaging design for better thermal and RF characteristics.

## 6. Noise Considerations

### 6.1. Downstream Point of Entry

Thus far we have focused on optimum design for maximizing LE Tx power and MER performance within legacy boundary conditions. The recent DOCSIS 4.0 specification establishes an input power range of +15 to -30 dBmV per 6 MHz channel. Low input levels are likely for distant reaches in a coaxial plant due to a combination of lower-grade coaxial cable, unfavorable tap location, and long drop length. In these cases, the overall SNR performance will be dominated by the Rx sensitivity and not distribution plant MER contributions.

To address the situation, we designed a low noise amplifier (LNA) stage with an integrated low loss linear bypass switch suitable to handle the wide input dynamic range. The bypass mode can be activated about midway within the range thereby alleviating the need for the LNA to have excellent linearity over the full range of input powers.

We used a linear pHEMT process with good noise characteristics. The process is consistent with a low-cost high-volume environment, not unlike mobile device applications where higher performance GaAs processes provide favorable cost-benefit to the network.

Simulated noise figure for the LNA path was <1.7 dB with a forward gain of 17 dB. Considering a secondary gain stage with noise figure of 5.0 dB, the overall noise figure can be < 2.0 dB. Comparing to today's cascaded noise figure of 4.5 dB, it's possible to improve the SNR performance, and hence the achievable data rate, for some locations at extreme locations in the plant. Just as in the case of maximizing Tx performance for added link budget with careful design, improving receiver sensitivity provides similar opportunity. Although improvement in distribution plant MER provides benefit across the serving area, input noise figure improvements at the point of entry are particularly helpful at extreme network locations. Improved receiver sensitivity is available to help overcome the significant link budget implied with Extended Spectrum deployments over lossy legacy infrastructure.

### 6.2. Upstream

PHEMT devices feature high intrinsic transconductance and excellent bandwidth. However, compared to other process technologies they unfortunately have poor 1/f noise characteristics. Often, 1/f noise corners for pHEMT devices can be around 30 MHz The 1/f noise corner depends on semiconductor start material properties which are generally not well controlled by epi vendors and fabricators alike who commonly target much higher volumes not sensitive to 1/f considerations. For these reasons pHEMT devices make inconsistent input stage devices in upstream applications. They may make suitable output sections for upstream applications since noise performance is dominated by input stage contributors. On the other hand, bipolar devices have 1/f noise corners well below 100 KHz and are better choices for input stages in upstream amplifiers.

## 7. Conclusion

Migrating to an extended spectrum architecture will require careful network planning and design of network elements. Given the magnitude of overcoming the substantial increase in passive losses we sought to design a family of components that could best serve the industry in this task. As with past upgrade cycles, newer component technology is available to help facilitate an upgrade with minimal disruption to existing networks. These technologies are best utilized by opening the design window to optimally allocate gain, bias, attenuation, and tilt in ES equipment design.

## List of Figures

# 1. Introduction

All service providers and retail businesses experience crime in the form of fraud. Fraudsters seek to monetize cybercrime and other crime by targeting our companies, our partners, and our customers. Annual fraud losses in the US represent a staggering $170B across all fraud types. Many of these fraud types apply to the provider's technical and financial operations including card fraud($32B), online fraud($26B), identity fraud($16B), check fraud($7B), synthetic fraud($6B), account takeover($5B), and new account fraud($3B)[1]. The methods to execute fraud vary from simple to very technical. In the fraud environment operators face today, fraud incidents are often proceeded by cybersecurity events. This requires a greater coordination and collaboration between fraud teams and cybersecurity teams. The fraudsters are creative and coordinated – they attack all aspects of our businesses, including care channels, video, wireless, Internet, mobile and voice services. This paper provides an overview of some examples of fraud experienced by cable operators, and then proposes a framework for fraud and a taxonomy, in order for it to be effectively described and discussed.

What is fraud? Why is it important? Operators are seeing an increase in external fraud resulting in service theft, device theft, and brand damage. In some cases, bad actors use compromised personal and payment information to create fraudulent accounts, or they may use Internet fraud resources to create fully synthetic identities. They may use modified devices to provide video and Internet services to customers they are servicing. Other approaches have been identified as well. In some cases, the subscribers working with the bad actor believe they are working with their actual carrier. Both wireline and wireless operators are being targeted across the globe.

There are many types of fraud being executed against cable operators and their partners. These may target the operators themselves, their customers, or even their business partners. We're focused on fraud that impacts the operator's service and the consumers of those services.

Different industry segments and their products experience fraud differently. Voice, internet, mobile, email, and video fraud all have characteristics that are unique to the operator and the product line. Supply chain and fulfillment may be part of fraud, as well – such as when a fraudster arranges for cell phones to be shipped to a certain location or sets up a new cable account resulting in shipment of cable modems and set top boxes.

# 2. Example Fraud Scenarios

This section examines three scenarios identified by service providers as being fairly common. Fraud follows the business context. It will be aligned and in context of the service or product being offered.

## 2.1. Fraud Example 1 – Account-Based Fraud

New accounts can be fraudulently created. These accounts are usually created to steal service. In these cases, the fraudsters often offer a product and service at a substantially reduced price. The fraudster will attempt to set up many fraudulent accounts to service their customers. These fraudulent accounts are set up with either stolen customer information or synthetic identities created for this purpose and to perform other fraudulent activities. In some cases, synthetic identities are set up and managed for years, for the sole purpose of defrauding companies over the lifetime of the synthetic identity.

### 2.2. Fraud Example 2 – Credential Based Fraud

A second common fraud leverages existing customer credentials. A common scenario starts with "credential stuffing" [2] and ends up as fraud against the customer or service provider. A customer's credentials are leaked from one of the "credential spills" that happen every month across the globe. These credentials are picked up by "credential testers," who will test the credentials against many websites, including those of the operator. If the credential is tested as valid on the operators' network, the "credential tester" will then post the credential for sale on a darknet marketplace. The credential is then bought by someone intent on committing fraud against the operator. The fraudster will use the credential to access the account and defraud the operator. This may be by ordering additional devices (mobile phones, set-tops, or cable modems). In the whitepaper "The Economy of Credential Stuffing Attacks" by the Insikt Group and available at Recorded Futures [3], the authors note that with an investment of $550 a "credential tester" can make up to $19,000 doing just the testing and sales of credentials in a matter of several weeks to months. A very lucrative investment indeed! This example helps illustrate the importance of collaboration between cybersecurity and fraud teams in deterring both the testing of credential as well as the fraud enabled by the validated credentials.

### 2.3. Fraud Example 3 – Brand-Enabled Fraud

Another example of fraud is one committed using the operator's brand to defraud the customer. An example of this is a fraudster who calls the operator's customer, poses as an operator representative and touts a special offer between the operator and a selected brand of gift cards. The fraudster will inform the customer that if they purchase gift cards and call back, they will reduce the customer's monthly bill substantially. Of course, there is no such offer. If the customer falls for the scam they will purchase the gift cards, call back a number they are provided, provide the information to the fraudster and the fraudster will claim that their bill will be lowered. When the actual bill from the operator arrives, there is no change. The customer calls the operator and then discovers the fraud, which frustrates the customer and damages the operator's brand.

## 3. The Business Context

There are many channels through which these frauds are conducted, which are depicted in Figure 1. Fraudsters may access the customer's operator web portal. They may call in and work with the interactive voice response (IVR) service or a customer care agent and escalate the call to full social engineering through direct, in-person interaction with retail employees, at kiosks or stores. On the other side, fraudsters may advertise services through social media, calling potential victims, or even doing door-to-door sales. Also, word of mouth by victims can lead to additional fraud: "Hey, I got this great deal on cable from this guy! Saved me lots of money. You should check them out. Here's the phone number."

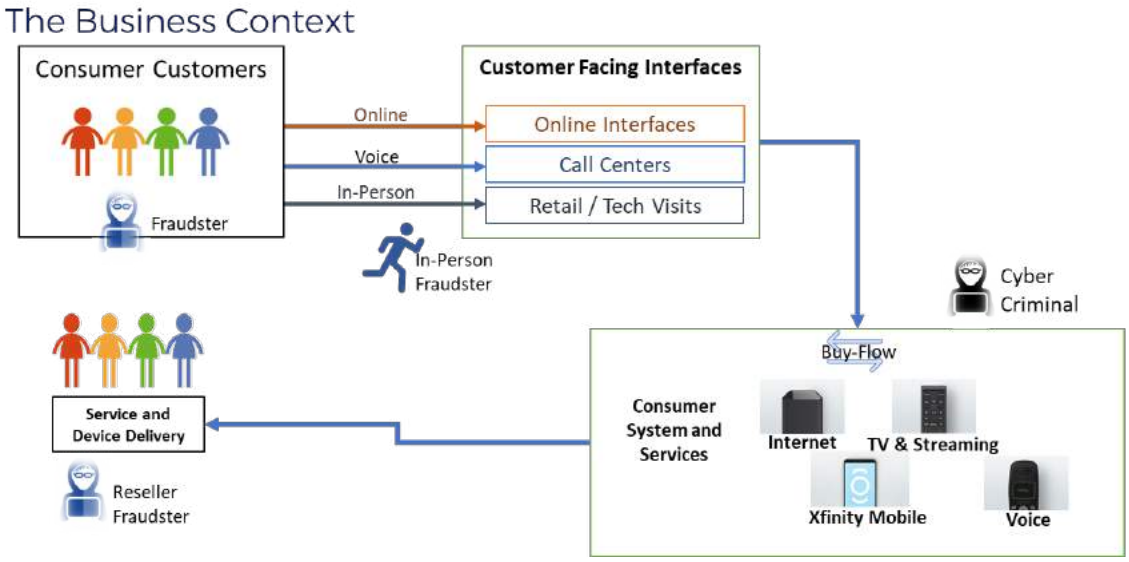

**Figure 1 - Fraud in the Business Context**

It's common to believe some of these frauds are victimless crimes. That is simply not the case. Service provider losses can be extensive and include theft of service, theft of equipment, loss of funds (through, for example, refund fraud), etc. Moreover, detecting, investigating, mitigating, and preventing fraud is quite expensive for operators. There are obvious victims, of course: victims of identity theft, stolen credit card information, cloned phones or cable modems, and more. One of the important aspects to keep in mind about frauds in this space is that they are usually done en masse. A given fraudster is likely to conduct hundreds or thousands of these frauds at a time, possibly against multiple service operators.

## 4. Fraud vs Cyber Security

There are many types of fraud, some very simple, some very complex. The Association of Certified Fraud Examiners (ACFE) defines fraud rather broadly: "In the broadest sense, fraud can encompass any crime for gain that uses deception as its principle modus operandus." Fraud involves, at some level, misrepresentation of fact in the course of conducting crime. This is an important distinction, in comparison to cybercrime. Cyber-attacks may, or may not, involve fraud. Fraud against an operator or its subscribers may or may not benefit from illegally obtained cyber or private information (though they often do).

One of the challenges that fraud and cyber teams face is the overlap between the work of the fraud professional and the work of the cyber security professional. In the hands of a technology savvy fraudster, the fraudster will often start their fraud attack as a cyber security attack. The cyber security attack, or a series of cyber security events, will end in a fraud event. For an operator whose products are primarily technology devices and services delivered via a technology base, the lines between what is a fraud event and a cyber security attack can be blurred. Given this context, there needs to be much greater collaboration between the cyber security teams and the fraud teams.

## 5. A Fraud Framework

An important distinction from the ACFE is that there are three primary types of fraud. *Internal fraud* is conducted typically by insiders and benefiting by the access those employees, partners, or contracts have to proprietary and unique resources. This is also known as *occupational fraud*. Another type is *external fraud* which is conducted by outsiders. Another large-scale distinction, *individual fraud,* is that fraud may be targeted against specific individuals. Operators can be impacted by individual fraud when their employees may be targets of individual fraud as part of attempts to defraud the operator. Fraudsters may also use an operator's services, reputation, or information illicitly to conduct individual fraud against subscribers. All three of these types of fraud are important to network operators.

In the business of a system operator, there are many products, and the technology platforms for service and device delivery are very complex. The "Fraud Framework" illustrated in Figure 2 provides a taxonomy for examining the customer contact points through which fraud will flow, as well as specific product areas, each with its own fraud challenges.

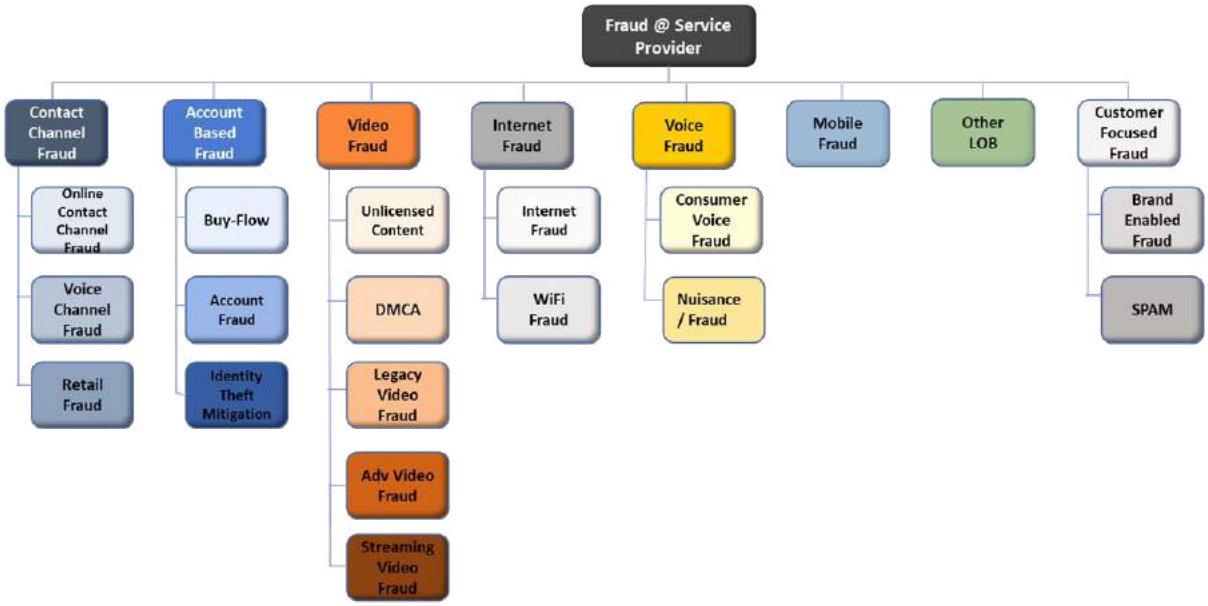

**Figure 2 - A Fraud Framework**

In collaboration between service providers, several fraud categories have been identified. Here is a list of only a few:

- **Contact Channel Fraud** – This is fraud that has as an entry point to the contact channels the service provider has created for its customers. The contact channel type will determine the class of fraud that is attempted through a contact channel. For the online contact channel, the attacks include credential stuffing, brute force attacks, and other cyber-based incidents. The voice contact channel will experience fraud attempts using social engineering as the primary tools. The retail contact channel will include social engineering, identity theft, synthetic identity, and cyber-attacks as the tools of fraud.
- **Account or Subscriber Fraud** - As described in the introduction, compromised private information, such as a Social Security number and payment form, are used to establish an account with a service provider. The payment method is fraudulent and is used to bypass the deposit

requirements. The fraudster resells the account with an end-user who pays for access. The fraud in this case is usually a representation, by the fraudster, of somebody else. Sometimes, there can be multiple frauds – the fraudster represents to the legitimate cable operator that they are a given party using stolen personal data, and represents to the end customer that they are an authorized agent or even employee of the cable operator.

- **Video Fraud –** Video fraud can manifest itself in many forms, including unlicensed content, notices from the Digital Millennium Copyright Act (DMCA) that the operator needs to process, legacy and advanced set-tops being used for illegitimate video service delivery, and finally streaming fraud enabled by credential sharing or credential fraud. There are many ways to monetize stolen content -- probably as many as there are to steal the content in the first place. The fraud here is that people distribute property and take payment for which they don't have the rights. Like voice fraud, there are several industry groups seeking to address video piracy and make the associated frauds simply unprofitable.
- **Internet Fraud –** Internet fraud includes the cloning or hacking of cable modems, as well as the illegitimate use of WiFi hotspots provided by the service provider.
- **Voice Fraud and Nuisance Voice** - There are many frauds conducted using fixed and mobile telephone networks. These range from toll fraud to spam to phishing and more. There are already several government agencies in many countries and group forums where operators, law enforcement, and regulators collaborate to address voice fraud. Voice fraud is obvious when someone calls a victim and misrepresents themselves. However, spoofing an originating phone number belonging to a known brand that is not owned by the fraudster to connect to a consumer is an effective way of committing fraud against unsuspecting consumers.
- **Mobile or Cell Phone Fraud** - This includes subscriber fraud, as described previously; it also includes cell phone cloning fraud. A common example today is SIM hijacking or SIM swapping, where a subscriber identity module (SIM) uses credentials from a legitimate subscriber's mobile phone's SIM card to activate one or more other cell phones. Because of the need for mobile service to support roaming, mobile networks have unique vulnerabilities to fraud that may impact multiple operators.
- **Customer-Focused Fraud** – in this class of fraud, the brand of the operator is used to gain confidence with the consumer either via voice contact or email. The confidence is used to defraud the consumer.

## 6. Details Relevant for Explaining Specific Frauds

Fraud is complicated. Many frauds are described by the Association of Certified Fraud Examiners and other groups. Two particularly good resources for understanding frauds are the Open Risk Manual [4] and the "Framework for a Taxonomy of Fraud" [5] developed by Stanford Center on Longevity, in collaboration with the Financial Industry Regulatory Authority (FINRA). Yet, cable operators experience frauds that are not even described by these resources. Our adversaries are very creative at finding ways to extract funds from our companies and our customers.

Can frauds be categorized and described in detail? What are the details that would be useful to cyber security and fraud professionals in describing types of fraud or related cybercrimes?

Like the frauds themselves, this gets complicated. However, an ontology and a taxonomy can be developed to describe and communicate about frauds. These details start with just basic descriptions and understanding the goal of the fraudsters. It's also useful at this level of detail to specifically identify the fraud that is being performed – exactly how is the criminal misleading their target, misrepresenting themselves, or otherwise specifically breaking the law. Who are the targets of the frauds and what type of fraudsters execute the fraud? (Yes, there are different skill sets and, as a consequence, different types of

 

fraudsters.) It is useful to specify the damages to customers, the operator, or other parties (such as the government or vendors). Then there are details of the fraud methods themselves. These may include:

- Tactics, techniques, and procedures (TTPs) used to conduct fraud (TTP is also a cybersecurity term)
- Target Orientation and Details
- Methodology Details
- Fraud Indicators
- Physical/logical locations of data centers and other facilities
- Hacking tools used to execute the fraud (credential stuffing tools or markets, phishing frameworks, social engineering tools, etc.)
- Information on dark markets and Internet marketplaces selling compromised credentials or other enabling information for the fraud
- IP addresses and other IT infrastructure details

Then there are information elements useful to the examiners and investigators researching the fraud: Priority of the investigation, interested industry partners (perhaps other operators also being attacked), information sharing guidelines (what can or cannot be shared outside a company, for example). There are details related to enforcement actions such as prosecution guidelines, law enforcement or regulator contacts, and identities of investigators themselves. Finally, it is useful to understand the statistics and trends of the given fraud. This may include damages per event, cost to mitigate per event, estimated number of events annually, known cases, and the scale of the fraudster ecosystem perpetrating the fraud. Collected over time, these details can be used to identify trends.

This information can be collated and then presented in a very concise manner to quickly describe a type of fraud. For example, consider the description in Figure 3, below, of subscriber credential attacks as part of the “Online Contact Channel” category. In one page, specific information is presented that specifically conveys what a subscriber credential attack looks like. This is, of course, simply illustrative and lacks details of an actual fraud.

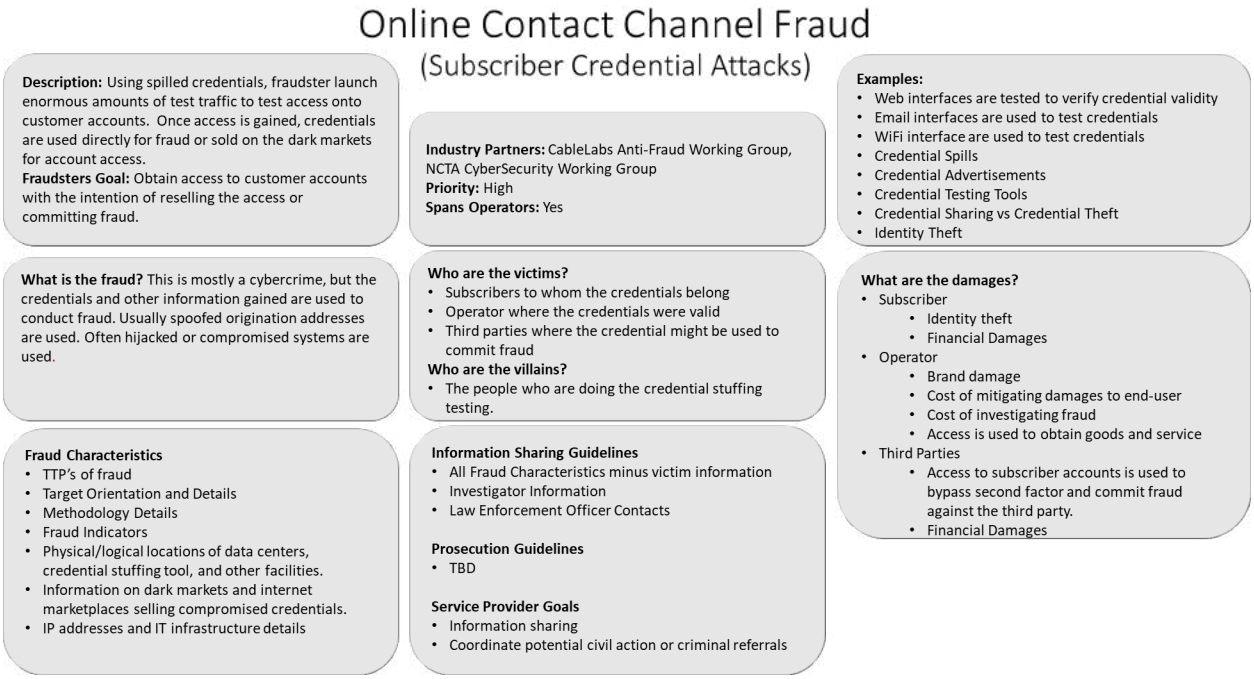

**Figure 3 - A Taxonomy Example of the Online Contact Channel Fraud**

## 7. What Use is a Taxonomy?

A taxonomy, defined loosely here as a classification of fraudulent activities, can be very useful. It provides a way to specifically describe a fraud, which can be useful for deciding how to respond, and possibly even to support workflow automation. The "Framework for a Taxonomy of Fraud" [5] provides an excellent example of how this might be done by actually codifying fraud. Their system formalizes the ideas above and uses codes to classify the fraud and adds tags for describing the incident, victim, and perpetrator. An example they show in their report is "1.7.1. AD:IE. PS:M. MT:PC. FV. EF. MP." This string of characters is translated as:

1.7.1-> Classification Number

1->Individual Financial Fraud

7->Relationship & Trust Fraud

1-> Romance Scam

AD:IE -> Method of Advertising Fraud(AD): Internet, email(IE)

PS:M -> Purchase Setting(PS):Mail(M)

MT:PC -> Method of Money Transfer(MT): Personal Check(PC),

VT:FV, EF -> Victim Tags(VT):Female Victim(MV), Elder Victim 65+((EV)

PT:MP -> Perpetrator Tags(PT):Male Perp(MP)

While it may not always be beneficial to develop or use such a proforma format, the notion of specifically describing fraud is clearly useful for ensuring accurate communications between professionals investigating and prosecuting frauds. A taxonomy allows very clear discussion of exactly the nature and method of fraud. This can help operators solicit input from other operators to see if a given actor is conducting similar fraud in other markets, for example.

We've also found that a taxonomy can help to provide an organizational structure for how operators respond to fraud. Once they've codified what frauds they experience, they can organize accordingly. Moreover, the taxonomy can be useful for ensuring resource allocation and that workflows are optimized to deal with specific frauds.

## 8. Conclusion

Fraud is a challenge to all operators and will continue to be. It has a large impact to services providers who are at risk for both financial fraud and technology enabled fraud. A fraud taxonomy provides a way to classify a complex fraud system and improves the industry's ability to communicate, discuss, and improve the service provider's fraud detection and prevention capabilities. While an individual fraud attempt aimed at a service provider is targeted to that operator, the tools, techniques, and procedures(TTP) are common and shared between the fraudsters. The fraudsters share TTP's and so should we as an industry. The authors are seeking collaborators to take this work to greater levels of detail.

## List of Figures

# 1. Introduction

Laws and regulations protecting privacy are not new. In Western civilization, case law on privacy extends back to the early 1400's, when the law prohibited eavesdropping. But what is new is the emergence of comprehensive privacy laws and their supporting regulations. These statutory schemes create broad rights for citizens and impose significant obligations on businesses with respect to collection, use and protection of personal information. Steep non-compliance penalties and short implementation timelines require businesses to build robust compliance programs.

In a global economy, building these new compliance functions is no easy task: each new comprehensive privacy law is different from the last, creating a challenging environment for multi-state or multi-national enterprises. New rights and obligations also have the potential to provide new lines of attack for fraudsters and can limit the ability to detect and prevent fraud. Finally, the global pandemic brings a heightened challenge and creates even more opportunities for bad actors to compromise privacy and evade consequences.

This paper examines two specific privacy requirements in light of an operator's need to conduct fraud detection, mitigation, investigation, and prevention. Considerations include anti-fraud information collection, sharing, and action. These areas, indeed anti-fraud operations in general, are often overlooked as risk and legal departments draft compliance program guidelines.

# 2. Comprehensive Privacy Laws

On May 25, 2018 the General Data Protection Regulation (GDPR) came into effect in the European Union, ushering in a new era for privacy protection: The Age of the Comprehensive Privacy Law. Rather than addressing privacy and data protection in an individual business sector or activity, a comprehensive privacy law grants citizens global control over the collection and use of their personal information. Broadly speaking, these rights allow citizens to access their data, understand how it is used and who it is being shared with, correct errors, restrict use, and require deletion.[1] New business obligations are also part of the landscape, generally requiring greater transparency as to data held by the business, limitations on processing and use, and enhanced duties on those who would use the personal data of their citizens.[2]

These laws require new regulations and new regulators, which in turn requires that businesses create new compliance programs to ensure that they do not fall afoul of another commonality of these laws: substantial penalties for non-compliance.[3]

In the United States, comprehensive privacy law at the state level is moving quickly. California's Consumer Privacy Protection Act of 2018 (CCPA) was the first such law to see the light of day – but more are coming. According to the International Association of Privacy Professionals (IAPP), sixteen

[1] The International Association of Privacy Professionals (IAPP) has identified commonalities that apply to these privacy laws: Access to collected data, access to shared data, right to correct data, delete data, restrict the use of personal data, data portability, the right to opt out of use, prohibit automated decision making, and whether or not a consumer can sue for violations of the law, also referred to as a private right of action.

[2] These obligations as identified by IAPP include: Age based opt-in, notice and transparency requirements, data breach notifications, risk assessments, prohibitions on discrimination, purpose limitations, processing limitations, and heightened or fiduciary duties for storage and use of personal data.

[3] General Data Protection Regulation, Chapter VII, Article 83; California Consumer Privacy Act of 2018 1798.150, .155

states have a comprehensive privacy bill at some stage of their legislative process. In addition to California (which is likely to revise the 2018 CCPA Act, which just became effective, via the California Privacy Rights Act of 2020), Maine and Nevada have already passed legislation. Other states with legislation in progress are Arizona, Connecticut, Hawaii, Illinois, Iowa, Louisiana, Maryland, Massachusetts, Minnesota, Nebraska, New Hampshire, New Jersey, New York, North Dakota, South Carolina, and Texas. Many of these states have more than one bill under consideration. Legislation was raised in eleven other states. This is summarized in Figure 1 (used with permission of IAPP). See the IAPP website for current details (https://iapp.org/resources/article/state-comparison-table/).

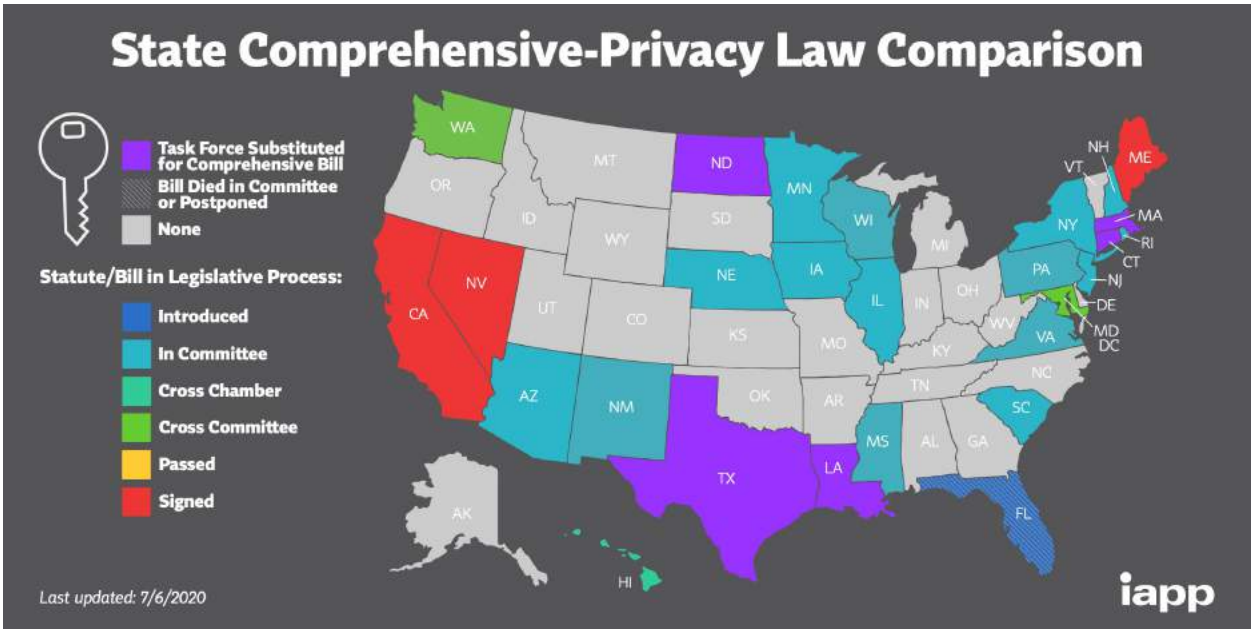

**Figure 1 - Status of US state level comprehensive privacy legislation**

Simply put, merely keeping up with all of the state legislative activity is a daunting task.

One of the challenges operators face is that different jurisdictions (*e.g.*, Europe, Canada, different states, etc.) have enacted and are in the process of drafting and/or enacting different laws, so there will be multiple frameworks to apply depending on the context of the private information being protected and the regions in which it applies or exists. For example, consider a seemingly simple concept like the definition of personal information. The GDPR defines personal data as:

any information relating to an identified or identifiable natural person ('data subject');

PIPEDA is equally brief in its definition of personal information:

information about an identifiable individual.

CCPA is considerably more verbose:

"Personal information" means information that identifies, relates to, describes, is capable of being associated with, or could reasonably be linked, directly or indirectly, with a particular consumer or household.

in fact, the full text of the CCPA definition extends to some 238 words, reproduced in the footnote below.[4]

The regulatory process that follows the enactment of the law adds to the complexity of the compliance landscape. The rulemaking process for the CCPA recently came to a close, six months after the underlying law came into effect.

In California, the cost of initial compliance with the law was estimated at a staggering $55 billion. Depending on the number of firms ultimately deemed to be covered by the CCPA, the ongoing annual compliance is estimated to be between $466 million and $16.4 billion.

In addition, once laws are enacted, court interpretations of those laws will doubtless vary. This paper provides examples of the challenges of compliance with the variety of privacy laws found in the CCPA (which may change again in November), the GDPR (which, while focused on data protection, does address privacy), and Canada's Personal Information and Electronic Documents Act (PIPEDA).

Complexities aside, the intent of a comprehensive privacy law is to allow a citizen greater visibility and control over the use of their personal data and to require businesses to focus attention and resources on the protection of that personal information. However, as written, these laws may actually make that task more difficult.

## 3. Comprehensive Privacy Law vs. Fraud Detection and Prevention

> Fraud (n): *deceit, trickery.* Wrongful or criminal deception intended to result in financial or personal gain.[5]

The data ecosystem of privacy law between company and citizen customer has a third actor lurking in the shadows: fraudsters. Such individuals, criminal rings, and nation-state actors all use the same basic

---

[4] '(o) (1) "Personal information" means information that identifies, relates to, describes, is capable of being associated with, or could reasonably be linked, directly or indirectly, with a particular consumer or household. Personal information includes, but is not limited to, the following:
(A) Identifiers such as a real name, alias, postal address, unique personal identifier, online identifier Internet Protocol address, email address, account name, social security number, driver's license number, passport number, or other similar identifiers.
(B) Any categories of personal information described in subdivision (e) of Section 1798.80.
(C) Characteristics of protected classifications under California or federal law.
(D) Commercial information, including records of personal property, products or services purchased, obtained, or considered, or other purchasing or consuming histories or tendencies.
(E) Biometric information.
(F) Internet or other electronic network activity information, including, but not limited to, browsing history, search history, and information regarding a consumer's interaction with an Internet Web site, application, or advertisement.
(G) Geolocation data.
(H) Audio, electronic, visual, thermal, olfactory, or similar information.
(I) Professional or employment-related information.
(J) Education information, defined as information that is not publicly available personally identifiable information as defined in the Family Educational Rights and Privacy Act (20 U.S.C. section 1232g, 34 C.F.R. Part 99).
(K) Inferences drawn from any of the information identified in this subdivision to create a profile about a consumer reflecting the consumer's preferences, characteristics, psychological trends, preferences, predispositions, behavior, attitudes, intelligence, abilities, and aptitudes.

[5] https://www.lexico.com/en/definition/fraud

approach to access the value contained within that ecosystem: they lie about their identity. Using a combination of personal data gathered from public and stolen private sources as well as purely synthetic identities, fraudsters attempt to deceive one side of the transaction into believing that they are the other expected actor, and then extract the value in the transaction for themselves.

Preventing such attempted deception is at once simple and complex: the key lies in having sufficient personal information about the other actor in the transaction to distinguish a fraudster from a legitimate actor. Techniques for accomplishing this range from a simple picture ID check by a retail clerk to sophisticated big data solutions that evaluate the risk of a transaction based on hundreds or thousands of data points processed by sophisticated algorithms. Simple or complex, the core component of every prevention technique is the use of personal information to disprove the fraudster's impersonation of the legitimate actor.

Comprehensive privacy laws can be used as both sword and shield to a fraudster. Offensively, the right to know can be used to gain information about an individual to make impersonation harder to detect. Defensively, fraudsters can use the transparency, opt-out, and deletion rights of the new laws to hinder or evade detection and to determine what data is being used to detect them.

## 3.1. Right to know

Citizen rights under comprehensive privacy laws start at a common point: in order to exercise the other rights granted, it is important for the citizen to know what personal data a given company is storing about them. Therefore, the first right granted under a CPL is the right for a citizen to require a company to provide a record of that data to the citizen. This represents a brand-new opportunity for fraudsters to accumulate the information necessary to impersonate their targets.

How this is done was documented by James Pavur and Casey Knerr at Blackhat 2019. In their seminal white paper, *GDPArrrrr: Using Privacy Laws to Steal Identities,* they show the weaponization of privacy tools and laws, using GDPR "right to know" requests on 75 companies, and providing only publicly available information about the subject as authentication. The GDPR right to know is one of the basic data subject rights; willful failure to comply with this requirement can subject a company to a penalty up to the greater of 20 million euros or 4% of the firm's annual worldwide gross revenue. Given the severity of the penalty for non-compliance, it is perhaps unsurprising that some companies erred on the side of compliance and divulged at least a subset of the requested personal information.

James and Casey then used the data from the responses to craft 75 additional right to know requests. Enriched with the data from their initial harvest, these requests were much more productive. They received 10 digits of credit card numbers, expiration date, login credentials for websites, educational test scores, complete hotel records, dating profiles, purchase histories, and much more.

## 3.2. Right to be forgotten

> Fool me once, shame on you. Fool me twice, shame on me… but what if I had to forget that you fooled me?

Some of the citizens' rights and business obligations created by new comprehensive privacy laws are being misused by bad actors to both further their fraud schemes and to escape or evade fraud detection. Fraudsters can leverage new consumer rights that commonly include access to collected data, access to shared data, correct data, deleting data, opting-out of use, and prohibited automated decision making. Business obligations can also be abused including notification and transparency requirements, purpose limitation, and processing limitations.

For example, under GDPR, bad actors use the right to know in order to gather personal information of their targets. They also have used the right to be forgotten to conceal their identities and reduce the effectiveness of notice, public safety, and fraud prevention tools.

Part of the challenge is that consumers don't have a specific, immutable identifier on which operators can tie personal information. Thus, it's very hard implement consumer interfaces to provide privacy management features that are secure – that is, hard to misuse.

In addition, privacy laws limit fraud investigations by limiting both what information is collected and how an operator may use it. For example, GDPR contains a limited exception to share information without consent when "processing is necessary for the purposes of legitimate interests pursued by the controller or by a third party". Preventing fraud has been defined as a legitimate interest. However, the sharing exception language was not carried over into the subscriber's right to have their information deleted.

The CCPA also includes several exceptions for the collection, retention, and disclosure of personal information that intersect with anti-fraud efforts. These are:

- To detect data security incidents, or protect against fraudulent or illegal activity;
- To comply with laws;
- To comply with government investigations;
- To cooperate with law enforcement; and
- To exercise the defense of legal claims, including evidentiary privilege.

Moreover, there are additional areas that must be considered that are not well defined within current laws. Privacy is transitive. So, as fraud investigations are conducted, while information that is shared with law enforcement and other governmental agencies may be in compliance with governmental investigations, does information shared with private entities that may benefit from receiving the information in relation to their own fraud investigations (such as other operators) give rise to privacy law violations? Other laws may also govern the disclosure and use of private information, such as the U.S. Fair Credit Reporting Act, which may govern how an operator may use information about prior fraudulent activity to deny a person service.

An awkward question is whether fraudsters themselves enjoy privacy protection. A clear example of contention, for example, is the case where fraudsters are also customers or even business partners (such as channel sales companies). However, many cases are not so clear. Is a fraudulent customer's personal data (which may not even be legitimate) protected? Is personal information from cyber-attacks protected?

## 4. Fraud Prevention and Privacy Law in a Pandemic

Finally, the COVID-19 pandemic has made the task of fraud prevention more complex while simultaneously raising the payoff for fraudsters.

Distanced communication makes the process of investigation more difficult. Interviews are being conducted via video or teleconference, depriving investigators of the ability to observe their subjects. In the pre-COVID world, many exception processes to web- or phone- based provisioning or identity flows would direct the individual to go to a physical location and present themselves with one or more forms of government issued identification for visual comparison by a human being. But in the present circumstances, consumers are unable to go to a physical service location and interact with an in-person

 

representative of an agency or a business. All parties in a transaction are instead left reliant on telephone or digital verification methods to measure the risk of a transaction and decide whether or not to proceed.

This weakening of in-person verification processes has not gone unnoticed by fraudfeasors. The FTC reports that, as of June 28th, U.S. citizens have reported losses more than $108 million to COVID-19 related scams and fraud schemes. Identity theft of both individual and business entities is on the rise as bad actors take aim at enriched unemployment benefits and small business support programs.

## 5. Conclusion

This article provides just a short survey of the issues that intersect privacy and fraud. It does not purport to provide any prescriptive approaches or formulas for how to address those issues. That is because it cannot do so—such solutions are simply too complex. Moreover, compliance is jurisdictionally specific. The requirements and obligations that drive compliance for one operator will not fully apply to another operator operating in states, let alone countries. Nevertheless, it is important that compliance teams consider fraud detection, investigation, mitigation, and prevention efforts as they develop and evolve guidelines and procedures for their companies.

# 1. Introduction

MSO networks that deliver services between the source and destination ends consist of multiple hops, i.e. different network segments. Customer experience is shaped by many Quality of Service (QoS) features that may be defined per hop-by-hop and end-to-end views. Traditionally, speed performance has been addressed as the main contribution to Quality of Experience in an MSO network. However, latency and jitter have a significant impact on many current and emerging services. MSOs have started modeling, monitoring and managing a more complete performance concept, including speed, latency, jitter, packet loss, security and reliability. The importance of this approach has been reiterated in lockstep with a significant increase in traffic volumes, across a very different mix of residential services, and because of a sudden pandemic, as MSOs who adopted this approach were successful supporting additional traffic volumes. This paper will describe current work on latency measurement, optimization and management platforms with hop-by-hop and end-to-end features. We will present current achievements and results for lower latency systems in the cable industry, and ongoing work on new optimization techniques and big data analytics. Architectural examples will be provided for a data-driven and knowledge-based converged access network with low latency service assurance and agility. Finally, we will discuss roadmap items MSOs may adopt to provide low latency services within their 10G initiative.

# 2. Latency Measurement

Subscribers' Quality of Experience is a subjective concept affected by the Quality of Service along the path between the service endpoints. QoS metrics are defined from the system's perspective and can be measured and managed. QoE requires a multi-disciplinary approach to assess the user's perspective that may be affected by factors unique to the user and the user's interactions with the service. Mapping QoS to QoE is still evolving as new services and applications emerge. Performance metrics such as throughput (speed) have been regularly measured by MSOs, but speed is only one of the performance indicators. Different services and applications require different levels of speed, latency, jitter and packet loss. For example, depending on the online gaming type and platform, the impact of latency, jitter and packet loss on the gamer's experience and his/her lag perception may be different [1]. Customer experience with gaming, videoconferencing, VR/AR and many commercial services can only be assessed if all the corresponding QoS metrics -- and especially latency and jitter -- are also well modeled, monitored and managed. Fairness, availability, reliability and security are other factors affecting customer satisfaction.

MSOs need to assess and optimize the latency/jitter performance in their networks to improve their subscribers' experiences, and to ensure a strong competitive position, as intended by the 10G initiative. Upstream and downstream usage changed, due to the Covid-19 pandemic, and the steady increase of low latency services in residential networks is increasing the priority of latency management systems.

Figure 1 shows latency measurement (LM) methods widely used by operators. The LM-1 method is a passive measurement method described in more detail later in this section. It measures the round-trip time (RTT) of Transmission Control Protocol (TCP) handshakes to assess access and internet hops, as well as end-to-end latency values (including home, core networks and internet.) It has the advantage of using actual production traffic with no impact on the network. Due to TCP's ACK suppression and expediting implemented in CMs, it may not be directly mapped to UDP type latency. This latency is affected by network conditions and utilization levels (e.g. media access delay due to utilization in DOCSIS bonding groups, or Wi-Fi channel and queueing delay due to HSD service consumption.)

The LM-2 method is an active measurement for upstream (US) and downstream (DS) traffic latency under load (LUL). The test starts with TCP-based connection establishment only if the gateway utilization is low because of potential customer-facing performance impacts. This TCP-based connection latency within LM-2 (conn RTT in Figure 1 and Figure 3) reflects the performance in idle conditions. After the successful connection, LUL in both directions are measured sequentially. US LUL is round trip latency under US load while DS LUL is round trip latency under DS load and they reflect the queuing delay ranges in the CM and CMTS respectively. The LUL test may use iperf TCP as the load to utilize the bandwidth up to speed tier rates in DS and US directions. UDP pings (e.g. Netperf UDP_RR or iRTT) are transmitted concurrently. All the additional test traffic is excluded from any billing. UDP ping latency, jitter and packet loss metrics are collected along with TCP load throughput. Any bufferbloating issue can be detected and the performance of buffer control and active queue management techniques can be optimized with this test method. It can be measured at different endpoints to assess home Wi-Fi and access network performance.

The LM-3 method comprises well known ping measurements (both ICMP and DOCSIS pings). ICMP pings can be used when data and control planes overlap, but are not suitable for SDN networks where data and control planes are not the same. ICMP pings may be routed differently than TCP/UDP packets and may be processed with lesser priority. This latency is also affected by utilization levels similar to LM-1 method, however these are periodic synthetic ping data.

An overview of the properties of these measurement methods is provided in Table 1. LM-1 and LM-2 methods are newer techniques that MSOs started to integrate into their performance measurement platforms. More detailed information on LM-1 and LM-2 methods with test and measurement points that can be integrated are described below.

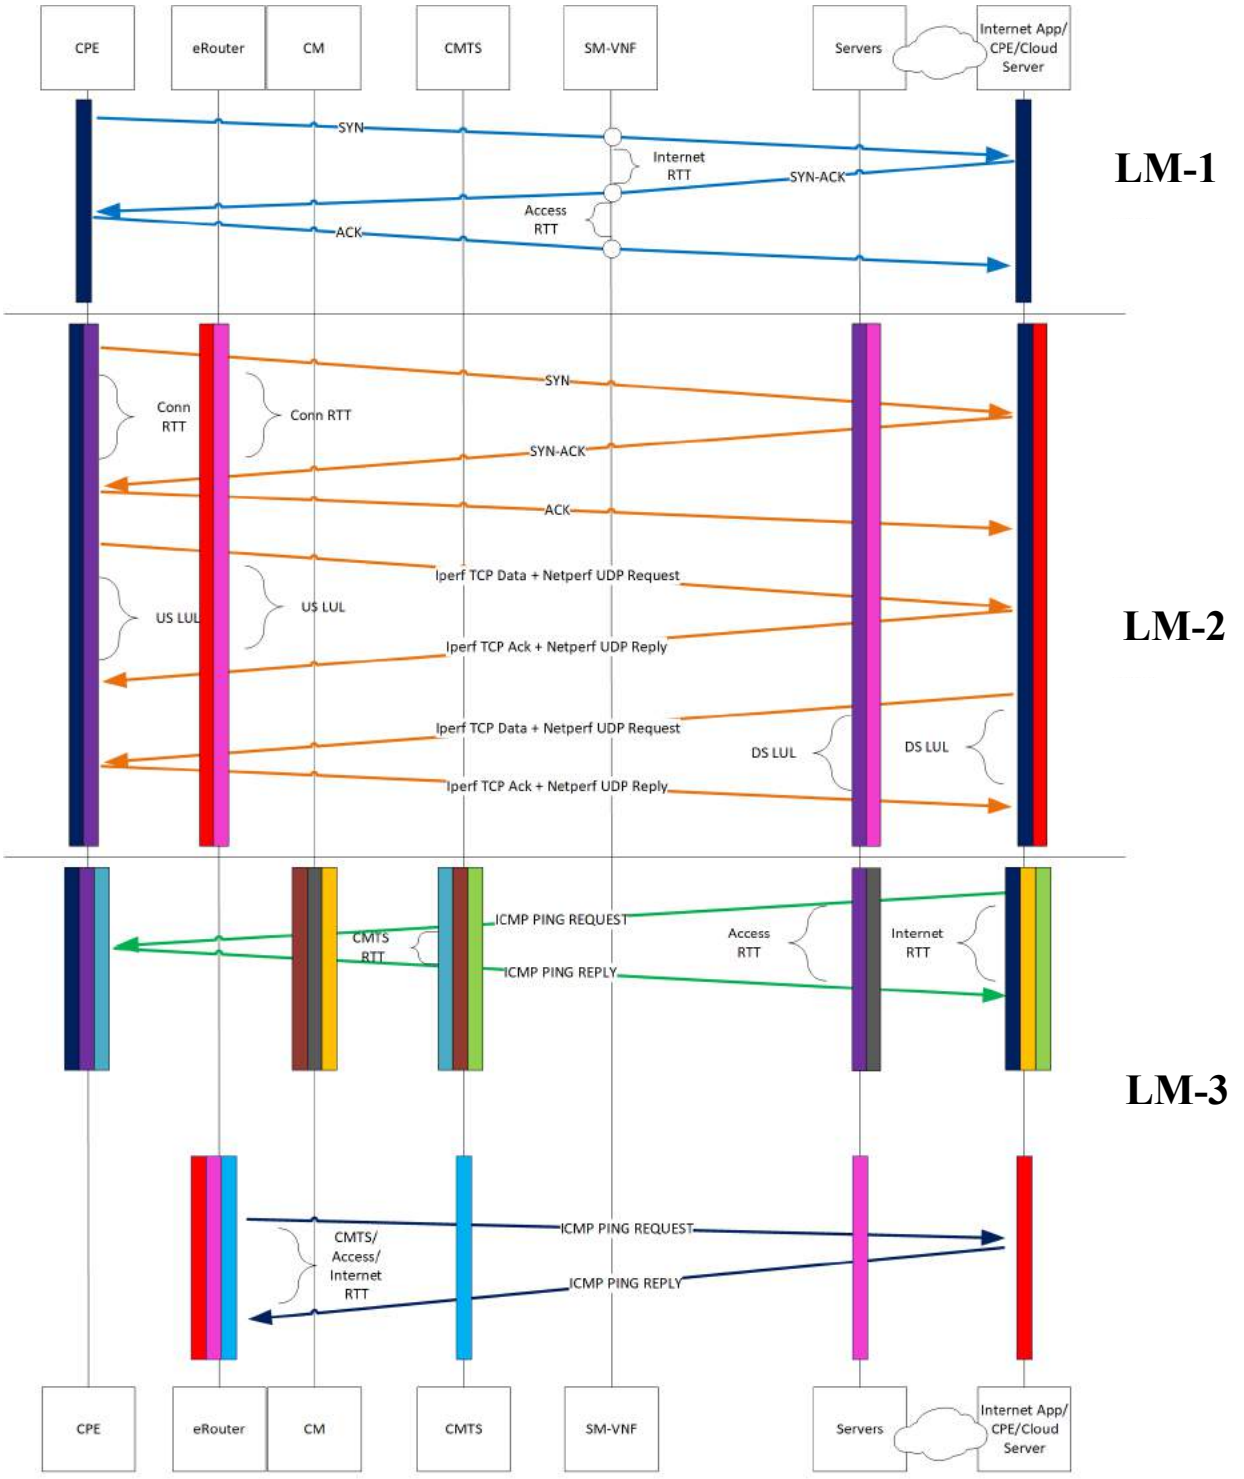

**Figure 1 – Examples of Latency Measurement Methods**

The LM-1 method has been used in Comcast Networks with Software Defined Networking (SDN) and Virtual Network Functions (VNF) components. As SDN has evolved over the last decade, the telecommunications industry has seen the opportunity that SDN presents as a means to develop new product service offerings, and specifically the means to rapidly deploy VNF in support of new products. Comcast

has realized SDN as part of its Active Core and Access platforms. Comcast has also realized SDN as part of its Virtual Services Gateway (VSG) platform. The VSG platform uses commercial off-the-shelf (COTS) compute servers, supported with appropriate network interfaces, upon which various VNFs can be instantiated in support of new products and services.

The VSG platform is deployed in line with the production data traffic and thus a variety of VNFs are envisioned, covering usage metering, monitoring, telemetry, reporting, and traffic marking. Multiple VNFs can be instantiated as supported by the platform's compute and network capability. The initial hardware iteration of the VSG platform is based on a dual-socket x86 compatible motherboard, with twenty cores per CPU socket. The VSG platform hardware also includes dual-100G interfaces, for interconnection to peer network elements. This compute & networking configuration can support the initial set of VNFs envisioned and planned.

The first VNF that we deployed on the VSG platform was a usage metering function. By offloading the existing usage metering function from the CMTS, the function becomes more versatile. That's because changes to per-user profiles can be achieved via real-time configuration, as requested through the OSS / BSS.

The second VNF that we deployed was the telemetry function introduced above. This VNF monitors the anonymized TCP connections of connected subscribers and provides a collection of TCP statistics per subscriber. Within a configurable reporting interval, the VNF is able to track things like TCP session count, TCP connection duration, total session packet count, and TCP retransmission count, per direction. Two key statistics provided by this VNF, and shown in Figure 2, are TCP SYN-to-SYNACK RTT (Server RTT) and TCP SYNACK-to-ACK RTT (Client RTT).

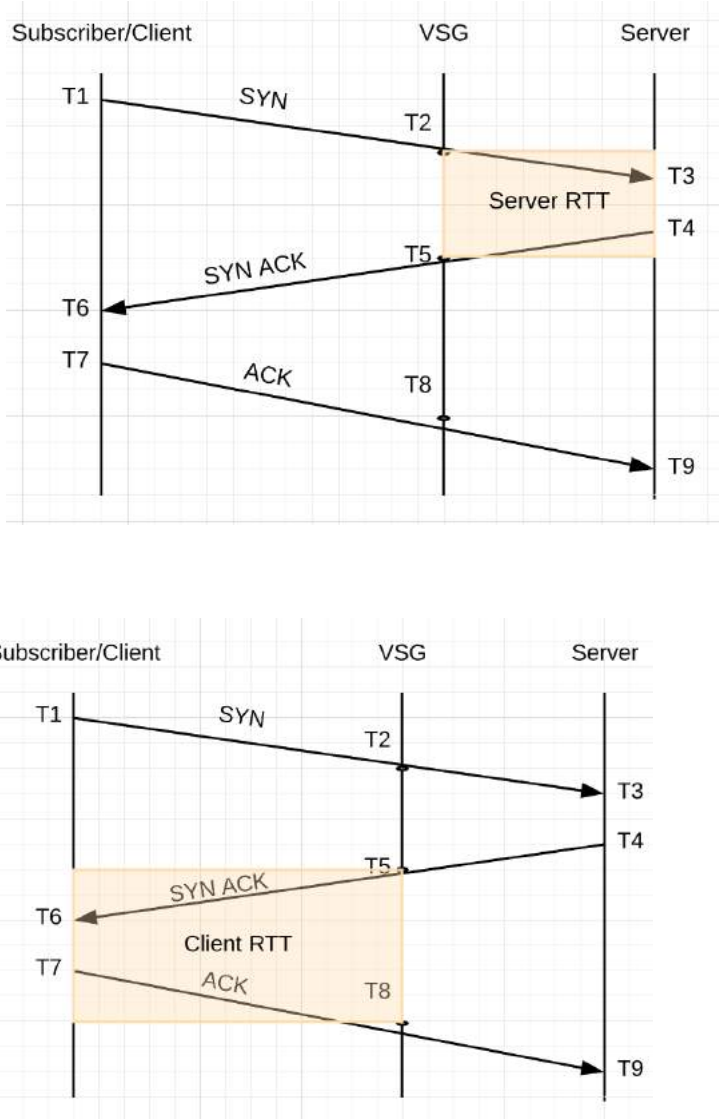

**Figure 2 – TCP connection based latency measurement. Top: Internet RTT; Bottom: Client RTT**

From the VSG's position in the network, looking at the TCP SYNACK-to-ACK timing (Client RTT) specifically gives a view into the performance of the access and home portion of the network, as the other network elements in the path to the customer device are the CMTS, cable modem and Wi-Fi Access Point. The per-subscriber metrics give an anonymized view into a specific customer's network experience. By looking at the aggregate subscriber metrics across a given service group or bonding group, we gain a view into the health of that service group or bonding group. Monitoring these metrics can serve as an early warning signal of the need for capacity expansion, even before traditional throughput and utilization metrics, thus providing a new way to plan for capacity expansion.

Providing insight into this timing serves also as a proxy for the customer experience. A part of how customers perceive the performance of the network is governed by the TCP 3-way handshake, to establish the TCP connection between the client and the server. The typical online application (Microsoft Office,

Google Docs, etc.) can open between 15-20 TCP connections. Delays in opening those TCP connections impact overall application performance, and thus impact the customer's overall experience.

While LM-1 helps the cable operators to assess the impact of typical home and serving group utilization levels on the network latency and jitter, LM-2 helps to assess the bufferbloating issues by measuring the latency and jitter at the highest home utilization levels.

The LM-2 method can be used within the MSO's network without requiring any HW test client in the subscriber's home as shown in Figure 3. In this case the test client is implemented within the eRouter firmware (e.g. RDK-B). The test can be initiated only when the subscriber's gateway (i.e. erouter+CM) has low utilization level not to degrade the subscriber's network performance. Hence, the connection RTT portion will be mostly ~10-20ms for current DOCSIS networks. This RTT includes media access delay in the US but queueing delay may not be high since the test is initiated when the home traffic volume is low.

Queuing delays in the CM and CMTS are the dominant factors in the US and DS LUL measurements respectively. UDP pings are impacted by queue building iperf TCP traffic since they are transmitted within the same service flow. LUL provides information on the latency variation subscribers may perceive when they use low latency applications. It reflects the impact of instantaneous bursts of queue building traffic (e.g. file download/upload, streaming) on the performance of the LL applications (e.g. gaming, videoconferencing).

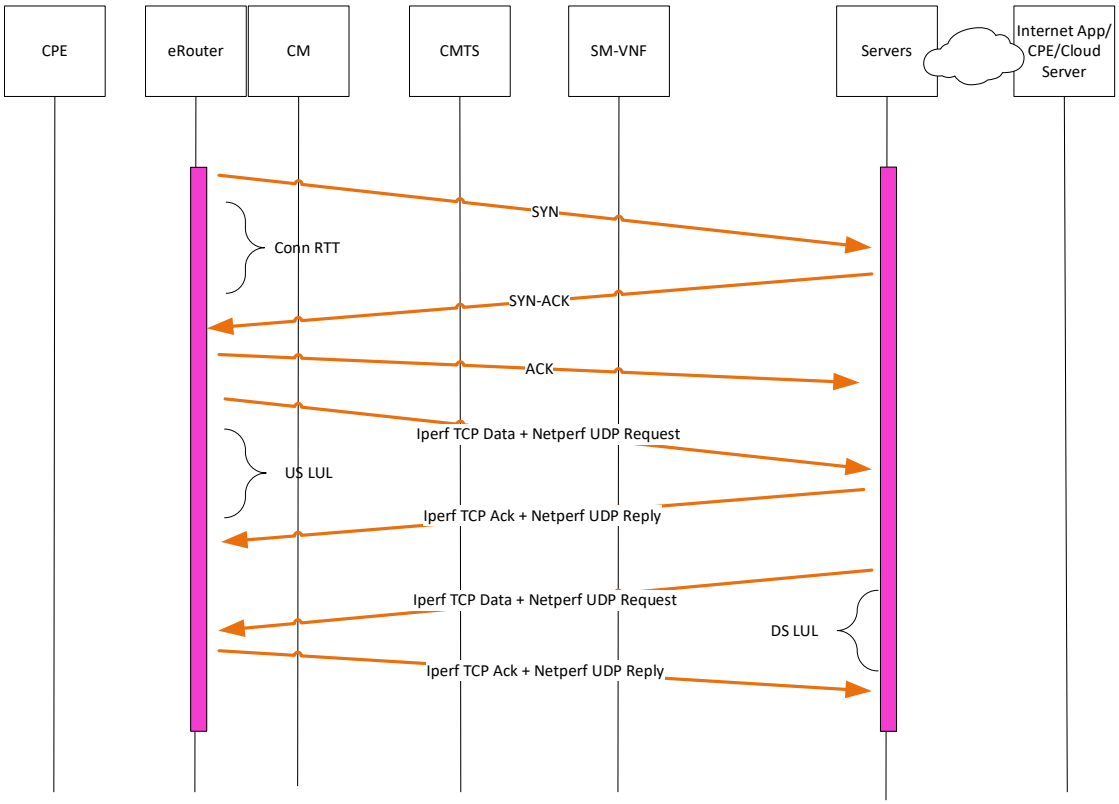

**Figure 3 – Latency Under Load Measurement**

# 3. Latency Performance in Current and Emerging Network Architectures

## DOCSIS NETWORKS LATENCY

As summarized in Table 2 – DOCSIS Networks Latency: RTT Between CM and CMTSTable 2 [3], the latency performance of DOCSIS networks has been improving with each version. A major delay source is queuing [3], that has been managed by the buffer control (BC) and active queue management (AQM) introduced in the D3.0 and D3.1 specifications. However, these improvements are not adequate for low latency service requirements and for providing MSOs a competitive edge in 10G era. Note that although CMs have mandatory AQM specifications (i.e. the PIE algorithm), queue management at the CMTS varies based on the vendor and its firmware releases. Table 2 levels correspond to latency under US load. As a result, latency under DS load and bi-directional load may be higher than shown in Table 2 for existing implementations. For example, we can confirm US LUL results with ~10-20ms for ~90$^{th}$ percentile, but when we run a bi-directional load, and depending on the CMTS implementation and configuration, the US LUL results can be in the order of a few hundred of milliseconds. CMTSs may have large physical queues. If cable operators do not optimize the configurations for the BC and AQM features of older CMTS deployments, they may create high queueing delays and inefficient network utilization. In Figure 4, below, we show some examples with test cases and configurations to depict the performance changes.

**Table 2 – DOCSIS Networks Latency: RTT Between CM and CMTS**

| | | When Idle | Under Load | 95-99$^{th}$ Percentile |
|---|---|---|---|---|
| **DOCSIS 3.0 Early Equipment** | | ~10ms | ~1000ms | ~1000ms |
| **DOCSIS 3.0 w/ Buffer Control** | | ~10ms | ~100ms | ~100ms |
| **DOCSIS 3.1 w/ Active Queue Management** | | ~10ms | ~10ms* | ~100ms |
| **Low Latency DOCSIS 3.1** | **Dual Queue** | <10ms | <10ms | <10ms |
| | **PGS** | ~1ms | ~1ms | ~1ms |

- Latency under DS load and bi-directional load may be ~50-100ms with current CMTS AQM implementations.

In the examples shown in Figure 4, the pre- and post-optimization settings for the DS AQM are shown. As seen in Figure 4, ~1-2 seconds of DS LUL is observed for pre-optimization, while post-optimization reduces this latency to the order of ~100-200ms. The suboptimal settings cause higher queueing delay caused by bursty queue-building traffic, as CMTSs may have large physical queues. Latency is reduced with the optimized settings and speed tests results show that there is no degradation in throughput. Note that outliers, e.g. some unexpected high latency results, due to test failures are not removed in these examples. When a D3.1 CM's US AQM is disabled, the default BC is 250ms as defined in the earlier D3.1 specifications, with US LUL around 250-300ms, which can be seen in the graphs (red CMs). This is also displayed in Figure 5 that shows the test US LUL results per speed tier rates and CM models, which are configured for different BC and AQM settings. The results show that when appropriate features are not enabled or configured with optimized settings, high US LUL may be observed. For example, a D3.1 CM with US AQM disabled and default BC settings (i.e. 250ms) has higher US LUL compared to D3.1CMs with US AQM enabled and D3.0 CMs with lower buffer sizes.

Figure 6 displays dslreports.com test results for the same CMTS and CM with and without optimized AQM settings. In this case, the test is done from a laptop connected via wired Ethernet to the CM. Optimized AQM settings improve LUL results (grade for bufferbloat) while still meeting throughput requirements.

These examples show that cable operators should measure LUL and audit CM AQM and BC configurations to make sure optimized settings are deployed.

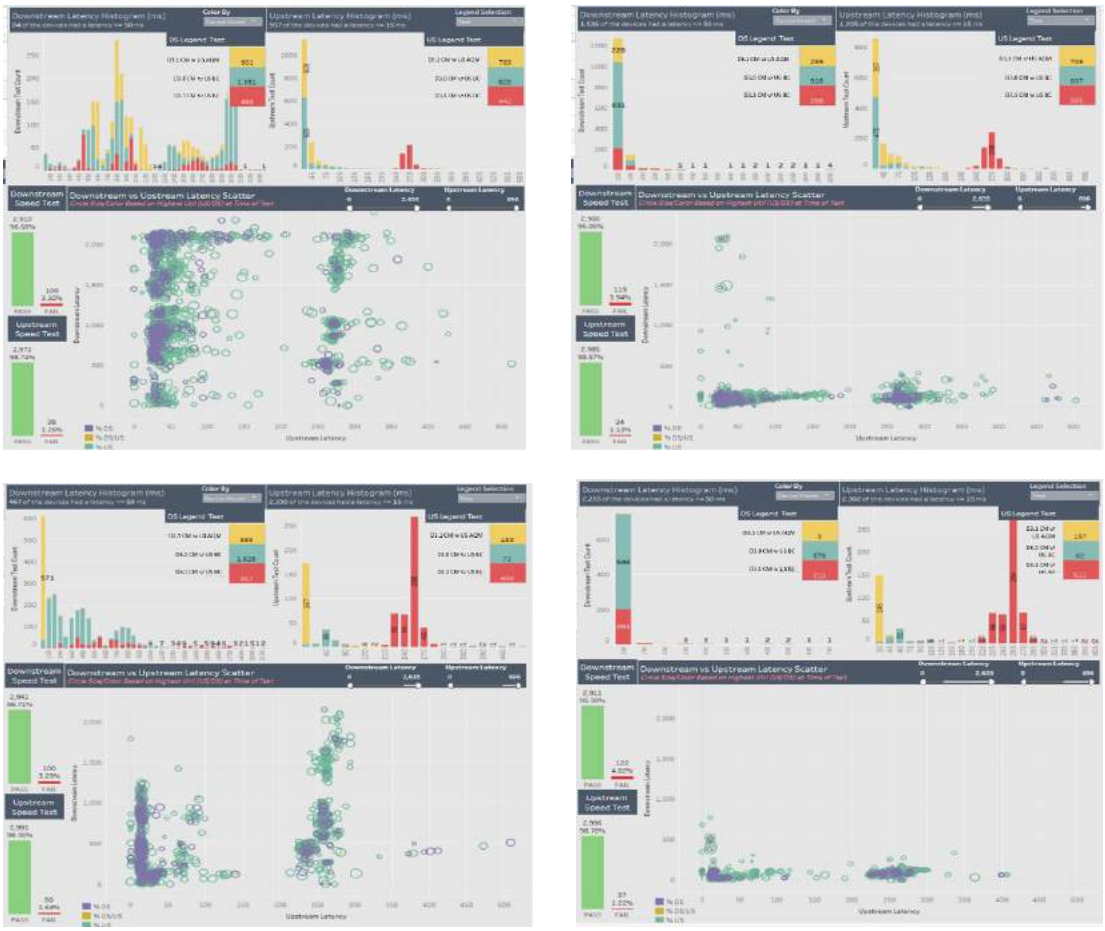

**Figure 4 – Top Left: Max DS and US LUL with suboptimal DS AQM settings; Bottom Left: Mean DS and US LUL with suboptimal DS AQM settings; Top Right: Max DS and US LUL with optimized DS AQM settings; Bottom Right: Mean DS and US LUL with optimized DS AQM settings**

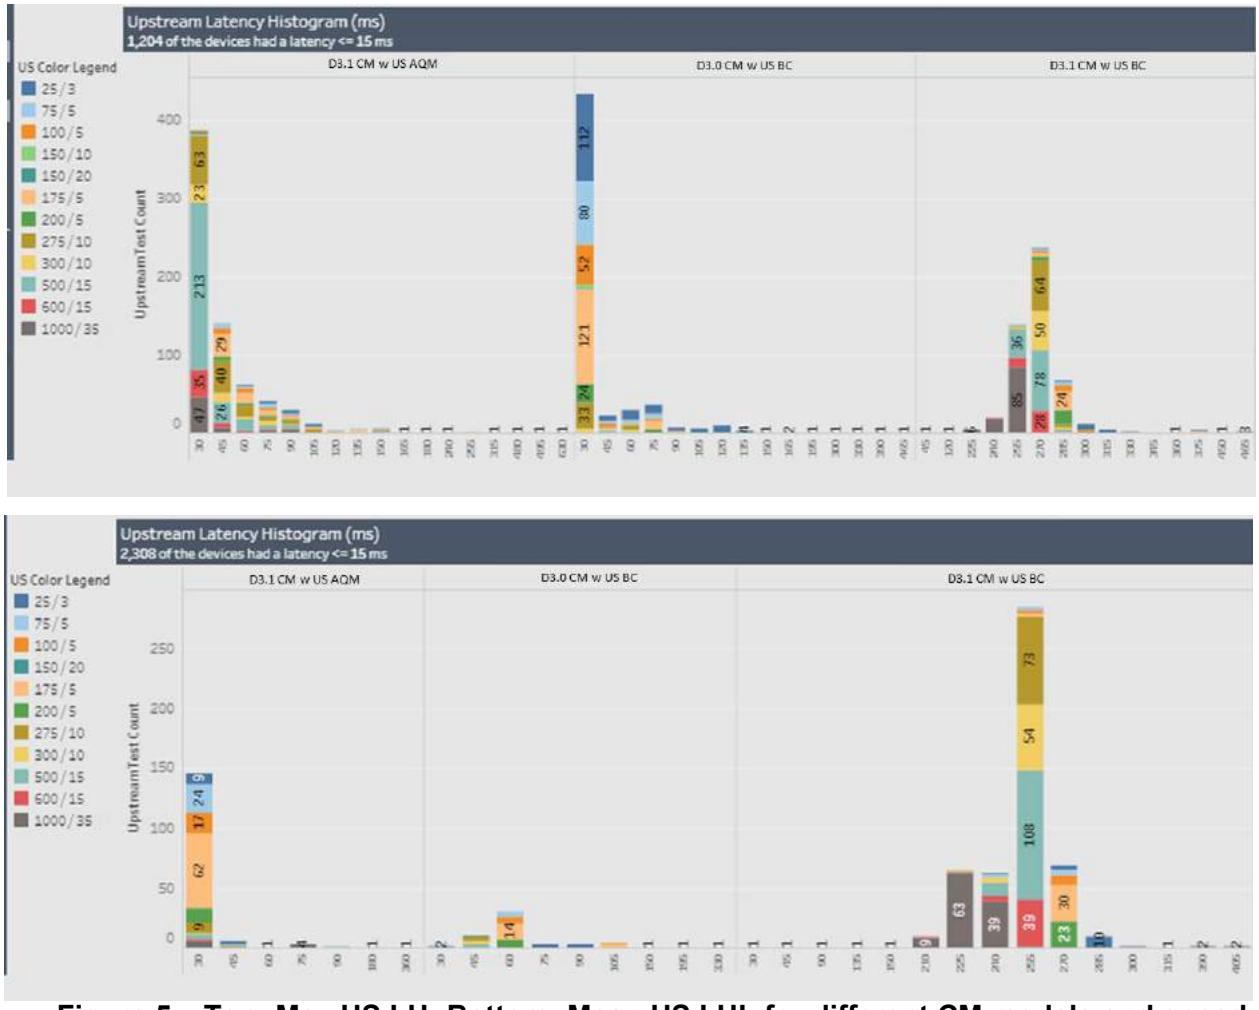

**Figure 5 – Top: Max US LU; Bottom: Mean US LUL for different CM models and speed tiers**

**Figure 6 – Left: dslreports.com results with suboptimal DS AQM settings and D3.1 CM with BC with 250ms default target latency; Right: Optimized DS AQM settings and D3.1 CM with US AQM with 10ms default target latency**

Depending on the buffer control and AQM, other factors, such as DOCSIS configurations, speed tier rates, additional RTT over the data path (e.g. additional delay at the home or northbound of the MSO's network), transport and congestion control protocols, duration of flows, rate adaptation schemes and the mix of traffic and utilization levels, all can affect the system performance. For example, Figure 7 shows that buffer sizes in a D3.0 CM affect how much throughput each concurrent flow within the subscriber's HSD SF gets, with different end-to-end RTTs. The graphs show US throughput for each flow within an HSD service of 10Mbps US speed tier rate. Although it may be desirable for a flow with a smaller RTT (e.g. an edge computing service) to have better performance, starving flows with long end-to-end RTTs should be avoided. In this example, 10, 30 and 50 ms target buffer sizes are set for the BC. 4 flows are destined to different servers, green flow's server is the closest to the subscriber's home while the purple flow's server is the farthest away. MSOs may improve their network with new features while optimizing configurations for the earlier versions of DOCSIS components.

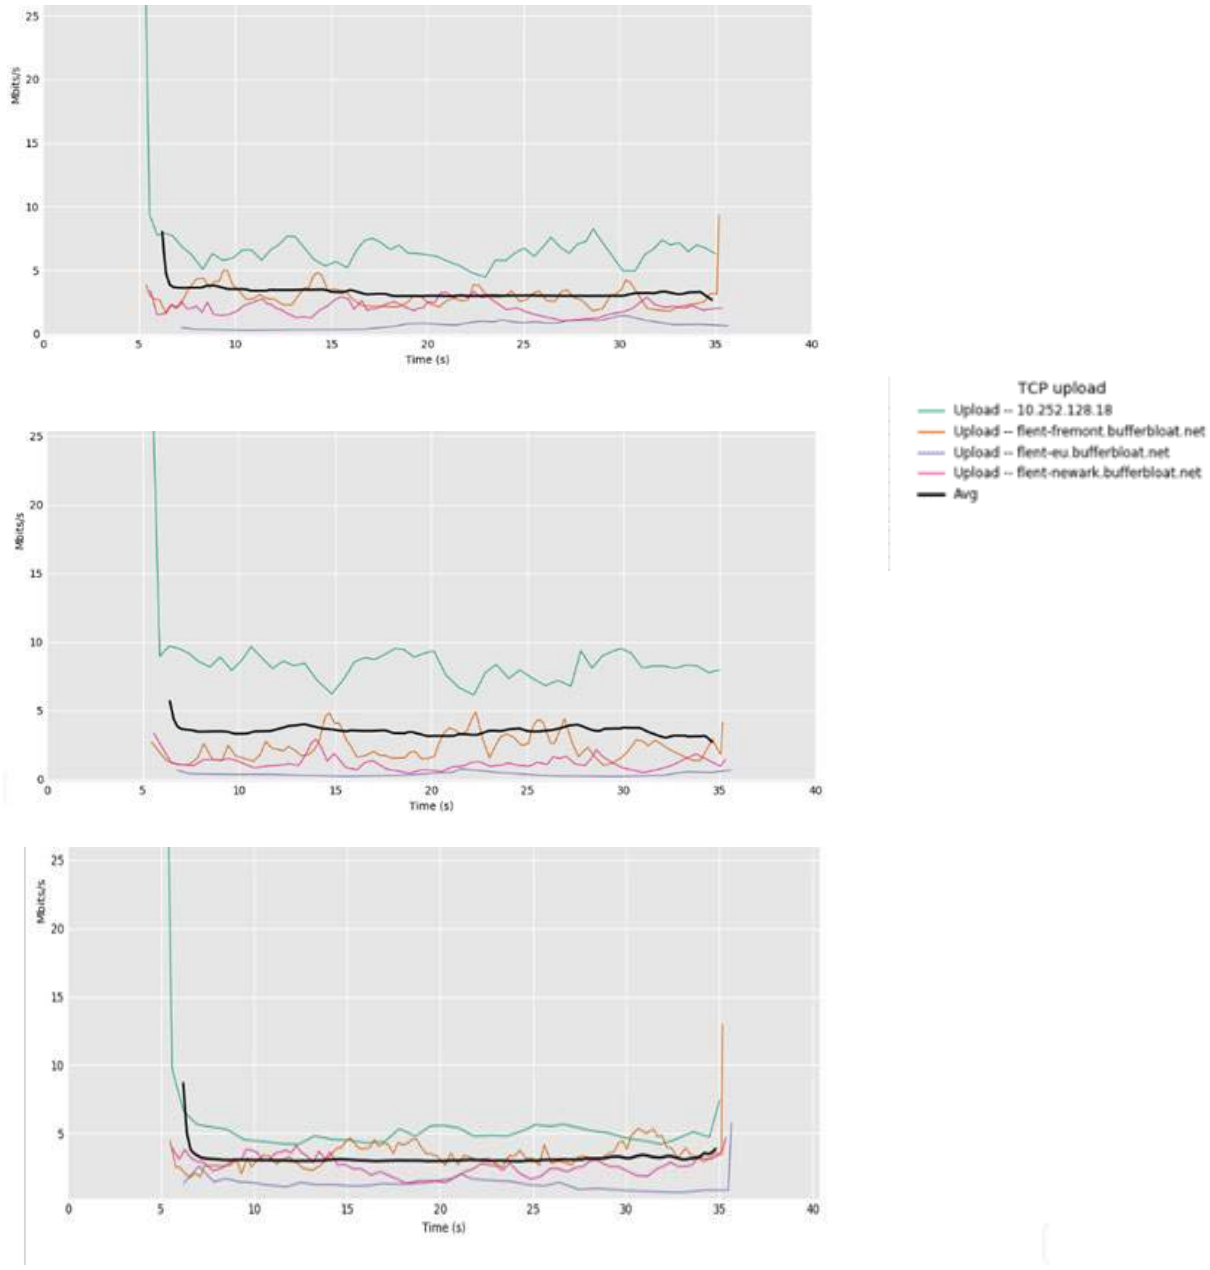

**Figure 7 –Throughput (Mbps) values over time for each flow per CM HSD buffer size. Each flow has different e2e RTT. Green flow's server is the closest to the subscriber's home while purple flow's server is the farthest away. Top: 10ms target buffer size; Middle: 30ms target buffer size; Bottom: 50ms target buffer size**

As described in Section 3, new D3.1 Low Latency DOCSIS (LLD) features with dual queue AQM and reduced bandwidth allocation map (MAP) interval time will enable non-queue-building low latency traffic to have an RTT of <10ms for the 95-99$^{th}$ percentile. This will improve gaming experiences, because gaming control traffic can be classified as NQB LL traffic and can be transmitted with much better jitter characteristics. Work is ongoing as it relates to scalable congestion control algorithms, so that streaming services can be also transmitted as NQB LL traffic. This area requires more research and development to analyze traffic characteristics and their impact on other service flows.

The LLD architecture is premised on the concept of separating Queue Building (QB) traffic from Non-Queue Building (NQB) traffic. An example of QB traffic is the typical file transfer. Online gaming control traffic is an example of NQB traffic. Current network deployments carry both QB & NQB traffic, transiting in the same service flow. When the service flow is unsaturated, this is not a problem. But when the service flow is at capacity, it is quite possible that NQB traffic gets stuck behind QB traffic. When this occurs, the NQB traffic incurs latency delays while the queue drains out the QB traffic and the NQB traffic awaits its transmit opportunity.

The LLD architecture attempts to alleviate this issue by separating QB & NQB traffic into separate sub-service flows, each with their own queue, as part of an Aggregate Service Flow (ASF). The available bandwidth of the overall ASF is still the same as what the customer has purchased, but the NQB & QB queues are drained in a manner that allows NQB traffic to be rapidly dispatch from the queue, while also ensuring that the QB queue receives adequate transmit opportunities.

Proactive grant scheduling is another D3.1 LLD feature, targeting a ~1ms RTT for the 99$^{th}$ percentile. Network efficiency for PGS must be analyzed for possible use cases.

## Wi-Fi NETWORKS LATENCY

Although avoiding Wi-Fi can result in more deterministic latency, jitter and packet loss, subscribers run low latency services such as gaming and videoconferencing over Wi-Fi all the time, because it is simply more convenient than wired Ethernet cables. Features such as WMM and AQM [4],[5] aim to improve latency and jitter for low latency services in Wi-Fi networks. Similar to DOCSIS networks, the tradeoffs between latency/jitter and throughput and fairness must be balanced (e.g. the tradeoff between efficiency with frame aggregation, vs faster channel access).

Although significant improvements may be observed with correct queue management and channel access control, factors such as outside interference and high concurrent utilization have been limiting the Wi-Fi performance for low latency services. The need for a more deterministic quality of service has been supported by Wi-Fi 6 (802.11ax) with MU-MIMO and OFDMA, enabling both DS and US increased simultaneous communications [7]. Removing contention along with deterministic QoS features (e.g. multi-user EDCA) that can provide low latency, jitter and overhead will be key to supporting low latency services.

In addition, Wi-Fi 6E, with its additional 1200 MHz in the 6 GHz spectral range, would be suitable especially for MDU type environments, but can be also used with multiple routers in large houses in the

future. Although 6 GHz is used by other networks, and more testing is required for range-speed-latency characterization, all of these improvements point to an optimistic future for low latency services. Most residential applications will not need Gbps symmetrical throughput anytime soon, but having this kind of speed both on the Wi-Fi and DOCSIS networks enables new services, including commercial and industrial services. Enterprise trials [6] have proven 2 Gbps speeds with consistent connections and latency around 2ms.

### CORE NETWORKS LATENCY

Game developers and providers, gaming router developers and network optimization companies have been developing products to optimized routing/tunneling to best gaming servers by measuring RTTs and/or establishing private networks. SDN-WAN has been applied for low latency services to intelligently shift traffic and dynamically adjust to network and traffic changes. Delivery at the edge by linking up data centers with ISPs' last mile networks has been proven to reduce latency and jitter significantly and improve fairness among online gamers.

MSOs have a unique position to provide the best end-to-end performance for gamers by applying low latency features at the access and home networks as well as at their edge core and peer routing platforms.

## 4. End-to-end Support For Low Latency Services

In addition to support LL service performance requirements, MSOs need to provide architecture changes for LL service classification, marking, service integration and assurance. Table 3 summarizes the main features for those architecture changes, and Figure 8 illustrates them for the corresponding components.

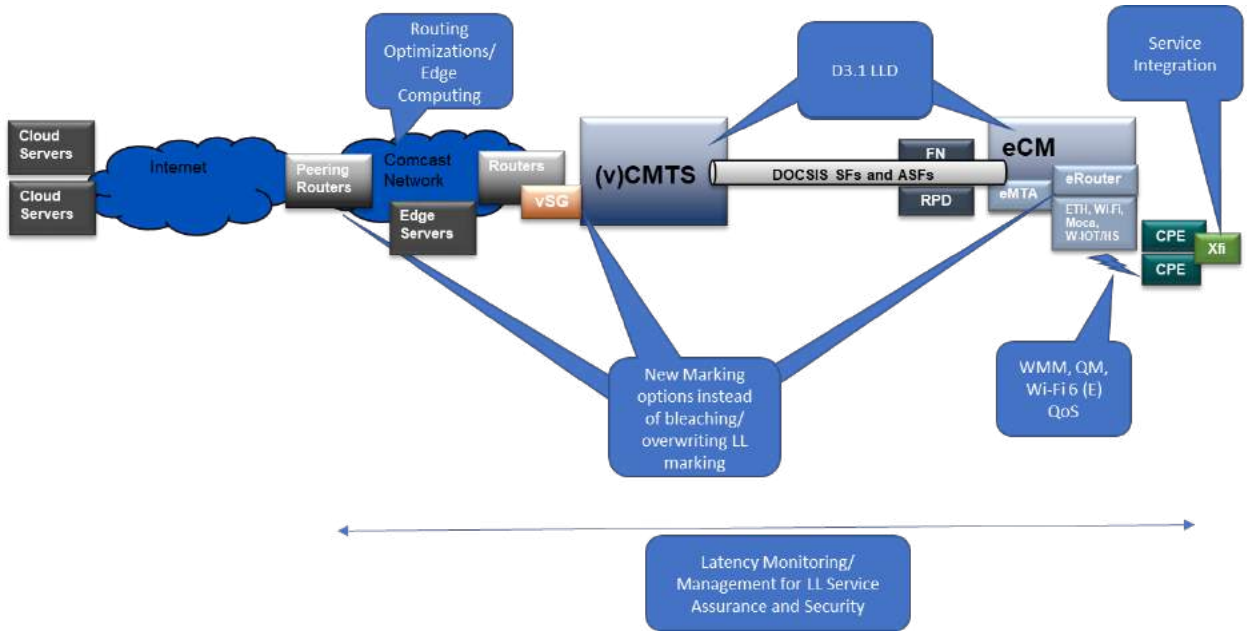

**Figure 8 – End-to-end LL services support**

**Table 3 – Architecture changes to support LL services**

| Current Architecture | | Target Architecture |
|---|---|---|
| • No classification and marking in untrusted network segments | → | • End-to-end classification with new security measures |
| • Single queue for all HSD applications and scheduler (in DOCSIS and most Wi-Fi networks) | → | • Dual/multiple queue and weighted scheduler for NQB-LL and other applications |
| • Lower US speeds; Wi-Fi contention and unreliable QoS | → | • > Gbps DOCSIS and Wi-Fi with deterministic latency/jitter for LL services |
| • Single performance measurement for all services within HSD SF | → | • Differentiated performance measurement for NQB-LL and other applications |
| • Single network optimization technique for all services within HSD SF in DOCSIS and Wi-Fi networks | → | • Network optimization techniques per traffic requirements within HSD service flows |
| • Loose coupling in design, development, testing, and operations among network segments | → | • Orchestrated end-to-end design, development, testing and operations for LL services |
| • Limited business models for HSD apps | → | • Flexible business models for LL services |

Marking options are being discussed in IETF WGs such as Low Latency, Low Loss, the Scalable (L4S) proposal and the Differentiated Services Code Point (DSCP) marking proposal[8][9]. Until these approaches are adopted widely, MSOs may support LL NQB traffic classification by changing their current marking options and taking new security measures. In this sense, another VNF envisioned for the VSG platform is in support of the Low Latency DOCSIS architecture.

This architecture can improve the customer experience by having QB & NQB traffic serviced, separately as addressed in Section 3. The challenge for the network operator then becomes how to separately identify NQB from QB traffic as it traverses the network. Assuming that business rules provide guidance on what qualifies as QB & NQB traffic, the data packets from each type of traffic must have some unique identifier, so that the CMTS can direct each type of traffic into the correct sub-service flow within the ASF. Here, a VNF can be deployed onto the VSG which includes rule mapping, to re-mark the data packets of the two types of traffic. This could be through changing the packet's DSCP value, based on other packet values, such as source or destination IP address, port number, protocol number, etc. A VNF supporting this re-marking can be dynamically updated to support changing business rules on the classification of QB vs NQB traffic, and re-mark (or not) accordingly. Thus, by providing a platform to instantiate this VNF, the VSG platform can play a part in implementing the overall LLD architecture live on the network.

VNFs such as a VSG platform are also crucial for end-to-end latency management systems. Figure 9 illustrates an example monitoring tool that collects hop-by-hop information such as network (including AQM, BC, and QoS MIBs), utilization and latency test results. A VSG or similar VNF can detect anomalies or changes that require correction actions. This information can also be used for performance

prediction and business intelligence purposes. Such a system may have limitations due to SNMP based polling scales, different monitoring systems with varying collection times and lack of efficient VNF to network segment mapping. These limitations are especially crucial for latency management since instantaneous changes in the network and traffic conditions may create lag spikes that are hard to analyze. New, push-based telemetry systems, that MSOs have been deploying for SDN/NFV enabled distributed architectures, can overcome these limitations, and are shown in Figure 10. Monitoring agents may be distributed and linked to local VNFs to have aggregated data processed in a cloud-based end system.

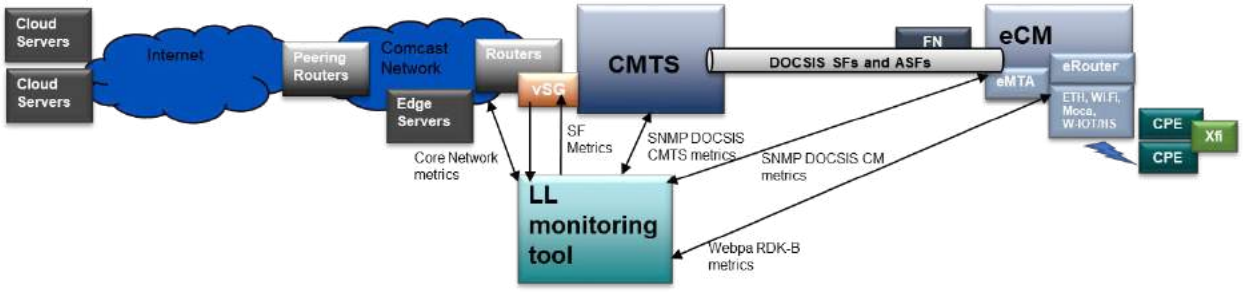

**Figure 9 – Low Latency Services Monitoring and Management for CCAP Systems**

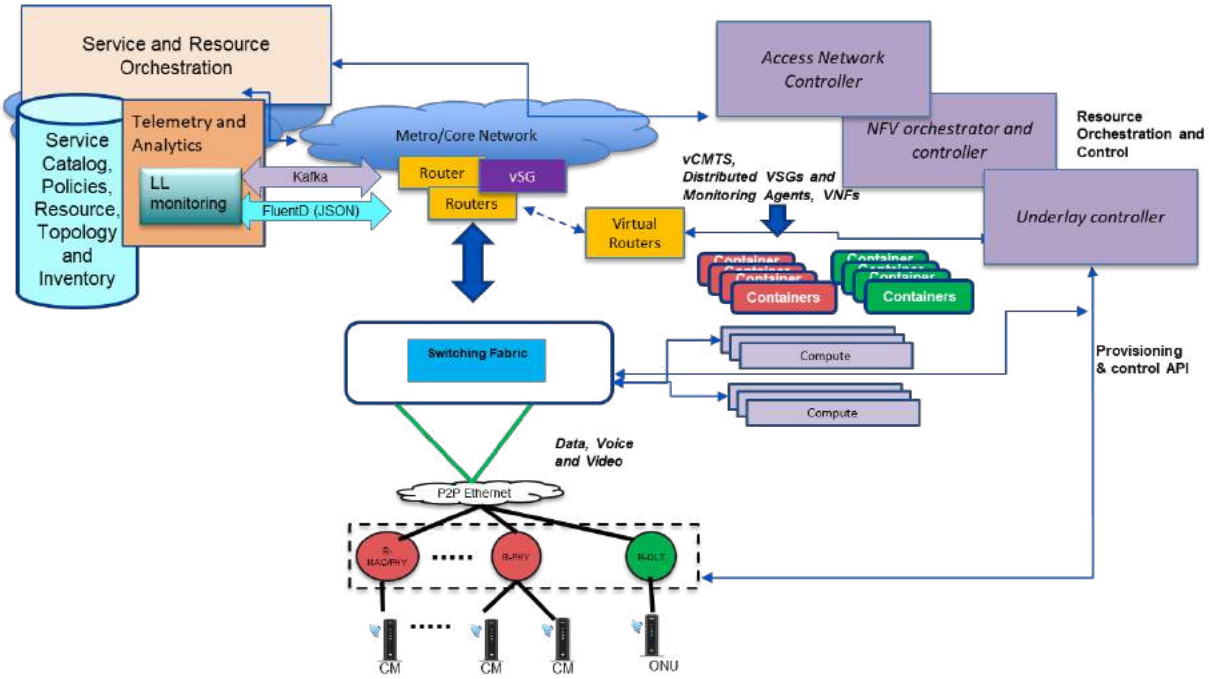

**Figure 10 – Low Latency Services Monitoring and Management for Distributed Systems**

Figure 11 displays an architecture where resources may be managed and configured based on monitoring and prediction systems control [2]. LL monitoring and management can then be part of the data center as an orchestration function. Today, even some simple configurations may not be available, because of a lack of provisioning flexibility. For example, buffer sizes in older modems may be expressed in bytes, and setting them based on speed tiers may require the coordination of service class names and boot file settings. There may be other configuration parameters that need to be coordinated as well. Flexible configurations and operations may seem like features for the farther future, but today MSOs already deploy SDN/NFV enabled distributed systems and new telemetry platforms. Configuration flexibility is already an integral part of such systems. The next section discusses new architectures where low latency services may be integrated.

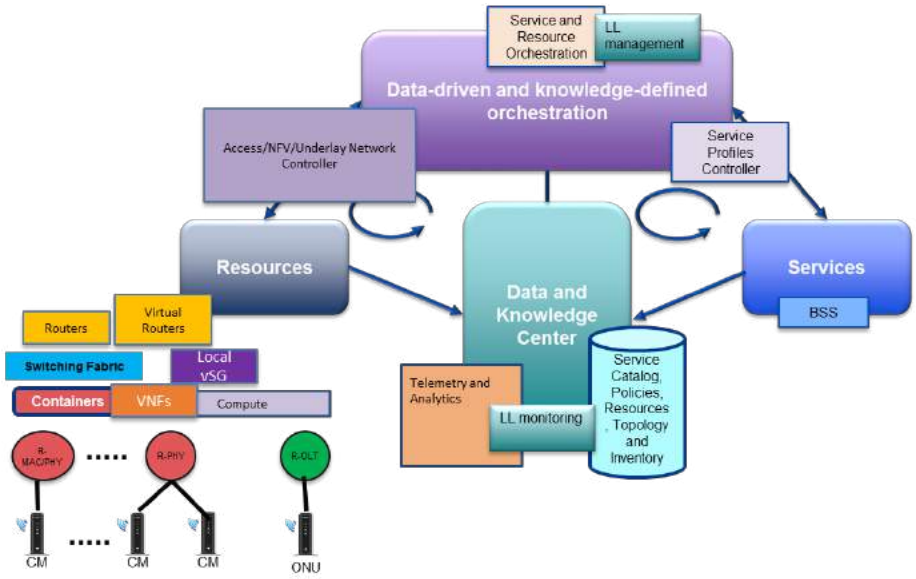

**Figure 11 – Low Latency Services Monitoring and Management Integrated within Data-driven and Knowledge-defined Architectures**

## 5. Conclusion: Final Thoughts on Latency Management

Although service assurance with performance management has been always the main driving force in designing access network architectures, a unified platform with an end-to-end orchestration approach has not been fully adopted, largely because of design limitations in many operators' networks. Recent changes in MSO network and service architectures provide the building blocks for such a unified platform, including:

- *Networking improvements:* New features in both wireline (e.g. DOCSIS/PON) and wireless (e.g. Wi-Fi) networking improve both the customer experience and network efficiency significantly. These features include frequency split and extended spectrum in DOCSIS, FDX, higher rate PON technologies and coherent optics, 802.11ax (Wi-Fi 6), low latency and distributed architectures for DOCSIS, Wi-Fi and mobile networks. Although some of these technologies aim at a specific hop or segment of the MSO network, initiatives like low latency networks target end-to-end improvements.
- *Data-driven networks and Monitoring:* Changes in telemetry, e.g. adapting push-based and cloud-hosted telemetry, enable data-driven network and service architectures. Both hop-by-hop, end-to-end latency and other performance metrics can be collected for overall latency management, troubleshooting, operations and planning purposes. Low latency services such as gaming will benefit from different latency measurement approaches, including concurrent and multi-hop measurements.
- *Software Defined Networking*: SDN enables centralized orchestration and coordination of the distributed controllers in different network and service segments. Dynamic and flexible configurations will help low latency services such as gaming, for example, by avoiding separate configurations of home and access network components. Some of the traditional latency measurement techniques assume that the control and data planes overlap, which wouldn't be the case for SDN networks. On the other hand, SDN enables an end-to-end data path view, with associated capabilities and monitoring that may be easily controlled for hop-by-hop and end-to-end measurements.
- *Network Function Virtualization*: MSOs have been introducing new VNFs over the control and data paths, with innovative functionalities in the areas of subscriber and service flow management that can help the differentiation of services per their traffic requirements. Virtualization in access networks may help to integrate new queueing and scheduling functionalities -- while special design requirements need to be considered for low latency services, as these designs may introduce additional latency not found in purpose-built, hardware-based architectures.
- *Knowledge-defined Networking*: Advances in the application of machine learning (ML) techniques to MSO networks and services open new doors for better performance prediction and management with self-optimizing capabilities. Recent advances in proactive network management (PNM) in DOCSIS and Wi-Fi networks can be extended for low latency services. The advantage of a knowledge-defined network is the ability to apply multi-hop PNM for end-to-end service assurance. In addition to smart networks and operations, MSOs have been using knowledge-defined systems for smart homes and customer interfacing platforms, which facilitate new low latency service offerings while assessing the customer experience for these services.
- *Cloud-based applications vs edge computing*: MSO integration of both cloud and edge computing based applications, depending on the service requirements, will enable low latency service providers to select the best architecture for the optimized customer experience. For example, cloud-based game providers can optimize network peering or consider edge computing based on performance, hardware and cost requirements.
- *Open source products and standards*: Many standardization efforts like the low-latency work within CableLabs and IETF enable support in a larger ecosystem. MSO use of open source products, and flexible integration of third party services in their platform, ensure the compliancy with regulations and policies as well.
- *Security*: Security, in terms of network and customer privacy protection, has become a vital item to be integrated into the design, instead of a later add-on feature. Low latency services require new classification and marking design, which requires new security elements. A proactive design approach is pivotal to a secure end-to-end solution, even while each network segment can have its own security feature (e.g. queue protection in D3.1 LLD specs).

- *Accessibility*: Similar to security in proactive inclusions, accessibility was a core part of the initial architecture design process for MSOs, instead of a later add-on feature. Low latency services may include strategies that offer control options to subscribers. MSOs that have an established framework to incorporate accessibility requirements early in the design can easily integrate low latency services by meeting every subscriber's needs.

## List of Figures

# 1. Introduction

Field meters have been on the first line of defense when determining if a cable plant is sufficient for installs, in need of repair, and for determining the quality of service. The original meters were expensive, heavy, and required a large amount of training. Contemporary meters are still relatively high-cost and in some cases require even more training to use than their predecessors. In order to get a tool in every technician's hands, the device needs to be light, lower cost, and use contemporary software to display and interpret the relevant data to help reduce the amount of training required.

In the past 20 years, improvements in cable technology have occurred often and at a larger scale. From the late 1940s through the mid-1990s, most cable plant was used to retransmit analog TV signals. This represents 45+ years of similar technology, with most advancements involving increasing the upper spectral boundary of the infrastructure to support a greater channel capacity. By contrast, and with the adoption of DOCSIS 1.0 (1997), 2.0 (2002), 3.0 (2006), and 3.1 (2013), the cable industry has experienced a major technology upgrade approximately every five years. With each upgrade in cable technology, testing devices needed to evolve in parallel, to keep technicians current and to provide more relevant information to perform their duties.

With the onset of COVID-19, which impacted both field upgrades and social guidelines, tools needed to evolve even more rapidly. New safety protocols for cable install and repair technicians resulted in new signal verification and testing processes. Recent increases in service bandwidth needs are forcing quicker deployments of multiple orthogonal frequency division multiplexing (OFDM) and orthogonal frequency division multiple access (OFDMA) channels. By developing a software-first, cloud-connected device, the operator can adapt to the current situation, access more technology and evolve it more quickly.

This paper discusses how cable modem technology was used to fulfill this role, evolving to be part of the operator's ecosystem and bringing tremendous value. The device we developed and characterize in this paper is referred to as a "field-capable measurement device," or "FCMD."

# 2. Historic Context

Original cable signal meters were very large and cumbersome. Ron Hranac, Technical Marketing Engineer in Cisco's Cable Access Business Unit, would know. He started as a technician in Idaho in the 1970s, working with up to seven other technicians, all of whom shared Jerrold Model 727 field strength meters (they also used smaller installation-specific meters). This particular meter was 13" x 8.5" x 8.5" and weighed 15 lbs. It was also very expensive. So expensive that after one of them was dropped from a telephone pole, instead of buying a new one, Hranac once spent 40 hours repairing it back into usability.

**Figure 1 – Jerrold 727 Field Strength Meter**

Newer field meters are much smaller, measuring around 6” x 10” x 3” and weighing about four pounds. This is an improvement of approximately a factor of three in both size and weight, compared to those very early meters available to cable industry technicians. One added benefit of the current meters is that they are battery powered and usually have a runtime of a couple of days, depending on usage patterns.

Until the advent of DOCSIS, the method to measure cable signals primarily involved measuring analog radio frequency (RF) signals. The process required the technician to properly adjust gain factors for a specific channel, measure, then repeat this process for the next channel frequency. It was a very time consuming and labor intensive process.

The arrival of the cable digital age dramatically changed how cable modems were used. Steve Zanetich, Executive Director of Technical Operations at Comcast, has seen more than a few signal level meters in his career, dating back to the times of manually tuning each frequency, through adjusting a series of pots and knobs. In the digital age, those same meters jumped light years ahead of their predecessors in terms of features, processing, and measurement accuracy. “In the past, we needed to change hardware and software, recalibrate regularly, and [perform] other costly routine maintenance in an effort to keep measurements accurate,” Zanetich noted. With today’s technology, by contrast, considerably more can be accomplished, at a fraction of the cost. “The days of manually writing down your levels at each job are gone,” he said. They’ve been replaced with real-time remote management, integrated business and performance tools, and collaborative software development, “all inside a feature-rich device that is capable of measuring so much more than just the amplitude of a single carrier.”

## 3. Problem / Opportunity Statement

Over the years, RF signal level meters (SLMs) have been made nearly indestructible, while being given the ability to make very accurate measurements. These requirements resulted in a meter with a significantly higher price point. The high price point, coupled with limited operator capital budgets, typically meant that most operators expected the meters to last between five and 10 years. With the rapid DOCSIS revisions, these meters can be obsolete before the cable operator can get a good return on investment (ROI).

The opportunity to use cable modems, which may not be as durable, but nonetheless make reliable and accurate measurements, was identified as a potential means to yield a better ROI.

After all, one element that is the same, between expensive spectrum analyzers and full-band-capable cable modems, is that they both thrive on the task that is demodulating signals. Developing a FCMD based upon a generic cable modem can help also achieve a good ROI.

# 4. Solution

The solution was to design a FCMD tool based on of a portable cable modem, using known hardware commodities to help reduce overall cost. Similarly, the software architecture was selected from well-known open-source commodities, to again save costs in the short and long term. Environmental and technological performance requirements were adjusted to achieve a desired price point.

In the process of achieving these goals, numerous additional benefits were identified that had not been originally anticipated. These include periodic software improvements to keep the devices reasonably current; cloud connectivity to "share the load" of processing, and to reference historical or informational data too bulky to be stored locally; and the development of "role-specific" user interfaces (UIs) such as "line technicians" and "install and repair technicians".

## 4.1. DOCSIS Based Cable Modem Gateway

The first SLMs could be considered high-precision near-laboratory-grade instruments that were ruggedized to handle the harsh outdoor field environments we frequently encounter. With the advent of DOCSIS and the use of microprocessors, SLMs transitioned to be high-end pieces of field test equipment. All DOCSIS cable modems (CMs) are required to perform measurements/tasks similar to current field SLM equipment, just to function. Example of these measurements include:

- Full bandwidth spectrum capture
- Downstream signal level measurements for automatic gain control (AGC)
- Quadrature amplitude modulation (QAM) measurement error statistics
- Upstream equalization coefficients
- Upstream transmit power
- Data throughput (speed test)

Since cable modems perform tasks equivalent to meters, and a goal was/is to reduce the overall cost per device, the decision was made to develop the field-capable measurement device using a known commodity. As a direct result, a DOCSIS 3.0-capable (to be followed by DOCSIS 3.1-capable) cable modem was selected as the hardware platform.

The cable modem housing was designed consistent with its consumer premise equipment (CPE) version, to minimize ruggedization costs.

## 4.2. Power Source

The development of a power source for the FCMD followed a similar methodology. Batteries have been used in our cable modem gateways for a long time, so the circuitry was extant. High capacity batteries have been around for a significant timeframe, and their technology is also proven. By selecting a generic form factor, we were able to decrease overall costs for the original product and any future battery replacements.

## 4.3. Graphical User Interface

Traditional SLMs are designed with a dedicated user interface as an integral component. This type of user interface usually touts benefits like being tightly coupled with the hardware, and ruggedized for daily field use. Those benefits can also represent drawbacks, however. Specifically, the drawbacks of an embedded graphical user interface (GUI) include:

- GUI is a possible point of failure requiring repair / replacement
- GUI software / GUI hardware is custom-designed on a per-product basis
- GUI hardware needs to be considered during power budget analysis
- GUI operating system includes licensing costs (sometimes but not always applicable)

At Comcast, technicians have been using existing network tools to interact with our cable modems for well over 10 years. Allowing them to interact with a portable cable modem, in the form of an FCMD, was an easy extension to those long-standing processes. The use of these tools brings additional benefits to the testing in the following ways:

- Cloud connectivity of the instrument (with consequent data ecosystem access)
- Common software development tools for application development
- Common operating system when mobile platforms are upgraded
- Global Positioning System (GPS) assistance with respect to application use
- Built-in, industry-standard accessibility features such as high contrast, large font sizes

Our technicians already use tools with adaptive and cross-platform form factors, suitable to their tasks, as depicted in Figures 2, 3, 4 and 5, which show the same ingress detection widget on a smart phone, small form factor tablet, large form factor tablet, and desktop computer, respectively:

**Figure 2 – Ingress Widget on phone**

**Figure 3 – Ingress Widget on Small Tablet**

**Figure 4 – Ingress Widget on Large Tablet**

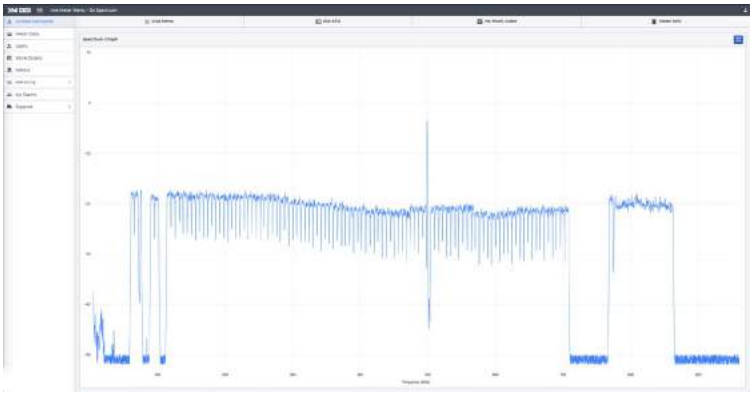

**Figure 5 – Spectrum Widget on Desktop Computer**

## 4.4. Performance Requirements

Environmental requirements for high-end signal level meters are developed with the overall price of the product in mind. This means being able to withstand a variety of weather, environmental and electro-magnetic interference (EMI) conditions. In addition, the RF front end of these meters is designed such that they have an extremely low noise figure, especially at low frequencies.

Based on over two years of field data, and despite fall-related ruggedization being a highly marketed feature of traditional SLMs, the truth of the matter is that product failures due to a drop are fewer than 0.1%. This is a very low calculated failure rate and was used as a consideration in the overall design. As a direct result, the FCMD was designed with the protection of an accompanying bag, designed to withstand a drop from a typical telephone pole height.

Environmental conditions, including rain, snow, heat and humidity, exemplify how cost reduction compromises carry some risks. For instance, temperature requirements required the addition of a fan on the second generation FCMD. The location of the ventilation holes, as well as the bag design, limited this risk. Over two years of data, the failure of this product due to environmental conditions is 0.2%. Again, with some mitigation in the design, the cost offset outweighed the risk.

Electrostatic discharge (ESD) and RF interference (RFI) issues are problematic for any cable field device. During initial development of the FCMD, multiple changes were made to minimize both internal and external issues which would affect performance.

High performance SLMs have an extremely low noise floor and a high dynamic range with respect to their input signal. A compromise was made during the design to accept and minimize the noise that is inversely proportional to the frequency common at low frequencies, 1/F noise. For a majority of technician tasks, the need is to see ingress about -30 decibel millivolt (dBmV) at 5 megahertz (MHz) – versus the ability to see ingress below 50 dBmV at 5 MHz. Specialized software was used to compensate for the front end design to achieve a sufficient dynamic range for ingress measurements, for both residential and line technicians.

# 5. Operator Benefits

The first generation FCMD device was based on DOCSIS 3.0 technology and was deployed in the fall of 2016. The second generation version was based on DOCSIS 3.1 and was deployed in fall of 2018. Beyond the lower cost, the benefits of the design were quickly realized over the past four years. By combining a non-proprietary software architecture with cloud connectivity, a number of features turned into benefits that were realized from this measurement device, versus a typical SLM. These feature/benefit pairings are bulleted below:

- *Reduced cost*. At a lower per-unit cost, the FCMD was and can be made available to more technicians, which translates into a higher adoption rate. It continues to increase employee satisfaction, and can be integrated into a larger tools and business metrics ecosystem within the company.
- *Cloud capable.* By linking the FCMD to cloud-based databases and processing functions, technicians gain immediate access to historic diagnostic data about a home or business, as well as performance metrics, remote diagnostics, and training opportunities.
- *Non-proprietary software architecture.* By taking an open-source, non-proprietary route to development, we were able to move in lockstep with agile software methodologies, which also reduced costs and improved employee satisfaction.

## 5.1. Adoption Rate

Perhaps not surprisingly, the capital expense budgets for network service providers are tightly controlled. By introducing a lower cost measurement device, operators can increase adoption rates, because more devices can be purchased from the same fixed capital budget. The first generation FCMD was, as previously mentioned, introduced in 2016, and achieved a 98% adoption rate across the operator's install and repair technicians within 13 months. This initial device was DOCSIS 3.0-capable, and despite a high adoption rate, its functionality didn't meet the need for a DOCSIS 3.1-capable device, especially for maintenance technicians.

The second generation FCMD device (DOCSIS 3.1-capable) was deployed in January of 2019. It achieved a 95% adoption rate for maintenance technicians within 16 months. Graphs showing the uptake for the first and second generation FCMD are shown in Figures 6 and 7.

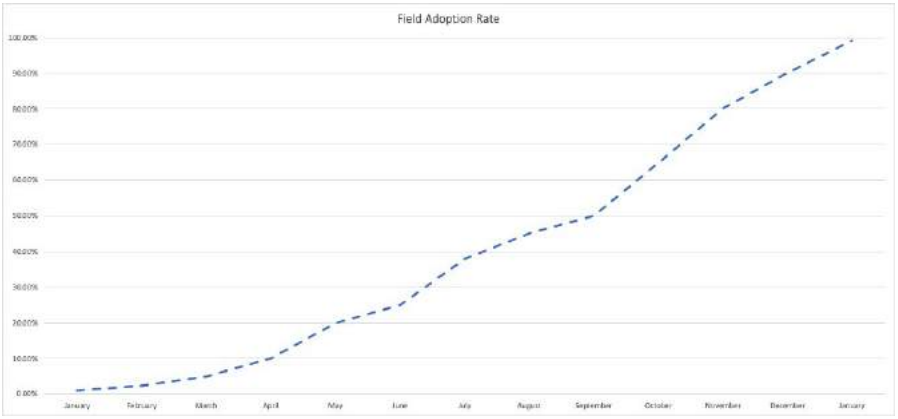

**Figure 6 – 1st Generation Adoption Rate**

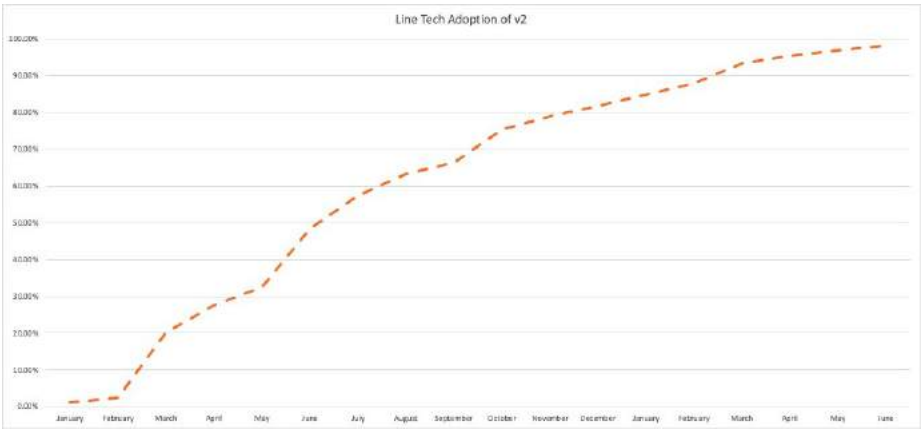

**Figure 7 – 2nd Generation Adoption Rate**

## 5.2. Employee Satisfaction

As mentioned previously, traditional SLM costs and functional lifetimes typically resulted in employees using the same meter for a minimum of five years. This can impact employee satisfaction, noted Tom Bach, Senior VP of Engineering for Comcast, who explained that employee morale can be affected, "especially when less-tenured employees are using the latest 3.0 DOCSIS-capable equipment, while long-term employees are still on DOCSIS 2.0-capable equipment." The ability to equip all technicians with the latest DOCSIS 3.1 technology quickly helped to improve overall employee satisfaction, he added.

## 5.3. Ecosystem

With the low cost and consequent high adoption rate across the company, the FCMD product could be designed to participate in the company's extensive and growing software ecosystem. All techs could be assigned identical devices, whether their primary roles involve installation and repair, maintenance, or headend tasks. This also allows data to be shared across functional groups. In turn, and over time, this improves the accountability and access to data across different populations of technicians.

The high adoption rate, coupled with being part of the company's overall data-driven ecosystem, and the availability of the cloud, allowed the FCMD product to go beyond a field measurement device, to a device that supports training opportunities, metrics, and even remote diagnostic capabilities.

## 5.4. Cloud-Capable

Existing SLMs do, of course, have the ability to work with a cloud infrastructure. However, access to proprietary cloud data can be cumbersome and cost prohibitive. By contrast, the FCMD became part of the operator's ecosystem, such that we were able to rapidly adapt its design to numerous cloud-capable applications.

Noted Larry Wolcott, Engineering Fellow at Comcast and a lead proponent of the industry's proactive network maintenance (PNM) efforts: "Because of the open nature of the software APIs, we were able to quickly attach this tool into our software ecosystem. Other systems had clouds, but they were not adaptable into the rest of the ecosystem."

## 5.5. Immediate Historic Data Collection

FCMDs have collected multiple terabytes of data over the past two years. The data collected include but are not limited to: ingress, full band spectrum capture, QAM channel signal analysis, OFDM signal analysis, and speed test performance. This information carries many long-term uses, including peer review, training, artificial intelligence (AI) and machine learning (ML) analysis, and system metrics. Figures 8, 9 and 10 depict different types of data collection using the FCMD:

**Figure 8 – Pre-Equalization Data Collection**

**Figure 9 – OFDM Data Collection**

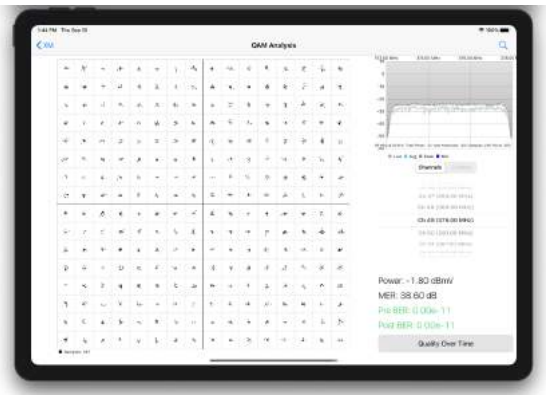

**Figure 10 – QAM Data Collection**

## 5.6. Peer Assistance

Many field problems are difficult to diagnose even by an experienced technician. Using the technician's tools as a medium to share data immediately to the cloud allows other technicians and supervisors to assist technicians remotely. The need for multiple truck rolls to diagnose and repair a difficult problem can be and was decreased. Figure 11 shows an example of a peer-assisted diagnosis, where a remote technician can assist the technician that is onsite by reviewing signal spectrum, DOCSIS and video channel powers, and DOCSIS locked signals statistics.

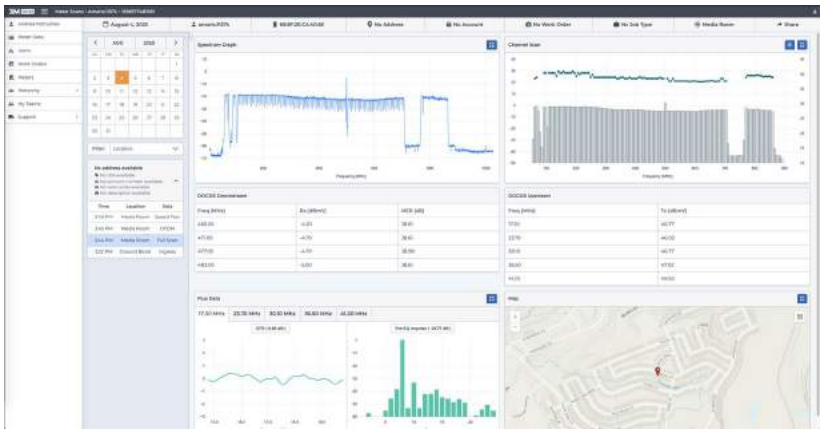

**Figure 11 – Peer Assistance Example**

## 5.7. Training

Post-job analysis of historic data per technician provides an opportunity to design individualized training, per employee, to improve overall cable plant health in the short and long term. For example, supervisors routinely review employee ingress measurement metrics and work with each technician to identify what would likely cause the ingress seen on their jobs and possible solutions for future reference.

## 5.8. Real time analysis and feedback

Measurement data, at the time of collection from the FCMD, is flowed into data streams that serve multiple purposes: overall company consumption; real time analysis for network performance; and adherence to employee metrics. The data is also stored for post processing and long-term data mining.

## 5.9. Metrics

For field technicians, metrics collections can simultaneously represent tremendous value and occasional contention – the latter because the addition of the cloud allows those metrics to be collected and validated on a per-job basis, which ultimately decreases the potential for obfuscation by the technician.

On the other hand, the ability to collect and analyze anonymized per-customer/per-incident performance data, over time, gives the operator the ability to document performance and determine possible customer improvements. These metrics help to improve the overall quality of the plant. In numerous cases, when we implemented a required set of metrics, a measurable decrease in repeat calls was seen.

Beyond per-technician or per-customer metrics used for diagnostics, the ability to collect meter application metrics has also been beneficial to identify the application usage statistics, which assist in application design. With the data available, the operator can understand which application widgets are being used and how much time it takes. Such metrics give opportunities to improve the widgets and employee training.

The collection of metrics into the ecosystem can also improve construction build-out processes. Upon completion of construction, the mobile measurement tool and ecosystem in the FCMD is able to document the RF performance of the new plant construction prior to operator acceptance – a capability deemed invaluable to building out plant infrastructure.

Metrics about various tasks can also be validated, by collecting demonstrated plant performance improvements that were observed on a job. One example might be when a speed test improves from 500 Mbps to 1 Gbps.

## 5.10. Remote Diagnostics

The addition of the cloud and Wi-Fi connectivity also allows for remote control and remote diagnostics through the FCMD. A technician can now connect the device to the ground block, establish a DOCSIS connection, and, through a remote application, move around the premises, fixing issues and receiving immediate feedback from the device, still out by the ground block.

In addition, the cloud allows the FCMD to become a short-term piece of diagnostic equipment. Through the ecosystem, many of the technician's applications have been re-hosted in the cloud and can be controlled remotely.

## 5.11. Software Architecture

A non-proprietary software architecture also enabled short-term product improvements that helped to improve overall acceptance and performance. Technicians have suggested numerous areas where the technology could be improved. Including technicians in the design feedback loop translates into quick product improvements. It also increases employee morale, by not only giving technicians a say in how they would like the gear to work, but also by rapidly implementing those suggestions.

"We get to make it do exactly what we want," said Patrick Stephens, a Senior Business Technician at Comcast, who also noted that "it makes honest technicians."

### 5.12. Reduce Development Costs

DOCSIS 3.0, DOCSIS 3.1, and high-split (5 MHz to 204 MHz upstream) cable modems have an underlying software architecture and operating system that is almost identical. Adding mid-split or high-split capability to an SLM is primarily a hardware (HW) upgrade and only requires minimal software upgrades. The jump to a DOCSIS 4.0-based cable modem will require additional software upgrades, but the backwards-compatible nature of DOCSIS indicates that a large amount of the existing development will be reusable.

Personal computer devices (desktops, laptops, tablets) continually evolve, yet the underlying operating system is usually 90% or more backwards-compatible. Similarly, a GUI that uses an operating system that has not significantly changed over the past five years can also dramatically decrease ongoing development costs. Additionally, with the mobile cable modem and control-plane in the FCMD being separate, either can be upgraded with minimal impact to the overall system.

### 5.13. COVID-19 Opportunities

Along the way, we've been able to identify and implement a quarterly improvement program to modify the FCMD's functionality, through software, to meet changing needs of the technicians.

One example of such dynamic adaptation, attributable to a non-proprietary software architecture and a cloud-based ecosystem, is the changes required to work in the physically distanced COVID-19 conditions that occurred in early 2020. Employee safety was crucial during this time, and required the development of new testing methodologies. Using existing and available field meters, processes would need to be identified and appropriate training would need to be developed and implemented. Additionally, there was no practical way to ensure that the process would be properly followed.

Our tools software architecture allowed us to build new signal processing algorithms to validate performance at taps, residential ground blocks and internal CPE -- without endangering employee safety by entering a premise containing potentially infected residents.

This is not the only use case where the software architecture has afforded us the ability to improve the product between hardware improvement cycles. We were able to rapidly build other tools, as well, to measure downstream alignment, improve speed test diagnostics, and log DOCSIS information.

## 6. Field Feedback

The integration of the SLM into our overall data ecosystem provided a number of time-saving and performance benefits. Todd Szuter, Director, Preventive Maintenance at Comcast, contributed this short-list of benefits:

- Old methods of collecting per-channel data on plotting paper, to see a standing wave, are gone.
- Instant cloud access dramatically decreased configuration headaches for residential technicians. No longer were techs using outdated channel maps, resulting in invalid refer to maintenance (RTM ) requests.
- Third party SLMs have cloud capabilities but are not integrated into our software ecosystem. The data may be recorded but it was rarely used.
- This cloud-enabled device keeps technicians honest by making data available. Those who want to succeed embrace the device.

- This capability has great value in validating new construction prior to marking the effort as complete. Performance metrics and pictures, including GPS data, can be recorded and validated prior to company acceptance
- Cloud metrics helped improve the plant by enabling all technicians to reduce issues at all jobs.

Szuter also identified some negatives and resistance with introducing new technology to the workforce. Many technicians, he noted, just don't want to switch, because embracing a new technology and/or paradigm can be difficult. Also, with the addition of cloud metrics, "even though we dramatically increased network health, reduced repeat rates and improved the overall customer experience, in some cases a job that used to take 10 minutes may take 50 minutes," he noted.

When asked about the challenges and rewards of pushing new technology so deeply into the field, Comcast's Zanetich, quoted earlier, reiterated that good design yields good usage. "I think with anything new, you will experience challenges, and the deployments of this platform were no different," he said. Specifically, encouraging technicians to embrace the idea of a portable FCMD, and trust its readings, takes time, but not that much time: "It didn't take long for our technicians to see the value of the powerful platform that we placed in their hands, which they themselves can iterate based on what they need," he continued. "It's amazing to see the changes in the field, that can now happen overnight with a software update – changes that used to require us to purchase a new device and spend months distributing."

Clearly, the adoption of new technology, especially test equipment, always comes with its challenges. With the introduction of the FCMD, technicians were able to find issues faster, improve rework metrics and optimize the customer experience. Gone are the days of hunting-and-pecking, from a troubleshooting perspective; as a result, technicians appreciate the platform and as a means to pinpoint what needs to be done to optimize product and services delivery. "As I talk to our technicians," Zanetich concluded, "they appreciate the investment the company is making to ensure they have the best equipment available."

## 7. The Future

When measurement tools are cloud-based, remote signal analysis can be done to reduce truck rolls – in some cases, truck rolls that weren't necessary in the first place. Eventually, the same software can be embedded in CPE like set-tops and gateways, because they all ultimately use the same DOCSIS underpinnings. The network becomes the test apparatus – and it runs constantly, finding problems, and self-healing when possible, via PNM, dynamic channel changes, and related adjustments: Informing customers so that they can help themselves, such as about loose connectors or too many splitters, or automatically creating outage information that can inform operations centers and network techs.

When asked for his opinion about adding more PNM features into CPE, Cisco's Hranac was enthusiastic. "I love it – the more information from premises equipment, the better, including what full band capture brought to cable modems, and PNM brought in DOCSIS 3.1-based cable modems."

Virtually all of the FCMD's functionality is based on software commonly found in all DOCSIS 3.1 compliant cable modems. The opportunity to add the underlying functionality to STBs and other CPE allows a large percentage of current truck roll analysis to be done via the cloud or autonomously. Currently, full band spectrum analysis is being performed on more than 85% of all deployed cable modems at Comcast. The ability to add constellation analysis on all channels beyond those representing the currently bonded channels, per modem, could yield additional insights about Moving Picture Experts Group (MPEG) video statistics, again to potentially prevent unnecessary truck rolls.

Meanwhile, DOCSIS 4.0 is coming. In order to be able to not limit the technology because of hardware limitations, the hardware should be overdesigned to allow options to be considered in software. As DOCSIS 4.0 evolves, there will likely be differences and improvements – and, as a result, any field tool should have the ability to accept over-the-air (OTA) updates to keep the devices in step with technology.

As a general rule, technician tools are continually getting smaller, faster, lighter and less expensive. Cable operators started with a field meter that was 25 pounds and required an external power source. Similar devices now are the size of a small loaf of bread. With the addition of software defined radios (SDRs) and system on a chip (SOC) designs, devices like cable modems and FCMDs at some point could be the size of a USB-connected Ethernet dongle.

The addition of AI/ML on all premise devices may improve troubleshooting. Cable modems and STBs can report network events at the premise level, between themselves. The aggregation of multiple events across devices sharing the same ground block can determine, for instance, if an issue is a single device issue, or one that affects the entire premise.

## 8. Conclusion

The software revolution of the FCMD has shown great benefits. The change to the ecosystem and returns on investment have so far outweighed the risks of this endeavor.

With the unanticipated adaptations to COVID-19 in the Spring of 2020, we demonstrated that the FCMD can quickly acclimatize to a new world, through software improvements and OTA updates, which brought tremendous value to the field.

This “cable modem as an analysis tool” paradigm, embodied in the FCMD, could apply to STBs and broadband gateways, as well. The ability to continuously innovate on this platform, depending on the needs of the operator, removes the hardware-based and proprietary constraints of the past. The software adaptability of the meter has accelerated innovation, improved employee and customer experiences, reduced cost and removed risk in our DOCSIS upgrades.

## 9. Acknowledgements

Much of the material within this document was sourced from interviews and written contributions of many Comcast leaders and industry experts. The authors would like to thank Ron Hranac from Cisco, and Tom Bach, Larry Wolcott, Stephen Zanetich, Todd Szuter, Rob Gonsalves, and Patrick Stephens from Comcast.

# 1. Introduction

The remote upstream (US) scheduler is a low latency Remote PHY solution proposed in [1] to maintain low latency for DOCSIS regardless of the CIN distance. Moving the US scheduler from the CCAP core to the remote PHY device (RPD) creates a new management interface between the remote US scheduler at the RPD and the upper MAC layer clients at the CCAP core. This entails a robust and standard application programming interface (API) for easy configuration / management of multiple remote US schedulers at scale and enabling interoperability between different CCAP core and RPD venders.

Towards this goal, we propose a YANG based API to manage the remote US scheduler. YANG is an API contract language widely used in the world of networking and is now being introduced into the world of DOCSIS. A specification written in YANG is referred as a "YANG module", and a set of YANG modules are collectively called a "YANG model". A YANG model characterizes the behavior of a network function with data hosted by the server that a client can manipulate and observe using standardized operations. Once the YANG model is published, both client and server can have faith that the other knows the syntax and semantics behind the modeled data.

In this paper, we describe how we used YANG to define the remote US scheduler service contract. Our YANG model has several modules. The first is the US scheduler itself that provides the scheduling services such as best effort, rtPS, nrtPS, UGS and PGS. The second component is the MAP Builder that that allocates bandwidth across the US RF channels. The remote upstream YANG model is intended to be included in the CableLabs' standard modules and become an integral part of the standard DOCSIS YANG ecosystem.

The rest of the paper is organized as follows. Section 2 explains why the remote US scheduler may help maintain low-latency for DOCSIS in R-PHY deployments. Section 3 shows how to separate the real-time scheduling functions from the CCAP core while keeping DOCSIS control plane intact. Section 4 examines the reasoning for using YANG data model-driven management for the remote US scheduler. Section 5 explains the fundamental modeling principles to establish the remote US scheduler YANG model. Section 6 presents the remote US scheduler YANG model structure and the key components. Section 7 discusses how to add the YANG based remote US scheduler to existing RPDs that are managed by the legacy Generic Control Protocol (GCP). Section 8 describes how to integrate the remote US scheduler into the upcoming DOCSIS YANG ecosystem. Finally, section 9 concludes the paper and highlights the takeaways.

# 2. Why Remote US Scheduler

In the R-PHY architecture today, the US scheduler is centralized at the CCAP core, leaving only the PHY elements at the RPD. This design choice fits most of the R-PHY deployment cases today where the CIN distance is less than 100 miles and the MAPs run at 2-millisecond interval. Under these operation conditions, CIN delay has no impact on the upstream scheduling latency based on the analysis in [1], and R-PHY system is equivalent to the I-CCAP (Integrated Converged Cable Access Platform) in terms of the latency performance, but with much better RF capacity.

As the distributed access architecture (DAA) transformation deepens, there are scenarios where the CIN is stretched beyond the 100-mile mark, for reasons such as hub-side consolidation that relocates a CCAP core to the central headend or a regional data center. Meanwhile, driven by the new low latency applications, such as cloud gaming and mobile xHaul, the DOCSIS upstream request-grant (REQ-GNT) protocol is tightened to a shorter MAP interval at 1 millisecond [2]. Under these new operation conditions, the CIN becomes contributing factor to the upstream scheduling latency. By relocating the

upstream scheduler to the RPD, the CIN delay factor can be effectively remoted from the REQ-GNT loop, therefore achieving latency improvement.

Figure 1 shows the centralized vs. remote US scheduler deployment scenarios and the traverse paths of the REQ-GNT(MAP) messages.

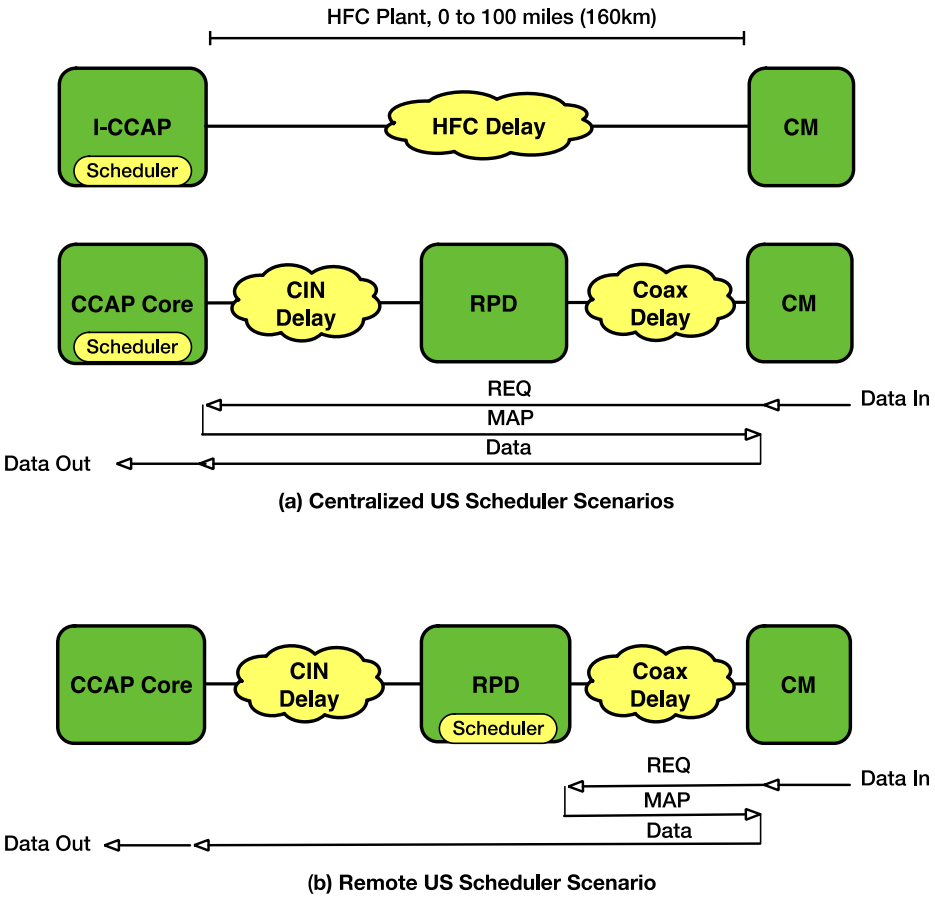

**Figure 1 – Centralized vs. Remote Upstream Scehduler Deployment Scenarios**

It should be noted that a centralized scheduler for Remote PHY will provide equivalent performance to a classic I-CCAP system as they both have the US scheduler in the same location. That location is the hub site that is 100 miles or less from the CM. The request and MAP messages are given high priority on the CIN so that any CIN queuing and latency will not add to the request grant delay.

Thus, the remote US scheduler is an operational option for when performance is desired that is better than a classic I-CCAP or if the CIN needs to be significantly longer than the 100 miles.

## 3. How to Spin off the Remote US Scheduler

In the R-PHY architecture today, the US scheduler is an internal component located at the CCAP Core, as shown in Figure 2.

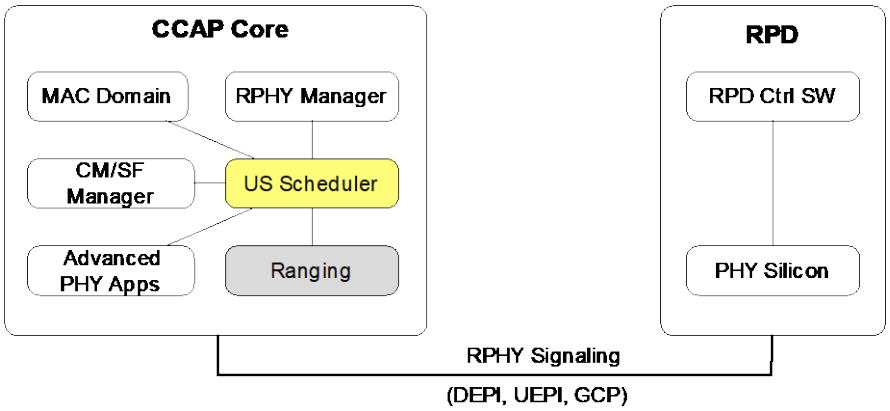

**Figure 2 – Centralized Upstream Scheduler in R-PHY Today**

The US Scheduler interacts with various clients in the DOCSIS control plane using vendor specific interfaces, as listed in Table 1.

**Table 1 – US Scheduler Clients in DOCSIS Control Plane**

| Clients | US Scheduler Northbound Interface |
|---|---|
| MAC Domain | Notifies per MAC Domain upstream channel configurations including the corresponding primary capable downstream channels for carrying the MAP messages. |
| Cable Modem (CM) Manager | Notifies the CM operation state. |
| Service Flow (SF) Manager | Notifies the SF QoS Parameters, SF SID / SID cluster assignment. |
| Ranging | Requests for ranging transmission opportunities in MAP, including initial ranging, maintenance ranging and probing in OFDMA. |
| Advanced PHY Applications | Requests for transmission opportunities for advanced PHY features, such as the data transmission opportunity for OFDMA US data profile (OUDP) test, or a silent transmission opportunity to capture per channel noise floor. |
| Remote PHY Manager | Notifies the DEPI and UEPI session / pseudo wires to transport the scheduler signaling messages, such as MAP and bandwidth request pseudo wires. |

Figure 3 shows a remote US scheduler architecture that separates out the real-time scheduling functions while keeping the northbound client interface intact. This is achieved by partitioning the US scheduler into a control component (US scheduler manager) in the CCAP core and a real-time component (US scheduler engine) in the RPD. The US scheduler manager interfaces the northbound control plane clients and manages the southbound US scheduler engines. The US scheduler engine fulfils the real-time scheduling services at the RPD.

In between the US scheduler manager and the US scheduler engine, we propose that a YANG data model-driven interface is used to formally describe the managed data source at the remote US scheduler engine. The US scheduler manager may simultaneously manage multiple US scheduler engines. To meet the timing and scaling requirements, a stream-lined YANG model-driven network protocol, such as gNMI, may be used to transport the API calls. gNMI stands for the gRPC Network Management Interface, and gRPC is known as Google remote procedure call.

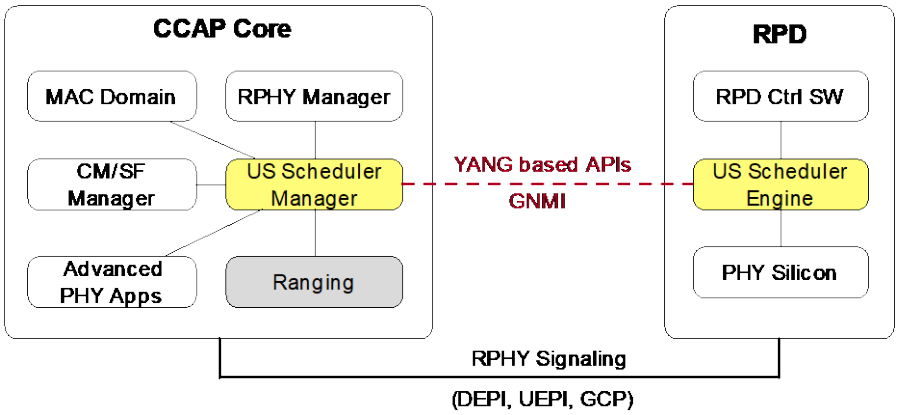

**Figure 3 – Remote Upstream Scehduler Architecture**

# 4. Why YANG Model-Driven API for the Remote US Schduler

## 4.1. A Formal Defination of Service Contract

YANG is a full, formal contract language with rich syntax and semantics. A YANG model is the specification written in YANG about the managed data objects that a client can manipulate and observe using standardized operations. The YANG model-driven management is about building the YANG data and using the model via tooling to generate code to access the YANG objects on the managed devices.

As displayed in Figure 4, which covers the data model-driven management components, once the YANG models are specified and implemented, a particular encoding (XML, JSON, protobuf etc.) can be selected along with a particular remote procedure call (RPC) protocol (NETCONF, RESTCONF, or gNMI/gRPC) for transport. Based on the encoding and protocol selections, code or API can then be generated via proper applications / tooling (for example, in Python, C++, Go or any other language) [3].

To enable remote US scheduling, a formal service contract is needed between the US scheduler manager and the US scheduler engine. The YANG model-driven API is a natural choice to achieve this.

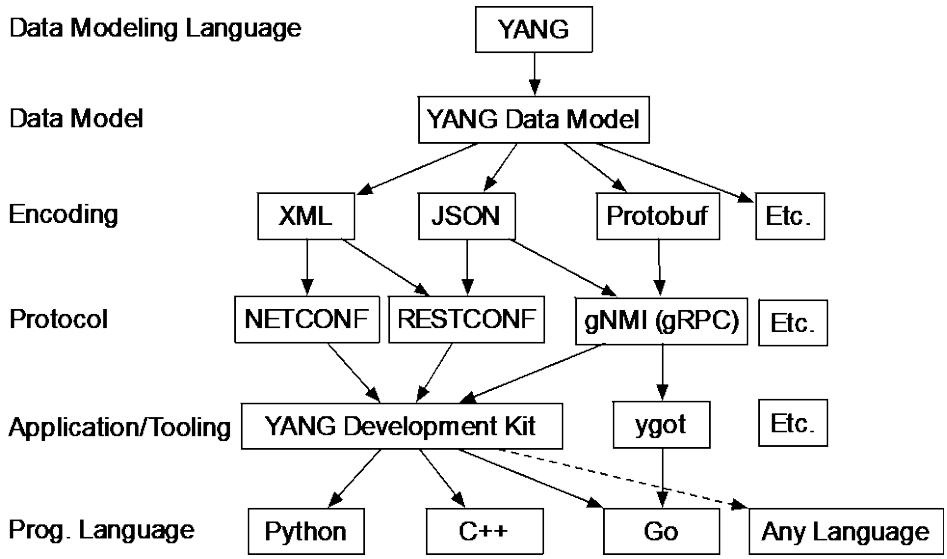

**Figure 4 – YANG Data Model-Driven Management Components**

## 4.2. Mature and Well Adoped

YANG was originally created at IETF in 2007 to describe standard data models for network automation via NETCONF. Since then, YANG data model-driven management has become a well-established trend in the network industry. YANG data models are produced by many parties including standard organizations, consortiums, forums and open source projects (such as OpenConfig and Broadband Forum), and network equipment vendors.

YANG data modeling has also been adopted in cable. There are several efforts involving YANG data modeling driven by CableLabs, including the ICCAP YANG modeling, as part of CCAP (Data-Over-Cable Service Interface Specifications) OSSI (Operations Support System Interface Specification) effort, the Flexible MAC Architecture (FMA) YANG modeling, and a recent initiative to build a common YANG ecosystem across different network elements (NEs), including CCAP Core, RPD, RMD and ICCAP.

## 4.3. Interoperation Made Easy

YANG solves the multi-vendor interoperability issue by using the data model as the core definition of the configuration and operational data and renders them to the management interface in a protocol specific construct. This approach is different from the traditional information model, which only models the managed objects at a conceptual level independent from the implementations. The YANG data model is intended for implementation. The YANG based API is bound to specific message encoding and data transport protocols that can be directly used by the client and server code. So as long as the underlying YANG modules are same, the client and server will have the same view of the API, avoiding the typical misinterpretation issues found at the interop.

## 4.4. Sufficiecnt Performance at Scale

The YANG based data model-driven management scheme supports a number of design options that can be used to achieve low-latency at scale. These include:

**Asynchronous and Parallel RPCs**

By using asynchronous and parallel RPCs, a client can avoid the serialization delay and manage multiple devices or data objects at the same time. YANG natively supports asynchronous RPCs using the concept of intended configuration and applied configuration. This allows a client to acquire the RPC result asynchronously by either polling the applied configuration or subscribing to the applied configuration update, without being blocked by the RPC results. Additionally, the client and server can use the YANG data tree to identify the interdependencies among the data objects and enable parallel processing of the data objects are isolated from each other.

**Long-lived RPC sessions**

Certain YANG based protocols, such as NETCONF and gNMI (gRPC), support long-lived RPC sessions to minimize session setup overhead. gNMI (gRPC), which uses HTTP/2, further allows multiple RPCs to be multiplexed onto one TCP connection. By doing so, it supports parallel RPCs without increasing the number of TCP connections.

**Binary Encoding**

gNMI (gRPC) supports Protobuf, an efficient binary message format, that improves message encoding/decoding processing time on both client and server. Based on Google's gRPC performance benchmark test, 700k unary RPC calls per second is achievable [5].

As to the remote US scheduler interface, the most stringent timing constraints come from two basic requirements. These are the dynamic service flow setup for voice, and the need for continuous ranging.

Let's first examine the dynamic service flow setup case as shown in Figure 5. After receiving the DSA-REQ for a voice call, the scheduler manager in the CCAP core needs to check with the US scheduler engine in the RPD to make sure the required quality path can be established. In this case, the YANG based API transaction delay contributes to the overall service flow setup time, which needs to be one second or less to meet the post-dial delay requirement [4].

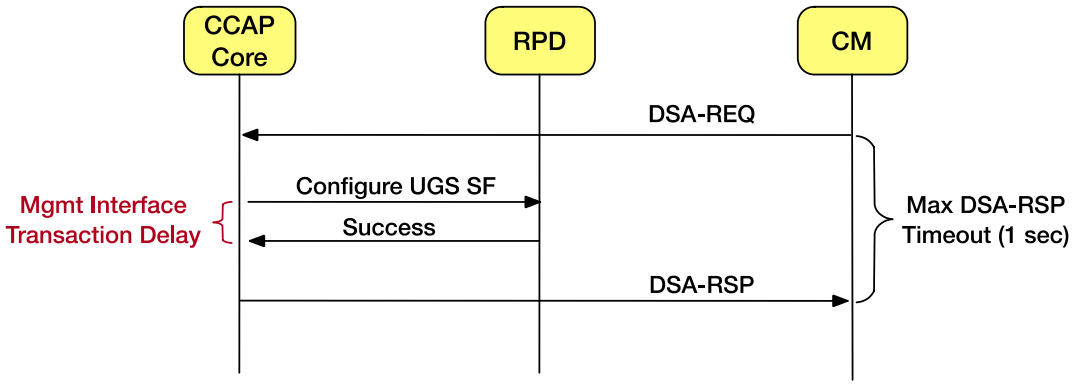

**Figure 5 – Adding a UGS SF in a CM Initiated DSA Transaction**

Now let's see about ranging as shown in Figure 6. After receiving the RNG-REQ from the CM, the ranging module in the CCAP core may decide to continuously range the CM by requesting a subsequent ranging opportunity in less than a second if it detects the CM deviates from the optimum timing/power/frequency settings.

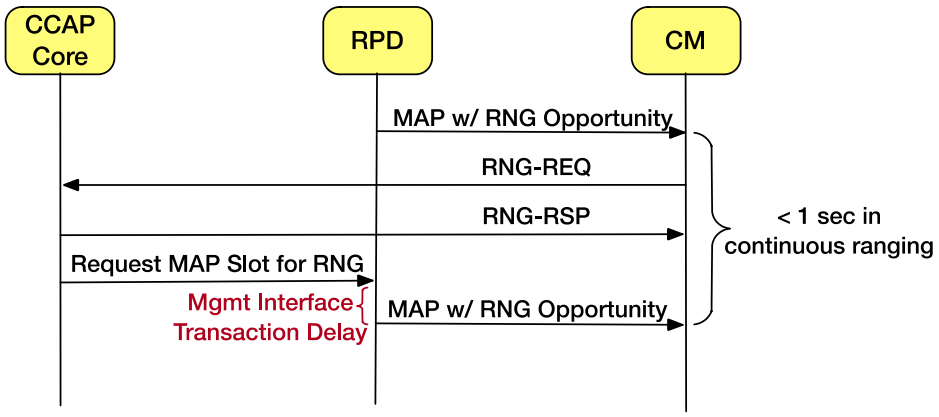

**Figure 6 – Adding a RNG-REQ Opportunity in MAP**

For both cases, the overall DOCSIS transaction delay is capped at one second or less. To meet this requirement, we can assume tighter budget of 100-millisecond delay budget for the YANG based remote US scheduler management interface, taking into consideration of the typical RPD CPU speed, CIN delay, and RPC transaction time.

### 4.5. Easy to Maintain

One advantage for using YANG based management interface is the rich tooling and applications for processing YANG modules and their metadata. YANG applications validate YANG modules, generate APIs and provide language binding. YANG metadata allows the client to pre-validate the instance data, confirm the module support in the network elements, and check for potential non-backward-compatible changes that could have been introduced between versions. YANG also has a huge library contributed by various organizations that promotes reusability.

YANG model driven telemetry (MDT) provides a new way to maintain service quality by streaming data continuously from the managed devices using a push model to give client near real-time access to the operational statistics.

## 5. Remote Upstream Scheduler Behavior Model

The goal is to place a remote upstream scheduling engine into an RPD that works in tandem with a remote upstream scheduling manager in the CMTS Core. Aside from the specific functionality of this system, there are some high-level objectives that have to be met to turn this into a product. Some of these at least are:

- It has to work
- It has to scale
- It has to interoperate
- It has to be maintainable

The following discussion is aimed at hitting all of these goals.

One option would just to let different manufacturers load their US schedulers from their cloud CMTS into someone else's RPD. In theory that could work, and may well be a product option. But then there is software from two manufacturers in one platform which is challenging from a built and test viewpoint.

Instead, this paper proposes building an US scheduler from one manufacturer that will interoperate with another manufacturer.

This paper proposes two fundamental principles for constructing a remote scheduler.

1. Create a well-defined behavior model
2. Use a well-defined API on that behavior model

In the construction of this behavior model and API, a very conscience decision was made to take the larger schedular and break it down into smaller independent schedulers that each had very specific functionality. There would then be a rule set on how the different schedulers interacted with each other. Finally, there would be another behavior model for the MAP Builder.

It's time for an example. Let's look at the behavior model for the unsolicited grant scheduler (UGS).

UGS Service Flow

- Service Flow ID (SFID)
- MAC domain name
- MAC domain upstream channel
- Service Identifier (SID)
- UGS QoS Parameters
    - request-policy
    - unsolicited grant size (bytes)
    - nominal grant interval (ms)
    - tolerated grant jitter (ms)
    - grants per Interval
- Grant statistics
    - cumulative grant size
    - grant rate

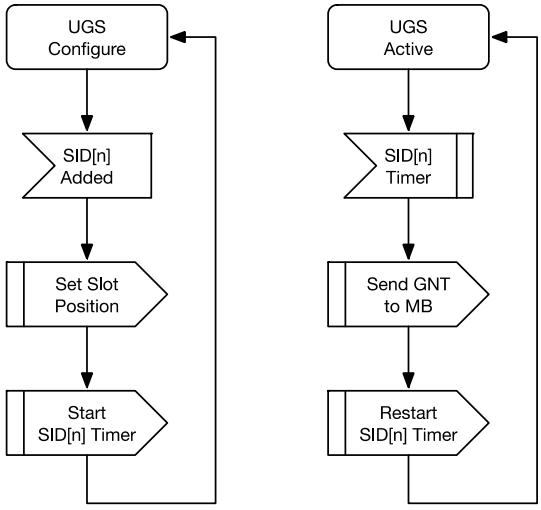

**Figure 7 – UGS Behavior Model**

A behavior model and a basic API is shown in Figure 7. This API will ultimately be represented in YANG but is shown here in variable form.

The behavior model has two states, configure and active. The configure state is for adding and removing service flows. The active state is run-time that generates the grants when needed. The model is simple. A service flow/SID is added into a scheduling wheel. For example, if a grant for voice-over-IP needs to be sent every 20 ms and a MAP message is every 2 ms, then there are 10 entries in the scheduling wheel. At run time, an event timer expires and a grant is scheduled.

Now let's look at the API. There are three basic elements. First, there is the logical associations. This is done with a service flow ID, a mac domain name, an upstream channel identifier and a SID. Second, is what action to take. This is described by the QoS parameters. The action is then with a request policy of UGS, to prohibit any request opportunities, instead, directly provide an unsolicited grant size (say 100 bytes) every nominal grant interval (say 20 ms) with a tolerated jitter (say 2 ms) with a grants per interval (say 1). Third, it is important to always measure what happened. In this example, the grant statistics include the cumulative grant size and the grant rate.

So, the API connects the two sides together, an action is requested, and a measurement is made to see how the action played out. That API describes a behavior model. That's it. This methodology can be repeated for the other schedulers and for the MAP builder.

In Figure 8, we see the actual implementation of the final model in the YANG tree and UML.

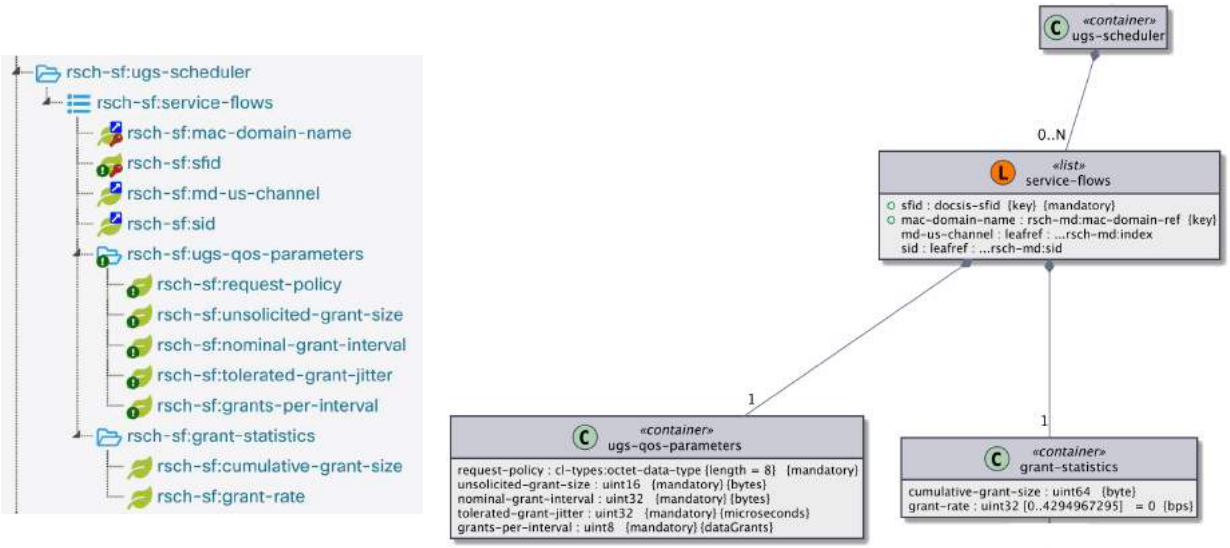

**Figure 8 – UGS Diagram and UML Model**

To go back to our original objectives, the model has to work. That is achieved through simplicity and modularization of the model. The model has to scale. That is achieved by setting realistic performance and scaling goals. The model has to interoperate. That is achieved by using YANG as the API and well-defined behavior models. And the model has to be maintainable. That is achieved again with YANG and the MDT features that allow monitoring and measuring of what has happened.

## 6. YANG Model for Remote Upstream Scheduler

The remote US Scheduler YANG model includes a base module that describes the remote US scheduler framework and several submodules that specifies the component level attributes. The overall remote US scheduler YANG model is intended for the following uses cases:

- Configure the remote US scheduler, e.g.,
  - Configure US SF scheduling type and QoS parameters
  - Configure US MAP attributes
- Invoke US scheduling actions, e.g.,
  - Request an US ranging opportunities in MAP
- Collect the remote US scheduling telemetry data, e.g.,
  - Acquire per SF requesting rate and granting rate

## 6.1. Base remote-us-scheduler YANG Module

The base module, titled "remote-us-scheduler" defines the remote US scheduler structure that holds together three functional submodules, namely us-scheduler-domain, us-qos-scheduler and map-builder, as shown in Figure 9. Each of the submodules can be defined separately and augmented into the base module. This arrangement decomposes a complex scheduler into smaller and simpler submodules that can be independently modeled and managed.

```
module: remote-us-scheduler
  +--rw remote-us-scheduler
     +--rw us-scheduler-domain
     +--rw us-qos-scheduler
     +--rw map-builder
```

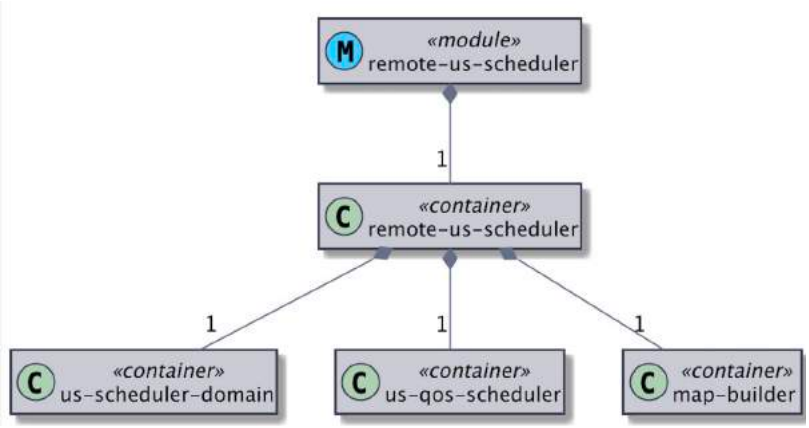

**Figure 9 – remote-us-scheduler base module tree diagram and UML**

## 6.2. us-scheduler-domain YANG Module

This module defines the MAC domains served by the remote US scheduler. Each MAC domain contains the parameters required for US scheduling, including common QoS policies, US channels and SID assignments and the list of primary capable DS channels for carrying MAP messages.

Figure 10 shows the top-levels of the us-scheduler-domain YANG module tree diagram, omitting the lower level leaf entries for simplicity. The us-scheduler-domain module is augmented to the us-scheduler-domain container in the remote-us-scheduler base module.

```
module: us-scheduler-domain
  augment /rsch:remote-us-scheduler/rsch:us-scheduler-domain:
    +--rw us-scheduler-domain* [mac-domain-name]
       +--rw mac-domain-name     string
       +--rw md-us-channel* [index]
       |  +--rw index                  uint8
       |  +--rw us-rf-chan-cfg
       |  |     ...
       |  +--rw ds-rf-chan-cfg* [port-number channel-index]
       |  |     ...
       |  +--ro md-us-channel-state
       |  |     ...
       |  +--rw sid-cfg* [sid]
       |        ...
       +--rw md-us-qos-policy* [type]
          +--rw type    identityref
          +--rw (parameters)?
```

**Figure 10 – us-scheduler-domain module top-three level tree diagram**

## 6.3. us-qos-scheduler YANG Module

This module defines the US QoS scheduler of different scheduling types, including best effort, rtPS, nrtPS, UGS, PGS and aggregated service flows (ASF). Each scheduler type represents a specific scheduler behavior as discussed in Section 5.

Figure 11 shows the top-level tree diagram of the us-qos-scheduler YANG module, omitting the lower level leaf entries for simplicity. Figure 12 shows a detailed tree-diagram for the best-effort-scheduler. The us-qos-scheduler module is augmented to the us-qos-scheduler container in the remote-us-scheduler base module.

```
module: us-qos-scheduler
  augment /rsch:remote-us-scheduler/rsch:us-qos-scheduler:
    +--rw best-effort-scheduler
    |     ...
    +--rw rtps-scheduler
    |     ...
    +--rw nrtps-scheduler
    |     ...
    +--rw ugs-scheduler
    |     ...
    +--rw ugs-ad-scheduler
    |     ...
    +--rw pgs-scheduler
    |     ...
    +--rw lld-asf-scheduler
    |     ...
    +--rw dhqos-asf-scheduler
          ...
```

**Figure 11 – us-qos-scheduler module top level tree diagram**

```
module: us-qos-scheduler
  augment /rsch:remote-us-scheduler/rsch:us-qos-scheduler:
    +--rw best-effort-scheduler
    |  +--rw service-flows* [mac-domain-name sfid]
    |     +--rw sfid                          docsis-sfid
    |     +--rw mtc-mode-enabled?             boolean
    |     +--rw mac-domain-name               rsch-md:mac-domain-ref
    |     +--rw (sid-channel-assignment)?
    |     |  +--:(non-mtc)
    |     |  |     ...
    |     |  +--:(mtc)
    |     |        ...
    |     +--rw best-effort-qos-parameters
    |     |  +--rw request-policy?            cl-types:octet-data-type
    |     |  +--rw priority?                  uint8
    |     |  +--rw data-rate-unit-setting?    cl-fma-qos:data-rate-type
    |     |  +--rw max-traffic-rate?          uint32
    |     |  +--rw max-traffic-burst?         uint32

## 6.1. Map-builder YANG Module

This module defines the MAP builder for the remote US scheduling. It contains MAP builder configuration and operational data, as well as RPC calls as shown in Figure 13.

The MAP building configuration parameters reflect channel level MAP attributes such as ranging and data back off window, broadcast IM and idle slot settings. The MAP builder RPCs are used to invoke dynamic MAP actions, such as building a station maintenance (SM) ranging opportunity or request for an OFDMA upstream data profile (OUDP) test slot in MAP. The input and output parameters allow the client to specify the action requirement and retrieve data coming out of the action. Unsolicited notifications can also be added to report the MAP builder operational status. Alternatively, the client can subscribe the operational data using telemetry.

```

# 7. Coexistence with Existing RPD Management Interface

In R-PHY today, the management interface runs over the Generic Control Protocol (GCP) using the Type-Length-Value (TLV) tuples to carry the signaling messages defined in the R-PHY specification [6]. Since the remote US scheduler is a new functional component, running GCP as it is today does not prevent using the YANG based API for the remote US scheduler, as the two management interfaces do not manipulate the same data objects.

Figure 14 shows the initialization sequence with the YANG based management interface coexisting with the legacy GCP based RPD management interface. Once the RPD is assigned with an IP address and paired with the CCAP core, the core can initiate the YANG capability discovery process. For an RPD that declares the remote US scheduler YANG support, the core can program the scheduler engine once the RPD is initialized. If there are any configuration dependencies on the GCP managed objects, for example the RF configuration, the US scheduler engine at the RPD can hold off the intended configuration and only apply it when the GCP dependencies are resolved.

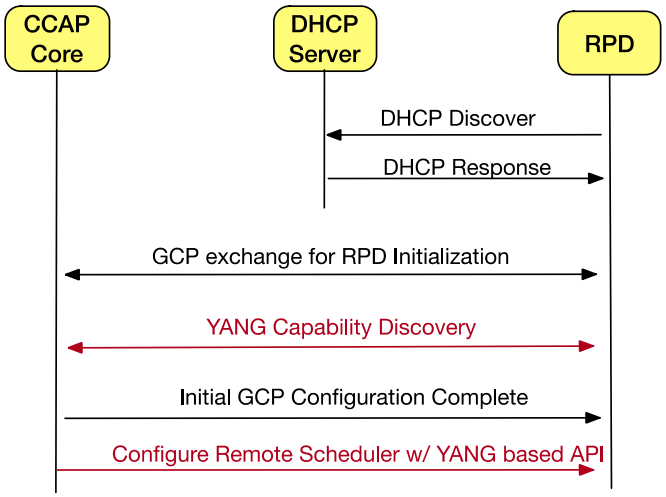

**Figure 14 – Coexistence with Existing RPD Mangment Interface**

With this hybrid management model, the remote US scheduler can be deployed on existing RPDs without waiting for the full-blown RPHY YANGification.

# 8. Remote US Scheduler in DOCSIS YANG Echosystem

In the DOCSIS YANG ecosystem, different CCAP network elements (NEs) can be organized into classification hierarchies as shown in Figure 15, where the rpd-ne (representing RPD NE) is one type of the CCAP NE that inherits the ccap-phy-ne attributes. The remote US scheduler YANG module can be incorporated into the CCAP NE hierarchy by augmenting the rpd-ne base module as shown in Figure 16. The “when” and “if-feature” tags allow the remote US scheduler module to be only present if the CCAP-NE is the RPD type and supports remote US scheduling.

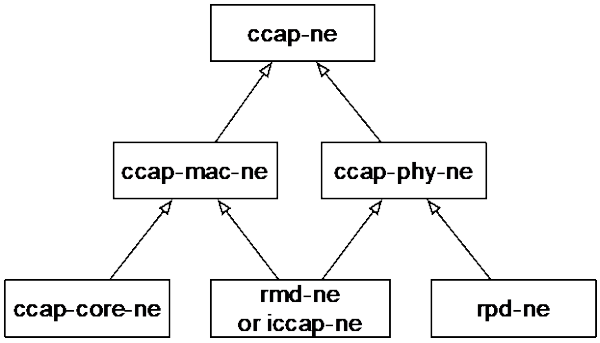

**Figure 15 – CCAP Newwork Element Types and the Subclassing Hierarchy**

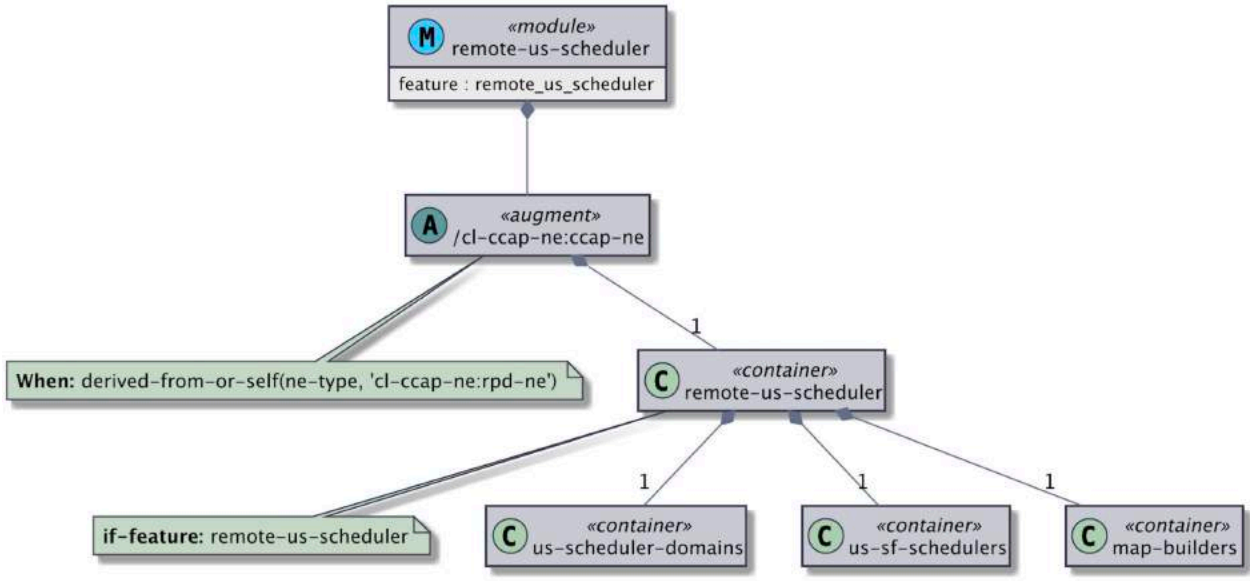

**Figure 16 – Remote US Scheduler Module in DOCSIS YANG Echosystem**

## 9. Conclusion

The remote US scheduler is an operational option for R-PHY when the desired latency performance needs to be better than a classic I-CCAP or if the CIN needs to be significantly longer than the 100 miles. The remote US scheduler design has two functional parts, the US scheduler manager that lives in the CCAP core and the US scheduler engine that lives in the RPD. The US scheduler manager northbound is internal to the CCAP core, while the southbound is a data model driven interface that allows the US scheduler manager to communicate with one or more US scheduler engines to fulfill the US scheduling services.

This paper proposes to use a YANG data model-driven interface between the US scheduler manager and the US scheduler engines. The YANG data-model driven management techniques are mature and well adopted in the network industry, with rich tooling and applications that can auto-generate code from the data model; hence facilitating multi-vendor interoperability. The YANG data model can be paired with high performance message encoding and RPC options (such as protobuf and gRPC) to meet the timing and scaling requirement for managing remote US schedulers.

To construct the remote US scheduler YANG data model, this paper presents a modeling method that involves decomposing a complex service function into smaller independently manageable subservices, creating a well-defined behavior model for each subservice, and defining the API that completely and precisely characterizes the behavior.

The YANG model-driven management interface for remote US scheduler can co-exist with existing GCP based RPD management interface, reducing time-to-market for the remote US scheduler feature while R-PHY is transitioning to YANG data-model driven management. The remote US schedule YANG model is an integral part of the DOCSIS YANG ecosystem, it is planned to be contributed to CableLabs as a feature augmented to the R-PHY YANG model.

# Abbreviations

# 1. Introduction

When informed by vast amounts of network performance information, identifying radio frequency (RF) problems with the Data-Over-Cable Service Interface Specifications (DOCSIS) isn't that hard. However, determining if the problems are inside or outside the home can be difficult. This is a decades-old problem, with hopes often pinned on the elusive promise of artificial intelligence (AI) or machine learning (ML) to help. The challenge that many data scientists will tell you is that having good training data is critical. The lack of a reliable feedback loop to establish cause-and-effect often results in poorly trained machines.

A significant amount of time and resources has been poured into remote diagnostic tools to identify plant problems. Those tools historically have been segmented, specialized, and tuned to evaluate singular aspects of the RF health – for example, receive modulation error ratio (RxMER) and forward error correction (FEC). Once a problem is identified, determining if its source is in a customer's home, drop or tap has historically been left to technicians, to provide feedback about what they found. The feedback mechanisms typically involve selecting a code or result and updating the work order when it's complete.

With the COVID-19 pandemic starting mid-March 2020, the rapid development of an "outside network check" provided an opportunity to gather better features and labels. With a renewed desire to keep technicians and customers isolated, the team is exploring new ML/AI models. These new models are trained to use cloud-based RF measurements. These measurements include remote telemetry from DOCSIS devices, and other equipment logged by collection systems. Another set of measurements is taken at the tap and ground block, finally offering a way to segment the network and train the machines differently. The authors review the outcome of this fascinating exercise currently under way, as this paper is being written, in the summer of 2020.

# 2. Acknowledgements

Much of the material within this document was obtained from interviews and written contributions of many Comcast leaders and other industry experts. The authors would like to thank David Monnerat, Gary Schwin, Justin Menard, Shawn Hughes, Patrick McDonald, Miles Pellegrini, Marty Marcinczyk, Jan Neuman, Rama Mahajanam, and Fan Liu from Comcast. You all collectively represent a large cross-section of unique perspectives and expertise. We also recognize Brady Volpe of the Volpe Firm and his award-winning products and services. Thank you, Brady, for your ongoing industry leadership and inspiration. Finally, we express gratitude to our distinguished colleagues Seamus Gallagher, Dwain Kelly and Paul Kelly from Liberty Global. Your global contributions and experience are invaluable to our industry.

# 3. A Brief History of RF Troubleshooting

For well over 40 years, cable field technicians have relied on signal level meters (SLMs) to take measurements that help determine a proper course of repair. Once alerted and dispatched to a problem, our technicians have been trained to use a divide-and-conquer approach for troubleshooting, and ultimately repairing the issue. These meters would usually be used to take measurements of RF signals to-and-from the customer at different locations on the network. They might start inside the customer location, to validate the service at the location of the customer's equipment, then work their way towards the network to determine where the problem begins or ends. There are other processes where technicians might start at the network tap and work their way towards the customer equipment. Of course, these are basic processes which traditionally made it very difficult to verify if, or how they were followed.

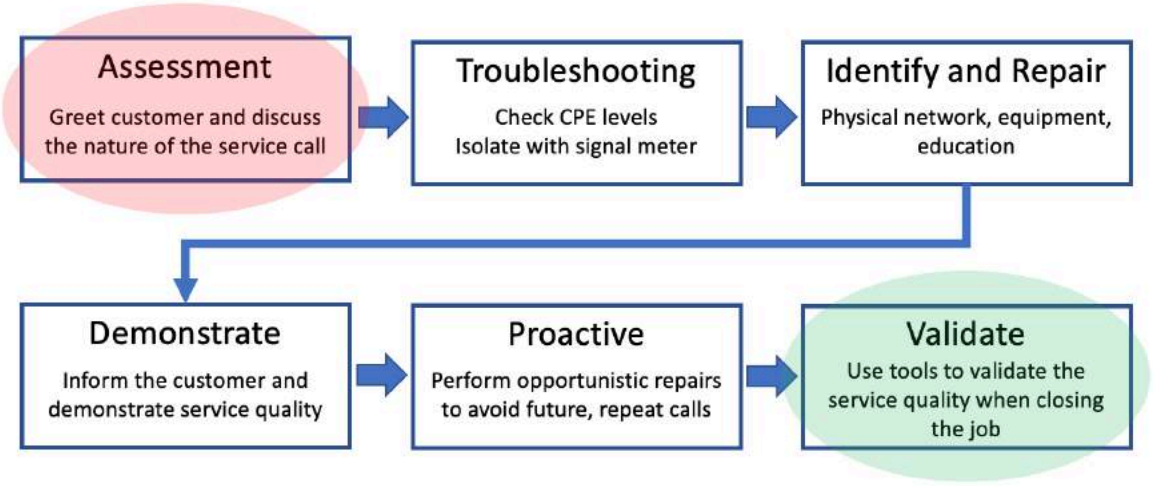

**Figure 1 – A Typical RF Troubleshooting Process**

Courtesy of Doug Kelly, Virgin Media, Ireland

Meanwhile, the cable industry has been investing in remote performance telemetry for a long time, beginning with the DOCSIS 1.0 release in 1997. For nearly 23 years, the DOCSIS specification has been evolving and growing, providing performance metrics for virtually every aspect of our cable networking protocols.

Since DOCSIS 3.0 was launched in 2006, the cable industry has been developing a proactive network maintenance (PNM) specification, which significantly improves the range and depth of available RF diagnostic capabilities. In the hands of a highly skilled technician, these tools can be invaluable and empowering. However, in some cases, they require certain skills and experience, in order to properly interpret and enact a correct repair. When a technician lacks the training or experience to properly use or interpret the tools, they often forego using them and rely a limited repertoire for repair, such as swapping equipment and resetting devices. Our technical workforce is made up of skills on both sides of this continuum and everywhere in between.

As the remote visibility of the customer equipment improves, so do the tools to detect problems, present data and dispatch technicians. Quoting Brady Volpe, owner of The Volpe Firm Inc., “In the mantra of PNM, we are often able to find and repair problems before they impact the performance of the service perceived by our customers.” While that’s an attractive statement to make, it can be difficult to determine exactly which problem is causing the trouble being experienced by the customer. We may be able to proactively detect RF problems before the customer is impacted, but they could be calling due to a completely unrelated problem. In many cases, our tools currently lack the ability to accurately establish cause-and-effect with the customer experience.

## 4. Fault Isolation on RF Transmission Lines

To people familiar with customer support and troubleshooting, there are a few relatively simple processes that tend to work universally. Sometimes, problem isolation can follow a basic divide-and-conquer approach, depending on the type of problem. However, RF transmission troubleshooting has special conditions and circumstances that can be problematic for a simplistic troubleshooting process.

It may be helpful to remember that our coaxial cables are essentially just a large, shielded transmission line. Our shielded transmission lines can cover long distances, spanning many splits and taps with little directional isolation, which can befuddle the divide-and-conquer approach. Fortunately, cable has some physical characteristics that help, but do not completely solve these isolation problems. It can be generalized that many problems are difficult or impossible to localize, inside or outside of the customer premises.

The most common and reliable method for automatically localizing problems within a location is the presence of multiple equipment. This allows the remote monitoring systems (and technicians) to compare the signals of multiple sensors within the location. By a process of comparison, all devices within the home sharing a common problem increases the likeliness that the problem is outside (Figure 2). Conversely, if a single device detects a problem while the others do not, it can be concluded that the problem is inside. In recent years, a boom in DOCSIS deployments has made this technique very useful. However, the latest industry trend is moving towards a single DOCSIS point-of-entry gateway, then relying on Wi-Fi to distribute content within the premises. Over time, this will diminish the value of this localization technique.

**Figure 2 – Common Problem Signature, Multiple Devices**

In a similar process of elimination, when a single problem signature is detected having multiple sensors available (Figure 3), it's a reasonable assertion that the problem is within the location. These types of issues are typical of wiring problems such as loose or damaged connectors, incorrect fittings on wall plates, damaged cables, and splitters that are installed backwards, to name a few. In some cases, the problems can be addressed by the customer without requiring a technician. Some operators use this technique to identify possible loose connectors and inform the customer, instructing them to tighten the connector. These types of problems may not cause a noticeable issue for the customer, but tightening loose connectors is one of the easiest and best ways to improve the overall reliability of a coaxial network.

**Figure 3 – Single Problem Signature, Multiple Locations**

The technique for comparison-based localization improves as more data is introduced, including sensor information from neighboring equipment connected to the same physical network tap (see Figure 4). When common problems are detected that have a shared network element, the shared network element is usually the cause for impairment. These types of problems are commonly found at the tap, and include damaged or corroded tap plates, incorrect termination, cut drops, incorrect pin length, loose pin seizures and more.

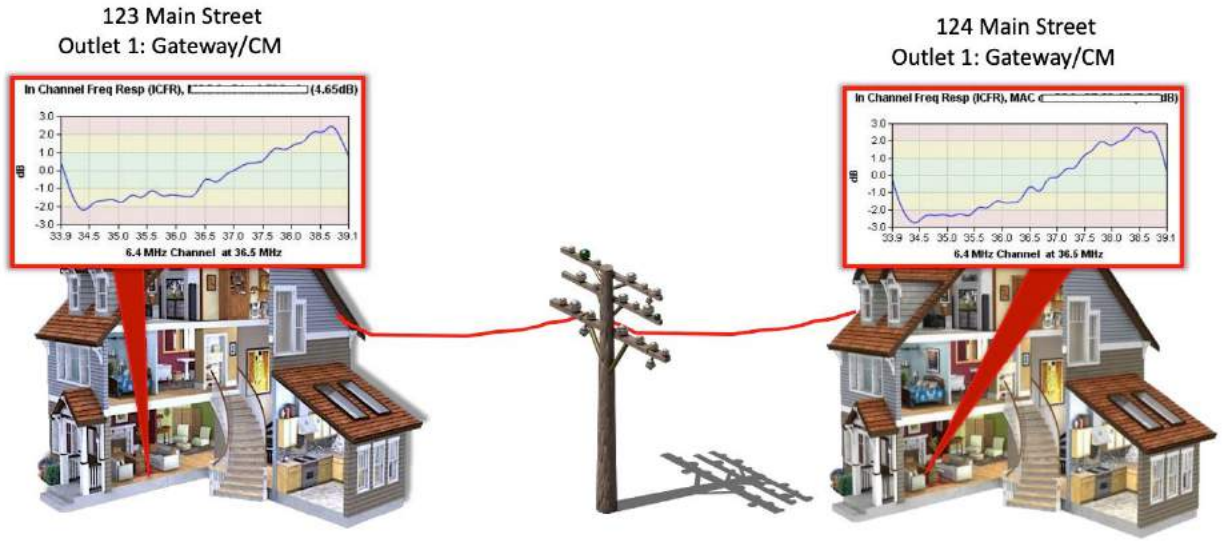

**Figure 4 – Problem Signature Compared to Neighbors**

Another useful method for localizing problems uses casual observation and makes inferences based on common signatures. For example, there are certain impairments which are well-known to be outside vs. inside. In the case of water damage, water enters a coaxial cable and creates a distinctive signature that is easily identified (Figure 5). These are nearly always outside, caused by environmental influences such as rain or sprinkler systems. There are possible examples where water can have entered coaxial inside the home, but those are minimal and unlikely. Other examples of inference-based signatures are the presence of filters, which are usually installed at the ground block or tap; old satellite splitters which can produce unique standing waves; and spectral roll-off from old passive equipment, to name a few. These types of signatures are automatically detected with specially designed spectral impairment detection (SID) software libraries available from CableLabs.

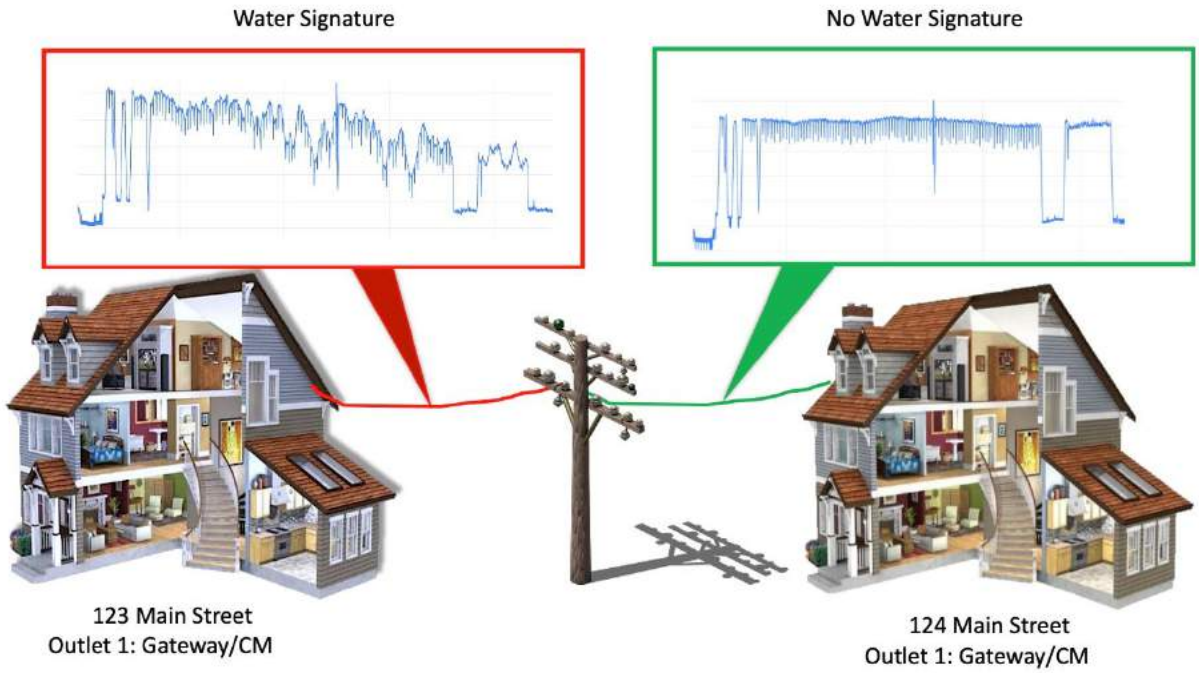

**Figure 5 – Localization Based on Signature Inference**

The techniques described above work on a subset of the common types of problems that are detectable with our DOCSIS PNM tools. They are especially useful for downstream RF impairments and anything that causes an impedance mismatch, any physical damage on the cable system. As previously discussed, these techniques do not work for certain types of problems. Unfortunately, some of our most impactful and common problems are invisible to this type of isolation technique.

Upstream noise is the most notable exception, including any other spurious types of interference which may be intermittent. The primary reason for upstream noise eluding these techniques is known as the upstream funnel effect. The upstream portion of the RF spectrum is coupled in a manner that allows all of the signals to travel towards the headend, then become combined together at the upstream receiver. The receiver has no way of knowing where this unwanted signal is getting in (ingress), and the noise impacts all cable modems on the same physical RF connection. This is particularly problematic because one ingress problem can impact an entire service group, consisting of hundreds of customers. Figure 6 shows the noise present, affecting a large service group. Finding the source of the ingress remains elusive and usually requires a maintenance technician. This is one of the primary motivators to keep our connectors tight.

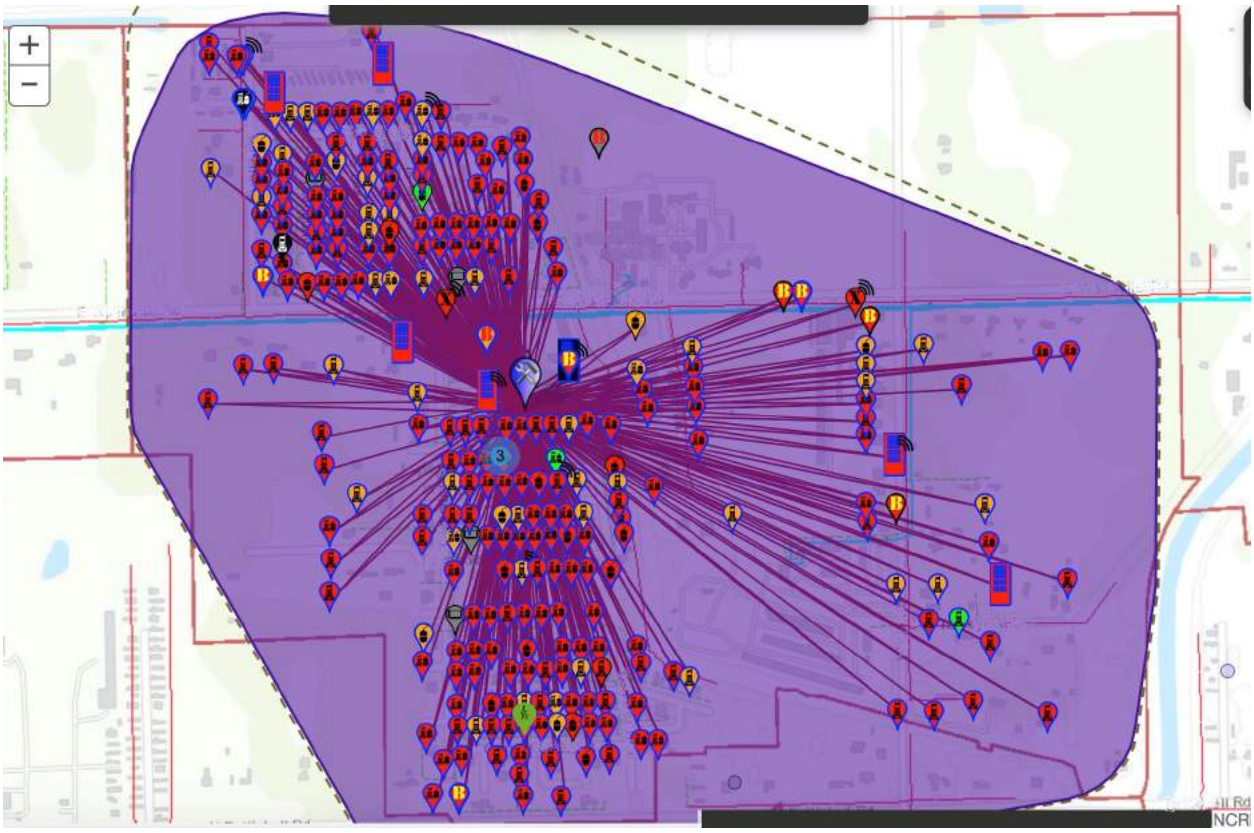

**Figure 6 – Upstream Noise Impact on Entire Service Group**

Occasionally, some upstream noise problems are localizable to a small area, but these are relatively uncommon compared to the more typical upstream ingress. These types of problems can be caused by faulty return amplifiers which have a detectable distortion effect on the upstream signal for a smaller group of cable modems. With these "pocket issues," it sometimes works to group devices that have a common RxMER or FEC-related problem. Unfortunately, this technique is minimally effective at localizing most typical upstream noise or ingress problems.

## 4.1. The Troubleshooting Process

In days prior to COVID-19, the troubleshooting process typically would begin with the technician making contact with the customer to obtain their perspective, in-person. This can transpire any number of ways and usually relies on customers using their own language to describe the service problem. For this to be effective, the technician needs to interpret the customer's description and translate it to any number of troubleshooting and repair processes. For example, the customer may describe the problem as "the cable isn't working," which would require additional questions to further inform a) which cable service (video, voice, broadband) and b) which troubleshooting process to use. Next, the technician may ascertain that the customer was referring to internet service, then further determine if the connection is Wi-Fi or wired, and so on.

This is the input-side of the instruction loop, usually referred to as "features" in machine learning nomenclature. It's easy to understand how translating the customer's intent can result in misunderstood features. David Monnerat, Sr. Director of AI at Comcast, noted, "I've been on truck rolls in three states, all good people trying to do the right thing. They have good knowledge and skills but not a consistent

process, all troubleshooting differently. Three out of five technicians would have a different resolution to the same problem." We're faced with a wide variety of products, experience and technical understanding across our customers, agents and technicians. Fortunately, our tools and technology have been evolving to help bridge these divides and produce more consistent outcomes for our customers.

## 4.2. Repair Feedback

After completing repairs, the technicians are usually required to provide some form of feedback about the work that was done to resolve the customer-reported problem. Typically, this is done when a technician closes a job (work order), and they are prompted to provide some mandatory selection from a list. This list can be vast and may allow for multiple selections, which will be discussed further. Most operators have used systems similar to this and experienced the same results regarding the unintentional bias in the resulting feedback. For instance, technicians might arbitrarily select the first code from a long list, regardless of the code.

### *4.2.1. Technician Performance Metrics*

Among of the most influential drivers of bias within the repair-feedback loop are the performance metrics used to measure technician productivity and effectiveness. These metrics are used for reports that assess how well technicians are doing, ultimately resulting in pay/career growth or the opposite, relative to their performance against the operator's established goals.

Lessening repeat or re-work is a common goal when a service call requires multiple technician visits within a specified time period, such as a month. Given the many possible scenarios of service repair, there are loopholes which can insulate technicians against demerits from having to go back at a later time. Depending on the reporting algorithms, a technician may improperly report that the customer was not home, even though they may have performed some repair activity.

Another of the more common re-work loopholes is to complete the work order as avoidable (not required) by coding the repair with something like "no trouble found." In this case, a technician may perform some repair activity, but depart unsure that it actually solved the problem. If they think there is a reasonable chance that the problem may be intermittent and unsolved, this provides some cover for a repeat visit in the future.

Although it doesn't directly impact the repair coding of work orders, it's not uncommon for technicians to leave their personal contact information with customers, so as to call them directly. This is another way for them to circumvent demerits associated with re-work. If the technician needs to go back and perform additional repairs or support, they do it off-record, avoiding negative performance reporting.

### *4.2.2. Customer Relationships*

The financial policies of cable operators can often influence technician repair feedback. It is not uncommon for operators to have a policy that establishes rules about when customers should pay for the service call versus it being free-of-charge, at the expense of the operator. These service call fees are often between $50 and $75, depending on the circumstances. Examples of chargeable service calls include scenarios such as a customer incorrectly re-connecting equipment when rearranging furniture, or if the power was simply turned at a power strip. In either of these examples, a minor oversight by the customer could prove embarrassing and is unfortunately all too common. Many technicians can empathize in these situations and find some menial form of repair that can be done to avoid an uncomfortable conversation about having to charge the customer for their oversight. It's simple enough to code the work order as replacing a connector or splitter, versus having to break the bad news about a charge for the service call.

There are many areas where technicians have never charged a customer for a service call, providing anecdotal evidence that this is an all-too-common scenario.

### 4.2.3. The Expert Technician / Opportunistic Repairs

There is a population of technicians that is especially enthusiastic about performing high-quality work. These technicians take pride in leaving every customer in better condition than before they arrived. They will scour the premises, starting at the tap, looking for loose or corroded connectors, then inspect the drop for leaks or damage, continuing to the ground block for distress or connector problems. These experts will invariably find plenty of opportunities for proactive repair, such as replacing old F-connectors, corroded ground blocks and imperfect cables. These are all great qualities that we hope all of our technicians would exhibit. However, they will often reflect every aspect of the repair in the work order. The multitude of proactive / opportunistic repairs may not have affected the original reason for the trouble call, although they certainly represent great hygiene for the network and insulation against a repeat trouble call. Also, by including multiple repair codes, this sometimes influences their performance statistics in a positive way. Naturally, this can result in an inflated number of repair codes that might not relate to the customer-reported problem.

### 4.2.4. Report Burden and Selection Bias

Although it may not seem over burdensome to provide thorough feedback after a service call, the reporting process after a long, hard repair job can prove mentally exhausting – especially if the technician doesn't believe the outcome of the report will have a meaningful effect on them or the business. In business terms, this represents a form of "decision fatigue," resulting in the technician not putting sufficient energy towards making a proper selection to describe the job. This is exacerbated with growing lists, of hundreds of codes, which can take a long time to scroll, read and contemplate. Several controlled studies at Comcast have shown that the top code arbitrarily gets picked the most. Further attempts to randomize the top selection result in randomization of the repair disposition. The results were predictably consistent with the first presented code.

Some operators have attempted to reduce the selection burden by ordering the codes by their predominance. For example, replacing equipment, resetting devices and reprovisioning service are usually among the top selected codes. As a matter of improving the user experience, these codes might be ordered as the top three in the selection list, to reduce the searching and scrolling required by the technicians. Unfortunately, by placing the top selected code in first place, the previously discussed problem of arbitrary selection becomes compounded. This creates a selection loop bias which further strengthens the predominance of a small number of repair codes used to characterize a repair.

### 4.2.5. Intermittent Problems and Upstream Noise

The nature of RF performance and troubleshooting can sometimes be intermittent. Upstream RF noise is notoriously spurious in nature. The source of the noise may be intermittent, such as turning on electrically noisy equipment, like the electric motors used in hair dryers or power tools. It's also possible that the place the noise is getting in may be intermittent, such as a loose connection on a drop cable that might be blowing in the wind. As the wind blows, this can cause unpredictable shielding faults within the connector's threads that intermittently allow the noise to enter the drop. If a customer calls at the time of the ingress and impaired service, it may be hours or days until a service technician may be able to visit the customer. It's also possible that the ingress may be coming in at a completely different location on the node, unrelated to the customer who's calling about the problem. In these cases, technicians will typically attempt some hygienic repairs, such as replacing connectors, without being able to confidently assert that

the underlying problem was fixed. In these examples, the technician may code the repair as no trouble found, replaced connectors, swapped equipment or any number of things.

#### *4.2.6. Insufficient Tools or Training*

As our services become increasingly more complex, it can take time for our technicians to learn how to properly troubleshoot and repair them. For example, when Comcast introduced DOCSIS 3.1 service, there was a learning curve and tooling upgrades that were required to diagnose and repair orthogonal frequency division multiplexing (OFDM) signals. There was a time when legitimate RF problems could have been impacting a customer's experience, but the technician lacked proper tools or training to identify and repair the issue. There are other problems such as capacity, congestion, software updates and a myriad of others that may not be presented to the technician's troubleshooting process. The result of an undiagnosed problem typically results in the "Hail Mary" approach. Left with no other options, a technician will often fall back to replacing the customer equipment, otherwise known as a box swap. The vast majority of times, the equipment is not at fault, but it is possible that this activity does improve the service. At the very least, it offers the technician an opportunity to demonstrate that they are doing something perceived as helpful. In some cases, the act of swapping equipment usually includes re-provisioning, which can help. An example would be correcting an incorrectly-provisioned boot file which was unnoticed by the tools or technician. It could also be possible that a new device would provision to a different RF channel set which is less impaired than the previous implementation.

One of the most common forms of service repair is simply resetting or rebooting the equipment. While this does nothing to physically repair RF problems, it can sometimes be useful and has a very low cost, other than temporarily disrupting the service. In cases where the equipment software may be having problems, rebooting the device can temporarily re-initialize the software and restore proper function. However, this tends to be a temporary fix until the software bug is encountered again.

The latest versions of DOCSIS have proven to be exceptionally resilient. Our DOCSIS specifications have many coping mechanisms available to enable operation even in the most hostile RF environments. For example, a DOCSIS 3.1 cable modem may have 32 or more downstream channels (in addition to the OFDM signal) available for use. It is not uncommon to see frequency-specific problems, such as LTE ingress, which can impair a few channels, while the others might be operating perfectly. DOCSIS can bond different channel sets or disable problematic interfaces to allow error-free operation. This is another example of how modem resets can restore service without performing a repair to the physical environment.

# 5. Cloud Connected Technicians and Equipment

Our field signal meters, and measurement systems have also been evolving, becoming more connected and integrated with the technician ecosystem. In our contemporary workforce, the signal analyzers are cloud-connected and augmented with all kinds of new information, such as technician identity, GPS coordinates, system design maps and telemetry measurements from customer equipment. This information-rich environment creates new opportunities for features and labels to provide to our ML and AI systems.

## 5.1. A New Troubleshooting Process

As discussed previously regarding the troubleshooting process, it becomes obvious that this is an area of opportunity for improvement. With the onset of COVID-19, our customers, technicians, agents and

business partners now have an entirely new set of constraints and motivators shaping how they approach the troubleshooting process.

The first and most obvious constraint is the desire to maintain physical isolation between our technicians and customers when servicing their equipment. Brady Volpe, when asked about his experience on RF related repair calls, cites that "about 75% of the time it's tap, drop or ground block. The other 25% of the time is in-home wiring … these statistics exclude many of the common trouble call issues, such as customer education, and Wi-Fi problems, and varies by area." Going by those statistics, and as a matter of efficiency, it makes sense to start the troubleshooting process outside. At Comcast, a new process was devised to help seize upon this statistical advantage and provide additional safety by allowing for physical separation. In addition to those two key benefits, it also facilitates a new opportunity for a consistent troubleshooting process.

As seen in the flow chart (Figure 7), technicians now start all RF troubleshooting by taking a signal measurement outside of the service location at the ground block. This is a critical demarcation, indicating where the cable service becomes physically attached and electrically bonded to a service location.

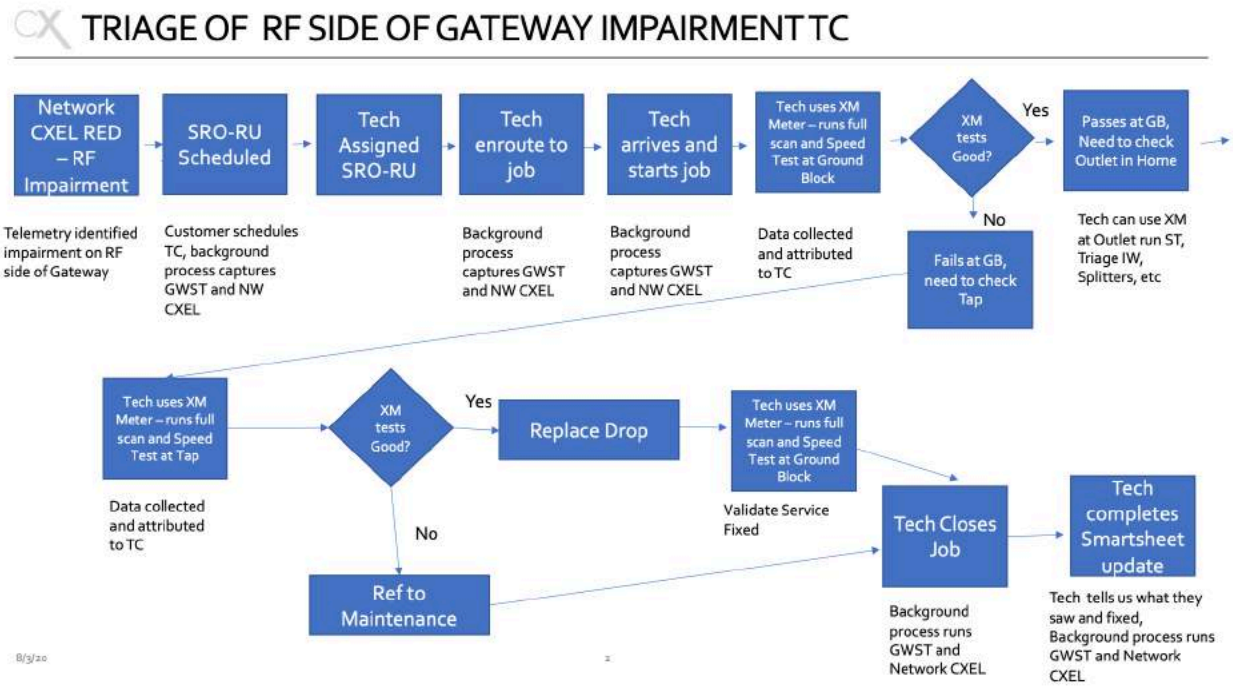

**Figure 7 – New Troubleshooting Process**

## 5.2. Process Compliance

Shortly after implementing cloud-based signal measurements, in early 2017, issues of process compliance became obvious. This was one of the first and most intriguing insights being provided by our new field measurement platform. A meager 22 percent of technicians were using their meters in a 24-hour period on any repair jobs. This quickly leads to all kinds of other questions about the troubleshooting process. How can someone possibly diagnose, repair and validate service without taking measurements? It stands to

reason that not all trouble calls require RF troubleshooting; however, these 22 percent of repair calls were service-related and resulted in RF specific repair codes.

At Comcast and a number of other operators, it has become common place to use the premises-located equipment to measure signal levels and performance. One of the leading causes for process non-compliance is that the technicians were relying on a premises health test (PHT) in lieu of taking measurements. This process evaluates the remote telemetry from the DOCSIS gateway and other equipment. While this is an acceptable way of validating service conditions, it's a procedural shortcut for the troubleshooting process. Lacking portability and segmentation of the network, this method results in a significant amount of "hunt and peck" rather than accurately diagnosing and repairing problems.

# 6. Machine Learning and Artificial Intelligence

ML and AI have become ubiquitous in modern computing systems. Cable operators are investing heavily in these platforms and continue to find opportunities to improve how we operate our systems. This section reviews some of the techniques used, and results achieved when attempting to segment the RF network using ML and AI.

## 6.1. Features and Labels

The review of the troubleshooting process was important to help convey an understanding of the features that we'll be using for our models. Features and labels are important constructs in ML and AI for both classification and regression problems. Features can be thought of as the inputs that will be available to the model. The features, in our case, will be any number of the measurement data which are available to our systems. Features might include in-channel frequency response (ICFR), full band capture (FBC) impairments, packet loss, speed test results, time of day and number of device resets.

Labels can be thought of as the output, or the desired prediction from the model. Examples of labels might be loose connectors, faulty drops or excessive splitters. These are the outcomes that we would expect our models to predict, given the proper features to inform its decision tree. Notice that the labels mentioned do not include customer behaviors, such as trouble calls or other service requests and interactions. One important aspect of this exercise is to decouple the objective service conditions from subjective customer experience. For instance, poor RxMER and packet loss may result in insufficient speed test performance. Some customers may call while others may not. That is discussed later.

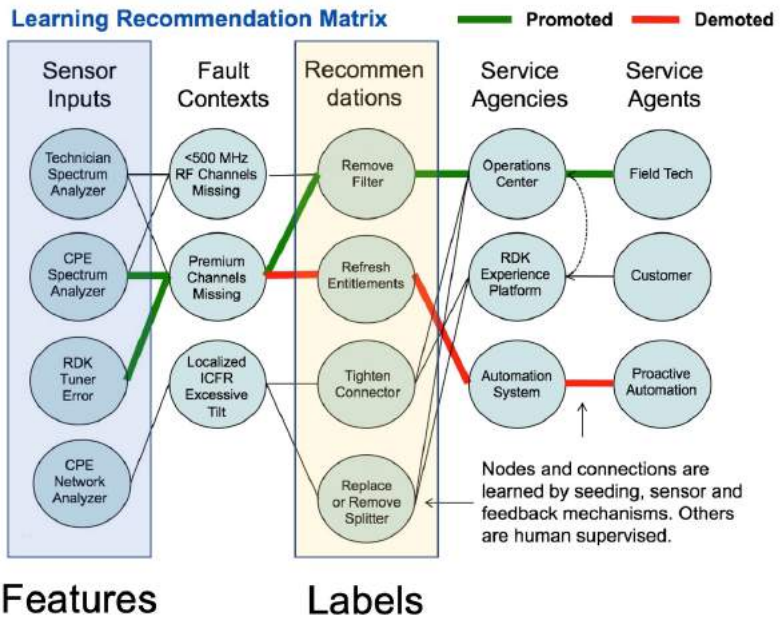

**Figure 8 – Example of Cable-Oriented Features and Labels**

### *6.1.1. Machine Data vs Human Data*

The previously discussed, fallibility of the human interpretation in our feedback system can become one of the most promising elements to improve our ML and AI model training potential. "You can think of machine learning using familiar terms to cable engineering. The goal of our models is to pick out the signal from the noise," stated Jan Neuman, Executive Director of Machine Learning at Comcast. "Objective measurement that is noise-free and repeatable can be used to refine other measurements. By adding a less noisy signal, this increases the overall fidelity of the model. Thus, increasing the signal-to-noise ratio (SNR) results in more accurate predictions." Put another way, improving prediction accuracy is the primary motivation for removing noise from our models.

Looking back on the discussion about the troubleshooting process, the first opportunity for noise begins at the input, or features. Although difficult to quantify empirically, the most fundamental features – such as "why did the customer call for help?", or "which service is having a problem?" can be corrupt. If customer language is interpreted literally, "the cable isn't working" could have many different meanings, causing noise in the feature. When this noisy feature is incorporated by the model and it starts making predictions, it is difficult to imagine that the results will be useful. By using machine data to refine the feature definition, the noise is reduced at the input of the model. An example of improving this feature with machine data would be a technician testing RF the ground block, outside of the location. If significant packet loss is measured, a noise-free feature now exists that is causal for a poor internet experience.

In addition to refining the features, machines offer an opportunity to improve the fidelity of the labels, or desired outcomes and predictions. While still not perfect, there are machine-provided data that can be reasonable proxies to some of the common labels. For example, the label of slow internet speed can be

approximated with automated speed testing. As expected, features of packet loss and labels of slow speed are clear machine signals that can be interpreted without added human noise.

### *6.1.2. Digital Interactions With our Customers*

For decades, our customers have been placing telephone calls to our call centers. As we drive towards more digital interactions with our customers, we're offered a unique and important opportunity to remove some degree of human interpretation (noise) from the models. Cable operators are embracing digital interfaces for our customers such as apps and online tools. By allowing customers to directly convey their intent, this offers an opportunity to bypass one of the most common causes of noisy labels, human-to-human communication on the telephone.

## 6.2. The Model

Comcast Applied AI researchers developed a classification model to identify service calls where only outside of the premises work was required. The team developed and deployed this model to schedule trucks with a goal to minimize contact between technicians and customers during the COVID-19 isolation policy. After the initial model was deployed, they explored additional data, such as field meter measurements, to improve the model's performance.

### *6.2.1. Outside of Home Applied AI Model*

The "Applied AI outside of home" machine learning model used features from several network telemetry sources that collect and aggregate DOCSIS measurements. These sources poll and analyze the network, looking for outages and impairments. Other systems collect network data and do the fault segmentation analysis described earlier, which was also included. Table 1 describes the different data sources.

| **Source** | **Description** |
|---|---|
| Account type | Account-level detail showing types of devices in the home (video gateways, wireless gateways, modems, etc.), days since account origination and since last device installation. |
| Prior truck history | Summary of technician-reported problems aggregated at the node level. |
| Account network degradation algorithm | Features developed from an algorithmic tool that polls devices four to six times per day to report account-level degradation issues related to disturbances in the RF spectrum. Features are based on issue counts related to network, drop, in-home wiring, loose connections, and isolated home concerns. |
| Connectivity between modem and CMTS | Features developed from a tool that polls devices three times per day to report raw measurements describing connectivity between the modem and the CMTS. Features include counts of impairment flags and means |

| | |
|---|---|
| | and standard deviations of measurements. Data reported include timeouts, system boot time, ripples, SNR, transmit and receive power, FEC errors, tap energy, and phase angle deviations. |
| Node network impairment algorithm | Features developed from an algorithmic tool that scans the network for RF impairments and reports them continuously. Impairments include plant Wi-Fi, suckout, wave, flux issues. |

**Table 1 – Model Sources Summary**

Node topology was instrumental in creating features that detect network impairments. Node topology maps describe how equipment such as amps, taps, splitters, and cables are connected from the node down to customers' homes (Figure 9). Node topology maps were used to aggregate and average measurements, to provide a wider view of the network events surrounding a customer when the service call was being scheduled. One type of aggregation is a weighted average over a customer's node, where the weight is determined by the graph distance from the customer with the truck roll to other customers in the node. Another type of aggregation is at the parent level, which averages the telemetry over all customers who are immediate neighbors in the graph. We also computed averages for each piece of network equipment and compared it to averages for neighboring equipment, then found the piece of equipment that the customer depends on which has the greatest (and least) difference from its siblings. The idea is that if a single piece of network equipment is broken, we can observe this by comparing all the customers who depend on it (and thus have impaired service) with customers who do not depend on it but are otherwise similar because they share the same upstream network components.

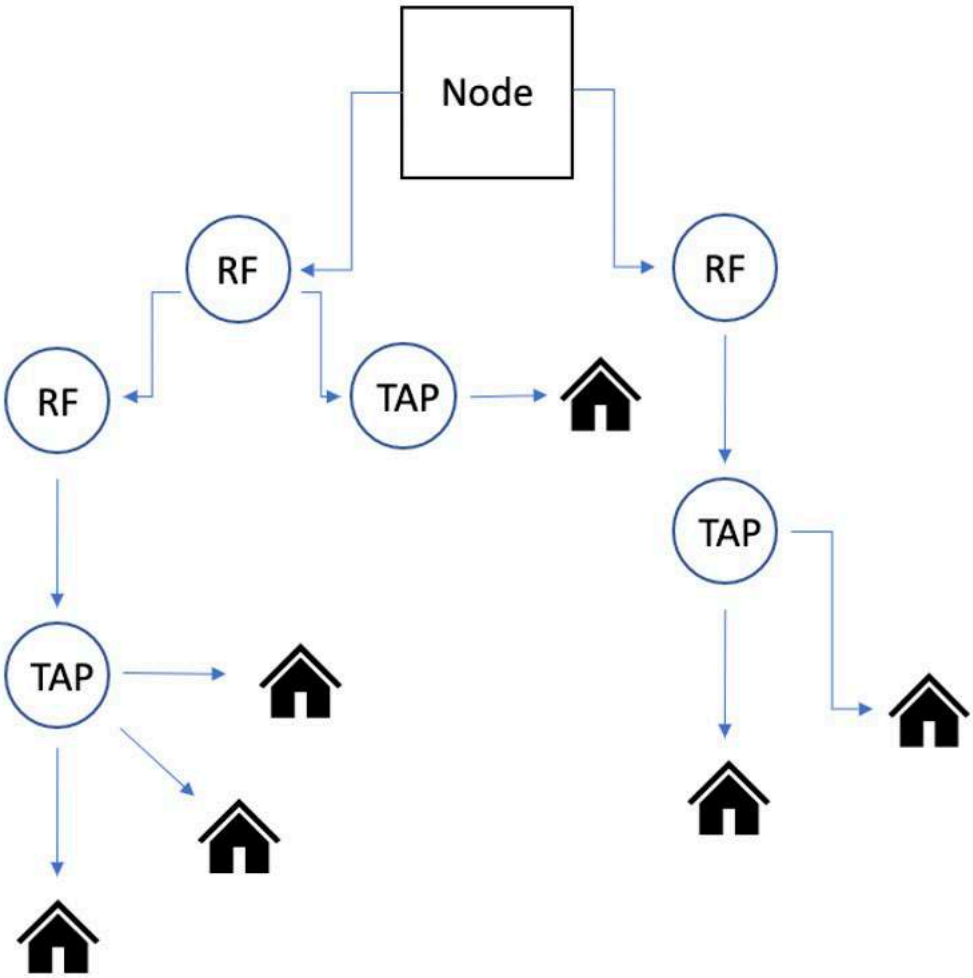

**Figure 9 – Node Topology Schema**

Finally, the feature engineering pipeline aggregated impairments and telemetry data in a daily timeframe, predicting whether the truck roll would only require outside work.

The model supplied predictions to the agents, who advised customers on the type of truck to schedule. The team defined the target label using repair codes, provided by technicians after the service was completed. The outside fix codes included "refer to maintenance," "construction," or, for underground teams, "replace connector," or "replace, repair, or run underground drop." The best performing model was trained with an-open source XGBoost classifier. The model was calibrated to achieve at least 5% recall and reported precision at 77% and lift at 2.48. Figure 10 illustrates the precision versus recall curve, normalized to a value of 1. Figure 11 shows the individual feature importance.

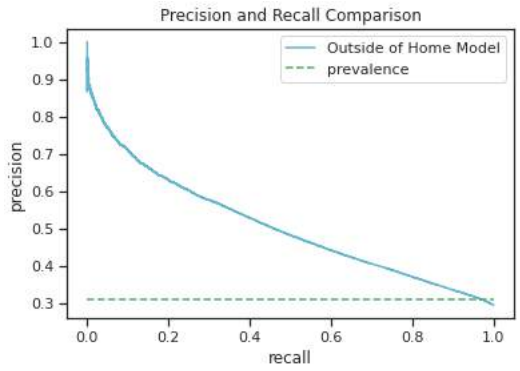

**Figure 10 – Model Performance, Precision and Recall**

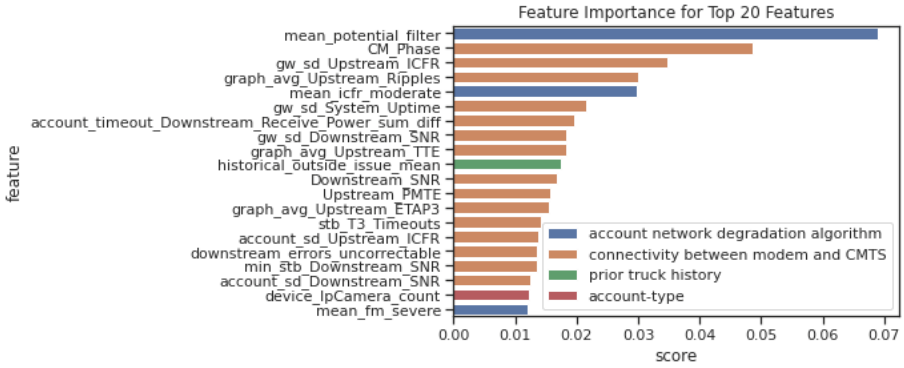

**Figure 11 — Model Feature Importance**

### *6.2.2. Using Weak Supervision to Improve the Model*

After the model was deployed, the operations team launched a survey asking technicians to specify whether work was needed only outside of the house. These data were considered to be ground truth to verify the output predictions. Using these labels could potentially improve the model performance. However, ground-truth labels data were small and modern machine learning techniques require a large volume of data to train the model.

To address this problem, the team applied weak supervision techniques using the open-source Python package Snorkel (https://www.snorkel.org/). The goal was to access data not available at the time of prediction, use those data to develop a labeling model, train the labeling model on the ground truth data, and assign labels to the larger corpus of data that was lacking ground truth labels. Then, our data size would be sufficient to train a classification model on labels close to the ground truth and with sufficient data size. In other words, we attempted to use the results of signal meter readings after a small number of repairs, to predict what will happen on all trouble calls before the technician gets there. Figure 12 illustrates the weak supervision approach.

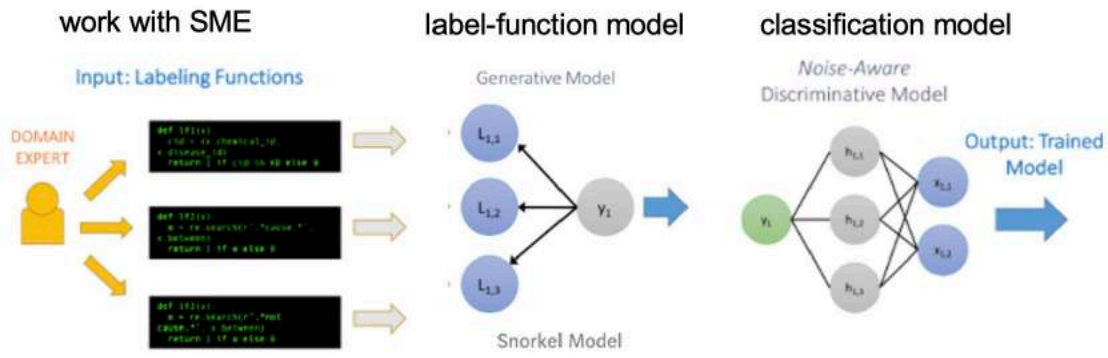

**Figure 12 – Weak Supervision Workflow**

The team gathered a corpus of data to use specifically for label development. Many of those sources were not available at the time of prediction. Those data included technician comments, repair codes, and signal meter data, among others.

Technicians took signal measurements on-site at the time of the truck visit. Of the total number of repairs, approximately 50% of them had field meter measurement data available. Engineers pre-processed the data for the team and developed labels by aggregating measurements such as per-channel RxMER, receive power and ingress. They assigned the following labels to each measurement: “ground block pass,” “ground block fail,” “tap pass,” “tap fail,” “refer to maintenance,” “tap,” and “tap fail ground block pass.” Accuracy of the functions derived from signal meter data ranged from 55% to 62%, surpassing the prevalence of outside labels in the survey data (at 45%). Table 2 enumerates the function performance.

| function | case | coverage | overlaps | conflicts | accuracy |
|---|---|---|---|---|---|
| lf_survey_outsidefittings | outside | 5% | 5% | 4% | 100% |
| lf_problem_tap | outside | 11% | 11% | 7% | 100% |
| lf_survey_abletorepair | outside | 33% | 33% | 24% | 100% |
| lf_problem_groundblock | outside | 5% | 5% | 4% | 100% |
| lf_problem_drop | outside | 18% | 18% | 13% | 88% |
| lf_problem_refer_to_maintenance | outside | 7% | 7% | 5% | 82% |
| lf_problem_refer_to_underground | outside | 4% | 4% | 3% | 80% |
| lf_xm_overallresult_gbfail | outside | 6% | 6% | 3% | 62% |
| lf_xm_overallresult_drop | outside | 2% | 2% | 1% | 61% |
| lf_xm_outsidelabel | outside | 16% | 16% | 9% | 59% |
| lf_xm_overallresult_gbpass | inside | 16% | 16% | 16% | 59% |
| lf_xm_overallresult_rtm | outside | 4% | 4% | 2% | 57% |
| lf_xm_overallresult_tappass | inside | 12% | 12% | 12% | 56% |
| lf_xm_insidelabel | inside | 41% | 41% | 41% | 55% |
| lf_xm_overallresult_tapfailgbpass | outside | 3% | 3% | 2% | 55% |
| lf_survey_issuefixed | outside | 54% | 53% | 40% | 55% |

**Table 2 – Labeling Functions with Highest Empirical Accuracy**

An important aspect of this exercise was the collaboration with data and field engineers to write functions and rules about the ground truth label. For example, if meter test interpretation was “ground block pass” or “tap pass,” the label model assigned the “inside of home” label. If test interpretation resulted in “drop,” for example, functions offered the “outside of home” label. Each function conveyed a proposed rule for labeling “inside of home” or “outside of home” case.

Many of the functions used technician-entered repair codes and free-form text comments. A set of these codes detecting tap and ground block issues had very high accuracy. Other repair codes varied in accuracy but made great contributions to the labeling model when they were combined with functions derived from signal measurements.

42 total functions were developed based on the combined labeling data corpus. Naturally, resulting functions varied in accuracy and coverage; some had labeling conflicts. We pruned the functions to include only those with higher accuracy. Then, we applied a majority voter strategy to assign predicted ground-truth labels and resolve function conflicts. In this strategy, cases where functions offered contradicting predictions were labeled neither inside nor outside in the training data.

Finally, a classification model was trained using Snorkel-labeled data. Both, benchmark and Snorkel-labeled models were trained on equal feature sets using the XGBoost classifier. We retrained both models on a limited set of data to benchmark the gains that can be achieved with the weak supervision method. Table 3 shows the precision at 5%+ recall target. The model trained with the snorkel-labeled data exceeded the performance of our benchmark model, with precision increase from 62% to 68%. By incorporating signal meter readings collected on-site, we were able to improve the accuracy of our labels and our model.

| Model | Precision | AUC | Prevalence | Lift | Data size |
|---|---|---|---|---|---|
| Ground truth label (benchmark) | 62.15% | 0.545 | 45.8% | 1.35 | 34,860 |
| Snorkel-labeled | 68.32% | .555 | 45.8% | 1.49 | 370,154 |

**Table 3 – Model Performance Comparison**

## 7. Conclusion

Although all manner of misdirection (noise) exists within the data, there are still valuable insights to be gained. Our research has demonstrated that weak supervision techniques, access to subject matter experts, and a corpus of data are useful in developing labeling functions can help us improve the model performance. Specifically, access to diagnostic tools such field meter measurements can help us to improve training data labels.

Machine learning is a logical next-step toward identification and isolation of problems in the RF plant. Adding new data – in this case, our signal meter data – enhances RF domain expertise, improves operational performance and eliminates repeat service calls. By converging the ML/AI predictions with a real-time recommendation and feedback loop, there are also operational improvements to be realized (Figure 13). In other words, by using the results learned from highly effective technicians, the entire workforce can improve, resulting in more efficient technicians and improved customer experience.

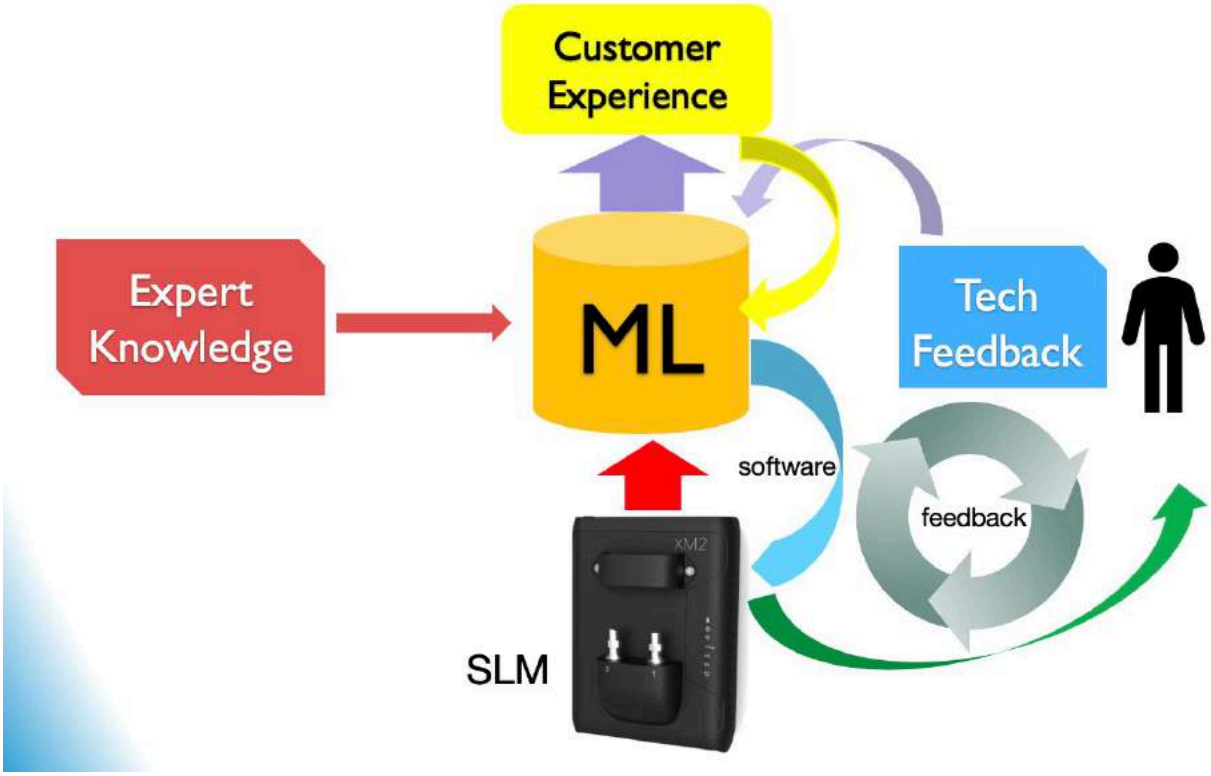

**Figure 13 – ML/AI Enhanced Process and Feedback Loop**

# Abbreviations

| | |
|---|---|
| AI | artificial intelligence |
| CMTS | cable modem termination system |
| DOCSIS | Data-Over-Cable Service Interface Specifications |
| FBC | full band capture |
| FEC | forward error correction |
| GPS | global positioning system |
| ICFR | in-channel frequency response |
| LTE | long term evolution |

## List of Figures

# 1. Introduction

A flu pandemic swept the world from 1918 to 1920, infecting approximately a quarter of the world's population and killing over 50 million. A century later, the world is again facing the reality of a viral pandemic. But things are different this time around: we have accumulated 100 years of health and technological advances that can fortify the fight against this pandemic. The invisible, hard-to-track, rapid transmission and replication of today's virus a critical danger, and these characteristics have caused the world economic and social wheels to grind to a halt. Absent a broader toolkit against this virus, the default defense strategy is isolation with everyone going on lockdown within their homes. Fortunately, now there are mature technologies in the world's arsenal that are being used to fight, in a smart way, the viral transmission and containment dilemma. These technologies are saving lives while enabling the gradual return to some social and economic normalcy. We will continue to embrace technology as the pandemic evolves, and to help with any future outbreaks.

**Figure 1 - Example City Scape with Different verticals and locations**

# 2. The MobileTelecommunications Revolution

A 2019 Pew Research Center Fact Sheet [1] showed that almost 96% of the US population owned a cell phone of some kind, up from 35% in 2011. Almost Two Thirds [2] of the world's population today have mobile phones, and this percentage is above 90% if you only consider the top industrial nations. Compare this to the few million switchboard-based telephones during the 1918 flu pandemic. In the early 1970's the first handheld cell phone was invented. Fast forward fifty years, and more people have mobile phones than toilets [3]. Astonishingly, if we create a 2 minute time-lapse video showing the fast and explosive penetration of mobile technologies in the last thirty years, and compared it with a 2 minute-time-lapse video showing the new virus infections rate throughout the world in the first three months of 2020, the similarities between the two videos would be eye opening.

## 3. Mobile Network Advantages

Unlike the hard-to-track location of new virus transmissions, all mobile phones rely on mature network technology that manages, tracks and operates these devices in real-time to provide several services and advantages. Many countries are using their mobile network to help track, surveil, and stem the spread of the novel virus pandemic. The mobile network offers a level of data and location-based analytics using anonymized, highly granular, and accurate data and location intelligence insights that are being used by local and regional decision makers and health professionals to save lives and control the spread of the virus. There are also significant advantages to using network based location data versus application-based location data. Indeed, there has been significant issues in countries using app-based data rather than network based data to help track and trace [4]. Testing of Apps has shown issues with the technology at scale, despite Apple and Google working together on a common platform. Using network based (subscriber generated) data is well known and deployed in many operators world-wide covering all network technologies and always-on regardless of data connectivity issues.

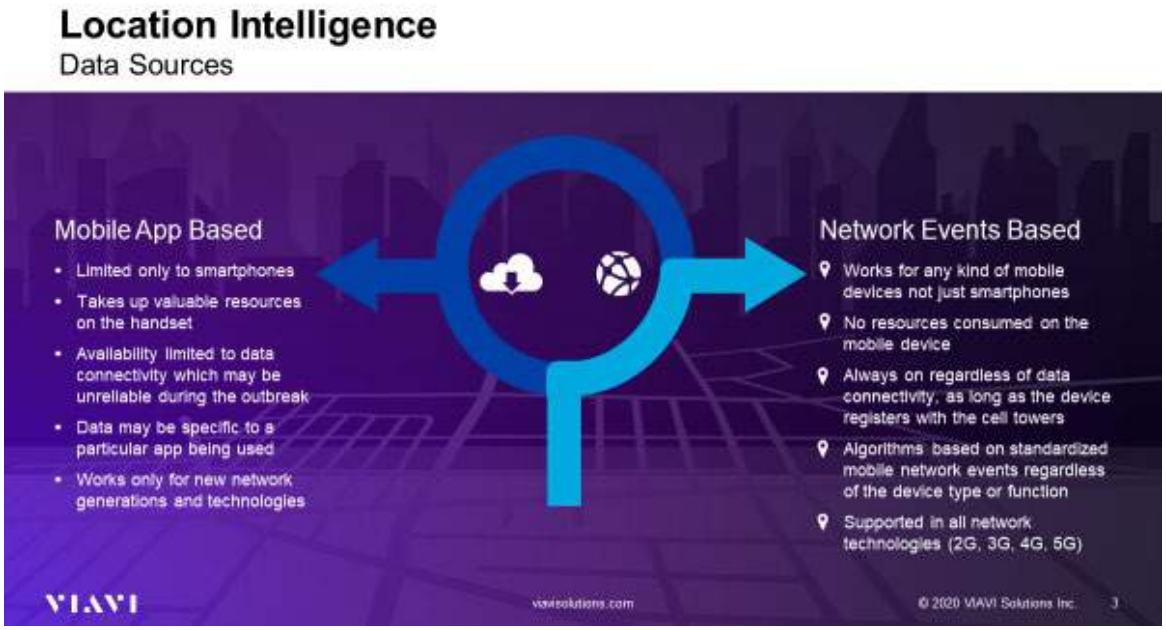

**Figure 2 - Comparison of App Based and Network Based Location Data**

## 4. The Role of Location Intelligence

At VIAVI, we are working closely with communications carriers and governments around the world developing and deploying solutions that leverage Location Intelligence (LI) and Machine Learning (ML) technologies derived from mobile network events. These solutions, traditionally used for engineering, optimization and troubleshooting, provide powerful, accurate and reliable geolocation of subscriber's activities across the network. Correlating these activities with other core network usage insights turns the entire mobile network into a data analytics engine. Applying Machine Learning (ML) and data mining algorithms on such an engine provides valuable and actionable insights into network traffic levels and patterns of population movement and usage behaviors. In addition, detecting international roaming and inter-states movements within the network helps to accurately identify where the majority of subscribers are and where they've been. These insights can be tracked back in time for weeks, and in some cases, several months, all depending on the amount of historic data that has been stored. With 5G

communications, Location Intelligence will apply to much denser networks, both vertically and horizontally, adding another 3D dimension to deliver insight into network activities.

**Figure 3 - Deriving Insights from Mobility Data**

## 5. The Privacy Debate

The issue of privacy is often raised when looking at the role of Location Intelligence because many countries have very strict regulatory policies on the use of this type of data. Operators have used individual subscriber data for troubleshooting and diagnostics at the consent of the subscriber. Here, Location Intelligence is predominantly anonymized and aggregated to look at patterns, trends, and changes rather than individual analysis. The use and availability of this data is generally dependent upon the specific country and its regulations.

The process of anonymization is critical. It needs to be performed in a manner that both protects the privacy of the individual end user while allowing the mobile operator or the relevant governmental agencies to perform the relevant analysis. So far, it has been most effective to use a 24-hour static ID as the anonymized ID for each user in order to be able to track the mobility and determine if this represents reduced mobility, for example, in the society at large. If the same ID is used for a shorter period of time, critical mobility may not be observed. And if the ID is used for a longer period of time, it becomes possible to analyze who is behind the anonymized ID.

## 6. Better Informed Decision Making

Location Intelligence analytics enables decision makers to track travelers to and from affected countries and determine when and where quarantine rules can be enforced. The algorithms use the Location Intelligence aggregate data over time to identify hotspots that at-risk subscribers visited or where they congregated to detect potential contamination areas and implement proactive containment policies. The solution also monitors, in real-time, events (lawful or unlawful) for potential outbreaks and enforcement issues.

It also assists in outbreak investigations to identify contacts and apply appropriate measures to prevent further spread. This is particularly important as borders start to open up where countries go through different waves at different times. Being able to capture analysis on hotspots (e.g. where and when the

population has been moving across borders) becomes more important. Indeed, as life gets back to something that looks like normal, location data and analytics can help to manage outbreaks as it can continuously monitor people movements.

## 7. Real-Time Pandemic Hostpots Tracking And Analysis

While the virus is invisibly attacking communities through travelers and locals carrying it from highly infected areas, its effect can still be uncovered, tracked, and quickly contained using Location Intelligence analytics. The Location Intelligence technology tracks inbound roamers from affected countries or high-risk areas and monitors their locations and interactions in real-time. It also alerts outbound roamers and provides the latest information on the outbreak and government policies to keep the roamer away from harm and potential hotspots. We continue to work with several governmental departments for disease control along with operators that requested help to monitor and manage the spread of the pandemic in their respective countries. In cooperation with in-region telecom operators, we are providing them with Location Intelligence and Machine Learning systems analyzing location data for inbound roamers and at-risk or positively-diagnosed cases of the virus. The system automatically identifies at-risk inbound populations, creates logical geofencing of quarantined patients with automatic alerting, and provides movement history and contact history for positive cases allowing notification and action to be taken to minimize infection risk. It also monitors critical infrastructure including hospitals, airports, and emergency services to assure they are getting the high connectivity, capacity, and performance from the network.

## 8. Ensure Enacted Policies Make a Difference

As many of us enter the next phase in defeating the pandemic and gradually restoring life to normal, the ability to monitor and ensure the policies enacted—such as shelter in place, work from home, and curfews—is making a difference in the war against the virus. Here again, Location Intelligence and Machine Learning solutions can be of great assistance. Our solution helps governments and telecom carriers across the world with implementation of their policies by providing them with insights and actionable information that tracks potential contamination areas and reinforces verifications, alerts and health support for these policies. Again, this is done by monitoring patterns and movements of people, analyzing transport usage (location can determine speed and so can make predictions on whether someone is for example walking or in a motorized vehicle).

As more and more governments order school closures, and as people are encouraged to work from home, an immediate load and shift in network traffic was noticed for collaboration applications on the operators' networks. Our solution helps to detect this shift in real-time and recommends load-balancing and optimization action to mitigate these issues and assure efficient use of network and services resources.

Working from home policies may continue to be the norm for many people as they embrace a more blended model of work place and home. This shift may be permanent with operators needing to continue to analyze usage by location enabling networks to adapt and change to the evolving environment and delivering an optimized network at all times.

## 9. The Day After

The use of Location Intelligence and Machine Learning does not stop when a pandemic ends. The question remains of how to deal with the aftermath—the unforeseen challenges that will arise from the social tensions, the economic impact, the shortage of essentials and food, unemployment, and so forth. The evolution of solutions like Location Intelligence, Network Assurance, and Machine Learning to

Artificial Intelligence (AI) helps governments and authorities to be prepared to tackle these issues with real time actionable information and decision making. Remote proactive monitoring and automation to actuate changes in the network or the services will be needed to offset the expected personnel shortages and the wide-spread nature of events

## 10. Conclusion: A Future with No Pandemics

Will we be able to completely defeat and eradicate viral pandemics in the next 100 years? The answer may be yes, if we consider the exponential advances in Artificial Intelligence, Machine Learning, data analytics, and the Internet of Things (IoT) coupled with the promises of 5G and next-generation networks. That conclusion is not a big stretch if we extrapolate the advancements achieved in the 100 years since the last deadly viral pandemic. The use of smart technologies is saving lives today, and the upward curve of innovations is not slowing. The network of the future will have the capability to detect a new viral pandemic at its onset, track all the infections in real-time, and stop it before spreading. Fully automated testing and in vivo monitoring are leaving the science fiction realm to become practical applications. Ultimately, we are on the side of technological innovations and human ingenuity to win the war against pandemics.

# Table of Contents

## List of Figures

## List of Tables

# Introduction

Machine Learning as a service (MLaaS) is a burgeoning field in the digital TV space. Its goal is to create AI/ML based revenue generating products. In this study, a novel use case is presented along with machine learning based enhancements. TV viewers routinely encounter shows that they dislike, but they are unable to avoid seeing them. While the consumer opinions are highly subjective, the end-result is the same: flipping the channel, which leads to advertising revenue loss for the programmer. Although retaining viewership of the channel is highly desired, technical challenges have precluded a satisfactory solution thus far.

The selected use case is of interest because unappealing content and recommendations contrast each other (dissuade vs. persuade). This distinction also manifests in the solution structure. For example, Recommender Systems (RS) are based on user ratings of liked content. In contrast, 'disliked content' may be so averse to a viewer thus it is not even rated. Not having user ratings is a barrier for applying the RS model, which uses similarity measures in the latent space to determine affinity. Hence, in this study a different metric based on implicit data is used for feature vector creation. The goal is to illustrate the challenges and opportunities in developing MLaaS products for carrier-grade video.

Presented is a distributed solution* applicable to vMVPD service. Enhancements to IP content delivery pipeline and Machine learning based automation are key for replacing disliked content. Additional scopes for MLaaS applications are also discussed.
*patent filing (16/167,766)

# Content

## 1. Machine Learning Applications in Digital Video

Machine Learning applications in the video delivery pipeline are ubiquitous. From content ingest to transmission to delivery, opportunities abound for applying algorithmic solutions. These would typically include ingest quality control, network and storage optimizing and a host of data analytics applications upon content delivery. For example, the manual scanning of thousands of TV ads at ingest can be automated with a classification engine [1]. Additional applications in operational and product improvement are discussed later.

Such applications in cable-tech however are internal to the enterprise. The premise of this paper is to make the case that the technology is ripe for the next stage of ML revolution. Known as MLaaS or Machine Learning as a Service, it is modeled similar to other 'as a service' paradigms such as SaaS and PaaS. Familiar examples are web-based emails and cloud DVR services. MLaaS goes a step further and facilitates machine learning based consumer technology applications. As an enabling technology it can create machine learning based revenue generating services for the cable operators.

In the ensuing sections we delve deeper into the problem. First, we review the functioning of general recommender systems. Then, to illustrate MLaaS, a novel application is presented along with machine learning enhancements. The selected use case is advertising revenue loss due to channel surfing. The recommender systems algorithms are applied with certain caveats. Finally, other MLaaS applications are briefly discussed.

## 2. Recommender Systems

Consumers are overwhelmed by the broad array of choices in product availability. Personalized recommendations are thus vital for a more satisfying user experience. Recommendation and Search are both similar in that they attempt to filter relevant information from a deluge of data. In the case of search, the user knows what (s)he is looking for. Recommender Systems (RS) on the other hand, attempt to determine user interests via automated search analytics. The 'items' in this context can be books, movies etc. Machine learning algorithms enable learning from the data and building predictive models.

Recommender Systems generally fall into two broad categories: Content-Based filtering (CB) and Collaborative-Filtering (CF). The CB approach is based on the attributes of each item and the user's affinity (rating) for similar items. Content may consist of movie genre, actors, theme etc. Based on the users previous ratings, movies that have similar content are recommended.

Unlike CB, the CF recommendations are based on multiple users' ratings. The assumption is that similar users share the same interest. Sometimes called 'neighborhood methods', they are categorized as user-based or item-based. The user-based CF make recommendations based on the ratings given by other users with similar profiles. In item-based CF, the neighborhood items are those with similar user ratings. The similarity is determined by first forming vectors (rows of ratings matrix) per each user, and computing similarity measures such as Euclidean distance or Cosine similarity between vectors in a multi-dimensional space. Mathematically, users in the same 'neighborhood' would have Cosine of angle close to 1. Dissimilarity is denoted by 90° separation.

$$similarity = cos(\theta) = \frac{\boldsymbol{u} \cdot \boldsymbol{v}}{\|\boldsymbol{u}\| \|\boldsymbol{v}\|} = \frac{\sum_{i=1}^{n} u_i v_i}{\sqrt{\sum_{i=1}^{n} u_i^2} \sqrt{\sum_{i=1}^{n} v_i^2}}$$

**Figure 1 – Cosine Similarity between multi-dimensional vectors**

(Technically there is a difference between Cosine Similarity and Cosine Distance due to Schwartz inequality. In this paper however, we follow the conventional definition and use inner angle as the similarity measure between the vectors.

### 2.1. Matrix Factorization

Among the algorithmic approaches to solve RS, matrix factorization is a well-known technique. The basic premise of matrix factorization is that there are *latent factors* that determine the user ratings of items. These latent factors are not measured directly, but their impact is reflected in the user ratings (observed variable). In the case of movies, those could range from obvious features such as action, romance and comedy to more complex psychological emotions. Such nuances may not have simple labels to describe them. The beauty of the matrix factorization method is that it can handle such complexity with poise via a multi-dimensional vector model.

The starting point is the user-item 'rating matrix' (utility matrix), which in practice may have millions of entries. Note that some cells are empty (user ratings not available).

| | Movie 1 | Movie 2 | Movie 3 | . . . . . | Movie n |
|---|---|---|---|---|---|
| User 1 | 5 | N/A | 2 | | 3 |
| User 2 | 1 | 3 | N/A | | N/A |
| User 3 | N/A | 4 | 1 | | 4 |
| . . . . . | | | | | |
| . . . . . | | | | | |
| User m | N/A | 4 | 1 | | N/A |

**Figure 2 – User-Item Rating Matrix**

Matrix factorization decomposes the user ratings matrix based on latent factors that contribute to user preferences and item attributes. It then predicts the unknown ratings through the scalar/inner/dot product of the latent features of users and items.

For example, if Bob is an action movie aficionado, his profile may consist of:

Bob = 60% Action + 30% Comedy + 10% Romance+ 0% Historical

Similarly, the profile for movie could be:

Titanic = 30% Action + 0% Comedy + 60% Romance + 10% Historical

The dot product of these vectors would determine Bob's affinity for the movie Titanic. The larger the dot product between a user vector and an item vector, the item is better suited for user's taste and can be recommended.

The rating matrix of Figure 2 has many empty cells (sparse), as only a fraction of movies are watched by users, let alone rated. The goal of recommender system is to fill these gaps. In Figure 3, the sparse matrix is expressed in terms of two latent factor matrices (one for user and the other for item attributes). The missing values are approximated by the dot product of the two latent factor matrices via optimization.

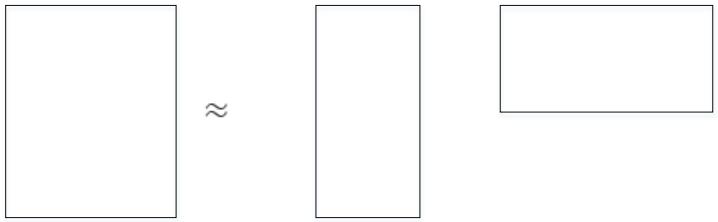

**Figure 3 – Matrix Factorization**

## 2.2. Singular Value Decomposition (SVD)

A prominent technique for matrix factorization is singular value decomposition. The SVD algorithm received wide recognition for its critical role in the $1 million Netflix prize competition [2]. The singular value decomposition (SVD) factorizes a given matrix 'X' into constituent arrays of feature vectors.

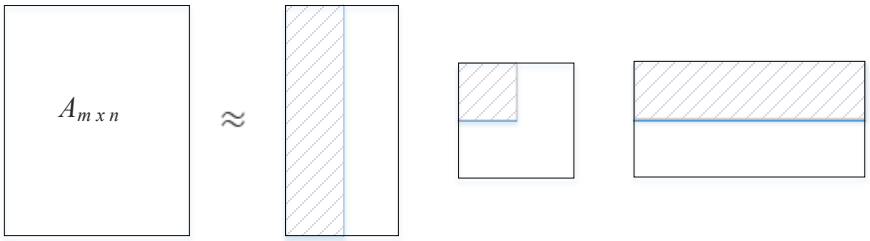

**Figure 4 – SVD Decomposition**

$$A = U\Sigma V^T$$

- $A$ is the given data matrix (m x n) of rank r
- $U$ is an orthonormal m x r matrix
- $\Sigma$ is a diagonal r x r matrix
- $V$ is an orthonormal n x r matrix

The diagonal matrix '$\Sigma$' contains the singular values in descending order. The higher values represent the dominant features or latent factors of the given matrix. We consider the reduced form with small Sigma values set to zero as shown in the Figure 4.

Collaborative filtering (CF) based recommender systems perform poorly when dimensions in data increases (sometimes called 'curse of dimensionality'). Reducing the extra dimensions while keeping the salient features is the function of a dimensionality reduction algorithm. SVD filters the dominant features from the data (Sigma matrix) and identify hidden correlations in the singular vectors U and $V^T$.

SVD helps find a lower rank matrix approximation to the original matrix. Mathematically this means picking only the top singular values from the sigma matrix and discarding others. Each singular value defines the 'strength' of the concept. e.g. a high value may indicate the genre of the movie cluster such as action or comedy.

$$A \approx U_{mxr}\ \Sigma_{rxr}\ V^T_{rxn}$$

$$\begin{pmatrix} a_{11} & a_{12} & \dots & a_{1n} \\ a_{21} & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots \\ a_{m1} & \dots & \dots & a_{mn} \end{pmatrix} \approx \begin{bmatrix} u_{11} & u_{12} & \dots & u_{1r} \\ u_{21} & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots \\ u_{m1} & \dots & \dots & u_{mr} \end{bmatrix} \begin{bmatrix} \sigma_{11} & 0 & \dots & \dots \\ 0 & \sigma_{22} & \dots & \dots \\ \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \sigma_{rr} \end{bmatrix} \begin{bmatrix} v_{11} & v_{12} & \dots & v_{1n} \\ v_{21} & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots \\ v_{r1} & \dots & \dots & v_{rn} \end{bmatrix}$$

**Figure 5 – SVD Decomposition in Elements Form**

An alternate way to perform matrix factorization is to calculate eigenvalues of the covariance matrix ($A^TA$). Both approaches are consistent in that the square roots of eigenvalues are equal to singular values. The Eigen vectors of the covariance matrix indicate 'principal components' of the matrix. Eigen method (sometimes called spectral decomposition), is computationally more involved, hence in this paper we explore SVD.

As mentioned, the main challenge with the matrix factorization methods is that the rating matrix is mostly sparse. This problem is addressed by iteratively calculating each cell value and updating them (using Gradient Descent and Alternate Least Square techniques). The error is minimized by applying Frobenius norm to data matrices. These steps are well-known in the literature and as such not discussed further.

We revisit the recommender systems in Section 4, in reference to disliked content.

# 3. Supplanting Unappealing TV Programs

In this section we change gears and review the technical aspects of the selected use case. Then, the machine learning enhancements are discussed for creating an MLaaS product.

Almost all TV viewers have their favorite shows, as well as the ones they dislike. The latter (unappealing content) is the focus of this study. When confronted with disliked content the normal user behavior is to flip the channel, which leads to advertising revenue loss for the programmer. IP based digital TV streaming has made it possible to supply alternate content on per user basis.

While IP streaming offers such capability, the requirements cannot be met by changing just one end of the content stream. The contractual obligations between Programmer and Content Distributer must remain intact as well. A distributed solution is presented, requiring enhancements on multiple components: Alternate content is supplied by the programmer, assembled and stored at the Content Distributor. The disliked content is replaced automatically.

## 3.1. Alternate Content Usage

A customer identifies a TV program/show/series that is unappealing to her, and would prefer to have it replaced with alternate content. Her choices can be supplied via a web portal/API or a clickable icon added to the TV Guide. The Content Provider establishes Alternate content channels for selected regular channels. The Alternate content could be programs that aired earlier in the day and stored in the CDN. Once the setup is complete, whenever the consumer tunes to an unappealing program content, it will trigger content replacement automatically and seamlessly. In this context, *'tuned to the channel'* could also mean accessing a web page, such as in a social-media based network.

**Table 1 – Alt Content Examples (names slightly changed)**

| Supplanting a Program by Alt Content (Traveler Channel) | | | |
|---|---|---|---|
| **Original Program** | **Alt content-1** | **Alt content-2** | **Alt content-3** |
| Ghoul Adventures | Bizarre Feasts | Museum Mysteries | Nay Reservations |

## 3.2. Content Replacement – Process Steps

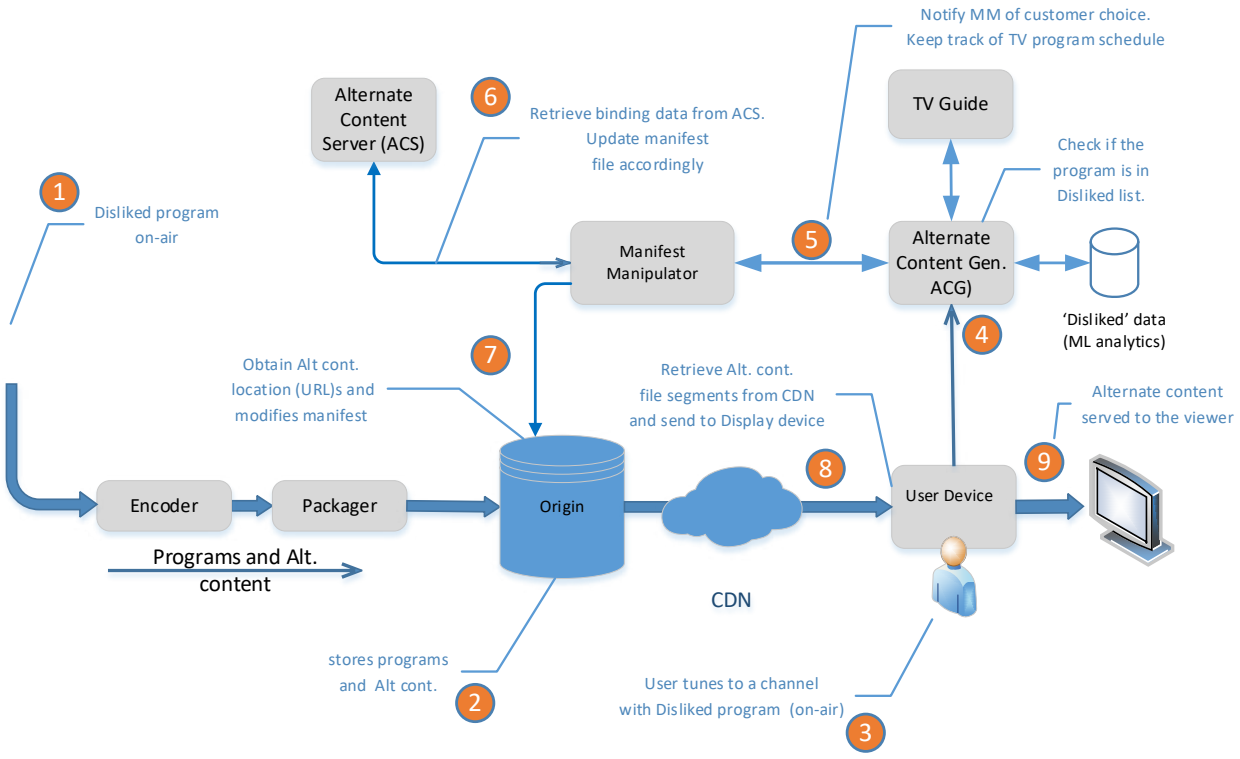

**Figure 6 – Process Flow for Alt Content Usage in Program Replacement**

**1.** Assume a previously identified 'disliked program' is on the air (e.g. Table 2 - *Ghoul Adventures* of Traveler Channel).

**2**. Program content and alternate content are stored on the CDN headend. The Alt. content could be previously aired shows or specifically targeted content.

(In a typical streaming scenario - The broadcasted TV/media content stream from Programmer is received by the content distributor. The Encoder/Transcoder may perform any format changes. The Packager/Segmenter will splice the content into many chunks. The video/audio segments (along with an Index file (Manifest) for segment identification), are placed for storage on a CDN Origin server).

**3**. Assume the previously identified 'disliked program' is on the air. The end-user tunes to the channel.

**4**. Alternate Content Generator (ACG) **i**nterfaces with TV guide to obtain program start end times. It queries the 'Disliked content database' for any matches.

**5**. If a match is found that information is passed back to the Manifest Manipulator. (Note – These messages are in addition to the regular manifest requests issued by a Client device during IP streaming)

**6**. Noting that there is a 'Dislikes' request, the Manifest Manipulator communicates with the Alternate Content Service (ACS) database. ACS module **binds** Customer Device ID to Program Alt cont. selection and returns to the Manifest Manipulator.

Customer Device Identifier ←→ Disliked content ←→ Alt. content

**7**. Manifest Manipulator modifies the index/manifest file, accordingly, replacing regular content with alternate content. The updated manifest is sent to the customer device (Client).

**8**. The Customer Device now retrieves corresponding alternate content from the CDN and send to the display device.

**9**. The original content is supplanted with alternate content and supplied to the display device for user consumption.

# 4. Replacing Disliked Content – ML Automation

## 4.1. Challenges in Applying Recommender Systems to Disliked content

In the movie recommendations example described earlier, the viewer inputs were explicitly supplied (e.g. one through five stars). In the case of disked content however, there is no explicit metric. The content is so averse, the viewer simply changes the channel. Not having user ratings is a barrier for applying the RS model, which uses similarity measures in the latent space to determine affinity. Hence, in this study a different metric is used for feature vector creation.

Another constraint is the sheer number of channels in a TV subscription. Most users have never even tuned to the hundreds of channels offered. It would be incorrect to categorize those as disliked content. Note that the present analysis applies to channels containing a mix of liked-content and disliked-content. The goal is to keep the viewer in the same channel. If there are no liked programs at all (i.e. customer never tunes to the channel), then the issue of ad revenue loss is moot.

## 4.2. Implicit Identification of Disliked content

The method adopted was to collect viewership data over time and apply data analytics to identify disliked content indirectly. One peculiarity with the viewership data is the vast difference in the time scale. For 'disliked content', the channel surfing times are about one to two seconds. But for 'liked content' (regular viewing), the durations could vary from several minutes per channel to hours. This disparity was addressed via a change of scale adjustment.

The wide range of the time scale is also a barrier for applying machine learning algorithms. This is illustrated below with reference to two algorithmic scenarios.

**a) Cosine Similarity**

Cosine similarity is easy to visualize in two dimensions, but its application in the present context is for a multi-dimensional space. Due to the large disparity in the time scales (few seconds for disliked content vs. thousands of seconds for liked content), the user/item vectors in the latent space will not be an accurate depiction. The impact of disliked-content will be hard to quantify. On the other hand, simply inverting the scale (e.g. assigning 5 stars for disliked and 1 for liked), will not capture the nuances.

**b) Singular Value Decomposition (SVD)**

Note that in the Singular values matrix, the dominant values are at the top left and decreases down the diagonal.

$$\text{Sigma } 1 \geq \text{Sigma } 2 \geq \text{Sigma } 3\ldots$$

The quantities of interest (disliked content with 1-2 seconds), are at the lower end of the time-scale and their impact is washed out by much larger terms in the matrix (thousands of seconds for liked content). As such, the dominant Sigma values do not reflect the impact of disliked-content, and skew the results. It is therefore necessary to rescale the data so that the disliked content reflect the dominant terms in the utility matrix.

## 4.3. Data Rescaling

The metric adopted for this task is the log reciprocal of channel surf time. Since the channel change time could vary from 1 second to several hours (thousands of seconds), we use the following formula:

$$\textbf{Disliked Content Measure} = \text{Log}_{10}\ (10^4/T) = 4\ - \text{Log}_{10}\ T$$

**Table 2 – Disliked Content Rescaling**

| ← Disliked Content | | | Liked Content → | |
|---|---|---|---|---|
| Duration | 1 sec | 10 sec | 15 min | 2 hours |
| Log10 (104/T) | 4 | 3 | 1.045 | 0.143 |

The logarithmic scale converts the wide range of channel view time values to a more manageable compact scale. The original span of 1 second to over 2 hours, is now rescaled to the more compact range from zero to four (Table 2). The Log scale captures 1–5 star ratings implicitly. It is also in line with behavior based algorithms due to the continuity of scale. Conversely, simply assigning 5 stars to shorter times would not be granular. Also, the user response times for channel surfing are subjective.

## 4.4. Enhancements to Recommender Systems

The result of applying RS is the creation of a disliked content matrix. This complements the more common liked-content matrix created by RS. The disliked-content analysis supplies additional data about user preferences to enhance the recommender system. This would be useful since a major issue with RS is the sparsity of the input data matrix.

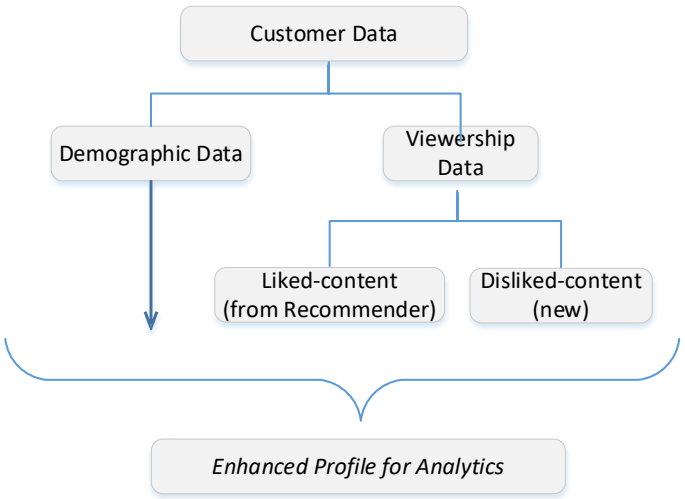

**Figure 7 – Disliked Content Usage to Enhance Consumer Profile**

# 5. Machine Learning in Digital Video – Additional Examples

Additional instances of potential usage are listed below for reference; not all are revenue related.

## 5.1. Enhanced Rating System for Movies

Current TV/Movie ratings are confusing (TV-Y7-FV, PG-13, TV-14…), as the restricted content definition is subjective. Parents would appreciate if they could know beforehand the type and placement of restricted content.

a) Scan videos in the repository and tag restricted content per pre-defined criteria, with time stamps.
b) Develop an API for one-click access for the 'Enhanced Ratings' from the program guide.

## 5.2. Video Content Analysis - VOD Storage and Ingest

a) Scan videos and generate descriptive metadata. Identify sentiments, underlying topics as well as any anomalies in the media content. Create a searchable catalog of videos based on tagged data.
b) Thematic advertising – Given an Ad-campaign theme (e.g. eco-tourism), find matching videos from the collection. Find effectiveness of ads by different demographics/audiences.
c) Celebrities - Find videos of a given actor, including duration/time stamps, from a collection.
d) Closed captions – Translate speech to text for assets that currently do not have captions.
e) Skipping content on VOD – User is presented with the option to auto-skip parts of a video based on pre-defined content identifiers. ML can tag content based on *heuristics*.

### 5.3. Personalized Ads - Combine Demographic and Viewing data

[Scenario – Demographic data may suggest that 3 people live in a household, but it cannot answer questions such as, "Of the 3 inhabitants, which one was watching TV at 4 PM)?" Data analytics based on viewing patterns can be used to enhance targeted advertising]

a) Develop individual user profiles for each household based on multiple data sources – customer demographics, online viewing history and navigation data.
b) Make recommendations for personalized ads based on time-of-day viewership characteristics.
c) Predict ad completion rates based on past viewing behavior and make ad recommendations.

### 5.4. Codec Quantization Parameter (QP) settings

In a video codec the DCT coefficients are quantized per Quantization Parameter (QP) settings. Coarse QP values mean high compression and lower quality. QPs are also proportional to the Lagrangian multipliers of Rate optimization.

The Neural Network based auto-encoders on the other hand, map the data to a lower dimensional latent space and then reconstruct it during decoding. It can predict pixel values fairly accurately and provide optimum QP values. The encode-decode pair is trained as a single unit in unsupervised learning. The adaptively tuned QP values will yield improved PSNR.

## 6. Benefits to Service Providers and Programmers

Machine learning enables identifying and auto-replacing of disliked content. MLaaS based novel offering ("Don't Like, Don't Watch!") would be a new revenue opportunity for programmers and content distributors. The disliked content could even be faces and voices based on pre-defined signatures.

Another improvement is in targeted advertising. Ad campaigns are generally based on consumer demographic data obtained from data brokers. The aggregated data can be refined by comparing with viewership patterns (e.g. time-of-day), garnered from liked and disliked content (Figure 7).

Recommender systems based on explicit data can be improved by combining with disliked-content analysis.

# Conclusion

Cable-tech is ripe for disruption and transformation with MLaaS based consumer technologies. Service providers will reap the benefits of new revenue generating opportunities. To illustrate the point, a novel use case was presented along with MLaaS enhancements. To circumvent the challenges with general recommender system model, a new metric was proposed based on *implicit* user data. The auto-discovery and replacement of disliked content would prevent revenue loss for programmers due to channel surfing. Additional benefits include enhancements to recommender systems and targeted ad-campaigns.

# 1. Introduction

UHD video streaming services have been launched worldwide. In Japan, 4K/8K broadcasting services has been promoting by "All Japan," which are organized by the government, broadcasters, telecommunicators, and TV manufacturers since 2014. Figure 1 is "4K/8K roadmap" advocated by the Ministry of Internal Affairs and Communication (MIC) and satellite, cable TV, and IP TV are picked up as the access networks for 4K/8K broadcasting services in the roadmap. According to this roadmap, cable industry in Japan has been started 4K community channel service organized by themselves, named by "Cable 4K", since 2015.

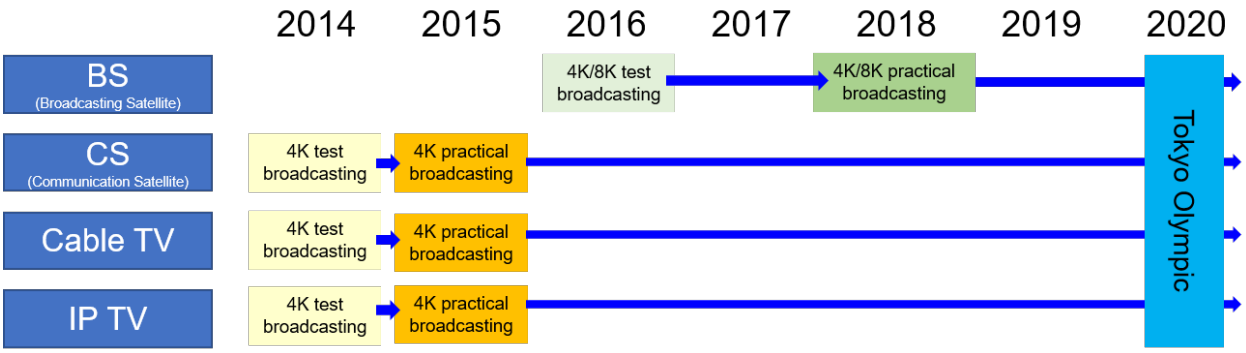

**Figure 1 - 4K/8K roadmap based on an interim report from the study group for 4K/8K broadcasting at the Ministry of Internal Affairs and Communication (MIC)**

# 2. Problem statement

Demand for 4K/8K video is increasing toward the Tokyo Olympic games, cable industry seeks to increase 4K video channels to respond the demand from customers. The final goal of Japanese cable industry is to convert over the 100 community channels with SD/HD resolution into 4K. The transmission capacity of HFC access networks is, however, limited by the existing TV services and Internet services, and the network band cannot be expanded due to the retransmission of satellite broadcasting ( 1~3GHz). Figure 2 shows the typical utilization of HFC network band in Japan. Cable operators needs to manage to deliver the over 100 broadcasting services and Internet services in the limited network band.

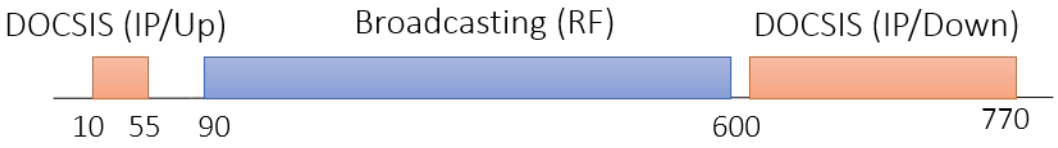

**Figure 2 - Typical utilization of HFC network band**

Furthermore, cable operators cannot easily replace HFC by FTTH because of the high installation cost of FTTH. Figure 3shows the portion of access network types of Japanese cable subscribers in 2017 and indicate the fact that HFC is still dominant. Because of this, the cable operators cannot easily enhance the network infrastructure to increase the 4K channels.

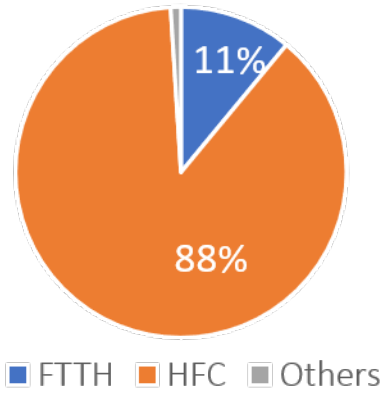

**Figure 3 - The portion of access network types of Japanese cable subscribers in 2017.**

Figure 4 shows the conventional scheme of video distribution over HFC access network. In Japanese, the most of the cable operators deliver the all broadcasting services on RF-network band as shown in Figure 4. This is because that the RF distribution scheme is consider to be more reliable than IP distribution scheme, that is IP multicast scheme. The detail is as follows. In general, with RF-distribution scheme, the received video quality is stable since the video is transmitted at a fixed coding bitrate over quality-guaranteed network where are fixed transmission band is reserved for each video channels. The utilization efficiency of video of the network band resource is, however, low since they occupied by the videos regardless audience ratings, In contrast, with the IP distribution scheme, the received video quality is unstable since the video is transmitted at a variable or adaptive coding bitrate over best-effort network where the bandwidth is not reserved for reserved for each video channels. The utilization efficiency of network band resources, is however, high since they are used for the transmission of not only video but also Internet data. Whichever method is used, therefore, it is difficult to realize 4K conversion of all existing video channels aimed at by the cable industry, and a novel approach is required.

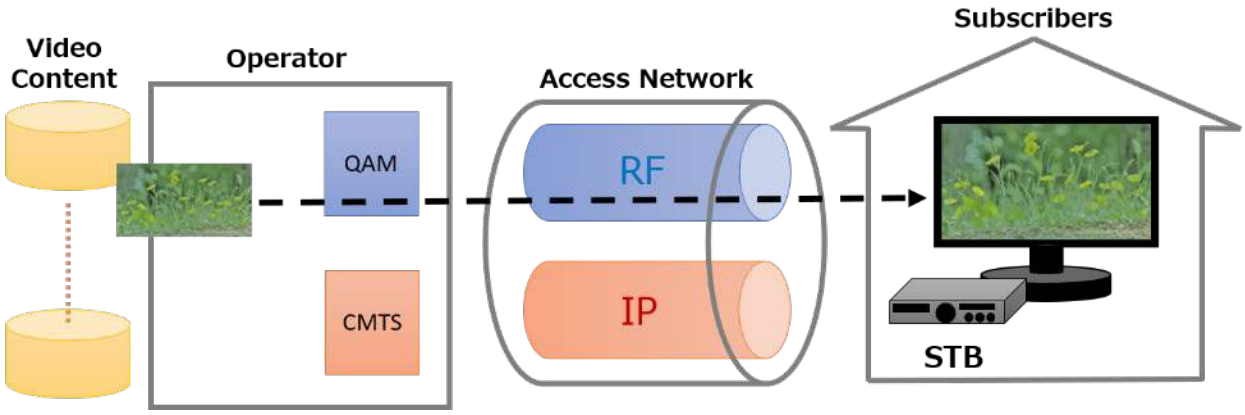

**Figure 4 - Conventional scheme of video distribution over HFC access network.**

# 3. Proposed method

## 3.1. Basic Concept

As the solution of the problem described in section 2, RF/IP adaptive distribution scheme is proposed. The strategy of proposed method is to create the environment where almost all the subscribers can watch 4K videos. According the strategy, the following two key ideas are proposed. The first idea is sharing of

the RF/IP network band resources. The second idea is adaptive control of video qualities and distribution scheme according to the following three parameters; attribute of video content (e.g., emergency degree), available network bandwidth, and audience rating of content. Figure 5 shows the priority rule of video regarding the second idea. In this rule, the scheme quality, that is video resolution and bitrate we defined, is controlled according to audience ratings and emergency degrees. By preferentially distributing video channels with a high audience rating in 4K resolution and high bitrate, it is possible to realize an environment in which almost all subscribers can watch 4K channels. The reason why RF distribution scheme is higher priority than IP distribution scheme is that RF distribution scheme is more stable than that of IP described section 2.

| Audience Rating<br>Emergency Degree | High | ← | | | → | Low |
|---|---|---|---|---|---|---|
| Scheme-Quality | RF-4K | IP-4K | RF-HD | IP-HD | RF-SD | IP-SD |
| Bitrate (bps) | 20M | 15M | 10M | 7M | 5M | 3M |

**Figure 5 - Priority rule of controlling video qualities and distribution schemes.**

Figure 6 shows the proposed RF/IP adaptive distribution scheme. The basic principle is as follows: First, the optimizer collects the audience ratings, available network bandwidth, and attribute of video content. Second, the optimizer calculates the switching indicator and determines the necessity of switching the video distribution scheme for each video channel. Third, the optimizer signals a switching order to the switcher for each video channel which the optimizer determined that the switching is required. Forth, the switcher change the video distribution scheme according to the switching order from the optimizer.

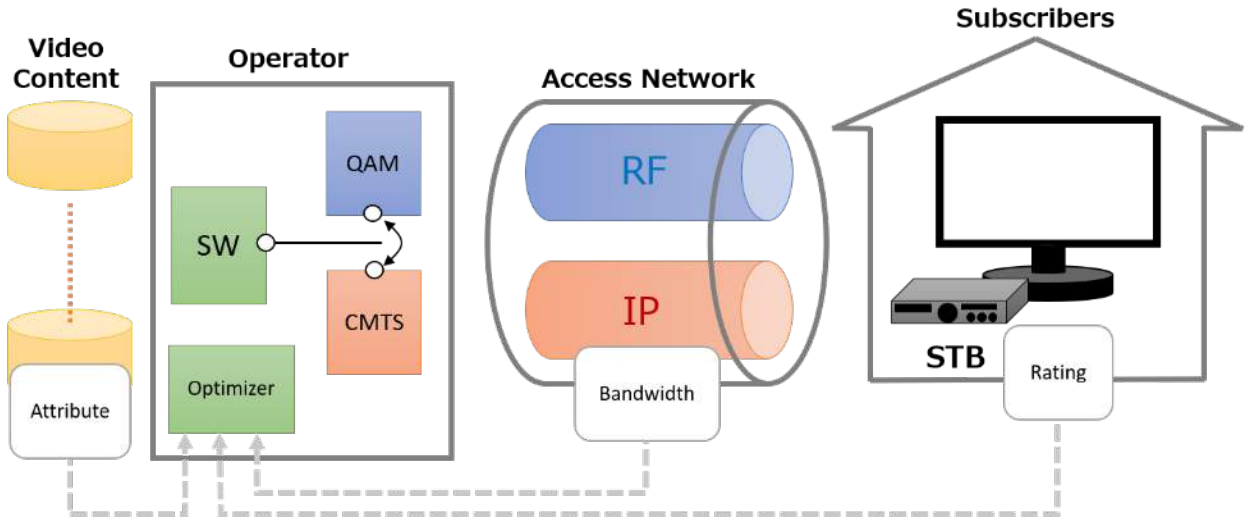

**Figure 6 - RF/IP adaptive distribution scheme**

## 3.1. System architecutre, Technolgoy

In this section, a system architecture and key technologies of key components are described. Figure 7 indicate a system architecture to realize the proposed RF/IP adaptive distribution scheme. Data collector in addition to optimizer and switcher is also key component. The role and technology for each key component is described separately in the following section.

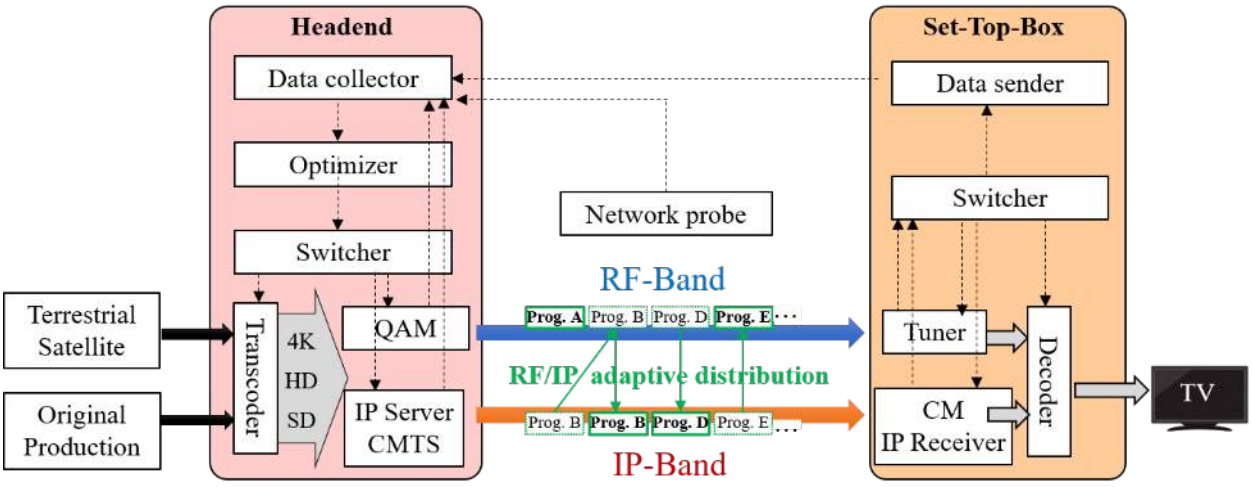

**Figure 7 - A system architecture to realize the proposed scheme.**

### *3.1.1. Optimizer / Switching Indicator*

The switching indicator is designed as like QoE with the following formula. We call it audience satisfaction degree (ASD). The definition of this is the ratio of A and B as shown in the formula. A is a measured score calculated with sum of products based on the actual audience rating and the score corresponding to the bitrate of the actually used video distribution scheme. B is an ideal score calculated with sum of products based on the actual audience rating and maximum score which is corresponding to the bitrate of RF/4K video distribution scheme.

$$ASD(t) = \frac{A}{B} = \frac{\sum_{i=1}^{n} R_{t,i} \times S_i}{\sum_{i=1}^{n} R_{t,i} \times S_{max}} \times 100$$

It is noted that *R, S, i, n,* and *t* indicate audience rating, score based on video bitrates, indicator of programme, total number of programmes, and distribution time, respectively.

### *3.1.2. Optimizer / Switching Algorithm*

The switching algorithm is designed to keep always the highest score of ASD even when the audience ratings and available network bandwidth, and attribute of video content vary. It is realized by recursively checking and assignment based on the priority rules. The overall processing order is as follows:

1. Collect the latest ratings, bandwidth, attribute
2. Sort programmes by ratings
3. Assign programmes with high ratings to the RF-band at a high bitrate preferentially.
4. Lower the rank of the scheme and quality if bandwidth becomes insufficient
5. Recurse No.3 and No.4 processes until all programmes are completely assigned.
6. Calculate difference of new/old ASD based on the new/old assignments
7. Switch scheme and quality if the difference is greater than threshold

Some simulation experiments for validation of the switching algorithm are conducted and those are described in section X.

### *3.1.3. Data collector, etc. / Real-Time and Large-Scale Data Collection*

Real-time and large-scale data collection in data collector, network probe, and CPE devices is essential to guarantee the accuracy of the switching scheme. To realized that, lightness and ease to implementation, will be required. From our preliminary study, MQTT (Message Queuing Telemetry Transport) is the best protocol in terms of the requirements.

### *3.1.1. Switcher /Seamless Switching*

Seamless switching is essential to avoid subjective side-effect from the switching shock. These are the requirement:

1. How to transmit the switching timing from HE to STB
2. How to remove the switching shock (e.g., stop playback, skip frame, etc.)
3. How to solve the difference in video format (e.g., resolution, frame rate, codec)

Feasibility study of seamless RF/IP switching is conducted thorough the prototype development of switching demo system, which is described in section X.

# 4. Simulation Experiment

## 4.1. Simulation System

To validate the proposed switching algorithm, simulation system is developed with two web application servers. Utilized CPU and software are as follows:

- CPU: 1vCPU, Memory: 2GB, OS: CentOS
- Software: Apache Tomcat, mysql, openssl, Echarts

A simulation engine where switching runs is implemented from scratch. Figure 8 shows the simulation system configuration. Time-varying audience ratings and IP network bandwidths are input as scenario files. Other basic parameters are set with GUI before the simulation.

Time transition of ASD ( = switching indicator ) is plotted as a result of simulation execution.

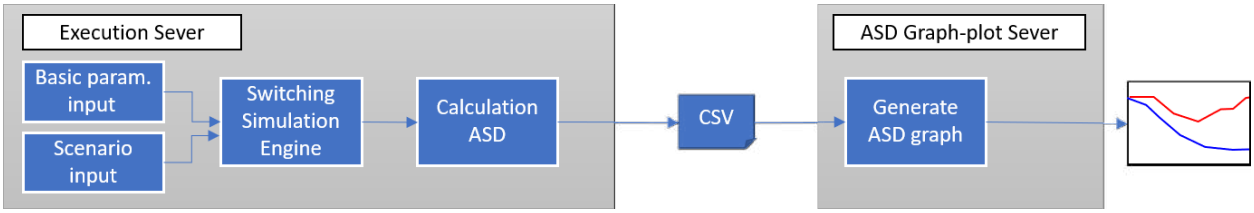

**Figure 8 - Simulation system configuration**

## 4.2. Simulation Condition

Utilized basic parameters and time-vary parameters are shown as follows:

- Number of video channel: 50ch, 75ch, 100ch
- Network capacity: Utilize 8 patterns of infrastructure referred to Japanese operators
- Video coding bitrate:

  - RF-4K: 25Mbps, RF-HD: 15Mbps, RF-SD:6Mbps, IP-SD: 4Mbps
- Number of STB: 10,000
- Emulation Time: 24 hours
- Switching Cycle: 5 min
- Switching Threshold: 0
- Time-varying parameters
- Audience rating: Utilize real data from Video Research Ltd.
- Internet traffic (affect the capacity of IP-bandwidth): Utilize statistical data of time transition of Internet data from MIC

## 4.3. Simulation Result

### *4.3.1. Validation from Time Transition*

Figure 9 shows the difference of audience satisfaction degree (ASD) between with the proposed method (w/ switching) and without the proposed method (w/o switching) where the number of video channels are 100 and network capacity is set as follows:

- Total of RF-network bandwidth: 900Mbps
- Total of IP-network bandwidth: 320Mbps

The red line an black line indicate the ASD with the proposed method and the ASD without the proposed method, respectively. From this result, it is confirmed that the proposed method has the effect to maintain high ASD value in all hours.

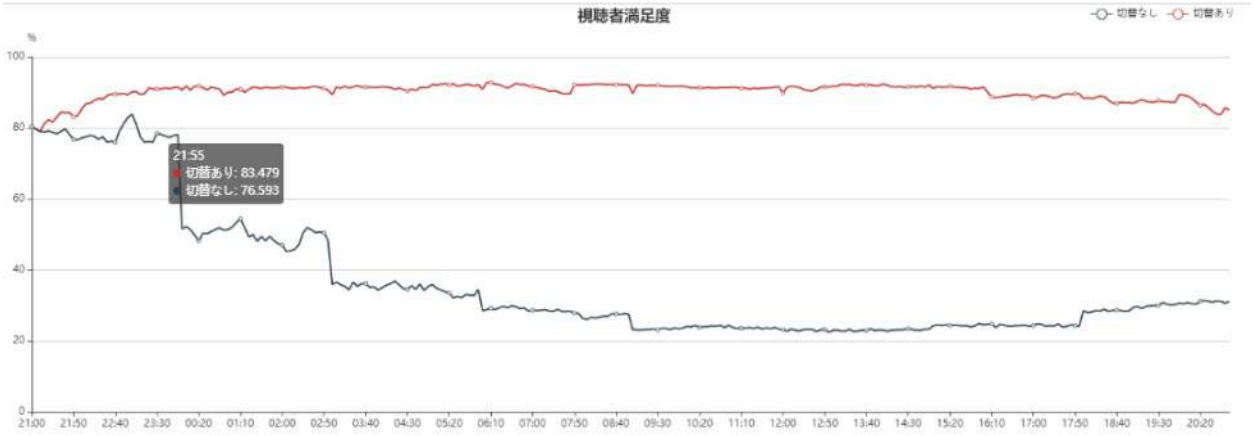

**Figure 9 - The difference of audience satisfaction degree between with the proposed method (switching) and without the proposed method (no switching).**

### *4.3.2. Validation for Various Condition*

The simulation of various condition regarding infrastructure type and the number of video channels are conducted. Figure 10 shows the comparison table of that. In total, 8 patterns of infrastructure types and 3 patterns of the number of video channels are tested as described in Figure 10. From this table, it is observed that ASD with switching is over doble score of that without switching as the maximum effect of the proposed method under certain conditions (described as red square frame in Figure 10). This means that the proposed method has the effect to doubles the utilization efficiency of bandwidth or the number of 4K content compared to without this scheme.

| Number of video channel (ch) →<br>↓ Infrastructure pattern (bps) | | 50ch<br>= 1250M (if all channels are 4K) | 75ch<br>= 1875M (if all channels are 4K) | 100ch<br>= 2500M (if all channels are 4K) |
|---|---|---|---|---|
| 1 | RF-band: 2070M<br>IP-band : 160M | N/A (Because all channel can be transmitted as 4K) | N/A (Because all channel can be transmitted as 4K) | w/o Switching: 83.7<br>**w/ Switching: 99.0** |
| 2 | RF-band: 1770M<br>IP-band : 160M | N/A (Because all channel can be transmitted as 4K) | w/o Switching: 95.4<br>**w/ Switching: 99.9** | w/o Switching: 72.3<br>**w/ Switching: 97.6** |
| 3 | RF-band: 1320M<br>IP-band : 160M | N/A (Because all channel can be transmitted as 4K) | w/o Switching: 73.7<br>**w/ Switching: 97.7** | w/o Switching: 52.7<br>**w/ Switching: 94.3** |
| 4 | RF-band: 1020M<br>IP-band : 160M | w/o Switching: 82.5<br>**w/ Switching: 98.9** | w/o Switching: 58.6<br>**w/ Switching: 95.3** | w/o Switching: 40.2<br>**w/ Switching: 90.5** |

**Figure 10 – Comparison of ASD in different types of cable infrastructure**

## 5. Prototype Development of Switching Demo System

To study the feasibility of seamless RF/IP switching, PC-based demo system is developed. Figure 11 and Figure 12 show the configuration and overview of switching demo system, respectively. We confirmed that the switching has been completed within 1 second from the switching order of the server PC (HE-PC) to switching video quality of client PC (STB-PC). It is noted that we used the 4K video test materials of ITE in the verification test.

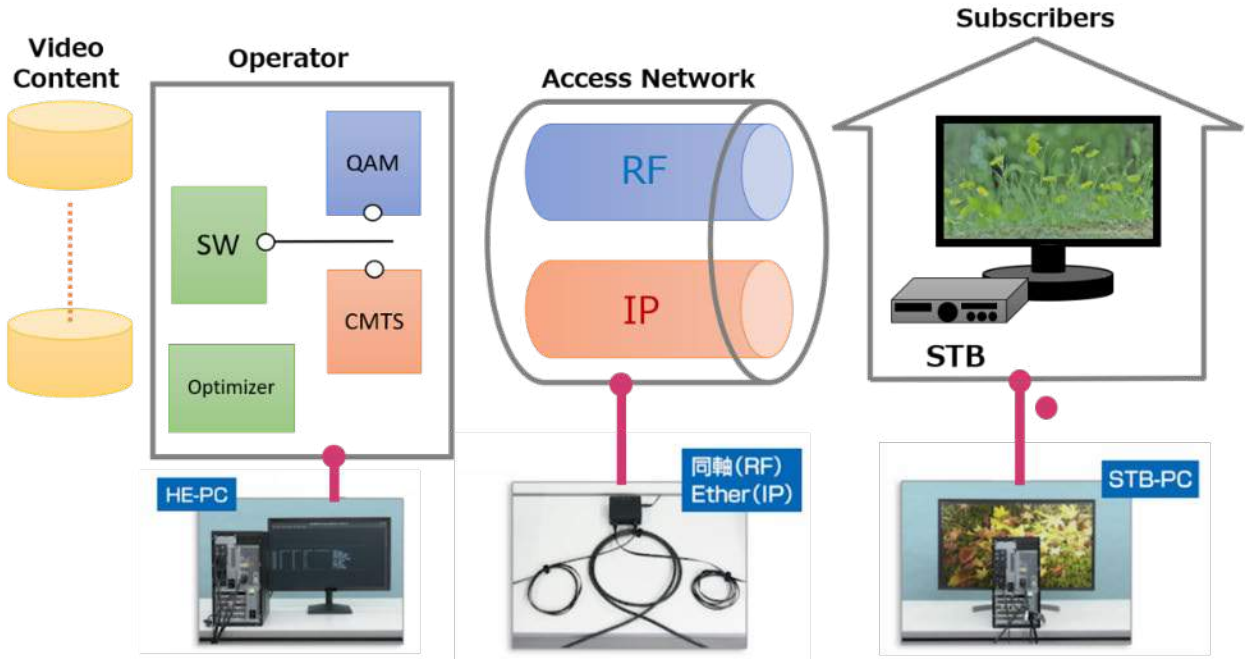

**Figure 11 – Configuration of switching demo system**

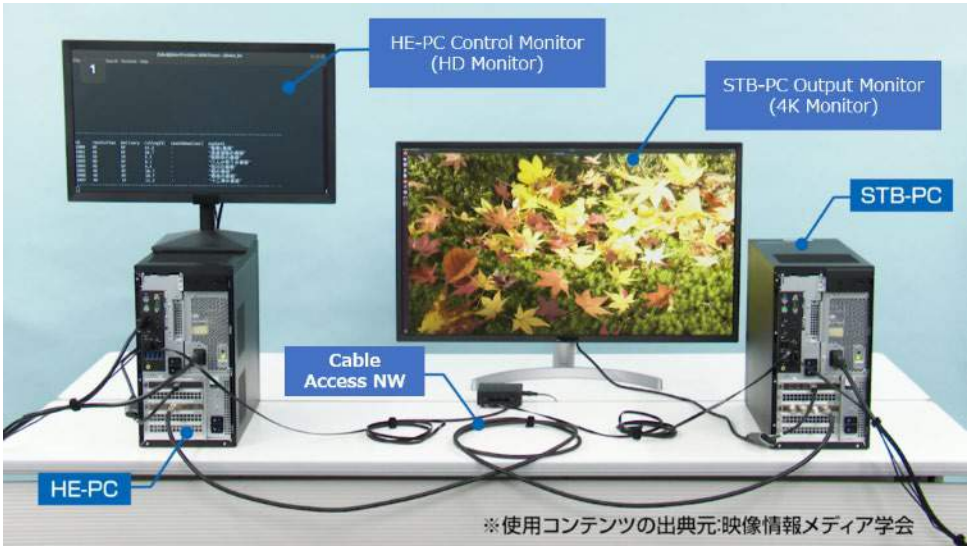

**Figure 12 - Overview of switching demo system**

## 6. Conclusion

Highly-efficient video distribution scheme over the existing HFC network was proposed. Basic concepts are sharing the RF/IP resources and switching RF/IP distribution scheme according to audience ratings, network bandwidth, attribute of video content. From the simulation results and the prototype development of demo system, it was revealed that theoretical effectiveness and feasibility of the proposed scheme. Especially, experiment results show that proposed scheme doubles the utilization efficiency of bandwidth or the number of 4K content compared to without this scheme. The switching demo system show the evidence of feasibility for seamless RF/IP switching. A total feasibility study by implementing optimizer and data collector on the demo system, and international standardization are future works.

# Unleashing Managed SD-WAN With Closed-Loop Automation

## A Standards Based Approach to Increased Operational Efficiency and Network Agility

A Technical Paper prepared for SCTE•ISBE by

**Tom DiMicelli**

Senior Product Marketing Advisor

Ciena Corporation

7035 Ridge Road Hanover, Maryland 21076

410-694-5700

tdimicel@ciena.com

# Table of Contents

# List of Figures

# 1. Introduction

Managed SD-WAN services underpin many strategic enterprise initiatives and provide cable operators with a high-growth market. As the market matures and cable operators expand their SD-WAN service portfolio, they must broaden their service portfolios and improve their operational processes to ensure they maximize this opportunity.

This paper summarizes SD-WAN trends and growth forecasts and highlights both market and operational challenges associated with managed SD-WAN implementations today; it also describes how progress that has been made in industry standards bodies can help cable operators implement an open, standards-based closed-loop automation framework that overcome these issues.

# 2. SD-WAN Market Trends and Forecasts

Enterprises are embracing SD-WAN as the foundation of their strategic SaaS, cloud, and digital transformation initiatives. The 2019 SD-WAN Market Trends Survey[1] showed that 54 percent of survey respondents had already deployed SD-WAN, and that enterprise adoption could reach 90 percent.

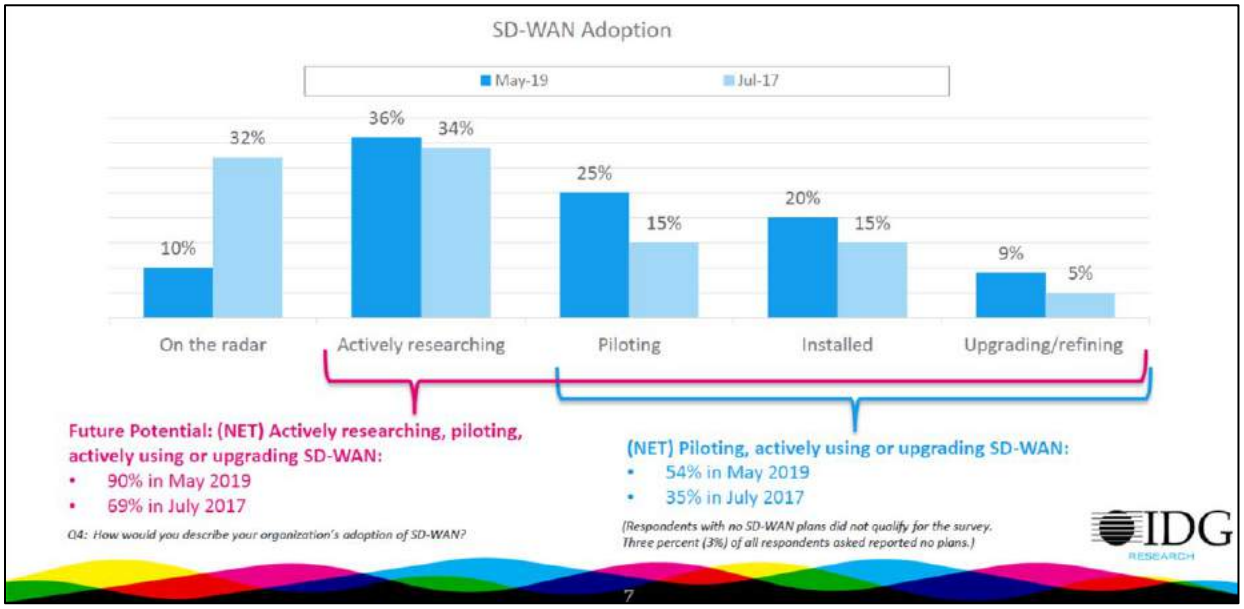

**Figure 1 – Enterprise SD-WAN adoption (source IDG)**

The results of this survey, and forecasts from other analysts, indicate that the SD-WAN market will likely grow at double digit rates for the foreseeable future. In fact, even though Vertical Systems Group lowered their 2020 U.S. managed SD-WAN revenue growth outlook due to pandemic-related disruptions, they also forecast high-growth rates through 2024,[2] as SD-WAN's ability to provide efficient connectivity to cloud-hosted applications are well-suited to post-pandemic business needs.

[1] IDG MarketPulse Research, 2019 SD-WAN Market Trends Survey on behalf of Masergy
[2] Vertical Systems Group STATFlash: 'How will COVID-19 impact SD-WAN?' See https://www.verticalsystems.com/2020/05/28/statflash-sdwan-covid-2020/

Enterprises continue to show a strong preference for managed SD-WAN services, with a combined 75 percent of respondents to IDG's 2020 SD-WAN Market Trends Report indicating that they currently utilize fully managed or co-managed service.[3] In line with these responses, Vertical System Group estimates that the number of billable U.S. installations of carrier managed SD-WAN services saw an 89 percent increase in 2019 - and they also recognized Comcast as a leader in this market.[4]

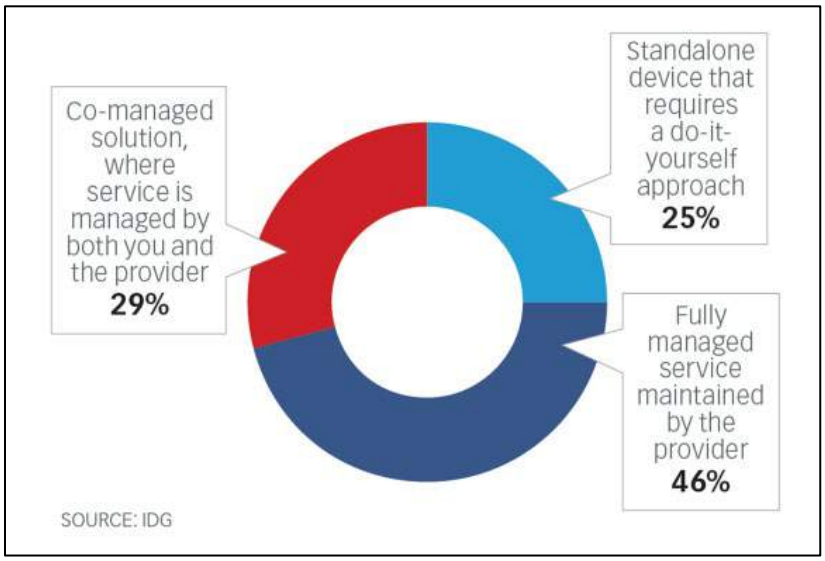

**Figure 2 – SD-WAN management preferences, source IDG**

## 3. Managed SD-WAN Service Evolution

For their initial managed SD-WAN offers, CSPs often deployed a single vendor's solution, which typically consisted of SD-WAN controller software and one or more Virtual Network Functions (VNFs), all bundled as a single package on an appliance or as software for deployment on a server.

As the SD-WAN market matures and segments, it is becoming clear that no one solution can address the full range of customer requirements and preferences.[5] Furthermore, CSPs that rely on a single vendors SD-WAN solution face heightened business risks: what happens if their vendor is acquired, fails to keep pace with market evolution, lacks one or more critical features, or develop support or quality issues?

Unfortunately, broadening their managed SD-WAN service portfolio is operationally challenging. In addition to investing resources to qualify and select vendors, the new solutions must be evaluated, tested and integrated with the B/OSS, new service design process must be established, and new methods of procedure (MOP) must be created for service activation and assurance. Additionally, activating and assuring managed SD-WAN services using traditional operations is both inefficient and expensive.

---

## 4. Managed SD-WAN using Legacy Operations

When a customer order is processed, relevant portions of the order are forwarded to the engineering team so that they can design the service and create a related provisioning work-order. To do this, engineers must gather data from the B/OSS as well as Network and Element Management Systems (NMS / EMS). These manual processes take hours per service endpoint, and it can take weeks or months to complete these tasks for a customer with dozens or even hundreds of branch locations.

Once complete, the work-order is split into task-specific work orders, each with their own MOP, and forwarded to technicians that will use Command Line Interfaces (CLI's) or NMS / EMS to configure the SD-WAN controller, SD-WAN appliances or uCPEs, VNFs, PE routers, and inter-provider interfaces. This manual configuration is tedious and time-consuming - configuring the SD-WAN controller alone can involve hundreds of inputs - and the process must be repeated for each branch sites that is part of the service. Further complicating this process, there are dependencies for workflow execution: equipment must be shipped, technicians scheduled, access to facilities arranged. Once again, this process takes weeks or months to schedule and complete.

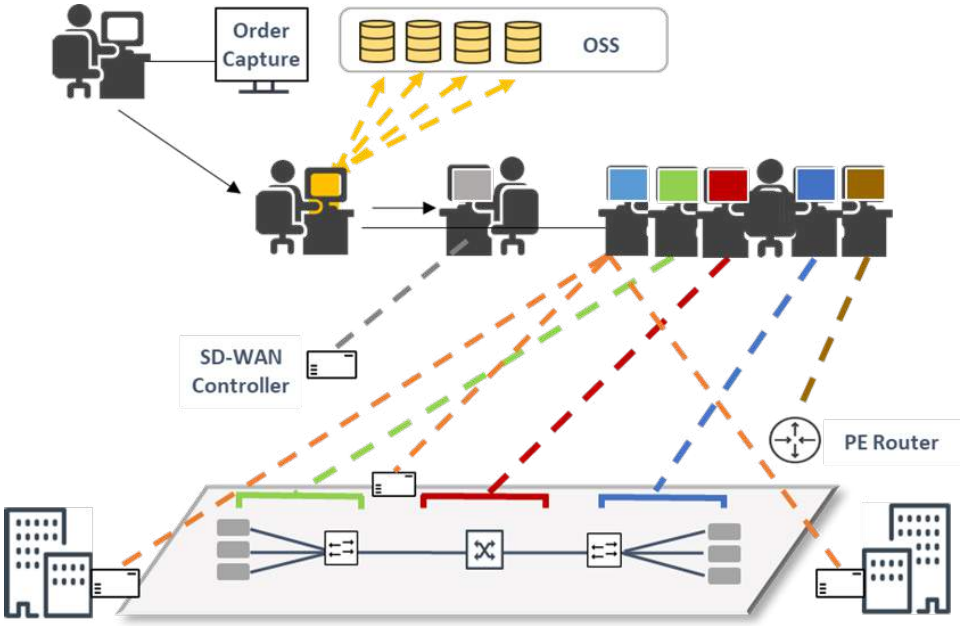

**Figure 3 – Manual SD-WAN service and network configuration**

Once the service is active, technicians must design and provision network and service monitoring and assurance. This is also a complex, manually intensive, and time-consuming activity, involving a wide variety of physical and virtual elements, network technologies, probes, and monitoring systems.

Because SD-WAN is an overlay technology that is disconnected from the underlay network, it is also difficult to use traditional trouble-to-resolve processes when performance issues occur. Fault isolation requires correlating data from a variety of independent service (overlay) and network (underlay) monitoring systems, making troubleshooting efforts slow, resource intensive, and frequently inaccurate. As a result, non-critical issues may become critical - and even service affecting - because they were not addressed correctly or in a timely manner.

# 5. The Business Impact of Legacy Operations

While Managed SD-WAN services are ideally matched to today's enterprise communications needs, designing, delivering, managing and assuring these services using traditional operational processes falls short of today's business environment, which calls for more velocity, agility, and visibility, at lower cost, from both the CSP and customer perspective.

Major limitations include

- Manual service design and work-order creation is slow, expensive, and prone to human error.
- Manual order process management is slow, opaque and error prone, leading to order fallout.
- Manual B/OSS interrogation and rekeying data into work-orders is slow, costly, and error-prone.
- Manual network configuration and service provisioning are slow, expensive, and error-prone—especially for NFV-based services—resulting in multi-week SD-WAN service activation per site.
- Manual intervention in fault isolation and remediation processes – especially alarm and event correlation between the SD-WAN overlay and network underlay – is too slow and difficult.

These limitations and related issues add cost and delay to the SD-WAN service lifecycle, which negatively impacts margins, impedes revenue recognition, and return on investment (ROI), and diminishes customer satisfaction. Worse yet, these issues are duplicated when a CSP adds new SD-WAN solutions to their portfolio, further increasing costs, complexity, and the burden on technical personnel.

# 6. SD-WAN-related Standardization Efforts

The MEF and the TM Forum and other organizations have developed standards to help CSPs build, deliver and manage services quickly and cost-effectively, using open interfaces and repeatable process. In large part, these efforts are complimentary and converge on similar architectures, protocols, and interfaces.[6]

## 6.1. MEF

The MEF[7] is an industry association of 200+ member companies that collaborate to enable the automated delivery of standardized services within and across multiple CSPs. SD-WAN service standardization has been conducted as part of the MEF 3.0 Global Services Framework.[8]

Important SD-WAN related MEF standardization activities include:

- MEF 70[9] - SD-WAN Service Attributes and Services – is the industry's first SD-WAN standard. It defines Managed SD-WAN Services as a specific use case for a MEF Third Network service and describes the requirements for an application-aware, overlay WAN connectivity service that uses policies to determine how application flows are directed over multiple underlay networks.

[6] Note that current standards and standards efforts at these two organizations are not designed to permit interoperability between SD-WAN solutions from different vendors.
[7] To learn more about the MEF, see www.mef.net/about-mef
[8] MEF 3.0, see www.mef.net/mef30/overview
[9] MEF 70 at www.mef.net/resources/technical-specifications/download?id=122&fileid=file1

- MEF W90[10] - draft SD-WAN Certification Test Requirements – is part of the broader MEF 3.0 certification program. It tests the service attributes and their behaviors as defined in MEF 70.
- MEF 55[11] defines a Lifecycle Service Orchestration (LSO) framework for standard, automated service lifecycle orchestration that applies to all MEF 3.0 services, including SD-WAN.

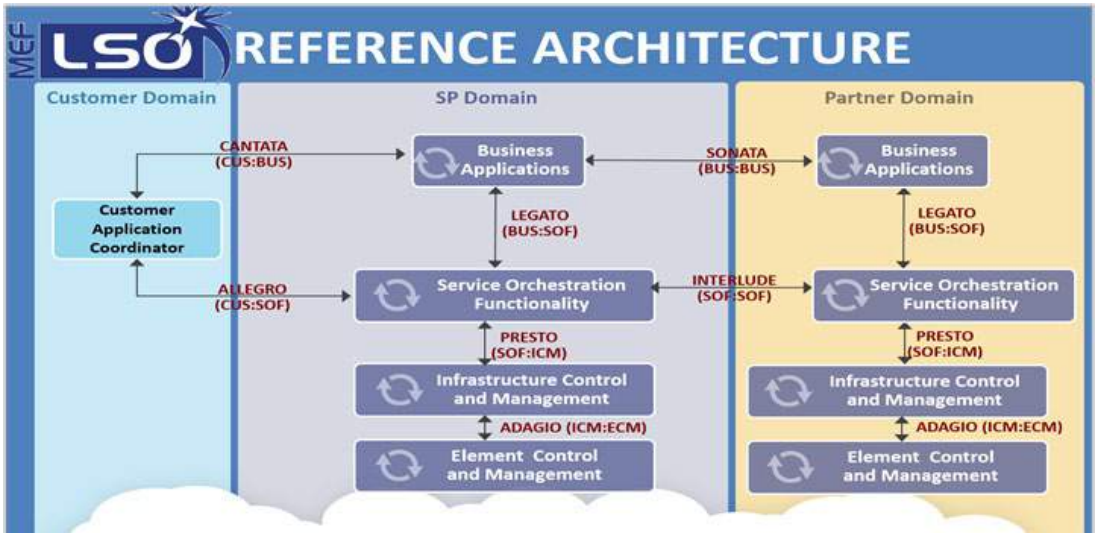

**Figure 4 – MEF LSO Reference Architecture diagram**

MEF LSO proposes to automate the service lifecycle across all network domains responsible for delivering MEF 3.0 Network Connectivity Services, which includes SD-WAN. As figure 4 indicates, MEF LSO also defines Management Interface Reference Points between LSO functional management entities (e.g., Cantata, Allegro, Legato, etc.); application programmable interfaces (APIs) at these reference points to facilitate service orchestrations and automation.

## 6.2. TM Forum

The TM Forum[12] is an association of over 850-member companies' customers across 180 countries that drives collaborative problem-solving to help CSPs transform their business operations, IT systems and ecosystems. Their Open Digital Architecture (ODA)[13] provides a layered architectural approach that separates areas of concerns and uses standard REST-based Open APIs to expose services within a layer to adjacent layers. This approach is markedly different from the tight vertical integration between the network and the B/OSS that is implemented in traditional CSP operations environments.

[10] MEF W90 - SD-WAN Certification Test Requirements at www.mef.net/mef-3-0-service-technology-certification.
[11] MEF 55 at www.mef.net/Assets/Technical_Specifications/PDF/MEF_55.pdf
[12] To learn more about the TM Forum, see www.tmforum.org/about-tm-forum/
[13] See www.tmforum.org/oda/

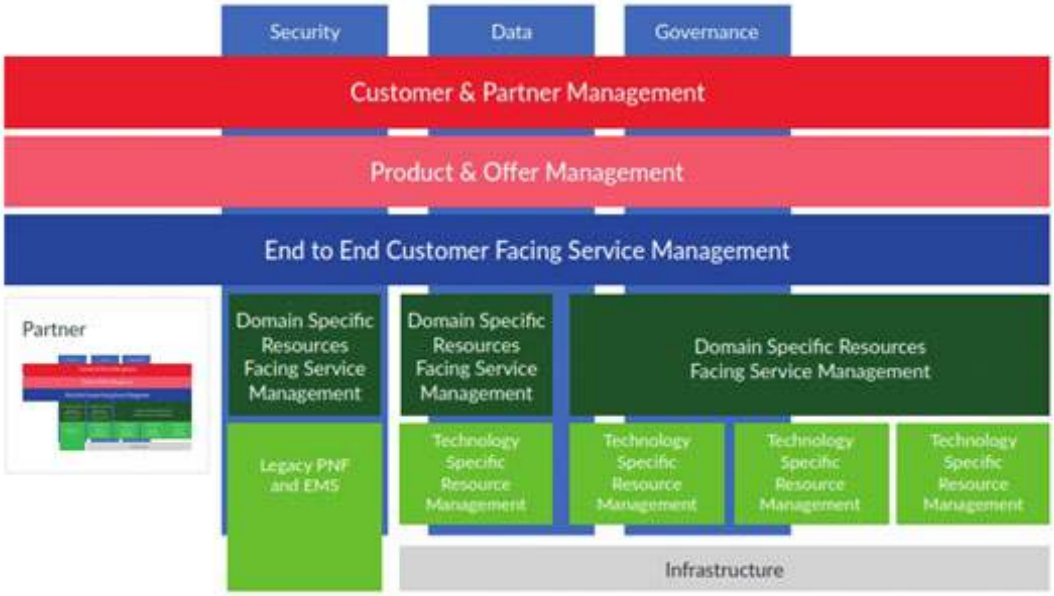

**Figure 5 – TM Forum Open Digital Architecture framework**

TM Forum's suite of 50+ REST-based Open APIs are reusable and enable standardized communications with B/OSS and management systems, making service creation and ongoing operations simpler and more efficient; additionally, they can be used to expose capabilities to partners. The use of standardized APIs also reduces the costs and risks associated with traditional B/OSS integration using proprietary interfaces.

As of July 2019, 18 leading CSPs and 48 leading technology vendors have signed the Open API Manifesto,[14] committing to include TM Forum Open APIs in their RFPs, and in products, respectively.

# 7. Automating SD-WAN operations

Today, CSPs can leverage standards from the MEF and TM Forum, together with advances in SDN and NFV technology to onboard new SD-WAN solutions and streamline the design, activation, and assurance of managed SD-WAN services in a closed-loop.

## Key Components of Closed-Loop SD-WAN Service Lifecycle Automation

The following systems work together to provide SD-WAN service lifecycle automation in a closed-loop.

- **Service order management system:** communicates with the Order Management System (OMS) and customer portals; maintains the service catalog; decomposes work orders; communicates with the orchestration system for order execution; coordinates the order workflow; and provides visibility into workflow status and issues, among other tasks and responsibilities,
- **Orchestration system:** communicates with a service order management system or OMS to receive service activation orders; orchestrates service design; communicates with SD-WAN controllers, domain layer controllers and NMS / EMS to configure provider edge (PE) routers, uCPE and other

[14] See www.tmforum.org/open-apis/open-api-manifesto/

elements; instantiate and chain VNFs as well as manage the VNF lifecycle; and communicate with assurance and analytics systems in a closed-loop, so that it can dynamically modify network paths to optimize resources or respond to issues when they arise.

- **Assurance and analytics system:** aggregates and analyzes network telemetry; monitors network and service health; dynamically correlates alarms and events from the SD-WAN overlay and network underlay to identify root-cause issues; and communicates with the orchestration system to enable resource optimization and to identify issues when they arise.

In addition to the basic functions listed above, these components must support open APIs, and provide a DevOps style ability to add new open APIs quickly and easily. Ideally, these components should also provide comprehensive visualization tools – graphically displaying workflow status, service path mapping across heterogeneous vendors, elements, and domains, offering a single unified view for monitoring all the resources.

Of course, beyond functionality, CSPs must ensure their vendors have the proven ability to support their systems and solutions at scale—large enterprises can have branches around the globe, and high expectations of pre- and post-deployment support.

Many different vendors provide one or more components that enable closed loop SD-WAN service lifecycle automation, and TM Forum Open APIs enable communications between these systems. This approach permits vendor innovation, and avoids vendor lock-in, and lets CSPs and their systems integration partners build 'best of breed' solutions that are closely aligned with their business goals.

CSPs should also be able to learn more about vendor capabilities by researching public proof of concept demonstrations, such as TM Forum Catalysts.[15] Another worthwhile and simple area to investigate is standards-compliance certification programs, such as those maintained by the MEF[16] and TM Forum[17].

## 8. Standards-based Managed SD-WAN Automation

Figure 6 depicts how a CSP can implement a MEF LSO architecture and use standardized APIs as the foundation for automated SD-WAN operations. MEF LSO management reference points are defined North – South between layers (e.g., between the business layer and service orchestration layer; and between the service orchestration layer and the infrastructure control and management layer, which includes the SD-WAN controller and domain controllers).

A variety of APIs can be used between different layers, including TMF APIs (TMF 641 Service Ordering API is depicted between business and service orchestration layers; the Open Networking Foundations (ONF) Transport API (TAPI) and several others are depicted between the service orchestration layer and the infrastructure control and management layer); TMF APIs are also depicted between systems within the service orchestration layer (TMF 641 and TMF 623 SLA Management API are depicted).

[15] TM Forum Catalyst program at www.tmforum.org/collaboration/catalyst-program/home/
[16] MEF Certification program at https://www.mef.net/certification/mef-certification-programs
[17] TM Forum conformance overview at https://www.tmforum.org/conformance-certification/open-api-conformance/ and vendor leaderboard at https://www.tmforum.org/conformance-certification/open-api-conformance/#table

In this simplified example, the service order management system receives an order from the OMS and communicates with the orchestration system for service design. It then decomposes the work order and coordinates the order workflow execution. The orchestration system sends configuration and provisioning instructions to the SD-WAN controllers and domain layer controllers in the infrastructure control and management layer for execution.

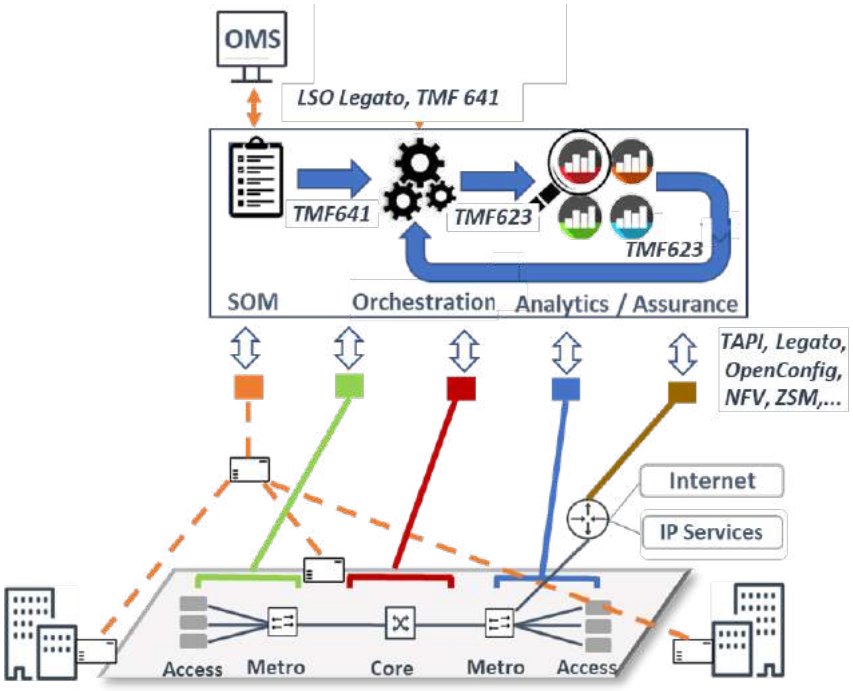

**Figure 6 – SD-WAN Automation framework**

Once the service is active, assurance is dynamically instantiated end-to-end across the service path. Remediation for service affecting conditions is typically triggered dynamically, while analytics automates the evaluation of all alarms and events to identify root cause conditions. Issue resolution can be fully automated, or a mix of human / automated operations can be used, based on policy.

## 9. The Business Impact of Standardized, Automated Operations

When CSPs implement standardized, automated operations to design, deliver and assure their managed SD-WAN services, there are significant advantages for both the CSP and their customers.

From the CSP perspective, the major advantages include:

- Standard-based APIs eliminate expensive proprietary B/OSS integration activities, catalog and APIs are re-used across use-cases, avoiding wasteful one-off development efforts.
- Automated order process management that eliminates hundreds of tedious, manual, and error-prone tasks and avoids expensive design errors that can negatively impact customer commits.
- Automated orchestration accelerates network configuration and service provisioning, especially for NFV-based and hybrid services—enabling rapid service activation per site.
- Alarm and event correlation between the SD-WAN overlay and network underlay streamlines troubleshooting and fault isolation activities and helps protect service level agreements (SLAs).

These advantages reduce cost and delay throughout the entire SD-WAN service lifecycle, helping CSPs improve margins, accelerate time to revenue and ROI, and increase customer satisfaction. Additionally, APIs, templates and MOPs can be reused with any new SD-WAN vendor solution, which accelerates new vendor and solution introductions.

# 10. Managed SD-WAN Automation in Action

Let us look at a few CSPs and recent catalyst demonstrations that have extensively incorporated TM Forum and MEF standards, and automation, into their managed SD-WAN services offerings

## TMF Catalyst Demonstration: *Automating Network as a Service*

SD-WAN was featured in the *Automating Network as a Service using Operational Domain Management (ODM), TM Forum Open APIs and MEF LSO Catalyst,*[18] which was championed by Telstra, Vodafone, Orange Business Services, AT&T and PCCW. The demo included DGIT Systems order management solution and the Blue Planet orchestration platform - both supported by Infosys – and leveraged MEF LSO with TM Forum Open APIs to dynamically activate SD-WAN and other MEF 3.0 services.

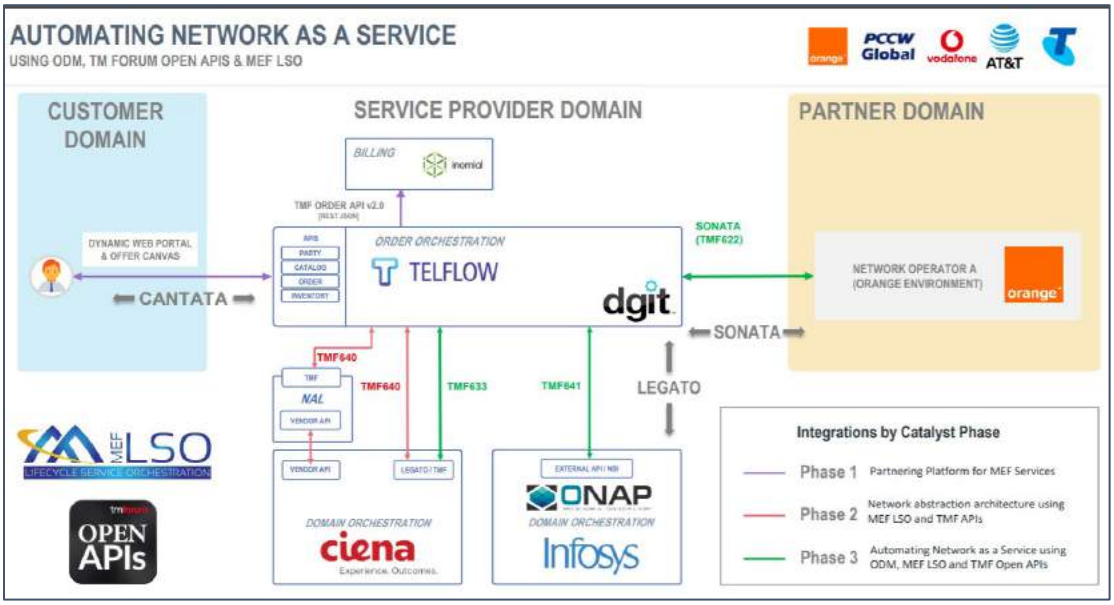

**Figure 7 – Automating Network as a Service Catalyst reference diagram**

[18] See https://www.tmforum.org/wp-content/uploads/2017/02/T.-Automating-Network-as-a-Service.pdf

## Comcast Business

Comcast Business - a subsidiary of Comcast Corporation, the second-largest broadcasting and cable television company in the world by revenue - was among the first cable operators to launch an SD-WAN service, among the few to achieve MEF 3.0 SD-WAN service certification, and the only MEF 3.0 SD-WAN Services certified CSP on the 2019 U.S. Carrier Managed SD-WAN Services Leaderboard. [19]

Their managed SD-WAN service is built on the ActiveCore SDN platform and leverages the internet or Comcast's nation-wide IP network as the network underlay, offering up to gigabit connectivity speeds.

Comcast Business is a 2020 LightReading Leading Lights Finalist in the Most Innovative SD-WAN Service category, and recently announced they would integrate Fortinet's virtual firewall appliances with ActiveCore to improve SD-WAN security by addressing threats such as malware.

## Windstream Enterprise

Windstream Enterprise is a leading provider of advanced network communications and technology solutions to enterprise customers across the U.S. and ranks fourth on Vertical Systems Group's 2019 U.S. Carrier Managed SD-WAN Services leaderboard.

As highlighted in a TM Forum case study,[20] Windstream's initial SD-WAN deployment relied on a manual service activation process, which had technicians collecting data from 10 independent systems, and then rekeying that data into the SD-WAN controller and PE router to configure those devices.

[19] See www.verticalsystems.com/2020/04/21/2019-us-sd-wan-leaderboard/
[20] See https://inform.tmforum.org/casestudy/windstream-use-intelligent-automation-to-cut-provisioning-time-by-80/

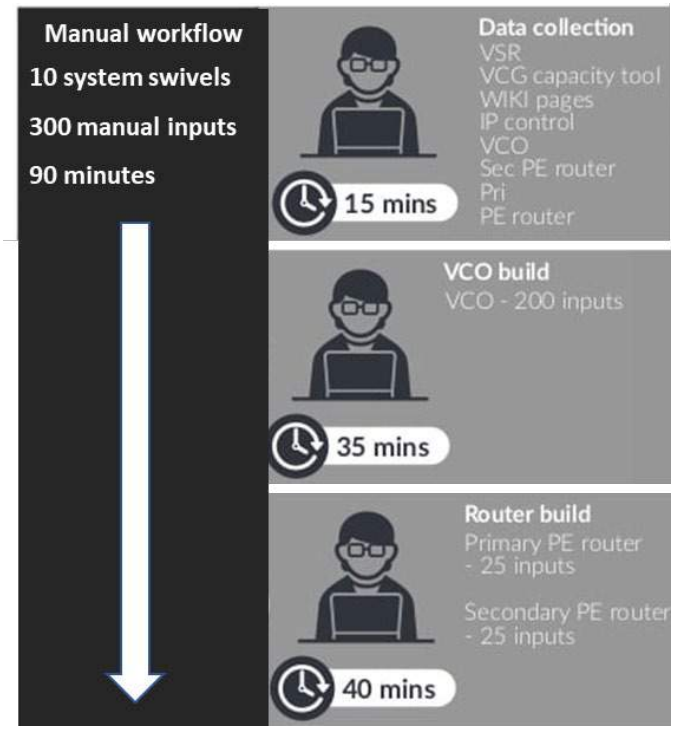

**Figure 8 – Windstream Enterprise legacy operational workflow for SD-WAN Services**

Recognizing that their outdated operational processes were constraining their market success, Windstream implemented TM Forum ODA and related APIs and an orchestration platform that automated service activation. Ultimately, Windstream reduced systems accessed by 90%, manual inputs by 99.7%, and the total number of technician minutes required for service fulfillment by 98.9%.

**Figure 9 - Windstream Enterprise's automated SD-WAN service activation workflow**

## 11. Conclusion

The SD-WAN market has moved into the mainstream, with even large conservative enterprises adopting managed SD-WAN services. Analysts are forecasting high double-digit growth rates through at least 2024, and while the current global pandemic may disrupt growth in the near-term, it is likely to accelerate adoption in the long term.

To stay ahead of the competition, CSPs must move beyond basic SD-WAN services and single-vendor solutions. Fusion Connect, Windstream and GTT Communications[21] are just three public examples of CSPs with multi-vendor managed SD-WAN portfolios, there are many others – including some with more than two vendors.

Of course, a broad portfolio alone is not enough. CSPs must also differentiate by providing a better customer experience through rapid delivery, deeper customer insight, and superior availability. And they must provide this experience efficiently if they are to fully profit from their efforts and investments.

Achieving a broad and compelling managed SD-WAN service portfolio and a superior, streamlined operations environment requires CSPs to implement open standards and automation – especially closed-loop service lifecycle automation. This modern approach allows CSPs to add new vendors and services without penalty, and removes slow, expensive, and error-prone manual intervention from SD-WAN service design, activation, and assurance processes.

Based on the progress that has been made at the MEF and TM Forum - with significant contributions from cable operators - CSPs can now deploy advanced orchestration, assurance and analytics systems in an open, modular and standards-based automation framework that addresses the entire SD-WAN service lifecycle.

CSPs that implement such solutions will be able to reduce operational expenses, maximize resource utilization and increase staff efficiency even as they add multiple SD-WAN vendors to their portfolio. Furthermore, they will be able to accelerate time to revenue and improve customer satisfaction, enabling them to lead and thrive in competitive markets, and adapt to ever-evolving market requirements.

[21] Fusion Connect recently announced the expansion of their managed SD-WAN service portfolio beyond VMware VeloCloud; they will soon offer the Fortinet Secure SD-WAN solution, which features a built-in next-gen firewall, web filtering and an intrusion prevention system. See https://www.channelpartnersonline.com/2020/08/26/fusion-connect-picks-fortinet-as-second-sd-wan-partner/

## List of Figures

 

# 1. Abstract

Broadband access networks continue to experience customer growth and higher capacity demands year over year. Early and ongoing analysis of these demand trends enabled Comcast to develop a Distributed Access Architecture (DAA) that enabled us to keep up with capacity needs and enhance customer satisfaction with appreciable capital economics.

Successfully virtualizing complex portions of our network, including the CMTS, resulted in network simplification and the harmonization of multiple purpose-built platforms into one common entity. However, DAA deployments require headend and field modifications as part of the deployment. Even before the 2020 spike in capacity demands created by the COVID pandemic, and its consequent work from home requirements, efforts were underway to accelerate the virtualization, and associated benefits, of our networks, and to separate headend-centric innovations from those in field construction. These parallel efforts enabled us to press forward more rapidly in the adoption of virtualized CMTS technology.

A new concept was developed called a Hybrid Fiber Shelf (HFS) that integrates with virtualized CMTS/DAA Switches at one end, and with transmit/receive analog optical signals on the other end into the outside plant. This innovation provides rapid and economically sustainable increases in capacity, by independently accelerating vCMTS integrations while DAA construction proceeds in other areas of the network. HFS improves critical infrastructure in headends by saving wasted space, power and time inherent in RF combining and splitting circuits. Extending HFS into secondary headends (SHEs) also enables significant fiber reclamation. Locating these assets in secondary facilities closer to the traditional HFC nodes improves performance in ways that translate into enhanced capacity with upstream profile management tools also presented at this SCTE.

In this paper, we begin with a description of the optical and RF innovations that enabled a hybrid fiber shelf concept, and its theory of operations. We then describe the end performance and the impressive improvements in headend critical infrastructure. We finally describe the commonalities and nuances of this approach and its fit within the overall DAA architecture.

# 2. Introduction to Virtualization

A typical Cable System uses Cable Modem Termination Systems (CMTSs) to provide high availability upstream (US) and downstream (DS) signals between IP-connected devices (cable modems, gateways, set-tops) and IP-delivered services in digital Quadrature Amplitude Modulation (QAM) format. These QAM signals are RF-combined with other video sources, and then provided as inputs to high performance analog transmitters. Multiples of such analog transmitters' output wavelengths are then multiplexed into one fiber and sent to multiple Secondary headends. At the secondary headend, these signals are either demultiplexed and retransmitted, or amplified and distributed to individual nodes. After the node, multiple RF amplifiers in cascades amplify this signal to reach homes. In the reverse path, signals from the home arrive back at the RF amplifiers, which are bidirectional, and then reach the SHE from where they are often aggregated and sent back to the PHE to be terminated in the CMTS to complete the signal circuit.

The traditional CMTS is a formidable equipment type, with purpose-built hardware and significant scheduling and modulation software that has soaked over decades. All high-speed data (HSD) traffic flows through and terminates at the CMTS, making it a gatekeeper of broadband traffic for the MSOs.

Each time additional data was needed in the plant, typically in chunks of 50 MHz, the CMTS capacity would have to be augmented by combining additional ports, which creates capital costs.

This type of traffic infrastructure was fine while the HSD was a sliver of the total cumulative spectra delivered to the home, which was dominated by MPEG video, pay-per-view and VOD and fit the overall criteria of "pay as you grow" dictum of the MSOs. Readers may remember that long span of time when two 6 MHz channels served most of the voice and Internet services for most MSOs. However, when HSD usage started to grow exponentially, with CAGRs of ~35% year over year, and the CMTS ports started piling up faster and faster, the model of a traditional CMTS started becoming unwieldy. Something had to change, when HSD traffic dominated the US and DS spectra.

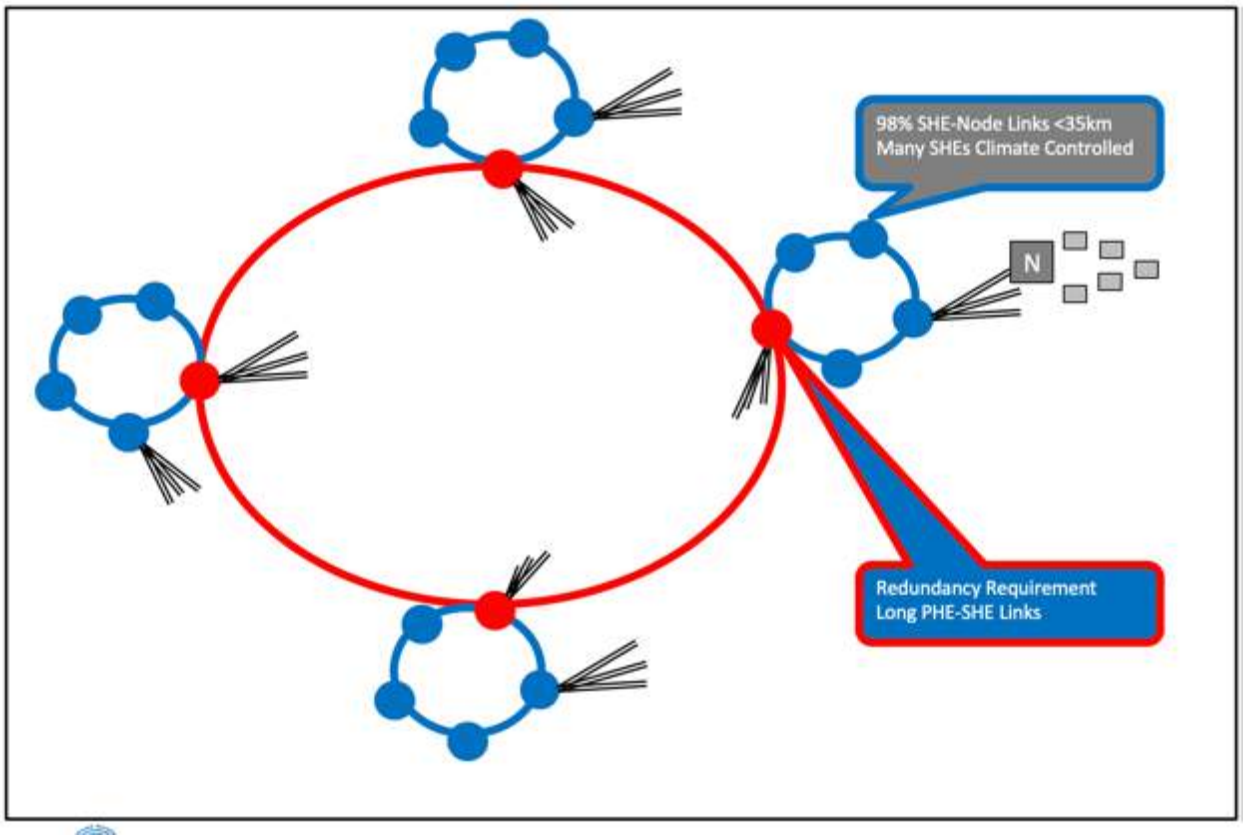

**Figure 1 – Simplified Connectivity Diagram. Red=PHEs, Blue=SHEs, N = Fiber Nodes**

It was around this time when we began to look at a new paradigm of network architecture. Distributed Access Architecture (DAA) envisioned the disaggregation of the CMTS into its component scheduling (aka MAC) and modulation (aka PHY) parts, accomplished by placing the PHY parts within the optical fiber node. Doing so would enable the headend to only concentrate on scheduling issues, while the PHY layer would concentrate on the modulation issues and thus distribute computational resources across the network, improve performance and reduce overall cost. The devices inside the nodes were called Remote PHY devices (RPDs) and thus was born the term "RPD node."

For the RPD nodes to function well, the CMTS functionality in the headend must be allowed to scale for traffic from day one. Because the RPD has just one 10G optical connection, we would ideally like to have all traffic flow to it from one source, without any RF combining of other formats that would mitigate the benefits afforded by the RPD.

This is what prompted us to rethink the CMTS as a virtual machine: One that depends less upon purpose-built hardware that controlled the RPD, and thru it the Cable Modems (CMs) in the house. By creative use of software structures, such as Containers/Kubernetes, the entire CMTS MAC was thus virtualized and distributed across the network. The success of this effort is of breathtaking importance, because for the first time it allows MSOs to increase traffic on the networks without the additional CMTS port license fees for each upgrade.

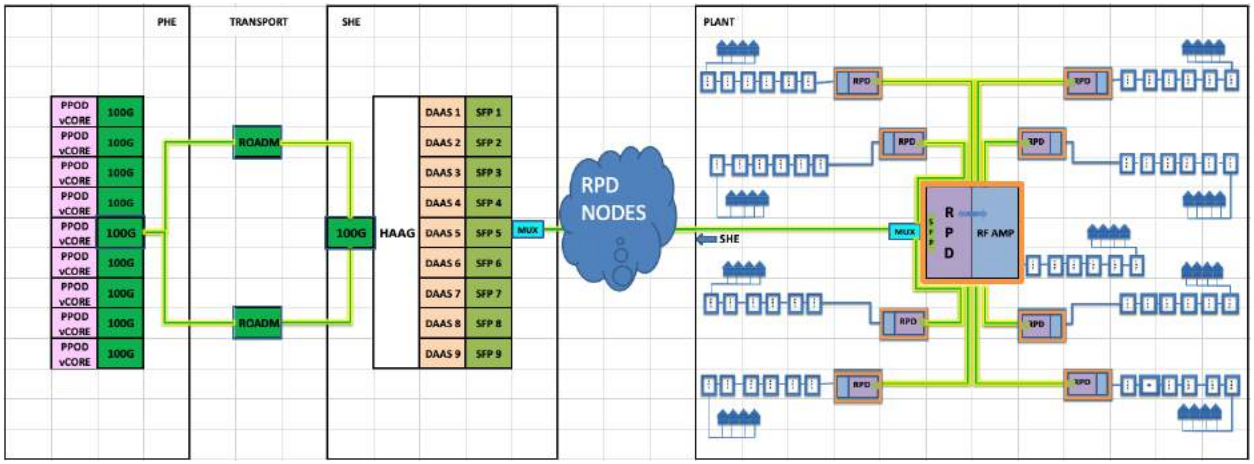

**Figure 2 – End to end DAA Architecture Diagram**

Once the CMTS is virtualized, the core CMTS functionality, known as the virtual core (vCORE) or interchangeably the virtual CMTS (vCMTS), is located in the primary headend (PHE), while multiple Secondary Headends host what are called DAA Switches (DAASs). These DAAS ports are connected to the vCOREs thru high speed, sometimes coherent links, while the DAASs themselves are connected to the RPDs via 10G DWDM links. The RPD node then converts the 10 Gbps baseband data into QAM format and then distributes it into the networks. At the home, the CM receives this data, and sends its US data to the RPD, which converts that into baseband data and sends them to the DAAS ports in 10Gbps format. The DASS then sends it back to the vCORE via the high-speed links, completing the circuit.

DAA is just one type of architecture in market in Comcast. In reality, we support more traditional HFC nodes than the DAA kind. Unfortunately, for the traditional nodes, the vCORE-RPD node connectivity architecture does not work, because there is not RPD in the picture. Therefore, some of the best benefits of the vCORE are not available to parts of our footprint.

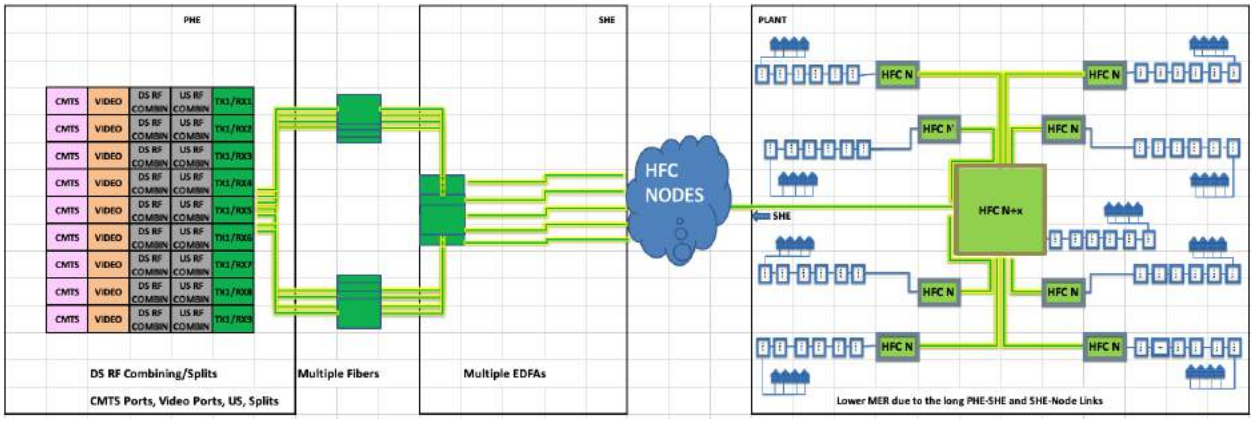

**Figure 3 – HFC Architecture Diagram**

Fortunately, there are ways in which this can be accomplished and in this paper we will discuss the basic idea of unleashing the vCORE onto a vast majority of our plant. Some of the ancillary benefits that accrue because of the vCMTS involve the significant critical infrastructure savings in the PHEs and SHE. Additionally, there is a potential for performance improvements over the existing link. Finally, we discuss a common wavelength plan that enables us to converge coherent, analog and 10G wavelengths onto one single fiber.

## 3. Architectures and Virtualization

The key to the success of any standard is its ability to fit into and enhance multiple diverse architectures. Such is the case with virtualization. Virtualization of the cable modem termination system (CMTS) began as a way to enhance Distributed Access Architecture (DAA) strategies. However, as it turns out, virtualization is a great fit for multiple architectures. Accelerating the reach of virtualization enhance all these architectures.

We have already seen that in the DAA architecture, the RPD node is a perfect fit for vCORE, however we have a preponderance of the original HFC nodes. Therefore, it is essential to provide an option for using the vCMTS architecture, so as to realize its benefits in regular HFC nodes as well. It may well be asked why we would not go about and change the entire architecture to DAA; however, that is not such an easy task. A typical DAA architecture can also be a “node plus zero” (N+0) architecture, meaning no amplification/amplifiers after the node. A that goes into making a system conform to N+0, not the least of which is the ability to secure enough HHPs per RPD. While this might happen easily in high density areas, such is not the case for lower density areas. For those areas, Grey Optics Aggregation (GOA) architectures will come in handy to shore up the number of passings per RPD. However, in current environments, and especially with COVID resulting in a lot of work from home households, the capacity needs for both US and DS are quite substantial, and capacity must be improved on a timelier basis. This is one of the reasons to leave node placements and RF amplifier placements as is.

It may further be argued that at least the nodes could be replaced, leaving RF amplifier cascades alone. While that is a better option, even it will take time. RPD nodes are physically bigger and will almost certainly need a complete node re-splicing. As well, a training regimen will be needed for field technicians who may not yet be trained on RPD devices. In some cases, it will continue to make economic sense to leverage existing investments in analog nodes and optics, especially in cases where additional capacity can be leveraged. In any case it is quite hard and inconsistent to migrate RPDs in the field.

For these reasons, the best approach for some of the network segments is to move the RPD into the headend and co-locate these with the DAAS ports in the SHE. The RPDs are then connected directly to the DAAS ports with active optical cables (AOCs), and the output of the RPDs are then fed to DS analog transmitters (TXs). These TXs feed typical HFC analog optical nodes, which reach household CMs. The return signals from the CMs arrive at the node and get transported to the SHE, where they are fed to the return receivers, then connected to the RPDs, which are then fed back to the DAAS ports, completing the signal circuit. These returns from analog nodes can represent typical digital or analog signals.

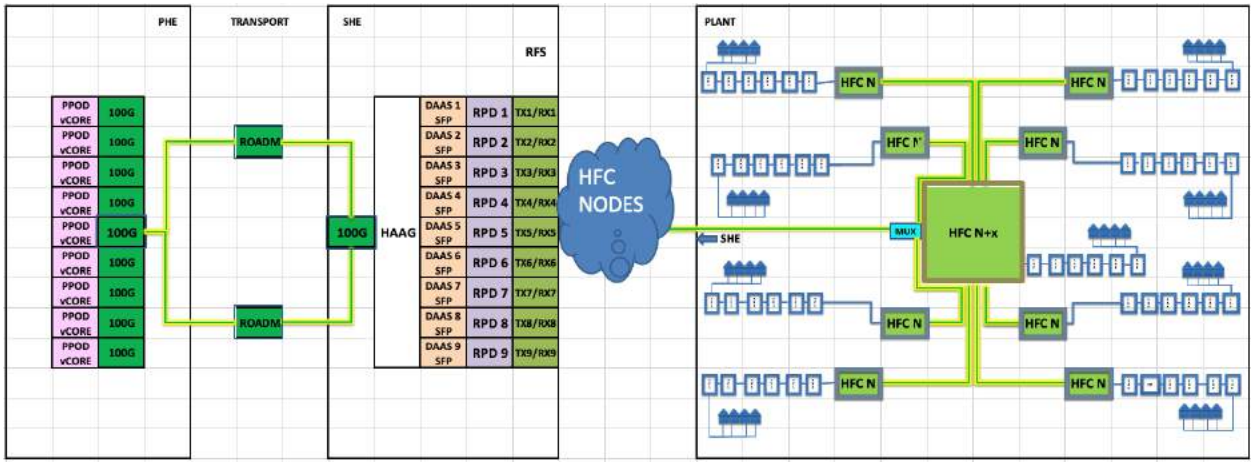

**Figure 4 – RFS Architecture Diagram**

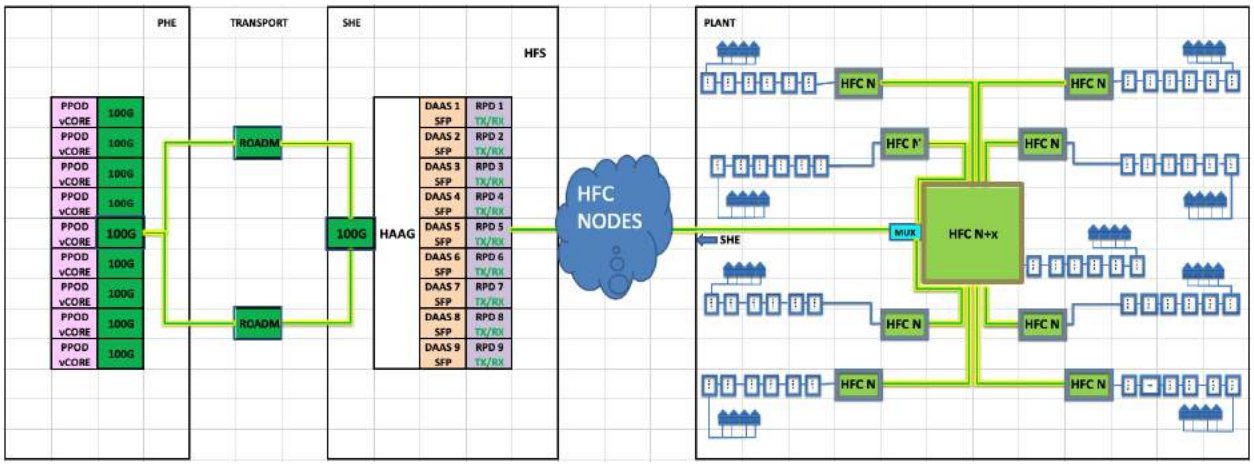

**Figure 5 – HFS Architecture Diagram**

This new approach to accelerate the rate of virtualization is called as the RPD Fiber Shelf (RFS) and Hybrid Fiber Shelf (HFS).

Figure 3 shows a set of details about a PHE and SHE within one of our regions. A general connectivity diagram for this was presented in Figure 1Basic Connectivity Diagram. We see here that the PHE hosts the CMTS and video traffic, along with the associated RF combiners. This primary headend also houses the analog transmitters that are multiplexed and sent over redundant links to the secondary headend. At

the SHE, and opto-mechanical switch resolves the redundancy, and, after amplification, passes it over to the optical node.

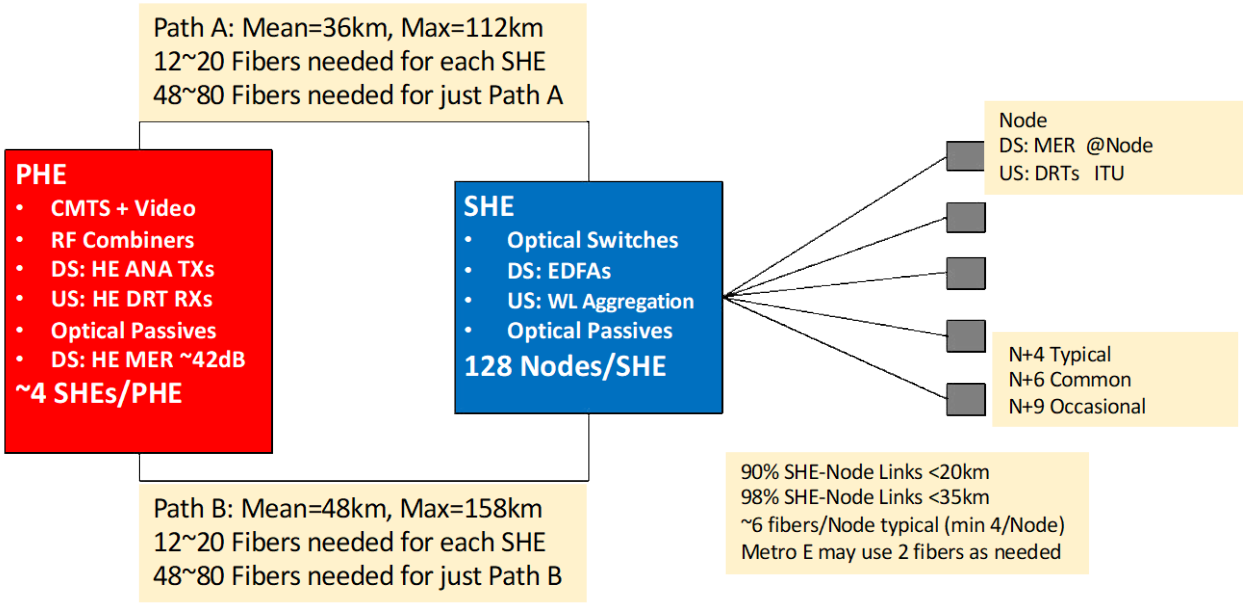

**Figure 6 – An example of Traditional CMTS and PHE to SHE to Node connectivity**

It must be noted here that due to the long reach from the PHE to the SHE and then to the neighborhood node, the Modulation Error Ration (MER) at the node itself is rather limited. Furthermore, the number of fibers need to traverse from the PHE to the SHE is substantial, because to avoid the deleterious fiber effects, analog transmission allows for 16 full spectrum wavelengths, which will be discussed in Section 4. In many cases, the rather large difference in primary and redundant routes creates a substantial MER delta when the redundant route becomes switched -- not to mention CMs generally reset themselves when there are substantial temporal changes caused by flight delay changes to the CMTS. The MER further reduces when we move from the node through the RF amplifiers.

In the return path, baseband digital returns have a rather large dynamic range, which gives them long reach capabilities. In this case, they are all combined together, and their light is shipped back to the primary headend. In any case, the number of fibers used from the PHE to the SHE are considerable, and any additions in the number of nodes to accommodate node splits, for example, could easily overwhelm the fiber infrastructure. Adding fibers to the PHE to SHE infrastructure is “easier said than done” due to cost of the large number of needed redundant links and also of the time associated with acquiring permits and the subsequent construction.

Fortunately, a move to HFS solves all these issues. In the diagram below, when HFS is applied, the PHE “only” has high speed coherent links of ~100-400G that traverse to the SHE over redundant routes. Since these are a well-established technology, and higher capacity, they require only a small fraction of PHE to SHE fibers. At the SHE, we connect up the coherent links to the DAAS ports. Typically, up to 48 DAAS ports can be lit with a 1RU DAA switch box. The DAAS ports are connected to the HFS and the analog link, then connected to the fiber node. Note here that the analog link traverses only the link from the SHE to the node.

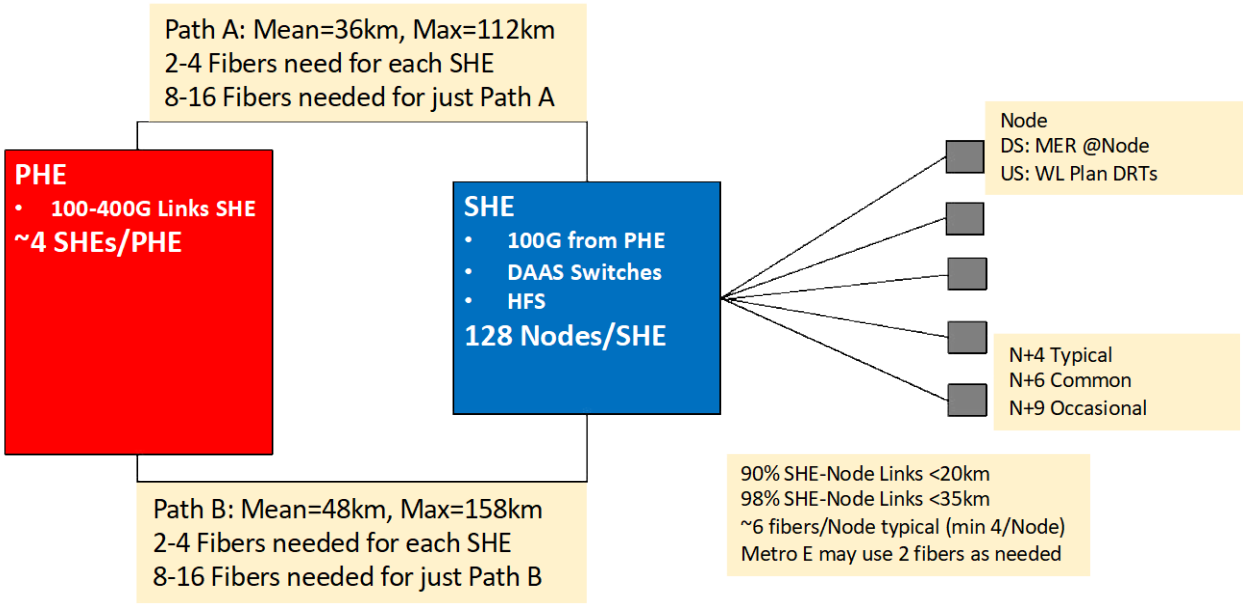

**Figure 7 - An example of Traditional vCMTS and PHE to SHE to Node connectivity**

By way of example, comparing the two figures immediately above, we see that there is a net savings of 10-16 fibers per PHE to SHE hop, and since there are typically 4 SHEs per PHE, this results in 40-64 fibers saved per SHE cluster. There is an equal number of secondary fibers that can be saved, as well. Some of our bigger markets may have as many as 100 SHEs, in which case the numbers of fibers saved on the (very hard to get) HE-SHE link would be up to ~1500 to 3000 when the primary and redundant routes are counted!

It is this huge savings in PHE/SHE fibers, and the associated reduction in critical infrastructure pressure at the PHEs, that accounts for a push towards HFS. But for this to happen, the HFS should be able to fit into a secondary headend – and some of them can be small and overpopulated. Furthermore, the link lengths from the SHE to the nodes are short enough for the HFS to offer good performance, even accounting for any RF cascades after it. All of these points are discussed in this paper, but we begin with a survey of our fiber links.

The graph shown in Figure 5 is the result of a survey of >100K geographically dispersed fiber nodes within our U.S. footprint. The average link length between the secondary headend to the fiber node is ~10 km; 98% of nodes within 30 km. This survey spans 16 major markets and all of our regional divisions.

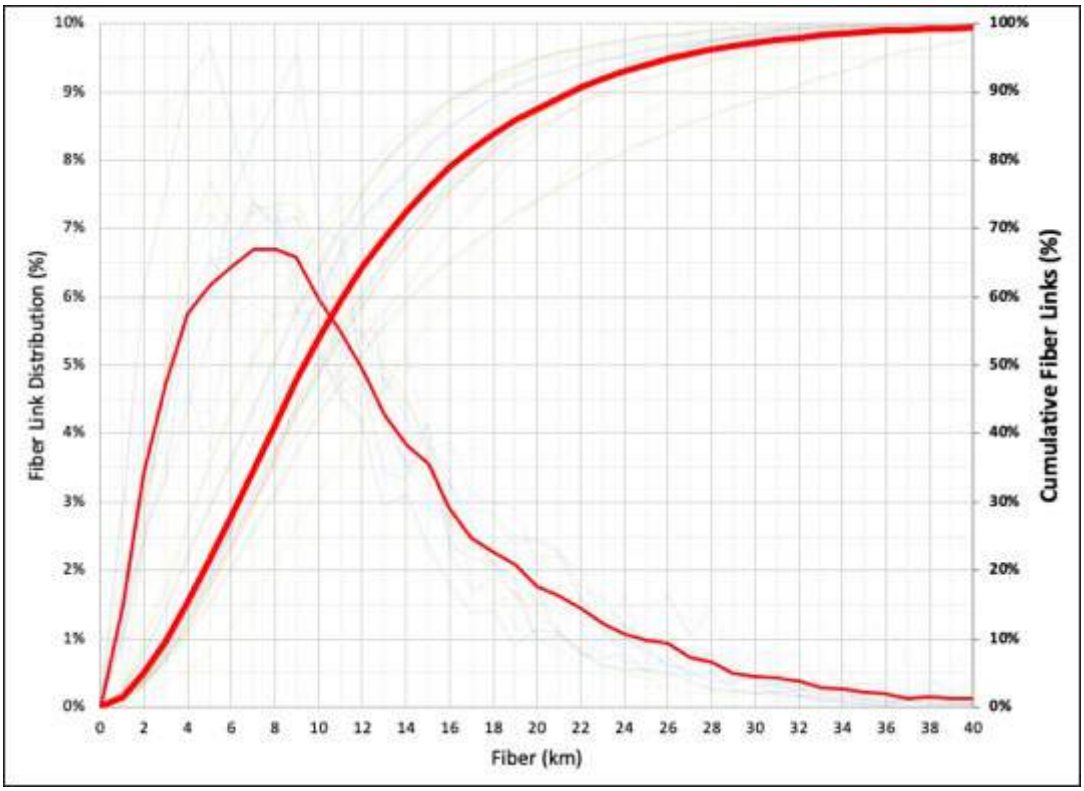

**Figure 8 – Analyzing ~100K SHE-Node Fiber Links Across Our Footprint**

With this visual, it can be seen that the MER of the node for a signal generated at the SHE and fed with an analog transmitter could have a much higher MER than that of a long PHE to SHE link followed by a fiber run to the node, which will be shown in Section 6.

To recap, a move to the HFS will result in a significant reduction in fibers from the PHE to the SHE. With fiber lengths that are more modest, there also a substantial improvement in MER at the node. The adoption of a Hybrid Fiber Shelf also results in critical infrastructure benefits, including substantial powering and space reductions in secondary headends. These savings, combined with the speed with which HFSs can be deployed, and the resultant uniformity of vCMTS usage across the company, are perhaps its most attractive features.

## 4. Converging the Headend and the Fiber Plant

We have seen in earlier sections that the primary headend/PHE hosts vCOREs and coherent optics, and the secondary headend/SHE hosts the same high-speed optics, as well as the DAAS ports and analog optics. In many cases, the PHE also supports nodes directly, which are (aptly) known as “direct fed nodes.” In this case, the conventional CMTS is replaced with the vCORE; the DAASs are also connected to the vCORE and fed to the analog transmitters as described earlier. In this instance, all forms of optical conversions take pace directly within one converged headend.

Similar to the case of a converged headend, we will encounter a substantial period of time when we might expect cases of converged fibers. By converged fibers, we mean fibers with bi-directional transmission of analog and digital wavelengths on the same single fiber. Consider the case shown in Figure 6, where a simplified diagram is presented.

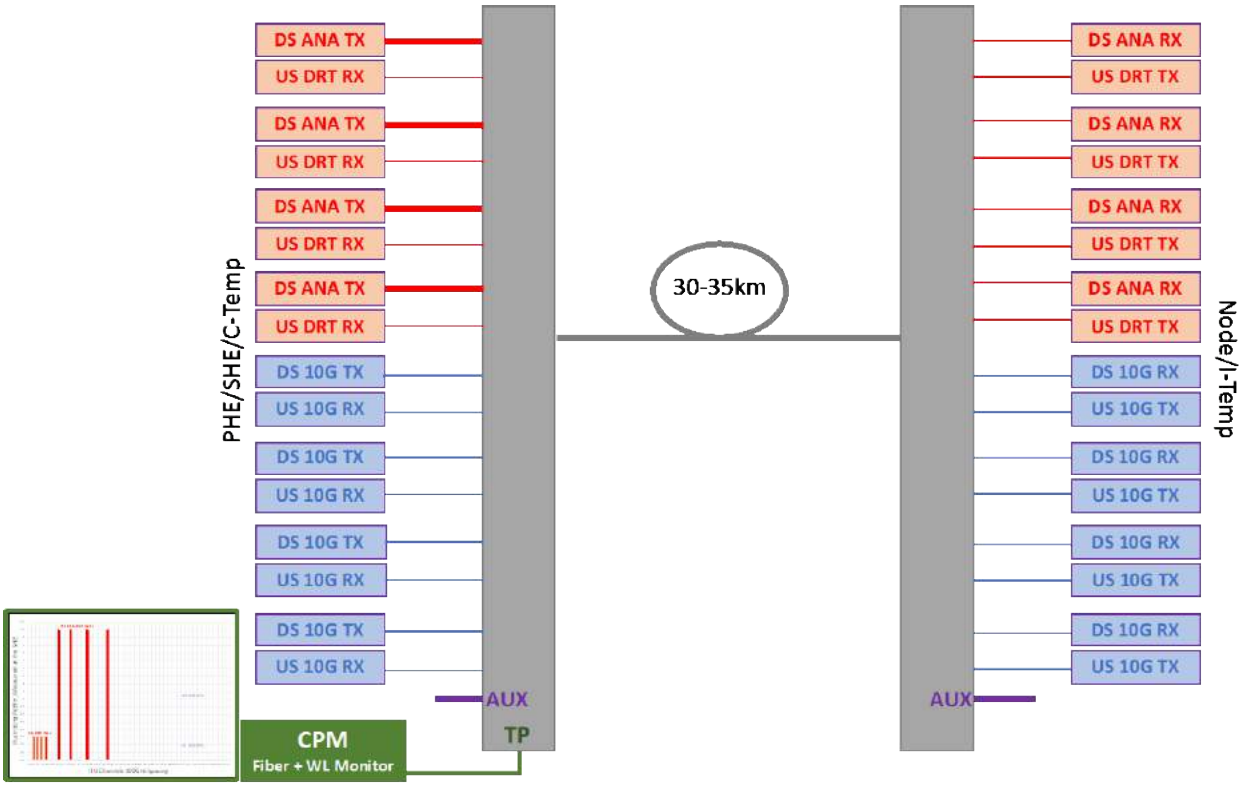

**Figure 9 – Converged Fibers**

On the same fiber that hosts analog DS wavelengths, the US digital return transmitter (DRT) wavelengths may be hosted as well. Furthermore, 10G wavelengths that support DAA nodes and some other 10G links may need to support MetroE links and be hosted as well. For DAA operation, today we use 10G tunable SFPs.

Considering Figure 6 as part of the SHE, we can see that there are up to 4 DS analog transmitter wavelengths and up 4 US DRT wavelengths, and up to 4 bidirectional 10G wavelengths circuits that could support any combination of DAA or MetroE circuits. A detailed description of the wavelength selection process is given in Figure 7. But here, we note that additional wavelengths that are part of a well thought out plan may still be added on the auxiliary port. In addition, the entire fiber and all sets of wavelengths are monitored over the consolidated test port by a continuous and pervasive monitor that is described in a different paper in the 2020 Cable-Tec Expo program.

There will be cases when over time, 100G/200G coherent wavelengths may need to be hosted on the same fiber, in order to enable Switch on a Pole (SOAP)-type architectures (this point will be discussed briefly in Section 5) In general, dual fiber options are not favored because the fiber coexistence use case presupposes a fiber scarcity that argues against this option. To enable multiple wavelengths of differing

power levels into the fiber, a comprehensive understanding of optical effects and non-linearities is needed.

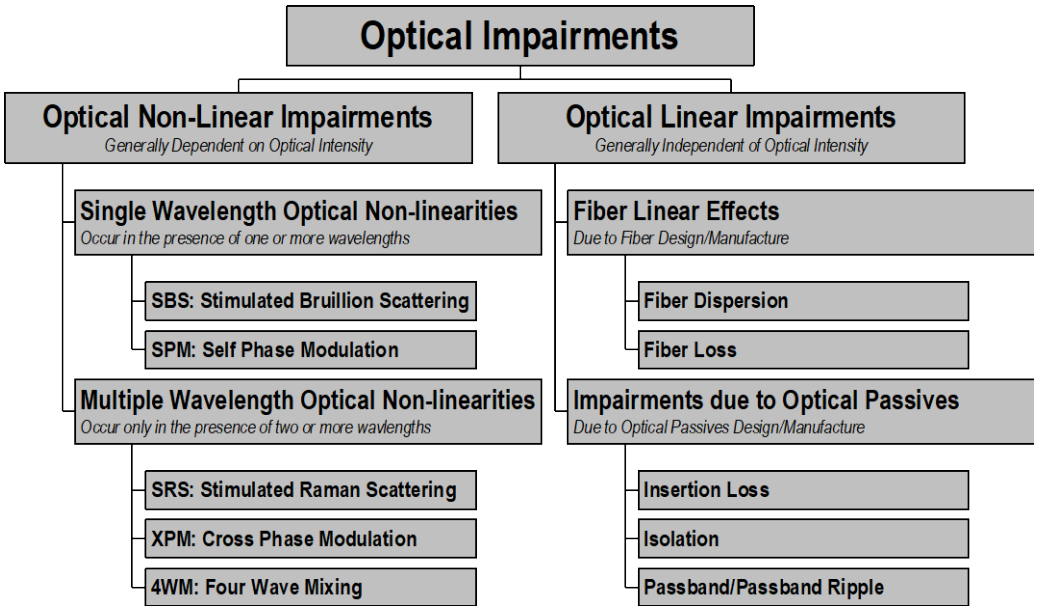

**Figure 10 – Taxonomy of the Optical Effects and Non-linearities**

Presented in Figure 7 is a taxonomy of optical impairments. We begin by dividing impairments into linear (those that do not generally depend upon the optical power level) and non-linear (those that generally become worse with higher optical levels) impairments. Linear impairments can be attributable to the fiber itself, such as dispersion and fiber loss, which have to be dealt with in all of the signal types. For example, the use of externally modulated transmitters heavily reduces the effects of dispersion, since they are almost chirp free. For baseband signals, propagation length is inversely proportional to the square of the dispersion. Therefore, a 10G link that can go over 80km can only go over ~15km with 25G line rates, and less than a km at 100G with the same Non-Return-to-Zero (NRZ) signals. Transmitting the signals in the 1310 nm region, where the dispersion is close to zero, would work, but here we run into the other impairment -- the fiber loss -- which is considerably higher at 1310 nm than it is at 1550 nm, with no recourse for easy optical amplification.

Add to this the fact that optical passives also add to analog system impairments. Directly modulated lasers (DMLs) can be affected by passive ripples (undulations in the passband), however, externally modulated lasers do not have this effect because they are chirp free. For digital systems, the passband of the filters should be large enough and the adjacent channel isolation deep enough for successful transmission. We currently use thin film filters, as they are well suited to indoor and outdoor plant, and because we also have high and low wavelength counts distributed throughout the infrastructure.

A common theme here is that that for analog transmission, externally modulated transmitters seem to be a good fit. They are able to handle dispersion and optical passives better. In fact, well designed externally modulated lasers can have much better MER than DMLs could -- over longer reaches and over a wider variety of optical passives. The industry has used EMLs for quite a long time, but in recent years their prices have compared favorably to DMLs. As such they represent a great alternative for the HFS and provide appreciable performance benefits.

We now come to non-linear signal performance. These generally present as single wavelength impairments which will need to be optimized. For example, while EMLs behave well with dispersion and over the passives in the linear domain, they have very aggressive single wavelength non-linearities due to stimulated Brillion scattering (SBS) which must be overcome. Fortunately for us, in HFS, we have modest fiber links, power levels are modest, and these have been overcome and are on par for the course. For digital transmission, these effects are minimal.

Finally, when we put multiple wavelengths on the same fiber, multiple nonlinear effects can take place simultaneously, such as Stimulated Raman Scattering (SRS), Cross Phase Modulation (XPM) and 4 Wave Mixing (4WM). SRS is mitigated by packing wavelengths closer; XMP is mitigated by moving wavelengths far apart; and 4WM is mitigated by avoiding all beat products that would produce significant SNR degradation by the effects of optical beat interference (OBI). OBI is a known issue in RF over Glass (RFoG) systems and has the ability to singlehandedly shut an entire system down.

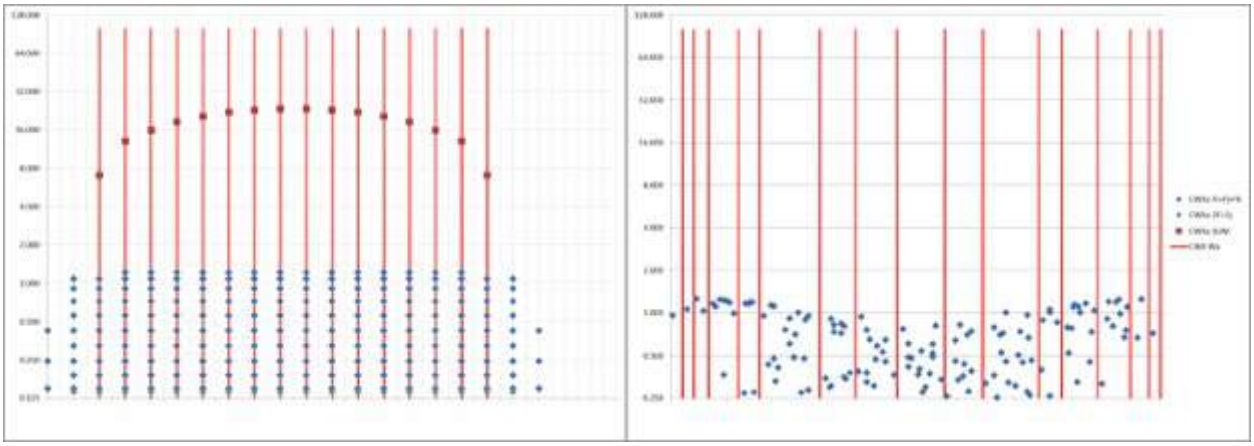

**Figure 11 – Full Spectrum Wavelength Planning**

To make matters worse, 4WM is intermittent, seeing as how it depends upon beats lining up with carriers. Therefore a standard uniform wavelength spacing is not appropriate. A wavelength plan that spreads the beats around is the only effective way to eliminate 4WM, while securing an effective, robust and high-power transmission in the optical fiber. Such a wavelength plan, as described above, can be enhanced with wavelength offsets, which are especially important for the EML lasers. This is so that they can accommodate the multiple lobes associated with SBS suppression circuitry.

Typically, the recommended maximum total launch power for a well-designed FS wavelength plan is 19 dBm. For 16 wavelengths, light may be launched with up to 7 dBm/wavelength of power launched into the fiber, and for 8 wavelengths light may be launched at 10 dBm/wavelength by the same token. Higher light may be launched for 4 wavelengths, but one must be careful to spread out the wavelengths within accepted guidelines to reduce the effects of SRS and XPM. Since analog wavelengths operate at high power levels, we use the wavelength plans noted above -- and therefore the links between some PHEs and SHEs are congested.

We have seen that the Analog FS wavelengths utilize the wavelength plan described in Figure 8. It is possible that the ‘gaps’ between the 16 wavelengths can be used by upstream Digital Return Transmitter (DRT) wavelengths. In fact, this is a way to enhance fiber efficiency, because the bi-directional transmission of light utilizes more wavelengths, without the consequent increases in optical intensity at any one end. Thus, we could have 16 WLs in the DS and a like number in the upstream with no significant degradation to the signal integrity in either direction.

The desire to use the same fiber for analog and digital (baseband) operation is an old one -- we first wrote about this in 2006 (SCTE ET). Some of the recommendations there still hold true (although that was about 1 GbE and for CWDM operations). The main idea is to ensure that the analog and digital (in this case 10 Gbps) wavelengths behave as good neighbors and do not influence each other. This is possible when we maintain a substantial optical level differential.

As mentioned, analog transmission is generally at very high levels since the performance needed is quite high. Not so for digital transmission, because the optical input requirement is really in the -21/-22dBm range for signal recovery. This being the case, there is really no need for high power transmission especially if the reach is limited (and we have seen that our links are maxed out at 35km). Therefore, one could launch light at much lower power, which would also reduce the contribution to optical non-linearities. For this reason, if we maintain a substantial optical level differential between the analog and digital transmission, the two formats would behave as good neighbors and not mutually affect each other.

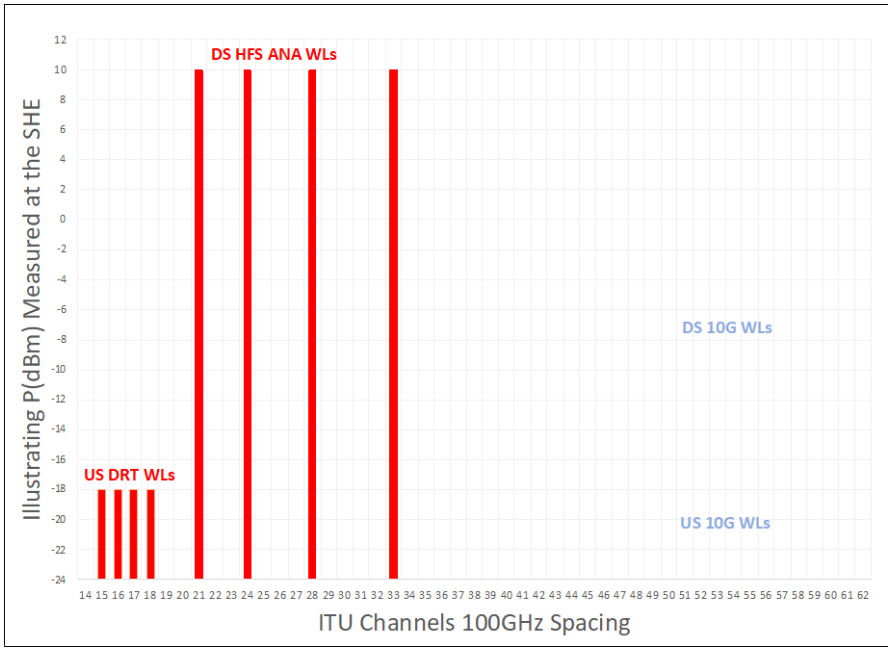

**Figure 12 – Illustrating Analog and Digital Coexistence on the Same Fiber**

Figure 9 shows a representative wavelength plan as seen on the CPM at the SHE, that minimizes non-linearities and enables 4 DS and US wavelengths along with 4 10G circuits on one single fiber. This type of wavelength selection and optical level differential will allow for several digital wavelengths to co-propagate with analog wavelengths. The counter propagation is considerably easier because the return wavelengths are all baseband digital and require very little power compared to the downstream.

# 5. A Word about Coherent Optics

Wavelength planning for accommodating Coherent Optics on the same fiber is an ongoing activity at Comcast and around the industry.

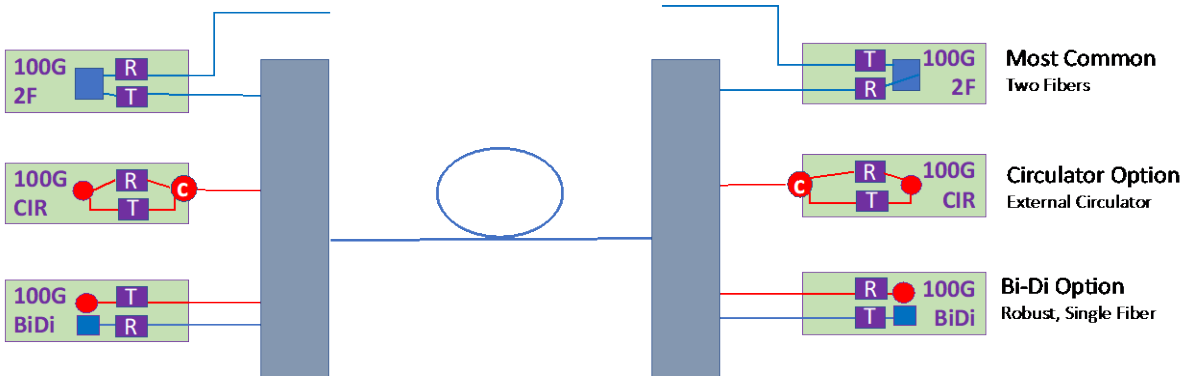

**Figure 13 – Coherent Optics Options**

Dual Fiber Single Laser Coherent Pluggable: Traditional Coherent Pluggables are built with an optical engine that has only one laser. The same laser pulls double duty as the transmitting light source that then passes through a nested modulator to create complex light forms to transmit over the fiber. At the far end, the laser receiver adjusts its wavelength precisely to the incoming light, and the heterodyne receiver deciphers the incoming complex signal and send it over to the DSP. The processor then decodes the signals and streams them in either 10Gbps or more likely 25Gbps binary signals to the outside world. The other half of the aforementioned laser's light is sent over to the nested modulator. Its light is then sent over a separate fiber to the first module, where the lasers will heterodyne and decipher the incoming light. This is perhaps the only place where the OBI is intentionally used to enhance the communication system. It is what makes Coherent systems so interesting and special. As mentioned in Section 4, coexisting in a single fiber means that there is not a second fiber available to be to be used, so this option may not work in those cases.

Single Fiber Single Laser Coherent Pluggable: For single fiber co-existence, it is proposed to use an optical circulator to reuse the same wavelength. In this case, the light in an optical circulator can move only one way, therefore the transmit light can only move out of the module while the received light might move only inside the module. With this arrangement the wavelength may be reused. The circulator has good but imperfect isolation and is prone to losing isolation at temperature extremes. While this may not be an issue at the PHE or the SHE, it may be an issue at the node, where temperatures can cycle between -40C to +60C. Furthermore, reflections in the system can also impinge on the available dynamic range and reduce the effectiveness of the coherent receiver, thus limiting the fiber reach or speed.

Single Fiber Dual Laser Coherent Pluggable: A dual laser design for the coherent pluggable has two separate lasers, one for light transmission and another to receive light. The corresponding transmitting and receiving lasers, in two separate pluggables across the fiber mutually lock on to each other. Because their sources are independent, they deliver true light bidirectionality over different wavelengths. As a result, this arrangement is not prone to any of the reflection issues described earlier. Previously, these types of devices were expensive and had higher heat dissipation. However, the advent of 7 nm DSP technology has propelled efficient drivers and with efficient lasers and cost-effective optical amplifiers these issues have been resolved. These modules are also now very cost effective and have been realized in (C-Formfactor Pluggable 2) CFP2 form factors.

This discussion on coherent optics is intended to prepare the reader for the notion of a “Switch on a Pole” (SOAP) type of an architecture, that would, with the help of a coherent termination device, transform the capacity of access networks dramatically. In this context, we gratefully note the efforts of CableLabs and its P2P link and Coherent Terminating Device (CTD) specification efforts. There are also multiple efforts underway towards 25G NRZ transmission, based on a 10G SFP platform, and also of a new type of point-to multipoint (P2MP) architecture using subcarriers. All are trying to bring higher speed optics closer towards the access space.

## 6. Hybrid Fiber Shelf

A typical headend that has CMTS is a pretty big facility. Generally, it holds the high-speed circuits coming in to connect to the internet, and video sources coming in either from a satellite dish farm or through terrestrial fiber. Multiple modulators groom the video to be on specific outbound frequencies. Any on-demand servers are connected to modulators as well. The CMTS itself is processing, scheduling and getting traffic, and modulating it. Finally, all of these signals are RF-combined and fed into an analog transmitter.

Each RF combining attenuates the output signal, so a very common requirement is for high RF output power as mentioned in DRFI (DOCSIS RF Interface) Specification to burn through all the of the combining network. Generating high output RF power of sufficient quality requires RF amplifiers and a high-power dissipation to power them up. Of course, all of this is frittered away in the RF combiners until it reaches the transmitter. If there is cabling in a PHE, then the cable loss and its tilt will have to be taken into account. Typical transmitters today require 10 dBmV/6 MHz (in days past they would have required 15 dBmV/6 MHz) but it is common to have individual per channel modulator outputs as high as 60 dBmV/6 MHz.

As we have discussed, there are two main problems with this scenario. For starters, as HSD traffic grows, so too will the CMTS ports or the needed capacity per port. At the limit when HSD has subsumed most of the traffic needs, then the RF can all be potentially available at one port. This will also require the maximum CMTS licenses (discussed in Section 2), but until that time, the entire RF combining infrastructure is carried. However, once the vCOREs come online, and the entire CMTS is virtualized, the timing is perfect to dismantle the RF combiners and recover the space. This is possible because the entire RF spectra is populated by the vCMTS output port and can be connected via a grey 100G connection to the DAAS switch. We note here that the DAAS output port of 10G puts out the complete RF spectra that may be generated at the RPD.

The DAAS may be connected to the headend RPD device thru 10G AOCs, which will have fairly low power consumption. If the RPD is co-located with the VCMTS then this might even be connected via DAC cables that are even more power conserving and at very low cost.

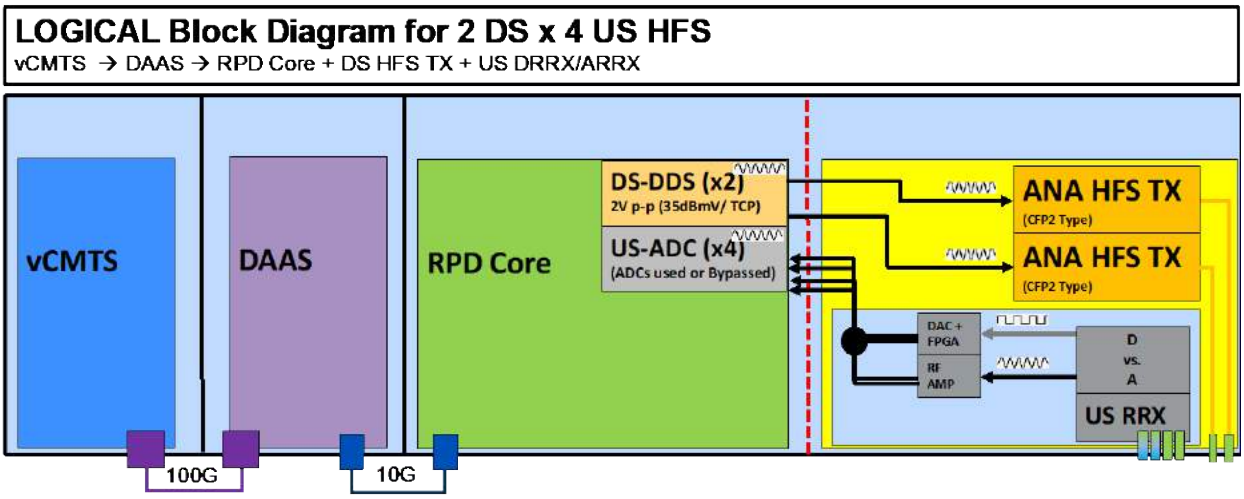

**Figure 14 – Logical Block Diagram for HFS**

A typical RPD without its post amplifier puts out 2V p2p. This is roughly 35dBmV of RF power (for distortion-free performance). Typically, the RPD MER is better than 50 dB, on average.

If a chassis has only RPDs in it, we call it an RFS (for "RPD Shelf") to distinguish it from a Hybrid Fiber Shelf (HFS), which would have had the transmitters and return receiver integrated. For our purposes, the red line shown in Figure 13 is the demarcation point. We will use the acronym "HFS" generically, to mean that the RPD Shelf and the optics shelf is either integrated or co-located – either way, the RF combining circuits are eliminated or heavily reduced. While the RFS is already of material benefit to us as an operator, the HFS enhances that benefit in cost effectiveness for critical infrastructure.

Years back, the analog transmitter was a device that took considerable space and power and used high performance Directly Modulated Laser (DML) technology. State-of-the-art transmitters are now built using Externally Modulated Laser (EML) technology within the size of a CFP2 form factor typically used for 10G transmission. These comprise an EML, the linearization circuit for it and any SBS suppression circuitry. Typically, we need only around 10-11 dBm of SBS suppression to cover the 30km or so of the SHE to node link. A typical HFS transmitter would have around 4W of dissipation and around 11 dBm of output optical power. As is oftentimes the case, EML transmitters have lower optical modulation depth (OMI) than do the DMLs, but their chirp free dispersion performance and lower RIN make up for it and generally provide a modicum of advantage. The best feature of these is that there is no reason now to declare the fiber lengths.

Using DMLs would have required us to declare fiber distances, because the electronic dispersion compensation would need distance to cancel fiber dispersion-based distortions generated in the fiber. Even though this is a one-time provisioning issue, it causes problems when a redundant route gets activated. As it happens, there is not redundancy from the SHE to the node, but still, eliminating this extra step is a welcome feature. So is the feature of being able to use common optical passives for 10G, coherent and/or analog, which was harder to do with DML transmitters.

In another paper this year, we have described a pervasive monitoring tool to track all wavelengths. That tool also needs a description of the fiber length. One thing to keep in mind here is that the needed number of analog wavelengths per fiber is going to be rather limited in this architecture. In this architecture we typically would have had each SHE feed one node, on average. This is because the link would have

started at the PHE, then thru the SHE and then all the way to the node, and we have seen that long-distance transmission of analog wavelengths is limited.

In fact, while multiwavelength analog transmission is limiting, single or limited wavelength analog transmission over modest fiber distances with EML transmission is has high performance. Figure 15 shows a measured result of an RPD followed by EML transmitter over 38km of fiber. This shows a node MER of ~45dB, which quite handily beats the 4K QAM requirement of 41dB.

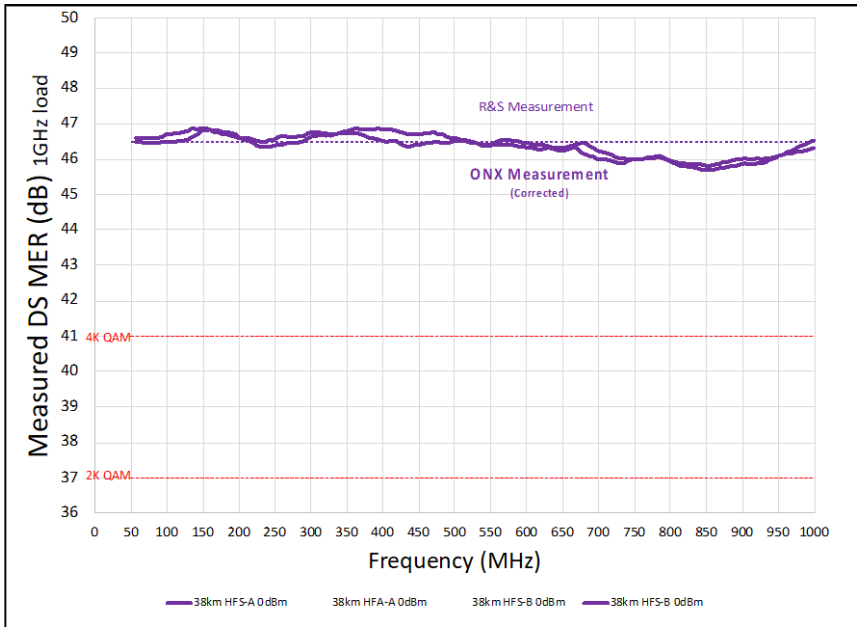

**Figure 15 – Measured RPD and EML Transmitter MER**

However, it is often the case that multiple amplifier cascades are in place after the RPD. In Figure 16, we can see the performance of an amplifier cascade that has been added to the RPD MER. Assuming each RF amplifier at around 50 MER each, this indicates that the cumulative MER performance is also dictated by the RF amplifier cascade as well as that of the RPD and of the HFS EML transmitter. Figure 16 shows a simulated performance of the RF cascade, beginning with an MER appropriately reduced to account for unit to unit variation and temperature performance. The cumulative performance is then very close to ~41dB MER, even for N+6. This performance complements the efforts of DS profile management application (PMA) that automatically adjusts the modulation complexity to available SNR and maximizes capacity deployed at Comcast. With smaller cascades, the performance is even better.

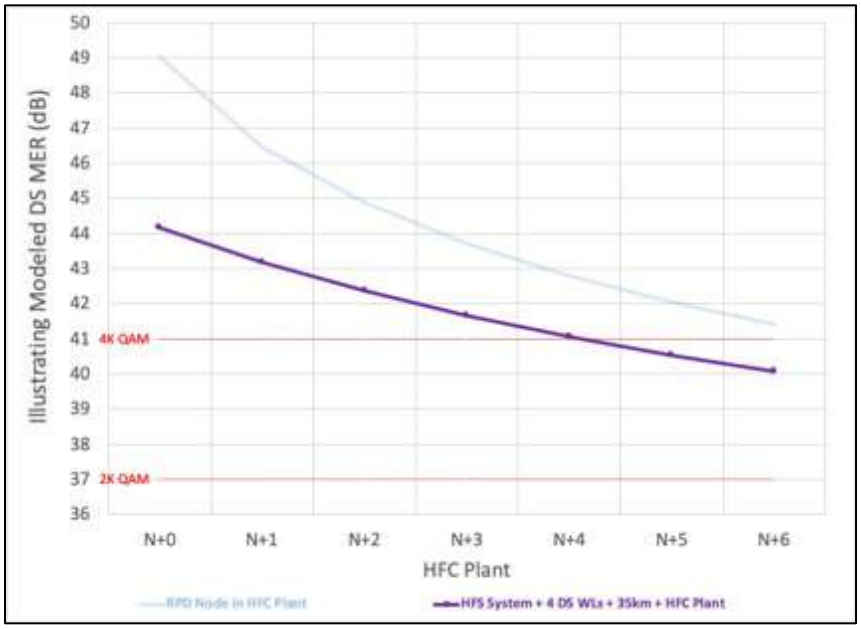

**Figure 16 – Node and RF Cascades**

Figure 17 summarizes the benefits of the Hybrid Fiber Shelf.

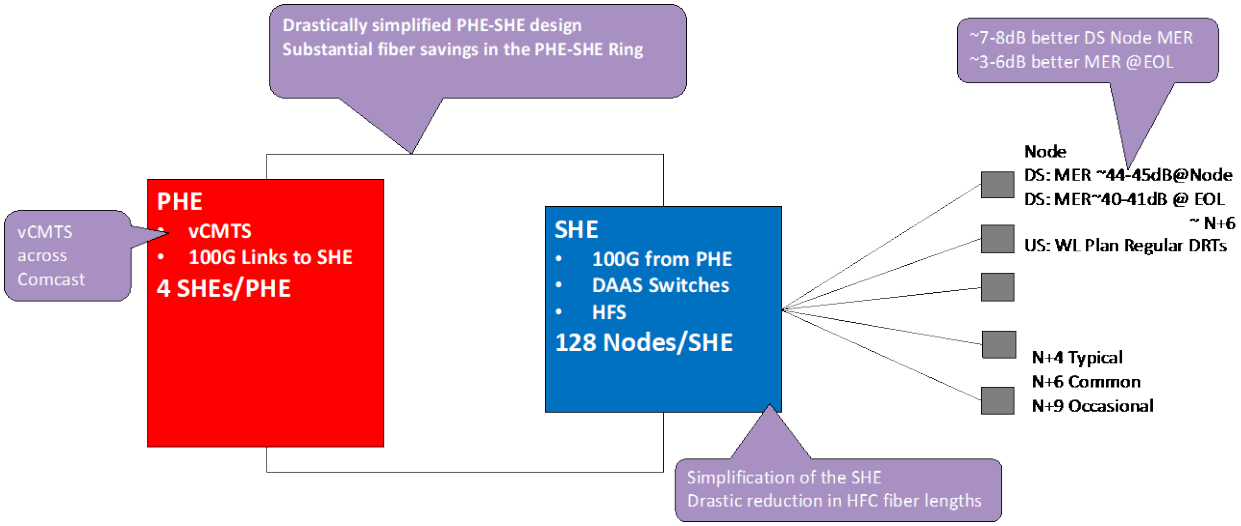

**Figure 17 – Summary of HFS**

## 7. Critical Infrastructure

In this section we talk about how both HFS and RFS can potentially save on Critical Infrastructure (CI) in the PHE and the SHE. As we have indicated before, a regular CMTS occupies several rack units (RUs). Further space is occupied by the video generators, and the most space is occupied by the RF combining circuitry. Overcoming the excess loss of the RF combiners requires that the CMTS and other video equipment put out a rather large RF level. This RF Level is then split and combined to incorporate the various signals and then provided to the Analog Transmitter at an appropriate level. A typical CMTS-based system connected to 192 service groups can take five 7-foot racks worth of valuable headend real

estate. Some of the older CMTSs and the existing RF combining equipment take up even more space, because the CMTS and the DS transmitters are not co-located in the building, so RF cables are run across the headend to connect them. This has the unfortunate result of needing to have slope and amplitude correction circuitry, on a transmitter by transmitter basis, to groom the input RF to the transmitter for distribution. Added to this, because RF combining is complex and folks will not want to touch it once installed, there are numerous test points distributed across the RF cables which provide the convenience of test points but at added power and cost. The same process is repeated for the US as well. The US RF out of the US RX comes in at a high level, is split multiple ways, and combined. This conserves CMTS ports, with enough test ports to track RF levels along, and is then connected up to the CMTS.

With a system described above, accommodating necessary node splits will require additional headend space that is hard to get. Adding to a headend is quite expensive and may not even be possible, in the time needed for the node splits, and after accounting for permits and construction.

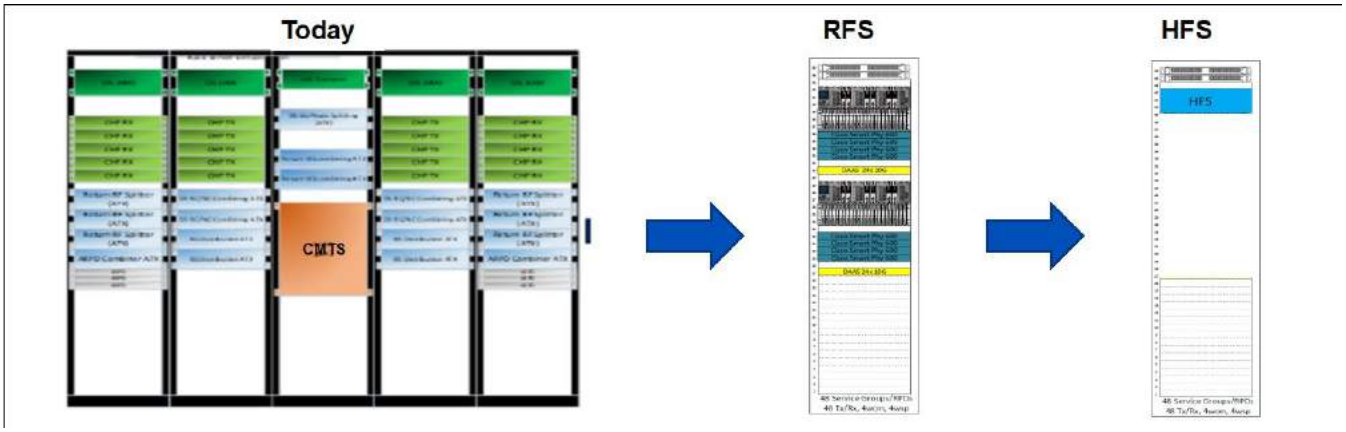

**Figure 18 – HFS Critical Infrastructure**

With an enterprise wide vCMTS/vCORE one can now compress all of the HSD, video and other assets into one converged platform and have a single RF connection. In Figure 18, we have indicated that the RFS is co-located. Here, the RF combining is totally replaced with just a DAAS port that is connected to the RFS via AOCs or DACs. Then, there is a modicum of RF circuitry before the output level is connected to the analog chassis. Thus, the space and power savings are considerable, as shown above. Even though the RFS is very compact, it still has a higher output, because we may need to feed existing analog transmitters which may require higher outputs. Sometimes the analog gear may not be co-located (especially in the PHEs) and therefore it may need to be connected to long sections of RF cable. For this reason, the RF output of the RFS is also higher and will require the consequent grooming. One additional fact will need to be considered as well: any time a new node is commissioned, it is common to perform what we call “First Node Provisioning” (FNP). This is done by connecting a CM directly to the chassis and ensuring that the CM can turn up and stay connected. This is done to ensure that there are no loose ends in the node commissioning process. It requires test points for the US that will be able to not only display the ingoing RF levels, but also provide a path for the CM signal to be injected. For this reason, the modicum of RF combining is also maintained.

A study by our Critical Infrastructure group on one of the PHEs found not only substantial space savings, but also that there would be 23% reduction in powering. A 23% reduction in powering is quite a major achievement, because it will also contribute to lower air conditioning costs and our corporate sustainability goals. There is a substantial overall cost reduction with a move to the vCMTS/RFS combining, as well, but that is out of scope for this paper.

The real breakthrough, in hindsight, was the move to a HFS: Integrating the whole Remote PHY device (RPD), downstream transmitter and upstream receiver, all in the same module and installed in the same chassis. When done this way, there is no RF combining, by definition, the test points are conducive not only to verify RF levels, but also to do FNP. Also, the RF level out of the RPD is exactly equal to the RF level needed by the DS transmitter, and the RF level out of the US RX is also exactly equal to the RF level needed for the RPD. In this case, the power requirement is much lower, while the overall density is higher. Note that the RFS will have higher density, but when combined with the need to add in the DS TXs, US RXs and the RF combining, it still results in an overall lower density than the HFS. Furthermore, since the transmitters are very low in power consumption, similar analysis indicated above shows a further 40% reduction in power and space. This makes it very attractive and enables us to start placing the HFS in secondary headends and other such "hard to fit" areas. This is where the maximum benefit of this architecture comes into effect.

It is important to realize that both RFS and HFS have their place. For example, in a PHE, where there is a preponderance of existing optical transmitters and there is a modicum of space, many of these could be repurposed and either co-located or distance located from the RFS. But if the issue is to move closer to the nodes or if node-splits are to happen and new transmitters and receivers are needed anyway, then a move to SHE may be warranted and here the HFS would be a far better fit.

It may be asked that if additional nodes are to be added, why would we not just deploy RPD nodes. Indeed, that may be a legitimate option, and 1x2 and 2x4 RPD nodes are more available now than they were a couple of years back. However, if the aim was predominantly to eliminate traditional CMTS and standardize on the vCMTS, replacing of all nodes would be too onerous of a task. A HFS would be a better choice and enable use of existing nodes with available segmentation capacity. We have further shown that the performance is quite good and holds itself well in a N+x type system, where there is a fair contribution from the RF cascade as well.

To summarize, a combination of DAA RPD nodes, 1x2, 2x4 HFC RPD nodes, RFS and HFS are a set of tools to accelerate the virtualization of CMTS and usher in uniformity and standardization within our access networks.

## 8. Conclusions

We began this paper with a recap of our work to virtualize what are some very complex portions of our network, including the CMTS, which resulted in network simplification and harmonization of multiple purpose-built platforms into one common entity. However, DAA deployments require headend and field modifications as part of the deployment. RFS takes great step forward by accelerating virtualization with a design of RPDs in a shelf, but still requires some RF combining and a separate optical chassis.

HFS takes that concept further, integrating with virtualized CMTS/DAA switches at one end and with transmit/receive analog optical signals at the other end, into the outside plant. This innovation provides rapid and economically sustainable increases in capacity by accelerating integration with the vCMTS, as DAA construction proceeds in other areas of the network. HFS improves critical infrastructure in headends by saving wasted space, power and time inherent in RF combining and splitting circuits. Extending HFS into secondary headends also enables significant fiber reclamation. Locating these assets in secondary facilities, closer to the traditional HFC nodes, improves performance in ways that translate into enhanced capacity.

## 9. Acknowledgements

It is with gratitude that we acknowledge the team within Comcast who has been working on the RPD and RFS projects. We also thank the Critical Infrastructure team for their analyses, and the Access Engineering team for their support on fiber convergence and planning efforts.

## List of Figures

# 1. Introduction

High Speed Data (HSD) customer growth and capacity requirements continue to increase year over year. A Distributed Access Architecture (DAA) provides enhanced upstream and downstream capacity to match demand. Last year, we covered a new approach in DAA called Grey Optics Aggregation (GOA) that provided significant savings and enables DAA deployment at scale regardless of plant density.

This year, we report on the lessons learned during our GOA trials and deployments of the architecture. In addition to proving out the technology and cost benefits in the field and observing its stability, deploying the architecture also enabled us to interconnect and create an ecosystem of remote monitoring and control for the various GOA elements. We will report on our ability to continuously monitor Grey Optical Terminating (GOT) nodes, detect cable modems connected to specific GOT nodes and remotely identify and mitigate ingress in the GOA domain.

Many of the remote techniques were used during the COVID pandemic and can potentially be generalized further to enable remote monitoring and mitigating capabilities across the network. Furthermore, we report on recent work on bi-directional Coherent Optical modules that enable efficient extension of the architecture, which, over a period of time, can create cost effective convergent and scalable “Switch On A Pole” (SOAP) access networks.

# 2. Architecture Recap

Last year, we presented a new Grey Optics Aggregation (GOA) architecture that can reduce cost in the outside plant, reduce cost and space in primary and secondary headends, and provide substantial upgrade opportunities to increase capacity and enable new Switch On A Pole (SOAP) type architectures. The GOA architecture works especially well in medium and lower density areas and can exist side by side with traditional nodes equipped with Remote PHY Devices (RPDs). As such it helps to accelerate the virtualization of the CMTS (vCMTS) by enabling it to be deployed across complete primary and secondary headends.

Figure 1 shows a simplified DAA deployment of vCMTS, DAA Switch (also called DAAS, connects vCMTS data to RPDs) ports and RPDs in the field. Recall that each RPD requires its own DWDM SFP (Dense Wave Division Multiplexer Small Form Factor Pluggable transceiver), multiple such SFPs can be optically multiplexed and connected to individual DWDM SFPs in DAAS ports through optical de-multiplexers. Multiple DAAS ports are aggregated and connected to the vCMTS core via optical methods common to long haul networks (~100G -400G).

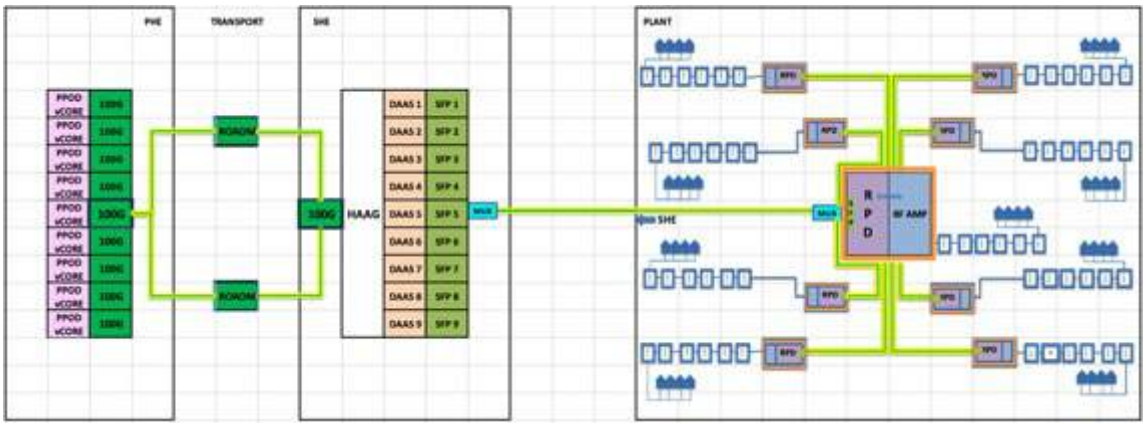

**Figure 1 – Traditional DAA in Primary and Secondary Headends and Plant**

This architecture works well when home/neighborhood densities are high and as such the cost of each RPD and the associated optics at the headends can be spread across a large base of household passings (HHPs). However, if the area is sparsely populated, this may be difficult. Even when a high-density residential area is selected, it can contain pockets of lower density. Addressing them cost-wise might be the proverbial tail wagging the dog.

Presented in Figure 2 is the GOA Architecture that provides a cost effective and pervasive way to deploy virtualized CMTSs across the whole DAA footprint.

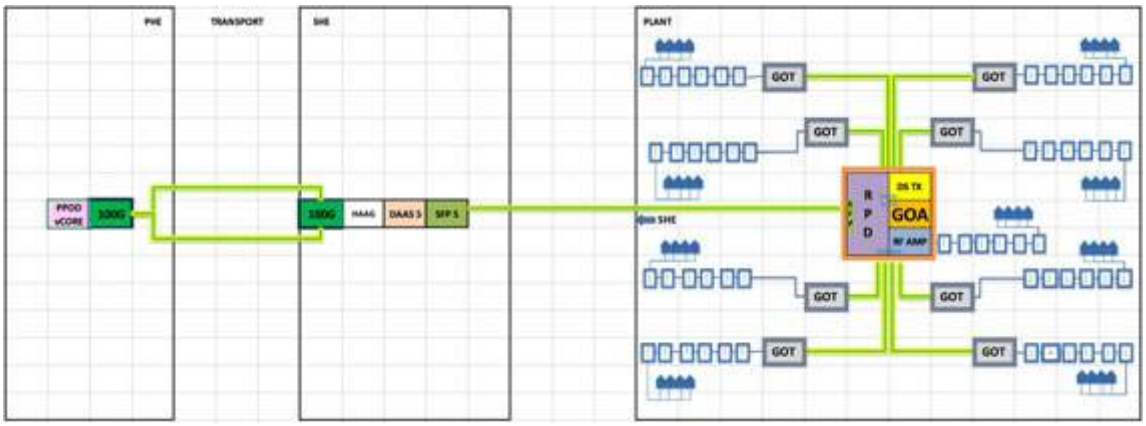

**Figure 2 – Illustrating GOA Architecture**

In this architecture, a prime node contains the RPD and is called the GOA (Grey Optics Aggregating) node, since it is populated with an analog forward transmitter and return receiver modules for aggregation. The downstream (DS) transmitter output is then split and connected to multiple (up to 8) nodes, called Grey Optics Terminating (GOT) nodes. Each of the GOT nodes contains a downstream receiver module and distributes the RF output to its four constituent RF blocks. The RF levels of the GOT node both for downstream and upstream (US) traffic are identical to regular RPD nodes. For the US, the RF signals get combined in the GOT RF tray and fed into a digital return transmitter (DRT). From there, the signals are sent to the GOA node, where they are fed to the aggregating receiver module, one each for each receiver. Then they are RF-combined and fed to the RPD, thus completing the signal circuit.

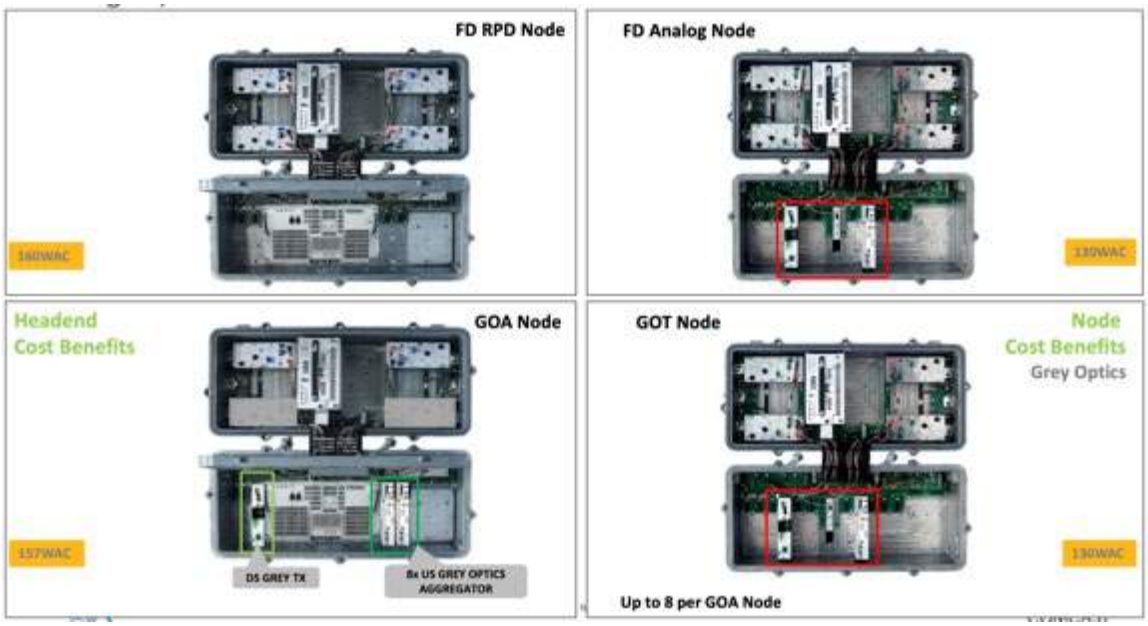

**Figure 3 – Illustrating all Nodes and their Power Dissipations**

As can be seen in Figure 3, all nodes are the same physical size. And it is the case that all of the above nodes have identical RF US and DS characteristics. The GOT node has an optical AGC receiver that always adjusts the RF level of the receiver to be identical to the RPD output. The DRT to the aggregate return receiver module gain is set to unity, so that the combination of thee DS receiver and the US DRT are an almost perfect replacement for the RPD RF levels. In fact, it is for this reason that replacing the DS receiver, the US DRT and the node monitoring card together with an RPD would instantly transfer the GOT into a full RPD node when and if needed.

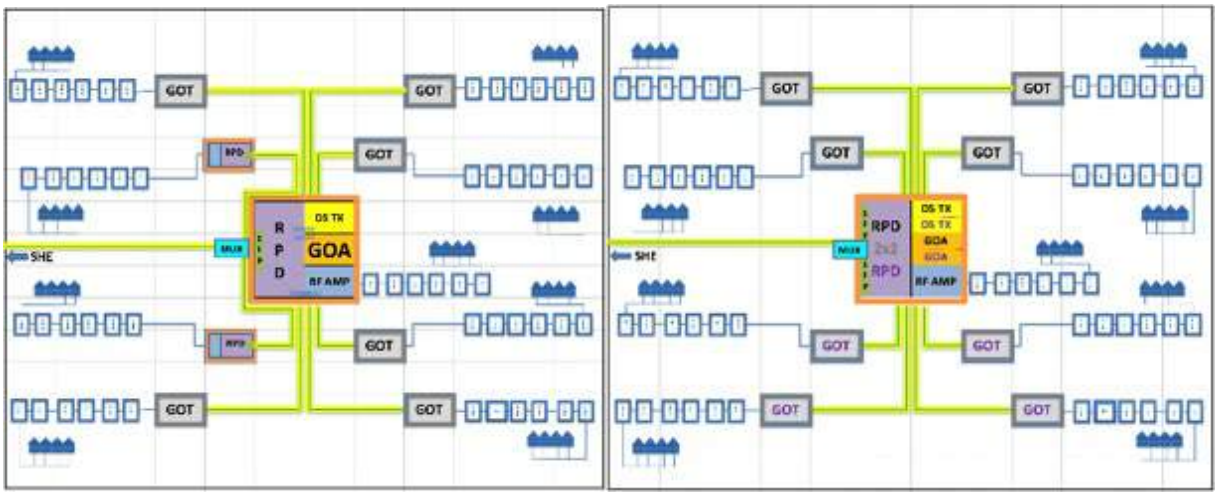

**Figure 4 – Upgrade Models: Localized Growth (Left) and Uniform Growth (Right)**

Figure 4 illustrates one of the major advantages of the GOA architecture: Not only does the GOA allow for cost effective fiber deployments across multiple areas, but it also allows for easy upgrades, should the need arise. Generally, the DAA deployments are projected to be stable and address growth needs for a substantial period of time. However, if there is localized growth at any one of the GOTs that defied earlier

predictions, the move from a GOT node to the GOA node is easy, from a field perspective, because it just replaces the analog receiver and DRT with the RPD and connects the two ends to the optical passive. Furthermore, the new RPDs that would need to be deployed would be more computationally capable, consume lower power and occupy less space (as described by Moore's Law, Dennard's Law and Koomey's Law, respectively) and cost less as well. This will, in all likelihood, enable us to use the uniform growth model (shown in Figure 4) to deploy a 2x2 RPD that provides increased capacity across the board, when the time comes thus requiring far fewer site visits for network upgrades. Furthermore, a move to Full Duplex DOCSIS (FDX) or Switch on a Pole (SOAP) that relies quite heavily on RPD, Node and vCMTS enhancements would also be well served by the GOA architecture.

For all of the above reasons, the GOA architecture was deployed on a trial basis and its performance, robustness, tech friendliness and customer satisfaction have been established. With this information, deployments are now occurring in additional areas.

In this paper, we discuss some of the lessons learned during the deployment. In addition to the above features, several innovative features suggested themselves. One was an intelligent use of the aggregation modules to associate cable modems (CMs) not only to the RPD and to the vCMTS core, but also to each of the GOTs. In addition, the same type of intelligence enables us to identify ingress or noise in each of the GOT nodes or on the RF blocks in the GOA node. These features and other interesting applications of harnessing the monitoring information flow between the GOTs and the GOA will also be discussed.

## 3. Initial Deployment Site

After discussions, a suburban area in one of the Comcast divisions was chosen for initial deployment. This area already had just been built with traditional RPD nodes. Figure 5 is a description of the chosen area, which served ~550 HHPs with 21 RPD nodes. Some nodes served as few as 15 HHPs while the maximum HHP count was 40, with an average count of 25 HHP / RPD.

| | HHP | NODE |
|---|---|---|
| 240 HHP | 19 | **GOA A** |
| | 18 | GOT A1 |
| | 27 | GOT A2 |
| | 20 | GOT A3 |
| | 40 | GOT A4 |
| | 38 | GOT A5 |
| | 33 | GOT A6 |
| | 23 | GOT A7 |
| | 22 | GOT A8 |
| 202 HHP | 24 | **GOA B** |
| | 26 | GOT B1 |
| | 39 | GOT B2 |
| | 15 | GOT B3 |
| | 29 | GOT B4 |
| | 19 | GOT B5 |
| | 29 | GOT B6 |
| | 21 | GOT B7 |
| 109 HHP | 24 | **GOA C** |
| | 31 | GOT C1 |
| | 28 | GOT C2 |
| | 26 | GOT C3 |

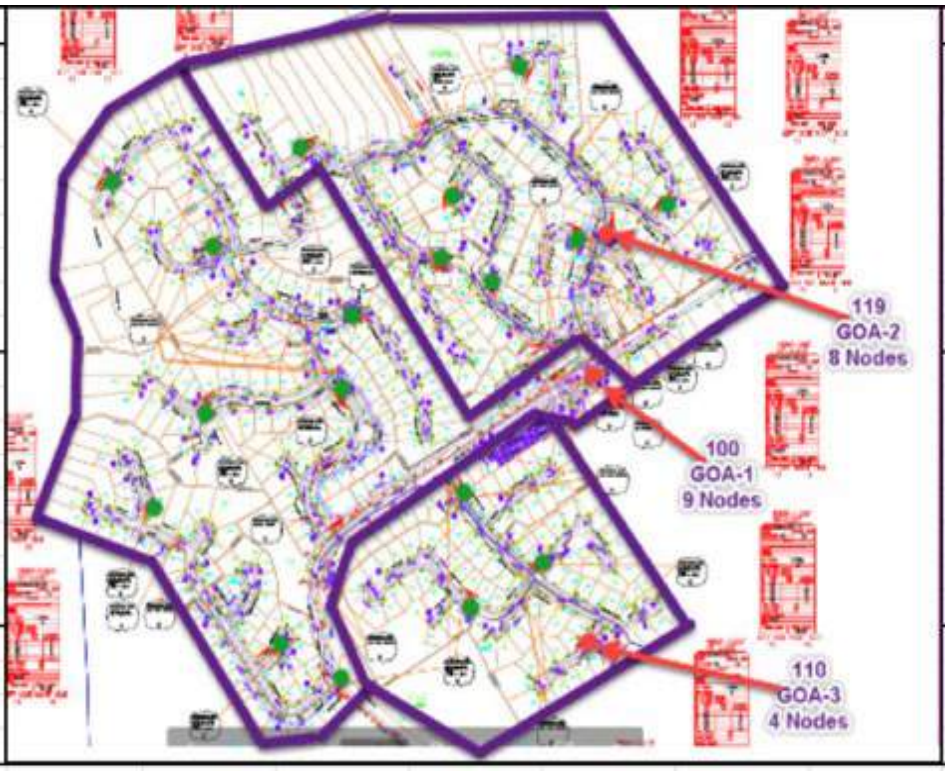

**Figure 5 – Technical Details of Initial Deployment Area**

As shown in Figure 6, the selected area was a regular subdivision, as would be expected off of a major metropolitan area. What we found was that the common RF build practice of running RF through the front of each property meant that the number of HHPs that could be served per node was rather limited. This is especially true given that DAA builds follow a node plus zero amplifier (N+0) design, thus do not have amplifiers to extend RF runs.

**Figure 6 – Geographical area illustrating the Physical Subdivisions**

Because of this, it is easy to see that a build that spans across a SHE location may have on average have high HHP/DAA Node density but could still have several nodes with much lower HHP/DAA node densities. We have investigated many ways to enhance the HHP/Node, including a thorough analysis of the drop levels needed. A judicious application of those design rules does extend the number of HHPs/Node and are defined as acceptable in newer playbooks.

In this case, taking a look at the geography enabled us to see that the 21 RPD nodes could be reduced to 3 GOAs and 18 GOT nodes. This represents a 7x reduction in amount of SFPs, DAAS ports and vCMTS microservice instances required. The GOA locations are indicated in Figure 5, along with the GOT nodes and their HHP counts.

## 4. Initial Deployment

To prep for the transition from RPD to GOA, we set up a team of analytics and traffic experts. We then charted all the CMs associated with each of the nodes and noted the cumulative traffic in each RPD. Then the team threaded the total traffic and time series, aligning them to estimate the cumulative traffic, were the nodes converted to the GOA architecture.

A word about HHPs and CMs. While there is wide variation in respect to broadband penetration rates and number of DOCSIS devices per HHP, in general, when both are taken together, the number of CMs in a given area is approximately equal to the HHPs in that same area (this was certainly true for our case here). With this in mind, we will use HHP and CM count interchangeably in this paper.

We did this to get a baseline view of the traffic before the RPD nodes would be aggregated with the GOA architecture. This laborious process was then automated, and we found that as the aggregated node size increases, the cumulative traffic increases, but at a slower rate than the increases in HHP. And, as expected, we find that the traffic, which is lumpy with small numbers of CMs, gets more blended with larger numbers of CMs. The idea was to ensure that none of the GOAs would be overwhelmed with traffic -- and none were.

We also put together a dashboard that threaded the US RF output levels and input levels, SNR, PER/FEC rates and RF frequency per CM, as well as DS input levels and MER for each frequency, from multiple sources. Some data were directly from the combined vCMTS/RPD and others from the CMs, as they reported back. All of these were time stamped and reported daily as Max, Min, Mean and 95$^{th}$ percentiles. This enabled us to be able to see each CM and all associated metrics simultaneously to see the impacts in almost real time. Over time, this was very useful.

Once the decision to move ahead was taken, the division leaders took over the process of combining nodes in an appropriate manner and drawing up a schedule for node cutovers. The leadership, engineering talent and commitment of the division was unquestionably paramount in the move forward. As can be seen from the figures above,

- GOA A had 240 HHP, with 8 GOT nodes
- GOA B had 202 HHP, with 7 GOT nodes
- GOA C had 109 HHP, with 3 GOT nodes

These were selected in this fashion to ensure that we had sufficient opportunities to verify performance with larger and smaller HHP groups and GOT node aggregation. In parallel, we also performed lab tests to determine that the RPDs could handle the 240 HHPs that were likely to be added. In reality, the RPD and vCMTS combination can handle much more in some of the newer virtualized systems.

**Figure 7 – GOA and GOTs assembled in the headend, Closed (Left) - Open (right)**

Once this was decided, we drew up entry and exit criteria and a backout plan. Part of the plan was to train our field technicians on the new products, and also to set up a full GOA-GOT system in the headend, to ensure that we had a working system for burn-in, and to work out any kinks. Setting up the GOA-GOT system allowed us to verify some of the very preliminary software features then available. These were road-mapped to improve over time and were deployed and tested on the headend system.

When it came time for construction, in a maintainence window, the first GOA was deployed. After a day of observing its performance, the GOTs were then cut in during daytime. This is because the RPDs have a turn-on time, while the GOT nodes (being analog) are turned on instantly with no additional settle-in time needed. All in all, the 21 RPD nodes were turned in to 3 GOAs and 18 GOTs with careful planning, diligent effort led by the division, and periodic checks on customer call logs and performance verifications, using available internal tools, which will be described in detail later in Section 7.

Overall, the construction of the GOAs and GOT (i.e migration from RPDs to GOA) was uneventful, thanks in large part to the planning and efforts described above. The performance of the units was well within what was predicted, there were no customer impacting events, and the customer experience was maintained well. Next we will characterize the many additional software and hardware innovations that were developed and deployed to enhance the useability of the platform.

## 5. Heart to Limbs

Construction of the GOA architecture follows a “Heart to Limbs” strategy. By that we mean that the GOA node is first deployed. Its functionality is established, the local splice enclosure is primed and then the GOT nodes are activated, one after another. Since the RPD in the GOA node feeds all other nodes, this strategy will require that the plant that feeds all other GOT nodes stays online even after the GOA is deployed. This is not the case for RPD deployments, since each RPD node is individually feeding its own limited set of HHPs. To achieve good visibility and to speed up the construction process, the team came up with an innovative splicing matrix approach, depicted in Figure 8.

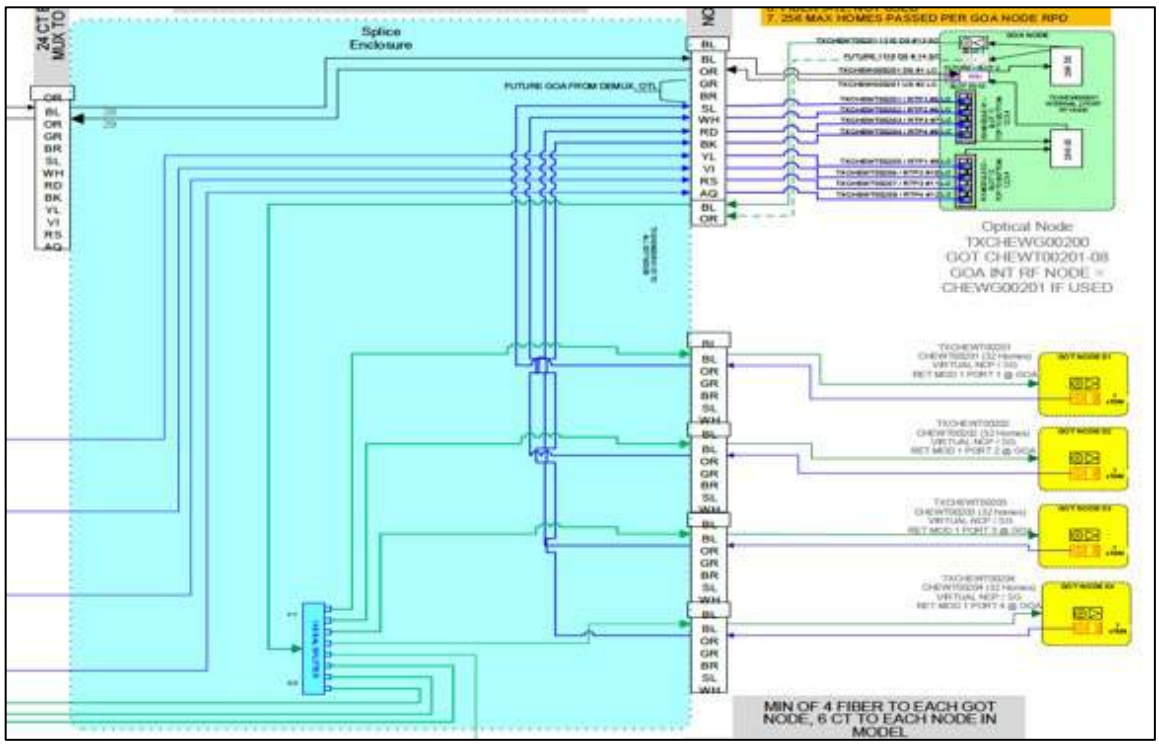

**Figure 8 – Splice Matrix and the Wiring Diagram**

In the case of the trial deployment, the fiber plant was already designed with RPDs in mind. In cases where GOA is the preferred deployment, we allocate a minimum of 4 fibers per GOT (typically 6 fibers). The GOA is allocated a 14-fiber pigtail. The standard 12 colors, from Black to Aqua and Black and Orange, repeated. For any GOT, the two fibers that are spliced are color coded so that the Black is always connected to the DS receiver and the Orange is always connected to the DRT. On the GOA side, the GOT designated GOTs 1 – 8 follow the Slate – Aqua colors of the standard Fiber Color scheme. For the GOA RPD, the Black is connected to the Rx of the SFP, and the Orange is connected to the Tx of the SFP. The other Black is connected to the DS Tx and goes to the 8-way DS splitter and then on to the GOT's DS Receiver.

We also followed a minimal design for optical passives that connect to the GOA RPD. We generally note that a parent node rarely has more than 3 GOAs. Therefore, the DAA Mux has been standardized to the 12 port Mux (ITU 61 – ITU 50) and exclusively uses sub-band tunable SFPs for the DAAS ports and for the GOA RPDs.

The GOA architecture, in addition to performing well as a cost reduced DAA option, also contributes to the elevation of DAA architectures as a whole. The GOA node has an I2C bus (this is a bus that enables protocols that can monitor or control various elements inside the node) that connects the RPD to the aggregating Receiver modules, and reports the state of DS receiver power, the US transmit power, the US receive power and the DS transmit power (more on this in Section 10.) But it also connects the RPD to the node itself and helps report on the RF amplifier blocks and the overall power and current usage of the node. Furthermore, each of the US aggregating receivers can either attenuate their own RF out by 6dB or turn themselves off. This helps identify ingress sources amongst each of the GOT nodes. This same feature is available in each of the RF blocks, as well, where the RF block can attenuate the US by 6dB or

turn it off. This feature is called the Ingress Control Switch (ICS). As an aside, we currently do not use these features in regular RPD nodes. The primary reason was the lack of available remote software control or monitoring. With the software development that took place for the GOA architecture use of I2C/ICS can now be used in regular RPD nodes as well in monitoring and ingress detection on the node ports. With this understanding, most of the software that is described in the paper can apply equally well to GOA architecture or to normal RPD deployments.

## 6. Deployment Guidelines

In terms of plant makeup, roughly 60% of our plant is aerial and 40% underground. While DAA is a preferred architecture for high growth tier 1 markets, and it helps us stay ahead of impending node splits and also prepare the plant for further DS and especially US capacity, it takes a fair amount of work to lay the fiber cable, optimize the RF cabling, condition the taps and light up the nodes. In recent times, we have made good progress on optimizing the various parameters that go into designing the network, to improve its efficiency and to select areas especially well fitted for DAA. As reality goes, this is easier said than done – which in turn makes the GOA architecture a good fit for enabling the DAA to be more successful in moving to the vCMTS architecture. To this end, a set of rules have been established for the GOA deployments:

- The GOA node has 2 RF ports and operates at standard DAA RF levels (73.6 dBmV TCP for 1.2 GHz load for the DS and 8 dBmV for the 85MHz US)
- The GOT node has 4 RF Blocks and operates at standard DAA RF levels (73.6 dBmV TCP for 1.2 GHz load for the DS and 8 dBmV for the 85 MHz US)
- The GOA the GOT and the RPD nodes use the I2C and the ICS functionality to communicate/monitor and identify/mitigate ingress
- The GOA RPD has a maximum of 256 HHP, this is the sum total of all passings of the GOA and all associated GOT nodes (in rare instances, an additional 30 HHP may be added to the total count if it can avoid having to add a GOA altogether)
- No more than 8 GOT nodes may be subtended by a GOA node, and it is highly preferred that the GOT nodes be contiguous (in other words, a GOA and its constellations should be in proximity rather than be interspersed with GOTs of other GOA nodes)
- A power interruption extension circuit must be deployed with the GOA RPD (this is a recommended for all RPDs, not just a GOA RPD), and no such power pack is required for the GOT nodes (since they are instant-on nodes)
- 160W is designated per node for dissipation, even though GOT nodes dissipate considerably less. This is to be prepared for when GOT nodes need to be upgraded to an RPD node.
- As discussed, the optical passives deployment uses 12 wavelength devices (ITU 61-ITU 50) and use the sub-band tunable SFPs for GOAs and the DAAS ports. The optical splitter will always be an 1x8 device
- Regular DAA nodes and GOA nodes can be used in the same build footprint at convenient locations, as needed, and the DAAS ports and the vCMTS continue functioning with these devices

These guidelines were presented to our design partners, and with their help we have elected to deploy the GOA architecture in two of our divisions this year (this is in addition to the GOA deployment discussed in section 2), covering multiple DAA builds. “Fingers are crossed” to achieve this, given the COVID pandemic and its impact on construction schedules. It is recognized that underground construction is especially challenging in the current environment and further thought is being directed towards this end.

# 7. Ingress Identification and Mitigation

As discussed earlier, all GOA and GOT nodes have the I2C connectivity to monitor and control many node components. The RPD itself is controlled by Command Line Interface (CLI) commands. There is a secure way to access the RPD to be able to determine how the GOA is configured and display it.

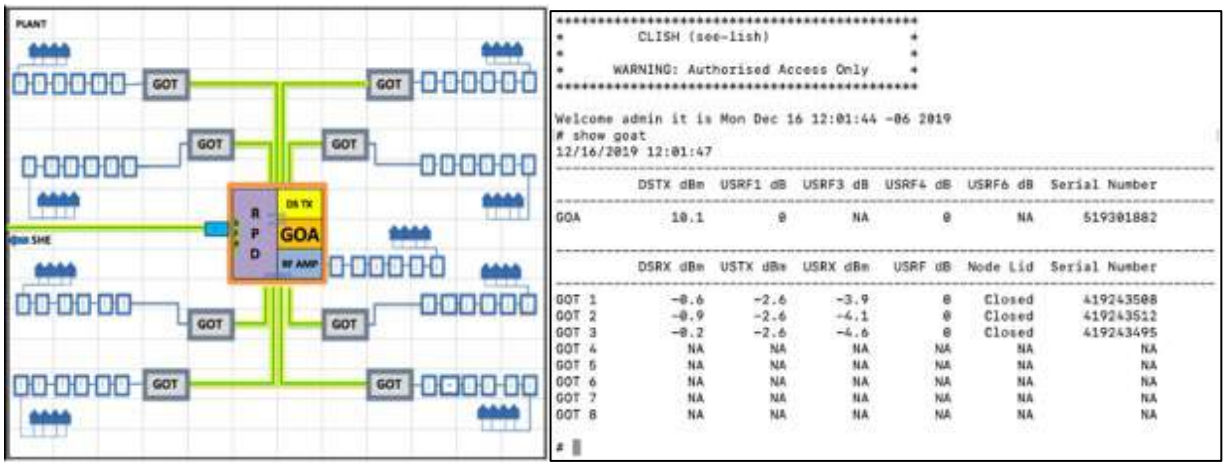

**Figure 9 – Illustrating the Basic CLI and how it summarizes the GOA Constellation**

Access to the CLI for a GOA RPD displays the entire constellation of GOT nodes connected to the GOA. All the GOT nodes that are connected to the GOA have a one-way EMS connection to the GOA via the DRT. Therefore, the GOA receiver is aware at all times about the GOTs connected to it. The GOT node sends its state periodically to the GOA, which then updates this information and passes this on to the vCMTS. In addition, this information is also available at the RPD and can be uncovered via the CLI described above. Section 10 will describe how the information that arrives at the vCMTS can be used, but for now we describe two important aspects of what the GOA can provide which could be of great value.

The entire GOA constellation is represented in Figure 9. The output power of the DS transmitter (DSTX) is displayed and it is nominally 10 dBm. Next, for each of the GOT nodes, the DS receiver power (DSRX) is displayed, which is nominally 0 dBm to -1 dBm, because the DS light passes through an 8-way splitter and traverses some fiber. The US Transmitter (USTX) power is shown next, which is nominally -3dBm (this is a lower-cost Grey 1310 nm SFP). The US Receiver (USRX) power reported by the GOA is shown next, and is nominally -4 dBm, because the US light does not go through any splitter or combiner.

In addition to the light levels, we mentioned earlier that there is an ICS; each of the states of each ICS are reported as well. Thus, the USRF ports refer to the attenuation setting of the ICS of each of the RF blocks in the GOA (recall that we have 2 RF blocks per GOA). Recall that the GOA US Digital Receiver has the capability to attenuate the RF output of each individual GOT US as well. That state is also represented in Figure 9. Furthermore, each GOA and GOT serial number is reported as well. As a neat feature, the GOT node lid is reported as open or closed.

With these settings established, we can now remotely monitor and control the whole constellation. We will show in Section 8 how we have automated this, and how a ticketing structure was developed to automatically indicate major and critical alarms and identify escalation and mitigation options.

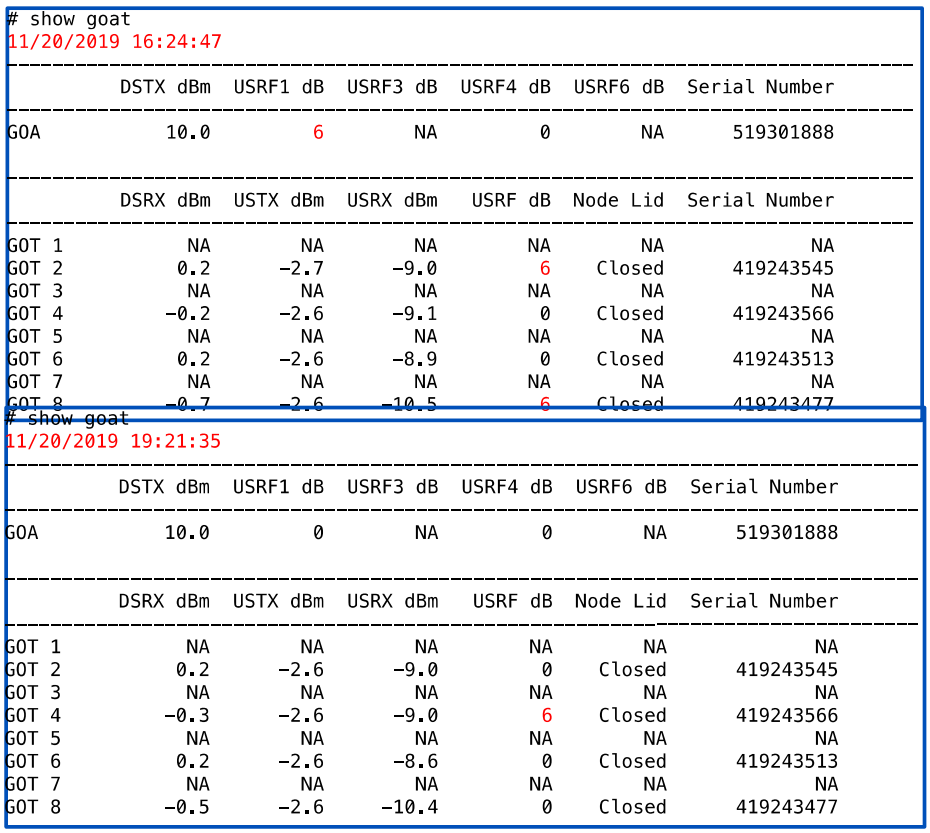

**Figure 10 – CLI with Various Settings**

Figure 10 shows how these values can differ. Notably, the USRX values are nominally at -9 dBm because each of the US links have a ~6dB optical pad. However, since the return path is digital, the optical attenuation does not affect the RF levels at all. The only thing that affects the RF level is RF attenuation, which is shown here in Red. On the top, GOTs 2 and 8 are attenuated as is the GOA RF Block 1. In the bottom picture, only GOT4 is attenuated.

When GOT 4 output level is attenuated in the GOA, two things happen:

1. The noise and the signal level of the GOT4 node is attenuated by 6 dB. Therefore, if GOT4 was the ingress culprit, we would have ingress relief of 6 dB
    a. Since all the RF was combined together, any reduction in ingress will beneficially improve the US SNR of the entire system
    b. If the aim is to identify the ingress point, that is now accomplished. If the aim was to mitigate ingress, then the attenuation stays on until technicians can trouble shoot and eliminate the ingress
2. In addition, the long loop AGC administered by the combined vCMTS/RPD kick in and the RF output levels of all CMs connected to GOT 4 are increased by 6 dB
    a. When this happens, the CMs connected to the GOT 4 benefit and their SNR improves as well
    b. Some CMs that are on the high edge of USTX could reset. This is dictated by the duration of the attenuation and how close they are to the edge

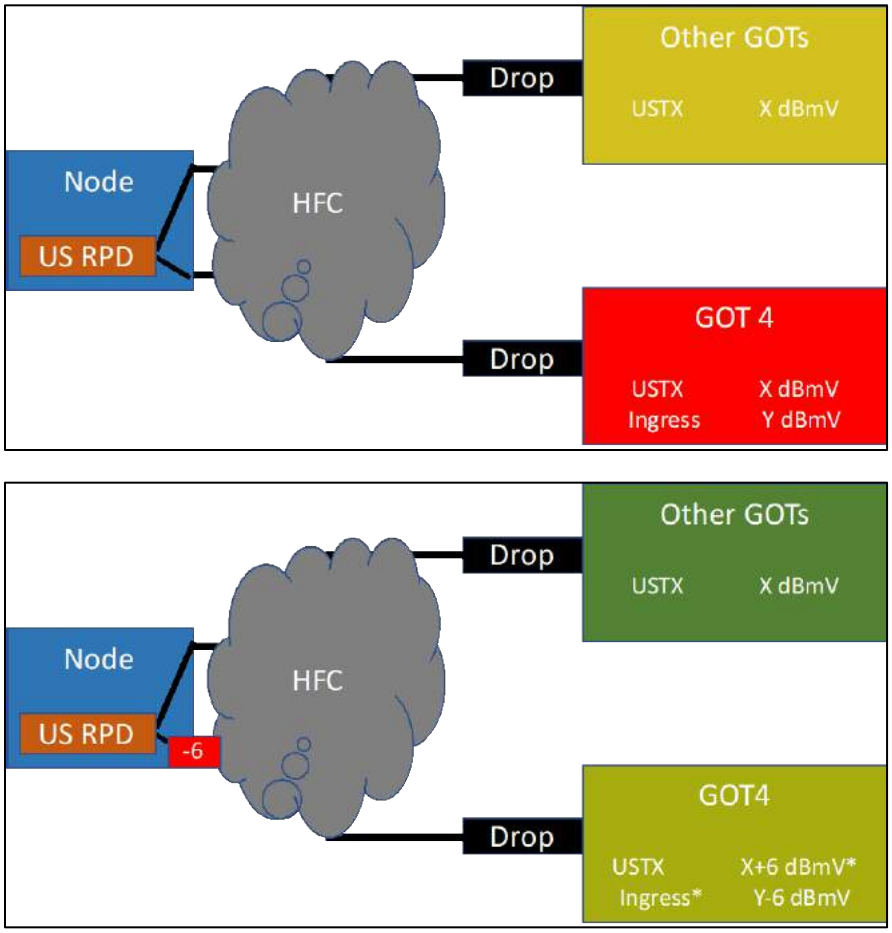

**Figure 11 – Highly Simplified Ingress Illustration and the Role of US RF Attenuation**

The above points are illustrated in Figure 11. Roughly 90% of upstream ingress accumulates at the home, as characterized in an excellent paper written by Larry Wolcott [5] who explains that minimal additions to it occur in the RF plant -- but the plant does funnel the ingress, which compromises the entire plant's SNR. At the extreme it is possible that an aggressive ingress source from a single household can impact the SNR of the entire system. Therefore, it is certainly possible that a single GOT can impact the SNR of the entire system. According to experts whose job it is to keep the upstream signal path functional, around 80% of trouble reports and technician time is spent on ingress identification and mitigation. Since ingress is generated at the home, it can occur in DAA plant and in GOA plant just as it can occur in a regular HFC plant. The ability to peer into the network remotely and identify the ingress-impacted GOT nodes or RF ports, and reduce its impact until it is all improved, is a potential game changer for the future of the RF plant. This capability, although developed for GOA, can be extended to any RPD node, whether it is deployed for DAA or HFC applications.

## 8. Tooling, Eventing, Layering … All in a Sprint

Using a Command Line Interface (CLI) for quick checks is one thing, but using it to continuously monitor and control a large number of GOA RPDs is not a good idea. This is because repeated logging into the RPD (using a scheduling utility such as a Cron job) has a way of destabilizing the network. In addition, RPD logging is taken very seriously in Comcast and the security steps make the process much more difficult.

Fortunately, we have a set of software that uses TLVs (Type Length Values that are used in data communication protocols) that specify information of interest and "broadcast" these to those interested. Harnessing the TLVs by appropriately defining them and connecting them to the various pieces of information will then enable us to "listen in" on them, and create dashboards that enable us to look at various network elements in real time.

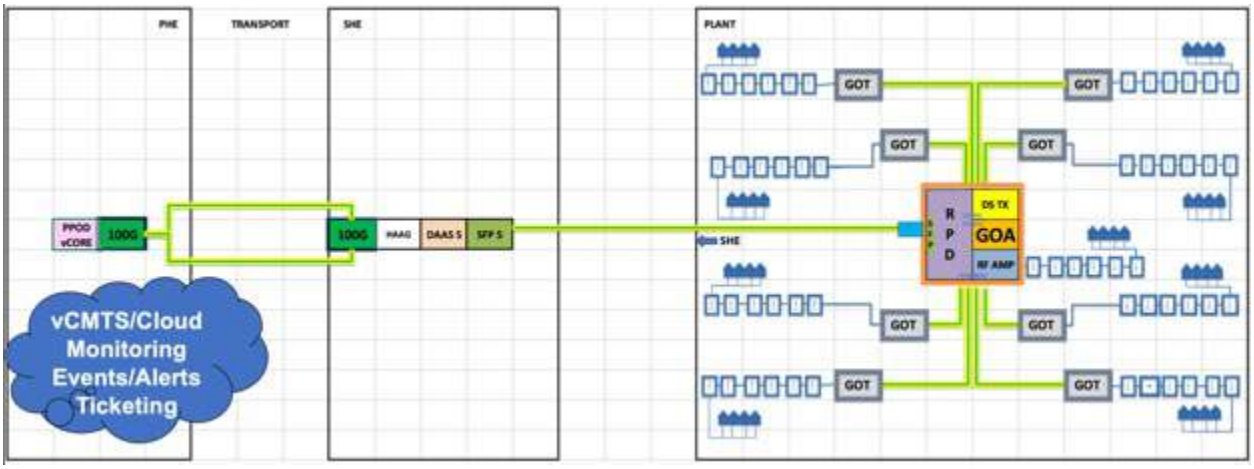

**Figure 12 – The Tooling Diagram – Cloud Based Provisioning/Monitoring/Tooling**

Within Comcast, a project or a product is never considered finished until the "tooling, eventing and layering" tasks are complete. This is a special lingo that takes a bit of time to absorb, particularly for a hardware optical engineer such as this author. But after a bit of learning, we focused on defining the TLVs for the various elements of the CLI table defined in Figure 12. Thus, all of this information would be continuously available (every 15s in the limit) and the entire constellation of the GOA, including all the GOTs and their US and DS levels and RF attenuation state.

This information is available to Grafana, an analytics and visualization tool, for read-only graphing and history purposes for anyone in the organization. This is especially useful to the engineers, and also to the technicians, division engineers/leaders and also to operations centers as necessary.

We also use a piece of software called the RPD Life Cycle Manager (RLCM). This is secure software that enables one not only to view all aspects of the RPD, but also to control aspects of it without additional security. Thus, the ability to manipulate the RF attenuation values are listed in the RLCM.

By now, it is clear that there is ample information available within the company to understand all aspects of our network. We continue to make strides in making all of this data actionable, with increasing application of machine learning and artificial intelligence algorithms. In fact, several of these aspects were used during the COVID pandemic to not only improve reliability but also increase capacity.

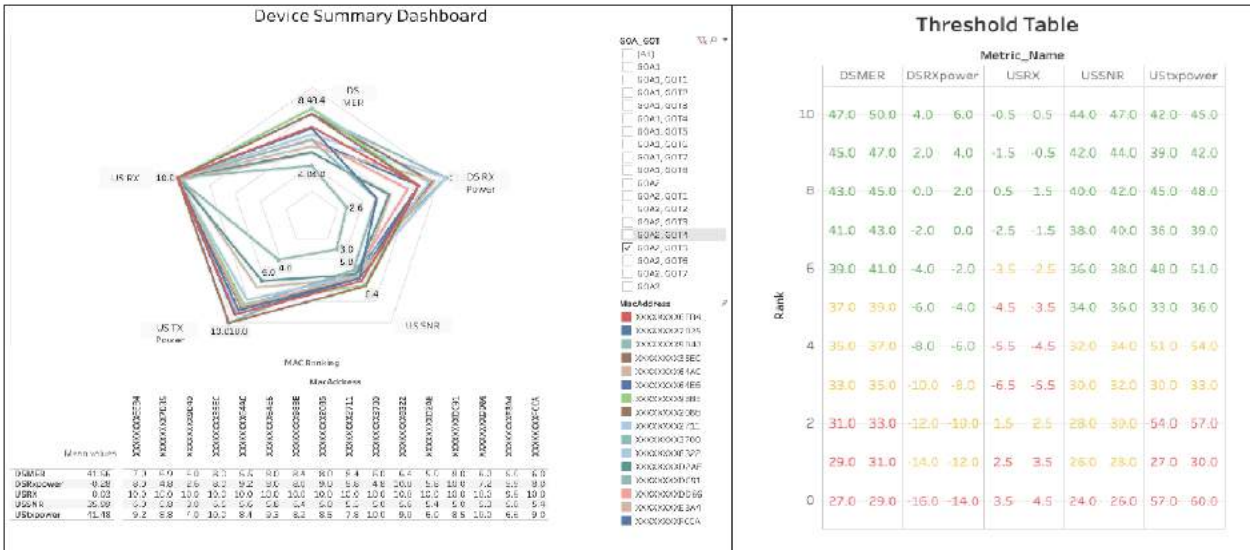

**Figure 13 – Visualizing All US and DS Metric at a Glance Across the Node**

For measuring performance of the network, however, we have so many metrics that it becomes difficult to look at all simultaneously, yet, looking at them is unsatisfying and probably dangerous as the limited information could lead us to incorrect remediation.

Consider a spider chart of the kind depicted in Figure 13. Here, 5 of the most important parameters have been coded to the table alongside and plotted. Since we have data on each modem in real time, these data are available for view on a modem by modem basis and available for display. It is easy to see here that for this node, the US RF RX is always close to ideal (0 dBmV in real life and 10 on the spider chart), but one of the CMs has a rather poor time of getting all other parameters out (DSRF MER is between 35-37 dB, DS RFRX is -8 to -10 dBmV, USRF SNR is 30-32 dB and the US RFTX is 51-54 dBmV). Meanwhile, all the other CMs are in much better shape. This allows us to know, at a glance, that this modem has a low DS RFRX and a high US RFTX value (probably due to a high tap value in an in-home network) which is why the DSRF SNR is low, so, improving it might serve all the parameters well. In general, the wider the "Spider Eye" is, the better the system is, and the eye opening may be used to verify overall performance in a non-invasive way as an added verification of the Orchestration process.

Together the RLCM and the RPD feed events to the internal National Watch Tower (NWT) engine. NWT is a powerful visualization and event reporting and ticketing tool that is one of our internal operational staples. For the architecture to function smoothly and be a template for the future crop of DAA RPDs, all these features must work seamlessly, and are next described in detail.

## 9. Provisioning the GOA-GOT system

We have now entered the Software World, where verbs function as nouns and all specific actions are gerund-sounding … starting with the provisioning process.

Provisioning an RPD is usually done by scanning the QR code of the RPD and matching the IP address, MAC address and the node name together as a first step. The case is similar with a GOA RPD. However, for the GOT node, there is no MAC address, nor is there an IP address. We solved this lack of information by using a piece of software we developed called the RPHY Scanner App.

The RPHY Scanner App provisions an RPD and recognizes when the RPD is a GOA RPD. This can happen because the RPD is connected to a Receiver aggregating module and has a DS Transmitter in the node. Therefore, the App automatically opens up a GOT tab. Recall that we always go from the 'Heart to Limbs' for the GOT deployment. Since the GOA RPD is already live, when the fibers (of specified colors as described before) are connected, and the DS light enters the GOT, the US light leaves the GOT and enters the GOA node, the node is automatically given a name, which is a single digital extension of the GOA node name. For example, if the GOA were called NGACD00110, then the GOT connected to GOA receiver 1 would just be NGACD001101, and the one connected to receiver 2 would be NGACD001102, and so on.

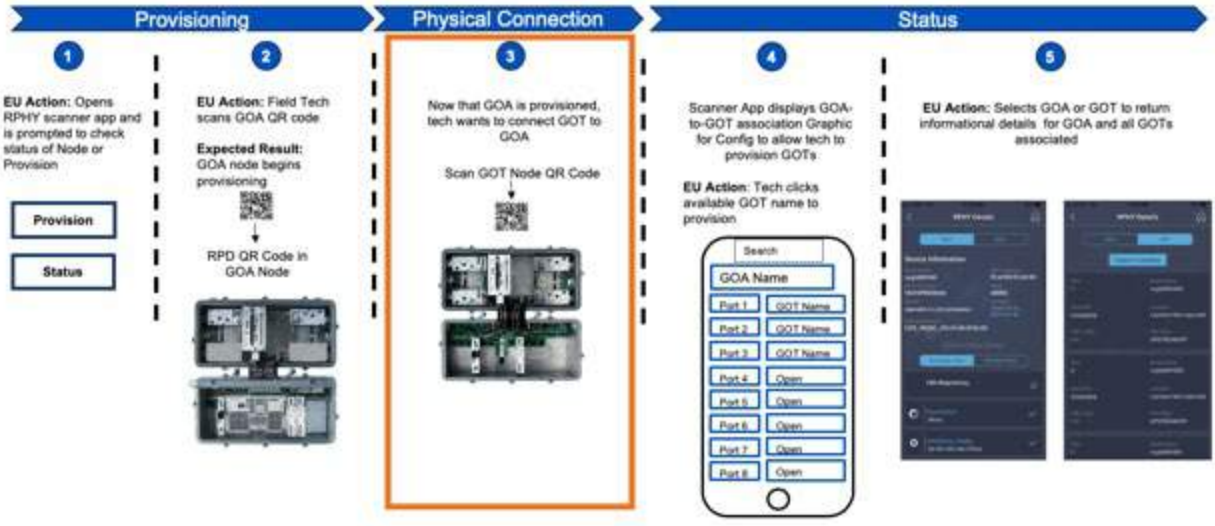

**Figure 14 – Provisioning Application Flow**

With a name available before the GOT is provisioned, the technician is prompted to take a picture of the GOT QR code. When that is done, the serial number of the QR code is matched against the serial number that is sent via the TLV. Assuming they both match, the Latitude/Longitude of the GOT position is stored and the node is declared provisioned. Thus, each GOT node is provisioned, its Lat/Long position set, its serial numbers verified, and it can start as a fully functional node in the GOA constellation.

## 10. "Grafana-ing" the Constellation

Grafana is a formidable tool that enables one to graph the performance of any device over time. As discussed, we get a range of US and DS RX and TX information along with data on the RF attenuations, in real time, every 15s or so. It should therefore be possible to slice that information and present it in a graphical form. Such a task is achieved in the 'GOA Constellation' part of Grafana as a read-only feature. This is especially helpful to see trends, identify intermittent issues, or perform historical comparisons (such as day to day or week to week).

**Figure 15 – Grafana and Real Time and Historical Constellation Information**

In Figure 15, the following can be seen:

1. Each GOA can be individually selected for viewing based on the PHE location or the node name The timeline can be varied as well.

2. The top portion of the dashboard shows the DSTX level in real time as a graph. The value is nominally 10 dBm, as we have seen before. Each of the DSRXs at each GOT are shown as well, and we know that the nominal values are -0.5 dBm. If, for any reason, the DS fiber were cut/disconnected, this would show as a disconnect and point to the issue.

3. The middle of the dashboard shows the USTX and the USRX data for each GOT. Here it is seen that the nominal value of the DSTX is ~-2.5 dBm and the nominal value of the USRX is ~-4 dBm, as can be seen in the drop-down list.

4. In the bottom part of the dashboard, one can see the RF attenuation experienced by the various ports. Recall that the GOA has 2 RF Ports, and each of the GOTs is treated as an RF port for purposes of attenuation, to identify and mitigate ingress. Here one can see the 8 GOTs undergoing RF attenuation, one after the other. Even though the attenuation is applied for a uniform time, the graph is limited by the resolution of the tool and the display and the time it takes for all the information to be collected.

This tool has been of utmost importance, as we have used it extensively to study the robustness of our constellation, especially as COVID raged across our country, with its unquestionable impacts on available capacity. Understanding these issues was impossible with direct observation. The vast amount of historical data is a perfect complement to the CM data and traffic data that is generally available and stored in other portions of the Grafana tool. This portion of tooling is vastly complex and not discussed further.

# 11. Orchestration and Association

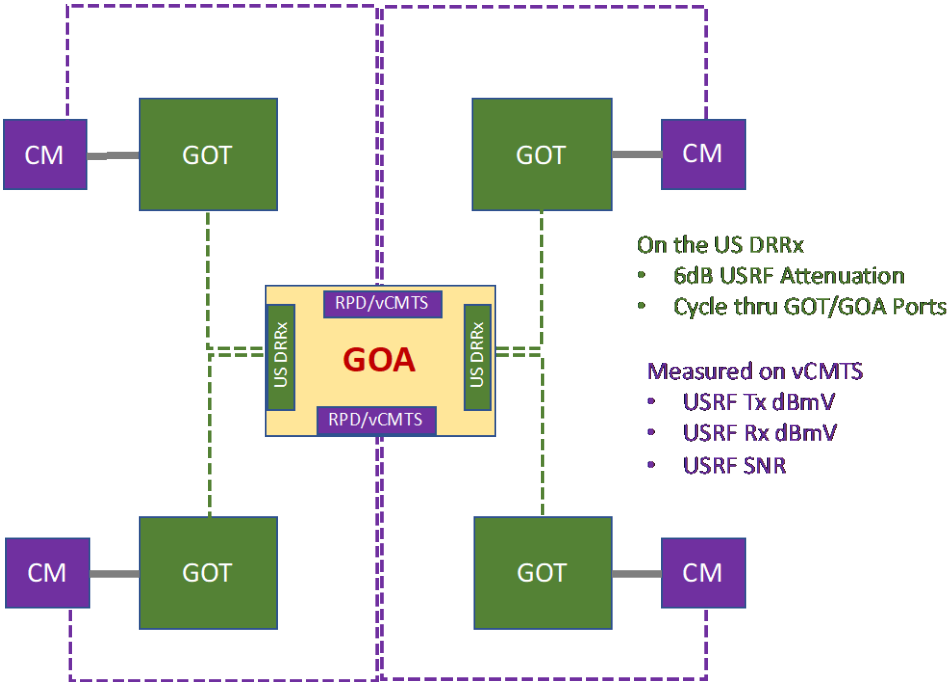

**Figure 16 – Illustrating the concept of Association and Orchestration**

It is common for the CMTS to know all the CMs connected to it, as well as the modem RF transmit power, the modem RF receive power, and also the RF receive power at the CMTS input. In this case, the vCMTS is expected to keep track of these parameters in concert with the RPD (since features of the CMTS have been distributed between these two by principles of virtualization described in the beginning). We have further seen that the GOA node knows about the existence and state of all the connected GOT nodes, and is aware of the optical DS input power, the optical US transmit power and the US received power. But since the US is a DRT/DRRx connection, changes in optical power do not affect RF power received power as long as the link is functional. Of course, we would not like the optical power to change because this will cause events. We will discuss how these are flagged and ticketed in Section 12.

In Figure 16, the situation described above is represented by the purple dashed lines connecting the RPD/vCMTS to the CMs, to signify that the US RF TX and US RF RX power, as well as the US RF SNR is known. In addition, the DS RF SNR and the DS RF MER is known. The green dashed line represents the connection between the GOA and GOTs via the constellation program described above. What we do not have is the knowledge of how the CMs are connected to the individual GOTs. Nor do we know if ingress exists, and if so, where it might be originating. Note here that even though the GOA itself is also connected to the plant, we have not depicted it, as a way of simplification.

The ability to map the individual CMs to the individual GOTs is called Association. To do this, we orchestrate 6 dB RF attenuation one after another on the various GOTs in the DRRx in the GOA node. This way, the RF levels of the CMs that are connected to the specific GOTs are raised by 6 dB, due to the long loop AGC of the CMTS in response to the attenuation. By keeping track of the US RFTX, US RFRX and the US RFSNR, we can pinpoint the CMs associated with individual GOTs, and also, by tracking the SNR improvements, we can pinpoint the magnitude and location of any ingress sources.

By way of explanation, we keep track of the baseline of all US RFTX, US RFRX and USRFSNR for each of the CMs connected to the GOA RPD. We then put in 6 dB attenuation on one of the GOAs, which will cause the RF levels of all CMs to rise by 6dB. Furthermore, we track if the SNR of the system has improved, and the extent of any improvement. All CMs that reacted by increasing their RF levels are associated with the GOT node. If the SNR improved, then said GOT is identified as an ingressor. We then rate this on a scale of 1-6, with 6 dB being the most egregious ingressor.

With proper verification, we have been able to secure 100% accuracy of the CM associations, in real time, remotely. Because DAA deployments tend to have RF transmit variables well within limits, we have seen very few (~1%) of CMs reset with changes in RF levels, and they come back online within the duration of the test, once the attenuation has moved away. We have also been able to track ingress events remotely, which was immensely helpful in the COVID environment. This is because technicians can approach the exact node and troubleshoot for ingress in the rare events that presented themselves during the deployment. This reduces their time in the field and reduces any associated virus exposure in customer homes. How exactly this is implemented securely, remotely and automatically is described next.

## 12. Secure, Remote and Automatic: RPD Life Cycle Manager

Enabling DAA is a complex operation. It not only required the vCMTS scheduling effort, but a similarly complex back office system to monitor and control various parameters that weren't normally visible or useable in real time. We described the provisioning application, as well as the traffic and connectivity managing application; next we described the process of using a complicated real time learning app that helps the RPD monitor and control the various parameters of devices connected to the RPD. We have previously indicated that the use of the I2C bus in the GOA node allowed us to be able to surface all aspects of the node to the RPD monitoring system. This system already exists with RPDs and has been updated to include the GOA-GOT system.

The RPD is controlled remotely via the RPD Life Cycle Manager Application (RLCM). This application identifies the RPD as a GOA. This then opens up a table with the various GOTs and their serial numbers and their latitude and Longitude information (recall that this is secured when the GOTs are provisioned). The App further maintains a list of all current CMs, and their state, as is expected of a CMTS. This is based on direct observation by the RPD/vCMTS and not based on inference of any sort.

The App has a soft button for association, which, when pressed orchestrates the 6dB attenuation periodically, using machine/logic in the cloud, and establishes the CM association and the ingress rating. A button allows one to download the data for further analysis. Currently this is an individual operation. The thought is to expand it for periodic data harvesting, and to use machine learning to understand the nature, frequency and magnitude of ingress. This will provide a lasting improvement to any cable system.

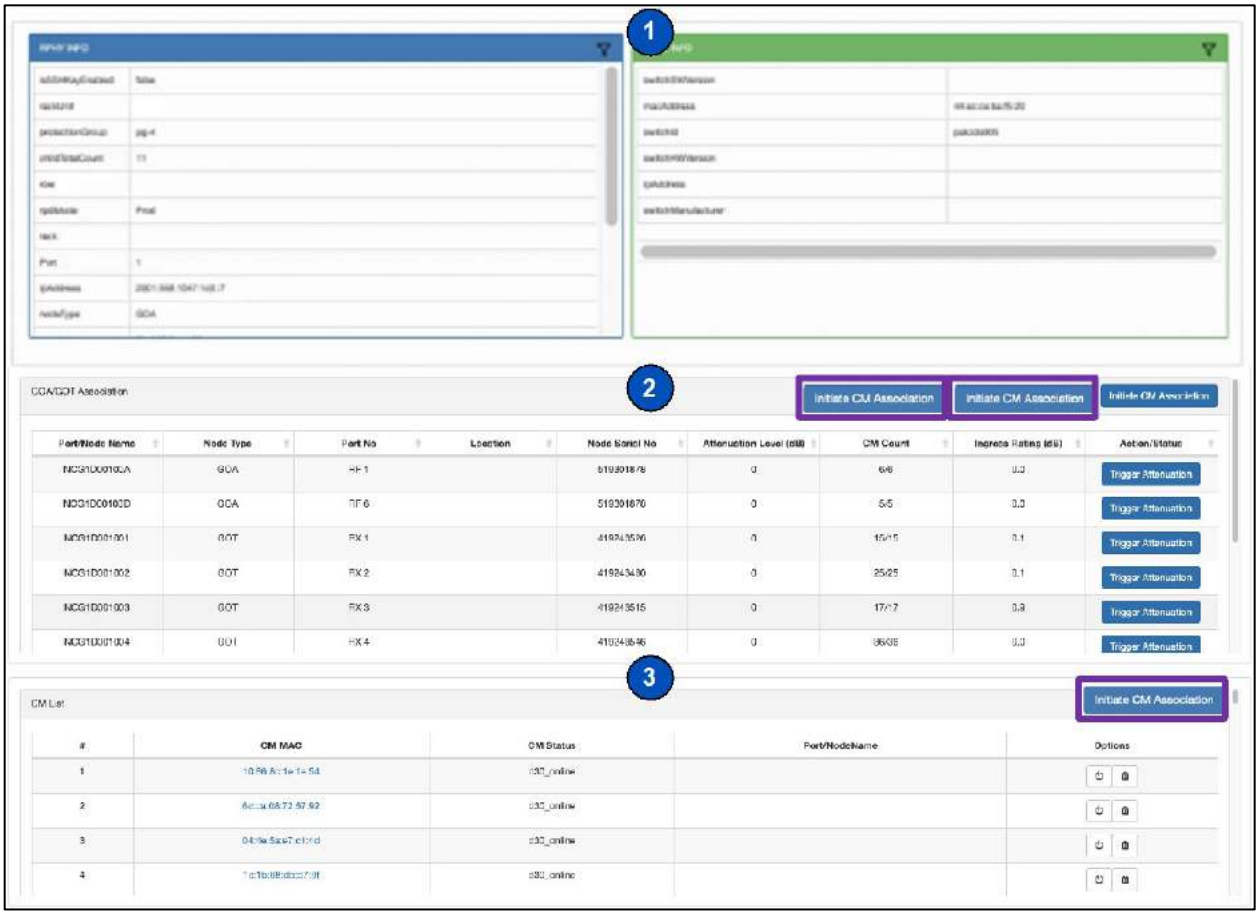

**Figure 17 – Association and Orchestration in the GOA RPD**

## 13. Eventing and Ticketing

The optical connectivity between the GOA and the GOTs is normally quite reliable, given that the fiber connections are typically less than a km. However, due to natural disasters and other events it is possible that the connectivity would get disturbed. If the DS and/or US fiber is cut, or if, for some reason, the GOT should lose connectivity to the GOA, it is imperative to identify the impacted GOA and GOT with a ticket to flag them for remedial actions.

It is, however, the case that information reaches the decision engine to call an event in multiple forms, all with delays peculiar to their content. If the fiber between the GOA and the GOT gets cut, the CMs go offline and this information reaches the decision engine via the vCMTS path. The fiber cut will also result in the GOA US RRX missing light on a previously lit receiver, which will then propagate this information to the decision engine. There may be outages attributable to power which could take down multiple nodes; this information reaches the decision engine via the powering network. Since outage information from various sources is arriving with various minor delays, if the decision engine begins reacting immediately, it will have reacted with insufficient information. Thus, to avoid this "race" condition, the decision engine "soaks" or stores all incoming information with various minor delays to look at it holistically.

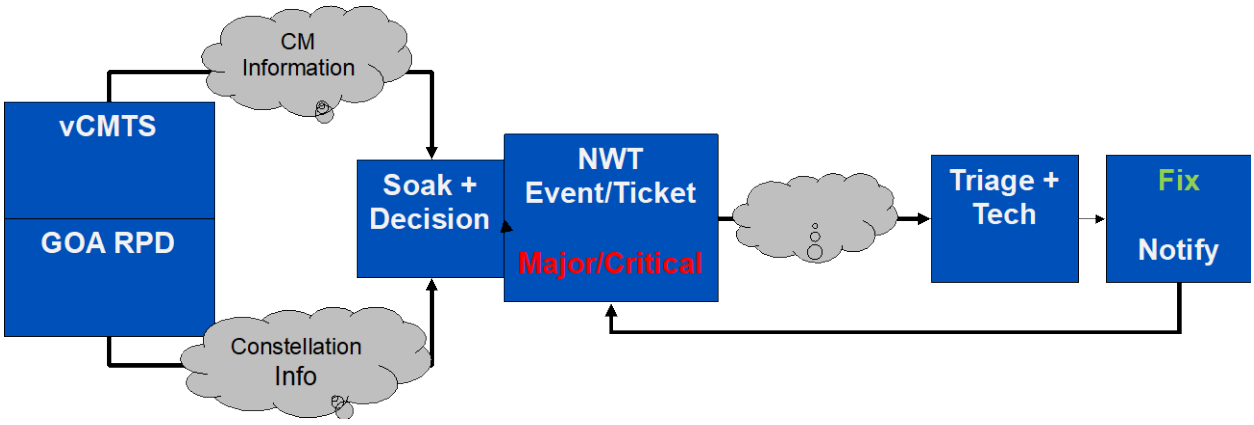

**Figure 18 – Automatic Eventing and Ticketing**

Having complete information from all sources, by inference and direct observation, the engine declares an informational/major /critical event, and an application such as National Watch Tower generates a ticket and sends it to the concerned division/headend/operations center. At the center, it is triaged and allocated to the technicians. All GOA-GOT outages are identified by a GOA and GOT node name and also the Lat/Long locations of both devices. This is to give as complete information as possible, to not only identify the devices, but also point out the likely fiber route that may have been taken. In the NWT, the GOAs and GOTs are layered, so that it becomes easy to match the outage to the map area.

Once the technician has fixed the problem, whether fiber cut or node maintenance or ingress event, the event is cleared by the technicians themselves. This way the node is brought back to an event-free state and normal operation resumes.

## 14. Future Steps

This year, we reported on the lessons learned during Comcast GOA trials and deployments. In addition to proving out the technology and cost benefits in the field and observing its stability, deploying the architecture also enabled us to interconnect and create an eco-system of remote monitoring and control of the various GOA elements. We will continue to report on our ability to continuously monitor Grey Optical Terminating (GOT) nodes, detect cable modems connected to specific GOT nodes and remotely identify and mitigate ingress in the GOA domain.

Many of the remote techniques were used during the COVID pandemic and can potentially be generalized further to enable remote monitoring and mitigating capabilities across the network. Furthermore, in the future we will report on recent work on bi-directional Coherent Optical modules that enable efficient extension of the architecture that, over a period of time, can create cost effective convergent and scalable ‘Switch on a Pole’ access networks.

## 15. Acknowledgements

It is our pleasure to acknowledge the entire team within Comcast who has been working directly and indirectly on the GOA project. A project of this magnitude benefits from the dedication of diverse expertise, from the hardware and software of the RPD team, the reliability and functionality testing of the Physical and Environmental team, the ticketing and alerting of the NWT team and the functional rules for deployment from the access engineering team for both ISP and OSP deployments. Special thanks to our

 

vendor partner CommScope for your insights. We sincerely thank the Senior Leadership Team at Comcast NGAN in supporting this project.

## List of Figures

## 1. Abstract

Today, the access fiber plant carries large amounts of varied data content deeper into the network. Analog wavelengths support traditional Hybrid Fiber-Coax (HFC) plant, 10 Gbps wavelengths support Distributed Access Architecture (DAA) network segments and other MetroE applications, while newer Coherent Optics modules support “Switch on a Pole” (SOAP) [1] type architectures. As use of the fiber footprint grows, so too will the need for comprehensive monitoring, to optimize the efficiency of access optical assets with the ability to inventory bi-directional wavelengths. These optimizations aid with capacity planning and to locate fiber cuts and other impairments across the plant, in real time, while identifying effective mitigation options.

For too long, such monitoring has solely been the purview of long-haul networks, but recent innovations in optical technology pioneered in part at Comcast enable automatic, continuous and pervasive monitoring of access optical assets without active user intervention. These cost-effective, switched optical devices, comprising an optical spectrum analyzer and optical time domain reflectometers modules, are co-located with access headend optics and continuously scan links to detect fiber cuts or individual wavelength outages. These headend tools are augmented with the same cost-effective optical measurement technology implemented in handheld meters for field testing. Headend and handheld tools together provide real time optical data to the cloud for data-analytics. Locating an access fiber-cut in real time, and automatically guiding the Comcast response team to its exact location, results in exceptional uptime, which enhances customer satisfaction -- especially in periods of disaster recovery.

In this paper, we begin with a description of the optical innovations and powerful techniques that enable this extraordinary tool set. We then describe the infrastructure that was stood up to intake, visualize and “event” this data, and detail our preliminary experience using this technology in the COVID lock down period. We will then venture into the future of continuous pervasive monitoring of access optical assets, and the positive impact such next-gen monitoring has on network robustness, which, in turn, enhances the customer experience.

## 2. Introduction

Readers will perhaps remember the popular public service announcement "It's 10 p.m. Do you know where your children are?" intoned before the nightly news. This was memorably used in a 1996 episode of *The Simpsons*, when Homer Simpson responds to his TV, "I told you last night — no!" And so it was with our fiber plant for many initial years -- as the plant grew in density and reach, then added multiple wavelengths for each fiber, we were often in Homer’s position, when it came to knowing where our wavelengths were, at 10PM or otherwise!

With improvements in technology and design, and as our long haul and back bone networks increased capacity and reach, we initiated programs to track and keep knowledge of wavelengths used, fiber cuts and impairments in the plant. With the advent of Remote Optical Add-Drop Multiplexers (ROADMs) and more sophisticated technology, this knowledge was now available, and in real time.

Comcast is one of the largest broadband providers in the country. Our network reaches from coast to coast. In total, in the U.S., our network comprises ~150,000 miles of fiber route miles, as shown in Figure 1.

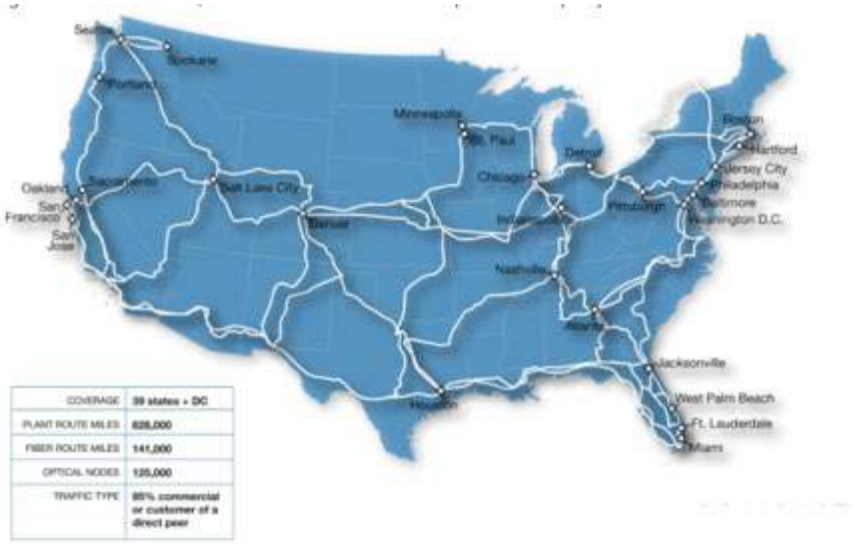

**Figure 1 – Comcast Long Haul Fiber Network**

Part of running a high-capacity backbone network is the ability to monitor and troubleshoot any outages and disruptions due to fiber cuts and/or equipment malfunctions. The larger the network, the more challenging this task.

Similarly, we run a very large footprint of Access Plant, covering ~55 Million Households Passed (HHPs), and illustrated in Figure 2. This access plant network (marked in dense Red points), also called Hybrid Fiber-Coax (HFC), generally has Cable termination to the end customers, but a vast majority of the access plant is also covered by Fiber, from the Primary headend (PHE) to the Secondary Headends/Hubs (SHE) to Fiber Nodes.

**Figure 2 – Comcast Residential Network Areas**

With new Distributed Access Architectures (DAAs), we anticipate the fiber content of this network to grow exponentially over time -- and by over 10x in the coming few years. With this huge growth in our fiber assets, it is now imperative to more tightly monitor and secure our high-capacity access networks as well.

In the remainder of this paper, we describe our efforts to create a hardware and software infrastructure that continuously and pervasively monitors our optical assets. We also describe how such monitoring can come in very handy during the present COVID environment, and likely in perpetuity.

## 3. Access Architecture

Figure 3 presents a highly simplified connectivity model for our access architecture. In big markets, we typically have a high availability fiber back bone linking the Primary Headends (PHEs). These are typically connected to Secondary Headends (SHEs) via a redundant route. Often the SHEs themselves are arranged in a ring connected off of the PHEs, also with redundant fibers, which then connect to individual fiber nodes.

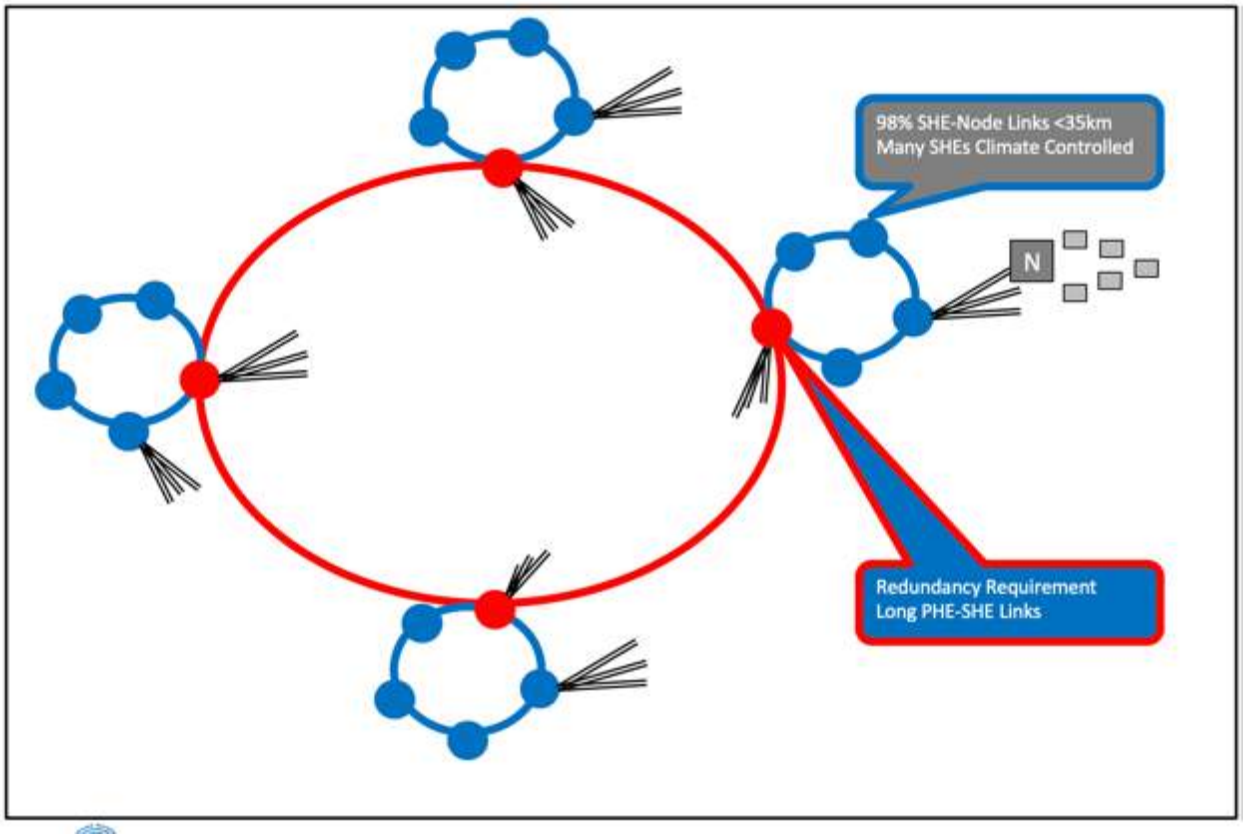

**Figure 3 – Simplified Connectivity Diagram**

Typically, the PHE network is supplied by high speed (such as coherent 100G-400G) links which have levels of monitoring for all optical wavelengths in use, and capabilities for locating fiber cuts or impairments.

As can be seen, for each PHE, there are several SHEs -- and for each SHE, there are a lot of nodes. While the SHEs are connected directly to the PHE with redundant routes, the nodes are directly connected to the SHE with straight fiber connections. Thus, the access plant has a lot more optical connections. Even considering the coaxial plant exiting the fiber nodes, the sheer amount of fiber links in the access plant is much greater than what exists in the long-haul plant.

With the Distributed Access Architecture (DAA), each of the parent nodes is now connected via fibers to multiple nodes within its footprint. We anticipate that the fiber plant will grow exponentially in the access domain.

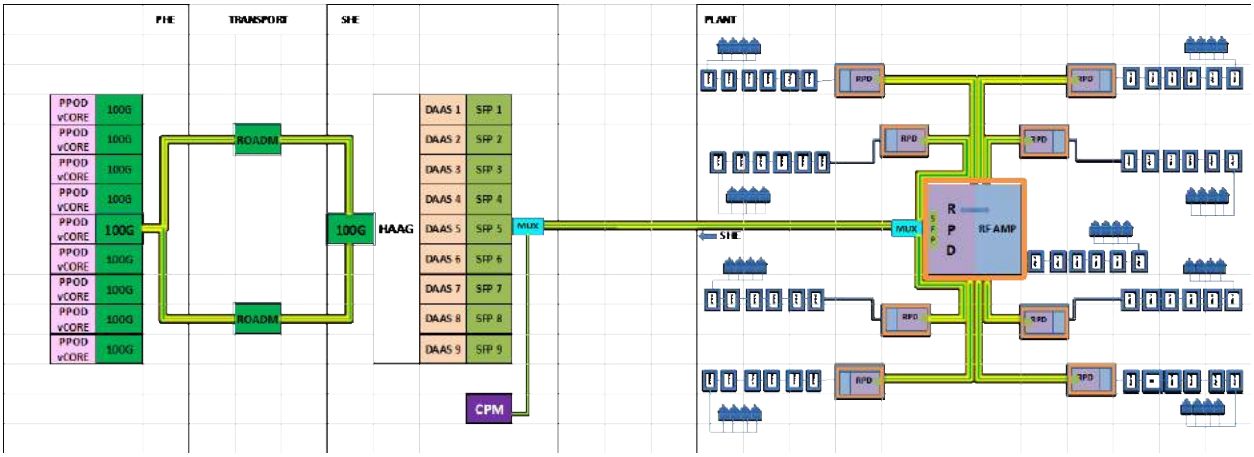

**Figure 4 – End to end DAA Architecture Diagram**

In the DAA architecture shown in Figure 4, PHEs would contain all of the virtualized CMTS (vCMTS) cores, connected to the SHEs through redundant routes to DAA Switches, and then via SFPs to the individual Remote PHY Device (RPD) nodes. These RPD nodes are connected to individual homes across coax. The return circuit is connected back via the RPD node to DAA Switch (DAAS) and then through to the vCMTS in the PHE.

Several other vCMTS-based architectures are in the process of being deployed and worthy of mention here. In one instance, the RPD is itself within the SHE and an analog link connects to the fiber node in the field. In this case, the trunk fiber would use Dense Wave Division Multiplex (DWDM) wavelengths on the 4 Wave Mixing mitigated plan (aka the “Full Spectrum” [FS] plan.) The reverse path typically uses baseband digitized return links (BDR links). In this case, the monitoring requirements would not change, but rather move to monitoring the analog links that have thus been established.

In other variations, the RPD node would still be in the field, but would encompass additional passings. This could be because of an internal split (such as 1x2 or 2x4), or due to RF amplifiers that exist in the plant. In this case, we have a need to monitor the digital links as described earlier.

In yet other variations, we may have analog nodes deeper into the plant with no RF amplifiers. These would have the downstream (DS) on analog FS plan described earlier but would have separate fibers for the upstream. What complicates the situation further is that these links have asymmetric US and DS wavelengths per fiber, thus resulting in asymmetric DS and US fiber counts. And the need is still to monitor these fiber links with a view to know individual node connectivity and inventory fiber capacity.

The vast majority of nodes, though, are the regular HFC nodes that are connected to the headend with either a single WL, or with multiple WLs on the FS plan, with US WLs sometimes on the same fiber, and sometimes on other fibers. All in the need of fiber monitoring for connectivity.

It is easy to see here that the sheer number and the variety of links present a unique opportunity for operators like us to improve further on our network availability to the node and prepare for the future. The difficulty has thus far been the cost of getting said monitoring developed and in place, plus the intensive manual nature of troubleshooting, which is discussed next.

## 4. Fiber Connectivity and Inference

An outage, particularly a suspected fiber cut, instantly calls attention to a wide variety of resources in Comcast. With advanced internal tools like National Watchtower (NWT), we are able to know within minutes that individual Cable Modems have lost touch with the CMTS. The inference engine in the NWT can identify a problem node, to which trouble tickets are then generated for workforce management. If the whole node is out, then chances are high that a fiber may have been cut, heavily impaired or involved in a utility power outage. An optical time domain reflectometer (OTDR) is pressed into service to determine fiber connectivity, after a quick check that the return light is absent at the headend. The OTDR reveals a fiber cut, which is then located using a Geographical Information System (GIS) and fiber plant data. Then, a crew is sent to the spot for repair. When they get there, the restoration duration depends upon the number of fibers to be re-spliced.

In such cases, it is quite possible that the fiber sheath that is cut could also house a number of fibers, some of which could serve multiple non-residential services, such as Metro Ethernet (Metro E) or other business services, all managed by Service Level Agreements (SLAs.) Sometimes, especially if the fiber cut location is inconclusive, field technicians have no choice but to OTDR the fiber backwards, to further attempt to locate the cut. This adds both time and frustration. After the cut is restored, fiber plant is put back and the ticket cleared.

If, however, the node is affected, but it is not due to a fiber cut (which is known after an OTDR shot is taken), or if other nodes known apriori on the same fiber are unaffected, then, without a power outage, the dispatch instructions for the node would be to replace its optics/RF components. All of this information is available in multiple places, and the amount of time effort and energy it takes to communicate effectively when responding to such incidences continues to improve, steadily, as tooling and integration improve. However, this is still a logical step in addressing the above need and improve the customer experience further.

## 5. Current State of the Art

Although technology has improved in major ways, and costs have come down, the current state of the art in mobile optical spectrum analysis and fiber connectivity is still quite expensive and localized. It is not unusual to see major equipment at headends and equipment moved around as needed. In an effort to lower cost, optical channel checkers have proliferated that enable us to measure individual WL power values. But these do not have integrated OTDRs. Many in the optical equipment manufacturing community now offer modular OSA and OTDR models -- but adding too many modules make the equipment bulky, and having fewer slots requires module swaps, which can be an issue in the field.

Since most of our access network footprint is in the 1550 nm region, using a standard 1550nm OTDR would not enable live scoping of the fiber plant since the OTDR light pulses could interfere with the smooth functioning of signals if the wavelengths coincide. Thus, this becomes used only in known or suspected fiber cuts or impairments. Mobile tunable 1550 nm OTDRs are a great innovation and could be used in live plant on unused channels, but we would need to apriori know that those channels are not in use. In addition, care must be taken in their use, to avoid damaging connected SFPs at the far end, because of damage or impairment to Avalanche Photodiode (APD) receivers in SFPs.

While channel checkers built with a filter/photodiode combination would track power levels, they will not be able to track wavelength movements, which can sometimes occur in the plant. Furthermore, it is not uncommon to use non-ITU wavelengths in the plant, such as when a broadcast transmitter is deployed in an overlay system. Comcast developed an architecture option for grey optics aggregation (GOA) that, as the name implies, uses Grey Optical Transmitters, where the transmitters are in the 1550 nm region without them being on any one specific ITU wavelength. In such cases a channel checker is insufficient and an OSA function is needed.

In a different paper [3], we discuss a more general convergence model at Comcast, where multiple services are all combined together on the same single fiber bidirectionally. In that model, analog DS WLs along with BDR signals of varying speeds, 10G RPD node connections, 10G Metro E connections, and 100G connections are all multiplexed on the same fiber.

## 6. Pervasive Monitoring Paradigm

Our thought process for continuous and pervasive monitoring began with three fundamental insights:

1. Use of commercially available components to cost effectively monitor individual wavelengths and to detect fiber cuts across the access plant
2. Continuous monitoring of all optical assets, using only test ports, without impacting the fiber reach of the access plant
3. Pervasive monitoring of optical assets in a cloud-based environment is essential to efficient correlation and problem resolution (as opposed to targeted stand-alone solutions.)

To elaborate further, it is observed that OSA chips are widely used in ROADM applications. Cost effective and plentifully available, these chips used in ROADMs in the test port path could enable us to view optical wavelengths in real time. Many of these chips have a ~500ms scan time for the entire C-Band, and function from ITU 14 thru ITU 62 range, which makes them capable of detecting and showing WLs regardless of being on the ITU spectrum.

Selecting an OTDR of 1611 nm enables cost effective fiber connectivity information over live plant. Furthermore, 1611 nm Coarse Wavelength Division Multiplexing (CWDM) optical passives are cost effective and plentifully available. Additionally, single mode optical fiber is weakly guided and much more sensitive to micro and macro bending losses at 1610 nm (than it is at 1550 nm), so that "fiber choking" described earlier is seen much earlier than on the signal. 1310 nm is much stronger guide and has higher losses over fiber, thus is less suitable than 1611 nm for this purpose. We also selected 1611nm vs. 1620 nm due to the more widespread availability of optical passives at this region, and the fact that we generally do not use the 1611 nm window in the access plant (except in FTTH/RFoG deployments). We have already indicated that a standard 1550 nm prevents live channel OTDR and violated our rules of pervasive and continuous use, thus deeming it unsuitable. A DWDM Tunable OTDR would be much more expensive and require spare ports, and therefore that option was also not selected at this time.

Even with cost effective and capable OSA and OTDR options, we still required additional insight into making this technology pervasive in general operating conditions. That insight led to the use of an optical switch, to enable a "round robin" perpetual scan of the multiple fibers in the access plant. As described earlier, the fibers from SHE to the node are multiplexed at the SHE and demultiplexed at a field location, then feed individual nodes. Several such links exist in the SHE -- typically one may see up to 128 fiber links in each SHE. Therefore, the ability to have a 48-port switch that can connect to the test ports enables us to cost effectively deploy the OSA and OTDR functionality over up to 48 links. This concept is shown in Figure 5.

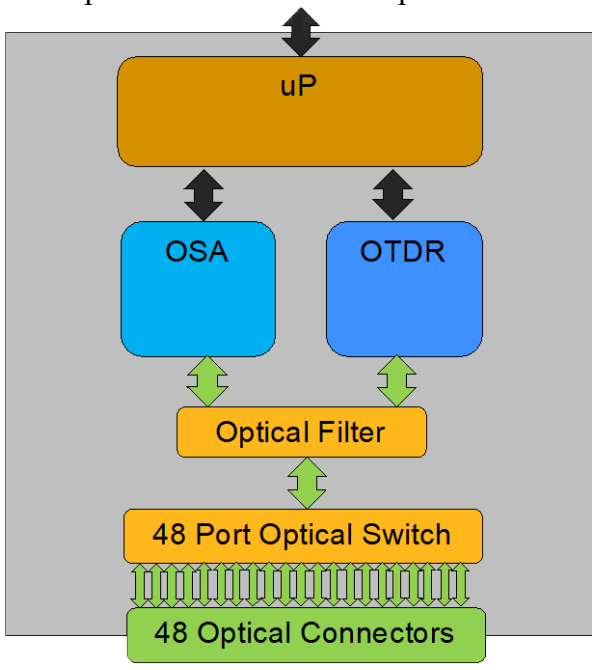

**Figure 5 – Highly Simplified view of the Continuous Pervasive Monitoring Tool**

As an aside, it is common to see fiber counts in multiples of 12 as opposed to in powers of 2, perhaps because 12 has many factors that make it convenient to divide a fiber's route after the fact. In any case, we extended this number of wavelengths available on optical passives to up to 48. Therefore, it is possible that one OSA, OTDR combination behind the 48-port optical switch to survey 48x48 = 2304 WLs, which can translate to 1152 optical WL pairs or nodes.

With this background, a pervasive monitoring tool was built, as described next. We began by selecting an appropriate OSA chip currently used in ROADMs with sufficient resolution (say 6.25 GHz). Typically, these are built using temperature-sensitive elements with a calibrated receiver that has a well-established relationship between temperature, wavelength passed and photodiode responsivity. This way, the whole C-Band is scanned, and power at each step classified within ~500ms. Tying up the OSA component to ROADMs gives us a reliable and sustainable way to ride their wave of cost effectiveness and performance enhancements. OTDRs function by sending out a series of pulses, receiving echoes, then analyzing the delay in the echoes to estimate the points of reflections. There is a fair amount of ambient reflection in fiber, due to Rayleigh scattering, and OTDR sensitivity is typically improved by higher laser power. The higher the laser power, the more the reach and the better the echo received back that enables one to estimate reflections. Sensitivity also improves with using an APD receiver vs. a PIN receiver. Finally, care must be taken to reduce any immediate initial attenuation, and therefore it enhances the launch power into the fiber and consequently improves sensitivity. It must be noted that all OTDRs have an initial dead zone that prevents identification of specific fault locations in close proximity to the OTDR itself. In our case we typically set fiber monitoring after about 250 m of the OTDR, which comfortably exceeds our dead zone.

Figure 6, reproduced with permission from Corning, shows the relationship between wavelength of operation and its effect on micro and macro bending losses for standard G.652 fiber (lower macro and micro bending losses are achievable using the ITU G.652D compliant fiber). Notice that the macro bending losses are low when the wavelengths are below 1400 nm due to exceptionally well guided light there. Also, notice how the losses are higher at 1550nm, but the losses increase dramatically past the 1550nm area. The micro bending losses also increase with wavelength, but the delta is rather limited.

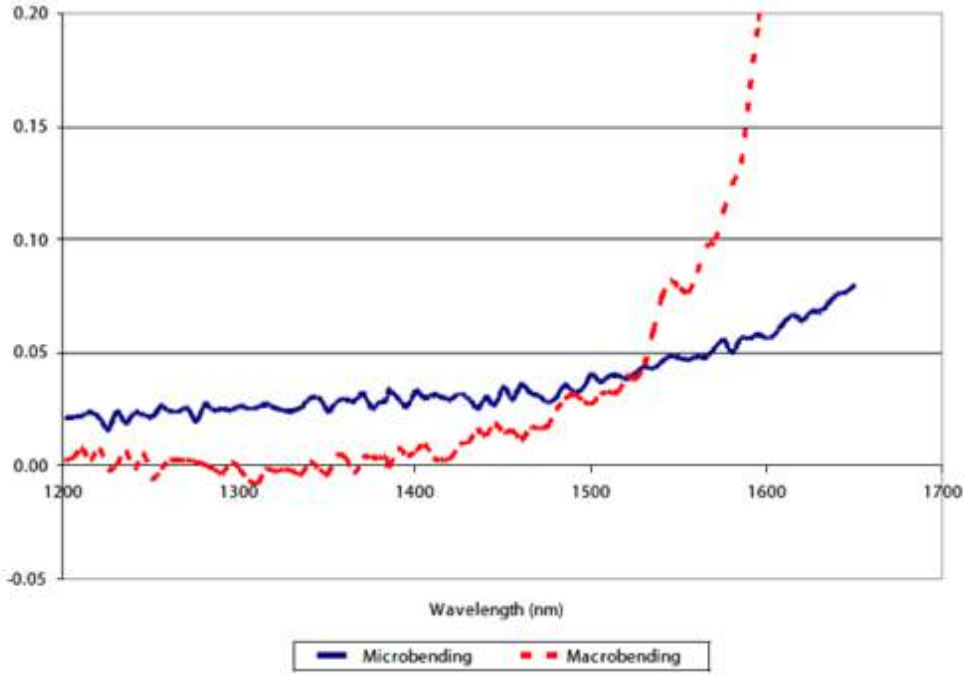

**Figure 6 –Micro and Macro Bending Losses for ITU Rec G.652 Fiber**

A typical New England winter brings with it a freezing cold followed by a thawing cycle repeated over several months. Over time, many of the splice boxes get filled with water and "choke" the fiber when frozen. This can attenuate fiber significantly, sometimes disabling a link. Unfortunately, this usually happens at inopportune times, the weather being bad and all, and resolving this issue has been a bugbear. Fortunately, the selection of 1611 nm enables us to see the drop in light levels as an event far earlier than we would have seen on the signal itself. This is because the fiber weakly guides 1610 nm and more strongly guides 1550 nm. In fact, it guides 1310 nm much more strongly, which is why it is a poor candidate for OTDRs wavelengths -- besides the fact that the fiber loss is much more at 1310 nm, and for that reason also has poorer sensitivity and reach.) Higher sensitivity in the OTDR not only enables one to scan longer reaches, but also to make out individual losses in the fiber path, attributable to bad splices or micro- and macro-bending.

The time required for OTDRs to declare a fiber length is typically dependent on pulse widths, anticipated fiber lengths and the number of averages needed to get a clear idea of the fiber distance. This computationally intense process could easily exceed one minute and sometimes takes several minutes. Since we need to be able to scan in round robin fashion through 48 individual ports, the dwell time in each port would need to be multiplied by 48 in order to calculate the maximum time before a fiber break is identified (for sticklers of accuracy, one must also take into account the switch time, which is ignored for the moment.) Even a 1-minute dwell time would require 48 minutes before a fiber cut could be declared. In fact, this is a major difficulty that limits very drastically the number of ports realistically used.

For the pervasive monitor, we set up a target of declaring a fiber cut within 3 minutes for any one of the 48 ports. Our effort began with a commercially available OTDR module that offered the right set of optical specifications for our application but required more time than we had budgeted for our polled-scan method of monitoring the optical links. After some consideration of the OTDR requirements, it was clear that moving some of the digital signal processing from the original FPGA-based soft-CPU, to the high performance ARM used in the CPM, and increasing the data transfer rates at a key point in the OTDR module, yielded significant speed-up in the scan time. Only minor rework of the OTDR hardware was needed to implement this. Systematically understanding the computational requirements, the time of exporting the data for calculations, and then to convey the computed result, along with any events (more about that in a bit) enabled us to reduce the dwell time to just under 3 seconds! Furthermore, the OSA and the OTR could run simultaneously and independently on live plant. Thus, we are able declare any wavelength outage or fiber cuts within a maximum of 3 minutes across the plant. This massive and substantial improvement truly enables us to understand our plant in real time.

As described above, enabling the OSA and the OTDR to operate independently requires a new set of optical passives that have sufficient isolation and minimal insertion loss to enhance sensitivity across the board. This is described next.

## 7. Role of Optical Passives

Architecting a pervasive monitoring infrastructure requires one to follow the fundamental rules laid out in earlier sections. It requires not only the ability to accommodate existing, set optical passives and access architectures, but also to define reference optical passives and architectures that can be better served. To this end, we have specified new sets of optical passives with consolidated test points.

Typical optical passives have had multiple filtered ports that either take in or put out ITU WLs. Then they have a COM port that combines these to launch on the optical fiber. WLs within the ITU range but that are not used in the Mux are typically available in the Upgrade port (UPG), whereas wavelengths outside of the ITU band are available in the Express (EXP) port. Typically, a test point for forward wavelengths is available (TPF) as well as a test point for reverse WLs (TPR).

Use of optical passives of this kind typically is less than optimal for pervasive monitoring. To peer in the network at 1610 nm, one would have to use the whole of the EXP; to check on outgoing WLs, one would have to use all of the TPF, and for the return WLs, the whole of the TPR. Doing this would require 3 ports on the monitoring tool, but more importantly it eliminates the future ability to add out-of-band wavelengths to the link, and requires manual troubleshooting, should the need arise, by the using TPF or TPR, since they are all connected to the tool. While this already considerable base of passives can also be monitored subject to the limits discussed, we opted to define a new set of optical passives to improve on this efficiency in a significant way.

Furthermore, optical switches are typically used for one WL at a time, and typically to direct light from one end to the other. Since all but one port is active, interactions between ports that are not in the optical path are generally not taken into account to build inexpensive switches. In our case, however, ALL ports that are lit on the switch are lit, which can cause unintended interaction between unrelated ports that are not in the intended light path. This is a fairly complex subject and not discussed further, but fortunately, optical passives can be designed quite easily to avoid this crosstalk issue altogether.

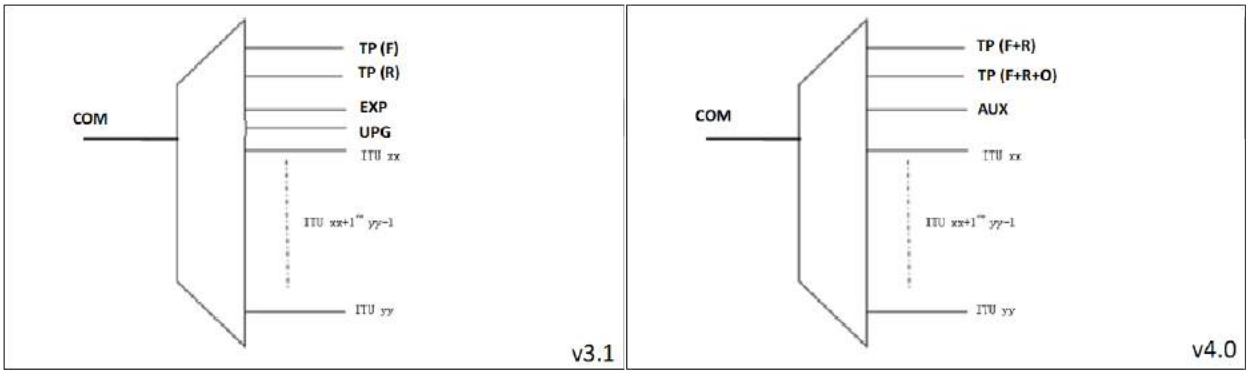

**Figure 7 – Optical Passives Old and New in Comcast**

The new standard of optical passives in Comcast today have consolidated test ports so that manual troubleshooting, if needed, can occur independently of pervasive monitoring. This is accomplished through an innovative optical filter design that consolidates the forward, reverse and 1610 nm part of the optical spectrum in one test port called TPFRO. The manual troubleshooting port is a consolidated forward and return test port called TPFR. The remaining optical wavelengths in EXP and UPG are all together combined into one consolidated Auxiliary port (AUX), which extends from 1260nm to 1598 nm (excluding the water peak WLs). This patent-pending concept is shown in Figure 7.

To enhance density as we prepare for the access growth, we have moved towards very small form factor (VSFF) connectors. These connectors can enhance deployment density, which is always useful in cramped PHEs and SHEs, thereby making space for pervasive monitoring tools.

## 8. Infrastructure Evolution

The Continuous Pervasive Monitoring tool (CPM) is implemented as a 1RU box that comprises the OSA, OTDR, 48-port optical switch and associated power supply and processors. As discussed, the processor must be fast enough to process fiber lengths, put out events, process the OSA and analyze wavelength information within the dwell time. The high reliability 48-port optical switch typically switches from port to port within 100ms. Therefore, within about 3 minutes (180 seconds), one can process up to 48 optical links, confirm their integrity as well as process up to 2034 wavelengths and confirm their well-being. It’s a good time to be a fiber wavelength.

**Figure 8 – Actual Comcast Installation of the Continuous Pervasive Monitor**

As shown in Figure 8, the CPM is connected to the headend optical passive test points, which are then connected to DAAS ports. Figure 9 shows a typical SHE layout that accommodates the CPM.

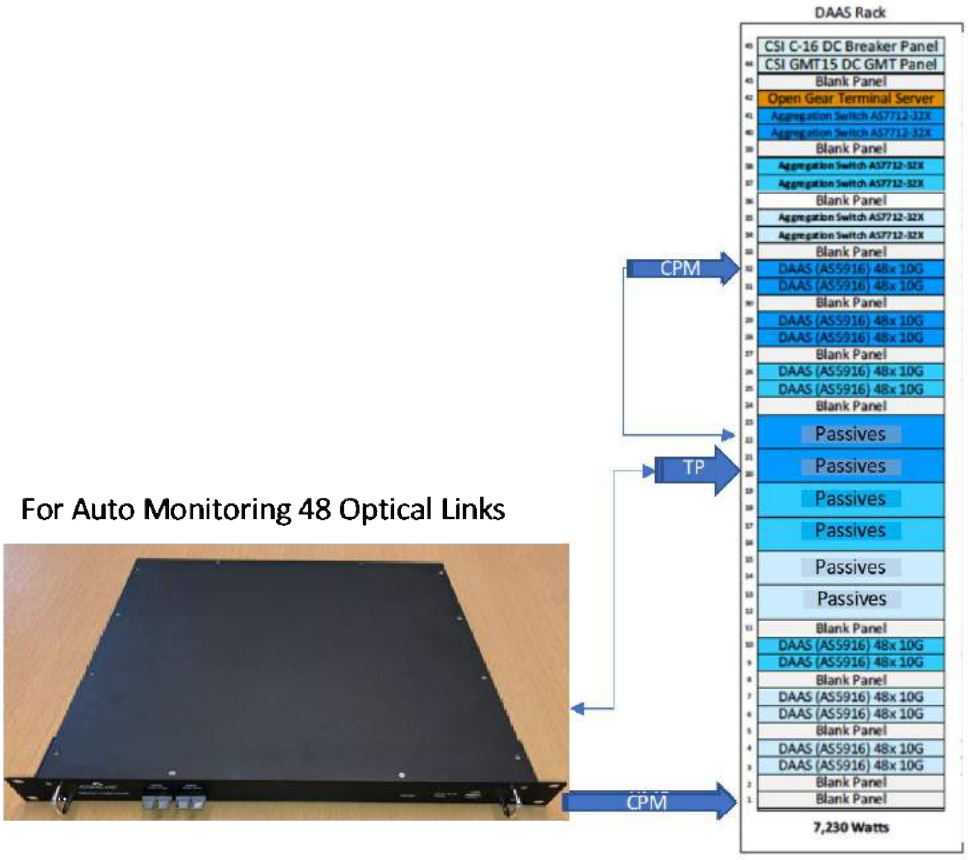

**Figure 9 – Describing the DAAS Pod and the Monitor**

As indicated in Figure 9, the (Continuous Pervasive Monitor) CPM is typically set up in the SHE alongside the DAAS pods. These pods were well defined and have their own power supply panels, aggregating switches if needed, and DAAS switches, along with optical passives, in one compact location. The DAAS pods connect to the vCMTSs that are typically located in the PHEs. From 192 to 576 service groups (SGs) may be served with one DAAS Pod. The CPM is thus exceptionally well suited to monitor each of these DAAS pods and additionally handle any additional service that may be typically lit up in the SHE.

Typical SHEs may contain DAAS pods, many MetroE service groups, some traditional analog links and the incoming high capacity coherent links. Some SHEs are co-located with the PHE (they are called direct feed links), while many are small, single room discrete locations within the footprint. Some of the SHEs could be smaller and be accommodated in large air conditioned cabinets.

Widespread use of CPMs in the system will also help with SLAs in MetroE links and enable us to enhance the customer experience for both residential and business services. As such, even though the CPMs are never in the signal path, they still undergo a stringent Physical and Environmental (PnE) evaluation process, to assess their suitability of existing in SHEs and

meeting the demanding standards of our field equipment. Furthermore, as will be seen in the following section, and since they are going to be connected to our network, they undergo a rigorous security audit to ensure that there are no open ports, and that their connections are secure. It was surprising to see how quickly open ports are pinged by untrustworthy IP addresses, within hours of installation, making one feel glad about the security process in place.

## 9. End-to-End Optical Architecture

We have so far described the process of building innovative and cost-effective monitoring equipment, and some of the infrastructure, such as optical passives, that enhance its usefulness. Creating a physical infrastructure is one thing, but creating an end-to-end software infrastructure based on the third insight -- to take the promise of pervasive monitoring -- and turning it to reality is another substantial endeavor, and demonstrates the great opportunity to bring complex ideas into existence.

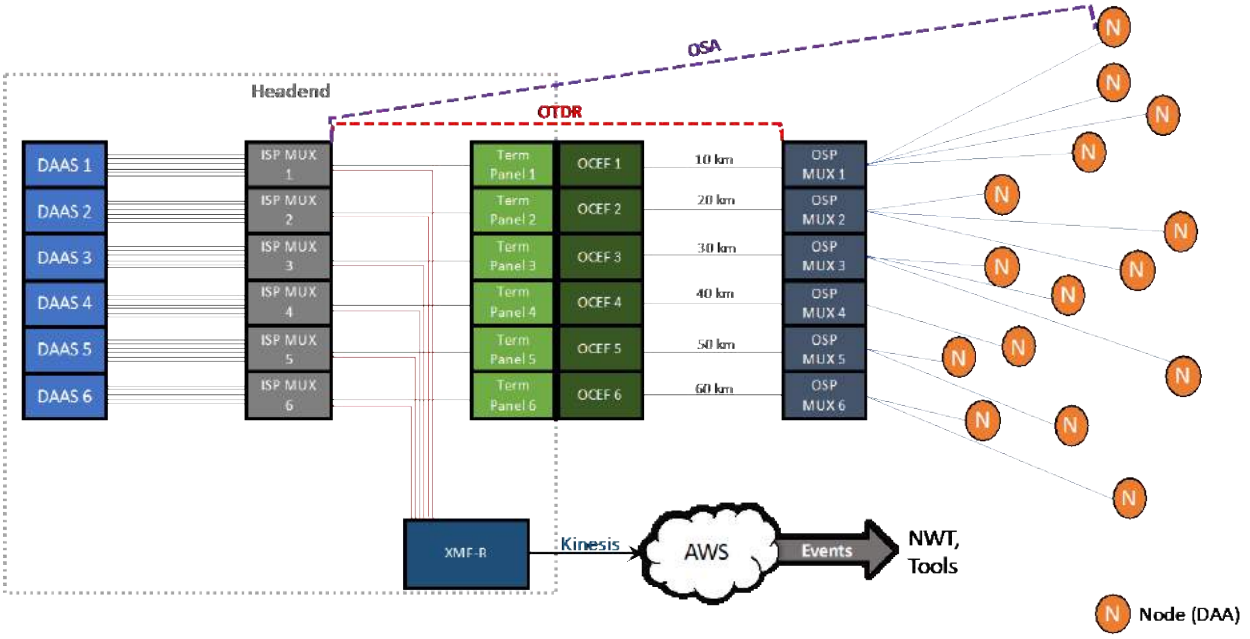

**Figure 10 – End-to-End Software Paradigm**

Figure 10 shows an end-to-end architecture in the context of our DAA architecture. As explained earlier, in the SHE, DAAS ports are connected to respective optical passives. Each DAAS port is logically connected to one optical node in the field and comprises two wavelengths, one downstream and one upstream. We also now use tunable SFPs in DAA applications that are typically spread from ITU 14 thru ITU 61. The light from multiple DAAS ports is multiplexed at the optical passives and is then connected to a termination panel in the SHE. This termination panel is the demarcation point between the SHE and the outside plant. Each fiber that goes to the outside plant has one optical connector on the termination panel. The termination panel fiber then passes thru a large conduit, called the Optical Cable Entrance Facility (OCEF) to the outside plant. Once outside, fibers are distributed according to plan to the various nodes. In our DAA

architecture, we use only one single fiber for US and DS operation. This makes the process of keeping track of fiber easier. With modifications, architectures that envision separate US and DS fibers can also be similarly monitored.

Typical Comcast links could be as long as 60 km, although the vast majority of our links for this type of architecture are around 30 km. After traversing the distance from SHE to node thru several splice enclosures, the fiber reaches the outside plant (OSP) mux. The fiber route is contained within our GIS systems, in special software entities such as SNET or Bentley.
As the fiber makes it way to the OSP Mux, we recognize that its weight causes the fiber to sag between poles in aerial plant. And, every 1,000 feet or so, about 150ft of slack cable is maintained to aid in fiber cut restorations. Finally, as the fiber is lashed, the lashing wire envelops the strength member in a helix pattern. Combined together, these three factors contribute almost 20% extra linear fiber, as compared to the ground distance on maps. Many GIS systems take this into account, however there is an opportunity to re-verify and fine tune these numbers using the CPM devices.

In the OSP Mux enclosure, the individual wavelengths are brought out and fibers connected to support each node. Since the OTDR is a 1610 nm OTDR, once we reach the Mux, and the individual wavelengths are separated, that also ends the OTDR's ability to peer any further into the network. Therefore, the OTDR system provides continuous monitoring from the Inside Plant (ISP) Mux to the OSP Mux. Farther from the Mux to each individual node are set two fibers, one for US and one for DS, and these are terminated in the node to the SFP. This SFP receives the optical input from the DAAS port SFP and sends out light to be received by the DAAS SFP, thus completing the circuit. Notice, however, that unlike the OTDR, the ability of the OSA to view DS and US wavelengths is unaffected. It is able to record all wavelengths that traverse the fiber. Thus, a combination of OSA and OTDR provide a continuous and end-to-end view of the entire DAA network.

In keeping with our objectives, the CPM is connected to the TPFRO test point of the ISP Mux. The CPM is thus in a great shape to dwell on each one of its ports, measure the input and output wavelength values and their power values, independently measure the fiber link, and record any events on the fiber link. Using the fast processor with the unit, any event information can be uploaded to the cloud.

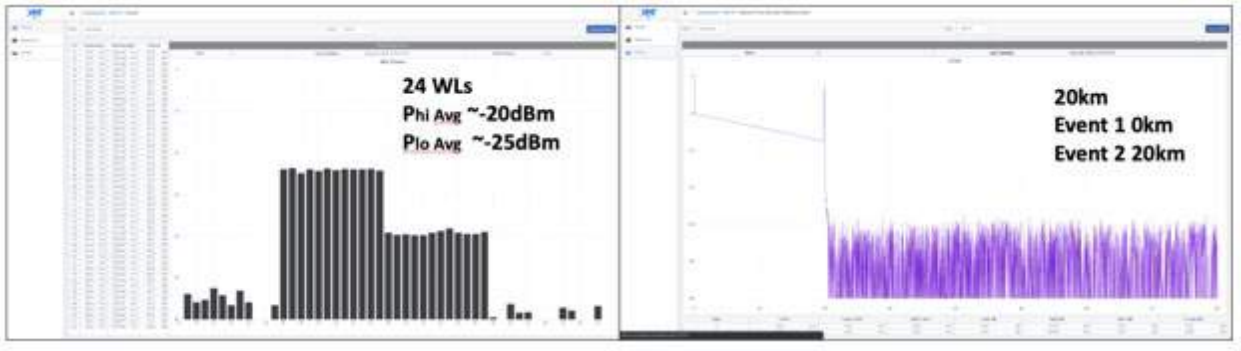

**Figure 11 – Sample view of the OSA and OTDR Output for each port**

## 10. Praemonitius est Praemunitious (Forewarned is Forearmed)

While information is uploaded to the cloud continuously, it is also used to train the monitor. This step is described later in the paper. Any changes to the optical levels or to fiber events are then reported via the automatic feed (called Kinesis) to an eventing engine that connects to a sophisticated internal resource called the National Watchtower (NWT).

Since outage information from various sources arrive at the decision engine with various minor delays, if the decision engine begins reacting immediately, it will have reacted with insufficient information. Thus, to avoid this "race" condition, the decision engine "soaks" or stores all incoming information with various minor delays to look at it holistically [4]. Then they are brought up as one unified ticket with actionable data and sent to respective locations. Ideally, if the contents indicate a fiber cut, these are also laid out on the GIS, and a street address location is also provided, in which case the repair crews also have a specific location to head out to. For this reason, slack/sag/helix and other such parameters are estimated from the appropriate databases to ensure a level of accuracy.

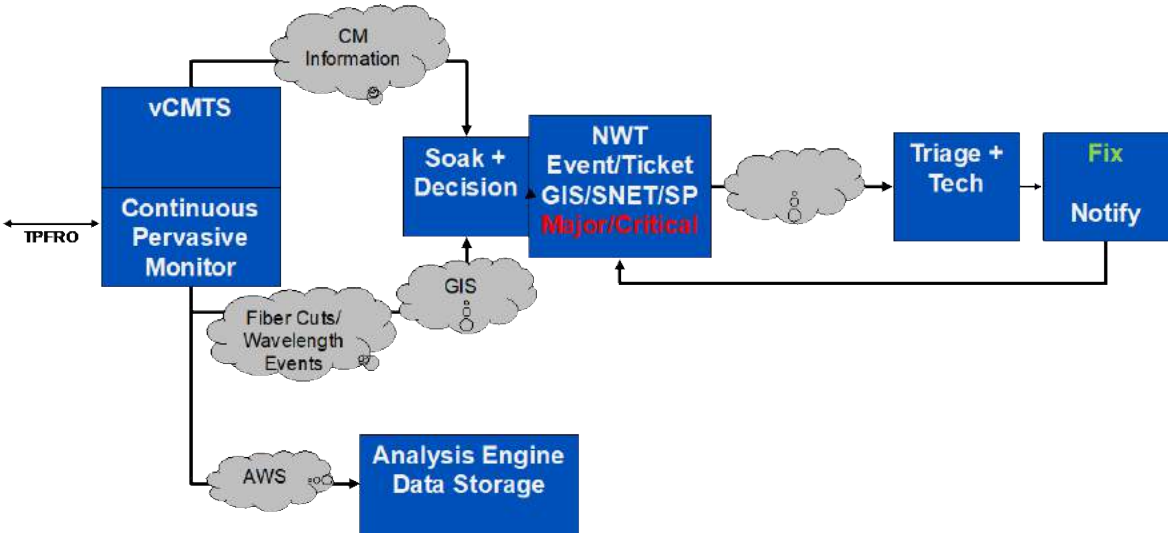

**Figure 12 – Sample view of the OSA and OTDR Output for each port**

We began this paper by noting the energizing effect of a suspected fiber cut. This process not only establishes the said cut, but also provides a specific location in almost real time. In Figure 12, it can be seen that the events are sent to the decision engine for handling related to ticketing from the CPM. To aid in fiber cuts, we also estimate the distance of the fiber cut and its relative location based on sag/slack/helix and compared to the GIS. At the decision location, this information is soaked and compared to other information also flowing, to avoid race conditions. At the NWT the ticket is generated with an appropriate alarm level, and the location of the fiber cut/node location is then sent to triage and to the technician. The problem is then fixed, and the tech clears the issue.

While events are sent to a decision engine, the periodic data collected is sent to the cloud continuously. This data is curated and available for deeper analysis. For example, this data may be examined to compare various links at locations at the same time, or to compare data from the same link during different parts of the years, for weather-related impacts. Over time, this data will be a treasure trove for a machine learner to sift thru for various patterns in optical preventative network management.

If, on the other hand, wavelengths disappear on the OSA, but the fiber link on the OTDR shows strong, the inference is that the node is individually affected. This could mean that the node has an electrical, RF or optical issue inside of it, or that the fiber between the node and the OSP Mux is cut. In this case, after a soak period, the affected node is identified, and the technician can easily figure out the node status. If the node is fine, then the fiber cut between the OSP Mux and the node is easily identified by an OTDR (this will require a handheld OTDR, which is a mobile equivalent of the rackmount CPM). One other option, which is a bit manual, requires disconnecting the headend DAAS port of the affected node and shooting the fiber with a tunable OTDR, but this process requires a fairly good view of the ISP optical connections.

Establishing and then maintaining end-to-end connectivity for all elements in the network is as complex as it is important. The OSP plant that begins from the OCEF is typically overlaid on the GIS, as described earlier. This can span several 10s of km of plant. Also, such connectivity must be maintained within the PHE or the SHE, which is considerably difficult. This is because equipment may be periodically rearranged, revamped and swapped out, sometimes in phases. Therefore, an auto discovery process for all field entities is the most optimal path, which begins with a robust provisioning process.

Because the data is stored in an efficient format in the cloud, this data can be compared year to year to understand how each of the fiber links perform in different weather conditions. The role of machine learning in this type of an effort cannot be overestimated. Through a systematic comparison of events and fiber profiles across the fiber lengths, not only can link performance be flagged, but weaker splice enclosures prone to fiber fills can be replaced to shore up the fiber availability. In a natural disaster, having access to multiple fiber cuts and their location in real time will enable a far more efficient dispatching of resources. Since optical passive information is stored along with the current usage of optical wavelengths, and available at any given time, capacity on each fiber link can be estimated in real time. This helps us to understand which links can handle additional wavelengths. Furthermore, some of our limits on optical level differentials and wavelength plans to accommodate analog, coherent and 10G wavelengths on the same fiber can not only be viewed but also enforced.

The CPM is deployed in all three divisions at Comcast. The cloud-based infrastructure component, with respect to its provisioning and continued use, is described next.

## 11. Provisioning and Training the Monitor

When the CPM is first deployed, the MAC is discovered, an IP address given, and a name established. In the provisioning process, the ports are assigned to each of the ISP Muxes, by

name, and each of the Wavelengths of each of the ports is connected to its respective node. Additionally, each port is also assigned to its terminal panel. Thus, by way of discovery of the DAA and OSP engines, auto discovery and alignment can occur to create an end-to-end connectivity diagram.

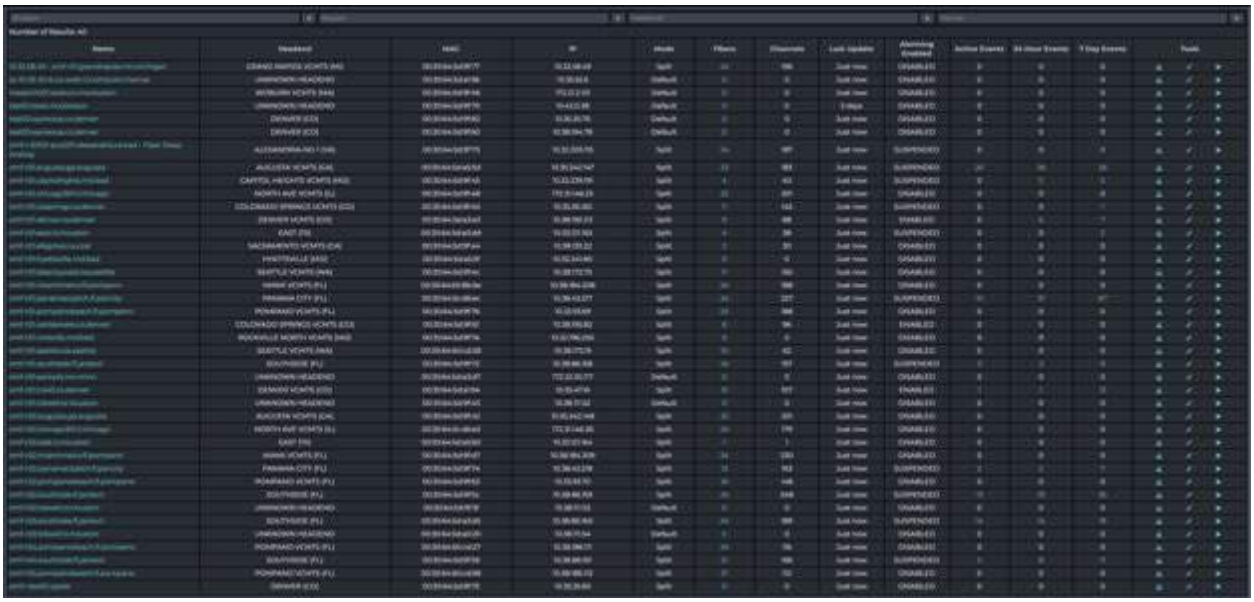

**Figure 13 – View of the Provisioning page in for the Monitor**

Once this is established, then the CPM is left alone until it has acquired, by the port dwelling process described earlier, a baseline of its fiber length and the wavelengths. Once the baseline is verified to be correct according to the maps, the baseline values are set, and then subsequent values are compared to the baseline in perpetuity. This is indicated by the green color of the OSA wavelength representation. In a typical day, each link is verified 480 times (or more per 24 hours), at three minute intervals. Thus, any change in the current vs. baseline situation is immediately flagged and sent to the NWT for ticketing.

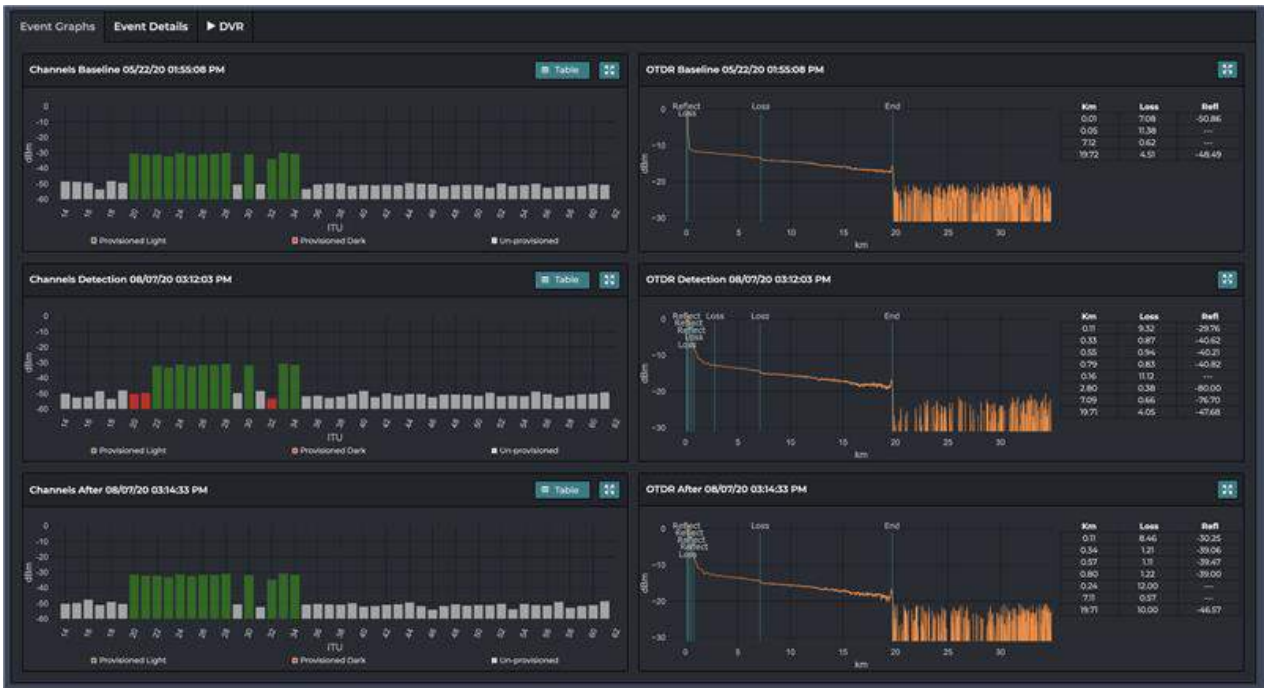

**Figure 14 – Fully Provisioned Port (notice the green and red WL colors)**

Figure 14 shows a case where the baseline has been set, as can be seen with all of the green ITU wavelengths. In the middle, we see that a power outage has taken out three nodes. Because in this case the CPM is monitoring the US ITU wavelengths, we see three of the green wavelengths are now in red. However, a quick check at the OTDR confirms that the trunk fiber is not cut -- it shows no events. We would be able to verify thru Continuity (an internal "source of truth" dashboard that indicates power continuity in the network) about the power outage. Once the power is restored, the wavelengths come back on-line and compare favorably to the baseline. In this case, this outage was resolved without the need to visit the node. However, if the power had been on, then the next step would have been to understand if there was a fiber cut between the OSP Mux and the nodes (although this is unlikely, given that more than one node was affected). In that case, a technician would resolve the issue by means of more sophisticated tools, described in the next section.

Occasionally, it becomes necessary to interrupt the automatic process to troubleshoot or verify performance. In these cases, the software also lets one SSH into the CPM to direct it to specific ports, out of the order for immediate real time view. In these cases, the CPM understands the legitimate request and pauses the auto view.

This level of automation and remote capability was especially helpful in the COVID environment, when folks from multiple locations were suddenly able to get on a conference call to view, inspect and troubleshoot specific links. In one specific instance, we were perplexed by a rather high loss appearing in the dead zone of an OTDR. The CPM was provisioned, by alerts that were not yet firing. Perplexed by this, and by good, old-fashioned process of elimination, we figured out that because of the unusually short fiber length, and to protect the APD of the SFPs, a rather large attenuation pad had been placed in the COM port of the ISP passive -- thus

contributing to the dramatic attenuation increase on the OTDR and the OSA. Thus, it is rather important to understand the role of attenuators (commonly used to attenuate light levels) and their effect on OTDR resolutions and OSA power levels.

## 12. Handheld to the Cloud

Thus far, we have described the role of continuous and pervasive monitoring of optical assets. However, many impairments in the system require human interaction and experience in order to reach a resolution. In these cases, we rely on the considerable acumen and insights of our headend and fiber technicians. We also outfit them with an array of sophisticated optical equipment. These could be full featured optical spectrum analyzers, high sensitivity and/or high input optical power meters, 1550 nm tunable OTDRs and SFP programmers. We have previously mentioned that the optical passives have been designed to enable manual as well as pervasive monitoring.

In the example in the previous section, if only one node was affected, the technician would have disconnected the port to the affected node and used a tunable OTDR to verify whether there was a fiber cut, as it can peer beyond the Mux. Alternatively, a technician would have been dispatched to the node location for troubleshooting.

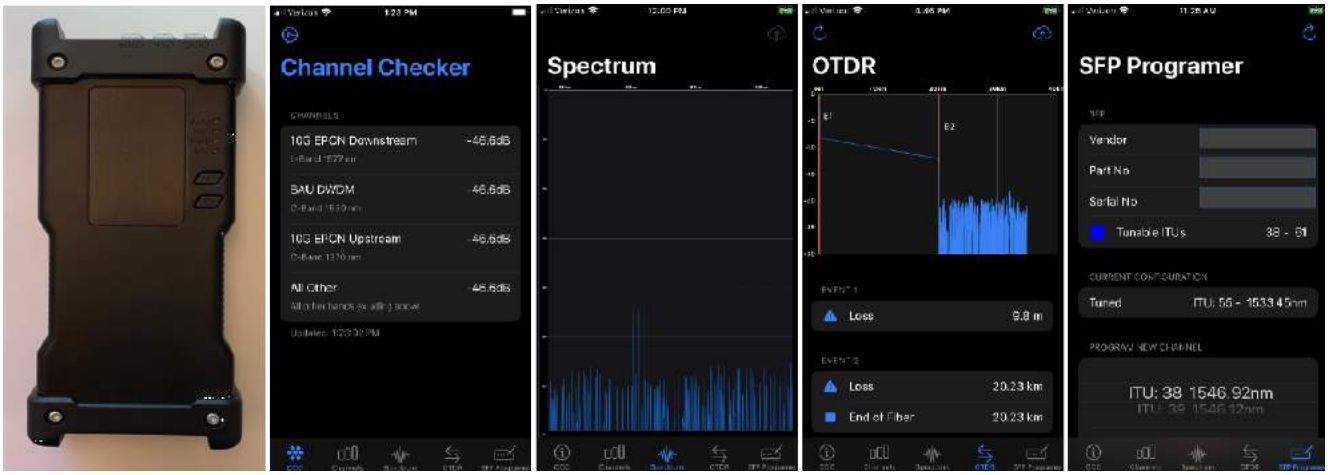

**Figure 15 – Handheld unit with a Mobile Application and Cloud connectivity**

The previously mentioned handheld equivalent of the CPM is also potentially useful for field technicians. This device has a C-Band OSA, the 1611 nm OTDR, an SFP Programmer and a Channel Checker/Power meter to aid in PON deployments. Designed with a long battery charge (a full shift) and WiFi hotspot, this device enables field technicians to troubleshoot a variety of fiber cuts, and SFP installations, along with routine troubleshooting. Based on popular RF meters of the same type, this device has impressive cloud capabilities, with a UI designed in-house. Because all of our technicians carry iPhones, the UI and display is adapted to the iPhone and shown in Figure 15. A device of this kind allows the technicians to troubleshoot and upload their observations to the cloud and helps round out our optical asset monitoring.

## 13. Conclusions

We began this paper with a description of the access footprint and our substantial efforts to address continuous and pervasive monitoring of our optical networks. An innovative mix of technology, in use in other areas of optical communications, including innovations in optical passives was critical in standing this system up. As important as the hardware is, the software infrastructure is even more so.

Being able to remotely and automatically get notifications of fiber cuts, with appropriate overlays on GIS maps, is extremely useful in reducing the time to repair. It is especially helpful to not only DAA and HFC links, but also to the MetroE links in the access domain. The hand-held unit offers an extra layer of efficiency across the board and helps fulfill the promise of continuous and pervasive monitoring of access optical assets. The benefit of CPM during the COVID pandemic has been rather positive and can potentially be generalized further to enable remote monitoring and mitigating capabilities across the network.

## 14. Acknowledgements

It is a pleasant duty to acknowledge the entire team within Comcast that has been working directly and indirectly on the Continuous Monitoring project. A project of this magnitude benefits from the dedication of diverse expertise from hardware and software at the Operations and technology team, the reliability and functionality testing of the Physical and Environmental test team, the ticketing and alerting of the NWT team and the functional rules for deployment from the access engineering team. Our thanks are especially due to our vendor and partner II-VI for their insights. We sincerely thank the Senior Leadership Team at Comcast NGAN in supporting this project and for their support in deploying it in all the three divisions at Comcast.

## List of Figures

# 1. Introduction

Few events in modern times have had as large an impact on society as COVID-19. Across the globe, people have been encouraged to work- and school-from-home. In many cases, this was mandated by governments by shelter-in-place orders –and for some, this continues to be the 'new norm'. Not surprisingly, this has resulted in a huge shift in network usage patterns. Several trends are apparent in the data that will be presented in this paper:

- Large increases in people working on the internet at home during the workdays
- Dramatic increases in the number of hours that devices are active on the home network, particularly computers, phones, and entertainment devices
- The workday is spreading into the evening hours as families try to juggle work and family commitments

Remarkably, wired internet access networks have held up to the added load well. **Figure 1** shows the download and upload speeds as recorded at more than 15 million households that are managed by the Plume Cloud. The delivered speeds, as measured by Plume, are remarkably consistent before and after COVID-19 caused the large increase in working-from-home. In fact, average speeds even trended *upwards* across the time due to subscribers upgrading to higher tier services to meet their expanded needs. At the onset of the pandemic many predicted that broadband service providers would struggle to meet higher and changing bandwidth demands–many OTT TV providers *even* reduced streaming quality to assist–however, Plume data shows that the networks coped admirably,

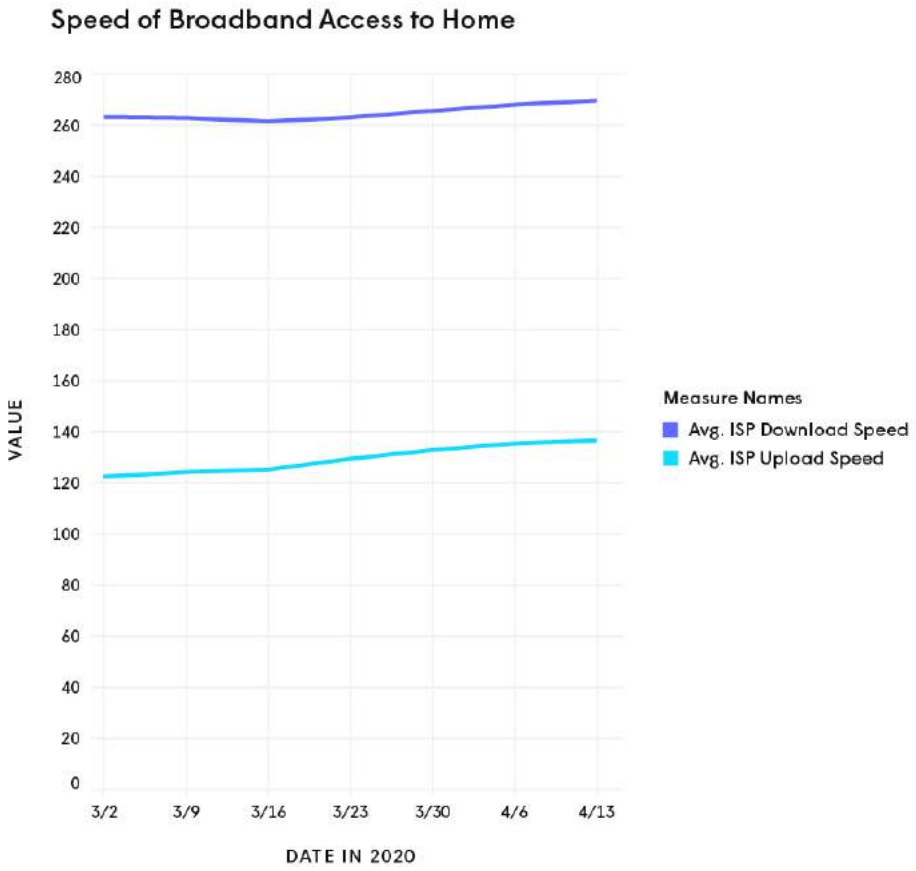

**Figure 1 - Speed of Broadband Access to Homes Before and After COVID-19**

While service providers have generally been able to keep up with the added load in delivering service to the edge of the customer's home, the story within the home could be much different. The majority of devices in homes today connect over Wi-Fi. Wi-Fi always has the fundamental problem of being a shared, and oftentimes best-effort medium, so handling increased load can be particularly challenging. **Figure 2** shows the dramatic increase in load from three key categories of devices: phones, computers, and entertainment devices (set top boxes, TVs, and gaming consoles). The increases are shown for both the amount of data consumed by these devices, as well as the number of minutes they were active on the network. In the stacked graph, the values are normalized to highlight the percent change from before to after COVID-19.

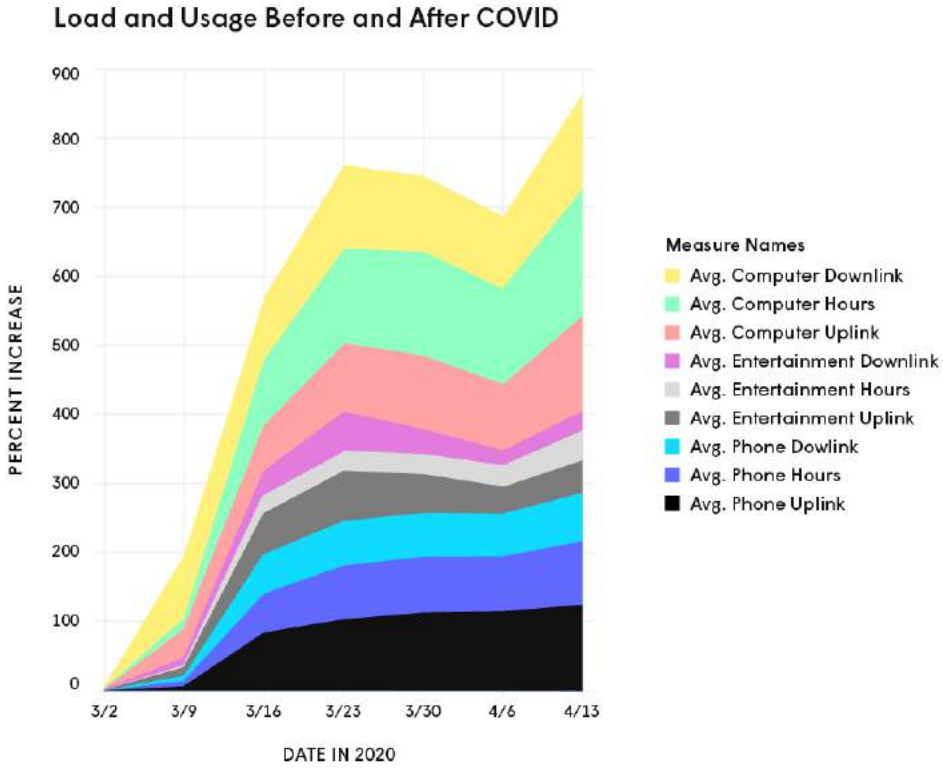

**Figure 2 - Load and Usage Before and After COVID-19**

The key takeaway from **figure 2** is that inside the home, a high degree of "wireless chaos" has been triggered by COVID-19. The remainder of this paper looks at this phenomenon in more detail, and describes what service providers can do to overcome this chaos and provide their customers with a highquality of *experience*.

## 2. The Effect of COVID-19 on User Behavior

As pointed out in the introduction, COVID-19 has changed network usage patterns significantly. This section examines these changes in more detail. While it is impossible to predict for sure, it is likely that

some of this behavioral change will persist long after COVID-19 has receded. If it recedes at all. For example, numerous companies, in the wake of the surge in working at home with COVID-19, have announced permanent acceptance of working from home. It is likely that many employees will take advantage of these offers. While this paper focuses on the changes before and after the onset of COVID-19, it is likely that the new behaviors, and the required adaptations by service providers for them, will be long term.

## 2.1. Changes in Working at Home

The most immediate effect of COVID-19 is an increase in the number of people working from home. Plume was able to analyze the data collected by Wi-Fi networks that it manages for service providers around the world to identify the change in the number of people who are working-from-home. The data analyzed included the type of devices, amount of data, amount of active time on the network, and domains accessed. Combining these observations, Plume is able to gauge homes in which at least one person is working from home during the 9am to 5pm weekday period. **Figure 3** shows the result for fourteen major metropolitan areas in the US:

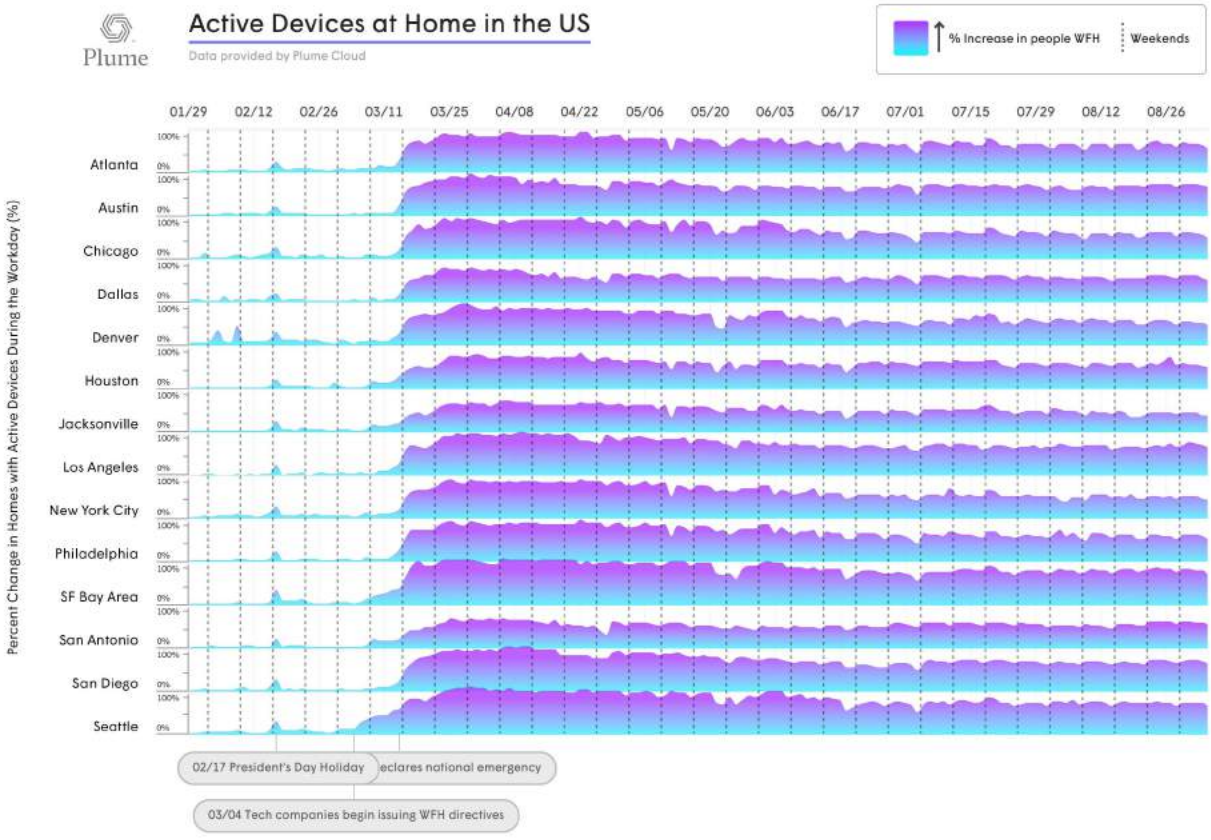

**Figure 3 - Increase in Working From Home in the US**

While the reaction across cities is relatively consistent, some details are instructive. The rise in working from home (WFH) occurred first in Seattle, the first city to see a significant number of cases, and the first

city to declare a shutdown. The San Francisco (SF) Bay Area had among the highest levels of extended WFH, perhaps enabled by its high percentage of tech workers. Cities in certain regions of the country (e.g. San Antonio and Jacksonville) have had somewhat lower levels of WFH. And we see some aborted attempts at loosening, followed by returns to higher levels of WFH.

Plume manages a large number of Wi-Fi networks in Canada and Europe as well as the USA. While the trends are similar, we can see a stronger, steadier downward trend in working-from-home in several Canadian cities and European countries **(Figures 4 and 5)**. These correlate with countries that have been better able to control their COVID-19 case counts.

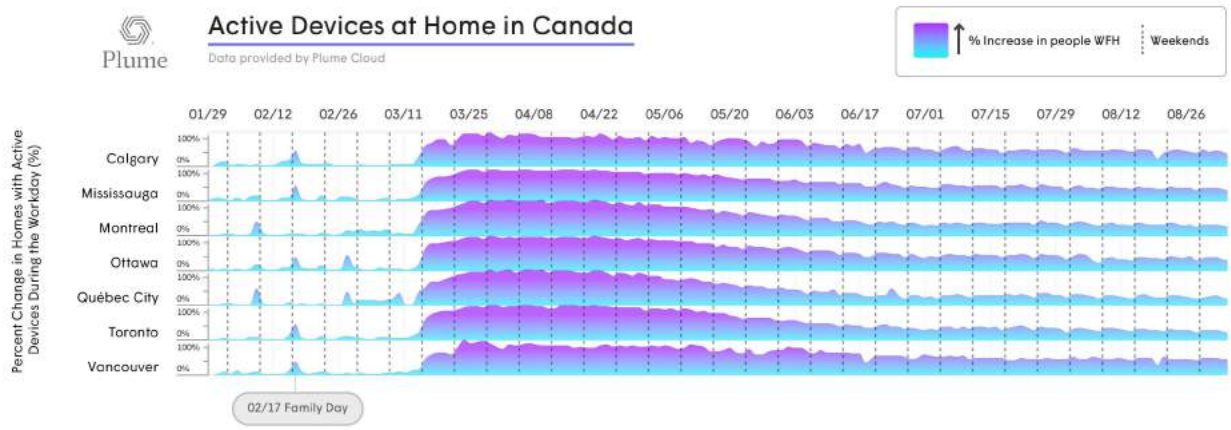

**Figure 4 - Working From Home in Canada**

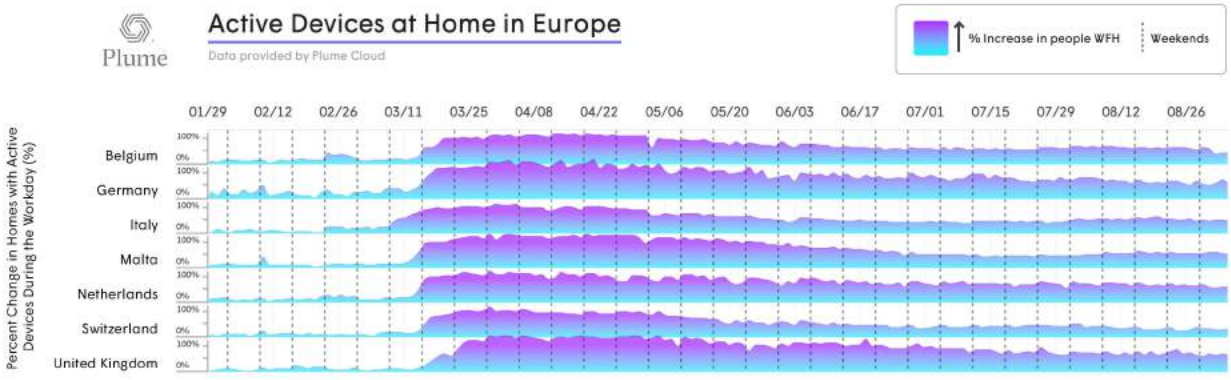

**Figure 5 - Working From Home in the EU**

## 2.2. Changes in Usage

Increased WFH is the first link in the chain between COVID-19 and increased in-home network distress. The change in usage of devices is the second. Devices don't readily identify their device type when they connect to a Wi-Fi network. But Plume is able to use a variety of factors including DHCP requests, UPNP transactions, DNS requests, Host Names, and user agent (browser) transactions to identify device types. This is based on machine learning across tens of millions of homes that are operated by Plume. After identifying the device type, Plume is able to observe the amount of data consume by the different device types, as well as the number of minutes that different device types are active on the network. **Figure 6** shows Plume's observations regarding the number of active minutes by device type across homes in the US. The "Computers" category includes both desktop and laptop computers, and the "Entertainment" category includes set top boxes, TVs, and gaming consoles.

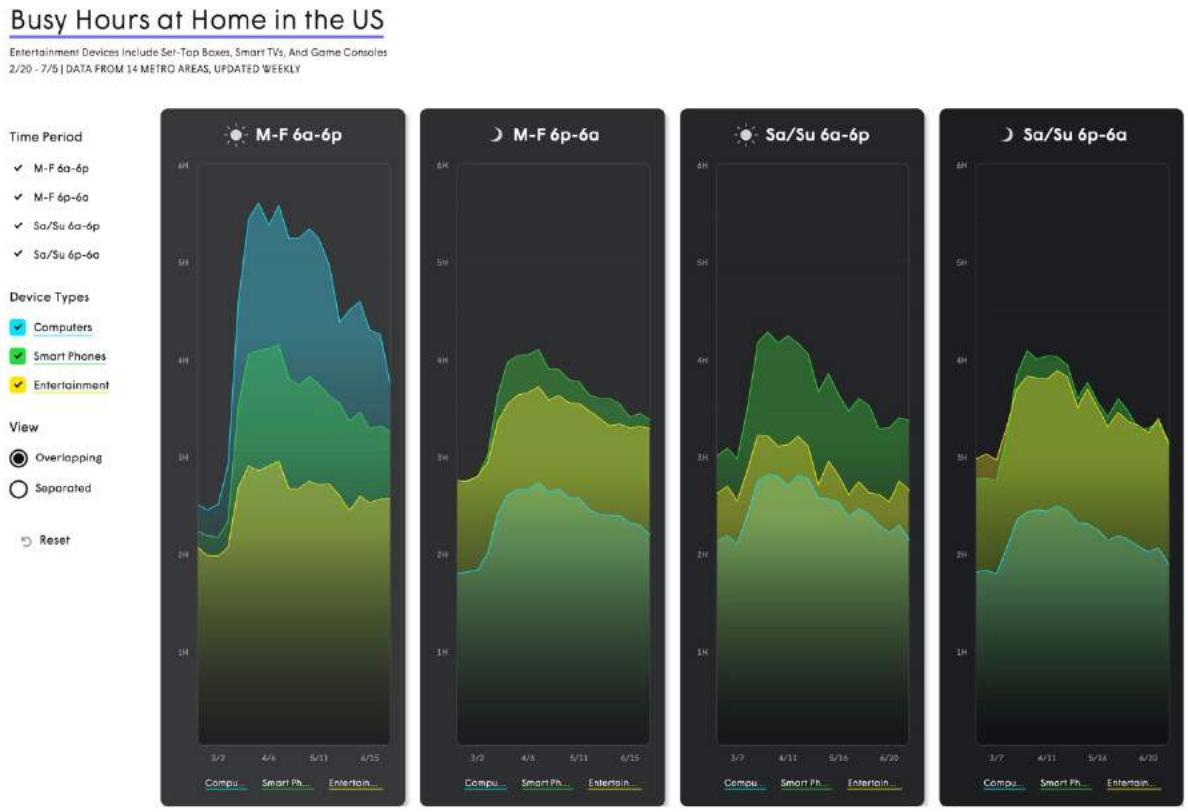

**Figure 6 - Hours of Active Time by Device Type**

By breaking the usage into days of the week and times of the day, several interesting before/after COVID-19 conclusions can be drawn. Unsurprisingly, the most dramatic increase in usage was for computers during the weekday work times. However, significant increases in phone and entertainment usage are seen in the evenings and on the weekends. This is likely due to the reduced entertainment options with social distancing. However, computer usage has grown significantly in the evenings and on weekends, indicating some spreading of working hours, as well as increased use of computers for entertainment.

# 3. The Effect of COVID-19 on Networks and Technologies to Compensate

The third link in the chain from cause to effect is how changes in usage due to COVID-19 impact the networks in people's homes. This section focuses on five of the most important effects. While these effects make the provision of adequate connectivity to provide high quality of experience more difficult, there are technologies that can compensate for the added challenges. These technologies are presented side by side with the description of the problem.

## 3.1. Demands on Coverage, and Multi-AP Solutions

The most basic requirement for any Wi-Fi user is to be able to physically connect to the network. When people have trouble connecting in their own home, the problem is usually caused by inadequate coverage. Coverage is defined the extent to which a given home has adequate signal strength to and from all devices at every location in the home. Homes often have "dead spots," regions that are not covered well by Wi-Fi. Behavioral changes due to COVID-19 have exacerbated this problem. As multiple people in the home search out areas where they can work in privacy, they are more often trying to use regions of the house with poor coverage.

Since client devices typically transmit at lower power levels than the Access Points (APs), it is often the connection that comes back from the client device that is the limiting factor. Plume's networks observe the signal strength of transmissions coming from client devices, moving this information to the cloud. Based on analysis of this information in the cloud, it is possible to determine which homes have a coverage problem. For this analysis, Plume defines a home to be in coverage alarm if more than 25% of the client devices have a coverage issue, a coverage issue defined as a device with under -70dBm signal strength 50% of the time. -70dBm is the level at which data rates start to drop quickly, and clients start to spend a lot of time searching for better APs or roaming, making media flows less reliable. **Figure 7** below shows the percentage of homes that are in coverage alarm for a large North American service provider. As can be seen, more than 40% of homes that have only one Wi-Fi AP are in coverage alarm. However, by adding additional APs ("Pods"), that can be reduced close to 10%.

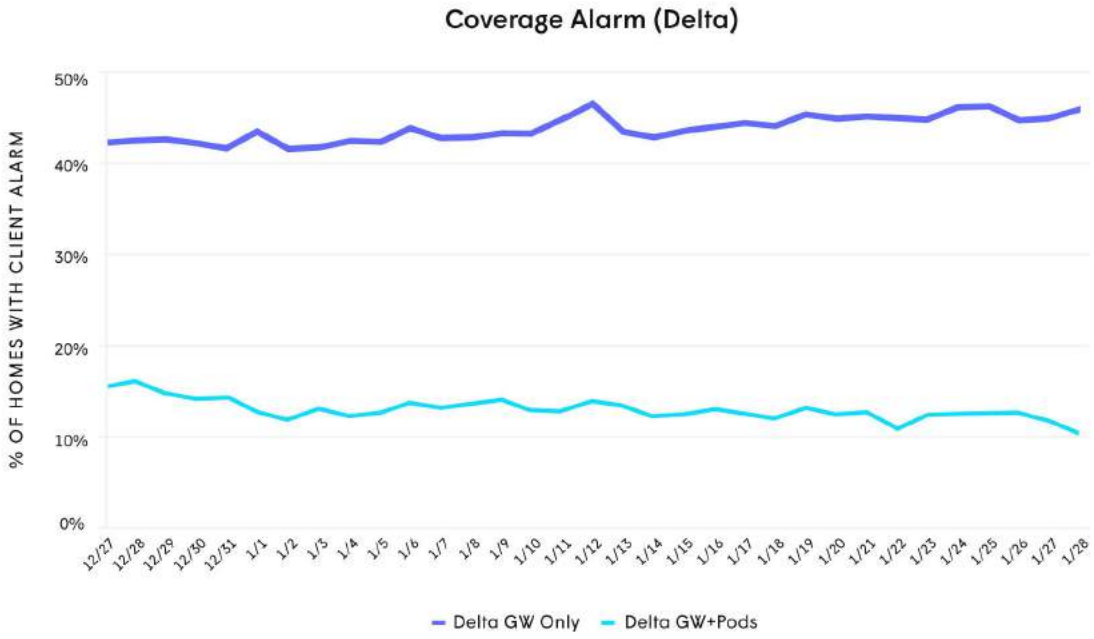

**Figure 7 - Coverage Alarm vs. GW only or GW + additional APs**

Typically, additional APs added into a home are connected wirelessly to each other. Few homes have Ethernet wires in locations that are appropriate for placing additional APs. Traditional Wi-Fi repeaters or mesh systems can solve the coverage problems just discussed, but they do so at the expense of throughput. These systems will utilize the same frequency channel for the backhaul connection between APs as is used to connect client devices to the AP (fronthaul). In fact, mesh systems often deploy the entire mesh, including all fronthaul and backhaul connections, on the same frequency channel. Such an arrangement suffers from self-interference in which transmissions on one hop in the network interfere with transmissions on other hops. For a two hop path, the throughput is more than halved, for a three or four hop path, the throughput is divided by more than 3 or 4 respectively.

This can be greatly improved if a different frequency channel can be used on each hop in the network. **Figure 8** shows a comparison between three approaches for serving a 20 meter connection in a typical home: direct connection to a powerful single AP, multiple hops through traditional repeaters or mesh system, and multiple hops through an optimized Adaptive Wi-Fi network. The difference in throughput achieved to the client is dramatic.

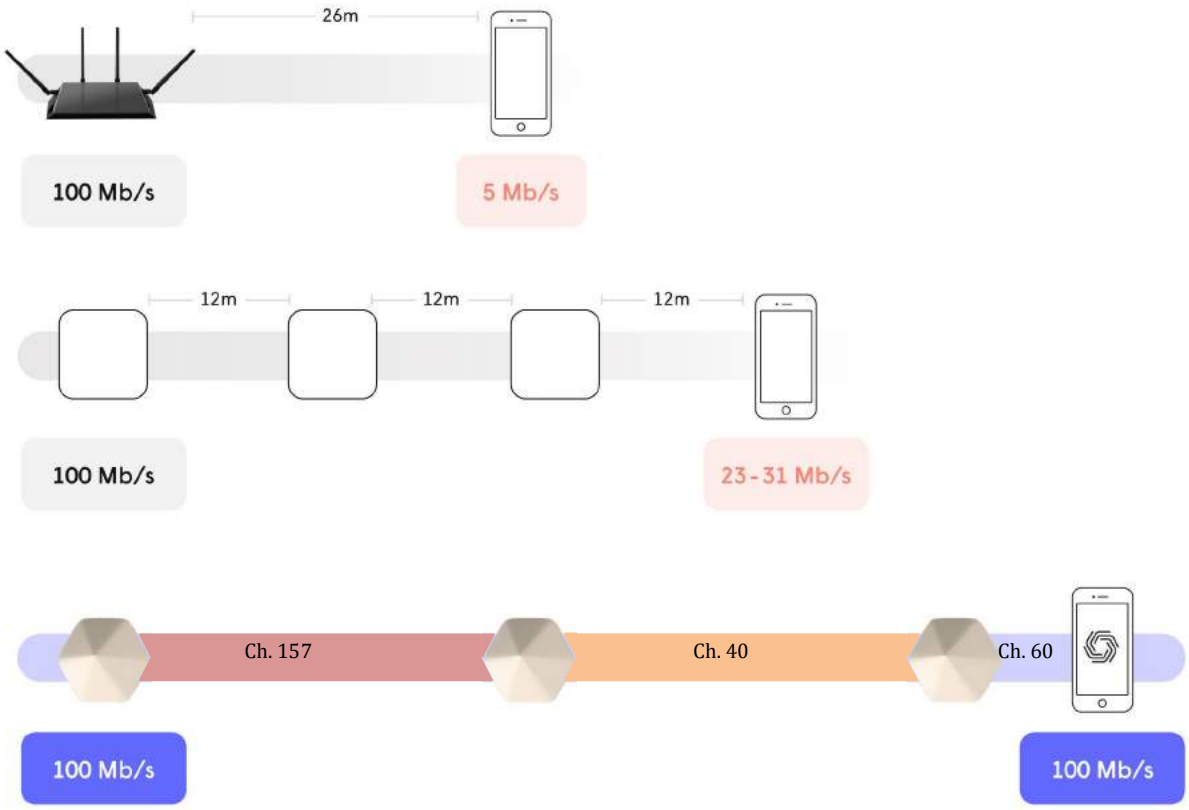

**Figure 8 - Single AP vs Traditional Mesh vs Optimized Adaptive Wi-Fi**

The complexity of choosing and configuring the optimized Adaptive Wi-Fi topology is why it is not often employed. However, modern cloud technology can enable sophisticated approaches. Rigorous optimization approaches, such as Mixed Integer Linear Programming (MILP), can be employed to maximize an objective function that includes throughput to individual clients, overall home system capacity, and fairness among the devices in the home. **Figure 9** shows a conceptual diagram of such an optimization system with its inputs and outputs. This approach is advantageous because the resulting topology deployed in a particular home will be optimal given the constraints of that particular home.

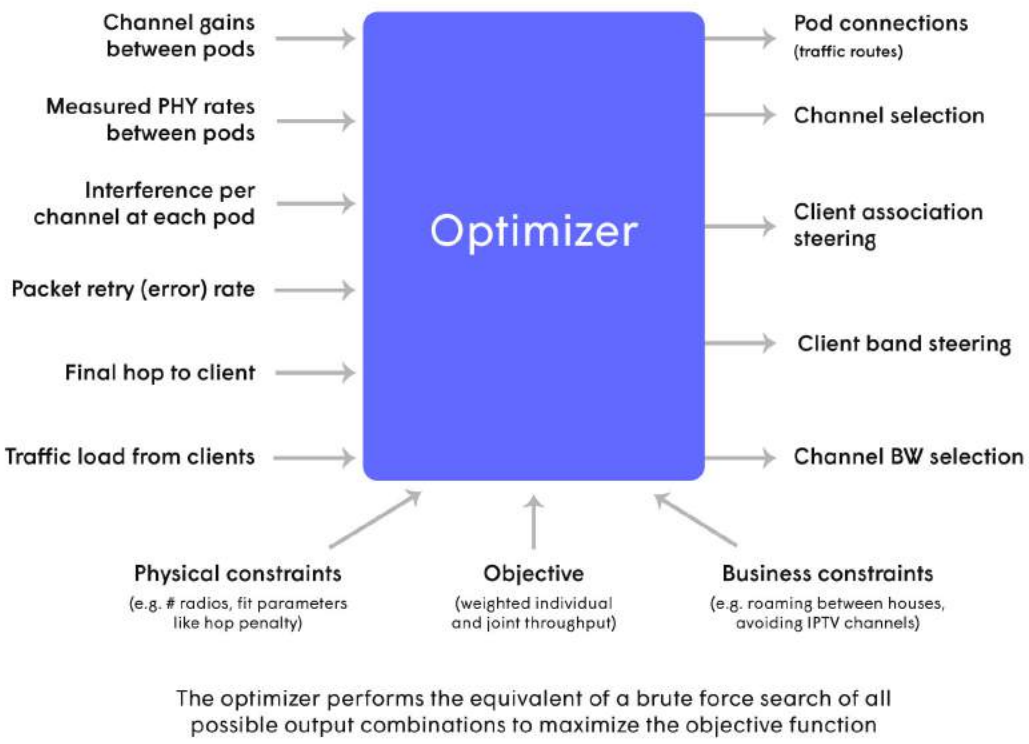

**Figure 9 - Optimization System for Wi-Fi Networks**

## 3.2. Increased Load, and Throughput Optimized Steering

The optimized Adaptive WIFI system presented in section 3.1 solves the problem of coverage while preserving optimal throughput. However, multi-AP systems in general bring the problem of where client devices connect into the network. Two problems are generally seen. First clients may be "sticky", remaining attached to one AP even as they move to the far side of the home. This has led some manufacturers to implement "sticky client steering" in which clients that are detected to be "stuck" on far away APs are kicked off that AP, forcing them to search for a closer AP for connection to the network. While this is better than nothing, the connections achieved in this way are not optimum. And second, even clients that dutifully shift to the closest AP are not necessarily connected in the optimum way. This is fundamental, as the client cannot know the complete pathway through the Wi-Fi network to the Internet. All the client can know is the signal strength from it to the APs it might connect to. To achieve the optimum connection requires understanding the speed of the complete connection, perhaps through multiple hops, from the client to the Internet for each option. [In response to SCTE editor comment.]

**Figure 10** shows the desired outcome in client steering and AP topology. First, the optimizer eliminates excessive hops that would degrade performance. It does this for example by connecting APs directly to the GW AP as appropriate, when an extra hop to get through the network is not justified. Second, throughput optimized steering is used to move the client device to the AP where it will achieve the best

performance. The highest performance connection point for a client is often *not* the closest AP. As can be seen in the figure, connecting to the closest AP sometimes adds unnecessary additional hops, and can even increase the individual hop lengths in the connection.

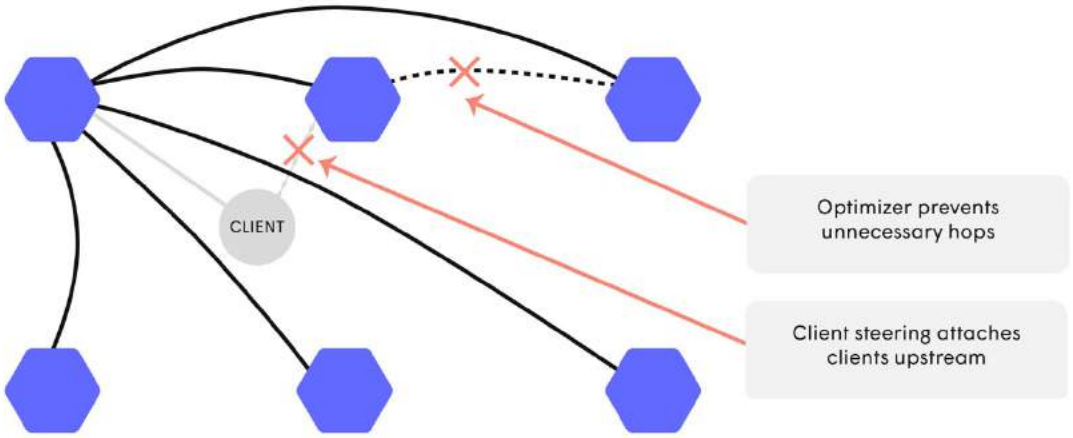

**Figure 10 - Throughput Optimized Steering**

The best location for client devices can be calculated as part of the optimization procedure. As clients move about the home and attach in inappropriate places, the results from the optimization can be used to identify where they would perform best, and client steering can be used to move them to the correct location.

## 3.3. Interference and MDU Joint Optimization

Increased usage due to COVID-19 also causes an increase in interference. Both interference (overlapping transmissions from neighbors) and congestion (self-interference from other devices within the home) are increased. While the increases occur across the board, these increases are particularly problematic in dense living environments such as Multi-Dwelling Units (MDUs), for example apartment complexes. **Figure 11** shows interference levels in suburban homes vs. urban MDUs as collected on Plume managed Wi-Fi networks. The graphs are histograms of the interference levels. The x-axis is the percentage of airtime consumed by the interference. For example, 33% interference indicates neighbors are consuming 33% of the available airtime, reducing throughput in the home in question by more than a third. The y-axis shows the percentage of homes/apartments in the particular interference bin of the histogram. 100% of homes surveyed are represented at some point in the histogram.

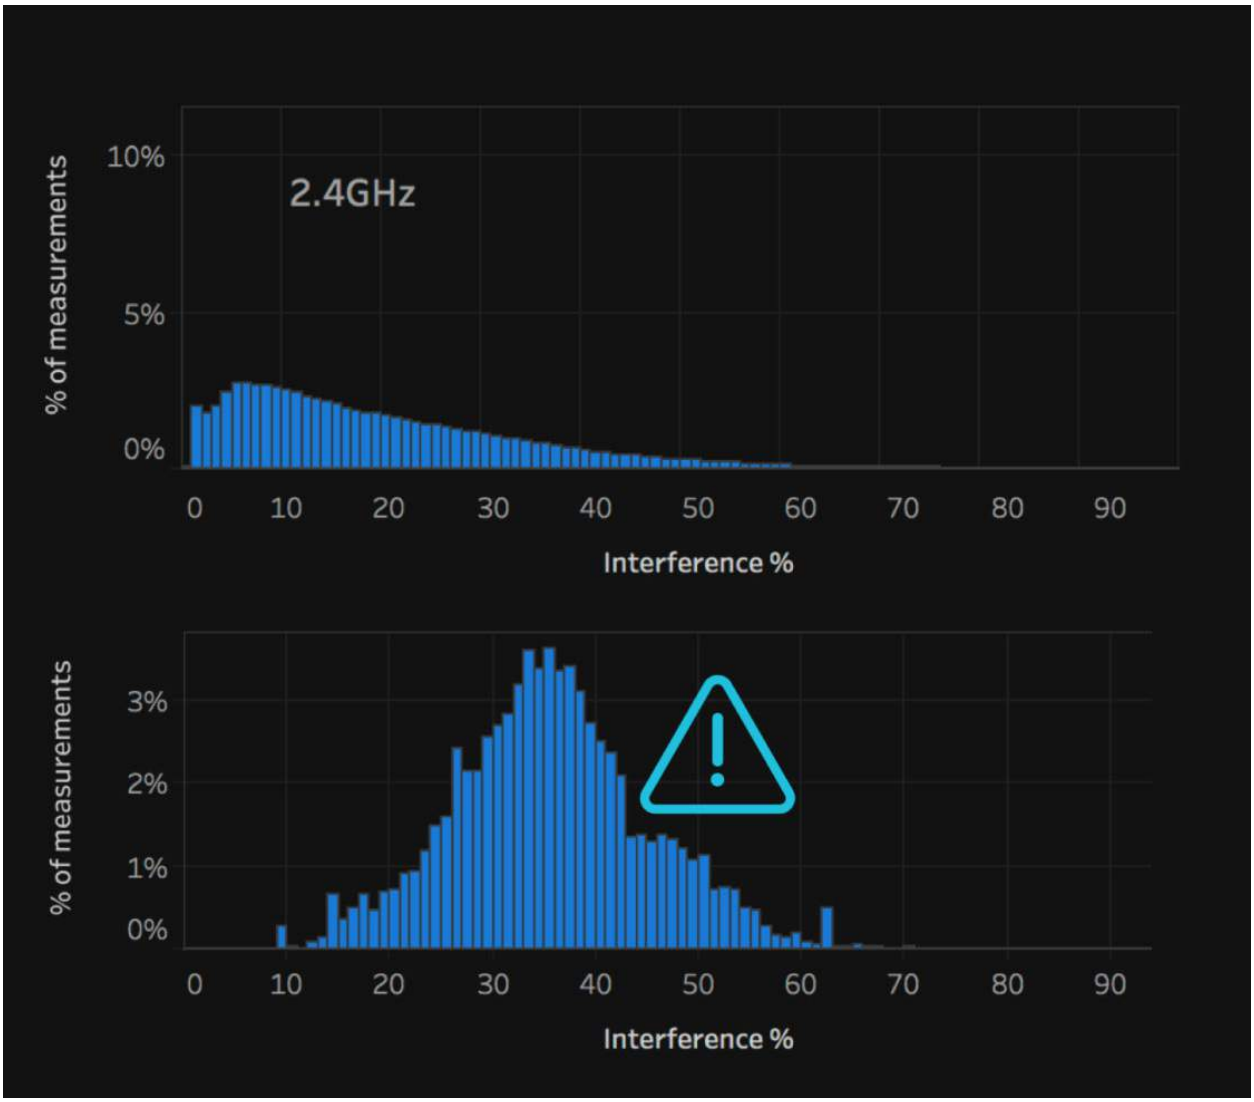

**Figure 11 - Interference Histogram for Surburban Homes and Urban MDUs**

As with previous COVID-19 related issues, the application of sophisticated cloud based processing can mitigate interference. In this case, the key is to consider the MDU as a whole. The algorithm begins with the APs reporting statistics about the neighboring APs they can see, along with interference levels and traffic loads. Based on the lists of neighboring APs, a clustering algorithm, run in the cloud, forms groups of APs that are tightly coupled to each other. The algorithm balances cluster size with the completeness of including all APs that interact with other APs in the cluster. Once the clusters have been formed, the optimizer can select frequency channels and bandwidths so as to maximize the performance of the entire cluster. **Figure 12** shows the result for a sample MDU.

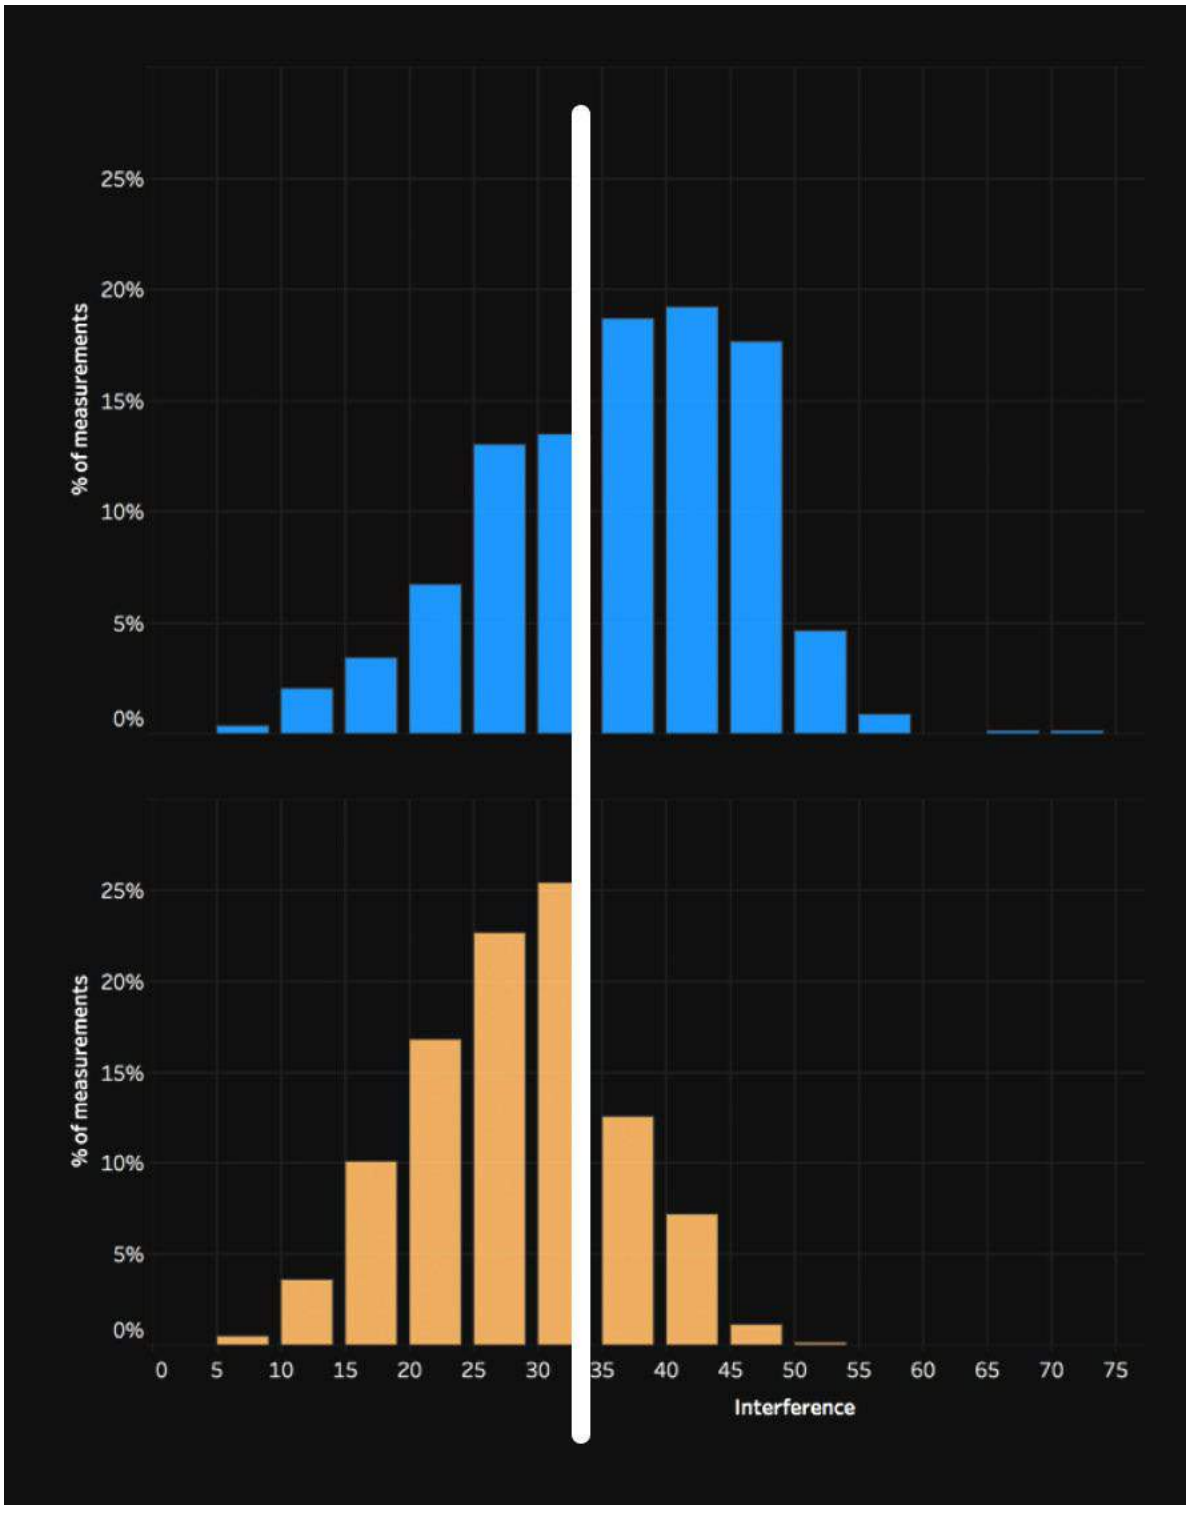

**Figure 12 - Before and After MDU Joint Optimization Interference Histograms**

The upper histogram shows the distribution of homes vs. interference levels before optimizing together as a cluster. The lower histogram shows the distribution after optimizing together as a cluster. The vertical line marks the point at which 33% of airtime in homes is consumed by interference. The joint optimization is able to significantly reduce the number of apartments experiencing interference above 33%, the point at which interference effects become significant.

### 3.4. Cyber Security Attacks and IoT Device Security

It has been hypothesized that criminals would take advantage of the fear, confusion, and increased internet use due to the COVID-19 pandemic. Sadly, it turns out this is true. **Figure 13** shows the increase in various types of threats before and after COVID-19, with several attack types doubling in frequency. In fact, across the period of this study 87% of the homes had some type of cyber security attack.

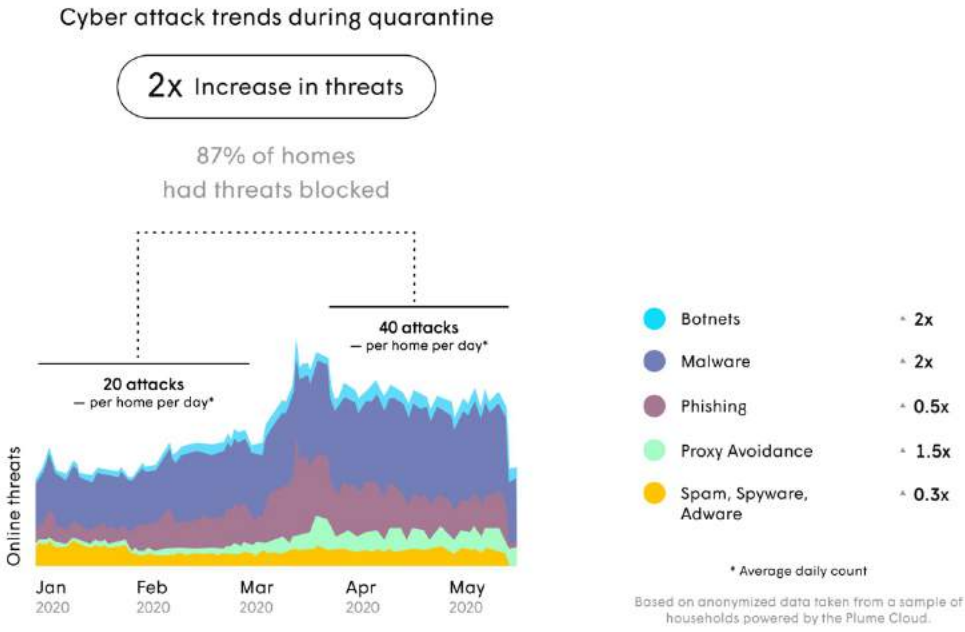

**Figure 13 - Cyber Security Attacks Before and After COVID-19**

To combat this, a robust cyber security system should be deployed. A system that includes a variety of layered protections will be most effective. Each of the following methods have their own advantages and weaknesses, but when taken together as a whole form an effective defense.

**DNS query checking**: Devices making an outbound connection to the internet often begin that transaction with a Domain Name Service (DNS) query to obtain the IP address for a given domain name. Domain names are generally logical and somewhat understandable, so it is relatively easy to maintain a list of high risk and low risk domains. A disadvantage is that creative cyber criminals avoid the use of domain names by creating viruses that use IP addresses immediately, without a domain name lookup.

**IP address reputation checking**: IP addresses can be checked similarly to domain names. The advantage is that this works well for incoming traffic as well as outgoing traffic, and it can cover cases in which viruses avoid DNS lookups. However, IP addresses change frequently, and maintaining a valid list of acceptable vs. unacceptable IP addresses is difficult.

**Port checking and anomaly detection**: Internet connections usually have an associated port number, which is frequently indicative of the application being used. Certain applications, such as ssh, should not be active on certain types of devices. Such basic rules can be augmented by doing machine learning (ML) based anomaly detection. The ML approach can be particularly powerful if data from millions of homes can be aggregated in the cloud, forming a robust dataset for training.

**Tx/Rx Data pattern anomaly detection**: The last line of defense is to observe the basic behavior of the device. For example, **Figure 14** shows a plot of the number of bytes transmitted and received by a Nest Camera in a given minute plotted as a two dimensional scatterplot. Regions that define different modes of operation can be identified, and behavior that does not fall into these regions can be flagged as anomalous, potentially caused by a virus or malware. This technique is particularly helpful for IoT devices, which are generally headless, and can't have aftermarket anti-virus software added. As with all ML based anomaly detection techniques, having a large training set is crucial. Cloud based management systems that aggregate data from millions of homes are beneficial for this approach.

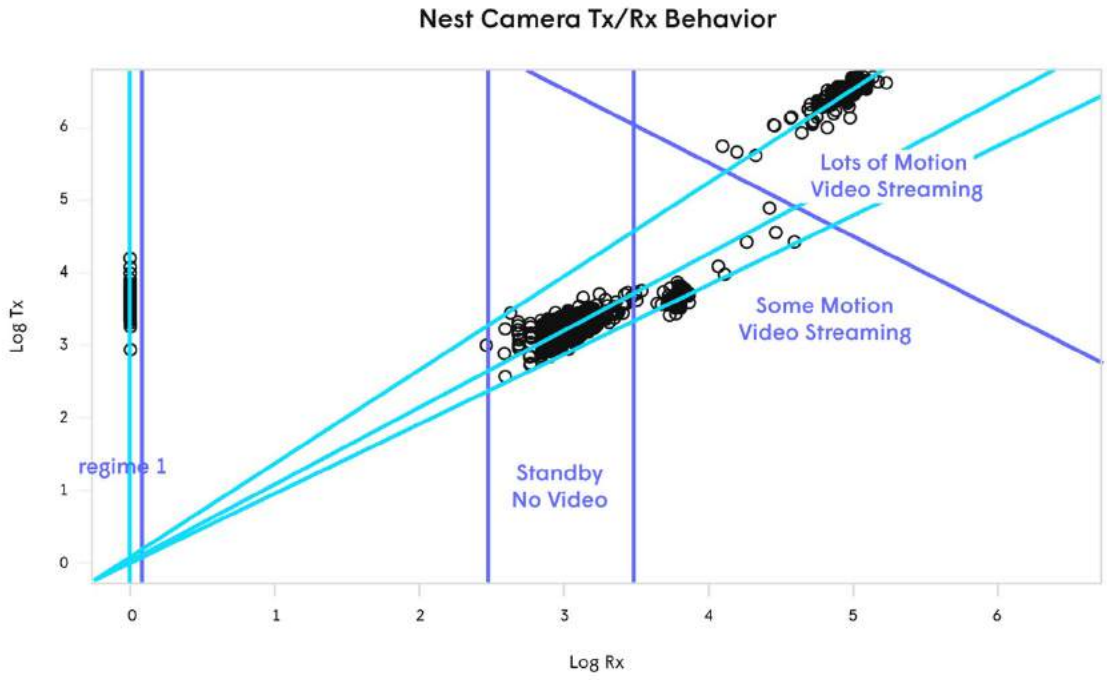

**Figure 14 - Scatterplot of Tx and Rx Bytes per Minute for Nest Camera**

**Cyber Security at every node**: Cyber security measures have traditionally been implemented only at the gateway or main router in a home. However, with the advent of extenders and repeaters, this invites the lateral movement of viruses or malware between devices in the home. Traffic that flows within the home is naturally routed over the shortest path, and this path may not include the gateway or router. And, many mobile devices leave the home and return, sometimes with a new virus on the device. Figure 15 shows the need to detect and stop viruses even for traffic flowing only through a repeater or extender.

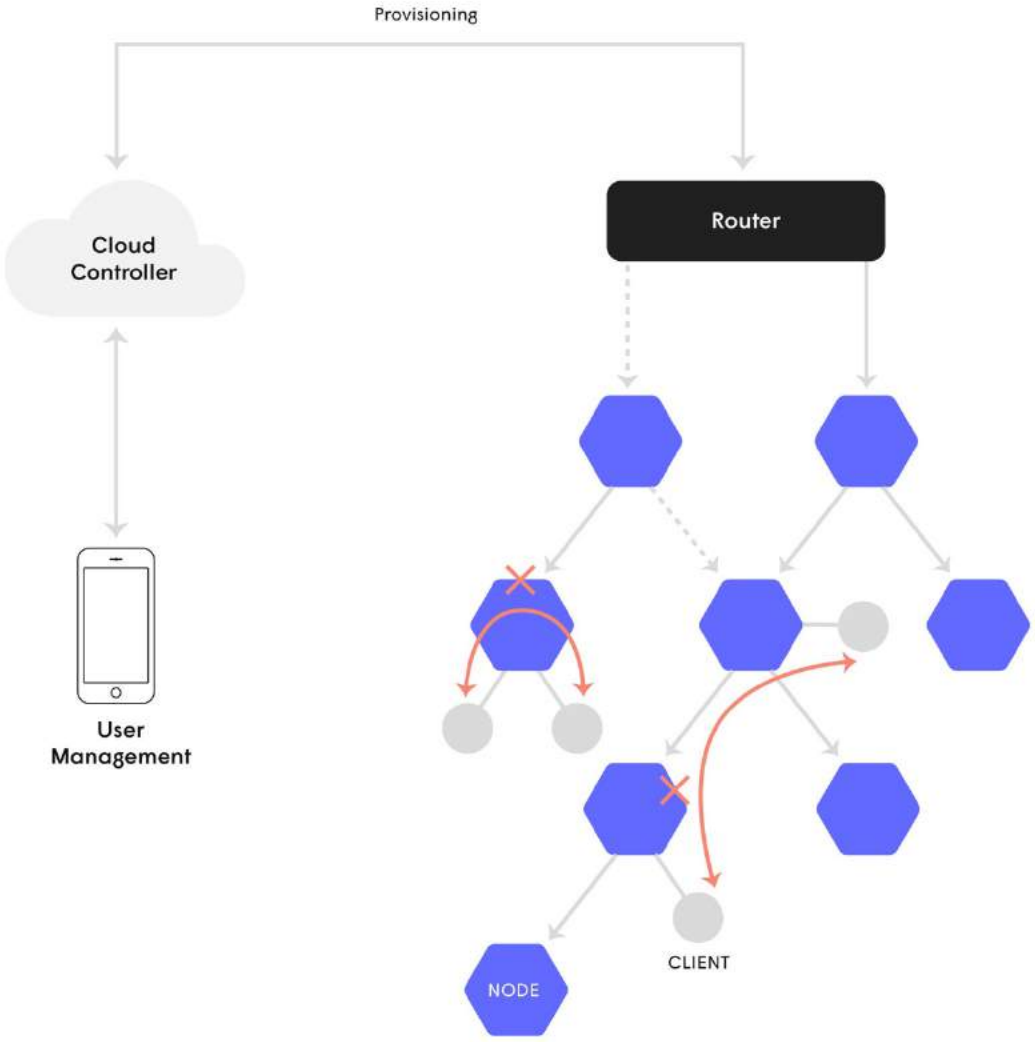

**Figure 15 - Lateral Movement of Viruses and Security at Every Node**

## 3.5. Traditional QoS vs. QoE

As COVID-19 puts more demands on networks, carriers are naturally concerned whether their networks are performing adequately to satisfy their customers. Quality of service (QoS) is the metric that has traditionally been used to indicate this. Typical Wi-Fi QoS metrics factor signal strength, data rate, and congestion/interference, to indicate the quality of the operation of the network. However, consumers are not actually interested in the performance of the network. Consumers are interested in the experience they have using services over those networks. To accurately reflect consumer's satisfaction, Quality of Experience (QoE) is a more effective metric than QoS. QoE starts with similar factors as QoS, but extends that to consider the devices and services that customers are using in a particular home. As an example, a customer with a Wi-Fi thermostat that receives reliable 1Mb/s service will be perfectly happy. On the other hand, a customer with a 4k set top box that receives 20 Mb/s service is likely to be unhappy. Along with factoring the type of device or service in question and their needs, the QoE metric factors far more conditions than just signal strength, data rate, and congestion. **Figure 16** shows the factors considered in a QoE algorithm, and how such a QoE score can be used.
