

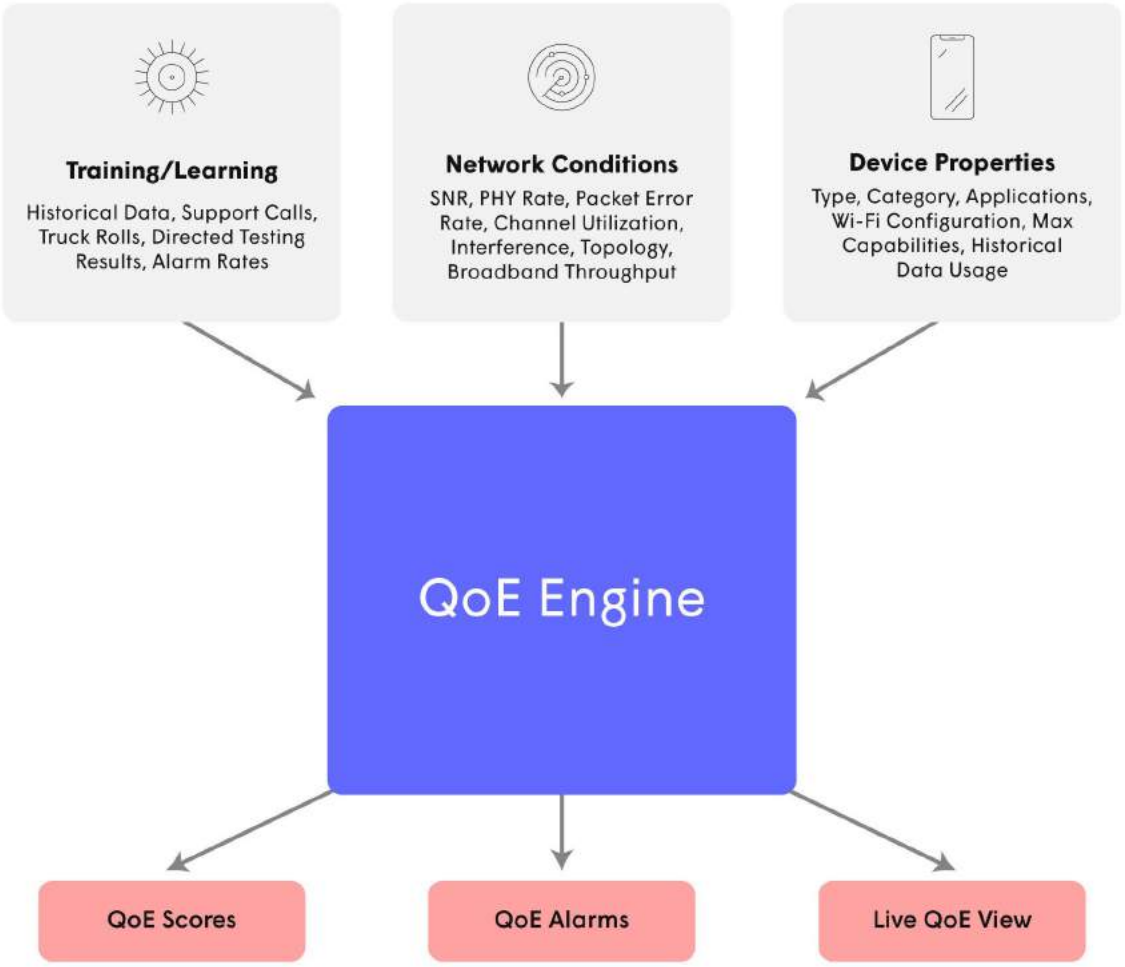

**Figure 16 - QoE Factors and Outputs**

The resulting difference between the QoS and QoE metrics can be compared by using traditional QoS metrics to identify devices that are performing poorly, comparing that set to devices identified using the more accurate QoE metric. **Figure 17** shows the statistics of such a comparison on networks operated by Plume. The Venn diagrams indicate that the different methods identify largely different sets of devices as requiring attention.

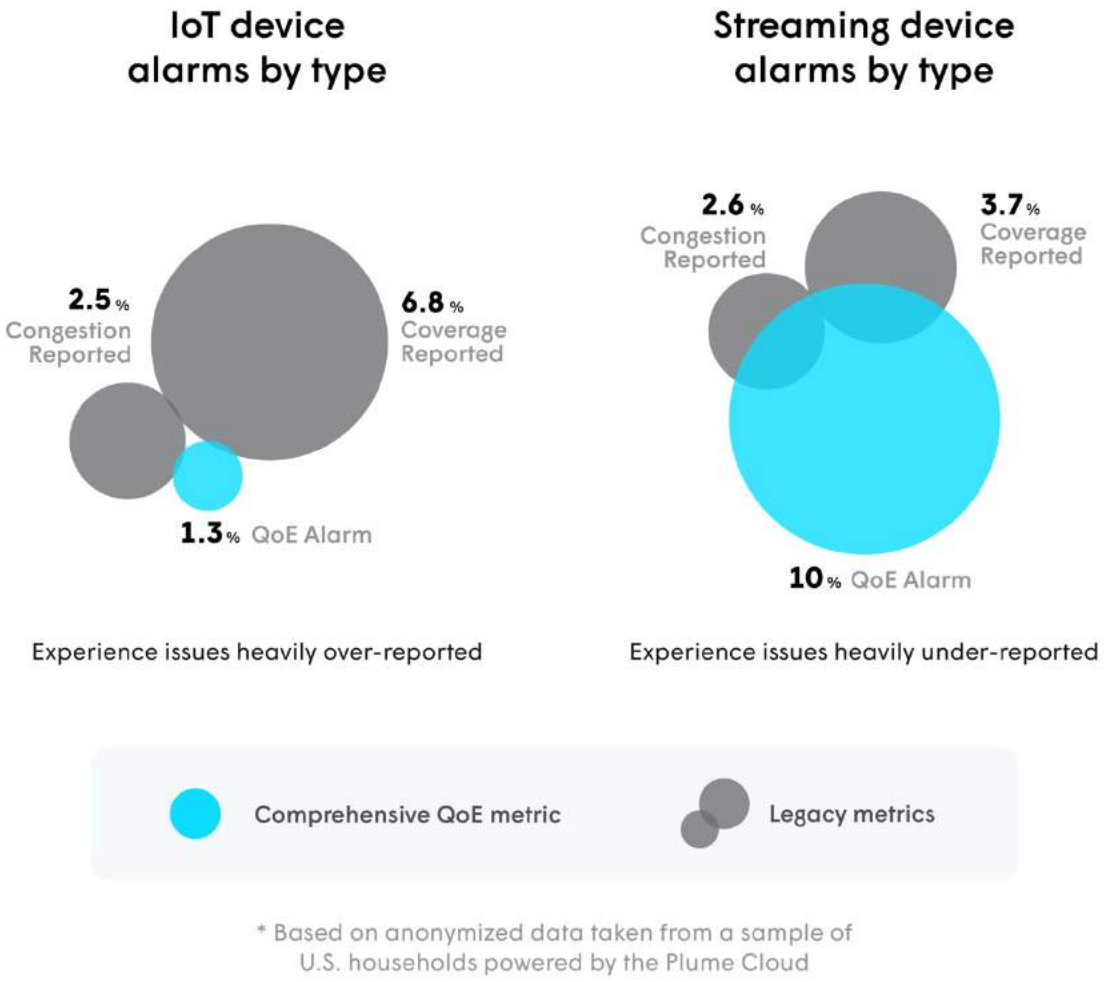

**Figure 17 - Struggling Devices Identified by QoS and QoE**

As could be predicted from the description above, too many IoT devices, which generally have lower networking requirements, tend to be identified as needing attention by traditional QoS approaches. This is significant, as service providers might spend too much money trying to fix those problems with additional repeaters or other steps. Conversely, streaming devices are under identified as needing attention by traditional QoS mechanisms. This also can be costly, as customers experience poor video quality and churn to another service provider.

## 4. The Effect of COVID-19 on Financials and How to Compensate

Luckily, COVID-19 is not having the devastating financial effect on service providers that it is having on other industries. However, the impact on carriers is still significant. New technologies can help service provider financials in at least two areas: the costs of customer support, and additional revenue from new services.

## 4.1. Proactive Support

As COVID-19 drives heavier use of home networks, and has consumers spending significant time on sensitive applications like teleconferencing, customer support becomes more heavily loaded. An innovative application of machine learning is to predict which customers are most likely to call in the next period of time. Such a capability can be used in a variety of ways:

- Direct proactive maintenance/care
- Send preventive email
- Understand what drives calls

ML cannot predict who is going to call perfectly, but it can do quite well. And, the algorithm can be adjusted to trade precision (the percentage of people identified by the algorithm who really would have called), and recall (the percentage captured on the list of all people who would have called). **Figure 18** shows results that Plume achieved on data from a North American deployment.

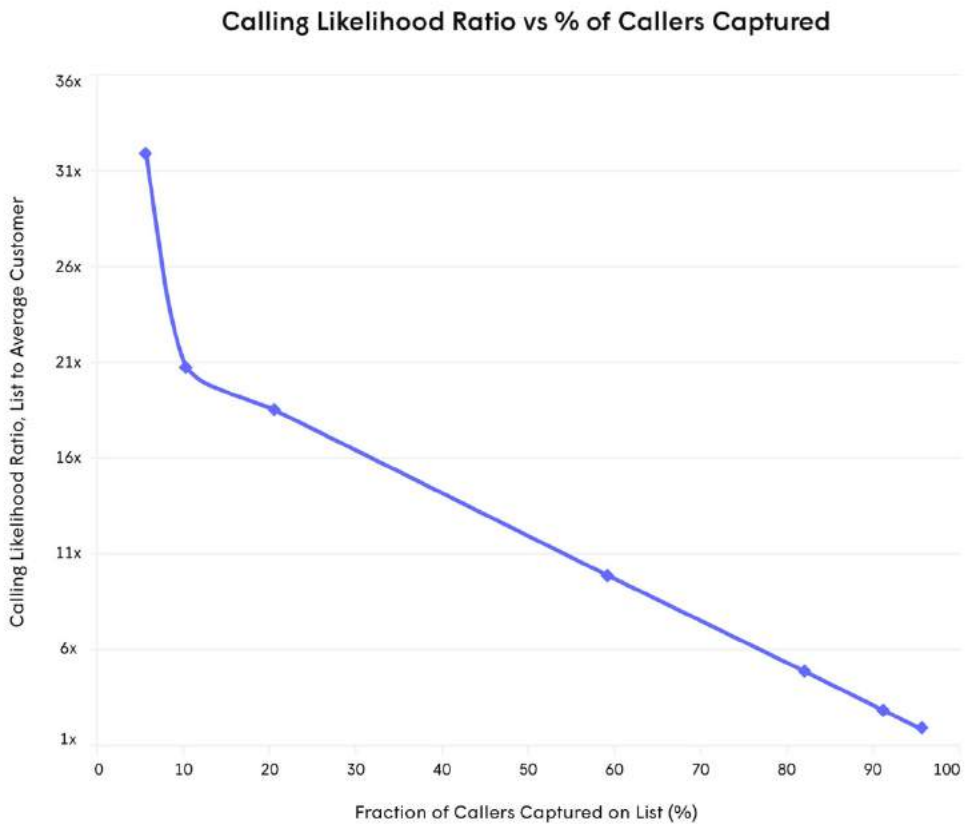

**Figure 18 - Support Call Prediction Precision vs. Recall**

Taking one particular point off the curve, it shows that we can form a list of people expected to call which includes 60% of people who actually will call (the x-axis), and the people on that list will be statistically 10x more likely to call than the population as a whole. The curve shows how these two values can be traded against each other.

## 4.2. Lost Revenue and Compensation with Additional Services

Another approach to make up for profit lost due to COVID-19 is to introduce additional services that users will pay a premium for. An innovative new service that can be offered using the in-home Wi-Fi network is motion detection. Motion in a home can be detected by watching the Wi-Fi signals between devices in a home. These signals will change in time if people are moving in the home due to changes in attenuation and reflection patterns. **Figure 19** illustrates the concept:

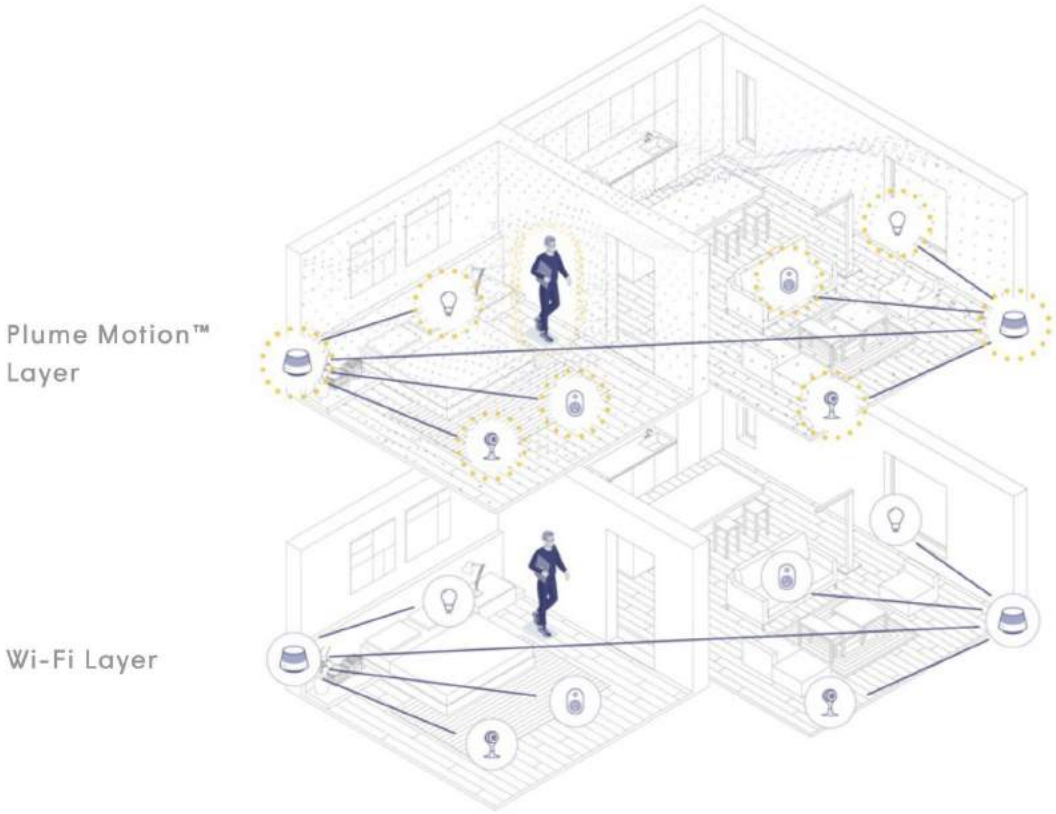

**Figure 19 - Wi-Fi Motion Detection Concept**

Using Wi-Fi to detect motion has a number of advantages:

- Far lower privacy concerns than using cameras in the home
- Does not require installation of extra sensors
- Does not require wearing of tags or sensors
- Comes with no hardware cost - can be implemented as a pure software solution on existing Wi-Fi gear

Wi-Fi motion can be used to provide a number of services of interest to the user. Home physical security is an immediate application. When out of the house, the system can be put into a mode where an alarm is sent if motion is sensed in the house. Elder care is another application, based on the reverse concept. In elder care, an alarm is sent if there is *not* motion across the appropriate periods of the day. Home energy management, for example turning on the heat when someone arrives home, is another application. Future versions of the technology may even be able to detect falls, and react quickly enough to control lights as you enter a room.

## 5. Conclusion

COVID-19 has changed the environment for service providers. It has dramatically increased the usage, loads, and sensitive traffic in homes, increasing the difficulty of providing sufficient quality to consumers. And, these changes are likely to persist even after COVID-19 has receded. However, technologies exist that have proven to mitigate many of the issues detailed in this paper. Multiple-AP deployments, with intelligent optimization and throughput optimized steering can ensure sufficient throughput to all locations in the home. Interference in the most challenging environments, multi-dwelling units, can be minimized through cloud based joint optimization. Increased cyber security attacks can be thwarted with machine learning based anomaly detection. And, accurate evaluation of networks requiring attention can be achieved using quality of experience metrics. COVID-19 is also affecting service providers revenue and profit. Artificial intelligence can be applied to perform proactive support, reducing the costs of service calls, truck rolls, and most critically, customer churn. And new technologies such as Wi-Fi motion detection can be used to create new services and new revenue streams.

Francisrsandoval@gmail.com

# Table of Contents

## List of Figures

# 1. Introduction

Specification of the Generic Access Platform is currently underway (Summer 2020) within SCTE, with broad participation of cable operator and vendor communities. In addition to the requirements for modularity and flexibility driving the effort, the platform will offer unprecedented communications to monitor and control the device and power management is an important feature in those communications.

The cable access network accounts for the vast majority of energy consumed by cable broadband providers, due to the very large number of devices in the outside plant. Measuring energy consumption deep into the network provides a number of business and customer-facing benefits, and the possibility of optimizing electrical usage under certain scenarios offers a glimpse of a more energy efficient, cost efficient, and reliable network.

This paper will briefly introduce GAP and the network configuration (NETCONF) protocol used for its communications, and dive into the SCTE-216 APSIS standard that will provide the power management facilities. APSIS - the Adaptive Power Systems Interface Specification has been developed by the cable operator community and published by the SCTE to provide a comprehensive and flexible data model to represent energy metrics and controls. By adopting a standard data model, costs can be driven out of the data supply chain, and this data can be merged across multiple platforms. A number of APSIS based energy use cases have been developed by the industry, many of which can be directly supported by GAP.

Finally, some suggestions for next steps for the industry will be outlined.

# 2. Power measurement and management on the Generic Access Platform

## 2.1. System Overview

The Generic Access Platform (GAP) is a set of specifications that will be published by SCTE that define interfaces to enable outside plant/access network components from multiple vendors to interoperate to provide a configurable set of functionalities. Unlike a traditional node that embodies a fixed set of features, a GAP chassis can be populated by sub-modules to provide a range of capabilities, and can be updated and reconfigured while in the field. GAP can support any mix of services such as DOCSIS, WiFi, PON, and 5G.

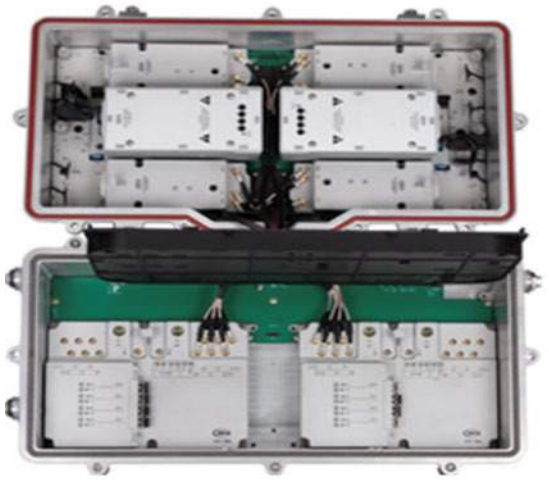

**Figure 1 - GAP**

For more detailed information about GAP, please see the SCTE online description of GAP.

Interoperability demands standardization so that the same type of component supplied by two manufacturers can appear to behave identically to other components in the system. GAP defines how sub-components within a device, such as amplifier, power supply, virtual Cable Modem Termination System (vCMTS) and other components interface with the device chassis. Additionally, GAP defines how the system communicates with an external control component, described as a node manager.

The node manager communicates with the GAP from the head end or other location in the broadband network via the NETCONF protocol.

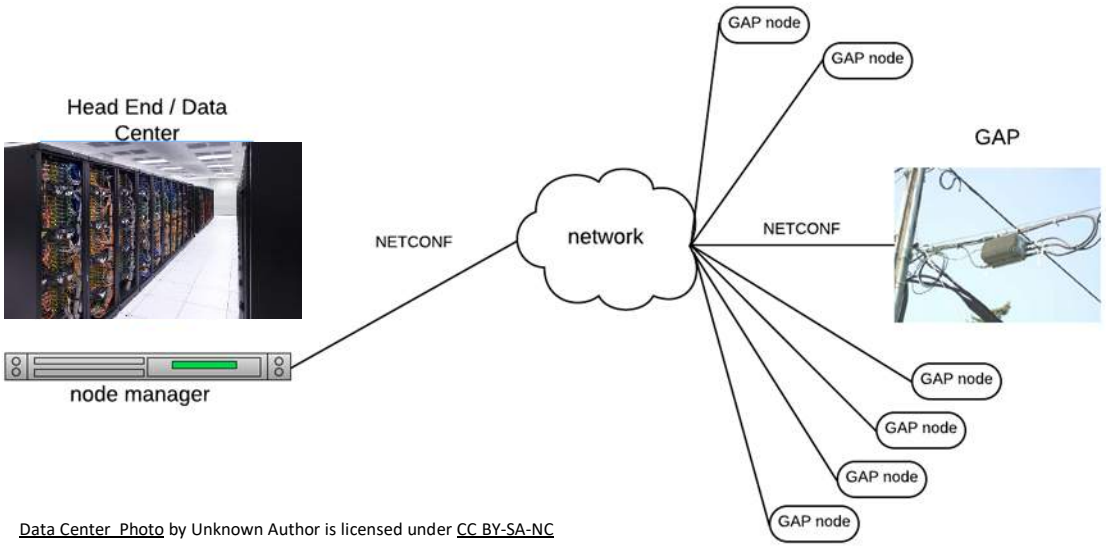

**Figure 2 - System Overview**

GAP specifications do not define elements outside the scope of the GAP device and its communications with a node manager, but implicit in the design are applications that make use of the node manager to configure and monitor a population of GAP devices. Applications can interoperate with multiple domains because GAP interfaces are well-specified. - For example, an application that listens to the node manager to detect a power outage on a set of GAP device could be leveraged across multiple cable operators. This 'write-once, run anywhere' facility can greatly speed innovation and reduce prices where it matters - in the development of the sophisticated logic that exists in applications. Even where applications are developed for a specific provider, the use of standards provides a 'loose-coupling' between application logic and the interfaces and data that feed them, reducing development time and maintenance costs. We discuss applications in more detail below.

## 2.2. Node Manager<->GAP Communications

The GAP communications drafting group has begun listing node level management objects that a node manager can monitor. These are in addition to sub-modules specific telemetry. The initial list includes categories for power, inventory, environmental, security, and other sensors.

There are numerous protocols that could be used for node manager to GAP communications. The communications protocol has to be bi-directional, support a rich data set, be fairly low-latency, and support high volume on the node manager side, as one manager may connect to a high quantity of GAP devices. While traditional legacy SNMP might have been selected, modern protocols are more efficient, secure, and easy to use. Of the possible candidates NETCONF was chosen because it meets all of the requirements and has a healthy ecosystem of tooling available.

The NETCONF protocol has been designed specifically for networking applications and is widely supported in routers, switches, and other networking gear. NETCONF messages are described using a formal DSL (Domain Specific Language) called YANG (Yet Another Next Generation). YANG is a human readable text format that can express hierarchical data trees (similar in some ways to an SNMP MIB), remote procedure calls (RPCs) and notifications.

```
container eoDevices {
    config false;
    list eoDevice {
        config false;
        key "id";
        leaf id {type int32;}
        leaf eocategory {
            config false;
            type enumeration {
                enum PRODUCER {description "energy object category";}
                enum CONSUMER {description "energy object category";}
                enum METER {description "energy object category";}
                enum DISTRIBUTOR {description "energy object category";}
                enum STORE {description "energy object category";}
            }
            description "energy object category";
        }
        uses energyGroup;
        container powerInterfaces {
            list powerInterface {
                key "id";
                leaf id {type int32;}
                uses energyGroup;
                description "collection of power interfaces";
            }
        }
        container components {
            list component {
                key "id";
                leaf id {type int32;}
                uses energyGroup;
                description "collection of components";
            }
        }
    }
    description "root of enam api";
}
```

**Figure 3 - YANG snippet**

Tooling is available to auto-generate NETCONF interfaces based on YANG, and to generate complementary RESTCONF interfaces. Where NETCONF is a low-level device oriented protocol, with support for connections and transactions, RESTCONF presents a more application friendly HTTP RESTful API.

In typical NETCONF usage, a software defined networking (SDN) 'controller' sits between a service provider's business applications and networking elements; presenting an easy to use RESTCONF API "northbound" to applications and handling the complexities of interacting with devices via NETCONF on "southbound" interfaces. In the GAP scenario, a node manager embodies the functions of an SDN controller.

## 2.3. APSIS

One of the initial efforts within the SCTE Energy 2020 initiative was to define software interfaces to measure and manage power. A working group was formed to develop the Adaptive Power Systems Interface Specification, or APSIS. Since engineers often like to borrow the work of others rather than build from scratch, a survey of existing power related standards was conducted. The Internet Engineering Task Force (IETF) Energy Management (EMAN) framework was selected as a basis from which APSIS could evolve. Originally defined as a collection of SNMP (Simple Network Management Protocol) MIBs (Management Information Base) contributed by Cisco's EnergyWise team, EMAN provides a

comprehensive and flexible data model for characterizing the power consumption, and production, of any sort of system. The EMAN structure applies well to the cable domain as it can describe a device with any number and configuration of sub-components (like GAP) and can be easily extended to accommodate special cases if the need were to arise. While the APSIS data model is fairly large, specific use cases need only utilize the portions that are relevant in their context.

After selecting IETF EMAN, the APSIS team developed a high-level, protocol independent Information Model and contributed it back to the IETF. The Information Model describes, in Universal Modeling Language (UML), the same data as encoded in the original EMAN MIBS, but in a way that facilitates additional protocol 'bindings'. With this mechanism, teams can develop NETCONF, IPDR, gNMI, or any other style of interface to suit their domain yet be confident that the resulting data can be merged with data sourced using another APSIS compliant protocol.

A protocol independent data model is extremely valuable as we consider the job of processing data at higher logical layers. Consider a predictive modeling application that consumes power data from a wide variety of devices to correlate variables in order to anticipate a service outage - perhaps an unusual oscillation of power quality is a predictor of service failure. If power quality measures are being collected from the widest possible population of sensors, perhaps some using SNMP, some NETCONF off of GAP, some using something else; the modeling application can only reliably utilize that data which is semantically identical, even where the on-the-wire syntax may differ. Where data sources use different models to describe similar things the data quality of the merged set can be unreliable. Data scientists can tell us that even where two differing data source formats use a common key name there is no guarantee the associated values mean the same thing.

By referencing APSIS in the GAP specifications, a reliable data model is established on which to build data processing applications. APSIS can further be adopted by other platforms, either as a native format directly supported by a device, or as a target format for which a defined mapping exists from a non-APSIS or legacy data model in the form of the APSIS model. Another opportunity for expanding the footprint of native APSIS support could be through upcoming revisions to the SCTE power supply/transponder interface specification, SCTE 25-3.

## 2.4. Power Requirements

Among the node manager to GAP communications requirements identified by the GAP working group, a number of power related requirements have been defined, including input voltage, power efficiency, line usage, and power per line, to name a few.

Power consumption is important to proper operations of the access network and it represents a vast majority of electricity costs for a cable provider. As part of the SCTE Energy 2020 program, the cable energy pyramid was published to illustrate the relative energy utilization across portions of a cable operator's footprint.

**Figure 4 – SCTE Energy Pyramid**

For a large MSO, the access network alone can consume hundreds of millions of electricity dollars in a year.

## 2.5. Power Use Cases

To this point, little has been done to systematically collect, analyze, or act upon energy data emanating from the access network, outside the scope of individual efforts within some MSOs. By including standardized energy metering and controls into the GAP, MSOs and partners may more cost-effectively build the tooling necessary to fully leverage such data.

A substantial number of use cases pertaining to powering the access network have been articulated by the industry, published as SCTE-245 'Use Cases for Adaptive Power Using APSIS'. Use cases have been grouped under several categorizes, including:

- Measurement
- Adaptation
- Demand Response
- Energy Supply monitoring
- Energy Services

As Lord Kelvin stated, "If you cannot measure it, you cannot improve it." Measurement of energy usage is a fundamental use case. Gaining near-real-time visibility into the sources powering the access network and the power state of components therein supports any number of valuable applications, including at least:

- **Detecting grid power availability.** The cable plant overlays the utility grid and can report with greater resolution the state of power outages. The CableLabs Gridmetrics project is working across the industry to support this and related use cases.
- **Assessing grid power quality.** Grid power is not simply off or on, fluctuations in voltage can impact system performance, reliability, and availability, and can have a dramatic impact on the useful life of equipment.

Please refer to SCTE-245 for details on these and many other important use cases.

## 2.6. Adaptive Power

The seed of the APSIS effort was the observation that while cable service demand swings widely between prime-time peak hours and the middle of the night, there is very little corresponding fluctuation in energy usage by the network. The service demand curve is very similar to what's been called the 'duck curve' in the utility industry since the shape of electrical load over the course of a day resembles the silhouette of a duck's back. As cable technologists, the fact that energy consumption remains high when service delivery plunges just feels like a system that is not optimally designed - it's a bit like leaving the lights on when you leave a room at night. The use case of adapting network behavior to correlate energy consumption to the stable and predictable daily service demand oscillation has been labelled 'diurnal adaptation".

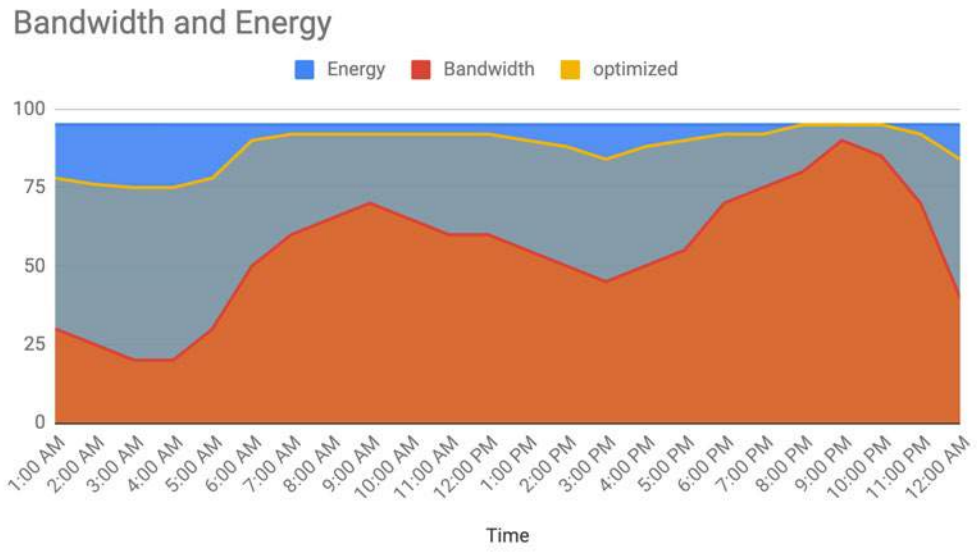

**Figure 5 - Diurnal Adaptation (illustrative)**

Figure 5 attempts to illustrate that the combined blue and grey areas are the flat, unoptimized energy consumption, and the blue is optimized by the effects of diurnal adaptation. The curves do not represent measured data but are simply illustrative of the phenomenon of daily service demand fluctuation and associated energy curves.

Research by vendors, including ARRIS (now CommScope), WES.NET, and Concurrent, demonstrated at earlier SCTE Cable-Tec Expo events, indicate that by carefully managing network resources, daily energy consumption by some networking elements, such as a Converged Cable Access Platform (CCAP), can be reduced by over %15. In the case of CCAP, as data throughput drops below defined thresholds, flows can be remapped to consolidate traffic onto fewer output ports, freeing up line cards that can then be temporarily placed into low power states.

A proof of concept conducted by Comcast with support from ARRIS, also discussed in a previous Cable-Tec Expo, demonstrated the use of APSIS in managing a CCAP to simulate diurnal adaption and confirm the results of earlier prototypes. The open-source OpenDaylight (ODL) SDN controller was selected to act as the control plane, playing a role similar to that of the node manager in the GAP scenario. An EMAN 'plug-in' was developed for ODL to present APSIS as a standardized Northbound API to an

energy management application, and a Southbound 'adapter' was developed to integrate with the command line interface (CLI) of the CCAP. A time-lapsed simulation of daily data traffic was fed into a lab installation of a CCAP using the iperf tool, while the energy management application monitored the CCAP to detect the data throughput. When throughput crossed a defined threshold, the application sent commands, via APSIS APIs, through the controller to the device to remap flows and power up/down line cards, as the volume of traffic dictated.

Adaptive control of the GAP could take several forms, including attenuation of the bias current driving the downstream radio frequency (RF) signal. The strength of the baseline bias signal, on to which service information is encoded and carried, can be correlated to the amount of information that needs to be carried. As data volumes increase and decrease to serve shifting demand, the strength of the baseline bias current could correspondingly attenuate. The strength of the signal is a function of the power used to generate it; therefore, a diminished bias current consumes less electricity. In a generic access platform, bias current might be controlled by the signal generator in response to the current service demand, or an external application that has access to other data sources and predicative models could augment this logic to provide a more timely and accurate control algorithm.

In a production environment, such real-time manipulation of the network could only be attempted with sophisticated control mechanisms. A production diurnal controller application would not only monitor data throughput but would factor in a variety of other metrics to maintain consistent quality of service and preserve the custom experience. An application could monitor customer experience metrics such as packet loss and jitter, and predicative modeling of anticipated data rates generated from Machine Learning agents. In addition, weather events, social events like sports, or other phenomenon that might perturb the historical norm could be factored in. The application would have to implement automatic and manual controls to back-off its optimization operations in order to ensure continuity of service. While this seems futuristic today, as network operations have been successful in maintaining their excellent service availability record by minimizing risks and limiting variables, we can anticipate that as software controls become more sophisticated they will be able to lower costs and increase customer satisfaction while addressing the risks of unintended consequences.

Adaptive control is a type of 'closed-loop automation'; a topic of intense focus within the telecommunications world at large. The dream of self-configuring and self-healing networks is in development today.

## 2.7. The Application Layer

Interface standards provide the plumbing through which data and commands can flow, but interface standards are valuable only in what business logic they support. When we include applications into our system view, we get a three-tiered 'full stack' model: devices at the bottom, node manager/SDN controller in the middle, and applications at the top. GAP is a special case of a more general data ingest/processing/business logic framework, as power related data is just one of a number of data streams that can and should be handled in the same general way. Another way of describing the general case is standards and processing system are the domain of data engineering, and the transformation of data into business intelligence is the domain of data science.

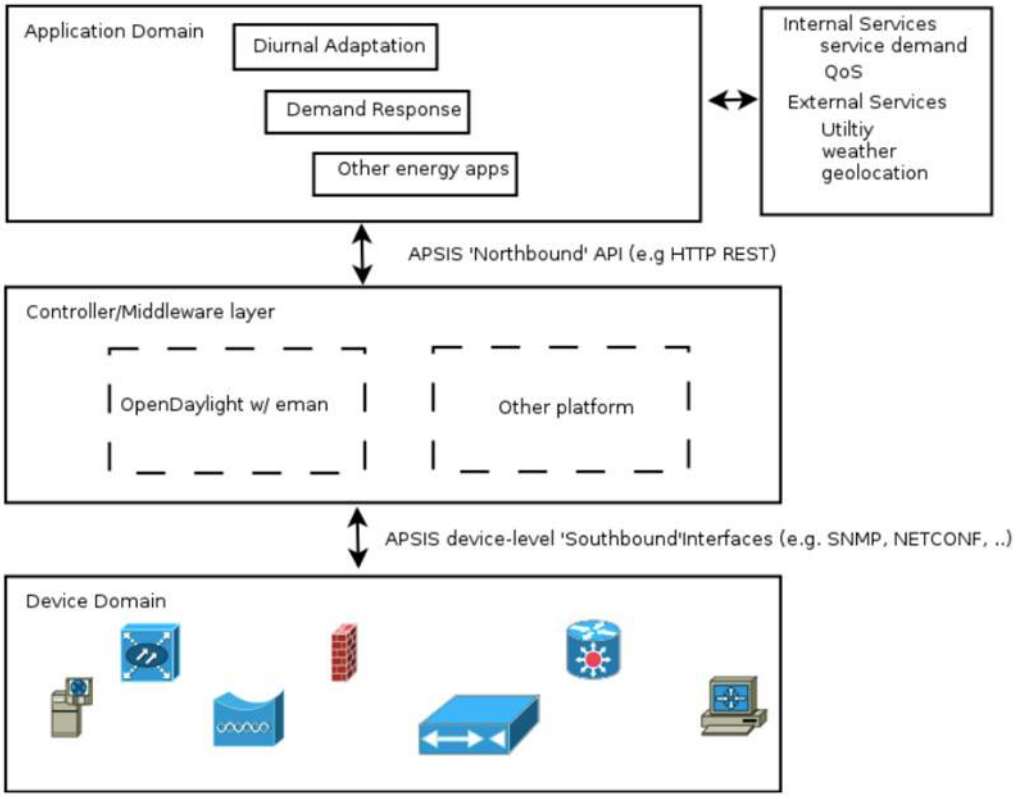

**Figure 6 - Full Stack**

Figure 6 illustrates a general model for a device/controller/application stack. GAP is a specific implementation of this general model, in which the 'Controller' in the node manager and the device domain is limited to GAP.

A healthy ecosystem utilizes standardized data flowing into cable operator data processing systems feeding an ever-growing number of applications. To foster innovation at the application layer, apps must utilize known interfaces and data models - otherwise developers will spend valuable time integrating with bespoke data sources rather than focused on creating valuable business logic.

Cable operators will use their in-house teams to develop some applications, but may also partner with application vendors (exporting data under strict privacy and security controls to authorized and authenticated partners), among whom might include value-added analytics services, utilities, industry consortia, researchers, and any other partner an operator wishes to engage.

## 2.8. Next Steps

Writing and publishing a standard is only worthwhile if it is adopted by multiple industry actors and lead to the creation of business value as previously mentioned in section 2.7. We can greatly speed adoption by performing activities above and beyond simply writing things down on a piece of (virtual) paper and posting it on the web.

The Java Community Process (JCP) provides a great example. A new Java API standard is not considered complete until three deliverables are made available: a specification, a Reference Implementation (RI), and a Technology Compatibility Kit (TCK), or test kit.

We might collaborate across the industry to develop a simple prototype of a node manager linked to a GAP simulator to serve as a first-generation Reference Implementation and make API calls to the RI to serve as the beginnings of a test suite.

Because GAP is using NETCONF, our initial prototyping would be quite easy. An NETCONF open-source SDN controller, such as OpenDaylight, could act as a Node Manager, and one of several NETCONF server simulators could present itself as a GAP, by serving up GAP YANG models. A couple of net-conf simulators are: ODL netconf testtool and ntsim.

With a working environment programmers and integrators can then begin to develop application prototypes to learn how best to process, analyze, and act upon GAP data, regardless of whether power related data or other GAP data. The value of an accurate simulation environment cannot be understated for application development - the key is having a system that supports very tight incremental code changes, e.g. tweak/modify a line of code, test it, repeat forever.

The GAP RI could be run on a laptop or could scale up in the cloud. If someone were to donate cloud resources, like a small AWS environment, the industry could share a 'GAP lab' to co-develop the RI, tests, and applications.

Finally, the adoption of APSIS by every platform that contributes to power monitoring or controls will drive costs out of developing data pipelines and applications that make use of power data. Think of plumbing a house. If: the sizes of pipes and fittings were all different, made up on the fly, changing from manufacture to manufacturer, and even changing between years and product lines from a single supplier, all of these factors could cause enormous costs and complexity to the modern day homeowner. This indeed was the case in the early days on modern plumbing. Let's not waste time and money pursuing non-standard solutions to data formats, including power data.

## 3. Conclusion

The Generic Access Platform promises an important evolution in access network technology by establishing a modular and configurable node architecture. Among the many benefits to operators is much improved visibility and control, including power measurement and management. GAP should incorporate the NETCONF protocol for communications with an upstream node manager, driven by well specified data models in the YANG format. For the power components of the communications platform, the SCTE APSIS specification provides an excellent solution as it defines a multi-protocol information model and a YANG binding to provide a comprehensive power measurement and management interface.

As a specification of GAP continues, we call for multi-party collaboration to develop a lightweight prototype implementation to 'burn in' the spec and identify gaps or mistakes in the written specification, and to provide an application development platform to generate tests and to research commercially valuable applications that process GAP data and support business value.

Finally, we encourage the adoption of APSIS for all power related interfaces and applications throughout the industry. There is little justification to re-invent a wheel and generating data in differing and potentially incompatible formats will only limit opportunities in deriving the utmost value in power data. Data, like social networks, can exploit 'network effects' to increase in value as they are merged and correlated with other data.

## List of Figures

# 1. Introduction

The digitization of the cable access network enables the promise of end-to-end network convergence for different lines of service. The promise, however, does not come with a framework and this leads to trepidation on how to proceed. A framework for service convergence must recognize three key principles. The first is that lines of services can have unique prioritization, throughput and latency requirements that need to be met. The second is that within a service there will be distinctions of endpoint types and applications that will eventually need their own unique treatment or policy through the network. The third is that the principles mentioned above are transitional over the lifecycle of the service and automation mechanisms to adapt and coexist are necessary to maintain viability over the long term.

In this paper we propose a framework for service convergence using network slicing for MSO networks. We review the network slicing principles for 5G and point to possible analogies that aid in developing a framework for MSO slices including residential services, business services, and mobile services. We cover the concept of network slicing functions which organize and partition network resources available to each service. We describe hard and soft slicing mechanisms, the implementation for slice-aware logical networks and the functionality necessary to maintain end-to-end slice visibility and usability over the lifecycle. We also provide several industry recommendations useful for a converged service environment utilizing network slicing, such as open interfaces for core functions, QoS implementation in packet networks, listing of slice expectations, usability of hard and soft slicing.

# 2. Opportunity Statement

The state of the cable industry has top-of-mind investments and revenues from mobile services, the growth of enterprise business services, and maintaining a robust residential high-speed internet and video service. There are multiple MSOs worldwide that already own and manage all three services, and for the last decade in the United States there have been coalitions formed with wireless providers to collaborate in transmission and management of wireline and wireless services. What has been noted, however, is that this is a financially complicated situation when done piecemeal, and that profitability has better odds coming from infrastructure-based network convergence. (BAUMGARTNER, 2019)

Enterprise business services on the other hand has been a solid growth engine for MSOs in recent years, becoming a solid primary connectivity option for enterprises. As a metric, in the past several years cable providers continue to make their way up in the Vertical Systems Group Carrier Managed SD-WAN Services Leader Board with a placement recently in the top seven (Vertical Systems Group, 2020). But one of the drawbacks to even more growth has been time to deployment and SLA enforcement partly due to a dependency on existing methods of non-automated bring up of circuits and separate networks including operation and engineering. Thus, the enterprise network depends on evolution to automation, for itself, in the context of automation being also useful for mobile and residential services.

The residential network continues to have solid growth, with revenues for high speed internet growing at 5-10% year-over-year (Comcast , 2020), (Charter , 2020). The status of the residential network exploring convergence with mobile services, and no convergence with business services is understandable due to historical precedents, but there are several dynamics at work in the evolution of the residential network that allows us to take a renewed look at converging multiple services on common network infrastructure. One is the nature of Distributed Access Architectures (DAA), where the legacy residential cable plant, both fiber and coaxial plants have used analog technologies for distribution, but are now transitioning the fiber portion to digital Ethernet and IP, thus all networks will now approximate the same format for transmission. Second is the evolution of DOCSIS and Video to cloud native cores. Now DOCSIS, Video,

 

Mobile and general broadband network gateways that handle subscriber management will have a deployment path to use containerized computation schemes with generic hardware support. And third is the large expansion of endpoints that need connectivity for 5G and DAA and enterprise 1/10GbE fiber services which could benefit directly from the very broad coverage of HFC and its availability of electrical power sources to distribute cells, Remote-PHY Devices (RPD) / Remote-MACPHY Devices (RMD), and aggregation points for CPEs (Chamberlain, 2018). From this perspective, the industry is ripe for full infrastructure convergence for the services mentioned above leveraging investments in an optimized and streamline manner.

From the user perspective convergence assists in typical usage methods. Take for example the smart phone user maintaining a session at a home, with Wi-Fi enabled backhaul, proceeding to a car driving down the road all on seamless session. Or the parent working from home at the same time and on the same high-speed internet that provides over-the-top video entertainment for the kids. These examples include seamless handoffs between different service types with different usage priorities.

### 2.1. Network as a Service

The drivers for network convergence not only include reduction of OPEX and improved general efficiency, it also includes the capability to add new revenue streams. Network convergence organizes the qualities of the network such that the network itself is an asset to sell. When the network understands the user transmission profile and its tendencies, then the path is set for creating a robust platform for network as a service (NaaS), where the operator offers highly customizable Virtual Network Functions (VNF) for customers who need a broad range of network capabilities (Hodges, 2019). A complete description of NaaS capability is left for another work, but necessary to mention in the context of a network slicing byproduct.

## 3. Solution Statement

The nemesis to converging residential, private line business services, and mobile services on common network infrastructure boils down to a possible acrimonious sharing of resources. After all, the networks mentioned above have grown up independently, with full control of their infrastructure, customer base, their priority structure and SLA compliance. These are valid concerns of a converged environment that merit a comprehensive solution. This paper proposes a method for developing a non-acrimonious solution for network and service convergence where the sharing of resources is possible. To do this we borrow from the principles of network slicing as recently defined for 5G. Naturally, an implementation of network slicing for the MSO will have its own idiosyncrasies consistent with our needs and expectations.

Before we discuss network slicing, we review a few technical principles that are key to understanding network slicing.

### 3.1. Convergence View

It is useful to catalog the extent of the convergence possibilities. Figure 1 provides a list of the different type of physical networks, services, and subservices that would be part of a converged end to end network. We list three access network types, the HFC plant, a point to point fiber plant, and a passive optical network. All these access types would converge on the same aggregation point C, at a hub or in the field, such as an unmanned cabinet or a strand-mounted device. Aggregation at point C could be done in fiber, per wavelength, in straight forward Time Division Multiplexing (TDM) using Optical Transport Network (OTN) or Flex-Ethernet (FlexE) framing, in layer 2 switching using Ethernet, or layer 3 routing using Internet Protocols. Northbound the aggregated signal could range from 10 Gbps to 400 Gbps

depending on optical technology and desired level of signal concurrency (Villarruel, 2018). The aggregated signal would then typically terminate in another aggregator, point B, whose job is to add/drop signals locally if a service core is present, or further aggregate signals onto a metro type network with signal rates in the 100 – 800 Gbps range. The technologies northbound are typically IP with embedded high throughput optics in the rage of 100-400 Gbps or a more advanced photonic layer in the range of 100-800 Gbps. Aggregation point A is then the termination point for the signals that originated in the access. Here they are evaluated in accordance to session and subscriber management at independent services cores. The Converged Cale Access Platform (CCAP) takes care of the DOCSIS signaling and represents in this case other auxiliary cores of other residential type functions, such as out of band set top box signaling and test and measurement. The video core cares for the distribution of MPEG sessions, broadcast and narrowcast. The 5G core cares for the mobility signaling. With the understanding that there is an ongoing evolution from LTE to 5G core, we shortcut to 5G for sake of expediency in this discussion.) The Metro Ethernet Forum (MEF) core stands for the session management for enterprise and applicable business customers. The Broadband Network Gateway (BNG) is the session and subscriber manager for the data subscribers of the Passive Optical Network (PON) network.

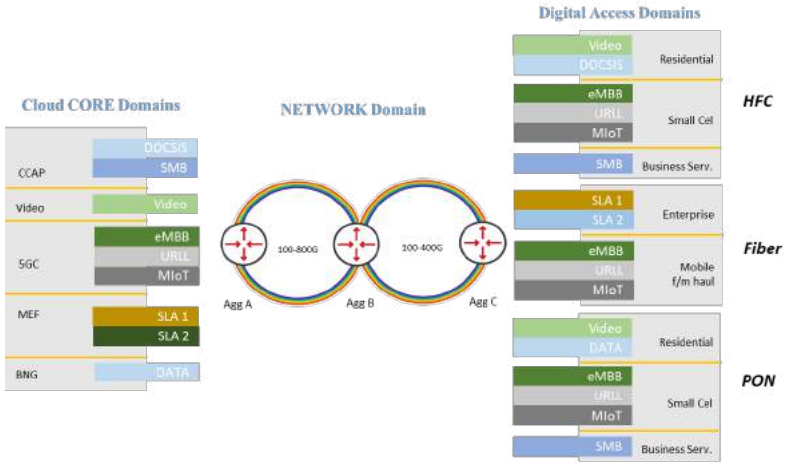

**Figure 1 - Convergence of services for MSOs**

Within each access network there are different types of services. Figure 1 shows a non-exhaustive list of service types. In the HFC access, for example, there are wireless small cells, which are also expected to use DOCSIS as backhaul (Andreoli-Fang, 2019), along with business customers. For Fiber access there are enterprise customers and mobile front / midhaul or backhaul customers. For PON access there can be residential, small cell and business services customers.

Figure 1 also shows that within each service vertical there are subservices, this is also a non-exhaustive list. These are unique user applications that have specific demands of their parent network consistent with the end user expectations. Within HFC/residential there is Video and DOCSIS data. In the HFC/small cell domain we list enhanced Mobile Broadband (eMBB), Ultra-Reliable Low-Latency Communication (URLLC), and Massive IoT (MIoT), which are specifically defined sub-service types for 5G. For Fiber/enterprise there are SLAs and in both PON and HFC there are SMB Business Services. Note that the same type of subservice could live within different access domains.

Now these different types of customers/services are managed by their respective core domain. In practice, and for the foreseeable future, we can assume that even though there is a transition to cloud-based cores, the cores would remain independent, i.e. not sharing compute or memory resources. Figure

1 however presents the cores as converged in the minimum sharing resources, (while keeping functional independence), but at some point, in time possibly sharing session and subscriber management functions.

Figure 1 also shows that subservice types have a unique termination point on the core, independent of access type they originate from. This is also a forward-looking proposition, as we recognize that each subservice now subtends to its own specific service core.

# 4. Convergence Drivers

## 4.1. Distributed Access Architectures

DAA is a technical driver for convergence. This is a topic that has received much due attention in the past few years and here we refer to work that has already been done. DAA is driven by the evolution of the residential network from analog fiber to digital fiber by extracting the physical RF layer from CMTS or effectively extending the Quadrature Amplitude Modulation (QAM) modulation platforms and positioning them in a separate location, where separate can mean a different shelf, in a different hub, or at the end of the deeper fiber additions in the outside plant, in a street cabinet or on strand mounted node like platforms. DAA technologies create an Ethernet / IP network where several aggregation points are needed to distribute or collect signaling. DAA because of its standards based digital transmission, is a natural platform for usage of other access endpoints that coincide using ethernet or IP access signaling (Villarruel, 2014). Ethernet point to point signals for business services apply, and so do recent pluggable OLT technologies that are granular OLTs, sprouting PON networks from any given 10GbE switch port (Villarruel, 2015). Figure 2 shows the evolution of the residential access plant, starting with analog based fiber then adding digital endpoints, followed by aggregation in the field and ultimately convergence of other services. On the core side it begins with legacy video and CMTS platforms evolving to cloud native cores along with a possible centralization of cores from smaller hubs to larger hubs or from hubs to headends, maximizing efficiency of compute. Not shown but also part of the DAA discussion is partitioning of software functions so not all of the DOCSIS stack resides in one location, this for example is the effort being done in the Flexible MAC Architecture (FMA) working group at CableLabs (BTR , 2019).

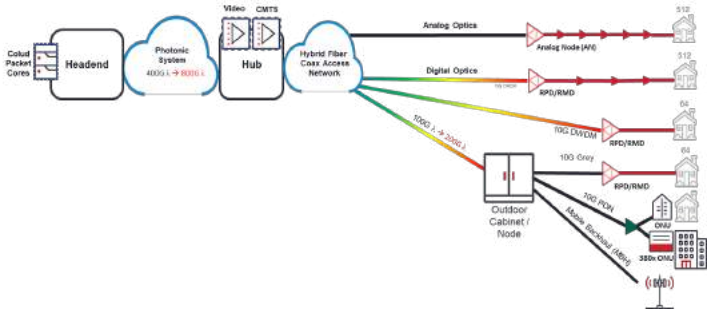

**Figure 2 - Evolution to Distributed Access Architecture, DAA**

## 4.2. Cloud Native Service Cores

The separation of specific PHY implementations in the CMTS has allowed a rethinking of its software architecture. Effectively virtualizing the CMTS by the decoupling of the software stack from vendor specific hardware. Beyond just virtualizing however there is a trend towards even more software flexibility by implementing a cloud native architecture where software is broken up by functions, and

these functions are presented as independent containers that run on a container platform and are orchestrated by a framework that facilitates their interrelation and thus present a complete service solution. Interestingly, these container frameworks are built with open source tools so both the hardware and software infrastructure for service cores is now open, in principle. Figure 3 is a simple view of popular cloud native implementations, where Linux is the operating system, Docker is the container platform and Kubernetes is the orchestrator, all of which were derived in open source communities.

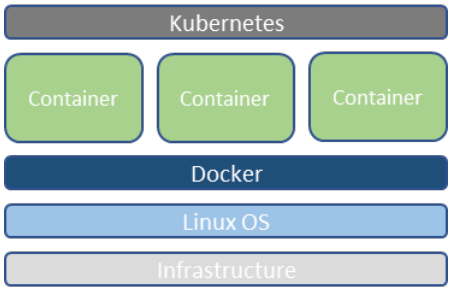

**Figure 3 - Cloud Native Framework**

The nature of containerization also allows for flexibility in geographical placement of containers, allowing for certain core functions to be closer to the user as needed. This is the science of edge compute, derived from cloud native architectures. This topic is beyond the scope of this paper, but it is a discussion that comes up in advanced implementations of distributed service cores and network slicing.

Also, of interest is the view of cloud native cores in deployment as shown in Figure 4. We see the system as a whole is broken up into functionalities. There is the Data Plane, the part of the software that processes and executes on data transmission requests, this notably includes the PHY layers and forwarding layers. There is the Control Plane that creates the configuration environment for the data. This includes things like path controls for a switched or routed network, session and subscriber control for the end user, bandwidth shaping for the network and authentication of endpoints. Beyond the data and control plane there is typically a Management Plane, which can also be part of the control plane, but here we call it out separately to make a point. This management plane facilitates the interdependencies of the control plane within itself and to the physical network items. In scale this typically cannot be done with simple network management system tools, and so an overall orchestration system is implemented. This orchestration system can have read write capabilities for all hardware and software elements and can provide a stateful view of the overall network to northbound operational and billing systems. This generalized view of cloud native deployments is useful as it sets up possible analogies to 5G.

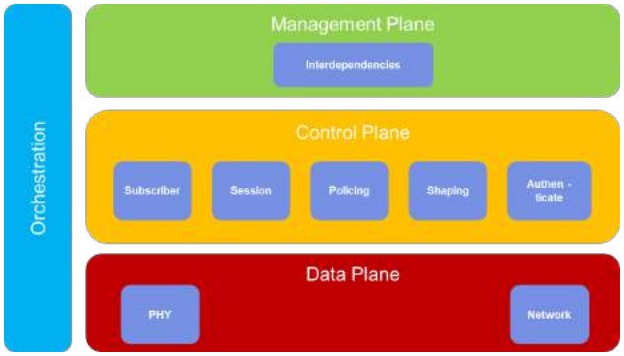

**Figure 4 - Typical Cloud Native Core Deployment**

## 5. 5G and Network Slicing

The recent and very popular evolution to 5G in the mobile space provides us a good reference to learn from as we look at the convergence of multiple services and subservices. 5G is the mobile evolution from 4G LTE with drivers coming from increased bandwidth throughput, many more subscribed endpoints, and most importantly for us a widely varied set of usage scenarios, effectively creating a wealth of service types that have broadly varied expectations from the 5G network, see Figure 5. All these varied services are set to run simultaneously making the 5G network a largely different proposition than its predecessors.

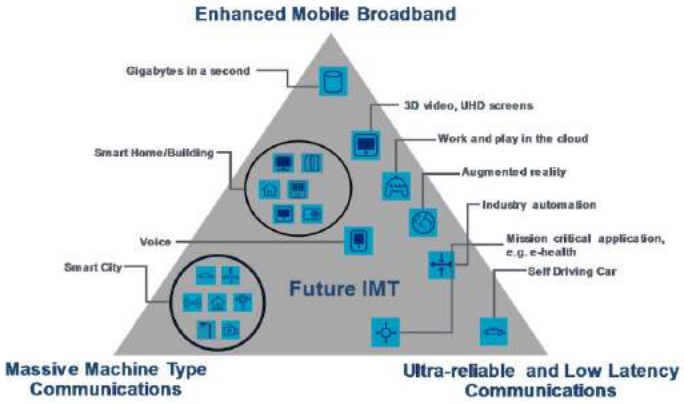

**Figure 5 - 5G Usage Scenarios, (SANTO, 2017)**

The capability for 5G to carry various services types has been expressed not only in the radio access network, with many more cell sites and increased bandwidth but also in the way the 5G core has been architected. In Figure 6 we show the 5G core architecture definition according to the third generation partnership project (3GPP), (Mademann, 2017).

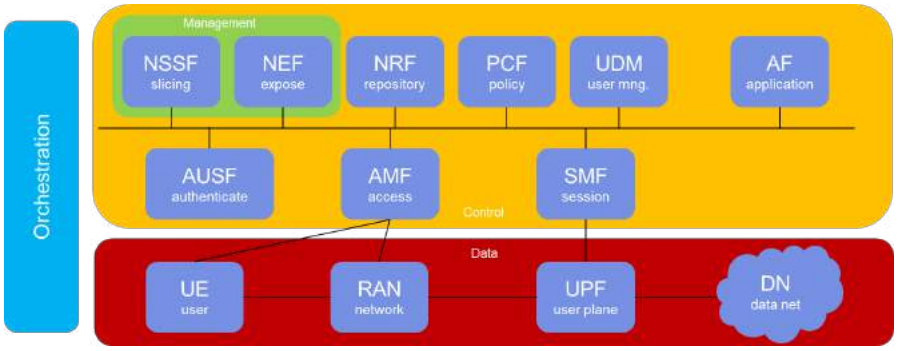

**Figure 6 - Cloud Native 5G Core**

A detailed review of the 5G NG architecture is beyond the scope of this paper but there are three notable evolutionary items making it different from its predecessor. They are listed below. In the next section we briefly describe each function.

- The 5G core is a cloud native, service based architecture, where architecture elements are defined as network functions with standard APIs such that they can be called on by any other network function with permission to do so (Felix, 2018). The standardized interfaces allow for multiple vendors to participate in the core, according to their capability in these discrete functions.

- 5G has separated the user plane and the control plane, allowing for top of the line hardware and software technologies and a flexibility of deployment models. This is referred to as Control User Plane Separation (CUPS). In this discussion we refer to the user plane as the data plane, see Figure 6.

- Most of the functions in the 5G architecture are carry over from LTE with some variations and containerization, however, some of them are new and specific to 5G. The new functions, we list under the management plane in Figure 6 are The Network Slice Selection function (NSSF), the Network Exposure Function (NEF). These functions were created specifically with the envisioned multiservice capability of 5G (variety of device types), and the dynamic nature of these services over time. Note that the calling out of NSSF/NEF as a management plane in Figure 6 is an exercise done for this paper to highlight the nature of these functions. The formal 5G architecture keeps them as just part of the control plane.

## 5.1. 5G Functions and Descriptions

Below is a brief description of the 5G core functions.

- UE: User Equipment. Any other device with mobile connectivity, such as smart phones.
- RAN: Radio Access Network. This is the network that connects user equipment to other parts of a mobile network via a radio connection.
- UPF: User Plane Function. Features to support packet routing and forwarding, interconnection to other data networks, and policy enforcement. Similar to the packet gateway in 4G LTE.
- DN: Data Network. Broader service provider network, "the internet."
- AUSF: Authentication Server Function. Authenticates UEs and stores authentication keys.
- AMF: Access Management Function. manages user equipment registration, authentication, identification
- SMF: Session Management Function. Establishes and manages UE sessions, static and in movement, allocate IP addressing, informs on quality of service.
- PCF: Policy Control Function. Provides policy rules to control plane functions.
- UDM: Unified Data Management. Stores subscriber data and profiles.
- AF: Application Function. Connectivity point for management functions and control plane and data plane.
- NRF: Network Repository Function. Registration and discovery of network functions so that they can find each other.
- NSSF: Network Slice Selection Function. Has the task of selecting and directing network traffic to the use of particular network slice? Its assignments are determined by allowed usage per a network slice library found in the network slice selection assistance information (NSSAI). It also determines the access and mobility function (AMF) settings applicable to a user entity.
- NEF: Network Exposure Function. A mechanism that securely exposes state information of the 5G core, which includes capabilities and events, packet flow descriptors, and translation services for the flow of internal external information.

Of greatest interest in this discussion are the NSSF and the NEF, as together the allow for a dynamic network slicing mechanism over time.

## 5.2. What is Network Slicing

Network slicing is formally a method to run multiple end-to-end logical networks on a common set of resources. Network slicing in the most basic sense is not new. We have to date used to layer 1 slices with

managed OTN, or layer 2 slices with managed Ethernet Virtual LAN Networks (VLAN), or layer 3 with managed IP virtual private networks (VPN). This is certainly a part of network slicing, but in the more general case the slicing logic also happens end to end, which includes the partitioning of not only of packet network resources but also software control and management resources. Figure 7 depicts a specific set of resources being partitioned for the whole network. This end to end network slice would be available for a service to subscribe.

**Figure 7 - End to end network slicing representation**

There are particular service and operational expectations for 5G slices according to the 3GPP definition (3GPP, 2016). We summarize the expectations below to promote an intuitive understanding of how network slicing is leveraged in deployments. Ultimately as the concept of network slicing matures in the cable space there will need to be a well understood set of expectations, not exactly like the one listed below, but most likely similar with variations addressing the specific needs of MSO systems.

#### *5.2.1. Service Requirements*

1. Slices are unique sets of network functions and configurations. The operator can create network slices from a multivendor environment of functions.
2. Network slicing is a dynamic exercise in an autonomous system applicable for diverse market scenarios.
3. A system can recognize a UE and its associated network slice.
4. A system allows the UE to subscribe to a specific network slice for service.

#### *5.2.2. Operation Requirements*

1. The operator can operate different network slices in parallel with isolation per slice.
2. Slices maintain the security profile expected of the service that uses it.
3. Network slices are isolated such that a cyber-attack would be confined to one slice.
4. Operators can authorize a third party to manage the network slicing environment, per suitable APIs.
5. The network slicing system is to scale in capacity with no impact to its service or other slices.
6. The system can accept changes to slices with minimal impact to subscriber services.

### 5.3. Service Convergence and Slicing

A service is the instantiation of a set of features, policies, and configurations. A service is facilitated using a set of well-defined network functions and resources. In the context of network slicing we refer to a service as having a unique “blueprint”, and a blueprint can be paired to one or more slices.

Service convergence then is the practice of multiple services (or subservices) coexisting in a well-defined manner on shared networking resources, (not unlike DOCSIS and Video do in legacy HFC). Service convergence is then simply the management of a collection of blueprints. Which implies, from previous sections, the management of parallel or interrelated slices.

For service convergence it is useful to take the birds eye view of a system, its multiple domains, slices, and their relationship. Figure 8 shows the components of a network slicing system for a typical service provider. There are several types of domains. The access domains with its multiple type of UEs which in the case of the MSO this would include the residential, enterprise and mobile access. We also have the network function domain, in practice this could include secure initialization, session bring up and tear down, encryption, etc. The network domain would be the resources for connectivity, in this domain there can be many slice types or various use cases available. This would be the case where you find distinctions for VLAN or VPNs, transmission methods for MPLS or Segment Routing (SR), each profile having its own slice. The core domain is a set of slices that give each service a unique profile southbound to the UE and interpret that service northbound to the operational and billing systems.

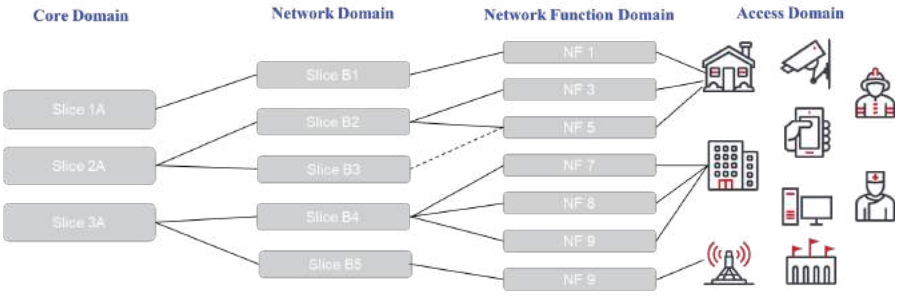

**Figure 8 - Domain and Slices Relationship**

What is important is not just the existence of slices but their inter-relationship in the system. We note that each service, or subservice can use a collection of network functions and subscribe to one or more network slices in a domain thus creating a specific blueprint. Figure 9, for example, shows a possible service blueprint in the highlighted mustard progression. Consider a security camera in the residential network. This camera needs resources from the network functions including the need for a timing service and local encryption. From the network domains it needs a VLAN or VPN tunnel, and from the core it needs a unique session and caching memory. This unique collection of resources is the blueprint for the security camera service.

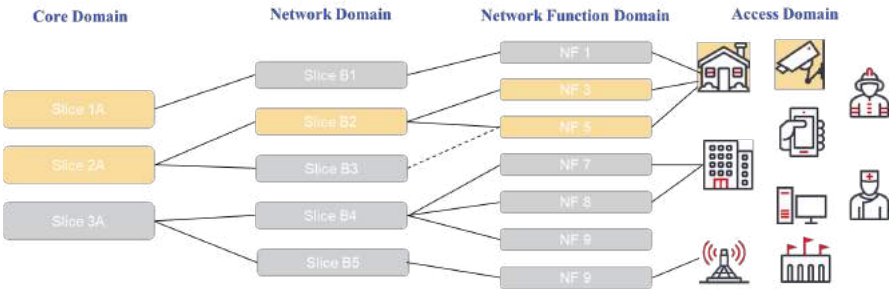

**Figure 9 - Service Footprint**

While the functions, slice and slice pairings in Figure 9 are unique they are also dynamic in nature, as the collection of needed slices and network functions can change over the lifecycle of the service. Thus blueprints create scenarios where the relationship across domains can be collaborative, interdependent, and pre-configured to particular scenarios.

The configuration of unique scenarios, as the example given in Figure 9, along with the end to end network slice management necessary over its lifecycle is what is referred to network as a service,

commonly referred to as NaaS, where the creation of particular revenue streams is now possible because there is an infrastructure to create and manage different blueprints. This can certainly be a usable capability for the MSO space moving forward. Consider the blurring lines between home and work because of the COVID-19 pandemic. As we considered the earlier example there is a case to differentiate, though the whole network, work traffic at home versus entertainment traffic at home—effectively two different blueprints.

## 6. MSO and 5G coexistance

In Figure 1, of section 3.1 we supposed the reuse of redundant functions in service cores, thus creating end-to-end convergence. But this goal is aspirational, and to thing about an interim path is necessary. We refer to the work done to support the momentum for integration of small cells onto the cable landscape, with DOCSIS backhaul (CableLabs, 2020). Per definition there is a generic satellite function to the 5G core that allows for a wireline system, to present itself as a user entity to the 5G core (3GPP, 2018). This function is called the Wireline Access Gateway Function, (W-GAF) and has standard interfaces, transmitting data plane traffic to the user plane function and control traffic to the 5G core control plane. This in effect allows for any non-5G system to have an embedded RAN and subtended devices, with the expectation that the wireline core has the capability to decipher separate data and control plane traffic.

In the case of cable, as shown in Figure 10, the W-GAF facilitates having small cells within the CMTS/DOCSIS system and creates an environment for UE's, behind the CMTS, to be treated as native participants of the 5G core. This is made possible in conjunction with the work done for DOCSIS MAC timing and latency functions (Cablelabs Timing, 2020) (Cablelabs Xhaul, 2020)

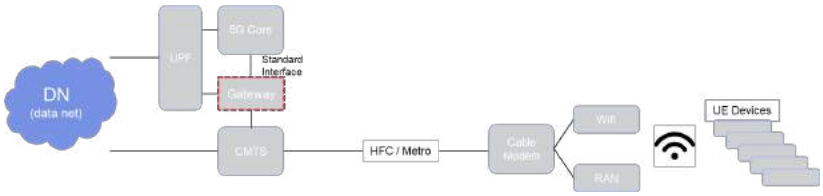

**Figure 10 - CMTS / 5G cores coexistence**

The working model for the coexistence of the CMTS and 5G, via a standardized gateway, gives a glimpse on the possibility to reuse the existing NSSF and NEF as a generalized slicing solution for other cores. The work at 3GPP championed by CableLabs, reported in the document "5G Wireless Wireline Converged Core Architecture Technical Report" (CableLabs, 2020) shows that there is already an established data model for an HFC system with a RAN that can subscribe to, be authenticated by, and admitted into the 5G core. Further there is a proposed method to extend not only subscription to the core but extend the QoS mechanism from the 5G core, available through the wireline gateway to the CMTS and its constituents. This is somewhat straight forward as the RAN components in the HFC have native wireless tendencies towards the control and data plane structure of the 5GC.

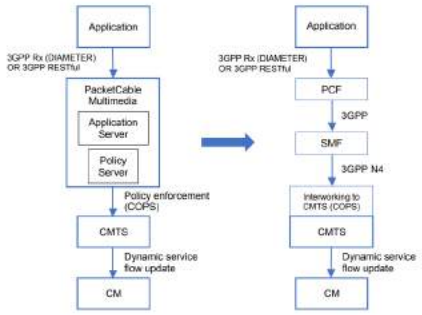

**Figure 11 - General QoS mapping CMTS and 5G core (CableLabs, 2020)**

Outstanding however is how to incorporate the non-wireless traffic into the global view for network slicing. What would be useful is a global QoS mapping to all CMTS traffic, as expressed in the DOCSIS 3.1 MAC Upper Layer Protocols Interface (MULPIv3.1) and Packet Cable Multimedia (PCMM), creating a complete map for all services, see Figure 11. The extension of QoS for native DOCSIS traffic can then be interpreted by 5G core Session Management Function (SFM) via a Common Open Policy Service (COPS) (CableLabs, 2020). With a global QoS structure in place the creation of MSO non-mobile specific slice types can be defined. The management of both HFC and 5G slices can then be done by the already existing SFFM.

It is worth mentioning that now QoS tagging is generally not a practice for DOCSIS packets in general and not over the new digital access fiber infrastructure. This is because it relies on the time map mechanism between CMTS and modems. There is a QoS mechanism that is embedded into the Xhaul specification, which will be necessary when transmitting small cells over DOCSIS and could prove useful if there is a general application of QoS for all residential signals would be necessary. An extension of QoS tagging to the Ethernet / IP network could prove useful or necessary as the MAC layer evolves in positioning, per the efforts of the FMA. In these cases, the network can participate in more intricate slices along with other elements of the end-to-end network.

An extension of this principle can be applied to the enterprise vertical, adopting enterprise bandwidth profiles to the global QoS mapping, starting at the first network aggregation point. The network slices for the enterprise would in principle use the structure laid out by native OAM signaling.

# 7. Slicing methods

## 7.1. Soft Slicing

Soft slicing refers to the practice of sharing resources with system enabled flexibility. In soft slicing the slices are statistically separate and transmit by logically multiplexing the data plane over some physical channel (IETF, 2018). Soft slicing makes use of the layer 2 Ethernet and layer 3 Internet Protocols we have grown accustomed to, dynamic MPLS, Segment Routing, other tunneling mechanisms, and even RAN frequency sharing.

Figure 12 shows a soft slicing example for convergence, with 5G, DOCSIS and MEF Enterprise services represented. Note that within each core there is a QoS priority structure, native to each one and the cores may or may not be sharing functional resources on the control plane. On the data plane however we see that there is an expression of an overall QoS per the management of the NSSF and the dynamic

 

management of the NEF. This exercise implies that the networking infrastructure is programmable with stateful telemetry to the management systems.

Soft slicing is useful when the operator is trying to maximize the return on investment on networking equipment or tying to minimize carbon and physical footprint of the data plane due to other forces. Note that the prioritization in Figure 12 necessarily implies a policy mechanism by the operator that sets the priority structure for the signaling and while technically possible it can have its hurdles per historical precedents discussed in Section 3.

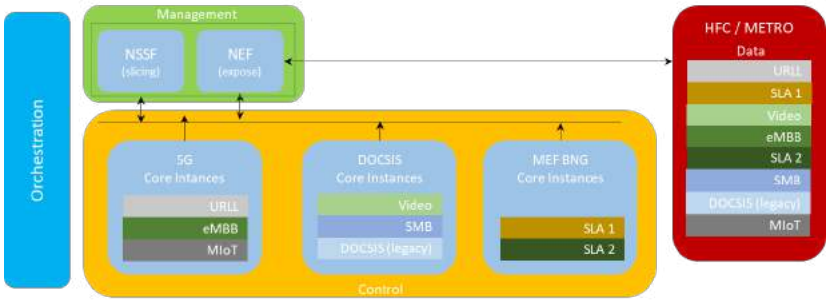

**Figure 12 - Soft Slicing Example for Convergence**

## 7.2. Hard Slicing

Hard slicing refers to the provision of resources in such a way that they are dedicated to a blueprint instantiation. This refers to a slice being assigned a particular lambda or ONT muxponder or Flex Ethernet (FlexE) channel.

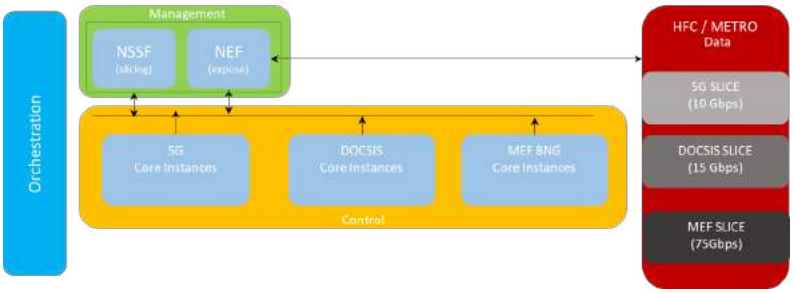

**Figure 13 - Hard Slicing Example for Convergence**

Figure 13 shows an example of convergence through hard slicing, using the mechanism of FlexE, as defined in the specifications from the Optical Internet Forum (OIF) and International Telecommunications Union (ITU): OIF-FLEXE-02.0IA and ITU-T G.mtn, respectively. FlexE is basically a time domain multiplexing of Ethernet signals where, as part of its capabilities, signals of lower bandwidths can aggregate to a higher bandwidth signal and vice versa, this channelization effect can be maintained throughout the Ethernet deployment, with 5 Gbps of granularity. Formally FlexE adds a flexible shim layer between the MAC and the physical coding sublayer, see Figure 14. Note that the implementation of FlexE is in a large part made possible by the arrival and availability of ZR type coherent optics in the range of 100-400 Gbps, which allow for robust access backhaul solutions.

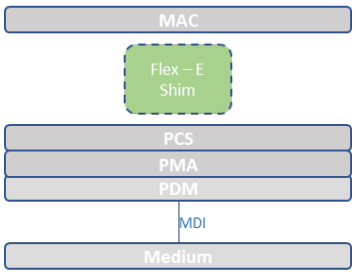

**Figure 14 - Flexible Ethernet Operational Definition**

In the Figure 13 example there is no system wide knowledge of the prioritization of the subservices within the 5G, DOCSIS or Enterprise services. Instead there is a bandwidth expectation for each service and a FlexE channelization assignment and an understanding from the NSSF as to the assigning of bandwidth per service. The bandwidth assignments themselves are flexible over the lifecycle of the service, however. Hard slicing is useful in cases where resource sharing is needed but hard boundaries between them are necessary. In the MSO case, this could prove a worthwhile steppingstone as the industry moves away from siloed operations per service.

## 7.3. Hard And Soft Slicing

The combination of hard and soft slicing for the MSO operator could be an implementable middle ground to optimize resources and create the right sort of boundary structure in the first implementation of convergence. As shown in Figure 14 soft slicing is limited to the purview of subservices within each core and in this manner there is no overreaching policy that pins a subservice on one core versus a subservice on a different core. Simultaneously an implementation of FlexE per core is introduced such that each core has a dedicated bandwidth to work with, allowing no confusion on usage limitation per QoS assignments of its subservices. In this case the NSSF is executing on blueprints that include several protocol layers, and as is expected the system is dynamic with the capabilities to evolve hard and soft slicing assignments over time. For the MSOs this can be a long term or near-term solution for convergence.

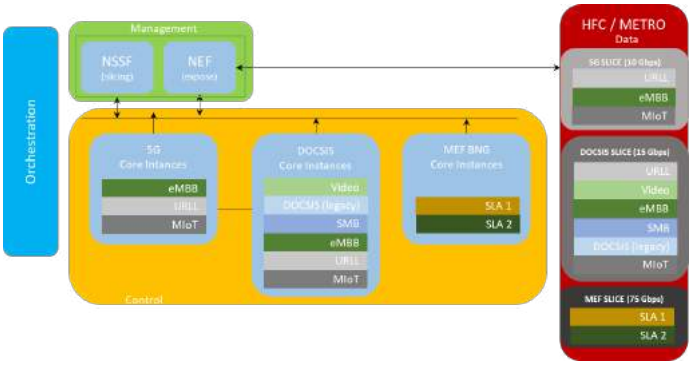

**Figure 15 - Hard and Soft Slicing Example**

## 8. Network Slice Lifecycle

It is useful to understand the lifecycle of a network slice. Note that the existence of the network exposure function is key here as by its gathering and maintaining of stateful system information the capacity of slices can be anticipated and thus react accordingly. Below we propose the 5 steps necessary for a lifecycle. These steps help the operator to appreciate the effort necessary in dealing with a network sliced system and creating an expectation for native or third-party enablement of these services.

- Creation
  - In this step a machine-readable blueprint definition is created. This is created by an operator or a third-party planner. The blueprint includes component resources, enabling features, workflow assignments and lifecycle expectation.
- Instantiation
  - At this step resource inventory and availability are counted. It is where function discovery of native or third party VNFs take place, and the orchestration of the system pushes for creation of slices.
- Scaling
  - This includes monitoring network throughput and trigger events. Allows for the extension or reduction of slice capabilities per need. All this is done with zero touch, it is an automated process.
- Isolation
  - This step manages resource impact of scaling on neighbor slices, including items like traffic, bandwidth among other processes. It insures parallel usage.
- Maintenance
  - This step facilitates in instantiation or tear down of slices, redirecting traffic to alternate slices as necessary with minimal or no interruption, and conducts proactive testing.

## 9. Industry Reccommendations

We list several helpful steps that are meant to help the industry facilitate convergence. The list below is non-exhaustive but does provide the industry with goals worth considering.

- Move towards industry-based open interfaces for cloud native core functions.
  - In the minimum open interfaces for network slicing like functions and network exposure like functions.
- Practice QoS and involve the packet network.
  - Even though QoS capabilities are inherent in DOCSIS for instance, they are not used all the time, nor are they generally reflected in the digital access network.
- Create MSO specific list of slice expectations and requirements.
  - This was an initial and necessary step in the creating of network slicing for the mobile industry. This is an activity CableLabs could lead for example.
- Implement hard or hard and soft slicing as a beginning step.
  - The cable industry must work with, not against, the reality of heavily siloed services, and move from there. Hard slicing is a useful tool in this direction.
- Move towards full functional convergence at the core.
  - This is a long-term goal, but it begins with definitions. The work done in the FMA of standard interfaces for certain MAC functions is a good example of how to start. Ultimately, legacy cable functions are competing with a system in 5G that is written for cloud and with standardized interfaces.

## 10. Conclusion

The topic of network slicing for convergence of services is novel and necessary. In this paper we have proposed a framework for service convergence using network slicing. We have reviewed the network slicing mechanisms for 5G and pointed out possible analogies that aid in developing slicing for MSO systems containing residential, business, and mobile services. We have covered the concepts of network slicing functions which organize and partition available network resources. We have described hard and soft slicing mechanisms and the necessary steps to maintain end-to-end slice visibility and usability over their lifecycle.

Lastly, we acknowledge the fruitful discussions we've had developing the content of this paper with Raghu Ranganathan and Darren McKinney from Ciena, along with Bernard McKibben from CableLabs.

# 1. Introduction

The world of broadcast video delivery is evolving rapidly, especially with the proceeding by the Federal Communications Commission (FCC) to clear the lower 280 MHz of the C-band spectrum, to pave the way for its use by 5G services (FCC Report and Order). Satellite companies including Intelsat and SES use the C-band spectrum to serve TV broadcasters and cable network operators with video feeds. The FCC ordered these companies to move their operations to the upper 200 MHz of C-band in order to prevent interference from mobile services (Reardon 2020).

As a result of the uncertainty of C-band going forward and the continual demands for higher video quality, broadcasters and content providers are considering transitioning more fully from satellite to fiber, and/or Internet-based delivery mechanisms. Linear channel delivery over terrestrial optical fiber offers lower cost, lower latency, lower bandwidth constraints, and higher quality than a corresponding delivery over satellite. With these benefits and the FCC mandates, operators have some compelling reasons to make the transition from satellite to fiber.

Any transition to terrestrial video delivery over fiber must occur with minimal impact to current customer workflows. The risks of transition certainly include disruption of primary service, but also of signaling for advertising, local contributions, and alternate programming, including blackouts. The benefits include additional over-the-top (OTT) distribution. Certain hybrid use cases increase disruption risk. For example, national feeds arriving by satellite can signal a local contribution arriving over fiber, or vice versa.

The SCTE Digital Video Subcommittee (DVS) maintains a family of standards that, when implemented together, help support a seamless transition from satellite to fiber.

Regardless of transmission path, linear streams carry in-band signaling following ANSI/SCTE 35, the "Digital Program Insertion Cueing Message for Cable" standard. ANSI/SCTE-35 signals convey the start and end of advertising, programming boundaries, and license boundaries.

The "Event Scheduling and Notification Interface" (ESNI; ANSI/SCTE-224) is an out-of-band signaling standard that allows the enforcement of viewing restrictions, such as web embargos, startover, lookback, and alternate programming. ANSI/SCTE-224 provides the mechanism to achieve the video markup and execution for all aspects of the workflow, including national and local contributions, ad insertion, as well as execution on the playout side for local broadcasts and OTT content.

And, the "Real-time Event Signaling and Management API" (ESAM; ANSI/SCTE-250) provides a software standard for converting in-band ANSI/SCTE-35 or out-of-band ANSI/SCTE-224 signals into real-time requests of a signal decision system. ANSI/SCTE-250 can be used to implement advertising placements, license constraints, and local programming.

A linear signal processing system that utilizes the combination of ANSI/SCTE-35, 224, and 250 requires a responsive and scalable architecture that can be implemented using a combination of on-premise systems and cloud-based services (Figure 1). Implementing this linear system enables the seamless transition of fully featured linear channels from satellite to the Internet.

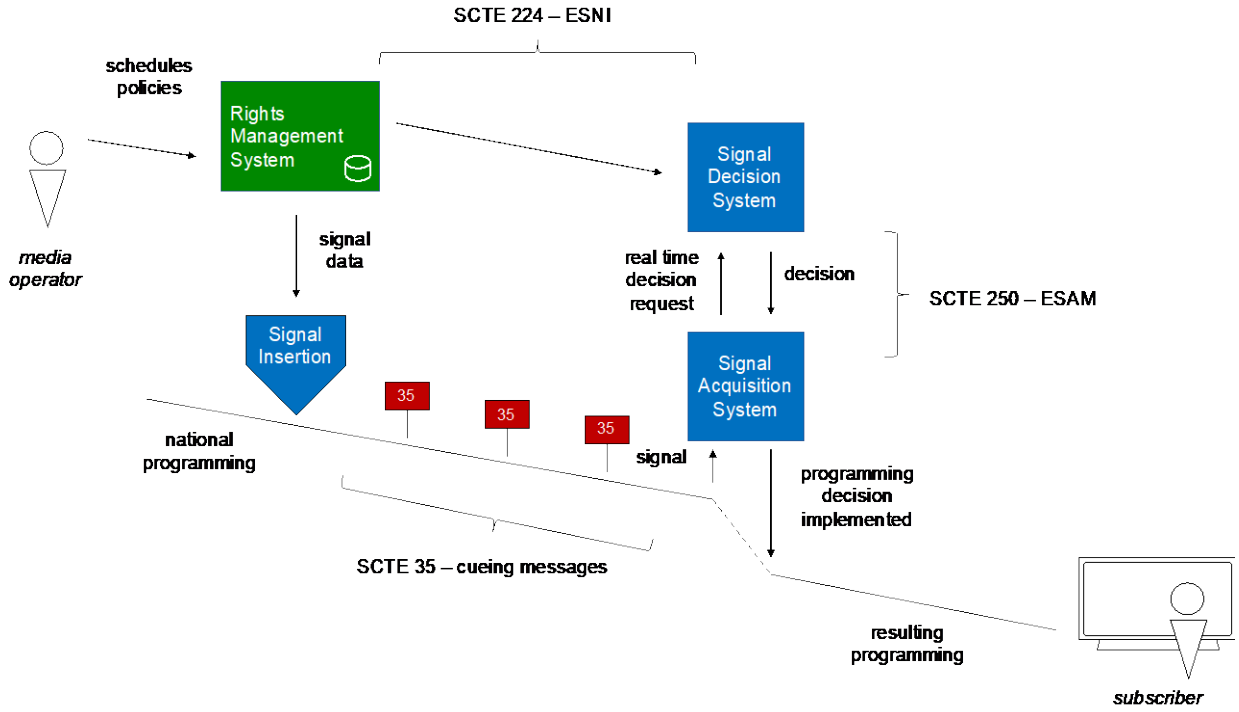

**Figure 1 - High Level Architecture**

# 2. Standards Background

The interplay between content rights and multi-platform distribution has become increasingly complex. Every component in a delivery workflow must weigh simplicity and deployment agility against quality of experience. Today, configuration data is manually entered into spreadsheets and application programming interfaces (APIs) that are distributed via multiple channels. Programmers are reliant on operators to acknowledge that data has been received, and then operators must ingest data from multiple sources and formats before it can be assembled and delivered. By utilizing standards created by the SCTE DVS and specifically Work Group 5, Digital Program Insertion, all parts of the workflow can work together at a machine-to-machine level. In the following sections we detail these various standards the enable this machine-to-machine workflow.

## 2.1. ANSI/SCTE 224

ANSI/SCTE 224 ESNI provides a robust framework of Extensible Markup Language (XML) messages. It details descriptions of audience characteristics, and viewing policies associated with each audience, it also allows for channels (Media) and individual events (MediaPoints) to describe start and end times (MatchTime) or in-band signaling (MatchSignal) information. With ANSI/SCTE 224, operators can implement bindings from events and audiences to specific programming signals; this will signal downstream systems the desired programming changes and exactly when to implement them. Although the framework is robust, operators must assemble meticulous programming details into a standard format, control metadata delivery targets, maintain metadata visibility across a diverse delivery ecosystem, and reliably communicating the resulting instructions to every relevant distribution point.

ANSI/SCTE 224 allows for rights convenience by setting up five different message types to carry the information: `Media, MediaPoints, Policy, ViewingPolicy`, and `Audience`. The following sections detail each of these message types and provide a brief description of each.

### *2.1.1. Media*

The `Media` object represents a linear television channel and its schedule of events. The `Media` is the container that contains the `MediaPoints` used to describe individual events that are scheduled to occur on that channel.

### *2.1.2. MediaPoints*

`MediaPoints` are individual events that occur within a channel or a show. These events are traditionally program start, ad start, ad stop, and program end. The `MediaPoint` is matched against an event in the video either by time-based triggers (e.g., program start at 2 PM) or matching against the SCTE 35 in-band signal described below. Using the in-band signal has the advantage of allowing the actions to be taken on a frame-accurate basis, making for a better user experience. When a `MediaPoint` is matched to an in-video event, it is "triggered," which means that one or multiple `Policy` messages can be applied to the state of the channel. The `MediaPoint` can also contain additional metadata such as alternate identifiers and electronic program guide (EPG) information. This enables live to video on demand capture or accurate EPG usage with the out-of-band ANSI/SCTE 224 data. See Appendix A for a complete example of a ANSI/SCTE 224 `Media` object.

### *2.1.1. Policy*

The `Policy` message is a container for `ViewingPolicy` that can be associated with an event (Figure 2). `Policy` elements are added and removed to control channel playout. For example, a `Policy` about trick mode restrictions can be added to the channel state and a second `Policy` that sends an audience to an alternate channel can be added as well. It is also at the `Policy` level that items are removed from the state, so in the previous example, if the `Policy` to send the audience to an alternate channel is removed from the state, then that audience will return to watching the main channel.

```
<Policy xmlns="http://www.scte.org/schemas/224"
  id="xyz/policy/any/slate"
  lastUpdated="2016-11-18T15:00:00.000Z">
  <ViewingPolicy xmlns="http://www.scte.org/schemas/224"
    xmlns:xlink="http://www.w3.org/1999/xlink"
    xlink:href="xyz/viewingpolicy/any/slate">
  </ViewingPolicy>
</Policy>
```

**Figure 2 - Example ANSI/SCTE 224 Policy Object**

### *2.1.1. ViewingPolicy*

`ViewingPolicy` elements are key messages, because they bring together the action for a triggered event and the appropriate audience. So, for example, the `ViewingPolicy` for one audience might be to message telling the view the programming is unavailable, while a different audience might be sent to an alternate feed (Figure 3). Defined sets of actions cover content directives, trick mode restrictions, dynamic ad insertion, capture controls for recording, and signal insertion and deletion.

```
<ViewingPolicy xmlns="http://www.scte.org/schemas/224"
  id="xyz/viewingpolicy/any/slate"
  lastUpdated="2016-11-18T15:00:00.000Z">
  <Audience xmlns="http://www.scte.org/schemas/224"
    xmlns:xlink="http://www.w3.org/1999/xlink"
    xlink:href="xyz/audience/location/any">
  </Audience>
  <Content xmlns="urn:scte:224:action">urn:scte:224:action:slate</Content>
</ViewingPolicy>\
```

**Figure 3 - Example ANSI/SCTE 224 ViewingPolicy Object**

### *2.1.1. Audience*

`Audience` is individual messages used to characterize the groups of viewers impacted by a `ViewingPolicy` (Figure 4). Numerous standard audience characterization elements include ZIP codes, latitude and longitude, device types, and viewer status.

```
<Audience xmlns="http://www.scte.org/schemas/224"
  id="xyz/audience/location/any"
  description="No Travel Restrictions"
  lastUpdated="2016-10-22T16:00:00.000Z"
  match="NONE">
  <Zip xmlns="urn:scte:224:audience">00000</Zip>
</Audience>
```

**Figure 4 - Example ANSI/SCTE 224 Audience Object**

Combining these five message types into sets of machine-to-machine executable instructions is the key to utilizing ANSI/SCTE 224 to manage the execution of content, at scale, across multiple distribution partners.

## 2.2. ANSI/SCTE 35

ANSI/SCTE-35 in-band signals appear in MPEG-2 video transport streams and narrate events as they play out. ANSI/SCTE-35 signals primarily mark when programs start or stop and when ad insertion should start and stop. Signals can also indicate emergency action messages. Each signal has an eight-bit segmentation_type_id that tells the receiver what type of event is being signaled (0x00 - 0xFF).

For example, if a baseball game started at 1 PM and ended at 3:45 PM, inside the stream would be a 0x10 signal at 1 PM for the program start and a 0x11 signal at 3:45 PM for the program end (and then probably a 0x10 signal at the same time for the next program start). There would be many 0x34/0x35 pairs that indicate when advertising placement opportunities appear. Program boundary signals 0x10 and 0x11 contain program identifiers, also known as unique program identifiers (UPID), that bind to ANSI/SCTE-224 rules based on programs.

In other words, programmers notify downstream devices by putting ANSI/SCTE-35 messages in a stream to signal ANSI/SCTE-224 channel events.

### *2.2.1. ANSI/SCTE-35 Serialization*

ANSI/SCTE-35 has two basic serialization forms. The most basic form is a raw binary sequence. Table 1 shows an example. What's shown is just part of the SCTE-35 message, not the whole container.

**Table 1 - Example ANSI/SCTE 35 UPID Types**

| Syntax | Bits | Mnemonic | Encrypted |
|---|---|---|---|
| splice_info_section() { | | | |
| table_id | 8 | uimsbf | |
| section_syntax_indicator | 1 | bslbf | |
| private_indicator | 1 | bslbf | |
| reserved | 2 | bslbf | |
| section_length | 12 | uimsbf | |
| protocol_version | 8 | uimsbf | |
| encrypted_packet | 1 | bslbf | |
| encryption_algorithm | 6 | uimsbf | |
| pts_adjustment | 33 | uimsbf | |
| cw_index | 8 | uimsbf | |
| tier | 12 | bslbf | |
| splice_command_length | 12 | uimsbf | |
| splice_command_type | 8 | uimsbf | E |
| if(splice_command_type == 0x00) | | | |
| splice_null() | | | E |
| if(splice_command_type == 0x04) | | | |
| splice_schedule() | | | E |
| if(splice_command_type == 0x05) | | | |
| splice_insert() | | | E |
| if(splice_command_type == 0x06) | | | |
| time_signal() | | | E |
| if(splice_command_type == 0x07) | | | |
| bandwidth_reservation() | | | E |
| if(splice_command_type == 0xff) | | | |
| private_command() | | | E |
| descriptor_loop_length | 16 | uimsbf | E |
| for(i=0; i<N1; i++) | | | |
| splice_descriptor() | | | E |
| for(i=0; i<N2; i++) | | | |
| alignment_stuffing | 8 | bslbf | E |
| if(encrypted_packet) | | | |
| E_CRC_32 | 32 | rpchof | E |
| CRC_32 | 32 | rpchof | |
| } | | | |

This signal can also be expressed in hexadecimal, as in a #EXT-X-DATERANGE tag in M3U8 (Figure 5).

```
#EXT-X-DATERANGE:ID="splice-6FFFFFF0",START-DATE="2014-03-05T11:15:00Z",PLANNED-
DURATION=59.993,SCTE35-
OUT=0xfc304c000000000000ffffff00506fee36333f70036021943554549008 82da97f80010a3030303839
323435383510000002194355454900 7ef2567f80010a303030383331393537341 1000058b3f887
```

**Figure 5 - Example ANSI/SCTE 35 Hexadecimal Tag**

It can also be expressed as Base64, as in ESAM messages, as described in section 2.3 (Figure 6).

```
<signaling:Binary
signalType="SCTE35">/DBMAAAAAAAA///wBQb+42Mz9wA2AhlDVUVJAIgtqX+AAQowMDA4OTI0NTg1EAAAAh
lDVUVJAH7yVn+AAQowMDA4MzE5NTc0EQAAWLP4hw==</signaling:Binary>
```

**Figure 6 - Example ANSI/SCTE 35 Base64 Tag**

The M3U8 EXT-X-SCTE35 and EXT-OATCLS-SCTE35 tags also use a Base64 implementation (Figure 7).

```
#EXT-X-
SCTE35:TYPE=0x10,TIME=1450707450000,ELAPSED=0,ID="dAQpTUaQSjOti/JZTqECfQ==",CUE="/DBMA
AAAAAAA///wBQb+42Mz9wA2AhlDVUVJAIgtqX+AAQowMDA4OTI0NTg1EAAAAhlDVUVJAH7yVn+AAQowMDA4MzE

...
#EXT-OATCLS-SCTE35:/DAlAAAAAAAAAP/wFAXwAAACf+/+AM3Qkf4AFJlwAAEBAQAAGkXGSg==
```

**Figure 7 - Example ANSI/SCTE 35 M3U8 Base64 Tag**

### *2.2.2. XML*

The ANSI/SCTE 35 standard describes an XML serialization of ANSI//SCTE 35 as shown in Figure 8 (with namespace declarations omitted for readability).

```
<SpliceInfoSection protocolVersion="0" ptsAdjustment="0" tier="4095"
xmlns="http://www.scte.org/schemas/35/2013a"
xmlns:ns2="http://www.thistech.com/schemas/scte35/1">
        <EncryptedPacket encryptionAlgorithm="0" cwIndex="255"/>
        <TimeSignal>
                <SpliceTime ptsTime="4151498432"/>
        </TimeSignal>
        <SegmentationDescriptor segmentationEventId="1"
segmentationEventCancelIndicator="false" segmentationTypeId="17" segmentNum="0"
segmentsExpected="0">
                <DeliveryRestrictions webDeliveryAllowedFlag="false"
noRegionalBlackoutFlag="false" archiveAllowedFlag="false" deviceRestrictions="0"/>
                <SegmentationUpid
segmentationUpidType="1">3030303935353232303839</SegmentationUpid>
        </SegmentationDescriptor>
</SpliceInfoSection>
```

**Figure 8 - Example ANSI/SCTE 35 XML Serialization**

## 2.3. ANSI/SCTE 250

The “Real-time Event Signaling and Management API” (ESAM; ANSI/SCTE-250) protocol is sufficient for communication between a signal acquisition system (SAS) and signal decision system (SDS). It describes the format and content of the messages required by the SAS to obtain instructions from the decisioning service for handling in-band ANSI/SCTE 35 signals (Figure 9).

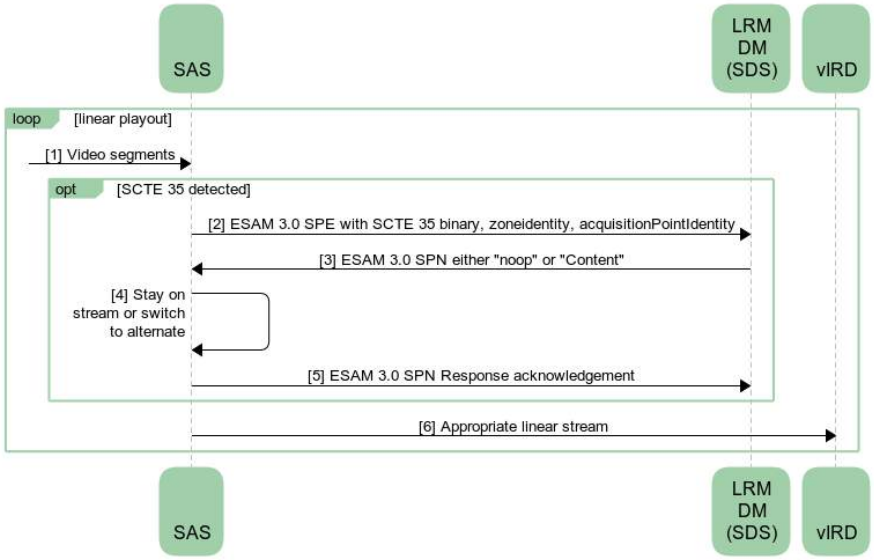

**Figure 9 - Traditional ESAM Exchange**

### *2.3.1. Message Transport*

Messages are formatted and delivered in accordance with the CableLabs ESAM I03 specification. (CableLabs ESAM) The signal processing services are exposed as an HTTP RESTful endpoint. HTTP POST is the required request method and XML is the required message format, so the Content-Type header is set to application/xml. The SAS in this model is expected to return acknowledgements and processing status in the response.

### *2.3.2. Message Namespace*

Table 2 shows the prefixes and namespaces that are used within the XML in ANSI/SCTE 35.

**Table 2 - Example ANSI/SCTE 35 Namespaces**

| | |
|---|---|
| adi3 | urn:cablelabs:md:xsd:core:3.0 |
| common | urn:cablelabs:iptvservices:esam:xsd:common:1 |
| content | urn:cablelabs:md:xsd:content:3.0 |
| manifest | urn:cablelabs:iptvservices:esam:xsd:manifest:1 |
| offer | urn:cablelabs:md:xsd:offer:3.0 |

| signal | urn:cablelabs:iptvservices:esam:xsd:signal:1 |
| signaling | urn:cablelabs:md:xsd:signaling:3.0 |
| terms | urn:cablelabs:md:xsd:terms:3.0 |
| title | urn:cablelabs:md:xsd:title:3.0 |
| xsi | urn:cablelabs:iptvservices:esam:xsd:signal:1 |

### *2.3.3. Message Time*

The CableLabs ESAM I03 specification requires that all object time values follow the ISO 8601 time format, hh:mm:ss, with an optional decimal fraction on the seconds component, e.g. 14:15:03.475. The

specification also dictates that times are to be provided as zero UTC offset. All times in this document are zero UTC offset and may contain fractional seconds, as per the specification.

#### 2.3.4. ESAM Interface

The ESAM interface supports signal confirmation. The ESAM interface carries ANSI/SCTE 35 signaling information from an SAS to the SDS for in-band processing. The originating system generates a processing signal event and submits it using the defined XML payload to the SDS. The event parameters provide as much information as possible about the signal point. Examples of in-band signal points are a splice out/exit point indicated by an ANSI/SCTE 35 splice_info_section()/splice_insert() command or an SCTE 35 segmentation_descriptor associated with a SCTE 35 time_signal() or splice_null() command. Using the provided information, the SDS derives information about the event start and end point(s) with the corrected timestamp and/or ANSI/SCTE 35 point data. Finally, the SDS generates a response notification detailing how the acquisition system might condition the video content and provides auxiliary data for downstream usage.

#### 2.3.5. In-band ESAM Message Exchange

A request via the SAS utilizes the SignalProcessingEvent message as a wrapper to the AcquiredSignal element. The acquisitionPointIdentity attribute is used to correlate the stream to the proper source in the signal processor. The content of the AcquiredSignal element is a ANSI/SCTE 35 descriptor and is sent as a binary payload. The binary payload is Base64 encoded.

### 2.4. Use Cases

#### 2.4.1. Decision Request

Upon detection of a ANSI/SCTE 35 marker, the SAS will assemble the ESAM Signal Processing Event (SPE) (Figure 10). For the SPE, the acquisitionPointIdentity must be set to the source of the video stream (i.e., KXYZ). The acquisitionSignalID is a uuid established by the SAS for correlating the SPE with other responses for tracking and logging. The acquisitionTime like acquisitionPointIdentity is required as well and represents the time the linear stream stitcher (LSS) created the SPE message. The last required element is zoneIdentity used to provide the name of the virtual integrated receiver decoder (vIRD) or station instance for matching against the ANSI/SCTE 224 audiences (i.e., WXYZ). Because ESAM does not provide a mechanism to differentiate between vIRDs and zipcodes, the SDS will use any five-digit numbers as a ZIP type audience. The UTCPoint represent the UTC of the signal in the video stream. Finally, the BinaryData element contains the binary data from the ANSI/SCTE 35 marker found in the video stream.

```
<esam:SignalProcessingEvent xmlns:esam="urn:cablelabs:iptvservices:esam:xsd:signal:1"
       xmlns:core="urn:cablelabs:md:xsd:core:3.0"
       xmlns:md="urn:cablelabs:md:xsd:signaling:3.0"
       xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
       xsi:schemaLocation="urn:cablelabs:iptvservices:esam:xsd:signal:1 OC-SP-ESAM-API-I03-
Signal.xsd">
   <esam:AcquiredSignal
      acquisitionPointIdentity="CH1"
      acquisitionSignalID="3c1e5cbe-648a-4d69-b740-570a99cb66d7"
      acquisitionTime="2018-04-05T00:00:04Z"
      zoneIdentity="KXYZ">

```

 

```
   </esam:AcquiredSignal>
</esam:SignalProcessingEvent>
```

**Figure 10 - Example ESAM SignalProcessingEvent**

### *2.4.2. Decision Response*

Once the SDS receives the ESAM decision request, it will execute the SCTE 224 logic described above and return to the SAS the action required based on the ViewingPolicys. The response will contain the action of the source to switch to or "noop," indicating the SAS does not need to switch from the source it is currently on.

Figure 11 shows the response the SAS will receive for no switch:

```
<?xml version="1.0" encoding="UTF-8" standalone="yes"?>

### *2.4.3. SAS Response Acknowledgement*

Upon receiving the SDS SPN response, the SAS will return an ESAM acknowledgement indicating the action taken by the SAS in the notes section. For the acknowledgement there are no specific requirements for the StatusCode::classCode for the ESAM-endpoint. The status code is only logged, but not used directly. For the Note element, there are also no specific requirements for its values. SDS logs this value, and currently SDS sees three common responses: "Successfully switched to CHXX," "Cannot switch, because already scheduled to switch to that channel," and "No switch, staying on CHXX" (Figure 13).

```
<?xml version="1.0" encoding="UTF-8"?>

</esam:ProcessStatusNotification>
```

**Figure 13 - Example ESAM SignalProcessingNotification Acknowledgement**

## 3. Distribution Workflow

With the ongoing consumer demands for higher quality video, as well as the new C-band rules from the FCC, content providers need to strongly consider a transition to non-satellite delivery. The workflow is similar whether there is a broadcaster distributing their 12-16 hours of daily content to an affiliate station, or if it is an affiliate station distributing their 24 hours of content to a distribution partner. In both cases there is content that needs to get to a distribution partner to be played out to a consumer. This disctribution workflow can be done with or without in-band signaling. This section will discuss the differences presented by the presence or absence of in-band signaling an dhow either situation can be handled.

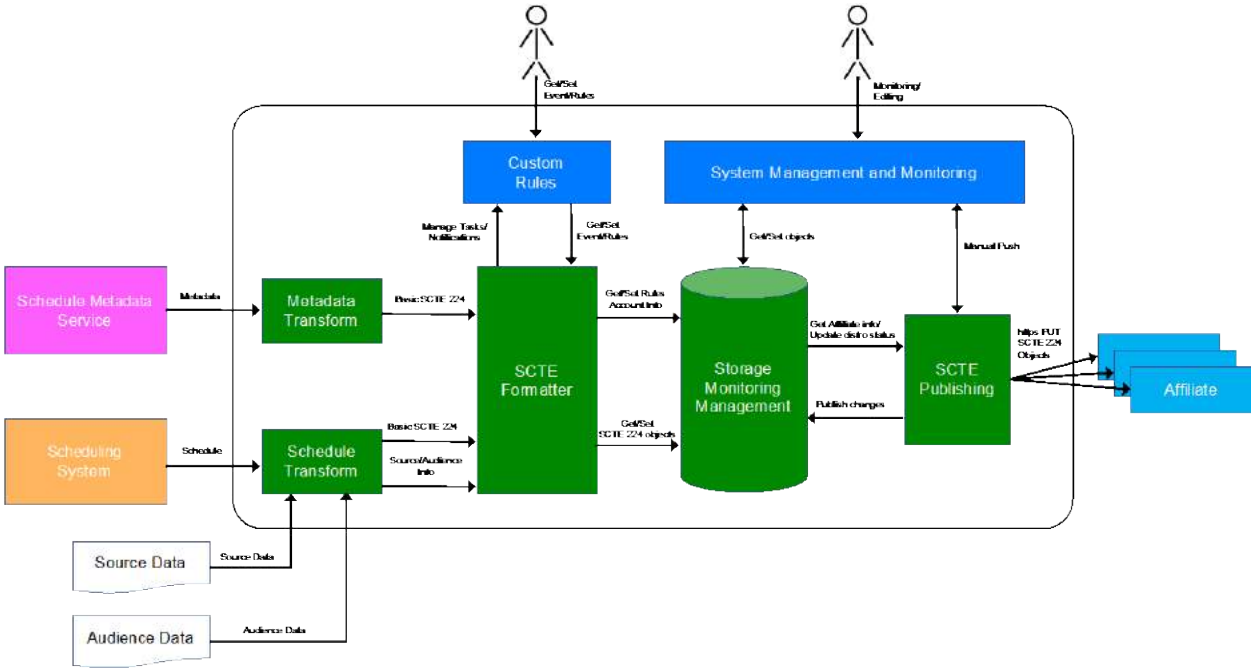

**Figure 14 – Detailed Workflow**

## 3.1. Transition with Automation

Many content providers use in-band signals even in the satellite feeds they are distributing today. This is most often the case for the full channel content being sent to multiprogram video program distributors (MVPD) or an OTT streaming service. This usually means that the content provider has an automation system capable of creating ANSI/SCTE 104 messages that are used to transfer signal insertion instructions from an automation system and convey those markings to the compression system. This ultimately results in creating the corresponding ANSI/SCTE 35 in-band markers for distribution in the video itself. If that is the case, and all program starts and ends are identified with ANSI/SCTE 35 binary signals, then in-band signals need not be injected into the video. Note that section 3.2 "Transition without Automation" describes the case where signals are missing and need to be injected.

### *3.1.1. Signaling*

When in-band signals are sufficient to declare the content start and end, the burden on the content provider is to extract or correlate those ANSI/SCTE 35 UPIDs with the ANSI/SCTE 224 ESNI that is generated. These UPIDs must be extracted from the ANSI/SCTE 35 binary and placed in the "MatchSignal" element of the ANSI/SCTE 224 ESNI MediaPoint that goes along with that event. So, for example, if a system uses the show's Tribune Media Service identifier (TMS ID) as the Upid to uniquely identify a program, then that TMS ID can be used by the ANSI/SCTE 224 generate platform to populate the XPath matching in the MediaPoint. Figure 15 shows an example of the MatchSignal portion of a ANSI/SCTE 224 MediaPoint.

```
<MatchSignal xmlns="http://www.scte.org/schemas/224" match="ANY">
    <Assert>
/SpliceInfoSection/SegmentationDescriptor[@segmentationTypeId=16]/SegmentationUpid[@segmentationUpidTy
pe=1 and contains(text(),'EP001786121816')]
    </Assert>
```

```
</MatchSignal>
```

**Figure 15 - Example MediaPoint MatchSignal**

Although automation inserts ANSI/SCTE 35 signals in the video stream, downstream automation needs to get Upid information (such as “EP001786121816” from the example above) to the ANSI/SCTE 224 ESNI creation system.

### *3.1.2. Additional Instruction*

At this point the in-band signaling information is in a MediaPoint’s MatchSignal element. On playout, if the SAS received the in-band signal, the SDS would match on a MediaPoint. The SDS replies with the “Action” to be taken by the acquisition system, based on the audience of interest. This is done in ANSI/SCTE 224 by using “Apply” policy to activate a policy. The Policy then points to the ViewingPolicy, which has the real functionality of bringing an audience together with an action.

For a broadcast solution, where a content provider is selecting a feed for a particular show, the provider can identify the desired audience, for example by ZIP code or audience type. If the SAS identity matches the audience then the action applies. The action could indicate the desired content, such as from an alternate channel source, or a URL from which the content could be retrieved. With this model, a content provider could tell one partner to play content from one channel and another partner to play content from another.

For example, a content provider of a broadcast network can tell its Eastern time zone partners to pull content from one feed, while telling its Central time zone partners to pull from a different feed. Alternatively, for a live event, the content provider could tell all partners to source from the same live feed.

Likewise, a content provider distributing a channel could tell one partner to black out or display a slate during a particular program, while having another region or provider play the content on the current feed. This situation is useful for sports blackouts or when content rights vary between regions.

## 3.2. Transition without Automation

In many cases, content providers do not have sufficient in-band signaling in their video feeds, possibly because satellite feeds rarely needed detailed signaling, or because most or all of the controls are done by integrated receiver/decoders (IRDs). Another situation is that OTT feeds, or higher quality feeds that are sourced terrestrially, are not subject to the same workflow. Additionally, the automation system driving the satellite delivery might lack signaling features whatsoever. SCTE 224 ESNI accommodates for these cases and still allows signals to be inserted without the corresponding automation.

### *3.2.1. Signal Insertion*

The ANSI/SCTE 224 ESNI standard provides actions in the ViewingPolicy to enable signal insertion. In this sense, the content provider delivers schedule information to the generator; the generator instructs the SAS to inject signals when needed. In this case, generator creates two sets of instructions in the system. The first set of Media contains MediaPoints for each show start and stop, but the action is a “SignalPointInsertion” action. The second set of Media are the same MediaPoints for the shows, but this Media contains the MatchSignal logic to connect to the signals that are being inserted. This second set of Media is for distribution to execute specific actions.

Figure 16 depicts the first Media, marking the distributed video for edge execution, and the second Media being used at the edge to execute the content provider's rights for the content.

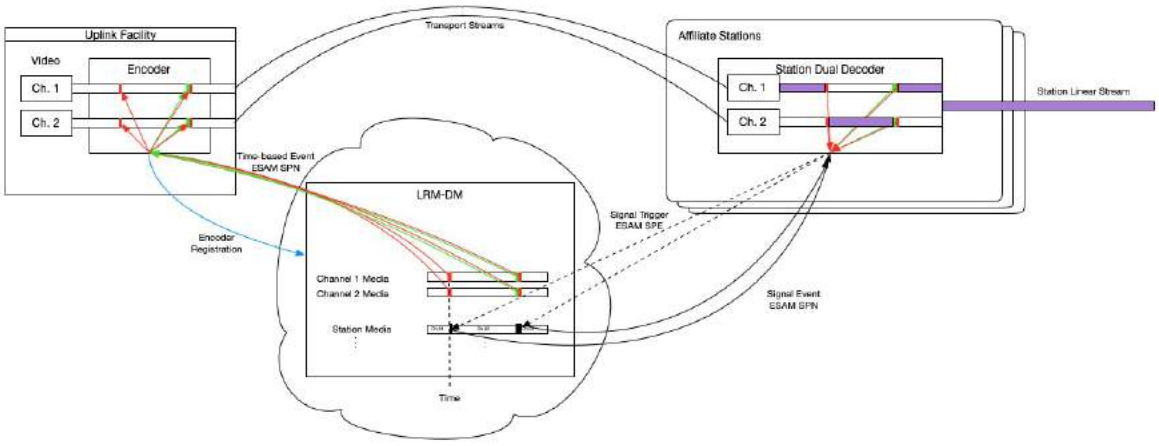

**Figure 16 - Workflow for Signal Insertion**

When the scheduling system sends the ANSI/SCTE 224 ESNI generator the schedule information, the generator has to know to generate two different Media elements. The start and end times are the same for both Media elements. The difference is the Policy that the MediaPoints point to, and that the MatchSignal element is only in one of the Media elements.

#### *3.2.1.1. Signal Insertion Media*

The signal insertion Media contains the audience of the channel into which the signals will be inserted. If the event will not be triggered by in-band signals, the insertion will be initiated by the SDS itself. These SDS-initiated ESAM communications are referred to as "unsolicited messages." In these cases, the MediaPoints in the containing Media element will have a matchtime attribute that represents the precise time that the event will occur, and the signal should be inserted.

In many SDS systems, a time-based, unsolicited message is coupled with an ANSI/SCTE 250 ESAM registration by the SAS. This registration tells the SDS which endpoint to send the unsolicited messages. It also usually contains lead-time information, about when to send the instructions, and, finally, the desired audience. For example, if a show starts on feed X at 2:00 PM, and an SAS registration is interested in receiving the signaling for feed X with a one minute lead time, then the SDS sends an unsolicited ESAM SignalProcessingNotification message at 1:59 PM to the SDS endpoint. This gives the SAS the time necessary to insert the signal at the proper time in the video.

Once this in-band signal has been inserted, the SAS will match it on the execution side using the other Execution Media.

#### *3.2.1.2. Distribution Media*

The second Media generated from the show's schedule has the same start and ends times, but in this Media the ESNI generator creates the MatchSignal elements and inserts the signal information used

above. It also can populate the show's asset distribution interface (ADI) information if the content provider so desires, since this Media is used on the edge by the distribution partner.

#### *3.2.1. Additional Instruction*

This Distribution Media then follows the same execution path that the "Automation" section described, where the SAS detects the in-band signal and sends it to the SDS for a decision about what to do at the point in the video feed. The SDS then responds with the appropriate action for the audience represented by the SAS.

# 4. Solution

At Comcast Technology Solutions, we created a solution that bridges the creation, management and distribution process of ANSI/SCTE 224 events for both broadcast and OTT environments. The service automates the manual processes and takes full advantage of the ANSI/SCTE 224 specification – not just by standardizing the formatting of metadata, but also by providing a software-based service that gives both programmers and operators unprecedented control of – and visibility into – their respective workflows. As more variables are introduced into the content delivery mix, whether they be new content types or new viewing policy actions, we will always need a flexible strategy that can deliver extraordinary experiences across every screen. Providers can simplify processes and utilize better content management tools, and then apply them to what matters most: creating an experience that turns viewers into ardent and vocal fans.

# 5. Additional thoughts

## 5.1. OTT Complexity

Complex viewing rights have become an increasing challenge for content delivery. No matter what the specific rights are for a program -- whether they pertain to regional networks, league- or match-specific arrangements, geography or user permissions -- it has become crucial that providers are precisely conveying the policies necessary to allow for authorized playback. Digital distribution partners require these rights in order to distribute the client's content outside the home viewing territory. ANSI/SCTE 224 stands out as the best way to deliver this information. The new metadata management approach is now an integral part of operational workflows and is managed by an internal operations team.

The solution supports both MatchTime-based event rules and MatchSignal-based event rules. This means a full functional adaptation of ANSI/SCTE 35 segmentation UPID, or signal ID's, at the ProgramStart and ProgramEnd boundaries of a MediaPoint, and is able to map the ANSI/SCTE 35 ID to the MatchSignal ID in the ANSI/SCTE 224 event. A clean transition is ensured when alternate content rules are applied to the linear feed. When an event window runs beyond the scheduled airing time, the alternate content execution is based on the segmentation UPID identified in the video feed, matching the UPID that is in the ANSI/SCTE 224 event. This allows for precision control from the content provider, while maintaining a positive user experience for the viewer.

Linear rights data can now be distributed as many as 14 days ahead of the airing of the event, and real-time distribution solves for event changes, such as a baseball game that goes into extra innings. As a broadcaster that distributes hundreds of regional sports networks, managed at a national level while being distributed by digital distribution partners or OTT services, solving for unscheduled event changes is important. Using a push model, linear programing events are distributed to the metadata management tool. Operations teams now have visibility into the program schedule for all channels, because that data is

 

normalized into ANSI/SCTE 224 and then distributed to all digital distribution partners. Through a desktop console, operations teams can:

- Make real-time changes to linear events
- View programming schedules
- Edit and create audience definitions
- Perform policy updates
- Validate decision logic and audit activity

Following the ANSI/SCTE 224 standard, all events are distributed using XML over HTTP to designated URL endpoints. Messages have an option to be signed using an assigned key value, and have a configurable frequency as well as a retry rate. The messages can also be individually targeted to each distribution partner and filtered, so each partner gets only what they need.

As an organization among the early adopters of ANSI/SCTE 224, it's worth noting that several of the largest broadcasters, at the forefront of the industry, are using these extant standards and resultant tools to take the lead on how linear rights metadata can and should be delivered.

### 5.2. EPG Usage

An additional benefit of transitioning to ANSI/SCTE 224 ESNI is ease in sharing data used to populate EPGs. Once broadcasters have an OTT schedule completely decorated in ESNI, then that schedule can be shared with an OTT partner, who can process the information in a separate workflow for the EPG. For example, if the ESNI schedule is populated for seven days in the future, then an OTT distribution partner can also populate its EPG into the future. Unlike the generic program guide information, an ESNI schedule contains alternate content information. Thus, the partner can present the subscriber with a highly accurate, tailored EPG. They may then look ahead in the schedule and see the "real" guide for the specific experience.

Likewise, if the content provider is making changes to the playout schedule, the corresponding ANSI/SCTE 224 ESNI schedule changes immediately. It flows to the distribution partner instantaneously, and faster than third-party services that manage program guide data.

## 6. Conclusion

As broadcasters adapt their access to and use of the C-band spectrum for traditional video distribution, concurrent with the FCC's reallocation of the lower 280 MHz of that band for 5G wireless service, many are opting to shift to terrestrial, fiber-based delivery. It's a compelling shift, with benefits that include lower costs, lower latencies, fewer bandwidth constraints, to name but a few.

Any transition to terrestrial video delivery over fiber must occur with minimal impact to current customer workflows. The risks of transition certainly include disruption of primary service, but also of signaling for advertising, local contributions, and alternate programming, including blackouts. The benefits include additional OTT distribution. Certain hybrid use cases increase disruption risk. For example, national feeds arriving by satellite can signal a local contribution arriving over fiber, or vice versa.

The SCTE DDVS maintains a family of standards that, when implemented together, help support a seamless transition from satellite to fiber. These standards can be applied, in real-world situations, to enable a transition to terrestrial, fiber-based delivery with minimal impacts to workflows.

This paper detailed an architecture and specifications for a linear content signaling and decision system that is useful for implementing the intricacies of rights management, affiliate programming, and satellite delivery replacement. It detailed the use of ANSI/SCTE-35, ANSI/SCTE-224 (ESNI) and ANSI/SCTE-250 (ESAM) into an architecture useable by on-premise and cloud-based systems.

Comcast Technology Solutions has developed and deployed this system for hundreds of channels and thousands of decisions per week. Implementing this linear system enables the seamless transition of fully featured linear channels, from satellite to the Internet.

## List of Figures

## List of Tables

# 1. Introduction

The newly available Gridmetrics data platform dramatically improves the situational awareness of the electric power grid worldwide by providing an entirely new and independent view of real-time, localized power conditions. Gridmetrics data deliver insights enabled by the existing cable broadband infrastructure that measures, monitors, and tracks the availability and stability of voltage and other power measures in the last mile of the grid known as the secondary distribution network. Voltage measurements can reflect stresses on the grid and provide an early warning of unstable, unsafe, or inefficient operating conditions. Insights include specific locations on the grid where voltage observations are abnormally high, low or fluctuating, and provide much-needed visibility to the vast majority of the grid, which heretofore has been sensor starved. Analysis reveals voltage anomalies and outages that likely impact customer experience, safety, and equipment longevity.

Situational awareness of the electric power grid is gaining in importance with the increasing number of power generators, powered devices, and power infrastructure failures. In the United States, 200,000 miles of well-instrumented high-voltage transmission lines make up the grid core, or backbone. However, the lower voltage, less-instrumented local distribution lines that connect the remaining 96.5% of the grid to end users, account for 5.5 million miles, with limited network visibility in the last mile.[1]

The rapidly growing penetration of electric vehicles (EVs), distributed energy resources (DERs), such as solar generation and battery storage, and connected buildings are creating new end-use dynamics and 2-way power flows that the existing grid was not designed to accommodate. These changes at the "grid edge" in the distribution network necessitate improving situational awareness to manage operations and detect grid stresses. State and local mandates to increase penetration of EVs and DERs, while critical to address the global climate crisis, further accelerate the changing grid edge dynamics.

Despite a mean life expectancy of 65 years, the average grid infrastructure element is 68 years old, with some elements well past the century mark. Unfortunately, we have already witnessed the effects of this aging infrastructure, through decreased reliability and deadly wildfires due to mechanical failures of the hooks that hold charged wires.[2,3] It is estimated that the U.S. power grid requires $51 billion of annual maintenance and capital upgrades (up 57% from 2016 to 2018) to improve reliability and catch-up on deferred maintenance.[4] Using information on the locations of voltage anomalies, provided through the Gridmetrics platform, can help electric utility managers to more quickly and efficiently target maintenance and upgrades on problem areas, increasing grid reliability and, ultimately, saving lives.

Gridmetrics is an early-stage project being incubated at CableLabs that connects and overlays a vast high-speed private communications network to supply as-delivered performance, insights, and knowledge about the power distribution grid. A new, widely available, and rapidly growing

[4] https://www.utilitydive.com/news/aging-grids-drive-51b-in-annual-utility-distribution-spending/528531/

dataset of voltage observations from hundreds of thousands of in-service cable broadband power sensors provides 5-minute updates, insights, and situational awareness of the distribution grid. Work from early Gridmetrics participants has shown a path to significantly more frequent updates, providing an increasingly real-time big data stream that represents multiple orders of magnitude improvement on existing distribution grid monitoring solutions. Power industry experts have estimated that utilities would have to invest billions of dollars over multiple decades to replicate the existing Gridmetrics sensor platform, which at the same time would have already evolved to superior higher fidelity spatiotemporal sensing and analytics.

The Gridmetrics platform makes sensor data available via secure, authenticated, machine-to-machine application programming interfaces (APIs) that allow utilities and other authorized third parties to access and utilize streams of readings and anomaly events to augment their existing supervisory control and data acquisition systems and processes. Using Cable's 10G broadband network, sensor data is transported at gigabit speeds and millisecond latencies to meet the immediate need to provide real-time APIs that improve grid visibility at a time when utilities need better insights now

## 2. Fundamental Cable Architecture

Understanding the cable television network and how it works can help decision makers outside the cable industry in considering the use and application of Gridmetrics data. By way of background, cable services are enjoyed by tens of millions of U.S. households in urban, suburban, and rural areas. Cable high-speed internet is available to 90% of U.S. households and 80% of homes have access to gigabit speeds.[5]

Similar to the evolution of the electric power grid, cable networks started as one-way transmission paths from a central location, called a headend, to each customer's home. The current cable architecture involves extensive use of fiber optics that carry two-way interactive data with millisecond latencies. Much like the grid, the cable network topology has evolved over the years into a tree-and-branch architecture as shown in Figure 1.

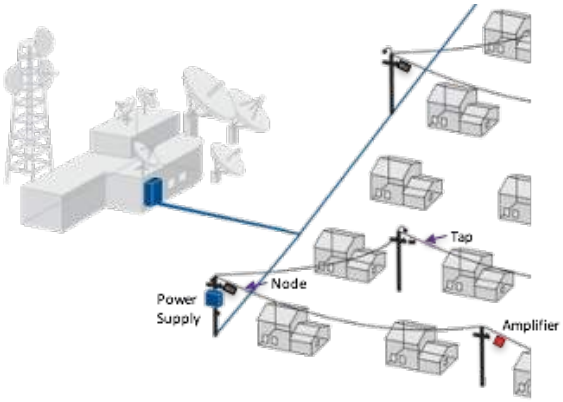

**Figure 1 – Cable tree-and-branch architecture**

[5] https://www.ncta.com/industry-data

## 3. Normal Grid Operating Voltages

The American National Standards Institute (ANSI) documents nominal voltage ratings and operating tolerances for electric power systems in ANSI C84.1-2016, which is available from the National Electrical Manufacturers Association (NEMA).[6] As shown in Table 1, the lower and upper acceptable voltage limits are 95% and 105% respectively, and there are additional considerations for the frequency, intensity, and duration of voltage excursions.[7]

**Table 1 - Normal operating voltage limits [Volts AC]**

| Nominal Voltage | 95% Lower Limit | 105% Upper Limit |
|---|---|---|
| 120 | 114 | 126 |
| 240 | 228 | 252 |

Within the normal operating voltages in Table 1, the customer experience is expected to be acceptable. Above or below voltage limits, issues may arise with billing, resilience, safety, and equipment longevity. For example, high voltages lead to higher energy usage and higher electric bills and may damage capacitors on electric motors widely used in refrigeration, heating, air conditioning, and water pumps. Low voltages lead to overheating and a shortened lifespan of motors. The observed voltages in the Gridmetrics national data set regularly deviate from the NEMA boundaries and are shown in Figure 2.

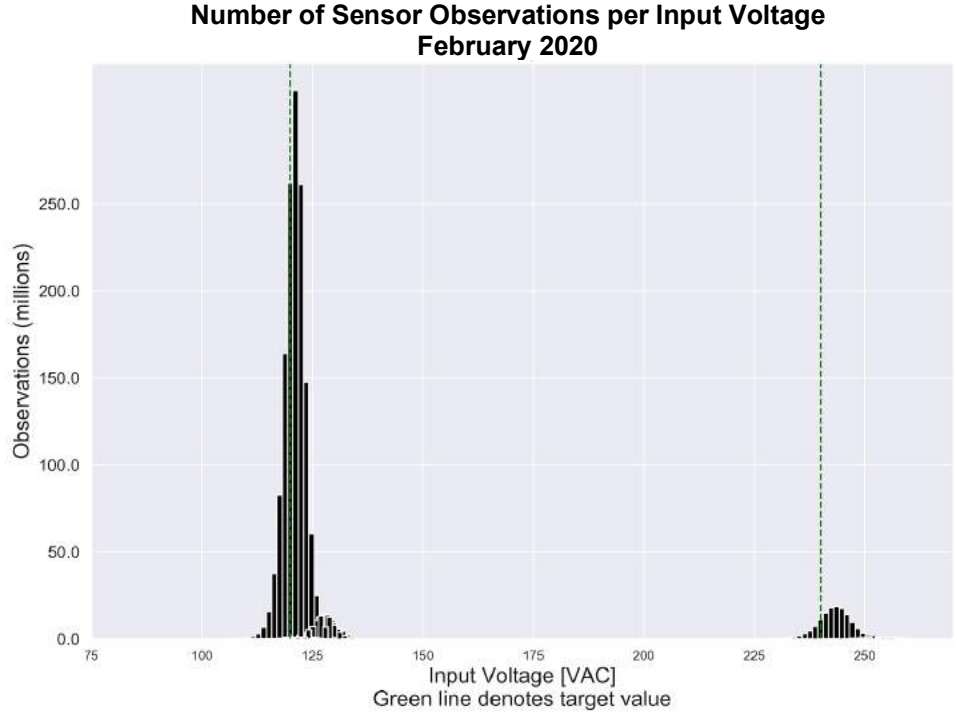

**Figure 2 - Observed voltages in Gridmetrics national data set**

[6] https://webstore.ansi.org/standards/nema/ansic842016
[7] https://www.spgsamerica.com/information/acceptable-voltage-ranges

Figure 2 depicts the distribution of voltage observations. The horizontal axis represents the range of sensor voltages and the vertical axis is the number of observations of each voltage. The green vertical lines represent the target voltages of 120 VAC and 240 VAC[8]. In the Gridmetrics national data set, approximately 92% of sensors are connected to 120 VAC, 8% of sensors are connected to 240 VAC, and less than 1% of sensors are connected to 208 VAC.

The average voltage per sensor in the Gridmetrics national data set is shown in Figure 3.

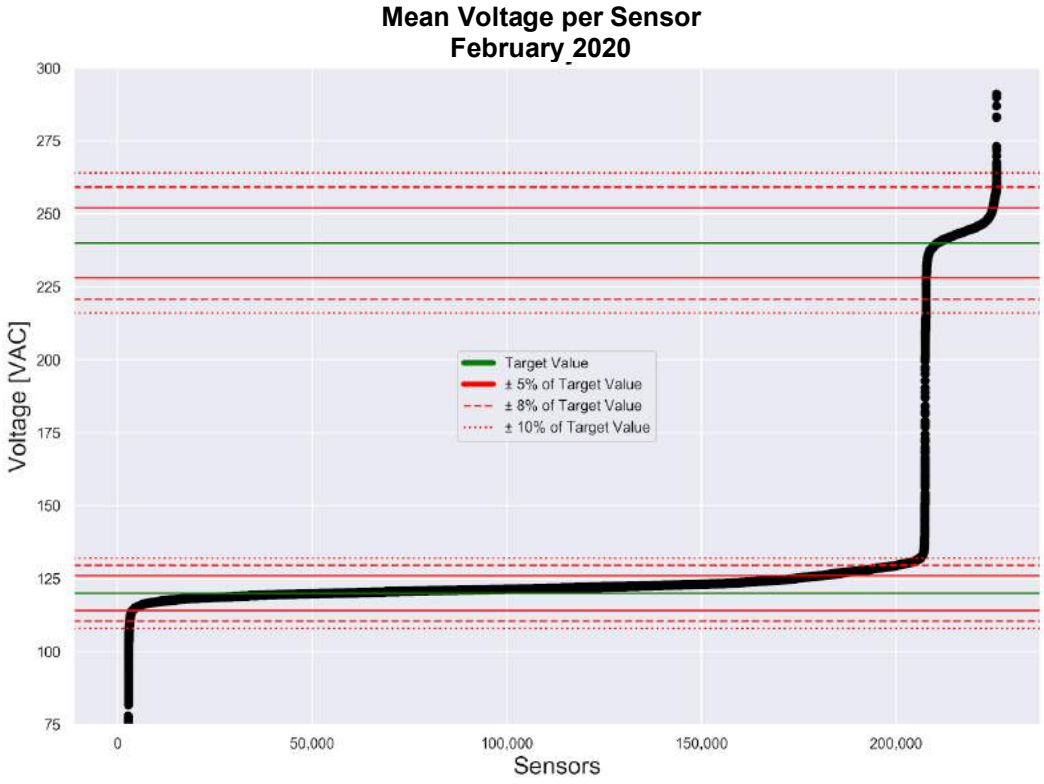

**Figure 3 - Observed voltages in Gridmetrics national data set**

Figure 3 depicts the mean (average) voltage per sensor in the Gridmetrics national data set. All sensors are sorted by mean voltage along the horizontal axis, with the lowest voltages at the left and highest voltages at right. The vertical axis is the mean of all voltages observed by each sensor. The target values of 120 VAC and 240 VAC appear in green, and NEMA limits of ± 5%, 8%, and 10% appear in red. In a perfect world, instead of voltage observations above and below the red lines, all voltages would be depicted along the flat green lines at 120 VAC or 240 VAC.

[8] Data used in all figures are available for select U.S. areas to allow for troubleshooting voltage quality issues and for comparison of the performance of individual utility serving areas to each other and to the national data set.

## 4. High Voltages

An example of high voltages observed by one sensor in the Gridmetrics national data set is shown in Figure 4.

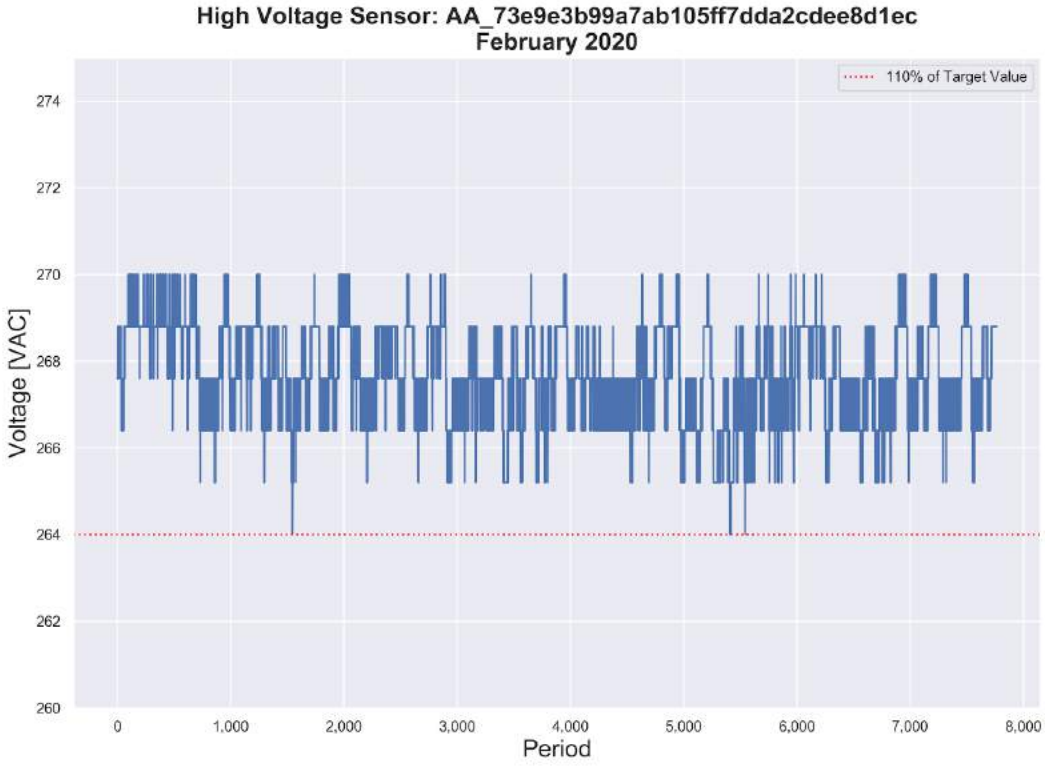

**Figure 4 - Example of high voltage in the Gridmetrics national data set.**

Figure 4 depicts voltages above 240 VAC that are so high that the target voltage and some NEMA limits are not visible. The horizontal axis is one month of time expressed in 5-minute periods and the vertical axis is the observed voltage.

Utility operations procedures can include checking sensor locations for anomalies. Additional examples of locations reporting high 120 and 240 voltage ranges are collected and available.

## 5. Low Voltages

An example of low voltage observed by one sensor in the Gridmetrics national data set is shown in Figure 5.

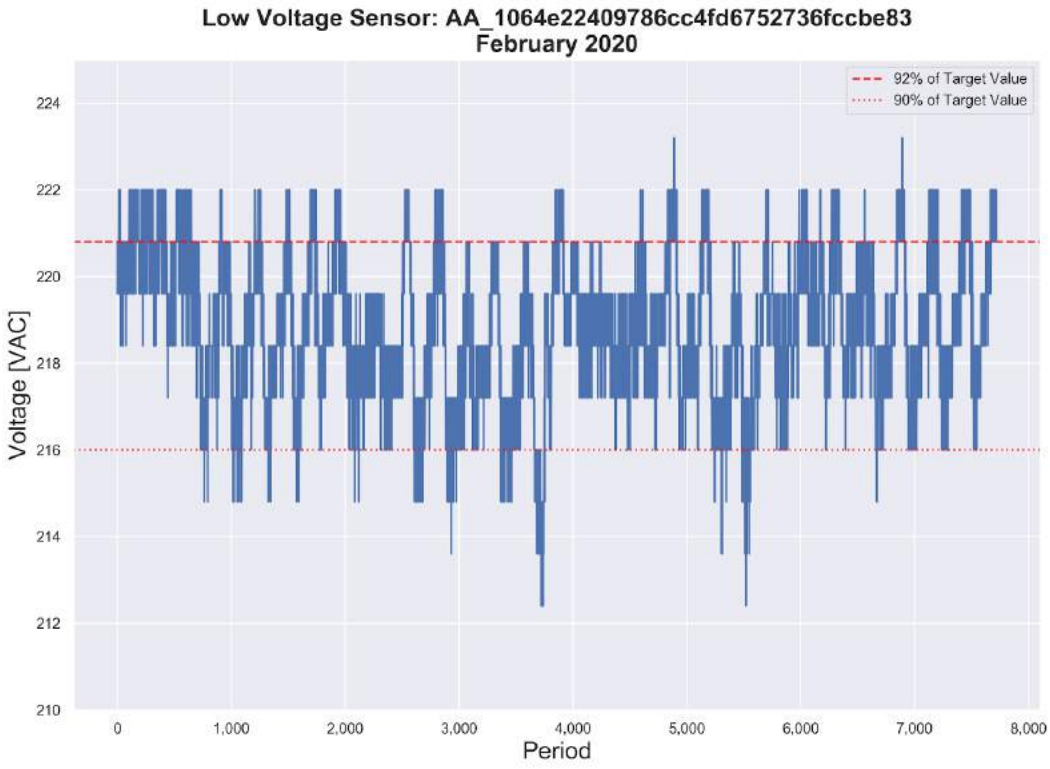

**Figure 5 - Example of low voltage in the Gridmetrics national data set.**

Figure 5 depicts voltages below 240 VAC, so low that the target voltage and some NEMA limits are not visible. The horizontal axis is the 5-minute time period and the vertical axis is the observed voltage. Additional examples of locations reporting low 120 and 240 voltage ranges are available.

## 6. Fluctuating Voltages

Some voltages fluctuate randomly, others fluctuate periodically. An example of a periodic fluctuation observed by one sensor in the Gridmetrics national data set is shown in Figure 6.

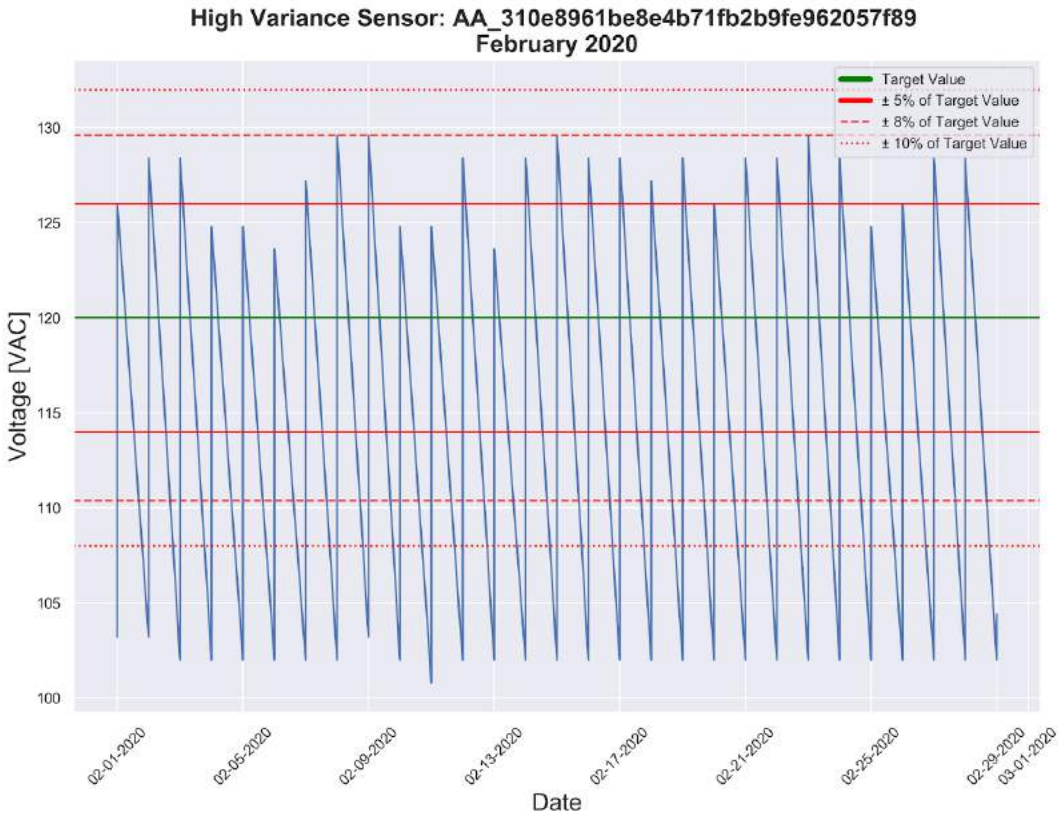

**Figure 6 - Example of fluctuating voltage in the Gridmetrics national data set.**

In Figure 6, the 120 VAC target is denoted in green and the ANSI limits are denoted in red. The horizontal axis is time in 5-minute increments and the vertical axis is the observed voltage.

Fluctuations can be caused by loose connections, faulty appliances, and malfunctioning motors. Large fluctuations from commercial and industrial loads can affect many consumers on the same circuit. Perhaps most problematic is electric arcing from loose connections that can result in overheating, sparks, and downed wires that cause wildfires. Additional examples of locations reporting fluctuating 120 and 240 voltage ranges are available.

## 7. Outages

Interruptions in electricity service vary by frequency and duration across geographic areas and are affected by weather and other variables. For any area, outage data can be very valuable to utilities in prioritizing and justifying investments that help mitigate outage impacts as measured in their System Average Interruption Duration Index (SAIDI) and System Average Interruption Frequency Index (SAIFI). In recent years, the number of outages and the number of customers affected have consistently risen, in some areas by as much as 200%.[9] For example, in 2017, the average U.S. utility customer experienced 1.4 interruptions and lost their power for a total of 7.8

[9] https://www.bloomenergy.com/bloom-energy-outage-map

hours over the year, nearly double the average total duration of interruptions experienced in 2016.[10]

Power outages are both irritating to utility customers and regulators and are also incredibly expensive. According to a 2017 analysis by Sentient Energy, each minute of mitigated SAIDI can save a utility $500K to $1.5 million in O&M (operation & maintenance) costs.[11,12] Gridmetrics data can aid in reducing SAIDI and SAIFI by assisting utility outage prediction and detection algorithms.

A smarter grid can reduce the economic costs associated with power disturbances. Studies by the Electric Power Research Institute have estimated the yearly cost of power disturbances across all business sectors in the United States at between $104 billion and $164 billion as a result of outages, and another $15 billion to $24 billion due to power quality phenomena.

Gridmetrics data are helpful in finding and quantifying unforeseen and previously invisible outages and power quality issues in the secondary distribution grid. Gridmetrics data can be leveraged to complement existing utility outage frequency and duration processes as well as the metrics that utilities are required to report to the U.S. Energy Information Administration.

For example, Gridmetrics automated 5-minute near real-time observations during a severe storm in Sioux Falls, SD, have proven insightful. Sioux Falls was struck by three tornadoes around 11:30 PM on September 10, 2019, as depicted in Figures 7, 8, and 9.

[10] https://www.eia.gov/todayinenergy/detail.php?id=37652
[11] https://www.sentient-energy.com/blog/15-minutes-could-save-you-15000000-or-more
[12] https://www.epri.com/research/products/1022519

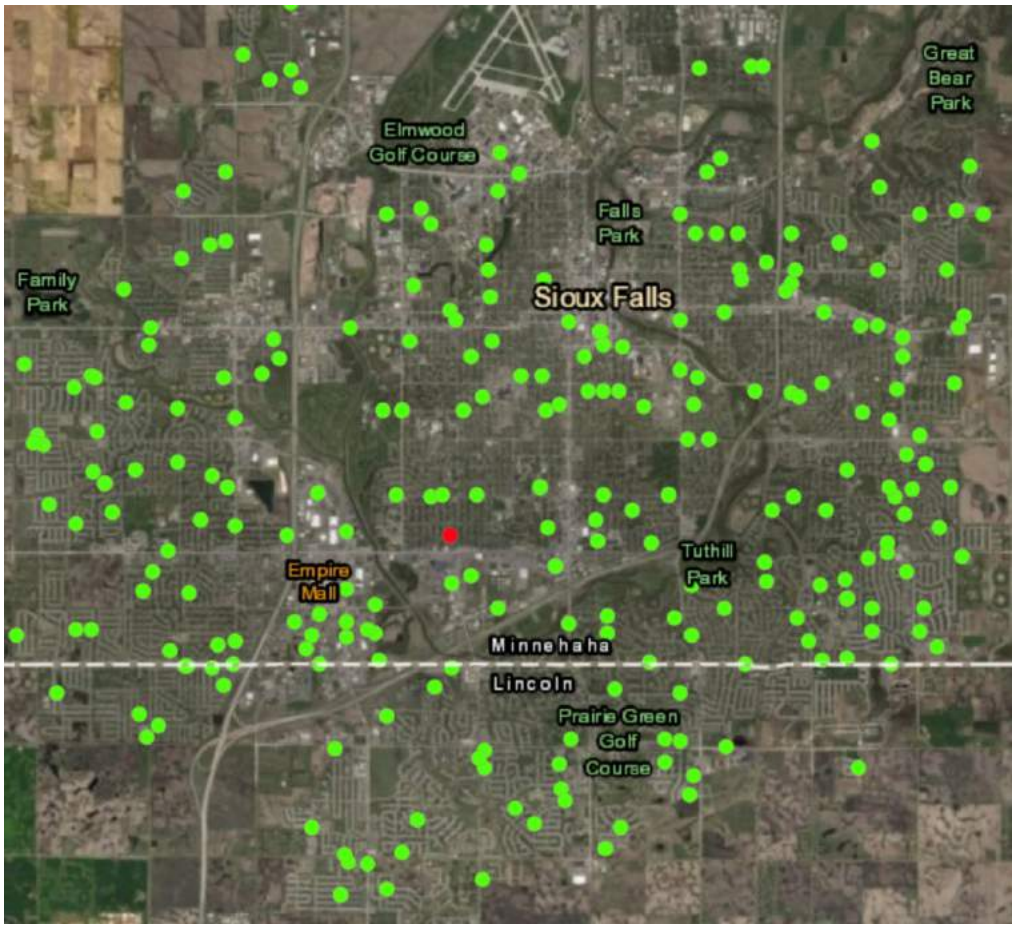

**Figure 7 - Status of the secondary distribution grid prior to the outage.**

Figure 7 shows the "green" status of sensors before the tornadoes hit. All but one sensor is green, indicating the grid power is "on" and widely available. This is a normal grid status.

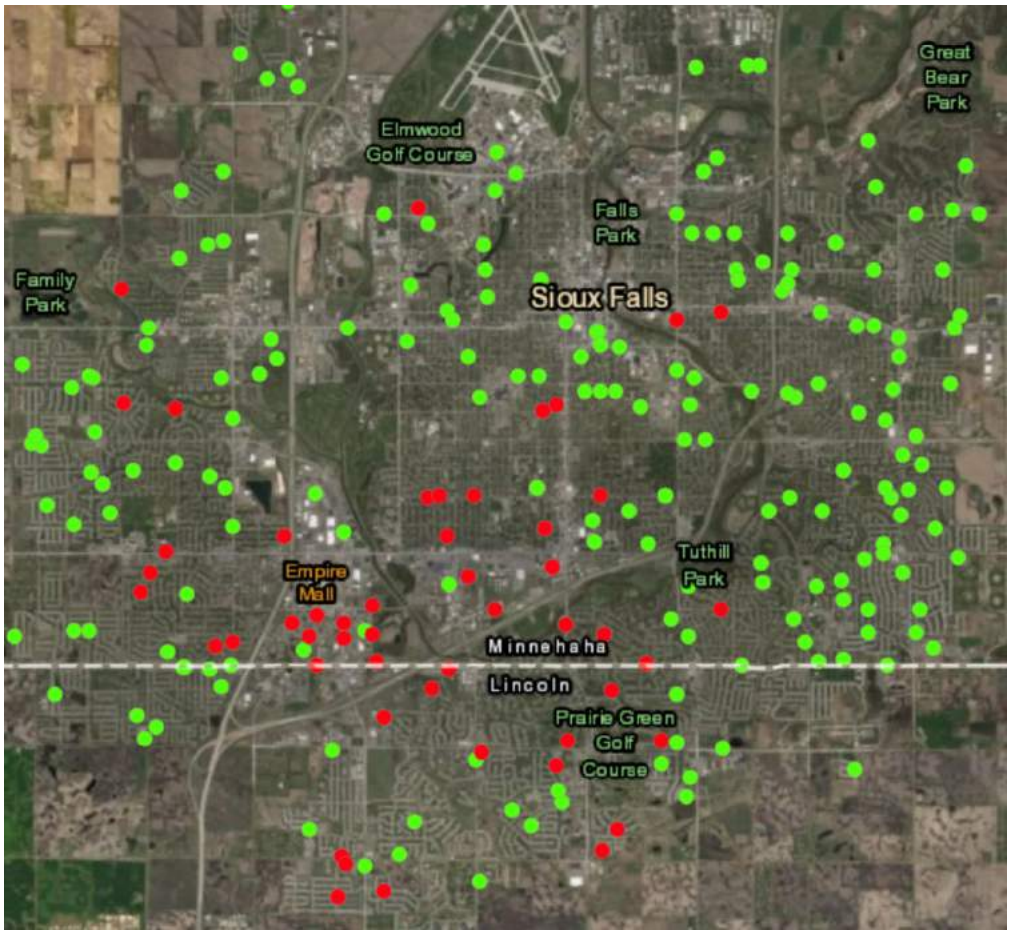

**Figure 8 - Status of the secondary distribution grid during the outage.**

In Figure 8, broadband sensors show the path of the Tornadoes starting at the lower left. The location of each red dot depicts a power failure. A changing map over time reveals where power outages come and go, while clusters of red provide a sense of the size of areas affected.

A unique capability of Gridmetrics sensors is their ability to continue to report status during grid power failures. Continuous reporting by all Gridmetrics sensors during weather catastrophes and other outages is made possible by battery-backed uninterruptible power supplies in each sensor. Batteries in each sensor provide 3 to 5 hours of backup power for sensing functions as well as high-speed real-time communications for backhaul of voltage observations.

Two benefits have become apparent to users of Gridmetrics data. First, due to Gridmetrics' enhanced visibility of the secondary distribution grid, new outages are being exposed over and above those detected by and reported through existing utility energy management and SCADA (supervisory control and data acquisition) systems. As such, the additional visibility in the last mile of the grid provided by Gridmetrics is benefiting utilities and their customers.

Second, utilities generally have limited tools to verify service restoration and as such can use Gridmetrics data to automate and augment their existing processes that involve utility staff

driving around to see where power appears to have been restored. As one might expect, few utility customers call to report their service has been restored, making Gridmetrics real-time data APIs a natural fit to fill this need.

Figure 9 depicts a reduction in outages after the storm passed.

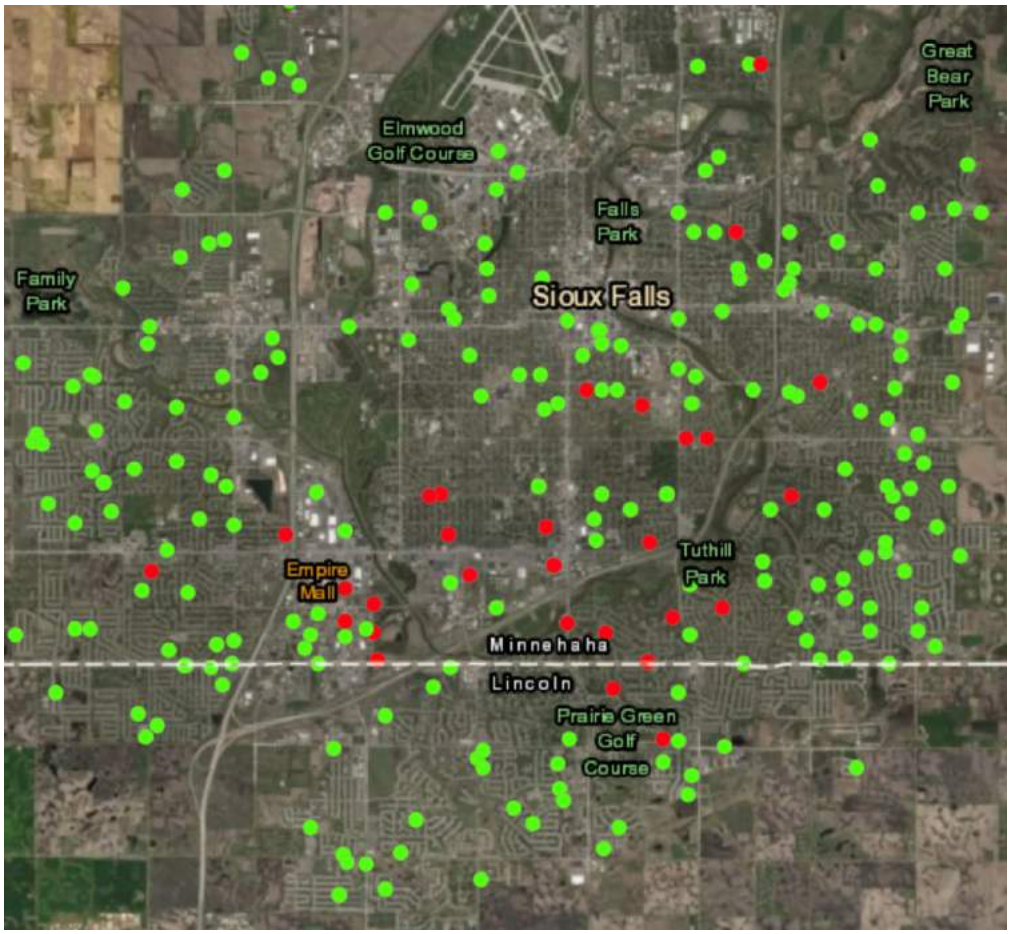

**Figure 9 - Example of service near the end of the outage**

The reduction in outages in Figure 9 is likely the result of utility service crews working to restore power around the city, especially at lower left. The remaining red dots depict serving areas that still require attention by utility crews.

## 8. Cable TV Broadband Sensor and Network Advantages

While most utilities have some level of experience with automatic meter reading (AMR) and advanced metering infrastructure (AMI), it is important to note inherent limitations of these technologies.

A) By design, all meters used for AMR in the U.S. are limited to 240 VAC split-phase leg-to-leg measurements, providing no measurement of the performance of ground or neutral circuits. For reference, all Gridmetrics sensors are grounded, battery-backed, and provide continuous

reporting during grid outages. Over 90% of Gridmetrics sensors are connected via leg-to-neutral to 120 VAC, which enables visibility of potential loss-of-life safety issues and reduced equipment longevity issues due to insufficient or intermittent grounding and unbonded neutral circuits.

B) While more than half of U.S. households have AMR deployed, the capability is often unused in daily operations due to bandwidth limitations in the backhaul communications infrastructure that results in bottlenecks in utilities receiving and processing AMR data.[13,14] In contrast, all Gridmetrics sensor data are backhauled over gigabit networks with millisecond latencies, allowing for near real-time 5-minute updates for all sensors in the national data set. The latency, loss, throughput, and jitter of the Gridmetrics sensor backhaul network far outperform commonly deployed AMI networks.

## 9. Conclusion

As the number of DERs and the two-way electricity flows they create rapidly increase, aging grid infrastructure elements that are supposed to keep the grid safe are failing and causing unprecedented loss of life and property.[15] While the enormity of the electric power grid is such that in the U.S. alone, the 5.5 million mile distribution network is long enough to reach the moon nearly 21 times--the performance of the last mile of the grid is sparsely monitored and hence unable to be optimally managed. Gridmetrics 5-minute sensor readings fill the immediate need to augment utility supervisory control and data acquisition systems by rapidly improving the monitoring of the secondary distribution portion of the grid by using an existing fleet of power sensors deployed across broadband networks.

The growing and evolving Gridmetrics data set is available to aid U.S. utilities in monitoring and managing the secondary distribution networks that make up the last mile of the grid. The locations of specific anomalies worthy of investigation are available for use in utility operations. Through utility maintenance and repair efforts, infrastructure aging, wear and tear, and local weather--the location and severity of anomalies will change over time, supporting the case for real-time Gridmetrics APIs and near real-time data feeds. Through collaboration with utilities and sharing best practices for anomaly detection and classification, it is expected that anomalies that foretell of impending infrastructure failures, resiliency and safety issues, and high-risk for loss-of-life can be identified. In addition, working with utilities, the criteria used to identify anomalies can be expanded, refined, and validated to achieve maximum benefit from Gridmetrics data.

Data from broadband power quality sensors can help utilities pinpoint existing portions of the grid that can be inspected for high, low, and fluctuating voltages which can cause unsafe conditions, poor customer experiences, and premature failures of customer equipment. In addition, outage data from broadband sensors can be correlated with existing utility data sets to create a more comprehensive understanding of distribution network frailties. Combining insights

# Powering the Near Future 10G Access Network

## Considerations for Assuring Sufficient and Reliable Power

A Technical Paper prepared for SCTE•ISBE by

**Rob Anderson**
Director of Product Management
EnerSys Energy Systems
3767 Alpha Way, Bellingham, WA 98226
360-392-2293
randerson@alpha.com

## List of Figures

## List of Tables

**Title** **Page Number**

# 1. Introduction

The 10G initiative is the catalyst behind several technology innovations designed to deliver future proof internet speeds up to 100 times faster than most consumers are experiencing today. These innovations will affect every aspect of the broadband network including headends, the access network and the customer premises. The access network specifically must undergo enhancements to support performance levels envisioned by the 10G initiative. Many of these network revisions involve technology that is either new or under development. Operators will need to make decisions about implementing new technology to be certain that their networks will be able to handle whatever is coming. A service provider's existing network architecture along with the cost for upgrades will steer operators towards the technologies right for their needs. Network upgrade options may include anything from standard node splits and remote PHY (R-PHY) node upgrades to potentially disruptive technologies like 5G fixed wireless or fiber overlays. Regardless of the network upgrade specifics, power is a common requirement for any network.

Assuring the availability of additional, reliable and intelligent power for the 10G capable network is both essential and challenging since network architectures are evolving and much of the 10G enabling technology is still being developed. In this paper we address the access network powering challenge by providing operators with a set of powering guidelines. Our objective is to help ensure that sufficient, reliable network power is available, irrespective of the specific technologies implemented to meet network performance objectives. We accomplish this by first describing a 10G reference access network. Our reference network includes architectures and technologies that are both current and that are under development. Next, we overlay our reference network with the appropriate powering architecture. Existing hybrid fiber coax (HFC) powering infrastructure is re-used wherever practical. Some new 10G network elements may require new and innovative powering options. While no single service provider would incorporate every element of our 10G reference network, operators can plan powering strategies to support those network upgrades that will meet their future performance goals.

# 2. The Near Future 10G Network

In early 2019 the 10G initiative was announced with the objective of providing 10Gbps symmetrical, secure, low latency data services. CableLabs coined the phrase near future in connection with 10G. A CableLabs paper provides the following description of the 10G near future network: "Immersive experiences like interactive holographic projections, video walls and next-generation artificial intelligence (AI) and virtual reality (VR) tools will all require a super high-capacity network that can deliver an immense amount of data to the end user ... 10G technologies will enable speeds 10 times faster than the 1 gigabit speeds that cable offers today, equally applied to both the upstream and downstream traffic over existing cable hybrid fiber coax (HFC) networks [1]."

Our 10G reference access network includes existing technologies and technologies that are under development. Figure 1 – 10G Influenced Technologies, highlights some 10G influenced technologies and their relative location in the broadband network.

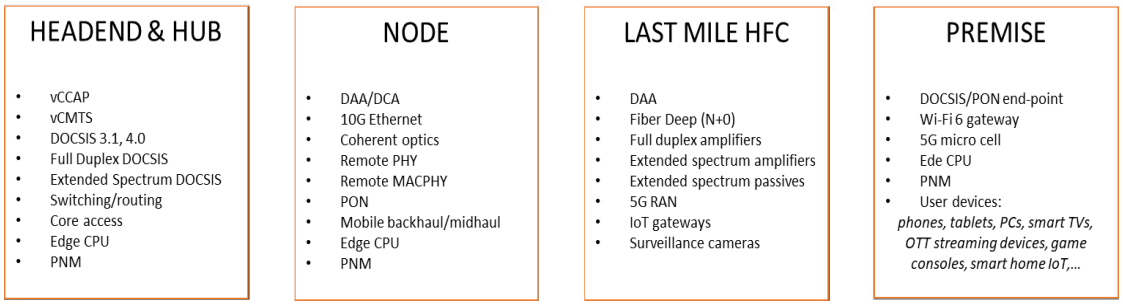

**Figure 1 – 10G Influenced Technologies**

Our discussion will focus on elements contained in the node and last mile HFC blocks shown in Figure 1. These access network elements are within the scope of our powering discussion.

## 2.1. Distributed Access Architecture (DAA) and Distributed CCAP Architecture (DCA)

Distributed Access Architecture (DAA) relocates or distributes functions that traditionally reside in the headend or hub closer to the user. Moving functions deeper into the network reduces power and space demands in the headend/hub. As functions move closer to users the network experiences increase in efficiencies, speed, reliability, latency and security [2]. Distributed CCAP Architecture (DCA) outlines specific technologies to distribute headend functions to the distributed network [3]. For the intent of our powering discussion DAA and DCA will be considered the same and we shall use the term DAA going forward.

## 2.2. Remote PHY and Flexible MAC Architecture

Remote PHY (R-PHY) and Flexible MAC Architecture (FMA) are implementations under the DAA umbrella. Both technologies move processing functions from the headend/hub to distributed optical nodes as shown in this diagram.

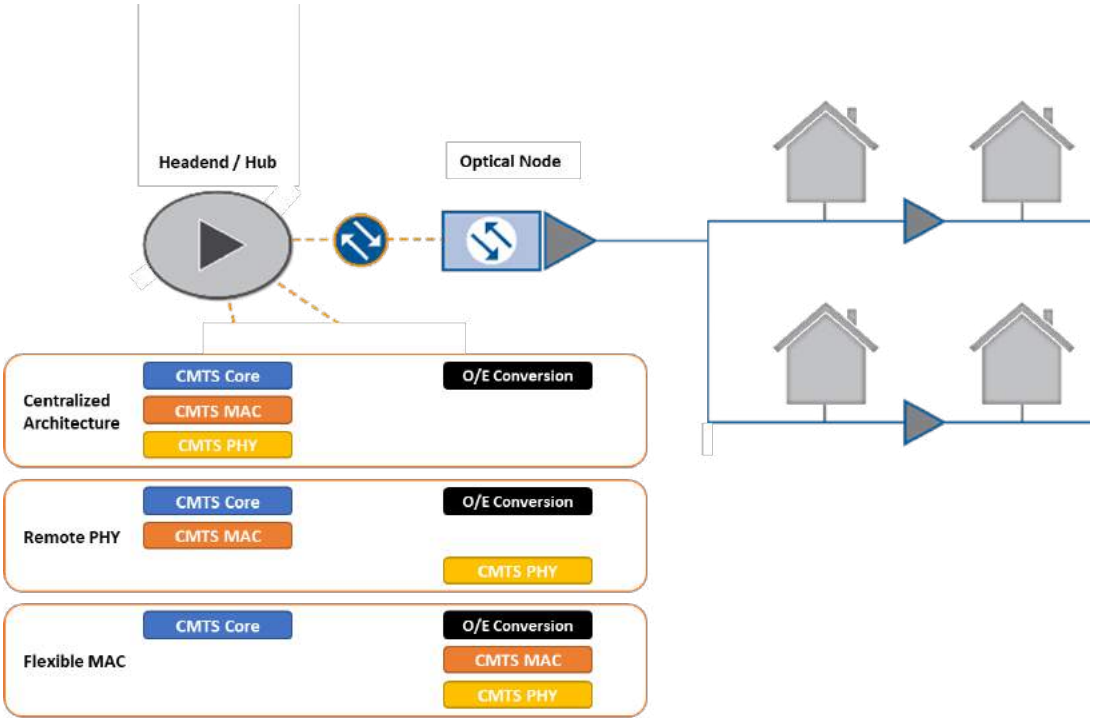

**Figure 2 – DAA Configurations**

Operators transitioning from traditional analog nodes to DAA nodes must increase their node power budget. Analog nodes consuming about 80W each are replaced by DAA nodes requiring more power (assuming similar configurations). Current industry data indicates that DAA node power consumption is in the range of 140W to 190W with FMA capable nodes requiring more power than R-PHY capable nodes. As field programmable gate arrays (FPGA) and application specific integrated circuits (ASIC) evolve, this power consumption is expected to improve. For our DAA node power budget we'll assume a nominal value of 165W per node.

At the time of this paper's publication DOCSIS™ 4.0 has not yet been implemented in DAA nodes. DOCSIS 4.0 radio frequency (RF) signaling, including Full Duplex DOCSIS (FDD) and Extended Spectrum DOCSIS (ESD) with downstream spectrum support to 1,794 MHz, are generated in the PHY component of the DAA node [4]. Specific power requirements for DOCSIS 4.0 enabled DAA nodes are not known. For estimating purposes we'll assume that future DOCSIS 4.0 enabled DAA node power requirements fit within our estimated DAA power budget of 165W.

Beyond the current DOCSIS 4.0 standards, there are industry proposals to extend the downstream spectrum beyond 1.8GHz to 3GHz. This next-generation RF band upgrade could enable upstream speeds in excess of 9 Gbps and downstream speeds to 25 Gbps. The proposal utilizes small RF amplifiers near the premises, providing signal amplification for the 1.2GHz to 3GHz range [5]. The impact of this enhanced RF spectrum on the HFC power network would be speculative at this stage so we will leave powering this concept for a future discussion.

## 2.3. Coherent Optics Backhaul

Coherent optics, or full duplex point to point (P2P) coherent optics, uses amplitude and phase to carry large amounts of bidirectional data over a single fiber using a single wavelength. In the DAA cable environment, coherent optics will be used to establish high-capacity links from the headend/hub to an

aggregation node or directly to the DAA node. The current state of the industry supports 100Gbps outdoor rated coherent optics pluggable modules with 200Gbps and 400Gbps modules planned for the future. Our access network powering model will consider two potential coherent optics use cases. First is a coherent optics module providing high speed backhaul direct to the DAA. Today's coherent optics modules consume approximately 15W which will be added to our DAA node power budget. Next, we consider the addition of an optical distribution center (ODC) or virtual hub containing the coherent optical components as well as Ethernet switching elements. An access network with an ODC is pictured here [6].

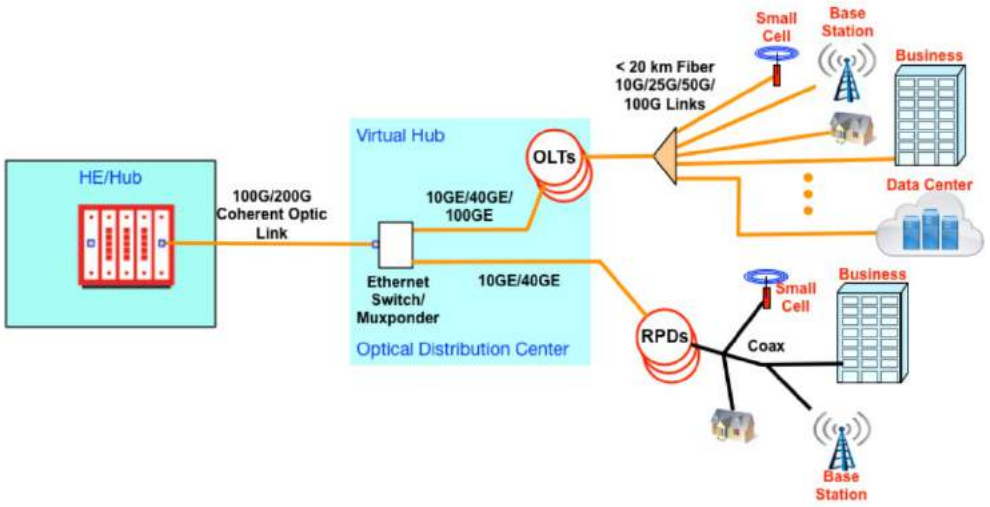

**Figure 3 – ODC/Virtual Hub Architecture**

In this network the ODC is shown supporting optical outputs to DAA nodes (RPDs) as well as supporting OLT functions for passive optical network (PON) network segments. For power budgeting purposes the ODC will be considered a strand mount style element with power consumption of 150W. Powering the ODC or other virtual hubs can be more challenging than powering optical nodes. With the ODC, there are no coax connections to source power to any of the fiberoptic inputs and outputs. If the ODC is installed in a location formerly occupied by an optical node then powered coax may be available at the location to power the ODC. If powered coax is not available, alternative powering options can include anything from installing a dedicated power cable from nearby powered coax to installing a new uninterruptable power supply (UPS) at the ODC location. Irrespective of the power input source, the operator will consider the ODC a critical location requiring extremely reliable power due to the number of downstream subscribers serviced by this device.

## 2.4. Generic Access Platform (GAP) Nodes

The SCTE Interface Practices Subcommittee, Working Group 1 (IPS WG1) is defining a set of specifications for a Generic Access Platform (GAP) node housing. One objective of the GAP node is "increased availability and ability to integrate advanced technologies within a modular approach [7]." Integrating additional technologies inside the node housing will increase power consumption which is why the GAP is mentioned here. Future plug-in modules discussed during GAP committee sessions include: radio access network (RAN) (Wi-Fi, 5G and citizen broadband radio service (CBRS)), Ethernet passive optical network (EPON) and edge computing modules. These three potential node enhancements are discussed here.

### 2.4.1. RAN Module

A potential access network upgrade includes a RAN component, potentially taking the form of 5G fixed wireless radio units (RU's) utilizing the coax for power and backhaul. It is not likely the DAA node physical location will align with RU location requirements for signal coverage. For simplicity we assume the DAA does not incorporate wireless modules. A 5G fixed wireless access network extension is discussed in section 3.4.2.

### 2.4.2. EPON Module

EPON modules could be installed in a DAA (GAP or traditional) node enclosure. A challenge comes with attempting to define a standard configuration. Some EPON components are light weight, layer 2 devices that combine with cloud based processing for full featured performance. One module from a well-known component vendor supports 2x10GigE x 2x10GEPON and consumes only 35W. Specifications for more full featured EPON units supporting 4x10GigE x 4x10GEPON and including native processing support for features such as DOCSIS provisioning over Ethernet (DPoE) and layer 3 networking have been identified as consuming up to 140W. To avoid numerous permutations of EPON and RF QAM node configurations and to simplify our powering discussion it is assumed that our DAA node may support one basic EPON module at 35W.

### 2.4.3. Edge Compute Module

CableLabs in 2020 announced a program called Adrenaline intended to "transform the network into a distributed heterogeneous compute platform with dynamic workload allocation". The Adrenaline concept is shown here [8].

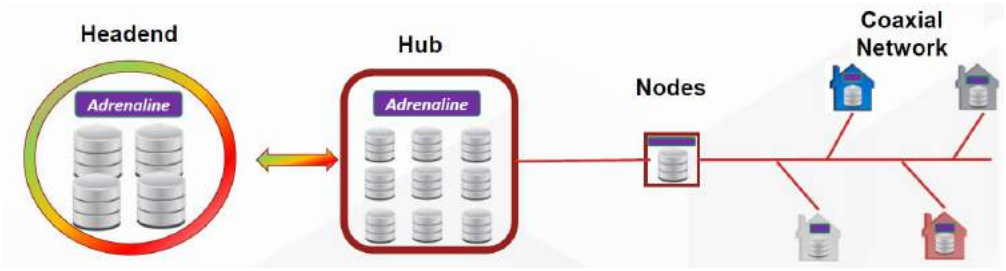

**Figure 4 – Edge Compute Concept from CableLabs**

An Adrenaline type distributed, or edge computing concept has been the topic of multiple industry webinars. Edge computing is distributed to intelligent components throughout the network, including the DAA node. The cable broadband industry is a few years away from realizing speed and performance improvements from distributed edge computing, but many are working towards this goal. For our access network powering budget, we assume our near future DAA node will be fitted with a processing module. Power estimates at this stage are speculative but let's assume our DAA processing element will add an additional 10W power requirement to the node.

### 2.5. DAA Node Power Budget Summary

From our near future access network concept node review the following table summarizes our DAA node powering budget.

**Table 1 – DAA Node Power Budget**

| Configuration | Power (W) |
|---|---|
| DAA (RPHY/ FMA) node | 165 |
| Coherent optical node backhaul | 15 |
| Edge compute module | 10 |
| Total DAA node power budget | 190 |
| Adding EPON | 35 |
| DAA with RF and EPON | 225 |

Our DAA node of the future requires significantly more power than traditional analog nodes. This difference combined with other related access network upgrades give cause to review powering assumptions and consider evolving needs.

## 3. Powering The 10G Access Network

### 3.1. Traditional HFC Power Review

The access network includes all network elements beyond the headend/hub and up to the premises. Some network architectures utilize virtual hubs housed within outdoor sealed enclosures which are also considered part of the access network. A simplified access network block diagram is shown in Figure 5.

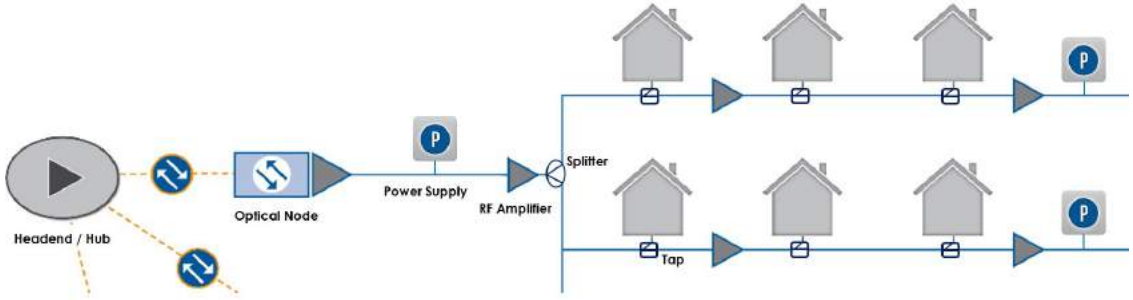

**Figure 5 – Traditional HFC Access Network**

In the traditional HFC access network signals from the headend/hub are transmitted over fiber optic cable to optical nodes. Nodes convert between optical and electrical signals and convey those signals to multiple coax network segments. Each coax segment typically consists of a tree-and-branch structure for signal distribution. Passive splitters subdivide the signal into multiple paths (branches). Amplifiers are located throughout the coax network segment to boost signals, providing appropriate signal levels to the end users, which are typically homes and businesses. Directional taps located near the end users will "tap off" the signal from the main coax cable into drop cables which bring the signals into the customer premises. Nodes and amplifiers require power. Power is also consumed by coax line loss from Joule heating ($I^2R$ losses). Power and RF signals are both multiplexed onto the coax, eliminating the need for separate power and signal cables. Power supplies are placed as needed throughout the access network to provide power to nodes and amplifiers.

### *3.1.1. HFC Power Supplies*

Power for HFC components is provided by a specialized backup power system known as a broadband UPS. UPS systems are physically located throughout the coax portion of the network where required to provide power for each active network element. UPSs are physically installed on outdoor utility poles, in dedicated ground mounted enclosures, and in secured utility areas of multi-dwelling units (MDUs). A typical utility pole mounted broadband UPS is shown in Figure 6.

**Figure 6 – Typical Pole Mounted Broadband UPS**

The UPS converts utility power (120VAC or 240VAC in North America) to 90VAC for insertion into the coax. Early cable networks used 30VAC then later 60VAC for network power. Today, networks almost exclusively use 90VAC power with a few older 60VAC networks still in operation.

Unlike utility service which provides sinusoidal AC power, the broadband UPS produces a quasi-square wave or trapezoidal shaped power output. This wave shape is a result of the ferro-resonant transformer used in broadband UPS systems. The ferro-resonant transformer provides a high level of electrical isolation, protecting powered nodes and amplifiers from utility line power surges and transients that could damage sensitive electronics.

Batteries within the UPS system enable the power supply to provide continuous, reliable backup power to the access network during utility disruptions. The output of the UPS is connected to a power inserter, which acts like a reverse directional tap, to inject power onto the coax cable. Some operators use the term "shunt" to describe the process of injecting power or shunting power onto the coax.

Each amplifier, splitter and tap can be configured to pass power through itself and on to the next device in the network or to block power from passing through itself. The decision to pass or block power within a specific network device is determined by the operator and is based on criteria including:

- Do downstream devices require power and if so, how much?
- Does the UPS have sufficient capacity to power future planned devices?
- Will powering additional devices cause this UPS to exceed the cable broadband operator's maximum powering policy?

### *3.1.2. HFC Powering Example*

Figure 7 uses a simplified HFC network segment to illustrate some basic powering concepts. In practice, HFC powering is more complex than illustrated but several basic principles are shown.

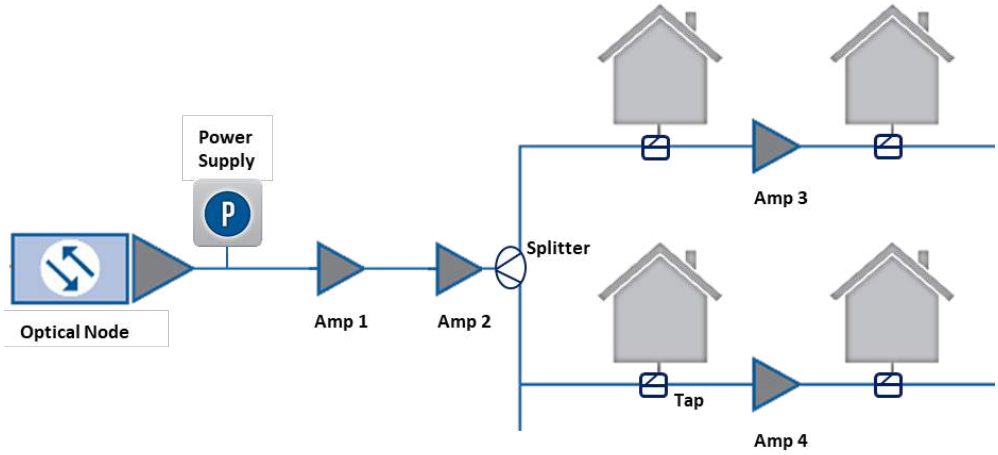

**Figure 7 – HFC Powering Example**

As stated, the diagram represents a simplified HFC network segment. In this example a broadband UPS is connected near the optical node. The node is powered from this coax segment. Amplifiers 1-4 are also powered from this UPS. Amplifier 1 and amplifier 2 are each configured to pass power through their chassis, enabling downstream devices to be powered from the UPS. The splitter is configured to pass power through both outputs. Amplifiers 3 and 4 are powered from the UPS and are configured to block power from passing to their respective outputs eliminating additional power draw from any components further down the coax.

Assume that the node requires 80W of power and amplifiers 1-4 each require 70W of power to operate. Also assume the UPS output is configured to 90VAC and that it has the capacity to provide up to 1350W of power. For simplicity, ignore coax line loss. The total power required is calculated as the sum of power required from each network active:

$$P(Actives) = P(node) + P(amp1) + P(amp2) + P(amp3) + P(amp4)$$

$$\text{Total Power (Actives)} = 80W + (70W \times 4) = 360W$$

To make our example more realistic we include coax line loss in our power equation. Assume all coax is 0.625 inches diameter which has a typical resistance of 0.0011 ohms/feet. Also, assume the following coax span lengths.

**Table 2 – Coax Spans for HFC Powering Example**

| From | To | Span (ft) |
|---|---|---|
| UPS | node | ~0 |
| node | amp 1 | 1,000 |
| amp 1 | amp 2 | 1,000 |
| amp 2 | splitter | 1,000 |
| splitter | amp 3 | 1,000 |
| splitter | amp 4 | 1,000 |

Note: Using these assumptions, the total coax length between the UPS and amplifier 3 or the UPS and amplifier 4 is 4000ft.

Let's calculate the power lost in a single 1,000ft segment of coax. Using Ohm's Law:

$$P(loss) = I^2R$$

Where:

P(loss) = power lost from coax line resistance, measured in Watts. Note: this energy is converted to heat, hence the term Joule heating for $I^2R$ losses.

I = current through the cable, measured in amps

R = resistance of the length of cable, measured in Ohms

Taking amplifier 1 in isolation, we calculate the power lost in the coax segment between the UPS and amplifier 1 as follows:

$$P(loss) = (70W/90V)^2 \times (0.0011 \text{ ohm/ft} \times 1{,}000\text{ft}) = 0.67 \text{ W}$$

In this example we used the Ohm's law relationship: I = P/V for the first term.

I=P/V is an ideal approximation. In real-world calculations we must account for accumulative voltage drops across each coax segment, i.e., the 90VAC at the UPS output is reduced through each coax segment. The voltage drop is proportional to both cable resistance and current per the relationship:

$$V(drop) = I(cable) \times R(cable)$$

HFC active elements, including nodes and amplifiers, are typically constant power devices. As input voltage to a device is reduced due to coax line resistance, the device's current will increase to maintain the required power load (P=VI). As the current increases, power loss through the coax increases. Recall this relationship discussed earlier: $P(loss) = I^2R$.

In this example the node and four amplifiers require 360W to operate. Additional energy consumed (lost) due to voltage drops across the various coax segments can be calculated to be an additional 36W. Detailed calculations have been omitted for brevity. Results are summarized as in Table 3.

**Table 3 – HFC Powering Example Results**

| Configuration | PS I(out) | EOL Voltage | Actives Load | $I^2R$ Loss | PS Utilization |
|---|---|---|---|---|---|
| Analog node, 4x Amplifiers | 4.4A | 79.4V | 360W | 35.5W | 29% |

With the UPS capacity of 1350W we've consumed 29% of the available power. End of line (EOL) voltage is another important parameter to monitor. EOL voltage is the input voltage of the last active device in the network and must remain above 45V for most HFC equipment to operate. For this example, we're well within acceptable operating parameters for UPS power and EOL voltage. This approach to HFC powering has worked well for many years. However, as the access network is upgraded to support our future 10G performance goals we will soon see how our powering approach must also be revised.

## 3.2. Powering the Evolving Access Network

Traditional HFC powering assumptions and methods must be reviewed as the underlying technology and in some cases the topology of the access network evolves to support higher performance and additional services. Section 3.2 examines a few of those network upgrades and their effect on the underlying power.

### *3.2.1. Node Splits*

Node splits are familiar to most operators as a method of increasing upstream capacity by reducing a node service group size. If one node services 400 homes, then two nodes can service 200 homes each. Benefits come from reducing upstream (US) traffic contention. US DOCSIS utilizes time division multiple access techniques to enable many users to share the same US frequencies. Each user is granted specific time slots for US transmissions. Smaller service groups through node splits mean fewer users contending for shared upstream capacity.

Powering new nodes after a node split is usually straightforward. Existing broadband UPS systems are often already installed within existing node segments. New nodes often get installed closer to the premises and may result in eliminating amplifiers which can offset incremental power required for the new nodes.

Node splits have limitations. US bandwidth is capped by the US diplex frequency defined in each network. A low split 5-42MHz US diplexer can support about 100Mb/s of data while a 5-85Mhz mid-split diplexer can handle roughly 200Mb/s of US data. Multi-gigabit US performance requires a different approach.

### *3.2.2. Deep Fiber (N+0)*

Expanding the node split concept to the point where all network amplifiers have been replaced by optical nodes leads to a deep fiber architecture consisting of a node + zero amplifier (N+0) configuration. Using DAA nodes in this configuration results in powerful, high performing nodes closer to the end user than ever before. With N+0 there are only passive components and coax between the DAA node and the premises. Potential data speeds are substantially higher than those possible from the traditional HFC network. Using technologies such as full duplex DOCSIS (FDD), extended spectrum DOCSIS (ESD) or both together can bring network performance much closer to the vision of the 10G concept.

However, powering an N+0 network may not be a straightforward transition from our traditional HFC powered network. Let's review a simple example to illustrate some potential challenges.

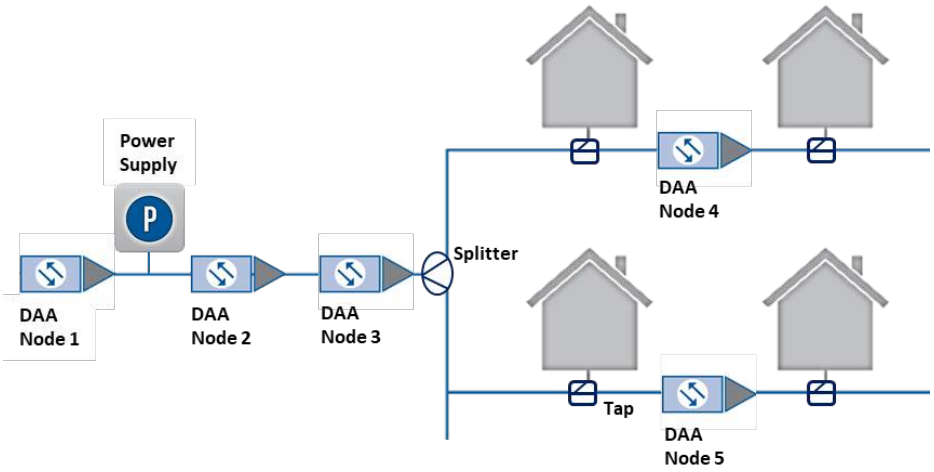

**Figure 8 – DAA N+0 Powering Example**

For our N+0 powering example we use the future DAA node defined in Table 1. Also, we're reusing the HFC node + amplifier layout from our HFC powering example but replacing the amplifiers with DAA nodes. Figure 8 shows the coax path to each DAA node. The coax is used for power only. Separate fiber connections not shown in this example carry the high speed data signals to each node.

Assume the UPS capacity is 1,350W and is configured for 90V output. Also assume that the EOL voltage must remain >45V for the nodes to operate. With our future DAA node requiring 190W, power for the active network elements is calculated as follows:

P(Actives) = P(node1) + P(node 2) + P(node 3) + P(node 4) + P(node 5)

Total Power (Actives) = 190W x 5 = 950W

To include coax line loss in our power equation, assume all coax is 0.625in diameter with resistance of 0.0011 ohm/ft. Assume the following coax span length:

**Table 4 – Coax Spans for DAA N+0 Powering Example**

| From | To | Span (ft) |
|---|---|---|
| UPS | Node 1 | ~0 |
| Node 1 | Node 2 | 1,000 |
| Node 2 | Node 3 | 1,000 |
| Node 3 | Splitter | 1,000 |
| Splitter | Node 4 | 1,000 |
| Splitter | Node 5 | 1,000 |

Note: Using these assumptions, the total coax length between the UPS and Node 4 or Node 5 is 4,000ft.

In this example the total power needed for the DAA nodes is 950W. However, higher current flow through the coax results in 560W of $I^2R$ power loss. Total power for this scenario is 1,510W which exceeds our UPS' capacity making this configuration invalid. Results are summarized here:

**Table 5 – DAA N+0 Powering Example Results**

| Configuration | PS I(out) | EOL Voltage | Actives Load | $I^2R$ Loss | PS Utilization |
|---|---|---|---|---|---|
| DAA node x 5, N+0 | 17A | 50.1V | 950W | 560W | 133% |

In this example the 1,350W UPS would be overloaded to 133% of capacity. It's also noteworthy that the EOL voltage has dropped to 50.1V. This is still above the 45V minimum but should be monitored as alternative powering is considered.

One option to solve our N+0 power overload is to install a second UPS and distribute the load between multiple power supplies. Adding UPS systems to the network is usually the operators last resort. Unplanned equipment costs and installation delays due to permits and local regulations can be problematic. Rather than default to installing new UPS systems as our corrective action let's look at another approach. By removing one of the DAA nodes from our test example we can solve part of our problem. Let's remove node 5 from our example, leaving the UPS to power nodes 1-4. Results follow:

**Table 6 – Modified DAA N+0 Powering Example Results**

| Configuration | PS I(out) | EOL Voltage | Actives Load | $I^2R$ Loss | PS Utilization |
|---|---|---|---|---|---|
| DAA node x 4, N+0 | 10.5A | 68.5V | 760W | 171W | 70% |

By removing one node our powering model now works and results in our UPS loaded to 70% capacity. Many operators place design limits on UPS utilization of between 80-85% of the UPS' capacity to reserve overhead for unplanned changes.

So how do we power the stranded node from our example? Keep in mind that this example was created specifically to illustrate the effects of $I^2R$ losses. In a live network many variables could affect the results. A few possible outcomes include:

- As the N+0 node architecture was implemented there would likely be multiple amplifiers decommissioned as part of the network upgrade. It's probable that the UPS would have spare capacity to power new nodes.
- Surplus UPS power from an adjacent coax segment could be routed to the new node(s).
- The UPS could be upgraded to a higher capacity to support the load and the required overhead (spare) power reserves.

Some operators have incorporated powering design rules into their network upgrade procedures to address these types of powering concerns. One major North American operator has established these options to address powering issues during advanced node upgrades:

- All power designs will assume advanced nodes will use existing power supplies. If any powering issues arise, the following will be allowed in order of preference:
    - Repowering of the nodes from adjacent node/power supply areas
    - 0.875" coax or dedicated power cable may be placed to reduce $I^2R$ losses
    - 15-Amp power supplies may be changed to 18-Amp at existing locations fed by 120VAC
    - 15 or 18-Amp power supplies may be added to the network
    - 15-Amp power supplies may be changed to 24-Amp at existing locations fed by 240VAC
- To prevent an overcurrent of line passives or active devices, all 24-Amp power supplies must include a protective interface module (PIM) to split current output and provide two

programmable, independent power outputs providing isolation between outputs so that a short circuit or other power anomaly in one section of the HFC plant will not cause a disruption of service to all plant fed from that power supply.

If our sample unpowered node were in an actual network, it's probable that a nearby coax segment would have enough power capacity to handle one additional node. Power from an adjacent coax segment can be bridged to the unpowered node using a technique similar to Figure 9:

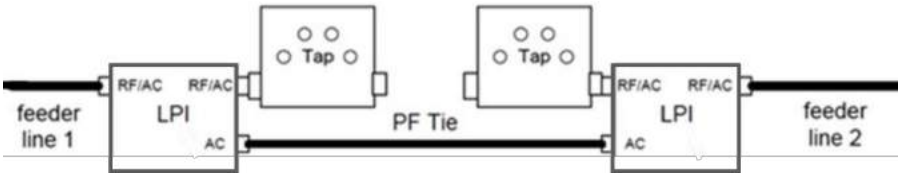

**Figure 9 – Coax Power Bridging**

This power bridging technique was developed by a major North American cable operator to solve the type of power shortage problem outlined in our example. Using this method power is bridged from one distribution leg to another while RF signals are blocked. RF signals from the node connected to feeder line 1 will support customers downline from the left tap while RF signals from the node connected to feeder line 2 support customers downline from the right side tap.

### *3.2.3. 1.8 GHz Extended Spectrum*

A widely discussed approach for increasing access network capacity is extending the upper limit of the usable RF spectrum to 1,794 MHz (1.8GHz). This approach is well defined in the DOCSIS 4.0 specifications [4]. What is not yet well understood at the time of this writing is the access network topology that will support the 1.8GHz extended spectrum. The DOCSIS specifications allow for different transmission profiles for frequencies above 1,002 MHz. Amplifiers capable of supporting the extended spectrum may be configured in such a way as to support higher frequencies at limited power levels. Once extended spectrum equipment is available, operators can evaluate network specific implementations to achieve their objectives. Then, the effect of extended spectrum implementations on power can be determined.

### *3.2.4. 5G Fixed Wireless Access*

The final communications link connecting end user devices such as phones, tablets and laptops is wireless. Wi-Fi 6 boasts peak data speeds in excess of 9 Gbps. Some operators are planning to deploy in-home 5G femtocells. 5G peak data rates can exceed 10 Gbps. A 5G small cell serving multiple homes on a street or throughout a neighborhood could realize similar data rates. This approach is called fixed wireless access (FWA). FWA is the process of providing wireless broadband using an RF link between two fixed points: a home and a small cell for example.

5G FWA could be either disruptive or complementary to cable providers. A telco or overbuilder with fiber capacity in a specific geographic area could use that fiber for backhaul and overlay a broadband radio area network (RAN) on top of the cable operator's service area to compete for broadband customers. This is clearly disruptive. Conversely, the cable operator could utilize 5G FWA to extend service to areas with no service or poor service without the expense of upgrading each premises and the surrounding infrastructure.

Powering an FWA network segment is similar to powering other HFC active network elements. Power per device, coax length between devices and distance from the power supply all factory into the powering equation. A simple example shown in Figure 10 illustrates the concept.

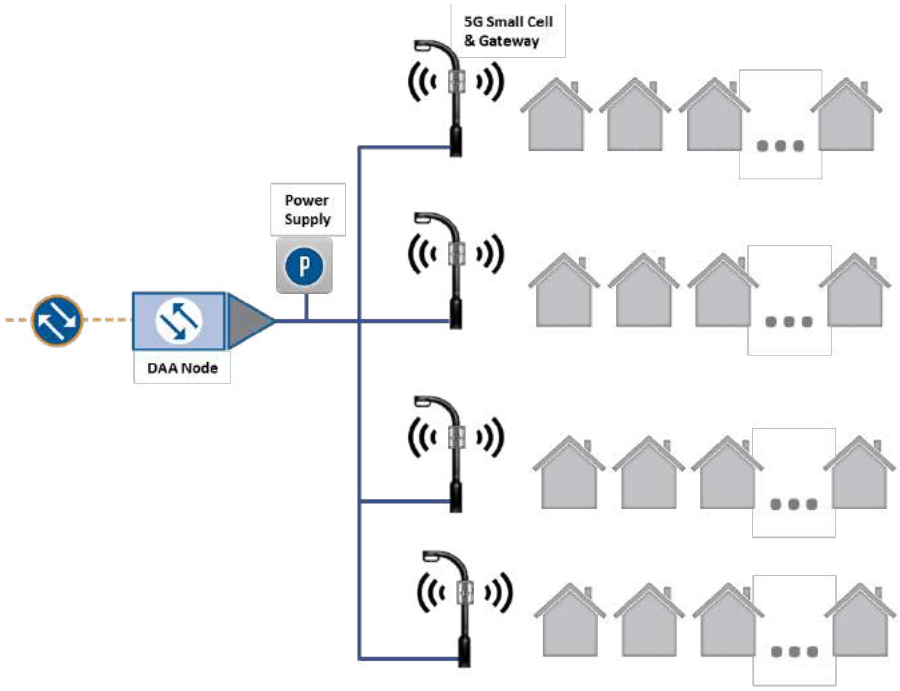

**Figure 10 – 5G Fixed Wireless Access Powering**

In this example a DAA node is shown servicing a neighborhood. Assume 4 small cell radios can service a total of 100 homes. To keep this example simple let's, make the following assumptions:

- The node and UPS power supply are co-located near a 4-way splitter
- Coax length from the splitter to each small cell is 1,500ft
- The UPS is configured to 90VAC output and is rated at 1350W
- The DAA optical node consumes 190W
- Each small cell requires 100W to power
- A gateway device interfaces each small cell radio to the coax for power conversion and DOCSIS backhaul. Each gateway requires 20W
- The coax is a common 0.625in diameter cable with resistance of 0.0011 ohms/ft
- The gateway / small cell minimum input voltage is 45V
- The operator's powering policy states that any broadband UPS can be loaded to maximum 85% of rated capacity.

With these parameters we calculate the power example as follows:

$$P(\text{Actives}) = P(\text{node}) + 4 \times (P(\text{small cell}) + P(\text{gateway}))$$

$$\text{Total Power (Actives)} = 190\text{W} + 4 \times (100\text{W} + 20\text{W}) = 670\text{W}$$

Adding coax line loss or $I^2R$ loss adds an additional 13W. The results are summarized:

**Table 7 – 5G Fixed Access Wireless Powering Results**

| Configuration | PS I(out) | EOL Voltage | Actives Load | $I^2R$ Loss | PS Utilization |
|---|---|---|---|---|---|
| DAA node, 4x 5G small cell radios each with HFC interface gateways | 7.6A | 86.7V | 670W | 13.4W | 51% |

### *3.2.5. EPON*

Ethernet passive optical network (EPON) has supported 10Gbps symmetrical data for years. Recently, the Institute of Electrical and Electronics Engineers (IEEE) has approved a 25G/50G-EPON standard. When viewed through the lens of the 10G initiative, cable broadband customers with EPON service are in good shape. Figure 11 represents an EPON network block diagram.

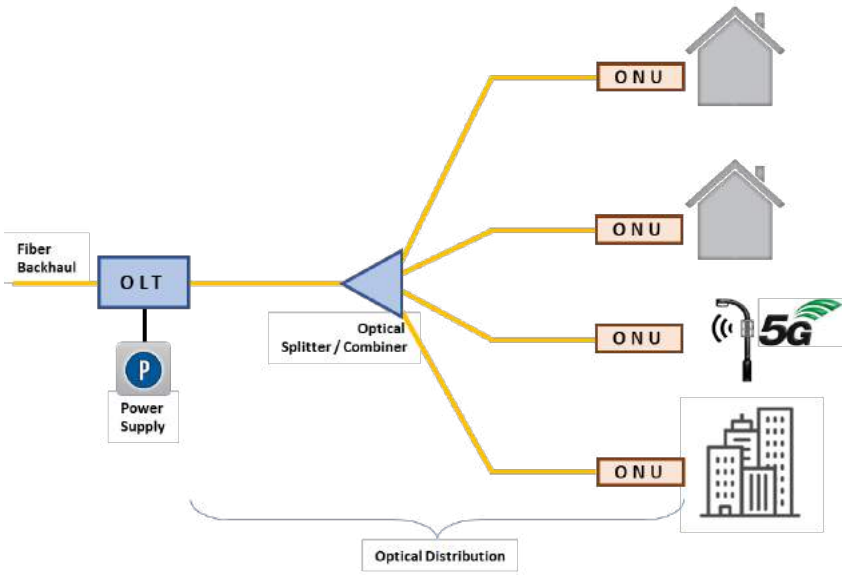

**Figure 11 – EPON Block Diagram**

Powering an EPON network segment is straightforward and familiar to most operators. EPON is an all-fiber network which consists of only passive optical components (splitters and combiners), except at the endpoints of each fiber, where there is an electrically-powered termination device – either an optical line terminal (OLT) or optical network unit (ONU). EPON is a point-to-multipoint topology in which downstream transmission from an OLT is received by all ONUs, but upstream transmission by an ONU is received only by the OLT. The OLT is often powered from a broadband UPS. That UPS may be dedicated to the OLT or may also power optical nodes and amplifiers in adjacent network segments. The ONU is powered from the premises (home or business) except for cases where the ONU services part of the access network infrastructure. An example is shown in our EPON block diagram where one ONU is

providing a backhaul connection to a 5G small cell radio. In such cases, the ONU and 5G small cell radio are typically powered from a nearby coax segment as described in a previous example.

# 4. Ensuring Reliable Power

## 4.1. Power Reliability Considerations

In 2019 a North American operator was experiencing problems with their digital nodes. Some of their R-PHY nodes were resetting. After a reset these nodes required several minutes to power-up and provision. The result was loss of service for several hundred customers within the service areas of the effected nodes. After extensive investigation by the operator and by multiple vendors the root cause for the resetting nodes was determined to be power related. Technicians working downline from the node were servicing network components and had inadvertently shorted the coax center conductor to ground causing a brief power disruption. The power anomaly was sufficient enough to cause the node to reset, dropping customer service for several minutes.

This example illustrates the critical nature of reliable power. Power reliability is especially vital with digital nodes where power disruptions can cause CPUs to reset. The node must reboot and then re-establish communications links independently to both the headend and to each user. The re-boot and re-provisioning cycle have been observed to take up to 15 minutes with some DAA devices. Many power related service disruptions can be mitigated with planning and preparation. A few ideas are discussed here.

### *4.1.1. Intra-Node Power Hold-Up Time*

In the prior node reset example the cause of the power disruption was a momentary short of the coax cable carrying power to the node. A UPS system that is operating perfectly could not mitigate this type of power disruption. To the UPS system a coax line short would appear as a current spike on its output. If the short occurred close enough to the UPS, its ferro-resonant transformer would fold-back, dropping output voltage until the fault was cleared. If the line short was some distance from the UPS, the coax line resistance would mitigate the short and it would appear to the UPS output as a temporary rise in current.

The UPS has no way of protecting the node power input from this type of line fault. Avoiding power glitch related node resets requires keeping the node's internal logic power bus from dropping. Node vendors are experimenting with internal capacitors and batteries to this end. Capacitors should prove effective for short power disruptions of no more than a few 60Hz AC cycles (60-70ms). Extended hold-up times my require an internal battery or second power input to the node. Neither option is desirable. Internal batteries would require eventual replacement and a redundant second power input is complex and expensive.

### *4.1.2. Utility Backup Time*

Increased power consumption from equipment such as future DAA nodes requires a review of UPS runtime capacity. With new architectures and equipment, what is the net effect on power consumption? Do the UPS systems still meet minimum runtime requirements? Operators must evaluate their networks by the criticality of each location. New DAA nodes may service business customers requiring longer utility backup than residential customers.

One utility power backup exception that California based operators must address is described in State Senate bill No. 431 introduced in June 2019. This bill requires some telecommunications equipment in

high fire threat areas to support 72 hours of communications during utility outages. If this legislation is applied to cable operators, extensive upgrades to their power backup systems will be required. For the access network, this would likely take the form of natural gas or propane generators at each broadband UPS installation. However, is it wise or even practical to have natural gas, propane or other combustible fuel source in zones declared high risk fire zones?

#### *4.1.3. Redundant Power Source*

Network equipment such as VHubs and DAA nodes often support large service areas or critical business customers. Do these devices have adequate power backup? In some installations operators have utilized a second (redundant) power pack within the node or VHub to insert power from a second UPS to create a fully redundant power backup for these critical devices. This redundant power may come from a second dedicated UPS system but would likely be diverted from a nearby coax segment powered from a different UPS than is powering the critical node or VHub.

### 4.2. Backup Power Requires Healthy Batteries

The ability of broadband UPS systems to provide uninterrupted power is directly related to the condition of the UPS system batteries. Aspects of battery health and maintenance relating to outside plant (OSP) UPS operation are discussed here.

Multiple factors impact battery runtime and health. For clarity, runtime as used here is defined as the instantaneous stored energy available from a battery or bank of batteries irrespective of environment or history. Battery health is defined as the present maximum capacity of a battery or bank of batteries. Five primary factors affect battery runtime and battery state of health. These are: state of charge, ambient temperature, temperature history, battery age and charge history. Sections in 4.2 discusses charge history and its effect on both battery runtime and battery health or capacity. Note that this discussion applies to lead-acid types of batteries, which are commonly deployed in HFC networks due to their lower cost. As new battery technologies become available and cost effectively deployed, the conclusions below will need to be modified based on the characteristics of the newer battery technologies.

#### *4.2.1. Effects of Charge on Battery Capacity*

Overcharging and undercharging batteries has a significant effect on battery life. Using charging specifications from battery manufacturers, the following discussion illustrates how overcharging or undercharging batteries can cause premature battery failure.

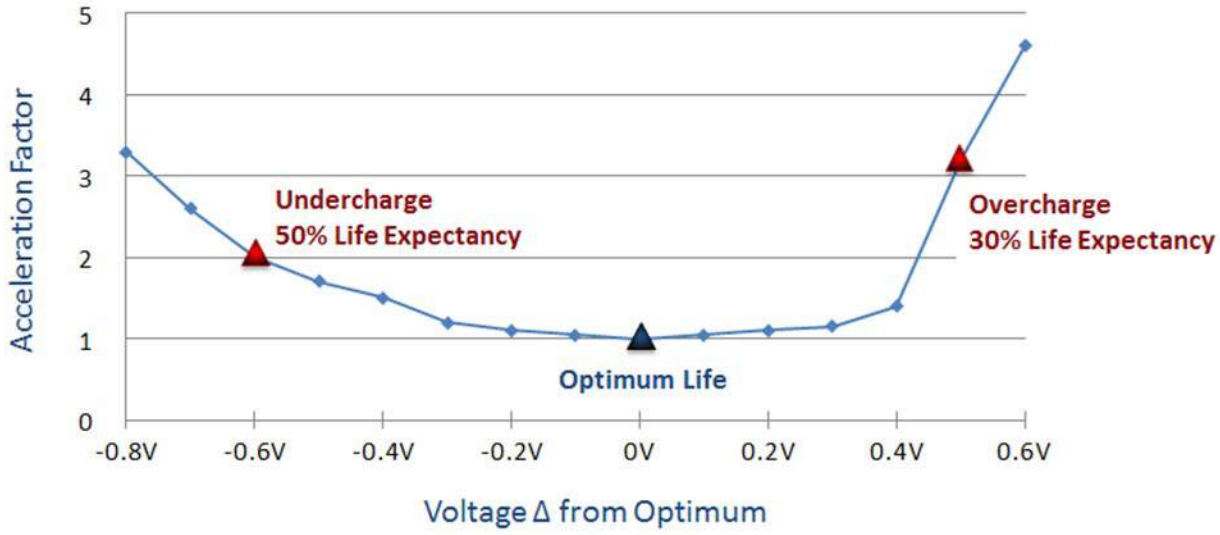

**Figure 12 – Charge Effect on Battery Life**

In this diagram, the X-axis identifies specific voltages under and over the optimum charging voltage. The Y-axis shows the acceleration factor or multiplier on battery life. For example, if a battery were undercharged by 0.6V, its effective age would accelerate by a factor of 2x resulting in a reduction of useful life to 50% of that battery's optimum life. Likewise, if a battery were overcharged by 0.5V, its useful life would be only 30% of its optimum life.

Any charge related degradation effect occurs only while the overcharge or undercharge condition is applied. For example, undercharging a battery by 0.6V for a period of 4 months (perhaps the duration until the next preventative maintenance cycle) would result in a loss of 2 months to the overall life of the battery (using a 2x acceleration factor for 0.6V undercharge.) Once the charge problem is corrected, no further damage will occur, however, the capacity has nonetheless been permanently diminished.

### *4.2.2. Battery Chemistry and Charge Mismatch*

Typical OSP power supply installations include one or multiple battery strings. Each battery string consists of 12V batteries connected in series. Three series batteries are combined to achieve a 36V string or four batteries are configured for a 48V string. The connection between the power supply and the battery string(s) is through a wire harness connected across the entire string (i.e., one connection is at the negative terminal of the first battery (ground), the second connection at the positive terminal of the third battery for 36V strings or the fourth battery for 48V strings). In this configuration, power from the batteries and charge to the batteries is routed through the wire harness for the entire string. A three battery, 36V battery string is shown in Figure 13.

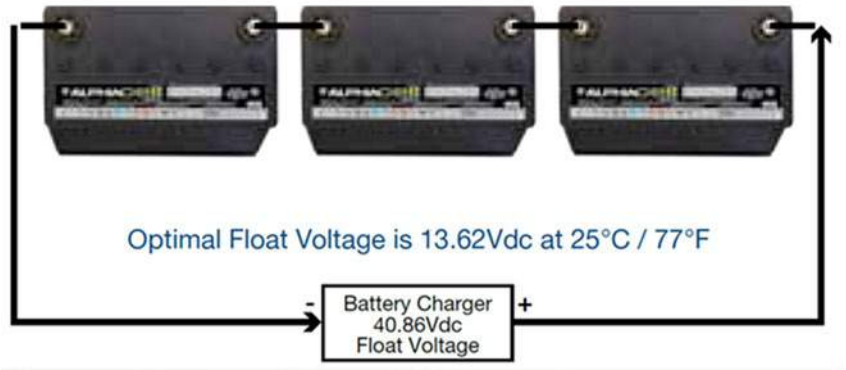

**Figure 13 – Battery Charge Configuration**

Optimal float voltage is also listed for this 36V string as 13.62Vdc per battery. This value may vary among different battery manufacturers and technologies. The broadband UPS is configured to supply 40.86Vdc across the entire battery string. From the charger's perspective, each battery appears in the circuit as a fixed resistance. Per Ohm's law, the three batteries, acting as resistors in series, create a voltage divider and the 40.86Vdc is distributed equally across each of the batteries at 13.62Vdc per battery.

Batteries operate via electro-chemical reactions. Time, temperature and charge history can affect this chemistry, thus altering the battery's internal resistance. If each battery in in a battery string has internal resistance values that change at different rates, the 40.86Vdc charge voltage will not be applied equally across each battery. The result of this unequal internal battery resistance is illustrated here.

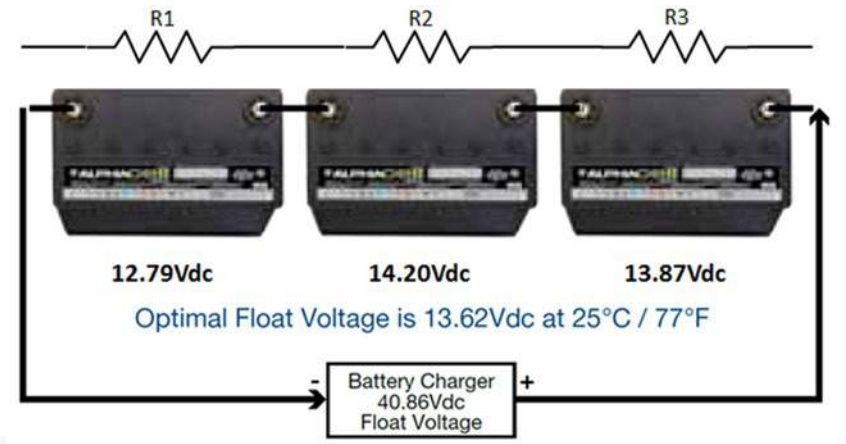

**Figure 14 – Internal Battery Resistance**

As the internal resistance of each battery changes at different rates over time, the effective circuit where R1≠R2≠R3 causes the charge voltage to be distributed unequally across the three batteries. The result is that some batteries will be undercharged while others are overcharged. In our example one battery is undercharged at 12.79Vdc while the other two batteries are overcharged at 14.20Vdc and 13.78Vdc. The total charge voltage of 40.86Vdc is correct, but the battery chemistry has caused an internal string charge variation that will shorten the life of all three batteries over time if not corrected.

OSP monitoring software can be configured to identify disparate voltages within individual battery strings for maintenance before extended battery damage occurs. Operators should consult battery manufacturers for specific voltage threshold parameters to trigger alerts and initiate corrective action. Multiple options exist to mitigate the effects of time on internal battery resistance. Some modern UPS systems are equipped with charge balancing technology that will automatically re-direct charge within a battery string to offset the effect of changes to internal battery resistance. This charge management technology is available from various manufacturers in a variety of configurations. Operators should be aware of the effects of charge imbalance on battery life and determine the best course of action for their situation.

### *4.2.3. Preventative Maintenance is Essential*

In 2016, a major North American operator conducted an investigation to determine the root cause of their growing number of OSP broadband UPS alarms. Standby test fail alarms were of particular interest due to the critical nature of this alarm. Across three (3) cities, this operator identified that 22% of their broadband UPS systems had failed standby tests, due in part, to battery cable corrosion. The following shows representative battery corrosion at one of these installations.

**Figure 15 – Battery Corrosion**

The center battery shows excessive corrosion around both the positive and negative battery posts. This type and level of corrosion can occur with some styles of OSP batteries that have not been properly maintained. At the conclusion of their investigation, the operator identified deficiencies in their local OSP preventative maintenance (PM) practices that led to these potentially service-impacting results.

Corrosion will damage battery power cables and battery voltage monitoring sense wires. As battery power cables degrade, electrical resistance increases and the ability of the batteries to provide sufficient current diminishes. Eventually, as this operator experienced, the corrosion will increase cable resistance sufficiently to cause a broadband UPS standby test to fail. Prior to a standby test failure, backup capacity had diminished and the expected runtimes during actual power outages were lower. Had an actual utility

 

outage occurred, standby power would be compromised and customer loads dropped, potentially before the standby test indicated any problem.

Could this liability have been avoided through more diligent preventative maintenance practices? The answer, of course, is yes. "How frequently should each UPS be visited?" is an often debated question. Responses vary between operators and even between systems within the same operator. These answers range from six-months to two-years when technicians are queried. Conducting PM visits and finding nothing to correct is wasting valuable service resources. Waiting too long between PM visits could result in service impacting situations going unchecked. One often hears reports of PM visits to multiple installations within a geographic area with some locations checking out OK while other sites require extensive maintenance. Clearly, there is no one right answer to the question of PM frequency. Can anything be done to reduce unneeded PM visits while focusing limited resource on locations needing physical intervention?

The answer to this question is two-fold:

- First, there are some issues that require on-site inspection to identify and correct. Examples include pest infestations and water intrusion due to physical enclosure damage. Because this category of problems exists, scheduled preventative maintenance visits are required.
- Second, it may be possible to identify a category of future service-affecting problems through analysis of data available from status monitoring systems. This would enable operators to prioritize site visits around locations at high risk of causing future service disruptions. Low risk sites could be visited less frequently and only to inspect and correct issues that are undetectable any other way.

# 5. Conclusion

This white paper discussed access network powering considerations related to network upgrades intended to support new services that will reach and eventually surpass performance goals of the 10G initiative.

A traditional HFC network powering approach was used as a baseline for other powering examples. Upgrading to a DAA network topology was reviewed and a near future DAA node defined and used in several powering scenarios. Between the DAA node and the premises, powering for multiple network architectures was discussed including last-mile access via a deep fiber N+0 approach and a 5G fixed wireless access approach.

Several powering themes became apparent as different access network scenarios were reviewed.

1. Experience with powering of traditional HFC networks is foundational. An understanding of both active loads and $I^2R$ losses is a good starting point for analyzing power demand of network upgrades. Coax line losses play a major factor in powering decisions, especially as new active devices are placed some distance from the UPS.
2. Digital line gear including DAA nodes require more power than their analog counterparts and they are more sensitive to power disruptions. A DAA node (or VHub) reset has the potential to drop many customers for several minutes as processors reset and communications are re-provisioned. Policies regarding power quality, redundancy and backup time should be established before any significant DAA system upgrades.
3. Since access network equipment presents a constant power load to the network, $I^2C$ line loss and EOL voltage are interrelated. Higher line loss (due to coax length as well as other factors) results in more current draw through the coax which results in lower EOL voltage.

This paper also discussed ways to ensure power reliability with an emphasis on batteries. Battery charge management is essential to battery life and ultimately to maintaining network uptime during power utility disruptions. Internal battery chemistry changes over time will result in the battery internal resistance changing at different rates, requiring active monitoring and management to ensure that batteries are charged correctly over their entire service life. Finally, on-site maintenance is needed to oversee aspects of the UPS system that cannot be managed remotely, such as damage and corrosion from weather and fauna.

This paper reviewed only a few representative network powering scenarios. Powering designs for live networks must be engineered alongside the network architecture being powered to ensure that power quality and quantity is sufficient for the near future network requirements.

# 1. Introduction

The COVID-19 health crisis is one of those unique transformative moments in time, resembling the effects of wars, economic, political, or governmental crisis. After a few months, human beings are trying to adjust to the changes triggered by social distancing effects.

Customer service providers (CSPs) are in the center of this cataclysm, providing the connection between people, entertainment, retail, hospitals, and governments, accelerating the need for more significant usage of digital services. The major part of the CSPs is embracing the journey to becoming a digital service provider (DSP). Being a DSP will require providers to attend to dynamic customers' demands. It will need to be part of a broader ecosystem of participants to offer not only connectivity but a full suite of digital products and agile services to end customers and partners with a complex business model—and finally increasing their value share in the market.

However, as COVID-19 lockdowns extend, the impacts in the macro-economies are profoundly affecting the population and the CSP's cash flows, forcing them to limit or even stop their investments for a few months. This change management process is shifting the CSP's focus to a myopic investment mode and adding to it telecom industry supply chain disruption shortage, this scenario is the recipe for stagnation.

Against all the odds, some CSPs are finding the creativity and the innovation to meet their customer's needs, but still far from the disruption model proposed by the digital transformation initiatives.

In this paper, the authors will examine the impacts and trade-offs of COVID-19 into societies, industries, economy, and the information and communications technology (ICT) market, reflecting on some post-COVID initiatives CSPs should embrace to expedite the informal labor economy, meet new digital consumer habits, attend public safety requisites and, definitively, reestablish its course to a sustainable digital service provider path.

# 2. General Pre-COVID Context

New technologies have enabled brilliant innovations and the new kid on the block is called the Fourth Industrial Revolution. According to the World Economic Forum[1], this revolution is defined by a fundamental change in the way we live, work, and relate to one another by merging the physical, digital and biological worlds. In its scale, scope, and complexity, the transformation will be unlike anything humankind has experienced before, in ways which we never saw before. One of the fundamental differences of the current industrial revolution from the previous ones is that previously the changes occurred outside of the human body; instead, in this case, they will involve it and even happen within it.

Today, industries around the world like factories, mining, logistics, and others have embraced their digital transformation. With the introduction of new technologies, widespread connectivity, and cloud workloads, these industries will transform themselves – increasing their process efficiencies, workforce safety, and growing their productivity – generating greater value to the market and back to the communities.

Beyond the current and known initiatives, the next ten years promise us a future where humans will be augmented by artificial intelligence (AI) and digital, physical and biological systems that will work in a tightly coupled mode, possibly changing us, as homo sapiens.

[1] https://www.weforum.org/focus/fourth-industrial-revolution

To name a few examples of the expected human revolution, we may see:

- Disappearing boundaries for human beings between what is natural and what is artificial. Not only as part of the human body itself but including concepts as "mirror world" or metaverse[2].
- Changes between our relationships with life, the planet, work, and consumption. The industries are aiming to cover every human aspect need and generating a new history of how we live.
- Thus, it covers aspects related to health care, equality, materials, energy, political and economic systems, having a context to produce a sustainable life for the planet and human beings.
- This comprehensive set of aspects proposes working with new and natural materials to decouple the economic growth from the constraints of the existing raw materials.

# 3. CSP's Pre-COVID Context

## 3.1. CSP's Challenges

CSPs have been facing a hard competitive scenario due to emerging digital disruptors, who are offering higher-value services demanded by the consumers and leveraged on the CSP's infrastructure. As most CSPs compete for similar business to consumer (B2C) & business to business (B2B) services with the lowest competitive advantage, revenues are commonly disrupted by new players. This disruption is commonly based on a combination of platforms, experience, and costs, reducing dramatically the friction for customers to access the products and services they are looking for.

This scenario is shown in Figure 1 and represents something well-known in the industry. The CSP´s revenues are becoming flattened and at the same time, their total cost of ownership (TCO) has increased drastically by significant infrastructure deployment to manage the traffic growth generated by hyperscalers and new consumers' demands.

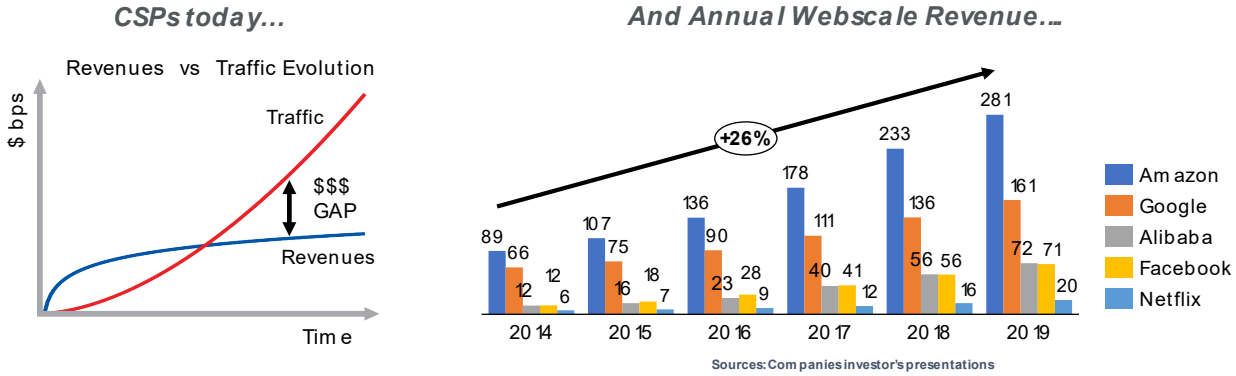

**Figure 1 – CSPs vs hyperscale current scenario outlook**

https://en.wikipedia.org/wiki/Mirror_world

### 3.2. CSPs need to do things differently

In the past five years, the telecom industry has been one of the worst-performing sectors for investors as global bets have failed to pay off. That has left companies with huge debts, and now CSPs are under intense pressure to invest in new 5G and full-fiber networks.

On the other hand, regulation has also played a significant role in challenging the telecom business model's execution. Meanwhile, OTTs are scoring higher revenue streams as they have better control of data propelling its business forward. Still, the difference in OTT regulation compared with telecoms has contributed to some disparity of outcomes.

Disruption in technology takes place silently, often too late to be noticed or worst reacted. History has proven that businesses that failed to perceive disruption and re-invent themselves had lost a tremendous amount of value or disappeared- and we all know who they are.

The foundational question is why CSPs fail to perceive the disruption surrounding them?

Kahneman, Lovallo, and Sibony[3] had provided us useful insights on complex corporate decision-making bias; For instance, preconceived notions are difficult to be contradicted even when confronted with strong evidence, leading to an effect named confirmation bias.

Anchoring decisions do leaders weigh one piece of information too slowly in making decisions, and finally, loss aversion makes them too cautious.

Most of today's CSPs' cash flows are defensive and, for the most part, structured by a supplier-buyer mindset and the blame game when things go wrong.

Suppose the traditional telecom operators don't try different strategies. In that case, they will lose value on the market and potentially be acquired, or struggle for the next few years with average growth, similar to the historical examples.

Based on the presented outlook, CSPs need structural transformations on their businesses to be able to compete for higher-value products and services, allowing them to reduce the gap between the revenues and traffic, cover the new and extremely dynamic consumers' demands in this fluctuating world and be able to make their business more sustainable.

**GAP + New Demands + Competition = New Products + Improve TTM[4] + Optimize TCO**

***Transformation***

If well inserted and with the right strategy, CSPs have the potential to disrupt markets, inserting themselves into new value chains & capturing new revenues from untapped industries going through Industry 4.0 development, which promises to bring more value in the short-mid term. According to the McKinsey Institute[5], there's near US$9T untapped value to be addressed in this sector by while the largest segment of traditional CSPs market ranges about US$1T - Figure 2.

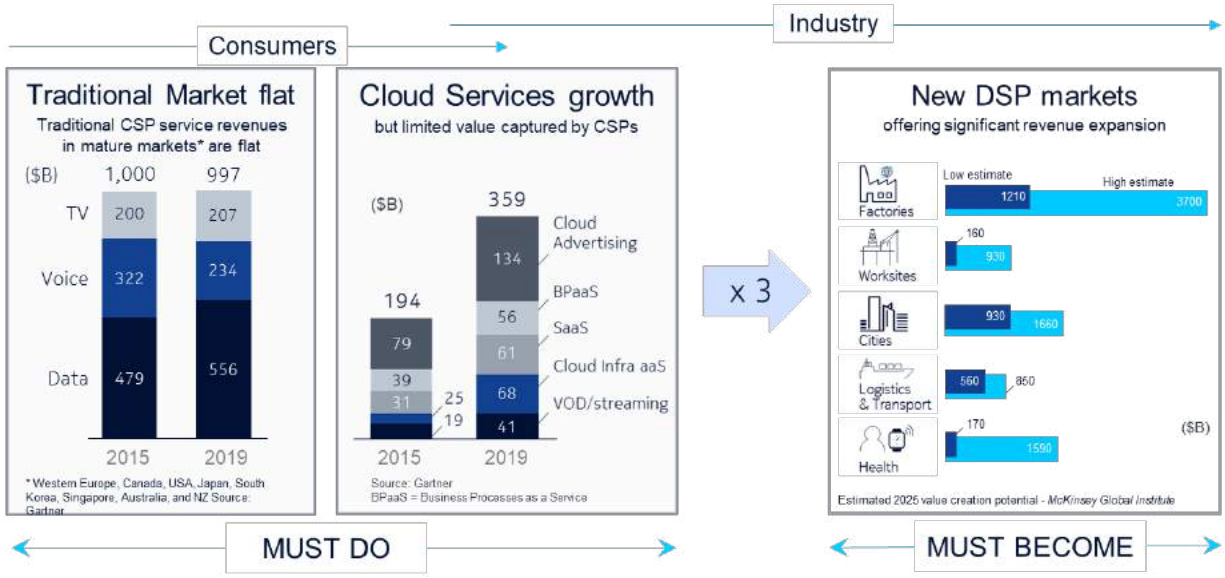

**Figure 2 - Nearly US$9B untapped industry 4.0 value to be addressed by CSPs (McKinsey Global Institute)**

### 3.3. What does transformation into DSP mean?

Eyeing the benefits described in the previous sections, many CSPs started journeys to become themselves more agile and digital companies, namely digital service providers or DSPs. According to Martin Creaner[6], DSPs are those capable of responding to the changing demands of their clients, fostering and being part of larger ecosystems based on much more complex business models, offering not only connectivity but a wide spectrum of digital products and agile services and therefore increasing the value for their end customers, partners and shareholders (see Figure 3)

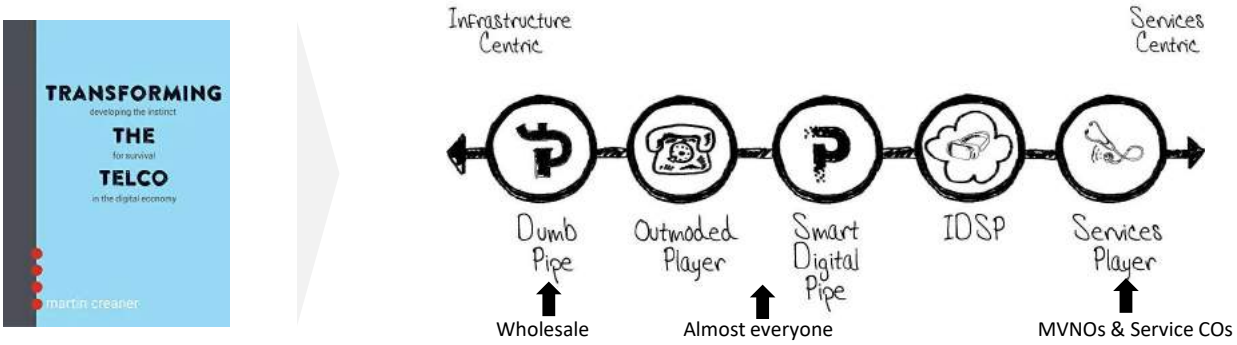

**Figure 3 – CSPs transformation options**

The authors researched six global CSPs located in six unique countries (see Figure 4). This picture emphasizes the difference in scale between current CSPs and hyperscalers and, for this reason, the need

[6] Creaner, M., 2020.*Transforming The Telco: Developing The Instinct For Survival In The Digital Economy*. CenterNODE.org.
https://www.youtube.com/watch?v=xl6gIEb8OAM (Martin Creaner - Former CEO & President - TM Forum)

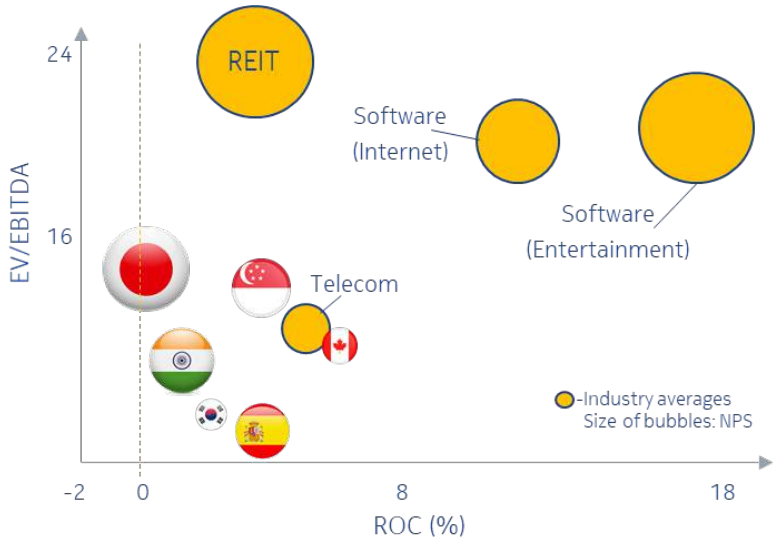
for this CSPs transformation to achieve greater value, allowing them to increase their margins in this new scenario.

In other words, those CSPs deciding to close the gap must offer higher value-added services and products to consumers. This will be only possible by implementing structural transformations, which will require strong leadership to manage the risks and failures.

In Figure 4, the listed CSPs are going or went through serious digitalization efforts, supported by automation, big data analytics, machine learning (ML), AI, network function virtualization (NFV), software-defined networks (SDN), and cloud strategies ranging from two to eight years.

These initiatives aim to improve customer experience, provide operational expenditure (OPEX) savings, and allow a shorter time to market (TTM). However, after careful investigation, these CSPs' digital transformation initiatives are failing to deliver on their value and efficiency results according to public market information.

Their valuation over earnings before interest, taxes, depreciation, and amortization (EBITDA) varies quite considerably, as well as their perceived Net Promoter Score (NPS), providing signs that it takes a good strategy and organization alignment to generate value back to the investors and clients.



Sources: December, 2019 - S&P, prof Damodaran Stern School of Business, Net Promoter Score Guru

**Figure 4 - –Six tier 1 CSPs' EV/EBITDA, ROC and NPS as of December 2019**

An effective approach to transformation requires establishing the business vision, assessing the present, and guiding the transformation to the target state. Aligned with its business strategy and a clear transformation roadmap, a CSP will need to re-arrange its organization's culture, skills, process, and technology to successfully embrace its digital transformation initiatives.

A common misconception is that if a company deploys an extra set of technologies, then digital transformation is done. However, Becky Frankiewicz and Tomas Chamorro-Premuzic[7] explain that the reality is that digital transformation isn't just about technology, but it's about organizational adaptability. To keep pace with the changes driven by digital transformation, organizations must learn to be an agile, adaptable, and organizational culture; and talent skills are crucial to the success of any digital initiative, including unlearning old behaviors.

For genuine change to happen, company-wide support is critical. The CSP leadership and executive teams must provide a clear vision and strategy for how the change will be realized, prioritize it properly, define concrete goals and accountability for the firm and measure its achievements. Thus, the entire organization must point in the right direction. The employees must understand their role in the transformation and how they are driving change. New technologies and change management will require new skills, culture, and processes, too.

The truth is that CSPs will need to have aligned the four pillars of the business strategy shown in Figure 5, the key structure over which workforce skills and culture, process, and technology will be based, to create a framework to support their employees to deal with the new software-centric technologies.

**Figure 5 - The four digital transformation pillars**

To promote cultural cohesion, soft-skills training will need to be included, intellectual curiosity must be permanent and fostered for continuous learning. Other important characteristics are teamwork, adaptability, and flexibility to unknown conditions, change management practices, effective communication, negotiation, and conflict resolution.

Re-skilling can cost a reasonable amount of financial investments and will need to be surgically inserted in the operator's context and budget to provide the right outcomes.

A business strategy, described above, is the fundamental pillar of the digital transformation. One typical proposal is to move forward with operational efficiency optimization, improving the current businesses as

[7]"Digital Transformation Is About Talent, Not Technology", Becky Frankiewicz and Tomas Chamorro-Premuzic, Harvard Business Review, May 2020. Available online at: https://hbr.org/2020/05/digital-transformation-is-about-talent-not-technology.

much as possible. In contrast, new services, products, and business models should be investigated to leverage competitive advantage. This approach is defined as the "S Transformation"[8]- Figure 6.

*The transformation process is not a project; it does not have an end; conversely, it is something that once it starts is the new mode in which the company will work. It becomes a new Business as Usual.*

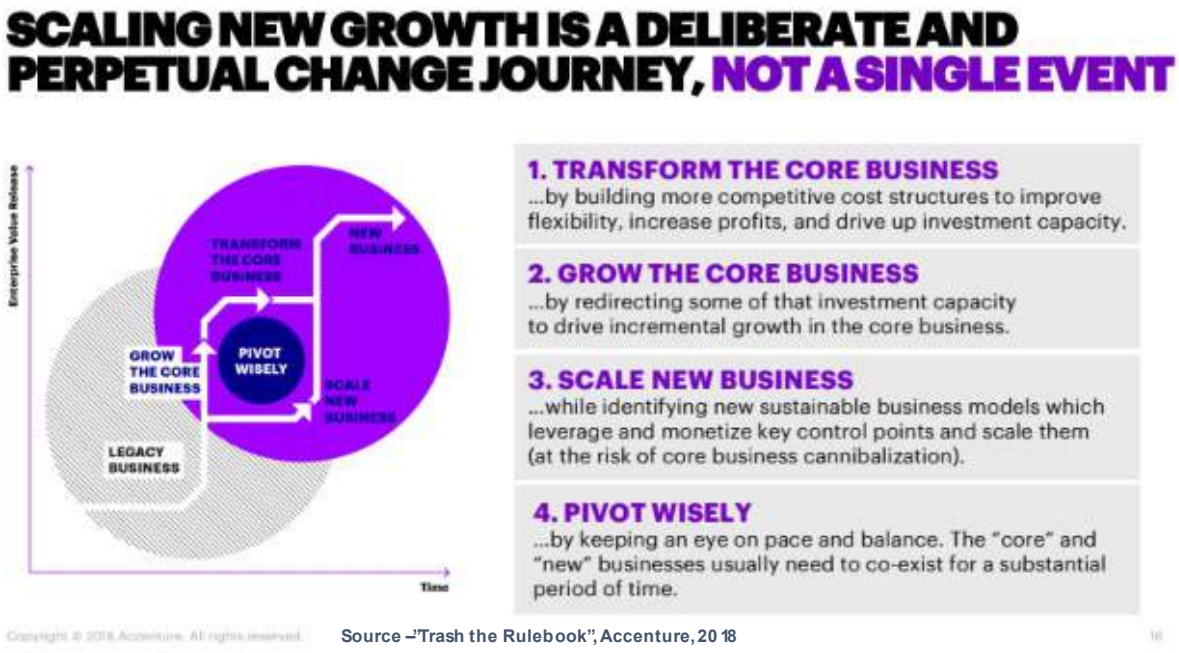


**Figure 6 – The "S Transformation" approach**

As CSPs are looking for ways to move towards its digital transformation journeys, there are notable pitfalls they should avoid.

Much has been studied and written on this topic and these extensive projects seem to have an interesting commonality on its pitfalls. According to the authors, one of the most comprehensive analysis of this topic is covered by John Kotter[9]. Figure 7 describes a graphical and rather pedagogical version of his framework.

[8] Accenture, 2018. Trash The Rule Book.
[9] "Leading Change - Why Transformation Efforts Fail", John P. Kotter, Harvard Business Review, January 1996

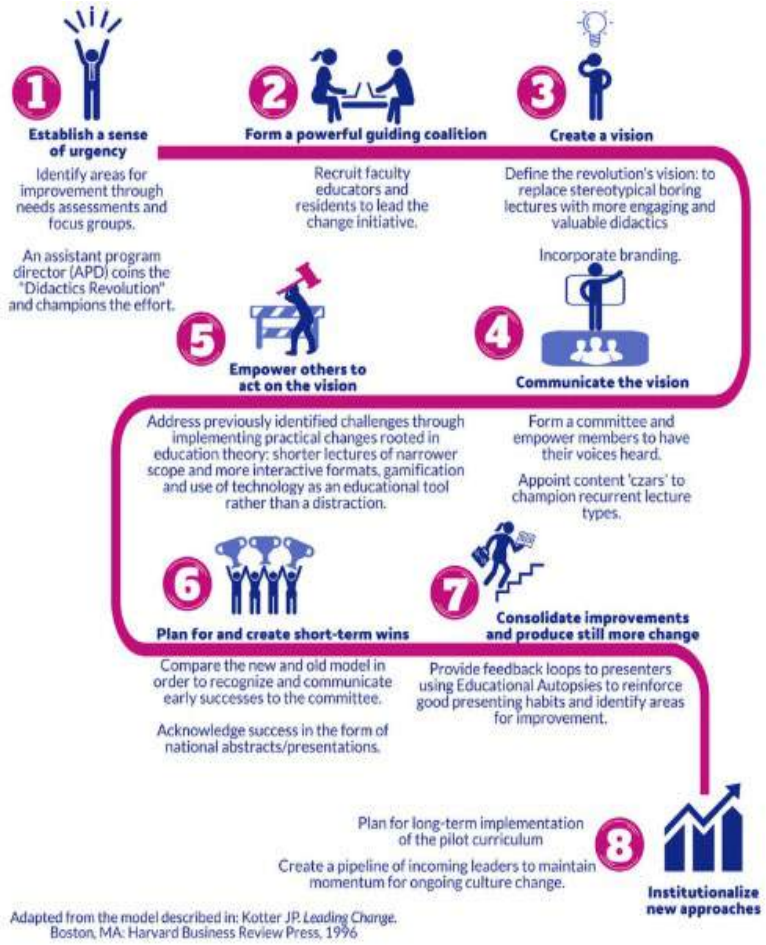

**Figure 7 – Kotter's vision about Digital Transformation Pitfalls**

According to another study, Mike Sutcliff, Raghav Narsalay, and Aarohi Sen[10], there are two major digital transformation challenges observed:

1) A silent disagreement between top-level managers on the project goals, leaving their direct reports confused on what to prioritize, and how to measure progress.
2) A gap between the digital capabilities that were used to support a pilot, and the capabilities required to support the scaling of it. If this problem isn't addressed, the firms could face lengthy delays to scale-up production or leadership team's hurrying things to meet the promised changes.

Both could be remediated, but they require communication and negotiation skills. The first challenge needs to be discussed between the stakeholder parties. The opportunities and the benefits need to be articulated, but also the problems it solves and how the firm will re-orient the organization before investing in the desired solution.

[10] "The Two Big Reasons That Digital Transformations Fail", Mike Sutcliff, Raghav Narsalay and Aarohi Sen, Harvard Business Review, October 2019. Available online at: https://hbr.org/2019/10/the-two-big-reasons-that-digital-transformations-fail.

The second challenge is more complex and will require the stakeholders to look outside the organization to close the divide or raise the capabilities from inside, starting with the pilot and growing from it.

Finally, Jacques Bughin and Nicholas Van Zeebroeck[11] describe six strategies to face this transformation. Within their studies, they concluded three offensive and three defensive options, being the former more successful to achieve the desired transformation.

- Offensive: Platform play, New marginal supply, Digitally-enabled products, and services
- Defensive: Rebundling and customizing, Digital distribution channels, Cost efficiency

Given that the pandemic crisis forced many operators to fix some operational inefficiencies, a few CSPs claim it helped them to prioritize their digital transformation efforts. We will look more carefully at this topic in the following sections.

*"Wisdom consists of knowing how to distinguish the nature of the trouble,*
*and in choosing the lesser evil"*
*The Prince, Niccolo Machiavelli*

# 4. COVID-19 pandemic impacts

## 4.1. Global Economy

In March 2020 many governments started taking measures to protect and mitigate the pandemic impact on the health of their populations. These decisions have heavily affected the global macroeconomy, as the International Monetary Fund (IMF) and World Bank have shown in their reports and forecasts - Figure 8Figure 8.

At the writing of this paper, it is impossible to estimate the economic impact of the health crisis, as it depends on its duration. Although some forecasts provide a more optimistic scenario, according to the World Bank, this is the most significant recession since World War II.

The critical question is how the macroeconomy, political tension, and exchange rate variations will affect the CSP's investments and, in particular, how it will affect its digital transformation initiatives to address the 4th industrial revolution requirements?

[11] "6 Digital Strategies, and Why Some Work Better than Others", Jacques Bughin and Nicholas Van Zeebroeck, Harvard Business Review, July 2017

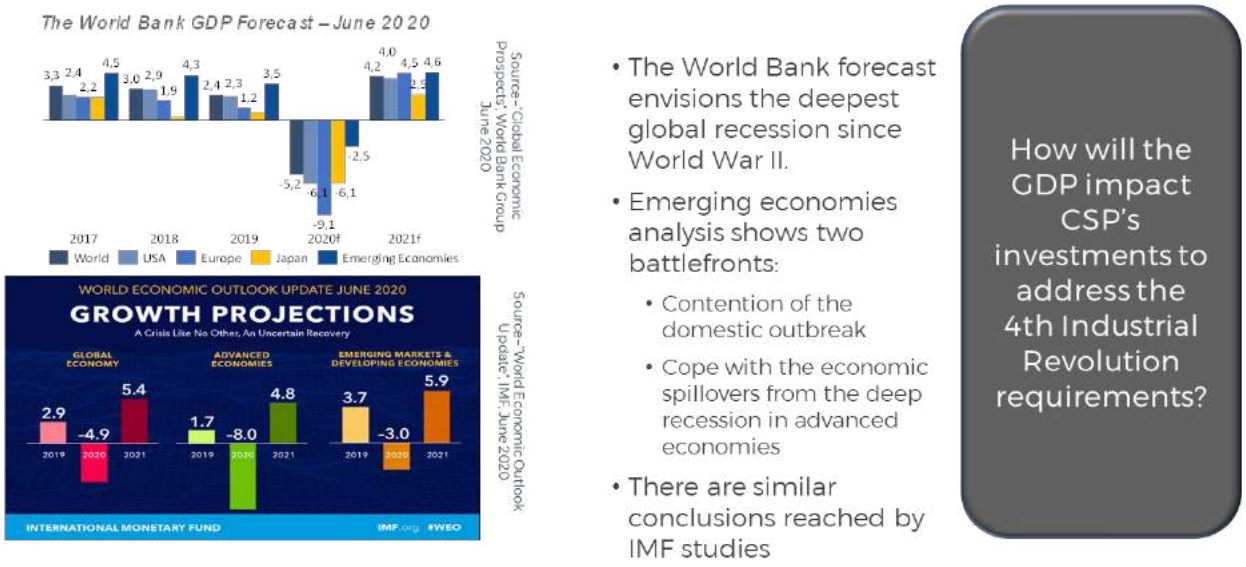

**Figure 8 – Global Economy Projections**[12]

There were severe decisions taken by governments to control the spread of the decease, which are affecting several industries around the globe. A few examples are[13]:

- During the lockdown -stay-at-home, shelter-in-place, and quarantines-, nearly 3 billion population were living in countries whose borders were shutdown to nonresidents, and 93% of countries had imposed immigration limits.
- As of April 10, governments across the globe had announced stimulus packages amounting to $10.6 trillion—this is the equivalent of eight Marshall Plans.
- The global macro-economy will affect enterprises, including CSPs, and finally, the governments will need to fund these stimulus packages to move the economy.

## 4.2. CSPs Traffic

Government measures described in the previous section have produced some changes in population habits. Work, study, leisure, and consumption from home are the new norm, all made possible by CSPs infrastructure around the world.

Change in traffic profiles has been significant, and behavior varies between regions and countries depending on several factors such as isolation intensity, lockdown periods, e-learning availability, and e-commerce maturity.

One remarkable aspect during the lockdown is that traffic volumes varied, but it all had a severe impact during peak hours affecting the current networks and the capacity planning cycles.

[12] https://www.imf.org/en/Publications/WEO/Issues/2020/06/24/WEOUpdateJune2020
https://www.worldbank.org/en/publication/global-economic-prospects
[13] "The future is not what it used to be: Thoughts on the shape of the next normal", Kevin Sneader and Shubham Singhal, McKinsey & Company, April 2020. The exact value of some figures from this article can be discussed, but undoubtedly, they are really large

The periods of peak hours had extended considerably, with upstream traffic struggling access network resources.

This can be seen in Figure 9, Figure 11, and Figure 11.

| Traffic Growth | 1 Feb – 1 Mar Growth | 1 Mar – 1 Apr Growth | 1 Apr – 19 Apr Growth | Total 1 Feb – 19 Apr |
|---|---|---|---|---|
| Upstream | +2.07% | +123.18% | -2.95% | +121% |
| Downstream | -2.39% | +11.72% | +13.67% | +23% |
| Total | -1.74% | +28.69% | +9.28% | +38% |

**Figure 9 – Global Pandemic Traffic Scenario**

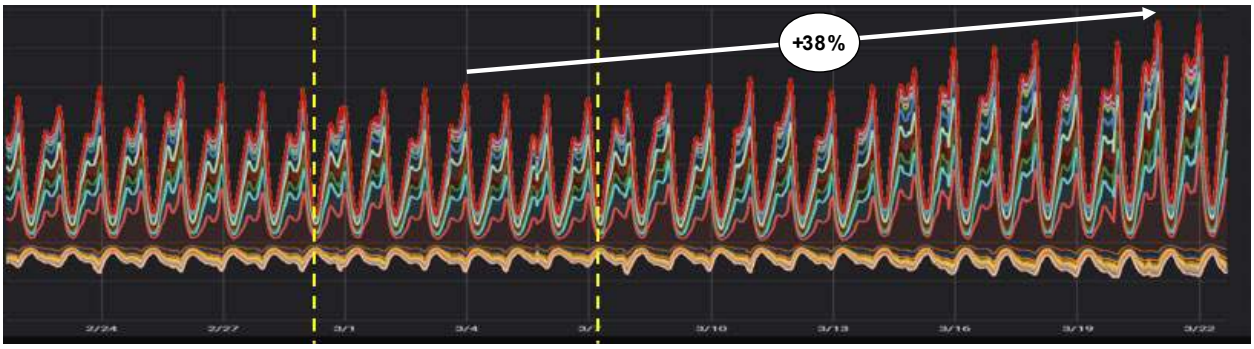

**Figure 10- Higher traffic volumes and peak hour period extension**

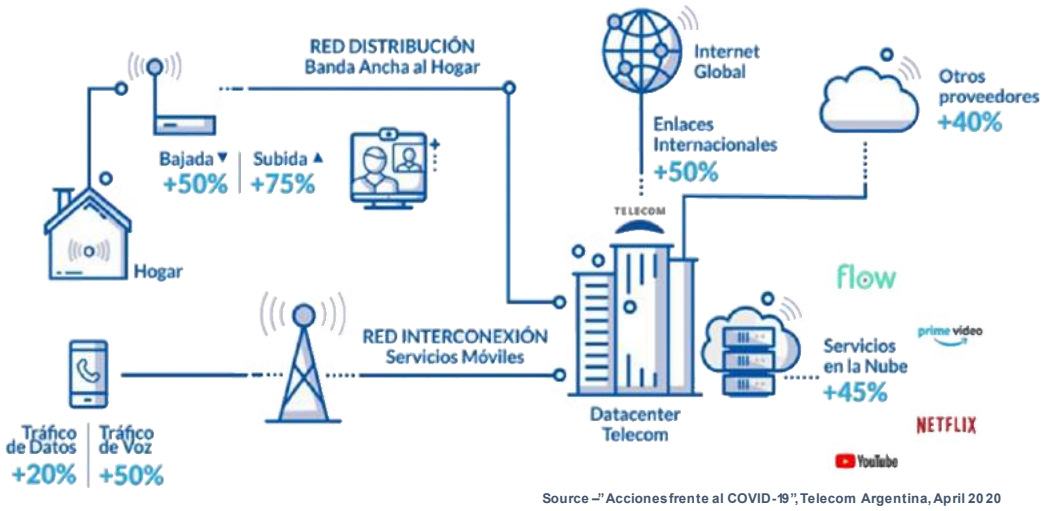

**Figure 11 – Public traffic impact from Telecom Argentina, April 2020**

### 4.3. Other CSPs Aspects

The situation was uncommon, but COVID-19 forced the CSPs to speed-up their operational initiatives to address the unexpected conditions.

During the past 5 months of social distancing and lockdown we observed:

1. CSP's networks have responded reasonably well to the change in traffic demands, including 40% to 50% traffic spikes.
2. Remote working and e-learning have amplified the gaps in the upstream capacity and also in the rural broadband connectivity.
3. The higher adoption of remote work accelerated the demand for the enterprise digitalization, including medium and large enterprises embracing more cloud services, and some CSPs providing higher capacity and resilient residential broadband access.
4. CSPs across the globe are going beyond the call of duty to help communities and consumers to manage COVID-19, including free access to e-learning resources, movies, games, and ultra-reliable services to first responder's authorities.
5. As consumers and SMEs' incomes were severely affected by economic stagnation and increasing unemployment rates, CSPs are facing a severe impact on their revenues and investment plans. Some consumers can't afford their billings, and some governments have temporarily suspended the option to disconnect the service.
6. IT Systems -e.g., business support systems (BSS) & operations support systems (OSS) - have to be re-oriented to these new conditions. In some countries, operators had to revise their prepaid recharge systems and policies quickly to provide a more seamless customer experience.
7. To keep up with the higher demands for traffic growth, e-learning, remote working, virtual private network (VPN) and security, CSPs had to revise their budget plans and invest capital expenditure (CAPEX) and OPEX to minimize operational issues.
8. Global supply chain disruptions have impacted the CSPs' ability to scale-up deployments.
9. On the fixed access networks, CSPs re-arranged their field operations to service their consumer's homes when outages related to their customer premises equipment (CPE) or residential gateways (RGWs) happened.

When CSPs look at the bright side of the COVID-19 pandemic, they list several opportunities to speed up a few digital transformation initiatives, such as those listed above.

As was previously described in this paper, also with the social distancing, the global macroeconomy is heavily affected and thus CSPs revenues and investments are at risk. When we look at the global CSP's revenue breakdown, approximately 50% of it comes from mobility products and services. As the population is in lockdown, they rely more on fixed internet access, affecting largely the CSP's mobile services and handset revenues.

During the 2nd and 3rd quarter of 2020, operators revised their CAPEX plans, and given the general economic and network effect from the pandemic, including revenue impact, disruption of the supply chain and the need to expand network infrastructure, their investments not related to short-term aspects are likely to fall compared to previous years.

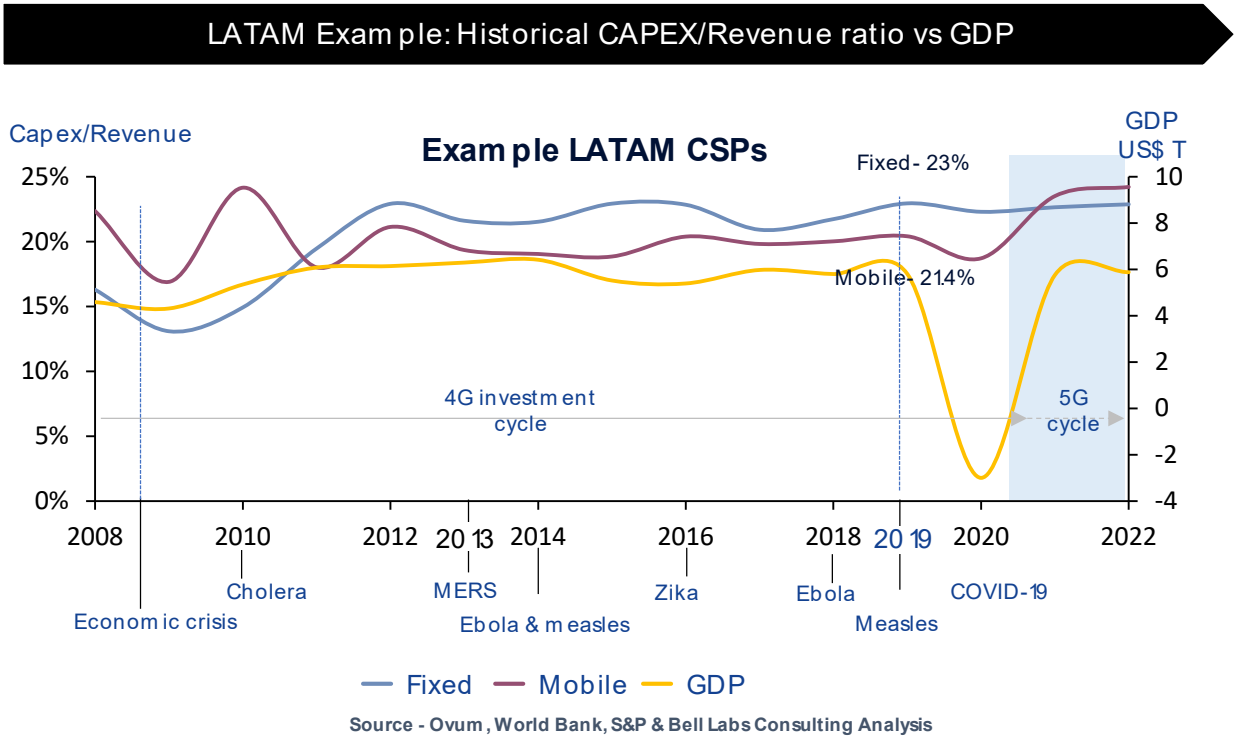

**Figure 12 - Historical CAPEX/Revenue ratio vs GDP**

Although traffic has surged and profile has changed due to COVID, operators will focus on improving and maximizing existing network and technology, so other investments will be pushed to late 2021-2022 whenever possible

In many emerging countries we observe a delayed investment in 5G networks, while developed countries slowed down their 5G network deployment plans in the first half of 2020. However, similar to the 4G deployments, 5G is expected to ramp up from 2021 onwards. Additionally, given that most of the wireless CAPEX comes from radio access network (RAN) investments, and the population will tend to be in-doors, investment in RAN will drop.

In the particular case of Latin America (LATAM) -see Figure 12- major CSPs will see a revenue decline in 2020 between -3% to -14%[14], directly impacting CAPEX growth, but although gross domestic product (GDP) impacts revenue, capital intensity has been reasonably constant, with peaks mainly in wireless due to technology refresh.

## 4.4. Some key questions remain

CSPs around the world have been relatively successful in dealing with the challenges that the current pandemic is presenting. Many of them have been displayed in the previous section.

But some key questions remain.

- Was the CSPs' success in managing the COVID-19 crisis achieved with the same principles required to transform them into a DSP or did accelerated efficiency only follow the existing CSPs' operating model?
- Can these results be claimed as part of a digital transformation?
- Will the macro-economic outlook delay non-critical investments like 5G and transformations to DSPs?

## 4.5. Pandemic Opportunities

The previous questions are even more crucial considering the opportunities that can emerge from this crisis. Some of them can imply permanent changes and, therefore, opportunities to be taken in the short-term.

In areas like e-commerce, fintech, telemedicine, automation, remote working, and e-learning, the COVID-19 pandemic could be a decisive turning point in the short and mid-term, laying a foundation for digital services adoption for the future[15]. For example:

- In China, individuals aged 36 and over and residents of smaller, less prosperous cities have begun to shop online.
- In Europe, 13% of consumers said they were planning to move to online purchasing options.
- In Italy, e-commerce transactions have risen 81% since the end of February.
- The business opportunities for banks and fintech companies are exponential with shifts to digital payments and remote cashless transactions.
- In the US, one of the largest stand-alone telemedicine service providers reported a 50 percent increase in remote consultation during the pandemic.
- France, Korea, and Brazil changed its regulations to ease access to telemedicine.
- Automation efforts are increasing in every industry. According to the McKinsey Global Institute, 60% of jobs could see more than 30% of their critical tasks automated, affecting 400 million to 800 million jobs by 2030.
- Remote working and e-learning will bring many opportunities to be explored by CSPs. In the short term, there are enhancements to the upstream capacity congested by the use of collaborative tools like Zoom, WebEx, and Microsoft Teams. In the long term, work, schools, and colleges will host a mixture of local and remote presence and the use of extended reality for an enhanced experience.

# 5. Post COVID-19 world

## 5.1. CSPs Additional Opportunities

Aside from the COVID-19 crisis, a few CSPs are targeting new B2B and business to business to consumer (B2B2C) services to the industries which will require low jitter, latency, and strict service level agreements (SLAs) only made possible by private wireless networks coupled with edge cloud. Currently, webscale and hyperscale companies need a more granular footprint to be able to fulfill these SLAs because it is not possible with their existing centralized architectures, and here is where the battle for edge space starts - Figure 13 and Figure.

Additionally, CSPs do not own the foundational capabilities that hyperscalers have, such as agility, flexibility, and shorter innovation cycles that allow them to offer these products and services at the pace and dynamism that the clients and the market are demanding.

Current hyperscalers are approaching CSPs worldwide, given its proximity to their end clients, proposing strategy agreements to provide their customers with new services soon. Just as a final remark, given the differences described in sections 3.1 and 3.3 of the present paper, authors suggest these agreements have to be carefully analyzed and be a critical part of CSPs' business strategy.

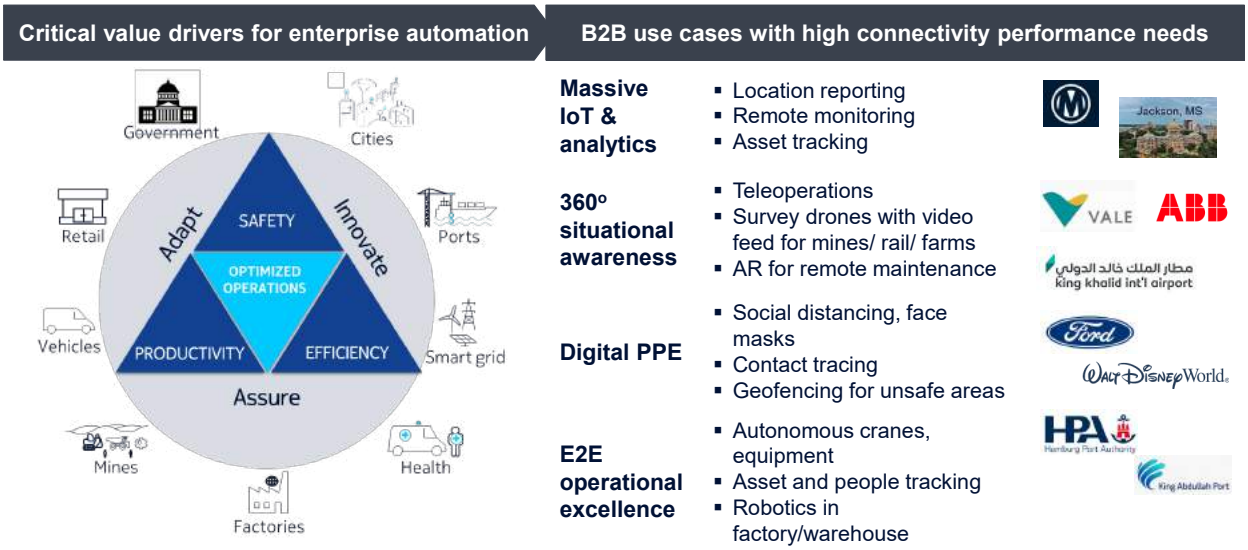

**Figure 13 – Some B2B/B2B2C use cases with strict SLA – Bell Labs Consulting**

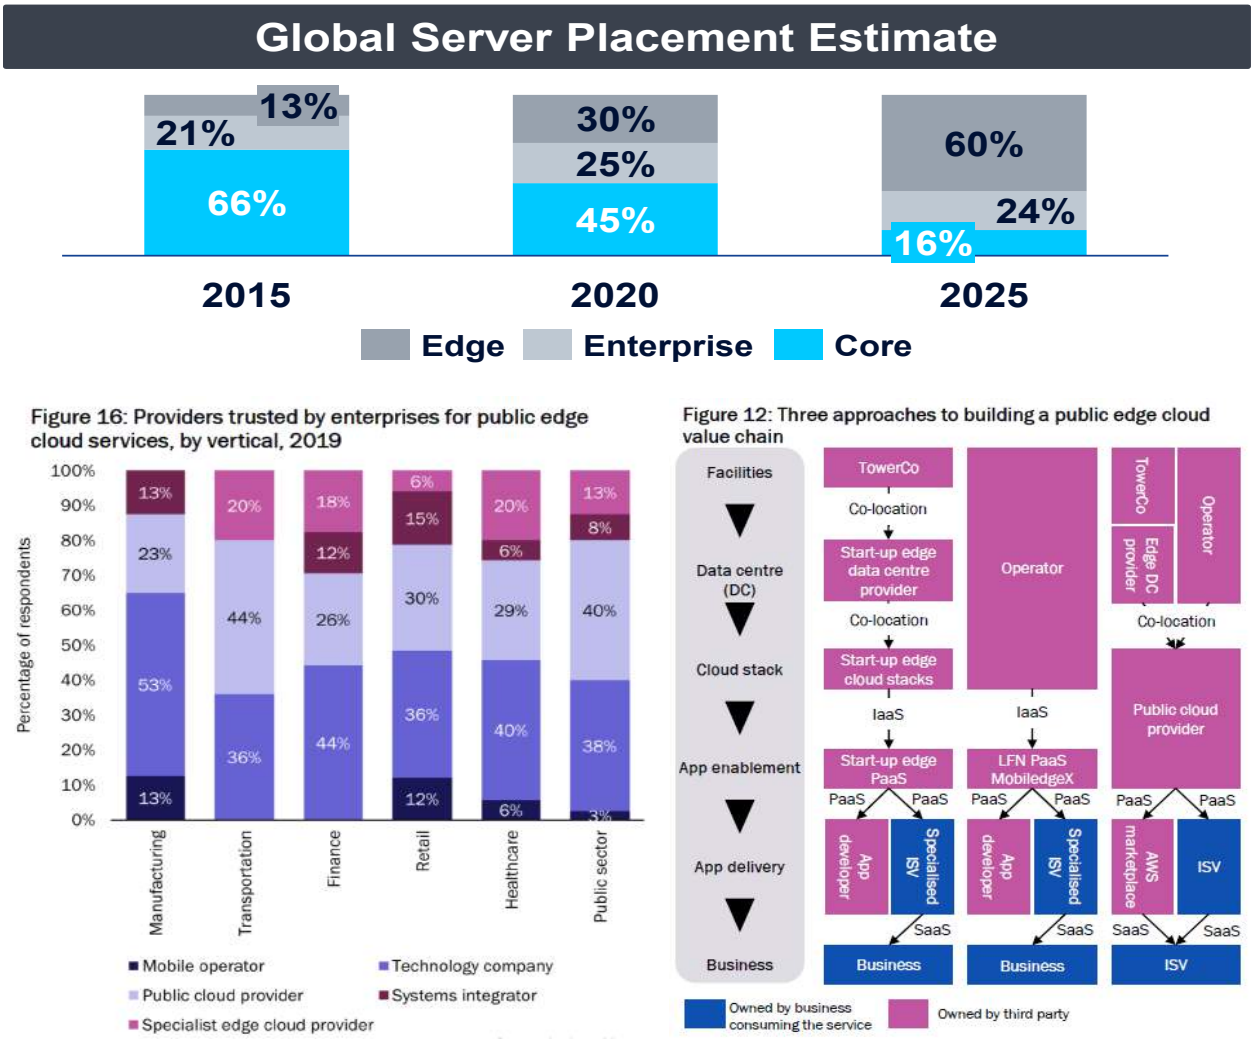

**Source –"Operator opportunities and threats in the public edge cloud computing market", Analysys Mason, April 2020**

**Figure 14 – Edge Battle – Footprint granularity can be a CSPs valuable asset coupled with the right strategy**

To make the context more complex, a few hyperscale companies are acquiring networking vendors[16] and also investing in CSPs, suggesting a strong ambition to move further into the CSP territory to address high-performance services.

Since 2018, many CSPs and technology companies are experimenting with 5G use cases for the enterprise, exploring the early days of Industry 4.0 stringent SLAs and services. Today, most industries use cases are in the fields of manufacturing, transportation & logistics, energy & mining, and utilities.

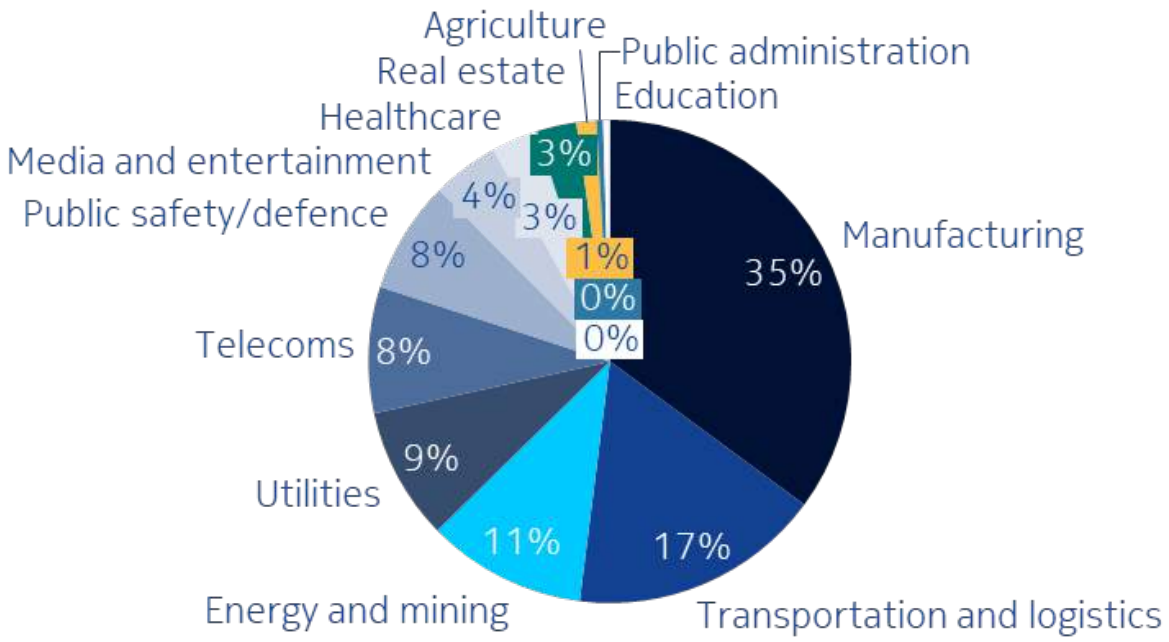

**Figure 15 - 5G announced activities by industry OMDIA July 2020**

In Table 1, there are a few public examples of CSPs and other companies using 5G access and edge cloud in gaming, public safety, and manufacturing space.

**Table 1 - 5G public announcements for enterprise - OMDIA, July 2020**

| Organization | Type | Country | Activity | Description | Telecoms operator | 5G | Edge computing | Date |
|---|---|---|---|---|---|---|---|---|
| Tencent 腾讯 | Technology vendor | China | Trial/test | Test project on Tencent's campus using a network from Huawei and China Mobile Chengdu to support MEC-hosted online gaming with low latency. (October 2019) | China Mobile | Yes | Yes | October-19 |
| OMRON | Enterprise | Japan | Trial/test | Tripartite test program with manufacturer Omron, Nokia, and NTT DoCoMo, evaluating layout-free factory designs at multiple Omron sites. Tests include support for autonomous robots, video analytics (used to assess the differences between the most-skilled workers and everyone else), edge computing, and radio propagation in the industrial setting. (September 2019) | NTT DoCoMo | Yes | Yes | September-19 |
| at&t | Telecom operator | United States | Trial/test | AT&T cooperating with Israeli drone detection startup Vorpal. Vorpal needed low latency networking and edge computing, and joined the 5G aspect of AT&T's Foundry innovation lab. (July 2019) | AT&T | Yes | Yes | July-19 |
| at&t | Telecom operator | United States | Alliance/sales partnership | Extensive partnership between AT&T and Microsoft on 5G and edge computing, including providing AI-based translation to emergency responders. (July 2019) | AT&T | Yes | Yes | July-19 |
| at&t | Telecom operator | United States | Network rollout | AT&T is collaborating with MxD (Manufacturing times Digital, a manufacturing industry group) to install 5G technology and Multiaccess Edge Compute (MEC) within MxD's Chicago-based innovation center. (July 2019) | AT&T | Yes | Yes | July-19 |
| BOSCH | Specialist/industrial vendor | Germany | R&D project | Bosch announces its vision for 5G-enabled future factories. Bosch aims to eliminate cabling in order to reconfigure production processes rapidly, perhaps even using wireless power. (April 2019) | n/a | Yes | Yes | April-19 |
| Telefónica | Telecom operator | Spain | Alliance/sales partnership | Telefónica provides private network connectivity using a range of access technologies, cloud computing, and security solutions for industrial specialist Geprom's smart factory projects in Spain. Geprom provides its LEGATO SAPIENT Manufacturing Execution System management software. (April 2019) | Telefónica | Yes | Yes | April-19 |

## 5.2. Three probable hypothesis

From the many outcomes of the COVID-19 impact for operators, the authors observe three probable hypotheses for CSPs' digital transformation efforts in the next few years, in Figure 16.

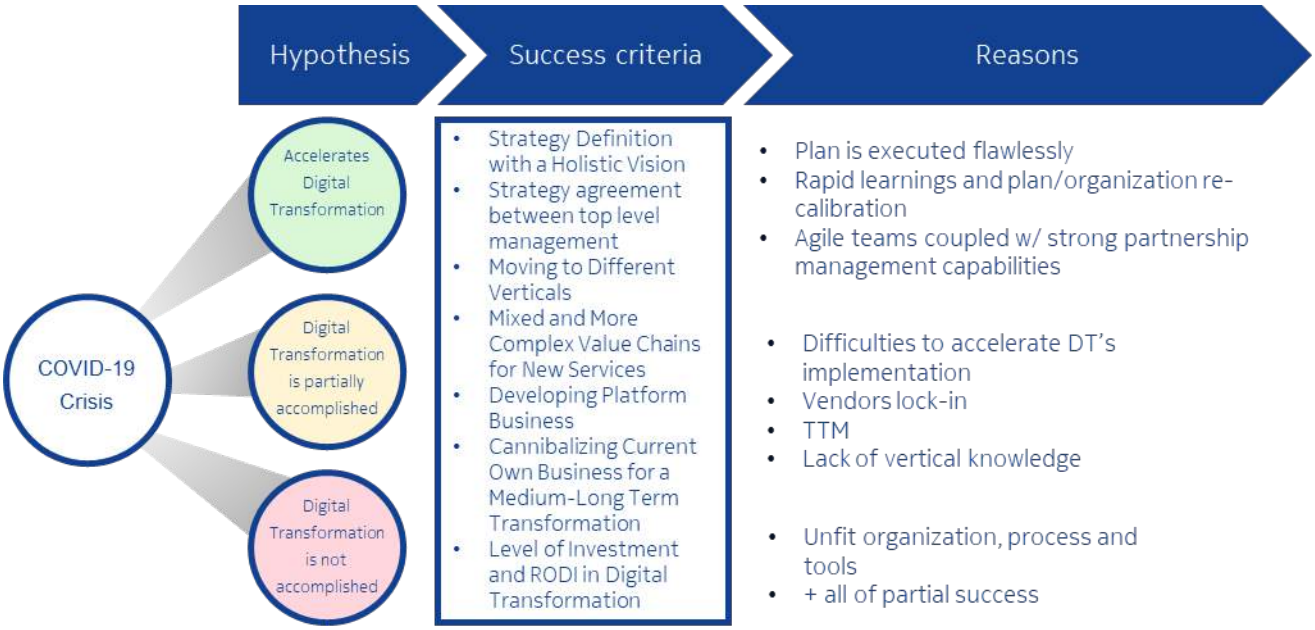

**Figure 16 - Digital Transformation's hypothesis after COVID-19**

In a best-case scenario, the CSP will accelerate its digital transformation efforts and will agree upon its objectives in terms of strategy definition with a holistic vision, common objective setting between top-level management, the possibility to move to different verticals, mixed and more complex value chains for new services, develop platform businesses, cannibalize current own business for a medium-long term transformation and setting levels of investment and shorter return of digital investments in its transformation plans, aiming for cost efficiencies, and additional revenues.

Besides the several moving parts, the plan would need to be executed flawlessly, with an agile organization that would follow closed-feedback loops and would be able to re-calibrate its actions to meet their main strategy. A wide range of partnership management capabilities would be instituted, and the teams would need to be able to embrace most of the challenges and successfully navigate through them.

In the second scenario, the digital transformation will be partially accomplished as some breakthroughs will be met, but the CSP may face vendor lock-in, a wide range of legacy and costly-to-replace or integrate networks and systems, which will delay their time to market and the digital transformation goals.

Last, some CSPs will start their initiatives with some guiding principles but will fall into difficult internal disputes for resources and budgets which will affect its execution. Quick wins will be achieved, for example, SD-WAN projects, but no meaningful impact on the expected cost efficiencies or in the top-line revenues.

Unfortunately, given the nature of the telecom business and its risk-averse propensity, the authors believe most CSPs will fall into the second or third categories.

### 5.3. CSPs Decisions

At this point, it is necessary to make a caveat and clarification. CSPs are not uniform entities, conversely, they constitute an innumerable amount of individual cases and particular situations. This myriad is determined by differences in some of the following aspects: strategic definitions and business volumes, contexts of regions, countries, markets, competition, technological and partnership strategies, skills, processes, and internal cultures to name a few. A few examples are the different consumption models of open-source tools[17], level of disaggregation for different DSPs[18] or their technological partnerships, and the activities they involve.

Digital transformation outcomes will depend on each CSP and how conservative or aggressive they move in the process. The COVID-19 crisis outcome is challenging, but the fewer CSPs invest in the long-term scenario more are the chances to be disrupted by hyperscale companies.

Additionally, CSP's leadership teams should define a clear business strategy with a structured roadmap, instill a sense of urgency in the management team, and re-orient their workforce, networks, process, and tools to embrace its DSP transformation.

Probably, today more than ever, decisions will be taken with courage and an optimistic conviction that the transformation from CSP to DSP is required.

*"Everywhere we see a motley confusion which draws us into its interests, and when one thing disappears, another at once takes its place"*
*Lectures on the Philosophy of World History - Georg Wilhelm Friedrich Hegel*

## 6. Conclusion

As mentioned exhaustively, CSPs before COVID-19, had to face their DSP transformation to increase their revenues, decrease their operational expenses, provide a differentiated competitive advantage, and raise their value to its shareholders.

The pandemic was a type of black swan that can and will surely have a significant impact on the defined strategy and goals, since it affects considerably the global economy and, therefore, CSPs' investments. On the other hand, it generates opportunities to accelerate the digitalization process avoiding losing these opportunities.

So far, CSPs were successfully coping with the demands related to increasing traffic consumption, shifts in traffic patterns, upstream bottlenecks, and rural coverage shortage.

Some CSPs have been even more creative and launched interesting new services to enhance home connectivity with redundant connections, coupling broadband and wireless connectivity in the same CPE[19], others were quick to attend the hospital's demand for connectivity, and some utilized IoT

[19] https://techround.co.uk/news/bt-launches-new-dedicated-connection-home-broadband-service/

solutions for tracking and even experimented with drone deliveries[20]. Many established banking institutes sped up digital banking best practices, and notably over the top (OTT) companies have launched mobile payment solutions to support their communities[21]. Other companies and cities deployed temperature screening cameras to help communities to monitor fever outbreaks[22]. An important CSPs with a wide presence in LATAM had created a crowdsourcing app to match unemployed workers to job demands[23]. These initiatives are spot-on with the near-term focus on current CSPs' B2B2C competence areas.

CSPs now need to look at what they will do in the post-COVID-19 world. Possible products and services' scenario can see the acceleration of such offers, especially the ones with faster return of digital investment (RODI) and slow others given the constrained investment priorities and supply-chain shortages.

Networks will demand more upstream capacity to manage collaboration tools based on unicast implementation. The access networks are expensive to deploy and redesign and doing it to attend greater speeds or resiliency will drive a considerable part of CSP's investments. Fixed or converged operators must have a strategy that will look not only for the near term demands but beyond as the fiber return on investment (ROI) ranges for the next 7 to 10 years. Considering what-if scenarios, for example, if a new catastrophe takes place in 3 years from now, how would one network behave in terms of capacity, upstream and resiliency?

Also, given its cost-saving nature, the cloud has been deeply embraced by the IT world and slowly, we see cloud-native network applications becoming mature. CSPs are now discussing if and how they should leverage the public cloud capabilities, including edge computing capabilities, services, and placement.

The cases listed in this paper involve decisions that have to take place now, and if not well-strategized, they will have a long-term network effect on the CSP's business plans.

But the mother of all battles is still the same as CSPs had previous to this crisis. The transformation from CSPs to DSPs, as authors explain in section 3.3. Namely, this means being capable of responding to the changing demands of their clients, fostering and being part of larger ecosystems based on much more complex business models, offering not only connectivity but a wide spectrum of digital products and agile services, perhaps thinking beyond the borders of their own networks and infrastructure, and therefore increasing the value for their end customers, partners and shareholders.

This paper also depicts that an effective approach to transformation requires CSP's leadership teams to define a business vision and strategy, aligning the management organization, assess the present, and guide the transformation to the target state with a clear execution roadmap, re-orienting their workforce, networks, process, and tools to embrace the transformation program. This means that CSPs will need to have aligned the four pillars shown in Figure 5, being the business strategy, the key structure over which the other pillars must rest and always avoid the common misconception that if a company deploys an extra set of technologies, then digital transformation is done.

The pandemic crisis can force a sense of urgency to define and adopt the long-term business strategy and take advantage of the short-term opportunities, as proposed by Kotter. And doing it in the right way,

[23] http://claro.pushdobem.com.br/novo-fluxo.html

without confusing operational efficiencies with the new business models that CSPs must generate to become DSPs.

Opportunities and the challenges are closely related and affected by these particularities such as region/country macroeconomics, strategy definitions, business models and scale, markets and competition, technologies, partnership strategies, transformation maturity, and internal cultures. Therefore, the transformation outcomes will depend on each CSP and how conservative or aggressive they move in the process, despite and exceeding the current crisis. As per the authors' experience, only a few CSPs design for a long-term strategy, leaving them prone to disruption from competitors. There are no magic recipes, short-cut solutions, or "silver bullets". Decisions will be needed with courage and an optimistic conviction that the transformation from CSP to DSP is possible.

*The challenge is enormous and never-ending, like a "LONG AND WINDING ROAD"*

# 1. Introduction

DOCSIS® 3.1 is now largely deployed in the field, but so far it has been an Orthogonal Frequency Division Multiplexing (OFDM) Downstream only endeavor. Operators are beginning to test Upstream Orthogonal Frequency Division Multiple Access (OFDMA) and are discovering various intricacies in getting the US OFDMA to work robustly. We CableLabs and NOS, a cable operator in Portugal have been working together and have been focused on DOCSIS 3.1 OFDMA in general and collaborating on the Upstream Profile Management Application (PMA). Defining appropriate Upstream profiles for an OFDMA channel affects the stability of the modems on the channel and also the capacity realized. We implemented data collection agents through the CMTS CLI to collect Upstream RxMER for each CM, or on other CMTSs collect the data manually for each CM. US RxMER looks very different than the Downstream RxMER, due to the noise funneling characteristics on the HFC plant. NOS engineering and CableLabs collaborated on various US PMA algorithms and this paper will describe some of the new methodologies we have developed. The NOS operations team is doing a field trial with the US data collection and then configuring the profiles/IUC (interval usage code) generated by PMA on a live plant to understand the impact and behavior. This paper focuses on the lessons we have learnt from the DOCSIS 3.1 upstream field trial and production systems.

# 2. US OFDMA background

DOCSIS 3.1 introduces OFDM downstream signals and OFDMA upstream signals to achieve robust operation and provide more efficient use of the spectrum than previous DOCSIS versions. OFDMA for the upstream path is a multi-user version of OFDM, and assigns subsets of subcarriers to individual CMs.

## 2.1. US splits

The DOCSIS 3.1 system will have options of several split configurations that can be exercised based on traffic demand, services offered and the capability of the cable plant. In the upstream direction, the cable system may have a 5-42 MHz, 5-65 MHz, 5-85 MHz, or 5-204 MHz pass bands. A D3.1 CM supports one or more of the following upstream upper band edges, (as long as one is 85 MHz or greater): 42 MHz; 65 MHz, 85 MHz, and/or 204 MHz. The DOCSIS 3.1 Network supports a minimum of two independently configurable OFDMA upstream channels with each occupying a spectrum of up to 95 MHz. A DOCSIS 3.1 CM is capable of transmitting on OFDMA channels and legacy single carrier-QAM channels (SC-QAM) at the same time (as controlled by the CMTS). There are no legacy SC-QAM channels above a frequency of 85 MHz.

## 2.2. OFDMA channel basics

The OFDMA upstream multicarrier system is composed of either 25 kHz or 50 kHz wide subcarriers. In the upstream, the subcarriers are grouped into independently configurable OFDMA channels each of up to 95 MHz encompassed spectrum, totaling 3800 25 kHz spaced subcarriers or 1900 50 kHz spaced subcarriers. When configured for 2K FFT (Fast Fourier Transform), the CMTS uses the subcarriers in the range $74 <= k <= 1973$, where k is the index of the subcarrier defining the OFDMA signal. When configured for 4K FFT, the CMTS number uses subcarriers numbered in the range $148 <= k <= 3947$.

The parameters of the two OFDMA channels can be independently configured thereby optimizing configuration based on channel conditions. The table lists the Upstream Channel parameters, from [PHYv3.1]

**Table 1 – D3.1 Upstream OFDMA Parameters**

| Parameter | Value | |
|---|---|---|
| Upstream Sampling Rate | 102.4 MHz | |
| Upstream Elementary Period Rate | 1/102.4 MHz | |
| Channel bandwidth | 10 MHz, …, 95 MHz | 6.4 MHz, …, 95 MHz |
| IDFT size | 2048 | 4096 |
| Subcarrier spacing | 50 kHz | 25 kHz |
| Symbol duration | 20 µs | 40 µs |
| Maximum active subcarriers (95 MHz) | 1900 | 3800 |
| OFDMA Cyclic Prefix size | 0.9375 µs, 1.25 µs , 1.5625 µs , 1.875 µs<br>2.1875 µs , 2.5 µs, 2.8125 µs<br>3.125 µs, 3.75 µs, 5.0 µs, 6.25 µs | |
| OFDMA Roll-off Period Size | 0 µs, 0.3125 µs , 0.625 µs , 0.9375 µs<br>1.25 µs , 1.5625 µs, 1.875 µs, 2.1875 µs | |
| OFDMA Modulation orders | (BPSK), QPSK, 8-QAM, 16-QAM, 32-QAM, 64-QAM, 128-QAM, 256-QAM, 512-QAM, 1024-QAM, 2048-QAM, and 4096-QAM | |

## 2.3. US OFDMA Frames & minislots

DOCSIS 3.1 Upstream transmission uses OFDMA frames. Each OFDMA frame is comprised of a configurable number of symbols (K = 6 to 36). Several transmitters may share the same OFDMA frame by transmitting on allocated subcarriers of the OFDMA frame. The structure of an OFDMA frame is depicted in Figure 1. The upstream spectrum is divided into groups of subcarriers called minislots. Minislots have dedicated subcarriers, all with the same modulation order ('bit loading'). [PHYv3.1] specifies two minislot sizes by specifying the number of subcarriers per minislot. There are 8 or 16 subcarrier minislots, a minislot is always 400KHz wide (25KHz subcarrier *16, or 50KHz subcarrier *8). Minislots have dedicated subcarriers, all with the same modulation order ('bit loading'). Though the span of the minislot is always 400KHz, the length of the minislot in the time is the same as the number of symbols(K) of the frame. An operator can configure the number of symbols in an OFDMA frame to pick an appropriate size for the minislots on a channel. A CM is allocated to transmit one or more minislots in a transmission Burst. The modulation order of a minislot, as well as the pilot pattern used may change between different transmission bursts and are determined by the profile definition. Several transmitters may share the same OFDMA frame by transmitting on their allocated minislots on the OFDMA frame.

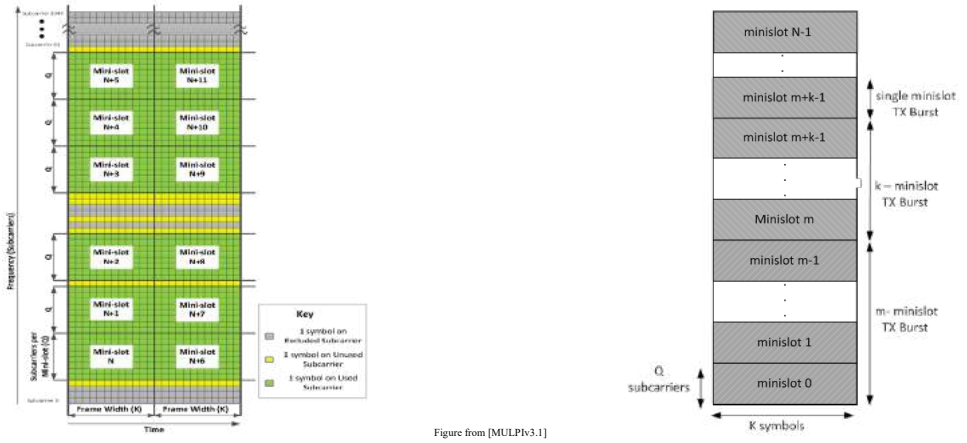

Figure from [MULPIv3.1]

**Figure 1 – Upstream OFDMA Minislot Layout and Grants across Minislots**

There are two types of minislots edge minislots and body minislots. An edge minislot is the first minislot in a transmission burst, and body minislots are used for all other minislots in a transmission burst. See [PHYv3.1] for minislot usage with exclusion bands etc.

Each minislot is comprised of pilots (P), complementary pilots (CP), and data subcarriers. Pilots are used by the CMTS receiver to adapt to channel conditions and frequency offset. Pilots are subcarriers that do not carry data and encode a pre-defined BPSK symbol known to the receiver. [PHYv3.1] also specifies complementary pilots which are subcarriers that carry data, but with a lower modulation order than other data subcarriers in the minislot. If the modulation order used for data subcarriers in the minislot is M, the complementary pilots are used with modulation order equal to the maximum between M-4 and 1 (BPSK). For example, if the bit loading in a minislot is 10, Complementary Pilots use 6 bits.

For each minislot size, seven pilot patterns are defined, see figure 2. Pilot patterns differ by the number of pilots in a minislot, and by their arrangement within the minislot. The different pilot patterns enable the operator to optimize its performance (physical layer rate and pilot overhead) according to different conditions and variations of SNR with frequency. Each pilot pattern defines edge and body minislots.

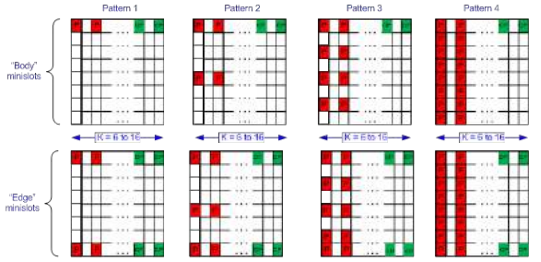

Figure from [PHYv3.1]

**Figure 2 – Sample Pilot Patterns**

## 2.4. US FEC

An upstream grant from the CMTS indicates which minislots are assigned to a given burst and which upstream profile is to be used by the CM. The CM and CMTS use this information to determine the total number of bits in the grant which are available to be used for FEC information or parity. Per [PHYv3.1], OFDMA use three Quasi-Cyclic Low-Density Parity-Check codes (QC-LDPC) for the upstream transmission, as depicted in Table below

**Table 2 - FEC coding parameters**

| Code | LDPC Code Rate | Codeword size in bits | Information bits | Parity bits |
|---|---|---|---|---|
| Long | 8/9 = 89% | 16200 | 14400 | 1800 |
| Medium | 28/33 = 85% | 5940 | 5040 | 900 |
| Short | ¾ = 75% | 1120 | 840 | 280 |

## 2.5. Upstream Noise funneling

The DOCSIS upstream behaves differently than the DOCSIS downstream. As the DOCSIS downstream signal is transmitted (from the CMTS to the CM) through the branched cable topology, the signal becomes attenuated and weaker at each branching and with cable distance. The strong signal at the headend now requires amplification to adequately reach the subscriber. Noise or interference in

downstream frequencies that enter the cable system say at a node or an amplifier only affects customers past that point.

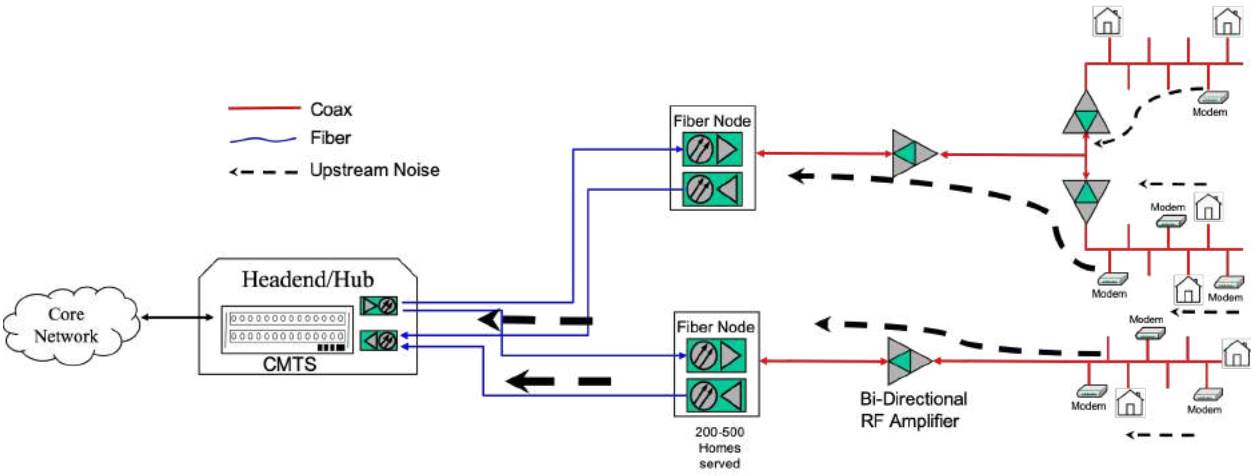

**Figure 3 – US Noise funneling**

In the downstream direction, there is one location from where the signals enter the HFC plant, specifically the cable modem termination system (CMTS) in the headend or at a node location with distributed access architectures (e.g. Remote PHY). The operator has control of the signal at that point and along the network, to ensure it reaches every CM. From the headend to the CM, the RF signal fans out in a star topology network in a point to multipoint fashion. It is the opposite on the upstream/return path: the RF signals enter the plant from every home that is attached to the plant, and all of those signals combine together as they travel to the headend. Typical of all point to multipoint networks, the noise from every device on the network gets combined as it travels upstream and is finally received on the upstream port at the CMTS. This is known as the noise funneling problem, as shown in the figure 3. The additive nature of noise has a large impact at the CMTS upstream receiver. A small amount of noise from every unterminated cable or loose connector enters the upstream path and is combined with other ingress noise and then amplified as it travels upstream and gets funneled up to the CMTS causing it to be unable to decode the communication from the CM. HFC plant segmentation somewhat mitigates the noise funneling effect by reducing the number of combined signals traveling on a given upstream path.

## 2.6. Common Upstream Issues

There are many upstream impairments on the cable plant, some of the causes and ways operators tackle them are described here. Cable operators are constantly working to mitigate upstream ingress noise. Cable operators have a hard time pinpointing where ingress noise is entering the plant. A spectrum analyzer can allow an operator to visualize the noise problem, but it doesn't tell the operator the location of the problem. A common method, to track ingress, is disconnecting each segment of the plant at a node to see the impact on noise levels on the spectrum analyzer. This is laborious and customer impacting and as the noise sources are bursty and intermittent, there is a bit of luck involved in the technician finding the source. A technician needs to visit the worst ingress locations, and make physical changes to the network. Often the ingress locations are also a place where signals leak out of the cable plant. There are many tools available which are based on this concept of looking for test signals leaking out of the plant.

Thermal noise at the amplifiers and fiber optic link noise can be sources of upstream impairments. Other ingress noise sources on the upstream path include impulse noise from loose connectors, reflections from unterminated splitters or taps, cracked cables, common path distortion due to corroded connectors or

cabling issues. Many of these are resolved by physical repair to the damaged cable network infrastructure (replacing drop cable, servicing defective network components such as power supplies). Reflections can be mitigated through equalization coefficients used within the DOCSIS technology. Identifying problem frequencies and avoiding them for upstream transmission is another method, to side step some problems at least temporarily. Using external data analytics an operator can potentially identify ingress locations and use frequency changes to dynamically avoid this type of noise. Impulse noise can be partially mitigated by the use of DOCSIS forward error correction (FEC) and interleaving algorithms. Again, a technician might need to visit the worst locations to make physical changes to the network. Correct amplifier alignment and setting up correct power levels in the upstream path also prevents issues like laser clipping.

## 2.7. CMTS Profile / IUC mangement

The CMTS assigns OFDMA Upstream Data Profile (OUDP) IUCs to the CMs based on the measured plant conditions. It is intended that the Data Profile IUC 13 is configured as a robust OFDMA profile usable by any DOCSIS 3.1 CM served by that upstream channel. Data Profile IUC 13 is used for all OFDMA data grants to modems which have not completed registration.

During or after modem registration, the CMTS has the option of assigning the CM to use any other configured data profile. Typically, the data profiles other than IUC 13 will be configured for higher performance than IUC 13, although not all of these profiles will be usable by all modems. The CMTS assigns the CM either one or two data profiles (IUCs) for each OFDMA channel in the modem's Transmit Channel Set. This can be assigned during Registration, and can be changed after Registration using dynamic messages (DBC transaction). After registration, the CMTS grants bandwidth on the OFDMA channel for data transmissions to a CM using one of the CM's assigned OUDP IUCs.

### *2.7.1. Upstream Profile Testing*

Because it is expected that not all upstream data profiles will be usable by all CMs, a CMTS can evaluate a CM’s performance using a particular profile before assigning that profile to be used for live user traffic. The DOCSISv3.1 technology [MULPIv3.1] provides various tools to aid the CMTS in gathering information about upstream profile performance. A CMTS performs such an evaluation in vendor-specific ways, usually revolving around modulation error ratios or codeword error ratios. These tools are based on two types of transmissions: upstream probes, and upstream Data Profile Testing bursts.

### *2.7.2. Upstream Probes and RxMER Measurements*

A CMTS uses upstream probes for ranging-related functions such as determining transmit pre-equalizer coefficients. A CMTS also has the option of using an upstream probe to take an RxMER (received modulation error ratio) measurement. The CMTS grants probe opportunities to a CM in a P-MAP message with the "MER" bit set. When the CMTS receives the probe transmissions from the CM corresponding to such a grant, it performs the RxMER measurement and uses the results in its decision making. It also populates the corresponding MIB object or can upload a RxMER per subcarrier file via TFTP, for the operator’s information.

### *2.7.3. Upstream Data Profile Testing Bursts*

Some types of upstream profile performance cannot be measured using probe bursts. For example, a CMTS might wish to gather information on FEC performance or count CRC errors for a particular profile. Probe bursts cannot be used for these purposes as don’t carry any information, and instead the CM&CMTS can send/receive upstream Data Profile Testing bursts. Per [MULPIv3.1], to command a CM

 

to send an upstream Data Profile Testing burst, the CMTS first assigns an OUDP Testing SID to the CM on one or more upstream channels. The CMTS then sends a grant to an OUDP Testing SID, the IUC of this grant is an Assigned OUDP IUC currently assigned to the modem. The modem responds to a valid grant to any of its OUDP Testing SIDs by sending a Data Profile Testing burst in the grant. The Data Profile Testing burst from the CM is a 64-byte Ethernet packet, with counting pattern in payload bytes beginning with 0x01, continuing with 0x02, 0x03, etc., and ending with 0x2E (count is re-started at 0x01 in each successive packet). The CM fills the grant with DOCSIS frames. The modem treats all grants to its OUDP Testing SID(s) as grants to a single flow existing across all OFDMA channels to the SID has been assigned.

#### *2.7.4. IUC/ Profile change*

The CMTS assigns one or two OUDP IUCs to a CM, once the assignment is successful, that CM is ready for transmitting data using the assigned IUCs. After registration, the CMTS grants OFDMA bandwidth for data transmissions to a CM using one of the CM's assigned OUDP IUCs.

A CM supports 2 US Profiles/IUCs at a time. A CM starts on the OFDMA channel with IUC 13 (e.g. say set to 16 QAM). At a later point the CM is assigned an additional IUC (e.g. IUC 12, say 256 QAM). When CMTS sees US FEC errors on the secondary profile (IUC 12 in this example), it chooses to rectify the situation. A CMTS can reassign the CM a new IUC, say IUC 11 (with 64 QAM in areas of high noise and 256 QAM elsewhere) dynamically via DBC messages. The CMTS continues to use the default IUC-Profile 13 to forward traffic to avoid any packet loss during IUC change, when the DBC is in process. In practice, this means that the upstream capacity for the CM is changing intermittently as it switches between profiles, which could lead to a degraded performance and user experience.

### 2.8. Upstream OFDMA : the need for Profile Management

The DOCSIS 3.1 specification fundamentally changes the nature of information delivery on the cable plant, and the way HFC networks will be maintained and managed. In a significant change from previous DOCSIS versions, the OFDM/OFDMA channel does not use a one-size-fits-all modulation scheme; rather, the modulation can be optimized based on actual plant conditions at different frequencies and individual devices. CMs and CMTS that communicate with a cleaner signal can utilize an efficient high-order-modulation, while devices that have a degraded signal will use more robust modulation, all on the same channel.

The DOCSIS 3.1 toolbox provides a wide range of modulation choices that can be used to fine-tune the transmissions to get the best performance from the current network conditions. To manage the optimization of these settings across the population of devices, the CMTS uses the concept of Upstream profiles. An upstream profile defines the modulation order (i.e., bit loading) and pilot pattern on each of the minislots on the channel (up to 237), spanning (up to 3800 or 1900 subcarriers) across the OFDMA channel.

DOCSIS 3.1 specifications [MULPIv3.1] provides for defining multiple upstream profiles, where each profile can be tuned to account for the specific plant conditions that are experienced by a set of CMs. A well-designed, optimized set of modulation profiles allows an upstream channel to operate with robustness and a lower SNR margin, potentially allowing a channel to deliver an overall higher throughput. In addition, it can allow for communication to devices by providing service even in situations where significant plant impairments exist.

The application that implements this optimization logic is external to a CMTS, enabling the most efficient use of profiles across channels and CMs. For an operator, it also allows uniform operation of such

 

algorithms across different CMTS platforms. This profile optimization and profile creation functionality is implemented as an 'application' running outside the CMTS and is known as the Profile Management Application (PMA). Managing profiles manually for an operator for thousands of CMTS Upstream channels is a labor-intensive process requiring a deep understanding of the channel conditions. The calculation and recalculation of profiles would overload human operators and PMA simplifies this process significantly.

## 2.9. Designing Profiles for US OFDMA channel

Now in the upstream, the noise from every house and every network element gets accumulated and is seen at the upstream receiver on the CMTS. Now a CMTS receiver can measure the received modulation error ratio (RxMER) for each CM, see figure 4 for some example measurements from a live network. In the upstream, this signal to noise signature for each of the CMs (that are sharing the upstream channel) starts looking very similar, as they all share the same noise across the channel with slight differences due to the signal levels itself or some in house network problems. This means common profiles can be designed for many CMs experiencing similar noise conditions and most CMs will be able to use a common profile. (This is very different from the behavior seen in the downstream, where different sets of CMs have very different noise signatures.) The variation in the Upstream RxMER from sample to sample for a single modem itself is much greater than the mostly tight RxMER variations that we are accustomed to seeing in the downstream. For CMs which suffer more noise, they can be put into a different profile optimized for their particular noise environment. The modulation orders within a profile can vary appropriately across the spectrum as per the noise levels in that part of the spectrum.

**Figure 4 – US RxMER Measured on multiple CMs on a upstream Channel**

The upstream Profile Management Application (PMA) can automate this design of the profiles on upstream channels across various segments in the cable plant. Reading the upstream RxMER from the CMTSs on the network, processing the RxMER information with intelligent algorithms to create profiles, and then configuring the newly optimized profiles on the CMTS are the primary functions an upstream PMA solution accomplishes. Configuring optimized profiles brings solid reliability to the upstream network connection and also increases the capacity in parts of the spectrum which can accommodate higher modulation orders.

Given this understanding of the upstream plant behavior and the RxMER signatures, the question now is, what are the best algorithms to design upstream profiles which give operators robust upstream operation as well as increase the throughput? We address this problem with a few different solutions in chapter 4.

# 3. US OFDMA Deployment at NOS

In this chapter we share some of the Upstream OFDMA field rollout experiences by the NOS access engineering team in Portugal earlier this year. After some lab trials the effort quickly moved to limited field trials with internal employees and then to customers, in a phased approach. The support for OFDMA on CMTSs and CMs is maturing, but some of the initial trials led to a lot of lessons learned. Many of these bug fixes and feature improvements may take time to make it into operator networks, and we hope that sharing those notes here helps other operators with their Upstream trials and roll-outs. There may be gaps in system implementations which could use some thought and new solutions. Data collection for Upstream is based on the CMTS and these capabilities are still limited across the different implementations. This data is necessary to ensure that an operator can design the correct IUCs for each of the US OFDMA channels. Like many European HFC plants , the NOS plant has a 65 MHz EuroDOCSIS® split, which leaves open a reasonable amount of spectrum of OFDMA channels. We discuss the reasons we decided to keep the trials above 23.5 MHz and also share some trial experiences below that. The HFC upstream plant clean-up is always good practice for all operators and this trial needed more of that to make the OFDMA operations more robust. Monitoring the network and developing a few Key Performance Indicators (KPIs) for the DOCSIS Upstream are important to evaluate the changes made to the network and understand the performance of the network.

## 3.1. Channel location

The NOS plant in Portugal has upstream spectrum up to 65 MHz and currently there are 2 to 3 SC-QAMs per serving group and up to 4 upstream serving groups (US SGs) per downstream serving groups (DS SGs). With a 65MHz split and SC-QAM channels being already located at the upper edge, the natural choice to place OFDMA was the lower part of the spectrum, with a hope to take advantage of the enhanced flexibility of OFDMA.

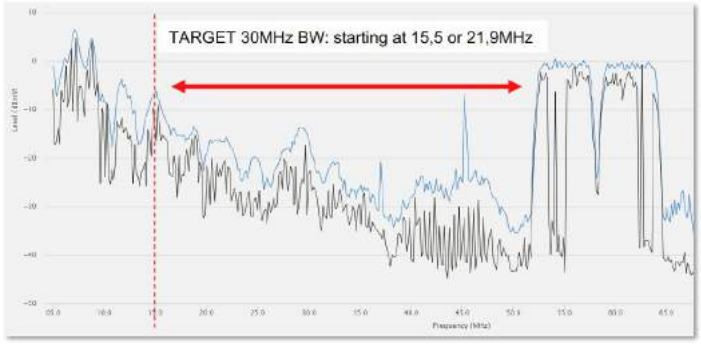

**Figure 5 – Target spectrum for OFDMA channel placement**

The initial trials started with OFDMA channels located at 15MHz up to 45.5 or 51.9MHz, depending on existing number of total SC-QAMs in the US SG, which were either 2 or 3. The spectrum below 40MHz was never used before for DOCSIS upstream and the initial analysis indicated that a high level of noise was sometimes present. Even after a fair bit of work to clean the outside plant, it turned out that using spectrum below 23.5MHz made the channel too susceptible to impulse noise. The result of this was that the OFDMA channel was affected, leading to channel impairment. So, the decision was made to locate the lower edge of the OFDMA channel at 23.5MHz for better stability.

At the time of this writing another approach was being tested: This approach chose to locate the SC-QAMs from 30MHz and use the upper part of the upstream spectrum for the OFDMA channel. As this is a much cleaner spectral area, more bits/hz can be extracted from the same bandwidth for the OFDMA

channel. Now this will only work if the SC-QAMs can work error-free in the lower zone of the spectrum. To ensure the stability of the US SC-QAMs, upstream agility features will definitely help.

Another approach that needs to be explored is to use two smaller OFDMA channels instead of a larger, single one. The idea is to have each of these OFDMA channels straddle the 2-3 SC-QAM channels. This way a smalled but highly reliable OFDMA channel can be obtained, providing a baseline capacity that is always present. The second OFDMA channel, due to its location in the lower end of the spectrum, will be much more susceptible to impairment or US IUC downgrades/flapping. This channel can then act as reserve capacity available most of the time to most of the CMs.

The field deployment was on two different CMTS platforms, both with different upstream capabilities, the table below describes some of the parameters chosen for the deployment.

**Table 3 – Upstream Channel Parameters Chosen on CMTSs**

| Parameter | CMTS vendor 1 | CMTS vendor 2 |
|---|---|---|
| OFDMA Bandwidth | 20.1 – 45.5/51.9 MHz | 15.5 - 45.5 MHz<br>21.9 - 51.9 MHz |
| Number of IUCs | 2 IUCs – 13; 12 | 2 IUCs – 13; 12 |
| Variable bit loading | Flat Profiles | Variable |
| K | 18 | 16 |
| Pilot Pattern | 4 | 2 |
| Subcarrier Spacing | 50 | 50 |
| Roll Off | 224 | 96 |
| Cyclic Prefix | 320 | 192 |

85 MHz Trial Learnings: In limited areas we also tried out OFDMA channels on an 85 MHz plant, as that was available in some areas. Here the OFDMA channel was located from 22MHz to 85MHz – with an exclusion band for 2 SC-QAM channels. Initially for the OFDMA channel we needed to create a 1.6MHz band in each side of the QAMs with 64QAM modulation, as per vendor recommendations, to protect the rest of the OFDMA channels. This configuration was revealed to be unstable with loss of IUC12 and OFDMA impairment. What solved the problems was adding a 500kHz guard band at the exclusion zone. Once this was added and the Upstream performed well. The calculated OFDMA capacity was 344 Mbps, and along with the couple of SC-QAM channels, actual speed tests gave us numbers of ~400 Mbps. We plan to use this selectively in very noisy and tough upstream environments, reusing existing 85MHz-ready equipment when available.

## 3.2. Phases of turning on OFDMA

OFDMA is a new technology for the Operators and for the CMTS and CM vendors, so a very cautious approach was used to deploy this technology in the network and enabling traffic on those OFDMA channels. After some initial lab trials, a three-phase approach was used. This was in parallel with continuous testing and upgrading of the CMTS and CM software with bug fixes.

Phase 1 – Activating the OFDMA channel, but not using it for customer data

In this phase we were able to check CMTS and CM behavior, regarding registration, CM management stability, etc. No service flows were assigned to the OFDMA channel. This was done to minimize the customer impact as the upstream traffic was not allowed to use OFDMA channel and instead the traffic continued to use the existing SC-QAM channels. To accomplish this, different techniques had to be used on the two CMTS models deployed in the network. We were able to build the data collectors and

 

processors, and start acquiring the KPIs selected and RxMER data files, which gives us visibility over the new upstream spectrum and the new OFDMA technology

Phase 2 – Using the OFDMA channel for customer data, but not upgrading their speed tier.

Once the data gathering and modem registration issues were crossed we moved into the phase of using the OFDMA channel for traffic. This phase allowed us to see the real impact of having live data traffic on the channel. Profile/IUC downgrades would happen in one CMTS just based on codeword (FEC) errors. So, with data traffic we could see the quality of the IUCs that we had created and the degree of readiness of the plant. During this phase IUCs were refined and there was a massive amount of work to go out and correct the plant when possible. At this point the customer was not given any speed upgrades, so any channel impairments on the OFDMA meant that the customers would fall back to DOCSIS3.0 capacity and still get the same capacity as they did before.

Phase 3 – Upgrading the upstream speed to customers

Once the IUC definitions were mature and robust, in this phase, the Maximum Sustained Traffic Rate was upgraded in the CM Config files for the eligible customer base. In this phase the impact could be significant as any channel impairments would directly mean less capacity and the customer might not be able to the reach the top speed offered in the service.

## 3.3. Technology maturity

At the time testing and field trialing started, both CMs and CMTSs Upstream implementations were quite immature. There were lots of feature limitations, and some features were not implemented at all, which constrained the roll-out across the footprint. Some examples in the CMTS were a very limited number of IUCs supported, CMTS management of IUCs not reacting to codeword errors, no Upstream PNM implementation, a very limited set of configuration parameters like pilot patterns, subcarrier spacing, cyclic prefix, etc. CMs were more comparatively mature from the beginning as regard support for the OFDMA set of features. Now both CMTS and CMs had numerous bugs that needed to be isolated and solved. This was by far the longest part of the work needed to get OFDMA out in to the field and make it generally available for customers.

Some challenges included issues like handling DBC messages to change IUC definitions as appropriate. Other CMTS devices had issues collecting US RxMER data reliably, and this was a key requirement to understand the plant and create appropriate profiles. Other initial limitations forced Service flows to be assigned to OFDMA channels, even when the operator was not planning on sending data traffic on those channels. Many CMTSs only support 2 IUCs one of which included IUC 13. The profile/IUC definition also only allowed 4 exception zones for modulation order changes, and allowed only one exclusion zone. What this meant was the that the allowed configuration options were somewhat limited. Load balancing of US traffic across SC-QAMs and OFDMA channels were also not fully mature.

## 3.4. Initial IUC definition for OFDMA chanel

The CMTS OFDMA channels need some initial IUC definitions to get the upstream channel up and running. For this initial phase of trials and the initial IUC definitions there was no US RxMER information available, as no OFDMA channel was provisioned in the network. Hence a PMA could not be used to create optimized profiles. So, another method was devised to define the initial IUCs for the 6000+ US SGs. The basic idea was to measure the noise on the plant when no SC-QAM or OFDMA channel was present and then use that to estimate the US MER.

### 3.4.1. Data collection for initial IUC

The Upstream data was captured with our data collection system (Viavi XPERTrak), which was continuously collecting signal power measurements in the spectrum where the OFDMA channel was to be located. The measurements were done before the OFDMA channel was turned on. This consisted of an average dBmV level value for each 250kHz bin of spectrum from 5 to 65MHz, collected every 15 minutes. Many days of historical data was used as input to a custom-made algorithm that returned IUC definitions for each US SG.

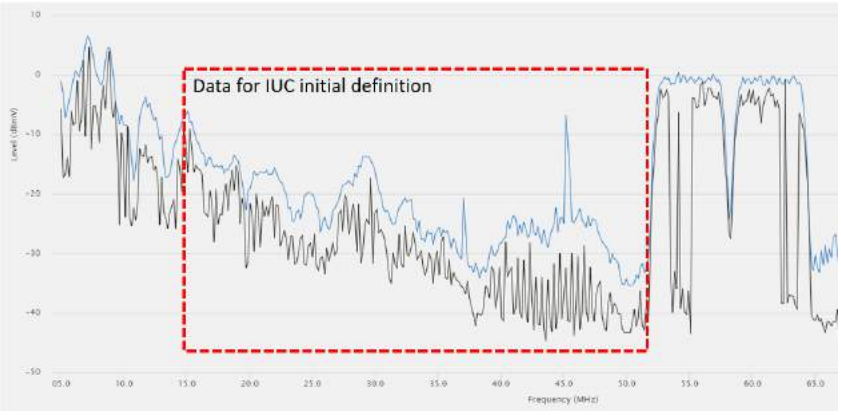

**Figure 6 - Example power level data used to calculate intial IUC definitions**

### 3.4.2. Initial IUC Definition

The MER was calculated from the noise level as measured in the signal power measurements in the previous section and the assumption that the CM signal arrives at the CMTS at 0dBmV. For IUC 13 we used the maximum power level found in the data set for each bin as the assumed noise level. For IUC12 we used the average level, choosing a bit more relaxed value for use in designing a higher profile. The power level data had to be tailored and adapted to minislot boundaries, and CMTS specific implementation rules needed to be accommodated on the design of profiles. This algorithm was implemented in a software program that could automatically read the data and output the needed CMTS commands for every serving group.

**Figure 7 - Example IUC definition from the deduced MER**

The OFDMA features available at the time along with the limitations of each CMTS vendor had to be taken into account for this algorithm to convert this power level measurements into MER and ultimately into modulation orders. Also, worth noting that this method only works before the OFDMA channel is turned on in the plant. As soon as CMs start transmitting in the OFDMA channel, this method cannot be used any longer as the external signal power measurements cannot separate the signal from noise.

## 3.5. Upstream Plant readiness

Level alarms were setup, in our data monitoring system, for the OFDMA band before OFDMA signals were activated. Whenever the threshold conditions were crossed, technicians were dispatched to check the plant, and correct noise sources or pinpoint customer installation problems. This happened for about 8% of the US SGs. Each and every US SG was again verified and acted upon just before provisioning a customer with a higher top speed that actually needs the OFDMA channel capacity.

Based on the KPIs described below, a technician truck roll was ordered for the SGs with high number of impairment-hours. Technicians would go through the plant, amplifier by amplifier, tap by tap, looking for the source of the noise impairment and trying to isolate it. If the source of the problem happened to be in the outside plant, the technicians would take steps to solve it. If the source was identified to be inside a home, a filter blocking part of or the complete upstream would be used on the drop, and a then a home network maintenance work item would be scheduled.

This is very similar to the normal maintenance of the upstream in DOCSIS3.0. The main difference here was the large amount of work it took to do this for the whole network in a short amount of time. The other difference from DOCSIS 3.0 is also the use of this new spectrum which is in the lower part of the upstream spectrum and very noisy. As with the legacy 3.0 spectrum, this is be a process which will continue on a daily basis, it is now even more demanding as this new lower portion of the spectrum is more susceptible to noise and interference. This will continue to be ongoing operations work, just like it was for the upper part of the spectrum before OFDMA. High pass filters that used to be deployed to block noise can no longer be used in the OFDMA region, making it harder and more expensive to maintain the outside plant.

## 3.6. KPIs for monitoring

We defined a new KPI to monitor OFDMA upstream channels: IUC-usage-hours. IUC-usage-hours is defined by number of hours in a day a CM uses each IUC on a particular OFDMA channel. This quickly became the main KPI that we tracked during these initial deployments and Upstream OFDMA roll-out. We tracked this metric of IUC-usage-hours over days, weeks and now months. As an example, a CM could be on IUC 12 for 22 hours a day and IUC 13 for 2 hours a day, while another CM perhaps could be in an OFDM-impaired state (partial service) for an hour a day.

Now in order to understand the reason for the variance in IUC-usage-hours, a homemade tool was built with the following additional KPIs:

- Codewords per IUC (total, errored): Per CM statistics on codeword errors, to understand the customer impact.
- Receive and Transmit Power: Per CM Rx/Tx power
- Data volume / Heavy user: The data volume metric was considered useful to diagnose different CM behaviors in the same US SG, as CMTS depends on codeword error ratios (CER) for IUC

management and its algorithm depends on traffic. Heavier users are more likely to hit thresholds and experience IUC changes.

These set of metrics proved essential, as this was the data used to fine tune IUCs, to make decisions along the trials and subsequent rollouts, to order plant cleaning or to dispatch a technician to the customer premises.

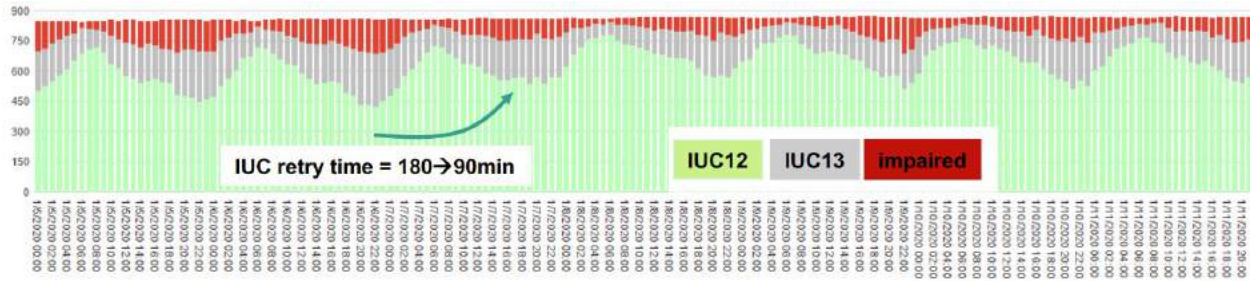

**Figure 8 – Tracking IUC-usage-hours per day (across CMTS)**

CMTSs automatically change the IUC used for each CM based on CER thresholds. The effect of one of the adjustments made during the process of deploying OFMDA can be seen in Figure 8 above. When changing the IUC retry interval from 180 minutes to 90 minutes, the percentage of time CMs spent in IUC 12 and 13 increased, and the time spent without OFDMA capacity decreased. At this point in time (i.e. prior to the PMA field trial) the CMTS IUC change mechanism algorithm was flawed and customers could sometimes have packet loss for a few seconds during IUC downgrade. So, the goal became not wanting to have many IUC switches. This testing allowed the operations team to decrease this time without any noticeable service degradation.

## 3.7. US RxMER Data Collection from the CMTS

The DOCSIS 3.1 CCAP OSSI specification defines a standard procedure to use SNMP to start upstream RxMER measurement on the CMTS and have the encoded binary files that comply to the specification defined format uploaded to a TFTP server. However, this feature is not currently supported by all of the available CMTSs. In our field data collection practice, 2 other methods were used to collect upstream RxMER data based on what the CMTSs support.

### *3.7.1. Standard SNMP + TFTP method*

The DOCSIS 3.1 CCAP OSSI specification defines MIBs and data formats to allow upstream RxMER data collection. The high-level steps are described below, on a per CM basis

- The data collector specifies the CM MAC address and CM upstream channel interface number, sets parameters for upstream RxMER data measurement, and specifies the TFTP server address and directory for file upload through the MIBs on the CMTS
- The CMTS performs upstream RxMER measurement for the specified CM and OFDMA channel
- The CMTS uploads the encoded file that contains the upstream OFDMA RxMER measurement data to the specified TFTP address and directory
- The data collector reads the uploaded binary file, decodes it and stores it into the data service for PMA profile calculation

### *3.7.2. SNMP + SFTP method*

Some CMTSs may comply to part of the DOCSIS 3.1 CCAP OSSI specification and may support the SNMP MIBs for upstream RxMER measurement. However, they may require different methods to gather the collected data, such as SFTP. The steps are described below, on a per CM basis

- The data collector specifies the CM MAC address and CM upstream channel interface number, sets parameters for upstream RxMER data measurement through the MIBs on the CMTS
- The CMTS performs upstream RxMER measurement for the specified CM and OFDMA channel
- The CMTS stores the encoded file that contains the upstream OFDMA RxMER measurement data in the CMTS's local storage (the CMTS may only store a limited number of PNM files)
- The data collector retrieves the stored binary file through SFTP from the CMTS, decodes it and stores it into the data service for PMA profile calculation

### *3.7.3. CLI method*

Some CMTSs may not support the MIBs for upstream data collection that are defined in the DOCSIS 3.1 CCAP OSSI specification. However, they may support measuring the upstream OFDMA RxMER data and presenting the data through the command line interface (CLI). In this case, we can parse the CLI output to collect the upstream OFDMA RxMER data. The steps are described below, on a per CM basis

- The data collector uses a CLI client to specify the CM MAC address and CM upstream controller/interface/channel number in the CMTS CLI and collects the CLI output (the CMTS may not support data collection triggering, instead, it may have a time interval to be configured to periodically perform upstream RxMER measurement)
- The CLI client automatically parses the CLI output and generates JSON formatted upstream OFDMA RxMER data
- The data collector stores the JSON formatted data into the data service for PMA profile calculation

### 3.8. US RxMER Data Collection in field deployment for PMA trials

CableLabs DOCSIS Common Collection framework (DCCF) software can collect PNM data from the plant. However, the CMTSs were not fully compliant to PNM specification for PNM testing and reporting. One CMTS could generate the RxMER files and store them in its filesystem, but it didn't implement the TFTP upload. So, for the sake of this field trial, some shell scripts were developed to trigger RxMER measurement through SNMP and fetch the encoded binary files from the CMTS using SFTP.

Data was collected for all the CMs and all the SGs in field trial every 2 hours, for a couple of weeks. A software limitation and the total number of CMs imposed this 2-hour limit. In total, more than 13,000 RxMER files were collected. For practical reasons, all SGs we collected data belonged to the same CMTS.

## 4. US PMA Algorithms

The upstream RxMER data has different features compared to what we see in the downstream. Although one could start with the downstream PMA's clustering algorithm to calculate upstream OFDMA modulation profiles, given the difference of the Upstream RxMER data (as explained in section 2.9) it become clear that a simple "clustering of CMs" approach would not be a good solution. Due to noise funneling since the US RxMER were similar many of the profiles are expected to have similar characteristics. So, we developed several new candidate algorithms for comparison and improving the robustness of the upstream. The immediate goal for this initial rollout was focused around developing IUCs which modems could stay on without profile flapping. Each profile is expected to be used by a group of CMs that have similar channel characteristics.

Each of the Minislots in the Upstream OFDMA channel can be configured to use a different modulation order. This allows the operator to optimize the upstream transmissions across the wide frequency band (10-96 MHz) of the channel. The specific choice of modulation order selected for each minislot is communicated to the CMs in the form of an IUC (modulation profile) which allows the CM to modulate the signal accordingly. An IUC/modulation profile consists of a vector of bit-loading values, an integer value for each active Minislot in the upstream channel. Since the modulation orders range from QPSK to 4K-QAM, the range of bit-loading values is from 2 to 12.

The PMA generates an IUC 13 that is the lowest common denominator profile, which can be successfully used by all CMs in the Service Group. A CMTS can support up to 7 modulation profiles, including IUC 13. Each CM can be assigned up to 2 modulation profiles at a time, including IUC 13 and an optimized profile for the CM's unicast traffic.

This capability, the ability to optimize the upstream transmission for the channel characteristics of the CM population, is a powerful feature that allows for a significant improvement in robustness and channel capacity. The CMTS and CM perform measurements and report network conditions as a part of supporting PNM functionality in the DOCSIS network. The DOCSIS 3.1 Upstream PNM Measurements includes: US active and quite probes, Triggered spectrum capture, US equalizer coefficients, Impulse noise statistics FEC statistics, Histogram, Channel Power and the RxMER per subcarrier. So far, we are basing the PMA profile creation algorithms on the US RxMER data, in the future one can include other upstream data sets to fine tune the profiles that we create.

## 4.1. Differences from Downstream Algorithms

The downstream PMA algorithm looks into the variances among the CMs, clusters the CMs into groups, and assign different modulation profiles to each CM group. The algorithm can use a data snapshot that's captured only once from the CMs, or it can use pre-processed data (average, minimum, percentile etc.) from each CM's multiple historical data captures.

On the upstream, each CM's RxMER data tend to have similar patterns when they are captured during the same time slot because of noise funneling. The variance is much more within the CM's RxMER captures over a relatively long period of time. Hence, the upstream PMA algorithm focuses more on optimizing the channels robust operation and CMs' upstream capacity over a certain period (when the operator does not plan to change upstream profiles frequently such as changing the profiles every few hours). The candidate upstream PMA algorithms also consider the fact that the CMTSs automatically upgrade/downgrade the upstream modulation profiles for each CM based on their monitored FEC performance, which makes the time clustering based profiles more effective.

Problem: Given a set of US RxMER data samples from CMs, return optimized profile definitions.

We have two classes of algorithms we developed and are field trialing, one is developing using the percentile method and the other is using time clustering methods. These methods and their variants are described below.

## 4.2. Percentile method

The CMTS is actively managing the CM's IUC/profile assignment as plant conditions change. The upgrades/downgrades to the CMs' upstream OFDMA modulation profile is based on the CMs' FEC performance or RxMER data. The percentile method for creating profiles is a simple statistical set of methods which can create robust profiles based on the past performance of the plant. The idea is to choose a conservative profile which can fit most of the CMs, most of the time. So, the algorithms arrange the CMs in descending order of their RxMER values and choose to design a few different profiles at a few different percentile values (e.g. 0.5 percentile and 2 percentile)

This method focusses on optimizing the overall channel robustness so that an CMTS can maintain good upstream service for most of the CMs.

### *4.2.1. Algorithm 1A : Per CM Percentile*

Inputs: A list of CM RxMER per subcarrier, choice of a percentile numbers that an operator wants to choose at the per CM level and for the profile level.

Outputs: List of robust profile definitions for use on the upstream channel

Algorithm:

- Calculate a representative CM RxMER sample for each CM from the data captured over time
    - For each CM on the US channel
        - Create an artificial '$x^{th}$' percentile sample of RxMER for this CM
            - Start with the first sub carrier in the channel
            - Find the '$x^{th}$' percentile RxMER value across all the samples for that sub carrier for that CM

 

            - Repeat for all subcarriers
        - Repeat for each 'x$^{th}$' percentile chosen by the operator.
            - E.g. 0.5$^{th}$ percentile and 2$^{nd}$ percentile could be the two percentile values for 'x$^{th}$'. The number of percentile values depends on the number of needed IUCs.
- Create profiles from CMs' representative RxMER samples (percentile samples)
    - Group each of the 'x$^{th}$' percentile data samples from the CMs (from the previous step)
    - Create new 'y$^{th}$' percentile (normally 0.5% or 0%) samples across each of the CMs' 'x$^{th}$' percentile groups.
        - Start with the first subcarrier in the channel
        - Find the 'y$^{th}$' percentile RxMER value across all the CM samples from an 'x$^{th}$' percentile group
        - Repeat for all subcarriers
        - Repeat for all 'x$^{th}$' percentile groups
    - Translate each of the 'y$^{th}$' percentile RxMER to Modulation orders per [PHYv3.1] spec.

### *4.2.2. Algorithm 1B: All CMs Percentile*

Inputs: A list of CM RxMER per subcarrier, choice of a percentile numbers that an operator wants to use to create profiles.

Outputs: List of robust profile definitions for use on the upstream channel

Algorithm:

- Create a profile from all of the RxMER samples from all of the data
    - Create a new 'y$^{th}$' percentile sample across all of the CM's RxMER samples.
        - Start with the first sub carrier in the channel
        - Find the 'y$^{th}$' percentile RxMER value across all the samples for all the CMs
        - Repeat for all subcarriers
    - Repeat for as many 'y$^{th}$' percentile values as many as IUCs are needed.
        - E.g. IUC 13 could be the 1$^{st}$ percentile, and IUC 12 could be the 5$^{th}$ percentile.
    - Translate each of the 'y$^{th}$' percentile RxMER to Modulation orders per the PHY spec.

### *4.2.3. Algorithm 1C: Remove Outliers + Percentile*

Inputs: A list of CM RxMER per subcarrier, choice of a percentile numbers that an operator wants to use to create profiles, and a choice of how to detect outlier CMs.

Outputs: A list of robust profile definitions for use on the upstream channel

Algorithm:

- Find and remove Outlier CMs.
    - Method C1
        - For each CM, across all of its samples: Calculate an average RxMER number for the CM
        - Calculate Standard deviation for each CM, with respect to all of its samples.
        - Remove CMs outside the Confidence interval (e.g.: 98%) lower bound.
            - Remove all samples of all outlier CMs from the data set

    - Method C2
        - Calculate average RxMER: Each CM, all samples
        - Remove CMs below 70% of average value (of all CMs)
            - Remove all samples of these CMs ( in some cases, this may be an empty operation), from the data set.
- Create a profile set from the remaining RxMER samples
    - Use Algorithm 1A or 1B

## 4.3. Time Clustering Methods

The CMTS automatically upgrades/downgrades the CMs' upstream OFDMA modulation profile based on the CMs' FEC performance. The hypothesis for the time clustering method is that we can find clusters of CMs with similar RxMER over time and design IUCs based on those clusters to keep the CMs on IUCs for long periods of time. The CM clustering algorithm that's been previously developed and used in downstream PMA is repurposed to calculate clusters from the data captured over time on all CMs. The time clustering methods focus on optimizing the overall channel capacity through days or weeks of time without recalculating or modifying the upstream modulation profiles very frequently. The J value that's used in the downstream for capacity gain measurement is repurposed to measure the theoretical capacity gain from the time clustering based profiles over a time period.

### *4.3.1. Algorithm 2A: Time Clustering using Actual CM Samples*

Inputs: A list of CM RxMER per subcarrier, choice of a number of profiles an operator.

Outputs: A list of robust profile definitions for use on the upstream channel

Algorithm :

- Find Time clusters from all CM's and all of their samples
    - Use actual sample of RxMER for every CM, every measurement
    - Use a clustering algorithm to find groupings across full-RxMER values.
        - e.g. reuse the PMA Algorithm (for Downstream)
        - Find 2-7 clusters
- For each cluster/group of CM-samples
    - Choose an RxMER value per subcarrier, from this groups samples as follows
        - The average value at each subcarrier
        - The minimum value at each subcarrier
        - A certain percentile value (picked by the operator)
        - Some other centroid definition
    - Translate each of the resulting RxMER vector to Modulation orders per the PHY spec.

### *4.3.2. Algorithm 2B: Time clustering using artificial Percentile Samples*

Inputs: A list of CM RxMER per subcarrier, choice of a number of profiles an operator.

Outputs: A list of robust profile definitions for use on the upstream channel

Algorithm:

- For All CM's and all samples

 

    - Create 199 artificial samples of RxMER for each CM as described below
        - An RxMER value per subcarrier is chosen using a percentile value across all samples of that CM
        - Samples will use percentiles from 0.5% to 99.5% in increments of 0.5%
- Perform clustering with these artificial samples
    - Use Algorithm 2A (This step will find the most common percentiles)

#### *4.3.3. Algorithm 2C: Time Clustering after removing outliers*

- For All CM's and all samples
    - Use all samples of RxMER for each CM
    - Create an artificial threshold sample using a percentile value (e.g. 1%)
        - RxMER value per Subcarrier is chosen using a %tile value across all samples
    - For every sample
        - If any individual RxMER within the sample is below artificial threshold sample, then bump up those RxMER values to the threshold MER level using a ceiling-like calculation. This keeps the weight of the sample for other areas in the channel which are unchanged
        - Instead of bumping up samples, we could also ignore the samples
- Now with the outliers removed, use Algorithm 2A.

### 4.4. Other PMA Considerations

Modulation order of profile from minislot RxMER: There are a few different methods to choose the Modulation order of the profile from the RxMER values of all the subcarriers within that minislot. One could choose one of the following RxMER values to use when translating to the modulation orders

- Average RxMER of subcarriers within minislot.
- Majority RxMER of subcarriers within minislot
- X percentile RxMER of subcarriers within minislot
- Minimum RxMER of subcarriers within minislot

Margins when translating from RxMER to modulation order: Different margins can be applied at different frequencies within the channel. Lower frequencies could have a higher margin, while higher frequencies wouldn't need as much of a margin. Another way to apply different margins is to preprocess the US RxMER data and if there is a higher variation in the data, one can apply a higher margin. This way the operator can lower the US RxMER before sending to PMA algorithm

Capacity gain Calculation/Optimization function: The downstream has a J-Value calculation which can calculate the capacity achieved by a set of profiles. In the downstream the profiles are also weighted by the number of CMs associated with the profile to calculate capacity. Also, the gain is calculated with reference to 256-QAM in the downstream. For the upstream given the dynamic nature of the noise on the plant and the fact that many of the CMs have the same RxMER signature, the idea of an optimization function can be built around how much time is spent on each of the IUC/profiles, i.e. of the many RxMER data samples of all CMs fit which a particular profile, we can weight each profile by that percentage of samples, to calculate an overall weighted capacity. To figure out if an US RxMER sample can fit a profile, the idea would be to establish a threshold across all subcarriers: e.g. only 1 or 2 % of subcarriers can be below the required RxMER level for that modulation order. Also, this comparison should be done on a on minislot basis. A good reference in the upstream to capture the capacity gain would be to compare to 16-QAM or 64-QAM, depending on the plant.

 

PMA Exception handling: Due to adjacent channel interferences (from adjacent SC-QAMs), there is a need to handle exceptions for the Higher and lower edges of the OFDMA channel. The ideas is that a few number of minislots (2-4) need to be limited to one or two lower modulation orders than normal to account for interference from an adjacent SC-QAM

# 5. US PMA Field Trial Results

## 5.1. US RxMER Field Data

The below figure 10 shows a sample of the US RxMER collected at the CMTS, for 4 cable modems within one Serving group. The data was collected for every cable modem, every 2 hours for over 3 weeks.

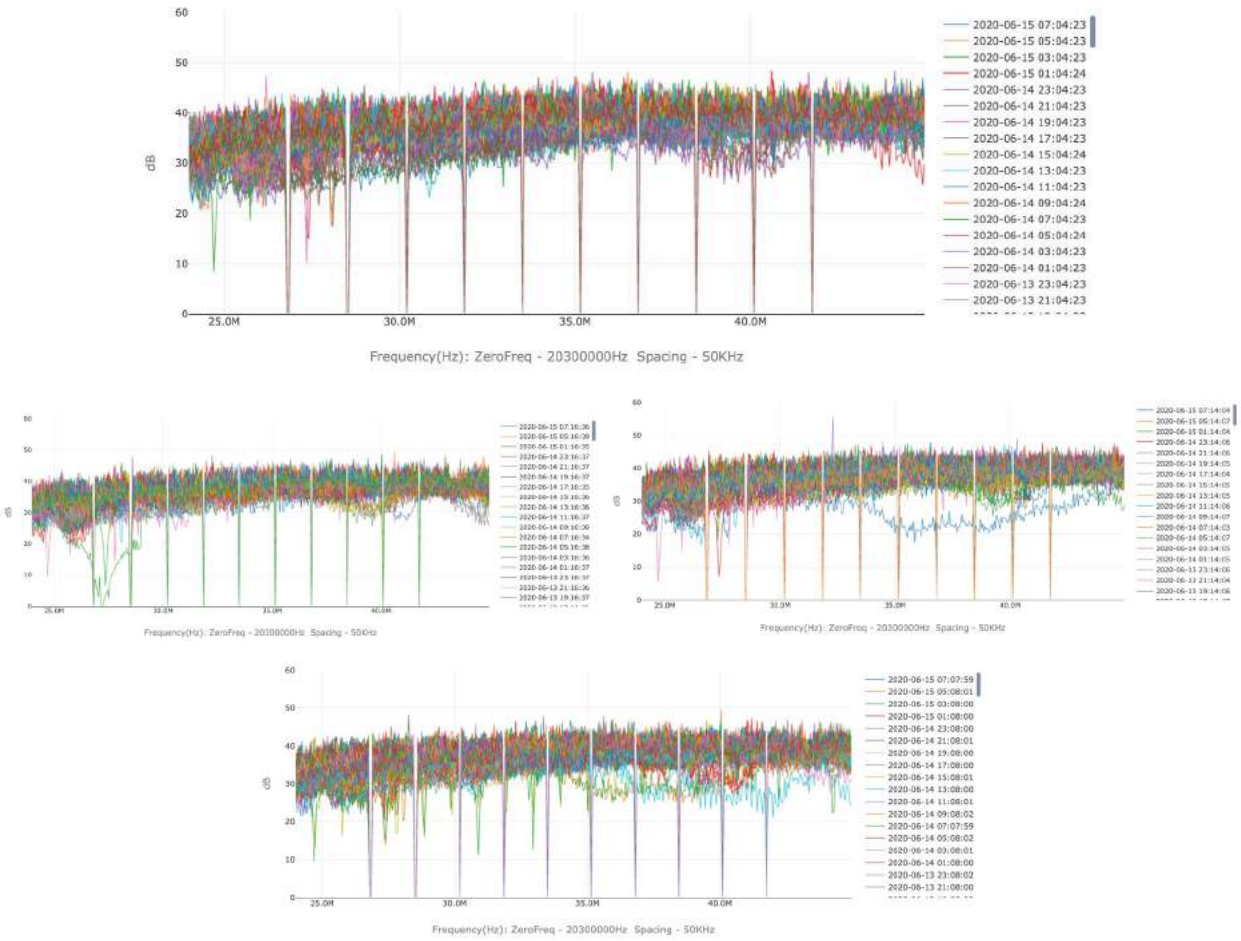

**Figure 10 – Us RxMER Samples from 4 CMs**

## 5.2. US IUCs/Profiles designed

The following figures show the profiles designed by the Algorithm 1A,1B,1C, 2A, 2B,2C from the section above. This iteration of profile creation was limited to 2 IUCs due to CMTS limitations. The profile 0 in blue is used as IUC 13 and the profile 1 in orange is used as IUC 12.

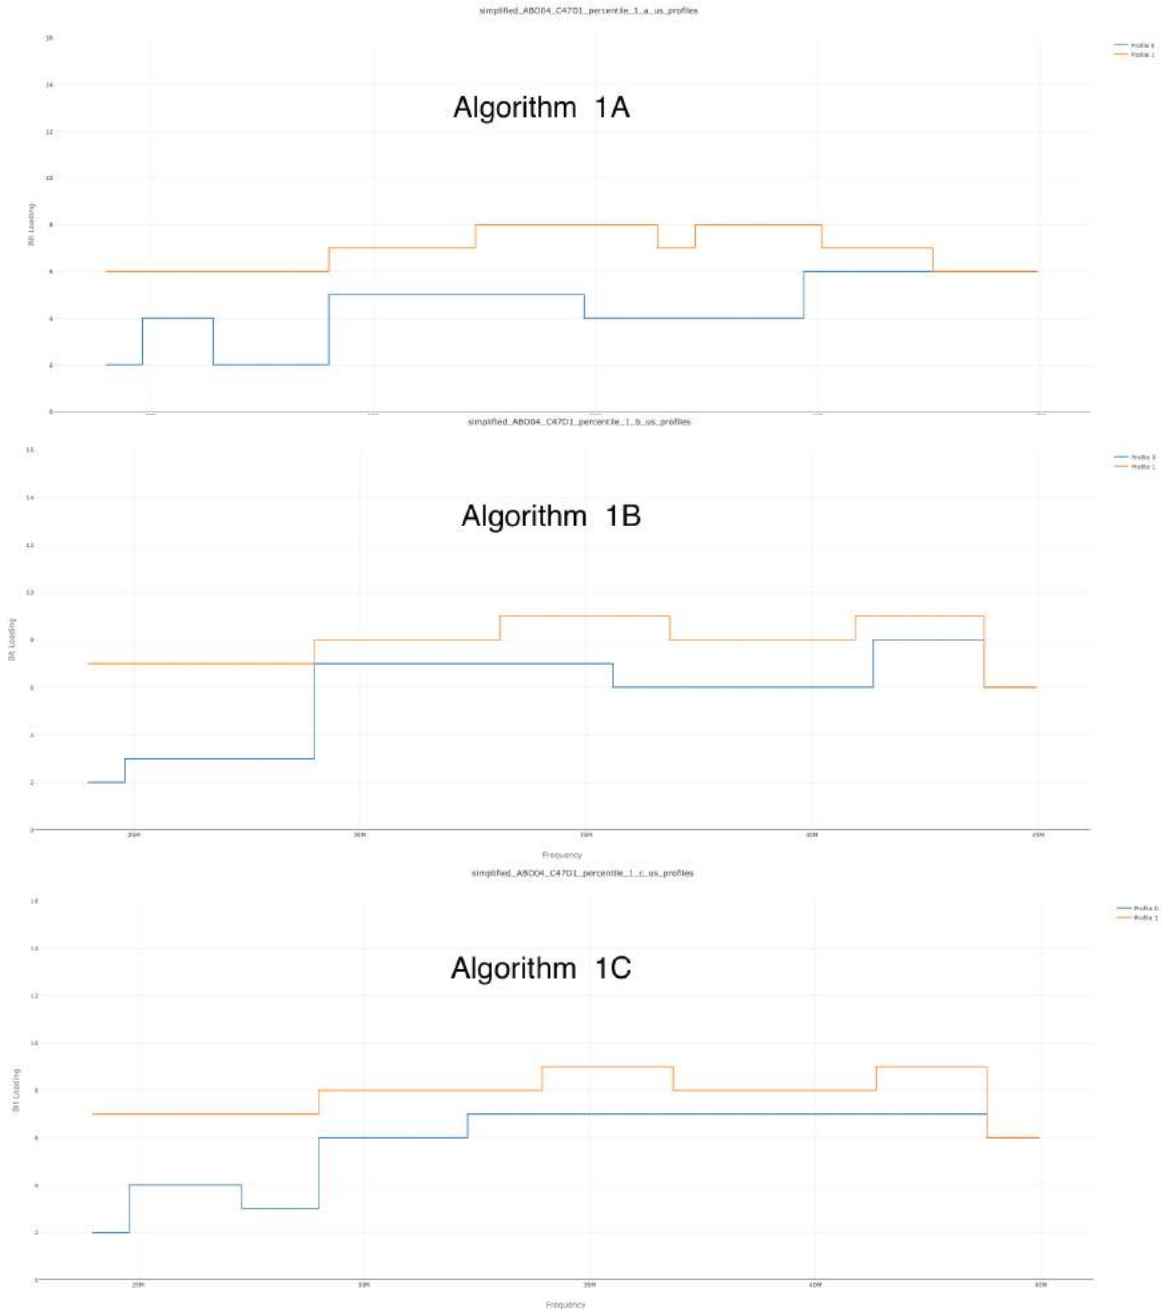

**Figure 11 – IUCs created using Percentile Algorithms 1A,1B,1C**

The profiles created by algorithm 1A are more conservative than the 1B and 1C as those algorithms remove the outliers or ignore the worst samples across all the CMs equally.

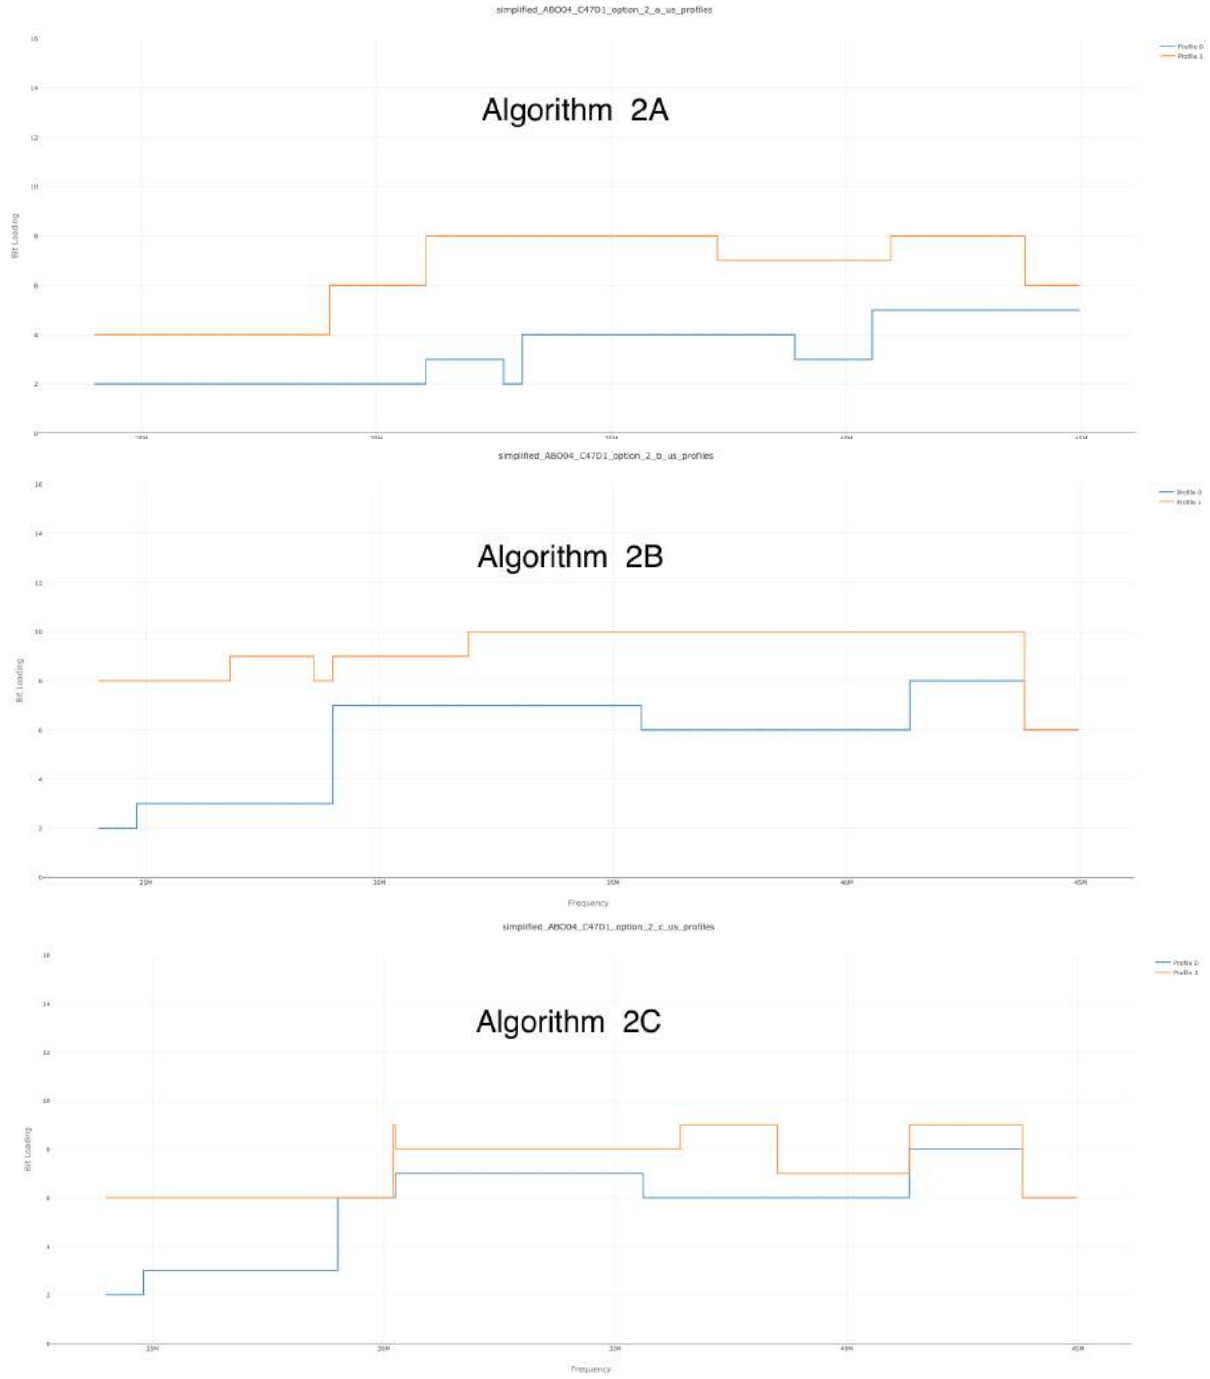

**Figure 12 – IUCs created using Time Clustering Algorithms 2A, 2B, 2C**

The profiles created by algorithm 2A is more conservative than the 2B as 2A operates on all the original data samples, whereas algorithm 2B operates on a subsampled percentile data set. Algorithm 2C is somewhat in between as it removes the outliers but keeps the weighting of all the samples.

The goal for the field trial is to try out each of these 6 methods of profile creation and uses the profiles they create in the field for a week and observe the performance of these profiles.

## 5.3. Performance and Stability

The table below depicts the field results for the profiles designed using algorithms 1A and 1B.

**Table 4 – Field Results from using PMA Algorithm 1A, 1B**

| | capacity (Mbps/MHz) | | | | Performance | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| *Upstream Serving group* | Algorithm 1A | | Algorithm 1B | | Algorithm 1A | | | Algorithm 1B | | |
| | IUC12 | IUC13 | IUC12 | IUC13 | IUC12 | IUC13 | impaired | IUC12 | IUC13 | impaired |
| ABO04 C47D1 | 5.9 | 3.7 | 6.8 | 4.8 | 97.8% | 1.6% | 0.6% | 96.4% | 3.4% | 0.2% |
| PAR06 2JD1 | 4.6 | 2.4 | 4.1 | 3.1 | 99.0% | 0.8% | 0.2% | 95.9% | 3.8% | 0.3% |
| PSL03 C53D2 | 4.4 | 2.3 | 4.8 | 3.6 | 92.0% | 3.6% | 4.4% | 93.8% | 4.5% | 1.7% |

The Table above shows the IUC-usage-hours percentage for the period and the channel capacity in Mbps per MHz for each algorithm.

IUC-usage data was collected each hour. This CMTS upgraded IUCs without any other consideration X minutes after it was downgraded and X was configured in this trial to 15 minutes. This means the results in the table are a sampling of the actual behavior, but still a good picture of the reality as each set of profiles (from each of the algorithms) was run for more than one week.

CMTS manages IUCs based on FEC errors. When the number of errored codewords crosses a threshold on a configurable codeword window, the IUC is downgraded (from 12 to 13, and from 13 to no-IUC, i.e., channel impaired). So, at this point we are not tracking FEC error rates because the CMTS will essentially downgrade the IUC up to the point that there are no errors.

Due to the working restrictions due to Covid, the field trials were delayed and slowed down a bit, and at the time of writing, we have not had a chance to evaluate the other 4 methods of profile creation. So far Algorithm 1A shows greater stability with the designed IUC 12. Our hypothesis is that profiles based on methods 2A,2B,2C will be likely give us more stable upstream operations. We hope to share those results in the near future.

## 5.4. US IUCs/Profiles designed with no IUC limitations

We ran the same algorithms on the data from the serving groups to create more than 2 IUCs, we chose 7 IUCs as that will be maximum number supported by the CMTS per channel, in the future. The figure 13 below gives us an idea of the profiles created for a single serving group. In these Serving groups we currently have only ~30 CMs each, so some of the profile definitions are overlapping (we chose percentile values of 0.5,3,6,9,12,15,18.) For a larger set of CMs we expect the profile definitions to be more spread out.

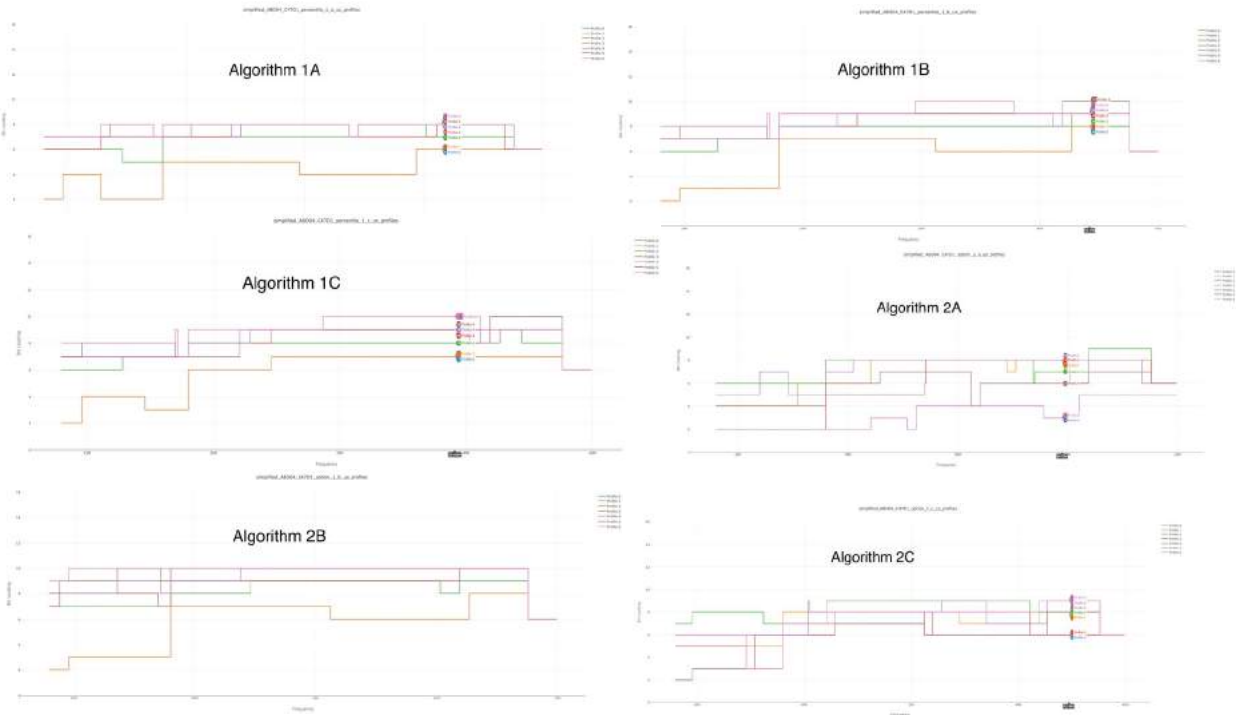

**Figure 13 – 7 IUCs created using all Algorithms**

## 6. Conclusion / Future Work

OFDMA is a newer technology with a lot of promise for operators looking to increase their upstream bandwidth capacity. At this point, OFDMA is a bit of a long walk to the finish line, because of novelty, the immature implementations of the technology (which is quickly being fixed) and the use of new-noisy spectrum which hasn't been used before. There will be a cyclic process of cleaning up the upstream plant, followed by degradation and new issues seen in the plant followed by more plant work and upgrades.

As it stands today, more flexibility in the CMTS OFDMA system functionality is needed, as this will enhance the upstream stability and ultimately the customer experience. There are many CMTS limitations, the most important of them being the limitation around just 2 IUCs per channel. The number of IUCs supported per channel needs to increase to accommodate the upstream variations. Improvements in the ability to define more than the limited (currently 4) modulation orders per profile would help design more granular profiles and improve the stability of the modems. There is an immediate need to measure and use the US RxMER to design and then select IUCs, and the use of FEC errors to downgrade IUCs. A fuller implementation of Upstream PNM functionality as defined in the DOCSIS 3.1 specifications will go a long way to ensuring a smooth transition from SC-QAM upstreams to OFDMA upstreams.

Lower frequencies in the upstream can be a very noisy and can make the channels using that portion of the spectrum unstable. DOCSIS 3.1 brought a high degree of adaptability with the new OFDMA technology. CMTSs can switch between upstream profiles (IUCs) to cope with the variability of the plant but the operator needs to create and design the IUCs optimally. So, a Profile management Application (PMA) is even more necessary on the upstream. The work done here shows some encouraging results for different upstream PMA algorithms and further testing is ongoing.

In terms of future work, we plan to complete the analysis on all the profile creation techniques and share the top methods with industry. Also, when more IUCs per channel are available, it would be interesting to see if which methods can be used to create better profiles which can increase capacity and keep the upstream operation robust. We also plan to experiment with pilot patterns and other OFDMA parameters like the number of symbols per frame, FFT size, Cyclic prefix, choosing exclusion bands etc. and see how best to optimize the OFDMA channel operation.

# 1. Introduction

Low latency is gaining importance in the internet experience. Low Latency is being approached as an end to end solution by operators. This includes Wi-Fi links in the home, DOCSIS links in the access network and core network segments. Providing lower end to end latency is a top priority for operators in the coming years. Measuring the latency in the network then becomes a vital requirement.

Operators (and 3rd party speed-test websites) have metrics on latency which they have reported and discussed with the community. Yet there is confusion surrounding the latency numbers and the ability to compare them between networks. The language and meaning of latency metrics (latency vs jitter, one-way vs round-trip, average vs 99$^{th}$ percentile), the latency measurement methods, what is being measured and when (peak vs off-peak periods), are varied. This paper provides clarity around these topics and discusses latency measurement architectures as well as best in class measurement tools to streamline latency measurement for the cable industry.

Operators want the ability to measure the difference in latency that is actually being delivered, before and after they deploy a new technology in their network, like DOCSIS 3.1 AQM, Low Latency DOCSIS, Low Latency WiFi etc. The latency portion of measurement reports (e.g. FCC's Measuring Broadband America initiative) are not optimal, and without a consistent measurement approach to latency, this could become a customer perception problem for the internet service providers. For new technologies that differentiate traffic, there are also questions around how latency for unmarked traffic vs marked traffic can be measured and reported. Operators will be asked to help troubleshoot latency issues and it will be important for them to identify latency within their networks vs. outside of their networks. This paper discusses the latency measurement frameworks which an MSO can integrate into their network deployment.

## 1.1. Quality of Experience

Latency is the time that it takes for a packet to make it across the network from a sender to a receiver and for the response to come back. Network latency is commonly measured as round-trip-time and is sometimes referred to as ‘ping time’. As applications turn ever more interactive, network latency plays an increasingly important role for their performance. Applications that are real-time perform the best when latency is low, and adding more bandwidth without addressing latency doesn’t improve the user experience. Packet forwarding latency can have a large impact on the user experience for a variety of network applications. The applications most commonly considered as latency-sensitive are real-time interactive applications such as voice over Internet protocol (VoIP), video conferencing such as Zoom, and networked online gaming. However, other applications are sensitive as well; for example, web browsing is surprisingly sensitive to latencies on the order of hundreds of milliseconds.

Test results in [ITU-T G.114], show that highly interactive tasks (e.g. speech, video conferencing and interactive data applications) can be affected by delays beyond 100 ms and users report significantly reduced mean opinion scores (MOS) when the voice delays are beyond the 150ms mark. The current [ITU-T G.114] recommends a maximum of a 150 ms one-way latency for VOIP applications.

Online games have some models [QoE and Latency] that indicate the impact that network parameters have on user experience. Some data exists to indicate that end-to-end round-trip latency should be kept below 25 ms or 50 ms in order to provide a good user experience, depending on the type of game (first person shooters, massively multiplayer online games, e-sports, etc.). When the operational response delay is less than 50 ms, the MOS scores tend to be high; when the operation response delay is around 100 ms,

the MOS decreases but is acceptable for some kinds of games, and when the operation response delay is beyond 200 ms, the interaction quality for the gamer is very poor.

If we assume that gaming servers centrally located in North America are serving gamers all over the continent, the round-trip time (RTT) on the fiber backhaul links for gamers in the west coast will be around 40 ms (assuming 4000 fiber kilometers between say San Francisco and Chicago, and speed of light in fiber as 0.67x speed of light in vacuum). These RTTs will be even higher for gamers across different continents, if they don't have separate gaming servers. So, for the games which require very low latency and latency variance, the 25 ms - 50 ms end-to end target implies that the access network latencies need to be consistently in the order of 5 ms – 10 ms target to meet the requirements for online games.

Web browsing performance is traditionally tracked using page load time. Web content can be sourced from different servers and web browsers typically fetch resources from each server by opening up multiple TCP connections to the server. As there are multiple handshakes/interactions in each of the underlying protocols (DNS, TCP, TLS, HTTP) and all of those handshakes are impacted by the RTT, higher RTTs increase the page load time. See the paper [Belshe M] "More Bandwidth Doesn't Matter (much)*"* for experiments on how RTT affects page load time.

### 1.2. Latency in the Internet

There are a few main contributors to the latency of a packet as it traverses the network. The switching/ forwarding delay, propagation delay, serialization/encoding delay are some of the factors which affect packets as they go across various network devices and links, from the source to the destination. Queuing delay is usually the biggest contributor to latency, and is mainly caused by the current TCP protocol and its variants. This delay is encountered at the bottleneck links like the home Wi-Fi network or the access network. The majority of TCP implementations use loss-based congestion control, where TCP ramps up the number of bytes "in-flight" (i.e. its congestion window) until it sees packet loss, cuts its congestion window in half, and then starts ramping back up again until it sees the next packet loss. (When the buffers in the device transmit queues are full, a new arriving packet has to be discarded). This way TCP automatically adjusts its transmission rate to fully utilize the available capacity of the bottleneck link.

The result of this congestion window ramp-up and cut-in half mechanism is a saw-tooth behavior for the buffer going between partially full and totally full. In every home there are multiple users and applications that will use the same connection to connect to the internet. Applications other than TCP will suffer as the packets from those applications will arrive to nearly full buffer that may take tens or hundreds of milliseconds to drain. This can make web browsing perform poorly, and make VoIP, video chat, or online games unusable when other TCP based applications (e.g. streaming video) are in use.

### 1.3. Common techniques to reduce latency

Setting the buffer sizes appropriately in each of the network devices is a first step to reduce the latency in the network. Active queue management (AQM) is the next step in mitigating queueing delay, where the basic idea is to detect the increasing queue created by TCP and, then drop a packet which will let TCP know to back off on its sending rate, much ahead of the time it takes to drop a packet when the buffer is completely full. There are variety of algorithms, such as random early detection (RED), Proportional Integral Controller Enhanced (PIE) etc., which an AQM system can implement.

The next stage in the evolution of latency reducing solutions is the dual-queue approach where the concept is to separate the traffic for queue-building applications from those applications/traffic flows which are non-queue building. See the paper [Greg W, SCTE 2019] Low Latency DOCSIS Overview and Performance Characteristics, for detail on these types of traffic flows and the dual queue approaches. Low

 

Latency DOCSIS and L4S technologies tackle the queueing delay by allowing non-queue-building applications to avoid waiting behind the full buffers caused by the current TCP or its variants.

## 2. View of latency measurements

Internet latency is crucial in providing reliable and efficient broadband services to customers who are connecting to servers across the country and the globe. The trend of real time gaming and other real time applications only accelerates the importance of accurately understanding the latency characteristics of the network. This bubbles up the task of latency measurement towards the top of an operator's priority list. Being able to accurately diagnose latency issues seen by residential or business customers is becoming more important. In order to support server selection in distributed /virtual computing environments measuring accurate latency becomes extremely important. Knowing the latency characteristics well allows an operator to make better decisions on which latency reducing technologies to deploy and where.

Accurately measuring network latency, however, is not an easy task due to lack of testing end points, lack of clock synchronization when needed, the sheer volume of collected data points, and aggregating and analyzing the data meaningfully. In addition, the time that latency is measured affects measurement results significantly due to network dynamics, volatile traffic conditions, and network failures.

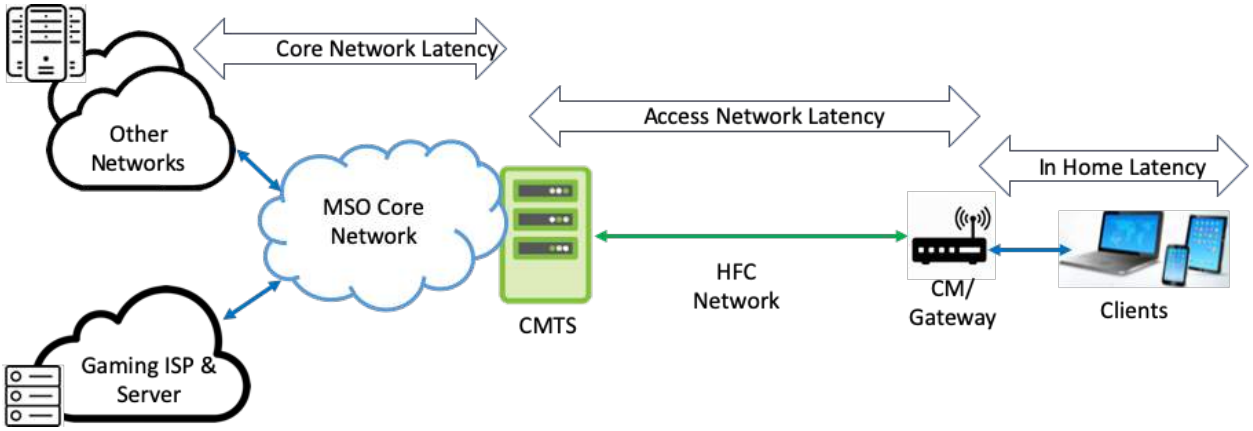

**Figure 1 – MSO view of Latency Measurements**

### 2.1. MSO Goals for Latency Measurement

Operators want to leverage existing available tools and standardized architectures to quickly set up a measurement infrastructure. Some of the common operator use cases and considerations are as follows.

- Identify Latency in 3rd party networks vs. MSO core network vs. Home network. In the Core network, there is a need to develop processes to identify routing issues, especially in the path to the egress point in the network which connects to a specific application server. For the Access & Home networks, it is extremely useful for an operator to be able to delineate latency from within the customer home (e.g. due to Wi-Fi) vs the access network latency vs the aggregation/core network.
- Operation Diagnostics Support: Operators would like to develop diagnostic tools, so that they can give meaningful information to their operations team. The use of latency measurements in NOC and field tester tools for live problem diagnosis is common at IP and Ethernet layers

- Operators would need to measure a variety of access and core architectures (R-PHY, FMA, Integrated) and need the measurement methods work across these range of deployments
- Network Architecture Analysis: The loss and delay performance metrics impact the scalability of the network and also on its behavior under load. For network architects, understanding both end-to-end network latency plus the contribution of the various links and nodes (network devices) that the network is comprised of is very useful.
- Understanding how to optimize the network deployments: e.g. with Distributed CCAP architectures an operator has to decide on a particular architecture, or where to place the physical or virtual components and decide on the location of certain functionality (e.g. MAC scheduler).
- There are many benchmarking purposes the latency measurement data can be used for e.g. different equipment (switches, routers) introduce different degrees of delay when processing packets. When moving from physical network elements to virtualized network elements, an operator needs to be able to quantify the latency difference.
- Lab latency measurements can compare the impact of introducing a new network element or configuration (e.g. a new technology like Low Latency DOCSIS) and verify the end user experience prior to deployment.
- Optimizing Network configuration: Appropriate latency measurement techniques can help diagnose intermittent issues (e.g. buffer overflows) and help fix them.
- Now with a goal of identifying per hop latency, operators need to identify the appropriate locations for the measurement end-points: end-device, gateway/CM, CMTS, router, interconnection point, etc.
- Any measurement architecture needs to support frictionless deployment of latency measurement infrastructure. This is dependent on how the specific measurement infrastructure is implemented and deployed (e.g. is it using hardware probes vs virtual probes). Scalability of the measurement platform across an entire operator becomes an important consideration.

## 2.2. Current National Latency Reports

Broadband infrastructure is gaining the attention of various national communications regulators, as countries focus on enabling their people with high speed internet connectivity. As a part of this many of these regulators measure the broadband deployments and report on various metrics such as houses covered, speed tiers available etc. and also conduct network measurements on actual upload and download speeds. Latency measurements are now also becoming an integral part of these reports.

### *2.2.1. Measuring Broadband America*

In the United states, the Federal Communication Commission (FCC) runs the Measuring Broadband America (MBA) program. The MBA program is a nationwide study of consumer broadband performance and it collects network performance data from a representative sample of customers from each of the fixed Internet Service Providers (ISPs). See the paper [MBA FCC] 'Ninth MBA Fixed broadband report', for the latest speed and latency data reported. The MBA tests conducted are automated, direct measurements of the customers service during a single month and is done in collaboration with the measurement company SamKnows. Each volunteer customer connects a 'Whitebox' client device to their home network which performs the tests after finding the nearest test servers.

The MBA program measures latency by measuring the average round-trip time from the consumer's home to the two closest measurement servers, one server chosen from each of two "pools" of servers. The report shows the median latency for each participating ISP and includes aggregated information for each ISP and type of access network. It reports the measured latencies for various DSL, cable and fiber based ISPs on an individual basis as well as aggregated. The MBA program has a limited number of test server

 

locations in each pool. Only six cities host test servers in both pools (an additional four cities host a server in only one pool). This means that client devices that are geographically distant from these six cities will report latency numbers that are more likely to be correlated to geography than to network capability. Difference in geographical distance to the server and also the distance in the of the number of hops internal and external to the ISP network, can make a difference in the number of network links the test packets have to travel across and ultimately the latency measured.

The MBA program latency and packet loss tests measure the round-trip times for approximately 2,000 packets per hour sent at randomly distributed intervals. Per the [MBA FCC] report, the latency and packet loss test records the number of packets sent each hour, the average round trip time and the total number of packets lost (a packet is considered lost if the packet's round-trip latency exceeds 3 seconds). The test computes the summarized minimum, maximum, standard deviation and mean from the lowest 99 percent of results. MBA determines the mean value over all the measurements for each individual's Whitebox and then computes a median value from the set of mean values for all the Whiteboxes.

#### *2.2.2. Measuring Broadband Canada Project*

The Canadian Radio-television and Telecommunications Commission (CRTC) has commissioned a study of the performance of broadband services sold to Canadian consumers. This project measures broadband Internet performance, including actual connection speeds, in Canadian homes. The CRTC collaborated with a number of Canadian Internet service providers (ISPs) and SamKnows, and produced a Measuring Broadband Canada Report, June 2020. See the paper at [MBC CRTC]. The report describes that, unlike in the US MBA program, the latency data was focused on Whiteboxes located within a 150km radius of the test server locations in order to minimize the effect of distance on measurements. See the paper [MBC CRTC] to understand the details on the average latency during peak hours for different Canadian service providers and access networks (Cable, DSL, Fiber) . Like the MBA report, the MBC report [MBC CRTC] also measures packet loss and average webpage loading times from a selection of websites.

#### *2.2.3. EU Broadband Report*

The European Commission has a vision around broadband connectivity and takes policy actions to turn Europe into a 'Gigabit Society' by 2025. In support of that the European Commission has commissioned a study to obtain reliable and accurate statistics of broadband performance across the different EU Member States and other countries.

#### *2.2.4. Speedtest (Ookla)*

Speedtest(Ookla) today publishes [SpeedTest] Market Reports as a guide to the state of fixed broadband and mobile networks around the world. Each report includes mainly speed (downstream and upstream) data and insights about country trends. Speed test data is based on the results of millions of tests run by Speedtest users. An individual user initiated Speedtest uses 'ping' to report the latency to the nearest Speedtest server. Speedtest is very relevant in the latency measurement landscape as that is how the majority of consumers understand what their service speed are and what latencies their connection achieves. Of course, consumers also tend to run Speedtests when they see an issue with the service or when they upgrade or get a new service, so this may also not be a representative sample across the consumers.

 

# 3. Latency Metrics

Each operator needs to track different metrics or KPIs when it comes to network latency. The network latency metrics important to operations teams will be different than what metrics are important to product or regulatory teams. Metrics can also be dependent on where the network is in the product life cycle. There are a variety of latency metrics to choose from and this section describes how to look at and understand latency.

As a packet travels across a network, the packet experiences different types of delays at intermediate hosts, routers, and network links. A host or a router needs time (processing/ switching/ forwarding delay) to process an incoming packet to determine its next hop. The packet also often waits in the transmit queue behind other packets (queuing delay). Transmission delay (serialization/encoding delay) is the time for a node to move out all the bits of the packet onto the link. Finally, it takes time for the packet to propagate over the link from one node to another. End-to-end latency is the sum of such delays at every step of the way.

## 3.1. One-way Latency (or Packet Delay)

One-way latency is the total time it takes for a packet of data to travel from the sender to the receiver, across one or multiple hops. The one-way delay will be dependent on congestion of the network at the time the packet was sent. It will also depend on the topology of the network and the distance and routing decisions between the two end points. Measuring one-way latency also implies that the sender and receiver have synchronized clocks, which sometimes is a challenge to set up and maintain when the end points are across multiple network domains.

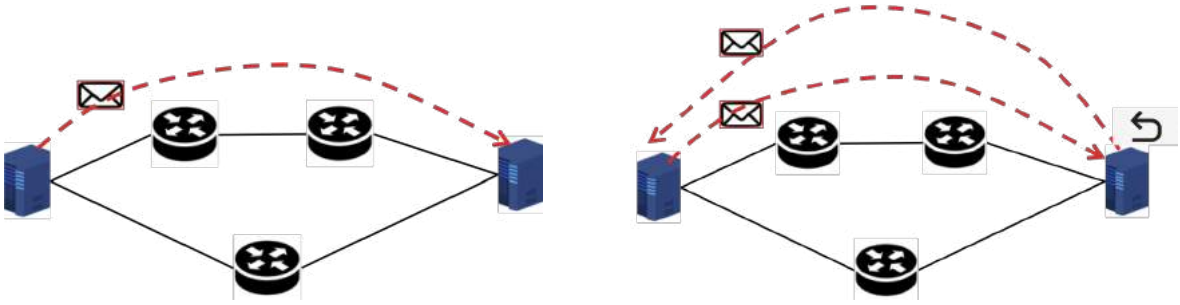

**Figure 2 – One way Latency vs. Round trip Latency**

## 3.2. Round Trip Latency

Round trip time (RTT) or round-trip latency, is the time taken for a packet of information to travel from the sender to the receiver and back again. RTT is the total time it takes for a packet of data to travel from the sender to the receiver, across one or multiple hops, plus the total length of time it takes for receiver to send a packet back to the sender, through one or multiple hops.

The Round-trip latency is more often quoted, as it can be measured from a single point. It requires a process running on the other end to mirror the packet back. The RTT can vary if the return path is different from the forward path. The most common example for round-trip measurements is the ICMP Echo Request/Reply, used by the ping tool.

### 3.3. Singleton Measurements vs Sets of Measurements

A singleton measurement test can send one packet and calculate the one way or round-trip latency of that packet. That is not the most interesting as that is just one sample on the network which is carrying millions of packets. Latency varies with different factors such as the location of the two measurement end-points, and with time (due to changes in route selection or due to congestion). So, most latency measurement tests use multiple packets in a test for one way or round-trip measurements. This gives an operator a sample distribution of latency measurements and paints a better picture of the latency behavior. A test would measure the latency of each of the test packets, and then an operator could understand what the behavior of the network latency is across that set of packets. Having more data samples allows the operator to observe the variations and better understand the network latency in a way that correlates to what the customer will perceive and experience.

Operators typically run each of these tests multiple times a day to get a feel for the network latency variation over time. These sets of measurements could be performed over time for one user, these could be tests done across multiple users or it could be both: tests done over time and for multiple users.

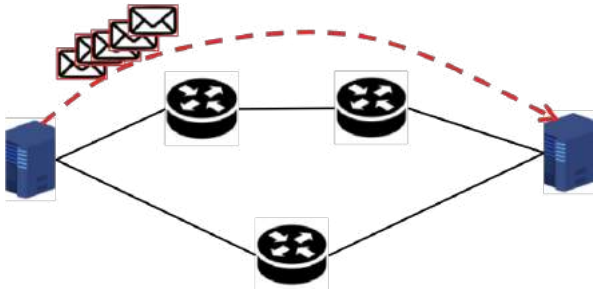

**Figure 3 – Sets of Latency Measurements**

### 3.4. Jitter or Delay Variation

The term ‘jitter’ is a commonly used term to refer to variation in the latency of arriving packets over time. Though prevalent in the networking parlance, the term is considered deprecated by technical bodies like the IETF. The IETF [IETF RFC 5481] now uses the term "delay variation" for metrics that quantify a path's ability to transfer packets with consistent delay. Note that jitter can also be used to convey undesired variation in signals in contexts beyond IP packet transfer. (e.g. frequency or phase variations in electronic circuits in reference to a clock, or sampling jitter in analog-to-digital conversion of signals etc.)

The term jitter can be defined within a specific context in order to provide a meaningful metric for a specific application, or it is sometimes defined simply in a manner that is convenient to calculate. Most real-time voice and video applications employ a (de-jitter) buffer to smooth out delay variation encountered on the path. Many of the commonly used jitter definitions are aimed at helping designers of such systems choose the size of the de-jitter buffer.

[IETF RFC 5481] notes that various standards for delay variation have allowed flexibility to formulate the metric and so the specific formulations of delay variation must be well understood. All definitions of delay variation are derived from the one way or round-trip delay metrics. The networking industry has predominantly implemented two specific formulations of delay variation: Inter-Packet Delay Variation and Packet Delay Variation.

### 3.4.1. Inter-Packet Delay Variation, IPDV

A latency test or application will send a sequence of packets to measure one way or round-trip latencies. Inter packet delay variation (IPDV) is derived from such a sequence of latency measurements. It is simply the difference in latency of each packet as compared to the previous packet.

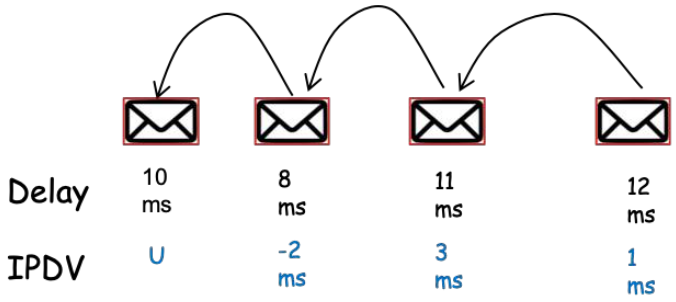

**Figure 4 – IPDV Calculation**

### 3.4.2. Packet delay variation, PDV

Packet Delay Variation, PDV, is also derived from a sequence of latency measurements where a single reference latency is chosen from the stream based on specific criteria. The most common criterion for the reference is the packet with the minimum delay in the sample. Other references such as average latency can be chosen as well. PDV is simply the difference in latency of each packet as compared to the one reference packet. In [ITU-T Y.1540] the ITU also chooses this definition of packet delay variation.

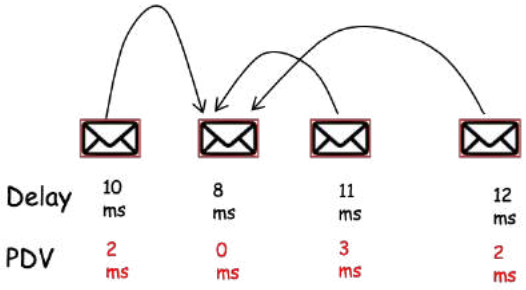

**Figure 5 – PDV Calculation**

### 3.4.3. Jitter Metrics in Use in industry

The formulations described in the previous sections result in a per-packet metric, which (across a set of packets) can then be summarized using descriptive statistics (e.g. mean, median, standard deviation, median absolute deviation, P99, P99.9, etc.) in order to come up with a summary of the delay variation across the set of packets.

There are different ways in which jitter definitions are used in different applications in the industry. [SamKnows], [Haste], [Excentis ByteBlower], [M-lab NDT] and [Network Next] use statistics derived from the PDV definition , while [WTFast], [3rdEchelon], [IETF RFC 3550] and [PingPlotter Pro] use statistics derived from the IPDV definition. The below table describes the way definition each of these entities use and how they aggregate it. As can be seen, there are significant differences in the meaning of the term from one entity to another.

**Table 1 – Jitter definitions in the Industry**

| Entity | Parameter | Definition |
|---|---|---|
| **PDV** based | | |
| SamKnows<br>*(Network performance measurement platform)* | Jitter | P99 PDV<br>(PDV referenced against min latency) |
| Excentis<br>*(Byteblower traffic generator)* | Jitter | Standard deviation of PDV |
| Haste<br>*(Optimized routing for game traffic)* | Jitter | Standard deviation of PDV |
| Network Next<br>*(Optimized routing for online games)* | Jitter | jitter = 3* RMS(PDV)<br>(PDV referenced against min latency) |
| MLab NDT<br>*(Network test)* | Jitter (round trip time variation) | max(PDV)<br>(PDV referenced against min latency) |
| **IPDV** based | | |
| RTP protocol<br>*(RFC3550)* | Interarrival jitter | Exponentially-weighted moving average of the absolute value of IPDV |
| PingPlotter Pro<br>*(Ping statistics tool)* | Jitter | Average of the absolute value of IPDV |
| 3rdEchelon<br>*(Internet Services company)* | Jitter | Average of the absolute value of IPDV |
| WTFast<br>*(Gaming VPN solutions)* | Jitter | Average of the absolute value of IPDV |

### 3.5. Descriptive statistics

Once we have a set of measurements (each of which is an individual latency measurement), a network operator wants to easily aggregate and make sense of those sets of measurements across the whole network and over time. The question is how best an operator can analyze the data to guarantee that the latency meets service requirements.

#### *3.5.1. Basic statistics*

Many operators start with basic statistics like mean, median or min-max. Each of these numbers have their place, but for large populations of data they often hide the actual network behavior. Mean and median tend to hide outliers, especially the high latency events which may happen only during specific times. In contrast, the maximum is overly conservative and is easily distorted by a single outlier event.

- Average: The arithmetic mean or average, is the simply the sum of the set of the latency measurements divided by the number of measurements. The set of results of each experiment or an observational study can yield its own average number. For latency measurements, though the average maybe a starting point, it hides a lot of the variation in latency. Some of the much higher excursions are diluted by the mean, and thus averages hide high latency events which would ultimately impact the customer experience. Outliers also skew averages, so the average doesn't represent typical behavior either.
- Min/ Max: The maximum and minimum of a set of measurements are the largest and smallest value in the set of measurements. These are useful to understand the limits of the network. In the context of latency measurements one can separate lost packets as a separate measure, instead of considering it as infinite latency.

 

- Standard Deviation: The Standard Deviation is a measure of how spread out the latency measurement numbers are. The standard deviation is calculated as the square root of the variance (average of the squared differences from the Mean, for each sample). This gives a measure of the amount of variation or dispersion of a set of latency values. A low standard deviation indicates that the values tend to be close to the mean of the set, while a high standard deviation indicates that the values are spread out over a wider range.

### *3.5.2. Percentile Numbers*

Many descriptive statistics like mean, standard deviation, and skew are most meaningful when the underlying data follows a roughly normal (Gaussian) distribution. In contrast, even simple latency distributions are often heavily skewed with a set of values around a certain range, and with many fluctuations and outliers. As a result, these traditional statistics offer very little value in capturing or describing latency, but percentiles can generally be much more effective.

Percentiles allow a better understanding of the latency distributions than averages. A percentile is a value below which are a certain percentage of observations. Percentiles show the point at which a certain percentage of observed values occur. For example, the 95$^{th}$ percentile is the value which is just greater than 95% of the observed values, i.e. 95 percent of packets got a lower latency than the P95 value. For example, to obtain the 99$^{th}$ percentile of a collection of latency measurements from a network, an operator can sort them and discard the highest 1% of values. The largest remaining value is the 99$^{th}$ percentile. This value is the largest latency that will be seen for 99% of the measurements. An operator can choose a measure like the 90$^{th}$, 95$^{th}$, 99.9$^{th}$ (or even more nines) percentiles, which are typically denoted as P90, P95, P99 etc.

Network latencies between machines can be low when the network path is idle, but when there is significant network activity packets can take anywhere from a few milliseconds to hundreds of milliseconds, or even seconds. Since many network segments (particularly broadband links) are idle, or nearly so, for a significant portion of the day, the median latency and the minimum latency are often pretty close to one another. Long tail latencies occur when the higher percentiles begin to have values that are many times greater than the median. In a long tail latency distribution, the 99$^{th}$ percentile can be fifty times greater than the median value, much beyond normal distributions.

Percentiles are often used to find outliers. When a range of percentiles are computed one can estimate the data distribution more accurately. Another use for latency percentiles is to implement a threshold beyond which issues are flagged to the operator. An operator could also track a combination of a few different percentiles, such as P50, P75, P95, P99 and flag issues when any of them change significantly with respect to previous measurements or thresholds.

Now the question is which latency response time metric is more representative of the user experience. Is it the 95$^{th}$ percentile or the 99.9$^{th}$ percentile? The below table tries to show how to think about the impact to an application like gaming. Gaming traffic flows are typically 60 packets per second at a rate of 100kbps-200kbps in the upstream direction and 60 packets per second at a rate of 500kbps-1Mbps on the downstream. Gaming clients or servers expect packets to arrive at that consistent rate of 60 times per second and any packets which arrive with a much higher latency cannot be used and are essentially thrown away. As an example, 99% of the gaming packets have a latency of 40ms or less, while 1% of packets are delayed for anywhere from 100ms to 500ms. For or a real-time game this 1% ‘latency event’ happens (on average) once every 1.6 seconds and such network behavior is unwelcome in gaming environment and may be a showstopper in other applications. Based on this view, perhaps the P99.9 value would be a good starting point to represent user experience for online gaming.

 

**Table 2 – Understanding Latency Percentiles**

| Notation | Percentile Latency | Meaning | Implication | Impact for a gaming application |
|---|---|---|---|---|
| P50 | 50th percentile - median latency | 50% of packets got this latency or better | 50 of 100 of packets got worse than this latency | Every other packet! |
| P90 | 90th percentile | 90% of packets got this latency or better | 10 of 100 packets got worse than this latency | 6 packets a second |
| P95 | 95th percentile | 95% of packets got this latency or better | 5 out of 100 packets got worse than this latency | 3 packets a second |
| P99 | 99th percentile | 99% of packets got this latency or better | 1 of 100 packets got worse than this latency | 1 packet every 1.6 seconds |
| P99.9 | 99.9th percentile | 99.9% of packets got this latency or better | 1 of 1000 packets got worse than this latency | 1 packet every 16.6 seconds |
| P99.99 | 99.99th percentile | 99.99% of packets got this latency or better | 1 of 10,000 packets got worse than this latency | 1 packet every 2 mins 46 seconds |

### 3.6. Histograms

A histogram is a graphical method for displaying the shape of a distribution and is particularly useful when there are a large number of observations. To construct a histogram, the range of values observed in the measurement is divided into a series of intervals or bins. The measurements are then classified into bins counting how many values fall into each interval. The bins are usually specified as consecutive, non-overlapping intervals of a variable. The bins/intervals are contiguous and are often of equal size.

The goal is to collect enough data points for good latency characterization. This means an operator needs to collect data to obtain acceptable precision for different percentile levels. A simple process in latency measurement is to record all the latency data over multiple sets of tests and then later analyze and sort the data into traditional histograms to get the required percentile data. Some alternatives to the traditional histograms with linear bins are logarithmic bins, or arbitrary bins. Linear bins in histograms require lots of storage to cover the range with good resolution, while logarithmic covers wide range of values but does not have good precision. Arbitrary bins work only when the operator already has a good feel for the interesting parts of the data range.

### 3.7. Visualization of Latency

Data visualization can reveal patterns and trends in the data, allows quick absorption of large amounts of data by network operators, and ultimately lets the operator understand the information and make decisions. This section describes some of the ways an operator can visualize latency data.

#### *3.7.1. Time series*

A time series is a set of observations ($x_t$) ordered in time, observed at a discrete set of (approximately) evenly spaced time intervals: at times t =1,2,..., N , where N is the length of the time series. The figure below, created using [PingPlotter Pro], shows a time series of ping data, once every second for 10 minutes. While the average ping time is ~12ms, one can quickly see that it is not the normal case and there are many latencies of 15-20ms and occasionally even up to 25 to 30ms.

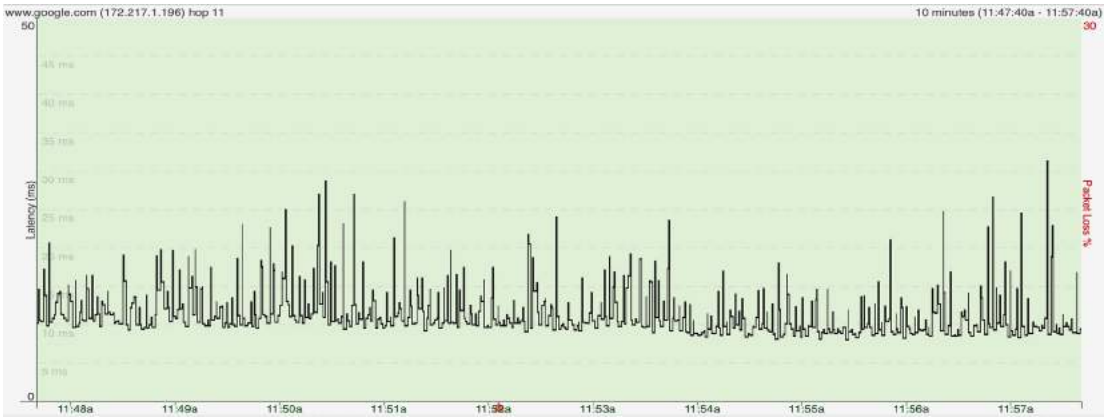

**Figure 6 – Example time series of Latency Measurement**

### *3.7.2. Probability density function (PDF)*

A Probability Density Function (PDF) is a statistical expression used in probability theory as a way of representing the range of possible values of a continuous random variable. For a continuous function, the probability density function (pdf) is the probability that the variable has the value x. The area under the curve represents the probability that variable will fall within an interval; and is expressed in terms of an integral between two points. $Pr[a \leq X \leq b] = {}_a\int^b f_X(x)dx$

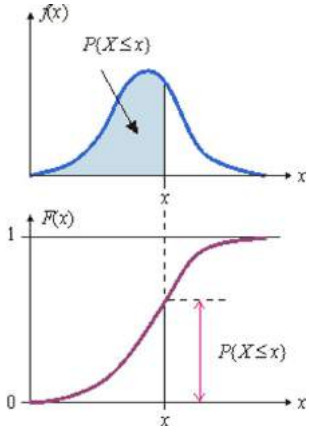

**Figure 7 - PDF-CDF relationship**

### *3.7.3. Cumulative Distribution Function, CDF*

The cumulative distribution function (CDF) of a random variable is another method to describe the distribution of random variables. A cumulative distribution function describes probability that a random variable takes on a value less than or equal to x. That is $Pr[X \leq x] = F_X(x)$

### *3.7.4. Complementary cumulative distribution function, CCDF*

A complementary cumulative distribution function, answers the opposite question, i.e. how often is the random variable above a particular level x. To obtain the Cumulative Distribution Function (CDF), the integral of the PDF is computed. Then inverting the CDF results in the CCDF. (CCDF is the complement of the CDF or CCDF = 1 – CDF.) One can also plot the CCDF in a logarithmic scale so that the more interesting percentile values are easily discernible.

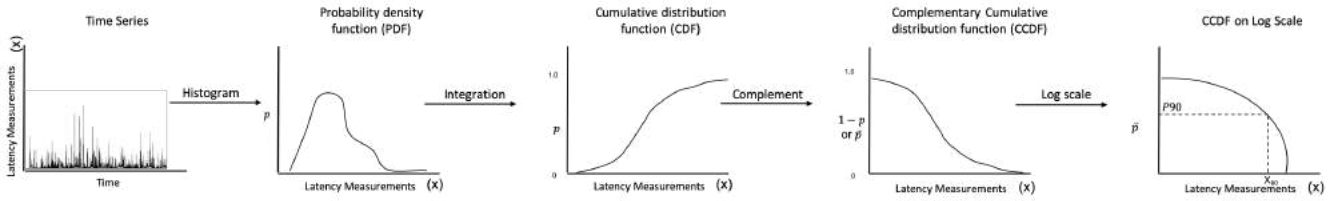

**Figure 8 – Conversion from Time Series to PDF to CDF to CCDF to Logarithmic-CCDF**

### *3.7.5. Example PDF/CDF/CCDF*

Below is an example of some latency measurements performed in the lab, of round-trip times from a client to a server, which are separated by a Wi-Fi link and a DOCSIS link (CM and CMTS) with a pseudo Low Latency DOCSIS configuration. The time series figure below shows the latency measurements of unmarked traffic (in blue), while the latency of DSCP marked traffic is shown in orange. It also shows the various latency and jitter metrics of the unmarked traffic and how varied the numbers can be.

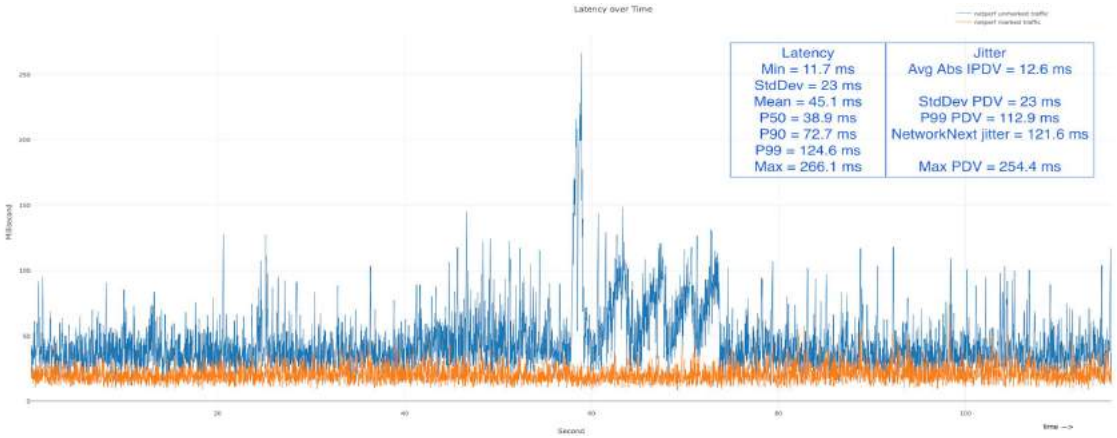

**Figure 9 –Time series latency data of Marked vs unmarked traffic**

The PDF figure below shows (using a histogram of 1ms bins) how different the two sets of latency measurements are, with the marked traffic flow(orange) having a lower and tighter latency numbers, while the unmarked traffic(blue) has latencies extending all the way from 100ms to 260ms.

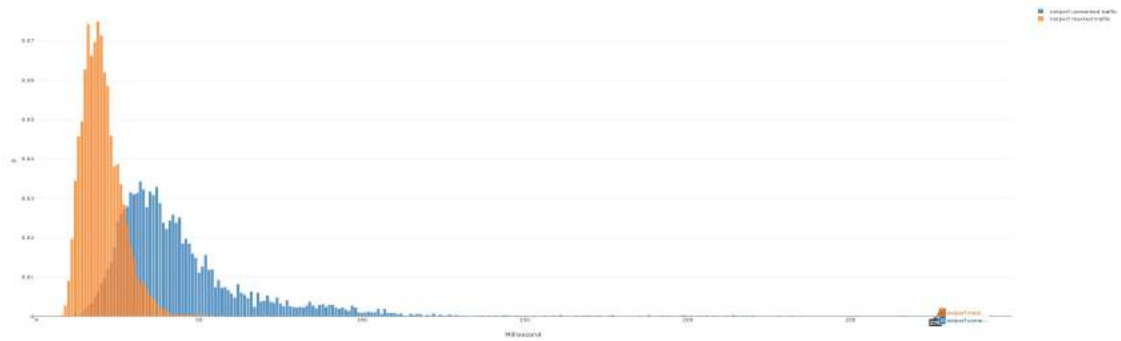

**Figure 10 – Probability Distribution Function (PDF)**

The Cumulative Distribution function (CDF) figure below for the same data set, show the marked traffic flow(orange) having a lower P99 ( ~38ms), while the unmarked traffic has a higher P99 (~125 ms).

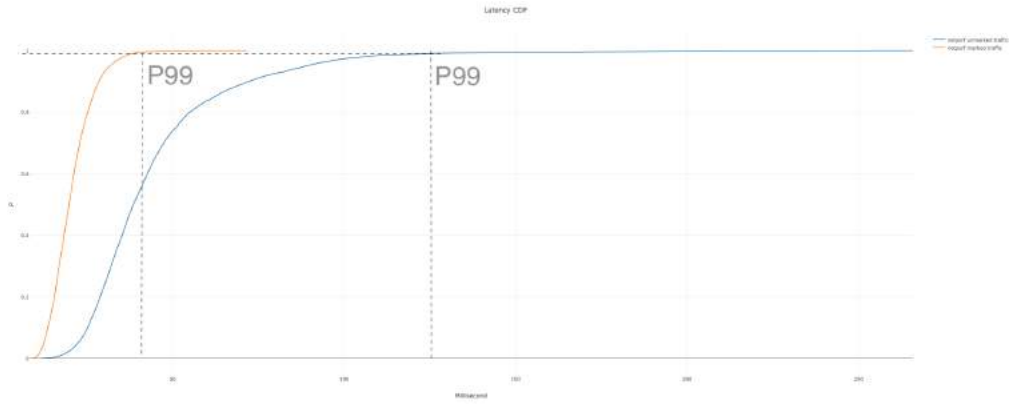

**Figure 11 – Cumulative Distribution Function (CDF)**

The CCDF figure below for the same data set, is essentially the same graph but inverted, with P99 readings closer to the bottom of the graph compared to the top.

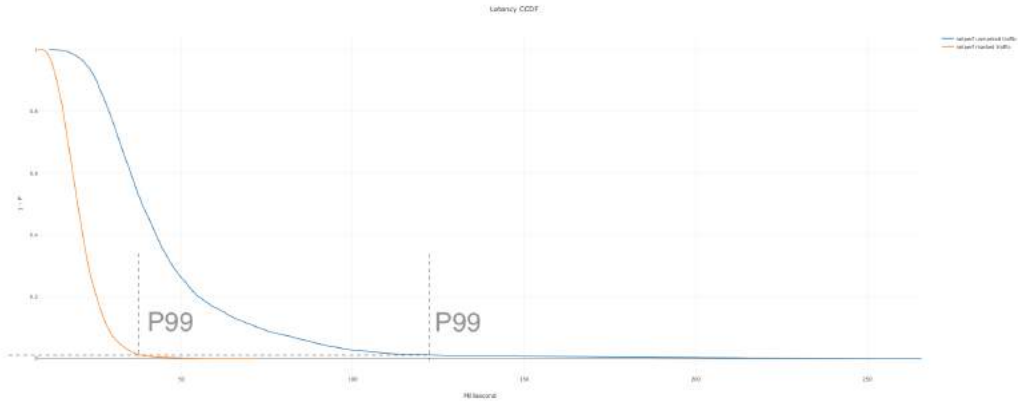

**Figure 12 – Complementary Cumulative Distribution Function (CCDF)**

The logarithmic CCDF figure, is the same CCDF graph but drawn on a logarithmic scale for both axes. Here we can compare the P90, P99 or P99.9 and see the differences in the percentiles we are interested in clearly at this scale.

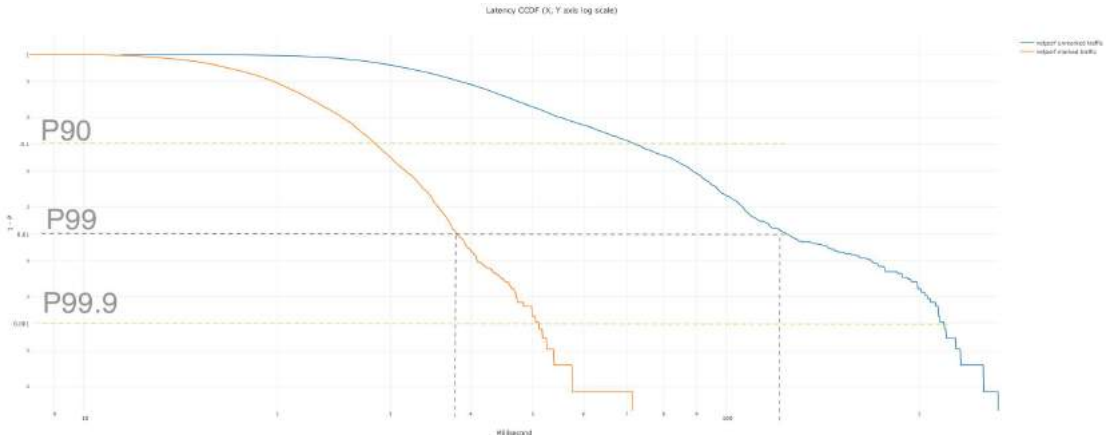

**Figure 13 – CCDF on a Logarithmic scale**

# 4. Latency Measurement architectures

## 4.1. Types of measurement

### *4.1.1. Active measurements*

Active measurements are conducted by generating traffic between two end points for the sole purpose of measuring the latency. For example, with ICMP ping a sender sends an ICMP packet(s) to the receiver, who replies back; the sender calculates the time between sending and receiving the packet(s). The measurement is considered to be active, as the reason the traffic is created and sent is to measure the latency between the end points.

Active monitoring involves injecting test traffic into the network, typically with the same forwarding criteria as the user traffic being monitored, and then measuring its performance. These tests can either be one-way (from site 'A' to site 'D' or round trip (from site 'A' to site 'D' and back to site 'A'), depending on what the operator wants to measure. Since the test traffic mimics the user traffic, active testing gives a packet by packet view of the end-to-end performance of a network with regards to such things as latency, delay variation, or packet loss.

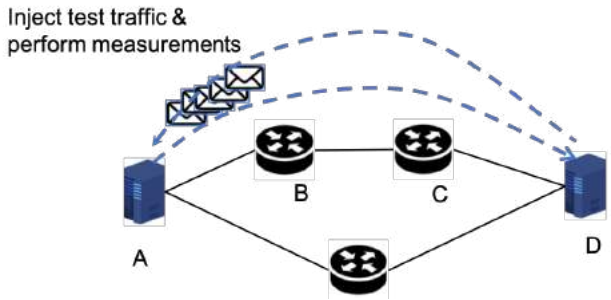

**Figure 14 – Active Measurements**

Active testing can be performed between successively longer paths along the network route, for example, from site 'A' to site 'B' or site 'A' to site 'C'. With this the operator can segment the overall end-to-end path so that performance indicators can be derived on a per segment basis, giving visibility into where issues might be located. Active monitoring is the primary method for policing service level agreements, since it provides a real-time view of performance. Active monitoring requires two end points to be able to create test traffic and respond back to complete the measurement

### *4.1.2. Passive measurements*

Passive measurements are done simply by observing normal host-host interactions. Instead of measuring the latency of specially created test packets like in active measurements, passive measurements are based on the normal user packets that traverse the network. Passive measurements observe the traffic exchanged between two end-points and calculates the latency based on observed activity. For example, during normal interactions between host A and D, say during the initial handshake, a packet sent from A to D would be immediately responded by D as per the normal protocol interaction. If this transaction can be observed say at a location B, one can measure the time between sending the packet and receiving the response. Passive methods obtain similar measurements as an active measurement, without creating any new test traffic in the network, but are reliant on the presence of user traffic and can thus be skewed (for better or for worse) toward periods of time when more such traffic is present. Passive monitoring involves

capturing and analyzing live network traffic, or traffic statistics, at a specific point in the network, for example at the network interface to an application server, or at an aggregation router.

Passive monitoring does not require another host in the network to be involved in the process. Passive monitoring involves capturing some, or all, of the traffic flowing through a port for detailed, offline analysis of things like signaling protocols, application usage or top bandwidth consumers. Passive monitoring is suited for in depth traffic and protocol analysis, and can give visibility into the customers actual quality of experience.

#### *4.1.2.1. TCP Analysis*

Analyzing the delay experienced by the TCP connection setup packets is an example of passive measurements. TCP uses a three-way handshake to establish a reliable connection. The TCP connection setup consists of a handshake with SYN, SYN+ACK, and ACK packets. The idea is to examine the data for outgoing connections, and compute the round- trip delay between the SYN & SYN+ACK packets as well as the SYN+ACK & ACK packet in the handshake. Since TCP connection endpoints normally respond immediately this is an easy way to compute the round-trip times.

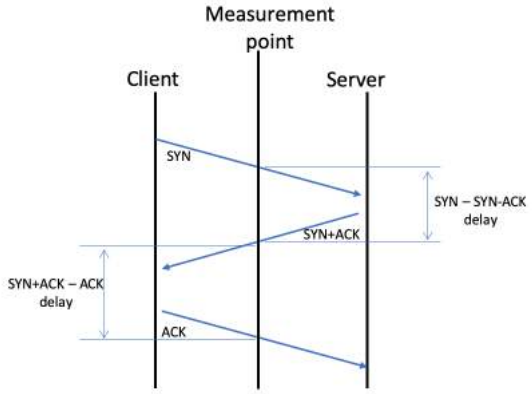

**Figure 15 – Using the TCP handshake to measure latency**

### 4.2. Industry measurement architectures

This section describes some of the commonly used measurement architectures.

#### *4.2.1. SamKnows Whitebox (dedicated test device solution)*

SamKnows has developed a “Whitebox”, a dedicated device with a test suite, for measuring internet performance. These Whiteboxes are used by service providers, government regulators etc. and the tests can also be incorporated into network devices like modems or routers. The [SamKnows] test methodology includes many aspects of measuring consumer broadband performance: providing consumer volunteers with the Whiteboxes to run tests on consumer internet connections, the mechanism for collecting and aggregating the data, and finally the format for presenting the data.

The following describes the overall latency measurement methodology followed by SamKnows Whiteboxes. As described in [SamKnows] literature, upon start up, the Whitebox runs a brief latency measurement to all measurement servers hosted by an operator, or hosted by Samknows on their behalf. The server with the lowest round-trip latency is selected as the target for all subsequent measurements.

Below are some of the latency specific tests that the SamKnows Whitebox, or routers with the test functionality can run, as described in the [SamKnows] documentation.

- Latency and packet loss (UDP): This test measures RTT of small UDP packets between the Whitebox and a target test server. Each packet consists of an 8-byte sequence number and an 8-byte timestamp. The test operates continuously in the background and randomly distributes the sending of the packets over a fixed interval, typically 2000 samples per hour. It then records the number of packets sent, the average round trip time of these and the total number of packets lost. The test uses the 99$^{th}$ percentile when calculating the summarized minimum, maximum and average results on each Whitebox.
- Contiguous packet loss / disconnections (UDP): This test records instances when two or more consecutive packets are lost to the same test server. Alongside each event it records the timestamp, the number of packets lost and the duration of the event. By executing the test against multiple diverse servers, an operator can begin to observe server outages or and disconnections of the user's home connection.
- Latency, jitter and packet loss (Fixed rate UDP test): This test uses a fixed-rate stream of UDP traffic, a bi-directional 64kbps stream (representative of the G.711 voice codec), running between the client and test nodes. The standard configuration uses 500 packets upstream and 500 packets downstream. The server and client record the loss rate and the jitter observed. Jitter is calculated using the PDV approach described in [IETF RFC5481]. The 99$^{th}$ percentile is recorded and used in all calculations when deriving the PDV.
- Latency and packet loss (ICMP): This test measures the mean round trip time (RTT) of ICMP echo requests in microseconds from the Whitebox to a target test node.

#### *4.2.2. The M-Lab NDT (User initiated)*

M-Lab is a consortium of research, industry, and public-interest partners, and provides an ecosystem for the open, verifiable measurement of global network performance. All of the data collected by M-Lab's global measurement platform are made openly available, and all of the measurement tools hosted by M-Lab are open source.

M-Lab defines a test suite known as Network Diagnostic Tool (NDT), which is a single stream performance measurement of a connection's capacity for bulk transport (as defined in IETF's RFC 3148). NDT reports upload and download speeds, and latency metrics. The M-Lab NDT is run by users to test their internet connections. As described in [M-lab NDT], when the test is run, the client attempts to pick the nearest server from the geographically distributed network of servers provided by the M-Lab platform. The test suite uses a 10-second bulk transfer from the server to the client. The server is instrumented with the TCP kernel instrumentation and captures several variables of the TCP state machine every 5 ms of the test. NDT uses the TCP RTT samples as the latency data points and reports the difference between the minimum and maximum RTT observed during a test run.

#### *4.2.3. TWAMP*

Two-way measurements are common in IP networks, primarily because synchronization between local and remote clocks is unnecessary for round-trip delay, and measurement support at the remote end may be limited to a simple echo function. [IETF RFC 5357] specifies the Two-Way Active Measurement Protocol (TWAMP), which provides a common protocol for measuring two-way or round-trip measurement between network devices.

The [IETF RFC 5357] TWAMP defines a standard for measuring round-trip network performance between any two devices that support the TWAMP protocols. TWAMP consists of two inter-related protocols: TWAMP-Control and TWAMP-Test. The TWAMP-Control protocol is used to set up performance measurement sessions, i.e. to initiate, start, and stop test sessions. The TWAMP-Test protocol is used to send and receive performance-measurement probes i.e. exchange test packets between two TWAMP entities. The TWAMP measurement architecture is usually comprised of two hosts with specific roles, shown below. The first host (controller) consists of the control-client which sets up, starts, and stops TWAMP-Test sessions, and the session-sender which instantiates TWAMP-Test packets that are sent to the session-reflector. At the second host (responder) the session-reflector reflects the measurement packet upon receiving the TWAMP-Test packet. The responder can also have the TWAMP server that manages one or more TWAMP sessions.

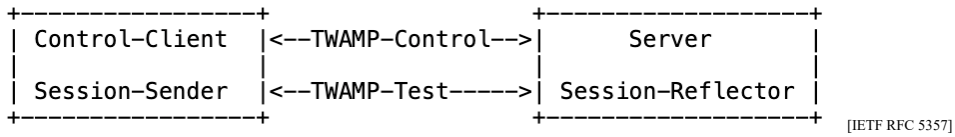

**Figure 16 – TWAMP reference Model**

TWAMP Light is an alternative architecture which eliminates the need for the TWAMP-Control protocol and assumes that the Session-Reflector is configured and communicates its configuration with the Server through non-standard means. The Session-Reflector simply reflects the incoming packets back to the controller while copying the necessary information and generating sequence number and timestamp values. In TWAMP light, the roles of Control-Client, Server, and Session-Sender are implemented in one host (the controller), and the role of Session-Reflector is implemented in another host (the responder).

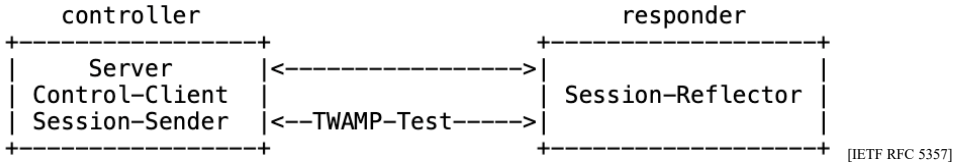

**Figure 17 – TWAMP Light reference Model**

TWAMP is more accurate than simple ping or traceroute measurements and is used by many operators in their transport, core and access networks. Several independent implementations of both TWAMP and TWAMP Light [IETF RFC5357] have been developed, deployed, and provide important operational performance measurements.

TWAMP is implemented in many of the core router products. TWAMP can provide accurate latency, jitter & packet drop KPIs, is supported by many probe vendors, and it can be integrated into network node equipment elements and CPE.

#### *4.2.4. Simple Two-Way Active Measurement Protocol*

Simple Two-way Active Measurement Protocol (STAMP), is a newer IETF standard [IETF RFC 8762] which provides a simpler mechanism for active performance monitoring. It separates the control functions (vendor-specific configuration or orchestration) and test functions. STAMP also enables the measurement of both one-way and round-trip metrics (delay, delay variation, and packet loss)

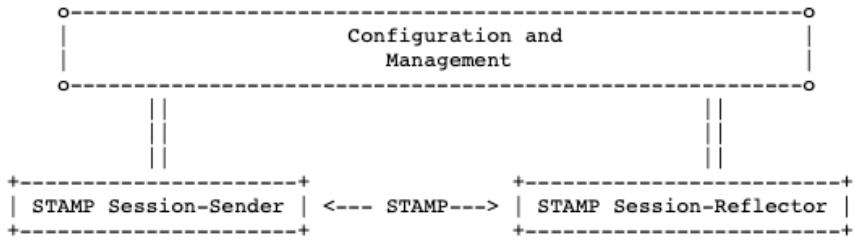

**Figure 18 – STAMP reference Model**

## 4.3. Measurement considerations

### *4.3.1. Measurement under load vs quiet times*

Latency measurement tests need to ensure that testing is done over a variety of times to understand the variation between when the network is relatively lightly loaded and peak load time. This can also be used to measure self-congestion vs. network-congestion. For example, measuring latencies at peak time in the evening when most of the subscribers on the plant are online is likely to catch incidents when the network is congested due to high overall network load. Another way latency numbers can be affected is the load within a single user's home itself or even within the same client. If multiple devices in the home are using the network for various purposes like consuming video, voice calls, gaming, then a latency measurement will likely yield different numbers than running the test at quiet times. The path to various servers can change automatically to accommodate network/routing changes, so measured latency may vary over time and it may be appropriate to get a broad picture of latency including such situations.

### *4.3.2. Window over which the measurement is done.*

Every latency measurement test can have a different purpose; one could be for a quick and immediate diagnostic purpose, while another could be to gather long term statistics. To diagnose issues in the network, an operator will need to consider the correct amount of time to run a test, how many latency samples will be collected in each run, and how often the test will be run. This could include sample rates of once per hour, once per minute, once per second, and as frequently as 50 times per second. The sampling rate and the number of measurements run will depend on the ultimate goal of the operator. If the goal is to reflect the worst gaming experience, then more measurements which mimic the game traffic flows will give us a better idea of the performance of the network.

To understand latency, one has to consider the entire distribution of latency measurements. While it is important for operators to look at latency numbers at the 99.9$^{th}$ percentile or higher, many monitoring systems stop at the 90$^{th}$ or 95$^{th}$ percentile. The reason is simply because it requires larger amounts of data to be collected, stored and analyzed. The data collected by most monitoring systems is usually summarized in small, five or ten second windows. Given we can't meaningfully average percentiles or derive five nines from a collection of small samples of percentiles, there is no way to confidently know what the 99.99$^{th}$ percentile for the minute or hour was. A related question is how many total samples are needed to get valid statistics. If an operator wants to measure the 99.9$^{th}$ percentile latency, then at least 1000 latency measurements are required, and a lot more (at least 2000-8000) would be needed to have an accurate statistical estimate.

 

### 4.3.3. Off-net and On-net testing

Active measurement architectures (e.g. SamKnows) may use client devices which run bandwidth and latency tests to a specific measurement server. A majority of test servers used by SamKnows customers are off-net, i.e. hosted on the internet outside the operator network. Reporting results to target servers off an ISP's own network represents a 'real world' experience for end users. However, an ISP is not in control of the paths that get to the server and would also like to understand and debug issues within their own network. Hence many ISPs install test servers inside their network ("on-net") to allow them to segregate on-net and off-net performance.

With both on-net and off-net servers in use, operators can see the difference in performance internal to their network vs. external to it. The results can be used to troubleshoot peering links, routing issues, or simply rule out any capacity problems within the operator's own network. Consequently, any active measurement deployment should have a mix of on-net and off-net servers.

### 4.3.4. Latency Measurement Test definitions

When designing latency measurement tests, an operator needs to define the test and the associated parameters such as the test traffic flow (i.e. the packet size and rate used), whether to test under load or without load, and the periodicity of the measurements.

Many IP network switches and routers need the full packet to be clocked into the device before it can be forwarded to the next networking device in the path to the end destination. This delay is referred to as a serialization delay and these delays are often tested using 64-byte packets. For example, a 64-byte packet will have serialization delays of 5.12 μsec when clocked in using a 100 Mbps port. However, serialization delays are usually proportional to the size of the packet. If the size of the packet was 1280 bytes, the serialization delays would be twenty times bigger at 102.4 microseconds. Though this doesn't include the processing delays through a device (router, switch, CMTS, CM), it gives a sense of the interaction between packet size and link speed (interface bandwidth) that each node in the network could add as an absolute minimum

Small (say 64 byte) UDP packets sent every few seconds from a test node is a good place to start for RTT measurements. Latency Tests which mimic the gaming experience, (e.g. 150 Kbps upstream, 600 Kbps downstream, ~200-byte packets) would be a good data set to collect to understand the impact to gaming or other real-time audio-conferencing services. Latency tests with bigger size packets (1500 bytes) could also be used to expose any packet size limitations in the network.

When testing latency, it is also a good idea to understand the latency when the network is under load vs. when it is not. Latency testing with load is typically done by running both a downstream and upstream speed test or something equivalent at the same time as doing latency measurements. While the speed test is running, the latency under load test can send packets to a target server and measures the round-trip time and number of packets lost. The test packets should be sent equally spaced over the duration of the speed test.

### 4.3.5. Marked traffic vs Unmarked traffic.

Differentiated services or DiffServ [IETF RFC 2474] specifies a simple mechanism for classifying and managing network traffic and providing quality of service (QoS) on modern IP networks. DiffServ can, for example, be used to provide low-latency to critical network traffic such as voice or streaming media while providing simple best-effort service to non-critical services such as web traffic or file transfers.

 

The six most significant bits of the DiffServ field (previously 'type of service' (TOS) field) in the IP header are called as the DSCP (differentiated services Code point) and the last two bits are the Explicit Congestion Notification (ECN) field. Routers at the edge of the network classify packets and mark them with their DSCP value in a Diffserv network. Other network devices in the core that support Diffserv use the DSCP value in the IP header to select a per hop behavior for the packet and provide the appropriate QoS treatment. Various applications and services (typically UDP based) can also mark the traffic they generate with specific DSCP values. For example, the popular video conferencing application Zoom uses a default DSCP marking values of 56 for audio, 40 for video, and 40 for signaling.

In the Low Latency DOCSIS technology, by default, the traffic within an Aggregate Service Flow is segmented into the two constituent Service Flows by a set of packet classifiers that examine the DSCP field and the ECN field. Specifically, packets with a Non-Queue Building DiffServ value, 0x2A, per a current [IETF NQB PHB] draft, will get mapped to the Low Latency Service Flow, and the rest of the traffic will get mapped to the Classic Service Flow.

In the context of Low Latency DOCSIS and other technologies which support dual queue mechanisms, the question is how can we modify latency measurement tests to also report metrics on unmarked traffic as well as marked traffic. One solution is to run any test twice, once as currently designed without any packet marking, and once with marked DSCP packets, and report results on both. As more games and other applications start marking their packets, public internet measurement reports will also have to start reporting latencies on both types of traffic.

## 5. Conclusion

Interactive applications like gaming or real-time communication, where real-time responsiveness is required, are more sensitive to latency than bandwidth. These applications really stand to benefit from technology that can deliver consistent low latency. Operators need to understand the latency characteristics of their network and be able to delineate the latencies seen in the customer home, the access network, and the MSO-core network. Using a common set of metrics to describe latency is the first step in understanding the state of the networks. Round trip times are relatively easy to collect compared to one-way latencies. Multiple sets of measurements paint a better picture of the latency characteristics than single measurement. Using averages to measure latencies can be misleading, so an operator can choose better performance indicators such as the $99^{th}$ or $99.9^{th}$ percentile to track and understand latency behavior over time. Latency is being measured by national entities, raising the importance of operators to have their own latency measurement infrastructures. Active measurement techniques give an operator good control over the testing and a better understanding of the network over various times and conditions.

# Abbreviations

| | |
|---|---|
| bps | bits per second |
| ms | millisecond |
| RTT | Round trip time |

# 1. Introduction

In the last several years progress toward securing Internet of Things (IoT) devices has been made on several fronts. There are now mature specifications for IoT devices that require with encryption, authentication and authorization for every device (1). Governments and industry have released baselines (2), (3), (4) that provide guidance on what should constitute a secure device. There is even recent legislation at the state level aimed at enforcing security in IoT (5).

None of this will guarantee secure devices. There will *always* be devices that are exposed, unpatched and vulnerable. Even companies and manufacturers that prioritize security will inevitably find themselves with vulnerabilities inherited in the supply chain from decades old code like Ripple20 (6). Combine this with malware like Mirai that is constantly being updated to take advantage of these newly discovered vulnerabilities (7) and it becomes clear that building strong security into individual devices is simply not enough. The question that now needs to be answered is, can secure systems be built from networks of potentially insecure devices?

The question posed above is not a mere hypothetical one. Today's subscriber networks consist of not just a heterogenous mix of devices, but also the implicit mix of vulnerabilities and attack surfaces inherent in today's complex home networks. To address this problem in a comprehensive and systematic way, intelligence must be added to the network so as to give the network the ability to know the devices running on it, learn how those devices behave and be capable of actively and surgically blocking traffic that is outside the bounds of what is deemed normal.

This research presents a method whereby a centralized router/gateway can learn a device's behavior on the network and based on that behavior, determine normal and abnormal behavior from that device. The model presented in this paper takes advantage of the predictability of an IoT device's network footprint by developing a formalized measurement of complexity for each device. Low complex and simple devices are more accurately modeled and thus can be more confidently managed autonomously by the network.

After describing the framework necessary to measure the complexity of network devices, this work then uses this complexity measure to inform and tune an anomaly detection algorithm to construct a behavioral model for each device. This tuned model represents the behavior footprint of each device learned from its network traffic and forms the basis for differentiating normal traffic from abnormal.

To demonstrate the efficacy of this model, this work analyzes boundary of each device's learned behavior against seven common types of malware traffic from infected IoT devices. Finally, to illustrate that the model can be effectively applied to a broad spectrum of devices, four different IoT datasets were analyzed: one residential dataset, two lab datasets, and a dataset based on commercial IoT devices. The results show that this model can be an effective way to actively block Distributed Denial of Service (DDoS) attacks and malware traffic especially on low complex devices.

# 2. Background

There has been a great deal of research in the past few years to grant the network with the capability to learn what devices are running on it, (8) and how to automatically block devices from contributing in DDoS attacks. The majority of recent academic research in IoT behavior and fingerprinting relies on various machine learning (ML) techniques. The ML techniques can be broadly categorized into two main groups, supervised and unsupervised.

## 2.1. Supervised

Supervised learning requires a large corpus of labeled data. The work that takes advantage of supervised learning typically tries to classify a device on the network based on previous traffic that has been labeled as that same device.

Loepz-Martin et al. (9) build a network traffic classifier (NTC) using a recurrent neural network (RNN) and apply it to labeled IoT traffic. The goal of this is to identify the types of traffic and services exhibited by an IoT device as a step toward identifying the device.

Miettinen et al. (10) have developed a method, called IoT Sentinel, that uses machine learning to designate a device type on the network, referred to by the authors as a device fingerprint. Using the random forest algorithm and 23 network features they were able to identify device types on the network based on the device's traffic. The 23 features are based on layer two, three and four of the OSI networking stack. Expecting that the body of the packet will be encrypted, all the features the authors employed are based on unencrypted parts of the traffic like IP headers information.

Bezawada et al. (8) build on the work done in Miettinin using a machine learning approach to broadly identify the device and place it in a predefined category, such as a light bulb. According to the authors, even devices from different manufacturers can be placed into general categories such as two separate light bulbs can be identified and placed into a lighting category and addressed by security policies based on this category.

Supervised methods are generally highly accurate but require large examples of labeled traffic to adequately learn. These methods generally cannot classify things that were not present in the learning dataset and are unable to classify new or unknown devices.

## 2.2. Unsupervised

Unsupervised learning does not need data with labels and instead tries to learn underlying patterns in the data itself. It has various advantages in the context of IoT security as there will often not be labeled data available and there will always be new devices for which there exists no labeled data.

AuDI (11) implemented an autonomous device-type identification that uses the periodicity of device communications resulting in abstract device categories that could be used to enforce access control policies. DioT (12) extends the AuDI classification model to create a federated approach by aggregating device anomaly detection profiles.

Ortiz et al. (13) set up a probabilistic framework to monitor device behavior using a Long-Term Short-Term Memory (LSTM) neural network, to learn from inherent sequencing of TCP flows to automatically learn features from device traffic with the intent of categorizing devices and distinguishing between IoT devices and Non-IoT devices. The authors are able to identify previously known devices after only 18 TCP-flow samples and categorize devices into two classes IoT and Non-IoT

# 3. Methodology

## 3.1. Data-Sets and Data Collection

### *3.1.1. Datasets*

This work analyzed four different datasets of IoT traffic:

- **home**: sourced from a residence and represents normal usage traffic contains 37 days of traffic from over 25 devices that are a mix of typical IoT devices and more general devices such as laptops and smartphones,
- **lab**: traffic is from several devices in a lab at Colorado State University, it contains approximately 22 devices and several month's worth of traffic,
- **unsw**: IoT traffic from a lab at University of New South Wales (UNSW) contains nearly three weeks of traffic from 29 devices that are mixed IoT and general-purpose devices,
- **scada**: traffic from a Supervisory Control and Data Acquisition (SCADA) test network at Colorado State University's Methane Emissions Test and Evaluation Center. It has nearly 40 devices mostly made up of SCADA devices called Lab jacks.

### *3.1.2. Attack Data*

The malware data comes from Stratosphere Laboratory (14) and contains 20 captures where malware was executed on IoT devices, and 3 captures for benign IoT devices traffic. This dataset was first published in January 2020, with captures ranging from 2018 to 2019.

**Table 1: Malware Data**

| Attack Name | Description | Unique Flows |
|---|---|---|
| C&C | This is traffic where a device is connecting to a remote command and control server. | 30 |
| C&C Heartbeat | This is traffic that is meant to monitor the status of an infected host. | 3 |
| C&C Torri | This is command and control traffic specifically from the Torri botnet | 1 |
| C&C FileDownload | This is traffic from an infected device downloading a file or malicious payload | 7 |
| DDoS | This is traffic where a device is participating in a distributed denial of service attack | 1 |
| Part of Horizontal Scan | This is traffic where a device is scanning locally on the network | 49959 |
| Okiru | This is traffic specifically from the Okiru botnet. | 99888 |

## 3.2. Data collection

For the home, and lab datasets data was collected in the form of IPFIX/Netflow flows from a centralized router to a flow collector as shown in Figure 1: Data Collection Architecture. Flows were saved in a SQL database. For the UNSW data set and the SCADA data set, the pcap files were analyzed by an open source tool called Joy (15). Joy transforms pcap files into json data which was then loaded into a SQL database.

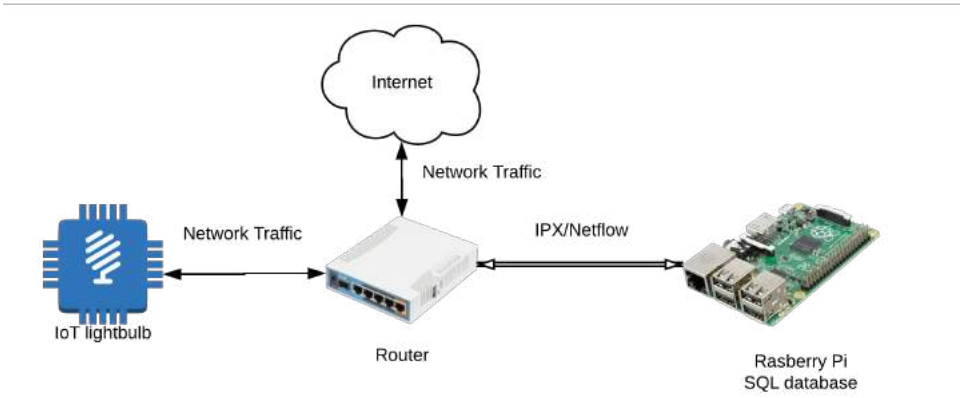

**Figure 1: Data Collection Architecture**

**Table 2: Features from network flows**

| Feature | Description |
|---|---|
| IPv4 Source Address | IP Address of the device |
| IPv4 Destination Address | IP Address the device is connecting with on the network |
| In Packets | Number of packets received by the device |
| Out Packets | Number of packets sent by device |
| L4 Source Port | Source port on device |
| L4 Destination Part | Remote port that the device is connecting with on the network |
| Protocol | IANA protocol, eg UDP,TCP |

## 3.3. Device Complexity

The complexity of a device on the network is based on its network traffic. Sensors that talk to a relatively few network endpoints will be measured as low complexity devices. This is compared devices such as laptops and smartphones that make highly varied requests to many network endpoints. These devices will be measured as high complexity devices. To illustrate this, Figure 2 shows where devices fall in a range from low complexity to high complexity.

**Figure 2: Spectrum of complexity**

**General Purpose Device**

A device that is capable of running multiple user-space applications. Some examples are smart-phones, tablets, laptops, some streaming devices, and smart TVs. These devices will have higher network complexity.

**Single Purpose Device**

A device that generally runs a single application. They often are capable of only one or two threads. These devices will have lower network complexity.

For a network flow there are several features that can be examined as shown in Table 2. This research focused on destination-based features. The complexity analysis is based only on destination IP address and destination port, though other features could be added.

To measure a device's complexity on the network this work uses a concept similar to one used in communications, called the Signal to Noise Ratio (SNR) which compares the level of desired signal to the background noise. Within the context of Internet traffic from a device, the signal is defined as traffic data points that can be clustered, and the noise is defined as the datapoints that cannot be clustered. Some of the devices measured had no noise components making the SNR ratio undefined. To account for this this research uses the reciprocal if the SNR, referred here as the noise to signal ratio (NSR) shown in Equation 1. In the case where there are zero points of noise the NSR=0.

This measure of complexity uses the DBSCAN (16) clustering algorithm to compute the number of clusters (signals) and the non-clusters (noise). This algorithm is good at finding areas of high density that are separated by areas of low density. The DBSCAN algorithm has several advantages in that it can find clusters of arbitrary shape and size, and can include clusters that are non-convex, unlike other clustering algorithms such as k-means.

The DBSCAN algorithm takes in two primary parameters, a distance parameter ε and a number of points that are within that distance called, *min_samples,* to form a cluster. To automatically find the distance parameter this work uses the device's *IP_Spread* as shown in Equation 1Equation 1: Distance Calculation. The IP_Spread is the set of IP addresses where the first order octet is unique and represents the total number of unique network that the device connects to.

**Equation 1: Distance Calcualtion**

$$\epsilon = 128 * IP\_Spread$$

128 is the midpoint of the address space of a class C network. Experimentally setting min_samples = 10 was a good starting value for the total number of neighborhood points necessary for a point to be calculated as a core point.

The number of clusters found by the DBSCAN algorithm and the number of non-clusters is used to calculate the NSR for the device using Equation 2.

**Equation 2: Noise to Signal Ratio**

$$NSR = \frac{n\_noise}{n\_clusters}$$

## 3.4. Results Methodology

To evaluate the results of the model a dataset consisting of traffic from several different malware types was used to see how well the model was able to predict normal traffic from abnormal attack traffic. Evaluating the model produces four metrics on how the model is performing. These four metrics are:

- true positives (TP): malware traffic correctly identified as malware traffic,
- true negatives (TN): normal traffic correctly identified as normal traffic,
- false positives (FP): normal traffic incorrectly identified as malware traffic,
- false negatives (FN): malware traffic incorrectly identified as normal traffic.

Table 3 shows the confusion matrix for this analysis.

**Table 3: Confusion Matrix for IoT Traffic**

| | **Predicted: Normal Traffic** | **Predicted: Malware Traffic** |
|---|---|---|
| **Actual: Normal Traffic** | TN | FP |
| **Actual: Malware Traffic** | FN | TP |

From these four metrics there are two important factors that are often used, precision, the ratio of correct positive predictions to the total predicted positives and recall, the ratio of correct positive predictions to the total positive examples.

**Equation 3: Precision**

$$P = \frac{TP}{TP + FP}$$

**Equation 4: Recall**

$$R = \frac{TP}{TP + FN}$$

And finally, the balanced method for measuring the efficacy of a prediction model is called the F1 score. The F1 score is the harmonic mean of the precision and recall.

**Equation 5: F1 score**

$$F_1 = 2 * \frac{P * R}{P + R}$$

In Section 4 the results are shown how each device model performs against the malware traffic using the F1 score. An F1 score of 1 is a perfect score, it means that the device model correctly identified all of the device traffic as normal and all of the malware traffic as abnormal.

# 4. Results

The results across all four of the datasets support the hypothesis that devices can be measured for complexity based on their network flows, and that this measurement can be used to categorize devices into two separate groups, single purpose devices and general-purpose devices. Further, the results support that measuring the complexity of a device is relevant to improve modeling of devices. For brevity only three devices from the Home dataset are shown, one of high complexity, one of median complexity and one of low complexity. Figure 8, Figure 9, Figure 10, and Figure 11 show the results of all devices for each data set analyzed and averaged against the seven malware traffic types.

## 4.1. Complexity Results

Figure 3 shows the Roku Express device in the home dataset with the largest NSR value of 52.25. Only four clusters were found with 209 points of noise. This is compared to the J Android device which falls in the middle of all devices with an NSR of 10.2 as calculated from 19 clusters and 194 points of noise shown in Figure 4. Finally, in Figure 5 we see the lowest complex device on the home network which is the Eufy light bulb. This device has only 2 clusters and zero points of noise leading to an NSR value of 0.

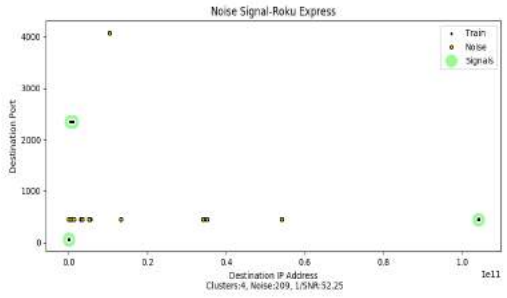

**Figure 3: Highest NSR Roku Express**

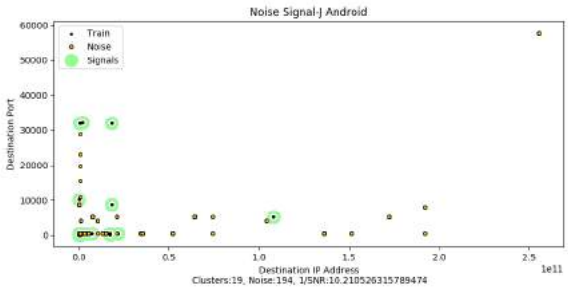

**Figure 4: Median NSR Android**

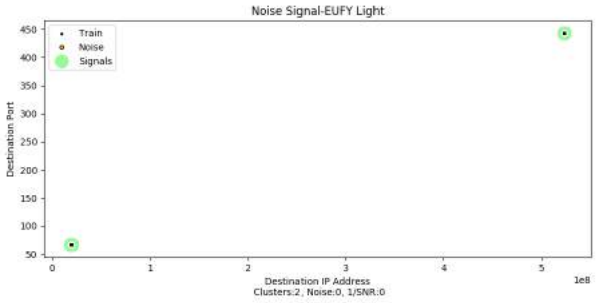

**Figure 5: Lowest NSR Eufy Light**

Figure 6 shows the NSR complexity of all the devices on the home network. A line is drawn at the average NSR value of 8.5. Almost all the devices that have an NSR above this value are general purpose devices and conversely almost all below 8.5 are single purpose devices. Streaming devices such as Roku and Smart TVs were consistently measured across the four datasets as higher complexity devices. This is likely because these devices are often Linux OS based devices capable of running several user space applications.

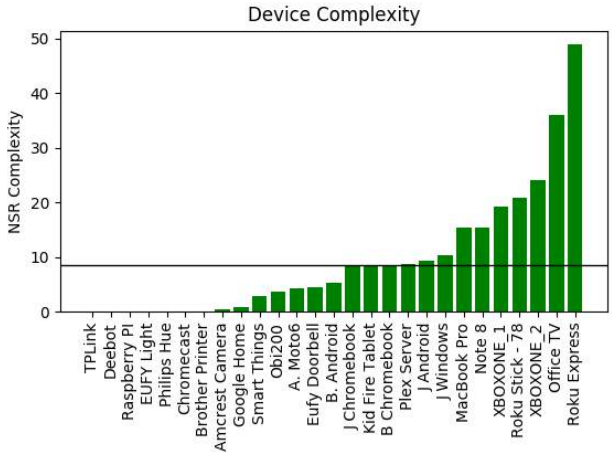

**Figure 6: Home Device NSR Complexity**

## 4.2. Behavior Results

Figure 7 shows the three devices, the Roku Express, J Android, and the Eufy light bulb. Each figure shows the normal traffic as black dots, the learned behavior boundary as blue ellipsoids generated from the Gaussians, and the attack traffic represented as red dots. In each figure the port and IP address have been normalized. Normalizing both improves classification and makes it possible to show the traffic and boundaries in non-logarithmic space.

The Roku Express has the highest NSR value of 52 in the home data set with only four clusters and 208 points of noise. This leads to a relatively poor model for the device with a 0.5% false positive rate against the C&C malware traffic. Visually, the figure shows large ellipses that fail to contain several of the normal traffic within their boundaries leading to 17 false negatives. Additionally, some of the ellipses overlap with the malware traffic leading to false positive identification. The number of true positive outliers detected is also poor with the model only detecting 43% of the malware traffic in the C&C traffic. This gives the model an F1 score of 0.59.

For the J. Chromebook device with an NSR value of 8.6 which is just slightly higher than the data set average of 8.548. This NSR value comes from a total of 15 clusters and 129 points of noise and leads the GMM to find a total of 15 ellipsoids. As compared to the model of the Roku, the J. Chromebook shows smaller margins on the ellipsoids that are centered around the normal traffic. The false positive rate of the J. Chromebook model is double that of the Roku model at 1%, however, there is less overlap in these ellipsoidal boundaries with the attack traffic than in the Roku model leading to a true positive accuracy of 100% for the malware traffic. This in turn leads to a much higher F1 score of 0.968 against the C&C malware.

Finally, in the figure for the Eufy light bulb there are only two ellipsoids generated by the model. The Eufy device is a light bulb and has the lowest measured NSR complexity in the home dataset with an NSR of 0 that is composed of just 2 clusters and 0 points of noise. This leads to a behavioral boundary tightly coupled around the normal traffic, with a 0.0% false positivity rate and a 100% accuracy in identifying the malware traffic. This leads to a perfect F1 score of 1.00.

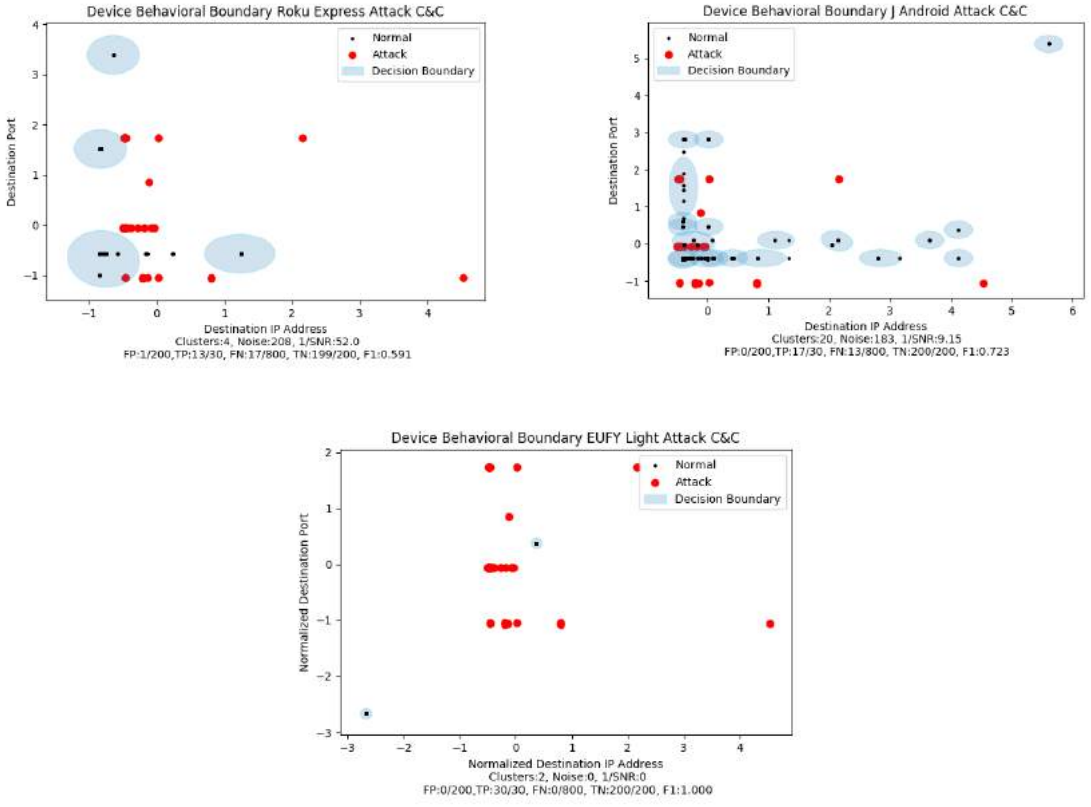

**Figure 7: Device Behavior Boundaries**

## 4.3. Overall Results

Every device in each data set was modeled and evaluated against each of the seven malware traffic types. The average NSR complexity score, and the average F1 score for each of the four datasets is shown in Table 4. The table shows the inverse relationship between average NSR complexity and average F1 score, highlighting the notion that simple devices can be more accurately modeled.

**Table 4: NSR and F1 Scores**

| Data Set | Average NSR Complexity | Average F1 Score |
|---|---|---|
| Home | 8.548 | 0.901 |
| Lab | 9.596 | 0.879 |
| UNSW | 7.170 | 0.942 |
| SCADA | 2.791 | 0.975 |

Figure 8 shows the average F1 score for each averaged across the malware traffic. The upper left of Figure 8 shows the model using the non-normalized data. It is shown to illustrate the negative correlation between a device's NSR complexity and the F1 score. This supports the idea that simple devices can be more accurately modeled. In the upper right of the figure we see how the model is improved by normalizing the data. Normalizing generally improves the efficiency and accuracy of clustering algorithms, this is especially true when the clustering algorithm uses the squared Euclidean distance metric as is done in the DBSCAN algorithm.

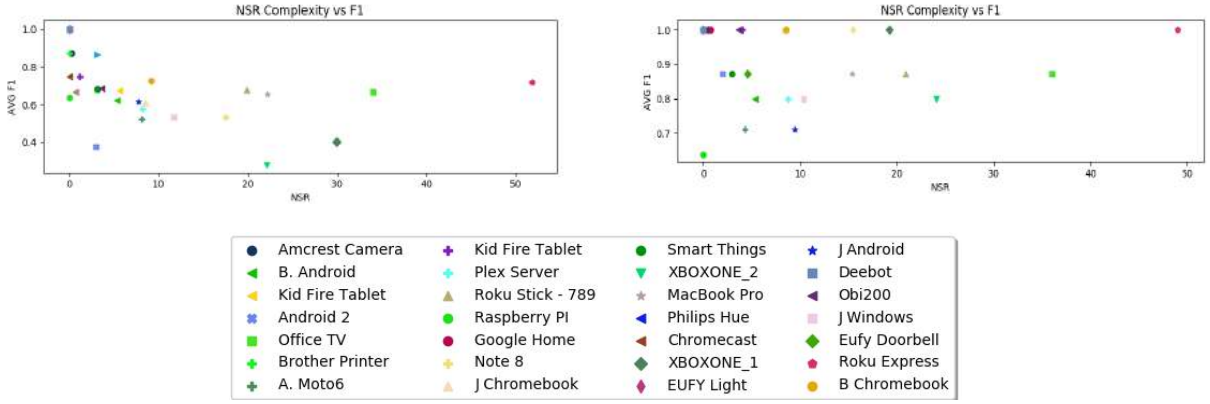

**Figure 8: F1 Score vs NSR Complexity [Home]**

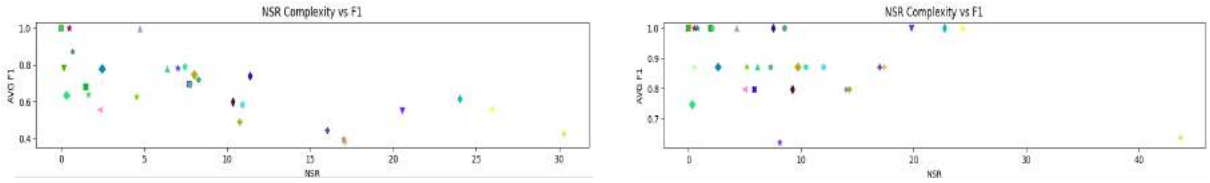
Figure 9 shows the average F1 score of each device against the seven types of malware traffic. Again, the upper left shows the non-normalized scores and the upper right scores based on normalized data.



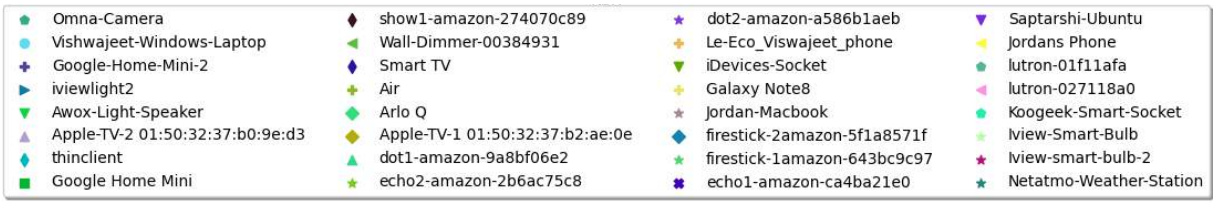


**Figure 9: F1 Score vs NSR Complexity [Lab]**

Figure 10 and Figure 11 show the results for devices on the UNSW data set and SCADA dataset respectively. The UNSW results are consistent with the Home and Lab data sets in showing a negative correlation of F1 score and NSR score for non-normalized data.

The SCADA data set is distinctly different from the other three datasets, in that there does not appear to be an obvious correlation with complexity and modelability. The SCADA dataset had the lowest average NSR and the highest average F1 score. This is consistent with the notion that SCADA devices are very simple in terms of their network footprint and the results support this.

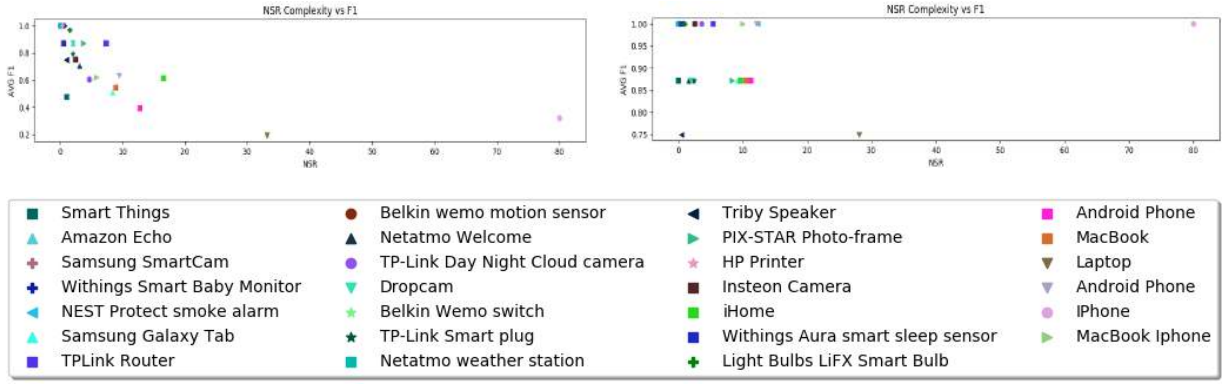

**Figure 10: F1 Score vs NSR Complexity [UNSW]**

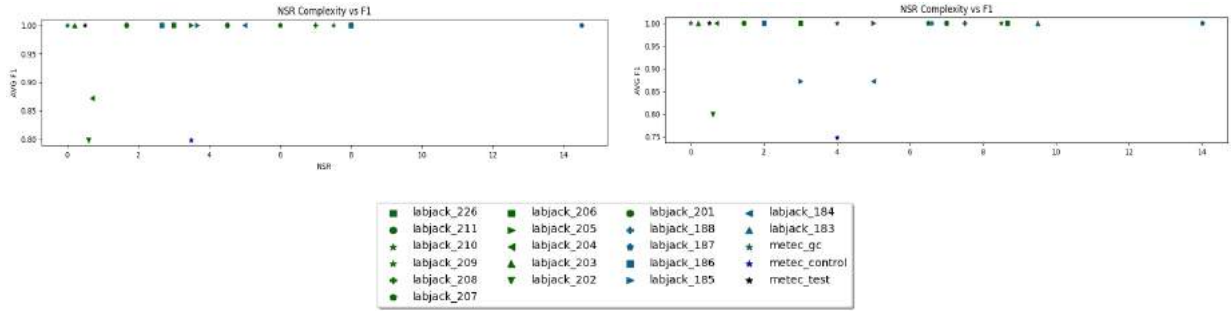

**Figure 11: F1 Score vs NSR Complexity [SCADA]**

## 5. Conclusion

This research developed a method for measuring the complexity of IoT devices based on their network traffic. This method called the Noise to Signal Ratio (NSR) uses a clustering algorithm to determine how much of the traffic from a device can be classified as a signal and how much as noise. The number of clusters from this algorithm feeds a Gaussian mixture model that is used to construct a behavioral model for each device and classify normal versus abnormal traffic.

This model was then run against seven very different types of actual malware traffic to determine the efficacy of the model in classifying a device's normal traffic from malware traffic. The results show that the model is effective, with many devices having perfect F1 scores. The results also show that F1 scores are generally higher for less complex devices, supporting the claim that simple devices can be more accurately modeled than complex devices.

This suggests that automatic blocking of malware traffic could be done, especially on devices that are simple, i.e. have low NSR scores.

Future work will examine how the NSR of devices can be applied to other anomaly detection methods such as isolation forest and single class support vector machines.

# How DOCSIS Time Protocol makes the SYNC Specification Tick

## Automating the DTP Algorithm

A Technical Paper prepared for SCTE•ISBE by

# 1. Introduction

CableLabs® released the I01 SYNC specification on April 20, 2020. The SYNC specification describes how to build and deploy an IEEE 1588/PTP participant DOCSIS network. The SYNC specification is targeted at the new and evolving mobile backhaul market.

The core technology that makes timing work is the DOCSIS Time Protocol (DTP). DTP was introduced in DOCSIS 3.1 and described in [1] but has not been deployed as of yet. The operation of DTP is not well understood and there are many new considerations in order to bring it from a specification to a deployed product. As a result of this strong interest by operators, there is a need to re-explore in detail several aspects of DTP, including:

- what DTP does,
- how it works,
- how it is calibrated,
- how it is used in a live system,
- how it interplays with other DOCSIS procedures,
- limitations, and tradeoffs.

The goal of this paper is to provide this detailed exploration of DTP and enable the Cable community to have a common understanding of DTP so they can confidently develop it and use it.

# 2. Market Opportunity

As highlighted in [2], mobile network operators (MNOs) are relying on densifying their radio access network (RAN) to improve the coverage, capacity, and throughput for both their 4G and, more importantly, 5G systems. As depicted in Figure 1, MNOs achieve this densification by installing low-powered base stations (called small cells) underneath their existing high-powered base stations (called macrocells), creating a heterogeneous network (HetNet).

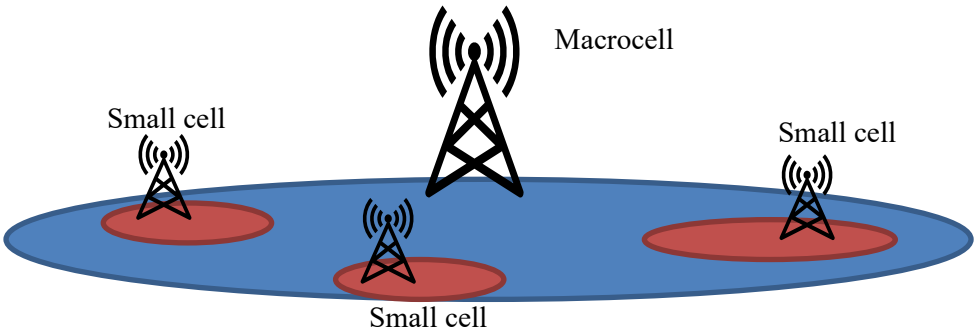

**Figure 1 – Heterogeneous Netwok**

For small cells to work effectively, three key elements are required:

1. Location
2. Power
3. Backhaul

Cable operators are in an advantageous position to offering a solution for these three requirements, as discussed in detail in [2]. As such, the authors strongly believe that cable operators of today are the mobile network operators of tomorrow.

In terms of backhaul, these are the requirements:

1. high throughput to sustain the traffic of the small cells,
2. low latency and jitter, and
3. network timing.

In [2], the authors focused on how to achieve low latency backhaul over DOCSIS. In this paper, we focus on how to provide network timing by using the DOCSIS Time Protocol.

## 3. Why is time synchronization needed?

In this section we explore in detail the need for time and frequency synchronization among the elements of the RAN in a mobile network.

First, we will clarify the concepts of frequency, phase, and time synchronization. In Figure 2, we depict the difference among the three. Frequency synchronization refers to two elements that are beating at the same pace, but are not necessarily aligned at the instant when they beat. Phase synchronization refers to two elements that are beating at the same pace, and are aligned at the instant when they beat; however, the time they report at each beat is not necessarily the same. Time synchronization refers to two elements that are beating at the same pace, are aligned at the instant when they beat, and the time they report at each beat is the same. Throughout this paper we will use the term "timing synchronization" to refer to frequency, phase, and time synchronization all together unless explicitly stated.

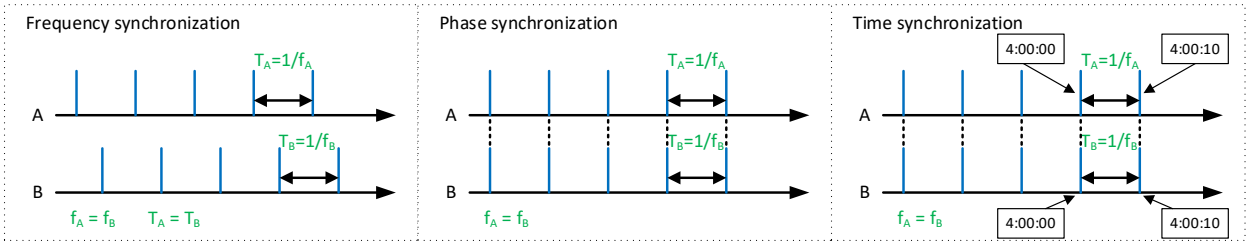

**Figure 2 – Frequency vs Phase vs Time synchronization**

Many mobile networks previously required only frequency synchronization. However, 4G and 5G networks require also phase and time synchronization for several reasons, including:

a) Use of Time Division Duplexing (TDD): In TDD mode, the base stations (also called eNBs) utilize a same frequency for both upstream and downstream transmission. A single base station will switch in time between transmitting and receiving data. Since base stations have overlapping coverage, particularly in a HetNet, those base stations need to be aligned in terms of when to be in transmission mode, or in reception mode; otherwise, they will cause interference to each other, as depicted in Figure 3. In Figure 3, the base stations are completely misaligned, causing interference between user equipment (UE) at the cell-edge, and also at the base stations themselves.

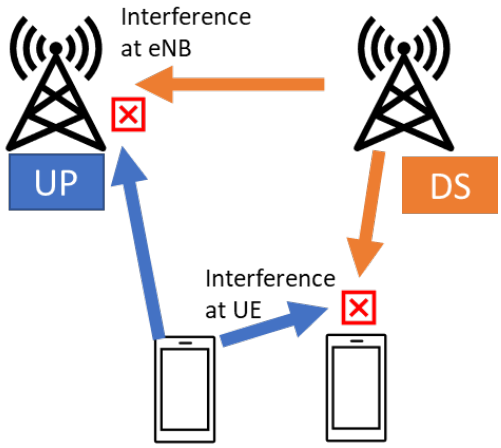

**Figure 3 – Interference at UE and eNB**

b) Use of advanced base station coordination techniques: In both 4G and 5G systems, new techniques were introduced to either mitigate potential interference among base stations operating in the same frequency band (e.g., enhanced intercell interference cancellation, or eICIC), or improve the throughput achievable by UEs under the coverage of multiple base stations (e.g., Coordinated Multi Point operation, or CoMP). For these techniques to work effectively, the base stations need to be tightly synchronized.

Table 1 [3] summarizes the synchronization requirements for 4G LTE Frequency-Division Duplex (FDD), 4G LTE TDD, and 5G TDD.

**Table 1 – 4G/LTE and 5G Air Interface Synchronization Requirements**

| Table Heading | Frequency | Phase | |
|---|---|---|---|
| 4G LTE FDD | ± 50 ppb | None | 3GPP TS 36.104 §6.5.1 |
| 4G LTE TDD | ± 50 ppb (wide area)<br>± 100 ppb (local area)<br>± 250 ppb (home) | 10 µs (wide: cell radius >3 km)<br>3 µs (local: cell radius <3 km)<br>1.33 µs + Tprop (home eNB radius >500 m)<br>3 µs (home eNB radius <500 m) | Phase:<br>3GPP TS 36.133 §7.4.2<br>Frequency:<br>3GPP TS 36.922 §6.4.1.2 |
| 5G TDD | ± 50 ppb (wide area)<br>± 100 ppb (local area) | ≤ 3 µs | 3GPP TS 38.104 Table 6.5.1.2.1 |

The SYNC specification was designed with the goal of achieving the 3 µs phase requirement. The key concept to note is that the ±3 µs requirement refers to the allowed time error between the RAN network elements. In a deployed system, this 3 µs requirement is typically achieved by setting a ±1.5 µs phase requirement between the RAN network elements and a common time source, as depicted in Figure 4.

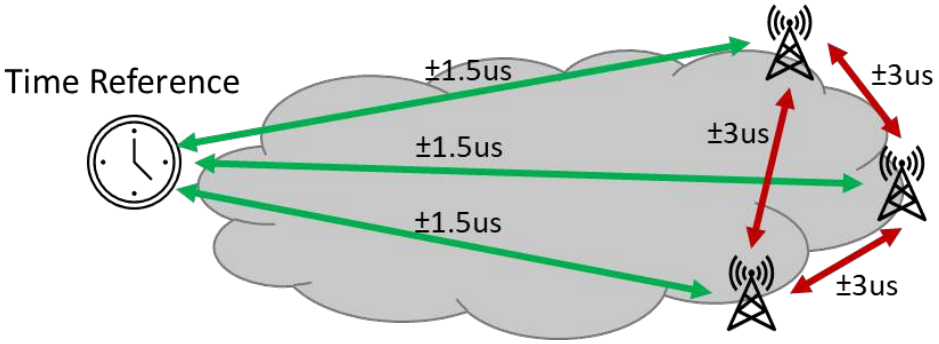

**Figure 4 – Phase Synchronization in a Mobile Network**

One way to achieve the timing synchronization is to use a Global Navigation Satellite System (GNSS) as time source, and equip every base station with a GNSS receiver. This works well for macrocells. Macrocells are typically deployed in outdoor environments, and the cost of the GNSS receiver is very small compared to the cost of the macrocell itself. For small cells, using GNSS may not work well for two reasons: GNSS signal availability and cost of GNSS receiver.

Small cells are meant to be low-cost devices deployed in large quantities and may be deployed in indoor environments where the signal from a GNSS could be unreliable. Even where the GNSS signal is reliable, the cost of the GNSS receiver might significantly increase the cost of the small cell. Because of these two reasons, network-based timing protocols, which do not depend on GNSS signal availability and have lower cost impact on small cells are preferable.

What Figure 4 shows with a single arrow from the base stations to the time source is actually comprised of the DOCSIS backhaul and other network elements, as depicted in Figure 5.

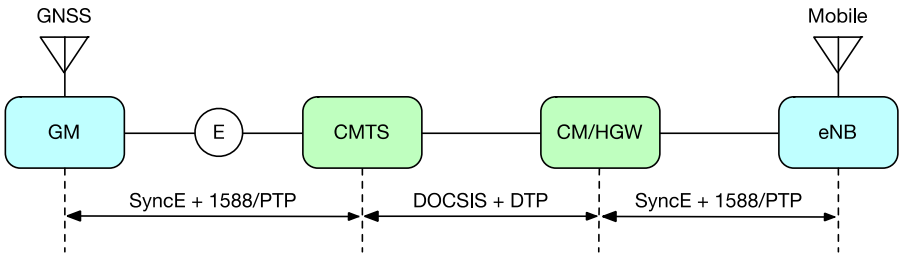

**Figure 5 – Timing Delivery over DOCSIS Backhaul**

Figure 5 shows a grandmaster (GM) synchronized to a GNSS. Through a series of network elements (marked as E), the timing information is delivered to the CMTS through the use of 1588/PTP and, optionally, SyncE. The CMTS utilizes existing DOCSIS timing properties and the DOCSIS Time Protocol (DTP) to convey the information that the CM needs to be properly synchronized. The CM then delivers the timing information to the base station, called eNB, using 1588/PTP and, optionally, SyncE. The end application resides within the eNB.

Comparing Figure 4 and Figure 5, we see that the DOCSIS backhaul, i.e.,. the CMTS and CM, is only one of the elements between the time source, i.e., GNSS, and the end application. Thus, the 1.5 µs budget is actually distributed among the DOCSIS elements and the rest of the elements sitting between the GNSS and the end application.

In the next section, we discuss the details of how DTP works.

# 4. DOCSIS Time Protocol (DTP)

## 4.1. How timing protocols work

Before diving into the specifics of DTP, we will provide a high-level view of how timing protocols work.

All timing protocols use a variant of a Two-Way Time Transfer (TWTT), as depicted in Figure 6.

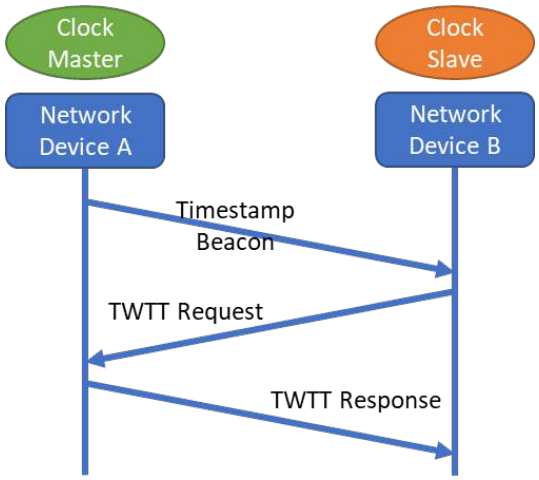

**Figure 6 – Two-way Time Transfer**

There are two devices, one containing the master clock (Network Device A), and one containing the slave clock (Network Device B). Network Device A sends a timestamp to Network Device B. This timestamp will arrive at Network Device B at some time after it was created by Network Device A. In other words, the timestamp is delayed. Network Device A and B exchange messages to determine the network delay and asymmetry. Once these two factors are identified, Network Device B corrects its timestamp to match the one of Network Device A. Even though this procedure was used to synchronize the time, the same mechanism can be used to synchronize the frequency.

## 4.1. What DTP does

In its simplest form, DTP allows the existing timing and frequency system of DOCSIS to be interfaced to external timing protocols with high accuracy, as shown in Figure 7. Once the CMTS has a frequency and time source synchronized to an external source, DTP allows the source to be replicated at the egress port of the CM.

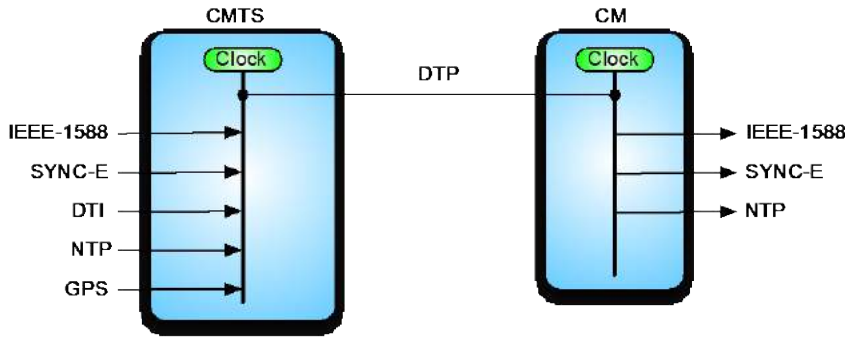

**Figure 7 – DOCSIS Time Protocol – System Overview**

As highlighted in [4], for the DOCSIS DTP frequency path, the CMTS PLL (Phase-Locked Loop) locks onto the frequency component of the external timing protocol, e.g., SyncE or IEEE-1588. The output of the CMTS PLL drives the DOCSIS downstream baud rate. The CM receives the baud rate frequency and locks to it with its PLL. The CM PLL then drives the frequency output on the CMCI port with SyncE and/or IEEE-1588.

As highlighted in [4], for the DOCSIS DTP timestamp path, the CMTS synchronizes its DOCSIS 3.1 Extended Timestamp to the timestamp of the external protocol, e.g., IEEE-1588. The DOCSIS Extended Timestamp is sent to the CM as part of the DOCSIS protocol where it is converted back to any desired format, e.g., IEEE-1588. The DTP protocol that runs between the CMTS and the CM computes the time delay in the downstream path while taking into account the asymmetry of the DOCSIS system. This delay is then added to the timestamp in the CM so that the timestamp that is sent out from the CM closely matches the timestamp received by the CMTS.

The main takeaways from the above two paragraphs are:

- The CMTS and CM are already synchronized in frequency. The CMTS frequency will need to be synchronized to an external frequency source. The CM will need to pass its local frequency to its CMCI port.
- The CMTS and CM are already phase aligned, but not time synchronized. DTP provides the means to achieving the time synchronization.

## 4.2. DTP Messaging

Similarly to how other time protocols operate (see Section 4.1), DTP operates under a master/slave approach. The DTP master is in charge of:

a) Initiating DTP message exchange, and
b) Computing the time adjustment for the CM.

The MULPI spec [4] allows for either the CMTS or the CM to be the DTP master. Figure 8 depicts the message flow between the DTP master and DTP slave for the case of the CMTS being the DTP master. The DTP request (DTP-REQ) provides configuration information to the CM regarding the CMTS and HFC timing values. The CM does not need these values to compute the ones that it sends back in the DTP response (DTP-RSP).

The key value reported back by the CM is the true ranging offset (TRO) and the CM timing values. The CMTS uses this data, the CMTS timing values, and HFC timing values to compute the DTP time

adjustment, and then sends this time adjustment to the CM in a DTP info (DTP-INFO) message. Once the CM receives the DTP-INFO, the CM replies back with a DTP acknowledgement (DTP-ACK).

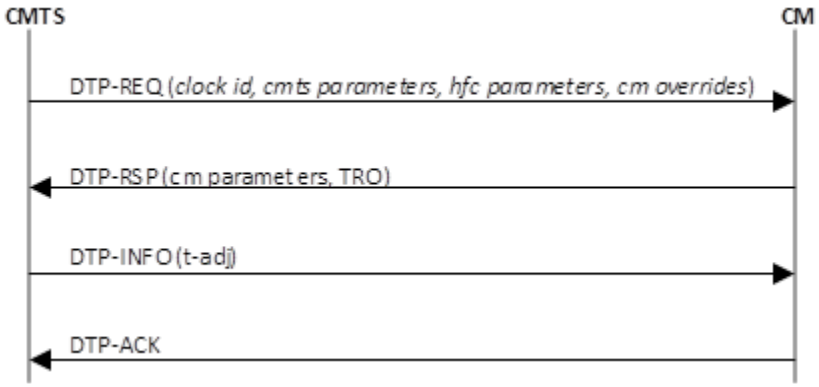

**Figure 8 – CMTS is DTP Master**

The time interval at which the DTP message exchange is repeated is configurable, with 10 seconds being the minimum value and no maximum value.

## 4.3. DTP – Determining the path delay

At a high-level, DTP relies on the exchange of messages (see Section 4.2) to determine the forward path delay needed to compensate the time at the CM.

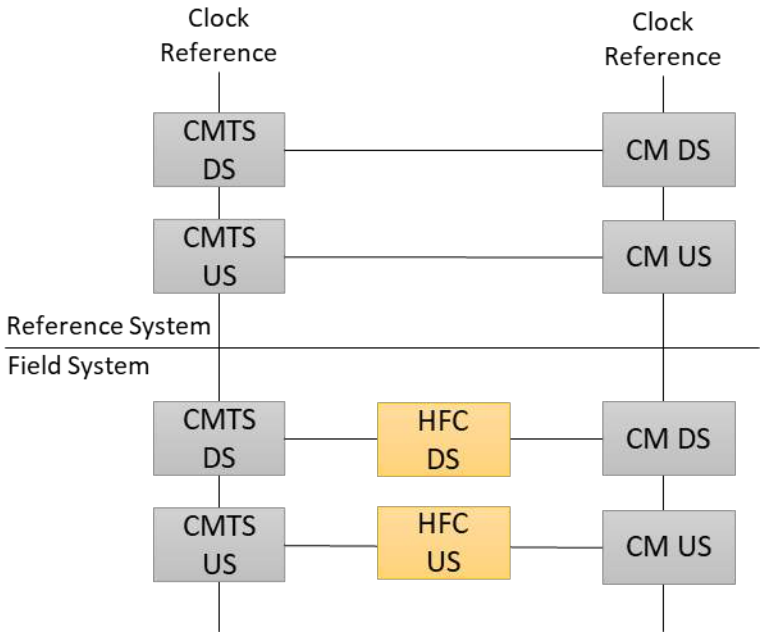

**Figure 9 – DTP Operation**

In Figure 9, we depict a simplified field system composed of a CMTS (downstream – DS, and upstream – US), and HFC plant (DS and US), and CM (DS and US). In this figure, the forward path delay is composed by the CMTS DS, HFC DS, and CM DS elements. The underlying assumptions used to compute these elements are:

1. The CMTS and CM parameters can be measured offline.
2. The HFC path delay in downstream is equal to the HFC upstream path delay. Note that this assumption is not always true; however, if the error is within the error budget allocated to the HFC, then the error can be ignored.
3. The difference in path delay between a field system and a zero-length plant is attributable to the total HFC path delay (DS & US).

With these assumptions in place, it follows that by computing the difference in path delay between a field system and a zero-length plant, we can obtain the total HFC path delay. We take this value and divide it by two, and we get the one-way HFC path delay. Now, because the CMTS DS and CM DS parameters were calibrated offline, the overall path delay can now be computed as the sum of CMTS DS, HFC DS path delay, and CM DS.

So, for the above to work, we need to have the CMTS and CM parameters calibrated offline, which an entity such as CableLabs® could lead. In the next section, we dive deeper into what exactly the CMTS, CM, and HFC parameters represent.

# 5. DTP Timing Model

The DTP timing model is depicted in Figure 10.

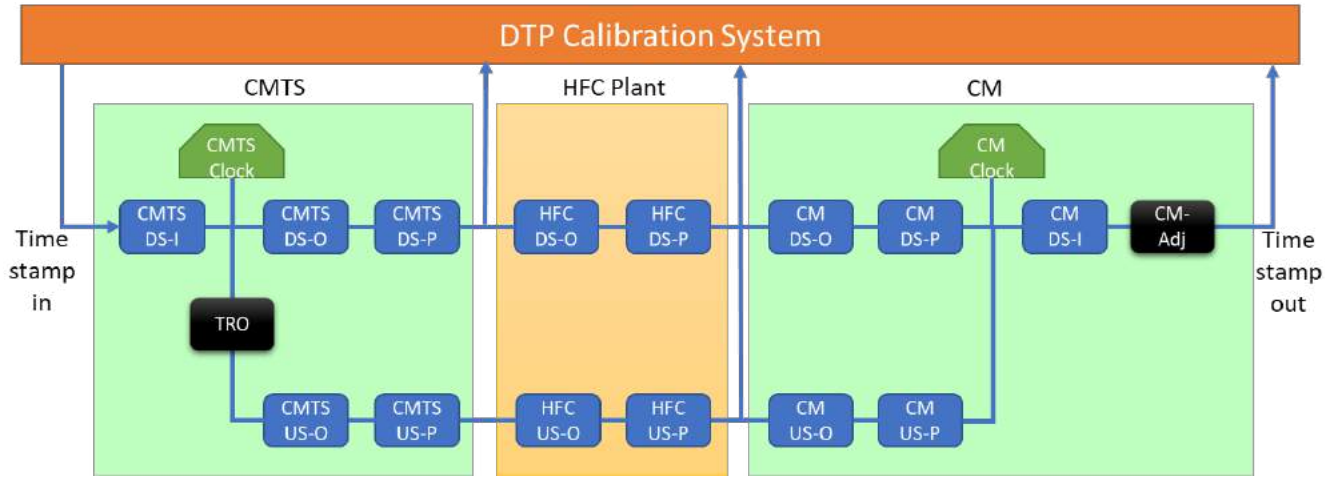

**Figure 10 – DTP Timing Model**

The timing values have blue background. The ones associated with the CMTS are preceded by the word "CMTS", the ones associated with the HFC are preceded by the word "HFC", and the ones associated with the CM are preceded by the word "CM". The parameters associated with downstream include the word "DS", and the ones associated with upstream include the word "US". There are three types of parameters:

1. Interface Delay: Include the suffix "-I"
2. Path: Include the suffix "-P". This is a vendor specific characterized delay of the physical circuit path. For the CMTS and CM, this may be a measured or calibrated value that is supplied as part of calibration. For the HFC plant, this is the value that is calculated as part of the DTP calculations, as discussed in Section Figure 9.
3. Offset: Include the suffix "-O". This is a known offset due to interleaving or some other configuration.

Table 2 summarizes all the parameters, as defined in [4]. Compared to Figure 10, the spec uses the additional prefix “t-” to refer to the timing parameters.

**Table 2 – DTP Delays**

| | Delay Type | Delay Name | Description |
|---|---|---|---|
| CMTS | Interface | t-cmts-ds-i | This is the circuit delay from the CMTS clock input interface (DTI or NSI) to the internal CMTS timestamp reference point. This is a manufacturer's value and is supplied by the CMTS. |
| | Path | t-cmts-ds-p | This is the intrinsic path delay contribution from the CMTS timestamp reference point to the CMTS downstream PHY output. This is a measured value and supplied by the CMTS. |
| | | t-cmts-us-p | This is the intrinsic path delay contribution from the CMTS PHY upstream input to the CMTS timestamp reference point. This is a measured value and supplied by the CMTS. |
| | Offset | t-cmts-ds-o | This is the known delay contribution in the downstream CMTS PHY path that is associated with configuration elements such as interleaving. This value is known and is supplied by the CMTS. |
| | | t-cmts-us-o | This is the known delay contribution in the downstream CMTS PHY path that is associated with configuration elements such as interleaving. This value is known and is supplied by the CMTS. |
| HFC | Path | t-hfc-ds-p | This is the intrinsic path delay of the fiber and coax elements of the HFC plant. The DTP algorithm calculates this value. |
| | | t-hfc-us-p | This is the intrinsic path delay of the fiber and coax elements of the HFC plant exclusive of fixed delay elements. The DTP algorithms calculate this value. The basic DTP algorithm assumes the upstream and downstream path delay are equal by using the offset values to compensate for fixed and asymmetrical delays. |
| | Offset | t-hfc-ds-o | This delay represents any fixed delay elements in the HFC path that contribute to delay. One example may be a digitization circuit, optical node and amplifier circuit delays. This value may be unique per HFC path due to different path elements. This value is supplied by the CMTS.<br>By specifying appropriate HFC downstream and upstream offset values correctly and by setting the asymmetry appropriately, the HFC downstream and upstream path delays can be assumed to be equal. |
| | | t-hfc-us-o | This delay represents any fixed delay elements in the HFC path that contribute to delay. One example may be a digitization circuit, optical node and amplifier circuit delays. This value may be unique per HFC path due to different path elements. This value is supplied by the CMTS. |
| CM | Interface | t-cm-ds-i | This is the circuit delay from the internal CM timestamp reference point to the clock output interface (CMCI). This value is manufacturer's value and is supplied by the CM or by a CMTS override. |
| | Path | t-cm-ds-p | This is the intrinsic path delay contribution from the CM PHY downstream input to the CM timestamp reference point. This is a measured value and supplied by the CM or by a CMTS override. |
| | | t-cm-us-p | This is the intrinsic path delay contribution from the CM timestamp reference point to the CM PHY upstream output. This is a measured value and supplied by the CM or by a CMTS override. |
| | Offset | t-cm-ds-o | This is the known delay contribution in the downstream CM PHY path that is associated with configuration elements such as interleaving. This value is known and is supplied by the CM or by a CMTS override. |

| | Delay Type | Delay Name | Description |
|---|---|---|---|
| | | t-cm-us-o | This is the known delay contribution in the upstream CM PHY path that is associated with configuration elements such as interleaving. This value is known and is supplied by the CM or by a CMTS override. |
| | Other | t-cm-adj | This is the value that must be added to the CM unadjusted timestamp to have the CM timestamp be equal to the CMTS timestamp in real time. This value is calculated by the DTP Master. |

In the addition to the timing values described above, the other parameter of relevance is the True Ranging Offset (TRO). The TRO is the measured ranging offset of the CM between two defined reference points. TRO is a measured (or derived) value that is different than the actual implemented ranging offset a CM might use in its communication with the CMTS. A key property of the TRO is that the value of TRO is the equivalent to the round-trip delay of the combined downstream and upstream propagation delays of the HFC plant, the CMTS and CM PHY paths. For more details on the TRO, see [4].

With the TRO, CMTS timing values, CM timing values, and HFC offset values, the DTP math described in MULPI [4] provides the formulas to compute the necessary time adjustment for the CM. Those formulas are shown here for reference:

*(1) t-tro = t-cmts-ds-o + t-cmts-ds-p + t-hfc-ds-o + t-hfc-ds-p + t-cm-ds-o + t-cm-ds-p + t-cm-us-o + t-cm-us-p + t-hfc-us-o + t-hfc-us-p + t-cmts-us-o + t-cmts-us-p*

*(2) t-cm-adj = t-cmts-ds-i + t-cmts-ds-o + t-cmts-ds-p + t-hfc-ds-o + t-hfc-ds-p + t-cm-ds-o + t-cm-ds-p + t-cm-ds-i*

The limitation is that there does not exist any measurement equipment that, as of the time of the writing of this paper, can measure separately the CMTS, CM, and HFC timing values. Until the testing limitation is addressed by test equipment vendors, rather than characterizing the CMTS and CM separately, they must be characterized jointly for specific configurations, as discussed in the next section.

# 6. DTP Calibration

The approach for DTP calibration is based on the following assumptions:

1. The timing values of the CM and CMTS will be characterized jointly due to lack of testing equipment, as of the time of the writing of this paper, that can characterize them separately.
2. The joint characterization of the CM and CMTS needs to be done for every configuration parameter, e.g., interleaving, that affects the upstream or downstream delay.
3. The timing values of an HFC element can be characterized indirectly by comparing timing behavior of a DOCSIS network without such an HFC element and with such an HFC element.

With the above assumptions, the SYNC spec provides the following three steps to perform the DTP calibration and using the measured values on a live system.

1. Measuring the CMTS-CM combined timing parameters: This is done at a reference-length plant. Ideally the plant would be zero-length, but it is sufficient for the plant to be as simple as possible and with a known length.

2. Measuring the HFC timing parameters: This is done indirectly by inserting the HFC element between the CMTS and CM, and computing the difference between this plant and the reference-length plant.
3. Computing the DTP Time Adjustment in a live DOCSIS system. This is done based on the values computed or measured in the previous two steps.

## 6.1. Measuring the CMTS-CM combined timing parameters

The goal is to jointly characterize the CMTS-CM timing parameters using a reference-length plant, i.e., the HFC path is just a coax connection of reference length from the CMTS to the CM, as depicted in Figure 11.

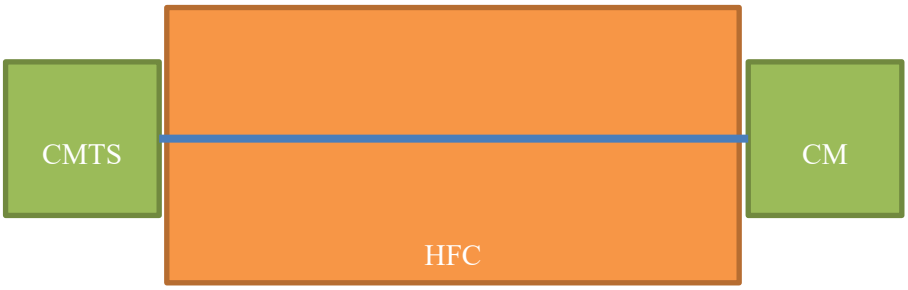

**Figure 11 – Measuring CMTS-CM combined timing parameters**

In the following formulas, we utilize the suffix "-R" to refer to any values that are specific to the reference-length plant.

For a reference-length plant, formulas (1) and (2) become:

*(3)* $t\text{-}tro\text{-}R = t\text{-}cmts\text{-}ds\text{-}o + t\text{-}cmts\text{-}ds\text{-}p + t\text{-}hfc\text{-}ds\text{-}o\text{-}R + t\text{-}hfc\text{-}ds\text{-}p\text{-}R + t\text{-}cm\text{-}ds\text{-}o + t\text{-}cm\text{-}ds\text{-}p + t\text{-}cm\text{-}us\text{-}o + t\text{-}cm\text{-}us\text{-}p + t\text{-}hfc\text{-}us\text{-}o\text{-}R + t\text{-}hfc\text{-}us\text{-}p\text{-}R + t\text{-}cmts\text{-}us\text{-}o + t\text{-}cmts\text{-}us\text{-}p$

*(4)* $t\text{-}cm\text{-}adj\text{-}R = t\text{-}cmts\text{-}ds\text{-}i + t\text{-}cmts\text{-}ds\text{-}o + t\text{-}cmts\text{-}ds\text{-}p + t\text{-}hfc\text{-}ds\text{-}o\text{-}R + t\text{-}hfc\text{-}ds\text{-}p\text{-}R + t\text{-}cm\text{-}ds\text{-}o + t\text{-}cm\text{-}ds\text{-}p + t\text{-}cm\text{-}ds\text{-}i$

Note that the CMTS and CM parameters do not require a "-R" suffix because their values are independent of the length of the HFC in the reference-length plant.

Since the HFC is just a coax connection in the reference-length plant, it is assumed that the HFC upstream and downstream offset timing values are both zero, i.e., $t\text{-}hfc\text{-}us\text{-}o\text{-}R = 0$ *and* $t\text{-}hfc\text{-}ds\text{-}o\text{-}R=0$. Thus, formulas (3) and (4) become:

*(5)* $t\text{-}tro\text{-}R = t\text{-}cmts\text{-}ds\text{-}o + t\text{-}cmts\text{-}ds\text{-}p + t\text{-}hfc\text{-}ds\text{-}p\text{-}R + t\text{-}cm\text{-}ds\text{-}o + t\text{-}cm\text{-}ds\text{-}p + t\text{-}cm\text{-}us\text{-}o + t\text{-}cm\text{-}us\text{-}p + t\text{-}hfc\text{-}us\text{-}p\text{-}R + t\text{-}cmts\text{-}us\text{-}o + t\text{-}cmts\text{-}us\text{-}p$

*(6)* $t\text{-}cm\text{-}adj\text{-}R = t\text{-}cmts\text{-}ds\text{-}i + t\text{-}cmts\text{-}ds\text{-}o + t\text{-}cmts\text{-}ds\text{-}p + t\text{-}hfc\text{-}ds\text{-}p\text{-}R + t\text{-}cm\text{-}ds\text{-}o + t\text{-}cm\text{-}ds\text{-}p + t\text{-}cm\text{-}ds\text{-}i$

Now, we record the following values for the reference-length plant:

- *t-tro-R*: True ranging offset as reported by the CM.

- *t-cm-adj-R*: Value of the DTP time adjustment that brings the average PTP 2-Way Time Error (cTE) to zero.
- *t-hfc-ds-p-R:* Downstream path delay introduced by the coax cable going from the CMTS to the CM. This is computed based on the length of the coax cable and the speed of propagation in the coax cable. Typically, this speed is around 1.5ns/ft.
- *t-hfc-us-p-R:* Downstream path delay introduced by the coax cable going from the CMTS to the CM. This is computed based on the length of the coax cable and the speed of propagation in the coax cable. Typically, this speed is around 1.5ns/ft.

Rearranging the terms in formulas (5) and (6), we get

*(7) t-tro-R - t-hfc-ds-p-R - t-hfc-us-p-R = t-cmts-ds-o + t-cmts-ds-p + t-cmts-us-o + t-cmts-us-p + t-cm-ds-o + t-cm-ds-p + t-cm-us-o + t-cm-us-p*

*(8) t-cm-adj-R - t-hfc-ds-p-R = t-cmts-ds-i + t-cmts-ds-o + t-cmts-ds-p + t-cm-ds-o + t-cm-ds-p + t-cm-ds-i*

The most important aspect of the formulas (7) and (8) is that on the left-hand side of each formula we have values that are either measured or calculated based on the reference-length plant, and on the right-hand side we have a combination of CMTS and CM timing parameters. Thus, we achieved the goal of measuring the CMTS-CM combined timing parameters.

Now that we have an expression that summarizes the combination of CMTS and CM parameters (right-hand side of formulas (7) and (8)), we use formulas (7) and (8) and combine those with the generic formulas (1) and (2). Here are the formulas (1) and (2) once more, with the CMTS and CM parameters moved as to group them for simplicity:

*(1) t-tro = t-hfc-ds-o + t-hfc-ds-p + t-hfc-us-o + t-hfc-us-p + (**t-cmts-ds-o + t-cmts-ds-p+ t-cmts-us-o + t-cmts-us-p + t-cm-ds-o + t-cm-ds-p + t-cm-us-o + t-cm-us-p**)*

*(2) t-cm-adj = t-hfc-ds-o + t-hfc-ds-p +(**t-cmts-ds-i + t-cmts-ds-o + t-cmts-ds-p + t-cm-ds-o + t-cm-ds-p + t-cm-ds-i**)*

The terms in bold in formula (1) are the same as the right-hand side of formula (7). The terms in bold in formula (2) are the same as the right-hand side of formula (8). So, plugging formulas (7) and (8) into formulas (1) and formula (2), we get new generic formulas:

*(9) t-tro = t-hfc-ds-o + t-hfc-ds-p + t-hfc-us-o + t-hfc-us-p + (t-tro-R – t-hfc-ds-p-R – t-hfc-us-p-R)*

*(10) t-cm-adj = t-hfc-ds-o + t-hfc-ds-p + (t-cm-adj-R – t-hfc-ds-p-R)*

## 6.2. Measuring the HFC timing parameters

The goal is to characterize the timing parameters of a single HFC element. While it is possible to characterize a set of HFC elements as a single unit, the results would only be usable when that same set is present in a deployment.

First, the HFC element of interest is inserted between the CMTS and the CM, as depicted in Figure 12. For the plant described in Figure 12, we utilize the suffix "-1" to refer to any values that are specific to this plant. This represents the plant under test in an actual deployment. The goal is to generate a formula for CM-adj.

 

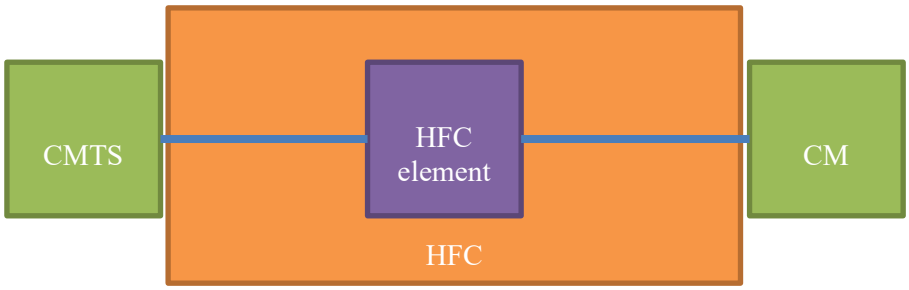

**Figure 12 – Measuring HFC timing parameters**

In Figure 12, the HFC is composed of three parts. Part 1 is the cable going from the CMTS to the HFC element. Part 2 is the HFC element itself. Part 3 is the cable going from the HFC element to the CM.

Now, we record the following values for the plant in Figure 12:

- *t-tro-1:* True ranging offset as reported by the CM.
- *t-cm-adj-1*: Value of the DTP time adjustment that brings the average PTP 2-Way Time Error (cTE) to zero
- *t-hfc-ds-p-1:* Downstream path delay introduced by the fiber and coax cables going from the CMTS to the CM. This value includes the downstream path delay from the CMTS to the HFC element and from the HFC element to the CM. This value is computed based on the length of the fiber and coax cables and the speed of propagation in each.
- *t-hfc-us-p-1:* Upstream path delay introduced by the fiber and coax cables going from the CMTS to the CM. This value includes the upstream path delay from the CM to the HFC element and from the HFC element to the CMTS. This is computed based on the length of the fiber and coax cables and the speed of propagation in each.

Note that there is no "-1" parameter for the HFC offset because the HFC offset parameter is independent of the coax and fiber lengths between the CMTS and the CM.

With the above values recorded, the following is obtained from formulas (9) and (10):

$$t\text{-}tro\text{-}1 = t\text{-}hfc\text{-}ds\text{-}o + t\text{-}hfc\text{-}ds\text{-}p\text{-}1 + t\text{-}hfc\text{-}us\text{-}o + t\text{-}hfc\text{-}us\text{-}p\text{-}1 + (t\text{-}tro\text{-}R - t\text{-}hfc\text{-}ds\text{-}p\text{-}R - t\text{-}hfc\text{-}us\text{-}p\text{-}R) \quad (11)$$

$$t\text{-}cm\text{-}adj\text{-}1 = t\text{-}hfc\text{-}ds\text{-}o + t\text{-}hfc\text{-}ds\text{-}p\text{-}1 + (t\text{-}cm\text{-}adj\text{-}R - t\text{-}hfc\text{-}ds\text{-}p\text{-}R) \quad (12)$$

Rearranging the terms in formula (11), we get:

$$t\text{-}hfc\text{-}ds\text{-}o + t\text{-}hfc\text{-}us\text{-}o = t\text{-}tro\text{-}1 - t\text{-}hfc\text{-}ds\text{-}p\text{-}1 - t\text{-}hfc\text{-}us\text{-}p\text{-}1 - (t\text{-}tro\text{-}R - t\text{-}hfc\text{-}ds\text{-}p\text{-}R - t\text{-}hfc\text{-}us\text{-}p\text{-}R) \quad (13)$$

Rearranging the terms in formula (12), we get:

$$t\text{-}hfc\text{-}ds\text{-}o = t\text{-}cm\text{-}adj\text{-}1 - t\text{-}hfc\text{-}ds\text{-}p\text{-}1 - (t\text{-}cm\text{-}adj\text{-}R - t\text{-}hfc\text{-}ds\text{-}p\text{-}R) \quad (14)$$

Plugging formula (14) into formula (13), we get

*(15) t-cm-adj-1 - t-hfc-ds-p-1 - (t-cm-adj-R – t-hfc-ds-p-R) + t-hfc-us-o = t-tro-1 - t-hfc-ds-p-1 - t-hfc-us-p-1 - (t-tro-R - t-hfc-ds-p-R - t-hfc-us-p-R)*

Now, simplifying formula (15), we get:

*(16) t-hfc-us-o = (t-tro-1 - t-hfc-us-p-1) - (t-cm-adj-1 - t-cm-adj-R) - (t-tro-R - t-hfc-us-p-R)*

The most important aspect of formulas (14) and (16) is that on the left-hand side of each we have the HFC offset parameters, and on the right-hand side we have values that were either obtained from the reference-length plant (the "-R" values), or measured/calculated in the plant with the added HFC elements (the "-1" values). Thus, we get a numeric value for the HFC offset timing values.

The second most important aspect of the above results is that the values obtained for the HFC offset timing values can later be used with any other CMTS-CM pair different from the ones used for the reference-length plant.

Note that if there are multiple HFC elements, then the values of *t-hfc-ds-o* and *t-hfc-us-o* should reflect the addition of the timing parameters of each HFC element.

An operator wanting to use DTP should have all its HFC elements characterized from a DTP point of view. Not doing such characterization would eat away from the overall time error budget allocated to the DOCSIS network. Alternatively, a rough characterization might work as there may be enough margin in the time error budget, or the length of the fiber plant dominates the overall time error and negates small changes on the coax plant. So, the difference in calibration may be the difference between a good result and a great result. Is good, good enough? It depends on the result and the cost.

## 6.3. Computing the DTP Time Adjustment in a live DOCSIS system

Now that we have the CMTS-CM pair and HFC elements characterized, we can use those values to compute the DTP time adjustment in a live system.

Note: The variables *t-hfc-ds-o* and *t-hfc-us-o* are chosen to model both fixed delays and any path asymmetry between the upstream and downstream HFC transmission paths. This allows the assumption to be made that the remaining path delay from the hfc downstream path and the hfc upstream paths are equal. Hence, *t-hfc-us-p = t-hfc-ds-p*.

Updating formula (9) based on *t-hfc-us-p = t-hfc-ds-p*, we get:

*(17) t-tro = t-hfc-ds-o + t-hfc-ds-p + t-hfc-us-o + t-hfc-ds-p + (t-tro-R – t-hfc-ds-p-R – t-hfc-us-p-R)*

*(18) t-tro = t-hfc-ds-o + 2*t-hfc-ds-p + t-hfc-us-o + (t-tro-R – t-hfc-ds-p-R – t-hfc-us-p-R)*

Rearranging the terms in formula (18), we get *t-hfc-ds-p*:

*(19) t-hfc-ds-p = [t-tro – t-hfc-ds-o – t-hfc-us-o – (t-tro-R – t-hfc-ds-p-R – t-hfc-us-p-R)]/2*

Plugging formula (19) into formula (10), we get:

*(20) t-cm-adj = t-hfc-ds-o + [t-tro – t-hfc-ds-o – t-hfc-us-o – (t-tro-R – t-hfc-ds-p-R – t-hfc-us-p-R)]/2+ (t-cm-adj-R – t-hfc-ds-p-R)*

Distributing the denominator and signs, we get:

$$(21)\ t\text{-}cm\text{-}adj = t\text{-}hfc\text{-}ds\text{-}o + t\text{-}tro/2 - t\text{-}hfc\text{-}ds\text{-}o/2 - t\text{-}hfc\text{-}us\text{-}o/2 - t\text{-}tro\text{-}R/2 + t\text{-}hfc\text{-}ds\text{-}p\text{-}R/2 + t\text{-}hfc\text{-}us\text{-}p\text{-}R/2 + t\text{-}cm\text{-}adj\text{-}R - t\text{-}hfc\text{-}ds\text{-}p\text{-}R$$

Re-arranging and grouping like terms

$$(22)\ t\text{-}cm\text{-}adj = t\text{-}cm\text{-}adj\text{-}R + t\text{-}tro/2 - t\text{-}tro\text{-}R/2 + t\text{-}hfc\text{-}ds\text{-}o - t\text{-}hfc\text{-}ds\text{-}o/2 - t\text{-}hfc\text{-}us\text{-}o/2 - t\text{-}hfc\text{-}ds\text{-}p\text{-}R + t\text{-}hfc\text{-}ds\text{-}p\text{-}R/2 + t\text{-}hfc\text{-}us\text{-}p\text{-}R/2$$

Subtracting like terms

$$(23)\ t\text{-}cm\text{-}adj = t\text{-}cm\text{-}adj\text{-}R + t\text{-}tro/2 - t\text{-}tro\text{-}R/2 + t\text{-}hfc\text{-}ds\text{-}o/2 - t\text{-}hfc\text{-}us\text{-}o/2 - t\text{-}hfc\text{-}ds\text{-}p\text{-}R/2 + t\text{-}hfc\text{-}us\text{-}p\text{-}R/2$$

Further assuming that $t\text{-}hfc\text{-}ds\text{-}p\text{-}R = t\text{-}hfc\text{-}us\text{-}p\text{-}R$, we get

$$(24)\ t\text{-}cm\text{-}adj = t\text{-}cm\text{-}adj\text{-}R + t\text{-}tro/2 - t\text{-}tro\text{-}R/2 + t\text{-}hfc\text{-}ds\text{-}o/2 - t\text{-}hfc\text{-}us\text{-}o/2 - t\text{-}hfc\text{-}us\text{-}p\text{-}R/2 + t\text{-}hfc\text{-}us\text{-}p\text{-}R/2$$

$$(25)\ t\text{-}cm\text{-}adj = t\text{-}cm\text{-}adj\text{-}R + t\text{-}tro/2 - t\text{-}tro\text{-}R/2 + t\text{-}hfc\text{-}ds\text{-}o/2 - t\text{-}hfc\text{-}us\text{-}o/2$$

Now, pulling the denominator back out and group terms for usability, we end up with the final formula for t-cm-adj

$$(26)\ t\text{-}cm\text{-}adj = t\text{-}cm\text{-}adj\text{-}R + [(t\text{-}tro - t\text{-}tro\text{-}R) + (t\text{-}hfc\text{-}ds\text{-}o - t\text{-}hfc\text{-}us\text{-}o)]/2$$

The most important aspect is that the only element on the right-hand side that was not a pre-calibrated numeric value is the TRO (*t-tro*) of the live system. The second important aspect that the formula hints at is that the DTP master, which is the entity computing the DTP time adjustment (*t-cm-adj*) should know what HFC parameters to use. In other words, some entity, e.g., the DTP master, should have an association between the CM and the HFC elements between the such CM and the CMTS. With this association, then the right HFC timing values could be recovered.

# 7. Requirements, Limitations and other aspects

In this section, we capture requirements, limitations, and tradeoffs related to the use of DTP.

## 7.1. Requirements

DTP relies on the true ranging offset (TRO), which is itself related to the ranging offset. As such, for the proper operation of DTP, the CM must have properly ranged. Moreover, the DTP message exchange should be repeated at least every time that the ranging offset changes.

The accuracy of DTP relies on the accuracy of the DOCSIS extended timestamp, which is obtained by the CM from an OFDM primary downstream channel. Thus, for the proper operation of DTP, the system must have an OFDM primary downstream channel. From the CM side, not only D3.1 support is needed but also DTP support (since its support is optional), and PTP support on its CMCI interface.

## 7.2. Limitations

The focus of DTP is on providing the CM with the appropriate time adjustment to be synchronized to an external time reference. However, what protocols such as PTP also provide is traceability information of the timing source and the path to the timing source. DTP does not provide this traceability. Rather than

making DTP aware of PTP-specifics, the SYNC committee decided to let the PTP traceability information be sent from the CMTS (acting as a boundary clock) to the CM (acting as a boundary clock). DTP does not need to modify the traceability information, but DOCSIS does need to transport it..

As discussed in Section 6, the calibration of the DTP timing values must be done jointly for the CMTS and the CM, and must take into account any configuration values, such as interleaving, that affects those timing values. The output of this calibration will be two-fold: a list of timing values per CMTS-CM pair and per configuration, and a list of timing values per HFC element per configuration. The industry can choose one of these two approaches to carry out the calibration efforts:

a) Let every MSO, CMTS, or CM vendor build its own calibration facilities and perform its own calibration measurements, or
b) Have a central entity, such as CableLabs®, be the one in charge of setting the calibration facilities and performing the calibration measurements.

It is the opinion of the authors that the first approach will be initially used by the CM and CMTS vendors releasing DTP support. However, for scalability and consistency purposes, it is the opinion of the authors that the second approach is better.

The I01 version of the SYNC specification was released on April 20, 2020. It includes a robust description of the overall system and its operation when the external timing sources are using PTP profile G.8275.1. The support for G.8275.2 is work in progress and expected to be added in a future release; this works includes the allocation of time error budget for the network elements and the definition of the transport mechanism for the PTP Announce and Signaling messages.

While the SYNC specification is not completed yet for G.8275.2, there is nothing preventing DTP to be tested in a network using G.8275.2 for the purposes of measuring the overall time error; the caveat is that the traceability information would not be available at the CM. In other words, DTP itself is agnostic to the PTP profile being used by the CMTS or the CM themselves.

### 7.3. Other aspects

The SYNC specification not only deals with the details of DTP, but also with the suggested allocation of the time error budget for the elements in the network. As discussed in Section 3, the DOCSIS network elements need part of the overall time error budget, but cannot be allocated all of it.

Each MSO needs to characterize the performance of their existing networks (from a time error point of view), including its non-DOCSIS elements, to validate if their existing networks can meet the total timing requirements or not. MSOs may find out that they need to upgrade parts of their networks, DOCSIS or non-DOCSIS elements, to meet the timing requirements.

For DTP to work effectively, the recovery of the DTP values by the DOCSIS system must be automated. As mentioned in Section 6.3, the DOCSIS system not only needs to recover the timing values of the CMTS-CM pair, but identify the HFC elements between the CMTS and CM to then recover the timing values for those HFC elements.

## 8. What's next?

In this section, we highlight the next steps for the industry to drive the adoption and use of DTP.

Key to the adoption of DTP is the calibration of the CMTS/RPD/RMD-CM pairs and the HFC elements. With these calibration values collected, a repository where this data is store needs to be established. CableLabs® is uniquely positioned to be the lead in this calibration initiative.

Having the calibration data available, DOCSIS systems need to introduce automated mechanisms to recover the DTP calibration data of the CMTS-CM pairs, identify the HFC elements between the CMTS-CM pair, and recover the DTP calibration data of those HFC elements.

In parallel, test equipment vendors need to build calibration tools to allow the calibration of CMTS, CM, and HFC elements separately from each other to simplify adoption of DTP.

## 9. Conclusions

The I01 version of the SYNC spec, released on April 20, 2020 describes how to build and deploy an IEEE 1588/PTP participant DOCSIS network. The SYNC specification is targeted at the new and evolving mobile backhaul market, if the DOCSIS system has the required throughput, latency, and timing.

The authors in [2] described how to achieve low latency backhaul over DOCSIS. In terms of timing, the DOCSIS system is already based upon highly precise timing. DTP leverages this asset to provide accurate timing to end applications connected through a CM. Rather than run NTP or PTP over-to-the-top, the DOCSIS system can be used as-is to generate or correct these timing protocols with a very high degree of precision.

# 1. Introduction

System leakage monitoring is an integral and extremely important aspect of system maintenance. Federal Communications Commission (FCC) leakage requirements, test and mitigation methods for present cable systems with 5-42 MHz and 5-85 MHz return bands are well understood. Leakage signal sources, monitoring equipment, methods and measurement programs are all in place for measurements in the downstream band, 54-1000 MHz, with an emphasis on the aeronautical band of 108-137 MHz. The FCC sets maximum individual signal leakage levels for cable systems, with more stringent limits on cable systems that may interfere with aeronautical and navigation communications.

In a traditional cable system with a 5-42 MHz return band, high level signals in the downstream are present at the headend or node output, and at the home, the downstream signal is at its lowest level. What happens if you increase the upper boundary of the upstream signal path to 204 MHz or higher? The system is essentially turned upside down, with the highest signal levels in the aeronautical band (108-137 MHz) at the home, and the lowest upstream signal levels at the headend or node.

This paper will look at the implications of these inverted plant levels. How do the FCC's cable signal leakage requirements apply to this scenario? Can the same leakage tools and methods be used? What changes and considerations need to be made? These questions not only apply to high split plants with 204 MHz upstream, but also to future full duplex data over cable service interface specification.

(FDX DOCSIS) and extended spectrum DOCSIS (ESD) systems, each with upstream signals well beyond 204 MHz.

This paper will review these considerations and discuss the implications of the "inverted" plant. Different options and scenarios will be examined, and their implementation and feasibility evaluated to help readers ensure a solid leakage measurement program is in place for when these plant upgrades are implemented.

# 2. Capabilities of DOCSIS 3.1

DOCSIS® 3.1 (D3.1) specifications expand the useable frequency spectrum as well as provide a more efficient use of that spectrum compared to its predecessor DOCSIS®3.0 (D3.0.) With downstream operation out to 1218 MHz along with a high-split (204/258 MHz) option, network capacity can be dramatically improved, particularly in the upstream direction. Included in these exceptional capabilities are orthogonal frequency-division multiplexing (OFDM) channels in the downstream and orthogonal frequency-division multiple access (OFDMA) channels in the upstream. OFDM and OFDMA channels permit a wide-ranging encompassed spectrum-improving capacity, while still allowing very small minislots for enhanced bandwidth utilization. With the 204 MHz upstream spectrum available, and with optimal use of the OFDMA technology, 1 Gbps symmetrical services become possible. In addition, higher-order modulations, including 1024 to 4096 QAM downstream and 256 to 2048 QAM upstream, as well as enhanced forward error correction (FEC) methods in both directions, provide another example of how D3.1 can improve overall capacity and customer experience. Modifications to the hybrid fiber coax (HFC) network parameters, as they pertain to a D3.1 upgrade, need to be continuously evaluated for impact on legacy and future FCC compliance.

# 3. The Need for High-Split Hybrid Fiber Coax Networks

The demands of an HFC network, and, in particular network traffic, continue to increase. Downstream traffic has seen tremendous growth, with over-the-top (OTT) video driving most of the surge. With D3.1, the downstream network is more than capable of handling this traffic increase. A typical High-Split D3.1 downstream channel lineup can accommodate over ninety (256 QAM) D3.0 channels and two 192 MHz (4096 QAM) OFDM D3.1 channels, exceeding throughputs of 9 Gbps.

The limited 5-42 MHz signaling spectrum is typically where the bottleneck in the upstream network performance occurs. Applications and hardware are continually being developed that utilize the upstream more frequently, and with higher bandwidth needs. Internet of Things (IOT), video doorbells, security cameras, online gaming and cellphone Wi-Fi handoffs are all taxing the upstream network.

Currently, and even more relevant, is the impact that COVID-19 is having on the network. In three months, from early March to late May, multiple system operators (MSOs) saw a 32% increase in upstream traffic and an 11% increase in downstream traffic. This added growth is due to a sharp rise in video conferencing and video streaming, now that so many employees and students are working/learning from home.

Beyond D3.1 improvements in efficiency, node splits have been the go-to method to increase upstream capacity. While node splits do increase capacity, they do so without increasing the upstream peak data rate. Upgrading to a mid-split (5-85 MHz) will increase the upstream data throughput to ~ 500 Mbps, and upgrading to high-split (5-204 MHz) will allow >1 Gbps upstream throughput, future proofing the network and keeping the DOCSIS network competitive with alternative technologies. Full duplex (FDX) technology further expands the upstream capabilities, enabling multi-Gbps upstream speeds.

High-split D3.1 technology and products are in high demand and readily available. End-to-end solutions from cable modem termination system (CMTS) all of the way through the plant to the customer premise equipment (CPE) can be procured and installed. This allows operators to upgrade to a high-split network quickly, drastically improving upload speeds, while maintaining extraordinary downstream traffic capacity.

## 3.1. Impact on Existing Legacy Customer Premise Equipment

A large majority of cable modems deployed in the field do not support high-split operation and will operate “business as usual” with the channels that reside in their existing spectrum allocations. Moreover, legacy set-top boxes (STBs) are limited to control channel frequencies between 70 and 130 MHz in the downstream direction, so the out-of-band (OOB) channel will not pass through any diplex filters notched at 204/258 MHz that are used in the traditional HFC network. MSOs are faced with two options: Replace all legacy STBs to support high-split systems with DOCSIS set-top gateways (DSGs) (with the OOB control channel carried over DOCSIS) or enable the OOB control channel signal to propagate through the high-split network to the legacy STB in the upstream spectrum band. For the latter solution, signal requirements defined by SCTE 55-1, 55-2 and SCTE 40 must be maintained, and with a broad range of possible OOB frequencies, challenges from a scalability and standardized solution perspective will need to be resolved.

# 4. Federal Communications Commision Requirements

Understanding the FCC requirements for leakage is a daunting task. The FCC requirements are a maze of different related and unrelated requirements. We'll take you through the main requirements as they relate to the CATV network today and as they relate to the high split network.

There are a few main key FCC requirements. **47 CFR § 76.605** Technical Standards defines the CATV signal and signal leakage limits for both analog and digital signals. Leakage limits are defined in § 76.605 and are shown below in Table 1.

**Table 1 - CFR § 76.605 Signal Leakage Limits**

| Frequencies | Signal leakage limit | Distance in meters (m) |
|---|---|---|
| Analog signals less than and including 54 MHz, and over 216 MHz | 15 µV/m | 30 |
| Digital signals less than and including 54 MHz, and over 216 MHz | 13.1 µV/m | 30 |
| Analog signals over 54 MHz up to and including 216 MHz | 20 µV/m | 3 |
| Digital signals over 54 MHz up to and including 216 MHz | 17.4 µV/m | 3 |

The following FCC requirements are applicable to all multichannel video programming distributors (MVPDs): §76.605(d) Technical Standards, § 76.611 Cable television basic signal leakage performance criteria, § 76.612 Cable television frequency separation standards, § 76.613 Interference from a multichannel video programming distributor (MVPD, 76.614 Cable television system regular monitoring, 76.616 Operation near certain Aeronautical and Marine Emergency Radio Frequencies, 76.617 Responsibility for interference, 76.1803 Signal Leakage monitoring and 76.1804 Aeronautical frequencies: leakage monitoring (CLI)

With respect to 47 CFR § 76.610 – Operation in the frequency bands 108-137 MHz and 225-400 MHz - scope of application, this requirement states: The provisions of §§ 76.605(d), 76.611, 76.612, 76.613, 76.614, 76.616, 76.617, 76.1803 and 76.1804 are applicable to all MVPDs (cable and non-cable) transmitting analog carriers or other signal components carried at an average power level equal to or greater than 100 microwatts across a 25 kHz bandwidth in any 160 microsecond period or transmitting digital carriers or other signal components at an average power level of 75.85 microwatts across a 25 kHz bandwidth in any 160 microsecond period at any point in the cable distribution system in the frequency bands 108-137 and 225-400 MHz for any purpose.

The requirements above warrant a look at the upstream levels generated at the cable modem, to determine if the additional sections referenced apply in a High Split system. Take, for example, an upstream channel configuration with four SC-QAM channels in the 5-42 MHz band and two OFDMA channels, each with a bandwidth of 81 MHz, from 42-204 MHz.

Per the D3.1 specifications, the maximum transmit power from a cable modem is 65 dBmV. With 4 SC-QAMs each 6.4 MHz wide and two OFDMA channels from 42-204 MHz, the total upstream utilized bandwidth is 187.6 MHz. This equates to a power per 25 KHz bandwidth of 5.6 uW and a power per 30 KHz bandwidth of 6.7 uW. This transmit power is below the 75.85 uW threshold in 76.610, which triggers applicability to; §§ 76.605(d), 76.611, 76.612, 76.613, 76.614, 76.616, 76.617, 76.1803 and 76.1804. Even though 76.1804 is not applicable, 76.1804 had a different threshold of 10 uW. In this example, the threshold of 10uW in 76.1804 is also not exceeded. 76.616 is also not applicable per the requirements, but the exlusion zones required to avoid any impact to these emergency beacons are supported by D3.1, are minimal in bandwidth impact, and have minimal effect on upstream capacity or peak speeds.

D3.1 has a maximum power limit for OFDMA channels of <= 24 MHz of -9 dBmV/Hz. As another example, consider a single OFDMA channel of 24 MHz, which happens to overlap with the 108-137 MHz aeronautical band. While a deployment that only uses 24 MHz is not a productive use of spectrum and is unlikely to be deployed, it could possibly be done as the worst case power spectral density, per the D3.1 specifications. The power per Hz is constant at -9 dBmV. This equates to a power per 25 KHz bandwidth of 42 uW, and a power per 30 KHz bandwidth of 50.4 uW, which is again below the threshold of 75.85 uW in 76.610, which triggers applicability to §§ 76.605(d), 76.611, 76.612, 76.613, 76.614, 76.616, 76.617, 76.1803 and 76.1804. 76.1804 has a power level requirement of 10 uW in a 30 KHz band. The threshold of 76.1804 is exceeded and FCC notification on form 321 is required. The same comments on 76.716 apply as in the first example.

To help navigate the FCC requirements, Figure 1 shows the majority of requirements and applicable conditions which apply to CATV systems.

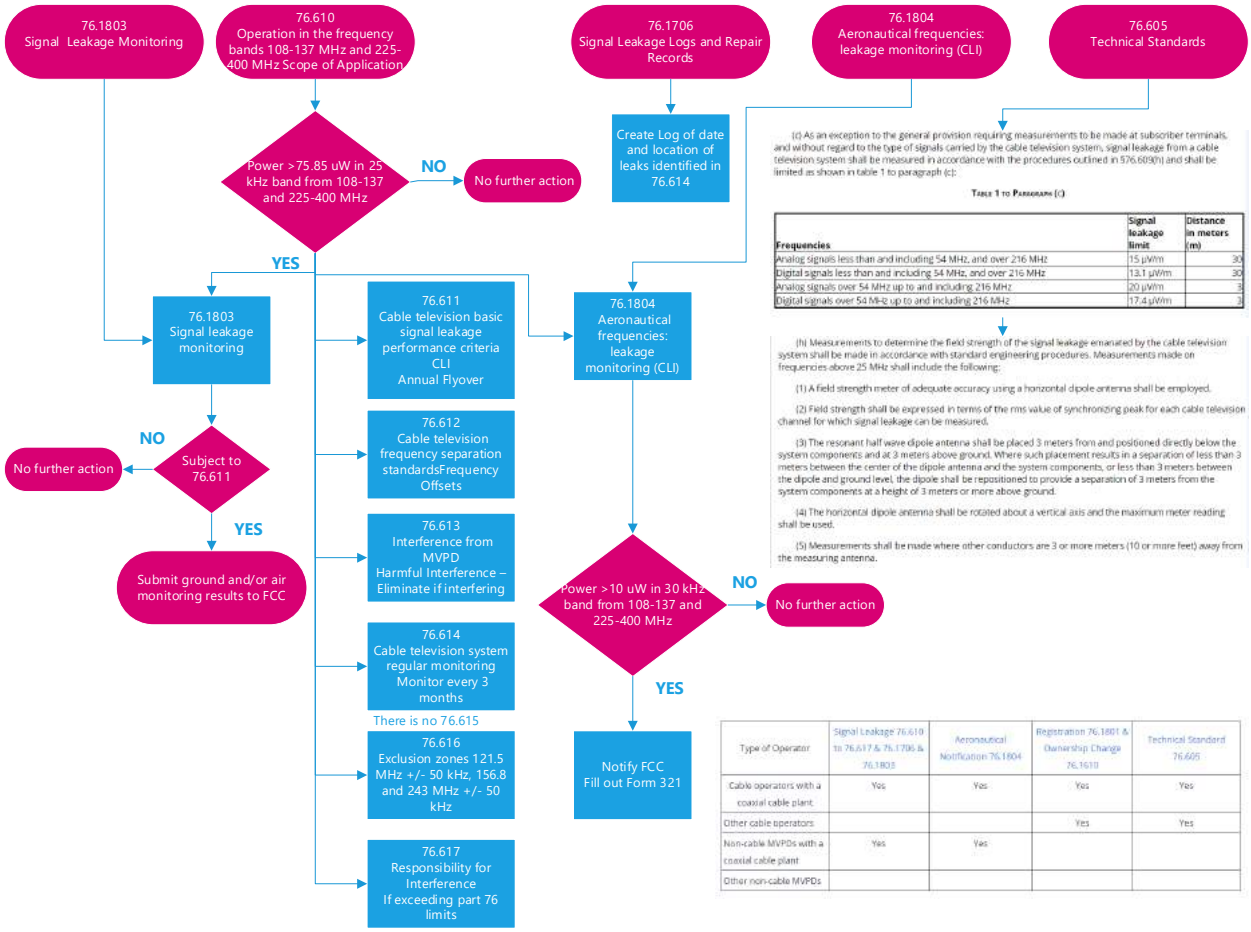

**Figure 1 - FCC Requirements Flow Chart**

## 5. How Leakage Detection is Currently Measured in the Downstream

There are several methods of signal leakage detection utilized by operators in today's HFC network. These can be broadly broken down into three categories: detection of low-level inserted carriers, direct QAM detection using correlation processing, and detection of harmonics of OFDM continuous pilots.

## 5.1. Detection of low-level inserted carriers

With this technique, two CW carriers are inserted into the network, at either the hub or at the R-PHY or MAC-PHY node, and the leakage signal is captured using a fast fourier transform (FFT) detector. The carriers are typically configured to be -30dBc, relative to the SC-QAM digital channel power. Various leakage detection vendors utilize different configurations of CW carrier placement or configuration of the inserted signal. Some examples of widely used signal types are provided in Figure 2 and Figure 3.

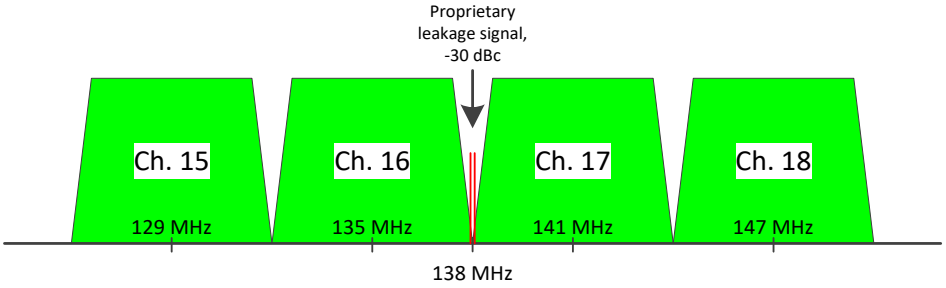

**Figure 2 - Leakage test signal injected at 138 MHz, on the channel boundary between adjacent SC-QAM signals (STD channel plan assumed).**

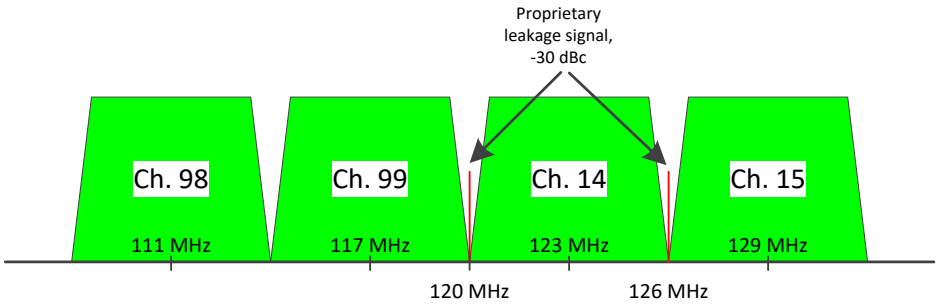

**Figure 3 - Leakage test signal injected at 120 MHz and 126 MHz, on the channel boundaries below and above SC-QAM signal (STD channel plan assumed).**

## 5.2. Direct QAM detection using correlation processing

With this technique, downstream signal samples are captured at the headend at the desired leakage detection frequency. The signal samples are time stamped using a GPS reference clock and transmitted to a leakage detector in the field. The leakage detector receives signals leaking from the HFC network, time stamps the received signals, and then applies a cross-correlation process on the two signal sets to resolve the detected leak.

## 5.3. Detection of harmonics of OFDM continuous pilots

With this technique, an FFT detector is again utilized in the field meter to capture the leakage signal – but with this method no additional tagging or CW signal is inserted into the HFC network. The detected signals are the existing harmonics of the OFDM continuous pilots, as show below in Figure 4.

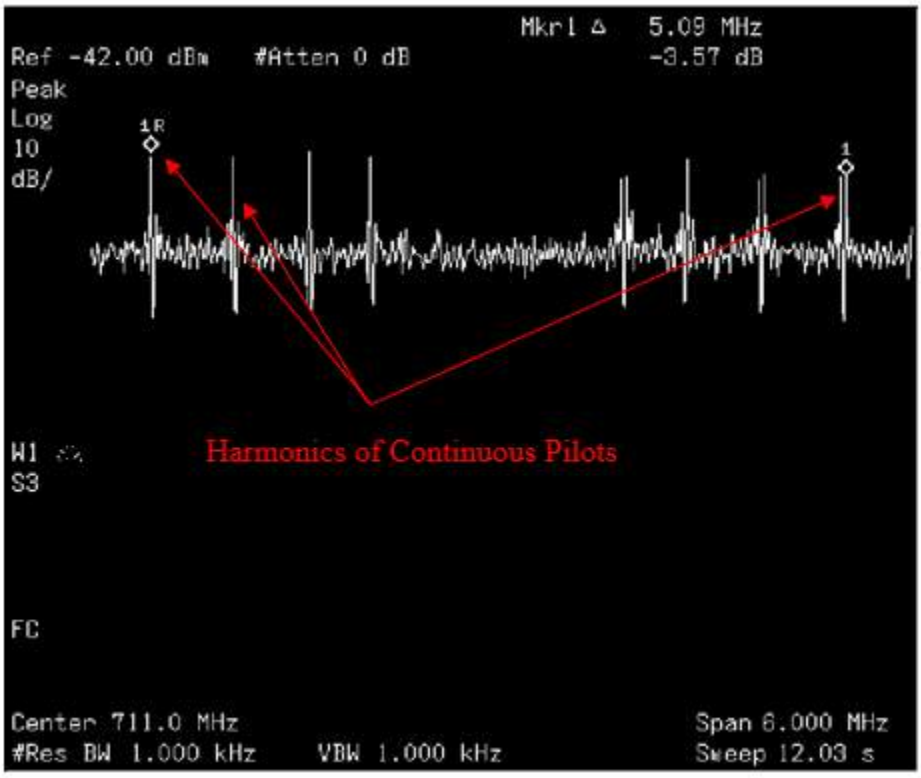

**Figure 4 - Harmonics of OFDM Continuous Pilots**

Unfortunately, none of the status quo approaches are suitable for use in the high-split network. This is mainly because the signals coming from the cable modem (CM) are inherently burst-like in nature, and instead of the leakage detection signal being generated from one source, as is the case with downstream detection, the detection signal is generated from the numerous non-coherent CMs in the upstream network. There are, however, some alternatives, presented below.

## 6. Similarities and Differences between Upstream and Downstream Leakage Detection

For upstream signal generation, the high-split cable modem must be the source of the leakage detection signal. With the majority of the emphasis for downstream leakage detection on the "feed" side of an HFC network, attention now inverts to the "drop" side, including the home -- where upstream signal levels in a high-split network now encompass the aeronautical band and are at much higher levels than the downstream. Cable modems can transmit a maximum power of 65 dBmV for a single 6.4 MHz SC-QAM channel and receive downstream signals within a recommended range of (10 to –10 dBmV, 6 MHz BW.) In this instance, the leakage level delta in terms of uV/m can be over **2000** times higher in the upstream direction versus the downstream, if the leak is on the output of the cable modem. Having multiple cable modems transmitting leakage tones (per the technique described in Section 5.1) at the same time and frequency can cause constructive and destructive signal combining because of the different phases of the signal. This will create a high likelihood of inaccurate leakage detection measurements. Furthermore,

 

upstream leakage detection signals should be in burst mode operation, as opposed to continuous mode downstream tones, to limit the impact on upstream capacity and to protect the upstream power budgets of the optical components. Figure 5 illustrates the inverse relationship of DS to US signal levels between the "feed" and "drop" side of a tap.

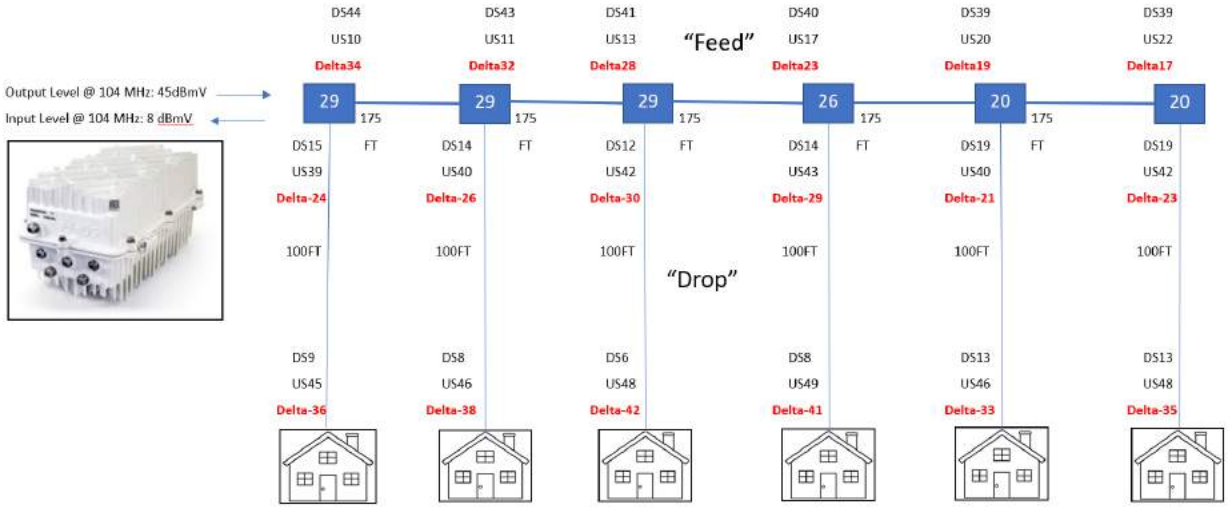

**Figure 5 - Example HFC Network Downstream to Upstream Level Deltas**

# 7. Upstream Leakage Detection Possibilities

## 7.1. Downstream Out of Band (OOB) CW pilots

With millions of legacy set top boxes that utilize SCTE 55-1 and SCTE 55-2 out-of-band data carriers in the forward/downstream, this functionality can be maintained through the distributed access architecture (DAA) node and amplifiers in high split systems. Two of the typical frequencies for the OOB carriers are 75.25 MHz and 104.2 MHz in 5-42 MHz systems. In mid split systems with 5-85 MHz upstream, 104.2 MHz is the typical frequency for the OOB carrier in the downstream.

In a high split system, 104.2 MHz sits in the middle of the upstream band and is also very close to the aeronautical band. To utilize a 104.2 MHz OOB carrier in a high split system, the 104.2 MHz OOB signal is generated in the CMTS or remote physical device (RPD), and via couplers and filtering this signal can be injected onto the plant on the low side of the diplex filter. Notch filters are required in the upstream to prevent the OOB signal from entering the return path receiver of the CMTS or RPD at a level that would cause distortion or interference. See Figure 6 for a simplified OOB implementation example in a high split RPD/node.

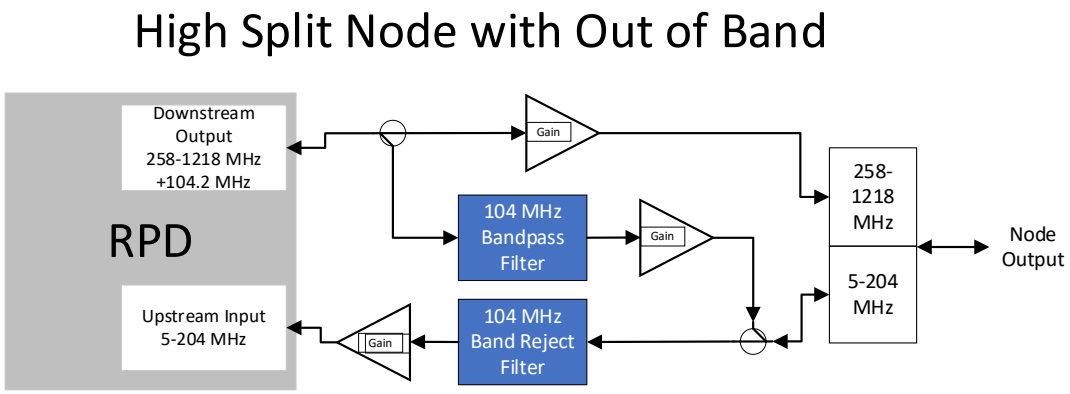

**Figure 6 - High Split RPD/Node with OOB Filtering**

Leakage tones can be generated in the RPD and placed close to the OOB carrier, and still fit within the 104 MHz bandpass filter passband. In a 5-204 MHz upstream, the two OFDMA channels can be placed above and below 104.2 MHz, to create a band gap for the 104.2 MHz OOB carrier. See Figure 7.

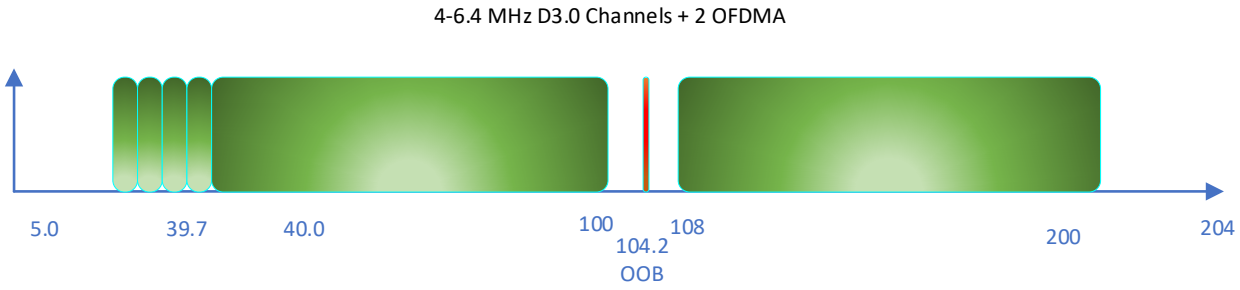

**Figure 7 - High Split Upstream Channel Configuration with OOB**

The 104 MHz bandpass filter can be made wide enough to include both the 104.2 MHz OOB and leakage tones. The leakage tones will then proceed down the plant along with the OOB carrier. See Figure 8.

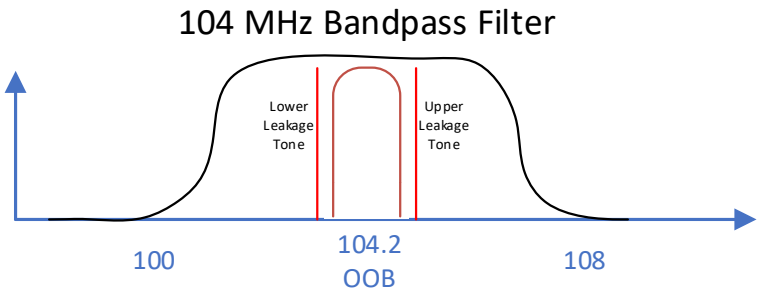

**Figure 8 - Out of Band Band Pass Filter Response with OOB Signal and Leakage Tones**

Although the leakage tones can be generated close to the lower edge of the aeronautical band, all the difficulties of the inverted plant and level differences between the downstream and upstream levels will make it difficult to correlate leakage measurements. Looking at Figure 5, the downstream-to-

upstream signal level delta is a positive 37 dB, and slowly decreases as you travel down the hard line plant, to a delta of 17 dB at the input to the last tap. Once you move to the drop side of the tap, the downstream-to-upstream delta decreases dramatically, with the largest negative delta at the premises. A method could be developed, based on plant maps and GPS coordinates, as leakage is measured along the plant. The maximum CM transmit level of 65 dBmV could be assumed, or additional information on CM transmit levels could also be determined from monitoring tools.

High Split devices will be introduced into the plant incrementally, as needed. Using the leakage tones generated at the RPD or CMTS could generate false readings, as the leakage tones are distributed to the whole plant and all homes. In most instances, using the default transmit value of 65 dBmV will be higher than the actual CM transmit values, and potentially create false high leakage readings. With the extensive mapping and software updates required, and the difficulty in correlating downstream-to-upstream levels, the other approaches described in this paper are likely more practical to implement. The goal is to be able to measure leakage events as reliably as possible, to meet regulatory requirements, without unnecessary increases in operational expense, or unnecessary risks for compliance issues.

## 7.2. Continuous Waveform Upstream Test Signal

One of the possibilities for upstream leakage detection is for the CM to generate continuous wave (CW) carriers. The CW carriers generated by the CMs cannot be continuously and simultaneously present at any one frequency, because the numerous out-of-phase signals would combine randomly and, as a direct result, yield random detection results. As an alternative, two CW approaches are presented below -- one with the CW burst controlled in time by the CMTS, and the second where each CM in a node transmits at a unique frequency. One important obstacle that will need to be overcome in these two approaches involves the fact that both are outside of the existing D3.1 specification. Also, current CMs are not able to generate the required CW carriers without updated firmware, and face constraints without updated hardware.

### *7.2.1. CW Time-Division Multiple Access (TDMA)*

In this scenario, there is continuous cyclical generation of two CW test bursts by CMs, under CMTS control, in an exclusion segment of bandwidth of the OFDMA spectrum within the aeronautical band. Detection of the leakage signal is provided by advanced FFT overlap processing, with leak signal validation accomplished by measuring the frequency offset between CW test tones, and by verifying the time sync and duration of the CW bursts. Figure 9 and Figure 10 below describe the burst schema and carrier placement.

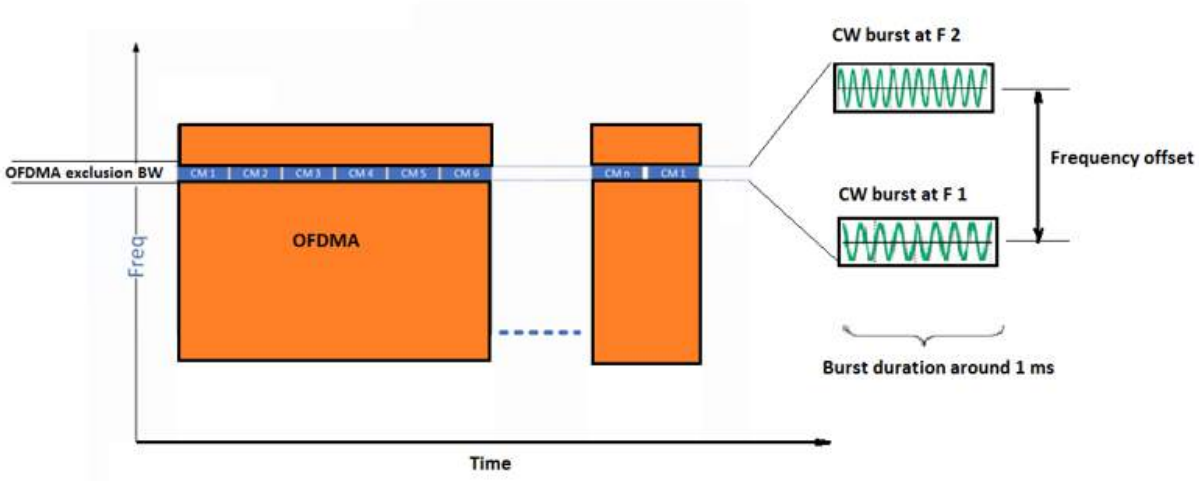

**Figure 9 - Illustration of permanent generation of CW test bursts by CM**

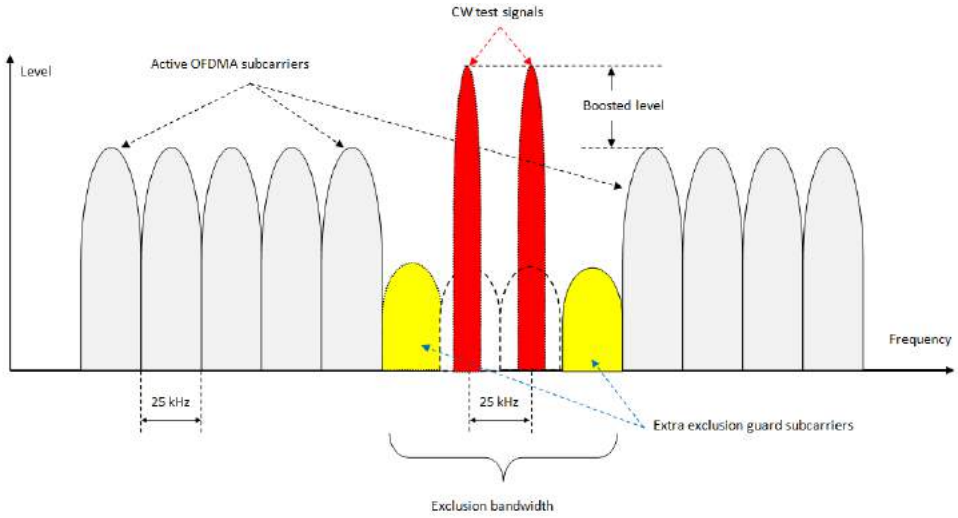

**Figure 10 - Illustration of CW test signals within exclusion BW of OFDMA signal (4k FFT mode)**

### *7.2.1.1.* Analysis of the parameters of the CW test signal*:*

The following parameters of the CW test signal are relevant for leakage detection and for compatibility with HFC data transmission:

- Frequency location of the CW test signal;
- Duration of the CW burst;
- Frequency offset between the CW bursts central frequencies;
- Level of the CW test signal relative to the level of the OFDMA subcarriers;

- **The frequency location of the CW test signal** should be within or very close to aeronautical band 108 - 137 MHz for accurate CLI reporting. Given that 108 MHz is the

edge frequency for FDX, it makes sense to assume that high split HFC upstream OFDMA spectrum also will also occupy the 108 MHz to 204 MHz band. This means the CW test signal could be placed near or within the OFDMA spectrum, in an exclusion bandwidth (BW), or below the edge frequency of 108 MHz, at a guard bandwidth within the lower adjacent OFDMA upstream signal.

- **The duration of the CW test** burst should be as long as possible, to provide improved sensitivity of leakage detection. On the other hand, the duration of the CW test burst is limited by the condition that each CM in a node serving group should be granted a transmit (Tx) test burst at least two times during the 1 second leak measuring session. Therefore, for a typical number of CMs in node, from 100 to 500 CMs, the maximum duration of the CW test burst is limited to around 1 ms.

- **The frequency offset between CW tones** should be as low as possible, to minimize the exclusion BW area of the OFDMA spectrum. On the other hand, the frequency offset needs to be sufficient to provide the FFT analyzer with enough resolution for correct leak signal validation. The bandwidth of a CW burst with a duration of 1 ms is a few kHz. Therefore, the minimum frequency offset should be around 10 kHz or more. To provide the minimum interfering effect, when receiving the OFDMA signal at the CMTS, it makes sense to establish the central frequencies of the CW bursts equally to the central frequencies of OFDMA subcarriers. In this case, the frequency offset between CW bursts will be 25 kHz (4k FFT) or 50 kHz (for 2k FFT) mode. The minimal exclusion bandwidth for placing CW test signals will be two subcarriers, however additional guard band carriers may be required for the exclusion area.

- **The level of each CW test signal** should be boosted as much as possible, relative to the OFDMA subcarriers level, to provide better sensitivity of leak detection. On the other hand, the level of the CW test burst must be below the possible interfering threshold at the receive (Rx) side of CMTS. According to the D3.1 specifications, OFDMA pilots could be boosted by at least 4.7 dB:[1]

> The CM MUST boost pilots and complementary pilots by a factor of 3 in power (about 4.7 dB).

Another approach to boosting the gain could be to increase the exclusion BW in the OFDMA spectrum and add the energy of the excluded subcarriers to the CW test signal. For example, in case of exclusion BW = 1.6 MHz, the boosting gain could be increased to +15 dBc. In this scenario, by placing the CW test signal outside the OFDMA spectrum (for example, below 108 MHz), the boosting gain could be increased up to + 20 dBc, where the power of CW test signal will be equal to the energy of one upstream SC-QAM. As a rule of thumb, the larger the spectrum exclusion, the more lost capacity for user data. Capacity calculation and OFDMA testing indicates that the goal of a 1 Gbps US product capability will require precise attention to spectral efficiency.

### *7.2.2. CW Frequency-Division Multiple Access (FDMA)*

This approach requires continuous generation of a pair of CW tones by each CM. The frequency offset between CW tones is the same at all CMs used for leak signal validation. The central

frequencies of the CW tone pairs at different CMs within one node will have a specific frequency offset, with each CM in a node transmitting at a unique frequency. This frequency offset is required for frequency resolution of signals from different CMs in the leak detector, and for correct measurement of the leak level, such as in the scenario where there is combining of CW tones from many CMs in the trunk line. All CW tones are located within the exclusion bandwidth of the OFDMA spectrum within the aeronautical band. The level of CW tones is suppressed relative to the level of the OFDMA subcarriers, to prevent interfering with the CMTS Rx side. Detection of the leak signal is provided by FFT processing. This is the same technology as is currently used for detection of DS harmonics of OFDM continuous pilots, and for pilots inserted between SC-QAM channels.

With this approach, permanent control from the CMTS side is not required, as is the case of CW time division multiple access (TDMA) burst or OFDMA upstream data profile (OUDP) approaches. The generation of CW tones can be activated at the CMs during initial provisioning by using direct access via telnet, simple network management protocol (SNMP) or the web. This provisioning of tone frequency, and the frequency accuracy, calibration to OFDMA power levels, and fidelity is not supported in current standards and would need to be agreed upon by all high split CM vendors, through the CableLabs specification and certification process. Figure 11 describes this concept.

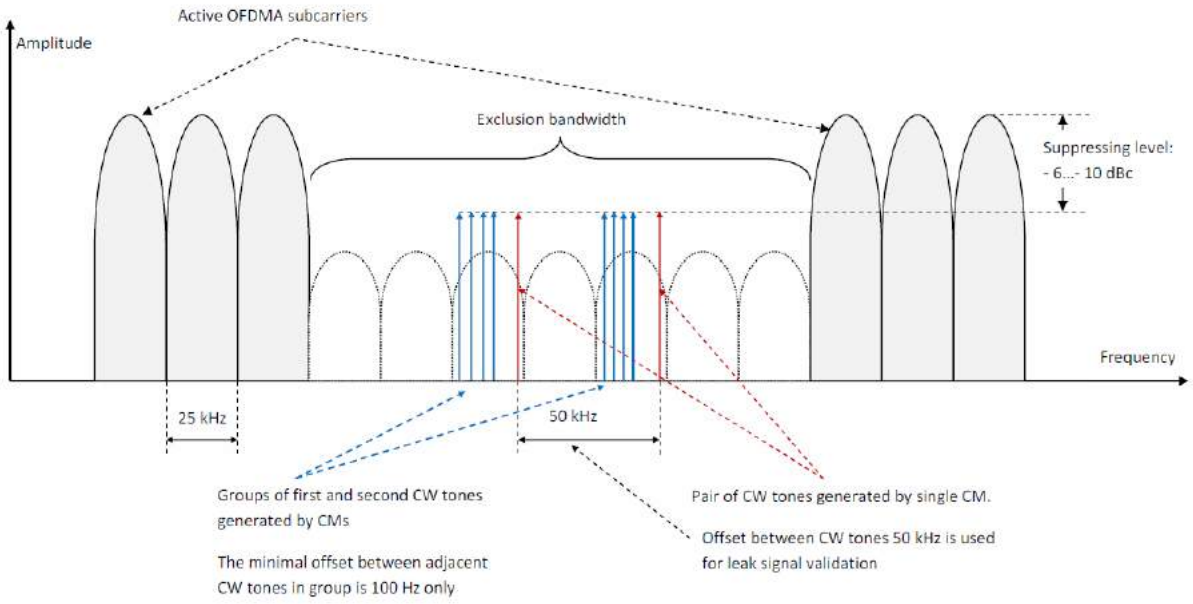

**Figure 11 - Illustration concept of continuous generation CW tones by all CMs**

### *7.2.2.1. Analysis of parameters of CW tone signal:*

The following parameters of the CW test signal are relevant for leakage detection and for compatibility with HFC data transmission:

- Frequency location of CW signal;
- Frequency offset between CW tones from different CMs within one node;
- Frequency offset between CW tones in each CM for leak validation;
- Level of CW tones relative OFDMA subcarriers and reasonable exclusion bandwidth.

- **The frequency location of CW tones** should be within or very close to the aeronautical band 108 - 137 MHz for accurate FCC reporting. Given that 108 MHz is the edge frequency for FDX, it makes sense to assume that for high split HFC, the upstream OFDMA spectrum also will be from 108 MHz to 204 MHz. This means that the CW tone signal could be placed within the OFDMA spectrum at some exclusion BW, or below the edge frequency of 108 MHz at the guard band of the lower adjacent OFDMA upstream signal.

- **The frequency offset between CW tones from different CMs within node** should be big enough to provide good frequency resolution of tones from different CMs in the leak detector FFT processor for correct measurement of leak levels. Absent this frequency offset, tones from different CMs will add with different phases, and the leak signal within the hardline will have random fluctuating levels, depending upon the number of accumulated CW tones. On the other hand, the frequency offset should be as minimal as possible, to reduce the required exclusion bandwidth in OFDMA spectrum. The frequency resolution of current FFT leak detectors is below 10 Hz, so a minimum frequency offset could be selected as 100 Hz. For a typical number of 250 CMs in a node, the CW tones will be grouped in two bandwidths (see Fig.10) of 25 kHz each within one OFDMA subcarrier.

- **The frequency offset between CW tones in each CM is used for leak signal validation**. This offset should be two times more than the bandwidth occupied by each group of CW tones (see Figure 11) to prevent overlapping groups of CW tones in the frequency domain. Therefore, the offset depends both upon the minimum offset and number of CMs in the node. For minimal frequency offset = 100 Hz and the number of CMs in node equal to 250 the minimal offset for leak validation will be 50 kHz as shown in Fig.10.

- **The level of each CW tone** should be as high as possible to provide good sensitivity of leak detection. On the other hand, the energy of CW tones from all CMs in node will be combined at the CMTS Rx side. This means that the level of CW tones should be limited (suppressed), relative to the level of the OFDMA subcarrier, to prevent interfering with and overloading the CMTS. It should be noted that increasing the excluded BW allows an increased level of the CW tones, from a point of view of saving the total energy of the signal in the same BW. Additionally, according to the DOCSIS 3.1 specs, OFDMA pilots can be boosted by at least 4.7 dB:[1]

> The CM MUST boost pilots and complementary pilots by a factor of 3 in power (about 4.7 dB).

With this, we can assume the energy of all CW tones must be no more than energy of all excluded subcarriers, plus 4.7 dB. Based on this assumption, the relative level of one CW tone is defined by formula:

$$L\ (dBc) = 10\ Log\ (M\ /2K) + 4.7\ dB,$$

where:

M is number of excluded subcarriers;

K is maximum number of CMs in node.

Table 2 below shows the relative level of CW tones dependent on the exclusion zone and the number of CMs. Continuously dedicated spectral exclusion bands of multiple MHz are material in the challenges they present to achieve the goal of Gbps US services.

**Table 2 - Relative level of CW tones vs OFDMA subcarriers, dBc**

| Exclusion BW | Number of CMs in node | | | | |
|---|---|---|---|---|---|
| | 100 | 200 | 300 | 400 | 500 |
| **400 kHz** | -6.27 | -9.28 | -11.04 | -12.29 | -13.26 |
| **800 kHz** | -3.26 | -6.27 | -8.03 | -9.27 | -10.25 |
| **1,600 kHz** | -0.25 | -3.26 | -5.02 | -6.26 | -7.24 |
| **2,000 kHz** | +0.72 | -2.29 | -4.05 | -5.03 | -6.27 |

## 7.3. OUDP Burst Test Signal (BTS)

This leakage detection method uses an OFDMA Upstream Data Profile (OUDP) burst that is generated by each high split cable modem, which is used to detect and monitor leakage in the aeronautical band of a high-split (204/258 MHz) HFC network. Within the DOCSIS specification, there are several predefined OUDP pilot patterns. Existing pilot pattern 11 contains the densest concentration of pilots, and as such it makes sense to use exactly this pattern for the CM burst signal used for detection. Detection of the signal is realized by utilizing a matched filter[1] for the predefined pilot pattern. Scheduling and overall configuration of the cable modem OUDP burst signals will be done through the CMTS service gateway (SGW.) OUDP burst test signal (BTS) has several advantages compared to the previous solutions, the most noteworthy being not having to modify existing D3.1 specifications for cable modem upstream signal generation requirements, and not having to update firmware in existing CMs to add the capability of generating CW carriers. Because there will initially be a limited number of high split cable modems, this approach is also advantageous in that it accommodates the overall time needed to generate the OUDP test bursts. Even in a larger node, sufficient time will exist for data to be interleaved into that spectrum, as needed. In the future, when all modems are high split or FDX capable, the OUDP test bursts can be scheduled only when needed, freeing that spectrum for data bursts most of the time.

An illustration of this OUDP BTS approach, with one frame of 8 symbols and 4 minislots, is shown **Figure 12.**

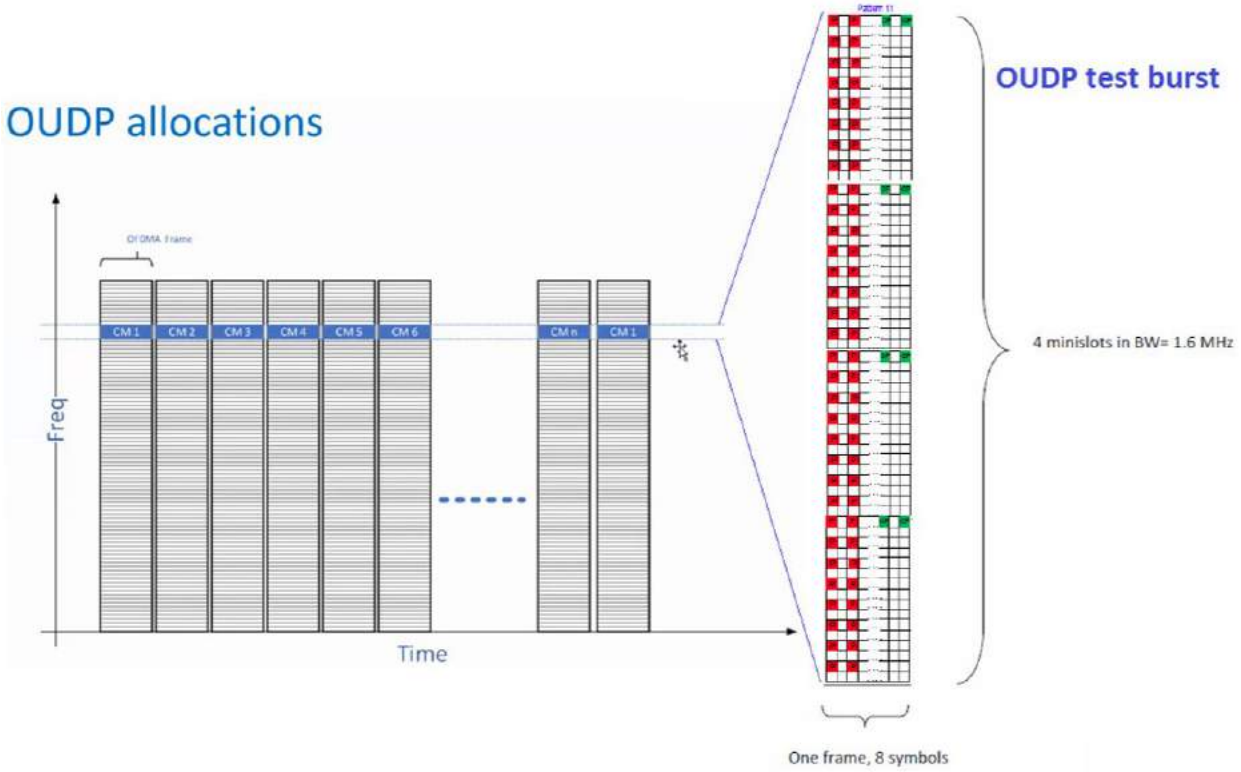

**Figure 12 - Generation of OUDP Test Bursts in a Service Group**

Using an OFDMA OUDP burst allows configurability in optimizing frequency placement in the upstream band; minimizes any impact to the overall upstream bandwidth/throughput; and optimizes duration to maximize the sensitivity of the receiver. The OFDMA OUDP burst is able to cycle through all the cable modems on the node and have a good probability of intercept (POI) for leakage measurements, as detailed in Section 10 Probability of Intercept: Moving Vehicle Analysis.

One example of an OUDP Burst Signal which can be configured in a high split cable modem is detailed below and shown in Figure 13. The parameters defining the OUDP signal are used to generate the matched filter within the leakage detector:

- Symbols Per Frame (K) = 6 (may be modified to improve network efficiency and robustness)
- Modulation Order = 64 QAM
- Pilot Pattern = 11
- Center Frequency of OUDP Signal = 136.0125 MHz
- 4 Minislots (1.6 MHz Upstream Bandwidth with the 4 adjacent minislots to the center frequency above)
- Number of Frames = 8 and 2.16 mS in transmit time duration. (For 256 House Holds Passed total roundtrip time = 552.96 mS)
- Transmit Power equal to the surrounding OFDMA P= 1.6 MHz channel transmit power
- 4K Fast Fourier Transform (FFT) = 40 uS per symbol + Cyclic Prefix
- Cyclic Prefix = 5.0 uS (may be modified to improve network efficiency and robustness)

- Window Roll off Period = 0.9375 uS (may be modified to improve network efficiency and robustness)

The pattern described above and illustrated in the far right of Figure 13 utilizes 8 frames of OUDP pilot pattern 11. This configuration provides the most pilot energy within the OUDP burst signal, which results in optimized sensitivity for detection, as compared to the other variants shown below. If there was the ability to define a new OUDP pilot pattern within the DOCSIS spec that contained an even more dense configuration of pilots, that would be a more spectrally efficient approach, yielding improved sensitivity.

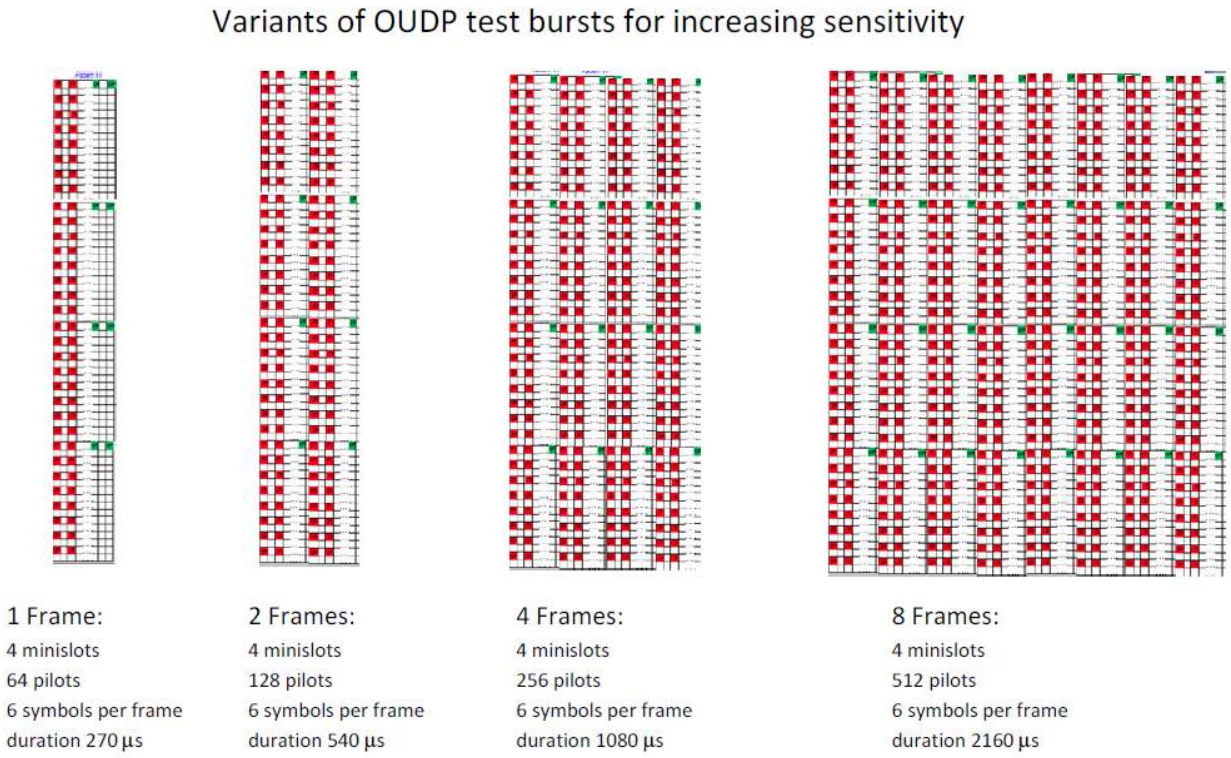

**Figure 13 - Patterns of OUDP Test Burst in Time-Frequency Domain**

# 8. Receiver Sensitivity analysis of the proposed detection approaches

## 8.1. Downstream Out of Band (OOB) CW pilots

The receiver sensitivity of this approach is identical to the status quo and well-known downstream leakage equipment widely used today. As such, no discussion on sensitivity is required.

## 8.2. CW Time-Division Multiple Access (TDMA)

**Estimated sensitivity of leak detection**

The sensitivity of the leak detector in the aeronautical band is a relevant parameter for FCC compliance. Technical standard § 76.605 specifies a signal leakage limit for digital signals at 17.4 µV/m @ 3 meters. This leakage level should be measured at a bandwidth of 6 MHz for QAM, which

is why it is be reasonable to assume that the energy of OFDMA leakage should be calculated in the same 6 MHz bandwidth.

Based on the above assumption, the sensitivity of OFDMA leak detector is calculated as follows:

$S_{OFDMA}$ (dBmV/m) = $S_{test}$ (dBmV) + AF (dB/m) + N (dBc),

where:

$S_{test}$ (dBmV) is sensitivity of CW test signal receiver;

AF (dB/m) is antennas factor;

N (dBc) is coefficient of recalculation level of OFDMA signal in BW= 6 MHz to the measured level of CW test signal.

The sensitivity $S_{test}$ depends on the BW of the detected signal, receiver noise figure, and detection threshold over the noise floor. For a test signal with a duration of 1 ms (BW = 1 kHz), the maximum realized sensitivity for a detection threshold of 6 dB is around -85 dBmV.

The antennas factor (AF) for a monopole antenna at 135 MHz is around 8 dB/m.

The coefficient N is defined by the formula:

N (dBc) = 10 Log(M) - K (dBc),

where:

M is number of subcarriers in BW = 6 MHz. M=240 for 25 kHz subcarriers spacing and M= 120 for 50 kHz subcarriers spacing;

K (dBc) is boosting gain of CW test signal.

Therefore, for 25 KHz spacing OFDMA signal (M=240) coefficient N (dBc) equals:

N (dBc) = 10 Log(240) - K = 23.8 – K

Finally, the sensitivity of the OFDMA leak detector can be estimated as follows:

$S_{OFDMA}$ (dBmV/m) = - 85 dBmV + 8 dB/m + (23.8 - K) dBc = - 53.2 - K dBmV/m

Table 3 below shows the estimated sensitivity for different boosting gains K:

**Table 3 - Estimated Sensitivity for Different Boosting Gains, K**

| Boosting gain K, dBc | Sensitivity | |
|---|---|---|
| | dBmV/m | μV/m |
| 0 | -53.2 | 2.19 |
| 4.7 | -57.9 | 1.38 |
| 10 | -63.2 | 0.69 |
| 15 | -68.2 | 0.39 |
| 20 | -73.2 | 0.22 |

Note, the above sensitivity estimation is for ideal conditions. In real life, in the presence of ambient noise, actual sensitivity will be less. For example, if ambient noise spectral density is anticipated to be 20 dBc above the thermal noise at the receiver, then the actual sensitivity will be also 20 dB (ten

times μV/m) worse. This is why a maximum boosting of a CW test signal is preferable for robust leak detection.

## 8.3. CW Frequency-Division Multiple Access (FDMA)

**Estimated sensitivity of leak detection**

Similar to the logic of the CW TDMA approach described above, for this approach (FDMA) the energy of OFDMA leakage also should be calculated in the same 6 MHz bandwidth.

Based on this assumption, the sensitivity of OFDMA leak detector is calculated as follows:

$$S_{OFDMA}(dBmV/m)=S_{test}(dBmV) + AF\ (dB/m) + N\ (dBc),$$

where:

$S_{cw\_tone}(dBmV)$ is sensitivity of CW tone receiver;

AF (dB/m) is antennas factor;

N (dBc) is coefficient of recalculation level of OFDMA signal in BW= 6 MHz to measured level of CW tone signal.

The sensitivity $S_{cw\_tone}$ depends upon receiver noise figure, bin spacing at FFT processor, and detection threshold over noise floor. In modern leakage detectors currently utilized, the sensitivity of detection for similar CW tone signal at OFDM and Pilot/QAM modes is around -100 dBmV.

The antennas factor (AF) for a monopole antenna at 135 MHz is around 8 dB/m.

The coefficient N is defined by formulas:

$$N\ (dBc) = 10\ Log(M) - L\ (dBc),$$

where:

M is number of subcarriers in BW = 6 MHz. M=240 for 25 kHz subcarriers spacing and M= 120 for 50 kHz subcarriers spacing;

L (dBc) is relative level of CW tone signal (see Table 2).

For 25 KHz spacing OFDMA signal (M=240) coefficient N (dBc) equals to:

$$N\ (dBc) = 10\ Log(240) - L\ = 23.8 - L$$

Finally, the sensitivity of the OFDMA leak detector can be estimated as follows:

$$SOFDMA(dBmV/m)= - 100\ dBmV\ + 8\ dB/m\ + (23.8 - L)dBc = - 68.2 - L$$

By using result for L (dBc) from Table 2, it can be seen that to provide sensitivity at around -60 dBmV/m (1 μV/m), a reasonable exclusion BW should be 800 kHz.

This sensitivity is sufficient for FCC compliance.

## 8.4. OUDP Burst Test Signal

The sensitivity of the OFDMA leak detector, in the case of the OUDP approach, is calculated as follows:

$$S_{OFDMA}(dBmV/m) = S_{OUDP}(dBmV) + AF\ (dB/m) + N\ (dBc),$$

where:

$S_{OUDP}(dBmV)$ is the sensitivity of the OUDP test signal receiver;

AF (dB/m) is the antennas factor;

N (dBc) is the coefficient of the recalculation level of the OFDMA signal in BW= 6 MHz to the level of the signal at the output of the OUDP-matched filter.

The sensitivity $S_{OUDP}$ depends on the number of pilots in the OUDP test burst, cyclic prefix duration, receiver noise figure, and detection threshold over noise floor. In a matched filter scenario, the energy of all pilots are coherently combined within time slot T of one OFDMA symbol, plus any cyclic prefix. So, the sensitivity $S_{OUDP}$ equals the sensitivity of the detection CW burst with duration T and level boosted K times, where K is the number of pilots in the OUDP test burst:

$$S_{OFDMA}(dBmV/m) = S_{CW\text{-}T}(dBmV) - 10\ Log(K)$$

The antennas factor (AF) for a monopole antenna at 135 MHz is around 8 dB/m.

The coefficient N is defined by formula:

$$N\ (dBc) = 10\ Log(M),$$

where:

M is number of subcarriers in BW = 6 MHz.

For 25 KHz spacing of an OFDMA signal, the number of subcarriers M is 240, and coefficient N equals to 23.8 dBc. Thus, the sensitivity of an OFDMA leak detector for 25 KHz spacing and T = 45 μs (symbol 40 μs plus cyclic prefix 5 μs) can be estimated as follows:

$$S_{OFDMA}(dBmV/m) = S_{CW\text{-}T} - 10\ Log(K) + 8 + 23.8 = S_{CW\text{-}45} - 10\ Log(K) + 31.8$$

The sensitivity $S_{CW\text{-}45\ of}$ detection CW burst with duration 45 μs is 13.47 dBc (in 22.2 times) worse than maximal sensitivity of detection CW burst with duration 1 ms and threshold 6 dB (see analysis sensitivity for CW burst approach). But lab tests showed that in case of OUDP the detection threshold should be increased at least to 12 dB or on + 6 dBc to prevent false alarms. Thus, the sensitivity $S_{CW\text{-}45}$ can be estimated as follows:

$$S_{CW\text{-}45} = -85\ dBmV + 13.47\ dBc + 6\ dBc = -65.5\ dBmV$$

Finally, the sensitivity of the OFDMA leak detector equals:

$$S_{OFDMA}(dBmV/m) = -65.5 - 10\ Log(K) + 31.8 = -33.7 - 10\ Log(K)$$

As follows from the above formula, increasing the sensitivity requires increasing the number of pilots. This means increasing the number of OUDP minislots and frames, and using a pilot pattern with the maximum number of pilots (pattern 11 within the existing specifications). Table 4 shows the estimated sensitivity for pilot pattern 11 and for different combinations of minislots and frames. This sensitivity is sufficient to meet the FCC's signal leakage requirements.

**Table 4 - Sensivity for Pilot Pattern 11**

| Number of minislots / frame | Number of pilots (K) | Sensitivity | |
|---|---|---|---|
| | | dBmV/m | µV/m |
| 2 /1 | 32 | - 48.8 | 3.6 |
| 2/2 or 4/1 | 64 | - 51.8 | 2.6 |
| 2/4 or 4/2 | 128 | -54.8 | 1.8 |
| 2/8 or 4/4 | 256 | -57.8 | 1.3 |
| 4/8 | 512 | -60.8 | 0.91 |

## 9. Using Full Band Capture to Evaluate Potential Aeronautical Band Leakage Issues

One of the features of D3.0 and consequent devices is the ability to view the downstream spectrum using full band capture (FBC). Comcast's network has 40M+ devices with FBC and this feature is widely used as part of our proactive network maintenance (PNM) program.

Prior to installing a high split device, FBC can be used to evaluate the quality of the home network by looking at ingress in the FM band from 88-108 MHz. This band is at the edge of the aeronautical band, so, high ingress will indicate the potential for leakage issues into that spectral region. The level out of the cable modem in the aeronautical band can be more than 2000 times higher than the downstream level into the cable modem. Below are two examples of FBC screen captures showing ingress. In Figure 14, the noise floor in the FM band is very low, indicating a home with high network quality, that is a good candidate for high split service with potentially little leakage.

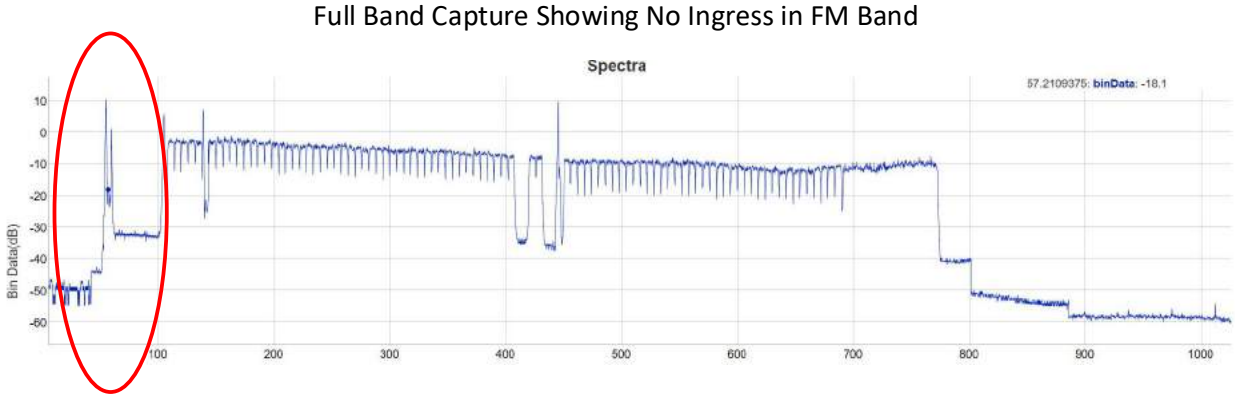

**Figure 14 - FBC Capture Showing No Ingress in FM Band**

Figure 15 shows high ingress and the potential for leakage if converted to a high split and transmitting in the aeronautical band. In this instance, remediation can be performed prior to providing high split service, to minimize leakage issues in the FM band.

Full Band Capture Showing High Ingress in FM Band

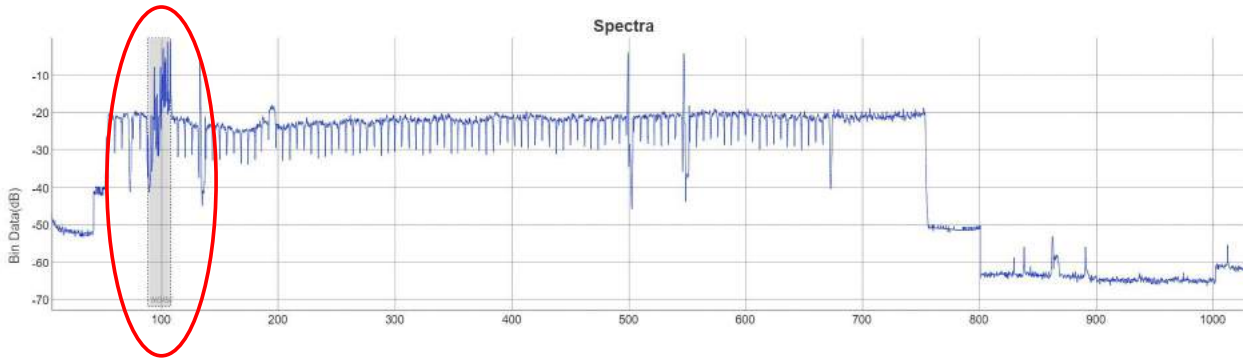

**Figure 15 - FBC Showing Ingress in the FM Band**

## 10. Probability of Intercept: Moving Vehicle Analysis

If upstream test signals used for leakage detection are bursty in nature, a careful examination needs to be conducted to assess how many bursts can be detected by a moving vehicle (in a one second time interval), equipped with a leakage detector. The probability of intercept (POI) is the probability of capturing a transmitted signal based on Tx/Rx timing and should be 100% of the time. With the burst signal approaches, including burst CW or OUDP, the transmit duration and cycle time can be configured such that each CM transmits approximately 2x per second. The real time FFT within the leakage detector is continuously on, so with certainty (timing-wise), signal detection will occur if the amplitude of the signal at the detector is greater than the sensitivity of the detector. See Figure 16.

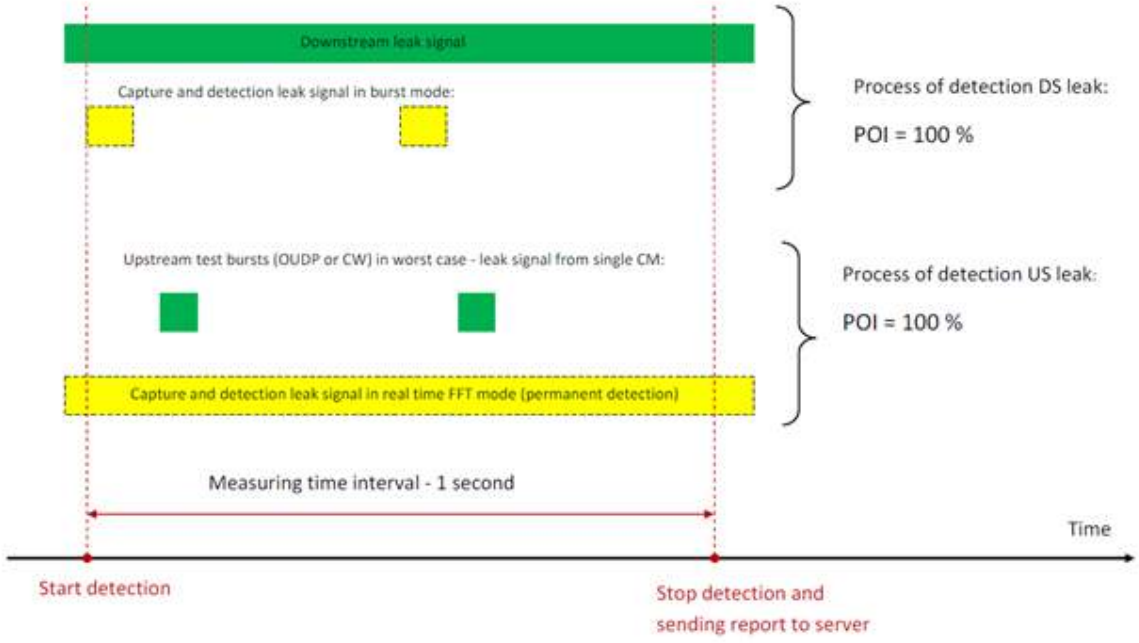

**Figure 16 - Probability of Intercept (POI), Detection of DS and US leaks from moving vehicle**

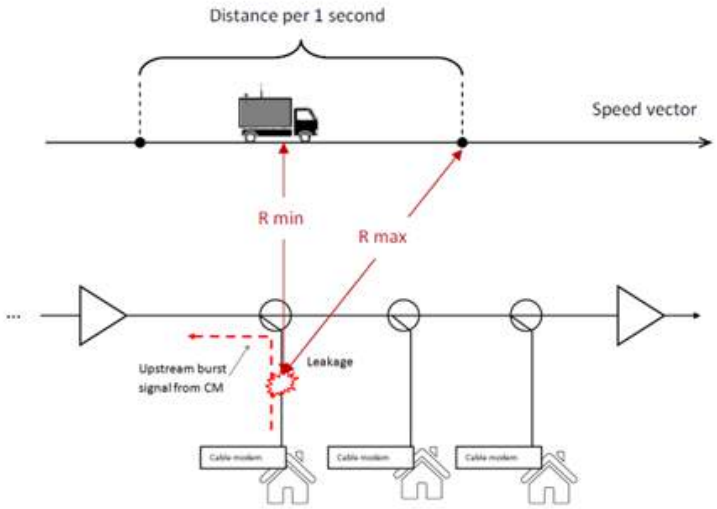
Figure 17 show the results of a model that was built to compare the ratio of the minimum to maximum distance a vehicle could have travelled before receiving a burst signal. The ratio allows an estimate of the change of a leaking signal's level, at a vehicular Rx point, during the 1 second measuring session. The maximum ratio of 1.78 applies to a max speed of 60 mph and a minimum distance (Rmin) of 30 feet. Definitely not a realistic scenario, but even in this case, the field strength variation will not be so big. For a typical scenario, of a vehicular speed of 30 mph and an Rmin of 60 ft, the ratio will be only 1.07. It means the same as changing 1.07 in µV/m or 0.58 dB in dBmV/m, a trivial difference.



| Speed, mph | Distance, ft | Ratio Rmax / Rmin , % | | | | |
|---|---|---|---|---|---|---|
| | | Rmin = 30 ft | Rmin = 40 ft | Rmin = 60 ft | Rmin = 80 ft | Rmin = 100 ft |
| 20 | 29.3 | 1.11. | 1.07 | 1.03 | 1.02 | 1.01 |
| 30 | 44.0 | 1.24 | 1.14 | 1.07 | 1.04 | 1.02 |
| 40 | 58.8 | 1.40 | 1.24 | 1.11 | 1.07 | 1.04 |
| 50 | 73.3 | 1.58 | 1.36 | 1.17 | 1.10 | 1.07 |
| 60 | 88.0 | 1.78 | 1.49 | 1.24 | 1.14 | 1.09 |

**Figure 17 - Distance covered in 1 second versus vehicle speed and ratio of the minimum distance to the maximum distance a vehicle could have travelled**

Using real time signal processing for upstream leakage detection allows the MSO to provide a 100% probability of burst leak capture (POI). The variation of leak level(s) at the moving vehicle will be within one dB and therefore can be ignored. With high-split cable modems following a gradual rollout, the total time needed to have all cable modems in a service group (SG) to burst leakage detection signals is lowered, allowing the 1.6 MHz BW used for the OUDP burst to transmit upstream data part of the time, as illustrated in Figure 18 - Leakage Detection OUDP Test Bursts and Data Transmission for a SG below. This technique of maximizing the use of the spectrum for data, while also ensuring the reliability of leakage compliance, helps meet the goals of moving to the 204 MHz split for both capacity and 1 Gbps

upstream performance. This scheduling capability can be easily facilitated with the virtual CMTS (vCMTS) architecture; other CMTS architectures can provide similar capabilities.

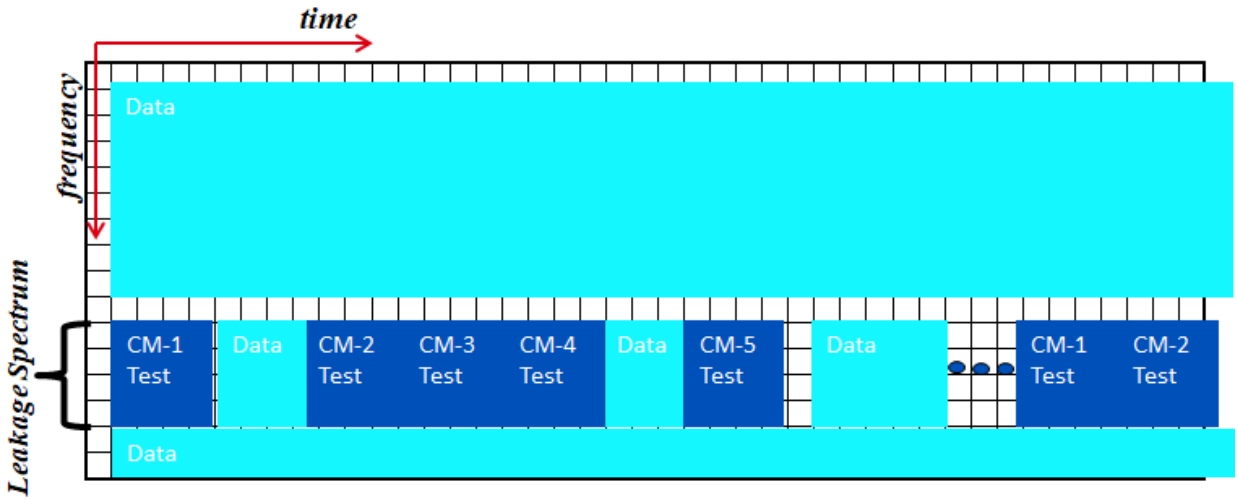


**Figure 18 - Leakage Detection OUDP Test Bursts and Data Transmission for a SG**

# 11. Digital Leakage Detection Test Results

Testing was performed on the various methods described within this paper to validate the concepts and determine minimum sensitivities for each.

## 11.1. CW Time-Division Multiple Access (TDMA)

To prove out the proof of concept for CW TDMA leakage detection, the test setup in Figure 19 was utilized. A DOCSIS generator supplied the OFDMA channel, and to create the exclusion zone within which the CW Burst carriers were placed. The test signal was directly connected to the leakage detector.

The CW test burst in the time and frequency domain are shown in Figure 20 below.

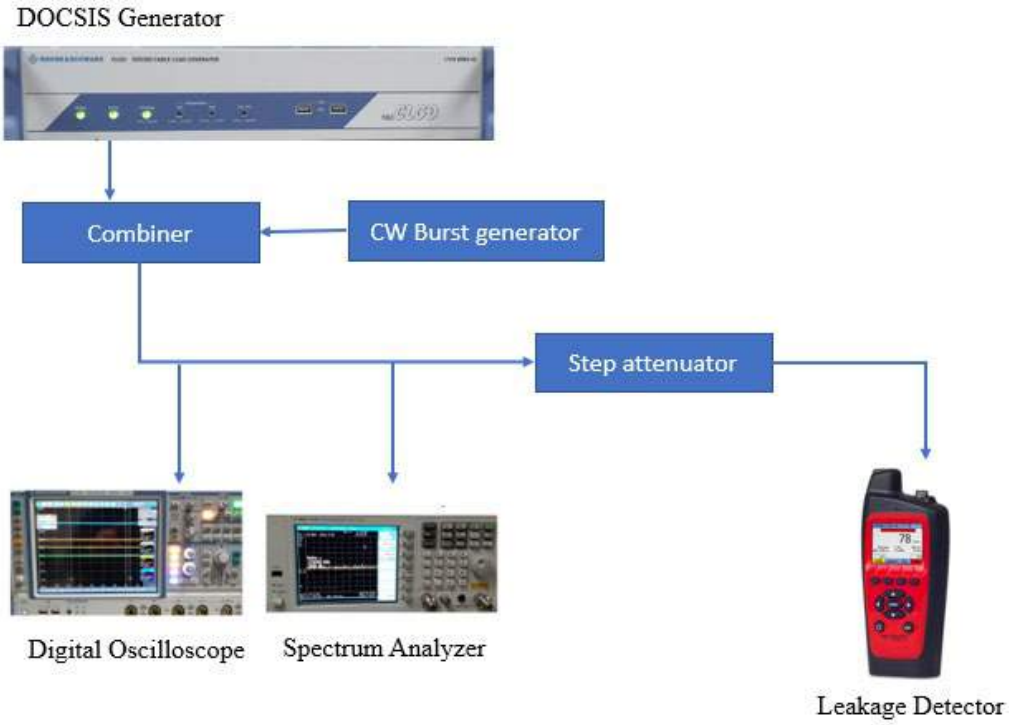

**Figure 19 - CW Leakage Detection Test Setup**

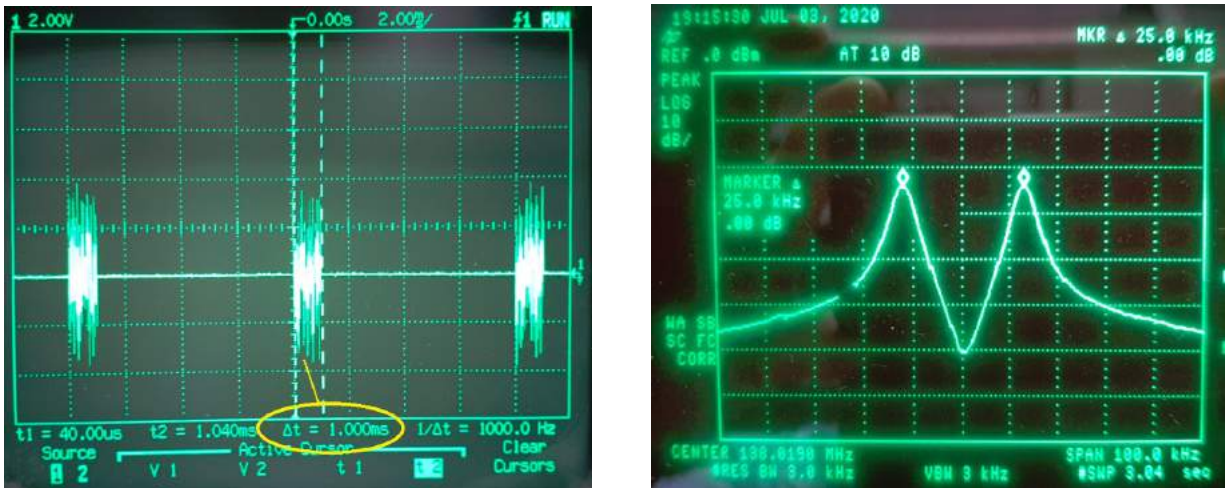

**Figure 20 - CW test burst in time domain and spectrum of CW bursts**

The test setup occupied a 4-subcarrier exclusion zone within the OFDMA, for an exclusion bandwidth of 100 kHz. The spectrum of the CW carriers within this exclusion bandwidth is shown in Figure 21.

**Figure 21 - Spectrum of CW test bursts within exclusion BW of OFDMA signal**

The FFT detection results and the corresponding leakage detection display results are shown in Figure 22. Boosting gain was K=+10dBc. In the top image, the detection result was 104µV/m. The CW carrier spacing is 25kHz. The signals were attenuated to a detected level of 10µV/m, and further attenuated to 1µV/m, which is just above the detection noise floor.

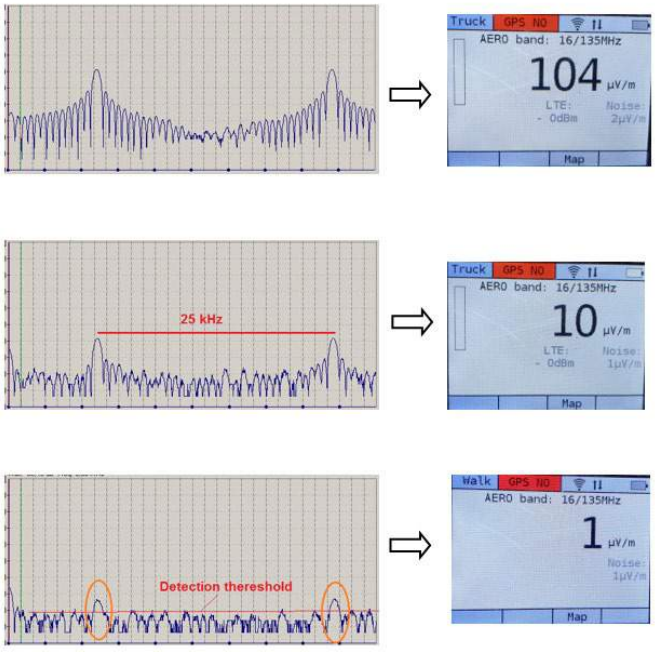

**Figure 22 - FFT spectrums and results of leak detection for boosting gain K=+10 dBc**

The measured sensitivity detection of OFDMA leakage in the aeronautical band is approximately 1 to 2 µV/m in ideal lab conditions, using a conductive test with a boosting gain +10 dBc. Increasing sensitivity during radiated tests in the presence of strong ambient noise could be provided, with extra boosting of the CW test signal if required. The sensitivity of this approach is sufficient for FCC mandated leakage compliance.

## 11.2. CW Frequency-Division Multiple Access (FDMA)

To prove out the proof of concept for CW FDMA leakage detection, the test setup in Figure 23 was utilized. A DOCSIS generator provided the OFDMA channel and to create the exclusion zone within which the CW tones were placed. The test signal was directly connected to the leakage detector.

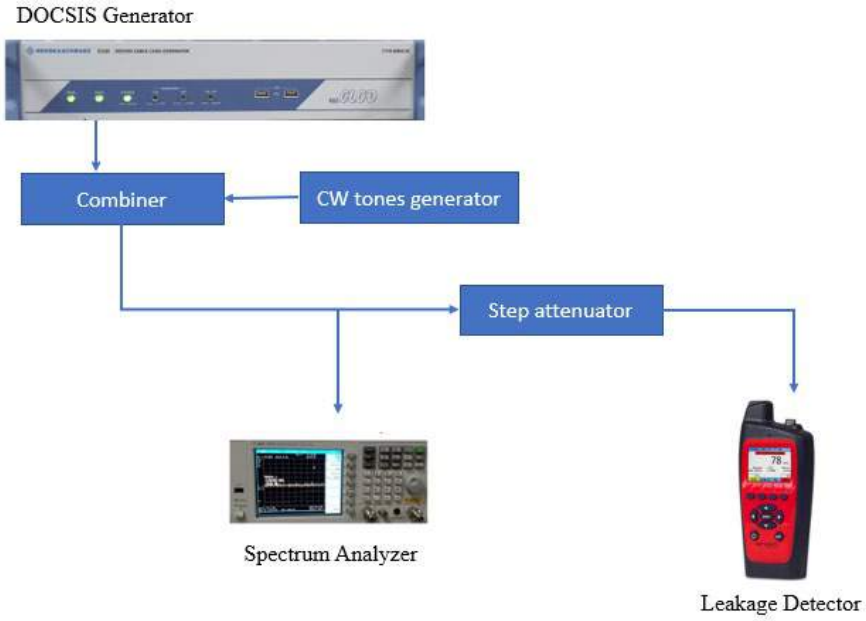

**Figure 23 - Continuous CW leakage Detection Test Setup**

The spectral response of the groups of tones within the OFDMA excluded bandwidth are shown in Figure 24. The left image displays both groups of CW tones, and the right image focuses on just one group containing 100Hz offsets from each other.

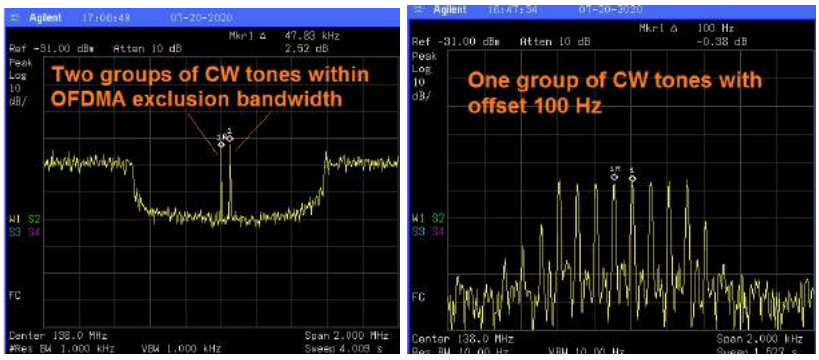

**Figure 24 - The Spectrum of Groups of CW tones within OFDMA exclusion BW**

An example of how the detector was configured is shown in Figure 25, importantly showing that with proper configuration, the detector is able to detect all the different tones simultaneously, with no change in detector setting required. An example of the detection test result of the minimum detected signal level is shown below.

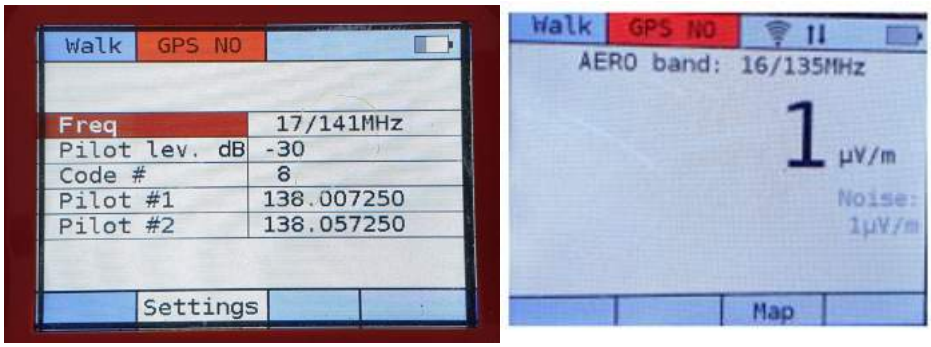

**Figure 25 - Leakage Detector settings for detection of CW tones and minimum detected signal**

Sensitivity of detection OFDMA leakage in the aeronautical band is approximately 1…2mV/m and can be provided by selection of an exclusion bandwidth of 800 kHz, which is a reasonable capacity loss while still meeting the goals of the high split. In this case, the CW tones level will be approximately 6 to 8 dB below the level of OFDMA subcarrier, or approximately - 30 dBc below energy of OFDMA signal in BW = 6 MHz. It's a very similar scenario of the status quo detection of pilots between QAMs in the downstream, with well-known results.

## 11.3. OUDP Burst Test Signal

To prove out the proof of concept of the OUDP Burst Test Signal detector, a method was needed to simulate the OUDP burst. Again, a DOCSIS generator supplied the test signal, which, after an attenuator, was directly connected to the leakage detector. The test setup is shown in Figure 26.

The test pattern supplied by the DOCSIS generator is shown in Figure 27.

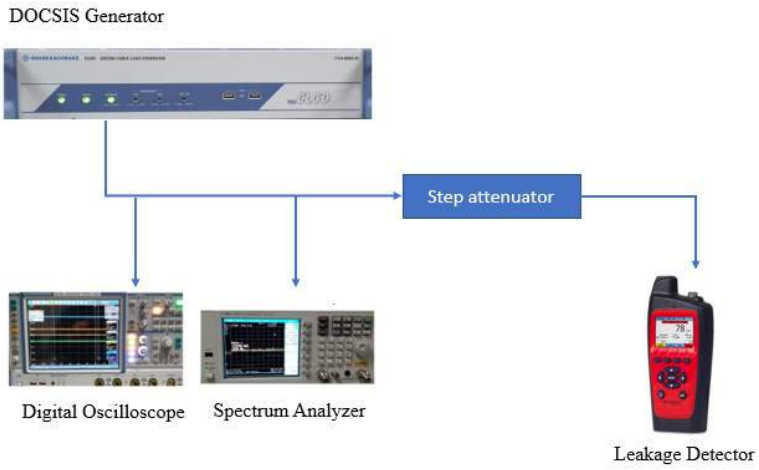

**Figure 26 - Test bench block diagram**

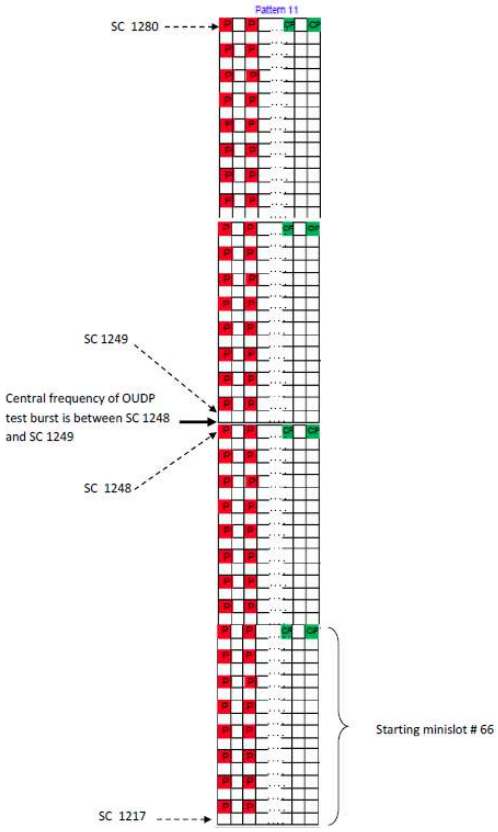

**Figure 27 - Pattern of the OUDP test burst in time – frequency domain**

The modulation of the OUDP test burst is shown in Figure 28.

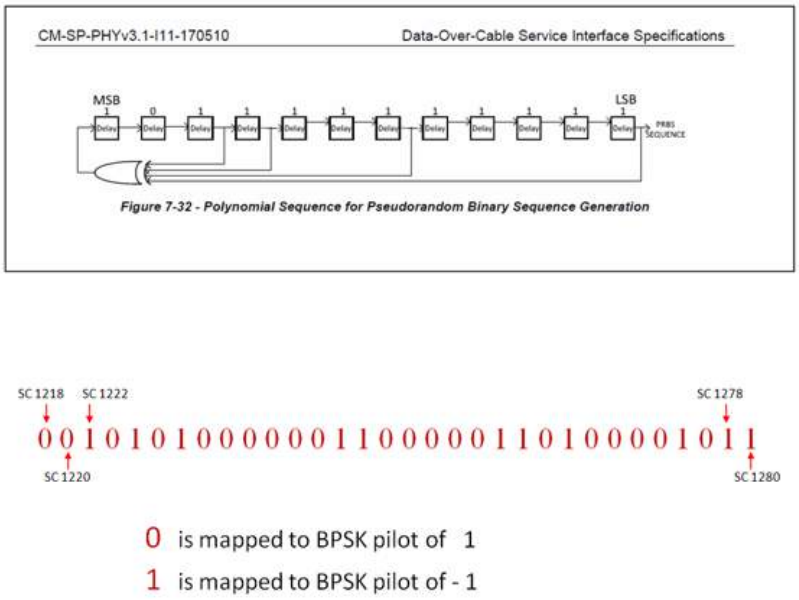

**Figure 28 - Pilot's BPSK modulation in OUDP test burst in Figure 27 [1]**

shows how the OUDP burst signal appears in the frequency domain, including central frequency, minislots, and subcarriers.

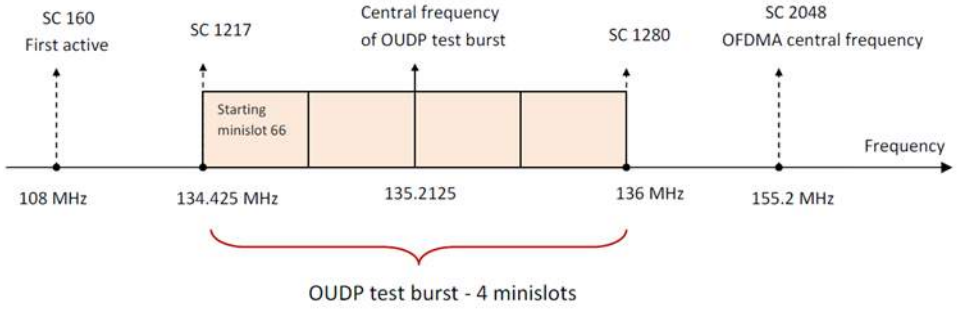

**Figure 29 - Allocation of OUDP test burst in frequency domain of aeronautical band**

Figure 30 - Arbitrary waveform generation settings at DLCG for simulation OUDP test burst shows the settings that were used in the configuration of the DOCSIS generator to simulate the OUDP burst signal.

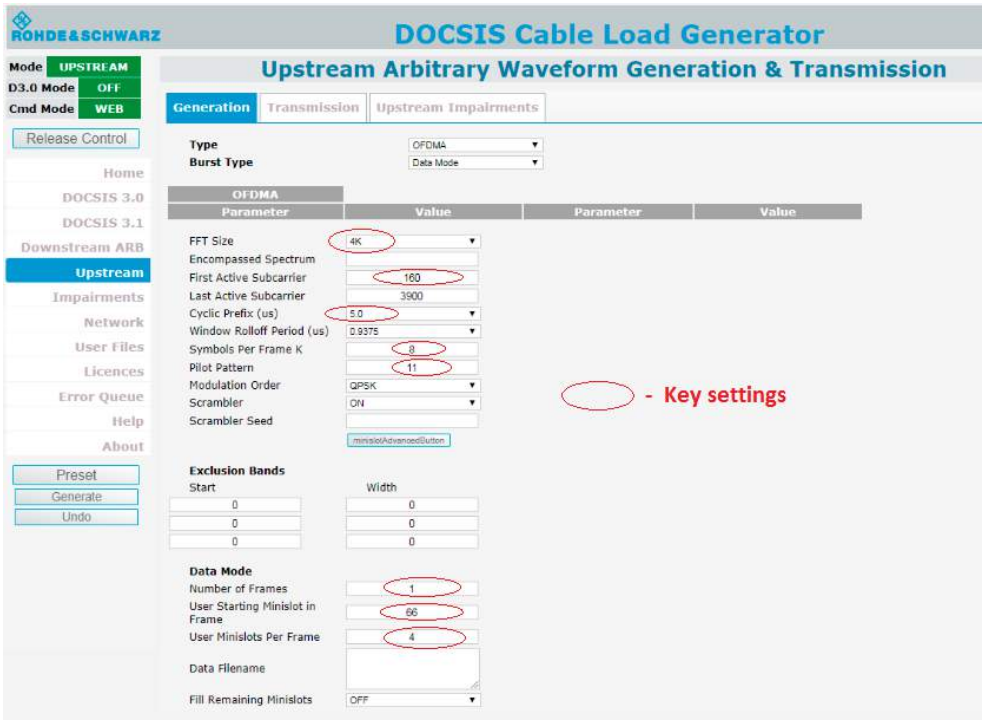

**Figure 30 - Arbitrary waveform generation settings at DLCG for simulation OUDP test burst**

The configuration of the RF transmission of the DOCSIS generator was performed as in Figure 31 - Arbitrary waveform transmission settings at DCLG for simulation OUDP test burst.

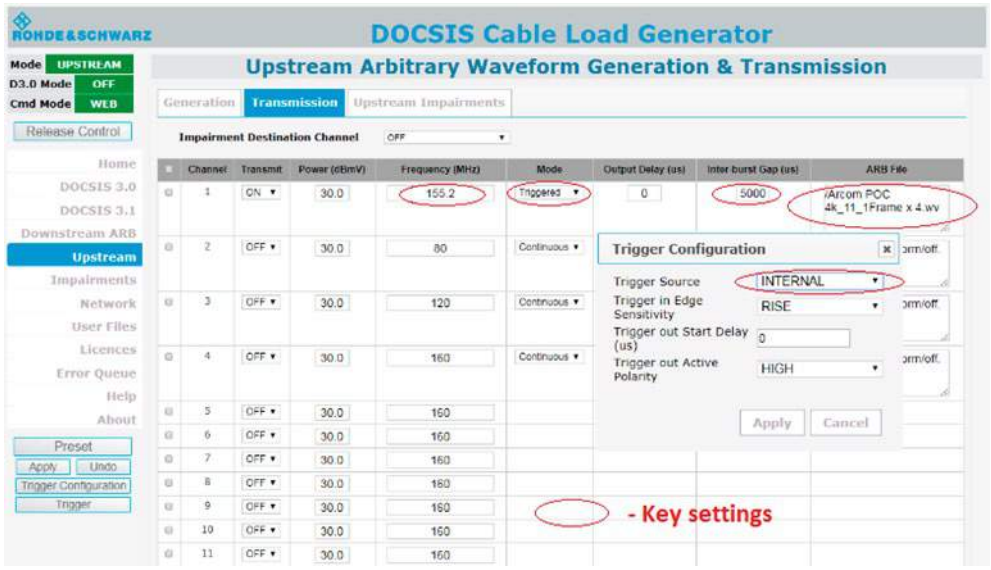

**Figure 31 - Arbitrary waveform transmission settings at DCLG for simulation OUDP test burst**

The simulated OUDP burst signal in the time and frequency domain is shown Figure 32 .

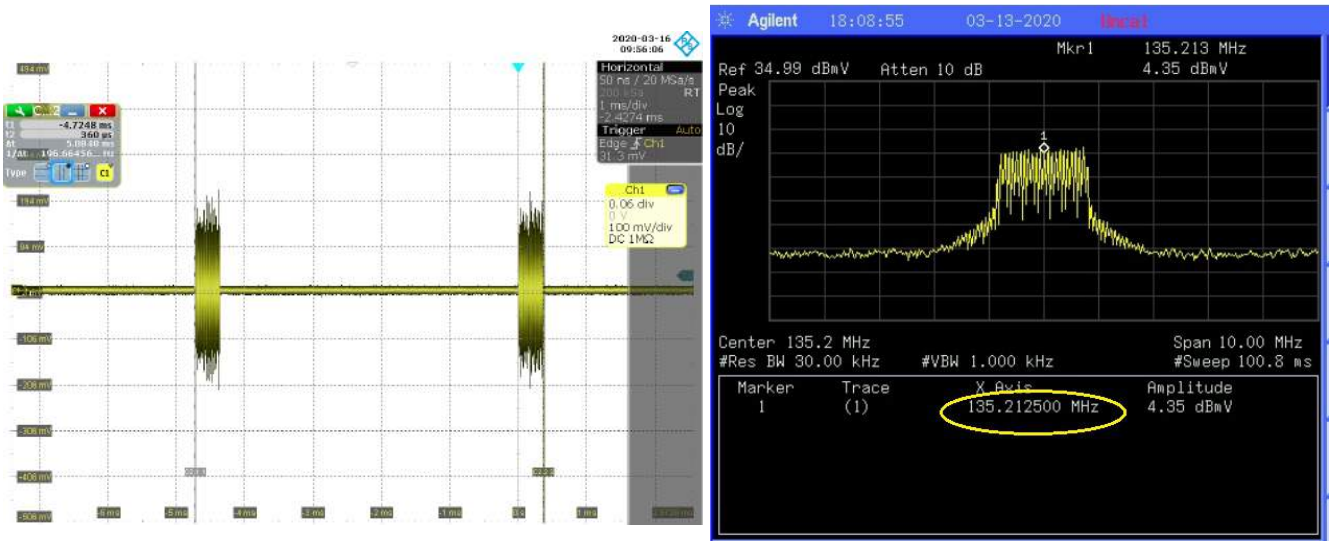

**Figure 32 - OUDP test burst in time and frequency**

The response of the matched filter in the time domain is shown below. The peak of the cross-correlation function represents the detected leak magnitude. The envelope of the OUDP burst signal is also visible.

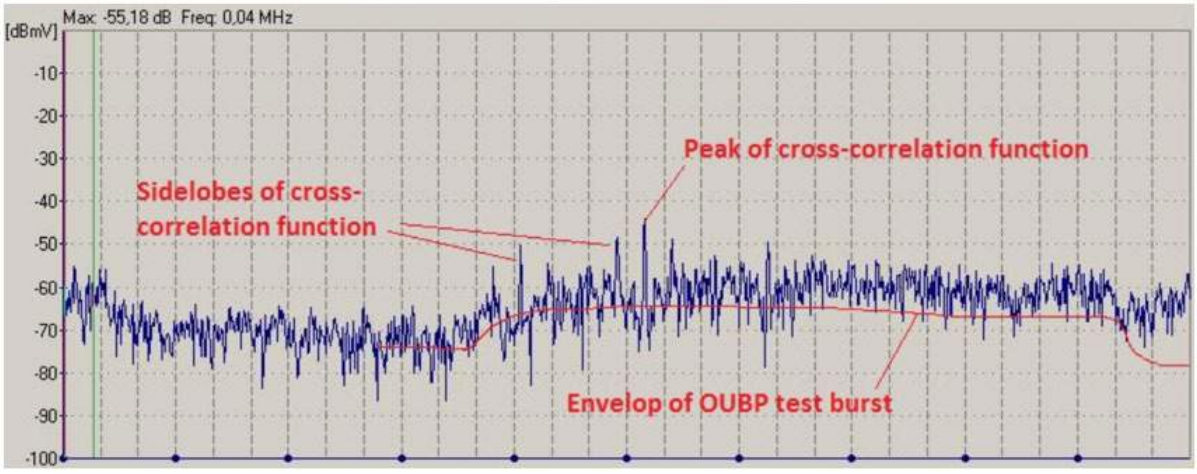

**Figure 33 - Response of matched filter for OUDP test burst with pilot pattern 11.**

In Figure 34 , the minimal detected leak level (sensitivity) for 4 minislots, with one frame in the conducted test, was 4µV/m as shown on the left. In order to investigate improved sensitivity, the test setup was re-run using 4 minislots and eight frames. Sensitivity was improved to 1µV/m, as shown on the right.

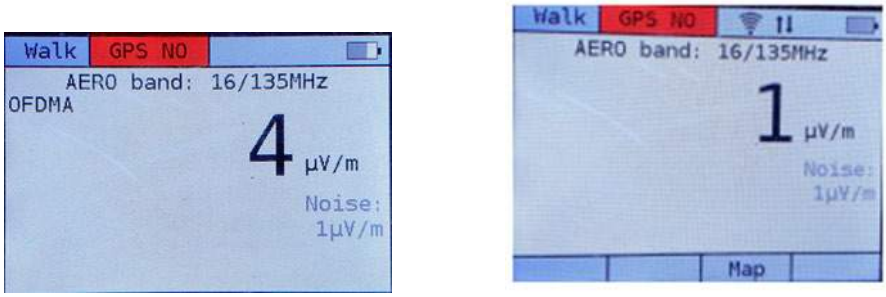

**Figure 34 - Results of implementation of UUDP burst detector into field meter**

This approach, of matched filtering detection of the OUDP pilot pattern 11, is sufficient to meet FCC requirements. The estimated sensitivity detection of the OUDP test bursts burst is approximately 4 µV/m for 4 minislots (BW = 1.6 MHz) with one frame, and approximately 1 µV/m for 4 minislots (BW = 1.6 MHz) with 8 frames. Therefore, operators will have an opportunity to select the optimal BW of OUDP test bursts for leak detection, depending upon desired sensitivity.

## 12. Conclusions

As cable systems evolve and the need for more bandwidth continues, high split systems are now needed; FDX systems that will be used in the near future and are presently being developed.

Current leakage methods are well established, and the need to build off these legacy techniques, while evolving to support new technologies and spectral designations is both necessary and required by federal regulations.

These new systems, and the inverted signal levels that high split systems create, pose unique challenges to leakage measurements and FCC compliance that have not been considered in the 60+ years of cable and broadband evolution. As discussed in this paper, there are several options to move forward with leakage measurements. In addition, operators need to evaluate FCC requirements based on signal type and transmission level in the aeronautical band.

The initial stance to detect leakage in a high split system is typically to continue to use and measure leakage tones in the downstream direction. A leak is a leak, right? However, the differences in signal levels from leakage tones in the downstream, vs actual upstream signals generated at the cable modem, are difficult to correlate. Complex GPS and system mapping algorithms are needed. Acceptance by the FCC for using calculated leakage values and not measuring in the aeronautical band will be difficult. All of the other proposed methods have shown, from a detection sensitivity perspective, to be sufficient for FCC compliance purposes.

Using CW tones -- either continuous or burst generated in the cable modems -- seems like the next logical solution. Cable modems are not designed to create CW tones, and they are designed specifically not to continuously transmit signals in the upstream band. If implementing one of the CW approaches is

desired, certainly the logistics required for the CM software updates would be formidable, and the cost of doing so would need to be analyzed. If the CW-TDMA approach is implemented, additional complexity involving CMTS capabilities would be required, in the form of controlled CM burst timing.

If the CW-FDMA approach is of interest, there exists the additional complication of tracking frequency designations for each CM in a node – a challenging task, made more so by the common practice of node splitting. One additional benefit of the CW-FDMA approach is that even if only the Tx frequency of one CM in a node is known, it is possible to precisely measure the frequency of the two detected CW leakage tones, and therefore exactly resolve which CM supplied the detected leak. This could result in multiple operational benefits.

In a High Split system, it is advantageous to use OFDMA blocks for as much of the spectrum as possible, for maximum upstream throughput. Measuring the OFDMA signal from normal traffic would be the ideal solution, but this is not feasible. DOCSIS 3.1 provides for an OUDP test burst to be generated, and this is the ideal signal to use for leakage measurements. It is configurable in both frequency and duration and can be set to the same transmit level as the cable modem. It provides the tools necessary to manage both the capacity and the leakage compliance, with flexibility for the operator. The pilot pattern can be chosen and configured such that the sensitivity of this signal at the detector is equivalent to the CW approaches currently used in the downstream.

Table 6 shows a summary of the solutions evaluated in this paper. Take note that the OUDP approach is already supported by both the CM firmware and DOCSIS specifications. This approach is also supported in FDX, and the frequency of the OUDP test burst can be configured higher in frequency as the upstream band is extended in FDX and other topologies.

**Table 5 - Summary of Leakage Detection Methods**

| | Leak Detection Method | | | |
|---|---|---|---|---|
| | OUDP | CW-TDMA | CW-FDMA | DS Pilot |
| Detected signal level correlated with actual aeronautical band signal level | yes | yes | yes | no |
| Detection sensitivity sufficient for FCC compliance | yes | yes | yes | yes |
| Realizable within current DOCSIS specification | yes | no | no | no |
| Realizable with current firmware in all High Split cable modems | yes | no | no | yes |
| Requires permanent orchestration from the CMTS | yes | yes | no | no |
| Requires some dedicated US Bandwidth | yes | yes | yes | no |

With the High Split leakage options evaluated in this paper, operators can derive a roadmap for continued leakage monitoring that not only allows for continued regulatory compliance, but also consistent plant monitoring and maintenance for optimal system performance.

# 1. Introduction

With the current state of the world in turmoil due to the COVID-19 virus, there has never been a time in history when cable, internet and communication networks have been so heavily stressed. Corporations, businesses, schools, healthcare and families have been thrust into new ways of meeting, learning, socializing and transacting business -- with almost all of them flowing through cable and Internet providers. With this massive increase in traffic on all of the broadband networks comes an increased use of electricity to power all of the components needed to keep the critical infrastructure (CI) up and running. This increased consumption of energy to deliver internet and cable television services is being offset by continued conservation efforts across the industry. This paper will identify how Comcast is contributing to those efforts with three case study results which show substantial savings potential if deployed across the cable operator industry.

The production spaces, where the servers, modems, switches and routers are housed, are called headends, which divide their energy usage into 2 main categories. The first is IT production load (modems, switches etc.) and second is the cooling load, with both expressed in kilowatts (kW). This paper will look at our efforts to reduce energy consumption from the cooling load at the headends. The pilot initiatives include set point adjustments on air conditioners, blanking panels in racks, and economizer options on air conditioners (also known as “free cooling”). Although these strategies have been publicly promoted in the past by trade groups, engineering firms and vendors, this paper will provide specific applications and verifiable results which have far exceeded the expectations of this author.

These programs will demonstrate saving opportunities primarily associated with computer room air conditioner (CRAC) cooling energy, ranging from **12% to 50%** without any negative impact to operations or reliability. These significant savings will be shown to measurably reduce operating expenses, carbon emissions and preserve capital with payback periods from less than 1 year to 3.5 years.

# 2. Historical Perspective

The issue of energy efficiency has long been a Comcast initiative, as evidenced by the partnership with the SCTE (Society of Cable Telecommunications Engineers), CableLabs and corporate commitments to building a more resource-efficient company, including the retention of a Chief Sustainability Officer in 2016. Comcast was a signatory to industrywide voluntary agreements in 2012 for energy efficiency improvement to set top boxes (STB) and again in 2015 for energy efficiency of small network equipment (SNE). The substantial savings from the STB initiatives across the entire cable operator companies are expressed in Figure 1 . Additional information can be found at www.energy-efficiency.us and www.cablelabs.com.

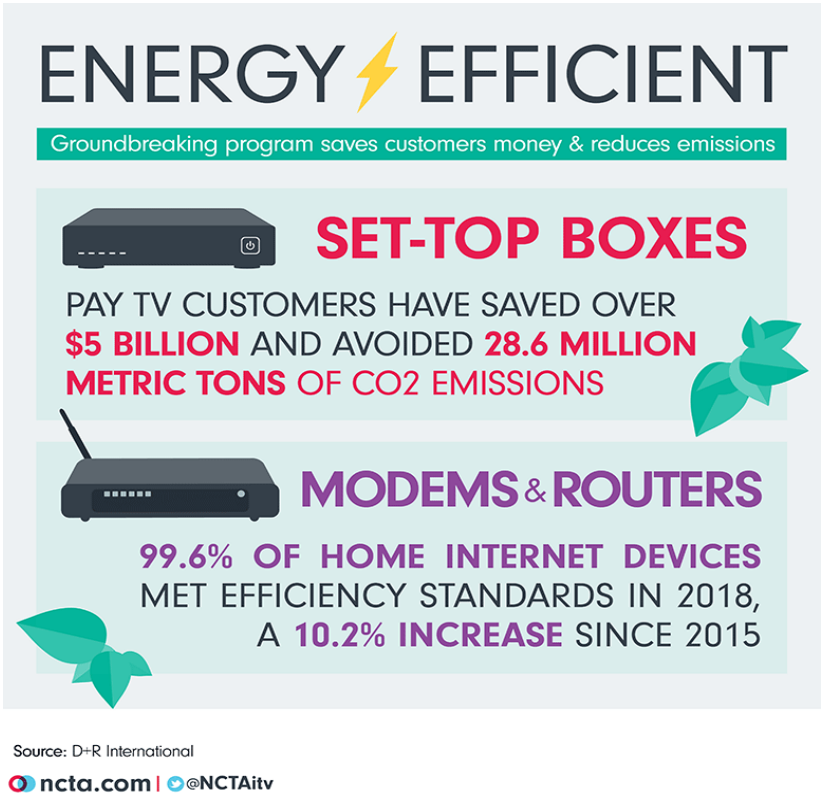

**Figure 1 - Cumulative Industry Savings Through 2018 for STBs and SNE Efficiency Compliance (D+R international/ NCTA.com)**

In its continued drive for efficiency and environmental impact reductions, Comcast agreed to participate in the SCTE Energy 2020 program, developed in 2014 as a multi-year program. This objective covered all aspects of the industry product delivery systems with three main goals to reduce energy use. These Energy 2020 goals include reducing power consumption by 20% per unit, reduce energy cost by 25% per unit and reduce grid dependency by 5%, by 2020. With the adoption of these goals Comcast and the many other members of SCTE, including vendors and contractors, joined forces with their respective Sustainability Offices and embarked on aggressive energy reduction strategies, including the case studies referenced herein, to provide measured and verified data to various applications for cable operators.

The Energy 2020 program initiatives took a hard look at the breakdown of the major areas of energy consumption in the cable operators' system, and it is abundantly clear that outside-plant access network, and specifically power supplies and edge facilities (aka hubs & headends), represent the major energy user groups for cable and internet, as shown in Figure 2.

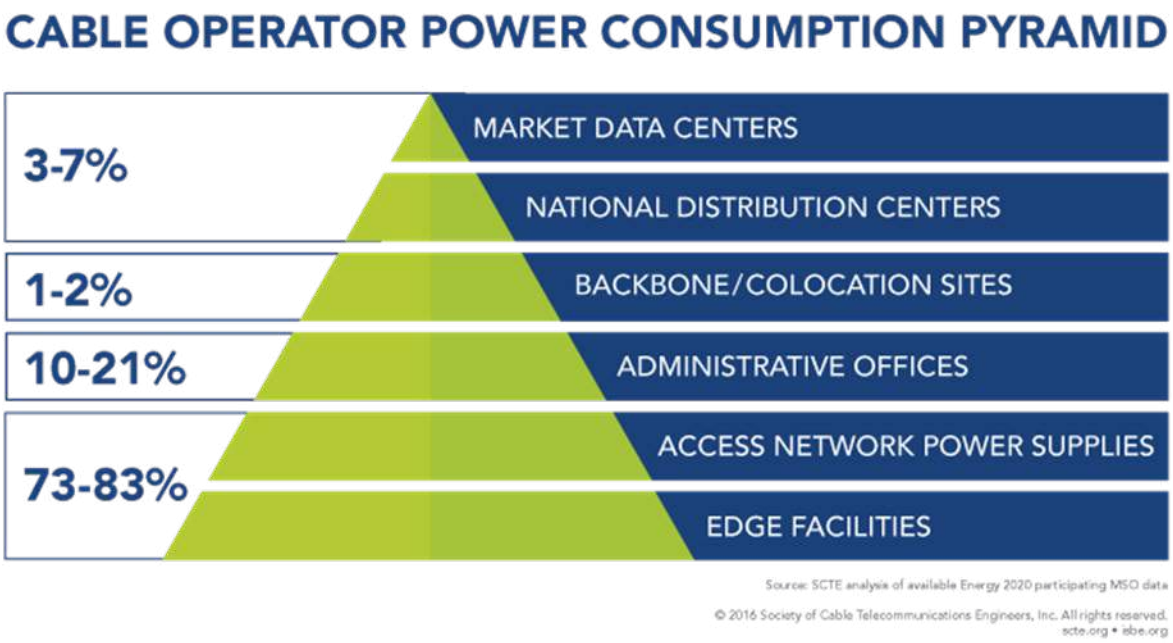

**Figure 2 - Cable Operators Power Use Distribution (SCTE)**

In the single use edge facilities referenced above (also known as Headends), the power breakdown consists of the production energy load (servers, modems, routers & switches), typically utilizing 45% to 55% of overall space electricity, and the Heating Ventilation and Air Conditioning (HVAC) load, using 40% to 45%. Miscellaneous office and lighting load use 3% to 5%. These loads are expressed in Kilowatts (kW) for point-in-time measurements, or, more accurately as kilowatt Hours (kWh) to capture the amount of Watts consumed by a device over 1 hour, that is, the energy consumption. The cost varies widely across the US, from $.06 to $.023 per kWh. California and the northeast states are in the highest electricity cost groups. It is also more likely that the higher priced areas will have more aggressive utility incentives, and the three case studies included below have been eligible for incentives either individually or as part of site upgrades. See the following link for state incentive opportunities: https://www.dsireusa.org/ with a focus on the HVAC systems. In most incentive programs the measures addressed by this document typically are included under the Commercial & Industrial programs (C&I). In this paper we will be looking only at the reduction of kWh from HVAC cooling power usage.

Many papers have been written on the subject of energy conservation measures (ECMs) for data centers. In particular, this very similar industry attracted worldwide attention in 2014 for reports that it was consuming nearly two percent of the total energy consumption (Arman Shehabi, 2016) with projected staggering growth. This growth did not materialize, thanks to the many efficiency efforts of manufacturers, engineers and end users. Data centers require many of the same infrastructure equipment as cable headends, and efficiency applications discussed in this work are very much applicable, with just as promising a savings potential. As indicated in Figure 3, a data center contains many more servers and storage elements for business applications (e.g. accounting, human resources, marketing, purchasing, legal), while the cable headends contain modems, switches, fiber terminations, router and other broadband equipment. Although slightly different in rack contents, the energy use percentages compare fairly closely.

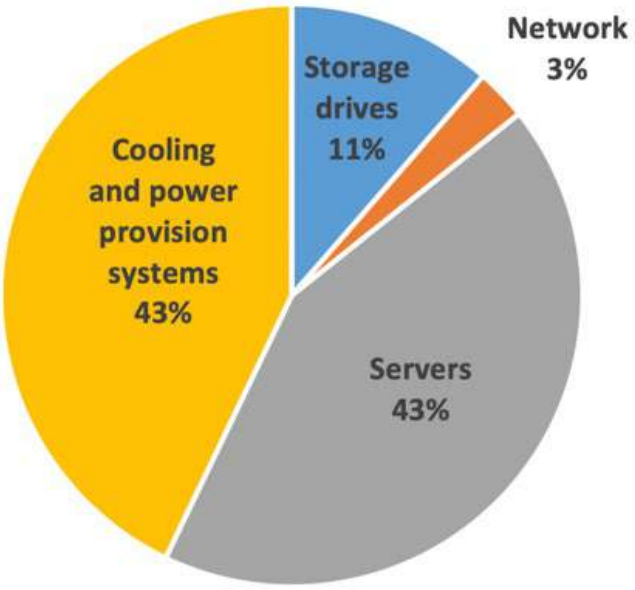

**Figure 3 - Data Center Power Use Distribution (Shehabi, 2016)**

A 2017 SCTE Expo technical paper titled "ECM Recommendations for Cable Edge Facilities" *(Dan Marut Senior Manager of Sustainability, 2017)*, detailed similarly combined ECMs that had been deployed, and the savings aggregated. This author is in full support of the recommendations from that paper and intends to show specific individual element savings.

# 3. Case studies and results

## 3.1. HVAC Set Point Adjustments

In this case study, 10 sites within the greater Chicago metro area were identified as candidates to raise the current HVAC set points in small (600 square feet) to medium (1,200 square feet) size power rooms. These sites were selected to minimize any adverse or customer-impacting events. Simultaneous with this effort was the installation of lockable and programmable thermostats used to control the CRAC devices. The installation of these secure thermostats ensured that they could not be adjusted by occupants. The addition of these devices served as qualification for a significant Commonwealth Edison (Com Ed) utility incentive. At the outset of the project, we estimated a potential energy savings of 3% to 5% for the cooling energy used, that would be attributable to the raising of return air temperature set points on the air conditioners from 68°F (Fahrenheit) to 75°F.

### *3.1.1. Set Points And Sensors*

Set points are the numeric control positions used to operate HVAC and many other types of equipment. The most common example is a thermostat which controls when an air conditioner or heater comes on or shuts off. The difference between the settings for when a unit cycles on and off is referred to the set point deadband. When conditions are within the deadband range, no action (to provide heat or cooling) is needed by the device. In headends, the air conditioners have historically run 24/7 365 days a year to maintain a consistent operating temperature in the room. This continuous duty requires greater reliability than a seasonal device, which may run 3-6 months a year.

 

There are multiple sensors located within and outside the HVAC equipment to measure and monitor various environmental conditions and the operating status of the system and components. Some of the sensors can have user adjustable settings while others are non-adjustable and meant to keep the unit operating safely per the manufacturer. Examples of other sensors include smoke detectors, air filter pressure differential to indicate a clogged or dirty filter, exterior ambient air conditions, high or low power supply voltage and current, fan state, cooling status and stages, refrigerant temperature and pressure and many more. When a component fails, malfunctions or strays out of set operating boundaries (set points), alarms or alerts are displayed or automatically forwarded to a building monitoring system. During the following case studies, the data from devices and space conditions were obtained via direct IP connections or data aggregators and exported to a third-party monitoring system branded Foreseer® (Eaton). This system allows remote site visibility and device alarming, so we can track and trend space conditions and device operational status..

The example power dashboard shown in Figure 4 shows the various areas of power monitoring available at this site including service entrance, generators, direct current (DC) plant, fuse panels, HVAC with environmental relative humidity (RH), and 3rd party aggregators:

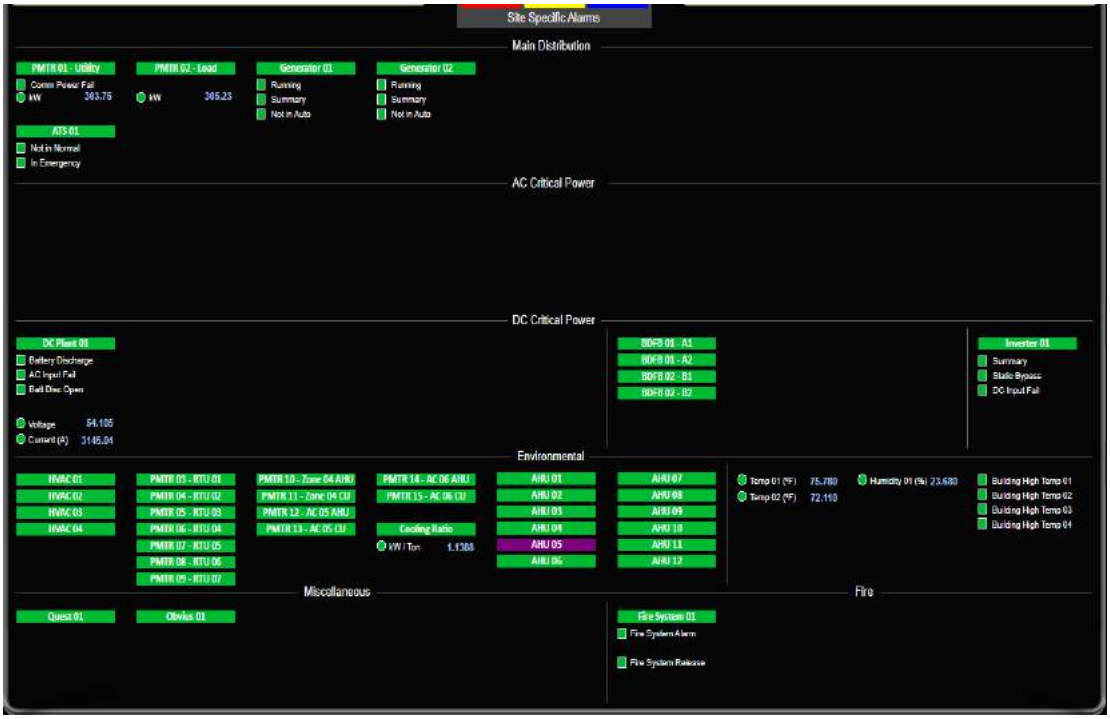

**Figure 4 - Power Monitoring Dashboard Example From Foreseer®**

In Figure 5 below we see the actual Return and Supply air temperatures as displayed at the CRAC unit and informed by on-board sensors along with room and outside air (OA) temperature. One can see that the cooling and room setpoint of 71°F is activating the cooling mode, as the recorded temperature in the room is 73.3°F -- indicating that the likely dead band setting is 2°F. Note that the Delta T (or ΔT is the difference in Temperature) between supply and return temperatures is only 5.7°F and the mechanical cooling is operating only Stage 01. Typical discussion of set points at this site would be described as: "temperature set points are 71°F/2°F and RH set points are 40%/10%," indicating set point and deadband setting.

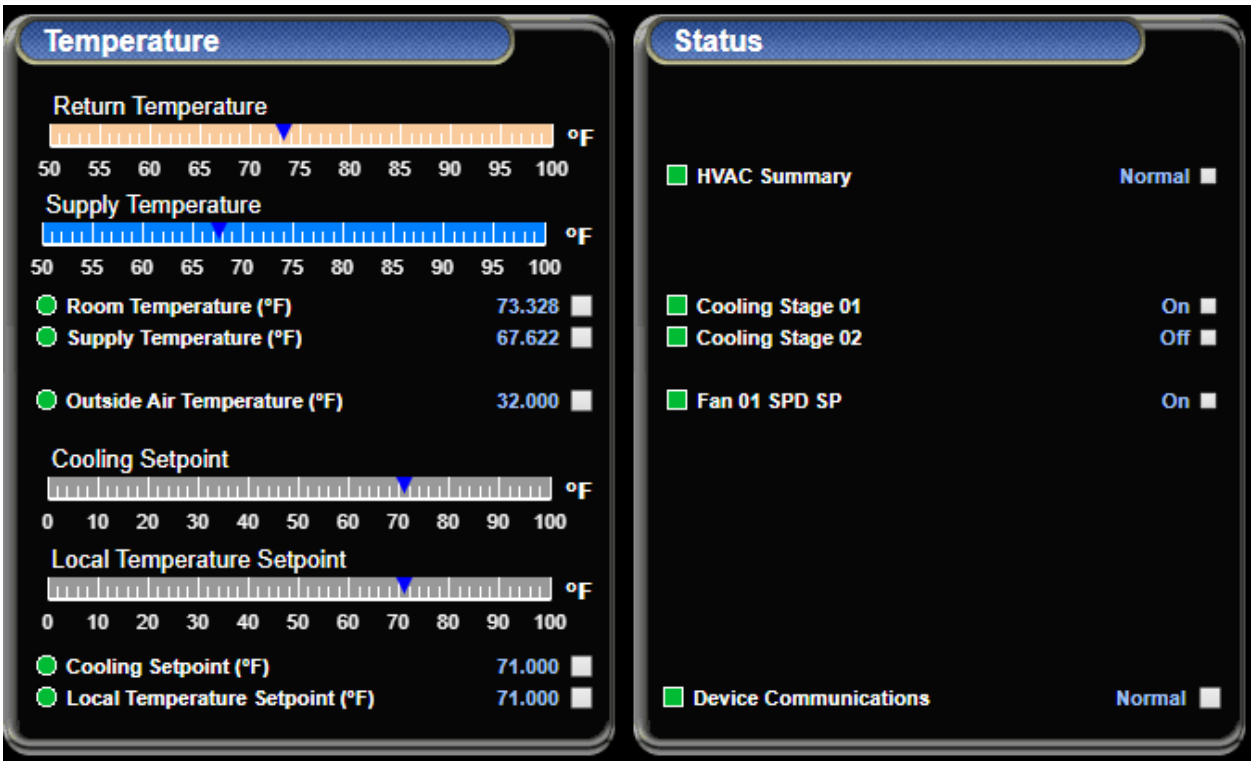

**Figure 5 - HVAC Set Point Monitoring And Operational Display From Foreseer**

### *3.1.2. ASHRAE Standards And Operating Ranges*

The cable and data center industries, as well as state and local municipalities, have adopted many code requirements from various governing or advisory bodies. Of specific reference to this case study is the ASHRAE (American Society of Heating Refrigeration and Air-conditioning Engineers) 90.1-2019 "Energy Standards for Buildings Except Low-Rise Residential Buildings" and subsequent 90.4 -2019 "Energy Standard for Data Centers." Generally accepted addendums also include publications from a formal ASHRAE Technical Committee (TC) TC 9.9, comprised of ASHRAE members who are subject matter experts in HVAC and data centers. Although headends are not yet called data centers, by definition many meet the criteria: Having a conditioned space, greater than 20Watts per square foot, and a production equipment load (commonly referred to as IT load) of more than 10 kW (ASHRAE, 2019). This widely accepted standard provides tables with ratings for various electronics equipment and the recommended safe operating temperature and humidity ranges (A1-A4), as shown in Figure 6.

In this case study, it was identified that many sites were operating at cooler than necessary space temperatures. Per the ASHRAE guidelines, the *recommended* area of the standard indicates that the temperature range is 18°C (64°F) to 27°C (80.6°F). Let it be noted that the *allowable* range is 15°C (59°F) at 80% RH up to 32°C (89.6°F) at 40% RH. This allowable range indicates the conditions that the production equipment can operate at occasionally, but only for limited transgressions and duration. These temperature and humidity ranges are meant to be measured at the face of the rack, where airflow is drawn in by the IT/Production equipment. The recommended ranges are the basis for this pilot, given that the premise is that raising the setpoints closer to the upper end of this range can be safely achieved, while significantly reducing energy costs, with little or no implementation or maintenance costs.

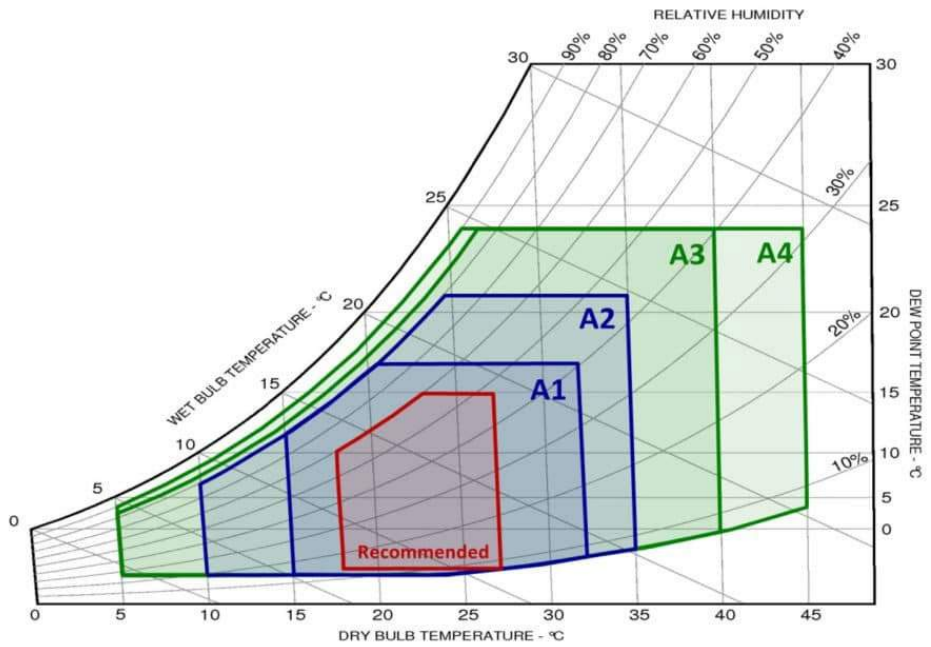

**Figure 6 - 2015 Recommended And Allowable Envelopes For Air-Cooled Equipment**

©ASHRAE www.ashrae.org, *Equipment Thermal guidelines for Data Processing Environments, Fourth Edition* (2015)

### *3.1.3. Capacity Impact*

All major HVAC manufacturers test and rate their devices at various operating conditions, and both openly publish that data and include it in design specifications. Per their testing, the higher the operational limit is to a device, the greater the capacity of the unit. As shown in Figure 7, data from the Vertiv™ system design catalog has the lowest operational limit published, of 75°F, or 27.5 kW. If the space is maintained at this lower limit, then the operator is reducing the sensible kW capacity of the unit to approximately 20% lower than the same output at 85° (34 kW). If we follow the shown reductions of almost 2 kW per 5°F then a set point of 70°F would have a capacity of approximately 26 kW, or a 24% difference from 34 kW. This is stranded capacity and forces a de-rating of the units when capacity models are run. Further, it will require additional HVAC units brought online or purchased in order to match the heat rejection capability of the production load. This de-rating does not include the many other factors that could also reduce the capacity of the HVAC unit, such as poor airflow distribution, low Delta T and low humidity levels, all of which are great discussions for another paper.

## 2.1 Air-cooled Units Application and Performance Data

Table 2.1 Application data—Air-cooled, under-floor discharge[1] with EC fans

| Model Size | 028 | 035 | 042 | 053 | 070 | 077 | 105 |
|---|---|---|---|---|---|---|---|
| **Net Application Data kBTUH (kW), Standard Air Volume and Evaporator Fan Motor** | | | | | | | |
| **Semi Hermetic Compressors (4 Step Cooling) with EC Fans** | | | | | | | |
| 85°F DB, 64.5°F WB, 52.3°F DP (29.4°C DB, 18.1°C WB) 32.4% RH | | | | | | | |
| Total kBTUH (kW) | 116.4 (34.1) | 143.6 (42.1) | 163.6 (47.9) | 210.6 (61.7) | 247.1 (72.4) | 270.3 (79.2) | 352.5 (103.3) |
| Sensible kBTUH (kW) | 116 (34) | 141.2 (41.4) | 160.9 (47.9) | 210.2 (61.6) | 245.9 (72) | 269.2 (78.9) | 337.5 (98.9) |
| 80°F DB, 62.9°F WB, 52.3°F DP (26.7°C DB, 17.1°C WB) 38.2% RH | | | | | | | |
| Total kBTUH (kW) | 110.5 (32.4) | 136.8 (40.1) | 156.1 (45.7) | 198.9 (58.3) | 234.8 (68.8) | 257.1 (75.3) | 338.2 (99.1) |
| Sensible kBTUH (kW) | 105.9 (31) | 128.1 (37.5) | 146.2 (45.7) | 193.9 (56.8) | 226.6 (66.4) | 248.8 (72.9) | 307.2 (90) |
| 75°F DB, 61.1°F WB, 52.3°F DP (23.9°C DB, 16.2°C WB) 45.1% RH | | | | | | | |
| Total kBTUH (kW) | 105.3 (30.9) | 130.8 (38.3) | 149.5 (43.8) | 189 (55.4) | 223.9 (65.6) | 245.8 (72) | 325 (95.2) |
| Sensible kBTUH (kW) | 93.9 (27.5) | 113.8 (33.3) | 129.9 (43.8) | 173.3 (50.8) | 201.3 (59) | 221.5 (64.9) | 80 (273.1) |

**Figure 7 - Vertiv Application And Performance Comparison**

### *3.1.4. Set Point Modifications And Results*

Figure 8 is a screenshot of a Vertiv CRAC unit with a return temperature set point of 67°F and sensor readings of 68°F and 39% RH. The fan is operating at 81% and mechanical cooling is at 72% of capacity.

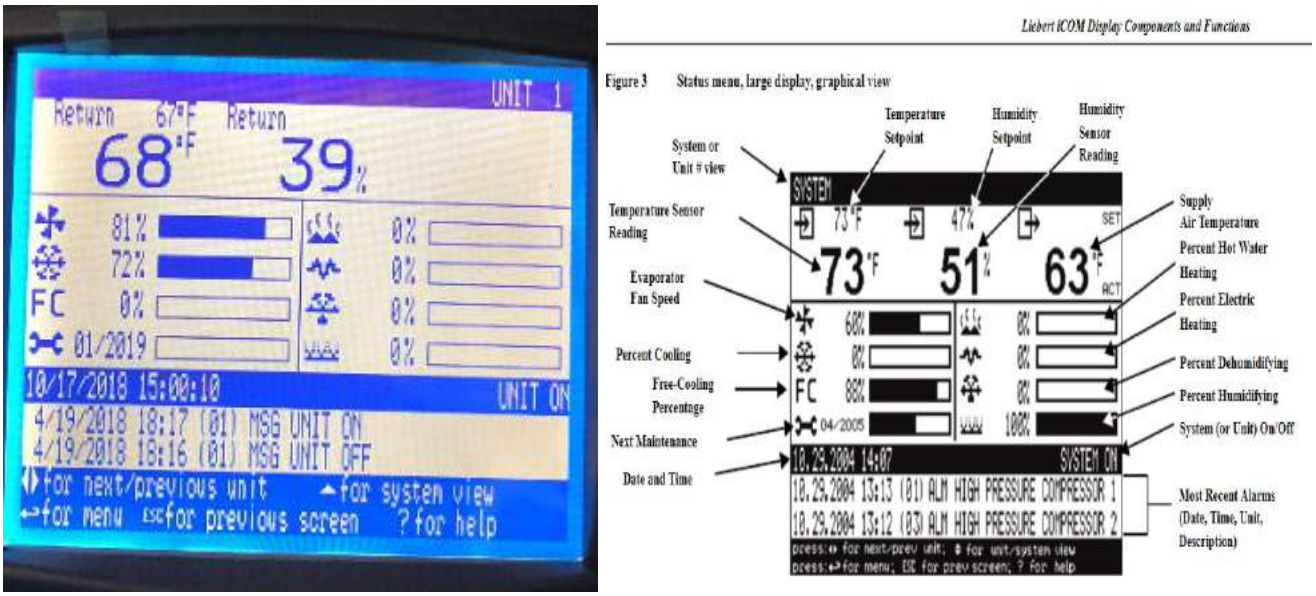

**Figure 8 - Vertiv Performance And Set Point Display With Function Key**

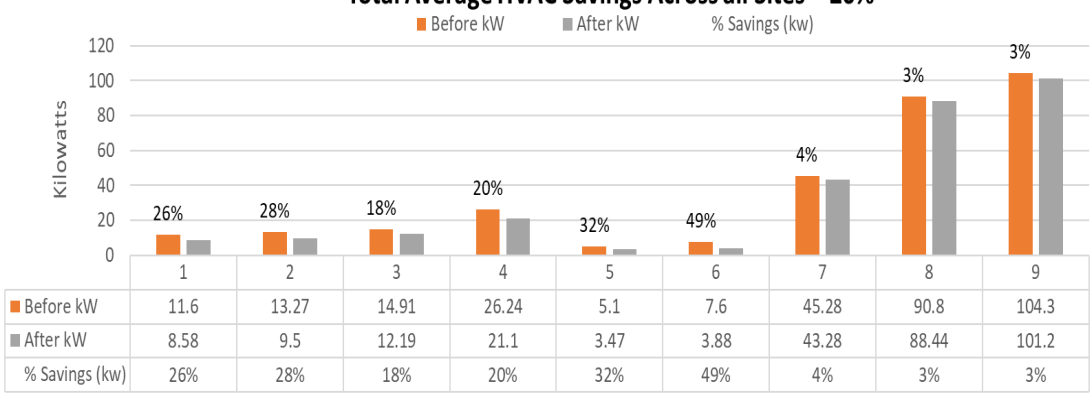
Nine sites were selected for this pilot (see Table 1) in conjunction with adding lockable and programmable thermostats to control the room temperatures. Utility incentives were awarded by Com Ed

to supply and install the thermostats and raise the set points. Energy use data was recorded and averaged 30 days prior to any changes (August 2019) and averaged for 30 days after the adjustments (September 2019). All sites were within 40 miles of each other, to maintain consistency of local weather impacts. The typical CRAC settings we encountered on this project had temperature set points of 68°F with a 2°F deadband. Humidity was 40% RH with a 10% deadband. The set points were raised by approximately 1°F per day over 2 weeks. There were no recorded thermal events or issues during this time.
The average outdoor temperature during August 2019 = 74°F and RH = 68%
The average outdoor temperature during September 2019 = 71°F and RH = 75%

**Table 1 - Site Energy Reduction Percentages After Set Point Increase**



| | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 |
|---|---|---|---|---|---|---|---|---|---|
| Before kW | 11.6 | 13.27 | 14.91 | 26.24 | 5.1 | 7.6 | 45.28 | 90.8 | 104.3 |
| After kW | 8.58 | 9.5 | 12.19 | 21.1 | 3.47 | 3.88 | 43.28 | 88.44 | 101.2 |
| % Savings (kw) | 26% | 28% | 18% | 20% | 32% | 49% | 4% | 3% | 3% |

Project payback period without incentives = 19 months

Project payback with incentives = 6 months

Summary

- Pre-adjustment energy savings estimate for this pilot was 5% of HVAC energy per site. Actual results averaged 20% of HVAC kWh savings.
- Addition of lockable thermostats allowed for a 60% project cost reduction via utility incentive
- Actual cost to adjust set points = $0 (self-performed by Comcast engineers)
- To date thermal events or impact at these sites with raised set points = 0
- Results of this pilot exceeded expected results

## 3.2. Blanking Panel Installation

Blanking panels (BPs) are a generic term for any device or product that will block open rack unit (RU) spaces in a typical production load cabinet, to prevent cold air from by-passing the in-rack devices. This by-pass conditioned cold air is considered wasted cooling, as it did not enter any production equipment and will return to the CRAC units unused. The BP is meant to plug the open rack gap and reduce the wasted cooling resource. See Figure 9 below. Blanking panels are an essential part of airflow management in a headend or data center and considered low hanging fruit to save energy and improve airflow distribution.

**Figure 9 - Open RUs On Left, PlenaForm Systems Blanking Panels Installed On Right**

### *3.2.1. Types Of Blanking Panels*

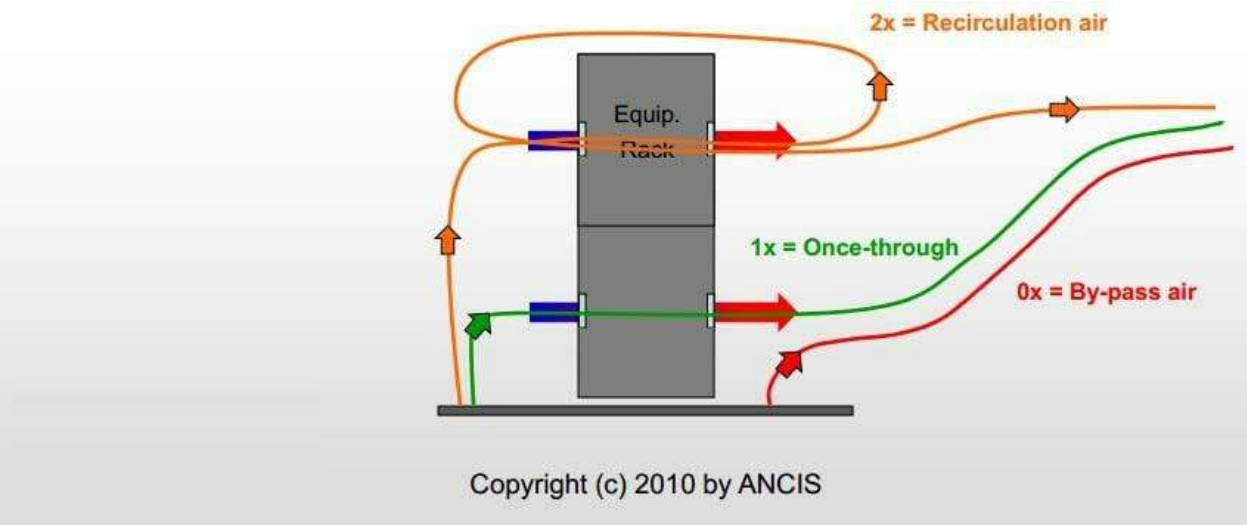
There are various sizes of pre-manufactured products fitting 1,2,4,6 and 10 RU in a single piece of material. The material is generally a fire rated molded plastic, sheet stock or sheet metal panels. One of the most common rack sizes is 42 RU, any time there is an open RU space, a blanking panel should be installed to maintain industry best practices for airflow efficiency. Common product types are shown below in Figures 10 and 11.

**Figure 10 - Upsite Technologies 2 RU White Molded Blanking Panel**

**Figure 11 - Polargy PolarFlex Sheet Blanking Panel**

### *3.2.2. Airflow Efficiency*

The visual depiction of airflow through and around an IT rack is well described below in Figure 12 which is still relevant and accurate to show where energy and efficiency is lost. This timeless summary by Dr. Magnus Herrlin (Herrlin, 2010) represents the good, the bad and the ugly from an airflow perspective. Cooling resources that are introduced into a space that move through an IT device (router, switch, modem or server) to perform work is the good. Airflow that never reaches its intended target (the in rack devices) is downright bad and that air that gets caught in an endless recirculating loop over the top of a rack, at an aisle end or through a gap where the BP should be is just plain ugly. Airflow management is comprised of several components and variables including rack layout, rack equipment orientation, CRAC positions, ceiling height and more, yet blanking panels are simply a must and diligence to this requirement is critical for efficiency. Many spaces today do not have full BP installations, yet the rooms stay mostly in compliance by brute force of the air conditioning (i.e. always running). It is not necessarily that the space needs more cooling tons but rather that the airflow distribution is so poor that many units are running with fan only. This has unintended consequences as the HVAC fan motor produces heat which is now added to the room. As well by operating in fan only mode the HVAC unit is pulling in warm return air and pushing this warm air back into the room without conditioning, meaning the supply air temperature is actually being raised by the HVAC unit.



*In the illustration above, from Herrlin's presentation titled Room-Level Energy and Thermal Management in Data Centers: The DOE Air Management Tool, you see that once-through cooling passes through the equipment rack only one time before returning to a cooling unit while recirculation air passes through twice. Bypass airflow on the other hand, does not pass through the equipment rack at all before returning to a cooling unit, hence bypass airflow.*

**Figure 12 - Visual Display of Airflow Anomalies**

### *3.2.3. Blanking Panel Case Study Results*

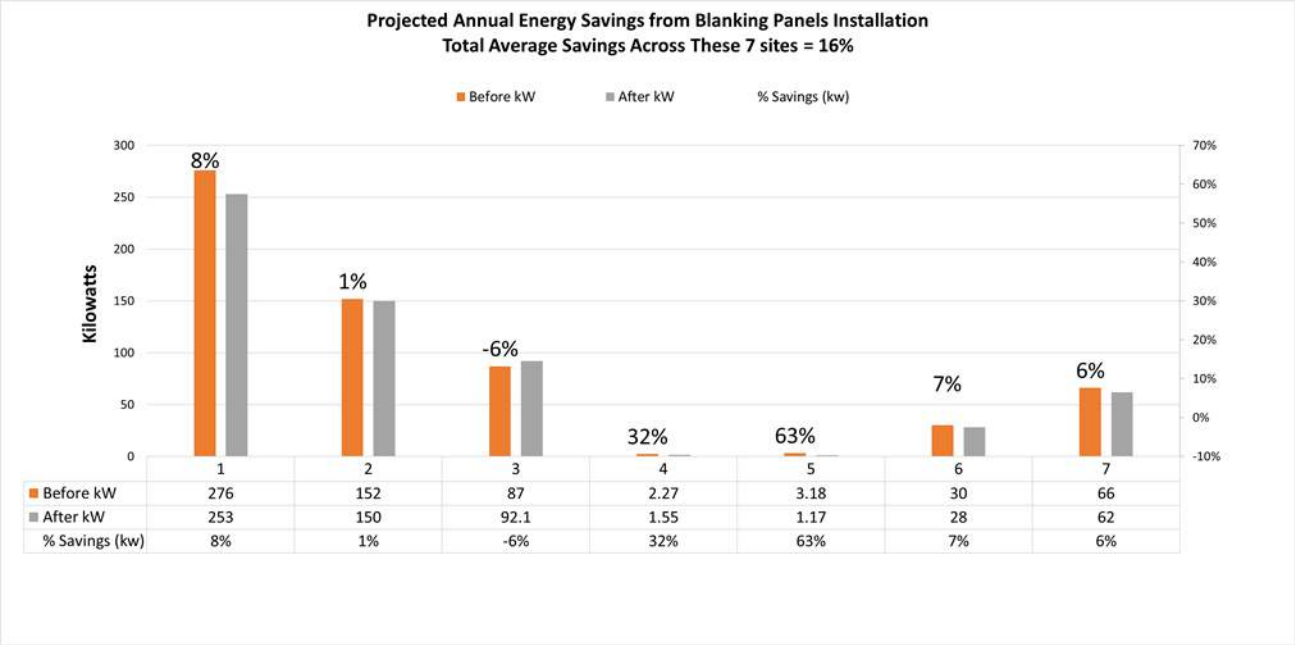
In this study we selected 7 sites across the US which were of varying sizes. We recorded the HVAC kW consumption before and after installation and examined consumption over the following 60 days. Weather changes were accounted for and data was averaged accordingly. One site in the west experienced an increase in energy use that was traced back to installation just before a prolonged and significant heat wave moved into this location. Labor to install was mostly self-performed with 3 sites using outside labor. Primary blanking panels used were the one and two RU molded plastic snap-in place devices.

Summary

- Pre-installation projections for HVAC cooling energy savings after blanking panel installation was 3-5%.
- The average energy savings reported as calculated from data in Figure 13 below was 16%. If we remove both the high and low readings from the list our average savings is 12%.
- The installation of blanking panels does not require any special tools or knowledge.
- Low cost low tech with high impact to cost reductions and reliability

**Table 2 - Site Energy Reduction Percentages After Blanking Panels Installation**



## 3.3. HVAC Economizer Options

The term economizer has become a generalization for many of the technologies or components that make an HVAC device more energy efficient. These include variable speed drives (VSD) for fans and pumps, electronically commutated motors, dual circuits (refrigerant and glycol/water mix) at the condensers, variable compressors and direct outside air. The technology discussed here will pertain specifically to airside economization for packaged ground mount or roof top HVAC units (RTU), where ambient outside air is mixed or directly fed into the headend space when temperatures are favorable for use. Typically, this is an add-on option on many devices, but the investment is worthwhile as the payback period is quite short due to substantial energy savings achieved in most parts of the US and Canada as shown in Figure 14. With the exception of the states bordering the Gulf coast most of North America can support over 5000 hours of economizer operation which is 57% of the hours in a year (8,760 hrs annually). This is a significant reduction of time required to run mechanical cooling which reduces operational expenses (OpEx) and extends the life of equipment.

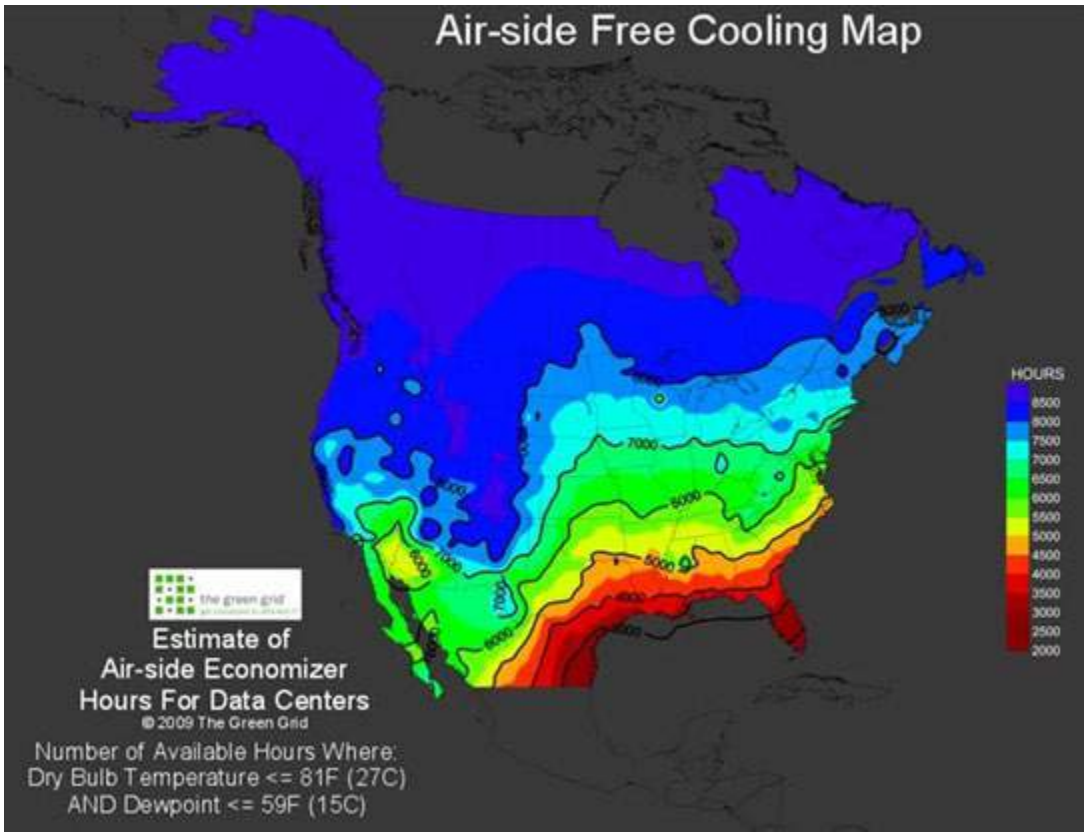


**Figure 13 - Hours With Ideal Conditions For Air-side Economization (DOE And The Green Grid)**

### 3.1.1 Economizer Operations

Most of the HVAC manufacturers combine the control operations of the Direct Expansion (DX) packaged HVAC device with the economizer components to provide for an automatic engagement when the outside weather is favorable or meets the requirements of the economizer set points (See chapter 1.4 of this paper). The economizer control setpoints will identify what the ambient exterior conditions need be to activate the dampers and louvers for fresh air mixing. Direct introduction of cold outside air into a space can create problems so the economizer should be mixing warm return air from the space with the colder air so thermal shock, low temperature alarms or condensation does not occur. This blending is necessary during colder winter months. Many geographical locations experience long term ideal conditions for economization and can position the set points for temperature, humidity, enthalpy or dewpoint control. It is typically the interior temperature set point that is the main controller or restrictor to full economization capability. If the set points for temperature and humidity are set higher than the economizer hours can be extended. Many manufacturers are using dew point temperatures as a more accurate and reliable control point for higher efficiency of their HVAC systems. The industry now recognizes that by allowing a wider range of RH, and given proper controls, a great deal of energy and water can be saved while maintaining acceptable IT performance. (Sorell, 2017). Simply stated the control system activates dampers to allow outside air into the device supply duct assembly providing cooling to the space and exhausts the hot room air directly outside. This can occur on one or all of the HVAC units per the sequence of operation set by the end user. As shown in figure 14 below of a sample HVAC unit dashboard the outside air (OA) is sufficiently cold for economization and the relative humidity is also sufficient to allow for economization.

The unit is allowing the OA damper to open to 46% mixing it with warmer return air to bring the supply temperature up to 54.3°F. The set point (return air temperature) for this space is set at 68.2°F which is unnecessarily low thus reducing many potential hours of economization.

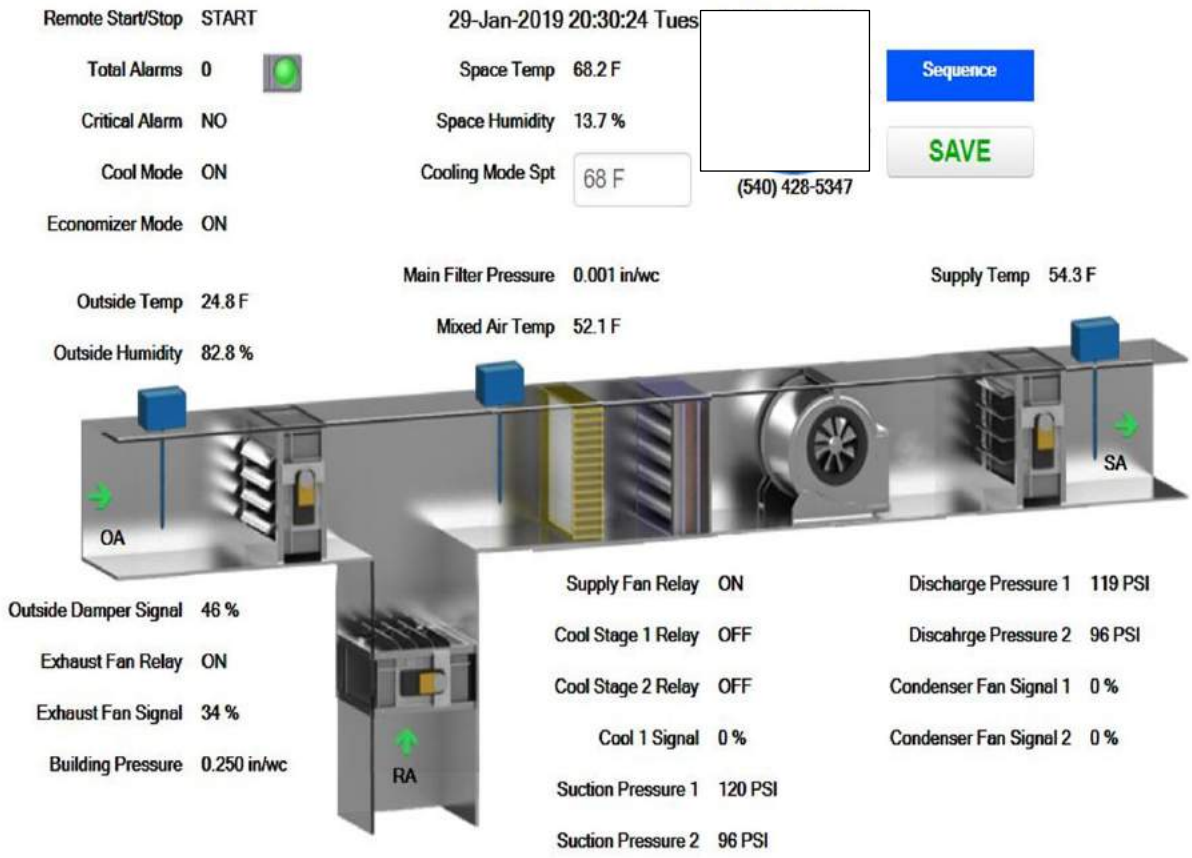

**Figure 14 - Aaon Dashboard With Operational Performance Of Economizer**

Figure 15 below shows a comparison of average Amps without Economizer engaged 55.6A (red) and with economizer engaged 28.9 (green) which results in a 48% energy reduction. The orange bottom line indicates when the economizer cycled on and off in October and November. This location seasonal climate change provides for 5 to 6 months of economization hours at a minimum when the control set point for activation of the economizer is set at 50° F.

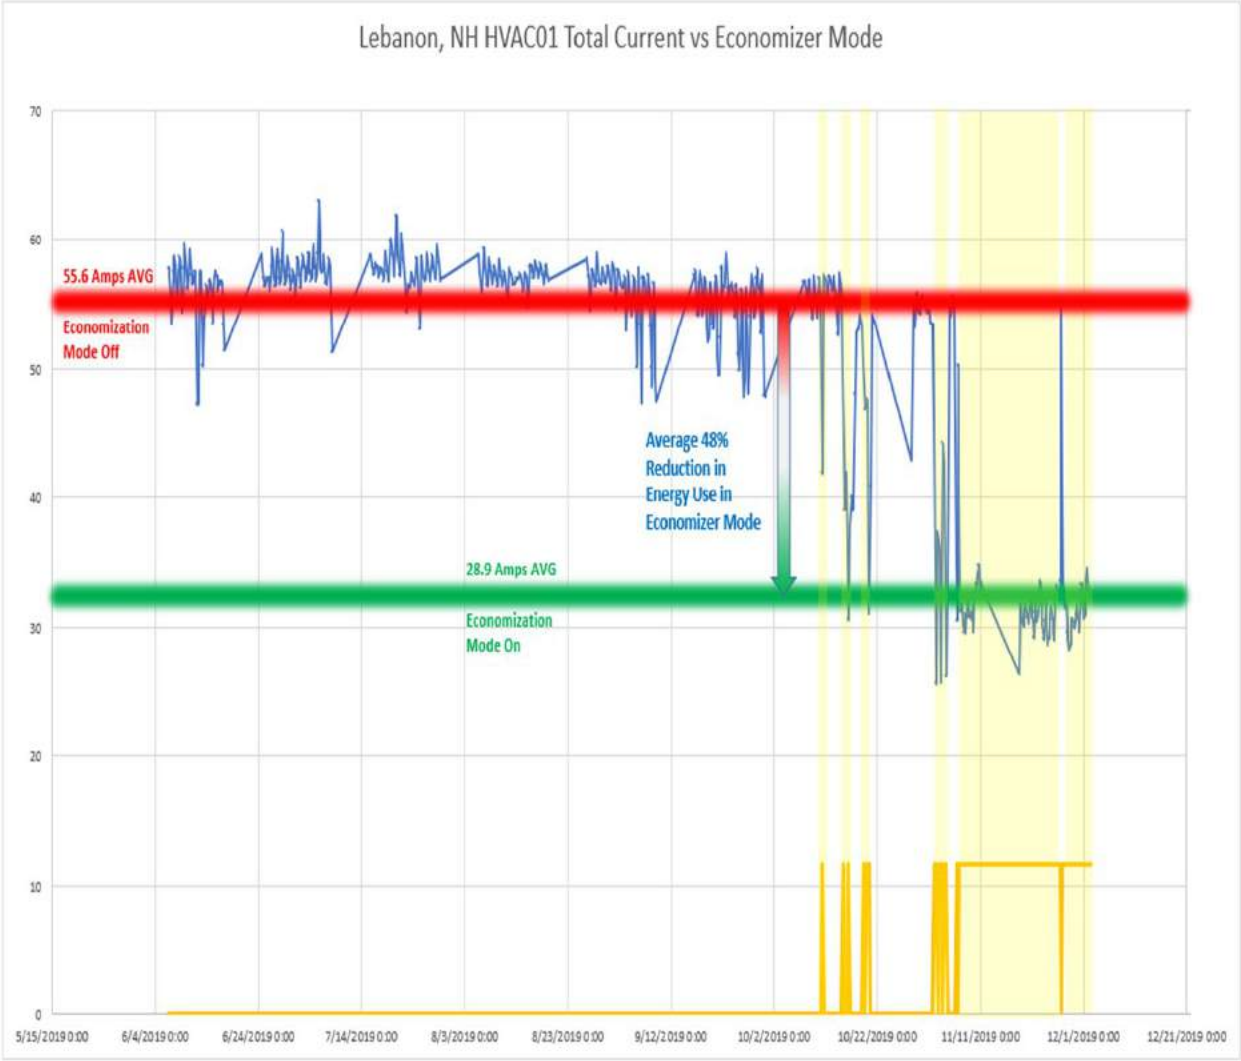

**Figure 15 - Energy Use Comparison With And Without Economizer Activated**

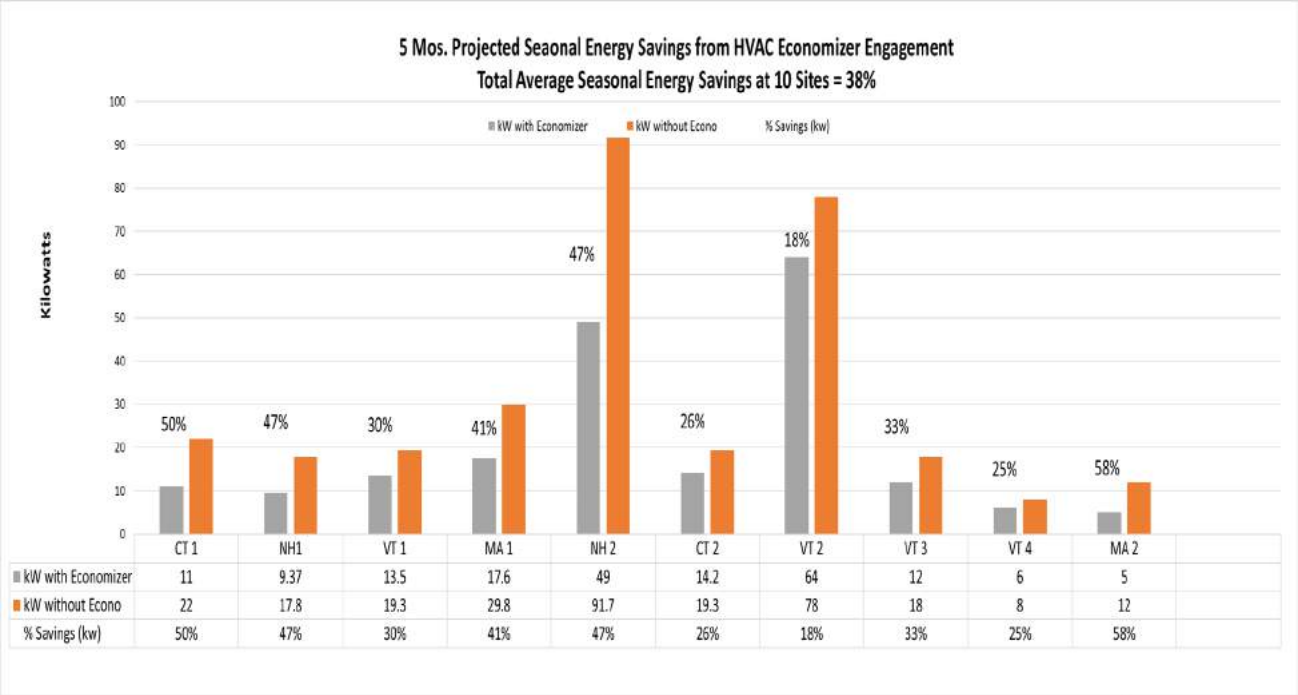
As shown in Table 3 the average energy savings projected across 10 sites is 38%. This figure can be increased by adjusting ambient room temperature control set points and the economizer set points. The MA 2 site indicated a reduction of 58%. These values seemed quite aggressive and with handheld meters and instruments our electrician confirmed the amp readings as correct.

**Table 3 - 5 Month Projected Seasonal Energy Savings From Economizer Engagement**



| | CT 1 | NH1 | VT 1 | MA 1 | NH 2 | CT 2 | VT 2 | VT 3 | VT 4 | MA 2 |
|---|---|---|---|---|---|---|---|---|---|---|
| kW with Economizer | 11 | 9.37 | 13.5 | 17.6 | 49 | 14.2 | 64 | 12 | 6 | 5 |
| kW without Econo | 22 | 17.8 | 19.3 | 29.8 | 91.7 | 19.3 | 78 | 18 | 8 | 12 |
| % Savings (kw) | 50% | 47% | 30% | 41% | 47% | 26% | 18% | 33% | 25% | 58% |

Summary:

- Most of North America is suitable for economization use
- Automated system controls require no manual intervention
- Significant energy reduction is achieved when economization is engaged
- Some state codes require economizer feature on HVAC

## 4. Conclusion

These three case studies have allowed us to identify substantial measured savings from multiple energy conservation measures. Although considered best practices blanking panels and many airflow efficiency measures often get overlooked or given low priority until an alarm indicates a thermal event. In many instances the network technicians who are "rack and stacking" their equipment in the space are not fully aware of the cost and impact of good airflow management resulting in limited compliance. On the other hand, those same technicians are keenly aware when a space is un-necessarily cold. It is not uncommon to see network or cabling tech's wearing coats inside a headend with low set points and we can surmise that not only is that space wasting energy but the productivity of the workers are likely to be reduced as well. The economizer technology available today has become an outstanding energy saver and has not received the attention or accolades that should make it a requirement everywhere. Several states have adopted building codes and included HVAC economizers as mandatory, but the magnitude of savings should support inclusion regardless of codes. It is the intention of this paper to raise awareness to the potential for significant verifiable energy cost reductions and associated emissions that if deployed and measured across the cable industry would help achieve Energy 2020 goals quite easily. Susan JinDavis VP of Environmental Affairs and Chief Sustainability Officer of Comcast recently stated "Different energy strategies are needed for our various locations. We are choosing solutions based on what will make the biggest difference location by location, whether that's on-site solar, green tariffs, renewable energy

supply contracts, or a combination. Across all of our operations, we want to find ways to not only power with renewables, *but to reduce our power needs overall*". As stated in the introduction the industry as a whole has been self-directed to maintain a commitment for efficiency and sustainability and the results of the measures presented here can provide financial justification for inclusion in long term planning and practices.

# 1. Introduction

Since the early 2000s, the cable television (CATV) industry has been playing its part in the Artificial Intelligence (AI) community by deploying equalization technology to enable its digital signals to survive varying frequency response conditions within its cable plants. Simon Haykin describes how the perceptron and the adaptive filter using the least mean squares (LMS) algorithm are naturally related [1]. Equalization has evolved into a powerful tool, enabling the CATV industry to achieve communication efficiencies once thought impossible -- but that story is not quite complete. The limits of equalization may extend beyond the linear frequency response, and cancel the nonlinear responses commonly associated with nodes and other active devices which use power amplifiers (PAs). Achieving nonlinear equalization requires new equalization methods, like receiver post-distorter equalization, where techniques include AI models, such as deep neural networks (DNNs). Furthermore, researchers have been advancing nonlinear distortion cancellation via other methods, including peak-to-average-power-ratio (PAPR) reduction, and digital pre-distortion (DPD). These technologies are beginning to show up in newer generation devices, where demands for radio frequency (RF) output power is high, while keeping power consumption low, like the full duplex DOCSIS (FDX) remote PHY device (RPD) nodes. DPD technologies cancel the contribution of the transmitting device only. More aggressive nonlinear distortion cancellation methods may be accomplished by advanced DNN approaches, such as incorporating input features derived from Volterra series models, which has become a popular model for nolinear distortion that can be used to describe multiple nonlinearity orders and memory. Then efficiencies across the CATV network could be considered, either by higher node RF output power, or more efficient PA architecture/bias within the node, amplifier, and/or customer premise equipment (CPE). This paper will propose how current CATV equalization systems could be enhanced to cancel severe nonlinear distortion based on some of these novel approaches to nonlinear equalization.

# 2. Artificial Intelligence (AI)

## 2.1. Historical Perspective

AI has existed for a very long time -- close to 80 years. In 1943, Warren Sturgis McCulloch and Walter Pitts published a paper titled “A Logical Calculus of Ideas Immanent in Nervous Activity,” laying the foundations for artificial neural networks (ANNs) [1]. Since then, many ideas involving AI have been shared, and this community has grown appreciably. Patrick Winston, who was born in 1943 and later became a MIT professor who taught a course in AI, described it as being about algorithms, enabled by constraints, exposed by suite of representations, that support the development of models targeted at thinking, perception, and action [2]. That definition is inclusive of many things -- in fact, some very simple internet searches can yield timelines rich with AI milestones, including events such as when Deep Blue defeated World Chess champion Garry Kasparov in 1997, or a more recent milestone, on October 15th, 2019, when OpenAI enabled a robot to learn how to single-handedly solve Rubik’s Cube with the support of two neural networks [3].

## 2.2. Common Solutions

There are many artificially intelligent solutions that we encounter every day, possibly without even realizing it. Comcast, for example, provides multiple products which incorporate AI technology. Some of these solutions include the Voice Remote, that adapts to the uniqueness of how each and every one of us speaks, and in turn assists with accessing and enjoying content on Comcast’s X1 platform. The X1 recommendation engine detects patterns in the content we consume, and assists users in navigating a wealth of available content and offer recommendations. Internet-based products like xFi Advanced

Security protect our home networks against constantly evolving network threats. Interactive assistants, like xFinity Assistant, help customers by leveraging an interactive knowledge base of common solutions.

## 2.3. Popular Tools/Models

There are many available AI tools and frameworks, including TensorFlow, and PyTorch [4]. These systems are designed to assist with navigating the vast array of models, each with their unique set of pros and cons, when it comes to approximating the functions that couple input and output data patterns together. Some of these tools readers may have already heard of, like DNNs [5]. Others, like support vector machines (SVMs), may be less familiar. Fortunately, finding the right model fit for a particular problem has been automated via tools like automated machine learning (Auto ML), which not only selects the best function approximation model, but also assists with tuning the parameters of that model to optimize its training and generalization properties.

## 2.4. Biological Inspiration

The perceptron model gets its inspiration from the Pyramidal cell shown Figure 1 [1]. One of the key characteristics of this model are its synaptic weights, which it applies to each of its input signals. The input signals are summed together and applied to an activation function. The sigmoid function is a popular activation function, which limits the output response to a specific range of continuous values. An Artificial Neural Network (ANN) connects multiple perceptions together in a variety of ways, in parallel, and/or in series. In doing so, interesting behaviors begin to emerge -- the most interesting being the nonlinear adaptation of the model weights. This could present interesting opportunities for linear adaptive equalization systems used today, where nonlinear adaptation enhancements could enable systems to account for both linear and nonlinear distortion present within the communication channel to improve the performance of equalization systems overall.

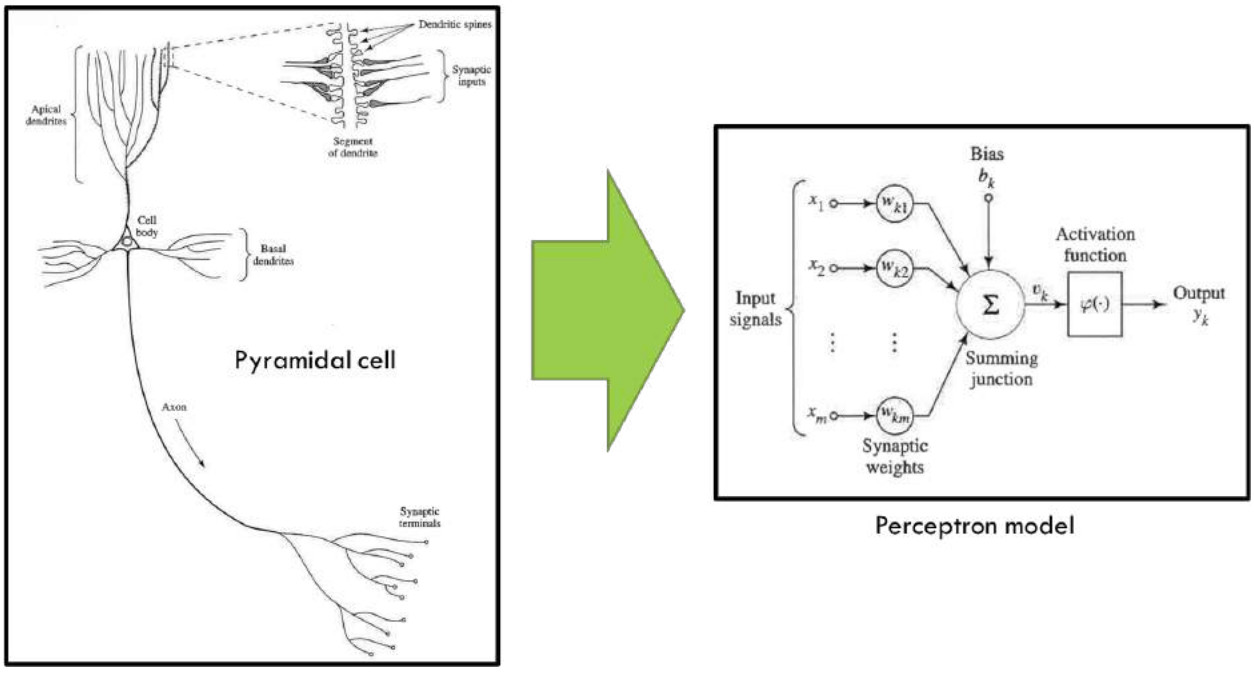

**Figure 1 - Biologically Inspired Perceptron Model**

### 2.5. DOCSIS Transmit Pre-Equalization

Since the early days of the Data Over Cable Service Interface Specifications (DOCSIS), equalization has enabled the cable modem termination systems (CMTSs) to adapt and learn the unique frequency response shared between it and each of the cable modems (CMs) to which it is connected. The CMTS shares this knowledge with the CM, via a coefficient vector or weights often times referred to as "taps", asking it to either convolve or overwrite its current set of weights, based on how quickly the frequency response was changing. The CM applies these weights to future transmissions to the CMTS, to cancel the frequency response effects of the channel, which could be micro reflections (echoes) or filter effects including group delay or amplitude roll-off [6]. This form of equalization came to be known as "transmit pre-equalization" in DOCSIS 1.1 [7].

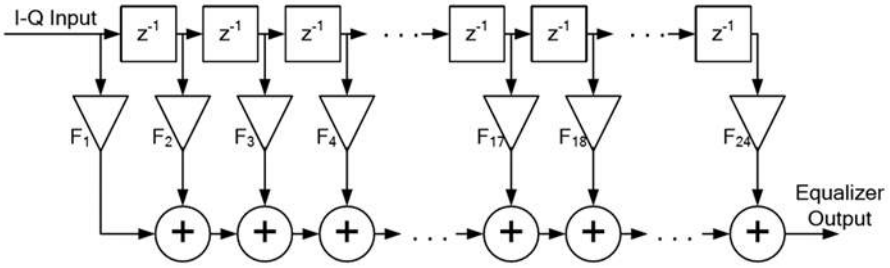

**Figure 2 - DOCSIS Transmit Pre-Equalizer Structure**

Comparing the DOCSIS 2.0 equalizer of Figure 2 to the perceptron of Figure 1, one cannot help but notice the similarities between the two models. What is most like the perceptron is the linear adaptive filter's weighted inputs feeding a linear combiner, and the ability to perform continuous learning – a single neuron operating in its linear mode [1]. The perceptron and an adaptive filter using LMS are naturally related [1].

## 3. Power Amplifier (PA) Efficiency Problem

Designer Charles Warren once gave a talk titled "How Might We: Three Words That Make Design Better" [8]. His thoughts are both refreshingly entertaining, and very helpful in organizing our ideas around innovation and establishing the following goal statement for this paper.

*How might we optimize PA efficiency in our RPDs?*

Improving PA efficiency in our RPDs may be beneficial in maintaining existing requirements, like RF output levels, as we introduce new capacity-enhancing technology. FDX falls into this category. Its accompanying echo cancellation (EC) technology, is necessary for facilitating bidirectional communication at the same operating frequencies [7]. EC technology additions will require compromises, especially while maintaining existing requirements for RPD RF output power, complexity, weight, power consumption, heat dissipation and cost.

At this point, the reader may be thinking "The goal statement is limited to RPDs, but why not optimize all the active components within the RF chain, including line extenders, mini-bridgers, trunk amplifiers, home drop amplifiers and even CPE front ends?" This is a thought we hope to address in paper as well, but in the spirit of following Warren's "How Might We" process through to its end, let's first consider some of the things that may stopping us from achieving our goal as stated.

First and foremost, there is a catch when it comes to increasing PA efficiency, and that is increased nonlinearity. Any savings in PA power consumption will have to be balanced with a system of mitigating any increases in nonlinearity, something we intend to explore fully in this paper. Another consideration is with respect to standards, and whether the solution requires standardization to ensure seamless interoperation across vendors that can be deployed, operated, and maintained in a consistent manner. Lastly, with introduction of any new technology, there is always consideration given to how to gracefully coexist with legacy products and services, ideally minimizing any impact to existing services.

## 4. Nonlinear Distortion (NLD)

Figure 3 illustrates how PAs strengthen their input signals [10]. When a PA's input power is at its lowest levels, its output power behavior is more linear than it is nonlinear, and its gain is constant. Ideally, PAs would behave linearly for all input signal levels, including high input powers, as illustrated by the dotted line. However, practical PAs generally available today cannot strengthen input signals without adding nonlinear distortion (NLD) to those input signals. As we will later see, NLD increases more rapidly than the illustrated input/output increases of the fundamental signals. Eventually, the PA reaches saturation, and its performance becomes more nonlinear than linear. At this point, the PA's output is no longer proportional to its input, and its performance is dominated by NLD. Further, a PA's linear operating region or dynamic range is a range of input powers that include a predictable mixture of impairments, including noise and NLD. At low input power, noise dominates the impairment mixture, but as input power increases, noise performance improves, while NLD worsens. The challenge for the network designer is to strike a balance between noise and NLD, so that their combined performance is within acceptable limits. Output-power-back-off (OBO) is a term used to describe this compromise, where the PA's operating point is typically several decibels (dBs) below its compression point and includes acceptable noise and NLD levels for overall system performance [11].

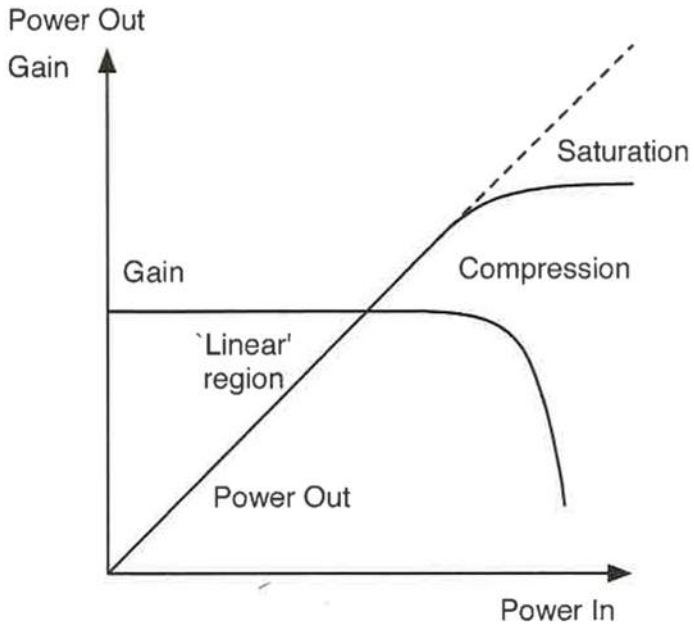

**Figure 3 - Power Output and Gain Compression Characteristics of a PA**

## 4.1. Digital Signal Impact

Metrics pertaining to Figure 4 node downstream transmission path (blue) performance for noise and NLD have been included in Table 1 [9]. These specifications are measured using 6 MHz wide channels and are based on a full channel loading consisting of 194 single carrier quadrature amplitude modulation (SC-QAM) signals. Decibel-millivolts, dBmVs, are generally used, for mathematical convenience, within the CATV industry, to reference operating levels, $O$, for analysis of these systems [12].

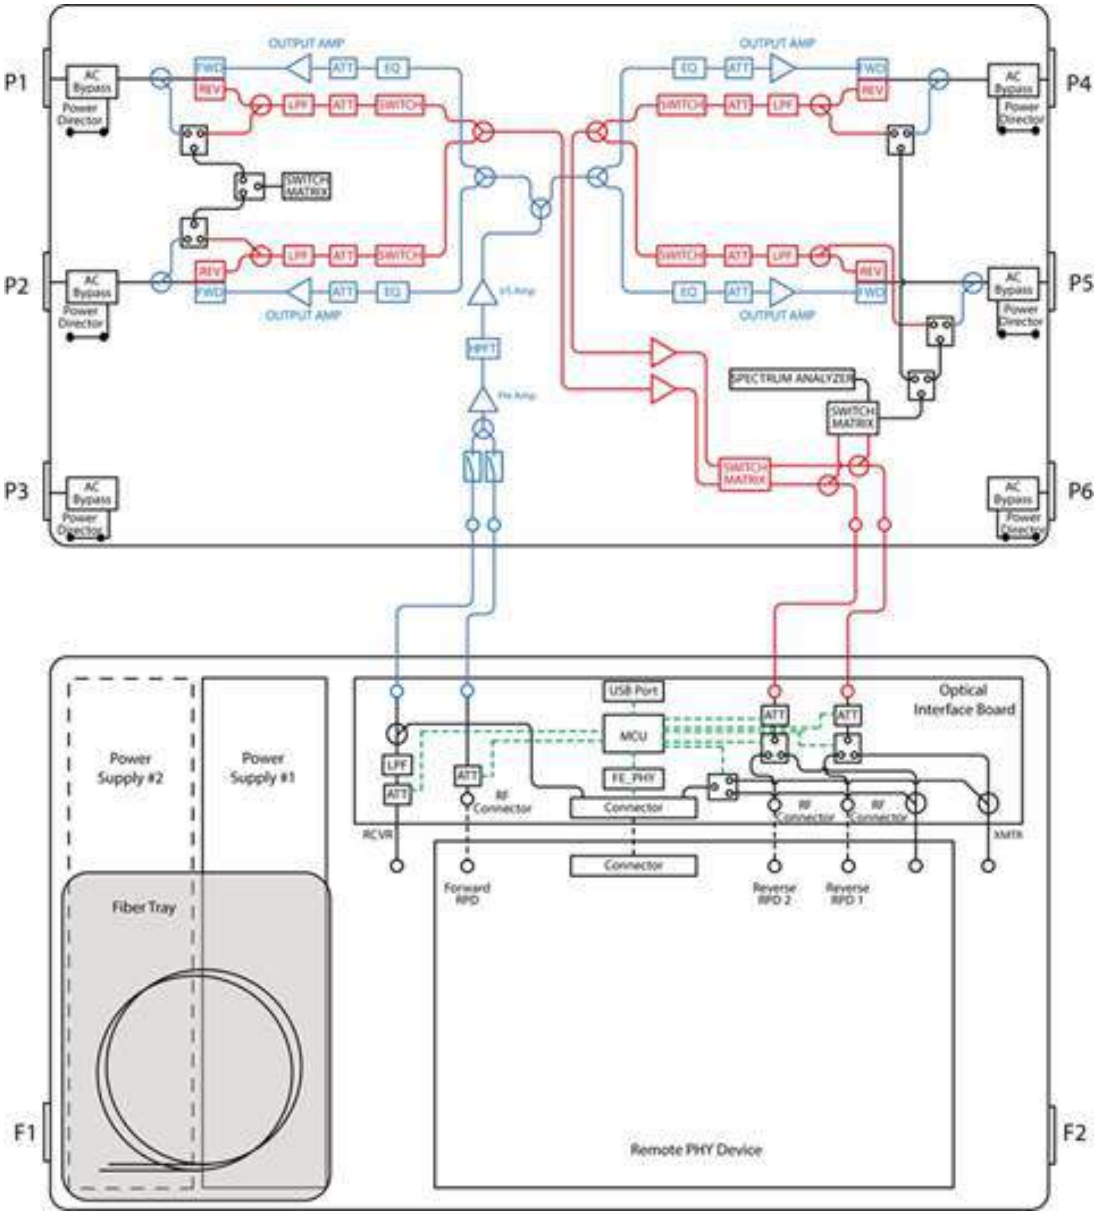

**Figure 4 - Sample RPD Node**

**Table 1 - Sample RPD Node Datasheet Summary**

| Sample RPD Node Specifications | |
|---|---|
| Minimum operational gain, $G$ | 42 dB |
| Noise Figure, $NF$ | 15.5 dB at 54 MHz |
| Composite-Intermodulation-Noise, $CIN_{ref}$ | 50 dB |
| Reference output level, $O_{ref}$ | 42 dBmV at 54 MHz |
| Power | 160.6 W @ 2.16 A, and 90 V AC |
| Weight | 49.8 lbs. |

Signal-to-noise ratio (SNR) describes the relative measure of signal power, $S$, to the noise power, $N_P$, which is the thermal noise or noise floor measured within the same bandwidth as the signal $S$, in this case 6 MHz. $N_P$ is estimated using (1), where $k$ is Boltzman's constant ($1.374 \times 10^{-23}\ joules/°K$), $T$ is the absolute temperature in degrees Kelvin ($°K$), and $B$ is the bandwidth of the measurement in Hertz (Hz). $N_P$ in the CATV industry is typically expressed in terms relative to 1 milli-volt (mV) across a 75 Ω impedance, therefore $N_P$ at 62 °F is approximately -57.4 dBmV [13].

$$N_p = kTB \tag{1}$$

Composite Intermodulation Noise (CIN) is a type of NLD which results from nonlinear distortion generated from loading conditions, which include digital signals, like SC-QAM. Node contribution for SNR and CIN can be calculated using (2) and (3) respectively, for changes in its output levels $O$ constrained over the node's dynamic range [12], [13]. In the CATV industry, CIN is typically dominated by 3rd-order NLD, which may not be the case for other communication systems, like those used in the satellite industry [14].

$$SNR = O + 57.4 - G - NF \tag{2}$$

$$CIN = CIN_{ref} - 2(O - O_{ref}) \tag{3}$$

Increasing the node's operating output power, from the originally specified $O_{ref}$, by 5 dB, will result in a new output level, $O = 47\ dBmV$ at 54 MHz. This new output level increase will also increase SNR to 47 dB at 54 MHz, using (2). However, CIN in (3) will decrease to 40 dB, leading to a 2 dB degradation overall of the System SNR, $SNR_S$, per (4).

$$SNR_S = -10log_{10}\left(10^{-\frac{SNR}{10}} + 10^{-\frac{CIN}{10}}\right) \tag{4}$$

Therefore, increasing node RF output signal levels may enable the designer to improve homes-per-node efficiency, such as with higher output level $O$, but will do so at the expense of increasing the node's power consumption and degrading the overall system performance criteria, $SNR_S$. Increasing PA RF output levels of networked devices is one of the ways in which to optimize PA efficiency. However,

higher RF output levels may drive power consumption above the network operator's acceptable threshold -- in the case of the node example, above a 160 W maximum. Power consumption threshold values are based on network operator's unique powering constraints, which may be limited by multiple factors, including network design, hardware capability and local regulatory restrictions. Regulatory restrictions here specifically involve the placement of powering hardware at specific telephone pole or pedestal locations. Increased power may also impact heat dissipation and design of the node's housing. These impacts may translate to the larger surface area and weight of the node's housing to facilitate necessary heat transfer, where weight may increase above an acceptable threshold, in this case 50 lbs. maximum. Node weight is an important factor, because technicians need to be able to lift the node in order to connect it to the cable plant. The activity could be above ground, attached to telephone poles, or below ground within a pedestal mount.

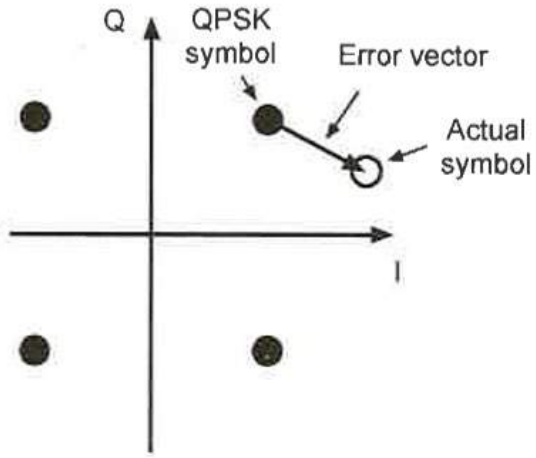

**Figure 5 – Error Vector Magnitude (EVM) for a QPSK Signal**

The effect of degraded performance on digital signals is illustrated in Figure 5. A quadrature phase shift keying (QPSK) signal degraded by $SNR_S$. will cause actual symbol reception to deviate from the ideal symbol receive point, shown as a dark circle. The resultant error vector, $e_j$, between the actual symbol and the ideal QPSK symbol receive point represents a measure of fidelity. Modulation error ratio (MER) in (5) measures the cluster variance in dB, that can be observed in a SC-QAM signal. It includes the effects of inter-symbol interference (ISI) spurious, phase noise, and all other degradations, where $E_{av}$ is the average constellation energy for equally likely symbols, and $N$ is the number of symbols averaged [7].

$$MER_{symb}(dB) = 10\log_{10}\left\{\frac{E_{av}}{\frac{1}{N}\sum_{j=1}^{N}|e_j|^2}\right\} \quad 5$$

Poor MER can lead to symbol decision boundary crossings, translating to symbol errors. If frequent enough, these symbol errors can overwhelm forward error correction (FEC) schema, leading to packet errors and ultimately loss of network payload.

## 4.1. Adjacent Channel Leakage Ratio (ACLR) Measurements

Figure 6 illustrates a nonlinear response to a band-limited signal, where the output of a system represents both linear (solid line) and nonlinear components (dashed line) [10]. The term intermodulation distortion (IMD) is synonymous with CIN.

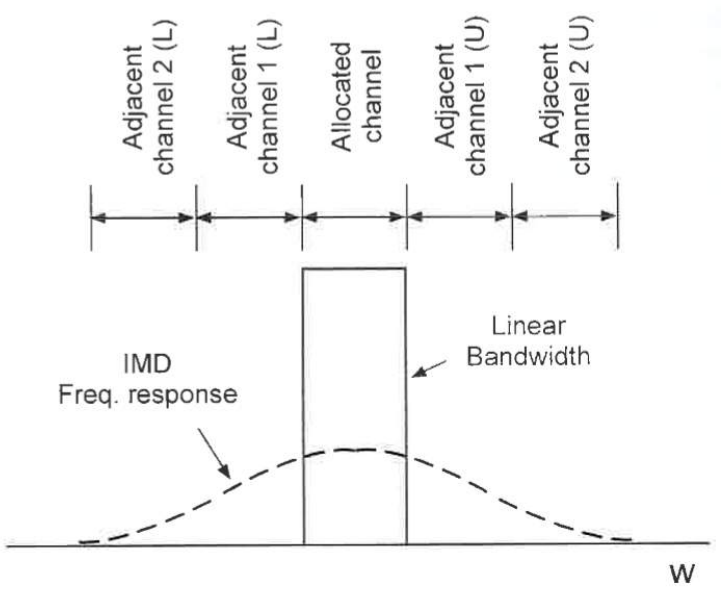

**Figure 6 - Output Spectrum Comprising Allocated and Adjacent Channels**

Figure 6 is an example of how CIN can accumulate under the signal(s). One in-band measurement approach of CIN involves the following steps:

1. Measuring $SNR_S$, in dBmV per 6 MHz
2. Turning the signal load off
3. Measuring the thermal noise contribution to $SNR_S$ at the same frequency, $N_P$, also in dBmV per 6 MHz
4. Calculating the difference between these two values, via algebraic manipulation of equation 4, as the CIN contribution

This is a reasonable measurement approach in a lab environment, where turning the PA's signal load off will likely not negatively impact a customer. Figure 6 illustrates a more customer-friendly approach that involves out-of-band distortion measurements of the integrated power in the adjacent channel(s), called adjacent channel power ratio (ACPR) or adjacent channel leakage ratio (ACLR), where these measurements are expressed in decibels relative to the signal's channel power, or -dBc [10].

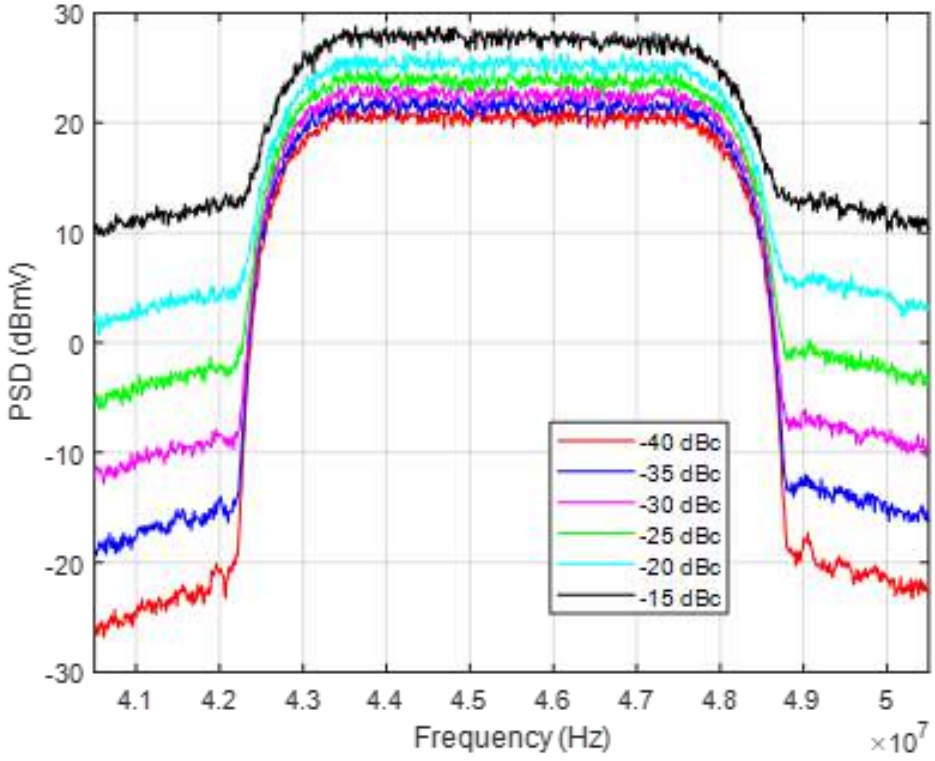

**Figure 7 - Increasing Spectral Regrowth over Amplifier Linear Region**

Figure 7 is composed of a series of output measurements of one PA, where each color corresponds with 5 dB changes in ACLR or spectral regrowth, resulting from incremental adjustment of the PA input power. ACLR measurements were made via Keysight's PXA signal analyzer model N9030A and vector signal analyzer (VSA) software, model 89601B. The 6.4 MHz bandwidth power delta marker measurements of both the received signal power and the spectral regrowth of the upper first adjacent channel were used to obtain the ACLR measurements.

Figure 7 data was obtained from a CATV drop amplifier, which is sometimes used within the customer's home to overcome losses associated with providing signals to multiple (1-3) client devices, primarily supporting video services, but also including voice and high-speed data services. PAs are used in many CATV network clients' front ends, used within the customer's home, like set-top boxes (STBs), cable modems (CMs), and digital terminal adapters (DTAs). The outside plant represents another group of network elements with embedded PAs, including the node previously discussed and additional amplifiers, called trunk amplifiers, line extenders and bridging amplifiers, which are used to compensate for cabling and passive losses incurred while distributing and aggregating services to and from the customer's home.

All of these cascaded PAs aggregate noise and NLD, resulting in an accumulated end-of-line (EOL) performance, which further restricts the individual contribution for any one PA in the chain to that of even higher fidelity (i.e. 50 dB per Table 1). This ensures that the customer's services meet, or ideally exceed, some minimum service level agreement (SLA). Additionally, variations in RF levels can occur for multiple reasons, like temperature changes, wind loading, and plant maintenance. Sometimes RF levels can change appreciably over short periods of time. Network designers may specify even better performance, to accommodate this performance variation in several of the components or sub systems in the network chain, a.k.a. 'margin-stacking' [10].

Similar ecosystems exist in other industries, including cellular, Wi-Fi, satellite, and the Internet of Things (IoT). For example, massive MIMO and millimeter wave transmissions use many PAs in cellular deployments and will also have similar end-to-end performance requirements [11].

## 4.2. PA Industry

The PA industry has a growth outlook from 2019 to 2025, with compound annual growth rate (CAGR) of 7.6%, primarily from anticipated developments in newer generation cellular communications. Some of the key providers include NXP Semiconductor (Netherlands), Broadcom Corporation (U.S.), Qorvo Inc. (U.S.), Anadigics Inc. (U.S.), RFHIC Corporation (U.S.), TekTelic Communications Inc. (U.S.), Texas Instrument (U.S.) among others [27].

Providers can supply a diverse range of PA classes suited for a variety of applications, some of which have been summarized in Table 2Table 2 - PA Classes.

**Table 2 - PA Classes**

| Class | Description |
|---|---|
| A | Very linear, especially for smaller signal amplitudes. Used for PAs at high millimeter-wave frequencies, but considered too inefficient, < 50%, for PAs in cellular wireless communications applications |
| B | Power transistor is biased just at the threshold voltage, so the transistor conducts for only a half-cycle of the RF waveform. This wave generates a significant amount of even harmonic distortion, and some self-bias. Maximum theoretical efficiency rises to 78.6%, compared with a Class A. |
| AB | Transistor is biased slightly into the "on" condition, usually specified as a constant quiescent drain current in FETs, with the DC gate bias adjusted to provide the design standing current. The optimal load is generally very close to the Class B value, and the achievable energy efficiency can be over 70%, theoretically. |
| C | The Power transistor is biased below threshold, so under quiescent conditions, the transistor is switched off. This mode can be very energy efficient, but the gain is low, and the harmonic output and intermodulation distortion can be considerable. |
| D, E, & F | Very efficient. No overlap between the voltage and current waveforms, so this amplifier converts the DC to RF with 100% efficiency. A resonator can be used to filter out the harmonics at the load. |
| D | Form of switching amplifier, where the PA is driven by a pulsed waveform and the output current is switched rapidly between on and off states. Uses two transistors in a push-pull arrangement. |
| E | Both 2nd, and 3rd harmonics are tuned |
| F | 2nd harmonic tuned |
| Inverse F | 2nd harmonic tuned |

The CATV industry primarily uses class A PA products because of high performance requirements, including low noise and high linearity, over a broad range of spectrum, typically between 5 and 1,218

MHz. While peak efficiencies for some of these classes may be high, they are attained only at or close to the maximum RF output power and will fall rapidly with OBO. To overcome this basic drawback, alternative PA architectures will be required.

### 4.1. NLD Modeling

Perhaps the simplest way to represent PA NLD is to describe what it is not. A distortionless PA would have a linear transfer characteristic, which is achieved when the waveform of the PA's output voltage precisely duplicates that of its input. Only when a PA distorts does the output signal contain additional components, at frequencies differing from the frequencies of the input signal. The nature as well as the degree of distortion is dependent not only on the shape of the transfer characteristic of the PA, but also on the loading condition and operating point (bias) [12].

At higher powers, we have seen that the output power and gain deviate significantly from the linear relationship at small signals. This is the compression region of operation, and at a sufficiently high input drive, we will get no more power out of the PA -- at this point, we are at the saturated power level. In these regions of operation, the PA is very nonlinear. This compression behavior is also known as amplitude modulation to amplitude modulation (AM-AM) conversion: by modulating (changing) the input signal amplitude, we affect or modulate the amplitude of the output signal in a nonlinear fashion [12].

Typically, frequency-domain polynomial models will be used to model the AM-AM and amplitude modulation to phase modulation (AM-PM) characteristics of the PA. In general, frequency-domain models can describe the RF frequency response phenomena quite well but are unable to accommodate the memory effects associated with long time constants -- for example, bias line reactance and charge storage [10]. A Volterra series can be thought of as a Taylor series with memory; that is, a Taylor series defines not only at the present instant in time, but includes terms at previous instants, up to some specified delay [10].

Consider the baseband discrete model of the PA $y(n) = f(x(n), x(n-1), \cdots)$, where $x(n)$ is the input signal, $y(n)$ is the output signal, and $f(\cdot)$ is some nonlinear function. The simplest nonlinear PA model is the AM-AM/AM-PM model. Let the amplitude of the input signal be $V_x = E[|x(n)|]$, where $E[\cdot]$ denotes short-term expectation or average. The output sample $y(n)$'s amplitude $V_y = E[y(n)]$ and additional phase change $\psi_y = E[\angle y(n)]$ depend on $V_x$ in nonlinear ways as (6) and (7):

$$V_y = \frac{gV_x}{\left(1 + \frac{gV_x}{c}\right)^{\frac{1}{2\sigma}}} \tag{6}$$

$$\psi_y = \frac{\alpha V_x^p}{1 + \left(\frac{V_x}{\beta}\right)^q} \tag{7}$$

where $g$ is the linear gain, $\sigma$ is the smoothness factor, and $c$ denotes the saturation magnitude of the PA. Typical examples of these parameters are $g = 4.65$, $\sigma = 0.81$, $c = 0.58$, $\alpha = 2560$, $\beta = 0.114$, $p = 2.4$, and $q = 2.3$, which are used in the PA models regulated by Institute of Electrical and Electronics Engineers (IEEE) 803.11ad task group (TG) [11].

More accurate models should take into consideration the fact that nonlinearity leads to memory effects. In this case, Volterra series (8), are typically used to model PAs [11]. A general model is shown in [11] with up to Pth order nonlinearity and up to D step memory.

$$y(n) = \sum_{d=0}^{D} \sum_{k=1}^{P} b_{kd} x(n-d) \, |x(n-d)|^{k-1} \tag{8}$$

It can be shown that estimation of only odd-order nonlinearity (i.e. odd k) may be necessary for limited narrowband loading conditions and specific center frequencies, because even-order nonlinearity falls outside of the passband and will be filtered out by the receiver bandpass filters [11]. To illustrate this phenomenon, we can consider some simple examples where the input signal $x(n)$ consists of a few (1-3) single frequency components only. Omitting the memory effects, if $x(n)$ is a single frequency signal, i.e., $x(n) = V_0 \cos(a_0 + \phi)$, where $a_0 = 2\pi f_0 n$. Then, using well-known trigonometric identities, the output signal can be written as

$$y(n) = k_1 V_0 \cos(a_0 + \phi + \psi_1) + \left(\frac{3}{4} k_3 V_0^3 + \frac{5}{8} k_5 V_0^5\right) \cos(a_0 + \phi + \psi_3 + \psi_5) \tag{9}$$

$$+ \frac{1}{2} k_2 V_0^2 + \frac{3}{8} k_4 V_0^4 \tag{10}$$

$$+ \left(\frac{1}{2} k_2 V_0^2 + \frac{1}{2} k_4 V_0^4\right) \cos(2a_0 + 2\phi + 2\psi_2 + 2\psi_4) \tag{11}$$

$$+ \left(\frac{1}{4} k_3 V_0^3 + \frac{5}{16} k_5 V_0^5\right) \cos(3a_0 + 3\phi + 3\psi_3 + 3\psi_5) \tag{12}$$

$$+ \frac{1}{8} k_4 V_0^4 \cos(4a_0 + 4\phi + 4\psi_4) + \cdots \tag{13}$$

$$+ \frac{1}{16} k_5 V_0^5 \cos(5a_0 + 5\phi + 5\psi_5) + \cdots \tag{14}$$

$V_0 \cos(a_0 + \phi)$ and $V_0 \sin(a_0 + \phi)$ are both sinusoidal voltages. Their waveforms are identical except for a 90° phase difference. The cosine form is used throughout this analysis because it results in simpler expressions [11]. The first line (9) is the in-band response with AM-AM/AM-PM nonlinear effects, the second line (10) is the direct current (DC) bias, and the remaining lines (11) through (14) include second through fifth order harmonics. At the receiving side, we may just have line (9) left, because all the other items will be canceled by bandpass filtering. Communication network filters, such as the root-raised cosine (RRC) filters, are typically implemented in two halves, one in the transmitter and the other in the receiver, so that overall, we get Nyquist rate sampling, and provide necessary impedance matching of the power transistor to its optimum load impedance of the network. Another critical filter function is in their use of controlling out-of-band emissions from sources including PA NLD, thus limiting the impact of distortion to within the operating band.

If $x(n)$ consists of two frequencies, i.e., $x(n) = V_1 \cos(a_1 + \phi_1) + V_2 \cos(a_2 + \phi_2)$, where $a_i = 2\pi f_i n$, then the inband response includes many more terms, such as the first order terms $k_i V_i \cos(a_i + \phi_i + \psi_i)$, the third order terms $k_3\left(V_i^3 + V_i V_j^2\right)\cos(a_i + \phi_i + \psi_i)$, the fifth order terms $k_5\left(V_i^5 + V_i V_j^4 + V_i^3 V_j^2\right)\cos(a_i + \phi_i + \psi_i)$, for $i, j \in \{1,2\}$. There are also intermodulation terms that consist of $na_i \pm ma_j$ as long as they are within the passband of the bandpass filter, such as $\left(V_i^2 V_j + V_i^2 V_j^3 + V_1^4 V_j\right)\cos\left(2a_i - a_j + 2\phi_i - \phi_j + 2\psi_i - \psi_j\right)$. For some specific loading conditions, there may be many other higher order terms with frequencies $na_i$, $n\left(a_i \pm a_j\right)$, or $na_i + ma_j$, that can not pass the passband filter. One of the important observations is that the contents that can pass the passband filter may consist of odd-order nonlinearity only for specific center frequency and narrowband conditions only.

If $x(n)$ consists of three or more frequencies, we can have similar observations, albeit the expressions are more complex. Let the input signal $x(n)$ be

$$x(n) = \sum_{i=1}^{3} V_i \cos(a_i), a_i = 2\pi f_i n. \tag{15}$$

The second order component includes the DC component $g_{2,0}(n)$, the sum/difference of beat components $g_{2,1}(n)$, and the second-order harmonic components $g_{2,2}(n)$. Specifically,

$$k_2 x^2(n) = g_{2,0} + g_{2,1}(n) + g_{2,2}(n) \tag{16}$$

Where

$$g_{2,0}(n) = \sum_{i=1}^{3} \frac{V_i^2}{2}, \tag{17}$$

$$g_{2,1}(n) = \sum_{i=1}^{3} \sum_{j \neq 1} V_i V_j \cos\left(a_i \pm a_j\right), \tag{18}$$

$$g_{2,2}(n) = \sum_{i=1}^{3} V_i^2 \frac{\cos(2a_i)}{2}. \tag{19}$$

The third order component includes the third-order harmonic components $g_{3,1}(n)$, the third intermodulation beat components $g_{3,2}(n)$, the triple beat components $g_{3,3}(n)$, the self-compression/expansion components $g_{3,4}(n)$, and the cross-compression/expansion components $g_{3,5}(n)$. Specifically,

$$k_3 x^3(n) = g_{3,1} + g_{3,2}(n) + g_{3,3}(n) + g_{3,4}(n) + g_{3,5}(n) \tag{20}$$

Where

$$g_{3,1}(n) = \sum_{i=1}^{3} \frac{V_i^3}{4} \cos\,(3a_i), \tag{21}$$

$$g_{3,2}(n) = \sum_{i=1}^{3} \sum_{j\neq 1} \frac{3{V_i}^2 V_j}{4} \cos\big(2a_i \pm a_j\big), \tag{22}$$

$$g_{3,3}(n) = \sum_{i=1}^{3} \sum_{j\neq 1} \sum_{k\neq 1} \frac{3V_i V_j V_k}{2} \cos\big(a_i \pm a_j \pm a_k\big), \tag{23}$$

$$g_{3,4}(n) = \sum_{i=1}^{3} \frac{3V_i^3}{4} \cos(a_i)\,. \tag{24}$$

$$g_{3,5}(n) = \sum_{i=1}^{3} \sum_{j\neq 1} \frac{3V_i V_j^2}{2} \cos(a_i)\,. \tag{25}$$

The simulated output containing continuous wave signals (CWs) and NLD aligns with measurement in Figure 8, given coarse approximations for nonlinear gain coefficients and odd-order memory, based on model described in (8). A Rohde and Schwarz DOCSIS Cable Load Generator (CLGD) generated the CWs. The CWs propagated through a nonlinear power amplifier. The resultant nonlinear output spectrum was measured using a Keysight vector signal analyzer, model MXA, running in spectrum analysis mode.

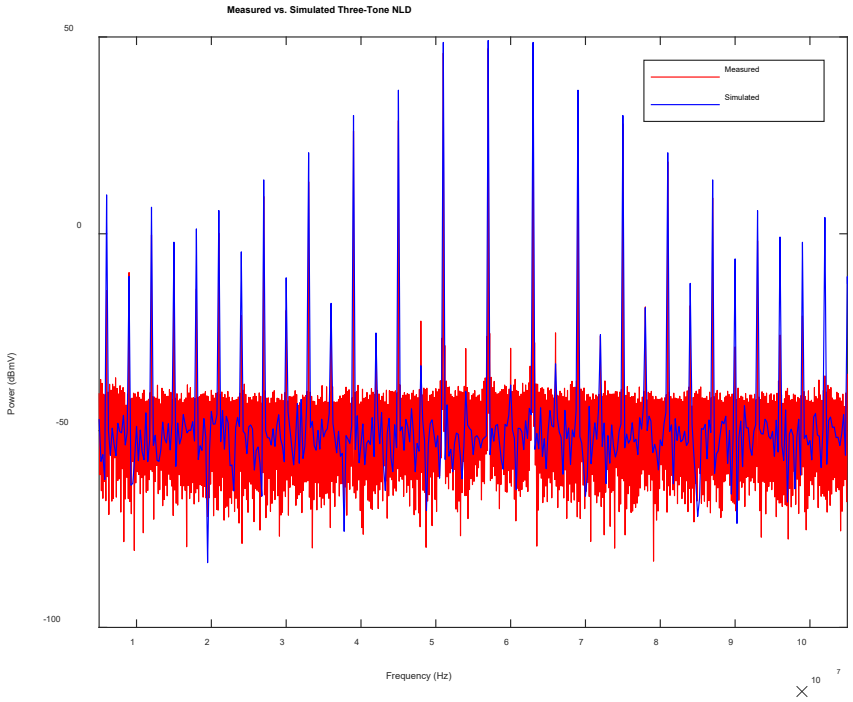

**Figure 8 - 3 Tone NLD Measured vs. Simulated**

# 5. NLD Mitigation

The focus of this paper up to this point has been on the levers associated with PA efficiencies (a) near saturation operation, and more efficient implementations via (b) PA classes, which may include (c) biasing the PA to consume less power. All these approaches result in degraded NLD, which becomes even more challenging as modern-day orthogonal frequency division multiplexing (OFDM) signals, which have a higher peak-to-average power ratio (PAPR), become more ubiquitous in communication network payloads [15]. One of the major design goals modern systems is to make the communication systems more power efficient. This needs efficient PAs, which is unfortunately more challenging since OFDM has much higher PAPR and wider bandwidth [11].

We will next explore a portfolio of current methods focused on harvesting PA efficiency and in most cases include mitigating NLD. These methods have enabled network designers to push the network operating boundaries that were previously constrained by lower amounts of NLD. These methods will include PAPR Reduction, Transmitter DPD, and Receiver Post-Distorter Equalization.

## 5.1. Peak-to-Average-Power-Ratio (PAPR) Reduction

Figure 9 illustrates how PAPR can interact with PA characteristics. OFDM signals can have a high degree of PAPR and push the PA operation into saturation at maximum signal amplitudes, also illustrated in Figure 9. PAPR reduction methods work to minimize the signal's PAPR, so that operation at PA saturation can be avoided, like OBO. There are multiple methods available to achieve PAPR reduction, as we will see, each with their own tradeoffs in benefit and cost.

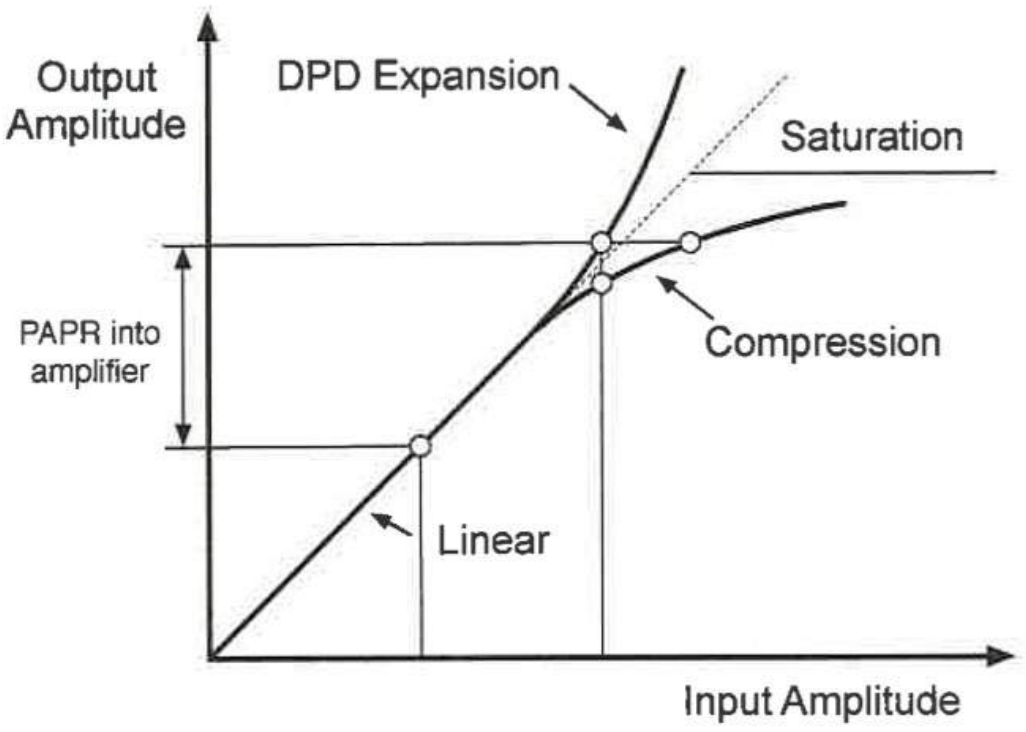

**Figure 9 - PA Characteristics with PAPR and DPD**

PAPR reduction was discussed during the deliberations of the DOCSIS 3.1 standard development, which introduced OFDM signaling into its portfolio of physical layer technology (PHY) [7]. The concern was that the increased PAPR of OFDM exceeded that of previous generation DOCSIS 3.0, SC-QAM on a 6 MHz bandwidth basis. However, the standards group ultimately decided against using PAPR reduction, primarily because the impact to CATV PAs would be negligible, given their broadband nature, which is an aggregate of over one hundred 6 MHz channels, up to approximately 1 GHz of bandwidth, total. Through lab measurement, these conclusions have been validated, but actual field results at scale have yet to be made [15].

High data rates have led to complex modulation schema, and ultimately higher spectral efficiency. One consequence of using spectrally efficient modulation schemes is that the dynamic range of the signal may be quite high [10]. This is generally measured in terms of the ratio of the peak signal power to the average power of the modulated signal, or PAPR [10]. While a large PAPR is not such a problem for signal transmission, it can have an impact on the efficiency of the transmitter PA [10], as illustrated in Figure 9, where the signal peaks can push the PA into saturation if the signal OBO isn't sufficiently below the PA compression point. Reducing the PAPR of the input signal using digital signal processing allows the PA to be operated at a higher efficiency, and it also reduces the dynamic range needed to represent the input signal digitally [10]. In addition, the reduced PAPR will often reduce the complexity of the linearization approach needed to compensate for PA nonlinearities [10].

The PAPR of a signal $x(n)$ is illustrated in (26), where $E[\cdot]$ denotes short-term expectation or average [10].

$$PAPR = \frac{\max(|x|^2)}{E[|x|^2]} \quad (26)$$

(27) illustrates how PAPR is based on the statistics of the signal rather than the absolute peak, while the practical peak is the level, $L$, at which the signal magnitude has a $10^{-4}$ probability, $P$, of exceeding.

$$P\{\,|x|^2 > L\} = 10^{-4} \quad (27)$$

The complementary cumulative density function (CCDF) of $|x|^2$, is a useful description of the signal statistics, often compared to that of a Gaussian waveform because the statistics of multi-carrier signals used in many of today's communications networks tend to approach that of a Gaussian [10]. Figure 10 is a Keysight PXA PAPR measurement for a 6 MHz, DOCSIS downstream SC-QAM signal whose PAPR (yellow line) is approximately 9.44 dB based on a 10 Mpt (million point) sample period [15]. Changing from DOCSIS SC-QAM to an OFDM-based PHY and limiting measurements to 6 MHz bandwidth, shows that PAPR will increase by approximately 0.96 dB, using M=256 QAM constellation levels for both signal types. However, much broader bandwidth comparisons over 192 MHz revealed that OFDM PAPR was lower than SC-QAM, by about 0.52 dB [15].

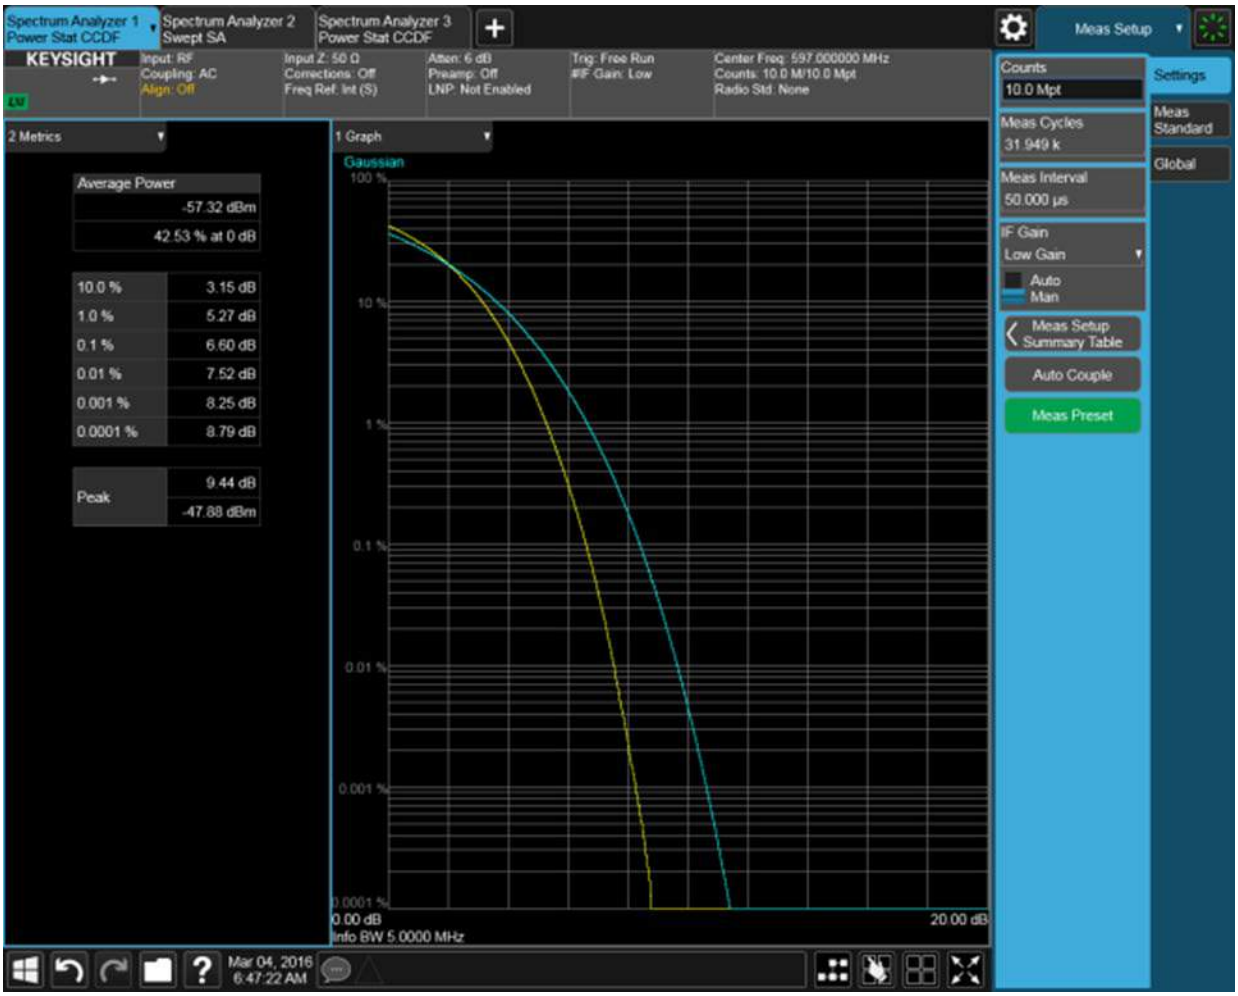

**Figure 10 - DOCSIS Downstream SC-QAM PAPR Measurement**

Many techniques have been developed for PAPR reduction, such as signal clipping, peak cancellation, and error waveform subtraction (noise shaping) [10]. These clip-and-filter approaches clip peaks exceeding a specified level and filter the waveform to remove out-of-band distortion [10]. Clip-and-filter and peak windowing are the easiest Crest Factor Reduction (CFR) methods to implement, making them the most likely to be used [10].

For OFDM-based formats, CFR is often achieved using redundant coding or the transmission of auxiliary information, both of which reduce data throughput of the system. Pilot tones and unmodulated subcarriers can be exploited to reduce PAPR with some special pre-coding techniques [16]. The selected mapping approach (SLM) from [16] provides good PAPR reduction performance, but may suffer from high computational complexity from using a bank of inverse fast fourier transforms (IFFTs), illustrated in Figure 11.

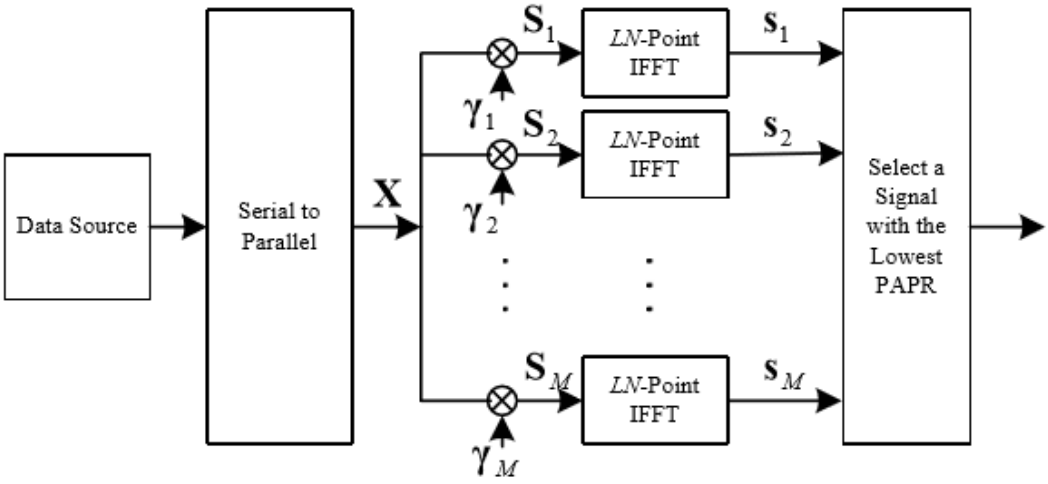

**Figure 11 - Traditional Selected Mapping, PAPR Reduction via Pre-Coding**

The new SLM approach from [16], shown in Figure 12, replaces IFFTs with new kinds of conversions, resulting in much lower complexity. Multiple IFFTs are replaced with transformation matrix, $T_r$, to produce candidate signals [16]. PAPR reduction for this approach is almost as good as traditional SLM approaches but uses much less processing overhead [16].

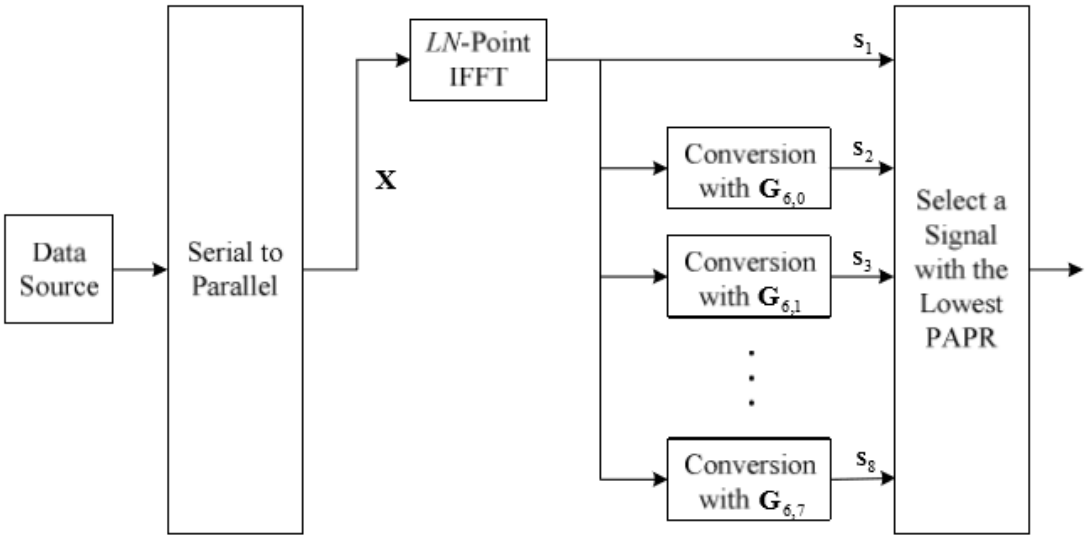

**Figure 12 - Transformation Based Pre-Coding for SLM PAPR Reduction**

CFR techniques are very appropriate for many wireless communications applications, such as cellular wireless handset PA applications, where Class AB operations are typically used [10]. CFR is a form of digital signal processing applied to the digital signal $x(n)$, used in combination with DPD to reduce the requirements on the RF PA within the transmit chain [10]. Although the distortionless PAPR reduction methods decrease the deleterious effect of nonlinear distortions, their effectiveness in improving the system performance is limited, since the main problem of the limited dynamic range of the PA remains unsolved [17]. Therefore, CFR often precedes DPD, per Figure 13. When CFR is used in conjunction

with DPD techniques, the expansive nature of the DPD function operates on the crest factor reduced signal, so that the resulting pre-distorted signal that enters the PA does not have an excessive PAPR, and the PA can still be driven hard to operate at its highest efficiency [10]. This behavior is also illustrated in Figure 9.

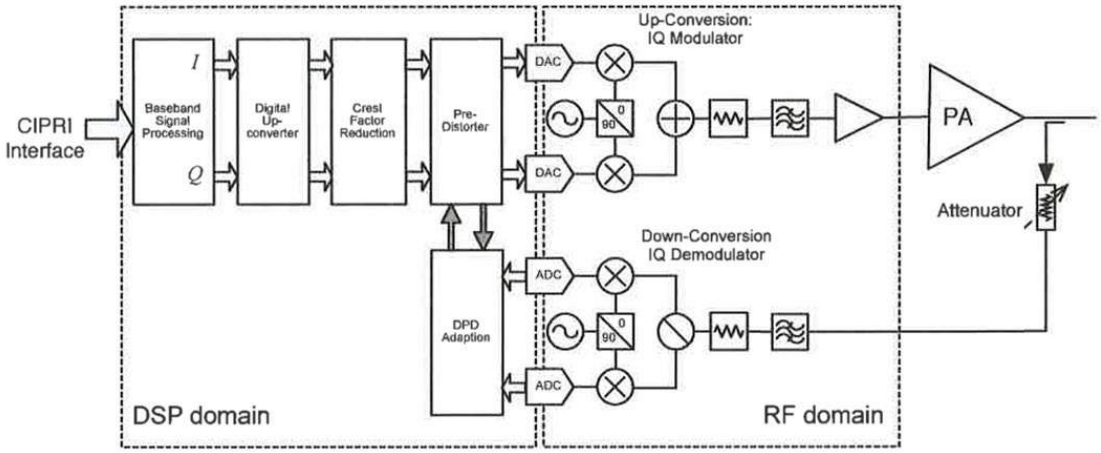

**Figure 13 - High-Level Transmitter with CFR and Adaptive DPD**

CFR assumes that reducing the peak of the signal is beneficial to the performance of the digital transmitter, essentially allowing the linearized PA to operate at a higher efficiency, while meeting the linearity requirements of the modulation format used [10]. CFR has drawbacks which degrade the system performance, either by increasing in-band degradation or reducing data throughput, but the overall system can be optimized to meet the performance specifications at higher PA efficiencies [10]. When applied properly, CFR allows the PA to operate more efficiently, thereby improving the performance of the transmitter [10].

## 5.1. Transmitter Digital Pre-Distortion (DPD)

One of the dominating practices in the cellular and satellite industries today is to insert a DPD circuit before the PA, which distorts the signals appropriately to compensate for the nonlinear PA response [11]. The distortion is added in such a way as to cancel the inherent nonlinearity of the PA, so that its output is a linear replica of the original input signal. DPD has been applied widely in many modern transmitters [2]. DPD can lead to the use of more efficient and cost-effective PAs [11] and is being considered for future generations of FDX RPD node hardware, where power consumption thresholds are already being encroached upon, while new capability is being added to increase its capacity as efficiently as possible.

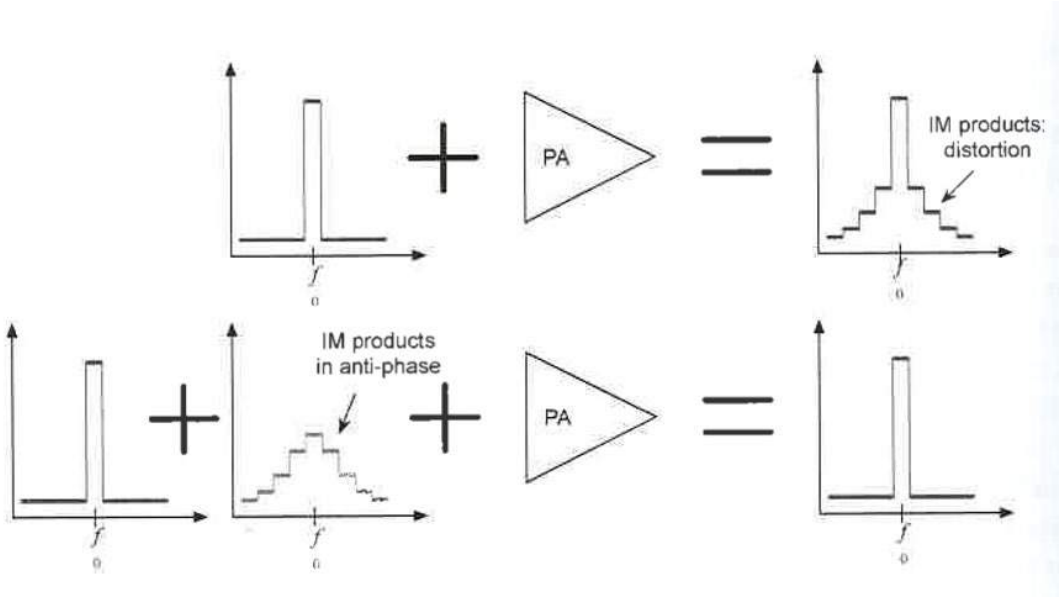

**Figure 14 - Nonlinearized PA vs. Linearized PA via Digital Pre-Distortion**

We will now focus on current approaches available to mitigate the effects of NLD, which are based on equalization, or creating an anti-phase version of NLD, as in the bottom part of Figure 14, which, when added to the signal from which it was derived, can negate the nonlinear effects of the PA. This essentially linearizes the PA's behavior.

In Figure 14, equalization is being performed prior to the signal's exposure to NLD, or pre-equalization. Pre-equalization of NLD is typically accomplished using DPD technology. DPD is analogous to DOCSIS Transmit Pre-Equalization, and the key difference is in the type of distortion that gets mitigated. DOCSIS Transmit Pre-Equalization mitigates linear distortion (LD), or plant echoes and other filter effects including amplitude roll-off, and group delay variation [7]. The key similarity here is that both signal processing techniques are applied as a signal bias, prior to the signal's impairment exposure, impairments being NLD for DPD, and LD for transmit pre-equalization.

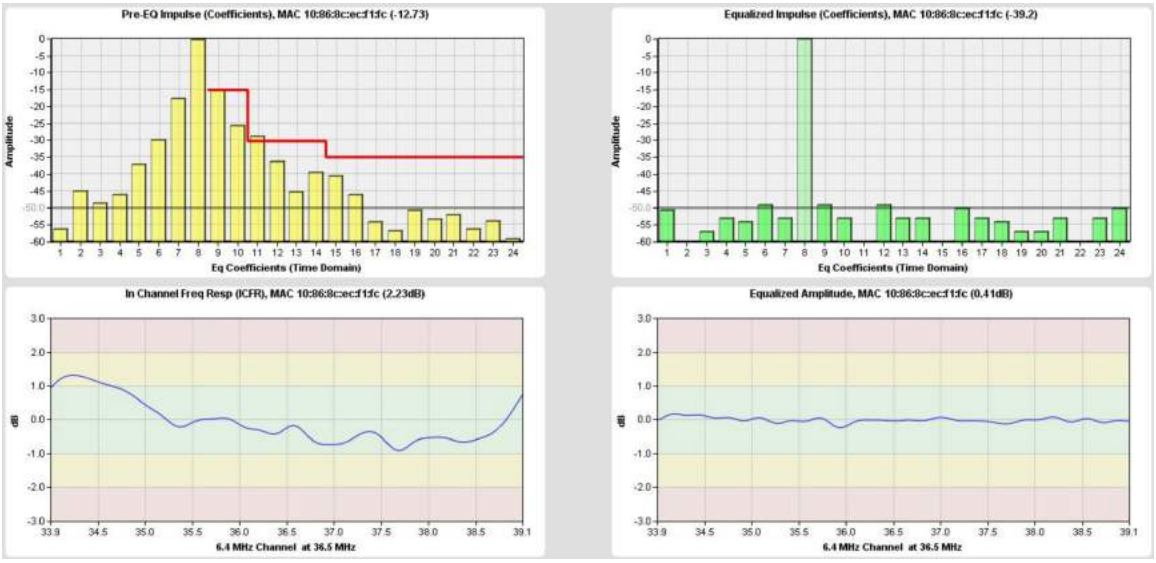

**Figure 15 - CM Upstream Transmit Pre-Equalization and Post-Equalization Functions**

Equalization functions can also be applied to the signal after impairment exposure, and this is known as post-distorter equalization for NLD and post-equalization for LD. In DOCSIS upstream communications, both Transmit Pre-Equalization and post-equalization functions work collaboratively to mitigate the effects of LD [7]. Figure 15 illustrates these two functions together compensating for the communication channel that exists between, say, my CM, and the CMTS that serves multiple neighboring towns, including my own. CMTSs may connect to hundreds of nodes, as discussed in earlier sections, and ultimately connecting to thousands of CMs. The CMTS's primary function is that of a router, facilitating communication between the local area network (LAN), comprised of many CMs, including mine, and the wide area network (WAN) or internet.

The collaboration between the CM and CMTS on how to equalize upstream LD is specified in DOCSIS, where transmit pre-equalization is a CM function and its DOCSIS 2.0, 24 symbol-spaced coefficients, shown in the upper left side of Figure 15 in yellow, are provided to it by the CMTS [7]. The CMTS post-equalization function is shown in the upper right side, in green. While performing its own post equalization function, the CMTS periodically sends a set of equalizer coefficients to the CM, via station-maintenance messages, with instructions to either overwrite or convolve the CM's current set of equalizer coefficients with the new coefficients.

An effect of this collaboration is to perform most of the channel equalization at the CM's transmit pre-equalization function, leaving only minor corrections in the post equalization function, at the CMTS. The equalizer's coefficients are colored yellow because of the intensity of correction, or, in other words, the variation of its amplitude frequency response, illustrated in the lower left chart, which exceeds ±1 dB peak-to-peak. Figure 15 illustrates how the CM is compensating for most of the channel's LD. Overall, LD equalization at both ends of the communication link has proven to be very robust and reliable in the CATV industry, but it does so with additional signal processing and overhead.

Adaptive pre-distortion techniques include an observation path that samples the output from the power amplifier and feeds the signal back to the pre-distorter to estimate system nonlinearity [10]. Additional components include analog-to-digital converters (ADCs) which are used to convert the observation signal back to baseband and digitize for digital domain operations. Components in this path will have better linearity than the desired performance of the transmitter to avoid introducing distortion at the PA output

arising from the observation process [10]. Input and feedback signals must be synchronized, accounting for the group delay of the PA, which tends to dominate the loop [10].

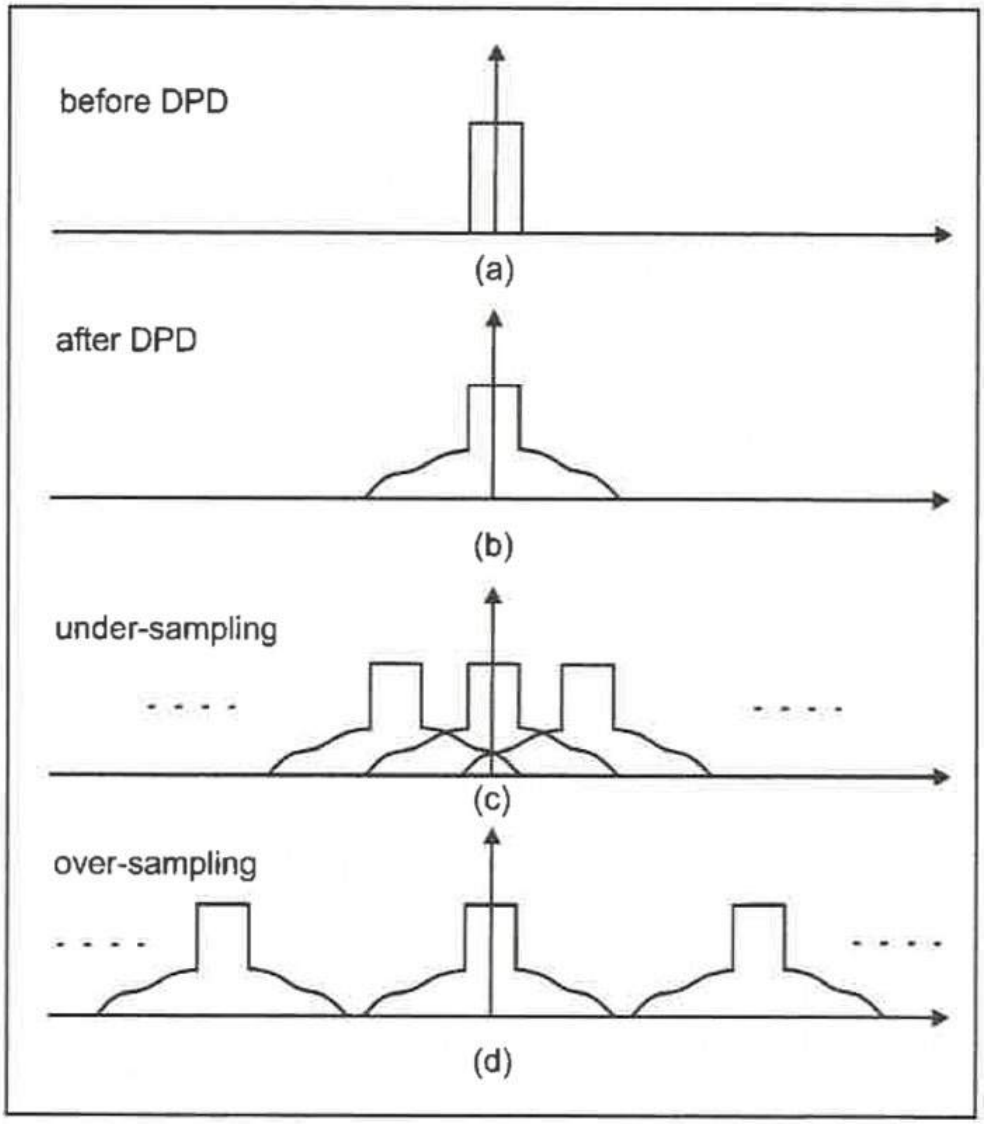

**Figure 16 - Effects of Sample Rate on a Pre-Distorted Signal**

Pre-distorters reconstruct the NLD in the analog domain, for input into the PA chain in the transmitter, which needs to be sampled at a higher rate to accommodate for the increased bandwidth. Therefore upsampling is required, otherwise under sampling the NLD could lead to aliasing in Figure 16 [10]. The output signal from the pre-distorter (b) has a much wider bandwidth than the input signal (a). Under-sampling of the input will lead to aliasing of the output signal (c), and the clean DPD. Typical oversampling by 5x will represent 5th order NLD [10]. Two main approaches have been adopted in the pre-distorter block:

(1) Look-up tables (LUTs) to provide a map relating the desired pre-distorter output to the input voltage

(2) Nonlinear basis functions to describe nonlinear pre-distortion function, requiring generation of the nonlinear functions and the multiplication of the basis functions by the input voltage [10].

Many PA models can describe the nonlinear pre-distortion function, including the Volterra series and Wiener model [19]. PA models will need to consider that PA characteristics do not change rapidly with time; changes in PA characteristics are often attributable to temperature drift, aging, etc., which have long time constants [19]. The cause of memory effects can be electrical or electrothermal [19]. Higher output power PA operation, such as those used in wireless base-stations, exhibit memory effects [19]. Having memory means that the output of the PA is not only a function of the current input, but also a function of past inputs and outputs [18]. Memory effects in the power amplifier limit the performance of DPD for wideband signals [18].

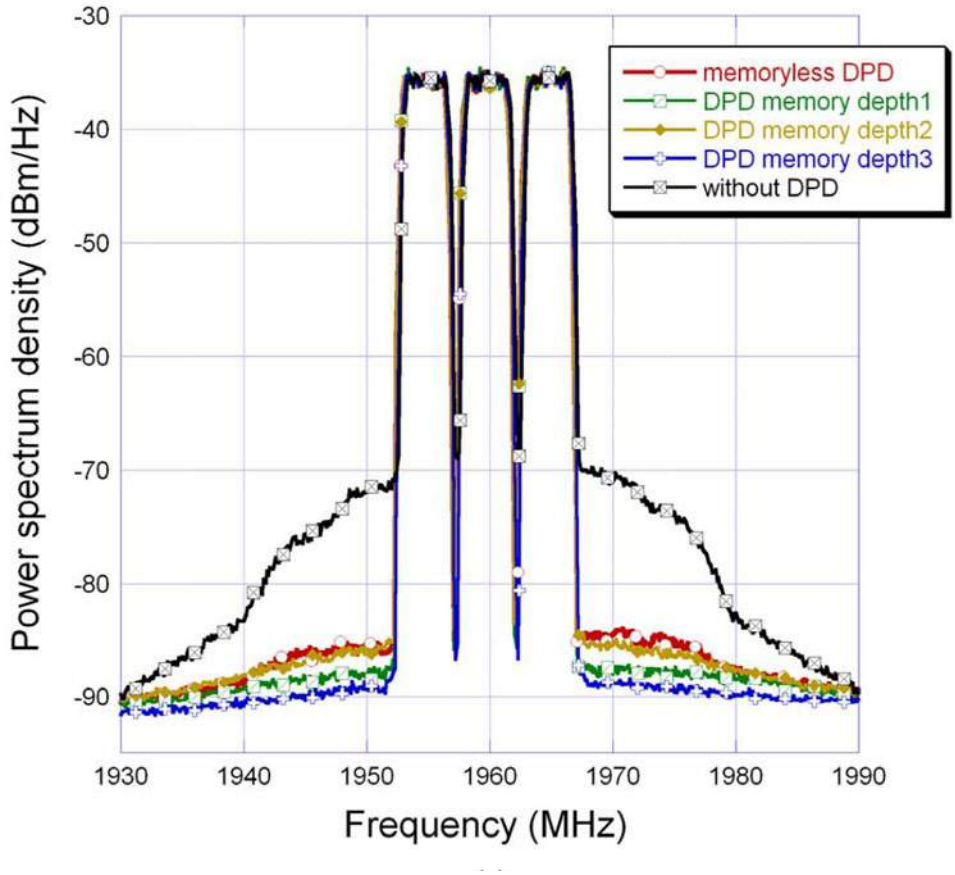

**Figure 17 - Memory and Memoryless DPD Results**

An issue with DPD is that it is compensating for the PA in the transmitter only, which, in most practical networks today, represents a fraction of the nonlinearity present in the communication channel. PAs are at least used in both the transmitter and receiver. Multiple PAs could be used in between the transmitter and receiver to extend the reach in many communication networks, such as CATV networks. Passive components are used to distribute signals to many receivers, and may also contain nonlinear components, such as inductors, that contribute to the channel's aggregate nonlinear NLD.

AI methods for DPD, using neural networks, illustrate the potential for improvement for NLD performance over traditional methods [20] [21]. However, incorporating additional NLD compensation

into the transmitter to account for the rest of the communication network chain, like similar closed-loop equalization systems, could lead to DPD reaching its full potential.

Implementations of DPD should be architected to compensate for stronger nonlinearity, much like the closed-loop LD equalization strategy described in the beginning of this section, for DOCSIS upstream signals can compensate for appreciably high LD. Because of bidirectional network connectivity, both the CMTS and CM can collaborate on the estimation of the total NLD present within the communication channel, and send coefficients via the downstream communication path, with instructions to either convolve or overwrite coefficients describing the estimated path NLD that will account for all the nonlinear elements within the communication network chain (transmitter, receiver, amplifiers, and nonlinear passive components). For this strategy to work, receivers must be capable of mitigating NLD. We will next review the current solutions available in receiver-based post distortion cancellation.

### 5.1. Receiver Post-Distorter Equalization

Another strategy is to mitigate the nonlinear PA distortions at the receivers via post-distorter equalization [22] [23] [24]. The solution presented in [25] develops a Bayesian signal detection algorithm, based on the nonlinear response of the PAs. However, this documented approach applies to a simple "AM-AM, AM-PM" nonlinear PA model only.

The authors of [22] propose a symbol-based equalizer, with nonlinear distortion cancellation for the forward link as an addition to the standard linear equalizer at the receiver, suitably adapted to incorporate specific channel functions in the forward link, including input multiplexing (IMUX) and output multiplexing (OMUX) filtering and the traveling wave tube amplifier (TWTA), using the memory polynomial model. The proposed setup is compared with current mitigation approaches, yielding significant efficiency gains [22]. The nonlinearity in the satellite channel is introduced primarily by the TWTA [22].

The objective of [22] was to compare the performance of the proposed equalizer with the state-of-the-art dynamic data pre-distortion, and to show that the best system performance is achieved when both pre-distortion at the transmitter and decision-directed equalization at the receiver are applied. In addition, the performance of a simple maximum likelihood (ML) demodulator in the detector in the cancellation loop is compared against a low density parity check (LDPC) decoder, to show the robustness of the proposed equalizer to decision errors [22]. Overall system complexity of the proposed nonlinear equalizer is argued to be less than current linear equalization approach, due to less-frequent updates [22]. As discussed earlier in the section covering DPD, similar transmitter and receiver equalization loops have proven to be robust against LD for DOCSIS upstream [7].

References [23] [24] and [25] approach receiver post NLD equalization via clustering methods, which is a subset of broader suite of AI models. [23] leverages SVMs, while [24] uses a radial basis function (RBF) network and [25] is Bayesian. ANNs have attracted researchers in the field of PA modeling, due to its successful implementation in pattern recognition, signal processing, system identification, and control [26].

## 6. Severe NLD Mitigation

One of the major design goals for modern systems is to make the communication systems more power efficient. This needs efficient PAs, which is unfortunately more challenging, since many modern PHY include OFDM, which has much higher PAPR and wider bandwidth [11].

Existing nonlinear PA mitigation strategies -- DPD, PAPR reduction, and receiver-based equalization, discussed in Section 5 -- may not be sufficient enough when considered individually. We can reduce PAPR to some extent only. DPD is too complex and costly for small and low-cost devices. Existing DPD and equalization techniques have moderate nonlinear distortion compensation capabilities, because they have been designed to cancel internal transmitter NLD only.

There is a larger system that must be considered, consisting of a transmitter, receiver, and nonlinear active/passive components in between them, all contributing to the overall NLD observed at the receiver. In some cases, the NLD can be quite severe, due to required higher-efficiency modes of operation. Supporting collaboration between the transmitter and receiver, like the LD cancellation systems used for DOCSIS, may be the key to achieving optimal network efficiency, while minimizing NLD. Severe nonlinearity estimation and mitigation is a requirement for the receiver, representing information that could then be shared with the transmitter through bidirectional communication. Ultimately, this lessens the burden at the receiver location and the NLD equalization system overall.

In this section, a system for cancelling severe NLD will be proposed which develops nonlinear equalizers that exploit both deep neural networks (DNNs) and Volterra series models to mitigate PA nonlinear distortions. The DNN equalizer architecture consists of multiple one-dimension convolutional layers. The input features are designed according to the Volterra series model of nonlinear PAs. This enables the DNN equalizer to mitigate nonlinear PA distortions more effectively, while avoiding over-fitting under conditions of limited training data. Experiments are conducted with real measurement data obtained from a highly nonlinear RFMD RF2317 Linear CATV Amplifier [11]. The results will demonstrate that the proposed DNN equalizer has superior performance over conventional equalization approaches, a necessary tool for more collaborative NLD mitigation strategy that could make more efficient network components potentially realizable.

## 6.1. Enhanced Equalization – Integrating Volterra Series and DNNs

Reference [11] proposes the use of DNNs to implement the nonlinear equalizer in the receiver, which can mitigate the nonlinear effects of the received signals, due to not only PAs but also nonlinear channels and propagations. The architecture of the DNN equalizer is shown in Figure 18.

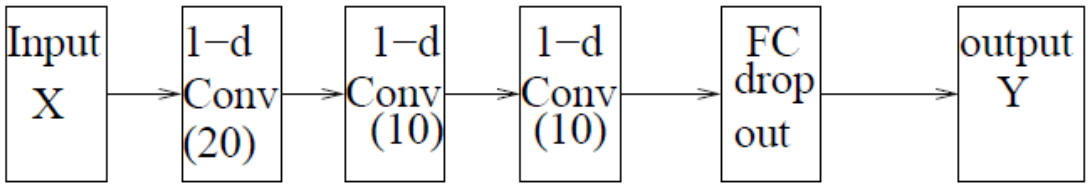

**Figure 18 - Block Diagram of DNN Equalizer**

Different from [28], [11] used multi-layer convolutional neural networks (CNNs). Different from conventional neural network predistorters proposed in [29], [11] used neural networks as equalizers at the receivers. Different from conventional neural network equalizers such as those proposed in [30] [31], in a DNN equalizer [11], a CNN is used and the input features in $X$ are not only the linear delayed samples $r(n)$. Rather, Volterra series models are used to create input features.

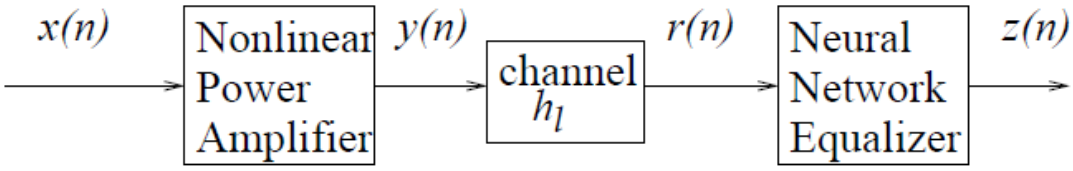

**Figure 19 - System Block Diagram with Nonlinear Power Amplifier and Deep Neural Network Equalizer**

To simplify presentation, according to the previous section, [11] assumes that the linear channel $\boldsymbol{H}$ has already been equalized by a linear equalizer of Figure 19, whose output signal is $r(n)$. According to Volterra series representation of nonlinear functions, the input-output response of the nonlinear equalizer can be written as

$$z(n) = \sum_{k=1}^{P} \sum_{d_1=0}^{D} \cdots \sum_{d_k=0}^{D} f_{d_1,\ldots,d_k} \prod_{i=1}^{k} r(n-d_1) \tag{28}$$

One of the major problems is that the number of coefficients $f_{d_1,\ldots,d_k}$ increases exponentially with the increase of memory length $D$ and nonlinearity order $P$. There are many different ways to develop more efficient Volterra series representations with reduced numbers of coefficients. For example, in [32], the authors exploit the fact that higher-order terms do not contribute significantly to the memory effects of PAs to reduce the memory depth $d$ when the nonlinearity order $k$ increases. This technique can drastically reduce the total number of coefficients. In [33] [34] [35], the authors developed the dynamic deviation model to reduce the full Volterra series model (28) to the following simplified one

$$\begin{aligned} z(n) &= z_s(n) + z_d(n) \\ &= \sum_{k=1}^{P} f_{k,0} r^k(n) + \sum_{k=1}^{P} \sum_{j=1}^{k} r^{k-j}(n) \sum_{d_1=0}^{D} \cdots \sum_{d_j=d_{j-1}}^{D} f_{k,j} \prod_{i=1}^{j} r(n-d_i) \end{aligned} \tag{29}$$

where $z_s(n)$ is the static term, and $z_d(n)$ is the dynamic term that includes all the memory effects. We can see that the total number of coefficients can be much reduced by controlling the dynamic order $j$ which is a selectable parameter.

[11] constructs the input features of the DNN based on the model (29). Corresponding to the static term $z_s(n)$, [11] changes it to

$$\widehat{z_s}(n) = \sum_{1 \le k \le P} f_{k,0} r(n)|r(n)|^{k-1} \tag{30}$$

The reason that (30) changes $r^k(n)$ to $r(n)|r(n)|^{k-1}$ is that only the signal frequency with the valid passband is of interest. This means that input feature vector $X$ should include terms $r(n)|r(n)|^{k-1}$.

Similarly, corresponding to the dynamic term $z_d(n)$, we need to supply $r^{k-j}(n)\prod_{i=1}^{j} r(n-d_i)$ in the features where half of the terms $r(n)$ and $r(n-d_i)$ should be conjugated. For simplicity, in DNN equalizer used in [11], the vector $X$ includes $r(n-q)|r(n-q)|^{k-1}$ for some $q$ and $k$.

By applying Volterra series components directly as features of the input $X$, the DNN can develop more complex nonlinear functions with fewer hidden layers and fewer neurons. This will also make the training procedure converge much faster, with much less training data.

In Figure 18, the input $X$ is a tensor formed by the real and imaginary parts of $r(n-q)|r(n-q)|^{k-1}$ with appropriate number of delays $q$ and nonlinearities $k$. There are three one-dimension convolutional layers, each with 20 or 10 feature maps. After a drop-out layer for regularization, this is followed by a fully connected layer with 20 neurons. Finally, there is a fully connected layer to form the output tensor $Y$ which has two dimensions. The output $Y$ is used to construct the complex $z(n)$, where $z(n) = \hat{x}(n-d)$ for some appropriate delay $d$. All the convolutional layers and the first fully connected layer use the sigmoid activation function, while the output layer uses the linear activation function. [11] uses the mean square error loss function $L_{loss} = E[|x(n-d) - z(n)|^2]$, where $z(n)$ is replaced by $Y$ and $x(n-d)$ is replaced by training data labels.

Measurement signals were obtained from an implementation of a RFMD RF2317 PA used in the cable industry, which are typically dominated by 3rd order nonlinearities. Various levels of nonlinear distortion, in terms of dBc, were generated by adjusting the PA RF input levels [11].

For the Volterra equalizer, reference [11] approximated the response of the nonlinear equalizer with delays including 8 pre- and post- main taps, and with nonlinearity including even and odd order nonlinearity up to the 5th order. To determine the values of the Volterra coefficients, we transmitted $N = 4{,}096$ training symbols through the PA and then collected the noisy received samples $r(n)$.

For conventional time-delay NN equalizer, [11] applied a feedforward neural network with 80-dimensional input vector $X$ and 5 fully connected hidden layers with 20, 20, 10, 10, 10 neurons, respectively.

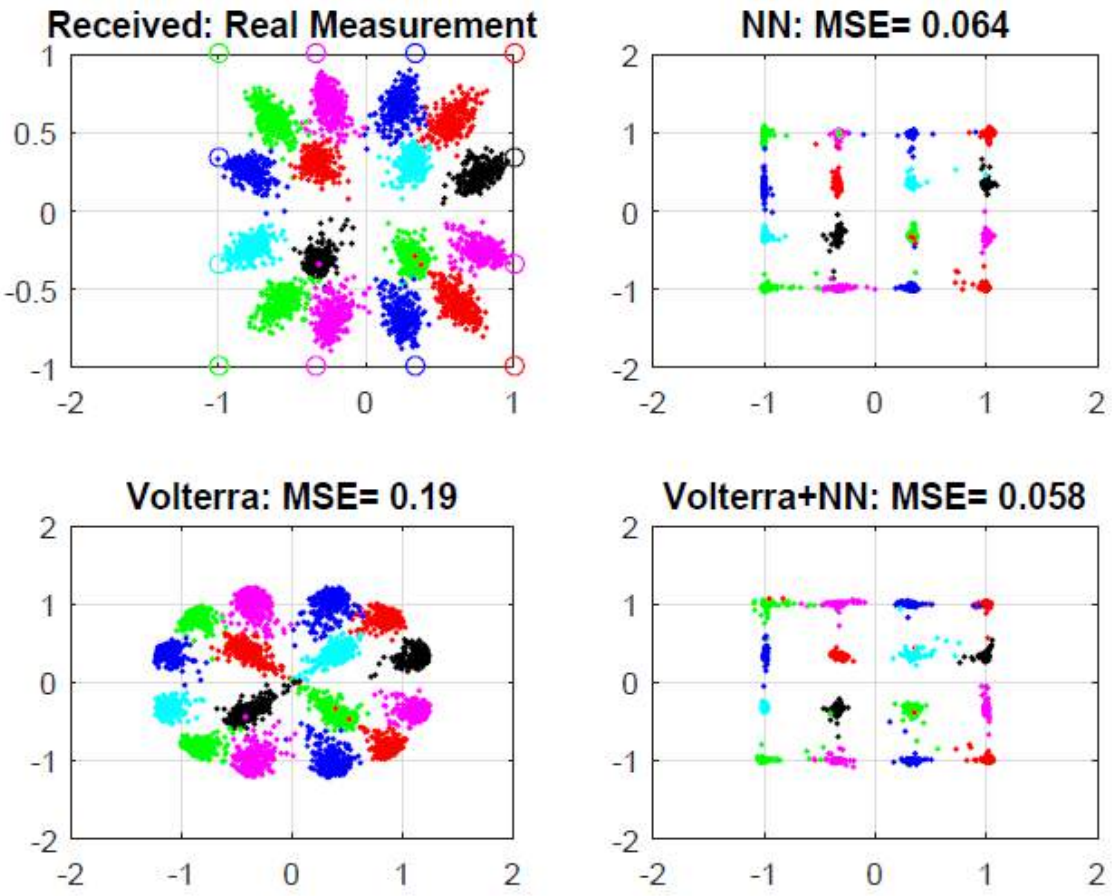

**Figure 20 - Constellation of 16-QAM Non-Equalized vs. Equalized**

Figure 20 shows the constellation of 16-QAM equalization over the real PA. The corresponding SER were 0.0067, 0.0027, 0.00025 respectively. Nonlinear filtering of both a DNN and DNN with Volterra input features show superior equalization over just Volterra filtering alone. Further, it can be seen that the proposed Volterra+NN scheme has the best performance.

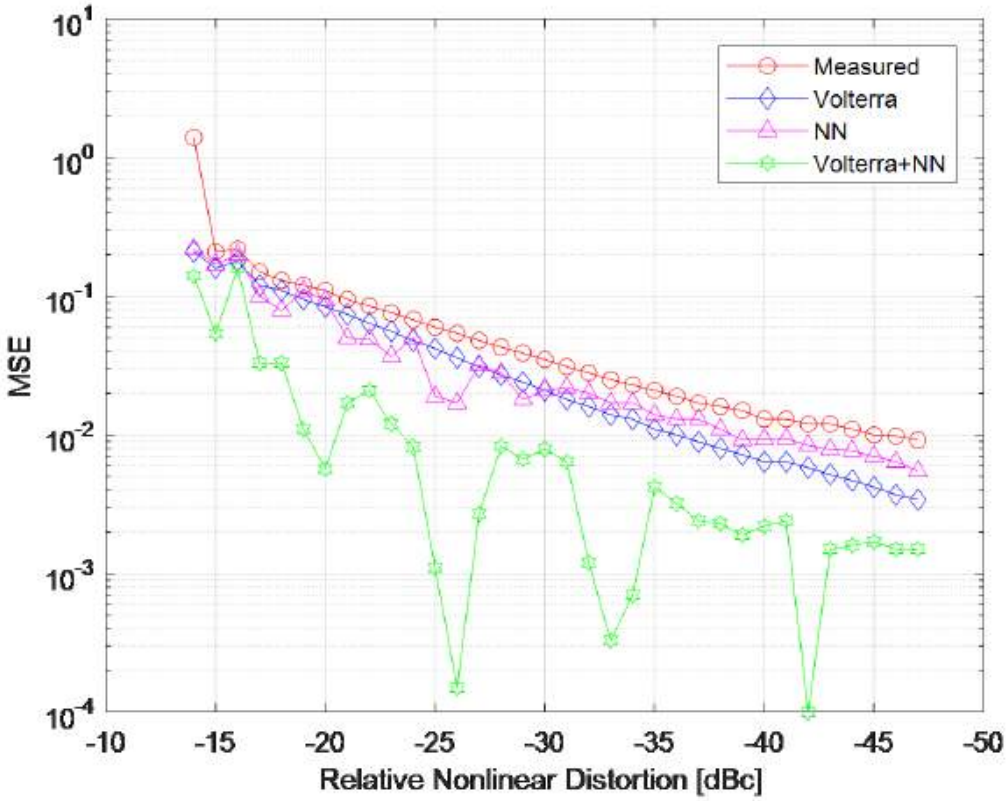

**Figure 21 - Comparing Three Equalization Methods for 16-QAM under Various NLD Levels**

Figure 21 provides MSE measurements for 16-QAM under various nonlinear distortion levels, dBc. For each 1 dB increase in NLD, the resultant MSE is shown for the "Measured", "Volterra", "NN", and the proposed "Volterra+NN" cases. MSE reduction diminishes appreciably as modulation order increases from QPSK to 64-QAM, but small improvements in MSE have been observed to lead to appreciable SER improvement, especially for more complex modulation orders. Unfortunately, the 4,096 symbol sample size limited measurements to a minimum measurable 0.000244 SER, which represents 1 symbol error out of 4,096 symbols.

**Table 3 - Comparing MSE/SER Improvement % for the Three Equalization Methods**

| | Volterra | | NN | | Volterra+NN | |
|---|---|---|---|---|---|---|
| | MSE | SER | MSE | SER | MSE | SER |
| 64-QAM | 16% | 26% | 10% | 25% | 42% | 44% |
| 16-QAM | 41% | 2% | 35% | 6% | 85% | 28% |

Table 3 summarizes equalization performance, which shows the average percent reduction/improvement in MSE and SER from NLD-impaired data for multiple modulation orders.

## 7. Conclusion

The enhanced capacity associated with FDX is increasing the need for higher efficiency PAs. A familiar scenario also playing out in the cellular, Wi-Fi, and satellite industries, where similar capacity-enhancing needs are increasing the needs for more efficient PAs. PA efficiencies can be realized by (a) near saturation operation, and more efficient implementations via (b) PA classes, which may include (c) biasing the PA to consume less power. All these approaches result in degraded NLD.

NLD mitigation techniques, like DPD, can lead to the use of more efficient and cost-effective PAs [11], and are being considered for future generations of FDX RPD node hardware -- where power consumption thresholds are already being encroached upon, while new capabilities are being added to increase their capacity as efficiently as possible. However, an issue with DPD is that it is compensating for the PA in the transmitter only, which, in most practical networks today, represents a fraction of the nonlinearity present in the communication channel. Incorporating additional NLD compensation into the transmitter, to account for the rest of the communication network chain, like similar closed-loop equalization systems discussed in this paper, could lead to DPD reaching its full potential.

Bidirectional network connectivity between the CMTS and CM can enable the convergence to an estimate of NLD present within the communication channel, in either direction, and send coefficients via the downstream communication paths, with instructions to either convolve or overwrite coefficients describing the estimated path NLD that will account for all the nonlinear elements within the communication network chain (transmitter, receiver, amplifiers, and nonlinear passive components).

However, for this strategy to work, receivers must be capable of mitigating severe NLD. Supporting collaboration between the transmitter and receiver, like the LD cancellation systems used for DOCSIS, may be the key to achieving optimal network efficiency, while minimizing NLD.

Thus, more aggressive NLD cancellation methods may be accomplished by advanced DNN approaches, such as incorporating input features derived from Volterra series models. Results from [11] demonstrate that the proposed DNN equalizer has superior performance over conventional equalization approaches, and is a necessary tool for more collaborative NLD mitigation strategy. Ultimately, this could make more efficient network components realizable.

# 1. Introduction

Traditionally, the CMTS market was dominated by hardware-based CMTS appliances, with no alternatives available. During the last few years, however, the cable industry took a leap forward and started adopting software-based CMTS solutions[4]. Disruptive benefits, long-term potential and deployment scenarios of such software-based CCAP solutions are analyzed in detail in References 1 and 2, while Reference 3 outlines real-world experiences and lessons learned from deploying virtual CMTS in centralized and distributed access architecture (DAA) environments.

This paper analyzes the background and deployment scenarios of a virtualized CMTS (vCMTS) and considers future development of disaggregated vCMTS from the standpoint of leveraging distributed edge compute. We also explore the notion of cluster multitenancy and its potential deployment scenarios in private, public and hybrid cloud.

Here and throughout the paper, we adhere to the following terminology:

- Cluster – a set of compute nodes that can be viewed as a single system. Cluster nodes are connected with each other via a common converged interconnect network (CIN) and managed by specialized platform management software.
- Pod – a group of one or more software containers, orchestrated by Kubernetes[16].
- Infrastructure (infra) pod – contains applications that perform a management role in the system. The resources and functions provided by infra pods are typically shared by multiple data plane pods. The examples of infrastructure pods are pods running databases used for storing internal system states as well as pods providing interfaces for interaction with users (e.g., command-line interface (CLI), web UI) and toward OSS/BSS applications (e.g., via SNMP, IPDR and other protocols).
- vCMTS pod – a collection of containers implementing DOCSIS[14] processing (excluding the PHY layer).
- Data plane pod – a more generic term for the vCMTS pod. A data plane pod contains software components performing data plane traffic processing for an access technology of choice (e.g., DOCSIS, PON, wireless). It should be noted that PHY layer processing is implemented in purpose-built hardware appliances (e.g., DOCSIS 3.1 Remote PHY Device) tailored for communication with the user equipment (e.g., DOCSIS 3.1 cable modem) over specific media type (e.g., coax cable or optical fiber).
- Multitenant cluster – sharing compute resources for infrastructure pods and data plane pods serving different types of applications (e.g., DOCSIS, PON, wireless), while providing required level of resources and components isolation.
- Hybrid cluster deployment – combining local compute resources and compute resources from cloud service provider (CSP) in the same logical cluster.
- Virtualized cloud-native access platform – software platform that follows the cloud-native paradigm[15] and provides facilities for life cycle management of compute resources and software applications running on top of them. This type of platform is agnostic to the type of applications (e.g., data plane pods) deployed on top of it.

In the subsequent sections, we look in more detail at a range of options that become available to operators when migrating to a cloud-native vCMTS.

## 2. Cloud-Native vCMTS Deployment Evolution

CMTS is not the only product that transformed dramatically over the last few years. Studies[11] show that both public and private cloud adoption grows, with larger enterprises increasing their focus on public cloud. Moving services to the public cloud entails an operations paradigm shift. It is possible to incorporate software-based vCMTS deployment and operations into cloud-centric business processes and automation tools. If done properly, it allows operators to take service agility to the next level, dramatically reducing time to market for rolling out new services and transforming the CMTS from a purpose-built and rigid resource in a headend to an on-demand scalable service.

Due to its disaggregated architecture, cloud-native vCMTS provides full flexibility when selecting deployment type – from on premises to public cloud (Figure 1 - Cloud-Native vCMTS Deployment Scenarios).

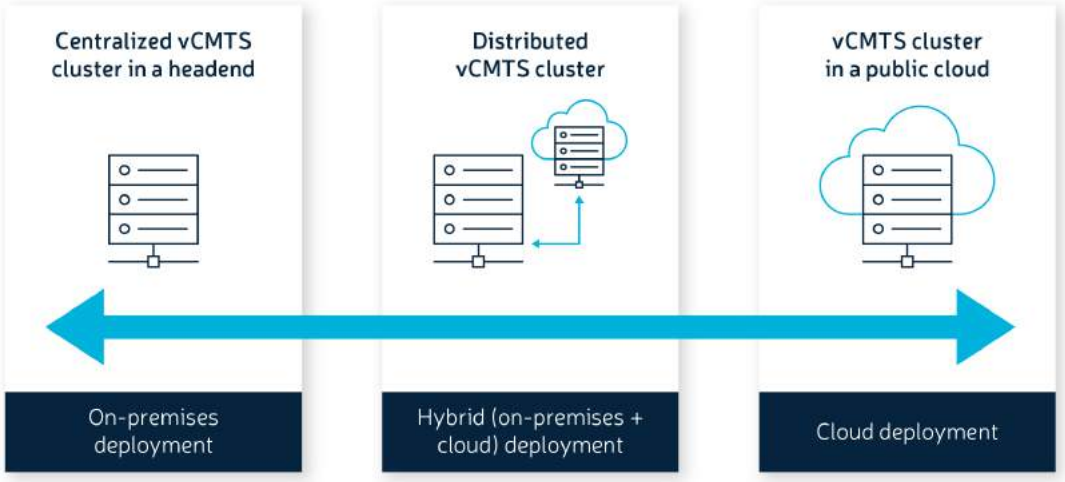

**Figure 1 - Cloud-Native vCMTS Deployment Scenarios**

Another dimension to look at is types of access technologies that can be deployed on the same cluster and managed in a uniform way: i.e., cluster compute resources that can be shared between different workload types (e.g., vCMTS data plane pods and virtual PON (vPON) data plane pods). It introduces the notion of cluster multitenancy, where the same virtualized cloud-native access platform accommodates data plane pods for different types of access technologies. We will use the more generic “access platform” term throughout the paper when it is required to refer to the workload-agnostic nature of the deployment type.

In the following sections, we look into different scenarios of disaggregated vCMTS deployment, from on-premises to public cloud.

### 2.1. Edge Deployment

One side of the spectrum of options when deploying cloud-native vCMTS is running it on dedicated compute and management cluster nodes located in the headends and remote hubs, the same way it is done for legacy hardware-based CMTS appliances.

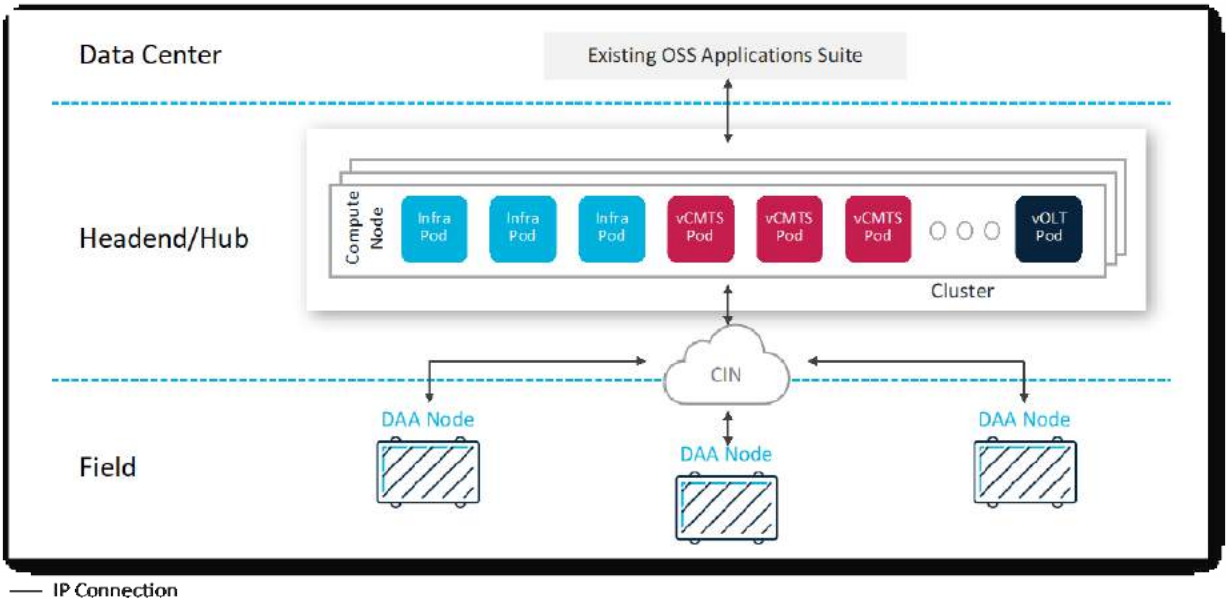

**Figure 2 - Disaggregated Virtualized Cloud-Native Access Platform as Stand-Alone Edge Compute Cluster**

In this scenario, individual clusters work independently of each other, and while cluster scale (e.g., number of compute nodes) can vary from site to site, every cluster acts as a single deployment unit. All resources required for CMTS functionality (e.g., data plane workloads, generic control plane (GCP) Core, interfaces to OSS applications) are unique per cluster. While at first sight it looks like yet another CMTS, there are clear benefits of migrating to a cloud-native architecture, even in a stand-alone edge deployment:

1. Increase reliability by leveraging cloud-native best practices and tools for high availability (HA).
2. Reduce operating domain to one or several service groups by isolating vCMTS resources with Docker containers.
3. Solve scaling issues by simple addition of compute nodes, with growth in bandwidth as well as the number of subscribers and/or service groups.
4. Significantly reduce power and cooling requirements, space footprint and wiring complexity in the headend.
5. Ability to share cluster compute resources between different types of workloads (data plane pods). As such, the same cluster can accommodate, for example, vCMTS and vPON pods, while new emerging types of data plane pods might be added to a cluster in the future.

Horizontal scaling in stand-alone edge deployment is achieved by scaling the number of vCMTS pods (or other data plane pods) on existing compute nodes, as well as by adding more compute nodes proportionally to the number of connected devices. The contributing factors into cluster scaling are:

1. The number of connected Remote PHY Devices (RPDs).
2. The number of connected Cable Modems (CMs) and Customer Premises Equipment (CPE) units.
3. Peak traffic load.

Cluster scaling implies increasing the number of data plane pods, while the number of infra pods remains constant. Keeping the amount of infra resources constant with the growing number of data plane pods further improves the efficiency of a virtualized cloud-native access platform.

Such a deployment scenario is most suitable for cable operators who would like to follow the traditional way of operating CMTSs and do not plan to take steps toward building network function virtualization (NFV) infrastructure and/or network automation or run some of the vCMTS components in the hybrid cloud.

## 2.2. CMTS in a CSP Infrastructure

Another potential scenario of cloud-native vCMTS deployment is to completely decouple it from hardware resources and run it in a public cloud on compute resources provided by a CSP.

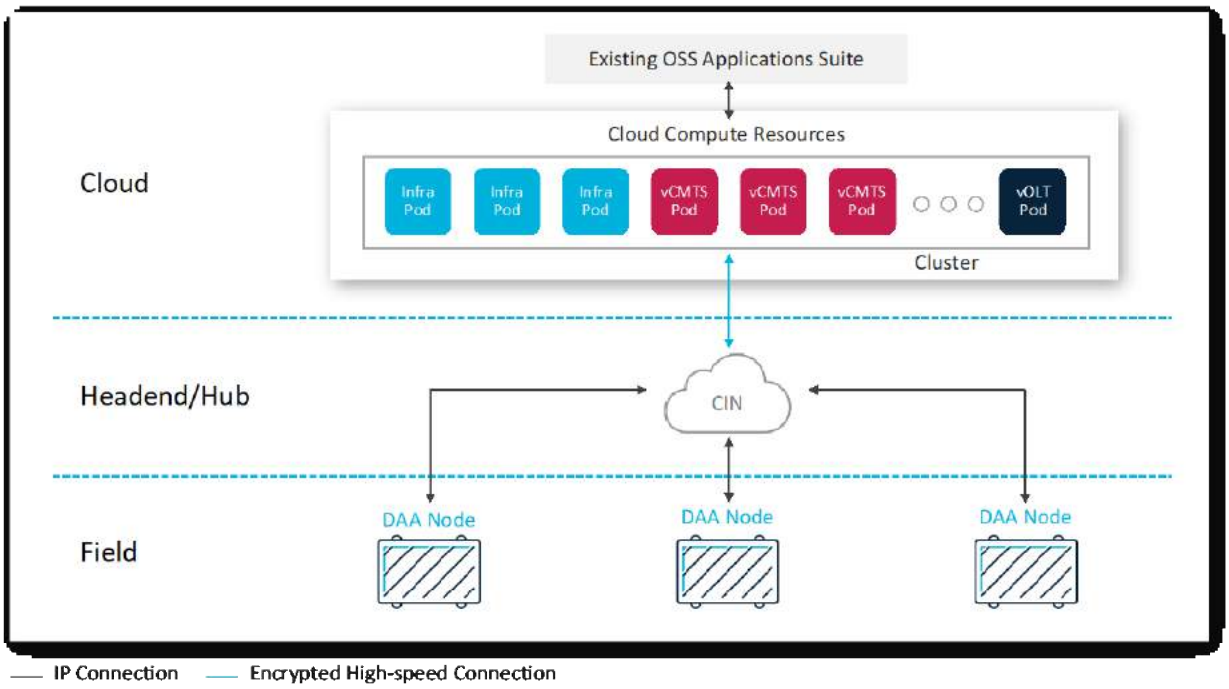

**Figure 3 - Disaggregated Virtualized Cloud-Native Access Platform in Public Cloud**

This type of deployment implies that all control plane and data plane vCMTS components run on compute resources in the public cloud. Remote PHY protocol (e.g., downstream external PHY interface (DEPI), upstream external PHY interface (UEPI)) tunnels are established between the vCMTS data plane workloads and R-PHY nodes, and all data processing is performed in the public cloud. The operations support systems (OSS) applications suite may remain in the operator's data center, or it can be deployed in the public cloud as well. The factors that contribute to the decision-making process are:

1. Network total cost of ownership (TCO) optimization.
2. Migration path for legacy OSS applications.
3. Regulations compliance.

Such a solution requires reliable and secure connections between the R-PHY nodes and vCMTS components running in the cloud. It is achieved in the following ways:

1. Using facilities provided by CSPs, such as encryption gateways that enable secure high-speed data transfer between the operator's data center and public cloud infrastructure[5].
2. By leveraging a suite of security features defined for RPD and CCAP Core Mutual Authentication[6] and DOCSIS Baseline Privacy[7].
3. Additional security measures might be applicable to other types of access technologies deployed on a multitenant cluster.

Moving all data and control plane resources to a public cloud can be considered by operators pursuing the following goals:

1. Minimize power consumption and space footprint in operator's facilities. In this scenario, only routing/switching equipment remains in the headend/hub.
2. Accelerate and streamline service deployment and nodes splits. vCMTS resources can scale on demand in a matter of minutes/hours in response to business needs.
3. Move to advanced high availability (HA) scenarios with geo-redundancy, with different components of disaggregated vCMTS deployed in different locations. For example, it should be possible to deploy critical system components in geographically distributed availability zones in public cloud and build redundant network paths between hub/headend and CSP infrastructure.
4. Unify vCMTS resource provisioning with existing business processes, such as service provisioning, and leverage cloud-native architecture for achieving CMTS-as-a-service deployment scenarios.

The CMTS scaling factors described for the on-premises edge deployments are also valid for a public cloud deployment scenario. Additional benefits in the latter case include:

1. Improved flexibility for horizontal and vertical node scaling.
2. Reduced time to market when adding more compute nodes to the cluster.
3. Transfer of compute resources life cycle management and associated cost from the operator's domain of responsibility to a CSP.

It should be noted that distance and latency between provider edge and cloud-based facilities should be considered when planning vCMTS deployment scenarios in the public cloud. Another important point is that measures to achieve advanced HA capabilities are not limited to protecting components deployed in public cloud and should also include necessary steps to protect system components in headend/hub and in the field (e.g., CIN redundancy, RPD network connectivity redundancy).

## 2.3. Hybrid Deployments of Virtualized Cloud-Native Access Platform

In a broad sense, hybrid cloud platforms from almost all the major infrastructure vendors not only manage clusters running on premises and in their own cloud platforms, but any cluster including those that are deployed in other cloud environments[8]. Due to its cloud-native packaging, disaggregated vCMTS provides enough flexibility to deploy it in hybrid scenarios, where data plane pods run on local edge compute nodes, while infra pods are deployed in private or public cloud. It allows operators to fill the gap between on-premises deployment and cloud-based deployment with other options that combine the benefits of both.

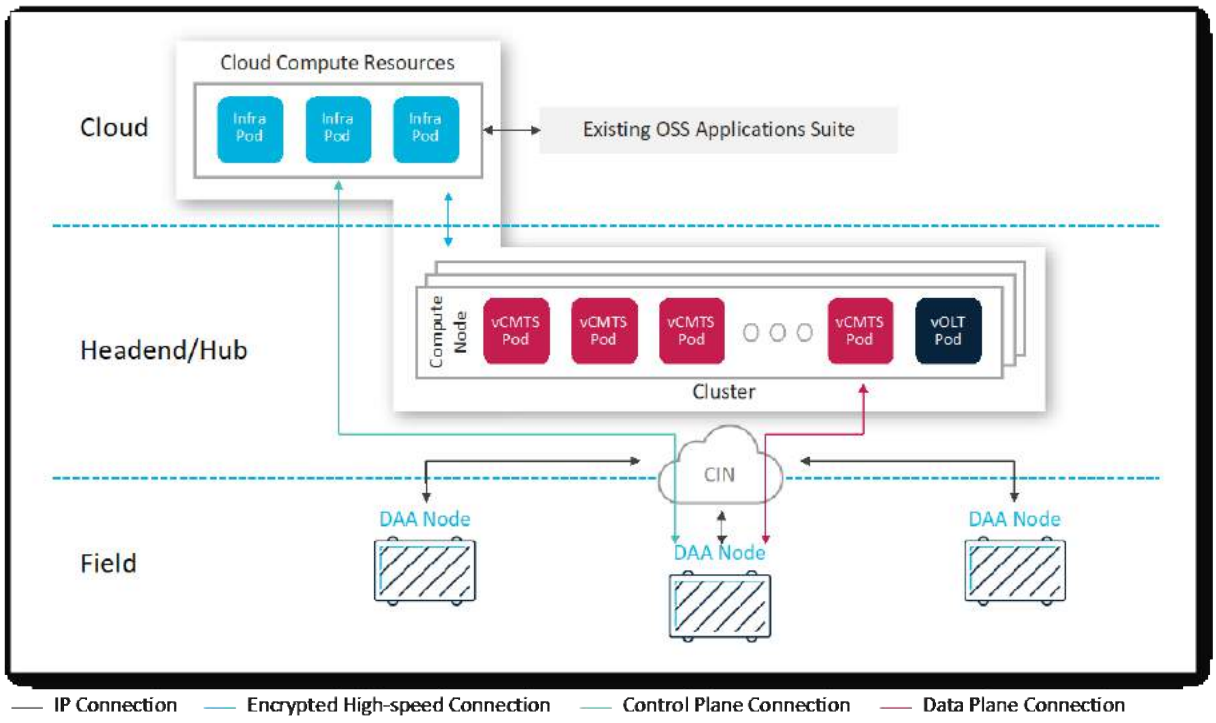

**Figure 4 - Example of Hybrid Deployment of Virtualized Cloud-Native Access Platform**

Hybrid deployment of the disaggregated virtualized cloud-native access platform is suitable for use cases wherein data plane processing is kept in provider edge facilities, orchestrated by virtualized control plane resources from public or private cloud. The benefits of such deployment type include but are not limited to:

1. Minimized latency between end-user equipment and data plane pods.
2. Possibility to deploy infrastructure and data plane resources in existing k8s clusters, with unified orchestration of vCMTS workloads and third-party workloads.
3. Ability to handle high-availability scenarios, possibly with geo-redundancy provided by a CSP, for control plane components and data plane components in a uniform way. From a pod orchestration standpoint, cloud compute resources and on-premises compute resources are considered to be part of the same cluster.

From a horizontal scaling point of view, the hybrid deployment scenario combines the benefits of on-premises and public cloud deployment scenarios.

There are, of course, other options for deploying disaggregated vCMTS in an operator's edge facilities as well as in a public and private cloud environment. In the following section, we'll look at how the concept of cloud-native disaggregated access platform allows operators to leverage emerging deployment scenarios.

## 2.4. Cloud-Native Virtualized Access Platform and Deep Edge Compute

So far, we discussed centralized compute resources available to cable operators in a public and private cloud, as well as edge compute resources distributed across headends and hubs. As equipment deployed on the outside plant becomes more intelligent and provides more processing power, we can leverage its

capabilities and extend the range of the compute resources available to cable operators to so-called "deep edge" compute. Therefore, deployment concepts we discussed so far can be considered as a superset of CableLabs' Flexible MAC architecture (FMA)[9] that specifies interoperable management, control and data plane interfaces on the digital fiber between the core components and a series of devices, regardless of compute locality.

A virtualized cloud-native access platform allows operators to control the following aspects of FMA deployments:

1. Locality of certain vCMTS components, based on the distance/latency requirements and constraints. Data plane pods can be placed on the compute resources located in the outside plant (so-called "deep edge" deployment), while infrastructure components can be deployed in a centralized fashion.
2. Flexible separation of individual vCMTS components (microservices) and their subsequent placement on the compute resources in the data center, headend/hub or outside plant.
3. Backward compatibility with existing OSS applications suite.
4. Fast time to market and ability to add new services and applications on top of the cluster that consists of general-purpose compute resources.

When deployed as part of a cloud-native virtualized access platform, a group of FMA remote MAC core units (RMC) and/or virtual core (vCore) units in effect becomes a pool of general-purpose compute nodes orchestrated by Kubernetes.

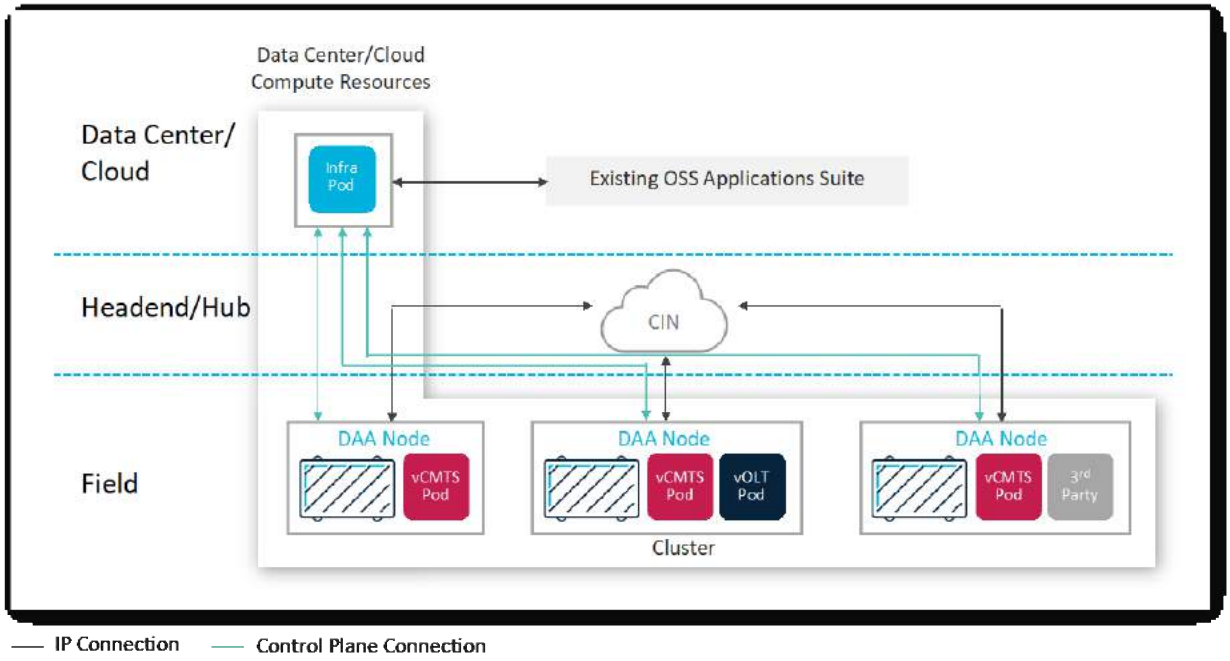

**Figure 5 - Disaggregated Virtualized Access Platform and Deep Edge Compute**

RMD/RMC/vCore can be considered as a generic compute resource that can be utilized, in particular, for DOCSIS MAC layer processing combined with purpose-built hardware that implements, for example, the DOCSIS PHY layer. In such a case, it is possible to push vCMTS pods to the very network edge for vCMTS software-based packet processing, while leveraging best industry practices for cloud-native

software deployment and life-cycle management. It also opens the door for utilizing RMD compute resources for other types of workloads, such as:

1. IoT edge processing.
2. Sharing common generic compute resources in RMD for different types of data plane pods (e.g., perform DOCSIS and wireless data plane processing on the same compute resources in RMD).
3. Hosting applications that can benefit from deep edge deployment: caching servers, speed test applications, VR-specific applications, machine-to-machine communication applications.

Horizontal scaling and infra resource-sharing concepts described earlier are also valid for multitenant clusters. Potential benefits from placing DOCSIS and third-party workloads on deep edge compute nodes include:

1. Reduced end-to-end network latency, which is inherited from the fact that compute resources are located in physical proximity to the customer end devices.
2. Maximized resource utilization that emerges from using generic edge compute resources for DOCSIS and non-DOCSIS applications.
3. Network traffic reduction and savings on bandwidth between deep edge devices and the central cloud.

## 3. Conclusion

Compute resources available for cable operators span from centralized compute in public and private cloud to the edge compute in headend/hub and deep edge compute in an outside plant. Cloud-native virtualization enables operators to leverage distributed compute resources in a uniform way.

A virtualized cloud-native and disaggregated vCMTS provides a wide range of options for deployment:

1. Traditional on-premises edge deployments in headend/hub.
2. Cloud-based deployments in private cloud and in CSP infrastructure.
3. Hybrid deployments, wherein certain vCMTS components remain in operator's facilities, while other components get pushed to a CSP infrastructure.
4. Deep edge deployments, where some of the cluster compute resources are located in the outside plant.

In all deployment scenarios, cluster resource and application life cycle management are performed in a uniform way:

1. Compute resources are considered to be general-purpose.
2. Heterogeneous workloads (different types of infrastructure, data plane and third-party pods) are placed on general-purpose compute resources, taking into account application locality preferences (e.g., cloud/data center, network edge or deep network edge).
3. Horizontal scaling is achieved by increasing the number of workloads (data plane pods) and by adding more compute resources (in the cloud or on premises).

The combination of the available compute resources and the flexibility of cloud-native access platform allows operators to deploy different types of access networks in a uniform and operations efficient way. Implementing as many network functions as possible in software and minimizing the number of purpose-built hardware appliances on the network provides a bridge to the future that was never more unknown than now.

## List of Tables

**Title** **Page Number**

 

# 1. Introduction

Consumer demand for home broadband access continues to be strong. Network operators are looking to grow their revenue by expanding services they offer. Home broadband offers that revenue growth opportunity.

1. Operators can expand home broadband services to unserved and underserved communities. Rural markets are one example of underserved communities.
2. For some network operators, even communities served by existing Internet service providers are attractive target for business expansion. These operators bring something new to the market, like higher data rate or lower cost or some other valuable feature.

When thinking about greenfield opportunities, operators must consider technology options available to them. Below we compare technology options for providing home broadband service.

**Table 1: Broadband access technology comparison**

| Technology | Unserved/Under-served (mostly rural markets) | Urban and suburban markets |
|---|---|---|
| DSL | It is expensive to build out DSL plant in rural areas since there is limitations on how far from central office can the plant be extended. Laying new copper is also an expensive proposition | DSL is less competitive with DOCSIS or fiber in more urban markets. For instance, maximum rates offered by VDSL2 could be greater than 100 Mbps with a range of around 500m from DSLAM node.<br><br>G.fast promises higher data rates for shorter straight loops. For instance, 600 Mbps for 200m distance. Speed limitation start kicking for longer distances. Also copper is hard to maintain.<br><br>There is no viable path for bit rate evolution beyond that. |
| DOCSIS HFC | May not be cost effective to expand cable plant into rural areas | DOCSIS 4.0 FDX or ESD offers 10 Gbps shared downstream capacity. It is an attractive option but fiber and 5G offerings could disrupt DOCSIS. |
| Fiber | Running new fiber to rural communities can get very expensive | Fiber is the leading medium for data transmission with virtually unlimited bandwidth. However, green field FTTH installations may not be economically viable. Similarly upgrading HFC or DSL plants to FTTH may only be feasible for selected communities |

| | | |
|---|---|---|
| 3GPP wireless (LTE/5G) | Since there is no need to run copper or fiber over long distances, 3GPP wireless constitutes an economic option to provide rural broadband service as long as the capacity needs and path loss are acceptable. | New technologies like massive MIMO and availability of more spectrum in 5G mmWave bands enhance available capacity and range of a single cell site. This improves business feasibility of fixed wireless access FWA services.<br><br>New operators can disrupt existing DOCSIS and fiber-based offerings.<br><br>Established operators should study leveraging 3GPP wireless to defend and grow their business. |
| Proprietary wireless | Proprietary wireless technologies are by definition not standards based, they may be limited to one vendor, have smaller ecosystem, an uncertain roadmap & lack of economies of scale and limited long term support | Whether rural or urban, proprietary technologies face similar hurdles. |

In this paper, we focus on 3GPP based FWA, as a promising technology for future home broadband access. We investigate the following in the coming pages:

1. Can today's wireless technology support FWA?
2. Is there a viable business case for FWA as compared to alternatives (DOCSIS, FTTH)?
3. Do any network operators have profitable FWA home broadband business?

## 2. Reasons for FWA Momentum

Several factors are coming together, boosting industry push for FWA:

1. Technology advances: Higher order modulation, massive MIMO, beamforming, carrier aggregation, multiple user MIMO are some of the features in LTE that are improving spectral efficiency of LTE. This has the dual effect of improving system capacity, but also cell edge bit rates – suitable for FWA. 5G adds further improvements to spectral efficiency by leaner air interface design.
2. Spectrum is the lifeline of wireless access. New spectrum has become available in mid band and higher bands. This spectrum offers wider channels and thus order of magnitude higher throughput than traditional cellular and PCS bands. LTE also allows use of unlicensed or semi-licensed frequencies in 5 GHz band and 3.5 GHz CBRS in conjunction with licensed bands to further uplift data rates.
3. As more and more network operators include FWA in their consumer offerings, a device and terminal ecosystem has developed. FWA offerings started in developing countries where high speed wireline infrastructure is lacking. That has helped to nurture the FWA ecosystem for everyone. One of the most important factors is formation of global ecosystem driving economies of scale. CPE price is a big factor in overall business case and hence it is important to have global economies of scale.

4. Governments realize the productivity gain and development effects of broadband connection availability to all citizens. Governments at many levels (federal, state, city) want to encourage deployment of high-speed home broadband in their jurisdictions. US federal government CAFII initiative is an example of subsidizing build out of rural broadband networks. CAFII program encourages network operators to ramp up broadband deployments in un/under served, mostly rural or exurban areas. RDOF (Rural Digital Opportunity Fund) focuses on areas unserved at 25/3 in traditional price cap territories and provides $16B funds to serve ~6M potential home locations with speed tiers of 25/3, 50/5, 100/20, 1000/500 Mbps (Downlink/Uplink).

## 3. Fixed Wireless Access Network

FWA largely reuses MBB network architecture, with similar nodes as mobile broadband sans network features related to terminal mobility.

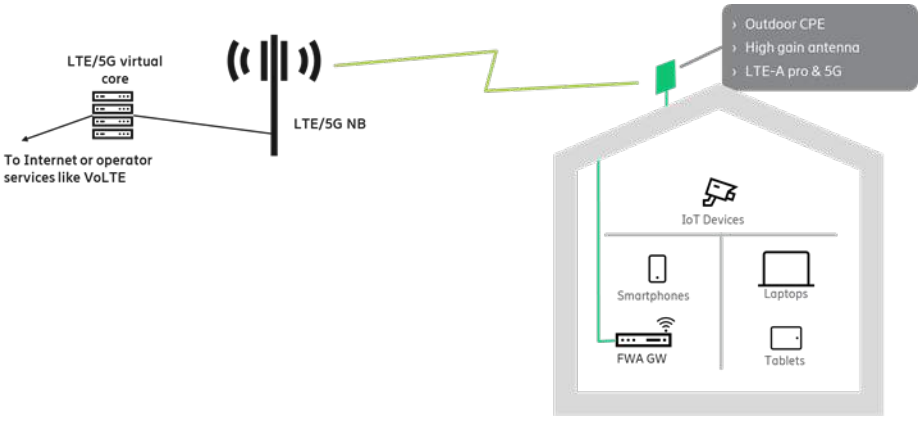

**Figure 1: Fixed Wireless Access network**

LTE or 5G or dual LTE/5G CPE is installed on the rooftop of the home. This is typically a professional installation. Some operators offer indoor CPEs which are self-installed by the homeowner. Outdoor CPE has high gain antenna and LTE/5G modem to provide connection towards nearest LTE or 5G base station. Operators may provision an FWA GW inside home or integrate it with the outdoor CPE. FWA GW provides home broadband management functionality to the operator.

FWA network comprises of standard 3GPP architecture with an LTE/5G base station and core network. Operator can choose their own deployment strategies. Some considerations below:

1. Dedicated base station and frequencies for FWA or sharing base station and frequencies between FWA, MBB, IoT and other operator services
2. Dedicated core network for FWA or shared with other operator services
3. Physical or virtualized core and radio base station
4. Placement locations of radio and baseband processing of base station, as well as user and control plane components of core network
5. Type of transport between remote (base station) site and aggregation and data center sites.

FWA may require different architectural optimizations different from MBB. For instance, both user plane and control plane design of core network could be different for FWA subscribers. FWA service has fewer users per cell, thus lower control plane load and light-

weight control plane nodes. On the other hand, data consumption is higher in the user plane. A more distributed user plane would be beneficial to improve network performance and reduce transmission costs. Similarly, centralizing baseband processing would have lower utility with reduced pooling gains and might not be worth the increased fronthaul transmission costs.

## 4. Spectrum Options for FWA

Spectrum is the lifeblood of wireless communications. Not all spectrum is the same. Table below summarizes spectrum options commonly used for FWA.

**Table 2: Spectrum for FWA**

| Frequency | Benefits | Challenges | Availability |
|---|---|---|---|
| Mid band FDD (PCS, AWS etc.) | – Widely available ecosystem<br>– Licensed<br>– Good propagation | – Fully utilized in urban and suburban areas<br>– Narrower channel bandwidths | – Now |
| 2.5 GHz TDD | – ~200 MHz of licensed spectrum<br>– Best propagation amongst TDD spectrum<br>– US ecosystem available today<br>– Highest predictability due to licensed spectrum | – Cost of acquiring spectrum<br>– Majority of spectrum in populated areas is owned | – Now |
| 3.5 GHz CBRS | – 150 MHz of spectrum<br>– Global LTE ecosystem<br>– Good balance between propagation, power and reuse<br>– Interference managed via SAS (Spectrum Access System) | – Spectrum demand in urban and suburban areas | – Late-2019 for GAA and PAL spectrum available by 4Q 2020 |
| 3.7 GHz C-Band | – 280 MHz of spectrum<br>– Global LTE ecosystem<br>– Better propagation and power compared to CBRS | – Cost of acquiring | – Auction Dec 2020; Deployment 1st phase: Dec 2021, 2nd phase: Dec 2023 |
| 5 GHz | – 555 MHz of spectrum | – Propagation challenges - Maximum of 36 dBm EIRP.<br>– Prone to interference due to contention-based access method | – Today |

| | | | |
|---|---|---|---|
| 5.9 GHz-6.425 GHz | – 500 MHz of spectrum | – Following unlicensed framework established for 5 GHz | – Estimated 2022 |
| 24 GHz – 39 GHz | – Channels of 100 MHz possible<br>– Carrier agg of 400 MHz or more | – Significant challenges - propagation | – Starting mid-2019 |
| 57 GHz – 71 GHz | – 14 GHz of spectrum<br>– Suitable for point-to-point | – Significant challenges - propagation and atmospheric absorption | – Partially Today; Partially in 2022 |

Operators providing MBB services could use any of the spectrum above for FWA depending on utilization of their spectrum resources. Greenfield operators could start off with CBRS spectrum in combination with 5 GHz band and perhaps also upcoming mmWave high bands.

Carrier aggregation of LTE/5G bands becomes a critical feature for FWA services:

1. There may not be enough spectrum in one band
2. Spectrum may not be contiguous
3. Combining high bands with lower bands improves cell edge rates and extends the coverage
4. Higher peak and average rates can be offered
5. Higher UL Data Rates may require carrier aggregation with other frequency bands

## 5. Starting Up and Evolving FWA Network

As network traffic grows and as operator offer higher rate broadband services, there will be a need to enhance and upgrade the FWA network. Operator with existing cellular assets could follow a network strategy as below.

1. Use existing MBB cell-site infrastructure for FWA sites, by just adding carriers or slices for FWA. This enables cost effective start up for FWA services

2. Install outdoor CPEs on rooftops of homes or on sides of buildings. Outdoor CPE enable better coverage, longer range and higher system capacity

3. For many existing operators, legacy bands are fully occupied by MBB DL traffic. There may still be capacity left over, specifically in the UL portion of FDD bands that could be given to FWA traffic

4. Operators could upgrade legacy FDD bands to 4T/4R configurations or even FDD massive MIMO to squeeze more network capacity out of legacy FDD bands

5. Operators could add TDD band in 2.5 or 3.5 GHz (with massive MIMO radios). TDD bands are well suited to FWA. Spectrum costs tend to be lower and TDD profiles could match asymmetric downlink heavy nature of home broadband traffic

6. Operators can add mmWave 5G sites in high traffic demand areas to offload FWA traffic from larger macro type sites. mmWave 5G could also be used to provide very high throughput (~ 1 Gbps) service to selected neighborhoods

7. To evolve networks further and to take advantage of 5G's better spectral efficiency and operational ease, operators could upgrade 4G bands to 5G. Since operators need to support both 4G and 5G terminals, there will be a need to operate 5G network together with 4G using schemes like real time spectrum sharing. Real time spectrum sharing allocates spectrum proportionally to 5G and 4G users, as per real time usage demand, without the need to partition spectrum statically and reducing data rates for legacy 4G users

8. Operators could introduce virtualized RAN running on COTS hardware and centralize deployment and management of pieces of FWA RAN functionality especially in Sub-urban and Urban areas.

Greenfield FWA operators that do not have existing spectrum assets could start with step 5 above. Greenfield operators would need to consider their migration strategies to 5G as well. 5G migration that could be accomplished with software upgrade to 4G eNBs and 4G CPEs provide a more compelling option. Even greenfield operators must consider implications of providing 5G and 4G services on the same spectrum, as their user base migrates over time from 4G to 5G.

# 6. 3GPP Data Rate Evolution

Following picture shows data rate evolution of 3GPP technologies. In LTE, this evolution is accomplished primarily by adding carrier aggregation and spatially multiplexed layers, using 4x4 MIMO and higher order modulation like 256 QAM. Carrier aggregation allows operators to bond together narrower spectrum from several frequency bands into one larger logical channel. This increases data rate to the user. 4x4 MIMO enables transmission of up to 4 layers of spatially multiplexed streams, using the same air interface time and frequency resources. Compared to single stream, 4x4 MIMO could quadruple effective data rate. Higher order modulation attempts to send more bits of information on a single OFDM symbol, thus enhancing end user bit rate.

5G NR introduces leaner air interface and wider carriers in mid (2.5-6 GHz range) and higher (> 6 GHz range) bands. Data rate enhancement support is available both in base station and UE equipment.

To provide an attractive FWA service, operators should aim to start off higher on the data rate ladder and strive to climb even higher with the right network infrastructure and terminal/CPE solution.

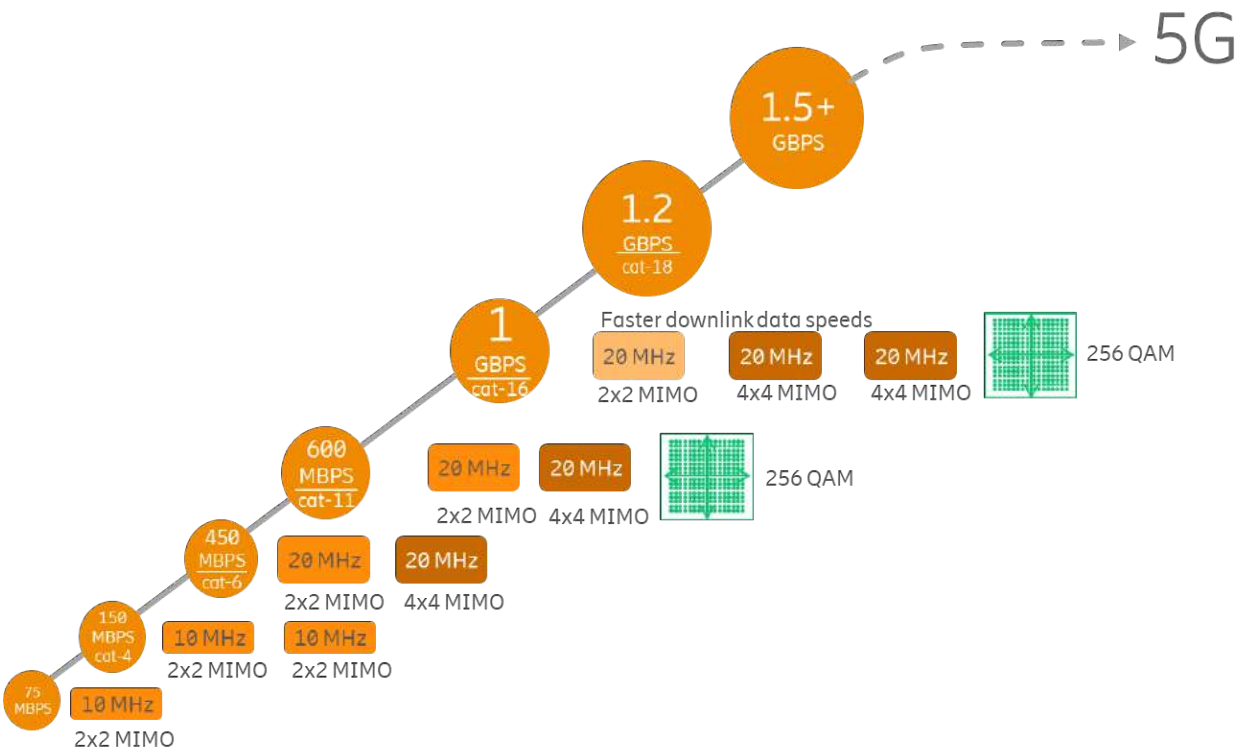

**Figure 2: LTE throughput ladder**

## 7. Beamforming Technology

Beamforming is the single most important advance in Technology needed for FWA. Beamforming can be done in many different ways. Most of them (not mechanical tilt included) involves time- or phase-shifts of the different antenna elements in an array. Time shift is the most "correct" way to do it, since it is independent of the frequency (e.g. within the bandwidth of the transmitted signal). But phase shift is in most cases easier to achieve practically.

The two main solutions for beamforming are: Digital and Analog Beamforming.

**Digital beamforming** has the benefits that it can be done in the baseband and in the frequency domain. This means that the scheduler and Link Adaptation directly can control the beamforming weights (phase shifts that control antenna pattern) simultaneously for different sub-bands within the same OFDM symbol, as illustrated in the figure below.

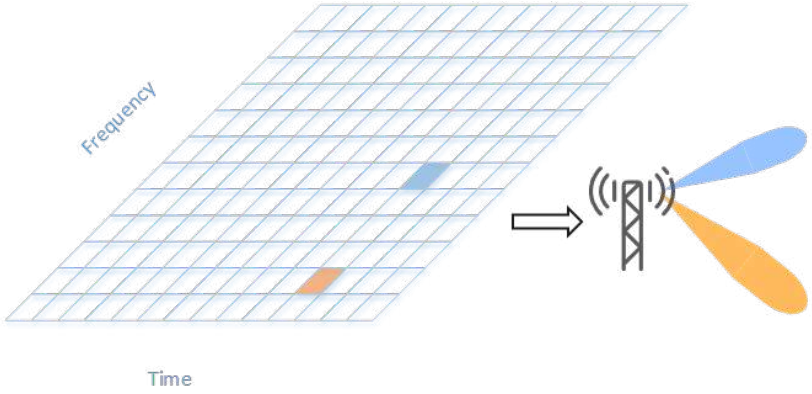

**Figure 3: Digital Beamforming**

**Analog beamforming** applies the weights in the time domain, i.e. all symbols within the OFDM symbol get the same weights (same beam direction), which means that Frequency Domain Scheduling, multi-user scheduling or frequency selective beamforming is not possible.

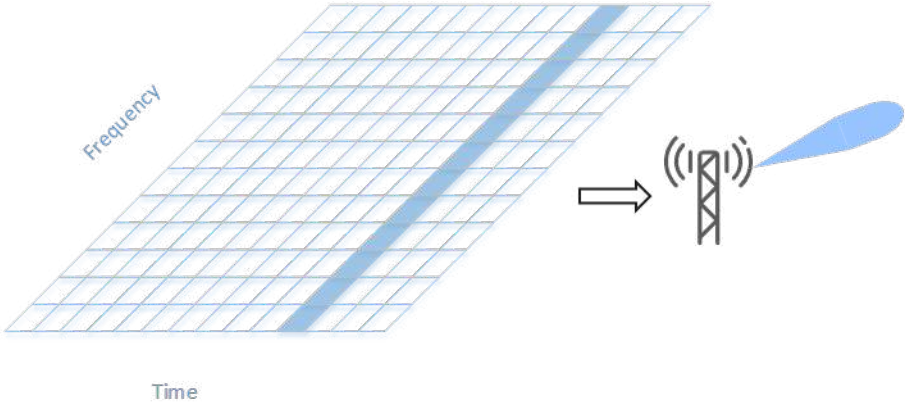

**Figure 4: Analog Beamforming**

## 8. CBRS for FWA

CBRS band in 3.5 GHz spectrum could be a good option for FWA services because:

1. Relatively larger amount of spectrum is available. 150 MHz total allocated for all users. 70 MHz would be dedicated to PAL operation in a licensed mode of operation, while 80 MHz would be available for GAA unlicensed operation. GAA interference and coexistence is managed by SAS. Even though GA is unlicensed, GAA operation is expected to be more predictable because of spectrum coordination functionality provided by SAS.
2. CBRS supports TDD operation, which is well suited to FWA.
3. CBRS provides a good compromise between coverage and capacity. The nature of the spectrum allows practical implementation of massive MIMO radios in this band. Using massive MIMO

radios and multiple user MIMO, capacity enhancement - even over narrower frequency bands – is possible.

4. Strong FWA ecosystem is developing in CBRS band.
5. CBRS implementations are beginning with LTE. We expect migration to 5G in CBRS from 2020.

## 9. Massive MIMO for FWA

Traditional cell sites broadcast signal from LTE sector in all directions covered by that sector. In some places, there would be users that can take advantage of the signal. But most likely, there would be many places where there are no users and the signal broadcasted spatially over wider area would be wasted. Moreover, this wide beam pattern from base station antenna causes inter-cell interference in neighboring cells. The result, from the point of view of a UE, is that total signal levels are lower, and the interference is relatively higher, resulting in a low baseline SINR. Lower SINR implies lower throughput.

**Figure 5: Coverage under broadcast beam**

Massive MIMO aims to solve this problem by employing beamforming. Large number of antennas are used in the base station radio to form narrower beams at the UE location. Because RF power is focused into narrow beams, desired signal level to the UE increases. Additionally, since the cell site is not broadcasting in the coverage area of the sector for traffic channel – it only transmits narrow beams, intercell interference to adjacent cells is reduced. Consequently, SINR experienced by UE improves and so does the throughput. Beamforming tracks channel conditions and strives to maintain optimum beam structure in the cell.

For FWA service, massive MIMO beamforming is useful in enhancing SINR and improving throughputs to the CPE. However, beamforming by itself only provides marginal improvements. Even though we have a higher sector capacity X in the cell, it is still shared between CPEs served by the cell. If there are 16 CPEs served by the cell at one instance in time, each CPE would get X/16 th of the throughput. These

CPEs are being scheduled in separate resource blocks as indicated by different colors of beams in the picture below, thus sector capacity is split among the CPEs.

Massive MIMO improves capacity but also coverage.

1. SINR improvement over cell edge implies cell edge could be pushed farther from the site, increasing cell range.
2. There is an indirect effect. On many occasions, DL rates are impacted by lack of UL coverage, since UL channel suffering from poor radio conditions may not be able to handle TCP flow control. TCP ACKs/NACKs may not be received from UL channel for DL data transmissions. Large number of base station RX antennas improves UL link budget, extending UL coverage, improving TCP flow control and indirectly helping DL.

5G massive MIMO beamforming adds beamforming to UE in addition to LTE eNB. This could result in further improvement in throughput.

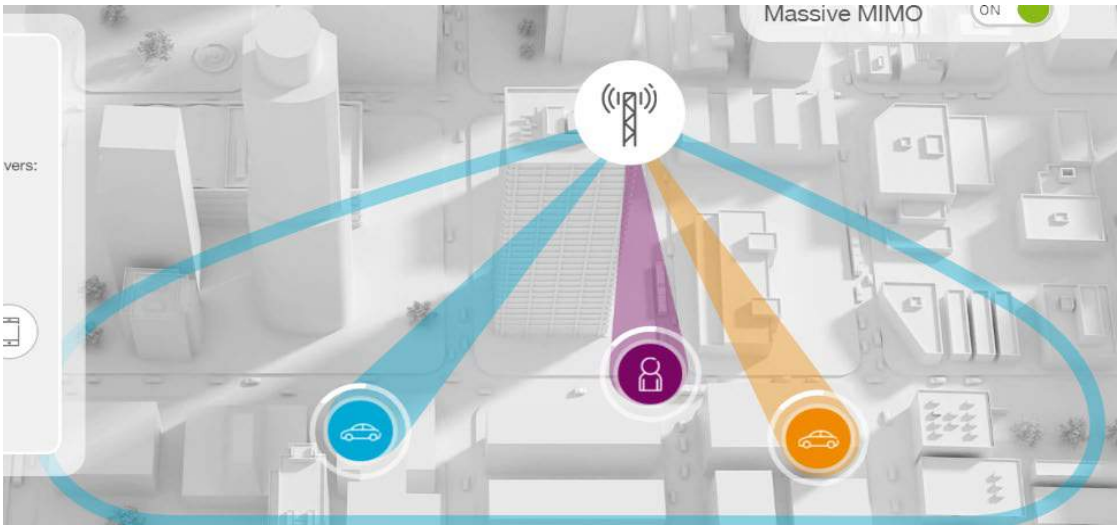

**Figure 6: Beamforming with SU-MIMO**

If the CPEs are orthogonal, so that beams transmitted to the CPEs do not interfere (i.e., overlap spatially), we could allocate the same resource blocks all over again to each CPE. This is shown by the same color of beam in the picture below and is called multiple user MIMO. If the sector capacity is X and there are 16 (full-buffer) users simultaneously receiving data in the cell, each user can be assigned as much as full capacity X. There are two benefits of multiple user MIMO.

1. System capacity is enhanced. In the example above, baseline sector capacity was X with just beamforming. After adding multiple user MIMO, sector capacity becomes 16X (since each of the sixteen users is receiving data with throughput X). This is order of magnitude improvement in system capacity, compared to when a single stream was sent to the UE.
2. User throughput improves also. Depending of the SINR experienced by user, their throughput would vary. But since we are allocating potentially all RBs to each user, individual user throughput would improve. For the example above, we assume all users are in good radio conditions, each user's throughput could be as high as X, which is a 16-time improvement.

We can think of multiple user MIMO creating 16 virtual sectors inside one physical sector in this example.

One consideration for multiple user MIMO is that users need to be orthogonal or spatially separated far enough, such that beams don't overlap. A more intelligent scheduling algorithm would aim to increase UE orthogonality by exploiting not only spatial but also temporal selection of transmissions.

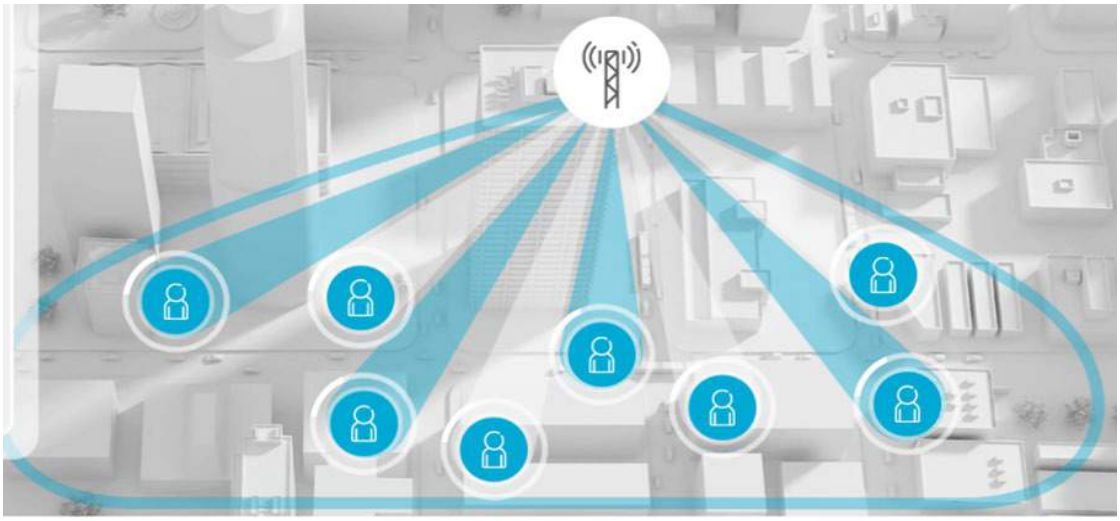

**Figure 7: Beamforming with MU-MIMO**

Since home broadband offers very high data buckets, capacity enhancement of LTE/5G network is always an important consideration. This is true for high subscriber density urban and suburban areas, but also for low density rural areas. In rural areas, improvements in coverage from massive MIMO beamforming may also be of interest. See picture below from field measurements conducted by Ericsson. Here we are comparing DL throughput for 4T4R system with 64T64R systems with massive MIMO. We can see that massive MIMO systems have better range.

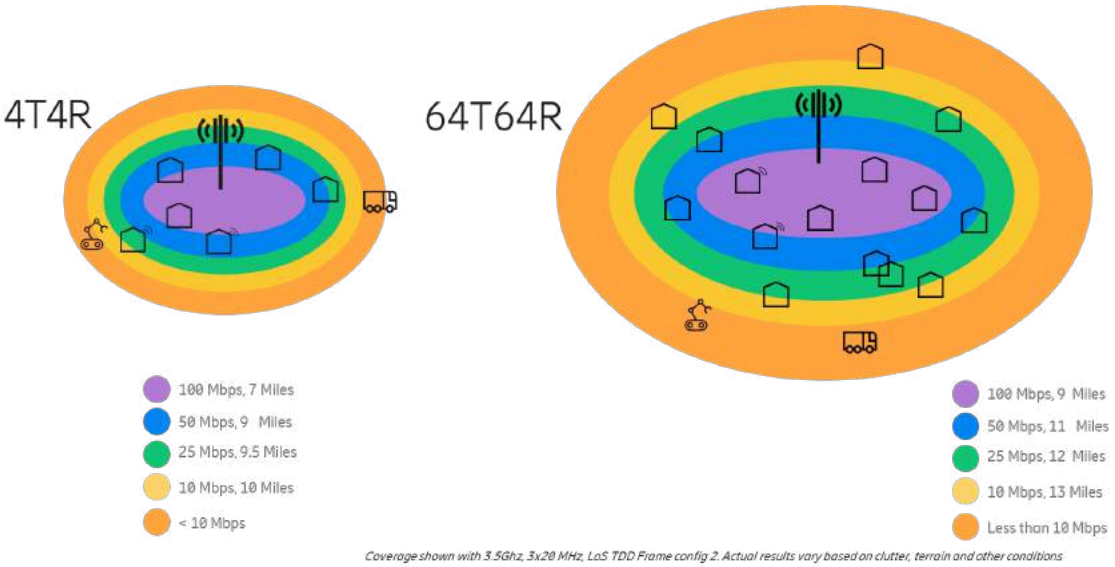

**Figure 8: Comparison of 4T4R and 64T64R user throughput and coverage**

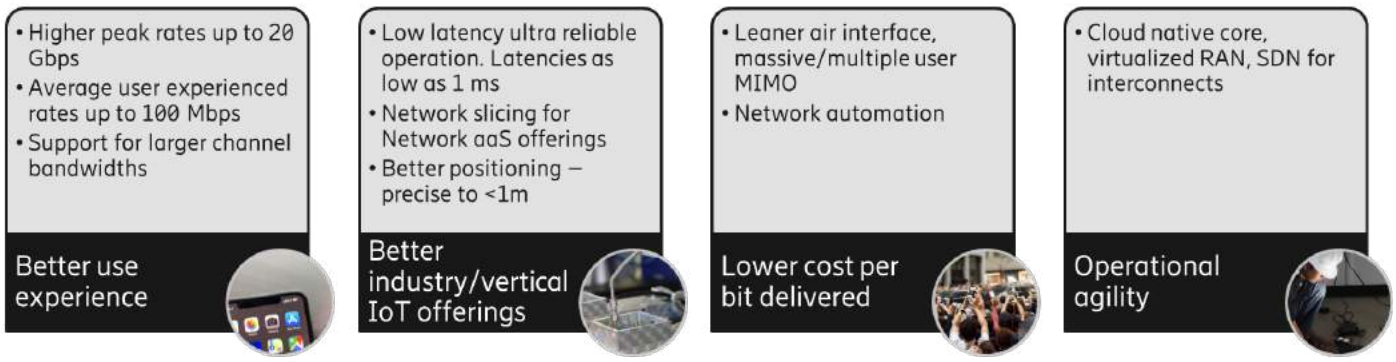
## 10. FWA with 5G

Picture below summarizes key benefits of 5G NR.



FWA operator can utilize each one of these aspects of 5G to their benefit.

1. 5G offers much higher peak and average data rates, allowing FWA operators to offer faster speeds.
2. Converged operators, offering MBB and FWA services, can use 5G's enhanced QoS and network slicing mechanisms to better use common RAN, transport and core infrastructure and provide guaranteed FWA SLAs to their subscribers – reducing their network costs
3. 5G leaner air interface and inherent support for massive MIMO/multiple user MIMO allows operators to transmit more data using limited spectrum, reducing cost per bit delivered. Additionally, mmWave bands with higher channel bandwidths could also allow lower cost per bit of FWA data
4. Cloud native core RAN and transport virtualization, software defined networking and use of COTS hardware enables agile operations and cost-effective networks

## 11. Improving 5G mmWave Reach

mmWave spectrum offers large channel bandwidths and large amount of spectrum. This enables peak data rates up to 20 Gbps. However, propagation of mmWave spectrum is challenging and range is smaller – less than 1 km. FWA deployment of mmWave and mid-band can improve on some of the propagation limitations as below:

1. 5G mmWave antenna arrays can be miniaturized, so large number of antennas can be built in mmWave radios. The antenna arrays allow use of massive MIMO and beamforming. In 5G mmWave, beamforming is used to mostly improve coverage by focusing the RF energy in the direction of intended receiver.

2. Outdoor CPEs become even more critical for 5G mmWave to avoid building penetration losses and to provide line of sight from 5G base station radio to 5G UE.
3. Dual connect operation further enhances coverage, which is typically UL limited. In NR Non-Stand-Alone(NSA) operation, UL from anchor LTE carrier in lower frequency bands could be used to improve cell range. In NR SA operation, a mid band NR carrier can be aggregated with mmWave NR carrier, further improving the effective range of NR cell. This is shown in picture below.

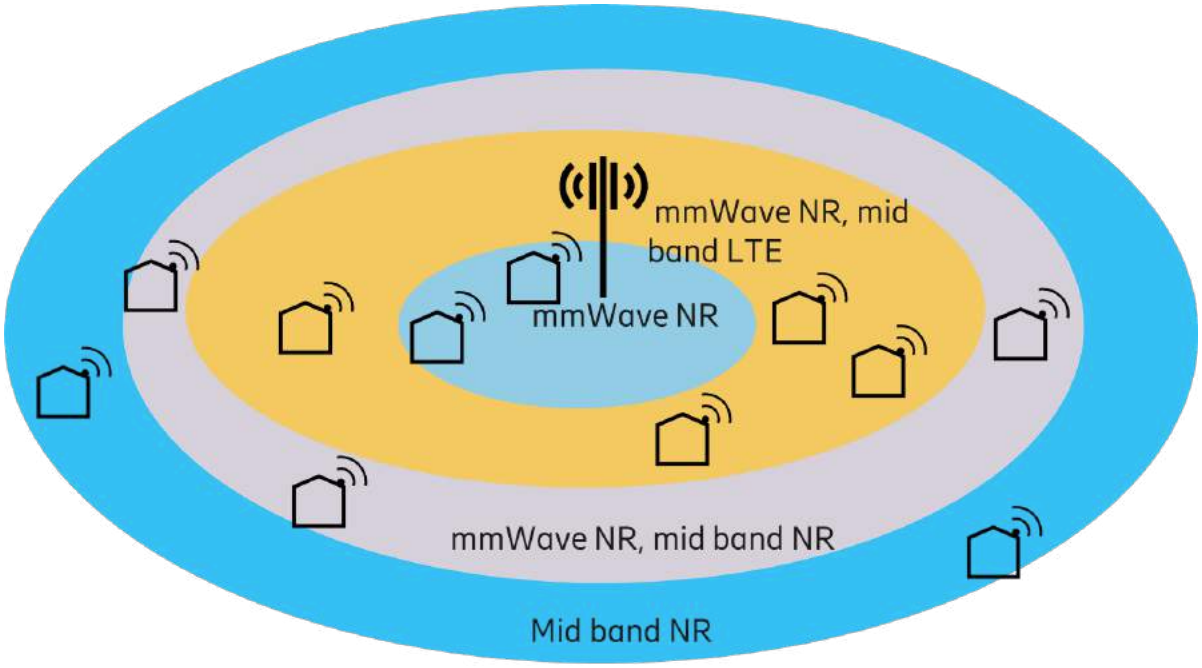


**Figure 9: Combining mmWave and mid band**

**Technology of combining mmWave and Mid-bands:**

To meet the ever-growing demand for wireless data and applications, service providers must find new sources of spectrum while using existing spectrum efficiently. In addition to enabling new applications and delivering higher data speeds, 5G is unlocking new sources of spectrum in both the mid-band and high-band radio frequencies. Though these new bands are a welcome addition to a service provider's spectrum assets, the mid and high-band coverage is limited by the radio uplink signal quality and characteristics associated with operating within the higher bands. In order to maximize the benefits provided by these new bands, solutions are needed to extend cell coverage.

UL coverage is challenging at higher bands, and also has significant DL throughput impact when loosing UL coverage. How much can we extend the range where higher band DL can be used by considering interworking with lower/mid bands?

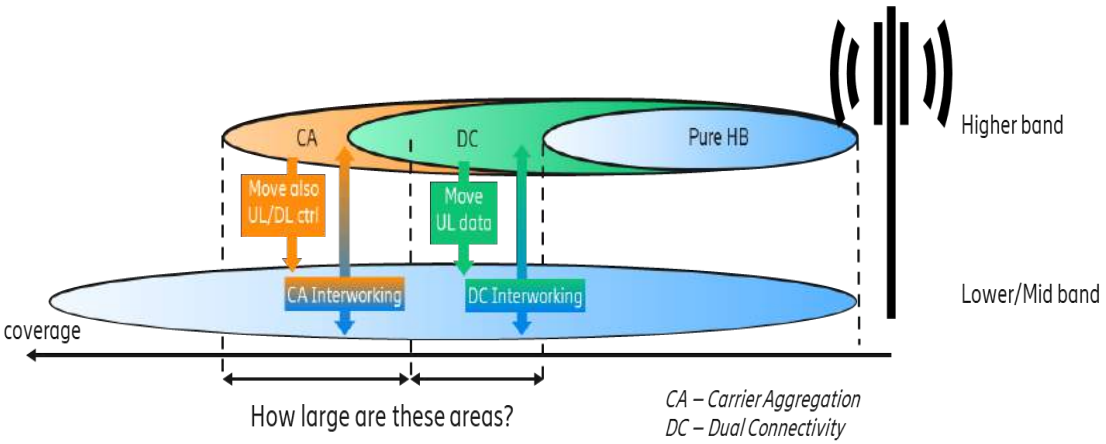

**Figure 10: Dual Connectivity and Carrier Aggregation**

The first step in the process is Dual Connectivity. In NR NSA operation, UL from anchor LTE carrier in lower frequency bands could be used to improve cell range. Dual Connectivity as defined in 3GPP will allow DL and UL data to switch between LTE and NR independently based on the best performance.

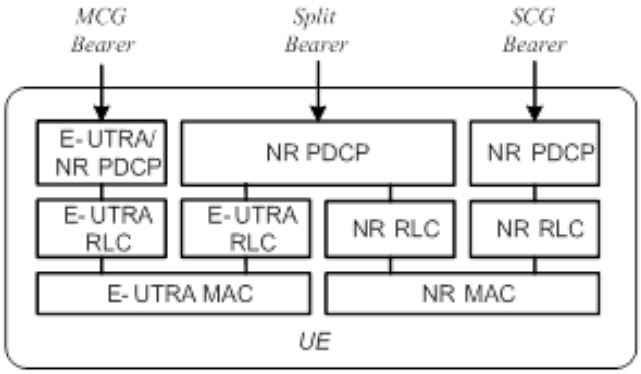

**Figure 11: Dual Connectivity Data Bearer Architecture**

UL and DL decoupling provides enhanced 5G coverage and performance by picking the best NR or LTE leg for uplink and downlink separately. NR coverage is extended by combining the high speed and low latency of NR with the high coverage and high reliability of LTE. Service utilization is maximized because leg switching can be used even with fast changing radio conditions. Allows e.g. the LTE spectrum, with superior coverage, to be used for uplink user data, while the NR spectrum, with superior peak data rate and latency, is used for downlink.

**Benefits**

1. Enhanced NR coverage by leveraging LTE for uplink
2. Increased UL and DL performance

For Dual Connectivity(DC), data is split at PDCP layer and unlike carrier aggregation, Layer1, MAC and RLC will be different for master cell group (MCG) and secondary cell group (SCG). From a link budget perspective, DC will need all L1 control channels on all bands, whereas Carrier Aggregation only needs a limited set of control channels on secondary cells.

With Dual Connectivity, on the UL Data channel (PUSCH) can be moved to low/mid band LTE. The coverage is improved but is often then limited by other UL control signaling.

With Carrier Aggregation, UL L1 control channels can also be moved to NR low/mid band and hence results in a better link budget when combining mmWave NR and mid-band/low band NR.

5G mid-band and high-band coverage limitations by developing a flexible 5G Carrier Aggregation solution which supports control and data traffic on the uplink using a lower frequency band which increases coverage, and on the downlink with a mid or high frequency band which increases capacity and data throughput. With 5G Carrier Aggregation, a service provider can support the 5G uplink operating on a lower band with the 5G downlink operating on a mid, or high-band thereby providing the best of all worlds – better coverage, increased capacity, and higher data speeds.

These solutions enable service providers to optimize the use of their spectrum assets when deploying 5G. A better 5G network will provide more subscribers with higher data speeds while enabling a host of new, low latency applications.

In the scenario considered in the analysis below, aggregating a 5G mid-band with a 5G high-band can improve high-band coverage by up to 7dB extending the high-band cell coverage area by up to 2.5 times. The extended mid-band and high-band coverage also enables a greater offload of traffic from the mid bands to the high-bands providing a higher throughput at the cell edge.

Link Budget Analysis for FWA using mmWave and CBRS using Carrier Aggregation:

- 3.5 GHz, 3X20 MHz, 28 GHz: 400 MHz Carrier Aggregation, CPE : CBRS -> 26 dBm EiRP/20MHz, mmWave CPE : 45 dBm EIRP.
- Propagation Model : 3GPP RMa LOS, UE height : 5m, RBS Height : 90% Coverage Probability, BS EIRP of 62 dBm on 28 GHz, and 50 dBm/20 MHz on CBRS

1. LOS scenario:

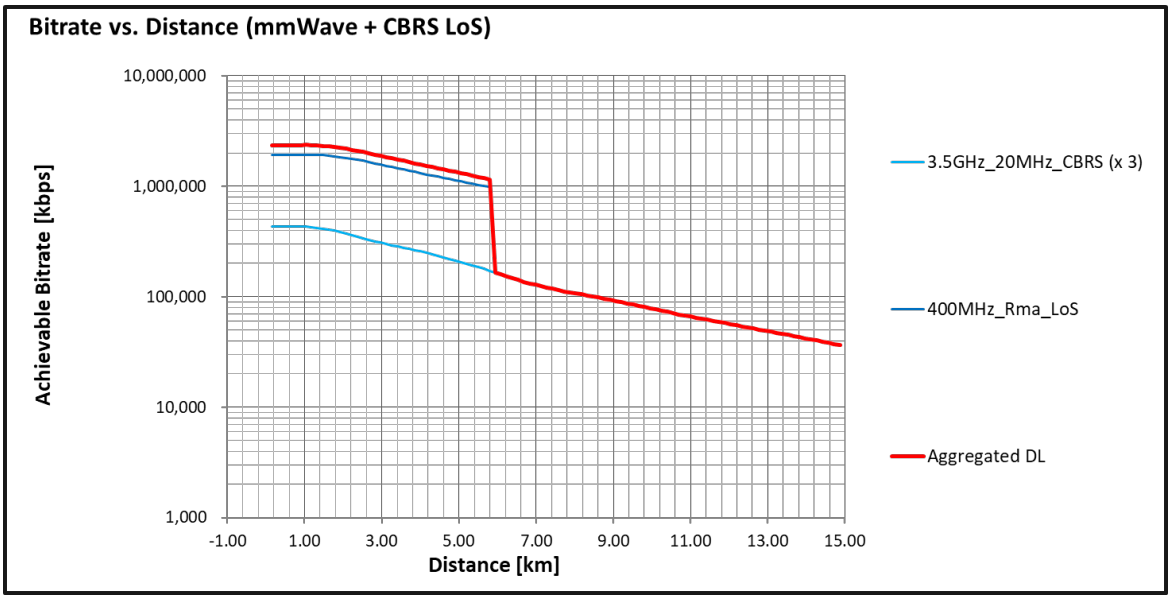

**Figure 12: mmWave and CBRS LOS Bandwidth vs Distance**

2. NLOS scenario:

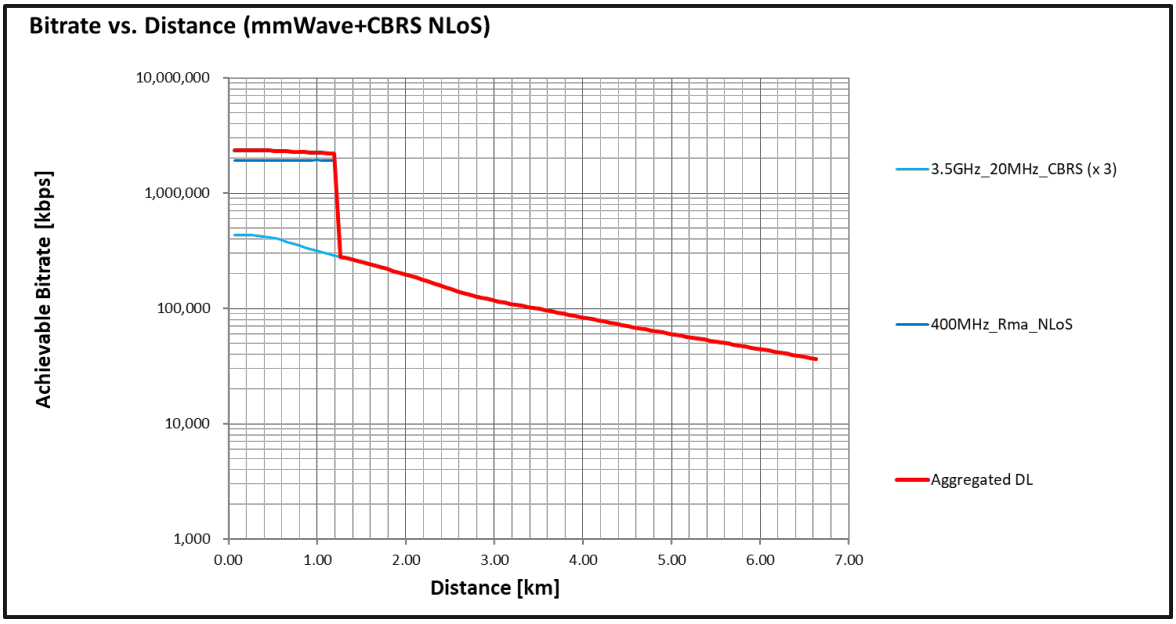

**Figure 13: mmWave and CBRS NLOS Bandwidth vs Distance**

## 12. Summary of Technical Section

We summarize our discussion of FWA technology below.

1. 3GPP LTE and 5G provide compelling option for FWA services both for existing and new operators.
2. LTE and 5G FWA solutions are applicable to rural, as well as suburban and urban markets.
3. Operators can start off with LTE and then climb the throughput ladder to more system capacity and higher end user rates.
4. Especially for new operators, CBRS provides an attractive way to start up FWA service offerings
5. 5G mmWave spectrum could be useful add on to mid band FWA. 5G mmWave based FWA could also be used in urban areas on its own.
6. Massive MIMO and multiple user MIMO are key techniques to increase system capacity and FWA user throughput.

We conclude that we have the technologies and spectrum today to enable FWA services both for new and existing network operators. In later section of this paper, we show actual FWA field experiences.

## 13. FWA Business Considerations

FWA can help operators with their business challenges:

1. Existing operators that have legacy wireline networks like DSL may find it costly to maintain and to upgrade. Operators that want to expand footprint or upgrade existing capabilities could do that with wireless.
2. The yardstick from broadband has moved since subscribers consume more data and expect faster speeds. Wireless technologies can allow operators to enable fiber like capabilities.
3. In some cases, wireless could be cheaper option than deploying fiber.
4. Expanding wireline plants can be time consuming esp. when it comes to the last mile. Wireless can help operators shorten cycle time and reduce customer churn.
5. Wireless networks are multi-service. Once established for FWA, operators can use them to generate new revenue from services like MBB roaming or IoT connectivity.

## 14. FWA economics

Below we look at factors effecting economics of FWA.

Cost of spectrum. Licensed spectrum could be expensive. For example, operators spent upwards of 40 BUSD for AWS3 spectrum licenses. Since spectrum is expensive, it is important to squeeze maximum utility from it. One strategy is to use inexpensive unlicensed or lightly licensed spectrum for FWA such as CBRS and 5 GHz spectrum. Another strategy is to use mmWave bands (28 GHz, 24 GHz, 37 GHz, 39 GHz etc) for capacity. 37 GHz mmWave also mmWave band offer large amount of spectrum for relatively lower costs.

Cost of network equipment. Since spectrum is scarce and expensive, operators should look at acquiring high performance base station equipment with advanced feature and functionality for FWA like massive MIMO, 5G etc. Similarly, base station sites could be expensive to procure, construct and maintain. A high-performance base station solution that maximizes coverage could also lower the overall costs of deploying and maintaining an FWA network. In previous sections, we saw system capacity improvements

from massive MIMO. Assuming a massive MIMO base station could provide 4x capacity improvement, that will translate into building 4x less sites and spending about 4x less on acquiring spectrum.

Network equipment also includes the LTE or 5G core network and any transmission and aggregation equipment in the operator transport network.

Cost of Site Acquisition and Construction could be significant and even higher than cost of network equipment on the site. Existing operators could leverage their MBB sites to lower site related costs. New FWA operators could also aim to reduce site related costs by deploying high performance base station equipment and by introducing automation in their deployment processes.

Site OPEX comprises of rent payments, backhaul costs, electricity bills and general maintenance costs. Site rent and backhaul comprise the major portion of OPEX costs. TCO for self-owned backhaul would be better than leased line OPEX over the long run. One factor to evaluate here is building of own microwave backhaul.

Cost of CPE. Operators would deploy 100x more CPEs than the number of base stations. For this reason, FWA business cases tend to be sensitive to the cost of CPEs. So, there is a need to drive down the cost of CPE. However, the specs of the CPE could impact network performance and system capacity. A lower spec inexpensive CPE may be detrimental to system capacity – forcing operator to spend more on spectrum and network infrastructure. Outdoor CPEs with high power and high gain antenna enhance network performance and system capacity. The biggest issue with Outdoor CPE is that they require professional installation which dwarfs the cost of the CPE equipment itself. Indoor CPEs could be self-installed by the subscriber. On the other hand, self-install prevents operators from providing SLAs. In the indoor model, you will have opex costs associated with loosing signal and hence using more radio resources, churn and in some cases an inability to serve. So outdoor model is best suited for providing a FWA broadband service with SLAs compared to indoor CPE deployments. Operators need to weigh all the cost and performance tradeoffs before crystalizing their CPE strategy.

Technology choice could be critical for the overall business case. A technology that requires frequent upgrades could be costly and may incur disruptions to service. Along this line, effortless upgradability of LTE to 5G (via software without hardware rips) could be beneficial. Since migration of users would not happen overnight, operators should also consider coexistence of LTE and 5G users in the best possible way. Here real time spectrum sharing between LTE and 5G users becomes critical. Without it, operator may be forced to procure new spectrum for 5G.

Subscriber density impact the business case for FWA. A higher subscriber density is preferable to generate higher revenues per cell site and offset operator's network CAPEX and OPEX expenses, but comes at the penalty that higher density makes fixed line competition more cost effective.

Similarly, a higher market share will allow operator to generate more revenue per site up until they reach their spectral capacity. An FWA business case resting on too small or to large market share or density of subscribers could be challenging.

Traffic growth projections factor into the business case in terms cost of future network expansion. This is tied to data speed offerings, since faster speeds may require FWA network densification or more spectrum etc. More traffic and higher data speeds could require more sites, more spectrum or more infrastructure equipment.

## 15. CBRS Business Case Example

It is possible to realize a viable business case for FWA – i.e., an FWA solution with positive cash flow and cost structure better than alternate solutions. Below we show a sample business case for rural and suburban FWA. In this scenario, operator could achieve less than $300 cost per home passed with a positive cash flow in 3.5 years.

| Budgetary Value* | Performance | Time to Revenue |
|---|---|---|
| – Suburban and Rural:<br>– $<300 Cost per Home Passed<br>– 600 homes/sq. mile – Suburban<br>– 10 homes/sq. mile - Rural<br>– Cash flow positive <3 years | – 10, 25, 50, and 100 Mbps Service<br>– Network supports, 2 Mbps Busy Hour Throughput per HHC with a 28% YoY growth<br>– Aligned with Marketing take rates, pricing, and targeted network design metrics | – Network Deployment can begin now |

## 16. mmWave and CBRS Business Case Example

Below we show a sample business case for rural and suburban FWA using mmWave Frequency and CBRS spectrum. In this scenario, operator could achieve less than $550 cost per home passed with a positive cash flow in 4 years.

| Budgetary Value* | Performance | Time to Revenue |
|---|---|---|
| –Suburban and Rural<br>–$<550 Cost per Home Passed<br>–500 Homes/sq.mile<br>–Cash flow positive <4 years | – 100, 250, 500, and 1000 Mbps Service<br>– Network supports, 6 Mbps Busy Hour Throughput per HHC with a 28% YoY growth<br>– Aligned with Marketing take rates, pricing, and targeted network design metrics | – Network Deployment can begin 1H 2021 |

Business case metrics used:

Cost per home passed: This is the cost of building FWA coverage for the number of homes in the service area. This cost does not include customer premises costs.

Cost per home connected: This is the cost of providing connectivity to a customer, including networks and customer premises equipment costs.

Time to revenue: Month or year to cash flow positive Return on investment

## 17. FWA business models

Operators have been trying different business models for FWA. Below, we list a few:

1. Rural high speed FWA. NBN in Australia provides broadband service to rural subscribers. Offering includes 1000 GB bucket with data speed as high as 100 Mbps. To achieve coverage and performance, NBN uses 60 to 100 MHz of licensed TDD spectrum. NBN provides service to otherwise un/underserved communities.
2. 5G FWA. Verizon has launched an FWA service over mmWave 5G variant for $50-70 per month with no contract. The 5G type FWA service is being deployed in targeted urban and suburban areas and it is meant to compete with existing cable, fiber and other home broadband offerings.
3. Converged MBB and FWA service. Here operator can offer a service to connect a WiFi router, MiFi devices, tablets etc. via the same network. Data consumption from all devices is pooled into a single bucket. Some of the supported devices are mobile and can roam outside of home. This offering has features of both mobile broadband and fixed broadband. T-mobile has just launched the service based on this model.
4. Rural FWA and IoT network: A rural operator provides FWA service and using the same network can offer up low power wide area or massive IoT for smart farms.
5. Rural FWA and MBB roaming: A rural operator deploys FWA LTE network. With network slicing, any residual capacity in the network could be used to accommodate roaming MBB subscribers.

## 18. CBRS FWA Field Experiences

In this section, we look at field trial results from FWA. We highlight performance potential of new technologies like massive MIMO and NR.

In the first instance, we show results from a rural FWA trial using CBRS spectrum. The cell site is configured as 4T4R and we are using two 20 MHz LTE carriers. Outdoor CPEs are used in this set up. Since, this configuration is closer to standard LTE, we can use this as baseline for comparisons.

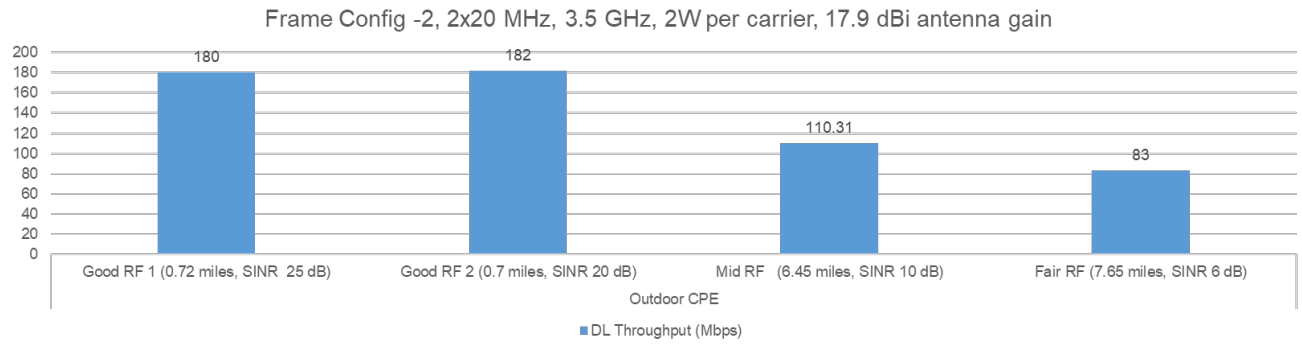

**Figure 14: Downlink thoughput under different RF conditions**

Peak throughput of 180 Mbps in the DL was seen at 0.7 miles from the site. An average home would experience 110 Mbps. One measurement was taken at around 7 miles from the site with 110 Mbps speed in the DL.

Each 20 MHz channel offered average sector capacity of 50 Mbps. Assuming busy hour demand of 2 Mbps per home, each sector would be able to support 50 homes. The number of homes supported by each sector could be increased by adding more CBRS spectrum (more than 2x20 MHz).

In the next instance, we show how massive MIMO can improve system capacity and individual CPE throughput. We note that CPE placement is ideal, i.e., CPEs are in line of sight and under good RF conditions. They are also spatially separated to minimize inter-beam interference and allow the possibility of achieving good multiple user MIMO gains.

**Figure 15: Setting for multiple user MIMO testing in ideal radio conditions**

These tests use a single 20 MHz LTE carrier with 256 QAM modulation in mid band TDD spectrum. 16 CPEs are configured to transmit simultaneously. System is set up to use up to 16 layers in DL. Total system throughput of ~937 Mbps was observed in the DL.

**Table 3: Results of throughput testing with 16 layer MU-MIMO in good radio conditions**

Finally, we show coverage capacity a massive MIMO and 4T4R FWA system in rural area. We used a single 20 MHz carrier in mid band with outdoor CPEs.

With Massive MIMO, high single user throughput performance is achieved with 10 CPEs between 6 to 8 km away from the cell site and 3 CPEs with in 500 meters of the site.

Total system capacity of 250 Mbps was achieved for 8 MU-MIMO layers with 8 CPEs in the 6-8 km distance. The 4T4R, we achieved a system capacity of 80 Mbps in a 20 MHz channel when testing 8 users. So in summary Massive MIMO 64T64R system achieved 3X more capacity compared to 4T4R.

Total system capacity of 400 Mbps was achieved for 13 MU-MIMO layers when tested Massive MIMO product.

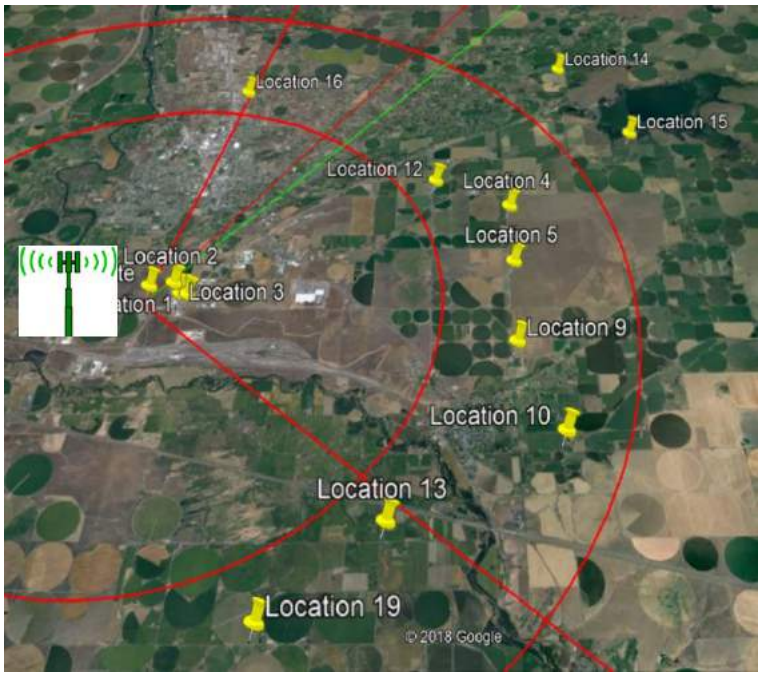

**Figure 16: FWA with beamforming and MU-MIMO in rural area**

Also, maximum cell range tests with Massive MIMO products demonstrated that speeds up to 50 Mbps can be achieved in a 20 MHz up to 20 Km distances in LoS conditions.

## 19. mmWave and CBRS Field Trial experiences

Prototype FWA CPE Devices with mmWave and 3.5 GHz support (Dual Connectivity) are currently being tested. Also, Outdoor FWA CPE devices with mmWave and CBRS will be available 1H 2021.

# Conclusions

In this article, we have shown:

1. FWA technology components are in place.
2. There is a viable business case for FWA.
3. Operators have been experimenting with different business models.
4. Deployments that began with rural FWA are moving into suburban and urban areas. Several operators in the US and globally have already been operating profitable FWA business.

FWA has the potential to disrupt existing broadband business. SCTE members could leverage FWA to further build out their own home broadband offerings.

# 1. Introduction

It seems longer, but 10G unveiled less than 2 years ago! As exciting as the vision is, implementation began well before. 10G has a multi-element roadmap, with its foundations part of MSO initiatives for years. Some are in networks now, while others are in phases of development, proof-of-concept, and trial. Together, they paint a holistic picture of innovation leading to transformative digital experiences for customers.

In this paper, we explore key components of 10G, their synergies, and how they enable new experiences for residential and business consumers. We examine the payoff in speed, capacity, latency, advanced services, reliability and security – all while reducing carbon footprint. In particular, we touch on:

-The symmetric Gigabit foundation of DOCSIS® 3.1 technology

-Advanced DOCSIS 3.1 features – narrow subchannels, shorter cyclic prefixes (CPs), frequency interleaving, diagnostics, and Profile Management Application (PMA)

-Proactive Network Management (PNM) advances in data capture, analysis, localization, and tools for DOCSIS 4.0 technology

-Low Latency DOCSIS capability and implications to gaming and emerging requirements of IoT, M2M, and AR/VR

-Metrics and insights of fiber rich densification at scale, enabling a flexible last mile, increased reliability, lower Opex, and elimination of disruptive node splits

-Experience operating the largest Distributed Access Architecture (DAA) deployment based on remote-PHY (RPHY) and a High Availability (HA) Ethernet switch fabric

-A virtualized core leveraging real-time compute and rapid innovation cycles in the data center space, yielding significant advantages in facility consolidation and costs

-Fiber-rich symmetric networks to power growth in small-to-medium business and enterprise services

-DOCSIS 4.0 features, capabilities, progress, and steps leading to multi-Gig symmetric and full 10G

-The complementary nature of DOCSIS 4.0 Full Duplex (FDX) and Frequency Division Duplexing (formerly Extended Spectrum DOCSIS) FDD

Across Expo Tech Sessions, deeper dives illuminating these and other innovations are explored and described by Comcast subject matter experts focusing on this strategic program.

# 2. Scratching the Surface

It is hard to believe, but the specification development for DOCSIS 3.1 technology began 8 years ago, and service was launched, at Comcast, now over four years ago. Much has been written about the DOCSIS 3.1 foundation changing to OFDM/OFDMA, coupled with a range of higher order modulation formats, including up to 4096-QAM downstream and 1024-QAM upstream, supported by more powerful Low Density Parity Check (LDPC) Forward Error Correction (FEC), and 1 Gbps services.

There are additional features that received less initial fanfare but are receiving more attention now. Figure 1, Figure 2, and Figure 3 highlight these features.

In Figure 1, we compare the common North American upstream band edge of 42 MHz, to the 85 MHz enabled by DOCSIS 3.0 specifications, and to the DOCSIS 3.1 maximum, 204 MHz, often referred to as High Split. The choice of 204 MHz was selected to achieve 1 Gbps of upstream speed and capacity, recognizing that 1024-QAM @10 bps/Hz of raw throughput put that into reach. As such, with DOCSIS 3.1 technology, 1G/1G can be a product offering on the road to 10G.

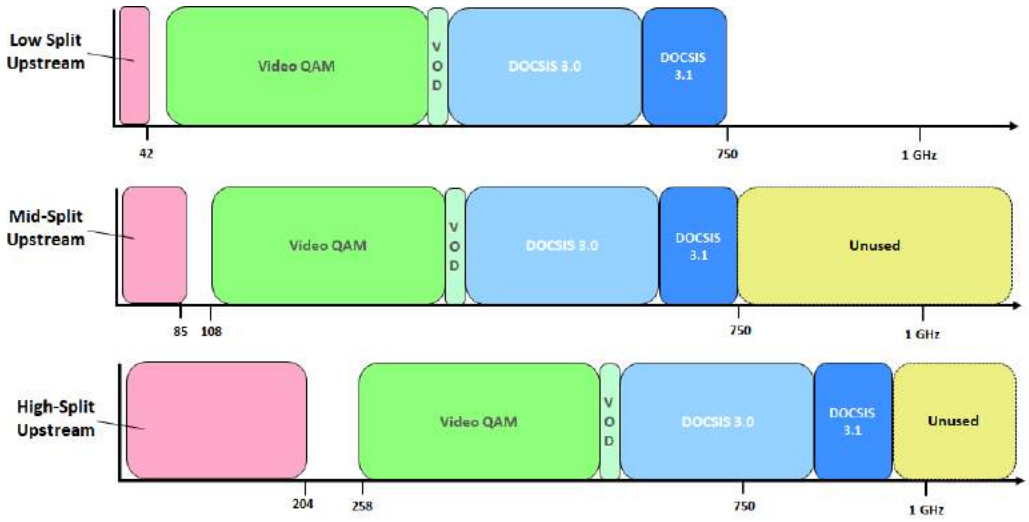

**Figure 1 - Frequency Split Options Focused on Increasing Upstream Bandwidth**

In Figure 2, the justification for defining Multiple Modulation Profiles (MMPs) is shown. DOCSIS 3.0 is limited to 256-QAM, and encumbered with a less effective FEC. With the combined effect of 1) better FEC (a lower SNR required for a given QAM format), 2) improved plant fidelity over time with deeper fiber and shorter amplifier cascades, and 3) migration to DAA, Cable Modems (CMs) are capable of much better bandwidth efficiency than 256-QAM. The dB attributable to the above can be used for capacity gain rather than just better performance margin of 256-QAM. Figure 2 shows why this is effective – many CMs that can support higher QAM efficiency than 256-QAM.

Lastly, note that it was determined during this study that this national SNR distribution also exists down to the service group (SG) level. Because of this, it makes sense for there to be different modulation profiles defined within a single SG, and these profiles cycled through based on their traffic demands on the time axis. This is shown in Figure 3, where sets of devices (color-coded) that exhibit common MER metrics have a time and a frequency slice of the downstream broadcast carrying their traffic.

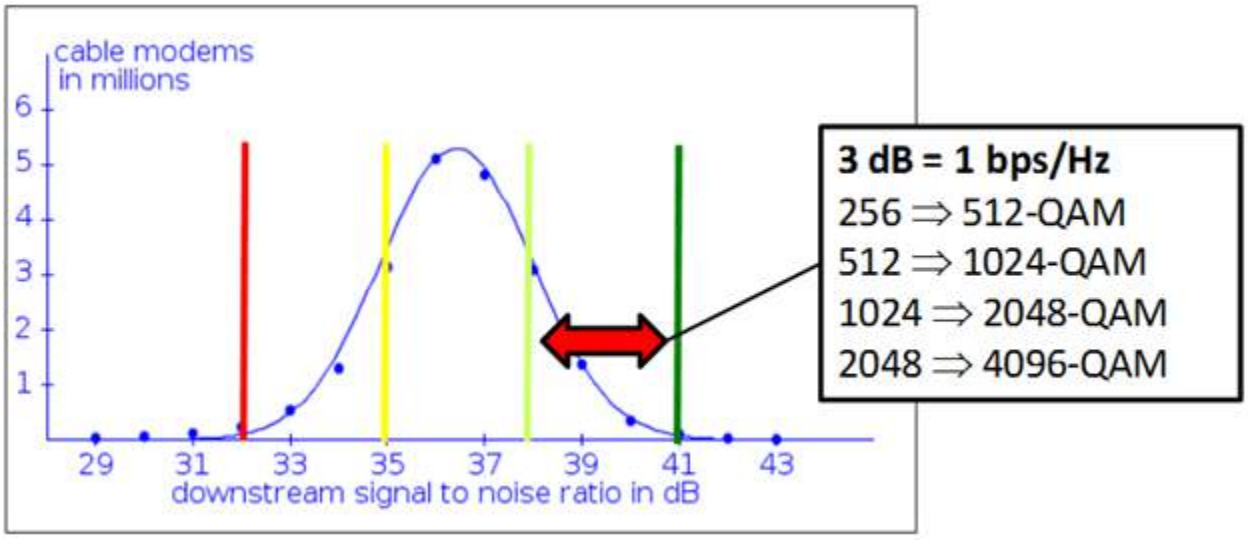

**Figure 2 - Available SNRs Enable More Efficient Modulation Formats and More Capacity with DOCSIS 3.1 [8]**

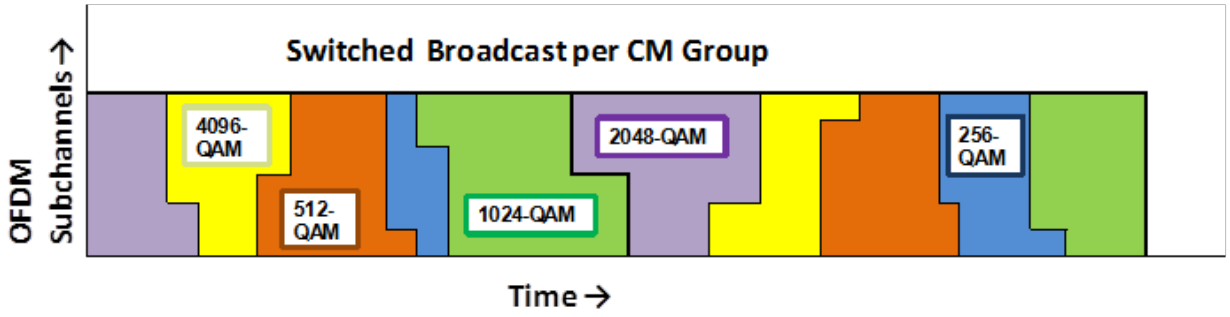

**Figure 3 - Time Slicing of the QAM Profiles Associated with Grouping CMs of Like Metrics**

## 2.1. Automated MMP: The Profile Management Application (PMA)

Efficiently managing the modulation profiles of DOCSIS 3.1 has proven to be a key component in successfully achieving the capacity promises of the technology. As DOCSIS 3.1 was deployed, it quickly became clear that dynamic and autonomous profile management is key to a holistic capacity plan [13]. Similar technology for DOCSIS 3.0 was recently deployed during the COVID pandemic to increase upstream capacity [14].

A PMA system leverages network data, such as RxMER per subcarrier in downstream OFDM channels, along with traffic, codeword, and signal level statistics to make optimization decisions that increase the capacity of the downstream, as shown in Figure 4.

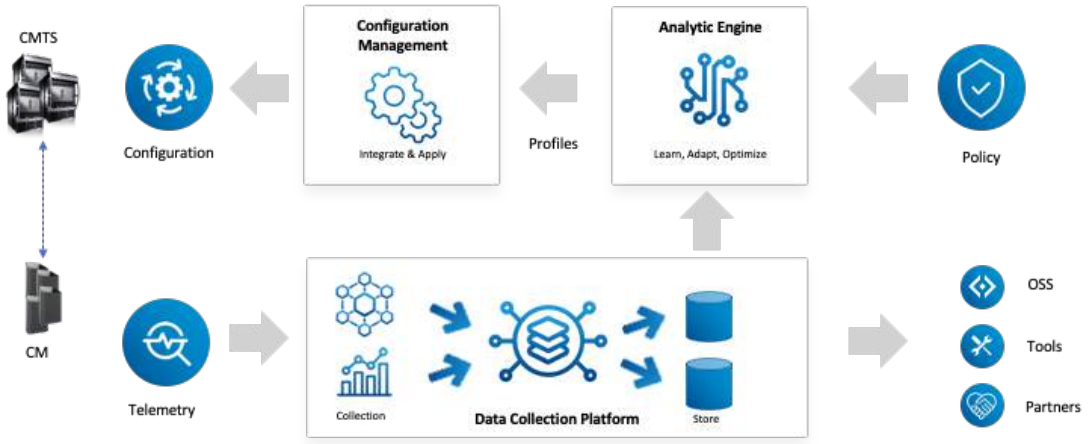

**Figure 4 - Modulation Profile Management Platform**

This same cloud platform has been used to optimize the capacity of DOCSIS 3.0 upstream channels. The optimization is based on three factors: upstream SNR, correctable and uncorrectable codeword errors, and signal levels. The metrics can be used by the analytics engine to adjust FEC and modulation for the data, Unsolicited Grant Services (UGS), and station maintenance Interval Usage Codes (IUCs). For DOCSIS 3.1 upstream transmissions, as in the downstream, optimization can be done by the analytics engine, which designs different modulation levels across the spectrum, tailored to channel fidelity.

This platform has enabled us to increase our access network capacity by over 36% in the downstream signal direction, and 20% in the upstream. The 36% is relative to a 256-QAM baseline and means PMA has brought the average efficiency close to 2048-QAM (37.5%). There is significant untapped gain in the upstream at this point, since 20% is comparing only different DOCSIS 3.0 settings. These results are tracked in operations as shown in Figure 5 and Figure 6.

**Figure 5 - Downstream OFDM Profile Management Operational Dashboard**

**Figure 6 - Upstream D3.0 Modulation Profile Management**

Beyond capacity gain for existing channels, this solution also enables spectrum to be used that was not previously possible. In some cases, spectrum is being used for OFDM downstream transmissions that are 100 MHz beyond common HFC frequency boundaries, driven by the pandemic-driven increases in traffic. In the upstream, a 6th DOCSIS 3.0 channel is being added below 15 MHz -- a notoriously noisy region that is suddenly more plausible when a PMA tool can be put to work to select the best FEC and modulation mix for a quality customer experience.

These PMA tools also help to ensure network robustness. For example, in the downstream spectrum, interference from mobile 4G Long Term Evolution (LTE) carriers is known to cause instability and loss of capacity without a system to effectively manage it. In the upstream, a variety of different noise sources [10] can be mitigated by a modulation profile management system. While these solutions mitigate the impact of the noise while maximizing the customer experience and capacity, the actual noise itself remains. It's still important to dispatch technicians to remediate the underlying issues. Combining profile management with PNM provides the best of both worlds. Technicians can be deployed to a specific network location that needs attention, and the customer is completely un-impacted and unaware through it all.

Similar techniques are being developed for upstream OFDMA channels, to optimize modulation profiles for challenging spectrum areas. The upstream signal path is a skinny, scrappy portion of total available capacity, routinely trampled by interference from FM radio, cascaded filter distortions, or the lower frequency noise common today, not to mention spurious/impulse noise. For DOCSIS 3.1, not only the modulation, but the pilot pattern, CP, and Roll-off Period (RP), along with subcarrier and mini-slot frame size are important attributes to optimize for robustness and capacity. These are important, for example, to achieving 1Gbps speeds in a high split configuration.

As product requirements grow beyond symmetrical Gbps to multi-Gbps symmetrical services, DOCSIS 4.0 Full Duplex (FDX) will be used. This technology will also benefit from OFDMA and OFDM modulation profile management. FDX introduces some new concepts that can also be managed as virtual network functions to optimize use of a shared spectrum resource, including Interference Group (IG) detection and Resource Block Assignment (RBA) usage.

## 2.2. Additional OFDM/OFDMA Specific Benefits

Two other features of DOCSIS 3.1 are worth mentioning. A key mechanism of how OFDM signals deal with linear distortion that results in Intersymbol Interference (ISI) is through a simple delay between OFDM transmission symbols. For frequency response distortion, it is also a simple mechanism – a single

complex multiplier applied to each subcarrier. Compared to the complexity of tapped-delay line SC-QAM adaptive equalizers for linear distortion compensation, these are simplifications that come directly from the OFDM signal structure.

The time delay inserted is determined by understanding the delay spread of the channel, and the idea shown in Figure 7. The delay is known as the "guard interval" and is implemented by the addition of a CP of redundant information that is easily generated as part of the IFFT algorithm that creates the OFDM symbol. The CP is wasteful overhead, but necessary for clean transmission – the SC-QAM parallel being the spectrum shaping factor "alpha" that amounts to bandwidth overhead beyond the minimum Nyquist bandwidth to transmit a QAM symbol of a particular symbol rate.

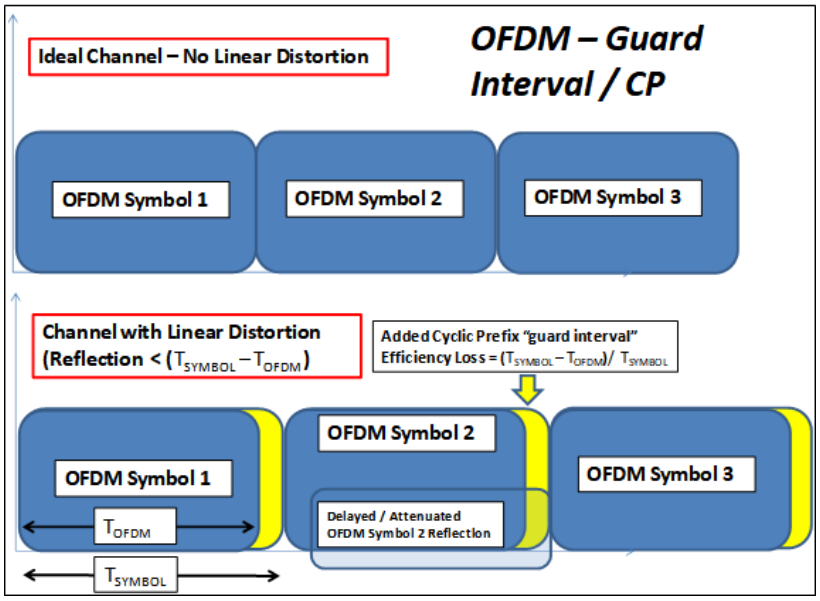

**Figure 7 - The OFDM Cyclic Prefix (CP) Guards Against Channel Distortions and Can be Optimized to Channel Characteristics for Maximum Efficiency**

Another DOCSIS 3.1 feature possible only because of OFDM is the frequency interleaver function shown in Figure 8. Each subcarrier is carrying a QAM symbol; a set of subcarriers form a codeword. However, when frequency domain interference strikes, only some of the OFDM subcarriers may be impacted. It is an OFDM advantage that subcarriers without interference continue to carry capacity, whereby an SC-QAM signal may be wiped out completely.

What the frequency interleaving attribute offers is the ability to spread the interference out such that it is not concentrated into a contiguous set of subcarriers or in a single codeword. By shuffling subcarriers prior to transmission, and then un-shuffling at the receiver, the tones with interference can be spread across the entire allocated OFDM band. They will then fall across multiple codewords, whereby each codeword will now have less interference than the single impacted codeword without interleaving, improving overall error correction performance.

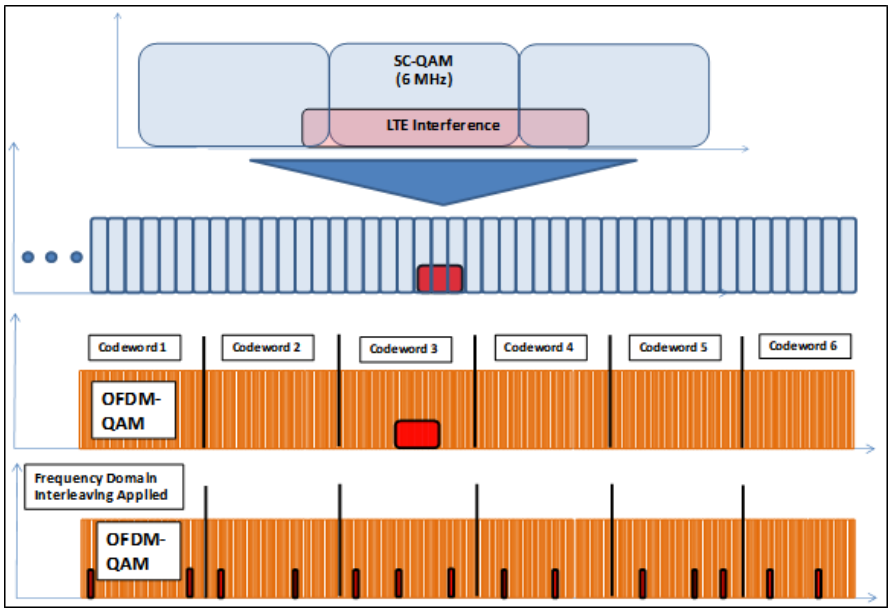

**Figure 8 - OFDMs Narrow Subcarriers Make It Effective Against Wideband Interference with the Aid of Frequency Interleaving**

## 3. Executing on the Fiber-Forward Future

Cable operators have been pulling fiber deeper into their network and splitting nodes for years, as one tool to manage the Compounded Annual Growth Rate (CAGR) of bandwidth usage and consequent capacity expansions. Node splitting reduces the number of customers in a service group by approximately two, doubling average capacity available to each home. Adding or reallocating channels of existing spectrum are other key tools to address CAGR. Spectrum flexibility, however, is very limited in today's upstream.

A "node split" can refer to a physical split, or the segmenting of an existing node by populating it with additional modules supported by new CMTS ports in the Headend. As nodes continue to be split and the serving group size shrinks, the efficiency of these splits decreases and the cost increases, because there are more physical splits rather than segmentation. A more forward-looking approach is to split multiple nodes at once. When many splits are projected over several years in an area, it may make sense to perform pre-emptive splits for labor efficiency and get ahead of trends as opposed to revisiting the same area repeatedly.

A version of "multiple node splits at once" is to be more methodical about the end architecture, as the node splitting occurs in these high growth areas. An approach we've taken in such areas replaces haphazard node splits with disciplined designs that optimize HFC design around a node with zero trailing RF amplifiers (N+0) end state, shown in Figure 9. Millions of homes passed are connected via this method today, and these networks will not have to endure disruptive node splits for many years, and possibly never.

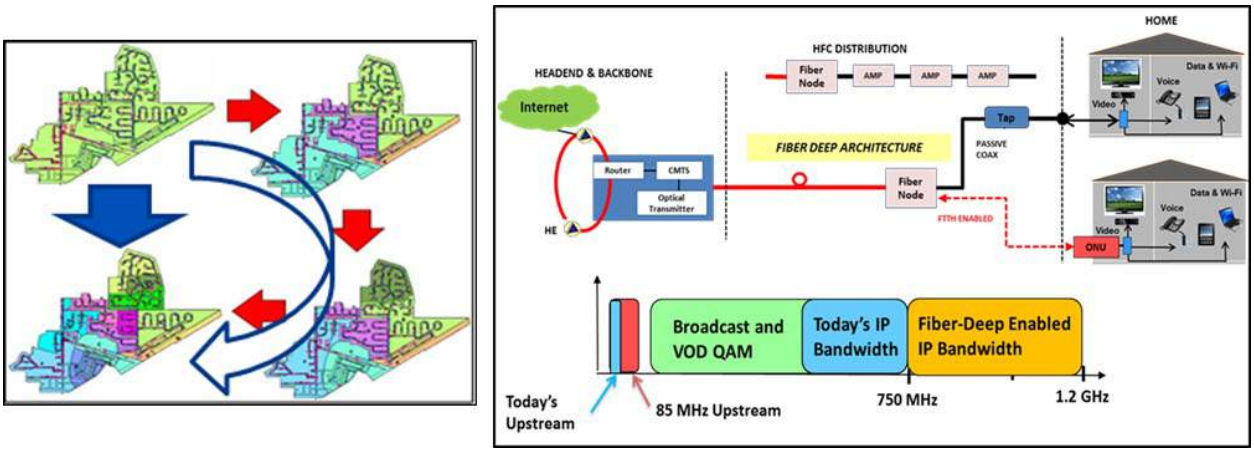

**Figure 9 - Node Splits vs. N+0 Architecture**

The N+0 architecture provides long-term capacity, improves End of Line fidelity, increases reliability, and adds substantial new spectrum currently limited by RF amplifiers in traditional HFC topologies. Operational performance is carefully monitored. Figure 10 is an example of comparative trends in Trouble Call (TC) performance between N+0 and standard HFC networks in a Comcast Division actively building N+0. Furthermore, the economics are favorable when compared to repeated node splits over time, especially in high growth areas of the network [7].

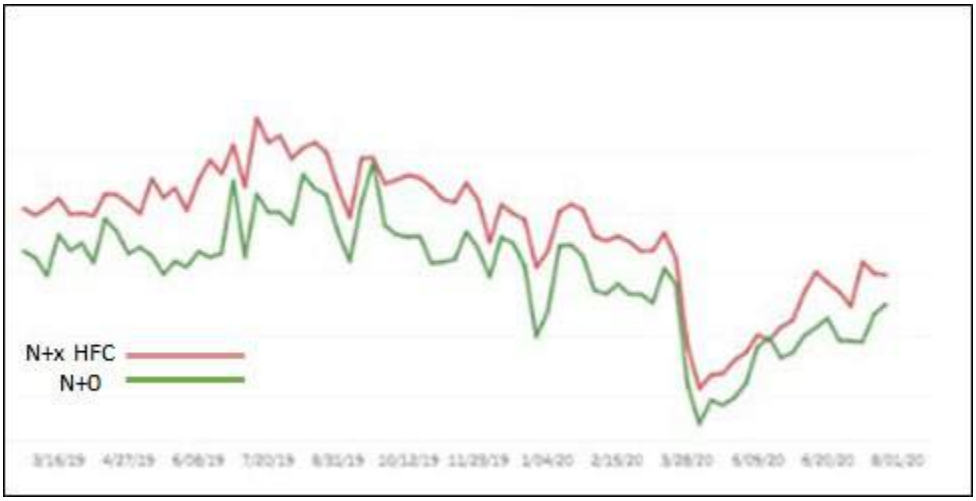

**Figure 10 - Reduction of Trouble Calls in N+0 (green) v. Traditional HFC (red) Infrastructure**

## 3.1. Remote PHY Based Distributed Access Architecture (DAA)

Traditional HFC networks have long used cable-specific analog optics to carry signals downstream; for the upstream, either similar analog optics or proprietary "digital return" systems. Our DAA deployments are based on Remote PHY device (RPD) technology and include all new N+0 systems because of the massive scale efficiencies, among other benefits, to the network and facilities. RPHY is by far the widest DAA flavor deployed. A brief summary of DAA benefits:

- Improved reach and wavelength efficiency of digital fiber versus analog
- Fidelity gains (MER) due to the removal of analog optics
- Physical scalability in the inside plant with the removal of RF cabling and combining networks
- Operational simplification, network availability, cost reduction
- Introduction of the global Ethernet ecosystem into the optical access network
- The vision of a network agnostic (at last!) to last-mile access technology
- Path to CMTS virtualization (vCMTS)

Regarding the last bullet, with DAA, a major part of the DOCSIS-specific CMTS functionality is moved into the plant. The subset that remains – packet processing, switching, storage, scheduling -- can be revisited from the perspective of today's compute power and the capabilities of real-time software. Commercial off-the-shelf (COTS) servers and switches can be combined with software to implement the CMTS function virtually. Our first DAA deployment, hosted by a virtual CMTS, or vCMTS, was introduced in 2018.

Figure 11 compares an N+0 network based on traditional AM optics and I-CCAPs to a DAA-based vCMTS solution. In the diagram, DAAS stands for Distributed Access Architecture Switch, and H-AGG stands for Hub Aggregation (also switching / concentration). Note the shifting of the CMTS core location to be further northbound in the vCMTS architecture, owing to the capabilities of Ethernet optics in terms of reach and wavelengths. This leads to opportunities for facilities reductions and consolidations in a massive way.

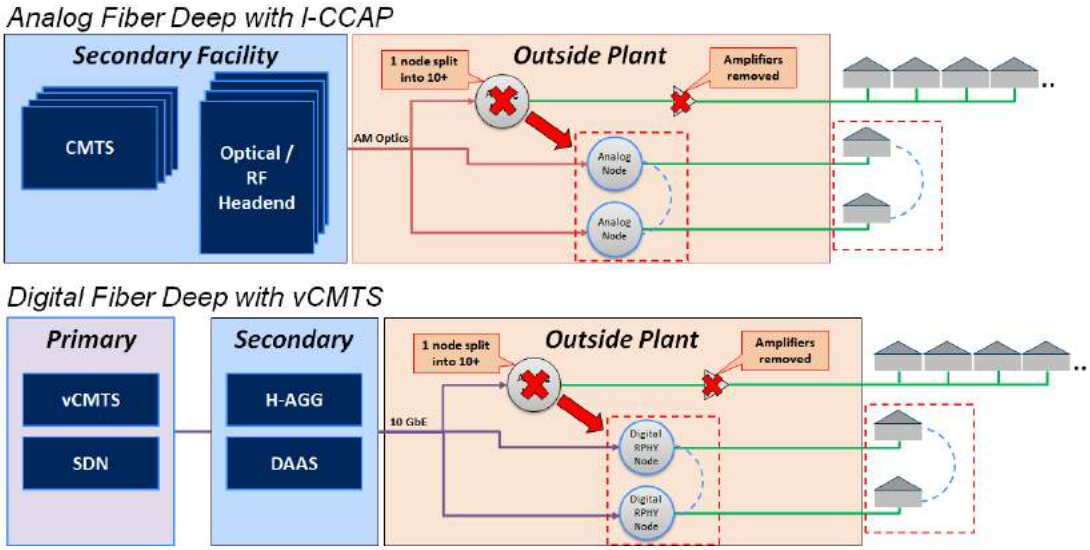

**Figure 11 - DAA Aligns Cable Systems to Networking Technology that Leverages Wide Scale Data Center Solutions and Protocols**

# 4. 10G: DOCSIS 4.0 Full Duplex Progress Update

DOCSIS 4.0 Full Duplex (FDX) enables multi-gigabit symmetrical capability over a coaxial last mile, a massive increase of upstream capacity and speeds. With the nature of consumer traffic being highly asymmetrical, cable operators optimized broadband for this reality, but are now getting ahead of requirements for new services and emerging applications that tax the upstream path – high definition (HD) home security cameras, cloud gaming, IoT, machine-to-machine applications, and those we cannot yet imagine. What FDX achieves is significantly more upstream bandwidth without a downstream bandwidth penalty, delivering new speeds while staying on top of CAGR of data traffic. Another key 10G pillar is low latency, which is also a key requirement of future applications, including many of those described above.

## 4.1. Key Innovations of FDX

Figure 12 shows the fundamental concept of FDX – access to massively more upstream. The FDX upstream is based on the same DOCSIS 3.1 physical layer – 96 MHz OFDMA blocks of 25 kHz or 50 kHz subcarriers, the same QAM profiles, and the same FEC. Six possible 96 MHz OFDMA blocks are added in the 108-684 MHz band as a complement to an 85 MHz "mid-split" system.

Figure 12 also makes clear the fundamental challenge of FDX – the new upstream overlaps with the downstream. This differs from the basic and, until now, exclusive Frequency Division Duplex (FDD) principle of cable TV. This dates back to the 1970s, when downstream and upstream signals began to exist in in separate regions, as in Figure 1. Coaxial cable is an inherently broadband medium, necessary originally to handle a multiplex of analog video channels, which deferred the need to be especially efficient with its use.

Meanwhile, phone companies had to work with much poorer physical medium – twisted pair copper wires -- to enable data services on a system optimized for voice bandwidth. Later, wireless networks had to manage within regulated spectrum. In both cases, spectrum efficiency was at a premium from the outset. Consequently, powerful technologies, including a technique known as Echo Cancellation (EC), were developed and matured to use available bandwidth in full-duplex mode. Years later, cable systems are now poised to leverage multi-octave, broadband EC as one of two key innovations of FDX, as efficient use of cable spectrum becomes increasingly important.

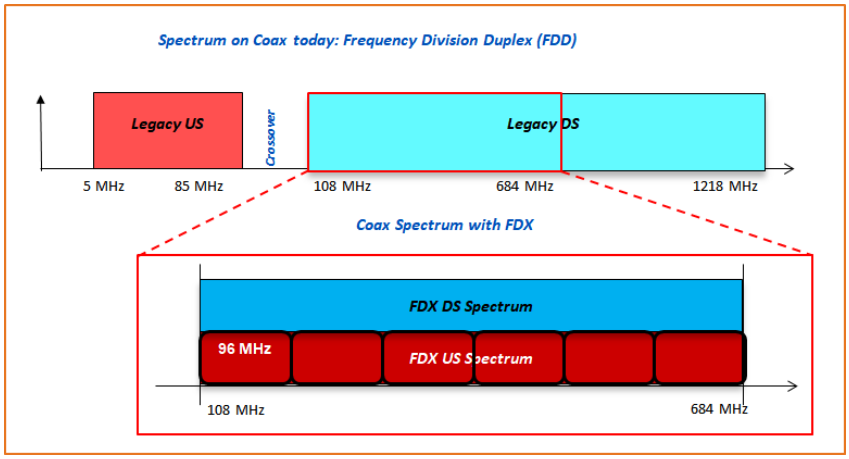

**Figure 12 - Spectrum Fundamentals of DOCSIS 4.0 Full Duplex (FDX)**

### 4.1.1. Learn to Share

The unique aspect of FDX is that the 108-684 MHz upstream can also be occupied by DOCSIS 3.1 downstream traffic. Echo Cancellation allow the simultaneous use of spectrum by removing the undesired signal from the desired signal at the receiver when they are sharing common spectrum. The term "Echo Cancellation" captures that: from a DAA node receiver perspective, it operates on undesired reflections of the downstream that bounce back from the plant. In fact, some of strongest interfering energy originates within the node itself, as either limited RF isolation or an internal reflection. Regardless of origin, it is handled by the same EC mechanism.

From the FDX RPD perspective, the EC function is conceptually straightforward – the downstream must be "subtracted" before the upstream receiver can process the upstream data. This is achieved through RF isolation of the downstream signal from the upstream receiver, and the ability to cancel residual copies of the downstream that make it to the receiver. It relies on the fact that the receiver "knows" the signal being transmitted and can therefore theoretically subtract the interference, as shown in Figure 13.

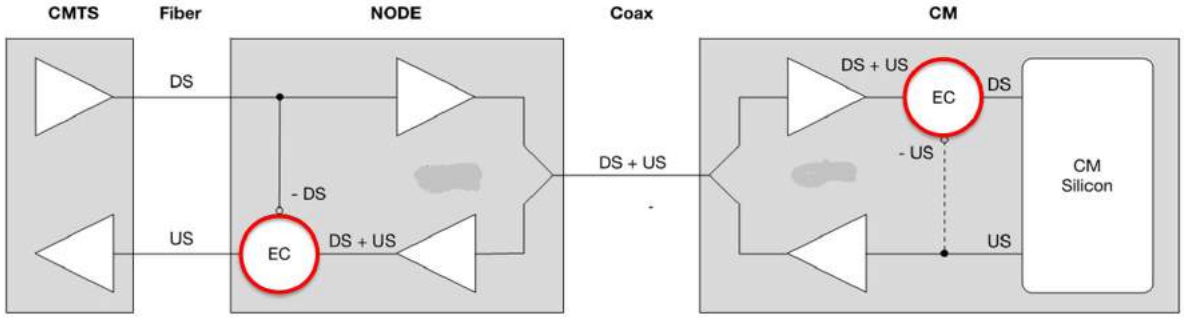

**Figure 13 - Echo Cancellation Removes Undesired Transmit Energy at the Receiver**

In practice, the upstream receiver must also measure the noise from the downstream transmitter and cancel it out for highest fidelity and maximum upstream bandwidth efficiency.

One important architectural difference of HFC compared to the telco last mile is that HFC is point-to-multipoint. This difference means one additional innovation is needed for FDX. That innovation involves clustering the users into groups that could inadvertently interfere with one another if any in the group were listening to the downstream while another in the group was transmitting. This is an extra scheduling exercise for the CMTS, which first determines the clustering, and then as part of its normal job of assigning transmit time slots to modems checks the upstream bandwidth allocation map (MAP) against downstream destinations, and if necessary, adjusts to avoid possible collisions.

These clusters, an important element of FDX technology definition and management, are called Interference Groups (IGs) and aggregates of IGs are called Transmission Groups (TGs). Figure 14 represents the two new techniques required to make FDX work, from the perspective of the FDX RPD.

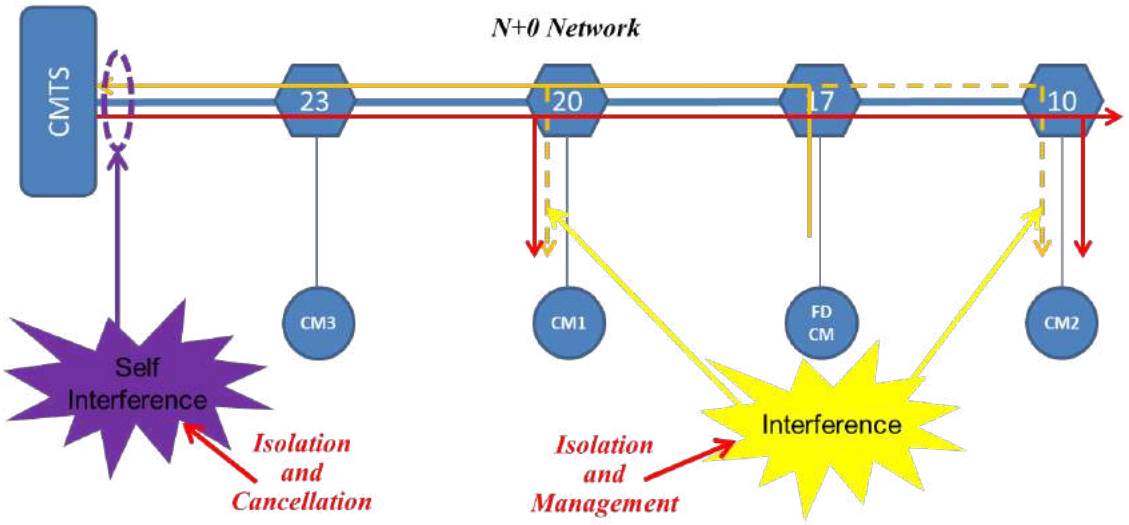

**Figure 14 - Two Key Innovations for FDX: Echo Cancellation and Interference Group Determination and Scheduling**

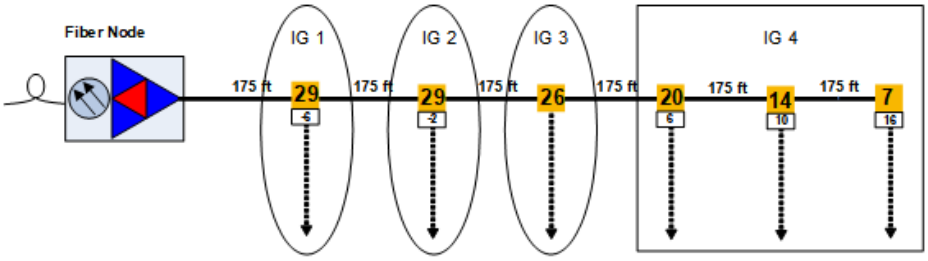
### *4.1.2. When You Can't Share, Be Fair*

Echo Cancellation is based on having or gaining knowledge of the transmit signal and noise to be cancelled. This can be a challenge in a point-to-multipoint architecture, and from the CPE's perspective. While an FDX CM has knowledge of its own signal, it will not have knowledge of its neighbor's. Only enough neighbor-to-neighbor RF isolation will prevent an FDX band transmission from interfering with another's downstream receive signal.

Unfortunately, enough isolation within a single tap or across taps cannot always be guaranteed. Some taps, in particular mid-to-high value Taps (29 dB, 26 dB, 23 dB), will have sufficient RF isolation from tap to tap. These dB relationships will be calculated by the CMTS as part of the network "sounding" process, used to determine IGs, TGs, and QAM profiles, and update them periodically. Figure 15 is an analysis of a single RF leg in an N+0 environment of a likely IG/TG determination using typical tap specifications.

As shown in Figure 15, users on the same tap are naturally going to form an IG. However, as we will see later, the statistical likelihood of such a small group competing for use of FDX bandwidth in a way that impacts services is negligibly low until FDX penetration becomes very high (for which further features can be enabled). This leads to defining TGs – aggregating IGs simplifies the scheduler aspect by having a smaller number of groupings to manage: Divide to conquer.



| | | SNR in Total Channel (108 MHz to 684 MHz) | | | | | |
|---|---|---|---|---|---|---|---|
| | | TRANSMIT | | | | | |
| RECEIVE | SNR (dB) | Tap 1 | Tap 2 | Tap 3 | Tap 4 | Tap 5 | Tap 6 |
| | Tap 1 | -4.7 | 40.4 | 40.4 | 40.4 | 40.4 | 40.4 |
| | Tap 2 | 40.4 | -7.2 | 36.2 | 36.2 | 36.2 | 36.2 |
| | Tap 3 | 40.4 | 36.2 | -5.4 | 32.2 | 32.2 | 32.2 |
| | Tap 4 | 40.4 | 36.2 | 32.2 | -7.3 | 24.0 | 24.0 |
| | Tap 5 | 40.4 | 36.2 | 32.2 | 24.0 | -5.7 | 13.7 |
| | Tap 6 | 40.4 | 36.2 | 32.2 | 24.0 | 13.7 | -7.2 |

**Figure 15 - FDX SNR per Interference Group Analysis using Current Tap Performance**

Figure 15 also shows the FDX band SNRs for each IG. Beyond the "same tap" limitations (shown in the white cells, with negative SNR if an FDX CM is transmitting at the same time), we can see, for example, within IG4, a useable but low SNR would lead to 128-QAM maximum and as low as 8-QAM when an FDX CM on one of these taps was transmitting. By forming an IG across these taps, these low SNRs are avoided by choosing different downstream and upstream time windows for the users in the IG.

Once IGs are established, the CMTS scheduler executes its "normal" operation with the additional rules. The CMTS scheduler is the arbiter of access to the network, allocating time slots for downstream and upstream transmissions to fairly and efficiently serve the aggregate demand. The CMTS does not typically or explicitly need to pay attention to a single user's downstream and upstream access. That changes with FDX, as there is an awareness needed that accounts for IG/TG relationships. This extra scheduler "step" makes sure that a downstream receiver signal of a potentially vulnerable user is not interfered with by an adjacent FDX upstream.

## 4.2. Symmetric Multi-Gigamania

What happens as FDX users increase in penetration? To enable fair and efficient access, these IGs and TGs can be granted slices into sub-blocks of the very sliceable OFDMA spectrum, so that availability of FDX bandwidth is always possible for any TG.

Figure 16 shows an example whereby the entire 108-684MHz FDX band is activated. Three TGs each have 384 MHz of downstream and 192 MHz of upstream capacity in the FDX band, or about 3 Gbps downstream and 1.5 Gbps upstream (including the 85 MHz legacy upstream). Sub-band allocations are called Resource Block Assignments, or RBAs. Of course, the FDX band is not all of the available DOCSIS downstream. For example, there could be another 192 MHz of non-FDX D3.1 spectrum in the downstream, for a total of 5Gbps, and also DOCSIS 3.0 spectrum.

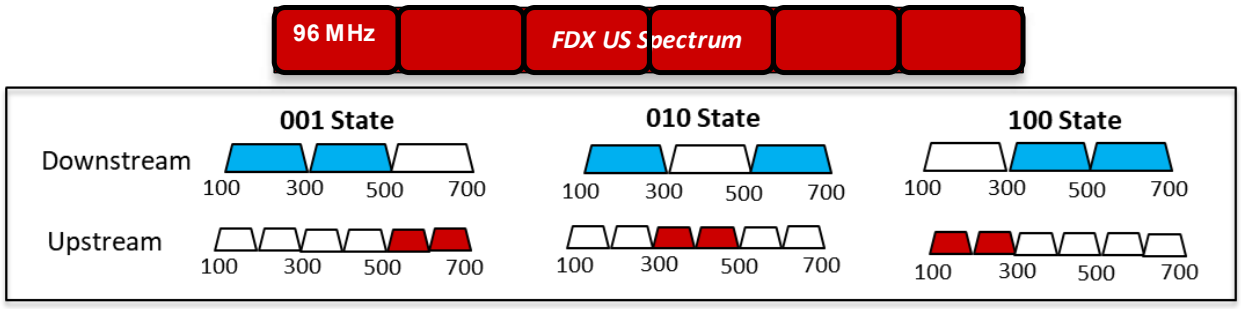


**Figure 16 - OFDMA RBAs Example Fully Utilizing the FDX Band**

FDX requirements have been written such that RBAs can be dynamically allocated as traffic demands shift with time. Figure 17 demonstrates this feature, with FDX band allocation on the vertical axis and time on the horizontal axis.

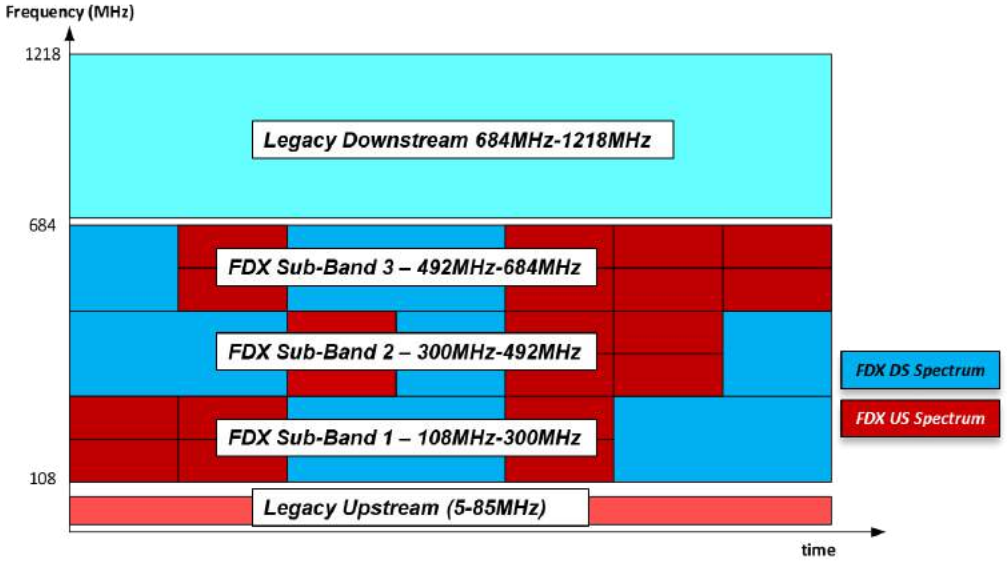

**Figure 17 - Example of FDX Band Utilization vs Time Enabled by Dynamic Resource Block Assignments (RBAs)**

Two last important points are in order with regard to FDX spectrum:

1) Because FDX is based on DOCSIS 3.1 technology, FDX can only be activated as FDX spectrum where downstream DOCSIS 3.1 spectrum is located.

2) Existing DOCSIS 3.1 devices using the FDX band must be aware of FDX, as this ensures they are effective participants in the IG/TG mechanism. This mode – a software (SW) upgrade to existing CPE – is known as FDX-Light (FDX-L) mode.

## 4.3. Network Components to Support FDX

Figure 18 identifies components of the end-to-end network effected by FDX. The red highlights identify areas of the network impacted by FDX that we will describe in the sections below.

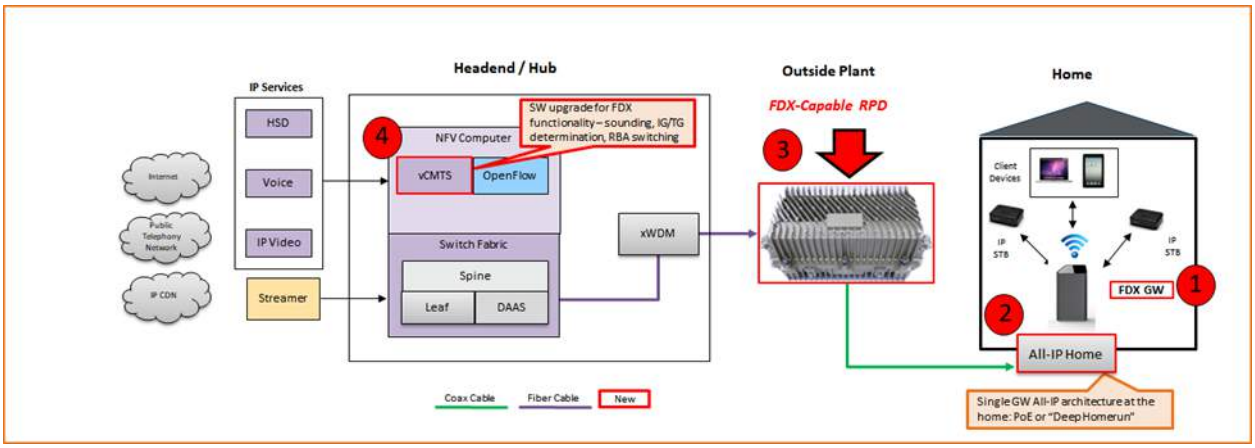

**Figure 18 - Network Component Upgrades for DOCSIS 4.0 Full Duplex**

### *4.3.1. Consumer Premises Equipment (CPE)*

As with DOCSIS 2.0, DOCSIS 3.0, and DOCSIS 3.1, support for FDX requires new silicon development to implement the wider upstream, the additional OFDMA blocks to fill it, and to enable EC. Support for the new scheduling aspects are also necessary, although this is SW functionality and not necessarily a new hardware requirement. Existing DOCSIS 3.1 modems are expected to participate in an FDX system in "FDX-L" mode, as previously described.

The overlapping spectrum means that the CPE gateway RF design deviates from the typical diplexer-first design, relying on an arrangement based on splitters/couplers to accommodate the overlap while maintaining legacy bands.

### *4.3.2. DAA Fiber Node*

Following the CPE upstream to the node, any node in an FDX system must also support the expanded bandwidth, OFDMA blocks, and Echo Cancellation. As with the home gateway, the internal RF design of the node must account for overlapping bandwidth in a way different than a traditional FDD node. This is one of the more complex parts of the node design – how to manage downstream and upstream paths to support additional couplers, while integrating EC functionality and minimizing RF losses affecting levels.

An example block diagram is shown in Figure 19, with new FDX items highlighted in red. The diagram represents a single node port or RF distribution and receive leg.

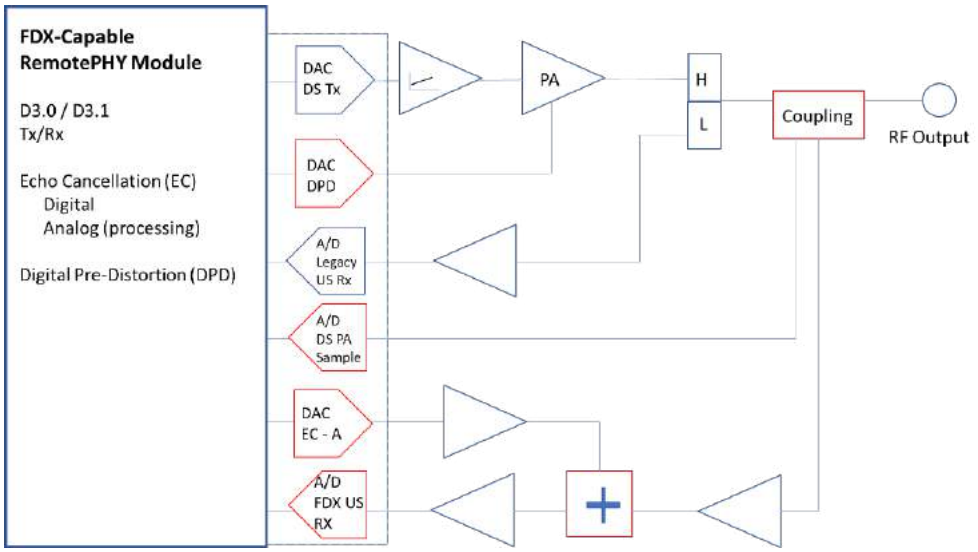

**Figure 19 - Simplified FDX-Enabled Node Diagram (Single Leg)**

It is possible that a DAA node can be a traditional FDD node on Day 1, and an FDX node later, when needed. Such a node would become FDX via a software upgrade and appropriately built-in hardware processing and RF capability. This would prevent future visits for FDX hardware upgrades.

### *4.3.3. CMTS Core*

As indicated, CMTS "sounding" determines IG/TG relationships. Fundamentally, the sounding process measures relative relationships of devices to one another to determine who may need to be kept apart to avoid interference when spectrum is being shared. It uses that information to adapt the scheduler to prevent interference when FDX CMs are transmitting. It does this by scheduling them in time slots that keep them away from vulnerable receivers based on the IG/TG matrix.

Note that IG/TG relationships are not static. New users can be added and subtracted, and devices may be moved around in a home or business, affecting network characteristics. While not very dynamic, the system has to periodically re-execute "sounding" to establish the correct IG/TG matrix for the scheduler.

The network itself is also not static. Again, while it does not change dynamically, it can move slowly over time and temperature, and/or have maintenance done that affects channel characteristics. The EC must track these and adapt accordingly. There are not explicit transient behaviors or convergence time requirements in the specifications, so this is an area that has seen significant characterization and is ripe for potential optimization and differentiation.

Lastly, as shown Figure 17, in the feature-complete implementation, the scheduler will support optimized RBA allocations that follow the needs of the traffic demands and service tier distribution among the IGs. Today's DOCSIS 3.1 schedulers are sophisticated, and their capabilities not fully leveraged. FDX will add the additional layer of IG/TG no-go zones – at first as simple as a "look-up table," but that will eventually become more dynamic based on traffic patterns, as use of the FDX band becomes better understood.

### 4.3.4. Home Architecture

The FDX specifications are written from a system engineering standpoint, assuming a point-of-entry terminating home gateway. Analysis was done that considers a single gateway termination, but one that may be located deep in the home, increasing RF loss. We refer to this as the "deep homerun." The advantage of this approach would be that it would give the customer the ability to center the device for Wi-Fi optimization. Also, importantly, a self-install kit (SIK) approach can be considered as a cost-effective way to deploy new devices. SIKs are also highly preferred by customers, compared to visits from technicians, pandemic or no pandemic.

These home install options are shown in Figure 20.

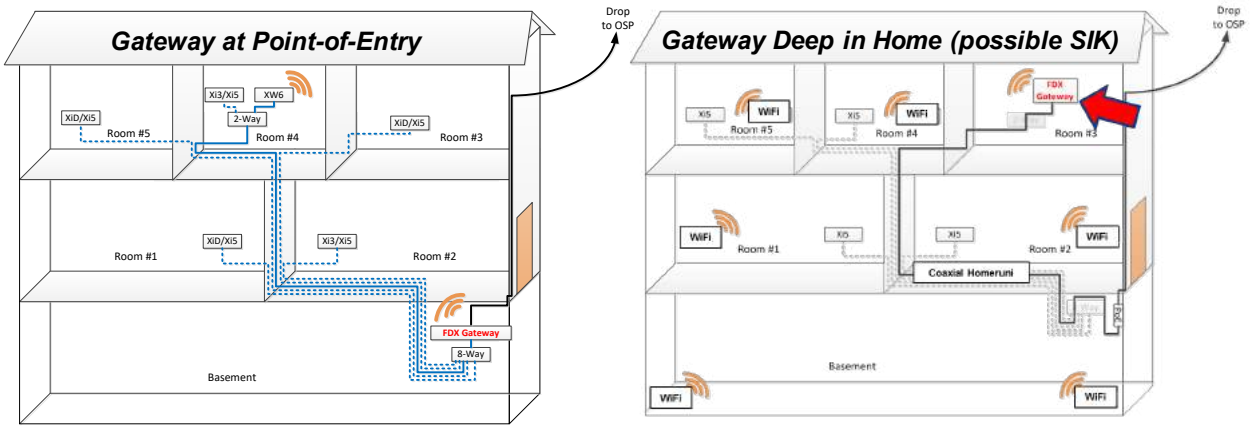

**Figure 20 - FDX In-Home Architecture Options**

With the practical complexities of having FDX upstream signals within the legacy downstream bandwidth of STBs, it is expected that an FDX home will become an All-IP home. This makes the "deep homerun" SIK approach more realistic if a proactive approach to determine the readiness of the home network for FDX is developed.

### 4.3.5. Development Progress

Full Duplex DOCSIS requirements began as an appendix to the DOCSIS 3.1 specification and was introduced as a CableLabs project in mid-2016. Recall, it uses the same OFDM and OFDMA-based physical layer for downstream and upstream communication, with the extension of the upstream band to include 108-684 MHz. The Engineering Change Release for this update was in late 2017, and the "cleaned up" spec released in early 2018. Comcast embarked on a node RFP for a DAA-based FDX node and RPD late in 2018 and launched the FDX development program mid-2019. All aspects of development above are underway. In the case of the CMTS, as noted previously, all of our DAA deployments are done with a virtual CMTS (vCMTS), and all FDX will be done via DAA. Thereby, development of FDX features such as MAC management messages, sounding, scheduling, RBA switching, etc., are features under development on the vCMTS.

Current expectations are that 10G FDX end-to-end integration will be taking place in labs across key technology partners, CableLabs, and Comcast in 2021. Operationalizing FDX via tools, training, processes, and integration of services with existing back-office system will also be taking place in order to ready FDX for scalable roll-out. There will be more news to come in 2021 as the integration comes

together and we look towards early sites to prove out 10G FDX technology and multi-gigabit symmetrical coaxial last miles. Stay tuned for Gigamania!

## 4.4. FDX Spectrum Definition

As would be expected, a significant part of the development of the FDX specification was defining the spectrum plan. Lifting the upper spectral edge of the tried-and-true 5-42 MHz upstream/reverse signal path was no small task. The detailed outcome, published in [17], is the 108-684 MHz FDX band – so-called regardless of whether FDX channels occupy the entire band. Figure 21 shows the band plan definition as written into the DOCSIS 4.0 PHY specification [17].

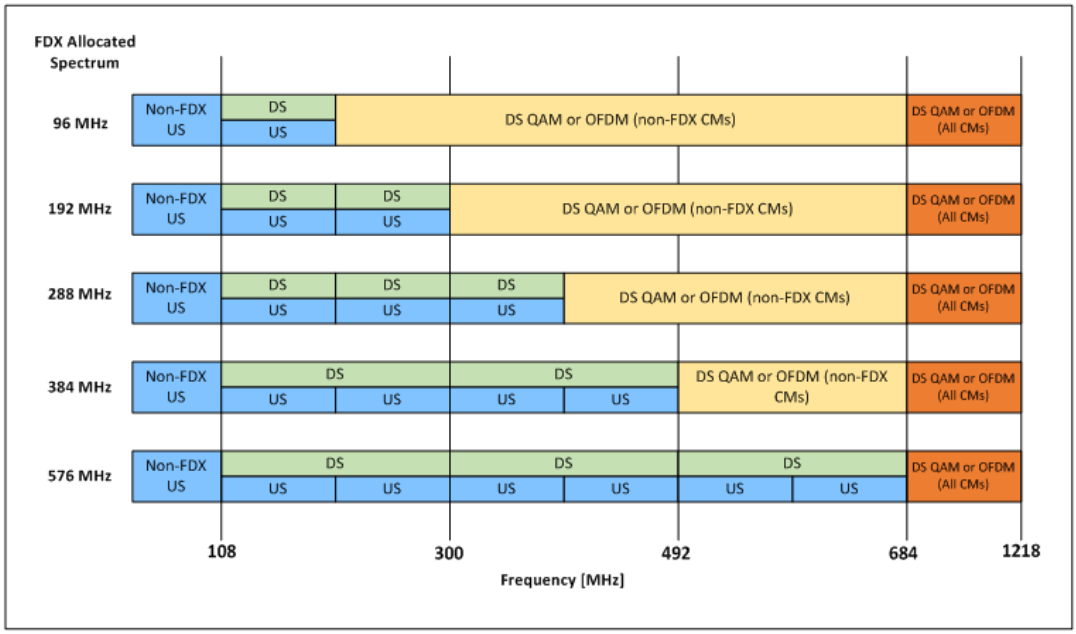

**Figure 21 - DOCSIS 4.0 FDX Band Plan [17]**

The MUST capabilities as articulated in the DOCSIS 4.0 specification include:

- Allocated FDX spectrum starts at 108 MHz
- 96 MHz of FDX Bandwidth: Located in a single FDX Sub-band from 108 MHz to 204 MHz
- 192 MHz of FDX Bandwidth: Located in two FDX Sub-bands from 108 MHz to 300 MHz, consisting of two 96 MHz downstream channels and two 96 MHz upstream channels
- 288 MHz of FDX Bandwidth: Located in three FDX Sub-bands from 108 MHz to 396 MHz, consisting of three 96 MHz downstream channels and three 96 MHz upstream channels
- 384 MHz of FDX Bandwidth: Located in two 192 MHz FDX Sub-bands from 108 MHz to 492 MHz, each consisting of a single 192 MHz downstream block and two 96 MHz upstream blocks
- 576 MHz of FDX Bandwidth: Located in three 192 MHz FDX Sub-bands from 108 MHz to 684 MHz, each consisting of a single 192 MHz downstream block and two 96 MHz upstream blocks
- The FDX downstream channel and upstream channels sharing the same sub-band must use the same subcarrier spacing and cyclic prefix length. The subcarrier spacing and cyclic prefix on different sub-bands are allowed to be different.

Now, because DOCSIS 3.1 enables a High Split upstream capability defined as up to 204 MHz, and because 1 Gbps is the first step to multi-gig symmetric services, the DOCSIS 4.0 FDX requirements also

accommodate the high split as a starting point. With FDX spectrum beginning at 108 MHz, high-split spectrum will overlap with FDX in the first 96 MHz block, between 108 MHz – 204 MHz.

Left to their own operation, a High Split upstream transmission could interfere with an FDX downstream. This is avoided by ensuring that existing DOCSIS 3.1 modems participate in the sounding and scheduling of the FDX band, although they will not be able to use the FDX downstream band. This is accomplished via the FDX-L software upgrade previously described.

The specification also calls out what are mostly intuitive rules for the use of non-FDX spectrum.

### *4.4.1. Operator Spectrum Management*

Figure 22 shows a typical view of the spectrum for an operator that has launched FDX. The specification basis is a 5-85 MHz Mid-Split upstream and a downstream spectrum to 1218 MHz. When activated, more upstream can begin at 108 MHz by adding 96 MHz at a time. The 85 MHz upstream bandwidth, under today's CAGRs, typical node sizes, and an average utilized bandwidth at peak-busy-hour (PBH), provides an upstream lifespan for many years (5-10 yrs.) when coupled with node splits or N+0. Thus, FDX spectrum is likely to be added to allow new product speeds above the approximate 300 Mbps limit of the 85 MHz band alone.

In Figure 22, the additional FDX bands above 300 MHz can be added as product demands deem them necessary, presuming operators have managed the rest of their DOCSIS 3.0 and video spectrum accordingly. Note that the FDX upstream spectrum can ONLY be spectrum allocated to where DOCSIS 3.1 downstream activities exist, and where that is so, the DOCSIS 3.1 device should be participating as an FDX-L modem.

Lastly, we note that product speeds over an 8-10 year time frame may move from 1 Gbps symmetric to 2 Gbps/2 Gbps, 3 Gbps /3 Gbps, etc. A 3 Gbps /3 Gbps service will extend the FDX band to the 492 MHz block edge (give or take and based on bps/Hz efficiency). This upstream allocation provides the spectrum necessary for the very rare bursts of full peak speeds. However, that spectrum is also available for use by the DOCSIS 3.1 downstream, between these rare bursts. By contrast, in an FDD system such as Extended Spectrum DOCSIS, there is still a need to allocate 492 MHz of spectrum for a 3 Gbps service. However, in this case it is a fixed upstream, set aside to be used only for the very rare upstream bursts. The vast majority of time this prime portion of coaxial spectrum sits idle. To compensate for idle spectrum no longer available for downstream, the entire plant needs to be rebuilt to extend the spectrum, including every active, tap and all in-home splitters, and in so doing also pay the penalty of another lost 100 MHz due to guard band above 492 MHz.

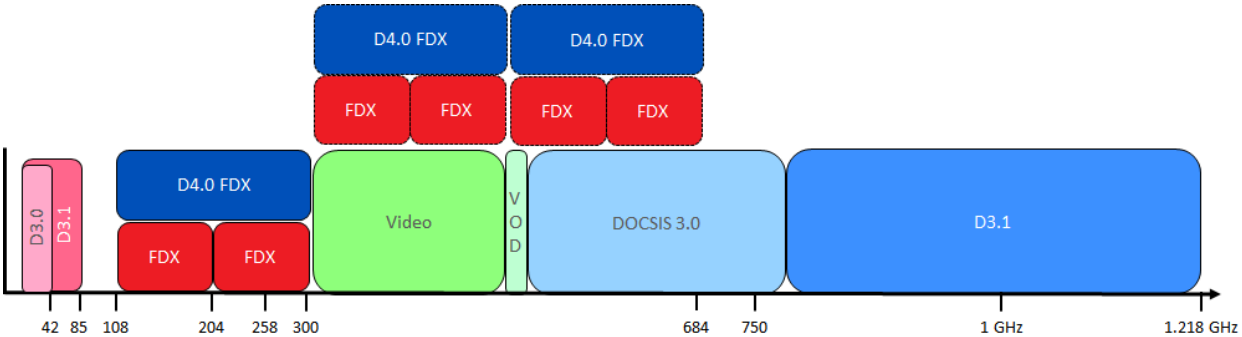

**Figure 22 - "Classic" View of Mid-Split Based FDX Implementation**

Figure 23 and Figure 24 show some of the practical scenarios to be accounted for as any FDX roll-out begins. In Figure 23, for example, High Split modems may be in the field alongside sub split modems and FDX modems. Often it is best to visualize the spectrum "as the node sees it" and "as the CM sees it," because the introduction of FDX and the mixing of CM splits on the plant tell a complete story. In Figure 23, we can see that as a node goes from High Split to FDX mode, the spectrum between 85-108 MHz is vacated, removing capacity from High Split only devices. This could matter to devices offering 1G upstream service, since High Split does not provide much margin above 1 Gbps of total capacity. It may, for example, force these CMs to move to an all-OFDMA upstream configuration if they are not already using that, or force the Time and Frequency Division Multiple Access (TaFDM) mode, whereby SC-QAM and OFDMA exist in the same spectrum in different time slots. Lastly, it could mean new FDX CMs for the 1G upstream users, since they are the more likely customers to require multi-gig performance sooner than the rest, and only FDX can go above 1Gbps.

The other item to identify in Figure 23 is that DOCSIS 4.0 downstream is shown in the 204 MHz to 300 MHz range, and a DOCSIS 3.1 downstream above 1 GHz. The line pointing at each is to identify this OFDM block can be in either location It is to point out that spectrum migration is a living plan, striking a balance between migration complexity and available empty bands to define the sequence of events. For example, if there is no spectrum used above 1 GHz, then adding more DOCSIS 4.0 (just DOCSIS 3.1 at that point) above 1 GHz can defer some of the complexities of overlapping FDX spectrum. Such a determination does not need to be made now, but as more DOCSIS 3.1 is demanded, the overall spectrum plan should be visited regularly against feature roadmap and device penetrations in selection of the optimal path forward.

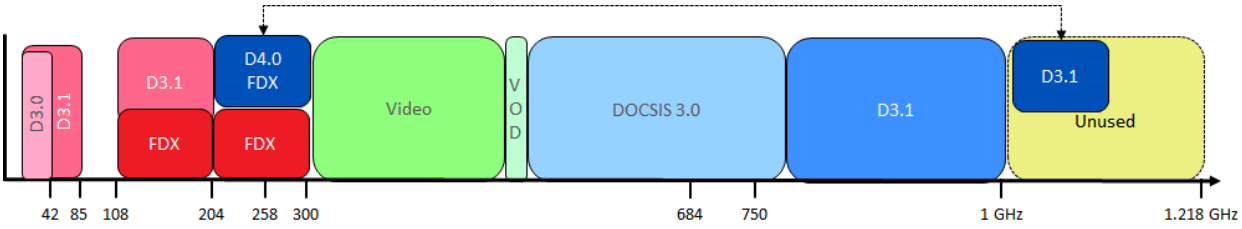

**Figure 23 - DAA Node in FDX Mode with Mid-Split, High Split and FDX CMs – Mid-Split based Diplex**

Lastly, consider Figure 24, which represents an FDX concept where the node in FDX mode has a High Split diplex instead of a Mid-Split diplex. New FDX spectrum is added "on top" of the High Split spectrum, as shown. There may be areas built only as High Split, such that an FDX upgrade that places 4+ FDX upstream blocks above the High Split band would enable current devices to operate as they already do, while allowing customers seeking >1G speeds upstream to obtain an FDX CM, and access the FDX channels beginning at 258 MHz.

As is common when engineers are tasked with defining what is often the far future when writing technical specifications, the specification's wording is ambiguous for anyone seeking to "comply to the letter" of its definition. However, this may be an implementable option and is currently being evaluated as a viable deployment model. As pioneering work on FDX integrations get underway, it is likely that many specification interpretations and meanings will need to be worked out among collaborating partners. This is a common component of technological advancements.

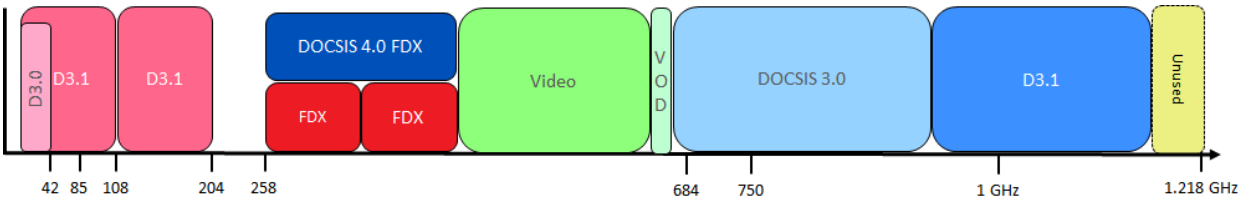

**Figure 24 - FDX Node Concept as a High Split Augmentation**

## 4.5. More DOCSIS 4.0

The 10G initiative is based on understanding the capabilities of the HFC network, and the emergence of key technologies and applications of the future. However, "10G" does not explicitly describe a "how-to." This is purposeful, because differences exist among MSO starting points and roadmaps. Different tools in the toolbox inevitably occur over time. A good example of this was different approaches taken to deal with the growth of HD television – analog spectrum recapture using Digital Terminal Adaptors, switched digital video (SDV), and/or 1 GHz expansion all were used.

Different approaches are also available for 10G. The DOCSIS 3.1 specification calls out optional use of spectrum to 1.794 GHz (which goes conversationally by 1.8 GHz). However, at the time (2012), the system engineering was deferred at that time, as this was not a 2012 priority. This has now been completed as part of the DOCSIS 4.0 specification and is referred to as "Extended Spectrum DOCSIS" or Frequency Division Duplex DOCSIS (FDD).

FDD goes beyond the original DOCSIS 3.1 upstream also, defining an upper spectral edge for upstream connectivity beyond 204 MHz, much as FDX does. The FDX upstream grid and current 96 MHz block OFDMA definition enables synergy between FDX and FDD. This synergy is shown in Figure 25.

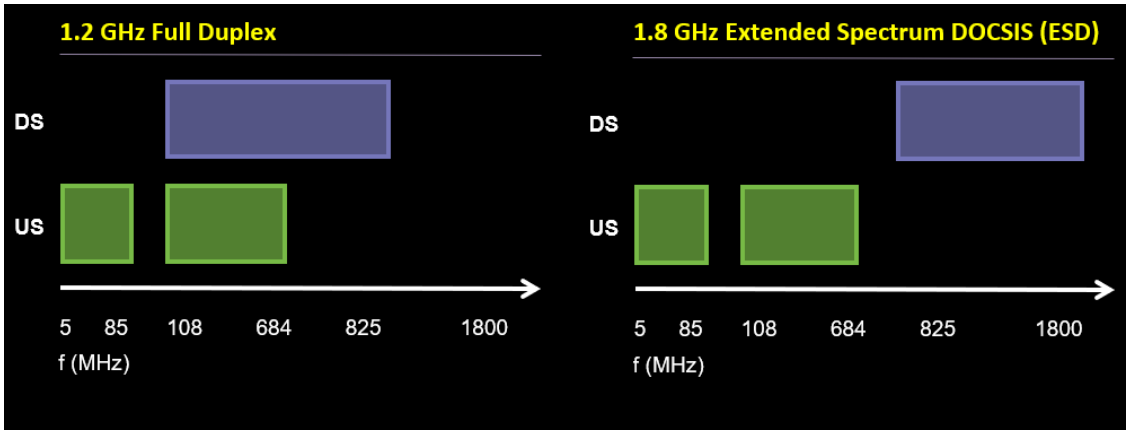

**Figure 25 - DOCSIS 4.0 Full Duplex and Extended Spectrum Increase DS OFDM and US OFDMA by Different Means**

As shown in Figure 25, a system design that supports both FDX functions and a 1.8 GHz downstream upper edge can have a common number of downstream OFDM and upstream OFDMA blocks. This is beneficial for silicon solution vendors when developing signal processing chains and sizing chip resources. However, they are allocated differently on the RF coaxial plant.

In a potential "DOCSIS 4.1" future, we can envision the two DOCSIS 4.0 technologies of FDX and FDD as complementary. The combined power of FDX and FDD provides yet another avenue for capacity expansion on the network. This is shown in Figure 26.

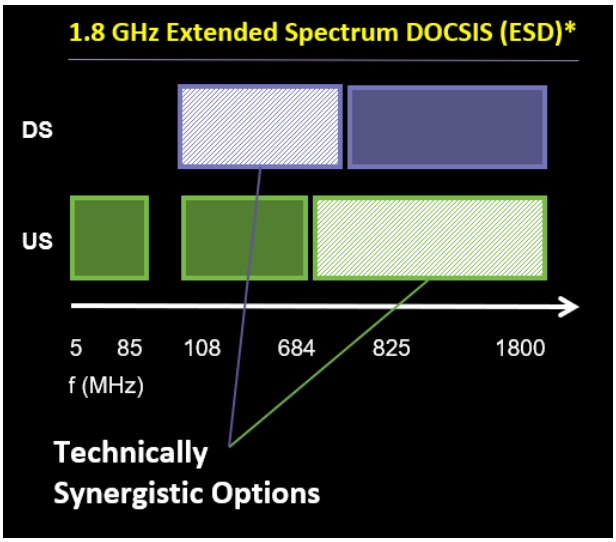

**Figure 26 - DOCSIS 4.0 Full Duplex and Extended Spectrum are Complementary in Nature**

## 4.6. FDX Amplifiers

### *4.6.1. Echo Cancellation-Based Amplifiers*

The FDX specification was written under the assumption of an N+0 network. This simplifies the introduction of FDX by getting fixed diplexed amplifiers out of the way, and it aligns with an architecture path some operators are taking. However, it is not technically limited to an amplifier-free plant. The EC technology developed can apply at any point in the network to manage overlapping spectrum, and this can include amplifiers. Of course, these are not traditional amplifiers, but a new class of device that includes this essential signal processing.

The system engineering aspects of EC-based FDX amplifiers includes:

1) How good does the EC need to be?

2) Amplifiers can have an "amplifying" effect on IGs, depending on the HFC design. How important is this?

3) How does the amplifier specification change with respect to RF performance? Are there cascade limitations?

An EC-based amplifier concept is shown in Figure 27. The nature of overlapping spectrum and gain in both directions creates a full-circle loop gain path, by design. There is a concern even in normal HFC amplifiers that indirect loop gains occurring in certain frequency bands could cause oscillation. The EC must, as a minimum, suppress this gain loop, meaning net gain around the path must be < 0 dB.

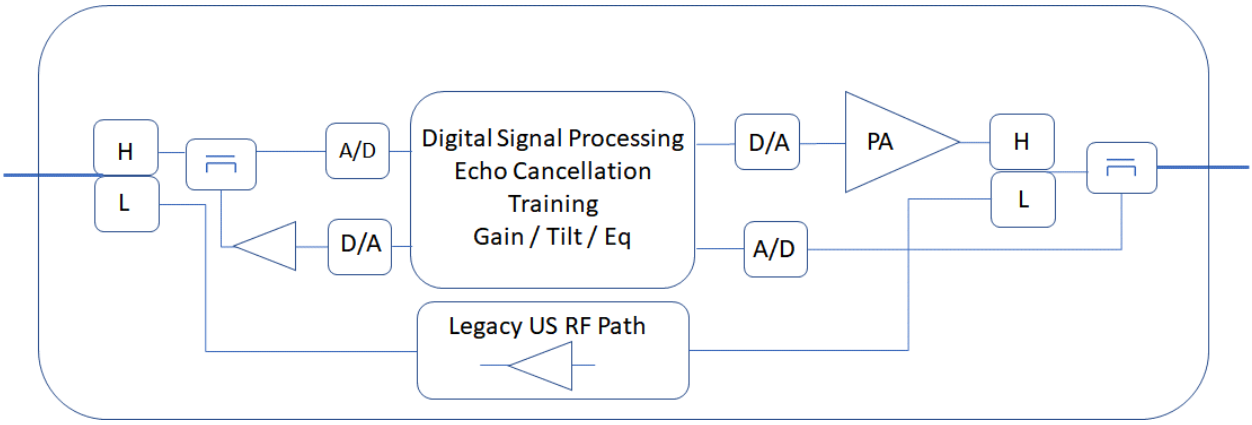

**Figure 27 - An Echo Cancellation-Based Amplifier to Support FDX Beyond N+0**

Echo-cancellation operates similarly to that of the node. A sample of the upstream signal is taken so that an opposite phase, equal magnitude version can be added in front of the downstream amplifier in Figure 27. Similarly, the signal from the downstream amplifier is sampled and an anti-downstream version added at the input to the upstream amplifier. As in the node, the EC adjusts for changes on the echo response.

Analysis of the EC performance necessary was calculated for two scenarios, based on common HFC amplifier RF level and noise parameters, and shown in Figure 28 [16]. The left figure shows the use of overlapping spectrum for the entire FDX band without constraints. In this case, the objective is to maintain high enough SNR (minimal residual EC degradation) to support the OFDM and OFDMA formats defined in DOCSIS 3.1, with the assumption being up to 2048-QAM in the downstream and 1024-QAM in the upstream, and assuming a reflection magnitude of -15 dB exists at each port. The EC performance requirement, shown along the X-axis, is about 75 dB before residual echo interference begins to impact the SNR required for 1024-QAM. Using the dB relationships between formats (3 dB per bit), these charts can be extrapolated in either direction (for more or less bandwidth efficiency) to arrive at EC requirements for other reflection or SNR assumptions under existing noise assumptions. For example, for a less-efficient 256-QAM upstream, which has a 6 dB lower SNR threshold, the EC requirement reduces to about 65 dB. These are challenging requirements, particularly for a single-stage echo-cancellation design.

For the second case, the amplifier is not required to support the simultaneous use of shared spectrum. In this case, the goal of the EC is to assure that the amplifiers are able to operate sufficiently in a linear mode, thus not degrading noise and distortion. This case, shown on the right, indicates that 25-30 dB is sufficient, which is a significant relaxation compared to the first case.

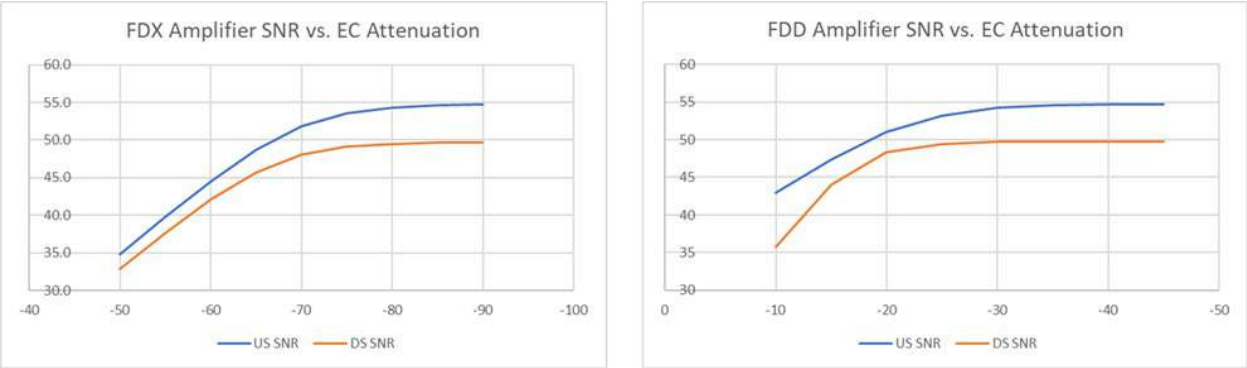

**Figure 28 - Worst Case SNR vs. Echo Cancellation [16]**

What this analysis points out is that FDX amplifiers are likely to be a tradeoff of complexity, cost, efficiency, HFC design, and also SW complexities associated with the additional EC to be trained and to manage. As well, possible refinement of IG/TG algorithms associated with RBA assignments to include the impact of FDX amplifiers.

### *4.6.2. RF Isolation-Based Amplifiers (No EC)*

Because HFC has always been an FDD system, diplex filters have always been used. Their purpose is to isolate downstream and upstream signal paths from each other. Diplex splits have evolved over time from 42/54 MHz to 65/85 MHz, 85/102 MHz, and 204/258 MHz. In the future, with Extended Spectrum DOCSIS, higher splits are expected.

The downside of diplexers are that when the split needs to be changed, it is labor intensive to change all of them (2 per amplifier) or swap active components. In addition, valuable spectrum – 20-25% of the band edge – is lost in the transition band to make filters of practical cost, size, and repeatability. The amount of MHz lost to diplexers increases with absolute band edge for the split. For a 492 MHz FDD split, it's about 100 MHz of lost spectrum!

An ideal solution would be an amplifier with NO diplex filters. This would make it feasible to build a transparent, flexible network with zero-touch for upstream/downstream spectrum re-allocation, and no guard bands.

There are two significant challenges to a diplexer-less amplifier:

1. How do you create an amplifier with loop gain below 1 to prevent oscillation?

2. How do you create a system able to work with real world return losses?

Consider Figure 29, which looks at the input port of a diplexer-less amplifier, where in their place are specialized multi-port directional couplers (MC x).

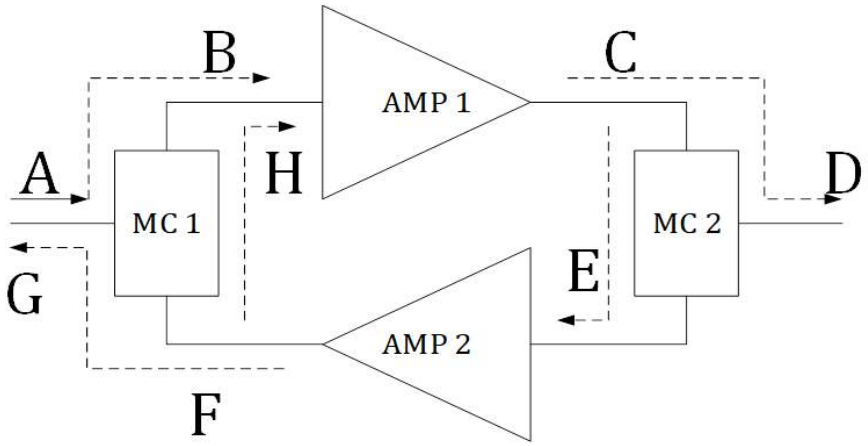

**Figure 29 - Evaluating the Signal Relationship of a Diplexer-Less Amplifier (courtesy Technetix)**

We define the following (all in dBmV):

A = input signal

B= (input signal A) – (insertion loss of the coupler MC1)

C = B + (gain Amp1)

D = C – (insertion loss of the coupler MC2)

E = (leakage of C in MC2)

F = E + (Gain Amp2)

G = F – (insertion loss of the coupler MC1)

H = (leakage of F in MC1)

Then, looking at the amplifier output to the downstream (point D):

D = (input A) – (Isolation MC1) + (Gain Amp1) – (Isolation MC2.)

Thus, the amplifier works only if:

(1) H < B :

(Gain of Amp1) + (Gain of Amp2) – (isolation MC2) – (isolation MC 1) < 1

(2) RL = G < A – 20dB :

(Gain of Amp1) – (isolation of MC2) + (Gain of Amp2) – (2xIL MC 1) < -20dB

An amplifier that can achieve both (1) and (2), can be a transparent, diplexer-less amplifier. By combining an amplifier with these two operating principles, along with a 54 MHz high-pass filter (HPF)

and a 684 MHz lowpass filter (LPF) – the edge of FDX or Extended Spectrum DOCSIS upstream – the frequency response behavior shown in Figure 30 is obtained.

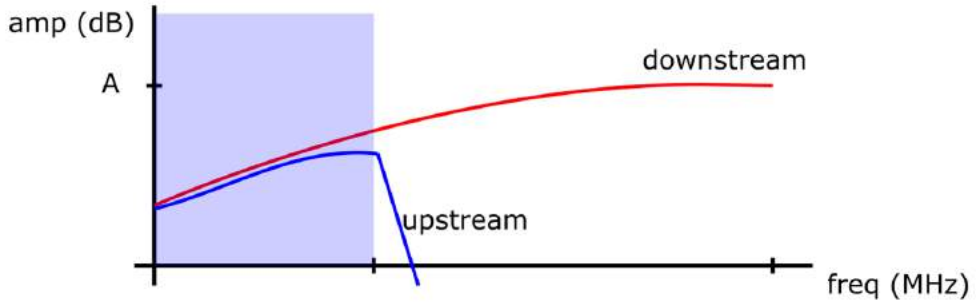

**Figure 30 - Forward and Reverse Freq Response Characteristic of a Diplexer-less Amplifier (Courtesy Technetix)**

In Figure 30, the purple area shows the region for which there is gain simultaneously in both the upstream and the downstream signal paths, without diplex filters in place. This creates a uniquely transparent and flexible network between the node and the customer premise, either by passing FDX signals seamlessly or by supporting any desired split that does not exceed 684 MHz in an Extended Spectrum FDD system.

From an FDX system engineering standpoint, the diplexer-less amplifier results in an extension of the echo cancellation capability in the time domain. For example, if a 5-tap string becomes a 10-tap string, reflections occur from further away points from the EC circuit. Typically, long-distance reflections also attenuate in magnitude with time. This will not be the case with gain in the return path that will forward along a reflection that is on the "south" side of the amplifier. This makes the job of the EC more challenging.

## 4.7. Traffic Engineering for FDX Services

Consider the case of an N+1 system based on FDX and shown in Figure 31. When an amplifier is included, using current tap RF performance, one of the effects is the expansion of Interference Group 4 (IG4) to the "south," or home-facing, side of the amplifier. These users become part of the last IG of the tap string before the amplifier. This is because of the limited drop-to-output isolation characteristics of today's taps.

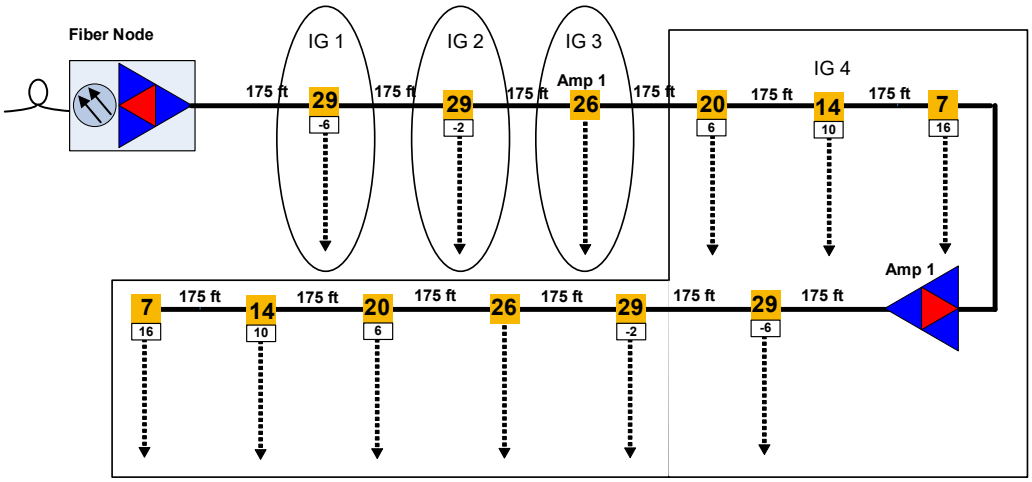

**Figure 31 - Potential Interference Group Expansion due to Amplifier on an FDX Network**

Taps with port-to-output isolation like those with higher tap values could eliminate this phenomenon. We have developed tap specifications with FDX requirements in mind.

Nonetheless, since current taps will be in the field for years, leading to enlarged IGs, traffic engineering analysis was performed to understand, quantifiably, the sensitivity of FDX performance to the size of an IG, the total spectrum, the service group size, speed tiers, etc. The empirically-based modeling is founded on real network traffic distributions gathered on production CommScope CMTS platforms over many years. Figure 32 shows the components of the traffic useful for helping to understand the problem and visualize the results [4].

The traffic can be broken into three components [4]:

1) Average Service Group (SG) Utilization = Number of subscribers in the service group x average utilization per subscriber at PBH.

2) Ripple = variations around the average utilization because traffic is bursty and not a constant stream equal to the average. Though statistically imprecise, the ripple is somewhat like standard deviation. However, it also encompasses a component tied to the probability of bursting to peak speed.

3) Max Burst = Just that, the moments when the traffic burst is 100% max'd out at the peak speed offering of the high speed data (HSD) product in this service group

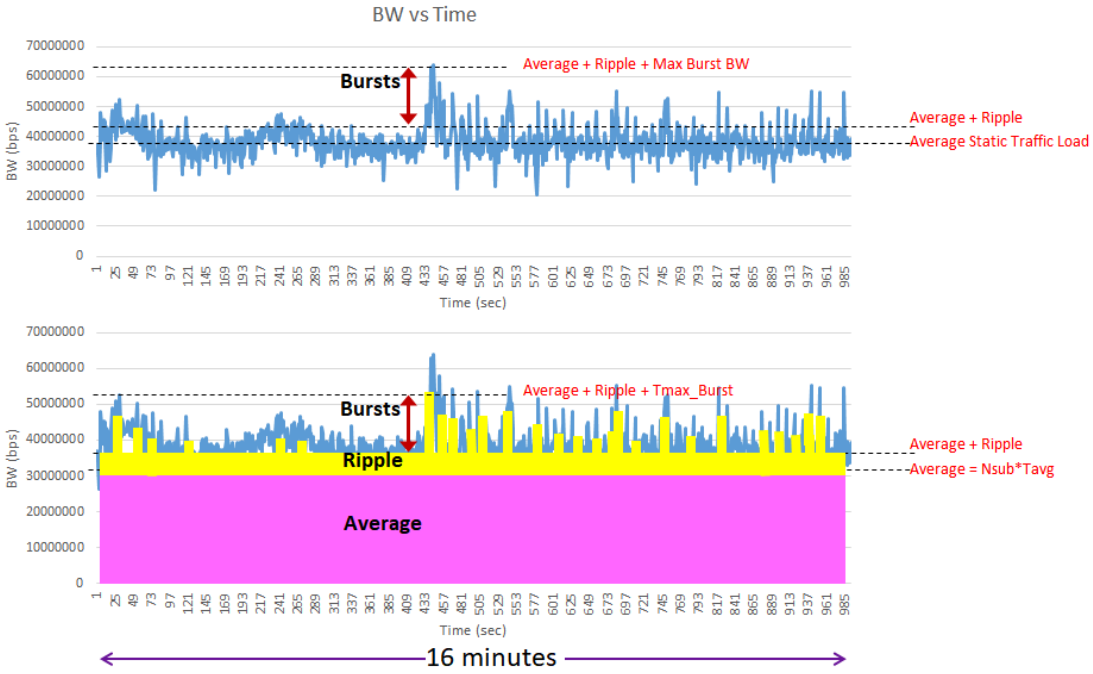

**Figure 32 - Breakdown of HSD Traffic Components [4]**

HSD product speeds directly translate into a minimum spectrum allocation needed to guarantee a maximum speed burst. Operators commonly allocate peak spectrum and an empirically derived additional capacity that accommodates the three components of Figure 32. On real networks, rules have been developed that link service group size, speeds, and percent capacity utilization to define the total capacity requirement. Then, with an awareness of device penetrations, this can be translated to DOCSIS 3.0 and DOCSIS 3.1 spectrum requirements. These rules were re-calibrated again with the introduction of DOCSIS 3.1 and 1 Gbps downstream speeds.

All of the above analysis and empirical rule making apply to FDX – it is still about downstream and upstream spectrum requirements to support certain product speeds. What changes for FDX is that the FDX band is allocated for both downstream and upstream. The infrequent bursts of peak speeds can therefore be called upon to service the downstream or the upstream, and they are not completely independent because of the IG phenomenon. Although from the node perspective there is full duplex spectrum operation, from the CM perspective the introduction of IGs places constraints on who can simultaneously access the spectrum. Figure 33 depicts this observation.

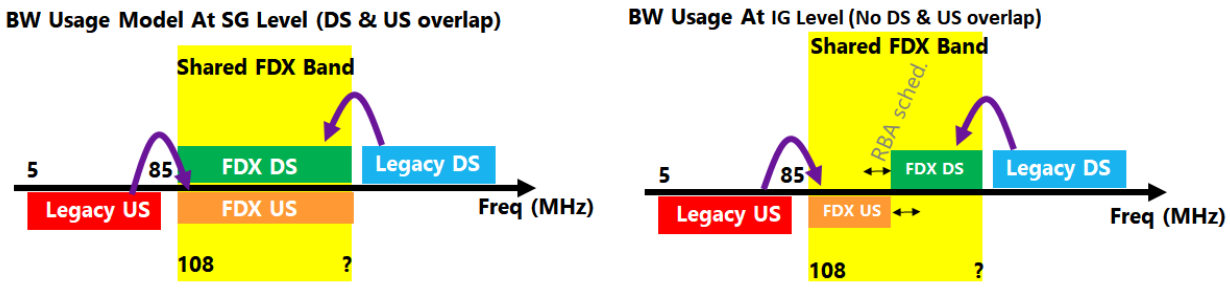

**Figure 33 - Managing FDX Bandwidth to Guarantee Peak Speed Bursts [4]**

Shared spectrum does not automatically mean peak bursts within an IG will compete for FDX spectrum. It depends on how much FDX spectrum is allocated, the distribution of peak speeds, the maximum speed offering, and of course the size of the IG and the number of subscribers in general. However, the FDX band carries around 5 Gbps. So, as speed tiers increase, at some point, from the perspective of an IG, there may not be enough FDX spectrum to avoid downstream and upstream burst demand exceeding available FDX band, as depicted in Figure 34. Naturally, it is much more likely to be needed for the upstream, since there is a substantially larger downstream allocation for DOCSIS 3.1.

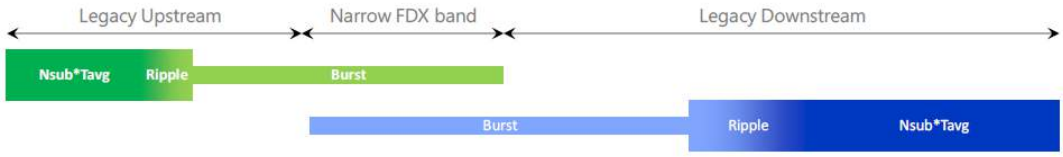

**Figure 34 - Representation of Colliding Simultaneous DS and US Bursts of Shared Spectrum [4]**

Some context may be helpful at this point. Development of the IG/TG concept was formulated during the early specification discussions of FDX. DOCSIS bandwidth has always been shared in the downstream and in the upstream with great efficiency by using relatively large service groups. For FDX development, instinctively there was a thought that having an IG as small as reasonably possible was a sound goal and would not significantly change the capacity utilization dynamics. A tap being its own IG, or several taps being part of the same IG, is what occurs using typical RF performance. There were not major concerns about the impacts of such small IGs; there was more concern about the process of sounding the network to define them.

The concern for IG/TG size increased when the concept of the FDX amplifier came into the picture to support FDX in non-N+0 systems. It was during system analysis with amplifiers that the IG elongation phenomenon shown in Figure 31 was uncovered. This led to questions:

1) How large can an IG be before there is an impact to the customer experience?

2) What service speed / IG size / spectrum rules exist when downstream and upstream traffic engineering become co-mingled in FDX?

We set out to find answers to these questions, working closely with experts with sophisticated HSD modeling tools at CommScope.

Figure 35 shows a model assessing the subscriber count, spectrum, QAM efficiency trade space for a set of input parameters projected for 2028 that includes a post-Covid average utilization baseline, assumed capacity CAGRs of 35% downstream and 30% upstream, and speed tiers up to 4 Gbps/4 Gbps. In these models every subscriber is given this peak service tier. Although the highest speed tiers are, in fact, typically the lowest penetrated, this obviously makes for a conservative analysis.

What can be concluded from this analysis and Figure 35 is that the subscriber group size (IG size) sharing FDX spectrum from 108-684 MHz can be as large as 64 (red circle) and stay within 1200 MHz of total spectrum, or even within 1 GHz for a 9 bps/Hz net downstream throughput average efficiency. The upstream, even for the 4 Gbps/4 Gbps (green) case, stays within the 576 MHz of maximum FDX band allocation, even for an IG size above 128.

What these studies reveal is that FDX bandwidth can be used extremely efficiently, shared across larger IGs than perhaps initially envisioned, and the statistical nature of peak bursts is better understood. What we have learned is these peak bursts are very infrequent per user, and the collision of bursts from concurrent peaking users is more infrequent still. With an 85 MHz legacy upstream, the upstream bandwidth is sufficient for PBH average utilization for a subscriber size of up to about 150-200 subscribers, shown in Figure 25 as approximately where the red arrow points to the FDX bandwidth breach. Thus, allowing the FDX upstream allocation to be a bandwidth reservoir for peaking users while still serving downstream capacity is an extremely efficient use of precious HFC spectrum, compared to setting aside hundreds of MHz of the highest quality HFC to, mostly idle.

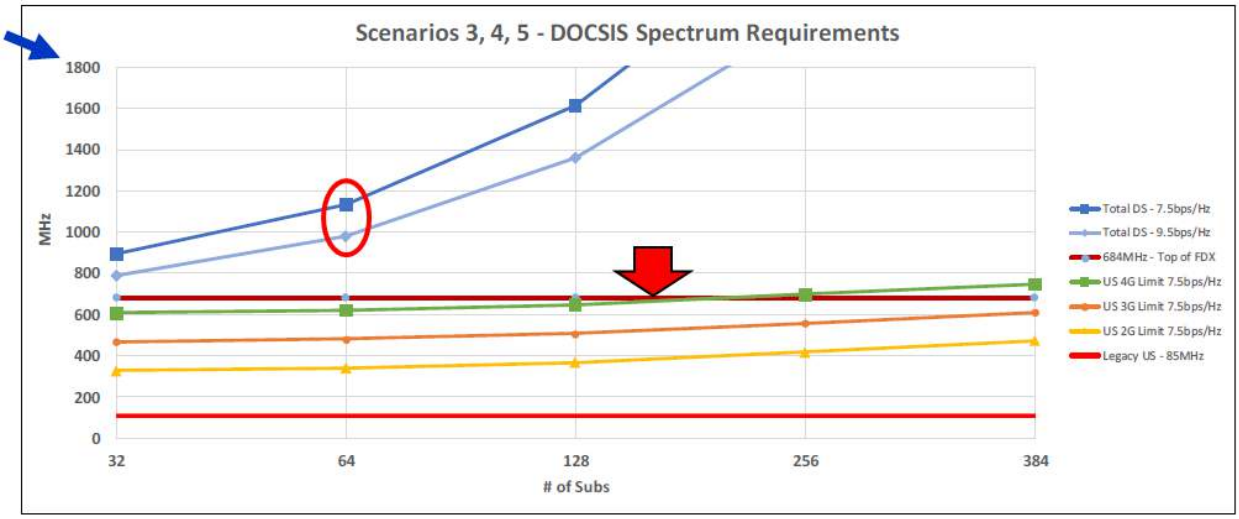

**Figure 35 - Total RF Spectrum Required vs Subs Sharing an IG for 3 Gbps/3 Gbps, 4 Gbps /2 Gbps, and 4 Gbps /4 Gbps [4]**

## 4.8. Operationalizing FDX

### *4.8.1. Echo Cancellation and Diagnostics - Live!*

As a starting point for understanding EC math, consider first a non-FDX signal. Let y(n) represent a noiseless signal presented to a receiver, which is a summation of the received signal, and its attenuated and delayed signal copies of delay, D.

$$y(n) = \sum_{d=0}^{D} b_d x(n-d) \quad (\text{non} - \text{FDX Signals})$$

The signal copies come from plant defects including micro reflections, and other frequency response effects like filter roll-off and group delay variation (GDV). Each delayed copy will be attenuated and phase-shifted by a complex coefficient, $b_d$ .

Non-FDX signals can be made quite robust, thanks to equalization technology available in DOCSIS today, enabling an efficient means of adapting equalizer coefficients that compensate for $b_d$, and deliver y(n) ≈ x(n).

By contrast, an FDX system will have both downstream and upstream signal components. At the node receiver, since signals overlap with no filters to separate them, the received signal y(n) is:

$$y(n) = y_{ds}(n) + y_{us}(n) \quad \text{(FDX Signals)}$$

The FDX echo canceller must estimate both the downstream signal, $b_0 x_{ds}(n)$ and its echo profile, $\sum_{d=1}^{D} b_d x_{ds}(n-d)$ to minimize the downstream contribution at the upstream receiver such that $y(n) \approx y_{us}(n)$, where:

$$y_{ds}(n) = \sum_{d=0}^{D} b_d x_{ds}(n-d)$$

In addition to echo-cancelled MER and the FEC, the coefficient $b_d$ can assist the MSO in understanding the impairments at the FDX receiver at any given time, similar to the familiar linear distortion impairment analysis that can be obtained from upstream equalization [15]. EC analysis can lead to a wealth of PNM knowledge previously unavailable because the non-FDX or traditional node receiver echo profile view was blocked by a diplex filter.

A sample echo profile is shown in Figure 36 in the brown trace labeled "Vendor EC", representing a snapshot of what an echo canceller would need to compensate for, when connected to a cable plant where the RF taps are spaced between varying lengths of cable (90-132 ft). If a time domain reflectometer (TDR) were to connect to the plant at the same location as the node, it would produce a similar echo profile, shown in the bottom blue trace labeled "VNA TDR."

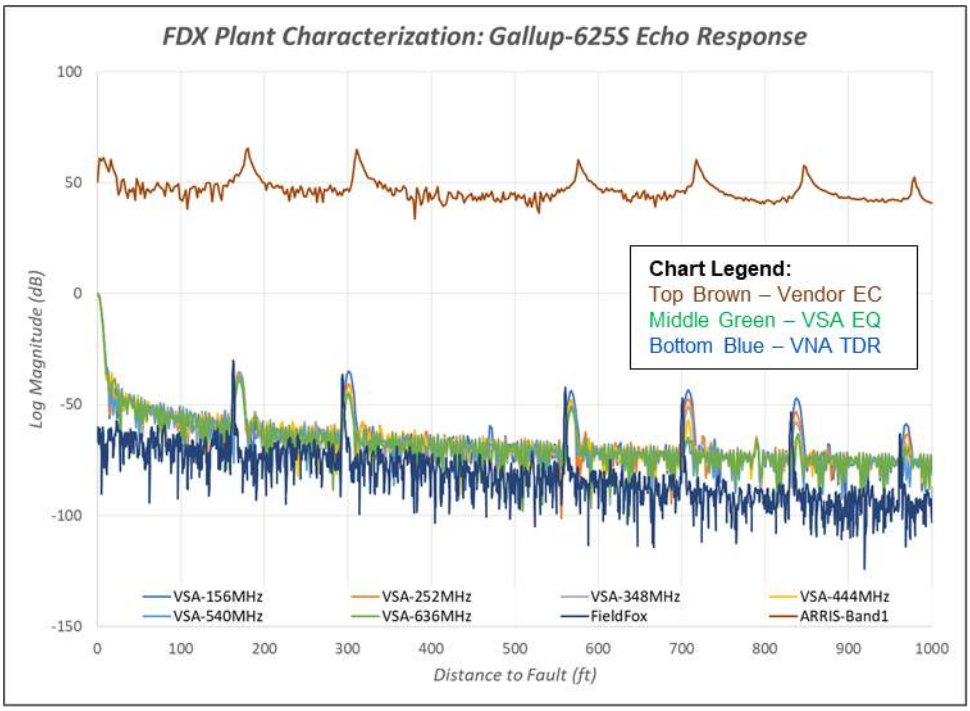

**Figure 36 - Echo Profile from New London, CT FDX Field Trial**

In Figure 37, the shaded block illustrates the coupling of a vector signal analyzer (VSA) and DOCSIS cable load generator (CLGD) via a resistive (low isolation) splitter at the same location of the node used in Figure 36. All of the remaining traces, labeled "VSA-156 MHz" through "VSA-636 MHz" are fully

adapted VSA equalization coefficients, $b_d$, at all of the FDX center frequencies associated with a 96 MHz OFDM block transmitted by a CLGD and received by a VSA. All VSA traces mostly overlap with one another except for minor differences at each of the tap locations, where it is clear the overlays are visible.

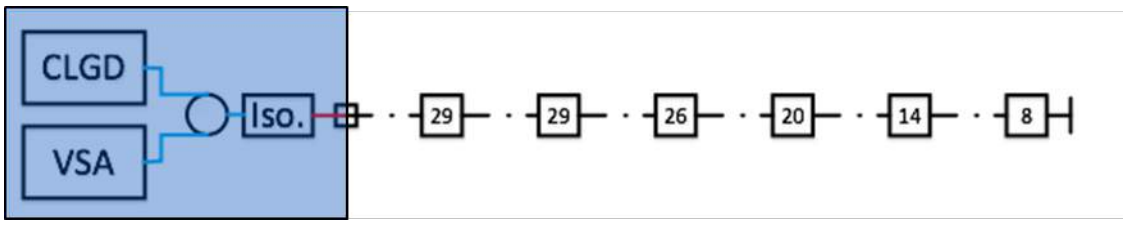

**Figure 37 - CLGD/VSA Echo Profile Coefficient Capture**

Diurnal and seasonal trends typically result in small and nearly continuous response variations over time. This includes changes in either temperature, or other weather-related events including wind loading. EC response data can tell us the same thing we'd learn by connecting a TDR at the node location. They can correlate to a plant map's precise location of every component, including taps, passives, splices, and cables. Each spike in the echo profile of Figure 36 corresponds to each tap within the feeder leg shown in Figure 38. The distance to the fault value of each spike directly relates to the length of cable between the node and each of the taps, specifically by a factor of 2. So, 90 ft between the node and the 2nd tap – a 2-port, 29 dB tap in Figure 38 -- is represented as approximately 180 ft from the fault measured in Figure 36.

**Figure 38 - CATV Plant Map Corresponding to Figure 36 Echo Profile**

It is expected that it will be reasonably easy for EC technology to adapt to these static or slow-moving echo profiles. Transient behaviors, on the other hand, can represent a more stressful scenario for EC. Plant maintenance activities alone can result in rapid and potentially discontinuous response variation over time. Some common plant maintenance activities include:

a) Tap face plate removal and insertion

b) Interference testing

c) Seizure screw checks (loosening and tightening)

Tap port termination quality was evaluated as well and showed negligible impacts to the echo profile.

Figure 39 shows how the reflections behave on a millisecond scale, as a technician removes or installs a tap face plate. When the faceplate is removed, an internal continuity switch occurs, resulting in a spike representing a nearly 30 dB change. In these cases, the EC will need some time to adapt to the abrupt changes, and both MER and FEC readings will also reflect this transition. However, MER and FEC will not be able to identify the precise location of where this change occurred. This is precisely where EC may provide MSOs with new value.

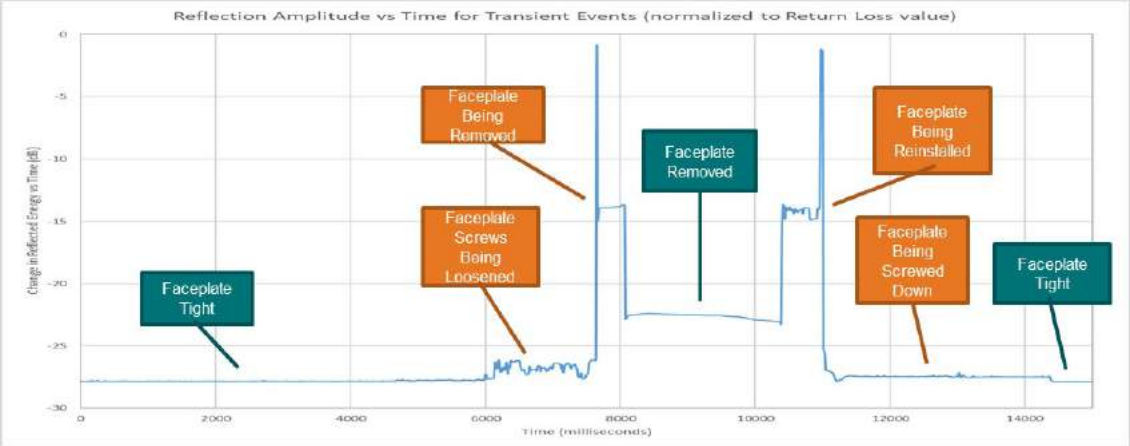

**Figure 39 - Single Coefficient Variation from Faceplate Removal and Insertion**

A potentially new operations dashboard may abstract away many of the gory details associated with analyzing EC echo profiles, perhaps only raising awareness when the EC has moved into a more aggressive mode of adaptation, due to a breach of a discontinuity threshold. This mode mostly provides confirmation of ongoing plant maintenance activities, but it can also assist MSOs in recognizing nearly equivalent changes occurring outside of planned plant maintenance activities. Those alerts, combined with precise location of the fault, could represent an unprecedented level of Proactive Network Maintenance.

### *4.8.2. Proactive Network Maintenance*

Speaking of Proactive Network Maintenance (PNM), it has been an integral part of the DOCSIS specification since DOCSIS 3.0. For nearly 15 years, cable operators have been learning how to harness the vast capabilities available within the PNM suite of tools. With the addition of Machine Learning and Artificial Intelligence (ML/AI), operators are gaining unprecedented visibility into the echo profiles of their coaxial distribution networks. These tools enable operators to remotely evaluate the spectral performance at nearly every location of plant that has a cable modem installed.

The (partial) list below summarizes why operators appreciate what PNM brings to the network reliability and positive customer experience fronts. The first four help to optimize the channel performance in the face of network variations that are different from one end-to-end connection to another. The bottom four are powerful tools for monitoring, identifying, troubleshooting, and remediating problems found.

- Upstream adaptive pre-equalization
- Channel estimate coefficients
- Downstream equalization coefficients

- RxMER per-subcarrier analysis
- Full Band Capture (FBC) spectrum analysis
- Spectral Impairment Detection (SID)
- Triggered upstream spectrum capture
- Active and quite probes

What do these PNM capabilities all have in common? Most of them can play at least some role in directly or indirectly measuring return loss and reflected energy within the coaxial plant. These tools can be used together with system design maps to inform echo cancelers in FDX deployments.

Typically, the PNM tools are used to detect, analyze and troubleshoot problems within their respective RF spectrum and direction. For example, in the case of upstream adaptive pre-equalization, DOCSIS station maintenance requests are used to continuously monitor and adapt the upstream channel for micro-reflections (echoes). Our PNM systems provide a high-resolution analysis of DOCSIS channels in use. In the case of a typical 24-tap SC-QAM pre-equalizer, there are resolution limits to the equalizer. For example, a 6.4 MHz wide SC-QAM channel will have a symbol rate of 5.12 Mbps, resulting in approximately 213.33 kHz resolution bandwidth (RBW). However, using DOCSIS 3.1 OFDMA upstream pre-equalizer coefficients, RBW will be as high as 25 kHz, and typically 50 kHz.

Collecting, analyzing and grouping the pre-equalizer response signatures results in an exceptional system for locating small pockets of network impedance problems that cause low frequency echoes. Figure 40 illustrates the effectiveness and accuracy of this technique. While the current DOCSIS upstream spectrum operates at lower frequencies than FDX, this will undoubtably play an important role in troubleshooting and maintaining our physical plant. Having the echo response at these low frequencies enables operators to pinpoint virtually every impedance mismatch on the outside plant. It's also important to note that pre-equalization is available on all DOCSIS compliant devices since version 1.1.

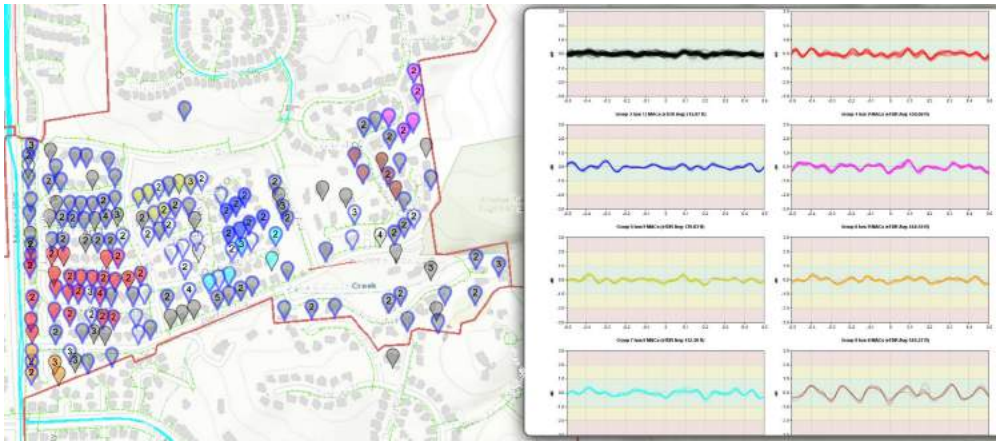

**Figure 40 - Upstream Adaptive Pre-Equalization Analysis; Echo Response Groups, Mapped**

Arguably the most useful PNM capability for troubleshooting RF performance is downstream Full Band Capture (FBC). The previously described technique of the pre-equalizer response grouping has been extended to downstream spectrum analysis. Figure 41 illustrates a common example of a standing wave,

created by a reflection cavity on the plant. Reflection cavities are created by two or more impedance mismatches, causing echoes that become superimposed to form standing waves. These waves have predictable periodicity that can be used to calculate the exact distance of a fault, if the cable type and length is known.

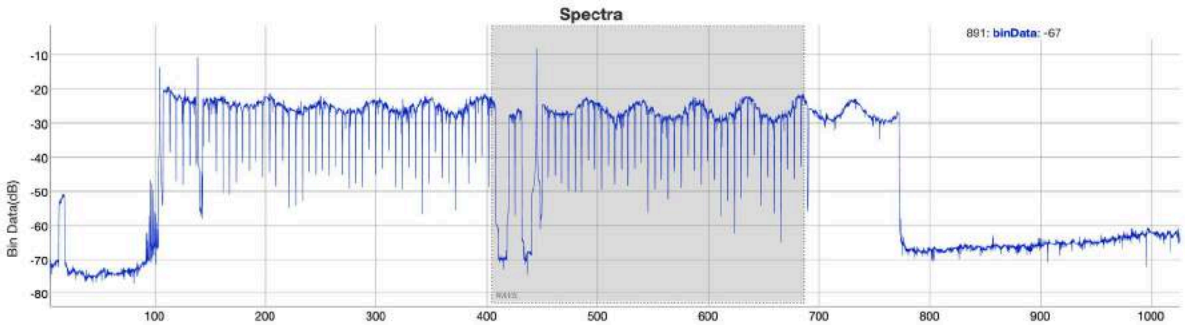

**Figure 41 - Downstream Full Band Capture, Standing Wave**

26 MHz to 1026 MHz at 117.18 kHz RBW

Similar techniques of signature matching based on Artificial Intelligence (AI) prove very effective at grouping common response issues. Figure 42 shows that the standing wave signature is localized to a group of 47 similar frequency responses. These 47 cable modems share a common 1842 foot .875 P3 trunk cable with a Velocity of Propagation (VoP) factor of 0.87. Having a peak-to-peak frequency separation of 47 MHz, the echo distance can be calculated using the speed of light in feet-per-second: (983,571,056 / 2) * 0.87 / 47 = 9 feet. In the case of this wave, the higher attenuation at lower frequency indicates that the primary reflector is near the launch end of the cable and the secondary reflector is most likely at the output of the node. In this example, the echo profile of this faulty cable can now be calculated in both directions, at any frequency within its operating range. Relying on well-known principals of antenna reciprocity, the important scattering parameters (S-parameters) can all be calculated for this network segment.

**Figure 42 - Artificial Neural Network, Response Grouping; Self-Organized Map (SOM)**

In summary, PNM tools have been around for a long time and have become extremely sophisticated at pinpointing plant issues, and typically before a customer would notice an impact. FDX relies by its very

nature on overlapping spectrum and knowledge of the plant echo characteristic over time. The advances in PNM align perfectly for the introduction of FDX, and the introduction of FDX will further empower PNM through the availability of EC coefficients, we well as the sounding and isolation information developed for FDX operation.

### 4.8.3. DOCSIS 3.0 and DOCSIS 3.1 Participation in FDX Sounding

Channel "sounding" is an essential tool for FDX. Cable modems transmitting at high levels in higher frequency spectrum will create new opportunities for co-channel interference (CCI) and adjacent channel interference (ACI) where isolation is insufficient. The ability to coordinate a sounding routine across all modems will be used to assign interference groups (IG). Similar to the PMA in DOCSIS 3.1, there will be opportunities to externalize the sounding routines, allowing for more context and better-informed IG modeling.

For example, a typical FDX deployment will co-exist with a majority population of DOCSIS 3.0 and DOCSIS 3.1 modems. In the case where a customer would like symmetrical multi-gigabit speeds, requiring an upgrade from DOCSIS 3.1 to DOCSIS 4.0 FDX, they will receive a new cable modem/gateway to replace the existing device. The condition of that customer's network and its upstream impact on adjacent customer communications will not be known until after the new modem is connected and sounding has occurred.

This scenario can be addressed by extending the sounding routines and adapting them to use the external PNM infrastructure. Having full band DOCSIS 3.0 and 3.1 spectrum analysis capabilities within the cable modems, the existing equipment can participate in the sounding routine. There are limits to using the log-magnitude data reported by the full band capture, such as lacking phase information. However, in early years of FDX availability, this type of analysis will provide useful information where FDX sounding clients may be sparse or non-existent.

### 4.8.4. "Inverted" Plant of FDX Band

Along with FDX, and like the High Split, comes a new paradigm of high-power transmission in higher frequency spectrum from the CM. In addition to CCI and ACI, there is another potential problem from these "inverted" levels in the plant. Due to dissimilar carbon content in the metallic cable components, and in the presence of electrical current, ionic migration is constantly occurring. In other words, corrosion is commonplace, and is especially exacerbated in the presence of water.

Corrosion in the form of a molecular junction is known to behave similarly to a diode and is often referred to as a corrosion diode. These corrosion diodes can function in unpredictable ways, often having resistive, capacitive and cascaded diode properties. One of the most common side-effects is a non-linear mixing effect that causes 2nd and 3rd order RF products. In traditional coaxial networks, this is known as Common Path Distortion (CPD) and typically occurs near the output of amplifiers, where composite RF power is high. In digital cable systems, the downstream channels become down-converted and mixed with the upstream frequencies, which are much lower in RF spectrum. The summation of the 2nd and 3rd order products typically manifests as an elevated noise floor in the upstream spectrum.

It can be anticipated that a significant number of corrosion diodes may exist in our collective drop networks, which tend to be older and less well maintained than the hardline portions of the plant. However, with the relatively low power levels of downstream RF in the drop cables, there is insufficient power to forward-bias any diodes that may exist. In the case of High Split or FDX, there will be higher power in the drop cables, which could begin activating countless dormant corrosion diodes. The resulting

2nd and 3rd order products could have significant impacts on performance. This phenomenon is referred to as Passive Intermodulation (PIM).

Fortunately, corrosion diodes tend to create impedance mismatches that can be detected and located using some of the previously mentioned PNM analysis techniques. The SCTE Network Operations Subcommittee for PNM has an ongoing workstream to evaluate the effectiveness of these tools for locating potential PIM sources.

### *4.8.5. Field Tools*

The fundamentals of cable haven't changed much since the advent of forward and return path RF, separated and protected by diplex filters. Our protocols have been designed to provide robust and reliable service, but human troubleshooting and maintenance are still required at times. FDX introduces a new level of complexity and data analytics that will become increasingly reliant on automations and algorithms to augment technicians existing tools for troubleshooting and repair. Many of the tried-and-true techniques for isolating service problems will have limited use in a world of bi-directional RF, and new processes will be developed and refined as FDX rolls out

# 5. Bringing Low Latency DOCSIS to Life

Without latency and jitter improvements, just delivering faster speeds will not guarantee the best customer experience. Low latency is pivotal to residential services such as gaming and video conferencing and are almost always tied into service level agreement (SLA) requirements for commercial services applications. The expectation that low-latency services will become increasingly important also revolves around AR/VR, IoT, and machine-to-machine (M2M) communications. Higher downstream and upstream utilization levels have an impact on latency, jitter and packet loss, that cannot be resolved only by increasing speed. These metrics and measurement techniques, in addition to speed and availability, must be integrated into design and operations and turned into actionable data. Although speed tests have been used as a measure of performance, other test tools tests have not yet been integrated into operations. Recent architecture changes have enabled MSOs to measure latency under load and without load. In this section, we will provide techniques and example performance that can be achieved in today's networks. We will then describe emerging features to deliver lower latency services as part of the 10G roadmap.

Current speed tests first check connection latency. Since the speed tests are performed during relatively idle utilization periods, connection latency measured between the customer router and test server within the MSO's network includes mainly basic DOCSIS media delay, as shown in Figure 43. For idle utilization levels and good network conditions, latency and jitter distributions do not have heavy tails of large values in their histogram.

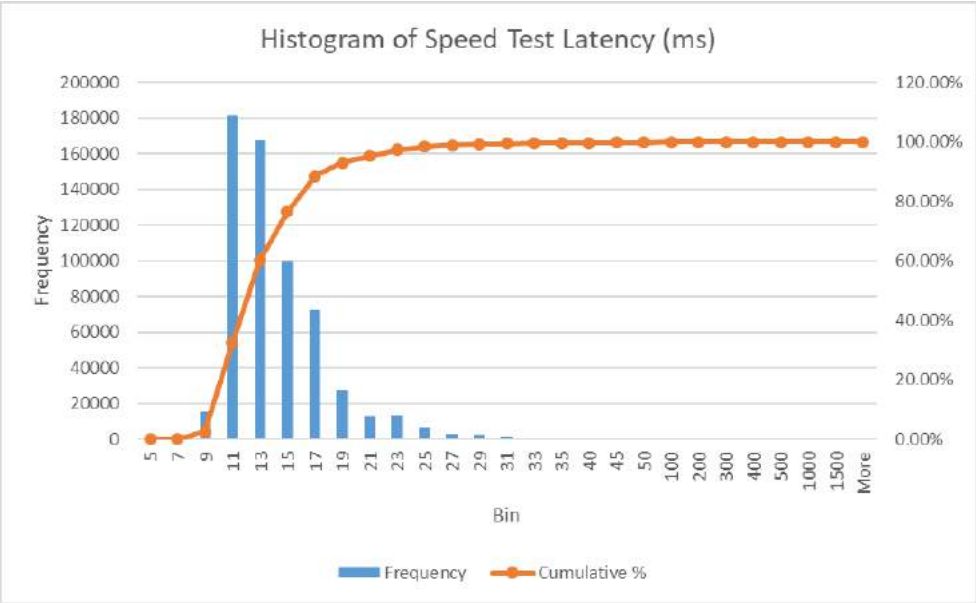

**Figure 43 - CDF of RTT Measurements Under Low Utilization Levels for a Mix of Different CM Types and Speed Tiers**

However, as shown below in Table 1 (https://cablela.bs/low-latency-docsis-technology-overview-february-2019), queuing is the largest source of delay when the home network is congested. Both downstream (CMTS) and upstream (CM) HSD service flow queues are single queues. Low latency services such as gaming may be delayed due to concurrent queue building (QB) applications, such as file uploads and downloads. It's the networking equivalent of "take a number." Furthermore, unmanaged large queues can lead to the "buffer bloating" effect. Finally, bonding group utilization and network conditions may delay packet transmissions, increasing queueing latency.

**Table 1 - Delay Sources in DOCSIS Networks**

| Delay Source | Upstream | Downstream | Total | Notes |
|---|---|---|---|---|
| Queuing | 0 – 100+ms | 0 – 100+ms | 0 – 200+ms | Largely caused by TCP |
| Media Acquisition | 2ms – 8ms | 0 | 2ms – 8ms | Request/Grant process w/ 2ms MAP interval |
| Serialization/Encoding | 0.38 – 2.8ms | 60µs – 720µs | 0.44ms – 3.5ms | Based on Channel Configuration |
| Propagation | 8µs - 300µs | 8µs - 300µs | 16µs - 600µs | 8µs/mile one-way based on furthest CM |
| Switching/Forwarding | 1-20 µs | 1-20 µs | 2-40 µs | Implementation dependent |
| **TOTAL** | **2.4 – 111+ms** | **68µs – 101+ms** | **2.5 – 222+ms** | |

Queuing algorithms vary widely among current CMTS and CM models, and DOCSIS versions. Buffer Control in D3.0, and Active Queue Management (AQM) in D3.1, aim to remove buffer bloat. Latency under load (LUL) measurements reflect the maximum latency/jitter a customer may experience under heavy home network utilization. Generally, these tests are done under downstream and upstream load, sequentially. Bi-directional tests are also used to measure the impact of downstream load on the upstream latency and vice versa. The FCC's "Measuring Broadband America" program, as well as third-party ISP rating tools, use LUL as a performance indicator.

If the queue size is not managed, customers may be affected by buffer bloat. An example is shown in Figure 44, which has a large queue setting in the CMTS. Traditional CMTSs have large physical queues. In this example, higher downstream speed tiers have downstream LUL smaller than 500 ms, compared to lower downstream speed tiers that can have ~2 sec maximum downstream LUL (top left) and 1-2 sec mean downstream LUL (bottom left). After optimizing downstream queue parameters, the same network has improved latency without degrading speed test results (top right, max LUL and bottom right, mean LUL).

Note that Figure 44 includes outliers and speed test failures that may be due to test and network issues in the test environment. Figure 44 also shows that although most upstream LUL readings are < 30ms, it may reach >100 ms depending on the upstream speed tier, buffer control, and queue management algorithms in cable modems. For example, CMs with buffer control where a 250ms default target latency is used have upstream LUL of around 250-300ms, much higher than CMs with optimized buffer control or AQM settings.

**Figure 44 - Maximum, Minimum and Mean DS and US LUL with (Left) High Target Latency Values for DS AQM and (Right) Optimized Target Latency Values for DS AQM**

Figure 45 displays the Cumulative Distribution Function (CDF) for round-trip-time (RTT) measurements between the CPE and measurement within the MSO network under real traffic conditions for a given test case. As expected, the latency values are between the idle latency shown in Figure 43 and the latency under load reading shown in Figure 44. The aggregate values show that the 85$^{th}$ percentile has RTTs of less than 50 ms. Although high speed tiers help to improve packet delay, the delay is not bounded, and packet delay variation (jitter) due to fluctuations in home network utilization, with bursty queue-building traffic, can cause a degraded experience. These bursts may be short lived and may have little impact on aggregate values, but the spikes may have a significant impact on services like gaming, videoconferencing and AR/VR applications.

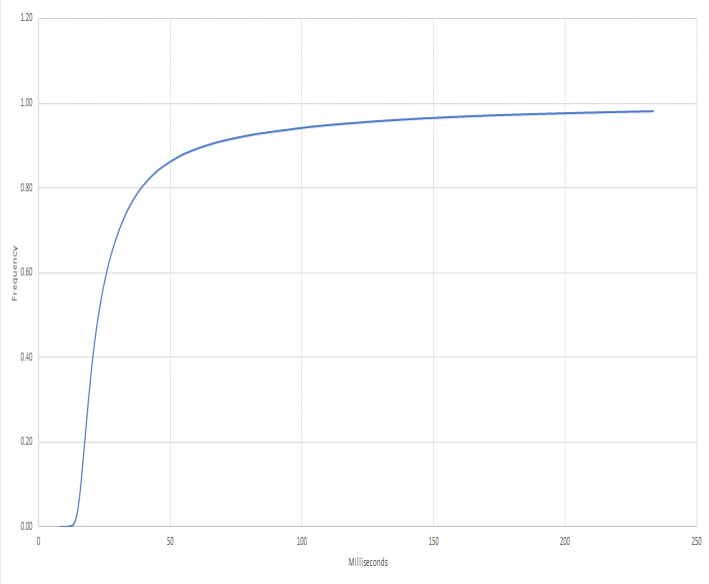

**Figure 45 - CDF of Connection Latency Based on TCP Handshake RTT Measurements Under Customer Traffic Load for a Mix of Different CM DOCSIS Versions and Speed Tiers**

Additional DOCSIS 3.1 LLD specifications aim to support bounded latency with three main new functionalities:

- Dual queue coupled AQM with queue protection
- Reduced MAP interval
- Proactive Grant Scheduling

Early results show that dual queue AQM can provide <10ms RTT for 95-99th percentile of packets for latency sensitive services. Proactive grant scheduling (PGS) aims to support ~1 ms RTT the 99th percentile of packets for latency sensitive services.

Deployment of a dual queue AQM approach requires other changes in the current architectures, including low latency service classification and markings integrated into operations. In addition to access networks, home (e.g. Wi-Fi) and core networks need to support these features for end-to-end support.

PGS requires more algorithmic development to optimize efficiency gain vs overhead with real traffic and to understand deployment costs and operational models.

# 6. 10G Security Initiatives

The 10G vision is most often associated with the capacity behind the “10 Gigabit” nomenclature. However, low latency is high among the 10G pillars, driven by gaming applications and more recently with the rapid growth of video conferencing, driven by the pandemic and work-from-home mandates/recommendations. However, low latency has a broad range of residential and commercial applications beyond gaming and Zoom/Teams/pick your most representative video conference app. The explosive growth in M2M and IoT are good examples.

The explosion of IoT devices and data, and other future applications, draw attention to another ever-more-critical area for customers – security. The smart home, security cameras, telemedicine, business data, and

industrial networks present services and application use cases with a high premium on data confidentiality and on the overall security of access and communications. Customers are hyper aware of the need, but at the same time don't want to think about it, and just expect it to be there, 24/7.

To consolidate a common 10G security vision across operators, CableLabs has several parallel programs targeting essential elements that look at both new applications as well as emerging technologies for operators' networks [18].

On behalf of operators, CableLabs is participating in key IoT Security forums in the Internet Engineering Task Force (IETF), National Institute of Standards (NIST), and the Open Connectivity Foundation (OCF), among others. Security of IoT services and devices is a common ground across the device and telecommunications ecosystem, and the cable operator perspective is being brought to these forums as standards and best practices are developed.

From a network perspective, the operator edge and access networks are beginning to incorporate DAA, which uses Ethernet-based optical transport, 10GbE today, and distributed compute and networking power in unsecured outside plant. Most operators' 10G vision involves DAA. This introduces a different type of security risk level compared to cable-specific analog optics and "dumb" HFC nodes. In addition, proprietary CCAP platforms – not invulnerable but purpose-built and highly customized systems – are giving way to virtual platforms, consisting of off-the-shelf servers and compute for packet processing, again creating a different category of security threat type. CableLabs' Distributed Virtualization Security is focused on threat assessment and recommendations for these NFV-based DAA systems, including understanding how similar problems are being tacked in other sectors moving in the same direction, such as the wireless and telco industries.

Another innovative program underway at CableLabs in support of 10G is the MicroNets project [19]. As the name may imply, MicroNets apply to the home, and aim to harden the home network against the increasing number of devices with a range of integrity. With applications racing ahead and devices multiplying, bad actors are at an advantage as standards for security mature. MicroNets recognizes this range of trustworthiness or hackability, and the basic premise is to create smaller networks, "micronets," within the traditionally single home LAN, with the walls of division associated with the security level of the devices and service. Issues that arise are isolated to a specific MicroNet, ensuring that as evolving IoT security addresses devices over time, adjacent devices and service are not impacted.

There is much more to come on the security front, as both emerging networking for 10G and target applications act to increase the significance of thinking through security up-front in the design development process.

# 7. Conclusion

Announced merely 21 months ago, 10G has rapidly become the industry's new North Star. As can be observed herein, the extremely efficient name of the initiative describes quite a wide range of technology elements that it is building upon and building anew. There are many reasons to be looking for the reset button for the year 2020. However, with the direct and critical contributions of our very industry, people and the network are adapting. Timelier than ever, progress towards 10G has not lost a step – indeed it is accelerating, as operators are moving from technology assessments and white board sessions to investment decisions, project definition and development (the fun stuff!). A comparison of 10G material from the 2019 SCTE Expo and the 2020 SCTE Expo shows remarkable progress on many fronts. It only magnifies the excitement for what 2021 will bring, masks or no masks!

## List of Figures

# 1. Introduction

Cable operators have embarked on a network transformation journey to evolve their networks from a centrally controlled, purpose-built platform to a distributed, programmable platform. A programmable network fabric drives service agility by allowing operators to create, change, and personalize services on demand, thereby shrinking service delivery intervals significantly. Together with business process automation and new service innovation, operators are well positioned to drive revenue growth and profitability. In this new era of service agility, operators will have to raise the bar on differentiating themselves on superior service quality to retain and grow their customer base amidst a highly dynamic and competitive landscape. In this paper we describe a powerful approach to service layer management utilizing packet data.

As operators evolve to a distributed, service-oriented architecture, the delineation between network and service management becomes more pronounced. Machine data (syslogs, telemetry, flows, session records, etc.) collected from the network elements is better suited for network management as they directly point to problems in the underlying infrastructure. Being vendor specific and fragmented, it is challenging to correlate machine data from various elements in the network to get an accurate view into service layer problems. A better and more direct way to identify service layer problems is to look at packet data, which is vendor independent, universally available, and carries all the contextual and relevant information pertaining to subscribers and the services they consume. Every transaction between subscribers or between a subscriber and an application leaves a footprint on the operator network which can be analyzed for service performance issues as well as security related threats.

Smart Data, which is actionable metadata derived from packets, delivers superior service management capabilities due to its high-definition nature. Smart Data coupled with Smart Analytics enables proactive service assurance, network automation, just-in-time resource management, SLA management and many other use cases at the speed and agility required for Network Operations 2.0. We also describe an actual operator use case for proactive service assurance of Wi-Fi networks.

# 2. Extracting Service Intelligence with Smart Data

Smart Data is high-definition, actionable intelligence derived from the ultimate source of truth, IP packets. It is contextual metadata that is structured, timely, and relevant. Smart Data gives operators complete visibility with holistic, end-to-end coverage of control and user plane traffic over multiple dimensions of their network, services, and subscribers. It addresses user experience covering all devices, network services, and applications consumed.

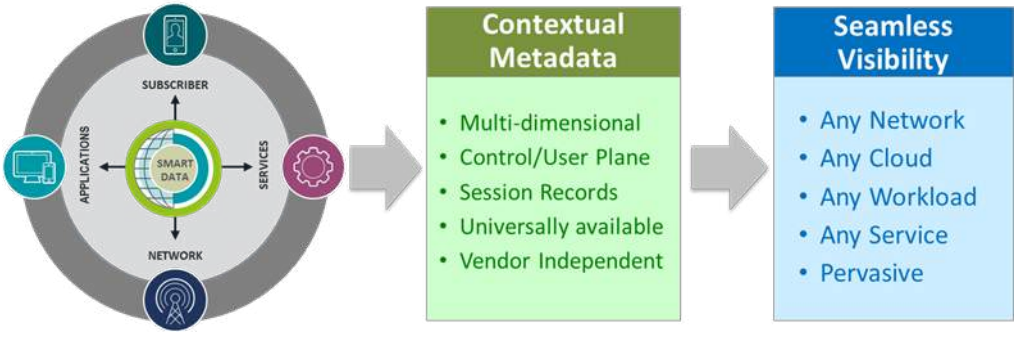

**Figure 1 - High Definition Smart Data**

Smart Data lowers the cost/complexity barrier of packet-based instrumentation and makes it affordable for pervasive edge to core deployment. Being a software solution it has an optimized, elastic footprint that scales up and down with traffic levels. It offers vendor independence by providing unified metadata with common views and workflows for any service (voice, data, video, IoT), over any network (physical, virtual, fixed or mobile), over any cloud (private or public), and for any workload (virtual-machine or container-based).

# 3. Addressing Operational Challenges with Smart Analytics

Smart Data is the fuel for Smart Analytics that addresses many operational challenges in current and future networks: providing proactive service assurance, enabling zero-touch automation, reducing churn and improving net promoter score, enabling just-in-time resource management, and advanced threat management for security operations. Having a unified data model that can be leveraged across functional and organization boundaries helps accelerate digital transformation by breaking down the information silos.

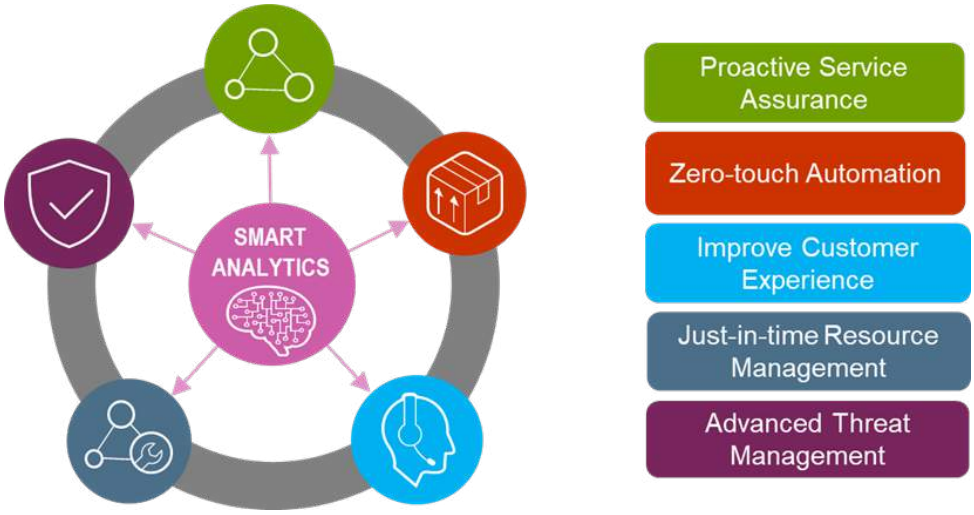

**Figure 2 - Smart Analytics**

## 3.1. Proactive Service Assurance

As services become mission-critical, especially for commercial customers, proactive service assurance becomes very important. Smart Data enables service assurance for proactive alerting, rapid problem isolation, and situational analysis. It helps in promoting trouble-free network operation by identifying potential problems before they become service-effecting.

For example, as cable operators deploy mobile services over a combination of Wi-Fi and cellular technologies (4G/5G), the complexity for end to end service assurance increases. Handovers across Wi-Fi and cellular technology domains must be carefully monitored to avoid dropped calls and degraded sessions. From an end user perspective, the service experience must be consistent and disruption-free across both network domains.

### 3.2. Enable Zero-Touch Automation

One of the benefits of moving to a software-centric network is that corrective actions in the network can be automated with little or no human intervention. In coordination with policy servers and orchestration platforms, service performance triggers based on Smart Data can be used to effect network changes in near real-time. Additional resources can be temporarily increased for virtual machines and containers to deal with traffic spikes in the network by the appropriate use of service performance triggers fed to the policy and orchestration platforms. Such "closed-loop" automation solutions can drastically reduce or eliminate service degradations that could negatively impact user experience.

### 3.3. Improve Customer Experience

Creating a composite customer experience indicator from Smart Data helps operators better understand their customer experience for the services they consume. Each user is measured for key performance indicators related to accessibility, retainability, and quality of experience for deriving the indicator. With such a customer experience indicator it is possible to visualize the experience for groups of users in different dimensions such as device type, location, service and more. When this indicator falls below the desired levels, network operations can drill down to the details of what caused the degradation. Understanding and rapidly responding to network causes for poor service experience is an important factor in improving customer experience and reducing churn.

### 3.4. Enable Just-in-time Resource Management

In a hardware-centric network, capacity management required careful planning because hardware had to be ordered and deployed ahead of realized demand. This process created inefficiencies and stranded capital in the network when demand would materialize differently than what was planned for. In a software-centric network, traffic data can be used to scale resources up or down in relatively shorter intervals than what was done before. Analytics based on Smart Data can be used to deploy just-in-time resources as dictated by key service performance indicators. Such a dynamic resource management process allows for more efficient use of capital as capacity deployments can be made to track more closely with the realized traffic demands.

### 3.5. Early Warning Detection of Advanced Threats

Security threats continue to rise. As networks evolve to a software centric architecture, new attack surfaces are exposed to potential hackers. Hackers have become more sophisticated and continue to develop new attack vectors for exploiting vulnerabilities in open source software and virtualized, cloud-native infrastructures. Smart Data provides deep packet intelligence to identify the potential onslaught of advanced threats which would otherwise escape detection. Sophisticated security analytics algorithms based on Smart Data provide early warning detection of anomalous behavior and alert operators for taking proactive actions to avoid service disruptions.

## 4. Smart Data Use Cases in Operator WiFi Networks

Wi-Fi networks are now held to a much higher standard than ever before. No longer is best effort wireless service considered acceptable. Additionally, the proliferation of MVNO agreements is further requiring the Wi-Fi service to be especially robust in order to meet subscriber experience requirements. Some of the common challenges that Cable MSOs face in offering carrier-grade Wi-Fi service include:

- Identifying customer login experience problems
- Problem isolation with limited subscriber feedback
- Identifying Wireless Access Gateway problems
- Last mile customer experience telemetry
- Controller stability
- Determination of Wi-Fi performance for operator provided devices versus other devices

This paper will focus on the first three use cases and will demonstrate how the use of Smart Data can help operators become more proactive, isolate the source of problems and reduce service disruptions.

## 4.1. Instrumentation

Proper instrumentation and Smart Data generation in modern operator Wi-Fi networks requires tapping and monitoring of the links that surround critical application flows that make up the wireless service offering. Figure 3 below shows the common visibility points (indicated by the NetScout logo) in an operator Wi-Fi environment for maximum visibility.

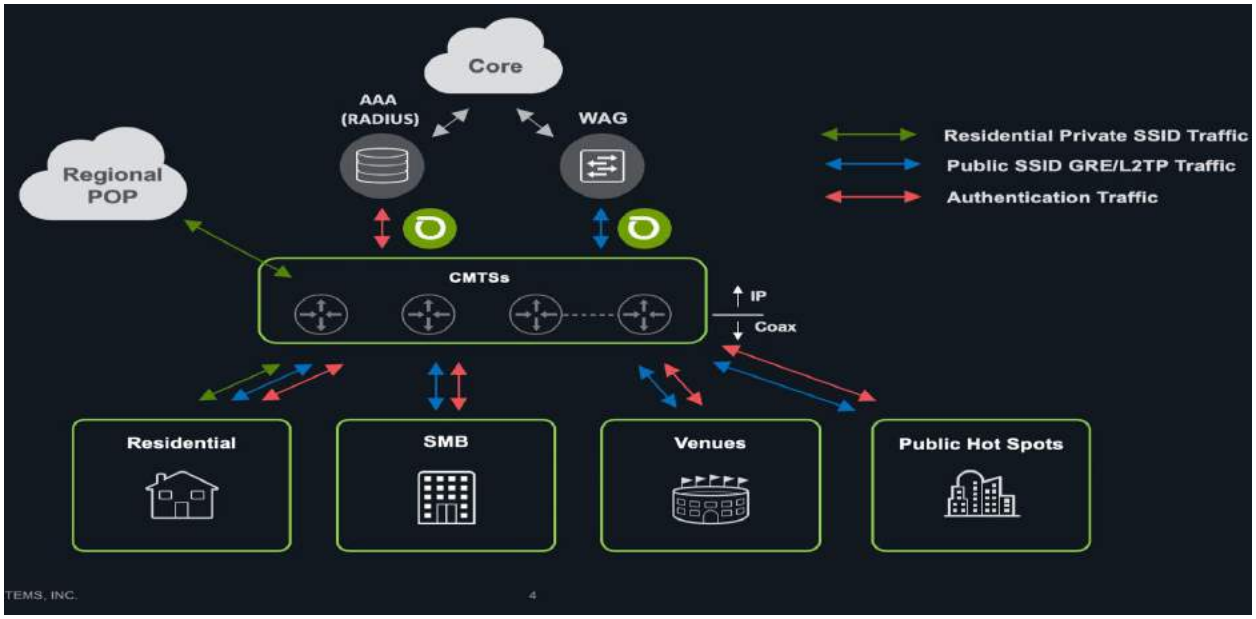

**Figure 3 - Wi-Fi Instrumentation Points**

## 4.2. Use Case 1: Slow Customer Login

In many public carrier Wi-Fi environments there is an inherent lack of customer service calls from the subscriber base even during a systemic outage. Subscribers traditionally have grown to view public Wi-Fi as best effort. This is changing rapidly. The ability to use packet-based Smart Data is more important than ever to solving problems quickly and identifying the true subscriber experience. Packet-based metrics are the ultimate source of truth and play a critical role in reducing churn and allowing the operator to become truly proactive.

Figure 4 below illustrates how Smart Data can identify and report on how long it takes for a mobile device to attach and obtain an IP address from the operator Wi-Fi network. The login latency distribution metrics can be dimensioned based on market, region, physical location, AP vendor or even client MAC address.

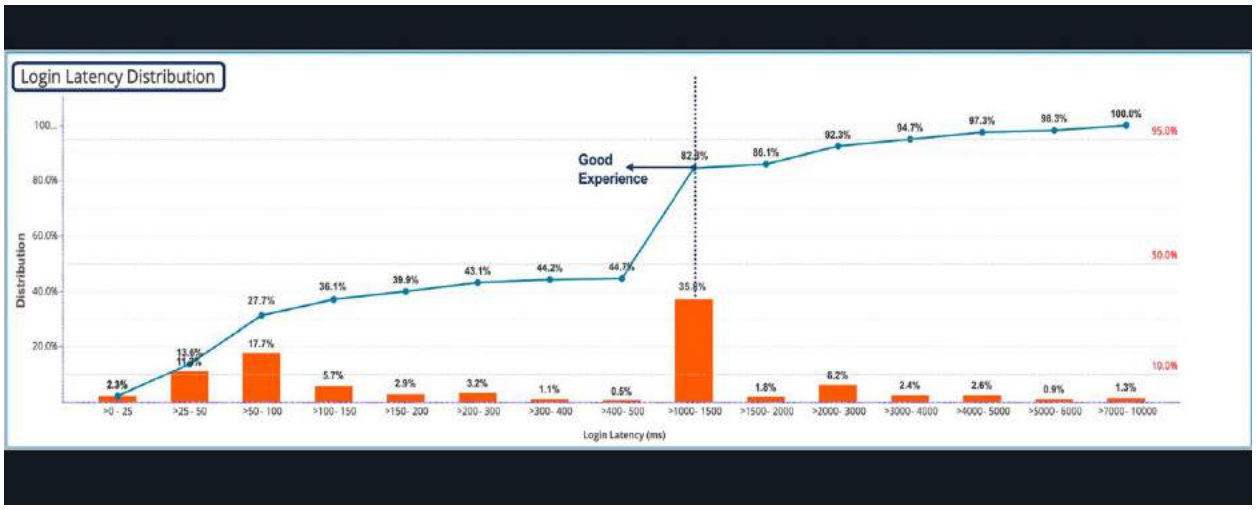

**Figure 4 - Login Latency over Time**

The figure above illustrates that the majority of devices will get an IP address within the 1 second to 1.5 second range. The ability to trend such data over time and alert on deviations from baseline values is critical to assuring the Wi-Fi service and improving subscriber experience, further illustrating the value of what a Smart Data model can provide in such scenarios.

## 4.3. Use Case 2: Intermittent Customer Attach Problems

An MSO provider of Wi-Fi service had a low number of problem calls where business subscribers would state that their customers could not connect to their network while waiting for service. The number of calls was not highly significant but was enough to cause the operator to look into whether or not this was a systemic problem.

Using multi-dimensional Smart Data, the operator was able to look back in time at only business vanity SSIDs and trend the portal performance. Figure 5 below shows a 31-day service dashboard view of captive portal transactions for business SSIDs.

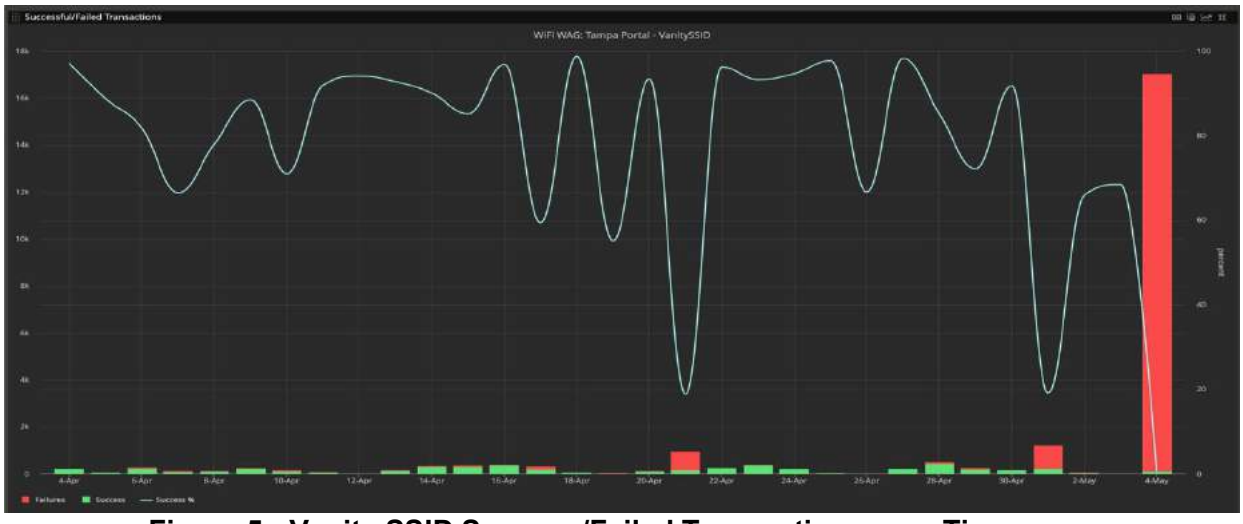

**Figure 5 - Vanity SSID Success/Failed Transactions over Time**

The operator found that there were periods of low success rates with one being the most severe. Figure 6 below shows a service monitor drill down into Vanity SSID portal transactions for that particular day.

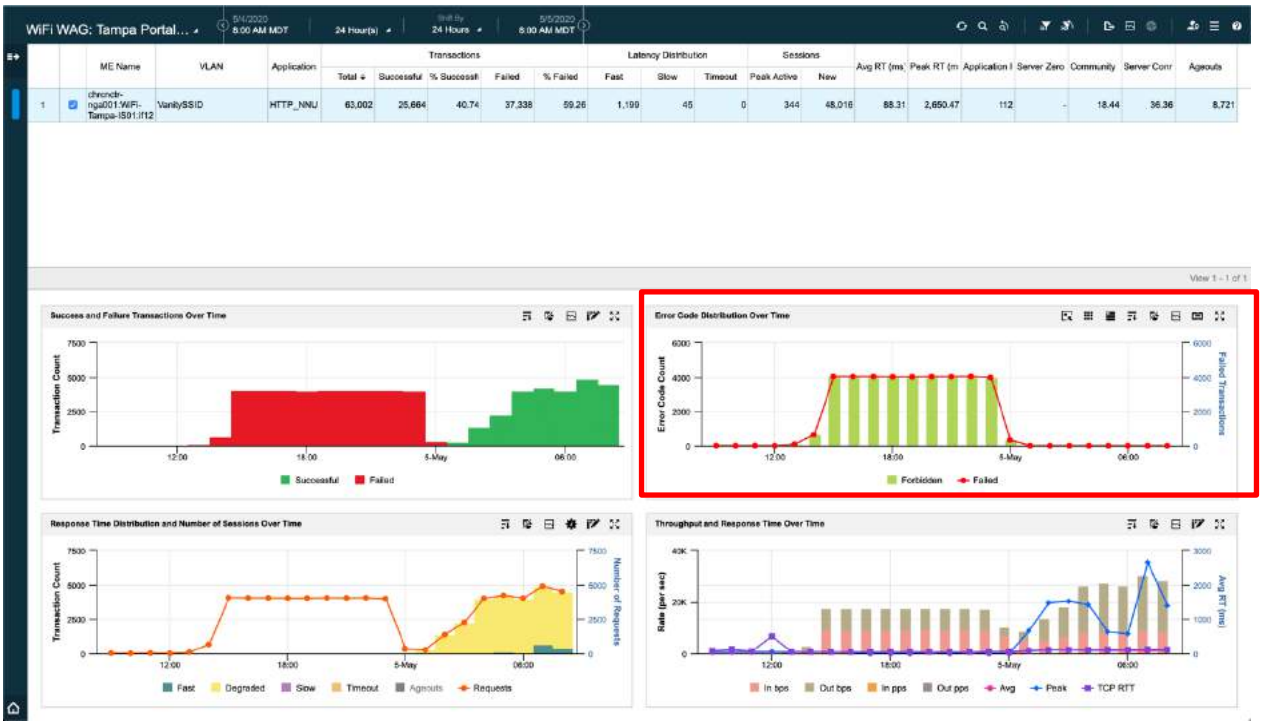

**Figure 6 - Vanity SSID Portal Service Monitor**

The service monitor shows that during the middle of the day there was a spike in HTTP 403: Forbidden errors. Further drilldown into the packet-based Smart Data showed that the devices that should have been granted access to the Wi-Fi network were not. This data allowed the operator to examine recent provisioning changes that were done incorrectly and put proper measures in place.

## 4.4. Use Case 3: Decreasing WiFi Network Usage

An MSO offering Wi-Fi service began to detect a downturn in usage over a period of weeks when the opposite was expected. Multiple systems including AAA were checked but nothing explaining the downturn was detected in the data that those systems produced. As a result the MSO turned to packet-based Smart Data to provide a view into individual device behavior.

| 10 | 1.575811560 | 100.64.250.1 | 100.64.250.250 | DHCP | 366 | DHCP Offer - Transaction ID 0x29bea3d5 |
| 11 | 2.064557190 | fe80::14a9:b772:673… | ff02::16 | ICMPv6 | 156 | Multicast Listener Report Message v2[Packet size limited during capture] |

**Figure 7 - Packets Showing Incomplete DHCP Exchange**

The packets in Figure 7 above revealed that there were devices that were not fully completing the IP acquisition process with the Wireless Access Gateway.

The raw packets were sent to the Wireless Access Gateway vendor and it was identified that there was a bug in their software that would prevent devices from completing the IP acquisition process in specific circumstances. A custom dashboard shown in Figure 8 was then produced to identify the same issue going forward.

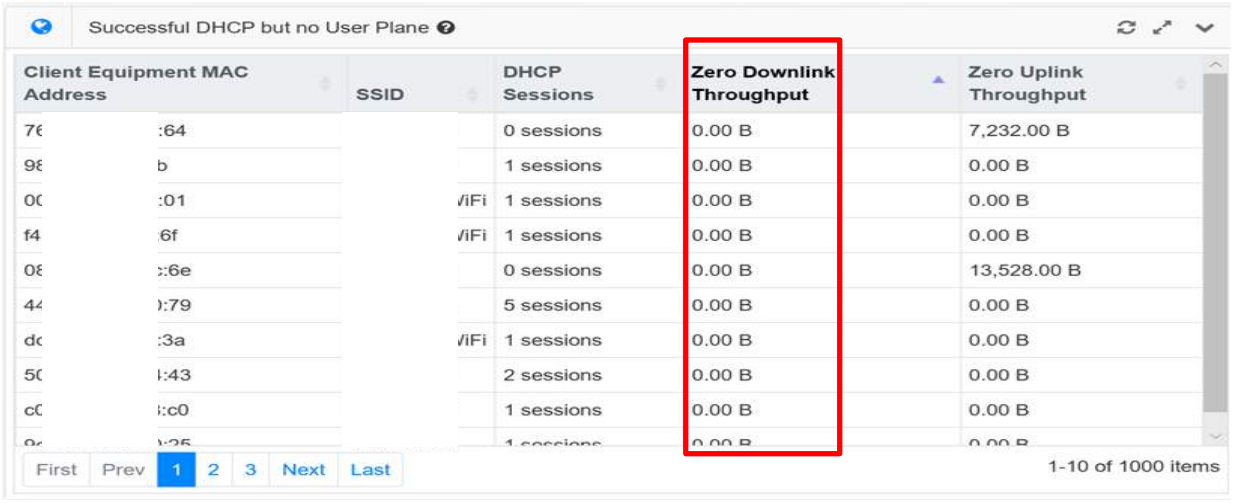

**Figure 8 - Custom Smart Data Dashboard**

## 5. Conclusion

Smart Data technology utilizes packet data and generates elastic metadata through pervasive, edge-to-core instrumentation in a distributed operator network. This metadata can be consumed by a variety of upstream applications focused on service operations, network automation, customer experience, SLA management, and security. By leveraging Smart Data technology, the operator teams can proactively monitor, assure and secure all IP services (voice, data, and video) which may run across different domains (physical, virtual, or cloud) and access networks (fixed or wireless) using the same views and workflows. By relying on a common, high definition data platform that provides "visibility without borders", operators can go through their network transformation journey with confidence to innovate while delivering an unparalleled customer experience.

# 1. Introduction

Cable operators are in the midst of deploying or preparing to deploy a variety of distributed access architecture (DAA) approaches. When this is done by aggregating multiple child nodes together onto a single point-to-point (P2P) coherent optics link, it has the effect of pushing very high capacity fiber-based Ethernet links deep into their networks. Beyond improving their DOCSIS®-based residential broadband services over coax, it also opens up numerous new business opportunities—such as mobile fronthaul and backhaul, business ethernet, remote passive optical networks (PON) and more—along with the ability to converge all of these different technologies onto a single network infrastructure.

CableLabs® has been working jointly with our members and technology vendors to develop the tools and technologies needed to make this vision a reality. However, while it's one thing to develop the technology, it's quite another to build devices based on it, and still another to integrate it together into a working whole. While CableLabs is not in a position to manufacture those devices, we are well positioned to bring them all together in a new network infrastructure convergence lab.

This convergence lab will allow us to demonstrate how these various technologies can be brought together to operate over a single physical network, showcasing the work that's already been done, and learning the implications of operating them together. It will also create a platform on which to test out new technologies going forward to see how they integrate together into a converged whole.

This paper goes through some of the background on DAA and P2P coherent optics technology, reviews the process we went through to build the lab, any lessons learned thus far, and the current status of what is an ongoing process of continuing to grow and develop this lab.

# 2. DAA and P2P Coherent Optics Background

## 2.1. Pre-DAA Hybrid Fiber-Coax (HFC) Networks

The typical access network architecture deployed by cable operators prior to the advent of DAA approaches employed a Hybrid Fiber-Coax (HFC) approach to reach their customers with video and data services. A simplified version of this architecture is shown in Figure 1 below.

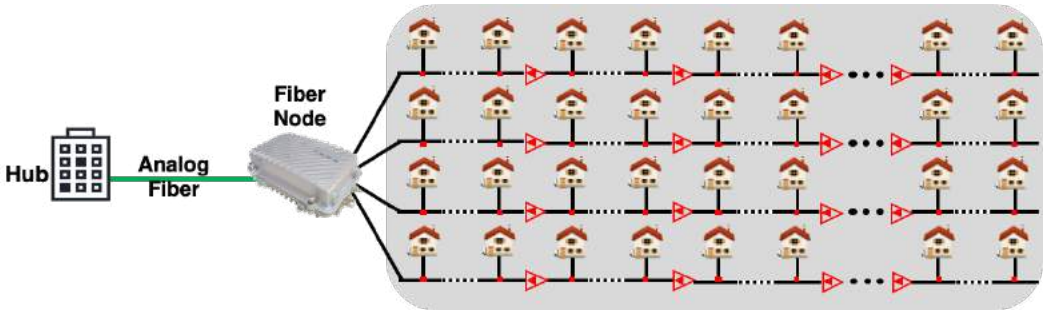

**Figure 1 – Simplified Cable HFC Architecture**

In this example, downstream radio frequency (RF) signals for data and video are generated in a Hub facility, converted from electrical to optical using an analog laser, transported over fiber to a Fiber Node at which point the signal is converted back to electrical, which is then transmitted over a coaxial cable network to end customers. In the upstream a similar set of operations occurs, originating at the customer premises and terminating at the Hub. The distance from the Hub to the Fiber Node is typically 20-80 km,

although longer distances are possible; the distance from the Fiber Node to the end customer is generally just a few km.

When the capacity requirements of the group of customers sharing a portion of the network (a Service Group) exceeds the capacity of a Fiber Node, operators will typically split a Fiber Node into multiple Nodes. Each of those Fiber Nodes will require a separate link back to the Hub, but will often share a single fiber pair using Dense Wavelength Division Multiplexing (DWDM) to save costs. Each new Service Group also requires new equipment at the Hub site, which can create pressure on space, power, and cooling.

## 2.2. A Fundamental Shift in Cable Access Networks

In response to these pressures, as has been covered in previous papers and presentations, many cable operators have begun a fundamental shift in their networks by moving the RF generation previously performed in the Hub out into the network. This allows them to convert their existing fiber network from analog optics to digital optics and to utilize Ethernet networking across the fiber portion of their cable plant. The effect is to create a deep fiber Ethernet network.

This approach is what we refer to as a Distributed Access Architecture (DAA), because functions that were previously centralized are now distributed. A simplified version is shown in Figure 2 below. On the surface it looks very similar to Figure 1: homes are still connected to coax, which terminates at a device that is connected to fiber, which in turn is connected to the hub. However, under the surface things are dramatically different: the fiber is carrying Ethernet data over digital optics rather than modulated RF signals over analog optics, and the RF is generated at a Remote PHY Device (RPD) or Remote MAC/PHY Device (RMD) directly connected to the coax without the electrical-optical-electrical conversion that occurred previously.

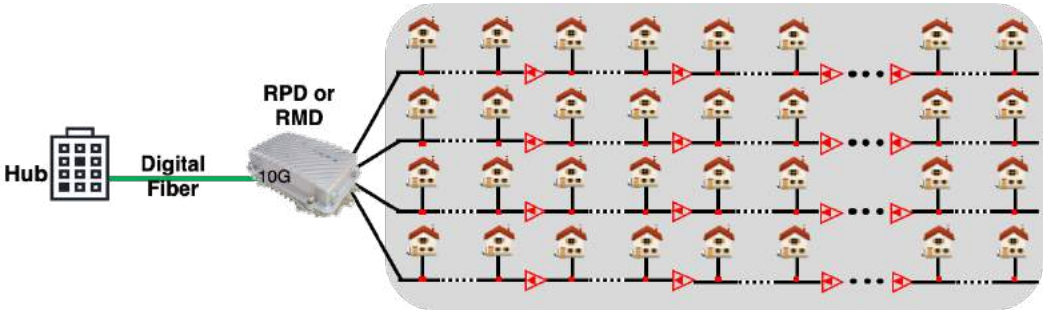

**Figure 2 – Simplified Distributed Access Architecture**

This change has a number of advantages:

- It reduces the equipment requirements for Hubs;
- It allows cable operators to utilize lower cost off-the-shelf digital optics for the fiber link instead of specialized analog optics; and
- By avoiding electrical-optical-electrical conversions, the signal to noise ratio (SNR) of the electrical signal on the coaxial cable is significantly improved.

That SNR improvement allows devices based on the DOCSIS 3.1 specifications to operate at higher modulation orders, which increases total network capacity.

## 2.3. The Need for Aggregation

Each RPD or RMD typically has a 10 gigabit-per-second (Gbps) port, which provides sufficient capacity for generating a full spectrum of digital video and DOCSIS 3.1 signals. Therefore, if Fiber Nodes were simply being replaced with RPDs or RMDs on a 1:1 basis, all that would be required to connect them to the Hub would be a single 10 Gbps optical link.

However, a key driver for the move to DAA approaches is to enable more Service Groups with fewer customers on each one. Figure 3 shows a simplified version of a scenario where the single service group from Figures 1 and 2 is split into multiple smaller service groups, each serviced by a separate RPD or RMD (each of which we refer to as a child node), and aggregated together at an aggregation node (AN) onto the existing fiber. The AN sits where the Fiber Node was previously.

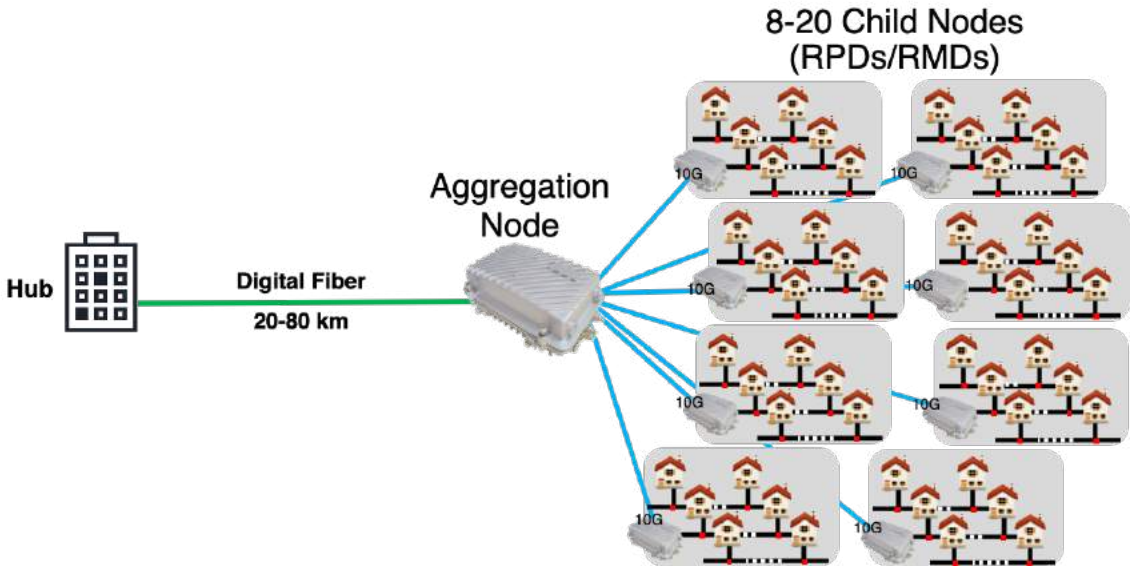

**Figure 3 – DAA with Multiple Child Nodes**

One straightforward means of building this approach would be to passively aggregate 10 Gbps optical links from each child node using DWDM, with the AN containing a passive mux/demux. This technology is readily available and well understood, and so represents a logical initial approach.

However, it has its limits, since at a typical spacing of 100 GHz for each signal cable operators will be limited to about 48 of these 10 Gbps links over a single fiber pair. And, the cost goes up linearly with every 10 Gbps link that is added.

## 2.4. The Case for Coherent

Architects at CableLabs postulated that utilizing a P2P coherent optics link operating at 100 Gbps or 200 Gbps per wavelength might prove advantageous over an approach using multiple 10 Gbps optical links with DWDM as described above. One end of the coherent optics link would be terminated at the Hub facility, and the other end at a device located in the AN called a Coherent Termination Device (CTD); the CTD would also terminate multiple 10 Gbps links from the Child Nodes, which could utilize low cost grey optics operating at 10 km or less. The aggregation could be performed in multiple different ways: at layer 1 with a muxponder; at layer 2 with a switch; or at layer 3 with a router.

Conceptually this looks exactly the same as what was shown in Figure 3 above, with the following exceptions: the AN has a CTD in it which forwards traffic at layer 1, 2, or 3 rather than containing a DWDM mux; the links connecting the CTD to the Child Nodes use low cost grey optics (instead of higher cost colored optics); and instead of carrying those 10 Gbps signals all the way back to the Hub (which requires longer reach, higher cost optics), they are aggregated onto one or more P2P coherent optics links for transport back to the Hub.

CableLabs staff conducted an analysis to compare the costs associated with each approach for supporting multiple child nodes in the same footprint as an existing fiber node. We found that the key determination for which approach would cost less depended on the number of child nodes. If the number of child nodes being aggregated together is relatively small, the DWDM approach was more cost effective, because the cost of the P2P coherent optics transceiver and the CTD is shared across only a few child nodes. However, as the number of child nodes increases that dynamic flips, because the cost of the DWDM approach goes up linearly with each child node due to the need to add a pair of higher-cost tunable 10 Gbps transceivers, whereas with the P2P coherent optics approach the cost for each additional child node is much smaller because only very low cost grey optics transceivers are added.

Further, while there are already cases where the P2P coherent optics approach was lower cost, we also saw potential opportunities to bring that cost down further, which would lower that crossover point.

Using P2P coherent optics provides additional benefits as well: it can coexist with existing signals using DWDM, which in turn also opens the door to add additional P2P coherent optics links in the future. The net result is a 10-20x increase in available capacity for the fiber that cable operators have already deployed into the range of terabits per second, extending the lifetime of their existing network investment dramatically.

## 2.5. The Pathway to a Converged Network Infrastructure

In addition to the benefits identified above, moving to an architecture utilizing P2P coherent optics opens the door to new business opportunities by enabling a converged network infrastructure.

A DOCSIS network is, in effect, a very deep Ethernet network optimized for running over an HFC infrastructure. However, the only points at which you could access that network are at cable modems attached to the coax portion of the plant: accessing the fiber portion of the network cannot be done via DOCSIS, and instead was only possible by using separate fibers or separate wavelengths over the existing fiber.

However, let's assume you've deployed a P2P coherent optics architecture using a network switch in the CTD. That CTD has become an Ethernet connection point that can tap directly into very high capacity fiber links. Any service that can operate with an Ethernet connection can connect at that point, including DOCSIS services, PON services, mobile xhaul services, business services, etc. All of them can be carried over the same Ethernet based fiber network, aggregated together via the CTD.

The result is a converged network infrastructure, as shown in Figure 4 below.

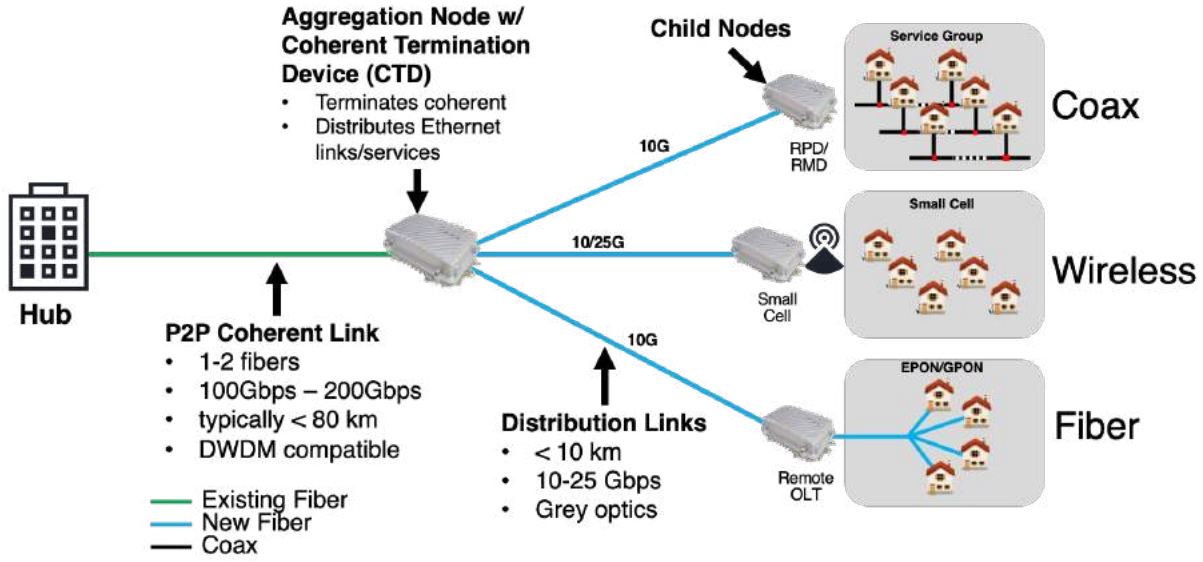

**Figure 4 – Converged Network Infrastructure**

With this type of architecture approach, the opportunities are limited only by our imaginations.

In order to help enable this future, CableLabs worked with our members and manufacturers to develop a series of specifications that define requirements for coherent optics transceivers operating at 100G and 200G. The intent was to provide manufacturers with guidance regarding the requirements for operating on a cable operator network, as well as to promote interoperability, which in turn helps promote scale and competition, thereby reducing cost. The specification for 100G per wavelength operation was initially released in 2018, and the specification for 200G per wavelength operation was initially released in 2019.

# 3. The Plan

## 3.1. Why Build a Convergence Lab

Another advantage of P2P coherent optics is that there is existing equipment that can be leveraged now, with more on the way. Interoperable 100G coherent optics transceivers that are compliant to the CableLabs specification requirements already exist, as do a variety of switches, routers, and muxponders that they can operate in, some of which are temperature hardened. Prototypes of interoperable 200G transceivers are expected this year as well.

However, we realized that a key piece – a fully weather hardened Aggregation Node with a CTD that could operate in it – was missing.

The plant architectures utilized by many cable operators around the world favor a clamshell type device that is fully weather hardened at the AN location. Unfortunately, that device doesn't yet exist and needs to be developed. In order for manufacturers to decide to invest the money to do that, they need to understand what requirements their customers have, and confirm that there's sufficient interest from those customers.

One way in which CableLabs is working to address these needs is by working with our members to define common requirements for a CTD.

Another way in which we realized we might be able to help was by demonstrating the capabilities of this new architecture, showing not only that it can support existing use cases exceptionally well, but even more importantly that it can support a broad range of other applications and services that could provide new revenue opportunities.

Thus, the idea for building a network infrastructure convergence lab was born. It would be a platform on which we could demonstrate how a variety of different services could coexist: DOCSIS broadband over coax; mobile fronthaul and backhaul; FTTH via PON; and business ethernet services. A showcase for products built to comply with a wide range of CableLabs specifications. And a test bed for validating how new products and technologies could integrate into that same infrastructure.

## 3.2. Finding Partners

In order to make that a reality, a key requirement would be obtaining the equipment—ideally from a variety of manufacturers—in order to make it work. So began a quest to find partners in this endeavor.

Utilizing relationships we had developed in putting together the CableLabs P2P Coherent Optics specifications, as well as relationships that were developed as a part of building the P2P Coherent Optics interoperability demo shown at SCTE Expo 2019, and also relationships from the work done with CableLabs on Distributed Access Architectures (DAA), we reached out to a number of manufacturers with a fairly simple pitch to build the network shown in Figure 4 above in a lab at CableLabs. The benefit for manufacturers: feedback regarding how their devices operate in the network, visibility to our members when we report on the activity, and visibility to anyone that visits CableLabs and tours our lab spaces.

As a part of these discussions, we proposed to develop the lab in four phases.

The first phase would be focused on the main optical link from the "Hub" to the CTD, since all other applications and services would run over that infrastructure.

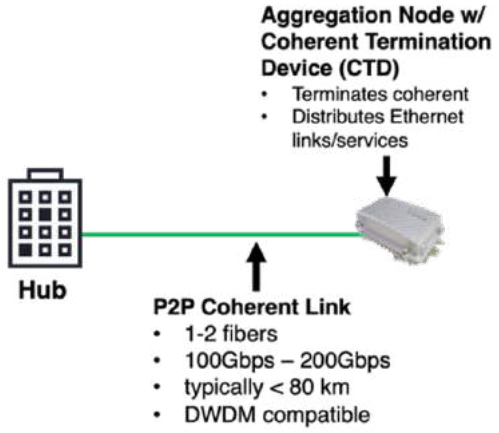

**Figure 5 – Phase 1: P2P Coherent Optics**

Ideally it would include equipment from multiple manufacturers so that we could demonstrate interoperability, and multiple transceivers operating simultaneously. That would demonstrate the ability of the solution to scale up as needed with multiple wavelengths operating at the same time. Playing the role of the CTD in the AN would be temperature-hardened equipment that would be suitable for deployment in a street cabinet (since clamshell devices were not available).

As a part of this phase we would also connect traffic generators directly to the CTD in the AN as well as in the Hub, which serves the dual purposes of validating the link and showing how a business ethernet service might work.

The second phase would be focused on building a Distributed Converged Cable Access Platform (CCAP) Architecture (DCA) network that would operate over the top of the P2P coherent optics link serving as the backbone of the architecture, since this would likely be the first, primary application for cable operators.

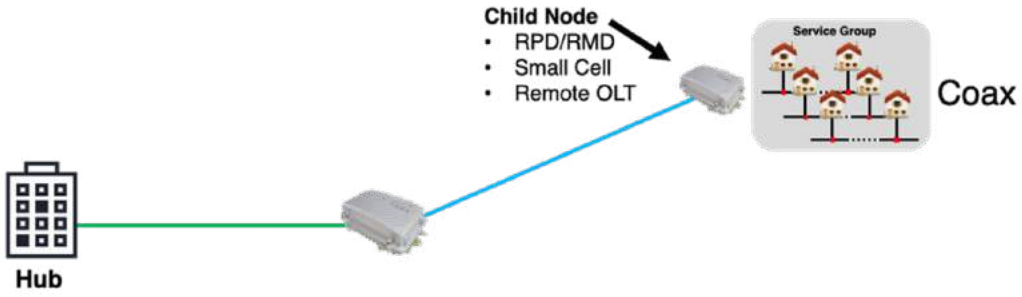

**Figure 6 – Phase 2: Distributed CCAP Architecture**

The intent was to start with the Remote PHY Devices (RPDs) that cable operators are starting to deploy, working with a CCAP Core in the Hub location.

The third phase would then look at layering in wireless solutions, which present an immense new business opportunity for cable operators, particularly with the rollout of 5G services that—in fronthaul applications in particular—have high capacity and low latency requirements, while also requiring higher densities than are typically the case today due to the use of higher frequency spectrum.

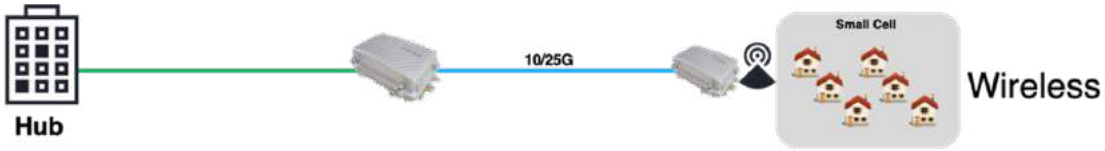

**Figure 7 – Phase 3: Wireless**

Within this, there would be opportunities to demonstrate the use of both direct fiber connections as well as DOCSIS links for backhaul and fronthaul transport of mobile traffic.

The fourth phase would incorporate a remote PON solution, with the remote OLT being either a standalone device connected via a short fiber run to the CTD (as shown below) or a device that connects directly to the CTD (such as an OLT in an SFP+ form factor).

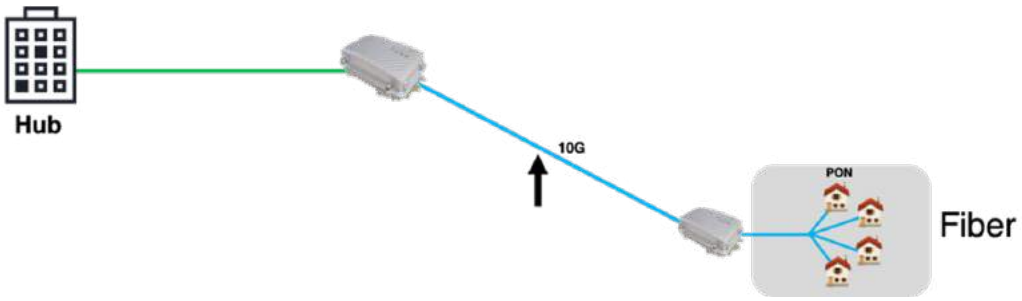

**Figure 8 – Phase 4: PON**

Note that any of the follow on phases after Phase 1 could be done in any particular order depending on equipment availability, and additional phases to add equipment to address other use cases would be possible.

Therefore, our primary focus was on finding partners to supply equipment to support Phase 1, with a lesser focus on Phase 2, leaving the remaining phases as future work.

### 3.3. The Construction Plan

Another question we addressed during these discussions was how to go about actually constructing the lab setup.

As mentioned, at SCTE Expo in 2019 the CableLabs booth featured a P2P coherent optics interoperability demo which included contributions from a number of different manufacturers. To prepare for that demo, we had held a sort of mini-interop, where each of the companies providing equipment sent an engineer out to CableLabs, and we spent several days piecing the demo together and ensuring we could make it work. We then took the demo apart, shipped it to New Orleans, and rebuilt the same setup we had used in the lab with substantial help from some of those same contributors.

For this effort, we proposed to do essentially the same thing: have each of the participating companies send out an engineer to work together over the space of several days to install the equipment and get it all working. In some ways it would be even easier than what we did the previous year, because we wouldn't have to tear it down and ship it out to be rebuilt; we could build it right where it stay and be used. If any issues came up, we could deal with them on the spot.

It seemed a straightforward, easy approach for getting the lab up and running quickly.

### 3.4. The Response

After making our pitch, a number of manufacturers agreed to provide equipment either on loan, as a donation, or at a substantial discount. Specifically, the following list of companies (in alphabetical order) offered the following pieces of equipment:

- II-VI (formerly Finisar): a C Form-factor Pluggable 2 – Analog Coherent Optic (CFP2-ACO) transceiver module
- ADVA Optical: a network switch that supports coherent optics, targeted for the "Aggregation Node" location, along with coherent optics transceivers
- Ciena: two network switches that support coherent optics, one each for the "Hub" and "Aggregation Node" locations, along with coherent optics transceivers

- Edge-Core: a whitebox network switch that supports coherent optics, targeted for the "Hub" location, including support for CFP2-ACO modules
- EXFO: a pair of traffic generators capable at running multiple 100G streams of data simultaneously
- Lumentum: a CFP2-ACO coherent optics transceiver module
- Vecima: a Remote-PHY Device (RPD) and associated management station

With verbal agreements in place, we began working on all the necessary paperwork to allow these transactions to take place, making arrangements for equipment to be shipped out, etc.

All was going relatively smoothly, if perhaps a bit slower than we'd all have preferred: getting executive approvals, legal approvals, and documents signed always seems to take longer than you'd expect. Still, given that the actual construction of the lab should only take a matter of days with engineering support on site, some amount of delay wouldn't prevent us from completing the lab in a reasonable amount of time. Enough so that I felt comfortable submitting a request to SCTE to create this paper.

Then the Covid-19 pandemic hit with full force, blowing up many of our plans.

# 4. The New Reality

## 4.1. Restricted Access

Like many companies, as the rapid spread of the virus became clear, CableLabs instituted a work from home policy. Specifically, unless being in the building was absolutely essential to the core operation of the company, we were all to work from home. Further, travel between our California and Colorado offices was halted, and visitor access to the building was cut off.

This obviously presented several problems for the lab construction plan. First, I'm located in California, but the lab was to be built at our main office in Colorado; therefore, I would be unable to work on building the lab myself. Second—and most significantly—we would not be able to have any outside engineers visit the facility, meaning we would not be able to rely on their expertise to get their equipment operational. And finally, since this work didn't necessarily count as essential to the core operation of the company, even staff located in Colorado were unable to enter the building to work on the lab.

However, at that point in time, there was still hope that these restrictions would only be temporary: after a month or two of a tight lockdown things would get better and we'd be able to travel and access the labs again. Besides which, it was taking longer than expected to get the equipment agreements signed, equipment shipped, etc. So, we had time to spare and hoped that by waiting things out we would still be able to build the lab as planned (albeit perhaps a bit later than originally envisioned).

Therefore, we continued to work on arranging equipment shipments to our facility in Colorado so that it would be ready to go as soon as virus restrictions were lifted.

## 4.2. Equipment Arrivals

Thanks in no small part to the contributions and efforts of the various companies that had partnered with us on this effort, who had continued to work through the pandemic and their own restrictions, the needed equipment did indeed start to arrive. However, since there was no one there to receive, unpack, and work with the equipment it began to pile up, as shown in Figure 9 below.

 

**Figure 9 – Packages piling up**

In fact, as shown above, the boxes were starting to clog up one of our hallways. As soon as one of our local team members was able to re-enter the office, we found a more efficient stacking arrangement, as shown in Figure 10.

**Figure 10 – Tower of boxes**

So now we had much of the equipment we needed, but still no way to put things together until our level of access to the building changed.

### 4.3. A New Hope

While the situation with the pandemic did not improve nearly as much or as quickly as we might have hoped, it did improve enough that CableLabs was able to relax some of our building access restrictions. Visitors to Colorado were still out of the question, but local staff would be permitted limited access to the building for short periods of time when arranged in advance.

Among those that would be given some access to the building were the members of the CableLabs Optical Center for Excellence, the team that we have working on next generation optical technologies: because they can't bring their experiments home, they needed access to the optical lab in order to continue their work. If they could spare some time to lend a hand, given their expertise, they would be perfect for setting up the lab.

Fortunately for me, they are some of the most helpful, generous people you'd ever want to meet, and they agreed to help me out and work on setting up the equipment there on site without complaint. The caveat was that they also had to make progress on their own work, and so would have only a limited amount of time each week to help out. But I was grateful for any help I could get.

A wave of outreach to our partners who were supplying the equipment to request remote support to our on-site team followed; they were all supportive, and so a series of introductions were made to connect those that would be supporting the work remotely with the team on the ground.

Our prospects for building the lab were looking up.

### 4.4. Everything takes longer in a pandemic

The local team was able to access the lab starting in mid-July. They began by unpacking equipment from one of our partners and trying to get it setup and running with remote engineering support.

What I didn't yet recognize—but would soon be brought face-to-face with—was that everything takes longer in a pandemic. In particular, when you can only access the lab two days a week (in order to limit exposure), and are relying on remote support, problems that might've been resolved in hours or a day if people were on-site and dedicated to the task can take a week or more.

And it seems like the simplest problems are the ones that catch you off-guard and cause the most problems.

For example, we discovered when we unpacked a network switch from one of our partners that it required a 220V power supply, something we didn't expect—since all the equipment we'd worked with up to this point worked on 110V—but admittedly should have asked about in advance. After several calls and emails, we discovered that we did in fact have 220V power supplies in the building at CableLabs, and members of our Kyrio lab team were able to set one up for us.

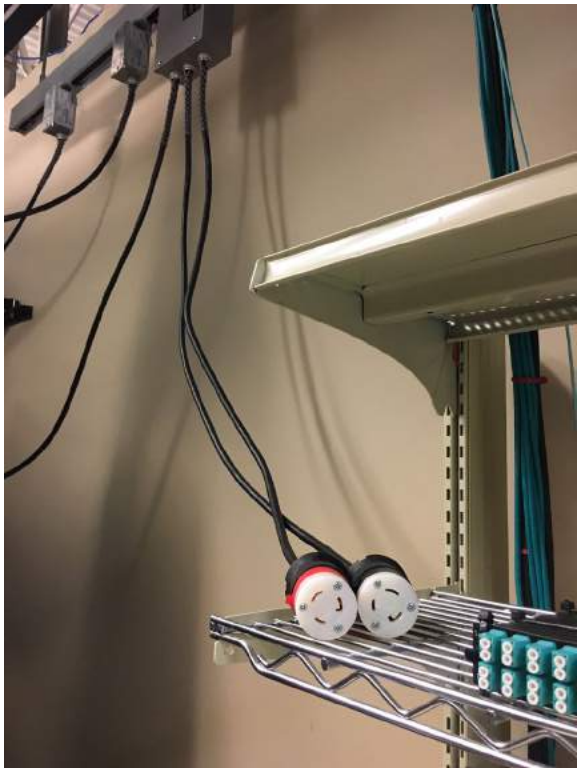

**Figure 11 – 220V power**

We initially thought we had overcome that issue with relative ease and minimal impact, but quickly realized that we weren't going to get off that easy:  the power supply we had at CableLabs used an L6-20 receptacle (rated for up to 20 amps), whereas the plug for the box we were trying to install and setup used an L6-30 plug (rated for up to 30 amps).

**Figure 12 – The plug doesn't fit**

We inquired with our partner regarding an alternate power cord, but were told that what we had was the only one they provided. We asked if the box would ever draw more than 20 amps, and were told that it probably wouldn't, although they didn't want to commit to that at that time. As a result, no one was comfortable simply using an adapter or replacing a plug. Instead, we started to look into purchasing a new 30 amp power dongle for our rail system, which we found would take at least 6 weeks.

This left us at a bit of a stand-still on this particular device until we eventually made two critical discoveries: while the plug on one end of the power cord that came with this network switch was specifically a 30 amp plug, the connector on the other end of the power cord was in fact only rated for 20 amps; and buried deep in the technical specs of the network switch we were using, we discovered that the switch itself had a max draw of just 9.3 amps. With that information in hand we became comfortable with the idea of using an adapter to connect the power cord to our 20 amp power supply, and quickly ordered one. And while that took just a few days to arrive, it also had to wait for the next window when someone would be in the lab, further delaying the day by which we could power up that device.

As I said, under these unusual circumstances, the simplest things become multi-week delays.

The power plug issue was just one example; each device setup ran into their own simple yet time consuming issues.

For one of them, the issue was licensing. For this particular manufacturer, they assumed that devices would always be connected to a live internet/network connection. Therefore, they had been designed to pull their license from over the internet, without which it wasn't operational.

However, in our case, we were setting these up in a lab without an external network connection; and while that might eventually happen, it certainly was not the case for our initial setup. There was an option to create a download for us to use, although we'd have to do it through their customer portal in which we

 

weren't set up. It didn't get setup correctly the first time around, given it was a non-standard way of doing things. In the end we got it all working, but only after multiple emails, phone calls, and aborted attempts.

For another network switch we were attempting to setup, the issue wasn't power or licensing, it was transceiver compatibility.

This partner had provided us with a network switch under the assumption—which we shared—that one of the coherent optics modules we already had on hand would work. And initially it did, as we were able to power up the switch and have it recognize the transceiver module. All seemed fine. However, we then discovered that we couldn't set the frequency on which we wanted it to operate. It would only operate on a single fixed frequency, even though we knew the module was capable of tuning to different frequencies. Eventually the problem was traced to a compatibility issue: the switch would only support controlling the coherent transceiver module if it were also from the same manufacturer.

Our partner who had supplied the switch graciously offered to provide us with a pair of loaner transceivers, and moved to make that happen as quickly as possible. However, quickly in this case means getting a loaner agreement drawn up, having it reviewed by one legal department, having those changes reviewed by another, and finally getting it signed and processed. And then of course, waiting for shipping.

All of our issues were ones that could be overcome given time, but all of which also took longer simply because of the unique situation we found ourselves in with the pandemic.

# 5. Today and Tomorrow

## 5.1. Current Status

As of the writing of this text, here's where we stand today.

We now have both of the two Ciena switches up and running in our lab, with a transceiver in each unit talking to a transceiver in the other, as shown in Figure 13 below.

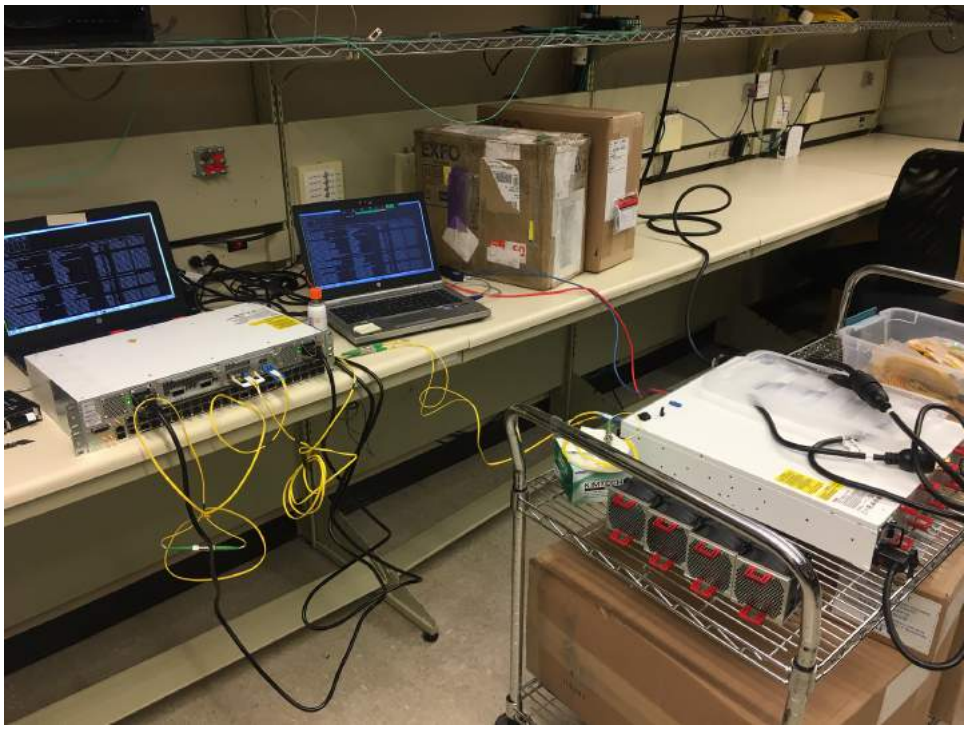

**Figure 13 – Ciena to Ciena communication**

The EXFO FTB-4 Pro traffic generators were recently unpacked and are now up and running; we're currently working on getting them setup to pass traffic across each of our switches.

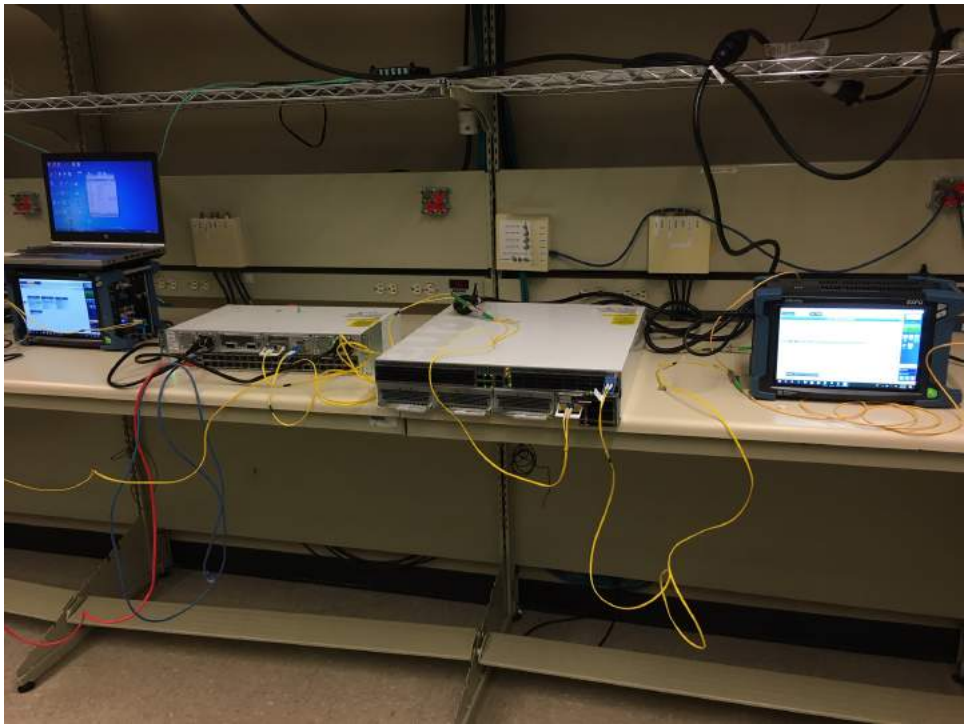

**Figure 14 – EXFO traffic generators with Ciena switches**

We've also gotten the ADVA switch up and running with in a loopback configuation.

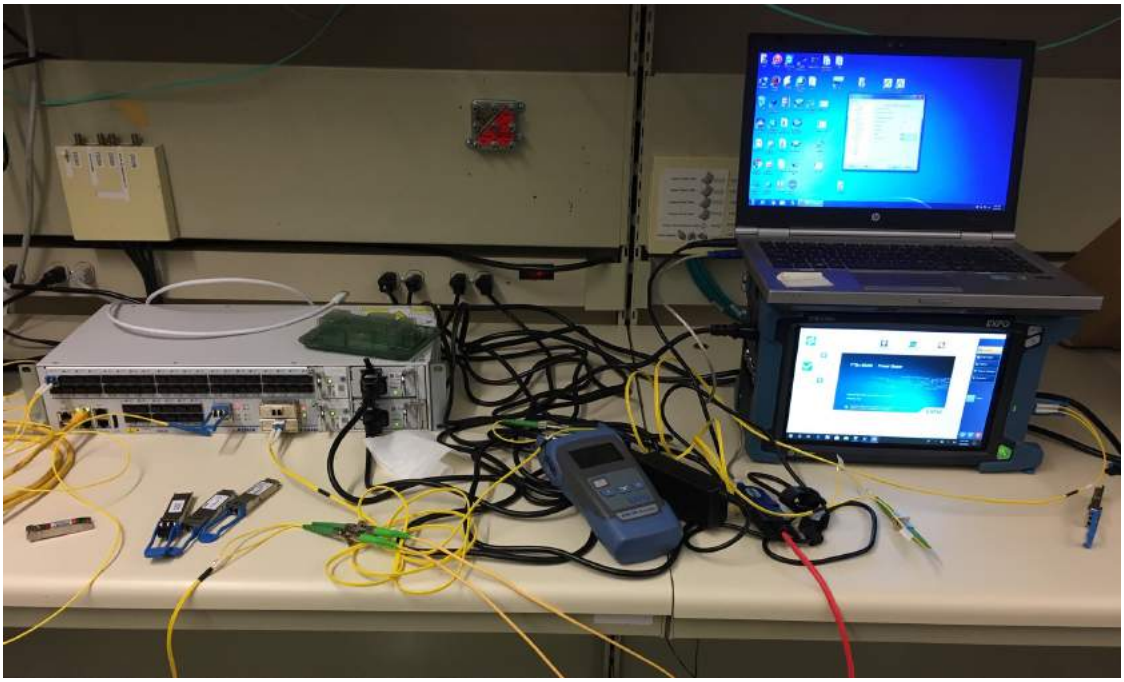

**Figure 15 – ADVA switch with EXFO traffic generator**

Other equipment is yet to be unboxed but will be soon.

## 5.2. Next Steps

In the short term, our plan is to get traffic running across the Ciena and ADVA switches, unpack and get the Edge-Core Cassini running with the CFP2-ACO modules that were provided to us by II-VI and Lumentum, and connect them all together using DWDM.

That will form the backbone of our lab to demonstrate network infrastructure convergence.

From there we'll be working on getting a Remote PHY implementation running over top of our optical network using the equipment provided by Vecima—in combination with a CCAP-Core already on-site—to demonstrate that service. That'll be followed by other phases as we're able, establishing that you can run multiple services over the same access network infrastructure simultaneously.

Beyond that, we plan to use this lab as both a showcase (it'll eventually be moved to a more visible location) and a working lab that we can use to test and demonstrate new components of a converged network. For example, we'll be interfacing it with equipment from other teams within CableLabs, such as those working on network virtualization, to create a truly converged network of the future. It's going to take a while to get there—much longer than I ever would have anticipated—but many of the building blocks are already in place, and more will be soon.

## 5.3. A note of thanks

While I may be the one writing this paper, given the restrictions on travel and building/lab access, I haven't been the one doing the work on the ground as I had hoped and intended. Instead, that's been done by a team of folks from multiple companies to whom I am greatly indebted:

- CableLabs
  - Haipeng Zhang
  - Jon Schnoor
  - Junwen Zhang
  - Mu Xu
  - Scott Bybee
  - Steve Jia
- Kyrio
  - Efren Torres
  - Mark Ambrozic
- ADVA
  - Clark Scott
  - Jack Yocum
  - Morgan Shaner
- Ciena
  - Craig McCoy
  - Darren McKinney
  - Fernando Villarruel
- Edge-Core
  - Jeff Catlin
- II-VI
  - John DeAndrea
  - Shan Esser
- IP Infusion
  - Srikanth Krishnamohan
- Lumentum
  - Ed Kirchoff
  - Ernest Muhigana
  - Jan Willem Poelman
  - Scott Swail
- Vecima
  - Colin Howlett
  - James Trueman

My sincere thanks to all of you, without whom none of what we have done (and will be doing!) would have been possible. And to anyone whom I may have inadvertently left off of this list, my apologies and deepest thanks.

This has been very much an industry wide effort, and it is my heartfelt hope that it will continue to be one going forward.

 

## 6. Conclusion

When I originally proposed this paper, the expectation was that I would be writing about what we had learned by successfully building a converged network infrastructure: that I would be describing why we had set out to build it, what had happened when we did, and hopefully about how we had demonstrated that these various services could operate effectively over a common access network infrastructure, along with perhaps a few issues the MSOs should watch out for in their own networks.

And while it did accomplish the first of those objectives, from there it instead evolved into a story regarding the very unusual and unique circumstances in which we all find ourselves, and the challenges that imposed in this particular situation. And a story about how we can push through those challenges when we all work together to overcome them.

Which to me is one of the key lessons to be learned here: that while everything takes longer in a pandemic, when we work as a team, we can push through those challenges and accomplish a lot.

This network infrastructure convergence lab is a work in progress, and in fact I hope and expect it will always remain one, with new equipment and technologies being incorporated for years to come. In fact, additional contributions are more than welcome, as we'd love to enhance what we can do in the lab and bring in as many different pieces of equipment for as many different services from as many different manufacturers as possible.

The lab may not be as far along as we'd like, but thanks to the contributions of multiple individuals we will get there , which I hope to be able to report on in the future.

# Abbreviations

| | |
|---|---|
| AN | Aggregation node |
| CFP2-ACO | C Form-factor pluggable 2 – analog coherent optic |
| CCAP | Converged cable access platform |
| CTD | Coherent termination device |
| DAA | Distributed access architecture |

Keith.hayes@immcoinc.com

# Table of Contents

## List of Figures

 

# 1. Introduction

- **>300,000** Nodes
- **~700,000** Power Supplies
- **~2,000,000** HFC plant miles
- **>70,000,000** US MSO Internet Consumers
- **>40% CAGR** Broadband Consumption
- **Streaming video** here and growing, **online game-streaming** and **AR/VR** coming
- Oh, by the way, **COVID-19** induced **telework** and **virtual classroom** data activity

There are more than 300,000 HFC nodes in the US currently, and several million more worldwide. The additional network traffic triggered by Covid-19 in the spring of 2020 increased the level of HFC capacity augments by as much as 300% compared to 2019 volume. Network augmentation techniques such as node splits, adding HSI EIA's (6 MHz channels), service group de-combines, bandwidth expansion, Node+0/RPD's and mid-/high split reverse path expansion require engineering and operations resources in both ISP and OSP.

This paper will examine techniques in which much of this activity can be automated and iteratively optimized through Machine Learning (ML). With inputs provided from network mapping systems, capacity monitoring platforms, spectrum management applications, and business rules such as preferred augmentation hierarchy, expected duration before next augment, balancing of house-counts, municipal permitting difficulty, and cost efficiency, the ML environment would rapidly analyze entire geographic segments of the network, and provide augmentation planning data including network design changes and BOM's for areas requiring immediate physical layer upgrades.

As the ML platform iteratively processes network geographies, it will learn from how past predictions tracked to current status and continuously adjust to optimize capacity augmentation methods and designs. As the ML environment will be analyzing the entire network geography, data to drive Capex planning for future years will be derived enabling the operator to more efficiently allocate capital.

The ML environment would also support "what/if" network topology planning for approaches, such as bandwidth expansion to 1.8 GHz vs Node+0 at current bandwidth, and provide data on cost, duration before next augment needed, and percentage of network elements requiring replacement or repositioning.

# 2. Artificial Intelligence (AI) and Machine Learning (ML)

There is a lot of interest in using advanced computing technology to automate and accelerate processes that when done by humans are slow and tedious – facial recognition for example.

AI and ML are often used interchangeably but as depicted in the figure below ML is a subset of AI – so how are they related?

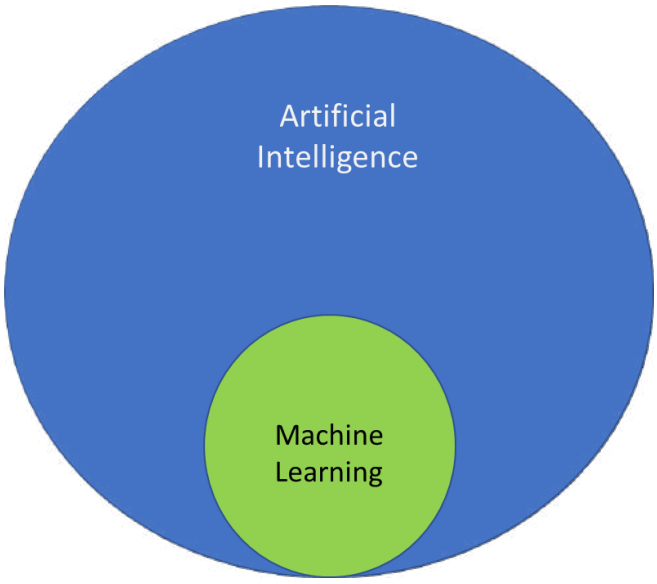

**Figure 1 – Relationship of Artifical Intelligence and Machine Learning**

**Artificial Intelligence (AI)** can best be understood as developing computer systems to perform tasks that humans can typically do better. A mechanical example would be a robotic welder in an auto manufacturing plant. A data analytics example would be Recommendations from your online retailer or streaming service that takes your past history and analyzes it against current inventory to "Recommend" items you may want to purchase or content you may want to watch.

**Machine Learning (ML)** is a subset of AI, and in addition to enabling computer systems to perform tasks with humans can typically do better, deploys "learning algorithms" that allows the system to measure performance and automatically improve outputs from those learnings. Back to one of the previous examples, if the robotic welder was coupled with an x-ray or gamma-ray measurement system that provided data on weld quality which then would change the parameters of the welding programming to improve performance without human intervention would be a good example of ML.

## 3. Network Capacity Augmentation Methods

One of the unique benefits of HFC architecture is the many options potentially available to add capacity, with more being developed as technology advances. The list below is not exhaustive but notes most of the typical options to add capacity without changing the bandwidth or US/DS ratio of the network, organized by rough order of difficulty to implement:

- Activate unused / repurpose EIA's (channels)
- Service Group de-combining/recombining
- Increase modulation density
- Extend fiber to heavy-use households
- Node Splits
    - Add transceivers to existing node (segmentation)
    - Add new node – minimum construction, no HHP balancing

    - Add new node – balance HHP
    - Add new node – balance for peak data utilization
- Add Remote Phy-Mac/Phy device

As evaluations are performed to determine the best approach on a node-by-node basis many other variables come into play:

- Municipal Permitting
- Maintenance Window availability
- Aerial/Underground

These many methods and variable are further complicated by the situation that most operators have separate departments managing ISP (Inside Plant) and OSP (Outside Plant) requiring careful coordination for those methods requiring both groups.

# 4. Implementing Machine Learning for Node Split Design

## 4.1. Programming Environment

When developing a Machine Learning application there are several fundamental environment decisions that must be made:

- Which programming language?
- Which IDE? (Integrated Development Environment)
- Which learning process – Supervised or Unsupervised?
- Which Decision Tree / Classification Engine?

### *4.1.1. Programming Language*

Most common programming languages are capable of being easily used for ML environments, including:

- Python
- Java
- C++
- C#
- R
- JavaScript
- Scala

### *4.1.2. IDE – Integrated Development Engine*

In order to provider an optimized development and debugging container, an IDE provides numerous tools and applications optimized for ML code development and testing. Many IDE's work with multiple programming languages but not with all, so analysis will need to be done to ensure the chosen programming language and IDE are compatible. Common IDE's include:

- PyCharm
- RStudio
- R-Brain
- Jupyter

- Spyder
- Geany

### 4.1.3. Learning Process

Machine Learning is either Supervised or Unsupervised. Supervised Learning is when the data being processed has been labeled and the ML system is taught by example, such as labeling pictures of items like a hammer and a banana so give the ML environment information to learn from. If the ML algorithm incorrectly identifies a shape, it would be "taught" by human input to improve its accuracy. Unsupervised learning is most useful in clustering and identifying similar objects and detecting significant anomalies – such as fraud detection identifying an abnormal financial transaction base on your spending history.

### 4.1.4 Decision Tree / Classification Engine

The last area that is needed to support the ML environment is a decision tree or classification engine. Common classifiers include:

- GBM Gradient Boosting Machine
- Random Forests
- Logistic Regression

The Python/Jupyter combination with Supervised Learning via random forest classifier was used for the development environment in which to build and test node split design via Machine Learning.

## 4.2. Network Data Extract

To provide data for the ML engine to examine it was necessary to extract every network element, both passives and actives, along with the HHP downstream/upstream, from the network map platform. As each element was geocoded distance calculations could be made without having to extract strand/cable/conduit data simplifying the extraction process. A table showing some of the parameters and results from a design iteration is shown below in Figure 2.

| Equipment | Element ID | DS HHP | Leg Balancing DS | DS HHP Ratio % | Leg Balancing US | US HHP | US HHP Ratio % | Cascade Limit | Power Supply Proximit | Voltage | Current | Proper Signal Strengt | Minimal Construction | Room at Pole or Ped? |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| BTD-75SH AGC | 5 | 523 | NO | 1 | NO | 0 | 0 | YES | YES | 50.56 | 1.5 | YES | YES | YES |
| BLE-75SH | 6 | 140 | NO | 26.8% | NO | 383 | 73.2% | YES | NO | 39.53 | 10.59 | YES | YES | YES |

| BTD-75SH AGC | 21 | 203 | YES | 38.8% | YES | 320 | 61.2% | YES | YES | 51.75 | 4.59 | YES | YES | YES |

**Figure 2 – Subset of Network Data Extract**

Each element from the node to a line extender to a terminating tap was assigned a unique ID number and as the several performance parameters such as signal level, voltage, current and the ratio of HHP both

downstream and upstream from the network element were calculated. The node in the example above had 667 discrete network elements that were loaded into the ML environment.

### 4.3. Business Rules / Design Rules

After the network data was loaded Business or Design rules had to be created to guide the ML engine based on customer requirements. For example, an operator might want to design for the absolute least amount of activity needed to add capacity – adding another transceiver to segment a node without concern about balancing the homes-passed by the old node vs the new node. Another operator (or heck, maybe the same operator in another part of the network) might want to design for balancing the homes on the old and new node, and provisioning for future nodes. Some of the more than a dozen Rules included in this model were:

- Can the node be segmented?
- Is the proposed location geographically centered or not?
- Are homes passed balanced?
- Is cascade limit exceeded?
- Is there space on the pole or in the pedestal for the node?
- Does RF signal meet specifications?
- Does node meet minimal construction parameters?
- Is any coax reversing needed?
- Is Fiber Splice location reachable?

One of the benefits of creating an ML environment is it is relatively easy to add additional parameters and rules as technology changes, for example adding a rule to validate is power ampacity for small cell deployment was available, or tying the network data to the capacity monitoring system which could enable a split location to be balanced on peak data consumption versus geographic center or balanced Homes Passed.

## 5. Let's go split a node….with Machine Learning!

### 5.1. Machine Learning Node Split Design Process

In a standard Node Split design process, a designer looks at the network topology, and applying the Busines Rules using his or her experience picks a likely location for the new node. Afterwards, calculations have to be completed using a design tool such as Lode Data to verify the location will "work" – all signal levels are acceptable, there is appropriate voltage and no excessive current draw, and if those tests are passed the design needs to be completed and a BOM created. If the new node location does not "work", the process has to be repeated, each iteration taking 30 minutes or so for an experienced designer. The ML environment was developed to automate this process.

To test the new process several relatively simple node splits were loaded and processed by the ML tool, which generated network element relational schematics as shown in Figure 3 below:

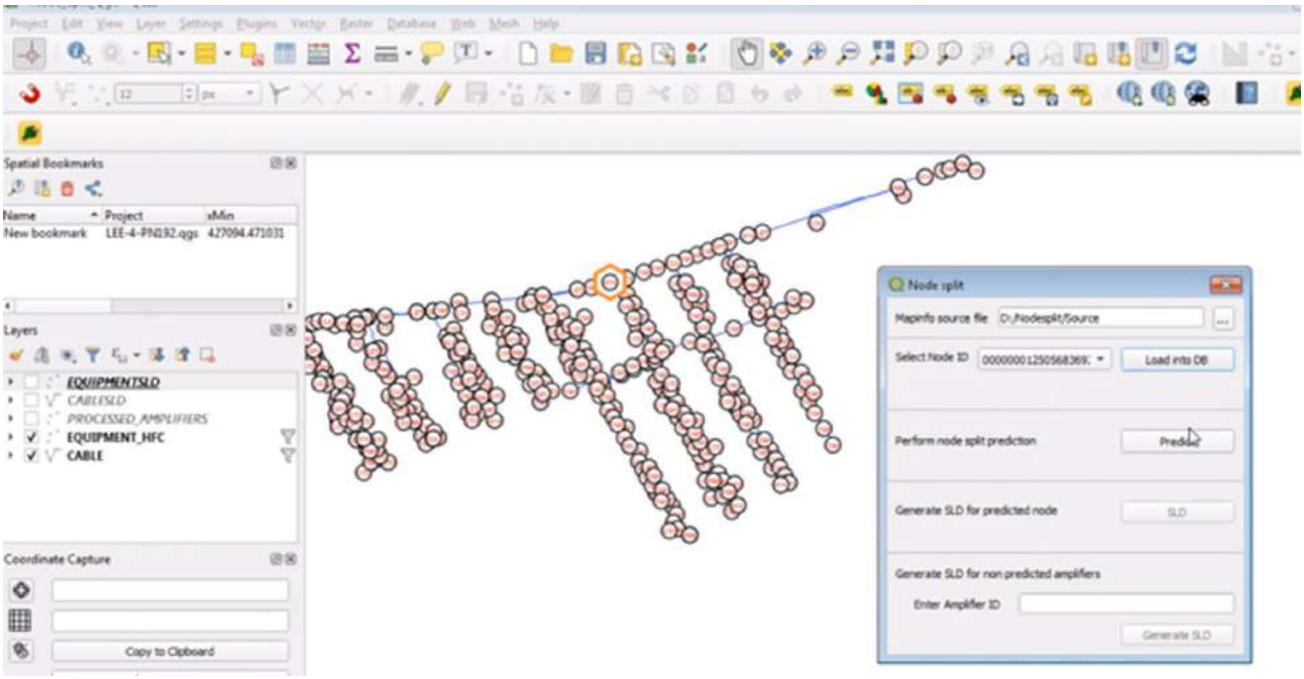

**Figure 3 – ML Network Element Relational Schematic**

The network element schematic is not needed directly by the ML tool but enables a designer to visually review the topology without using a network map system. Figure 4 is a close up showing the original node location and elements near it.

**Figure 4 – Network Elements near the original Node**

This particular Node was non-segmentable, and the Business Rules required minimal construction with no requirement to balance homes passed. The first iteration proposed the new node be placed on the fiber path to the existing node using spare fibers to connect it. As the new node location was an existing amplifer, there was no coax-resplicing required further complying with the minimal construction instruction – Figure 5 below:

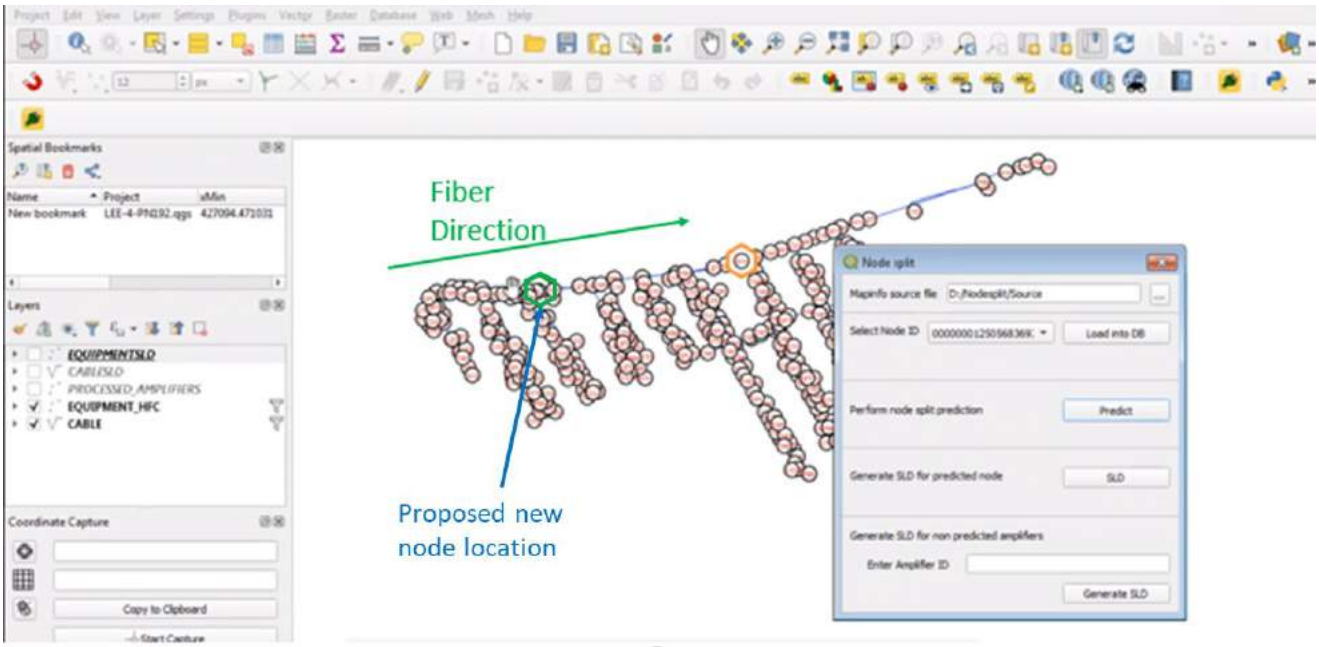

**Figure 5 – New Node Location**

When the households passed were calculated for the Original Node and New Node, there was definitely a mis-balance as shown in the table in Figure 6 below, but the operator would be able to provide additional capacity with little cost, time, or likely municipal permitting.

| | HHP | Ratio |
|---|---|---|
| Original Node | 457 | 100% |

| | | |
|---|---|---|
| Original Node after split | 329 | 72% |
| New Node after split | 128 | 28% |

**Figure 6 – HHP after minimal construction Node Split**

To "train" the ML environment, a dozen nodes of varying complexity, size and geographic orientation were used. Each node was "designed" manually with optimum location and business rule adherence, and several deliberately incorrect designs were created for each node configuration. The ML engine "learned" by comparing the correctly designed node split to ones that were incorrect.

After several iterations of supervised feedback, the ML node split algorithm was tested in 200 locations and determined the optimum location in 196 – an accuracy rate of 98%! Even more noteworthy was each location was processed in seconds versus around a half-hour for a human designer.

Below in Figure 7 is an example of a geographically complex node where the ML business rules required HHP balancing, future node segmentation capability, and construction costs and difficulty were not considered.

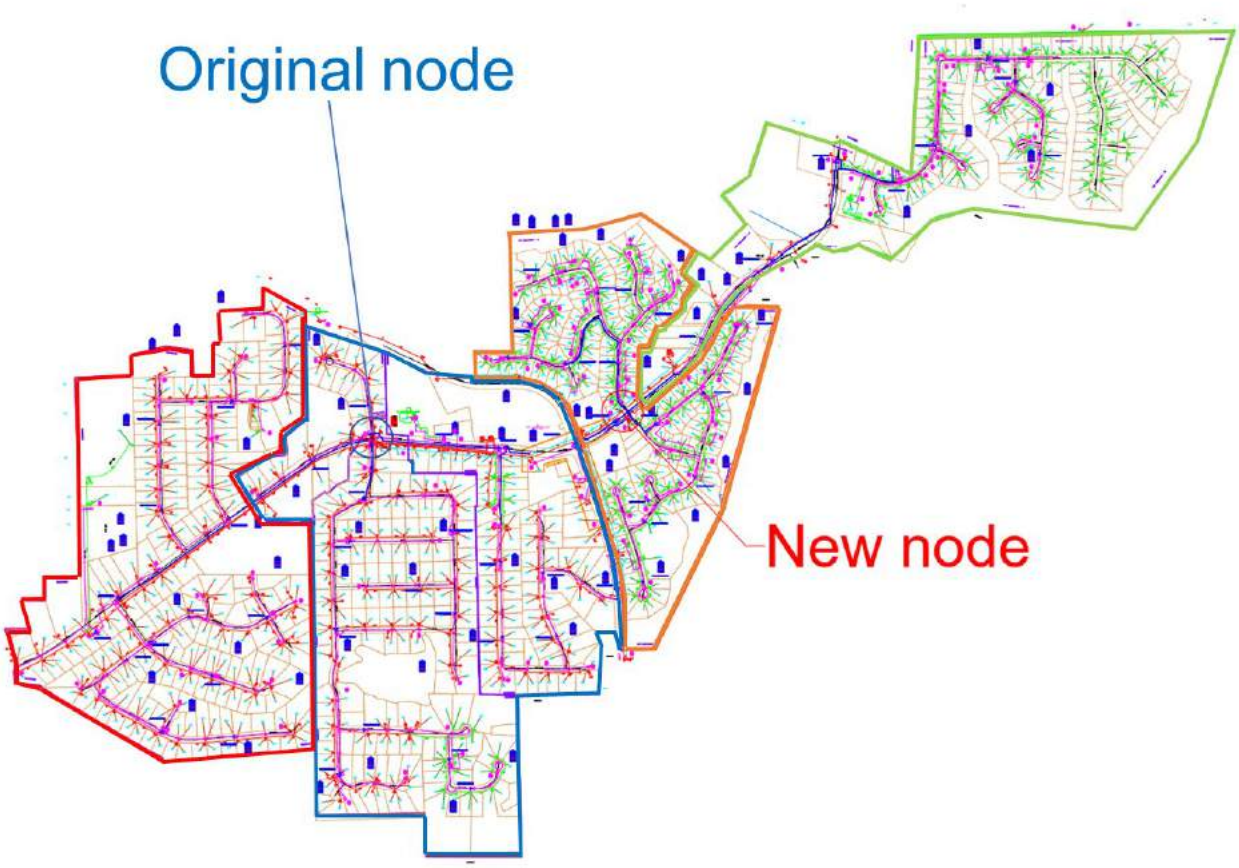

**Figure 7 – ML – Designed Node Split with balanced HHP**

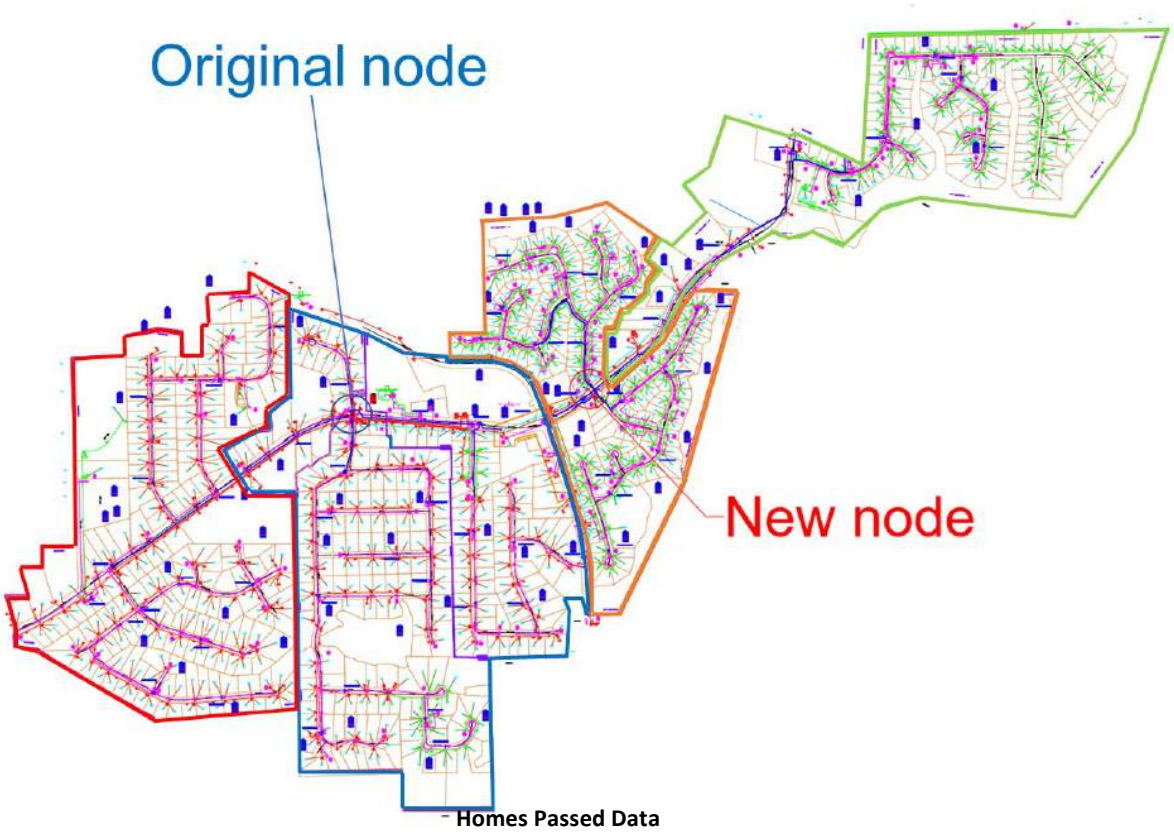
This node served 523 HHP before the split, and after the split the ML design determined four legs each of which could be segmented into a node in the future with no construction needed, however more than 2,000 feet of fiber and extensive coax-reversing would be required. The HHP data is in the table in Figure 8 below:



| | |
|---|---|
| Original Node | 523 |

| | Original Node Leg A | Original Node Leg B | New Node Leg A | New Node Leg B | Coax Reversing? | Fiber Extension Footage |
|---|---|---|---|---|---|---|
| Balanced HHP | 111 | 136 | 178 | 98 | Yes | 2284 |
| HHP % / leg | 21% | 26% | 34% | 19% | | |

**Figure 8 – ML-designed Node Split HHP data**

With good HHP balance and the ability to quickly double capacity via node segmentation this serving area will not require significant capacity upgrade activity for several years at nominal HSI bandwidth growth rates.

## 5.2. Implementing and Scaling Node Split Machine Learning Environment

The benefits of implementing a Machine Learning Node Split Design Environment are numerous and give the operators the analysis capability that would be cost-prohibitive in a standard design environment. For example, the nodes that are currently on the high-contention report could be quickly run through the ML design tool, under different business rules, and a Capital Expense projection could be created to guide

the budgeting process, and to inform the business about the tradeoffs involved where minimal construction augments result in more frequent network touches.

One challenge in implementing is the ML platform requires local data access – if your network is using a centralized network map platform such as GE SmallWorld or Synchronoss SpatialNet the maps would need to be "checked out" for data extract to the ML environment.

## 6. Creating a Holistic Network Capacity Augmentation Environment

As Machine Learning is integrated into the Network Planning and Operations process and platforms, as more systems and data are connected much more comprehensive design and analysis could be accomplished.

The chart in Figure 9 below shows some example inputs that if connected to a ML Prediction Engine could provide the network operator with planning information that could be calculated rapidly on a per-node basis for the entire network without significant human effort.

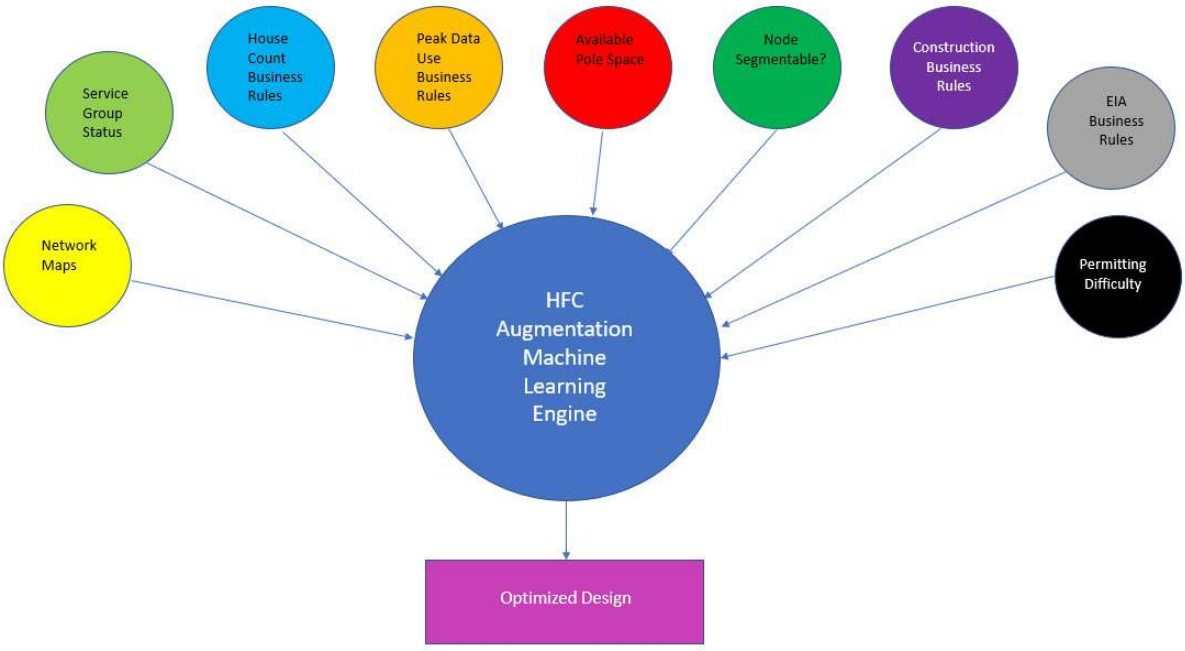


**Figure 9 – Possible inputs to holistic HFC Analyis, Design, and Planning Engine**

One possibility would be to connect the HSI network capacity platform and provide the ML environment data consumption information at a Peak-use-by-household basis. The ML business rules could be modified to optimize the node split based on real data usage versus just simply dividing the homes passed. A further business rule could identity the top 1% users and design and create BOMs for fiber connections to them to remove their data consumption from the HFC network – and cost scenarios could be quickly compared.

## 7. Conclusion

Network planning via Machine Learning is in its infancy but holds exciting promise to provide accurate and rapid automation of time-consuming network design activities. Network Operators should consider implementing network-based Machine Learning and over time connecting all network management platforms to enable comprehensive network design and capital expense planning.

# Table of Contents

## List of Figures

# 1. Introduction

The Common Public Radio Interface (CPRI), which is commonly used to connect cell sites and base stations, imposes ultra-low latency and transparent communications requirements that effectively force operators to provide dark fiber to carriers who purchase their services. But using dark fiber for a single service to an end customer is not only a wasteful use of a high-value asset, it is operationally inefficient. Dark fiber gives no visibility into the services the customer is running, and consequently the operator has no proactive way to monitor and manage the health of these services. Often, operators are alerted to outages when the customer calls to report them, which is, at best, a weak mechanism for support visibility. This paper will outline how new technologies—such as low latency Ethernet and hybrid active/passive networking—enable operators to create CPRI-as-a-Service offering that overcomes this key disadvantage, improves overall management and maintenance of their xHaul natworks, and lets them reclaim valuable unused fiber assets.

# 2. Are we stuck in the dark?

One of the little known secrets in the industry is that Cable Company owned fiber services the vast majority of cell towers in the United States. Pat Esser, Chief Executive Officer for Cox Communications shared during a Fox Business interview from the floor of the Consumer Electronics Show in 2019 that they provide the fiber to 82% of the cell towers that are located in their footprint.[1] Within the United States the fortunate convergence of a regulatory environment that created a robust private cell tower ecosystem and that resulted in the MSO community investing a rich fiber deep network infrastructure resulted in the majority of wireless carriers opting to lease xHaul services from the cable companies rather than investing in this infrastructure themselves. In the early days of xHaul, SONET was often used to provide traditional TDM based transport of bandwith from the cell tower back to the wirless service provider's telecommunications facilities. Over time as higher performance and lower cost Ethernet transport became available, this became the preferred transport mechanism commonly served via MPLS services from the cable company. In parallel to this transport evolution the wireless telecommunications equipment located at the towers also evolved an important technology. The Common Public Radio Interface specification or CPRI, created a mechanism which allowed the Baseband Unit (BBU) that performs all the signal processing and management to be physically separated from the wireless radio, allowing Remote Radio Units (RRUs) to be located several thousand feet away. The original intent of the CPRI specification was to allow distributed RRUs and their antennas to be remotely located on the tower with the baseband processing systems located in buildings a short distance away. Because of this short distance expectation, the CRPI specification has very strict network timing and low latency requirements. The specification also requires transparent layer one connectivity to in-band communication between the BBU and RRU. With an allowed latency of 75 microseconds, wireless operators realized that they could take advantage of economies of scale and lowered operations efforts by centralizing their BBUs in facilities located up to 20 kilometers away from the cell towers. This low latency, transparent communication link between the radios and base stations is commonly referred to as "fronthaul" and unlike legacy backhaul networks could not be supported via MPLS or Ethernet service offerings from the MSO forcing them to use dark-fiber to support the transport needs of the wireless carriers.

But dark fiber is an extremely valuable asset. In the United States the average cost to build out fiber infrastructure is around $100,000 per mile, assuming a blended aerial and underground mix. Not only is that a difficult return on investment model, especially considering that the perceived service value of the carrier purchasing dark fiber service is that it is in the range of lit Ethernet services, repaying out a fiber build in the tens of thousands of dollars from a single cell town is a real challenge. Now it should be pointed out here that when fiber is built, we do not just pull a pair of fibers as the general practice is to pull a sheath of fibers with hundreds of fibers. While these extra fibers can be used to facilitate other

 

network needs such as multiservice distributed access or other commercial customer buildouts, the needs of the other services may not be optimally placed in relation to the cell tower. The question should also be asked, "even if I can pay the cost of the build and/or make some profit off providing dark fiber service….is that the best fiscal use of this high value asset?" A single fiber strand can provide services to hundreds, and sometime thousands of residential and commercial subscribers. Dark fiber service delivered to the tower orphans that asset to a single customer.

While the economics of providing dark fiber as a service are arguable, there will always be a need for dark fiber and there will always be companies willing to offer it, what is not debatable is that dark fiber is difficult to monitor for service health.

Wireless carriers are notorious for their high expectations of service health and reliability. Since they are service providers themselves, they have an accountability to what can be hundreds of their customers who may be impacted by outages. Since the MSO will have no visibility into the network equipment connected to the dark fiber, they will also have not be able to monitor service health. This often means that the first notification of a customer affecting outage the MSO will likely receive is when the customer calls to tell them they think they have an issue with their fiber. Since the MSO has no visibility into the services running on the fiber they are left blind to the root cause of service degradation. Is the cause an impairment caused by damage to the fiber, an issue at the CPRI or Ethernet layer, or some other issue? Without visibility into the service layer the opportunity for finger pointing between customer and provider in the fog of war that comes with service degradation effecting multiple downstream customers becomes a common event that can negatively impact the relationship between MSO and carrier.

So, is the option only to offer dark fiber with its high cost and low service value because the needs of the CPRI protocols cannot be support by traditional Ethernet or MPLS? The good news is that technology has evolved and the options are no longer just a binary dark fiber or nothing to satisfy the requirements of wireless carriers.

## 3. New technologies to change the game

One set of technologies that is a game-changer in the ability to introduce concepts known as low latency Ethernet and/or Time Sensitive Networking. Time Sensitive Networking is a series of standards built on the 802.1 working group standards that allow Ethernet to support very low latency and jitter as well as introducing strict network time synchronization required to so support CPRI fonthaul applications as a service.[2] The technology advancements introduced by TSN have allowed for the introduction of CPRI as a service. Much like traditional SONET, ATM and Ethernet services, CPRI services allow the MSO to deliver the service requirements of ultra-low latency and strict network time synchronization while also allowing them to manage, monitor and maintain the quality of the service to ensure a consistent and high customer experience level. Still, having the technical capabilities to deliver a CPRI service may not be sufficient by itself to wean carriers off their dark fiber addiction. Since there are fiber over builders often willing to construct in fiber, many MSOs have been reluctant to push their customers to a CPRI service offering out of concern that another fiber provider will overbuild their footprint, a very real risk. So, we need to discuss how to increase the customer perceived value of the service and discuss new service capabilities that will improve the customer experience.

But first, we need to touch on one other networking technology that is also viable for carrying carrier distributed antenna network, passive DWDM. It is quite common for larger wireless carriers who also have some of their own fiber to use passive DWDM with tunable optics to carry distributed antenna traffic in their networks. There are a good variety of 10G and 25G single-and dual-fiber options that can plug directly into the remote radio units to carry the traffic back to the baseband unit for processing.

Much like DWDM is used for DAA and business services traffic in the MSO network, this is an excellent low cost option for metro networks. However, just as with dark fiber, passive DWDM lacks service layer visibility and monitoring. Unless the MSO has visibility into the edge equipment carried on the passive network, they will have no idea that there is service degradation until the customer calls them and even then, it will be just as difficult as with dark fiber to quickly troubleshoot and isolate the root cause.

As stated previously, wireless carriers justifiably, have a high expectation for service availability and quality. What is needed to elevate the level of these technologies to a true service offering is a way to make the network more intelligent, more automated and easier to manage and maintain, and more transparent to both the MSO and to the wireless carrier.

It is becoming increasingly more common for modern network transport and access equipment to be equipped with standardized APIs and YANG models to allow them to be part of a Software Defined Networking or SDN ecosystem. SDN allows operators to evolve the paradigm of network management from provisioning to programming. By imagining a network as a programmable set of components that can obey defined rule sets and consistently report information such as network topology and system and service health, we can take advantage of SDN technologies to create new service capabilities.

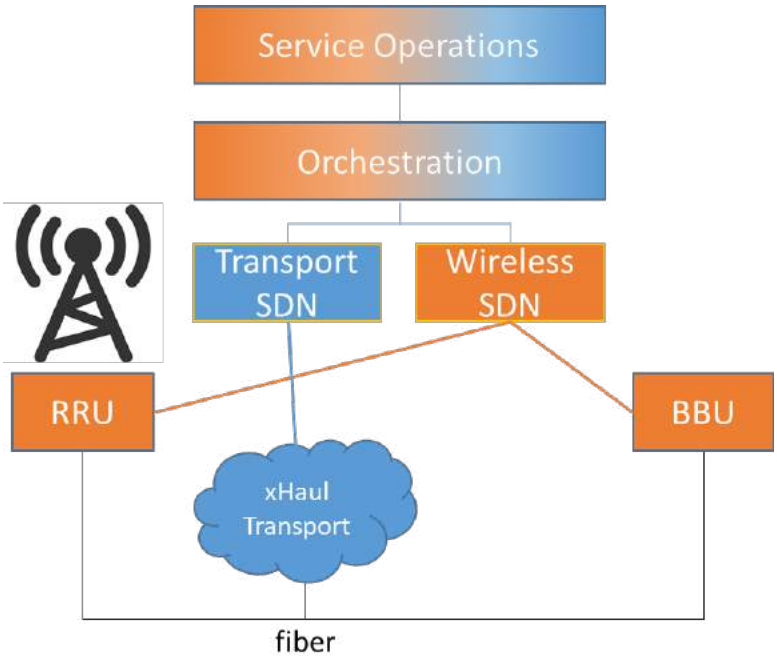

**Figure 1 - Unified Software Control**

In figure 1 we see a block diagram example of how we can use software control over the end to end network to provide a unified operations view for both the MSO and the wireless operator. Taking advantage of open APIs we have a transport SDN controller that is within the MSO network and a wireless SDN controller in the wireless operator's network. Both the wireless and transport networks are controlled by an orchestration system and service operations that both operator and customer have delegated views into but with walled garden control. Both operator and customer can "see" the status of the other network and their orchestration systems can respond to and honor network demands from the controllers as well as provide unified topology and management views of the end-to-end network and its health.

This mixed management methodology will operate and behave based on service rules agreed to between operator and customer. Operations engineers familiar with traditional network management systems and more importantly the lack of multi-vendor and multi-layer management capabilities will undoubtedly be skeptical of the image in figure 1. This has traditionally been true as both network equipment and management systems have been closed, monolithic ecosystems lacking a high degree of flexibility and extensibility. But, modern network automation software is capable of introducing this new functionality into existing operations and control systems. Today we can take advantage of open APIs and microapps to introduce functionality into operations systems incrementally without the need to tear out the existing infrastructure. This method is also capable of connecting multiple vendor systems because it can integrate either with existing management platform northbound APIs or integrate directly with the network infrastructure itself via document YANG model. Both of these mean that no longer must a new, monolithic system be stood up next to existing infrastructure. The MSO can add the new functionality a service at a time using microapplications and microservices.

One example of where using software automation to modernize networks is improving the functionality of passive DWDM networks. As previously stated, traditional passive DWDM networks allowed for very

limited visibility into the topology and health of the underlying transport infrastructure because there was no direct way to query this equipment. This meant, as an example, If an operator wanted to provide a service level topology view of their network their technicians would be required to manually provision wavelength services as they were added, moved, or deleted. Since manual efforts like this are both labor intensive and fraught with potential for error, the result was that not many if any operators have a live topology view of services running on their passive optical networks for monitoring and troubleshooting purposes. In addition to a lack of service visibility as passive networks require the client pluggable to be correctly tuned to the wavelength supported by the port into which they are plugged, they increase the operational effort to provision network additions or changes. They also increase the potential for error as the technician can select the wrong port or pluggable.

Modern smart pluggables overcome this issue as they are tunable across the full optical spectrum and are able to determine which wavelength they should auto-tune to in order to establish service. These pluggables are also capable of some service monitoring to determine the health of the optical link. By using software intelligence to monitor this, a micro-application can be introduced into the network management system to determine which wavelength the pluggable is tuned, correlate this with the known passive topology, and then draw a visual representation of the service path through the passive network. This can then be later used for system alarming, showing the network operations team that not only that the pluggable is in alarm, but the expected path through the network. This provides additional service context that can be useful in quickly isolating and resolving service faults. Additionally, the operator can provide the smart pluggables to customers who are connecting in their remote radios or other devices to the passive network. Since the pluggable will auto-provision and tune to the appropriate wavelength, the wireless operator can self-install their equipment once fiber has been terminated at the appropriate demarcation point. As the pluggable can be monitored by the MSO, they now have service visibility for the optical layer without having to have access to the customer's edge equipment. This topology is known as Hybrid Active/Passive and can greatly improve the customer experience while improving MSO installation and operations efforts.

# 4. Conclusion

In addition to allowing for multi-layer, multi-vendor operations, these modern systems often have well documented APIs it becomes practicable to implement intersystem communications and control between operator and customer. Since the implementation can be done on a per-function application via a micro-app or micro-service, this integration work can be done within the context of a specific customer agreement and the cost of implementation can be tied to the revenue generated by that agreement. Open systems and open architectures in the transport and wireless networks and their control systems mean we can now extend automation and visibility of the network to allow for lower operations effort and provide a better customer experience.

Advances in time sensitive and hybrid active/passive networks now allow the capability to carry wireless operators xHaul traffic in an efficient and reliable manner negating the use of dark fiber as the only method to support the needs of wireless operators. These technologies are deliver a better customer experience by enhancing the MSO's visibility into the service health, which is not feasible with dark fiber. These technology advances are likely enough in their own right for MSOs to justify offering CPRI as a service in lieu of dark fiber.

But the industry should not stop there when considering their xHaul service offerings. With modern software intelligence, further improvements can be added to the service that increase collaboration and trust between the MSO as a transport operator and the wireless carrier. Ultimately these will lead to an increase in customer satisfaction and increase the product "stickiness".

bill.beesley@fujitsu.com

# Table of Contents

# 1. Introduction

MSOs seeking to increase service delivery speed and reduce the high cost of cell site transport over fiber now have a new option. Low-latency DOCSIS has made the HFC network viable for midhaul and backhaul transport applications. The Telecom Infra Project's vRAN Fronthaul Project Group has developed a means to use cable modems for some cell site transport applications. Using SDN to provide unified management and control of the fiber xHaul; DOCSIS BSOD services; and the RAN, operators can now create the consistent operational views and control needed to fully support this new application for cable modems. This paper will outline the future of wireless transport and discuss how to operationalize cable modems into the existing fiber transport architecture. Topics will include how to implement automated setup and provisioning of network demands, along with a single view of service health, in an overall consistent provider experience whether they use traditional fiber transport or cable modems for xHaul service delivery.

# 2. A Convergence of Technologies

The Common Public Radio Interface specification or CPRI created a mechanism that allowed the Base Band Unit (BBU) that performs all the signal processing and management to be physically separated from the wireless radio allowing Remote Radio Units (RRUs) to be located several thousand feet away. The original intent of the CPRI specification was to allow distributed RRUs and their antennas to be remotely located on the tower with the baseband processing systems located in buildings a short distance away. Because of this short distance expectation, the CRPI specification has very strict network timing and low latency requirements. The specification also requires transparent layer one connectivity to in-band communication between the BBU and RRU. With an allowed latency of 75 microseconds, wireless operators realized that they could take advantage of economies of scale and lowered operations efforts by centralizing their BBUs in facilities located up to 20 kilometers away from the cell towers. The industry uses the term "fronthaul" to describe the access layer connection between the centralized base band units to the distributed antenna system. Because of fronthaul' s low latency requirements, optical fiber based solutions are the common method for building this access layer. But with millions of disturbed antennas predicted to be deployed to support continued growth of the 5G era, especially in remote and rural areas, the industry is seeking to advance other technologies like cable modems to be able to support fronthaul requirements.

The Telecom Infrastructure Project vRAN Fronthaul Project Group has set out to develop solutions that would allow the connection between the baseband unit and the remote radio unit to have much lower latency requirements than currently allowed by the CPRI specification. The first round of technology labs testing access technologies such as PON, G.Fast and cable modems was completed in 2019. CableLabs® served as the community lab that provided proof of concept testing for the use of cable modems and they were able to successfully demonstrate support for fronthaul services over an HFC network in their lab environment. While non-ideal fronthaul is still in the proof of concept stages as of the time of this paper, the results are promising and could be standardized and supported by the radio vendor products in the next few years. This would do much to accelerate the deployment of 5G services and give cable operators another viable choice for access network transport of fronthaul. (see https://telecominfraproject.com/vran/)

In parallel to this activity, CableLabs® has developed mechanisms to significantly improve the latency in HFC networks. Because of the communications handshakes between the cable modem and the CMTS and the nature of the way DOCSIS schedules upstream timeslots, latency in the HFC network has generally been way too high to ever consider it for use in the split RAN architectures described above. The industry needed to be able to support applications like gaming and split RAN xHaul which have very low latency demands. CableLabs® accomplished this by introducing low latency DOCSIS for gaming and low latency xHaul for wireless transport. Many papers go into the details of how both of these work but a simplified description is that by modifying the scheduling mechanism to be preemptive and allow for parallelism it becomes possible to get the latency of the HFC network down into the one to three millisecond range. While this does not currently support fronthaul, in combination with non-ideal fronthaul at some point in the near future it will be entirely possible to support all xHaul architectures via the HFC network.

But as we move into the "can we" question of using HFC for fronthaul, we also need to consider the "should we". No network tool is universal and there are several operational considerations for using coax versus fiber to support the deployment of fronthaul based radio units

## 3. Choices, Choices

The first consideration is the utilization of the asset itself. Wireless deployments are not "bursty" like residential or other commercial data users. Today, a radio unit will use the maximum amount of bandwidth with only one radio connected to it. In addition, the preemptive nature of low latency xhaul means that some amount of upstream bandwidth will need to be allocated in case the radio needs to communicate with the base band unit. When planning for future cable modem based fronthaul deployments, the question will need to be asked if the HFC bandwidth could be used for other revenue generating services. In addition, HFC network reliability is significantly lower since all but one MSO does not use a ring architecture. Depending on the sizing of the wireless service group, thoughtful consideration will need to be given as to whether it may make economic and operational sense to deploy fiber even where coax may be readily available. Of course, where fiber assets are unavailable, or too expensive to extend, coax will still be a great option for fronthaul. Operations staff will just need to measure the options.

An old telecom service adage goes something like, "it is easy to deploy the first service. It is deploying the next ten thousand that is hard." As the paradigm for fronthaul services moves into the HFC world, operations staff will need to be retooled and retrained to support a new class of customer. Wireless carriers have much higher service level expectations than existing residential and commercial HFC based customers. This, along with the introduction of new technologies such as remote radio units will increase expectations placed on frontline operations staff. One example of this change was experienced a bit over ten years ago when the first cable modem based, strand mount wireless hotspots were introduced into the market. A major cable operator in the US decided to deploy this new technology to support wireless data based services in public spaces and event areas. These devices were mounted on the existing HFC strand and obtained both their access and power from the coax to deliver a public hot spot service. What the cable operator quickly learned was that the outside plant technicians didn't have a working knowledge of cable modems and wireless access points and that the wireless data engineers did not have experience working with HFC hardline, plant power and even if they did, they didn't have bucket trucks. It because quickly clear that these groups were going to have to develop new tools, training and working methods in order to successfully ensure the delivery of the new service.

When considering adding coax as a service delivery mechanism for fronthaul, operations teams need to plan on how they will deploy the new service in a consistent and repeatable manner. How will service

 

adds, moves and changes be managed quickly and efficiently? Who will monitor and manage service health and how will they accomplish this? There will be new tools, new methods and of course, new training necessary. Frontline operations leadership needs to carefully document and prepare their teams for the changes that will come.

Another consideration often overlooked is that there are a large number of wireless carriers currently supported by the MSO fiber infrastructure. In the US, the cable companies own the majority of fiber infrastructure delivering services to wireless carriers. Pat Esser, Chief Executive Officer for Cox Communications shared during a Fox Business interview from the floor of the Consumer Electronics Show in 2019 that they provide the fiber to 82% of the cell towers that are located in their footprint. Due to the fiber rich nature of the HFC architecture, it is likely other MSOs are enjoying similar service numbers within their footprint. As the cable industry evolves toward delivering some wireless xHaul via cable modems there will need to be a mechanism to provide unified and consistent management and support for the customer where their services are running on both fiber and coax networks.

## 4. An evolution

The industry will need to evolve towards support for a unified topology paradigm that allows the end-to-end management both fiber and coax networks along with the wireless radio network. New technologies like software defined networking controllers will be required to allow for collaboration across these network domains in order to not only support functionality, such as 5G network slicing, but also to allow operations teams to be effective. Future networks will require operations teams to shift from managing network equipment to managing customer services. Services will need to be automatically created at both the fiber access and DOCSIS network based on service demands from the wireless access layer and then effectively chained together to provide an end-to-end service. To avoid the need to add additional operations resources as new, more complex services continue to be added to the network, it will become the software management layer that will be the critical linchpin in the operators network. Software interfaces will need to become more open. Systems will need to allow for more intelligence and automation. Emerging technologies such as AI/ML will need to be introduced into the management of the end-to-end network. The alternative is operational overload.

## 5. Conclusion

The cable industry is at another turning point in service delivery. Wireless deployments will continue to grow exponentially to meet growing demand for more bandwidth and lower latency. As the deployment of fiber deep assets to support HFC allowed them to secure the access transport for the majority of the cell towers deployed in the past, the MSO community is well positioned to support the next round of wireless growth. But they will need to prepare more than their network technologies to support this next wave of new services. They must also invest in and prepare their operations systems and teams. By doing so, cable networks will continue to be the dominant method for delivering access transport for wireless deployments

# 1. Introduction

We are in a unique time in our history of Wi-Fi with three major changes happening in less than a 3 year period that fundamentally challenge us to look at our traditional view of Wi-Fi home architectures in the home. In particular how a Service Provider keeps pace with change and reaps the benefit of the increase in bandwidth, increase in coverage and decrease in latency while at the same time providing their customers with a clear and concise device and services roadmap.

The 3 fundamental changes are

(i) Wi-Fi 6 – just starting to deploy this year for most service providers in their primary Gateway or Access Point. Wi-Fi 6 extender solutions typically lagging behind the primary AP function.

(ii) Wi-Fi 6E and the addition of 6GHz spectrum. In particular in the US the allocation of 1.2GHz of new unlicensed spectrum has now fundamentally opened up a new approach to how Wi-Fi and all wireless services play out in the home. And provide a path to even higher bitrate immersive video services and lower latency services over Wi-Fi.

(iii) IEE802.11be and probably the next Wi-Fi 7 standard which takes the opportunity now of 6GHz spectrum and opens up single channel capabilities to support 320MHz channels from the present 160MHz channels supported today in Wi-Fi 6/6E.

| Date | Standard | Wi-Fi | Frequency | Bandwidth MHz | MIMO | Bitrate |
|---|---|---|---|---|---|---|
| 1997 | 802.11 | | 2.4GHz | 20 | NO | 2Mbps |
| 1999 | 802.11b | 1 | 2.4GHz | 20 | NO | 11Mbps |
| 1999 | 802.11a | 2 | 5GHz | 20 | NO | 54Mbps |
| 2003 | 802.11g | 3 | 2.4GHz | 20 | NO | 54Mbps |
| 2009 | 802.11n | 4 | 2.4+5GHz | 20/40 | 4x4 | 600Mbps |
| 2013 | 802.11ac | 5 | 5GHz | 20/40/80/160 | 8x8 | 6.9Gbps |
| 2019 | 802.11ax | 6 | 2.4+5GHz | 20/40/80/160 | 8x8 | 9.6Gbps |
| 2021 | 802.11ax | 6E | 2.4+5+6GHz | 20/40/80/160 | 8x8 | 9.6Gbps |
| 2023/24 | 802.11be | 7 | 2.4+5+6GHz | 20/40/80/160/320 | 16x16 | 30-40Gbps |

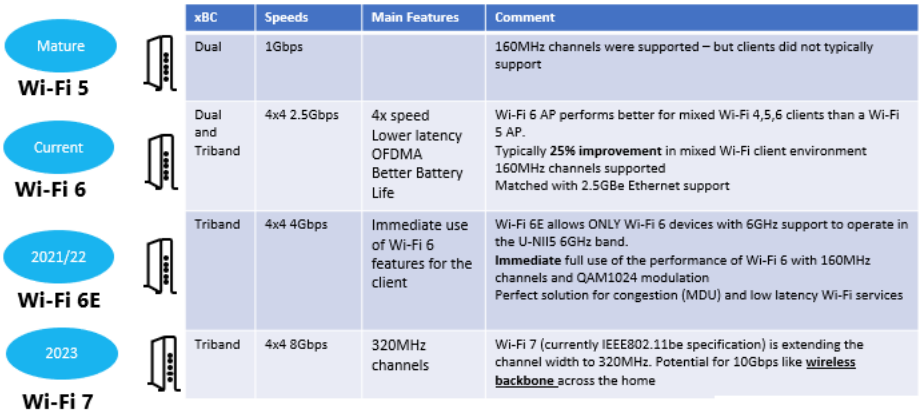
**Figure 1 - The Wi-Fi Standards**

While Wi-Fi took 20 years to finally revise its MAC for the creation of IEE802.11ax and subsequent Wi-Fi 6 standard we now have both 6E and Wi-Fi 7 happening over a 3 year period so need to now look ahead to the next 3 years and how the

- Transition from current home solutions of mixed mode g/n and ac to emerging Wi-Fi 6 AP and the start of third party Wi-Fi 6 clients
- Introduction of specific Wi-Fi 6 clients for Service Providers – typically first STB and Extenders
- Planning for use of 6GHz spectrum and the introduction of Wi-Fi 6E. Current discussions are around potential introduction by all new Tri-band Gateway or AP or with the introduction of a Wi-Fi 6E extender that supports augmentation for Wi-Fi 6 as well as first Wi-Fi 6E usage.

- Use of Low Power Indoor power levels for Wi-Fi 6E and the utilization of higher Standard power levels utilizing Automated Frequency Control mechanisms
- Exploitation of the 33-66Gbps of Wi-Fi spectrum available with 6GHz channels alone for the next generation home and services
- Use of 320MHz high capacity channel for high capacity client applications or use for backhaul to 10GbE capability in the home.
- Separation of 2.4GHz and 5GHz usage from 6GHz channels for legacy solutions as well as potential new usages for these legacy spectrum channels. 2.4GHz for example is now in stark relief for its limited capacity versus the other frequency levels but also may have a key role to play in the home for long range 'Narrow Band' Wi-Fi IoT functionality. Its current role for being primarily a reliable long range coverage channel when 5GHz is not usable or the device types are cheap and only support 2.4GHz radios.

This paper will discuss these areas in more detail in the following sections and hopes to offer a good discussion on the parameters and decision points to consider in the next 3 years of fast moving Wi-Fi technology changes. It should help the Cable Operator with the transition decision points of moving from Wi-Fi 5 through 6 and 6E as well as Wi-Fi 7.



| xBC | Speeds | Main Features | Comment |
|---|---|---|---|
| Dual | 1Gbps | | 160MHz channels were supported – but clients did not typically support |
| Dual and Triband | 4x4 2.5Gbps | 4x speed<br>Lower latency OFDMA<br>Better Battery Life | Wi-Fi 6 AP performs better for mixed Wi-Fi 4,5,6 clients than a Wi-Fi 5 AP.<br>Typically **25% improvement** in mixed Wi-Fi client environment<br>160MHz channels supported<br>Matched with 2.5GBe Ethernet support |
| Triband | 4x4 4Gbps | Immediate use of Wi-Fi 6 features for the client | Wi-Fi 6E allows ONLY Wi-Fi 6 devices with 6GHz support to operate in the U-NII5 6GHz band.<br>**Immediate** full use of the performance of Wi-Fi 6 with 160MHz channels and QAM1024 modulation<br>Perfect solution for congestion (MDU) and low latency Wi-Fi services |
| Triband | 4x4 8Gbps | 320MHz channels | Wi-Fi 7 (currently IEEE802.11be specification) is extending the channel width to 320MHz. Potential for 10Gbps like **wireless backbone** across the home |

**Figure 2 - The evolution of Wi-Fi from 5 to 7**

So, from an availability for a Cable Operator to be able to deploy new Wi-Fi technology today we are in the Wi-Fi 6 era with Cable Operators expected to deploy Wi-Fi 6E solutions end of 2021 or early 2022. This is then followed in 2023 by the ability to upshift once more with the proposed availability of Wi-Fi 7 solutions in market in 2023 – potentially even trialing as early as 2022.

Cable Operators need to invest in their device strategy wisely and ensure as usual that

- They minimize SKU's for keep down inventory and operational cost overheads
- Return the investment in their investment in GW and Extenders deployed
- Not confuse their customers with too many Wi-Fi changes
- Associate Wi-Fi changes with other consumer friendly features and performance metrics that they understand
- Align their Wi-Fi 6, Wi-Fi 6E and Wi-Fi 7 upgrades with their DOCSIS 3.1 to DOCSIS 4.0 evolution and increasing PON speed solutions.

See below a potential evolution roadmap that highlights the introduction of both DOCSIS GW and Extenders to bring in the new Wi-Fi features. One potential alignment of Wi-Fi 7 now is DOCSIS 4.0 and these two technologies could be aligned for common introduction based on their current schedules. It

highlights the probability of Wi-Fi 6 GW today lasting well into the introduction of 6E and the continued use of Wi-Fi 6E devices in the Wi-Fi 7 domain particularly. It also brings up questions about Extension of Wi-Fi which we will also touch on more in the paper.

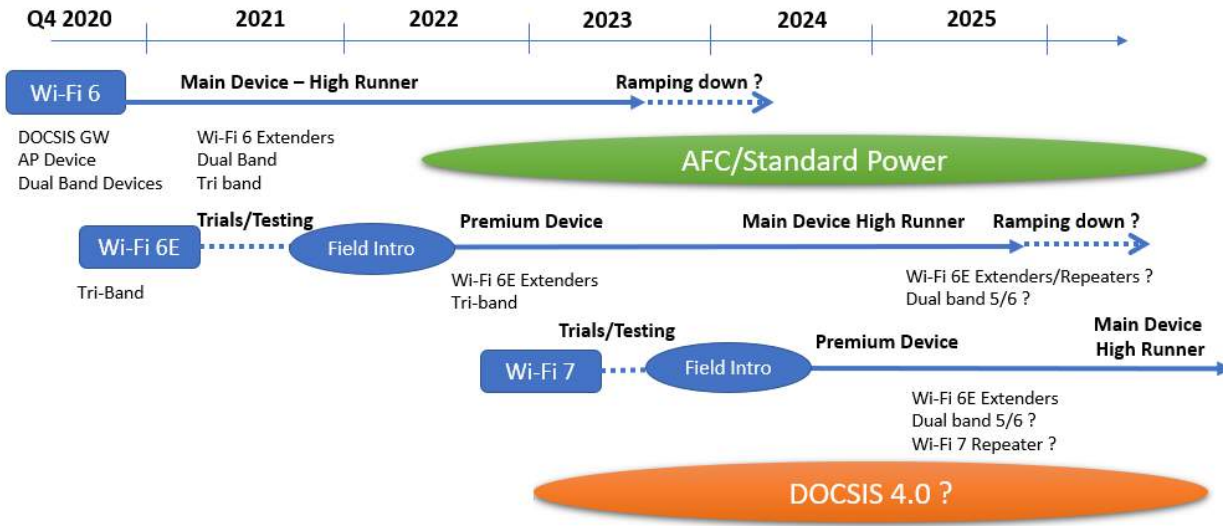


**Figure 3 - Potential overlapping Wi-Fi DOCSIS GW solutions in the 2020-2025+ timeframe**

Before we continue, we also want to outline some of the reasons why we need to make this investment in

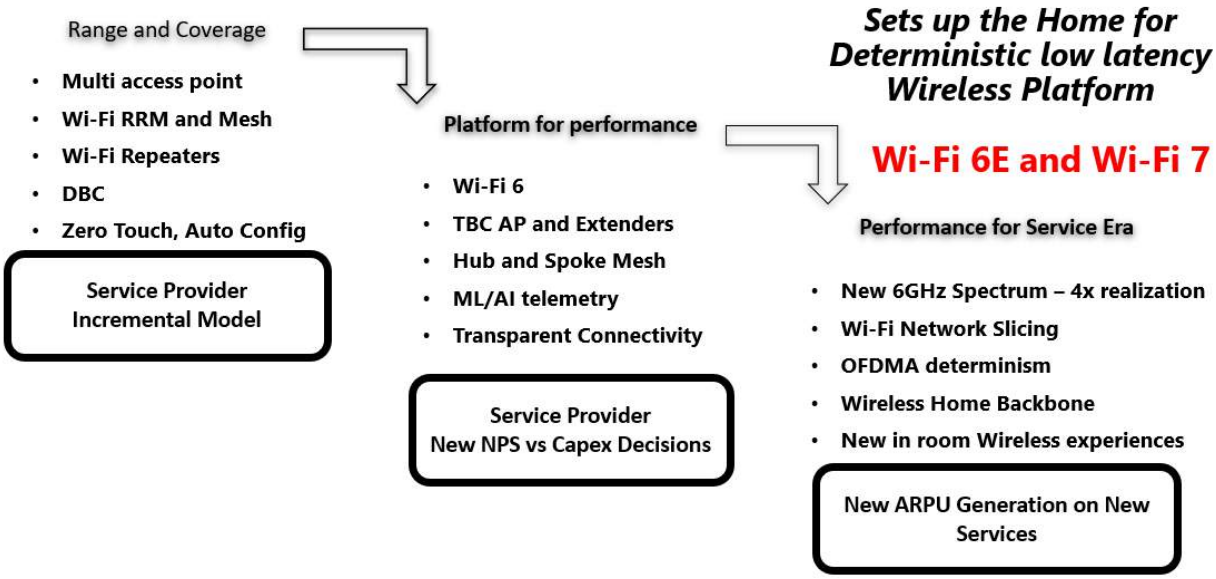

**Figure 4 - The Wi-Fi Eras and where we are going**

We have been focused over the last 20 years of Wi-Fi on

- 802.11 b/g - getting untethered from the ethernet cable
- 802.11 n – using 5GHz spectrum which formed the basis of being able to support streaming IP video
- 802.11ac – which got us to 1Gbps speeds on Wi-Fi

- 802.11ax – which redefined the MAC and added the foundation for added Spectrum for Wider Channels

We got to a point where we also

- Initially had one AP per home
- Added Repeaters for 'barely their capacity coverage'
- Improved with Wi-Fi Meshing solutions for better coverage
- Introduced new Wi-Fi 6 MAC and improved FEM technologies to be able to get more efficiencies in Mixed b/g/n/ac and ax client networks

But Wi-Fi still had difficulties getting 80MHz and 160MHz channels reliably enough, had high congestion issues in MDU's and could never really get the determinism to feel reliable to have it as a foundation for new wireless high capacity and low latency services in the home.

Now with 6GHz spectrum (1.2GHz in the US) we have the new Era of Wi-Fi – Deterministic, Low latency high capacity platform – to build new Wi-Fi home services.

## 2. Todays home – legacy g/n and ac devices and emerging Wi-Fi 6

If we could change everyone's Access Point to a Wi-Fi 6 device and every client to a Wi-Fi 6 device – we could take advantage of the improvements in features Wi-Fi 6 immediately. However, that is not possible for the Service Provider and even for the retail consumer. So, we currently have in everyone's home a mixed environment for Wi-Fi where there are variances in the primary Access Point

- 802.11n and 802.11ac access points still dominate the distribution for homes
- Over 90% of deployed Access Points are Dual Band Concurrent
- The majority of Wi-Fi extenders are really repeaters with the majority of those still running dual band 802.11n
- The breakdown of client devices (taken from various CommScope sources) are spread across
    - Pre AC (Wi-Fi 4) devices are > 43% of the current home devices (but in some regions of the world (are as high as 71%)
    - AC (Wi-Fi 5) devices are about 56% of the current home devices (in some regions of the world are as low as 27%)
    - Wi-Fi 6 devices still only number about 1% of the current home devices

**Figure 5 - Wi-Fi Speed evolution**

Within the client base there are also new devices like the popular Wyze cameras that only support 2.4GHz Wi-Fi 4 because of cost points and cost maturity of 2.4GHz only solutions for IoT and Camera applications.

From CommScope's analysis of the home 802.11b and 802.11g only devices have almost fully flushed through to later and better Wi-Fi solutions.

There are several significant device types in the home that have different replacement cycles for Wi-Fi but typically group into the following categories

- Wi-Fi Access Point or Primary Gateway – typically Service Provider supplied
    - Average time in the home – probably decreasing with technology acceleration but typically lasts for 5 years without change
    - Typically, not changed by the SP when new technology introduced if the household has no issues or requires a new service that requires a GW or AP upgrade
    - Wi-Fi upgrades may be tied to WAN access technology changes, such as DOCSIS 3.0 to DOCSIS 3.1 or GPON to XGS-PON
- Extenders – have a higher churn rate with consumers as they move through lower cost devices that underperform purchase improvement devices when necessary – probably a 3-4 year life cycle. Consumers have purchased retail repeaters themselves to remediate SP Wi-Fi issues. Some consumers have purchased their own meshing Wi-Fi solutions in recent times to bypass the primary service provider issued GW solution.
- Wi-Fi Client Devices
    - Static Clients
        - Wi-Fi Smart TV – TV's have a 5-7 year life but can be moved from Room to Room
        - Wi-Fi STB – churn faster than Smart TV but typically have 3-4 year lifecycle and higher for quality SP issued solutions or Apple TV devices
        - Wi-Fi printers – 5 year cycles
        - Wi-Fi based PC/iMac – 5+ year cycles
        - Smart Assistants – 5+ year cycles
        - Camera typically indoor but often edge of range outside the house – Doorbell or Security cameras
    - Mobile Clients
        - Smart Phones – depending on model and who supplies the phone but now tracking 2.5 to 2.88 years

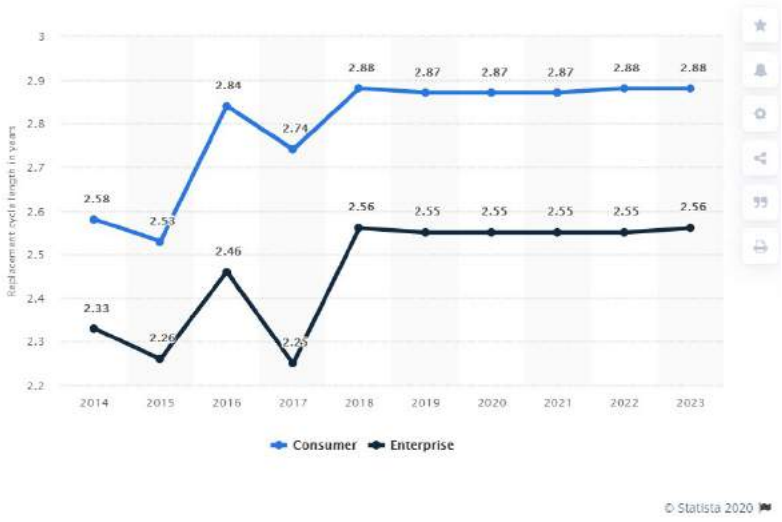

**Figure 6 - Average time to replace Smartphone in the US**

- Tablets – until they break or die
- Laptops – 4-5 years. Corporate Laptops churn faster at 3 year cycle

- Apple Watch – churn time 3-4 years. Note even Apple Watch just uses 2.4GHz Wi-Fi.

- Low cost IoT Wi-Fi devices (typically last a long time until they die)
  - Smart Power Switches
  - Smart Sensors

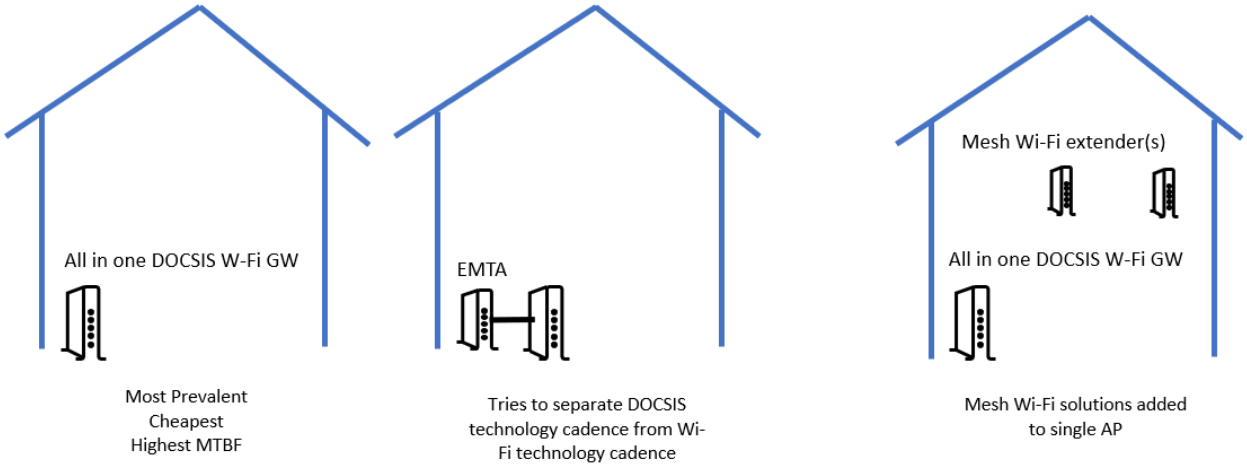

**Figure 7 - Todays Wi-Fi architectures**

There are 3 typical Wi-Fi architectures found in most Cable Homes.

1. **The most economical and the majority of households**

   Single all-in-one DOCSIS and Wi-Fi Gateway. Offers the lowest cost to the Cable Operator to provide both DOCSIS access and Wi-Fi services. Typically does a great job in homes less than 2.600sqft and offers also the highest MTBF because of single PSU. Highest Self install capability particularly in homes with existing DOCSIS modems as a replacement.

   Downsides of the all-in-one Gateway is that it tends to be located at an outside wall location close to Cable ingress point to the home rather than more centrally in the home to accommodate better whole home Wi-Fi coverage.

2. **The '2 box' solution where a separate eMTA and Wi-Fi AP are installed**

   Typically, both devices are connected by 3 feet of ethernet. Main driver for this architecture is to separate out the cadence of DOCSIS evolution and Wi-Fi evolution. The faster speed cadence of Wi-Fi technology and the consumer desire for the latest Wi-Fi solution has driven this solution. It does carry a higher initial CAPEX costs and probably over its lifetime, but the key metric is how often both the eMTA and AP are replaced vs one of them only. It also offers potential Operational improvements particularly for CSP's with multiple Access Networks like PON, DOCSIS, FWA where the same LAN based AP can be added to all access networks.

   This architecture is also the Cable Operators nemesis when customers add their own Access point and NAT out the Cable Operator services.

## 3. The Wi-Fi Mesh solution

We have now moved into the era of the Cable Operator deployed Mesh solution that extends Wi-Fi across the home, especially in larger homes. There are lots of discussions how best to extend coverage and the types of Wi-Fi extension

- Repeaters – trending away from these now to smart Repeaters
- Dual Band Smart Repeaters – employing some Wi-Fi Management RRM solution trying to maximize channel and band usage across the home
- Tri-Band extenders – with typically 5GHz backhaul solutions on a dedicated backhaul link that can also be used to attach clients under QoS mechanisms. Tri-band typically 2.4GHz+5GHz+5GHz – with U-NII1/2 and U-NII3 support one each radio.
- Other debates continue on how many streams and radios to use. Popular setups now are
  - 4x4 (2.4GHz) + 4x4 (5GHz) for the primary Wi-Fi AP when DBC
  - 4x4 (2.4GHz) + 4x4 (5GHz) + 4x4 (5GHz) for Wi-Fi AP when TBC
    - Similarly, for High End TBC extender
    - Lower end 4x4 (2.4GHz) + 4x4 (5GHz backhaul) + 2x2 (5GHz)
  - Low cost Smart Repeaters 2x2 (2.4GHz) + 2x2 (5GHz)

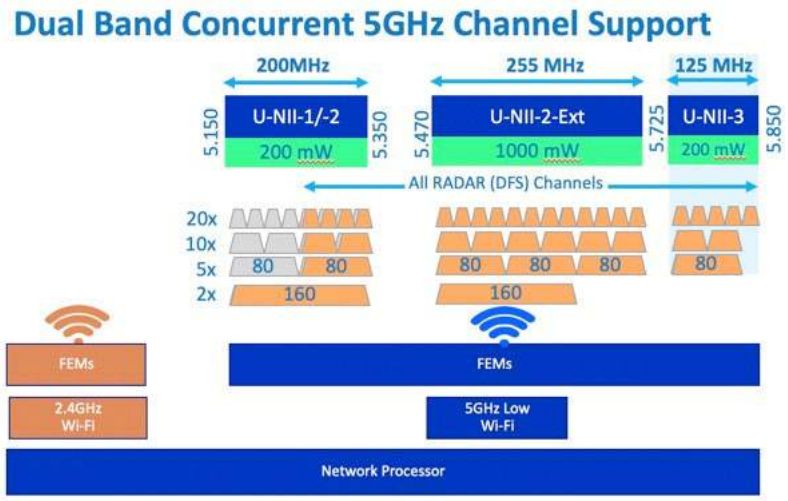

**Figure 8 - Dual Band Concurrent AP (2.4+5GHz)**

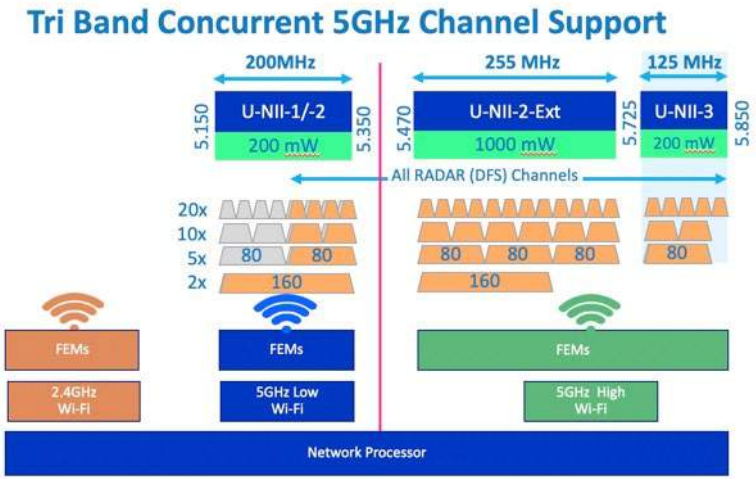

**Figure 9 - Tri Band Concurrent (2.4+5GHz Low+5GHz High)**

These have been introduced initially on Wi-Fi 5 architectures and within the constraints of 5GHz frequency availability in particular where 160MHz channel use has been almost non-existent because of (i) lack of client support during Wi-Fi 5 standard and (ii) no channels available with congestion and DFS requirements. Typically, most of the Wi-Fi transmissions in 5GHz are using 80MHz and 40MHz channels.

## 3. Service Providers and the introduction of Wi-Fi 6

Wi-Fi 6 introduces a significant number of new features for the operation of Wi-Fi, including a 4x average improvement per user in dense or congested environments (stadiums, etc.), a 4x improvement on network efficiency, and far better battery life for Wi-Fi 6 devices. Most importantly it offers a significant boost in performance over Wi-Fi 5 in terms of rate and range, promising about a 40% increase in data rate. The addition of 1024-QAM and 8 spatial streams as part of Wi-Fi 6 enables the highest speed of 9.6Gbps. From an AP technology perspective, it includes general signal handling improvements that not only benefit Wi-Fi 6 devices, but also previous generation devices, based on improvements with silicon process and front-end modules (FEMs).

Virtually all shipping Wi-Fi 6 APs are dual band concurrent, bringing these new benefits to both the 2.4 and 5GHz bands. Wi-Fi 5 did not address the 2.4GHz band, while Wi-Fi 6 has introduced improvements bringing beamforming and Multi User (MU) MIMO operation to 2.4GHz. Wi-fi 6 capability of using very narrow 2MHz frequency allocations to 2.4GHz clients enables a big increase in the range that is possible, as well as reducing power requirements for some IoT devices where they are not required to transmit across the entire minimum 20MHz channel as with previous versions of Wi-Fi. IoT devices can also benefit from Target Wakeup Time feature allowing them to spend more time “asleep” and save battery life.

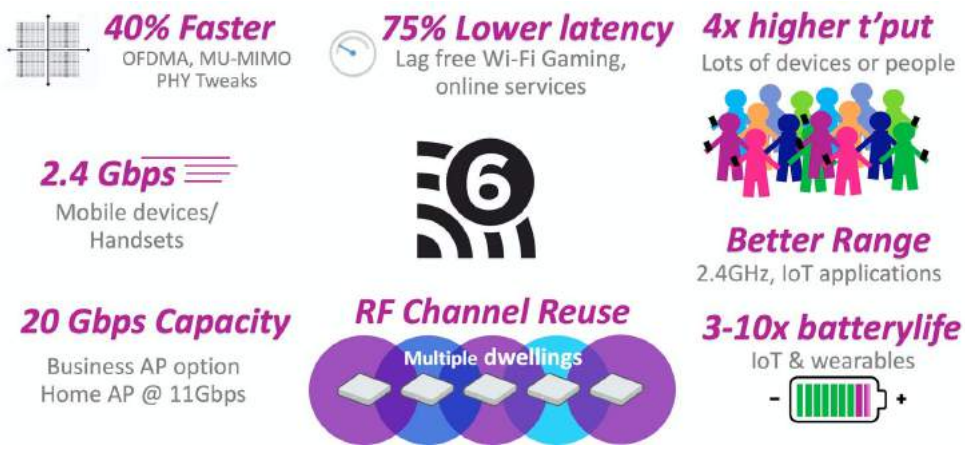

**Figure 10 - The Primary Features of Wi-Fi 6**

The addition of OFDMA in Wi-Fi 6 brings a lot more control over how the allocated channel spectrum is used by devices and can be used for both Downlink and Uplink communication. Traditional OFDM clients are allocated channel access on the basis of time only, where a single client is assigned a period of time to use a channel. OFDMA is a multi-user version of OFDM, enabling control over both time and frequency enabling multiple users to transmit at the same time, using different/unique ranges of frequencies allocated to them. Wi-Fi 6 has quadrupled the number of sub-carriers within a 20MHz channel to 256, by reducing the sub-carrier width from 312.5KHz down to 78.125KHz. These sub-carriers are grouped together into smaller groups spanning contiguous spectrum, known as Resource Units (RUs). Wi-Fi 6 OFDMA operation assigns different RUs to different clients to use at the same time. OFDMA enables a reduction in the time a client must wait to transmit data, improving performance and latency in Wi-Fi 6.

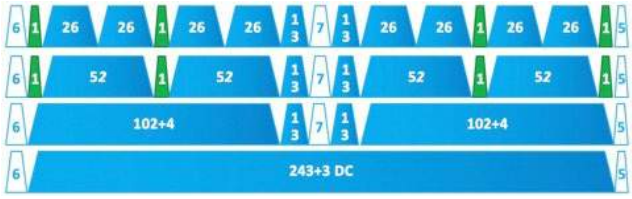

**Figure 11 - 20MHz RU allocation mapping**

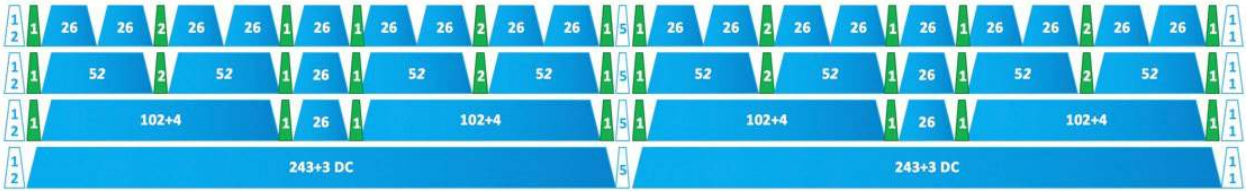

**Figure 12 - 40MHz RU allocation mapping**

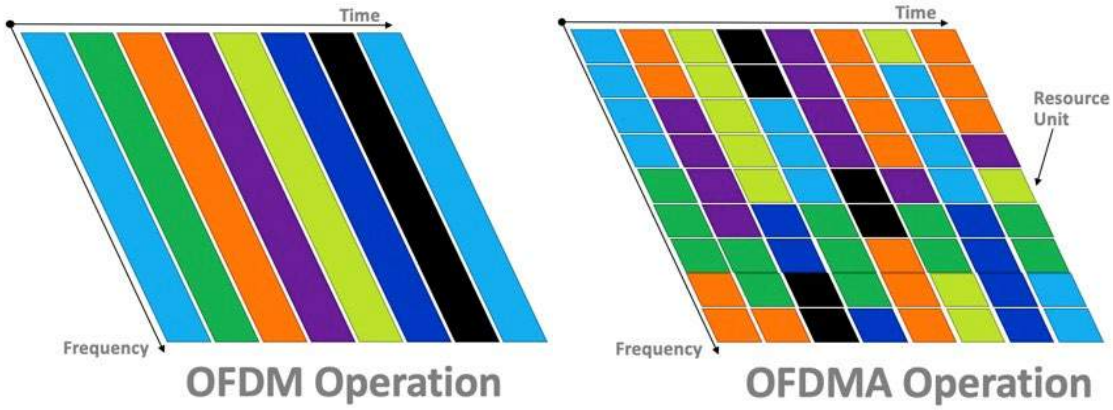
The ability to have parallel transmissions means that applications, such as audio or video streaming, that send chunks of data continuously can be served simultaneously. A 20MHz channel can support up to 9 concurrent clients, while a 160MHz channel can transmit to 74 clients in parallel. mixtures of RU allocations are also possible, providing more spectrum to some clients than others, depending on airtime demand and policies.

The AP is responsible for downlink OFDMA transmissions, coordinating the client to RU allocations. For uplink OFDMA transmissions, the AP coordinates the different associated clients and issues a trigger frame to get them to transmit at the same time. All clients using OFDMA must tune their power, frequency and timing to be able to join in the parallel transmission



As can be seen from the above diagram, the ability to send or receive traffic from different Wi-Fi users in the same time period has a significant improvement in link sharing and latency reduction. The "dark blue" user above gets services in the 3rd time period using OFDMA compared to the 7th time period with OFDM. There is a bit more signaling required for OFDMA in terms of link overhead, but the benefits, especially when user devices are sending short bursts of traffic (typical for interactive applications, or even voice/video conferencing), outweigh these significantly. Having parallel transmissions, as opposed to consecutive transmissions enables much lower latency which brings benefit to all services. A 75% reduction in latency is possible with Wi-Fi 6, due to OFDMA operating in both the DS and the US. Coexistence with Wi-Fi 5, where the traditional airtime access procedure (EDCA access) is present can be challenging, but through effective management of the EDCA minimum contention window ($W_0$) and maximum contention stage ($m$), controlled access between Wi-Fi 6 and Wi-Fi 5 devices can be achieved.

Wi-Fi 6 also supports up to 8 spatial streams, (Wi-Fi 5 offered it already but was rarely implemented) along with Multi User (MU)-MIMO. Most Wi-Fi clients include 1 or 2 spatial streams, so with an 8x8 AP, it will be possible to service 4 such clients at the same time using MU-MIMO, delivering gigabit speeds to each device. DL MU-MIMO is a mandatory feature of Wi-Fi 6 certification. Depending on the location of an AP relative to clients within a home, the use of MU-MIMO can really improve networking performance. Note that MU-MIMO is very effective at short to medium ranges, while OFDMA is effective at all ranges, short, medium and far. Also note that MU-MIMO is also available for 2.4GHz band, something that was not part of the Wi-Fi 5 standard. And finally note that it is possible to operate OFDMA and DL MU-MIMO together, identifying different users to different spatial streams while also using OFDMA to offer partial bandwidth to users on the same spatial streams.

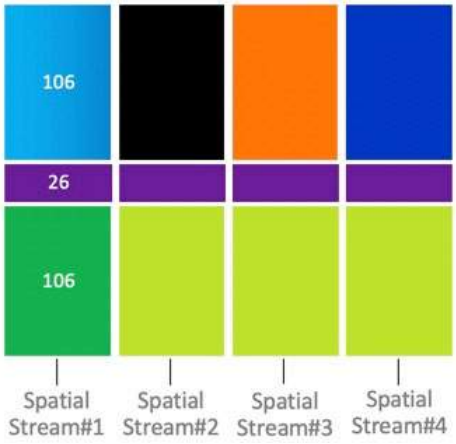


**Figure 13 - DL MU-MIMO + OFDMA**

The above figure shows how DL MU-MIMO and DL OFDMA can be put to good use, enabling 7 different users to receive data within the same transmission period. One user (in light green) received 3 separate RUs (106 sub-carriers each) from 3 different spatial streams, 5 other users got individual 106 sub-carrier RUs, while 1 user got 4 separate 26 sub-carrier RUs, one from each spatial stream. With increasing bandwidth to 160MHz, operating with a 4x4 setup, OFDMA+DL MU-MIMO will really improve network performance.

Decision points on Wi-Fi 6 introduction

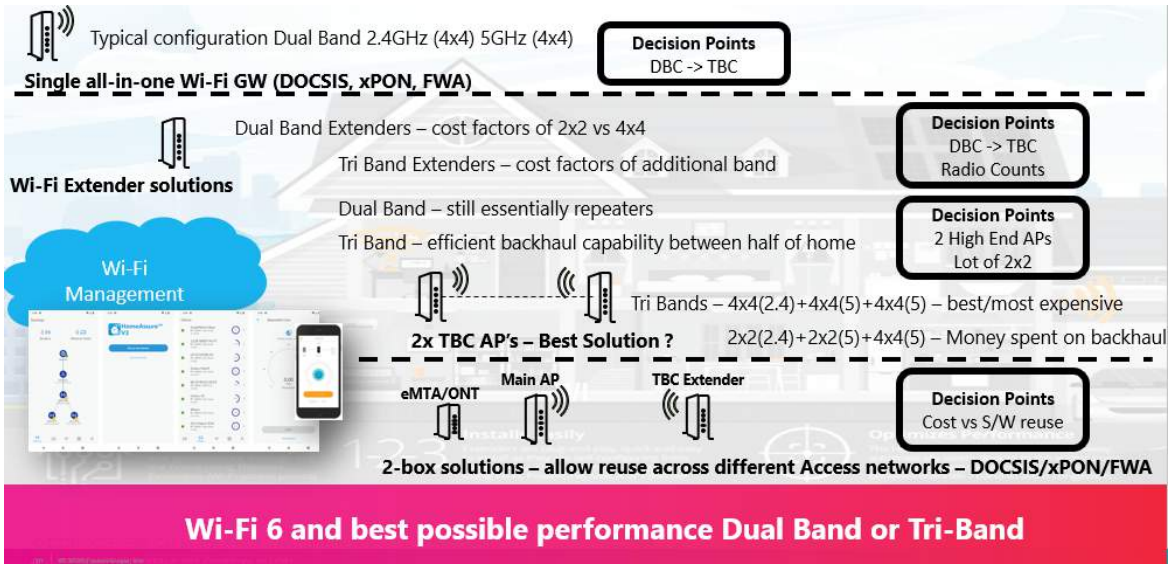

**Figure 14 The decision points for Wi-Fi 6 introduction**

From a service provider perspective, the introduction of a Wi-Fi 6 AP brings performance benefits even for previous Wi-Fi generations due to the hardware design improvements, including range and rate.

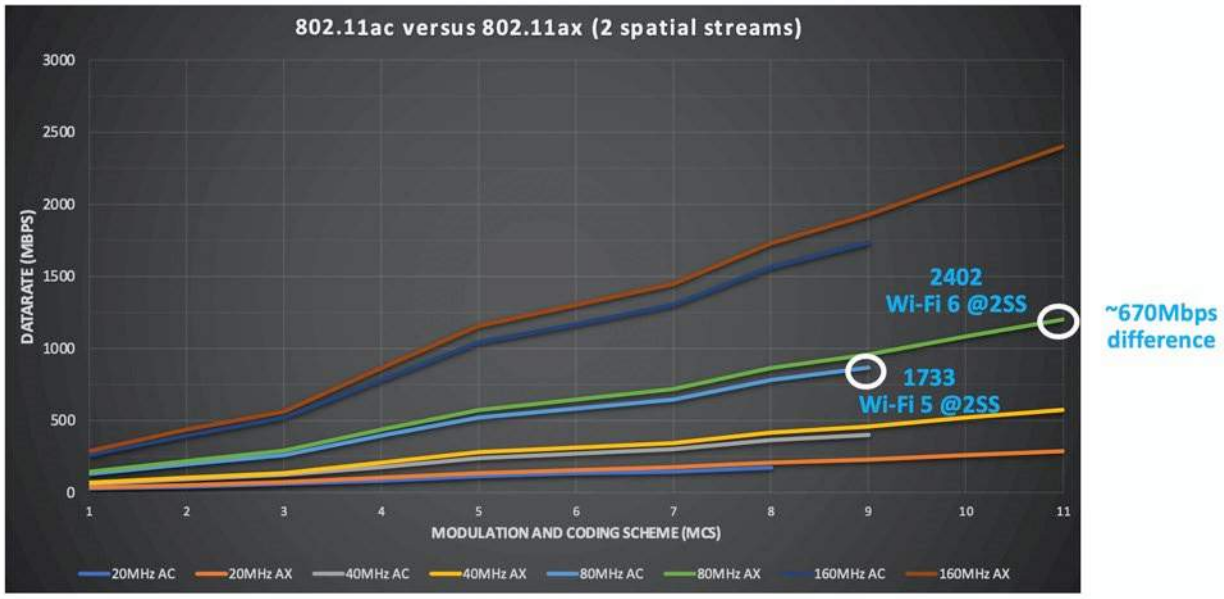

**Figure 15 - Wi-Fi 5 vs Wi-Fi 6 2x2 Client Performance Capability (Mbps)**

The real benefits are only realized when new Wi-Fi 6 non-AP STAs (devices) are added, such as service provider supplied STBs/SMDs and mesh extenders, or consumer owned mobile devices (phones, tablets) or media streamers (smart TVs, Amazon fire, etc.). The mix of Wi-Fi 6 APs matched with Wi-Fi 6 devices enables all the new technology features in Wi-Fi 6. See below the performance of

- AC only AP with an AX STB client – showing improved performance at range of the AX client with the AC AP
- AX AP against AC and AX STB – showing improved performance for both

**CommScope recommends that future STB should use 2x2 instead of 4x4 to get the performance needed at lowest cost points and lowest thermals.**

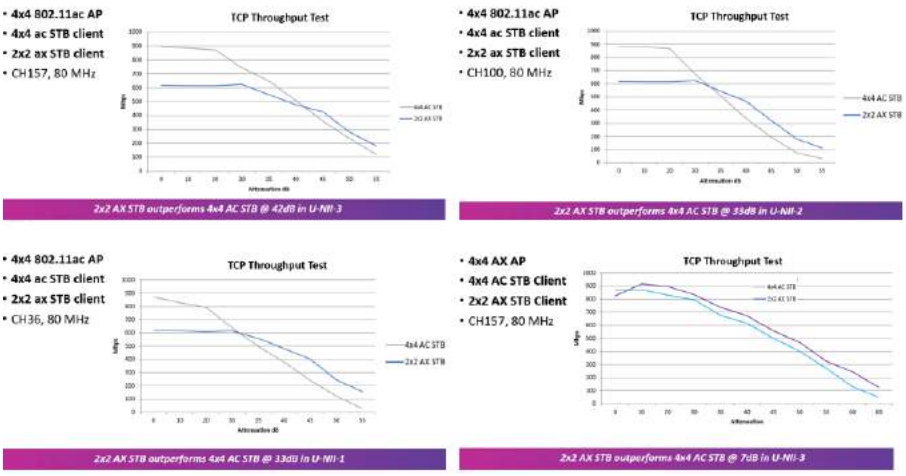

**Figure 16 - STB client performance showing 2x2 Wi-Fi 6 outperforming AC 4x4**

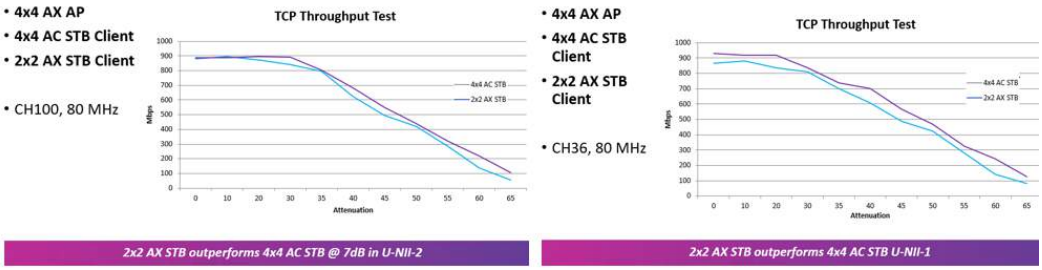

**Figure 17 - STB client performance showing 2x2 Wi-Fi 6 outperforming AC 4x4**

STB devices with Wi-Fi 6 will work extremely well with Wi-Fi 6 APs, bringing better overall experience to subscribers from greater range as well as more reliable service. Wi-Fi Extenders used to add coverage throughout a subscriber home will also benefit, especially due to the lower latency provided by Wi-Fi 6, which becomes very important when data has to bounce from the AP to the Extender, and then from an extender to a Wi-Fi device.

The ability to use OFDMA for serving AP connected devices and extenders in parallel cuts latency significantly when serving devices connected to extenders, as any queued traffic can be sent at the same time. Multiple hops back and forth through extenders all increase latency, which then has a knock on effect on the throughput devices can achieve – lower the latency and throughput increases, enabling adaptive streaming protocols like DASH/HLS/etc. used by STBs to operate at higher display resolutions, etc., giving a better quality of experience to the end subscriber.

## 4. Setting the stage for Wi-Fi 7 entrance – Wi-Fi 6E

The available spectrum used in Wi-Fi 6 is the same as Wi-Fi 5, and is limited to long standing 2.4 and 5GHz regulatory bands defined by the FCC, which covers about 400MHz of spectrum. Recent changes by the FCC, after many years of discussion between industry and regulatory stakeholders has led to the opening up of the 6GHz band offering up to 1.2GHz of additional spectrum for unlicensed usage, with Wi-Fi being one of the key benefactors of this spectrum. This effectively quadruples the spectrum available for Wi-Fi. To help differentiate the use of the 6GHz spectrum Wi-Fi Alliance have coined the term “Wi-Fi 6E” to identify Wi-Fi 6 devices capable of operating in this “Extended” 6GHz spectrum.

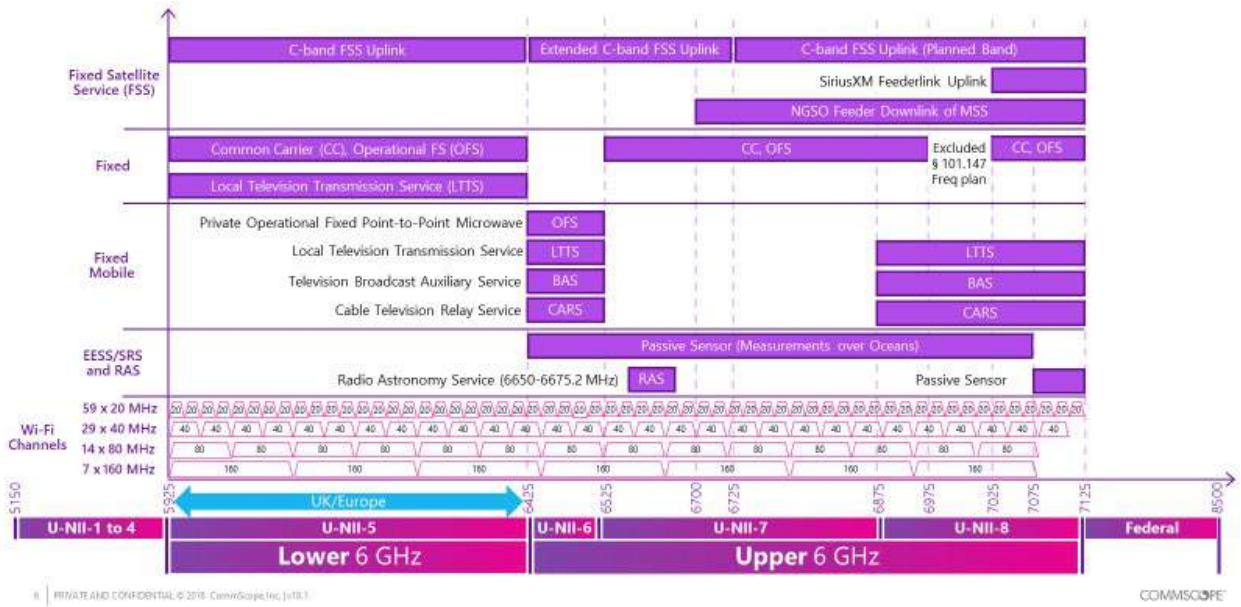

**Figure 18 - US 6GHz spectrum and channel allocation to Wi-Fi**

This extra spectrum will enable Wi-Fi innovation for decades to come, and some reports indicate it will add over $183B to the US economy by 2025, with Wi-Fi equipment sales being $1.54B of that figure. A key element of the use of 6GHz is the displacement of the need to adopt 5G cellular connections for high speed wireless access, leading to significant cost savings of over $54B by enterprise customers (note that this may be impacted by consequences of COVID-19). With the extra spectrum capacity, Wi-Fi has room to grow, and most users of Wi-Fi would likely stick with Wi-Fi than need to switch to a completely new 5G architecture, be it licensed or unlicensed.

One of the biggest drawbacks with Wi-Fi has been the lack of available spectrum to enable the HW capability of Wi-Fi 5 and Wi-Fi 6 APs that offered 80 and 160MHz channels. The existing spectrum enabled a maximum of two 160MHz channels, which typically required a TBC (Tri Band Concurrent) AP enabled with two 5GHz radio lineups. However constraints in the spectrum related to DFS/Radar access meant that it was often not possible to get that capacity, and APs were limited to using the available 80MHz wide channels (additional constraints relating to overlapping Wi-Fi APs in dense spaces also meant that 160MHz channels were difficult to operate due to interference).

| | 2.4 GHz | 5 GHz | 6 GHz |
|---|---|---|---|
| Available Spectrum | 85 MHz | 480 MHz | 1,200 MHz |
| 20 MHz | 3 | 25 | 59 |
| 40 MHz | 2 | 12 | 29 |
| 80 MHz | 0 | 6 | 14 |
| 160 MHz | 0 | 2 | 7 |
| 320 MHz | 0 | 1 | 3 |

**Figure 19 - Channel Availability over Spectrum**

The 6GHz spectrum that the FCC has released has the capacity to support 7 additional 160MHz channels in addition to the existing roughly 400MHz of capacity in 2.4 and 5GHz. A single 160MHz Wi-Fi 6 channel can support up to 9.6Gbps (when using 8 spatial streams), meaning that the 6GHz band can offer over 67 Gbps (7 * 9.6 Gbps) of additional bandwidth.

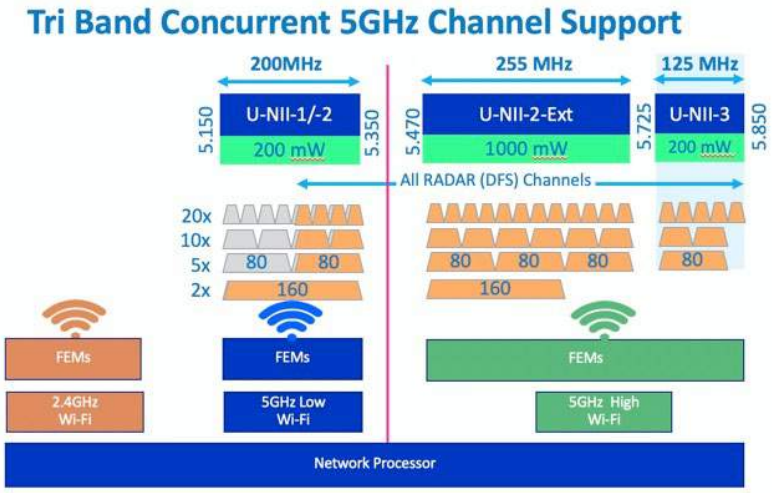

**Figure 20 - TBC 2.4+5GHz AP**

The 1.2GHz of spectrum in 6GHz was already categorized by the FCC into 4 separate bands, that were aligned to the various requirements of existing incumbent users. In order to operate in this new spectrum, APs either have to lower their operating power or work with a spectrum supervisory service

Wi-Fi 6e builds on top of Wi-Fi 6 to enable operation in the 6GHz spectrum, identifying the necessary controls around how the spectrum is channelized and various performance limits. Channel access details are also included to ensure a common set of rules around how 6GHz APs and devices can use the new spectrum. Wi-Fi 6e will be limited to the current performance outlined in the Wi-Fi 6 standard (which is 9.6Gbps).

The following diagram outlines the UDP rate over range/attenuation for a 4x4 AP to a 4x4 Client (typically a backhaul application on a 6E mesh solution). This is done at the current 5dBm/MHz PSD approved by the recent FCC Low Power Indoor specifications. **Note – all the Throughput/Attenuation plots in this paper assume perfect signal, with no noise and no co channel interference. They also show just Tx potential only and don't take into account factors like the Wi-Fi beacons which transmit in 20MHz channels and at 18dBm EIRP. So, the actual performance will be somewhat poorer than illustrated. Unless otherwise stated as a specific test for different client configurations assume all plots are just theoretical best case from AP for illustrative purposes.**

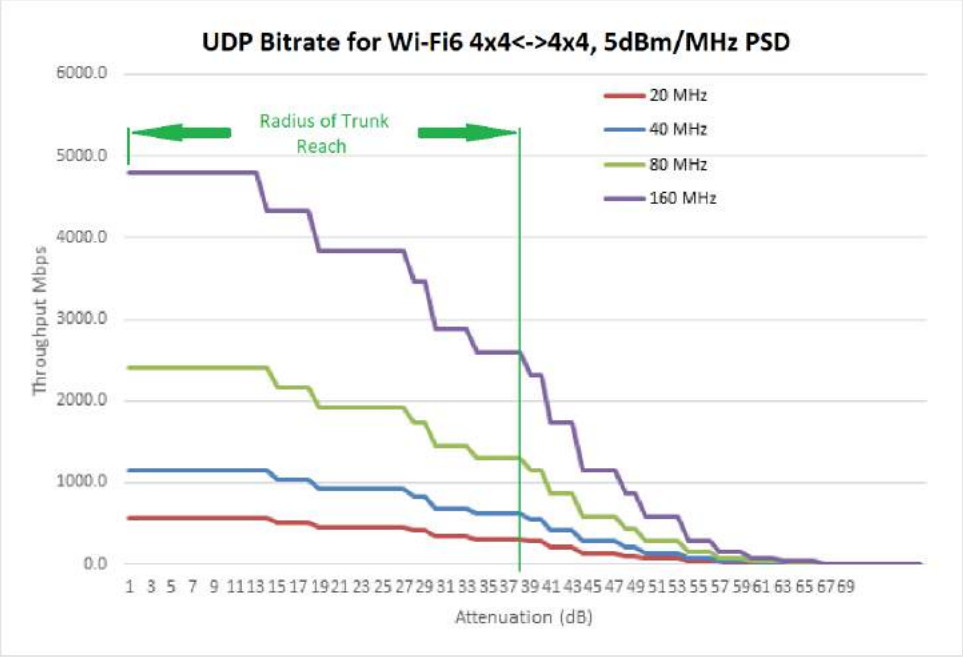

**Figure 21 - 4x4 to 4x4 Wi-Fi 6E performance at 5dBm/PSD - LPI specification**

In addition to the Wi-Fi Alliances efforts on enabling access to the 6E spectrum using Wi-Fi, one of the main questions affecting equipment vendors is how to create cost effective hardware that addresses the existing 2.4 and 5GHz landscape while also offering the benefits of 6GHz

Current TBC designs that operate two 5GHz radio lineups (5GHz Low (UNII-1 and UNII-2) and 5GHz High (UNII-2 Extended and UNII-3)) need additional filtering and power in order to provide the best performance. Operating two transceivers with just 160MHz of separation has required considerable isolation filtering to ensure that as one transceiver transmits at a high power that the other transceiver can receive signals from connected devices. The filtering adds cost to the standard design. Another constraint is that some Wi-Fi devices limited themselves to only operate in non-DFS channels, which is an 80MHz wide part of the 5GHz Low spectrum, meaning that this part of the spectrum must be supported.

Including a separate dedicated 6GHz only subsystem into an AP is possible from an engineering standpoint but adds additional cost to a product that may see limited initial 6GHz use while waiting for new devices to appear. Such a solution may also increase the industrial design/enclosure size beyond what would be acceptable for a home Wi-Fi AP format factor, as it is likely there would be 15 radios and associated antenna (3+4+4+4) for the 4 different bands to be supported. Such a unit is unlikely at this point in time. The simplest and likeliest deployment of 6GHz is to offer a tri-band that supports 2GHz+5GHz+6GHz. The tradeoff as discussed is the additional complexity of supporting U-NII1/2/3 in the 5GHz band and the initial relative little use of the 6GHz radio with the sparsity of 6E clients in the home.

Options are being considered as to what makes the best combination of low cost and flexibility for radio operation across the 5/6GHz space. Note that flexibility in terms of switching between filters and radio lineups unfortunately has a knock on effect on the total output power, as signal losses creep in as a result of passing signals through switch banks that enable such flexibility. Switching solutions overall also significantly increase the cost of the AP so for the moment its unlikely that Cable Operator devices will add 5/6 switching on the radio. Additionally, the decision as to when to switch a radio to use either 5GHz

or 6GHz is also complex. Manually switched based on a consumer or Cable Operator policy or some algorithm based on some intermittent sampling of the 6GHz capabilities of the home 6GHz client arrivals. The following diagram illustrates the complexity of trying to support a Tri-band that can

- Switch between all U-NII1/2/3 bands on 2 chains
- Switch between 5GHz and 6GHz
- Support the Filtering required for 5/6GHz and within the 6GHz channel plan

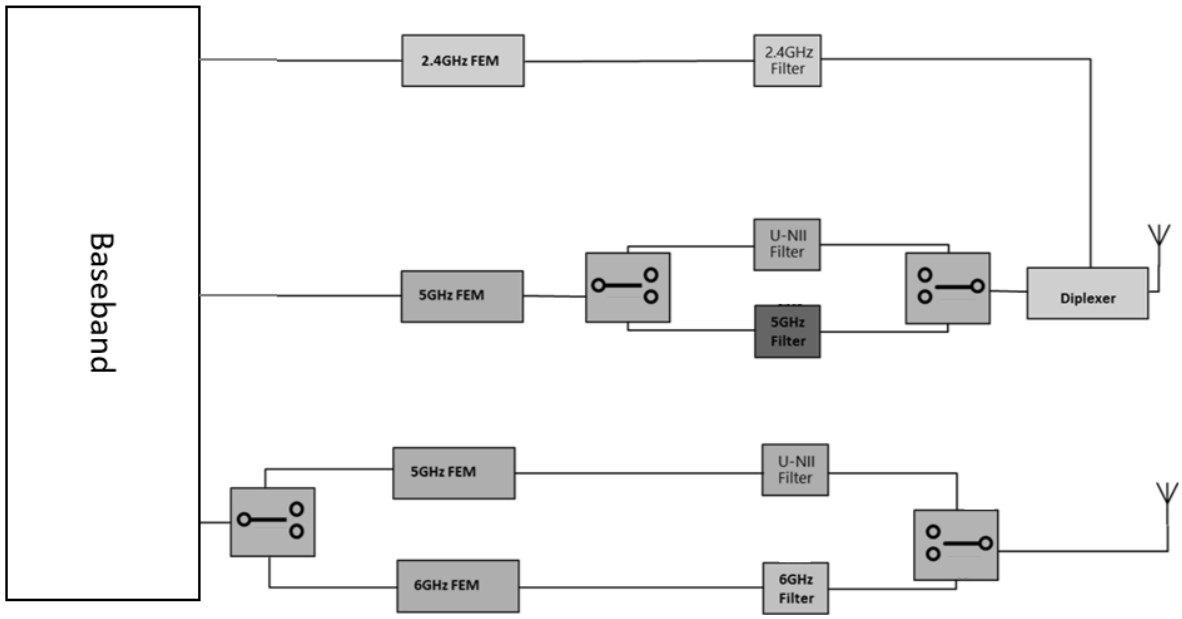

**Figure 22 - Switchable 5/6 designs will bring in cost and complexity levels that may not be acceptable to Operator cost points**

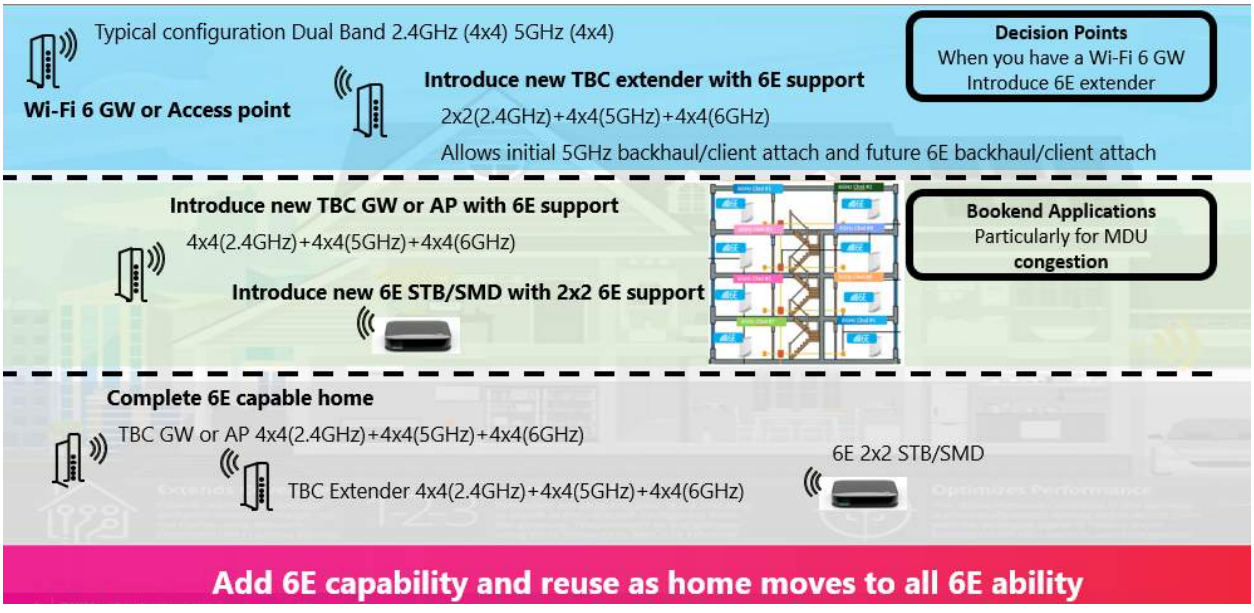

The 5GHz High spectrum is closest to the new 6GHz spectrum, so there is some interest in having a TBC AP design that continues to offer 2.4 and 5GHz Low and mixed 5GHz High and 6GHz support. This appears like a good tradeoff, but a key drawback with this approach is that the 5GHz High spectrum that is subject to DFS is also a part of the spectrum that enables greater radio output power (1W compared to 200mW in the other 5GHz Low spectrum). Using a mixed 5GHz/6GHz option means that once a single 6GHz device associates with the AP, the 5GHz High spectrum is no longer available as the AP has to switchover to 6GHz.

A lot of recent AP designs have incorporated Wi-Fi 6, and are either being deployed or going through the final stages of acceptance testing in service provider labs. Obviously, service providers want to keep in step with technology choices, but struggle with the economics and operational headaches of deploying a new Wi-Fi 6E AP so soon after launching their Wi-Fi 6 AP. To overcome this issue and enabling the adoption of 6GHz, one approach is to use 6GHz adapter devices. Ethernet (either 1Gbps or 2.5GBps) is used to connect to these new 6GHz adapters. Such an option is not unique, as pre-standard Wi-Fi 5 video bridge adapters were deployed by many operators in the past to provide whole home HD video streaming over Wi-Fi to ethernet connected IP STBs.

**Figure 23 - ARRIS VAP2400 Wi-Fi Video Bridge**

This approach relies on one adapter being connected to the main AP, configured to create a new 6GHz Wi-Fi network that other devices connect. These 6GHz adapters enable the adoption of 6GHz within the home, either to act as a 6GHz Wi-Fi backhaul to existing extenders in the home, or to enable subscriber devices take advantage of the high speed, low latency wireless connectivity over 6GHz back to the main AP. No change is required on the existing home devices, apart from using Ethernet to connect to the adapters. USB is also a possible interface (offering both a data/control path as well as bus powering).

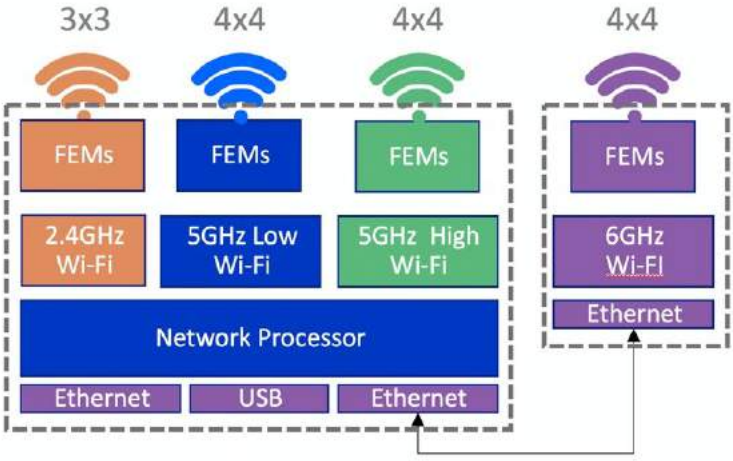

**Figure 24 - External Wi-Fi 6E dongle for existing GW**

This also brings up the question of the effective relevance of the 2.4GHz radio. With its primary purpose today as

- Supporting low cost devices like cameras and IoT devices
- Providing the comfort of connectivity at range particularly in single AP homes without meshing systems extending 5GHz particularly.

But given the sheer capacity of the spectrum shift now to 6GHz which has only 80MHz – 450-600Mbps vs 66Gbps capacity in the 6GHz band with 8 spatial streams and the Wi-Fi 7 standard even allowing for 16 spatial streams – what role does 2.4GHz have going forward in the home Wi-Fi ecosystem. Should we now look to

- Have a single point in the home for 2.4GHz AP for legacy devices and to support 2MHz channel IoT capabilities built in the Wi-Fi 6 standard for up to 4 times more range on narrow carriers.
- Focus a 5GHz and 6GHz solution on the high capacity single AP across the home or the multiple mesh APs – for maximized use of higher capacity bands and take every opportunity to reduce any effect on 5/6 designs that 2.4GHz drags in and see can we
    - Lower gate counts in silicon
    - Not having to trade off antenna placement for best 2.4GHz and 5GHz on the same antenna
    - lower costs and reduce thermals

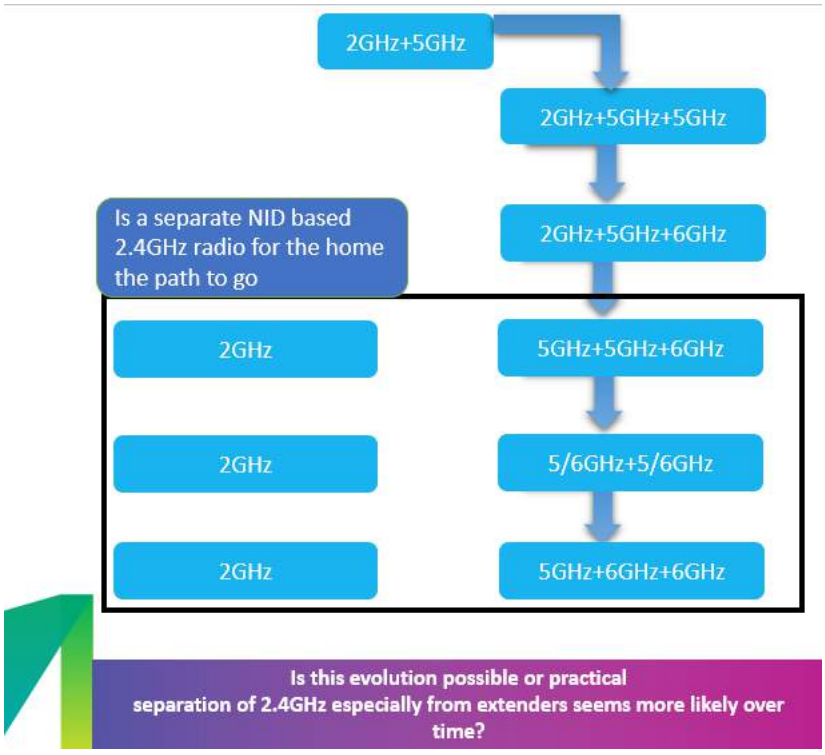

**Figure 25 - Can 2.4GHz be separated from the Wi-Fi mesh 5/6/7 devices in some future architecture**

It may take until Wi-Fi 7 is introduced to relook at the grouping of 2.4GHz the 5GHz U-NII-1/2/3 bands and the U-NII5/6/7/8 bands for optimal architectures in the home based on the evolution of FEM and

Filter technology to try and ensure the best possible designs to address the widest frequency range in the smallest form factor package.

This idea may not have a lot going for it, but in some ways the other 2.4GHz wireless systems, such as Bluetooth and Zigbee, putting all of these together into its own AP package may make sense for optimal coverage given that 2MHz use of 2.4GHz , Zigbee and BLE would have similar ranges from the same location of this 2.4GHz AP as illustrated below

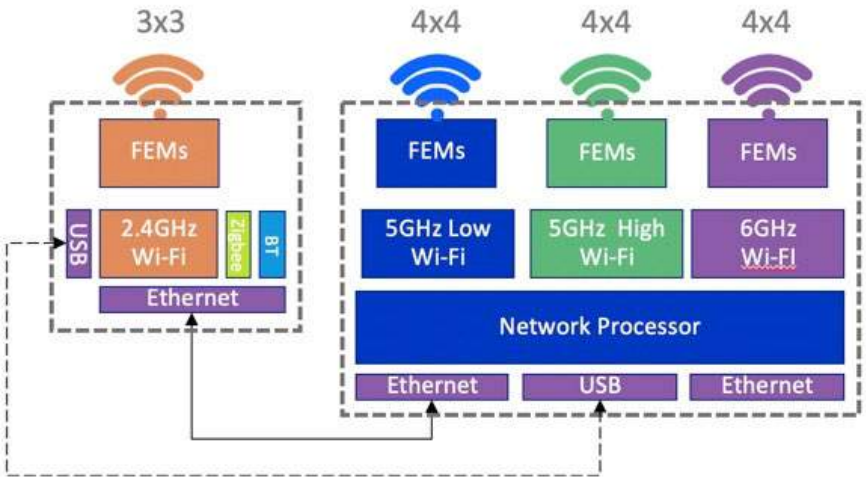

**Figure 26 - Add 6GHz to AP, but extraction all 2.4GHz Radios**

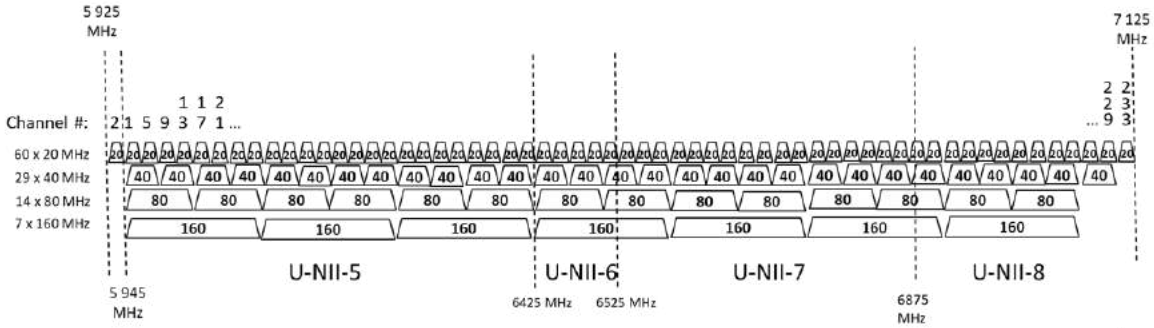
## 5. Low Power Indoor Mode to AFC controller Standard Power

Some of the FCC rules about 6GHz operation are specifically about power levels that APs can use when operating in the band. Serious consideration was given to the coexistence of future unlicensed operation of Wi-Fi devices and the incumbent 6GHz users (mostly Microwave links, Fixed Satellite Services (FSS), Cable TV relay and Broadcast services). This has led to various compromises about acceptable power limits across the different UNII bands.

A Low Power Indoor (LPI) only power level applies across the entire 6GHz band (from the bottom limit of UNII-5 to the upper edge of the UNII-8 band). This corresponds to a Power Spectral Density of 5dBm/MHz EIRP. For a 20MHz channel this is 18 dBm, while a 160MHz channel is allowed 27 dBM. Note that LPI APs can ***only*** operate indoors, and the FCC rules have very explicit limitations for such operation, as follows.

- Low-power APs can't be weather resistant, preventing them from being installed outside permanently;
- Low-power APs can only have integrated antennas and it is prohibited to provide the capability of connecting other antennas to the devices;
- Low-power APs can't be battery operated;
- Low-power APs must be clearly labelled with a notice that states that "FCC regulations restrict operation of this device to indoor use only."

From a 6GHz regulatory perspective in the US the following is in play to try and number the potential channels in the 1.2GHz of 6GHz as well as define which channels and bands can be used for Standard Power under AFC control.



| Operating Class | Channel width | Channel #s |
|---|---|---|
| 131 | 20 MHz | 1, 5, 9, ..., 221, 225, 229, 233 (as shown above) |
| 132 | 40 MHz | 3, 11, 19, ... |
| 133 | 80 MHz | 7, 23, 39, ... |
| 134 | 160 MHz | 15, 47, 79 ... |
| 135 | 80 MHz (for 80+ operation) | 7, 23, 39, ... |
| TBD | 20 MHz (at 5925 MHz) | 2 (only) |

**Figure 27 - Current potential channel numbering scheme for U-NII5 to U-NII8**

Standard Power (SP) is a higher output power that APs can also use but under very strict conditions. Such power levels are only applicable to UNII-5 and UNII-7 bands (comprising 850MHz of the total of 1.2GHz of spectrum). SP operation is subject to a spectrum supervisory service called Automated Frequency Coordination (AFC). The AFC system relies on the AP reporting its geographical location to the AFC to identify any incumbent systems in the area, and what frequencies those systems may be using. The AFC will make a decision if Wi-Fi 6E operation is allowed by the AP, and if so, will identify the exact list of frequencies and power limits that apply. The AP must repeat this exchange with the AFC on a regular basis, as the data that the AFC relies upon may receive dynamic updates relating to existing or new 6GHz users that could impact the APs use of 6GHz. This approach will enable coexistence with the incumbent users of this spectrum. 320MHz channels are now part of the IEEE802.11be initiative and there is no final answer yet. The only 2x160MHz channels that fit in U-NII band is U-NII-5. There is also some opportunity to put 320MHz channel in U-NII-7 but as its mis-aligned in the current 160MHz allocation discussions are ongoing how this could be managed

Once an AP is enabled and compliant with the AFC system it is allowed operate outdoors as well as at the higher power level of 36 dBm EIRP for all channel bandwidths. This is a key enabler for outdoor APs, as well as potentially enabling higher indoor powers. As an industry we are still working through the architectures and process to be able to give location to an Indoor AP particularly and there are various mechanisms being considered that are trying to exclude the use of any additional GPS cost burdens on the AP. The frequency of the AP having to check with the AFC is also another part of the equation to try and create a cost efficient but friendly solution to incumbents. More on this area as the decisions unfold.

## 6. Wi-Fi 7 and the 320MHz channel what does it mean for the home

The current highest speed possible with 802.11ax on a 160MHz wide channel is 1.2Gbps per spatial stream. Using the typical allocation of 4 spatial streams ~4.8Gbps can be realized and with the maximum of 8 spatial streams in MIMO, this can enables a maximum data rate of just over 9.6Gbps, and this requires both the AP and client device to support 8x8 operation. The IEEE802.11be is now proposing to add the following features to the Wi-Fi 6E specification

- 320MHz and more efficient utilization of non-contiguous spectrum
- Multi-band/Multi-channel aggregation and operation
    - Multi-Link Operation - MLO. Arguably one of the most important features from a pure BW or latency perspective. MLO also ties together the important of 2.4GHz, 5GHz and 6 GHz frequencies and bands as you can utilize all or any combination of the bands
- 16 spatial streams and MIMO protocols enhancements
- Multi-AP coordination (e.g. Coordinated and Joint Transmission)
- Enhanced Link adaption and transmission protocol (e.g. HARQ)
- Adaptation to regulatory rules specific to 6GHz spectrum
- Refinement of 802.11ax features

If there are two clear 160MHz channels in 5GHz, and an AP supports 8x8 for both 5GHz Low and 5GHz High, the can allows for up to 19.2Gbps of capacity at just 8 spatial streams. In the next version of the Wi-Fi standard, 802.11be, the primary feature that is being added is the ability to use a 320MHz channel and to increase the spatial streams to 16 for the current 8 in Wi-Fi 6. This fundamentally then creates a unique platform to feed the new low latency and future high bit rate services. In the US with the entire 6GHz spectrum being 33-66Gbps of capacity it creates a fundamental platform for low latency and high capacity services. This paper is not going to outline these services but for example LighField TV at 8K levels comprising 43 or more planes of video at 8K rates can reach well above 2Gbps levels. If you look at products from Looking Glass (www.lookingglassfactory.com) you will see ‘holographic’ LightField TV solutions giving ‘no glasses required’ immersive viewing experience and showing real depth and volume. Solutions like Wi-Fi 7 and Wi-Fi 6E will enable these solutions to be un-tethered from Ethernet interfaces at 2.5GBE and even 10GBE.

**Figure 28 - Immersive display on the LightField Video Looking Glass display at 8K levels**

If we look at the current FCC specification for 320MHz channel usage in the 6GHz band, the power level has been set to 30dBm for the 320MHz channel. With 30dBm at 5dBm/MHz the following performance levels can be expected. You can see below the performance of both 8x8 and 4x4 in the UNII-5 band with 30dBm. Performance levels are substantially improved with Airtime throughput over range and offer the potential of really good whole home coverage from a single GW/AP for all but the largest of homes in the US. Can we realize the following architecture for Wi-Fi 7 – with single high performance AP driving Gbps across the home. Up to 20Gbps could be realized with an 8x8 device with 8 spatial streams.

**Figure 29 - Basic single 30dBm - 8x8 or 4x4 Cross Home Wi-Fi 7 Architecture**

This single 1W 8x8 device with only 8 spatial streams providing cross home Gbps speeds driving opportunity again for single AP and no ethernet wire solutions for homes in the 2600sqft to 5,000sqft range. The rates range close to theoretic 20Gbps at the AP to maintaining a Gbps to 54dB of attenuation.

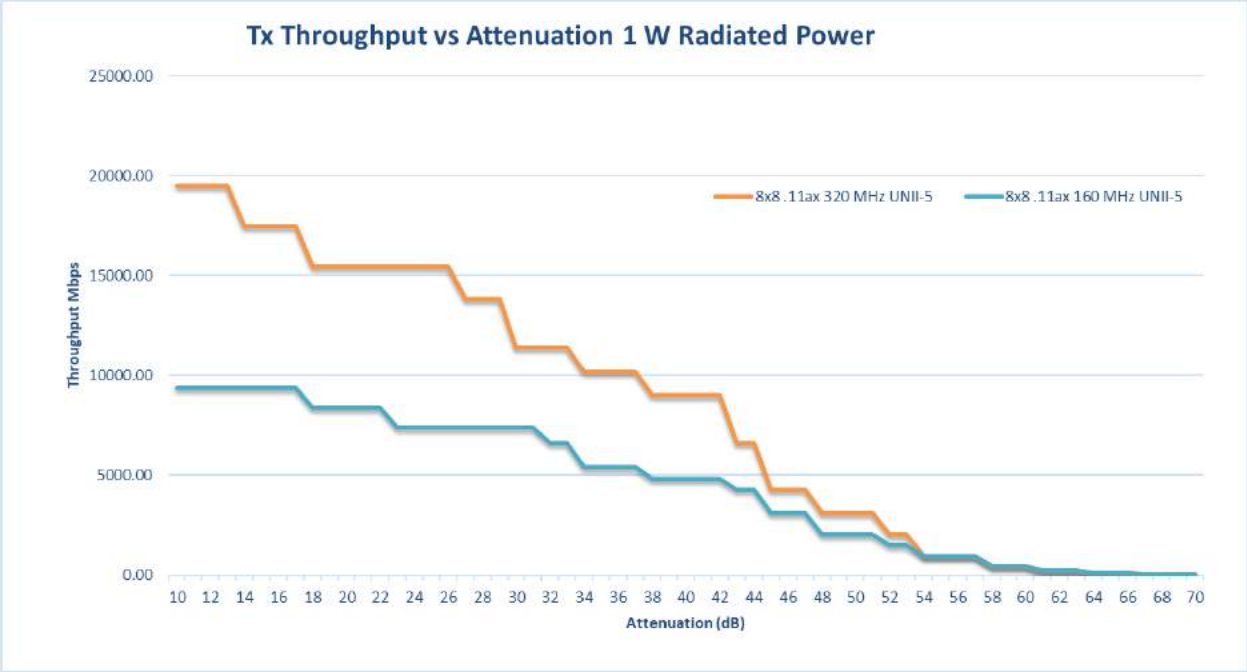


**Figure 30 - 8x8 AP/GW at 30dBm in both 320MHz and 160MHz channels**

Even for a 4x4 the potential for high performance across the home is high with a Gbps of throughput potential even at 55dB of loss and theoretically ~9Gbps at the Access point.

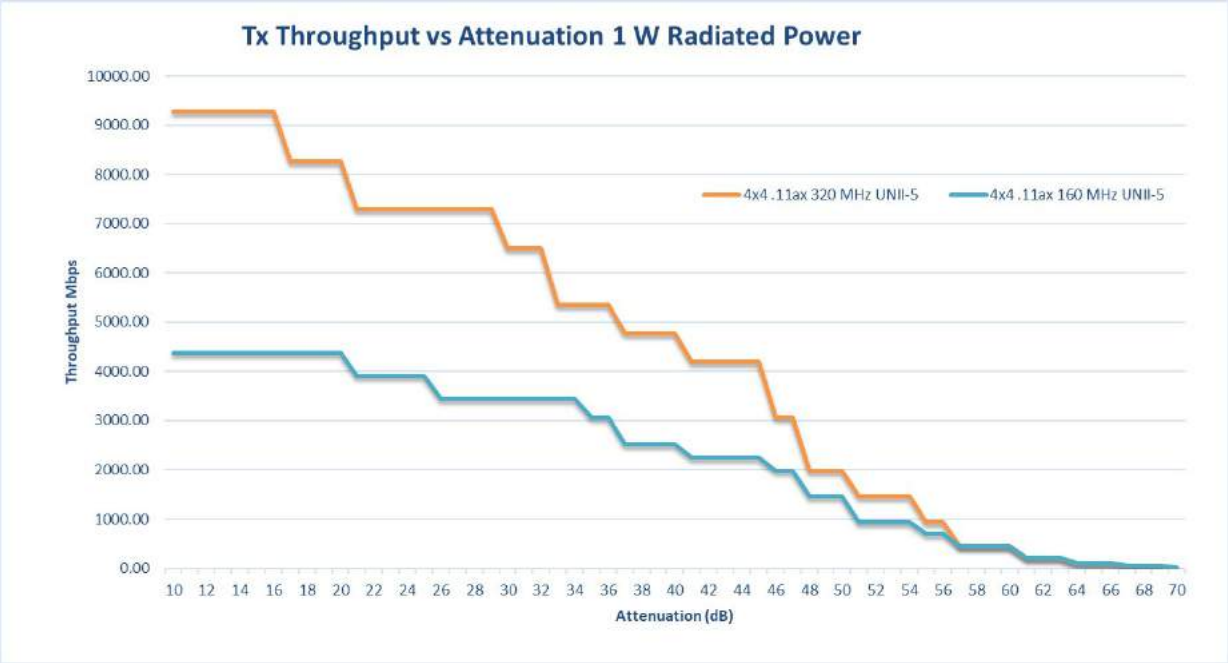

**Figure 31 - 4x4 performance at 320MHz and 160MHz at 30dBm**

As AFC standard power currently allows for higher power solutions outside – if we were to have approvals for 33dBm/2W Radiated power in a solution its performance over attenuation would improve as defined in following graphs.

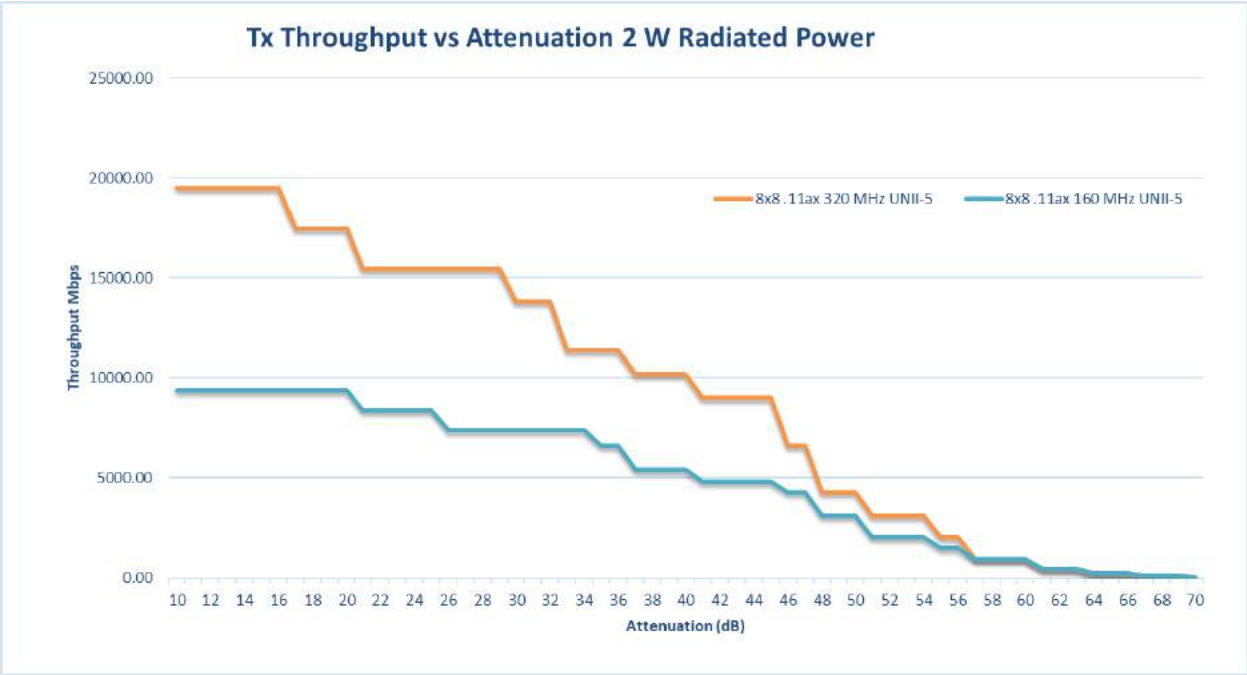

**Figure 32 - 8x8 performance of 320MHz and 160MHz at 2W radiated Power**

At 33dBm GBps speeds would be maintained to almost 54dB attenuation.

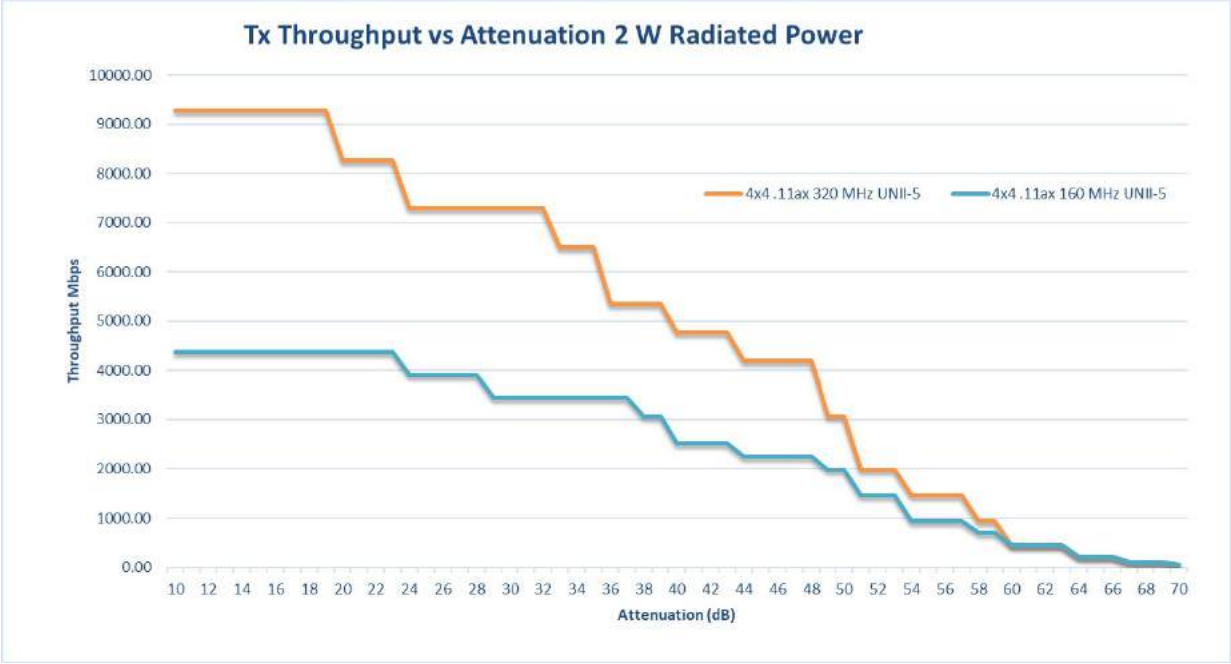

**Figure 33 - 4x4 performance of 320Mhz and 160MHz at 2W radiated Power**

Even 4x4 and 4 spatial streams would support Gbps speed to 53dBm attenuation.

However, there could be even more performance for Wi-Fi if we consider the room vs the home. With 6GHz spectrum we have the potential to create an intra room AP backbone using one 320MHz and an inter room 160MHz channel all using different spectrum and potentially to optimal single use levels particularly for larger homes.

If we assume, we want to bias more to 6GHz capable devices in some future scenario

- One primary home AP providing 320MHz cross home 8x8:8 (20Gbps) or 4x4 (10Gbps) at 30dBm.
    - Wi-Fi 6E/7 capable clients can attach to this AP, but its primary role is providing intra room Backhaul
    - The device could also offer 5GHz and 2.4GHz support as well
        - 4x4(2.4GHz) + 4x4 (5GHz) + 8x8 (6GHz) or 4x4(2.4GHz) + 4x4 (5GHz) + 4x4 (6GHz)
- In Room (potentially 4 other 160MHz channels that can be used – 4 rooms) that have a dual or triband
    - This device could be a triband 4x4 (5GHz inroom) + 4x4 (6GHz in room) + 4x4 (6GHz backhaul)
        - Could potentially even use 25mW VLPI mode for in Room LAN to create smaller form factor and lower thermals. Device could potentially adapt power to the room conditions and increase output power with appropriate PA designs.

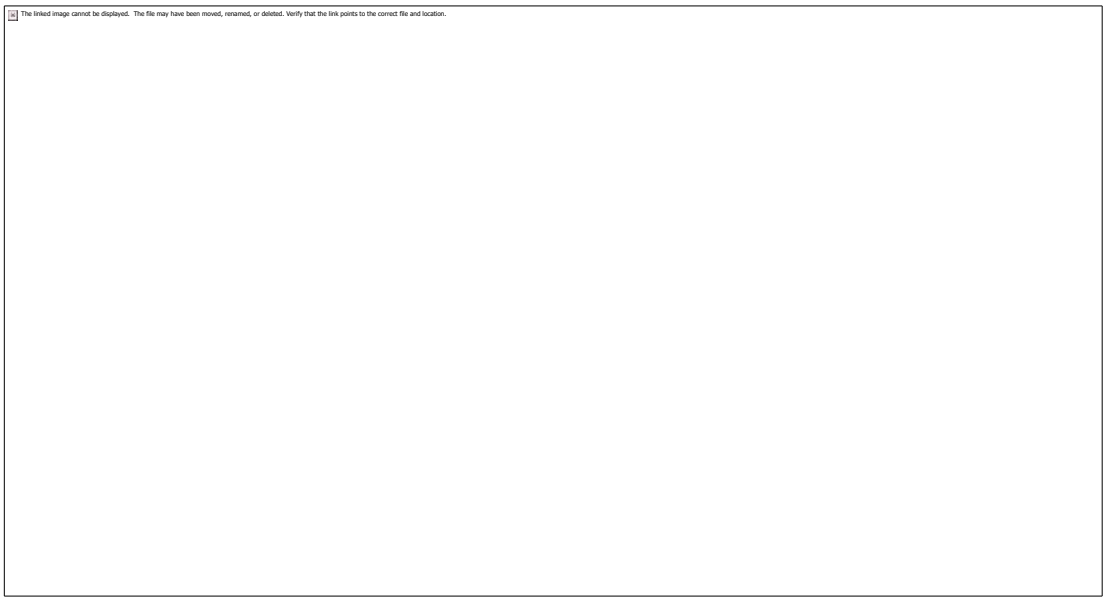

**Figure 34 - Performance of VLPI in room potential low power solution**

    - In room clients would also reduce uplink power to connect with these in room AP
    - The device could offer additional radios for 2.4GHz and 5GHz as well as 6GHz as backhaul

**Figure 35 - Wi-Fi 7 backhaul - Wi-Fi 6E in room - Ultimate Home Wi-Fi ?**

This is simply illustrated below with 3 in-room AP's using different in Room 160MHz channel to the 320MHz backbone channel across the home.

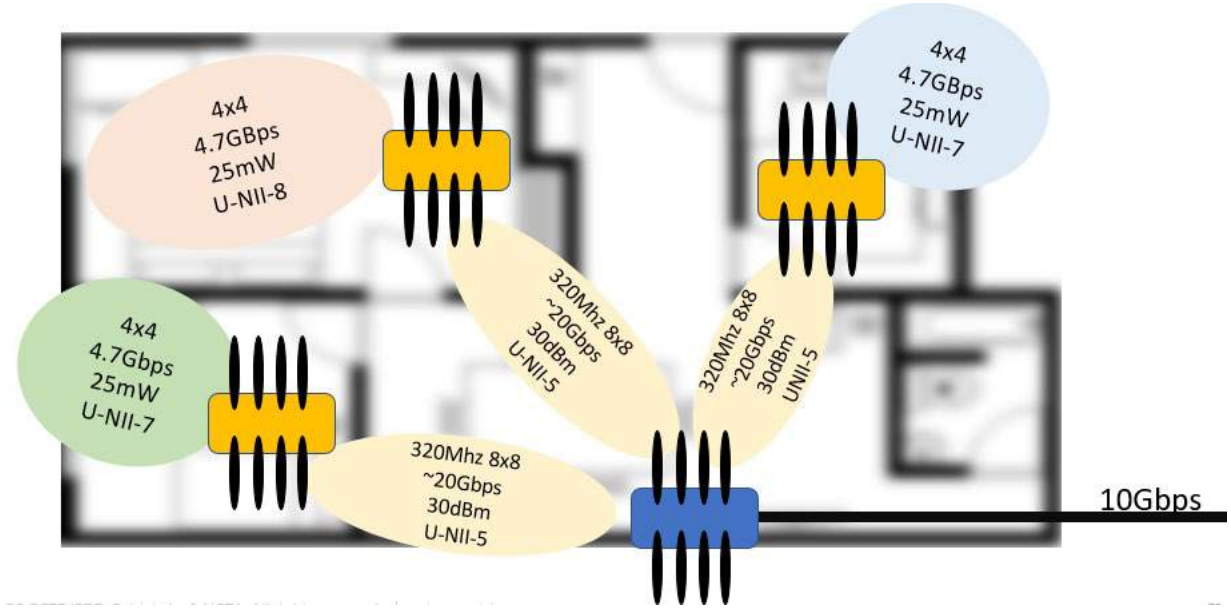

**Figure 36 - use of Wi-Fi backbone and in room 4.7GBps networks**

What would such an architecture be used for and what does 4.7GBps of in room clean Wi-Fi drive for new platform for applications and services. We are still trying to figure that out – but having this new bandwidth will accelerate more immersive video services and potentially drive applications like lower

latency VR bandwidth to Wi-Fi 7 capable HMDs using lower power Wi-Fi to make the connection in room, increase battery life of HMD and reduce Heat in the device.

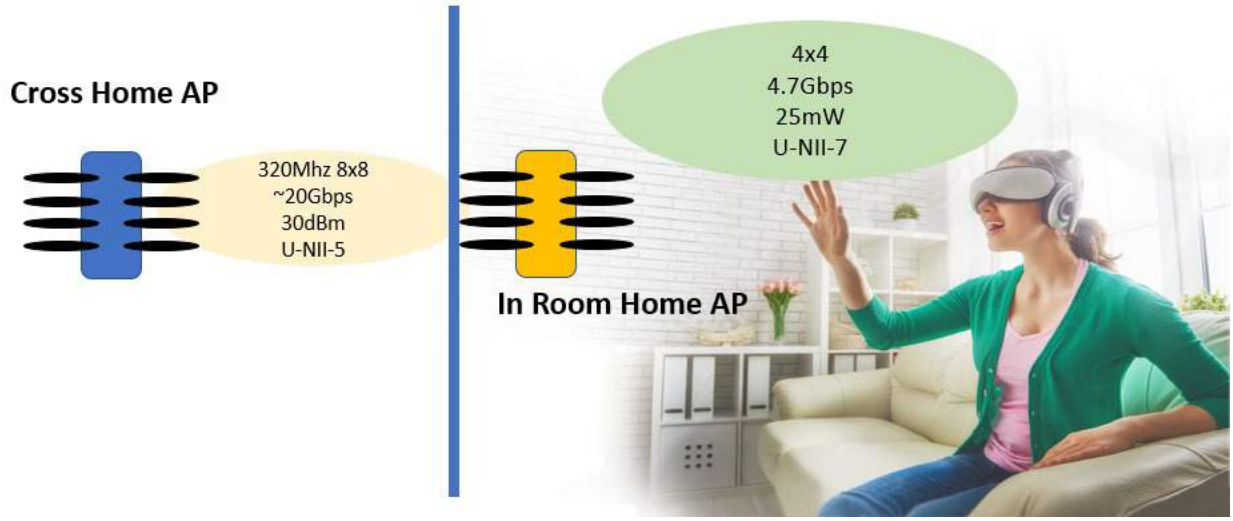

**Figure 37 - Wi-Fi 7 and Wi-Fi 6E - driving high capacity low latency services**

Additional services with lower decoding or encoding time for latency sensitive video could emerge and certainly the bandwidths supported in 6GHz allow for wireless HDMI services for the first time on Wi-Fi above 4K or even 8K levels with the full 16 spatial stream capabilities that 802.11be is driving.

The above architecture is a North start where we can take this new home Wi-Fi capacity. Challenges exist to continue to

- Make the solutions cost effective for the masses vs the minority of home budgets
- Keep the size and thermals in check – as the ergonomics of Wi-Fi AP's still has a big factor on any architecture.
- Keep latency over Wi-Fi at a minimum to ensure latency sensitive services are covered

**The above requirements could see 320MHz solutions offered in a 2x2 solution play for 6GHz – given the math of getting to >4Gbps of airtime capacity on a 320Mhz channel. This would be in contrast to the higher more future proof capacity architectures at 8x8 and 4x4 illustrated above. So, there could be architectures that align more with keeping 4x4 for the 5GHz bands and legacy and using 2x2 for 320Mhz for 6GHz capable clients using Wi-Fi 7. Its not even clear if any initial Silicon directions would focus on a cost optimized 2x2 320Mhz solution for 6GHz.**

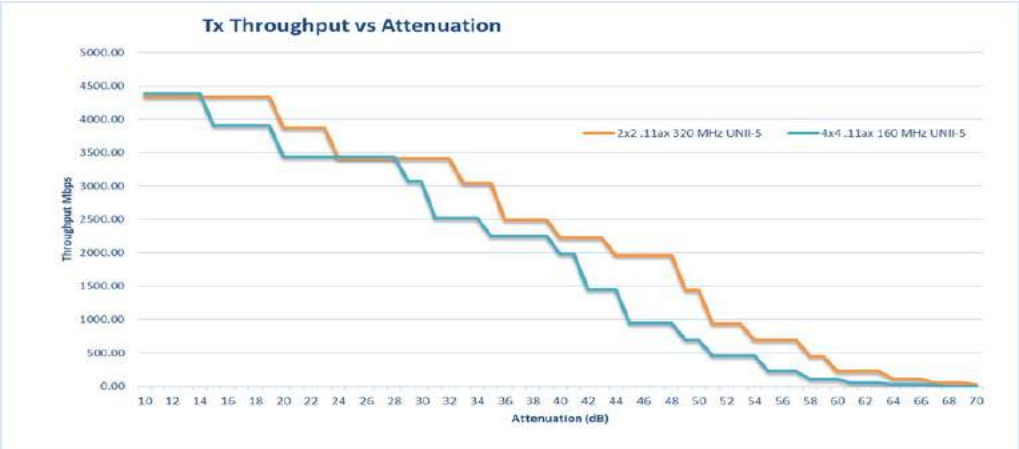

**Figure 38 - 2x2 320MHz Wi-Fi 7 vs 4x4 160MHz Wi-Fi 6E**

so, it will be interesting to see how single Wi-Fi 7 Wi-Fi Gateways and Access Points emerge to push into the highest performance levels vs keeping the cost economies for Cable Operators in particular. Who knows even Wi-Fi repeaters may make a comeback. Repeaters have always been problematic particularly for 2.4GHz low capacity or high congestion 5GHz networks as they receive and transmit the same packets on the same frequency typically halving the available airtime (typically more). With 6GHz channels however you have lots of capacity to half each time you repeat from 20Gbps in Wi-Fi 7 320Mhz channels to ~4.8Gbps in 160MHz 6GHz channels.

A single Wi-Fi 7 Gateway with 320MHz capability and Tri-band support will probably be the primary workhorse for the Cable Operator from 2024/25 onwards. However, as guaranteed Gbps applications in room emerge there may be the first in room high capacity APs that potentially focus specifically on driving applications only for 6GHz capable clients.

## 7. What do we do with 2.4GHz and 5GHz spectrum in the Wi-Fi 7 era

We have discussed a lot about the high capacity applications that can run in the 6GHz spectrum and why not with 66Gbps+ of capability there (increased spatial streams and modulation). Like any investment the focus should go where the growth will be so where does this leave the 2.4GHz spectrum and in particular the different performance/range ratio to 6GHz based devices. When 802.11ax was conceived one of the features added to it was to potentially complete the journey of 2.4GHz spectrum as the range work horse and the most likely to make a connection service, was a 2MHz channel that could be used for Narrow Band IoT services. This channel could carry the low bit rate IoT device services at ranges up to 4 times that today of 2.4GHz channels. This could then create a wider separation to the 6GHz access point role and would mean that a single 2.4GHz AP for NB-IOT functions in even the largest homes is feasible.

Wi-Fi 6 has brought fresh ideas to the 2.4GHz space, including the ability to deal with 2MHz wide channels for power sensitive IoT devices. Combining 2MHz, OFDMA, and Target Wakeup Time (TWT) together means that IoT devices are now capable of offering a significant competition to Zigbee, Z-Wave and BT devices. The 2MHz wide channel offers an 8 dB improvement on noise power, allowing the signal power to be 8 db lower enabling a greater coverage area for IoT devices. The TWT feature enables devices to remain in deep sleep mode for much longer than ever before, avoiding the constant need to listen to beacons transmitted by the AP, and allowing the conservation of the all important device battery life.

The flexible guard interval ranging from 0.8us (indoor) to 3.2us (outdoor) also makes the transmitted signals more robust, improving decoding ability at the receiver side. In addition to competing against existing LWPAN networks, Wi-Fi 6 also has the potential to avoid transmitting in the frequencies already used by these networks by not using OFDMA RUs that overlap the same frequencies. Another Wi-Fi 6 feature that helps IOT is the ability within OFDMA to repeat a device transmission in two different RUs, where a transmitted RU is repeated within the same time but on a different RU boundary.

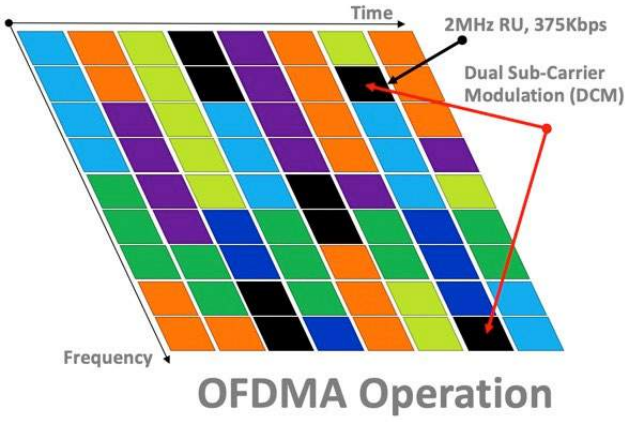

**Figure 39 - OFDMA with 2MHz DCM**

This Dual SubCarrier Modulation (DCM) feature helps the robustness of the IoT transmissions, increasing the chance of a successful data exchange. The use of OFDMA and 2MHz RUs (enabling 375Kbps) reduces the amount of bandwidth wasted by previous versions of Wi-Fi that had a minimum speed of about 6.5Mbps, and allows other active users to operate at the same time

**Figure 40 - Improved Wi-Fi 6 IoT co-existence with ZB/BT**

The 5GHz band is certainly getting close to capacity with existing Wi-Fi 4 and 5 devices, most of which are likely to remain in use for an extremely long time. While cellphones get replaced at some regularity, most other Wi-Fi devices, as long as they perform satisfactorily, are unlikely to be switched out. The gradual introduction of Wi-Fi 6 devices will show case the performance of OFDMA and DL MU-MIMO operation in the 5GHz band, and lead to a general appreciation of the benefits of using the newer standard. Initial releases of APs supporting the IEEE 802.11ax standard resulted in a mix of Wi-Fi 6 capable and not capable devices in the field. Some expected features like OFDMA were either not present or performed badly. Once a general adoption of Wi-Fi CERTIFIED 6 (per Wi-Fi Alliance standard) APs occur, these early teething issues will disappear. Additional advances in the mixing of Wi-Fi 5 and Wi-Fi 6 devices in 5GHz will occur, as well as more advanced and optimized OFDMA schedulers for Uplink and Downlink handling. It is important for silicon providers to allow scheduler interfaces to be exposed

beyond todays interfaces as there will be requirements and opportunities to customize scheduling of packets and device transmissions based on lots of new innovative ideas, services and solutions.

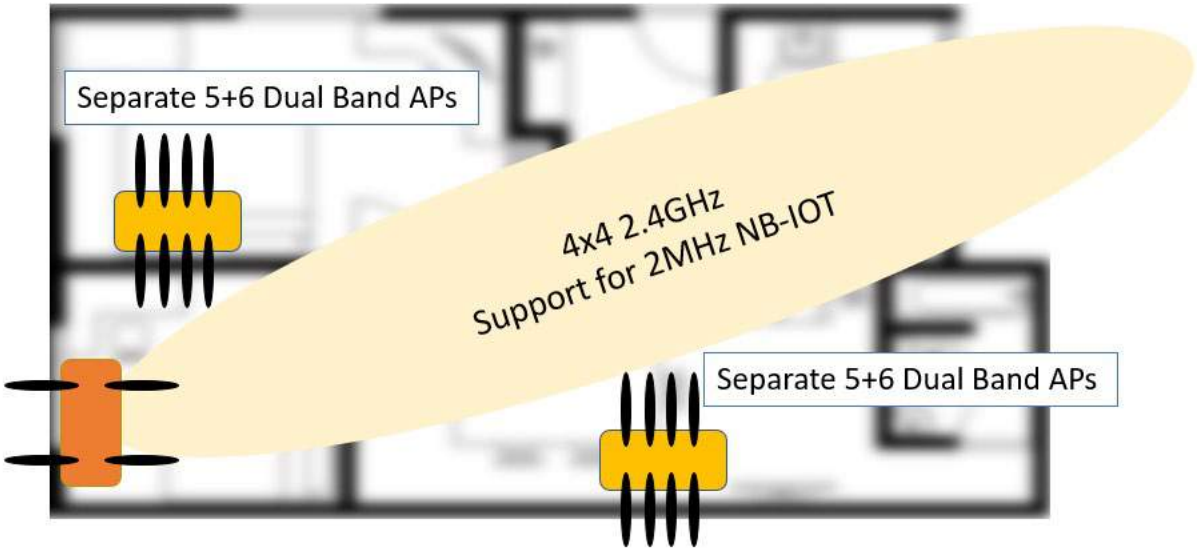

**Figure 41 - Does 2.4GHz separate out from 5/6GHz in the home over time ?**

There are many options then for the future home Wi-Fi home that could emerge over the next 5+ years

# 8. Challenges and opportunities for Wi-Fi ecosystem

Wi-Fi ecosystem faces significant opportunities with new technologies as was described in previous section. This section describes some of the ecosystem challenges and potential solutions for Wi-Fi.

## 8.1. Enhanced quality of service for applications like VOIP, voice and gaming

Currently QoS implementation, enforcement and management for Wi-Fi is done an individual system level – at client level, router level or at network core level. Client devices like phone and laptops can prioritize traffic in devices using WMM, and DSCP. The implementation and the use of these tags is not uniform end to end. In addition, much of the traffic from devices does not have any priority assigned. Wi-Fi 6 has made significant improvements in prioritizing latency sensitive traffic with support from OFDMA scheduling. However, without accurate tagging from client devices, traffic from applications like VOIP, voice and gaming cannot be prioritized.

A few of the techniques that are proposed to improve QoS are given below.

- Future Wi-Fi standards that can address QoS end to end management

- Automatic classification of QoS for applications using known parameters including UDP/TCP size, frequency, IP address etc.

## 8.2. Onboarding of IoT devices in Wi-Fi networks

Onboarding of IoT devices into Wi-Fi networks can create potential issues for customers. Many of the Wi-Fi IoT devices including sensors, cameras etc. support only 2.4 GHz spectrum and this creates onboarding issues. IoT devices are onboarded using many techniques including key presses, connecting to Wi-Fi hotspot in mobile device and using other side channel mechanisms. Some mechanisms for device onboarding require both the IoT device and mobile device to be on the same band. Since mobile device may prefer 5 GHz when connecting to router, there are issues onboarding devices that support only 2.4 GHz.

An industry wide solution that encompasses the solutions from WFA including Easy Connect/Device provisioning protocol is needed to simplify customer experience.

## 8.3. Virtualization in Wi-Fi networks

Virtualization has been used in 3GPP networks starting with 5G networks. Virtualization brings many benefits including simplifying network costs, management of devices and improved network utilization and performance. With the advent of Wi-Fi extenders and mesh networks, virtualization of Wi-Fi networks can yield potential operational improvements for network providers. In multi-dwelling unit deployments, virtualization can simplify operational challenges and reduce the overall network deployment costs by enabling multiple units to share a common infrastructure. In addition, virtualization can be used to provide different quality of services to different classes of devices.

## 8.4. Operational improvements and network monitoring

Wi-Fi networks tend to have wide variability in quality of network connectivity, primarily due to deployment considerations. Wi-Fi channels may be overloaded due to interference from adjacent networks, use of other unlicensed technologies and due to router placement.

Having robust ability to understand network quality is important for an operator to maintain customer satisfaction with Wi-Fi networks. Network operators have a variety of tools at their disposal including ability to monitor device connection quality, interference in channel, signal strength of device transmissions etc. Some of the newer techniques can also be used that proactively flag network quality issues using anomaly detection techniques.

## 8.5. Devices supporting multiple networks

Many of the mobile devices support multiple networks including Wi-Fi, LTE/5G, CBRS and public/private versions of Wi-Fi. Traditional mechanisms that primarily default to Wi-Fi networks may not be ideal tradeoff of cost and quality of service. In some cases, operators have multiple networks that can be used by the mobile devices including simultaneous availability of Wi-Fi and LTE/5G/CBRS. Devices may get better network connectivity using LTE/CBRS when outside homes compared to Wi-Fi. A robust mechanism that enables devices to make the right selection is required. This requires collaboration between operators, operating system providers and device manufacturers. This also requires operators to collaborate to create robust mechanisms to share common network infrastructure.

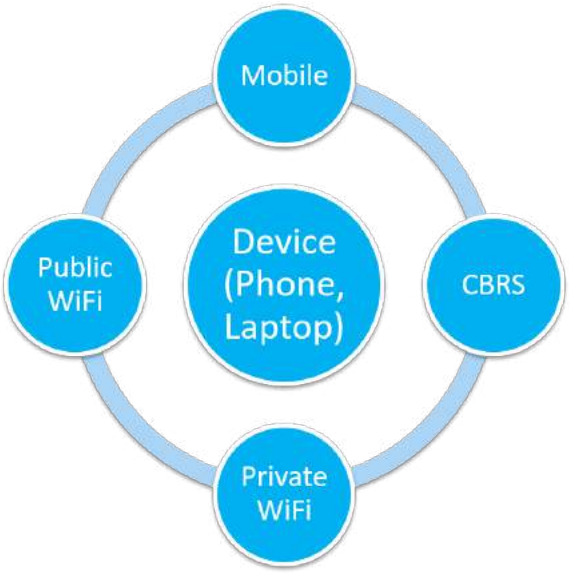

**Figure 42 - Potential synergy between different Operator Wireless networks**

## 9. Conclusion

Since the invention of Wi-Fi and the first packets sent wireless from an AP to a client there has never been a more exciting time for Wi-Fi than the current era of Wi-Fi 6, Wi-Fi 6E and Wi-Fi 7. It is unique in its Wi-Fi cadence and something that needs to be well understood by Cable Operators to plan a 5 year roadmap for their adoption of these technologies and fitting them into their overall customer experience plans. It is clear there will be overlapping SKU's of GW. AP and Extenders for Cable Operators to deploy for different levels of Wi-Fi performance. As Access speeds move to Gbps and beyond then 6GHz becomes the key spectrum to migrate to and to match the Access speeds with LAN performance. However, client upgrades to support 6E and 7 and customer satisfaction of increasing promises of performance will also have to be closely managed. Its clear that Cable Operators can exploit 6GHz immediately by leveraging it for high speed backhaul, cross home wireless backbones and most importantly high performance STB and SMD's as the quality of video increases to 4K and 8K (more driven now by better compression of AV2 and VVC). History has proven that applications will absorb the bandwidth available to leverage and the breach of the 5Gbps, 10Gbps and even 20Gbps over Wi-Fi with scheduled low latency will be quickly filled in by new immersive video and high capacity low latency applications. We typically don't see Cable Operators driving 'Build it and they will come' architectures but there will be fierce battles for consumers connectivity business over the next 5 years with 5G services also trying to leverage new spectrum and drive even Fixed Wireless Connections to overlay Cable Homes. So, the investment in getting 6GHz based services and capabilities into the consumer home to drive new video, immersive services may be the new direction for the Cable Operator and set them up for customer retention for the next 10 years of any new service that emerges. Did I hear someone say Wi-Fi 8?

## List of Figures

# 1. Introduction

Wi-Fi is a physical medium that is impeded by distance and materials that cause interference. In order to ideally place access points (APs) the physical space needs to be understood. Relevant variables much as spacing, shape of the space, and interfering objects need to be consistently measured. Measuring and evaluating all of these variables creates challenges for technicians to properly optimize networks. APs may be placed optimizing for either cost to the consumer and service provider or coverage. We have built an application that will help a technician or customer design an ideal Wi-Fi space. This paper will outline design issues in Wi-Fi and how an augmented reality application can solve them.

Traditional Wi-Fi design utilizes a meter to collect data about the behavior of the electromagnetic radio waves within a physical space. This provides the technician insight into variables that impact radio waves that are hard to visualize. Interference from other radios and the differing amount of signal degradation caused by materials the radio waves pass through can be interpreted using a Wi-Fi meter. Our AR application combines the traditional data that would be collected using a Wi-Fi meter with additional information about the space such as the area and shape that require coverage.

Additional AP hardware is expensive for service providers and too much coverage overlap can cause negative network performance for clients. If the APs aren't placed close enough together then clients will experience low signal or loss of signal. It is ineffective to train technicians and customers to measure and consider so many variables in order to decide where to place their APs. Instead, service providers may utilize augmented reality to gather data about the physical world and feed that data to systems that may make informed and consistent decisions about how the APs should be placed.

A customer's living space contains three key components of relevant data when deciding where to place APs. The most important factor for effective mesh Wi-Fi design is distance between APs. If the distance is too great dead zones are created and mesh steering becomes ineffective. Conversely, when APs are placed too close to each other interference may be caused on overlapping channels. The service provider also incurs expense due to the additional hardware they are utilizing to cover the space.

The shape of the living space is also an impactful factor when considering AP placement. Wi-Fi radios can cover different shapes based on their design, and location of APs is important to make sure the coverage is complete. For example, if a space has a room adjacent to the square common space, that room may be outside of the coverage for the rest of the living space. As shown in figure 1, non-uniform environment layout can lead to difficult design choices when placing APs. Radios often cover a omni-directional space uniformly meaning that if a space is not uniform in its shape there will be regions that require a different coverage solution.

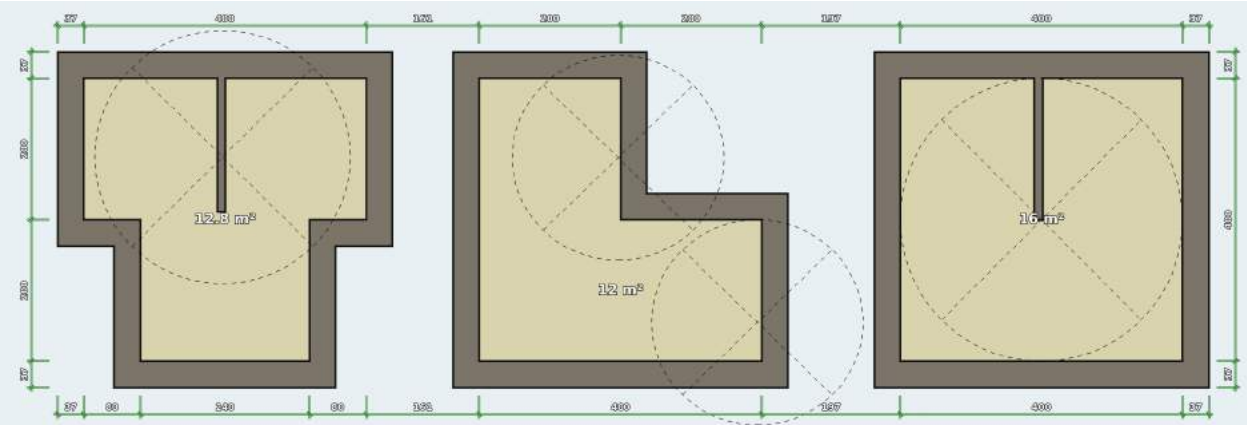

**Figure 1 - APs in different shaped environments**

The last relevant variable to be considered is noise and interference caused by foreign materials and appliances. There are some common materials such as mirrors and concrete that can cause a high degree of Wi-Fi attenuation and reflections. Detecting and designing a Wi-Fi system around them is important. The most common device that can cause interference is the microwave, although devices like cordless phones can also cause problems. Locating potential trouble devices and accounting for them can help alleviate problems. This type of interference is hard to visually detect and is often measured through a Wi-Fi meter.

Designing Wi-Fi coverage is not as simple as adding more antennae. It is a problem of design, consideration, and optimization. To design a Wi-Fi system the variables must be known, measured, and weighted. This is a process that is very difficult and not practical for consumers. Technicians are able to be trained as to what variables are important, general guidelines for what thresholds indicate for each variable, and the importance of each. This results in installations that are more efficient than if the customer were to perform the installation, but leads to inconsistencies as much is left to the discretion of the technician. Technicians must spend time measuring and designing the Wi-Fi, which increases the amount of time spent in the home and reduces the number of home installations per day.

## 2. Overview of the Wi-Fi Augmented Reality Application

The augmented reality application is designed to assist with Wi-Fi AP setup by guiding the user to collect all required data. The user is guided through the room and instructed to tap on the borders of the room as well as locating relevant connected devices and APs. Upon opening the application, the user is asked to move through each room, position the camera to view the corners, and then tap on the corner. The user is also prompted to tap on any connected network devices or APs. As the user tags each border or device the augmented reality application will place a virtual tag over the feature, showing the user where the application understands the feature to be. While the user navigates through space the device location and its current RSSI are recorded. After the user has successfully tagged all of the corners and devices they may move their device around the room to see the virtual overlay of how the application understands the environment. This displays to the user the dimensions of their environment and where the variations in signal strength are.

The principles described in this paper have been implemented as a proof of concept application by Charter's Emerging Technology group. The application is an iOS app utilizing ARKit APIs in order to gather relevant data. The application measures the path that the user walks through the home, timestamps

associated with points of the walk, and the relative location of all data points. Once the features have been captured all of the data is sent to a cloud for processing and use by other applications. The APs are also configured to collect high definition RSSI measurements for the AR device during the walk, allowing the device to act as a Wi-Fi meter.

Currently many technologies exist that could make the design of the user interface more accessible for users. The user interface accepts touch input to identify corners defining a room as well as allowing the user to tap on any device in their home that is connected to their network. These events can be seen from an interface perspective in figure 2. This however could be enhanced and even automated using plane detection to automatically locate the intersection between three planes. In an implementation following that pattern, the user would simply move through the space and the layout would be generated as they pass the camera over features. The user could after the fact, or while moving through the space, make any adjustments to correct where the plane detection is erroneous.

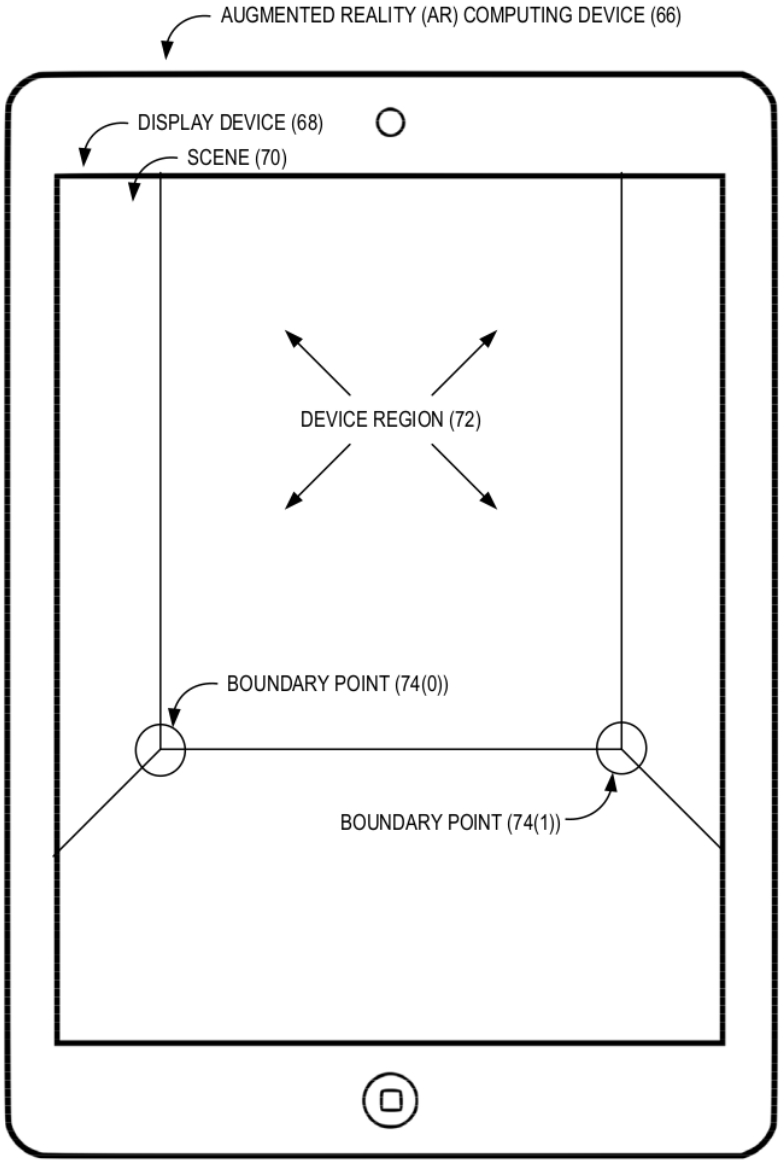

**Figure 2 - Edge Detection**

Machine learning can also help automate the placement of network devices. The augmented reality application samples the environment and identifies features including devices. The current implementation allows the user to tap on any device that is currently connected to their network and a list is then provided of currently connected devices for them to select from. This interface is seen in figure 3. Instead of requiring user interaction to select which device is present, image recognition could be employed to match images of known network devices against devices seen in the camera of the augmented reality device.

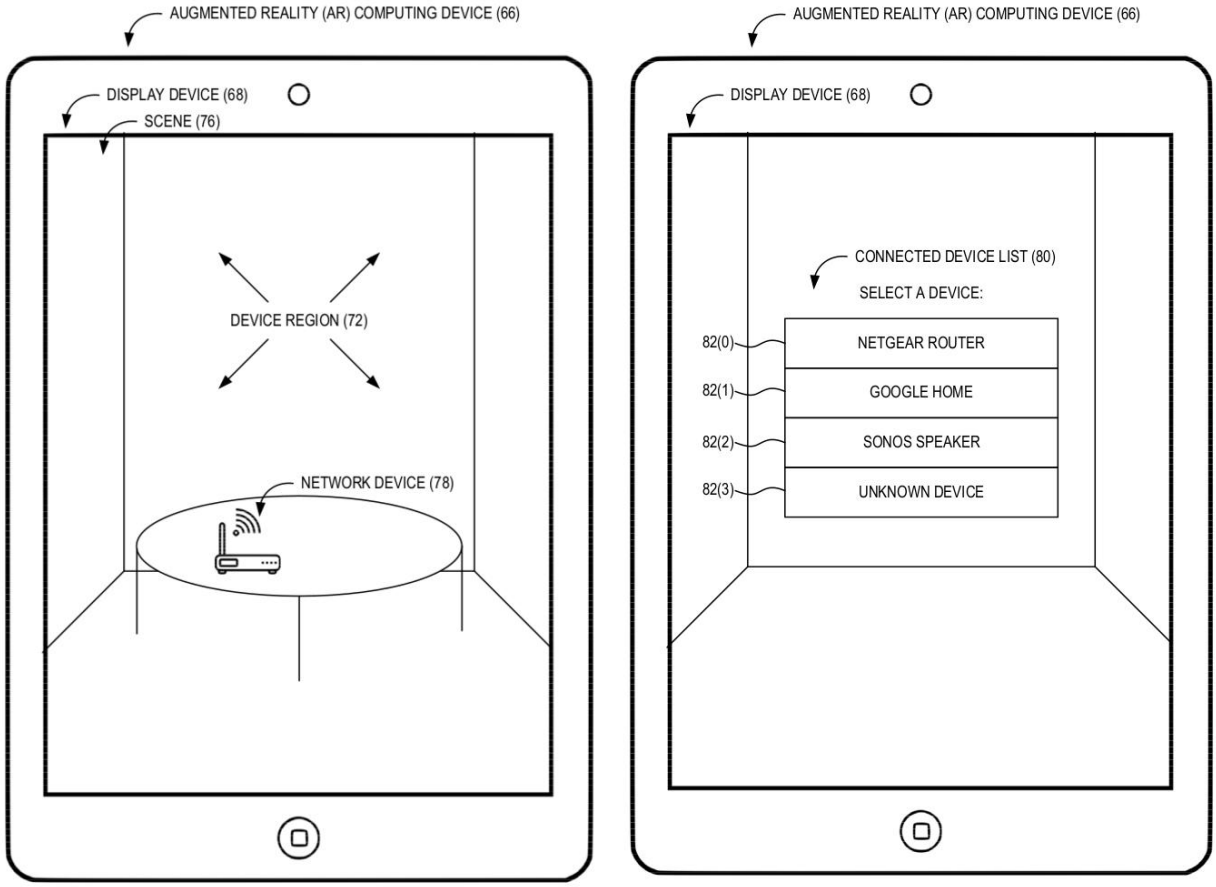

**Figure 3 - Viewfinder and device selection**

A great benefit of collecting information about the layout of a space and devices within is to enable cloud applications with extensive features. Currently, an application has been developed to consume the input data and render a floor plan for the user and to show their currently connected devices. Many next steps involve the development of new applications using the data, such as an application that would make recommendations for AP placement given the spatial and RSSI variables. Future iterations would also look to expose rules to automation systems like If This Then That or SmartThings in order to provide the ability to interact with their devices based on room or location.

The current working implementation has a lot to expand upon, but even the initial state helps to bring great benefit to the technicians and users. With real data available about the space they are installing APs in, a technician will be able to make a more informed decision about how to design a Wi-Fi system. As the current system doesn't include an engine in the cloud to recommend the location of APs, the technician will follow a process similar to the current process for assessing placement. With the addition of this application technicians will have access to more granular data that maps directly to the criteria they are asked to assess.

## 3. Setting up effective Wi-Fi

Wi-Fi installation is approached differently based on the environment and requirements. Two approaches of relevancy are enterprise installations and retail installations. Enterprise installations are buildings such as restaurants, office spaces, and hotels. Retail installations are environments such as homes and

apartment buildings. The enterprise approach uses an array of tools to gather data about the premises, considers the use cases and number of clients, and utilizes floor plans to add context to the data. In retail installations a technician uses a Wi-Fi meter to map out RSSI in the space and then place an AP if the RSSI falls into the 'weak' category. The first approach considers the shape and size of a space and then allows the engineer to design a system based on the data they have gathered. The second approach uses a very simple system to address poor signal allowing for an easily replicable process.

Enterprise grade Wi-Fi installations start with data collection, often move off site for design and architecture, and then conclude with installation and validation. The engineer will either be provided floorplans, or they will create their own by tracing the building. The engineer moves through the building measuring the radio signals and recording them in relation to their location on the floor plan. This is a slow and manual process as the engineer populates the floor plan with all of the measurements. The engineer will also take notes about potential interference locations such as thick walls, concrete structures, etc.

Once all of the data is compiled it will be correlated with information about the use cases the business will experience. This involves understanding the number of clients that will be interacting with each AP and the manner of those interactions. Radios can support different numbers of clients 'transmitting' and 'receiving' simultaneously. The MIMO configuration allows for fewer or more concurrent clients, and the common radio configurations range from (2x2) MIMO to (8x8) MIMO. In addition to the number of transmitters and receivers, enterprise grade installations need to consider the directionality of the radio. Radios may come as either omni-directional, meaning they cover a 360 degree radius, or directional meaning they cover a longer range in a specific direction. Omni-directional radios are best placed on interior walls and spaced to allow for clients to cleanly be transitioned between APs. Once the engineer has considered all of the measured variables they place their hardware configuration choices onto the floor plan. They return to the site and install the APs based on their architecture documentation. Generally a final sweep is done to verify the design choices and measure the new radio signals.

Retail grade Wi-Fi installations have some shared principles with enterprise, but the process is more rigid and leaves fewer design choices to the technician. In a retail installation a technician is sent to the customer's home where the Wi-Fi connectivity troubles are being experienced. They will then use a meter to conduct Wi-Fi analysis of the premises and then use a guide to determine whether an AP is necessary. Technicians are asked to rank RSSI in four categories ranging from excellent when greater than -50dBm to weak when less than -70dBm. The technician is asked to determine whether network extenders would remedy a poor network, and in the case that they would they are asked to determine the number of extenders and the location. General rules are provided to the technician in the form of a short video during their training. Technicians are asked to consider the square feet of the building and the shape of the building. No firm guidelines are given, however the technician is informed to distance APs twenty to thirty feet apart when through walls, and thirty to fifty feet apart when in an open space. In their training they are told to consider client usage, density of walls, and to be wary of common objects such as mirrors and household appliances.

Common themes are apparent in both enterprise and consumer grade AP installations. In both situations, the data that is gathered is generally not available after the installation has been completed. This means that there is no easy way of knowing the distance between APs and their efficacy after the fact in both enterprise and retail. The real differences in process are the data that is available to the installer and their level of expertise. Creating a uniform and optimized on boarding experience for enterprise and retail involves making sure the same data points are available to the system that is deciding how to design a Wi-Fi space, and creating a standard method for choosing AP locations.

## 4. Impact of Augmented Reality

In order to optimally place Wi-Fi APs a myriad of data needs to be gathered; The shape and size of the space, RSSI levels at locations within the space, and client use cases are all necessary for effective Wi-Fi design. The augmented reality application asks the user to move through the customer home and move the view over each corner that exists. A user will get within a few feet of the corner and then tap on the corner to record the its location in space. A very similar path needs to be walked to generate a floor plan as is required to sample RSSI. These tools can be combined and provided to the technicians, so they have similar efficacy as enterprise installations. Giving the same tools to technicians that exist in enterprise enriches the data they have access to. Ensuring that the data is stored in a standard way allows the process to get smarter and improved based on past installations.

Augmented reality allows a user to view their environment through a device that overlays relevant metadata into the space. For example, the user is able to point their device at an object, tap on it, and then a virtual tag is added to the object and its location is recorded. The user can visualize all of the recorded tags as virtual stickers they can see when looking through their device at the location.

This interface directions the user to navigate through the space and locate the corners of each room. As corners are identified, a virtual marker is placed over the identified corner and lines are created on the edges. This process gradually builds up a virtual representation of the space the user is navigating through, recording all of the nodes within a relative Cartesian space. These recordings are precise enough to allow for distance and area calculations, meaning that upon completion a record of square footage and shape of the location is fully available as data that can be fed into other systems.

Understanding the physical layout of an environment is critical to effective Wi-Fi design. Measuring the current RSSI helps account for an array of variables that confound proper design, such as interference from appliances and structures. As the user walks through the space to record the relevant corners, they walk a relatively complete path through the environment. As the device moves through the building it's RSSI is recorded by the AP it is connected to. The location measured by the device is correlated to the RSSI recorded by the AP using a synchronized clock allowing the floor plan to be enriched with the data about the radio signals in the space.

In an enterprise system, the architect manually combines the location they take the measurement and RSSI data. They then compare the radio topology with the client use cases, such as number of expected connections. Most modern network installations gather data about what devices are connecting to the network and measure the amount of traffic transmitted and received. These same data points are used by an engineer to decide the proper MIMO configuration for a given space. As the augmented reality application is used to map the environment, network devices may also be identified through image recognition or manual user input. Identified devices may be cross correlated with the devices known to be on the network and then placed into the space. This allows for understanding potential sources of interference, assistance for troubleshooting performance, as well as allowing other applications to integrate with the data. When this data is combined with the data provided by the augmented reality walk, a retail Wi-Fi design may now be as efficient, effective, and fine-tuned as an enterprise installation.

The last variable that differentiates a consumer grade install and an enterprise installation is the knowledge of the installer. The data recorded by the AR application is encapsulated in a standard format and then stored in the cloud. This allows for developers to consume the data after the fact to create models to better advise AP topologies in a space. This removes the potential for human error from the design and allows providers to algorithmically select the variables they would like to optimize for, be it the cost of the hardware or the performance of the Wi-Fi system.

## 5. Extra Use Cases

The data that can be gathered by an augmented reality device is quite useful for Wi-Fi design and optimization of hardware, but it's use cases extend further. The application provides relative spatial information for the devices on a network, borders for each room, and distances between all devices and APs. This data can be sent to the cloud and added to the other associated information known about a user's home such as the network devices and known users. Applications can be built to utilize this extra set of metadata to either enrich existing features or curate a new feature set.

One such application is Wi-Fi based presence detection. This is a technology that exploits multipath reflections and other data from the Wi-Fi radio to detect movement between two APs. This allows users "peace of mind" security to be notified when there is activity within their home. One element that is missing from this solution is the difficulty in communicating to the user the location of detected motion. An application such as this could hook into the data provided by the augmented reality application to show the user the room or predicted area where movement was detected between two APs. Currently the platform just simply alerts the user of activity on an unidentified link between two APs. Visible in figure 4 is a home layout with configured APs. This layout shows that a movement between two nodes in this design would indicate movement in a specific room. Providing the user with a graphical representation of their space helps to empower the user and give credibility to applications built on top of the technology.

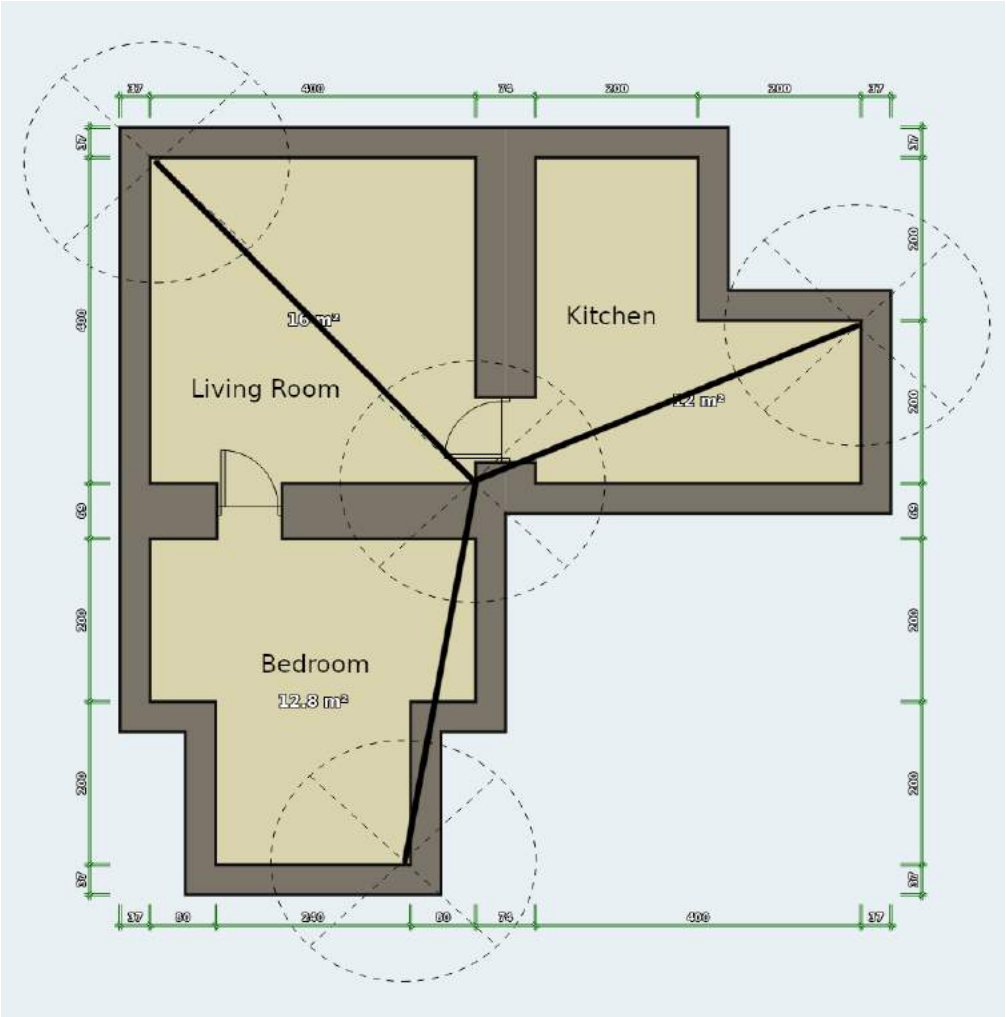

**Figure 4 - Presence Detection in home**

The Internet of Things (IoT) space can also benefit from the addition of location based metadata to devices and the rooms they exist within. Users are often guided through a cumbersome process of selecting their devices, creating groupings for them, and then naming the groups to indicate where the devices are connected. This is a manual process and is often required to be repeated for every application that contains connected devices. With a service provider able to expose information about what rooms exist in the home and the locations of the devices, IoT applications would be able to automate the forming of groups and creation of rules. IoT applications could now expose rules such as "when a user enters the Living Room, turn on all lights within" and "when movie night is run, dim all lights within ten feet of the television."

Building metadata about rooms and device location into the dataset for a user is useful for designing a powerful network, yet also provides foundational building blocks for new applications. When enterprise Wi-Fi data is sampled and utilized it's generally discarded after the topology is designed. Creating a standard system that works in enterprise as well as retail and exposing that data to other applications allows for intelligence to be brought into many feature sets.

## 6. Conclusion

Wi-Fi design is critical to get right when providing service to any customer base. There is a gap between the highest quality Wi-Fi design in enterprise and the methods used to design systems in a consumer's home. This gap may be overcome when augmented reality is used effectively benefiting both enterprise and retail. Proper use of this data enables cloud systems to learn from previous recommendations and grow in capacity to make placement decisions. New systems can be built to help show the customer their environment, communicate where their devices are, and understand their network on a new level. Instead of a user understanding their network as a list of MAC addresses with current DHCP assignments, the user can gain real world context to what is active and where it exists in their home.

Enriching the data that a service provider associates with devices is key to building smarter networks and a broader feature set. In an effort to achieve this, it's important to standardize the approaches taken to design systems and remove as many variables as possible from the system. Instead of giving a technician a set of rules to attempt to apply to a new location, we can gather the data and allow an engine to build the Wi-Fi system. This approach allows the user to better understand their network, empowers the service provider, and gives the technician access to the same tools used by enterprise Wi-Fi architects.

The tools accessible within a mobile device or tablet have evolved to a high degree, it's important to audit new tools as they are available and assess how they can complement service offerings. The processes described in this paper are immediately and directly expected to enhance the capabilities of technicians. A sufficiently intelligent interface should give an end user similar capabilities as a technician in terms of troubleshooting and designing a Wi-Fi network. An external application may make recommendations for where the APs should be placed. The AR application collects and exports all relevant data for designing a network topology. The requirements for running this application are enough compute power to handle augmented reality and a sophisticated enough camera array. This technology has become standard among consumers in the form of their mobile device or tablet. This means that instead of requiring special technology used by technicians, anyone with a modern device can exercise this approach.

## List of Figures

# 1. Introduction

Gunshot detection has become a major request from many cities deploying smart city solutions. Current state of the art solutions requires a human interaction mechanism to detect the gunshot incident and number of shots through an operations center (OC). Based on this requirement, current solutions may introduce latencies ranging from 5-10 minutes from the moment a gunshot is detected to alerting of first responders.

According to the FBI, about 70% of active shooter situations are over in under five minutes [1], and the website of National Sheriffs' Association states that "shaving even seconds off the notification and response times can result in vastly different outcomes in these situations." [2]

The response time and latency introduced by existing solutions cannot be reduced as the OC in the loop introduces a human factor that needs to listen to the scene before calling and manually dispatching first responders.

In this paper we introduce a novel gunshot detection mechanism that is fully automated. Our paper describes the software platform along with algorithms that enable:

- Detecting, classifying and localizing gunshots (Audio)
- Recognizing the shooter(s) in the scene (Video)
- Recording the scene from different angles (Video)
- Sending messages in real time to first responders dispatch center as well as authorized personnel with the accurate location and short video recording of the scene.

Our approach applies machine learning (ML) algorithms at the edge to detect and discriminate gunshots from indoor/outdoor ambient sound. When gunshots are detected, the sound direction is also derived, and security cameras follow the direction of the sound to capture the scene, identify the shooter(s) and automatically inform responders about the incident, thus providing significantly improved situational awareness.

# 2. AI-based Gunshot Detection

## 2.1. Hardware Platform

In our approach, we rely on machine learning and artificial intelligence (AI) algorithms to isolate and identify the gunshots from other sounds.

Our approach consists of hardware (HW) and software (SW) platforms enabling automatic gunshot detection, localization of the active shooting incident and real-time communication to police and first responders.

Figure 1 below depicts the HW platform controlling the cameras.

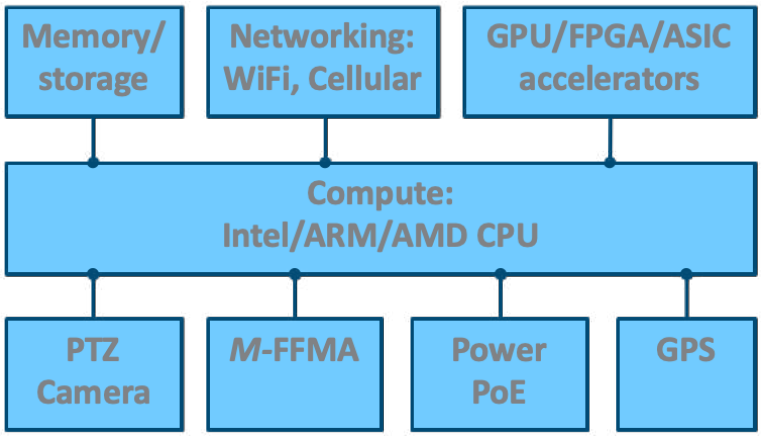

**Figure 1 - HW platform for automatic gunshot detection**

The cameras and their controllers are mounted on street fixtures, e.g. lighting poles or intersections poles.

The HW platform consist of the following components:

- Compute element (central processing unit (CPU) / microprocessor unit (MPU)
- Memory for internal storage
- Networking: either Ethernet, Wi-Fi, cable or cellular for backhauling
- Accelerators enabling different algorithms: graphic processor unit (GPU) for image processing, FPGA for audio and mic-array management, ASIC for image processing acceleration.
- *M*-element far-field microphone array (M-FFMA)
- Pan-Tilt-Zoom (PTZ) Camera: to enable dynamic scene acquisition
- PoE: to enable simultaneous communication and power delivery
- Global Positioning System (GPS): to localize the HW platform and fine timestamp events of active shooting

## 2.2. Software and AI Platform

Figure 2 below describes the end-to-end flow of the automated gunshot detection and reporting framework.

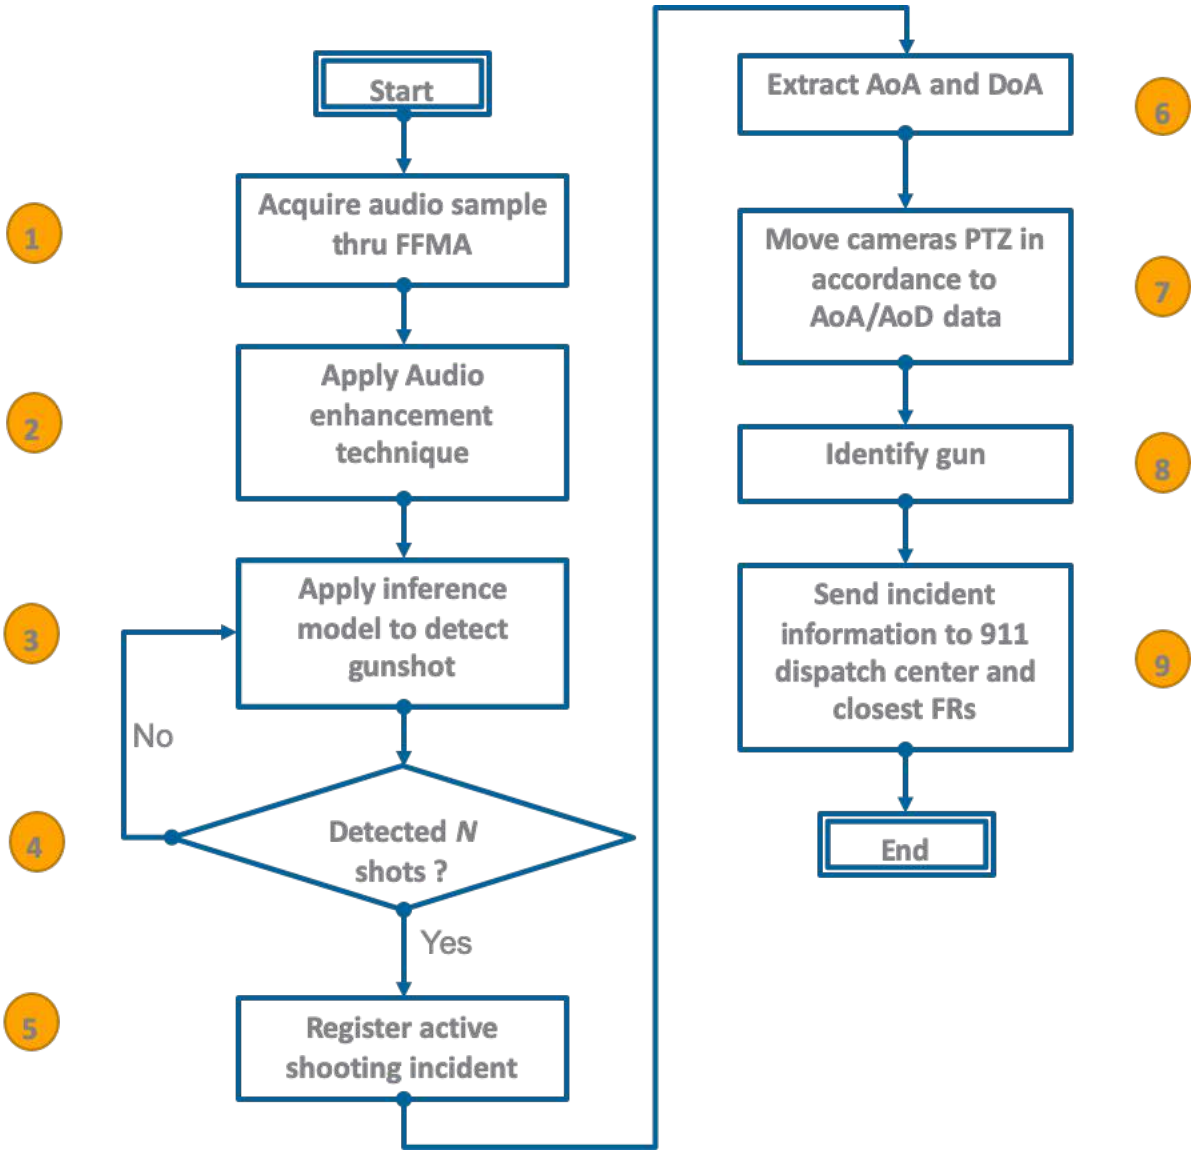

**Figure 2 - SW and AI stack for gunshot detection**

1. Audio samples are acquired through the M-element far field microphone array (FFMA). The FFMA allows active noise cancellation (ANC) and direction of arrival (DoA)/angle of arrival (AoA) algorithms to run simultaneously with high accuracy.
2. Given that the gunshots have spike-like behavior in the audio temporal domain, we introduce the algebraic detector (AD) to act as both a detector and an ANC for the audio captured by the microphone array. This will increase the accuracy of the ML inference model that detects the shots. The AD is a pre-processing step that locates the shot in time domain prior to applying our ML model. This will reduce the $P_{\text{False Alarm}}$ for the end-to-end (E2E) application.

One of the metrics that confirms the accuracy of the AD as a joint ANC and denoising technique is highlighted in the receiver operating characteristic (ROC) curve in figure 4 below and the example of gunshot detections in time domain. From the ROC curves, up to 70% accuracy at 1% false alarm rates are achieved using just 30 samples. This will scale to over 95% accuracy with a constant probability of false alarms at less than 1% at full MPEG Audio Layer-3 (MP3) audio quality (44100 samples).

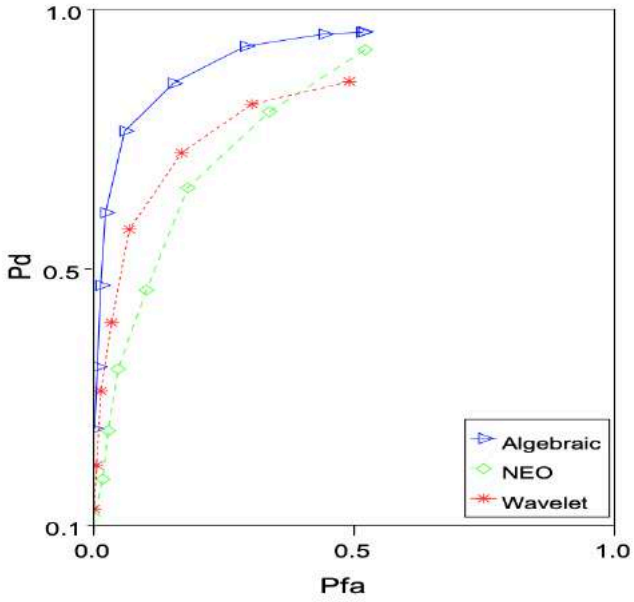

**Figure 3 - ROC curves comparison SoTA vs. AD**

We can see from the Figure above that the ROC curve associated with AD outperforms both NEO and Wavelet detection algorithms.

Another metric that helps assess the AD performance is an example of gunshot detection in time domain and the capability of the AD to denoise and separate the spike-like behavior of the gunshots from other noise at a location.

The Figure below shows an example of ground truth and isolated gunshots from city noise. The AD can run either offline or in real time to simultaneously reduce noise and locate spike-like shots in time domain.

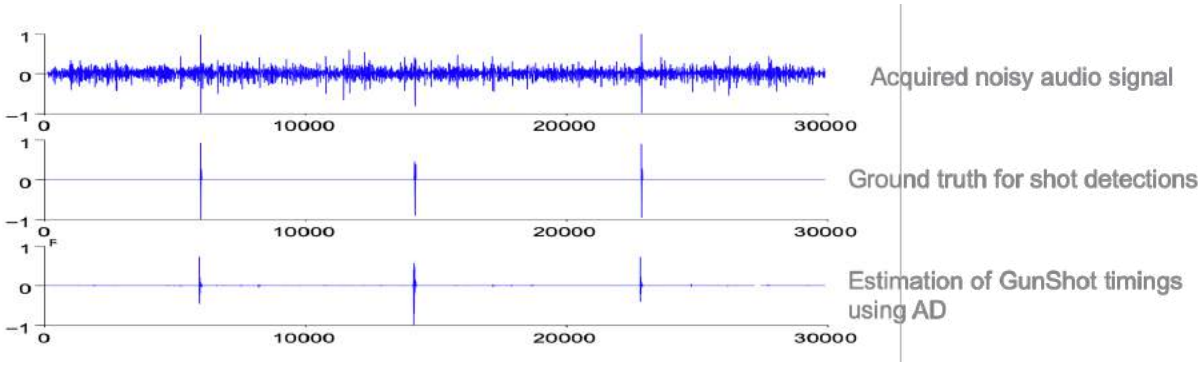

**Figure 4 - Time domain gunshot detection and audio denoising**

3. After detecting the likelihood timing of the shot, we apply a pre-trained model on gunshots over the cleaned audio signal. The pre-processing ANC through AD step allows for cleaner, better audio signal to feed into the ML classifier and allows better results with fewer false alarms for the E2E application.
4. If a gunshot is detected, a counter and a timer turn on. The counter is set to a value of N shots and the timer is set to P seconds. We set these conditions to further ensure robustness of the solution. As we do not trigger an alert at each shot, we need to aggregate N shots within P seconds to classify the event as an active shooting incident and trigger the rest of the algorithm. Shots fired from different people are processed concurrently.
5. If the algorithms register N shots within P seconds, it triggers an active shooting event. The algorithm will keep a counter increment of each shot it is detecting in the background.
6. Using the FFMA capabilities to run AoA and DoA, the system infers the angle and direction from which the shots are being fired.
7. The system issues pan-tilt-zoom (PTZ) "OnVif" commands to the camera to pan and tilt to the direction of the active shooting. The zoom is calibrated thru the Received Signal Strength Indicator (RSSI) of the audio track to estimate how far the shooting is from the camera and the microphone array. Depending on the deployment settings, the gunshot is most probably detected by more than one system. Each system is commissioned with its GPS coordinates and the shot is either identified by the closest detection system (if there is only one system deployed) or by triangulation of the different systems. The system starts recording and storing the scene in the camera's internal storage as well as exposes the live stream thru real time streaming protocol (RTSP). The system also runs on-camera facial recognition and captures all faces in scene.
8. Another advantage of our approach is the capability to recognize guns by correlating the noise-free sound provided by the AD and ANC to an on-device database containing the sound signature of the most sold guns.
9. A standardized report is created by the system and sent to first responders. An example of the aggregated data sent by the system is as described by the following JavaScript Object Notation (JSON) meta-data, in Figure 5, with the following fields:
    - **NB_Shots_Per_Platform**: identifies each HW platform that detected the shooting as well as the number of shots detected per platform.
    - **AS_GPS_Coordinates**: either the trilateration GPS location of the shooting or the closest HW platform that detected the active shooting.
    - **Timestamp**: timestamp at which the alert was sent.
    - **Video_Streams**: links to the live-feeds from each HW platform that detected the active shooting for first responder and 911 network operations center (NOC) to evaluate in

real time the logistics needed to handle the active shooter (casualties, injuries, number of shooters, number of first responder units needed, etc.).

- **Faces_Captured_At_Scene**: as the camera is capturing the scene, we run in real time face detection of all people present at the scene and store and send images as part of the JSON in base64 encoding.
- **Gun_Type**: is the identified gun involved in the shooting alongside its presence likelihood

## 3. Example Deployment of the Gunshot Detection System

In this section, we give concrete examples and results from a proof of concept (PoC) that is running the gunshot detection system indoors in an office setting.

Our HW platform is built on top of GPU-accelerated embedded single board computer and we also show the FFMA running the AD for noise cancelation and DoA/AoA algorithms in Figures (6) and (7), respectively.

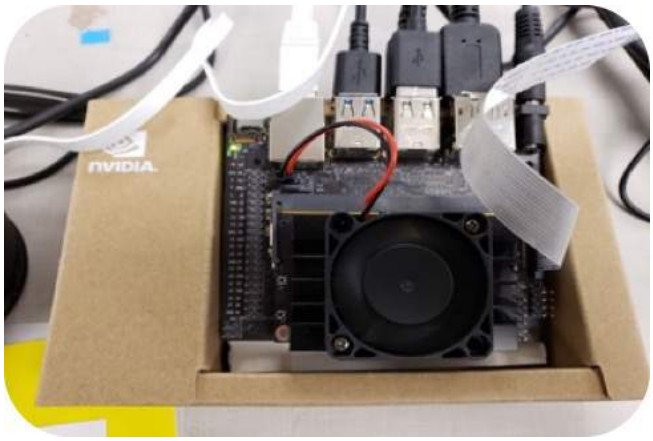

**Figure 6 - SBC HW platform**

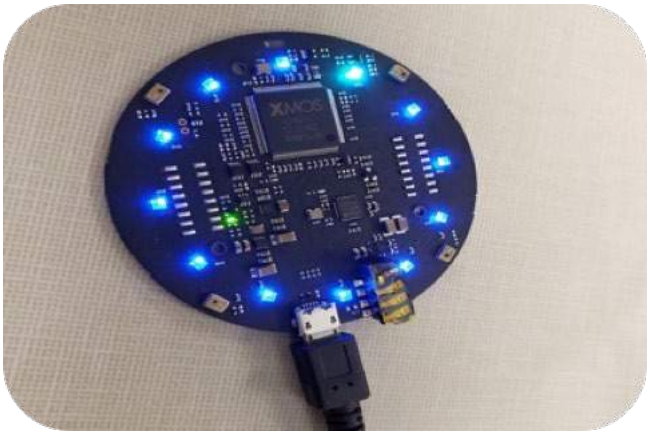

**Figure 7 - FFMA running AD and AoA/DoA**

Figure (8) shows one of the PTZ cameras used that is connected and controlled by the automatic gunshot detection system.

**Figure 8 - PTZ camera example**

## 4. Conclusion

In this paper, we presented a unique and novel approach to an AI-assisted automatic gunshot detection and reporting system. Our approach enables fully-autonomous isolation of gunshot sounds and recognition of gun types as well.

We have deployed and tested our solution in our lab using recorded gunshots to test the resiliency of the algorithms and test the end-to-end performance and latency of the solution. Our tests show conclusive results on the detection time: near real-time detection with under two seconds to detect an active shooting situation, take photos of the likely shooter and the scene and send them to first responders and police for dispatch.

Future work includes testing the system using real gun shots in the shooting range, as well as collecting more gun sound samples from the shooting range to enhance the model.

# 1.0 Introduction

The instant network stress test that resulted from COVID-19 is something the most precognizant of network engineers could not have foreseen. Even if they had, the most convincing of them would have little chance of swaying financial teams to increase investment for a traffic spike to come, and a ramp to all-time high sustained usage plateaus that would come in a matter of days.

Most importantly, the performance of the network during this most demanding and critical period shone a light on the industry in a way no press release, marketing campaign, or new service feature could. Nothing was more essential to our customers than delivering their known services, on steroids, robustly and 24/7.

This paper will review the COVID-19 period in five parts. First, we look at the raw numbers as work-from-home, school-from-home, zoom-from-home, and virtual happy hour became everyday behaviors. We will review the data and applications, downstream and upstream, against network capabilities and explain why things went well and where there were challenges.

We will then look at the response from three perspectives. First, we will assess utilization metrics in the most challenged areas, evaluate vulnerabilities, and describe quick response actions that maintained network health.

Secondly, we discuss acceleration of near term initiatives to further enhance capacity in these areas, but also more broadly to address the national rising traffic tide.

Lastly, we will zoom out and discuss how the dynamics of 2020 effect the strategic network plan.

In the final part of the paper, we will discuss the "new normal" of usage, applications, and behaviors, and describe how network planners should consider them in strategy development. Among the silver linings of the pandemic is confirmation that the industry has been focusing on, and executing on, all of the right things over the years leading up to it, and the network is indeed prepared for scenarios that are, literally, beyond imagination.

# 2.0 By the Numbers…..

The two months after the first reported case of COVID-19 in the United States (January 21, 2020) dispelled the notion that the country might escape catastrophic ravages of a pandemic that began overseas, the dreaded "community spread" of the virus kicked into gear. In a period of time on the order of weeks, a population that had been largely not focused on COVID-19 was experiencing some of the most extreme changes to life-as-we-know-it in a generation.

Just as incredibly, an initially bewildered population adapted to this new normal, following rules and recommendations from government leaders for what would otherwise be considered draconian civil liberties restrictions. Furthermore, the rules and recommendations changed frequently and varied from state to state. Nonetheless, the US population, at least initially, rallied behind "we're all in this together" to achieve the objective of flattening the curve. Indeed, all "you-know-what" broke loose later in the Spring, but that's left for another genre of publication to discuss.

Figure 1 captures this COVID-19 case-tracking period, showing the rapid rise that began in the second half of March.

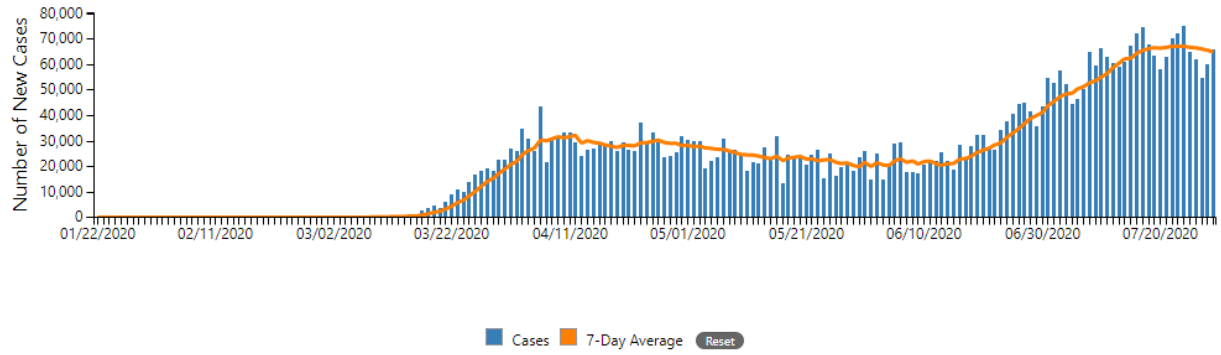

**Figure 1 - COVID-19 Cases vs Time in the United States [15]**

As admirable as the American people may be, one of the major contributors to the adaptability and relative smoothness of the transition into this unusual new routine was the capability and performance of the broadband network. It allowed for the virtual connectivity essential for the transition, and enabled high volume use of bandwidth-heavy, video-rich applications in homes to be exercised at unprecedent scale, often to substitute for activities no longer available to individuals under "shelter in place" orders. In addition, while massive furloughs and increased unemployment are tragedies caused by the pandemic, the broadband network provided a means for a large percentage of the population to work from home and do so effectively. It is estimated that about 29% of the US workforce is able to effectively work from home [11]. The network also enabled schools to continue to operate, albeit at a reduced level of intensity and effectiveness.

Figure 2 and Figure 3 show the Downstream (DS) and Upstream (US) traffic growth, respectively, over time, as shelter-in-place struck. Most honest broadband technologists would tell you that if you had predicted on March 1 that their networks would see traffic spikes over a period of two weeks like those shown in Figure 2, they would have expected some crash-and-burns in the field, and accompanying negative media coverage.

Rather than a spike of Internet outages, however, what was observed was that while there was an occasional connectivity "housefire" (which was able to be extinguished relatively quickly), in fact there were simply not huge numbers to address. Generally speaking, the impact was absorbed well due to years of experience of managing network traffic, understanding peak and average utilization thresholds that effect the customer experience, and continuously preparing and optimizing the network for traffic growth [1]. Internet traffic growth has not abated since the launch of cable broadband in the late 1990s; only the pace of growth changes year to year – the so-called Compounded Annual Growth Rate, or "CAGR." Network engineers responsible for traffic management of their systems speak and think CAGR in their sleep, with an occasional nightmare about 8k streaming holograms.

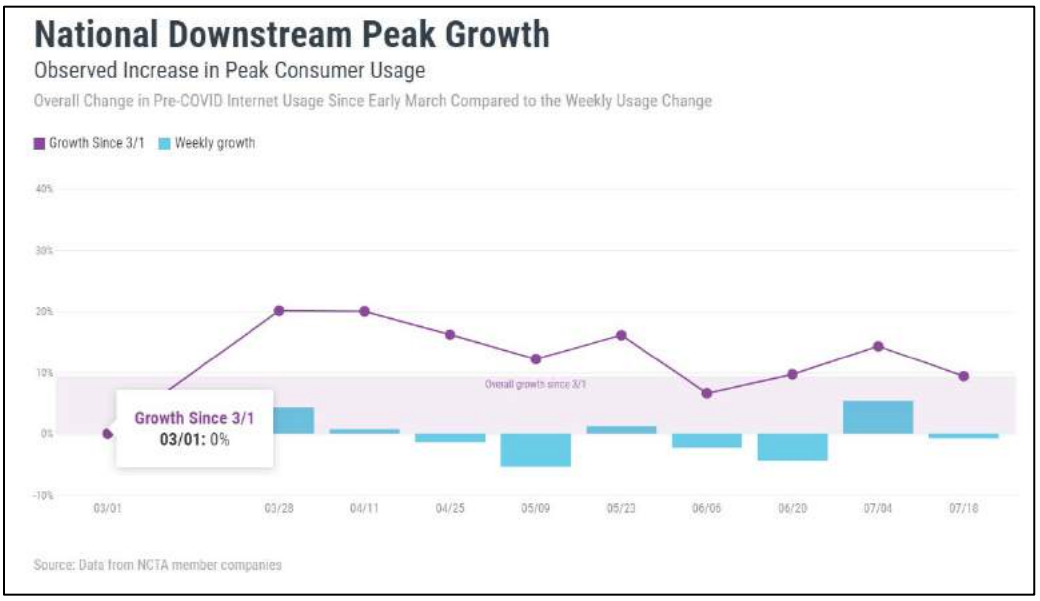

**Figure 2 - COVID-19 Induced Downstream Traffic Growth [14]**

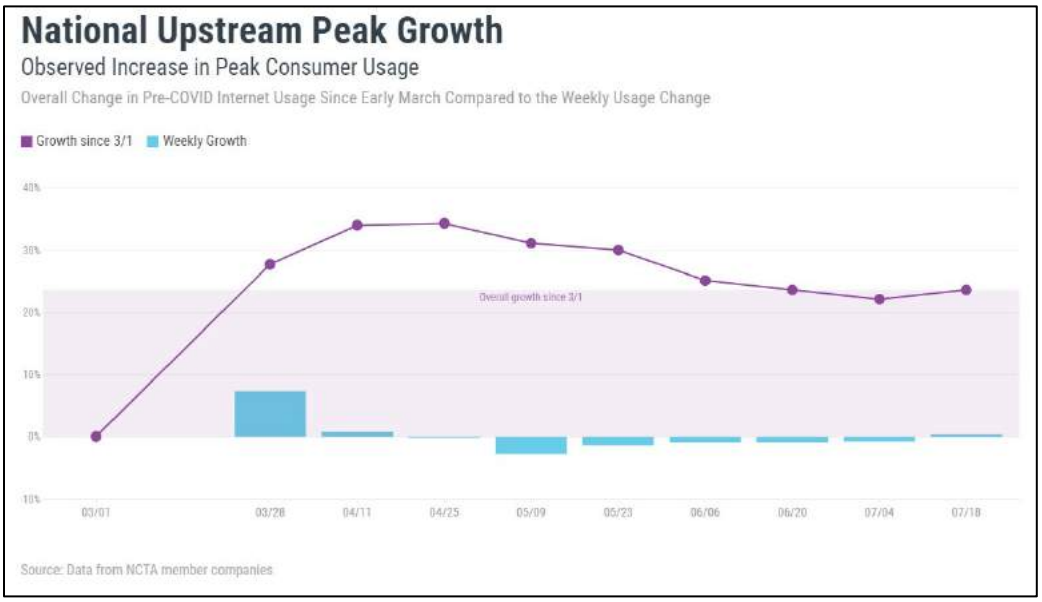

**Figure 3 - COVID-19 Induced Upstream Traffic Growth [14]**

Let's look at the COVID-19 spike in the context of CAGR. DS and US CAGR vary, of course, and historically the DS has grown 40-50% per year, while the US has been closer to 20-25% per year and has been more dynamic year-to-year. Upstream years of 15% have been recorded as well as very aggressive years, such as when peer-to-peer file sharing took off in the early 2000s. More recently, home security cameras streaming video are becoming noticeable contributors as their popularity increases, and this increase is tied to smart home automation trends in general.

In recent years for the Downstream, many over-the-top (OTT) video service options have fully matured into the marketplace. And yet, people have not grown more than two eyeballs to consume the

voluminous programming. It is a bit early to make the call of a downward trending DS CAGR, but it has settled into the 30% range.

Below are some very useful "napkin math" rules of thumb (pre-COVID speak alert – oh, how great will it be to be able to grab a bar napkin to do math, diagram architectures, and sign contracts!). We can relate CAGR to the so-called Traffic Doubling Period (TDP):

TDP = 2 years when CAGR is ~40%

TDP = 3 years when CAGR is ~ 25%

TDP = 4 years when CAGR is ~ 20%

Now, consider the COVID-19 traffic spikes in Figure 2 and Figure 3. Downstream growth peaks at about 20% and has since receded to 10%. This tapering to 10% coincides with the loosening of restrictions, but also with the onset of spring and summer weather. This year more so than any other people were anxious at the first opportunity to get outdoors. Furthermore, the summer broadband season is typically slower. So, it may be premature to assume that the 10% is a settling point for DS CAGR after the pandemic. If we use the more conservative guideline (from an architect's perspective) of 20%, at least until we know more about what a post-COVID new normal looks like, then the virus has accelerated Downstream traffic growth by 7-8 months, using 35% as a reference DS CAGR. The Compounded Monthly Growth Rate (CMGR – unfortunately not as easily expressible as "CAGR" in conversation!) for 35% works out to 2.5%. It seems clear that some behavior and societal impacts will remain after the virus is no longer a threat large enough to warrant restrictions.

For the Upstream, an initial spike of 35% has receded to about 25% as of July of 2020. Using an US CAGR of 25% means that traffic has accelerated by just about one year. The 35% spike, however, if sustained, is an acceleration of about 16 months (1.9% per CMGR). Generally, cable operators are driven to action in the network by congested upstream. The primary reason for this is simply that there is much less upstream, home-to-headend spectrum available, and it is more difficult to use. The network was built as a one-way video broadcast network originally, so Downstream spectrum was emphasized. Fortunately, analog video is so sensitive to noise and intermodulation distortion that the network was built with very high fidelity, even after being carried through dozens of amplifiers, in the earliest days of cable, enabling today the opportunity with fiber and DAA to have tremendous digital communications efficiency. So, the limited upstream has been able to be made quite powerful, given the available spectrum, which is typically 5-42 MHz in North America – or about 5% of total available capacity, depending on where you draw the upper spectral boundary for the downstream signal path. Cable operators have dealt with this limitation of available US spectrum since the launch of High Speed Data services (HSD), in the late '90s, and of course benefit from the fact that the residential asymmetry ratio of DS to US traffic is about 12:1 today, and has never ventured below about 7:1.

The bottom line is that while the US has been exploited very effectively, it more often than not drives plant upgrade strategies. Several access network initiatives in the industry are about adding US spectrum via 85 MHz Mid-Split, 204 MHz High-Split, and DOCSIS 4.0 Full Duplex and Extended Spectrum. The COVID-19 acceleration of 16 months is especially meaningful in terms of its impact to US ports close to the congestion threshold. A traffic spike such as this would normally occur over many months, and under normal circumstances that yields sufficient time to plan the upgrades necessary to avoid oversubscribing the link.

On the flip side, operator awareness of US bottlenecks had already been quite high, so the tools and strategies to deal with it were well known and in place to manage it. The difference with COVID-19 is

 

that the multi-year plans lost the luxury of much of that prep time and budgets, when it accelerated forward. It is in scenarios where fiber nodes were on or approaching utilization alarms within a year that network congestion was triggered – the aforementioned "house fires" – where work to resolve it needed to begin immediately.

## 2.1 By the Geography….

Averages provide a general understanding of network behaviors and trends. However, they can be dangerous as well, as regional traffic variations and network performance are tied to the issue that matters most – the customer experience. Where technology-centric businesses, professionals, and universities are key tenants of a region's environment, populace and demographic, average and peak traffic metrics and growth will be correspondingly higher than in locations without these characteristics. So, as valuable as National averages are, operators have to be much more surgical in their knowledge, and in their response. Regional variations are too significant to have a one-size-fits-all network strategy, under normal circumstances, much less considering something as dynamic and unprecedented as a pandemic spike.

Figure 4 is a snapshot the network numbers for several representative states, all of which are served by Comcast as well as other cable operators.

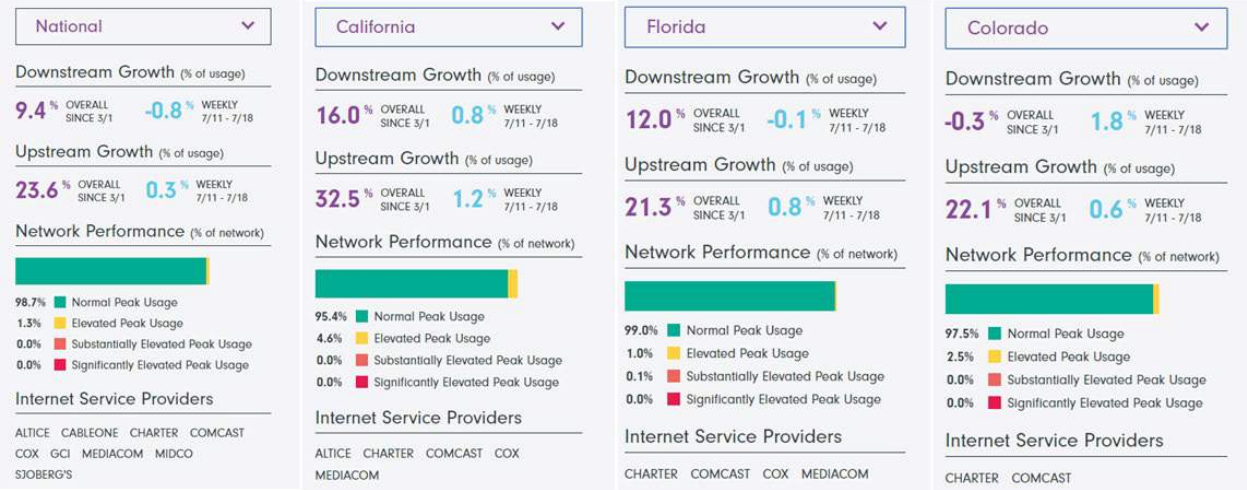

**Figure 4 - Regional Traffic Variation are Significant [14]**

What is clear from Figure 4 is that the National average would be insufficient as a guide for a COVID-19 response plan for California but might hit the mark in Florida. Alternatively, Colorado appears to be an area where prioritizing US should definitely take precedence over the DS. It is often the case that when addressing congestion in one direction, such as upstream, it is cost effective to address the other direction at the same time.

A conclusion that can be drawn, and a reality of the experience in the early weeks of the pandemic, is that reactive operations to put out the "housefires" were not uniformly distributed. High tech corridors, such as exist in California and other parts of the country, accounted for a disproportionate share of rapid response efforts. Pandemic or no pandemic, non-uniform implementation or staggered timing of network strategies is a common component of access evolution.

## 3.0 Online During a Pandemic: What Are We Doing?

It is clear and by now intuitive what applications fueled the surge in traffic, including why the US has seen the larger increase. Figure 5 shows the rapid rise of video conference and video chat applications in response to the shelter-in-place lockdowns. Such a rapid spike over a short period of time is exactly the kind of thing that a network engineer loses sleep over. The increasingly popular business conferencing tool Microsoft Teams is overshadowed by the Zoom application, which exploded as the pandemic hit, as a physically-distanced, family-friendly chat experience. However, in relative growth terms, Teams also exploded exponentially, going from 560 Million minutes on March 12 to 2.7 Billion minutes by March 31, or about 70% growth per week during that period of time [4].

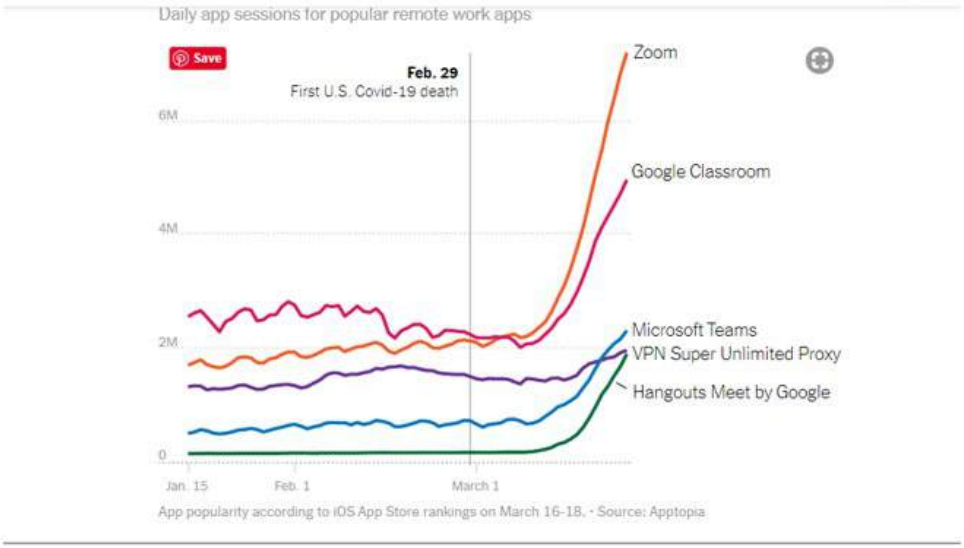

**Figure 5 - COVID-19 Impact on Video Conference and Chat Applications [9]**

Figure 6 shows the traffic on a weekly timeline, highlighting how much can be attributed to work-from-home (WFH) employees, as evidenced by the dip in traffic over the weekend.

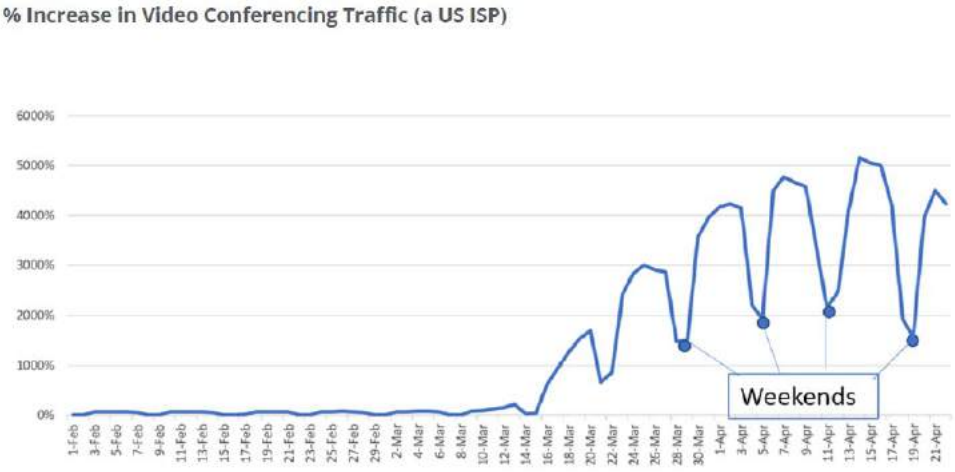

**Figure 6 - COVID-19 Impact on Weekly Video Conference Traffic [2]**

To punctuate this conclusion, Figure 7 shows how the upstream has experienced a shift in its Peak Busy Hour (pbh) usage, from about 9 pm local time, to 2 pm local time. The biggest percentage increase over pre-COVID utilization is actually at 1 pm, but because the characteristic of the US is a gradual rise throughout the day, the absolute peak has moved to about 2 pm [1].

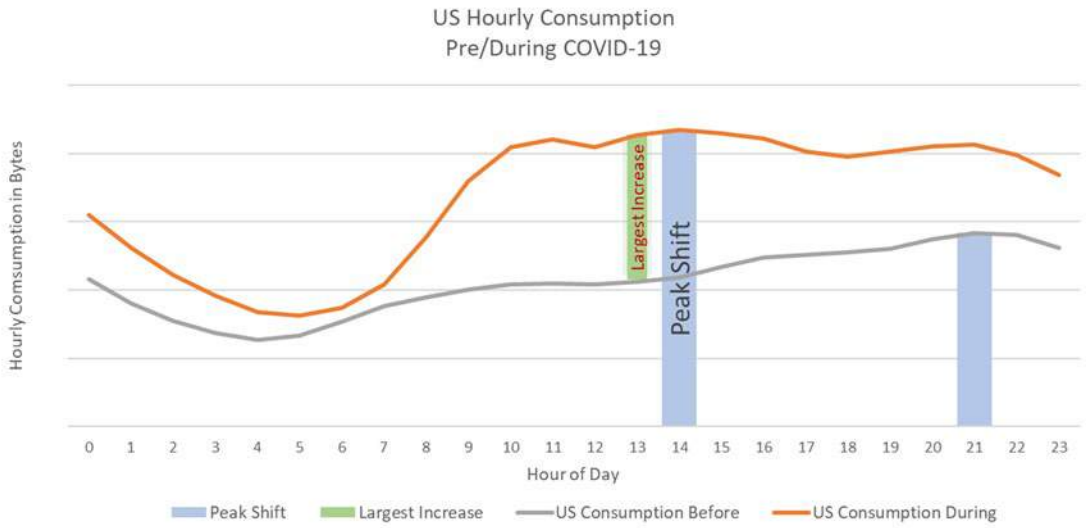

**Figure 7 - COVID-19 Impact on Peak Busy Hour Time Shift of Upstream Traffic [1]**

Finally, Figure 8 shows the predictable spike of virtual private network (VPN) traffic at the onset of the lockdown, such as would be expected when a massive shift to WFH has taken place.

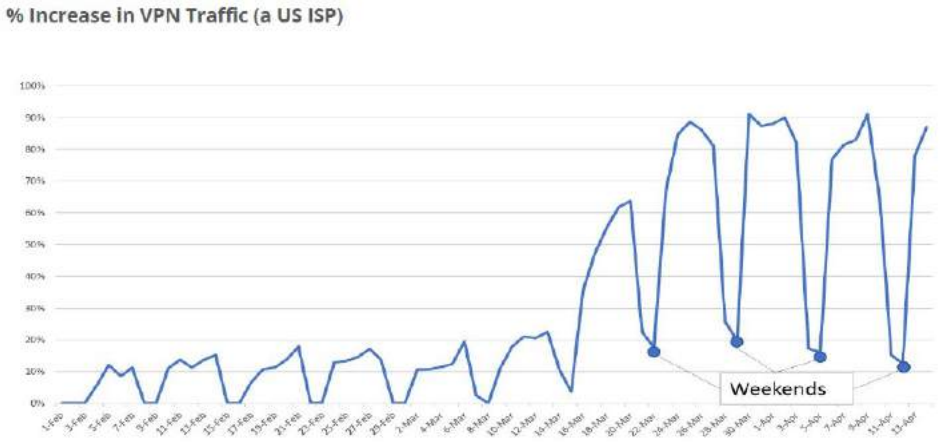

**Figure 8 - COVID-19 Impact on Weekly Virtual Private Network Traffic [2]**

Moving onto other expected online implications of shelter-in-place, Figure 9 shows the increase in use of streaming video usage, as alternative entertainment options – movies, concerts, etc. – were eliminated. The taper not long after the upward trend is attributed, again, to a combination of spring weather providing opportunities to relieve cabin-fever, and possibly, "binge watching fatigue," as reality set in following initial estimates of short term lockdowns. Note that the call-out labeling on this figure appears to be in error – the highlighted dates appear to be weekends.

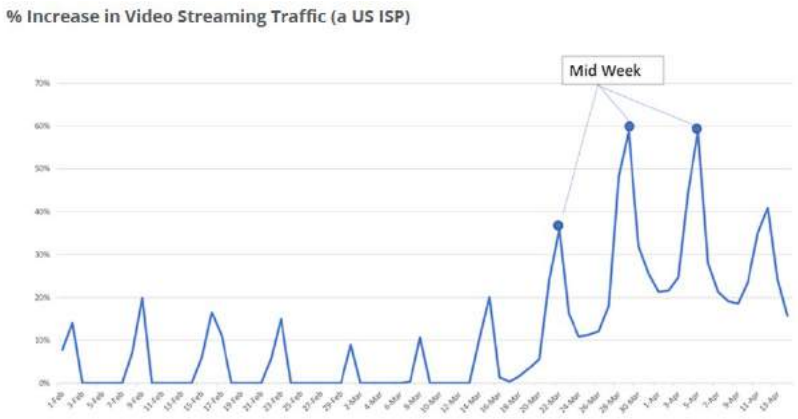

**Figure 9 - COVID-19 Impact on Streaming Video Traffic [2]**

Not captured in any of the charts but also intuitive is that the applications identified have seen growth in being accessed through web URLs instead of mobile applications. Figure 10 shows how trends for popular applications representing streaming video shifted rapidly away from apps and towards websites. The relevance to this paper is somewhat secondary. The large increase in streaming video traffic, which makes up approximately 70% of all web traffic, is still the main story. However, the secondary effects are twofold:

1) Applications accessed on small screen devices will on average translate to lower bit rates of video compared to their desktop or larger screen/tablet counterparts
2) Web access as well as the mobile devices themselves are more often accessing content via Wi-Fi instead of mobile networks, driving more traffic to the wireline broadband network.

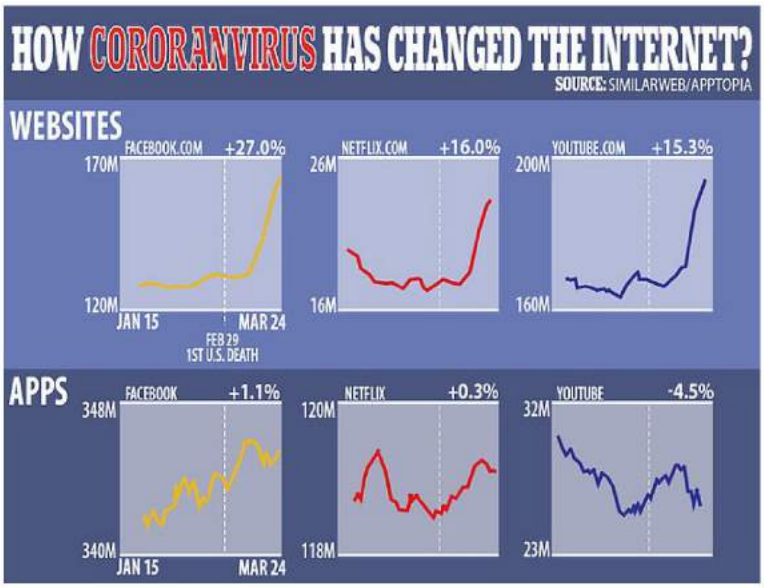

**Figure 10 - COVID-19 Impact: Web Access vs Mobile Access [10]**

A final interesting traffic dynamic is shown in Figure 11, which captures gaming application growth. Again, with entertainment options limited, and gaming already a popular and growing online activity, regular gamers had less reason to back away from the console, and casual gamers had good reason to increase usage. An interesting observation is that, while Figure 9 has the familiar peak and lull pattern

common to weekly residential traffic behavior, the pattern itself was altered in the gaming space, at least in the early weeks. Weekdays and weekends blended into one continuous gaming binge! It will be interesting to see over the long term if gaming was a temporary diversion or if it also has achieved a new baseline level of significance and permanence due to once-casual gamers becoming more hardcore participants.

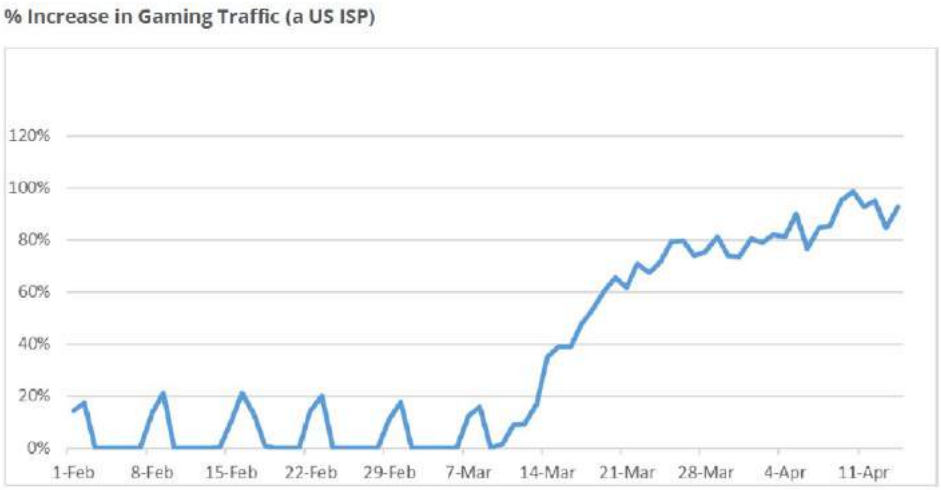

**Figure 11 - COVID-19 Impact on Gaming Traffic [2]**

## 4.0 Post-Pandemic: So….What Might Normal Look Like?

As mentioned at the outset of this section, in retrospect we have a largely intuitive outcome from the pandemic restrictions. While it is difficult for anyone to "crystal ball" in such an unprecedented situation, there are some consensus beliefs emerging about the Post-COVID-19 "new normal" with respect to traffic and the network. Permanent changes of the traffic baseline above the pre-pandemic steady state is an expected outcome. Summarizing some of this emerging conventional wisdom:

- It will be truly awesome when we will be in a position to compare projections with the real Post-COVID-19 traffic data!

- *Working from Home (WFH)* – WFH will play a larger role for office workers. The comparable productivity observed, for companies where this was the case, will have companies reconsidering the potential savings associated with the operating expenses of commercial office complexes. People density in an office building may be changed forever, and trends like open floor plans re-thought. Video conferencing had been adapted at Comcast by the end of 2019, and in many other companies as well. With an expected permanence to more WFH, applications like Microsoft Teams, WebEx, Zoom, etc., which have been indispensable from the outset of the pandemic, will be more essential. Also, their capabilities are likely to improve with a higher focus on scale, emulating face-to-face features, and blending in attributes that f2f meetings cannot obtain, such as the virtual backgrounds (I'm in Hawaii! I'm on a ski lift!) and associated computer-aided graphics seen in some of these applications already today.

- *Normalization of Online Education* – Universities have been offering online classes for many years, and some universities are entirely online. However, for most full-time universities and

certainly primary and secondary schools, face-to-face instruction is still considered as the most effective means of instruction. Online courses offer much more convenience, if a somewhat less effective alternatives. However, tools focused on a classroom experience will now get significantly more attention in a bid to emulate true classroom environments, while offering capabilities only a digital environment can easily do, such as shared whiteboarding, offline non-disruptive chat, and an audio and video record of the experience.

- *Normalization of Virtual Social Gatherings* – The "virtual happy hour" has become a ritual among my spouse and her friends and with family. Despite no ritual clinking of glasses to "cheers", shelter-in-place orders caused a much wider interest in applications like Zoom. A positive side effect of requiring such applications for any social contact is that through this new familiarity, families who were physically separated by virtue of living in different parts of the country for years began to use it to virtually visit each other far more often than they otherwise would have. In this way, the pandemic has brought families which are naturally distanced from one another into more frequent contact. It remains to be seen if that continues post-COVID, but it seems likely that the impact can only be a net increase in these applications.

- *Preparation for the Next Apocalypse* – Many businesses reliant on personnel in factories, warehouses, logistics centers, etc. suffered substantially with the absence of these employees, especially in those industries not considered "essential." Production, logistics, supply chains, employment itself, etc. were disrupted, magnifying economic woes. Companies with bread and butter in goods and services tied to manufacturing, shipping, and logistics are expected to invest in increased digitization and automation of operations, including use of more machine-to-machine communications (M2M) as part of robust contingency planning, to limit the financial damage that future pandemics or unforeseen interruptions of operations can cause.

An interesting pandemic perspective, from a sales point of view is that, as a salesperson, face-to-face meetings, lunches, dinners, etc. are a key element of the business relationship. Sales teams are generally in a similar boat regarding access to face-to-face meetings. While established accounts are generally as vulnerable (or not) as always, given this equal playing field, new business accounts are increasingly difficult to land, as the reliance on relationship building and face-to-face discussions are magnified.

If this is so, the pandemic effect may be detrimental to disruptors, as well as to new business areas in the incubation phases for established OEMs. Beyond the survival mode drag placed on technology development already, this could result in a stall to innovation in the industry as a whole. As technologists and representatives of the industry with a mutual desire to keep our ecosystems healthy, this is something to keep an eye on. There has been an appropriate focus on "keeping the lights on" activities and minimizing risk to keep people at least virtually connected. However, given traffic acceleration impacts of COVID-19, it is even more important that innovation does not suffer a setback as technologies to deal with it have been essential.

## 5.0 Next Generation Nimble

The above data tells a clear story and suggests an expected post-pandemic permanence to some of these trends. That said, the job of any access network team is to determine what revisions may be necessary for the path forward. We will note that the broadband network is but one of many potential traffic bottlenecks and addressing it in isolation will not necessarily eliminate all customer issues. Many of the mature applications identified within, that are shifting with the trends of the pandemic were, like the

 

network, operating in a "business as usual" (BAU) pace of upgrades of features, capabilities, and scalability. The application servers themselves, and interfaces to and from them, also experienced an unforeseen step function increase in demand.

VPN servers, for example, perhaps accessed routinely by 15% of a company's remote workforce --with compute and I/O sized accordingly -- suddenly saw perhaps 4-5x the number of remote employees vying for access, slowing everyone down. A video conferencing application, for example, may be fully suitable for cross-country meetings from several remote offices, but ill-suited for 30 individual streams. Lastly, we have seen in the news the challenges the Zoom application has had with security of sessions, a feature important to all, but with very significant implications to business data compared to the virtual family video chat. So, as mentioned, while network engineers revisit their strategies and plan for evolving the network, there are many parallel efforts across the products and applications such as these, and the companies who own or operate them. The end performance for customers involves successful migration and execution on both fronts.

Lastly, we note that the focus will be on the edge and access network, which is generally the cable system bottleneck. But we should note that the in-home broadband network, in particular the multiple and simultaneous user Wi-Fi experience, may also come under duress as a bottleneck. The new generation of Wi-Fi 802.11ax (Wi-Fi 6), and the new 6 GHz band are arriving at just the right time to improve the in-home experience. In-home Wi-Fi mesh extenders have also matured to provide a significantly improved coverage experience. Depending on their current Internet service and gateways, customers may need to upgrade their in-home network.

## 5.1 The Near Future Has Arrived Ahead of Schedule

We have seen the drivers of new behaviors, and, to the extent that we can use the word "predictable" in a discussion based on an unfinished global pandemic, the network traffic aspects and key applications of pandemic life are, in fact, predictable – except perhaps that gamers evidently never EVER take breaks. Furthermore, we can recognize that the pandemic has not changed very much materially about what the important initiatives for advancing the access network are. All of them are things that we should have been thinking about already.

What has changed, however, is the execution timeline of these strategies, including the relative priorities and the proper sequence of initiatives. And, importantly, it has increased greatly the level of awareness of our customers, and the nation as a whole, to the criticalness of the network and availability. This plays a role in the approach to phasing, execution, and risk assessment, as initiatives are brought to trials and rolled out. In access network engineering, it has normally been the case that the job is well done when major network-impacting technology upgrades take place and the customer does not notice you were there, unless it's having a new product offering to consider, or because they cannot remember the last time they had to call to talk to a care agent on the phone. As the shelter-in-place orders came out and companies started dispatching their employees to work from home, ALL eyes were on the network. And broadband engineers everywhere should be very proud of what they built and how this situation has played out so far.

Armed with the trend data shown earlier in this paper, the recognition that the trends are likely not temporary, that precise accuracy of end-state traffic behavior will be uncertain for some time – yet the ability to surgically address rapidly changing dynamics has never been more essential – a recalibration of the network evolution makes sense. This should be done with the following considerations in mind:

1. *Enable Agile Coaxial Capacity* – Quickly add capacity, above and beyond "BAU" increases, necessary to recover the pre-COVID bandwidth-versus-time runway, and in anticipation of increasing US CAGR and that the observed trends so far get rooted beyond the first wave of adopters.
2. *Hardening and Resiliency* – Enhance the reliability and availability to enable a seamless WFH and online education experience for all types of remote workers and students. Increase visibility and proactivity to the customer experience. Create a resilient and self-healing network.
3. *Responsivity* – Drive down network-induced latency and jitter to support the increase in real-time applications, such as video conferencing, and to ensure the increased in gaming traffic does not impact the gamer experience.
4. *Enabling of Enterprise Services* – Perhaps this seems out-of-touch with the obvious softness in office-based business services. However, economic losses suffered due to shutdowns of industries dependent on "non-essential" workers are expected to lead a drive to digitization of processes and industry. This includes M2M communications, coupled with data analytics, in order to be less vulnerable in the future.

### 5.1.1 It's the Bandwidth, Stupid

Bandwidth, bandwidth, bandwidth. When is it ever NOT about the bandwidth when it comes to access network evolution? Well, this is NOT the exception.

One of the valuable lessons confirmed by the pandemic is the value of building ahead of the traffic curve. How far ahead is an ongoing debate and a target that shifts around many technical, business, competitive, market, financial dependencies. Generally it is good to have several years of network runway ahead at all times, simply because we KNOW traffic will continue to grow and because it is only every so often that the opportunity to touch the network takes place, and certainly not continuously. It is this built-ahead-of-the-curve discipline that allowed network operators to not just survive the pandemic storm but excel in it. The spike in traffic was unprecedented but did not exceed the amount of time "runway" operators routinely plan for.

Despite pre-planning, the magnitude of the spike did create some of the aforementioned housefires where, for example, a portion of the network may have had an upgrade cycle a number of years ago, and at the time of the onset of the pandemic was not far from its next upgrade. In a "BAU" cycle there was more than sufficient capacity to make it to the scheduled upgrade – typically a node split. Capacity management teams carefully project "by when" an upgrade must take place or else risk a utilization/congestion alarm, by monitoring the network traffic at all sites and for all service groups, and building dashboards to make ongoing decisions, as shown in Table 1.

**Table 1 - Capacity Management Dashboards Guide Targeted Network Upgrade Investment [1]**

| | Month 1 | | Month 2 | | Month 3 | |
|---|---|---|---|---|---|---|
| | % >80% Utilization | Count >80% Utilization | % >80% Utilization | Count >80% Utilization | % >80% Utilization | Count >80% Utilization |

#### 5.1.1.1 Rich Fiber Diet

Like all MSOs, Comcast continues to split nodes as traffic grows – it is a great advantage of the HFC architecture, that it is so incrementally scalable in a success-based way. However, several years ago, Comcast embarked on a network upgrade path that complements the typical node splits with a more aggressive approach that effectively acts as multiple node splits in a single upgrade. By design, this strategic plan will last for many years, in order to get ahead of the cycle of repeatedly going into the field in a matter of a couple of years. This is often referred to as a "Fiber Deep" or node plus zero ("N+0") architecture. Millions of households passed have been built in this manner since introduction of this adjustment to the evolution plan was introduced. Much has been written about this architecture [5,6], which is shown in Figure 12.

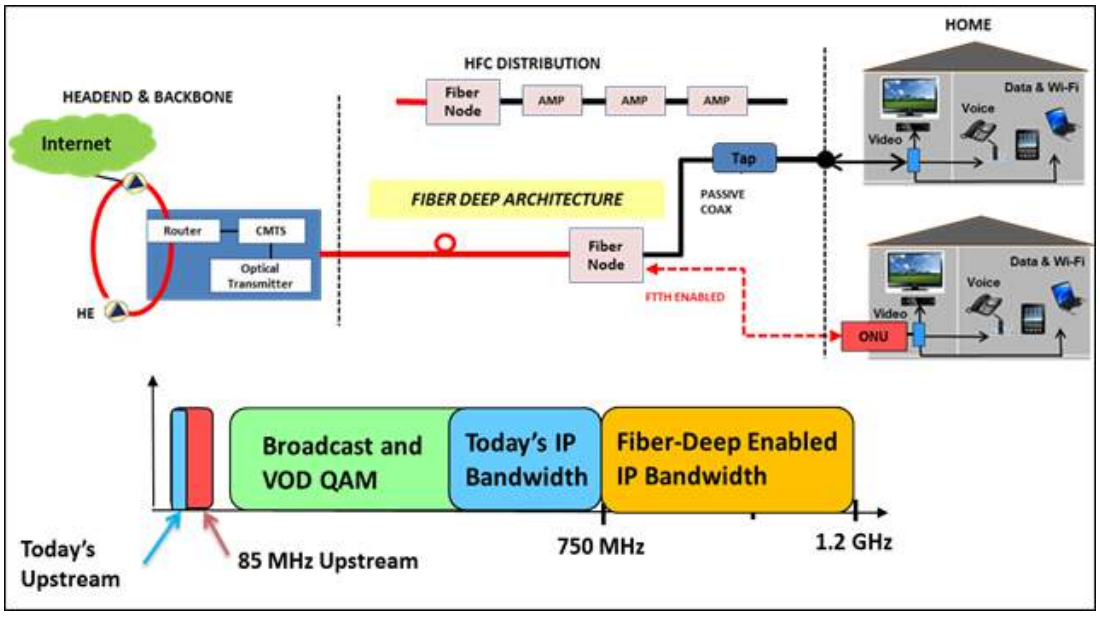

**Figure 12 - N+0 Architecture Basics: No RF Amplifiers and Expanded DS and US BW**

A fundamental premise of Fiber Deep that led to its adoption is that it could be shown in certain areas to provide not just a simpler, higher performing, more consistent, and generally better last mile architecture of increased bandwidth, but it was also more cost effective over time than the series of node splits that would otherwise be needed to manage the traffic, as shown in Figure 13. It is not shown in Figure 13 but the "breakeven" time frame between those two options was about 7 years.

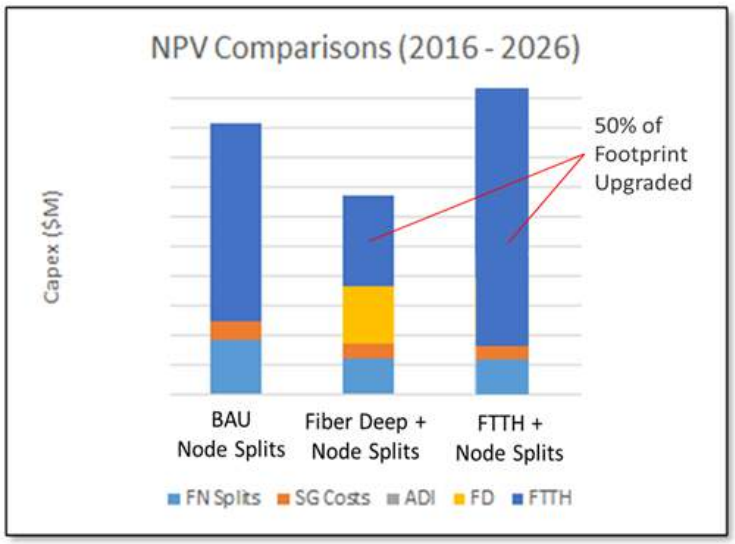

**Figure 13 - Fiber Deep Cost Effectiveness Compared to Continued Node Splitting Only [6]**

In summary, Fiber Deep is essentially the equivalent of executing multiple node splits at once, while expanding the spectrum in both directions. The architecture decreases the size of the node service group by typically 4-5x, while nearly tripling the US capacity and adding 60% more DS bandwidth.

Most notably, as the pandemic struck, utilization issues above thresholds marking them for augmentation were nearly non-existent in the footprint where this architecture was in place, owing to its proactively taken large bandwidth step. These networks will not require follow-up upgrades for many years, and thus were generally not under duress, despite the traffic spikes caused by COVID-19. From the CAGR and timeline perspectives, an architecture installed with a lifespan of 7-10 years holds up pretty well, even if a year, or 10-14% of it, is eliminated.

#### 5.1.1.2 Widen the Lanes

The Fiber Deep architecture identified increases the available spectrum in both DS and US. The US expansion takes the available bandwidth from 37 MHz up to a limit of 80 MHz, also known as the Mid-Split architecture. It was defined in DOCSIS 3.0, with the upper limit selected in part to fall just below the FM radio band in the US, while preserving the important DS video out-of-band signals used by legacy QAM set-top boxes (STBs) widely deployed today. Per the earlier discussion, it is typically the US that drives network upgrade activity.

While Mid-Split is deployed in current N+0 networks at Comcast, it can also be deployed in N+X HFC networks, by installing different diplex filters in the RF amplifier cascade as well as the node. Because of the average per-user peak-busy-hour US is only in the hundreds of kbps range, US generally grows

slower than DS, and the new US spectrum is much cleaner, the impact on network lifespan of mid-split is very powerful.

Figure 14 shows the time runway generated by the three options – node split, node split plus upgrade to Mid-Split, and finally N+0. While N+0 offers the longest runway of the three, it is clear that an N+X migration tied to a node split is also a very effective way to extend HFC lifespan to nearly 7 years. Even with a COVID-19 traffic hit, it is easily absorbed while maintaining a multi-year runway.

Another benefit of N+X with spectrum migration is that it addresses the COVID-19 inspired objective to "add capacity quickly", when compared to N+0. With the COVID-19 spike eliminating months of lifespan margin, N+X upgrades bring more US bandwidth to the network quickly to reset the lifespan timeline, and also support the growth of applications and new service speeds. The naturally slower pace of deep fiber construction will leave areas unaided by this architecture for a period of time, and with the "time" erased due to the pandemic, alternatives such as drop-in HFC upgrades that are both fast and effective make a sensible COVID-19 remediation step. Having a diverse strategy, not one-size-fits-all, adds important flexibility to deal effectively with adjustments to COVID-19.

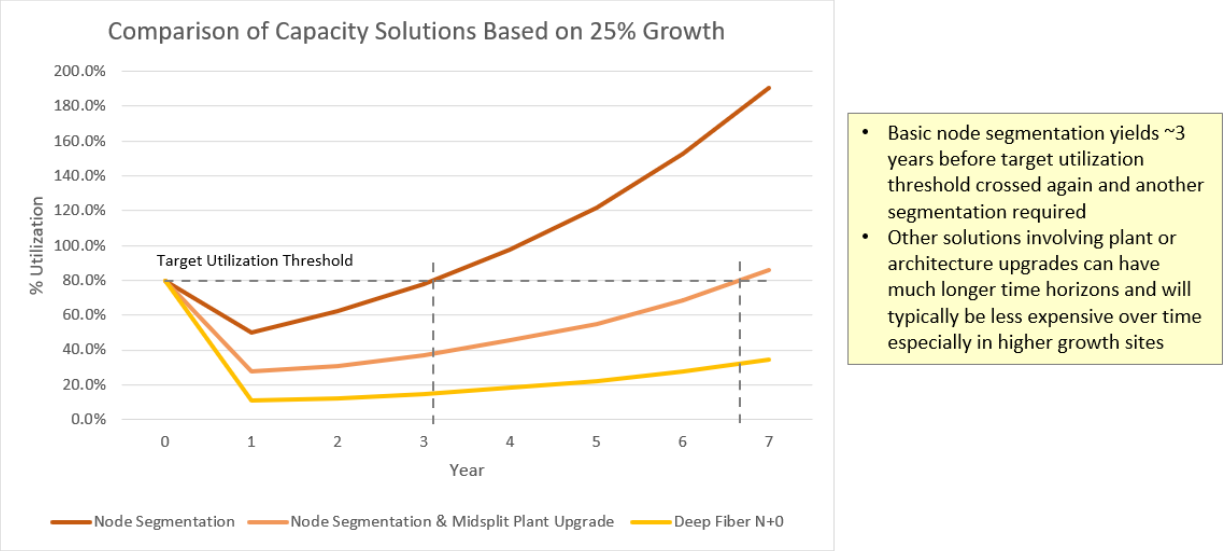

**Figure 14 - Upstream Lifespan Expansion Options [1]**

Lastly, with speed to increased bandwidth support in mind, coupled with the desire to push fiber deeper into the network whenever possible, adjustments to Fiber Deep architectures and practices are worth considering. For example, adding fiber in the underground network is an inherently slow process. However, given the freedom to allow a strategically placed amplifier (e.g. to allow an N+1 network), then lessening fiber construction, increasing the node size, and decreasing cost all speed the pace of the network upgrade and deliver the added bandwidth to more households passed (HHP)/year, if the long-term capacity benchmarks can still be obtained.

#### 5.1.1.3 Every Bit Counts

Both Fiber Deep and upgrades to new frequency splits are plant operations, and as such require planning and coordination. This is because they carry regional dependencies associated with construction processes, permits, municipal intervention, etc. In addition, the ability to access some portions of the network during a pandemic itself is limited. Fortunately, there is another important tool in the DOCSIS

toolbox that can address bandwidth directly and quickly and can provide a significant measure of relief. The tool is the DOCSIS 3.1 Profile Management Application, or PMA. It is closely related to the DOCSIS 3.1 feature known as Multiple Modulation Profiles, or MMPs. It fits the bill well as a quick relief valve to "recover" from COVID-19 traffic effects, while architectural plans of larger scope take longer to come together.

First, recall two of the major new changes between DOCSIS 3.0 and DOCSIS 3.1:

1) Single Carrier QAM (SC-QAM) was replaced with Orthogonal Frequency Division Multiplexing (OFDM) and Orthogonal Frequency Division Multiple Access (OFDMA). DOCSIS 3.1 recognized that it was the right time to break the mold and adopt more modern and mature OFDM. OFDM has the unique ability to optimize capacity across an uncertain channel in a way that SC-QAM cannot, at least not as easily. Instead of a 6 MHz chunk of spectrum to manage the signal over, the DOCSIS 3.1 flavor of OFDM uses granular subcarriers of 50 kHz or even 25 kHz in making up the composite signal. OFDM allows for narrow slices of spectrum to be optimized, and the overall channel to be used at its most efficient.
2) More QAM profiles and more efficient QAM modulation options were introduced, enabled by very powerful new Forward Error Correction (FEC). The base DOCSIS 3.0 of 256-QAM was increased to up to 4096-QAM, accounting for 50% more efficient use of bandwidth. All half-steps between 256-QAM and 4096-QAM were also enabled (512-QAM, 1024-QAM, 2048-QAM). QAM orders higher than 4096-QAM were added, but not as MUST requirements, and the efficiency bang for the dB-buck for these profiles is not very attractive.

Why is this so important after many successful years of 256-QAM? Figure 15 shows the recorded range of signal-to-noise ratio for millions of DOCSIS 3.0 cable modems, taken as part of the early work to develop the DOCSIS 3.1 standard. What it clearly shows is that, with the new FEC of DOCSIS 3.1 applied, many modems could achieve better than 256-QAM performance, and therefore many bits-per-second could be left on the table. How many bits are thrown away would vary depending on the particular modem.

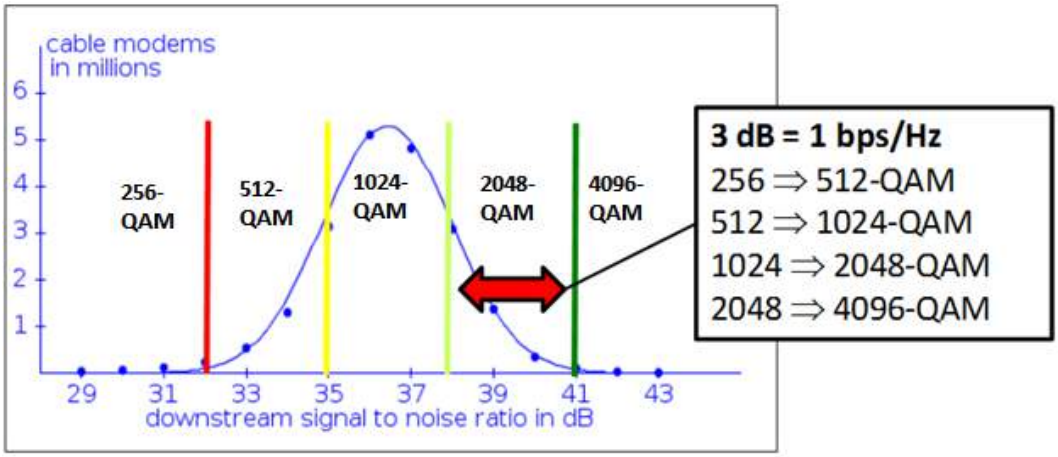

**Figure 15 - Multiple Modulation Profile Potential of D3.1**

Because of the characteristics observed in Figure 15, multiple modulation profiles (MMPs) were defined in the DOCSIS 3.1 spec, allowing clusters of modems seeing similar fidelity across the band to be formed

into groups that operate with common QAM modulation orders on their subcarriers. In the DS, each set of modems clustered by a common profile configuration would have their time on the wire per profile, as shown in Figure 16.

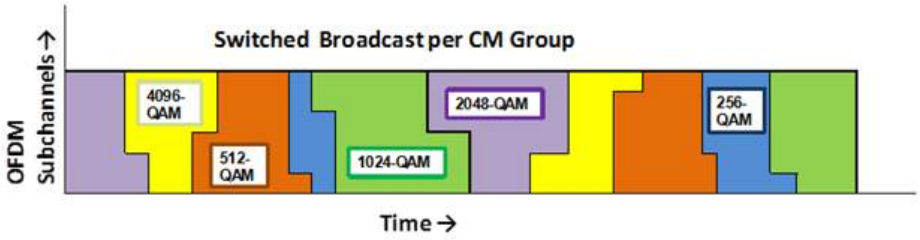

**Figure 16 - DOCSIS 3.1 Multiple Modulation Profiles vs Time and Freq [8]**

Figure 17 represents the workflow of fully capable, PMA-based capacity relief. It is coming to market in a very timely fashion to recover capacity taken away by COVID-19, and ensure that going forward the most efficient use of the channel is always available for the expected growth ahead, and furthermore executed as efficiently as possible with minimal human intervention. With MMP rather than a "flat" profile, for example, of all modems set at 1024-QAM, MMP fueled by PMA allows different modems to have a range of QAM profiles based on MER value. PMA brings an automated implementation, rather than thinking of MMP in a static sense or as a configuration set by the Headend Technician. PMA automates the process and allows for periodic checks and, if warranted, pushes updates to the modulation profiles without technician intervention. PMA will continually optimize algorithms as DOCSIS 3.1 continues to scale and big data metrics reveal more insights into temporal fidelity behavior on the coaxial plant.

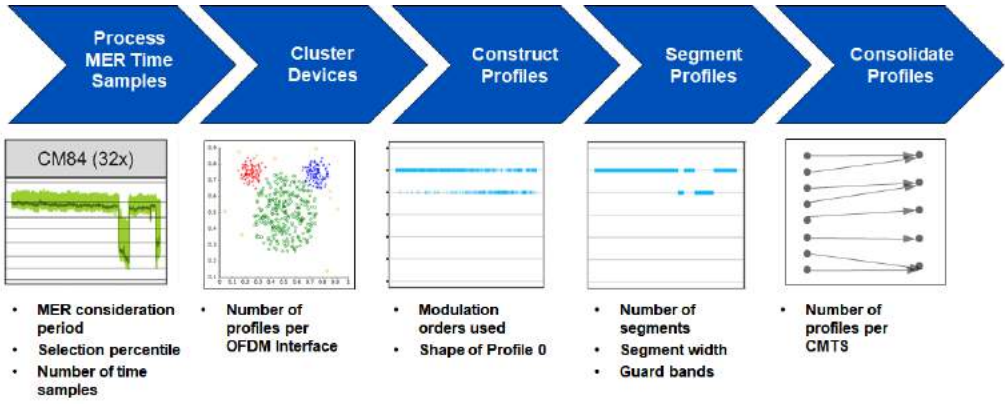

**Figure 17 - Programmable Modulation Application Workflow [12]**

While the example above was based on the DS, the DOCSIS 3.1 US uses OFDMA, which has the same fundamental signal structure as OFDM. Like the DOSCSIS 3.0 US, however, it must schedule and grant time-sliced access to the spectrum. Nearly all of the same logic of the DS applies with respect to optimizing the US channel in DOCSIS 3.1 However, most operators still have the majority of their network deployed with DOCSIS 3.0 modems, with DOCSIS 3.1 devices in the field supporting the higher DS speed tiers. Because of this larger percentage of D3.0 modems in the field, adding DOCSIS 3.1 in the US does not move the needle much to relieve capacity, since most devices cannot use it. Fortunately, with the US feeling more pressure from the COVID-19 traffic spike, and generally being more vulnerable, there are still DOCSIS 3.0 options available for capacity increases.

A common US configuration for operators is four bonded US 64-QAM carriers, each 6.4 MHz wide, which fills most of the high quality spectrum of a 5-42MHz US. However, there is additional spectrum, perhaps lesser in quality, that can be activated for more bps. Example use of the "5th and 6th" upstream in what had generally been empty spectrum is shown in Figure 18.

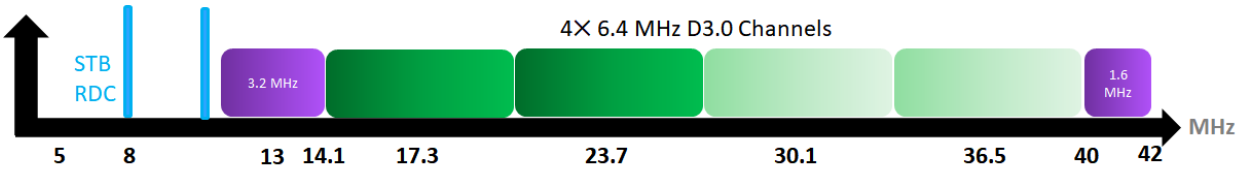

**Figure 18 - Exploiting More DOCSIS 3.0 Upstream in 5-42 MHz Systems**

Figure 18 suggests the presence of about 19% more useable spectrum, so in a 20% CAGR example would buy almost a year of time to work through a COVID-19-like spike. However, the spectrum available is likely to be impaired more than the existing 6.4MHz carriers, either due to filter roll-off and group delay variation at the high end, or low MER (noise aggregation) at the low end. So, the net capacity gain may be less than the spectrum gained, and the time bought by it shorter – but still meaningful for addressing a short-term crunch like COVID-19 while planning larger scale remediation steps.

Also, the DOCSIS 3.0 US offers several (four) settings for FEC overhead, where higher overhead means stronger FEC, and better protection for the packets on the DOCSIS 3.0 channels. DOCSIS 3.0 introduced 64-QAM about ten years ago, and, thinking in terms of in HFC network quality vs time, it was naturally set to maximum protection at launch, and rarely looked at since. However, since that time, node splits have shrunk service group sizes, and amplifier cascades have shortened. Initiatives that significantly enhance fidelity such as Fiber Deep and Distributed Access Architecture (DAA) are underway and in production at scale. As a result, some of those US channels, in particular the ones in the 25-40 MHz range, may no longer need maximum FEC protection. As such, there is a percentage of extra payload bits that can be gained in exchange for FEC overhead, depending on the quality of the highest MER US channels, from about 6% to, realistically, about 17% on a particular channel.

We will describe more about it in the following section, but modulation profile efficiency benefits considerably from the migration to DAA, which is being built in Fiber Deep markets and moving into N+X configurations also. The 10GbE digital fiber connectivity used in DAA significantly enhanced DS fidelity, by removing the analog optical links that typically had set the MER limit. It also enables higher-fidelity US signals to be present at the digital receiver. These higher MERs translate to more bandwidth efficient QAM signals.

In a situation like COVID-19, where a rapid response is essential, prioritizing software-based network enhancements, like PMA for capacity relief, can be executed and deployed generally more quickly than construction projects. They become exceptionally valuable tools for low-touch capacity augmentations, well suited to the kind of immediate response needs produced by the pandemic.

### 5.1.2 Be There for Me Always

One of the key principles of the Fiber Deep architecture described is the simplification of the network. It reduces the number of active devices in the plant, removes the oldest actives in the plant, and provides a repeatable template for a last mile architecture that breeds consistency of process, equipment, RF level and fidelity performance, and aligns with expectations of future network applications and services.

Figure 19 shows a large sample of CMs taken across N+0 deployments. When compared to Figure 15, it is clear that the average MER has increased by 3-4 dB. Note that MER is slightly different than SNR, in that MER considers not just the noise degradation added to the signal, which SNR technically represents, but all of the other impairments as well. However, they have, unfortunately, come to be used interchangeably in the industry. Also, the bell-shaped curve seen previously is now favorably skewed towards higher MERs. In fact, the red arrow identifies the approximate average MER in the Figure 15 BAU N+X case when compared to the N+0 network. With the combination of significantly higher fidelity and the PMA tool, the network is well positioned to provide a higher quality, more consistent customer experience and effectively serve the increased volume of traffic the pandemic has wrought.

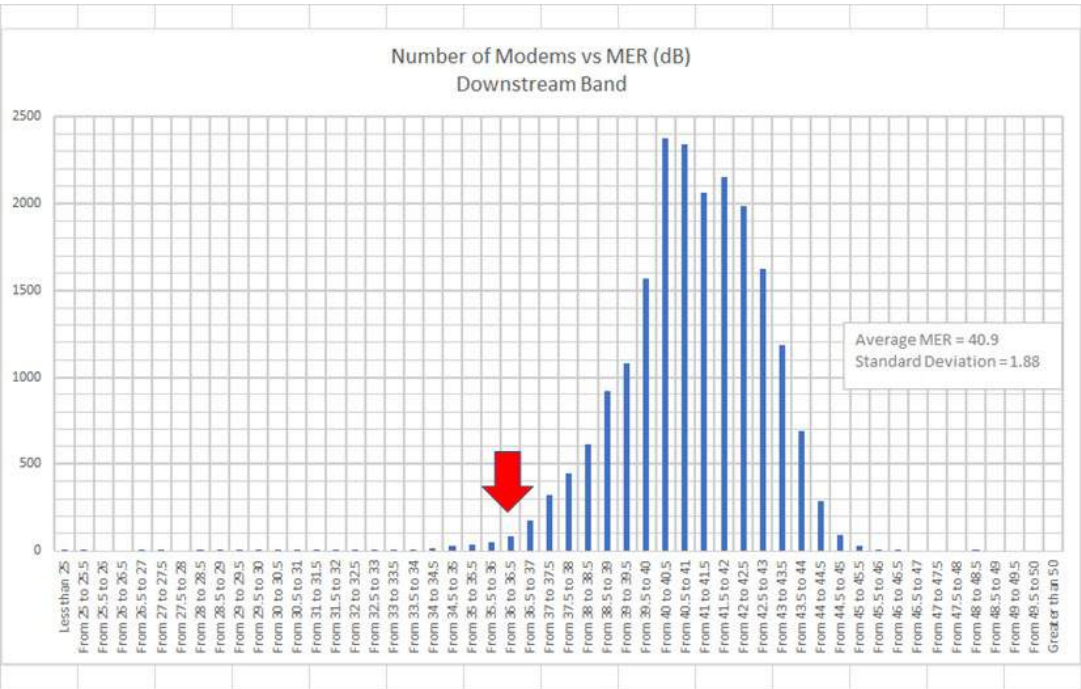

**Figure 19 - MER Distribution for a Large Sample of CMs on a N+0 System**

Indeed, trouble calls run consistently lower on the Fiber Deep parts of the network – ranging from 10-15% for the calendar year 2019, confirming the expectation that it is not only a superior network, it is also more cost effective to operate, and causes less disruption for busy WFH employees and online students.

Figure 20 shows a characteristic view of trouble call (TC) tracking in one Comcast Division that was very actively building N+0 in 2019. Note that the onset of COVID-19 during the initial "shock and awe" of shelter-in-place restrictions froze everything in place for a period of time (3/26/20) as companies and customers focused on getting a wide range of new priorities and changes in their day-to-day.

Not very long after – broadband being among the highest priorities – a return to normal TC interaction was taking place – but note this return to "normal" is with significantly increased COVID-19 traffic, now more essential traffic, and high awareness to network behavior among customers in the early days of the pandemic response.

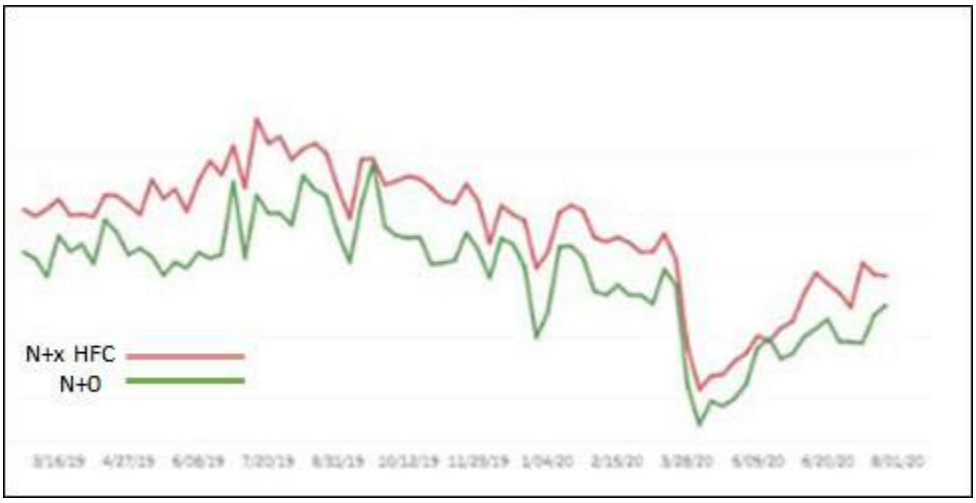

**Figure 20 - Reduction of Trouble Calls in Fiber Deep Deployments**

In addition to prioritizing dense fiber access as an architecture, Comcast has pivoted to deploying Distributed Access Architecture (DAA) at scale, based on Remote PHY technology, using Remote PHY Device (RPD) Nodes from multiple established vendors. In conjunction with the transition to DAA, we launched a Virtual CMTS (vCMTS) core, leveraging 10 GbE connectivity from facilities to the RPD nodes in the field. The vCMTS is built as a containerized set of micro-CMTS cores, such that each RPD node has its own packet processing compute and is arrayed in a robust redundancy scheme with a very small blast radius, increasing availability and redundancy to guarantee the always-on WFH experience. The 10GbE connectivity sets the network up well to be last-mile access agnostic by implementing a range of last mile access technologies fed by simple Ethernet links deep into the plant.

The introduction of DAA and vCMTS delivered orders of magnitude more real time visibility into the network via streaming telemetry, and with it the ability to process advanced metrics and use machine learning in operations. The increased visibility is essential to deliver the proactivity critical to network availability, enabling tools and views to quickly assess and make determinations about anomalous network behavior, raise alarms, trigger self-healing and re-routing as necessary, and capture detailed logs to continue to learn about and optimize network robustness and flexibility in modern ways. Proactive visibility and availability are, of course, among those high priority areas of focus in support of the WFH and online education trends now and ahead.

A sample dashboard summarizing the network status, with visibility on the order of seconds, is shown in Figure 21, encompassing information on CMs, RPDs, switches and routers. Virtualization in operator access networks leverages years of development and maturation in large scale data centers, driven by the likes of Amazon, Google, Facebook, etc. These providers, of course, have very stringent requirements for availability and reliability of their services, much like network operators do. While there are some important differences between operating a large data center that is handling "horizontal" data flows, compared to operating a network directly serving customers, the technological roots and the ecosystem scale created in establishing these data centers provides much of the foundation for virtualizing the access network edge.

**Figure 21 - Real-time Dashboard of Network and Component Availability and Uptime**

Another benefit of the virtualized core is its ability to throw packet processing compute in the direction where it is needed most, as shown in Figure 22. The pre-pandemic common example was daytime business services traffic in one part of the network geography, shifting to distributed residential web traffic during peak busy hour of the evening at home. In other areas of the footprint, such as universities and in apartment complexes tuned to a demographic, studying, gaming, chatting, or streaming late into the night is more the norm. The nimbleness of a virtual cloud could fall under the category "agile capacity" noted in the prior section. It landed here to separate this technology directional shift towards DAA and virtualization from the RF capacity focus of the prior section.

Enterprise services for office complexes are obviously not viewed as a segment that is expected to see a return to growth imminently. However, a network looking ahead should be considering the changes to business services and what might be their renewed directions of focus and investment. As implied in the example of Figure 22, business services traffic is a growing and increasingly important part of a cable operator's services and revenue. Business for mid-size and large commercial enterprises often have specific, quantified, requirements for throughput, latency, jitter, packet loss, and availability. While the coaxial network is optimized for residential use, it does support a wide range of small-to-medium businesses (SMBs) with DOCSIS-based cable modems, typically with specific software loads that include certain features important for businesses, but with more limited Service Level Agreement (SLAs) than enterprise class services. And, while the coaxial system is undergoing development to improve availability and resiliency, as well as latency and jitter (to be discussed) – all key aspects of post-COVID applications – larger scale enterprise services are still better served by fiber-based Ethernet architectures.

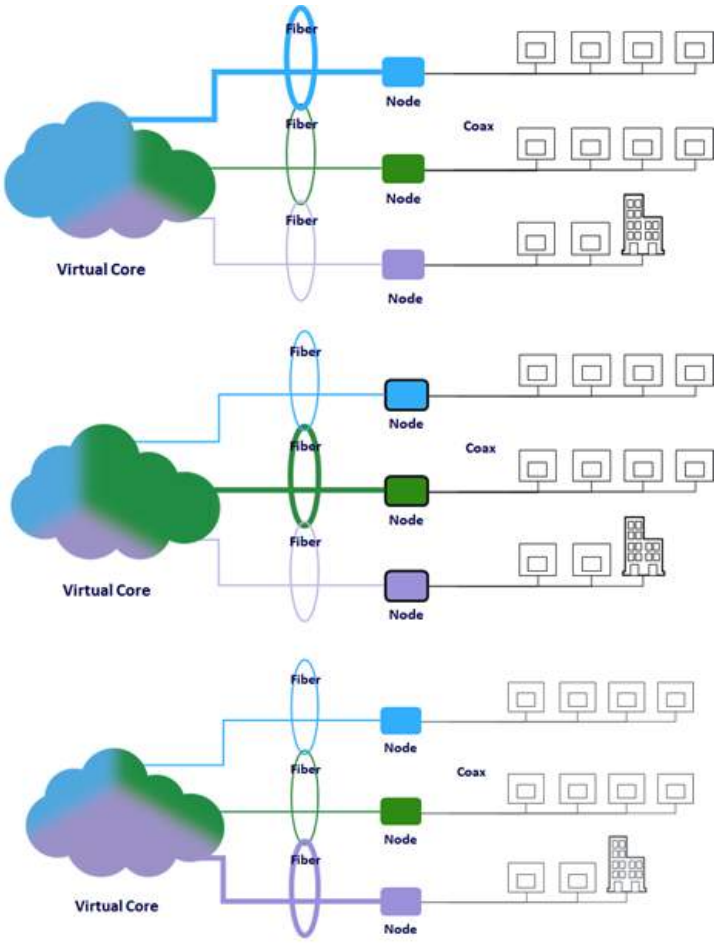

**Figure 22 - The Virtual Cloud Efficiently Shifts Capacity Where it is Needed**

A further key principle behind the Fiber Deep architecture is that it is an investment in a platform that supports the growth in business services, many of which are fiber-based. With fiber reaching to less than 1000 feet of every coaxial connection, there will be increasing access to fiber for nearby business services. Furthermore, the migration to a DAA architecture means that this fiber infrastructure is becoming digital fiber based on 10 GbE. As the residential network evolution takes place, a more scalable, resilient, high visibility network is being put in place. On it, Layer 2 Ethernet services can share the wavelength space, the latter of which is multiplied substantially when going from traditional analog fiber optics, and 16 wavelength limitations, to the DWDM grid supporting up to 80 wavelengths. This 5x bandwidth multiple into these dense pockets has the network well-prepared for post-pandemic applications and traffic growth, such as commercial opportunities in industrial automation, M2M, and digitization applications tied to the COVID consequences on the manufacturing economy.

### 5.1.3 Be Snappy

Latency and jitter have historically applied primarily to voice services, before becoming dominated by the increasingly popular gaming segment. Gamers are no longer kids hiding in their parent's basements. They are professionals who still love their games, and the games have become ever more elaborate and globally interactive. There have been many studies highlighting the sensitivity of games of certain types to network performance. Games generally do not generate high traffic volumes, but the customer experience can be significantly impacted if the packets are held up excessively between the gamer and the game server (or host). The bandwidth statement above does not necessarily apply to the category of cloud gaming or Augmented Reality/Virtual Reality (AR/VR) scenarios.

Of course, yesterday's voice sensitivities to real-time attributes is today's video conference. A major difference is that while there remains a sensitivity to latency and jitter, the bandwidth of these applications is much higher because they are video streams, and in a "Teams" meeting, for example, there can be a streaming video for each attendee using a camera. So, while capacity, bandwidth, and speed always dominate the discussion of access network evolution, latency is as much a factor if not more to the customer experience, and certainly becomes magnified in the pandemic-driven video conference world. Speed represents the amount of data that can be sent across a connection over a fixed period of time, whereas latency is the time it takes for a packet to cross the network and get a response. It is the "ping" time.

Seeing latency as an emerging priority for real time services such as gaming, video conferencing, IoT M2M, etc., working to address the components of the latency budget attributed to the DOCSIS network is an industry priority. A program was initiated at CableLabs to standardize the approach across the technology ecosystem. Obviously, the added impetus given by WFH has only increased the interest in developing Low Latency DOCSIS (LLD). In the DOCSIS 3.1 network, the dominant causes of latency are queuing and media acquisition [13], as shown in Figure 23.

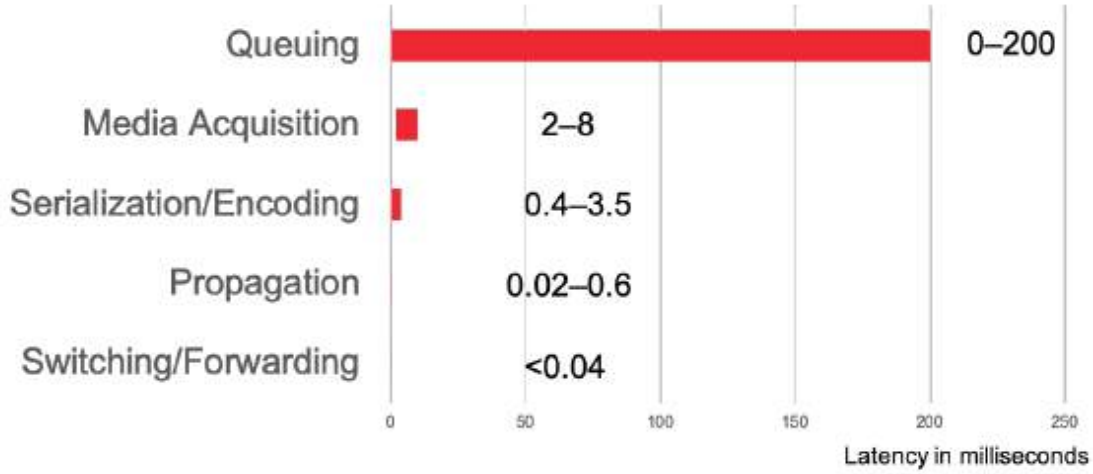

**Figure 23 - Sources of Latency in DOCSIS 3.1 Networks [13]**

The lowest hanging fruit is in the area of queuing. Once controlled, there is a potential to drive latency into single-digit milliseconds in the "media acquisition" area. The term "media acquisition" in this case refers to the request-grant mechanism by which a CMTS makes determinations about access to the upstream channel time slices and provides that information to the modems. Low millisecond values are instantaneous in "human" time and open the door to future IoT and machine-to-machine communications

where millisecond and sub-millisecond delays can have meaningful impact, for example, in stock trading or industrial machinery.

The potential for major improvements by managing queueing more effectively is clear from Figure 23. These queueing drivers are primarily the nature of the Transmission Control Protocol (TCP), the Layer 4 mechanism used throughout the Internet. High bandwidth applications ramp to a rate faster than the network bottleneck can support, and rely on TCP congestion control, which inform the sender to back off when buffers holding the traffic bursts fill, at which point it begins to drop packets to manage the queue. Because of this, latency and packet loss are inherent in TCP links. LLD aims to improve upon this behavior.

LLD does not create a fast path and a slow path or prioritize traffic one way or another. The approach is to identify traffic characteristics in applications that contribute to building of the queues which create latency, and steer traffic to a second queue if it is a so-called Non-Queue-building (NQB) traffic. This "dual queue" approach, shown in Figure 24, shares the bandwidth allocation to the user amongst all of their active applications, and also means less packets dropped out of the queue-building buffer. It is easily enabled using DOCSIS Service Flow (SF) definitions, available today, that shape the aggregate traffic, and the individual flows defined by the dual queues have shaping turned off, avoiding prioritization. This approach improves the customer experience for applications that are latency sensitive without affecting the experience of the other services.

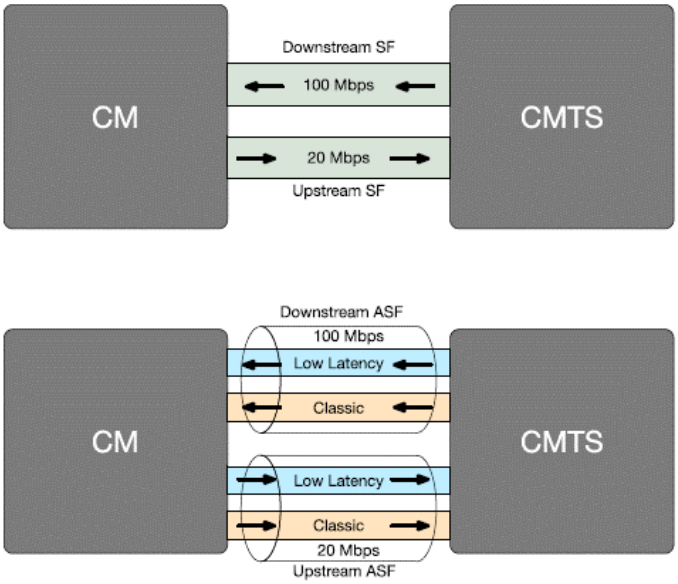

**Figure 24 - Traditional and LLD Service Flow Architecture [13]**

In addition, statistics are generated on the queueing delay by the CM and CMTS for use by MSOs, enabling them to fully understand the contribution of the DOCSIS network and help itemize their end-to-end latency budget. The customer experience can be closely correlated to these latency metrics. We already have tools in place that observe network latency further northbound in the network, and use this data, filtered and correlated across devices and bonding group assignments, to make proactive determinations to drive optimizations and customer QoE.

CableLabs is engaged with the IETF and the broader industry to identify the proper queue-using classifiers within the fields of IPv4 and IPv6 traffic. Most of today's traffic volume is queue-building

(QB), in particular streaming video. These services transmit packets faster than the network bottleneck can support, relying on the TCP algorithms to buffer and alert the source to adjust accordingly. By contrast, NQB traffic sources generally do not send data faster than the network can directly support. Skype (and similar) and online games generally fall into this category, as does basic web browsing. Despite their inherent "good behavior" relative to utilization of network resources, their packets are unnecessarily mingled into the queue created because of the QB applications today.

The LLD effort includes additional options to further reduce latency, in particular to speed up the DOCSIS request and grant cycle of scheduling packet transmission US. These include shortening the window between request options and proactively granting access based on traffic trends and utilization, which can be learned over time, such that inefficiency is minimized. Figure 25 shows the potential for reducing the DOCSIS network latency as these features become available over time.

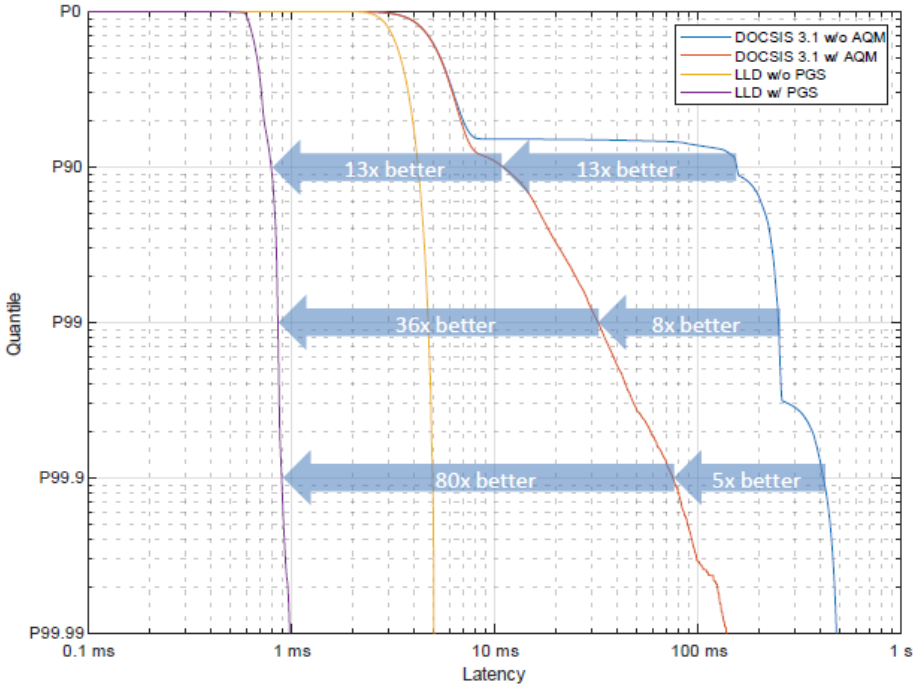

**Figure 25 - Industry LLD Efforts are Promising for Supporting Real Time Services Such as the Recent Explosion of Video Conferencing Due to WFH [13]**

As with other access network initiatives, existing technology development underway is aligned very well with addressing the impacts of the pandemic. The immediate WFH thrust and online schooling is certainly a reason MSOs have cause to consider adjusting priorities to move LLD higher on the list of To-Do's. These performance improvements also align well to broadband requirements that are expected to be part of industrial digitization.

## 6.0 Conclusion

One way to look at the COVID-19 situation as it applies to the network is to acknowledge two things that are somewhat in opposition to one another:

1) We have never before seen a traffic dynamic like this – the magnitude of the increase plus the abbreviated period over which it occurred – in our broadband cable lifetime
2) Simultaneously, there is little new that needs to be learned to figure out how to handle it.

We identified four areas of priority from which to re-calibrate access evolution plans, given the observed trends and anticipated permanent impacts on the network attributable to COVID-19:

*Enable Agile Coaxial Capacity* – Take advantage of existing DOCSIS 3.0 platforms to add new channels, optimize DOCSIS 3.0 US profiles, and DOCSIS 3.1 PMA to add capacity to recover the "time" lost by the COVID-19 traffic wave. These techniques complement more time-consuming operator network upgrade plans, such as changing the frequency split in the network by swapping actives, splitting nodes, and pulling fiber deeper.

*Hardening and Resiliency* – Synergistic with pulling fiber deeper, adding more nodes, and removing the oldest actives in the plant – to reduce trouble calls and increase availability – is a transition to DAA and virtualization of the CMTS core. Granular streaming telemetry keeps an eye on the network more closely and in real time than ever before, data analytics trigger proactive alerts and notifications, and the micro-CMTS architecture further maximizes availability and adds resiliency.

*Responsivity* – Drive down network-induced latency and jitter to support the increase in real-time applications, such as video conferencing and online classrooms, ensure the increased in gaming traffic does not impact the gamer experience, and to support new opportunities that arise in business services that have real-time and near-real time broadband implications.

*Enabling of Enterprise Services* – Change often leads to opportunity, and major change, on the COVID-size scale, will likely lead to a range of new industrial opportunities aimed and helping companies be prepared to "weather the storm" in the future. What may at first be a softness in business services opportunities is likely to take a favorable turn in the future, with perhaps a change in the types of business markets served. The fiber-rich, Ethernet-based DAA system has the flexibility to be well-suited to deliver a complete range of last mile solutions and capabilities that may be uncertain today.

If there was ever a scenario to be caught by surprise and in a desperate scramble to recover, this would have been that time. While there was indeed some scrambling, the broadband cable network gets an "A+" for its performance in the face of this unprecedented traffic wave. The reasons for this are many, and boil down to a few key points

- Planning several years ahead is the nature of the job for access network architects and capacity managers, and it paid off in this crisis
- Very familiar muscles can be exercised efficiently to deliver additional capacity, built upon many years of experience honing these processes
- Additional network technology was already in the works that was aimed at addressing the needs observed during the pandemic and what is expected to be ongoing beyond it

- Efficient-to-deploy, SW-based new technologies, such as PMA and LLD, are emerging at a very timely moment, because the benefits they bring had already been deemed important for future applications that happened to arrive at scale a bit earlier
- For specific applications of increased priority, the scale and penetration pace of them changed quickly, but there are not additional technology barrier dependencies
- Cable operators have been highly focused on the upstream very recently, because bandwidth from the home is close to filling the availability capacity
- Cable operators have been highly focused on network monitoring and availability as the cable product offering has shifted towards always-on Internet access as a top priority

Let's hope this is the last pandemic any of us witness in our lifetimes. However, having passed the network stress test of a generation, we can all be comforted by the recognition that the power of the broadband network is there to ensure that some semblance of "life goes on" is still achievable. And undoubtedly, there will be lessons learned that can make us even better prepared should such a situation strike again.

# 1. Introduction

By all measures, Wi-Fi is a phenomenal success. As broadband availability and capacity increased, the speed of Wi-Fi also increased. As the number and nature of devices supported by Wi-Fi expanded, the range and capabilities also expanded. And when Wi-Fi entered the corporate/enterprise workspace, accommodations were added to allow for Wi-Fi credentials to be provided via integration with enterprise-level user authentication systems.

## 1.1. One Password to Rule Them All…

For most Wi-Fi networks, credential provisioning comes down to the question: "What's the Wi-Fi password?", followed by the tedious task of verifying the spelling and punctuation. And while there have been various mechanisms created to share Wi-Fi passwords across devices, the vast majority of Wi-Fi networks utilize a single shared password.

The implications of having a single credential for a Wi-Fi network have been known for years. With the first version of Wi-Fi security (Wired Equivalent Privacy or WEP), the fact that there was a single persistent key for the network (among other issues) led to a serious security vulnerability that would allow the key to be derived by simply observing a sufficient amount of network traffic. WEP password cracking was addressed in WFA Wi-Fi Protected Access 2 (WPA2) [3]. But even in WPA2, one authorized Station can observe the traffic of any other Station by observing its authentication exchange. And one issue is inescapable: once a password is shared, it cannot be unshared. The only remedy today for revoking a station's credentials on a single-password networks is to change the password and reprovisioning all devices that need access with the new password.

While reprovisioning all Stations on a Wi-Fi network might have been a practical (if not tedious) task in the past - with perhaps a half-dozen interactive devices on the network (laptops, smart phones, etc.) - today it is a virtual impossibility. IoT devices in particular have proliferated enormously in recent years and are notorious for having inconsistent means of provisioning Wi-Fi credentials. And their interfaces and documentation workflows are geared for initial "quick start" setup, not reprovisioning. Many devices even require a complete factory reset to be provisioned – leading to a cascade of issues with device reconfiguration, updating apps, and reassociating devices with their various cloud services.

## 1.2. The Evolution of Wi-Fi Credentials

There have been a variety of solutions proposed and implemented to help mitigate the single password issue: Multi-zone networks (e.g. "guest" networks) allow for one password to be used for resident users/devices and another for non-resident users/devices. However, the way guest networks are implemented requires multiple Wi-Fi networks (SSIDs) to be configured on a wireless Access Point (AP) – which either dedicates separate Wi-Fi channels to the guest network or increases the amount of overhead on shared channels. And as soon as the password for the resident zone is shared with a device or user, the zone can be compromised.

WPA2/3 Enterprise was designed to support the integration of enterprise environments utilizing centralized user provisioning systems with Wi-Fi provisioning. These user-level authentication systems were tailored for interactive enterprise devices (e.g. laptops and mobile devices). This allowed the use of enterprise management systems to manage Wi-Fi access. The same aspects that make WPA2/3 Enterprise well suited to enterprise environments, however, make it difficult to use for home/SOHO environments. For instance, while it can be natural to provision interactive devices such as laptops and mobile devices with user credentials, IoT devices are not as easily associated with a single user – and almost universally

lack support for WPA2/3 Enterprise. And the infrastructure required for WPA2/3 Enterprise support is too complex for the average user to configure and manage.

MAC address filtering solutions attempt to provide per-device in a different way: While a user/device may gain access to the network using a shared password credential, other components of the Wi-Fi Access Point can filter traffic based on the MAC address of individual device(s). Revoking "access" to a device can be done at-will and based on various criteria – such as time of day, the internet host(s) being accessed, or metering criteria (e.g. time on-line or data usage). These solutions are currently employed by many network providers and are the bane of teenagers across the Internet. But they are also easily defeated by credential sharing and MAC spoofing – and they don't prevent the observation of network traffic using the shared credential.

### 1.3. Goals for the Next Generation of Wi-Fi Authentication and Security

Ultimately what is needed for truly manageable Wi-Fi networks is a mechanism that allows each device to have a unique, verifiable identity and allows for the provisioning of credentials which are cryptographically strong, unique and revocable. And to help ensure adoption and make everyone's life easier, provisioning of devices should be as easy – if not easier – than the single-password method. Once individual identities and credentials can be associated with Wi-Fi devices, a new world of possibilities opens up for Wi-Fi network management and device/network security.

One solution that has been in development in the Wi-Fi Alliance is the Device Provisioning Protocol (DPP) specification – also referred to as "WFA Easy Connect". The DPP specification enables the secure transfer of device credentials and metadata on both home and enterprise networks using a variety of provisioning mediums and mechanisms without complex infrastructure and without entering password/pre-shared keys (PSKs). In this paper we describe how DPP/Easy Connect works, the context and justification for it, and how it can be built upon to provide more safe and secure Wi-Fi networks while also enabling the advanced networking features we need in the future.

## 2. Wifi Device Authentication and Key Establishment

### 2.1. WPA2 (802.11i-2004)

The first generation of Wi-Fi security (WEP) required all the wireless-enable devices ("Stations") to share a common 40- or 104-bit encryption key. The Access Point and Stations were all manually configured with the same 10- or 26-digit hex-coded key. This key was used directly to encrypt every payload packet sent across the network. Fatal security issues were discovered in WEP that led to it being deprecated – and replaced by WPA. But security issues aside, there was also a need for more flexible per-Station key establishment methods than either WEP and WPA could provide in order for Wi-Fi to be adopted in more environments.

To allow for more flexibility in how keys are associated with Stations, the WPA2 specification (802.11i-2004) introduced "pairwise" and "group" keys. Specifically, WPA2 defines the following keys:

- **The Pairwise Transient Key (PTK)**: This key is used to encrypt all unicast (non-broadcast/multicast) traffic between one Station and the Access Point. The PTK is established using the "4-Way Handshake"
- **The Group Transient Key (GTK)**: This key is used to encrypt all broadcast and multicast traffic on the network attached to the AP. The GTK is established and distributed using the "Group Key Handshake"

- **The Pairwise Master Key (PMK)**: This key is used, along with other parameters, to establish the PTK. The method for establishing the PMK varies according to the authentication method.

All Wi-Fi key establishment methods use the 4-way handshake to establish the PTK and GTK for a Station. What varies between the methods is the establishment of the PMK, which will be described in later sections.

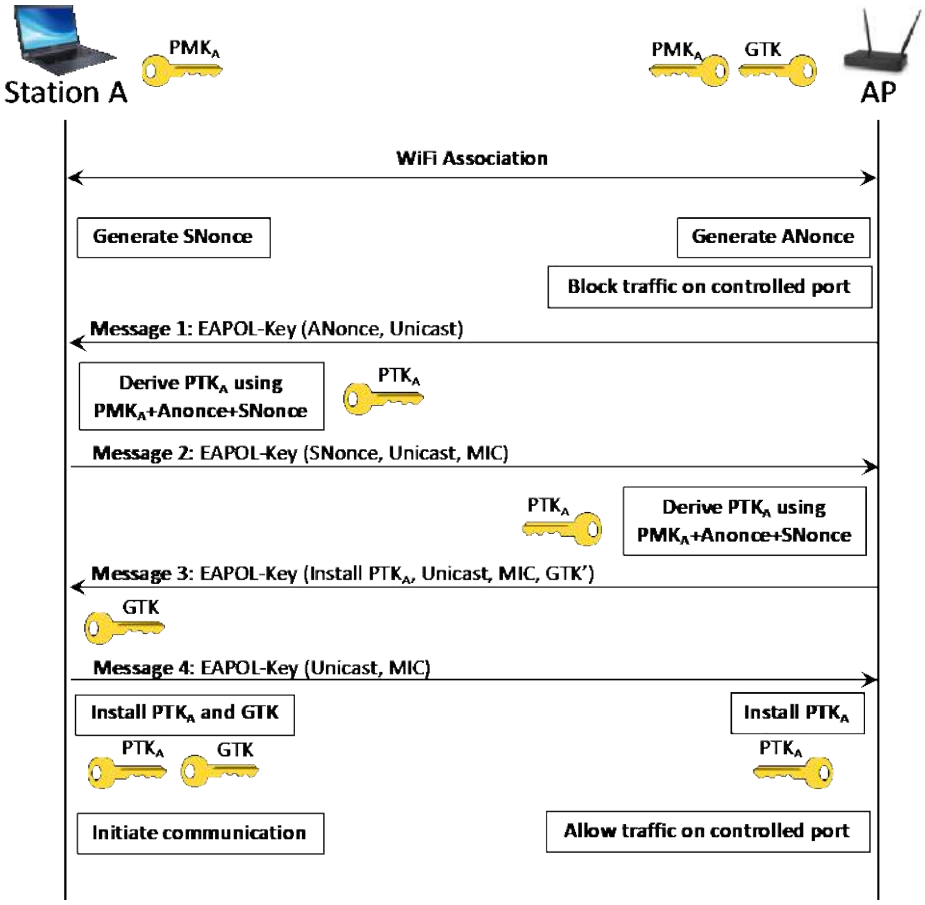

**Figure 1: The Wi-Fi/EAPOL 4-Way Handshake**

### *2.1.1. WPA2 Personal*

Residential, small/home office (SOHO) networks often use the WPA-Personal profile – which utilizes a shared password to determine the PMK. All that is required to establish a WPA-Personal Wi-Fi network is to configure the AP with an SSID and password and configure all the Stations with the same password.

The 4-Way Handshake allows the Station and the AP to establish that they both have the same password and allows for the establishment of a per-Station PTK.

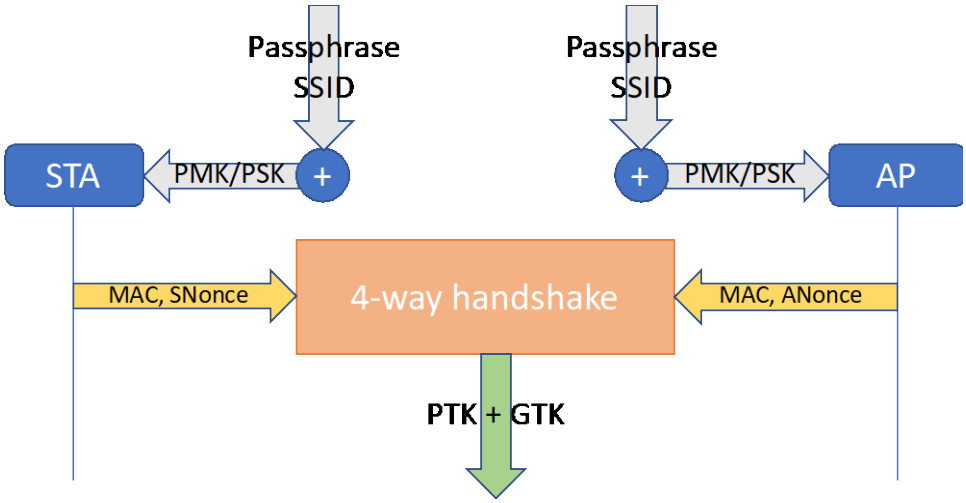

**Figure 2: PTK establishment in WPA-Personal**

What's notable here is that – while each Station and the AP will have the same PMK (by virtue of using the same password) – the 4-Way Handshake ensures that each Station has a *unique* PTK (by virtue of the fact that the Snonce and Anonce are randomly generated). The GTK, on the other hand, is the same for all entities on the network so that shared traffic (such as broadcast and multicast) can be decrypted by all parties on the network.

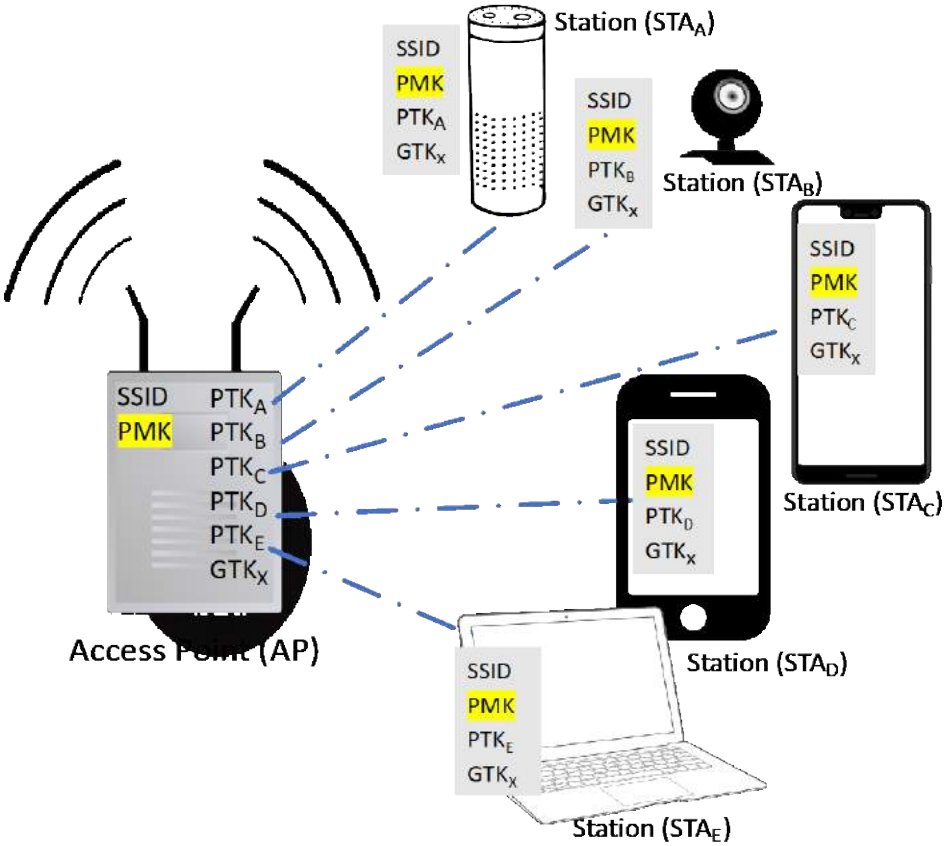

**Figure 3: Key Usage in WPA2-Personal**

Note that every time a Station reauthenticates, a new PTK is generated. And any time a Station leaves the network, a new GTK is generated by the AP and distributed to the currently authentication Stations to ensure that Stations which have been removed from the network cannot decrypt group traffic using a previously derived GTK.

While WPA2 Personal is simple to setup – and simple to authenticate – this simplicity comes with a price: any Station(s) with the active password can authenticate. And the only way to prevent an unwanted Station from authenticating is to manually change the password on the AP and all the Stations – which is highly disruptive, especially with IoT devices. Additionally, any Station with knowledge of the Password/PMK can derive the encryption key of any other Station by observing the authentication exchange of that Station and the AP.

### *2.1.2. WPA2/WPA3 Enterprise*

As mentioned previously, shared passwords are not an appropriate authentication solution for environments where user/Station access needs to be tightly controlled. Specifically:

1. In enterprise environments, there is typically already an authentication system in place – and corporations wishing to deploy Wi-Fi want to use their existing systems to authenticate Stations using existing user credentials.
2. The level of access to an enterprise network is often user-dependent. A shared password does not allow for differentiated or revocable Wi-Fi service. Some form of user identity is required. E.g. The user ID can be used to establish which VLAN (Virtual Local Area Network) and other resources the Station will have access to.
3. Revoking access to certain users/Stations should not require disrupting the Wi-Fi network and/or reconfiguring other Stations – as is the case with WPA2-Personal.

WPA2-Enterprise addresses the limitations of WPA2-Personal by providing a means of user-level authentication prior to the 4-Way Handshake using EAP-based (Extensible Authentication Protocol) authentication with a AAA server implementing the RADIUS/Diameter protocol. WPA3-Enterprise utilizes the same authentication methods and protocol as WPA2-Enterprise while updating the security profile of the various authentication methods and management messages. For example, WPA3-Enterprise requires Wi-Fi management frames to be protected and deprecates the use of cipher suites that are now considered insecure.

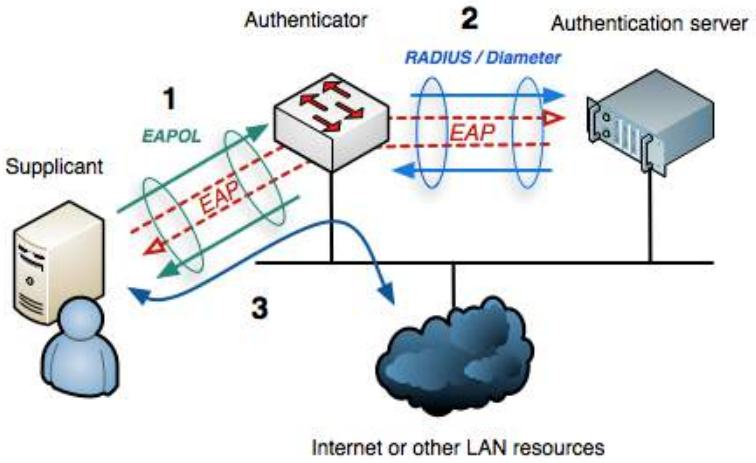

**Figure 4: WPA2-Enterprise Authentication**

Once the Station ("Supplicant") and Authentication Server agree on an EAP method, they can exchange an arbitrary set of EAP messages to perform authentication. If authentication is successful, the Authentication Server and Station derive a shared key and the Authentication Server provides the derived key to the Authenticator. The Authenticator uses the EAP-derived PMK to drive the 4-way handshake with the Station.

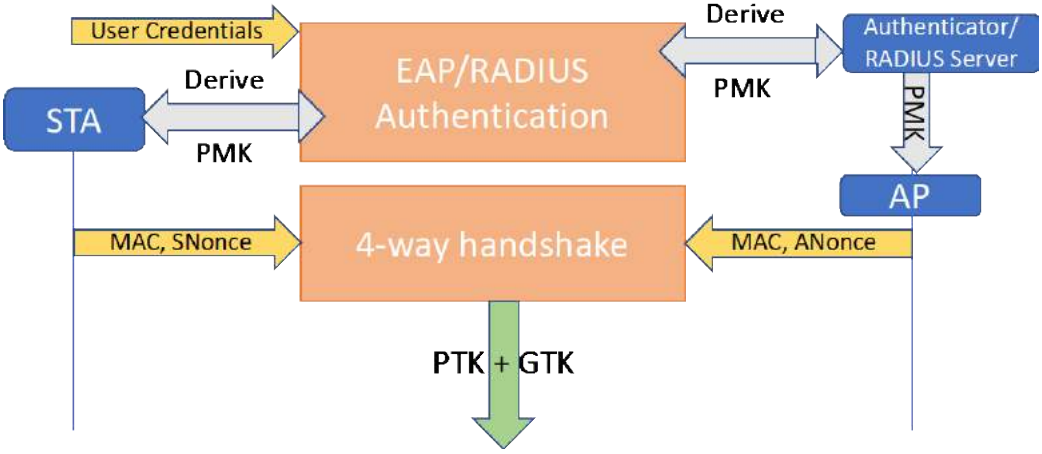

**Figure 5: PTK Establishment in WPA2-Enterprise**

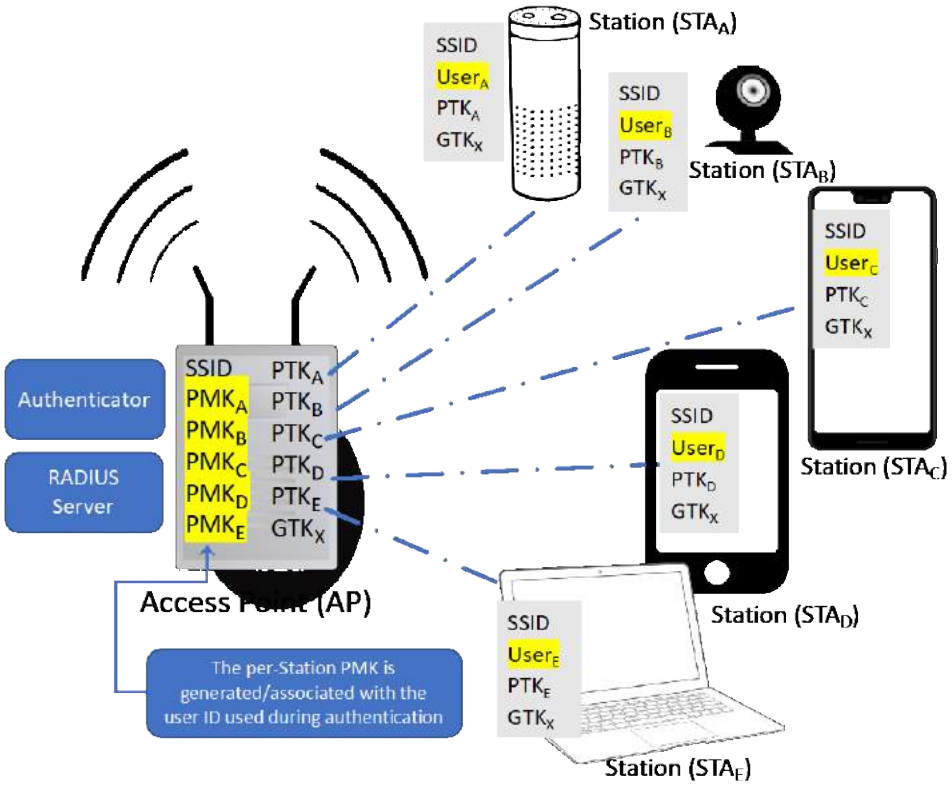

**Figure 6: Key Usage in WPA2-Enterprise**

WPA2-Enterprise addresses the single-password shortcomings of WPA2-Personal – and can satisfy the common enterprise requirements listed above when properly deployed and configured. But it does so at

the cost of additional infrastructure, user/credential provisioning, and additional configuration. In particular, WPA2-Enterprise solutions are often tailored for user-based authentication using enterprise credentials. While this is well-suited to enterprise environments with interactive clients and a centralized user credential database, it's less suited for IoT and other dedicated-use devices.

User or device-level authentication can alternatively be performed in WPA2/3 Enterprise by using X.509 certificates. This form of authentication requires installing certificates and keys into the devices. However WPA2/3 Enterprise by itself does not provide a standardized mechanism to provision certificates/credentials and associated CA certificates into device trust stores.

### *2.1.3. Other WPA2 PMK Establishment Methods*

As noted in section 2.1.1, the simplicity of using a shared password in WPA2-Personal is also its main deficiency. And while WPA2-Enterprise enables per-device credentials, it introduces other issues. But as might be clear by now, any method that provides a per-station PMK can enable per-Station credentials, Station-specific policy, and Station revocability.

The key to deriving a unique per-station PMK is to determine an identity for a Station. The simplest form of identification for a Station is the MAC address of its Wi-Fi interface. Each Station can be configured with a unique WPA2-Personal password and the AP can associate a password with the MAC of the station. When the Station attempts authentication, the AP can look up the password associated with the MAC address of the authentication frames and initiate the WPA2 4-Way Handshake. The same MAC association can be used to establish per-Station policy (e.g. VLAN association, access policies, etc.).

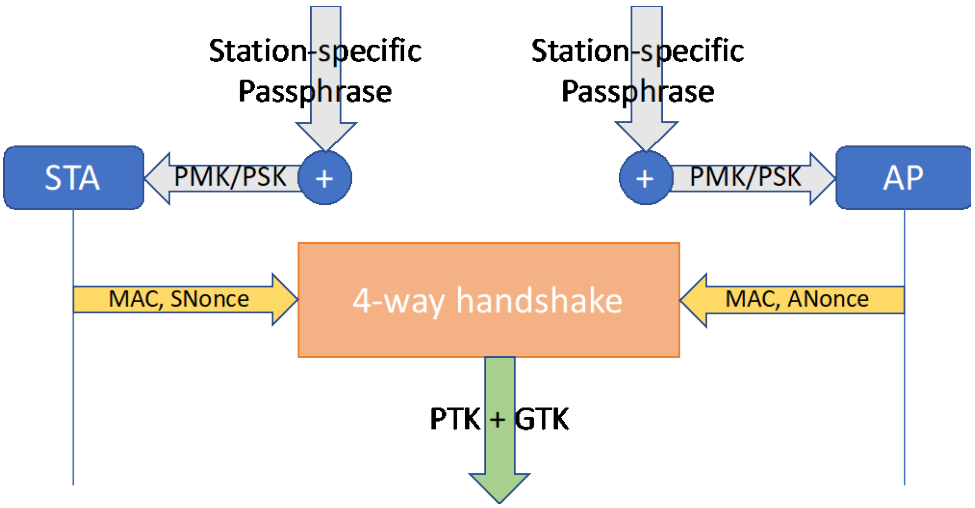

**Figure 7: PTK Establishment Using MAC-associated Password/PMK**

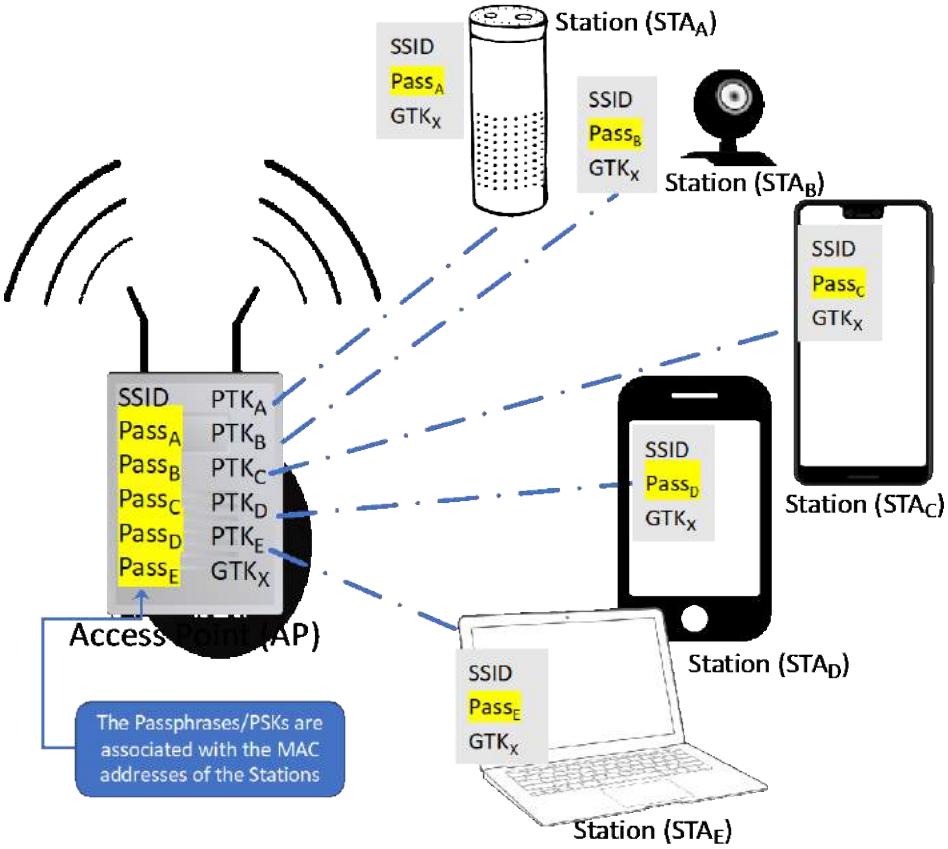

**Figure 8: PMK Distribution using MAC-associated Password/PMK**

This MAC association method is supported by the reference Wi-Fi AP implementation *HostAPD* as well as a variety of commercial products/offerings.

There are some issues with this method however:

- The first time a Station connects with a password, the MAC isn't known by the AP. If the password/PSK is a single-station credential, the AP will learn the MAC address of the first Station that connects with the Password/PSK – which may not be the intended Station.
- If the password/PSKs are auto-generated, they may be cumbersome to enter by the user. If they're user-generated, it can become tedious – potentially leading to poorly chosen passwords.
- For a multi-station password/PSK credential, there's no reliable way to control which Station(s) are allowed to use the credential.
- Some devices use MAC address randomization prior to AP association for privacy protection. This can prevent the methods used for establishing initial MAC-to-PSK associations from working.

What is needed is a form of Station identification and credential that is nontransferable and attestable. In other words, Stations need an identifier that can be proven using secure methods and cannot be easily transferred from one Station to another. One such method will be discussed in Section 3.

## 2.2. WPA3-Personal

As discussed in Section 2.1.2, the basic messaging and authentication of WPA3-Enterprise is identical to WPA2-Enterprise – and the method to exchange the PMK is unchanged. WPA3-Personal, however, uses a dramatically different method than WPA2-Personal for mutually deriving the PMK. Rather than using the password/PSK (and SSID) to derive the PMK, WPA3-Personal uses an exchange called "Simultaneous Authentication of Equals" (SAE). SAE is a PAKE-based (Password Authenticated Key Exchange) cryptographic exchange that can derive a cryptographically strong shared secret from a low-entropy password.

This method solves one of the largest issues with WPA2-Personal shared passwords: the ability to derive and Station's PTK and decrypt all the traffic on the network – including traffic captured before the PTK was known. Here's an illustration of the SAE exchange:

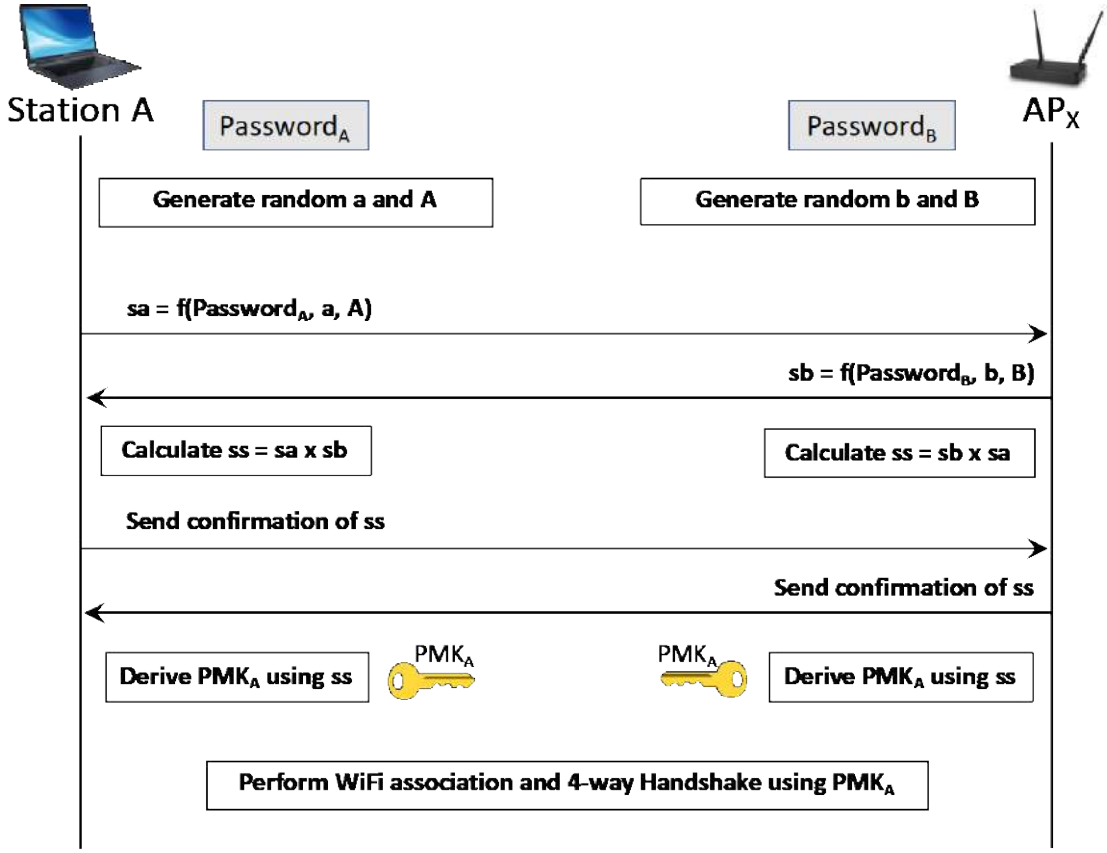

**Figure 9: WPA3 Personal SAE Exchange**

Some advantages of the SAE exchange:

- Both parties can calculate and send their components independently
- The computations used to derive the shared secret/PMK ensure that the password and the PMK cannot be determined
- Ensures perfect forward secrecy

# 3. Provisioning Station Credentials using DPP

The Wi-Fi Alliance Easy Connect ™ specification defines mechanisms for provisioning a Station with Wi-Fi network credentials without user entry of passwords/keys or installation of enterprise certificates. While simplifying the task of device onboarding, Easy Connect also provides stronger security methods, per-device credentials, revocation, mutual authentication, and reliable/secure device- and group-level identification.

## 3.1. DPP Provisioning

There are a variety of means in Easy Connect by which a device can be discovered and authenticated for provisioning. Figure 10 and Figure 11 illustrate the provisioning of a DPP "Connector" and PSK, respectively, on devices using a scanned QR code to provide network authentication and connectivity.

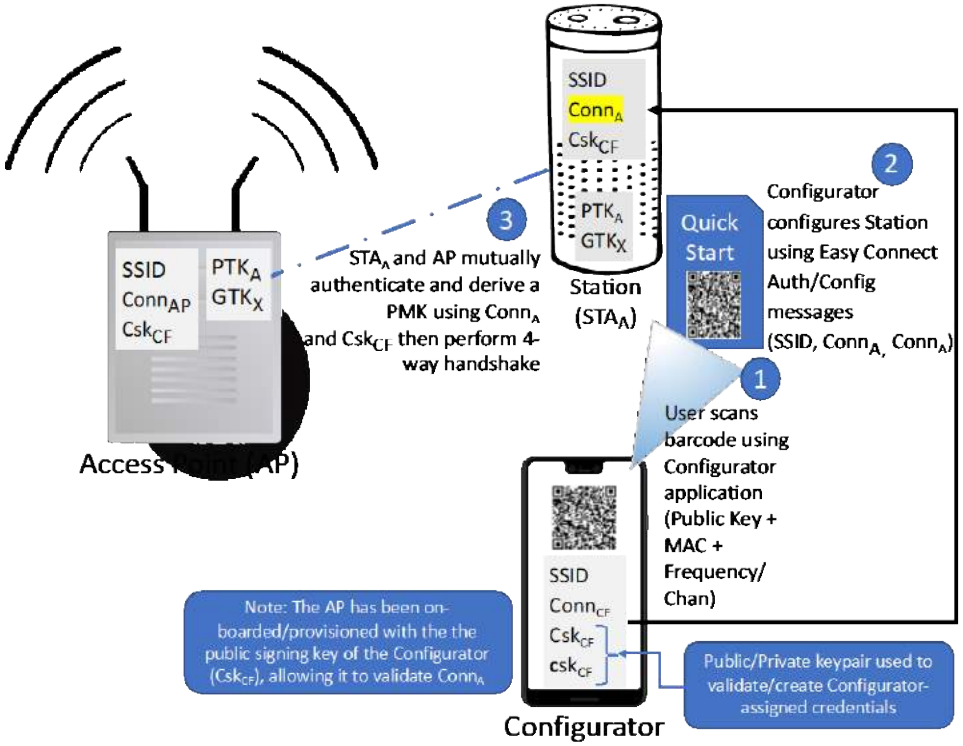

**Figure 10: DPP Direct Provisioning of Connector Using QR Code**

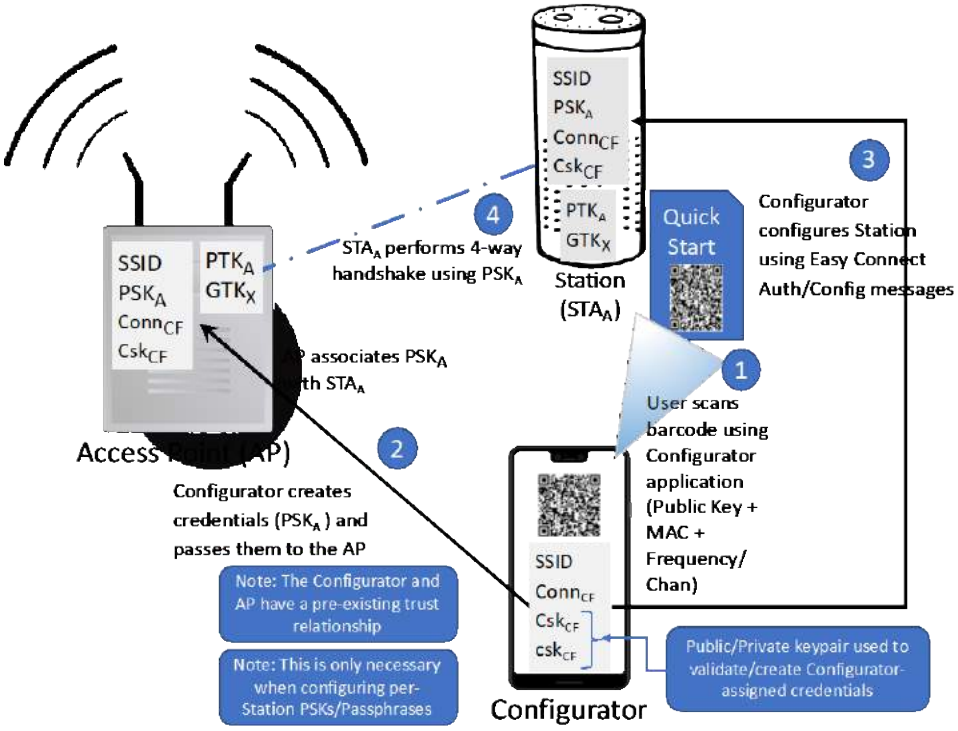

**Figure 11: DPP Direct Provisioning of PSK Using QR Code**

Figure 10 and Figure 11 illustrate a stand-alone Configurator directly provisioning the on-boarded Station ($STA_A$). But it can often be advantageous to have the Configurator co-located on the AP. This model ensures that (a) the Configurator is always accessible (which simplifies the discovery/initiation process) and (b) ensures that credentials stored by the Configurator are not easily lost (e.g. if the device with the Configurator is lost or the application is deleted). Figure 12 illustrates a Configurator which operates on the AP.

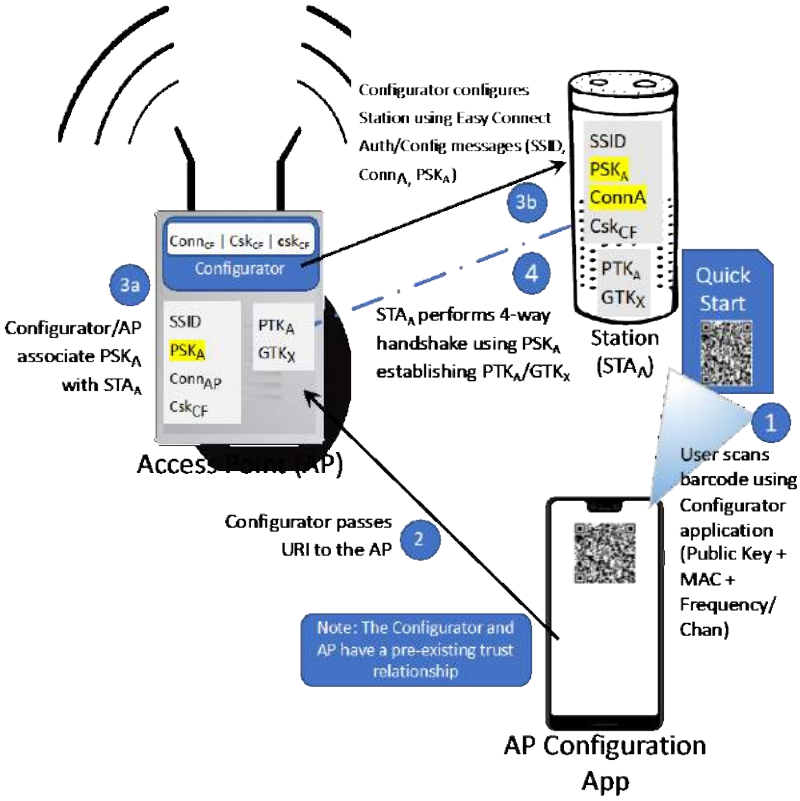

**Figure 12: DPP AP-based Provisioning of PSK using QR code**

Regardless of how provisioning is performed, all Stations can be provisioned with a PSK, WPA2 password, Enterprise credentials (certificate), WPA3/SAE Password, and/or DPP Connector credentials. The Configurator can offer more than one type of credential to a Station. And a Station can accept more than one credential. A network can be provisioned with a combination of credentials depending upon the

credential types supported on the AP, the credential types supported on the Stations, and what credentials the Configurator creates/supplies.

Below is an illustration showing Stations provisioned with a combination of different credential types:

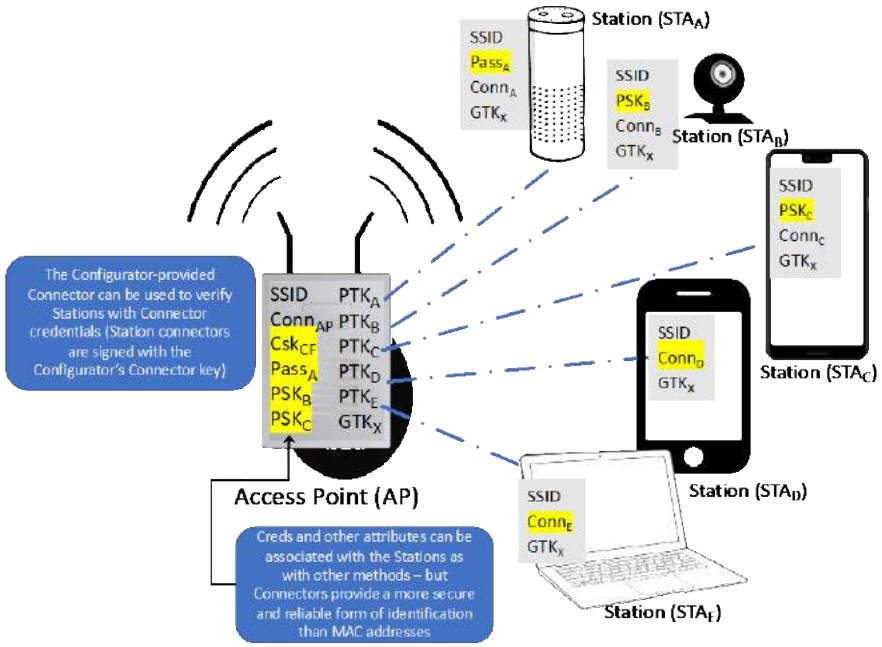

**Figure 13: DPP Provisioning of PSKs**

The DPP onboarding process also provides the opportunity for the Configurator application (or its proxy) to interact with the user and configure the Station and the AP/Wi-Fi network according to user interaction/direction or other technologies. For example, during the onboarding process, the user may designate that a Station may only connect to the Internet and not to other devices on the home network, that a device should not be able to use more than a particular bitrate of uplink bandwidth, or that a Station should not be able to use the uplink during particular hours of the day

## 3.2. DPP/EasyConnect Connectors

Many of the solutions currently deployed to provide device/Station-level policy depend upon MAC addresses to identify devices and associate per-device and per-group policy, as described in section 2.1.3. There are a number of issues using MAC addresses as identifiers:

1. MAC addresses are easily observable via traffic monitoring – even by parties that are not part of the Wi-Fi network (since every Wi-Fi packet contains a MAC address),
2. The MAC address of an adapter is changeable. This is especially problematic when an AP/gateway with shared password credentials attempts to assign policy based on MAC address. It is trivial for one Station to take on another Station's MAC-associated policy by simply cloning the MAC address. E.g. A child in a household can circumvent MAC-associated network time or usage restrictions by stealing a parent's MAC address or assigning a random MAC address.
3. Due to (1), MAC addresses have become a privacy concern. Device manufacturers have announced initiatives to use randomized MAC addresses to avoid device/identity tracking.

Today's systems that utilize MAC-based policy assignment will likely encounter issues as these privacy initiatives are implemented. [4][5]

DPP solves the issue of identification with *Connectors*. Connectors provide a secure and durable identity for a Station while also enabling mutual authentication and verifiable metadata. Connectors are JSON Objects created by the Configurator at the time of onboarding, cryptographically signed using the private key of the Configurator ($\mathbf{c}sk_{CF}$), and encoded using JWS (JSON Web Signature) serialization.

Here is an example of a Connector, prior to encoding and signing using JWS:

```
{
  "groups": [
      {
         "groupId": "home",
         "netRole": "sta"
      },
      {
         "groupId": "cottage",
         "netRole": "sta"
      }
   ],
   "expiry": "2019-01-31T22:00:00+02:00",
   "netAccessKey": {
      "kty": "EC",
      "y": "LUsDBmn7nv-LCnn6fBoXKsKpLGJiVpY_knTckGgsgeU",
      "x": "Xj-zV2iEiH8XwyA9ijpsL6xyLvDiIBthrHO8ZVxwmpA",
      "crv": "P-256"
   }
}
```

**Figure 14: DPP Connector Example**

Once encoded and signed, the same Connector appears as three base64-encoded fields separated by "." characters – with the first group being JWS "protected" header values, then the encoded Connector, followed by a signature of the two fields. The signature (or hash of the signature) can be used to identify the Connector. Here's an example of a JWS-encoded and signed Connector:

```
eyJ0eXAiOiJkcHBDb24iLCJraWQiOiJrTWNlZ0RCUG1OWlZha0FzQlpPek9vQ3N2UWprcl9uRUFwOXVGLUVEbVZFIiwiYWxnIjoiRVMyNTYifQ

```

**Figure 15: Encoded DPP Connector Example**

As part of the Wi-Fi authorization process, a Station supporting DPP can authenticate with the Access Point using the Connector supplied to the Station during provisioning. Figure 16 illustrates the mutual authentication and derivation of the PMK using Connectors.

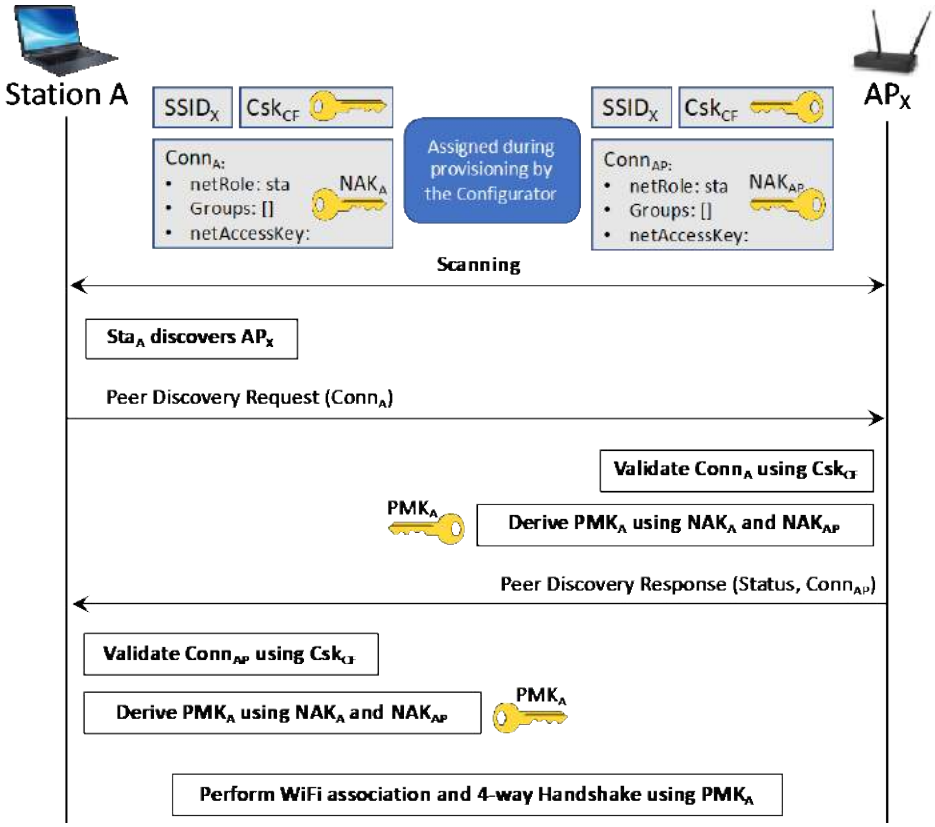

**Figure 16: DPP Connector-based Authentication**

Note that Connector-based authentication addresses the major issues of WPA2-Personal described in Section 2.1.1 – by utilizing a PMK/PSK that's device-specific and non-transferrable. And they also address the major issues of WPA2/3-Enterprise described in Section 2.1.2 – since Connectors are easily generated and easily validated without the need for enterprise infrastructure and provisioning.

## 3.3. Applications of DPP Connectors

As reliable identifiers, Connectors allow for the association of metadata with a Station. During the DPP device onboarding process, arbitrary metadata can be associated with a newly onboarded Station by associating the metadata with the Station's connector (Specifically, the Connector signature or a hash of the signature).

For instance, during the provisioning process, a user could designate that a device should only operate during particular hours. Or a Station can provide, via the DPP Configuration Request object, a MUD (Manufacturer Usage Description) URL that – when processed – indicates that a Station/Device should only connect to a particular host. These provisioning attributes can be stored on the AP by associating them with the Station's Connector.

Connectors also solve the issues related with MAC address reassignment described in Section 2.1.3. When the device authenticates – as shown in Figure 16 – the MAC address of the Station can be associated with the Station's Connector after mutual authentication is completed. MAC-based policies/ACLs can be implemented on an AP/gateway without any requirement on MAC addresses being immutable across Station associations.

For example, the application of time-based Internet access restrictions for a Station "kidtab" for 10pm to 6am can be implemented by an AP/gateway using DPP Connectors via the following steps:

1. The Configurator onboarded "kidtab" and assigned it Connector C
2. The Configurator (or proxy application) is used to configure an access restriction for "kidtab" from 10pm to 6am
3. The Configurator adds a time-based policy attribute for 10pm to 6am (daily) and associates it with Connector C on the AP/gateway (using previously established credentials).
4. When "kidtab" authenticates/associates with the network using Connector C, the AP/gateway associates the MAC address with Connector C (the "kidtab" Connector).
5. Once "kidtab" is fully connected, the AP/gateway looks up the policies for "kidtab", finds an associated time-based policy, and sets a timer for 10pm.
6. When the timer goes off at 10pm, the AP/gateway sets packet blocking rules that prevent any traffic with the source MAC address associated with "kidtab" (determined in step 3) and a destination IP outside the local network.

With MAC-associated policy (as is the case with Wi-Fi policy systems today) steps (3) and (4) can fail if/when endpoints utilize MAC randomization – even when per-Station passwords are used. And when shared passwords are used, these kinds of policies can be easily defeated by simply cloning the MAC address of another authorized Station.

Another application of DPP Connectors is reprovisioning. Since all DPP-provisioned Stations and APs are configured with both a Connector and the public key of its Configurator (enabling mutual authentication), the Stations and/or AP can be dynamically and securely reprovisioned at any time by the Configurator using the Connector-based trust relationship. Reconfiguration can be used to update the network configuration of a Station without user intervention – for example to change the SSID of the network. DPP reconfiguration can also be used to provision new Connectors (with new attributes) based on changes made in the Configurator application.

## 4. Wireless Network Segmentation

The number and nature of wireless devices connected to home/SOHO networks has changed dramatically since Wi-Fi was introduced. Smart TVs/speakers, set-top boxes, and streaming devices interact with both the local area network and cloud-based services, while IoT devices such as doorbells, lightbulbs, thermostats, security cameras, and appliances interact and integrate exclusively with cloud-based services.

Additionally, the single- or limited-purpose nature of IoT devices makes them more commoditizable. For instance, to many people, most brands of smart plugs, switches, and bulbs are inconsequential. The considerations are (a) are they compatible with the smart speaker/home automation system that people use and recognize (e.g. "Alexa-Compatible", "Google Home Compatible", "Apple HomeKit Compatible", etc.) and (b) purchase cost. Each device – and its associated (and necessary) cloud-based controller – represent a distinct risk to the user's network and even to networks/systems outside the home. One compromised cloud-based controller can be used to facilitate a botnet-based DDoS (Distributed Denial of Service) attack.

With more devices there's also more demand for shared resources. Most notably, Wi-Fi bandwidth and Internet uplink bandwidth can become strained. And there may be a desire to prioritize traffic to reduce latency for applications such as interactive gaming and video conferencing.

One solution to address the current needs of the modern Wi-Fi network and devices – and to provide capabilities for future network requirements – is *network segmentation*. Network segmentation can be implemented in AP/gateways using a combination of virtual bridges and SDN (software-defined networking). But this form of network segmentation can only be reliably and securely implemented when there's a solid means of attestation for a device's identity and layer 2 (MAC) addresses – as described in Section 3.

Network segmentation can enable:

- The separation of Stations by risk category and/or function. E.g. Home automation (HA)/security devices can be allowed to connect to the Internet but cannot initiate connections to devices in other segments. Or devices with a higher quality of credential (e.g. a DPP Connector) can be separated from those with lower-quality credentials (e.g. a PSK).
- Segment-level access controls. Stations in some segments can discover/initiate connections to devices in other segments, but not vice-versa. E.g. Interactive devices such as smart phones and tablets can initiate connections with home automation/security devices, but those HA/security devices cannot access non-HA/security devices
- The "quarantine" of Stations that are suspected of being compromised – either explicitly via user direction or automatically, based on behavior/AI or external threat notifications
- The application segment-level policies – such as usage and time quotas.

Figure 17 illustrates an example network segmentation.

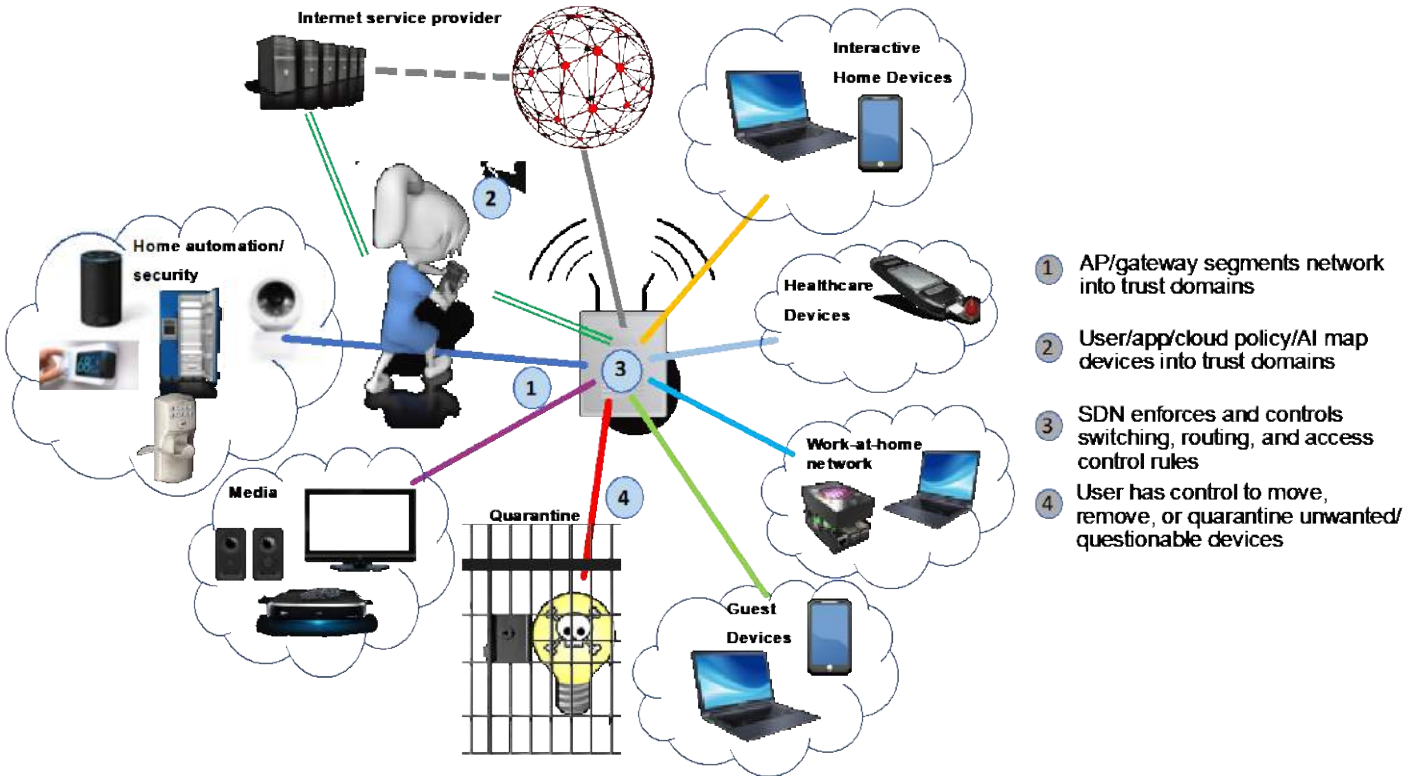

**Figure 17: Example Network Segmentation**

### 4.1. Network Segmentation using DPP Connectors

The disposition of Stations into particular segments can be done initially during onboarding – based on Station information provided in the DPP Config Request, initial or historical profiling of the Station (e.g. via device fingerprinting), and/or user direction (e.g. the user choosing a segment from a drop-down on the Configurator UI). A Station can also be moved from one segment to another, based on preference changes or updated information. E.g. If an advisory is published about a particular device, the AP/Gateway could move the Station into a "Quarantine" segment until its software is updated.

To implement segmentation using SDN an AP/Gateway minimally requires:

1. Each Station to have a unique identity – which allows a Station to be associated with a segment.
2. Each Station to have its own security credentials which are associated with the identity and non-transferrable.
3. The MAC address of each Station – which allows SDN rules to be applied to the Station's traffic.

As outlined in Section 3.2, DPP provides (1) and (2) directly. And as described in Section 3.3, it indirectly provides (3) in a way that is much more robust than today's methods that presume immutable MAC addresses.

For example, the provisioning of Station "kidtab" into the network segment "Home-Secure" (a segment designated for laptops, tablets, and smartphones for household residents) could be accomplished with the following steps:

1. The Configurator (or proxy application) is used to onboard "kidtab". The Configurator creates Connector C for it with a "groups" containing "net-seg" and provides Connector C and an SSID of "HomeNet" in the DPP exchange.
2. The Configurator adds a "net-seg" attribute with the value "Home-Secure" and associates the attribute with the Connector C on the AP/Gateway (using previously established credentials)
3. When "kidtab" mutually authenticates with the "HomeNet" AP/gateway using Connector C, the AP/gateway associates the MAC address in the message exchange with "kidtab".
4. Once "kidtab" is fully associated, the AP/gateway looks up the "net-seg" policy for "kidtab", finds the name "Home-Secure" and:
    a. allocates an IP address for "kidtab" in an IP subnet associated with the "Home-Secure" network segment.
    b. Ensures that SDN rules are written appropriately for "kidtab" to be in the "Home-Secure" segment – and to enforce any segment- or Station-specific policy – using the MAC address for "kidtab" (determined in Step 3).
5. If/when "kidtab" disassociates from "HomeNet", the AP/gateway removes the MAC association for "kidtab", the IP address assignment, and all SDN rules associated with its MAC address. This effectively removes it from the "Home-Secure" network.

There are, of course, many ways to implement segmentation. But invariably there will be both Layer 2 and Layer 3 processing required to implement segmentation – especially for Station-specific rule enforcement.

## 5. Conclusion

The amazing success of Wi-Fi now presents its greatest challenge: Supporting the security, scaling, and privacy needs that are required going forward while still supporting the successful Wi-Fi technologies that we're all using today.

DPP bridges that gap by supporting the provisioning of current WPA2 and WPA3 credentials while also supporting advanced credentials that allow for mutual authentication and identification. And by integrating with the existing Wi-Fi 4-way handshake protocol, DPP is able to provide that support without introducing new hardware requirements on APs or Stations.

The features of DPP in and of themselves make a compelling case for the protocol. But when you take into consideration the security issues with IoT devices, the need to provide per-Station policies for managing/prioritizing access for non-IoT devices, and the privacy concerns related to MAC addresses, the importance and value of having a non-spoofable Station and AP identity becomes obvious. And the application of per-Station policies and network segmentation – built on the foundation of DPP – can ensure that Wi-Fi will be able to meet the evolving needs of users and devices.

**Title** **Page Number**

# 1. Introduction

A defining moment of the century, so far, is the unprecedented impact that COVID-19 has brought to the economies world-wide, the populations and defining new norms in society.

Our paper details how we can enforce the new rules of society like social distancing and wearing face masks in open-spaces using computer vision and deep learning through:

- Detecting people on a particular scene,
- Calculating and monitoring the distances between the different people,
- Tracking movements and segregating moving people (might come close to each other during brief moments) from people standing still and violating the social distancing rules, and
- Creating alerts (audio, visual, light…) to enforce social distancing.

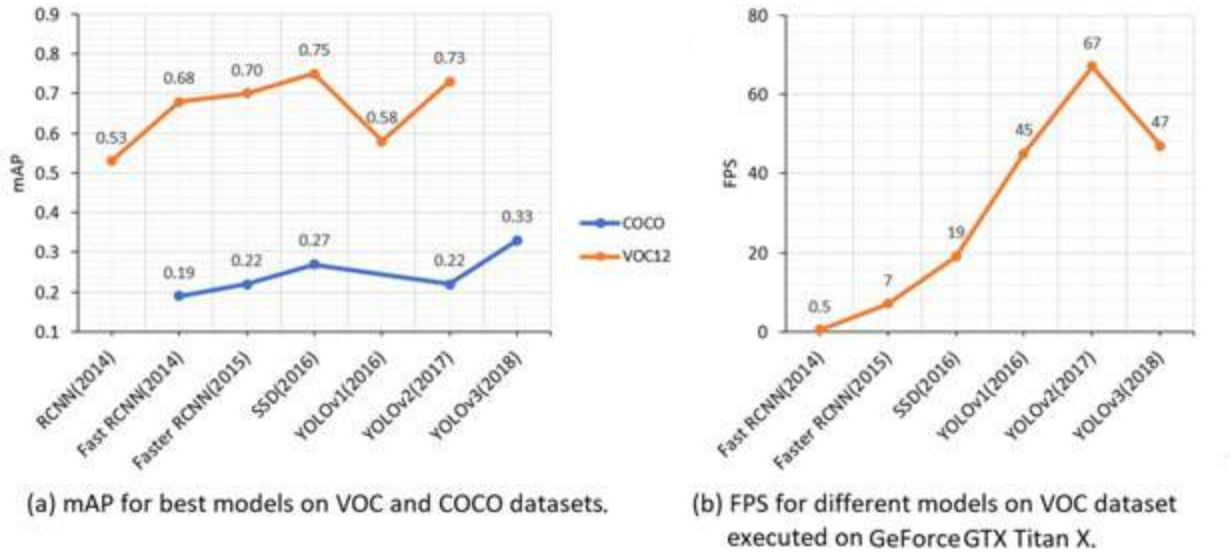
Our approach also ensures that, in confined spaces, we count people and create visual and audio alerts when the number of people exceeds the Center for Disease Control (CDC) guidelines (10 people per room).

We detail in the paper the computer vision and deep learning frameworks we used to achieve high confidence in detecting human presence, calculating and calibrating distances in the frames, and removing false positives (eg. people crossing paths while walking versus people standing still).

# 2. Computer Vision and DL-based Social Distancing Application

The emergence of deep learning has brought the best performing techniques for a wide variety of tasks and challenges including medical diagnosis, machine translation, speech recognition, and a lot more. Most of these tasks are centered around object classification, detection, segmentation, tracking, and recognition.

In recent years, the convolution neural network (CNN) based architectures have shown significant performance improvements that are leading towards the high quality of object detection, as shown in Fig. 1, which presents the performance of such models in terms of mAP and FPS on standard benchmark datasets, PASCAL-VOC and MS-COCO, and similar hardware resources. In this paper, a deep learning-based framework is proposed that utilizes object detection and tracking models to aid in the social distancing remedy for dealing with the escalation of COVID-19 cases. To maintain the balance of speed and accuracy, YOLO v3 alongside Centroid tracking are utilized as object detection and tracking approaches while surrounding each detected object with bounding boxes. Later, these bounding boxes are utilized to compute the pairwise L2 norm with computationally efficient vectorized representation for identifying the clusters of people not obeying the order of social distancing. Furthermore, to visualize the clusters in the live stream, each bounding box is color-coded based on its association with the group where people belonging to the same group are represented with the same color. Each surveillance frame is also accompanied with the streamline plot depicting the statistical count of the number of social groups and an index term (violation index) representing the ratio of the number of people to the number of groups. Furthermore, estimated violations can be computed by multiplying the violation index with the total number of social groups.



(a) mAP for best models on VOC and COCO datasets.

(b) FPS for different models on VOC dataset executed on GeForce GTX Titan X.

**Figure 1 Performance overview of the most popular object detection models on PASCAL-VOC and MS-COCO datasets**

## 3. System Description

In this section, we descibe the end-to-end (E2E) system flow for people detection, tracking and social distance measurement.

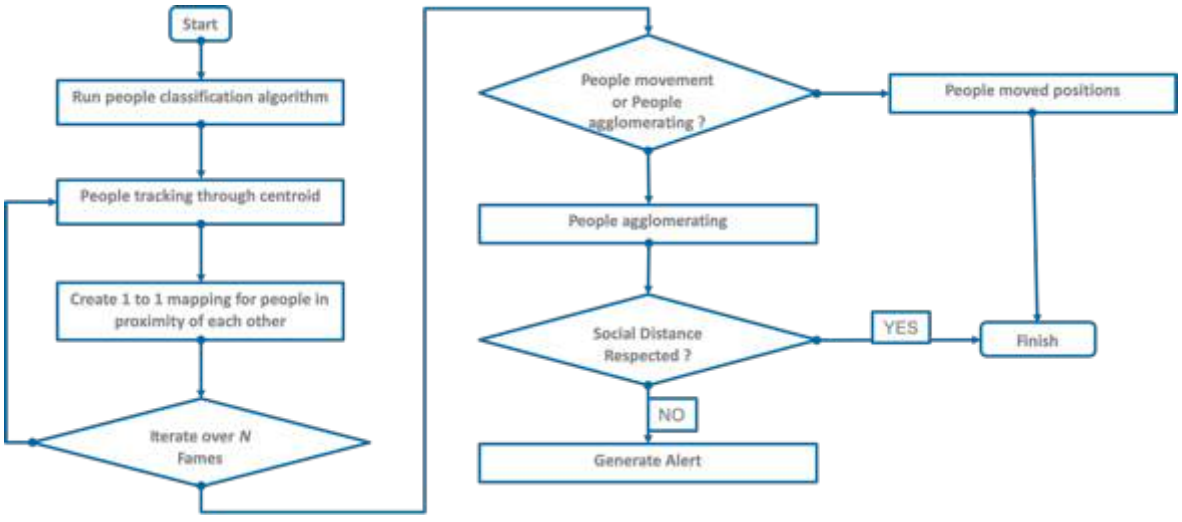


**Figure 2. E2E Detection and Tracking Flow.**

The flow as depicted in Fig.2 starts when the system is receiving frames via RTSP from a networked camera (WiFi, Ethernet, CBRS, LTE…). The algorithm performs the object classification until classifying objects as people. Each person in the scene is tracked via centroid algorithm. A "security/privacy zone" surrounding each person of X ft is created and the algorithms keeps tracking distances between the closet centroids to each other. In order to minimize false alarm, we re-iterate over N frames in order to rule out people moving from people standing still. If the same centroids are identified in a single group over the N frames, the algorithm classifies the group as standing still and conglomerating, if the group is not respecting the social distance of X an alert (visual, light, voice) is issued to remind the group of social distancing rules.

## 4. People Detection Algorithm

From the Camera stream, we run an object identification and classification algorithm to infer with high precision the presence of people in the video stream.

Each frame is sub-divided into smaller Regions of Interests (ROIs). Each boundary box or ROI contains 5 elements: (x, y, w, h) and a box confidence score. The confidence score reflects how likely the box contains an object (objectness) and how accurate is the boundary box. We normalize the bounding box width w and height h by the image width and height. x and y are offsets to the corresponding cell. Hence, x, y, w and h are all between 0 and 1. Each cell has 20 conditional class probabilities. The conditional class probability is the probability that the detected object belongs to a particular class (one probability per category for each cell). So, our approach's prediction has a shape of (S, S, B×5 + C) = (7, 7, 2×5 + 20) = (7, 7, 30). The major concept is to build a CNN to predict a (7, 7, 30) tensor. It uses a CNN to reduce the spatial dimension to 7×7 with 1024 output channels at each location. The algorithm performs a linear regression using two fully connected layers to make 7×7×2 boundary box predictions. To make a final prediction, we keep those with high box confidence scores (greater than 25%) as our final predictions.

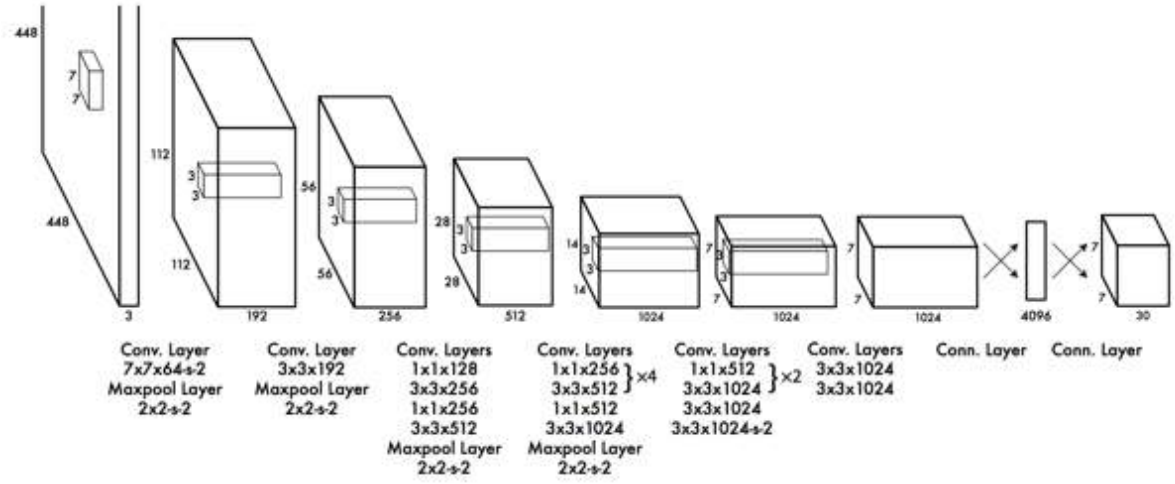

**Figure 3 Classification using YOLO v3 Framework.**

## 5. People Tracking via Centroid

**Step 1: Accept bounding box coordinates and compute centroids**

The centroid tracking algorithm assumes that we are passing in a set of bounding box (x,y)-coordinates for each detected object in every single frame. These bounding boxes can be produced by our object detector provided that they are computed for every frame in the video. Once we have the bounding box coordinates we must compute the "centroid", or more simply, the center (x,y)-coordinates of the bounding box.

Figure 4 bellow demonstrates accepting a set of bounding box coordinates and computing the centroid. Since these are the first initial set of bounding boxes presented to our algorithm we will assign them unique IDs.

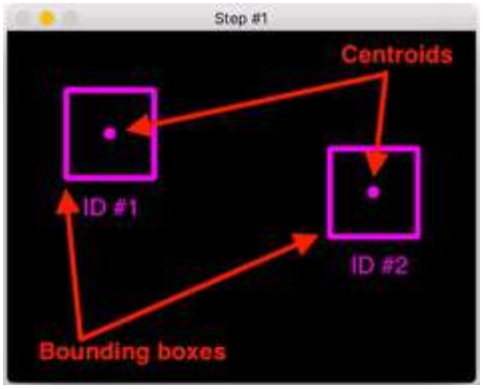

**Figure 4. Centroid tracking step 1.**

**Step 2: Compute Euclidean distance between new bounding boxes and existing objects.**

For every subsequent frame in our video stream we apply Step #1 of computing object centroids; however, instead of assigning a new unique ID to each detected object (which would defeat the purpose of object tracking), we first need to determine if we can associate the new object centroids (yellow) with the old object centroids (purple). To accomplish this process, we compute the Euclidean distance (highlighted with green arrows) between each pair of existing object centroids and input object centroids. From figure 5, we can see that we have this time detected three objects in our image. The two pairs that are close together are two existing objects. We then compute the Euclidean distances between each pair of original centroids (yellow) and new centroids (purple). But how do we use the Euclidean distances between these points to actually match them and associate them? → Step 3

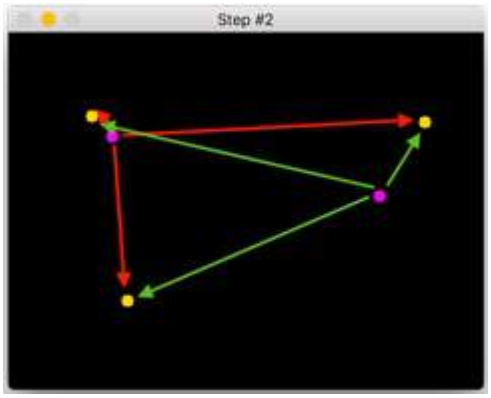

**Figure 5. Centroid tracking step 2.**

**Step 3: Update (x, y)-coordinates of existing objects**

The primary assumption of the centroid tracking algorithm is that a given object will potentially move between subsequent frames, but the distance between the centroids for frames F_t and F_(t+1) will be smaller than all other distances between objects. Therefore, if we choose to associate centroids with minimum distances between subsequent frames we can build our object tracker. In figure below, we can see how our centroid tracker algorithm chooses to associate centroids that minimize their respective Euclidean distances.

The new point that appears at the bottom left mean that we see a new object we need to register → Step 4

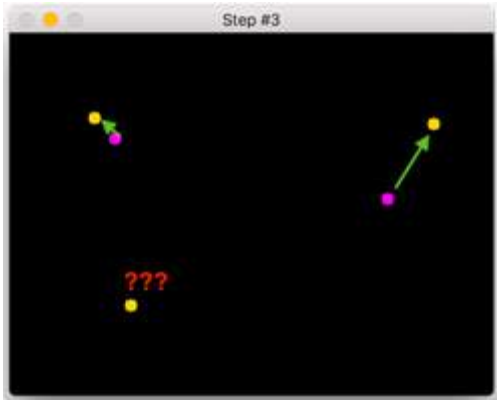

**Figure 6. Centroid tracking step 3.**

**Step 4: Register new objects**

In the event that there are more input detections than existing objects being tracked, we need to register the new object. "Registering" simply means that we are adding the new object to our list of tracked objects by:

- Assigning it a new object ID, and
- Storing the centroid of the bounding box coordinates for that object, then
- We can then go back to Step #2 and repeat the pipeline of steps for every frame in our video stream.

 

Figure 7 depicts the process of using the minimum Euclidean distances to associate existing object IDs and then registering a new object.

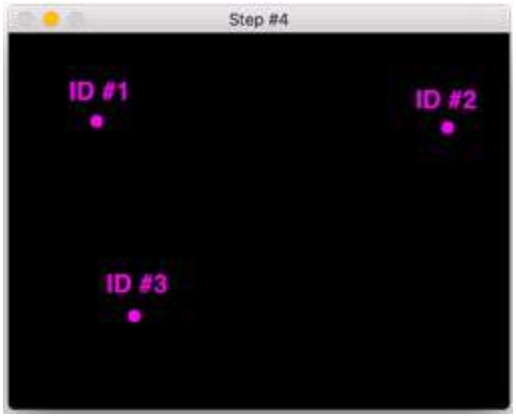

**Figure 7 Centroid tracking step 4**

**Step 5: Deregister old objects**

We deregister old objects when they cannot be matched to any existing objects for a total of N subsequent frames.

## 6. Social Distancing PoC

In order to validate our approach, we implemented and validated our algorithms in our offices in Greenwood Village.

Bellow figures depict the outcome of the PoC:

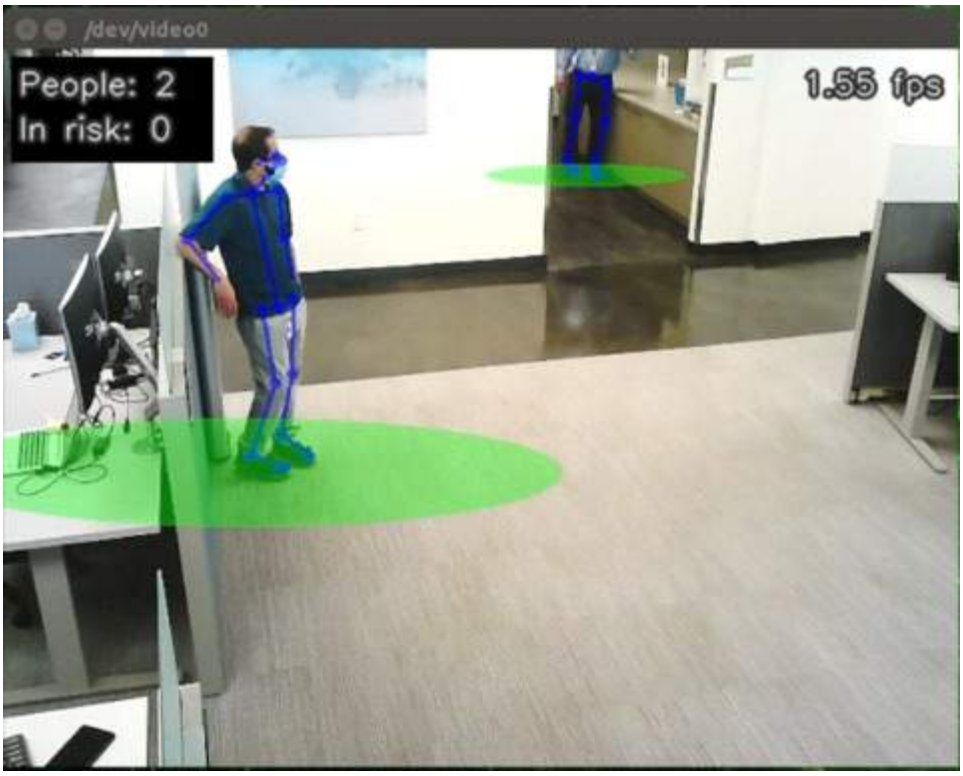

**Figure 8. Social Distance fully respected.**

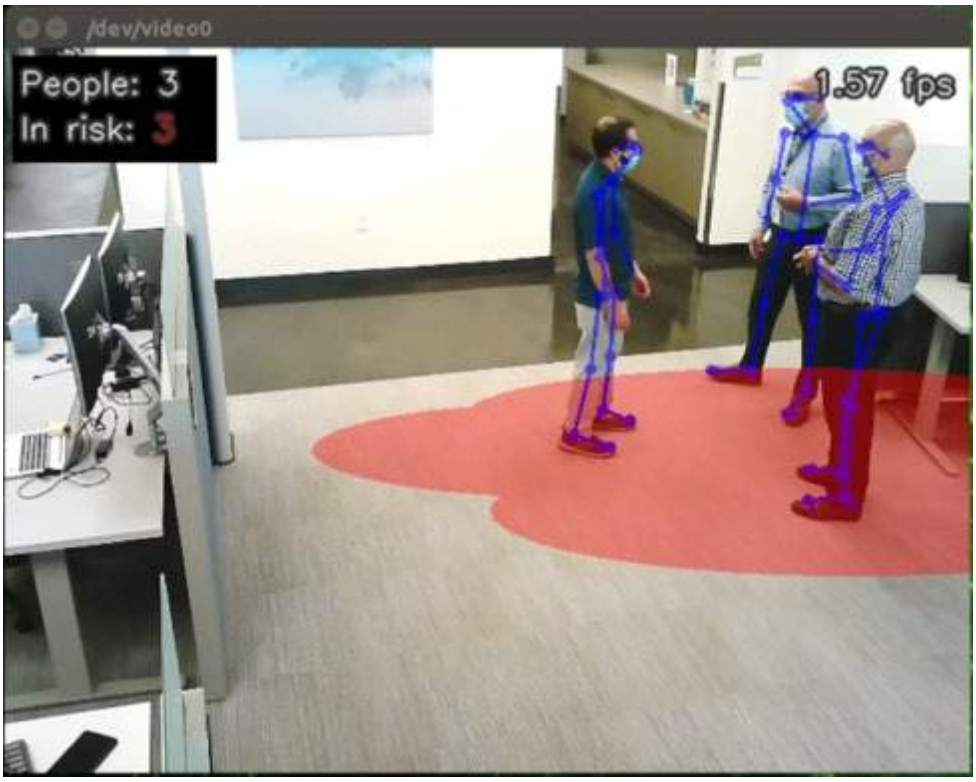

**Figure 9. Social Distance not respected.**

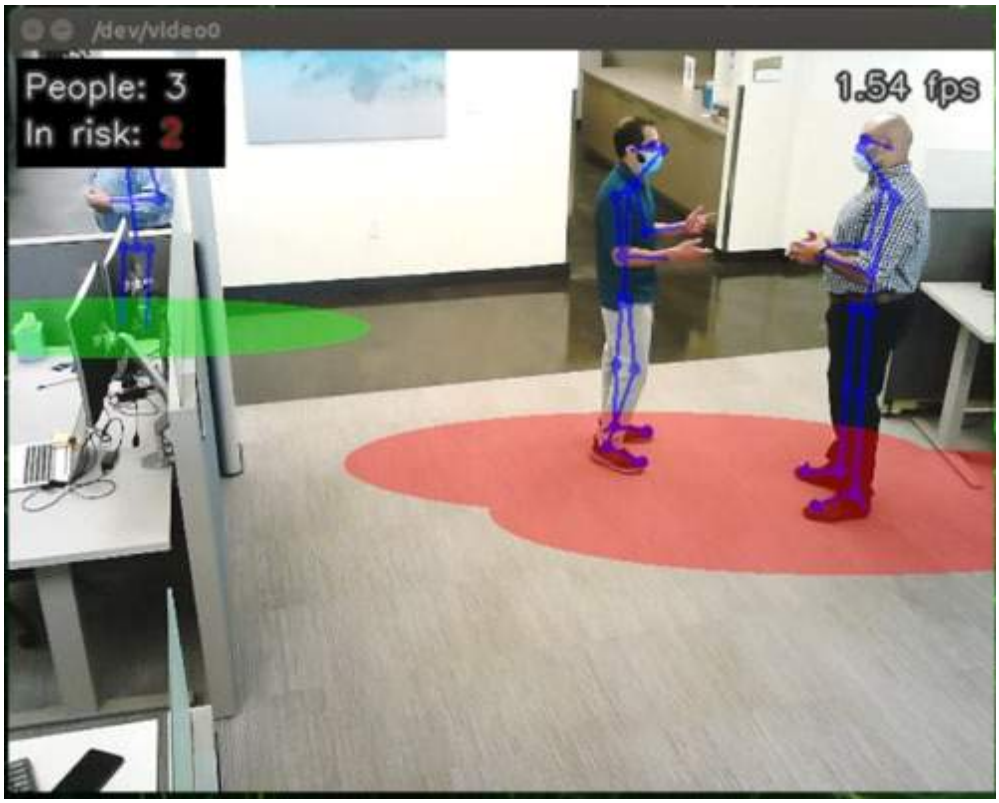

**Figure 10. Social Distance partially respected.**

## 7. Conclusion

In this paper, we presented a novel approach to an AI-assisted social distancing application for safer back to work situations.

This solution can be applied to indoor or outdoor scenarios ensuring social distances are met and respected.

We have deployed and tested our solution in our lab, and it has shown promising results and good accuracy for measuring distances and alerting (via sound and lights) when social distancing is not respected.

# Table of Contents

## List of Figures

# 1. Introduction

As means to control the spread of the COVID-19 virus, many countries implemented measures to quarantine large portions of their populations in early 2020. Remote working and schooling policies were applied to a fairly large extent. Large portions of the workforce, especially in the hospitality industry, were laid off. Essentially, many people found themselves stuck at home for one reason or another.

This resulted in a significant increase in network traffic in many areas for many service providers. This was especially true for upstream traffic generated by various teleconferencing and VoIP-type protocols that were heavily leveraged to support remote working and schooling. Additionally, there was a noted shift in the daily peak time - from evenings to daytime in many locations.

Traffic increases caused an increase in the utilization of all network elements including cable modem termination system (CMTS) service groups (SGs) which provide connectivity between the core network the access network where customer homes and businesses reside. High utilization can result in potential impact to customer experience such as slow speeds, poor video quality, and intermittent service if not resolved. Speed test data and various industry models have helped us to define highly utilized CMTS SGs as those with utilization exceeding 85% consistently.

Sharp increases in traffic and CMTS SG utilization like what was observed during the COVID-19 event can be well-managed through a combination of proactive and reactive capacity management activities. Proactive measures are mainly focused on predictive traffic forecasting and capacity deployment planning. Reactive measures include a plethora of specialized reporting mechanisms, to help prioritize near-term capacity work, and adaptations to existing long-term plans where applicable.

Accelerated development of new solutions, techniques, and technologies is also a key aspect of any strategy during a crisis. To expand upstream capacity, development and testing for additional upstream channels was prioritized and successfully deployed. The profile management application (PMA) platform, known by the name “Octave” at Comcast and initially developed for DOCSIS 3.1 downstream capacity, was rapidly modified to enable more DOCSIS 3.0 upstream capacity. To help operationalize and deploy new solutions, other tools and automation were also quickly developed and modified.

Furthermore, the partnership between capacity management, engineering, finance, and technical operations teams on the planning and execution of capacity solutions was critical to tackling the challenge imposed by the sudden network growth. It was only through this partnership and alignment that extraordinary innovations and accomplishments were made. Node split work to mitigate highly utilized CMTS SGs, for example, increased 100% from normal levels as all teams rallied around a common goal. This would not have been possible otherwise. All efforts to manage capacity in extreme circumstances like during COVID-19 are only effective when there is good partnership and solid alignment across the organization.

# 2. Historic Context

There are various factors involved in the management of traffic growth and customer experience. Subscriber growth and increased usage per subscriber are key factors in driving traffic growth over time. In recent years, annual upstream network traffic growth has been in the 15-25% range, on average. Downstream traffic growth has typically been in the 25-35% range on average. Not accounting for seasonality, this has translated to averaged monthly growth of approximately 1-2% for upstream traffic and 2-3% for downstream traffic.

While traffic grows on some average amount, it typically does not grow in a linear or consistent manner in most locations. In reality, traffic follows seasonal patterns in which it grows faster or slower based on the time of year. Generally, traffic growth is higher during the autumn and winter months in most areas in the United States especially in the northern latitudes for a multitude of reasons. Schooling, for example, typically resumes in the late August and September timeframes with ever increasing reliance on the internet to complete homework assignments and projects. In this same timeframe, new primetime television shows and series are released both on traditional broadcast and over-the-top (OTT) providers. Not surprisingly, content from traditional broadcast providers is mostly watched via video-on-demand (VOD) platforms to better fit with hectic schedules. All OTT content and much of the VOD content is IP-based and delivered over DOCSIS for cable operators. Near the Thanksgiving and Christmas holidays, even more video content is made available as well as new games and gaming updates, all of which are delivered over DOCSIS and manifest in higher traffic than normal. And of course, winter weather events and generally unfavorable outdoor weather conditions cause many people to stay inside and spend their time watching more video content or playing more online games. Traffic then typically begins to flatten and even decline going into the spring and summer months, as people spend more time outdoors and new video content is limited.

Vacation areas also demonstrate seasonality on network traffic. Summer vacation homes near beaches, lakes, or mountains drive a significant amount of localized traffic, mostly during the summer months. Likewise, winter vacation homes near winter activity areas and in warmer southern latitudes (i.e. "snow-bird" communities) drive higher localized traffic during the winter months.

Daily peak usage time is another factor that may affect how capacity is managed. In most areas, the daily peak usage time happens during the evening hours. Some areas with a heavy penetration of business services customers may peak during the day.

Traffic growth and timing of traffic growth impacts the utilization of network elements including CMTS SGs and potentially customer experience. Most providers strive to account for the various factors related to traffic growth in order to minimize high utilization and ensure good product quality and service reliability at all times. At Comcast, the number of highly utilized CMTS SGs has typically been managed to a nominal number, even accounting for factors like seasonality and peak time usage.

There are various approaches to measuring CMTS SG utilization used across the industry. Our approach is based on calculating the 98$^{th}$percentile of peak, of weekly 5-minute polling data averaged over four weeks. Each week, there are 2,016 5-minute utilization measurements collected. The data set is then sorted in descending order and the top 2% or 40 of these data points are removed. These top 2% or 40 data points are considered outliers. The 41$^{st}$ data point becomes the reported weekly utilization value for a given CMTS SG. We then calculate the average of the trailing four weeks to derive the official utilization value per CMTS SG. CMTS SGs with 4-week utilization values exceeding 85% are considered highly utilized. Normally, less than .1% of downstream SGs and less than .5% of upstream SGs exceed 85% utilization.

## 3. Problem Statement

Rapid growth in network traffic can cause an increase in highly utilized CMTS SGs, resulting in potential impact to customer experience in some areas. In April 2020, upstream traffic increases in excess of 30% and downtstream traffic increases in excess of 20%, on average, were not uncommon (Figure 1). This was especially true in more urbanized areas and areas where large populations of the workforce teleworked. Voice over IP (VoIP) and video teleconferencing traffic generated by remote working and

 

schooling applications increased in excess of 200% in many locations. Not surprisingly with limited entertainment options outside the home, gaming downloads increased 20-80% and streaming and web video increased 40% on average.

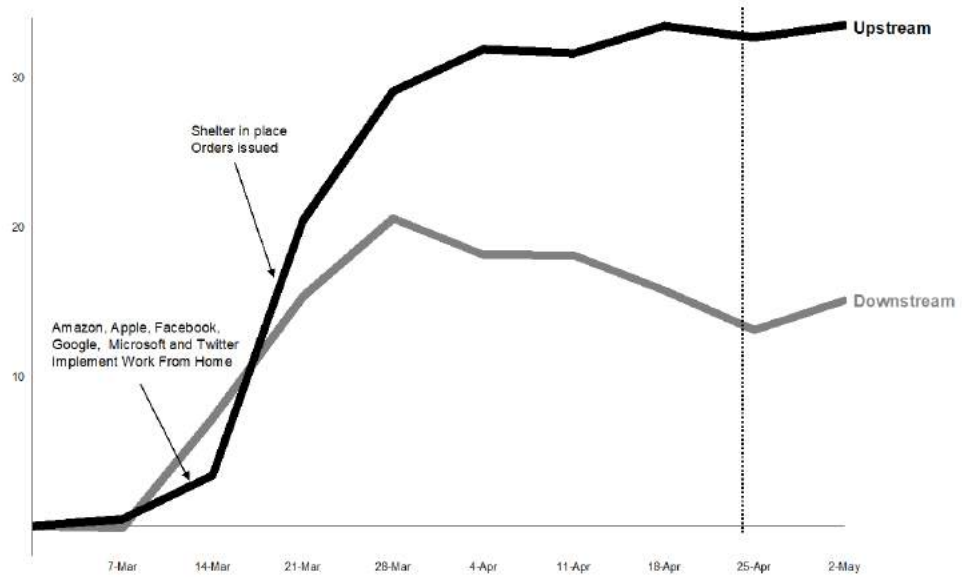

**Figure 1 – Traffic Growth Since Late February 2020** (*Source: Comcast Capacity Management)*

This rapid increase in upstream traffic manifested itself as an overall increase in upstream CMTS SG utilization, including an increase in highly utilized CMTS SGs (Figure 2).

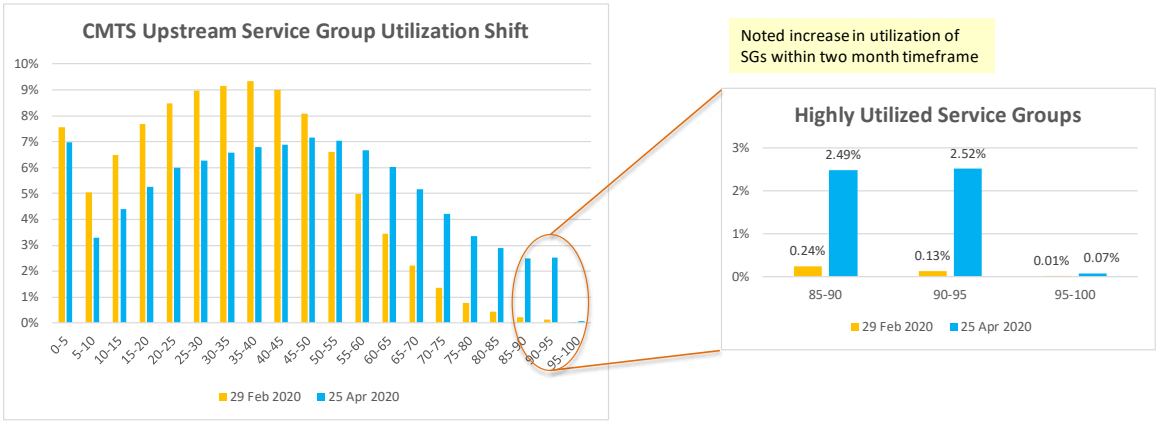

**Figure 2 – CMTS Upstream Service Group Utilization Shift** (*Source: Comcast Capacity Management)*

Additionally, upstream peak traffic tended to shift from 9pm to 2pm local time. The highest hourly increase, of over 100%, was at 1pm (Figure 3). The traffic also flattened throughout the day and evening time from 10am to 10pm local. Most of the increase in daytime usage was, not surprisingly, driven by specific applications and protocols supporting virtual private network (VPN), VoIP, and video teleconferencing.

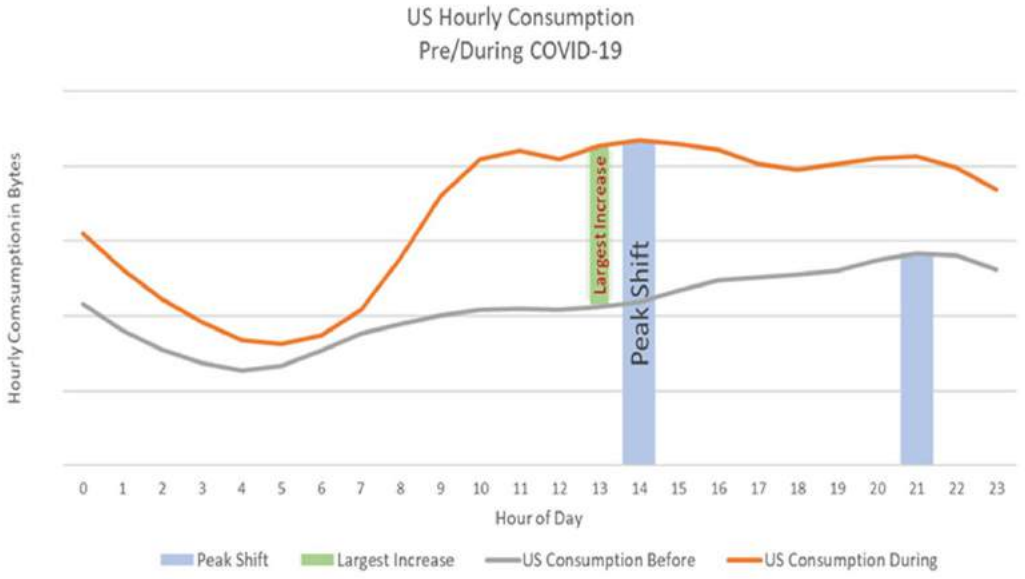

**Figure 3 – Upstream Hourly Consumption Shift** (*Source: Comcast Capacity Management)*

## 4. Solutions

The good news is, as part of an overall capacity engineering and management program, a combination of proactive and reactive measures can successfully mitigate and resolve the impacts of a rapid increase in network traffic due to an event like COVID-19, in a fiscally responsible manner. Proactive measures include predictive traffic forecasting, capacity planning, and proactive capacity deployment. Reactive measures include new and modified reporting, re-prioritization, and accelerated solution development/deployments.

Arguably, proactive capacity management efforts, and particularly those related to predictive forecasting and planning, set the foundation for all other efforts related to capacity management - whether during normal times or during events with extreme growth. According to Elad Nafshi, SVP of Next Generation Access Networks in Comcast, "proactive capacity management was the key to Comcast's access network not only surviving but thriving during the COVID-19 event in the spring of 2020." Having proactive plans already in place (and, in some cases, already in motion) made it much easier to enable reactive efforts like accelerating work and re-prioritizing focus. By the early summer, most highly utilized CMTS SGs from the spring were either resolved or had firm completion dates planned, near-term.

## 4.1 Proactive Capacity Planning

Detailed traffic forecasting at the hub site level can be used to proactively build capacity with a fairly high degree of accuracy. The behavior of traffic growth varies significantly between different geographies and demographics. Understanding these variations at a granular level is key to being able to accurately predict growth and even acceleration of growth due to an event like COVID-19. This is not to say that traffic forecasts related to specific one-time events can be predicted, but rather that the propensity of a site to be affected by a major event can be better understood. Higher growth sites, for instance, will likely react the most dramatically to specific events that drive sudden increases in traffic.

Various traffic forecasting and modelling approaches such as the Exponential Smoothing (ETS) methodology can be used to account for historical trends and seasonal behavior per site (Figure 4). Actual traffic observed is collected typically in monthly intervals. After some pre-conditioning of the data, it is broken down into seasonal and underlying trend components. Assembled series are then created and ETS forecasts are generated for each series. The ETS forecasted series will fall within some range of values. The mean value is used for the base traffic forecast.

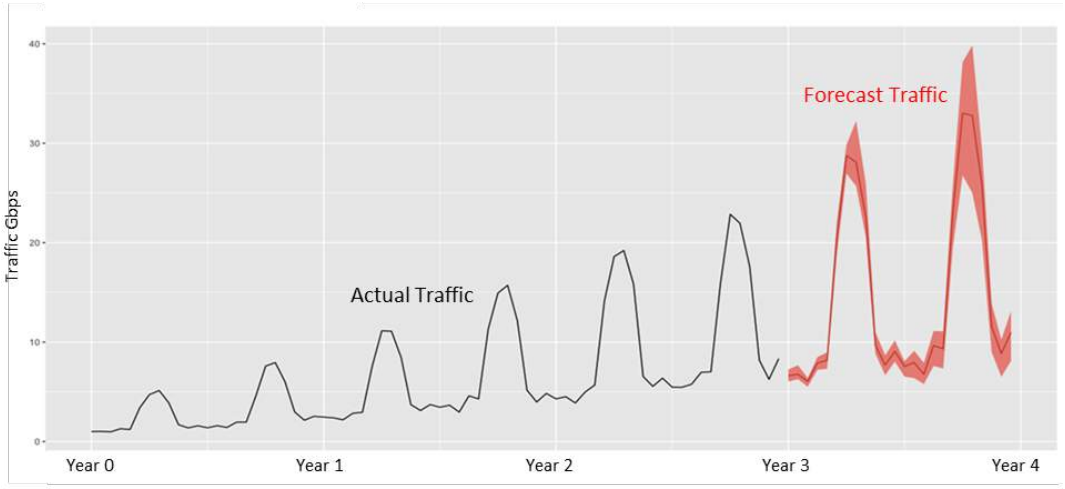

**Figure 4 – Traffic Forecasting Using ETS Methodology** (*Source: Comcast Capacity Management)*

Once the base traffic forecast is understood, traffic impacts from future product offerings and predicted disruptors can then be incorporated to further enhance the forecast and determine capacity needs for a hub site looking forward some period of time. A twelve to eighteen-month forecast is not unreasonable if the quality of trending data is sufficient and predicted product impacts are somewhat accurate.

Not surprisingly, most hub sites which incurred the largest traffic increases during COVID-19 were already identified as higher growth and therefore had plans in place for increasing capacity, albeit a bit further into the future. The COVID-19 event acted like an accelerator of predicted traffic growth. Most of the higher growth sites were in more urbanized areas and areas with larger populations of teleworkers. More rural sites, with lower forecasted growth, tended to not be as impacted.

The proactive deployment of capacity is a preventive measure that can be used to mitigate the effects of a rapid and significant increase in network traffic. It is most effective when used in conjunction with a predictive hub site forecast.

One fairly common aspect of a proactive capacity deployment program is the use of utilization thresholds. Utilization thresholds are used to initiate capacity work before a CMTS SG becomes highly utilized. If set appropriately, this threshold would allow enough time to complete the required capacity work and provide ample headroom to account for unforeseen circumstances, such as work delays or a sudden spike in traffic growth. A more sophisticated use of utilization thresholds involves leveraging a hub site's traffic forecast to inform growth trajectories. Higher growth sites likely need to set a lower utilization threshold for capacity deployment. Thresholds could be intelligently set per hub site based on the predicted growth rate.

Proactive capacity deployment also considers the implementation of capacity solutions which provide some minimum time horizon before having to be addressed again. This varies depending on hub site growth rates. To meet a certain desired time horizon, higher growth sites require a more aggressive capacity solution. For example, a CMTS SG may breach 85% utilization and get resolved with a basic node segmentation. If the annualized growth rate of the CMTS SG is roughly 25%, it will return to the 85% utilization level again within approximately three years. If the desire is to have a longer time horizon for this CMTS SG, then a more aggressive capacity solution would be required.

Capacity solutions with longer time horizons provide proactive capacity. Deep fiber architectures and mid/high split plant upgrades are examples of proactive capacity solutions which ensure longer time horizons for a given growth rate (Figure 5). Proactive solutions tend to cost more up front but are typically less expensive over time, especially in higher growth sites where multiple node segmentations could otherwise be required every few years, and associated plant construction costs will likely continue to increase with increasing labor rates. Net present value calculations evaluating different capacity solutions have proven this in general. Another factor is customer impact. While massive plant rebuilds or deep fiber architecture solutions can sound daunting, customer impact due to capacity can be contained to one or two moments in time and then not again for several years. More short-term solutions like node segmentations would require impact to customers every few years especially in higher growth sites.

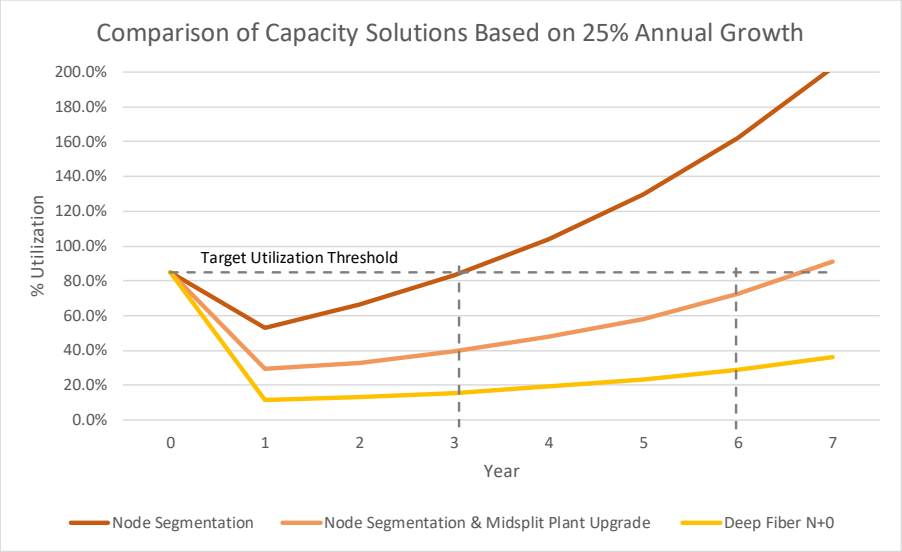

**Figure 5 – Comparison of Capacity Solutions** (*Source: Comcast Capacity Management)*

Hub sites built with deep fiber architectures were found to be very resilient to the rapid increases in traffic during COVID-19. Especially where N+0 amplifier cascades are implemented, node sizes for deep fiber architectures tend to be relatively small. This enables less subscribers to share the same or more capacity available on a normal node resulting in lower utilization. The percent of increase in traffic on deep fiber nodes was still relatively significant, but the impact to utilization was generally not a concern given the low utilization prior to the increase. For example, a 50% utilized node that incurred a 30% increase in traffic became 65% utilized - far below the 85% thresold of being considered highly utilized. By constrast, a 70% node that incurred the same 30% increase in traffic became 91% utilized - above the 85% threshold befor being considered highly utilized. Of course, deep fiber nodes will continue to grow naturally with growth in traffic over time and will eventually need to be addressed, but that time horizon is many years down the road.

## 4.2 New and Modified Reporting

A successful capacity management program is not only proactive by nature but also very adaptable to sudden change. Adaption is largely supported by exposing the right metrics and data in order to focus and prioritize capacity work efforts in the most productive ways possible. Specialized reporting and dashboards can be very helpful to this end and do not have to be overly sophisticated. Data is the foundation, and how it is manipulated and used to tell a clear and compelling story is the key. Ideally, there are already reports and dashboards in place to help manage capacity, which can be modified during events like COVID to help adapt activities as needed.

Capacity scorecards or ranking reports are common reporting methods used to manage capacity for mostservice providers on a normal basis (Figure 6). These scorecards or ranking reports typically contain specific metrics and thresholds by which network capacity health is evaluated and capacity work is managed. Highly utilized nodes or CMTS SGs, for example, would be exposed and appropriate capacity mitigation work like node segmentations could be assigned and managed.

| | Month 3 | | Month 2 | | Month 1 | | |
|---|---|---|---|---|---|---|---|
| | %>=85% Utilization | Count >=85% Utilization | %>=85% Utilization | Count >=85% Utilization | %>=85% Utilization | Count >=85% Utilization | Legend - % of CMTS SGs |
| Site A | 0.02% | 2 | 0.04% | 5 | 0.17% | 22 | 0.00% |
| Site B | 0.21% | 33 | 0.43% | 67 | 1.65% | 251 | <.05% |
| Site C | 0.09% | 13 | 0.06% | 9 | 0.33% | 49 | <.1% |
| Site D | 0.00% | 0 | 0.02% | 2 | 0.10% | 11 | <.5% |
| Site E | 0.12% | 8 | 0.16% | 11 | 0.78% | 52 | <1% |
| Site F | 0.03% | 2 | 0.17% | 13 | 0.34% | 27 | >1% |

**Figure 6 – Example CMTS Scorecard** (*Source: Comcast Capacity Management)*

During times of significant traffic growth and increases in highly utilized CMTS SGs, reporting can easily be modified or developed to provide better focus and prioritization. For example, a scorecard may be measuring how many CMTS SGs exceed an 85% utilization threshold normally. The expectation is that this number is relatively small and manageable. A sudden increase in traffic, similar to that seen during the COVID-19 event, could cause a seemingly insurmountable of CMTS SGs to spike above that 85% threshold. While efforts to increase capacity would likely happen, there are unfortunately physical limitations to how much work can be executed in a short period of time without causing other negative impacts to the network. Temporary modifications to existing scorecards could be implemented to

prioritize work efforts on all CMTS SGs exceeding 90% utilization, for example. Once the elements exceeding 90% are resolved, then focus can be placed back on those exceeding 85%. This approach was successfully adopted and implemented by Comcast to improve prioritization of work.

Other modifications to existing reporting could involve the frequency of data evaluation. Data may normally be evaluated on a weekly or even monthly cadence in the interest of removing any anomalies, such as temporary traffic spikes and CMTS SG utilization that could occur in a very specific timeframe, but subsequently decline back to pre-existing levels. Unfortunately, sudden and less temporary increases in traffic from events like COVID-19 would not be exposed initially using weekly or monthly data. Additionally, granular changes in traffic and utilization would not be known until well after the fact. A switch to more frequent reporting using daily, hourly, or even shorter time intervals is required to gain visibility to rapid increases in traffic and utilization and allow capacity management efforts to start mobilizing to the right areas faster. Furthermore, a daily review of the capacity data is warranted to ensure work teams are aligned and focused on the core priorities.

New reporting may also be warranted to drive focus and priority of capacity work efforts. At Comcast, one particular new report, called the "Minutes over Threshold (MoT)" focused on CMTS SGs and nodes with consistently high utilization over long periods of time. Some CMTS SGs incurred a level of traffic growth resulting in saturation or "flatlining," which rarely happens normally (Figure 7). A new report was specifically created to bring even more focus and attention to these specific SGs and prioritize work accordingly. The new report not only evaluated the SG utilization level but also how many consecutive minutes those SGs remained above a certain utilization threshold. The number of minutes over threshold (MoT) metric helps identify the most severely congested SGs. Standard operating procedure would be to focus the most resources on these SGs first, then focus on SGs with lower MoT and/or lower utilization.

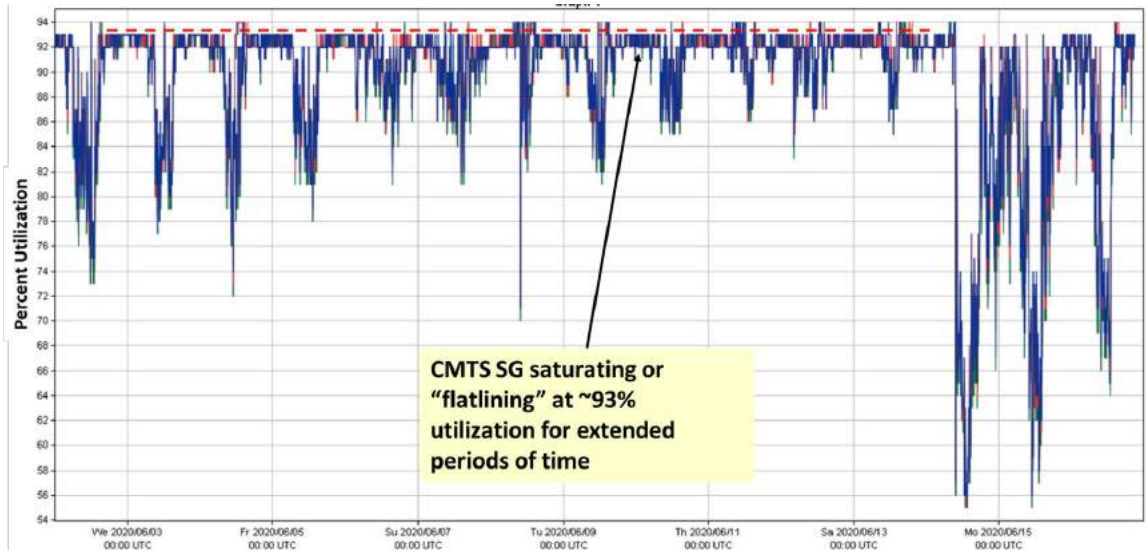

**Figure 7 – Example CMTS SG Saturation or "Flatlining"** (*Source: Comcast Service Performance Database)*

## 4.3 Capacity Acceleration

Once CMTS SG prioritization is better determined, efforts can quickly be mobilized to accelerate capacity solutions and deployments. Fast-tracking development of new innovations is very typical when new problems or challenges arise and COVID-19 was no exception for Comcast. Modifications to

existing processes and tools, accelerated bulk purchasing of materials, and rapid deployment are some other areas where Comcast focused to quickly react to the rapid increase in traffic during the COVID-19 event.

To specifically address upstream capacity challenges caused by significant teleworking and remote schooling, Comcast became highly focused on building innovative solutions to provide more upstream capacity in a condensed development timeframe. Fast-tracking development of new innovations was an essential part of our strategy during COVID-19. Resources for development and testing of new solutions were quickly re-prioritized in order to maximize speed to market of new solutions needed to expand upstream capacity. These solutions involved adding upstream channels into already fairly limited spaces in the DOCSIS radio frequency (RF) return path spectrum and implementing PMA/Octave for improved efficiency of DOCSIS 3.0 upstream performance.

Upstream channel capacity is always a challenge for cable systems limited to a 5-42 MHZ DOCSIS RF return path. The typical 5-42 MHz DOCSIS return path is built with four contiguous channels at a 6.4 MHz channel-width and 64 QAM modulation roughly in the 14-40 MHz range. This is typically the maximum configuration utilized to date in most systems and enables approximately 123 Mbps of total upstream capacity. After removing all time and physical layer overhead, the usable MAC layer data rate is approximately 86 Mbps.

In order to meet the new demands on upstream capacity, qualification and testing work for the addition of a fifth and sixth upstream was ramped up. These channels would be placed in spaces above and below the four existing DOCSIS upstream channels as able depending on the channel lineup within a given cable system (Figure 8). A fifth upstream channel with 1.6 or 3.2 MHz channel-width was successfully deployed to most locations at the upper end of the 5-42 MHz range yielding a gain of 5-10% of upstream capacity, depending on channel-width. CMTS SGs at 85% utilization were effectively reduced to approximately 77-81% utilization with the addition of a fifth upstream channel. While this does not seem significant, it essentially "buys time" to complete a more impactful but more difficult-to-implement solution like a node split while striving to maintain good customer experience. A sixth upstream was also tested and deployed on a limited basis. Residing below the four existing DOCSIS upstream channels, a sixth upstream yields another 5-10% of upstream capacity but requires some changes to current DOCSIS RF return path channel lineups in most systems as well as implementation of Octave for DOCSIS 3.0 upstream.

**Figure 8 – Example DOCSIS Upstream Channel Lineup With Fifth and Sixth Upstream Channel** (*Source: Comcast Next Generation Access Engineering)*

Regarding Octave, this was also an effort requiring accelerated development in order to provide additional upstream capacity. Originally built to support DOCSIS 3.1 downstream, Octave is an artificial intelligence (AI) platform which leverages data collection and analytics to optimize capacity based on the performance characteristics of a cable plant (Figure 9). Channel modulation can be dynamically adjusted up to a maximum of 4,096-QAM for downstream based on changing plant conditions for the DOCSIS 3.1

downstream. Without Octave, a least common denominator approach was in place typically using no more than 256 or 1,024-QAM modulation for all CMTS SGs thereby limiting potential capacity gains. Octave enabled an average gain of approximately 36% for downstream capacity. With updates to the Octave policy, we expect to be able to increase that capacity another 8% in the future.

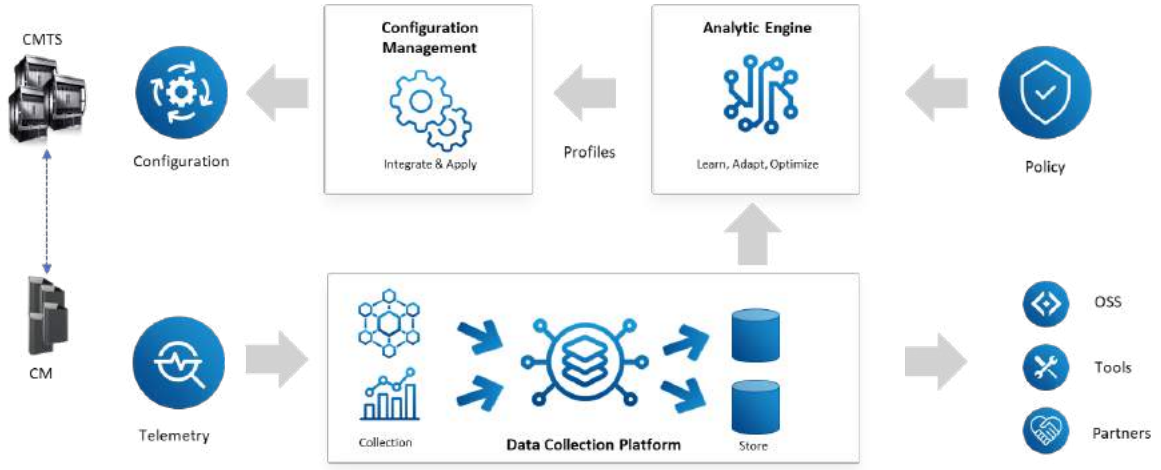

**Figure 9 – Octave High Level System Diagram** (*Source: Comcast Next Generation Access Engineering)*

Long term, the plan was to always modify Octave to be used to enable more capacity for DOCSIS 3.0 upstream. COVID-19 was the impetus to accelerate the required development work and testing. At a high level, Octave operates the same way between DOCSIS 3.1 downstream and DOCSIS 3.0 upstream in that it leverages AI and automation to optimize capacity throughput given cable plant performance. The big difference though is with regard to how capacity is optimized. For DOCSIS 3.0 upstream, capacity is gained by improving mini-slot efficiency. Mini-slots are units or blocks of time used in DOCSIS upstream communication. The goal of the CMTS is to make every mini-slot productive. Depending on how various upstream parameters are configured, there may be wasted mini-slots and therefore sub-optimized data transmission. Octave was successfully leveraged for DOCSIS 3.0 upstream to evaluate the upstream parameters and optimize mini-slot utilization based on plant performance. More mini-slots are then made available for more data transmission and therefore more effective capacity. Coupled with the addition of the fifth and sixth DOCSIS upstream channels where able, Octave enabled an average gain of approximately 20%. The MAC layer data rate for the baseline four upstream channel configuration increased from 86 Mbps to 103 Mbps consistently for over 98% of CMTS SGs.

Development efforts were also accelerated on Comcast's capacity management platform known as Enterprise Capacity and Facilities (ECAF). To facilitate the need to rapidly plan and execute capacity mitigation work, modifications were developed and implemented to add new functionality to ECAF in a short amount of time. Capacity augmentation plans, for example, would normally be entered into ECAF one at a time. To help accelerate the process, bulk entries were enabled, thereby reducing the time it took for capacity engineers to submit capacity mitigation plans. Time spent on associated documentation and administrative steps was also reduced to accommodate the much larger volumes. Daily reporting functionality was added to enable more timely and granular tracking of highly utilized SGs. This allowed teams to more quickly react to hot spots and evaluate post-mitigation effects. Automated creation of capacity mitigation plans was an existing function that was simply adjusted to a higher threshold to help manage the volume of active plans and focus on the more highly utilized SGs.

Node split planning and implementation is a key element of most capacity management programs. Depending on the specific type of split required, there are opportunities to fast-track work when circumstances require it. More simple node decombines are low-cost and easy-to-execute with little labor required and little (if any) infrastructure work. Adding optics to existing segmentable node housings is another relatively low-cost effort with a reasonably low amount of labor that can be executed fairly quickly. Construction-based node splits are relatively high-cost and labor intensive and typically require more time. Nonetheless, resources can be shifted away from other priorities, like new plant builds and metro Ethernet fiber construction, for example, and focused strictly on construction-based node splits. Node split construction permit approvals can be fast-tracked with municipalities in the interest of supporting good services to communities. Comcast effectively leveraged most of these solutions to increase node split production by 100% from normal business as usual (BAU) levels during the COVID-19 event.

Like node splits, DOCSIS channel adds are also a key part of capacity management normally. This has typically been supported over time by implementing better compression on both broadcast and narrowcast video, and then migrating available spectrum to DOCSIS. Once spectrum is available, it is fairly easy to implement on the CMTS platforms at a reasonable cost. Unfortunately, there may not be a viable means to recover further spectrum to support DOCSIS capacity near term. There may be longer term dependencies, such as conversion of video from QAM to IP-delivery. For the upstream signal path specifically, there may not be an ability to activate more DOCSIS spectrum without a costly plant upgrade. Despite the challenges, DOCSIS channel adds can easily be fast-tracked when able to make a practically instant impact on capacity utilization. As mentioned previously, adding a fifth upstream adds approximately 5-10% of capacity depending on channel-width and modulation configuration. This effectively results in a reduction of utilization of ~4-9%. Adding eight 6 MHz downstream channels to an existing 32-channel SG reduces utilization by 18-23% on average.

Regardless of the type, most capacity work requires some amount of hardware and software investment. This is where solid communications and relationships with a company's finance and procurement organizations come into play. Vendor relationships are also a crucial part of the overall supply chain. Normal planning should be in place to set internal budget forecasts and provide some degree of material forecasting and revenue planning for vendors. Rapid increases in node splits and DOCSIS channel additions drive the need for more hardware and DOCSIS licensing sooner. Capital was efficiently accelerated to support higher volumes of work needed. Vendors mobilized resources to support the higher demand even amidst challenging workplace restrictions. Not surprisingly, acceleration of hardware and software is most successful when a proactive site-level plan in is already in place. The effort is mostly a matter of accelerating existing plans and making slight adjustments where needed.

The numerous capacity solutions and efforts described here have proven successful in mitigating highly utilized CMTS SGs. From its peak in mid April, upstream SG utilization was reduced approximately 70% by early July. Likewise, downstream SG utilization was reduced approximately 90% by early July and lower than pre-COVID-19 levels tracked in February (Figure 10).

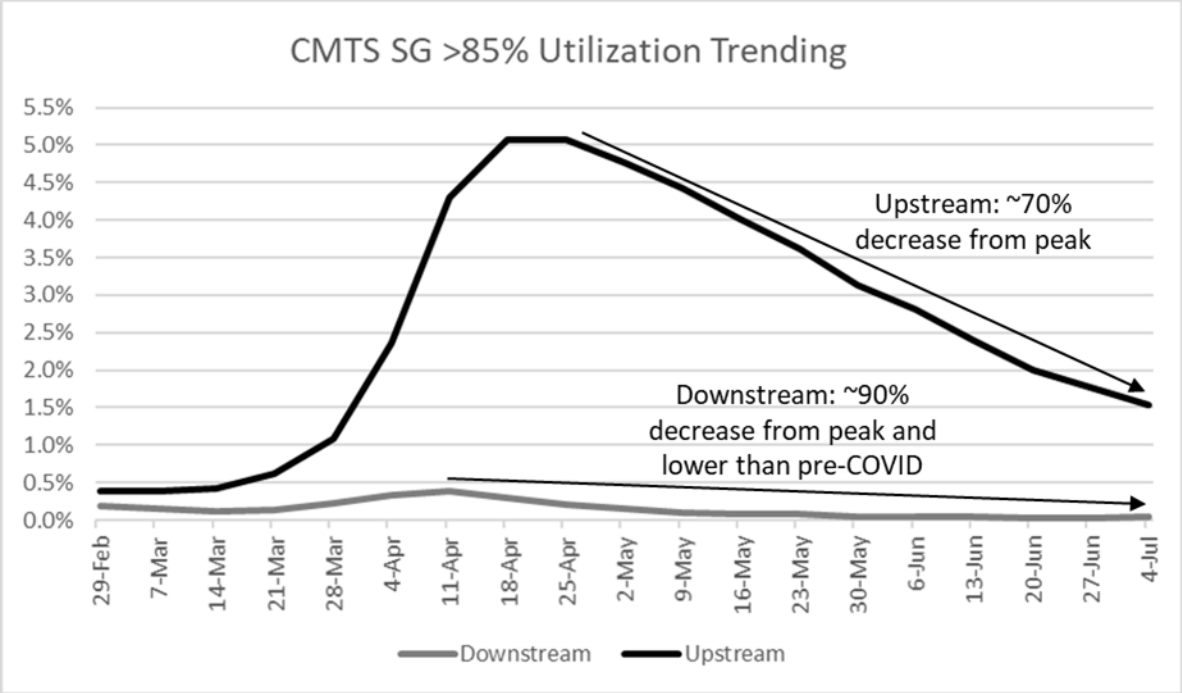

**Figure 10 – Highly Utilized CMTS SG Trending** (*Source: Comcast Capacity Management)*

## 5. Conclusion

COVID-19 is inarguably one of the most impactful and disruptive events in recent world history. Much of the world's population has been forced to react and change lifestyles in an effort to mitigate the spread and effects of the virus. Many of these lifestyle changes required people to work and school from home at a scale never before observed. This resulted in massive increases in network traffic on service provider networks in many areas. For MSOs, this increased traffic manifested itself as higher and in some cases much higher utilization on CMTS SGs potentially causing impact to customer service and experience.

Much was learned from the COVID-19 event in terms of how to successfully manage the access network and ensure good customer service. Above all, a solid capacity management program with the right people, processes, and tools is fundamental at all times and not just when a pandemic hits. It is too late to put such a program in place when that happens.

A good capacity management program should have a bias toward proactivity. It should strive to maintain some amount of available capacity at all times to account for sudden increased demand on the network. There is simply never enough time to react to sudden events that impact network utilization. This necessitates the need implement proactive capacity efforts, particularly around predictive traffic forecasting and capacity planning. This is not suggesting that timing for events like COVID-19 can be predicted. Rather, understanding the growth potential of nodes and CMTS SGs in different geographic areas based on historical behavior allows capacity management teams to appropriately plan some amount of proactive capacity with the ability to adjust quickly if needed.

Proactive deployment of capacity naturally follows from predictive traffic forecasting and planning. Normally high growth hubsites are likely to be the most impacted during an event that drives a rapid increase in utilization. Capacity plans for hub sites need to take into account this potential for growth.

More aggressive and proactive capacity solutions like deep fiber or plant upgrades should be deployed into sites with higher growth. Lower growth sites may be fine with less aggressive solutions. In most cases, proactively deployed capacity will be sufficient to handle extreme events that drive rapid increases in network utilization. In others, additional reactive measures may be required. Either way, there is no chance for success without proactive capacity in some form.

As an event unfolds driving significant network utilization growth, capacity management programs need to implement a variety of reactive measures building from a foundation people, processes, and tools that should already be in place. Reactive measures start with enhancements in reporting such as scorecards and dashboards to better identify problems and prioritize capacity mitigation work. Altogether new reports may need to be developed using existing or new data feeds. Development resources may need to be shifted to focus on building new functionality in reporting and tools.

Once impacts from suddent increases in network utilization are better understood leveraging enhanced reporting and data, efforts can be made to accelerate and prioritize capacity work. Fast-tracking development of new innovations such as Octave are effective ways to rapidly deploy additional upstream capacity especially to areas with high utilization without any additional hardware or physical work required. New functionality in capacity management platforms like ECAF enables higher velocity of capacity solution execution.

Acceleration of existing capacity plans like node splits and DOCSIS channel adds are extremely effective and generally easy to execute depending on the specifc circumstances for a given node, CMTS SG, or hub site. Node split volumes were doubled at Comcast as part of efforts to accelerate capacity. Additional or accelerated purchasing of hardware and software may be needed.

Solid partnership with finance, purchasing, and vendor teams is needed here. Rapid execution of physical work in support of capacity solutions requires commitment and dedication from construction, operations, and government affairs teams to name a few. Ultimately, victory in the battle against rapid growth in network utilization happens when all teams and organizations come together on the aligned goal to accelerate capacity,

Hopefully, we will not see another pandemic like COVID-19 for a very long time. But, the reality of the matter is that unforeseen events of varying magnitude and impact will always happen. That's life. For those events that drive significent impact on service provider networks even if only on a limited scale, the lessons learned from the COVID-19 about capacity management will always be valuable and applicable.

# Acknowledgements

I would like to thank all of the Comcast capacity management, engineering, and operationsteams and partners for their hard work, effort, and relentless passion.  Their perseverence was key to successfully managing capacity during extreme circumstances.

I would also like to ackowledge the great work done by Dan Rice, Vice President of Access Engineering at Comcast Cable, and the extended Octave team for their efforts in rapidly adjusting focus to develop and test new upstream capacity solutions for accelerated deployment in response to extreme network growth incurred after lock-downs imposed at onset of COVID-19 .  Dan's team enabled the accelerated deployment of fifth and sixth DOCSIS upstream channels in the 5-42 MHz DOCSIS return path. Additionally, Dan's team was able to successfully modify and launch PMA/Octave for DOCSIS 3.0 upstream capacity optimization.

# 1. Introduction

The world as we know it in cable is about to change.

Today's cable operators are tomorrow's mobile operators

This is being driven by a multitude of factors. For one, it is a way of significantly increasing revenues. All the cable broadband customers have cell phones and are often paying two different service providers, one for wireline and one for wireless. Does that really make sense?

Remember the telephone network? That country wide collection of twisted pair copper and T1 lines? It does not exist anymore. Telephony is an application that runs over an IP network. There is no Wi-Fi network. Wi-Fi is a radio gateway that exists at the end of an IP network that provides end point connectivity.

Today, we still have separate and distinct mobile and cable networks. But not for long. These too will soon also become applications running over an IP network. As mobile moves to 5G and deploys small cells running at higher frequencies, that small cell will become a Radio Frequency (RF) gateway that converts between wireless and a wireline IP network with traffic tunneled to a 5G core (5GC).

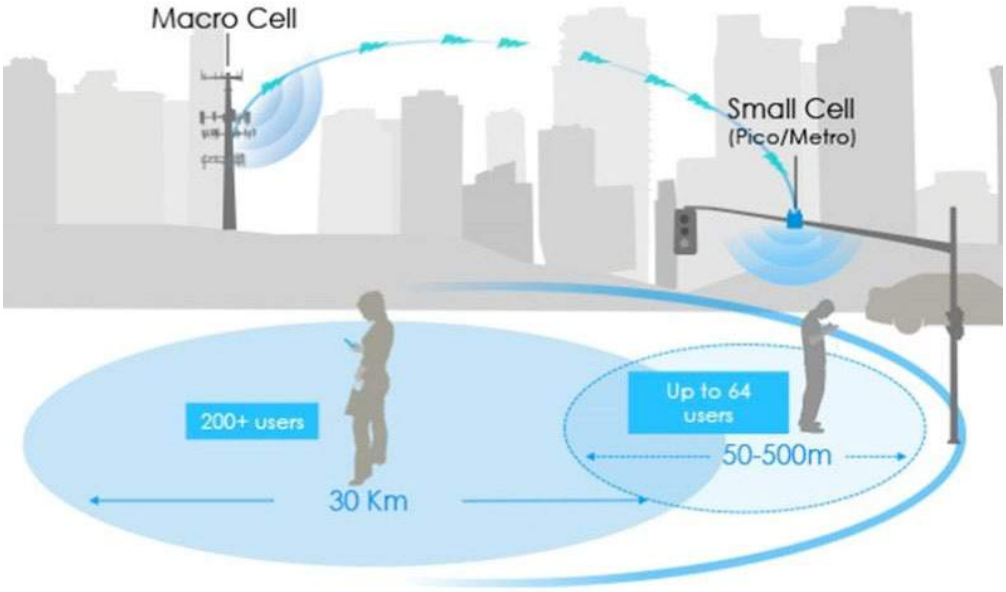

**Figure 1 – Small Cell Deployment Model**

The same is true with cable. DAA (Distributed Access Architecture) [1][2] nodes are simple RF gateways that convert between digital fiber and RF over coax. This results in fiber to the neighborhood and DOCSIS to the door. With DAA, there is IP over Ethernet over fiber, followed by IP over Ethernet over DOCSIS over coax, followed by IP over Wi-Fi or Ethernet.

This leads us to another important premise.

Behind every great wireless network is a great wireline network

Every radio that creates its part of the mobile wireless network must be connected to a wireline network. In Figure 1, we see the deployment model published by the city of Danville, CA [1]. Notice that the small cell coverage is a fraction (0.2% to 2%) of the macrocell coverage. That is a big difference.

How many small cells will it take to provide the equivalent coverage of a macrocell? How will those get connected? What is the impact to cost? Those are the questions we will tackle in this white paper.

# 2. Small Cells per MacroCell

## 2.1. CBRS Quick Primer

Going forward, a very important frequency band of interest to the cable and mobile industry is the Citizens Broadband Radio Service (CBRS) which is a 150 MHz band located between 3550 MHz and 3700 MHz. This RF region is also known as band 48.

The CBRS spectrum is allocated amongst three tiers. The first tier and highest priority are the incumbents like the US Navy and they get first use. The second tier is a licensed spectrum known Priority Access License (PAL) and is composed of operators who have bought local spectrum in the lower 100 MHz through a system known as the Spectrum Access System (SAS). The third and lowest priority tier is unlicensed (which means it is free) known as General Authorized Access (GAA). GAA is composed of 80 to 100 MHz of spectrum that is dynamically allocated out of the 150 MHz CBRS band. This is where "Private LTE" will exist.

CBRS spectrum tends to get allocated out in sub-bands of 10 MHz. Sub-bands can be combined together. As an example of performance, an example outdoor small cell radio would have 40 MHz max RF bandwidth, 200 Mbps max throughput with one-watt Effective Isotropic Radiated Power (EIRP). That works out to 5 bits/Hz. Note how well 100 Mbps to 200 Mbps throughput matches to a DOCSIS CM.

## 2.2. Small Cell and Macrocell Coverage

**Macrocell on a Tower** **Small cell on a Lamp Post**

**Figure 2 – Macrocell versus Small Cell Sites**

Radio coverage depends on three fundamental factors:

- Frequency
- Power
- Height and physical interference

The higher the frequency, the higher the propagation loss and hence the smaller the coverage area. Higher frequencies generally tend to experience higher loss from objects in the path of propagation. The higher the power, the longer the propagation. And the higher the antenna, the less likely it will have physical interference from tree, hills, and walls.

Macrocells tend to be lower in frequency, higher in power, and mounted at higher heights. Small cells tend to be higher in frequency, lower in power, and mounted at lower heights. These combined factors drastically lessen the coverage ratio of a small cell compared to a macrocell. Some typical installations are shown in Figure 2.

There are other factors to be sure such as modulation and error-correction that impact channel capacity and toleration to distance, but they are more secondary factors.

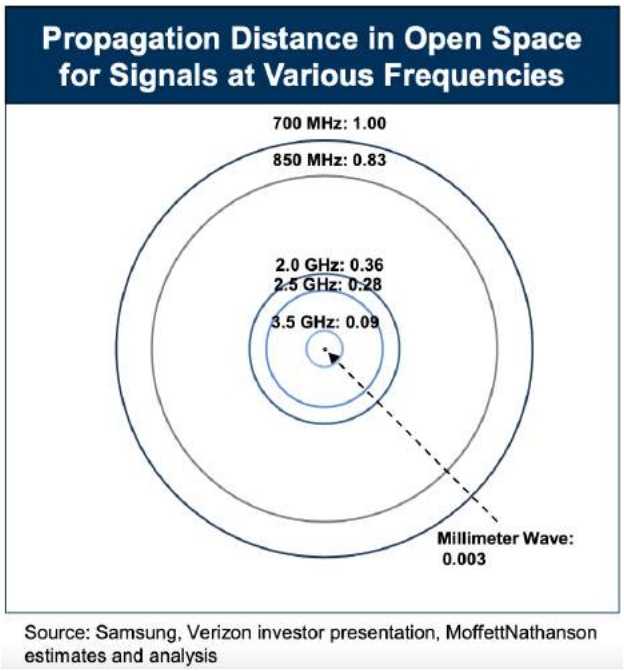

**Figure 3 – RF Cell Radius Comparison**

Figure 3 shows the ratio of a macrocell radius to a small cell radius [4]. The cell radius at 700 MHz is normalized to one. The frequencies at or adjacent to 700 MHz are used for Long Term Evolution (LTE) mobile systems. The values from Figure 3 are also shown in Table 1.

**Table 1 – RF Cell Radius Comparison**

| Band | Service | Cell Type | Relative Radius |
|---|---|---|---|
| 700 MHz | LTE | macrocell | 1.0 |
| 3.5 GHz | CBRS | small cell | 0.09 |
| 28 GHz | mmWave | small cell | 0.003 |

MoffetNathanson states that the numbers are just illustrative; they assumed the same power level and antenna height for each spectrum band. When compared to Figure 1, where the ratio was 0.2% to 2%, the numbers in Table 1 which are based on free air may actually be optimistic. This means in practice, with lower heights and lower powers, the relative radius may be lower and the calculated small cell count will be higher.

Conversely, small cells can take advantage of the latest technologies including beam forming and MIMO to extend their reach. It also makes a big difference whether the small cells are deployed on a strand-mount in a crowded downtown area or in a rural area or a rooftop or hilltop. Still, it is important to start somewhere to establish a baseline, and then that baseline can be adjusted up or down.

With these data points and some high school algebra, we can calculate how many small cells it would take for an equivalent macrocell footprint.

## 2.3. Mathematical Model I

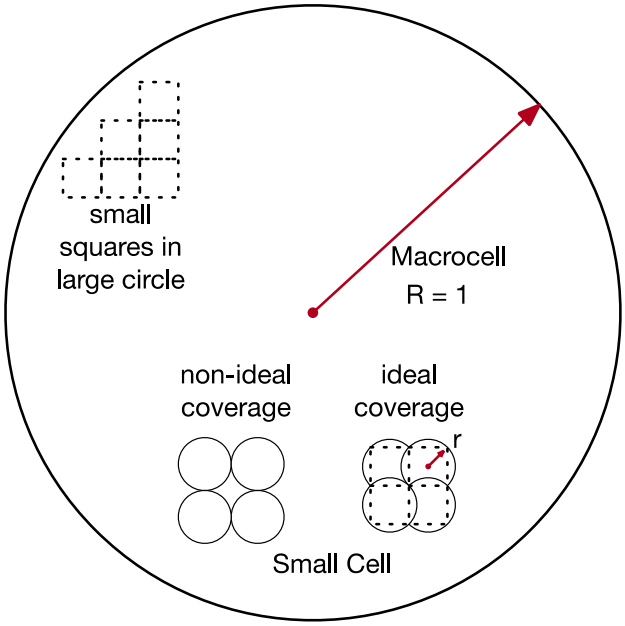

**Figure 4 – Model of Small Cell per Macrocell (Max)**

The following is a mathematical model of how many small cells it would take to achieve 100% coverage equivalence to a macrocell. The analysis assumes free air, so real-world results will vary.

The models in this white paper are derived here and do not reply on previous literature.

Let's first assume that a cellular radio cell RF coverage is a perfect circle. It is not enough to divide the area of the small circle of the small cell into the large circle of a macrocell since this would assume no overlap. Circles that have no overlap also have gaps in coverage as shown in Figure 4. Instead, if we assumed a maximized square inside the small circle, then the squares can then be tiled to create 100% coverage.

In practice, there is almost always either too much overlap of cell radius, resulting in some loss of coverage efficiency, or not enough overlap, resulting in gaps of coverage. Also, the macrocell itself is overlapping or gapping with other neighboring macrocells. None the less, this model provides a starting point where the optimized configuration which can then be adjusted up or down, based on deployment considerations.

The following should bring back pleasant memories of high school algebra. If those memories are more of a nightmare, then just skip this section. I won't be offended.

Let's define:

R = Radius of the macrocell

r = radius of the small cell

The coverage of the macrocell area, based on a large circle, is:

$$macrocell\ coverage = \pi R^2 \qquad \textit{formula (1)}$$

That was easy. Now the next part. The coverage of the small cell area is based on a maximum sided square inside the small circle. The radius of the small circle is equal to the distance from the center of the square to the corner of the square. That radius is part of a small triangle in the corner of the square. This is shown in Figure 5.

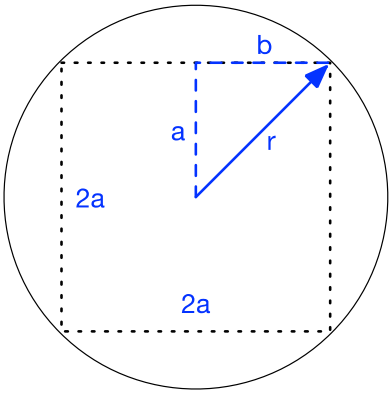

**Figure 5 – Coverage of a Small Cell with Ideal Overlap**

The Pythagorean Theorem provides the length of the triangle side.

$$a^2 + b^2 = r^2$$

If b = a, then

$$a^2 + a^2 = r^2$$

$$2a^2 = r^2$$

$$a^2 = {}^{r^2}/_{2}$$

$$a = {}^{r}/_{\sqrt{2}}$$

The length of the side of the square is twice this value.

$$box\ side = 2a = {}^{2r}/_{\sqrt{2}} = \sqrt{2}r$$

The area of the square, and hence the small cell coverage we are looking for, is the square of the box side.

$$small\ cell\ coverage = (2a)^2 = \left(\sqrt{2}r\right)^2$$

$$small\ cell\ coverage = 2r^2 \qquad \textit{formula (2)}$$

We can now compute the ratio of macrocell coverage, formula (1), to small cell coverage, formula (2).

$$\#SC\ per\ MC = {macrocell\ coverage}/{small\ cell\ coverage}$$

$$\#SC\ per\ MC = {\pi R^2}/{2r^2}$$

$$\#SC\ per\ MC = {\pi}/{2}\left({R}/{r}\right)^2 \qquad \textit{formula (3)}$$

If R is normalized to 1, then we get a simplified version that looks like

$$\#SC\ per\ MC = {\pi}/{2r^2} \qquad \textit{formula (4)}$$

## 2.4. Mathematical Model II

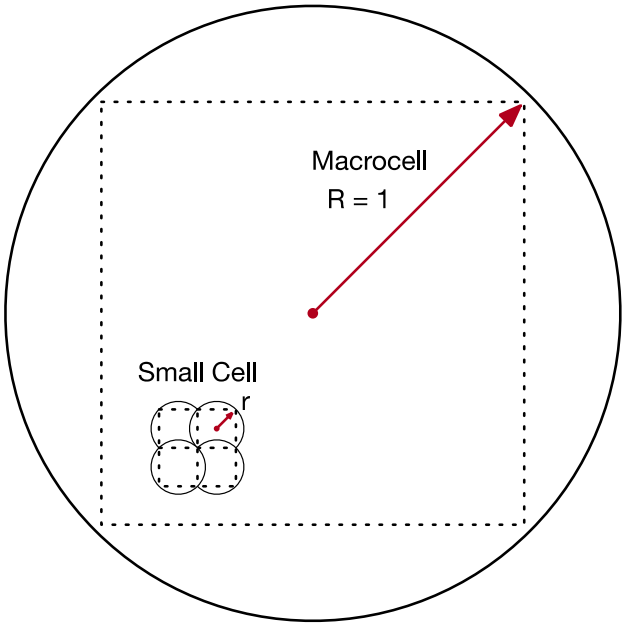

**Figure 6 – Model of Small Cell per Macrocell (Min)**

In the previous section, we placed overlapping small cells into a macrocell radius. To be a bit more optimistic, what if that macrocell was also was just perfectly overlapping with other macrocells. Then, the calculation would simplify to small squares filling a big square. This approach provides a range between two extreme cases – one with no overlap and one with perfect overlap.

Formula (2) provided the area of a square based on its radius. This can be applied to

$$\#\ SC\ per\ MC\ min\ = {\pi R^2}/{\pi r^2}$$

$$\#SC\ per\ MC\ min = \left({R}/{r}\right)^2 \qquad \textit{formula (5)}$$

Normalizing the larger radius R to R = 1:

$$\#SC\ per\ MC\ min = {}^{1}/_{r^2} \qquad \textit{formula (6)}$$

There, that was not so bad. Now let's plug in some numbers and see what happens.

## 2.5. Small Cell Radios per Macrocell Example

Now let's take the values from Table 1 and insert them into formula (4) and formula (6) to get Table 2.

**Table 2 – RF Cell Radius Comparison**

| Band | Service | Cell Type | Relative Radius | # Radios |
|---|---|---|---|---|
| 700 MHz | LTE | MC | 1.0 | 1 |
| 3.5 GHz | CBRS | SC | 0.09 | 125 to 200 |
| 28 GHz | mmWave | SC | 0.003 | 110,000 to 175,000 |

The results in Table 2 state that for the CBRS band which located at 3.5 MHz, it would take about 125 to 200 small cell radios to match the coverage of one LTE macrocell at 700 MHz. Note that the results in Table 2 have been rounded off in alignment with rules for significant figures.

28 GHz is the band of interest that Verizon is currently using for 5G mmWave [5]. It would take 110,000 to 175,000 small cell radios to replace one LTE macrocell. That's a lot of radios. Even at only 1% coverage, that would be 1750 radios.

Now, if the strategy is to not achieve 100% coverage and to also rely on the LTE network as a background network, then these numbers can be scaled down. Conversely, small cells that operate at a both a higher frequency and a lower installation height than LTE towers are also more likely to get blocked by trees or walls. Under those circumstance, the number of radios in Table 2 may actually need to be increased.

## 2.6. Cost Implicatons

Depending upon business needs, operators may not need a 100% replacement of the macrocell. For example, when AT&T used LTE femtocells to supplement LTE, those femtocells were only needed in areas of weak or no coverage. Conversely, as US cable operators enter into mobile virtual network operator (MVNO) arrangements, they will be financially motivated to put CBRS small cells in areas where there is any significant amount of traffic so that they do not have to pay back carriage charges to their MVNO partner that manages the LTE network. The flow of money from roaming fees for an MSO acting as an MVNO and its host network partner is shown in Figure 7 which is from the discussion in [6].

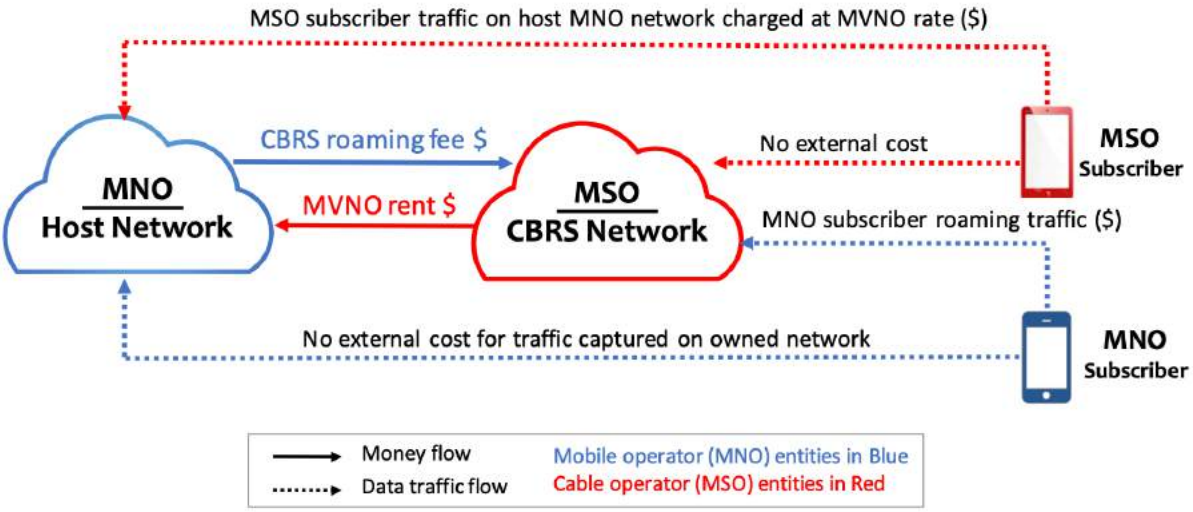

**Figure 7 – MVNO Roaming Costs**

This paper has shown that it can take 200 CBRS small cells to cover an area equivalent to the area covered by one LTE macrocell. Even if the goal was only 50% coverage, that is still 100 small cells. And if the goal was to build a new radio network that cost equal to or less than the LTE network, then the install cost of each small cell would have to be 1% of what it took to install an LTE macrocell.

So, it has to be almost free.

A typical macrocell installation cost is $20,000 to $50,000 to rent a tower, get permits, trench and run power and fiber, and mount a radio. If economics need to drop to 1% with 50% coverage, then the small cell deployment installation would have to be $200 to $500 per small cell. Is that possible? Well, that is about the cost it takes to deploy a residential CM if there is a truck roll. So, if a small cell was as cheap and easy to deploy as a CM, then yes. As a case in point, Wi-Fi is almost free to install because it is included in the CM install. So, if a small cell cost were also included in the CM cost, it could see similar cost structures.

So, it can be almost free.

There is another important consideration, and that is xhaul. Xhaul refers to backhaul, midhaul, or fronthaul. For LTE, the eNB generates GTP (GPRS Tunneling Protocol) encapsulated packets ready for backhaul. In 5G, the equivalent gNB is divided into an RU (Radio Unit), DU (Distributed Unit) and a CU (Centralized Unit). DOCSIS can support either the backhaul from a gNB (RU+DU+CU) or midhaul from a RU+DU. DOCSIS does not have the bandwidth or latency to support fronthaul from an RU.

Today's macrocells often have a fiber backhaul. If you had to deploy 100x more radios at 100 new locations, is it cost effective to run 100 more fibers? If the broadband cable team could not justify the cost of the additional fiber for residential broadband, how is it that the company business case changes such that it works for small cells?

These economics are now driving cable operators such as Charter and Telecom Argentina [7], Cogeco [8], Shaw [9], Cox [10], and Altice [11] amongst others, to deploy mobile backhaul over DOCSIS. I have also previously discussed this business case in my blog post [11].

In the next section, we will look at some real-world results between using coax direct connect versus running fiber a few blocks.

# 3. Small Cells per HFC Fiber Node

## 3.1. DOCSIS-Attached Small Cells

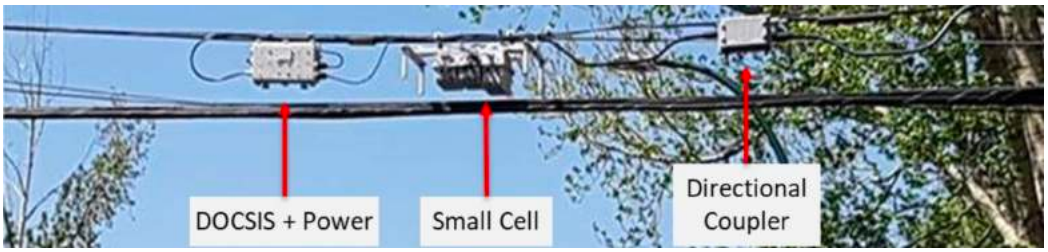

**Figure 8 – Strand-Mount Small Cell Deployment**

Macrocells have traditionally been on towers and backhauled by fiber, but there are not enough towers or fiber for the new 5G small cells.

Cellular radios require the following basic requirements:

1. Site/Location
2. Power
3. Backhaul

The following requirements are also useful based upon the installation

4. Timing support
5. Low latency

DOCSIS over HFC (Hybrid Fiber Coax) supports all these requirements. HFC passes 93% of USA HHP and provides strand mount or in-home. Altice, Cox and Shaw have already deployed strand-mount small cell Xhaul over DOCSIS (>20,000).

Figure 8 from [13] shows a typical strand mount small cell. There is a directional coupler that couples power and RF from the coax plant. This goes to a strand mount CM which then connects to a strand mount small cell.

It should be noted that the HFC plant has to be designed to allow for the power drop across the directional coupler and for the additional power draw of the small cell as well as the additional power dissipation of the cable modems and small cells.

An alternative mounting configuration is to locate the small cell in the subscriber residence. This again provides location, power, and backhaul.

So, what does this cable plant look like, and how many small cells would a fiber node in an HFC plant be expected to support?

## 3.2. Real World Case Study

A study was done by Shaw Communications in 2019 [9] that compared a fiber backhaul solution to a coax/DOCSIS backhaul solution for a set of 15 small cells deployed across 13 node locations. In this study, only time and construction costs were considered. The deployment diagram is shown in Figure 9.

For fiber backhaul case, fiber was run (yellow lines) from the small cell location (red stars) to the node location and connected to available dark fiber. Only the cost of this short fiber run was included. The cost of the fiber from the node to the hub was not included. If it was, the difference would even be more dramatic.

For the coax backhaul case, the small cells were powered from the HFC plant with a 10' coax drop and a connected with a bidirectional coupler. The strand mount small cells did not require any permitting or have any access issues and no civil build was required.

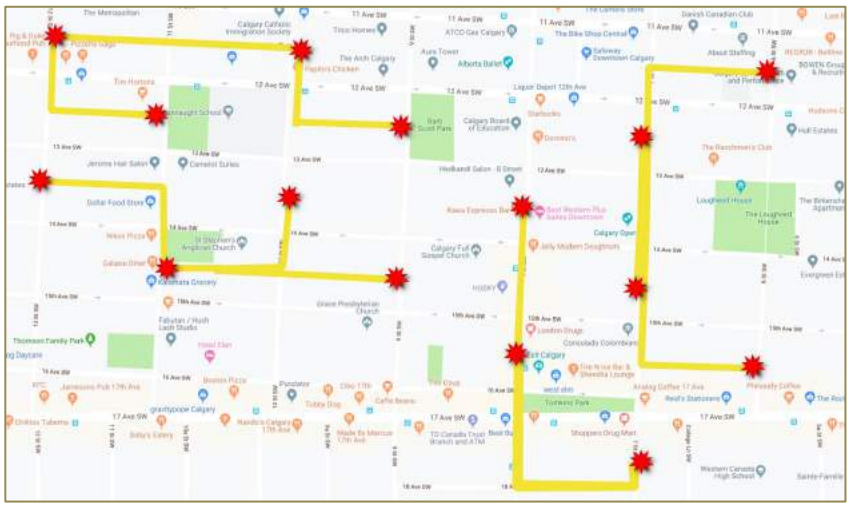

**Figure 9 – Real World Analysis of xHaul**

The results are in Table 3 and are astonishing. The cost of installation dropped to 1% and the time-to-deploy became 20x faster. Using an available HFC plant instead of new fiber was a clear winner.

**Table 3 – Real World Case Study of xHaul over DOCSIS**

| Backhaul Option | Broadband Fibers | Construction Cost | Time to Build |
|---|---|---|---|
| Fiber | 1 | $182,500 | 4-6 months |
| Coax | 0 | $1,500 | 1 week |
| **Savings** | | **1% of the cost** ***99% reduction*** | **20x Faster** ***95% reduction*** |

Now that we have established a deployment and business case baseline, let's figure out how many small cells might fit into an HFC plant.

### 3.3. Mathematical Model

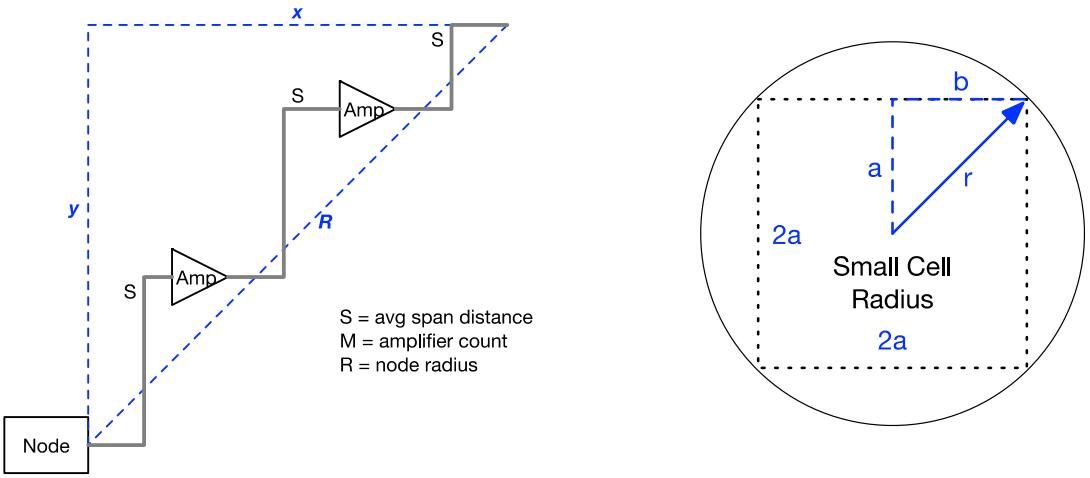

**Figure 10 – Model of Small Cell per HFC Optical Node**

So how many small cells would it take to cover an area that is currently covered by a DOCSIS service group that is associated with one fiber node?

That depends on the size of the plant. HFC plants are described by their amplifier depth. An N+0 plant is a node plus zero amplifiers. An N+5 plant is a plant with a node followed by five consecutive amplifiers. Note that the signal path in an N+5 plant is constantly being split, which creates the area coverage. Thus a single node could have as many as 25 to 40 total amplifiers across all paths.

Let's define the following variables:

S = the average span distance between node-to-amp and amp-to-amp

M = the number of amplifiers in the longest cascade, as in "N + M"

R = The resulting node radius

A diagram of an N+2 plant is shown in Figure 10. A radius line "R" is drawn from the node to the end of the last cable segment. Note that a two-amplifier system has three cable segments. Coax is usually run down streets which leads to rectangular shapes. It can be seen that the horizontal segments fully line up with the "x" axis and the vertical segments fully line up with the "y" axis. These observation leads to the following formula:

$$x + y = (M + 1)S$$

So, the total horizontal "x" and vertical distance "y" is equal to the average segment length "S", times the number of segments which is one more than the number of amplifiers "M". If we assume that the triangle is an isosceles triangle where x = y, then:

$$x + x = (M + 1)S$$

$$2x = (M + 1)S$$

$$x = {(M+1)S}/{2} \qquad \textit{formula (7)}$$

Checking back in with Pythagoras, we also know from Figure 10 that

$$x^2 + y^2 = R^2$$

Since y = x

$$x^2 + x^2 = R^2$$

$$2x^2 = R^2$$

$$x^2 = {R^2}/{2}$$

$$x = {R}/{\sqrt{2}} \qquad \textit{formula (8)}$$

Equating formula (7) and formula (8) yields

$${R}/{\sqrt{2}} = {(M+1)S}/{2}$$

$$R = {(M+1)S}/{\sqrt{2}} \qquad \textit{formula (9)}$$

Formula (9) calculates the radius of a fiber node serving area. An alternate form of formula (9) is

$$R = 0.707(M+1)S \qquad \textit{formula (10)}$$

As a rule of thumb, that means the radius of an HFC plant is approximately equal to 70% of the total span length.

Formula (9) can be put into formula (3) to calculate the number of small cells that are needed to cover the fiber node serving area.

$$\#SC\ per\ FN = {\pi}/{2}\left({R}/{r}\right)^2$$

$$\#SC\ per\ FN = {\pi}/{2}\left({(M+1)S}/{\sqrt{2}r}\right)^2$$

$$\#SC\ per\ FN = {\pi}/{4}\left({S}/{r}\right)^2(M+1)^2 \qquad \textit{formula (11)}$$

Formula (11) calculates the number of radios in a fiber node serving area for an average amplifier span distance of S, and amplifier count of M, and a small cell serving radius of r.

What we can observe from this formula, is that when the small cell radius is equal to the node segment distance (S = r) on a deep fiber plant (M = 0), only one small cell radio is needed per node. This makes sense.

As HFC plant grows beyond N + 0, the number of radios required is proportional to the square of the number of amplifiers plus 1. If the small cell radius is larger or smaller than the span distance, then there is also an additional relationship to the square of the ratio of the span distance, S, to the small cell radius, r, as well.

### 3.4. Small Cells per Fiber Node Example

Formula (9) and formula (11) use the average span length of an HFC plant. The average span length depends on how many spans there are. So, to construct a table of results, we need to modify the average span length for each N+M plant design. Here is the methodology used to construct Table 4.

- An N+0 HFC plant can actually run the fiber node output amplifier closer to saturation and achieve longer distances. This example will add 10% length for N+0.
- An N+M HFC plant will have an initial span length. A typical value is 1000' (300m).
- Each amplifier adds to the noise floor which reduces MER, so the span length is shortened slightly for each subsequent span. This is a minor consideration as each plant is unique. The number of tap groups per span also may change. The table uses a manual entry for total plant length for each case and calculates an average.

Note that in deployment, the fiber nodes that drive an N+M plant are often called BAU (Business as Usual) nodes and the nodes that drive an N+0 plant are often called SHO (Super High Output) nodes.

To make comparisons easy, the small radius has been chosen to be 50%, 100% and 200% of the initial span length. This will illustrate the squared relationship of the span length to cell radius ratio and the number of small cells needed.

The results of this study are in Table 4. There are some interesting takeaways. First, there is not one rule for all deployments. It is not that one small cell per fiber node always works. Instead, it depends upon the size of the HFC plant. There could be anywhere from one to 20 or even 80 small cells required to cover a plant area.

Does that make sense? Well, if you had a 500 HHP (households passed) N+5 node with 50% of those households being cable-mobile customers, and the small cell was located inside the house, then that would be 250 small cells per node. So, by that argument, the results in Table 4 are conservative or should be looked at as strand-mount numbers.

Note that these calculations are for free air, which implies line-of-site with no hills, trees, or walls, so more small cells are likely to be needed in a real-world deployment.

**Table 4 – Small Cells per Fiber Node**

| | | Small cell radius r: | | 500 | 1000 | 2000 |
|---|---|---|---|---|---|---|
| M Amps | Total Span | Node Radius | Avg Span | # radios | # radios | # radios |
| 0 | 1100 | 778 | 1100 | 4 | 1 | 1 |
| 1 | 2000 | 1414 | 1000 | 13 | 3 | 1 |
| 2 | 2850 | 2015 | 950 | 26 | 6 | 2 |
| 3 | 3700 | 2616 | 925 | 43 | 11 | 3 |
| 4 | 4600 | 3253 | 920 | 66 | 17 | 4 |
| 5 | 5460 | 3861 | 910 | 94 | 23 | 6 |
| 6 | 6300 | 4455 | 900 | 125 | 31 | 8 |

The caveats are all around height of the small cell, trees, hills, and walls, as well as HFC plant design. Individual results will vary. However, the basic principle remains.

Reach out to me on LinkedIn or email if you would like a copy of these calculations in a spreadsheet.

### 3.5. Kindred Spirits

Here is a philosophical-techno thought.

The mobile small cell RF downlink and the HFC node RF downstream both try and do the same thing, and that is to propagate RF through a media. One does so through the air and the other through coax. The one through the air runs into trees, hills, and walls, while the one on coax goes past trees, over hills, and through walls.

Both cover a serving radius. The one that propagates through air goes wherever air goes, which is everywhere. The one that propagates through coax goes only where coax goes, which is strand, underground coax and customer premises wiring.

Both have the same propagation limitations based on frequency and power, although that for a given frequency, the loss per unit distance is much higher through coax than that through air. They both use similar electronics and modulations, and sometimes similar frequencies. Where the coax distribution loses power to taps, the air distribution loses power to trees and walls.

Each has similar goals but has its own struggles and accomplishments.

So, it makes some sense, that the radius of a small cell might be on the order of a span of coax.

Note that coax express runs are one dimensional with no taps and go longer distances. They do not apply to this study or analogy.

# 4. Is DOCSIS Up to the Job?

## 4.1. CBRS Use Case for HFC

A common misconception is that if you deploy many small cell radios, the network bandwidth required is an aggregate the sum of all that bandwidth. CBRS radios can support 50 Mbps per 10 MHz of spectrum (advanced configurations may get to 100 and 200 Mbps by combining spectrum). If you take a serving area that is supported by one large radio at 100 Mbps and replace it with 50 small radios, each at 100 Mbps, would you need 50 radios x 100 Mbps = 5 Gbps of data capacity? No, you would not.

This is about capacity versus connectivity. Small cells, like CMs, need to be at a certain location like a home to provide coverage, regardless if the network is idle or active. When replacing one macrocell with say 50 small cells, it is about coverage and connectivity first and capacity second. Those 50 small cells will connect to the same end points – that would be you and your family, with your smart phones, laptops, and IP set-top boxes.

For these reasons, not all small cells will operate at peak capacity at the same time. We see that with cable modems deployments where there is a large over-subscription of offered data bandwidth with respect to the actual data bandwidth used. This also occurs in fiber installations where the backhaul interface from a fiber OLT has a typical concentration of 20:1. This is traffic engineering at work. Small cells can take care of this over-subscription as well. The inverse of over-subscription is concurrency. A 20:1 over-subscription would support 5% concurrency.

We also know that the radios peak throughput decreases with distance. That means that different users will get different peak throughputs. In traffic engineering, that is managed with an average throughput per user. A more reasonable way to calculated network loading of small cells (SC), taking into account 75% average throughput per user and a generous 20% concurrency (5:1 over-subscription), would be:

$$SC\ Network\ Loading = \#\ SC * 100\ Mbps\ peak * \ avg\ capacity * \ concurrency \quad \textit{formula (12)}$$

$$SC\ Network\ Loading = 50\ SC * 100\ Mbps\ peak * 75\%\ avg\ capacity * 20\%\ concurrency$$

$$SC\ Network\ Loading = 750\ Mbps$$

Now, if those small cells are added to the home network with existing subscribers and existing devices, this bandwidth may already be accounted for and very little increase may be seen. If those small cells are located outdoors and pick up new subscribers and new devices, then 750 Mbps is about one-half of an OFDM channel backhaul.

As a gut check, the CMs in deployment typically provide 100 Mbps to 1 Gbps of service. If in a deployment of 200 devices (CMs), you added 50 more devices (small cells) at 100 Mbps, the difference would be incremental, not monumental.

## 4.2. The Future Potential of DOCSIS Capacity

A common question often comes up. Does DOCSIS have enough bandwidth to support a small cell infrastructure? DOCSIS has two growths paths. These are spectrum and segmentation. Let's look at both.

Figure 11 (original by author) shows select downstream and upstream spectrum usage for DOCSIS 3.1 and the upcoming DOCSIS 4.0 [14]. Today the downstream spectrum is shared with legacy MPEG-TS

video, so the entire downstream is not available for DOCSIS. Actually, a good way to increase DOCSIS spectrum is through legacy video reclamation.

Today's deployed DOCSIS downstream paths are 1 to 2 Gbps in capacity. Many downstream paths are still 750 MHz or 862 MHz. With an increase to full DOCSSI 3.1 1218 MHz spectrum and with video reclamation, this could provide a 200% to 400% increase in data capacity. With DOCSIS 4.0, there can be an additional 40% to 60% increase. With these numbers multiplied, the downstream has a 10x growth potential in data capacity.

The upstream spectrum is defined by a 42 MHz return path with about 100 Mbps. An upgrade to 204 MHz would be a 1400% increase and DOCSIS 4.0 could more than double that again. So, the return path has considerably more than 10x growth to go.

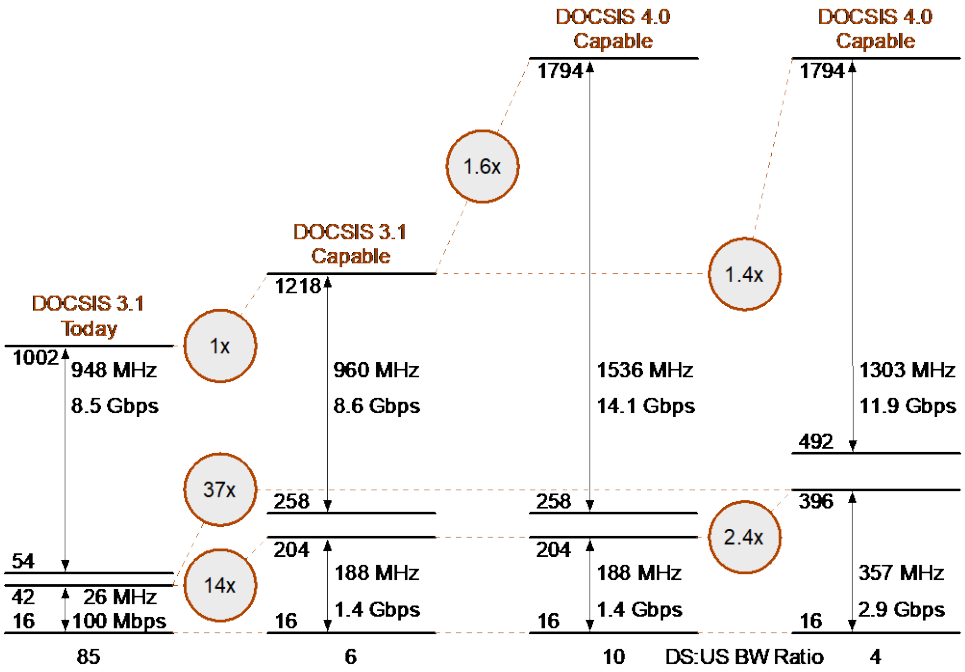

**Figure 11 – DOCSIS Plans for Spectrum Increases**

Then there is segmentation. A 500 HHP N+5 plant could be segmented down to 50 HHP N+0. These are approximate numbers as each plant is unique. However, this represents another 10x increase in capacity.

Combining the 10x growth available through spectrum and the 10x growth available through segmentation, there is 100x growth potential available in the DOCSIS HFC network.

CBRS small cells are on the order of 100 to 200 Mbps, depending upon spectrum usage and distance. Cable Modems today are 100 Mbps to 1 Gbps in the downstream. So, roughly, another small cell load is like another CM load, or less, on the network.

DOCSIS could even be extended to 3 GHz one day in the downstream using distributed gain amplifiers (DGA). This was first discussed in [15]. As an alternative to extending the downstream frequency range, DOCSIS 4.0 permits the use of full-duplex technology which would allow up to a 5 Gbps in the 5 to 684 MHz return spectrum to co-exist with the 10 Gbps in the 108 to 1218 MHz forward spectrum downstream spectrum. This technology was laid out in the following papers [16][17][18][19][20][21][22].

So, yes, DOCSIS does have enough bandwidth to handle small cell distribution.

## 4.3. SYNC – 1588 and SyncE Support

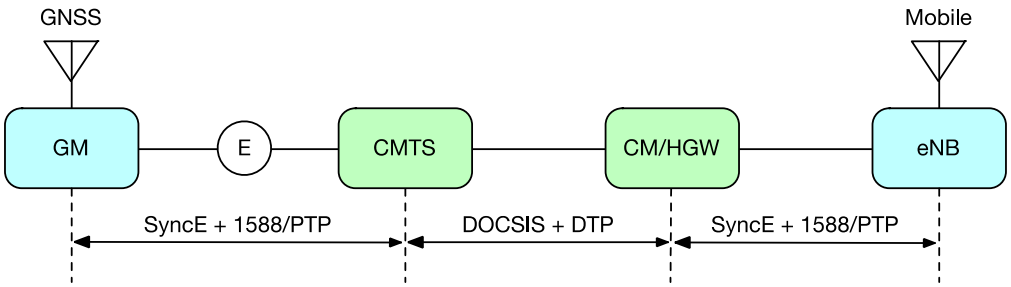

**Figure 12 – SYNC Operating Model**

In addition to the three basics of location, power, and backhaul, small cells that are located indoors and do not have access to the GNSS network, will need timing support. This is often done by having a synchronized wireline network using Synchronous Ethernet and IEEE-1588. Support for these two protocols are being designed into the DOCSIS protocol and product. The approach is shown in Figure 12.

DOCSIS is a highly accurate synchronous network. DOCSIS 3.1 defines a method to derive the DOCSIS timestamp from a Precision Time Protocol (PTP) slave port. DTP (DOCSIS Time Protocol) is used to measure the time difference across the DOCSIS network. The CM implements a PTP master clock and uses this time difference and the DOCSIS timestamp to regenerate an accurate PTP clock. This has been standardized at CableLabs [15] [24] and is described further in [25][26][27].

LTE small cells at 700 MHz are frequency division duplex (FDD) based and can use ranging to work around timing. This allows LTE FDD small cells to not have to worry about network timing. CBRS small cells at 3.5 MHz typically uses TDD (Time Division Duplex) which requires tight timing synchronization of +/- 1500 ns from radio to radio in order to prevent the radios from stepping on each other's transmissions.

## 4.4. LLX – Low Latency Xhaul

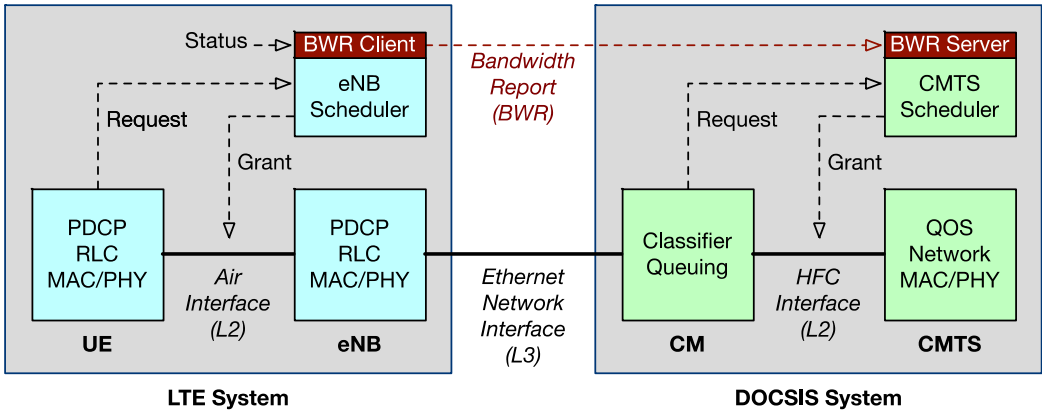

**Figure 13 – LLX Operating Model**

As mobile networks move to 5G, there is an interest in low latency operation. DOCSIS has a new protocol called LLX that pipelines the requests from the eNB/gNB to the CMTS scheduler so that packets do not have to re-request for bandwidth when entering the DOCSIS system. This will allow the DOCSIS system to have approximately 2 ms of equivalent latency. This is illustrated in Figure 13. This has been standardized at CableLabs [28] and is described further in [29][30][31][32][33].

# 5. Conclusion

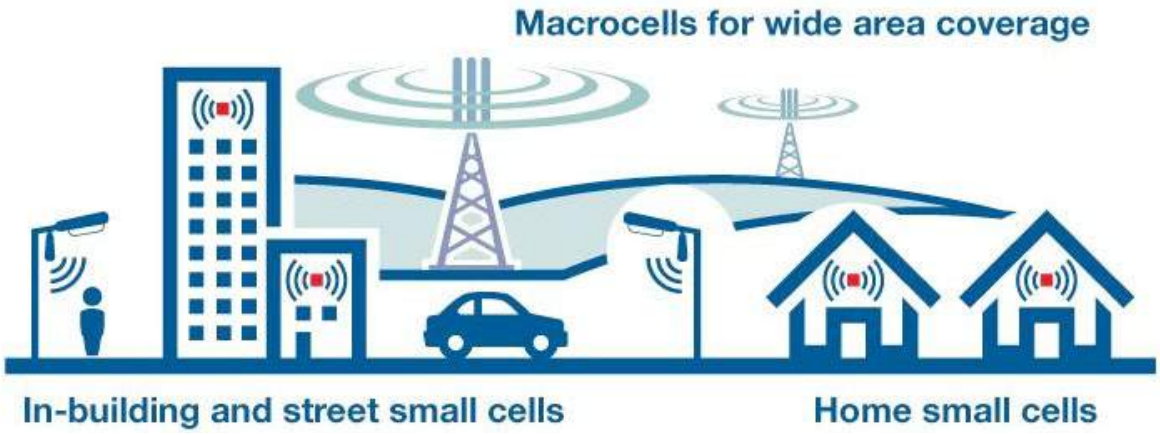

**Figure 14 – Macrocells and Small Cells in Deployment**

We started this paper with a deployment model from the City of Danville and we are ending with another diagram in Figure 14 also from the city of Danville, CA [1] . This diagram clearly shows that small cells will be located on poles, in buildings and in homes. Today's foreground macrocell based LTE network will become tomorrow's background network to fill in the gaps in the new 5G small cell architecture.

Here is a summary of the important formulas:

$$\#SC\ per\ MC = {}^{\pi}/_{2}\left({}^{R}/_{r}\right)^{2} \qquad \textit{per formula (3)}$$

$$\#SC\ per\ FN = {}^{\pi}/_{4}\left({}^{S}/_{r}\right)^{2}(M+1)^{2} \qquad \textit{per formula (11)}$$

*where:*

*R = larger radius of macrocell or node*
*r = smaller radius of small cell*
*S = average coax span between actives*
*M = number of amplifiers in an N+M cascade*

Here is a summary of the important points raised in this white paper:

- Today's cable operators are tomorrow's mobile operators
- Behind every great wireless network is a great wireline network
- The number of radios for CBRS can be 100x that of an LTE macrocell, and for mmWave, the number of radios could be 100,000x that of an LTE macrocell.
- This dramatically impacts deployment economics and makes the existing HFC plant and interesting choice for mobile backhaul.
- The number of small cells in an HFC plant is proportional to the square of the span count and the square of the ratio of span length to cell radius.
- DOCSIS has a 100x growth potential in downstream and upstream bandwidth
- The DOCSIS HFC network is a viable backhaul/midhaul network that can meet the location, bandwidth, powering, timing, and latency requirements of a small cell network.

## List of Figures

## List of Tables

# 1. Introduction

Streaming video represents nearly 80% of all traffic carried over the internet. It's growing by 22% each year [1]. Technological evolution in video compression, from MPEG-4/AVC [2] to HEVC [3], paired with techniques like Adaptive Bit Rate (ABR), to "right size" a video segment into multiple bit rates, represent some of the core building blocks that contributed to the huge marketplace success that is streamed video. However, a third building block is becoming necessary, to go a step further in both an improved, adaptive video experience, at the device end, and optimized bandwidth usage, to lessen network strain. Specifically, and considering the remarkable and mushrooming growth of IP video streaming, there exists a growing need for systems to leverage Content Aware Video Streaming solutions, like the one discussed in this paper.

In IP video streaming, video is typically generated at several bitrates, in order to accommodate the varying network bandwidth available between IP Video consumer devices and content delivery networks (CDNs) and varying consumer devices. Consumer devices will typically try to download the highest bitrate video possible that the device can support, with the intent of providing higher video quality to the viewer. Higher bitrate video segments for certain content do not necessarily translate to higher video quality -- if there is any improvement at all, it might be marginal. Acquiring higher bitrate segments when it does not really enhance user video viewing experience results in wasted network bandwidth. This wastage can be avoided by having the devices only download segments that would make a difference in video quality for the viewer. For the devices to do a quality-based download decision, they would need to be provided with info on the content in the segment. In this paper, an algorithm that determines if a segment is going to enhance viewer video experience is presented. This algorithm is based on video analysis without a full video decode of frames in the segment. This algorithm would need to be implemented at the content origination end and the generated info transmitted to consumer devices.

With the content information communicated in each segment, devices can then make a network bandwidth and quality based decision on the next segment to be downloaded. This would minimize network bandwidth usage and at the same time providing the highest video quality. The algorithm presented supports processing of live linear stream segments and would minimally impact the content generation workflow and therefore scalable. Included in this paper are results showing network bandwidth savings realized by this algorithm. This algorithm could also be used to reduce storage needs by only storing segments from a bitrate ladder that enhances video quality on various devices.

# 2. IP Video Architecture

At a high level, the IP Video architecture is as shown in the Figure 1 below. In this figure, the compressed or uncompressed video stream is transcoded into several streams (variants), each at different fixed bitrate, to accommodate the varying network bandwidth available between IP Video consumer devices and the content delivery network. The transcoded streams might be encoded using one of the MPEG compression codecs (MPEG-2[4], MPEG-4/AVC, HEVC). This is then packaged into one of the many streaming formats, for example MPEG-DASH [5], or HLS [6]. These are then placed on the Origin Server and IP CDN for delivery to IP Video clients. This would apply to both linear and on demand IP video.

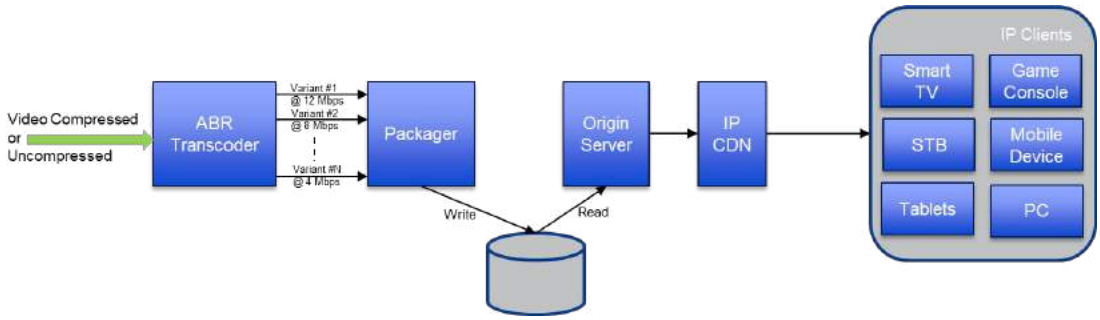

**Figure 1 – IP Video Architecture**

## 3. Segment Video Analysis

The IP Video variant streams shown in the Figure 1 are typically split into segments of a few seconds duration, and these segments across the variants are assumed to be time-aligned. The IP Video variant streams are part of a constant bitrate ladder as shown in Table 1, below:

**Table 1 – Constant AVC Video Bitrate Ladder**

| Resolution | Video Bitrate (Kbps) |
|---|---|
| 1920x1080 | 6000 |
| 1920x1080 | 4000 |
| 1280x720 | 3000 |
| 1280x720 | 2000 |
| 720x480 | 1600 |
| 640x480 | 1000 |
| 512x384 | 700 |
| 384x288 | 400 |
| 384x288 | 300 |

An IP Video consumer device traverses up and down this ladder, based on varying network conditions between it and the CDN. During stable network conditions the device might be playing segments from the 6 Mbps video stream but for some of these segments it might be of the same quality as the 4 Mbps segments, therefore the device could downshift to the 4 Mbps segments for those segments and then go back to the 6 Mbps segments when there is an actual gain in the video quality by doing so. By taking this approach network bandwidth usage is reduced. Similarly, in another scenario when the network condition improves after a degradation and the device sees that the network can sustain a higher bitrate, the device which is currently playing a 4 Mbps video stream would try to display a high quality video by moving up the bitrate ladder. In this case, it would try to download and play a 6 Mbps higher bitrate variant segment, even though the gain in the video quality by doing so may be minimal. So in both these scenarios, during the download process, if the device is told that downloading the 6 Mbps segment would result in a minimal video quality gain, then it could avoid the unnecessary download, which saves network bandwidth. Therefore, there is a need for an approach that can detect if a segment would enhance video quality and communicate that to IP Video devices. Also, with this information, the device could look at downloading the next higher bitrate variant segment that really would improve the user experience.

Similarly, when the network condition is worsening and the device is moving down the bitrate ladder, and if it is told that the next lower bitrate stream does not enhance quality, then it could select the one below it in the bitrate ladder, again saving network bandwidth.Video Analysis Algorithm Details

In this section, an encoded video analysis algorithm is detailed that determines if an IP video segment does not enhance video quality and is therefore optional to download. The results of this algorithm are then communicated to the IP video device, which would utilize it to determine the segments to download, in order to save network bandwidth and enhance video quality.

The algorithm analyzes all encoded video frames in a segment to determine if it is optional to download the segment. This is done in the following manner:

1. The compressed bitstream in the segment is first entropy decoded and inverse quantized to access the many frames in the segment and its compression details.
2. The frame type (Intra [I], Predictive [P], Bidirectional [B]) is determined for each frame in the segment. The frame type determines how that frame is going to be analyzed to determine its contribution to the segment relevancy.
3. If the frame is an I type, we determine the frame's compression ratio (defined as the number of bytes to represent the frame / the number of bytes to represent the compressed frame). If the compression ratio is less than a predetermined threshold, then this frame is marked as a frame with high detail and activity. If the compression ratio is low, it would mean that there are a lot of details in this frame and less redundancy.
4. If the frame is a P or B type, we again determine the frame's compression ratio. As with I-frames, if the compression ratio is less than a predetermined threshold then this frame is marked as one with high detail and activity. If the compression ratio is higher, then some of its compression attributes are analyzed to determine if it would still qualify as a frame with high detail and activity. The compression attributes that are analyzed are listed below:

    - *Number of skipped Macroblocks/Coding Unit (CU):* The number of skipped macroblocks in the frame is determined. If it exceeds a certain threshold, then it is counted towards the determination of a high level of detail and activity and is marked as a High Skipped MB/CU frame. A frame with a lot of skipped macroblocks indicates that there isn't much motion between this frame and its previous frames, used for motion estimation. A macroblock is the basic processing unit in AVC/MPEG-2, and the CU, in HEVC, is where the prediction type is decided, as well as which frames are skipped when their motion vector is zero and coefficients are zero.
    - *Partition (Prediction) block size:* A prediction block is the block split from a macroblock or coding unit that is used for motion estimation. This attribute determines the size of the prediction block that is the most widely used in this frame. If it exceeds a certain threshold, then it is marked as a Large Partition Block frame. A comparatively small size indicates a lot of details in the frame.
    - *Inter coded blocks count*: Determines the number of inter-coded blocks in frame. If the number of inter-coded blocks count exceeds a threshold, then it is indicated as High Inter-Coded Block Count frame. A low number of inter-coded blocks implies that there is a scene change, therefore unable to predict from reference frames.
    - *Motion vector component measure*: Determines motion vectors for each inter-prediction partition block in the frame and determines the 90% trimmed standard deviation of the motion vectors' horizontal and vertical components. The 90% trimmed standard deviation of the components is to ignore extreme values to give a better measure and is determined by ignoring the lower 5% and top 5% of the values. These vectors are

 

encoded differentially, with respect to predicted values from nearby vectors. If greater than a certain threshold, it would be considered a high MV measure frame. Large variations or standard deviations would indicate a lot of activity.

Note that the thresholds used for these compression attributes for P frames are different from those used for B frames, and these thresholds for P and B frames also factor in video frame rates and resolution.

The information gathered by analyzing these compression attributes is then used to determine if this P or B frame is a high detail and activity frame, as shown in Table 2, below:

**Table 2 – P/B Frame High Activity and Detail**

| High Skipped MB/CU | Large Partition Blocks | High Inter Coded Blocks Count | High MV Measure | High Activity/ Detail? |
|---|---|---|---|---|
| False | False | False | True | True |
| True | N/A | N/A | N/A | False |
| False | True | False | True | True |
| False | True | True | True | False |
| False | True | True | False | False |
| False | False | True | True | True |
| False | False | True | False | False |
| False | False | False | True | False |

Once all the frames in a segment have been analyzed using the approach detailed above, the percentage of high activity/ detail frames in the segment is determined. If this percentage is below a certain threshold value, then it is marked as a segment for optional download. So, when an IP video consumer device is trying to display a higher quality video by moving up the bitrate ladder and encounters this optional download segment, it would not download it, because there is no appreciable gain in video quality by doing so. It would, however, consider downloading a higher bitrate segment that is not marked as an optional download.

Table 3 shows the resultant bitrate ladder after the video for segment “n” has been analyzed, using the algorithm detailed in this paper:

**Table 3 – Bitrate Ladder after Video Analysis for Segment n**

| Resolution | Video Bitrate (Kbps) | Download for Higher Quality? |
|---|---|---|
| 1920x1080 | 6000 | No |
| 1920x1080 | 4000 | Yes |
| 1280x720 | 3000 | Yes |
| 1280x720 | 2000 | Yes |
| 720x480 | 1600 | No |
| 640x480 | 1000 | Yes |
| 512x384 | 700 | Yes |

| Resolution | Video Bitrate (Kbps) | Download for Higher Quality? |
|---|---|---|
| 384x288 | 400 | No |
| 384x288 | 300 | Yes |

This video segment analysis does not need to be done for all the video segments across the variants -- only those necessary to determine a high level of activity and detail for each segment time duration. For example, each segment duration could be 4 seconds across the variants. Since the encoded video analysis is done without a full decode, this algorithm does not add latency, in the case of linear video, or increase encoding time, in the case of non-linear video.

### 3.1. Enhanced IP Video Architecture with Video Analysis

An enhanced architecture that utilizes the algorithm detailed in this paper is shown in the Figure 2 below. The key difference between this and the architecture shown in Figure 1 is the addition of a functional block that processes the IP video segments and generates content-specific information sent to the client.

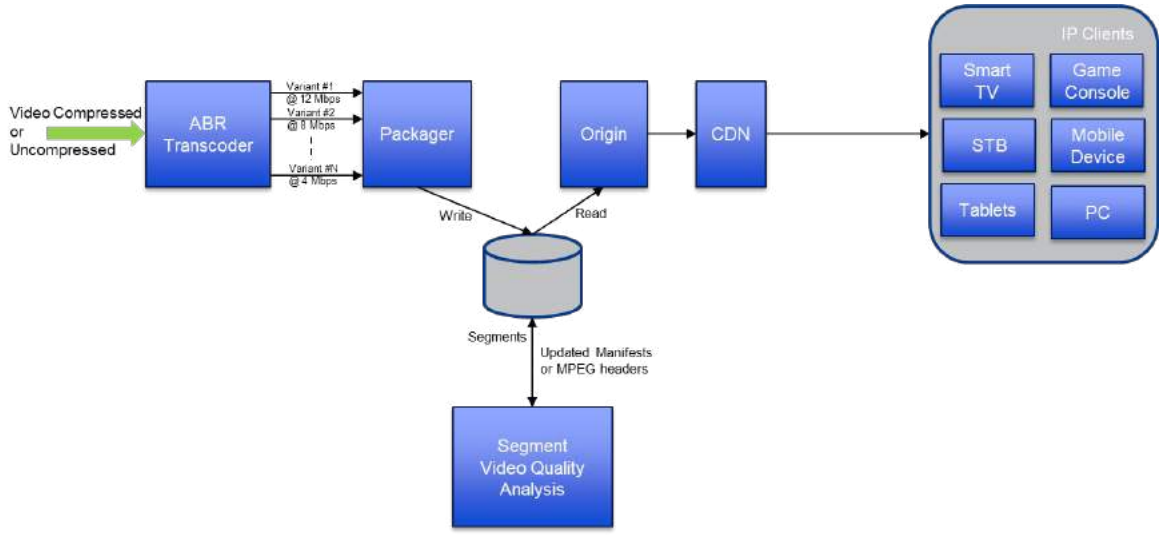

**Figure 2 – IP Video Enhanced Architecture**

## 4. Carriage of Optional Download Information

There are multiple approaches to send the optional segment download information to IP Video consumer devices.

One approach would be to signal those segments that are optional to download in the manifest files. For example, in the case of DASH, this would happen in the Representation element; in HLS this would happen in the Media Playlist. In the case of live linear, as the segments are generated, the optional

download information is determined and included in the updated manifest files. When signaled in the manifest, the consumer device could base its next download decision on this value.

Another approach would be to remove the segment that is optional to download from a Representation, in a DASH manifest file, or, in the case of HLS, to remove the media file URL from the Media Playlist.

Potentially one other approach would be to indicate the optional segment download information via fields in the segment. For example, in user data fields in the MPEG-2 Transport packet headers, or ISOBMFF m4s file box structures.

Please note that none of these are currently standardized.

## 5. Benefits

There are many benefits reaped by utilizing the Content Aware streaming solution described in this paper. Primarily by not downloading higher bitrate segments that does not necessarily provide a gain in video quality streaming network bandwidth usage is reduced. Lab studies have shown a reduction of 20%.

Since this algorithm identifies segments that do not contribute to higher video quality, one approach would be to not store those segments and instead point the consumer device to an alternate segment that has the same quality as this one. This would save storage in applications like Cloud DVR, Video On Demand and CDN. Another benefit from this is that since the segments are of smaller size during certain times, the downloads will be faster.

The algorithm detailed in this paper does not do a full decode of the compressed bits in a segment but does partial decode resulting a fast video quality assessment.

The intent of this solution is to not impact the existing transcoders and packagers but execute this algorithm on the content generated by packagers before they are made available to IP video consumer devices.

## 6. IP Video Network Bandwidth Utilization

Figure 3 shows instantaneous video bitrate when consumer device is downloading segments with and without using the solution detailed in this paper. The black curve plots the video bitrate when segments are downloaded without looking at the segment quality whereas the blue curve shows the bitrate when the consumer device downloads segments based on its quality. So, for example at Time 7 the device downloads a segment from a lower bitrate stream that has the same video quality as the segment downloaded at the higher bitrate indicated on the black curve. It is observed that the video quality is the same with the two type of downloads.

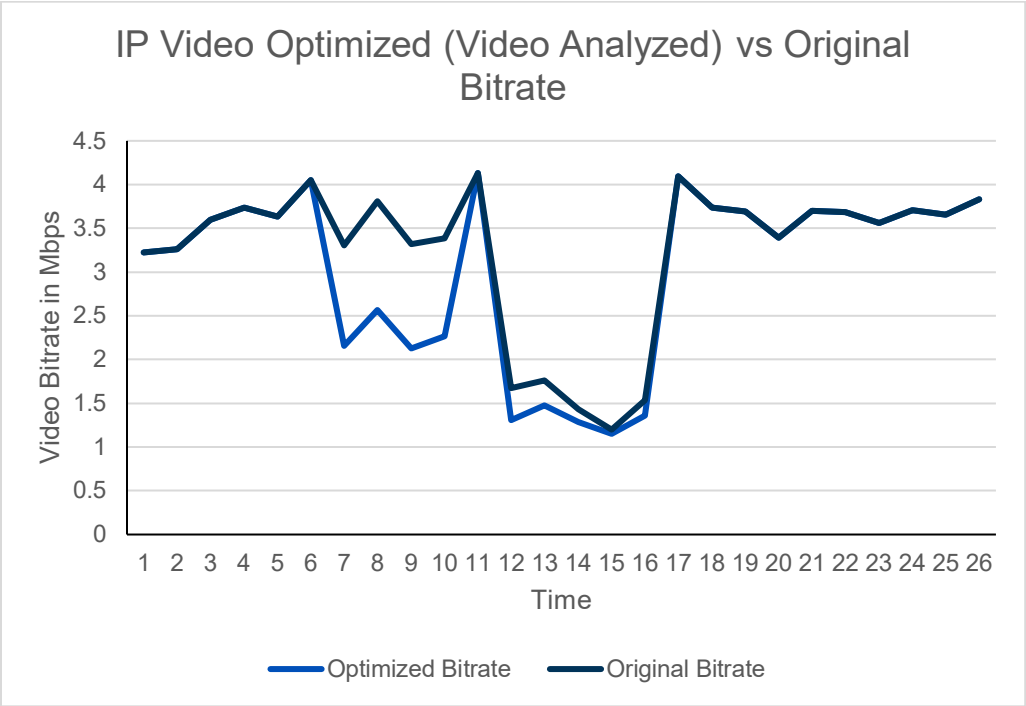

**Figure 3 – IP Video Network Bandwidth Utilization**

## 7. Conclusion

IP Video Streaming is widespread and consuming valuable network bandwidth – as in, almost 80% of all internet traffic. This traffic is expected to grow by 22% yearly. Considering this growth, it is important for systems to leverage Content Aware Video Streaming solutions such as this to optimize network bandwidth usage. In this paper an algorithm is presented that determines if an IP video segment is going to enhance viewer video experience. This algorithm, which analyzes encoded video without a full decode, in linear IP video. Also included are approaches to communicate an IP video segment's relevance to enhance viewer video quality to IP video devices. In addition to optimizing network bandwidth usage and adapting to changing network conditions, it also reduces storage requirements and enhances consumer video viewing quality.

## List of Tables

## 1. Introduction

The signal quality on HFC networks can degrade over time, from an impairment perspective, if not proactively maintained. Comcast manages hundreds of thousands of miles of network throughout the world in which we experience a wide array of conditions that can degrade the performance of the network. From connections loosening and cracks forming, to lines getting cut, destructive energy and signal impediments are part of maintaining modern networks. Early detection, mitigation, and routing fix agents efficiently, to the right location, can not only improve customer experience but also enable operational efficiency.

Adaptive Profile Management Application (PMA) systems continue to be deployed to manage downstream and upstream network capacity and network stability. However, and perhaps ironically, PMA systems can mask the degradation of the network, as an inherent function of the optimization and mitigation process. It therefore has become increasingly important to develop systems that can support automated Proactive Network Maintenance (PNM) to reduce the impact of network impairments on customer experience and enable the highest possible capacity and performance.

In this regard, Comcast has invested heavily in data platforms and data science functions across organizations, to become more data driven and to incorporate Machine Learning (ML) approaches into the network. In this paper, we will describe the use of Convolutional Neural Networks (CNNs) to identify network impairments within DOCSIS 3.1 (D3.1) channels with a high degree of accuracy.

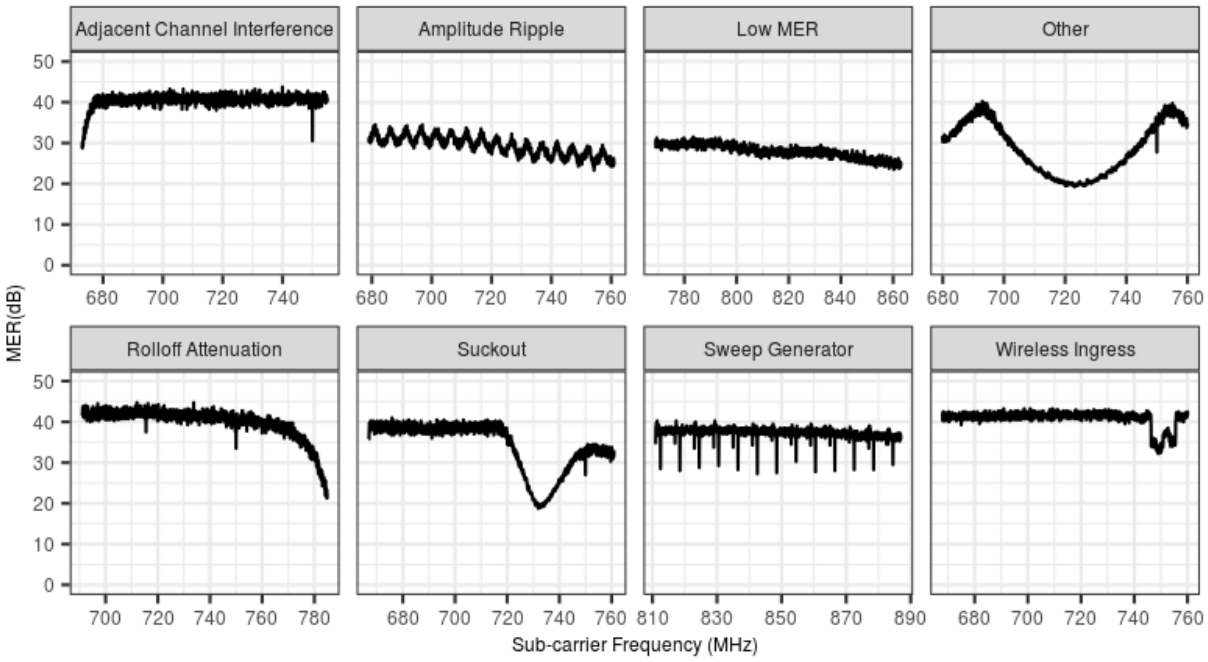

**Figure 1. Different types of impairments seen in D3.1 OFDM Channels**

It is beneficial to classify the various network impairments (shown in Figure 1) as they may warrant different responses from techs in the field to enable fastest possible Mean Time To Repair (MTTR). In

addition, clustering of these impairments across geographic locations and network topology may be exploited to identify the root cause impacting multiple customers that share common points in the network. Note that the latter requires a second layer model to be built on top of the classification model described in the paper.

The model we describe improves on the rule-based approaches currently being used to identify Mobile Wireless Ingress and Sweep Generator patterns. Notifications from the current rule-based model for detecting Mobile Wireless Ingress are sent across a notification bus to other Comcast OSS tools, to ensure that technicians are dispatched to the right hubs, network segments, and homes to remediate issues. The rule-based approach also provides a baseline for evaluation for the ML approaches. We also developed a real time version of the algorithm that techs can use to check that issues have been fixed after remediation. The same workflow described in this paper could also be used with alternate CNN-based models.

## 2. Data Collection: OFDM Receive Modulation Error Ratio (RxMER)

The underlying data for the model comes from a data collection platform, which acquires telemetry from cable modems and CMTSs for various performance-related measures, as well as other characteristics, such as make, model, hardware and software versions. The API platform runs both on pre-determined intervals as well as on-demand to collect data from the entire access network. Real time use cases are typically focused to specific groups of cable modems or interfaces with higher periodic rates. The collection platform also provides synchronous and asynchronous API requests so that response from cable modems and CMTSs can be returned back to the consumer, sent on a message bus for multiple consumers, and captured into our data lake.

Comcast supports millions of D3.1 devices. The data collection captures high resolution Receive Modulation Error Rate (RxMER) data from these devices at regular intervals. The methods described to identify various impairments for OFDM Channels in this paper are based on this high resolution RxMER measure per subcarrier (as shown in Figure 1). Modulation Error Ratio is an important measure for consideration, as it not only picks up on core signal-to-noise (SNR) characteristics but also all signal imperfections. Therefore, high resolution (high frequency and per-OFDM subcarrier) captures of RxMER is the primary measure and focus for characterization of impairments.

## 3. Labels and Supervised Learning

Methods for training models with well labeled data sets are well established and vastly varietal. While initial attempts focused on non-supervised machine learning methods, such as clustering, to separate out impairments into similar groups, the results were not promising. Thus, we recognized the need to label a set of training data to be applied to supervised machine learning methods. Labeling can be labor-intensive activity that, in this paradigm, would also rely on subject matter experts to examine and classify the impairments based on their expertise. In order to make the labeling process robust, we developed a Pattern Labeling user interface (UI) that makes RxMER samples available to labelers. To help capture impairments, and given that a majority of RxMER samples do not have impairments, the sampling strategy focused on capturing samples with high variance over OFDM subcarriers. When presented, the labelers can examine and submit their assessment for the impairments within a few mouse clicks.

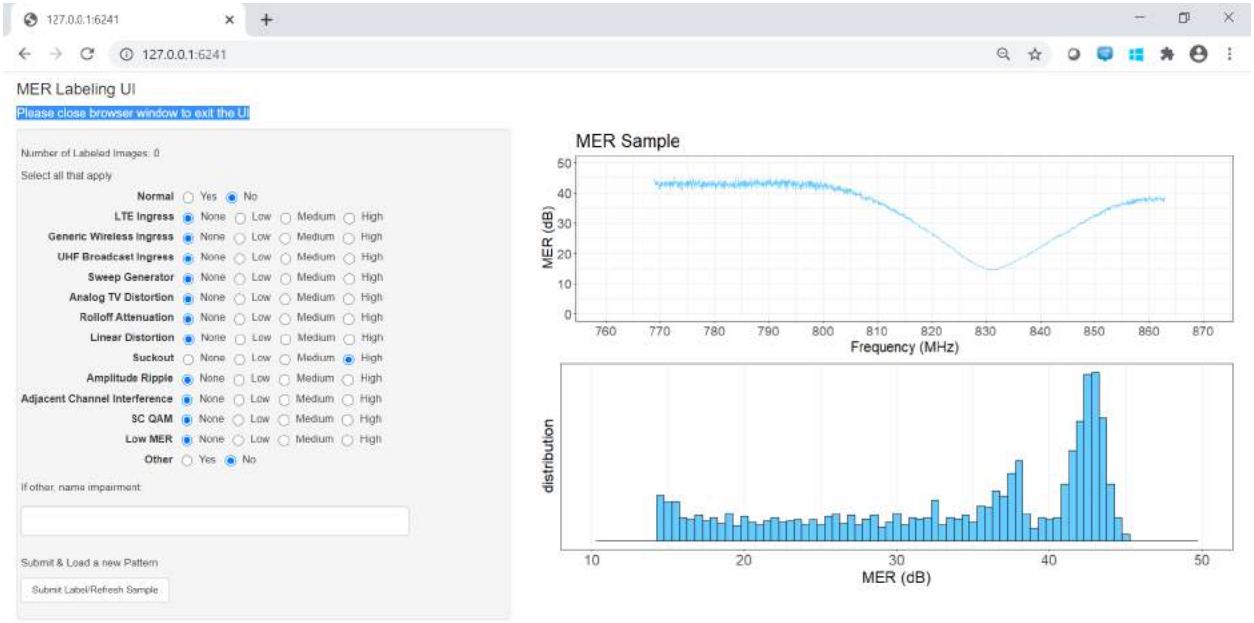

**Figure 2. Screenshot of the RxMER Pattern Labeling UI**

Labels are a critical component to building a good performing classification model. Given the significant value of enhancing capacity and improving customer experience by being able to identify and characterize specific impairments, we aimed for a crowdsourcing approach involving field technicians and other SMEs to generate labeled data using this UI. Once initial models are developed, we plan to pre-populate the Labeling UI with the impairments predicted by the different models to make the process more efficient.

D3.1 OFDM Channels are configured to extend from 24 to 192 MHz and often placed in the highest spectrum of the Hybrid Fiber Copper (HFC) network above the video and D3.0 channels. In many service groups, some portion of the OFDM channel is outside the HFC design, in what is often referred to as the "roll-off" spectrum. Given the size of the channels and where the OFDM channel may be located, it is possible that some cable modems could experience multiple impairments. Thus, the Labeling UI allows a sample to be labeled with multiple impairments. Also, when impairments exist, the level of severity (low, medium, high) needs to be specified. Future versions may allow for more nuanced severities. Note that characterizing severity will likely increase the number of training samples needed to build good models. The labeling effort is designed such that each sample would get multiple responses from different experts, to resolve conflicting labels and to build confidence in the label value.

For the models described in this paper, we labeled approximately 4,000 RxMER samples. Severity of the impairments was not considered while building these proof-of-concept models.

## 4. Data Preprocessing

OFDM channels in Comcast typically vary in width from 48-96 MHz. This results in an approximate array of 940-1880 RxMER sub-carrier measurements per cable modem, per poll. Since the algorithms in consideration of this paper require a fixed input shape, the following options were evaluated:

- Fixing the width of the spectra to 1,880 by padding the end point with the following options:
    - Zeros
    - The average MER value
    - The last MER value
- Fixing the width of the spectra to a set value (e.g. 900) and applying a smoothing function to transform the raw input to the fixed length input.

As will be seen in the results section, the option of fixed spectra width of 1,880 with average MER value performed the best in our experiments.

## 5. Model Evaluation

The model evaluation strategy uses the typical train/test split, with 80% of the approximately 4k labeled RxMER samples to be used for training, and 20% kept out for validation. Figure 3 shows the distribution of samples by impairment. About 1,400 of the sample are normal -- i.e. they contain no visible impairment -- while the rest are distributed over several categories. Figure 4 shows the distribution of number of impairments by sample. Approximately 60% of the samples have a single impairment.

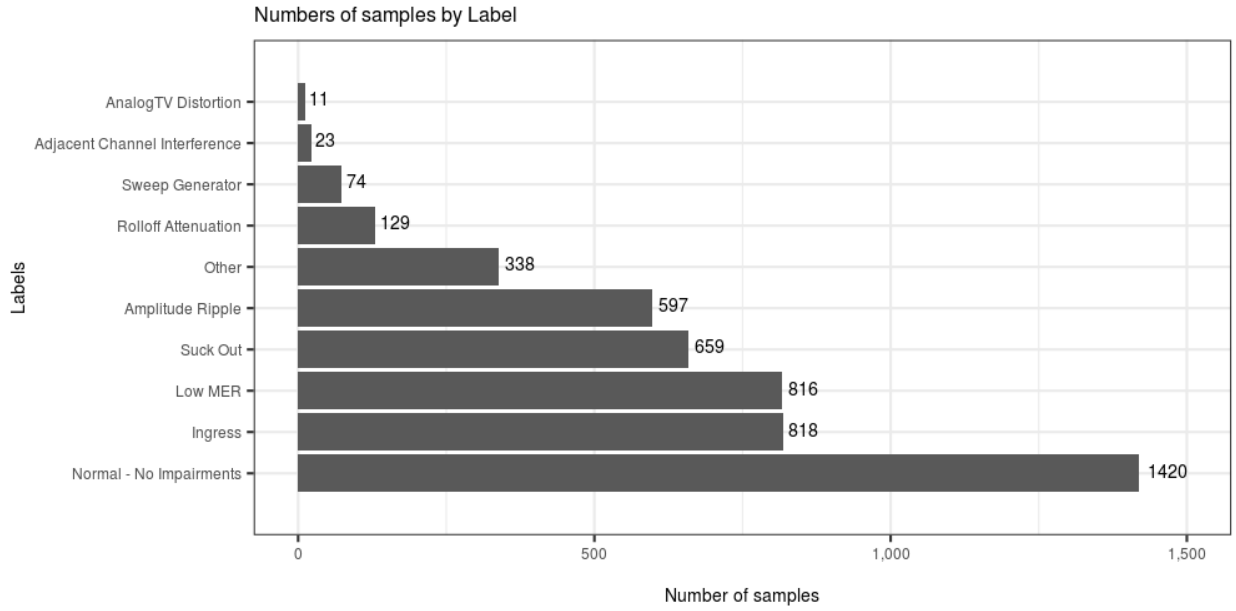

**Figure 3. Number of samples by label (impairment type).**

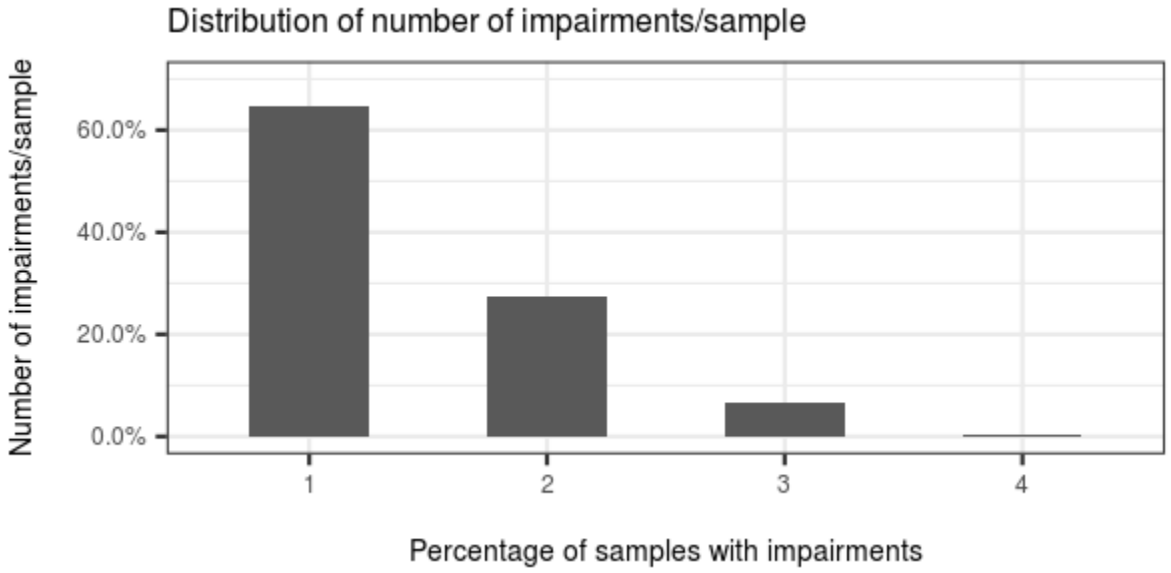

**Figure 4. Distribution of number of impairments/samples**

Since an RxMER instance for an OFDM Channel can have multiple impairments, detecting impairments is a multi-label classification problem. Predictions for an instance is a set of labels, and therefore the prediction can be fully correct, partially correct or fully incorrect. This makes model evaluation more challenging than binary classification problems, where accuracy, precision, recall and receiver operating characteristic (ROC) curves are typically used as evaluation criteria. In addition to determining accuracy, precision, recall and ROC for individual classes, we will be using the following evaluation criteria:

1. Exact Match Ratio (subset accuracy) – This indicates the percentage of samples that have all their labels classified correctly, given by:

$$Exact\ Match\ Ratio = \frac{1}{n}\sum_{i=1}^{n} I(Yi = Zi)$$

2. Hamming Loss – This indicates the fraction of labels that are incorrectly predicted, given by:

$$Hamming\ Loss\ = \frac{1}{n}\sum \mathrm{i} = 1^{|\mathrm{n}|}\frac{\mathrm{xor}(Yi, Zi)}{|L|}$$

In the formulas above,

- $n$ is the number of multi-label samples
- $Yi$ is the ground truth
- $Zi$ is the prediction
- $L$ is the number of labels

The following are the definitions of Accuracy, Precision, Recall and F1 Score that will be used to evaluate the predictions of individual classes by a model:

$$Accuracy\ = \frac{(TP\ +\ TN)}{(TP\ +\ TN\ +\ FP\ +\ FN)}$$

$$Precision = \frac{TP}{(TP + FP)}$$

$$Recall = \frac{TP}{(TP + FN)}$$

$$F1\,Score = 2 * \frac{(Precision * Recall)}{(Precision + Recall)}$$

In the formulas above,

- True Positive (TP) – A true positive is an outcome where the model correctly predicts the positive class
- True Negative (TN) – A true negative is an outcome where the model correctly predicts the negative class
- False Positive (FP) – A false positive is an outcome where the model incorrectly predicts the positive class
- False Negative (FN) – A false negative is an outcome where the model incorrectly predicts the negative class.

## 6. Convolutional Neural Networks(CNNs)

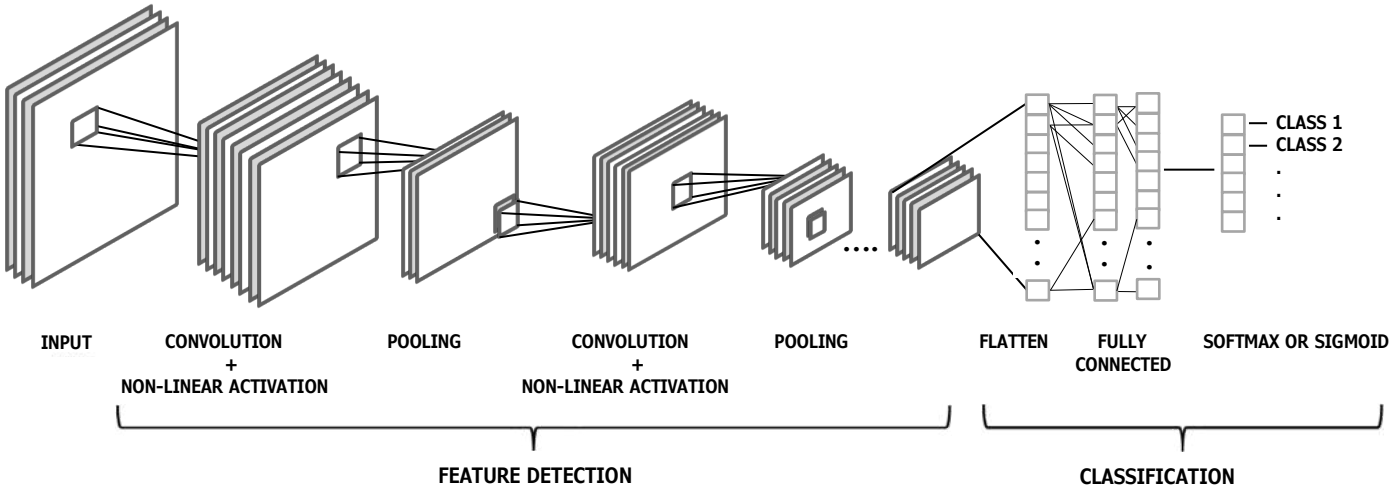

**Figure 5. Convolution Neural Network (CNN) components**

CNNs are a class of neural networks that have proven to be extremely effective in recent years in the field of perceptual problems, specifically image recognition. They can be used to process data that has a spatial structure. In addition to being used for images that have a 2-D grid, they can also be used for 1-D structures, such as time series. In our use case, we use CNNs to classify impairments based on the 1-D RxMER per subcarrier array for OFDM Channels.

The model architecture is shown in Figure 5. CNNs contain the following components in addition to the input and output layers:

- Convolutional layers: Convolution layers use filters that perform convolution operations to scan the input layers with respect to dimensions. Convolution layers perform several convolutions in parallel, to produce a set of linear activations. Then, each linear activation is run through a nonlinear activation function, such as the rectified linear activation function, to generate a feature or activation map.
- Pooling layers: Pooling layers are typically applied after a convolution layer and perform a down sampling operation. They replace the output of the feature map with a summary statistic, such as max or average of the nearby outputs.
- Fully connected layers: Fully connected layers are typically present toward the end of a CNN architecture, and operate on a flattened input where each input is connected to all neurons.

There is no single network architecture, and understanding the network architecture is an area of great study. CNNs typically have a series of convolutional and pooling layers that are stacked together. The features that the convolutional/pooling layers detect increase in complexity as we go further down the network[1]. The convolutional and pooling operations provide translation invariance that uniquely distinguishes CNNs from other types of neural networks. Invariance refers to being able to recognize an object even when its appearance varies in some way.

## 7. Modeling

We experimented with CNN architectures that had between 1-3 convolution blocks and 1-3 fully connected layers. A grid search was performed on the following hyper-parameters before selecting the final model:

**Table 1. Hyperparameters, Ranges evaluated during training**

| Hyperparameter | Range | Hyper-parameter Type |
|---|---|---|
| Number of filters in convolutional layers | [32, 64, 96, 128] | Network Structure |
| Kernel size in convolutional layers | [3,5,7,9] | Network Structure |
| Pooling Size | [2,3,4] | Network Structure |
| Fully connected hidden layer size | [100, 150, 200, 250] | Network Structure |
| Dropout | [0.3, 0.4, 0.5] | Network Structure |
| L2 Regularization | [0, 0.0001, 0.0005, 0.001, 0.005, 0.01] | Network Structure |
| Learning Rate | [0.0001, 0.0003, 0.0005, 0.001, 0.003, 0.005, 0.01, 0.03] | Network Training |
| Batch Size | [16, 32, 64, 128] | Network Training |

In addition, we evaluated the different methods to get an input of fixed shaped described in the data pre-processing section.

## 8. Results

We compared our models to 2 dummy models – one that has all labels assigned the most frequent class and another that randomly assigns labels based on the distribution in the training data. These 2 data points serve as benchmarks to compare against. In addition, we also compared the performance to a 3-layer conventional neural network.

**Table 2. Subset Accuracy, Hamming Loss for models**

| Model | Subset Accuracy | Hamming Loss |
|---|---|---|
| Model that predicts most frequent class | 0.319 | 0.163 |
| Model that randomly assigns labels based on distribution | 0.146 | 0.202 |
| Neural Network – 3 dense layers | 0.645 | 0.047 |
| CNN – Zero padding at end to get 1880 Subcarriers | 0.778 | 0.031 |
| CNN – Average MER padding at end to get 1880 Subcarriers | 0.852 | 0.018 |
| CNN – Last MER seen padding at end to get 1880 Subcarriers | 0.824 | 0.022 |
| CNN – Fixed width of 900 Subcarriers | 0.809 | 0.024 |

As seen above, the CNN-based models significantly outperform the dummy and the neural network-based models on the validation dataset. While all the CNN based models had results in the same range, the model with average MER padding performed the best in our experiments.

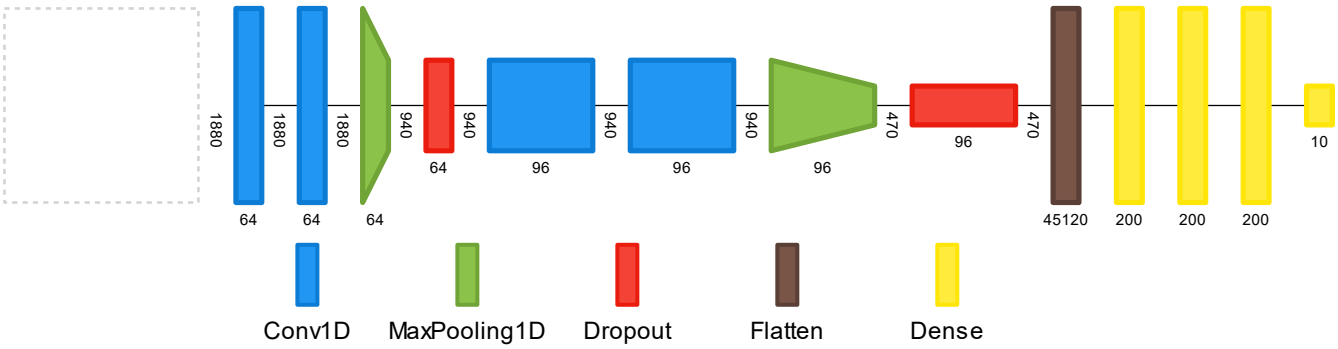

**Figure 6. Network Architecture CNN model that had best performance on validation dataset [2]**

All the classes have accuracy above 90% on the validation dataset. Apart from amplitude ripple, they also have very good precision, recall and F1 scores. Due to its fine-grained nature, amplitude ripple does not perform as well and probably needs more training samples to get better scores. Another observation from the results is that incorrect classifications were often attributable to multiple impairments being present. This also indicates the need for additional labeled data.

Analog TV distortion and adjacent channel interference had fewer than 5 samples in the validation dataset and were not evaluated.

**Table 3. CNN model with average MER padding - Individual classes performance metrics on validation data**

| Impairment | Accuracy | Precision | Recall | F1 Score |
|---|---|---|---|---|
| Normal – No Impairment | 0.989 | 0.976 | 0.992 | 0.984 |
| Ingress | 0.980 | 0.975 | 0.935 | 0.954 |
| Sweep | 0.997 | 0.933 | 0.933 | 0.933 |
| Roll-off | 0.996 | 0.938 | 0.968 | 0.952 |
| Suck out | 0.974 | 0.939 | 0.911 | 0.925 |
| Amplitude Ripple | 0.939 | 0.912 | 0.715 | 0.802 |
| Low MER | 0.974 | 0.958 | 0.924 | 0.940 |

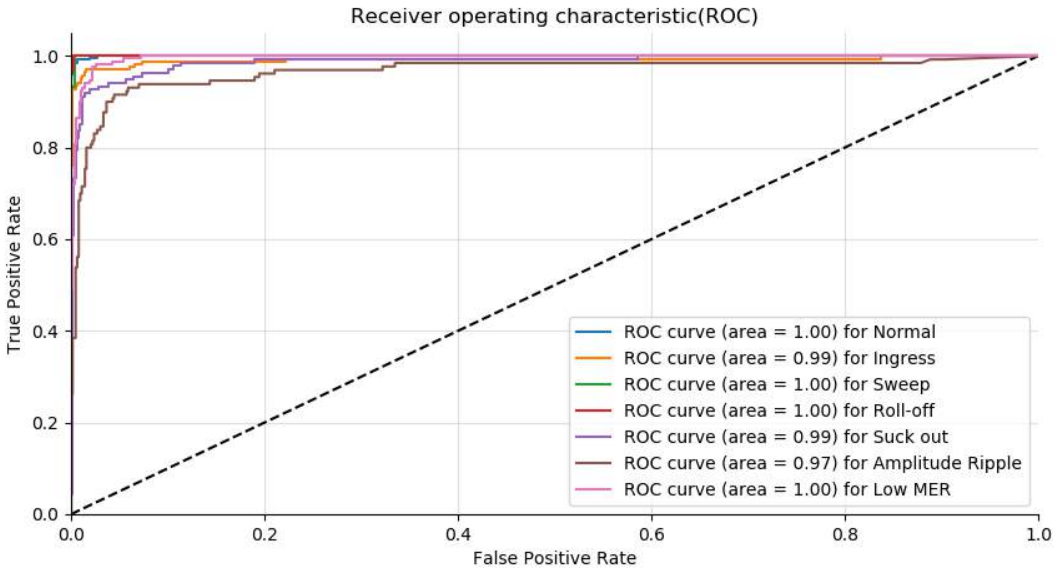

**Figure 7. ROC Curves**

## 9. Machine Learning Pipeline

At a high level, the platform driving proactive network maintenance consists of 3 layers – Data Lake, Compute Engine and Integration Layer, as depicted in Figure 8.

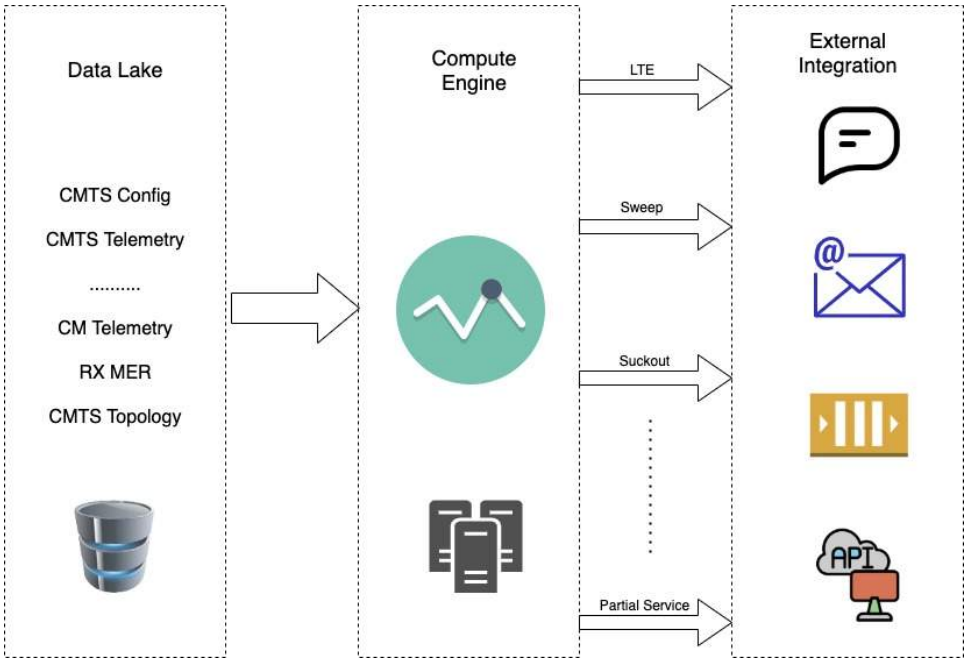

**Figure 8. Machine Learning Pipeline Layers**

## 9.1. Data Lake

Comcast's cloud-based data lake storage solution plays a pivotal role in our efforts to apply data science and develop analytical solutions to better understand and build a highly dynamic, resilient access network. The data lake also acts as a source of truth for a wide variety of data streams across Comcast. While the primary application of this data lake is to drive ML and analytical applications, custom integration and other solutions built on top of this data lake help power a wide variety of use cases. The platform is highly elastic, reliable and offers a rich set of tools for our analysts, engineers and data scientists to easily access this data and form a unified view of our network, customers and devices. It helps them use this data for analysis, visualization and ML applications, without the technical barrier of knowing the underlying infrastructure. The queries on the underlying data run on a Spark-based distributed computation engine, which is purpose-built to handle large data sources.

## 9.2. Compute Engine

The compute engine refers to the actual implementation of feature pipeline and ML models on polling data from the data collection framework. The standard ML life cycle involves model development, experimentation, training, test, validation and supporting model evolution. These ML models could be custom implementations developed from scratch or based on popular ML frameworks. During the development phase, the Compute Engine provides support to track and compare metrics for various experiments involving different models, features, tuning hyperparameters, etc. It also helps track code, data and model lineage while supporting promotion of models between different stages. To build the Compute Engine, we use open source ML frameworks and enhance it with custom functionality to suit our pipeline.

### 9.3. Integration layer:

The integration layer provides support to successfully integrate the recommendations from the pipeline to various OSS tools or directly to SMEs and technicians, through a broad set of interfaces and tools. The more seamless programmatic integration involves APIs and streaming events that would integrate with other OSS tools within Comcast. In severe cases, notifications could also be evented through Comcast's IM application, SMS and emails so they can be attended with greater urgency.

As a standard route, consumers would subscribe to the streams through Comcast's streaming data platform, which would event out our impairment notifications at pre-defined intervals. Once these events are consumed, they result in tickets/work orders being created automatically. This event-driven architecture enables any number of tools to easily integrate with our ML platform and track network events in real time. The following data are provided as part of notifications to assist with event prioritization and triangulation:

- Interfaces details such as PLC Location, Start/End Frequency, Total/Impacted cable modem counts
- List of impacted nodes
- List of impacted cable modems with severity of impairments
- Interface impairment rankings at the national, divisional and regional levels
- Reference to the API for historical data stored in the data lake related to the event
- Reference for API to enable fix agents to collect real-time on demand data, to confirm the issue is still present and to assist in isolation and confirm mitigation
- Other data sources to enrich the event, such as the mobile wireless carriers that overlap with the OFDM Channel

We also provide a real-time API that OSS tools integrate with and can be invoked on an on-demand basis. Once the impairments are attended to and a fix is identified, the network technicians can invoke the API through the UI of the OSS tools. Once a request is made to our API, the devices on the relevant interfaces/nodes are polled in real-time. Those polling results analyzed and scored through the model and a response is sent back to the UI, which indicates if the identified fix resulted in clearing the impairment. If the impairment is no longer seen, the OSS tool automatically clears the ticket. It is important to note that the compute engine handles model management for both offline scoring of the models for the entire footprint, and real-time scoring based on live polling data.

## 10. Conclusion/Next Steps

We've seen very promising results in being able to classify impairments for OFDM channels using CNNs on our validation dataset, with a high degree of accuracy. However, we need to continue to iterate and use additional labeled samples to address the following:

- The samples we've used may not cover the gamut of RxMER curves for the entire footprint
- There are some impairments that had very few examples
- Impairments that were incorrectly classified were often due to multiple impairments being present
- Detecting severity in addition to the impairment

A crowdsourcing approach to labeling that involves field technicians and other SMEs would be beneficial and increase confidence in the models being developed. SMEs are also needed for addressing edge cases, where the impairments were not always well-defined.

In the models/data pre-processing phase, there are a couple of areas that can be explored further:

- Increase the number of training samples by using data augmentation techniques such as flipping the RxMER curves horizontally or scaling the entire sample. We'll need to consider that some augmentations cannot be applied to all impairments, as it would modify the RxMER curve in a way that makes the impairment no longer applicable. For example, samples with roll-offs cannot be flipped horizontally.
- Impact of data pre-processing techniques on models needs to be understood better. For example, a sample having roll-off may be incorrectly classified as having suckout, due to the average MER padding added to get to the standard width.

We will also be extending this effort beyond OFDM channels to cover upstream, video and D3.0 channels. For OFDM channels specifically, building models for classifying impairments that include both RxMER and RxPower will be explored.

# 1. Introduction

Cable operators have been actively converging video and data services into a common Converged Cable Access Platform (CCAP) platform for a few years now. This trend, which requires an evolution towards newer, more modern, and denser equipment, should free up space in the headend.

However, as the success of high-speed data and video-on-demand services continues its seemingly eternal growth, the evolution of the access network progresses relentlessly towards expanded capacity and ever-smaller service groups. As a result, the spectrum allocated to narrowcast services increases, driving operators to deploy Data Over Cable Service Interface Specification (DOCSIS©) services including 32 SC-QAM (Single Carrier Quadrature Amplitude Modulation) channels and at least a fraction of an OFDM (Orthogonal Frequency Division Multiplexing) channel. In some cases Cable operators have even gone farther, to 36 and even 40 SC-QAM channels, and moving beyond a single OFDM channel onto a second one. In addition, if free spectrum in the network is not available, operators support capacity growth by segmenting service groups into smaller and smaller areas.

These expansion trends result in a continuous growth of headend equipment, which is already starting to exceed the capacity that headend facilities can support.

Therefore, the above trends are now intractably linked to two additional evolutions: distribution of components of the access network and virtualization of the core network functions. Furthermore, the implementation of a Distributed Access Architecture (DAA) is different in places where the plant is being upgraded, such as where a migration to a deeper use of fiber or N+0 is being implemented, versus in Cable networks where the existing plant needs to be segmented or expanded.

This paper will begin by outlining the evolution of service provider networks, and then describe why and how the migration to a distributed architecture is necessary and beneficial. The paper will then expand into features that can be implemented with Distributed Architectures and discuss the topic of Virtualization. Finally, the paper will explore how the implementation of DOCSIS 4.0 could be implemented in Distributed Architecture networks.

The paper is divided into the following sections:

- Cable network evolution, including:
    - Typical HFC networks today and growth projections
    - Advent of DOCSIS 3.1
    - The analog modulated forward link, options for its implementation, and comparison of the various options
- Why and how distributed architectures are useful, covering the following key benefits:
    - HFC network performance improvements by migrating to digital transport, especially to maximize the use of the higher order modulation rates that DOCSIS 3.1 and beyond offers
    - Headend density increases, which is becoming critical as service providers are segmenting service groups more and more, including extending fiber deeper into the plant and implementing passive networks
    - Trunk fiber savings as we move to higher capacity digital links that can be muxed much more than analog links, and
    - The ability to eventually virtualize the remaining upper layers of the CCAP
- Describe a Distributed Access Architecture, including:
    - DAA components
    - Key aspects of DAA interoperability
    - Use Cases
    - Generations and the advent of DOCSIS 4.0

 

# 2. Cable Network Evolution

## 2.1. Typical HFC Networks Today

Most MSO's hybrid fiber-coax (HFC) networks have been designed with an upper spectral boundary of 750 or 860 MHz, while some are designed to support 1 GHz and other newer networks designed to support 1.2 GHz. For the more abundant 750 or 860 MHz networks, if not already fully utilized, it is expected that use of their capacity will be increased to the point of exhaustion This will happen as a result of 1) increased DOCSIS® usage for even faster high-speed data (HSD) service tiers; 2) additional high-definition (HD) programs (for broadcast [BC] and especially narrowcast [NC] services, such as video on demand [VOD] and switched digital video [SDV]); and 3) new service additions such as internet protocol (IP) video and cloud-based digital video recorder (cDVR.)

In recent years the growth in, and demand for, HD programming has resulted in the need for allocation of large numbers of EIA (Electronic Industries Association) channels for HD services, both for BC (Broadcast) and NC (Narrowcast), which has filled every available portion of the spectrum. This is especially true for BC, where large numbers of programs are offered in HD format, while simultaneously the need for distributing the standard definition (SD) version has persisted. This has resulted in the need for use of 3x to 5x the number of EIA channels than previously required. For example, a typical digital multiplex including 10 to 15 programs would require an additional 3 to 5 EIA channels for the HD equivalent streams, even assuming the newer, more sophisticated multiplexing schemes available in the market. Of course not every program is available, or still sought by subscribers, in HD format. But very large numbers of them are, including 100 to 150 BC programs.

The above is also applicable to a great extent in systems utilizing SDV technology for content distribution. The difference is that the HD and SD versions of the program are not distributed unless a subscriber is requesting them, which reduces the marginal increase in capacity. Assuming that all programs are distributed in only one format, which is certainly a valid expectation for programs of low viewership, then the increase in capacity for a conversion from SD to HD would just be the increase in capacity required for the transmission of the HD program without requiring the simultaneous use of bandwidth for both formats.

Additionally, considerable spectrum is needed to deploy high-capacity narrowcast legacy video services, especially cDVR, and a full-array of HD video-on-demand services. For the former, initial observations suggest that network requirements for cDVR may be as high as 4x to 5x that of VOD, and that peak utilization overlaps, at least partially, with that of peak use for other narrowcast services.

Finally, the growth in HSD services continues. All network operators have offered increased service tiers and observed an increased use of HSD service capacity for well over a decade now, as shown in Figure 1, which amounts to a constant year-over-year compounded growth. The applications have changed throughout this time, and the demand has continued to increase at the same relentless rate.

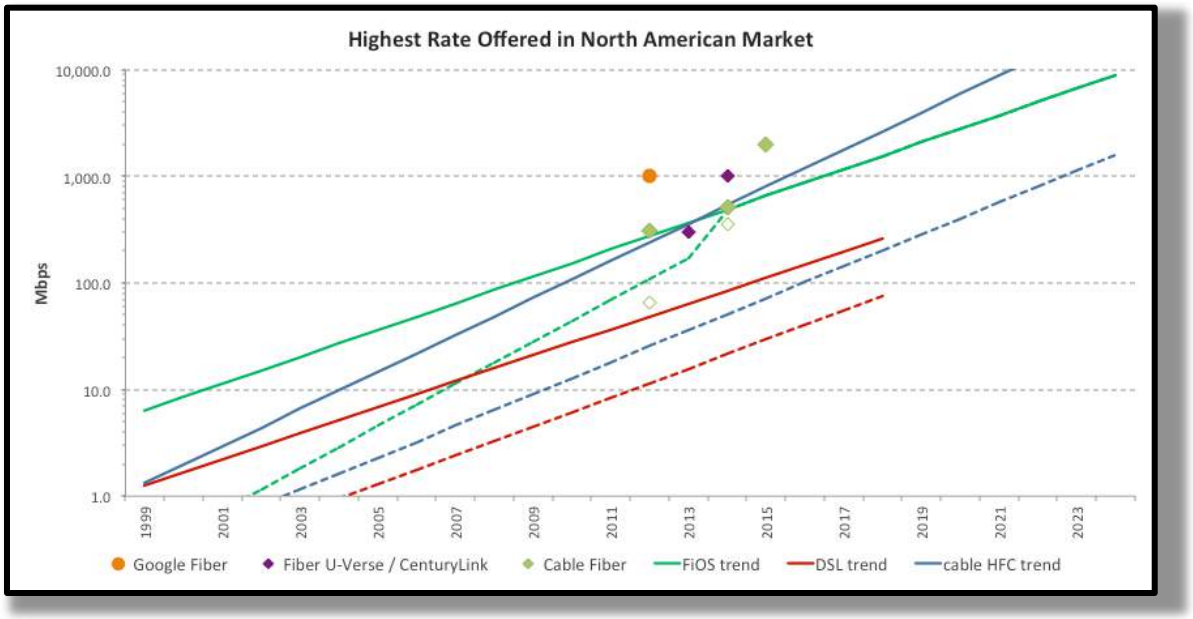

*Figure 1: Examples of HSD service tier capacity increase over time*

How does this compare to other operator's data services and a longer period? Projecting an operator's HSD service growth back in time to when Internet services started 25+ years ago, services should have been about 100 bps. This coincides with the history of telephone modems from 110 and 300 baud modems from the mid-80s, to 56 Kbps/V.42, into ISDN (Integrated Services Integrated Network) services.

This demonstrates that the growth seen in MSO's HSD services is typical over a much longer period of time, rather than an exception observed by operators in recent years.

## 2.2. Growth Projections

From all of the above, it follows that, should the usage growth pattern continue at the same rate as in the past, networks will be required to provide >1 Gbps HSD services within the next few years. This growth, coupled with the surge in HD video formats, and more personalized narrowcast services, will result in a significant growth in narrowcast capacity, as shown in Figure 2.

To support this growth, MSOs have deployed bandwidth reclamation tools such as SDV for digital broadcast, digital terminal adapters (DTAs) for analog service reclamation, or a combination of both. These tools have been extremely valuable to MSOs, and their operational complexity and cost well justified.

In the case of SDV, early predictions from industry analysts projected that the efficiency of SDV would reach 40% (e.g., programs requiring 10 EIA channels could be carried in 6). This has proven to be understated, since it was based on the use of SDV to reduce bandwidth required for existing services. As SDV's role in the network grew, the efficiencies have been even greater, especially as SDV expanded in scope to support niche service introductions that have low initial viewership and would have otherwise been difficult to deploy.

The benefit of DTAs has been just as, or perhaps even more striking. MSOs deploying DTA devices are able to eliminate the need to distribute the analog channels in the network. Even if DTAs are

distributed to top tier analog customers, such as only the traditional expanded basic subscribers, the move would reduce a channel line up from perhaps 50 EIA channels dedicated to 50 analog programs to perhaps as little as 4 EIA channels dedicated to transport the 50 programs in their digital-equivalent transport. Using the same comparison method as the above SDV case, this is a >90% efficiency. If extended to the entire analog tier the efficiency gains are very significant.

Despite the availability of these tools, they are not universally applicable. With respect to SDV, in general it is not likely that all broadcast programs will be switched since experience shows that many broadcast programs are constantly viewed by someone in the service group during peak hours, which will leave a large portion of the spectrum still used for broadcast. Similarly, not all analog channels can be removed in the short term due to operational and/or cost constraints.

Additionally, while many MSOs will use one or both tools, in general these tools won't be used by every MSO for all applications.

Finally, there are also significant potential gains to be achieved from the use of advanced video compression standards (VCS), and variable bit-rate (VBR) multiplexing. In the case of VCS, coding efficiencies of approximately 50%, depending on implementation and content type, can be obtained with H.264 / MPEG-4 Part 10 . Furthermore, with the release of the H.265 standard in April of 2013, it is possible to achieve a 50% improvement over H.264. The use of VBR promises to result in a capacity efficiency gain of as much as 70% versus constant bit rate (CBR) . The combined gains from using the above approaches for multiple services are even more significant.

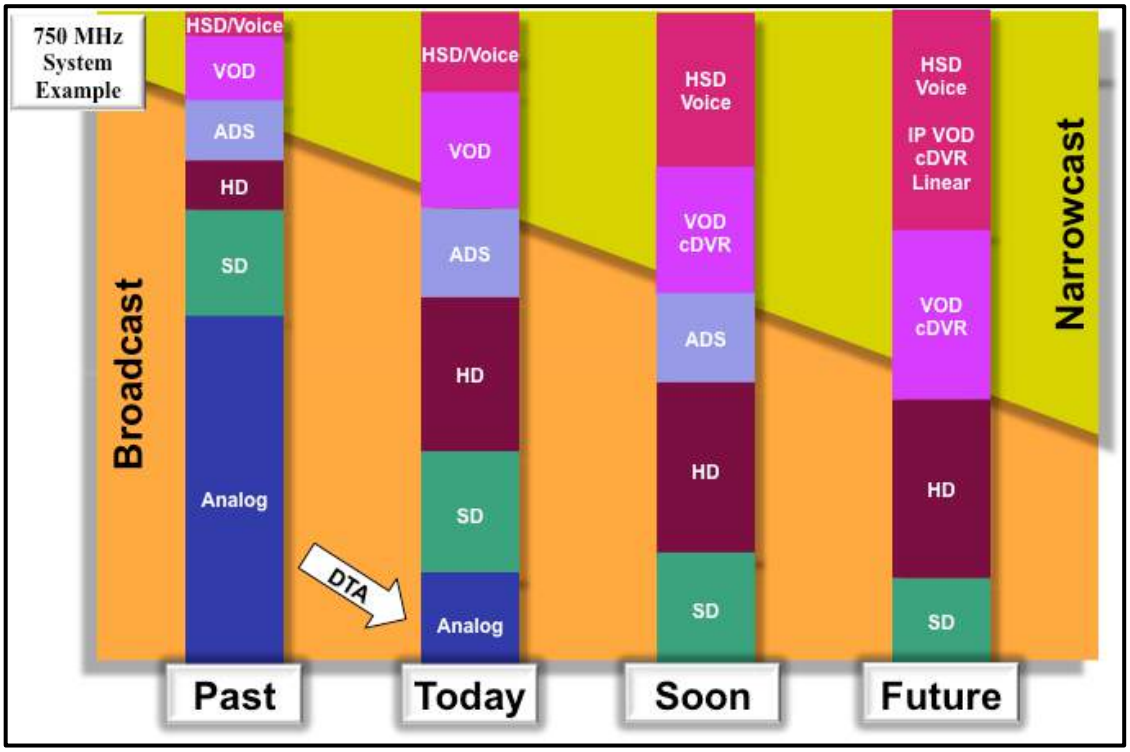

*Figure 2: Example of narrowcast service growth over time*

However, these are difficult tools to take advantage of, from a network perspective, because on a proportional basis, relatively few legacy set-tops will support all these technical advances, especially

H.265. These tools are more likely to find significant support in equipment designed to handle newer, IP-video based services.

And, this approach will nonetheless require additional capacity from the network. This is especially true when considering that the deployment of these advanced video services will result in an additional simulcast of video programs, at least initially. This is because, realistically, advanced services will not, at least initially, replace the currently deployed service formats

Furthermore, ubiquitous support for such devices would require considerable spectrum if the legacy services are maintained for an extended period-- which is expected, given that legacy devices will continue to be deployed, for some amount of time.. Moreover, this increase in simultaneous use of the more advanced IP video services while maintaining legacy services will be especially impactful over time, as the number of IP video services increases.

All of the above, coupled with the success experienced by MSOs in recent years with business services, homes security, etc., will likely require the deployment of IP capacity beyond what can be supported today. As well, it will require the development of tools for increased spectral efficiency and/or unleashing additional spectrum in the HFC network. The following sections of this paper will enumerate some ways in which this can be achieved.

## 2.3. The Advent of DOCSIS 3.1

As it has been pretty well advertised in the media, DOCSIS 3.1 development has been quite extensive. Most MSOs announced deployments of DOCSIS 3.1 across their markets, and several operators have even deployed DOCSIS 3.1 throughout their entire footprint.

The key motivation for the 3.1 version of the DOCSIS specification is, in a nutshell, to scale DOCSIS more efficiently, both from the cost and operations perspectives.

While for the first 10 years of DOCSIS deployments it was possible to offer Internet services and support its growth with just one downstream DOCSIS channel, over the last 5-10 years services have required many more channels. This is because the year-over-year growth drove service speeds well above the initial levels, to speeds of 50 Mbps, 100 Mbps, and even much higher Mbps tiers today, which can't be supported by the single channel. Therefore, MSOs deployed multiple DOCSIS channels using DOCSIS 3.0, sometimes using 32 or more channels, and even requiring capacity beyond that supported by DOCSIS 3.0.

To that end, the 3 key goals and features of DOCSIS 3.1 are:

1. Much more efficient use of spectrum, with up to 50% improvement in bandwidth efficiency (or bps/Hz), resulting from:

    a. The use of more efficient forward error correction (i.e., replacing the older and less efficient Reed-Solomon approach with the far more efficient Low Density Parity Check (LDPC), and

    b. The addition of the higher-order modulations 1024 and 4096 QAM downstream and 256 and 1024 QAM upstream.

    These new modulation schemes provide 2 and 4 bits per Hertz/second of improvement in both the upstream and downstream signal directions, while the use of the new forward error correction approach provides approximately 5 dB better RF performance. The end result is that MSOs are

able to transport 1 Gbps of DOCSIS capacity in about 120 MHz of spectrum. For context, doing the same with DOCSIS 3.0, using single-carrier QAM requires about 180 MHz of spectrum.

2. Cost reduction, mainly by leveraging technologies commonly used in other transmission media, such as the inclusion of Orthogonal Frequency Division Multiplexing, which is used extensively in wireless and wireline transmission media. Specifically, the addition of OFDM for the downstream and OFDMA (Orthogonal Frequency Division Multiple Access)for the upstream should enable MSOs to reduce costs by "packing" more bits in the HFC network more efficiently. As a result, these technologies will likely attract a larger supplier ecosystem, increasing innovation and fueling competition.

3. Enable a simple and orderly transition strategy, both with respect to compatibility with the previous generation of CMTS and CM equipment while simultaneously supporting an expanded spectrum capacity in the HFC network.

Specifically, DOCSIS 3.1 cable modems operate with DOCSIS 2.0 and 3.0 CMTS/CCAP equipment, enabling deployment of DOCSIS 3.1 CPE (Customer Premise Equipment) as soon as available. Similarly, DOCSIS 3.1 CCAPs support DOCSIS 2.0 and 3.0 CPE allowing MSOs to upgrade headend equipment without having to change any of the existing CPE. And, both DOCSIS 3.1 CM and CMTS equipment support the currently required upstream and downstream spectrum, plus an expansion of the upstream to 85 MHz and beyond, and of the downstream up to 1.2 GHz.

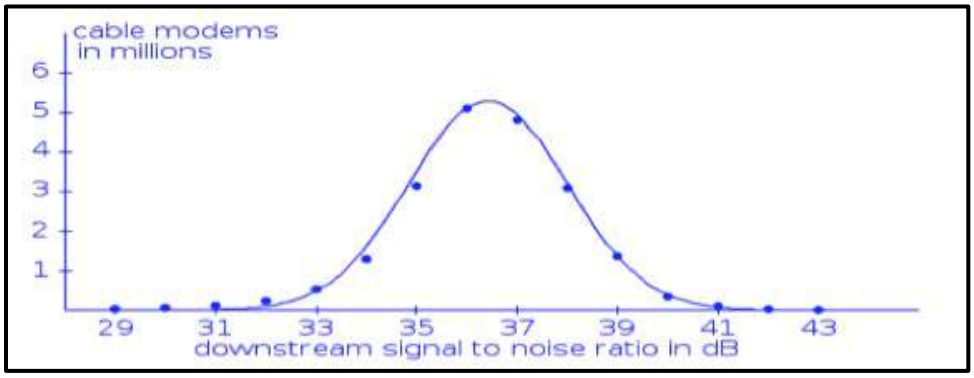

*Figure 3: Example of downstream SNR for a large population of cable modems*

Figure 3 depicts the downstream signal-to-noise ratio (SNR) as reported by a very large population of cable modems. This data shows that many cable modems will be able to support the high-order modulation profiles included in DOCSIS 3.1.

| Modulation | Signal-to-Noise Ratio |
|---|---|
| 512 QAM | 27 dB |
| 1024 QAM | 30 dB |
| 2048 QAM | 33 dB |
| 4096 QAM | 36 dB |
| 8196 QAM[1] | 39 dB |
| 16384 QAM | 42 dB |

*Table 1: SNR required for DOCSIS 3.1*

[1] 8196 QAM and 16384 QAM are included for future consideration in the DOCSIS 3.1 specifications

Assuming an 8/9 LDPC coding ratio, Table 1 shows the required SNR for the modulation rates included in DOCSIS 3.1:

Applying the SNR requirements from Table 1 to the population of modems shown in Figure 1, we can easily see that a large population of cable modems would not achieve sufficient SNR to operate at 4096 QAM. Furthermore, if sufficient headroom is allowed to account for environmental fluctuations, the population of cable modems that would not receive signals with sufficient SNR to operate at 4096 QAM would be significant.

## 2.4. The Analog Modulated Forward Link in HFC Networks

As their name indicates, hybrid fiber-coax networks use a fiber transport between the headend and the coaxial cascade. This fiber link, intended to reduce the size of cascades, as a means to improve performance, was originally developed with analog modulated lasers and receivers in both signal directions, upstream and downstream.

Over time, the performance of the upstream link was improved by replacing the analog modulation with a digital transport. This change improved performance significantly, and allowed for longer distances between the headend and the node. Different vendors implemented their own methods and technical capabilities to implement a digital transport, which resulted in incompatible systems and required the use of the same vendors' components for both the node and the headend.

However, the downstream link remained almost unchanged over time, with the only enhancements focused on improving distance and RF spectrum capacity. Performance has not really been an issue like it was in the upstream.

But more importantly, while the digital capacity of the upstream was limited to a few Megabits per second, well under a gigabit of digital capacity which could easily be digitized and carried with Ethernet optics, the downstream digital capacity needed to transport the downstream spectrum has been considerably higher, reaching and even exceeding 10 gigabits per second.

Because of the above, analog forward links continue to be used. Even though headend equipment is currently capable of launching signals with >47 dB MER performance, which is sufficient to generate and transport 16,384 QAM signals, analog lasers are limited to about 35-38 dB of MER performance, which would limit end-of-line performance to barely enough for 2,048 QAM or 4,096 QAM in short cascades in the best of the cases.

## 2.5. Description of Options for Digital Forward Link

As time has gone by, technology evolution and certain developments as described below have enabled options for implementing a digital forward link. These include:

1. Evolution of QAM edge modulators which have gone from single and/or a few modulators to supporting 32, 64 or even more modulators,

2. Development of the CCAP, combining the functions of the video QAM modulator and DOCSIS into a single platform, and

3. Migration to digital video, either partially or completely.

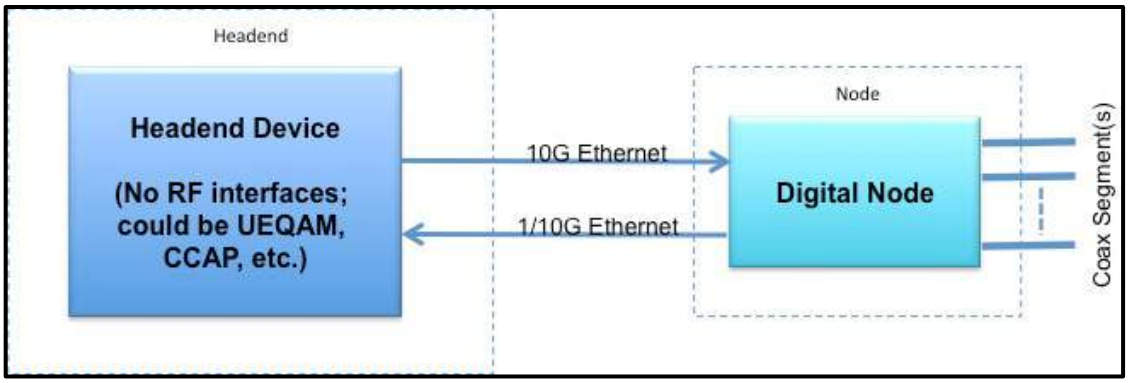

*Figure 4: Digital Forward - High-level Architecture*

With this technological evolution, it is conceivable to remove the RF combining network, and instead implement it digitally in the edge device, such as the CCAP.

This evolution of the edge headend devices makes it possible to envision several options for digitizing the forward link.

Fundamentally, the migration to a digital forward includes the components included in Figure 4, as follows:

- The headend device, such as a CCAP, which would be a high-density edge QAM comprising QAM modulation for the entire spectrum,
- The node would contain components normally implemented in the edge QAM or CCAP which generates the RF signals,
- The link between the headend device and the node would be comprised of a digital interface, such as an Ethernet link.

There are then various approaches for how a digital forward link can be implemented to replace the currently used analog link. These various approaches for distributing the various components can be categorized into 4 groups, plus 1 option that would still leave an RF generation at the headend device, as outlined in Table 2:

| Option | Description and Approach |
|---|---|
| 1. Maintain RF output in the headend | 1.a Headend equipment remains unchanged<br><br>1.b Headend RF output is digitized, transported digitally, and RF is regenerated in the node |
| 2. Remote the DAC from the PHY | 2.a The DAC is removed from the headend<br><br>2.b Digital samples are transported digitally to the node where the DAC generates the RF signals |
| 3. Partition the PHY and remote the lower portion of the PHY | 3.a The PHY is split between the headend and the node<br><br>3.b The digital bit stream between upper and lower PHY is transported from headend to node |
| 4. Remote the entire PHY | 4.a The entire PHY modulation is moved to the node<br><br>4.b The MAC remains in the headend, and MAC frames are transmitted from the headend to modulator that resides in the node |
| 5. Remote the entire PHY and MAC | 5.a The entire PHY and MAC is removed from the headend device and placed in the node<br><br>5.b IP frames are transported from the headend to the node. |

*Table 2: Categories of options for implementing a digital forward link*

## 2.6. Comparison of Options for Digital Forward Link

There are pros and cons for each of the options. The following sections outline these tradeoffs.

### *2.6.1. Option 1: RF remains in the headend*

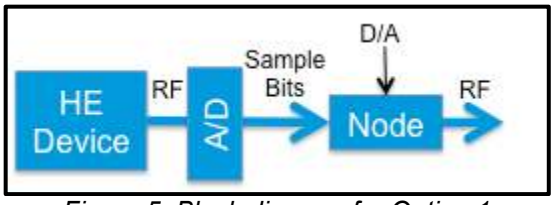

*Figure 5: Block diagram for Option 1*

- Equivalent to digital return, the RF output from the headend device is digitized, transported digitally, and converted back to RF in the node.
- Maintains HFC transparency
- This option results in the highest bitrate over fiber; the capacity for multiple nodes would not fit into the available capacity of one 10G fiber

- There is a loss of MER (Modulation Error Ratio) in the double conversion, so this option provides the least performance improvement
- Results in the least intelligence placed in the node, but an additional conversion stage is added in the headend

### 2.6.2. Option 2: Digital-to-analog conversion is moved to the node

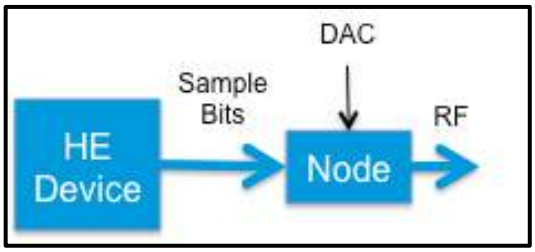

*Figure 6: Block diagram for Option 2*

- Requires separation of the digital-to-analog conversion from the modulator
- Together with Option 1, results in the least intelligence in node
- Similar high bitrate over fiber as Option 1; capacity for multiple nodes would not fit into the available capacity of one 10G fiber

### 2.6.3. Option 3: Lower PHY is moved to the node

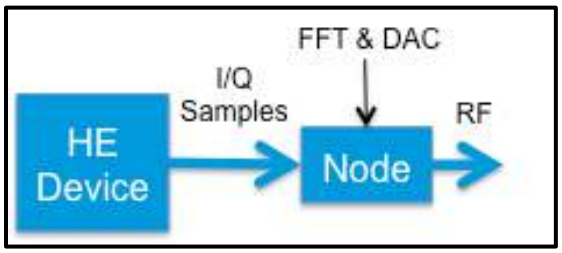

*Figure 7: Block diagram for Option 3*

- The PHY layer needs to be split into two components: upper and lower PHY
- More intelligence than in either of the previous options is placed in the node
- Although lower than the previous options, this option also results in a very high bitrate over fiber
- This option would require an industry proprietary point-to-point link between the headend port and the node to transport the I and Q samples
- Implementation of this option would require the definition of interfaces which have never been defined in previous versions of the DOCSIS specifications, which in turn would result in modification of the silicon used and/or planned to date, and therefore results in the highest implementation complexity

### 2.6.4. Option 4: Entire PHY is moved to the node

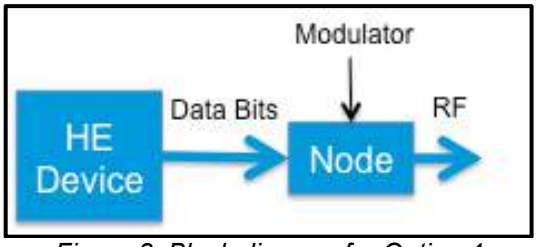

*Figure 8: Block diagram for Option 4*

- More intelligence is placed in the node than with all previous options
- This option results in the lowest bitrate over fiber; multiple nodes fit into the capacity of a 10G fiber
- Enables a packet-based link between the headend and node, which results in significant benefits outlined later in this paper
- Could use existing/planned silicon devices, and thus may be the easiest and quickest to implement
- Offers the best MER performance improvement over analog

### 2.6.5. Option 5: Move PHY and MAC to the node

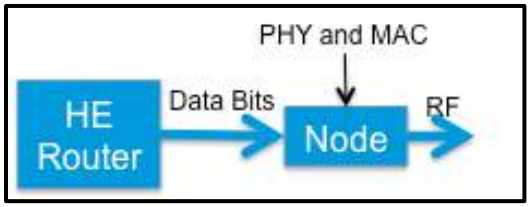

*Figure 9: Block diagram for Option 5*

- This option puts the most intelligence in the node
- The data rate between the headend and the node is equivalent to the actual data transmitted, except for the addition of ancillary network data
- Same packet-based network benefits as Option 4
- Same highest MER performance as Option 4

Either of the 5 options described above accomplishes a migration away from the analog-modulated forward link and into a new era where the link between the headend and the node becomes a digital link. And, while either of the above approaches accomplishes a migration towards a digital link, over the years options 4 and 5 have received the most attention because of their relative implementation simplicity versus options 1, 2 and 3. We now call these options Remote PHY and Remote

MAC(Media Access Control)-PHY, and we call the devices that implement them RPDs (Remote PHY Devices) and RMDs (Remote MAC-PHY Devices) respectively.

As we migrated towards the implementation of a digital link, and separated either the physical layer in a Remote PHY implementation, or also migrated the MAC in a Remote MAC-PHY implementation, we stepped into the era of the Distributed Architectures. In these Distributed Architectures, the remainder of the CCAP in the headend no longer needs to be implemented in an application-specific hardware design. Instead, the remainder of the CCAP in the headend can be implemented entirely as software running in general purpose compute platforms, which we now call a Virtualized headend platform.

The next sections of this paper will focus on the benefits of a distributed architecture, discuss some of the features of distributed architectures, and outline network evolution strategies.

# 3. Benefits of Distributed Architectures

There are many benefits from the implementation of Distributed Architectures. The following sections of this paper describe them.

## 3.1. Improved performance

Improvements on performance are achieved in multiple ways, including:

- Improved SNR characteristics
- Longer link distances
- Higher reliability
- Better use of capacity

As described in the above sections of this paper, one key benefit of Digital Forward Link is the improved performance resulting from the migration from an analog to a digital link. This gain varies depending on the characteristics of the analog link being replaced, but can be generalized as an improvement of 5 dB in signal-to-noise ratio at the end of the line. This gain will result in higher capacity/Hz as it will be possible to run the higher order modulations as shown in Figure 3 and Table 1 for more of the cable modems in the network. This will enable significantly higher transport capacity for customers in the HFC network.

In addition, the Digital Forward Link will enable longer distances between the headend and the node. This is because digital interfaces, such as an Ethernet link, are designed to operate over much longer distances while carrying the designated capacity. Extending the distance between the CCAP and the Digital Node would enable MSOs to move their CCAP devices back in the network to more centralized facilities, leaving the hub or OTN free of CCAP equipment. The benefit of such change could be very big for some MSOs, especially as segmentation of the network continues towards smaller service groups, for which additional CCAP equipment needs to be deployed.

A third benefit from the Digital Forward Link is improved reliability of the optical link. It is well known that analog links require periodic maintenance and are subject to the effects of environmental changes. By contrast, Ethernet optical links are far more stable across a wider range of environmental conditions, and require little to no maintenance. The impact of this benefit could be very significant to MSOs.

Finally, the data transmitted through the link can be used more efficiently. One key example of such efficiency is the case where one link is used for multiple remote devices. As shown in Figure 10, one link from the headend CCAP device can be used to transport broadcast services once for multiple remote devices. This is achieved by using multicast addressing, whereby each of the remote devices uses the same lineup for each of the respective service groups. In doing so, a single link from the headend CCAP can be used for all the remote devices without exhausting the transport link capacity.

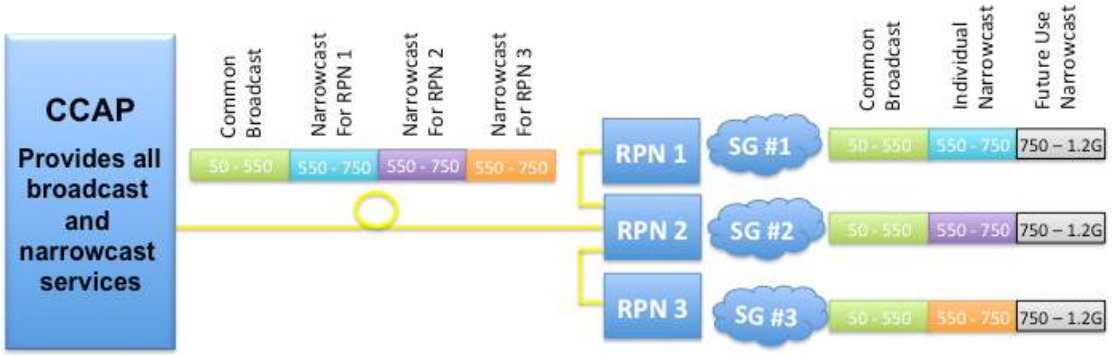

*Figure 10: Reuse of broadcast capacity across multiple RPNs*

## 3.2. Increased Headend Equipment Density

The implementation of distributed architectures makes it possible to improve the density of CCAP devices in several ways.

First, while CCAP devices are normally implemented via separate upstream and downstream line cards, a distributed architecture line card could implement both upstream and downstream. This, in effect, doubles the capacity of a CCAP chassis.

In addition, a typical CCAP downstream line card will house 8 or perhaps 12 RF ports, as defined by the printed circuit board space consumed by the components required for RF modulation, plus the sheer connector spacing required. However, Ethernet connectors can be placed considerably closer to one another, allowing a similar line card to easily house 16 to 24 ports. This additional density gain once again doubles the capacity of a CCAP chassis.

Finally, it is possible to consider "daisy chaining" digital nodes (RPNs) off of a single CCAP Ethernet port. This is because, on the one hand, the capacity of an 10 Gbps Ethernet link would support the capacity needed for a single RPN. Plus, it is possible to generate an RPN "channel lineup" by transmitting the broadcast content once to multiple RPNs. As depicted in Figure 10, the data stream transmitted from the CCAP could contain a single "copy" of the broadcast line-up content, plus individual versions of the narrowcast content for each of the RPNs. The RPNs would then reuse the broadcast lineup content to recreate the individual RPN channel lineup. In this way, each service group served by the CCAP port would contain the same broadcast lineup while allowing for its own unique narrowcast line-up.

Then, as the narrowcast lineup capacity grows over time, CCAP ports would be segmented to support less RPNs, akin to the way service groups are split today to provide more narrowcast capacity as it is required.

As summarized in Table 3 below, the combined effect of the 3 factors described above is very significant, ranging from 8x to 18x of headend capacity gain. From a space and power perspective, this can facilitate huge savings.

| Density Factor | Density Gain |
|---|---|
| Combined US/DS line card | 2x |
| Greater number of ports per line card | 2x to 3x |
| Multiple RPNs per CCAP port | 2x to 3x |
| Combined capacity gain | 8x to 18x |

*Table 3: Distributed architecture headend density gain*

But, just how meaningful is this headend density gain?

Consider: A migration from an HFC architecture with an average of N+5 (meaning an optical-to-RF node followed by 5 cascading amplifiers) to N+0 would require about 10x the number of nodes, and the headend density benefits resulting from the distributed architecture would neutralize the potential increase in CCAP equipment.

It is then quite clear that from a space and power savings, distributed architectures take the benefit of CCAP to a whole new level.

## 3.3. Integration of HFC and Fiber Services

One of the largest areas of growth for MSOs is business services. MSOs have deployed business services via both cable modems and fiber-based infrastructure. The fiber-based services are either point-to-point, using Ethernet and wave-division multiplexing (WDM), or point-to-multipoint, using PON (Passive Optical Network) technologies (either EPON [Ethernet Passive Optical Network] or GPON [Gigabit Passive Optical Network]).

This duality results in the existence of two parallel networks. One of them, the HFC infrastructure, uses fiber from the headend to the node via an analog modulated link for the forward direction and either analog or proprietary digital return, followed by coax infrastructure from the node to the home. The other consists of digital fiber from the headend to the subscriber, which is used for commercial services.

Given the use of a digital fiber in both the forward and the return for the RPN, and especially because this digital fiber is based on Ethernet technology, it is possible to collapse both of these networks into a single infrastructure. Even without fully collapsing the Ethernet network better utilization of physical fiber can be enabled by the move to common DWDM wavelengths and multiplexers.

Therefore, the implementation of RPNs with an Ethernet interface between the CCAP and the RPN would make it possible to implement a PON interface at the RPN.

The benefits from this integration include:

- Reduction of the optical link for PON to the distance between the node to the customer premise

- The typical distance from a node to a customer premise in an N+0 architecture is 1-2 kilometers. This would virtually eliminate any distance limitations for PON, making it possible to implement the largest possible densities.

- In addition, this shortened distance would enable the use of lower power optics, which can translate into significant savings -- especially for 10 Gbps optics, and especially for the upstream, which results in significant savings in the ONU.

- Leverage a single network for multiple services, which will reduce maintenance and increase operational efficiencies.

## 3.4. Migration Strategy

Clearly, one of the more concerning issues to MSOs is the migration strategy.

Any migration that requires synchronized cut-overs, or which requires changes in multiple locations to execute, is problematic, and usually results in a barrier to adoption. Therefore, it is very important that the migration to distributed architectures allow for unsynchronized changes.

Furthermore, ideally the migration to distributed architectures allows for opportunistic changes in the network. For example, one such change would be to migrate a single node, such as would be the case in an MDU to increase capacity.

As it turns out, distributed architectures enable such gradual, unsynchronized and opportunistic changes in the network. What follows is an overview of the steps and components involved in the migration to distributed architectures.

Starting with the components of the network on both sides of the distributed architectures, neither the back-office nor the various components in the customer premise need to be modified in any way. All back-office components are unaffected by the migration to distributed architectures, and any additional MIBs for management and/or commands for configuration as needed can be added well before the first distributed architecture CCAP line card or node are deployed. With respect to customer premise devices, these would not be affected in any way in order to deploy distributed architectures, and any enhancements that are made possible through the introduction of distributed architectures would be implemented in CPE equipment that can be introduced before or after the migration to distributed architectures.

The critical portion of the network where changes need to be made are in the headend and the plant.

To begin with, the changes required in the headend are primarily in the CCAP platform. The CCAP architecture was specifically designed to support multiple technologies simultaneously, which makes it possible to install regular RF upstream and downstream line cards and distributed architecture line cards in the same chassis. While some MSOs may choose to deploy a separate CCAP platform for distributed architectures, it is certainly possible to support both types of line cards in the same chassis. Of course, these distributed architecture line cards can be installed at any time prior to beginning the migration in the plant, and any removal of RF upstream or downstream line cards can follow the deployment of any number of distributed architecture line cards or nodes.

Turning our attention to the plant, it is similarly possible to migrate regular nodes to distributed architecture nodes in any sequence. As an example, what follows is a sequence of steps where a single node is gradually converted from standard HFC to distributed architecture.

Figure 11 depicts a single HFC node connected to a CCAP device.

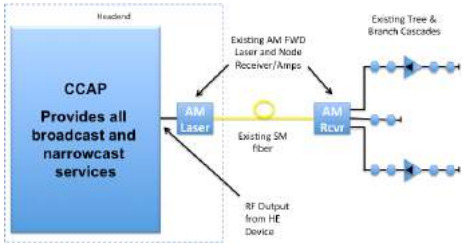

*Figure 11: Single traditional HFC node*

Figure 12 shows how the HFC node would be converted to RPN while the rest of the HFC network remains unchanged. The distributed architecture line card in the CCAP would have been deployed in the headend in a prior activity, and even the RPN could have been deployed before the day of the cutover. Then on the day of the change the fiber cable could be swung in the headend from one AM laser to the CCAP distributed architecture card, and in the field from the HFC node to the RPN. Of course it is not necessary to perform the migration in such a fashion, but it would be possible if desired.

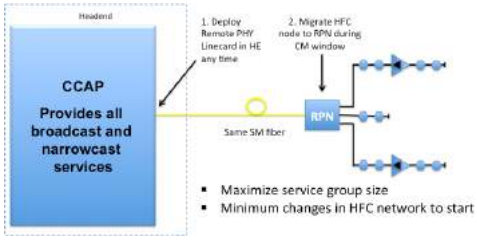

*Figure 12: RPN deployment step 1*

Figure 13 depicts a possible step 2 in the process, whereby additional RPNs are installed to segment the original service group further. These additional RPNs could be daisy chained from the original RPN node by taking advantage of the broadcast reuse feature, minimizing complexity in the deployment process.

NOTE: The example depicted is one in which fiber is run to every amplifier station. However, a more efficient segmentation scheme would include optimal placement of RPNs in an N+0 HFC architecture with some turnaround of passive components.

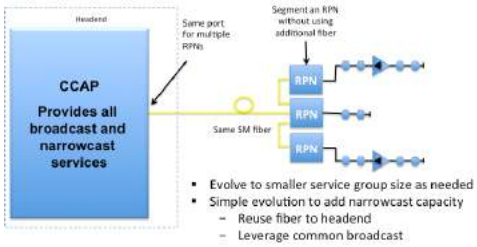

*Figure 13: RPN deployment step 2*

Figure 14 shows how further segmentation could take place by replacing the remaining amplifiers in the network with RPNs.

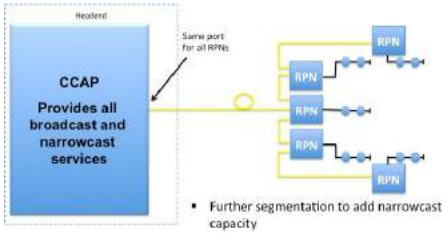

*Figure 14: RPN deployment step 3*

Figure 15 shows that the RPN service group depicted above is segmented as additional narrowcast capacity is required. In this example, 2 of the RPNs from the distributed architecture service group shown in Figure 14 are split into separate service groups using separate CCAP ports.

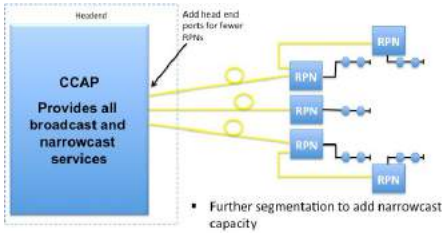

*Figure 15: RPN deployment step 4*

Eventually each of the RPNs could be connected to an individual CCAP RPN port as shown in Figure 16. This would provide up to 10 Gbps of capacity to each RPN. This could, for example, be desirable to provide both RF and PON services from the RPN.

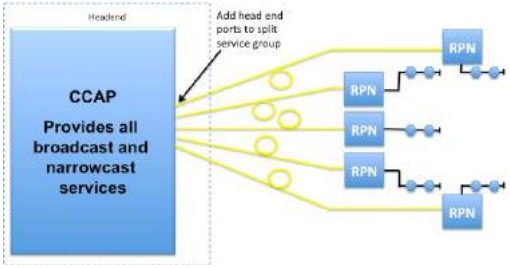

*Figure 16: RPN deployment step 5*

Similarly, the distributed architecture line card in the CCAP could be upgraded to support even more capacity as such capacity is needed and becomes cost effective. For example, the Ethernet link from the CCAP to the RPN could eventually be upgraded to 40 or 100 Gbps, both of which are already commercially available.

## 3.5. From Today to Virtual CCAP

As the network has to continue in operation through the transition, virtualizing the CCAP requires careful planning and a sensibly staged process. As with roads, where cars must be kept moving during any lengthy highway reconstruction, in the network customer traffic must continue flowing day after day. In a sense, while road work is visible to car drivers, in a network the modifications remain invisible to the end user.

One way to do so is to migrate individual functions, one at a time. So, one must develop a list of the functions that would be virtualized, and this list would be prioritized, such as on the basis of complexity of implementation and benefit. Those features with the lowest implementation complexity and the highest benefit would be prioritized higher in the list, and consequently implemented first.

In DOCSIS 3.1, one of the functions that would rise to the top of any such list is Modulation Profile Management (MPM). This is because MPM will take time to be implemented by vendors in a CCAP chassis, but implementing externally via virtualization could be quite simple. In the process, its benefit to operators is quite significant since it would enable better efficiencies from DOCSIS 3.1.

Over time, implementing virtualization of the various functions of the CCAP would lead to a completely virtualized CCAP platform. Such a platform would be more easily scalable than CCAP platforms are today, where segmentation of service groups requires the addition of more chassis in a linear relationship fashion.

In addition, and perhaps more importantly, virtualizing the CCAP will enable the development of additional functionality, and improvements to such functionality, to occur much more rapidly than it is possible to do today.

# 4. DAA Components, Use Cases and Generations

As MSOs move forward with the implementation of Distributed Access Architectures, there are already many useful lessons learned. The following sections of this paper describe three key aspects: DAA components, use cases, and the generational aspects of DAA.

## 4.1. DAA Components

As the link from the headend to the node is converted from analog modulated forward to digital, using Ethernet as the transport, several approaches can be taken for the implementation of the remaining headend components. In this section we will examine one approach in some detail, for which a key goal is to convert all required components into functionally individual software pieces implemented independently.

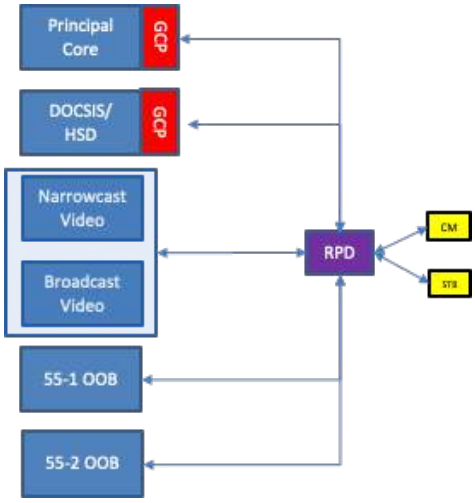

*Figure 17: DAA implementation components*

### 4.1.1. Advantages and disadvantages of discrete components

As shown in Figure 17, an implementation approach for DAA is to develop discrete SW components for each of the various DAA components. Some of the advantages for doing so include:

- The implementation can consist of a multi-vendor platform, where each component can be developed by a different party.
- By having smaller functional components their implementation tends to be simpler.
- Time to market also tends to be reduced.

However, implementation of smaller discrete components has its downsides, such as:

- There is an implied requirement to more tightly specify the behavior of each component to ensure that the overall system will operate as intended.
- Interface specifications between the various components is required.
- Management of the various components, including their configuration and upgrade is generally more complicated, and requires more elaborate orchestration.

### 4.1.2. Key DAA discrete components

The key components depicted in Figure 17 include:

- The Principal Core, which is the first component that the RPD will contact after receiving an IP address.
    - The Principal Core is implemented such that it will configure all the RPD functions except DOCSIS channels and behavior, which will be implemented by the DOCSIS CMTS.
    - As depicted in Figure 17, the Principal Core communicates with the RPD using the GCP protocol, for which it is known as the GCP Principal, or GCPP for short.
    - Included in the GCP Principal Core are all the non-DOCSIS command and control functions for the RPD, including configuration, management and reporting.
- The DOCSIS Core, which is the second component that the RPD will contact in the network.
    - The DOCSIS Core also communicates with the RPD using GCP.
    - The DOCSIS Core provides all configuration, command and control for DOCSIS channels, both downstream and upstream.
- Narrowcast and Broadcast Video engines

- Implemented as separate components, the Narrowcast and Broadcast Video engines provide all the content services for the various RPDs in the network.
- Neither the Narrowcast nor the Broadcast Video engines communicate with, nor have knowledge of, the RPDs.
- Services are configured statically in the Narrowcast and Broadcast Video engines upon their bring-up, and are multicasted to all RPDs, which listen for these services as configured by the GCP Principal.
- The Narrowcast and Broadcast Video engines could be implemented separately, but they could be operated together as a single functional system.

- Out-of-Band engines or cores
  - The OOB (Out Of Band) functions are implemented separately from the video engines.
  - Given that video systems are implemented using a single encryption and command/control technology, only one (i.e., either SCTE 55-1 or SCTE 55-2) of them is deployed in any one system.
  - The OOB function may or may not implement GCP for communicating with the RPD. When GCP is implemented the OOB server is a Core, and it will configure the OOB downstream and upstream OOB channels in the RPD. However, when GCP is not implemented the OOB server is an engine, and the GCP Principal will configure the downstream and upstream OOB channels.

- Finally, not depicted in Figure 17 is a very important component: the Timing Server.
  - The Timing Server, also known as the Grand Master, provides the critical timing synchronization for all the DAA components.
  - Each of the DAA components will include a Timing Client, which will communicate with the Timing Server to maintain timing synchronization.
  - While timing synchronization is not absolutely critical for video services, it is imperative for DOCSIS service to operate. Therefore, video services may be initiated before timing synchronization is achieved, but DOCSIS services will not.

## 4.2. Key aspects of DAA interoperability

The base implementation of a DAA system is generally simple. However, significant complexity is introduced when interoperability with different vendors' components are introduced.

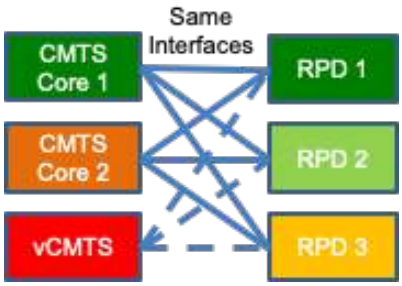

*Figure 18: Functional CMTS-RPD interoperability matrix*

As depicted in Figure 18, the number of combinations of interoperable components increases geometrically as additional components are added on either side of the interoperability matrix. Having a single CMTS interoperate with multiple vendors' RPDs is complex and requires a lot of careful planning and implementation. If the number of CMTS implementations is increased to 2 or 3, the interoperability complexity doubles and triples respectively.

When considering the overall CCAP system, the complexity to achieve multi-vendor interoperability is even larger. For example, if multiple GCP Principals and/or multiple video engines and/or multiple OOB engines/cores are introduced into the mix, the amount of complexity and work required for testing and interoperability results in increases by orders of magnitude.

Therefore, a multi-vendor RPD deployment coupled with a single headend implementation is a sensible approach to an interoperable DAA ecosystem.

## 4.3. Use Cases

In the same way as there are different kinds of nodes for different HFC network applications, there are Remote PHY devices with different characteristics that are best suited for each of the specific HFC network use cases. Similarly, while there are use cases for Remote PHY devices in the outside plant, there are also applications for Remote PHY devices in headends, or "inside plant" as it is frequently called, which will have different implementation characteristics. The following sections cover the key scenarios.

### *4.3.1. Outside plant*

The environmental characteristics of Remote PHY devices developed for outside plant make the design of such devices very different than for RPDs developed for inside plant. The key characteristics for outside plant RPDs are as follows:

- Designs must conform to very tight space availability requirements inside of a node enclosure
- RPDs must support an environment where heat dissipation without the use of fans is critical
- Powered from quasi-square wave power supplies used in HFC networks
- Minimize power consumption to the extent possible given the limited amount of power during normal operation and especially during stand-by power mode

In addition, and perhaps more importantly, there are different kinds of nodes for different HFC network applications, which will drive varying designs for RPDs for outside plant, as follows:

- Traditional HFC networks include cascades of multiple amplifiers and cover a plant footprint of a few hundred homes. In such cases the network capacity offered by the Remote PHY device should be maximized, such as including multiple downstream and multiple upstream ports.

- Newer HFC networks are built with less, or even no amplifiers, and are targeted to cover smaller network footprints. In such cases it is not necessary for the RPD to support much more than a single downstream port, with either a single or dual upstream ports.

- Finally, given that scaling is needed as in any other network application, it should be possible to support greater capacity over time to the extent possible. For example, while initial deployment may only require a single downstream and/or upstream, over time service group segmentation may require additional downstream and/or upstream ports in a single node. For that purpose it is usually a design requirement that multiple individual RPDs fit into a single node enclosure.

Given the above, Remote PHY devices that are built with a single downstream and a single upstream (frequently called 1x1) or a single downstream with dual upstreams (1x2), such that MSOs can place a single one in the node or place additional units when capacity demands require it. Newer silicon designs include more capacity at lower power levels, making it possible to develop RPDs that contain multiple downstream ports and multiple upstream ports, such as 2x2 and 2x4 designs in a single Remote PHY device.

### *4.3.2. Inside plant*

In contrast to the outside plant environmental characteristics, Remote PHY devices developed for inside plant have other constraints that make the design of such devices very different than for RPDs developed for outside plant. The key differences in the design of RPDs for inside plant are as follows:

- Rather than the physical volume of the allocated space, the layout is a primary concern so that dense set-ups in a rack are possible, including cabling distribution in the front and/or back of the rack

- Designs must support an environment where forced air is used for heat dissipation, requiring airflow from front-to-back or back-to-front, sometimes allowing airflow from side-to-side and/or in a vertical direction

- Powering frequently requires DC power supplies, but AC power supplies are used in other cases

In the case of inside plant RPDs, these are frequently implemented in one of two different form factors:

- Modular, where RPDs are individually removable in a chassis-based design, or

- Fixed, where the entire set of RPDs are part of a monolithic device

The modular design is generally used in larger headends where the ability to replace a defective individual unit is a paramount concern. The fixed design is targeted for a smaller facility, or even a cabinet, where space is the primary concern.

### 4.4. Generational considerations

One final consideration for this paper is the evolution of the Digital Access Architecture to support new generations of equipment.

The initial implementation of the DAA components included support for DOCSIS 3.1. The main component that is specifically developed and implemented for DOCSIS 3.1 is the Remote PHY device, which incorporates ASIC devices which support up to DOCSIS 3.1, but will not support DOCSIS 4.0 functionality.

As newer parts of the DOCSIS 4.0 specifications are implemented, such as FDX, the RPDs will have to be swapped out in order to expand their support for DOCSIS 4.0. This process is akin to what had to be done with CCAP linecards in the past, where either upstream and/or downstream linecards are swapped over time as new versions become available. And, as part of this upgrade, the older equipment is reused in other locations where the newer equipment is not yet needed.

However, for the remaining DAA components, if these are implemented in software on general purpose compute platforms, these should be upgradeable to support newer DOCSIS specifications such as DOCSIS 4.0 and/or other enhancements by simply expanding the functionality implemented in software and downloading it to the platforms in which they run.

In fact, the process for upgrading the DAA components to support changes in the functionality including enhancements to DOCSIS, becomes easier than ever before given the nature of the DAA platform, especially when the DAA implementation includes a minimalistic Remote PHY device at the edge of the HFC network and virtualized components for the remainder of the DAA components.

## 5. Conclusions

Demand for more narrowcast service capacity has driven many changes for MSOs to reclaim spectrum. Splitting nodes to reduce the number of homes passed in an HFC node's footprint is another method used to provide more narrowcast capacity. Enabling narrowcast services on this reclaimed and newly added spectrum requires more equipment in the headend. Given the trajectory of growth using existing equipment will create demand for more headend space. Deploying DAA allows for this growth without expanding facility footprint.

DOCSIS 3.1 created a demand for higher MER out of the node to take advantage of the highest modulation orders available. Transitioning to a digital forward link is the enabling function to achieve this demand. Moving the entire PHY layer to the node has become the standard method to implement a digital forward link.

Deploying DAA in the outside plant allows for more efficient infrastructure utilization between services. DAA and commercial services can share physical fiber due to common DWDM wavelengths and spacing. There is also the possibility of a converged Ethernet switching network to serve both DAA nodes and commercial customers. Having Ethernet inside of a DAA node allows for efficient PON deployments sourced from the same node.

DAA migration scenarios were outlined showing how RPNs can be initially deployed and scaled to offer more bandwidth in their lifecycle. This includes capacity on both the RF and ethernet sides.

Moving from specialized CCAP hardware to a virtualized system can lead to a more scalable system where scale can be added without the step function of adding new CCAP chassis. Feature velocity can be improved on a virtualized system.

Deploying DAA can be done with a CCAP core that provides all needed services or with discrete components that allow for a multi-vendor platform that includes smaller functional components. Implementing discrete components requires well behaved components that adhere to a well-defined specification. Key DAA functions include a GCP principal core, a DOCSIS core, a narrowcast and broadcast video source, an SCTE 55-1 or 55-2 OOB source, and PTP timing distribution.

Remote PHY devices are available for both inside and outside plant applications. Power level and segmentation capability / capacity are key attributes of outside plant RPDs. Density and serviceability are key attributes of inside plant RPDs.

Even though current generation RPDs lack support for FDX operation the other DAA components may have the ability to be upgraded for FDX operation using the current hardware. This enables an easier transition to FDX on an as needed basis later by swapping hardware on desired nodes while utilizing the existing platform.

# 1. Introduction

The Internet of Things (IoT) is connecting any device or "thing" to the Internet. These devices include sensors, actuators, machines and wearables that are capable of collecting and transmitting data about location, activity, situational awareness, environmental activity, etc., to allow autonomous or real-time changes that can enhance or optimize everyday activities.

The number of "things" connected to the Internet is growing at nearly an exponential rate and delivering data about everything from the temperature of an industrial refrigeration unit, to household water consumption, to your heart rate. Each one of these "things" is a doorway into a larger network. Together, these generate colossal amounts of data and can add enormous value to many spheres of society. To realize this value, these things and the systems they are connected to and the data that is generated must be reliable and trustworthy. Thus, it is of paramount importance to secure the things, associated systems and the data generated.

More and more connected devices are being deployed, and a threat or security breach in one area or in one device can have a domino effect on other devices connected to that same network. Potential damage can extend past the network and the data. Finances, reputation, brand and disruption of city services are just some of the areas to be considered in a security assessment to mitigate potential risk. We'll discuss how devices and networks can—and should be—protected as part of an overall strategy of sensor deployment, data collection and analysis.

The Industrial Control Systems (ICSs), which preceded today's IoT systems, existed in silos and used proprietary protocols, networks and technology. Conventional network and system security were provided by establishing a perimeter around the entities which needed to be safeguarded. Once established, firewalls, intrusion detection and prevention systems served as the foundation for security and virtual private networks provided a tunnel into the network. But IoT is drastically reshaping how applications and ICSs operate and are secured.

Current IoT devices have ubiquitous connectivity to the network using open standards, which no doubt is beneficial in providing rich functionality, but enhances threat surface significantly. The network, the things, the associated systems and applications need to be secured. IoT induced reshaping is based on the differentiators in an IoT network versus conventional ones. The differentiators individually impact security, but, when combined, portend exponential security threats and subsequent impacts. Key IoT differences include:

(1) The network topology is ever expanding, pushing the boundaries of the network with the constant addition of functionalities, applications, devices and equipment.
(2) With the constant network expansion, more functionality gets incorporated in to the edge of the network. While edge computing has many advantages, including improved response time and localized services and processing, it exposes the network as a whole to significant vulnerabilities.
(3) Diverse functionalities/applications require different levels of authorization and access to data and systems in the network, edge and backend systems. Improper use of authorization and access or providing blanket permissions to a large number of systems may make the entire network vulnerable.

(4) There is shared multi-tenant cloud usage for compute and storage. Vulnerability of any service or user in any part of the network can impact the entire network.
(5) Critical infrastructure in factories, utilities, cities, etc., can be managed and operated from mobile consoles and personal devices, which brings additional security challenges.
(6) Due to perpetual addition of new applications and functionalities, the network is in a continuous state of flux.
(7) State, federal and international data privacy and security regulatory compliance requirements, under the Federal Trade Commission's (FTC) privacy framework and Federal Trade Commission Act ("FTC Act"), the California Consumer Privacy Act (CCPA), the European Union's (EU) General Data Protection Regulation (GDPR), city/state specific regulations etc., mandate operators/utilities to ensure data security and privacy over a broad range of personal information and/or data.

Ultimately, the highest level of security is paramount, and the network is only as secure as the weakest connected device, with the quantity of devices expanding and changing daily (theoretically). Furthermore, conventionally used perimeter-based security measures (e.g., firewalls, De-Militarized Zones (DMZs), etc.) are not sufficient for IoT networks as one has to consider both fixed IoT devices (e.g., water meters) and mobile IoT devices (fleet management) that extend the edge and make it dynamic. For example, government employees leveraging mobile IoT devices frequently access critical infrastructure networks in cities and utilities. Malicious access through one of these IoT devices could cause catastrophic network effects.

Compounding security problem are data flows (from sensors through networks to public clouds and third-party devices and services) outside of service provider or network operator control. This adds additional dimensions for IoT data security. For instance, data exchanged with water meters by a utility over an operator's network needs to be secured and protected for privacy across all the segments during transit and storage. It requires clear delineation of responsibilities and adherence to protocols for secure operation and management of the devices in transit and data generated from these devices. Not only is the IoT infrastructure itself exposed, but citizens' personal information (PI) could also be exposed, which could be out of compliance with data security and privacy regulations such as California Consumer Privacy Act (CCPA) and General Data Protection and Regulation (GDPR).

According to some industry studies, IoT security still comes up as the number one deterrent to IoT adoption year after year.[1] Having mentioned different vulnerabilities of an IoT network and its impact on network security, we'll now discuss the approaches that may be adapted to mitigate some of these concerns.

IoT devices are relatively inexpensive, have ubiquitous connectivity to the critical network infrastructure, possess enough compute and storage, but probably are not ruggedized enough from a security perspective. This makes them attractive for rogue players with malicious intent to potentially harm the network systems, applications and critical infrastructure. A case in point—in 2016, in one of the infamous IoT DDoS attacks, a botnet infected nearly 65,000 devices in its first 20 hours, doubling in size every 76 minutes. [2] Before eradicated, it infected thousands of devices globally and halted the Internet for a portion of the U.S. for some time.

Cloud computing has become pervasive with many domains, including IoT, rapidly adapting to it. Cloud computing is attractive in providing flexibility in deployment, providing scalability and is cost effective. Also, the multitenancy aspects of cloud are especially attractive as it is an enabler for scaling different applications or verticals of the IoT network independently. However, as some recent incidents[3] across many organizations, including the US Navy, major corporations and more than a dozen cloud providers globally have shown, vulnerability in one segment can be exploited to impact other parts of the network. Even if one maintains one's own network diligently from a security perspective, it may still become a victim of vulnerability of a different entity in the shared cloud. The sensitivity level of the data may trigger regulatory compliance requirements or create enhanced risk if not properly secured under the FTC's privacy framework or GDPR. Private and hybrid clouds are also not immune from this problem by virtue of their accessibility needs over a public network.

Having mentioned different vulnerabilities of an IoT network and the impact on network security, now let us discuss the approaches that may be adapted to mitigate some of these concerns.

## 2. Proposed IoT Security Framework

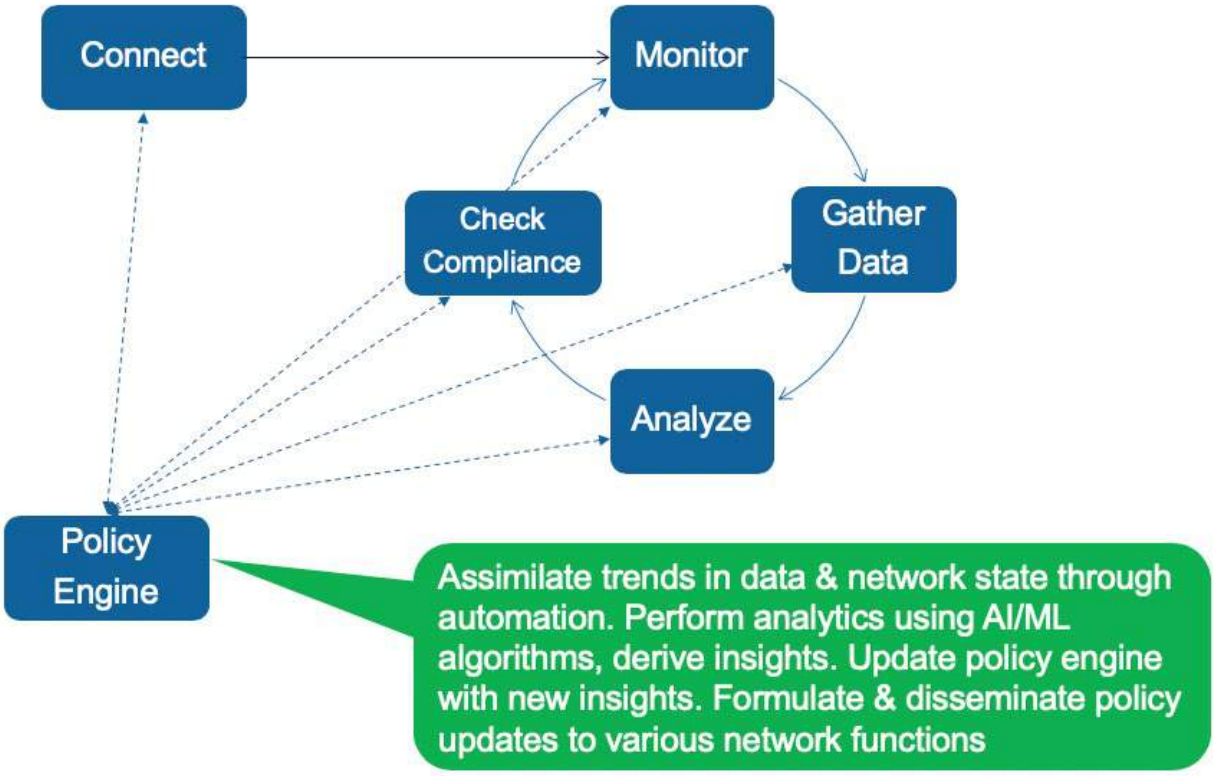

**Figure 1 - IoT Security Life Cycle**

As depicted above, each entity in the IoT network should be provided with *minimum viable access* (to connectivity, bandwidth, amount of data transmitted and frequency of transmissions, authorization to connect to systems and access to data). All this should be continuously monitored through an automated process to gather the data, analyze to discern insights and identify anomalies. The policies need to be updated based on gathered insights, observed trends in data and operator input. This minimal viable access and compliance with policies for each entity, including devices, edge compute nodes or more complex core/access network functions, forms the foundation of IoT network security.

To illustrate the importance of this point, it may be noted that in 2017 a casino lost its high roller database through the network connectivity provided for a fish tank. [4] The fish tank had sensors connected to a PC that regulated the temperature, food delivery and cleanliness of the tank. This vector was used to steal the high roller database. Needless to say, a temperature control system for a fish tank does not need, and should not have had, any possible connectivity to critical data, and it is a failure of formulating and enforcing effective security policies (e.g. minimal viable access to connectivity, data and authorization).

It is important to recognize that, network security is ***not*** an isolated standalone function, rather it is an overarching, all-encompassing characteristic of a system. As the saying goes, a given system is only as secure as its weakest constituent component. It is imperative that the security of the entire system be looked into as a whole, not as individual isolated components.

### 2.1. Connect:

The diversity and volume of IoT use cases are numerous. Equally large are associated devices, network components and diversity of their connectivity needs. This diversity certainly increases the threat surface area, variety of threat vectors and vulnerabilities. To mitigate this risk, a strong connectivity policy needs to be created and enforced. The policy should be customizable and consider the characteristics of each device, the evolving trends in the network, the availability of the network resources, the relative priority and criticality of various functions and their connectivity needs. This can be arrived at after a thorough analysis of various components in the network and building a subsequent enforcement framework.

### 2.2. Monitor:

The diversity of devices and network functions in an IoT network have different capabilities and provide different metrics to gauge and monitor these capabilities. The monitoring function needs to consider a profile for each entity (devices, edge/core/access network functions) and create a set of characteristics to be monitored and adapt these characteristics to evolving conditions in the network. Some of these may be conditional on meeting certain thresholds in different areas.

Continuous monitoring of the different aspects of the network, such as traffic patterns, directions of data flow, any norm breaking trends in data or traffic, and evolution in the network are key to highlighting the existence of potential security threats and identifying them. Today's network technologies also offer greater visibility into application and device activity. Software designed to detect anomalous behavior at the network level, revealing Distributed Denial of Service

 

(DDoS) and other attacks, can now leverage artificial intelligence (AI) and machine learning (ML) to respond. Changes in behavior at the application and device level can raise alerts.

### 2.3. Analyze:

The IoT network is diverse in topology and in its constituent network elements. The security issues often cannot be detected or identified by looking at the snapshot of the network at any given time in isolation. It requires a thorough analysis of data gathered from the above mentioned continuous monitoring of the different aspects of the network. The analysis needs to examine not only individual snapshots of the network, but also needs to correlate data points from different parts of the network and across different points in time to identify any emerging trends and discern insights. The insights derived may lead to the addition of new policies or updating existing policies.

### 2.4. Compliance:

This is a gating function, which ensures all entities in the network adhere to respective policies and rules that need to be enforced strictly without exception. Any updates needed to these enforcement rules should come through the policy engine after careful analysis of the impact of the proposed changes across the entire network based on available data and/or operator input. Automation of policy adoption and enforcement is critical for ensuring continued compliance and building resiliency into the process. Automation also helps recognize and address shifting trends in the network.

### 2.5. Improvement cycle:

The IoT Security Life Cycle is a continuous improvement cycle. The accumulation of data and analytics previously mentioned and the correlation of different data points across time and different parts of network provide insights about the network and applications in their current state, as well as for emerging trends in the future. These insights can be used to mitigate current threats and plan for, and address, any emerging threats in the future even before these are materialized.

The improvement cycle comprises identifying potential threats and fine-tuning security policies to adapt to the perceived and emerging threat vectors, based on the insights gathered from analysis and correlation of various data points. This process of keeping the security policies in sync with current and emerging needs of the network allows for continuously updating the policy engine based on the insights. This can also make the network more efficient by eliminating any redundancies, in addition to enhancing the robustness of the network. In summary, this continuous improvement process helps to mitigate security threats of the IoT network, constituent devices, supported applications and enables realization of value of five Vs *(volume, velocity, variety, veracity and value)* of IoT data generated and processed.

## 3. IoT Data : Security, Inegrity and Ownership

People now often say that data is the new oil. However, it doesn't fully characterize the value of IoT data. To quote Adam Schlosser of the World Economic Forum, "unlike oil, the value of data

 

doesn't grow by merely accumulating more. It is the insights generated through analytics and combinations of different data sets that generate the real value." [5]

IoT data promises to convey more useful information than ever before, and the volume and velocity could improve the speed and accuracy of all sorts of business and strategic decisions significantly. Reliability and security of data is essential to make the available information actionable. IoT data security, integrity and ownership are the building blocks of this trust and are of paramount importance.

### 3.1. Security and Integrity:

As described previously, IoT networks comprise a diverse collection of devices, and applications on the network are evolving and generating enormous amount of data. The security solution for this dynamic, ever-evolving network cannot be static. The security policies, framework and measures need to adapt to this diversity in devices and applications. We propose the following framework for securing IoT data and ensuring its integrity:

- The data shall be secured while it traverses through the network across different network elements, including end to end.
- A chain of custody shall be established for the data generated from the point of origin until it is processed/transmitted/stored.
- There may be different stakeholders for each segment of the network, such as device-users, access network providers, core network providers, application server providers, etc.
- There are clearly delineated responsibilities and expectations for each of the stakeholders regarding how to handle the data as it enters the entity and how the data gets processed and leaves the entity.
- Any two entities exchanging data shall have a *security association (SA), minimum viable connectivity, access and authorization driven by the security policy,* which may differ in each direction of data transfer.
- The overhead associated with above mentioned security association and chain of custody is not cumulative and additive for each piece of data transferred across this interface.
- All data is secured in transit and storage. The data security shall include both ciphering and integrity protection as dictated by the security policy.
- Each entity in the network shall have no more visibility and authorization than absolutely necessary to perform its function. This applies to data as well as other network resources.
- AI/ML based algorithms shall be used to correlate different metrics in the network to detect and mitigate any suspicious activity.
- A process is established to isolate and quarantine the impacted applications, devices and segments of the network through a rapid response system.
- A security model shall be adopted to create micro-segments and enable granular enforcement of security policies. This model shall be used to manage data and devices, and migration of data across different components, both external and internal

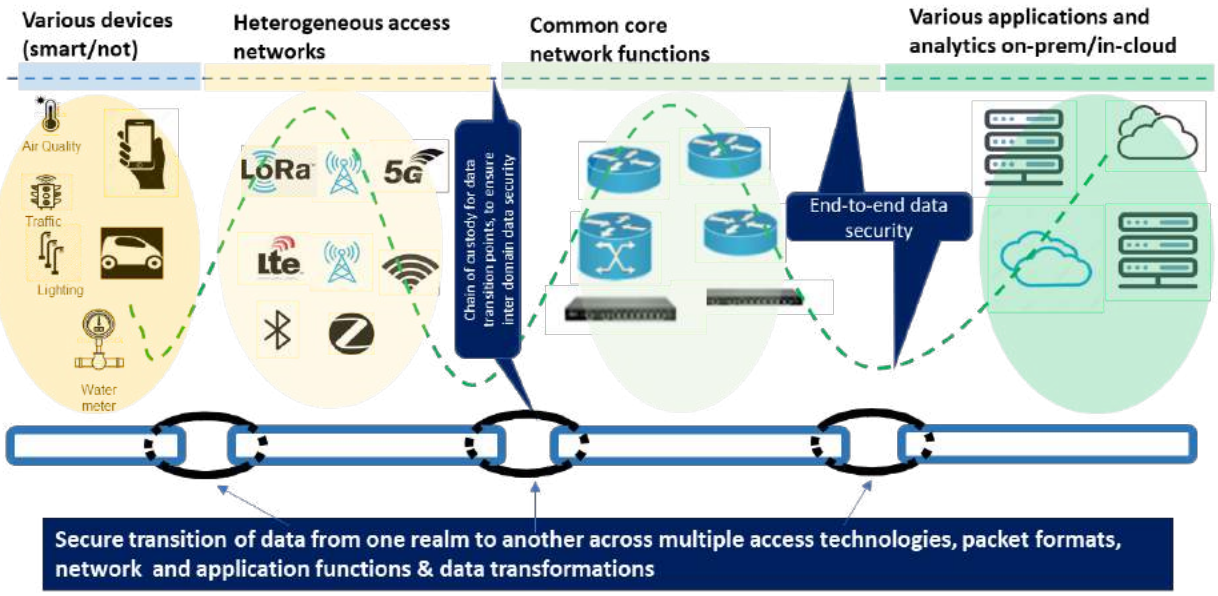

**Figure 2 - Chain of Custody for IoT Data Security**

To establish this chain of custody (CoC) for the data as it traverses through the network across different network elements, access/segment specific methods shall be used. For resource constrained (i.e. low bandwidth, smaller payloads, high latency) segments of the network, access segment specific methods are needed. Any two entities exchanging data shall have a *secure association, minimum viable connectivity, access and authorization driven by the security policy.* For the segments of the network, based on the sensitivity of the data and availability of bandwidth, a blockchain-based method may be adapted. It may be noted that the distributed ledger/blockchain based methods are suitable for IP networks and have cumulative overhead for securing the data. Our proposed method is adaptable to different access technologies and transport methods and does not incur cumulative overheads. However, the proposed chain of custody is complementary to blockchain-based technologies. To secure data in any given segment of the network, blockchain-based methods may be adapted within this framework.
A robust set of security policies shall be formulated taking the above into account. The more granular these policies are, the more fine-grained control it provides on different aspects of data, applications and network. Automation is key to ensuring persistent compliance with established security policies with aforementioned characteristics.

Below is an illustration of messages and information exchanged between different entities in the network to establish a policy driven chain of custody for secure exchange of data without incurring cumulative overhead.

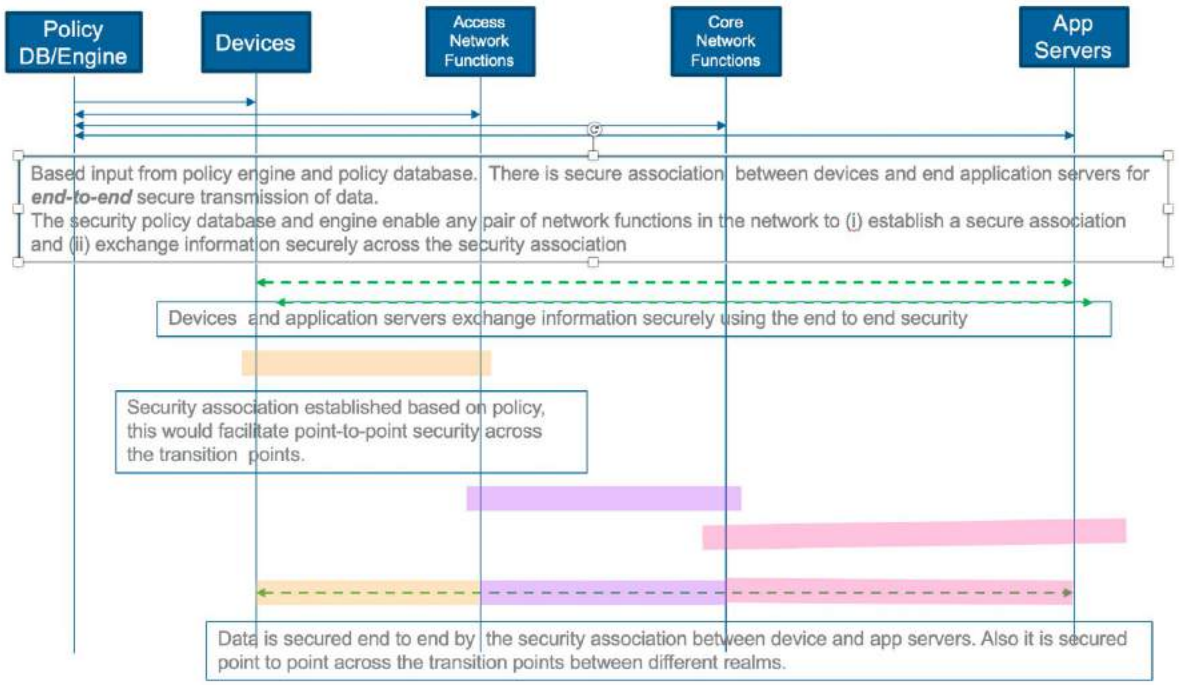

**Figure 3 - Message Flow for Chain of Custody for IoT Data Security**

### 3.2. Ownership:

Data is an asset. With IoT, data is collected and acted upon at different points within the larger IoT framework. The stakeholders for different parts of the framework may be different. For this reason, it is essential that ownership of different aspects of the data and its visibility among the stakeholders is clearly defined upfront.

As an illustration, consider autonomous/connected vehicle data. Vehicle manufacturers, the companies that produce the individual components, telecommunications providers and possibly insurance companies may all want the data produced during an operation. Meanwhile, the vehicle owner might have qualms about sharing personal data. In any event, there's value in that data, and, naturally, each stakeholder desires to capitalize on it.

With Smart Cities, data ownership is further complicated. In addition to different stakeholders like utilities, consumers, etc., city projects may have regulatory compliance requirements, as well as implications associated with public funding of city projects. Unlike the enterprise data, public funding of various city projects often triggers various concerns of the public's right to information aspects for the city's IoT data. Usage, disclosure and monetization of this data may have additional constraints. To avoid any confusion about the ownership of data and insights derived from it, it is imperative to establish upfront roles, responsibilities and rights as to the ownership of data among all stakeholders at the beginning of the project.

## 4. Standards support

Technologies like IoT evolve faster than related standards. What makes IoT unique is that standards are required for multiple enablers such as communications, semiconductors, devices, privacy and security to name a few. Standards are also the foundation for interoperability. The faster they can be defined and adopted, the faster IoT systems will deliver potential advantages. The IoT standards for access networks, security and core functions are at various stages of evolution.

In a report titled *Hype Cycle for IoT Standards and Protocols, 2020,* [6] Gartner states "we still see many standards overlapping, or competing directly, especially in areas with large commercial potential. There are also areas of the IoT in which standards are incomplete or lack full stack support. Consequently, new standards will continue to emerge in the coming years." Currently available security standards from various standards bodies such as LoRa Alliance, 3GPP, IETF, NIST, GSM-A, etc., can be leveraged, adapted and enhanced to secure an IoT network. These standards, originating from diverse standards bodies, were originally intended to address different needs. Adaptation of these for securing an IoT network requires a thorough analysis of the network being secured, configuring, customization and integrating these protocols together to address the specific needs of the IoT network under consideration.

## 5. Conclusion

There are many challenges in the rapidly evolving IoT applications, network and devices with huge amounts of data generated. Security is of paramount importance among all of these. To realize the promise and potential of the IoT network, it is clear that the data generated and needed to be acted upon must be secured and trusted. Ownership is an imperative and requires clear and upfront delineation of roles and responsibilities of all stakeholders.

## 6. Acknowledgements

The Authors would like to express sincere gratitude to Mr. Satya Parimi and Ms. Patricia Zullo for their time and effort for many cycles of reviews, industry insights and valuable suggestions for improvement.

# 1. Introduction

During the COVID-19 pandemic, millions of people around the globe have become far more reliant on their broadband internet connection to stay connected to their family, friends, and co-workers. The broadband internet has emerged as an essential technology that is keeping society together and the economy running in this stressful time.

The growth of broadband internet traffic was bound to happen due to "Work from home" and "Stay at home" instructions around the world during the pandemic. The dependence upon virtual meeting and online collaboration applications has become increasingly important during the pandemic as well. The web apps that are helping us stay connected must work reliably for people to be able to socially connect and stay productive. A few key questions had to be answered quickly during these crises by the broadband operators and vendors – Are the bandwidth surges during the COVID-19 pandemic breaking the broadband Internet connectivity? How are the commonly used applications handling these surges?

There are many popular web applications that drive the conferencing audio and video traffic in any broadband network. Many cable operators have reported a sudden growth of Upstream and Downstream traffic in their networks resulting from these conferencing apps[1]. Due to the tighter constraints that currently exist on the Upstream spectrum, the DOCSIS Upstream is more sensitive to this uptick in bandwidth consumption. In this paper, we will present our research and analysis of the major sources of DOCSIS Upstream bandwidth surge. Specifically, this paper will provide insight into the surge impacts on video conferencing applications and observations on latency, jitter, packet loss, and throughput as DOCSIS Upstream channel utilizations reach an extraordinary tipping point.

# 2. Impact of bandwidth surge on DOCSIS networks

Key application drivers for the bandwidth surge are quite similar on both DOCSIS upstream and downstream networks, including:

- Work-at-home applications – VPN traffic, video conferencing (Cisco Webex™, Microsoft Teams™, Zoom™ and others) and cloud sync for upstream traffic
- Remote learning applications including video conferencing/Zoom™
- Video streaming (Netflix™, Hulu™, Amazon Prime™, Disney+™ and others) predominantly as downstream traffic
- Gaming applications (more actual gaming traffic on the upstream as well as Twitch broadcasts, while downstream is impacted by Twitch video streaming of games)
- Social networks (Facetime/Skype increased usage between families etc.)
- Increased TCP Acks on the upstream due to increased downstream traffic

Based on our studies, as shown in Figure 1, downstream bandwidth usage increased by 12-25% during the busy hours (typically evening prime-time) and also significantly increased during midday by 26-86% again due to video conferencing related traffic loads. On the upstream, this surge was even more profound as peak periods of upstream bandwidth shifted towards the afternoons and the overall "sleep or quiet" periods of traffic was much lower. Upstream peak usage during typical evening peak periods increased by 20-50%, while midday usage showed a much more substantial increase of 30-150%.

The increased upstream usage is typically an achilleas heel of DOCSIS deployments for Multiple System Operators (MSOs) as today's deployment are based on low-split with upstream channels in the frequency range of 20-42MHz or 20-65MHz. Future migration to mid or high splits may reduce the impact of such an upstream bandwidth spike.

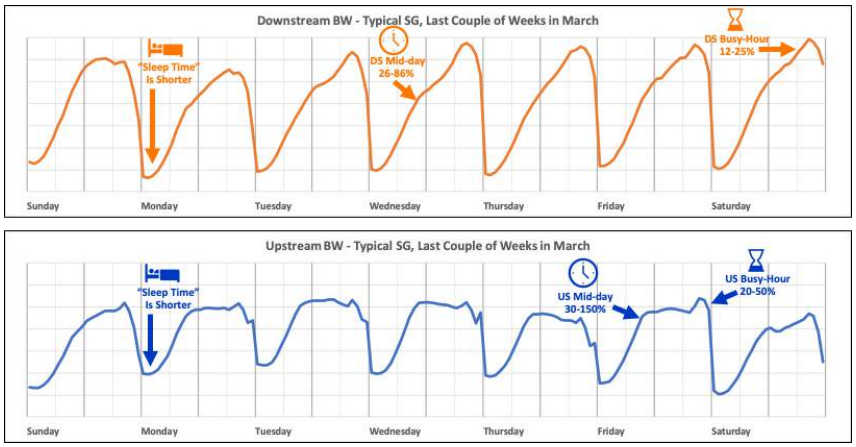

**Figure 1 – Downstream and Upstream impact during COVID-19**

Based on data analytics collected from multiple MSOs using the CommScope ServAssure program, we were able to observe network utilizations levels before and after the pandemic[2]. DOCSIS channel utilization increased significantly week over week during the pandemic lock-down for both upstream and downstream. While these rapid surges may have pulled back as the lockdown eased, the overall congestion observed, and the significant number of service groups impacted shows the need to be prepared for such bandwidth surges in the future. This paper focuses on impact of upstream DOCSIS channel congestion on applications such as video conferencing. It also studies how key performance metrics (KPIs) such as latency and throughput perform under such constrained channel conditions.

Overall, DOCSIS based cable broadband networks managed to handle the bandwidth surge pretty well. Key factors contributing to this positive result include:

- CMTS scheduling algorithms are adaptive handling congestion with fairness based algorithms
- Most Internet applications, especially high bandwidth ones like streaming video and conferencing apps, are adaptive in nature and adjust well to bandwidth fluctuations
- Mechanisms in modems and gateways like Active Queue Management have worked in tandem with application adaptive behavior to keep latency and jitter to somewhat an acceptable level
- Several MSOs have planned additional capacity headroom in their network planning and deployment (for example, 1.2 times Tmax rate to absorb SLA surges)

However, it should be noted that it was not all positive news when it comes to the sudden increase in bandwidth need. Applications like gaming suffered from increased "lag" (latency/jitter) due to buffer bloat issues. Due to packet delays and drops, video tiling and macroblocking effects were also observed in streaming and video conferencing applications. In addition, for subscribers with data caps for their broadband access, those data caps were hit more frequently during the pandemic.

## 3. The Experiment

Our study in this paper focuses specifically on video conferencing applications and how they are impacted by increased in-home traffic and by shared traffic within a DOCSIS service group. In a typical cable broadband access network, congestions points are typically encountered in these areas:

- In-home Wi-Fi Congestion: Predominantly caused due to large number of WIFI users or endpoints in the home. Other factors like wireless interference and distance-to-the-WIFI-gateway related issues also has an impact to overall network congestion, latency and packet losses.

- Cable Modem (CM) Congestion: This is often due to increased bandwidth from in-home applications. Algorithms like Active Queue Management on CMs that manage buffer bloat also influence performance KPIs.
- DOCSIS Channel Congestion: This is attributed to increased bandwidth usage in the neighborhood (associated with the specific Service Group) and scheduling algorithms in the Cable Modem Termination Systems (CMTS) that go hand-in-hand in managing this increased bandwidth.

The focal point of the study presented here is on #2 and #3 from the list above, specifically on the DOCSIS upstream channel which is usually more constrained due to limited bandwidth availability.

## 3.1. Focus on Video Conferencing Applications

As noted earlier, one of the key drivers of Internet traffic during the COVID-19 bandwidth surge was video conferencing. Applications such as Cisco Webex™, Zoom™ conferencing, Google Meet™ and Microsoft Teams™ were used extensively by work-at-home employees, remote learning and other e-learning activities and even as virtual video meetups for social events.

For the sake of this study, we took three of such commonly used applications which allow simultaneous sharing of audio and video along with the ability to be in "presentation mode" with a number of users. The chosen applications will be referred to as App 1, App 2 and App 3 in the remainder of this paper as the intention of our study is not critique the behavior of such applications, but rather to illustrate how diverse the behavior can be and how changing bandwidth conditions can affect the QoE of various conferencing apps.

All three video conferencing apps chosen are capable of running over UDP or TCP as the transport protocol for media traffic, however the default protocol (and the preferred one) is typically UDP. For our experiments, all conferencing apps were using UDP as their transport protocol for media (audio/video) traffic.

It should be noted that outside of audio and traffic, each conferencing application also had its own set of signaling protocols. Some of these leverage existing protocol standards such as Real-time Transport Control Protocol (RTCP) and Session Traversal Utilities for NAT (STUN). For all experiments, we did not make any modifications to the behavior of these signaling protocols but some of the traffic patterns resulting from how these applications reacted to packet loss and latency via signaling were observed.

It was also determined that all three apps have their own flavor of "adaptive streaming" behavior to handle congestion control and ensure that the end user behavior is kept to a minimum due to changing network conditions (and other factors in the streaming path).

## 3.2. Experiment Goals

Some key questions we attempt to find solutions for include:

1) How do key performance metrics like latency, jitter and application throughput change with increased DOCSIS channel utilization and in-home congestion?
2) What happens to Quality of Experience (QoE) of video conferencing applications when DOCSIS upstream channel is congested (70% or higher capacity used)?
3) How does the QoE change when the congested channel issue is combined with increasing home Internet traffic including multiple conferencing sessions?

## 3.3. Experiment Approach

Our initial setup in conducting these experiments was to determine how many active cable modems or gateways are "active and interacting" in a typical DOCSIS Service Group during the course of the pandemic. We expected that our previous figures on such active CMs may not be accurate due to the increased activity due to the lockdown effect in the pandemic. Our study of traffic patterns from North American MSOs during the late March and early April timeline showed us that typically 75-80% CMs were active and transmitting during a 15-second window during peak traffic periods. This number (80%) was used in our study to emulate traffic from multiple modems in a service group.

Another key aspect that was considered during these experiments was using emulation versus simulation techniques. Due to the complex nature of traffic patterns and changing server behavior of conferencing applications, it was decided that real-world traffic emulation communicating with real-world conferencing servers was the preferred approach.

As part of the experiment setup, we had an array of traffic generators that was modelled from statistical models derived from real-world, sampled DOCSIS upstream traffic. Specifically, bursty traffic loads were initiated from these traffic generators using statistical models of three key parameters:

- Duration of traffic burst
- Varying bandwidth levels within each traffic burst
- Inter-burst interval – idle time between successive bursts

The DOCSIS upstream was congested to the desired channel congestion levels (70%, 80% etc.) depending on the experiment needs using these traffic generators. Once this was achieved, real-world video conferencing applications were run with multiple users with the target user on a PC behind the CM under test. The test PC was then broadcasting a video stream and the QoE of that media stream was observed. Additional metrics such as latency and throughput were measured during the video conferencing session.

A conceptual representation of the experiment testbed is shown in Figure 2.

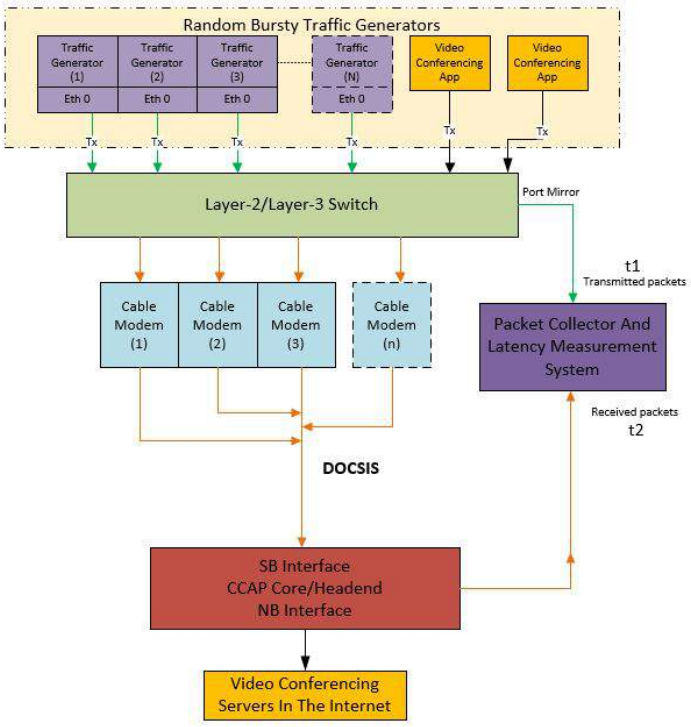

**Figure 2 – Testbed Setup**

## 3.4. Inputs

A service group size of 400 cable modems was chosen for the experiment setup. Based on the prior analysis of real-world subscriber activity, 80% of those modems were considered to be active and interacting.

Four service tiers were part of the testbed as shown in Table 1, along with the distribution of CMs across these tiers. 319 of the 320 modems (excluding the CM under test) were then connected to Traffic generators (as Customer Premises Equipment/CPE devices) and real-world modelled bursty traffic were sent from these generators based on the experiment's need to achieve the desired DOCSIS upstream channel utilization (70%, 80% and so on).

The "**CM under test**" was chosen from service Tier 3 which had a 25Mbps downstream and 5Mbps upstream Service Level Agreement (SLA). This was chosen as the "minimal acceptable upstream bandwidth" needed to run at least a couple of video conferencing applications from the home. Depending on the experiment, devices behind the test CM were one or more PCs running video conferencing applications or traffic generators for throughput/latency/packet loss measurements.

For all video conferencing tests, the test video was chosen to be an animated GIF image (repetitive motion) to account for motion based video transmission and the setup was maintained in a controlled lighting environment with minimal human interference during tests. Fluctuations in video quality (lighting, scene changes etc.) can result in significant variation in transmission bandwidth and the purpose of the controlled environment was to keep any drastic bandwidth fluctuations to a minimum. It should be noted that the animated GIF image was streamed via video during the conference rather than as a "screen

share". Screen sharing typically uses less bandwidth than video transmission itself in such applications, so the experiment was focused on the more bandwidth-intensive video stream sharing.

**Table 1 – Experiment Parameters**

| Key parameters | Values |
|---|---|
| Number of active CMs in SG | 320 |
| Service tiers (DS/US bandwidth) | Tier 1: 100Mbps DS/40Mbps US<br>Tier 2: 50Mbps DS/20MBps US<br>Tier 3: 25Mbps DS/5Mbps US<br>Tier 4: 12 Mbps DS/1 Mbps US |
| Distribution of service tiers | Tier 1: 10%<br>Tier 2: 65%<br>Tier 3: 15%<br>Tier 4: 10% |
| CM configuration details | DOCSIS 3.1 CMs, default values for AQM/buffer controls, ACK suppression enabled |
| DOCSIS Upstream Channel capacity | ~100Mbps (4xATDMA channels: 3x6.4Mhz channels and 1x3.2Mhz channel)<br>DS is not congested in these tests |

## 3.5. Experiment Setup

Two primary setups were used for these experiments. The first set of experiments were focused on DOCSIS upstream channel loading using traffic generators as shown in Figure 3. Along with the traffic generators loading the DOCSIS channel, a single PC client is behind the test CM on a video conferencing session with 4 other participants. A small "test" stream is used to measure latency and packet loss metrics due to the congestion.

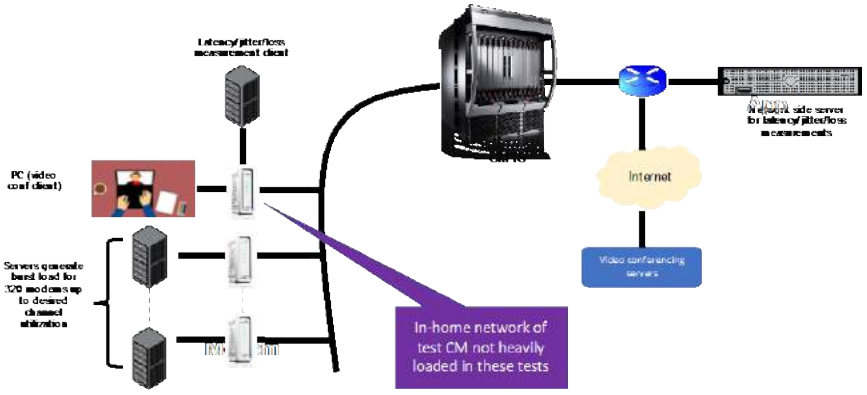

**Figure 3 – Setup 1: QoE impact due to DOCSIS upstream**

The second setup, as shown in Figure 4, adds multiple conferencing clients behind the test CM and also generates in-home traffic loads to emulate aspects like a speed test or file upload. Overall throughput achieved by the conferencing clients as well as other KPIs were measured using this setup.

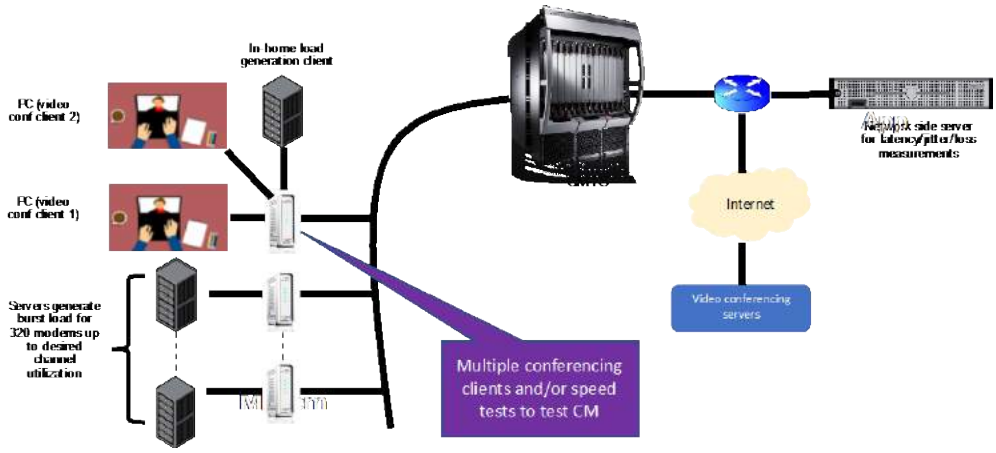

**Figure 4 – Setup 2: QoE impact due to in-home and channel congestion**

# 4. Observations and Analysis

## 4.1. Network Congestion related measurements

To obtain an understanding and a good baseline of how key performance metrics like latency, jitter and packet loss behaved under network load, experiments were conducted loading the DOCSIS upstream with bursty "real-world-like" emulated traffic from the traffic generators. Test streams were injected behind cable modems in every service tier defined in Table 1 to measure (mean) latency, jitter and packet loss at three key channel loading points – 78%, 100% and 122%. It should be noted that this baseline experiment did not have other high bandwidth applications like video conferencing.

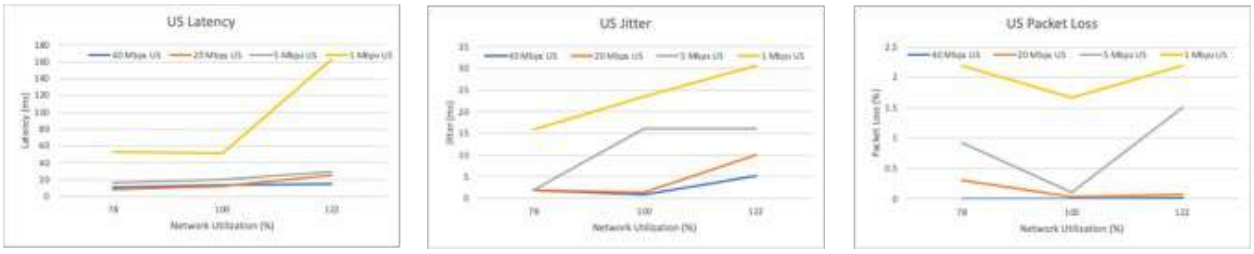

**Figure 5 – Latency, Jitter and Packet Loss under DOCSIS upstream load**

From Figure 5, it can be observed that (mean) upstream latency was not impacted heavily by channel utilization unless the Tmax was at the lowest performing tier (=1Mbps). The jitter graph shows that even with 5Mbps upstream Tmax, packet jitter starts becoming an issue as channel gets congested. This was further validated during our video conferencing tests which we describe in detail in the sections below. Packet loss in general was pretty low to be significant concern to typical applications.

Now that we have a rough idea on how performance KPIs change under DOCSIS channel conditions, let us focus on specific impact of upstream traffic – both in-home and on the shared DOCSIS channel – to video conferencing applications. All experiments described further were conduction on the "CM under test" which was using the upstream Tmax of 5Mbps – as it indicated the "tipping" point where impact on latencies and jitter can easily be observed.

## 4.2. Understanding Video Conferencing App Operating Points

All three video conferencing apps studied were adaptive to changing network conditions – available throughput, packet latency and jitter as well as packet drops. Each application had a preferred sweet spot for optimal operation, especially for video streaming bandwidth. Table 2 shows typical operating bandwidth range for the video stream from these apps as well as where they tend to "converge" if they have sufficient bandwidth.

**Table 2 – Conferencing App operating "sweet spots"**

| App # | Operating video throughput range | Optimal Target throughput |
|---|---|---|
| App 1 | 200Kbps – 1.2Mbps | 700-800 Kbps |
| App 2 | 500Kbps – 2 Mbps | 1-1.25 Mbps |
| App 3 | 1Mbps – 2.5 Mbps | 2.25-2.5 Mbps |

Conferencing app behavior for media traffic bandwidth with and without network congestion is shown in Figure 6, Figure 7 and Figure 8. It can be observed that some Apps like App 1 are conservative in bandwidth usage while others like App 3 tend to be aggressive in maintaining good video quality pushing continuously to use bandwidth above 2Mbps against traffic congestion. Others like App 2 follow a more step-wise increase approach not unlike several standard adaptive streaming video protocols.

It was observed that at least 500Kbps was required to have minimal acceptable video quality in terms of frame rate and resolution and ideally that close to 1Mbps was required for good quality video streaming. Below 500Mbps, some apps like App 1 continued to show video streams at very low frame rates or video resolution, while other apps moved to "audio only" mode often against the bursty network load.

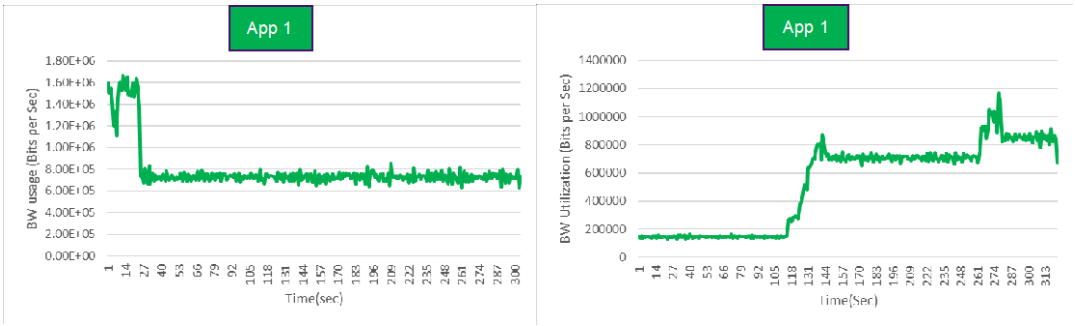

**Figure 6 – App 1 without (left) and with (right) heavy network load**

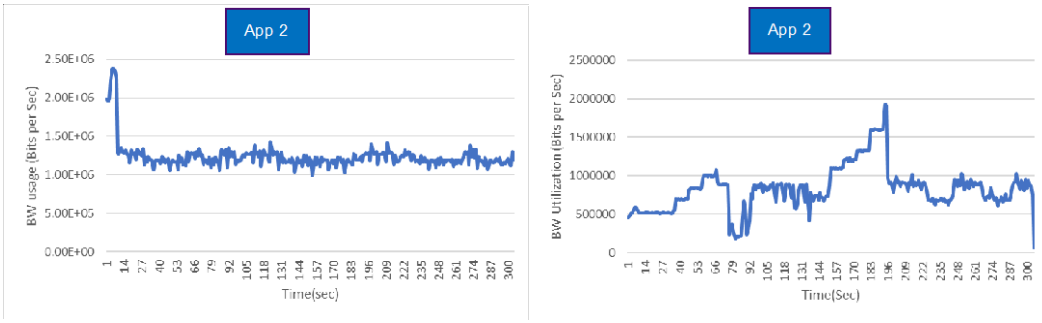

**Figure 7 – App 2 without (left) and with (right) heavy network load**

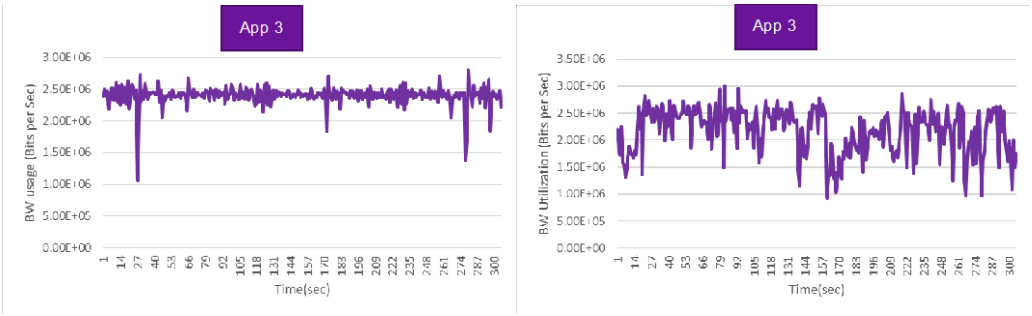

**Figure 8 – App 3 without (left) and with (right) heavy network load**

## 4.3. Speed test & Conferencing App throughput behavior

With multiple conferencing clients behind the test CM, a speed test-like behavior was emulated using TCP tools and the achieved throughput of the speed test app was studied. Figure 9 shows the behavior of such speed tests when 2 conferencing client apps (of the same type) are running in conjunction with a speed test behind the test CM. The baseline speed test shows a typical reduction in achievable throughput with increasing DOCSIS channel congestion (the max upstream is 5Mbps for the test CM).

As seen in the figure below, anomalies in app behavior are observed when network congestion exceeds 75-78% of channel capacity. Interestingly, at lower network congestion levels, the adaptive algorithms were trying to maximize bandwidth use and not let the TCP-based speed test achieve adequate throughput. Once the network gets congested, the algorithms tend to back off and this allows for better speed test results.

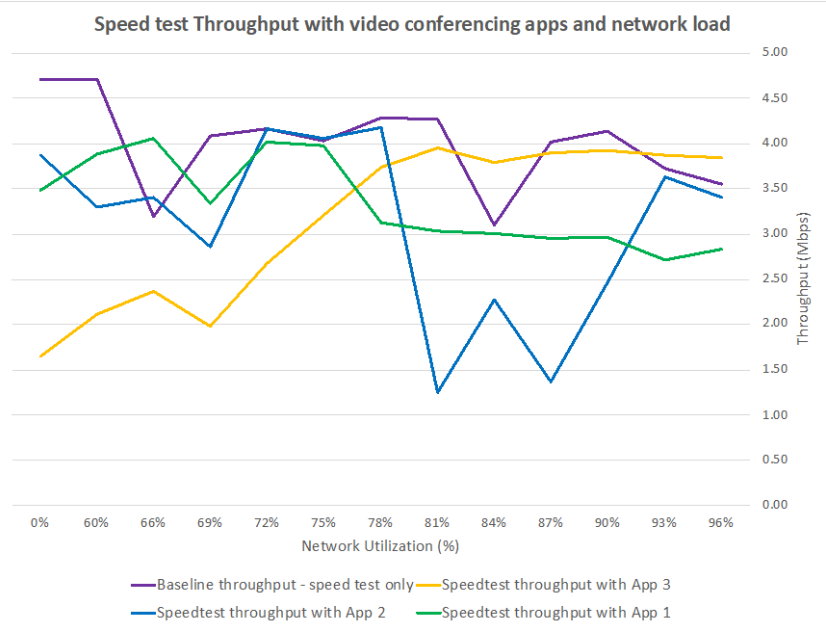

**Figure 9 – Speed test along with multiple conference apps**

Looking at the throughput dataset from an alternate perspective, Figure 10 shows how much throughput a single video conferencing app can achieve when a speed test type data is running along with other conferencing sessions behind the test CM. When varied with DOCSIS channel load, this gives an indication of how congested the channel can get before there is deterioration in the conferencing app QoE to the user.

Each App shows a distinct behavior against network congestion.

1. App 1 uses low bandwidth (600-800kbps) when the network is not congested. That is the typical baseline throughput for App 1. However, at around the 75% mark, the bandwidth used starts increasing to around 1Mbps – likely due to packet retransmissions needed to maintain the same video resolution and quality. No impact was seen to the actual video quality of the app until the congestion in the network exceeded 90%.
2. App 2 shows a much more classic adaptive video streaming behavior with a sawtooth-like variation with throughput. While it is not visible from the graph itself, looking at the raw statistics of throughput vs latency, it was evident that the two KPIs worked in tandem with each other. When app latency increased, the video dropped in resolution and quality, allowing less bandwidth to be used.
3. App 3 had the highest bandwidth utilization of the three, typical of the nature of the app as described in Section 4.1. However, it was the most yielding of bandwidth usage, once network congestion hit 75% or higher, dropping to as low as 600Kbps.

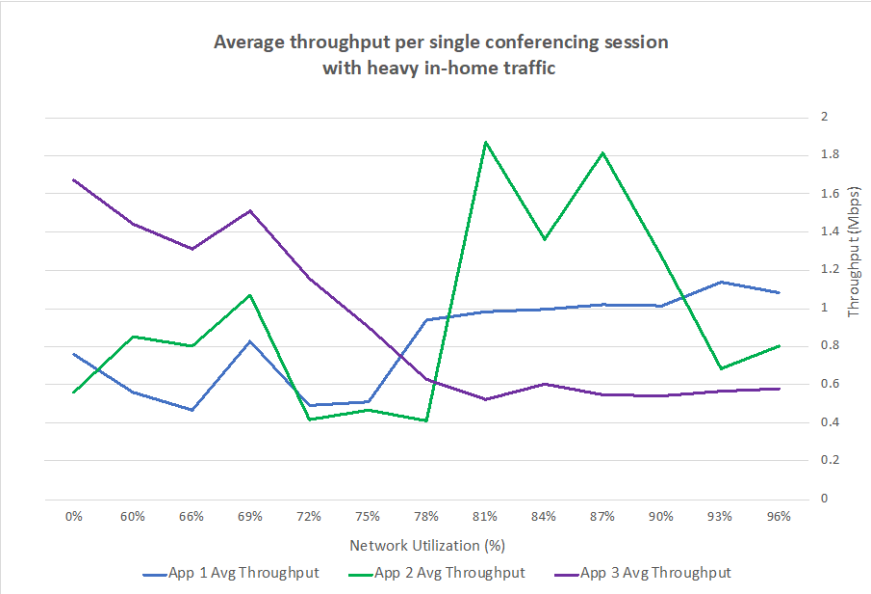

**Figure 10 – Speed achieved by a single conference session under CM+channel load**

It should be noted that while having a 1Mbps target for app video throughput is optimal, the app is still very functional at lower throughputs around 500Kbps however with reduced frame rates and/or video quality. All apps were very effective in working with congested networks and working for optimal performance. The tipping point of network congestion where apps tended to react rapidly to changing conditions was around 75-90% of channel capacity.

## 4.4. Video Conferencing Latency measurements

To measure latency of packets through this congested network, a low bit rate UDP stream was injected from a traffic generator behind the test CM and packet transmission times were measured over the DOCSIS upstream (to the Network Side Interface of the CMTS). Latencies of the data sets were computed and compared, both with and without conferencing apps running, as well as in the presence of the speed-test traffic behind the test CM.

Figure 11 and Figure 12 show mean latencies of conferencing apps under varying upstream DOCSIS channel congestion, with and without additional CM loading with speed test traffic. Both set of graphs have two concurrent conferencing sessions behind the test CM.

Looking at Figure 11, where the home network is not congested, App 3 is showing the highest latency impact. This is to be expected as App 3 had a tendency to take as much as 2.5Mbps per video session if the bandwidth is available. Hence 2 concurrent sessions with additional latency measurement traffic can lead to traffic bursts close to the 5Mbps Upstream Tmax of the service tier of the test CM. App 1 is not impacted much by latency and track very close to the baseline latency (when no conferencing apps are running). App 2 starts getting impacted by latency as network congestion hits 78% and the “sawtooth” behavior mimics the throughput graphs of the same application.

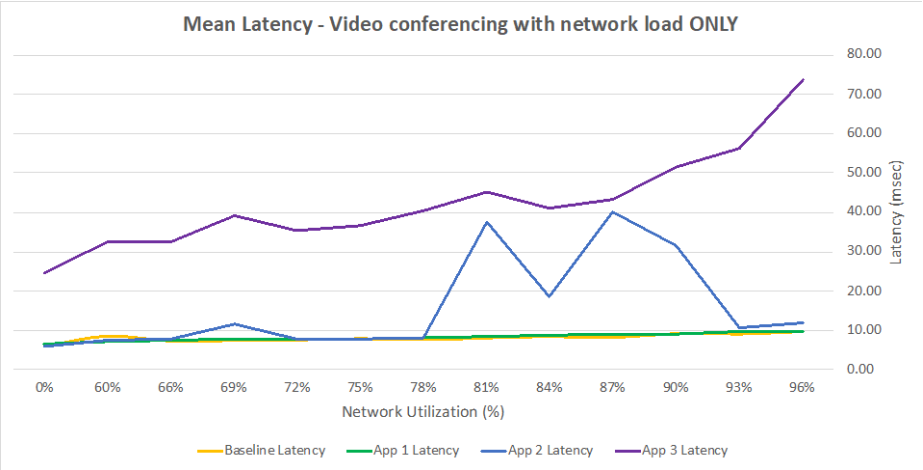

**Figure 11 – Mean Latency for conferencing apps under channel loading ONLY**

In Figure 12, we can now see that once the home network is loaded, latency impact on conferencing apps are much more prominent. Similar to throughput graphs, the inflexion point where apps tend to adapt their reduce their latency is around 78% of network congestion. App 3 being the most bandwidth hungry tends to be most impacted by heavy traffic loads, while App 2 shows a similar behavior to throughput variations with a sawtooth-like fluctuation in latency under heavy congestion.

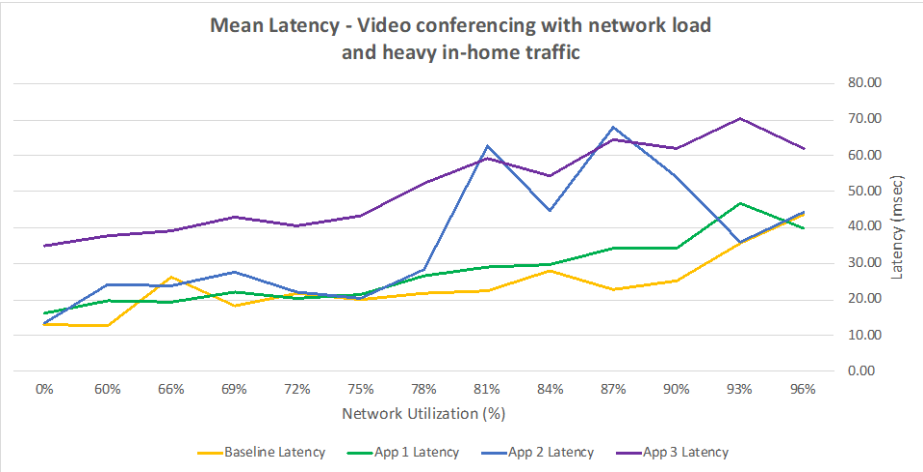

**Figure 12 – Mean Latency for conferencing apps under CM+channel load**

However, mean latencies only tell part of the story. Jitter or delay variation is key in how these conferencing apps are responding. Most of the packets should be within the latency threshold of 150ms, based on ITU-T G.114 specifications[3] for optimal performance of video conferencing style applications. Let us look at how 95$^{th}$ percentile of these latencies to see how the operating points look – to monitor if most of the video packets are maintained under the recommended 150ms threshold.

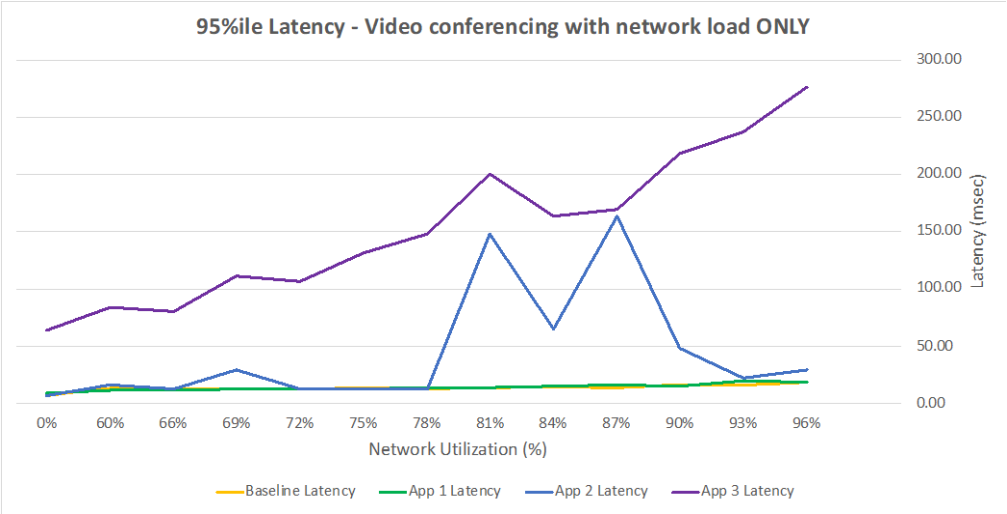

**Figure 13 – 95th percentile latency for conferencing apps under channel loading only**

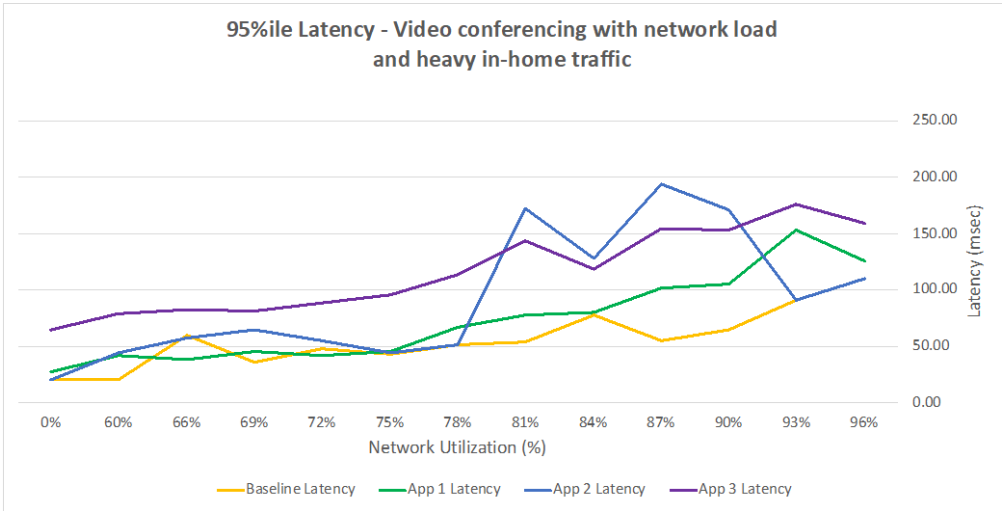

**Figure 14 – 95th percentile latency for conferencing apps under CM+channel load**

Based on Figure 13, with only network loading, App 1 latency is hardly impacted by network loading only. App 2 starts showing increasing latencies when network load exceeds 78% of channel capacity. However, its adaptive algorithm is able to keep latencies under 150ms by reducing video throughput. App 3 shows increasing latencies beyond acceptable threshold when network congestion is around the 78-80% mark.

Figure 14 shows the 95th percentile latency of conferencing apps when the TCP speed-test is also running behind the test CM. The apps are much more susceptible to latency impact with this increase load at home, but the inflection point seems to be still around the 78-80% of channel capacity. While increasing in-home traffic impacts App 2 more, App 3 is actually showing improved latencies when the congestion at home increased. One possible explanation for this could be the fact these applications are adaptive in nature. The presence of additional traffic at the CM and algorithms like Active Queue Management could result in better latency metrics.

## 5. Conclusion

Our experiments with various video conferencing applications indicate that these applications adapt well with varying network conditions and traffic patterns. To keep the desired throughput higher than 1Mbps for video quality and less than 150ms of latency for majority of the traffic, our study shows that a DOCSIS upstream channel utilization should not exceed 75-80% of its full operating capacity. Additionally, ensuring optimizations at the cable modem or home gateway level such as Active Queue Management, Buffer Control TLVs and TCP ack suppression will help reduce the impact of a highly congested channel and allow conferencing apps to adapt better to changing network conditions.

Our study focused on a service tier with fairly stringent bandwidth constraints. To mitigate the impacts of home congestion on these applications, it is desirable to move more subscribers to higher tiers. In the medium term, adding any additional available DOCSIS spectrum, leveraging DOCIS 3.1 technologies like OFDM/OFDMA and performing physical node splits for smaller service group sizes can help mitigate pressure from such bandwidth surges. Long term solutions include moving to mid or high splits, moving to fiber-deep and distributed access architectures including Full Duplex DOCSIS and Extended Spectrum DOCSIS solutions.

# 1. Introduction

In typical linear adaptive streaming deployments, much thought is given to bitrate optimization, in order to maximize a viewer's quality of experience. The non-negligible overhead of the manifest traffic is, however, typically overlooked. A manifest contains information essential for streaming a video asset, identifying the contents of the stream and the location of where constituent components, like URLs, can be found. A manifest which is frequently refreshed can significantly impact bandwidth consumption and number of requests made to Content Delivery Networks (CDNs). This is true for both Apple® HLS and MPEG DASH streaming systems. While the "manifest bloat" problem is endemic for both systems, this paper concentrates on MPEG DASH and DASH-specific tools. In the case of MPEG DASH, there are several major sources contributing to manifest growth, such as the number of included content periods and the sheer volume of DRM license information. Frequent requests further compound the burden of what is essentially "manifest bloat." Altogether the manifest overhead can easily reach 250Kbps and go past 2Mbps in some pathologic cases. These numbers are well beyond the typical low-rate video bitrate.

There are several different approaches to minimizing the manifest overhead. Some are as simple as using HTTP lossless compression algorithms, such as gzip, or the more exotic Brotli [11]. Current DASH practices, such as predictive templates, events, and the timeline extension process, provide an orthogonal approach. Operational experience with large-scale, DASH-based linear programming resulted in a set of new manifest reduction tools that were consequently added into the recent version of MPEG DASH. For example, a recently introduced MPD patching mechanism dramatically reduces the manifest overhead by only sending updates when possible. Several other additions reduce the size of the DASH manifest, by reducing the "bloat" due to license acquisition information in multi-DRM content and segment losses.

Adaptive streaming over HTTP emerged as the mainstream method of delivering video IP-based networks roughly a decade ago as a response to the challenges of network unpredictability and device heterogeneity. Adaptive streaming technology is what powers over-the-top (OTT) services such as Netflix, YouTube, Hulu, Disney+, Peacock, and HBO Max, among others. In aggregate, adaptive streaming techniques reach hundreds of millions of viewers on a dizzying variety of devices.

Adaptive streaming is by no means a new technology. C. Gonkin et. al. [1] wrote the one of the earliest papers on adaptive streaming describing the Real Networks implementation of the approach. The technology became mainstream much later, after the introduction of the first version of Apple HTTP Live Streaming [6] (HLS) in 2009. Several additional streaming systems, such as Microsoft's HTTP Smooth Streaming (HSS) and Adobe's HTTP Dynamic Streaming (HDS) emerged at around the same time and became viable alternatives. Two years later, MPEG Dynamic Adaptive Streaming over HTTP [2] (DASH) became an international standard. Today, HLS and DASH are responsible for the vast majority of adaptive streaming deployments. DASH also made its way into broadcast as a part of Advanced Television System Committee (ATSC) 3.0 and Europe's Hybrid Broadcast Broadband TV (HbbTV).

As opposed to traditional broadcast, cable, and IPTV systems, which push content to receivers, adaptive streaming is a "pull" system, where a streaming client makes an autonomous decision about what to download based on current network conditions and device capabilities. The content is encoded in multiple bitrates referred to as *representations*. Each representation is encoded as series of short *segments* (playable pieces of video, typically 2-10 seconds each). Representations which have the same media content (e.g. video at different bitrates) and have aligned segment boundaries are grouped into *adaptation sets*. The complete asset (e.g. a movie, a pre-recorded or live show) is broken into one or more independent *periods*, which cover a uniform period of time within a presentation. While video on demand (VOD) assets without advertisements consist of a single period, linear channels typically contain multiple periods. An example of such a multi-period asset can be a linear channel where the first period covers

entertainment content, the next three cover three different advertisements, and the fifth covers the continuation of the entertainment content.

HLS is similar. Its manifest is a collection of media playlists listing segment URLs, and a master playlist that references the media playlists and lists their properties. The media playlists are conceptually identical to representations, while the master playlist combines the roles of both period and adaptation sets.

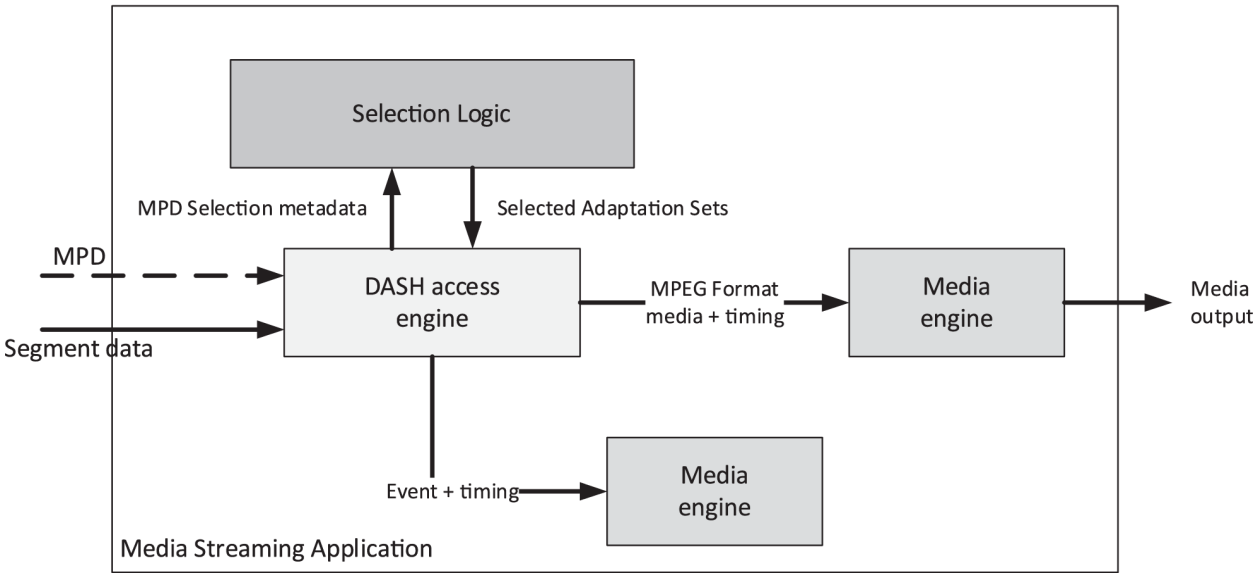

**Figure 1: Anatomy of DASH-based streaming application[2]**

A DASH streaming session starts with downloading a Media Presentation Description (MPD), which is an XML document containing information about media segments, their timing, and the inter-relationships between them. After parsing the MPD, the client selects the representations it sees fit, given its capabilities and network conditions. It starts downloading the media segments from the selected representations. The segments are typically kept in a player buffer, and eventually decoded and rendered. The client also continuously estimates available bandwidth and monitors buffer fullness, and given these it re-evaluates its representation selection.

A. C. Begen et al [8] provide an excellent introduction to the concepts of adaptive streaming. A much later work by A. Bentaleb et al. [9] provides an overview of modern rate adaptation techniques.

## 2. Session overhead and HTTP compression

Any streaming session starts with downloading the manifest. In cases of linear content, this manifest is periodically updated. HLS downloads the master playlist at the beginning of the session, and refreshes the media playlists per each segment [6]. While DASH has several tools for avoiding unnecessary MPD requests, many naïve implementations do not use them, and end up implementing an HLS-like client, where new MPD is requested prior to each segment request.

MPDs can be quite “chatty”. Table 1 below lists linear channel streaming bitrate overheads as measured with several production-grade MPDs, and quantifies the corresponding bandwidth overhead associated with 2-sec segment durations. This 2-sec duration implies an MPD request every 2 seconds (i.e. per each segment).. Two-second segment durations are both a common practice and a recommendation (see e.g. S. Lederer [10]).

**Table 1: MPD overhead**

| MPD | MPD Size (bytes) | Bandwidth (kbps) |
|---|---|---|
| A | 61904 | 247.62 |
| B | 326933 | 1307.73 |
| C | 425867 | 1703.468 |
| D | 552219 | 2208.88 |

We are seeing nearly 250Kbps of overhead with a single-period MPD A, and quickly exceed 1 Mbps as the number of periods in the MPD grows. Using the HLS bitrate ladder described in [7], a 1.3 Mbps overhead translates into the difference between 360p and 540p resolutions. This is hardly negligible. Beyond pure traffic, the size of the MPD also translates into parsing time and memory footprint, both functions of number of XML elements.

HTTP/1.1 allows compression of the body of the HTTP response. This is achieved using transfer coding and happens between the endpoints of the protocol, thus it is mostly transparent to the application. Gzip compression is mandatory in HTTP/1.1, while the newer and widely supported Brotli compression [11] provides noticeably better results. Session-related traffic overhead shrinks dramatically – up to 98% – if HTTP compression is used. – this is illustrated in Table 2 . Even with the most efficient Brotli compression, however, the bitrate overhead is still 50 Kbps for an 18-period MPD D, and nearly 250 Kbps with the ubiquitously supported gzip.

**Table 2: MPD size (in bytes) with and without HTTP compression**

| MPD | Uncompressed | Gzip | Brotli |
|---|---|---|---|
| A | 61904 | 7096 | 5598 |
| B | 326933 | 37322 | 5589 |
| C | 425867 | 17266 | 6583 |
| D | 552219 | 16885 | 10975 |

We can see that application of HTTP compression is essential to make MPD traffic overhead manageable and reduce the start-up time (due to a much faster MPD download).

The HTTP compression approach only addresses the size of the MPD in bytes on the wire and on the CDN. There are additional aspects which depend on the number of XML elements in the MPD: the memory footprint and the MPD parsing time. These need to be addressed using DASH-specific techniques, which are described in the next section.

# 3. Reducing traffic overhead

This section reviews DASH-specific approaches which can be used to reduce the MPD size, number of XML elements, and parsing time. First we discuss MPD patching, a very powerful tool introduced in the latest amendment to MPEG DASH. Patches provide an extremely significant improvement in traffic overhead. Other techniques are needed to remove unneeded XML elements from the actual XML document, and are instrumental in reducing MPD parsing time and its memory footprint.

### 3.1. MPD patch

In the vast majority of cases the change between the previous and the current MPD is minimal. For example, a new segment may have been added in all representations, and the oldest segment may have been removed. This means that the change affects a minimal number of XML elements. Sending only the difference across consecutive MPDs, as updates, is undoubtedly more efficient than downloading full MPDs. This technique can be far more efficient than the generic application of HTTP compression.

The MPD patching framework was first introduced in 3GP-DASH [13] as MPD Delta. The delta format was line oriented, where operands (insert, remove, replace) applied to lines of text. This approach has a major weakness – it implicitly assumes existence of an actual MPD file on the client. This is often not the case, as clients often store the MPD in an in-memory structure, which may be Document Object Model (DOM) or a custom data structure. Secondly, line-oriented syntax is ill-suited for the case where XML document can be regenerated by different entities – whitespace differences can result in patch application errors. Lastly, the MPD Delta syntax ignored version mismatches – e.g. when a modification made to an MPD which differs from the one used for the creation of the delta file, which may render the MPD constructed in the client memory invalid.

The more recent MPEG DASH patching framework takes a slightly different approach: it operates on XML elements and not lines, and addresses elements using XPath as opposed to line numbers. The syntax of the MPD patch is a very restricted subset of the IETF XML patch framework [15]. The restricted syntax creates a system where there typically is only one way of addressing each specific element, and a mandatory check for the client MPD version precedes each patch application. Amendment 1 [3] to the 4th edition of MPEG DASH allows explicit requests for MPD patches as an alternative to requesting a full MPD.

MPD patches change the way the client operates: instead of a simple repeated request to an MPD URL, the client alternates between full MPD and patch requests. When the client starts the streaming session, it downloads an MPD. This downloaded MPD provides URLs for both the next MPD and the next MPD patch. If the client decides to download the patch, the patch process will first validate the MPD version, in order to avoid a mismatch. If the download is unsuccessful, or the patch process fails, the client will request the full MPD as an update.

The results of patch application are strikingly better than those achieved by plain HTTP compression: a single patch for the MPDs listed in Table 2 is 944 bytes uncompressed, and only 349 bytes if Brotli compression is applied.

**Table 3: Traffic overhead in megabytes for 1-hr session**

| MPD | Naïve | Naïve + Brotli | Patch | Patch + Brotli |
|---|---|---|---|---|
| A | 106.26 | 9.61 | 1.34 | 0.678 |
| B | 561.22 | 9.59 | 1.59 | 0.678 |
| C | 731.05 | 11.30 | 1.10 | 0.630 |
| D | 947.95 | 18.84 | 1.81 | 0.683 |

Table 3 shows the impact of using patch updates during a 1-hr streaming session. It assumes 2-sec segments and a period being added every 5 minutes. We can see that the effect of patching is more pronounced than the one of the most efficient HTTP compression alone. For example, in case of MPD A Brotli compression resulted in 90.96% reduction in traffic, while patching alone resulted in a 98.74% reduction. Combining both tools is most efficient, as also reduces the first MPD download by the same 90.96%, which results in a shorter start-up time.

Figure 2 below shows an example MPD which adds 7 new segments. As we can see, it contains the MPD identifier and its version information (publication time) in order to ensure the validity of the patching operation. Another method of ensuring the right patch is downloaded is embedding the version on the new (post-patch) MPD in the URL for the next patch. This example is adopted from [3].

```

**Figure 2: MPD Patch example**

## 3.2. Segment Gap Signaling

There is no such a thing as 100% reliability in a complex content origination system. Encoders may fail, packagers may fail, networks may fail. As a result, having ideal continuous sequence of segments is hard to achieve over a long enough period of time. There will always be segment gaps – short periods where a segment was not generated by the transcoder.

Many things can go wrong. For example, when the encoder output is a MPEG-2 TS over UDP and a datagram is lost en route to the packager, the segment is lost as well. If the encoder output is a multicast per representation (a very common configuration), occasional packet loss will affect a single representation at a time.

Another example is an encoder failure – if an encoder fails, for some reason, and a redundant encoder is started and starts outputting segments, there may be a gap of one or more segments, between the last segment written to origin by the primary encoder, and the first segment written by the redundant encoder. When different representations are generated by different encoders, and an encoder fails, there is a gap only for a subset of the representations, and there will be a segment in one or more representations.

One of the advantages offered by DASH periods is that they are independent, and it is possible to vary the number or character of representations across periods. The main driver behind this design was advanced advertising. For example, the entertainment content may carry audio in English, French, and Spanish languages as well as an English narration (video description) audio track. Moreover, some languages will be available as both stereo and multichannel audio. An ad inserted into this content may only have English stereo. This ad will be represented as a separate period in DASH; pre-ad and post-ad periods would also be periods on their own.

In case a segment from a representation is missing, many implementations assume that the representation no longer exists in the presentation. This triggers creation of a new period without that "lost" representation. At some point in time the packager will again start generating segments for the "lost" representations, which will, in turn, trigger creation of a new period.

In the author's experience, occasional segment gaps resulted in MPDs with 100-300 periods, which made them both exceptionally large and non-trivial for a player. An alternative to this would be using the SegmentTimeline element, which allows gaps in presentation time. With that said, the use of SegmentTimeline in the case of per-representation gaps is also inefficient, as it will need to appear in every single representation -- as opposed to the common practice of including them only at the adaptation set level. For example, in the case of an unencrypted, 12-representation HLS bitrate ladder [7], and a 2-min MPD, the MPD size increased nearly ten-fold, form 11KB to 105KB.

All of this can be avoided at a low cost if a missing segment is explicitly identified. Both DASH and HLS recently allowed such signaling. In DASH this is achieved using a FailoverContent element, which indicates time gaps for which the representation has no segments. This translates to just a few of lines, with a single gap (i.e., one or more consecutive missing segment) corresponding to a single XML element. This has very little impact on either the MPD size or the number of XML elements it contains.

### 3.3. Efficient multi-DRM signaling

The overhead of DRM license inlining traffic can be significant, especially in context of linear channels with multi-period, multi-DRM MPDs and multiple video and audio options. The Common Encryption standard [4] and several DRMs define a way of including license acquisition information in the MPD. This is needed in order to start the license acquisition in parallel with the download of an initialization segment, as opposed to waiting for it and parsing this information out of a box contained in it. This inevitably grows the MPD size.

For example, consider a single-period MPD with stereo and multi-channel adaptation sets for both English and Spanish, video, and trick modes has 6 cenc:pssh elements. The number is multiplied by the number of DRMs – meaning that the same single-period MPD service with 3 DRMs contains 18 cenc:pssh elements, but only 3 of them are unique.

What makes the problem acute is that these elements are fairly large. For example, the 18-period 320Kb MPD B contains 171Kb worth of license acquisition data embedded in its ContentProtection element. The vast majority of this data is redundant.

The recent amendment to the 4th edition of MPEG DASH [3] introduced a referencing mechanism for ContentProtection elements. Unique ContentProtection elements (one for each DRM) are placed once, at the MPD level, and given unique IDs. They are then referenced by ContentProtection descriptors at adaptation set level, which results in 3 unique elements in the reference ContentProtection descriptors and 18 one-line dependent ContentProtection elements. This on its own dramatically reduces the MPD size. For example, the 320Kb MPD B is reduced to 86Kb.

Table 4 illustrates the results of referencing in MPDs A, B, and D, which have 3 DRMs. We can see that referencing results in a very significant reduction in uncompressed size of an MPD. As opposed to HTTP compression, this result translates directly into reduction in memory footprint. With that said, the result of applying lossless Brotli compression to an MPD with referencing is near-identical to applying same Brotli compression to the original MPD.

**Table 4: MPD size (in bytes) with referencing and HTTP compression**

| MPD | Periods | Original | ContentProtection Referencing | | |
|---|---|---|---|---|---|
| | | | Uncompressed | Gzip | Brotli |
| A | 1 | 61904 | 18170 | 6447 | 5596 |
| B | 10 | 326933 | 88010 | 7350 | 5568 |
| D | 18 | 552219 | 155650 | 16128 | 11051 |

Referencing can also be used to reduce the size of an MPD patch carrying a new period, as the license acquisition information would be a significant part of the patch, and it typically does not change every period.

# 4. Reducing the number of HTTP requests

A naïve HLS-like implementation also implies that MPD traffic is responsible for a third of CDN requests. The number of CDN cache misses is lower for the MPDs, but the number of actual requests is still quite large – a third of the requests for an asset containing video and audio. The sheer number of HTTP GET requests is taxing the edge caches.

Several tools in the MPEG DASH specification are intended to reduce the number of HTTP requests for linear content.

## 4.1. Asynchronous MPD updates

DASH has an inband event mechanism largely modeled after SCTE 35 cue messages in MPEG-2 TS. DASH inband events are timed "blobs" of metadata embedded in an Event Message (`emsg`) box. This box resides in the beginning of an ISO-BMFF media segment, before the Movie Fragment (`moof`) box. In order to ensure that the event is received regardless of the representation, all representations within an adaptation set carry the same inband events. A client is expected to parse the very beginning of the incoming media segment, and in case it finds an `emsg` box, it is expected to pass it to the application or process itself.

One key event type defined in the DASH specification is the MPD Validity Expiration event. It lets the client know the time at which its MPD is going to expire. If the presence MPD Validity Expiration event is signaled in the MPD, the client does not need refresh the MPD until explicitly instructed by the MPD Validity Expiration embedded in a media segment. This is a very powerful feature when coupled with the features described in the next two sections – predictive templates and timeline extension.

## 4.2. Predictive templates

Templates are one of the major differences between DASH and HLS. In DASH, templates are mandatory for all DASH Live profiles intended for linear channels and events. A template is a string similar to the one used in printf functions in the C programming language. The template string has several predefined variables, two of which, $Number$ and $Time$, are of particular interest.

$Number$ stands for the number of the requested segment. This number is incremented for every segment, and URLs for every segment are derived by inserting the value of $Number$ into the template string. This way, given a more or less constant segment duration, there is no need to update the MPD, because future segment URLs can be derived along with an approximation of their availability window. The DASH-IF guidelines [5] allow segment duration to vary within ±50% of the target segment duration, however they limit the accumulated drift of any number of consecutive segments to the same 50% of a segment duration. For example, if we assume 2-sec segment duration, each segment can be between 1 and 3 seconds, but the cumulative duration of 1000 segments has to be between 1999 and 2001 seconds.

The $Time$ variable leverages the precise value of the start time of the segment. It is used with the SegmentTimeline element, which contains one or more S elements. Each S element represents a sequence of one or more consecutive segments of equal duration, and does this using the principle of run-length coding. For example, a single S element describes 42 consecutive 2-sec segments as a run of 42 segments with length (duration) of 2 seconds each. The start time of the first segment of the run, the run, and the common duration of the segments are all indicated in the S element. Note that the durations are precise -- if the 43rd segment is even one frame shorter or longer than that, it will be described in a separate S element.

A special run value (i.e., the value of the S@r attribute) of "-1" means "until further notice". This way there is no need for an MPD update as long as the segments are precisely identical – start time and duration allow calculation of the value of $Time$ and hence the derivation of a segment URL for a segment which has not yet been encoded. This has the same effect as the $Number$-based approach, but is easier to use and validate, since the times are precise and not an approximation with a ±50% tolerance.

Templates using the autoincrementing $Number$ or $Time$ with run of -1 let us predict URLs of future segments. This way no MPD update is required as long as segments are being made available in time – their URL and the time at which they can be requested can be calculated way before these segments are even created. This works fine if there is no change in the MPD beyond adding and removing new segments.

The likelihood of not having any other changes in a linear manifest is nil – for example, due to advanced advertising which adds new periods and new SCTE 35 events. This commonly leads to an HLS-like implementation where MPD request is issued for every segment. However, the MPD Validity Expiration event can be used to trigger an MPD update before a material change in the MPD, such as a new upcoming period. This approach reduces the number of MPD requests to the bare minimum – potentially, once per every period as opposed to once every 2-second segment. For example, an hour long MPD with an entertainment period, followed by an ad period, followed by the next entertainment period, may require just one MPD update (prior to the start of the ad period) as opposed to 1,800 requests for the traditional per-segment polling.

## 4.3. Timeline extension

The SegmentTimeline predictive mode is based on an assumption of frame-identical segment durations. Given US fractional frame rates, this is not always possible, because there is no reasonably short segment

duration to align a 1024-sample AAC frames, 1536-sample E-AC-3 frames, and 29.97 fps video. As a result, audio segments typically have a duration pattern where periodically adding one longer or shorter segment prevents a drift from forming. This reduces the efficiency of $Time$-based addressing by limiting run values in audio adaptation sets.

A more efficient mode, commonly referred to as "timeline extension," is documented in DASH-IF IOP [5] as "MPD and Segment-based Live Service Offering". Given that each S element provides a time precisely matching the time in the Track Fragment Decode Time (`tfdt`) box of the media segment, it is possible to predict the URL of the next segment, having parsed the beginning of the current segment. This approach allows a reliance on event-driven, asynchronous MPD updates and results in the same performance as in the $Number$-based case, but with much higher precision.

**Table 5: Request and traffic overhead of a 1-hr session with asynchronous updates**

| MPD | Naïve | | Asynchronous updates | | |
|---|---|---|---|---|---|
| | Traffic (MB) | GET requests | Uncompressed (MB) | Brotli (MB) | GET requests |
| A | 106.26 | 1800 | 0.71 | 0.064 | 12 |
| B | 561.22 | 1800 | 3.74 | 0.064 | 12 |
| C | 731.05 | 1800 | 4.87 | 0.075 | 12 |
| D | 947.95 | 1800 | 6.32 | 0.126 | 12 |

Table 5 shows the effect of using asynchronous MPD updates (without any of the traffic-reducing techniques from section 3) in a scenario we used in Table 3 above: 1-hr session with 5-min periods and 2-sec segments. We further assume that an MPD Validity Expiration event is sent before the start of the period. This scenario results in a 99.33% reduction in HTTP GET requests and shows the best result in traffic reduction. With that said, the numbers below represent a "happy path", and every missing segment in each currently playing representation will trigger an extra MPD request. DASH allows a "missing content segment" – a segment which contains no media data and only provides segment timing information. In case of timeline extension, such a segment will prevent unneeded MPD requests.

Note that asynchronous updates can be combined with MPD patches to get to even greater efficiencies.

# 5. Conclusion

In this paper we quantified the impact of "manifest bloat" specific to DASH and its MPD traffic and reviewed several methods of reducing it. While application of brotli compression reduces the traffic on its own by at least 90%, we recommend a combination of the proposed measures. Note that both the timeline extension and the

Measures such as ContentProtection referencing and gap signaling reduce the memory footprint and improve parsing performance by eliminating redundant elements in the MPD.

From a pragmatic standpoint, HTTP compression is the ultimate "low hanging fruit," in that it carries a significant traffic impact at a fairly low cost. Gap signaling and ContentProtection referencing are relatively easy to implement and operate. MPD patches are also a new feature and requires an implementation effort on both the client and the packager side, with that said its benefits are significant enough to justify those efforts.

## List of Tables

**Title** **Page Number**

 

# 1. Introduction

After tremendous growth and success in video, data, and voice services, cellular wireless is the next frontier for cable. Quarter over quarter, the US cable mobile virtual network operator (MVNO) business continues to see mobile subscriber growth. As of the Q2, 2020, less than three years after the launch of the first MVNO by Comcast, the three US cable MVNOs combined have amassed 4.2 million customers [1]. This is shown in Figure 1.

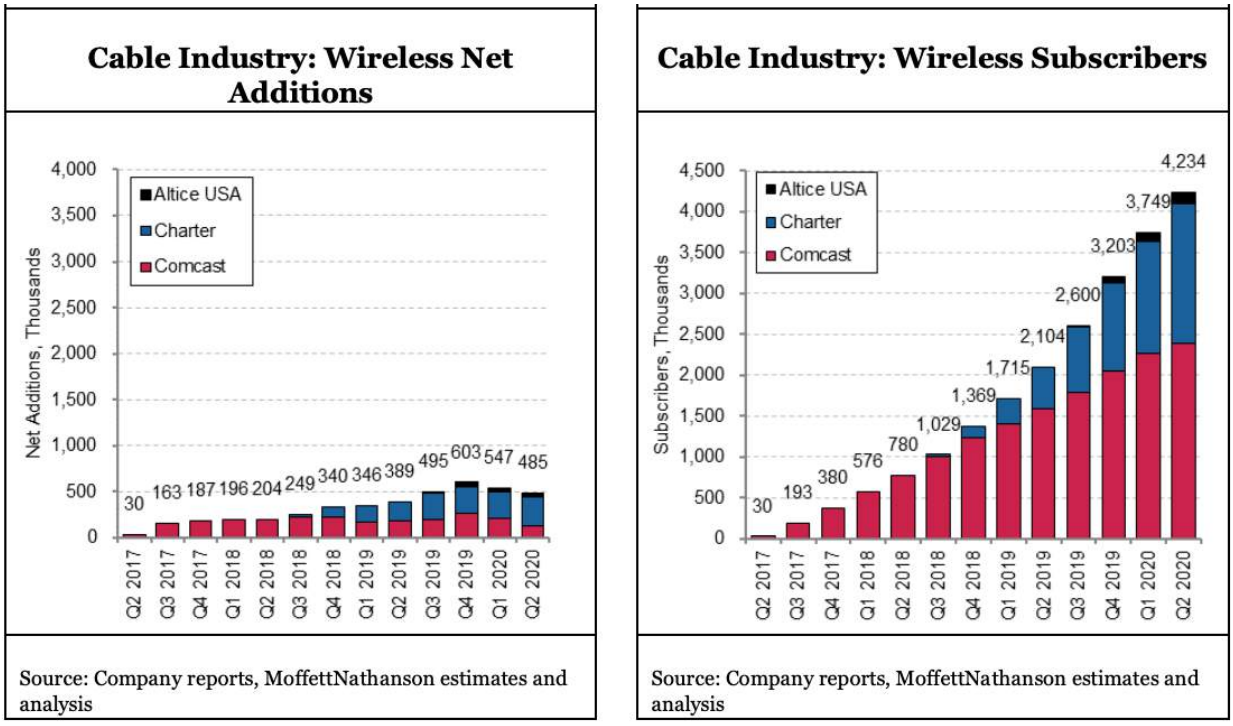

**Figure 1 – Cable MVNO Customer Adds**

While Comcast and Charter MVNO utilize Verizon as the mobile network operator (MNO), Altice USA has an agreement with Sprint (now T-Mobile). Recently, Cox Communication also demonstrated an interest in starting an MVNO.

The momentum is there. Consistently, executive leadership at cable companies has shown strong support for and interest in growing the wireless business.

The mobile customer growth is not restricted to the cable operators in the US. Cable operators in the neighboring north – Canada – are also reporting impressive number and innovative business model.

In contrast to the US, virtually all of Canada's largest cable and telco operators offer both wireline and mobile services on their own infrastructure. Rogers, Canada's largest cable and mobile operator, has been offering mobile services since 1985, with Vidéotron launching its wireless services in 2010, Shaw acquiring Wind Mobile in 2015, and Cogeco aiming to enter the Canadian wireless market through a Hybrid Mobile

 

Network Operator (HMNO) model. The Canadian market also faces strong competition from Canada's large incumbent Telco operators, which have invested heavily in fiber to the home, connecting more than 60% of their broadband homes directly to fiber, and leveraging a robust RAN sharing agreement to minimize their infrastructure costs.

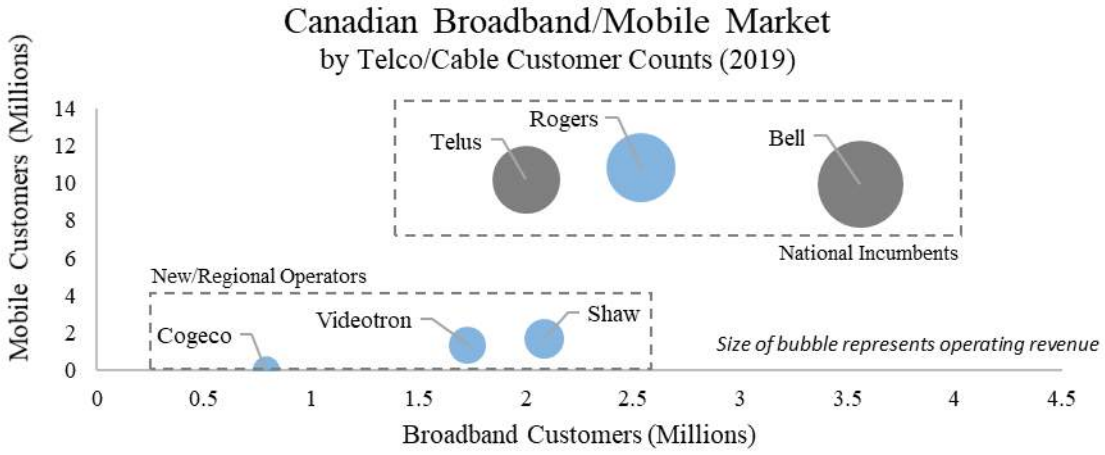

**Figure 2 – Canadian Service Provider Market**

In the South America market, Telecom is a leader in the Communication Service Provider (CSP) industry in Argentina. It is a merger of two companies – the former Telecom, incumbent telco, and former Cablevision, a cable operator. The merger of companies was approved in 2018, and the name TELECOM was kept as the name of the new company.

Telecom is the first CSP in Argentina to provide quad-play services: it serves 4 million fixed broadband subscribers, 18.8 million mobile subscribers, 3.5 million TV subscribers and 3 million fixed voice subscribers. It also provides business services. Telecom Argentina is a connectivity solutions and entertainment company transforming the digital experience of its customers, providing them a secure, flexible and dynamic service on all of their devices, with high speed mobile and fixed connections, and a live and on-demand contents platform which includes series, films, gaming, music and TV shows. It is also present in Paraguay, providing mobile service, and in Uruguay, with pay TV.

In Europe, the transformation of cable company to mobile company is mostly done. One of the biggest cable companies in Europe, and the world for that matter, is Vodafone. Vodafone acquired a variety of cable properties across Europe and now operates cable franchises in Germany, Spain, Czech Republic, Hungary, Romania, Albania.

The mobile journey of the cable companies will become an amazing success story. This white paper is intended to grab a snapshot of that story as it is coming together today. The paper will start with a framework for looking at different types of convergence which is also different ways of investing capital for different outcomes. The paper will then showcase six different cable operators with mobile plans, each of whom have common goals and technologies, but a unique point of view. Once the goals and objectives are understood, the paper will highlight technologies that are common to the solutions. These are some of the important technologies that we want the industry to focus on.

## 2. Four Stories of Convergence

There is a lot of buzz round convergence. What is convergence? Is it something in a 3GPP specification? Is it a product? Is it something in your architecture? Is it your customer's experience? Is it your experience? In this section, we would like to describe four stories of convergence. These are shown in Figure 3.

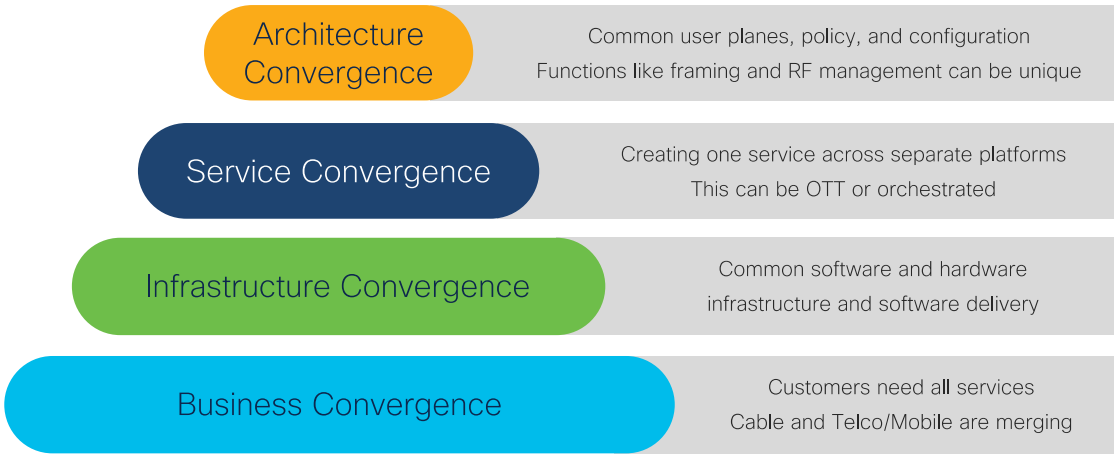

**Figure 3 – The Four Stories of Convergence**

### 2.1. Business Convergence

First things first. It does not make sense to converge technologies and architectures if there is not a business reason. As a stark example, it does not make sense to merge a DOCSIS and 5G system if your company is a pure mobile / telco company that does not have cable properties. Conversely, if you are just a cable operator with no mobile operations, does a 5G driven CMTS add profit to the bottom line? It doesn't.

So, the first step of business convergence is subscriber convergence. The same subscriber needs to pay for both cable broadband service and mobile service. This has already happened across the world. As you are reading this paper, you own a smart phone, a laptop, and have some kind of broadband service at home with either a legacy video service or some type of over the top video service, as does everyone in your family and so do your friends. Subscriber convergence is a done deal.

The second step in business convergence is convergence of cable and mobile operators. As shown in Table 1, this is currently happening around the world. Today's cable operators are tomorrow's mobile operators.

**Table 1 – Operator Convergence**

| Region | Cable Operators | Status |
|---|---|---|
| USA | GCI | MNO |
| | Comcast, Charter, Cox, Altice | MVNO |
| Canada | Shaw, Rogers, Videotron, Eastlink | MNO |
| Latin America | Telecom Argentina, Claro Brazil, Liberty Latin America | MNO |
| Europe | Telenet (Belgium), SFR (France), Vodafone (Germany, Spain, Czech Republic, Hungary, Romania, Albania), NOS (Portugal), Telenor (Norway), TDC Net (Denmark), VodafoneZiggo (Netherlands), Telia (Norway/Finland), Tele2 (Sweden/Baltic), Virgin Media+Telefonica/O2 (UK) | MNO |
| | Virgin Media (UK), UPC Poland, UPC Switzerland | MVNO |

Now, it would make sense that if you were to get both your cable broadband service and your mobile service from the same operator, that you would want to get a discount? What is that impact to the operator?

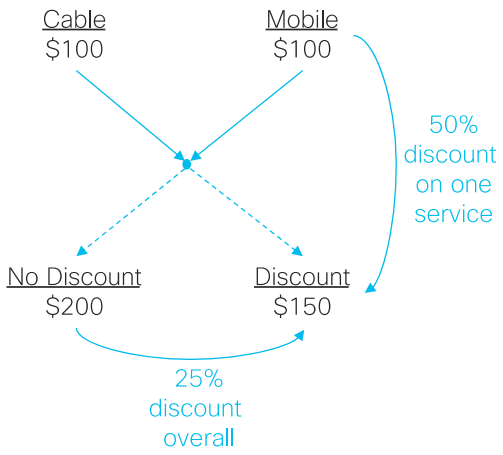

**Figure 4 – Subscriber Convergence**

Let's say you pay $100 a month for broadband and a $100 a month for mobile. If you combined your services with one operator, getting both services for $150 would seem like a reasonable deal. This is shown in Figure 4. Now, as an operator who now owns both the mobile property and the cable property, this means less overall revenue for the same customer base. That means that either one of those operations – cable or mobile, needs to reduce its operating expenses by 50%, or both operations have to reduce their operations by 25%.

An important aspect of converging cable and mobile businesses together is organizational convergence. Otherwise, you just have two companies within one company, sometimes each with their own network. The challenge and importance of this is not to be underestimated and it often requires some sort of cultural convergence. There can no longer be a cable vs mobile competition within the new company. Everyone

must work together to make their subscribers happy with their services at the best cost operating model for the new company.

Subscriber convergence has already happened. Business convergence is happening now. Technology convergence is next [2]. And the outcome that overall convergence should strive for should be at least a 25% reduction in operating costs, if not more.

## 2.2. Infrastructure Convergence

If you could wear the same set of clothes every day and for everything you do, you would save a lot of money in clothing. Well, that may be impossible for most people, but what about converging the network that hosts a DOCSIS and mobile service? Could that save some money? There are many opportunities for infrastructure convergence. Here are a few examples.

### *2.2.1. Transport Network*

Macrocells and small cells are typically connected using dedicated fiber. For new small cell locations, this might necessitate pulling fiber to a new location along with some copper for powering. This may prove cost prohibitive if a large number of fibers have to be pulled just to support a new service. Alternatively, the cable HFC plant is already composed of fiber and copper, each of which provide an opportunity for transport convergence.

The fiber portion of the HFC network currently uses an "analog" transport that is composed of modulated wavelengths. As the HFC plant gets upgraded to the new Distributed Access Architecture (DAA), that fiber will be converted to "digital" which refers to Ethernet over a wavelength. The analog lambdas are sensitive to noise and cannot coexist with digital lambdas.

As discussed in this paper, the HFC plant with DOCSIS as the transport layer is a great choice for mobile xhaul. So, just using HFC/DOCSIS as backhaul for mobile, even though DOCSIS and mobile might be two different services, is an example of transport convergence that has the potential to save a considerable amount of money by not having to deploy more fiber. By connecting the small cell to the coax side of the HFC plant, the fiber can be analog or digital.

While the HFC plant is still analog, analog services and digital services can use the same plant but must be on separate fibers. When the HFC plant is upgraded to DAA and the fiber becomes digital, then different services can be connected to the fiber, either through dense wave division multiplexing (DWDM), with one service per wavelength, or with an Ethernet switch located in the field that aggregates services on separate 10 or 25 Gbps links and then backhauls them all together on one 100 Gbps to 400 Gbps wavelength.

### *2.2.2. Open Source Code*

Almost all products these days use open source. One of the nice things about open source software is that there are a lot of creative solutions and interesting choices. Open source can save considerable development time. One of the downsides of open source is support. Open source code goes in and out of style. If your system adopts some popular open source that suddenly becomes unpopular, you will lose the support of the community. This means it will be harder to add features and get bug fixes.

Another challenge for open source is that there are security holes and sometimes hundreds of them. Each release of open source needs to be properly vetted to close those security holes. And then there is personnel training. Each piece of software needs to be installed, supported, and upgraded by someone.

 

Wouldn't it make sense to use the same revision of open source across multiple systems? Would it not make sense to have a uniform code security policy? Wouldn't it make sense to use the same Kubernetes deployer for microservices?

To be fair, much of this open source is very transparent to the operator and is packaged internally by the vendor. There could be separate vendors for cable and mobile systems. Still, tracking open source issues is a real issue to consider.

#### *2.2.3. Data Center*

Software used to run in dedicated hardware boxes. Then in the mobile world, software was virtualized and placed onto servers. Now the software is being rewritten using cloud native technologies with microservices and containers intended for an SP edge (data center) environment.

This is cloud and edge ready software. Unfortunately, not all data centers environments are the same and cloud native technologies have been evolving at such a rapid pace recently, that it is currently an operational challenge to completely mix different applications from different vendors into a common cloud or data center deployment. But, it will happen, and this will help achieve a goal of operational simplicity where servers are installed in server farms and software does not much care where it lands.

Infrastructure convergence is happening and is a natural consequence of getting a product to market in an efficient manner. There is more work to be done, but it is a well understood problem that can be worked and optimized.

### 2.3. Service Convergence

A service is something a customer receives, experiences, and pays money for. It has a meaning and a feeling. The challenge is to identify those services that cross the mobile/cable boundary that can generate additional revenue, reduce operating expense, or both.

A converged service would imply that it should not matter where you are, or if you are connected by mobile, Wi-Fi, DOCSIS or PON -- you get the same service and experience.

Some examples of converged services that come up are the following:

**Parental Controls:** A parent can assign parental controls to a child's device and those controls work whether the device is on the cable broadband network or on the mobile network

**Service Class Roaming:** If you are a premium subscriber with a higher bit rate, you get the same service at your neighbors or the local coffee shop, even if those locations have lower service

**Shared credentials on Mobile/WiFi:** WiFi is often the extension of a DOCSIS network. This convergence would allow a single sign on and may even allow the network to direct which path to take based upon local mobile or cable network loading.

**High Availability:** If one of your transports such as cable access goes down, your services would transfer to the mobile access. This could occur transparently in the network or with some kind of blended service environment in the home.

It should be noted that mobile service today is per device – typically per cell phone and this per user. Cable broadband service is per home and the billing entity is per home which is per cable modem. There is a difference in device identification technologies. Cable modems do not use SIMs. Cell phones do.

 

One example of distinct separate networks but with a converged service is video conferencing where the video stream is sent over the broadband Internet, but the voice is sent over mobile as the mobile voice connection seems more reliable than the Internet connection. This convergence is simply achieved by the video using an IP address and the audio using a telephone number.

The key question is if the networks need to be converged to achieve these goals, or can dissimilar networks like mobile and DOCSIS just share common policy?

## 2.4. Architectural Convergence

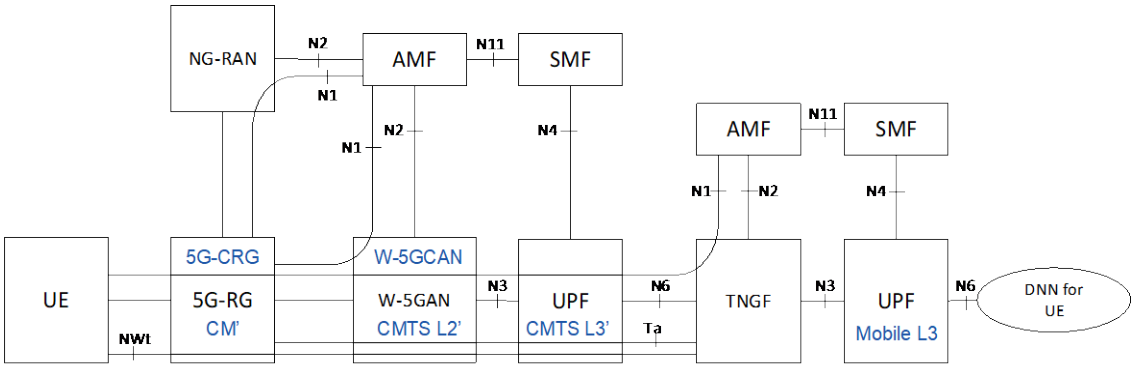

**Figure 5 – Architectural Convergence**

Architectural convergence is where the cable and mobile networks are truly converged. They share a common user plane and a common control plane. This convergence allows for different messaging over the RF interface. The classic example is the wireless and wireline convergence (WWC) work done in 3GPP [3][2]. This is shown in Figure 5, annotated with DOCSIS and mobile functionality. The groundwork for this architecture is partly based in joint CableLabs-Cisco whitepaper at a previous SCTE Expo [4].

Does this architectural convergence add simplicity or complexity? The DOCSIS system works fine and has worked fine for 25 years. Does drastically changing a 25-year old system add value or just add complexity?

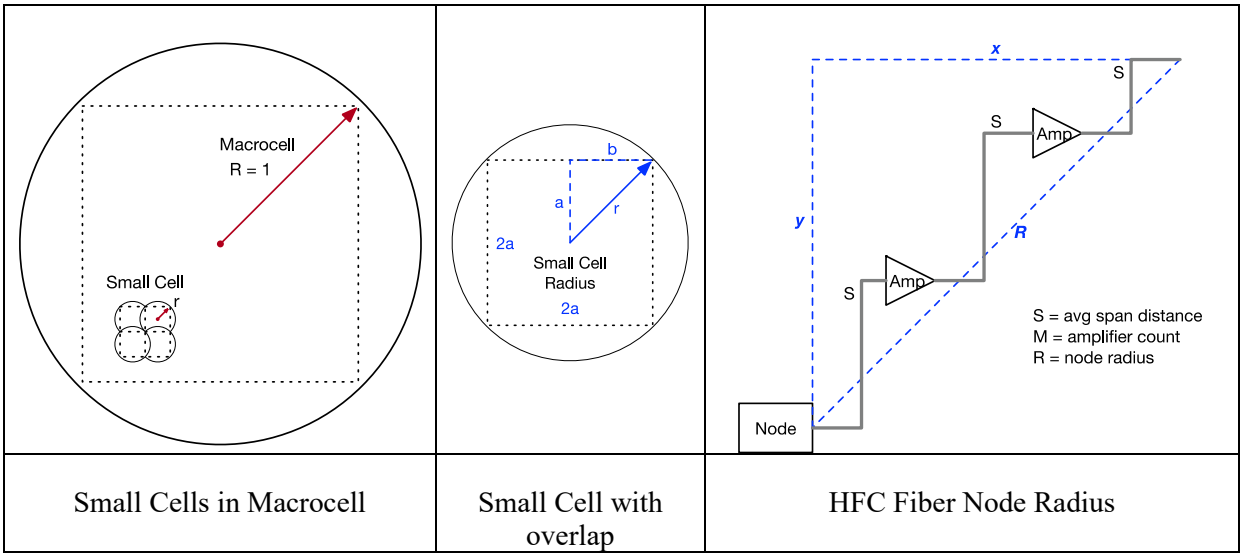
What about software upgrades? Do the mobile and DOCSIS systems now have to be upgraded at the same time since that may be how they were tested? How does that impact the service velocity, which is the ability to roll out new services and bug fixes?

Does it reduce OPEX and CAPEX costs or does it add to those costs? Can you still mix and match vendors when the systems are highly interconnected? That may impact the operator's ability to buy best of breed. Can the entire DOCSIS CM provisioning system be replaced or augmented with a 5G provisioning system? Is there enough financial motivation for vendors to implement these changes?

These are important questions that are not fully answered yet, even though the early architectural pieces have been put into place. One thing is certain though, and that the work does not begin here, it ends here. Before architectural convergence takes place, there has to be business, infrastructure, and service convergence first.

## 3. Traffic Engineering

As the cable network adapts to the connectivity of small cells to fiber or HFC, it is instructive to know how many small cells are required to replace of supplement a macrocell installation. Those numbers are calculated in [5] and briefly summarized here.



| Small Cells in Macrocell | Small Cell with overlap | HFC Fiber Node Radius |
|---|---|---|

**Figure 6 – Small Cell Traffic Engineering**

An ideal overlap of one a small cell radius to another is equivalent to placing a square in a circle and seeing how many small squares (for small cells) fit into a large square or circle (for macrocell). A similar calculation can be done by calculating the radius of the coax segment of an HFC plant. This is shown in Figure 6.

The number of small cells required depends upon the ratio of the service radius and is given by the formulas:

$$\#SC\ per\ MC = {}^{\pi}/_{2}\left({}^{R}/_{r}\right)^{2}$$

$$\#SC\ per\ FN = {}^{\pi}/_{4}\left({}^{S}/_{r}\right)^{2}(M+1)^{2}$$

*where:*

*R = larger radius of macrocell or node*
*r = smaller radius of small cell*
*S = average coax span between actives*
*M = number of amplifiers in an N+M cascade*

The results of these formulas are shown in Table 2 and Table 3. The relative radius in Table 2 assume same power and same height. In reality, the small cells will be lower power and lower height, plus there will be RF blockage from tree, hill, and walls. As a result, actual deployed results may be higher. Likewise, if less than 100% coverage is needed, the numbers scale back down.

**Table 2 – RF Cell Radius Comparison**

| Band | Service | Cell Type | Relative Radius | # Radios |
|---|---|---|---|---|
| 700 MHz | LTE | MC | 1.0 | 1 |
| 3.5 GHz | CBRS | SC | 0.09 | 125 to 200 |
| 28 GHz | mmWave | SC | 0.003 | 110,000 to 175,000 |

The first conclusion is that it can the number of radios for CBRS can be 100x that of an LTE macrocell, and for mmWave, the number of radios could be 100,000x that of an LTE macrocell. This dramatically impacts deployment economics and makes the existing HFC plant and interesting choice for mobile backhaul.

**Table 3 – Small Cells per Fiber Node**

| | | Small cell radius r: | | *500* | *1000* | *2000* |
|---|---|---|---|---|---|---|
| M Amps | Total Span | Node Radius | Avg Span | # radios | # radios | # radios |
| 0 | *1100* | 778 | 1100 | 4 | 1 | 1 |
| 1 | *2000* | 1414 | 1000 | 13 | 3 | 1 |
| 2 | *2850* | 2015 | 950 | 26 | 6 | 2 |
| 3 | *3700* | 2616 | 925 | 43 | 11 | 3 |
| 4 | *4600* | 3253 | 920 | 66 | 17 | 4 |
| 5 | *5460* | 3861 | 910 | 94 | 23 | 6 |
| 6 | *6300* | 4455 | 900 | 125 | 31 | 8 |

A second conclusion is that there is not just one small cell per fiber node on an HFC plant. It depends on the size of the coax segment the HFC plant. So, an N+0 plant may need one to four small cells, where as a N+5 plant may need 25 to 100.

# 4. A Survey of Mobile Deployment Plans by MSOs Around the World

Now that there is a framework and traffic engineering that show the need to connect small cells in an economical way, let's look at the goals and achievements of six prominent cable operators who are also MNO or MVNO as well.

## 4.1. Charter Communications

Since the merger earlier in the decade, Charter has been bullish on wireless and continues to invest significantly in research and development. Charter participation and leadership in industry forums and investments in startup ecosystem are a few obvious evidences of the long-term interest and strategy.

### *4.1.1. Spectrum Mobile Data Offload*

In the second half of 2018, Charter launched a mobile service (Spectrum Mobile) via a Mobile Virtual Network Operator (MVNO) agreement with Verizon Wireless. All Spectrum Mobile voice and SMS traffic is transported over Verizon Wireless' cellular network. Spectrum Mobile data traffic is either transported over Verizon's cellular network or over Wi-Fi networks.

One of the core technologies enabling cable MVNO is wireless data offload. Charter has an extensive indoor and outdoor Wi-Fi network, which, in addition to providing broadband services, is used to offload the mobile data traffic away from Verizon's network. The contribution of Wi-Fi data-offload in making Spectrum Mobile a fast-growing and economical business can't be overstated.

However, there are limitations on where and how much Wi-Fi can be effectively used to offload cellular traffic. There are some well-known challenges with Wi-Fi data offload. For example,

- Some Spectrum Mobile customers manually switch off the Wi-Fi interface on the End-User Devices
- In congested networks, it isn't easy to manage the Quality of Experience (QoE) on Wi-Fi networks

As a result of these challenges with Wi-Fi, a decent size of the "off loadable" traffic is not offloaded from the Verizon network.

Operators are evaluating multiple solutions and tools to improve the offload numbers. One solution of particular interest is CBRS small cell, which could be used to complement Wi-Fi networks. Not only the CBRS 4G LTE networks could help with the offload, but also offer better QoS and mobility than incumbent Wi-Fi networks.

The CBRS RAN could target a range of indoor and outdoor deployment scenarios, such as outdoor, strand installations covering high demand areas and indoor, small and medium business (SMB), enterprise, residential femtocell deployments. These deployment scenarios are described in more detail later.

### *4.1.2. Cellular Wireless – A New and Exciting Frontier*

The deployment of new wireless technologies from scratch is not without challenges. Cable companies have years of experience designing, deploying and managing Wi-Fi based networks both outdoors and indoors.

The 3GPP wireless technologies have unique requirements, which require attention of the cable operators and vendors alike. We talk about these unique requirements in the following sections to draw attention of the cable ecosystem and work together to conquer the wireless frontier at scale.

### 4.1.3. Possible Wireless Deployment Scenarios

#### 4.1.3.1. Fixed Wireless Access (FWA)

FWA can target rural areas to extend the broadband service to unserved or underserved areas, and expand the footprint of the HFC network economically. FWA requires a transceiver outside the home. This use case can be realized by installing RAN equipment onto telecommunication towers and/or other suitable mounting locations, such as water towers.

#### 4.1.3.2. Strand Mount (Aerial)

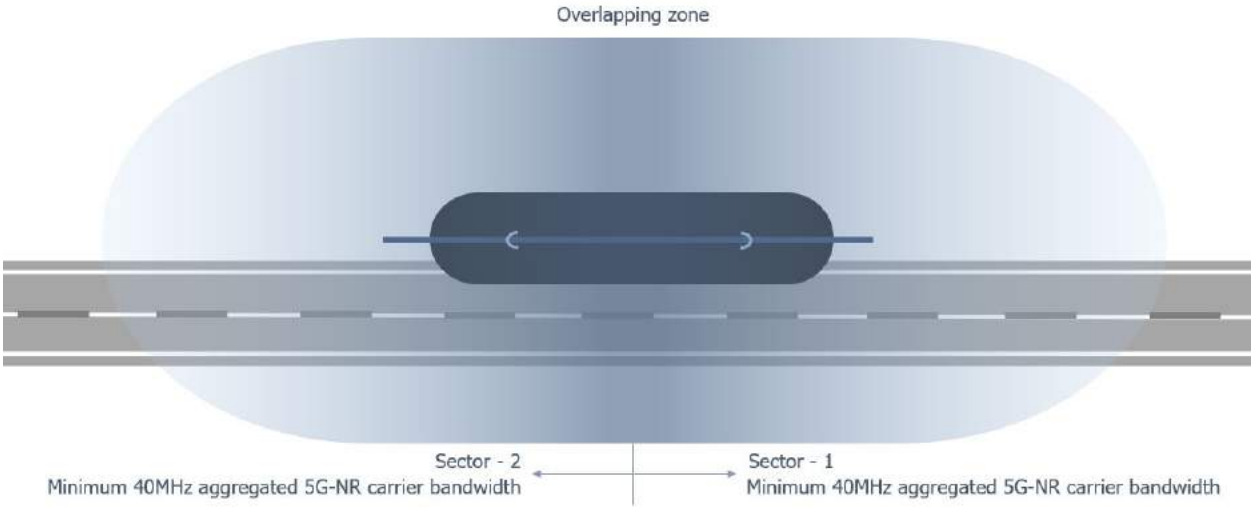


**Figure 7 – An Example CBRS Strand Mount Deployment with Overlapping Macrocell**

This is a one box solution that is mounted on the strand, where wireless radio is integrated with a DOCSIS 3.1 cable modem (CM). CBRS Category-B device types are planned with a quasi-omni and dual sector design.

Virtual RAN Deployment Model: operators are exploring technologies with split option 2 (shown later in Figure 58) for its vRAN based 5G CBRS wireless network deployment over DOCSIS because of its data transmission latency advantages. Since the DOCSIS network provides advanced latency reduction features such as the Bandwidth Report in the Low Latency Xhaul (LLX) technology [6], Charter may leverage such a feature to further ease CBRS wireless network deployment on cable strand. We will keep monitoring the latest advancements in vRAN field, and latest releases of 3GPP standards, together with O-RAN Alliance initiatives to fine tune our vRAN network deployment strategies.

Strand-mount appears to be the most cost-effective solution where aerial cable strand lines exist. The size and power of strand-mounted solutions are lower than attached mount (explained in a later section) CBRS device (CBSD), but their biggest limitation is power consumption from the HFC plant power supply. Another potential limitation of a strand unit is the mounting orientation – it has to be always along the strand and thus hotspot-targeted deployment in this case might be challenging. To mitigate this, engineers are evaluating quasi-omni strand design that has dual sectors with two sets of antennas covering NE and SW directions. Their height is always 18 feet and typically comes with 2 transmitters 2 receivers (2T2R)

multiple-input multiple-output (MIMO) capability. Utilizing existing assets to mount, connect to, maintain and operate may make these the most cost-efficient deployment type for outdoor Category-B CBSDs.

#### *4.1.3.3. SMB Inside-Out*

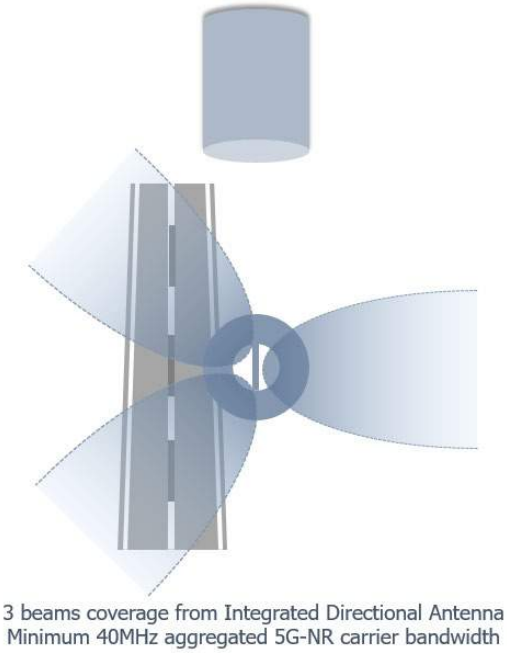

**Figure 8 – Tri-Star Configuration Product**

"Inside-out" could provide outdoor / pedestrian street coverage utilizing its small and medium business customers' locations. Charter has conducted tests in various SMB locations in New York and Los Angeles markets. Results show that the indoor low power Category-A CBSDs can provide blanket coverage when deployed every 400 – 500 ft.

A strand or attach mount usually compliments SMB coverage by serving as an umbrella cell and fill in any coverage holes. A Tri-Star configuration which adds a third sector to cover indoor and two sectors pointing outside the stores from behind a glass window is being evaluated. Operators can make use of this deployment type where applicable to form a uniform layer of CBRS coverage targeting an areas of interest (AOI) and have run trials confirming seamless connectivity and performance between them.

#### *4.1.3.4. Attached Mount*

In high demand markets such as New York, operators may leverage locations where it has wireless rights on the buildings to deploy high power Category-B CBSDs for outdoor mini-macro type deployment. Attached mount nodes can be installed more strategically than strand mount or SMB to clear obstructions or point to a targeted hotspot with required down-tilts like other two types (strand, SMB) of deployment. Attached mount deployment use case brings possibility to deploy most advanced antenna features such as MIMO and antenna beamforming to support 5G technology deployment and provide high end user performance speeds. This type of deployment provides larger coverage and capacity than strand and SMB scenarios.

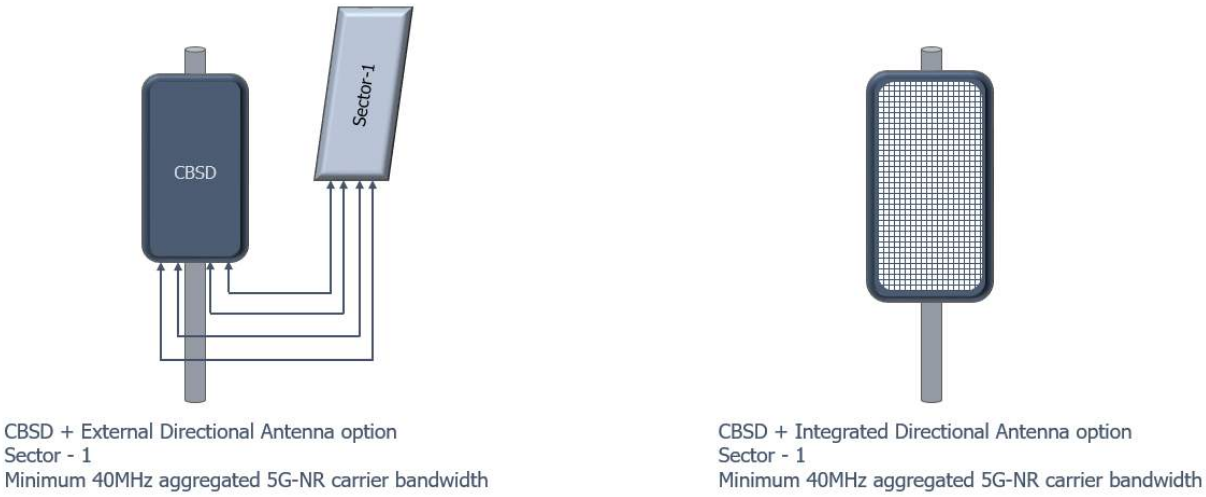

**Figure 9 – Attached Mount Mini-Macro**

#### *4.1.3.5. Indoor Enterprise*

This scenario covers indoor deployment of CBSDs into large enterprises, multi-dwelling units (MDU) and indoor venues. Charter has done indoor enterprise trials in its Spectrum Plaza office building with 50 indoor Category-A type CBSDs with 4G CBRS service.

**Figure 10 – Example Cat-A CBSD**

#### *4.1.3.6. Residential Femtocell*

For a typical residence, a femtocell shall provide comprehensive coverage inside and around the house.

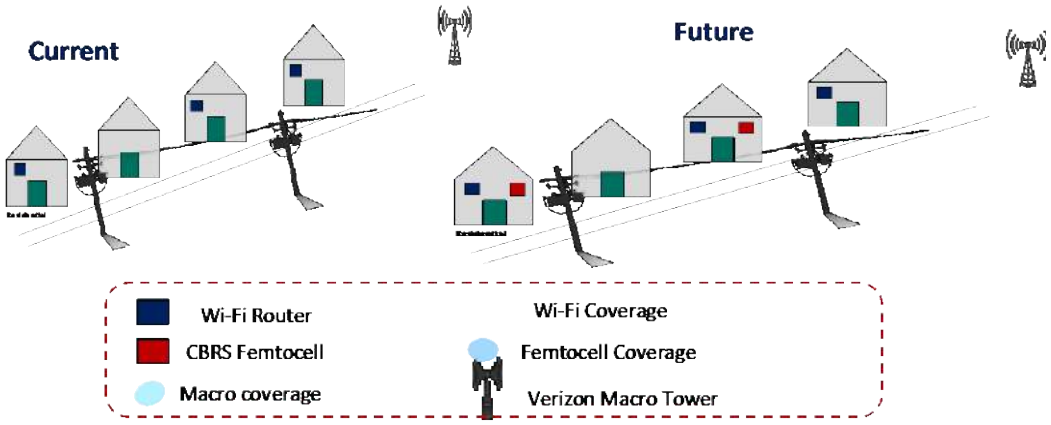

**Figure 11 – Residential Femtocell Deployment**

Key Features of Residential Femtocell scenario are as follows:

- Deployment Type: Indoor
- CBSD Class: CAT A
- EIRP: 30 dBm
- Antenna: Integrated Omni
- Backhaul: Ethernet/DOCSIS
- Power: AC

#### *4.1.3.7. Residential Femtocell and In-home Connectivity*

MSOs have a range of options for standalone femtocell connectivity in the home, which are depicted in Figure 12. Each option has its advantages and disadvantages. Option #3 in Figure 12 is intuitive and used by a couple of MNOs in the USA, but can it support TDD LTE timing and synchronization requirements without requiring hardware upgrade on the Wi-Fi router? Option #1 will require the addition of new LAN ports on the CM. Option #2 will put the femtocell in the path of all the broadband traffic in the home, which may not be optimum.

The solution the industry selects for timing and synchronization will be one of the primary factors in deciding the in-home connectivity model. The timing and synchronization topics are covered in Section 5.3 of this paper.

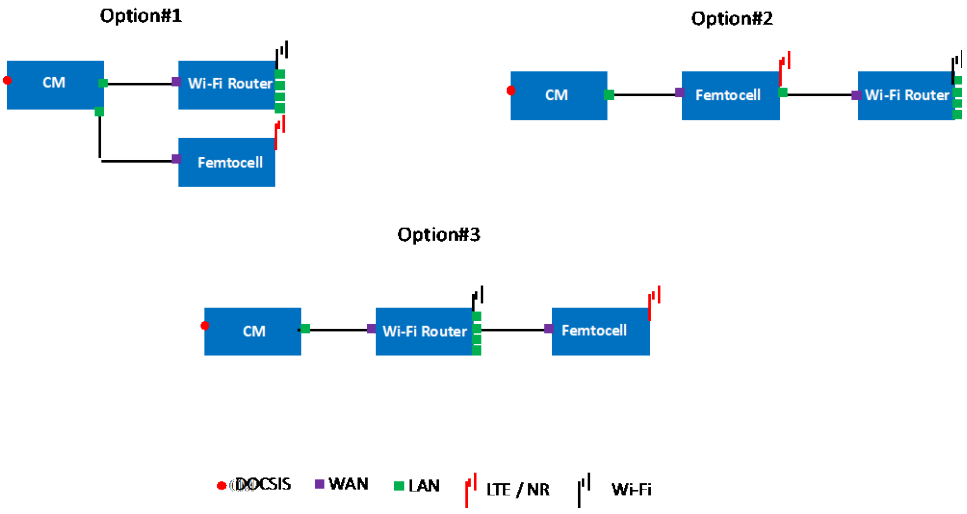

**Figure 12 – Residential Small Cell Gateway Options**

### *4.1.4. Backhaul*

The near-ubiquitous availability of cable and DOCSIS assets in urban and suburban areas may be one of the key enablers for the industry to deploy small cells at scale economically.

There are, however, some preparation and planning around bandwidth, latency, QoS, and timing that operators need to make.

#### *4.1.4.1. Bandwidth*

Depending on the wireless node capabilities, configuration, and network architecture, the peak and average bandwidth demands on the DOCSIS backhaul will vary.

For example, a 20 MHz TDD LTE small cell will demand much less peak bandwidth than a 40 or 100 MHz 5G NR small cell. Similarly, an integrated small cell architecture will require less average bandwidth per node for control plane traffic than a vRAN based architecture.

#### *4.1.4.2. Latency*

Latency is a critical factor in determining the quality of experience for the end-users. High end-to-end latency for user plane traffic can deteriorate user experience enough to render some applications unusable. Additionally, high latency for the control plane traffic may break important cellular features such as seamless handover.

MSOs are evaluating the application of CableLabs' Low Latency Xhaul (LLX) [6] technology in reducing latency through mobile and DOCSIS scheduler pipelining.

#### 4.1.4.3. Quality of Service (QoS)

The HFC plant is a shared medium used by many customers and applications simultaneously in the time and frequency domain. Luckily, DOCSIS offers an extensive set of tools (e.g., service flows and classifier) to logically separate and treat traffic differently for different applications.

Layer 2 and layer 3 traffic tagging capabilities to allow the cable modem to apply operator provisioned classifiers and ultimately customized QoS for all traffic originating from and terminating at the small cell.

#### 4.1.4.4. Timing and Synchronization

Unlike Wi-Fi, 4G LTE and 5G NR require stringent synchronization (frequency and phase) of wireless transmissions to avoid interference between uplink and downlink. Since the CBRS spectrum is a shared band, the clock synchronization across base stations of both the same and different operators is critical for full realization of the spectrum and to avoid unwanted interference.

As laid out in Table 4, the timing and synchronization requirements for TDD LTE and 5G NR are especially stringent.

**Table 4 – Timing and Sync Requirements of LTE and 5G**

| | Frequency | Phase |
|---|---|---|
| **4G LTE TDD** | ± 50 ppb | ± 1.5 µs |
| **5G TDD** | ± 50 ppb | ± 1.5 µs |

These synchronization requirements are documented in 3GPP specifications TS 36.133, TS 36.922, and TS 38.104.

The acquisition of accurate phase and frequency for outdoor small cell deployment is rather straightforward using GPS.

On the other hand, the acquisition of accurate phase and frequency for indoor wireless deployment is much more complex and requires evaluation of multiple options.

As highlighted in the table below, there several options for timing and synchronization. For outdoor deployments, GPS is the most widely used timing source. However, for indoor applications such as femtocell, the combination of precision time protocol (PTP) and DOCSIS Time Protocol (DTP) ranks higher on the list and is being carefully studied and tested.

**Table 5 – Options to Provide Timing and Sync**

| | Advantages | Disadvantages |
|---|---|---|
| **DOCSIS Time Protocol (DTP) with PTP** | Supports LTE TDD and 5G timing precision requirements<br><br>Timing from operator-owned and operated network<br><br>CableLabs standard promoted by cable vendors | Requires significant changes to DOCSIS infrastructure, including hardware upgrade to CM<br><br>Grand Master clocks in each headend<br><br>Regular network calibrations MAY be required |
| **Global Positioning System (GPS) *With and without network assist** | No upgrades to DOCSIS network required<br><br>Supports LTE TDD timing precision requirements | Receive challenges indoors, susceptible to jamming<br><br>Placement not in the control of the operator<br><br>Installation and operation cost external antennas |
| **Network Listen/Macro Sniffing (e.g., synchronization signals from Macro cells)** | No upgrades to DOCSIS network required | Reliance on macro network for timing, availability everywhere could be an issue<br><br>Out-of-band listen requires dedicated radio – additional cost & more space |
| **PTP over-the-top** | No upgrades to DOCSIS network required | Timing synchronization not precise enough for TDD LTE even with DOCSIS QoS. (5-10 millisecond range)<br><br>Performance is negatively impacted with network loading and uplink packet delay variation (uplink bandwidth limited) |
| **Network Time Protocol (NTP) over-the-top** | No upgrades to DOCSIS network required | Timing synchronization not precise enough (100 millisecond) even with dedicated QoS on DOCSIS |
| **TV Broadcast Listen** | No upgrades to DOCSIS network required | Need a receiver for TV broadcast<br><br>Femtocell must know its own location & TV tower |

### 4.1.5. Dual-SIM

#### 4.1.5.1. What is DSDS

Dual SIM dual standby or DSDS is a device that has 2 SIMs installed into it. Both SIMs are active only when not in a call but when the user places a call, the other SIM is placed in standby. In the case where a service provider (SP) wants to use one SIM subscription for voice and text and the other SIM subscription for data, updates to the device firmware are required for the reconfiguration.

#### 4.1.5.2. Charter Use Case

MSOs are typically in a MVNO relationship with an MNO. Charter wants to improve the MVNO economics. Since Charter is not providing voice or text on its RAN networks, at this time, Charter requires the device to scan and connect to both networks at the same time or switch back and forth as needed. This requires two subscriptions which entails the need for two SIMs.

#### 4.1.5.3. How Does DSDS Work

DSDS is a derivate hybrid between dual SIM single standby (DSS) and dual SIM dual active (DSDA). In DSDS, both SIMs are in standby mode as long as neither is in a call nor actively listens for paging messages from both networks while idle. However, once a call is received on one of them, the other SIM becomes inactive and is unable to receive calls or messaging. When incoming calls come in for the inactive SIM they are simply routed to voicemail and SMS messages are held until the active SIM goes idle.

**Table 6 – Comparison of Three Dual-SIM Technologies**

| | Dual SIM Dual Standby | Dual SIM Single Standby (Passive) | Dual SIM Dual Active |
|---|---|---|---|
| **Overview** | A hybrid between Dual SIM Standby and Dual SIM Dual Active | Worst implementation of Dual SIM technology, and affordable phones commonly use it | It can also receive calls on either of the two SIM cards, at the same time |
| **Technology** | Smartphone have two active SIM cards, and they both use only one radio transceiver. However, they are both active only as long as they are not used, hence the name of Dual Standby.<br><br>As long as the SIM cards are both in Standby mode, calls can be made and received on any of them. However, once a call on one SIM card is taken, the other becomes inactive and the first card is no longer actively used. | Capable of using two different SIM cards, but only one of them can be active at any time, hence when one SIM card works, the other is unreachable.<br><br>To use the second SIM card, it needs to be manually activated and the first SIM deactivates | Both the SIM cards are permanently active. During a conversation on one of them, the other still works and receives calls, messages or data.<br><br>The disadvantage of Dual SIM Dual Active phones is that the devices have two radio transceivers, one for each SIM card, hence consuming more battery than regular Single SIM smartphones |

| | | | |
|---|---|---|---|
| **Usage** | Most popular implementation | Used in older mobile phones (not smartphones) and lower priced phones | High battery consumption and more expensive to manufacture, leading to a higher device price |

#### *4.1.5.4. How Switching Decisions Are Made*

In normal DSDS, the device will not switch on an active data session until it is no longer able to maintain connection to the network. Charter has worked with the original equipment manufacturers (OEMs) to switch based on several factors. Signal strength and signal quality are used to determine the need for the device to switch networks. When a device is out of coverage of operator's CBRS network, it maintains data, voice and text on the MNO's network. This allows the user to maintain their experience at all times.

When a device enters a geographic local, geo-fenced area, the device enables the second SIM and the device begins to actively search for a suitable network. Once the user equipment (UE) determines that the level, quality and hysteresis timer has elapsed, it will then preform an attach request to the network. The UE will maintain normal mobile operations with the one exception that it continues to listen to the first network for incoming pages for text and voice calls.

When the device receives a voice call from the MNO network, it then answers this request and reattaches to the data network of the MNO so the user may continue to use data. This is done due to the fact that the UE can still only have one active network on a DSDS device. When the call ends, the device again searches for the MSO network and, if available and criteria met. reattaches the data stream.

As the device begins to leave the MSO coverage area, signal quality and strength reduce. Rather than allowing it to lapse into a radio link failure (RLF), the device moves back to the MNO network if available, based on predetermined exit levels of strength and quality.

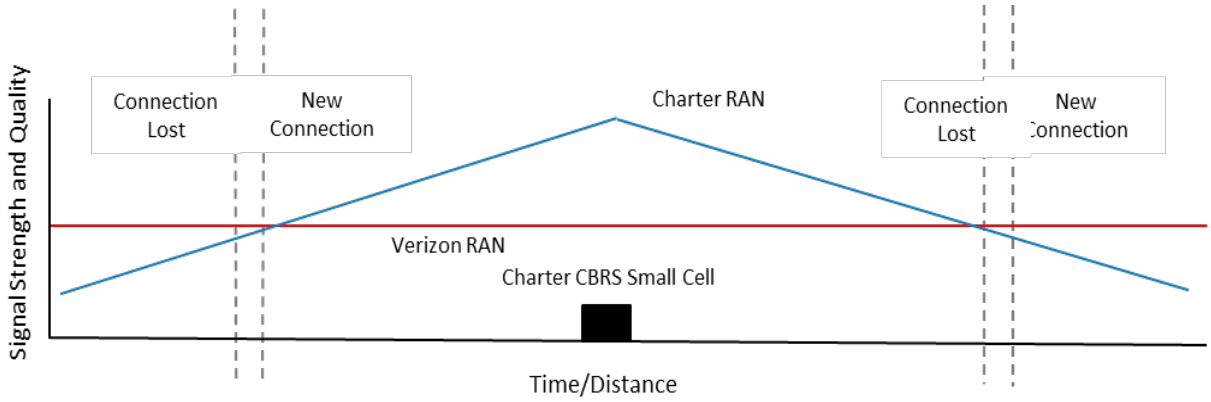

**Figure 13 – How a DSDS Device Moves Across Networks**

#### *4.1.5.5. Dual eSIM*

Embedded-SIM or eSIM is an embedded universal integrated circuit card that allows a user to store a cellular profile without the need for a physical chip that needs to be inserted into the device. It allows for the storage of multiple SIM profiles to be stored, but at this time only one can be used at a time and the user

has to manually switch between each profile to use it. New features will need to be developed to allow two eSIM's to function as the current physical SIM (pSIM) and eSIM.

#### 4.1.5.6. Is DSDS Good Enough

With the modifications to the operating systems and the chipset enhancements that have occurred over the last year, DSDS functionality is very good. As it stands to date, the user would generally not realize as the device moves between the networks. Working with the chipset vendors and the device manufacturers, there may be some room for improvement. Regardless, the technology today will satisfy many needs for private network owners who wish to connect or offload data to their network. This allows them to control the access to their network with increase security and still allow calls and messages to be received without having to set up their own voice and data network.

### 4.1.6. Virtualized RAN Architecture

Charter's medium to long-term network vision is to transition from standalone RAN to a vRAN architecture where baseband functionality is centralized and virtualized, and supports standard open interfaces. Ultimately, Charter is driving for flexible hardware and software implementations affording scalable, cost-effective network deployments.

The transition to a vRAN based architecture is being evaluated for all the mobile-offload deployment scenarios described earlier in the paper. For emphasis, the use of vRAN is not only being evaluated for outdoor deployments but also for indoor residential deployment using femtocells.

For the near-term deployments, an operator's focus can be on the integrated solution, which includes both the Radio Unit (RU) and baseband unit (BBU) functionality in a box at the edge.

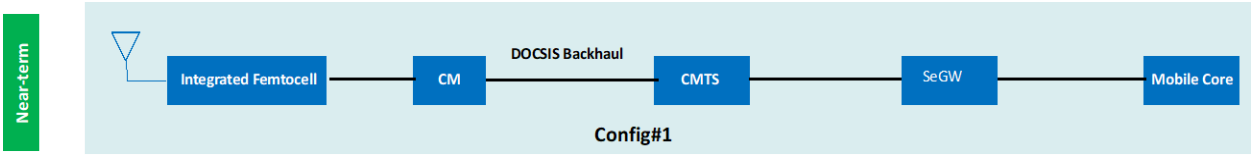

**Figure 14 – vRAN Architecture – Backhaul**

The long-term RAN architecture aims to centralize and virtualize the Centralized Units (CU) functionality, leaving the RU, and Distributed Units (DU) features at the edge of the RAN. Operators also want the flexibility to dynamically allocate DU functionality either at the edge of the RAN or centrally depending upon the backhaul option available.

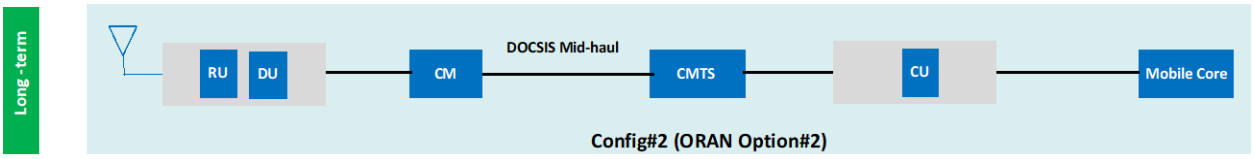

**Figure 15 – vRAN Architecture – Midhaul**

When fiber backhaul is available, operators can consider two options: collocating the DU/RU to align with the DOCSIS deployment scenarios or to move the DU to a centralized location.

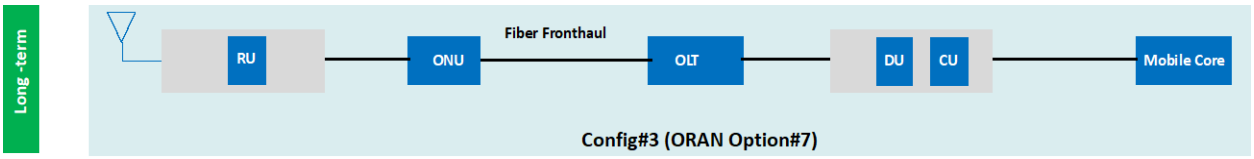

**Figure 16 – vRAN Architecture – Fronthaul**

The mobile community envisions improved RAN performance with vRAN architecture compared to a traditional, integrated RAN. For example, the performance enhancements would be realized by utilizing better interference management and improved mobility. In the long run, there are opportunities to reduce total cost of ownership (TCO) from baseband pooling.

### *4.1.7. Fixed-Mobile Convergence*

Charter has years of experience designing, deploying, and managing Wi-Fi networks both outdoors and indoors, leveraging Charter's extensive DOCSIS and PON networks. Charter will expand its wireless networks with the deployment of 5G NR small cells. Charter's availability of DOCSIS and PON assets in urban and suburban areas is one of the key enablers allowing Charter to deploy 5G NR small cells at scale economically.

However, fixed mobile convergence is more than network convergence, it is about customer experience. Fixed mobile convergence allows Charter to provide a single cohesive experience to its customers. Convergence at the service level consolidates subscriber management and policy enforcement allowing customers to enjoy their services as they move between access networks. A parent can assign parental controls to a child's device and those controls work whether the device is on the cable broadband network or on the mobile network. A premium subscriber would get the same service at the neighbor's house or the local coffee shop, even if those locations have lower service. With a converged service, the network would be able to identify and enforce network policies on customer devices no matter where they are and give them the same service and experience.

Charter's vision for fixed mobile convergence is to deliver ubiquitous wired-wireless connectivity to our customers anywhere and on any device. Customers would carry their services, policies, and identity with them wherever they go. Through Charter's unique broadband and wireless assets, this can be delivered through the deployment of high capacity and low latency networks.

### *4.1.8. Automation*

Charter envisions a new automation tool in its production network for its commercial network for applications such as network automation intelligence and workflow orchestration, network integration and network management. The tool enables end-to-end automated network life-cycle management for a large-scale network rollout and also enables automated reporting and provides a high level of customization. The tool's customizable dashboards and dynamic widgets provide end-to-end project visibility for seamless status tracking of network elements, work orders and tasks. It's a real-time, technology-agnostic single platform for live network analytics by leveraging data points from multiple sources for an enablement of valuable insight about network's health.

The tool is closely integrated with different network elements for an end-to-end network visualization, configuration management, performance management, fault management, change management features. It enables not only proactive network diagnostics but also provide remediation for performance enhancement. It is scalable platform with fully developed infrastructure to handle massive data volumes and transactions,

allowing an operator to handle continuous growth in user data due to high bandwidth speeds and an increase in number of mobile devices.

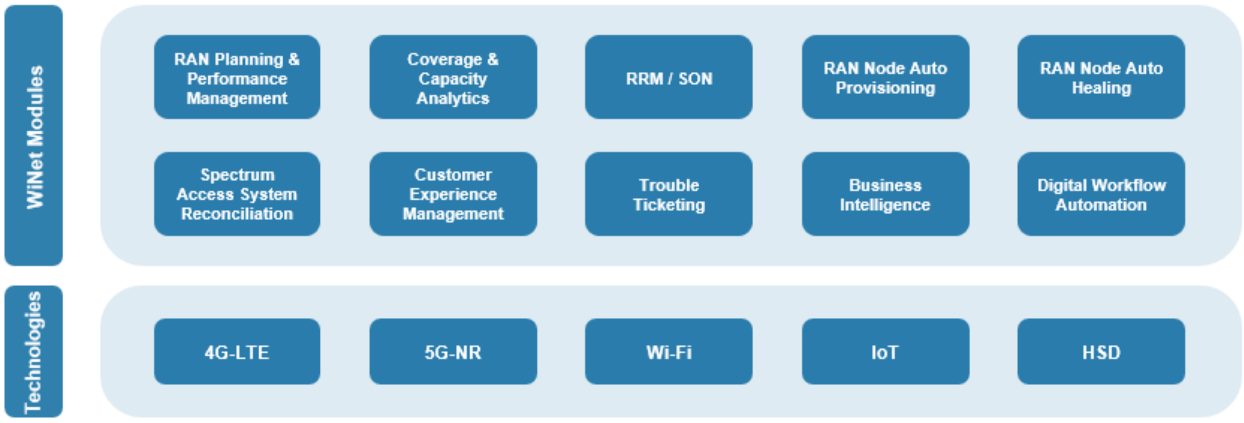

**Figure 17 – Charter Wireless Automation Framework**

### 4.2. Cox Communications

Convergence with wireless is currently centered around leveraging our fiber and HFC plant to provide services to the MNO's that include: Fiber To The Macro Cell Site (FTTX), strand mount small cells on our aerial HFC plant that incorporated AC power and DOCSIS backhaul transport, and offering CRAN (Centralized Radio Access Network) facilities space and fiber transport to upgrade the MNO's architecture as they move toward cloud native RAN.

Cox believes the market is becoming more attractive for us to enter the wireless space and we are exploring it more aggressively now but have not announced any specific plans.

As Cox looks forward to evaluating the current wireless segment, we look back to take the lessons learned from our earlier wireless attempts of both an MVNO and MNO solution. The challenge 10 years ago was in understanding the customer demographics with the then recently launched iconic smartphone device that limited our differentiation, as well as having wholesale metered voice, text and data on a much slower and costlier 3G network from our MVNO provider. With the trial markets we built in our cable franchised footprint, we wanted to provide ubiquitous service and our subscriber penetration rates couldn't support the cost of the wireless infrastructure as well as having to work roaming agreements without the scale of a large MNO. We are more optimistic with today's wireless environment as other cable operators have successfully launched MVNO's using high speed LTE networks and having driven their wireless offload tonnage by Wi-Fi both in the home and metro systems as well as evaluating other solutions such as small cells to drive the wholesale usage costs down.

As we look to the future, there are several fronts we see opportunity that include: driving Low Latency Xhaul (LLX) that enables low latency 5G wireless backhaul, looking at fixed wireless access that extends the edge of our HFC and fiber plant to add incremental households as well as enabling the opportunity to support rural broadband deployments, deploying Wi-Fi 6E in our wireless gateways that we can drive higher data throughput experience to our customers over our broadband network, and finally as we explore opportunities with retail wireless.

### 4.3. Shaw Communications

Shaw Communications is a Canadian cable and mobile operator that provides both wireline services to over four million homes and businesses in western Canada, as well as mobile services to customers in British Columbia, Alberta and Ontario. Shaw has offered broadband services in Canada since 1996 and became a mobile operator in 2015 with the purchase of Wind Mobile, which it has since rebranded to Freedom Mobile. In July 2020, Shaw launched the Shaw Mobile brand to provide a new wireless service that leverages Shaw's Fast LTE and HFC/DOCSIS networks to provide Shaw Internet customers with an innovative wireless experience.

Over the past five years, Shaw has invested heavily in its wireless network, adding macro sites and purchasing new spectrum in order to improve the performance and reach of its rapidly growing wireless service. Since its entry into wireless, Shaw has focused significant effort on leveraging synergies between its established wireline business, and its new and growing wireless division. Indeed, access to Canada's largest public Wi-Fi network (Shaw Go WiFi), fiber backhaul, critical facilities, buildings, operational teams, retail, as well as many other opportunities proved to be of significant value early on. However, the ongoing exponential growth in wireless traffic and the impending arrival of 5G has put network and service convergence as a key focus area.

Seamless connectivity is the foundation for our future economy, but this future will require extremely close interplay between mobile and fixed technologies. The deployment of the 5G vision will require an unprecedented level of network connectivity and densification, as well as previously unseen levels of collaboration between wireline and wireless technologies [7].

In order to deliver both 5G as well as 10G (multi-gig fixed broadband), converged Canadian operators like Shaw will need to find ways to leverage their key strategic advantages to compete with their well-funded and converged Canadian Telco competitors. The top three strategic opportunities are:

- **Hybrid-Fiber Coax Infrastructure** – Already deployed to virtually every house and business in the country, HFC infrastructure makes an ideal solution for the densification of wireless networks. Able to transport multi-gigabit traffic today, it can also transport power, greatly reducing the time and cost of small cell deployments.
- **Hub Site Facilities** – Cable's historic hub-site topology, gives operators access to significant spare power and cooling, just a few miles from the customer. Thanks to the new "Distributed Access Architecture", these new facilities will soon be vacated, giving cable operators access to a network of distributed mini-datacenters, which can then be leveraged to provide ultra-low latency virtual/cloud RAN services, which are likely to be a key component of 5G roll outs.
- **Core/Service Convergence** – Both wireless and wireline networks leverage virtually the same architecture, leveraging a "wireless core" or "CMTS" to control the flow of wireless or wireline traffic. The convergence of these two cores will ultimately enable a truly seamless and differentiated experience for customers, increasing security, flexibility and control.

The opportunities described above are indeed highly strategic to virtually all cable operators globally. However, in order for them to be realized, several key challenges must be addressed as an industry. These challenges include:

- **Latency Reduction** – 5G as well as new mid/fronthaul solutions will require ultra-low latency, which cannot be easily met by today's consumer focused shared access networks like DOCSIS and PON. Improvements in new DOCSIS technologies, such as Low Latency Xhaul (LLX) [6], will be required

in order to reduce latency to sub 1ms level, making HFC virtually indistinguishable from dedicated fiber for 5G and mid/fronthaul purposes.

- **Timing Distribution** – Delivery of highly accurate timing to small cells is challenging using today's DOCSIS protocol. However, innovations such as the DOCSIS Time Protocol (DTP) [19] will solve this challenge, eliminating the need for costly GPS integration, and greatly improving the flexibility and efficiency of small cell installs.
- **Xhaul Over HFC** – Today's fronthaul protocols are extremely demanding and designed for dedicated fiber use. In order to enable the ultra-dense and demanding wireless networks of the future, new "xhaul" techniques must be developed that will allow operators to leverage the efficiencies of fronthaul while using shared access topologies such as HFC and PON.
- **Core Convergence** – While similar, wireless and wireline core technologies differ in numerous ways. Converging these technologies to enable a host of benefits for consumers will require development and integration across a diverse vendor ecosystem.

While challenging, the issues outlined above are certainly possible to overcome, and the industry is already making progress to address these. Recent models built at Shaw, indicate that a cable operator could reduce its build cost by up to 99% and build time by up to 95% by leveraging existing HFC infrastructure, rather than extending fiber to feed small cell densification [8]. The promises of cloud RAN and core convergence also carry similar promises of greatly reduced costs and improved customer services. However, operators will need to rally behind these new technologies and drive their development in order to see the benefits realized.

Ultimately, we believe that both cable and wireless technologies are evolving in lock step, and our industry is exceptionally well positioned to realize the incredible synergies between two of our most important assets. As shown in Figure 18 below, today's exponential growth in broadband is necessitating densification of our networks, accomplished through distributed access architecture (DAA) in wireline and small cell deployment (ideally enabled through DOCSIS) in wireless. That densification is also an enabler for multi-gigabit symmetrical services, enabled through DOCSIS 4.0 in wireline, and 5G in wireless.

In the future, competitive and efficiency drivers will require operators to embrace cloud and virtual network infrastructure, enabled by virtualized CCAP (vCCAP) in wireline and vRAN/vEPC in wireless. Shaw believes all of these steps will happen in very close timing, which will lead to the ultimate convergence of both network infrastructures. The final converged state will enable a myriad of new opportunities and efficiencies, such as the unified edge cloud, universal nodes, end-to-end network slicing and orchestration, converged wireless/wireline cores, new services and much more.

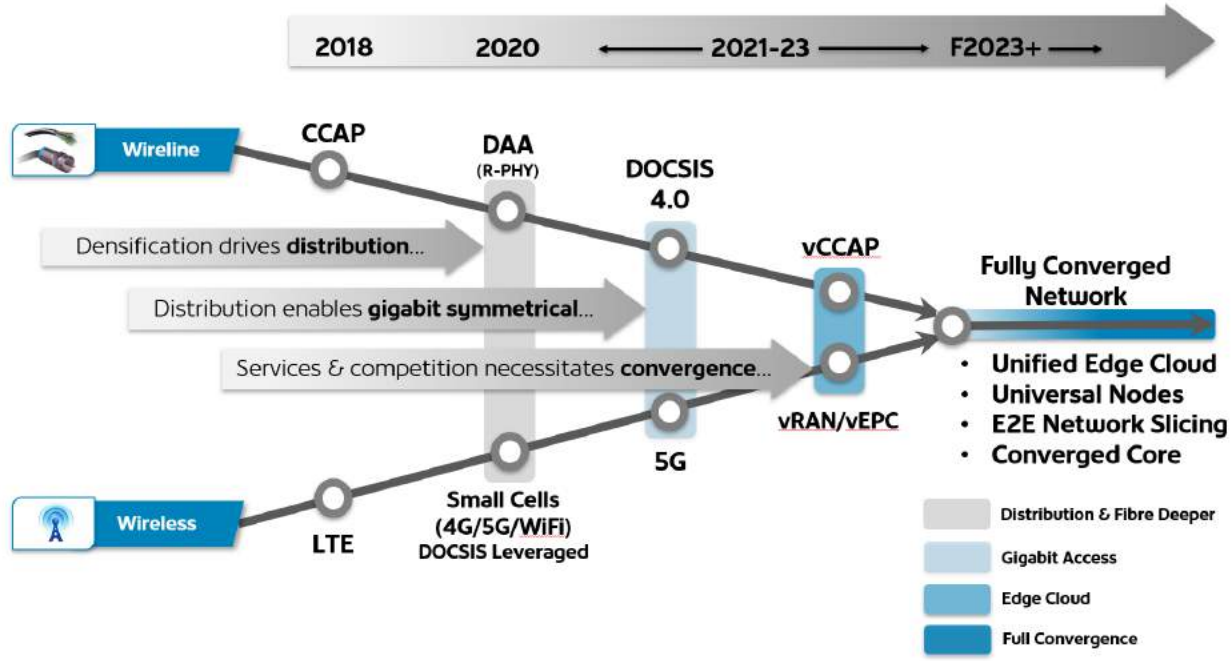

**Figure 18 – Wireline and Wireless Convergence Roadmap**

In addition to new technology changes, Shaw strongly believes that several other industry challenges must be overcome in order to ensure Canadians have access to world leading wireless services and 5G. These include inter-operator handover, access network convergence, and Wi-Fi interoperability, and will be discussed in more detail in the sections below.

### *4.3.1. Inter-Operator Handover*

Existing regional MNOs, like Shaw, typically rely on domestic roaming agreements to provide coverage outside of their home network footprint. With traditional roaming interfaces, however, subscribers often experience network problems such as dropped calls or interrupted downloads/uploads as they move between the home network and the roaming partner's visited network. This negatively impacts customers' perceptions of network quality and brand, which undermine a regional operator's ability to effectively compete and grow in a new market. This will also be the case for MSOs planning to deploy CBRS, where the initial coverage areas will typically be more localized.

Fortunately, the 3GPP Home Routing (HR) specification provides a standards-based approach for supporting seamless inter-operator handover between the operator's home network and its roaming/MVNO partner's visited network. With HR, the data plane traffic is routed back to the home network, giving the home network operator control over the subscriber's traffic and its IP context. This allows subscribers to roam between the home and visited networks without service interruptions. Figure 19 shows the network architecture for HR.

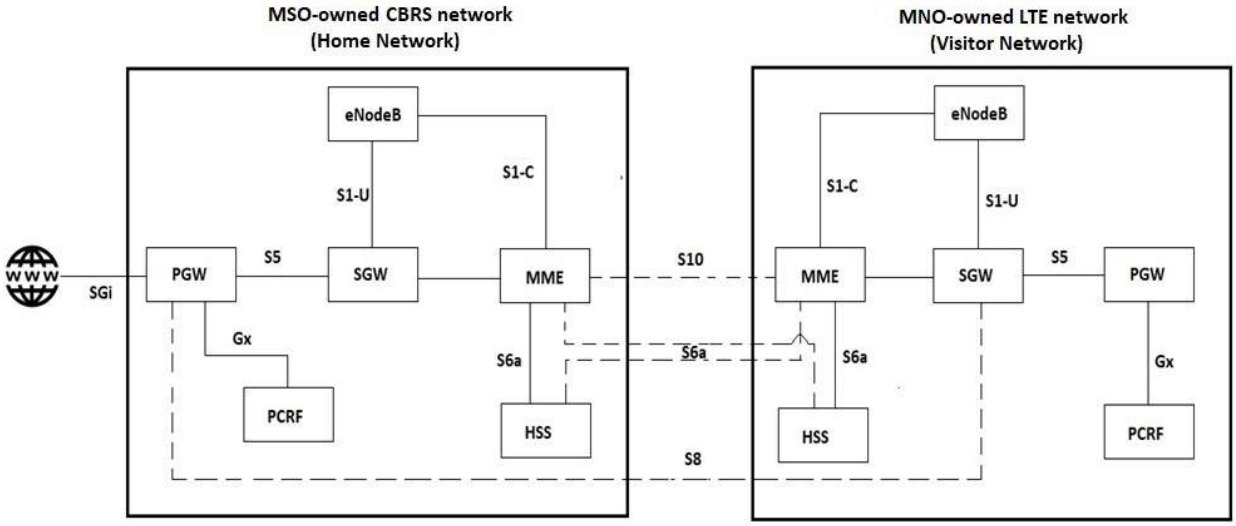

**Figure 19 – Home Routed (HR) Network Architecture**

To implement the HR model, the home and visited networks are required to share three interfaces: S6a, S8, and S10. These are described briefly below.

- S6a—is an interface between the Mobility Management Entity (MME) and the Home Subscriber Server (HSS) of both networks that enables the transfer of subscriptions for authenticating and authorizing user access to the network.
- S8—is an interface between the Serving Gateway (SGW) of the visited network and the Packet Gateway (PGW) of the home network, acting as an inter-Public Land Mobile Network (PLMN) reference point to transfer user traffic back to the home network. S8 allows the home network to control a subscriber's traffic even when the subscriber is roaming on the visited network.
- S10—is an interface between two MMEs used for bearer modification with MME relocation and MME-to-MME information transfer. S10 enables seamless data session transfer in connected mode. In addition to sharing roaming interfaces, HR implementation requires each network to be configured with mobility parameters that utilize connected- and idle-mode triggers.

The HR implementation is ideal for operators that have a roaming/MVNO agreement with an MNO that allows sharing of the roaming interfaces (i.e., S6a, S8, and S10) and control over mobility configuration. In addition to establishing the roaming interfaces, both operators also need to exchange cell site information to update their neighbor relations tables that identify the other operator's adjacent cell sites to which handovers occur.

Inter-operator mobility allows regional operators/MSOs to provide high quality services to their subscribers on par with the national wireless carriers as they expand their networks into new markets. Adopting inter-operator mobility would also promote competition, investment, and network deployments by regional operators, particularly in rural and remote areas. With inter-operator mobility, regional operators will have the ability (and incentive) to expand into smaller communities and rural areas more quickly and compete with the incumbents more effectively because they can ensure high quality service to their customers as they build out their network footprint.

### 4.3.2. Access Network Convergence

5G deployments will drive a dramatic increase in network density through small cell deployments. Although dark fiber has been used extensively in the past to support 3G/4G macro site deployments, unprecedented levels of new fiber builds would be required to support the roll-out of 5G. Fortunately, MSOs have already been deployed HFC/DOCSIS access networks down virtually every street and to almost every building on the continent to the point where today it reaches 93% of American households. And with the recent release of the DOCSIS 4.0 standard, HFC networks will soon be able to deliver multi-gigabit capacity.

As such, MSOs are uniquely positioned to create ultra-dense 5G small cell deployments by leveraging their existing hybrid fiber coax (HFC) networks and emerging technologies such as DOCSIS 4.0, DAA, LLX, and multi-access edge computing. The main advantages of HFC/DOCSIS networks relative to other alternative networking technologies (e.g., dark fiber) are its low cost, scalability, access to power, and ease of deployment. For the past couple of years, Shaw has utilized its aerial HFC plant to deploy LTE small cells for additional capacity and/or coverage in targeted areas. Deploying small cells on aerial plant addresses three major challenges with outdoor small cell deployments: site access, backhaul and power. That is, site access is usually already covered by existing pole-line attachment agreements and both backhaul and power are provided over the coaxial cable plant.

Figure 20 shows as example of a converged access network architecture with several options for transporting 5G small cell traffic over the HFC/DOCSIS network.

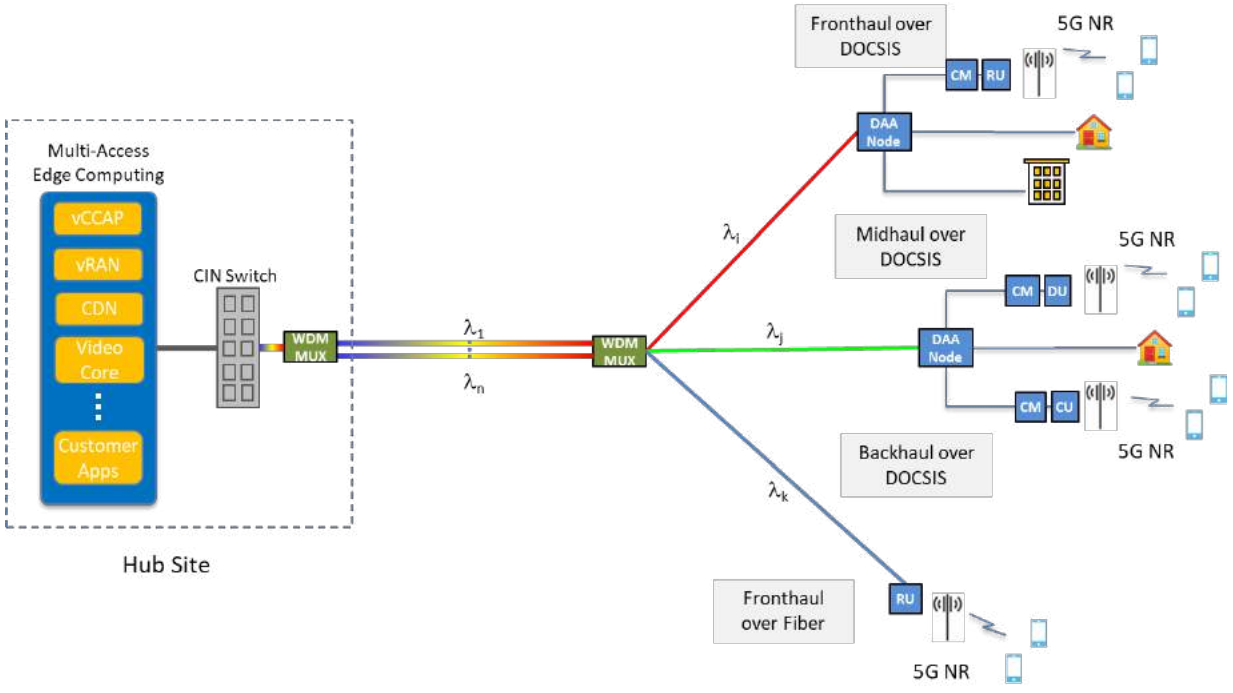

**Figure 20 – Converged Access Network Architecture**

As shown in the figure above, 5G fronthaul, midhaul and backhaul can be viably transported over DOCSIS using the technologies mentioned earlier (e.g., LLX, DTP). With fronthaul, the 5G remote unit (RU), which implements basic RF functions (e.g., filtering, amplification), is located at the cell site and the other radio functional blocks are implemented within the virtualized RAN (vRAN) at the hub site. Fronthaul offers the

highest performance and efficiency but has the most stringent latency and throughput requirements. Midhaul and backhaul implement different functional splits, at what are known respectively as the distributed unit (DU) and centralized unit (CU). These splits have less demanding transport requirements but provide lower performance and efficiency compared with fronthaul.

In cases where the small cell is already near existing fiber plant, fronthaul can also be carried over fiber by assigning a dedicated wavelength to the small cell and sharing the common wavelength division multiplexing (WDM) link between the hub site and a remote WDM multiplexer (MUX). The preferred transport option depends on several factors such as the latency requirements of the end user applications, the available 5G spectrum (and hence capacity) the radio site, and the cost of deployment.

The other opportunity for access network convergence is at the hub site (or headend). Both the virtualized CCAP (vCCAP) and vRAN can be implemented on multi-access edge computing platforms in which compute and storage resources are shared across multiple applications. CableLabs and other standards bodies are developing architectures and specifications to realize this important opportunity.

With the fundamental technologies (e.g., DOCSIS 4.0, DAA, LLX, DTP, multi-access edge computing) needed for wireless/wireline access network convergence still at relatively early stage of development, broad support is needed across the industry to make them a commercial reality.

#### *4.3.3. Wi-Fi Interoperability*

Although 5G mobile networks will be deployed extensively throughout the world, Wi-Fi will continue to carry the bulk of Internet traffic well into the future. According to Cisco's latest Annual Internet Report [9], public Wi-Fi hotspots are expected to grow four-fold from 2018 to 2023. As such, public Wi-Fi networks represent an important opportunity for MSOs to offload mobile data traffic from their own mobile networks or those of their MVNO partners to reduce network build and/or roaming costs.

Over the past decade, Shaw has built Canada's most extensive service provider Wi-Fi network, Shaw Go WiFi, with over 100,000 public access points deployed to date. Shaw Go WiFi extends our Internet customer's broadband experience beyond the home as a value-add to our customer's wireline network experience. Over 3.6 million devices have authenticated on the Shaw Go WiFi network, which is used by our customers in coffee shops, restaurants, gyms, malls, public transit and other public spaces from British Columbia to Ontario.

Freedom Mobile and, more recently, Shaw Mobile customers are also able access to the Shaw Go WiFi network along with over 300,000 home hotspots deployed in our Internet subscribers' homes across the country. Our mobile customers' devices automatically connect and authenticate to our public and home hotspots via Hotspot 2.0 (aka Wi-Fi Certified Passpoint) using their wireless credentials stored on the SIM. This provides mobile customers with extended network coverage and offloads a significant proportion of traffic from the mobile network.

With the introduction of Wi-Fi 6 (IEEE 802.11ax), dramatic improvements are expected in Wi-Fi capacity, efficiency, and reliability in the coming years. The Cisco Annual Internet Report predicts that Wi-Fi 6 hotspots will grow 13-fold from 2020 to 2023 and represent 11% of all public Wi-Fi hotspots by 2023. The recent allocation of 1.2 GHz of unlicensed spectrum in the 6 GHz band in the U.S. also has huge potential for Wi-Fi and will enable the Wi-Fi 6 evolution by alleviating congestion in the existing 2.4 GHz and 5 GHz unlicensed bands. The first wave of unlicensed devices capable of leveraging 6 GHz is expected in the U.S. in the final quarter of 2020 and 60% of devices are anticipated to be Wi-Fi 6 capable by 2022.

3GPP Release 16 also promises to further enhance mobile/Wi-Fi network convergence through Access Traffic Steering, Switching and Splitting (ATSSS). Based on Multipath TCP (MPTCP), ATSSS allows separate 5G NR and Wi-Fi traffic flows to be simultaneously established between an ATSSS-capable mobile device and the core network, providing highly available and robust services. At present, ATSSS is an optional feature for user devices and the 5G core network so operator support is vital to its success.

## 4.4. Vidéotron

### *4.4.1. Who is Vidéotron?*

Videotron (www.videotron.com), a wholly owned subsidiary of Quebecor Media Inc., is an integrated communications company engaged in cable television, entertainment, Internet access, cable telephone and mobile telephone services. Videotron is a leader in new technologies with its Helix home entertainment and management platform. As of June 30, 2020, Videotron was serving 1,497,300 cable television customers, and 472,200 subscribers to its Club illico video streaming service.

Videotron is also the Québec leader in high-speed Internet access with 1,753,100 subscribers to its cable service as of June 30, 2020. As of the same date, Videotron had 1,404,900 subscriber connections to its mobile telephone service and was providing cable telephone service to 979,600 Québec households and organizations. Videotron has been recognized as one of Montréal's popular employers.

In 2010, Videotron built and launched its own 3G (AWS) network and upgraded it to LTE in 2014.

In 2018, Videotron Launched Fizz Mobile, 100% digital mobile service brand[1]. This virtualized service provider model is based on Digital Business Platform utilizing TM Forum's Open Digital Framework, which includes business process and information frameworks and Open APIs.

Videotron is currently preparing the upgrade of the wireless network to serve Videotron and Fizz customers with LTE-Advanced and 5G evolutions.

### *4.4.2. 5G Opens a Very Wide Range of Applications*

5G opens the way to many new opportunities. One of the challenges for operators is to select the right markets to address first with this technology.

There are so many applications that can benefits from 5G, operator will have to expand and consolidate some of their "natural skills". For example, those related to entertainment and content distribution that may evolve to massive contents distribution VR/AR or telepresence, to provide a full set of immersive experiences. An example of the 5G set of services is shown in Figure 21.

IoT is an unmissable opportunity but it has such a wide field of applications that service providers will have to build a strong strategy to select the profitable and strategic markets and serve them with the right IoT technologies and services.

Then many new fields are now being opened to operators with 5G used for example in the "intelligence" field or "autonomy". That creates room for new businesses innovations but also require operators to change their way to do business to be able to propose solutions adapted to this new market in their portfolio.

In this new environment of constantly emerging innovations, operators must consider more than just 5G Radio Access Network and core and include all their network elements in a converged solution to provide a wide range of features to address different markets and services with the right solution.

---

[1] "Videotron's disruptive all-digital brand, Fizz, goes from concept to launch in 10 months," by John C. Tanner, Contributing Editor, TM Forum, September, 2019. https://inform.tmforum.org/casestudy/videotrons-disruptive-all-digital-brand-fizz-goes-from-concept-to-launch-in-10-months/

 

Wireless access convergence, fiber network convergence and virtualization are some of the main elements that operators will have to integrate in order to be able to actively participate to this new network panorama.

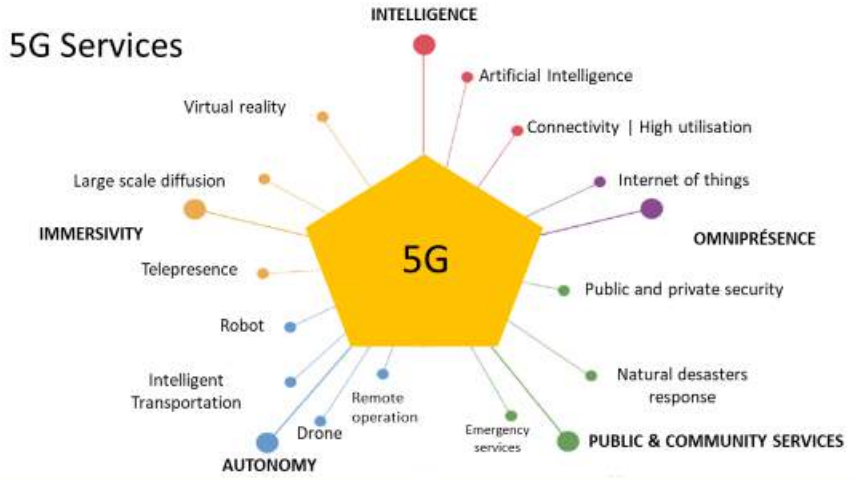

**Figure 21 – 5G Diversity of Services and Applications**

### *4.4.3. Wireless Access Convergence – Building on Wi-Fi Assets*

Access to a wireless network coverage is now a fundamental service and all consumers are expecting a good connection at all time for their mobile devices.

But building a mobile network providing a full coverage in any point is a challenge, especially for indoor locations. For LTE networks and for future 5G networks, many solutions exist to improve coverage at any point. For example, small cells to address a specific location that could require better coverage or higher capacity, as well as low band frequencies for long range and better penetration in buildings.

Mobile Network Operators (MNO) are using those tools in the design of their networks, but Wi-Fi is another element that can be very beneficial to wireless coverage, in addition to lowering the cost for MNO and the end user. Indeed, Wi-Fi is now widely deployed in homes, building and many public spaces.

Recent developments in the wireless technologies allow a much greater performance and transparency for users when it is time to decide to connect to traditional wireless network (LTE, or 5G networks normalized by 3GPP) or Wi-Fi Network. Those developments also improve the transition from 3GPP networks to Wi-Fi access point (AP) when the user is moving.

With a strong convergence between 3GPP access and Wi-Fi, it is possible to offer new services or to improve existing services for example:

- Access to a large free Wi-Fi coverage and create a community of users.
- Better customer experience is provided by an automated and seamless connection to the best network available.
- Allow customers to save on their data plans.

 

- Allow operators to minimize costs as Wi-Fi can be deployed with a lower cost in $/Bits. This is valid for MNO as they can save on deployment CAPEX & Network OPEX.
- Those technologies also allow agreements between operators for access to Wi-Fi network, including international roaming solutions in order to improve the connectivity for travelers.
- The improved customer satisfaction through the ease of use of Wi-Fi will result in increased customer satisfaction and thus will reduce the level of churn for the operators.

Among all the technologies that enable the convergence between Wi-Fi and 3GPP access network, are:

**Hotspot 2.0 or Wi-Fi Certified Passpoint** (based upon the IEEE 802.11u protocols) now allows the mobile device to connect and authenticate without the need for the user to manually select a network with a very high level of security. This is an essential tool in order to allow the users to connect automatically to the Wi-Fi network (on which they are authorized to access). Hotspot 2.0 thus provides a much easier access to Wi-Fi networks. A single login is required to set the system up and then the system does the rest: searching for accessible networks and gaining entry.

**Access Traffic Steering, Switching and Splitting (ATSSS)** is a featured included in 3GPP Rel-16 to enable high level of convergence between 5G and Wi-Fi networks. This feature that can be hosted in the User Equipment (UE) and the 5G Core (5GC) to provide 3 essential features for convergence:

- Steering: ensure the best network selection between 5G and Wi-Fi
- Switching: allows seamless handover between 5G and Wi-Fi
- Splitting: enables network aggregation to combine capacity of both 5G network and Wi-Fi

ATSSS allows this advanced management of connection independently for data link and voice service.

**Intelligent Wireless Network Steering (IWiNS[2])** developed by CableLabs is complementary with ATSSS as it enhances mobile steering and switching between LTE, Wi-Fi and CBRS nodes. iWiNS also has the granularity to apply per-dataflow steering policies by multi-users and multi-networks feedback. This solution requires an application to be installed on the UE and can be improved if the app is integrated into the Operating System (OS) of the device. It can take decisions depending of the state and traffic of the networks (Wi-Fi and LTE/5G) to optimize the communication on a real time basis.

These powerful tools used in conjunction with Wi-Fi 6, the most advanced version of Wi-Fi, will enable wireless access convergence and provide a better connectivity to customers at all times and all places.

[2] See "iWiNS Architecture – An aware approach to mobile traffic steering", Mario Di Dio, Rich Terpstra, CableLabs, August 2019.

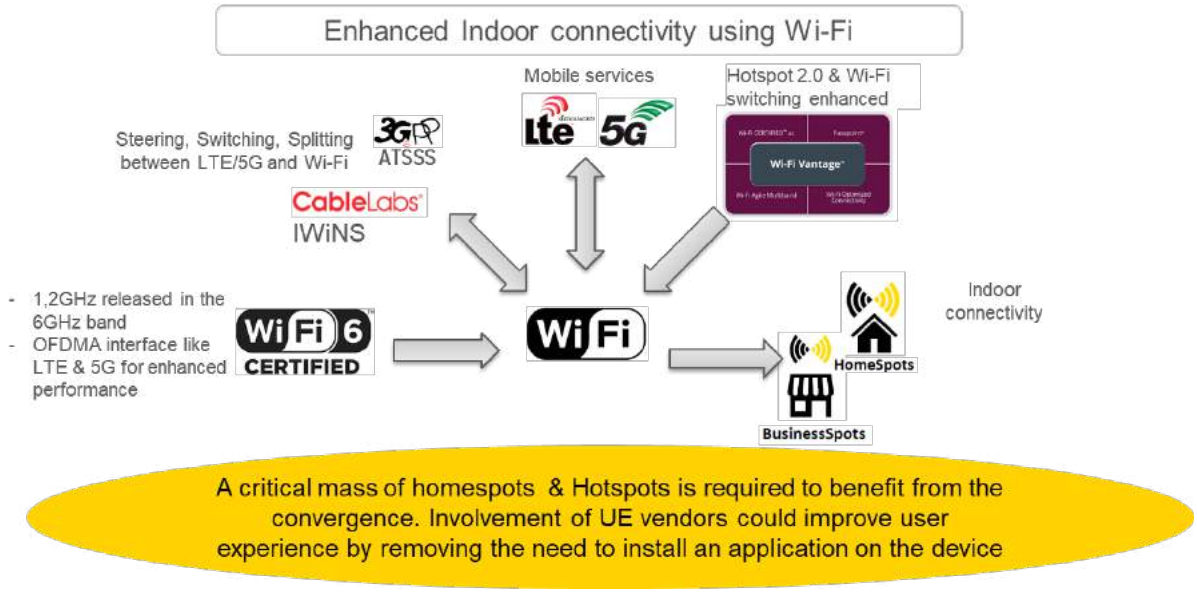

**Figure 22 – Wireless Access Convergence**

### *4.4.4. Network Convergence – All-in-One Fiber Network*

With the arrival of Distributed Access Architecture (DAA), network operators will soon extend their Ethernet network outside of headend and indoor sites to build a new digital network outside plant rather than the current analog amplitude modulation used to transport the digital services (DOCSIS and digital video).

In the next generation of HFC network, operators will deploy DAA and the new nodes will integrate the DOCSIS Physical layer (R-PHY) or the DOCSIS Physical and MAC layers (FMA, Flexible MAC Architecture). In both cases those nodes will be interconnected through an Ethernet digital fiber optics link, sometime called Converged Interconnect Network (CIN).

Coax is not the only medium fed by this CIN, some operators will also choose to evolve a part of their network to Fiber To The Home (FTTH) solutions.

Some operators, especially those who already own an HFC network may be attracted by the opportunity to build a PON network (for example 10G EPON) matching the topology of the HFC network. This is now possible using a "remote OLT" (R-OLT) installed in the field and built in a "clamshell" housing like a legacy HFC node or a new DAA node. The position of DAA nodes and PON nodes will then be similar and the topology of digital fiber network (or CIN) used to interconnect DAA nodes and R-OLT will be equivalent.

This CIN being an Ethernet network (typically 10GE), it is possible to aggregate multiple channels (or wavelength) on the same link using DWDM aggregation. In addition to HFC DAA nodes and PON R-OLT, this CIN can also connect some wireless sites (LTE, 5G, Wi-Fi, small cells, macro-sites, hotspots) and some business customers.

As this converged DWDM network will serve a higher number of customers but also a wide variety of services including some with high reliability requirements (for example wireless macro-sites, or business

 

customers), a redundancy can be deployed. Using a backup path and LACP for management of the traffic the critical nodes or sites can be fed with the second link in addition to the first one in order to prevent service interruption in case of fiber break on the common part of the link.

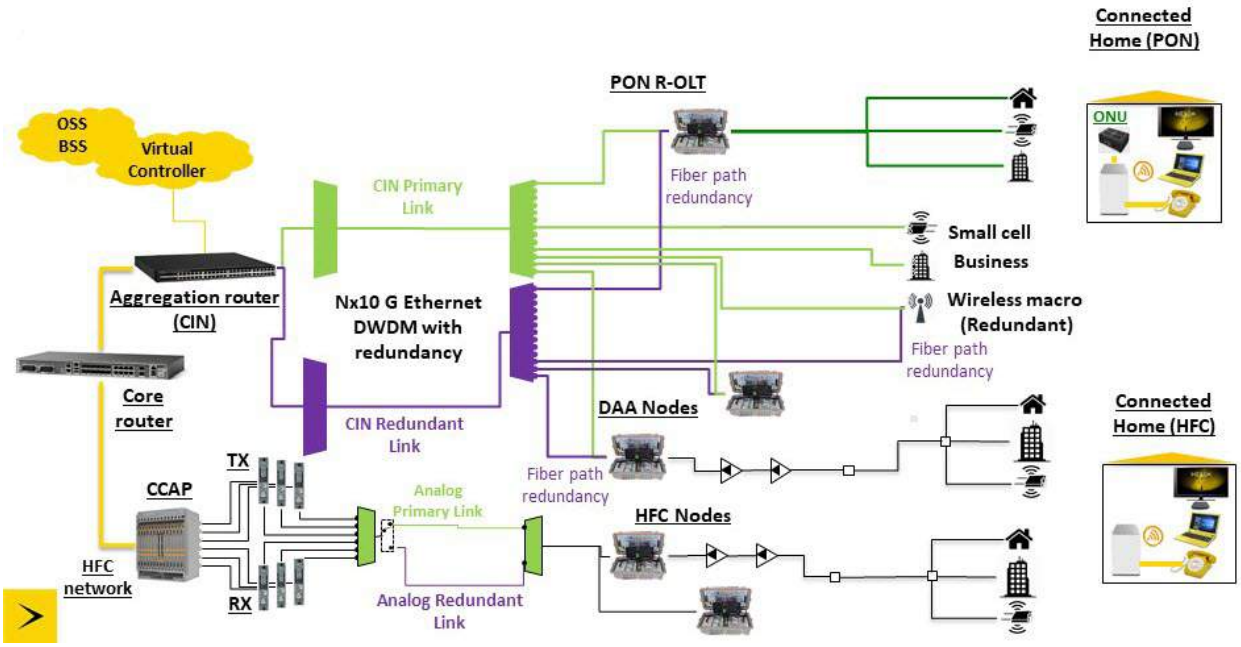

**Figure 23 – Fiber Network Convergence with DWDM Ethernet Aggregation**

In a next evolution step, this converged network will evolve to a more efficient architecture. Indeed, the DWDM aggregation allows to improve fiber utilization. On the other end, this method of aggregation is very static and does not allow to manage traffic from one node to another. The physical link is shared but the logic association is still a point to point (P2P) connection from the CIN router to each node.

A next step will be to replace this DWDM aggregated link by a high capacity link. 100 Gbps and more will soon be available for the access network as coherent optics can now be used for transport on the shorter ranges required for access network.

In this context, an aggregation node with coherent termination device (ANCTD) could be used as a transition between 100 Gbps P2P link and the lower capacity ports of the converged nodes (Typically connected with 10GE or 25GE links).

This ANCTD may take different aspects depending on operator's preference and target architecture:

- Layer 1 muxponder
- Layer 2 switch
- Layer 3 router

A Layer 3 routers would support very well a ring architecture for redundancy and allow a more advanced traffic management. In that case, the performance and metrics (capacity, QoS, latency) can be adapted depending on the requirements of the nodes or the services provided through those nodes.

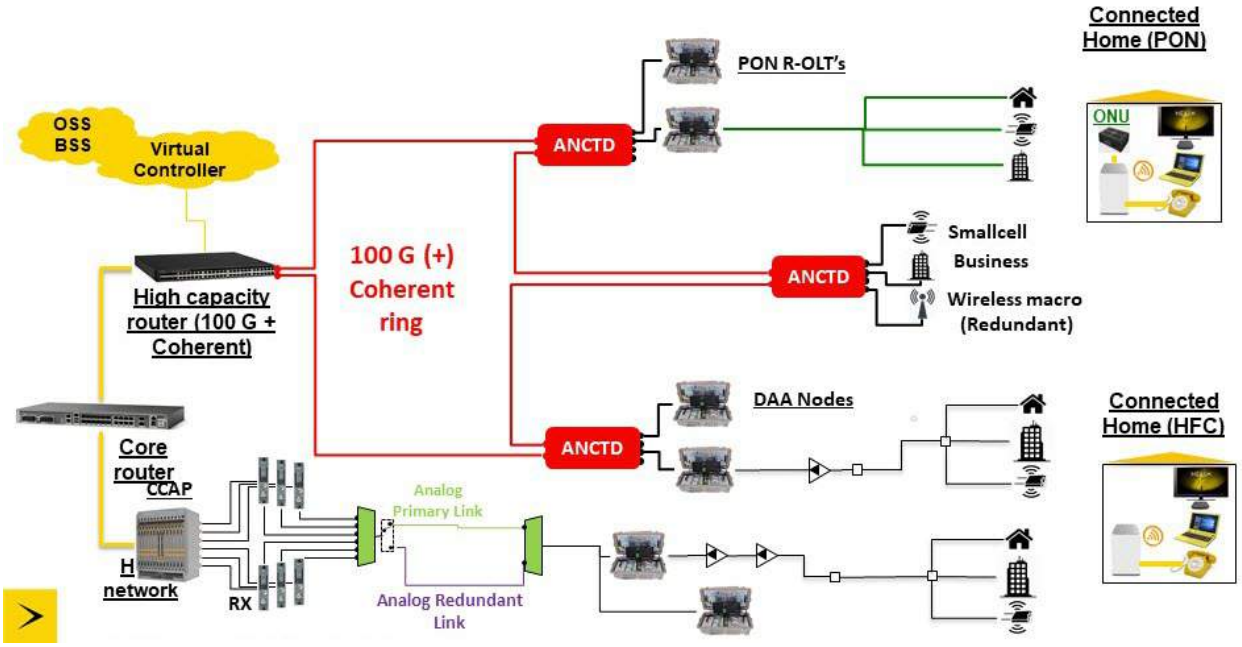

**Figure 24 – Fiber Network Convergence with High-Capacity Coherent Ring**

### *4.4.5. Virtualization – A Core Ready for All Opportunities*

Our vision about the virtualization is to create an open ecosystem in which our internal developers and our external partners will be able to integrate their solution. Our foundation uses different sets of technology and hardware based on different standard: ETSI, TM Forum and MEC. We strongly believe that each virtualization technology will benefit Videotron to implement new services and facilitate and support our innovation process.

Hybrid cloud strategy allows deployment of a new business support systems (BSS) system in the public cloud as well as the 5G RAN components in private cloud. The success of the OSS 5G RAN deployment in less than a week has proved that having the right technology in place has improve time to market. Next achievement is to make sure private cloud is up to run network function virtualization (NFV) virtual RAN for the 5G radio. In fact, the 5G is the main telco application that will benefit from the virtualization technology and the automation & orchestration framework we are deploying.

Through our automation and orchestration knowledge and process, we are targeting the creation of new values for our customers. The idea is to provide the right technological foundation for any new digital services. Any new digital services will require a specific part of the network and a specific location deployment (fog, edge, data center, public cloud). With network slicing, specific resources will have to be delivered for a specific B2B customer, and specific applications will be deployed near the customer to improve real-time experience. These use cases require a virtualized infrastructure and an automation & orchestration framework as shown in Figure 25.

One of the most challenging aspects is related to the maturity of the different virtual network function (VNF) partners to adequately run their VNF in an open virtualized ecosystem. They provide an entire virtualized stack that meet any operators needs in term of performance, scalability and service availability, but they require more investments than expected. Based on Gartner analysis and the open standard of the

 

industry (ETSI, TM Forum), we concluded that we need to limit the implication of such vendors in the value chain and spend more investments and time in the automation & orchestration area. The idea is to integrate properly any NFV stack at the OSS (our ecosystem for automation, orchestration, resource inventory, security tools and monitoring) level. That way, we let the NFV vendors be good at what they are good at, and we integrate their NFV stack to our OSS & BSS catalogue.

All the efforts done so far has created a new digital culture across the engineering team. The industry and our IT team has provided the right framework, knowledge and process to proceed to our NFV deployment. The future is to make sure our foundation will evolve the right way to host the 5G core, to enable new digital services area such as 5G network slicing and cloud gaming.

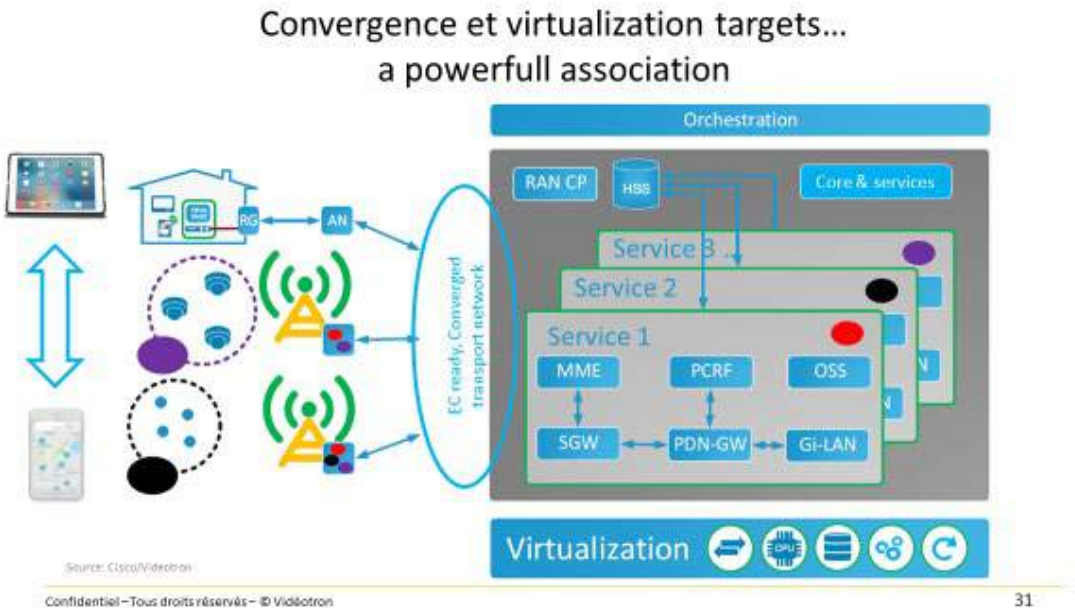

**Figure 25 – Convergence and Virtualization**

## 4.5. Telecom Argentina

### *4.5.1. Introduction*

Telecom is the result of merging two former companies, one a mobile operator and one a cable operator. It has four main access network technologies that were evolving in different ways and then came together. The question is, how should Telecom evolve these networks in order to meet the capabilities and services that they will have in the future, while trying to choose the best of these different technologies, reusing the infrastructure, evolving the future access services, increasing the customer experience and avoiding duplicating investment due to the overlapping of different access network technologies in a same area.

Figure 26 shows Telecom's four access technologies, overlapping each other, in the same area: HFC (DOCSIS), fiber to the cabinet (FTTC) supporting xDSL, fiber to the home (FTTH) and 4G.

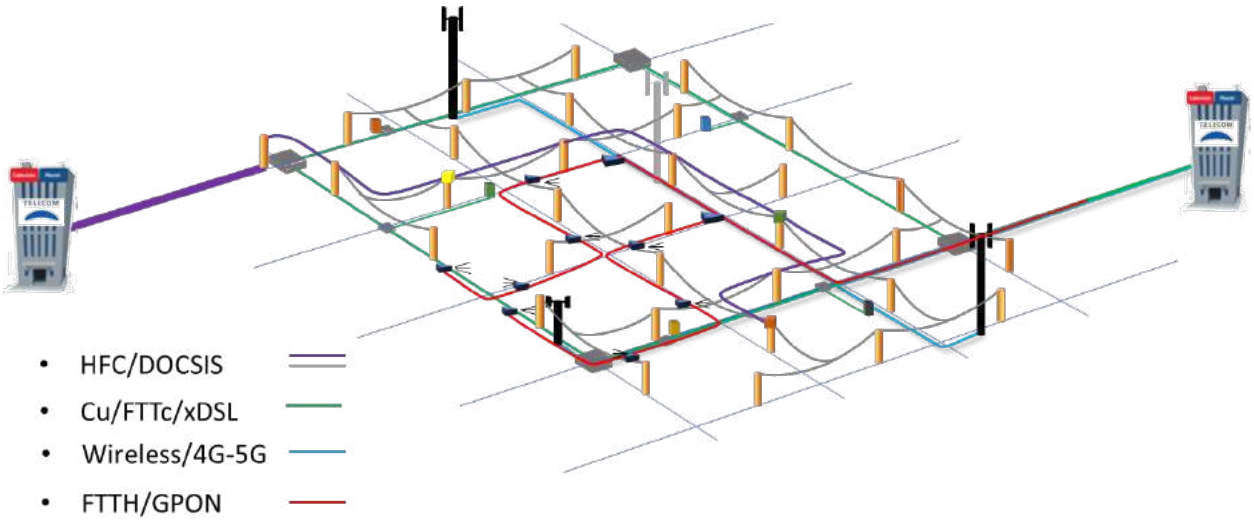

**Figure 26 – Telecom Access Network**

Figure 27 shows the deployment topology for each access in a cleaner fashion. Each of these networks has different capacities, characteristics and connection flexibility. For example, the HFC network reaches an area of 1,000 households with a couple of fiber optics (FO) from the hub to the fiber node, while the FTTC network reaches an area of 400 households with one FO. Even when the first one can provide more and better services, the second one provides very valuable growth potential for example with its underground wiring.

On the other hand, the 4G/5G wireless access network actually uses technology that could provide not only mobile services but also fixed services (especially on 5G). It also has a mobile backhaul over dark fiber to reach the base station from the central office. Finally, during the last few years, a new FTTH-based network has been implemented in certain areas and will be our target access network in long term.

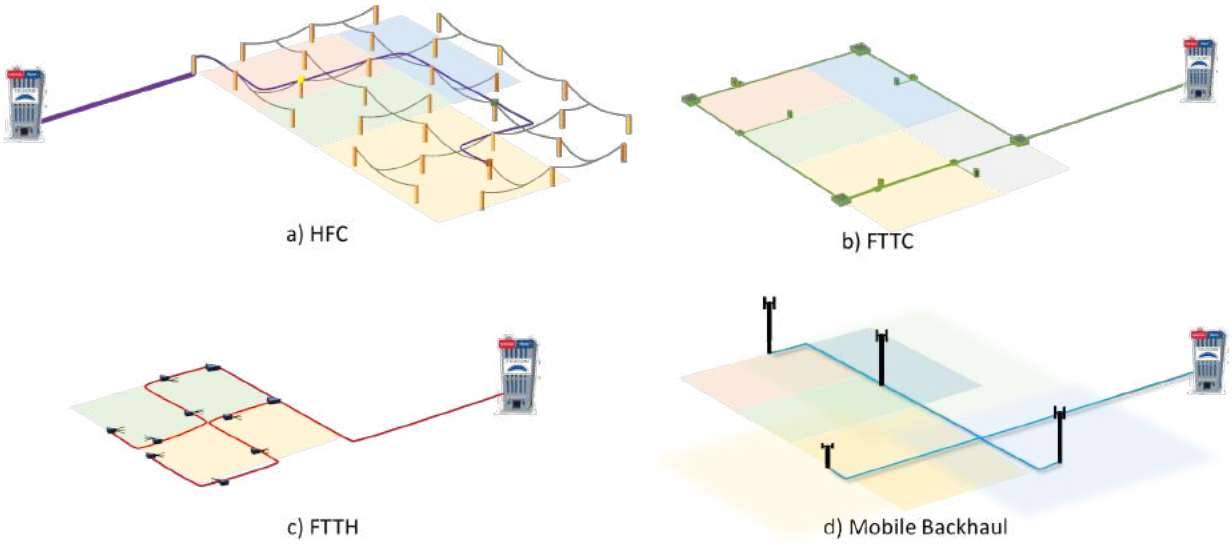

**Figure 27 – Telecom Access Technologies**

The goal must be to find a **target access network** to provide the capacity and attributes for the future services, as well as a **converged access transport** to distribute and connect each access with the different core services in the data centers (those being national, regional, or even at the edges of the network).

Figure 28 shows the complete picture of the four access technologies combining the access distribution, access transport network and the services that could be provided locally from the hub or central office (CO) or it could extend through different data centers (DC), like 4G in the national DC.

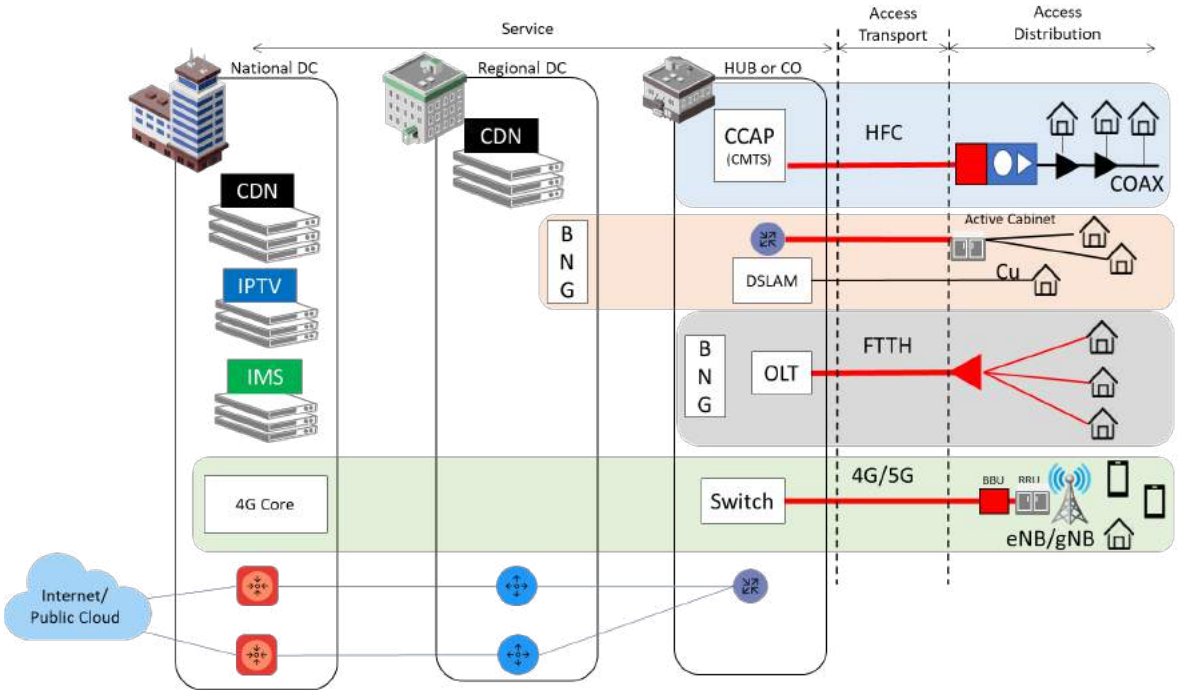

**Figure 28 – Telecom Access Network Prior to Convergence**

### *4.5.2. Convergence Access Network and Convergence Access Infrastructure*

After several studies that Telecom did during 2019, based on different requests for information (RFIs), consultancy processes, and internal analysis, we found different approaches for Distribution Access Networks and Transport Access Networks. Figure 29 shows the new picture with convergence access network and transport infrastructure.

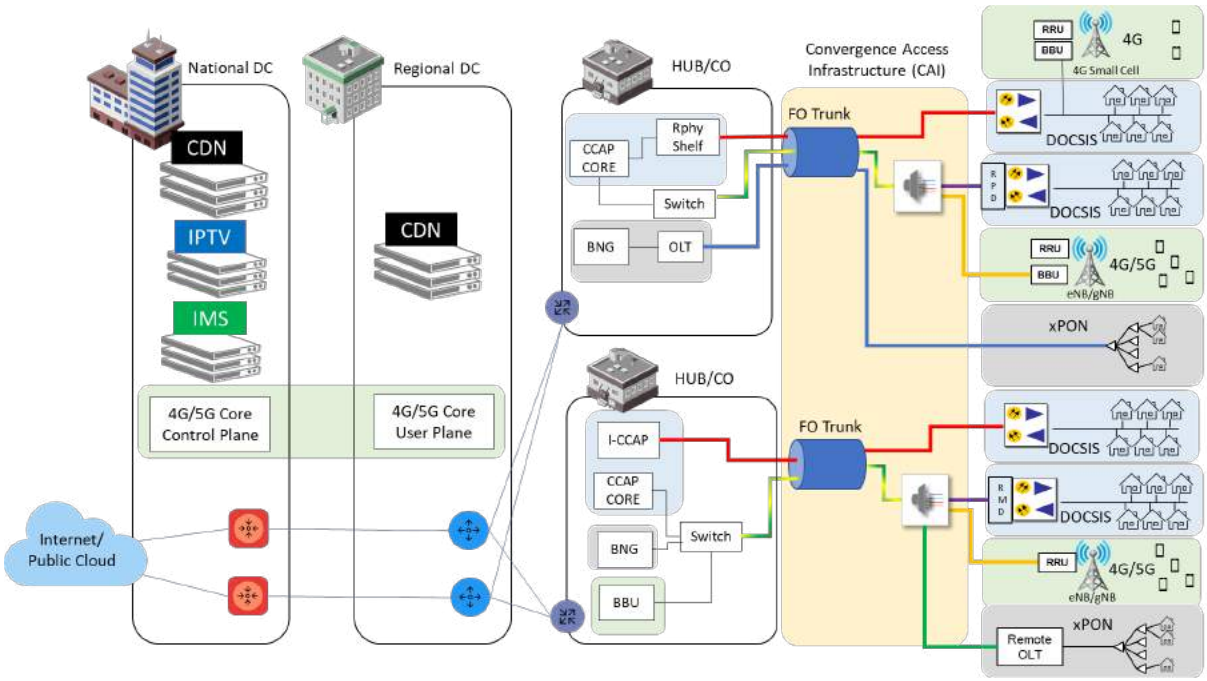

**Figure 29 – Access Convergence**

### *4.5.3. Fixed Access Network*

For fixed access services, there is not just one recipe. Depending on the homes passed density of the area, take rates, product roadmap, and existing technologies deployed in those areas, there are different criteria on how to evolve the access network.

For instance, in areas where there are more than 50 homes passed per block, and take rates that are greater than 25%, and if the area has DOCSIS and DSL technologies, the analysis shows that the fixed access technologies evolution will first evolve on HFC capacity up to DOCSIS 3.1 on 1 GHz or 1.2 GHz spectrum and will then evolve towards FTTH overlay (GPON and XGSPON).

That means that Telecom will leverage the existing HFC/FTTC infrastructure to build an overlay network and it will smoothly move DOCSIS subscribers to xPON technologies. It doesn't mean that we are going to shut down the HFC network. Even in 10 years we are going to have our HFC network.

FTTH overlay doesn't mean a FULL FTTH migration. What the strategy of FTTH overlay means is that the target fixed access network should be FTTH at the end of the road. In our case, the period of analysis was 10 years, and just a percentage of the customers will be migrated to GPON and this will be a function of different factors such as product tier, churn, competition, and DOCSIS offload necessities. That strategy shows a smaller TCO compared to keeping HFC technology while evolving it towards DOCSIS 4.0. Two key points for that are:

- Leverage the existing fiber infrastructure from both former companies using a converged access transport network. Most of the HFC plant has aerial fiber and it could be extended if needed for optical distribution network (ODN), and there are underground fibers and/or fiber ducts from the former FTTC network. This strategy should lead us to an underground fiber trunk – whenever possible – towards field nodes, even active or passive.

- Home network services must be completely an IP environment. CMs must be replaced by optical network termination (ONTs) in case of DOCSIS to xPON customer migration. Home services must be the same for residential gateway (RGW) features, Wi-Fi capabilities, and monitoring. The most important thing is to protect the investment in set-top boxes (STBs). TV services are based on IPTV in the home network, which is something that Telecom already started to deploy (Telecom have analog clients, and the analog reclamation will be based on IPTV directly, so most of the home will be prepared to be migrated towards xPON during next years).

In areas with DOCSIS and digital subscriber line (DSL) technologies, but with lower households passed density and/or take rate, we found that the FTTH overlay was not so cost-effective in terms of total cost of ownership (TCO). However, DOCSIS evolution could support future demands, so we defined an option called HFC Target which moves xDSL customers towards DOCSIS. The risk of this option relies in ultra-high tier requirements driven by competition.

There are some older areas where the network is just asynchronous DSL (ADSL) technology or one-way HFC. These are in general suburban or rural regions with even lower households passed (HHP) density. Here, fixed wireless access (FWA) service was analyzed as the best choice to provide triple-play services.

The finding was that the best combination is to start the deployment with FWA, and then after some years, move to FTTH (assuming aerial fiber), and then reuse the FWA deployed capacity for mobile services. This alternative de-risked the investment of building a fixed network in areas where the take rate could not be properly estimated.

#### *4.5.4. Small Cell Backhaul over DOCSIS*

As depicted in Figure 29, there are small cell deployments over DOCSIS. The main use case here is to deploy pico-cells over HFC to improve the coverage service and provide better service quality to small, mid-size and large enterprises mainly inside offices, rooms, basements or to cover particular public indoor spaces (like shopping malls). The service must provide 4G and 3G connectivity.

Figure 30 shows a simplified architecture that provides 4G services over DOCSIS backhaul. The HeNB (Home eNodeB is the name used in 3GPP to refer to small cells in 4G) is connected to the 4G EPC using DOCSIS as backhaul. The BBU is connected through a CM and establishes a secure connection with IPSec tunnel, that goes through the CMTS, the IP backbone (IPBB), and it is then terminated at the SeGW (Security Gateway).

Optionally, the architecture considers adding a HeBGW (Home eNodeB Gateway) that works as a concentrator of S1-U (i.e., user plane) and S1-MME (i.e., control plane) interface when there is a big amount of HeNB in order to avoid overload, especially in the MME. Finally, the HeMS (Home eNodeB Management) is the component that is in charge of the management of HeNB.

 

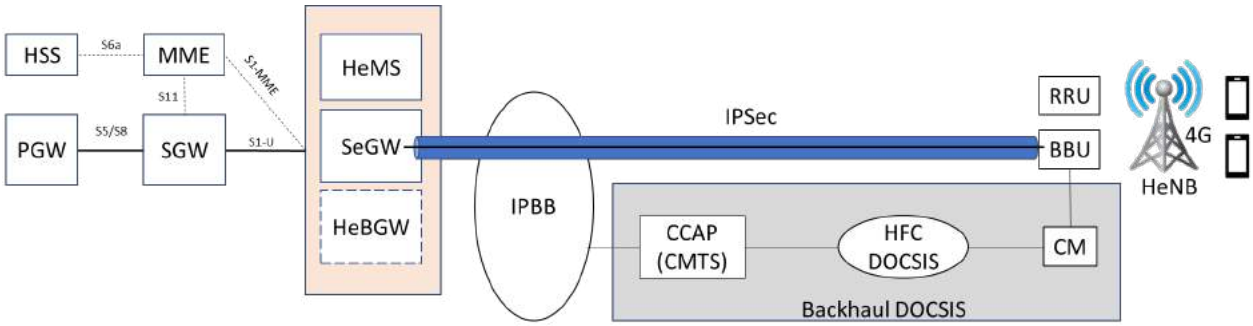

**Figure 30 – 4G Small Cells Backhaul over DOCSIS Architecture**

The following graphs show the distribution of average and peak throughput of LTE microcells for 2T2R[3] microcells during the peak hour, for downlink (DL) and uplink (UL).

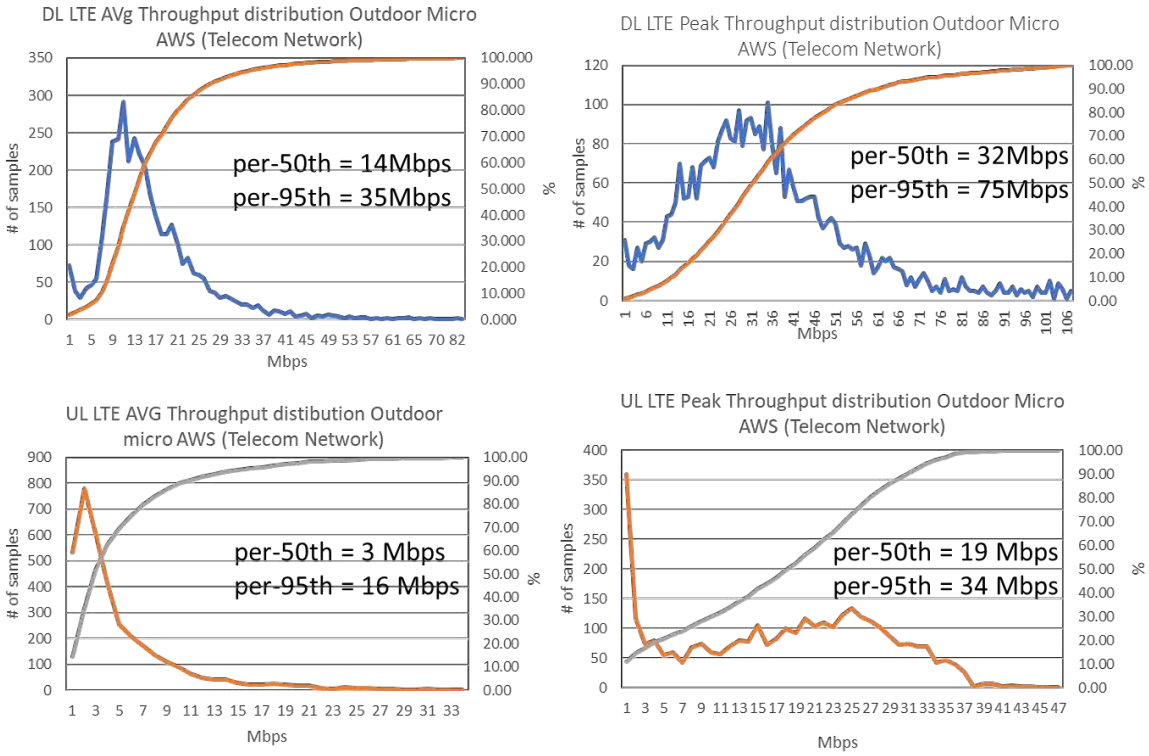

**Figure 31 – LTE outdoor microcells Throughput**

For DL direction, LTE backhaul over DOCSIS is not a big concern in terms of peak traffic. Nowadays we have products of 100 Mbps in downstream (DS) for residential subscribers, then a small cell could be considered as another CM in the DOCSIS DS service group (SG). However, a small cell requires an average DS throughput of 35 Mbps, while a regular residential subscriber requires an average throughput of at least 10 times lower than that of a small cell. Therefore, sharing the DS SG between small cell deployment and residential subscribers must be done in a planned way.

[3] Measurements were taken in June 2018 – 2T2R Bandwidth = 15 MHz at AWS band.

From the upstream (US) point of view, assuming 70% utilization for capacity planning, 42 MHz split HFC networks provide approximately 47 Mbps (three 6.4 MHz channels with 64 QAM @70%) or 76 Mbps (four 6.4 MHz channels @ 64QAM @70%). On the other hand, the graph above shows that meeting the 95% of the times with the needs of UL LTE peak traffic demands a DOCSIS US SG capacity of at least 34 Mbps. Then in this configuration, it could be a challenge to use DOCSIS as backhaul sharing the resources with other residential CMs in the same service group. Hence, is highly recommended move the US split to the mid-split of 85 MHz and deploy D3.1 in US for more capacity, if the small cell is to share the same SG with residential subscribers.

Regarding 5G, in terms of capacity, if DOCSIS is considered as a backhaul solution, then mid-split and DOCSIS 3.1 in the DOCSIS US is a must, whilst in DS SG, the number of SC-QAM/OFDM blocks should be increased. Tests conducted in Telecom Lab with 5G gNodeB (gNB) showed DL peak rates of 1.5 Gbps and 130 Mbps in UL.

Another point to consider in backhaul over DOCSIS is the latency added to the end-to-end service. Round trip time (RTT) latency values that were obtained during the trials were in the range of 30 to 50 msec. In order to improve those values, the Low Latency Xhaul (LLX) over DOCSIS technology [6] is required (see Section 5.2).

#### *4.5.5. Evolution Towards 5G*

Deploying previous generations of mobile technologies, i.e., 2G, 3G, and 4G, involved abrupt changes, where, in addition to radio access, a complete change of the core was required to support the next generation. In stark contrast, 5G supports deployment alternatives that can leverage part of the 4G infrastructure, thus easing the inception of this technology.

The 3GPP defines a set of standard deployment options as shown in Figure 32. Regarding the evolution of mobile services from 4G to 5G, the first step is to deploy a 5G non-standalone (NSA) option 3x architecture [10]. Option 3x is one of the NSA options where an improved 4G EPC (EPC+) can be used to connect the RAN, which is composed of eNBs as master nodes as well as gNBs. Option 3x architecture gives Telecom a fast time-to-market and the possibility to provide enhanced mobile broadband (eMBB) services (for instance for FWA) in certain areas, as a complement to other fixed-wired services as well as 5G mobile services. For that, new gNBs are collocated next to the 4G's eNBs in areas where the service is required.

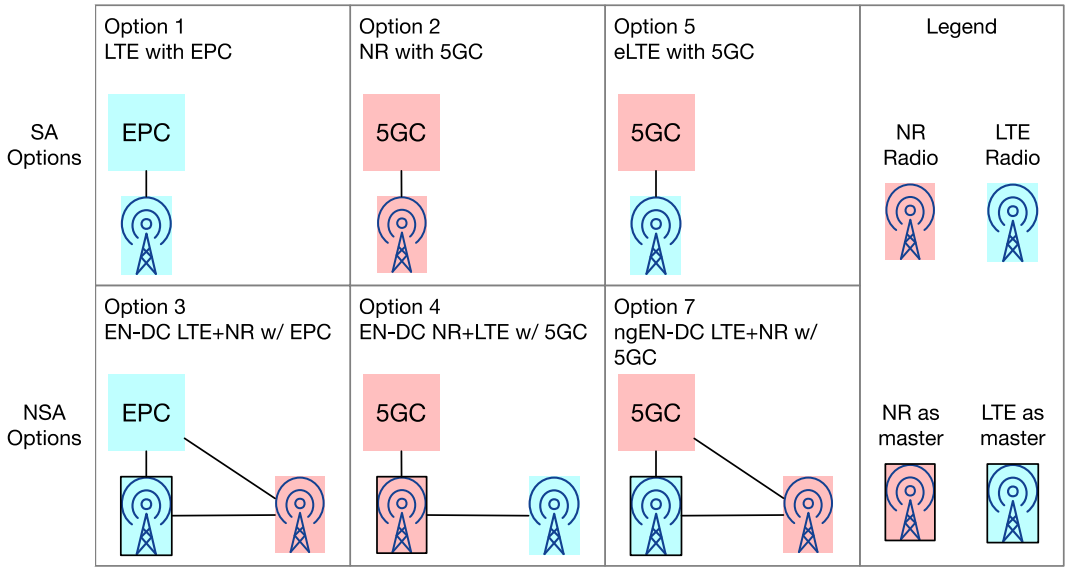

**Figure 32 – 3GPP Deployment Options**

Some upgrades are needed in the core to evolve the 4G EPC (EPC+) in order to support the NSA capabilities. At the same time, to improve the capacity and improve the traffic distribution, control/user plane separation (CUPS) architecture is implemented that splits the control plane in the national DC and user plane in the regional DC.

This will be followed by a coverage strategy that will be given depending on the commercial demand that we have, but also on the spectrum available. Here, there are several options. For example, using the spectrum in 3.5 GHz which requires regulation definitions in Argentina. Other options may be to make use of the existing bands ("refarming"). The problem is that it would take capacity out from 4G services.

However, a technique called Dynamic Spectrum Sharing (DSS) began to be developed. DSS allows dynamic use of the spectrum by arranging resources for 4G and 5G terminals at different portions of time and frequency subcarriers. It's like doing an on-demand refarming. This is not really going to generate much more capacity than what we have today for 4G, because, at the end of the day, the amount of bandwidth is still the limit, but it will give the possibility that 5G terminals can camp into a 5G service area. Figure 33 shows a potential roadmap, from the initial state in LTE Advanced Pro, then 5G NSA core plus new generation radio deployment and coverage expansion.

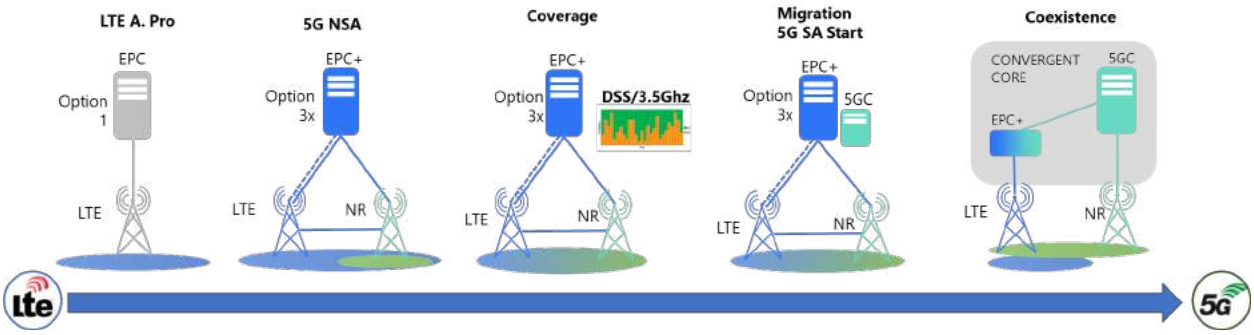

**Figure 33 – Possible Evolution Toward 5G**

To offer the other 5G attributes, aka ultra-reliable and low-latency communications (URLLC) and massive machine type communications services, a new generation of radios (NR) are necessary but not enough. A full fledge 5G core using a service-based architecture is mandatory. This means beginning a process of core evolution and integration to include the new 5G standalone (SA) components in place.

Finally, we will have a converged 5G core with embedded capabilities that support 4G services since 4G will remain for many years still in our mobile access network. The first step is moving from LTE to option 3X NSA. The next step is to introduce 5G SA. In the industry, there are not much interest in option 7 or option 4. In theory, an operator could simply introduce a new 5G SA option 2 to connect new 5G UEs, then to operate 2 different cores, the "legacy" 4G and 5G NSA and the new one 5G SA.

However, while we introduce a 5G SA, we must guarantee the service continuity between LTE, 5G NSA option 3x and 5G SA option 2. Use 5G SA option 2 to connect 4G UE is another challenge because this migration strategy would require upgrading the eNB to gNB, while also would likely need to acquire new licenses in the new 5G SA option 2 to include the legacies 4G UE. This migration strategy requires more cost without any extra benefit.

What Figure 34 depicts is a combination where we keep the components of 5G NSA supporting 4G UE and 5G UE that works in option 3x, combined with 5G-SA components that connects the UE in option 2.

What we have is an evolution of our today 4G core including LTE+5GNSA 3x capabilities and finally we add 5G SA core components but all in the same "convergent core" solution. That allows us to keep the investment that we did for 4G and 5G NSA, to introduce the 5G SA, providing service continuity and giving the benefit to operate just one "platform."

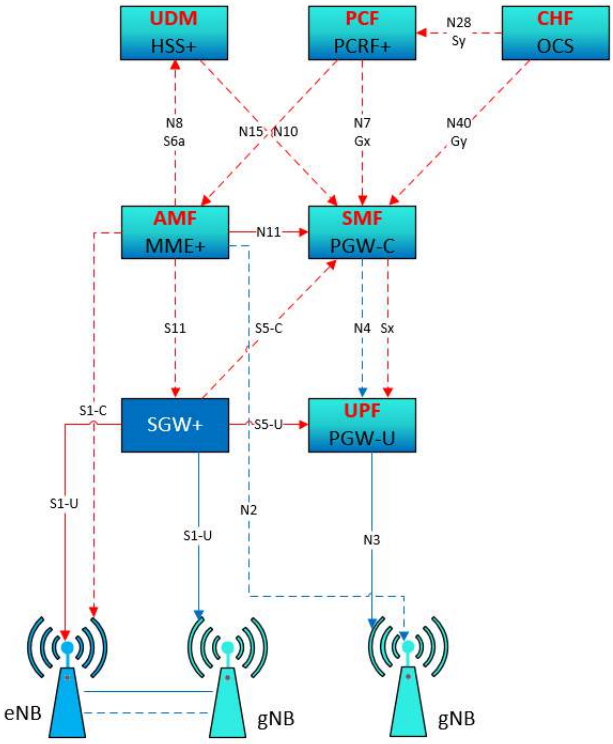

**Figure 34 – Convergent 5G Core**

### 4.5.6. Convergence Access Infrastructure

Figure 29 showed access distribution areas that are connected towards the hub and CO with a Convergence Access Infrastructure (CAI). That means that the same fiber trunks are used to support different services such as RPD, RMD, R-OLT, eNB, SMB CPEs, and to connect the access distribution area.

One option is to carry those services directly on dark fiber from the hub or CO to RPD, RMD, R-OLT, eNB, etc. In this scenario, each service uses one or two dark FO.

Another option could be multiplexing several services in one fiber and field devices to demultiplex or disaggregate the services. There are different techniques in this case: with passive architecture using wavelength division multiplexing (WDM), or with active architecture with Ethernet aggregation switches, and/or xPON technologies.

In Figure 35, (a) and (b) show passive WDM transport architecture. They could be distributed or centralized architectures respectively. In these cases, the field devices are passive optical filter and the services (RPD, R-OLT, eNB, etc.) requires a colored small form-factor pluggable (SFP). Figure 35 (c) and (d) depict an active Ethernet aggregation switch in the field, where (c) shows distributed architecture, and (d) shows centralized architecture.

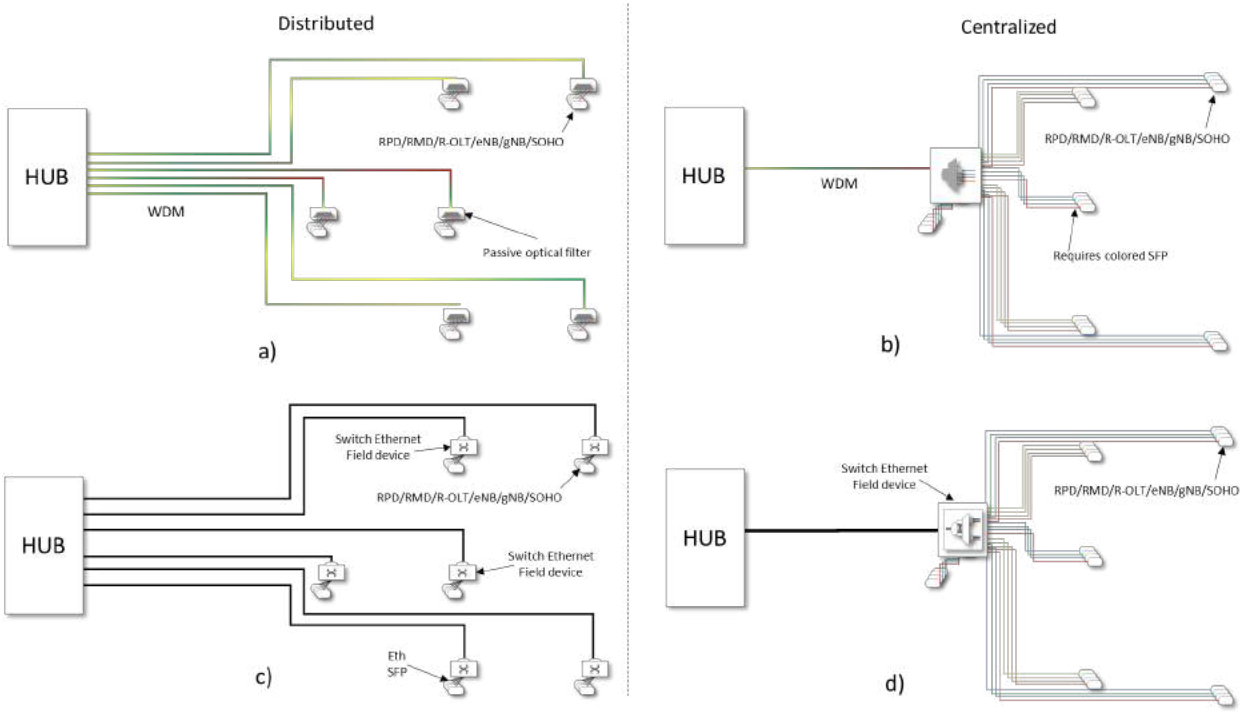

**Figure 35 – Access Transport Technologies**

The realistic criteria to build the access transport network is based which part of the former companies' networks that is more appropriate. The analysis is based on using the part of the network that is convenient for Telecom due to its strategic location and getting the fiber vacancy to support the technology and the future service requirements. The goal is to protect the existing investment, while reducing the TCO and time-to-deployment, reducing the time-to-market, and avoiding delay that external plant construction could generate.

In the scenarios that Telecom has analyzed, in general, the WDM solutions are more cost effective than Ethernet aggregation switches solutions. The Ethernet aggregation switches solution requires a bigger initial investment. This is the reason why the rest of the analysis was done comparing WDM with dark fiber from a switch in the hub directly to the services such as RPD, RMD, etc., without any multiplexing mechanism in the fiber (dark fiber). The use of WDM techniques is the result of different considerations:

- Not every technology is suitable to be carried in WDM systems, as is the case of xPON over all passive external plant, referred to as the optical distribution network (ODN).
- The tradeoff between reusing the existing FO with WDM techniques and install new fiber trunks will depend on the distance of the trunk and the amount of the services to be carried (DOCSIS, mobile backhaul/midhaul, business services, remote OLTs). WDM could accelerate the time-to-market because it requires less deploying time and less labor force than deploy new fiber trunks.
- As an alternative to new fiber cable installation, neither of them represents significant TCO compared with fixed access infrastructure (CPEs, ODN, etc.), but WDM accelerates time-to-market and does not require labor force for cable landing.
- WDM introduction can be cost effective when the plant evolution is distributed in time, i.e. an area with many HFC nodes that has to be evolved with FTTH overlay at one node per year.
- In the FTTH overlay and HFC scenarios, as the external plant requires active equipment in outside plant, the use of remote optical line termination (rOLT) for residential and some small office home office (SOHO) customers, and direct fiber for bigger customers, the use of WDM optimizes the reuse of existing fiber infrastructure without regard for the former company's origin.

### *4.5.7. Virtualization and Cloudification*

Access services have dedicated infrastructure for CMTSs, OLTs, and broadband network gateways (BNGs). With the network virtualization, or network cloudification, there are some components of those equipment that will be virtualized. Several functions that are in a CMTS are also in the BNG. For instance, subscriber management, DHCP, IP/MPLS forwarding, routing protocol, and others. Of course, there are certain functions that are only characteristics of technology with CMTS, BNGs and OLTs, but those also could be virtualized and there are other functions that will keep as physical network functions.

Nowadays most of the developments in the industry are moving from a legacy concept of virtualization to the new one, that is "cloudification." The "legacy" way to virtualize a network function has been changed with the new cloud native paradigm. This means rebuilding the system based in open-source software components and in microservice oriented architecture, where those microservices are containerized and orchestrated dynamically.

Microservice architecture means that the system is divided into small applications that could be developed and scale independently of each other, improving and accelerating the agility, maintenance and development of new capabilities. Containerization provides a light way to virtualize each microservice or process, it could be packaged in isolated way, which provides an easy way to be reproduced and deployed. Finally, the orchestration and automation manage and schedule the resource utilization, providing mechanism to simplify the deployments and scaling of containerized applications.

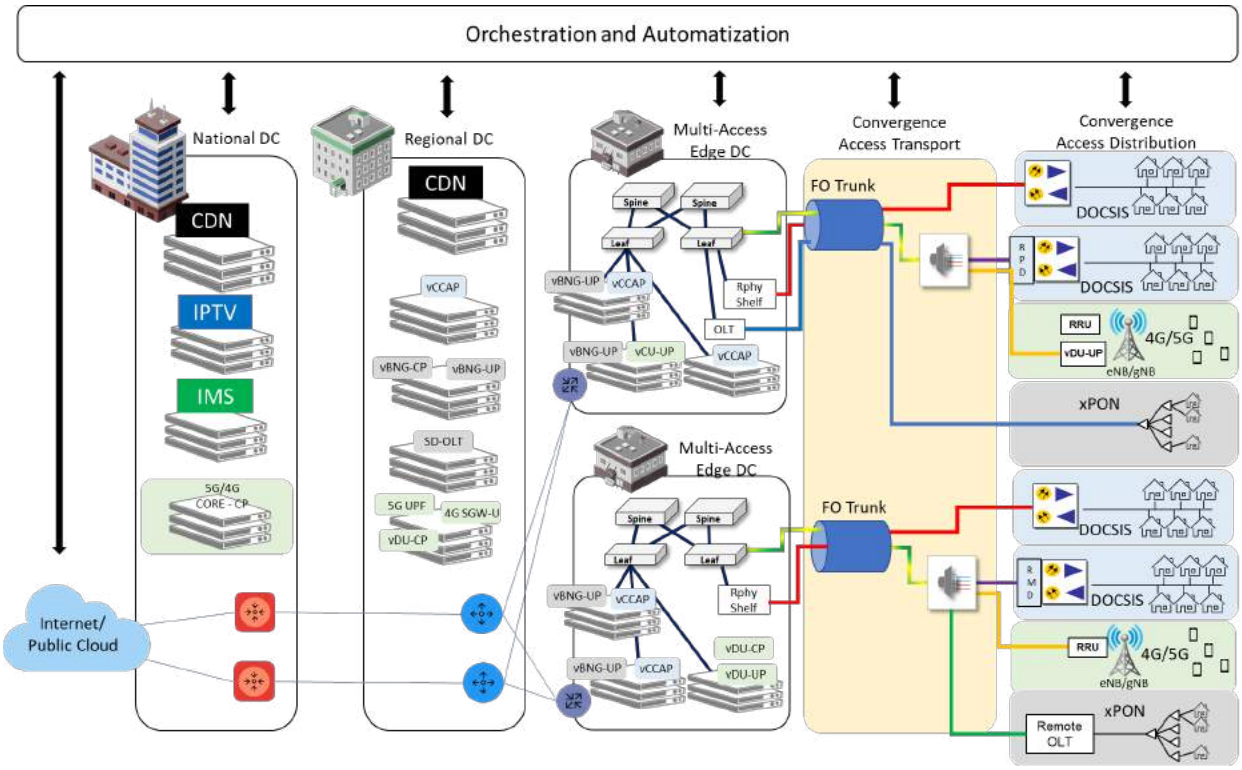

**Figure 36 – Virtual or Cloud Access Services**

Those virtual network functions or cloud native functions will share almost the similar physical and logical infrastructure. That is a big advantage if we think in FTTH overlay architecture where we could reuse the same infrastructure to deploy capacity for CMTS, BNG and OLTs. Furthermore, if we think in a DOCSIS to FTTH migration, we could discuss with the vendors to move licenses cost from a virtualized CMTS to a virtualized BNG, for example, to protect investments. Of course, we would not replace the CMTS and BNG that we have today with virtualized versions. However, when capacity expansion is needed, we will deploy the new virtualized CMTSs or BNGs instead of the traditional physical versions.

Virtualization would also enable us to move some of the functions to a more centralized location, such as a regional data center (DC), to have a better scale, and leave in the hub/CO, or the new edge DC, or far edge DC, just the functions required to guarantee latency or to keep capacity closer to the end user. Regarding the optimization of the location of different components, the CUPS architecture applies too. The BNG is a typical use case of CUPS where the control plane (CP) can be in a regional or national DC, and the user plane (UP) is distributed across edge DCs. This substantially improves the management of BNG infrastructure.

## 4.6. Vodafone

### *4.6.1. Background and Context*

Vodafone started as a mobile operator in the UK in 1985 and subsequently expanded its mobile operations into other countries around the globe via a combination of owned networks and partner markets to reach over 300 million customers. Vodafone has mobile operations in 22 countries and partners with mobile networks in 42 more.

Vodafone has grown its fixed line business via a combination of acquisition, self-build and joint ventures. Examples of fixed network acquisitions include Arco in Germany, Tele2 in Italy and Spain, C&W in the UK and Hellas Online in Greece. Vodafone then became the largest local loop unbundler in Europe using its own ADSL and single-pair high-speed DSL (SHDSL) equipment on rented copper lines from incumbents. It also used sub-loop unbundling in Italy and Germany to deploy its own very high-speed DSL (VDSL) equipment in street cabinets.

Vodafone has been deploying FTTH for over a decade and, for example, has now fiber-passed over half the population in Portugal. It has also expanded FTTH via partnerships and joint ventures (JV) such as in Ireland where SIRO is a FTTH JV between Vodafone and ESB, the electricity utility.

In terms of cable, Vodafone acquired KDG in Germany, ONO in Spain and more recently the Liberty Global cable networks in Germany, Czech, Hungary and Romania. Vodafone also acquired ABcom in Albania. This has resulted in Vodafone becoming the largest broadband operator in Europe and one of the largest cable operators globally.

Vodafone provides fixed broadband in 17 countries. As of 30 June 2020, Vodafone Group had 27 million fixed broadband customers and 22 million TV customers, including the customers in Vodafone's joint ventures and associates. Vodafone's European fixed broadband technology presence is illustrated in Figure 37.

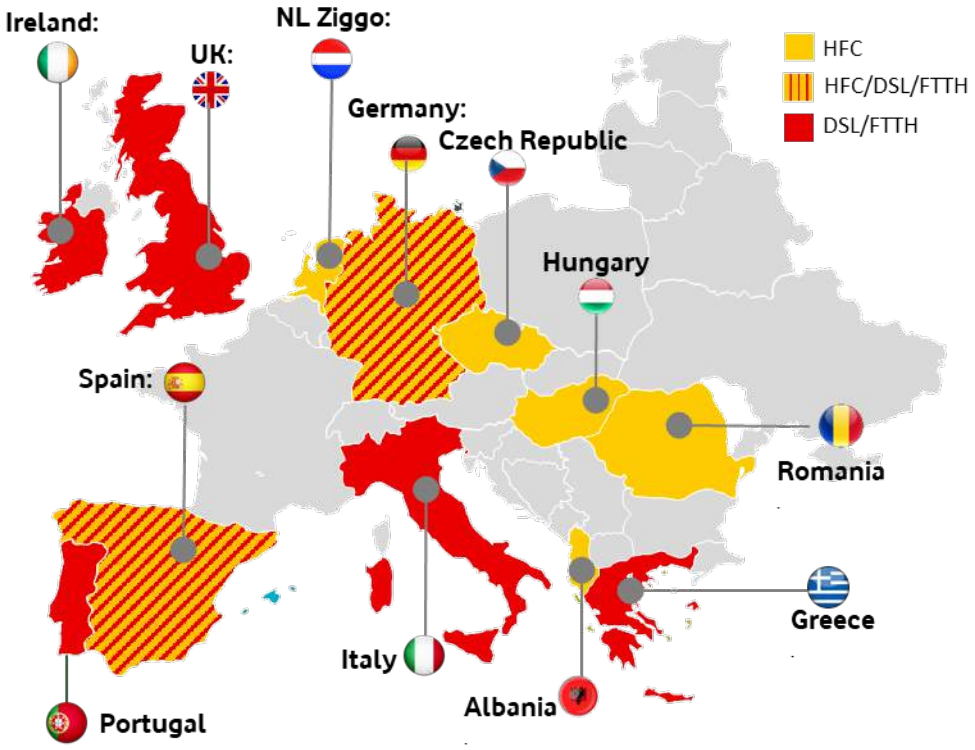

**Figure 37 – Vodafone's European Presence**

Outside of the European footprint above, Vodafone also has operations including fixed broadband in Turkey and a number of AMAP (Africa, Middle East, Asia-Pacific) countries too including South Africa and Ghana.

Vodafone is now a converged operator whose roots are in mobile. Hence in comparison to many US and Canadian cable operators, Vodafone has significant mobile spectrum and network assets. It therefore has a slightly different approach to convergence in that it is not an MVNO and it does not seek to use the CBRS spectrum. Also, whilst Vodafone has experience of deploying Wi-Fi hot spots in some markets, it is not highly dependent on having a vast number to offer "wireless untethered access" outside of the home.

Vodafone has 2G, 3G, 4G and 5G networks. Mobile network evolution will significantly grow 5G coverage, capacity and functionality over the next few years in addition to other mobile network capabilities such as narrowband IoT (NB-IoT). Mobile innovation will continue with developments such as Open-RAN and Crowd-Cell. There are also opportunities to couple such mobile capabilities with our fixed network assets for convergence at the network and service layers. The following sections give an overview of Vodafone's approach to convergence.

### *4.6.2. Motivation for Convergence*

It has been over a decade since some service providers offered "triple-play" service bundles of fixed voice, broadband and video. Convergence refers to combining both fixed and mobile capabilities resulted in "quad-play" with the addition of mobile voice/data to the bundle. This has become increasingly common across Europe where some markets such as Spain are highly converged with multiple operators offering converged service bundles to customers.

There are three main commercial benefits that have motivated Vodafone's move to become a converged operator:

1. *Reduced Churn*

Customers buying a bundle of converged fixed plus mobile services tend to be "stickier" and less likely to churn. They are often incentivized by getting a discount on the bundle (compared to procuring each service individually), and/or more included benefits (e.g. extra data, additional mobile lines, higher speed).

2. *ARPU Improvement*

When a service provider becomes a converged services provider for the first time then they have the opportunity to cross sell fixed services to mobile customers and vice versa.

3. *Cost Reduction*

Convergence at the network level enables savings compared to operating disparate fixed and mobile networks. Hence, this is usually one of the first activities to drive synergy savings following M&A activity between fixed and mobile operators. The fixed and mobile services can then share common backhaul and core transport networks as well as data centers and server capacity, which is increasingly important as we move to software-defined virtualized networks. This is illustrated in Figure 38.

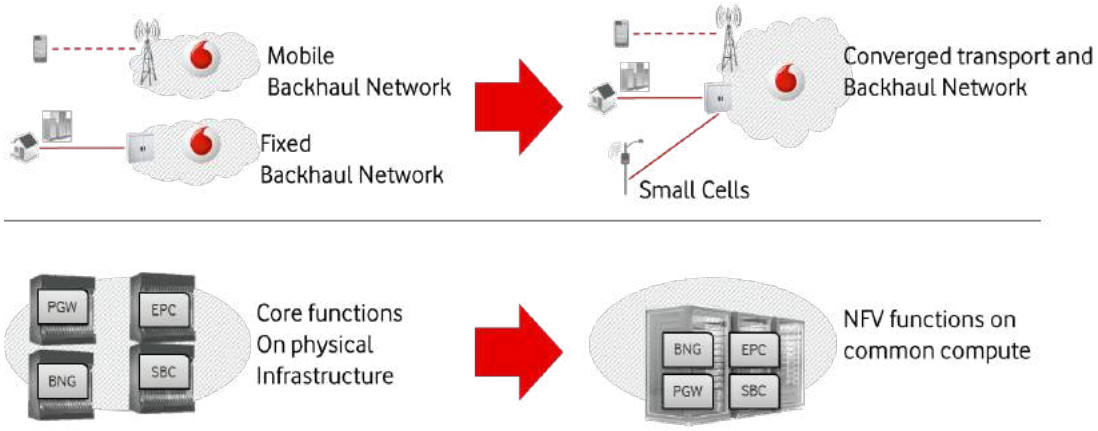

**Figure 38 – Infrastructure Convergence**

The simplest form of convergence is on the customer's bill – a single bill to span both fixed and mobile services. However, more sophisticated convergence approaches are feasible, convergence can take several forms from convergence at the service level through to convergence at the network infrastructure level. A simplified view of convergence in four different domains (or layers) is illustrated in Figure 39 for the Vodafone context.

 

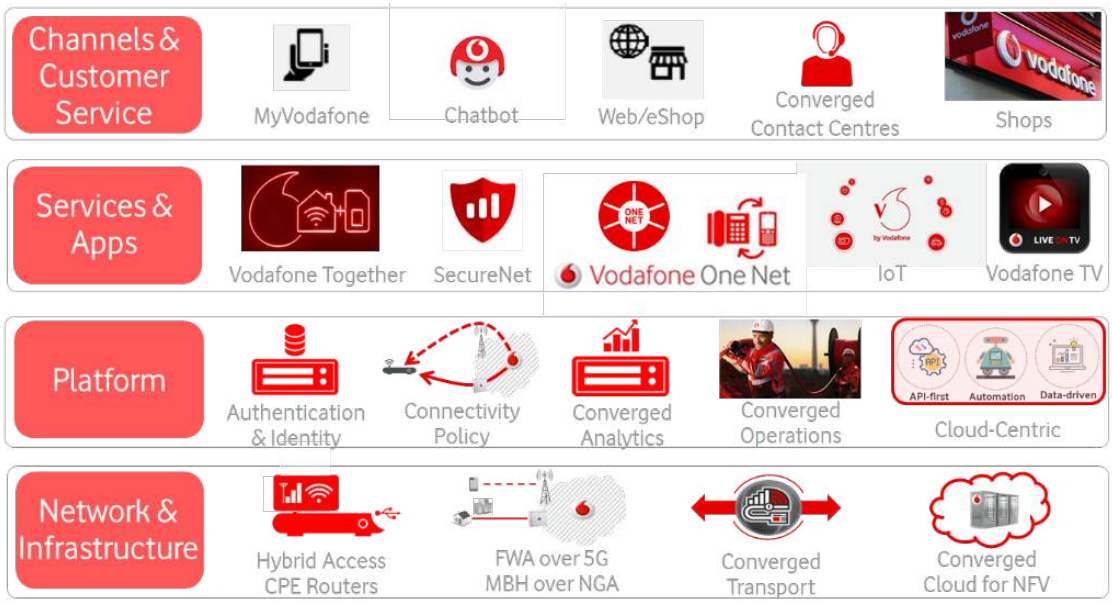

**Figure 39 – Vodafone Four Layers of Convergence**

At the bottom layer we have network connectivity and infrastructure such as compute processing capacity in data centers. The next layer has the capabilities, systems and processes that turn the network and compute resources into a technology platform. This is where policy, analytics, operations processes and automation (SDN control and orchestration) reside. This layer interfaces to the Services and Application layer above it via standardized APIs (effectively a Network Exposure Layer) to create a "Network as a Platform" paradigm. Then any converged product and service development can focus on developing to the APIs (ideally TM Forum compliant) with worrying about details of the underlying network technologies and their associated idiosyncrasies.

Development of new products and services can then be more rapid and also more rapidly deployed across multiple markets (without repeating integration heavy lifting for each new geography). This benefits time to market for internal Vodafone product development teams but also facilitates engagement with third-party partners. Finally, the top layer is for Channels and Customer Service – effectively the touchpoints for the end user customers.

### *4.6.3. Convergence Use Case Examples and Network Scenarios*

A converged network, as illustrated in Figure 40, allows a variety of converged services to be offered.

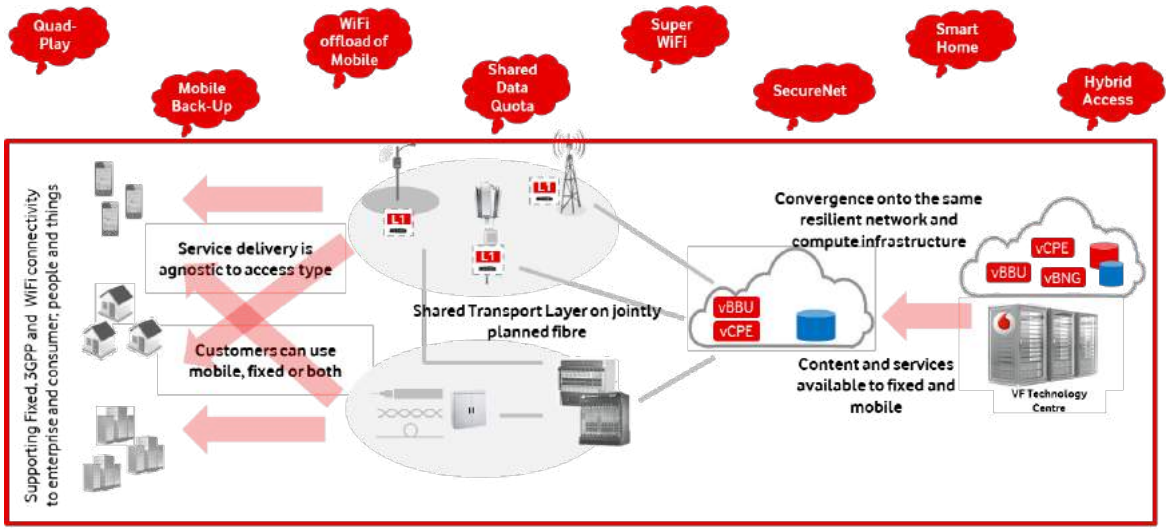

**Figure 40 – Convergence Use Cases**

The following sections discuss examples of converged services and network capabilities.

#### *4.6.3.1. Vodafone TV*

This enables a seamless, device agnostic TV experience in and out of the home which is personalized across all sources. It gives easy access to all content – integrating traditional/linear channels with on-demand, catch-up and the best OTT streaming services – with advanced search, including voice. The banding is shown in Figure 41.

**Figure 41 – Vodafone TV**

A further converged Vodafone TV variant that had previously been deployed in one of Vodafone's local markets is illustrated in Figure 42.

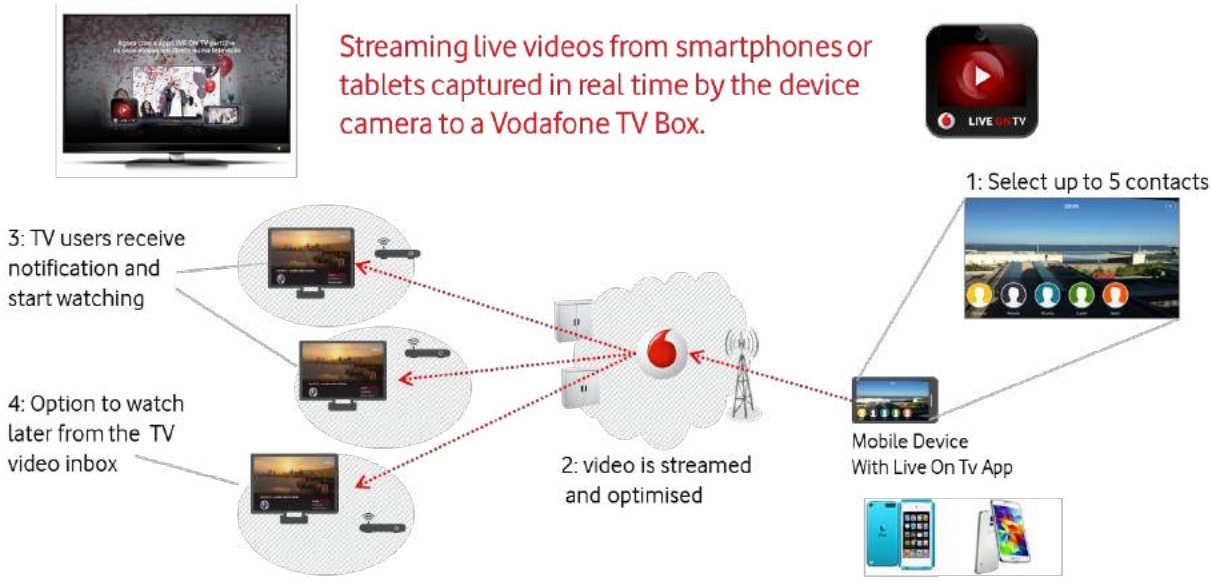

**Figure 42 – Local Streaming**

For example, if one of your children was playing a football game on a cold, wet Saturday morning, someone from the family could attend and use their smart phone camera to "video" the game which would be relayed to the TV where the rest of the family can watch it in warm, dry comfort. The process of making this happen is shown in Figure 42. There are now alternative ways to achieve similar capabilities since over-the-top (OTT) platforms (Facebook, YouTube, etc.) can offer live streaming capabilities and cast them to the TV too.

#### *4.6.3.2. Safety, Parental Control & Smart Home*

A range of "Smart Home" services is illustrated in Figure 43 are connected to the fixed broadband access line (via Wi-Fi, Zigbee etc.), but the control point is the customer's mobile handset. Such services can provide customers with control in and out of the home, across all devices, fixed and mobile. Capabilities can include mobile control and notifications. Security capabilities can include alarms, locks, smoke and leak sensors, IP cameras. Smart energy can also be facilitated via remote mobile control of thermostats.

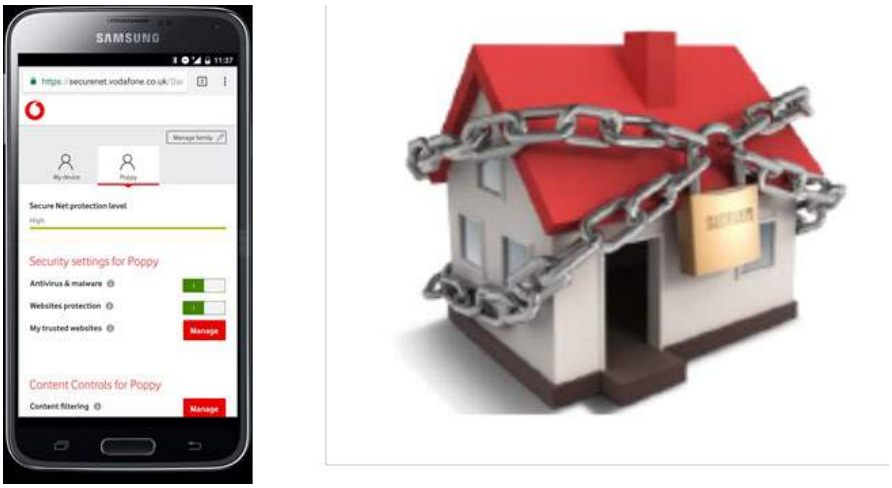

**Figure 43 – Smart Home**

#### 4.6.3.3. Hybrid Access (Fixed-Mobile Bonding)

Hybrid access combines the throughput of a low-speed fixed broadband connection such as ADSL with mobile 4G/5G data using a hybrid router. This enables customers to burst to higher speeds beyond the capacity constraints of their fixed broadband connection. It can be used to provide an 'always-on' service i.e. a resilient service with mobile backup in case of fixed service failure.

Vodafone's initial deployment of this capability, optimized for the small-medium enterprise market, integrated the bonding client into the consumer broadband CPE. This is shown in Figure 44. A variant is also feasible that uses a customer's mobile handset to provide the mobile access connection to temporarily boost the customer's fixed broadband access speed.

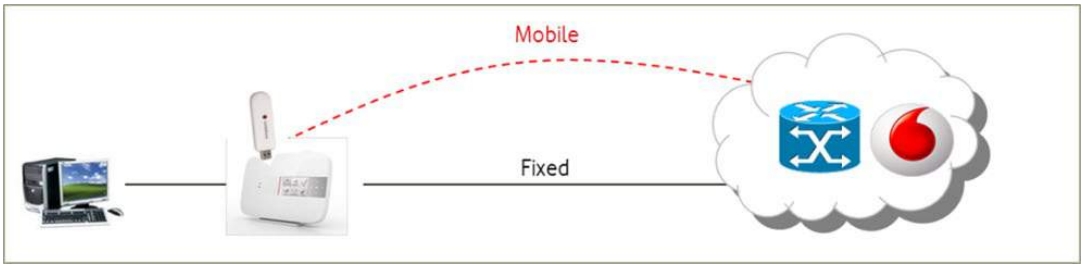

**Figure 44 – Hybrid Access**

Other variants of such technologies (including 3GPPs ATSSS) can also help to facilitate seamless roaming between mobile and Wi-Fi connectivity, preferably whilst maintaining the same IP address. This can ensure that the customer always has the best connectivity (based on both RF signal strength and network congestion). Such mobile/Wi-Fi roaming capabilities also have Enterprises use-cases e.g. in hotels, conference facilities etc.

#### 4.6.3.4. Always-On Service

A precursor to the hybrid access approach illustrated above was to leverage the availability of both fixed and mobile access connectivity in a more manual way in order for the customer to be able to carry on accessing the Internet if their fixed broadband fails. This was deployed in a few countries including in Vodafone Greece.

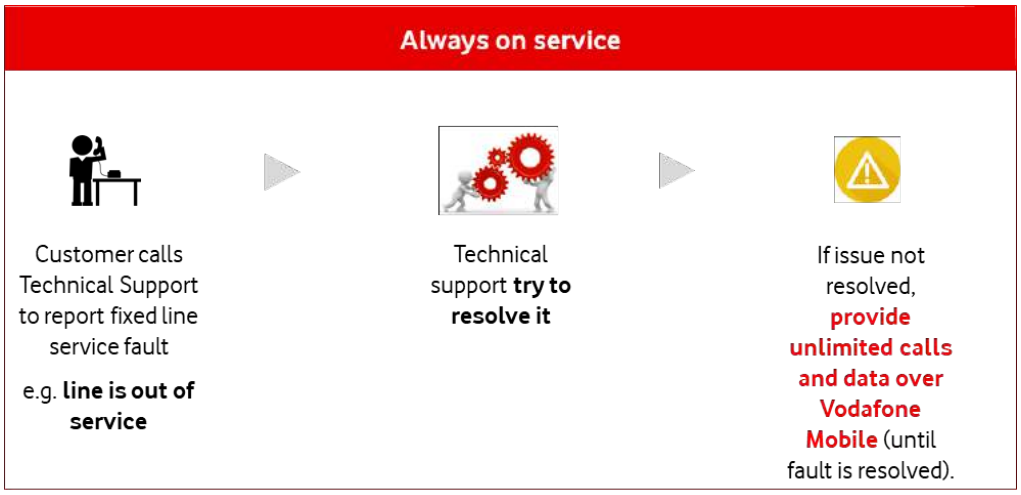

**Figure 45 – Always-on Service**

#### *4.6.3.5. Fixed Wireless Access (FWA)*

FWA is a technology option as illustrated in Figure 46 is considered for low to medium speed broadband access for areas with no or poor fixed access. It can be used as a tactical deployment where wholesale fixed broadband costs are excessive. It is usually avoided for deployment in urban and sub-urban (Residential) areas with good next generation access (NGA) penetration. It is often a "last resort" technology because there can be high customer equipment costs (especially if outdoor hardware and professional installation is required).

There can also be significant capacity implications for the costly spectrum on the mobile network (e.g. somebody binge-watching a 4k video stream for a few hours. Hence such solutions are most commercially viable in areas underserved by high-speed fixed networks and with low customer penetration, or amongst specific customer segments (e.g. customers who move residences frequently etc.). The Vodafone "Gigacube" 4G/5G FWA product has been deployed in Germany, UK and Ireland.

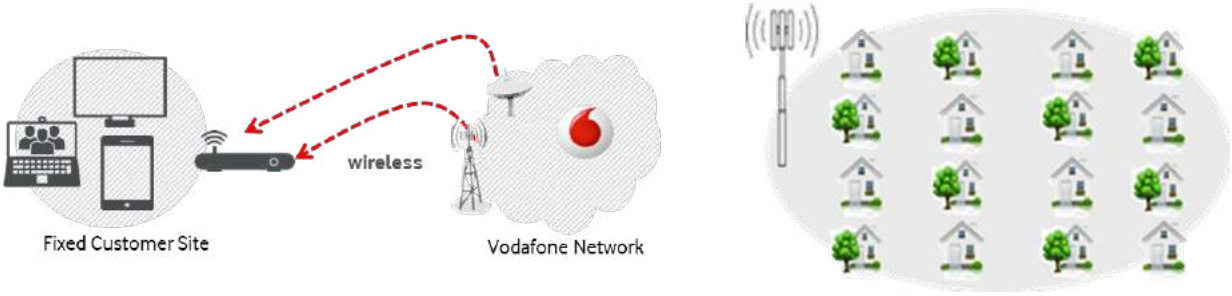

**Figure 46 – Fixed Wireless Access**

#### *4.6.3.6. Converged Access & Aggregation Network*

As NGA technologies have evolved, it becomes feasible to examine their potential to provide backhaul from mobile base-stations as an alternative to point-to-point fiber and leased lines. Vodafone had previously used GPON to connect a few base-stations in some countries. This approach then evolved to evaluate PON backhaul from 4G and 5G base-stations including the evolution from GPON to XGS-PON. XGS-PON products including the necessary Synch support (IEEE 1588v2 & SYNC-E) and have been

 

successfully proven. DWDM over PON is also a potential technology option which is under investigation. This is illustrated in Figure 47.

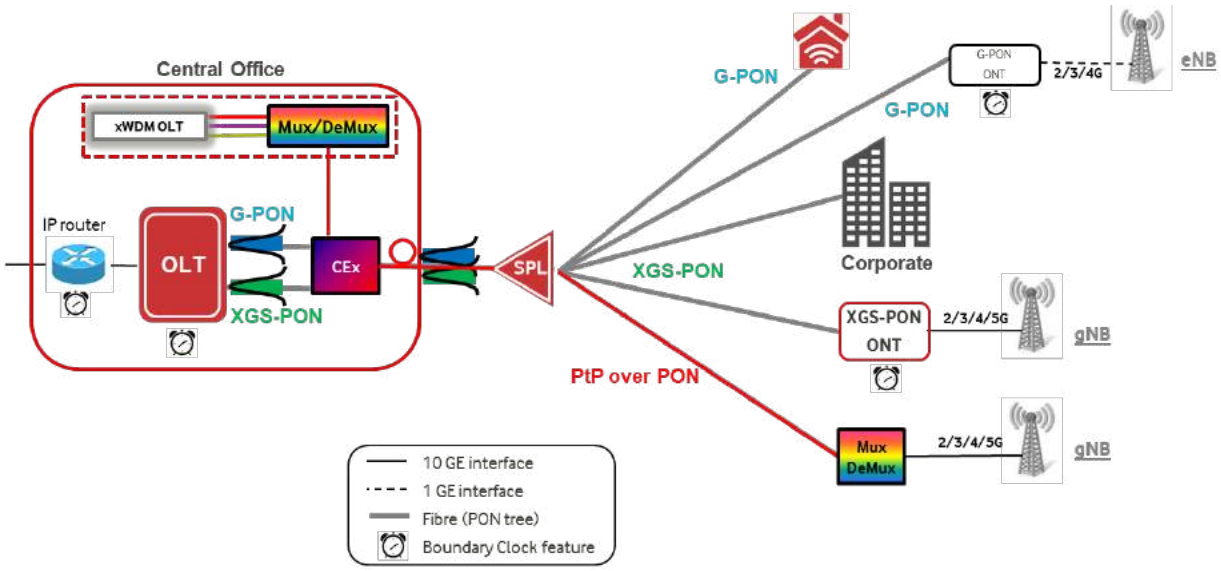

**Figure 47 – Converged Access with DWDM PON**

Thus far, mobile RAN developments such as SON (self-optimizing networks) and active antennas (also known as massive MIMO) have successfully increased the RAN capacity from macro-cell base-stations, which has deferred the need for large-scale deployment of small cells. Nevertheless, where required, Vodafone has deployed a number of external public small cells as well as indoor femto-cells for consumers and pico-cells for business customers to enhance indoor coverage.

Vodafone has previously trialed mobile backhaul over DOCSIS 3.0 in order to understand synchronization and bandwidth utilization requirements. The focus then shifted to examining mobile backhaul over DOCSIS 3.1. This is more challenging for macro-cells compared to using XGS-PON due to the lower bandwidth and potential implications for residential broadband users. However, there is a potential future role for using DOCSIS to provide backhaul from small cells, as and when their deployment may become necessary at any significant scale.

For mobile backhaul over DOCSIS, the phase and time requirements can be met due to the inclusion of the DOCSIS Time Protocol (DTP) in the DOCSIS 3.1 standard. QoS and mechanisms to manage the jitter are needed. Also, low latency (e.g. leveraging CableLabs Low Latency Xhaul – LLX) is needed to stay within a target latency of 5 ms (base station to backhaul aggregation). The various synchronization mechanisms are shown in Figure 48.

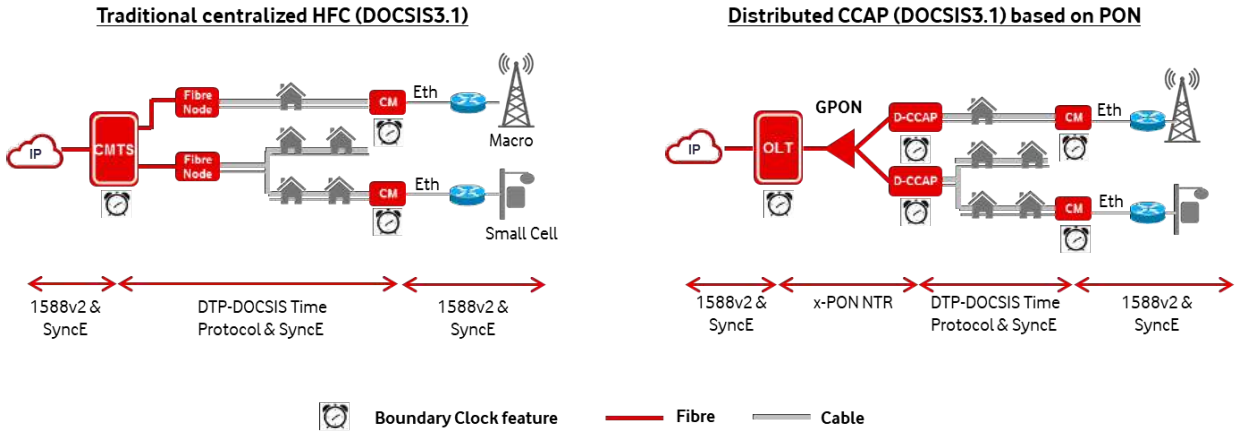

**Figure 48 – Network Timing with DOCSIS and PON**

Vodafone has been evolving its cable networks to a distributed architecture in some markets as we introduced DOCSIS 3.1. This requires fiber to be pushed deeper into the access network to connect to a remote PHY device (RPD) and remote MAC device (RMD) remote devices. This trend will continue as we evolve towards DOCSIS 4.0. Hence it creates the opportunity to have a single fiber access and aggregation network that can provide direct fiber connectivity (PON or point to point) to macro base-stations, enterprise customers, business parks and the cable network's remote nodes.

As more bandwidth is required on such a "unified fiber access/aggregation" network, coherent optical technology has the potential to play a key role, especially for the backhaul from remote aggregation locations. This converged fiber access/aggregation network approach is illustrated in Figure 49.

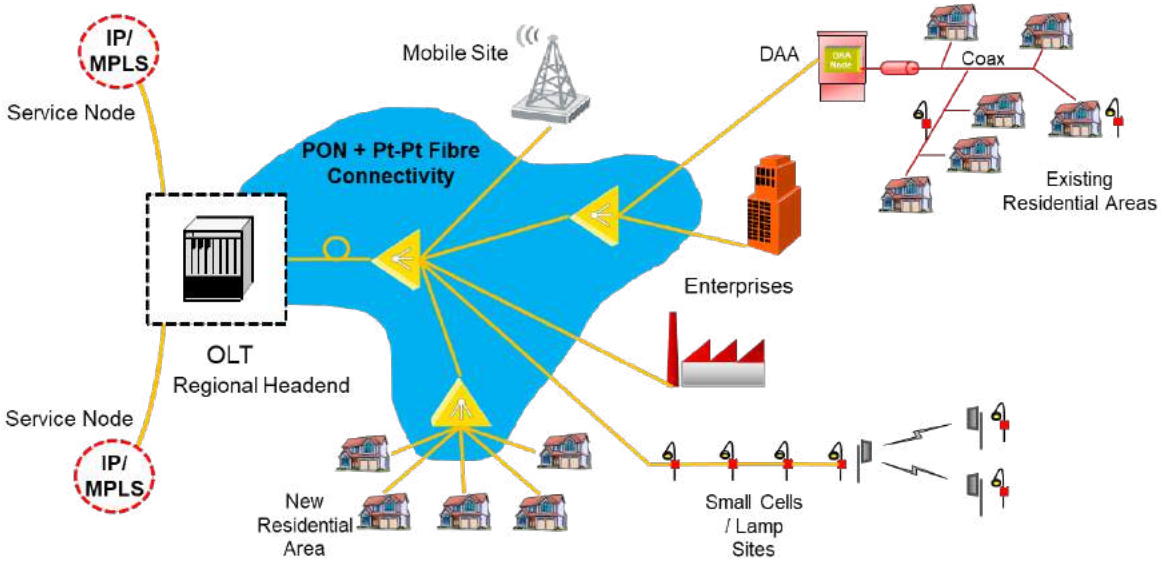

**Figure 49 – Unified Fiber Access/Aggregation Network**

A further enhancement to this access network is to introduce session steering or slicing from the access node in order to steer sessions to a user plane (software or hardware) that is appropriate in terms of location (latency) and scalability/cost to the particular session's traffic. For example, low margin consumer traffic from OTT streaming could be steered to a scalable, cheap (and dumb) user plane whereas enterprise traffic

may be steered to a user plane where service chaining is to occur for value-added services like security (firewall, malware scrubbing etc.). In the convergence context, LTE mobile backhaul traffic could be steered to the Gi LAN.

#### *4.6.3.7. Broadband Access to Converged 5G Core*

There are a number of incentives for ensuring that the next generation 5G core network can support wireline access instead of treating it as "untrusted", as was the case in previous 3GPP mobile core network standards. These are summarized in Figure 50.

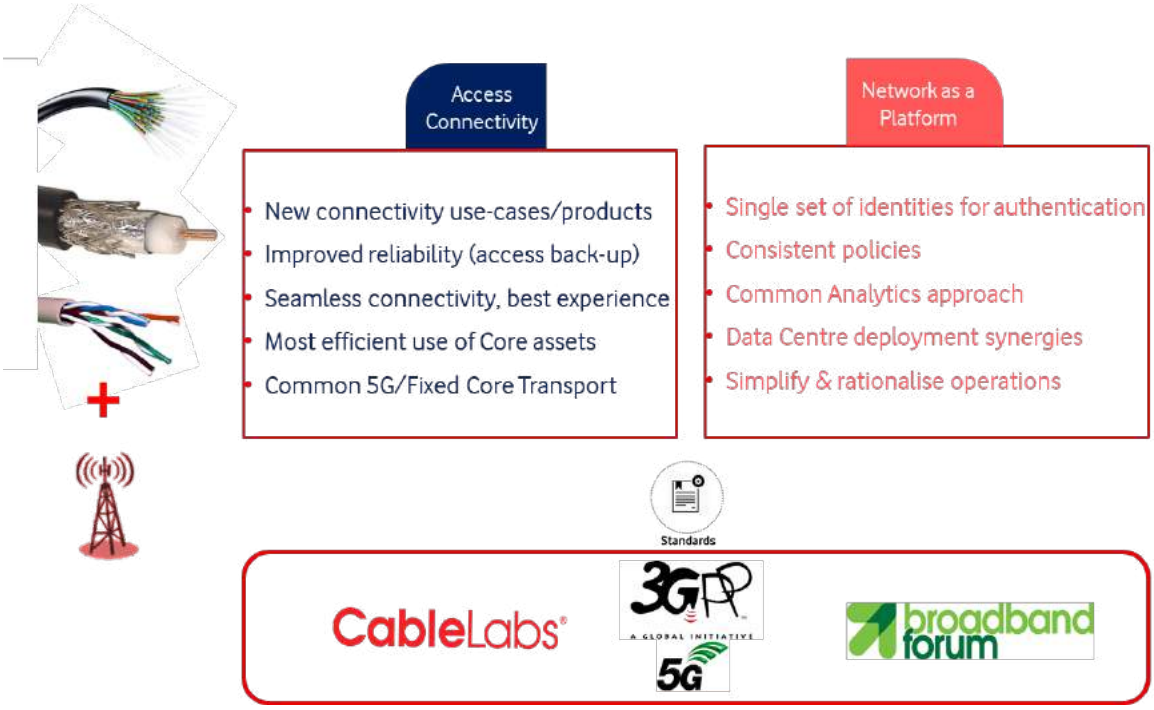

**Figure 50 – Wireline Support in 5G**

The technical approach has been to develop an Access Gateway Function (AGF) that effectively translates from the wireline protocols to those used by 3GPP. 3GPP has been working with both CableLabs and the Broadband Forum on standards in this area. The network context of the AGF is shown in Figure 51.

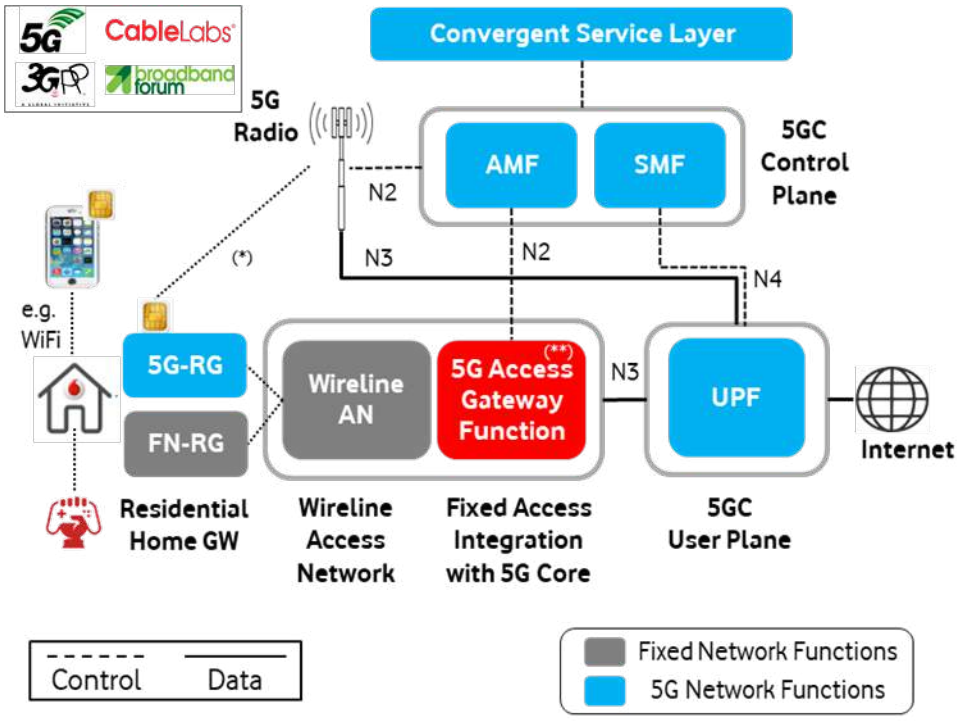

**Figure 51 – Wireline Connection to 5GC with AGF**

Residential gateways (RGs) will also evolve to encompass functionality that enables enhanced capabilities. These new RGs are denoted "5G-RG" in the standards documents. The new "5G-RG" functionality in CPE will enable more dynamic session connectivity. A 5G device (UE) behind the 5G-RG can be treated as "trusted". QoS requirements can then be signaled on a per application basis and multiple IP sessions can be added dynamically for a class of device. The 5G-RG is illustrated above. The "FN-RG" is the legacy fixed network RG that can be used to access the converged 5G core but will have less flexible/dynamic capabilities than the 5G-RG.

#### *4.6.3.8. Improving In-Home Mobile Voice Coverage*

Vodafone has extensive experience of using femto-cells plugged into the customer's broadband router to improve in-home mobile voice coverage. A product known as "Sure Signal" which was a 3G femto-cell was used in significant numbers in Vodafone UK. During Covid-19 lockdown in 2020 it proved useful for some of Vodafone's own staff where, for example, their home office was in the basement or modern building materials (especially glazing) meant their home was effectively a Faraday cage.

An alternative to femtocells for improving mobile voice coverage is to enable VoWiFi on the mobile network (assuming internal Wi-Fi coverage in the house or basement it better than the mobile coverage). This is supported and easy to set up on modern smart phones. This is shown in Figure 52.

**Figure 52 – Voice over Wi-Fi**

#### *4.6.3.9. Converged Measurement & Analytics*

As both fixed and mobile access speeds have increased, latency (and other aspects of "broadband quality") have become more important. 5G in particular was the first technology to use ultra-low latency in its marketing. Cable technology has also evolved to include Low Latency Xhaul (LLX) and Low Latency DOCSIS (LLD). In addition, CableLabs has worked on Low Latency Wi-Fi.

Vodafone's recommended latency measurement method at the IP layer has been TWAMP (Two-Way Active Measurement Protocol). However, as we seek to further optimize customer experience and application performance we needed a more hi-fidelity technique for latency and performance measurement.

After extensive scouting and testing we selected the new Quality Attenuation technique, sometimes referred to as ΔQ (pronounced Delta Q). ΔQ emphasizes the gap between real performance and perfection (i.e. zero loss and delay) and has been standardized in BBF TR-452.1 with some early vendor capabilities available. The Quality Attenuation measurement and analysis approach can disaggregate a round trip time (RTT) into three constituent components as shown in Figure 53 in each direction (downstream and upstream), for a total of six components.

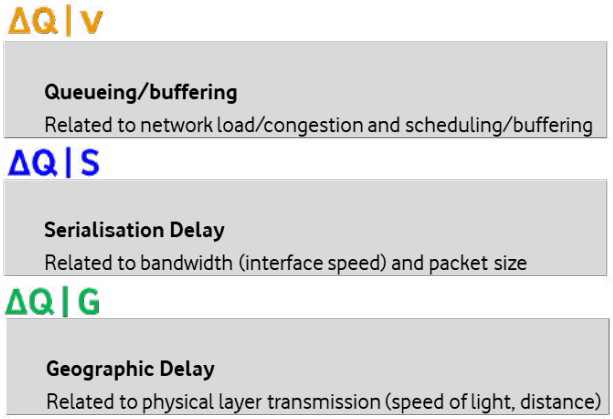

**Figure 53 – Quality Attenuation technique**

Vodafone has trialed the Quality Attenuation technique in four countries over a range of fixed and mobile access technologies including DOCSIS, 4G, GPON and VDSL. Different fixed and mobile access technologies behave differently at the physical layer and these manifests themselves as different packet latency and loss characteristics at the IP layer, which in turn determines the application outcome and customer experience.

50 Mbps on 4G is not the same as 50 Mbps on DOCSIS or FTTH. It is increasingly important to understand such issues as in the converged network we increasingly seek to use FWA, hybrid access to boost speed or to back-up fixed access with a failover to mobile access. Common tools for measurement and analytics across the mobile and fixed access elements of the converged network will become increasingly important as we seek to deliver our customer's applications in a seamless manner, irrespective of access technology.

#### *4.6.3.10. CPE Management*

Vodafone has millions of Customer Premises Equipment (CPE) devices managed using the TR-069 protocol. Globally, there are now over a billion devices worldwide managed by hundreds of service providers using this protocol which is included as an option in CableLabs' eRouter standard. 3GPP and the Small Cell Forum have also developed data models to be used with TR-069 for the management of small cells.

TR-369 is the successor to TR-069 and is a new standard known as the User Services Platform (USP). It has a number of improvements but the most notable is the ability to have multiple controllers. This facilitates new commercial models with external 3rd party partners for example the ability to outsourcing Wi-Fi optimization to an external partner with smart algorithms, AI and machine learning based in their own Cloud. They would only be able to access the Wi-Fi parameters in the Residential Gateway. An overview of user services platform (USP) as defined by TR-369 showing the multiple controller capability is illustrated in Figure 54.

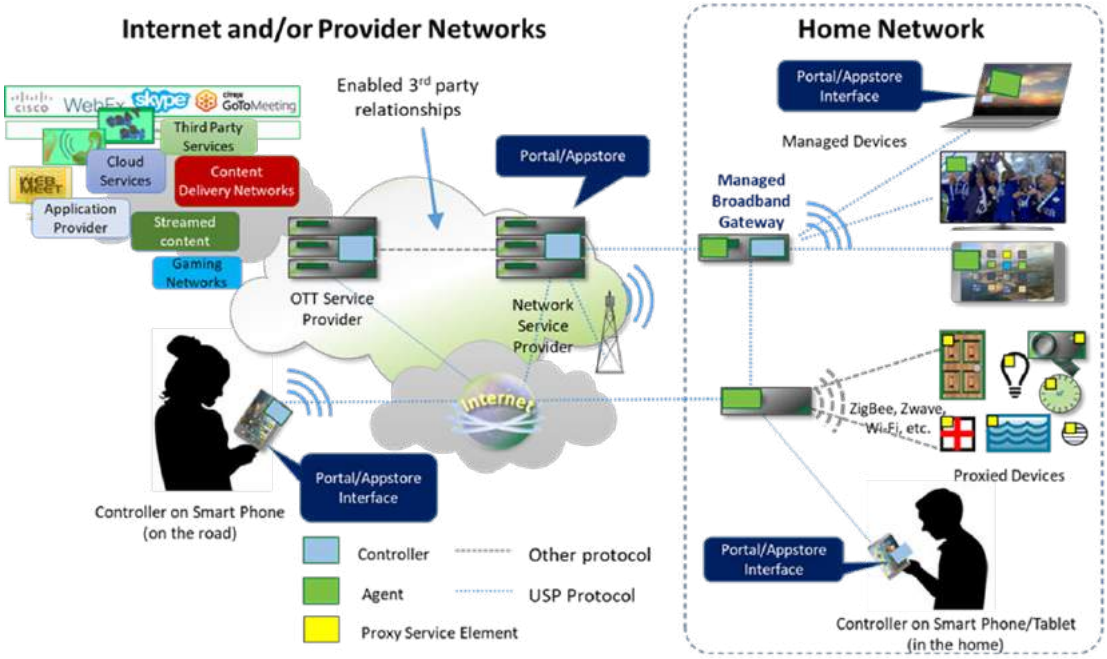

**Figure 54 – USP TR-369 in Deployment**

In the convergence context, this could, for example, enable the fixed broadband experts to manage the residential gateway but the mobile experts to manage any connected small cells.

For an integrated CM and Residential Gateway (router), TR-369 can be used in conjunction with existing DOCSIS provisioning systems and processes as illustrated Figure 55.

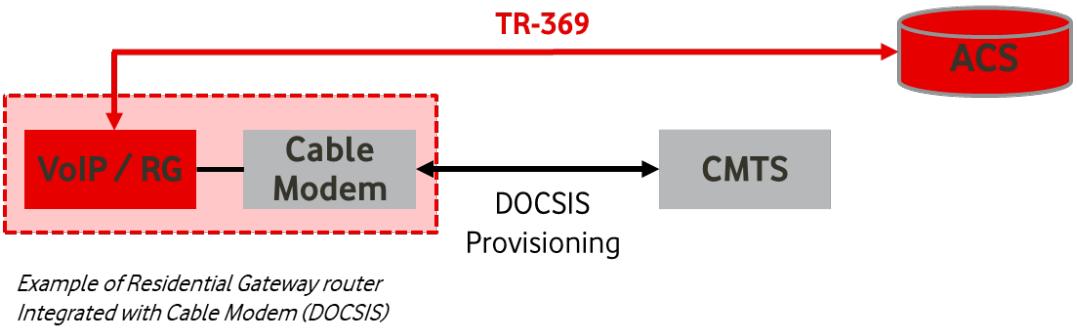

**Figure 55 – DOCSIS GW with TR-369**

### *4.6.4. Summary*

This section has presented how a range of technologies can be used to facilitate convergence at the network and service layers for a converged operator. It is important to note the key role that standards play in this evolution. In the past, standards have been siloed in either the fixed domain or the wireless domain. In an increasingly converged business, it is vital that CableLabs, 3GPP, Wi-Fi Alliance and Broadband Forum and other such organizations collaborate and cooperate in order to deliver effective solutions for network operators and service providers.

This is especially true for capabilities above the physical layer such as architecture frameworks, management protocols, data models, performance measurement techniques, telemetry and analytics. Alignment on such areas will be key in the new software-centric world of virtualized, distributed and disaggregated networks with a growing focus on automation leveraging SDN, AI and ML.

# 5. Convergence – Technologies

In the previous section, we covered business objectives and technology viewpoints of the cable-mobile operators. In this section, we recap some of the common technologies that have been highlighted to enable convergence between cable and mobile deployments.

## 5.1. DOCSIS Technology

Every wireless network is dependent on a wireline network. Traditional wireline network that supports the wireless deployment is fiber. But that is about to change. DOCSIS technology is one of the key enablers for mobile deployments because of its near-ubiquitous availability in urban and suburban areas. Residential femto, strand-mounted small cells, as well as SMB inside-out will provide inside and outside coverage economically compared to fiber.

Since the cable industry first specified the DOCSIS standard in 1997, the technology has evolved through five generations of progressive improvements over several key performance criteria, including capacity and latency. Table 7 shows the capabilities of the most recent DOCSIS standards. The currently deployed DOCSIS 3.1 is capable of supporting multi-gigabit per second downstream speeds. As MSOs move to reclaim spectrum previously used for traditional video services, upstream spectrum can be significantly increased by moving from the low split of 42 MHz to the high split of 204 MHz. Multi-gigabit per second of speeds on the upstream can be reached this way in the near term. In the longer horizon, DOCSIS 4.0, currently being specified, is expected to provide greater upstream speeds.

**Table 7 – DOCSIS Capabilities**

| Requirements | D3.1 today (2020) | D3.1 max (future) | D4.0 (2023-2024) |
|---|---|---|---|
| | Shared spectrum with video | Full spectrum through video reclamation | Extending to 1.8 GHz, possibly 3 GHz |
| Downstream spectrum | 54 - 1002 MHz | 258 - 1218 MHz | 602 - 1794 MHz |
| Upstream spectrum | 5 - 42 MHz | 5 - 204 MHz | 5 - 492 MHz |
| DS Capacity | 8.5 Gbps | 8.6 Gbps | 10.8 Gbps |
| US Capacity | 0.1 Gbps | 1.4 Gbps | 3.7 Gbps |
| Latency | Best Effort : 5 - 50 ms. | With LLX / CTI : 1 - 2 ms (can be further reduced) | |
| Synchronization | Frequency sync only<br>No time sync | Frequency + time sync through DTP | |

## 5.2. Low Latency Xhaul (LLX)

DOCSIS technology supports a variety of scheduling mechanisms to meet the latency needs. The most commonly used best effort scheduler can deliver a typical latency of around 10 to 15 milliseconds (ms), but is dependent on the channel loading condition (see Table 7). DOCSIS also natively supports real-time polling (RTPS) and proactive grant service (PGS). These schedulers intend to reduce the request-grant delay that is typical in any point-to-multipoint scheduled systems. But they have some drawbacks, such as not able to achieve low enough latency needed for mobile xhaul, or incurring too much bandwidth overhead.

To address these drawbacks and to better support mobile xhaul over the DOCSIS network, Cisco and CableLabs co-invented a mechanism that pipelines the scheduler operations of the mobile and the DOCSIS systems. The pipelining mechanism forms the basis of the Low Latency Xhaul (LLX) technology, which has been standardized by CableLabs [6].

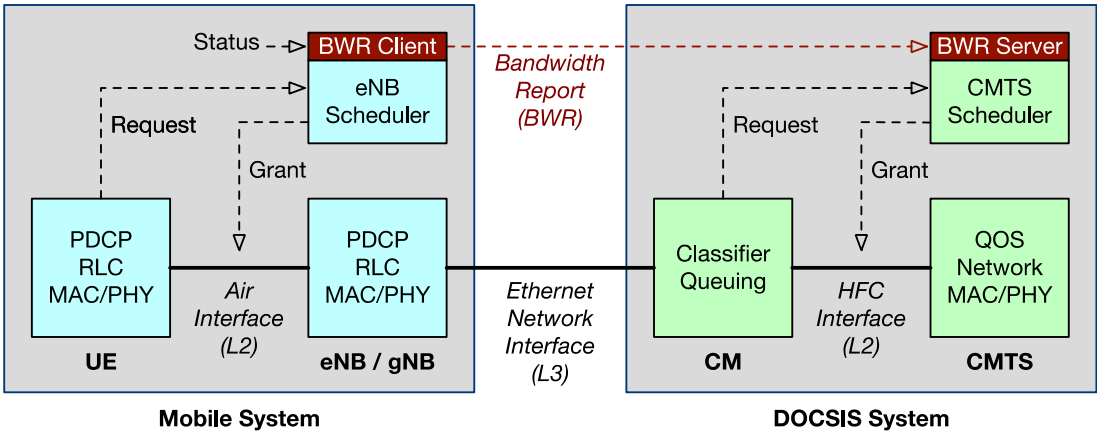

**Figure 56 – Scheduler Pipelining with Bandwidth Report (BWR)**

In a nutshell, LLX uses the decisions made by the mobile scheduler to inform the CMTS scheduler what is about to happen. By doing so, LLX creates a low latency transport for mobile traffic.

As shown in Figure 56, mobile and DOCSIS systems are both point-to-multipoint scheduled systems. This means both systems have an inherent latency due to request-grant delay in the upstream. In LLX, that latency is incurred once in the mobile system. The results of the request-grant process, in the form of a BWR message, are then passed to the DOCSIS system so the CMTS can grant the CM directly without waiting for a native layer 2 DOCSIS request.

Let's look at an example.

1. The UE has an application that wants to send 1000 bytes. It sends a request to the eNB scheduler.
2. The eNB schedular responds and says that the UE may send the 1000 bytes 8 ms from a reference time.
    a. The eNB scheduler, now that it knows what is about to transpire on its air interface, makes a determination of what will happen across the network interface that it shares with the DOCSIS system. In our example, the eNB adds 1 ms of engineering margin to cover any buffering and internal path delays.
3. The eNB sends a BWR message to the CMTS system that says that 1000 bytes will be arriving on the shared network port 9 ms from the reference time.
    a. The CMTS scheduler, now that it knows when the bytes will arrive in the CM, determines when it wants to send a grant to that CM. In this example, it adds 1 ms of engineering margin to cover any buffering or scheduling jitter.
4. The CMTS sends a DOCSIS MAP to the CM at the correct time telling the CM to transmit the 1000 bytes 10 ms from the reference time.

The net result is that the latency of the DOCSIS system is effectively reduced by hiding it under the mobile system. In theory, LLX should be able to achieve near-zero latency on the DOCSIS upstream. In practice, one to two milliseconds of engineering margin is added.

Numerous test results have been previously published using a physical testbed and reported that BWR achieves one to two milliseconds of DOCSIS upstream latency in a variety of channel loading conditions up to 70% on the DOCSIS network. Details of how LLX works and lab trial results can be found in [11][12][13][14][15].

### 5.3. Synchronization and Timing

Depending on the type of mobile deployment, frequency only, or frequency and phase, synchronization is required for the small cell. Timing and synchronization requirements for FDD, TDD, LTE, and 5G are shown in Table 4.

Table 5 in Section 4.1.4.4 lists common options to consider when it comes to support timing and synchronization. Network-supported timing using Precision Time Protocol (PTP) is needed for indoor deployments and to lower the cost of the small cells.

The DOCSIS network is asymmetrical. If the PTP protocol is sent over-the-top of the DOCSIS network, it may incur variable buffer delay which can cause packet delay variation (PDV) and large time transfer errors. For LTE FDD, PTP over-the-top may be a workable solution with some mitigation work, such as assigning PTP packets with higher priority DiffServ code point (DSCP). But the mitigation may not be enough for LTE and 5G TDD.

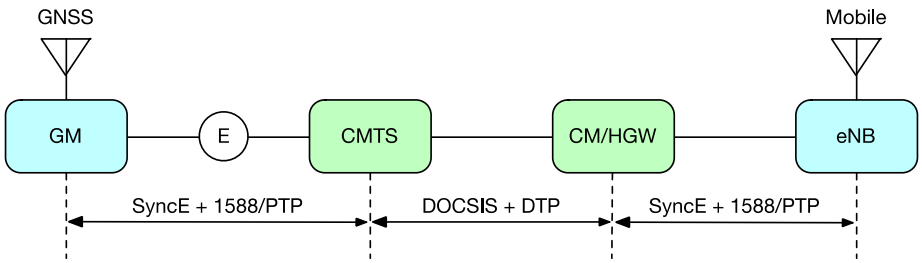

**Figure 57 – 1588 Timing over DOCSIS Network with DTP**

To meet the TDD requirement, a better way to carry PTP over the DOCSIS network is through the DOCSIS Time Protocol (DTP), as shown in Figure 57. In a nutshell, timing from the global navigation satellite system (GNSS) is received by a primary reference time clock (PRTC) that generates the PTP messages. The PTP messages are sent through one or more Ethernet switches that support PTP. The PTP timing domain is terminated by the CMTS.

The DOCSIS system is already a synchronous network with its own timestamp. The CMTS's job is to align the DOCSIS timestamp with the PTP timestamp. The DTP algorithm is run between the CMTS and the CM to compute the one-way downstream delay. Upon receiving the DOCSIS timestamp as part of the normal DOCSIS operations. The CM adds the one-way delay to the DOCSIS timestamp. The CM passes on the recomputed timestamp and appears as a PTP master to the small cell downstream.

Details of the DTP algorithm and preliminary test results can be found in [16][17][18]. DTP is now part of the synchronization specification standardized by CableLabs [19].

### 5.4. DOCSIS DAA for Mobile People

This section briefly discusses the splits for the 5G radio access network (RAN) and then compares them to the choices made by DOCSIS when it split its access network with the distributed access architecture (DAA). The contrast of the two architectures are shown in Figure 58.

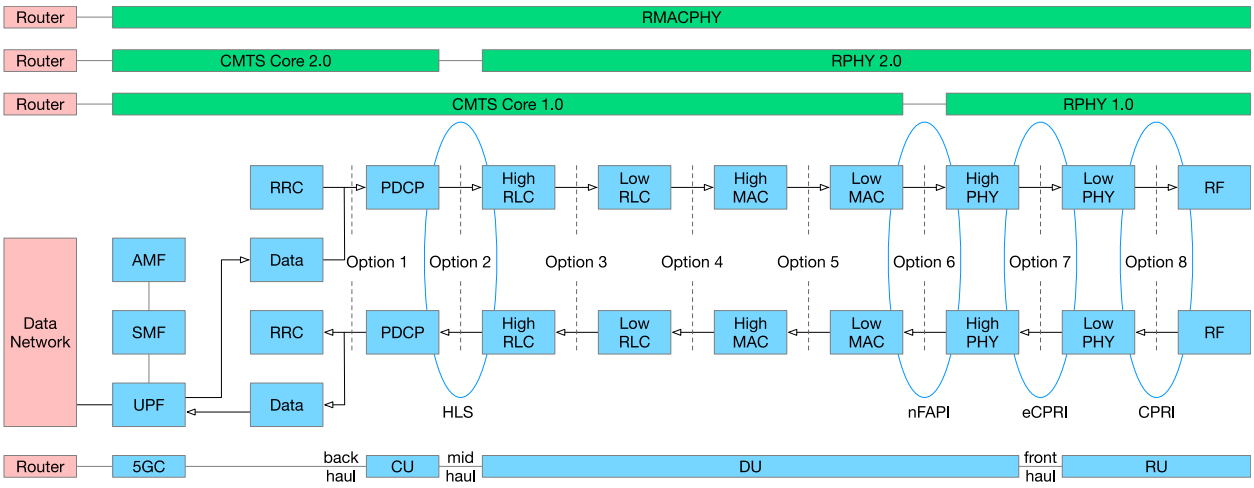

**Figure 58 – Mobile RAN Splits with DOCSIS DAA**

The 3GPP task force defined eight splits in the RAN architecture and then picked higher layer split (HLS), while the O-RAN Alliance further specified the interoperability required to enable lower layer split (LLS). The original common public radio interface (CPRI) was a raw digital to analog conversion style of interface. It has a very large bit rate and is considered semi-proprietary. The enhanced CPRI (eCPRI) lowered the bandwidth to make it fit better on 10 Gbps fiber links and was adopted as the LLS / option 7 split between the radio unit (RU) and the distributed unit (DU). This interface is also referred to as the fronthaul interface.

The DU contains layer 2 framing and the uplink scheduler. The DU is intended to be located near the RU location. Typically, the RU is outdoors and the DU is indoors. A DU product may service multiple RU products. The network side of the DU is a packet interface with a data throughput slightly above the payload rate due to only having payload encapsulation and signaling. The split between the DU and the centralized unit (CU) is done with option 2 and is referred to as the HLS.

The first architecture for DAA was Remote PHY (RPHY) [20][21]. Remote PHY is well defined as an open standard [22]. It is a shipping product with multiple manufacturers and operators deploying RPHY with several million attached devices. The goal of RPHY is to centralize software and distribute the radio frequency (RF) hardware. Because the DOCSIS protocol has encryption built into it, it was convenient to put the DOCSIS layer 2 framer centrally to ensure the backhaul link was encrypted. This would be the equivalent of 3GPP's option 6. In fact, before option 2 and option 7 were chosen for the mobile RAN, there was a proposal from Cisco for an option 6 network functional application platform interface (nFAPI) in the Small Cell Forum (SCF) [23].

After Remote PHY was defined, and broader architecture was defined called the flexible MAC architecture (FMA). The first phase of FMA is the remote MAC and PHY (RMACPHY) which is really a full layer 2 cable modem transport system (CMTS) that includes the entire CMTS Core, or the equivalent of a full EPC,

located in the remote fiber node. In the mobile world, FMA resembles incorporating the 5G Core into an integrated gNB, both located the remote node. At the time of writing, FMA is a pre-standard draft.

There is a next generation of Remote PHY, informally called RPHY 2.0 [24], that is proposed but not yet standardized. A RPHY 2.0 Device (RPD 2.0) provides DU-like capabilities that include the DOCSIS upstream scheduler [25] and the DOCSIS framer. The first version of RPHY was designed about a remote RF device and a centralized physical set of DOCSIS and video cores that were located within a 100 mile (160 km) radius of the RPD. By contrast, the second version of RPHY will be designed to put latency sensitive signaling such as the upstream scheduler into the remote node. Doing so allows distances in excess of 100 miles to cloud-based cores that are located at the service provider (SP) edge or in true cloud such as Amazon or Azure.

### 5.5. DOCSIS for Mobile Xhaul

Similar to the DOCSIS protocol, LTE and 5G have their own protocol stack. LTE eNB or 5G gNB are full-stack integrated units. In 5G, the RAN can be further functionally decomposed into a central unit (CU), a distributed unit (DU), and a radio unit (RU). Mobile standards organization 3GPP specified the option 2 split, which splits the PDCP and above layers into the CU while the layers below remain in the DU and RU. The ORAN Alliance defined option 7-x split, in which the RU consists of the RF and a portion of the PHY, while the layers above remain in the DU and the CU. A backhaul, midhaul, or fronthaul network, collectively known as xhaul, interconnects the different functional components together.

Functionally, the DOCSIS network can interconnect the small cells as shown in Figure 59. However, the requirement on capacity and latency vary between backhaul, midhaul, and fronthaul. Backhaul and midhaul are both based on an IP encapsulation of the original mobile transport. Thus, the bandwidth requirement on the transport network roughly matches the mobile traffic rate.

The latency requirement for backhaul is based on the application. Additional service-level agreement (SLA) can be specified by the mobile operator. Midhaul latency is less deterministic. Some standards have defined it to be less than 10 ms [26], while some vendors require one to three milliseconds of CU-DU latency. LLX can be implemented to ensure these requirements can be met, as well as providing better latency performance, particularly for latency-sensitive flows.

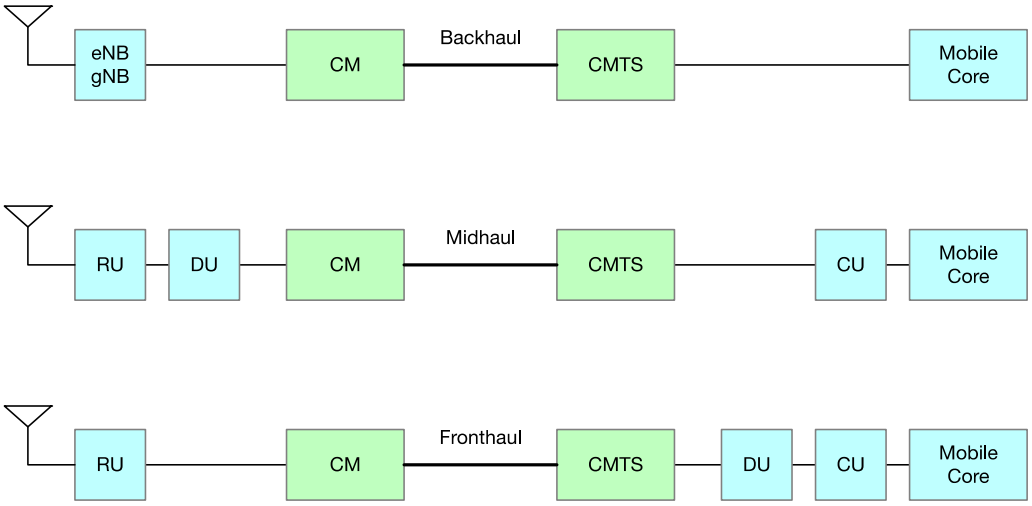

**Figure 59 – Mobile Xhaul over DOCSIS Architecture**

Fronthaul is much more difficult to support over the DOCSIS network. Studies have shown that the eCPRI-based fronthaul transport needs significantly more bandwidth, overhead, and one-way latency in the neighborhood of 250 microseconds between the RU and DU [20]. Even with LLX, it will be difficult to reduce the DOCSIS latency to this level. Because of the stringent requirements, fronthaul is better carried over fiber.

## 5.6. Common Quality of Service (QoS) Framework

The DOCSIS network is a finite pipe with multiple endpoints sharing resources. Rather than dedicating resources to meet the peak capacity all the time, the DOCSIS network is designed to meet the bandwidth demand most of the time. Traffic is separated into multiple flows. During times of congestion, latency-sensitive flows such as signaling or 5G ultra-reliable low-latency communication (URLLC) traffic are sorted into separate queues and are generally served before latency-tolerant flows. This is the goal of quality of service.

The mobile system is also a point-to-multipoint system where resources are shared among users. It has its own set of QoS rules and queue configurations that may be different from the DOCSIS network.

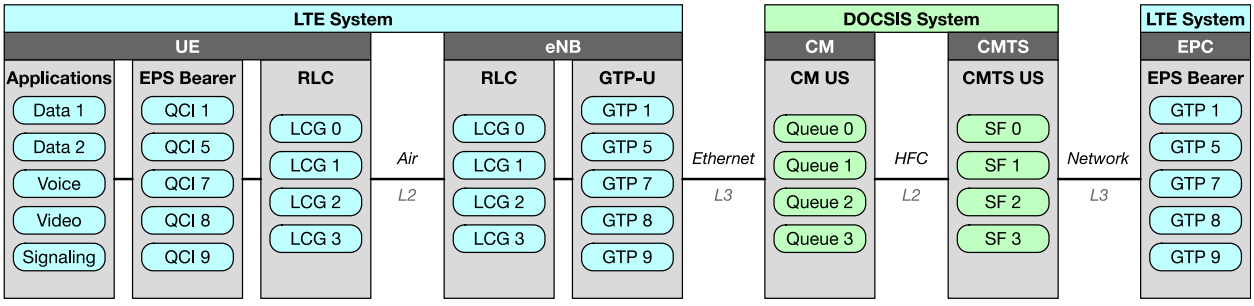

**Figure 60 – Common Quality of Service Framework for MBH over DOCSIS**

To ensure consistent treatment of traffic when they move across the mobile and DOCSIS networks, a common QoS framework as shown in Figure 60 between the mobile system and the transport system needs to be supported. There are many variations of how this could be done, but fundamentally, it should:

1. Use the same number of queues in the transport system as there is in the mobile system
2. Use the same classifier mechanism in the transport system as there is in the mobile system
3. Use the same policy/queue-weighting mechanism in the transport system as there is in the mobile system

Details of the common QoS framework can be found in [6][9][27].

### 5.7. A 5GC View of Convergence

The advent of 5G promises several key enhancements to previous mobile technology generations including faster speeds, lower latency, and increased service velocity which enables new use cases such as enhanced mobile broadband, massive IoT and mission critical enterprise applications. Along with new enhancements in the RAN, the 5G core (5GC) has been rearchitected to support these new use cases.

The 5GC architecture includes service-based design concepts, on-demand network slicing and service orchestration, and cloud native design principles such as web-based control plane protocols, microservices and container orchestration. One of the most innovative architectural concepts is wireless and wireline convergence (WWC); allowing different access networks such as Wi-Fi, cable, and fixed broadband networks to interwork with the 5GC as shown in Figure 61. Achieving 5G convergence enables new use cases and consistent subscriber quality of experience (QoE) while reducing cost of ownership.

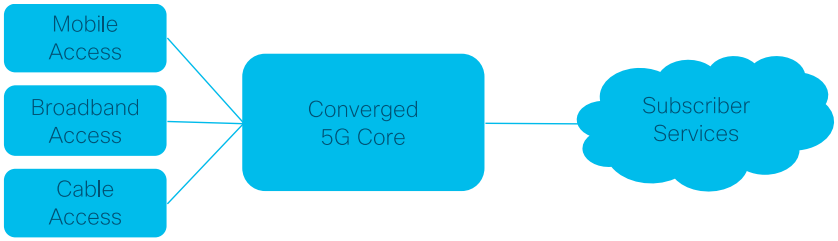

**Figure 61 – 5G Convergence**

5G convergence enables multi-access operators to harmonize subscriber services across access networks. As subscribers move between their home broadband and mobile networks, a converged core enables an improved quality and consistency of user experience. This includes use cases such as call continuity so that voice and video calls are seamlessly handed off between connections. Policy based services, such as bandwidth speed and latency tiers, as well as parental controls, security and content filtering can also be consistently enforced.

Convergence also enables connection redundancy which has become increasingly important for enterprises and consumers as users are working and schooling from home during the pandemic. For example, a 5G fixed wireless access service can be coupled with a fixed broadband service to enable service resiliency in an active/active or active/standby design.

Arguably as important as QoE, convergence allows operators to reduce their capital and operating expenditures. Historically, each access network has been deployed and operated as a silo in the SP network

with different infrastructure, networking and applications. Network convergence allows SPs to collapse these silos into a common, converged network where the edge and core infrastructure, applications and orchestration systems are common across access networks. Convergence also results in OpEx reductions as existing siloed networks collapse into a common converged core.

In addition to the network, convergence allows the consolidation across all aspects of the SP operations extending into OSS/BSS systems (not covered in this paper). There are three common approaches to converging subscriber QoE across access technologies. The platform, policy, and system level convergence approaches represent different steps towards the path to convergence. Each of these steps, along with their benefits, are shown in Figure 62 and are described in the following paragraphs.

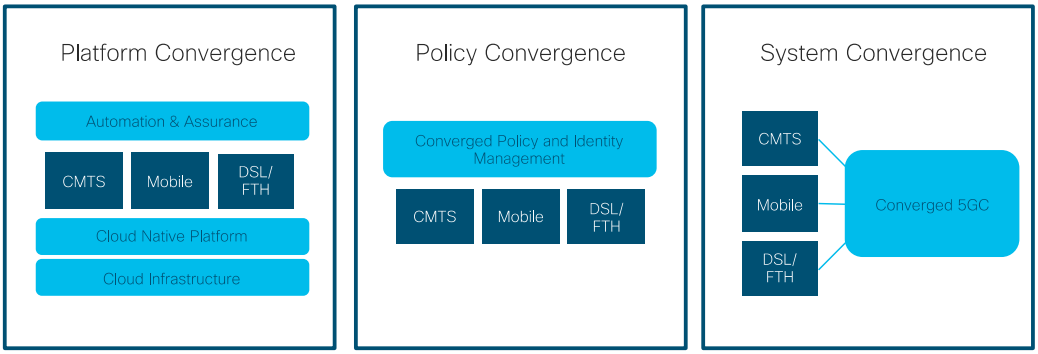

**Figure 62 – Platform, Policy, and System Convergence**

Platform convergence utilizes a common platform to achieve operational and software development efficiencies. The converged platform includes both physical and virtual infrastructure, as well as cloud native application technologies to deploy and operate the different access systems. It provides common compute and virtualization technologies, such as microservices, containerization, Kubernetes, and cloud assurance and automation systems, to provide a consistent operations experience for SP operation teams. Platform level convergence does not require each access function to be converged by a common system and protocol architecture, but means common tooling is used for deploying, automating, orchestrating and assuring each access function.

Policy level convergence enables common policy and identity control plane systems but does not try to converge the network user plane components. This approach enables policy coordination across access networks where each access network is responsible for enforcing policies provided by the common policy layer. Therefore, although there are separate transport and user planes for each access network, the subscriber experience is maintained by the converged policy layer across networks, e.g., a parental control service can be enforced on both a broadband and mobile network. Many SPs are already on the path to subscriber and policy level convergence as a first step towards transport and user plane convergence across accesses.

System level convergence of the end to end architecture is not a new concept and has been a topic of previous technology generations – but as an afterthought. Convergence was included as part of the 5G standalone design from its inception and allows existing access networks to be integrated with a common converged core based on an interworking approach. This allows existing access technologies to be integrated into the converged core as opposed to requiring each access to be reimplemented. WWC is being designed in standards as a cooperation across 3GPP, BBF, CableLabs and other standards bodies. WWC is the long-term strategy for most multi-access providers, but it comes with significant cost and complexity for brownfield networks. Many MSOs are deploying greenfield 5G networks and are looking to provide

convergence with their Wi-Fi and DOCSIS networks over time. Figure 5 in the earlier section provides a detailed view of the converged access architecture proposed for combining mobile and cable access.

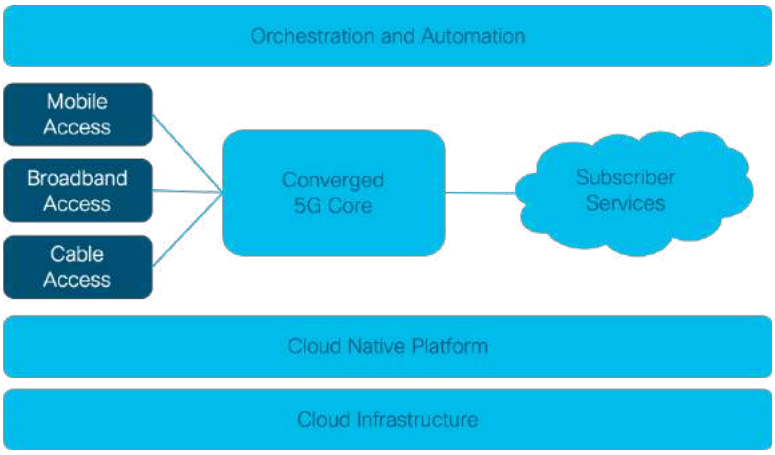

**Figure 63 – Common Cloud Native Platform**

To successfully navigate the migration to a converged core, operators must determine which convergence type can be justified based on their business. Additionally, operators must structure their product and operations teams to align with their chosen level of convergence. Ultimately, we expect the industry to pursue a common cloud native platform architecture as shown in Figure 63 to simplify and automate operations, common policy and subscriber components to unify the subscriber QoE, and a fully converged core to harmonize the services and applications into a common network architecture.

### 5.8. Managing the RAN with YANG

One of the key principles of the vRAN architecture is to establish open, standard interfaces, facilitating a transition from today's single vendor, monolithic RAN solutions, to a competitive, multi-vendor environment where functionality can be sourced from a variety of vendors that address the unique needs of MSO deployments around the world. While control and user-plane protocols are naturally required to be interoperable, an often-overlooked aspect is the integration "tax" required to deliver a fully orchestrated multi-vendor system.

Crucially, there are no procedures in 3GPP to ensure that all the parameters necessary for 5G can be configured using the 3GPP management specifications. This gap is being filled by the Open RAN (O-RAN) alliance that has already defined the use of native YANG models for configuring it distributed Radio Unit, the so-called O-RAN RU (O-RU). Not only does the use of native YANG models ensure the easiest route to full multi-vendor interoperability, but it also eases the integration of the management for the lower layer split deployment into existing systems. This has been demonstrated by multiple multi-vendor deployments of the O-RAN fronthaul interface.

YANG (RFC 7950) is a modelling language that was initially adopted by the xRAN Forum in March 2018, to model the configuration and operational state of its 5G Radio Unit, together with defining remote procedure calls (RPCs) for supporting tasks like software management, and notifications for indicating xRAN defined alarms. In 3GPP Release 16, YANG has been adopted as a new protocol-specific solution-set that leverage a protocol-neutral Network Resource Model (NRM). Now incorporated into the O-RAN Alliance, the O-RU specifications use YANG to define syntax, relationships and constraints between the data, enabling operators of O-RAN's open fronthaul to validate configuration data against the model before committing the configuration of the O-RAN Radio Units.

Recognizing that O-RAN Radio Unit suppliers need to be able to support vendor differentiation, the YANG models are extensible, allowing them to be augmented to support enhanced vendor-specific functionality, while simultaneously ensuring baseline multi-vendor interoperability of the standardized functionality defined by O-RAN.

The use of augmented IETF standard YANG models, together with O-RAN specific models, lays the foundation for cross-domain orchestration of the RAN with other domains that have already adopted NETCONF/YANG. Importantly, the definition of the transport interfaces in O-RAN leverages the IETF standard defined YANG models which should then facilitate the use of common tooling to be used across transport and RAN domains.

These same YANG models also provide the foundation for model-driven telemetry. Instead of ill-documented command line interface (CLI) or poor scalability of simple network management protocol (SNMP), model-driven telemetry enables data to be streamed from network devices continuously using a push model and provides near real-time access to operational statistics. Applications can subscribe to specific data items they need, by using standard-based YANG data models over NETCONF-YANG.

# 6. Convergence – A Vision of What is to Come

## 6.1. Integrated and Converged HFC, DOCSIS and Mobile Network

To converge or not; the answers may be in the business case. The operators have the choices of levels of convergences that they are comfortable with, starting with spending little CapEx and loosely coupling the two systems, to spending more capex and tightly coupling the two systems.

Up to this point in the paper, we have looked at a broad framework for convergence, the visions of convergence from multiple operators, and specific technologies of convergence. In this section, we will pull the basics of transport and infrastructure convergence into one vision.

Figure 64 represents a vision of the points of convergence that might ultimately take place:

- transport network convergence – common CIN and coax carry mobile, DOCSIS, and PON traffic
- common cloud platform – run apps on common edge
- converged cloud native functions (CNF) – common policies, common user plane functions

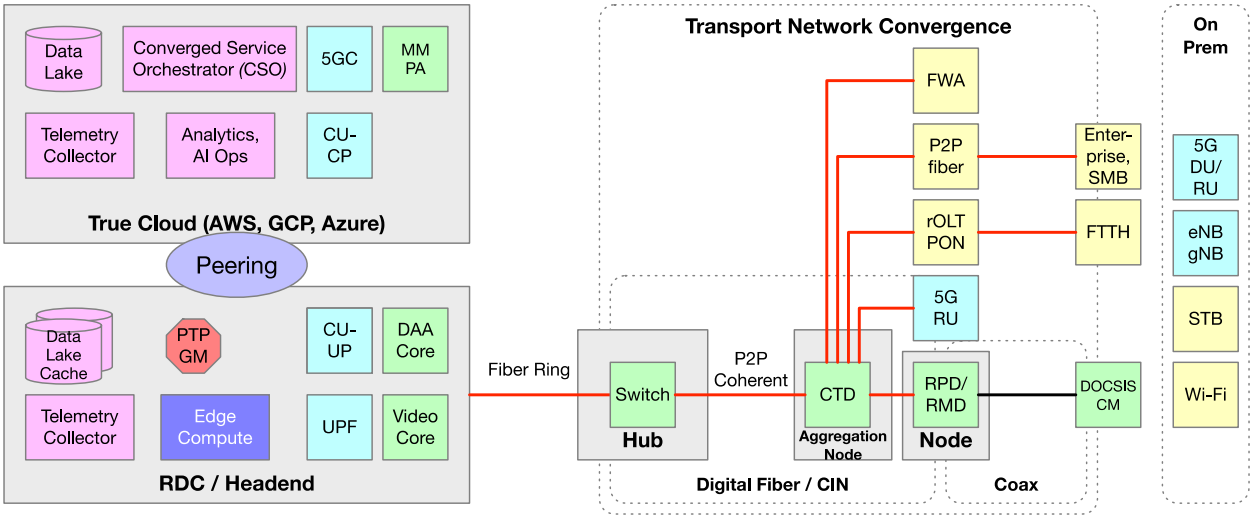

**Figure 64 – DOCSIS-Mobile Network Convergence**

## 6.2. Converged Transport of Mobile Xhaul over DOCSIS

Mobile xhaul over DOCSIS is a form of transport network convergence that does not require significant CapEx spending by allowing the MSOs to reuse their HFC plant to carry mobile traffic. All MSOs deploy integrated CMTSs (I-CMTS) today. The DOCSIS network today can be used to carry mobile traffic. Some of the technologies described in a section above such as LLX and DTP can enable enhanced and optimized mobile xhaul deployments.

### 6.3. Converged Transport with Common CIN

The next level of convergence takes place as MSOs modernize their DOCSIS network to meet the capacity demands on the HFC network.

One of the classic tools in the MSO toolbox to increase plant capacity is node segmentation. When an operator decides to segment a node, there is an opportunity to transform the cable-specific analog optics technology into digital. This is one of the benefits that the remote PHY (R-PHY) architecture brings. By disaggregating the PHY and RF-generating components of the DOCSIS stack to the node location, operators can replace their old analog lasers with new digital lasers, and in the process, increase capacity and open up the optical network. This upgrade also means that a generic Ethernet switch can be deployed in the aggregation node, connecting not just the remote PHY device (RPD) or remote MACPHY device (RMD), but also small cells and PON networks.

The analog to digital optics transformation of the HFC plant requires the buildout of the converged interconnect network (CIN), which includes the layer 2 switches that enable the same fiber network to be used by DOCSIS, mobile, and PON. This is another important aspect of transport network convergence.

### 6.4. Common Cloud Platform

As mobile and cable vendors adopt cloud native technologies, many software processes that run on dedicated hardware platforms today can be run as cloud native applications on generic servers. This can include upper layers of DOCSIS, 5G core, and some of the RAN functions. These processes from the DOCSIS network and the mobile network can run on the same server complex.

With control and user plane separation (CUPS) architecture, user plane processing that requires lower latency can be split from the more latency-tolerant control plane functions. These data plane functions, including CU-user plane (CU-UP), 5G's user plane function (UPF), and DOCSIS data plane (DP), can be run as software process at the edge, whereas CU-CP, much of the 5GC, and DOCSIS CP can be relocated to the cloud for large scalability.

To operate and monitor a network, telemetry data need to be collected and processed as part of the service assurance framework. A converged data lake and telemetry collector can be used for both DOCSIS and mobile networks.

Traditionally, MSOs own and operate a variety of real estate besides the fiber and coax runs. Of these resources, headends or regional data centers (RDC) can most likely be scaled to run data center applications. It is here that DOCSIS and mobile software processes can be located.

### 6.5. Virtual and Cloud Native Functions

When software was first moved to server complexes, which was primarily with mobile architectures, it was done using virtualized network function (VNF). In virtualization, existing code can be ported from a physical platform, such as a physical EPC, into a virtual machine (VM) on a server. The advantage of this approach was preservation of code and time to market. The goal was cost reduction and a use of generic servers. Unfortunately, the costs savings did not materialize, and the code was still old code with maintenance, complexity, and scalability challenges.

The new way of writing code involves cloud native functions (CNF). In cloud technologies, old code needs to be rearchitected and rewritten, often using newer languages such as the Go language. The code is often written to be stateless so that processes can quickly restart when the crash without the loss of a session.

The code is partitioned into microservices which are then placed into Docker containers. Kubernetes (K8S) is used to do workload placement of these containers into a server-based system. The result is a system that is highly elastic and highly resilient. This represents new functionality which has tremendous market value and makes the move to servers based on an increase in value, rather than just cost reduction.

# 7. Conclusion

Convergence is equally important now as providing a clear path to the end of the tunnel. On the road to that end deployment state, tools controlling the operating costs are evolving today, including the movement to cloud-native architecture. In addition to virtualization, the following are the common technologies to enable mobile deployment identified by most MSOs:

- optimizations to enable mobile xhaul over DOCSIS such as DTP, LLX, and orchestration
- the upcoming HFC buildout from analog optics to a digital fiber network
- the CIN, whether be it simpler DWDM multiplexer or Ethernet switch for better scalability
- 5G NSA core for MSOs operating existing LTE networks, while transitioning to 5G NR
- DSS for migration from LTE RAN to 5G NR in existing LTE spectrum
- DSDS to support better MVNO economics with better data offloading
- CUPS to enable virtualization while still providing lower user-plane latency
- tools for service convergence: common policy, common subscriber management
- model-driven telemetry and AI operations for network automation

*Today's cable operators are tomorrow's mobile operators.*

Subscribers, operators, and networks are converging. Ignoring that reality is no longer an option. There is now a whole new world of mobile operators, just in time for 5G.

*Every great wireless network needs a great wireline network.*

Of all the variations amongst the operators, there are some commonalities. Most certainly, the end state for network deployment will not be a single physical fiber-based network to rule them all, but a combination of physical networks that involve fiber, coax, and wireless, to support DAA, FTTH, FWA, mobile deployments.

Everything reduces to an IP network with different edge connectivity with common services, management and provisioning.

Remember the telephone network. It connected voice end points called telephones. The telephone network does not significantly exist anymore. The same will be true for cable and mobile networks. They were separate networks because they were owned and run separately, and they may have had unique backbone and edge requirements. But that is or has already changed.

Today, the mobile network has really become an IP over Ethernet network that connect radio gateways to specific user plane points and run by control and management applications running on generic servers. The mobile network is becoming a software-based design with an IP transport terminated in radios for end-point connectivity.

The same transformation is happening to the cable network. Once a closed HFC plant, with DAA there will be IP over Ethernet to the neighborhood with the RPD acting as a radio attachment point that drives the last mile of coax. Even DOCSIS is just a form of Ethernet over coax and acts like a fiber extension in DAA. That is why either fiber or coax can be used for mobile xhaul. Mobile xhaul over DOCSIS provides MSOs the economic advantage for deploying wireless networks. It is an obvious convergence opportunity.

Careful decisions have to be made on where convergence adds value and simplicity, or where it adds cost and complexity. Which decisions make money and which ones lose money. It is often elegance versus execution. But that is just the challenge of getting innovation right.

So, in the most simplistic of terms, both cable and mobile are really composed of different radios on a common IP network trying to do the same thing, and that is to deliver a common set of services to a subscriber no matter how they are connected. The job of convergence is to make this reality come true with both a common service model and an efficient and economical network and application infrastructure.

Let's go make it happen.

## List of Tables

# 1. Abstract

Data is the new oil driving the digital world. There is a massive amount of data being generated as more and more cities around the world roll out smart city applications and deploy IoT sensors. Managing, analyzing and correlating data from multiple sources can help cities in many ways, including lowering operational costs, creating environmental sustainability, increasing citizen engagement, enhancing healthcare, improving public safety and providing an overall improvement in the quality of life for its citizens.

Spectrum is engaged in a smart city proof of concept (POC) in St. Petersburg, FL, in collaboration with the University of South Florida St. Petersburg campus, US Ignite and the St. Petersburg Innovation District. Several IoT sensors and use cases involving pedestrian safety, video analytics, edge computing and smart street light management are currently being tested.

This paper discusses the uses cases and several types of sensor data collected in the St. Petersburg POC project. Details include the collection, storage, visualization and analysis of IoT sensor data.

# 2. Introduction

Data-driven decisions are made more than ever before in every domain today. Cities can also benefit from IoT sensor data to draw insights that can improve the quality of life of its citizens, allow cities to make better decisions on infrastructure planning and can help lower operating costs by efficiently using resources to deliver services to its citizens. In this paper, we share some examples of smart city use cases, technology and the methodology used to collect and analyze a broad array of IoT data from the proof of concept project implementation at the city of St. Petersburg, FL in collaboration with US Ignite, the St. Petersburg Innovation District, the University of South Florida St. Petersburg and Spectrum Enterprise.

## 2.1. Data and the smart city

Data is ultimately what makes a city smart. But it not just the collection of data through the deployment of sensor technology, it's also the ability to analyze and use the data in near real time to make informed decisions. When it comes to data, privacy is, of course, very important, especially if the data collected has personal information (PI). Such data should be handled as per the agreement with the city, and it must also meet regulatory compliance.

## 2.2. Why do we need smarter cities?

As cities around the world grow at an unprecedented rate, it is putting a strain on the environment and on cities' resources and services such as water, electricity, parking, waste management and many more. The gap between demand and supply of city resources is growing, affecting the quality of life of citizens. One way to close this gap is to use a city's limited resources more efficiently by deploying smart city applications. A forecast from the International Data Corporation (IDC) Worldwide Smart Cities Spending Guide shows global spending on smart cities initiatives will total nearly $124 billion this year, an increase of 18.9% over 2019.[1]

 

# 3. Proof of concept setup

In the POC deployed in St. Petersburg, FL, we are using several IoT sensors, edge computing, computer vision, wired and wireless connectivity, cloud services for data storage, analysis and visualization to help the city improve pedestrian safety, lower energy costs for street lights and improve citizen engagement and safety.

## 3.1. Connectivity architecture

In this POC, we have installed four smart light poles. Each light pole has dual connectivity. Fiber as a primary and 4G LTE as a secondary connectivity to backhaul the data to the cloud from all the sensors.

## 3.2. Hardware setup

The fiber switch inside the light pole has multiple Power over Ethernet (PoE) ports providing power and data connectivity to a camera, WiFi, emergency button, digital banner, weather and air quality station as shown in Figure 1.

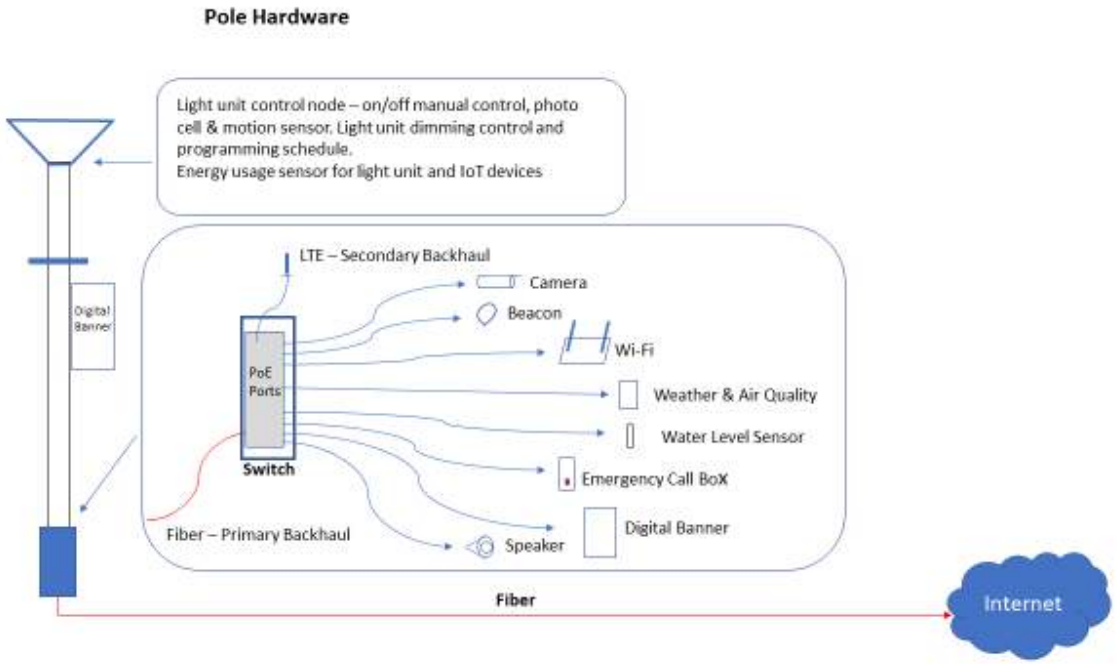

**Figure 1 – Hardware Setup**

## 3.3. Smart light controller

The smart light pole uses energy-efficient LED lightbulbs. The smart light can be controlled via an easy-to-use user interface which provides a broad range of capabilities and functionality. The light can be remotely operated to activate at certain hours. Schedules for events can be set up or the light can automatically turn on when the photocell measures the ambient light level below a certain threshold.

Additionally, the light allows for integrated notification capabilities to provide updates or alerts to the operator when issues occur, delivering the city with a more efficient overall operating model.

### 3.4. Camera

Each smart light pole is fitted with a camera that can be used for a variety of use cases including situational awareness and public safety. The camera has several alert features, e.g., guard zone, virtual fence, loitering alert and motion sensors to enhance public safety and protect city assets. We are using two types of cameras on the smart light pole. The Pan Tilt Zoom (PTZ) camera and fixed view camera with a 180-degree viewing angle. The power and data connectivity to the camera is provided by PoE switch as shown in Figure 1.

### 3.5. Pedestrian counter camera

The pedestrian counter camera on the smart light pole is pointed downwards overlooking the sidewalk and is used to monitor the number of pedestrians and their direction of movement.

### 3.6. Connectivity

Each smart light is also enabled with fiber connectivity to support a broad range of the features and functionality embedded in the light structure, from camera technology to integration of the smart intersection.

### 3.7. WiFi

Each light is fitted with WiFi AP (802.11ac) with an external antenna mounted at the top of the light pole.

### 3.8. Weather station and air quality sensor

The weather and air quality sensor is mounted on the top of the smart light pole and can collect various environmental parameters at specified intervals.

### 3.9. Emergency button

Each smart light pole has an emergency voice over Internet protocol (VoIP) call box and routes the call to the iPBX over the fiber backhaul. The emergency call box is programmed to dial the local police emergency number. Each emergency call box hardware address and location is registered in the call manager, which enables the first responders to identify call origination location.

### 3.10. Digital signage and speaker

The digital banner and the speaker can be remotely managed via a cloud-based dashboard. The display image and audio file can be sent over the network to be played at the smart light pole.

### 3.11. Smart intersection proof of concept

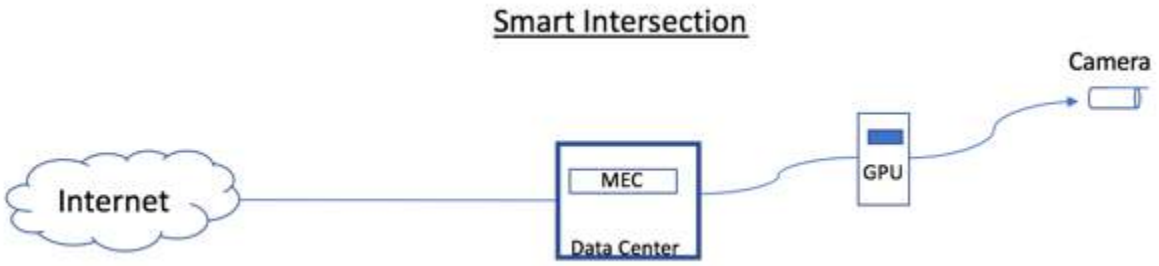

**Figure 2 – Smart Intersection System**

The smart intersection POC solution as shown in Figure 2 is designed to increase pedestrian safety at an intersection near the university. This POC requires ultra-low latency and uses edge computing technology with high computing power offered by the graphical processing unit (GPU) to process computer vision. There are three cameras mounted at the intersection as shown in Figure 3.

**Figure 3 – Smart Intersection Camera Zones**

# 4. Data collection and analysis

In this section, we will discuss the sensor data collection and flow as shown in Figure 4 below. Then we will highlight the data processing capabilities and driving insights in three examples: smart light energy usage, video analytics of surveillance camera and the smart intersection.

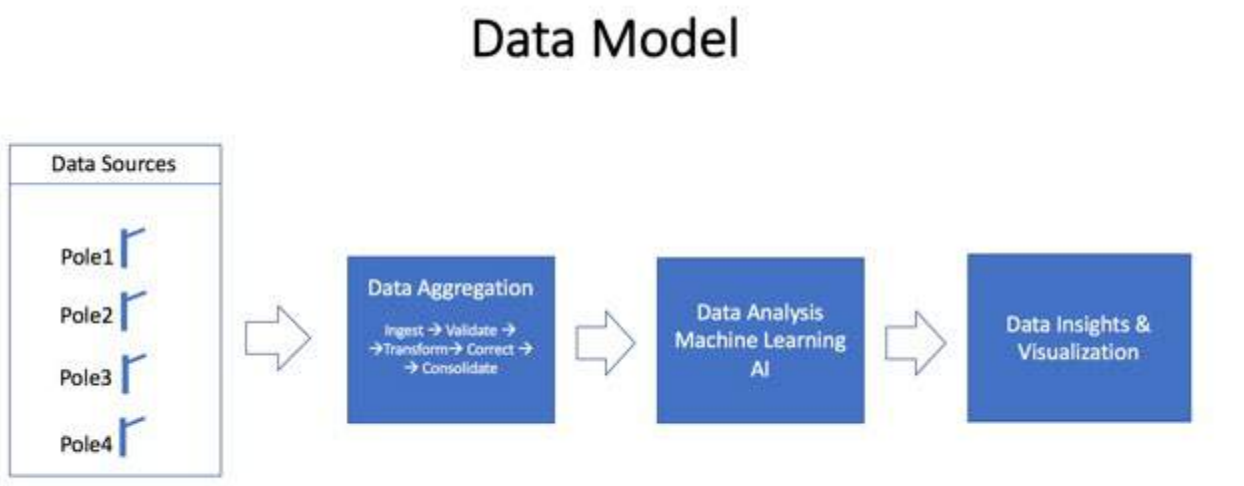

**Figure 4 – The Data Model**

## 4.1. Smart light energy usage

The smart light offers significant savings in energy expenses to a city, and we wanted to analyze ways to lower energy usage by using different settings on the unit. A LED lightbulb draws almost half of the energy as compared to High-Pressure Sodium (HPS) lightbulb. These savings can be further increased by using IoT sensors to control the light unit.

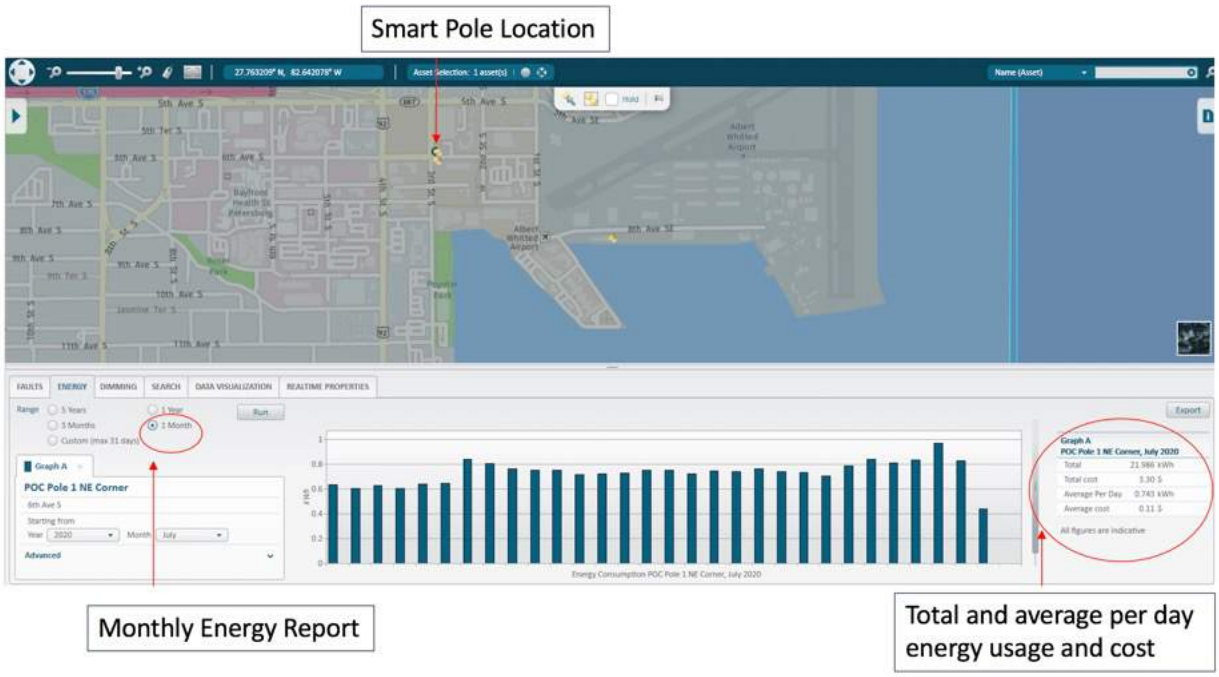

**Figure 5 - Dashboard**

The dashboard for the smart light as shown in figure 5 provides a means to view, control and manage the smart light remotely, thus increasing operational efficiency and lowering operating costs. The operating rules for the smart light, such as turn on and turn off schedule and managing the brightness level can be set remotely. We tested the two different settings on the smart light pole:

1. With dimming activated - in this setting the brightness changes when pedestrian movement is detected (via motion sensor/camera)

2. Without dimming - the light stays at full brightness level at all times.

We recorded the lowest energy usage with the dimming control activated as shown in Figure 6. The motion sensor increased the brightness of the light only when pedestrian activity was detected. When no activity was detected, the light pole stayed in dim state and provided maximum energy savings and a lower carbon footprint.

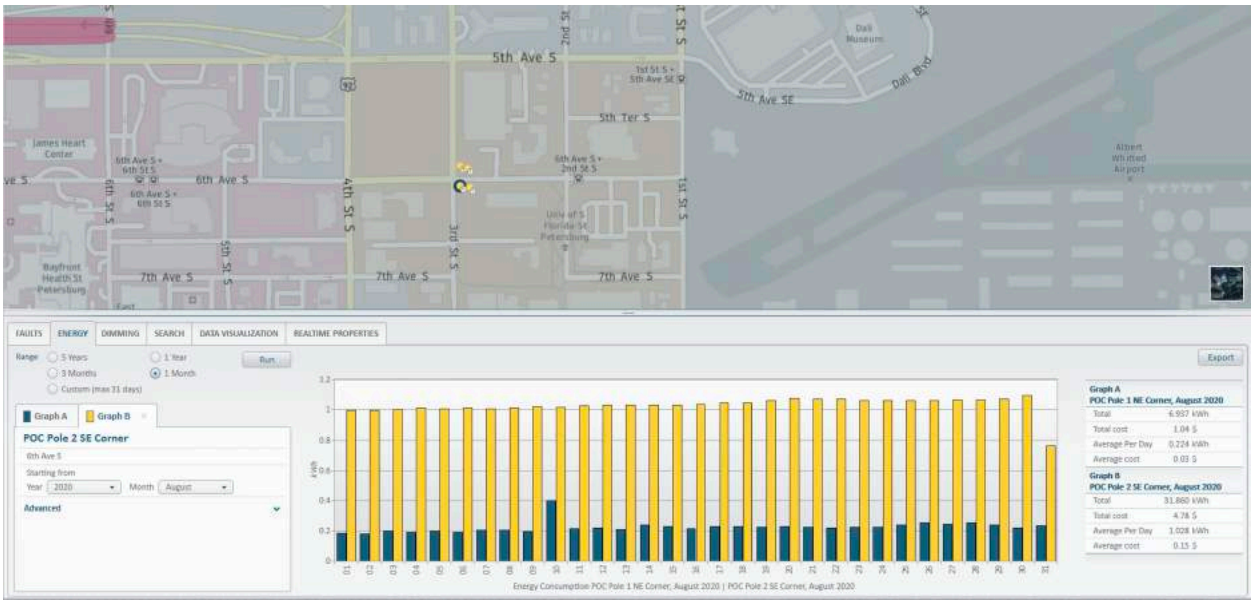

**Figure 6 – Energy Usage (Dimming vs No Dimming)**

**Table 1 – Energy usage per day (Dimming vs No Dimming).**

| Smart Light Configuration | Average Energy Per Day (Watt Hour) |
|---|---|
| Without Dimming | 1028 |
| With Dimming Activated | 224 |

**Energy usage during winter and summer months**

We studied the variation in energy usage during the winter and summer months as shown in Figure 7. This information is useful for preparing for the load on the energy grid for each month.

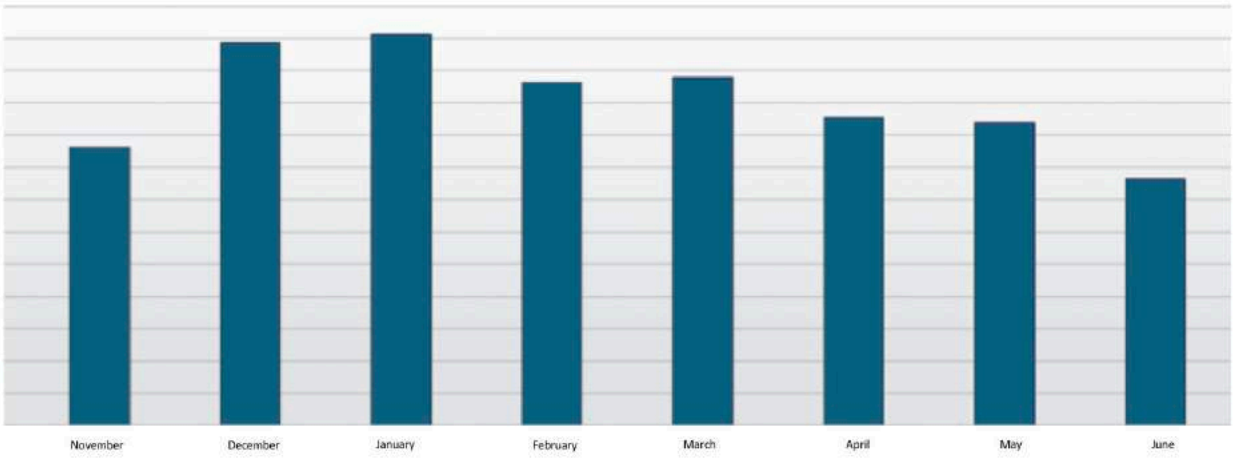

**Figure 7 – Energy Usage in Winter and Summer Months**

Insights from alerts: The smart light system monitors many parameters and can send alerts when it detects an unusual reading from the sensor as shown in Figure 8. These insights can point to expected fluctuations on the power grid or high usage of the camera as result of pedestrian activity in the area, emergency button or WiFi.

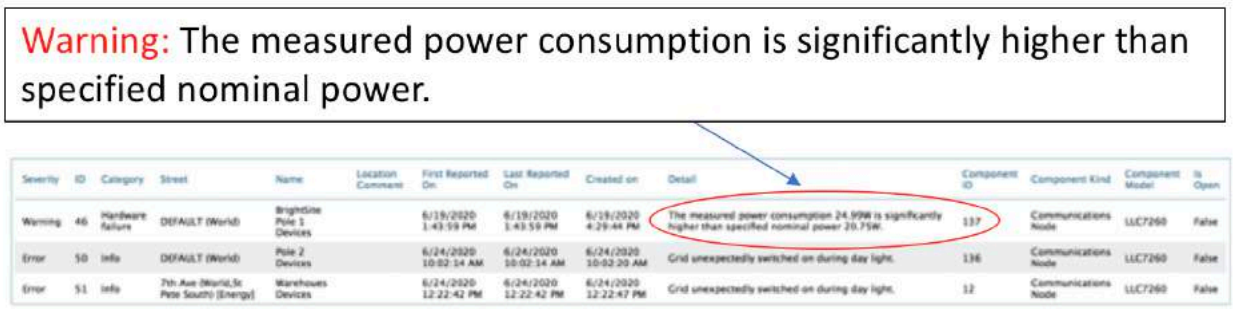

**Figure 8 – Alarms and Alerts**

## 4.2. Camera

The camera is one of the most effective tools in the smart city tool kit for enhancing public safety and protecting city assets. As an example, many cities have some renovation and new development activities in progress. At these construction sites, expensive construction equipment and supplies are stored. After the work shift, when the workers leave the site, there is a possibility of theft or vandalism. Each year around $300 million to $1 billion worth of construction equipment is stolen and only less than 25% is recovered. Florida is ranked third in the nation for construction equipment theft.[2] We tested several camera alarms, e.g., virtual fence alarm, guard zone alarm and loitering alarm as shown in Figures 9, 10 and 11, at a construction site across the street from the proof of concept light pole.

A virtual fence has been useful to monitor unauthorized access at the construction site.

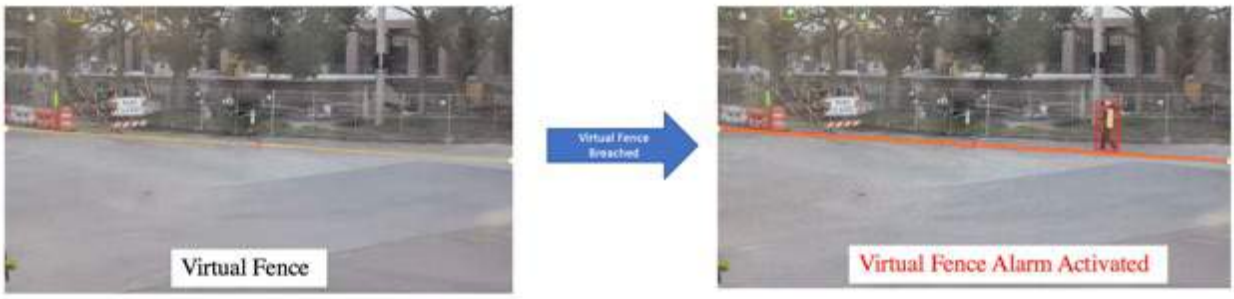

**Figure 9 – Virtual Fence**

**Figure 20 – Loitering Alarm**

**Figure 11 – Guard zone alert**

### 4.3. Smart intersection

The goal of the Smart Intersection proof of concept is to improve pedestrian safety. The State of Florida has nine of the top 20 least safe cities in the U.S. for pedestrians and is also considered the most dangerous state for the pedestrians.[3] As per the National Highway Transport Safety Administration, pedestrian fatalities in crashes increased 53 percent in the last decade (2009 to 2018), with the pedestrians' share of traffic fatalities increasing 42 percent, from 12 to17 percent.[4]

One initiative cities like St. Petersburg are working on is to bring the number of fatalities or collisions in an intersection to zero. This effort is called Vision Zero. Data collected from road sensors and cameras can help cities better understand everything from crosswalk signal timing to traffic patterns that may lead to these collisions.

The Smart Intersection proof of concept uses computer vision and edge computing to detect the presence of a pedestrian as shown in Figures 12 and 14. The camera's technology can be used to set the zone within the view of the camera that needs to be monitored for pedestrian activity. The anonymous pedestrian and vehicular traffic data is stored in the cloud for further analysis, planning and design of components of the intersection, including stop signs, traffic/pedestrian light timing, crosswalks and sidewalks to improve pedestrian safety.

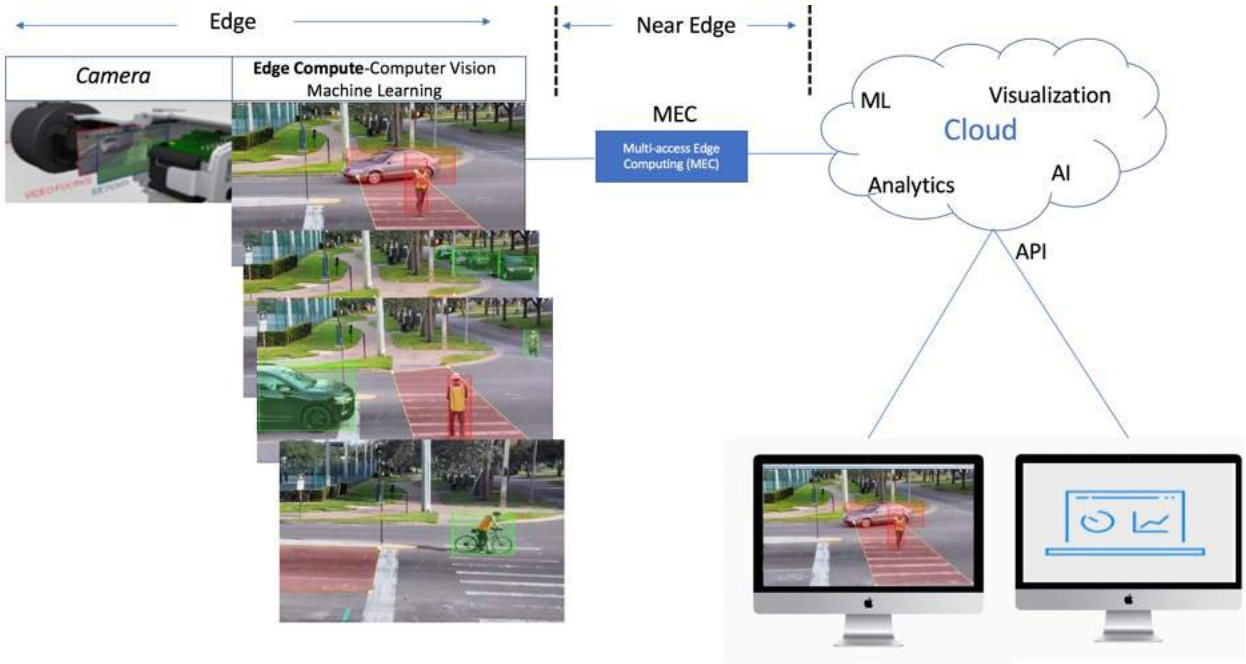

**Figure 32 – Computer Vision for Smart Intersection**

We are currently collecting the following metadata as shown in Figure 13 to assist St. Petersburg with the design of the intersection that would improve pedestrian safety:

- Number of pedestrians crossing the crosswalk
- Direction of pedestrian movement e.g., north, south, east, west

| | Last Hour | Daily | Monthly |
|---|---|---|---|
| North to South | 11 | 242 | 7260 |
| South to North | 22 | 484 | 14520 |
| East to West | 89 | 1958 | 58740 |
| West to East | 113 | 2486 | 74580 |
| Totals | 235 | 5170 | 155100 |

**Figure 43 – Pedestrian Count**

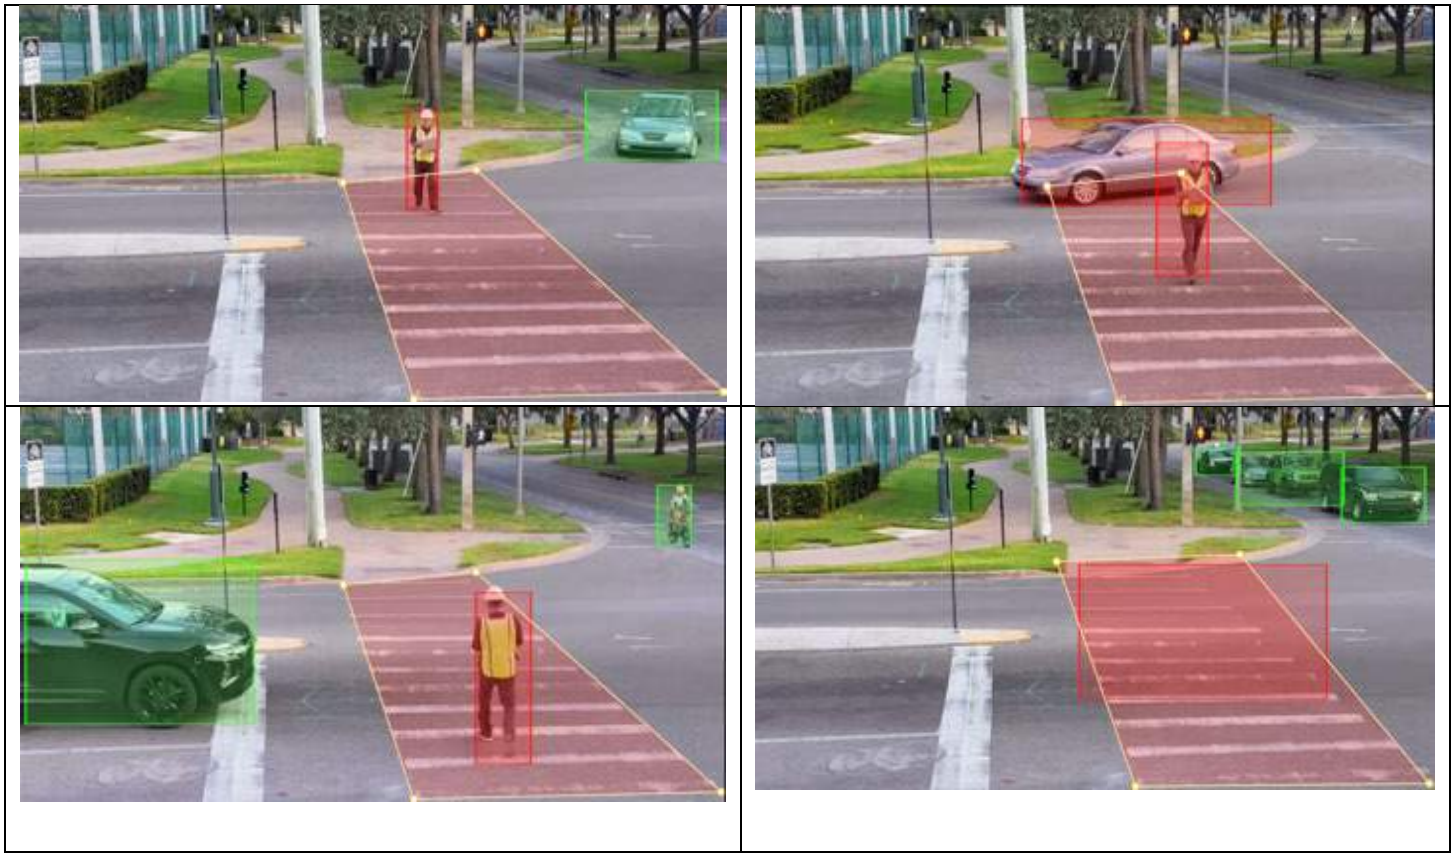

**Figure 54 – Monitoring Pedestrian Movement at Smart Intersection**

## 4.4. Environmental

Florida is home to some extreme weather conditions including hurricanes, extremely hot temperatures, humidity, fog and a high number of lightning strikes from thunderstorms. Florida leads the country in both the number of fatal lightning hits and the density of strikes, with just over 20 flashes per square mile every year.[5]

**Figure 65 - Weather**

Weather can have a big impact on citizen safety, city operations and its economy. Cities and businesses today not only need a general weather forecast for the whole city, but a micro-forecast for each neighborhood. The weather sensors are one of the largest sources of IoT data and help in micro forecasting of weather. Data from local weather sensors can micro-forecast weather that can help utility companies predict the energy load for each part of the city. Cities can predict and monitor flooding in each neighborhood as shown in Figure 15 and prepare the water pumps; detect a lightning strike at a particular location and alert the public; and detect fog on a certain part of the highway and warn motorists.[6]

Air pollution is responsible for five million premature deaths each year and nine out of ten people around the world breathe unhealthy air.[7] The sensors installed on the light pole in the POC collect several weather and air quality parameters as shown in Figures 16 and 17 and provide the city with interesting and pertinent insights on air quality at the location of the sensor.

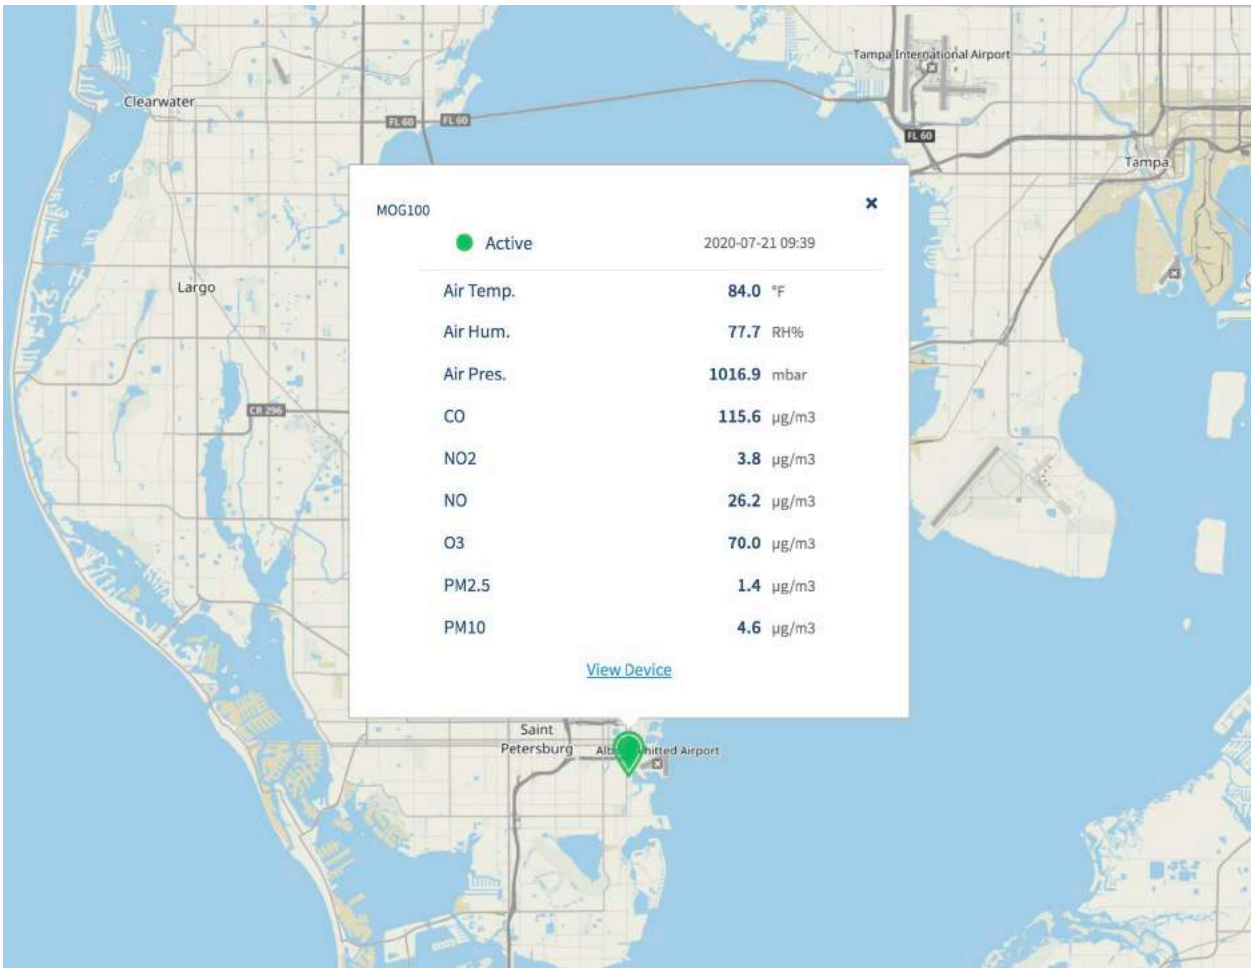

**Figure 76 – Air Quality**

Following are some of the parameters collected by this sensor:

**Table 2 – Weather and Air Quality**

| Weather | Air Quality |
|---|---|
| • Temperature<br>• Humidity<br>• Dew Point<br>• Air Pressure<br>• Wind Direction and Speed<br>• Precipitation Intensity<br>• Radiation<br>• Lightning | • Carbon Monoxide<br>• Nitrogen Dioxide<br>• Nitric Oxide<br>• Ozone<br>• PM 1<br>• PM 10<br>• PM 2.5 |

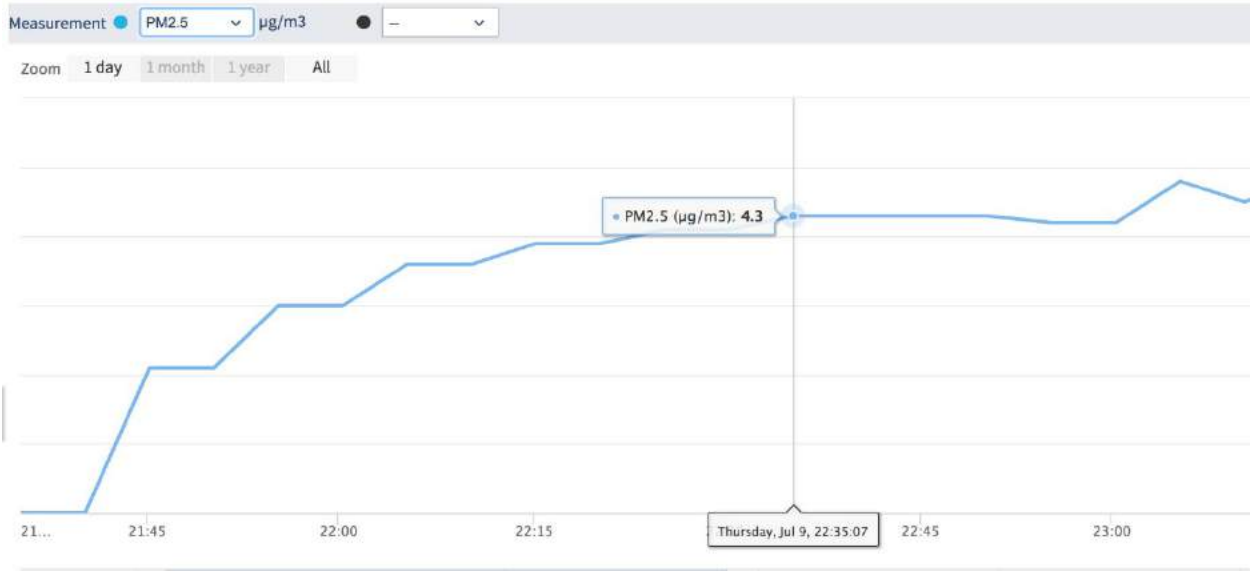

**Figure 87 – Air Quality (PM2.5)**

The data from all the sensors is collected and sent to the cloud where it is analyzed to draw actionable insights, as shown in Figure 18

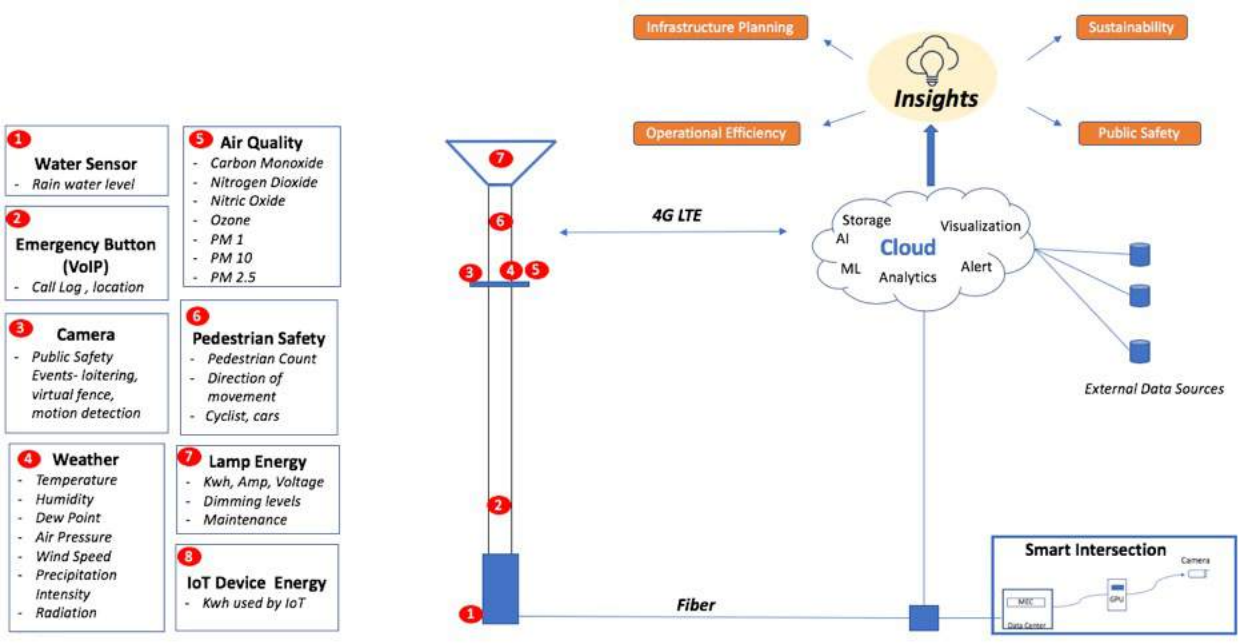

**Figure 98 – Insights from IoT Data**

## 5. Conclusion

In this proof of concept, we have demonstrated how much data can be collected and potentially analyzed from a few key IoT sensors.

As we collect more data and datasets get richer over time, we expect to draw more insights. Using the richer data sets, we can train the computer vision model and capture additional metadata to make our roads safer, predict and manage energy usage to lower costs and reduce the carbon footprint, and improve public safety and citizen engagement.

Installation of IoT hardware requires permits and inspections from many city departments before the sensors can be activated. When selecting a location for a POC, pick multiple locations that represent different sections of the city and also future-proof the POC to add scale and capability.

Close collaboration with academia, local communities and the government is important for the successful deployment of smart city solutions. Each city is unique; therefore, smart city solutions and use cases should be customized. The cable companies, with its vast network infrastructure and strong public-private partnership, are well positioned to lead the way in offering smart city solutions.

## 6. Acknowlegements

The authors would like to acknowledge Alison Barlow from the Innovation District at the city of St. Petersburg, FL and representatives of the University of South Florida St. Petersburg campus, US Ignite and St. Petersburg, FL, for the support and guidance during the execution of the POC.

# 1. Introduction

Comcast has been deploying optical fiber deeper into its infrastructure, in “Node + 0” /, “N+0” mid-split configurations to support the ever-increasing demand for higher speeds and throughput to customers. The first step was the transition from traditional Node + N sub-split networks, with 5 to 42 MHz upstream and 1002 MHz downstream bandwidth, to current mid-split Node + 0 networks with 5 to 85 MHz upstream and 1218 MHz downstream bandwidth.

Future Node + 0 networks will transition to Full-Duplex (FDX) DOCSIS, to significantly increase the upstream bandwidth to multi-gigabit speeds with high throughput. This will not be accomplished in one giant leap, but rather a transition from mid-split to high-split networks. The first step will be a shift to a 5 to 204 MHz upstream and 1218 MHz downstream bandwidth, supporting a 1 Gbps upstream tier and multi-Gbps downstream. As demand for multi-gigabit services grows, FDX can be deployed, with overlapping bidirectional spectrum from 108 to 204 MHz that eventually increases up to the full 108 to 684 MHz FDX limit plus legacy DOCSIS 3.0 to the 1002 MHz limit and legacy DOCSIS 3.1to the 1218 MHz limit.

This paper will discuss considerations that need to be addressed in the transition. Scenarios will be described, as well as some node and modem architectures that provide flexible signal support to optimize the end-to-end performance, toward 10G Full-Duplex operation of the network.

# 2. Cable Network Design

Traditional hybrid fiber/coax (HFC) cable distribution networks were built as-tree-and branch networks consisting of a fiber node connecting multiple cascaded amplifier coax cable sections. Each section connects to a series of multiport taps, transmitting signal to and receiving signals from drop cables to customer premise equipment (CPE.) An example of one coax branch of a conventional Node + N HFC architecture is shown in Figure 1. The node span contains multiple amplifier spans, each with multiple taps between amplifiers.

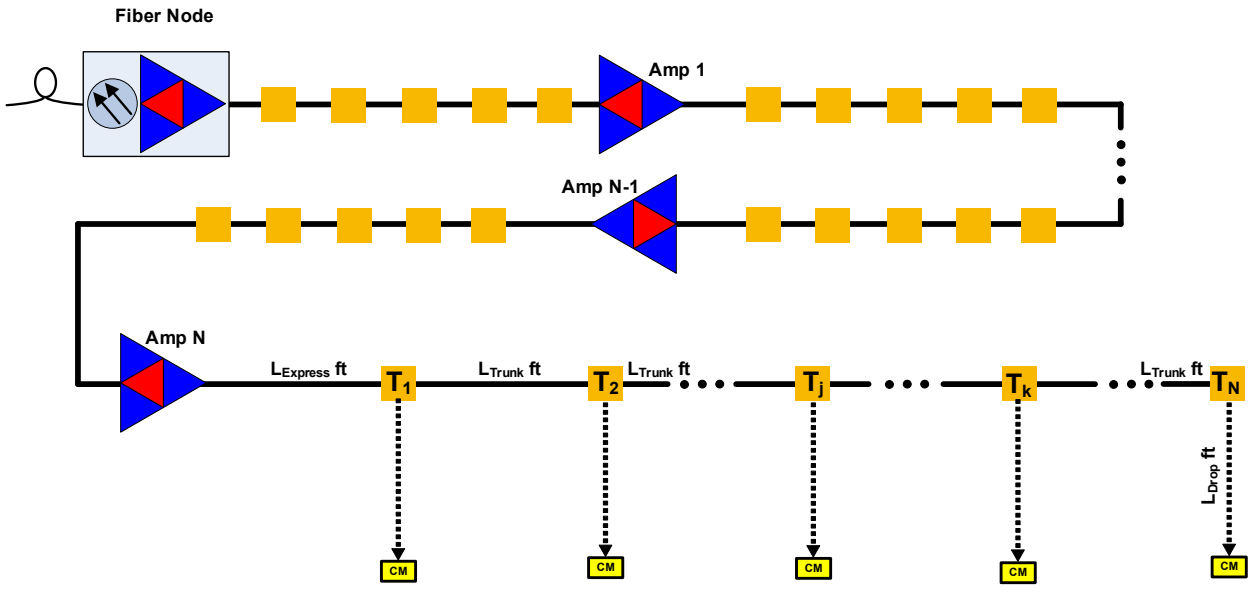

**Figure 1 – Conventional Node + N network architecture**

This conventional architecture provides two-way signal transmission on separate spectral bands using frequency division duplex (FDD) operation. Each amplifier section uses diplex filtering to separate upstream transmissions, toward the node, in the narrower lower frequency band (typically 42 MHz for sub-split, 85 MHz for mid-split, and 204 MHz for high-split systems) from downstream transmissions, from the node, in the much wider upper frequency band (up to 1.2 GHz). RF spectrum examples for sub-split, mid-split, and high-split systems are shown in Figure 2, Figure 3, and Figure 4 respectively.

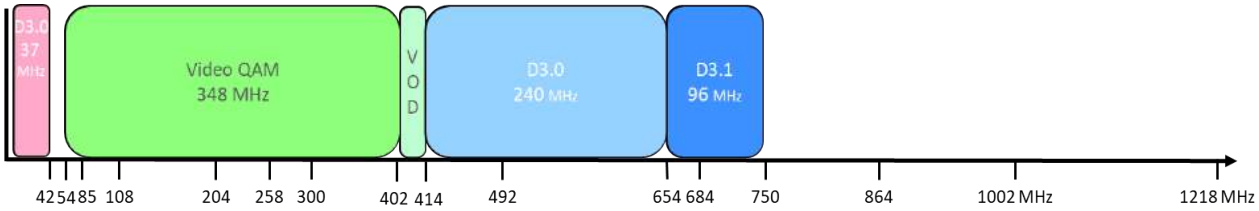

**Figure 2 – RF Spectrum: Sub-Split STB Compatible – 750 MHz Plant**

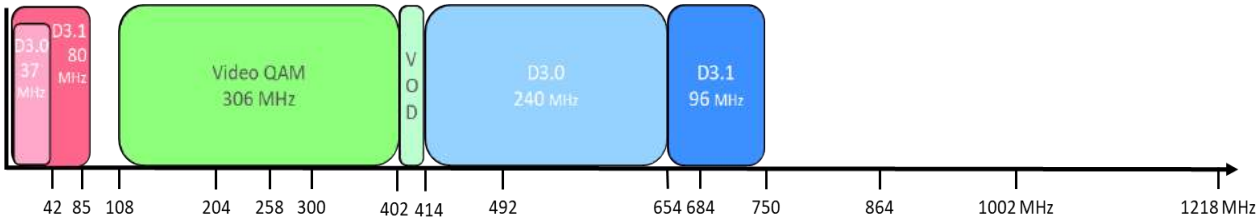

**Figure 3 – RF Spectrum: Mid-Split – 750 MHz Plant**

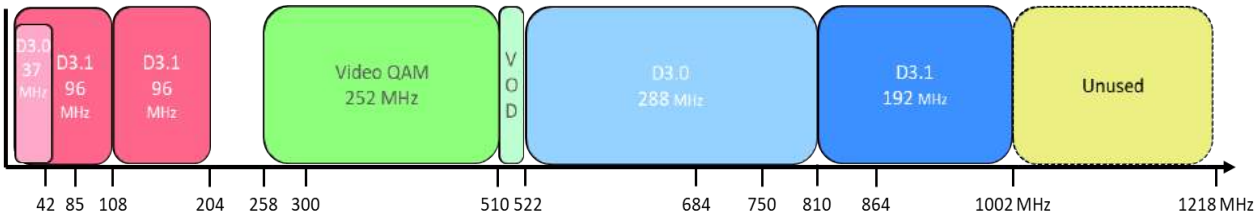

**Figure 4 – RF Spectrum: High-Split – 1 GHz Plant**

Such diplex filtering prevents two-way transmission within the same spectral band. Each multiport tap contains a directional coupler that diverts a portion of the downstream signal to the drops connected to the tap ports, and injects the upstream signals present on the tap ports toward the node. The directivity of the directional coupler prevents upstream signals from propagating in the downstream direction or from diverting to other drops upstream from that tap port.

Comcast has been deepening its deployment of fiber via Node + 0 mid-split systems, which separate the CMTS core functions that connect to Remote PHY (R-PHY) nodes using a Distributed Access Architecture (DAA). The Remote PHY Architecture shown in Figure 5 moves the RF modulation and demodulation closer to the customer, either in a node in the HFC plant or in a hub location.

The Media Access Control (MAC) layer processing is in the headend, where a CCAP-Core is responsible for all MAC-layer processing and multiplexing. The Remote PHY Device (RPD) performs the PHY-layer functions and transmits the PHY-processed RF signals on subscriber ports connected to coax segments closer to the customer. The RPD is connected to the CCAP-core via a digital Ethernet connection over digital fiber optics.

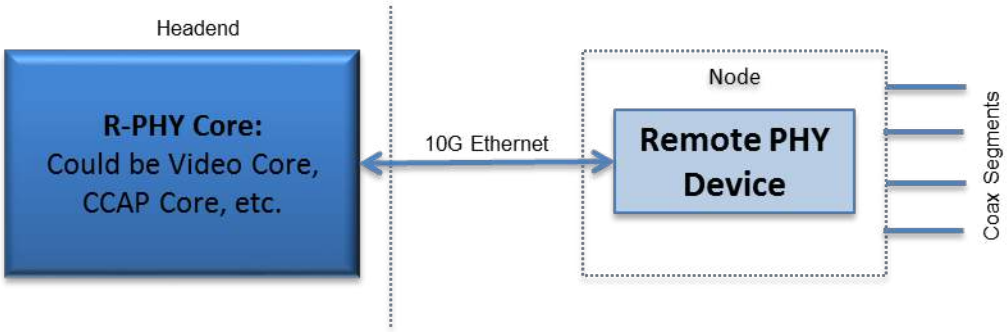

**Figure 5 – Remote PHY Architecture**

The digital replacement of conventional analog fiber optics and elimination of cascaded amplifiers in the tapped coax cable spans from the node, as well as the reduced distance to the customer from the node, results in a substantial increase in delivered Signal to Noise Ratio (SNR.)

## 3. The 10G Transition Path to Full-Duplex DOCSIS

The deployment of FDX will follow an evolutionary path involving upgrading the fiber depth into the networks, in mid-split and/or high-split FDD operation, to limited FDX bandwidth operation. Then the amount of FDX spectrum will gradually expand as future demand for higher speed and throughput increases.

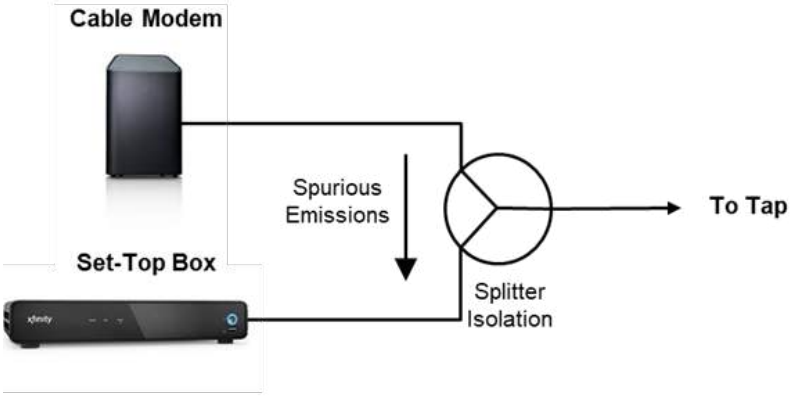
However these transition scenarios require management of both the legacy and new consumer premises equipment (CPE) and R-PHY node upgrades to support multiple generations of video and data services. Currently, Node + 0 mid-split systems supply video to legacy sub-split set-top boxes (STBs) in portions of the mid-split spectrum while simultaneously deploying new mid-split cable modems in the same customer premises.

As the transition progresses, the R-PHY node will need to be upgraded. New CMs will need to be added to support higher speed tiers with increased spectral efficiency. A description of the intermediate steps to support this 10G evolution, some problems that arise in supporting legacy CPE in upgraded systems, and solutions to mitigate these problems are presented.

## 4. Preparing the Transition from Sub-Split to Mid-Split

The 10G transition provides higher speeds and throughput with reduced latency. Getting there requires expanding capacity -- primarily the upstream, but also the downstream spectrum as demand increases. Currently, our cable networks are a mix of sub-split, business as usual (BAU) Node + N networks, and mid-split Node + 0 networks. Upgrading BAU topologies or taking fiber deeper to support mid-split spectrum can happen, in terms of DOCSIS 3.1-based cable modems (CMs) and gateways, by launching initially in sub-split mode. This supports legacy (sub-split) STBs while the network is being prepared for the transition to future mid-split operation. The mid-split CMs will be “seeded” into the existing sub-split networks, operating within the existing sub-split RF spectrum. All DOCSIS CMs receive downstream channels in the mid-split downstream frequency band above 108 MHz regardless of the upstream frequency split (42 or 85 MHz), except DOCSIS 3.1 high-split CMs (with upstream and downstream band edges at 204 and 258 MHz respectively).

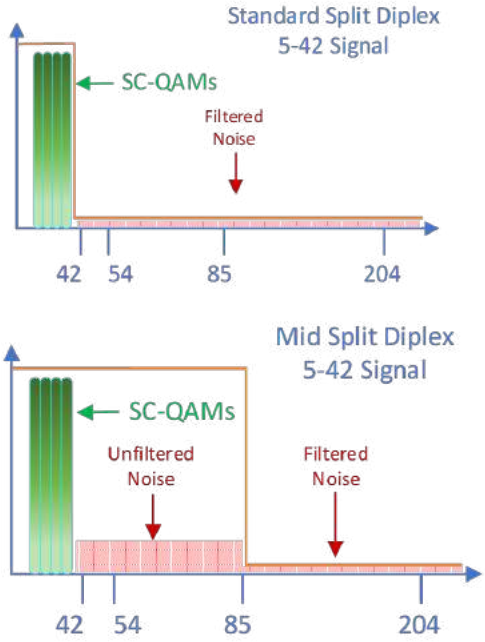
All upgrade considerations for mid- and high-splits would do well to revisit the notoriously noisy and hostile spectral environment that is the upstream path. In particular, a mid-split CM transmitting upstream in the sub-split 5 to 42 MHz spectrum can produce spurious emissions in the 42 to 85 MHz band, below the mid-split cutoff of the CM's diplex filter. Also within that region, between 54-85 MHz, are STB downstream video channels prior to enabling mid-split operation. A customer equipped with a DOCSIS mid-split CM and a sub-split STB will be connected to the drop via an in-home splitter, as shown in Figure 6.



Comcast Field Equipment Specification: Passive RF Drop Splitters

| MINIMUM OUTPUT PORT TO OUTPUT PORT ISOLATION | | | |
|---|---|---|---|
| 5-10 MHz | 11-85 MHz | 86-1002 MHz | 1003-1218 MHz |
| ≥25 dB | ≥35 dB | ≥25 dB | ≥20 dB |

**Figure 6 – In-home video and data connection to the cable plant**



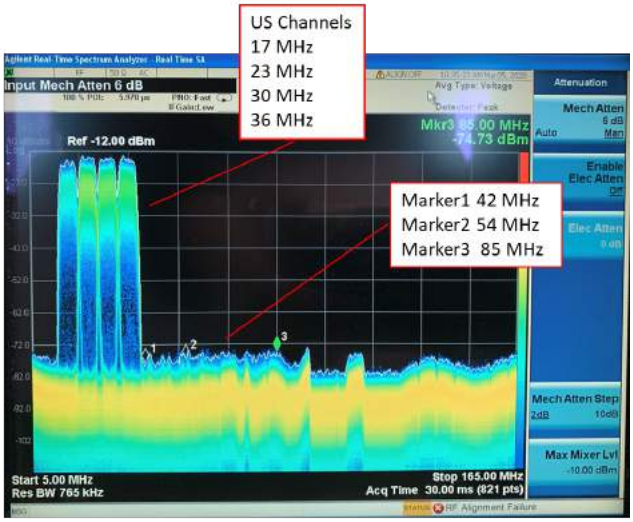


**Figure 7 – Spurious emissions below diplex filter cut-off**

Figure 7 shows spurious noise in the mid-split CM 5-42 MHz upstream transmission path that can interfere with an STB's downstream video reception between 54 to 85 MHz. Measurements of the spurious emissions levels and the reduced levels below the spec limit of -44 dBr are shown in Table 1. Notice that the highlighted maximum spurious emissions level reduction at the maximum transmit power per channel is at least 10 dB below the -44 dBr spec limit.

**Table 1 – Mid-Split Spurious Emissions of Sub-Split Upstream Carriers**

| Device Model | US TX power per channel (dBmV/6.4 MHz) | Spurious power @54 MHz (dBmV/200 kHz) | Spurious Emissions (dBr) | Spurious Emissions Reduction from -44 dBr spec (dB) |

| Pace | XG1v3/PX013ANM | 177 MHz | 27.2 | 27.1 |

The port-to-port isolation of the in-home splitter in Figure 6 will determine the attenuation of the coupled interference. The magnitude of the interference depends on each CM transmit level, and the STB receive level separated by the splitter isolation. If the resulting interference from a CM lowers the SNR of the STB's downstream receiver below the video channel SC-QAM threshold, then video artifacts, or a complete loss of reception of some channels below 85 MHz, may occur for that home. Measurements of the STB SC-QAM video threshold SNR levels below the SCTE 40 spec limit of 30 dB that exhibited "tiling" (macroblock freezing/errors in portions of the decompressed video) is shown in Table 2, for several deployed STB models at several frequencies. The video SC-QAM level was -5 dBmV/6 MHz for these measurements. The maximum SNR threshold level where video artifacts are observed is 27.5 dB, which is more than 2 dB below the SCTE 40 spec limit.

Field data was obtained for the following analysis using the above determined parameters of mid-split CM noise and spurious emissions interference into STBs in the same home. Over 21 thousand CMs in Comcast employees homes were polled using Comcast field analysis tools tabulating over 23 million CM MER, transmit and receive levels at multiple frequencies with multiple samples per frequency for each CM from more than 800 CMTS network locations. The following analysis shows the number of cases that could cause observable STB video artifacts are few.

The SNR metrics for spurious emissions interfering with the video SC-QAM signal across a two-way splitter are the carrier-to-interference ratio (CIR) and the carrier-to-noise-and-interference ratio (CNIR). The interference level, I, is the spurious emissions level calculated from the DOCSIS 3.1 PHY spec using the measured upstream transmit power at the CM F-connector. The background noise level is determined by the reported downstream CM MER. All such measurements are averaged for each CM MAC address.

The maximum allowed spurious emissions level of each CM is calculated per the DOCSIS 3.1 PHY spec. For a legacy Transmit Channel Set (TCS) with four 6.4 MHz SC-QAM channels (5.12 Msym/s), the 100% Grant spectrum is 25.6 MHz. The measurement bandwidth (Measurement BW or Interval) is 1.6 MHz.

The SpurFloor is defined as

SpurFloor = max[-57 + 10*log(100% Grant Spectrum/192 MHZ), -60] dBc

Thus the SpurFloor for the 100% Grant bandwidth in the Measurement BW is -60 dBc, and the emissions level within the Measurement BW is:

Spec in Interval (dBc) = -60 + 10 log[Measurement BW/(100% Grant/40)] = -56 dBc

Emissions Limit (dBr) = Spec in Interval + 10 log[100% Grant/Measurement BW] = -44 dBr

Note that the measured emissions limit in Table 1 shows a 10 dB reduction in practice. The noise and spurious emissions power per 6 MHz channel for the total composite power TCP dBmV of all TCS channels is:

TCP – 56 dBc + 10 log[6/1.6] dBmV/6 MHz

The data analysis method is as follows:

Calculate the average MER, transmit and receive level for each modem over all upstream and downstream frequencies per MAC address.

Calculate the average emissions level for each average transmit level for each CM MAC address.

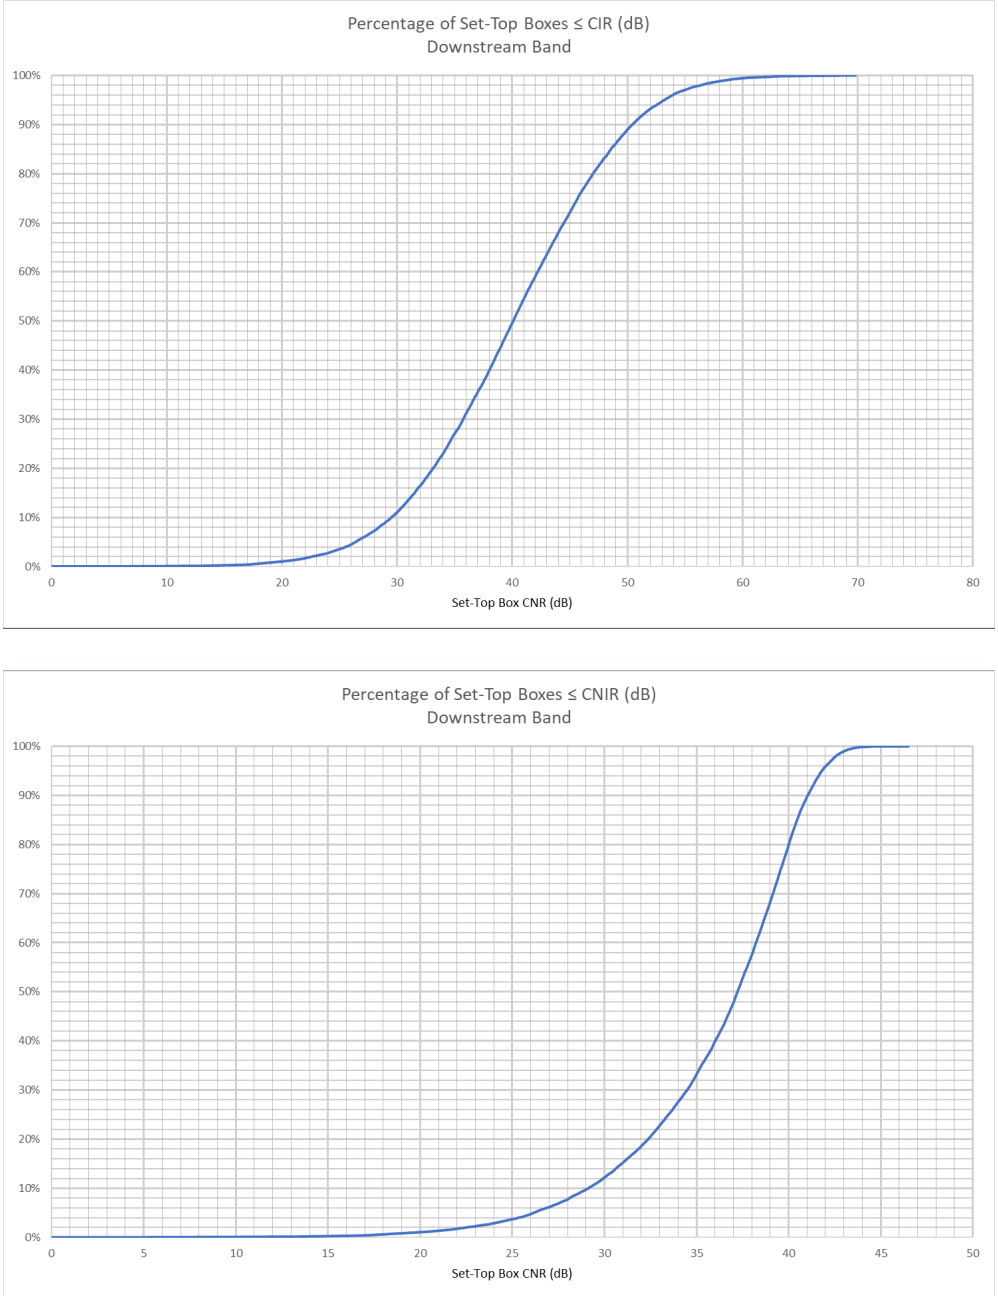

**Figure 8 – Percentage of STBs ≤ CIR and CNIR**

Calculate the STB downstream CIR for each average receive level and each CM computed average emissions level as:

CIR = DS Average Receive – US Average Emissions + Splitter Isolation
CNIR = -10 log($10^{-CIR/10} + 10^{-MER/10}$).

Sort the calculated STB CIR and CNIR levels in ascending order (plotted in Figure 8).

Calculate the percentage of CMs ≤ each STB CIR and CNIR level as:

%CMs ≤ CIR value = Number of CIR entries ≤ CIR / Total Number of CIR values*100
%CMs ≤ CNIR value = Number of CNIR entries ≤ CNIR / Total Number of CNIR values*100

The parameters used and analysis results shown in Figure 8 are given in the following table:

**Table 3 – Analysis of Percentage of STBs Below Threshold SNR**

**Specifications**

| CPE Parameters | |
|---|---|
| Splitter Isolation (dB): | 35 |
| Set-Top Box Threshold CNR (dB): | 28 |
| Spurious Emissions Reduction (dB): | 10 |
| Downstream Boost 54 to 85 MHz (dB): | 0 |

| D3.1 Spurious Emissions Spec | |
|---|---|
| 100% Grant (MHz): | 25.6 |
| Spur Floor (dBc): | -60 |
| Under-grant Hold Number of Users: | 40 |
| Under-grant Hold BW (MHz): | 0.64 |
| Measurement BW (MHz): | 1.6 |
| Spec in Interval (dBc): | -56 |
| Emissions Limit (dBr): | -44 |

**Threshold Video CIR**

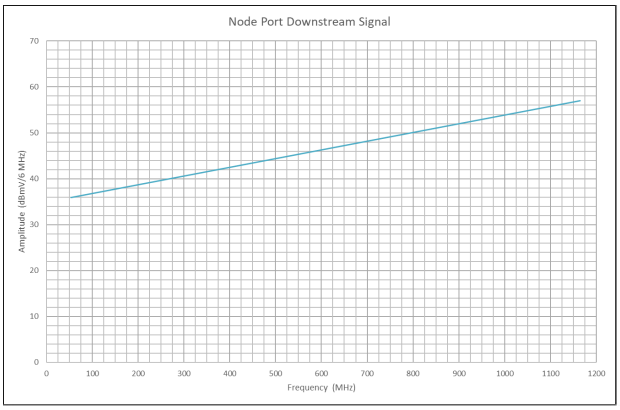
| Total Downstream Band | |
|---|---|
| % Set-Top Boxes with < 28 dB CIR | 7.24% |
| Set-Top Box CIR(dB): | 28.0 |

**Threshold Video CNIR**

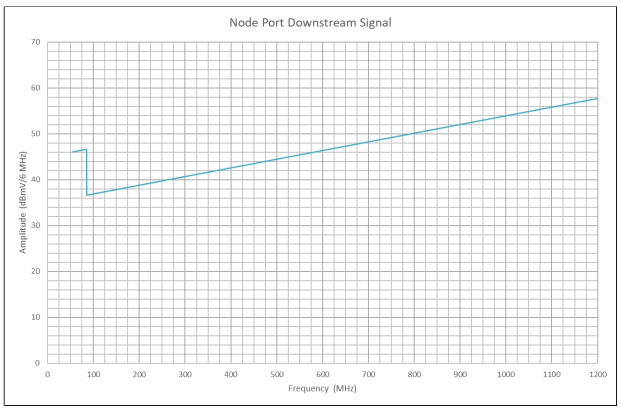
| Total Downstream Band | |
|---|---|
| % Set-Top Boxes with < 28 dB CNIR | 7.71% |
| Set-Top Box CNIR(dB): | 28.0 |

The cases which have sufficient interference magnitude will require mitigation. The percentage of STBs below the SNR threshold for the specifications in Table 3, including background noise plus spurious emissions, is below 8%. This percentage can be further reduced which decreases the number requiring 85 MHz low pass filters on the CMs on the same splitter as the low SNR STBs. Mitigation strategies that limit the number of cases where interference-blocking low pass filters needed at the CM output are discussed next.

The lower frequency sub-split video channel RF levels from 54 to 85 MHz can be boosted up to 10 dB at the node with a deminimus (0.04 dB) increase in total composite power (TCP) as shown in Figure 9.



Total Composite Power(dBmV): 73.8



Total Composite Power(dBmV): 73.84

**Figure 9 – Node Sub-Split Video Transmit Power Boost in the Mid-Split Band**

The result of applying a 6 dB downstream power boost below 85 MHz is given in the following table:

**Table 4 – Analysis of Percentage of STBs Below Threshold SNR with 6 dB Power Boost**

**Specifications**

| CPE Parameters | |
|---|---|
| Splitter Isolation (dB): | 35 |
| Set-Top Box Threshold CNR (dB): | 28 |
| Spurious Emissions Reduction (dB): | 10 |
| Downstream Boost 54 to 85 MHz (dB): | 6 |

| D3.1 Spurious Emissions Spec | |
|---|---|
| 100% Grant (MHz): | 25.6 |
| Spur Floor (dBc): | -60 |
| Under-grant Hold Number of Users: | 40 |
| Under-grant Hold BW (MHz): | 0.64 |
| Measurement BW (MHz): | 1.6 |
| Spec in Interval (dBc): | -56 |
| Emissions Limit (dBr): | -44 |

**Threshold Video CIR**

| Total Downstream Band | |
|---|---|
| % Set-Top Boxes with < 28 dB CIR | 1.68% |
| Set-Top Box CIR(dB): | 28.0 |

**Threshold Video CNIR**

| Total Downstream Band | |
|---|---|
| % Set-Top Boxes with < 28 dB CNIR | 1.90% |
| Set-Top Box CNIR(dB): | 28.0 |

The percentage of STBs below the SNR threshold for the specifications with 6 dB boosted downstream transmit power below 85 MHz in Table 4 including both background noise plus spurious emissions is now below 1.9%. This virtually eliminates the mid-split CM emissions into a sub-split STB interference problem without an increase in the transmitted total composite power of the node.

The initial deployment of mid-split CMs described above prior to enabling mid-split operation were limited to transmit in the sub-split band. Video signals remained in the sub-split downstream band with the lower band edge at 54 MHz. The downstream signals can be moved to occupy anywhere in the 108 to 1218 MHz band to transition to mid-split operation. These mid-split upgrades will move the video channels anywhere between 108 to 1002 MHz. This will prevent the spurious emissions interference problem previously discussed, as the video channels will be moved above the 85 MHz upstream cutoff frequency of the mid-split CM's diplex filter.

However, the sub-split STBs will encounter a different problem after the transition enabling mid-split operation or when upgrading to high-split operation. This is discussed in the next section.

## 5. Completing the Transition to Mid-Split or Upgrading to High-Split

Node + 0 networks have been and continue to be deployed in a mid-split frequency division duplex (FDD) configuration, where upstream signals can occupy the 5 to 85 MHz band and downstream signals can occupy the 108 to 1218 MHz band. This will increase the upper frequency limit of the upstream signal path from the Node + N sub-split 42 MHz limit, to 85 MHz. This represents more than a 2x (43 MHz) increase, and an increase in capacity by more than 2x when CPE based on DOCSIS 3.1 1024-QAM OFDMA replacing CPE based on DOCSIS 3.0 64-QAM SC-QAM in the additional 43 MHz bandwidth, for over 500 Mbps total throughput.

The next upgrade transition will be to high-split networks, with upstream signals occupying the 5 to 204 MHz band. That yields an additional 119 MHz of upstream bandwidth, for over 1.5 Gbps total throughput. The downstream signals can occupy the 258 to 1218 MHz band. These high-split upgrades will move the video channels above 258 MHz prior to enabling high-split operation. This will prevent the spurious emissions interference problem previously discussed, as the video channels will be moved above the upstream cutoff frequency of the CM's diplex filter.

However, the legacy STBs will still have a sub-split diplex filter instead of the upgraded CM high-split diplex filter. Thus the cutoff frequency (54 MHz) of the sub-split STB's diplex filter will see signals in the 54 to 204 MHz upstream band from the high-split CMs. These signals will be adjacent to the 258 MHz-and-above STB video channels. If the CM's transmit power adjacent to the downstream video channels is strong enough, this can cause adjacent channel interference (ACI) which could impair the STB-delivered video channels.

This ACI scenario will also occur in the transition to mid-split operation previously described, but in the 54 to 85 MHz upstream band from the mid-split CMs. These signals will be adjacent to the 108 MHz-and-above STB video channels. The ACI power will be lower for the same power spectral density as the upstream bandwidth is limited to 85 MHz in the mid-split case. The total ACI power will be less than one-third of the high-split ACI power. Thus neighbor video interference is much less likely for mid-split operation.

If a customer desires a 1 Gbps upstream service with a high-split CM replacement, then any STBs present in that premises can be fitted with high-pass filters. The filters suppress the high transmit level of the high-split CM leaking across an in-home splitter, if needed. But, a neighbor on the same tap may see the increased ACI leaking across drops, as shown in Figure 10.

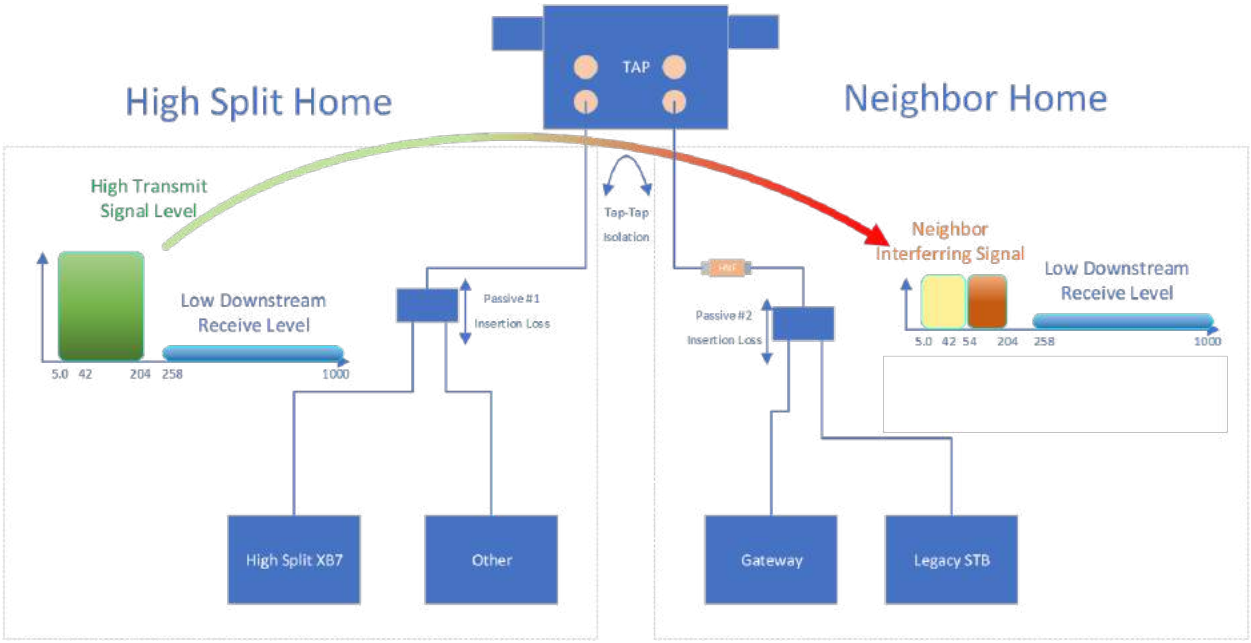


**Figure 10 – High-Split CM ACI into Neighbor Legacy STB**

**Table 5 – High-Split CM Carrier/ACI Ratio at STB Impaired Video Threshold**

| Model | Measured Peak Power of Interferer (dBmV/96 MHz) | Measured Delta Peak to 6 MHz Video SC-QAM (dBc) | Corrected Power Delta (dBc) | Downstream Power (dBmV/6 MHz) |

| DCI105COM | 27.35 | -36.08 | -24.08 | -5 |

The port-to-port isolation of the tap, plus the drop cable and in-home splitter insertion losses in Figure 10, determines the path loss between neighbors, which determines the attenuation of the CM-coupled ACI. The magnitude of the interference depends on each CM's transmit level, and the STB's receive level separated by this path loss. If the resulting ACI level from a CM exceeds the STB downstream receiver susceptibility threshold, then video artifacts or complete loss of reception of some channels above 258 MHz (that are adjacent to the CM's upstream transmit signal interference below 204 MHz) may occur for that customer. Measurements of the STB Carrier/ACI Ratio (CACIR) video threshold levels that exhibited "tiling" (macroblock freezing/errors in portions of the decompressed video) are shown in Table

5 for several deployed STB models at several frequencies. The video SC-QAM receive level was -5 dBmV/6 MHz for these measurements. The maximum CACIR STB threshold level where video artifacts are observed is below -20 dB across all models tested.

The same 23 million CM transmit and receive level statistics from the field are used for the analysis of the percentage of STBs with CM ACI resulting in CACIR below the -20 dB threshold of impaired video reception. The following analysis shows an estimated upper bound on the number of cases which have sufficient CM interference magnitude impairing STB video reception.

The data analysis method is as follows:

Calculate the average transmit and receive level per channel for each modem (per MAC address) over all upstream and downstream frequencies.

Estimate the isolation between neighbors (i.e. path loss $P_{loss}$) as:
$P_{loss}$ = Tap Port-to-Port Isolation + 2*(Drop Cable Attenuation + Splitter Insertion Loss)

Calculate the average ACI level for each average transmit level for each CM MAC address as:
ACI = CM Transmit Level - $P_{loss}$

Calculate the STB CACIR for each average downstream receive level and average upstream transmit level as:
CACIR = CM Receive Level - ACI

Sort the calculated STB CACIR levels in ascending order (plotted in Figure 11).

Calculate the percentage of CMs ≤ each STB CACIR as:
%CMs ≤ CACIR value = Number of CIR entries ≤ CIR / Total Number of CIR values*100

**Table 6 – Analysis of Percentage of STBs Below Video Threshold CACIR**

| CPE Parameters | |
|---|---|
| Splitter Insertion Loss (dB): | 3.5 |
| Splitter Isolation (dB): | 35 |
| Set-Top Box Threshold CNR (dB): | 28 |
| Set-Top Box Threshold CACIR (dB): | -20 |

| | |
|---|---|
| Drop Coax Span (ft): | 100 |
| Drop Attenuation per 100 ft (dB): | 1.33 |
| Tap Port-to-Port Isolation (dB): | 24 |

**Threshold Video CACIR**

| Total Downstream Band | |
|---|---|
| % Set-Top Boxes with < -20 dB CACIR | 9.49% |
| Set-Top Box CACIR(dB): | -20.0 |

The cases which have excessive adjacent interference will require mitigation. The percentage of STBs below the -20 dB CACIR threshold for the specifications in Table 6 is estimated to be below 9.5%. These STBs would need high-pass filters on each tap port to block the ACI from neighboring CMs on the same tap.

However this is a conservative estimate as the higher CM upstream levels in many cases is due to higher attenuation in the path from the CM to the tap port including the in-home network which lowers the interference level into the neighboring tap ports.

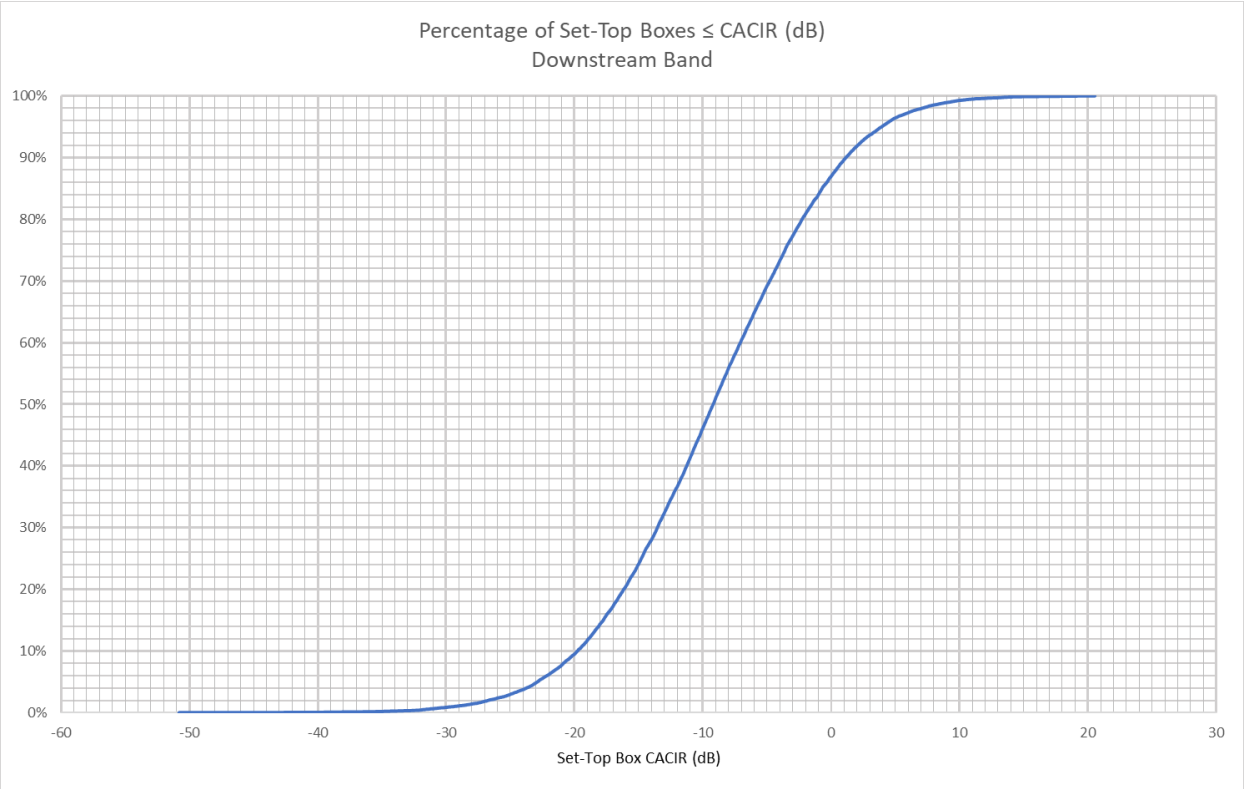

**Figure 11 – Percentage of STBs ≤ CACIR**

# 6. Accomodating Legacy MoCA in 1.2 GHz System Upgrades

Legacy STBs have an SC-QAM upper frequency limit of 1002 MHz. In these legacy designs, the MoCA channels are situated starting with a lower band edge frequency of 1125 MHz. Mid-split and high-split systems with DOCSIS 3.1 CMs, as well as forthcoming DOCSIS 4.0 FDX CMs, can support an extended OFDM upper frequency limit above 1002 MHz to 1218 MHz. In order to utilize this additional DOCSIS bandwidth, MoCA channels have to migrate to higher channel frequencies.

Figure 12 illustrates the lowest non-overlapping MoCA channel and the DOCSIS 3.1 OFDM upper frequency limit. The minimum separation for non-overlapping MoCA channels is from the edge of the MoCA channel to the edge of the second adjacent emissions sideband equal to 75 MHz. The DOCSIS 3.1 highest maximum bandwidth (192 MHz) OFDM channel extends from the DOCSIS 3.0 upper limit of 1002 MHz to 1194 MHz (not up to the DOCSIS 3.1 1218 MHz upper limit).

The MoCA Extended Band D frequency plan is shown in Table 7. The lowest frequency MoCA 1.1 and 2.0 channels with a bandwidth of 50 MHz and 100 MHz respectively, that are separated by at least the minimum non-overlapping channel gap of 75 MHz, are noted in the table. The minimum gap from the respective DOCSIS and MoCA channel boundaries is 81 MHz.

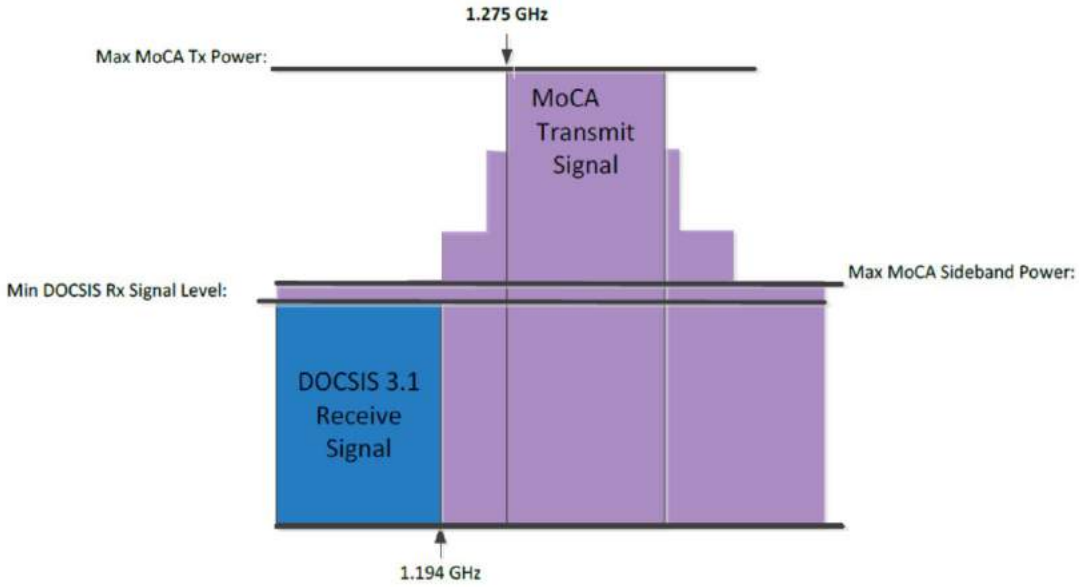

**Figure 12 – MoCA Non-Overlapping Channel & DOCSIS 3.1 Downstream Frequency Limit**

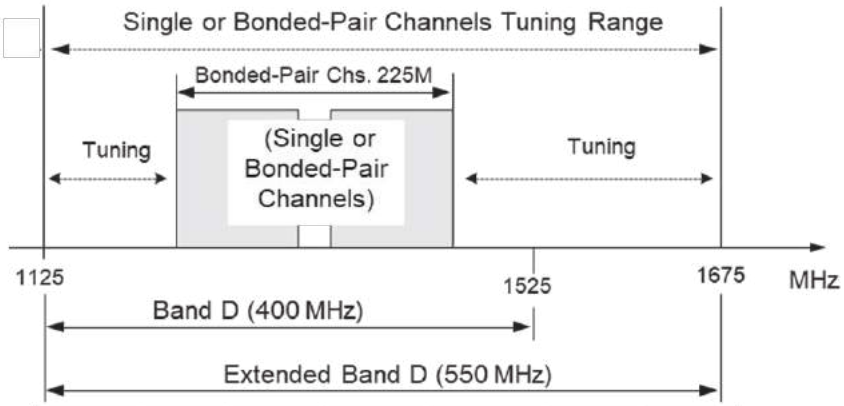
The MoCA Alliance performed a MoCA 2.0 field trial in a number of homes to determine the percentage of coax outlets that can support a given MAC rate over all the D band channels [3]. The results for Comcast participants extracted from that field trial report data is shown in Figure 13. The D band channels D4 through D6 in the 1275 MHz to 1475 MHz frequency band were shown to deliver a 400 Mbps MAC rate in over 90% of measured outlets.

In order to place the DOCSIS and MoCA channels in such close proximity, the RF isolation requirements and the resulting trade-offs in DOCSIS 3.1 SNR are analyzed in the following. An evaluation of required isolation between MoCA transmit and DOCSIS 3.1 receive signals in the common RF port is performed for two sources of adjacent channel interference: Susceptibility (maximum power of signals adjacent to the desired signal) and Noise and Spurious Emissions (out-of-band interference from signal emissions adjacent to the desired signal). The DOCSIS 3.1 PHY spec and the MoCA 2.0 spec determine the signal and emissions levels and bandwidth tabulated in Table 8 and Table 9 respectively.

**Table 7 – MoCA Extended Band D Frequency Plan**



| Frequency [MHz] | Channel # | MoCA 1.1 Channels | MoCA 2.0 Primary Channels | MoCA 2.0 Secondary Channels | Beacon Channels | D-Low / D-High |
|---|---|---|---|---|---|---|

| 16 | 15.0 | -15.0 | -12.8 | -44.5 | 52.5 |

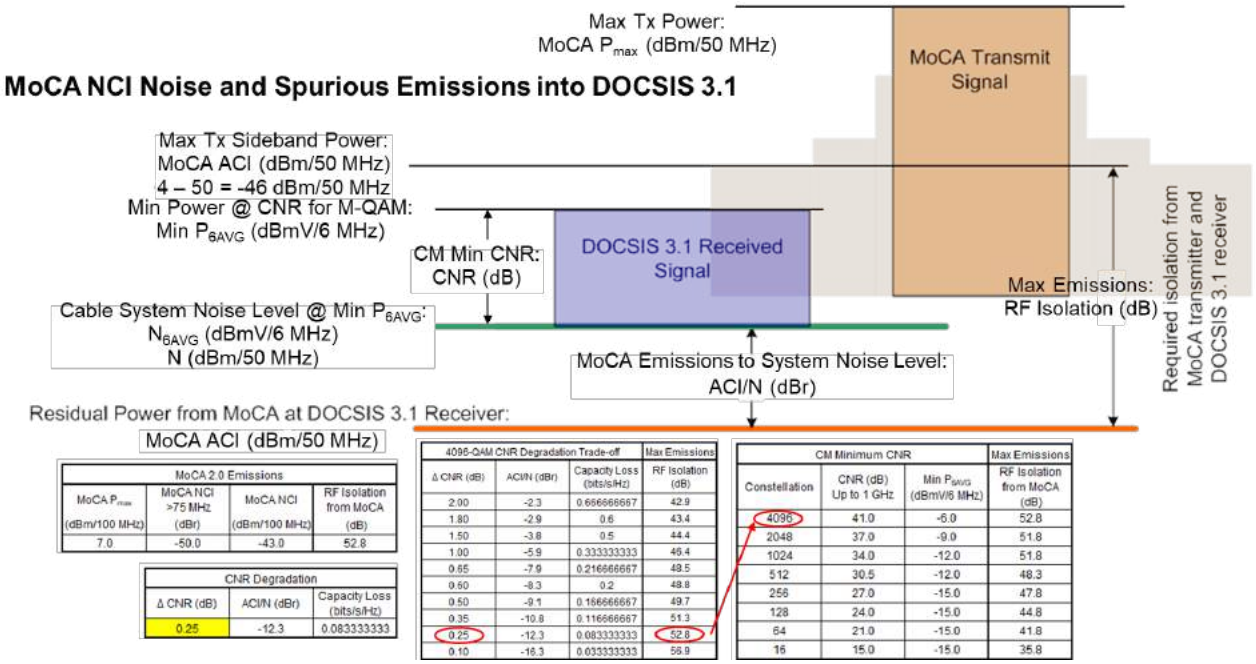
**Figure 14 – Analysis of MoCA Susceptibility into DOCSIS 3.1**

The other RF isolation requirement is from noise and spurious emissions interference from a MoCA 2.0 transmitter, into a DOCSIS 3.1 receiver. Our analysis and results of MoCA 2.0 and MoCA 2.0 in 1.1 mode for non-overlapping channel noise and spurious emissions into DOCSIS 3.1 follow the methodology in [2]. The methodology evaluates the MoCA emissions impact on DOCSIS 3.1:

- A maximum tolerable level of degradation to the input CNR is chosen ΔCNR = [C/N]/[C/(N+ACI)] dB corresponding to a maximum ACI emissions-to-noise ratio ACI/N
- The input noise floor is calculated for any spectral efficiency (modulation order) at its minimum required DOCSIS 3.1 signal level
- The required RF isolation is calculated over all modulation orders for this maximum input CNR degradation or less at the calculated ACI/N ratio and maximum MoCA ACI emissions level

The required RF isolation, so calculated, should be greater than or equal to the highest RF isolation required for all other ACI susceptibility cases previously considered (i.e. 52.5 dB MoCA ACI susceptibility into DOCSIS 3.1.)

The analysis and results are summarized for MoCA 2.0 and MoCA 2.0 in 1.1 mode in Figure 15 and Figure 16, respectively. The MoCA transmitter to DOCSIS 3.1 receiver minimum RF isolation to meet the limits of noise and spurious emissions into DOCSIS 3.1 for non-overlapping channels between these signals is 52.5 dB. The ΔCNR limits to match the previous susceptibility isolation requirement are 0.25 dB for the MoCA 2.0 transmitter to DOCSIS 3.1, and 0.65 dB for the MoCA 2.0 in 1.1 mode transmitter to DOCSIS 3.1.



| MoCA 2.0 Emissions | | | |
|---|---|---|---|
| MoCA Pmax (dBm/100 MHz) | MoCA NCI >75 MHz (dBr) | MoCA NCI (dBm/100 MHz) | RF Isolation from MoCA (dB) |

**Figure 16 – MoCA 2.0 in 1.1 mode Transmitter to DOCSIS 3.1 Receiver RF Isolation**

Incorporating the CNR requirements for DOCSIS 3.1 provides the required RF isolation between a MoCA transmitter and a DOCSIS 3.1 receiver in non-overlapping channels, resulting in a practical isolation filter with minimal loss in spectral efficiency (bit-loading or bits/s/Hz), or alternatively maintaining spectral

efficiency with an increased minimum DOCSIS receive level where increased minimum receive level = nominal minimum receive level + CNR loss (ΔCNR).

MoCA Noise and Spurious Emissions into DOCSIS 3.1 for minimally impacting the required CNR at the minimum receive level of the highest spectral efficiency (modulation order) in the DOCSIS 3.1 specification requires a minimum RF isolation equal to the 52.5 dB minimum susceptibility interference isolation. This is requirement is achieved with 0.25 to 0.65 dB CNR loss for Non-Overlapping Channel (NCI) with > 75 MHz transition band with MoCA 2.0. This can be implemented with a DOCSIS 3.1/MoCA triplex filter incorporated into the in-home network CPE, with at least 52.5 dB of stop band attenuation in the DOCSIS 3.1 band pass and MoCA high pass filter sections, with an 81 MHz transition band and a low pass legacy upstream band filter section.

# 7. Upgrading to Full Duplex DOCSIS for the Node + 0 Architecture

The transition from either mid-split or high-split networks to FDX, with a progression of increasing FDX bandwidth from 192 MHz to 576 MHz, is described in this section.

The DOCSIS 4.0 FDX architecture provides two-way signal transmission within the same spectral band. This requires a passive architecture without amplifiers. In this case, the fiber node connects to a single series of multiport taps. Without any amplifiers that require diplex filtering, both upstream and downstream signals can share the part of the same spectrum (108 MHz to 684 MHz in up to three 192 MHz sub-bands in the FDX band) but with the same directivity of the conventional architecture.

The FDX DOCSIS PHY layer design and performance detailed analysis is discussed in [1]. An example of one coaxial branch of a Node + 0 architecture and model used in [1] is shown in Figure 17.

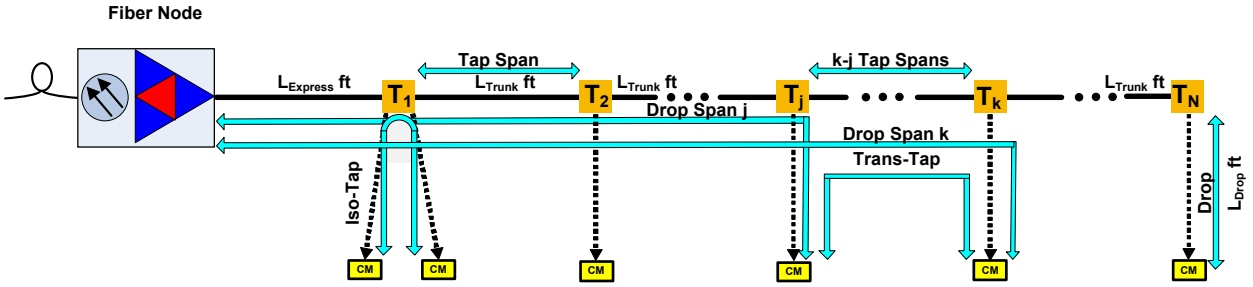

**Figure 17 – FDX Interference Analysis Model in the Node + 0 Network**

This model is used to analyze co-channel interference (CCI) between cable modems (CMs) both across the same tap and different taps to calculate SNR and bit-loading (i.e. spectral efficiency). Also calculated is the self-interference resulting from transmitting and receiving signals including reflections (echoes) within the same frequency bands in the node, and adjacent channel and leakage interference (ACI and ALI) within adjacent frequency bands in each modem. It is shown that these interference levels need to be sufficiently suppressed through Echo Cancelation (EC) to obtain high SNR and bit-loading of both the upstream and downstream signals in the FDX band.

The DOCSIS 4.0 FDX allocated spectrum bandwidths can be configured as shown in Figure 18. Non-allocated spectrum is shown within the FDX band between the highest frequency of the FDX allocated spectrum and 684 MHz. There are no US channels in the non-allocated spectrum of the FDX band.

An FDX Node must be able to place either SC-QAM or non-FDX OFDM channels in the non-allocated spectrum of the FDX band with RF performance requirements specified in this section.

An FDX CM in FDX mode is not required to receive either SC-QAM or non-FDX OFDM channels in the non-allocated spectrum of the FDX band.

The FDX transition band is the spectrum between 684 MHz and 804 MHz. It is possible that performance in this band could be impaired compared to a compliant DOCSIS 3.1 CM. As such, performance in the FDX transition band for an FDX CM operating in FDX mode is not specified.

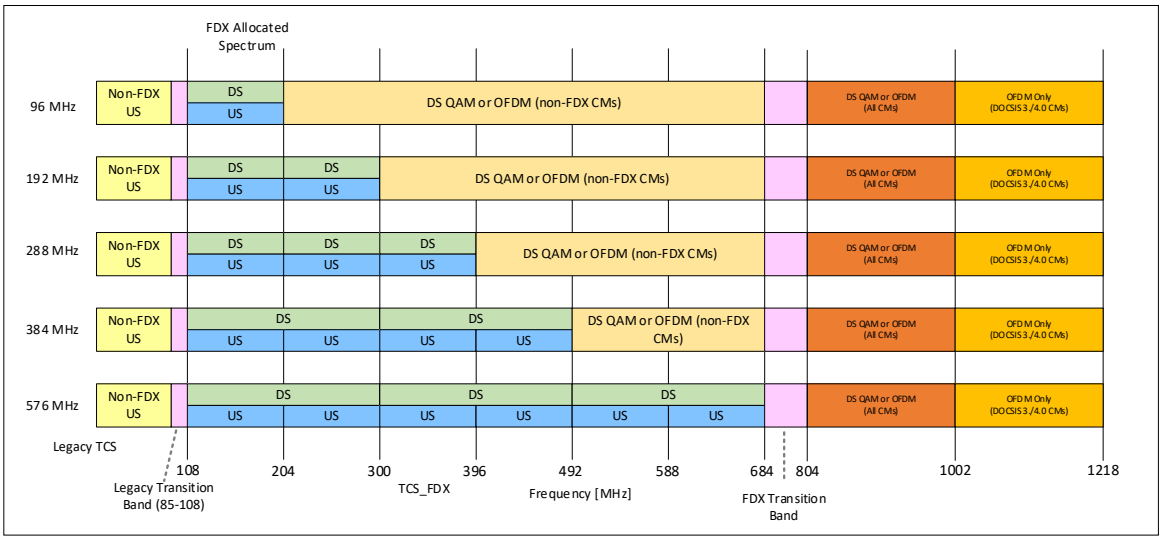

**Figure 18 – Configurable FDX Allocated Spectrum Bandwidths**

An example of an initial FDX spectrum allocation for the 192 MHz allocated spectrum of Figure 18 is shown in Figure 19. The DOCSIS 4.0 FDX specification always starts the first of three sub-bands in the FDX band at 108 MHz. Video SC-QAM channels are supported in the lowest downstream frequency band above the FDX allocated spectrum bandwidth. This initial upgrade, supporting one allocated FDX sub-band, has two Resource Blocks (RBs). Each can be set to either the upstream or downstream direction.

The first Resource Block Assignment (RBA) in the 108 MHz to 204 MHz is set to a static upstream direction. The second RBA in the 204 MHz to 300 MHz sub-band can be set dynamically to either the downstream or upstream direction. Full duplex operation in the network branch of Figure 17 is therefore possible within this second RB, if two or more Interference Groups (IGs) can be divided up between two Transmission Groups (TGs) that have low Co-Channel Interference (CCI). This would allow one CM in one TG to transmit upstream while all CMs in the other TG receive downstream.

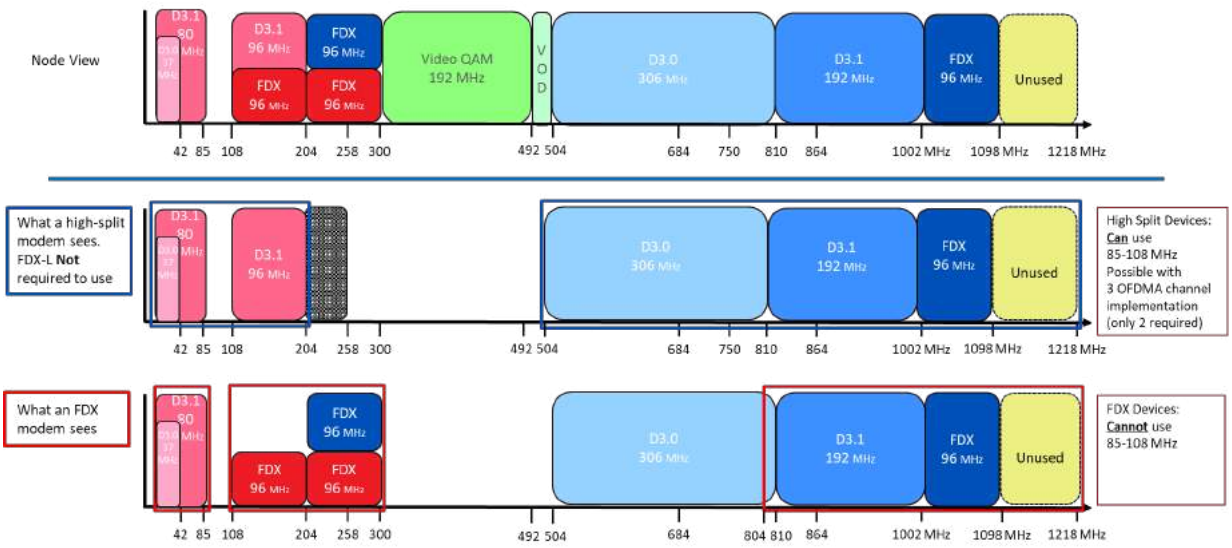

**Figure 19 – RF Spectrum: FDX with Sub-Split, Mid-Split and High-Split – 1.1 GHz Plant**

The reason to set the first RB to a static upstream direction is to allow high-split CMs that were added to the network before the initial FDX upgrade to continue to share the 108 MHz to 204 MHz band with FDX CMs. If this RB could be assigned to the downstream direction and if the high-split CM was in the same TG, then that CM could not transmit when the RBA was set to the downstream direction.

In order to determine if a high-split CM was in the same TG as an FDX CM, the high-split CM would have to participate in the sounding process, along with the FDX CMs. This sounding capability in a high-split CM requires a software upgrade to a legacy DOCSIS 3.1 cable modem (FDX-L) which can transmit in the 108 MHz to 204 MHz Full Duplex upstream channels and receive in the 258 MHz to 684 MHz Full Duplex downstream channels in a high-split access network, or it can receive in the 108 to 684 MHz Full Duplex downstream channels in a mid-split access network with no access to upstream Full Duplex Channels.

As shown in Figure 19, FDX downstream reception is disallowed in the first RB. Only upstream transmissions from either high-split CMs or FDX CMs is allowed. High-split downstream reception is only allowed above the allocated FDX band, where no upstream transmission are present in the DOCSIS 3.0 SC-QAM band above 504 MHz. Therefore no FDX-L software upgrade is needed to support sounding in the high-split CMs. There is never an opportunity for a high-split CM to transmit in a frequency that can be used to receive downstream by FDX CMs. Conversely there is no FDX upstream transmission in the high-split downstream band above the FDX allocated spectrum band.

As previously stated above, an FDX CM in FDX mode is not required to receive either SC-QAM or non-FDX OFDM channels in the non-allocated spectrum of the FDX band. So an FDX CM operating in the RF spectrum allocation of Figure 19 receives downstream above the FDX transition band starting at 804 MHz.

This initial FDX upgrade to a Node + 0 node provides FDX CMs with 192 MHz of additional upstream spectrum to the 5 MHz to 85 MHz legacy upstream spectrum and 192 MHz of additional FDX downstream spectrum to the legacy high-split downstream spectrum. This upgrade also provides high-split CMs with 96 MHz of additional FDX downstream spectrum to the legacy high-split downstream

spectrum -- but loses 23 MHz of the upstream spectrum from 85 MHz to 108 MHz, in the original 199 MHz upstream band from 5 MHz to 204 MHz.

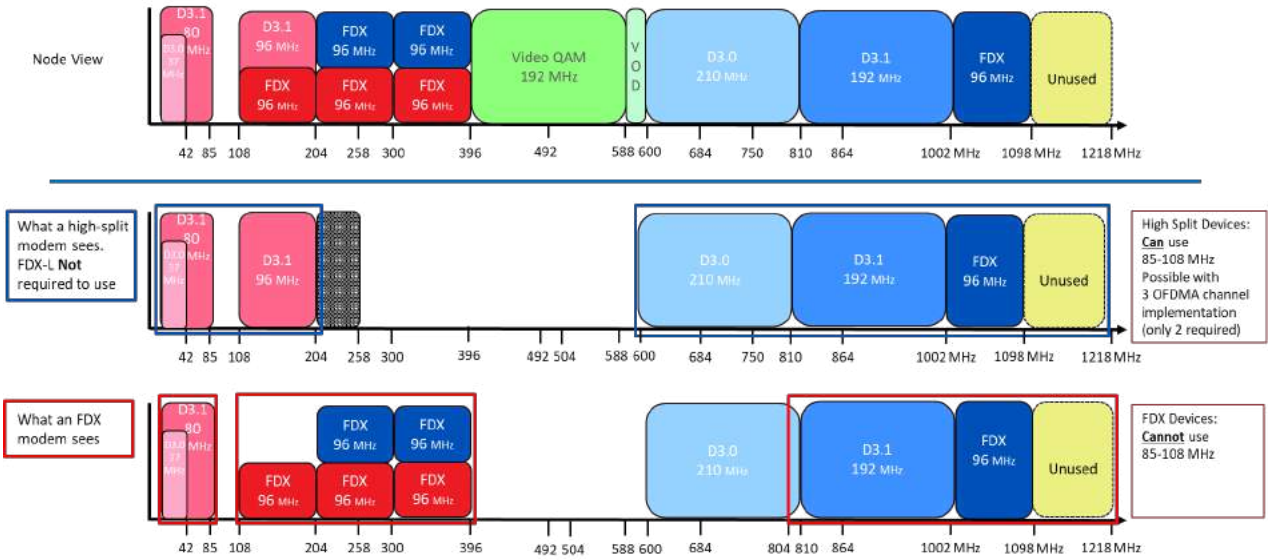

**Figure 20 – RF Spectrum: FDX with Sub-Split, Mid-Split and High-Split – 1.2 GHz Plant**

Future demand for bandwidth growth can be provided by reallocating the same total RF spectrum as shown in Figure 20. This next upgrade preserves the video SC-QAM channels moved up by 96 MHz to allocate that spectrum to a third 96 MHz FDX RB. The DOCSIS 3.0 SC-QAM channels are reduced by the same 96 MHz as more customers choose to upgrade their DOCSIS 3.0 service tier to the high-split tier or higher still to the FDX tier.

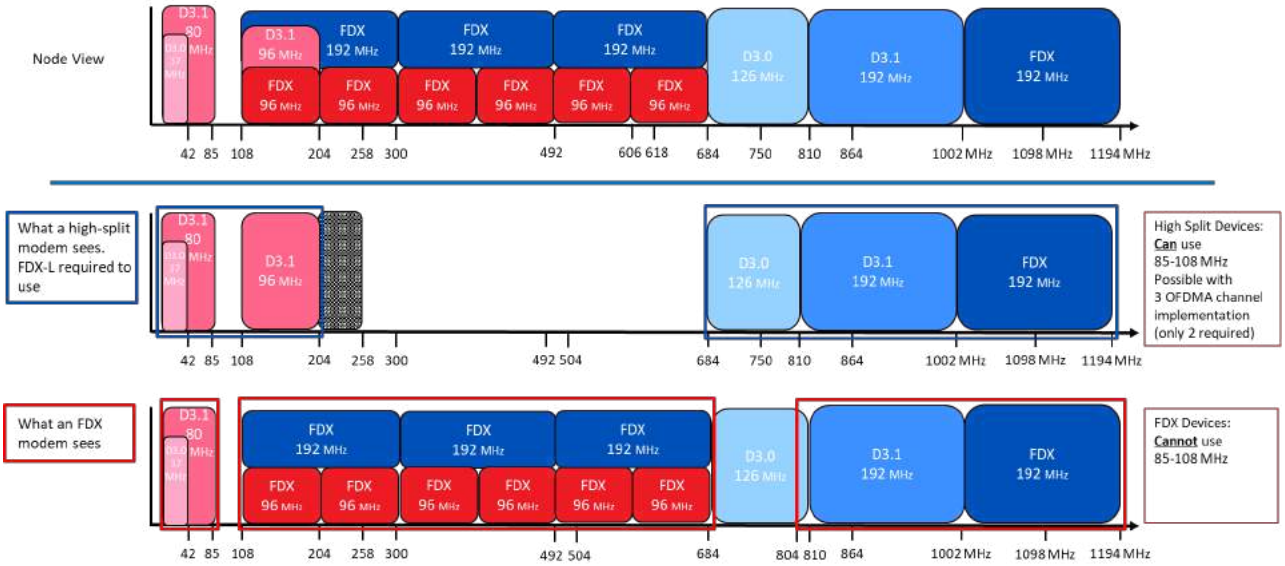

**Figure 21 – RF Spectrum: Full FDX with Sub-Split, Mid-Split and High-Split – 1.2 GHz Plant (Compliant with DOCSIS 4.0 Spec)**

Continued demand for more bandwidth in the future can be provided by reallocating the same total RF spectrum as shown in Figure 21. This next upgrade removes the video SC-QAM channels to allocate that spectrum to a third 192 MHz FDX RB, and doubles the bandwidth of each of the first two FDX RBs to 192 MHz. The DOCSIS 3.0 SC-QAM channels are reduced by 84 MHz as more customers choose to upgrade their DOCSIS 3.0 service tier to the high-split tier, or, higher still, to the FDX tier. However, in this upgrade, the high-split CMs must be software-upgraded to FDX-L, because the 108 MHz to 204 MHz high-split upstream shares some of the downstream FDX bandwidth in the first FDX RB.

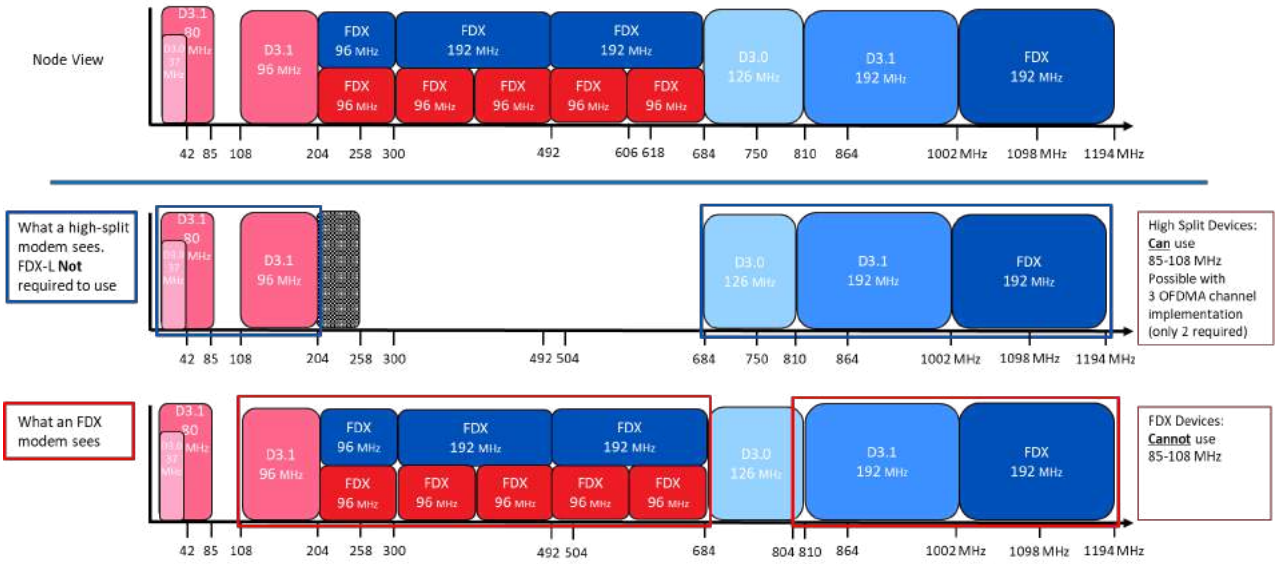

**Figure 22 – RF Spectrum: Full FDX with Sub-Split, Mid-Split and High-Split – 1.2 GHz Plant (Non-Compliant with DOCSIS 4.0 Spec)**

An alternative to the full FDX upgrade of Figure 21 is shown in the nearly full FDX upgrade of Figure 22. In this RF configuration, the FDX band starts at 204 MHz instead of 108 MHz, sacrificing 96 MHz of FDX bandwidth. This obviates the need to upgrade the software of all high-split CMs to FDX-L, as the high-split CMs do not share any upstream bandwidth with the FDX downstream band. However, this configuration does not start the FDX lower band edge, at 108 MHz, which, strictly speaking, is not compliant with the DOCSIS 4.0 spec. But this should not require a hardware change to the FDX CM or CMTS.

# 8. Optimizing Full Duplex Architecture and Operation

## 8.1. FDX Modem Downstream Legacy Band Receive Power

In December 2018, a proposal to the CableLabs FDX Working Group by CM silicon providers with two options, A and B, was presented for the CM architecture, which proposed changing either the CM input minimum return loss or the maximum insertion loss into the CM F-connector when operating in FDX mode. The two options discussed are shown in Figure 23. The difference in the options was in the placement of the directional coupler for splitting and combining upstream and downstream signals in the FDX band.

If the FDX diplex filter common port is connected to the CM F-connector, and the diplex filter legacy downstream port is connected to the legacy downstream receiver, as shown in Option A, then the only insertion loss seen at the legacy band receiver is the small diplex filter insertion loss. However, the return

loss in the 684 MHz to 804 MHz filter transition band between the FDX band and the legacy downstream band can be quite low, approaching a couple dB. This would reflect most of the signal power back to the drop, rendering the legacy downstream in the transition band largely attenuated and unreceivable by the FDX CM. But the legacy downstream band from 804 MHz to 1218 MHz incurs very small insertion loss.

If the directional coupler common port is connected to the CM F-connector, and the 7 to 10 dB directional coupler tap is connected to the FDX/legacy band diplexer, as shown in Option B, then the coupler tap insertion loss in incurred across the entire FDX and legacy downstream band from 804 MHz to 1218 MHz. However, the return loss of the coupler common port is greater than 20 dB.

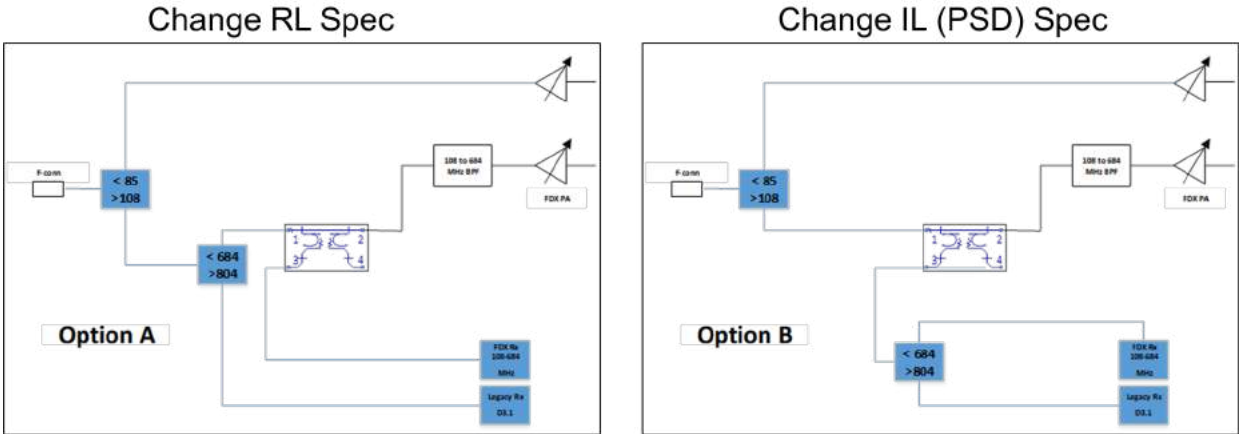

**Figure 23 – Specification Topic, CPE Architecture: Option A vs Option B Discussion**

Option B was chosen, which significantly attenuates the entire legacy downstream band. This led to specifying a higher minimum CNR, by up to 1.5 dB, and required input power levels to increase by up to 7 dB above the DOCSIS 3.1 downstream spec. The solution to this disparity in legacy downstream performance was to determine if a filter could be designed with a return loss that meets or exceeds the CM return loss spec of 6 dB. A CM analog front end architecture with such a filter characteristic was proposed by this author and is shown in Figure 24.

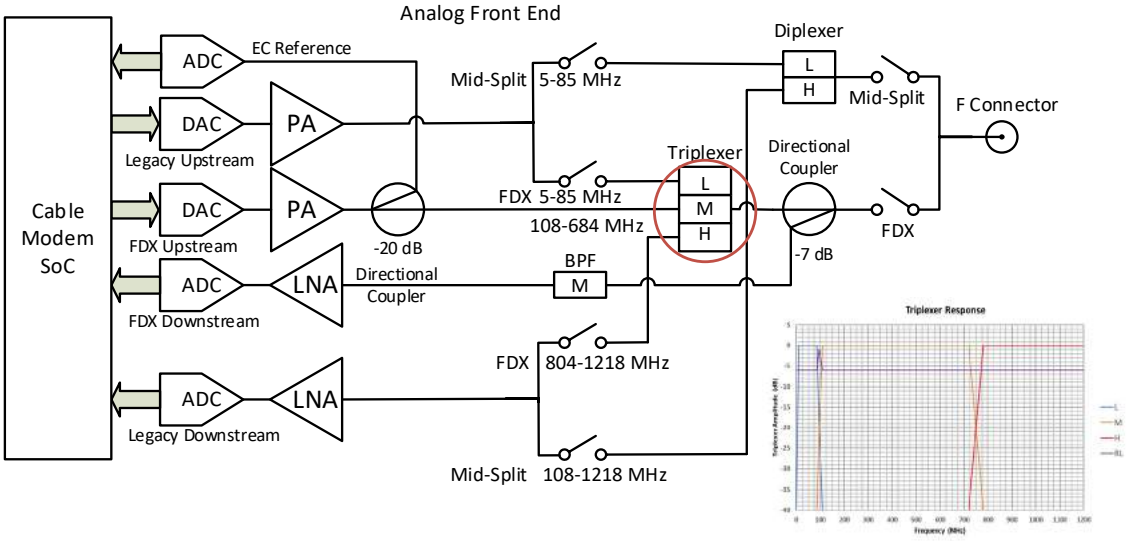

**Figure 24 – CM Architecture with Filter Response Avoiding Legacy Downstream Loss**

Multiple vendors obtained filters from third parties that meet the 6 dB minimum return loss spec across the entire band from 108 MHz to 1218 MHz. Thus the DOCSIS 4.0 legacy downstream spec was restored to the original DOCSIS 3.1 spec in the 804 MHz to 1218 MHz band.

## 8.2. FDX Modem FDX Band Receive Power

The directional coupler tap insertion loss for the legacy downstream can be avoided with the CM architecture of Figure 24 discussed in the previous section. However, the FDX downstream band will necessarily incur the insertion loss of the directional coupler tap. There are several mitigation approaches to increase the input power level to the FDX downstream receiver:

1. Decrease the directional coupler tap loss with a splitter or power divider/combiner
2. Switch the coupler inputs so the through port feeds the downstream receiver and the power amp transmits through the tap port
3. Increase the FDX band downstream power spectral density to counteract the coupler tap loss.

The first two approaches have the drawback that they require significantly higher total composite power from the upstream power amplifier. This total power spread over a wide bandwidth up to 684 – 108 = 576 MHz is specified to supply 65 dBmV minimum. Increasing power amp output by 4 to 10 dB significantly increases the modem input power dissipation and heat. The last approach does not need to modify the modem architecture and places the increased downstream power requirements on the node.

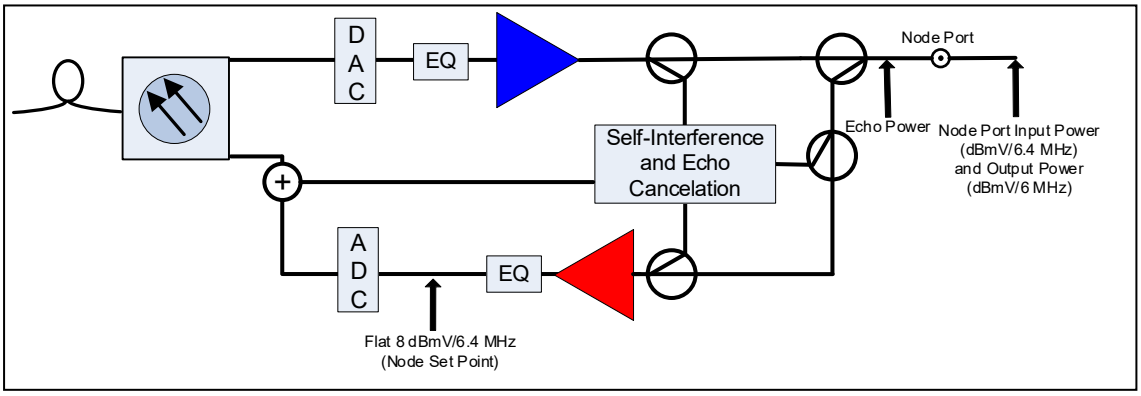

**Figure 25 – FDX Remote PHY Node Functional Block Diagram**

Figure 25 depicts a high level functional architecture for an FDX Remote-PHY node. To overcome the frequency-dependent attenuation of the hardline coax, which increases with increasing frequency, the downstream DAC provides digitally-generated uptilt and may be cascaded with an analog equalization filter (EQ) at the input of the downstream power amplifier (PA).

The resultant power spectral density (PSD) for two PSD vs frequency profiles at the node port is illustrated in Figure 26 and Figure 27. The nominal FDX PSD profile for a Node + 0 node output is a linear straight line, with 21 dB uptilt from 37 dBmV/6 MHz at 108 MHz, to 58 dBmV/6 MHz at 1218 MHz, with a Total Composite Power of 73.8 dBmV in both figures.

Figure 26 shows a “sawtooth” shape with a 7 dB boosted level over the nominal FDX PSD profile in the FDX band, from 108 MHz to 684 MHz, and a 3 dB attenuated level below the nominal FDX PSD profile from 876 MHz to 1218 MHz. The 7 dB boost matches the 7 dB attenuation of the CM directional coupler tap port in the FDX band to restore the receive level equal to the legacy downstream band, where legacy

DOCSIS 3.0 and 3.1 CMs receive in the 684 MHz to 876 MHz band for 750 MHz and 860 MHz cable plants.

Note that the level for legacy modems is unchanged in the band from 684 to 876 MHz where modems receive their downstream currently. Also note that the Total Composite Power of 73.8 dBmV is preserved with a larger boost at the lower FDX frequencies and a smaller attenuation at the highest frequencies above the current legacy downstream band. The reason for this behavior is that most of the power loading results at the highest frequencies due to the uptilted PSD. So no additional output power from the amplifier is required when balancing the higher boosted low frequencies with the lower attenuated high frequencies.

| Downstream Start Frequency (MHz): | 108 |
| Downstream Stop Frequency (MHz): | 1218 |

| | |
|---|---|
| Power @Downstream Start Freq 108 MHz: | 41.0 |
| Tilt Step-Down Low Frequency (MHz): | 684 |
| Tilt Step-Down Low Amplitude (dB): | 4.0 |
| Tilt Step-Down High Frequency (MHz): | 1002.0 |
| Tilt Step-Down High Amplitude (dB): | 5.0 |

| | |
|---|---|
| Total Composite Power (dBmV) - Linear: | 77.8 |
| Total Composite Power (dBmV) - Sawtooth: | 73.8 |
| Total Composite Power (dBmV) - FDX: | 73.8 |

**Figure 27 – FDX Node RF Level with FDX Band Downstream Level Boosted +4 dB**

Figure 27 shows a “sawtooth” shape with a 4 dB boosted level over the nominal FDX PSD profile in the FDX band, from 108 MHz to 684 MHz, and a 1 dB attenuated level below the nominal FDX PSD profile from 1002 MHz to 1218 MHz. The 4 dB boost partially restores the 7 dB attenuation of the CM

directional coupler tap port in the FDX band, to partially restore the receive level closer to the legacy downstream band where legacy DOCSIS 3.0 and 3.1 CMs receive in the 684 MHz to 1002 MHz band for 1 GHz cable plants. The 3 dB reduction in level will reduce the received OFDM bit-loading by about 1 bit per symbol.

Note that the level for legacy modems is again unchanged in the band where modems receive their downstream currently. Also note that the Total Composite Power of 73.8 dBmV is preserved in this case as well with a larger but less than the previous boost at the lower FDX frequencies and a smaller but less than the previous attenuation at the highest frequencies above the current legacy downstream band in 1 GHz cable plant. So no additional output power from the amplifier is required in either case.

## 8.3. Signal-to-Echo Ratio Optimization

In the previous section, it was noted that increasing the node downstream PSD level increases the CM (downstream) Signal-to-(Upstream) Interference Ratio. The CM interference consists of self-ACI and its echoes (reflections) plus Adjacent Leakage Interference (ALI) and its echoes when transmitting upstream signals in one RBA while receiving downstream signals in another. The CM never transmits and receives in the same RBA whose direction is assigned either upstream or downstream dynamically. The CM essentially is working in frequency division duplex (FDD) mode but in a dynamically scheduled way without switched diplex filters and their associated transition bands but instead with echo cancellation and no guardbands and their associated spectral efficiency loss.

While this will increase the Signal-to-Echo Ratio and spectral efficiency (bit-loading) in the CM downstream receiver, the increase in the PSD in the node will decrease the Signal-to-Echo Ratio in the node upstream receiver. This ratio in the node is much lower as the upstream and downstream signals are full duplex with the co-channel interference ratio being orders of magnitude higher than non-overlapping adjacent signal emissions of the CM. Thus the node requires very high dynamic range echo cancellation.

Figure 28 shows an FDX network simulation we developed of the Upstream Node Signal/Interference Ratio vs FDX Downstream Band PSD Boost. The top pair of graphs are for a +4 dB boost; the middle pair of graphs are for no boost or a linear uptilt PSD; and the bottom pair of graphs are for a -4 dB attenuation. The left side shows all upstream and downstream signal levels, downstream echoes, and leakage across the FDX directional coupler ports, and the total combined interference level into the upstream received signal at the node. The right side shows the resulting calculated upstream Signal-to-Interference Ratio (SIR) of the node. These results show the direct correlation of the downstream node PSD level in the FDX band and the resulting upstream SIR of the node in that band.

For a +4 dB downstream PSD boost, the SIR averages from -20 dB at 108 MHz to -28 dB at 684 MHz. The tilt in the SIR is due to the downstream PSD uptilt launched by the node power amp and relatively flat upstream received signal. For a 0 dB downstream PSD boost (strictly linear without step-downs), the SIR averages from -16 dB at 108 MHz to -24 dB at 684 MHz. For a -4 dB downstream PSD attenuation, the SIR averages from -12 dB at 108 MHz to -20 dB at 684 MHz. So decreasing the PSD level in the FDX downstream directly increases the SIR dB for dB.

Figure 29 shows an FDX network model we simulated of the Downstream CM Signal/Interference Ratio vs FDX Downstream Band PSD Boost. The top pair of graphs are for a +4 dB boost; the middle pair of graphs are for no boost or a linear uptilt PSD; and the bottom pair of graphs are for a -4 dB attenuation. The left side shows all upstream and downstream signal levels, downstream echoes, and leakage across the FDX directional coupler ports, and the total combined interference level into the downstream received signal at the CM. The right side shows the resulting

 

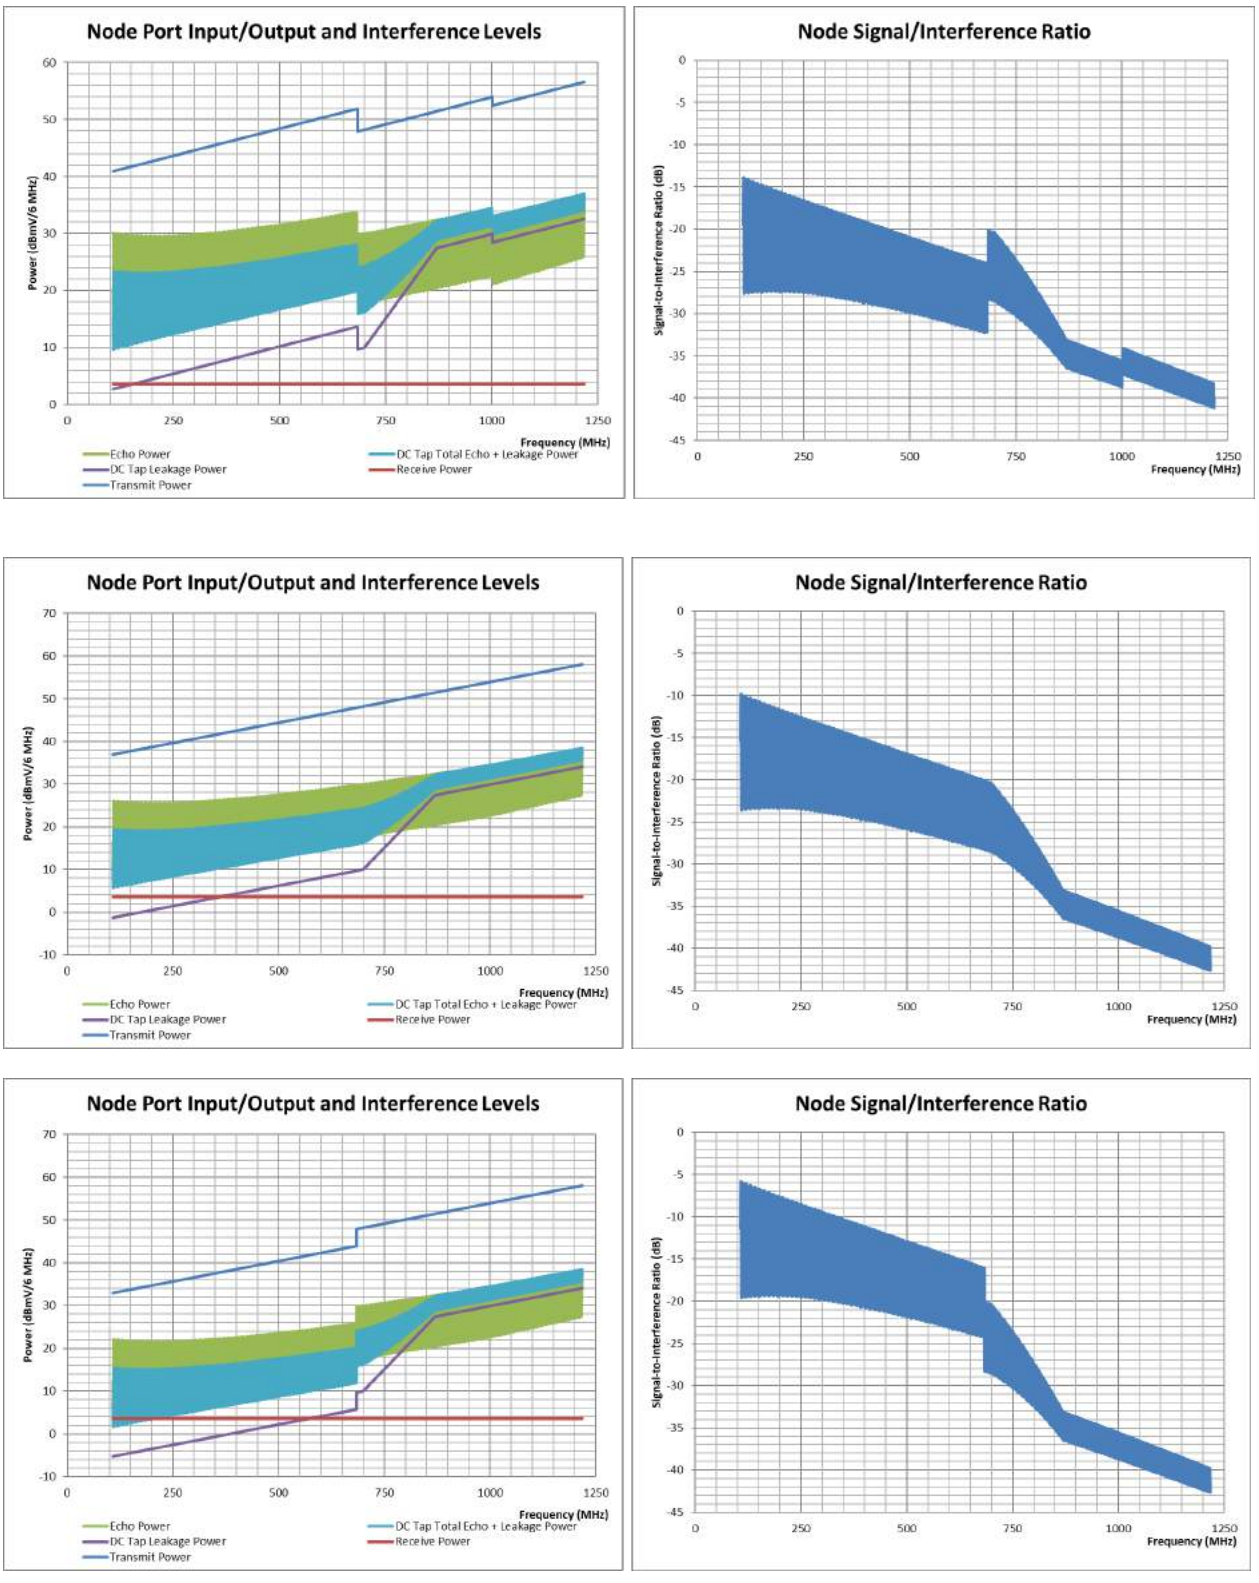

**Figure 28 – Upstream Node Signal/Interference Ratio vs FDX Downstream Band PSD Boost (Top: +4 dB Boost, Middle: No Boost – Linear, Bottom: -4 dB Attenuation)**

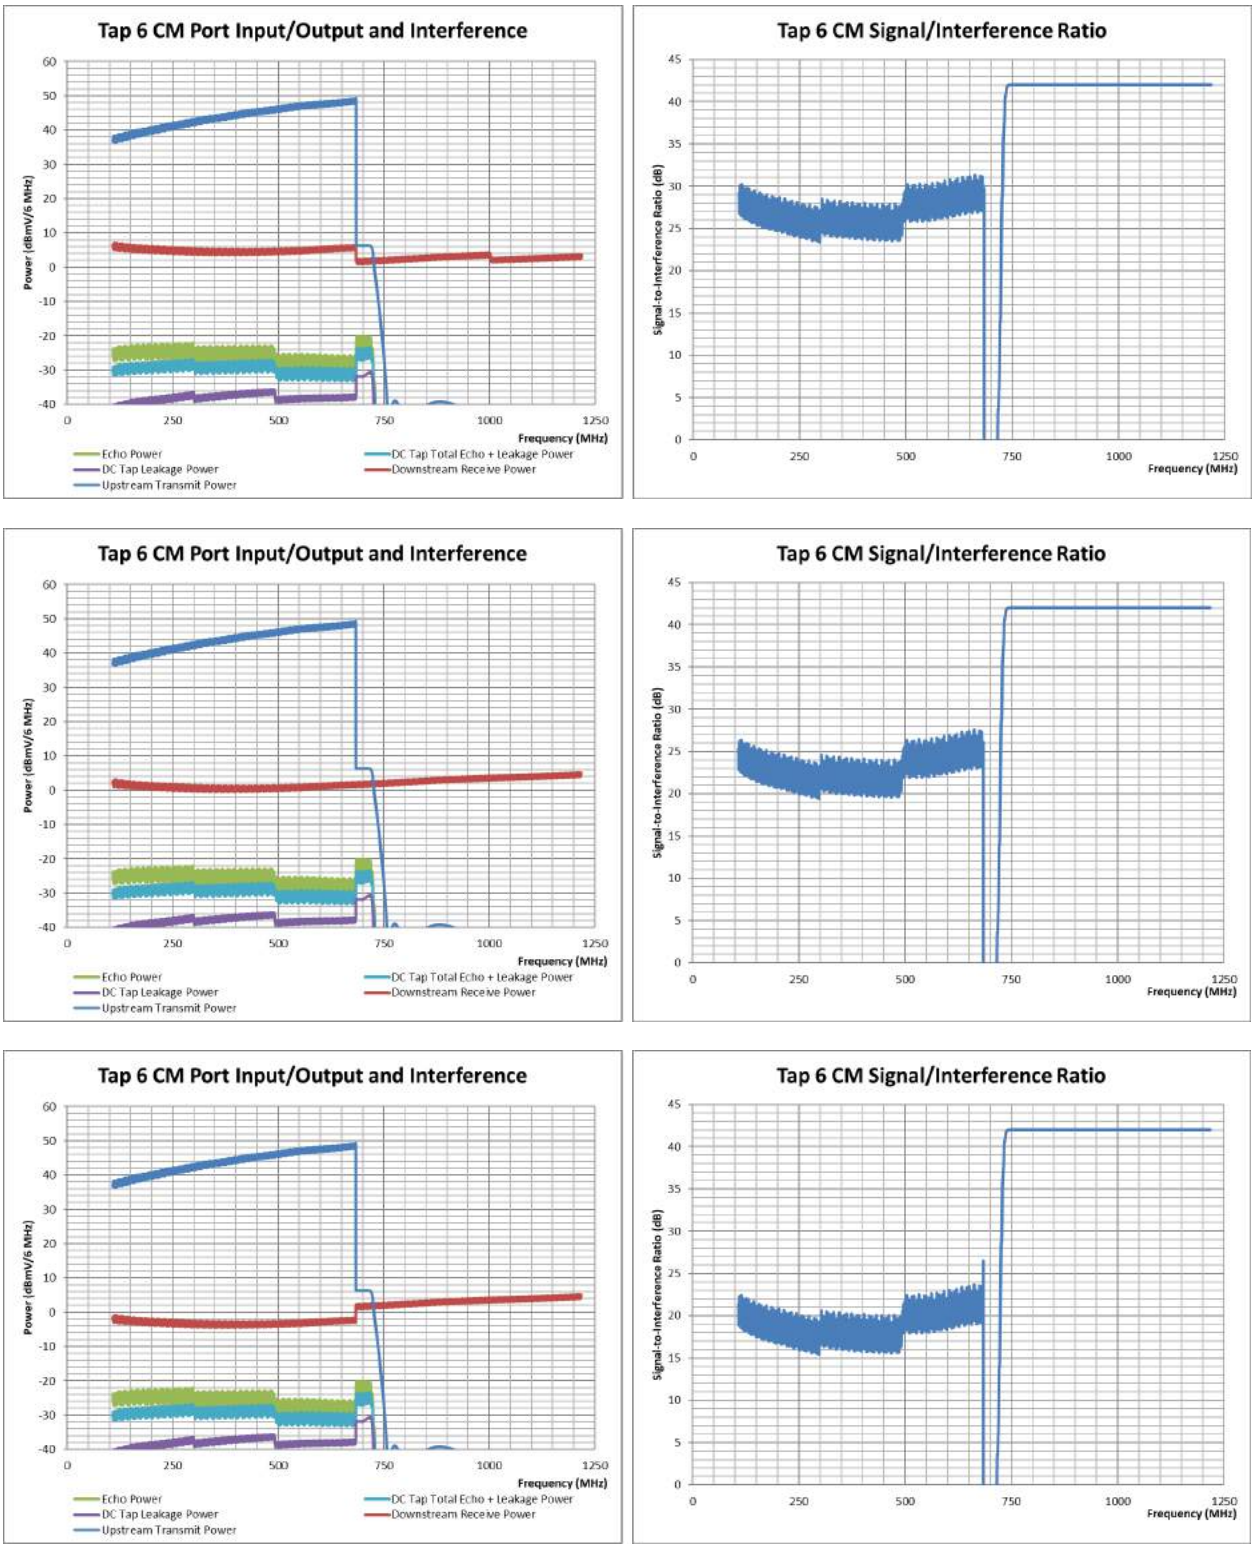

**Figure 29 – Downstream CM Signal/Interference Ratio vs FDX Downstream Band PSD Boost (Top: +4 dB Boost, Middle: No Boost – Linear, Bottom: -4 dB Attenuation)**

calculated downstream Signal-to-Interference Ratio (SIR) of the CM. These results show the direct correlation of the downstream node PSD level in the FDX band and the resulting downstream SIR of the CM in that band.

Unlike the node where the full duplex upstream and downstream signals are present in the same spectrum in the FDX band, with the high downstream launch power in the same spectrum as the upstream received signals render the SNR in negative territory, the CM operates in FDD mode. In this case, one of the three FDX sub-bands receives the downstream signal while the other two sub-bands are transmitting upstream, causing adjacent noise and emissions. And, there are echoes into the downstream receiving sub-band resulting in a positive (but low) SNR. Thus the echo cancellation in the node must have a cancellation depth of the interference in excess of 50 dB, while the CM, without self-induced co-channel interference instead requires a cancellation depth of adjacent channel interference of only around 20 dB. The details of such an analysis can be found in [1].

For a +4 dB downstream PSD boost, the SIR averages from 23 dB to 31 dB across the FDX band. For a 0 dB downstream PSD boost (strictly linear without step-downs), the SIR averages from 20 dB to 27 dB across the FDX band. For a -4 dB downstream PSD attenuation, the SIR averages from 16 dB to 24 dB across the FDX band. So decreasing the PSD level in the FDX downstream directly decreases the SIR approximately dB for dB for the CM.

This end-to-end FDX system analysis demonstrates the trade-off one can make for improving the reception on the CM side while degrading the reception on the other (node) side, and vice versa, using a different stepped PSD downstream profile at the node, tailored to the desired directional bit-loading increase while lowering the PSD slightly in the highest frequencies to maintain a constant total composite power in the node. The choice depends on the objective desired – higher spectral efficiency and bit-loading of the chosen signal direction (upstream or downstream) at the expense of the other virtually dB for dB. Note that 3 dB change in SNR corresponds to one bit per symbol difference in bit-loading.

# 9. Conclusion

The transition from conventional sub-split Node + N systems to mid-split Node + 0 systems enables several steps toward the ultimate goal of FDX DOCSIS 4.0 that will significantly increase the upstream bandwidth to multi-gigabit speeds with high throughput. The first step in this transition has been described, starting from conventional sub-split cable systems to mid-split systems to high-split systems and eventually to a phased approach to enabling FDX DOCSIS. The RF spectrum to support both legacy video and data services and the separation of the CMTS core functions that connect to Remote PHY (R-PHY) nodes using a Distributed Access Architecture (DAA) enables this transition in both conventional and Node + 0 networks.

The path to higher speed networks, while supporting legacy video and data consumer premises equipment was explained. Lab and field data was analyzed together to provide the confidence in layering these technologies in an evolutionary fashion. Some mitigation strategies involving signal design launched from the R-PHY node and their effectiveness were explained. Cable Modem architectures to optimize both FDX and legacy DOCSIS signals were explained. Accommodation of legacy video set-top boxes and in-home networking with MoCA in order to fully utilize the 1.2 GHz design bandwidth of our cable systems has been shown.

All of these intermediate steps prepare for the initial introduction of FDX technology in a phased deployment as capacity and speed demands continue to grow. Configurable FDX allocation of RF spectrum will continue to support legacy SC-QAM video, SC-QAM based DOCSIS 3.0, and

OFDM/OFDMA based DOCSIS 3.1 in a compatible and compliant way with an evolutionary path to transition to all IP video with FDX DOCSIS 4.0. Some optimizations of RF spectrum allocation and the conditioning of transmission and reception of FDX signals to improve the effectiveness of the echo cancellation technologies have been proposed. The evolutionary path to 10G networks using FDX DOCSIS 4.0 will enable our networks to grow with the ever increasing demand to support both existing and future services for our customers.

# 1. Introduction

Cable infrastructure is at the heart of voice, video, and Internet services. Subscribership across classic cable services has been evolving rapidly across our ecosystem, which prompted MSOs to invest in the development of new products and services that help enable diversification and initiate new subscriber growth.

As such there is burgeoning demand for enterprise class, wireless-based IoT platforms to enable operators to expand their product and service offerings to address the needs of the enterprise, SMB, B2B2C, and even the consumer market segments. Enterprise IoT platforms in particular are essential to enable adoption, when new, disruptive technologies are involved. The availability and use of DIY (Do-It-Yourself) or BYO (Bring-Your-Own) to support the large-scale enterprise IoT deployments is proving to be challenging, if not an impediment. Forcing or expecting adopters to locate, validate, deploy, and manage all the critical components, securely, slows adoption and inevitably growth. Further, Enterprise IoT platforms are particularly important when adopters require the ability to manage IoT offerings across multiple media, wireless or otherwise. As the IoT landscape evolves beyond devices that leverage broadband connections, facilitating the deployment of and offering a seamless, streamlined customer experience is difficult if not impossible if an operator is relying on a swivel chair approach. Enterprise class IoT platforms must offer the ability to manage the deployment and operations of a vast, virtual IoT network that span multiple geographic regions. A purpose built enterprise IoT platform must truly be an enabler of mission critical use cases across a wide range of verticals.

The vision outlined here is one that envelops the following:

- An Enterprise IoT Platform that enables global adoption and enablement
- Spans multiple media, mainly wireless
- Illustrates the need for scale and performance
- Couples in enterprise-class functionality
- Leverages best in class security

The vision components listed above are the core characteristics of any enterprise IoT platform that intends to fuel adoption and operation at scale, while enabling a broad base of market verticals -- from Quick Service Restaurant (QSR), to asset tracking pharmaceutical manufacturing and laboratories, all while spanning the use of multiple wireless media including LoRAWAN, BLE/Bluetooth, and others. Supporting multiple connectivity methods helps to uniquely address each vertical's specific challenges and operating environments.

The world is changing for MSOs, and so is the definition of IoT. More specifically, Enterprise IoT. How we plan for and build to support, manage, and operate Enterprise IoT is rapidly evolving, in lockstep with the demands set forth by our customers. These requirements range from touchless, automated solutions to enable temperature/humidity monitoring and high value asset tracking, to energy monitoring and management for cable infrastructure.

# 2. Definition of Enterprise IoT

The IoT (Internet of Things) carries a wide range of meanings and the term continues to evolve on practically a daily basis. For the purposes of this document, IoT will generally refer to the act of connecting or enabling the connection of a device to utilize the Internet or network, with the intent of interacting with a human or consumer. Or, according to Oxford Languages:

"The interconnection via the Internet of computing devices embedded in everyday objects, enabling them to send and receive data." [1]

Conversely, Enterprise IoT refers to the enabling of machines to interact and exchange data with other machines in a manner that may or may not be usable by a human. Further, the machines in the case of Enterprise IoT are not strictly required to have a direct connection to the Internet. However, the machines may leverage other elements to facilitate communications.

The Enterprise IoT is viewed by some [2] as the "next advancement in technology that enables physical 'things' with embedded computing devices (tiny computers) to participate in business processes for reducing manual work and increasing overall business efficiency."

An example of consumer-grade IoT, generally, is a video camera connected to the Internet or home network using Wi-Fi via a broadband connection that supports two-way video and audio. Whereas, Enterprise IoT is best exemplified by a wireless (not necessarily Wi-Fi) temperature and humidity sensor that transmits data periodically from multiple locations in a QSR to automate food monitoring. The bandwidth, connectivity model, wireless characteristics, and power consumption vary widely across these and numerous other scenarios.

# 3. Wireless Communication Considerations

Not all wireless communication protocols are created equal, nor do they need to be. Further, it should not be expected that a single wireless communication protocol be able to universally address every technical and/or business use case. Each form of wireless communications carries its own distinct pros and cons. A summary is provided here, as an in-depth compare-and-contrast of IoT wireless protocols is beyond the scope of this document.

## 3.1. 2.4 GHz

Wi-Fi, BLE/Bluetooth, Zigbee all commonly support wireless communications using the 2.4 GHz frequency band. Characteristics include:

- Capable of high bandwidth, two-way communications
- Limited range, limited mobility
- Reasonable propagation for short range wireless communications
- Higher power consumption

## 3.2. Cellular

- Capable of high(er) bandwidth, two-way communications
- Extend range and mobility
- Reasonable propagation
- High power consumption

## 3.3. ISM (Industrial, Scientific and Medical) Bands

- Capable of low bandwidth, limited two-way communications
- Extended range, mobility support varies
- Optimal propagation for long range wireless communications
- Low power consumption

Given the nature of this document the above focuses on the technical considerations for each type of wireless communications protocol. Cost, while of out scope, is most certainly an essential detail that must be factored into any wireless protocol evaluation.

# 4. Enterprise IoT Platform

Most every wireless communications platform consists of one or more of the following:

1. Wireless devices including sensors or endpoints that typically send and/or receive data
2. Wireless base stations or gateways that enable or facilitate communications to and from wireless devices or remote systems
3. Wireless controllers and related sub-systems that govern the wireless communications between wireless devices and base stations

Common misconceptions suggest that one or all of the above adequately provide the tools required to enable Enterprise IoT for an operator or adopter. In fact, regardless of the wireless communication chosen, the attributes listed above only provide the building blocks to enable basic wireless communication for an Enterprise IoT environment. A platform approach supporting any form of wireless communication must minimally account the following:

- Heterogeneity regarding wireless communications as well as from a device and base station perspective
- Operationalization including measurements and monitoring ensuring service quality and reliability

The following sections further delve into key factors that must be considered when evaluating and/or building a platform oriented for wireless, enterprise IoT.

## 4.1. Integration

Deep integration is essential to ensure the effectiveness of any platform that will effectively be utilized to manage large scale, complex deployments. While integration with internal operational support systems (OSSs) and business support systems (BSSs) is critical, the context here refers to integration with the core hardware elements that truly enable large scale adoption. Wireless communication integration can occur in multiple ways.

First and most common is adherence to a common wireless communication standard. In the case of LoRAWAN® [3], this would imply that a given device or sensor, gateway or base station, and LoRAWAN Network Server (LNS) have all implemented compatible versions of the communication specifications. Compliance at this level simply ensures that elements that are attempting and expecting to interact, can do so.

Alternatively, deeper integration across this confluence of key elements -- where software meets the embedded systems (or hardware) -- affords adopters a “surgical” level control and flexibility. Both matter to confidently, reliability, and seamlessly managing enterprise IoT deployments. This inevitably requires that some form of a platform’s software components reside natively on critical embedded systems. Embedded system integration, in this case, specifically refers to the integration of platform functionality that spans sensors as well as base stations.

## 4.2. Security

Credible enterprise IoT platforms must tout the ability to secure communications end-to-end. While many of the individual elements available today that can be used as piece parts to orchestrate an enterprise IoT deployment are secure, component-level security does not assure that the concatenation of those elements carries the same level of end-to-end security. Nor does this guarantee that critical aspects have not been overlooked. End-to-end visibility across an entire platform provides security assurance specific to data integrity and communications. Data integrity ensures that the data received is, in fact, the data that was sent, while data communications ensures that the transport mechanisms carrying the enterprise IoT data in uncompromised. Further, control of data encryption by the originator (or customer) from a sensor that is independent of transmission or delivery (by an operator) extends a level of independence that secure, trusted enterprise IoT platforms are expected to support. The capability to securely provision sensor communications while maintaining trust must not be overlooked.

In order to maintain the integrity and value that a secure wireless communications protocol affords it must be coupled with a platform that directly enables its streamlined use. Manual configuration and "swivel chair operations" create process gaps that inevitably result in security challenges.

## 4.3. Management

Enterprise IoT management, broadly speaking, builds strongly but not solely on the concept of integration and is the backbone for security. The depth of integration is directly proportional to an organization's ability to manage key aspects of their Enterprise IoT deployment. Key considerations include:

- Remote, over-the-air firmware management for both sensors and base stations
- Security management and monitoring
- Configuration management for wireless IoT communications
- Base station backhaul connectivity and configuration management

In a world where new vulnerabilities and viruses are discovered on practically a daily basis, the ability to remotely update your IoT infrastructure on a scheduled, automatic basis is essential to ensuring that your deployment is robust. Updating firmware and configurations over the air (or over any backhaul network) can be a complicated affair. Further, with the rapid evolution across the wireless communication spectrum, where the likes of 5G, Citizens Band Radio Service (CBRS), and Narrowband (NB) IoT are becoming a reality, it is perhaps a forgone conclusion that adopters will require a unified platform to enable the management across any and all wireless communication protocols.

Finally, where adopters are choosing LPWAN alternatives like LoRAWAN, given its favorable performance characteristics over long distances, superior propagation, and optimal power consumption, there are in fact bandwidth considerations that must be accounted for from a management perspective. Namely, facilitating firmware updates over the air for LPWAN must be implemented diligently. In an Enterprise IoT sense, diligence means leveraging partial or delta updates in lieu of full image updates, as a means to dramatically reduce update times, positively impact power consumption, and improve hardware life expectancy.

## 4.4. Performance

An enterprise IoT offering that cannot perform well impedes adoption and growth. The advent of inexpensive, battery powered devices that can last for 5 to 10 years (or more) introduces many new performance challenges. The need to provision large volumes of inexpensive devices with a lengthy

lifetime translates into millions if not billions of sensors that need to be managed over time. This includes high performance provisioning to support rapid deployments and the processing of data from the same. Processing data from an exponentially growing population of enterprise IoT sensors has the potential to yield billions of data payloads -- daily.

Succinctly put, solving problems, creating value, and generating revenue are tightly coupled with the rate at which sensors and base stations can be provisioned and deployed. One of the main purposes of any high-performance enterprise IoT platform is to enable the currency of enterprise IoT, data, to flow as quickly and in as timely a manner possible. The frequency of data transmissions is often a byproduct of the market vertical or use case.

Essential characteristics related to Enterprise IoT performance include:

- Web-scale Application Program Interfaces (APIs) and backend implementations that support large volumes of provisioning events that enable sensors instantaneously
- Intuitive user interfaces allowing for streamlined, high-performance management
- Carrier-grade base station performance and sensor data processing ensuring that payload delivery performance is optimize globally

### 4.5. Scale

Global scale and locally optimized performance and resiliency are absolute musts for modern day enterprise IoT adopters. Enterprise IoT adopters today have different characteristics and requirements than consumer IoT adopters. Enterprise IoT adopters are multi-national, global corporations that are seeking to form partnerships and build relationships with similarly-sized firms that are able to service their needs around the globe, not just in one region specifically. The scope of scale reaches far beyond, but is anchored in, the scale and performance of an enterprise IoT platform. Scale encompasses service (installation, deployment, etc.), support, and global capacity.

Global scale is, in many ways, a culmination of the characteristics outlined throughout this document. Assembling a platform and business to address the evolving needs of enterprise IoT adopters globally starts with borrowing from the experiences in scaling other businesses, including Internet, voice, and video. Scaling Enterprise IoT, while sharing many similarities with scaling some of the largest data, voice, and video networks in the world, carries many unique nuances. Most Enterprise IoT platforms and networks are designed to support enormous volumes of small payloads originating from sensors across a large heterogenous (global) customer base. Further, ensuring that base stations, which route the lifeblood of most LPWAN networks, have robust, reliable backhaul is essential to every enterprise IoT deployment.

## 5. Conclusion

Orchestrating a large-scale Enterprise IoT deployment is a complex endeavor. Choosing which wireless communication protocol(s) best address requirements alone is a complex task. Identifying or building a platform that enables an organization to manage it globally increases the sophistication, timing, and investment. Factoring in carrier-class scale, performance, and best-in-class embedded systems like sensors and base stations is also critical to any well-intentioned plan. Ensuring that all embedded systems are qualified regionally, and that all regulatory guidelines are adhered to, are significant tasks.

It is important to not discount the effort involved in operationalizing the use of Enterprise IoT to generate revenue or accelerate cost savings across your own or your customer's enterprise. Implementing an enterprise IoT solution for temperature and humidity monitoring across thousands of locations, globally, or leveraging it to deploy advanced power management and analytics across cable networks for an MSO,

are both real and valid use cases. Discounting the need for and the investment required to build a robust, globally scalable multi-wireless media enterprise IoT platform will impose substantial limitations. Limitations that will impact an operators ability to deliver a reliable, future proofed service that will fail to comprehensively and proactively addresses their customers' requirements. Customers' whose revenue relies on you and yours on them.

# Private Mobile Networks - A New Service Option for Enterprise Wireless Connectivity

## Understanding Enterprise Needs and Use Cases for Private LTE/5G Services

A Technical Paper prepared for SCTE•ISBE by

**Dr. Mehmet Yavuz**
CTO and co-founder
Celona, Inc.

# 1. Introduction

Just in the last few years, a multitude of new technologies and methodologies have emerged that are forcing cable telecom engineers to reevaluate their networking architectures and service offerings, particularly those targeting the enterprise. Whether it is 5G, the Internet of Things (IoT), low-power wireless protocols, open source hardware, or some combination of these new tools, there is little doubt that big changes are coming to wireless service offerings for Multi-Service Operators (MSOs) and cable operators of all kinds. The viable application of these technologies vary widely, and it is up to MSOs to sort near-term practicality from marketing vaporware.

One recent development that has immediate potential for MSOs is the decision earlier this year by the FCC to make the Citizens Broadband Radio Service (CBRS) spectrum band available for use by businesses. The net result is that MSOs/cable operators now have a new option for predictable mobility that can serve a variety of needs on mission-critical infrastructure for enterprises across a broad swath of industries, from outdoor campuses, to healthcare, manufacturing, logistics/transportation, higher education, and more. This new option is called a private mobile network and it is poised to change how MSOs view wireless networks in their environments.

# 2. What is a Private Mobile Network?

First, let's provide some background on what we mean by a private mobile network in the context of enterprises. We all know that enterprises heavily rely on wireless connectivity both indoors and outdoors, two different environments that present separate challenges for different types of wireless technologies. For the last two decades, "wireless" for the enterprise setting meant two things; Wi-Fi or a public cellular network.

The advent of private mobile networks is something new. They are very similar to the public cellular network that most of us use every day with our smartphones and tablets. They are built on technologies like LTE and 5G as the wireless protocols for connectivity, but the networks themselves are not owned and operated by wireless service providers like Verizon, AT&T, and others. A private mobile network is an LTE or 5G network that is owned and operated by a single organization and geographically bound by that company's property (like a smart factory, hospital, university campus, or shipyard). In the U.S. these networks use the CBRS spectrum band between 3.55-3.7Ghz and can be used by enterprises to give them their very own LTE or 5G network, but managed as easily as the Wi-Fi network.

So why add a new wireless option? First, a private mobile network based on CBRS spectrum operates within a dedicated and interference-free spectrum by FCC regulations in the United States. Not only does this significantly reduce the ongoing operational expenses and support costs, it makes a private mobile network ideal for applications that need to be up and running at all times. Solutions like IoT devices and systems need ultra-reliable connectivity in order to perform their core functions and, from a wireless perspective, private mobile networks are the only option capable of delivering on that requirement.

In addition to reliability, CBRS-based networks provide the type of latency that businesses need for both current systems and future applications. Even if based on LTE, a private mobile network can provide specific performance guarantees at an established Quality of Service (QoS). Today's networks deliver 20ms latency one-way. That latency will be even further reduced for private mobile networks based on 5G. This is a critical requirement for any type of factory automation task and for many Industrial IoT applications.

Another benefit of this new spectrum-based "traffic lane" is that it ensures the enterprise data traffic is kept local and separate from networks that may be used by guests or other personnel that do not need access to secure data. That built-in security can be a critical element for business and safety reasons, as well as a big reason that enterprises will avoid services leveraging public cellular networks delivered by the traditional wireless operators.

CBRS-based private mobile networks are also ideal for connectivity across outdoor settings such as university campuses, transportation yards, outdoor warehouse locations, or manufacturing site parking lots. With the ability to cover one million square feet of outdoor space with a single outdoor wireless access point (AP), a private mobile network significantly reduces the amount of outdoor cabling required to support a wireless network infrastructure - reducing a good chunk of an enterprise's capital expense and thus making a private mobile network service attractive.

Private mobile networks are an ideal extension of another new networking architecture that is quickly establishing itself in the enterprise sector - edge computing. As demands for low latency and computing intelligence increase, most IT network architects are looking for the means to place at least some of this functionality physically closer to applications themselves, thus making the "edge" of the network closer to the "action" so to speak. Analytics, information applications, business processes and other functions will likely still reside in the cloud or in an onsite data center, but private mobile networks can extend operational technologies and thus the network edge to the enterprise for security applications, computer vision apps, system automation, delivering predictable communications for guided vehicles, and guaranteeing reliable voice communications for staff.

## 3. Determining Enterprise Needs and Technical Requirements

In evaluating the enterprise market for private mobile network services, it's clear that there are businesses that do NOT yet need a private mobile network. If they are not pushing the limits of their current wireless network or if they are not looking at business process automation or the Industrial IoT, it's possible they do not have a need for this technology yet.

However, based on the demand we're seeing here at Celona, there are definitely many horizontal service applications for private mobile networks that are being currently evaluated, so let's discuss what MSOs need to consider when implementing services based on this technology. There will likely be many different ways of providing private mobile networks, each depending on the specific needs of the organization's IT department. Some groups will want to have this supplied to them and managed by a third party, like an MSO, wireless operator, or channel partner. Others may wish to simply purchase an end-to-end system and install and manage it themselves.

Regardless of the go-to-market model, in order for private mobile networks to truly fulfill their potential for the enterprise, they need to evolve their basic architectures to leverage the devices and apps that are primarily used "at work" and integrate with existing device and network-level access policies and provide enterprise IT full ownership of data, analytics and insights. Such an architecture would be tightly integrated to the existing enterprise network underlay and deployed as fast as you would deploy an enterprise Wi-Fi solution today with the primary goal of serving apps that demand guaranteed service levels. With a flexible IT-friendly approach, managed private mobile networks can enable custom implementations across islands within the enterprise: on the road, across remote sites, at the branch locations and within the campus - indoors and outdoors. By making such a solution IT-friendly, MSOs can ensure their offering will stand out compared to those from a telecom-oriented background (such as a wireless operator).

One of the biggest issues is figuring out the total number of indoor and outdoor CBRS LTE access points (AP), an enterprise might need at a facility given size, geo-location, density and performance requirements. Let's look at one scenario for an indoor factory and what would be required for establishing total network coverage, but also then designing that network to provide maximum capacity as well.

With the ability to cover 1M SQFT of outdoor space with a single outdoor wireless AP, a private mobile network significantly reduces the amount of outdoor cabling required to support a wireless network infrastructure - reducing a good chunk of your capital expense.

Additionally, if you are designing for coverage, CBRS spectrum availability does not impact the number of APs required in the network. In standard mode of operation, since all traffic flows in the download and upload direction to an LTE radio is scheduled by the infrastructure, even a single channel of 10MHz across all APs will work. If you are designing for network capacity, as you move from the maximum possible 150MHz of CBRS spectrum availability across the entire network to 80MHz - which happens to be the worst case scenario for any environment in the United States - you are looking at about only 10-15% increase in the total AP count in a given enterprise network.

If we consider an indoor facility size about one million square feet, there is a reasonable chance most facilities this size will have around 2500 devices (give or take a few dozen) activity simultaneously. In this scenario, we would require around 43 APs to ensure highly-reliable coverage of the entire facility. If you're designing for capacity, we've included a chart below that details what kind of infrastructure will be needed, assuming a download capacity of 3 Mbps and an uploaded capacity of 1 Mbps.

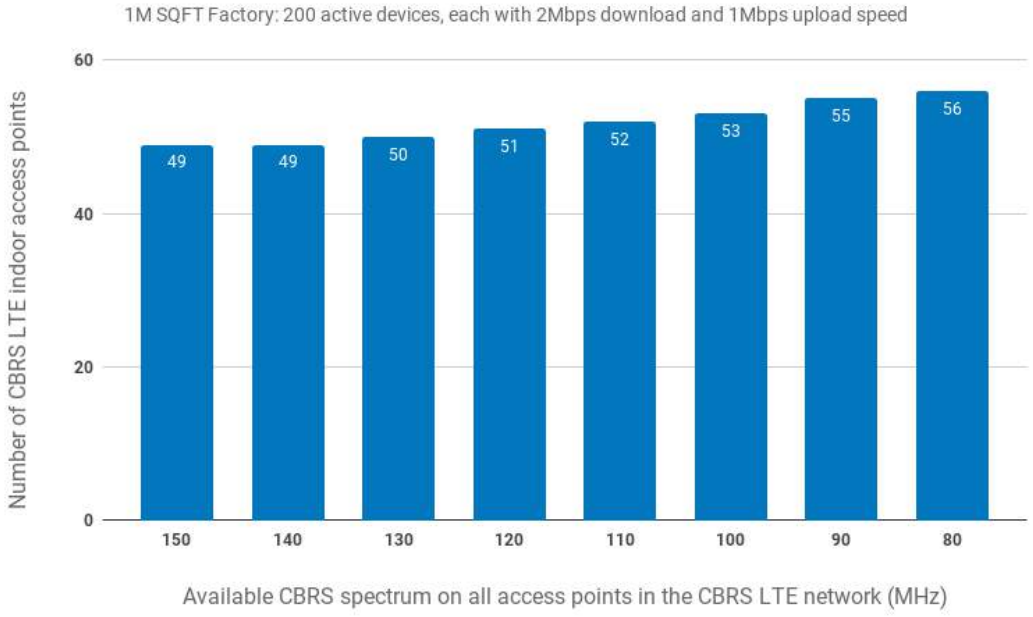

**Figure 1 - CBRS LTE Network Design Tool**

As you can see, the design scenarios for enterprises to implement private mobile networks are already well-defined and available. If you find this type of tool useful, Celona's network planner available at

https://planner.celona.io. There are others that would give you the ability to compare and contrast multiple solutions from different vendors, as any reasonable purchaser would need.

# 4. Use Cases

Now that we've established enterprise design requirements and general applications, let's take a closer look at specific vertical market use cases for private mobile networks.

## 4.1. Supply Chain and Logistics

The need for mobility for this industry is real with supply chain facilities going through significant changes in layout and product placement across aisles on an hourly basis. With its ability to "hold onto" the signal in challenging environments, a CBRS-capable device can support a new set of applications that require real-time response from the network. For instance, leveraging computer vision to automatically and wirelessly identify fleet vehicles as they enter and depart warehouse facilities for the purposes of inventory tracking and fleet management.

From my own personal experience, we are working with a major global supply chain firm that requires connectivity within a large, outdoor railyard. Using the public cellular network was not an option since this organization does not want their sensitive private data traveling across the operator network. Implementing a private mobile network - in this case based on LTE - the firm is planning to blanket the area with reliable wireless connectivity for video applications without breaking the bank.

The rise of private mobile networks are an inevitability for supply chain firms, but there will likely be many different ways of implementing them, depending on the specific needs of the supply chain management IT department. A solid percentage of these organizations will want to have this supplied to them and managed by a third party, including MSOs. The opening of the CBRS spectrum in the United States - with many variations of it on the horizon across different countries - has made private mobile network services for this market segment a real opportunity for many years to come.

## 4.2. Healthcare

Private mobile networks based on LTE and eventually 5G represent an entirely novel means of healthcare IT professionals delivering the predictable performance that modern medical facilities require in wireless communications. With security, privacy and reliability as core tenants, CBRS based LTE is available today to meet the connectivity needs for iOS and Android devices operated by the clinical staff.

As a result, healthcare institutions, including hospitals, clinics, campuses and even testing centers are actively evaluating private mobile networks as a potential solution for their wireless needs. The current pandemic has also uncovered new use cases that would require the deployment of private mobile networks using LTE or 5G in order to augment their existing wireless connectivity options. Beyond general enterprise connectivity, private LTE/5G opens the door to supporting mission-critical applications deployed via enterprise-owned devices on their own clean and dedicated lane of wireless communication. Thanks to CBRS spectrum availability in the United States via FCC's recent commercialization of the 3.5-3.7GHz spectrum, private mobile networks can enable critical mobile connectivity indoors and outdoors across hospitals, newly constructed make-shift healthcare treatment locations, and drive-through testing centers.

A typical drive through testing center like the one at 945 Sansom St. in Philadelphia covers an area of approximately 60,000 sq feet, which can be covered with a private LTE network of just 3 access

points. Due to its strong rate vs range performance, deployment and management of the radio infrastructure can also be accelerated. Private mobile networks, by design and per standard, come with configuration of service level objectives: latency, throughout, packet error rate and jitter metrics can be pre-defined against a given set of mission critical devices and/or applications – making sure that what's most important is protected.

## 4.3. Manufacturing

The manufacturing market segment often has connectivity needs similar to transportation and supply chain organizations, as both share large swaths of "non-carpeted" and outdoor facilities that require connectivity. These include vehicle-mounted devices, as well as other "ruggedized" devices including smartphones and tablets carried by staff. These devices require inference-free operation, so dedicated spectrum for devices from Samsung, Zebra, and Getac can be critical. In a factory setting, this may also include automated guided vehicles carrying out mission-critical tasks for which other solutions may not be reliable enough.

Manufacturers may also evaluate private LTE and private 5G networks for latency-sensitive operations that may include predictive maintenance and factory automation. These applications are often running non-stop twenty-four hours a day while simultaneously requiring real-time connectivity and response, making them ideal for the reliability and low-latency provided by 5G and LTE.

Many manufacturers are also evaluating private mobile networks for applications that include video surveillance for security. These video applications could also extend to computer vision cameras for inventory and other "parking lot" technology that might be utilized outside the manufacturing plant.

Finally, many manufacturers require interference-free connectivity for executive staff mobile devices and dedicated spectrum for new product lines that are currently under research & development that, due to their experimental nature, cannot be part of the existing Wi-Fi network.

## 4.4. Higher Education

Institutions of higher education have a unique set of needs that set them apart from standard enterprises when it comes to network architectures. Large amounts of outdoor areas, 24/7 operation of computer labs and research facilities, a high reliance on voice communications between staff members, and municipal-like requirements for parking lots, emergency response systems and video surveillance. These use cases combine to create multiple challenges for predictable performance for wireless networking - especially when the student Wi-Fi is the most important application for many and cannot be interrupted at any time.

Up until recently, higher education IT departments had two choices for outdoor wireless - Wi-Fi or public cellular networks. The FCC's recent decision to make the CBRS spectrum available for use in private mobile networks has now provided a novel solution for outdoors for critical infrastructure connectivity - university's very own LTE and 5G wireless infrastructure.

Given the coverage patterns of a CBRS LTE access point that reach up to million square feet, IT departments in higher ed can extend critical infrastructure connectivity across the campus without breaking the bank by digging up campus parking lots and other property to lay more fiber. Some of the outdoor use cases that our university customers are evaluating include public safety cameras, emergency phones, Internet backhaul for shuttle buses, outdoor lighting controls and monitoring solutions. Indoor use cases include everything from lighting controls and door locks to vending machines and panic buttons.

A big point for the higher education is that these IT departments want to extend reach to areas where Wi-Fi is not a fit and to keep Wi-Fi spectrum open for users and saving private LTE or 5G for infrastructure.

## 5. Conclusion

The bottom line is that private mobile networks offer a robust solution for multiple near-term enterprise needs. In an era in which we are assailed with far-off applications and nice-to-have functionality, private mobile networks deliver real performance with practical value today. If you're an MSO reading this now, I can also tell you that I am actively engaged with many of your likely competitors – from wireless operators to cloud service providers - as they are carefully evaluating different solutions from the multiple vendors in this market segment. What's clear is that for the enterprise, private LTE and 5G networks are going to be a critical option for enterprise connectivity going forward. If you plan on serving this market segment, you owe it to yourself to learn more.

# In Pursuit of the Dark NOC: Driving Change With Automation & AIOps

A Technical Paper prepared for SCTE•ISBE by

**Marcus Rebelo**
Head of Americas Sales Engineering
Resolve Systems
https://resolve.io
775.842.4469
Marcus.rebelo@resolve.io

# Table of Contents

**Title** **Page Number**

 

# 1. Introduction

Network operations have evolved radically in the wake of digital transformation – and the increasing infrastructure complexity that accompanied it. As communication service providers (CSPs) roll out and support next-generation technologies like NFV, SD-WAN, IPv6, 5G, and soon 6G, network engineers face a myriad of challenges and changes in their daily operations.

The coronavirus pandemic has presented additional challenges, such as new network traffic patterns and a shifting workforce and has put unprecedented pressure on network teams to safeguard business continuity, network security, and quality of service at all costs. Reliable and high-performing connectivity has truly never been more important, making the role of the NOC more critical than ever before.

This paper explores the future of network operations, examining where we are and what's next. Drawing on real-world experience, the paper presents a blueprint for success when it comes to modernizing network operations. It also delves into the increasing role that automation and AI for IT Operations (AIOps) play in laying the foundation for the next-generation of NetOps, as well as how they are helping CSPs address current IT challenges including those stemming from COVID-19.

Becoming an "operator of the future" will require CSPs to maximize the potential of artificial intelligence, machine learning, and automation in pursuit of the so-called "Dark NOC." There are a number of actionable steps that teams can take today to achieve both quick wins and long-term success on the road to the Dark NOC and beyond.

# 2. Key Challenges Facing CSPs

CSPs face extraordinary circumstances when it comes to network operations due to the immense scale of the infrastructure they manage. New technologies are aggressively ramped up to remain competitive and meet customer demands, resulting in much larger scale deployments compared to average enterprise organizations – whether it's network virtualization, software-defined infrastructure, IPv6, 5G, or the imminent 6G.

Key challenges facing CSPs include:

- Managing network infrastructure complexity, including legacy networks, while rolling out complicated and demanding new technologies
- Maintaining high levels of network connectivity and service delivery
- Contending with massive amounts of data being generated by the infrastructure and the monitoring tools that have been deployed to keep an eye on it
- Ensuring network security
- Morphing, unpredictable network traffic patterns
- Meeting tight margins, requiring continual improvements in operational efficiency
- Quickly rolling out new services and infrastructure (without increasing headcount) to remain competitive

As we battle a pandemic, CSPs must also contend with workforce fluctuations (or in some cases reductions) and tightening budgets, meaning that NOC technicians need to do more with less and workloads need to be left-shifted.

To address these challenges, CSPs must embrace new technologies and advance their use of automation, AI, and machine learning. Manual processes simply cannot keep pace with the evolution, complexity, and rapid change in modern networks.

## 3. The Role of AI and Automation in the Dark NOC

Automation and AI are front and center in the Dark NOC. Today, automation handles not only the mundane, repetitive tasks that most network engineers dread, it also tackles complex processes that are otherwise impossible to execute on a regular basis due to time constraints. In the future, automation will replace even more of the manual activities performed by network engineers. Humans will focus on new technologies, creative problem solving, and innovation, while automation addresses much of the day-to-day.

While the Dark NOC is the long-term goal, automation offers immediate, incremental benefits, allowing operations to run much more efficiently with fewer resources. In fact, several CSPs have consolidated their NOCs with just a modest level of automation, resulting in significant costs savings. Others are turning to automation to fill the gap as baby boomers in the NOC reach retirement age.

AIOps is another important technology powering the Dark NOC. It harnesses artificial intelligence and machine learning to ingest, aggregate, correlate, and analyze millions of data points to produce insights into the health and performance of the network infrastructure and applications running on top of it. This powerful technology dramatically reduces alarm noise by performing advanced event correlation to highlight real problems and intelligently group events to isolate the root cause of issues. AIOps also has the capacity to predict and prevent outages by identifying anomalies, conducting advanced pattern analysis, and performing intelligent, dynamic thresholding. Collectively, these capabilities improve performance and reliability, accelerate incident response, and prevent outages, all while streamlining operations.

Leading analyst firms have reported a significant rise in automation and AIOps initiatives in the last year, laying the groundwork for the future state of the NOC. Gartner research indicates that 94% of executives are investing in I&O automation or plan to start. And, while less than 20% of the Global 5000 have a centralized automation function today, that is expected to grow to 90% by 2025.

EMA Research reports that 85% of enterprises have AIOps underway or planned as a major initiative. Their data shows that AIOps in deployment correlates strongly with more progressive levels of automation, closely coupling these technologies. In fact, combining the two offers a closed loop of discovery, analysis, detection, prediction, and automation.

Together automation and AIOps offer a path to the Dark NOC as the insights from artificial intelligence fuel the automation ecosystem, with increasingly less oversight from humans and increasingly more direction from artificial intelligence. These capabilities bring us closer to the promise of self-healing networks and the desired state of the future NOC.

# 4. Building Culture to Embrace Automation and AI

Creating the Dark NOC requires not only great technology, but also a culture that embraces automation and AI, a framework for organizational development, and process optimization.

## 4.1. New Roles in the New NOC

The first and most significant step in advancing the NOC doesn't involve technology at all. It's all about people, organizational structure, and up-leveling current employees into new positions that are focused on leveraging automation and AI to solve problems and improve efficiency.

Some network engineers may worry about the impact of automation on their jobs. The reality is that networking roles are moving in an exciting direction with new opportunities to drive the business. The goal is to up-level and retrain, not to displace. AT&T set an early example in 2016 by investing $1 billion in workforce retraining specifically to pivot to a software-centric network.

Among decision makers at firms that are adopting automation, 26% told Forrester that they face challenges with culture and change management; 25% believe they have gaps in their organizational structure, alignment, and readiness; and 25% said their firm lacks an overall vision or strategy for automation. Similarly, Gartner asked clients to identify their top three organizational challenges related to automation: 53% reported a shortage of people with necessary skills; 46% cited a lack of documentation of existing processes; and 44% said cultural resistance was a concern.

Taking the time to define what your Dark NOC team looks like and crafting new roles and responsibilities is essential for success. This should be part of a broader effort beyond the NOC to create, as Forrester puts it, "an automation strike team" and Center of Excellence (CoE).

Repurposing skillsets to support the transition to a Dark NOC means shifting people to focus on more data-driven customer service and moving them up in the knowledge stack to identify candidates for automation, validate automations, build automation content, and take on responsibilities that require more human-centric skills. What have traditionally been operations-oriented roles are morphing into more critical-thinking roles to facilitate digital transformation. New skillsets require understanding data and processes and making thoughtful decisions about how to leverage that data to optimize operations, advance services, and deliver innovation.

More specifically, emerging roles in the NOC include network automation architects who focus on determining the best processes to automate and how to go about doing so, as well as network automation managers who establish governance processes, run automation teams, manage the toolsets, and collaborate with business stakeholders.

## 4.2. Crafting a Culture of Automation

With the right roles in place, CSPs can implement initiatives that help promote the culture of automation both within and beyond the NOC. Some real-world examples include:

- Educating the workforce on the benefits of automation and how they can be a part of it
- Identifying champions and giving them a platform to socialize the benefits of automation
- Creating an internal brand for your automation strike team

- Providing easily accessible training on automation and AI tools
- Developing an automation forum to share ideas and promote what's coming down the automation pipeline
- Publicizing how automation is contributing to strategic initiatives and how it aligns with business objectives
- Showcasing automation success and rollouts in internal newsletters, videos, town halls, internal chat channels, and employee portals
- Establishing a simple process for people to recommend processes for automation
- Incentivizing employees to participate with automation awards and cash prizes

### 4.3. Capturing Tribal Knowledge with Automation

All too often tribal knowledge and expertise still reside primarily with a handful of subject matter experts (SMEs), especially when it comes to complex technologies and legacy toolsets. Documenting this know-how (and best practices in general) is critical to advancing automation initiatives and should be part of any plan for long-term success.

Valuable tribal knowledge can be captured and encoded into automation workflows, preserving this expertise for the long term and making it available in such a way that it scales. SMEs can even capture knowledge with conditional logic to create interactive automations that step through best practice procedures while automation executes the tasks behind those steps. In doing so, CSPs can left-shift workloads, minimize unnecessary escalations, and keep costs down.

## 5. Jumpstarting & Scaling Network Automation

Forrester reports that many networking teams are still in the early stages of automation, despite advances in virtualization and programmable infrastructure. One of the key challenges to any automation initiative is determining where to start.

The use cases below provide a guide to jumpstarting and scaling network automation initiatives to support digital transformation and next generation technology rollouts, as well as to improve operational efficiency. Rolling out these use cases at scale will put CSPs well on their way to achieving the Dark NOC.

### 5.1. Proactive Network Testing

Automating proactive network tests can avoid costly and time-consuming truck rolls, prevent network outages, and provide real-time insights into service quality – not to mention reducing repetitive workloads on the NOC.

Automation can be leveraged to:

- Execute multi-step testing processes, like PIM testing, circuit testing, and customer turn-ups
- Capture network testing and diagnostic information for analytics, compliance, auditing, and change management purposes

 

- Build comprehensive reports on the health of the network, so key stakeholders and executives can always be on top of service delivery and quality

Benefits of automating network testing include:

- Identifying performance and connectivity issues before they impact users
- Speeding up network testing, while simplifying the process
- Reducing reliance on operator interpretation
- Improving efficiency by replacing manual efforts with automation
- Enforcing consistency and standardization across testing procedures

### *5.1.1. A Real-World Proactive Network Testing Example*

Cell tower outages were causing major impacts for the customers of a large CSP, and their NOC needed a way to validate customer service complaints, perform diagnostics, and quickly implement fixes. With a daily rate of 500K alarms coming in, their Tier 1 analysts couldn't keep pace.

They also needed to automate a set of complex testing procedures on more than 57,000 cell towers. By running these procedures consistently, they could verify mobile connectivity for their millions of subscribers.

Today, an automated process polls the entire radio network every hour and compares outages it identifies to existing tickets and events. It then automatically updates these tickets and generates validated events that are sent to the NOC for follow-up. Additionally, complete coverage and outage reports are auto-generated and sent to each of the market owners, providing unprecedented and accurate visibility into real-time network health and performance.

By automating network testing procedures, the CSP saves 40,000 man hours every year while also accelerating incident resolution and improving service delivery.

## 5.2. Incident Resolution

Network uptime and performance are mission critical, putting incredible pressure on the NOC to resolve incidents as quickly and efficiently as possible. Automation can radically transform the entire incident resolution process and overcome common challenges – for example, avoiding unnecessary escalations or delays by encoding systems access in the automation itself, thereby enabling lower level analysts to resolve the problem on their own.

Automation can be leveraged to:

- Reduce alarm noise by automatically validating events, correlating related events, and consolidating duplicates
- Collect troubleshooting data from multiple systems across environments and locations, build timelines, and diagnose issues
- Centralize incident management to oversee all aspects of the incident resolution process from a single pane of glass
- Automatically resolve common incidents with pre-built workflows that can be triggered in a variety of ways

- Arm admins with interactive automations to address outages that require more complex resolution workflows, including step-by-step instructions, incremental automations, and decision paths
- Enable agents to safely execute remediation tasks without system access or the necessary CLI or coding skills
- Eliminate time-consuming handoffs between the ITOps and NetOps teams with centralized orchestration of the end-to-end, service-level workflows
- Auto-create and update tickets with a log of all actions and automations that were completed

#### *5.2.1. Real-World Incident Resolution Examples*

The NOC for a leading multinational CSP leverages automation to process both traditional and non-traditional alarms, such as network configuration, compliance, and inventory validations. By automating alarm handling, trouble ticketing, triage, intelligent decision-making, and dispatch operations, the organization has accelerated incident resolution time from more than 1800 minutes to less than 60 seconds.

Similarly, another North American provider also relies on automation to reduce alarm noise, enrich events, and triage resolution procedures. They have even extended automation to customer communications. When nodes are impacted by an outage, an automated process quickly cross references those nodes with their CRM system to determine which customers are impacted, and notifications are automatically sent out to keep customers informed in real time.

### 5.3. Network Provisioning

Automating network provisioning is significantly faster, more reliable, and more accurate than manual efforts – and automation eliminates human error. It also enables CSPs to deliver scalable new services to customers much quicker.

Automation can fast-track network provisioning by:

- Executing pre-provisioning checks to eliminate hours of manual effort
- Conducting pre-configuration checks for authorization and/or billing
- Automating post-configuration checks and any necessary remediation steps to verify connectivity and performance
- Performing network configuration tasks to enforce standard operations and secure configurations
- Auditing every process – whether human-directed or automated – for a real-time, centralized audit trail essential for troubleshooting and compliance
- Integrating and automating updates with service and change request systems

### 5.4. Leveraging AIOps

AIOps and automation can radically improve network reliability and reduce outages by combining predictive analytics with proactive automations.

Key applications include:

- **Sequential Pattern Analysis & Time-Series Event Correlation:** AIOps has the ability to normalize and sequence millions of events across applications and infrastructure into a time series that can be

analyzed by machine learning algorithms to identify patterns. These patterns can then be leveraged to identify potential outages and trigger intelligent automations to resolve problems proactively.

- **Dynamic Thresholding & Multi-Variate Anomaly Detection:** Anomaly detection algorithms use unsupervised machine learning to learn network environments over time, recognize expected behavior, and set dynamic thresholds across multiple performance metrics that account for seasonality. As events are analyzed in real time, they are compared to expected behavior to provide alerts and/or trigger automated actions when a sequence of events demonstrates anomalous activity.

- **Dynamic Capacity Adjustments:** AIOps leverages historical utilization trends to predict when infrastructure will become non-operational due to capacity exhaustion. These predictive capabilities ensure more capacity can be added dynamically via triggered automations (or through manual intervention) to avoid outages stemming from common capacity issues.

## 6. A Blueprint for Getting Started – Actionable Steps to Transform the NOC

The technology to implement a Dark NOC is rapidly maturing. Depending on where you are in the process, here are some recommended steps towards achieving self-healing networks and automation excellence.

Phase One (2-3 months):

- Document key processes and troubleshooting activities
- Improve visibility with discovery, network mapping, and identifying application flows across hybrid networks
- Identify quick wins for out-of-the-box automation use cases
- Validate integrations across the technology stack
- Identify internal champions for automation and AIOps initiatives
- Build executive support

Phase Two (3-6 months):

- Identify the next phase of automations, including more complex processes
- Optimize the processes on paper before automating them
- Leverage technologies that deliver noise reduction, event clustering, and correlation
- Engage employees in identifying processes to automate

Phase Three (6-12 months):

- Create an Automation Center of Excellence to centralize automation efforts
- Connect AIOps to automation and start with an initial set of autonomous actions
- Activate your “army of automators” to scale
- Integrate analytics and automation
- Expand usage of autonomous automations that can be triggered by AIOps insights

## 7. Summary – Innovation Powering New Services

Evolving NetOps means addressing operational challenges at scale. It requires a deep understanding of how the NOC will evolve, as well as how people, processes, and technology intersect. It requires leveraging automation and AIOps to manage increasing network complexity that has far surpassed the capacity of manual processes and human analysis.

By darkening the NOC, CSPs can address tactical challenges related to cost reduction, workforce fluctuations, and tight margins, but even more importantly, they can free valuable resources to focus on innovation and creative uses of technology to offer new and improved services to propel the business forward.

# 1. Introduction

As of April 2020, all the 1,000+ pages of the Data Over Cable Service Interface Specification (DOCSIS) 4.0 PHY and MULPI specs, combined, are out and about. That's step one in making the 1,794 MHz top frequency in the downstream, combined with up to 684 MHz for the top frequency in the upstream, a new reality for the hybrid fiber-coax (HFC) plants. As part of the greater 10G initiative, this is what will be needed to support the many Gbps in both the upstream and the downstream for nodes with amplifier cascades (a.k.a. N+X). The multiple system operators' (MSOs') successful business model and existing HFC broadband networks are our starting point. All that's needed is a simple upgrade to get from here to there, easy peasy!

Not so fast?! Well, OK, there are some "minor details" to sort in the process of getting there: Where is the Goldilocks zone – not too little but not too much either – for the RF amps gain and power? There are many items to consider.

With a comprehensive network model of a node + 6 cascade, should the "unity gain" concept be extended all the way up to 1.8 GHz? Once modeled, what would an optimal power spectral density (PSD) distribution across the forward spectrum look like? What happens as the distance between the amps increases? Does the tap position on a link make a difference? What is the impact of the drop cables? Should we continue to use end-of-line (EoL) throughput as our capacity benchmark?

There are many, many questions and this paper will start to look at some of the considerations with rolling out 1794 MHz HFC plants. All of this is distilled into conclusions and best practices guidance – to help make 10G and the DOCSIS 4.0 networks a reality for the time to come!

# 2. Unity Gain Overview

Figure 1 is a big picture view of a Hybrid Fiber Coaxial (HFC) network. It shows a "40,000-foot view" of an HFC plant. While the plant and its architecture kept evolving – for example, a head end to node fiber link took the place of a much longer cascade of trunk amps – it is also amazing how many things remain the same: fiber nodes feeding RF amplifiers, amplifiers feeding taps, and taps, via "drops" delivering signals to ever-important subscribers.

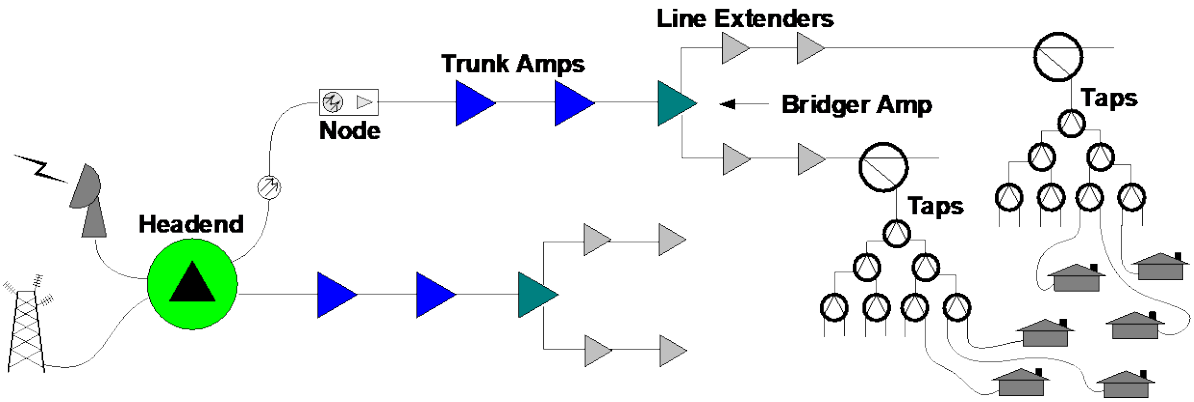

**Figure 1 – A big picture view of a Hybrid Fiber Coaxial (HFC) network**

Another HFC aspect that has remained the same is that of "unity gain" – a concept of setting every amplifier output signal to the same shape and magnitude, no matter if the amp is first or last in the

cascade nor how “lossy” the span in front of the said amplifier was. This consistency of output is shown via blue “amplifier output” lines in Figure 2 for the downstream direction.

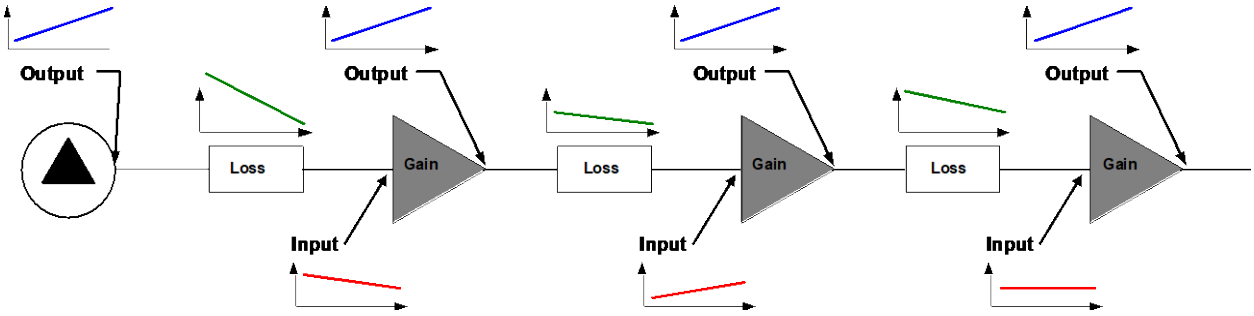

**Figure 2 – Illustration of the "Unity Gain" concept, applied to an RF amplifier cascade**

In this example of a three-amplifier stage cascade, each output stage (in blue) is the same. However, the coaxial cable and tap loss preceding each of the amplifiers is of a different value, as illustrated via green “loss over frequency” lines. These various length cable spans, driven by the same previous-amplifier output, will produce various inputs, shown via red “amplifier input” lines. It is the gain and slope of every amplifier that is tuned, traditionally via selection of proper attenuator, cable simulator, and/or cable equalizer, to make every amplifier output the same. One goal of the tuning is to set each amplifier’s input stage signal as flat as possible to minimize noise figure contribution, the other is to up-tilt the final output, to minimize non-linear distortion effects. Nevertheless, the noise effects and the non-linear distortions still add up as the cascade length increases, despite keeping outputs of each amplifier the same.

Another rationale for unity gain is to provide a common input power and modulation order (e.g. 256-QAM) for every cable consumer premises equipment (CPE) including legacy video set top boxes (STB) as well as DOCSIS 2.0 &/or 3.0 cable modems (CM). This holds no matter what channel frequency is being used or whether the CPE device is next to the node or at the end of line (EoL).

The span length between the amps, and how much of the corresponding amplifier gain is needed to achieve “unity gain” has been the cable engineers’ focus for many years. Many HFC plants were originally designed with amp spacing to accommodate lower frequencies, e.g. 450/550/750 MHz. Over time, these were then “pushed” to higher frequencies, e.g. 870/1002/1218 MHz. Due to much higher cable losses at higher frequencies, this resulted in amplifiers needing significantly higher output gains to maintain the unity gain in the system. If the cable losses were more than the increased amplifier output gains, then the HFC plant needed to be “re-spaced” where amplifier locations were moved, something that is highly undesirable. This issue now gets exaggerated with pushing the HFC to 1.8 GHz.

As a point of reference, consider 750 MHz HFC plant that many “first world” countries built quite a few years ago. At 750 MHz, these spans amount to ~20 dB attenuation following trunk amps, ~40 dB attenuation following multi-port bridgers and ~30 dB attenuation following single output line extenders.

## 3. Network Capacity Planning for Cable 10G

The network capacity analysis in [ULM_2019] provides an insight into the capacity requirements needed to support the cable 10G initiative. It first looks at the traffic engineering needed for a common 10G network using both PON and cable systems. Then a closer look is taken at the spectrum planning for an HFC system.

The CommScope (formerly ARRIS) team has been providing industry leading research in traffic engineering for many years which was recently highlighted in [ULM_2019]. Some additional references of note include [CLO_2014], [EMM_2014], [ULM_2014], [CLO_2016], [ULM_2016], [ULM_2017] and [CLO_2017].

## 3.1. The "Basic" Traffic Engineering Formula

Previously, [CLO_2014] introduced traffic engineering and quality of experience (QoE) for broadband networks. From there, the paper went on to develop a relatively simple traffic engineering formula for service groups that is easy to understand and useful for demonstrating basic network capacity components.

The "Basic" formula shown below is a simple two-term equation. The first term (Nsub*Tavg) allocates bandwidth capacity to ensure that the aggregate average bandwidth generated by the Nsub subscribers can be adequately carried by the service group's bandwidth capacity. The first term is viewed as the "DC component" of traffic that tends to exist as a continuous flow of traffic during the peak busy period.

**The "2014" Traffic Engineering Formula (Based on Tmax_max):**

$$\mathbf{C \geq (Nsub*Tavg) + (K*Tmax\_max)} \quad (1)$$

where:

C is the required bandwidth capacity for the service group
Nsub is the total number of subscribers within the service group
Tavg is the average bandwidth consumed by a subscriber during the busy hour
K is the QoE constant (larger values of K yield higher QoE levels)…
where $0 \leq K \leq$ infinity, but typically $1.0 \leq K \leq 1.2$
Tmax_max is the highest Service Tier (i.e. Tmax) offered by the MSO

There are obviously fluctuations that will occur (i.e. the "AC component" of traffic) which can force the instantaneous traffic levels to both fall below and rise above the DC traffic level. The second term (K*Tmax_max) is added to increase the probability that all subscribers, including those with the highest service tiers (i.e. Tmax values), will experience good QoE levels for most of the fluctuations that go above the DC traffic level.

The second term in the formula (K*Tmax_max) has an adjustable parameter defined by the K value. This parameter allows the MSO to increase the K value and add bandwidth capacity headroom that helps provide better QoE to their subscribers within a service group. In addition, the entire second term is scaled to be proportional to the Tmax_max value, which is the maximum Tmax value that is being offered to subscribers.

In previous papers [CLOONAN_2013, EMM_2014], found that a K value of ~1.0 would yield acceptable and adequate QoE results. [CLOONAN_2014] goes on to provide simulation results that showed a value between K=1.0 and 1.2 would provide good QoE results for a service group of 250 subscribers. Larger service groups (SGs) would need even larger values of K while very small SGs might use a K value near or less than 1.0.

## 3.2. Broadband Subscriber Traffic Consumption

CommScope/ARRIS has been monitoring subscriber usage for over a decade now from the same group of MSOs. The data from this set has been compared and aligns closely to many other MSOs globally.

Figure 3 shows the average subscriber downstream consumption, DS Tavg, during peak busy hours for several MSOs over a ten-year period. At the start of 2020, DS Tavg had surpassed the 2 Mbps barrier.

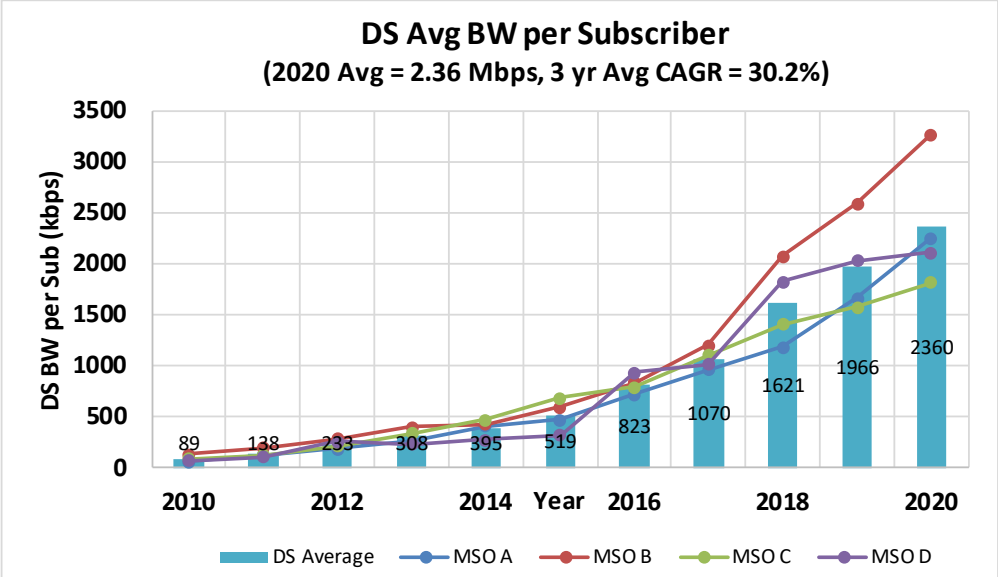

**Figure 3 – Downstream Average Bandwidth per Subscriber through Jan '20**

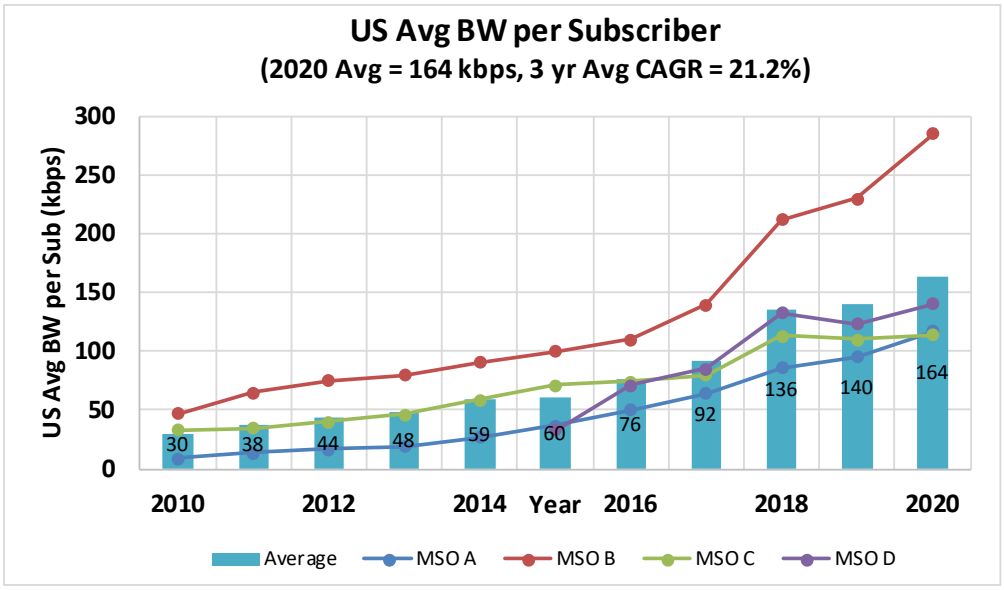

**Figure 4 – Upstream Average Bandwidth per Subscriber through Jan '20**

It turns out that the Tavg growth rate was higher at the start of this decade and has tailed off a bit in recent years. Over the last 3-4 years, this group of MSOs had an average downstream traffic growth that had been around 30%. Interestingly, the upstream traffic is growing at a significantly slower rate than the

downstream as shown in Figure 4. During the same ten-year period, the upstream Tavg generally grew at less than 20% compound annual growth rate (CAGR).

This MSO data provides a good indication of Tavg, at least before the Coronavirus bandwidth (BW) surge hit. Note that figures 3 and 4 are very generalized results that are averaged across millions of subscribers.

Over recent years, there has been a slowing in the downstream usage growth rate (i.e. Tavg) compared to the service tier growth rate (i.e. Tmax). This has several consequences including that the networks become more "bursty". It also means that the overall utilization of the network is lower too. In this respect, it is important to try and maximize subscribers per service group (SG) in order to take advantage of statistical multiplexing and get better economics.

### 3.3. Network Capacity Modeling for Cable 10G Downstream

[ULM_2019] used the CommScope network capacity modeling tools to see how a 1218/204 MHz HFC plant could support the cable 10G downstream requirements. This analysis will first be reviewed and then look at what changes for the extended spectrum DOCSIS 4.0 (ESD) scenarios.

The network capacity results from [ULM_2019] show the potential capabilities for a 1218/204 MHz HFC plant. It begins with a 512-home passed (HP) service group with 256 subs (i.e. 50% penetration). The max downstream (DS) service tier starts at 1 Gbps and grows by 1 Gbps per year from 2022 until it finally reaches 8 Gbps DS SLA in the year 2028. For this case study, it is assumed the Tavg growth rate continues its gradual decline over the next decade. This will leave Tavg at ~15 Mbps by the end of the decade. If the Tavg growth rate does not decline, then these dates might get pulled in by 2-3 years.

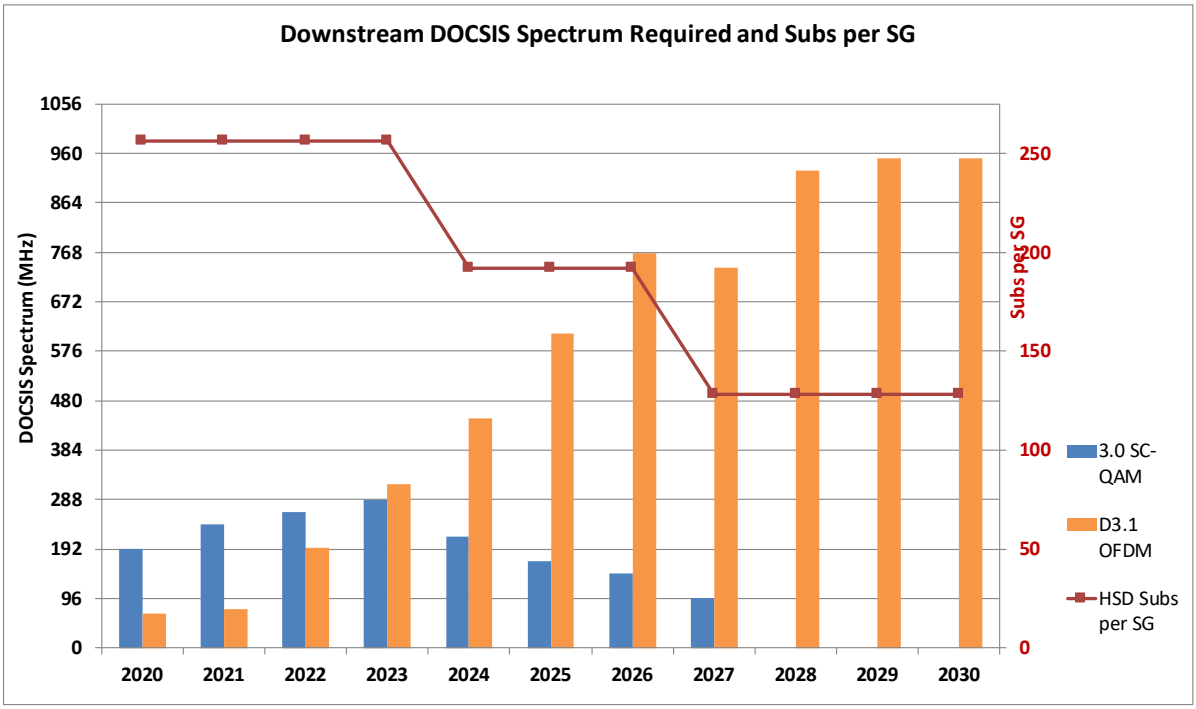

**Figure 5 – 1218/204 MHz System – Subs per SG, DOCSIS Spectrum Needs**

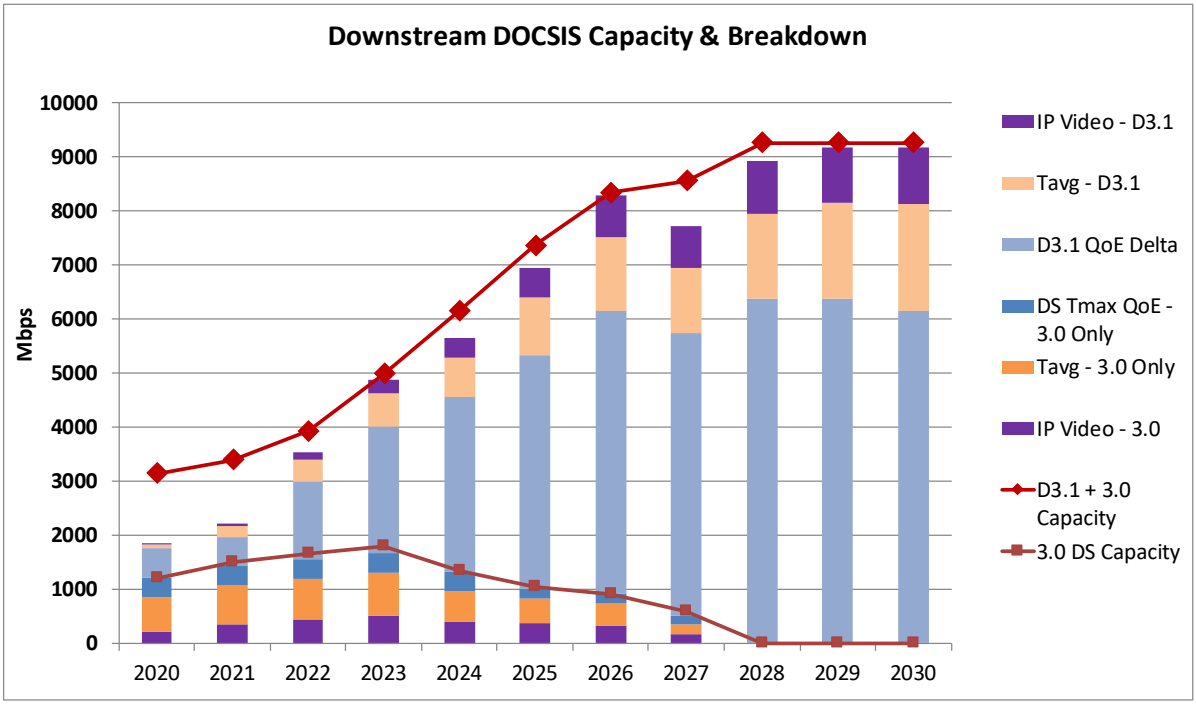

**Figure 6 – 1218/204 MHz System – DOCSIS Usage: Tmax, Tavg, IP Video**

This 1218/204 MHz scenario shows that by 2027, all SGs need to be at 128 subs or fewer. The max subs per SG is shown in Figure 5. The figure also breaks out the downstream spectrum amount needed for both DOCSIS 3.0 SC-QAM and DOCSIS 3.1 OFDM. Note that by 2028 in this case study, 100% of DOCSIS cable modems have been converted to DOCSIS 3.1 enabling OFDM channels across the entire spectrum to maximize capacity.

The DOCSIS capacity usage is broken out in Figure 6. It shows the amount of capacity needed for both DOCSIS 3.0 and DOCSIS 3.1. As can be seen, the Tmax component dominates over time. The upper red line shows the combined 3.0 + 3.1 total capacity for the system.

Perhaps a key point of this case study was that a reasonably clean 512 HP node can be upgraded to 1218/204 MHz and support a service tier of 8 Gbps x 1.5 Gbps for the next decade. The only change needed will be a SG segmentation (i.e. upgrade node from 1x1 to 2x2) somewhere in the middle of the decade. There is no pressing near term need to push the HFC to very small (but inefficient!) SG sizes found in N+0 systems.

## 3.4. Network Capacity Planning for DOCSIS 4.0 ESD

The cable 10G initiative strives for a more symmetric network with multi-gigabit upstream service tiers. DOCSIS 4.0 ESD has evolved as a way to offer even higher upstream tiers while remaining in an N+X environment. Thus, ESD also is trying to avoid the costs of an N+0 upgrade such as that needed with DOCSIS 4.0 FDX.

### *3.4.1. Cable 10G Service Tiers*

As shown in [ULM_2019], the subscriber is actually getting an 8 Gbps SLA in a 10G world after accounting for all the different overheads (e.g. PHY, MAC, IP layers). Table 1 summarizes the various

options from that study and their respective downstream (DS) and upstream (US) SLAs that service providers can consider offering. Because capacity in an HFC system can vary quite a bit based on many variables, the offered SLAs are actually a range of values.

**Table 1 – Summary of SLA Options for 10G PON & 1218 MHz Plants**

| 10G PON Options | DS SLA (Gbps) | US SLA (Gbps) |
|---|---|---|
| 10G/1G EPON | 8 | 0.8 |
| 10G/10G EPON | 8 | 8 |
| XG-PON | 8 | 2 |
| XGS-PON, NG-PON2 (single wavelength) | 8 | 8 |
| **10G HFC Options** | **DS SLA (Gbps)** | **US SLA (Gbps)** |
| 1218/85 MHz | 8 – 10 | 0.4 – 0.5 |
| 1218/204 MHz | 6 – 8 | 1.0 – 1.5 |
| 1218/300 MHz | 5 – 7 | 2.0 – 2.5 |
| 1218/396 MHz | 4 – 6 | 2.5 – 3.0 |
| 1218/85 MHz + 108-684 MHz FDX/Soft-FDX | 8 – 10 | 5 – 6 |

Perhaps the key motivating driver for DOCSIS 4.0 FDX and ESD is the ability to offer more symmetric multi-gigabit upstream tiers. The minimum goal for ESD would be to at least match the DS tiers for a 1218/204 MHz plant while offering substantially higher upstream tiers. Ideally, ESD would be able to match the DS tiers capabilities of 10G PON and 4.0 FDX systems.

The table above shows upstream splits up to 396 MHz. The DOCSIS 4.0 working group has also added a 492 MHz split and 684 MHz split as additional options.

### *3.4.2. DOCSIS 4.0 ESD – Tavg and Nsub targets*

The [ULM_2019] study assumed that the Tavg growth rates continue to decline and estimated that Tavg would reach 15 Mbps per sub by 2030. Given the additional investments needed for ESD, a Tavg of 20-40 Mbps per sub will be considered to make sure there is additional lifetime for this investment.

Since ESD is targeted at N+X environments, our analysis will assume at least 125 subscribers per SG, which was the ending point in the 2019 study.

### *3.4.3. DOCSIS 4.0 ESD – Network Capacity Requirements*

The 2019 study showed that ~9 Gbps of DS capacity is required for 125 subs @ Tavg=15 Mbps. If Tavg is bumped up to 25 Mbps, then total system capacity pushes above 10 Gbps. Pushing Tavg up to 40 Mbps increases the required system capacity to around 12 Gbps. These are key targets that will be used in our following analysis.

# 4. Simulation Model Overview

Our network performance estimates were done using a MATLAB simulation model. The model simulated the effects of attenuation in the hardline coaxial cable, taps, drop cable and home entry port, and amplification in the intermediate amplifiers, to calculate the received power levels at modems at different locations. The effects of noise and distortion accumulation in the cascade were also simulated to calculate the effective SNR at the modem. The results were compared with DOCSIS 4.0 received power and SNR thresholds to estimate the available modulation and bit-loading at each frequency, yielding the total gross throughput. Physical layer overheads such as cyclic prefix, FEC (LDPC), guard bands, pilot and PLC tones were subtracted from the integrated bit-loading curve (gross throughput) to calculate the net system throughput. The model used 78% efficiency for the PHY layer.

## 4.1. Cable Model – PSD and TCP

The DS power spectral density (PSD) at the node output was represented as a tilt/drop/tilt (a.k.a. lightning bolt) in order to achieve a sensible total composite power (TCP) (nominally 70 dBmV based on 4.0 working group discussions, but this parameter could be varied if needed) while providing adequate levels for legacy SC-QAM services at lower frequencies (up to 860 MHz). The PSD is shown in Figure 7.

Cable attenuation, for both hardline and drop cables, was calculated as a function of frequency and cable segment length from tabulated data from cable manufacturers. A large database of tap response curves from several tap families, taken from a combination of manufacturers' data and our own measurements, was available in the model. Note that no tap equalizers (or "cable simulators") were present in the model; all available RF power was used to optimize the bit-loading from each tap.

## 4.2. Amplifier Model

The amplifiers were modelled as non-ideal near-unity gain devices. The gain of each amplifier was tuned to approximately match the attenuation of the preceding cable span, subject to a configurable maximum gain. This approximate match used a linear-tilted gain over most of the spectrum, producing a small gain deviation; over longer cascades, this produced a slightly U-shaped end-of-line PSD, in contrast to a flat received PSD which would occur if perfect unity-gain amplification was possible.

The gain limit became significant for longer cable runs that is referred to as stretched plant. At higher frequencies, the inter-amplifier span attenuation sometimes exceeded the assumed maximum gain, resulting in progressively lower PSD at these frequencies after each stage in the cascade. Hence the stretched plant did not quite achieve unity gain at 1800 MHz. Figure 8 shows an example of the inter-amplifier attenuation and amplifier gain for a stretched plant.

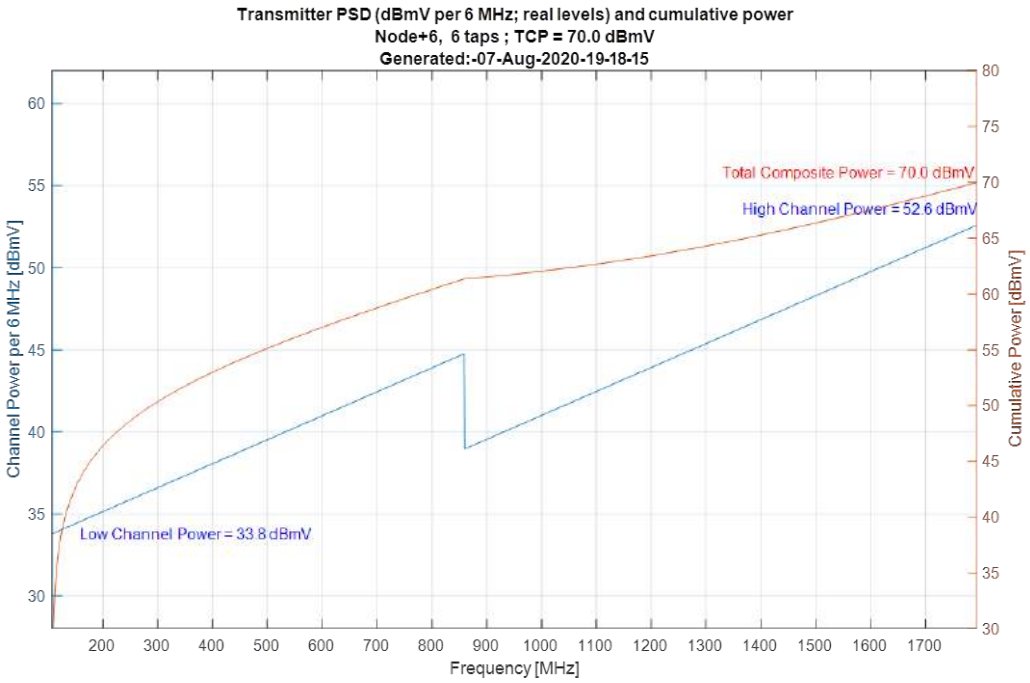

**Figure 7 – PSD Profile Showing Tilt/Drop/Tilt Characteristic**

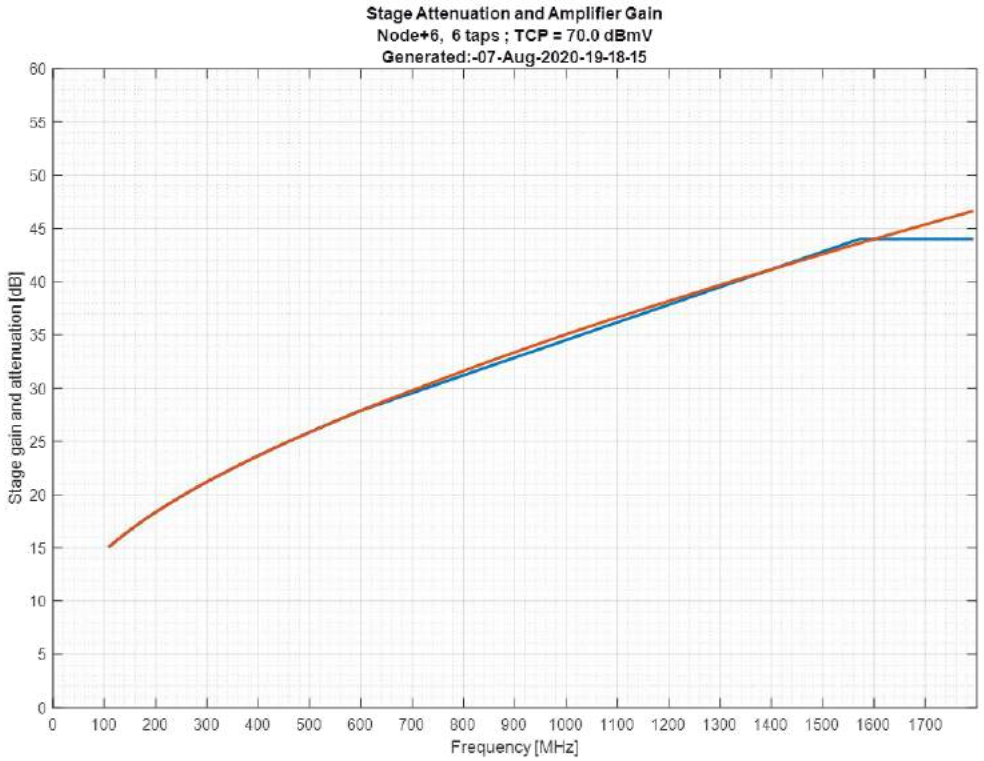

**Figure 8 – Inter-amplifier Span Attenuation & Amp Gain (With 44 dB Gain limit) in a Stretched Plant**

### 4.3. System Noise Performance

The noise performance of the system was modelled using an estimate of the node's output SNR, and noise figures for the amplifiers in the cascade, and for the cable modem. The various noise components were modelled through the successive attenuation and amplification stages of the cascade to produce a received noise estimate. Distortion was treated in a similar way; distortion at the node output and each amplifier output was modelled as a third-order function of TCP, and coherence effects were also calculated.

### 4.4. Amplifier Spacing – Typical and Stretch Networks

For our network simulations, it was important to model amplifier spacings that were representative of real-world data based on customer's amplifier spacing data. A cumulative distribution function (CDF) of some sample amplifier spacing for single output line extenders (LE) is shown in Figure 9, while the CDF for multi-port bridgers (MB) is shown in Figure 10. Line extenders often account for more than 60% the total number of amplifiers. This data is courtesy of Cox Communications.

Most of the simulations used either "typical plant" or "stretch plant" parameters for plant length. "Typical plant" parameters are chosen to include a majority of inter-amplifier span attenuations (for line-extender (LE) spacings). A total attenuation of 30 dB at 1 GHz and 40 dB at 1794 MHz is used, which is an attenuation value greater than that of ~65% of line-extender to line-extender spacings according to Figure 9. This attenuation is simulated with 6 segments of 175' of P3 625 hard-line and 5 taps, a total of 1050' between amplifiers. Note that 850' of P3 500 would give similar results.

Unless otherwise specified, each simulation used the same parameters for the node to first amplifier span and for the last amplifier to end tap as for the inter-amplifier spans.

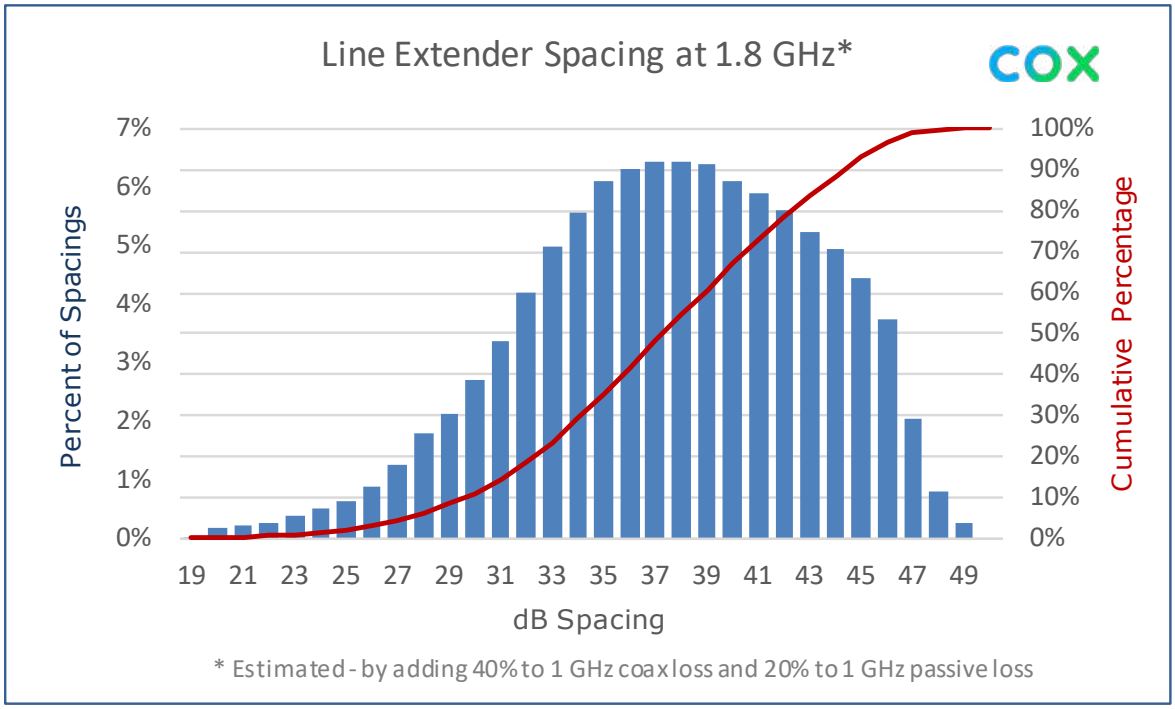

**Figure 9 – Amplifier Spacing – Single Output Line Extenders (LE)**

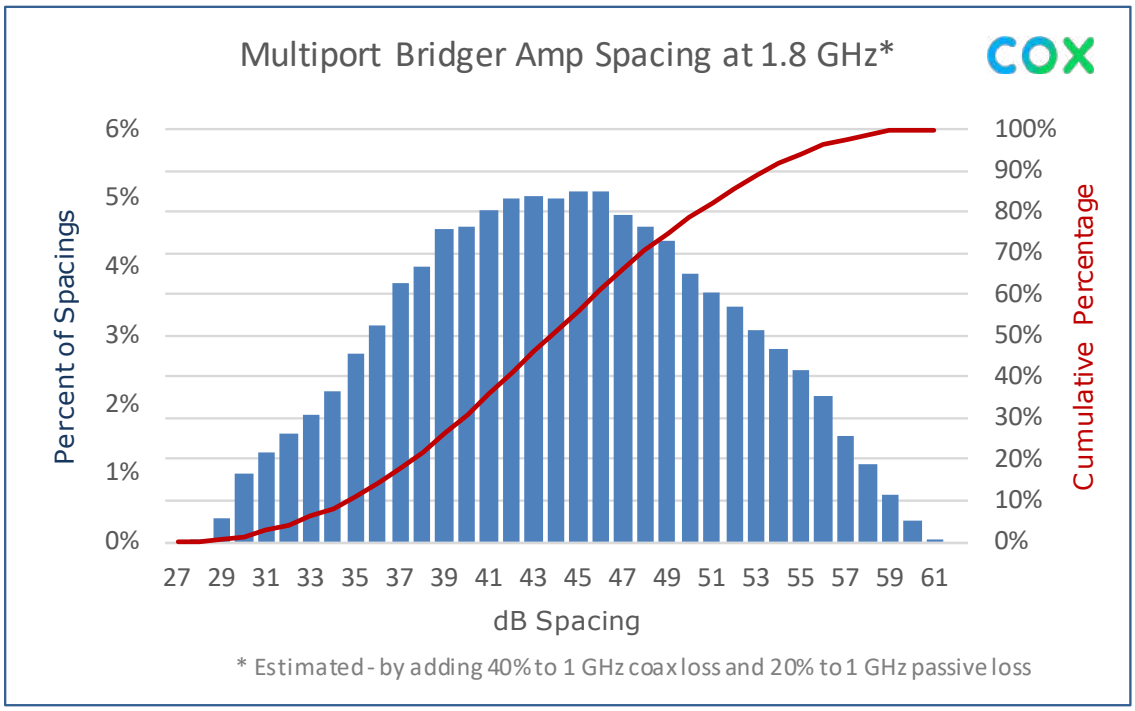

**Figure 10 – Amplifier Spacing – Multi-Output Bridgers (MB)**

"Stretch plant" parameters are chosen to exceed most inter-amplifier span attenuations; the corresponding attenuations are 35 dB at 1 GHz and 47 dB at 1794 MHz. This is greater than ~97% of LE-to-LE spacings, and two-thirds of bridger-to-amplifier spacings according to Figure 10. Overall, this would cover more than 85% of the amplifier links. This attenuation is simulated with 6 segments of 215' of P3 625 hard-line and 5 taps, a total of 1290' between amplifiers. Note that 1050' of P3 500 would give similar results.

For both typical and stretch plants, the baseline case used 150' of RG-6 drop cable along with a 3.5 dB loss inside the home (e.g. splitter at point of entry or 20' of RG-6 inside the home). Note that cable losses from 150' of RG-6 drop cable would be roughly equivalent to 210' of RG-11 drop cable.

## 5. Conventional Wisdom Using Unity Gain Approach

As discussed previously, unity gain helped maintain a constant QAM-modulation for legacy STB and DOCSIS 2.0/3.0 cable modems. System performance was defined by the lowest common denominator. The end of line (EoL) provided a key performance monitoring spot to determine whether every CPE device could successfully receive the 256-QAM downstream channel. But future systems will be migrating to DOCSIS 3.1 and 4.0 cable modems. Our network simulations calculate the maximum downstream network capacity achievable using 3.1/4.0 OFDM channels with variable-bit loading per sub-carrier with up to 4096-QAM modulation.

For our network simulations, the EoL performance is first checked for both 1218 and 1794 MHz systems to see how well unity gain performed. Figure 11 looks at the network capacity for a 108-1218 MHz downstream for various amplifier cascade lengths, from Node+0 up to Node+6. This was done for both a typical plant and a stretch plant conditions.

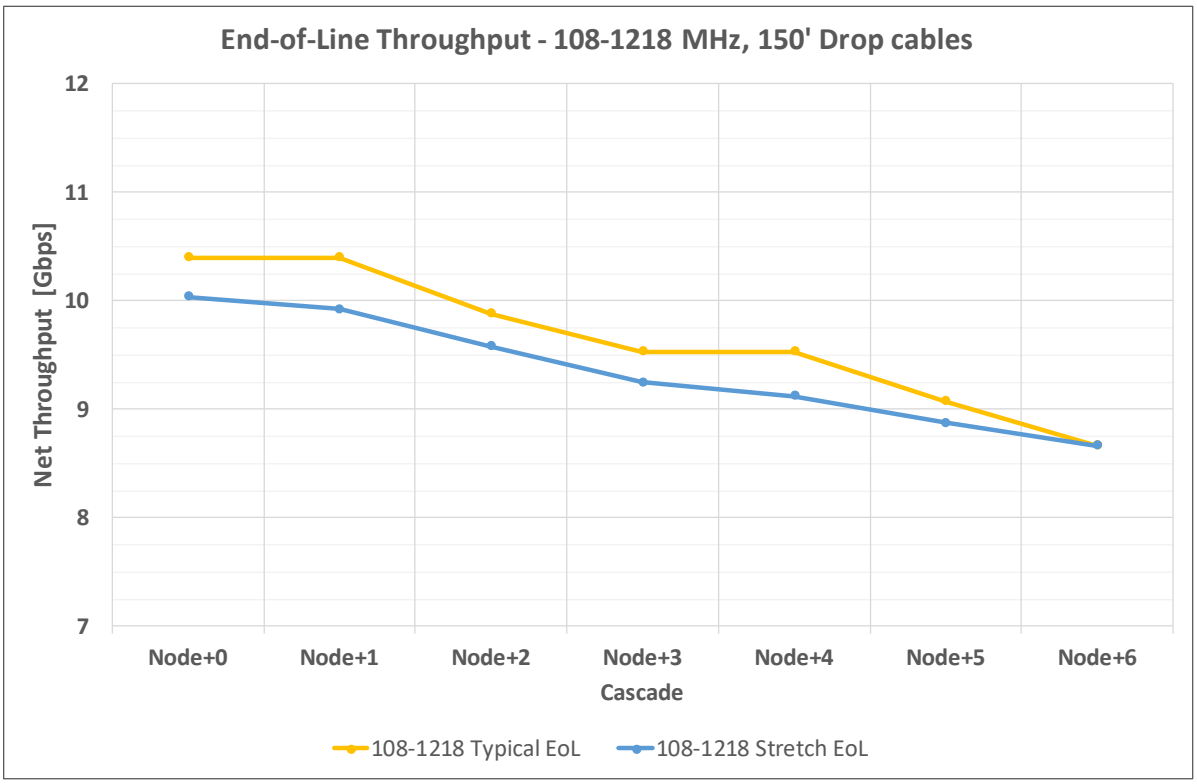

**Figure 11 – End-of-Line Throughput - 108-1218 MHz, 150' Drop cables**

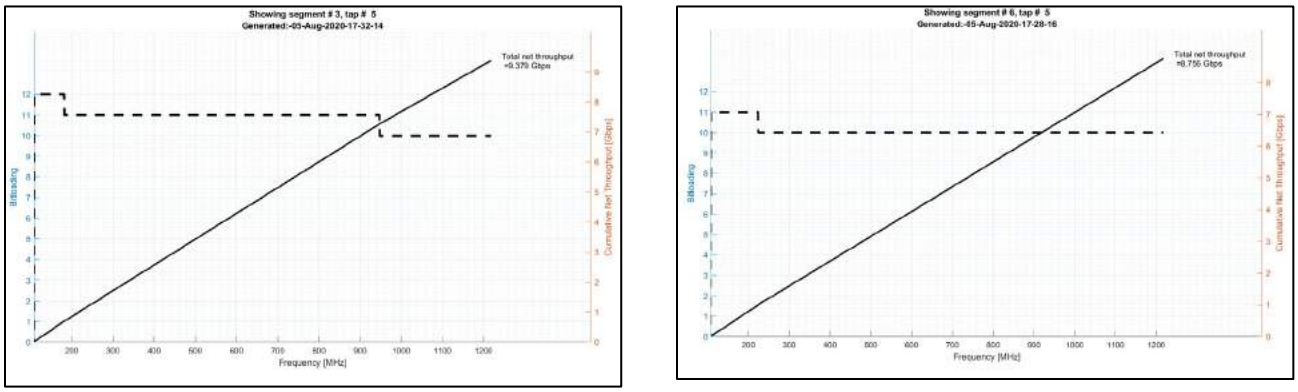

**Figure 12 – Stretch 108-1218 MHz Plant Bit-loading – Tap 5 for N+2 and N+5**

The 1218 MHz system maintains unity gain for both the typical and stretch plants. The network capacity degrades slightly as the amplifier cascades increases due to the accumulated noise and distortion from each additional amp stage. The additional cable loss in the stretch plant degrades network capacity slightly from the typical plant, but each amplifier stage is still able to maintain its unity gain.

Figure 12 shows the bit-loading for the 5th tap in a N+2 and N+5 stretch 108-1218 MHz system. As can be seen, the bit-loading remains fairly constant over the entire spectrum gain. This is what one might expect with unity gain.

Figure 13 now shows the EoL throughput for a 492-1794 MHz downstream system with cascade lengths varying from Node+0 to Node+6. This has 192 MHz more total downstream spectrum than the 108-1218 MHz system, but it is spectrum at higher frequencies with higher losses. Note that the downstream network capacity of the 492-1794 MHz typical plant in Figure 13 is very close to the 108-1218 MHz typical plant in Figure 12. However, the EoL throughput for the 1.8 GHz stretch plant in Figure 13 is substantial lower than the typical plant by around 20% or almost 2 Gbps. The stretch plant is also below the minimum 9 Gbps capacity target that was discussed in section 3.

Figure 14 shows the bit-loading for the 5th tap in a N+2 and N+5 typical 492-1794 MHz system. Since unity gain is maintained, there is no drop-off in bit-loading at higher frequencies. In fact, there is a slight increase in the bit-loading at the higher frequencies due to some non-linear effects in the amplifier.

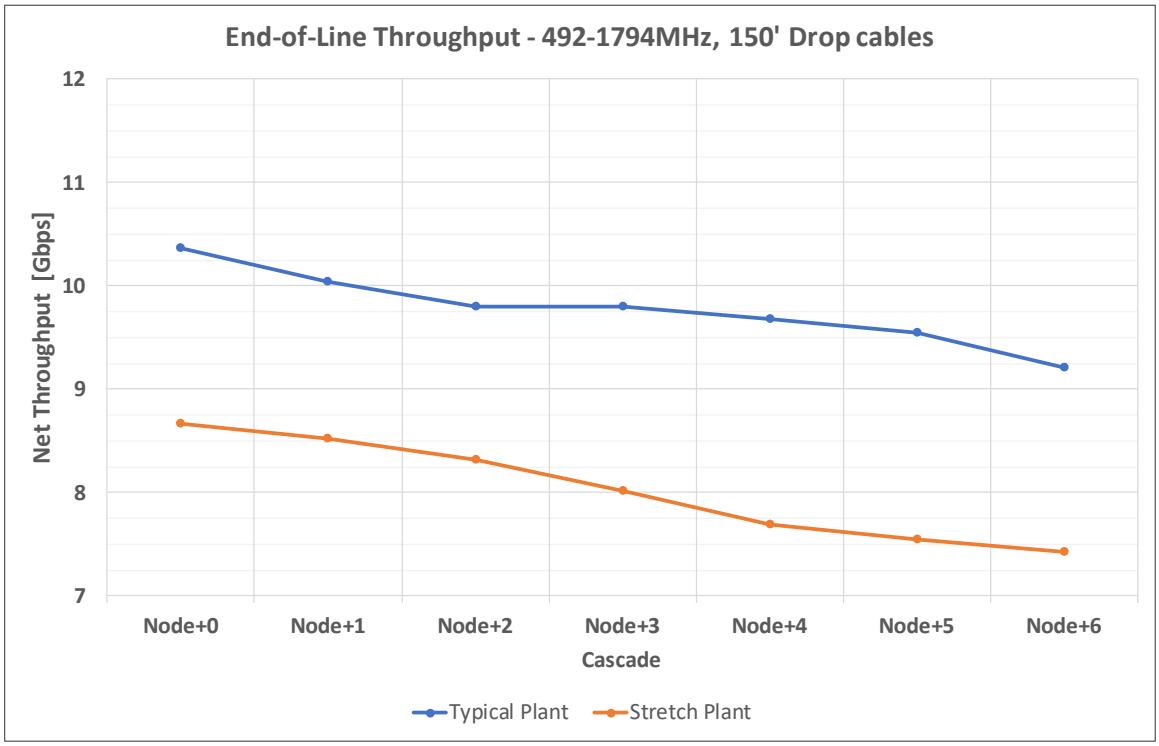

**Figure 13 – End-of-Line Throughput - 492-1794 MHz, 150' Drop cables**

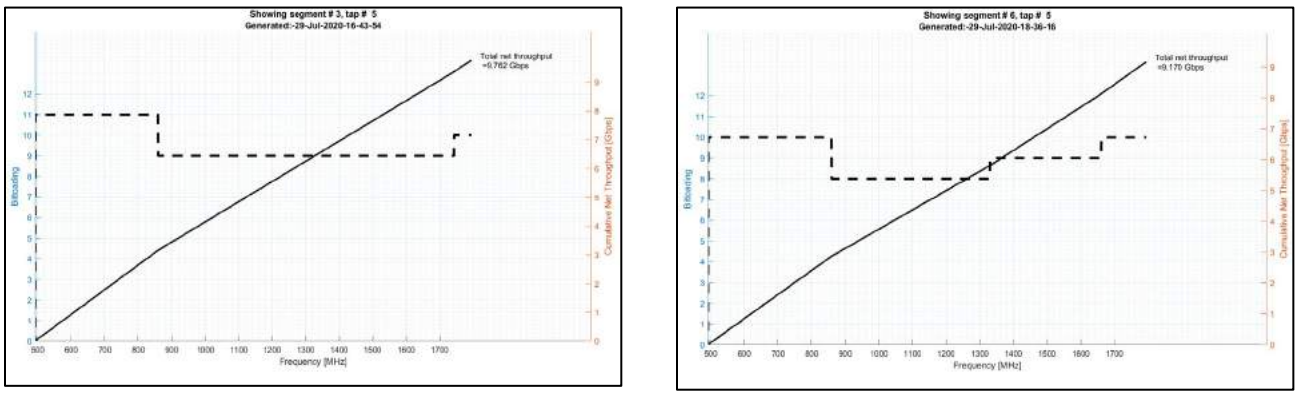

**Figure 14 – Typical 492-1794 MHz Plant Bit-loading – Tap 5 for N+2 and N+5**

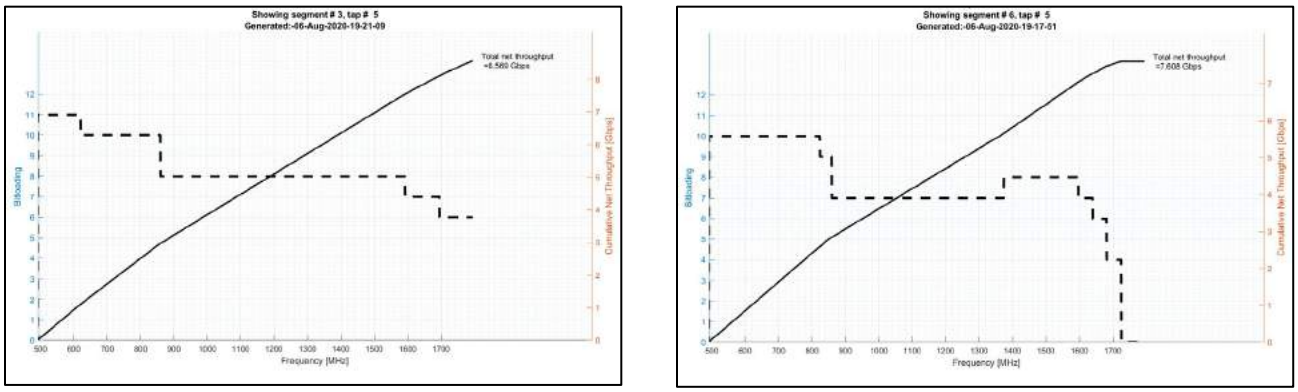

**Figure 15 – Stretch 492-1794 MHz Plant Bit-loading – Tap 5 for N+2 and N+5**

The stretch 492-1794 MHz system does not maintain unity gain. Figure 8 showed that the amplifier gain reaches its maximum output around 1600 MHz. Figure 15 shows the bit-loading for the 5th tap in a N+2 and N+5 stretch 492-1794 MHz system. It clearly shows how the bit-loading starts to drop-off above 1600 MHz. Note that the loss is relatively minimal after the 2nd amplifier output, only 1-2 orders of modulation. However, by the output of the 5th amplifier, the 5th tap is seeing a dramatic drop in bit-loading, losing roughly half the capacity in the 1602-1794 MHz OFDM channel.

Based on our earlier network capacity planning targets of needing 9-12 Gbps, the stretch 492-1794 MHz plant would not have acceptable system capacity using EoL throughput measure. Our conventional wisdom would dictate that these plants would need to have the amplifiers re-spaced or a mid-span amplifier added in order to maintain unity gain.

## 6. Game Changer – DOCSIS Compensates When Unity Gain Lags

When the DOCSIS 3.1 (D3.1) specification was written, the authors had a vision of a new DOCSIS PHY layer that squeezed every last once of capacity out of the cable plant. DOCSIS 4.0 inherits all these capabilities. Some of the most important D3.1 capabilities were wide OFDM channels with variable bit-loading along with the support of multiple profiles.

Previously, all modems would receive the identical downstream data stream. Therefore, the entire network had to operate for the lowest common denominator. Hence, the EoL capacity was a good metric for determining the plants capabilities. Each OFDM channel has a group of D3.1 profiles. Within that channel, modems are put into profile groups with similar modems and receive data at an optimal data rate. For example, modems in one profile could be receiving at 4096-QAM modulation while other modems in a different profile are receiving at 256-QAM modulation. This allows the DOCSIS system to optimize system capacity. This means that total system capacity depends on the capacity seen by every home on every tap in the system.

Figure 16 shows a 108-1218 MHz downstream example in a N+6 plant for both typical and stretch amplifier spacing. Network capacity is shown at every tap in the system. Modems further out on the cascade are seeing slightly lower performance and would be operating with D3.1 profiles that are using QAM modulations one or two steps below the best profile. In this example, the best profile would have 20% more capacity than the lowest profile.

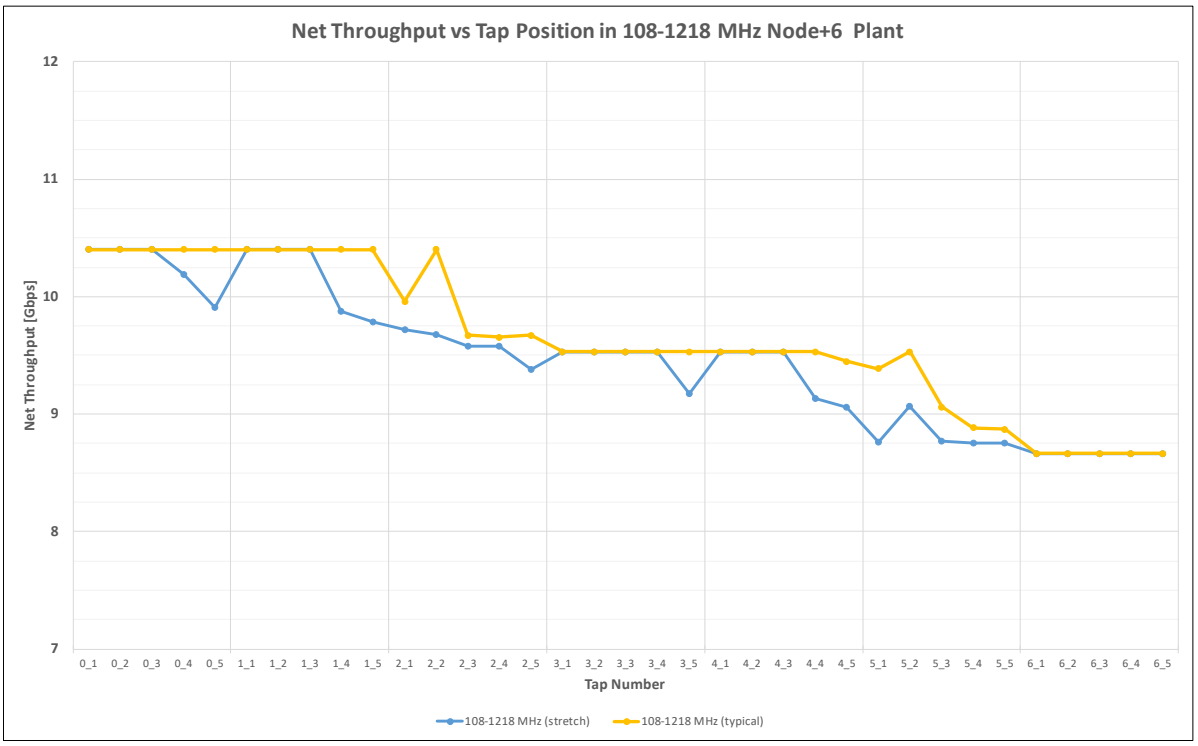

**Figure 16 – 108-1218 MHz Net Throughput vs. Tap Position in N+6 Plant, 150' Drop cables**

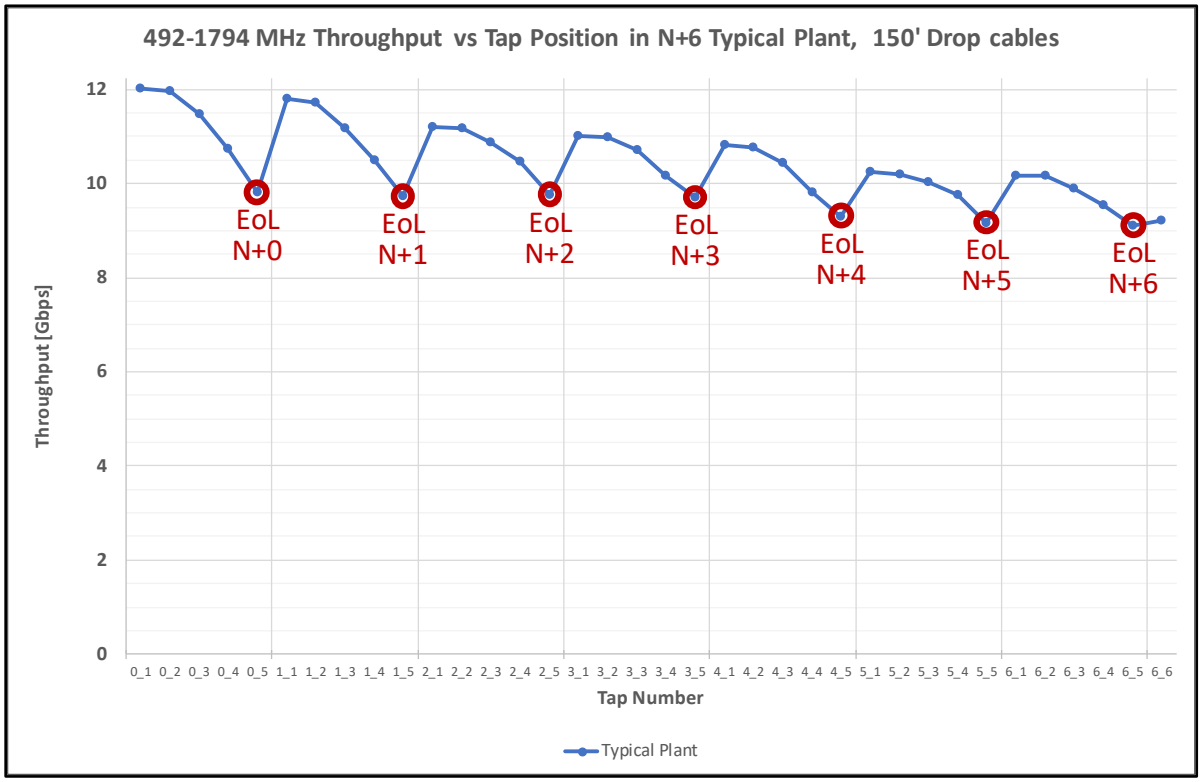

**Figure 17 – 492-1794 MHz Throughput vs. Tap Position, N+6 Typical Plant, 150' Drops**

For 1.8 GHz plants, the cable losses at the higher frequencies will magnify the differences between the best profiles and the lowest profiles. Figure 17 helps give a glimpse into the wider discrepancy seen by modems across an entire typical plant. Capacity changes based on two factors: # of amplifiers passed; and # of taps from the amplifier output. Figure 18 shows the stretch plant that has even more of a swing. In this example, the typical plant has a 32% swing from the lowest to highest capacities while the stretch plant sees a 60% swing from low to high! It goes from ~7.5 Gbps at tap 5 on the 6th amplifier up to almost 12 Gbps at the 1st tap from the node.

Remember, the EoL capacities discussed earlier basically aligns with the 5th tap value after the last amplifier, so it is basically following the troughs on this chart (see EoL for each N+X in Figures 17 & 18). These wide variations are just waiting to be optimized by DOCSIS. Many of the modems will have capacities significantly above the EoL capacities.

The profiles are set up separately for each DOCSIS OFDM channel. The OFDM channels are up to 192 MHz wide. So, the 492-1794 MHz downstream will have up to 7 OFDM channels with each channel getting its own optimized profiles.

In addition to optimizing each channel, the CMTS scheduler does load balancing between the channels. And an intelligent scheduler can factor the profiles for each modem to determine which channels it should use to optimize total network capacity.

So, if EoL is not a good measure of the network capacity, what should be used? It turns out that this is an extremely complex answer based on many different variables. The following sections will explore a number of these variables and make some estimates of network capacity for a 'reasonable' system.

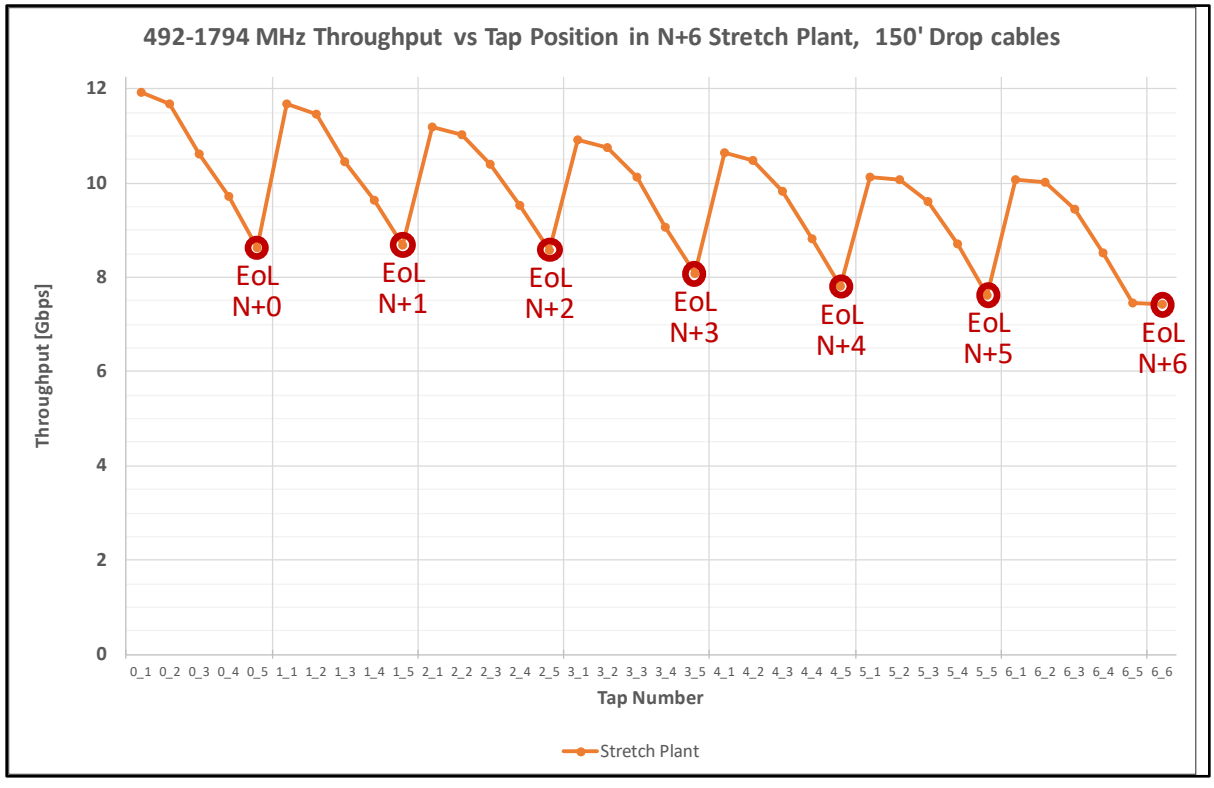

**Figure 18 – 492-1794 MHz Throughput vs. Tap Position, N+6 Stretch Plant, 150' Drops**

## 6.1. Estimating HP/Subscriber Distribution across N+X HFC Plant

As can be seen in Figures 17 & 18 above, the available capacity to any given modem is a function of where it is located on the plant relative to the fiber node. The HFC plant is a tree and branch topology that fans out for each additional level in the cascade. If one blindly assumed that each amplifier has 2 outputs feeding the next level of amplifiers, then a N+6 plant would have 64 amplifiers at the last stage in the cascade and a total of 126 amplifiers per node. If the outputs per amplifier is increased to 3 or 4, then it grows exponentially to where there could be 1000's of amplifiers from a given node.

But this is not reality. To understand what is out in the real world, the authors spoke with our customers and tapped into the knowledge of the in-house CommScope HFC design team. This in-house design team is perhaps the most experienced HFC design team anywhere, with a legacy going back 30+ years at some of our previous incarnations: ARRIS, C-Cor, Motorola, General Instrument, Philips.

The first thing we learned is that there is really no "typical" system. Real world HFC plants vary all over the map. So, we set out to define a "reasonable" scenario to get some baseline capacity estimates. From there, certain variables can then be changed to understand their impact on network capacity.

In general, amplifier spacing on average is relatively constant at 4-5 amplifiers per mile – especially if the networks considered include a mix of low density rural, medium density suburban and high-density urban areas. The homes passed (HP) density impacted how many homes might be off each tap (e.g. 1-2 HP per rural tap, 4-8 HP per urban tap). So, for our analysis, it is assumed that HP would be distributed evenly across all taps in the system.

As a starting point, a suburban build with 80-110 homes passed per mile (HP/mile) was chosen. From there, plants of various cascade lengths (i.e. N+0 to N+6) were analyzed. Table 2 shows an estimate of RF amps and homes passed based on input from our expert in-house HFC design team. This table shows that the number of RF amplifiers per node grows almost linearly with the cascade depth. It is NOT exponential! For each level in the cascade, another six to eight amplifiers are typically added.

Why is this??? It turns out there are several factors. First, the majority of amplifiers are single output line extenders (LE). These are amplifiers just cascading down a street without any branches. Next, multiple output bridgers (MB) would often have some outputs feeding side streets without connecting to another amplifier (i.e. a dead end). Finally, not all branches go out the entire cascade depth. In a N+6 plant for instance, many branches might terminate after 3, 4 or 5 amplifiers and not reach the sixth cascade level.

The homes passed per node also tended to follow the amplifier count with typically 16-20 HP per amp.

This knowledge then let us model how the homes passed (and hence subscribers) are spread across the HFC plant. After the first amplifier, a linear increase in HP per cascade level is used.

The next task was to understand how many taps are typically following each amplifier. As noted above, the amplifier spacing is fairly constant, and hence the number of taps were too. But there is some variation. The HFC design team might need to shorten or extend a leg based on the real-world geography. The vast majority of amplifiers have either 4 or 5 taps at its outputs. The number of fewer taps (e.g. 3) or more taps (e.g. 6) was trivial for this analysis. It turns out that percentage of amplifiers with 4 taps is roughly twice that of the amplifiers with 5 taps.

**Table 2 – Example RF Amps and Homes Passed per Node for N+X**

| HFC Cascade Lengths | # of RF Amps per Node | # of Homes Passed per Node |
|---|---|---|
| Node + 0 | 0 | 40 - 60 |
| Node + 1 | 4 – 6 | 80 - 150 |
| Node + 2 | 10 – 12 | 150 - 240 |
| Node + 3 | 15 – 20 | 240 - 360 |
| Node + 4 | 22 – 28 | 360 - 480 |
| Node + 5 | 28 – 35 | 480 - 600 |
| Node + 6 | 35 - 45 | 600 - 720 |

## 6.2. DOCSIS Optimized Network Capacity Analysis

The first order of business was to look at the 108-1218 MHz plant shown in Figure 16 and see how much additional DOCSIS capacity might be available compared to the EoL measurements. Figure 19 shows the DOCSIS optimized weighted average capacity compared to the EoL capacity for both the typical and the stretch 1218 MHz plants.

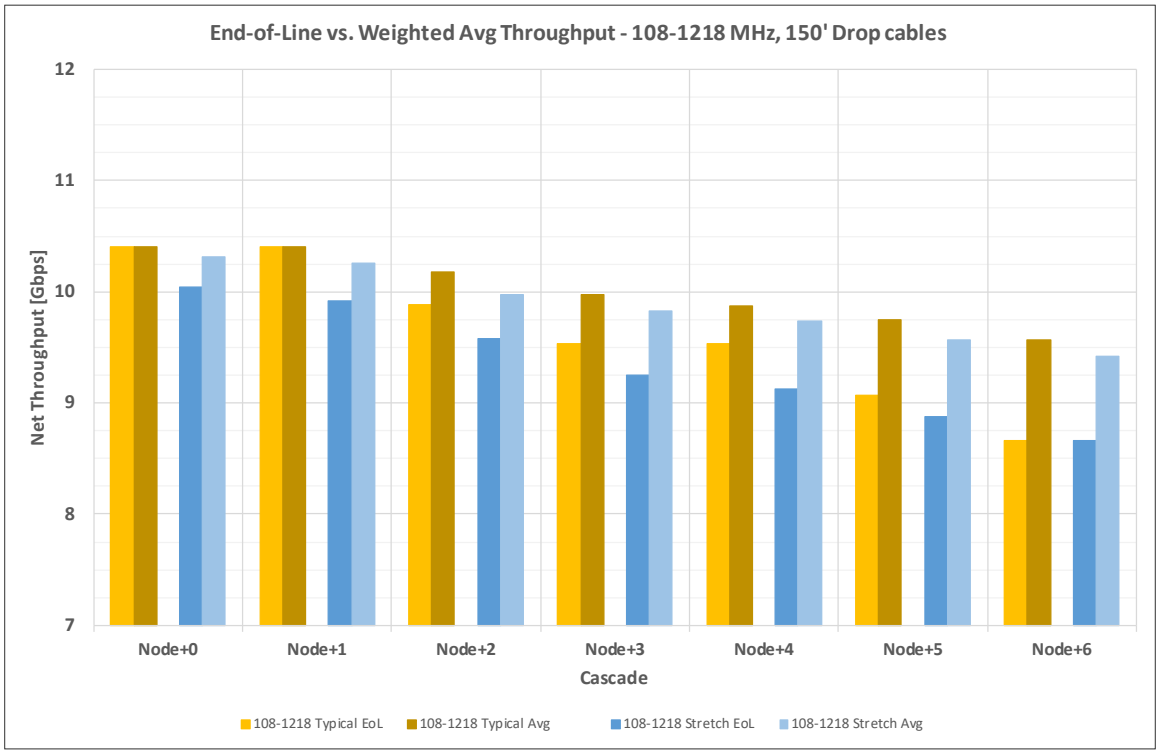

**Figure 19 – End-of-Line vs. Weighted Avg Throughput - 108-1218 MHz, 150' Drop cables**

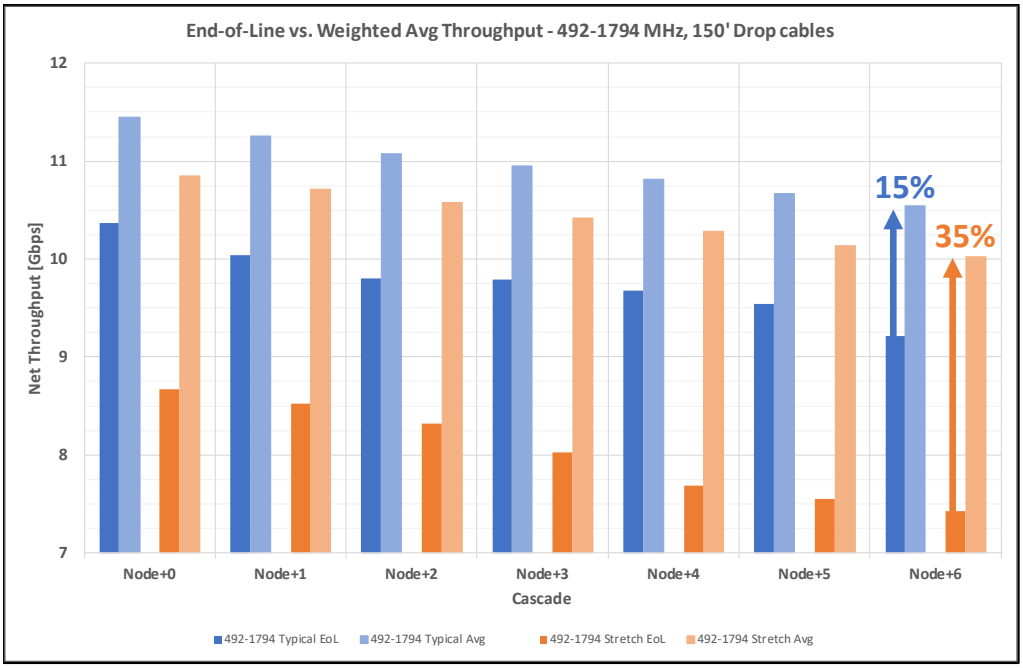

**Figure 20 – End-of-Line vs. Weighted Avg Throughput - 492-1794 MHz, 150' Drop cables**

Both typical and stretch plants saw very little gain for shorter cascades while N+6 plant saw up to 10% gains over the EoL calculations. So EoL appears to be reasonably accurate for the 1218 MHz plant.

The next scenario looked at the 492-1794 MHz plant previously shown in Figure 17 & 18 to see how much additional DOCSIS capacity might be available compared to the EoL measurements. Figure 20 shows the DOCSIS optimized weighted average capacity compared to the EoL capacity for both the typical and the stretch plants.

The difference between the DOCSIS optimized weighted average capacity and EoL capacity is significant. For the typical plant, the gains start around 10% for N+0 and increase to 15% for N+6. The stretch plant sees even larger gains, from 25% gains for N+0 plant to 35% for N+6 plant. The EoL measure is grossly underestimating the capacity of the stretch plant. The EoL measure showed that typical plants had 20% to 25% more capacity than the stretch plant. The DOCSIS optimized capacity results above shows that the gap between typical and stretch plant is significantly less, in the 5% range!

Perhaps one of the most significant conclusions from this study is that the stretch plant that was considered inadequate, is actually capable of supporting the network capacity requirements and does NOT need any extra help (e.g. re-spacing amps or adding mid-span amplifiers).

### 6.3. Impact of shorter drop cables (66'/100'/150')

Drop cables are less costly than trunk lines, but also do not have as good RF characteristics. This becomes a big deal as the HFC plant pushes to 1.8 GHz. Per our in-house HFC design expert, most drop cables out there today are RG-6 cables. Higher performance RG-11 drop cables are typically used for extremely long runs, e.g. 200' or longer.

Our expert felt that our 150' drop cable assumption in the previous results was on the high side. Figure 21 and 22 show the impact on total network capacity by varying the drop cable length from 66' to 100' to

150’. This was done for the typical plant in Figure 21 and the stretch plant in Figure 22, using RG-6 cable for all cases.

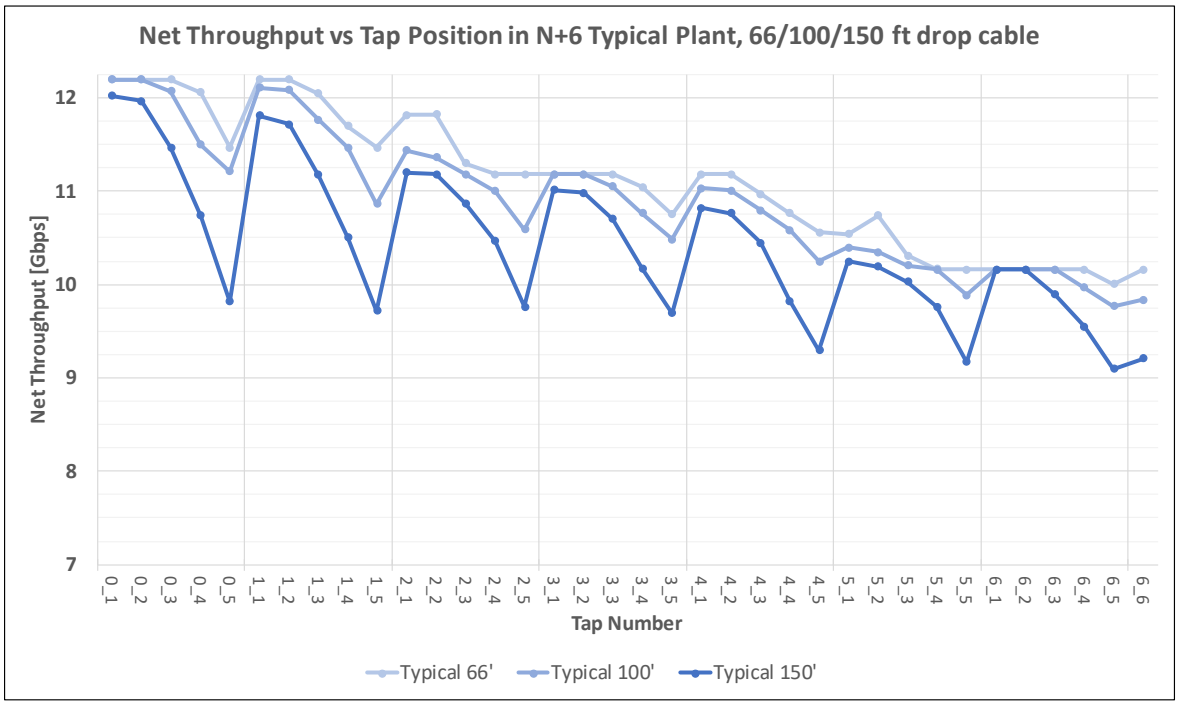

**Figure 21 – Net Throughput vs Tap Position in N+6 Typical Plant, 66/100/150 ft drop cable**

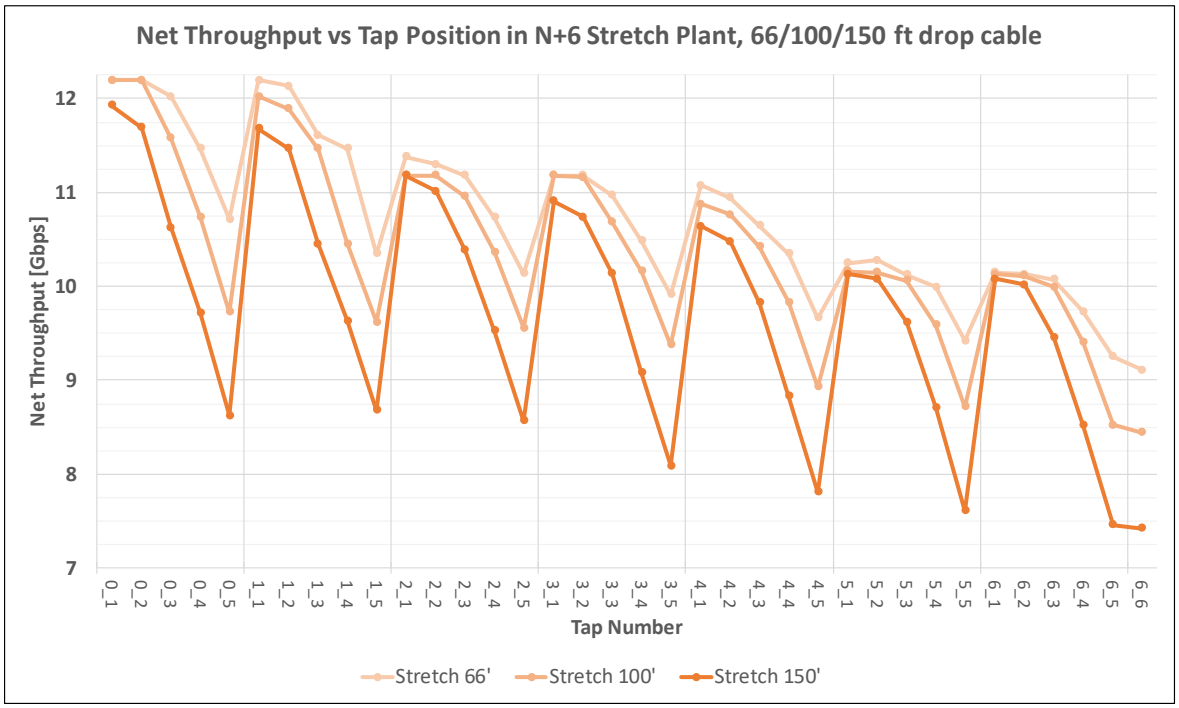

**Figure 22 – Net Throughput vs Tap Position in N+6 Stretch Plant, 66/100/150 ft drop cable**

In general, the short drop cable makes a significant difference, especially for the fourth and fifth taps. For the typical plant, there is less than a 3% difference on the first two taps after the amplifier for 100' compared to 150'. The 4th tap has gains in the 7-10% range while the 5th tap sees 7-15% improvements.

The stretch plant shows even wider spreads between 100' and 150'. The gains on the first two taps can be up to 4%. The 4th tap sees improvements up to the 8-12% range and the 5th tap sees 10-16% gains with the shorter 100' drops.

> *Note that replacing a 150' RG-6 drop cable with RG-11 will result in improved performance that is very close to the 100' RG-6 drop cable.*

Migrating from 100' to even shorter 66'drop cables did not have as big effect, especially on the typical plant. The 66' drop cable did show some gains over the 100' drop on the 4th and 5th taps of the stretch plant. The largest gains being 7-10% after the first two amplifier and then shrinking gains with more amplifiers in the cascade.

## 6.4. Impact of Super-stretched Links (56dB)

As shown on Figure 10, a small percentage of multi-port bridger amplifiers have extremely large dB spacings that are >55 dB. Figure 23 shows the impact of inserting one or two of these super-stretched links with 56 dB spacing into a typical plant. For reference, 56 dB spacing between amplifiers could represent any one of the following scenarios:

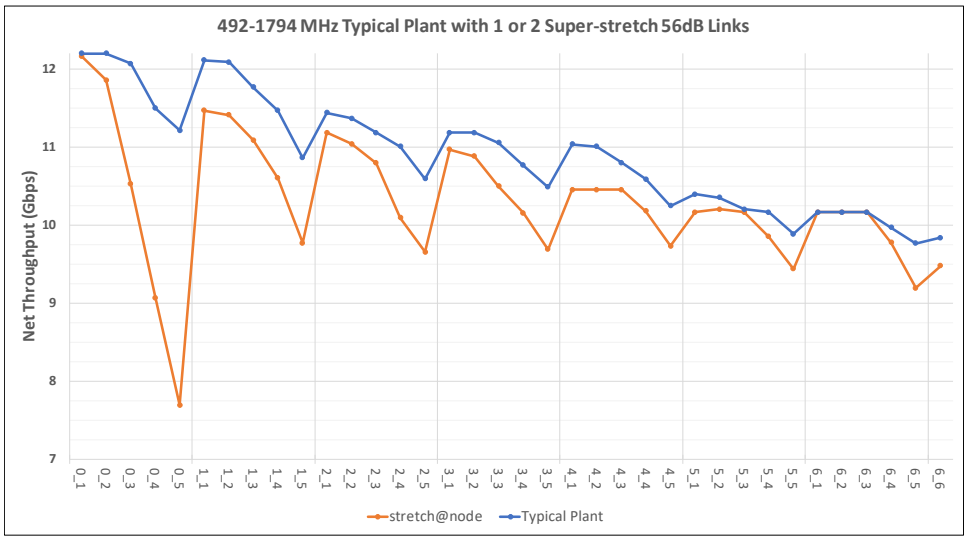
1. 1560 ft of 0.500 cable
2. 1920 ft of 0.625 cable
3. 2640 ft of 0.875 cable
4. Or 1560 ft of 0.625 plus 5 taps

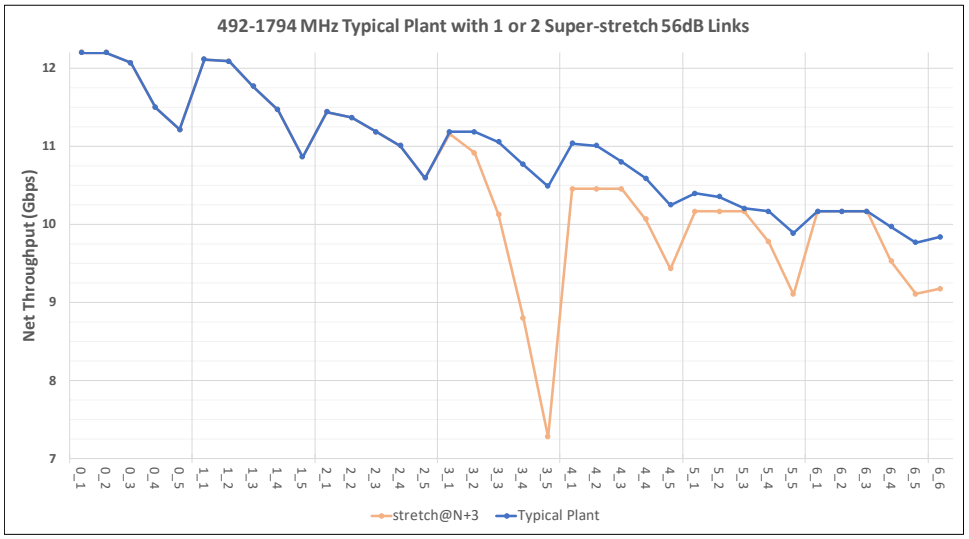
In general, it would be expected that these super stretched links are express feeder runs over a long distance without any taps. For this example, Figure 23 shows scenario 4 with 1560' of 0.625 cable plus 5 1.8 GHz taps to demonstrate the impacts of the distance on these taps.

For the first case, a super-stretch 56 dB link is inserted following the node. As can be seen, the total capacity seen at the output of the 1st amplifier drops by ~0.5 Gbps at the 1st tap and over 1 Gbps by the 5th tap relative to the typical plant. After each additional amplifier in the cascade, the delta with the typical plant shrinks as the noise introduced by each amplifier accumulates and starts to dominate.

For the second case, the super-stretch 56 dB link is inserted after the 3rd amplifier. The outputs after the node, 1st and 2nd amplifiers are identical to the typical plant. The outputs after the 4th, 5th and 6th amplifiers are very close to the first case in which the super-stretch link is at the node.

The final case shows a scenario where two super-stretch links are inserted, one after the node and one after the 3rd amplifier output. Adding the second super-stretch link shows a noticeable degradation to the total network capacity after the 4th, 5th and 6th amplifier outputs.





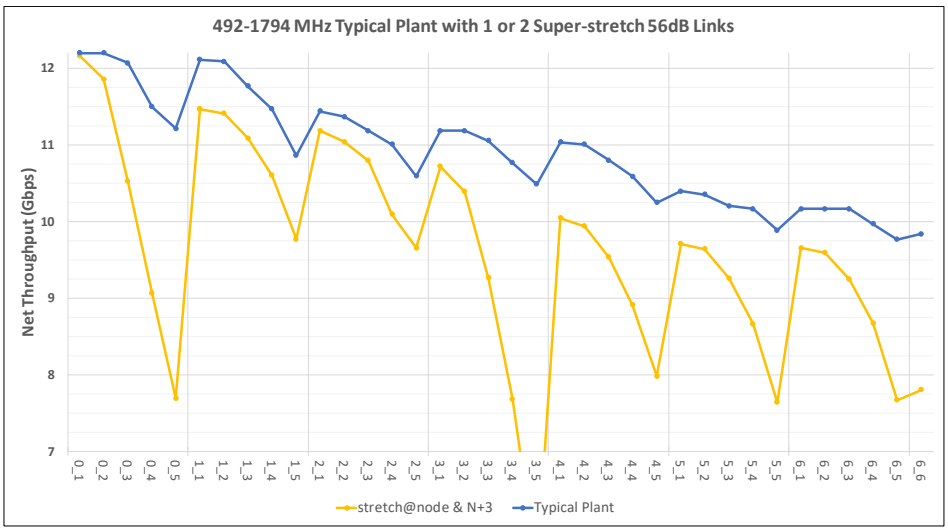


**Figure 23 – 492-1794 Typical Plant with 1 or 2 Super-stretch 56 dB Links**

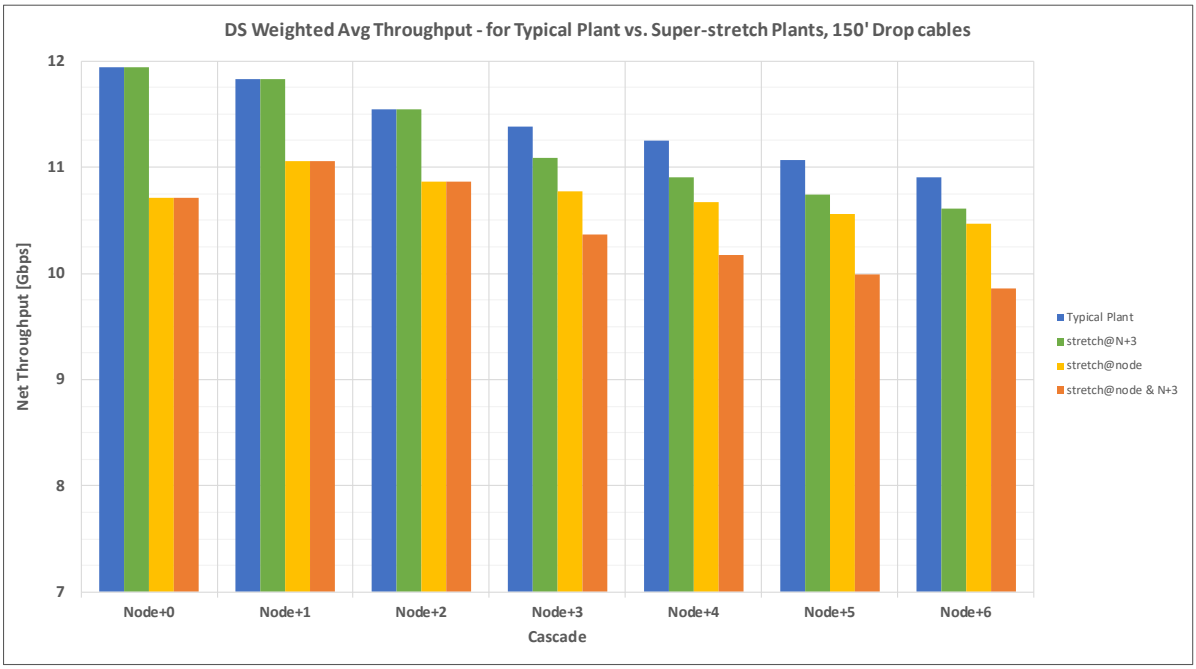

**Figure 24 –Weighted Average DS Capacity with 1 or 2 Super-stretch 56 dB Links**

Figure 24 compares the DOCSIS optimized weighted average DS capacity for the three super-stretch cases compared to the typical plant. With the CMTS scheduler effectively averaging capacity across all the taps, this helps to minimize the impact of these super-stretched links. For Node+6 plant, adding one super-stretched link drops average capacity by <5% while adding two super-stretched links only has ~10% impact.

## 6.5. Downstream ESD Capacity for various US/DS splits

The DOCSIS 4.0 specification allows for many different upstream (US) options. For a static ESD system, the possible diplexer splits are:

- 85/108 MHz
- 204/258 MHz
- 300/372 MHz
- 396/492 MHz
- 492/606 MHz
- 684/834 MHz

The first number is the upper edge of the upstream spectrum. The second number is the starting edge of the downstream. The guard band is the region between these two and is not usable. Notice that the guard band grows larger as the US/DS split frequencies increase.

Our network capacity modeling research has shown time and again that downstream bandwidth capacity is the limiting factor in almost every analysis. So, it is extremely important to try and maximize the downstream bandwidth capacity.

The DOCSIS 4.0 specification also supports a dynamic FDX option. For FDX, the shared band starts at 108 MHz and can go up to 204, 300, 396, 492 or 684 MHz. The FDX downstream goes up to 1218 MHz. So downstream bursts can potentially leverage the full 108-1218 MHz.

Figure 25 shows the downstream capacity at each tap location for various static ESD US/DS splits for a N+6 typical plant and 150' drop cables. It also compares these to a 108-1218 MHz DS similar to that used by FDX (although full-duplex operation may add other impairments which are not factored into this example). Figure 26 then shows the DOCSIS optimized DS weighted average capacity for the various static ESD splits and the dynamic FDX for various cascade lengths from N+0 to N+6.

Because the changes between the US/DS splits are in the lower frequencies (i.e. below 684 MHz), the capacity differences remain constant. For each static ESD curve, there is a drop in capacity with increasing taps. This is the same for all static ESD scenarios, so they all have the same shape. Note that the 684/834 split has a noticeably larger gap than the other splits. This is a combination of two factors. First, it has the largest guard band. Second, its downstream is missing a lot of the lower frequencies which tend to have higher bit-loading as shown previously in Figures 14 and 15.

The 108-1218 MHz FDX DS spectrum is also shown for reference and appears to align closest with the 492/606 MHz static ESD DS capacity. The next section takes a closer look at that.

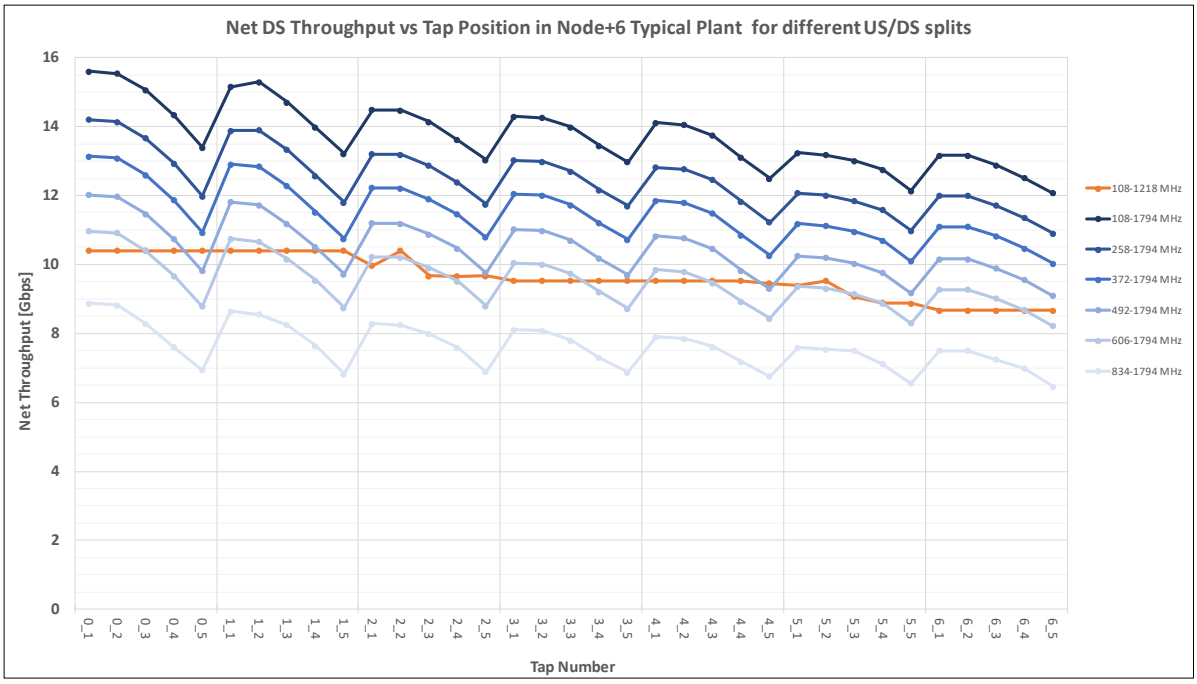

**Figure 25 – Net Throughput vs. Tap Position in N+6 Typical Plant, different US/DS splits**

Table 3 looks at some potential service tier combinations that could be considered for the various ESD split options. These SLAs are based on the basic traffic engineering formula discussed earlier in section 3. Remember that it is a function of the number of subscribers, Nsub, and the average peak period consumption per sub, Tavg. Both may change over time. For this table, the base assumption is Nsub=200, DS Tavg=20 Mbps, US Tavg=1.2 Mbps and K=1.0-1.2. Note that 100 subs @ DS Tavg=40 Mbps would be roughly equivalent.

By comparison, the SLA for 10G PON with 64 subs and same Tavg would be 6-7.5 Gbps for both the US + DS. The last row in Table 3 shows the theoretical best SLA's on a 1794 MHz plant. This uses dynamic soft-FDD where the CMTS scheduler switches between two diplexer settings (i.e. 85/108 MHz and 684/834 MHz) to time division multiplex the 108-684 MHz spectrum between US + DS.

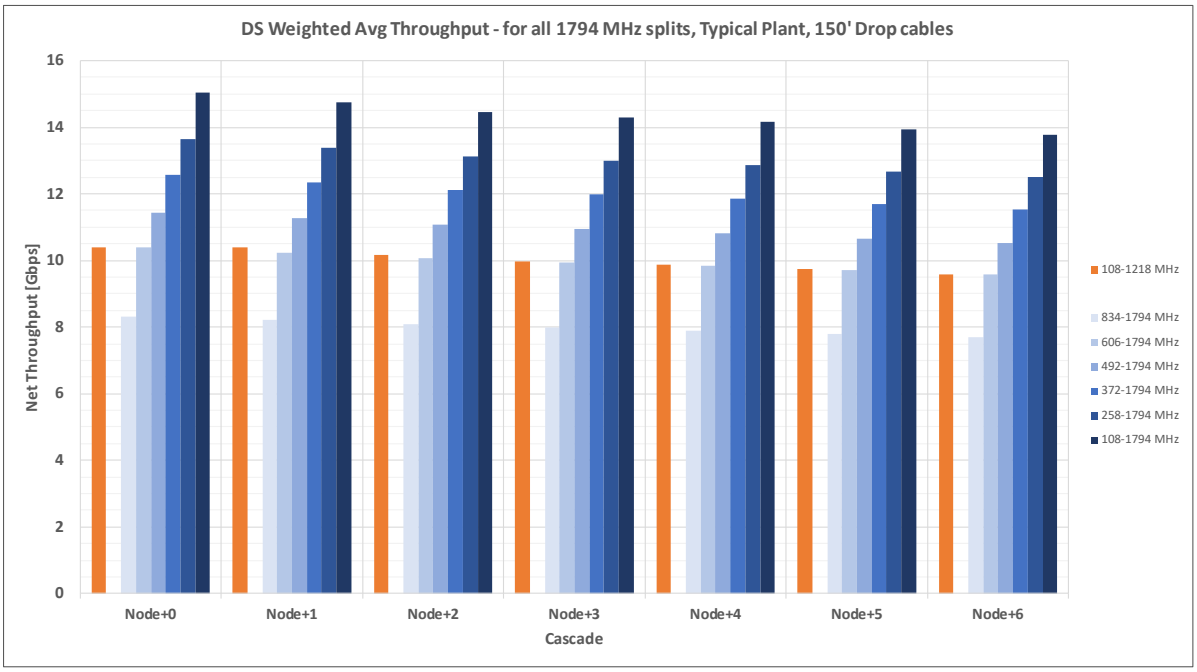

**Figure 26 – Weighted Average DS Capacity for different US/DS splits**

**Table 3 – Summary of SLA Options for 1794 MHz Plants**

| 10G HFC Options | Top of US (MHz) | Start of DS (MHz) | DS SLA (Gbps) | US SLA (Gbps) |
|---|---|---|---|---|
| 1794/204 MHz | 204 | 258 | 7 – 9 | 1 – 1.5 |
| 1794/300 MHz | 300 | 372 | 6 – 8 | 1.5 – 2 |
| 1794/396 MHz | 396 | 492 | 5 – 7 | 2.5 – 3 |
| 1794/492 MHz | 492 | 606 | 4 – 6 | 3 – 3.75 |
| 1794/684 MHz | 684 | 834 | 3 – 4 | 4 – 5 |
| 1794/85 MHz with 108-684 MHz dynamic Soft-FDD | 684 | 108 | 8 – 10 | 4 – 5 |

## 6.6. Comparing 108-1218MHz FDX vs. 606-1794MHz ESD DS Capacity

The DOCSIS optimized capacity for both the static 606-1794 MHz ESD and the 108-1218 MHz dynamic FDX DS capacities are compared in Figure 27. This gives a better handle on how these two stacks up against each other. Note – FDX in N+X plant would require FDX-capable amplifiers which are still under investigation.

For typical plant conditions, the DOCSIS optimized weighted average capacity for the 606-1794 MHz ESD is almost identical to the 108-1218 MHz FDX system.

On a stretch plant, the 606-1794 MHz ESD takes a hit in the higher frequencies, especially above 1.5 GHz. This reduces its DS capacity by about 5% compared to the 108-1218 MHz DS in a stretch plant.

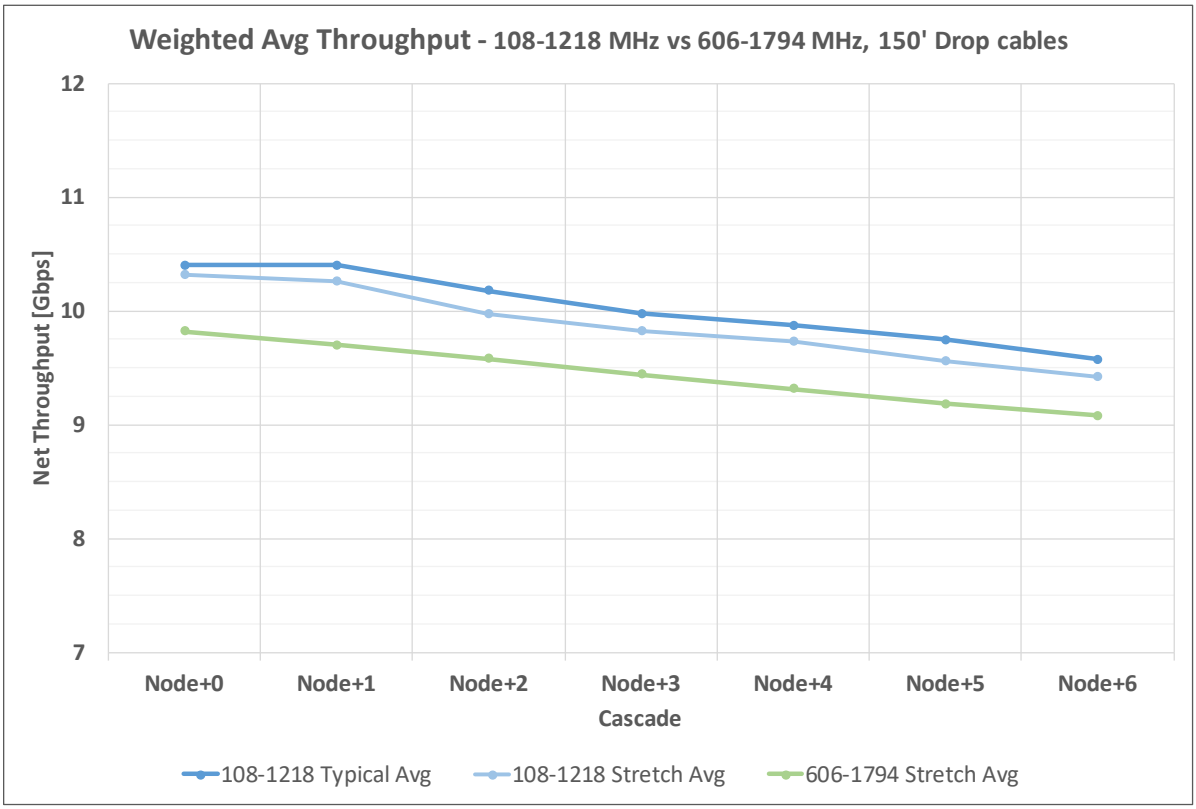

**Figure 27 – Weighted Avg Throughput - 108-1218 MHz vs. 606-1794 MHz, 150' Drop cables**

## 6.7. Improving on the DOCSIS Weighted Average Capacity

The DOCSIS weighted average capacity in the earlier analysis's assumes that the subscriber's data usage is relatively evenly distributed across the HFC plant AND the subscriber's data usage is evenly distributed across all the available OFDM channels. However, each channel has its own unique set of profiles that can vary significantly from channel to channel.

Figure 28 below looks at the bit loading for two extreme cases in the 492-1794 MHz plant. The first case is a home on the 1st tap after the 1st amplifier for a typical plant amp spacing. The second case is a home on the 5th tap after the 6th amplifier on a stretch plant.

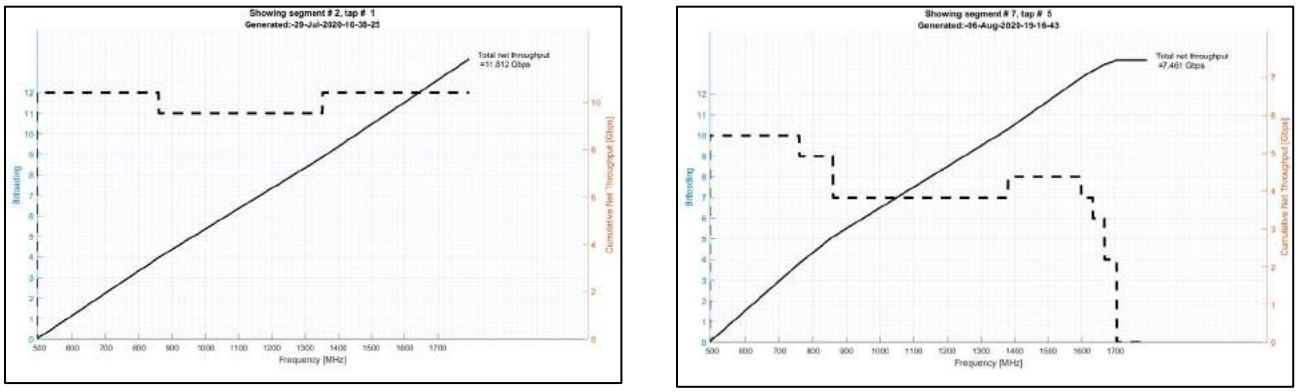

**Figure 28 – Example Bit-loading for Near and Far Homes**

As can be seen, the modem at the far home has vastly lower bit-loading capacity in the upper frequencies, and in particular, the top OFDM channels, i.e. 1602-1794 MHz. If the far modem has a 5 Gbps burst, the CMTS could schedule it in the 492-1218 MHz OFDM channels. Note that the near modem still has ~5 Gbps available to it in the top 3 OFDM channels from 1218-1794 MHz. So, both modems could be bursting to 5 Gbps simultaneously even though the EoL throughput for this plant is less than 7.5 Gbps. And the total burst rate is higher than the average of the two bit-load maps put together.

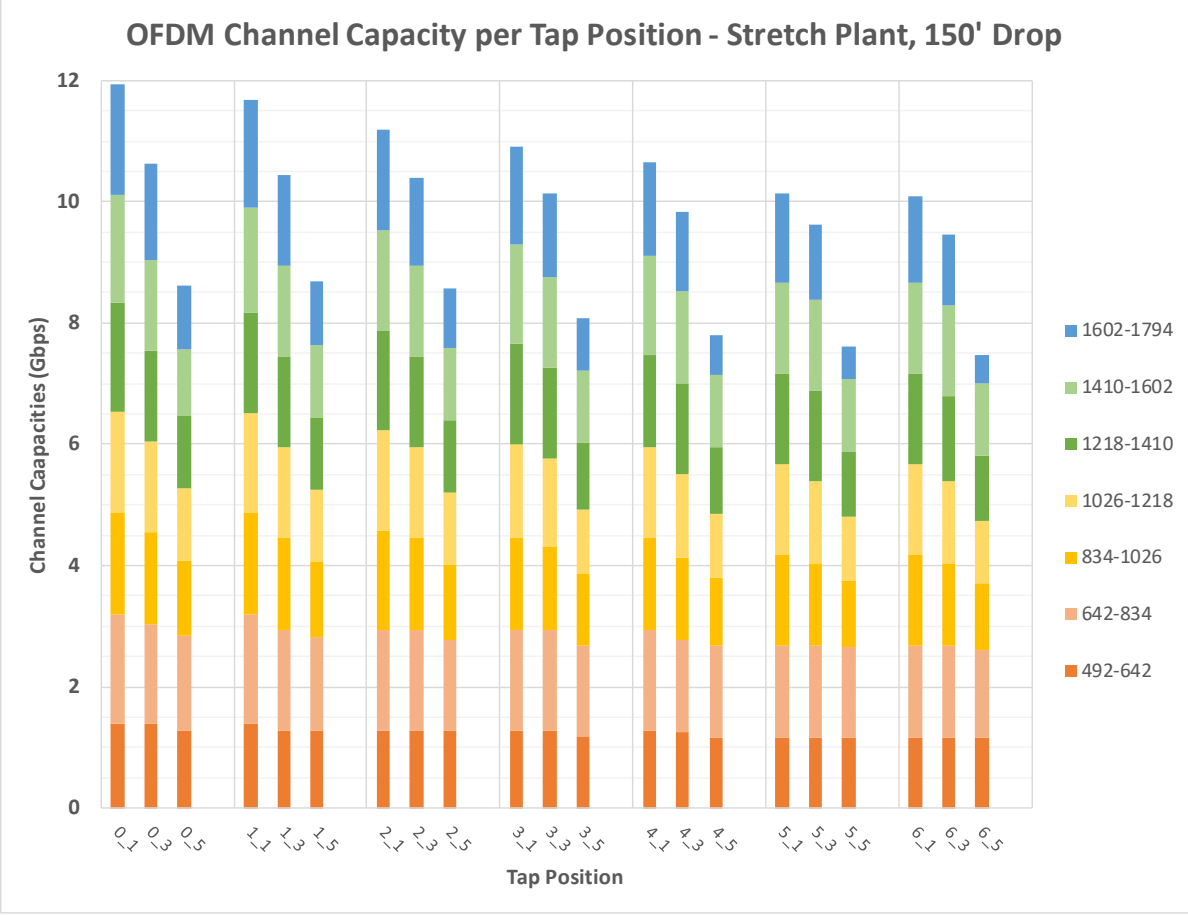

**Figure 29 – Example Channel Capacities for various Tap Positions**

Figure 29 shows how these bit-loadings map to the individual channel capacity for the 1st, 3rd and 5th tap on every amplifier output stage. As can be seen in the above channel capacities, the top OFDM channel for the 5th tap is practically unusable. For the other high frequency OFDM channels (i.e. 1026-1602 MHz) the 1st and 3rd taps can be 30% to50% higher capacities than the 5th tap location. Overall, the 1st tap position is getting reasonably good capacity across all the channels, even at the higher frequencies.

For over a decade, the CMTS schedulers have been load balancing across multiple DOCSIS 3.0 bonded channels. And they have been doing a great job at it. In the above scenario, the CMTS scheduler can tend to put data from the further taps in the lower frequency OFDM channels while the nearer taps utilize the relatively empty upper frequency OFDM channels. This means the CMTS can achieve even higher capacities than those shown with the weighted average capacity analysis above.

## 6.8. Handling the Corner Cases – Meeting Tmax Burst QoE

The DOCSIS weighted average capacity and the intelligent CMTS scheduler improvements addresses the total system capacity available to the scheduler. However, as seen previously, the capacity seen by any individual home can vary dramatically. The CommScope basic traffic engineering formula discussed in Section 3 can help determine the capacity needed for each individual home so it can obtain its appropriate Quality of Experience (QoE).

Consider a worst-case scenario where an operator wants to support a 7.5 Gbps DS service tier across their entire footprint, including 10G PON FTTH and DOCSIS 4.0 ESD 492/1794 MHz HFC plant. As seen in Figure 18, some home locations might only see total available capacity around 7.5 Gbps. That means that whenever that home wants to burst to its full 7.5G Tmax, it will need to use every ounce of spectrum available to it. That would leave practically nothing left for the remaining subs (i.e. Nsub*Tavg component from the formula).

In reality, the CMTS would not let these other subs starve, but will tend to allocate higher capacity lower spectrum to the bursting modem and others near the EoL. Meanwhile modems closer to the node and amplifier outputs will be using their higher capacity profiles in the higher frequency OFDM channels. So, the bursting modem might only get 5-6 Gbps out of its 7.5G tier during peak busy times.

So, how probable is this worst-case scenario? There are several factors that must all align for this to happen. These factors and the individual probability of each include:

- Subscriber takes the premium 7.5G DS top billboard tier [~1% to ~5%]
- Subscriber home is on the 5th tap [20%, i.e. 1 out of 5]
- The probability that this link even has 5+ taps [~30%]
    - Majority of amplifier outputs have 4 taps or fewer
- The tap is after the 5th or 6th amplifier [~25% of amplifier outputs on N+5/N+6 plant]
- % of MSO plants that are even N+5 or higher [1% to 20%???]
- The amplifier output is being stretched beyond unity gain [~5% to 15%]
- The RG-6 drop cable is >125’ [~25% to 50%]

On N+5/N+6 plants, only 1 out of every ~200 to ~1,000 amplifier outputs might fall into this category. While it varies greatly by MSO, N+5 and N+6 plants are also becoming a smaller and smaller percentage of their total HFC plants. Of these potential problem amplifier links, it is only a problem if there is a subscriber on the 5th tap that takes the 7.5G DS top billboard tier. For all these stars to align, it looks like a probability on the order of four or five 9’s that this won’t happen.

 

It may be the end of this decade before the 7.5G DS tier is being offered and this worst-case scenario can potentially kick in. So, what options are available to the operator over this time window to handle this potentially rare event? Here are some possibilities:

1. MSO accepts slight QoE degradation (i.e. 7.5G drops to 5-6G during peak busy hour for these very infrequent customers)
2. MSO only offers 4G-5G DS service tier to this customer
3. Pull fiber to that subscriber's home and switch them to 10G PON
4. Reduce the N+5/6 cascade depth
5. Add mid-span amplifiers to boost higher frequency signals
6. Replace the RG-6 drop cable with RG-11

Option 1 might be very acceptable, but potentially dependent on your regulatory environment. The customer perceived QoE between 5 Gbps bursts and 7.5 Gbps burst capacity may not be perceptible. And this is only happening for rare times when the consumers bursts to the max and for a very small percent of the customer population. If the operator is still uncomfortable with this, they can choose option 2 and only provide the consumer with a slightly reduced Tmax (e.g. 5G instead of 7.5G). Note, this is something that the DSL world has had to always deal with, but this is not nearly as dramatic. In older DSL technology, customer capacity might have varied from 2 Mbps to 25 Mbps.

If the operator wants to correct the situation and provide additional capacity where needed, then options 3-6 would need to be considered over the next 5-8 years. An economic analysis of some of these choices is in the next section. Since this scenario does not need to get resolved until the end of the decade, the operator has plenty of time to correct the issue before it happens.

Everyone agrees that the long-term strategy is to eventually get to FTTH. However, many consider this a multiple decade transition to get to the point where fiber is pulled down every street. Option 3 jumps directly to FTTH as the solution. However, since this is a N+5/N+6 plant, chances are that the fiber is not nearly as close to the home as it might be in N+0/N+1 plant. It might be over a mile away from the customer. So, option 3 is expected to be the most expensive.

With the long-term strategy to continually push fiber deeper, then option 4 above is making a step in that direction. If these problem amplifier spans can be identified today (e.g. N+5/N+6 with stretched outputs), then the operator can spend the next decade gradually attending to these and pushing fiber deeper. Grey optics aggregator (GOA) / grey optics terminator (GOT) is a cost-effective fiber deep architecture that could be used to reduce the cascade length, without necessarily going all the way to N+0. The GOA functionality is placed at the parent node location. The downstream optical signal is split and passed on to the GOT node using short distance optics. The GOA also aggregates all of the GOT return signals. The GOT nodes are transparent to the head end and does not require any additional head end optics.

A low cost GOT fiber node can replace one of the multi-bridger amplifiers on the path to these problem spans to reduce the cascade length. If an operator has a 20 year plan to convert to a fiber deep network (e.g. 5% of plant per year), they can target these problem spans now to make sure issues with these are corrected before the end of the decade. Later in time, the GOT node can be upgraded to a full-fledged fiber node as needed.

Options 5 and 6 both fix the potential capacity issue but are not in alignment with the strategic direction of pushing fiber deeper towards eventual FTTH. Option 6, pulling a new drop cable, could be aligned with this strategy if it is a "siamese" cable that contains both fiber and RG-11 drops. Option 5, adding a mid-span amplifier, might make sense if the logistics do not allow option 4 to pull fiber deeper to reduce cascade lengths.

# 7. Cost and Logistic Analysis

Our starting point for economic analysis discussion is a 750 or 860 MHz HFC network case study depicted in Figure 30. The fiber node area, serving 400 HP, is also a single Integrated Converged Cable Access Platform (I-CCAP) service group. It is a 42/54 MHz "sub-split" system with a total of 20 RF amplifiers, 10 each of bridger and line extender type. There is a total of 100 taps, on 25,000 feet of hardline coax plant, for an average density of 84 HP/mile and ~4.2 amps/mile. The longest RF amp cascade length is N+4.

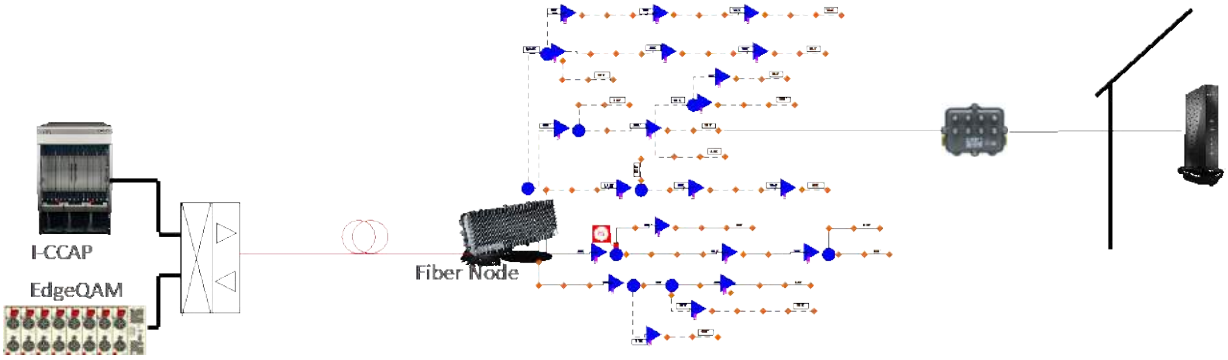

**Figure 30 – I-CCAP N+4 HFC network with 42/54 MHz sub-split**

The cost of upgrading this network to 1218 MHz with a 204/258 MHz high-split is analyzed by (a) replacing "ePack" node and amps modules and (b) adding appropriate I-CCAP license to augment both DS and US data capacity. The left-most column of Figure 31 depicts this network upgrade, along with the percent breakout of various elements. Furthermore, this 1218/204 MHz upgrade is normalized to 100%, in order to be the baseline to compare to the other cases, namely 1.2 GHz FDX N+0 and 1.8 GHz ESD N+4. The 2nd column shows the 1218/204 MHz upgrade where the tap faceplates are also upgraded to 1.2 GHz. This adds ~25% premium on top of the base case.

The network shown in Figure 30 is applicable to the 1.2 GHz high-split case. For the other two cases, however, networks of Figure 32 and Figure 33 are the respective representations. FDX requires a N+0 "fiber-deep" upgrade. The original fiber node plus 20 amplifiers end up being replaced by 4 fiber nodes with ~50% of the original hardline coax over lashed by new fiber. For the 1.8 GHz ESD N+4 case, whole-station amplifiers, as well as all 100 tap housings are replaced.

As shown in Figure 31, the FDX N+0 upgrade comes to 454% of the "base case", that is, the 1.2 GHz high-split upgrade. The fiber material plus labor costs really dominate for the N+0 upgrade. Our analysis assumed 80% aerial plant. This component could be much higher if the percentage of underground plant increases over 20%. The 1.8 GHz ESD upgrade comes to 214% of the "base case", or a 114% premium.

If only 1 to1.5 Gbps US service tiers are needed, the 1218/204 MHz upgrade is the most cost effective. However, once multi-Gbps US tiers are needed, then the FDX N+0 or the 1.8 GHz N+4 upgrade is required. Our study shows that the FDX N+0 upgrade is roughly twice the cost of the 1.8 GHz ESD N+4 upgrade for this N+4 plant case study.

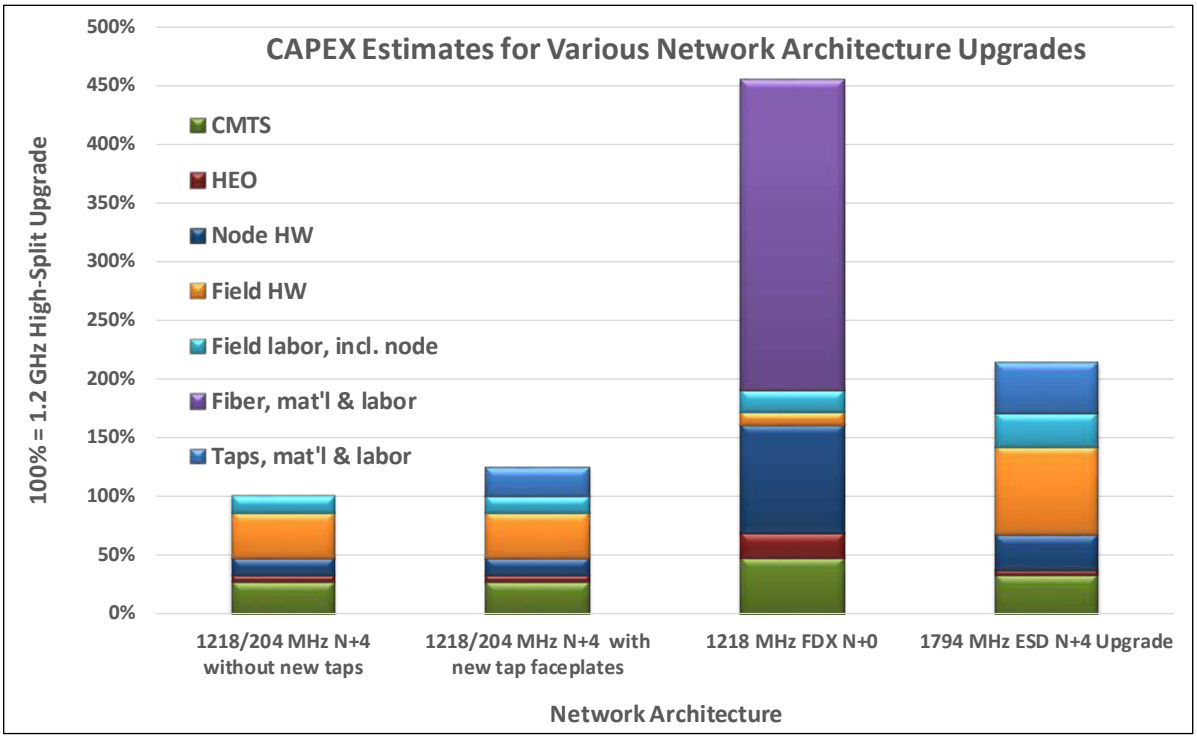

**Figure 31 – CAPEX estimates for 1218/204 MHz N+4 (both without and with new tap faceplates), 1218 MHz FDX N+0, 1794 MHz ESD N+4 upgrades**

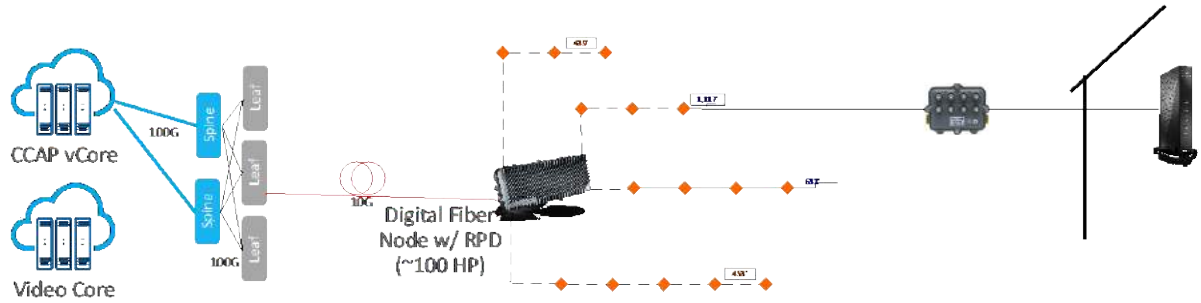

**Figure 32 – DAA N+0 HFC Network Model for 1.2 GHz FDX Upgrade**

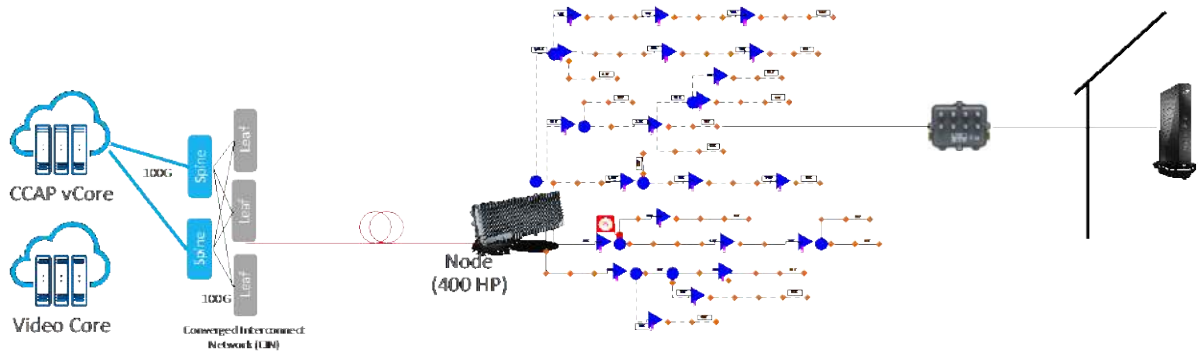

**Figure 33 – DAA N+4 HFC Network Model for 1.8 GHz ESD upgrade**

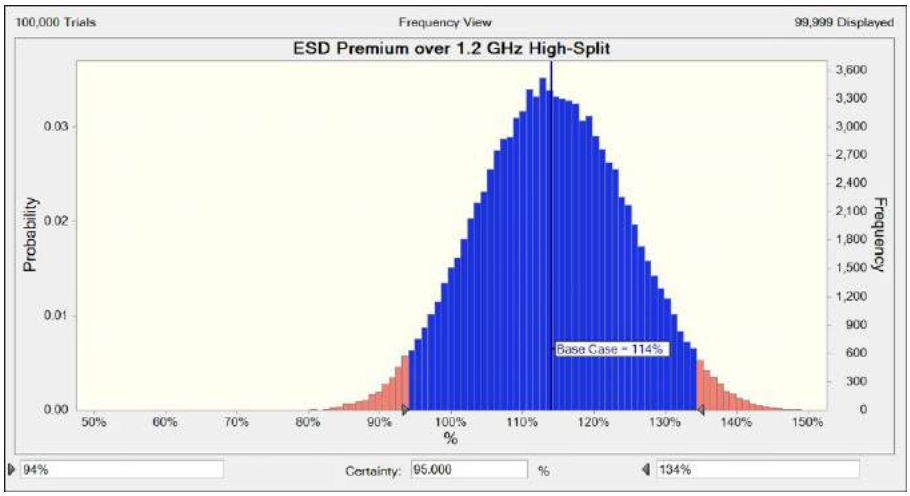

**Figure 34 – Monte-Carlo analysis of "premium" for 1.8 GHz ESD case**

There are other benefits to the ESD approach. For one, it is providing dedicated upstream capacity while FDX is relying on statistical time sharing of US+DS spectrum. The second is that ESD is a much simpler system than FDX which should result in OPEX savings through reduced maintenance and easier to diagnose plant issues.

Because many elements go into an evaluation of this type, a Monte-Carlo analysis was run with various assumptions varying over a reasonable range for the ESD upgrade case. A total of 100,000 Monte-Carlo samples were run to see how much the ESD "premium" might vary. Figure 34 shows that the ESD "expected" premium of 114% expands into a 94% to 134% "confidence interval".

What is driving the 114% ESD premium, while the FDX N+0 premium is 354%? Figure 31 offers some answers: fiber over lash required for N+0 accounts for 264% of the 354% premium for FDX! The 2nd most dominant FDX component is node hardware at ~90%. For ESD, RF amplifiers, labor to replace those, and a material and labor to upgrade tap housings and faceplates to 1.8 GHz account for most of the cost.

For the ESD case, a reasonable "workload" for the whole amplifier and taps upgrade were considered, especially allowing for the whole housing to get replaced. This assumed there is 1 tap per 4 HP; the RF amplifiers are closer to 1 to 20 HP ratio, and nodes are even further – in the assumptions made above it's 1 to 400 HP. If an amplifier module takes approximately 1 hour to replace and a tap housing takes 45 minutes to replace, how much of an additional labor force would an operator need in order to do these upgrades?

For an MSO serving a region with population of one million people (e.g. ~400,000 HP), Table 4 holds the answer. For the taps portion, it would require an additional full-time crew of ~10, working full-time, over a 5-year period; and doing nothing else. One may describe it as a large task, but 10 additional employees to do this task seems reasonable.

The previous section discussed a corner case where a subscriber with a long RG-6 drop cable at the EoL on a N+5/N+6 stretch plant does not have sufficient network capacity to obtain the highest service tier. Of the half dozen potential options mentioned, the most cost effective would be to replace the drop cable with RG-11. The operator might also consider putting it in a conduit for reliability and ease of later upgrading to a fiber drop as well as consider siamese cable/fiber pair. Adding a mid-span boost amplifier for high frequencies on the last link might triple or quadruple the cost of the drop cable option. And, more

than one mid-span boost amplifiers might be needed on some of the other links in the cascade. Neither of these options pushes fiber deeper so they may not be aligned with the longer strategic direction.

**Table 4 – Estimate of Labor force required to replace amps and taps in 5 years**

| | Nodes | RF Amps | Taps | Homes-Passed |
|---|---|---|---|---|
| Quantity | 1,000 | 20,000 | 100,000 | 400,000 |
| Task duration | 1 Hour | 1 Hour | 45 minutes | |
| 24/7 Person-Years | 0.1 | 2.3 | 8.6 | |
| 40hr/week Person-Years | 0.5 | 9.6 | 36.1 | |
| 30hr/week Person-Years | 0.6 | 12.8 | 48.1 | |
| Required size crew to complete the task in 5 years | <<1 | <3 | <10 | |

Trying to jump directly to FTTH can be extremely costly. Since this home is EoL on a N+5/N+6 plant, it might be up to a mile and a half from the fiber node. The costs of pulling fiber can skyrocket, especially if the plant is mostly underground. Some estimates show this to be 100 times the cost of just replacing the drop cable. This is hard to justify for a single customer.

One strategy is to push fiber deeper over a 20-year window to get most customers within 1000' or 1500' of fiber access. At this point, the operator can offer FTTH on demand when and even if needed (e.g. 90%+ of subs may stay on cable 'forever'). To achieve this, the operator can focus on the N+5/N+6 stretch plants in the near-term, with the goal of getting all of their HFC down to N+2/N+3 by the end of the 2020 decade. Then in the decade that follows, the operator can push fiber deeper to achieve N+0/N+1 that can enable FTTH on demand by the end of the 2030 decade. Analysis such as [ULM_2016] have shown that fiber deep N+0/N+small upgrades are more cost effective than FTTH for HFC brownfield upgrades.

## 8. Conclusion

The title of the paper posed the question "Is "Unity Gain" Still the #1 Objective?" as the cable world migrates to 1.8 GHz DOCSIS 4.0 plant. The paper has shown how much more difficult the 1.8 GHz unity gain task will be compared to 1218 MHz. Looking at stretch plant, the unity gain starts to come up short and the cracks become obvious at the longer cascades like N+5 and N+6.

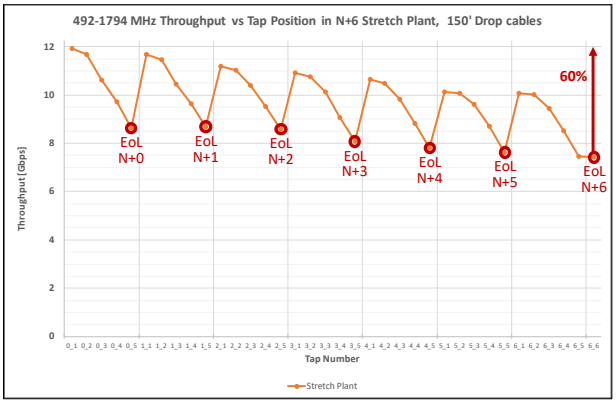
Previously, conventional wisdom would have said that the amplifiers would need to be re-spaced; a potentially expensive proposition. Recently, there has been discussions of adding a mid-span amplifier to boost the gain for these links, which should not be taken lightly, as this adds more active components into the system.

Instead, inherent DOCSIS capabilities can leveraged to compliment unity gain when it comes up short. Previous thoughts of using EoL throughput as an indicator of plant capacity are no longer accurate at 1.8 GHz. DOCSIS 3.1/4.0 OFDM channels with variable bit-loading and multiple profiles enable the CMTS scheduler to maximize the system capacity. This was shown nicely in Figures 18 & 20, which are repeated in Figure 35 below. The N+6 stretch plant saw DOCSIS weighted average capacity gains that were 35% higher than EoL throughput.

The paper explored some of the variables that impact system capacity. In addition to amplifier spacings (e.g. typical vs. stretch plants), it looked at various cable drop lengths and the addition of super-stretched

links into a typical plant. These are all scenarios that allow DOCSIS to optimize the system capacity some more.

The 1.8 GHz ESD plant offers several options for different upstream splits, varying all the way up to 684/834 MHz. Choosing different splits lets the operator balance between upstream and downstream bandwidth. The paper looked at the DS capacities associated with the different splits and then showed the range of DS + US service tier SLA combinations that might be supported near the end of this decade.



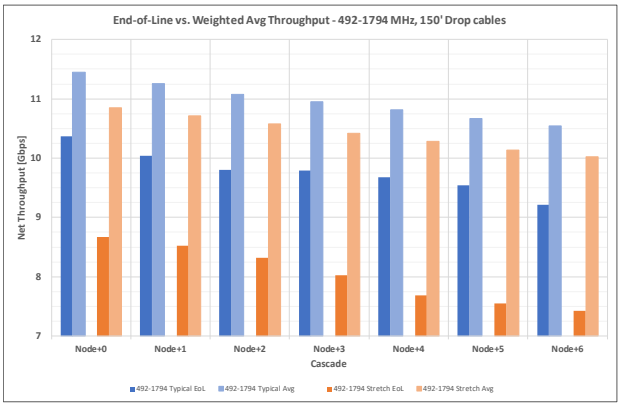


**Figure 35 – EoL vs. Weighted Avg Throughput – Typical and Stretch Plants**

The cost and logistic analysis section hopefully gave the reader some sense of the economic tradeoffs that will be encountered when looking at these various options. When the operator finally needs multi-Gbps US tiers, the 1.8 GHz ESD is more cost effective, potentially half of the cost of a FDX N+0 upgrade.

So, to answer the question from our title, the answer is: Maybe Yes! The authors still believe that trying to maintain unity gain is a key objective in any HFC design. It has shown its worth time and time again. However, as it approaches the breaking point, DOCSIS scheduling can fill the gaps on many of these plants on the bubble, reducing the number of HFC links that need drastic action to a significantly smaller amount. The two work well together.

# Acknowledgements

The authors would like to thank Cox Communications and in particular David Job, Principal Eng of OSP Engineering at Cox, for providing the data and insights into the HFC amplifier spacing distribution.

The authors are also extremely grateful to everyone that gave us insights and advice on HFC design and doing a sanity check on what “reasonable” might be. In particular, we want to thank Stuart Eastman of CommScope for sharing some of network design wisdom; and Jay Lazorcik of CommScope for HFC network and unity gain diagrams.

# Abstract

Augmented Intelligence, also known as intelligence amplification, cognitive augmentation, decision support, machine augmented intelligence, and enhanced intelligence, is essentially Artificial Intelligence with a novel approach. While Artificial Intelligence is creating machines to work and react like humans, Augmented Intelligence is using those same machines with a different approach to improve human capabilities. In fact, Augmented Intelligence involves people and machines working together, leveraging their own strengths to achieve greater business value. In other words, the primary goal of Augmented Intelligence is to empower humans to work better and smarter. In this paper, we present the journey we are taking in Telecom Argentina, from data analytics, ML, AI to Augmented Intelligence.

# Content

## 1. Introduction

We started applying data analysis technologies, then machine learning and Artificial Intelligence applied to our networks and services more than a decade ago in the former Cablevisión Argentina and continue after the 2018 merger, in Telecom Argentina. Telecom is in a process of digital transformation and as part of that process we understood that we should not only continue with the application of AI to our mobile, fixed and service networks, but take another step. Focus AI technology on humans.

Many times when people hear about algorithms, robots and AI, they imagine that such technologies compete with them. "*The technology is the easy part. The hard part is figuring out the social and institutional structures around the technology*" [ REF John Seely Brown]

The application of Artificial Intelligence technology may not be successful if it is poorly adapted, designed or implemented. We must ensure that it is designed to help humans think better.

That's why we focus not only on AI technology, but also on human-machine collaboration, processes, and interfaces. This is Augmented Intelligence seeking to elevates human capabilities and experiences. By focusing AgI on serving people rather than replacing them. AgI can help them achieve their greatest potential.

### 1.1. Humans developing AI algorithms

It is well known that supervised ML algorithms are trained and tested with a large amount of data whose output variables are known (either numerical or categorical). These data consist of a large number of explicative variables or attributes that are in principle chosen at random.

Before "feeding" the machine the data are "worked", eliminating for example the missing data and outliers, standardizing, etc., all this so that no problems in learning the algorithm occur. With the algorithm written by humans, with the data that feeds the training also chosen by humans, we expect that the algorithm can predict a numerical or categorical variable with very little error when an unknown data is presented. The error is inherent in the system because this is an algorithm that does not want to "interpolate" the results but rather "approximate" them and therefore its goal is to minimize the error of its approximation. One way to

fully understand this process is to use the PAC ("probably approximately correct") Learning framework [1] [ ] .

In a second phase, the human, can diminish the number of explicative variables with which he fed the system and the amount of the same ones, going from a big data to a small data. In short, we are moving towards a process of purification in terms of data quality. The human, expert, could be constantly testing new explicative variables, new sources of data, perhaps unconsciously pursued by the search for a causal law.

But we are not in a world of rules and laws, we are in a world where we are offered an innumerable amount of data with its attributes and we want to use them to decide or to predict at best. But sometimes what "is not" is as important as what "is". What we are not considering because of our own limitations or bias could be being left out of the data that train the algorithm.

And that should be a human task, to go out in search of the unknown, to make them present to us. As we see, human action is immersed in all aspects of AI. Defining the data, building the algorithms, which are constantly evolving and becoming more specialized, interpreting the results.

We could make an analogy with Kant's Copernican revolution, paraphrasing him and say that all knowledge has to "start" with data, but knowledge does not have its only origin in data. The constantly evolving algorithms used do not have their origin in data. Neither does the interpretation we give to the results according to our expertise.

In short, in this phase of our technology, a feedback process is needed between us, the humans and the machines we also create, constantly mediated by the data we know how to get.

As you can see, just like "Artificial Intelligence is not Intelligence, Machine Learning is not Learning" [ref Burkov, Andriy. The Hundred-Page Machine Learning Book (Páginaxvii). Andriy Burkov. Edición 2019].

## 2. What is Augmented Intelligence and why?

Our definition of Augmented Intelligence (AgI) is a powerful intelligence as the result of the collaboration between humans and machines, is the evolution of the Artificial Intelligence (AI) that enables humans to make better-informed decisions from complex data and Machine Learning (ML) algorithms. One aspect of AI that disturbs humanity is the possibility that people may be replaced by machines at their jobs. The goal of augmented intelligence is not to replace human beings or automate them out of existence but to enable them to make better decisions. From our perspective this collaboration between humans and machines will be the enabler for our industry to transition to the information revolution that is coming.

Gartner identifies this emerging technology as key for the design approach of new business solutions, balancing short-term automation with a mid/long-term approach that ensures improving quality not only by automation means, but also by amplifying human talent.

---

[1] In this framework, the learner receives samples and must select a generalization function (called the hypothesis) from a certain class of possible functions. The goal is that, with high probability (the "probably" part), the selected function will have low generalization error (the "approximately correct" part). The learner must be able to learn the concept given any arbitrary approximation ratio, probability of success, or distribution of the samples. The model was later extended to treat noise (misclassified samples). Source: Wikipedia

 

Figure 1 corresponds to the Hype Cycle for Emerging Technologies that Gartner publish every year, since 1995. According to the cycle, we can see that this technology will reach the plateau in 2 to 5 years [ref: gartner.com/SmarterWithGartner].

**Figure 1 – Gartner Hype Cycle for Emerging Technologies, 2019 (Source: Gartner)**

## 2.1. Some definitions

According to Merriam-Webster, information can be defined as the "communication or reception of knowledge or intelligence; knowledge obtained from investigation, study, or instruction". The future information revolution will be conducted by three main pillars: Free data and information, Small data and Augmented Intelligence (ref en Bell Labs). In this future, the goal will be to store the right amount of data that enables data scientist to discover knowledge and extract useful information by using new tools provided by the AgI.

We found that there is a confusion about the meaning of the terms data and information, it is believed that they both mean the same. These are the definitions we considered for this paper:

- *Data*: the actual captured observations.
- *Information*: the determination of relationships between data.
- *Knowledge*: the determination of models that describe the meaning of Information.
- *Technology*: a manner of accomplishing a task especially using technical processes, methods or knowledge (ref: Webster's Dictionary 2015).

Although data is easy to obtain, to establish the relationships between data is not. In many cases, it is possible to determine this relationship as the statistical correlation but it not necessary implies causation. Determining models and applications where this correlation makes sense is the most important component to succeed in discovering the meaning of information, that is, knowledge. We can define the five basic

 

knowledge acquisition questions: *who, what, when, where* and *why?* These questions are an ideal starting point for assessing the relative value of information.

But the question *why?* is distinct from *who, what, when* and *where?* because forming an answer to *why?* implies some understanding or knowledge of a situation.

## 2.2. The goal of Augmented Intelligence

How this human-machine collaboration works? Both humans and machines have limitations doing their tasks. Humans cannot process or understand huge amount of data or complex data such as metadata, images, videos, etc. that machines can do and in a very fast way. On the other hand, machines cannot make business or economical decisions or understand the quality of data that they are processing or to choose the best strategy to achieve the industry goals.

Therefore, this collaboration surpasses humans and machines limitations by combining their intelligence and strengths. Humans are the ones that must use their knowledge and expertise to redesign the business process because the technology is not going to make such difficult decisions to transform the industry.

Augmented Intelligence will produce outcomes that neither humans nor machines could achieve alone (IBM). There are some steps to implement AgI:

- Decide whether to change the business process and task flow for human-machine cooperation[2].
- Select which tasks and decisions within the business process to automate.
- Determine the proper AI tools.
- Determine what data to acquire to better understand and model the business and customers.
- Build the data models.
- Test the results for reliability and accuracy.

Businesses powered by AgI systems have these four key attributes in common [ref: AgI eBook]:

- Discover and learn from hidden meaning in data and user interactions.
- Continuously learn, evolve, and improve with time.
- Build and test new user and process engagement capabilities.
- Drive new business processes and business model innovation.

In the last years, AgI was ranked in second place in AI technology rankings in terms of the value they create for businesses. However, Gartner predicts that "Decision support and AgI will surpass all other types of AI initiatives", as it is shown in Figure 2, doubling virtual agents by 2025.

[2] We will see later in section 2.3 the importance of this point in the power of AgI

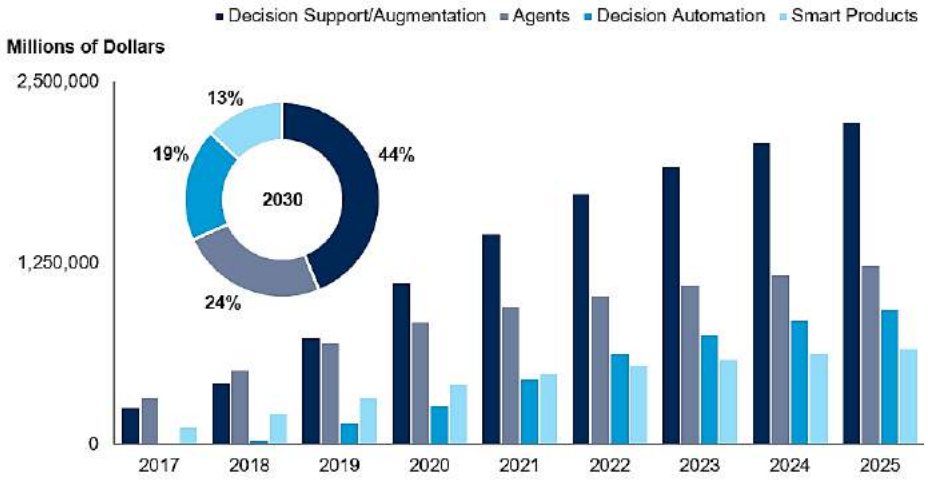

**Figure 2 – Business Value Forecast by AI Type through 2025, expressed in millions of Dollars (Source: Gartner).**

## 2.3. Historical Background of Augmented Intelligence

Throughout the history of humanity, man has created tools (language, writing elements, mathematics, etc.) that have allowed him to increase his intelligence. In the early 1960s Doug Engelbart [3]was researching how those tools shape our thoughts, founding the field of human–computer interaction. At the time, most of his colleagues only viewed computers to compute numbers and somehow man machine competition. However, he saw something deeper: He saw a way to increase the human mind [ ref Engelbart, D. C. (1962, October). "Augmenting Human Intellect: A Conceptual Framework." Retrieved 10 July 2020 from https://www.dougengelbart.org/pubs/papers/scanned/Doug_EngelbartAugmentingHumanIntellect.pdf]

On February 10, 1996, a computer won a game of chess against a world champion for the first time. The computer was Deep Blue, a machine designed by IBM. An improved version of Deep Blue recorded its famous May 11, 1997 victory over world champion Kasparov, a milestone in artificial intelligence. Designed to understand high-power parallel processing, the "brute force" system could examine 200 million chess positions per second, beating Grandmaster 3.5-2.5. The story quickly centered around a Man vs. Machine narrative. For Kasparov it was a turning point. He may have asked himself : "Why want to compete against a machine when we could play with a machine?"

The next year, Garry Kasparov held the world's first game of "Centaur[4] Chess" [ref https://www.parc.com/blog/half-human-half-computer-meet-the-modern-centaur/] or, as it is more commonly known today, "freestyle chess" [5] (The concept of using computers to augment play had been around for a long time.) Humans can use input from chess programs to select their moves.

[3] Was an American engineer and inventor, and an early computer and Internet pioneer. He is best known for his work on founding the field of human–computer interaction, particularly while at his Augmentation Research Center Lab in SRI International, which resulted in creation of the computer mouse, and the development of hypertext, networked computers, and precursors to graphical user interfaces. These were demonstrated at The Mother of All Demos in 1968. Engelbart's law, the observation that the intrinsic rate of human performance is exponential, is named after him" https://www.dougengelbart.org/

[4] A centaur (/ˈsɛntɔːr/; Greek: κένταυρος, kéntauros, Latin: centaurus), or occasionally hippocentaur, is a creature from Greek mythology with the upper body of a human and the lower body and legs of a horse.

[5] In Freestyle Chess, human players are assisted by computers, software, and database tools.

In 2005 a freestyle chess tournament was organized, team called ZackS won by beating an opponent that included Vladimir Dobrov, a grandmaster, his highly rated teammate, and their computer programs.

The two members of the team were amateur chess players. They didn't play with the best hardware in the world. In fact, they had three different AI systems that run on mass-use computers. We had average players, with average computers, but a very good workflow. One of them was a soccer coach, the other was a database administrator. In this team the important thing was how they interacted and collaborated with the machines. That interface is what allowed it to succeed.

"Weak human + machine + superior process was greater than a strong computer and, remarkably, greater than a strong human + machine with an inferior process." [ref Garry Kasparov, How Life Imitates Chess: Making the Right Moves—from the Board to the Boardroom (New York: Bloomsbury, 2007), pp166]

By combining human intelligence with technological intelligence (Augmented Intelligence), these players tend to outdo anyone. In other words, centaurs can outperform humans and machines in the chess domain.

Summarizing centaurs combine the main characteristics of humans: INTUITION, JUDGMENT and FLEXIBILITY. With those of the machines: CONSISTENCY, PRECISION, SCALABILITY. Machines are for giving ANSWERS and humans are for asking QUESTIONS.

$$Centaur > Man\ or\ Machine$$

The "platforms" [6] have long since incorporated centaurs, today we say Augmented Intelligence, into their work teams.

## 2.4. Augmented Intelligence use cases

Although it is early days, AgI has already had a positive impact on many sectors and the nature of this technology, which learns more, adapts faster and continuously improves with time, means that early adopters do gain an advantage. But the main source of augmentation's business value will continue to be an improved human experience. AgI will deliver a level of personalization and it will also minimize errors, creating a higher standard of service.

Some of the following examples correspond to real applications and others are just possible use cases.

### *2.4.1. Healthcare*

Augmented intelligence is transforming the industry, from detecting outbreaks to providing more customized care and explainable diagnoses. It has also been used in the fight against COVID-19.

### *2.4.2. Biotechnology*

Biotech companies help augment doctors for radiology and clinical data. They use machine learning algorithms to extract key characteristics from radiology and pathology images and also organize the unstructured data of each patient's clinical notes, test results and health history. Doctors are provided with information to combine with their expertise in selecting treatment options for the patient.

[6] The Business of Platforms: Strategy in the Age of Digital Competition, Innovation, and Power

#### 2.4.3. Financial services

Assisting financial planners to offer personalized services based on the customer's goals, capacity and risk appetite.

#### 2.4.4. Retail

AgI helps increasing shopper engagement and conversion by enabling online shoppers to shop the way they think, using machine cognition of their declared, observed, and inferred behaviors.

#### 2.4.5. Manufacturing

Aiding and accelerating the generative design process, whereby a human worker inputs the parameters and the machine finds countless ways of designing the object. The machine explores a plethora of options in record time and the human uses their expertise to select the best option, delivering value to customers and boosting efficiency.

#### 2.4.6. Oil and gas

Optimizing precision drilling. The human worker can understand the environment they are operating in more accurately, leading to faster results and less wear, tear and damage to machinery. The list of possibilities is endless, but the common element is clearly to increase efficiency by heightening the worker's knowledge.

#### 2.4.7. Geospatial images

Machine Learning is used to analyze geospatial imagery data. This provides real estate, energy and government agencies with information on land use, car and air traffic, and demographic trends so they can make better decisions.

#### 2.4.8. Telecommunications

AgI uses information gathered from applications to maximize network configurations and simplify troubleshooting. This next level of network intelligence comes from AI, data analytics and ML, to enable better correlation among events on the network, user and device behavior.

## 3. The technology behind Augmented Intelligence

There is a convergence of technologies that have come together to lead the market towards the reality of augmented intelligence and in this section, we will explore them.

### 3.1. Types of data

Augmented Intelligence systems can work with all types of data (structured, unstructured, semi-structured and metadata) from many sources, across disparate and siloed systems.

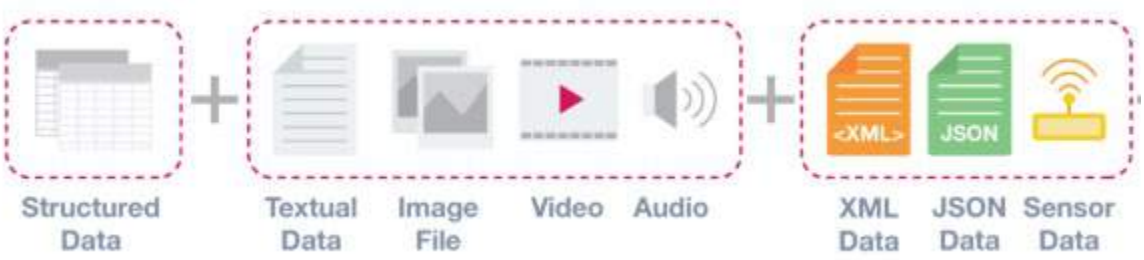

**Figure 3 – Three types of data: Structured, Unstructured and Semi-structured Data**

### *3.1.1. Structured data*

It is considered the most 'traditional' form of data storage. It refers to information that has a defined length and format such as numbers, names or dates. This type of data is linked to a pre-defined data model and is therefore straightforward to analyze. They fit to a tabular format with relationship between the different rows and columns. This structure made it possible to create understandable answers to questions inside this data [ref: https://www.bigdataframework.org/data-types-structured-vs-unstructured-data/]

### *3.1.2. Unstructured data*

It does not have a predefined data model nor is it organized in a predefined manner. Therefore, it is not surprising that most of the information in the world is unstructured, for example, videos, images, text documents. The ability to analyze unstructured data is especially relevant in the context of Big Data, since a large part of data in organizations is unstructured. Of course, there is inherent structure, but the difference is that humans must do the hard work to understand the hidden structure of the data.

### *3.1.3. Semi-structured data*

It is a form of structured data that does not conform with the formal structure of data models associated with relational databases or other forms of data tables, but nonetheless contain tags or other markers to separate semantic elements and enforce hierarchies of records and fields within the data. Therefore, it is also known as self-describing structure. JSON and XML are two examples of this type of data. They are considerably easier to analyze than unstructured data and many tools have the ability to 'read' and process them.

## 3.2. Big Data and Small Data

The terms Big Data and Small Data have become popular buzzwords over the last years and it is not always clear what either of these terms means or how or when to use each.

The acquisition of information requires the ability to capture data, compute something based on the data available and obtain a result.

Over the last decade, the promising concept of Big Data has generated huge expectations to industries. Therefore, companies have purchased and deployed scalable storage and processing systems with the intention of preserve every single byte of data obtained from their systems and customers. But actually, much of this data has no real information or valuable content. As storage costs began to increment, big data applications suffered a transformation into a new type of applications of small data where the value arises not from the volume of the data set, but from the ability to extract useful information and to make decisions

 

based upon the smallest data set. The goal will not be to measure and store every byte; it will be to measure and store "just the right amount" of data [ref Bell Labs].

Next, we present some formal definitions with respect these concepts.

#### *3.2.1. Big Data*

Gartner proposed an early definition using three 'Vs' (Volume, Velocity, and Variety) to represent the key characteristics of Big Data. Certainty, it is still widely used.

"Big Data is high-volume, high-velocity and/or high-variety information assets that demand cost-effective, innovative forms of information processing that enables enhanced insight, decision making, and process automation."

More recent definitions include other "V-terms" into the Gartner model, adding Veracity to reflect data accuracy and Value to address the usefulness of the data.

Big data techniques are designed to manage a huge volume of disparate data at the right speed and within the right time frame. The goal is to enable near real-time analysis and action.

#### *3.2.2. Small Data*

A formal definition of small data has been proposed by Allen Bonde, former vice-president of Innovation at Actuatet:

"Small data connects people with timely, meaningful insights (derived from big data and/or "local" sources), organized and packaged – often visually – to be accessible, understandable, and actionable for everyday tasks".

Martin Lindstrom defines it as 'the tiny clues that uncover huge trends', based on observational data. It's also defined as data that is small enough size for human comprehension.

From the white paper [ref Philosophy of Small Data], "Just only one apple falls on Isaac Newton's head, not ten, not thousand".

### 3.3. Artificial Intelligence

Artificial Intelligence means getting a computer to mimic human behavior in some way. The goal is to get computers to perform tasks as human: things that required intelligence.

Despite recent hype around the technology, AI is not a new technology and not a product of this century's innovations. The beginnings of AI can be traced to the middle of the 20th century. During the second world war, an English mathematician and computer scientist, Alan Turing documented his ideas on creating an intelligent machine. He proposed a test for machine intelligence:

A human evaluator would judge natural language conversations between a human and a machine designed to generate human-like responses. The evaluator would be aware that one of the two partners in conversation is a machine, and all participants would be separated from one another. The conversation would be limited to a text-only channel such as a computer keyboard and screen so the result would not depend on the machine's ability to render words as speech. If the evaluator cannot reliably tell the machine from the human, the machine is said to have passed the test. The test results do not depend on the machine's

 

ability to give correct answers to questions, only how closely its answers resemble those a human would give [ref Wikipedia Turing Test].

In short, if a machine can trick humans into thinking it is human, so then it has intelligence.

Marvin Minsky of MIT's Project Mac, who has made major contributions to Artificial Intelligence, in 1970 said: "In from three to eight years we will have a machine with the general intelligence of an average human being. I mean a machine that will be able to read Shakespeare, grease a car, play office politics, tell a joke, have a fight. At that point the machine will begin to educate itself with fantastic speed. In a few months it will be at genius level and a few months after that its powers will be incalculable."

Figure 4 illustrates the AI Timeline. Despite the fall between 1966-1997, which was called the AI winter, the constant evolution of this technology is evident.

Today, AI refers to a range of technologies form automation to deep learning. It includes the subfields of natural language processing, vision, robotics, machine learning, and knowledge representation and reasoning.

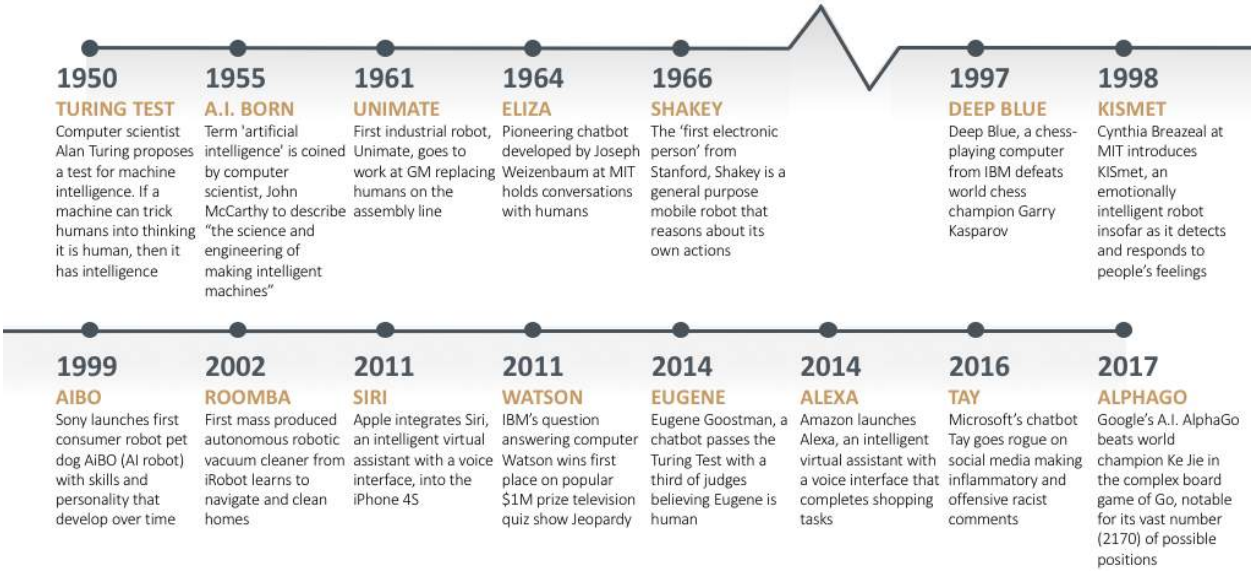

**Figure 4 – Artificial Intelligence Timeline: It is not something new.**

The question that arises is what the difference between Artificial Intelligence and Augmented Intelligence is. The answer can be found within its objectives; the goal of an artificial intelligence system is to simulate human cognitive capabilities in a system that can function independently of humans. In contrast, the goal of an augmented intelligence system is to enhance human intelligence by human–machine collaboration to get work done.

### 3.4. Machine Learning

Machine learning is a form of artificial intelligence that enables a system to learn from data rather than through explicit programming of a set of rules. It consists of a variety of types of algorithms, all of which learn from data. A machine learning model is the output generated when you train your machine learning algorithm with this data. After training, when you provide the model with new data input, its output will be providing new insights such as data classification or prediction.

The end-to-end machine learning process includes the following phases:

- Business Goal Identification
- ML Problem Framing
- Data Collection and Integration
- Data Preparation
- Data Visualization and Analytics
- Feature Engineering
- Model Training
- Model Evaluation
- Business Evaluation
- Production Deployment

Machine learning models can be online or offline, online models are constantly ingesting data and interacting with it in near real time mode improving the model outcomes. On the other hand, offline models once they are deployed, they only can be retrained manually with new data.

There are several approaches to machine learning that are relevant to the ability to create algorithms that support the industry problems, they are based on the type of the data. These approaches are divided into three main areas: supervised learning, unsupervised learning (it includes deep learning) and reinforcement learning.

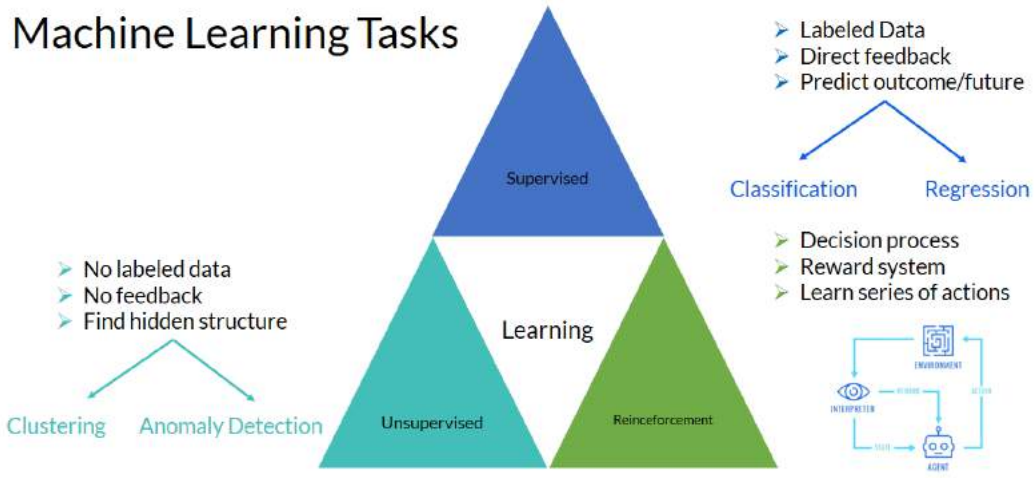

Figure 5 gives an explanation about the type of data, type of outcome and the algorithms methodology of each category. It also shows some of the most common techniques: regression, classification, anomaly detection, etc.

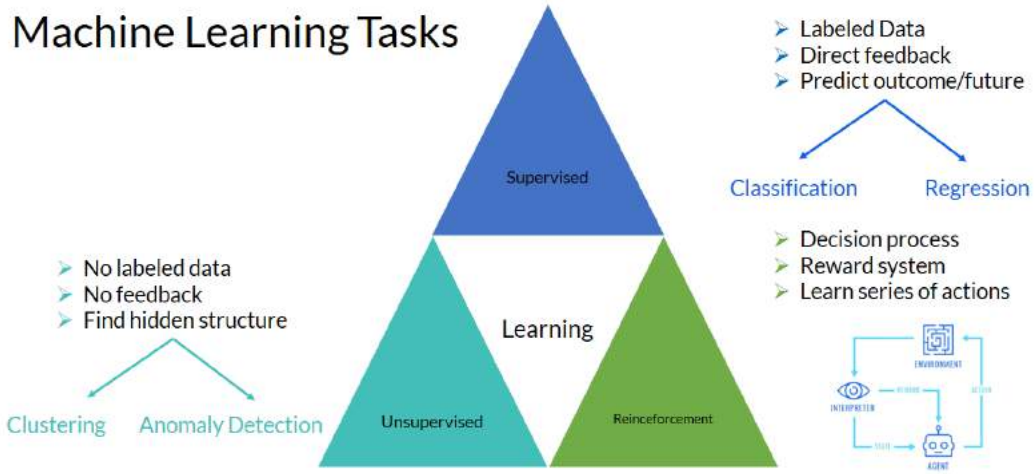

**Figure 5 – Machine Learning tasks divided by the three main categories and most common algorithms.**

### *3.4.1. Supervised Learning*

Supervised machine learning algorithms are designed to learn by example. During training, the algorithm will search for patterns in the data that correlate with the desired outputs. After training, a supervised learning algorithm will take in new unseen inputs and will determine which label the new inputs will be classified as based on prior training data. The resulting model must be evaluated against test data to see how well it learned. If the model is fit to only represent the patterns that exist in the training set, overfitting[7] occurs. Using unseen data for the test set can help you evaluate the accuracy of the model in predicting outcomes.

### *3.4.2. Unsupervised Learning*

Unsupervised learning is a set of statistical tools for scenarios in which there is only a set of features and no labels. With these techniques we are interested in finding discovering subgroups of similar observations. It tends to be more challenging, because there is no clear objective for the analysis. Besides, it is hard to evaluate if the obtained results are good, since there is no accepted mechanism for validating results on an independent dataset, because we do not know the true answer.

### *3.4.3. Reinforcement Learning*

Reinforcement learning is a behavioral learning model. It is about taking suitable actions to maximize reward in a situation wherein an agent interacts with a new environment using actions and discovering errors or rewards. It is employed by various software and machines to find the best possible behavior or path it should take in a specific situation. In short, a reinforcement learning system learns through trial and error. Therefore, a sequence of successful decisions will result in the process being "reinforced" because it best solves the problem at hand. Gaming and robotics are the most common applications of this technique.

[7] The production of an analysis that corresponds too closely or exactly to a particular set of data, and may therefore fail to fit additional data or predict future observations reliably [ref: Oxford Dictionaries.com]

 

### *3.4.4. Deep Learning*

Deep learning is a specific method of machine learning that incorporates neural networks in successive layers in order to learn from data in an iterative manner. Deep learning is especially useful when you are trying to learn patterns from unstructured data.

A neural network consists of three or more layers: an input layer (ingested data), one or many hidden layers (which include weighted nodes), and an output layer (the outcome). The term deep learning is used when there are multiple hidden layers within a neural network.

Neural networks and deep learning are often used in applications where images, videos or speech are involved.

## 3.5. Automation

Within MSOs and MNOs, this means automation of processes that were previously carried out by people like configuration, management, operation and testing of physical and virtual devices within the network. With growing costs and the daily emergence of bandwidth-hungry applications, networks cannot be managed manually. Increased levels of network automation help to reduce complexity and are essential for businesses to keep up in the digital world. AI is an enabling technology that may (or may not) help with the process of automation. What it culminates is a network that is highly predictable and highly available improving the business outcomes.

## 3.6. Cognitive computing

Like AI, cognitive computing is based on the ability of machines to sense, reason, act and adapt based on learned experience. Cognitive computing refers to computing that focuses on reasoning and understanding at a higher level and in a manner that is analogous to human cognition, rationale, and judgement. Applications of cognitive computing include speech recognition, sentiment analysis, face detection, risk assessment and fraud detection. The difference between AI and cognitive computing lies in the way they approach the purpose of simplifying tasks. AI is used to augment human thinking and solve complex problems. Cognitive computing mimics human behavior and reasoning to solve complex problems similar to the way humans solve problems.

## 3.7. Intent-Based Networking

“Intent” is the keyword in this technology, which describes a network’s business objective or an outcome.

Intent-based networking (IBN) is an emerging technology concept that aims to apply a deeper level of intelligence and intended state insights to networking. Ideally, these insights replace the manual processes of configuring networks and reacting to network issues. The goal is networking that uses machine learning and cognitive computing to enable more automation and less time spent on manual configuration and management. With intent-based networking, network administrators define the intent and the network’s software finds how to achieve that goal using AI and ML by performing routine tasks, setting policies, responding to system events, and verifying that actions have been done.

These systems not only automate time-consuming tasks and provide real-time visibility into a network’s activity to validate a given intent, they also predict potential deviations to that intent,

 

and prescribe the action required to ensure it. This greater intelligence makes the network faster and more agile and reduces errors [ref https://www.vmware.com/topics/glossary/content/intent-based-networking#:~:text=Intent%2Dbased%20networking%20relies%20on,and%20actions%20have%20been%20achieved.].

# 4. Knowledge Plane, state of the art

The research community has considered in the past the application of AI techniques to control and operate networks. For example, in 2003 David Clark et. al propose the knowledge plane (KP) as a *pervasive system within the network that builds and maintains high level models of what the network is supposed to do, in order to provide services and advice to other elements of the network. The knowledge plane is novel in its reliance on the tools of AI and cognitive systems* (Clark, Partridge, Ramming, & Wroclawski, 2003).

The Knowledge Plane (KP) paradigm proposes the evolution to a cognitive network, where the devices learn, decide, and act to achieve end-to-end goals. This emerging paradigm is clarifying a set of new cognitive-based protocols and algorithms that optimize network's performance.

In (Mestres, y otros, 2017) progress is made in the definition of a new paradigm based on this plane. This is knowledge-defined network (KDN) operates by means of a control loop to provide automation, recommendation, optimization, validation and estimation.

## 4.1. Introduction

There are several organizations and working groups proposing frameworks, standards and how to apply the AI to the industry of communications, networks and services. Below we detail those in which Telecom Argentina is participating or is in consultation with:

- SCTE & CableLabs AI/ML Working Groups
- Telecom Infra Project - AI/ML Working Group
- TM Forum - AI & Data Analytics
- ITU-T Study Group 13 and ITU-T FG ML5G Studying network architectures, use cases, and data formats for the adoption of machine learning methods in 5G and future networks.
- ETSI ISG ENI (Experiential Network Intelligence). Defining a cognitive network management architecture based on AI methods and context-aware policies; five deliverables have already been released
- 3GPPP
- ONAP

AI began to be studied in most of the different Standards Developing Organizations (SDO). We provide in this item a summary of what they are proposing, how they are defining it and the specific use of this new technology in each branch of the networks.

As has been said repeatedly in various academic circles, AI makes use of another phenomenon that occurs: the massive growth of data, driven mainly by network technologies such as IoT, 5G and 10G project.

The introduction of AI and automation using AI, in short, seeks to ensure greater performance and efficiency of networks.

The paradigm shift that will be brought about by the introduction of these new technologies includes a substantial shift from a focus on network operations to a focus on the user experience.

We have conceptualized these AI and automation tools that interact with the different types of networks as **Knowledge Plane**, a "place" where the massive amount of data obtained from the network is processed with the different AI tools, either in real time or in a post-processing, and that, based on results, produces modifications in the network itself. This is called **closed-loop automation**.

Before we start it would be necessary to break down what we used to call “network” into a general form.

*Mobile networks:*

Split up into:

- Terminals (mobile phones, IoT device, etc.)
- Access (cells, RAT, Fronthaul/Midhaul/Backhaul)
- Packet core (EPC (4G), 5GCN, etc)

*Fixed networks:*

- XDSL (DSLAM/BNG)
- FTTH, GPON (ONT/OLT)
- HFC (CM/CMTS)
- IPBB (routers, DNS, CDN, etc.)

And in common with all of them, a growing trend towards virtualization.

## 4.2. Autonomic networks

### *4.2.1. ETSI (European Telecommunications Standards Institute)*

In the current research on the ETSI recommendation we still do not see clearly the difference between the initiatives that are established within this SDO, as some of them promote doing exactly the same thing. This is further complicated by the fact that each of them does not refer to interaction with the others. Anyway, we consider it important to explain them.

#### *4.2.1.1. ETSI-ENI (Experiential Networked Intelligence)*

The concept of ENI refers to a working group developed at ETSI to improve the operator's experience that is active since 2017.

This working group has collaboration with all the SDO's in the industry.

 

It is based on the introduction of AI systems in the Network Management System and a control model that takes the following actions:

- Observe
- Guide
- Decide
- Act

The **knowledge plane**, in ETSI is the ENI, which is materialized in this recommendation as a layer that covers transversally all the layers of the MANO (NFV Management and Orchestration) architecture.

In this case the AI-based system will have to adjust the services offered according to the following possible changes:

- In the client's needs
- Under the ambient conditions
- In business objectives

As a challenge it is established:

- Determine which services comply with the SLA and which would be about to fail to comply depending on the changing context.
- Provide an experiential architecture (i.e. an architecture that uses the benefits of AI).
- Establish incident detection.
- Possessing the capacity for autonomous incident management.

#### *4.2.1.2. ETSI-ZSM (Zero-touch service and network management)*

In 2017 ETSI launched the Zero touch network and Service Management Industry Specification Group (ZSM ISG).

The aim of this group is to specify all processes and operational tasks as an example:

- Deployment
- Configuration
- Assurance
- Optimization

are executed automatically (agile, efficient management and automation).

#### *4.2.1.3. ETSI-GANA (Generic Autonomic Networking Architecture)*

It is a reference architecture model for the creation of autonomous networks, "cognitive" networks and self-management of networks and services in which the AI plays an important role in such autonomy.

It is designed to realize the AMC (Autonomic Management and Control) paradigm (closed-loop service instantiation and adaptive operations) of networks and services with reference to:

- Control architectures
- Management architectures

The relevance of each of these ETSI proposals needs to be analyzed to see if they replace or complement each other.

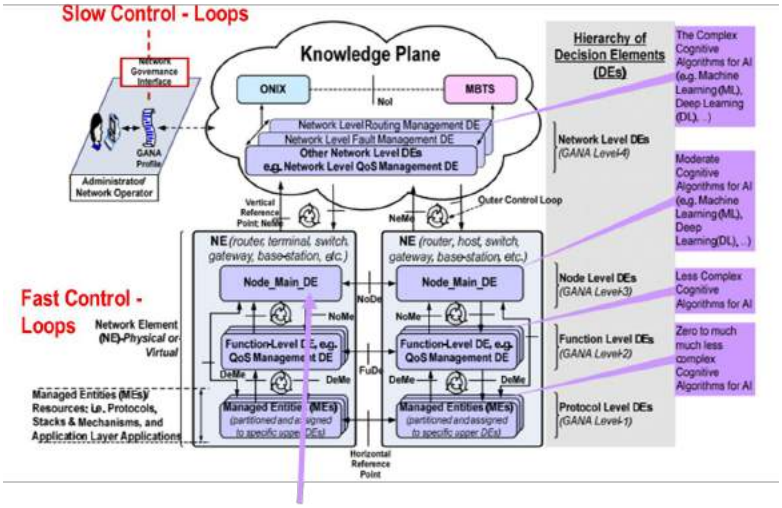

**Figure 6 – GANA Architecture**

### *4.2.2. ONAP (Open Networking Automation Platform)*

ONAP provides a comprehensive platform for the real-time, policy-based orchestration and automation of physical (PNF: Physical Network Functions) and virtual (VNF: Virtual Network Functions) network functions that will enable software, network, IT and cloud providers and developers to rapidly automate new services and support full life-cycle management.

In short, ONAP is a platform that offers a complete set of tools to automate assurance processes in the field of network management.

Some operators have selected it to automate layers of:

- The MANO domain (except for the VIM functions (VNF life cycle management).
- The orchestration service for both PNFs and VNFs.

ONAP makes use of a functionality called DCAE (Data Collection, Analytics and Events Project) that is the general name for several components that collectively fulfill the role of Data Collection, Analysis and Event Generation.

The DCAE architecture aims at the deployment of components and the composition of flexible, pluggable, microservice-oriented and model-based services. DCAE also supports multi-site data collection and analysis that are essential for large ONAP deployments.

The DCAE is a place where analytics applications and AI/ML models could reside.

## 4.3. Mobile Networks

### *4.3.1. O-RAN Alliance (Open Radio Access Network)*

This SDO, which is "openness", proposes exactly the same solutions as the SDOs in terms of the use of the AI, but specifically applied to the RAN.

It proposes that networks should:

- Be self-managed.
- Be able to take advantage of new learning-based technologies to automate the operational functions of the network and reduce OPEX.
- Leverage emerging deep learning techniques to integrate intelligence into every layer of the RAN architecture.

Embedded intelligence, applied at both the component (NE) and network levels, will enable dynamic local allocation of radio resources and will optimize the efficiency of the entire network in closed-loop automation using AI.

As it is possible to see, the O-RAN describes in the orchestration and automation layer a Non-Real Time RAN Intelligence Controller (RIC) with AI/ML capabilities.

It should be remembered that there are currently initiatives for the virtualization of the Non-Real Time BBU.

### *4.3.2. 3GPP (3rd Generation Partnership Project)*

Service and System Aspects (SA) is the Technical Specifications Group of 3GPP where most work is currently being done on the use of AI, especially in

- SA WG2, Architecture
- SA WG5, Telecom Management

#### *4.3.2.1. SA2 NWDAF (Network Data Analytics Function)*

The NWDAF was first introduced into the 5G system architecture at the 3GPP SA2#119 meeting in February 2017.

The NWDAF (Network Data Analytics Function), as defined in TS 23.503, is used to collect data such as FCAPS (Fault Configuration Accounting Performance Security) events and Data events, and then perform the analysis of the data centrally. An NWDAF can be used for analysis of one or more network slices.

 

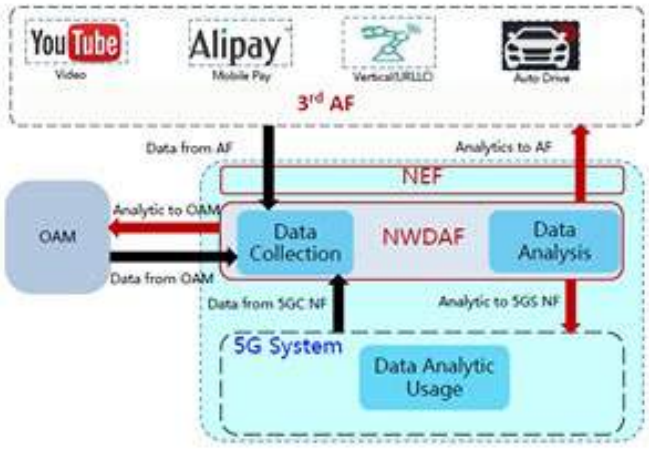

**Figure 7 – NWDAF uses case**

#### *4.3.2.2. SA5 MDAF (Management data analytics function)*

MDAF (management data analysis function) uses network management data collected from the same network, for example data related to

- Services
- Slicing functions
- Network functions
- Related slicing and networking functions

and perform the corresponding "analytics".

The MDAF can be deployed at different levels, for example, at the domain level:

- RAN Management Data Analytics Function
- Network Management Data Analytics function
- Network Slice Subnet Instance Management Data Analytics function

In order to establish a difference between NWDAF and MDAF we can say that the first one is a function in the Packet Core domain or for the management of use cases in the slice domain, while the last one is in the OAM layer supporting the assurance. Both relate to each other by exchanging information.

### 4.4. Use cases of AI in networks

#### *4.4.1. General use cases:*

The following cases are added to those already established in each standard:

- In the NOC (Network Operation Center):
  - In the preventive support to allow to identify and solve problems before they affect the performance of the network, avoiding critical cuts and providing stability.

 

    - Incident pattern recognition.
    - Incident based subscriber type clustering.
- Anomaly detection
    - Discovery of deviations from standard behavior.
    - Determination of outliers is multidimensional spaces.
    - AI Tools:
        - ARIMA (autoregressive integrated moving average)
        - Random Forest
        - Self-encoder
        - Principal Component Analysis
- In the RAN
    - Embedded Analytics components (incorporation of chips) in the same Radio Base Stations to perform:
        - Closed-loop automation (internal automation and localized training components).
        - Improve performance and spectral efficiency.
        - Improving Mobility Management.
        - Adaptation of links.
        - Energy saving in MIMO (Multiple Input Multiple Output) in its sleep state.
        - Reduce energy consumption.
        - Evolution of SON (Self-organizing network).
        - Interference diagnosis.
        - Real-time analysis in the baseband unit.
        - ML to improve the algorithms of the cell itself:
            - In the User Plane.
            - With QoE optimization.
            - In the management of radio resources.
            - In the scheduler (especially for MIMO).
- On terminals connected to the mobile network.
- IoT terminals.
- AI can improve network efficiency by being able to cluster and detect anomalies in the initial state of implementation of the ever-growing diversity of devices, in an environment where vendors freely interpret GSMA standards.
- Cellphones.
- The application of the AI tools as in the case of the RAN network elements, will allow them to
    - Reduce latency time and optimize spectrum management.
    - Applications are developed where they can be made:
        - Image and sound recognition and interpretation.
        - Development of Augmented Reality and Virtual Reality.
- Visual inspection of network equipment (deep learning).
- In Energy.
- In Planning:
    - Work is already underway with the mobile access management of Network and Service Planning using forecasting methods (e.g. ARIMA).

 

- On the WiFi:
    - Not yet determined by any organism.

#### *4.4.2. Particular use cases with 3GPP SA2 NWDAF (Network Data Analytics Function)*

The NWDAF can be used for the following applications:

- Assist in the provision of Quality of Service (QoS) profiles.
- Assist in the adjustment of the quality of service (QoS).
- Assist in policy determination.
- Collaborate with 5G Edge Computing.
- Improve performance and monitoring of mIoT (massive Internet of Things) terminals.
- Assist in load/balance balancing of NF (Network Function).
- Assist in areas of the network with instability (oscillating conditions).
- Improve performance and monitoring of mIoT terminals.
- Support for the exposure of the network status on the Northbound interface using APIs (application programming interface).

# 5. The Future of Augmented Intelligence

## 5.1. Augmented Intelligence

As we mention before Augmented Intelligence is still in the technology trigger phase in the hype cycle according to Gartner. And, in early stage of the evolution of Artificial Intelligence and Machine Learning. The main question that organizations is asking about the future of these technologies is: Will the human-machines collaboration result in fewer jobs for people?

What is clear is that the nature of work is already changing and will continue to change through the human-machine collaboration. Both, humans and machines will do what they do best. Machines will automate routine tasks that don't need human intelligence to let humans focus on handling exceptions. When humans handle exceptions, they must get an informative alert with context from the machine, often with a recommendation on how to proceed.

There will be many new jobs that do not exist today. With the evolution of augmented intelligence and its presence in more and different domains, there will be a greater need for regulatory frameworks. In the future, many jobs will be needed to manage augmented intelligence and handle the exceptions have not existed before. One of the greatest challenges for society will be the massive training of those who are displaced by intelligent systems to fill the new jobs that augmented intelligence enables.

Also, in the future, data and information will become free and freely available, big data will be replaced by small data to discover “knowledge”, and new augmented intelligence tools will be developed that assist in the acquisition of knowledge (cognition) by enabling critical thinking from multiple perspectives.

 

### 5.2. Explainable AI

Another emerging field is Explainable AI (XAI). Whether when an expert must decide based on augmented intelligence tools or when they are implemented in our networks and services, they must understand how the results were achieved and the level of confidence that the model has.

The goal of enabling explain ability in ML, as stated by "is to ensure that algorithmic decisions as well as any data driving those decisions can be explained to end-users and other stakeholders in non-technical terms". S. Barocas, S. Friedler, M. Hardt, J. Kroll, S. Venka-Tasubramanian, and H. Wallach. The FAT-ML Workshop Series on Fairness, Accountability, and Transparency in Machine Learning. Accessed: July. 20, 2020. [Online]. Available: http://www.fatml.org

Explain ability sits at the intersection of transparency (consumers have the right to have decisions affecting them explained in understandable terms), causality (it is expected of the algorithms to provide not only inferences but also explanations), bias (the absence of bias should be guaranteed), fairness (it should be verified that decisions made by AI are fair) and safety (reliability of AI systems) (Hagras, 2018).

According to ((BSI), 2016), (Gasser & Almeida, 2017) we know that many machine learning algorithms have been labeled "black box" models because of their inscrutable inner-workings. What makes these models accurate is what makes their results difficult to interpret and understand they are very complex. So, even when some abstraction or transformation the models can be explainable, not always they are auditable. The discussion about audit AI is still open (Forum, 2019).

## 6. Augmented Intelligence at Telecom Argentina

More than a decade ago, in the former Cablevisión Argentina, we started working with Analytics to generate outcomes about our networks and services. Then, we began to innovate with other technologies related to Machine Learning and Artificial Intelligence and we continue after the 2018 merger, in Telecom Argentina.

Nowadays, as a STEM management our mission at Telecom Argentina is:

- Find new AI and ML based technologies to add value to the business.
- Define the technological strategy and emerging technologies.
- Develop innovative scientific tools to improve our infrastructure based on the demand for our services.
- Generate dimensioning models and performance parameters from statistical and mathematical analysis.

Our industry is undergoing a process of digital transformation and we, Telecom Argentina, are part of this process. Being part of this process also implies a transformation in our ways of working and in how we focus on them, but always oriented towards networks and services. So, we understood that we should jump to the next level.

We are not alone doing that; we belong to different Working Groups with the objective to define standards and best practices of these technologies. We also share our experiences and use cases.

They are:

- Artificial Intelligence and Machine Learning - SCTE
- Cross Industry AI/ML/Data Analytics Collaboration - CableLabs
- DOCSIS Data Analytics Work Group - CableLabs

Below, we detail some of the challenges we face from the emergence of this new AI that is human-machine collaboration.

### 6.1. VMAF: a tool for measuring video based on human perception

VMAF (Video Multimethod Assessment Fusion) is a model proposed by Netflix in 2016 and is a video quality metric that combines human vision modeling with ML in order to provide a great viewing experience to their members.

VMAF is a fusion of elementary metrics into a final metric using a Support Vector Machines regressor which assigns weights to each elementary metric (Visual Information Fidelity, Detail Loss Metric, Temporal Information). In this way, the final metric is able to preserve all the strengths of the individual metrics and deliver a more accurate final score.

The model is trained and tested using a dataset of several 10 seconds long clips of different video genders and content characteristics. Those videos are distorted using different resolutions and bitrates. Then a subjective experiment is performed where a focus group of non-expert viewers score a source clip and the same clip distorted. From this experiment, the Mean Opinion Score (MOS) is calculated and it is also used to train the model.

Last year we have been working in an adaptation of this algorithm to our own OTT video platform: FLOW. We designed our datasets based on FLOW catalog and produced the distortions. Then, we performed some focus groups in order to obtain the corresponding MOS [ref SCTE 2019]. After doing that, we train and test the model with the elementary metrics mentioned before but applied to our content, the obtained MOS from the focus group and the SVM parameters that fitted the best.

With this tool we can qualify videos in a scale from “bad” to “excellent”, not only from an objective perspective but considering human perception too, in an automatic way with the help of machines. Previously, this task was performed by video experts, consuming a lot of time and resources. One of the advantages of VMAF is that video experts can dedicate time to analyze other video aspects and making decisions that machines can’t do and letting them do the repetitive tasks. This is a clear example of human-machine collaboration.

### 6.2. STEM-ML: a tool for capacity planning

We developed a neural network-based machine learning tool for planning the capacity of the DOCSIS network [SCTE 2017], which was clearly superior to the tools used at the time.

However, it was very costly for us to adopt the tool by the teams responsible for capacity planning.

The business teams won't use the models because they do not know how they made their decisions and cannot be sure they work as advertised. It was difficult for us to explain to them that the decision to divide or not a node results from patterns in the data that the ML algorithm found and fixed into the model.

We finally understood that it was very risky for them to rely on models that cannot be explained.

From that moment on, we involve the teams from the moment they raise the need for an augmented intelligence tool. We focused on humans who for example carried out mobile network planning.

Although we have not yet used the formal tools that are being developed to explain the models, we have involved the team from the beginning of the development of STEM-ML for the planning of our 4G network. Applying agile methodologies for development. Explaining each model using and providing the planning team with the design criteria. Once an algorithmic model is up and running, the team must test the model carefully to see that it is operating in a reasonable way.

We were also developing with the team how to make the comparison between the results of the model and the methodology they had been using before.

We are defining with the team different levels of testing before putting the tool into production.

### 6.3. Telecom Argentina Knowledge Plane

We at Telecom Argentina adopt the knowledge plane paradigm for our Telco Cloud project [paper 2019]. During the proofs of concept that we will begin to deploy with next year, we will not only advance on AI / ML technologies, but it is essential to understand this abstraction as an AgI tool that will allow us to operate our future networks and services.

At the beginning, and in order to have a common language, a framework was defined in which the preponderance of the knowledge plane in the different layers of the network, both virtual and physical, is highlighted.

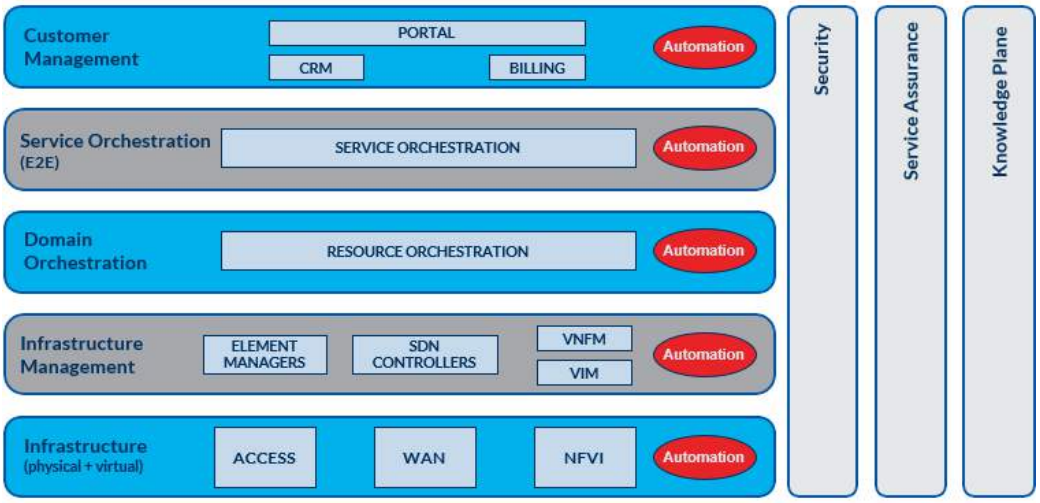

**Figure 8 – Telecom Argentina Knowledge Plane**

There is no doubt that in the course of time this general vision will not only be modified but also specified. A result that only experience can provide.

## 7. Conclusion

Humans and machines working in collaboration can have a powerful impact on the effectiveness of business processes. Augmented Intelligence overcomes the limitations of isolating human understanding from the massive amounts of available data to analyze complexity in record time.

Telecom Argentina has begun the journey to AgI. In a jungle of recommendations from the different SDOs for each technology, the proof of concept with vendors and developers will introduce us to the best practices of human-machine collaboration, human beings contributing with interpretation, critical thinking and multiple perspectives or looks to the solutions that AI provides us.

# Managing the Coronavirus Bandwidth Surge

## How to Cope with the Spikes and Long-term Growth

A Technical Paper prepared for SCTE•ISBE by

**John Ulm**
Engineering Fellow, Broadband Systems
CommScope – CTO Network Solutions team

# List of Figures

# 1. Introduction

"With all due respect, sir, I believe this will be our finest hour." That quote from the movie *Apollo 13* is strangely appropriate for what happened with the broadband industry after a global lockdown at the start of the COVID-19 pandemic. The Coronavirus pandemic turned the whole world upside down, with entire countries forcing their population to live, work, learn and play from home. There was a year's worth of bandwidth growth (or more) in a 2-week interval. The broadband industry held its breadth to see how our broadband infrastructure would cope.

Broadband kept society and the economy running (as best we can) in these hard times. This is arguably its most significant contribution to society in its short life-span. Hats off to everyone who has created and helped make broadband and the Internet available to society.

In this paper, the bandwidth (BW) impact to our broadband networks from around the globe is reviewed and showed how it was handled. The upstream got crunched much more than the downstream. Network capacity planning was key to having sufficient headroom to withstand an unexpected jolt. Some network capacity guidelines are reviewed and show how the Quality of Experience (QoE) level varies with different margins.

For those severely congested networks, some helpful tips when in crisis are provided. These overnight quick fixes can give a little breathing room until more permanent capacity can be added. The relative merits of some near-term solutions to deploy over coming months are discussed. These include: more DOCSIS channels, especially OFDM/OFDMA, more CCAP ports, segment congested nodes, rapidly increase DOCSIS 3.1 (D3.1) modem penetration, and deploying Wi-Fi 6 services.

Some bandwidth projections and mid- to long-term migration strategies are reviewed that operators should consider moving forward before the next bandwidth surge hits. These include: Migrate to 1218/85 or 1218/204 MHz plant today, with a transition to DOCSIS 4.0 over time; reduce legacy Video QAMs using IPTV/SDV/compression; Fiber Deeper; DAA; and Wi-Fi 6E. It is more important than ever to plan and start to implement our long-term strategies like 10G, especially for the upstream – cable's Achilles heel.

Finally, the longer-term impact of the pandemic is considered. What is the new normal? We don't expect bandwidth levels to ever go back to pre-COVID days. We'll touch on how user's behavior patterns changed and what new applications had the door opened.

# 2. Pre-Pandemic – the Calm before the Storm

Before we dive into the bandwidth impacts of the pandemic, let's take a look at the world pre-COVID. CommScope/ARRIS has been monitoring subscriber usage for over a decade now from the same group of MSOs. The data from this set has been compared and maps closely to many other MSOs globally.

The chart below, Figure 1, shows the average subscriber downstream consumption, Downstream (DS) Average BW per subscriber (Tavg), during peak busy hours for a number of Multiple System Operators (MSOs) over a ten year period. At the start of 2020, DS Tavg had surpassed the 2 Mbps barrier. It turns out that the Tavg growth rate was higher at the start of this decade and has tailed off a bit in recent years. Over the last 3-4 years, this group of MSOs had an average downstream traffic growth that had been around 30%.

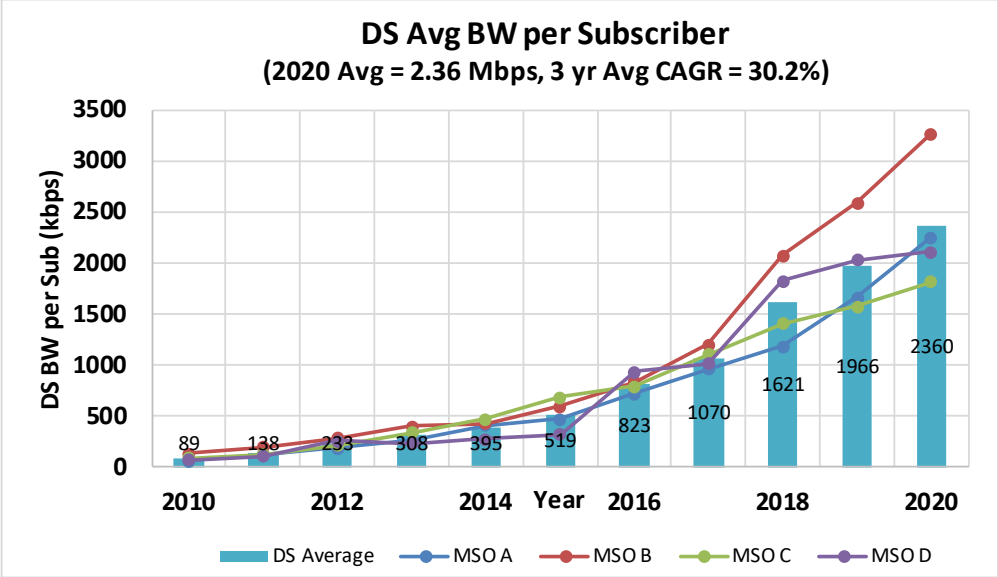

**Figure 1 – Downstream Average Bandwidth per Subscriber through Jan '20**

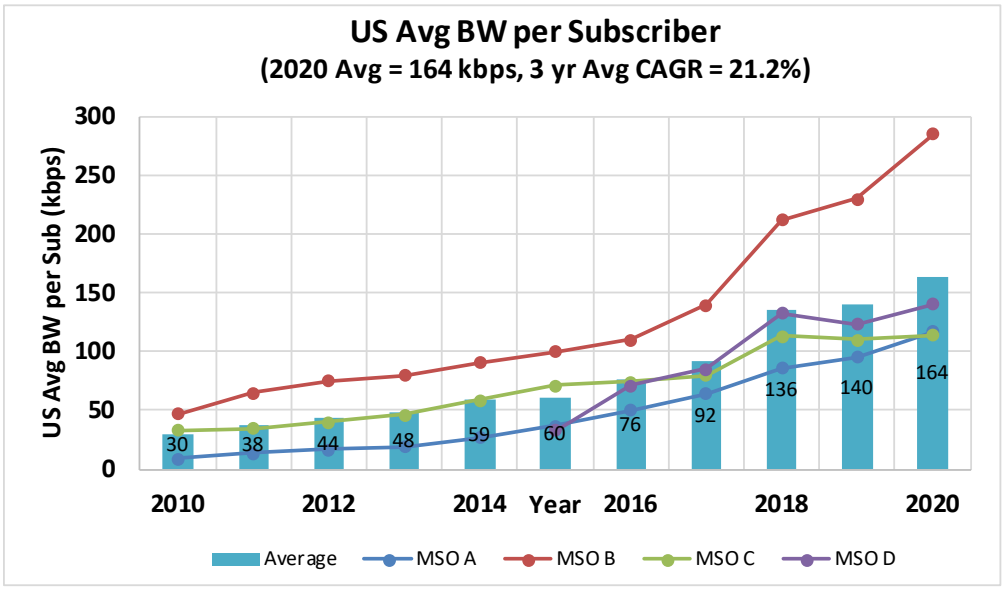

**Figure 2 – Upstream Average Bandwidth per Subscriber through Jan '20**

Interestingly, the upstream (US) traffic is growing at a significantly slower rate than the downstream as shown in Figure 2. During the same ten year period, the upstream Tavg generally grew at less than 20% compound annual growth rate (CAGR).

Over the years, traffic has also become more asymmetric with video applications driving downstream consumption [EMMEN_2014]. The average DS:US ratio is about 14:1, the MSO with the largest DS:US ratio seems to have stabilized around an 18:1 ratio. The MSO with the lowest DS:US ratio was about 11:1 ratio.

# 3. COVID-19 Pandemic hits – the Storm Surge

During mid-March, our lives got turned upside down and the entire world suddenly had to work, learn and play from home. To monitor the impact of the Coronavirus BW surge, we had access to live data through the CommScope ServAssure program and were able to monitor 1000's of nodes to study the effects.

Below are some very representative data samples taken during late March to demonstrate some of the changes seen. Broadband usage started picking up earlier in the morning and slowing down later at night such that the lull in the wee hours of the morning shrunk. Daytime usage was up significantly. Some networks saw daytime downstream usage increase as much as 86% while daytime upstream usage increased as much as 150%. The shape of the upstream was also dramatically altered. The upstream would reach its peak around 10am and then stay plateaued for the rest of the day until about midnight.

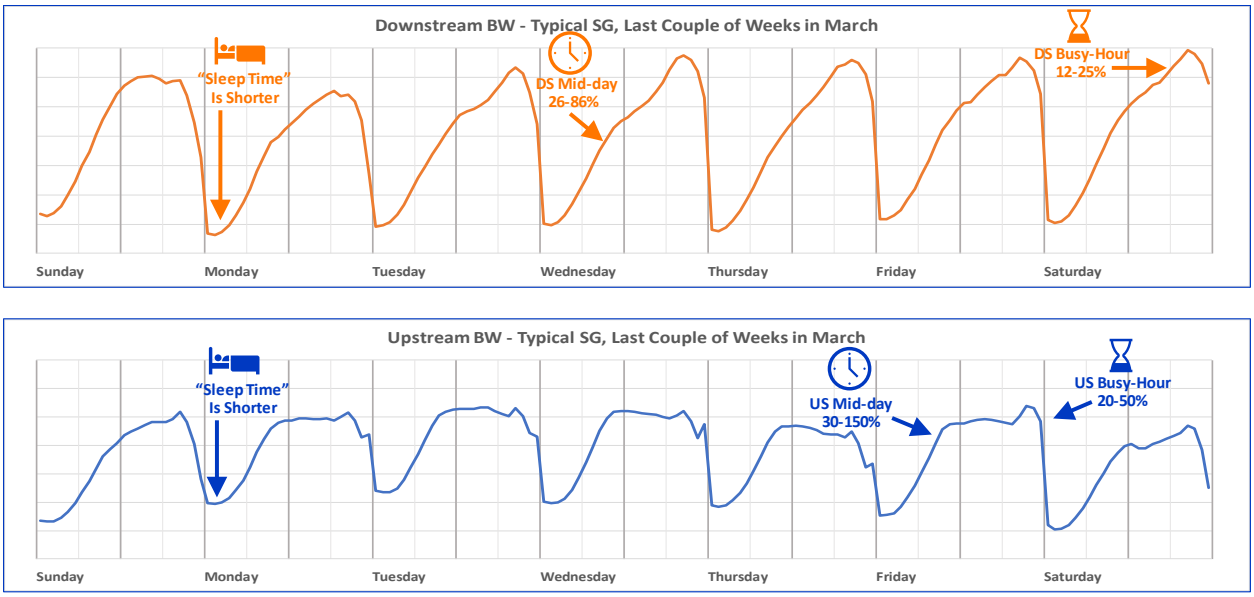

**Figure 3 -Coronavirus BW Surge impacts across Time of Day**

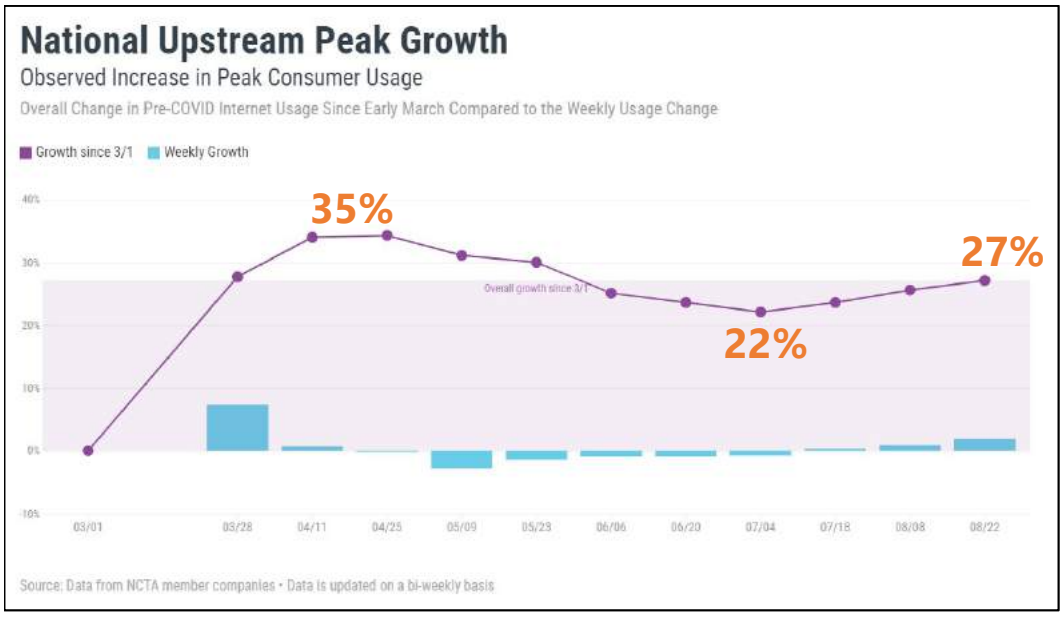
While the staggering daytime usage increases made for good press, it did not impact the overall network capacity requirements. Networks must be designed for peak utilization. The daytime usage was starting from a much lower point, so its percentage increase is exaggerated. Our focus going forward will be on the increase to the peak busy period for the day. For the above nodes that we monitored, we saw peak downstream increases in the 12-25% range while peak upstream increases were even higher in the 20-50% range.

## 3.1. NCTA COVID-19 Dashboard website

During the pandemic, the NCTA (The Internet & Television Association) was particularly proactive in publishing its members' network status. It collected nationwide information from the following MSOs:

- AlticeUSA, CableOne, Charter, Comcast, Cox, GCI, Mediacom, Midco, Sjoberg's

Altogether, this group represents 94% of the entire U.S.A. cable subscriber base. The NCTA published its data on the website: https://www.ncta.com/COVIDdashboard. The National Upstream Peak Growth and National Downstream Peak Growth charts are shown in figure 4 below.



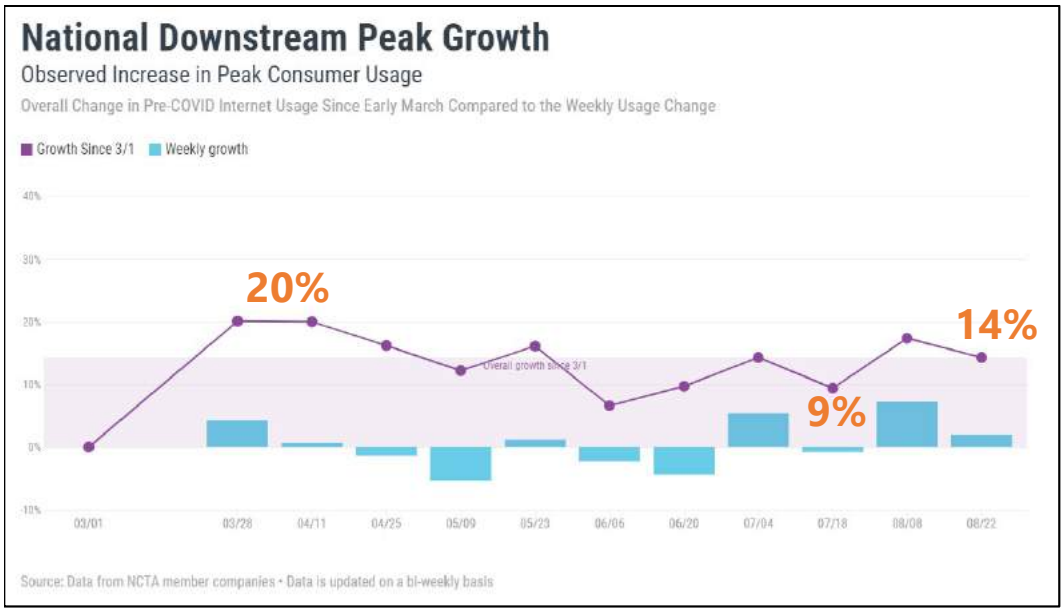


**Figure 4 – NCTA COVID-19 Dashboard: National Peak Internet Growth**

These charts show the change in peak consumer usage relative to March 1st, before the pandemic lockdowns began. By early April, the upstream peak was up 35% while the downstream peak was up 20%. After flattening out for a bit, these peak increases started to gradually drop. As of mid-July, the upstream peak was still 24% higher than March 1st, while the downstream peak was down to just a 9% increase from the start. There has been a slight uptick with the end of summer.

At this point, it is not clear if the dip in the peak increases is a result of the gradual re-openings happening around the country, or whether this is just a typical summer slow-down as people start to do more outside

activities instead of being in front of their computers. It will also be interesting to observe the behavior of the above curves in the Autumn of 2020 with many schools planning to re-open with both face-to-face and on-line classes; this may result in an interesting bandwidth surge with more ubiquitous push towards on-line learning than was carried out in the Spring of 2020. Another interesting observation in the above curves is that the downstream peak increase of 9% after four months is actually in line with a 30% annual growth rate. So the downstream may be close to being back to normal levels. The upstream peak is definitely still elevated considering its historical 20% annual increases.

The NCTA website provides a wealth of additional information. It shows a dashboard with peak usage network status for the nation or for a given state. A snapshot of the National dashboard for mid-May is shown in figure 5. As can be seen, 97% of networks nationally were within their normal peak usage range with 2.8% at an elevated peak usage (i.e. yellow zone). Only 0.1% of networks were in the orange zone of substantially elevated peak usage and hardly any were in the red zone with significant elevated peak usage. This shows how well our broadband networks fared.

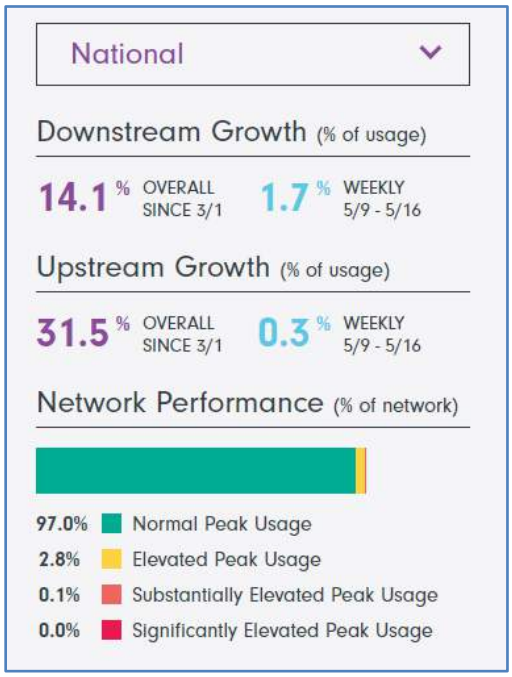

**Figure 5 – NCTA COVID-19 Dashboard: Peak Usage status as of mid-May**

The NCTA website also provided some additional key takeaways. Here were some given in mid-May:

- National US peak ***growth remains mostly flat*** with slight dip from 35% Peak
- National DS peak ***growth receding*** over last 2 months from 20% Peak
- Provider backbone networks ***have significant capacity***
    - Show no signs of congestion
- US peak hours in many regions have shifted from late evening to afternoon
- Wi-Fi data traffic & Wi-Fi calling are increasing as compared to mobile
- Networks are supporting more Wi-Fi-connected devices

## 3.2. Comcast COVID-19 Dashboard website

During the first few months of the pandemic, Comcast also published information on their own website, https://corporate.comcast.com/covid-19/network. Figure 6 below shows the Comcast Bandwidth Chart from mid-May. The upstream peak growth was holding fairly steady around 30-32%, while the downstream peak growth shot up to ~20% in late March and then slid back down to ~10% in mid-May.

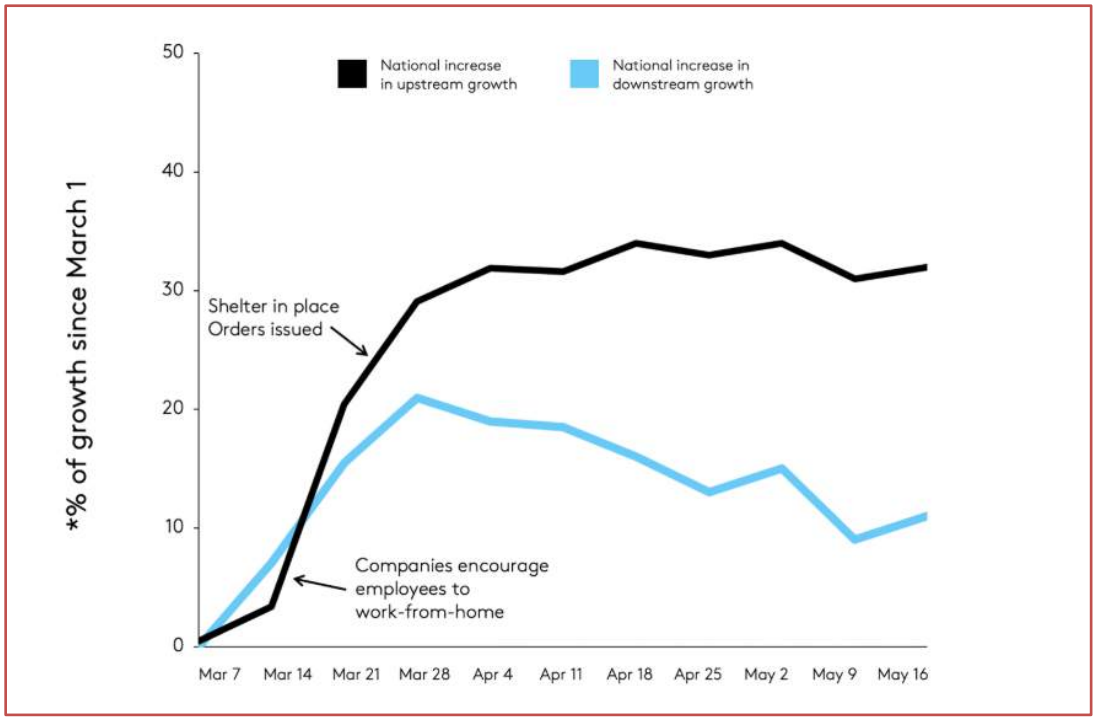

**Figure 6 – Comcast COVID-19 Bandwidth Chart**

Some observed effects on bandwidth as seen by Comcast include:

- Weekday usage is up:
  - VoIP & Video Conferencing is up 210-285%
  - VPN traffic is holding steady, up 30-40%
- Evening & weekend usage is up:
  - Gaming downloads are up 20-35% generally, up to 80% during new releases
  - 20-40% increase in streaming and web video consumption
  - Linear video consumption increased +2 hours per day per household
  - Video OnDemand (VoD) hitting record highs, up 50% YOY
- Xfinity Mobile sees a 36% increase in mobile data usage over Wi-Fi
  - But a 17% decline in LTE Data usage

Comcast also provided a number of interesting quotes, some of which are shown in figure 7. Of particular note is the quote from Comcast President Tony Werner: "We engineer the network to handle spikes and shifts in usage, and what we have seen so far with COVID-19 is within our capacity". The authors have seen this numerous times –

> *Networks that have been designed with sufficient capacity have been resilient and has handled the Coronavirus BW surge.*

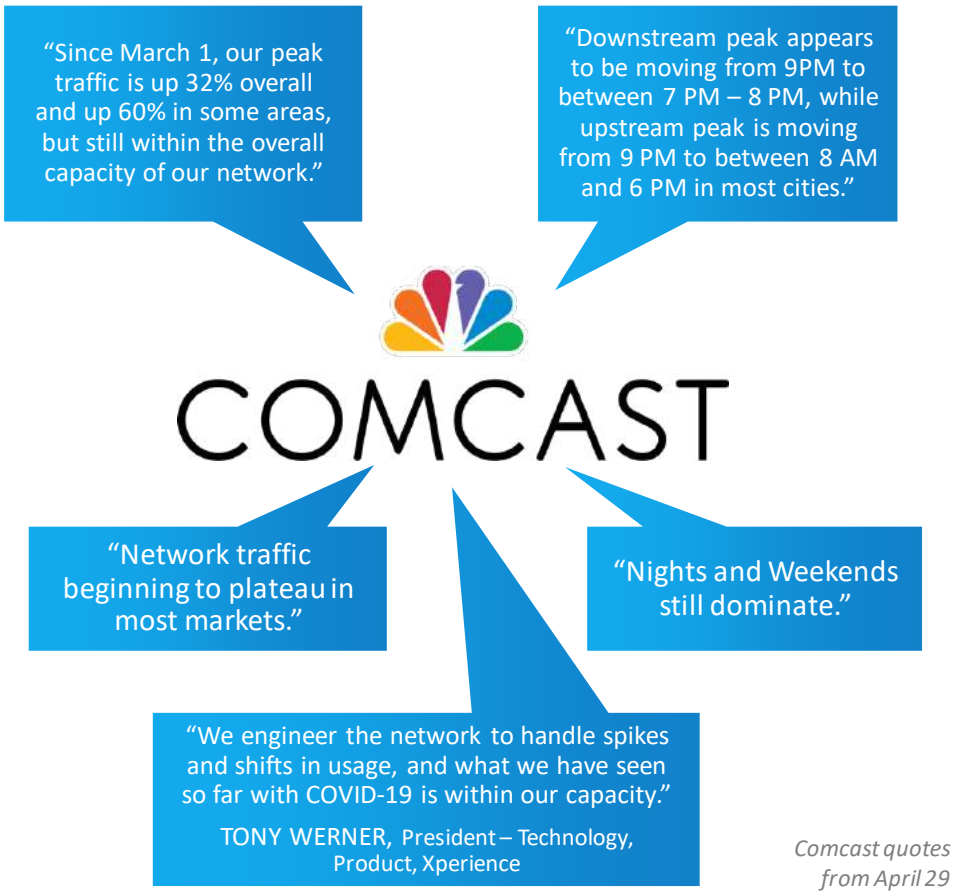

**Figure 7 – Comcast COVID-19 Quotes**

### 3.3. Other data gathered from various MSOs around the Global

The CommScope ServAssure program allowed us to collect data from multiple MSOs from around the globe. We were able to look at data from before and after the start of the pandemic.

One set of data came from a North American metro-area and covered 1000's of nodes. From that we were able to get the network utilization levels for every service group during the four weeks in March. The relative downstream (DS) service group (SG) utilization levels are shown in figure 8. The left side of the chart shows the entire node population while the right side zooms in on the "yellow" to "red" regions.

During the first week before the lockdown, almost 90% of the SGs were in the "green", i.e. <65% DS utilization. These networks were in great shape and in no immediate need for additional capacity. Around 10% of SG were in the "yellow" or "orange" zones (i.e. between 65% to 80%) indicating that they might need extra DS capacity in the next 3-9 months. Only ~1% of SG were in the "red" that needed immediate attention (i.e. "red" means >80% utilization).

As utilization increased dramatically with the pandemic lockdown, there was a noticeable change in the DS SG utilization numbers by the last week in March. The number of DS SG in the "green" dropped to

about 80%, while DS SG in the "yellow" almost doubled to 18%. The DS SG in the "red" tripled to around 3%.

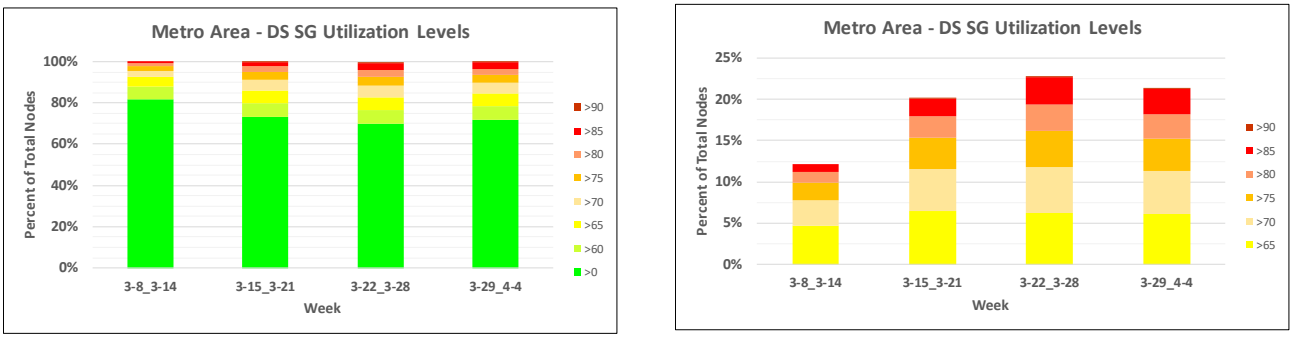

**Figure 8 – Downstream Service Group Utilizations from No. American Metro-area**

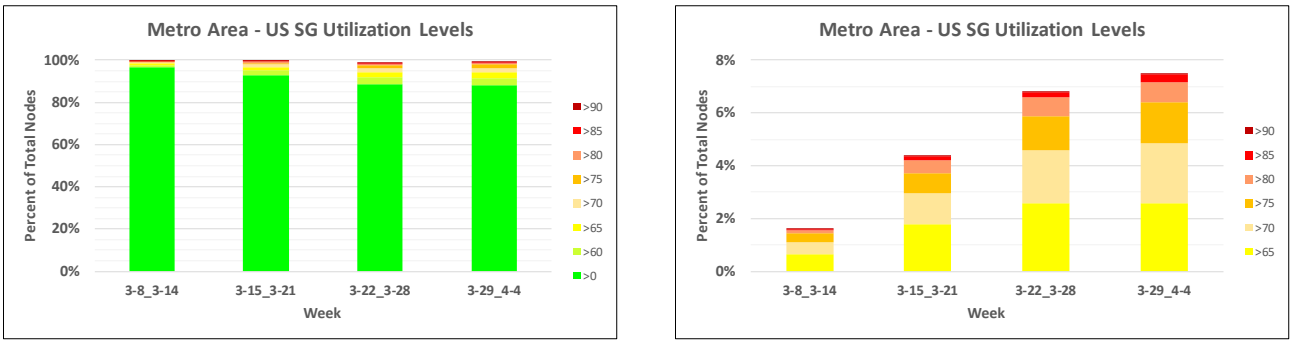

**Figure 9 – Upstream Service Group Utilizations from No. American Metro-area**

Figure 9 provides the upstream (US) service group (SG) utilization for the same North American metro-area. The entire node population is shown on the left while the right chart zooms in on the SG in the "yellow" to "red" zones.

This particular MSO has been meticulous with plant maintenance and reducing cascade lengths. Most of their upstream networks have at least four DOCSIS ATDMA channels. So in general, they have made sure there is plenty of upstream capacity. The early March data bares this out as approximately 98% of the US SG were in the "green"; ~1.5% were in the "yellow" and less than 0.25% of US SG were in the "red".

As the pandemic hit, it took its toll. The "green" US SG dropped to almost 90%. The number of US SG in "yellow" quadrupled to ~6% while "red" US SG also quadrupled to 1%. While these percentages look low, this is across 1000's of nodes that were impacted. The number of nodes that needed immediate attention increased dramatically, as well as the number of nodes needing extra capacity in the next 3-9 months.

Figure 10 takes a closer look at the downstream impacts using a typical DS SG. The chart on the left shows the utilization levels for different hours during the day and how it changed from week to week during March. The chart on the right shows similar utilization levels for the evening hours.

Notice how the DS utilization builds during the course of the day, from 10am to 2pm to 4pm to 6pm. By the 6-7pm hour, the DS SG is approaching its peak busy period. In general, 9-10pm was the busiest hour and used for our Tavg calculations. Although, 8-9pm and 10-11pm were very close. It shows that the DS peak busy period is close to a 3 hour window. There was a noticeable drop-off in utilization after 11pm.

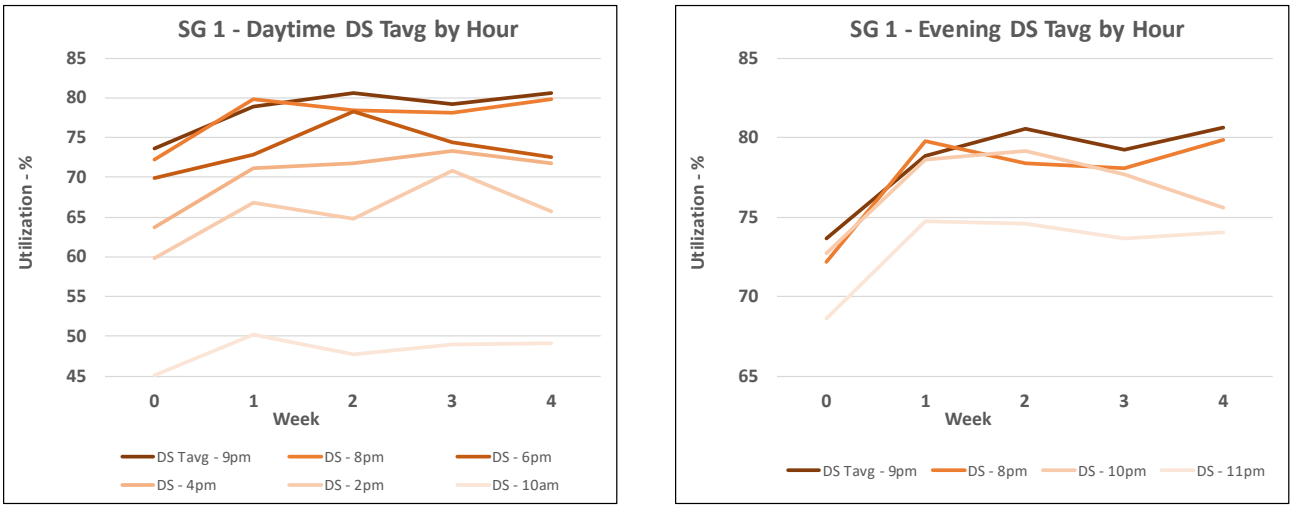

**Figure 10 – Downstream Service Group Utilizations per Hour from N.A. Metro-area**

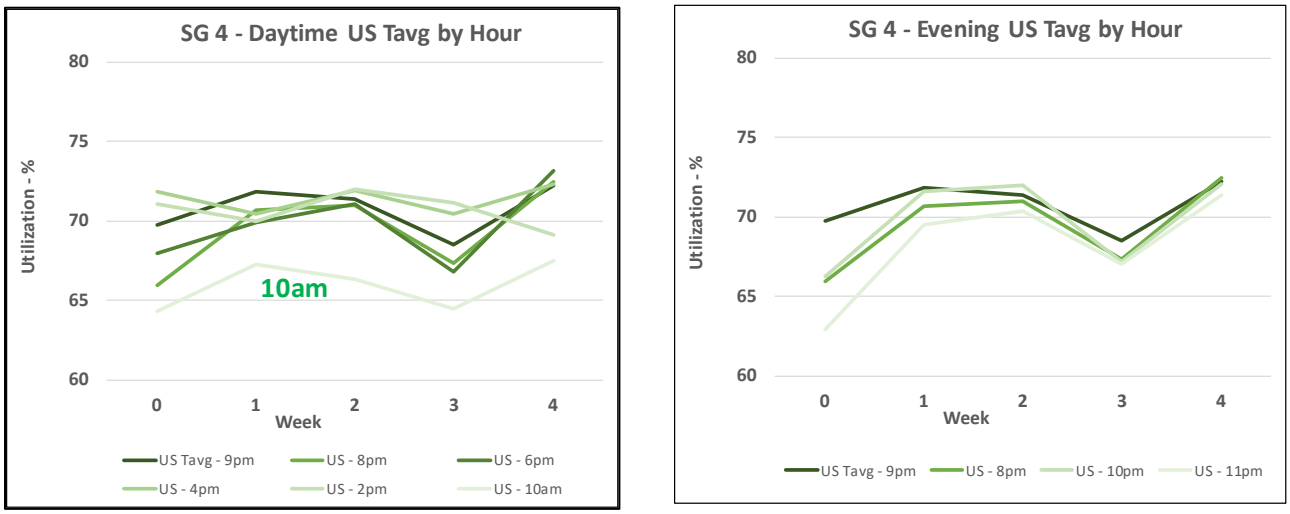

**Figure 11 – Upstream Service Group Utilizations per Hour from N.A. Metro-area**

Figure 11 takes a closer look at the upstream impacts using another typical US SG. The chart on the left shows the US utilization levels for different hours during the day and how it changed from week to week during March. The chart on the right shows similar US utilization levels for the evening hours.

Right away, the differences from the DS utilizations in figure 10 are obvious. By 10am hour, the US utilization is up to 65% and then the rest of the day it stays near peak levels. A closer look at the evening hours on the right shows how steady the US utilization remains for the entire evening. The peak busy period is now 11am to 11pm for this SG.

# 4. The Cause of the Surge – the usual Suspects

Taking a closer look at the various applications that caused the Coronavirus BW surge, it turns out it is basically just a lot more of things that are already been seen.

## 4.1. Work @ Home

The first very obvious impact of the lockdown was the significant increase in work@home employees. Some estimates showed that pre-COVID only 5%-10% of the workforce would work@home on a full or part-time basis. Overnight with the lockdown, this number skyrocketed to the 50%-90% range depending on locale. Working from home increases the use of Virtual Private Networks (VPN) and file transfers. Video conferencing would also jump up using programs such as WebEx, Microsoft Teams, Skype, Zoom, etc.

In general, many of these work applications are symmetric in nature, so they would tend to have a much bigger impact on the upstream capacity. Many current work environments are leveraging a cloud infrastructure and common applications such as Microsoft Office will routinely auto-save files to the cloud. This has big ramifications as employees work from home. If a worker is updating a 20MB PowerPoint or Word document, the cloud-sync function may cause it to get uploaded a dozen times over an hour of working. Again, adding additional burden to our upstream networks.

## 4.2. Remote Learning

Schools were one of the first institutions to close down when the pandemic hit, and school districts scrambled to set up their remote learning programs. Zoom and Skype became two of the favorite video conferencing methods to reach students during the day. Again, a symmetric application putting additional burdens on the upstream.

YouTube usage also saw a big uptick as a way for teachers to distribute their lesson plans. And with everyone at home, YouTube became a big source of educational material as people researched the pandemic and looked for ways to pass the time.

## 4.3. Video Streaming

As was noted by Comcast above, viewers had more time on their hands and hence the viewing hours per week went up. Many video content providers offered free trial subscriptions to entice folks to sample their content. It remains to be seen how many of these consumers will stick with the service after the trial is over.

## 4.4. Social Networking

With chatting around the water cooler removed, there was a definite increase in social networking apps as folks looked at ways to stay in touch. Facetime, Skype and Zoom sessions became very popular, not only to keep in touch with current contacts, but to re-establish with some long lost folks too.

## 4.5. Gaming

With everyone at home and more spare time available, gaming applications such as Twitch also a sparked increase. For many of today's on-line games, a download might be on the order of 100GB. There were several instances of a new release of a popular game that directly impacted network performance.

While, in general, gaming applications tend to impact the downstream more, they may often be accompanied by some social networking interaction and possibly some video conferencing.

The gamers are the ones that may have been impacted the most as these networks became congested and latencies increased.

# 5. QoE Impacts of the Surge – the Good, the Bad & the Ugly

With network congestion comes impacts on subscribers Quality of Experience (QoE). The Coronavirus BW surge introduced 12-18 months' worth of upstream BW growth in a 1 week period. The downstream was only slightly more forgiving with 8-12 months of BW growth when the lockdowns started.

Some of the negative QoE effects on subscribers include:

- Packet delays for gamers from higher latencies and buffer-bloat
- Video tiling in streaming & video conferencing from packet delays and drops
- File Download & Upload times increased (a little bit)

In addition to the above impacts, some subscribers who are working/learning/playing from home have insufficient service tiers to support their traffic load and/or are running up against any data caps that their service provider may have.

## 5.1. Upstream Capacity – Achille's Heel of Cable

And this heavy usage is lasting longer throughout the day. The upstream peak period now lasts 12-14 hours from mid-morning to midnight. Because the upstream pipe is much smaller while having the more significant BW surge, it has come under the most scrutiny. At this point, the upstream is considered the Achille's Heel of the cable industry. Current North American 42 MHz systems might support 60-100 Mbps from 3-4 DOCSIS 3.0 ATDMA channels. European 65 MHz HFC systems have a little more breathing room with up to 175 Mbps from up to 7 DOCSIS 3.0 ATDMA channels. But this capacity pales compared to the 5+ Gbps of downstream capacity found on an 870 MHz plant. Because of this, a lot of the focus on following sections will be on enhancing the upstream capacity.

## 5.2. BW Impacts as measured by Speed Tests

For many consumers, when network performance starts to lag, they run a speed test. One of the most common available is Ookla's www.speedtest.net.Ookla. Ookla tracks and publishes its speed test results from around the globe. They did a very good job of showing how every country fared during the pandemic:

https://www.speedtest.net/insights/blog/tracking-covid-19-impact-global-internet-performance/

Figure 12 shows a snapshot of the USA Internet performance based on the Ookla speed test. It covers a timeframe from December 2019 to May 2020. When the lockdowns first occurred in mid-March, the Fixed broadband networks recorded a 9% drop. Note that this was actually less than the drop seen during the holiday week of December 23-29.

The downstream internet performance then gradually recovered over the following weeks until it was only down about 1% from March 2nd until mid-May.

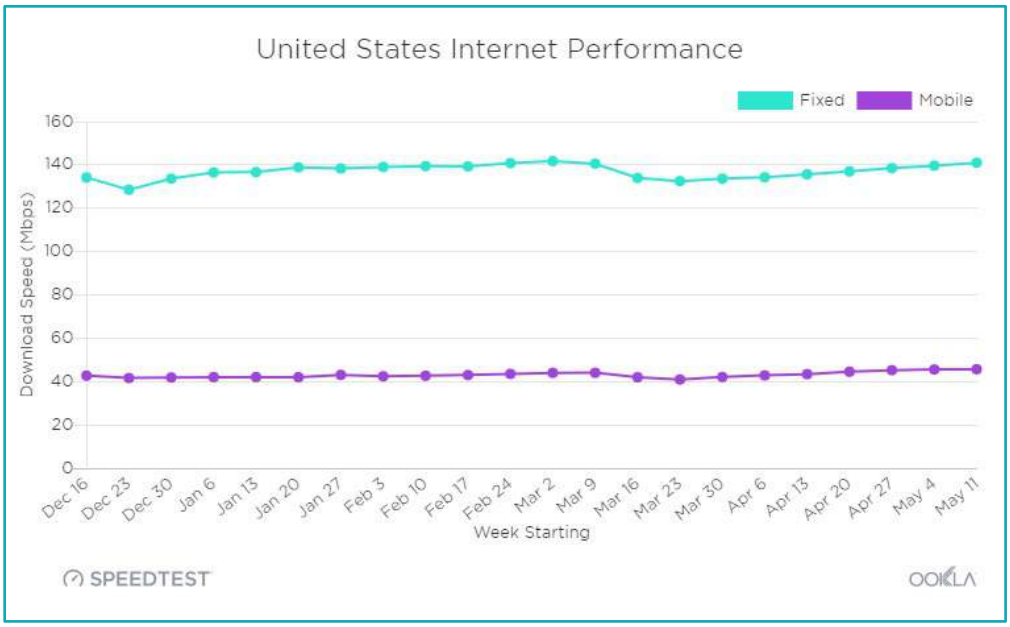

**Figure 12 – Ookla Speedtest: U.S. Internet Performance during Pandemic**

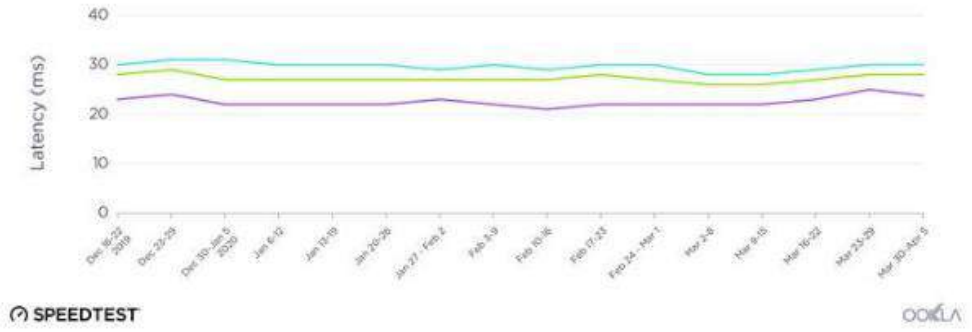

**Figure 13 – Ookla Speedtest: U.S. Internet Latency during Pandemic**

Figure 13 shows the latency measurements from Ookla speed test during this same period. Notice that there was no perceived impact on latencies due to the Coronavirus BW surge. More evidence that broadband networks are holding their own!

## 5.3. Handling Congestion – DOCSIS to the Rescue

Overall, most of these bad QoE effect have been relatively minimal to date for most service groups. Only a handful of SGs that were pushed to the limit before the BW surge had detrimental QoE. In general, the DOCSIS networks are holding up to this sudden, stressful packet load. Why, despite heavily congested upstreams causing delays and drops? Several reasons:

- Good network capacity planning added plenty of headroom
  - e.g. enough headroom to absorb the largest Service Level Agreement (SLA) bursts
- Excellent CMTS Scheduling algorithms
  - These are sophisticated AI Engines that have evolved over the last two decades
  - They are excellent at adapting to congestion, with fair BW distribution

- Most internet applications are elastic and forgiving; TCP and ABR recover from thruput reductions & packet loss

And it also doesn't hurt that subscribers are more tolerant about small lapses when they are more worried about the virus et. al.

To bring home this point of having good bandwidth capacity planning with an excellent CMTS scheduler, figures 14 and 15 show a before and after picture of a hypothetical upstream channel. These upstreams will have traffic from many different service flows (SF) from many different modems. These will present a fairly static load on the system. But at any instant in time, any one of these SF might burst up to its maximum SLA capacity. This is shown in the yellow spikes in the figures.

Before the BW surge with good network planning, then the available US capacity is sufficient to handle the largest SLA burst. Everyone is happy!

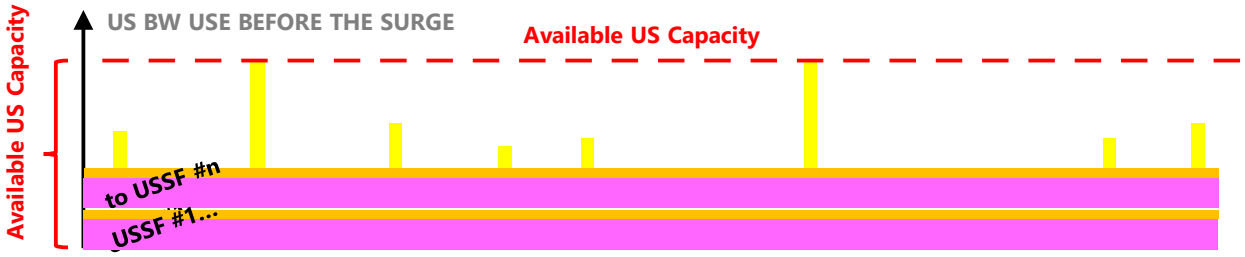

**Figure 14 – Upstream Bandwidth depiction before the Coronavirus BW Surge**

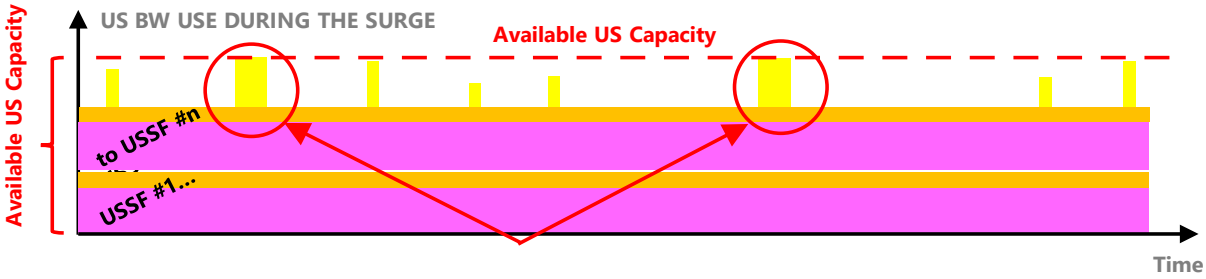

**Figure 15 – Upstream Bandwidth depiction after the Coronavirus BW Surge**

After the Coronavirus BW surge, many of the service flows increase their traffic load and the tide rises. There is no longer sufficient room to handle the largest BW bursts. This is shown in the red circles in the figure. This is also when the CMTS schedulers kick into high gear.

Great CMTS schedulers will throttle down these high bursts, delaying packets and perhaps dropping packets when needed. They are also looking across all SFs and prioritizing as needed. The bottom line is that these bursts get spread out slightly in time with barely a notice from the subscriber. Many subscribers with smaller SLA's may not see any impacts at all. This is the beauty of statistical multiplexing traffic and intelligent US scheduling during the Coronavirus BW surge.

# 6. Repairing Leaks during the Storm – Short-term Fixes

For those handful of SGs that became super-congested during the BW surge, operators were looking for some quick fixes that might gain an additional 5% or 10% or 15% of capacity gain. They also wanted something that they could implement in the matter of hours or days to relieve the immediate heartburn.

Below is a smattering of small things that might help. By themselves they may not add up too much, but collectively a handful of these might be enough to get an operator through the rough patch until more permanent capacity can be added to the system.

## 6.1. Simple I-CCAP related changes

Today's Integrated CCAP (I-CCAP) are very powerful and flexible networking devices with a lot of capabilities. The most straightforward solution to the BW crunch is to add more DOCSIS channels which can be done under software (SW) control using licensing. This would be the first choice solution provided there is spectrum available.

If the operator has a substantial mix of DOCSIS 3.0 and 3.1 modems, then they will need to consider whether to add 3.0 SC-QAM channels or 3.1 OFDM/A channels. In general, the 3.1 OFDMA US channels provide 65% to 100% better spectral capacity (Mbps/MHz) than 3.0 ATDMA channels. The 3.1 OFDMA channels are also more robust and can operate over a much wider frequency range, even well below 20 MHz in the "muck". In general, the 3.1 OFDMA channels have been under-utilized by many operators to date.

But even some 3.0 ATDMA channels could be operated below 20 MHz as well. The operator might need to use a lower modulation (e.g. 16-QAM or QPSK) and/or lower channel widths with increased FEC and interleaving. Some I-CCAP might have an integrated US agility capability to auto-adjust QAM levels.

If there is not sufficient available spectrum in the downstream, the 3.1 OFDM channel is robust enough to run in the roll-off region. E.g. put an OFDM channel from 750-942 MHz in a 750 MHz system. There might be 1 Gbps or more of capacity available in the roll-off.

In a very congested network, the CMTS scheduler is using the SF Tmax value (i.e. its SLA burst value) to fairly assign bandwidth. So, for example, maybe all SF will receive 60% of Tmax during congestion. But there might be a big discrepancy between the highest and lowest Tmax SLA. For example, the top tier in the upstream might be 50 Mbps while the lowest tier is 5 Mbps. The lowest tier will only get 10% of the capacity of the high tier. One strategy might be to temporarily boost the lowest tier (e.g. up to 20 Mbps) to ensure that these customers get adequate US performance to work successfully from home.

The DOCSIS CMTS has dozens of other configuration parameters that could be tweaked to help things. One could enable "Power-Boost" modes; configure Tmin parameters to provide minimum BW guarantees; adjust SF priorities; or tweak any scheduler parameters that might be available.

## 6.2. CM related changes

There are a handful of cable modem (CM) based configuration items that can be done to help. First, the operator should turn on the TCP Ack suppression on all modems if they haven't already. This will help reduce the number of TCP Acks in the upstream and every little bit helps when severely congested.

Buffer-bloat is another problem that has been studied for many years. This is the large increase in queue depths during congested intervals. This then results in very high latencies seen by the applications. The

operator can enable some Buffer Control TLVs and turn on DOCSIS 3.1 Active Queue Management (AQM) to help suppress buffer-bloat and reduce latencies when congested.

### 6.3. In-Home changes

From the subscriber's home perspective, there are a number of items that fall under the quick fix umbrella. First, an operator might encourage subscriber to upgrade to a higher service tier. A new promotion that is geared towards families that are working at home and remote learning might gain a lot of traction while bringing in extra revenue.

With so many people in the home trying to actively use the internet simultaneously, many Wi-Fi routers may be caving under the load. An operator might provide some guidelines to their customers on improving the Wi-Fi router location within the house.

Finally, some I-CCAP might have capabilities like Integrated Service Class Agility (ISCA) that can dynamically reduce the Tmax value temporarily for any "bad actors".

### 6.4. Plant Optimizations

Sometimes operators will use a common configuration across all of their downstream and upstream CMTS ports. This may result in using the lowest common denominator and many SG may be leaving unused capacity on the table. For heavily congested SG, the operator may need to optimize the configuration parameters for those channels.

Depending on the Signal-to-Noise Ratio (SNR), an operator may be able to increase the QAM modulation and/or optimize the Forward Error Correction (FEC) for a given channel. For example on a cleaner plant, the US ATDMA channel might get bumped from 32- to 64-QAM modulation. An US OFDMA channel might go from 256- to 512- or even 1024-QAM modulation. In the DS OFDM channel, an operator might jump from 1024- to 4096-QAM.

The I-CCAP may ship with a default FEC setting that is very robust, but not efficient. Optimizing the US FEC could increase US capacity by as much as 13%. That may be enough to get that SG out of the dog house.

**Warning** – only change the QAM-modulation and FEC to values that can be supported by the SNR. Being too aggressive may introduced undetected packet errors causing dropped packets and making performance worse than before. An operator should use tools like the Intelligent Channel Optimizer (ICO) to optimize settings. For OFDMA channels, optimize bit-loading settings in Modulation Profiles using PMA tools (while still maintaining adequate Packet Error Rate, PER).

## 7. Cleaning up after the Storm – Near-term 6-12 month Strategies

The previous section talked about some quick fixes that could be done to relieve pressure on SGs in the "red" zone. This section takes a look at what can be implemented over the next 6-12 months to address SGs in the "yellow" zone. These can prepare an operator in case another BW surge arises.

### 7.1. CMTS related changes

Rinse and repeat – add more DOCSIS channels is the recurring theme here. Any additional capacity means adding more DOCSIS channels. The questions become: where does the spectrum come from and what is the mix of 3.0 and 3.1 channels.

 

Once the available spectrum is used including the roll-off region, then the operator will need to look at reclaiming spectrum from Legacy video QAMs; upgrading plants to 1218/85 or 1218/204 MHz; and/or segmenting service groups in either hubs or in nodes. Segmenting SG implies that the operator will have to add more CCAP ports to their system.

These options will be detailed below.

## 7.2. Legacy Video

For many operators, Legacy video still consumes a significant portion of their downstream spectrum. This is predominantly broadcast video QAM channels but also may include a handful of Video-on-Demand (VOD) QAMs.

Operators should consider converting any remaining older MPEG-2 encoded broadcast programs over to MPEG-4 encoding. This cuts their bandwidth requirements in half. This also means they will need to retire any MPEG-2 only settop boxes (STBs) that are still out there.

With all the improvements in encoding and stat-muxing technology, the operator may be able to increase the number of programs per QAM channel. For example, they may be able to jump from 2-3 HD programs per QAM up to 4-5 HD programs per QAM.

Perhaps the most powerful tool available to the operator for reducing Legacy video spectrum is Switched Digital Video (SDV). This technology has been around for 15 years but has undergone a bit of a renaissance by migrating to cloud-based infrastructures. This mature technology is now more cost effective than ever. SDV plays well with I-CCAP that integrate the SDV video QAMs directly into it. You can turn on an SDV system in a matter of weeks. And by aligning the SDV group with the shrinking DOCSIS SG, the operator could free up enough spectrum for a pair of 192 MHz OFDM channels.

## 7.3. CM & In-Home changes

The operator's biggest weapon in its arsenal is DOCSIS 3.1. But it doesn't help if there are not enough 3.1 modems in the field. The first priority for the operator should be to upgrade ALL modems for high tier customers (e.g. 200Mbps+ DS). By getting all the high tier customers onto 3.1 OFDM/OFDMA channels, they get better service. And this off-loads the potentially congested 3.0 SC-QAM channels for the lower tiers.

As mentioned before, the upstream is the cable operator's Achilles heel. 3.1 OFDMA channels can more than double the upstream capacity in a 42MHz system. Operators should be rolling out more and more OFDMA channels. As the 3.1 modem penetration starts to overtake 3.0 penetration, then 3.0 SC-QAM channels can be reclaimed and converted to OFDMA spectrum.

Another big in-home improvement that an operator can make in the near-term is to start upgrading their customers to the new Wi-Fi 6 routers (i.e. 802.11ax). These can significantly increase the in-home Wi-Fi capacities and reach, which are both critical with so many people working from home.

The Wi-Fi 6 routers could be bundled with 3.1 modems for new service tiers that target work and learn at home families.

### 7.4. RF Plant Upgrades

There are a number of things that an operator can do with respect to the outside plant to enhance capacity in the near term. Perhaps the lowest hanging fruit with minimal investment is to segment existing nodes. Typically nodes are deployed with a single downstream module and a single upstream module. This configuration is referred to as 1x1 and maps to a single CMTS US port and a single DS port. The node may have two or four RF ports, and this DS and US are shared across all RF ports.

Some nodes with a digital return can easily be re-configured to support a second US. This effectively splits the node into 1 DS and 2 US or a 1x2 node. This will help relieve US congestion on that SG.

Later, another DS module can be added to the node to make it a 2x2 configuration. Eventually more modules can be added so the node evolves into a 4x4 configuration. All of this can be done at the node location without touching the rest of the outside plant. Additional CCAP ports will be needed in the hub site as well.

For severely congested SG, an operator might consider upgrading those first to 1218/85 or 1218/204 MHz plants. This is part of the longer term strategy and provides enough capacity for the rest of the decade. The 85 MHz return almost triples the amount of usable US spectrum. Combined with 3.1 OFDMA, it can support 400-500 Mbps US tiers. The 204 MHz return enables 1 Gbps US services. Upgrading all of your plants to 1218 MHz will take a while, so start today with those SG that are most congested.

DOCSIS 3.1 is very powerful and optimizes capacity according to the quality of the plant. It turns out that long fiber runs (e.g. >40km) with AM optics can have a detrimental effect on 3.1 OFDM capacity. This can be remedied by replacing those AM fiber runs with digital optics when Remote PHY devices (RPD) or Remote MAC-PHY devices (RMD) are placed in the node. And again, this might be part of a longer term MSO strategy to migrate to a complete Distributed Access Architecture (DAA).

## 8. Preparing for the next Storm – Network Capacity Planning

The CommScope (formerly ARRIS) team has been providing industry leading research in traffic engineering for many years which was most recently highlighted in [ULM_2019]. Some additional references of note include [CLO_2014], [EMM_2014], [ULM_2014], [CLO_2016], [ULM_2016], [ULM_2017] and [CLO_2017].

### 8.1. The “Basic” Traffic Engineering Formula

Previously, [CLO_2014] provided an introduction to traffic engineering and quality of experience (QoE) for broadband networks. From there, the paper went on to develop a relatively simple traffic engineering formula for cable service groups that is easy to understand and useful for demonstrating basic network capacity components.

The “Basic” formula shown below is a simple two-term equation. The first term (Nsub*Tavg) allocates bandwidth capacity to ensure that the aggregate average bandwidth generated by the Nsub subscribers can be adequately carried by the service group’s bandwidth capacity. The first term is viewed as the “DC component” of traffic that tends to exist as a continuous flow of traffic during the peak busy period.

**The “2014” Traffic Engineering Formula (Based on Tmax_max):**

$$C >= (Nsub*Tavg) + (K*Tmax\_max) \quad (1)$$

 

where:

C is the required bandwidth capacity for the service group
Nsub is the total number of subscribers within the service group
Tavg is the average bandwidth consumed by a subscriber during the busy-hour
K is the QoE constant (larger values of K yield higher QoE levels)…
where 0 <= K <= infinity, but typically 1.0 <= K <=1.2
Tmax_max is the highest Service Tier (i.e. Tmax) offered by the MSO

The MSO data collected and shown in section 2 provides a good indication of Tavg, at least before the Coronavirus BW surge hit. Note that figures 1 and 2 are very generalized results that are averaged across millions of subscribers. A given operator will need to take a look at their own networks to ascertain what is an appropriate value for them. Regarding SG congestion, they need only look at the total SG consumption (i.e. Nsub*Tavg product term) and there is no need to break it down into the individual Nsub and Tavg components.

There are obviously fluctuations that will occur (i.e. the "AC component" of traffic) which can force the instantaneous traffic levels to both fall below and rise above the DC traffic level. The second term (K*Tmax_max) is added to increase the probability that all subscribers, including those with the highest Service tiers (i.e. Tmax values), will experience good QoE levels for most of the fluctuations that go above the DC traffic level.

The second term in the formula (K*Tmax_max) has an adjustable parameter defined by the K value. This parameter allows the MSO to increase the K value and add bandwidth capacity headroom that helps provide better QoE to their subscribers within a service group. In addition, the entire second term is scaled to be proportional to the Tmax_max value, which is the maximum Tmax value that is being offered to subscribers. A change in the K value results in a corresponding change within the QoE levels experienced by the subscribers who are sharing the service group bandwidth capacity (C). Lower K values yield lower QoE levels, and higher K values yield higher QoE levels).

In previous papers [CLOONAN_2013, EMM_2014], found that a K value of ~1.0 would yield acceptable and adequate QoE results. [CLOONAN_2014] goes on to provide simulation results that showed a value between K=1.0 and 1.2 would provide good QoE results for a service group of 250 subscribers. Larger SGs would need larger values of K while very small SGs might use a K value near or less than 1.0.

## 8.2. Providing Sufficient Headroom for a BW Surge

It will be useful to provide some examples on how the CommScope Basic Traffic Engineering formula can be applied to provide adequate headroom to sustain a BW surge. The first DS example is shown in figure 16. It assumes that the SG size is 100 subs. Before the BW surge (on the left in the figure), it uses a Tavg value = 2.36 Mbps taken from figure 1. The highest tier is 1G (i.e. Tmax_max = 1 Gbps) with a QoE constant K = 1.2. The basic formula says that the operator needs at least 1436Mbps to maintain that Kvalue. This might be a combination of 3.0 SC-QAM and 3.1 OFDM channels bonded together. The Nsub*Tavg component equals 236 Mbps (shown in blue) with the K*Tmax_max component = 1200 Mbps (shown in yellow).

After the surge is shown on the right hand side of figure 16. It assumes DS usage grows by 25% to Tavg = 2.95 Mbps. The Nsub*Tavg has now increased to 295 Mbps while overall capacity has remained fixed at 1436 Mbps. This reduces the K*Tmax_max component to 1141 Mbps which is an effective K value

equal to 1.14. This is still in the "good" QoE range, despite seeing an instantaneous 25% increase in usage.

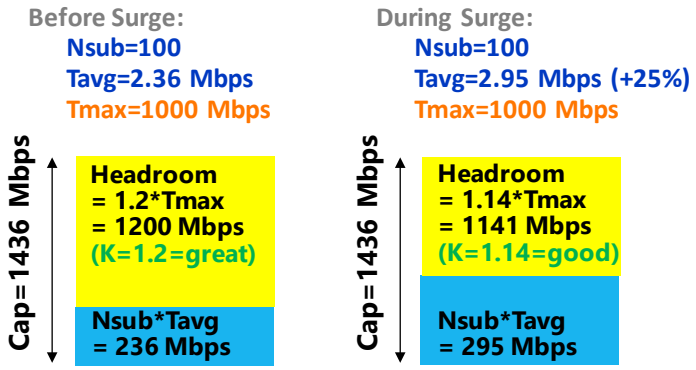

**Figure 16 – QoE-based Traffic Eng Formula at Work during DS BW Surge, small SG**

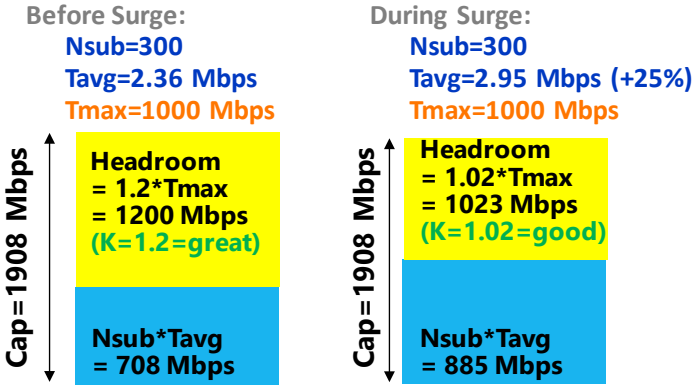

**Figure 17 – QoE-based Traffic Eng Formula at Work during DS BW Surge, large SG**

The second example in figure 17 increases the number of subscribers in the SG to 300 subs. Before the surge, this increases the Nsub*Tavg component to 708 Mbps. The overall required capacity is now increased up to 1908 Mbps to still maintain a QoE constant K = 1.2.

During the surge, the increased Tavg now has a bigger impact due to the increased SG size. The Nsub*Tavg component has now swelled to 885 Mbps. This now leaves 1023 Mbps for the K*Tmax_max component which provides an effective QoE constant K = 1.02. This is still in the "good" region, although near the bottom. So for larger SG, it is more important to have the cushion associated with K=1.2.

The third example in figure 18 takes a look at what happens if sufficient headroom is not applied. This example assumes the operator has rolled out the same 1436 Mbps overall capacity across their entire footprint, regardless of the SG size. This example looks at a SG with 250 subs. The Nsub*Tavg component before the surge is 590 Mbps. This makes for an effective K = 0.85 which is in the "fair" region. This means that the 1G customers will have good QoE much of the time, but may see some congestion periodically during peak busy periods.

Once the Coronavirus BW surge hits this SG, its Nsub*Tavg jumps to 738 Mbps. This reduces the K*Tmax_max component down to 551 Mbps which results in K=0.7. This is in the "poor" region. The 1G customers QoE impact becomes more noticeable.

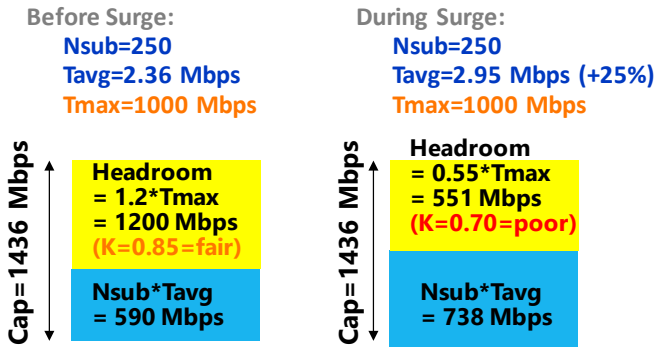

**Figure 18 – QoE-based Traffic Eng Formula at Work for Marginal SG**

It is important that operates not only monitor their network utilizations, but they must also understand the highest tier being offered and adjust their thresholds accordingly. For example, just having a utilization threshold of 80% to take action is not good enough by itself. That might have been adequate when the top tier was 100 Mbps, but then starts to fail when the top tier is 1 Gbps.

> *As the top tier is increased, the utilization threshold to take action must be correspondingly decreased to maintain consistent QoE.*

# 9. Building the Storm-proof Network – Mid- to Long-term Strategies

The Coronavirus BW surge is a glimpse at our future BW trends. We will not return to our pre-COVID days and will need to deal with a "new normal". This surge should serve as a wake-up call to make sure our industry continues to push its networks forward. We'll take a look at some mid-term solutions that can be implemented over the next couple years and then look at what will be coming later this decade.

## 9.1. Mid-term Solutions – for 1-3+ Years of Capacity Needs

Over the next couple years, operators need to focus on getting switched over to DOCSIS 3.1. This is the industry's workhorse right now. Operators should have plans in place to try and become 100% 3.1, phasing out their 2.0 and 3.0 modems. This can be done over a 5-8 year window, but needs to start in earnest now. Remember, DOCSIS 3.1 is your biggest weapon with your biggest bang for the buck.

### *9.1.1. CCAP related changes*

As time goes on, operators should continue to maximize their 3.1 OFDM/OFDMA capacity. Any older CMTS should be upgraded to support the full 3.1 capabilities, including OFDMA in the upstream with both 85 and 204 MHz splits; and multiple 192 MHz OFDM channels in the downstream.

Over time, SG sizes will continue to shrink with node segmentations, so new CCAP ports will continually be added. Segmenting SG size is especially helpful in containing Tavg growth as was shown in the examples of the previous section.

During this timeframe as 3.1 penetration increases and high tier customers are moved to 3.1 modems, the operator should start considering switching some 3.0 SC-QAM channels to OFDM/OFDMA spectrum.

### 9.1.2. IP Video Migration

As part of the strategy to completely remove the Legacy Broadcast video spectrum, operators should have their IP video migration plans in full swing. It may take 5 to 8 years or more to get all of the Legacy STB swapped out for IP STB or other IPTV devices.

Ramping up the IPTV consumption while it coexists with Legacy Broadcast QAMs may create a sizable bandwidth bubble. The operator may also need to consider SDV or encoding enhancements as described in section 7.2.

Some other technologies to consider when deploying Adaptive Bit-Rate (ABR) IP video is multicast-assisted ABR (M-ABR) and Smart ABR technologies. Using multicast in an IP video world may still be very important when considering special events with large viewer populations tuned in. M-ABR also significantly reduces the BW requirements between the CDN and the CCAP. For a CCAP with 25,000 subscribers, it could potentially reduce IP video capacity originating at the CDN from several hundred Gbps down to 10's of Gbps.

### 9.1.3. CM & In-Home changes

During the mid-term phase, operators should get the remaining high tier subs completely on 3.1 modems. Not only does this make it easier to provide them with good QoE during times of congestion, it will free up precious 3.0 bandwidth that will be needed by the lower service tiers.

And with higher penetrations of 3.1 modems, the operator can make better use of OFDMA spectrum. OFDMA has the potential of increasing the 42 MHz upstream capacity from 100 Mbps with 3.0 to the 200-250 Mbps range depending on plant quality.

In addition to the migration to 3.1 modems, operators should also be deploying Wi-Fi 6 throughout the rest of its customer base.

### 9.1.4. RF Plant Upgrades

During the mid-term years, operators should be upgrading their older 550/750/870 MHz plants to 1218/85 or 1218/204 MHz plants. These technologies are available today and will carry the operator through the rest of this decade. [ULM_2019] takes a look at how 1218 MHz networks can achieve our Cable 10G DS goals. DOCSIS 3.1 specification was written in 2014 and is just now becoming widespread. DOCSIS 4.0 specification just became available and requires an even bigger plant investment with new taps. So don't expect 4.0 to become mainstream until the end of this decade. And if growth rates continue to slow, maybe the need for 4.0 will be pushed out further in time.

The long term strategy for every cable operator should be to push fiber deeper. Eventually we may see fiber passing every home, but that level of investment takes multiple decades. However, MSOs should continue the fiber deep march in the mid-term and continue to reduce serving area size and cascade lengths.

There are some significant benefits with a fiber deep approach (e.g. N+0, N+1). In addition to the reduced SG size and increased 1.2GHz spectrum, the total number of active components can be reduced

increasing reliability AND cutting OPEX costs in half. Fiber deep networks are also much closer to homes and become a jumping off point to selectively offer FTTH services.

Finally, some operators may be on the road to DAA. The mid-term period will be a good time to start that transition and start ramping up their deployments of RPD or RMD in the field.

### 9.2. Long-term Solutions – for 5-10 Year Horizon

What does the distant future hold? Nobody knows for sure and the crystal ball is cloudier than ever. Bandwidth usage may not snap back to its original pre-Coronavirus levels when Coronavirus ends. Why? Because this novel social experiment we are all involved in may foster a new social paradigm. Workers and companies may decide to explore more work-at-home activities and students and schools may decide to explore more on-line education activities.

Bandwidth will obviously continue to grow into the 2020's, although the rate of growth has a lot of debate. We are starting to see new applications like eSports getting a boost right now. The problem experienced during Coronavirus is only a sampling of what will happen in the future when that bandwidth growth crosses certain thresholds

> ***MSOs & Vendors need to begin working now to upgrade the HFC Plant to support the future Bandwidth Growth.***

While DOCSIS 3.1 can carry us a very long way, the industry needs to work on new technologies today to be ready for the future. This is what the Cable 10G initiative and DOCSIS 4.0 specification are all about. DOCSIS 4.0 will give us a choice of two options. Full-Duplex (FDX) technologies for N+0 plants that support dynamically shared spectrum from 108-684 MHz. This will enable 4-5 Gbps US tiers.

Alternatively, 4.0 also specifies some ultra-high split options paired with extended spectrum (ESD). These can offer service tiers similar to FDX on a 1794/492 MHz plant using simple FDD techniques. Both of these technologies are enabling multi-gigabit upstream tiers to be competitive with 10G PON symmetric offerings.

Inside the home, there will also be a migration from today's Wi-Fi 6 routers to the next generation of Wi-Fi 6E. The new generation will have a new spectral band from 5.9-7.1 GHz that enables new use cases and opens consideration of 10 Gbps around the home wirelessly that pairs nicely with 4.0 modems.

## 10. Conclusion

The Coronavirus BW surge gave us 12-18 months of upstream usage growth overnight, and about half that in the downstream. And despite the surge, we have seen that the DOCSIS network continues to work very well. But this event has shown weaknesses in the system that need filling to make it through the near-, mid- and long-terms.

Some operators needed some immediate quick fixes for severely congested service groups to relieve the pressure. These needed to be rolled out in a matter of hours or days. Adding DOCSIS channels with the I-CCAP was first choice if spectrum was available, with the roll-off being a good option for the 3.1 OFDM channels. Turning on OFDMA in the upstream should be a priority as well. There are a number of various configuration changes that could be done to improve operation including:

- Enabling TCP Ack suppression
- Reduce buffer-bloat latencies with Buffer-control TLVs, 3.1 AQM

- Optimizing QAM-modulation or FEC
- Re-locating in-home Wi-Fi

These might only provide 5% or 10% or 15% improvements, but everything helps in a congested network.

In the near-term over the coming months, operators can add more substantive improvements to their network capacity. To find spectrum for additional DOCSIS channels, operators can use SDV or improved encoding to reduce Legacy Video spectrum. Node segmentation might split SG to help manage BW. Nodes might go from 1x1 to 1x2 to 2x2/2x4 to 4x4 segmentation. This can be done simply by upgrading the node and not touching anything else in the outside plant. Meanwhile, more DOCSIS 3.1 modems and Wi-Fi 6 routers should be deployed to customers' homes.

Network capacity planning is key to being able to withstand another bandwidth surge. The CommScope/ARRIS Basic Traffic Engineering formula provides guidelines on how much capacity is required to provide good QoE. We saw some examples on what happens before and after the BW surge and why the QoE headroom is important.

> *Networks that have been designed with sufficient capacity have been resilient and has handled the Coronavirus BW surge.*

In the mid-term over the next several years, many plants will be upgraded to 1218/85 or 1218/204 MHz. Fiber Deep networks will continue to be our long term goal as we look to push fiber closer to the home while increasing plant reliability and reducing OPEX. Distributed Access Architectures including RPD and RMD will take hold, especially on longer fiber runs where they provide the most performance gains. And the IP video migration should be in full swing with technologies like M-ABR supplementing it.

Looking into the distant future, BW will not snap back after the pandemic. It will continue to grow through the decade. MSOs need to begin upgrading their networks for the future. While DOCSIS 3.1 continues to be the workhorse today, development of 4.0 products will help to enable symmetric multi-gbps services later in this decade.

Broadband kept society and the economy running, as best we can, in these hard times. This is arguably its most significant contribution to society in its short life-span. Hats off to everyone who has created and helped make the Internet and Broadband available to society.

While collectively we should all be proud of the infrastructure we have created, we still have much work to do. The Coronavirus BW surge has exposed cracks in the system. This should serve as a wake-up call. We still have improvements to make to the infrastructure. It's time to start upgrading the network for the demands of the 2020s.

# 1. Introduction

Today's internet traffic typically comprises data, voice, or video traffic with no extraordinary means to logically segregate traffic based on its network latency sensitivity. Applications have varying requirements for bandwidth, latency or jitter. Some apps require high bandwidth, such as large file downloads or video traffic, and certain apps require low latency, such as online gaming traffic or high frequency trading. The online gaming industry is on a rapid growth path and has become an exciting mainstream revenue source. With an increasing demographic that streams gameplays, the cloud gaming services are bringing new online gaming experience closer to the consumers and it will require support from the 10G initiative driven MSOs to deliver the best quality of experience by ensuring *high* bandwidth and *low* latency or *low* lag support. By enhancing the user experience, the MSOs have an opportunity to generate a new revenue stream. Welcome to the world of Low Latency DOCSIS!

The LLD architecture as proposed by CableLabs enables a logical separation of the latency sensitive non-queue building traffic and regular queue-building internet traffic in to two separate queues. The two queues, Low Latency SF and Classic SF are encapsulated in an Aggregate Service Flow (ASF) to shape the traffic. A key innovation that is part of the LLD architecture is a new scheduling service known as Proactive Grant Scheduling (PGS) [1].

There are multiple sources of latency in DOCSIS networks, including protocol/application dependent queuing delays, propagation delay, Request-Grant delay, channel configuration (OFDM or SC-QAM interleavers, cyclic prefix, FEC, etc.), and switching/forwarding delays. The purpose of LLD is to reduce latency from two of these sources – protocol/application dependent queuing delays and Request-Grant delays.

This paper will focus on the LLD architecture basics and experimental results from the lab studies using the concept of an LLD ASF and PGS in the *DOCSIS Upstream*. The paper will also compare LLD capable system latency with classic latency.

# 2. Low Latency DOCSIS Architecture And Goals

Often times, the bandwidth or speed of a connection is confused with latency of an application. Bandwidth or speed of a connection means how much of the data can be downloaded or uploaded within a time interval. For example, to watch a 4K YouTube video or to download a Call Of Duty 25 GB game patch, a user would need a good bandwidth. There are times when the bandwidth of a connection isn't enough to deliver the best QoE. For example, a multiplayer game of Call Of Duty requires players to  to shoot at other players as well as download any real time rendering of dynamic game environment. This typically results in packets being transmitted at a bit rate of 100 kbps to 200 kbps in the Upstream and Downstream direction.  It is important that the packets reach their destination as quickly as possible so that the player does not get shot themselves first and the game environment rendering is synced with a player's action. If the gaming environment actions are not synced with a players action then it is because of a "high lag" in the network. This time duration of the packets to reach the Call Of Duty gaming server and returning a response to the multiplayer gamer is called Latency. So, to deliver the best QoE it is important to maintain reasonable bandwidth and latency. Inside a home there are multiple users transmitting traffic in the US and DS. Some of the internet traffic may be file download, or a YouTube video, or a Netflix video and other may be gaming traffic or video conferencing.

 

Typically all the traffic will flow in to a single DOCSIS service flow, with a mix of traffic that builds queues like the video streaming apps and other traffic that doesn't build queues like a multiplayer gaming app. The problem with this architecture is that the gaming app gets treated similar to a video streaming app, appending non-queue building traffic in to queue building traffic. Hence, this adds latency & jitter to an already latency sensitive application.

The LLD architecture uses a logical construct called an Aggregate Service Flow (ASF) that encapsulates two underlying service flows – one for Non-Queue building traffic and the other one for Queue building traffic. The intention of separating application's traffic in to two logical queues is to make sure that the application data that builds queues in the DOCSIS access network don't cause delays for data that does not build queues.

For example, let us assume there are two applications that are transmitting traffic in the DOCSIS channel.

1. Online gaming application traffic is typically a few hundred kbps of UDP payload and will not cause queues to build in a SF. UDP does not have any congestion algorithms and will transmit at a set rate, without retransmissions. We call this traffic as the NQB or Low Latency traffic

2. Large file upload traffic in the order of a few MB of TCP payload and will cause formation of queues in a SF. The inherent nature of TCP congestion algorithms is to seek as much bandwidth as possible, cause retransmissions in case of packet loss which results in formation of queues. We call this as QB or Classic Traffic

As compared to a large file upload, the gaming traffic requires the best latency possible so that a gamer can have the best Quality of Experience. If both the traffic types i.e. gaming & file upload are contending in the same SF, although the UDP traffic is so low in bandwidth, it gets congested with the TCP traffic that causes queues to build-up. In other words, the a latency sensitive application gets delayed in the SF queue by a queue building application. So, by using LLD, the latency sensitive NQB application gets its own SF queue without impacting the latency of other QB applications.

Now, lets take a look closer look at the features provided by the LLD architecture. Figure 1 shows the LLD architecture and its components. The CMTS has many important functions in defining the QoS in LLD:

1. A new ASF encapsulating LL and CL SF, known as the LLD ASF
2. A new Weighted Round Robin Scheduler for the two SFs
3. Rate shaping these two SFs at an aggregate level
4. A new scheduling type known as the Proactive Grant Service
5. Traffic Classification in to SFs using DSCP and ECN fields in the IP header
6. Active Queue Management – a new AQM algorithm called the Immediate AQM and Coupled AQM for the two constituent Service Flow
7. Queue Protection
8. Latency Histograms

 

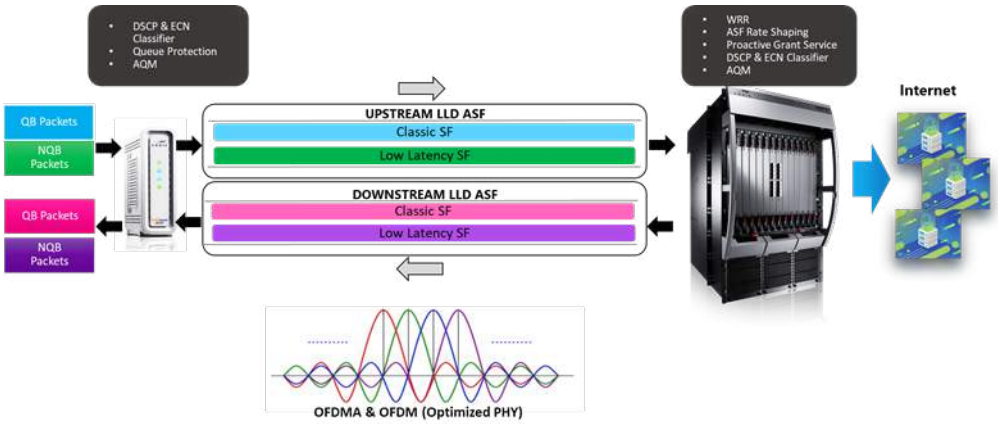

**Figure 1 LLD Architecture**

The LLD ASF provides an encapsulation to the traffic shaping of the LL SF and CL SF by enforcing an Aggregate Maximum Sustained Rate (AMSR). LL SF and CL SF are not like traditional service flows that are shaped by an MSR value. There are always only two SFs in the LLD ASF. For example, if the ASF AMSR is set to 100 Mbps then the traffic flowing in to LL and CL SF can be 20 Mbps and 80 Mbps or it can be 30 Mbps and 70 Mbps respectively, or in any other proportion but bounded by the ASF AMSR. In the upstream LLD ASF, the traffic flowing in the individual SFs will depend on the number of grants each service flow receives.

The Granting mechanism in LLD is governed by a Weighted Round Robin Inter-SF Scheduler running on the CMTS. The scheduler is to behave with conditional priority of providing LL SF grant priority without starving the CL SF. The WRR weight is a configurable parameter with a maximum value of 255. A 230 value set in the LL SF would mean 90% weight (230/255) of grants is to be provided to the LL SF. The weights provided by scheduler does not result in an unfairness between the two service flows because of the Coupled AQM feature of the LLD architecture. More on that later in this section.

Traditionally, the DOCSIS upstream data transmission follows the mechanism described in Figure 2. As soon as a packet arrives, a Bandwidth (BW) Request (REQ) is transmitted to the CMTS to allocate bandwidth requested by the CM. CMTS responds to the CM by sending a Bandwidth Grant (GNT) to the modem based on QoS parameters governed by the CMTS. Once the modem receives the Bandwidth Grant in a MAP packet, it will process the MAP and transmit the data packet to the CMTS, from where it is routed towards a server in the internet. The time for the entire process is given by $\Delta 1 + \Delta 2 + \Delta 3$, where $\Delta 1$ = Packet Processing Delay at the CM + Waiting for a REQ transmission slot + US propagation delay of BW REQ; $\Delta 2$ = BW REQ processing delay at the CMTS + MAP generation delay + DS propagation delay + Wait Time for GNT; $\Delta 3$ = US propagation delay of actual data to be transmitted

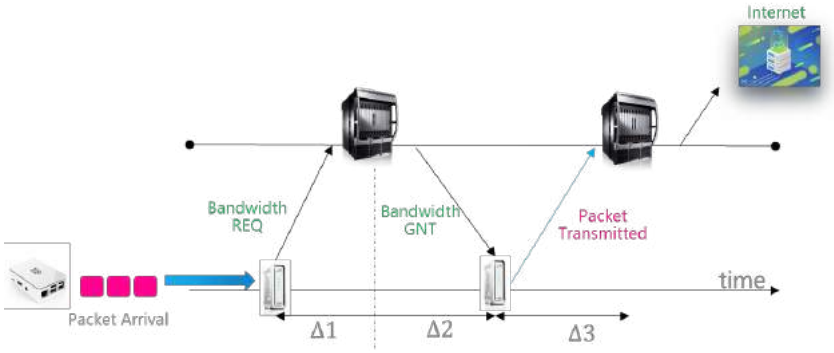

**Figure 2 Traditional DOCSIS REQ-GNT Cycle**

LLD introduces a new data scheduling type known as the Proactive Grant Service or PGS. PGS enables a faster request grant cycle by eliminating the need for a BW REQ even though it's not prohibited to send a BW REQ on a PGS SF. CM will still be able to send BW REQ if the SF bandwidth demands are not met by PGS alone. In PGS, BW GNTs are continuously sent to the modem at a Guaranteed Grant Rate (GGR in bps) and at a Guaranted Grant Interval (GGI in microseconds) value as soon as some activity is detected by the CMTS's proprietary Activity Detection algorithm. GGI is the interval between successive data transmission opportunities. CMTS can track the bandwidth utilization and can adjust the GGR depending on any anticipated future demands, but at the time of writing this paper, the current CMTS implementation  does not adjust GGR. If there is no activity detected on the SF then PGS will switch to sending unicast request opportunities at Guaranteed Request Interval (GRI in microseconds). The CMTS traffic shaper makes sure that the SF is not getting more grants than its maximum sustained rate by verifying the bounds of GGR and GGI. GGR, GGI, and GRI are configurable values in a PGS enabled flow. Figure 3 shows that with PGS, the upstream transmission time is shortened to Δ2' + Δ3 where Δ2' includes DS propagation delay and a reduced processing time for MAP generation. It is typically less than or equal to the GGI.  If GGI is set to a value less than Δ1 + Δ2, PGS will provide a reduction in the upstream transmission time.

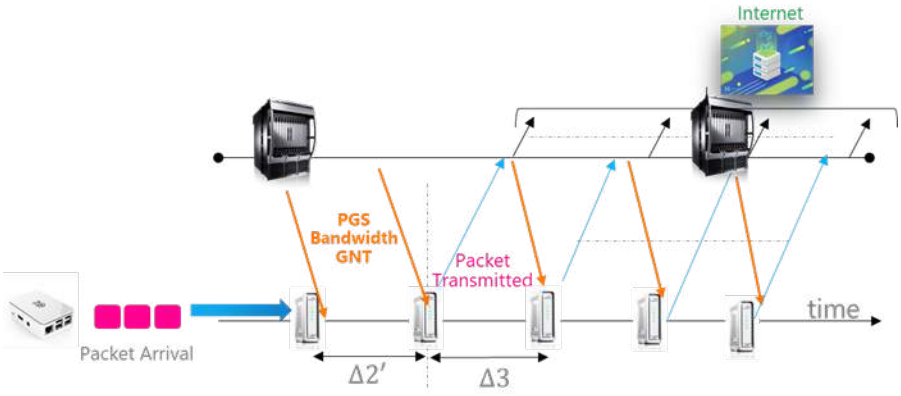

**Figure 3 PGS Granting Mechanism**

In LLD, packet classification plays an important role in placing a packet into a particular SF – CL or LL. The classifiers in LLD examine the 8 bit Differentiated Services field in the IP header for DSCP (MSB 6 bits) and ECN value (LSB 2 bits). For example, the classification can be made based on a packet's DSCP field marked as EF or ECN field is set to ECT(1) or CE (see figure 4) then it will get mapped to the LL SF and any other traffic will be transmitted in the CL SF by default.

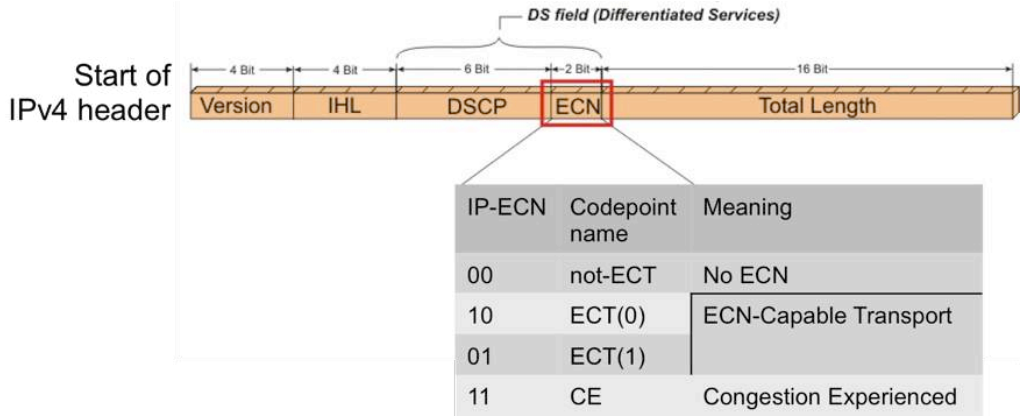

**Figure 4 Differentiated Services Byte in IP Header**

The Active Queue Management algorithms run on CL and LL SFs, both. The CL SF is to use the DOCSIS PIE algorithm, that drops packets as the queues build, to maintain a target latency defined by the configuration. The LL SF will implement a new AQM algorithm known as Immediate AQM, that does not drop packets but marks them with ECN bits. Default marking starts at 475 µs and will always mark the packets beyond 1 ms of latency. As stated earlier, the AQMs act as coupled AQM on both of the constituent SFs i.e. the IAQM of LL SF is coupled to the DOCSIS PIE of CL SF. The coupling will act as a backstop on the LL SF if the CL SF is getting overwhelmed by traffic. When the CL SF throughput is overwhelming the system with requests for the grants to keep up, the ECN marking is induced in the LL flow. The induced ECN marking in the LL SF reduces the bandwidth demands in the LL flow and the remainder grants from the ASF token bucket will be available for the CL flow.

Queue Protection categorizes packets into the application data flows, termed Microflows. All packets of each Microflow are characterized by identical values in a set of header fields. QP algorithm must act on every Microflow that becomes a queuing source in the LL SF. If the LL SF buffers are getting filled at a critical threshold then that queuing source needs to be redirected in to the CL flow.

## 3. Experimental Setup

There are some delays associated with the Upstream and Downstream PHY layer of DOCSIS. These delays can be minimized depending on an MSOs network conditions because there are trade-offs between channel robustness vs latency. For the experiments in this paper, the following PHY and MAC layer settings were configured.

In the upstream, an OFDMA channel with symbols per frame (k) set to 16 with 50 kHz subcarriers. The Cyclic Prefix value = 0.9375 µs and the Rolloff Period = 0.3125 µs were set for the channel to reduce PHY latency. The channel width of the OFDMA channel was set to 42 MHz. With 1K QAM, this resulted in a channel capacity of 336.60 Mbps.

In the downstream, a 192 MHz wide OFDM channel was configured. Cyclic Prefix = 0.9375 µs and Rolloff Period = 0.625 µs. The time interleaver depth = 1 (Depth of the time interleaver in symbols of an OFDM channel). With 4K QAM, the resulting downstream channel capacity is approximately 2100 Mbps.

There are some delays associated with the MAC layer of DOCSIS. These delays can be minimized depending on an MSOs network conditions. Values of these parameters can be adjusted to further reduce DOCSIS MAC latency.

MAP-size of the channel can be adjusted between 1 to 13. MAP-size is configured as an average size in 800 microseconds ticks. A setting of map-size = 1 implies 800 µs. Lowering the MAP-size results in faster acquisition of a bandwidth slot. For these experiments, the MAP-size was set to 2 i.e. 1600 µs based on a MSO feedback. More MAP means messages mean more opportunities to transmit in the upstream. There is a tradeoff between choosing lower MAP-size with downstream bandwidth. Lower the MAP-size, more the downstream bandwidth consumed by Maps.

"max-round-trip-delay" is the RF RTT from a cable plant that can be configured in the CMTS. This delay should be adjusted based on expected distance between the Upstream burst receiver and the CM. In our experiments the value was set to 800 microseconds in propagation delay that equals to 100 miles in distance between the CMTS and CM.

Databackoff configuration can assist in spreading the effect of collisions in the broadcast request opportunities in a highly bursty and congested upstream. In this experimental setup we set it to a value in the range 5-8.

Figure 5 shows a high-level network diagram of a complex test rig to measure end-to-end DOCSIS Upstream latency. To emulate a typical MSO service tier, the CM's SLA was set to 100 Mbps in the DS and 20 Mbps in the US.

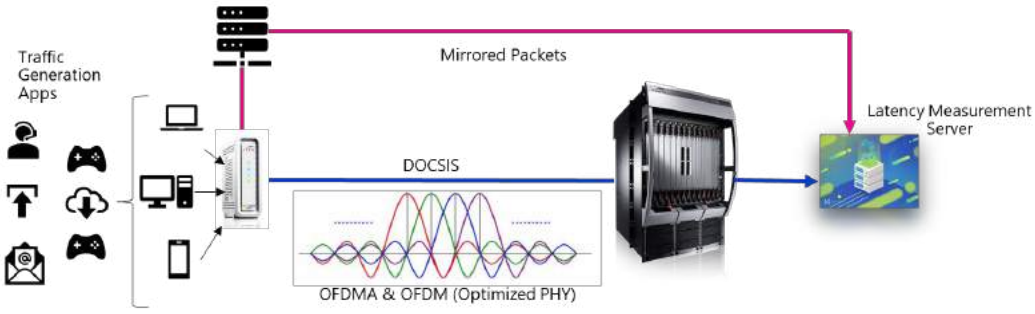

**Figure 5 Experimental Test Setup**

For all the experiments that were done using the PGS scheduling, the parameters were set as GGR = 2 Mbps, GGI = 1080 µs, GRI = 540 µs. The Weighted Round Robin scheduler is set to default weight of 9:1 ratio for the constituent service flows. The IAQM algorithm in LL SF is using default parameters of Ramp Function Exponent = 19 and the threshold = 1000 µs. The DOCSIS PIE AQM algorithm in CL SF is using a target latency = 25 ms based on MULPI spec recommendation to set AQM latency target between the range of 10 ms to 100 ms. The service flow buffer size is set to 50 ms based on previous experimentation and recommendations.

## 4. Experimental Analysis Of Latency In DOCSIS 3.1 System

Since the LLD architecture is defined in the realm of the DOCSIS 3.1 standard, we will first dive into an experimental analysis of latency in DOCSIS 3.1 system. CableLabs has used simulation studies to analyze the dual-queue architecture. While those studies were useful, real-world empirical studies using

real-world non-deterministic data traffic model, real-world CCAP with real-world Schedulers and Mappers will provide even more valuable information to MSOs as they try to deploy LLD in the field.

Before we start our deep dive in to the experiments, it is important to note that all the information is experimental since a lot of MULPI spec specific development is still under development on the CMTS and CM software.

## 4.1. Single Upstream Service Flow Experiments

The first set of experiments used a DOCSIS 3.1 modem with AQM enabled on a single Service Flow emulating a single home with multiple users. This a traditional Service Flow setup that ingests all types of traffic i.e. QB and NQB. The AQM in this scenario is set to a target latency of 25 ms and uses DOCSIS PIE algorithm. In this experiment, we monitored the gaming traffic latency. One gaming stream was always transmitted in the LL SF and another in CL SF, in the case of LLD ASF experiments in order to measure the impact of QB and NQB on the gaming traffic.

**Scenario 1**

This scenario acts as a baseline experiment. The traffic mix included 2 UDP gaming streams in the US and DS directions, and a simple web browsing session.

**Scenario 2**

In this scenario, the traffic mix included 2 UDP gaming streams in the US and DS directions, 2 web browsing sessions, 2 ABR video streams (DASH) sessions that emulate OTT content like Netflix or YouTube, and an Upload speed test.

**Scenario 3**

In this scenario, the traffic mix included 2 UDP gaming streams in the US and DS directions, 2 web browsing sessions, 2 ABR video streams (DASH) sessions that emulate OTT content, and a file upload session emulating picture or short video upload.

**Scenario 4**

In this scenario, the traffic mix included 2 UDP gaming streams in the US and DS directions, 2 web browsing sessions, 2 ABR video streams (DASH) sessions that emulate OTT content, and a file upload session emulating picture or short video upload on a social media platform, and two video conferencing sessions.

Table 1 provides a summary of number of streams of different traffic mixes for all of the four Scenarios.

**Table 1 Summary Of Number Of Traffic Pattern Streams Per Scenario**

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| Scenario 1 | **1x** | **1x** | **1x** | | | | |
| Scenario 2 | **1x** | **1x** | **2x** | **2x** | **1x** | | |
| Scenario 3 | **1x** | **1x** | **2x** | **2x** | | **1x** | |
| Scenario 4 | **1x** | **1x** | **2x** | **2x** | | **1x** | **2x** |

Table 2 covers all 4 scenarios that are mentioned above for single service flow setup.

The first scenario helped baseline the behavior of BE vs PGS for low-bit rate gaming traffic. The PGS enabled service flow showed a mean latency of ~1.5 ms and jitter of ~0.3 ms for the gaming traffic stream. Meanwhile, a BE enabled service flow showed a mean latency of ~5.5 ms and jitter of ~0.8 ms for the gaming traffic. This baseline behavior shows that use of PGS reduced latency by ~72%!

We can see that a single US SF with BE scheduling type has high latency (mean, 95$^{th}$ percentile, and 99$^{th}$ percentile) as the traffic mixes are increased in different scenarios. It is important to note that jitter* in all tests except Scenario 1 is pretty high. If there is anything that impacts a gamers QoE more than latency, it is jitter.

In all the experiments of this paper, Jitter is measured as the Mean Absolute Packet Delay Variation.

**Table 2 Single Service Flow Gaming Traffic Latency With Best Effort and Proactive Grant Scheduling**

| Scenario | Scheduling Type | Mean Latency (ms) | 95 Percentile Latency (ms) | 99 Percentile Latency (ms) | Jitter* (ms) | US Throughput (Mbps) | DS Throughput (Mbps) | PGS Efficiency (%) |
|---|---|---|---|---|---|---|---|---|
| **1 (Baseline)** | BE | 5.5 | 7.7 | 7.9 | 0.8 | 2 | 2 | N/A |
| **1 (Baseline)** | PGS | 1.5 | 1.7 | 2.7 | 0.3 | 2 | 2 | 44 |
| **2** | BE | 27 | 37 | 42 | 79 | 20 | 35 | N/A |
| **3** | BE | 27 | 43 | 50 | 142 | 20 | 35 | N/A |
| **4** | BE | 27 | 47 | 54 | 148 | 20 | 36 | N/A |

*Mean Absolute Packet Delay Variation

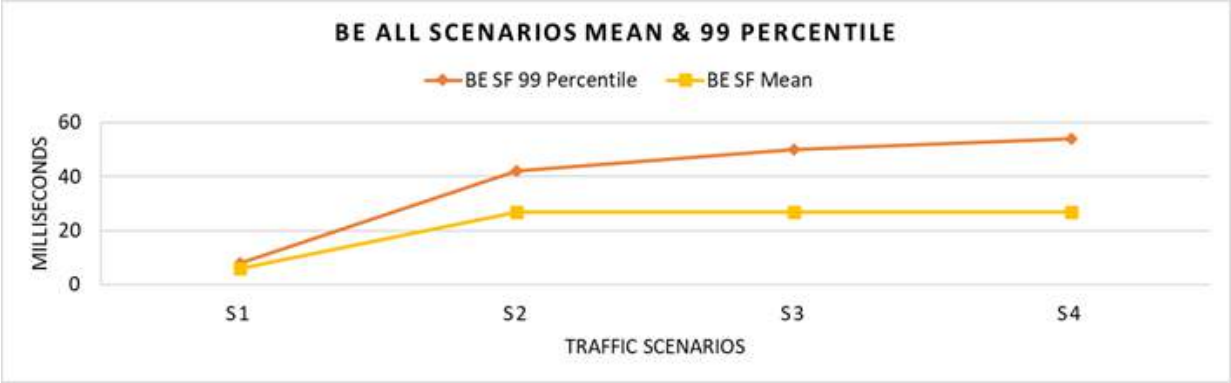

**Figure 6 Single SF BE Mean and 99 Percentile Of Gaming Traffic**

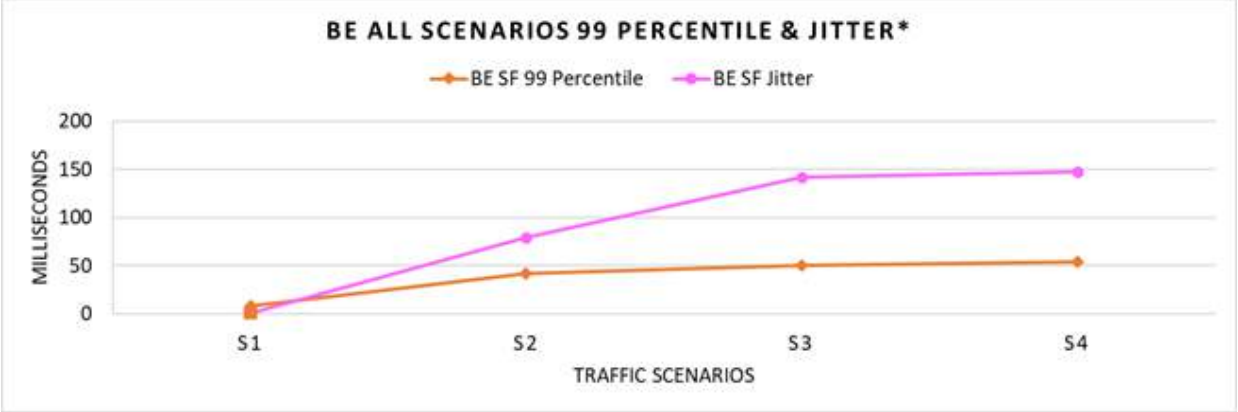

**Figure 7 Single SF BE 99 Percentile and Jitter Of Gaming Traffic**

### *4.1.1. Comparing Single Service Flow With LLD ASF Classic Service Flow*

So how does the Single Service Flow latencies compare to the LLD ASF Classic SF latencies? In a Single Service Flow, QB and NQB traffic fill the SF buffers together, while in a LLD ASF there is a separation of QB and NQB traffic. We want to compare the latency metrics of gaming traffic in a Single Service Flow versus the latency metrics of gaming traffic within the Classic Service Flow that carries the QB traffic. The expectation in this experiment is that the latency metrics of gaming stream in a Single Service Flow will be approximately equal to gaming stream latency metrics within the Classic Service Flow.

Based on the data in Table 2 and Figure 8, it can be observed that the gaming traffic mean latency in CL SF is under the Single SF Mean up to Scenario 3, but for Scenario 4 the values are at a close approximation. These data points confirm that the theoretical expectation is correct.

The 99 percentile level for CL and single SF is approximately the same. This should be a good indicator that the NQB traffic within QB traffic in LLD architecture is fairly treated like the current circumstances of using a single service flow. In other words, latency performance isn't a zero-sum game. By separating

 

QB and NQB traffic, the NQB traffic can achieve much better latency performance, without degrading the performance of the QB traffic.

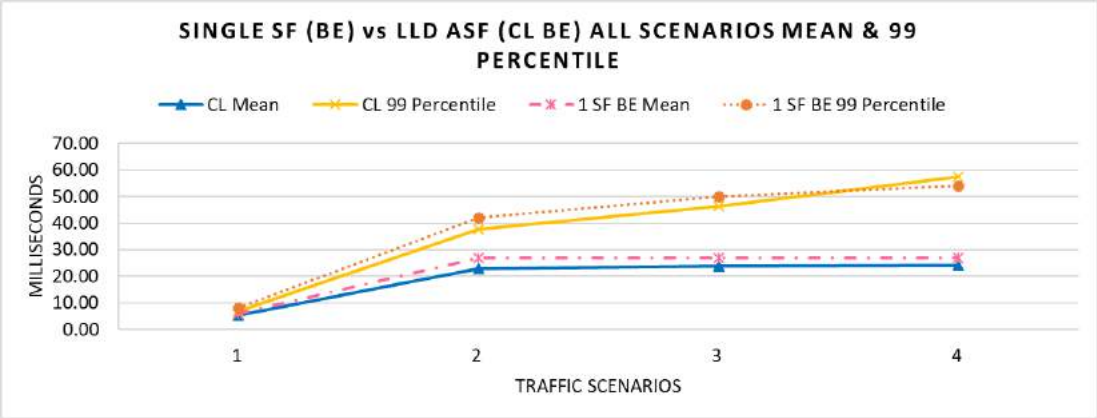

**Figure 8 Single SF vs LLD ASF CL SF Mean And 99 Percentile Of Gaming Traffic**

Figure 9 shows the 99 Percentile and Jitter data for the same comparison, and it can be observed that the CL Jitter is tracking to the single SF Jitter.

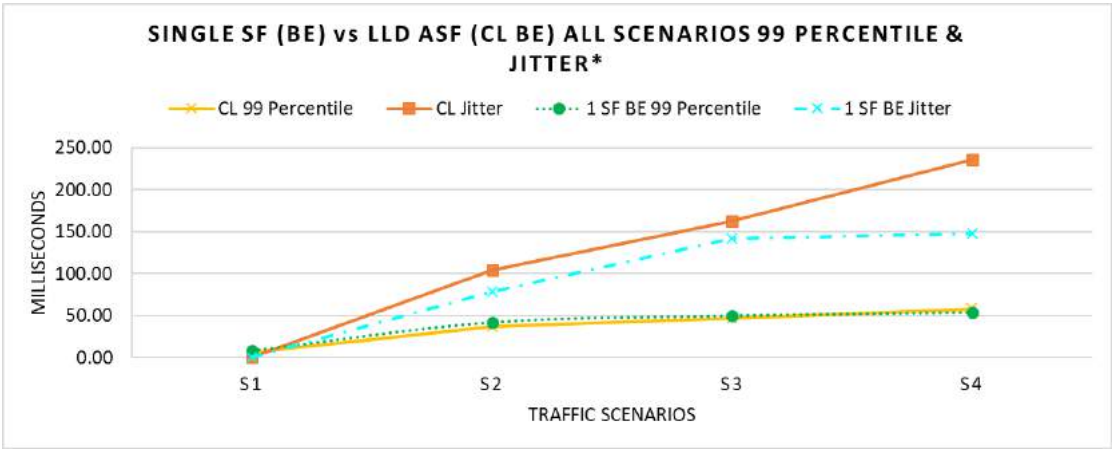

**Figure 9 Single SF vs LLD ASF CL SF 99 Percentile and Jitter Of Gaming Traffic**

## 4.2. LLD ASF With Best Effort Scheduling Experiments

This next set of experiments were focused on using LLD ASF, where a separation of Queue Building traffic and Non-Queue Building traffic was done by using relevant classifiers. By default, Queue Protection was enabled in these experiments and so was AQM as described in the experimental setup section.

The goal of this section is to highlight the importance of separating QB and NQB traffic. All the experiments were done with two configurations – 1. LL SF with BE scheduling and 2. LL SF with PGS scheduling. This is to contrast the behavior of two scheduling types.

### 4.2.1. Scenario 1

Table 3 shows the results of Scenario 1. The first scenario acts as our baseline for the separation of QB and NQB traffic since it includes only two gaming streams, one in each flow and the web session traffic in CL SF. It was observed that gaming latency is the same when the Best Effort scheduling is used in both the constituent SFs, CL and LL SF. Gaming traffic latency in LL SF is reduced by ~72% when PGS scheduling is used in the LL SF. The jitter also drops by ~70% when PGS is used in the LL SF.

**Table 3 LLD ASF Scenario 1 Results**

| ASF With BE In LL SF and CL SF | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| Scenario | Flow Type | Scheduling Type | Mean Latency (ms) | 95 Percentile Latency (ms) | 99 Percentile Latency (ms) | Jitter (ms) | US Throughput (Mbps) | DS Throughput (Mbps) | PGS Efficiency (%) |
| 1.00 | Low Latency | BE | 5.33 | 6.81 | 6.97 | 0.93 | 1.00 | 3.00 | N/A |
| 1.00 | Classic | BE | 5.35 | 6.77 | 6.97 | 0.93 | 1.00 | | N/A |
| ASF With PGS in LL SF and BE in CL SF | | | | | | | | | |
| 1.00 | Low Latency | PGS | 1.27 | 2.28 | 2.50 | 0.29 | 1.00 | 3.00 | 0.44 |
| 1.00 | Classic | BE | 5.24 | 6.68 | 6.89 | 0.86 | 1.00 | | N/A |

### 4.2.2. Scenario 2

In Scenario 2, the traffic is increased significantly. The impact of QB and NQB is much clearer for either of the tests – with BE in both SF vs. with PGS in LL & BE in CL SF. The gaming traffic in LL SF continues to experience low latency and jitter compared to QB and NQB traffic mix in the CL SF.

**Table 4 LLD ASF Scenario 2 Results**

| ASF With BE In LL SF and CL SF | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| Scenario | Flow Type | Scheduling Type | Mean Latency (ms) | 95 Percentile Latency (ms) | 99 Percentile Latency (ms) | Jitter (ms) | US Throughput (Mbps) | DS Throughput (Mbps) | PGS Efficiency (%) |
| 2.00 | Low Latency | BE | 5.54 | 7.13 | 7.37 | 0.88 | 1.00 | 35.00 | N/A |
| 2.00 | Classic | BE | 22.93 | 35.09 | 37.71 | 124.29 | 19.00 | | N/A |
| ASF With PGS in LL SF and BE in CL SF | | | | | | | | | |
| 2.00 | Low Latency | PGS | 1.19 | 1.62 | 1.79 | 0.10 | 1.00 | 35.00 | 44.00 |
| 2.00 | Classic | BE | 23.41 | 33.51 | 37.29 | 104.34 | 19.00 | | N/A |

### 4.2.3. Scenario 3

In Scenario 3, the traffic is more bursty because of frequent FTP file upload sessions. The Jitter experienced in CL SF is upwards of 150 ms which is detrimental to gamers QoE. The queues are filling faster and the 99 percentile traffic waits longer in the queues even though AQM is trying to maintain the average latency of 25 ms.The gaming traffic in LL SF continues to experience low latency and jitter compared to QB and NQB traffic mix in the CL SF.

**Table 5 LLD ASF Scenario 3 Results**

| ASF With BE In LL SF and CL SF | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| Scenario | Flow Type | Scheduling Type | Mean Latency (ms) | 95 Percentile Latency (ms) | 99 Percentile Latency (ms) | Jitter (ms) | US Throughput (Mbps) | DS Throughput (Mbps) | PGS Efficiency (%) |
| 3.00 | Low Latency | BE | 5.53 | 7.17 | 7.28 | 0.88 | 1.00 | 35.00 | N/A |
| 3.00 | Classic | BE | 23.73 | 40.74 | 46.21 | 143.82 | 19.00 | | N/A |
| ASF With PGS in LL SF and BE in CL SF | | | | | | | | | |
| 3.00 | Low Latency | PGS | 1.23 | 1.61 | 1.74 | 0.10 | 1.00 | 35.00 | 44.00 |
| 3.00 | Classic | BE | 23.49 | 42.38 | 47.46 | 162.47 | 19.00 | | N/A |

### *4.2.4. Scenario 4*

In Scenario 4, the traffic adds to burstiness by adding a couple of video conferencing sessions alongwith frequent FTP file upload sessions. Note that the video conferencing data is passing through the CL SF. The Jitter experienced in CL SF is upwards of 200 ms which is detrimental to gamers QoE and also the video conferencing QoE. The queues are filling to latencies of 50 ms and more. The 99 percentile traffic waits longer in the queues even though AQM is trying to maintain the average target latency of 25 ms. The gaming traffic in LL SF continues to experience low latency and jitter compared to QB and NQB traffic mix in the CL SF, which is the same as the results found in the previous three scenarios.

**Table 6 LLD ASF Scenario 4 Results**

| ASF With BE In LL SF and CL SF | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| Scenario | Flow Type | Scheduling Type | Mean Latency (ms) | 95 Percentile Latency (ms) | 99 Percentile Latency (ms) | Jitter (ms) | US Throughput (Mbps) | DS Throughput (Mbps) | PGS Efficiency (%) |
| 4.00 | Low Latency | BE | 5.58 | 7.02 | 7.31 | 0.88 | 1.00 | 39.00 | N/A |
| 4.00 | Classic | BE | 24.01 | 46.90 | 57.58 | 231.19 | 19.00 | | N/A |
| ASF With PGS in LL SF and BE in CL SF | | | | | | | | | |
| 4.00 | Low Latency | PGS | 1.16 | 1.66 | 1.76 | 0.10 | 1.00 | 41.00 | 0.44 |
| 4.00 | Classic | BE | 24.27 | 49.07 | 58.02 | 236.24 | 19.00 | | N/A |

### *4.2.5. Summary Of LLD ASF Experiments*

The following graphs summarize the data in the tables for the four LLD ASF experimental scenarios.

Figures 10 to 13 signify the importance of separating QB and NQB traffic. Scenario 1 acts as the baseline and incremental traffic types are added up to Scenario 4. In general, it can be observed that the 99 Percentile latency of the traffic and the Mean latency and Jitter of the traffic in CL SF is >> than LL SF.

An MSO can choose to use Best Effort as the scheduling type in the Low Latency Service Flow and the Classic Service Flow. The applications that require high throughputs and which are not sensitive to latency can be classified into the CL SF, and they will be treated in a fashion similar to today's latency standards. On the other hand, the applications that are sensitive to latency can be classified into the LL SF, and they will be rewarded with latencies that are much better than today's latency standards. Furthermore, the additional enablement of PGS scheduling within the Low Latency Service Flow will

reduce the latency metrics to millisecond values. But the PGS parameters must be carefully optimized so as to not overgrant or undergrant or a learning mechanism can be introduced to optimize the PGS grant efficiency.

# 5. Conclusions And Future Work

We proved that the concept of separating QB and NQB traffic assists in NQB traffic achieve lower latency than QB traffic, without degrading the performance of the QB traffic. We conducted experiments with the Proactive Grant Service Scheduling that send guaranted grants at guaranteed intervals in order to meet the demands of traffic in the LL SF. We observed ~1.5 ms latency and extremely low jitter of 0.10 milliseconds for PGS enabled Low Latency SF within an LLD ASF.

The experiments also showed that either of the scheduling types can be used for LLD ASF – Best Effort or Proactive Grant Service. But it is important to note that Proactive Grant Service can reduce the latency further by proactively granting and reducing the traditional REQ-GRANT time by ~72%!

The CMTS and CM software and the MULPI specification are maturing to achieve the LLD goals. At the time of conducting the study, there were many moving parts because of many different features of the LLD architecture – Queue Policing, Weighted Round Robin, AQM algorithms etc.

There is a need for standard tools to measure latency statistics such as mean, 95 Percentile, 99 Percentile latency and Jitter values. LLD provides a Histogram feature that will give a deeper look in to the service flow buffers and queue build-ups. At the time of writing this paper, we did not have the standard toolset.

In the future, we plan to learn more about tuning of Proactive Grant Service parameters for optimized use of available upstream channel capacity and service flow Maximum Sustained Rate.

Since traffic classification into QB and NQB plays an important role, a future challenge lies ahead for the adoption of traffic classification rules in the LL and CL service flow at the application layer.

This real-world experiment with the CMTS and the LLD capable CM and the bursty traffic generators shows that low bit-rate traffic patterns (i.e. gaming traffic) that behave as NQB can achieve low latency with LLD ASF without impacting QB traffic.

LLD Interops at CableLabs are underway to ensure that the CMTS and the CM equipment are ready for deploying the LLD feature set. Once the spec and software are fully developed and tested, the

introduction of LLD to the consumers will be exciting. LLD is one of the key enablers for the future of DOCSIS in the world of 10G.

## List of Figures

# 1. Introduction

For many service operators—service, value, and revenue begin and end with the broadband pipe which is the primary commercial connection between the service provider and the consumer. But as networks evolve and the needs of business customers continue to grow, one of the largest opportunities for increased monthly recurring revenue, churn reduction, and customer service takes off where the first network ends: beyond the pipe.

Service providers are delivering on the promise of the "first network", broadband, at very large scale, but aren't fully leveraging their opportunity to deliver the "second network" to their customers. This second network is beyond the pipe and typically consists of router / firewall, switching and Wi-Fi access points to facilitate the day to day operations of the business. In the business segment we estimate that broadband penetration is over 80%, but second network penetration is very low, estimated at less than 10%.

The second network opportunity is significant. As an example, in the SMB market, with less than four access points, there is a willingness to invest by the business. A typical entry broadband circuit for a business will be in the range of $100 per month. A managed networking offer that consists of a router, switch and APs significantly increases the target addressable market. Business owners are often willing to invest another $100-$200 per month in their internal network solution that offers security, wired and wireless connectivity that is proactively monitored and maintained. The monitoring and maintenance of the second network is now business critical to business owners. As bandwidths available to the business regularly exceed 100Mbps, business owners are relying more and more on secure network connectivity to cloud based customer management, accounting, payroll and Point of Sale services for their daily business needs. These cloud-based applications simplify the business owners' operational requirements and allow them to leverage cloud-based economics for their business applications, but connectivity is no longer a convenience, but a necessity.

Managed enterprise networks involve more than just installing Wi-Fi equipment and incidental hardware for customers. They are in fact fully managed services where the operator is responsible not only for providing and installing the equipment, but customizing it to match the customer's needs, managing it on their behalf, and providing value-added services on top of it. The typical Managed Networks digital experience that provides a sticky engagement with the customer both from a branding point of view as well as useful customer engagement around second network status and analytics specific to their business. With these deeper second network solutions, Service providers can significantly increase their value to their customers across all enterprise business types, large and small. Service providers do have an opportunity to further enhance their value beyond the "Second Network" once they have reached beyond the network edge. This opportunity is delving further into the business with additional value-added services such as video security and other managed IOT offerings that a typical business owner needs but doesn't have the IT resources to deploy and maintain.

The immediate benefits for operators as well as their business customers are obvious: Customers have access to professionals who manage the entire install, setup and operation of their entire network. Because they don't have to be their own network support organization; they can focus on their core business. A single provider that delivers both the first network and the second give the enterprise a single point of contact if they need assistance with the network or the service. For operators, this value-added relationship not only provides more sticky touch points with the customer, but it also represents the opportunity for revenue through equipment sales as well as recurring revenue through network management. As business networks evolve, so too can operators' role beyond the first network, also known as the pipe.

Value added services such as the second network are instrumental in maintaining service provider wallet share. Legacy services including broadband, voice and video are at high and consistent penetration levels across the service provider customer set, which leads to commoditization. Service providers are in a fantastic position to expand their portfolio and increase their customer value. Increased customer value is key to reducing churn and preserving service pricing.

This paper will provide an in-depth review of the market opportunity operational considerations for delivering effective managed enterprise networks. It will also feature a case study with a major US operator to illustrate the challenges and upside in moving past the demarcation point to owning the second network.

## 2. What is the second network?

The second network, depicted in Figure 1 below, is what business users connect their devices to in order to access the internet. This behind the broadband pipe enterprise network is typically composed of a router and firewall platform, Power over Ethernet switching and Wi-Fi access points with enough scale to provide adequate performance and connectivity through the business. This so called second network is viewed by many non-technical users as simply "Wi-Fi", but people in the know realize that behind every great Wi-Fi experience there's a fantastic wired backbone. The fact of the matter is every first network, the broadband pipe, is completely unusable without the second network and many times do-it-yourself solutions are under specified, poorly installed and many times not secure. The other fact we all know is the perception of the first network can be severely impacted by the stability and performance of what is deployed behind the pipe. These can be impacted by poor design practices, poor installation practices, inadequate equipment and/or cybersecurity breaches.

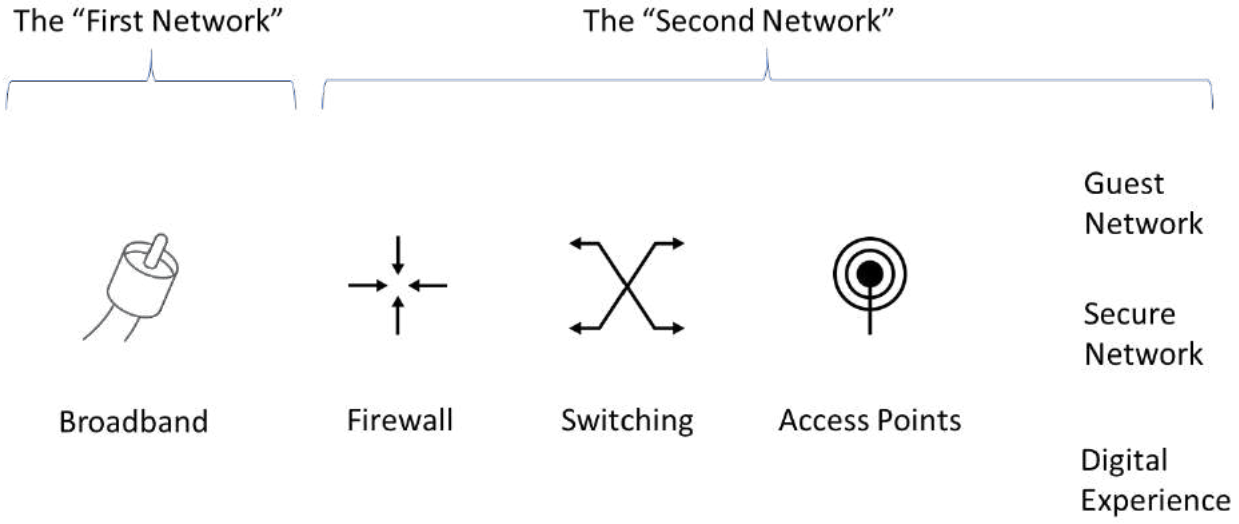

**Figure 1 – The First and Second Network**

## 3. How large is the second network opportunity?

The second network opportunity is very large especially when all applicable vertical markets are considered. The addressable vertical market with a second network offering spans across several different enterprise business types including SMB, hospitality, Multi-dwelling unit, mid-market and large enterprise. For the purpose of this paper we focus on the SMB market in the interest of brevity, but the second network TAM is significant across all verticals.

The target addressable market (TAM) of the small to medium business (SMB) segment alone is approximately $6B per year for broadband alone. Research group Gartner defines SMB "by the number of employees and annual revenue they have. The attribute used most often is number of employees; small businesses are usually defined as organizations with fewer than 100 employees. The second most popular attribute used to define the SMB market is annual revenue: small business is usually defined as organizations with less than $50 million in annual revenue."[1] According to the Small Business Administration there are 30.7 million small businesses in the United States alone employing millions of Americans. Of those small businesses there are approximately 5-6 million that employ people and likely need internet access at their place of business [2]. This segment broadband TAM is in the range of $500M per month assuming a conservative business circuit price of $100 per month and 5 million SMB locations that need internet access.

In this SMB segment, the broadband TAM is just scratching the surface of the total networking opportunity. This is because every business needs a highly reliable network on which to run their operation and are more than willing to purchase the solution from their broadband service provider. Our world's dependence on connectivity has reached utility level especially with the prevalence of cloud-based services for point of sale, customer relationship management and financial accounting. A rough estimate of the second network TAM is estimated to double the broadband TAM at a minimum, perhaps even 1.5 to 2 times the TAM. A rough dollar estimate is $500M to $1B per month depending on the product offer or as stated previously $6B annually. This estimate is limited to the united states due to market data availability, but the true opportunity is worldwide.

Keep in mind that SMB is just one vertical segment that can benefit from a second network offering. The service provider TAM outside of SMB can be expanded to Mid-market, Hospitality, Multi-Dwelling unit, etc.

## 4. What is required to operationationalize the second network?

Providing the second network has many operational considerations that must be addressed as part of a new product launch. Service providers have nationwide scalable expertise in the deployment of circuit related infrastructure, but because most are not broadly addressing the second network they need to thoughtfully prepare. Addressing the second network requires more advanced networking and wireless pre-sales, design, deployment and operational capabilities. The figure below depicts some of the key capabilities that are needed as service providers take their second network journey starting with product planning and moving into product launch and product operations.

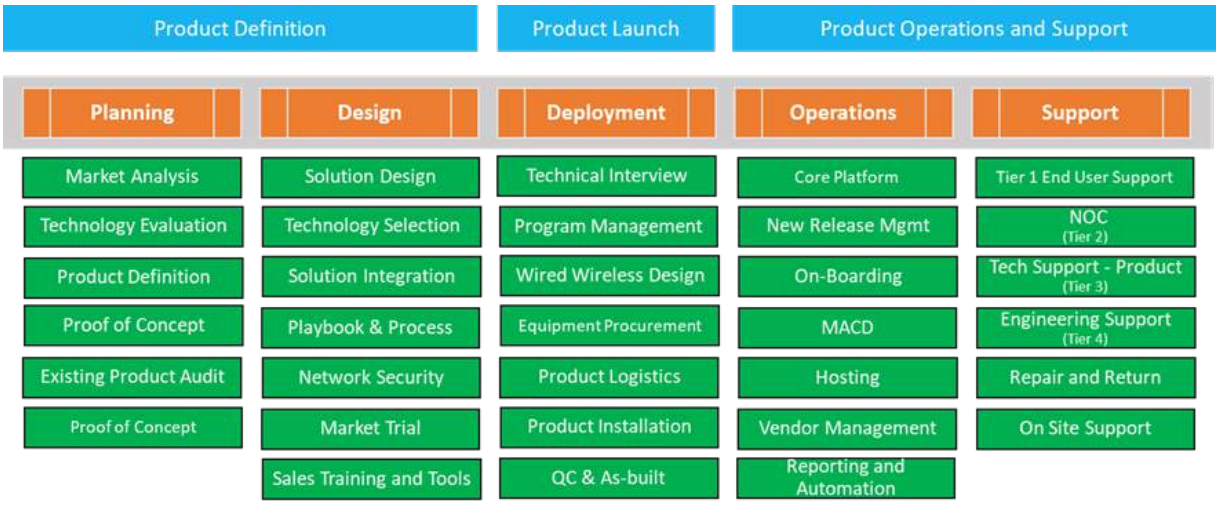

**Figure 2 – Operational Capabilities**

As service providers start to address the second network opportunity across verticals, the most careful consideration must be given to defining a very concise product definition tailored to the vertical market as necessary. Each vertical market has different nuances and desires. For example, SMB users want a very simple, reliable solution that is rapidly deployed by the service provider. Mid-Market, MDU or hospitality have more complex requirements and typically require a different product definition. Service Providers are best positioned to address the high-volume opportunities that can be served by a repeatable product definition. The well-defined product with a repeatable architecture and feature set will lead to a more scalable solution that is easier to deploy and support longer term. Managed enterprise services bring the service provider into a realm of a myriad of vendors and solutions that can quickly overwhelm engineering, deployment and operations teams if the service provider doesn't have a structured approach to addressing new Second Network opportunities. There will be a tendency to address every second network opportunity that presents itself, but there must be a method of controlling what non-standard or Individual Case Bases (ICB) projects are pursed. Service providers who establish an ICB control board can determine which of these opportunities will be scalable and repeatable in the future and make good business sense to productize.

Once a clear product definition is established the service provider's engineering organizations supported by the vendor community need to select and integrate a technology platform that will deliver the capabilities of the product definition. This development process can be iterative and time consuming depending on how many different equipment suppliers are involved, the level of pre-integration already performed and the complexity of the vertical market's requirements. There are two portions of a new product launch that are often overlooked are the OSS / BSS order to cash process and the back-office reporting and customer facing self-service dashboard platforms. The integration of these platforms typically involves service provider IT resources and need to be addressed early and often in the development cycle.

Typically, after, but preferably before, system integration efforts are complete and a market trial has been successfully executed, it's time to start training sales, sales engineering, day two support organizations, design and deployment organizations and preparing for life cycle management. Sales and sales engineering training and tools is where a significant investment needs to be made when launching a second network offering. The typical service provider sales teams are used to a very short sales life cycle

and positioning a broadband product that has a pretty clear value proposition and a very limited set of competitors. The second network is very different and requires some level of retooling including training and sales incentive plan adjustments. There are two typical second network products that sales teams will be asked to sell. One will be very standard and meant to serve end customer locations that are less than approximately 15,000 square feet. This product will be easy to position and will typically be sold via an inside sales channel based on the square footage of the business. The second network product to establishments that are over 15,000 square feet is where the sales and sales engineering teams need to be trained and incented to sell. The larger and more complex second network sites will require pre-sales quote tools and outside sales executive and engineering teams that can help interview customers to understand the requirements of their deployment from an existing infrastructure, features and scale point of view. This technical interview will determine if the property fits into the standard product definition, the scale of the deployment, the complexity of any required construction and the wireless coverage areas. From this technical interview the Sales executive and sales engineer have the information they need to create a quote for the prospective customer. A key to collecting this information is well defined survey tools for the account team to leverage as input to budgetary quote tools.

Assuming the outside sales team is effectively trained to perform a survey of the customer and the physical location, the next critical step in the operational journey is to manage and build the complex second network opportunity funnel. The smaller sights are straightforward to managed, but a key to developing and managing this funnel for more complex sites is a rough order of magnitude quoting tool. The rough order of magnitude quote tool removes sales quote friction by providing a simple self-service mechanism to generate complex second network proposals. Traditional manual quoting mechanisms in the complex second network space are too labor intensive and costly, but most importantly slow. If service providers are slow to turn around proposals to their prospective customers, it's very likely they will lose to local competitive options. With an online rough order of magnitude calculator, the account and sales engineering teams can quickly interview a customer and provide a proposal within minutes. Removing this sales friction will drive funnel growth and result in a viable business.

Now that the service provider has a second network product and a sales organization closing business, it's time to start designing and installing new properties. The simple second network that suffices for a less than 15,000 square foot location is sold and delivered on an inside sales and ticket basis. The installation technicians must be trained on equipment installation best practices, deal with sometimes complex ethernet cabling and the nuances of enterprise Wi-Fi access point deployment to maximize coverage and performance. Another key component of the simple second network deployment is trying to simplify scheduling of the deployment. Where possible service providers should build processes to facilitate a single truck roll to install broadband and the second network assuming a new customer acquisition. This will create a better customer experience and reduce expenses related to deploying the new customer. For larger second network deployments that have a varying number of network components such as routers, switches and Wi-Fi Access Points, a design and deployment program management team to assist sales and sales engineering with creation final bill of materials with the assistance of design engineering and ensuring resources are available for the installation are critical. The design and deployment team help shepherd a project from customer contract, through the wireless, physical and logical network design process, the deployment process all the way to ensuring final as builts are captured and customer acceptance is received.

As new properties are onboarded, engineering and operations teams that can support past the edge and into the premises with complex Wi-Fi and networking systems that have a variety use cases helps ensure the ongoing customer experience is a high quality one. Tier 1 end user support and network operations teams will need to be trained to now support issues that are past the first network. This is facilitated by as builts that are captured by the design and deployment PMO and field services teams during the

installation and quality check process. The as-builts provide network diagrams, network element location, photo evidence of a quality installation, performance results from day of install quality checks, customer acceptance and even a customer survey. This as-built information is an excellent source of information to help Tier 1 and NOC agents perform move, add, change, delete requests, as well as debug and support the second network through its lifecycle. The NOC teams are supporting service delivery and assurance tasks associated with the deployment of properties and have the capability to support end customers that can exist past the circuit. The most critical function of the NOC related to the second network is providing a proactive response to second network outages and anomalies. Traditionally service providers are providing a reactive approach to service assurance, i.e. waiting for the customer to call to report an outage, but a proactively monitored solution is a unique value proposition and a significant differentiator. The proactive monitoring offering is enabled by advanced reporting and analytics that reaches behind the first networking demarcation point and into the second network infrastructure. Advanced second network reporting and analytics at the Tier 1 and NOC level is also critical to implementing a continuous improvement plan around technology and operational execution. This depth of insight is a tremendous value to the second network customer versus the reactive response nature of a typical broadband offering. This enables a one number to call solution for service provider customers, which is a very compelling proposition.

Finally, a retooled cloud operations team is also needed to scale a second network product offering. This team is responsible for operating the back-office technology associated with the second network and advanced debugging of property level issues related to the second network. The Wi-Fi, switching and routing systems ideally have cloud-based systems that provide a second network element management systems, differentiated customer self-service platforms, device authentication, reporting, analytics and other technology associated with the second network. One of the most critical components of the cloud team is facilitating automation of property deployment and flow through provisioning. This is not only critical to scalability, but also repeatability of deployment that leads to lower day two support costs and higher customer satisfaction.

In summary, launching a second network product offering touches nearly every part of the service provider operational organization from sales, to engineering, to operations, to support. This effort is more than worth it given the opportunity to increase the target addressable market and become a more valuable partner beyond the pipe.

## 5. Altice Business Smart Wi-Fi Case Study

A smart small business is a connected business. Today, both employees and customers not only expect but require reliable connectivity while working, shopping or waiting. A secure private Wi-Fi network now a business-critical item, whether the office footprint is 100 square feet or 100,000 square feet. The service providers are responding to the demand. Small business owners and property managers are focused on obtaining practical, turnkey onsite Wi-Fi capability that just works. Beyond connecting employees securely to boost office productivity, guest Wi-Fi is a customer experience definer that can build positive relationships with visitors and vendors while reinforcing the business brand. In many cases though, it is and can be, the opposite whereby the Wi-Fi is more a detriment due to it being complex and/or underperforming. This will yield the opposite effect business owners are trying to achieve as they are aware the better the Wi-Fi the longer the customer stays, yielding higher revenues.

In addition to serving 4.9 million residences, Altice USA offers voice, data, video and security services to more than 400,000 small and regional commercial businesses, nationwide. Altice Business' managed Smart Wi-Fi solution is a seamless, carrier-managed wired/Wi-Fi network for locations requiring indoor

or outdoor wireless coverage along with wired connectivity, from workspaces to churches, from coffee shops to cultural centers, from medical offices to car dealerships.

Altice Business customers are freed from tedious network configuration tasks, but can offer Guest Wi-Fi to their customers, manage network names (SSIDs) and analyze statistics such as the number of guest Internet users and bandwidth consumed during specific hours of the day and days of the week. The Smart Wi-Fi product enables Altice Business to serve businesses with up to 250 guests and employees and deliver speeds of up to 1 gigabit per second (Gbps), with coverage spanning 24,000 square feet indoors and 12,000 square feet outdoors.

Altice Business Smart Wi-Fi combines both private and guest networks, each with separate access controls. Guest Wi-Fi includes a self-service customizable splash page providing branding and promotional opportunities for the business owner and Altice Business. Content filtering is also offered on the Guest network to enable a safe browsing environment. The business owner can also survey guests as part of the onboarding experience and report on the results of their surveys via the guest experience. For business employees and internal use, Private Wi-Fi includes encrypted private wireless networks for point of sale and other back office use cases in the business. Devices connected to the Private Wi-Fi network can also quickly and safely access wired systems like printers and servers while being protected from cyberattacks from outside the business. Altice Business is helping its customers by creating a high-performance offering that gives SMBs the simplicity and reliability they need to grow their bottom lines without struggling to put people online.

Altice Business has deployed Smart Wi-Fi to thousands of customers across 21 states, performing hundreds of installations per month on the behalf of their customers. This is only achievable due to the simple, effective solution and configuration outlined at the onset of the product development process in conjunction with the various stakeholders.

## 5.1. Benefits for Altice Business Customer

Business owner's with Altice Business services benefit by having a professional, reliable, and yet simple to use solution whether it be the deployment, integration or usage. It allows the business owner to focus on operating and growing their business and not have the headaches managing the technology as well.

Given the multiple touch point businesses have, it becomes a bit overwhelming at times to identify and connect with the various vendors/providers involved with running a business network. Altice Business has solved for that issue here by provide the necessary technology products and services through one single source.

By offering these services through a single source, it is an enhanced overall customer experience and the provider becomes the trusted advisor to the business.

Customers who now frequent the business recognize the ease and reliability of the Wi-Fi and as mentioned earlier, have a tendency to stay longer periods of time, and purchasing more products/services during that extended timeframe, yielding again a much more enhanced customer experience.

## 5.2. Benefits for Service Providers that Employ Managed Services

TSIA reports that the Managed Services industry, as evidenced here with Altice USA, is growing by leaps and bounds. Below is a graph outlining managed service growth as a percentage of total revue.

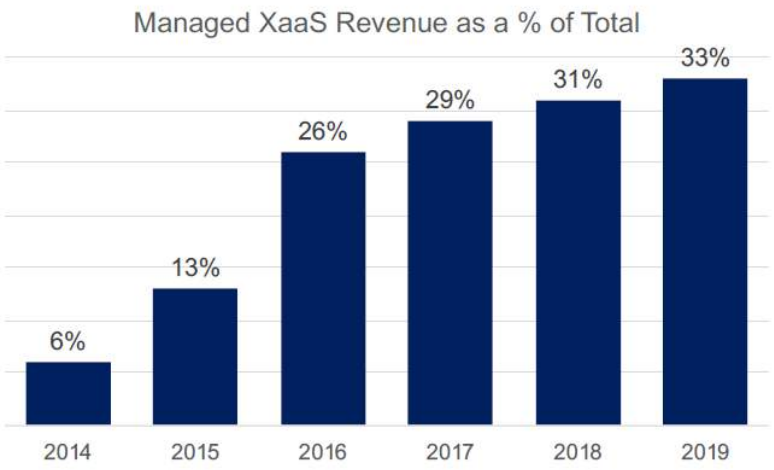

**Figure 3 – Managed Services Growth**

Manages Services with a customer focused outcome through partnerships have yielded a considerable increase in amount of revenue as a result, including ARPU, attach rates, and customer satisfaction. Additional favorable aspects exhibited are reduced churn, minimizing operational expense, increased rate of provisioning by utilizing flow through automation, and the ability to provide additional value add services such as content filtering, additional wireless security features, and reporting capabilities.

Customization for the business owners is a major aspect of the Altice Business' Smart Wi-Fi offering and one that allows the customer's brand to be front and center in the eyes of Altice USA enterprise clientele. This goes to the customer experience aspect of the journey and has assisted in raising Altice USA NPS scores.

While we tout the benefits of all this wonderful collaboration and technology, it doesn't come without some heavy lifting. Training, planning, coordination and systems integration are just a few of the hurdles that teams have overcome. Luckily, the state of technology through the use of APIs and other integration techniques, helps to overcome these challenges.

In the end, the system may be complex, the integration advanced to be able to provide the suite of products and services, but the business, their customers, and our sales teams all view this as a simple, easy to sell, easy to deploy, reliable solution that enables all involved to stay connected, stay informed, and stay focused on their own tasks at hand.

## 6. Conclusion

Small and Large businesses alike are demanding more from their service provider partners regarding networking solutions. Service providers that offer the second network as part of their portfolio have an opportunity to provide a valuable service to their customer, increase revenue and prevent damage to their brand out of their control caused by substandard networking solutions deployed behind the first network. Second network managed service solutions enable service providers to offer an end-to-end enhanced network experience to their business customers that is second to none. Furthermore, coupling a reliable

second network offering and very highspeed first network positions the service provider for additional value-added services further increasing their customer value and target addressable market.

Service provides that extend their reach beyond the pipe and into the second network with be rewarded with a loyal customer base that is willing to invest in the value they are receiving from their service provider partner.

# Table of Contents

## List of Figures

# 1. Introduction

This paper will provide insights and lessons-learned from Comcast's Next Generation Access Network (NGAN) team as we have increasingly deployed open source software (OSS) to virtualize the access network. Using GNU/Linux, Kubernetes, Prometheus, OpenFlow and many other open-source software distributions for automation (Ansible), test (Wireshark) , troubleshooting (smartmon), and Continuous Integration/ Continuous Development (Jenkins, Git), etc., we have achieved some fantastic results. This did not come without a great deal of heavy lifting, new process development, and flexibility. On occasion, it also required re-direction.

By sharing our experience, we hope that other Multiple System Operators (MSOs) will realize the same cost benefits and new feature speed to market we have seen. By providing details on our software selections, others should be able to achieve an even faster pace of innovation as the cable industry moves towards Network Function Virtualization and Software Defined Networking. Key insights we will share include the detailed network visibility gained by using real-time network monitoring tools like Grafana and Kibana, as well as, requirements to use white box switching equipment, commercial off-the-shelf servers and open source operating systems in the network. Last but not least, we will discuss the importance of actively contributing to the open source community while monitoring community developments and building your own internal expertise.

# 2. Brief History of Open Source Software at Comcast

With the launch of the X1 platform in 2012, Comcast quickly transformed from a multiple system operator dependent on suppliers for innovation to become a software and technology company. Since that time, we have significantly consumed and produced open source software (OSS). Notable Comcast contributions include developing the Reference Design Kit (RDK) platform, which now powers over 60 million consumer premises equipment worldwide. We have also made significant contributions to OpenStack, Apache Traffic Control, and the Apache Hypertext Transfer Protocol (HTTP) Server. OSS users within Comcast include our Video Internet Protocol and Research (VIPER) team who have been using Kubernetes, for cloud DVR and IP Video and have been sharing their insights at conferences including KubeCon and CloudNativeCon since 2016.

In 2016, recognizing the growing importance of OSS, Comcast launched an Open Source Practice Office (OSPO) (figure 1) to drive a more coordinated and planned strategy towards OSS. OSS is a key driver of differentiation, cost reduction and innovation for many leading companies and has become a business imperative for us, as well.

**Figure 1 - Comcast's Open Source Program Office**

Comcast's OSPO's goals include acceleration of software delivery and focus on core differentiation. Comcast's focus is to leverage open standards for innovation and time-to-market while reducing work on commodity non-differentiating software. We are also using OSS to improve cost efficiency and reduce operating expenses while improving software quality, reliability and security.

## 3. Open Source Software within NGAN

Comcast's Next Generation Access Networks (NGAN) team uses open source software (OSS) throughout its Distributed Access architecture (DAA). From Ansible to Wireshark, we are leveraging the innovation and speed-to-market for new feature development that comes from participating in community development.

Four key categories of OSS for NGAN include telemetry, containerized applications, automation and operating systems.

Telemetry tools include Grafana, Kibana, Fluentd and Thanos. Containerization tools include Kubernetes to manage Docker containers which house our virtual Cable Modem Termination (vCMTS) application. For automating runbooks, we have deployed Ansible with zero issues. Finally, our first generation DAA utilizes Ubuntu Linux on our servers and the Open Networking Foundation's Open Network Operating System (ONOS) to manage the control and data plane of our Spine/Leaf switching network.

## 4. Telemetry

Our team realized from the start of the DAA program that the traditional ways of collecting operational statistics regarding the health of our network would not fit the needs of our new architecture. A distributed architecture such as ours was going to be very difficult to troubleshoot and Standard Network Monitoring Protocol's (SNMP's) pull model wouldn't scale for our needs. We wanted to continuously push data to assess the health of the network.

We also wanted to avoid using Command Line Interface (CLI) because they can only be used to check one parameter at a time. With CLI, you need to be very precise with your instructions to get the information needed and there are no graphical views of the information. There were also performance concerns about having too many people logging into critical infrastructure, as well as, security concerns with the likely sharing of passwords.

Using OSS platforms like Prometheus, Grafana, Kibana, and Fluentd for data collection, we were able to provide our operations teams and field personnel with a single pane of glass that provides a view of what is happening across the entire network. Our monitoring probe is recording data every 15 seconds to capture key events and is used to create alarms in Slack to notify support personnel regarding potential issues. Alarms on key parameters are typically triggered after waiting a pre-programmed 5 minutes. As we learn about new types of issues, we continually create alarms to proactively address issues before they become outages.

Any telemetry data being collected can easily be shown in a new Grafana dashboard (figure 2) created as required. Grafana's on-line tutorials make it simple for anyone in NGAN (without programming knowledge or Grafana expertise) to create their own dashboard view.

Internally, we have since settled on seven key dashboards to make sense of the DAA environment and they are typically monitored by hundreds of simultaneous users from divisional business leaders to field technicians. Visibility into network performance and understanding of key network parameters has increased dramatically with these tools.

**Figure 2 - Grafana dashboard used for network monitoring**

The increased visibility into network performance has been eye opening. We're now aware of every minor glitch in the network. If a technician opens an optical node in the field, we see it. If power goes out in a particular geography, we are aware ahead of any announcement on the power company's website. One particular use case is that of a supervisor viewing Grafana dashboards in the field to ensure that Remote PHY (RPHY) node cuts are going, as planned.

This architecture was not without its issues. There were gaps in telemetry due to bugs and latency. The initial design (see figure 3) had too many components including stream processors. Stream processors were introduced because the virtual cable modem termination system (vCMTS) was not originally sending data in a Prometheus required format.

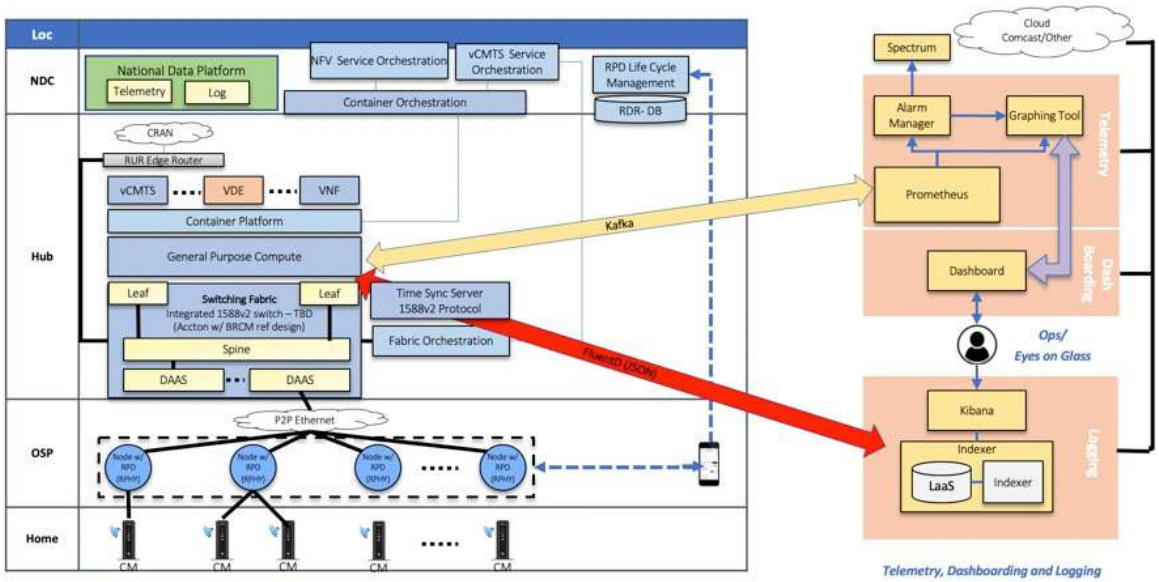

**Figure 3 - Original Telemetry Architecture in Comcast DAA**

Most of our users are looking at Grafana for telemetry. This simultaneous usage does not slow the vCMTS system as telemetry data is coming from stream processors in AWS but the number of users can affect the load of Prometheus which in turn may affect the response time to Grafana. This is something we are addressing in our next generation telemetry solution.

There are storage costs associated with all these metrics and that has to be considered when architecting the solution. We continue to optimize costs for Amazon Web Services (AWS) including limiting metrics storage to 15 days.

Changes were made to improve scalability as we continually add more R-PHY nodes to the network (figure 4).

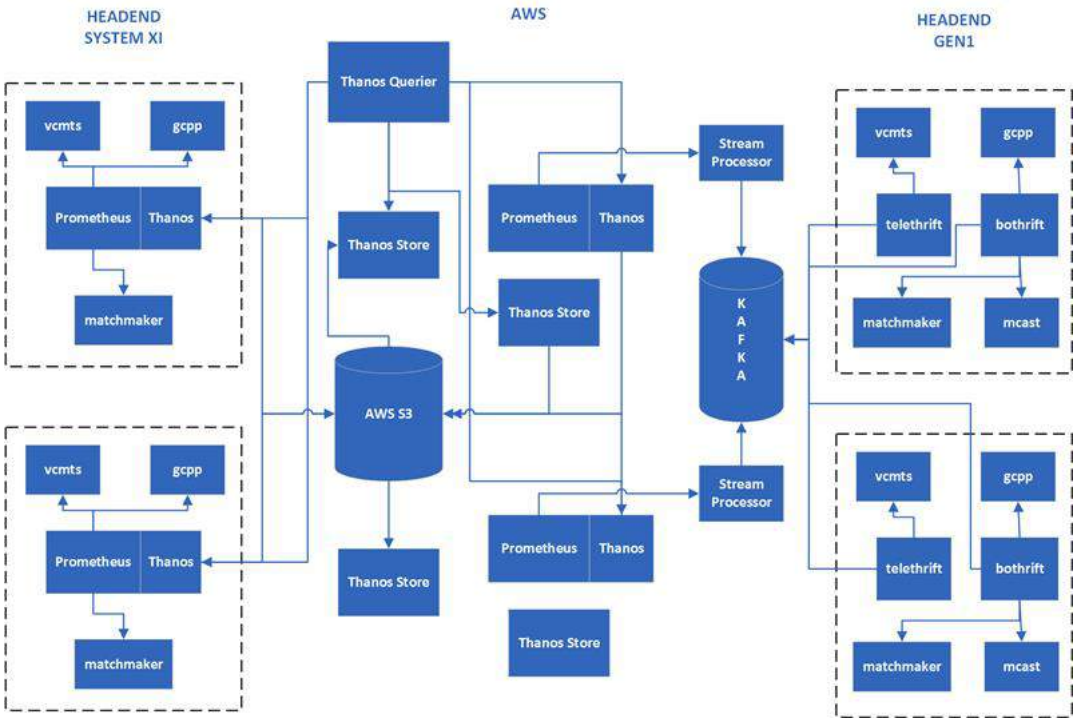

**Figure 4 - New Telemetry Architecture**

## 5. Containerization

Our containers run in Docker using Kubernetes nodes. We initially saw high CPU loads and high input/ output queue latency which often resulted in server cartridges hosting vCMTS worker nodes going into read-only mode. This resulted in having to cordon the read-only host, adding additional hardware (figure 5) to increase standby capacity and then fixing the read-only host during a maintenance window. Working closely with our server provider, HPE, we decreased latency of some Input/ Output requests that measured 25 milliseconds to around 0.8 milliseconds by changing Input/ Output timers in Kubernetes, changing queue sizes, and enabling multi-queue devices in Ubuntu Linux.

We also resolved Etcd issues that affected performance. Etcd is often referred to as the brains of the Kubernetes cluster. It is a distributed, reliable key-value store for the most critical data of a distributed system.

Lessons learned include regularly updating the Linux kernels and hardware drivers to take advantage of issues previously solved by the open source community. There has to be a balance between uptime and system maintenance. Also, it is important that your hardware provider understands how you are using their server (Kubernetes, Docker, Ubuntu, etc.) to optimize performance and assist you with choosing the best CPU and SSD for your application and alerting you regarding issues seen by other customers.

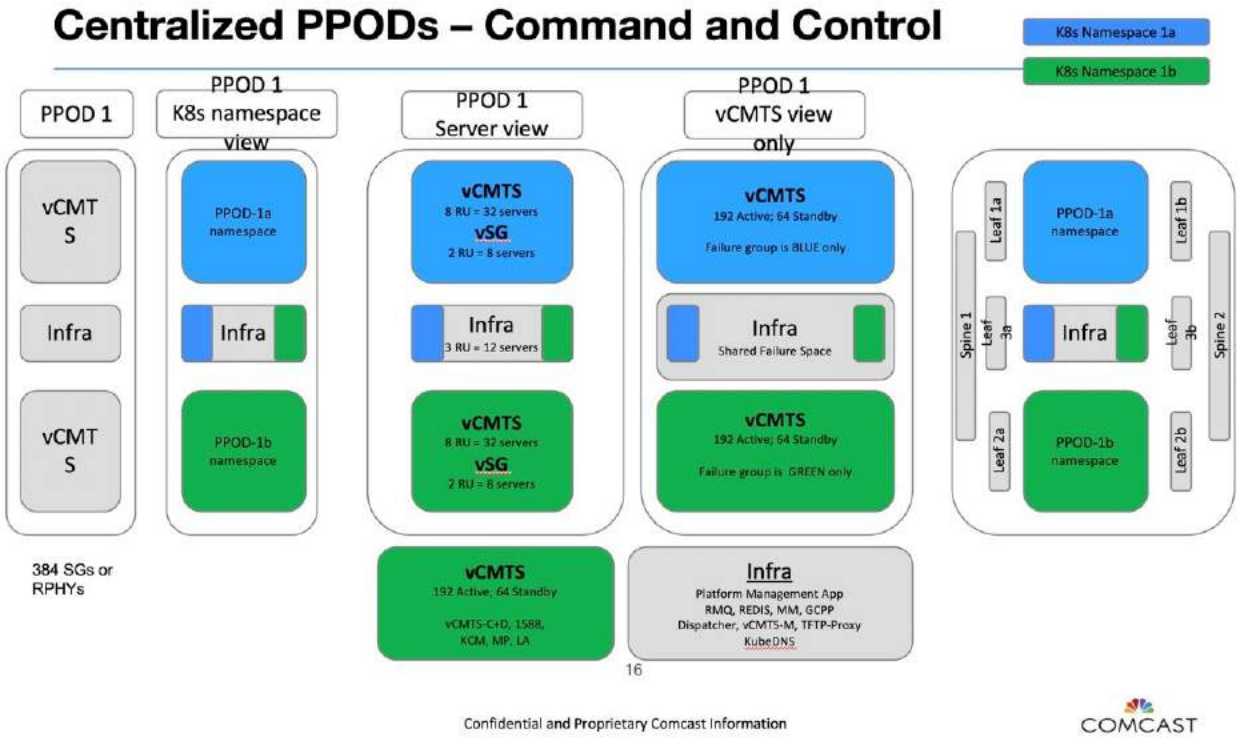

**Figure 5 - PPOD showing Active and Standby nodes**

## 6. Automation

We have had nothing but a great experience using Ansible for automation playbooks. Prior to Ansible, our team used hand-crafted scripts which were subject to human error. Other groups within Comcast use Jenkins and Puppet with equal performance.

## 7. Network Operating System

NGAN began using the Open Networking Foundation's (ONF's) Open Network Operating System (ONOS) in production during the first phase of DAA launched in May 2018. With this first generation, we realized significant cost savings in hardware while eliminating software licensing and software assurance costs. Using commercial off-the-shelf servers and white-box switches and working closely with ONF, we achieved limited scale (figure 6) by resolving a number of technical issues.

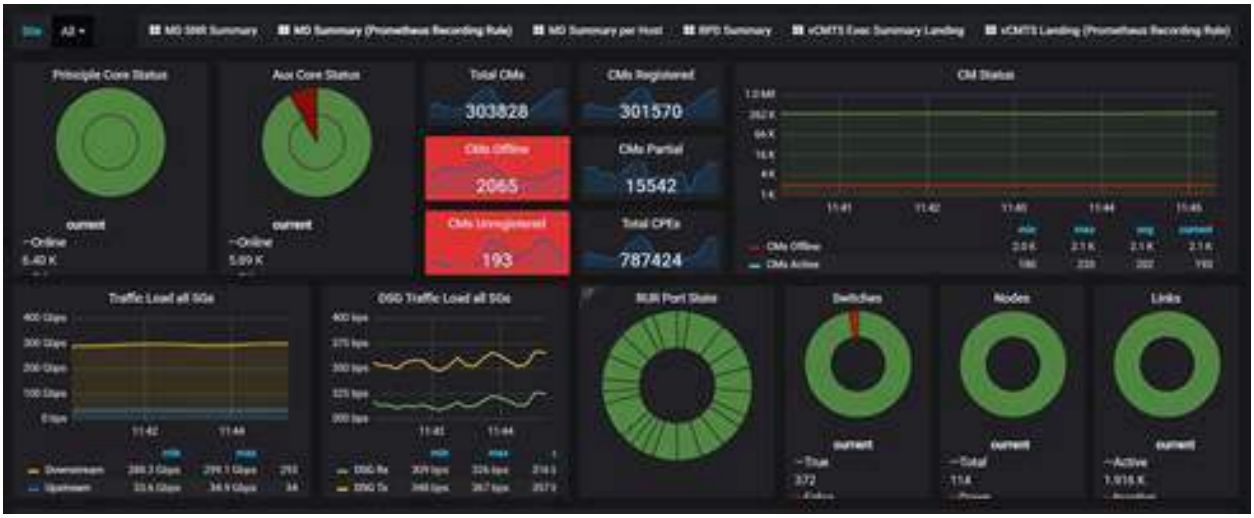

**Figure 6 - Grafana Dashboard showing ONOS at scale**

Progress included improving reliability during mastership changes, improving multicast handling performance, improving Atomix memory mapping and eliminating silent switch disconnects due to Open Flow socket closures. We achieved up to 40,000 cable modem scale in production by refactoring the route service.

While we had come a long way in terms of stability and performance improvements, ONOS clustering issues still persisted making it unlikely we could achieve our 99.999% uptime goal at 80,000 cable modems scale in time to support our deployment schedules.

Troubleshooting and redundant switch recovery at scale needed additional improvement. To operate at scale, additional features like headless operating mode, a more robust in-band management, handling internal queues , monitoring internal stores, and debugging issues at store level were also needed.

Despite the progress made and the significant investment in gaining ONOS expertise within NGAN, we made the difficult business decision in 2020 to move to a new, generation 2 architecture abandoning the open source network controller in favor of commercial network operating system (NOS)-based switches and a hybrid SDN Controller.

I believe we would have achieved our scaling and reliability goals, but we ran out of time to continue to optimize. We learned a lot in the process and contributed greatly to ONOS community with a number of key innovations. As a result of the progress that Comcast and its partners made commercializing ONOS, it is being evaluated by a number of wireless carriers in the 5G space.

## 8. Conclusion

Comcast was able to utilize OSS to build the access network with vCMTS and R-PHY. We continue to optimize the solution evaluating new hardware and software to improve reliability and scalability at reduced cost per subscriber. Telemetry, containerization and network controller changes were made to improve performance. A switch to a traditional Network operating system was made to immediately reach

scalability and up-time goals. We continue to evaluate new software (including OSS controllers) and hardware technologies to reliably improve cost per bit.

# 1. Introduction

For as long as the Multiple System Operator (MSO) community has built and operated networks, we have been looking for better ways to segment it, and to optimize the work needed to update and maintain it. In addition, serious efforts emerged over the last several years to add other access media to the mix, such as passive optical networks (PONs) and wireless technologies. Among these efforts is network function virtualization (NFV) and software defined networking (SDN), which have captured the attention of the MSOs and of the networking world at large. How does the MSO community take advantage of these concepts to fulfill both today's needs as well as the desire for an easier, quicker deployment of access network technology going forward into the future? In this paper, we will explore:

- Challenges faced by MSOs in deploying new types of access technologies alongside the current (virtual/"v") CMTS
- A method for abstracting service activation to allow for common control of dissimilar access technologies
- A flexible virtual broadband network gateway (vBNG) structure that matches MSO service formats to operate non-DOCSIS access technologies (e.g. PON)
- Advantages of this NFV and SDN approach compared to a traditional hardware BNG

# 2. The challenges of today's access network

The traditional cable operator's access network is centered around the DOCSIS technology that we all know and love. The business support systems (BSS) and the operations support systems (OSS) that are employed are equally centered around supporting the protocols defined by the DOCSIS protocols. CableLabs and we, as a community, have done an excellent job of extending those systems to support our business needs, as our customers and the Internet as a whole evolved from basic data services into voice, IP video, and commercial services.

The focus on a single technology with a single provisioning and operating model led to development of Cable Modem Termination Systems (CMTS) and Optical Line Terminators (OLT) that are fully integrated, as shown in the blue and orange boxes in Figure 1. These systems are typically developed by a single vendor to support all of the service, routing, reporting, and physical functions. The Distributed Access Architecture (DAA) separated the physical generation of the signal, but otherwise remained as integrated as the original CMTS systems. Likewise, the virtual CMTS (vCMTS) has given us a peek into the future by allowing the CMTS functions to live in a server environment, with all of the technology used to accomplish that, but still retains the unified structure seen in prior iterations of the CMTS.

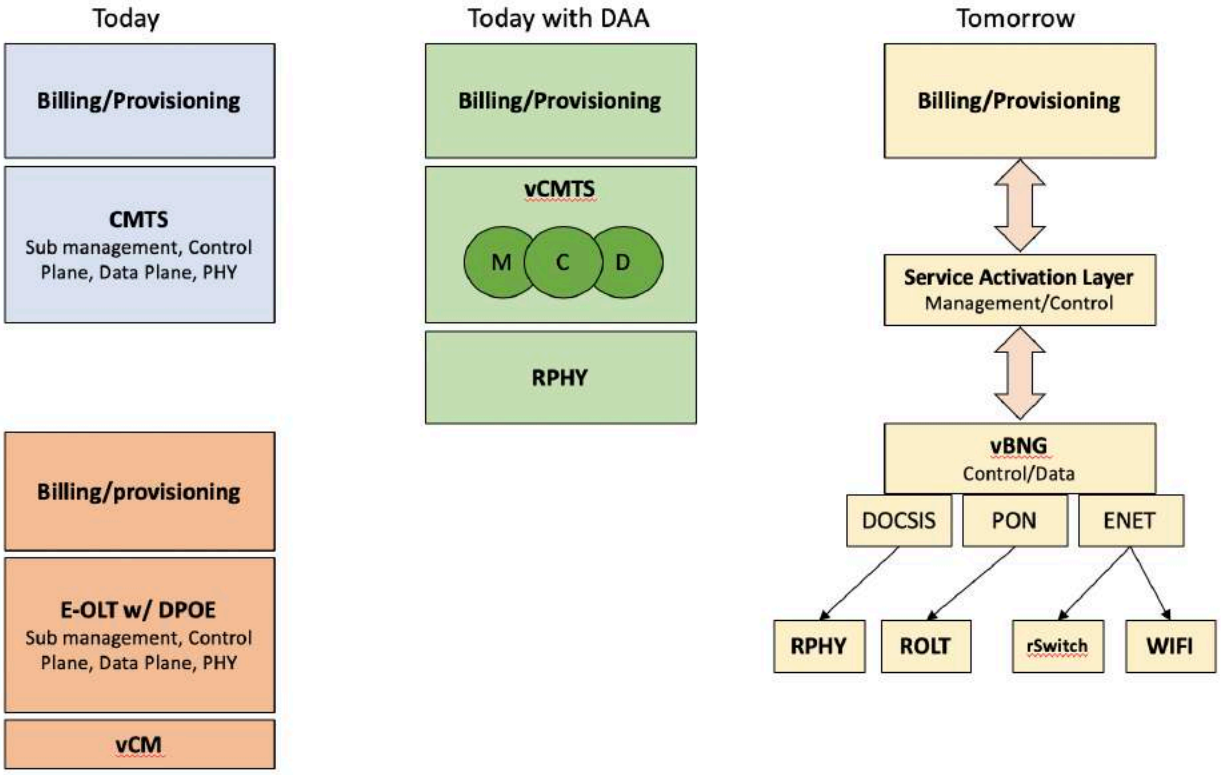

**Figure 1 – Evolution of the Access Network**

The challenge with this integrated structure begins to clearly show itself once we consider providing our services through other access technologies. The expansion into other access technologies is happening for a number of reasons including demand for multi dwelling unit solutions, changes in physical construction costs, and the desire to compete in the Wi-Fi and wireless arenas. Although more distinctly seen now, these issues have been lurking in the shadows all along. The DOCSIS service, provisioning, and operational models do not mesh well when combined with the wireless, fiber, and ethernet technologies that allow us to expand our network in non-traditional directions. On the other side of the coin, the BSS and OSS systems that have grown up in reaction to the DOCSIS architecture force us to attempt to have other access technologies mimic that architecture to avoid major back office changes. The following paragraphs provide a brief synopsis of five admittedly intertwined priorities that are difficult to achieve with the current structure.

- *Swift integration of new access technologies*. Beyond the need to develop a technology for our physical network, new technologies typically also come with a full system design and integration. All of these system components require time to develop, and often duplicate the same functions from other systems. Most introductions of new vendors cause us to start this cycle again, representing a high barrier to entry and ultimately fewer options for technology partners.
- *Consistent services provisioning*. It is cumbersome to develop and maintain separate BSS systems, in whole or in part, for every technology that we deploy. The problem is a compounding one. It is a massive effort to deploy new authentication and service definition systems, and once they exist, they are difficult to maintain while assuring that service definitions remain aligned

with the existing DOCSIS systems. The way around this problem is to create a translation system, such as the virtual cable modem introduced by DOCSIS Provisioning of EPON (DPoE). This, too, needs to be maintained and updated with the latest changes, and can easily fall behind. Workaround remedies add time to any process and represent custom work for the MSO community.

- *Service consistency*. DOCSIS provides a robust set of service features, which are implemented in its service flows with extensive classifiers, subscriber management filters, and frame accounting with Simple Network Management Protocol (SNMP) and IP detail records (IPDR). Other access technologies have similarly robust features that are simply different from what we typically use. Aligning these methods can cause hardware and feature control issues that limit our choices. The worst-case scenario is the network could look and act differently for one customer than it does for another.
- *Testing velocity.* Swift testing is an inherent challenge with any additional development. What exacerbates it is the unnecessary replication of the same function within multiple systems. Rather than testing the unique functions, much time is spent retesting different implementations of the same function.
- *Operational model differences*. With different systems come different interpretations of specifications and different interface models. This is aggravated by specifications created by organizations with very different goals, that apply to other access technologies. They also create additional work, to translate from one system to another.

## 3. A method of network abstraction

There is no simple or fast solution to the challenges stated in the previous section. A new system organizational abstraction is needed to make significant progress in resolving these issues. The existing system needs to be broken into distinct components that can evolve in isolation from each other. In kind, these components need to be linked by extensible application programming interfaces (APIs) that can be modified to meet the needs of the future. With this isolation and extensibility, we remove the need to replicate functions that are common to all of the access technologies and give ourselves the flexibility to integrate any technology quickly. Figure 2 below represents the proposed network abstraction.

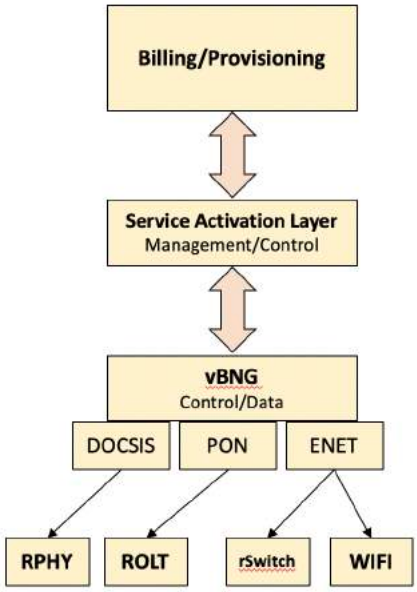

**Figure 2 – Functional components of this network abstraction**

This architecture focuses on three major areas of providing services through a scaled access system:

The billing and provisioning systems manage the customer entitlements and interactions with us as cable operators. It is necessary to break away from the tight DOCSIS integration that our back-office systems are built on. Much of the goal of this architecture is to enable that transition. The change itself is a massive amount of work that is not directly addressed within this paper.

The service activation layer receives the entitlements from the BSS and creates the detailed service description for a particular customer device.

The vBNG implements the service description provided by the service activation layer and manages the moment by moment experience of the customer. This layer can be broken down further, which we will explore in the following sections. We can add a fourth area to this list of three areas to include the operations and data gathering systems. This has been explored by prior papers in detail, for example, in the SCTE paper "The Future of Operations: Building a Data-Driven Strategy" [1] and will not be explored here.

## 3.1. Service Activation Layer

The service activation layer exists to create a means of defining the customer's access network services that is abstracted away from both the BSS system and the access technologies that those services ride on. There are several aspects to this component that are necessary to be able to provide this function as illustrated in Figure 3.

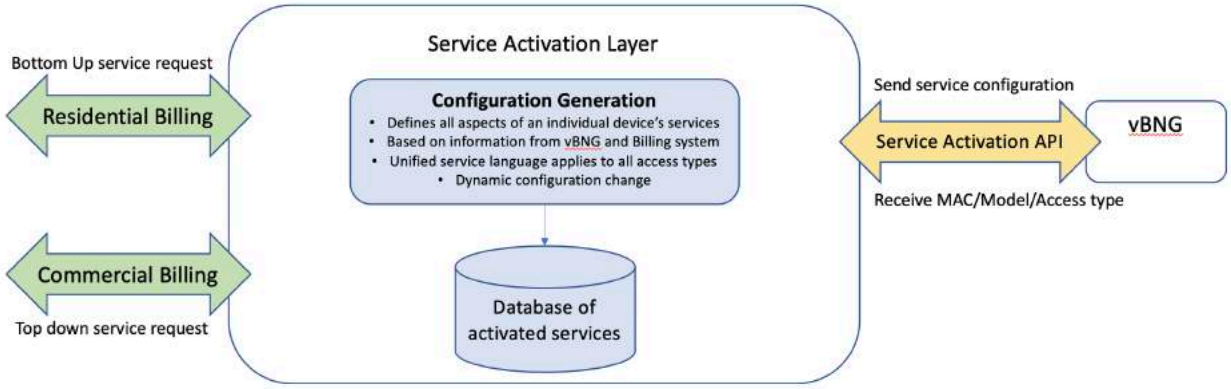

**Figure 3 – Interfaces and functions of the Service Activation Layer**

- *Service Entitlement flexibility*. Many access networks, such as DOCSIS, use a bottom up provisioning methodology where the end device requests service. However, there are examples of top down access networks, such as commercial ethernet and residential ethernet, where the end device does not include this capability. It is important to have an API that allows for both methods of entitlement and configuration.
- *Unified Access Service Descriptors*. These descriptors are imagined to be in the form of a YANG data model to communicate the services to the vBNG deterministically. They would be formed via a configuration generator that takes the access device type and model along with the customer's entitlements into account. With a common vBNG data plane and a desire to have consistent services, it is imagined that the YANG model for the customer's services would be largely common between access types. The Virtual Provisioning Interfaces Technical Report [2] produced by CableLabs has defined a YANG model that may be a good fit for this language.
- *Access/Customer Premise specific configuration modifiers*. While the majority of the service definitions will be common, there will certainly be access-specific configurations that would be of interest. For example, a PON system may want to be able to configure optical parameters that do not apply to other access technologies. Access-specific extensions of the universal YANG model would cover this case.
- *Database of activated services*. With millions of devices in our networks, it is often difficult to have a definitive knowledge of the exact service configuration the customer device is operating upon when a problem is discovered. The service activation layer should record the exact configuration given for each device to aid in troubleshooting and to add traceability.
- *Push/Pull of configuration*. In the same vein as supporting both bottom up and top down provisioning, this is the mechanism for providing the YANG model configuration to the vBNG. This also enables the ability to change customer device configuration dynamically.

Introducing the service activation layer gives us several capabilities and advantages that help us overcome the problems defined earlier in this paper.

- It abstracts billing and provisioning away from the configuration of the network.
- It presents a consistent service provisioning mechanism for all access networks and all services running through them.
- It brings consistency to service definitions across all access technologies, making their implementation also consistent, within the vBNG
- It eases the application of dynamic services to existing devices and allows for modification of existing services.

## 3.2. The virtual Broadband Network Gateway structure

Many of the issues discussed here can be resolved with a proper vBNG implementation. There are a number of options, in terms of how the vBNG can be laid out, and which components are included. Let us start with a description of the basic components in this method.

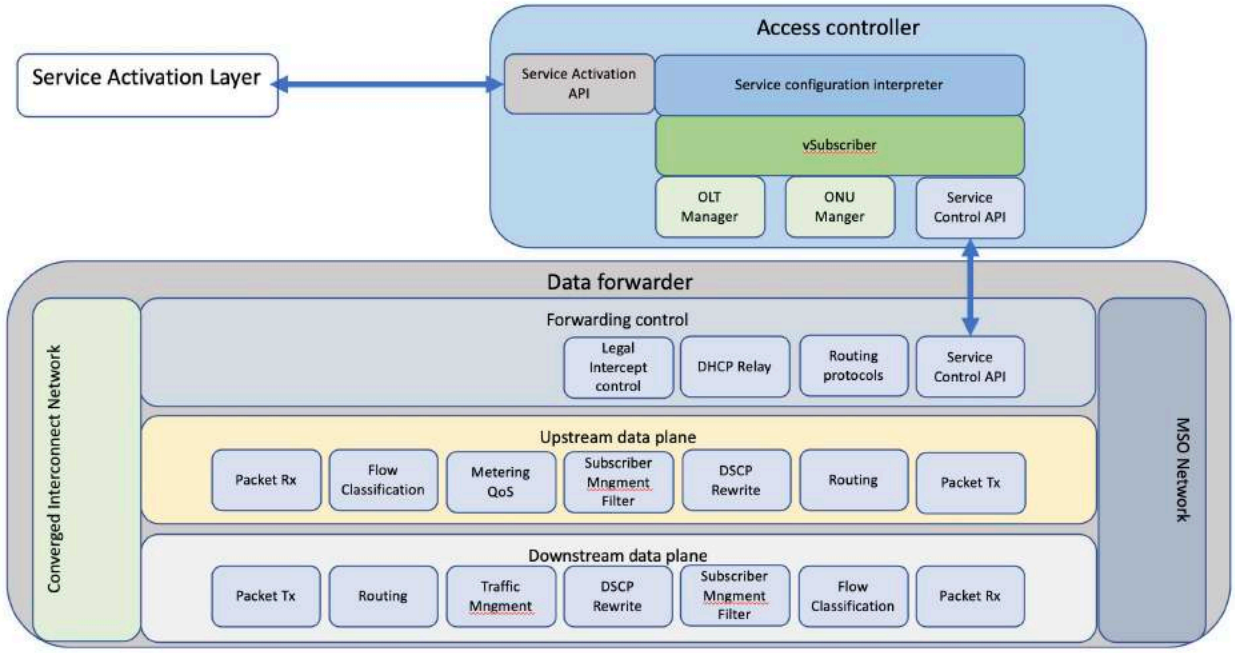

**Figure 4 – vBNG structure (OLT example)**

*Access controller*. This sets up the access network itself and the services that flow through it. To accomplish this task there are several steps that are necessary. A service configuration interpreter translates the YANG model produced by the service activation layer into access-specific configurations used by the vSubscriber data construct. The access manager, displayed as an "OLT" or "ONU Manager" in the diagram, is responsible for configuring all remote access components. A service control API then sends the necessary configuration information to the data forwarder, which is where components common to all access networks are configured.

*Data forwarder.* This provides frame processing and basic subscriber services. Certain functions can be enabled or disabled, such as a traffic manager, for access networks that do not have a built-in means of doing so. On a per customer basis, features like subscriber management filtering and DSCP rewrite can be enabled or disabled based on the services defined via the service activation layer. To aid in effective use of network and processor resources, the data forwarder can be implemented as a single unit or can be separated out for greater flexibility. The first logical separation is the network control, which includes the functions necessary to connect to the MSO network as well as typical services such as DHCP relay, routing protocols, and legal intercept controls. The upstream data plane is the next separation and provides data forwarding services from the customer into the network. Upstream traffic typically has a lower volume expectation. Finally, the downstream data plane provides data forwarding services from the network to the customer. In this case, all access networks would utilize the traffic manager function to shape traffic going downstream. Downstream traffic typically has a higher volume expectation.

These components give us several advantages, no matter how they are laid out in a virtualized system.

- The data forwarder includes common code for all access networks. This is a major facilitator of service consistency, as all customers are served by the same implementation for many of functions provided. From a development perspective this allows us to develop once but use the code many times. Adding new routing protocols, for example, only requires the single implementation to be tested. There is also no need to test the common code extensively when a new access network is developed.
- The Service control API is well defined between the access controller and the data forwarder. This allows for easy and unambiguous integration with new access controllers.
- New development for a new access technology is primarily limited to the access specific functionality such as the access controller, the remote access element, and interoperability with in-home equipment.

# 4. Advantages of an NFV and SDN approach compared to a traditional BNG

The traditional BNG is the staple of many telecommunication companies' network and has proven to be a solid solution for their access needs. So, why not use the same thing? The answer lies in flexibility. Just as with traditional CMTS deployments, a network operator must choose and size the BNG appropriately for both their current and future needs. Inevitably, when the network capacity or business needs surpass that BNG's capabilities, the operator must upgrade or add more BNGs -- or worse, do both.

Flexibility and reuse are where NFV and SDN shine. This is exemplified by allowing the system to expand functionality naturally into new access networks, while also allowing each of the components to continue to evolve -- to remain the best they can be, without requiring that the entire system be recreated. In terms of capacity, the system relies on generic processing hardware to do its job.

The first advantage with this approach is the ability to directly add capacity by adding more compute power, without touching the rest of the system. Secondly, when using generic hardware, the system can be laid out in different ways to fit the most effective technology, in terms of cost and efficiency.

There are several ways in which these components can be laid out in a virtualized system to optimize the available technology.

The first decision for optimization is whether one instance of the vBNG will handle one service group or many service groups. A single service group vBNG gives you the greatest control and isolation at the expense of more wasted processing cycles, while a multiple service group vBNG gives you more efficient processor utilization at the expense of more complex control and isolation.

The other area of opportunity is whether and how to separate the components of the vBNG to more efficiently assign processing resources. Separating the access controller from the data forwarder is attractive as the access controller and the data forwarder have very different functional and service assurance metrics. This separation would allow for a considerable amount of processor utilization optimization. Perhaps this would give us the ability to have the access controller live higher up in the cloud. Another way to optimize the component separation is to divide the upstream and downstream data planes. This would allow us to take advantage of inherent differences in upstream and downstream utilization. The upstream data plane has significantly less usage, even with symmetric access technologies, and can be multiplexed more effectively, while the downstream data plane has significantly more usage and needs more network and processor resources to be assigned.

Details of these approaches are a subject of considerable discussion in and of themselves. Intel has published an architectural study that dives deep into the factors of these decisions [3] that may be interesting to the reader of this paper.

## 5. Conclusion

The protocols defined in the DOCSIS specifications have led us down a path that has centered our back office and access networks around those protocols. This has been very good to us, but it is time to integrate other access technologies into our portfolios. The NFV and SDN evolution gives us an opportunity to refactor the way that we build and run our networks to support both the network of today and the multi-technology network of tomorrow.

In light of this goal, this paper has described an access network abstraction which defines a clear demarcation of system functions between the BSS and OSS, service activation, and network access. This architecture should allow us to:

- Deploy new technology quickly.
- Provision access networks in a unified way.
- Have consistent services.
- Minimize testing.
- Enjoy one operational model.
- Evolve each component of our network without interfering with the others.

We must not only produce a network that solves the problems that we can foresee, but one that allows us to continue to adapt well into the future.

# The Future of Cable Television Audio is Accessible

A Technical Paper prepared for SCTE•ISBE by

**Mark Francisco**
Fellow
Comcast Cable
1800 Arch Street Philadelphia, PA 19103
(215)286-8959
Mark_francisco@comcast.com

# Table of Contents

## List of Figures

## List of Tables

# 1. Introduction

Television sound hasn't changed much since its first appeared in the U.S. in 1941. In the 1940s, television audio was broadcast as a frequency modulated (FM) subcarrier to the video program. A stereo subcarrier was added in the 1970s. A secondary audio channel was introduced in the 1980s, primarily for dominant non-native languages such as Spanish. Digital audio introduced surround sound over cable and satellite services in the late 1990s, and over-the-air transmission with the conversion to Advanced Television Systems Committee (ATSC) broadcasting in the 2000 aughts. Twenty years later, despite the explosion of Internet Protocol (IP) and Internet delivery, television audio has made little progress, with the exception of the broadcast of Descriptive Audio or Video Description (formally named as Audio Descriptions) and the expansion of two dimensional audio to three dimensions with object-based audio, the latter of which is only available using IP-delivery and Blu-Ray. The future of broadcast television has been standardized internationally. with the recent release of ATSC 3.0. Its advances include video and audio formats by moving to IP encapsulation, adding high-dynamic range and UltraHD (4K) video, and advancing audio to a novel audio ecosystem, AC-4 [1], supporting greater efficiency, fidelity and personalization compared to current audio delivery.

Since the advent of "talkies," in the late 1800s, audio has always been an appreciated accompaniment to video. There is a long-standing truism that "sound is more than half the picture". Despite its ability to convey a story comprehensively (as in radio), however, television sound is seldom delivered on its own.

For 12 million people in the US [2], sound conveys the entire television experience. Sight impairment and blindness affects a large and growing segment of the population. Congenital conditions, disease, injuries and age fuel the reliance on audio over visual inputs, and these causes are predicted to grow over time. Conversely, the same is true of those who rely partly or completely on vision over hearing. The need for information, communications and entertainment in video- or sound-only format is increasing.

The desire to advance single sensory experiences is not just a regulatory or moral imperative -- it is good business. Inclusive products yield business opportunities for disabled and abled people alike. Disability is not necessarily a permanent condition -- it is defined by the World Health Organization [3] as a mismatch between the individual's ability at the moment and the environment with which they are in. Therefore, we may all experience disabilities (and need for accommodation) at some point in our lives.

While much has been accomplished in the pursuit of equivalent experiences for people of all abilities, many opportunities exist. Cable television is a sexagenarian industry with incredible establishment, reach and constraints preventing evolution. This fact can only serve to increase resolve, as disruptive change is possible and can offer large advances in value, equitability and experience.

# 2. What we must do – Regulations for MVPDs and Broadcasters

The Twenty-First Century Communications and Video Accessibility Act of 2010 [4] resulted in the creation of a set of Federal Communications Commission (FCC) regulations. Enacted in 2011, these regulations require commercial television stations that are affiliated with one of the top four commercial television broadcast networks (ABC, CBS, Fox, and NBC) and are located in the top 60 television markets to provide 50 hours of video-described programming per calendar quarter during prime time or on children's programming, as well as an additional 37.5 hours of video-described programming per calendar quarter at any time between 6 a.m. and midnight. In addition, multichannel video programming distributor (MVPD) systems that serve 50,000 or more subscribers must provide 50 hours of video description per calendar quarter during prime time or on children's programming, as well as an additional 37.5 hours of video description per calendar quarter at any time between 6 a.m. and midnight, for each of

the top five national nonbroadcast networks that they carry on those systems. The top five nonbroadcast networks currently subject to the video description requirements are USA Network, HGTV, TBS, Discovery, and History. The FCC published a Notice of Proposed Rulemaking (NPRM) on April 22, 2020 proposing an expansion from the top 60 markets by 10 annually for four years beginning in 2021. [5]

The NPRM also recommends changing the term for video-described content to "audio description" from the current convention of "video description". Additionally, the apparatus must provide a simple and easy-to-use mechanism for activating the secondary audio stream for audible emergency information.

Manufacturers must provide access to video description through a mechanism that is reasonably comparable to a button, key, or icon.

Digital apparatus must be designed so that control of appropriate built-in functions included in the digital apparatus (i.e., user interfaces) are accessible to and usable by individuals who are blind or visually impaired, if achievable. Specific requirements exist with respect to on-screen text menus and other built-in digital apparatus functions.

Manufacturers of digital apparatus must ensure that information and documentation it provides to its customers is accessible, if possible (e.g., user guides, bills, etc.). Digital apparatus manufacturers also must comply with requirements relating to the manner in which they notify consumers that digital apparatus with the required accessibility features are available.

# 3. Conventions in Cable Television Audio

Cable television is accessible. As a primary and often lifeline service to its customers, cable, satellite and fiber providers of multi-channel television services are responsive to regulation, social need and the business opportunity that serving the entire market can bring. Being accessible can often result in unanticipated benefits in what is not traditionally considered disability usage. An example is the use of closed captioning in health clubs and bar/restaurants to benefit patrons who are unable to hear due to the high ambient noise level. Cable television companies are subject to regulation by the FCC, state regulators and franchisers and must adhere to content carriage contracts. The result is high availability of accessible content and services. Many do not stop at the minimum bar of regulation, and add additional features that benefit people with disabilities beyond the law. Examples include the Comcast Accessible Remote and the Altice One Voice Remote, among others. The benefits are significant to the populations served, be they with disabilities or without, and to brand identity.

## 3.1. Retransmission

Either by convention or contract, broadcast over-the-air networks and cable channels are typically retransmitted in their as-received state, that is MPEG-2 Transport Stream with MPEG-2 video compression and AC-3 audio compression. Approximately 2/3 of cable television stations are received in 1080i (1920 x 1080 interlaced, 30 fps) video, 5.1 channel primary audio with AC-3 compression, monaural secondary (SAP) audio with AC-3 compression and CTA-608 closed captions wrapped in CTA-708 transport. The majority of the remaining 1/3 of stations are 720p (1280x720 progressive, 60 fps) video, 5.1 channel primary audio with AC-3 compression, monaural secondary audio program (SAP) with AC-3 compression and CTA-608 closed captions wrapped in CTA-708 transport. A small number of stations are received as standard definition 480i (640 x 480 interlaced, 30 fps) video, 2.0 channel primary audio with AC-3 compression, monaural secondary (SAP) audio with AC-3 compression and CTA-608 closed captions wrapped in CTA-708 transport. This is almost identical to the ATSC over-the-air

broadcast format, with the exception of the vestigial sideband (VSB) modulation required for radio transmission. Increasingly, MVPDs are converting the received video compression to a more efficient H.264 while retaining the audio bitstreams unchanged. Typical as-delivered cable channels require 8-12 Mbps for MPEG-2 video (less for standard definition), 3-6 Mbps for H.264 video and 384-512 kbps for two audio services.

Due to constraints in receivers and the inability for broadcasters to dynamically change descriptors, the primary and secondary audio streams, when both are present, have differing but no more than two language codes. This results in the typical practices of signaling the primary language as English (ISO_639_Language code ENG) and secondary audio program language of Spanish (SPA), Portuguese (POR), French (FRA) or Middle English (ENM). The secondary language codes are often not representative of the audio program's actual language, potentially resulting in viewer confusion. Furthermore, broadcasters that deliver audio descriptions (AD) can change the service provided on the secondary audio program between a secondary language such as Spanish and a complete mix of English program with English Audio Descriptions but retain a consistent but incorrect SAP language code of Spanish.

## 3.2. Conventions in Streaming Media Provider Audio

Streaming media providers are content creator, aggregator, and hosting entities that rely on user-supplied internet network connections. They deliver content using Hypertext Transfer Protocols (HTTP) protocols such as HTTP Live Streaming (HLS) or MPEG-DASH (dynamic adaptive streaming over HTTP). These relatively modern packaging methods are more flexible in terms of variety of content presentations, and this can include multiple audio and video formats. These providers deliver almost exclusively video on demand, rather than broadcast formats, so they use file-based rather than live workflows. This agility and lack of linear complexity results in a much greater offering of audio selections on a per-asset basis. A recent survey of popular streaming media providers discovered thousands of assets containing audio descriptions as an audio option. Many are delivered as a complete mix in surround sound format, rather than monaural. The most advanced offerings are found on Apple TV+ which includes several languages of audio descriptions in object-based audio format (Dolby ATMOS). Table 1 lists the number of titles available with audio descriptions from popular streaming media providers. [6]

**Table 1 – Streaming Offerings with Audio Descriptions**

| Provider | Count (with AD) |
|---|---|
| Apple TV+ | 32 |
| iTunes | 1341 |
| Disney+ | 589 |
| Hulu | 91 |
| Netflix | 1271 |
| Amazon Prime | 1831 |

## 3.3. Conventions in Cable Television Broadcast Programming

A check of a single day's (August 5, 2020) programming listed 109 shows with audio descriptions. (Table 2)

**Table 2 - Broadcast Offerings with Audio Descriptions**

| Broadcast Network | with AD |
|---|---|
| ABC | 28 |
| CBS | 13 |
| Discovery | 25 |
| Fox | 25 |
| HGTV | 35 |
| History | 28 |
| NBC | 18 |
| Oxygen | 4* |
| SyFy | 2* |
| TBS | 19 |
| Telemundo | 7* |
| CW | 5* |
| TNT | 12* |
| USA | 20 |

* denotes networks without AD mandates

These numbers are substantial, and they are generally increasing. The challenge remains in finding specific programming with AD, and then selecting the proper audio service when desired, and deselecting it when not. Most households with visually impaired residents are shared with household members who lack vision challenges, and these individuals may not want audio descriptions present while viewing programming.

Broadcast television programming audio services are ambiguous for a number of reasons. Due to constraints discussed in section 3.1, cable channels are limited to two audio services and the two must be identified with differing languages. Audio descriptions are conventionally placed in the SAP, often displacing a second language such as Spanish. Broadcasters do not dynamically change language codes, which are part of the MPEG-2 transport stream that is created by the broadcast contribution encoder. Therefore, if a broadcaster occasionally transmits Spanish as SAP and occasionally transmits AD as SAP, the broadcast language (ISO_639_Language) is always set to the SPA denoting Spanish. In the U.S. a workaround is often used that signals AD as Portuguese (ISO 639 language code POR), and in Canada, Middle English (ENM) and Middle French (FRM) is used. If a cable service-provided user interface allows a user to select from the languages signaled by the network broadcaster, audio descriptions are almost always incorrectly identified. The network also supplies metadata to populate program guides, and these often have correct information about audio services, but only for time of broadcast. Shows are increasingly viewed in a time-shifted fashion through digital video recording, start-over and on demand methods, and these may differ in provided audio services. Programs that are broadcast with audio descriptions as SAP are not available with SAP when viewed on demand. MVPDs have increasingly been improving their user experiences, using logic to assist with selecting audio descriptions. Oftentimes, program metadata is considered first, followed by selecting SAP when the program data is not affirmative as the existence of AD.

The ambiguities mentioned above do not apply to streaming media providers. There, the content hosting and user experience is tightly bound, and content is accurately and affirmatively identified in the file-based metadata and presentation information.

# 4. Where Do We Go From Here

Technology is quick to change, standards are very slow to evolve, and consumer behaviors range the entirety of the space between. The technologies to improve the user experience around accessibility of content are with us already, and some of them have been defined in standards for some time. Let's look at what can be done now and what we can anticipate in the near future.

## 4.1. The United Nations Already Solved This Problem

The International Standards Organization (ISO) of the United Nations includes the Moving Picture Experts Group (MPEG). The system standard for MPEG, including the basis for ATSC and Digital cable transport streams (ISO13818-1), was released in the late 1990s [7]. Version 2, released in late 2000, contains a second field to the ISO 639 [8] language descriptor entitled **audio_type**. The values for audio type are located in Table 3.

**Table 3 – MPEG-2 Transport Stream Audio Type Values**

| Value | Description |
|---|---|
| 0x00 | Undefined |
| 0x01 | Clean effects |
| 0x02 | Hearing impaired |
| 0x03 | Visual impaired commentary |
| 0x04-0xFF | Reserved |

Inserting the code 0x03 in the MPEG-2 headers will result in unambiguous signaling of the AD content. While conceptually simple, this method is challenging for broadcast workflows, as encoders do not dynamically change headers. Content selection is also challenging, as the value is embedded in the audio stream, requiring decoding of the asset to examine. Nonetheless, this method is of interest and being pursued.

Fast forward to modern Internet streaming, which is also standardized by MPEG through MPEG-DASH, which includes a similar audio type descriptor entitled role. Other streaming standards exist, such as the Internet Engineering Task Force (IETF) standardized HLS format, a segmented transport stream format that mirrors the descriptors identified in the MPEG system specification ISO13818-1.

## 4.2. Accessibility is About More Than Just Content Signaling

Disambiguation of accessible content audio will be a great benefit to viewers with interest and disinterest in audio descriptions. Nothing is more impactful to the interested parties than more quantity and quality of content. The tallies of content shown in Table 1and Table 2 include children's shows, movies, and episodic series. However, live content, including news, sports and events, such as awards shows and concerts, is absent. This is partially due to the lack of regulation around live or the explicit exemption of live programs and programmers, and the technical challenges of creating descriptions in a live workflow. Describing live events is possible using a commentator calling a live baseball game. Several events have been live described, including parts of the 2018 Winter Olympics in PyeongChang, and the GlobalCitizen One World Together at Home Concert in April of 2020. These events were challenging only due to their non-standard inclusion of audio descriptions. Several professional agencies, including the Media Access Group at WGBH, have demonstrated proficiency in live descriptions. An important aspect of the creation is appropriately "ducking" the program audio during narration. A depiction of ducking is shown in Figure 1.

Lower waveform - recording audio description
Upper waveform is base music and effects
Dotted white line in upper waveform is result of ducking

**Figure 1. Audio Ducking Example**

Narrators are proficient with the timing of their descriptions, and automatic or manual equipment is used to ramp down the main program audio and ramp it up prior to and after the audio description segment. To date, live descriptions have resulted in time-delayed versions of the events, as the live descriptions were conformed to the event after completion. What will it take to produce described live events and deliver live?

As you will learn in the next section, new technologies are on the horizon to make live event descriptions possible.

### 4.3. The Future of Over-the-Air Broadcasting

Today's over-the air-broadcast format is three decades old. Three decades ago, the Internet was accessed through dial-up modems, smartphones were ten years away, and compact discs were in their prime. The Americans with Disabilities Act was brand new at the time, and the 21st Century Communications and Video Accessibility Act was still twenty years away. So much has changed in thirty years. In 2019, the NextGen TV brand was created, which embodies the new ATSC 3.0 broadcasting standard, which was authorized by the FCC in 2017. ATSC 3.0's key features include higher resolution, dynamic range, IP delivery, interactivity and greater audio fidelity. The very modern HEVC video compression and a pair of audio compression standards, AC-4 and MPEG-H, have been selected. Selection of the national audio format is per country. The U.S. has selected Dolby's AC-4 compression as standard for NextGen TV. Two generations ahead of current over-the-air television audio compression, AC-4 is approximately three times more efficient, from a pure compression perspective, and when combined with its novel capabilities to deliver audio in substreams and objects, the bandwidth efficiencies are much higher. In the next section we will discuss some of these new audio features. [9]

### 4.4. M&E+D

While sounding like a math formula or SMS shortcut, M&E+D refers to a common Music and Effects mix and additive Dialog track. This is a key enabler for next generation accessible audio experiences. Allowing a single common Music and Effects mix to be delivered with synchronous but separate (and multiple) additive Dialog streams, M&E+D offers personalization, bandwidth savings and reduced production complexity. No longer is a complete main -- a mix of all music, effect and dialog -- required

for each audio service. The viewer/listener may select from multiple presentations, mixes of common plus one or more dialog tracks. Furthermore, these mixes can be adjusted to the listener's preference, allowing dialog to be enhanced or diminished quite easily. In the use case of audio descriptions, the narrative can be created and delivered without requiring a mix-down to the primary audio. This reduces time to deliver and offers the opportunity to lay narrative on top of a surround base. Spatializing audio is of great benefit to the vision impaired community, as it provides direction and space to the experience. Today, almost all broadcast with descriptions are delivered as monaural audio. Figure 2 illustrates how multiple audio presentations can be assembled through an AC-4 bitstream.

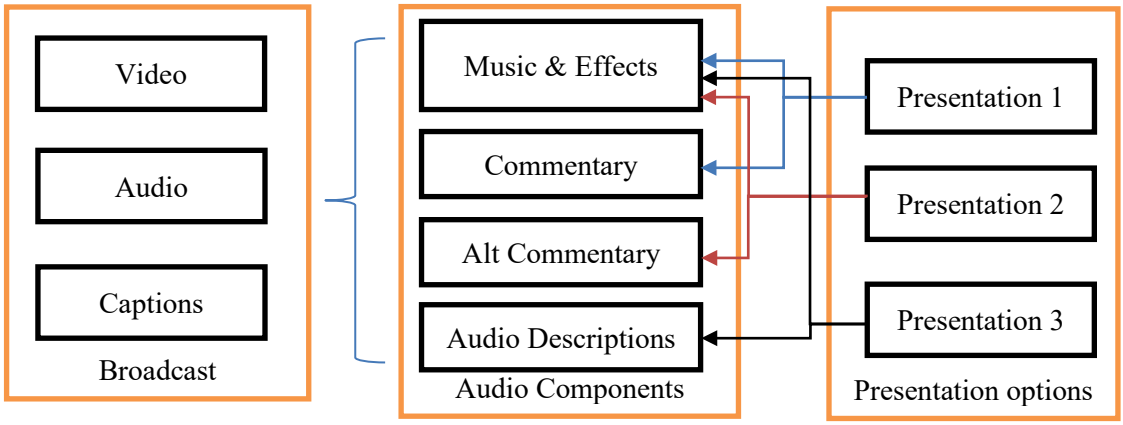

**Figure 2. Multiple Audio Presentations Through AC-4 Substreams**

AC-4 audio can be frame-aligned with video frames, unlike preceding audio formats. This offers seamless switching at content insertion (i.e. advertising) boundaries. Seamless switching can ease the addition of accessible advertising, ads with audio descriptions, a benefit to the viewer and provider alike.

### 4.5. Why is this important

To understand the impact of AD, a survey of 626 visually impaired adults was conducted in 2017 by the American Foundation for the Blind (AFB). It found that over half reported watching television 4 or more hours a day -- and 65% reporting problems looking up what is on TV. Less than half were aware of assistive technologies such as AD.

Comments filed with the FCC by the AFB in support of expanding coverage of audio descriptions included the following from Jerrell Harris of Paragould, AR, which really sums up the impact of AD:

> "I do not currently receive audio description from ANY of my current local channels or cable channels. I do get some audio description on NETFLIX and OMG, I ABSOLUTELY LOVE IT!!!! It changes the way I watch TV and now I feel like I am included and can SEE what's going on, on the screen. There is SO much that we visually [interpret] on the TV screen and audio description is AMAZING and describes in detail what is on the screen and what is going on. As a blind person, it is frustrating to me to watch TV without audio description because we miss so much of what is going on. My husband will tell me what is happening on a show, but I know that gets annoying to him at times. The audio description lets us enjoy TV again, and gives a sense of confidence that we are almost on the same playing field as the sighted now because we actually have the description of what is going on the screen."

This quotation speaks to the expansion of availability and ease of selection of audio descriptions in broadcast and cable television.

### 4.6. Automating Audio Description

Machine-based transcriptions of program audio to create closed captions is commonplace and steadily improving as models evolve and model training continues. Is it possible to automate the creation of audio descriptions? Image classification is mature and implemented in accessible applications, such as Microsoft's Seeing AI, benefitting the visually impaired as they navigate unfamiliar places and things such as food packaging. The Massachusetts Institute of Technology recently completed research analyzing television images to determine the point of focus where the actor's attention is placed [10]. Constantly describing each scene would be distracting, which makes the remaining challenge to describe the instrumental parts of a scene. It seems within reach to train domain-specific programs, such as sports or news, to machine-describe the segments and plays. Consider the ease with which a sports radio commentator describes the play of game.

## 5. Beyond Audio Description

Audio is instrumental in creating an accessible television experience beyond audio description. The FCC requires that all features of apparatus that consumers use to display television programming are accessible. Voice guidance is increasingly the means of complying with this requirement. Many features of televisions appear on video menus, which can challenge those with visual impairments. Voicing out the elements of a screen menu as they are navigated is a standard feature of screen readers applications on PCs and voice out features of smart phones. Smart televisions and cable receivers are increasingly implementing voice guidance to voice out menus and program guides. These applications typically rely on an active Internet connection to the device, which is a challenge as many smart televisions remain unconnected to networks. Embedded text-to-speech technology has evolved in performance and compactness and will increase in availability in consumer and subscriber devices.

Emergency information is new to ATSC 3.0. This information differs from Emergency Alerts, which may take over the audio and or video programming during emergency events. Emergency information may include warnings, such as weather and school closings, but doesn't automatically preempt programming. Through the use of text-to-speech technology and signaling in the AC-4 audio stream as type E, these textual alerts can be converted to audio and added as a presentation option for viewers who prefer audio narration of emergency information.

## 6. Conclusion

Cable television is accessible. That said, Internet streaming media providers offer more content and better fidelity of accessible audio than over-the-air networks and cable channels. Next generation broadcasting and pending regulation will offer expanded coverage of accessible audio on cable television programs and provide a path to more innovation in terms of immersive audio experiences, multi-language, multi-cultural accessible audio experiences and description availability on live and event-based programming. Improved signaling of audio content can improve the ability to find accessible audio. ATSC3.0 includes a new audio subsystem, AC-4, that offers presentation options that can improve personalization and lead to more descriptions on live programming.

# 1. Introduction

Deployment of an expanding range of upstream split options for the return path in coax systems has many challenges. Among these challenges are old infrastructure components such as drop-amps and splitters, legacy customer premises equipment (CPE) and services sharing common or overlapping spectrum. This technical report presents a scheme that leverages remote feature control (RFC) and remote health monitor (RHM). These systems selectively enable enhanced return path high-speed internet service (HSI) for Cable Modems based on a quality of service (QoS) measurement from all CPE in the household. Specifically, current use cases will describe how DOCSIS© TLV84 is used to remotely enable mid and high-split. At the same time, downstream and upstream performance metrics, such as signal-to-noise (SNR), modulation error ratio (MER), and other metrics are remotely monitored from all CPE devices within the home and, in the case of high split and full duplex (FDX), within neighboring homes as well, to evaluate potential disruption of revenue generating services. Households are scored to determine whether they are capable of self-installation of enhanced HSI services. The advantage of this technique includes allowing: 1) scalable individualized and progressive HSI deployment with a remediation strategy focused only on customer networks where potential issues exist and 2) proactive and adaptive network operations in accordance to a varying environment thus minimizing trouble calls, truck rolls, and customer contact.

## 1.1. Benefits to Mid-split Deployment

DOCSIS has been a frequency-division duplex (FDD) access scheme, in that the upstream and downstream transmissions occupy different bands of the spectrum (Cablelabs, 2009) (Cablabs, 2017) (Cablelabs, 2019). Standard-split operates in the 5 – 42 MHz band for the upstream transmission and has been deployed in many operator networks. Standard split has served operators well, enabling them to provide their customers with up to 35 Mbps upstream capacity since the late 1990s.

CableLabs has provided multiple options for enhancing upstream capacity with multiple versions of DOCSIS. DOCSIS 3.0 introduced the 85 MHz upstream option and with it, the ability to increase upstream capacity via channel bonding. DOCSIS 3.1 required upper edges of the upstream band to include 85 MHz and 204 MHz, so named mid-split and high-split, respectively. DOCSIS©4.0 introduces full-duplex DOCSIS (FDX) that allows upstream and downstream transmissions to share the same spectrum band where the new upstream band edge requirement extends to 684 MHz (Cablelabs, 2020).

The mid-split scheme doubles the upstream bandwidth of the standard-split scheme, which immediately translates to an augmented capacity and increased quality of service. Since many operators limit their use of the standard split band to primarily the upper two-thirds of the band, the midsplit represents nearly a 3x increase in useable bandwidth. Usually, four 6.4 MHz SC-QAM upstream channels are configured in the 5 – 42 MHz regopm, providing 122 Mbps data rate with 64-QAM modulation. The mid-split scheme is able to add four more SC-QAM channels and offers a total upstream data rate of about 250 Mbps. Alternatively, it allows configurations of advanced OFDMA upstream channels. For instance, a 48 MHz wide OFDMA channel will enable a 500 Mbps upstream data rate with 2048-QAM modulation. With another bandwidth doubling offered by the high-split scheme, more than 1 Gbps of upstream data rate can be achieved.

With all of these options available to operators, it is likely that the upstream will evolve from standard split, to mid-split, to high-split, and beyond. The good news about this approach is that all of the lessons learned from incrementally increasing capacity with customer demand can be applied to the following evolutionary step. For example, the challenges for midsplit that are discussed in this paper will also be challenges for high split, and so on. Thus, solving these challenges now with new innovative approaches

sets operators up for the future, with techniques and processes for deployments of even higher capacity upstream.

## 1.2. Challenges to Mid-split Deployment

The relatively limited upstream bandwidth of the standard-split has been satisfactorily serving customer needs of internet access, from web surfing to video streaming. Interactivity-intense applications, including gaming, video sharing and teleconferencing have become increasingly popular, especially since the COVID-19 pandemic and work-from-home have become a new normal for many customer households, resulting in higher demand for new upstream bandwidth. This trend has accelerated changing the DOCSIS network to the mid- or high-split.

Deployment of the mid-split involves re-allocation of the spectrum used by many existing services. For example, video services on standard EIA channels 2 to 6 with carrier frequencies 57 – 87 MHz will need to be moved to make space for mid-split upstream channels. The cable plant also needs upgrades of the diplexers used in active devices, including nodes, line extenders, trunk amplifiers, and even in-home drop amplifiers. These products must support specifications for mid-split between the forward and return bands. The above requirements are challenges in and of themselves. However, the thorniest problem is in the customer premise, where a mid-split capable gateway and legacy standard-split set-top boxes (STBs) need to seamlessly coexist. The former may cause interference to the latter due to adjacent channel interference (ACI) susceptibility.

Standard-split customer premise equipment (SS-CPE) includes video set-top boxes (STBs), pre-DOCSIS 3.0 cable modems (CMs) and DOCSIS 3.0 CMs with fixed standard-split diplex filters. Mid-split CPE (MS-CPE) are usually designed with software-selectable diplex filters which can switch between the standard-split and mid-split modes. Within a customer premise, CPE devices are usually connected to the cable feed off of a splitter -- which, without sufficient port-to-port isolation, will allow the MS-CPE's upstream transmission to interfere with the SS-CPE. The "mid-band" part of the upstream signals from the MS-CPE leak through the splitter into the downstream receiver of the SS-CPE, unfiltered. Even though spectrum re-allocations are implemented, such that the SS-CPE are not expecting any services in the mid-band, thus its tuners are not tuned to any frequencies in that band, the leaked signals unfortunately raise the noise floor at the radio frequency (RF) mixers and degrade the receiving SNR for all downstream services. The consequences will be increased receiving errors and deteriorating service quality. Adjacent channel interference (ACI) susceptibility is a term commonly used for this type of indirect interference scenario.

It may appear straightforward to solve this SS-CPE and MS-CPE coexistence problem by simply replacing the splitters with ones with higher isolation specifications. This solution may turn out to be prohibitively expensive, as it may not be an easy customer self-installation procedure, i.e. truck-rolls may needed, especially in the cases where there are many home devices, or when drop amplifiers are used. It is also unnecessary to blindly replace the splitters in all customer premises, as only a small portion of them would likely have experience-impacting effects due to the interference.

When systems allow, increasing the downstream transmission power may also help mitigate this ACI problem. However, most cable operators will have already maxed out downstream RF output power for other reasons, for instance to achieve household-per-node efficiencies. Therefore, increasing node output power is not always practical, and usually requires a whole-plant calibration for stable operations.

Deployment of the mid-split at the headend, in the cable plant and at the customer premise should be a gradual procedure. A progressive and adaptive approach is one in which the mid-split mode is "turned on" at customer premises, individually, and based on their unique site conditions, which may be more efficient and beneficial from an operator's perspective. Modern IP-based CPEs are mostly capable of remote feature control (RFC) and remote health monitoring (RHM). Enabling protocols such as SNMP and TR-069 will allow network operators to selectively turn on certain services, based on viability, and continuously monitor the quality of services, so as to proactively adjust operation modes and class of services.

This paper presents a scheme for mid-split deployment, which focuses on the SS-CPE and MS-CPE coexistence problem. Applying a number of existing RFC and RHM technologies, this procedure includes a proactive on-line evaluation of network conditions and service quality, thus is able to isolate sites suffering the coexistence interference without requiring an installer to be on-site. The procedure subsequently supports a progressive mid-split turn-on in a home-individualized, and, most importantly, cost-effective manner.

The rest of the paper is organized as follows: Section 2 and 3 will describe in detail the SS-CPE and MS-CPE coexistence problem and the proposed procedure of online detection of it. Section 4 will present data from a field trial and other similar use case scenarios.

## 2. Problem Statement – Coexistence of Mid-split and Standard-split CPE

To better appreciate the problem, refer to Figure 1 for an illustration of a typical configuration in a customer premise with coexisting MS-CPE and SS-CPE. The MS-CPE and SS-CPE share the cable feed through a splitter. The MS-CPE's upstream operates in the 5-85 MHz band, while the SS-CPE's diplexer cuts off 54 MHz and above for downstream traffic. With imperfect isolation of the splitter's output ports, the MS-CPE's upstream signal may leak into the SS-CPE's downstream RF front end. Even when careful spectrum arrangement avoids the 54-85 MHz band being used by any services for the SS-CPE, the leaked signal from the MS-CPE upstream may result in increased noise floors at the SS-CPE's demodulator, which consequently causes the SNR to deteriorate, bit error rate/modulation error ratio (BER/MER) to degrade, and ultimately service quality to be impaired.

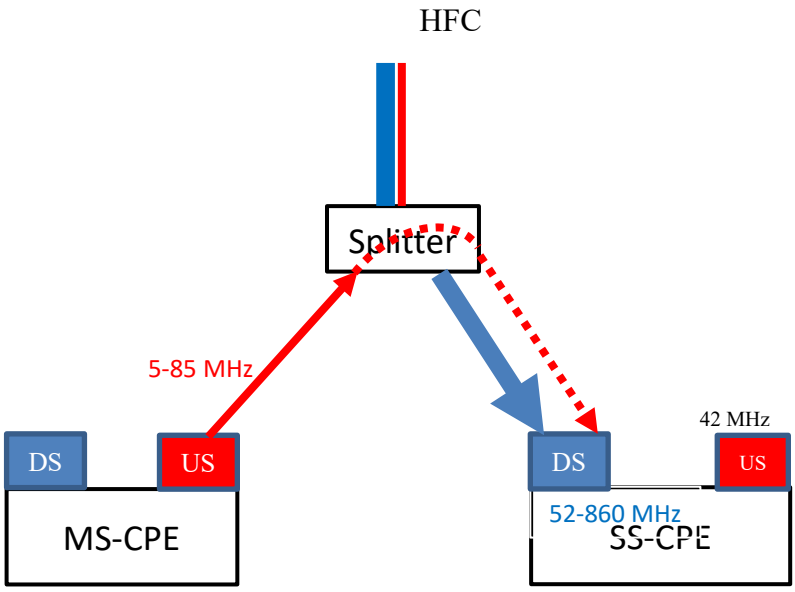

**Figure 1 - Coexistence MS-CM and Pre-DOCSIS CPE**

A simple estimate of a dominant noise floor increment could be as follows: The maximum transmission power of a 6.4 MHz DOCSIS 3.x SC-QAM upstream is 51 dBmV per 5.12 MHz; note that the maximum modulation bandwidth is 5.12 MHz. Assume the splitter port-to-port isolation is of a typical value of 30 dB. Then, the mid-band upstream signals from the MS-CPE will generate 51 - 30 = 21 dBmV per 5.12 MHz interference at the SS-CPE's downstream receiver. If the downstream bandwidth is of nominal value 800 MHz, the interference will add a noise of level $21 - 10\log_{10}\left(\frac{800}{5.12}\right) \approx -1.9$ dBmV per MHz. For a 6 MHz QAM channel, the increment of the noise power at the tuner would be $-2 + 10\log_{10}6 \approx 5.8$ dBmV.

Assume that the SS-CPE requires a minimum of 30 dB receiving SNR for satisfactory quality of services; also assume the cable plant is calibrated such that the CPE receiving SNR is of mean 40 dB and variance $3^2$. With these conservative parameters, one could expect that about 10% of the SS-CPE population will suffer impairment to quality of services due to the 5.8 dBmV SNR degradation.

The interference to SS-CPE may not necessarily come from the MS-CPE's upstream transmissions directly. Even when there are no upstream channels configured within the mid-band of 42 – 85 MHz, the spurious emission of the existing upstream transmissions in the band of 5 – 42 MHz may still fall in the mid-band and then leak to the receiver of the SS-CPE, in the form of interference.

To target the root cause of the described problem, a simple solution may be to replace the splitter with one of higher port-to-port isolation specifications. For example, if a splitter of 40 dB port-to-port isolation is used, in the above calculation, the SNR degradation will become practically negligible. However, replacing splitters in customer premises may not easily be a self-installation procedure. Complex on-site work by technicians may be needed when the splitters are in hard-to-reach places. The solution will become prohibitively expensive if it has to be executed for every customer premise. It is also very inefficient based on the estimated percentage of the affected population.

## 3. A Proposed Method

An efficient solution should be proactive and individualistic. Proactivity means that the RF and network performance at the customer premises should be measured on site and in real time. Individualism means that the mid-split mode should be turned on or off for each customer premise individually, based on its unique RF and network conditions. The proposed method employs RHM and RFC technology to decide the mid-split readiness per customer premise and make a progressive deployment.

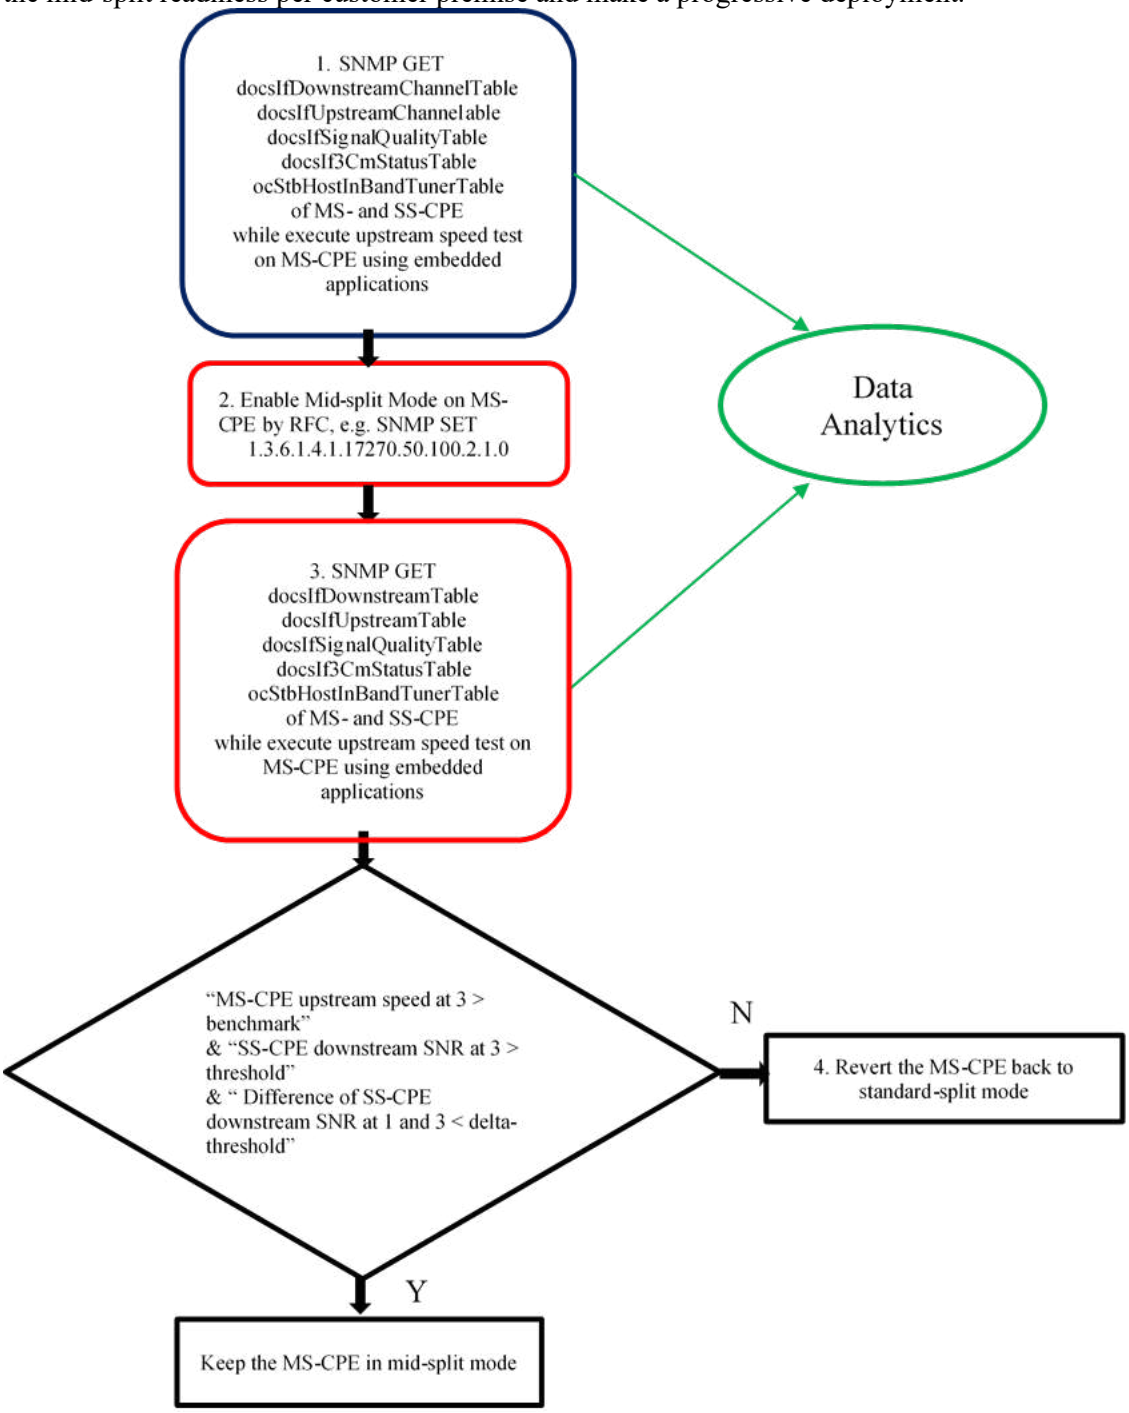

Figure 2 depicts an abstracted procedure of the proposed method. The first step is using SNMP to get the upstream and downstream metrics for the MS-CPE and SS-CPE, particularly under controlled upstream traffic that have been triggered using a speed test application. The data obtained at this step serves as a baseline for evaluating the improvements and impacts of a mid-split spectral allocation. The second step is turning on mid-spit mode on the MS-CPE. This can also be achieved through SNMP, by setting the MIB object 1.3.6.1.4.1.17270.50.100.2.1.0. Then the third step is to repeat the first. Finally, by comparing the data from the third and the first steps, operators can determine the mid-split readiness of the studied customer premises. If all criteria are met, the site can stay in mid-split mode; otherwise, it could be reverted back to standard-split mode.

The speed test part of the procedure serves two purposes: It provides a direct measure of the performance merits of the bandwidth augmentation brought about by the mid-split. It also facilitates the evaluation of impairments to SS-CPE by MS-CPE as an emulated interference.

The above procedure applies to each customer premises. The data from a large number of customer premises, correlated with MAC domains and other geographic information, can offer an inference of the network readiness for mid-splits at a larger scale. Potential issues in network components, such as standard split drop amplifiers blocking midsplit upstream transmissions, could be isolated.

Note that the above procedure exemplifies a usage of some standard RHM technology, such as the DOCSIS and OpenCable MIBs (Cables, 2020) (Cablelabs, 2013). Other technologies, such as TR-069 (Broadband Forum, 2018), are equally applicable, if corresponding data models are supported by the CPE. The speed test application is generally proprietary, which, nevertheless, is widely embedded in CPE firmware. Attention must be paid on running speed tests in that they may affect customer experience; therefore, the data collection steps are better performed during scheduled maintenance windows.

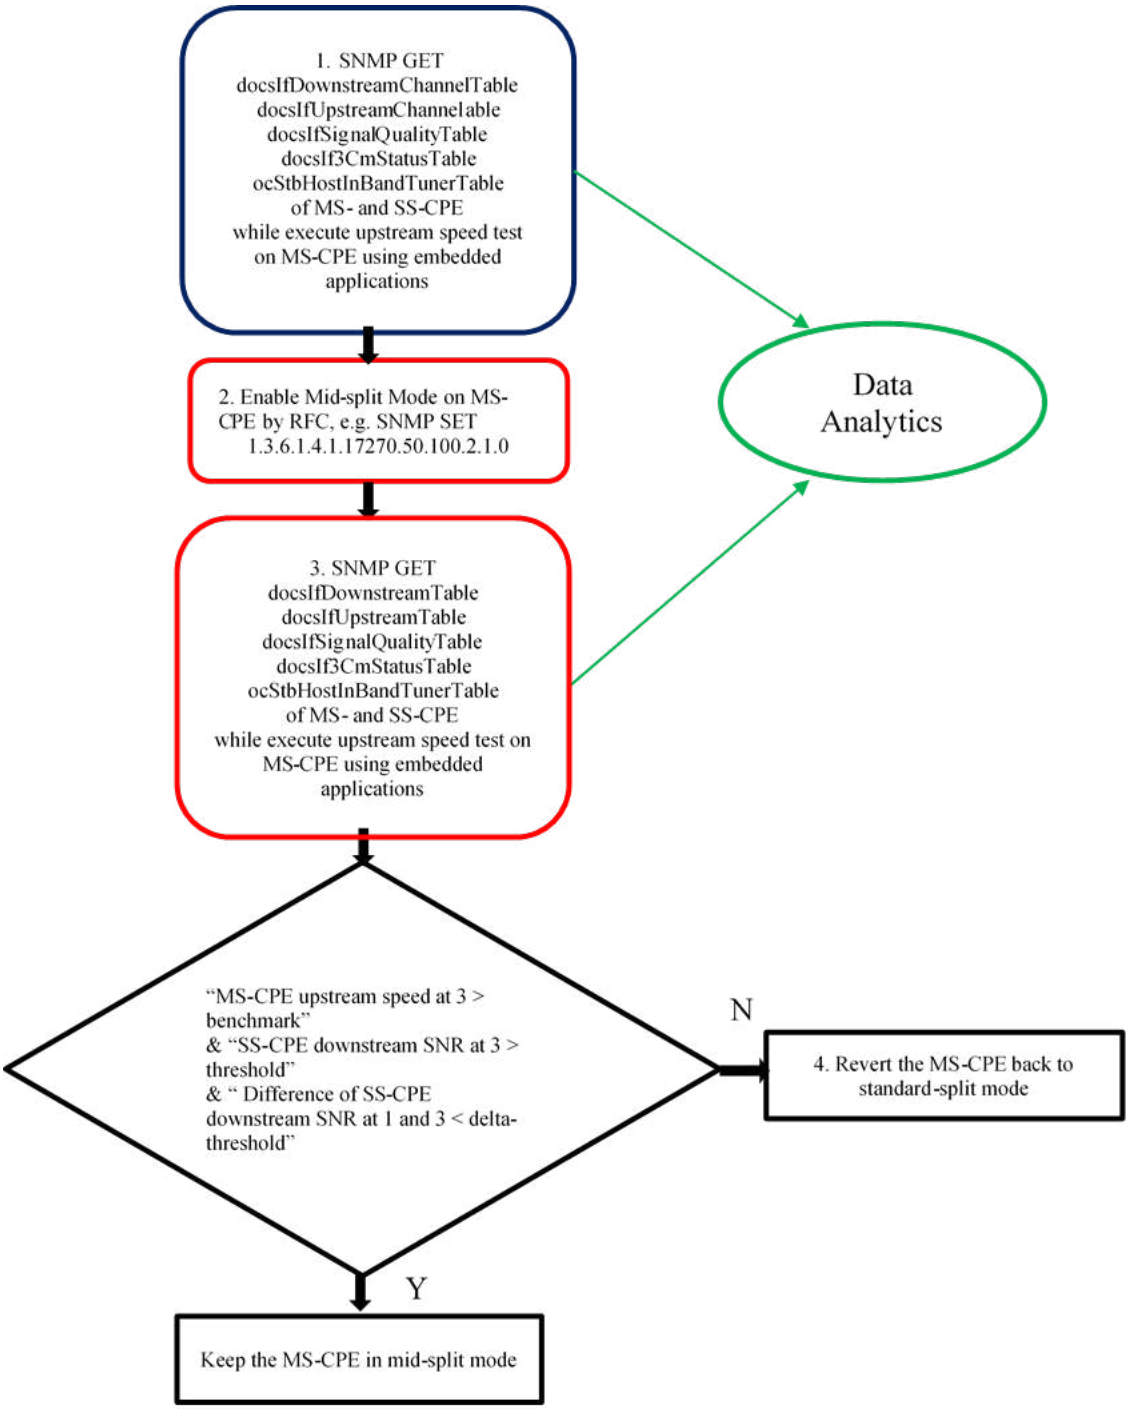

**Figure 2 - RFC and RHM Procedure for Mid-Split Deployment**

## 4. Case Studies

This section presents several trial cases of the application of the proposed proactive network management method in mid-split deployment at various levels.

## 4.1. Upstream Trial

This was a full-fledge mid-split deployment trial. The RHM had focused on noise level increases in the downstream band in the coexisting scenario. The docsIfSigQTable MIBs of the SS-CPE were specifically used as a sampling of the downstream spectrum at the 8 – 24 downstream frequency points. It was predetermined that if the MS-CPE would fall into a partial-service mode (indicating standard split drop amplifier issues), or the SS-CPE downstream SNR would drop below some threshold level (indicating splitter isolation or ACI susceptibility issue), then the customer premises would be failed for the mid-band mode.

Sixty-three customer premises were selected for the trial. Automated RHM and RFC activities take about 30 minutes. The trial results are shown in Table 1.

**Table 1 - Results of the Eight Upstream Trial**

| Results | Automated Testing |
|---|---|
| Pass (SIK) | 65% (41 subs) |
| Fail (Drop Amp) | 29% (18 subs) |
| Fail (Isolation) | 6% (4 subs) |

## 4.2. Mid-split Spurious Emission Impairments to Video STB SC-QAM

The objective of this trial was not to add upstream channels in the 42 – 85 MHz band, but only to enable mid-split mode on the MS-CPE in standard split plant. Its purpose was to evaluate the interference resulting from spurious emissions of the MS-CPE to the coexisting SS-CPE. Note that even the MS-CPE's transmission in the 5-42 MHz band may generate spurs in 42-85 MHz band, which leak to the SS-CPE's receiver. Therefore, the method described in the previous section is readily applicable.

The MS-CPE involved in the trial were DOCSIS 3.1 cable modems, and the coexisting SS-CPE were set-top boxes. The metrics of interest in this trial were primarily the quality impairments of QAM videos on EIA channels 2-6. The MIB ocStbHostInBandTunerSNRValue had been specifically used for RHM. To make the SS-CPE tune to the designed channel between 2-6, a proprietary remote tune application was also used.

Twenty-one geographically-dispersed customer premises were selected. Automated RHM and RFC activities took about 45 minutes. Twenty premises showed no SNR degradation, and one suffered about a 2 dB SNR drop. Sample data of passed premises and failures are presented in Table 2.

**Table 2 - Sample RHM Data**

| | | | | | | | | | | | | | | | | | | | |

| MS-CPE US frequency/Tx Power in stdsplit mode | 30100000 | 43.3 | 17300000 | 44 | 23700000 | 43.3 | 36500000 | 43.5 | | | | | | | | | | | |
| | 57000000 | | | | 63000000 | | | | 69000000 | | | 79000000 | | | 8.5E+07 | | | | |
| SS-CPE1 Tuner SNR (std-split/mid-split/mid-split with traffic) | 40.5 | 40.3 | 38.4 | | null | null | null | | 41.9 | 41.9 | 40.5 | 42.5 | 42.5 | 40.8 | 42.5 | 42.5 | 42.5 | | |
| SS-CPE2 Tuner SNR (std-split/mid-split/mid-split with traffic) | 38.2 | 38.1 | 36.7 | | 39.1 | 39 | 37.4 | | 39.8 | 39.8 | 38.4 | 40.1 | 40.1 | 39.6 | 40.1 | 40.1 | 39.9 | | |

This implies that future CPE deployments could continue to use a switchable diplexer, but using mid and high-split switchable CPE instead of low and mid split switchable variations. This technology re-use not only minimizes the variations in future CPE products, but also maintains high levels of return on investment in CPE to enable service growth, as customers progress from 100 Mbps to 1 Gbps upstream services.

### 4.3. 5th-Upstream Trial (In Progress)

The 5th-upstream is a 3.2 MHz wide channel with center frequency at 41.3. MHz; so, part of its spectrum is above 42 MHz. The purpose of this configuration is to increase the upstream bandwidth of the SS-CPE as well as the MS-CPE. The theory of such an operation lies in that, the transient band of the SS-CPE's diplex, combined with adaptive equalizer, may provide a sufficient 3.2 MHz wide frequency-flat channel. The RHM focus is on the partial service status, as well as spurious emissions to the 57 – 87 MHz band as discussed in the previous use cases.

The authors believe the above use case scenarios represent the tip of the iceberg when it comes to using online tools for solving a variety of challenges associated with enhancing upstream capacity. There will likely be multiple opportunities to reuse the tools discussed above to solve new, but similar, challenges associated with high split and FDX.

## 5. Conclusion

This paper illustrated a proactive and adaptive network management scheme which employs RHM and RFC to allow for progressive and individualistic deployment of a wider upstream signal path to mid-split frequency allocations, as it relates to the customer premises. The scheme is generic, such that various RHM and RFC technologies can plug-and-play. Besides automatic mid-split enablement on a per-home basis, the scheme also affords data analytics for network service quality.

The cases presented in this paper are for mid-split deployment. The proposed methods are equally applicable to high-split scenarios. As the high-split scheme is deployed in the vCMTS/R-PHY architecture and with OFDMA upstream channels, additional RHM tools may be needed and be available for the proactive network management tasks.

# Case Study of Social Distancing on Mentorship Programs

## CLEAR Program Introduction

A Technical Paper prepared for SCTE•ISBE by

**Andrew Frederick**
Principal Engineer
Comcast
4100 E Dry Creek Rd, Littleton, CO 80122
(303) 881-6103
andrew_frederick@comcast.com

# Table of Contents

**Title** **Page Number**

 

# 1. Introduction

CLEAR is a mentorship program that was started in Denver by engineers, for engineers. The Mentors, Mentees, and Committee Members are all volunteers giving their time back to each new year's cohort. CLEAR stands for Comcast Leadership Engineering Achievements and Relationships.

# 2. CLEAR Program Introduction

## 2.1. Acknowledgements

Simply stated, the only way that the CLEAR Program could have been created and sustained was because of the environment, culture, and leadership. There are several instances in this paper where this is presented as pretext for creating the conditions enabling the operation of this program. The author would like to acknowledge his role and experience shaping the program over the past four years to bring this perspective to the industry at large, but not without mentioning the countless others who have founded and created the initial vision of the program in 2011. Literally hundreds of people who have given their time, energy, and dedication to pursuing the craft of mentorship and giving back to their fellow coworkers. Without their output, the CLEAR Program would have died a long time ago- the reason this program has sustained itself is by listening to feedback from Mentees, Mentors, and Committee Members about how to create a more meaningful experience and curriculum. Denice Loud has effectively been the Program Lead in Denver for the past six years, and without her dedication and execution, the sessions would not be nearly as polished and professionally presented. Her attention to detail has set the bar for expectations in how our program is run. Leslie Chapman has been the Engineering Lead in Philadelphia for the past two years and has been instrumental to launching the Philly chapter in 2019. Leslie's natural abilities have suited her ideally for making leadership accessible to her cohorts and her excellence and accomplishments in her engineering background give her the perfect experience to lead and share with each year's class. The author would like to acknowledge Denice and Leslie's contributions, not just to the CLEAR Program, but also for their contributions to this paper.

## 2.2. About the CLEAR Program

The CLEAR program pairs junior engineers with more experienced engineers on a year-long mentorship experience. The Mentee has a series of classes they will take over the course of the year that focus on professional development: Intellectual Property, DiSC, EI, Presentation Skills, Personal Branding, Leadership, and Cross Functional Relationships are the foundational topics to the program, and each year the focus for special topics changes based on executive leadership direction. The format of the program through 2019 was to meet every month for in-person sessions for a day of focused learning, and inevitably when lunch and breakfast are provided, networking. When each cohort is formed, the Mentee will propose a capstone project that will be the technical focus for the year and will serve as a vehicle to incorporate all the professional development topics together. Deliberately, CLEAR requires that all projects must not be part of the Mentee's day job- they must be cross functional in nature. This opens the door to creating a web of relationships across the organizations that don't typically happen on their own. It teaches the Mentees that the world is what they can create of it, and it empowers them to put pencil to paper, to make their vision a reality.

As the cohort moves to graduation and completing the program, the Mentee will have a demonstrable project to present and show off to their colleagues and to senior leadership at a project fair. The project fair is *THE* opportunity for the Mentees to demonstrate all the soft skills they have learned throughout the year as they showcase their technical projects as they communicate across all levels of engineering peers, management, and executives in the same conversation!

 

Over the past seven years, the program has been growing and one of the keys to that success has been to keep evolving the curriculum and be willing to throw things out that aren't working or are no longer relevant. The CLEAR Committee has a strong culture of adaptation and evolving with the times and is probably a key trait that has helped to carry them through the jarring transition of COVID-19. Another testament of the program's success is the launch of the Philadelphia chapter in 2019. Despite having two vastly different working environments, cultures, and locations, the core tenants of the program have been the binding agent that has kept the chapters together. CLEAR has an interesting history of how it began and how it grew to be what it is today, but that would be the subject for another discussion.

## 2.3. Supported Relationships

CLEAR deliberately mixes oil and water together as often as possible- the Mentee project selection must be cross functional, and the partnering on projects must also be a new relationship. When the Committee pairs Mentors and Mentees together, one of the key pieces of data that's used is if either party knows each other. If there is a previous relationship there, we avoid making those matches to try and maximize the exposure of these relationships across the organization- it's a deliberate and concerted effort to force people into these relationships. One of the things that has surfaced over the years is that this works well on paper but growing these relationships doesn't just happen without some additional magic. This is where the CLEAR Committee members add that spark and give these relationships the extra push and support they need. Sometimes this pairing of "odd couples" has style conflicts, or maybe communication weaknesses that can impede this Mentor and Mentee relationship. The Committee Member forms what is known as the Triad. The Triad Committee Member (TCM) is embedded in the relationship and they are invested in making sure that the relationship between Mentee and Mentor is going well. They are also there to help provide advice, input, and guidance for any questions that come up.

One of the amazing features of the program is how much the Mentees are motivated to give back to the program and come back and serve on the Committee, or if they end up promoted to a requisite title, back as Mentors in the program! This feedback loop channels the experiences of the previous year forward into the next cohort and gives each Committee a chance to improve the program. Ideas and change are democratized as they pass through each chapter's Committee and are ultimately approved by chapter leaders in unison for the year. It's important that each chapter holds each other accountable and is supportive of moving together as a team – after all, each chapter has benefitted from the new relationships created on both ends. The hope is that each Mentee's journey in CLEAR will be unique to the individual, but the overall experience in the program will be the common bond that will be the common ground to unify Mentees, Mentors, and Committee Members from different generations of the program.

## 2.4. Living in the Moment

Prior to the year 2020, CLEAR was an entirely in-person experience. The monthly sessions, the lunches, the project fairs- these are all designed specifically to maximize and to deliberately focus energy and resources on networking and professional relationships. The ground rules and tone that the Committee sets for the year is that the expectation is to have all electronic distractions closed and away, and to be solely focused on being in the moment to fully experience the topic and learning for the day. The expectation is that if you're in class, you have delegated your responsibilities for the day, and you are provided operational cover and support from your direct manager to be absent for the day. The goal is to create an environment and atmosphere where all the road blocks are out of the way to eliminate distractions. With this kind of environment created it was important to curate this culture and exemplify it at all levels. We created the conditions where we could maximize the time we spent together, and with all these people in the room on the same frequency it naturally brings its own energy. Running a session was no picnic, but the energy quickly overflows once we get into breaks and have lunches together. It

 

was a symphony of managing and releasing energy in a deliberate setting. These sessions were as much about the social growth of the Mentees and Mentors and Committee- the class and learning for the day is a convenient means to package some truly important content into a setting which promotes relationship building. A few years ago the logo was redesigned, and the Committees chose a design that emphasized the "R" being represented in a different color. The reason behind this choice is because the Relationships are the most important product from the program. It became apparent over the years that the projects, ideas, and technology ebb and flow, but the people seem to be the biggest constant in a healthy organization. The relationships are what seemed to outlast any idea in a digital world and are what brought many Mentees future opportunities after graduating from the program.

## 2.5. Social Capital

The emerging theme here is that for this kind of mentorship program to be successful, it had to invest heavily in social capital. Long before this pandemic, Comcast has been investing in social capital and empowering their employees to do the same. Mentees who graduate the CLEAR Program return to their teams and get a chance to flex their new skills and experiment with what they have been learning. Alumni know how to network and aren't afraid to reach across organizational boundaries, and their experience empowers them to communicate with leadership when they have an important idea. It can take a few years to build this kind of cohesion and camaraderie between the Mentors and Committee members, but once this trust is built, the group can go far and fast together. Maggie Heffernan says it best in her TED talk,

> *"When the going gets tough, and it always gets tough if you are doing breakthrough work that really matters. What people need is social support, and they need to know who to ask for help. Companies don't have ideas; only people do. And what motivates people are the bonds and loyalty and trust they develop between each other. What matters is the mortar, not just the bricks."*

Mentorship programs like CLEAR are essential for companies to have as part of their DNA- these programs are what gives companies the ability to weather the storms like COVID and come out the other side moving in a positive direction. CLEAR focuses on the strength of the organization, not solely on the individual. Back to Maggie:

> *"And when I talked to producers of hit albums, they said, "Oh sure, we have lots of superstars in music. It's just they don't last very long. It's the outstanding collaborators who enjoy the long careers, because bringing out the best in others is how they found the best in themselves."*

CLEAR has grown to the point where their social capital compounds, even as it's being spent. Every year there are new individuals coming back to the program to help as Mentors or as Committee Members. The main reason these groups can survive is because they find other like-minded people who enjoy giving their time to others.

# 3. The COVID-19 Disruption

## 3.1. Situation Report

The events that unfolded going into 2020 may not happen again within our lifetimes, but it is important to reflect on the state we were in and how it was disturbed by a global pandemic.

The awareness of the pandemic was not beginning to be realized in the USA until the end of the first quarter of the year, and it was largely something that caught businesses off guard. Companies had work from home policies and plenty of employees contributing in this manner, but what the world wasn't prepared for was the tectonic shift to moving most of their employees to the safety of their homes. It's important to note that this transformation had to be created at rapid speeds across massive organizations, which is about the equivalent of power sliding a battleship into a parking space. The CLEAR program was on the receiving end of the information pipeline which meant the Committee had precious little time to react and pivot.

## 3.2. Novelty of Information

In the early stages of the pandemic, there wasn't a unified sense of purpose or mission about how our lives were going to change. It's important to note that there were voices across the spectrum which had varying degrees of opinions about what the next few months held, and how temporary or permanent these changes would be. CLEAR is a volunteer organization and it was important for the group to reach consensus quickly about coming to terms with the situation and how to best move forward.

The truth of the matter is, nobody knew exactly what was going to happen in the short or long term, so we're dealing with the novelty of information mixed in with human emotions. The plans that were made "yesterday" were thrown out the following day. Responses ranged from denial to panic depending on personal situations and how close to home the virus was hitting. Executive leadership was key in these early stages to setting the tone and direction for how we were going to respond to these changes to our business. Within the company, the response from leadership has been amazing. Experts had been consulted and leadership began providing more frequent updates, coupled with meaningful plans about how our business is going to change and walking us through this transition. This is important to mention because it was absolutely critical for our volunteer organization to have an example to follow and emulate. Leadership being comprehensive, direct, and focused allowed the message to penetrate to the core of the organization and offered a path forward. This new path was not a like-for-like replacement. It was a new landscape to navigate, fraught with a unique set of opportunities and challenges. Had the guidance from above been delayed or not effectively communicated with timely updates, the CLEAR Program would have had a difficult time trying to execute their program in 2020.

## 3.3. Turning on a Dime

The 2020 CLEAR program began its year as it has for the past several years by collecting our feedback from 2019, digesting it as a committee, and then having committee leads parlay that into a conversation with the other chapter and represent how we want to move the program forward for the year. Nobody in either chapter could have identified the potential threat resulting from the virus and planned the necessary changes. We got so far as to have one of the first kickoffs (the Mentor kickoff) in person in Denver. The plan for Denver was to push forward and try to host our Mentee kickoff on schedule the following week. COVID's disruption had the Philadelphia's chapter decide to inject a delay in the start of the program to allow them time to recover their footing and figure out how they were going to proceed. Bear in mind that the East Coast of the USA was starting off in a vastly different situation than the Midwest was which

 

influenced the different paths forward chosen by each CLEAR chapter. It turned into a favorable formula for the setup of the 2020 year, as this placed the Denver chapter in the hot seat to be the experimental group who got to trial the virtualization changes to the program first and passed along the learnings to Philadelphia so they could minimize the novel challenges we were uncovering along the way and host a better experience. This offered yet another iteration to which the formula can be evaluated and tweaked without having to wait another year to try something different. It allowed us to iterate quickly and early, and when we found something that worked, we brought those learnings forward for each chapter's benefit.

When the pandemic was hitting home, both chapters put forward discussions about what it meant to continue forward. Honestly, we entertained the idea of not hosting the program in 2020. We also entertained delaying the start of the program for a few months. At the end of the day, both chapters decided that it was best to figure out a path forward and seize the opportunity. The mindset was that we needed to choose a conservative route forward, and the most conservative path showed that this virus would possibly be impacting our lives in 2021 and beyond. If 2021 was going to be a repeat of 2020, we needed to take our lumps sooner rather than later and be leaders in this space. The Committee should be applauded for their hard work keeping the program together and staying the course in the face of such adversity!

# 4. Silver Linings

## 4.1. The Technology Leap

Being a technology company and having a strong culture of innovation was essential to transforming the workplace overnight. This created the spirit of challenge and curiosity to explore the question of this mentorship program's ability to survive this conversion. We explored this question in good faith and inevitably the tool that brings us all together isn't a great tool for making us feel connected. The same online environment we create for learning and sharing information in a top-down approach inevitably leaves a gap for people to socialize and interact. Bringing large groups of people together is a powerful top-down way to distribute information- this inevitably creates a fast ingestion of information but leaves no time for the social aspects of working on a team. Collectively as a society, this online format should be considered a new venue, and will influence different personality types in new ways. We're naturally not going to get a lot of lateral networking opportunities in this top-down format. To with; we must find ways to synthesize effective team building in a virtual environment. Each of the CLEAR Committees has found different ways to cope that are meaningful to them. Philadelphia, for example, gives a five-minute break before starting their calls. Denver dedicates this time for small talk and surface level conversations about how we are doing in our personal lives. It's important to start a practice now of taking some time to have this relaxed conversation in order to build a strong team that will be able to respond to new challenges.

It's tough to say, ultimately, how the cohorts for the class of 2020 will feel at the end of the year and how satisfied they will be having undertaken this experience of Mentorship in a new format. By the time of publication, the ending of the story will not be known and could be covered in a future update to this paper if there is enough interest. The concept previously discussed about creating time for networking didn't occur to the Committees until feedback from the Mentees started to come in through surveys and our monthly check-ins. In hindsight, it feels like an obvious miss that we didn't seize on this opportunity sooner in the year. For next year, the Committees are considering changing the curriculum to build the socialization events into the third month in the program after the teams are formed and capstone proposals are due. The conclusion CLEAR arrived at is that it's important to lean in early and spend time strengthening the team and interpersonal dynamics early and often. Not taking time up front when

 

forming the new cohort probably held Mentees back from feeling connected to the rest of the Mentors and Committee Members who have already got previous experience with the program. Another piece of feedback CLEAR has found to work for these socialization opportunities is to create small groups for these interactions. The online format doesn't necessarily scale well beyond more than a few people in a conversation at once- the upper limit is probably around five or six individuals. After a certain point, large groups are going to be counterproductive to the networking experience.

## 4.2. Changing Spaces

Technology has opened new doors for us, but it would be worth mentioning that working from home shouldn't mean that we always feel obligated to be working from the same desk. There are some obvious limits to what's acceptable on camera − that said, it's possible to both work and be in an enjoyable space at the same time. After all, why shouldn't we make lemonade when life has handed us lemons? This doesn't work for everyone − someone must be facilitating and running the agenda. The result should be a relaxed group setting where the team can take a call in a fresh space and recharge themselves mentally. Take turns leading on different occasions so everyone can get the benefits from this practice.

Having a home office should be a consideration for every professional person or family when they acquire a new residence, post COVID. Working from the kitchen or the dining room may be effective for a few weeks or months, but it's not sustainable in the long term. These statements are made with consideration and understanding that it's not that easy for everyone to just do. But if professionals are finding themselves with a move coming up, having dedicated office space will be the equivalent of having a guest room in your home. It's probably something new owners are going to be actively looking for going forward, and reflecting on the pandemic, it's probably a good thing to have in general. COVID isn't the first or the last disease to transform the world − in the spirit of using this tragedy as a learning experience and a preparation exercise, it would benefit us all to have dedicated workspaces at home that we can fall back to should there again be conditions to keep us from socially collecting in an office together in the future.

It may be helpful for leaders to set some expectations for what a productive home office should be comprised of as employees are looking to make changes to their homes. Some things that should be standard in a home office for a technology professional would be a dedicated desk or workspace, at least one external monitor, and a door that can be closed. Ensure that the natural and artificial lighting can be controlled. Employees should have their own dedicated Internet connection with reliable Wi-Fi or direct hard line connections to their cable modem − not borrowing Wi-Fi from a neighbor. Should you have a family working and learning from home, consider upgrading your service if that's an option to support the needs of the family unit.

Most families and individuals renting or buying domiciles in 2019 didn't consider additional rooms in the off-chance that they'd be working from this space long-term. The reason is simple − homes and real estate are expensive, and it would have been cost prohibitive to try and plan for that pre-COVID. Professionals who are changing spaces in the COVID market should actively seek out situations where they can create a workspace that will suit their needs for the next few years − possibly even for the long term. Employers are also going to have to be flexible and compromise, here, too. If employees are going to be moving a little farther away from their jobs to be able to reasonably afford this extra space without assistance, we need to remain flexible with working from home policies as the situation (hopefully) changes in the future for a more traditional in-person experience. It's not convenient to buy/rent/sell homes and move families on a whim, so we should be mindful about permanently allowing work from home flexibility in the future for everyone as the commute times may become a new factor as employees move to areas that fit their new needs.

 

## 4.3. The Work/Life Balance

One skill that can be sharpened like a sword during COVID is patience. Things are probably not going to go back to normal for quite some time − possibly years − possibly never. We all need to have a survivor's mentality, and it's important to keep this in mind to maintain a healthy work and personal life balance. This new normal has finally removed the burden of valuable time spent idling in traffic and instead gives us the opportunity to become stronger families. It's exciting to think that this is a chance to break out of the mindset of forcing ourselves into the office every day. Just as a general note, not even specific to the CLEAR program, everyone should be practicing strong mental health routines and habits now and be prepared to settle in to this new normal. We have seen varying degrees of success with our CLEAR Mentees retaining this balance. Unfortunately, our impressions would have us say that most of the Mentees struggle with breaking away from their desks and getting outside for fresh air and exercise. This is a dangerous trend that has long-term health implications. It takes energy and active polling to reach into this level of concern for our coworkers as human beings. Those of us who are taking care of ourselves are doing their best to help break the barrier down and remind our colleagues that if we are to emerge from this situation, it's going to take a lot more effort than usual to stay healthy and strong when so much has been taken from us.

Non-traditional meetings can be a fun way to change up the scenery and find a way to interact in a small group. All government advisories should be strictly adhered to, but within that framework there may be a comfort zone that people can live with to maybe go for a walk in a park, a hike, or on a bike ride. This is a great opportunity to refresh yourself outside and build a relationship with someone in a safe manner. This may be more difficult in urban settings but look for creative ways to use your lunch hour or set a 7:00 a.m. meeting and go for a hike before work. COVID has created a mentality that it's OK or expected that you're working from home constantly. Most employees surveyed during this pandemic feel like they are trying to outcompete their peers and that they are literally competing to keep their jobs. Especially for newcomers to this landscape, it's important to hear that within reason, you are empowered to spend time in other meaningful ways.

It's important to remember not to burn out. We all must find ways to stay sane, and in case it wasn't clear before, COVID has given us all a fresh start on creating new routines and changing how we spend time in our lives. Start now, not in year three of the pandemic. Protect your physical and mental health – without these assets, it will be impossible for us to sustain our families, teams, and companies through this change. Use this as a chance to examine how you are managing your energy. Ask questions of yourself about if you're being stretched too thin, or if you don't have enough on your plate. Be honest − COVID has changed our home family dynamic and upended our lives. If your home life is drawing more of your time and attention, ask yourself what you do in your professional life that you can give up and get some of the time back. There will always be new ways for you to contribute and step up into new roles – we must remember to take care of ourselves first before we can share our best with others.

## 4.4. Bringing It Home

Some of the blessings of being forced to work from home is being able to see leadership in their home setting. Comcast leadership has opened themselves up and brought their employees into their homes and provided us with meaningful and timely conversations about how we're moving forward as a company. It's been a connective experience to be in such an intimate setting and it shows great leadership to be vulnerable. It's effective within the Comcast culture, and it's working. In a post-COVID world, we should leave the door open for these settings to continue to be experienced by our employees. In the meantime, it continues to motivate and set the tone for how we move forward. It's humanizing to see that your favorite executive has a dog that can also interrupt meetings when the Amazon delivery driver shows

 

up, or that another leader is into restoring an old VW bus. These are truly memorable distractions that help bring us closer together and feel like a family.

# 5. Key Conclusions

## 5.1. No Substitutions for the Real Deal

One of the hard realities that must be acknowledged is that trying to create this kind of mentorship program during a pandemic may be impossible or may be an exercise of diminishing returns. CLEAR had the benefit of growing in popularity over the past seven years and was able to build this culture of creating meaningful relationships and embed it into the Committee and Mentors. The CLEAR Program has concluded that there are no real substitutions for building that social capital in the electronic space, or perhaps the working culture is not yet there. The broad population is burning out from being on camera all the time. Over time this disruption may become more accepted and ingrained into our experience, but many people are struggling with the new challenges present in their everyday lives, plus this new work environment. When this pandemic does finally end, it's an important reminder for leadership at all levels to remember that we need to actively create time to value each other and have meaningful social experiences that bring us together. Programs like CLEAR will likely sustain themselves over the next few years because they have a strong culture built around their nucleus and can probably weather the storm. When society finds a way to safely come back to the workplace together, we need to embrace active team building and make this a priority for business. In the meantime, this will be the next challenge at every leader's feet. For existing teams, this problem may be diminished because of time spent together. But the next pandemic may be more deadly, and it's important that we embrace this opportunity to prepare our companies to survive greater threats to our businesses. Even if within our lifetimes we never have to be forced to work from home for a long duration again, we'll still have a stronger workforce that doesn't feel as constrained by virtual walls – it also opens the door to more diverse future employees who no longer have to be embedded in metropolitan centers. These teams are going to be central to creating and maintaining the technologies that run our businesses, and we owe it to them to invest heavily in their success. Virtualization challenges are not going to go away, and the longer we operate in these conditions, the more exposed we become to the challenges of starting new projects and forming new teams. The author feels like there's a lot more work to do in this space, and we may have to change our perceptions about how we're evaluated at doing our jobs and what performance measures are weighted towards.

## 5.2. The Investment of Time

We have probably all felt this experience in 2020 that time is simultaneously going by faster and slower. The Groundhog Day cycle of getting up and being on camera day-in and day-out has created an emotional and mental crash where some have adapted, and others continue to struggle. This means that what we did before, now costs us more. There has been a big shift in the investment of our time, and ultimately, our energy. It takes significantly more energy to focus on listening and watching at the same time, plus incorporating our natural social anxieties about being on camera means that it takes a lot more energy and time to do everything with video.

Consider going 20th Century – especially if it's a meaningful relationship. A phone call can feel like something we used to do a lifetime ago. It is a bit more impersonal, but focused listening and engagement on a meaningful level in a one-on-one situation can create the same meaningful connections. The great thing about phones is that we can walk around and be free – watch a nice sunset, watch a child

 

play – passive viewing experiences allow us to have a little room for our minds to naturally wander while still allowing fully focused out-of-band engagement.

With this oversaturation of communications taking place in both the visual and audio formats, we should be honest and consider that not even a year ago, most of our meetings that took place remotely were done over the phone. Taking time to call someone instead of setting up a video conference can be a nice break for both parties. It's much easier to move yourself outside to get some fresh air, or take a small walk, rather than being tied to a desk or reliable Wi-Fi to hold that face-to-face conversation.

Being on camera all day at work is exhausting and creates an even more energy draining experience than we've been used to for our working lives. We should consider trying to remove some of this extra energy and go camera off with intention. Can you move non-critical meetings to audio only? Is it possible to save our camera energy for the important meetings? Leaders should be encouraged to set some intentional boundaries, so we avoid burning each other out. Maybe a "No Camera Friday" or something easy to show that it's OK to turn our cameras off, and not have to be a TV anchor for the day. It's impossible given the current working climate to assume that everyone is always going to have a perfect hair day while dealing with family and children and working from home for the 200$^{th}$ consecutive day in a row. Even the most consummate professionals will find that the energy must come from somewhere, and productivity is probably the first to fall to the wayside.

Another mindset we should all look at making a shift towards in this pandemic is to trim our calls down to 30 minutes at a time, 60 max for critical content. Time is a commodity in a pandemic, and there are only so many hours in a workday. It may become necessary for corporate cultures to shift away from so many meetings and allow employees half or more of their work week to dedicate towards productivity. In the always-on environment in the pandemic where we're all trying to save our jobs, it's important to reserve our energy for things we can actually produce and create. It helps us feel fulfilled in our roles and creating output for most people is a fulfilling experience. At the end of the day, it's all about carefully balancing collaboration with productivity. Perhaps the impact of COVID has shifted us into a modality where we're trying to maximize or overcorrect for collaboration in favor of productivity. It may be helpful to trim out unneeded calls from our calendars and pull back on commitments so we can self-manage this balancing act on our own accords.

CLEAR struggled with this a lot this year. Early on we took a poll to see if our cohort wanted to keep our sessions into one single day, or if we split them up over two days in the month. Denver and Philly both voted to keep their schedules into a single day, but for 2021 this decision will be revisited. CLEAR has such a dense agenda during a non-COVID year that we often found ourselves underbudgeted for time and our sessions ran long. Even when we had our sessions fully prepared and time boxed to our expectations, we found it difficult to keep the group together electronically over the course of the day. A continued theme was that everything seemed to take a bit longer when we were asking groups to collaborate. When the CLEAR Program sets their schedule for 2021, we're going to be pulling back on the content to try and consciously open up any group work to deliberately have more socialization time included. Next year's practice should embody more robust group time to allow not just focus on the learning topic, but also for the social interactions within the group.

Another learning point was not scheduling more time up-front in the year. We learned as time went on from our monthly check-ins and surveys that the networking wasn't happening well. For next year, we're going to build more time in the program for this socialization early on after the teams have been formed.

 

## 5.3. Making Time to Take Time

It bears repeating again, as this is a central thesis of this paper, that time is a commodity in this pandemic. With the experiences we've seen running the CLEAR program, we've noticed that it takes a lot more energy to do the same things we used to do pre-COVID. It's hard to imagine that technology would be the barrier, but in a way, we're mismanaging ourselves into this modality. It's easy to see why, because the desire to socialize and have a more interpersonal experience will always be there. The old expression says if you're going to do something, you might as well do it right. This mindset extends to mentoring and networking − if you aren't making time to get to know someone better, what are your expectations for the relationship to grow and develop? If time is considered valuable and sacred, it places more meaning on those moments that are spent together.

## 5.4. Recalibrating Expectations

Once committed down the path of hosting a 2020 CLEAR cohort, it was important to begin managing our expectations for the year. As a Committee, we discussed our threshold for success this year wasn't the typical 100% graduation rate we normally target, but if we got 66% of our Mentees across the finish line, we'd have done a decent job of holding the program together. As time passes and without knowing the future, both chapters are likely going to approach a 100% graduation rate during the pandemic, which is a testament to the leadership of both chapters, and the networks of professionals that are being created and sustained by this program. As chapter leaders, we felt it was important to not let our Committee get singularly focused on repeating the past seven year's performances. It was more important to move forward and make mistakes than to be distracted by metrics we would normally hold ourselves accountable to during a non-pandemic year. It was important to give ourselves that break, mentally, and lower our expectations and the measurement of success. That action relieved the pressure, allowing the committee to focus on the larger issues of restructuring the program in the virtual setting and solving for those problems. We didn't expect to get it all right this year, but it was important for us to get in the batter's box and start taking swings. There will still be several months of the program that transpire after this paper is presented − there are no guarantees that the current trajectory will hold. But we are hopeful that as an entity, we've learned enough from this year to reimagine the 2021 structure, and simultaneously having the experience for running the program virtually.

## 5.5. Attrition

It's important to note that CLEAR wasn't immune from attrition due to the pandemic. There was a pair of Mentees who withdrew from the program in 2020 that was a direct result of the pressures placed on their personal and professional lives. As a Committee, we mentally prepared ourselves of the possibility of sustaining major losses as we transitioned to the virtual environment.

## 5.6. Moving Forward

When the pandemic was breaking in the USA, the CLEAR program had to make a decision. The syllabus takes place over the course of the calendar year, with each cohort graduating after Thanksgiving in early December. What were we to do? 2019 was the most successful year of the program − with an eye for founding two additional chapters in 2020. We had varying perspectives about the duration and intensity of this change in work styles, and nobody had the crystal ball to give us a prediction where we'd be in four weeks, let alone four months. The Philly and Denver Committees had to discuss this and quickly reach an answer about how to move forward. Should we pause for a few months and try to start late? Or do we cancel 2020 altogether and hold out that 2021 will be back to normal? The Committee had a lot of doubts about the effectiveness of taking a 100% physical program and transforming it overnight into a

 

virtual one, especially without any prior thought or preparation. Most of the foundational concepts and principals for the constructs of the program centered around being there in person, distraction free, and deliberately creating time for these horizontal networks to grow. The projects are a great vehicle for the Mentees to drive on this journey, but as was discussed previously, the strong relationships were truly the key outcomes from the program. It has taken and will continue to take a lot of time, good ideas, and bad ideas to figure out what works to make up for the ground that COVID has taken from us.

The author would consider the decision to move forward under complete uncertainty to have been particularly wise choice in hindsight. One prominent theme that has emerged during COVID is that scientific and medical information keeps evolving and our company is also changing the dynamics and conditions on which we could engage each other in person. Moving CLEAR to a virtual space allowed us to move forward and face the challenges of this space head on. The author is the Engineering Lead for the Denver chapter and on the inter-chapter panel, allowing visibility to how two geographic locations within the company tackled challenges in similar spaces, how effective those problem-solving strategies played out, and the unique challenges that were surfaced from each location. Being able to have a larger sample size effectively doubled the interactions and outcomes and provided a meaningful backdrop of experiences to base the advice, guidance, and observations that are foundational to this paper. The goal of this paper was to provide a deeper view inside the CLEAR Mentorship Program, and to serve as a mirror and a reminder that even a prestigious institution like CLEAR is not immune to the challenges presenting themselves during a pandemic.

This paper has discussed the sustainment of an existing mentorship program with a historic context and rich culture. What this paper does not address is the fact that life must continue forward outside of CLEAR. Leadership will be forced to contend with company reorgs and creating new products as we have done in the past, but with new challenges and barriers. How will leaders look to solve the issues of creating new teams and build those horizontal relationships as we found new teams, or create new organizations? On paper, the exercise is simple, but the author believes that this will be a large question that's on CLEAR's horizon for years to come, as well as the leaders within a given business. The crux of the problem isn't how to move forward when we've built an amazing ship, we're navigating to a destination, and have the winds at our backs. What do we do about the boats that haven't been built, and the teams who haven't yet set to sea? CLEAR's issue of adaptation may be an opportunity and a challenge at the same time − on one hand, CLEAR had to change directions, not create something from new. It's the author's hope that many of the challenges presented with virtualization in 2020 would be points of interest for anyone starting a new team or for moving an organization forward and is hopeful that the lessons learned here will be a useful analog for how we each have to move forward.

In conclusion, the author will go out on a limb and put a prediction into print about how long it will take most of us to adjust to these conditions − barring a vaccine or other breakthrough. 2020 will feel like the year that didn't exist for most people – we're in the denial stage, still, especially in the USA. 2021 will dawn, and there will be a realization at some point where people will observe that we've been under these conditions for a year, and the reality will start to sink in – acceptance. By the time 2022 arrives, the Groundhog Day novelty has faded, and we'll be in the new normal. 2021 will see some oscillations as we struggle to cling to the past and the reality of coping and dealing with the new normal − in this year do we finally start to achieve group awareness that this problem is not temperamental and employee cultures will become more accepting to this change? We probably won't have the full focus of problem solving in this space achieved until sometime in 2021, with 2022 becoming the foundation for the new normal.

Stay healthy and safe.

# 1. Introduction

Deployment Engineering in the cable sector is where the rubber meets the road. These groups are responsible for taking products from the prototype stage to a scaled solution across the entire enterprise. Deployment Engineering is an in-house specialty that creates the cloud resource experience and delivers that to the local headend. An idea begins much like how a single raindrop falls thousands of miles upstream, then gathers and runs to the ocean. This is a useful analogy for the lifecycle of a product, too. By the time it reaches the ocean – in this analogy, our customers -- it reshapes the environments that it passes through. Cable products can be based on web applications, but when dealing with real time video or streaming video, it becomes impractical to distribute content centrally, and must be decentralized in order to maximize efficiency. One can simply look to the Content Distribution Networks (CDNs) that the industry's Multiple Systems Operators (MSOs) have spent billions of dollars building to move video to the edge as evidence of this truth.

Deployment Engineering holds the unique perspective of being at the nexus of product creation and customer integration. Over the years, the methodologies change (waterfall, agile, lean, scrum, Kanban, CI/CD, etc.) to embrace new ways of tackling problem spaces, and offer meaningful ways of reinventing the wheel. Such methodologies will continue to change and evolve with time – however, the problem space of deploying products at an enterprise scale has a core foundation of challenges that are common to nearly all products. Therefore, it becomes more critical for engineering leads, architects, and executives alike to understand the environment and problem spaces than it is to be masterful of any given tool used on the same old problem. Whenever shifts occur to adopt the latest methodology, as an industry, we put our momentum at risk and can be prone to recreating and reliving the same mistakes. We sacrifice the valuable experiences and lessons learned to move to a new methodology, and in doing so tend to be more focused with how we're operating in the new system rather than staying focused on the big picture. This paper aims to reinforce the common elements within new products and deemphasize the tools used to build them. In other words, technique matters more than the actual tools used to build something.

## 1.1. Traditional CI/CD Model Overview

It's helpful to take a moment to acknowledge the landscape of contemporary software and hardware implementations in an MSO. An appreciable trend over the past decade is to build your own system, using off-the-shelf vendor hardware. In some cases, that extends to the development of in-house and at-scale technology solutions that can be syndicated to business partners. It's a high risk, high reward endeavor, and being the first to market can be the difference on that investment paying out or not. To that end, the current method of maximizing efficiency and speed is the Continuous Integration/Continuous Development (CI/CD) pipeline. Some define this acronym as Continuous Integration and Continuous Deployment. Others, to be tongue in cheek, call it Continuous Integration and Continuous Disruption. In any case, and if not managed properly, CI/CD can become a dangerous feedback loop that pulls on products like a black hole -- and can grind a product's market introduction to a halt.

Why are cloud services successful to the point of creating a $150B per year industry? Because the cloud offers the most direct and rapid route to putting bits on the pipe. The ability to instantly scale one's computing needs is insanely attractive, but it doesn't come for free. For web services, where traffic is bursty and light, and done over a Transmission Control Protocol (TCP) connection with retries, it's relatively affordable to purchase CPU, memory, and disk in a datacenter, spin up an application, and you're off to the races. In the cable video portfolio, however, it's not always possible to create a good user experience by running applications out of a hosted datacenter, and the need to move large volumes of data can be cost prohibitive in leased space. Often the locations of national and regional data centers can be hundreds of kilometers from customers, which makes them impractical. This begets the need to build

 

custom hardware solutions at the edge. These products are typically homed at the edge, or use tiered caching models to distribute efficiencies of storage and transport. One of the main trappings of CI/CD is that it can be "loved to death," meaning it can be so appealing that it becomes overused and negatively impacts the outcome. This vulnerability that presents itself with many modern methodologies, including scrum, agile, lean, etc. CI/CD must be mindful about the state of the platform and the ability to make architectural changes at scale. Without this perspective, if the sole focus is on constant delivery, it's easy to create more work than resources can support, and accumulate unmanageable volumes of technical debt. Technical debt is usually accumulated when decisions are made that favor short-term and easy solutions, rather than using a better approach that would take longer. Tech debt, like financial debt, carries interest and makes it harder to implement changes to a product. For best results, a careful balance between change and progress must be struck that emphasizes the maximal efficiency of this model, rather than the act of change and flexibility itself.

## 1.2. Multitasking and Task Changing

It's no secret that there's benefit to being able to simultaneously handle multiple workflows. Modern CPUs are a fantastic example of being able to handle large workloads and change tasks, for virtually an unlimited amount of time. A CPU doesn't care what kind of processing it's doing -- it marches along endlessly forever. It feels obvious to say, but human beings are not CPUs. A certain amount of task switching and busy work is helpful, but taken to extremes, it can quickly overwhelm teams of humans who aren't able to work around the clock. To use an example, if you were to write a sentence ten times on a piece of paper ("I am a very good hexadecimal mathematician.") using two different methods and timed this exercise. It takes a lot longer to write one letter on each of the ten lines serially, rather than writing the complete sentence ten different times. Task changing can be done so rapidly that all meaning is lost in the work, and the rush is placed on the quantity of the output, not the quality.

Taking this example a step further, operating teams in this manner, where humans and projects are multitasking and changing tasks constantly, is counterproductive. When a product must be re-architected or a code base refactored, it's a common trapping to forget all the newly accumulated technical debt. A tendency is to keep pushing forward, without being mindful of the train we're pulling behind ourselves. A train can't stop and take a 90-degree corner, and it's not practical to pick every train car up and reseat it on the tracks when a product takes a turn. Good product owners and engineers know that it's important to get all the work done before the train arrives. You can't lay track under the train and you can't survey your route one mile at a time. This paper doesn't assert that we make less changes or stop enhancing and evolving our products, but rather that a longer view is necessary when considering the prioritization of features and functionalities that yield the best long-term outcome. All the short-term planning in the world can't make up for a poorly managed long-term goal, or a product that isn't ready for customers. Directional changes need to be planned and managed, especially including solutions for moving the platform and keeping it together through these transitions. Very often the focus is on the locomotive doing all the pulling up front, but if the cars fall off the tracks behind it, any first mover advantage is jeopardized. Maybe the next train can survive without derailment, but isn't it more important for customers to get it right the first time?

## 1.3. The Eighty Percent Rule

To create a construct to help balance progress and stability, the Eighty Percent Rule is a good tool to evaluate both micro and macro levels of decision making related to industrial innovation. It's instructive to not get caught up "chasing the nines" when building a proof of concept, but rather to start out with a much looser framework. "Chasing the nines" as it relates to product reliability and uptime is something that comes later on down the development path of mature products. In early product stages, the Eighty

 

Percent Rule paves the way to make active decisions about overall readiness for providing the nines of reliability. Only after obtaining this benchmark is it appropriate to begin working towards that plateau of of uptime and reliability.

The Eighty Percent Rule can be loosely defined as a means to strike a balance between efficiency and speed. The guiding idea is that there is a need for product owners to honestly rate the product experience, from the position of the consumer, and knowing its technical shortcomings. Simply put, if you wouldn't give your product an honest B rating, then it's not ready to be put in front of customers, let alone mass deployment and exposure. If a feature isn't going to function at 80% efficiency or more, it should probably hold.

The Eighty Percent Rule is also helpful for resolving discrepancies – because it's usually impractical to think in terms of getting something absolutely right. Corrections are expected as part of the process, so the aim is to get it mostly right, in order to resolve gridlock and move forward. This also serves as a nice goalpost to evaluate forward progress. The Eighty Percent Rule is designed to favor and reward long-term planning. It would be a foolish task to think we're going to show up and win a marathon when we haven't done any preparation for the race, so it's important to know where you're going in order to steer your product farther down the road. One of the tradeoffs of the Eighty Percent Rule is that it can take time to build the necessary momentum to get a product launched; it's important to keep in mind that this construct doesn't necessarily include a fast start, and it takes time to move with precision. If products are built with these key concepts, the time investment to moving quickly is minimized.

## 1.4. Hitting the Moving Target

The final piece of the puzzle requires our leaders to think in three dimensions. At a critical junction, a product goes from a small patch of trial sites to a multi-million-dollar production across dozens of geographic locations. At this point scale becomes a more heavily-weighted factor when making decisions about a product. The more knobs turned, the longer corrections will take to execute -- but oftentimes product leaders can inadvertently forget about reality testing decisions that can get made in haste. Was sufficient time budgeted for changes to be cascaded throughout the system? Was time budgeted to pay off technical debts, or did the trajectory lead straight into the next development hurdle? This methodology can appear to be cumbersome on the surface. In practice, however, managing low technical debt prevents a product or a team from falling into the abyss. Changes that are more deliberate and paced tend to yield better decisions about future planning. A useful goal is to consider the best decisions for the month, not the moment.

A premature commitment to a product build can have the same effect as changing a product too rapidly. Essentially, it's two sides of the same issue: Scaling an enterprise product is not assembly line work, and the best way to do that, especially with a lean team, is to keep the product flexible. When the product reaches this phase, it's useful to focus on the realities of expontential scale. It's no longer trivial to make changes to a few sites by hand anymore, or to rebuild the system from scratch. Any change is multiplied by the size of the deployment footprint. Making an architectural change at scale? That's going to be costly to go back and redo all those sites a second time. Need to make a global configuration change? Even a simple task can take hours when multiplied over a large footprint, let alone complex changes. Have to make several changes to a product? Validating that all those changes were made correctly can be error-prone, especially if a human must do all that swivel chair work. Incredible amounts of cost and resource losses can accrue very quickly at this stage -- because hitting a moving target is difficult. We have to be mindful about predicting where we're going to be upon impact. A simple miscalculation can cause a missed target -- which results in a wasted first attempt, as well as time lost to take another shot.

 

When time to market is critical, making the first shot will yield the best return on investment. Customers won't be impressed by a half-baked product, and first impressions are critical to new product adoption.

# 2. Launching A New Product

## 2.1. Universal Truths

The information outlined in subsequent sections of this paper intend to reinforce or structuralize what it takes to rapidly deploy a new product to the market in the cable sector. These tenets are reasonably ubiquitous, regardless of work portfolio, and can be considered common regardless across frameworks.

## 2.2. Challenge of Scale

### *2.2.1. Inventory and Accountability*

In 2020, some take for granted that modern cloud computing products have built-in reporting, monitoring, or telemetry features. In some products, the physical layer has been completely abstracted, so that consumers don't have to manage that layer of infrastructure. But when a company sets out to build a new product at the edge, a lot of those efficiencies stop at remote access, and each hardware manufacturer has its own interface and operating system. There may be a common management interface, or SNMP trapping, but it's worth recognizing that to the operations product owners, it looks like a blank slate. If the hardware platform is an internal build, it's most likely going to require specific firmware revisions, or specific driver requirements. When this hardware platform serves dozens or thousands of devices, visibility across the footprint is necessary, to audit for discrepancies. At a minimum, telemetry should be built into the product, to inventory critical platform components, such as: installed RAM, SSD wear rate, drivers, firmware, BIOS, fan status, power supply status, and temperature alarms, among others. Such visibility is a minimum requirement -- for further efficiencies, auditing capabilities can be added to actively seek out exceptions and raise their visibility, resulting in corrective action. Mastery of cloud components includes the ability to not just audit the footprint, but also to take components out of service for patching with minimal to zero intervention. After all, once the product is running, it's likely going to be run by a lean team, so this functionality will realize a vast amount of utility through the end of the lifecycle of the product. It's important to be able to build into a product the ability, early on, to know how many exist, where they are, and their current state. In order to move faster, having the ability to orchestrate the hardware layer is an essential foundation to any enterprise product. For best results, it is one of the first components at the integration layer, built after the proof of concept is working.

### *2.2.2. Monitoring*

Monitoring is another component that is often overlooked until the product gets closer to launching to customers. There are advantages to beginning to monitor the hardware installations coincident with the system being built, but be careful -- this can also be taken a bit too far. Example: A product launch involving SSD drives, which, in older installations, had completely worn themselves out -- before it was ever used for customers. Had this been monitored earlier, the issue could have been identified with an immediate impact assessment because of good inventory practices. This kind of surprise usually happens near the moment when the equipment is lit up with customers, and it throws another technical barrier in front of the product launch. And because the solution usually involves coordinating either with a vendor on site or asking for help from local site personnel, it's not exactly the fastest procedure, and usually ends up involving multiple resources. At this point there are usually a host of other critical issues being

 

addressed before launching the product -- a good project lead will work to identify the platform's critical components, and build systems to monitor and assess system health so that a lean team can operate the platform with maximum efficiency.

While it is critical to build monitoring early and often, it is also helpful to suppress or mute production alarms while the system is being built. If the system is in a full production monitoring mode before customers are on the equipment, that usually means change management tickets need to be coordinated to make updates to the platform. This creates additional overhead by means of adding additional layers of process to the workflow, and across many sites this can add up quickly. While the system is greenfield (in this case, meaning no customers are on it), the platform may need to change frequently to keep up with the pace of the developers. For best results, build alarming into the system early and schedule regular reviews of the alarms to make sure the system is behaving as expected. But don't paint your teams into a corner by creating additional administrative overhead for anyone making changes to the platform when there is no exposure to customers. A good monitoring system, when implemented early, can help identify problems in the platform and surface them before they become critical. Maintaining a platform, at scale, while building it, carries a higher up-front cost, but the payoff resembles that data center experience that every product wants to operate in. By conquering the hardware footprint with good inventory management, and having the ability to automate upgrades and by monitoring those investments, products are in a very good position to sustain a much more rapid CI/CD model.

## 2.3. Challenge of Change

### *2.3.1. Data In, Data Out*

This paper will conclude with some insight about users and user experiences, as it relates to expediting customer hardware deployments. At this stage, it's useful to keep in mind that it is when products scale that the most can be learned about the platforms that were designed. It's unacceptable to just have the data if it can't also be managed. CI/CD wants to always be moving. In order to stay highly effective, which is to say moving without stumbling, any management systems that are built should prioritize consideration of the teams who will ultimately run or use the platform, day after day after day. Ideally, both back end and front end teams coordinate on the architecture and data flows, to make the language and technology decisions. After that, how do the teams go about building the system and adding components? Do they build a UI that allows for manual data entry, so configurations can be managed in a central database? Or do they build a protocol and an interface to onboard devices to an endpoint, and have devices send their configurations into a central repository? The best answers here depend on how the data needs to be maintained, and there may not be a wrong answer. Now that this large data set has been created, do the teams have the ability to make bulk updates across the platform? Not everything needs to be mutable, but building it such that the most common data points that can change are scalable is useful. Also: Does the system expect that it can be handled by a database admin, or are end users also empowered to manage the data?

Building on the previous tenets of inventory and monitoring, data is the next piece of the system that must be reinforced. This user interface may account for the needs of users for several years to come, so this step is critical to getting right. The cold reality is that once a product is launched and there are customers on it, operators tend to become risk averse. This can sometimes mean having to settle for a mediocre UI. A good timeline to keep in mind is about ten years. If the platform can be put to good use for about a decade, before having to rebuild it, that's a good system. Such timelines are also useful for future planning: can any shortcomings of the system be tolerated for the next ten years? Or will running the platform always require more resourcing? How does one not only support the platform, but any syndication partners, too? What kind of example does this set within a company if its enterprise tools are

 

subjected to compromise and work-arounds, just to perform daily functions? Put another way, does the platform inspire your teams to do their best work?

### *2.3.2. The Hardware Lifecycle*

Nothing in the hardware computing world lasts forever. In 2020, a best-case scenario for a syndicated product is a lifespan of about a ten years. Some older systems in the industry, built in the early 2000s, could have easily been designed to last ten years -- but as the product space for today's technology gets more crowded, stagnation becomes unprofitable. Old equipment and legacy technologies will end up costing money in the long run. Because the pace of innovation and competition is relentlessly increasing, hardware platforms are unlikely to have the same lifespan they enjoyed twenty years ago.

It may not be possible to know what a replacement hardware platform will be, but when building a platform, it's useful to ask suppliers questions about how long that model of equipment will be in service. There are no guarantees, and it can happen that a custom hardware product may be use equipment that is near the end of the manufacturer's hardware refresh cycle. Or, the opposite can happen, in that the appliance could enjoy a foreseeably favorable lifecycle. Gathering data points that can inform an estimate about your hardware's expected life span will help guide any decision making about how much time and energy are invested into the platform. While we don't want to withhold functionality or usability from the users, it may be prudent to investigate what compromises should be made if the platform is going to have to be rebuilt for technical reasons and in short order.

## 2.4. Meltdown Intel Security Vulnerability – Retrospective

Catastrophic events in the digital world are uncommon, but they aren't impossible. Looking at a fairly recent example, the Meltdown Intel security vulnerability, discovered in 2018, triggered major impacts on the hardware and software world – especially for delivering video. When this vulnerability was disclosed, it brought home a very real problem to an internal project involving thousands of Intel Xenon CPU processors, distributed across dozens of locations, to do real time linear encryption and ad insertion. The performance of the product, at the time, was calculated based on a a certain density of the hardware solution which met the product's architectural needs for streaming throughput. After the Meltdown vulnerability was published, the resulting software patching of this vulnerability generally resulted in a performance loss of the CPU. If your product is very CPU dependent, a performance loss can have major impacts on its ability to service the needs of your customers. These kinds of incidents can have major architectural impacts to custom hardware products. This kind of vulnerability doesn't happen often, but that such a sizeable one did within the last five years is a good reminder about diligence in system design.

If you have a CPU intensive product, and something like Meltdown happens again, how do you quickly evaluate what options are available? How does your product recover and move forward? What if it costs money because in choosing not to compromise on security, you trade off being able to support the service levels of syndication contracts? Is it possible or cost effective to throw more CPU at the problem to make up for the shortfall? Do you focus on gaining efficiencies from the software and try to get that to be more performant? Or does the product team need to look at other options, to determine whether there is a critical tipping point that will need to be crossed in the design? As the investment into a product increases, it behooves product owners to be able to immediately materialize specific information about their platform to make the most informed decisions possible. If another Meltdown happens tomorrow, does the product have the telemetry in place to support good decision making? With so much invested into building these products, it's borderline negligent to build products without telemetry. Product owners should be able to assemble a data set of information about their platform in time for their next meeting, not in a few days. This same principal applies to other consumables for your product -- whether

 

it's CPU cycles or network bandwidth, it's going to be critical to have real data about your product to make the best decision to build it on or ahead of schedule.

### 2.5. Who Can Move My Cheese?

Each product is different, and with this uniqueness comes a host of common and individual characteristics that are important to manage for any given system integration. The previous tenets of this paper discussed how essential inventory and monitoring are to building a good product. If there is an outage and teams are escalated to troubleshoot a problem, time is money, and finding the problem becomes a race. A well-built product, that has visibility into all the code bases across the footprint, can quickly help rule out problems and steer troubleshooting in a positive direction. If the product can detect that there's a firmware mismatch, or that a node failed an upgrade, this can lead the production teams to the source much more efficiently. On the other hand, if there is a good auditing system and all the basic health checks for the system are coming back clean, then we can assume the problem lies elsewhere and quickly rule out the first layer(s) of the product. When systems grow large and there are thousands of data points to look at, humans are going to be not well equipped to spot those small exceptions.

On top of the physical layer, enterprise products are typically built with redundancy in mind. Oftentimes modern products are geo-redundant (meaning there are multiple co-locations where the loss of a physical facility can be carried by another peer). Is it possible to build this logical layer into the management of the product, so it can understand product states? Can the platform be upgraded without requiring a skilled operator who understands the specifics of failing the systems over, in order to perform work on the platform? The reminder here is that operations teams are generally lean, so anything we can do as product builders to make common tasks easier, or find a way to decrease the amount of time and skill required to accomplish maintenance work, is beneficial. A core theme for this paper is that to encourage and promote CI/CD, we MUST be designing products platforms that are easy to upgrade and efficient to operate. We need to eliminate the technical debt so efficiency is baked into the system. There's a benefit to being able to build and scale a platform with small teams, so the small teams of operators are best equipped for this task. Time and time again in cable we make the same mistakes by pushing unsupported products to market too quickly. We fail to recognize that the lean teams handling the build, the customer transition, and the operation of the platform are not going to be the best suited to find time and necessary skills to work backwards through the hardware stack to create a useful orchestration layer, after a product has been built. This is the crux of the issue -- products are created in a vacuum, then pushed out the door without proper supportive tooling. They change too frequently before getting in front of customers, and lack a good orchestration layer to manage these changes. Products end up behind schedule because they aren't built in a way that helps operators get them to customers faster. We must collectively stop this behavior if we expect to improve our time to market. We must stop believing that as leads, our job is done once the proof of concept is working in the lab. We must be invested in the management of the platform and product that comes after this idea.

## 3. System Users

### 3.1. Someone Else's Problem

Traditional product lifecycles dedicate much of their development to creating a working product, and frequently this comes at the expense of the end users. As developers, we often lose sight of the fact that the product isn't complete until we have system users and managers. The R&D road to successfully solving a new problem is often a challenging journey, and it's a common trapping to collapse across the

 

wrong finish line. So much time is focused on the problem that we forget to also deliver a solution that works for the end users. Engineers can become hyper-focused with building a working proof of concept and are allowed to completely ignore the complexity of the system they've built. Very often, the mindset of being aware or caring about the next phases of a project differs from the traditional build mindset. Often the product builders don't have any connection to the UI, the users of the system, or the operations of the system, which become a problem for "someone else". Or, more formal barriers emerge and takes the incarnation of a handoff between product development teams and operations teams, further exacerbating the problem. Building a management and orchestration layer then becomes automatically inherited technical debt. Operations teams aren't typically staffed or funded to build a UI that meets the complex needs of its users. Each of us in the industry, not to mention our end customers, can probably think of a product we worked on which had a compromised UI. The product itself works just fine but using the system to manage the product can come with a lot of work arounds or hang ups. This isn't the hallmark of an enterprise or world-class product, and as project leads aiming to improve our speed to market, it will be imperative to think through these challenges in a new way. The team who built the prototype typically has the most working experience building the product. Why wouldn't we leverage this experience and have this team construct the UI or the basic foundations for manipulating data within the system? Instead we allow these experienced teams to discard this knowledge and then the snowflake becomes a snowball rolling down the hill. The last barrier for innovation and correction of a management platform is exposing the product to live customers. The appetite for product owners to make big changes to their platform once customers are stably onboard approaches zero in a short time span. The risk vs reward construct comes into play, and with paying customers on your product, that is the most prudent business decision. We then find ourselves in a place where customer migrations override any needs for the operations teams to manage the product, and the window for making changes to the platform closes like a feedback loop, underscoring the importance of good tooling.

## 3.2. Accessing, Viewing, and Changing Data

Big changes don't typically happen to a product after it has been launched to customers, but in the beginning stages of a product, large changes and disruptions are much more common to the landscape. Couple this with productivity methodologies like CI/CD, which aim to continually keep making changes, and we have a recipe for creating a lot of technical debt. Often, we find that our engineering assumptions don't always happen in the real world, and we're forced to make pivots to designs and plans when new information presents itself. This is a common theme for prototyping – we make enough assumptions to move forward and reserve resources for when that doesn't always work out. When we must make these corrections, how will the middle and end users be able to access, view, and manipulate the product's data? At scale, changing data by hand is inefficient and impractical, so we need methods of importing and exporting data if they can't be manipulated in the tool directly. How will other users or teams consume the data your product will generate? Will other users or systems have access to the data? It's imperative to be able to make scale changes to a product, especially in the early stages of its deployment. Product leads need to be finding ways to minimize technical debt from the earliest stages of a product's lifecycle in order to sustain the changes needed to mature the product.

Balancing the needs of the product's users and the development cycles required to achieve those goals requires a delicate balance to be struck- products can't wait forever before they need to be exposed to real world challenges. With some foresight and experience, we can anticipate what our user's needs will be and find compromises in functionality that help us achieve rapid product penetration.

### 3.3. Why Did We Wait This Long?

Waiting to add users in to the closing stages of your product's development is an open invitation for rework, and by nature of what's been discussed in this paper, a challenging exercise with diminishing opportunities and resources. There is logic to building a prototype first before creating a UI, but we must acknowledge that there is a lot of development time ahead that need to be spent transforming a prototype into a world-class product that's not only fit for your customers, but valuable enough to market to syndication partners. There is a flexible window in building a product to introduce your users and start building for their needs. But when prototyping new products, we should be doing the basic research to anticipate what the users will need, and what data is going to be valuable, ahead of time, then bake that into the fabric of the product. We need to be building platforms that have the full vision for what the product needs to do, how it should behave, and how it's going to be used, from the earliest stages of conception. The users are what bring the product alive -- without them, it's just a bunch of ones and zeros.

### 3.4. Build a User Interface That is Meaningful; Build Your UI in a Meaningful Way

When you interact with something that is designed well, it feels natural and intuitive for how to accomplish a given task. UIs that don't feel obvious leave users frustrated and can create barriers to adoption. It's important to represent your company's investment by creating a UI that works well and works well for your users. A UI will seldom be perfect, as that is an objective measure, but having a UI that is in agreement with what your users want and need is central to the long-term success of the product. A UI represents your product, and a misrepresented UI can leave a user speculating about the effectiveness of the underlying technology. It's the paint job on the car, or the finishing materials selected in the interior. A sloppy build on the surface will be an implied reflection on the underlying technology. The UI should do all the talking and speak for itself, leaving all explanations absent.

As important it is to have a natural interface, it's also crucial to make sure that the UI can do all the heavy lifting for your users. If large, bulk updates must be made to the platform in order to maintain it, the UI needs to have a way to orchestrate these large changes without needing to involve a back-end user to facilitate the change. End users must be empowered to care for and manage their platform. If doing so is hard to use and time consuming, the userbase will not be inclined to maintain non-critical data. Working on the product will become tedious, and the employees supporting it will only do the minimum required to "keep the lights on."

## 4. Conclusion

Whatever productivity suite we're operating in for the moment is only as effective as the experience it's being built on top of. If we lack the vision and experience of working on a product through all stages of its life, we can compartmentalize deficits and defer responsibility without consequences. All this comes at a cost, and these assumptions we make about other teams who will pick up the slack usually means that there's not a coherent plan or vision for the lifecycle of the product. If we have no common vision or goal, and no means to get there quickly, we must expect that projects will meander through time and will eventually arrive in front of our customers. If we want to empower ourselves to take control of these timelines, we must start by being honest about planning around the full spectrum of the product's lifecycle at every stage with every team involved. We can't unfurl the Mission Accomplished banner across the windshield just because we solved the prototype challenge -- there's a long road ahead to taking this fledgling product to millions of customers. We find that when projects are run well and have this vision in mind from the beginning, they often start slowly, but finish quickly. It takes time to invest

in orchestration, management, and user requirements, and when platforms are being built, they are often done so through lots of learning (see: failure) and chaotic change. Product leads need to be mindful to create and build orchestration and management into the platform so that navigating all these changes and managing technical debt is factored into the platform. Our modern productivity suites emphasize rapid and dynamic changes, and without a proper support system for this disruption, we can quickly find our products in the middle of a vortex.

Building a product should be done so with the least technical and experienced users in mind. This is a great pipeline for engineering talent -- more experienced engineers design and build a platform, and more junior engineers can learn how to operate and support the platform. It's a great way to get to know your product and business from the inside out. As these engineers grow, they accumulate experience and knowledge of how a good product is built and operated, thus helping to create the next crop of engineers and leaders in the company. To do so, we must create meaningful UIs that make the operators passionate about their product and give them a sense of authority and accomplishment. We can't expect every end user to be a database administrator, therefore we need to build our systems for the most common denominator and prioritize functionality that will empower our engineers to be a force multiplier, especially considering that lean teams are typically "keeping the lights on" for these products.

By nature, prototyping a new product means to boldly go where no person has gone before, and building new world class products doesn't happen overnight. Often, it takes years of work to find the balance between budgets, expectations, technology, and resources to craft a meaningful middle layer to manage your architecture. Being able to keep an enterprise platform running at scale with a lean team demands that all the hard work be done up front and most of the challenges and desires of the users can be met autonomously. Platforms are born, and they are born to change. Flexibility, inventory, and scale are critical components to master when building and finishing building your platform. Hardware is going to change due to natural or unnatural causes; additional technology disruptors like those that surfaced in recent history are practically inevitable. The most effective product leads know how critical it is to account for consumables in real time and are robust enough to support large changes across the footprint in a short period of time.

In conclusion, project leads shouldn't wait too long to invite users into your system to find out all the ways your they will need to access and consume data from the platform. Establish relationships early and engage users directly about how they think the system should behave and what their pain points are with the existing system. For best results, build a user interface that removes technical burden from the operations teams so they can be left to an already important task of running, monitoring, troubleshooting, and repairing their platform twenty-four hours per day, 365 days per year. Product leads need to be mindful about not leaning in so far to the Continuous Delivery that we forget that the other half of the feedback loop is Continuous Integration. We can't simply ignore the process for the sake of meeting deadlines and pushing an unsatisfactory product out to our customers too early. Product leads need to incorporate tooling from the ground up and across team handoffs in order to build a product that can get to market the fastest and most direct route possible.

## List of Tables

# 1. Introduction

Recent advances in digital communications algorithms and artificial intelligence, coupled with the exponential growth of personal computing power, have positioned software-defined radio (SDR) technology as a viable tool for RF signal capture and playback, simulation, and testing. Popular applications for modern SDR designs include:

- Cellular handsets with programmable digital signal processing (DSP)
- University research / teaching aids
- Military and satellite communications platforms that make use of programmable cores for intermediate frequency (IF) and baseband signal processing
- Cognitive radio – a "smart" radio mesh that can adapt to interference adjusting frequency or power for example
- Amateur radio

The goal of this paper is to outline the general architecture and capabilities of a software-defined radio, followed by some basic principles of digital signal processing. A familiarity with sampling theory and the discrete Fourier transform, for example, will be very helpful for anyone looking to get started with SDR.

Finally, two lab applications of software-defined radio will be detailed. Both of these applications were used in testing a profile management application implementation, so a section on PMA is introduced. After familiarization with PMA, the first test example uses SDR to capture long term evolution (LTE) signals, then re-play them back into the RF plant to be subsequently detected by pattern recognition software that is a function of PMA. The second case recreates plant conditions from a cable modem's perspective by translating its reported receive modulation error ratio (RxMER) values into a waveform to be used as an impairment profile applied to an orthogonal frequency division multiplexing (OFDM) channel. Again, this impairment can then be analyzed by the analytics engine of PMA, and a custom OFDM profile recommendation can be verified.

# 2. Software-Defined Radio General Architecture

A software-defined radio is a radio that replaces traditional hardware components such as mixers, filters, and modulator/demodulators with software implementations, typically running on personal computers and driving a minimalistic hardware set. The Wireless Innovation Forum and IEEE P1900.1 working group has further simplified the definition down to:

*"Radio in which some or all of the physical layer functions are software defined"* (1)

There are many advantages to software-defined radio designs. Potentially first among these is the low cost. Devices can range from $10 USB-powered dongles, up to $10,000 high performance units with multiple transmit/receive (TX/RX) channels, higher maximum sampling rates, and greater usable bandwidth. Another primary advantage is flexibility. SDRs are not hardware limited to any particular specification standard, modulation type, or operating frequency range,

for example. The ability to test new designs in software also aids in the rapid prototyping of communication systems.

Conceptually, an ideal software-defined radio would eliminate any analog signal processing stages, aside from an antenna, power amplifier, and input/output (I/O) sink or source such as a speaker or microphone. In reality, today's SDRs use an analog frequency conversion stage at the receiver, with all signal processing thereafter being digital. Similarly at the transmitter, the digital-to-analog conversion stage is followed by local oscillator/mixer for transmit frequency conversion along with power amplification.

To illustrate a typical SDR design, the block diagram in Figure 1 outlines the functional components. This was the hardware used in the two practical example sections to follow.

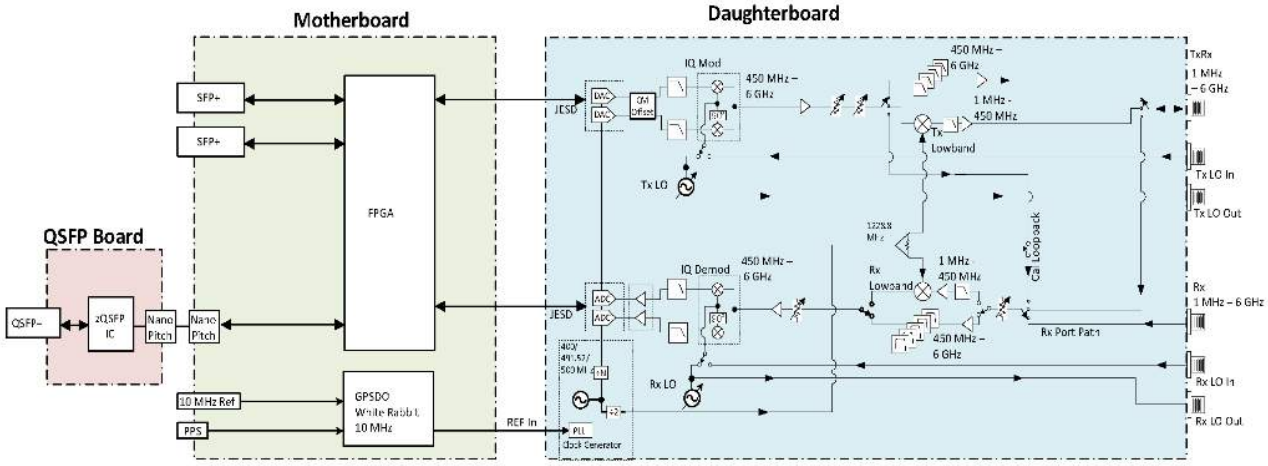

**Figure 1 – SDR Architecture Block Diagram**

The key features of this design include:

- Xilinx Zynq-7100 FPGA SoC
- Dual-core ARM A9 800 MHz CPU
- Two RX, two TX in half-wide RU form factor
- 3 MHz to 6 GHz frequency range
- Up to 200 MHz of instantaneous bandwidth per channel
- Sub-octave RX, TX filter bank
- 14 bit ADC, 16 bit DAC
- Configurable sample rates: 200, 245.76, 250 MS/s
- Two SFP+ ports (1 GbE, 10 GbE, Aurora, White Rabbit)
- One QSFP+ port ( 2x 10 Gb / Aurora )
- RJ45 (1 GbE)
- 10 MHz clock reference
- PPS time reference

- External RX, TX LO input ports
- Built-in GPSDO

One of the main factors to consider in selecting a radio is usable bandwidth. The specification above lists 200 MHz of available bandwidth that will allow us to simulate or impair a full OFDM block with 190 MHz of modulated spectrum. Another point to consider is sampling rate. Radios range from fixed, to selectable, to fully configurable sampling rates, with the fully configurable ones being the most flexible, because in some cases they can eliminate the need for additional resampling functions. Many designs use open-source Verilog code for the FPGA that can be modified for high performance applications.

## 3. SDR Software: GNU Radio

GNU Radio is a free open-source development project that implements signal processing blocks in software for waveform creation, sampling, and analysis, that supports a variety of software-defined radio hardware. It is used extensively in academic and commercial environments for wireless communications research and real-world radio systems.

GNU Radio consists of software-based signal processing blocks used in conjunction with hardware drivers to build applications capable of transmitting or receiving digital data streams. These streams can be directed to disk and saved in different file formats, or to a software-defined radio sink. GNU Radio resource blocks include equalizers, filters, modulators/demodulators, filters, and other common radio elements. These blocks' inputs and outputs are then connected in software to build an end-to-end flow.

Being software based, GNU Radio operates on digital data. It uses complex baseband samples as input for receivers and as the output data type for transmitters. Analog mixing hardware can then shift the signal to the proper frequency.

One of the biggest advantages to working with GNU Radio is that it is primarily written using the Python programming language, with the computationally intensive operations written in C++. GNU Radio also incorporates a graphical user interface – creatively named GNU Radio Companion – that offers drag-and-drop software blocks to construct flowgraph applications. These GRC flowgraphs present an intuitive approach to thinking about the discrete signal processing stages. Once a flowgraph contains a source and sink, the file can be saved and executed, and Python code is automatically generated. At this point there is no need to run the flow from within GNU Radio Companion, as the Python code can be executed directly from the command line or Python shell.

The GRC flowgraph shown in Figure 2 is an example of how a fast Fourier transform (FFT) block can be used to reproduce the same output as another GRC provided block: the Qt GUI frequency sink. The only difference is that Qt GUI frequency sink has the FFT, stream-to-vector, magnitude, and log functions built in.

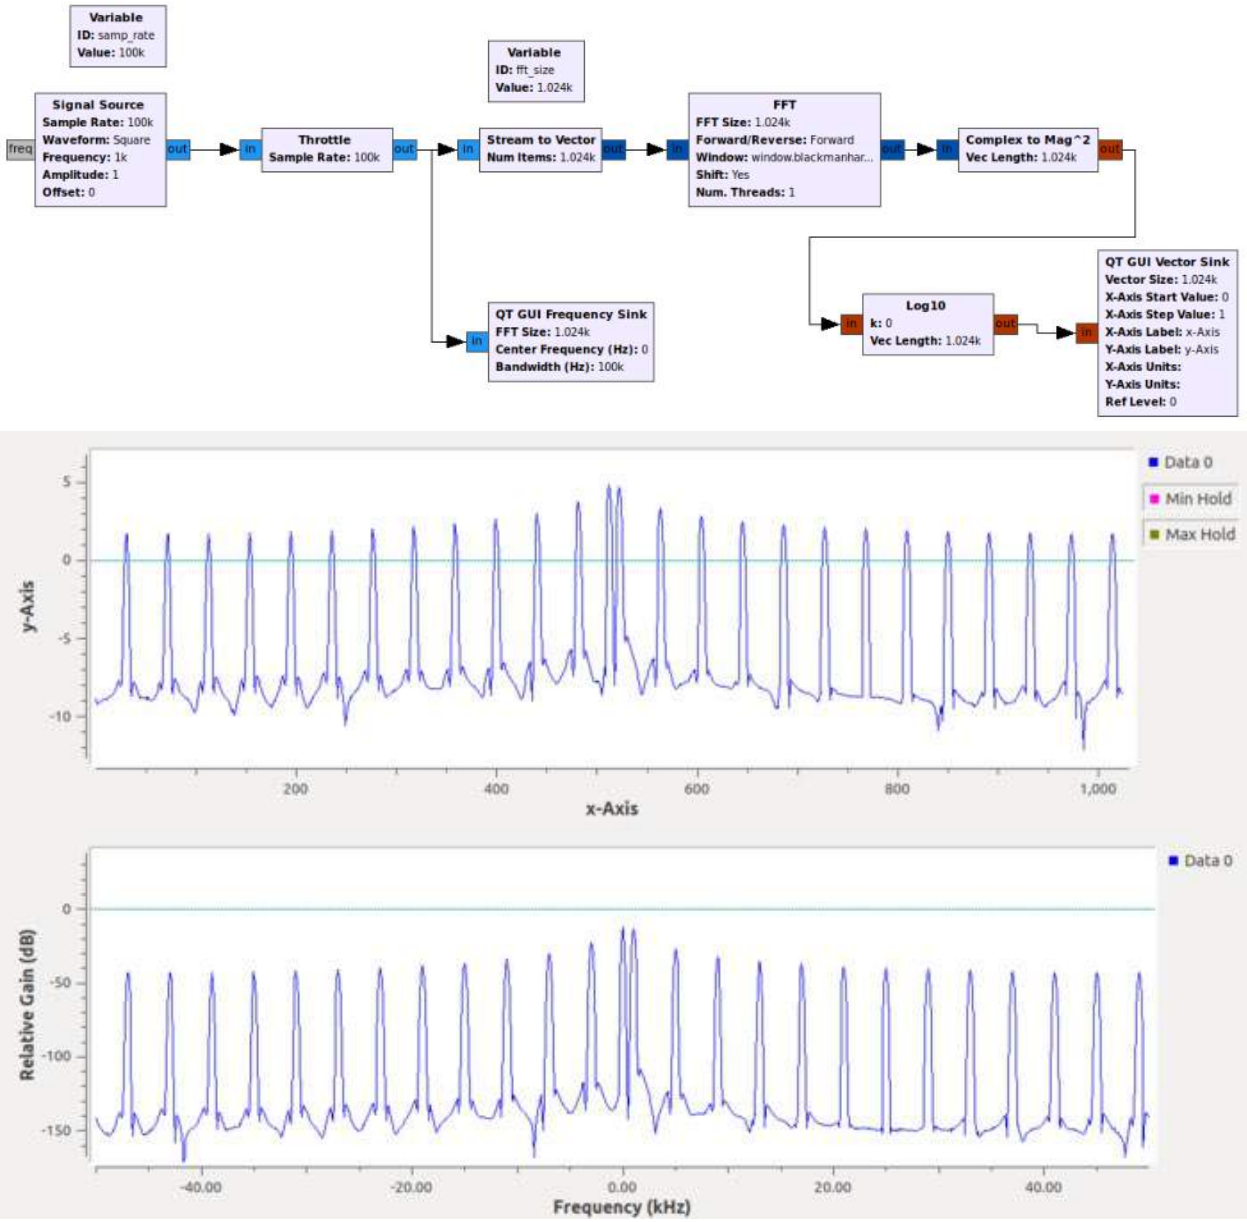

**Figure 2 - GNU Radio Flowgraph Example**

In my experience, it is best to compile GNU Radio, SDR drivers, and associated software from source code for your specific operating system. GNU Radio can compile on Windows, Mac OS, and Linux. Ubuntu 20.04 has been used for the testing contained herein.

## 4. Sampling Theory

When beginning to work with software-defined radio, it may be helpful to review some basic principles of signal processing.

In digital signal processing, sampling of a continuous-time input signal is performed in an analog-to-digital converter (ADC). The output of the converter is a series of data points that sample the instantaneous value of the input signal, and are taken at a given sampling rate. These discrete samples may be used to perform filtering or other processing in the digital domain using a digital signal processor, and then converted back to the analog domain using a digital to analog converter (DAC) as needed. Key to the sampling process is the sampling rate, or the number of samples taken per second (measured in Hz).

Different sampling rates are specified for different purposes. For example, 44.1 kHz is the standard sampling rate used in CDs, and 48 kHz is the recommended sampling rate for many other applications, including audio in digital video recordings. If the signal is sampled properly, the original analog signal may be reconstructed perfectly from the digital samples.

In order to choose the sampling rate for a specific application, the concept of aliasing is important to consider. Aliasing refers to the phenomenon that results in an imperfectly reconstructed analog signal from digital samples created when the sampling rate is too low. As we can see in the illustration in Figure 3, the blue signal has been reconstructed erroneously from the red signal due to the inadequate number of samples taken.

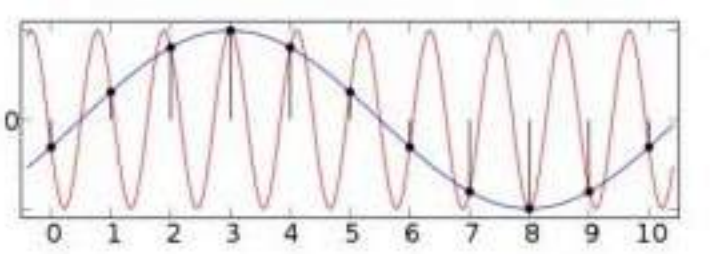

**Figure 3 – Aliasing Due to Undersampling**

In order to avoid aliasing and accurately reconstruct a signal from its samples, the Nyquist condition must be satisfied. This condition requires that the sampling frequency $f_s$ must be greater than or equal to two times the frequency bandwidth $B$ of the input signal $f(t)$:

$$N = f_s \geq 2B$$

As long as the Nyquist criterion is met, it is theoretically possible to exactly reconstruct $f(t)$ from its discrete samples $f_n$, where

$$f_n \equiv f(nT), -\infty < n < \infty$$

The samples of $f_n$ are spaced at time $t = nT$, where $T$ is the sampling interval $\frac{1}{f_s}$.

Under the Nyquist sampling condition, $f(t)$ can be reconstructed from its discrete samples $f_n$ by using the reconstruction formula:

$$f(t) = \sum_n f_n sinc(\frac{\pi}{T}(t - nT))$$

The sinc function, $sinc(t) = \frac{sin(t)}{t}$ is also known as the interpolating function.

## 5. The Discrete Fourier Transform or DFT

Mathematically, the Fourier series is used to represent any periodic function as a sum of sine and cosine functions. If we have any $f(t)$ with period $T = \frac{2\pi}{\omega_0}$, then the Fourier series is

$$f(t) = \sum_{n=\infty}^{\infty} F_n e^{jn\omega_0 t}$$

with the Fourier coefficients

$$F_n = \frac{1}{T}\int_T f(t)e^{-jn\omega_0 t}dt$$

where Euler's formula is used to give us our sinusoids:

$$e^{jn\omega_0 t} = cos(n\omega_0 t) + jsin(n\omega_0 t)$$

where $\omega_0$ represents frequency, $t$ represents time, and $j$ represents the imaginary number $j = \sqrt{-1}$.

To visualize the construction of a periodic function as a sum of sines, the animation in Figure 4 depicts the construction of a square wave that becomes closer to the ideal with higher frequency resolution:

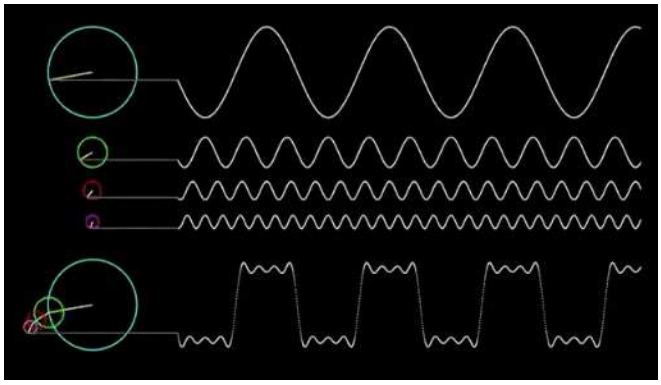

**Figure 4 – Square Wave Construction From Sine Waves**

If a function is aperiodic, it can still be represented as a sum of sinusoids, but the frequencies of the sinusoids are no longer simply harmonics of a fundamental $\omega_0$. A general aperiodic signal consists of a continuous spectrum of frequencies, so rather than integrating over a single period of $f(t)$ as is the case with Fourier series coefficients, we must integrate $f(t)$ over all time to derive the exact Fourier transform, which is the equivalent to the Fourier series coefficients but in a continuous frequency range. In the limit as the period $T = \frac{2\pi}{\omega_0}$ approaches infinity in an aperiodic signal, then the fundamental frequency $\omega_0$ approaches 0, and so we must integrate over the entire period of an aperiodic signal, which in other words, means we integrate over all time:

$$F(\omega) = \int_{-\infty}^{\infty} f(t)e^{-j\omega t}dt, \omega \in (-\infty, \infty)$$

In analog signal processing, the Fourier transform $F(\omega)$ is used to determine the characteristics of the signal $f(t)$ in the frequency domain. We can determine the frequencies or spectral content present in $f(t)$ using the Fourier transform, and manipulate or filter the signal as needed in the frequency domain.

Then, we can use an inverse Fourier transform to go back to the original time domain function from the frequency domain:

$$f(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} F(\omega)e^{j\omega t}d\omega$$

Similarly, in digital signal processing, the discrete-time Fourier transform (DTFT) is used in order to convert a continuous discrete-time signal (input sequence) into its counterpart in the continuous frequency domain. It is modeled by the equation

$$X(\omega) = \sum_{n=-\infty}^{\infty} x[n]e^{-j\omega n}, \omega \in [-\pi, \pi)$$

where $x[n]$ represents a discrete-time input signal, and $n$ is an integer.

The inverse DTFT is given by

$$x[n] = \frac{1}{2\pi}\int_{-\pi}^{\pi} X(\omega)e^{j\omega n}d\omega, \omega \in [-\pi, \pi)$$

Finally, the discrete Fourier transform (DFT) is simply a "sampling" of the DTFT in the frequency domain – a finite version of the DTFT taken over a specified interval or number of samples. It is modeled by the equation

$$X[k] = \sum_{n=0}^{N-1} x[n] e^{\frac{-j2\pi kn}{N}}, k = 0, 1, \ldots, N-1$$

where N represents the total number of samples.

And we can also define the inverse DFT by:

$$x[n] = \frac{1}{N} \sum_{k=0}^{N-1} X[k] e^{\frac{j2\pi kn}{N}}, n = 0, 1, \ldots, N-1$$

The DFT is a mainstay in the digital signal processing toolbox. It allows us to determine the spectral components of a sampled signal and to determine the frequency response of a system given the impulse response of the system in a completely digital manner. It uses a finite number of samples which can be easily used in computations of all kinds.

The FFT, or fast Fourier transform, is an algorithm that is used to calculate the DFT in a mathematically efficient manner. The FFT is employed by mathematicians, engineers, musicians, and scientists to rapidly analyze, modify, or utilize sampled signals in the frequency domain for myriad applications.

## 6. Introduction to Profile Management Application

The next two sections of this paper provide examples of using SDR to generate impairments for profile management application testing. A brief overview of PMA will demonstrate how highly customizable impairment profiles can aid in OFDM profile management testing.

A profile management application system builds an optimized set of OFDM channel modulation profiles based on current plant conditions. It does this by collecting receive modulation error ratio data from cable modems, analyzing this data to sort modems into impairment groups, and finally building the modulation profiles and applying them on the CMTS (see Figure 5). The modulation profiles themselves typically contain variable bit-loaded regions ranging from excluded regions (0-QAM) for highly impaired subcarriers, to 4096-QAM in the low noise areas of the OFDM channel. In this way, the PMA algorithm is able to maximize overall channel capacity while maintaining robust profiles that are noise-tolerant.

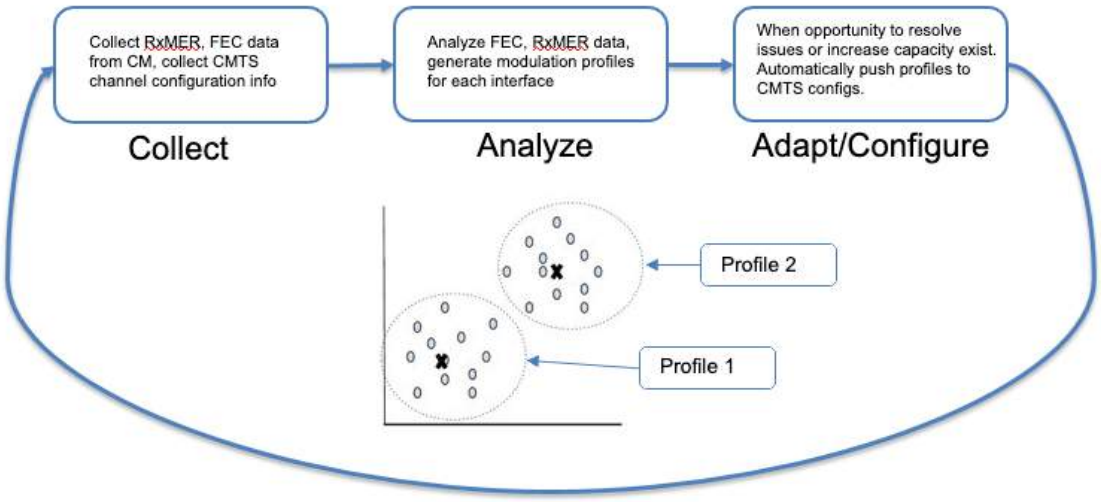

**Figure 5 – The Profile Management Application System**

Laboratory RF environments are often very clean, with short cable runs, limited ingress, and few taps or active elements such as amplifiers or line extenders. To test profile recommendations generated by the PMA algorithm (Figure 6) we will need to introduce impairments with variable power levels, widths, and durations. The following sections demonstrate how software-defined radio can be used to create these impairments.

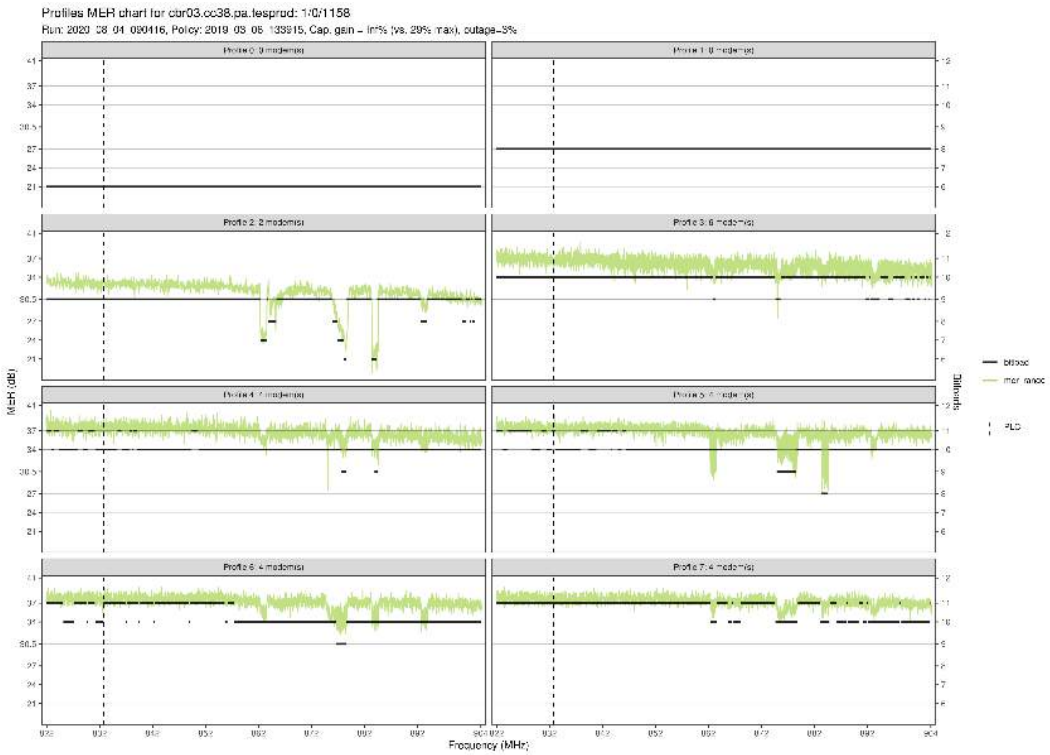

**Figure 6 – PMA In Action: Building Custom OFDM Profiles**

## 7. Practical Application Example #1– Capturing LTE Signals For Replay as an Impairment Source

Problem Statement: How can we capture LTE signals and introduce them as ingress interference in a laboratory environment?

SDR Solution Outline:

1. Using a cellular telephone as a signal source, find the LTE band currently in use
2. Prepare the SDR to capture at the LTE uplink frequency
3. Start a speed test on the UE to generate traffic
4. Observe/capture the LTE signal on the SDR
5. Combine SDR TX into the lab RF plant and playback capture file
6. Observe effect in the cable modem's downstream OFDM channel and verify PMA OFDM channel profile recommendation

Detailed Steps:

1. Most modern UE devices include hidden service menu interfaces that can be accessed by dialing certain sequences. For example:
    a. Apple iPhone (all): *3001#12345#*
    b. Samsung (Android): *#*#197328640#*#*or *#0011#
    c. Sony (Android): *#*#*386#*#* or *#*#*585*0000#*#*
    d. HTC (Android): *#*#7262626#*#*

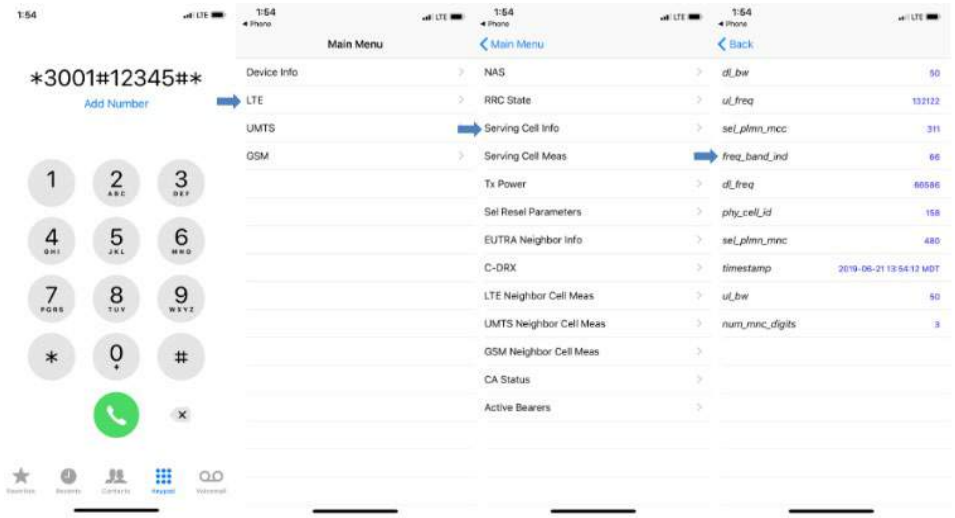

**Figure 7 - Finding LTE Band In Use on iPhone**

From the above example, we can determine what uplink frequencies are assigned to Band 66:

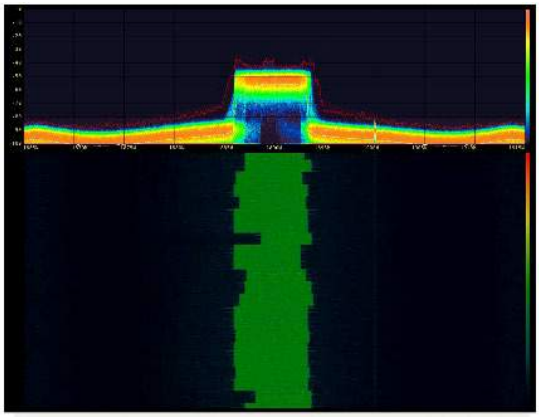
**Table 1 – LTE Frequency Bands (3)**

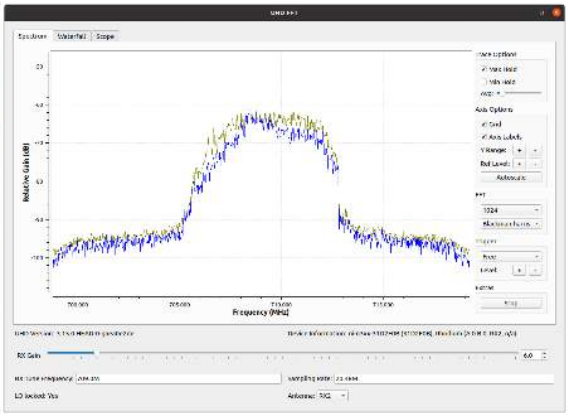
| Band | Duplex mode[A 1] | f (MHz) | Common name | Subset of band | Uplink[A 2] (MHz) | Downlink[A 3] (MHz) | Duplex spacing (MHz) | Channel bandwidths (MHz) |
|---|---|---|---|---|---|---|---|---|
| 2 | FDD | 1900 | PCS[A 4] | 25 | 1850 – 1910 | 1930 – 1990 | 80 | 1.4, 3, 5, 10, 15, 20 |
| 13 | FDD | 700 | Upper SMH[A 7] | | 777 – 787 | 746 – 756 | −31 | 5, 10 |
| 66 | FDD | 1700 | Extended AWS (AWS-1–3)[A 17] | | 1710 – 1780 | 2110 – 2200[2] | 400 | 1.4, 3, 5, 10, 15, 20 |

2. Osmocom_fft is a simple spectrum analyzer and capture tool that can be used to write sampled data directly to a file. Using a command such as:
   osmocom_fft -f 1.89e9 -s 40.96e6
   will launch the application and tune to 1.89 GHz.
   If the Osmocom utilities are not available, a GNU Radio Companion flowgraph can be created to output the data from a UHD:USRP source to a file sink block.
   The RX port of the SDR should be fitted with an antenna capable of receiving the LTE frequencies, such as a mini GSM/cellular quad-band antenna with 2 dBi of gain and 50 ohm impedance.

3. Install Speed test on the UE LTE source, disable Wi-Fi, and begin a speed test. Most testing includes a downlink and an uplink speed test portion. If the energy is not seen at the expected frequency, the downlink test may not have completed or the UE may have changed bands or moved to a neighboring macro cell.

4. The LTE signal should now be see on the analyzer. For live, raw IQ capture, Gqrx is a free open-source software-defined radio receiver that supports many popular radios including Airspy, rtl-sdr, HackRF, and USRP devices.





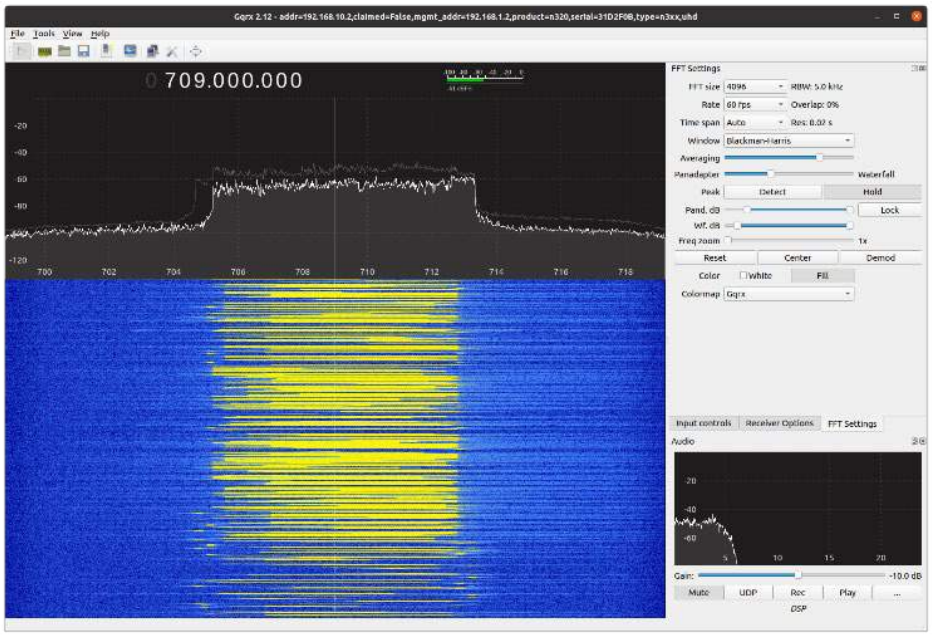


**Figure 8 - Real Time Spectrum Analyzers for IQ Capture (clockwise): osmocom_fft, uhd_fft, gqrx SDR**

5. Combine the SDR TX Port 1 into the laboratory RF plant as needed to impact the desired set of modems. For example:

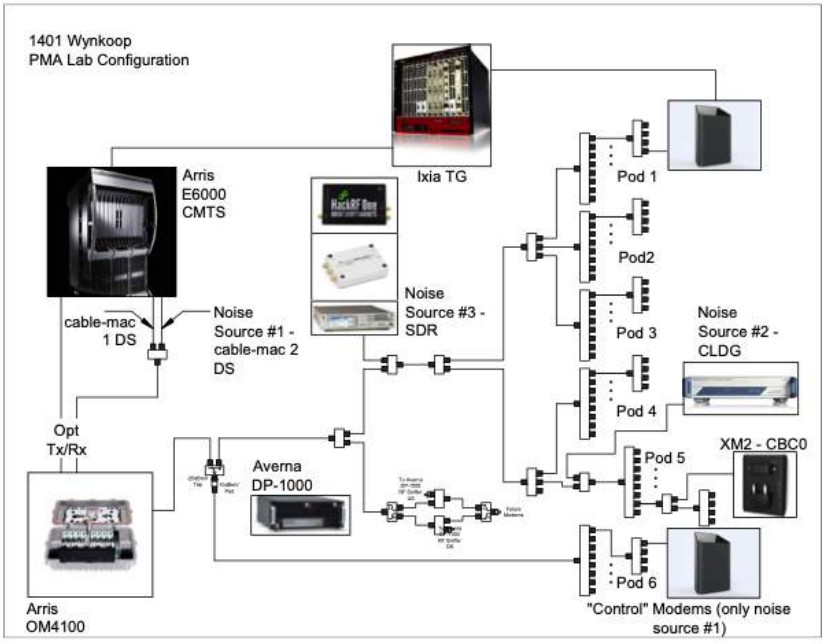

**Figure 9 - Combining of Noise Sources in Laboratory Environment**

7. Through the splitting and combining network, different interference groups can be created. In this way the k-means based clustering algorithm that the PMA analytics engine implements can be fully tested, as multiple, custom OFDM channel profiles are supported.

## 8. Practical Application Example #2 – How SDR Has Aided Profile Management Application (PMA) Testing

Problem Statement: How can we re-create an OFDM channel impairment profile using a cable modem's reported RxMER values?

SDR Solution Outline:

1. Read in cable modem RxMER data file
2. Convert the data from ¼ dB values to dB
3. To create the impairment profile, set all values that are within a threshold (say 6-10 dB) of the maximum value to zero. We will be using the values outside of this "good" range to create our impairment.
4. Convert the RxMER value from a ratio of power values to output voltage for the DAC
5. Normalize the voltage value vector
6. Use GNU Radio to stream out the data to an inverse fast Fourier transform block to convert from frequency to time domain
7. Stream the data to either a file to use for later playback, or directly to the software-defined radio sink
8. Inject this RF impairment into the lab environment physical plant to re-create the impairment seen at the customer premises

Detailed Steps:

1. The cable modem RxMER values can be obtained either directly from CMTS CLI or via TFTP download. The values are reported in quarter-dB, for example:

```

```

If using the values from the TFTP downloaded RxMER file, the RxMER per subcarrier data follows after a header using the specified format:

**Table 2 – RxMER TFTP File Format (4)**

| Element | Size |
|---|---|
| File type (value = 504E4E04) | 4 bytes |
| Major Version (Value = 1) | 1 byte |
| Minor Version (Value = 0) | 1 byte |
| Capture Time | 4 bytes |
| DS Channel Id | 1 byte |
| CM MAC Address | 6 bytes |
| Subcarrier zero frequency in Hz | 4 bytes |
| FirstActiveSubcarrierIndex | 2 bytes |
| Subcarrier spacing in kHz | 1 byte |
| Length in bytes of RxMER data | 4 bytes |
| Subcarrier RxMER data | RxMerData |

The other data such as the subcarrier zero frequency, first active subcarrier index, subcarrier spacing, and length in bytes of the RxMER data will all be used to fully describe the OFDM channel impairment profile.

2. The RxMER data itself is defined as the ratio of the average power of the ideal QAM constellation to the average error-vector power. The error vector is the difference between the equalized received pilot or preamble value and the known correct pilot value or preamble value. The reported values are represented in hexadecimal values of ¼ dB. Multiple each value in the array by ¼ to properly scale.

3. In this step we discard (set to zero) all values that are within a configurable threshold of the maximum reported RxMER value. Only the low RxMER values will be used to construct the impairment vector. This example used a value of 10 dB.

4. Convert every value in the impairment array to an output voltage value for the DAC using the formula:

   $V = 10^{(dB/20)}$

5. Divide every voltage value by the sum of values (new values will all sum to 1) to avoid overloading the SDR output stage.

6. The processing of the RxMER data, along with the streaming to either file or directly to the software-define radio sink was achieved through the creation of a GNU Radio Companion flowgraph (Figure 10).

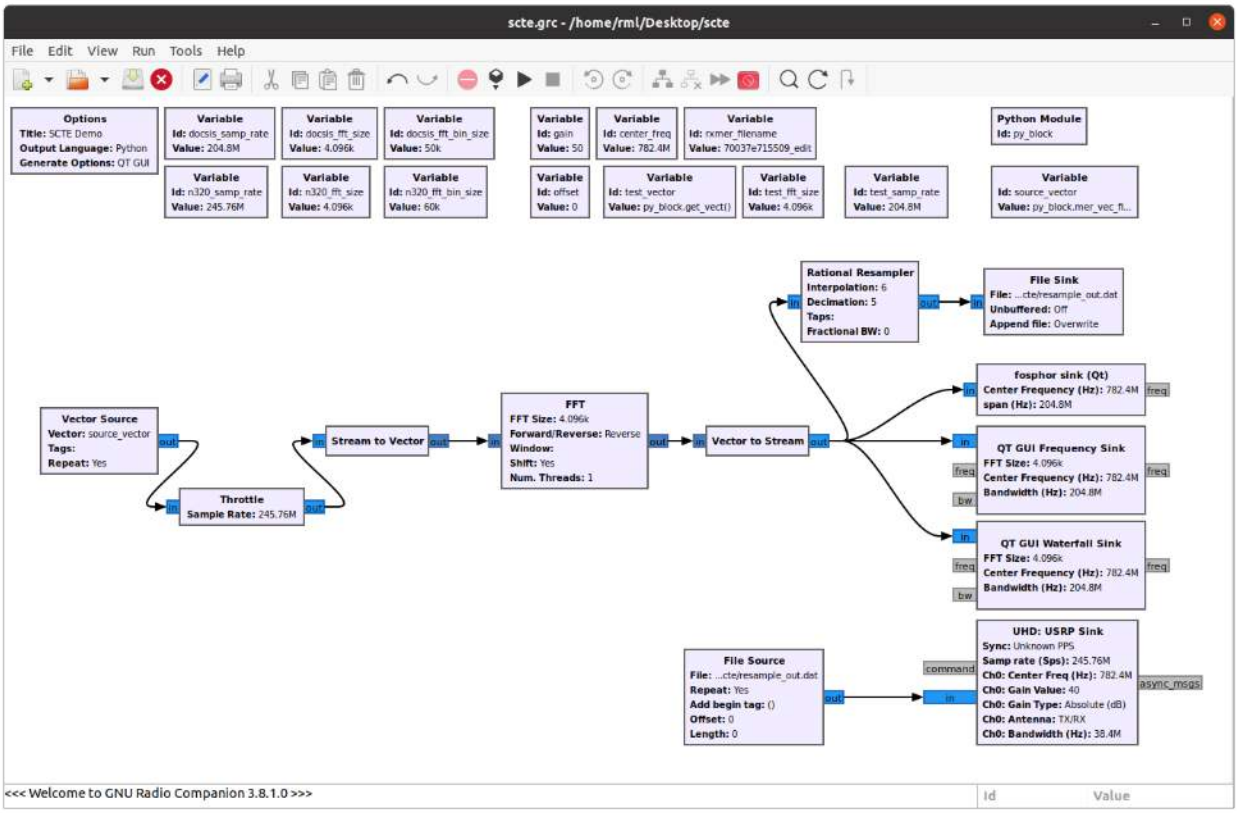

**Figure 10 - GRC Flowgraph to Contruct and Transmit Custom Impairment Waveform**

Flowgraph Details:

Embedded Python Module-

The previous six steps were all done in the embedded Python Module block. GNU Radio companion allows you to create and use custom Python code within your flowgraph. In this example, all the RxMER data manipulation and plot generation was done within the embedded Python block. After reading in the modem's RxMER data, the values are written to disk as a Matplotlib Pyplot (Figure 11):

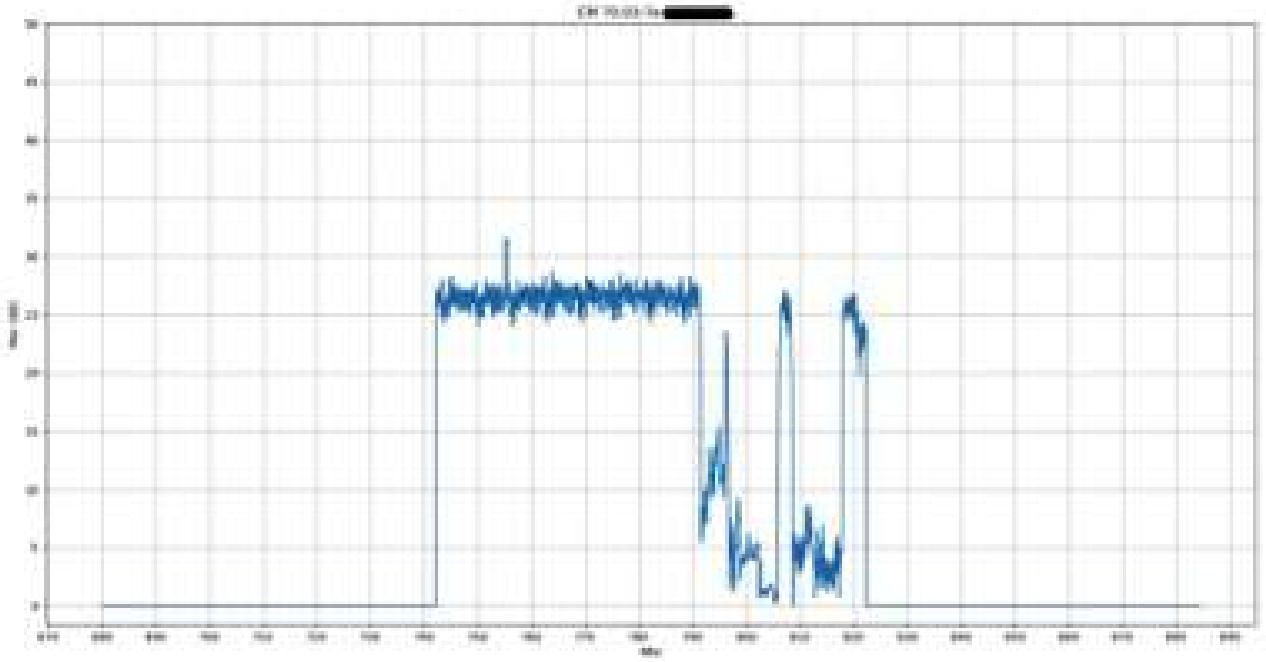

**Figure 11 - Graph of RxMER Data Generated by Embedded Python Block**

Vector Source Block -
This flowgraph begins with the vector source block. This block streams items based on the input vector, which in this case is the output of a Python method in our embedded Python block.

Throttle Block -
This stream feeds a throttle block. This block will be set to "bypass" when using the real SDR hardware which will set its own sampling rate. It is used in combination with the software sinks or file output, when the sampling rate would only be determined by the host's CPU clock.

Stream to Vector Block –
This block converts the stream of items into a stream of vectors containing N number of items. In this case the number of items will be the FFT size (4096). The stream-to-vector and vector-to-stream blocks are special in that the input and output types differ by a decimation or interpolation factor. In our example, the stream-to-vector block produces one output vector for every 4096 input samples.

FFT Block –
The complex valued output vector from the previous stage feeds the fast Fourier transform block. The key parameters of the FFT block are: FFT size (number of samples used in each FFT calculation), direction (forward for FFT, reverse for inverse FFT), window, shift (puts DC – 0 Hz – in the center of the FFT block for complex input type), and number of threads.

Vector to Stream Block –
The output of the FFT block will always be complex-valued. This block will convert a stream of vectors from the FFT block to a stream of items that can be fed directly to an output file, the

SDR hardware, a GUI frequency sink that offers spectrum analyzer functionality, or a Fosphor or Waterfall sink for more real-time spectrum analyzer-like output.

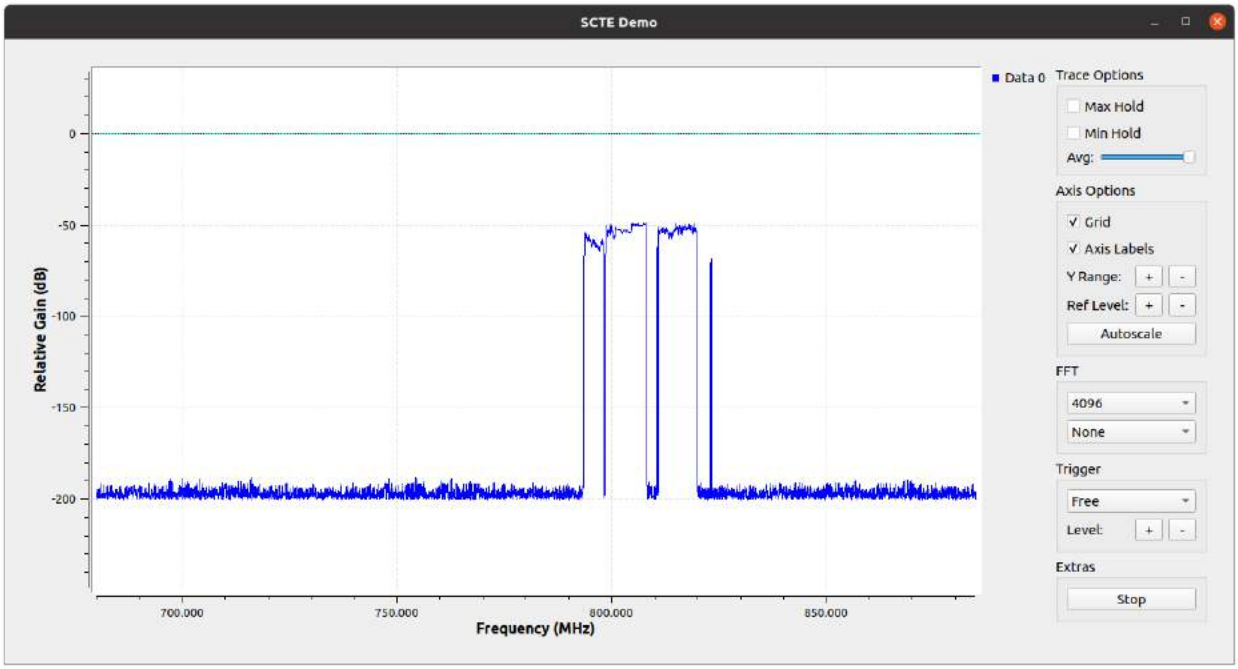

**Figure 12 - Qt GUI Frequency Sink Visualization of Impairment Signal**

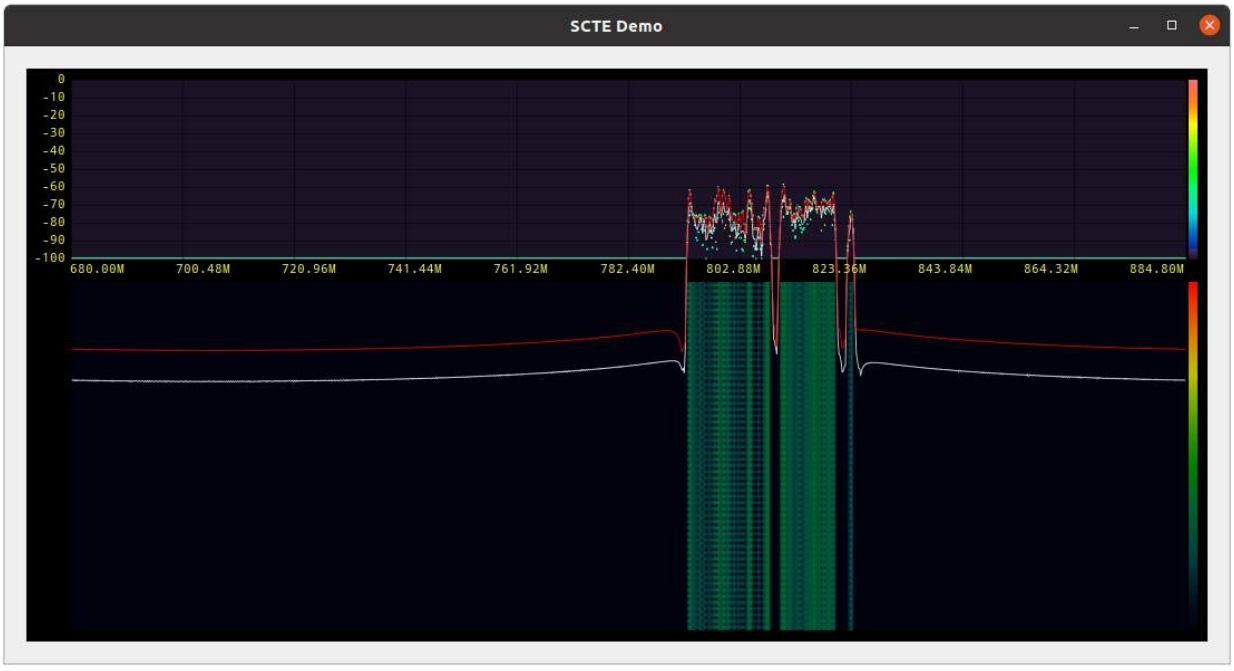

**Figure 13 - Qt Fosphor Sink Visualization of Impairment Signal**

Rational Resampler Block –
If trying to stream a file that has been sampled at a rate that is not supported by the SDR hardware, the rational resampler block allows us to change the sampling rate (e.g., from the DOCSIS standard 204.8 MHz). In this example the default hardware sampling rate is 245.76 MHz so we could set the interpolation factor to 6 and the decimation factor to 5 to upsample to 245.76 MHz.

7. If the output is sent to a file, we can replay directly to the SDR sink without continuously performing the IFFT calculation repeatedly. The act of streaming 32 bit IQ data at 245.76 MHz is very I/O intensive and requires a powerful host computer with a 10 gigabit interface. As seen in Figure 14 this stream from the host to the SDR hardware averages around ~7.8 Gbps:

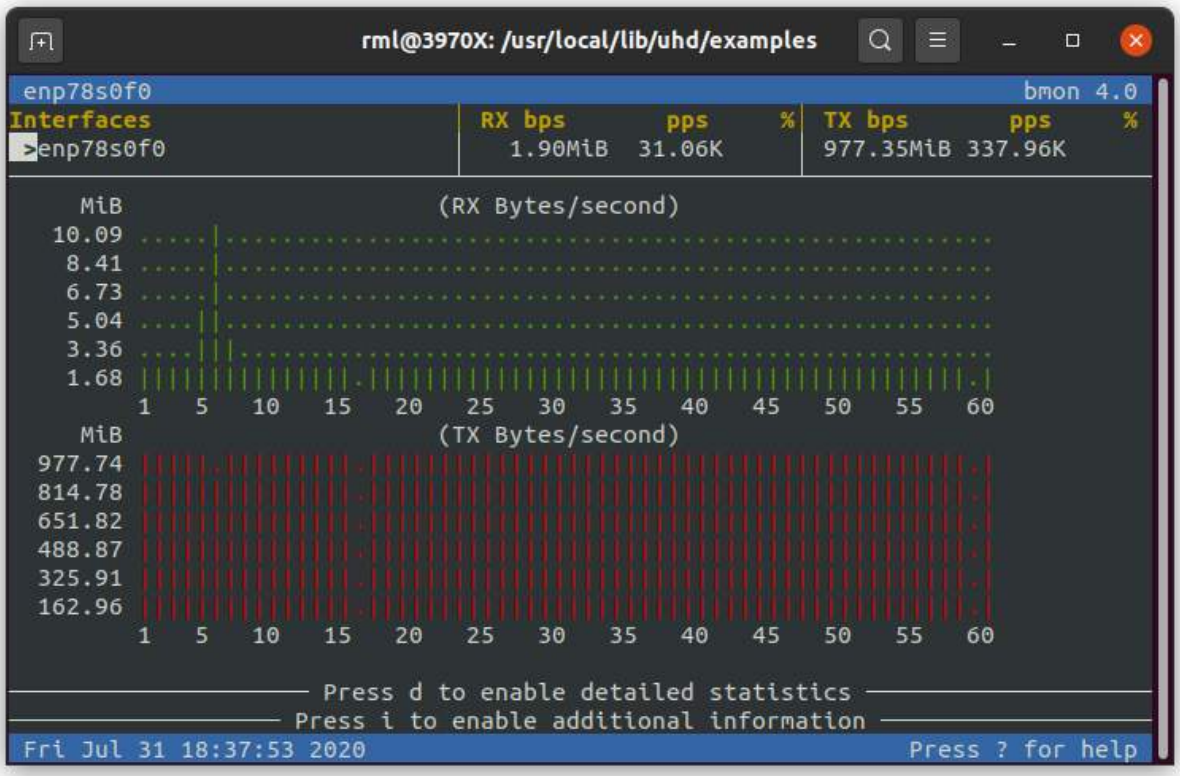

**Figure 14 - Bandwith Monitor of IQ Data Stream**

8. The SDR TX output can then be combined into the laboratory plant, and the effect can then be observed in the OFDM channel RxMER data (Figure 15).

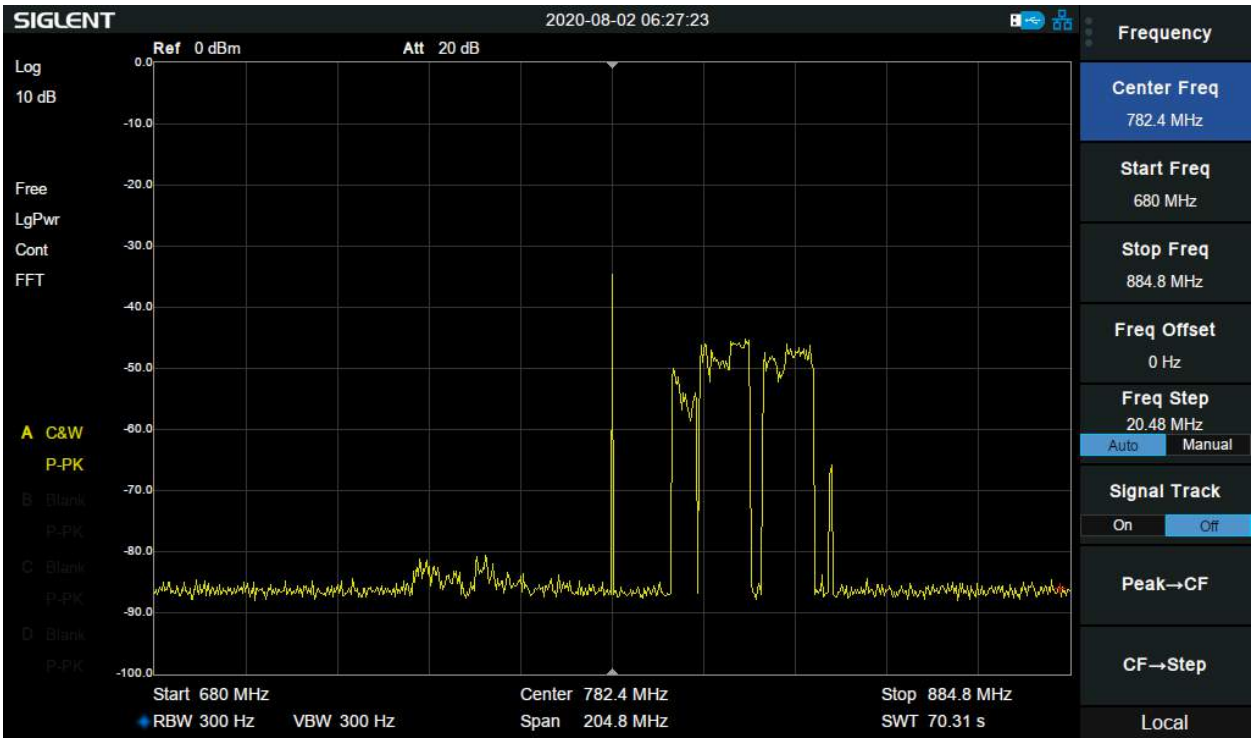

**Figure 15 - Impairment Signal on Spectrum Analyzer**

In this case we were testing the response of our profile management application (a.k.a. Octave) to verify that proper bitloading values were being set for the impacted frequency ranges. For an example OFDM profile, see Figure 16.

```
  DS     DS   Low-High Freq          Bits/Symbol/   MaxRate

## 9. Equipment Used

Software-Defined Radio Hardware:

1. Ettus Research USRP N320
2. Ettus Research USRP B210 Mini
3. Great Scott Gadgets HackRF One
4. 75 MHz to 1 GHz telescoping antenna
5. SMA Make Right Angle antenna (850/900/1800/1900/2100 MHz, 2 dBi gain, 50 ohm)
6. 10 Gb direct-attach copper cables

Software-Define Radio Software:

1. GNU Radio v3.8.1.0
2. Ettus Research UHD drivers UHD_3.15.0.HEAD-0-gaea0e2de
3. GNU C++ v9.3.0
4. Python 3.8.2
5. Various libraries including libosmodsr-dev, libhackrf-dev, gr-osmosdr, gr-fosphor,

SDR Controller Host Computer:

- CPU - AMD Ryzen Threadripper 3970X
- Motherboard - Asus ROG Zenith II Extreme Alpha
- RAM – 32 GB Corsair DDR4 3600
- Storage – Samsung 970 EVO M.2 1 TB (x2)
- GPU - EVGA GeForce RTX 2080 Ti Xc Hybrid 11 Gb DDR6
- Network – Asus XG-C100C 10G Network Adapter PCI-E x4
- Power – Thermaltake 1200 W 80+ Platinum

OS Software:

1. Ubuntu 20.04 LTS
2. Windows 10

Spectrum Analyzer:

- Siglent SSA 3021X Plus (9 kHz to 2.1 GHz)

## 10. Conclusion

In this paper, we have explored what software-defined radio is and what it offers to engineers, students, and designers. We presented a general architecture as well as some needed background information on sampling theory and the discrete Fourier transform. Finally, the hardware, software, and drivers used to implement real data flows to sample and/or generate signals were detailed, along with two laboratory use cases.

With the abundance of open-source community supported software and low cost hardware, software-defined radio is proving be a valuable laboratory and field testing tool. By abstracting the functionality from a specific piece of physical hardware, we can transmit and receive various modulation methods, perform signal processing and filtering, and customize routines though Python extensions all within a common software framework. These advantages, combined with the ability to embed Python code for customized signal processing routines, positions software-defined radio as a valuable laboratory and field testing tool.

# 1. Introduction

The term “Industry 4.0” refers to the 4th industrial revolution brought about by digital technologies to dramatically increase operational efficiencies primarily through the use of analytics and automation. Wireless systems are seen as playing a primary role in this revolution to more easily allow for on-demand manufacturing process reconfigurations along with high volume data collection via industrial internet of things (IIoT) networks. The motivation of the project described in this paper is to investigate the performance and feasibility of using multi-hop pseudo-mesh indoor networks in the 60 GHz V-Band for industrial automation applications to support Industry 4.0 use cases. These use cases include the real-time control of multiple robotic apparatuses using a dedicated multi-access edge compute (MEC) system. Another goal of the project is to characterize the deployed wireless connection robustness and their practical limitations in both static and dynamic links. In addition to performace evaluation it is also important to understand the current state of supporting component technologies and the viability of a robust technology ecosystem for deploying and supporting these networks.

The main challenge for the initial phases of this project was the fact that there are no commercially available 60 GHz true mesh products currently available on the market. Mesh connectivity for this project was emulated using multiple point-to-multipoint links. Another challenging aspect was that the 60 GHz Consumer Premises Equipment (CPE) endpoints in our trials are the same physical devices as the access nodes with a different operational configuration which would not be the case in an actual commercial deployment. Lastly there were some use cases on our trials which required connectivity translation to interwork with 60 GHz network, so there may be issues addressing some of the needs of some potential customers depending on their specific objectives and equipment. Many of these issues are being addressed in later phases of this project and will be detailed in a future publication.

However despite the challenges of these initial project phases, it has been found through measurements and practice that networks with 60 GHz technology can meet needs of (Industrial Automation) (IA) use cases today if deployed and managed properly.

# 2. Industrial Automation System Requirements

There are many specific situations within the Industrial Automation use case umbrella. One expert who is active in the field has stated that a good place to start would be to “duct-tape an iPhone to a milling machine”[1] which would enable the collection of a production asset’s operational parameters. A very high value use case that does not require huge bandwidth and low latency is to perform what is known as “finding the hidden factory”. This refers to operational inefficiencies which are found through process monitoring, data collection, and targeted analytics to determine the efficiency of the end-to-end production process and identify sections of it that may not be performing as intended. In so doing, surprisingly large amounts of money are saved simply by reducing otherwise unknown waste [2].

The 3rd Generation Partnership Project (3GPP) have identified target requirements for specific IA use cases, and these can be found in TS 22.104 [3]. **Error! Reference source not found.** below is a table showing the 3GPP use cases (columns) with their associated application areas (rows). As seen, not every application area employs every use case. So different industrial customer segments can potentially be addressed with different target service and application packages, although this concept is not explored further in this paper.

**Table 1 - Industrial automation application areas and associated use cases**

| 3GPP TR 22.104 Annex A | Motion Control | Control-to-Control | Mobile Control Panels With Safety | Mobile Robots | Remote Access and Maintenance | Augmented Reality | Closed Loop Process Control | Process Monitoring | Plant Asset Management |
|---|---|---|---|---|---|---|---|---|---|
| Factory Automation | X | X | | X | | | | | |
| Process Automation | | | | X | | | X | X | X |
| HMIs and Production IT | | | X | | | X | | | |
| Logistics and Warehousing | | X | | X | | | | | X |
| Monitoring and Maintenance | | | | | X | | | | |

Each of the use cases listed in Table 1 has a set of system level parameters which should be met in order to provide the expected level of performance. A representative sampling of these requirements is given below in Table 2.

**Table 2 - - Selected 3GPP technical requirements for industrial automation use cases**

| Use Case | Service Avail | Message Size | Transfer Interval | Survival Time | UE Speed | # of UEs | Service Area |
|---|---|---|---|---|---|---|---|
| Motion Control | 5-7 9's | 50 bytes | 0.5 ms | 0.5 ms | ≤ 75 kph | ≤ 20 | 50x10x10 m |
| Mobile Robots | 6 9's | 40 - 250 bytes | 1-50 ms | 1-50 ms | ≤ 50 kph | ≤ 100 | < 1 sq km |
| Process Monitoring | 4 9's | 20 – 255 bytes | 100 - 60k ms | 3 x Trans Intv | 0 | 10k – 100k | 10x10x0.05 km |
| Mobile Control Panel | 6-8 9's | 40 - 250 bytes | 4-8 ms | 4-8 ms | ≤ 8 kph | TBD | 50x10x4 m |
| Process Control | 6-8 9's | 20 | 10 ms | 0 | 0 | 10-20 | 100x100x50 m |
| Control-to-Control | 6-8 9's | 1k bytes | 10 ms | 10 ms | 0 | 5-10 | 100x30x10 m |
| Augmented Reality | 3 9's | unspec | < 10 ms | unspec | < 8 kph | unspec | 20x20x4 m |
| Asset Management | 4 9's | 20 – 255 bytes | 'several seconds' | 3 x Trans Intv | 0 | Up to 100k | 10x10x0.05 km |

In addition to the requirements listed in Table 2, 3GPP TR 22.104 [3] further segments each use case into sub-categories so that there are multiple sets of requirements for each of the use cases listed in the columns of Table 1. For example, the Motion Control use case (UC) has 3 sub-categories which are listed below in Table 3.

**Table 3 - Motion control use case sub-categories**

| Use Case | Service Avail | Message Size | Transfer Interval | Survival Time | UE Speed | # of UEs | Service Area |
|---|---|---|---|---|---|---|---|
| Motion Control UC #1 | 5-7 9's | 50 bytes | 0.5 ms | 0.5 ms | ≤ 72 kph | ≤ 20 | 50x10x10 m |
| Motion Control UC #2 | 6-8 9's | 40 bytes | 1 ms | 1 ms | ≤ 72 kph | ≤ 50 | 50x10x10 m |
| Motion Control UC #3 | 6-8 9's | 20 bytes | 2 ms | 2 ms | ≤ 72 kph | ≤ 50 | 50x10x10 m |

The most stringent use case sub-category of all those listed in [3] is Motion Control #1. This is the use case that is typically focused on in marketing literature and used as ***the*** requirements for Industrial Automation, but as can be seen in Table 2 there are other sub-categories of Motion Control that are not as

demanding as Case #1 and many other use cases and their sub-categories which are not as demanding as Motion Control #1 but are very useful for Industrial Automation networks and services.

Consider a 100 byte packet sent every 1 msec. This results in a required throughput of 8*100*1000=800 kbits/sec. As can be seen from the previous figures this represents a sufficient amount of bandwidth and transmission interval for every listed use case above. So a system throughput budget of 1 Mbps per Industrial Automation endpoint can be viewed as being representative of what IA systems require.

Another important requirement for IA networks is service availability which is an end-to-end network requirement for delivering specified services. System redundancies, both at the node level and in available paths, can be employed to increase the overall end-to-end availability beyond what a single node/path can deliver.

An illustration of service availability with respect to redundancy is shown below in Figure 1. In this case reliability concerns only the wireless network portion of the end-to-end network. The table embedded in Figure 1 gives the relationship between service availability and reliability when the survival time is equal to the transfer interval. These will be discussed shortly. More information concerning service availability and its relationship with reliability can be found in 3GPP TS 22.241[4].

In order to increase the reliability of the wireless network portion of Figure 1 and the overall availability of the end-to-end service, a wireless mesh network can be employed. This type of network provides an endpoint with multiple paths through which to send data so as to eliminate the sole dependency on any particular node for communication.

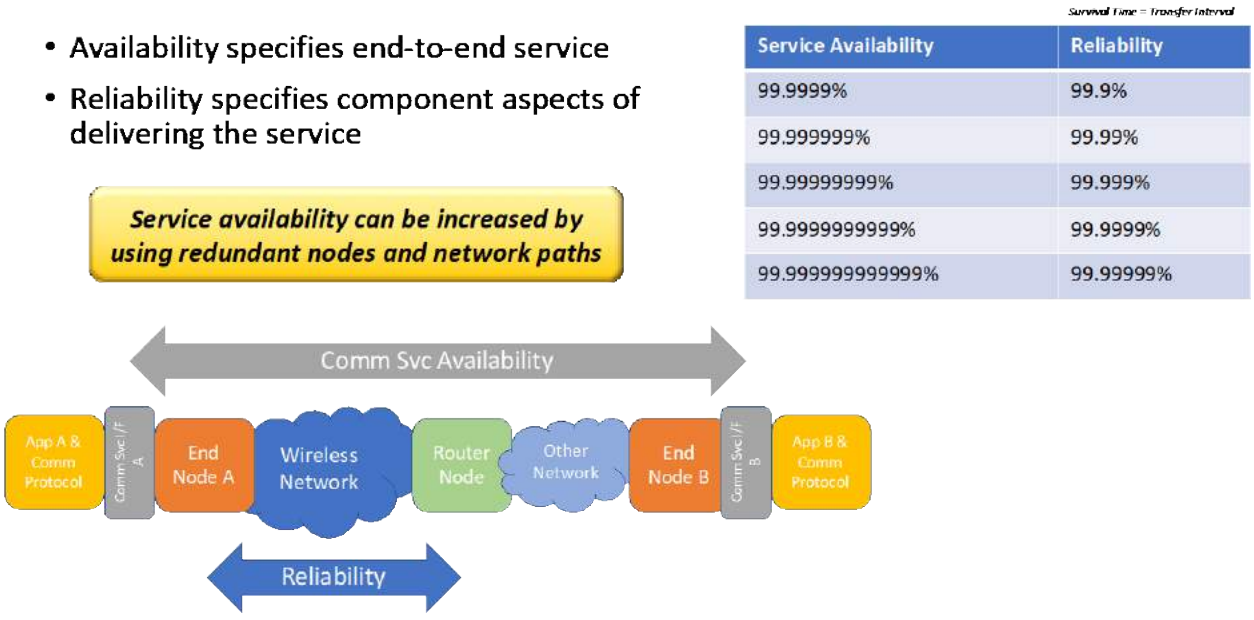

**Figure 1 – The relationship between service availability and reliability**

As seen in Figure 1, service availability and reliability are related by parameters called transfer interval and survival time. These are system delays that affect an endpoint's response time to a command from a control system. These delays are illustrated below in Figure 2. In this illustration the transfer interval from the MEC to the endpoint is the same as the one from the endpoint to the MEC since they traverse the

same path. This is not always the case and must be taken into account for round trip response time calculations. The survival time is the amount of time it takes an endpoint to respond to a command and issue a status response back to the control system.

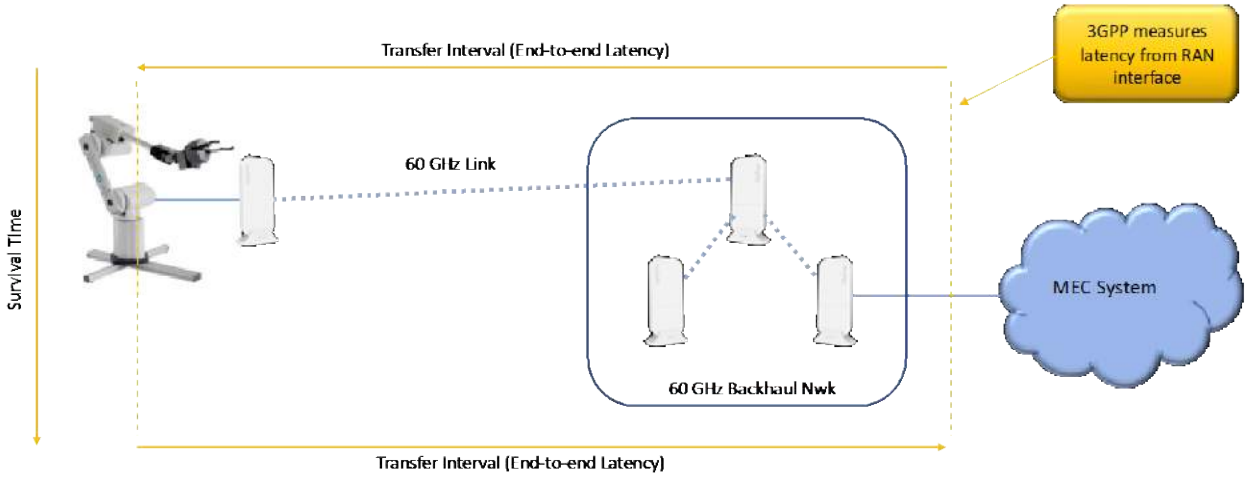

**Figure 2 - Industrial Automation network delays**

The IA network requirements discussed in this section illustrate the level of performance expected to be able to perform the target IA use cases. As seen in Table 2 not every use case requires a very high degree of performance and many of them can be enabled with equipment that is widely available.

# 3. 60 GHz Indoor Deployment Aspects

## 3.1. Indoor Scattering

Historically 60 GHz wireless transmission has been regarded as being problematic due to the oxygen absorption characteristic in the radio frequency band. This phenomenon really only affects very long links as the effect is described in dB/km. However for shorter links (< 100m) this effect is negligible.

60 GHz radio signals do not pass through materials as well as radio signals do in other bands. As such there is a tendency for a large amount of environmental scattering which makes antenna directionality indoors much less critical or even important. For indoor 60 GHz applications this means that line-of-sight and precise beam pointing deployment aspects are not as critical as in other bands where the radio signals scatter less.

## 3.2. Antennas

The typical antenna devices in 60 GHz products is found to be a patch array that is used in conjuction with beamforming/beam-switching to provide higher gain for longer links and alleviate the need for antenna alignment during installation. The standard antenna array module is similar to the one shown below in Figure 3.

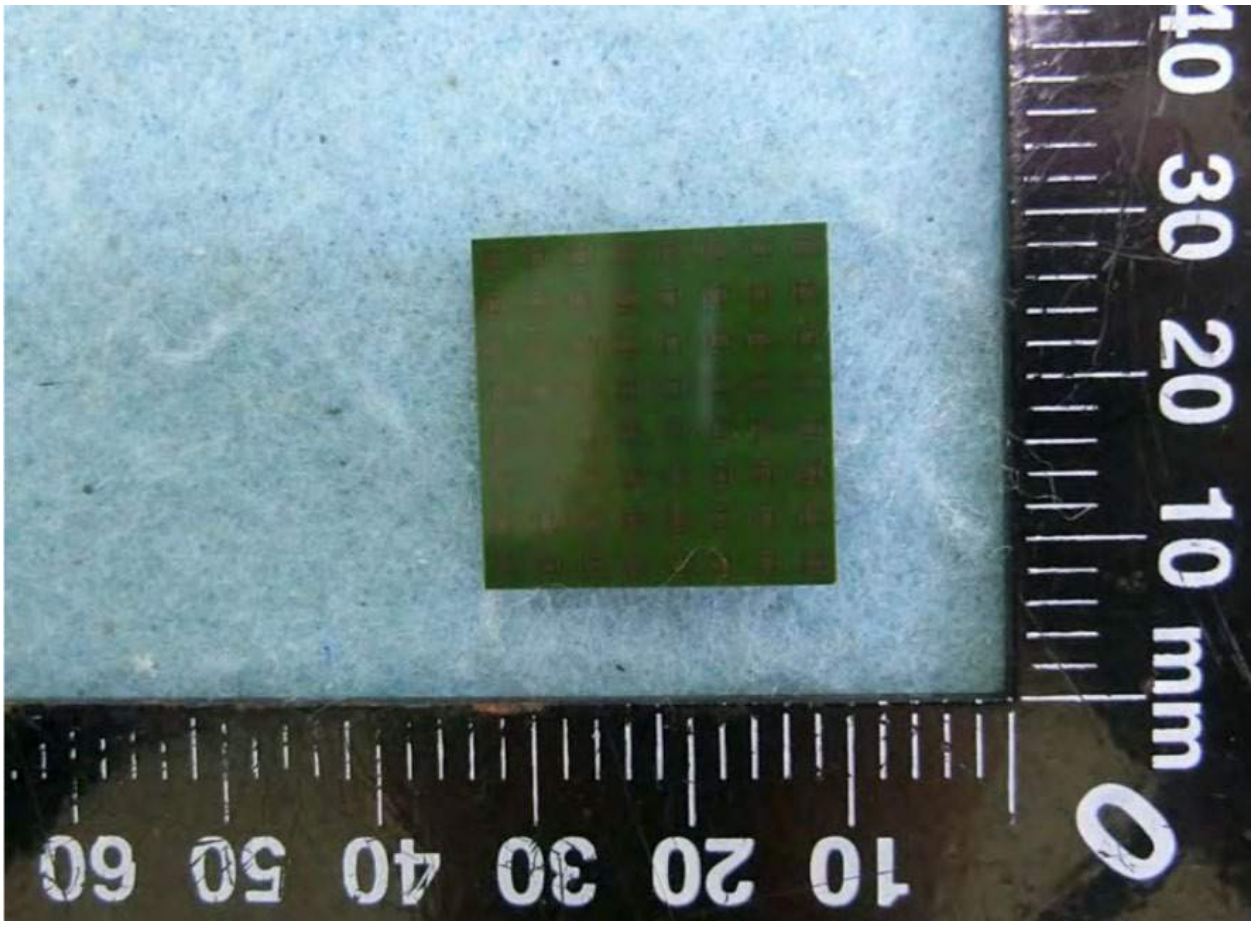

**Figure 3 - Typical 60 GHz MIMO antenna array module**

These standard multiple-input and multiple-output (MIMO) patch array modules have the typical specifications given below in Table 4.

**Table 4 - MIMO antenna module parameters**

| MIMO Module Parameter | Value |
|---|---|
| Number of elements | 64 |
| Coverage angle | 90° horizontal / 40° vertical |
| Max Effective Isostropic Radiated Power (EIRP) | 36 dBm |

In a representative warehouse indoor environment we have seen through field testing, which will be further described in Section 4.2, that a hemi-spherical pattern from the same AP is better overall in terms of coverage and robustness. This was done by substituting a hemispherical antenna module for the standard MIMO array module and then testing both configurations in the same deployment locations. The hemispherical antenna has the specifications given below in Table 5.

**Table 5 - Hemi-spherical antenna module parameters**

| Hemi-Spherical Module Parameter | Value |
|---|---|
| Number of elements | 32 |
| Coverage angle | 180° horizontal / 180° vertical |
| Max EIRP | 30 dBm |

For product commercialization, the radio units with hemi-spherical antenna modules can simply be variants of existing products with an antenna module substitution.

## 3.3. Diversity and Coverage Robustness

In order to meet the more stringent requirements for IA use cases (e.g. motion control), deployments should make use of overlapping coverages from more than one access point (AP). During the network planning phase, the coverage areas from different APs should be planned with substantial overlap to allow for secondary or alternate connectivity options for each endpoint.

One possible system configuration could be to install multiple access point radio units feeding a single baseband unit which would then employ various diversity combining techniques. This concept is being investigated in an ongoing phase of this project.

## 3.4. Fast Reassociations

IEEE specification 802.11r-2008 [5] describes a fast transition technique for a client station (STA) to move its radio connection from one AP to another in a more expedited manner without having to undergo the full authentication procedure [7]. Doing so can reduce the reassociation time to perhaps 50 msec and is recommended to be done within enterprise networks using WPA2 Enterprise security. This technique should be utilized in IA systems to minimize the impact of reassociations on system performance.

It may be possible to make use of an edge compute system to help facilitate these transitions. This concept is being investigated in an ongoing phase of this project.

## 3.5. Edge Computing System

To truly enable the most meaningful IA use cases requires an edge compute system. A computing system is required to provide control and computing functionality for automated industrial endpoints and tasks. Having this computing system collocated with the endpoints minimizes latency and enables certain use cases that could not be enabled if the system was located further back in the network.

# 4. Performance Evaluations

## 4.1. First Indoor Trial

In order to test and evalutate the suitability of 60 GHz for use in Industrial Automation networks, we constructed an indoor network consisting of 10 nodes that were installed around the floor of a typical office building environment. Another 4 units were nomadic meaning their location was not permanent and could range throughout the coverage area. All of the radio nodes used in this trial were from the same vendor, identical, and based on a well known 802.11ad chipset. Three of the units were configured to be point-to-multipoint access points, and the rest were configured as client devices of those access points. Along with the radio nodes, a server cluster was installed in the telco room on the same floor to serve as a MEC system. The layout of the installed network is shown below in Figure 4.

**Figure 4 - 60 GHz indoor test network**

Since the deployed radio units do not provide a true mesh operation capability, we needed to emulate one by using multiple point-to-multipoint connections which could be configured and controlled through the switching infrastructure. To provide characteristic industrial network loading we used multiple Raspberry Pi devices to emulate industrial endpoints with 50 byte payloads at 50 packets per second. A representative test network configuration is shown below in Figure 5.

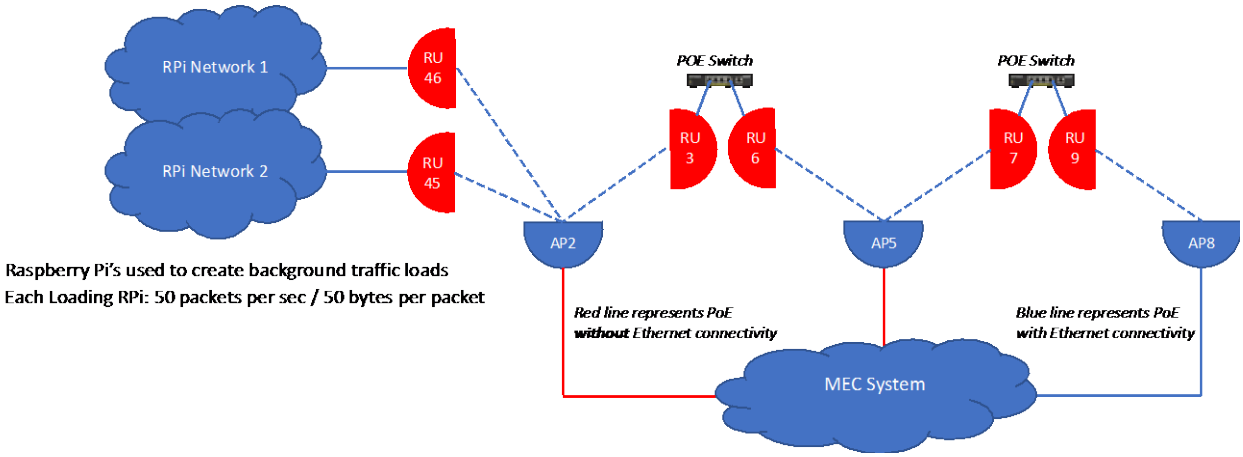

**Figure 5 - Example test network configuration**

In the example test network of Figure 5 the blue half-circles represent APs and the red half-circles represent remote units (RUs). The only egress point for packets from the MEC system is the blue line to AP8. The red lines to AP5 and AP2 have PoE to power the access points but the Ethernet connection on each switch port has been disabled. So the packets from the MEC system must traverse the path from AP8 to RU46 through 5 airlink hops. This effectively emulates a situation where the traffic from an endpoint would traverse multiple intermediate mesh nodes before arriving at the intended destination.

Several network configurations were employed and round trip delay measurements were collected for different scenarios with different types of traffic loading. In the cases labeled "Case1", the device under test (DUT) was connected to the same RU as the Raspberry Pis that were emulating industrial endpoints and a varying number of Raspberry Pis were used. In the cases labeled "Case2", the DUT was connected to a different RU than the Raspberry Pis but both Rus were connected to the same AP. Lastly bidirectional iperf traffic was used in differing amounts to create network loading. The results are shown in Figures 6-8.

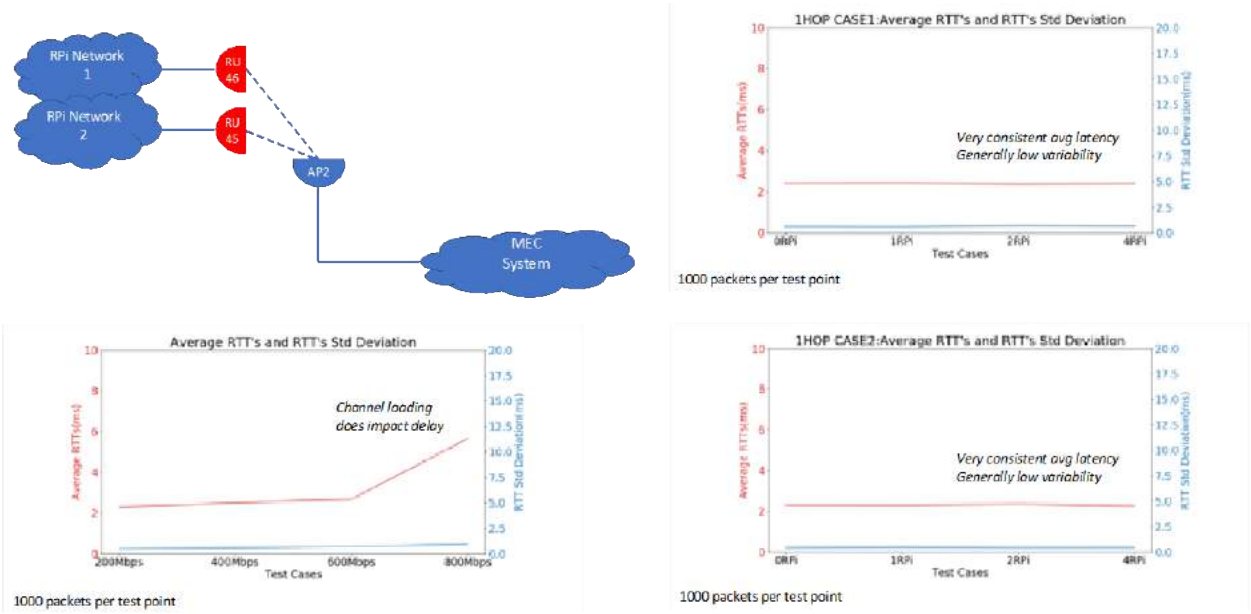

**Figure 6 - Round trip delay statistics for the 1-hop test network configuration**

As seen in Figure 6 the two sets of data from the Raspberry Pi cases are very similar. There does not seem to be enough loading from the endpoint emulators to really affect the outcomes significantly. This means that in a scenario with a fairly low number of industrial endpoints per access point with a direct connection to the MEC system the delay performance should be very consistent. This is further corroborated by the 3rd case with the iperf traffic. The delay results are very similar to the Raspberry Pi cases until the background traffic gets very high at which point the delay jumps significantly. It has been observed with certain chipsets that airlink errors which require retransmissions can stall the data queue and create a buffering delay which impacts the transmission time. This effect appears to be the cause of the increased delay for the last iperf case data point. But with lower amounts of background traffic the results track those of the Raspberry Pi cases.

In the test network configuration with 3 wireless hops as shown in Figure 7, the Raspberry Pi case results are largely just an overall increase from the 1-hop case due to the increased amount of network elements. However the last data point in Case 2 seems to show a slight increase from the buffering delay effect mentioned above. The iperf background data results show a more dramatic variation, likely due to the increased number of airlink hops presenting more opportunities for retransmissions and thus a larger impact from the buffering delays.

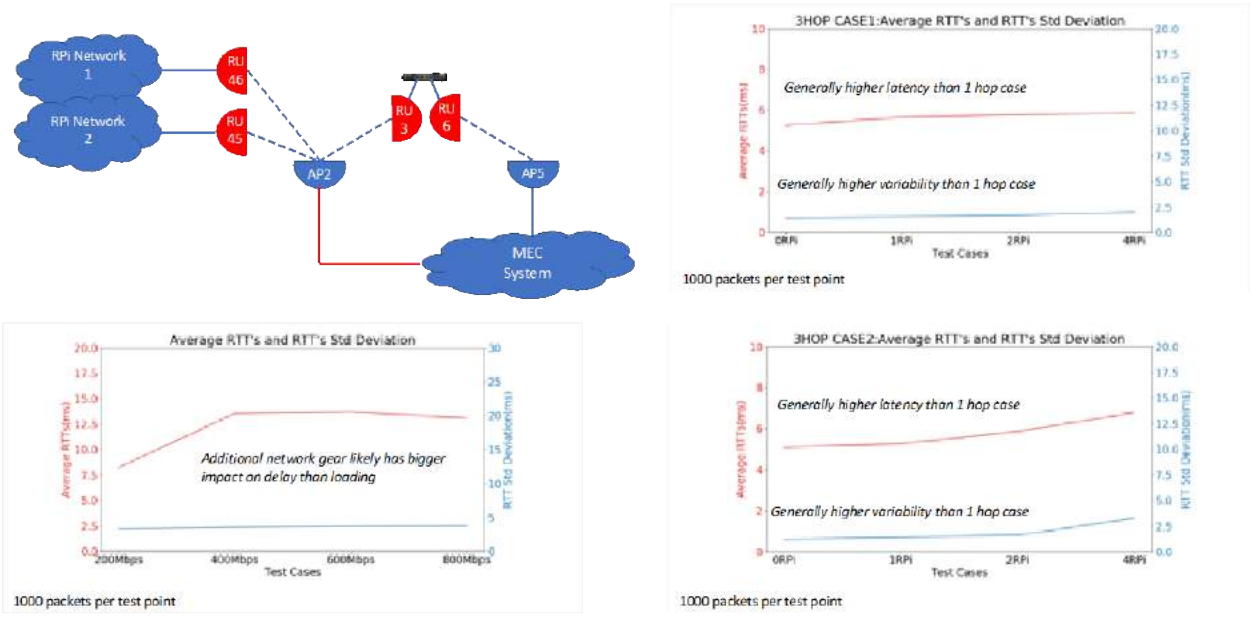

**Figure 7 - Round trip delay statistics for the 3-hop test network configuration**

For the test network configuration with 5 airlink hops, the results are even more varied as is expected. The Raspberry Pi cases are still generally consistent with more overall delay due to the increased amount of network. Again Case 2 shows more variation than Case 1 with some buffering delays being a likely culprit for the increased delay statistics during the test run.

Perhaps the most interesting results come from the iperf background data case. It is seen in that the test point with 800 Mbps background traffic, the mean delay is significantly lower than that of the test point with 400 Mbps background traffic. I believe this further exemplifies the buffering delay effect as there are now even more opportunities for retransmission events and the results reflect that.

A new aspect of 802.11ay that could be very beneficial in regulating the flow of traffic through the network is the time division duplex (TDD) scheduling feature. 802.11ad uses the typical listen-before-talk (LBT) mechanism which can lead to congestion and collisions is various points of the network, particularly the APs. With TDD scheduling each endpoint has a timeslot on the airlink reserved for its use along with an assigned priority. This new mechanism and its possible benefits will be investigated in an upcoming phase of this project.

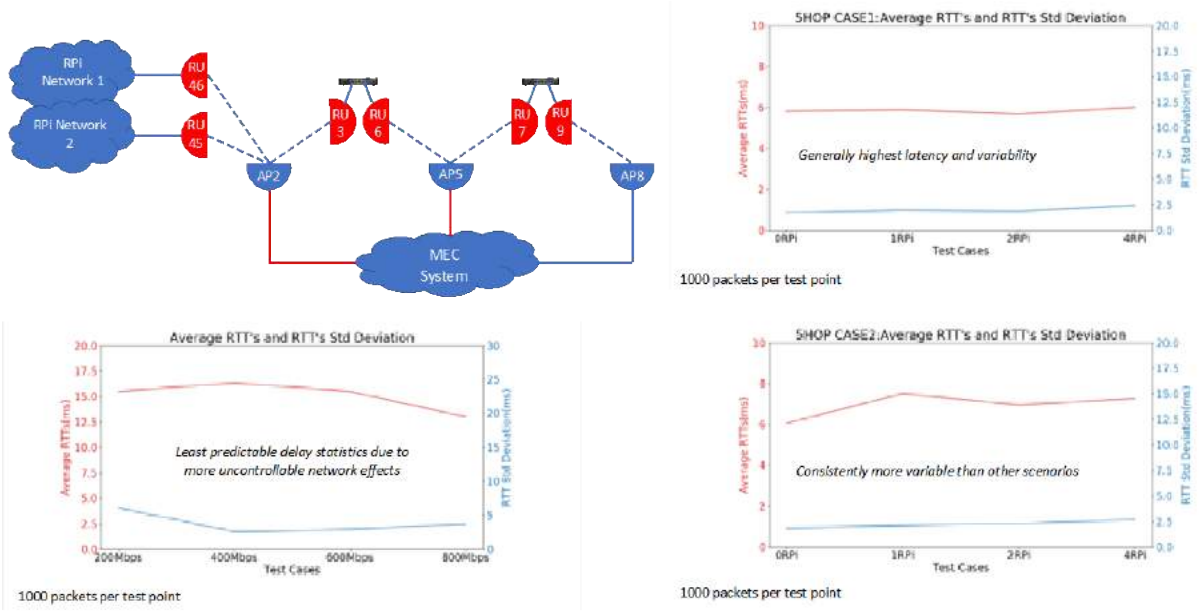

**Figure 8 - Round trip delay statistics for the 5-hop test network configuration**

Other considerations that have been observed to affect delay statistics are the sizes of the packets and the number of packets per second required for an endpoint as seen below in Figure 9 and Figure 10. The data in both of these figures was captured with the network in the 5-hop configuration along with 500 Mbps of background traffic.

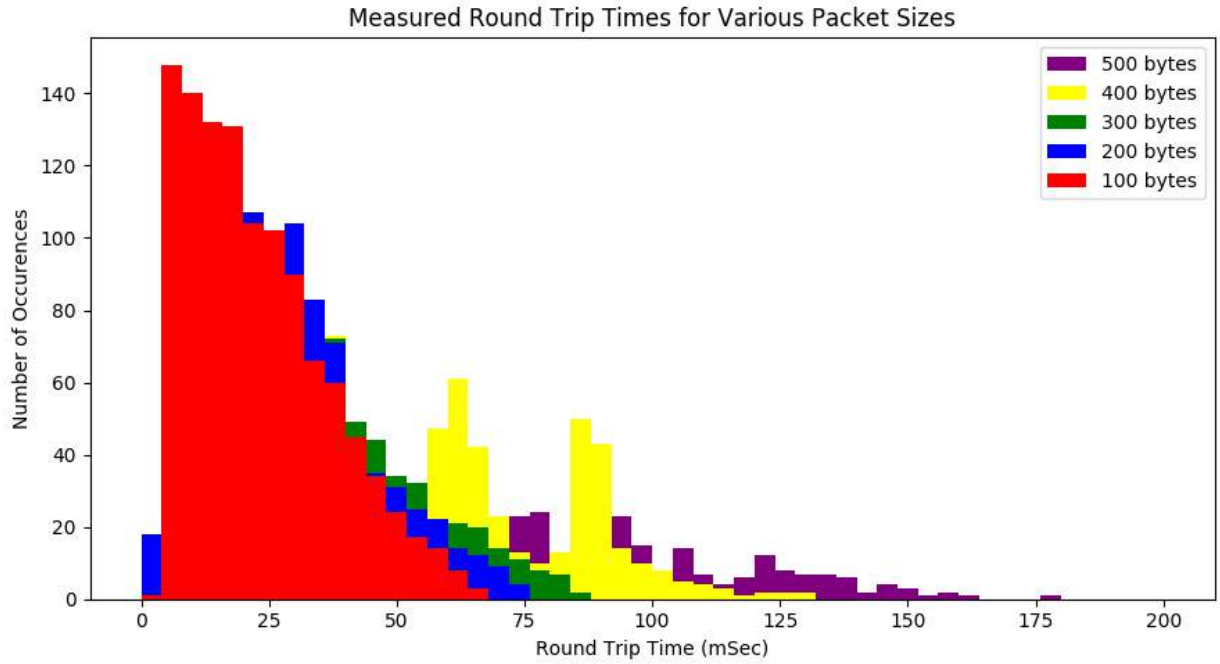

**Figure 9 - Measured round trip times for various packet sizes**

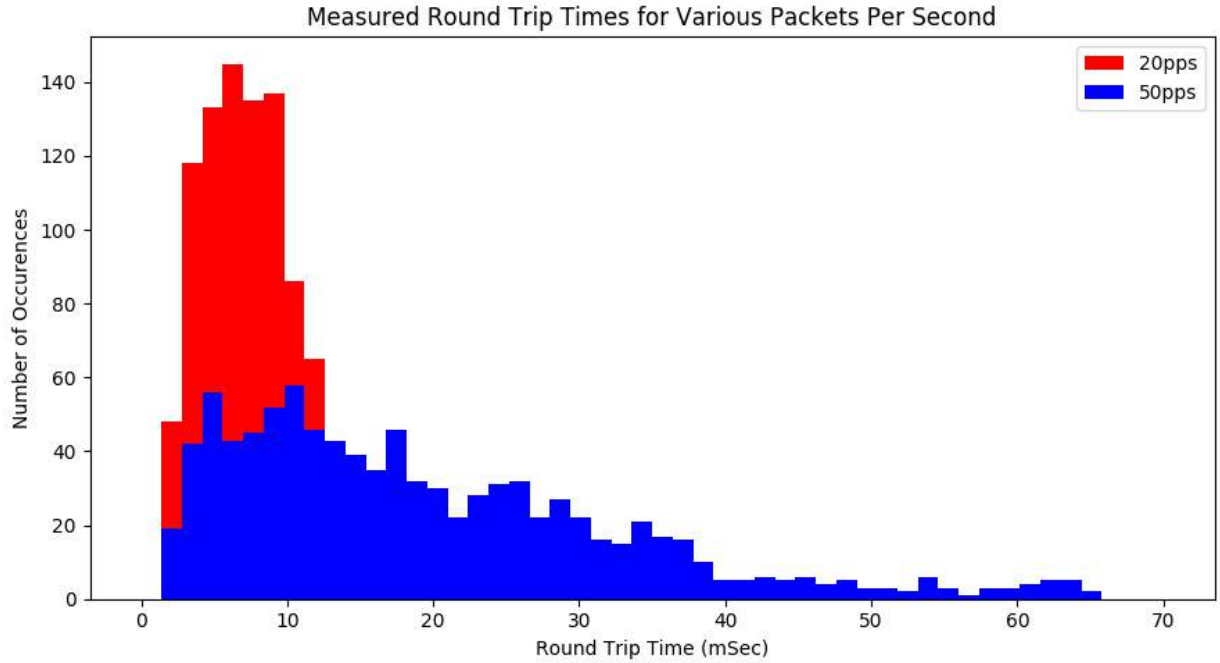

**Figure 10 - Measured round trip time with 20 and 50 packets per second**

The data runs for both figures was comprised of 1000 packets. The packet rate for Figure 9 was 10 packets per second. The packet size for Figure 10 was 50 bytes. As can be seen from the figures, packet size and packet frequency can both have significant effects on the measured round trip times, especially in the multi-hop network configurations. These parameters need to be carefully considered when deploying networks for industrial automation.

## 4.2. Second Indoor Trial

In another trial at a different location, 60 GHz indoor nodes from a different vendor were modified and deployed with different antenna modules to evaluate their suitability for IA applications. Hemispherical antennas were determined to be the best choice at both APs and clients. The use of hemispherical antenna modules are recommended for indoor IA applications which can provide performance improvements compared to the multiple input multiple output (MIMO) antenna modules.

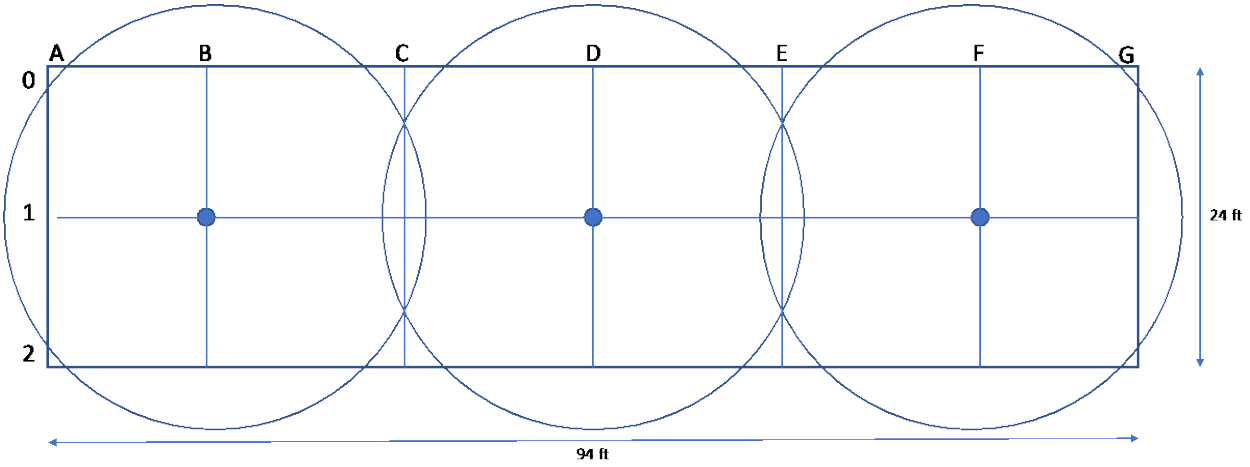

**Table 6 – Measured RSSI (dBm)**

| Row | A | B | C | D | E | F | G |
|---|---|---|---|---|---|---|---|
| **0** | -55 | -59 | -57 | -57 | -60 | -55 | -59 |
| **1** | -55 | -55 | -61 | -55 | -59 | -55 | -58 |
| **2** | -59 | -57 | -58 | -54 | -60 | -55 | -57 |

**Table 7 - Measured round trip delay (microseconds)**

| Row | A | B | C | D | E | F | G |
|---|---|---|---|---|---|---|---|
| 0 | 282 | 333 | 397 | 380 | 345 | 339 | 311 |
| 1 | 390 | 363 | 351 | 468 | 452 | 471 | 532 |
| 2 | 410 | 384 | 354 | 385 | 418 | 369 | 380 |

Delay measurements seen in this second trial are much lower and more consistent, so equipment selection is critical for IA network performance. Even though vendor #2 uses the same chipset as vendor #1, the performance characteristics, especially delay, are substantially different due to the specific equipment implementations. As with any network application, equipment selection should be carefully considered for IA networks to achieve the required level of performance.

Use cases that require endpoint mobility along with real-time and/or constant control cannot readily achieve the required QoS with standard 802.11ad equipment. Of course there are many factors that govern this situation, but the amount of time required for endpoint reassociations between APs can easily exceed the required control packet interval resulting in performance issues for the more demanding use cases such as motion control. Further enhancements are needed for mobility situations and robustness against connection issues due to objects moving within the environment if real-time control is required. Improvements for these scenarios are being investigated as an ongoing phase of this project.

# 5. Use Cases and Demonstrations

In order to assess and characterize the performace of 60 GHz networks for industrial automation applications, several demonstrations were developed each employing several IA use cases.

## 5.1. Demonstration System #1

The first demonstration involved a user-controlled mobile robot car that is piloted through a series of gates in a timed course. A live video stream from the robot car is displayed on a computer monitor and the user is told by the MEC system which gate to navigate to next. The position of a game controller joystick is read by the system and converted to servo motor parameters which are sent to the robot car to control its speed and direction. The user is then able to pilot the car using the displayed video and the joystick control. The elapsed time is also displayed for the user. Infrared (IR) sensors in each gate detect the presence of the robot car and the user is then given the next gate in the course on the screen by the system. If the wrong gate is detected by the system, this notification is displayed on the screen. The course continues until the last gate is reached at which point the elapsed time is recorded.

### *5.1.1. Use Cases Demonstrated*

The industrial automation use cases demonstrated in Demo #1 are listed below in Table 8.

**Table 8 - Demo #1 use cases**

| Use Case | Description |
|---|---|
| **Motion Control** | Robot servos updated 20 times per second according to the joystick position |
| **Control-to-Control** | Live video stream (4 Mbps) from robot to desk client |
| **Closed Loop Process Control** | Next gate indication and elapsed time display |
| **Process Monitoring** | Gate status messages including wrong gate detection |
| **Mobile Control Panel** | Real time progress and status displayed on desktop |

### *5.1.2. Demonstration System Architecture*

The system architecture of the demonstration system is shown below in Figure 11.

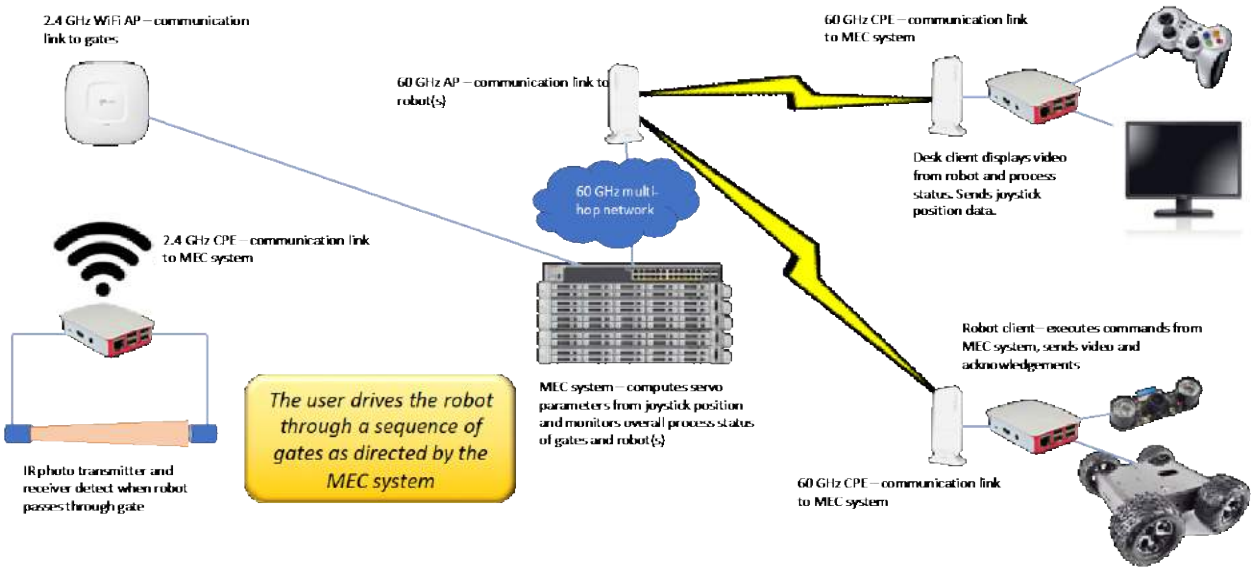

**Figure 11 - Demo #1 system architecture**

This demonstration system features a mobile robot which is controlled by a game controller joystick. The mobile robot includes a camera which streams video back to the user. The user then moves the joystick to control the speed and direction of the robot. With this interface the user directs the car through a series of gates which is monitored by the MEC system. The elapsed time is displayed on the output screen, and the overall goal is to have the robot go through the correct sequence of gates in the shortest amount of time.

### 5.1.3. Demonstration System Data Messaging Architecture

The sequence of messages that flow between the various functional entities of Demo #1 is shown below in Figure 12.

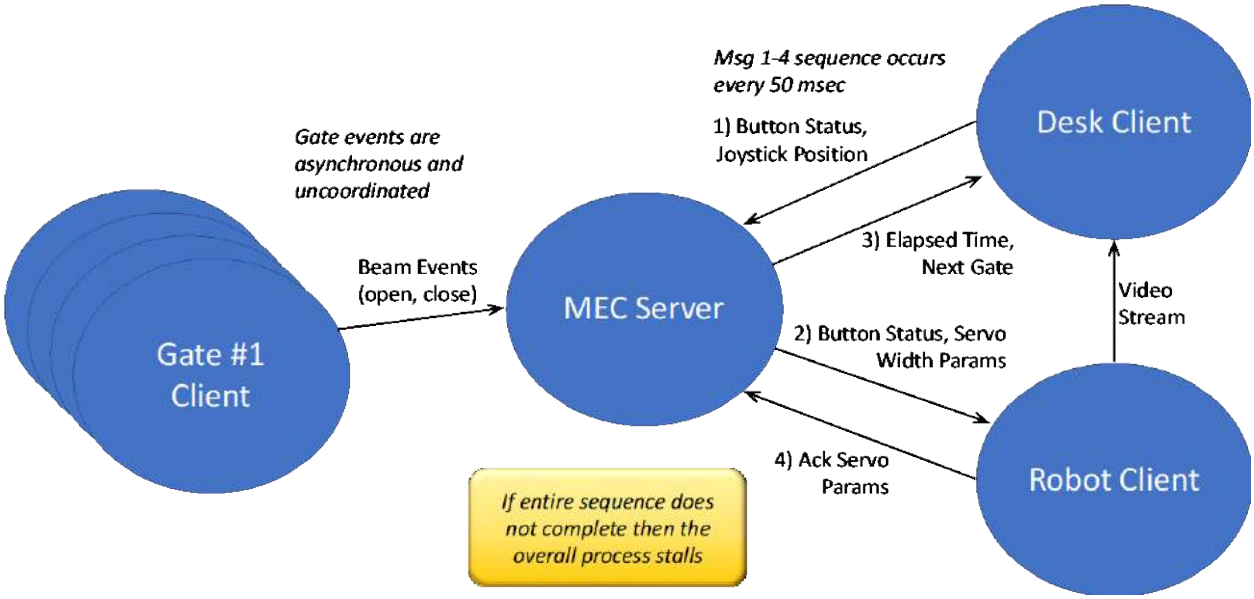

**Figure 12 - Demo #1 data messaging architecture**

The data architecture and message flows depicted in Figure 12 is implemented rather poorly on purpose. If any of the messages in the continuous sequence 1-4 are lost then the entire process will stall. Admittedly this is poor software design, however for our puposes this will readily illustrate when a packet loss creates a critical problem for a use case. During the normal course of the demonstration this situation never occurred. It can occur if the robot car is driven beyond the coverage area of the access point. This would be considered a mobility situation and as stated above, mobility enhancements are being investigated in an ongoing phase of this project.

## 5.2. Demonstration System #2

A second system was developed to demonstrate a fully autonomous scenario involving 2 robots performing interactive tasks as directed by the MEC system. The demo consists of a robotic arm loading a number of widgets into bins mounted on a mobile robot. The MEC system directs the mobile robot to go to the first loading position and monitors its progress during the trip. Once the mobile robot is in the correct position the MEC system directs the robot arm to load widgets into the first bin mounted on the mobile robot. The robot arm movements consist of a series of poses that are directed and monitored by the MEC system and require quite a large number of messages to perform. Once the first set of widgets is loaded, the MEC system directs the mobile robot to turn around so a second set of widgets can be loaded into a second bin. Once the mobile robot is in the new position the robot arm performs a similar series of actions as before to load another set of widgets into the other bin. Once the second set of widgets is loaded the mobile robot is sent off to its next location and its progress is monitored.

### 5.2.1. Use Cases Demonstrated

The industrial automation use cases demonstrated in Demo #2 are listed below in Table 9.

**Table 9 - Demo #2 use cases**

| Use Case | Description |
|---|---|
| **Mobile Robots** | Mobile robot with 3 pre-programmed waypoints and position status checks every 100 msec. ~1100 messages exchanged during the demo. |
| **Motion Control** | Robot arm with 58 separate poses controlled by the MEC system. ~144,500 messages exchanged during the demo. |
| **Process Monitoring** | 5 interlinked segments monitored and coordinated by the MEC system during the demo. |

### 5.2.2. Demonstration System Architecture

The system architecture of the second demonstration system is shown below in Figure 13.

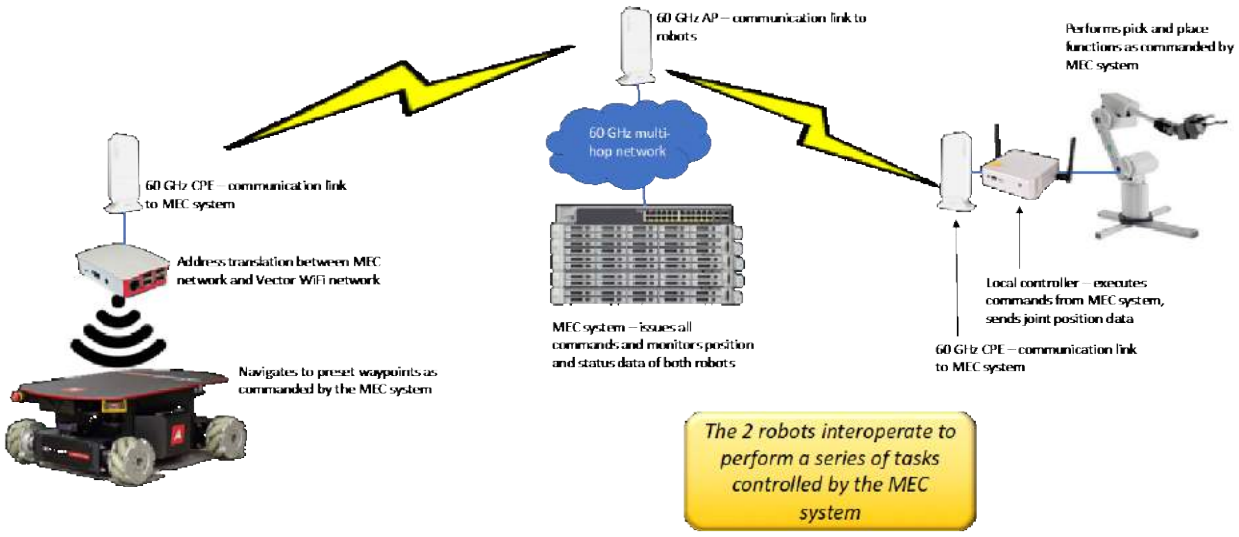

**Figure 13 - Demo #2 system architecture**

In this demonstration everything is controlled and monitored by the MEC system. The robots are programmed to perform certain tasks which requires both to operate appropriately in order to complete the overall job successfully. The overall job is for the mobile robot to collect a number of widgets which

are loaded onto it by the robot arm. So there are five distinct job phases that are controlled and monitored by the MEC system.

# 6. Economics and Ecosystem

In this section I will define and illustrate an example industrial space for comparative purposes (50 m x 20 m). The following sub-sections give the expected equipment for deploying networks based on 60 GHz nodes vs a 5G system.

## 6.1. Example Network Comparison

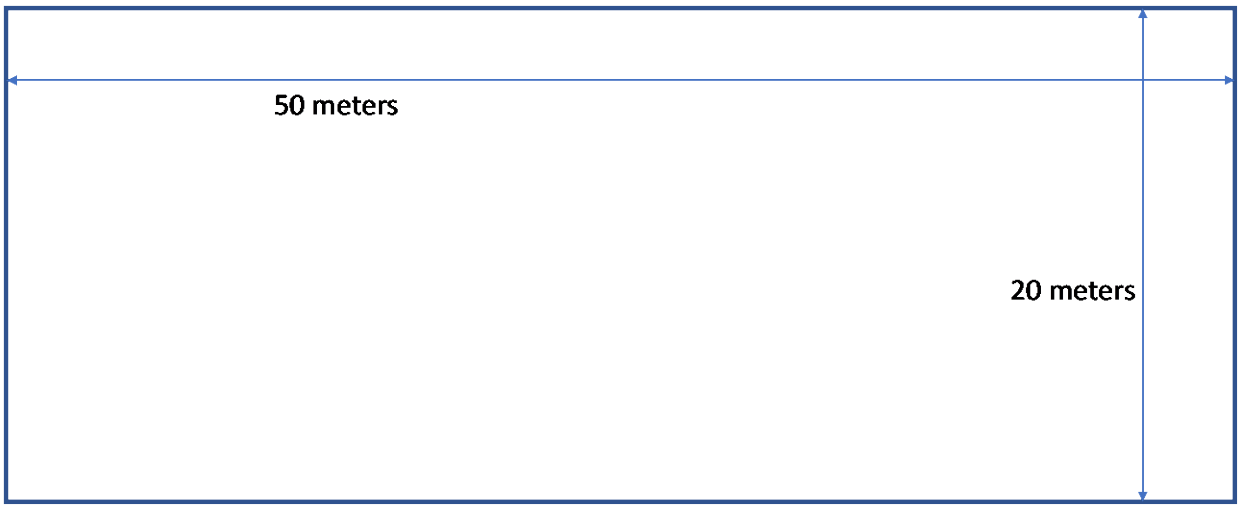

**Figure 14 - Example industrial space**

### *6.1.1. 60 GHz Example Network Costs*

Based on the network deployed in the 2nd indoor trial described above, it is reasonable to assume that 2 rows of 4 access points would be needed to cover the example space defined above. Although fewer APs might serve to provide adequate coverage, this number will provide the desired overlapping coverages to allow endpoints to reassociate as required to meet the necessary level of performance.

The costs of capital expenses (CapEx) for a 60 GHz network to address the example space are listed below in Table 10. These include both equipment and installation costs.

**Table 10 - Example 60 GHz network CapEx costs**

| Element | Unit Cost | Quantity | Subtotal |
|---|---|---|---|
| Access Points | $500 | 8 | $4000 |
| AP Installation | $250 | 8 | $2000 |
| STA Endpoints | $200 | 20 | $4000 |
| STA Installaion | $50 | 20 | $1000 |
| Edge Compute System | $5000 | 1 | $5000 |
| Total 60 GHz (CapEx) | | | $16000 |

The example 60 GHz network would not require any additional components beyond what is already part of the customer's IT infrastructure. Operational expenses for the network equipment (e.g. power) would be covered by the customer. The CapEx costs would be factored into a services offering by the MSO as part of a larger bundle which could include value-add services such as analytics and predictive maintenance. The relatively low network expenses, both capital and operational, could make this approach quite attractive for MSOs and their service integrator partners.

### *6.1.2. 5G Example System Costs*

For the example space the most appropriate 5G radio units would be industrial picocells. Based on the dimensions of the space it is likely that three units would be required to allow sufficient coverage overlap. Assuming the 5G core network (5GC) is located in the multiple-system operator (MSO) network, an on-premises user plane function (UPF) unit is required to handle local Ethernet traffic between the MEC and the picocells.

**Table 11 - Example network 5G CapEx costs**

| Element | Unit Cost | Quantity | Subtotal |
|---|---|---|---|
| **Industrial Picocells** | $5000 | 3 | $15000 |
| **Picocell Installation** | $250 | 3 | $750 |
| **Enterprise UPF Unit** | $2000 | 1 | $2000 |
| **STA Endpoints** | $250 | 20 | $5000 |
| **STA Installation** | $50 | 20 | $1000 |
| **Edge Compute System** | $5000 | 1 | $5000 |
| **Total 5G (CapEx)** | | | $28750 |

The 5G system does require connectivity to a 5GC which for this exercise could be located in the MSO network. The MSO would likely factor the operation and maintenance cost of the 5GC into the offered

services package which would be an additional monthly operational expense for the customer. If the customer requires or does not wish for their internal traffic to be exposed to the MSO they could be provided with an on-site 5GC to enable a private network for an additional CapEx cost plus it is likely the MSO would charge an operations and maintenance charge for the local 5GC.

Another aspect of the 5G system is that of usable spectrum. Currently 3GPP 5G systems require licensed spectrum over which to operate. The standards for 5G NR in unlicensed spectrum (NR-U) are expected to be ratified in September, 2020, and this will allow for operation of 3GPP 5G systems in unlicensed frequency bands once equipment is commercially available in 2021. However, most 5G networks are non-standalone (NSA) meaning they require a 4G anchor channel in order for the 5G channel to operate. As networks evolve these limitations will go away, but they will be a major deployment consideration for the next few years and should be factored into any service offerings and target markets.

## 6.2. Ecosystem Comparisons

### *6.2.1. 60 GHz Equipment Ecosystem*

Currently the 60 GHz equipment ecosystem is not large. In 2018 the global millimeter wave technology market was $289.2M with the frequency range 57-86 GHz having the primary revenue generation for the market [10]. This market is primarily focused on outdoor equipment with few offerings for indoor gear. The 802.11-based 60 GHz equipment market is expanding due to Facebook's Terragraph initiative, but that equipment is largely targeted for outdoor access and backhaul. Indoor is becoming of more interest, but it will take time for new players and offerings to come to market.

The largest 802.11ad chipset supplier is Qualcomm, but there are several others as well. Most notably Sivers and Peraso supply 802.11ad radio ICs along with Peraso and Blu Wireless who supply 802.11ad baseband ICs. Intel produces 802.11ad ICs for endpoints, but they seem to be used only in Intel modem products. With the advent of 802.11ay it remains to be seen how the chipset and corresponding equipment landscapes may change. Qualcomm is producing an 802.11ay chipset that is being used extensively in the Terragraph equipment, but it is not yet available in mass market quantities. Peraso has also announced an 802.11ay chipset and others will as well as the equipment market develops further.

Much of the currently available equipment has similar specifications due to limited number of chipset suppliers and equipment manufacturers vying for largely the same target markets. Differentiation and competitive advantages seem to come largely from support systems e.g. management, configuration, etc.

***Bottom Line: The 60 GHz chipset and equipment markets comprise both large and small players, but the equipment target markets have not taken off so overall there is not a lot of muscle behind the current offerings.***

### *6.2.2. 3GPP 5G Equipment Ecosystem*

The 3GPP ecosystem is very robust, but sadly the 3GPP ecosystem is no longer as diverse as it once was due to many consolidations amongst vendor companies. Last year the 5G global infrastructure market was nearly $1B and by 2026 it is predicted to be over $50B [11]. The market is supported by heavyweight equipment and chipset vendors that can be considered telecom institutions. The variety of offerings is staggering with a range of radios that run a gamut from ones that suppport very large cells to ones used in very small cells in a wide variety of frequency bands and combinations of frequency bands. The radio platforms can be based on anything from standard chipsets to purpose-built designs to commercial off-the-shelf (COTS) hardware.

The 5G standards targeting industrial automation operation are still expected to be fully ratified in September of 2020. This operation is called ultra-reliable low-latency communication (URLLC), and equipment that supports this feature is expected to be available near the end of 2021 at the earliest.

The 3GPP 5G standardization activities are very active and highly dynamic with 370 total 3GPP members and 1267 5G related standards in Release 16. The 5G promotional activities as well are highly spirited with many companies touting the virtues of the new technology in creative and interesting ways.

***Bottom Line: The 3GPP 5G chipset and equipment markets are dominated by heavyweight telecom giants offering a wide selection of gear for many target markets. This includes Industrial Automation with the new URLLC feature once equipment is available late next year.***

# 7. Conclusion

60 GHz radio technology can provide robust connectivity for indoor environments. Line of sight is not necessarily required due to the tendency for the radio signals to undergo a considerable amount of scattering from objects and surfaces in the environment. As such, precise antenna orientation does not seem to be as critical for the target environments. There is naturally some variability in the radio signals, but generally the radio links have been seen to be very stable and provide robust connectivity. The emerging 802.11ay standard will provide true mesh capabilities which will further enhance performance and robustness of the target scenarios compared to the equipment and network configurations that were used for this study so far.

In general the observed performance of the tested representative network configurations can support 3GPP use cases with the sole exception of the most stringent motion control case. Other sub-categories of motion control require 3 and 6 msec round trip performance which can readily be achieved with proper network planning and equipment selection. For these use cases networks should be limited to the 1-hop configuration to ensure that the required performance is achieved.

Multiple ingress/egress points are critical for fault tolerance and for system performance as well. Mesh is best suited for this, but a nearly equivalent situation can be achieved with multiple Point-to_Multi-Point (PtMP) deployments provided the clients can reassociate as required to meet the system performance criteria. IA networks should be designed for service delivery aspects, but this can lead to complications if reconfigurations are needed. Packet sizes and repetition rates are key parameters for IA network designs.

As observed in our testing some equipment can exhibit uncontrolled behaviors. This may limit the addressable target applications in the short-term, but with new chipsets and equipment (e.g. 802.11ay) these limitations are likely to disappear. Another aspect of 802.11ay that could be very beneficial in this regard is the TDD scheduling feature which should regulate the traffic flows through the network much more than the listen-before-talk behavior of 802.11ad.

In conclusion, 60 GHz networks can deliver < 2 msec round-trip time (RTT) latency and meet 3GPP use case performance requirements today with proper equipment selection and network design for substantially less total cost of ownership (TCO) and will offer better capabilities for addressing these use cases in the near future.

Acknowledgements: The author would like to thank Pooja Shankar for conducting much of the testing done in the first indoor trial.

# 1. Introduction

Security and Privacy must be top line features of any service operating today. Twenty years ago, the team at CableLabs prescribed SNMPv3 with Diffie Hellman key exchange for encrypting management traffic from DOCSIS cable modems. While SNMP is dated, simple non-sensitive management data is still integral to CM operations. Yet in 2020, few production implementations of encrypting SNMP have been reported. Because CM management traffic lives behind numerous other layers of network and physical security, this has not been a significant issue. Still, leaving the CM management data in clear text SNMP is an operational luxury that should be phased out of practice. Switching to newer, more secure protocols is a future solution that overlooks the millions of installed DOCSIS CMs. As part of Comcast's ongoing evolution of security and privacy, clear text SNMP data has been deprecated. DOCSIS cable modem management is now encrypted with SNMPv3 utilizing Diffie Hellman key exchange as specified by CableLabs. Associated mechanisms for securely managing the privacy keys and bootfiles are part of the larger solution. This paper will highlight technical issues of implementing SNMPv3 with Diffie Hellman key exchange at MSO scale.

# 2. Don't Panic

The information exchanged over SNMP is focused on operating network equipment. The information includes data such as the uptime of the device,. the list of interfaces and their name, and the number of packets going in and out of the device. There should not be any sensitive material such as credit card numbers, account numbers, or other identifiers contained in the data. Since the first two versions of the protocol had no security, the optimistic expectation for implementors was "don't put sensitive data into SNMP MIBs".

This understanding may have been adequate in the 1980s, when SNMP was first created. In 2020, this is no longer tenable. Various SNMP-based denial of service attacks pose new threats. In addition, privacy requirements that have evolved make this a protocol that should be removed from modern networks.

There are hundreds of millions of DOCSIS cable modems providing service in cable operators' networks that use SNMP. Replacing all of them to remove SNMP is operationally unrealistic.

This is where adding encrypted SNMPv3 with Diffie Hellman key exchange provides an important layer of privacy for these devices. CableLabs and the IETF released RFC 2786 in 2000, and DOCSIS cable modems are required by the CableLabs DOCSIS CM-SP-OSSI specification to implement the RFC.

Actually deploying DH key exchange at scale was left to implementers: "The configuration [of the cable modem SNMP agent] would be done either manually (in the case of a small number of devices), or via some sort of distributed configuration file. The actual mechanism is outside the scope of this document [RFC 2786]."

This document provides a guide for that out of scope effort. This document does not reveal Comcast's implementation of an SNMPv3 DH key management system. There are decision points and examples for needed subsystems that can constitute an overall solution. Any given implementation will be unique to the environment where it is deployed.

All examples are for illustration purposes only and should not be used in actual production without formal review.

# 3. Get On With It

Key design decision: Get over the debate and get on with the deployment of DOCSIS CM SNMPv3 with DH key exchange.

The MD5 hashing algorithm and the DES encryption algorithm with 56-bit keys prescribed in RFC 2786 have been deprecated. They are obsolete because they can be compromised. The SNMP User Security Model described in RFC 3414 highlights the limitations of the overall SNMP security model.

If the information from the cable modems has a low security value, and it is protected by many other layers of security, why even bother obscuring it with known weak encryption?

This question may be argued numerous times and numerous ways by numerous engineers. They will raise valid technical points. Undertaking the journey to SNMPv3 with DH key exchange starts with managerial direction, not technical requirements. For instance, there may be a corporate directive to remove SNMPv2 in the network. A corporate information policy may require that systems encrypt all data in transit. The key here is to stop the debate and get on with implementation.

# 4. Cue the Diffie Hellman Key Exchange

Key design decision: Validate whether your code base supports the use of local keys for the SNMP agent on the cable modem.

As of this writing, the Net-SNMP utilities and Java's SNMP4j library support the use of local keys. This section summarizes differences between SNMPv2 community, SNMPv3 USM, and SNMPv3 USM with DH key exchange. It uses the Net-SNMP command line tools to demonstrate these differences in the calls to each service. This knowledge is required to plan necessary upgrades to the current SNMP polling software. An SNMP poller is formally an "SNMP Command Generator" or "SNMP manager" and can be implemented in numerous forms.

## 4.1. SNMPv2 Community

Reinforcing that "S stands for Simple", the SNMPv2 community string is a plain text way to group SNMP managers' and agents' commands and responses. The community string is sent in clear text as part of an SNMPv1 or v2 packet. This offers no security at all nor was it intended to.

```
$ snmpget -v 2c -c commString 10.168.6.82 system.sysUpTime.0
10.53.115.71.58645 > 10.168.6.82.161:  { SNMPv2c C="commString"
{ GetRequest(28) R=445233587  .1.3.6.1.2.1.1.3.0 } }
10.168.6.82.161 > 10.53.115.71.58645:  { SNMPv2c C="commString"
{ GetResponse(32) R=445233587  .1.3.6.1.2.1.1.3.0=182774513 } }
```

**Figure 1 - SNMPv2 Community Example**

## 4.2. SNMPv3 User-based Security Model with no authentication or privacy

This may seem counter-intuitive, but SNMPv3 provides a method for unsecured communication. The SNMPv2 "community" evolves into the SNMPv3 "user". There is a default user with default views and

permissions prescribed in RFC 2786 that all DOCSIS cable modems implement. This becomes important later on for exchanging keys. This example uses the default DOCSIS user “dhKickstart” with no authentication or privacy keys in the request.

```
$ snmpget -v 3 -l noAuthNoPriv -u dhKickstart 10.168.6.82
system.sysUpTime.0
```

**Figure 2 - SNMPv3 No Authentication No Privacy Example**

### 4.3. SNMPv3 User-based Security Model with authentication and privacy

SNMPv3 adds methods for authenticating message transmission and reception. It also provides methods for encrypting the contents of the message in transit. The standard RFC 3414 implementation uses an authentication key and a privacy key that are loaded into the SNMP manager and the SNMP agent(s). The manager and agents use these keys in the algorithms prescribed by RFC 3414 to transmit and decrypt messages in lieu of plain text SNMPv2.

```
$ snmpget -v 3 -l authPriv -u v3keysTest -A TestAuthenticationKey -X
TestPrivacyKey 10.168.6.21 system.sysUpTime.0
```

**Figure 3 - SNMPv3 Authentication + Privacy Example**

### 4.4. SNMPv3 USM authentication and privacy with DH key exchange

The addition of DH key exchange prescribes a method where the authentication and privacy keys are derived based on cryptographic methods. This improves on the standard SNMPv3 implementation because it removes the actual keys from the cable modem configuration. This example shows authentication and privacy keys that are precomputed based on the DH key exchange, and are then used in the call to the Net-SNMP utilities.

```
$ snmpget -v 3 -l authPriv -u v3localKeys -3k
0xf9c96a9232ee65a08aa9085e6f1ff82c -3K
0xedebac85112645218fb7a63659a332c2 10.168.6.21 system.sysUpTime.0
```

**Figure 4 - SNMPv3 Authentication + Privacy + Local Keys Example**

These examples are simple demonstrations of how calls from an SNMP manager to an SNMP agent change. The specific code used in a cable provider’s system will need to be upgraded similarly.

## 5. Roll a Random Number

Key design decision: Creating and managing the distribution of the Manager Random number(s).

The manager random number is the basis for all subsequent activities associated with RFC 2786 DH key exchange. A random number is transformed according to the algorithms in RFC 2786 to arrive at the

manager public key that must be included in the cable modem boot file. Each calculated public key is exposed through the CM's SNMP MIB as a "usmDHKickstartMgrPublic" key. Each SNMP user profile must have its own manager random number to create its unique key. The cable modem follows a similar process and creates its own "usmDHKickstartMyPublic" key for each user as well. These values are then further processed and used in calls from the SNMP manager to the SNMP agent as shown in the previous section.

The simplest and least secure way to manage the random number is to make it available to the SNMP polling systems the same way the SNMPv2 community string was provided. Methods such as email, text files, or hard coded configuration pushes allow any system to calculate the DH keys based on the manager random number. This is also the least secure method a system designer could choose.

More secure solutions also require more effort to manage. Code repositories or secured APIs with token authentication schemes can be used. A formal key vault or similar key management infrastructure may be used to authorize access to a given manager random number for a given user.

Since an SNMP manager needs to be able to calculate the authentication and privacy keys any time a cable modem reboots, the scaling of the system which manages needs to be carefully considered and expanded to accommodate the potential query traffic. The parameters a system designer needs to consider include: the number of SNMP USM profiles with unique manager random numbers, the number of different boot files in the system, and the frequency of change of the manager random numbers. Since an SNMP manager could calculate the keys itself, the number of cable modem reboots in the overall system is less important at the manager random number distribution level.

The system designer may also wish to avoid handing out the manager random number(s) completely, and instead offer a service that provides the pre-calculated keys to requestors. This keeps the manager random numbers from being cached or redistributed to other parties.

## 6. Keeper of the Keys

Key design decision: Manage the distribution of calculated USM keys in lieu of sending out manager random numbers

Another layer of flexibility can be added with a USM key management service. Instead of directly sending out the manager random numbers, a dedicated service can be created to produce the authentication and privacy keys to requestors.

There are security benefits to a USM key distribution service. The manager random numbers are not divulged to the requesting SNMP manager, only the calculated keys. This improves the security of the overall system. It also removes the necessity of SNMP managers to calculate the keys themselves, which may require significant code updates.

There are also drawbacks to distributing calculated keys. The primary challenge is scalability. Since the cable modem public keys change every time the cable modem reboots, the service must be able to refresh the CM public key from any modem when it reboots. A separate key distribution also creates a serial failure scenario. If SNMP managers must retrieve the precomputed keys from a key distribution service, and the service is impaired or down, visibility will be lost to the CMs as they reboot over time.

A separate USM key service like this may be used for all the users and all the keys, or it may be selective for only the user(s) that have read and write access. This may provide a compromise between potential loss of visibility, query rate, and key integrity.

The final consideration for a USM key service is the potential query rate. The CM keys change every time they reboot, hence the USM service must retrieve and recalculate the keys each time. Then the new keys must be made available to any SNMP manager using the service. The number of cable modems, the number of reboots, the number of SNMP managers in the system, and the frequency of SNMP queries from the SNMP manager are all scaling factors that will result in the potential query rate the key store would need to accommodate.

## 7. Pick User Profiles

Key design decision: SNMP users and roles to include in the CM bootfile to generate DH keys. Each user profile will create its own public key based on its own manager random number, which will then be used to calculate the local keys for that user.

The unsecured "dhKickstart" user documented in RFC 2786 has a basic view and access to the public keys necessary to calculate the actual CM local keys. Additional users should be added with appropriate views and permissions to monitor the cable modems. Operators may leverage existing RFC 3414 USM and RFC 3415 VACM profiles in their cable modem boot files. These may be copied or further refined as desired for SNMPv3 with DH key exchange.

There is nothing extraordinary about these users or profiles. The one decision point of note is whether to partition a read/write user and read/only users.

## 8. Break Out the Bootfiles

Key design decision: How the system will manage the bootfiles with the new users and keys.

Cable modem provisioning systems already manage multiple bootfiles. Adding the SNMPv3 users and manager random numbers to the bootfiles may increase this quantity. There are numerous ways for a cable operator to partition the bootfiles. Groupings might include the CM manufacturer, model number, physical location, organizational responsibility, provisioning complex, or other criteria.

Dynamically generated bootfiles with a unique manager random number for each user on each cable modem would be the most secure solution. If an actor obtained one manager random number for a given CM, an SNMP session could be negotiated to only that cable modem with the specific user. The manager random number would change when that CM rebooted, and all the security parameters would be reset. This is also the most difficult scenario to manage. The provisioning system that generates the bootfiles would also have to seed the distribution system for all the manager random number(s) as described above.

A single random manager number that is used for the keys in every bootfile is the easiest solution, and clearly the least secure. Any actor that obtains the manager random number could securely negotiate DH sessions with any cable modem in that system.

Deciding how many users and manager random numbers could thus simply leverage the existing bootfile management method. It could also completely change the management and distribution of them.

## 9. Double Click

Key design decision: Whether SNMP pollers rely on cached keys, or query and calculate keys for each session.

As shown below, querying the usmDHKickstartMyPublic key(s) from a given cable modem with the default dhKickstart user should always return the cable modem public keys.

```
$ snmpbulkwalk -v 3 -m ALL -l noAuthNoPriv -u dhKickstart 10.168.6.82.161
snmpUsmDHObjectsMIB
SNMP-USM-DH-OBJECTS-MIB::usmDHKickstartMyPublic.1 = Hex-STRING:

```

**Figure 5 - CM Public Key Query Example**

Whether the SNMP manager is a subsystem within a USM key management service described previously or a separate manager that has access to the SNMP manager random number for a given user, the fact that the keys only change when the cable modem reboots can be used as a convenience to avoid double querying the modems.

## 10. Prime the Pollers

Key design decision: Scaling the SNMP poller inventory to accommodate the key exchange and encryption overhead.

The additional response time from the CMs with the key exchange and encryption at MSO scale is non-trivial yet manageable. Response time measurements of agent response in laboratory settings have shown small increases of a few milliseconds or less. Scaling out to CMTSs with thousands of CMs and carrying full customer traffic have shown increases from a few milliseconds to a few seconds depending on CM and CMTS load at the time. Some phenomena observed in the production network include:

“Warm up failures”, or CM key exchanges that take longer than expected.

Serialized key negotiation to sets of modems that should be converted to parallel queries.

Data response times that take randomly longer than the SNMPv2 equivalent.

The solution for a system designer is the same: additional SNMP pollers with code optimized for parallelism. Experience at Comcast’s scale shows a 30% to 300% increase in resource needs depending on the polling software and computing platform. Physical servers, virtual containers, threading models, cloud computing instances, and more may need to be scaled specifically to meet the overall system demands. There has not been a universal solution observed at Comcast’s scale; all of the above have needed some adjustment based on full production deployment. The good news is they were all identified during the roll out and addressed so that the project was deployed successfully.

## 11. Conclusion

Adding privacy by encrypting cable modem management traffic starts by opening the door to RFC 2786. The keys in this presentation are provided to help guide design decisions necessary to implement SNMPv3 with DH key exchange on CMs at production scale. The balance between maintainability and scalability of each key must be considered as part of the overall system design and implementation.

# Appendix 1 RFC 2786 DH key exchange simulation

All of the constants and mathematics associated with the DH key exchange are documented in RFC 2786. The following illustrates these calculations using open source tools. The methods shown are long, single steps for demonstration purposes. Actual systems implementation would be succinct.

Pick a 1024 bit manager random number:

```
$ python3 -c 'import secrets; print( hex ( secrets.randbits(1024) ) )'

0x8ad7112ed1742765da233bb761f44cc69b329161e1a2a1c28032c25445566284bf6ca06a8a91b2a49c06
b7198aeb1574570b1e1ab22f7a9c471d01ed1f260f7356e3c88b92f06e70a14ac91480677aa4c571fb0d1c
f0a9857d027f98b1426701ab6fb27a933b0db3821b7c401fdcb7f4077ae87c4f64f682a0ffe54ff5c90928
```

Then transform the random number as prescribed using the prime number listed in the RFC The equation to derive the keys is: ( ( (base number) ^ random number ) modulo DH prime number ):

```
$ python3 -c 'print( hex( pow (2,
0x8ad7112ed1742765da233bb761f44cc69b329161e1a2a1c28032c25445566284bf6ca06a8a91b2a49c06
b7198aeb1574570b1e1ab22f7a9c471d01ed1f260f7356e3c88b92f06e70a14ac91480677aa4c571fb0d1c
f0a9857d027f98b1426701ab6fb27a933b0db3821b7c401fdcb7f4077ae87c4f64f682a0ffe54ff5c90928
,
0xFFFFFFFFFFFFFFFFC90FDAA22168C234C4C6628B80DC1CD129024E088A67CC74020BBEA63B139B22514A
08798E3404DDEF9519B3CD3A431B302B0A6DF25F14374FE1356D6D51C245E485B576625E7EC6F44C42E9A6
37ED6B0BFF5CB6F406B7EDEE386BFB5A899FA5AE9F24117C4B1FE649286651ECE65381FFFFFFFFFFFFFFFF
) ) )'
```

The result is a “usmDHKickstartMgrPublic” number that would then be included in the CM bootfile and exposed by the CM SNMP MIB:

```
0xef26516697b54859842f6fdc933a9aeac3750a1d50472808e62f845efb604caf5e97b117b061538a057b
1fef375da865cc0344d36f7cc6e0cc7265aa439f423d250c20518ba8459df50d710ba30a4292d43b7fbcee

2b24d5eea0a0fde537424f2fc09f8a1d65539d26472bc45b60bbc2ea03d2fa98b996c8677e0419c4fe825d

$ python3 -c 'print ( hex ( pow (2,
0x94815e16cb9ac643050278ef80825a384f946d3c050228c440700a7cfd7b4f4acc58b095d51be81ec11e
d5129434588384e771d98d327282fc9d4ff1b81930563a0d5f988952f6b166cbcd6bb692d8c1b2c320762d
2b24d5eea0a0fde537424f2fc09f8a1d65539d26472bc45b60bbc2ea03d2fa98b996c8677e0419c4fe825d
,
0xFFFFFFFFFFFFFFFFC90FDAA22168C234C4C6628B80DC1CD129024E088A67CC74020BBEA63B139B22514A
08798E3404DDEF9519B3CD3A431B302B0A6DF25F14374FE1356D6D51C245E485B576625E7EC6F44C42E9A6
37ED6B0BFF5CB6F406B7EDEE386BFB5A899FA5AE9F24117C4B1FE649286651ECE65381FFFFFFFFFFFFFFFF
) ) ) '
```

The result is a simulated “usmDHKickstartMyPublic” key that would be exposed by the CM:

```
0x992d538d0cf24e4869b3cdc8e04f7ee6c6fb454b2b7b412a585dc09d9c293167cea9af58710695ff9344
ca7770da876f3124034af013933d257cddc21930886b364dcad417d8af56ed8b7b6953e7de5f8f0ad3c5a1
5f85578d9a64a7900bb58646c8bf804dc099da5428d1308db33c4cab828ca1618e2258561ba66f9c23ad3
```

Now that both the CM and the SNMP manager have known public keys, each calculates a shared secret using the other's public key:

At the SNMP manager:

pow ( usmDHKickstartMyPublic, manager random number, DH prime)

```
$ python3 -c 'print ( hex ( pow
( 0x992d538d0cf24e4869b3cdc8e04f7ee6c6fb454b2b7b412a585dc09d9c293167cea9af58710695ff93

# Table of Contents

# 1. Introduction

The modulation profiles for Cable Modem Termination Systems (CMTSs) have been historically applied manually, only changing with response to stimuli such as frequency impairments identified by field engineers or, worse, customers. This manual feedback loop is inherently slow, resulting in profile configurations that are limited by the impairments of the lowest common denominator on a given cluster of customers. With the advent of Data Over Cable Service Interface Specification (DOCSIS) 3.1 came the amazing and powerful ability to automatically adapt downstream profiles in near real-time leveraging machine learning and the Profile Management Application (PMA) concept. Tightening and automating the feedback loop allows for the recovery of previously wasted capacity, thereby making the entire network more efficient.

The authors of this publication have developed an implementation of the PMA concept that allows Comcast to manage the downstream and upstream environments efficiently at scale. Our current nascent architecture allows us to run a complete feedback loop every 6 hours; this runtime should only get better with further optimization of the Analytic Engine (AE) service, which is currently the bottleneck. Comcast can now optimize for the best performance, reliability and throughput in an automated and scalable fashion.

In this paper, the service architecture platform for dynamic data collection is called Genome, and it offers a key component of the overall configuration management system. Genome is responsible for the aggregation of data collected from cable modems and other customer devices, and the configuration management service is responsible for the application and validation of generated modulation profiles to their respective parent CMTSs. In particular, the details of adapting modern cloud computing tools to architect a reliable software solution for both downstream and upstream configurations are discussed. There are many details involved in the data aggregation, application of configurations, and validation of configurations, all of which are discussed.

# 2. Historical Context

The ability for cable providers to manage communications parameters for essential hardware has improved dramatically over the past several decades. The industry began with hardware that was statically configured or configured by physical manipulation. The invention of the DOCSIS specification allowed for configurable modulation profiles; however, profiles were statically defined by nature. In addition, while there is physically no difference between downstream and upstream channels, they have evolved differently over time due to how they have been historically allocated and used. This section will cover the evolution of both channel types and the difficulties in data collection and configuration management that arose because of this.

**Data collection Limitations:**

It is not a trivial task to collect the large amount of data required to create a continuous feedback loop for profile management at the scale of a national footprint. Previous attempts at creating a standard approach have been found wanting in terms of speed, cost, and maintainability. This section covers the limitations of common historical methods of data collection.

The most basic form of data collection has been to allow network engineers to manually record data in spreadsheets. This method is undeniably easy to implement but has many pitfalls. The most obvious is that the minimal feedback loop time is limited by human processing. In order to avoid potentially impairing customer experiences due to configuration changes, the sampling time must be reduced to as short a time frame as possible. Other difficulties that are associated with this method are those of standardization and the inclusion of human error. It is imperative that data sets are well sanitized before they are fed into a machine learning algorithm as input. Last, but not least, most solutions are plagued by scale. To consistently and reliably collect data at scale manually would require many network engineers, therefore increasing costs drastically.

As manual data collection can be ruled out due to practical limitations, the next step is to attempt to implement an automated collection scheme. Such a scheme must be able to scale in several different facets such as number of customer devices, number of CMTSs, and number of data points collected. Data collection from physical CMTSs such as the Arris E6000 converged edge router and consumer cable modems such as the Motorola surfboard SB8200 is limited to polling methods due to neither type of device having native software capable of pushing the required data types. One possible solution to scale is to manually segregate by CMTS or group of cable modems and put each partition onto its own Virtual Machine (VM). This is a practical solution given that the network does not change much over time; however, the demand for data services is growing at an unprecedented pace. Adding more data to feed additional features may result in the need to vertically scale VMs, while adding more CMTSs may require provisioning more VMs. While this is feasible, it would require considerable amounts of manpower in order to manage on a constantly changing edge network.

**Configuration management Limitations:**

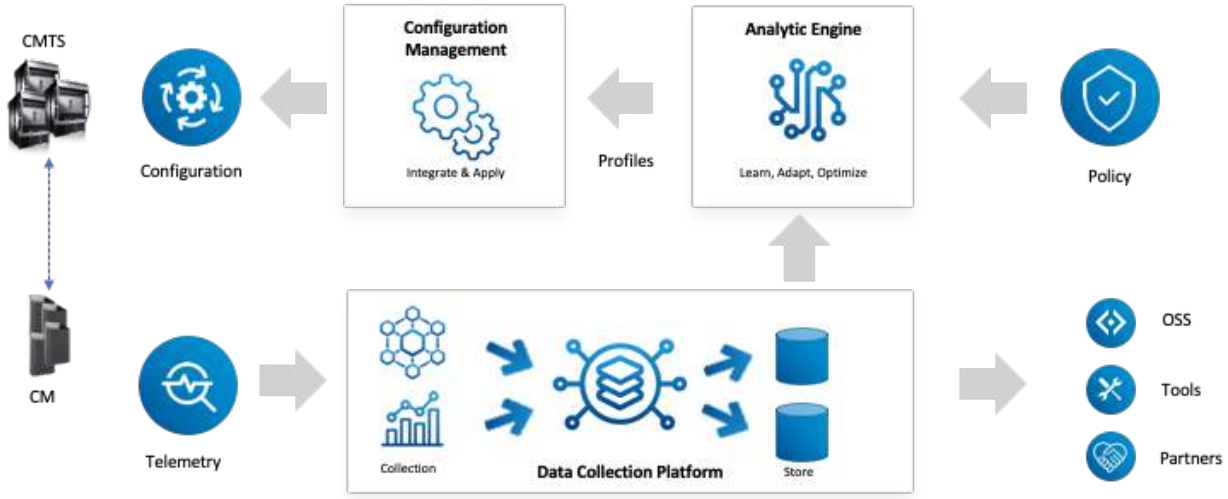
While the problem of dynamic data collection has historically been one of scale, the problem of configuration management has largely been one of standardization, process, performance, and risk. In the recent past, CMTS configurations were statically defined and rarely revisited for optimization due to manpower cost and risk. Even if one were to develop practical methods to collect the required data and use that data to generate optimized configurations, it would still be risky to apply manually said configurations as any mistakes made could negatively impact the customer experience. This fact has resulted in CMTS configurations that are generally very conservative in nature.

The tools and software available for configuration management in the past did not typically yield effective solutions. Most cable companies have, at some point, kept configurations tracked in spreadsheets. As in the case of data gathering, this is prone to human error and is limited in speed due to the human element. Previous solutions have also lacked standardized rules defining how conservative any given configuration should be. As a result, some areas may have more performance-oriented configurations at the cost of possibly degrading the experience of some customers, while others may have tended towards more conservative solutions that may have synthetically decreased the amount of usable bandwidth. Ultimately, the act of changing the configuration for a CMTS has not been something that could be done with the flip of a switch. Numerous validation checks must be completed both to adhere to lawful practices and to ensure that customer service is not impacted negatively. Any such system must also be agile enough to pivot in the case of process failure or external duress.

## 3. The Solution

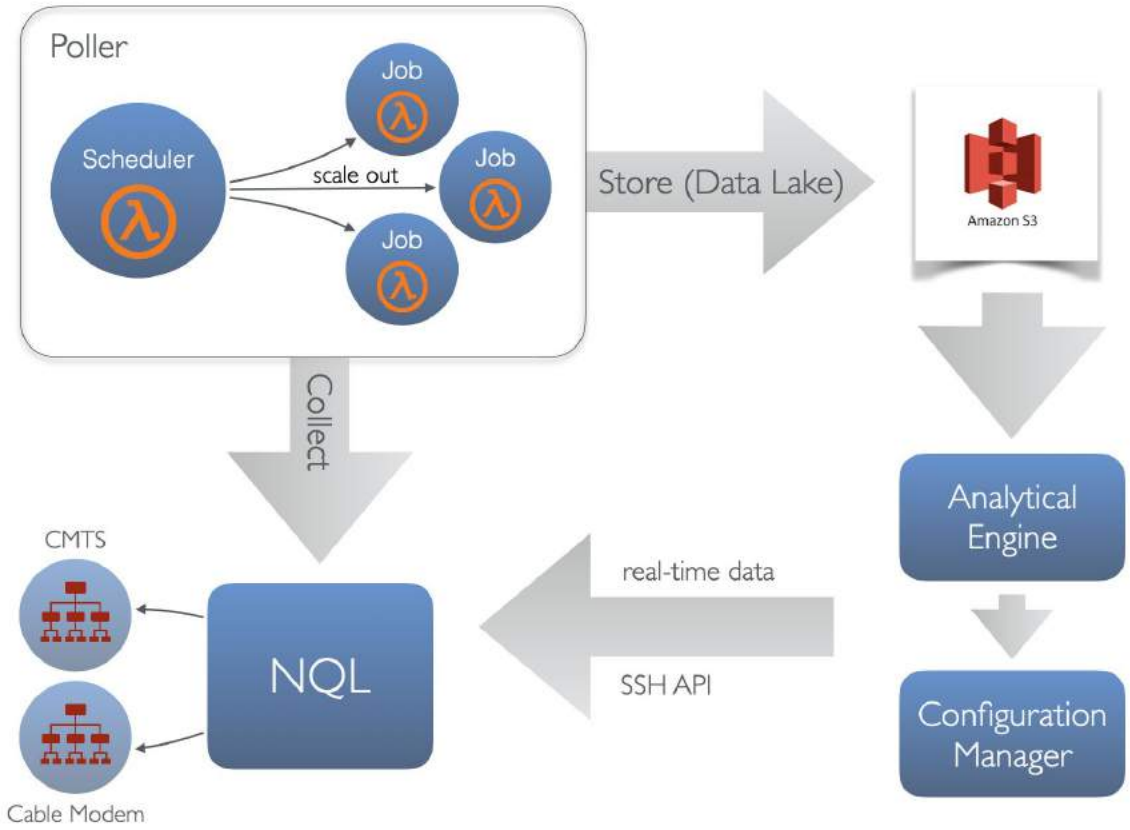
The previous section illustrates the need for a scalable, reliable, and automated approach for the activities involved in dynamic data collection and configuration management. This section discusses one implementation for such an architecture. It is important to note that this architecture is not limited in application to PMA, as it was built to be modular and support other internal processes around operational analysis and field support.

The main driver for the development of these services was to serve Comcast's PMA (Octave) efforts. Considering this, a brief refresher of Octave's architecture is given below before the focus is given to data collection and configuration management.



The first step of the Octave process is data collection, done by the data collection platform, which is internally named Genome. The purpose of this service is to poll both CMTS and cable modem telemetry data, sanitize it, aggregate it, and store it in a data lake for further use. In the case of Octave, the consumer of this data is the Analytic Engine (AE). For the purpose of this publication, this service will be treated as a black box, but interested readers can delve into the details in *A*

*Machine Learning Pipeline for D3.1 Profile Management* Harb 2019. The AE service generates optimized recommendations, then passed to the configuration manager service for translation into configurations. The configuration management service then does all the required validation checks before finally applying the CMTS configurations. This repeats in an infinite loop in order to keep the network configurations optimized.



### 3.1 Data Collection Platform (Genome)

The Genome platform was originally built to serve the Octave initiative but has grown into a platform in its own right since inception. The main purpose of Genome is to actively poll and cache data from devices such as cable modems and CMTSs in a scalable and configurable way while offering consumers the ability to analyze the cached data or get live data in a seamless fashion. This positions Genome to be the sole data provider for cable modem and CMTS data, eliminating inefficiencies around oversaturating CMTSs or cable modems with connections and over fetching duplicative data. In the context of Octave, Genome is responsible for collection, standardization of data required for the creation and management of modulation profiles. Genome

data collection is utilized in the analysis of Proactive Network Maintenance (PNM) activities as well as other field support analysis tools internal to Comcast in addition to Octave.

Genome is made up of two layers, the poller layer, and the query layer. A "poller" is simply a piece of software that is responsible for scheduling, collecting, and standardizing a set of data from devices. Pollers are built to be lean, modular, and extensible. The query layer for Genome is called Network Query Language (NQL), which exposes a declarative API service through which consumers request live or cached data. All pollers are primary consumers of NQL to collect live data, while also offering external consumers to do the same. NQL's goal is to offer a declarative abstraction layer for edge network devices, allowing consumers to query using standard HTTPS instead of SNMP, TFTP, and various other network communication protocols.

Genome requires a master list of all CMTSs to poll as well as a configuration for the polling cadence for each data property. When a CMTS gets added to the network, it should be added to this master list. In the case of Octave, this master list is automatically updated through Comcast's deployment ticketing system. On the next poling cycle, Genome will discover the newly added CMTS and request a list of all cable modems it serves. Afterwards, Genome maintains a cached list of all cable modems associated with the CMTS. The list is the source to get the OID data from all saved devices. The polling could be done at any configured frequency or on-demand.

In addition, Genome must ensure that data collection can scale when CMTSs are added over time such that data collection and aggregation can be achieved in a given polling window. It must also ensure that the ingested data is validated and cleaned before it is cached. As the amount of data is large, especially in the case of cable modem data, Genome must also manage data retention policies in order to reduce cost.

The following are some examples of data points that Genome collects:

- OFDM Channel
    - OFDM channel width
    - Subcarrier width
    - Start frequency
    - Active & excluded regions
    - Position of PLC channel
- OFDM Subcarrier
    - Modulation efficiency per subcarrier
    - Subcarrier type
- CMTS
    - Make
    - Model
    - Hardware
    - Software version
- Telemetry
    - MER
    - FEC
    - Traffic

NQL's journey began in the early days of Octave development. The goal was to create an API service which abstracts away all different protocols around networking and let end users interact through HTTPS. The first iteration came in the form of a REST API which accepted OIDs parameters and returned the output through HTTPS. While this iteration ran in productions for several months, several shortcomings were brought to light. For example, use cases involving many data points per CMTS, necessitated making multiple requests to the API. Each request would connect to the CMTS, which resulted in opening and closing sockets many times over multiple requests. Furthermore, the work of encoding and decoding large amounts of JSON data was repeated for each request, degrading the overall performance of the service through repetition of work. It became clear that the architecture needed to evolve in order to overcome these shortcomings. Indeed, with the vision that, Genome, and by extension, NQL, would grow to encompass more and more, it was clear that a technology would have to be chosen to all for incrementally extending the codebase without causing breaking changes at every turn. GraphQL was a natural option that allows data schemas to easily evolve and can handle complex relationships between data sets. NQL was born.

As NQL offers an abstraction layer for connectivity to both cable modems and CMTSs, it must therefore manage all writes as well as reads to each network device. In order to accomplish such a feat, it supports both IPv4 and IPv6 communication protocols. NQL is built primarily using the GraphQL specification and has been optimized at node level. In some cases, consumers may require a request-response type handshake, where the consumer keeps a socket open until the requested data is returned. However, many queries may be long running and it may not be practical or possible for a consumer to keep a connection open for the duration of the process.

Nodejs Historically, the team used Nodejs as a declarative jack-of-all language. However, in this use case, performance is king. As Golang is routinely touted as a performance-oriented language geared towards networking applications, it was a simple choice after orchestrating some internal benchmarking. Simple GraphQL APIs were built in both languages to test a small fraction of our total scale. The goal was to see how many VMs would be needed to handle the same amount of work while profiling the performance of each VM by measuring CPU and Memory usage. As Nodejs is single-threaded language, it is more difficult to saturate a larger VM without adding complexity. To keep it a simple apples to apples comparison, small VMs were used for both languages. After few weeks of tweaks and testing, the conclusion was that Golang is around 3-4 times faster in handling the same work as Nodejs for this use case. This was not a perfect apple to apples comparison since many variables are in play here. Particular to note is the reliance on third party open-source packages, whose performance is out of our control. Another thing that was found is that Golang was very consistent in its response times and overall API metrics, while the API built using Nodejs would suffer spikes in response times. This is likely due to node's single-threaded nature, which makes it not well suited for CPU intensive tasks that block the main execution thread. Golang was the clear winner in this exercise and was used going forward.

NQL's SSH feature allows consumers log into a supported remote device through HTTPS rather than SSH. This allows NQL to abstract away details around authentication, authorization, and managing the underlying SSH connection. Users are able to connect to a host, run multiple commands, and get output back for each command. NQL uses GraphQL to define the API, which

allows developers to develop powerful features and evolve our API without breaking the world. NQLs SSH is a simple layer around secure shell, all the logic around what commands to run in what order and what to do with the output is handled by the client itself. For example, CM can apply configurations to a CMTS and then analyze the output to see if everything went well. All this is done through HTTPS using NQL. NQL has evolved from a standalone service running on a EC2 VM to where it could be leveraged anywhere within our codebase and able to run in any container or lambda alongside our codebase.

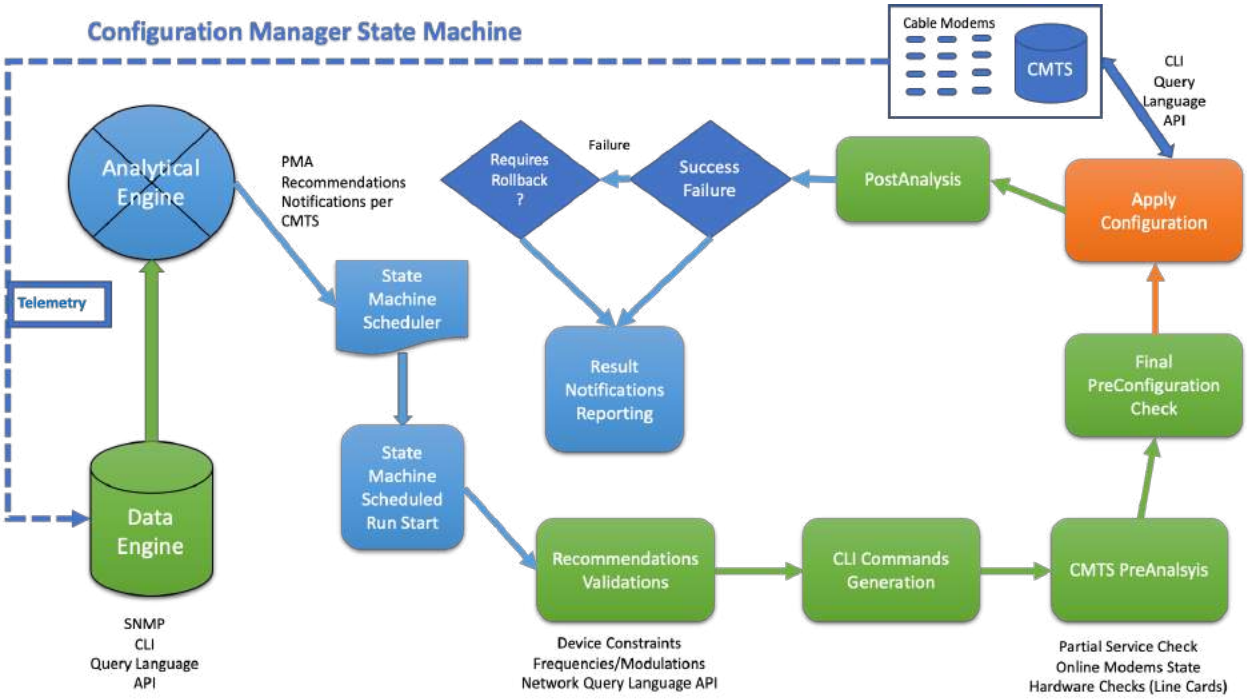
SNMP v2/v3 capability

- Genome by default uses the polling on using SNMP V3, and if the device is not V3 enabled, the fall back option is V2.
    - Get public and manager key from cable modem
    - Use manager key and V3 security name as input to get vault secret
    - Use cryptographic hash function on vault secret and public key and compute auth priv keys.
- Collect the SNMP data and stream to Kinesis which will be used by Analytical Engine from PMA and other consumers of the data as need basis.
- AE consumes the data and suggests the profile which will be sent to configuration manager, which further defined below how the process works and how the recommended profile has been applied to using the configuration manager

### 3.2 Configuration Manager

The Configuration Manager (CM) service is a scalable state machine application which is able to generate and apply modulation profiles to CMTSs based on suggestions provided to it by the AE service. It was designed to enhance DOCSIS3.1/3.0 downstream/upstream capacity and correct for RF noise impairments without manual interaction. Unlike the Genome service, it is currently not a standalone service and requires input from the AE service to function.

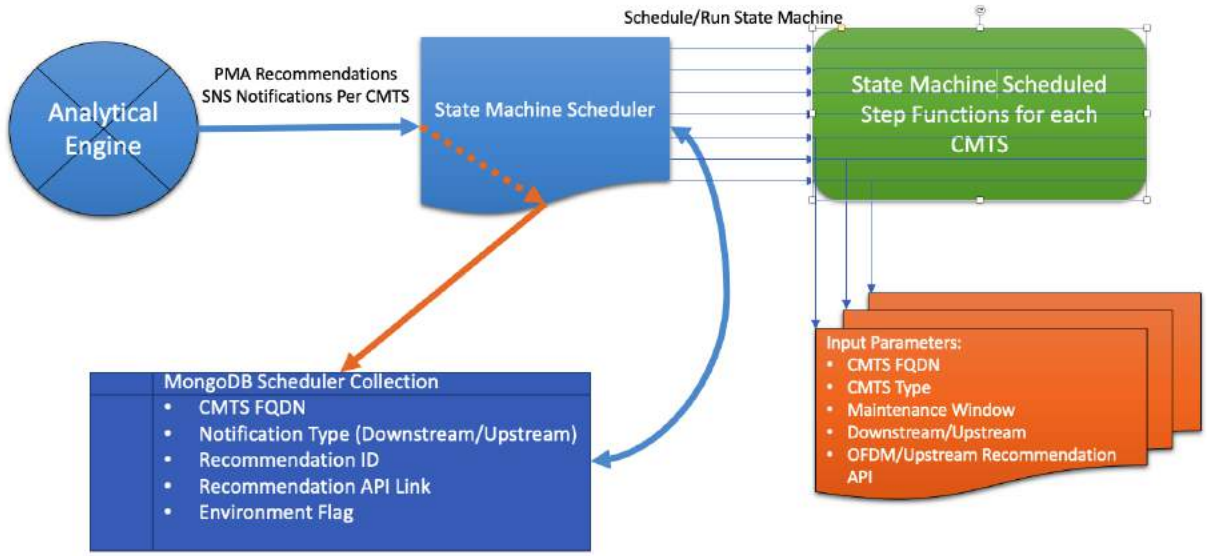
Detailed Work-flow description of Configuration Manger:



- The Configuration Manager State Machine receives a decision recommendation in a continuously timed workflow from the analytical engine. The recommendation can be to adjust or change the DS OFDM profile modulation (frequencies, QAM modulations, default modulations for each subcarrier) or can be to adjust or change the upstream profile modulation. These recommendations are based on telemetry feedback from the data engine. The recommendations should be universal in nature and are not tied to specific type of CMTS machine.
- The application schedules the state machine runs for the particular CMTS according to a predefined schedule.
- At the time of state machine operation, the CM application validates the recommended changes, conducts numerous pre-analysis checks on the CMTS using telemetry information, verifies the proper current state of the machine, and validates the overall system health.

- If the validations pass, then commands will be generated based on the AE recommendation, the type of the CMTS device, and whether it is a downstream or upstream modification.
- Before applying the commands on the CMTS machine, other validation checks are made.
- Modification to the CMTS will be made and tracked for any failures during post analysis, and the system decides if any rollbacks are required or not. The system will finally report the result of the state machine run for the CMTS, which can be tracked through the database, reporting, and dashboards.

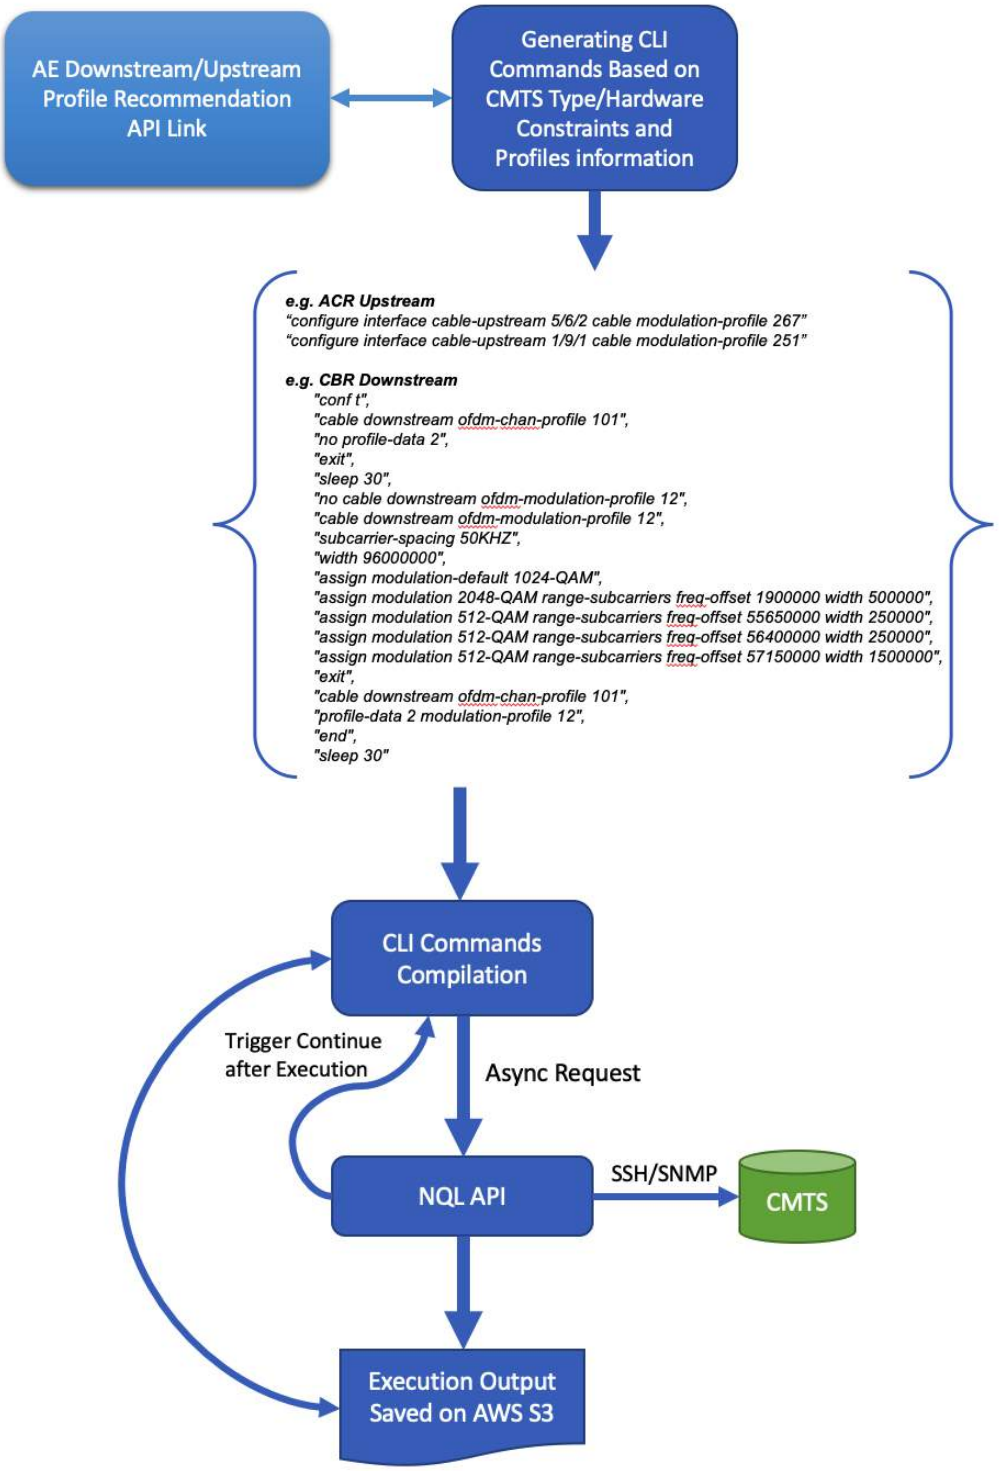
### 3.2.1 Configuration Manager State Machine Scheduler



### 3.2.2 CLI Commands Generation and CMTS Device Configuration

- In the CLI command generation phase, the function generates arrays/objects containing list of the commands which will be executed in order on the CMTS device.
- The method with which the commands are generated depends on the type of device, as each device uses its own set and way of CLI configuration. It is also based on the profile recommendation received from AE. For example, modulations and frequencies are calculated in real time based on OFDM segment start/stop, modulation bits provided, and other parameters such as lower and higher OFDM frequencies spectrum on a particular interface.
- The commands are saved in AWS S3 for the current step function to be executed during apply configuration phase in the state machine.
- In the apply configuration phase, the application uses the S3 file data object to compile the list of commands to be executed by NQL API

- An Async request is then sent to NQL API to execute the commands, the state machine waits a trigger back from NQL API for the full execution output for all CLI commands sent.
- The CLI commands output is analyzed for any errors, failures, or timeouts during execution on the CMTS.



### 3.2.3 Configuration Manager State Machine Supports and Uses the Following Technologies:

- AWS Serverless Step Function Architecture:

Each step of the state machine is handled with separate lambda function. The result of each lambda function dictates the next step of the state machine

- AWS DynamoDB
  Used for device inventory collection
  Environment flags
  Device Constraint Information
- AWS S3
  Used for dynamic command generation
  Pre/Post Analysis Device output
- MongoDB:
  State Machine Scheduled Collections and Reporting
- NetScout API for Analysis of 911 Calls in Progress on CMTS
- ServiceNow API for Change Management
- ASYNC Apply Configuration and Device Checks

# 4. Challenges / Discoveries

## 4.2 Genome

Major improvement of genome is to move from the Initial old solution with physical servers to a much more efficient and performance oriented solution.

**Iteration # 1 Moving from old solution to Improved process – Tech stack change**
Financial Implications:

- Resources
  - Had to come up with new resources who suits and understands new technology
- Infrastructure
  - Build most scalable and maintainable solution
  - Select and move to the technology stack which is cost effective
  - Secured solution
- Standardization of network
  - Support all different versions and different OS's differences
  - Solution which supports, evolving network with minimal changes
- Data reliability
  - Techniques in place to make the data reliable
  - Ways to track the data and blockers through dashboards

Political implications

- Sell the business case and architecture solution with the right reasons
- Show the brighter side of the new solution than seeing reasons how old solution didn't do
- Take the limitations had before as requirements
  - Performance improvements
  - Data Reliability
  - Dashboards
  - Alarms and notifications to act on

    - SLA's in place to support downstream systems
- Long term vision of scalability and reliability
    - Minimal investment
    - Minimal efforts in upgrades
    - Much more configurable

**Iteration # 2 Moving improved process to stable platform**
Considerations around the Stable platform:

- IPv6 protocol compatible
- Migrating from SNMP v2 to V3
- Supporting both SNMP V2 and V3
- All new solution around USM Key store

Advantages presented with the new stable platform:

- Cost effectiveness
- Reliability of network connectivity
- Security enhancements
- Enterprise level USM key store solution
- Long term vision of scalability and reliability

### 4.3 Configuration Manager

Most of the challenges we encountered was related to CMTS hardware limitations, configuration or CLI limitations, and cable modem bugs/firmware issues which cause modems not to behave as expected with upstream or downstream profile modifications.

Iteration #1 Arris ACR E6000 Downstream:

- CLI Timeout Enhancements
- 911 Check Enhancements
- Validation Enhancements
- Working on improving overall state machine work flow for scalable deployment

Iteration # 2 Arris ACR E6000 and Cisco CBR8 Upstream:

- Cisco CBR8 implementation was challenging, during testing we found out that after modifying upstream channel profile IDs, the SNMP validations were incorrect and profile were not aligned, after significant troubleshooting, we realized that CBR8 requires upstream channel to upstream controller mapping to modify proper assigned upstream profile IDs.

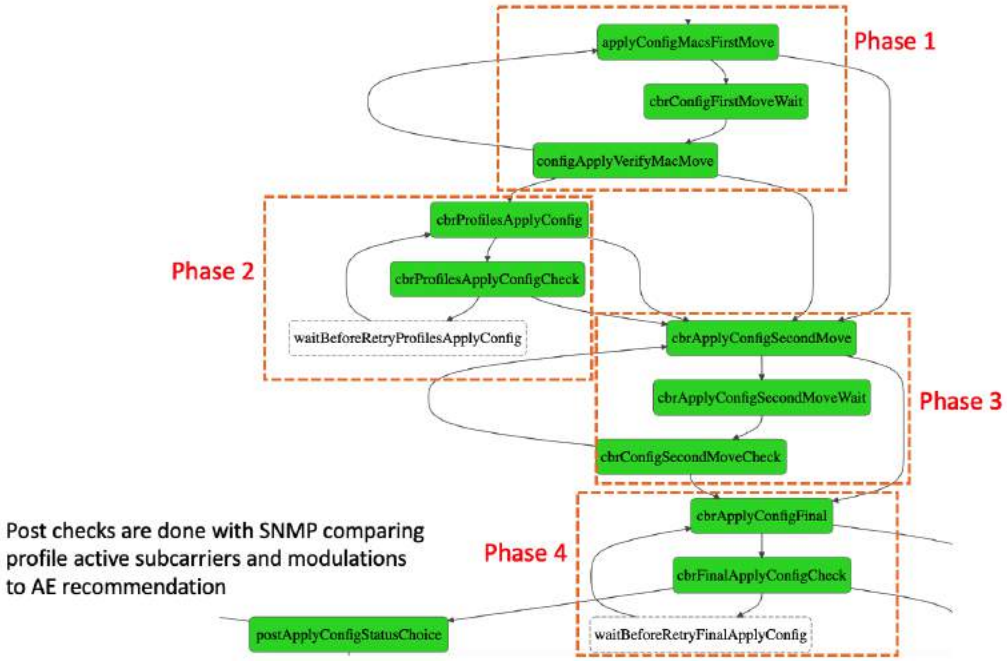
- Arris ACR E6000 encountered significant issues where cable modems go into upstream partial service, which was concluded to be a bug on the E6000 which was resolved with a firmware update, and also bug in few of particular types of the Motorola modems SB21x and SB61x which we had to work on some workarounds and run debug commands to move the modems out of partial service, as well as Zoom modems required firmware upgrade which was required to prevent them from going completely offline.

Iteration # 3 Cisco CBR8 Downstream:

- Cisco CBR8 implementation required almost a complete new design for the state machine, since CBR8 doesn't support modifying OFDM profiles globally on the cable channel, each DOCSIS 3.1 modem must be moved from a particular profile and to another one in order to modify the profile that this modem is currently using, then moving the modem back to use recommended profiles, this means significant number of CLI commands had to be generated and executed on the CMTS, one thousand modems requires 3000 CLI commands along with other profile modification commands
- We were able to achieve this by splitting the commands and apply configuration into four phases in the state machine, with each phase requiring validation check, we also used ASYNC apply configuration to limit timeouts, maximum time for each phase is about an hour to hour and half which should be fine for implementation on a fully loaded CMTS with about 3-4K DOCSIS 3.1 cable modems.

1. **Phase one:**
   Shutting down internal PMA
   Locking cable modems to control profile 1 and moving service flows to profile 1 (only for profiles requested by AE)
   Verifying all modems are now locked to profile 1 after waiting few minutes, if any modem(s) still stuck on other profile, CM will put the profile into ignore list and will not modify its OFDM subcarriers in phase two
2. **Phase two:**
   Applying OFDM profile changes (subcarriers and default modulations) and verifying configuration lines are applied
3. **Phase three:**
   Unlock all modems in phase one from profile 1 (moving service flows from profile 1)
4. **Phase four:**
   Turning internal PMA back on
   Do OPT commands on all modems from phase one to speed up process of modems to use appropriate profiles

Phase 3 and Phase 4 will run regardless of Phase 1 and Phase 2 result, this is basically rolling back the modems to their original state and letting the CMTS assign profiles, this must be done even if we have failures in phase 1 or phase 2, or modems will stay locked to profile 1 and will stay locked for subsequent PMA runs unless manually unlocked.



## 5. The Future

We have built a platform which is scalable and maintainable. Where do we do we go in the future? What are the possible improvements and upgrades that we could add to make the platform work even better for the organizations? How could we use the data that is being collected beyond the initial reason it started?
What else can we do with the configuration management platform to go beyond applying configurations? How could we improve our processes?

We will now share a couple of ideas and architectures for our future work in the areas of data collection and configuration management. Irrespective of the data collection side or the configuration side, major focus for future for the platform as a whole would be:

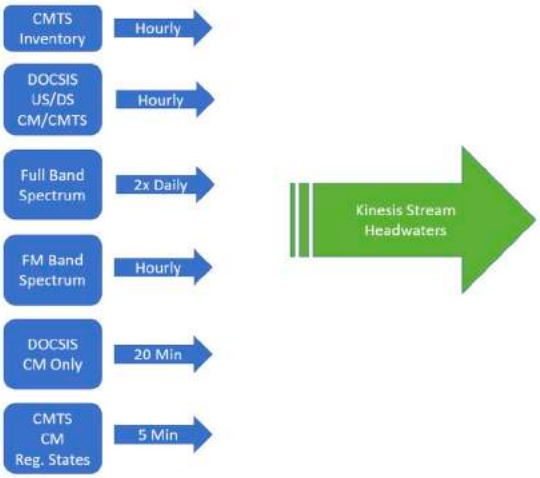
- Vendor agnostic
    - Customizable and configurable metadata for data collection points
    - Irrespective of the vendor
    - Configuration application API
    - Configuration template management
    - Upgrades to all kinds of OS upgrades and patches

- Vendor specific
    - Standardized and easy update and upgrade of vendor specific data points

- Upgrades to all kinds of OS upgrades and patches
- Easily updatable configuration templates methods

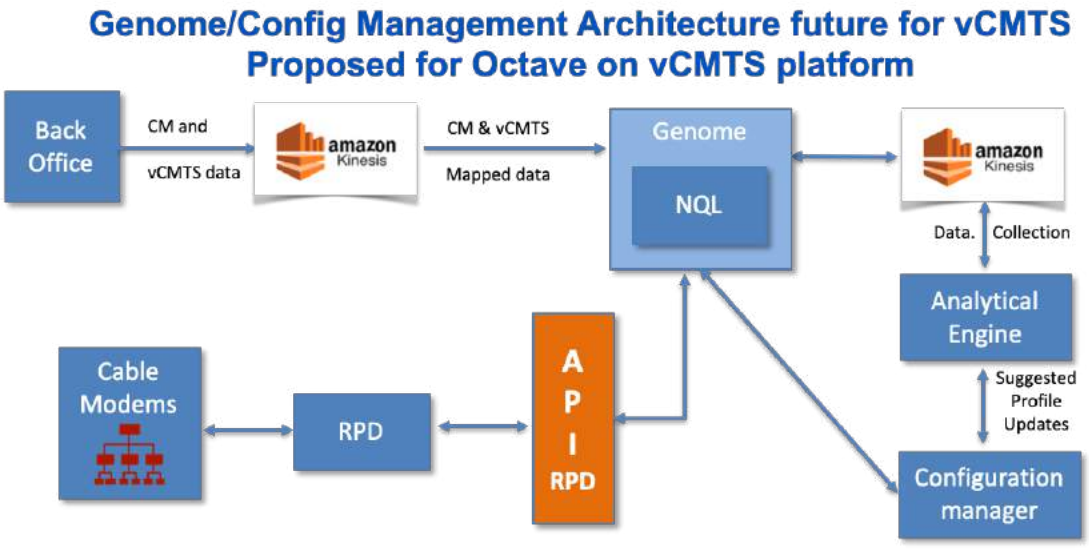
**Data Collection: (Not Limited to)**

- Consolidation of the data collection across the organization
- Reduce the number of pollers connecting to devices
- Improve the performance of the devices with less pinging
- More optimizations for better performance
- Expanding the data collection beyond CMTS and CM to power supplies, RPD's ,vCMTS
- Expanding the data collection specific with adjustable frequencies



**Configuration Management: (Not limited to)**

- Standardization of the configurations across organizations make deployments easy
- Separate it into a standalone service that so that other services can take advantage of the validations and checks it employs
- Standardize managing configuration templates
- No manual errors in initial system configurations
- Site specific customized configuration templates
- Vendor agnostic platform
- Easily adaptable, manageable, expandable



## 6. Conclusion

Reliability, Manageability, Consistency, Usability, Performance, and Scalability are the most popular buzz words in the market, and they are now becoming the base necessary requirements for the creation of any software product/platform. Keeping that in mind, this study provides valuable insight to the ongoing evolution of creating cutting edge technology solutions for the Cable Industry.

In addition to a review of the past and present, the paper also demonstrates the benefits of using modern tools and infrastructure components. In the opinions of the authors, reliability in any kind of service/platform is the most critical component to create customer satisfaction. A commitment towards the better Customer Satisfaction always results in the best product.

## List of Figures

# 1. Introduction

One of the higher-ranking intangibles on any field technician's wish list is the desire to spend more time fixing things, and less time finding them. In an industry with physical network assets measured in the hundreds of thousands of miles, in all imaginable terrains and environments, locating physical elements can be as challenging as their repair or replacement.

For many years, network technicians have used computer-aided design (CAD) maps to help them locate underground cables, aerial spans, taps, amplifiers, nodes, and other network elements. While helpful, CAD maps are two-dimensional, static and not always updated with current coordinates for the components listed – let alone Mother Nature's contributions, in the form of nightfall, snow-covered taps, shrubbery-occluded pedestals, or spans lost in heavy tree foliage!

Simultaneously, the landscape of Augmented Reality (AR) is emerging as a beneficial tool for just such circumstances. Not, as the reader may first connote, with special glasses, or helmets, or anything of the sort, but with a tool technicians use routinely in the field: A smart phone or a tablet. After extensive and ongoing laboratory reviews of various "smart glasses" and "AR helmets," designed to help technicians to access expert help in a "see what I can see" environment, our conclusion remains that such devices need a few more design cycles – and cost reductions – before they will represent a plausible field tool.

Instead, in 2019, Comcast Labs began to investigate the use of an AR modality as a network visualization tool that technicians can access with the same field tools (e.g. iPhones and iPads) that are part of their day-to-day lives. It applies Apple's open sourced ARKit framework to the integrated camera in an iOS device (iPhone or iPad), then draws upon graph database information, derived from latitude/longitude and GPS coordinates of plant elements, to present a near-real-time visual guide, regardless of time of day (or, especially, night) – there's a pedestal within 20 feet, but it's behind something tall, like a fence – as one of many examples. It gives technicians a sort of "x-ray vision" for the network, and moves the evolution of Proactive Network Management (PNM) from 2D to 3D. The tool, which we call "VON" for "Visualize Our Network," went into the field in early 2020, as a component within the tool suite technicians use daily.

This paper will describe the VON work to date, including the evolution of network visualization, how AR works to visualize the plant, development challenges, why graph theory was an important design component, the importance of "occlusion," lessons learned, and next steps (if only in the form of a "design wish list.") Note: "Occlusion," which will be mentioned frequently in this paper, is defined here as "the blocking of a view of part or all of something, but something else."

# 2. A Brief History of Plant Element Visualization t

Network visualization, in a classic two-dimensional, addresses-on-paper and rolled-up-maps sense, has long been a vitally important, if passive, component of proactive network maintenance (PNM). Many "cable old-timers" recount stories of entering the industry via a summer job – "here's a clickwheel, and here's how to use it" – to measure, verify and/or document the physical topologies of the network.

The state-of-the-state is now digitized, and revolves around spatial mapping in graph form. A Graph Database is a database that not only stores the elements of data, but also stores the relationships between those elements. The data is actually stored in the graph in the same way that they are connected in the "real world." Graph, in this sense, means "visibly connected," in the sense of showing the relationships between mapped elements: The amplifier goes to the line extender, which connects to the tap, then the splitter, and so on. Graph databases are the latest in what's been a long progression, happening in parallel

 

with other PNM initiatives, and all in the pursuit of identifying and resolving plant issues before they impact customers. Graph databases will be discussed further in Section 3.

Most (but not all!) operators long ago mapped their network topologies into formats that can be reasonably easily translated into graph models. It was a natural evolution from computer-aided design (CAD), back when the state-of-the-art for network visualization were lists of addresses, which could be assembled into problem clusters.

Geographic Information Systems (GISs) came next, which yielded "dots on a map" informed by Global Positioning Data (GPS) coordinates. GIS/GPS advanced network visualization into tree-and-branch representations, which showed subscribing households connected to the branches. Since then, Google Maps emerged as a powerful visualization tool, but even in "satellite view" it's largely ineffective in seeing anything smaller than, say, a car in the driveway. Certainly not a tap; maybe a pedestal, depending on seasonality and camera angle at the time the image was collected.

The next step in network visualization, fueled by AR, takes matters one important, three-dimensional step further. Previously, the "dots on a map" showed the connection between, say, an amplifier and a tap, using each element's GPS-based latitude (X-axis) and longitude (Y-axis.) AR brings a new dimensions – a Z-axis – which adds visual depth and the camera attitude (pitch, yaw and roll) for first-person viewing perspective. This added depth allows the technician to do something that they've not previously had the capability of doing – visualizing multiple elements of the network, overlayed on the "real world" simultaneously. Not quite Superman-grade x-ray vision, but close enough to draw the parallel!

## 3. Realities & Challenges of Visualizing the Physical Plant with AR

As a painfully basic observation, Augmented Reality, as a technology modality, augments actual reality with informational overlays. And, as it turns out, overlaying the "this" onto the "that" – meaning most types of ancillary information designed to augment a reality – isn't the hard part of AR. The core technologies, like ARKit, are largely open-sourced, and substantial amounts of documentation exists online. This makes the actual "overlay" part of AR implementations reasonably straightforward.

The first reality when building an AR model of the network is the need to build a graph database of the network. If each element in the graph has latitude and longitude coordinates, and we understand the relationships of each element to one another, we can represent the network in 3D space. This brings us, again, to a discussion about the necessity of graph databases when developing AR-based plant visualization techniques for technicians.

Traditional relational databases rely on tables, where the data are organized into well-defined columns and data formats. This system works well when dealing with a modest number of relationships between a few different tables. But traditional relational databases are woefully underpowered to meet the needs of visualizing all of the components present in a modern broadband network.

A graph database is one that organizes data according to the elements of a graph – with its own "nodes" and "edges" that represent the relationships between the edges. Graph databases represent network connections in real time, which closely resemble how we interpret them naturally. As such they are ideal for informing network topologies and related maps in a visual way.

That said, there is the matter of the "Z-axis," mentioned in the previous section – another reality encountered when developing an AR-based plant visualization tool. Creating an AR session necessarily includes X, Y and Z coordinates: Latitude, longitude, and in this case, depth. Depth and attitude augmentation were a challenge, in part because ARKit was in beta when we began this effort, and partly

 

because our use case required continuous depth detection, while in motion, to direct a tech to the desired destination. We added the Z-axis by using an ARKit feature called *plane detection,* and in the case of the Visualize Our Network AR effort, vertical plane detection.

Consider the technician looking for a pedestal in an established neighborhood, which is to say "in full foliage," because it's summertime. Or, that same neighborhood, buried under a foot of snow in February. Either way, the pedestal in question is behind a fence. To handle those frequent cases where a network element of interest is occluded by something – a fence, a tree, a building – we detect and notate the occlusion by marking it blue. This tells the tech that the object of interest is behind something vertical. We determine occlusion by detecting vertical planes in front of the object of interest.

Without vertical plane detection as a means of marking occlusions, it would be very hard, if not impossible, to pinpoint a specific location, in 3D. Figure 1 shows the VON app with Occlusion turned on, to indicate a vertical plane obstruction. Hence, any objects beyond the Occlusion would not be visible, such as pedestals, cable, and other elements of our plant.

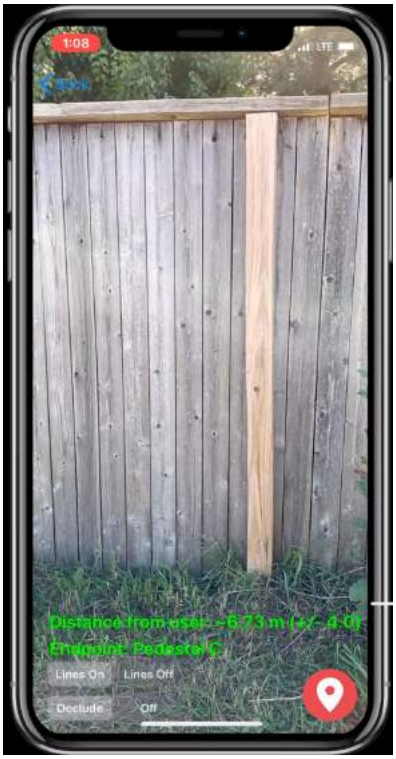

**Figure 1 - The AR-based VON app indicating a vertical plane occlusion**

Figure 2 (next page) shows the same vertical occlusion – the same fence – with occlusion turned off. This allows the technician to view the elements of our infrastructure, including the vertical occluded objects, but without noting them as such. This combination gives a visual depth to VON that previously didn't exist.

**Figure 2 - The AR-based VON app with occlusion turned off**

For underground plant, we applied a "snap-to-ground" focal point for the VON app, which, in essence, extended a "negative vertical plane" of -6 feet. As a result, by starting at a node, then going "down" the graph database to the first tap, then the second, and so on, we were able to make the assumption that if Node A is connected all the way down to those seven taps, there's likely a buried cable between them, which at best is observable as not being aerial, but rather, underground, indicated by a line/plane on the ground. Without a graph database, that job would've required a physical walk-out.

So: The hard part of AR-based plant visualization, in practice, isn't the AR. The hard part, perhaps not surprisingly, is assembling the information correctly: Latitude, longitude, depth, what kind of object, and whether it's occluded by another object. An early and persistent challenge was simple GPS inaccuracies, either from a faulty phone/app interpretation, or from incorrect GIS entries. Truth be told, we encountered at least one pedestal that was, according to its GPS coordinates, in the middle of a lake!

Another challenge: Point of view. While AR technologies continue to advance, there's still a lot of room for improvement. For instance, a marker representing a pedestal on the phone's or iPad's screen may appear to be three feet away on the screen – but actually, it's 30 feet away. The reason is the perspective: The phone is stitching a camera feed together with a virtual object. The virtual object has no explicit knowledge of what the camera is seeing. Rather, it exists in an empty world, with only an X (latitude), Y (longitude) and Z (depth) axis as a landing spot. If the perspective is off, while you're walking down an alley, looking for a plant element, it can *look* like you're close, when you're not. Resolving this took some iterations (understatement)! While tying a virtual object to a scene could be achieved with the use of model detection and logic code, to detect and identify scenes, such a plan would rapidly deplete the phone or iPad's battery.

A third challenge involved the previously mentioned matter of occlusions encountered along the way, and especially vertical occlusions – the fence, with the pedestal behind it. The VON, without scene detection of some kind of understanding of the surroundings, can't know that there's a "fence" in the way, only that there's a vertical plane occlusion. We resolved this by incorporating a way to adapt the vertical plane, to show / not show a vertical object in the way of the desired plant element. This discovery went a long way in making the user interface look realistic, and created a means for the technician to interpret depth. Without the Occlusion information, it doesn't make sense, because it lacks visual depth.

## 4. Findings and Next Steps:

The core technology enablers that made it possible to develop the VON application, as a PNM tool, were ARKit 3 Beta (at the time), GIS, and Graph Theory/Database. It is important to again note that the graph database aspect was crucial to VON as it described the relationship between each element of our infrastructure and how it all comes together. Graph theory, in combination with the GIS data that we had on our infrastructure, allowed for a graph database to exist and then be used by VON to visually represent all the different elements.

ARKit 3 was in a Beta state from Apple at the time we embarked on the VON tool. Because of the new-ness of the release, it allowed VON to tap into the potential for occlusion, and how it can beneficially alter the perspective of a user. Specifically, in terms of marking and presenting the visual depth of the geographical virtual objects, portrayed ontop of a digital camera feed. This is also known as "Markerless Augmented Reality," defined as AR that doesn't need prior knowledge of a user's environment in order to overlay 3D content into a scene and tie it to a fixed point in space. After the introduction of ARKit 3 in mid-2019, creating AR Sessions with virtual objects based on geographical data acquired from graph databases was straightforward. The challenge (still) is the available plant data and the GPS inaccuracies of sensors within our handheld devices.

Simply put, accuracy matters to visualing the physical plant with AR. It matters in particular as to how we place the virtual element, onto the digital (camera image) feed. Both the stored geographical data about our infrastructure elements, and the GPS circuitry present in handheld devices, need a reasonable degree of accuracy to best inform the VON effort. Currently, inaccuries can create a visual drift from the intended object of three to 12 feet. This is why a favored new feature for VON is the ability to re-tag a network element with correct location coordinates, quickly and easily, and as technicians use the app to locate objects. Better data = better accuracy = finding hidden elements faster.

To more thoroughly test the VON application, in real-world circumstances (no pun intended), it was "easter egged" into an existing suite of PNM apps used by Comcast's field technicians. In that sense, it's "out now," although truth be told, only a slight percentage of the field has yet to find it and put it to work. Also, it requires an iOS device that is optimized for ARKit 3 and above (iPad mini, iPhone 7 and above), which not all technicians have, as a function of routine device upgrades.

As with any new Augmented Reality application, the initial reactions run the gamut from "how cool" the application is, to an overall and genuine excitement about it. The excitement about it will drive more technicians to use the application, and provide feedback to improve it. As we gather this feedback, and continue to experiment with the "art of the possible," a few items tend to rise quickly to the list of desired feature additions for VON.

Most involve giving technicians more information about a task, by providing historical context. For instance, the ability to "hover" over a home, then "see" as an AR overlay its known technological history – CPE spectrum measurements, or full spectrum analyses from gateways, as two of several potential

 

examples. From a plant element perspective, the ability to augment, say, an amplifier, with a visual overlay of its latest sweep trace measurement, would be a time-saving and useful troubleshooting tool for the field.

Another and more practical/tactical consideration is an easier, on-the-spot/in-the-moment way to correct incorrect database entries, as mentioned above, by visually "attaching" to a plant element, and thereby correcting bad data.

## 5. Conclusion

This paper described an ongoing effort within Comcast Labs, and active in the field with technicians, to use Augmented Reality for finding specific plant elements – and especially those that aren't plainly obvious, either because it's dark out, or because they're covered up by something else. Called "Visualize Our Network," or VON, it uses AR to add a 3D element to Proactive Network Management. It very specifically uses an iPad for the visual element, and not "AR glasses," which can get lost, or be unwieldy for people who already wear corrective eyewear.

Equipping technicians with this kind of 3D "find it" tool is both approachable and very well received, both for the on-the-job assistance, and the "cool factor." Using open-source elements like ARKit, and assuming an accurate plant database exists, with latitude and longitude coordinates for key plant elements, like nodes, amplifiers, and taps, you too can trick out your PNM tools with 3D plant visualization!

## List of Figures

# 1. Introduction & History

Electrical grounding and bonding, as a means to provide a low-impedance electrical connection between two or more metallic bodies that are normally not current-carrying, has long been a necessary task for the industry. Electrical groudning prevents circuit overloads and removes dangerous ground-fault voltage on conductive parts. Primarily, grounding and bonding is a mechanism to protect homes and businesses, and their contents (including people), from electricity surges, such as from lightning.

When all of the communication and power grounds are working at a home or business, and are all "good grounds," any stray current in the system goes to ground and no voltage differences exist between themwhich is the desired state. However, when grounds are bad, the current can and will find its way into the CATV network. When voltage appears in the CATV network the voltage potential problem appears to "drop the voltage" of anything connected to the network. Set-top boxes, modems, gateways, or, in the case of large MDUs, line extenders all have seen the drop in voltage. Stories abound from technicians taking the hit of 90-volt shocks from power-passing taps, or 120-volt shocks when hooking cable up to taps in MDU lockboxes – which makes for a decidedly unpleasant site visit! Proper electrical grounding and bonding is as equally or more important to business/enterprise customers especially when lightning hits a facility, knocks out half of its servers, and turns out to be a grounding issue – as in, "our fault" (pun intended.)

This paper describes the use of Computer Vision (CV), Artificial Intelligence (AI) and Machine Learning (ML) to provide technicians with a visual verification that gives them a high level of confidence that the structure (the home or business) they're visiting is properly grounded and bonded, using an app developed at Comcast Labs, on their work-issued iPhone or iPad. The paper covers the background and history of grounding and bonding; why those activities continue to be vitally important in communications network performance; and the importance of images and image annotation to build a production-grade database of proper grounds/bonds that can be put to work by field technicians when assessing a home or business.

## 1.1. A Brief History of Electrical Grounding and Bonding

While electrical grounds and bonds have been overseen since the late 1960s by entities like the National Electrical Code (NEC), in part 820 [1], compliance reporting is generally not a requirement. Unlike rules like Cumulative Leakage Index (CLI), which require quarterly compliance reports, the job of making sure the ground/bond is true is voluntary and not enforced. That said, some cities and franchise authorities have instituted grounding and bonding inspections, to monitor how many jobs are properly grounded and bonded. Improper grounding/bonding in those instances have incurred fines, which is to say it also impacted profits.

Our work to automate the inspection process for proper grounds and bonds began as an offshoot of a related project, which uses CV, ML and AI to catalog the contents of racked equipment in data centers. The intent was to automate regular equipment inventories and establish a visual map of where servers are, physically, in what can be large and cavernous facilities full of such

gear. Late in 2019, we were approached with the idea of extending the effort towards outside plant activities, in particular, helping technicians to verify that the electrical ground is good. Considering the fact that electrical grounding activities began before WWII, and that the U.S. counts roughly 125 million homes (a number that does not include businesses), the range and types of electrical bonds we encounter are vast. Countless (and uncounted) variations exist in the field. Hence the importance of training data and the establishment of a solid visual database to catalog existing manners of grounds and bonds.

## 2. Job #1: Images & Training Data

The reason why we're talking about good electrical grounds and bonds in the year 2020 is the as network operators we are responsible for the safety of our technicians, customers, their homes/businesses, and the electrical devices within those homes and businesses. Merely through expectations and the accountability that we take each day, in connecting customers to our network, the electrical ground and bond is a vital, if sometimes overlooked, activity. After spending the last decade stabilizing the major portions of the network – platforms, headends, CMTS devices, outside plant components – another domino in the lineup, in the pursuit of overall network reliability, is grounding and bonding.

This effort started by developing an app, accessible on an iPhone, iPad or web browser, with linkages to images of about 30 grounding/bonding implementations encountered in the field. The app was given to roughly 50 employees, at the start, to capture and ultimately catalog a visual database. These employees were spread out over the United States, giving us a varied dataset of 1,500 bonding and grounding images. This varied dataset helps combat the identification problem of the many different types of grounds and bounds that stem from WWII-era home construction onwards.

In order for the system to be production-gradefrom a Computer Vision perspective, substantially more training images will be required – as many as 10,000 or more. This estimate can be drastically increased if proper selection of images is not taken. For example, the bonding hardware, the bond block, and filters can all vary in appearance depending on the region of the country and when the home was built. This data variance makes it harder for the system to learn all of the different types of bonding and grounding hardware it will see in the field. Consequently, if not addressed correctly, the system will require additional training images to be production-grade.

The visual database is split into two categories: house box and power bond. The house box category generally consists of a frontal shot of a house box. The house box is in most cases mounted to the side of the home and houses the bond block and the Multimedia over Coax Alliance (MoCA) filter (see Figure 2). The power bond category generally consists of many differently angled shots that capture the bonding hardware (see Figure 4). Categorizing the images in the visual database into these two categories is an essential part of training a production-grade system. It allows the system to learn the specificities of each category, improving accuracy and robustness.

Currently, our bonding and ground AI uses approximately 1,000 house box images and 500 power bond images to train the system. Using machine learning techniques called Transfer Learning, Data Augmentation, Regularization, and Semi-automated Image Selection, we are able to drastically reduce the total number of images needed for training. Based on our current rates of accuracy for both power bond and house box, we estimate we'll need upwards of 10,000, or more training images to release a production-ready system.

**Figure 1 - A selection of images from the House Box category**

**Figure 2 - Image example of House Box category; panels 2 and 3 highlight the bond block and filter, respectively**

**Figure 3 - A selection of images from the Power Bond category**

**Figure 4 - Each panel shows the bonding hardware highlighted**

## 3. The Other Job #1: Annotating Images

Once the visual database is established, and growing, a corollary and vital task is image annotation – to manually mask the objects of interest within an image. As important as the image itself, image annotations are the backbone of training a Computer Vision system. Annotation requires a person to open the image in an image annotation tool and "mask over" the object of interest with a polygon shape (see Figure 5). All pixels within the polygon shape are then labeled to correspond to the object of interest. In bonding and grounding, the objects of interest are the bonding hardware, bond blocks, and filters. Note the points that make up the polygon mask. All pixels within this mask are deemed to correspond to the filter object for this specific image, which is used to train the Computer Vision system.

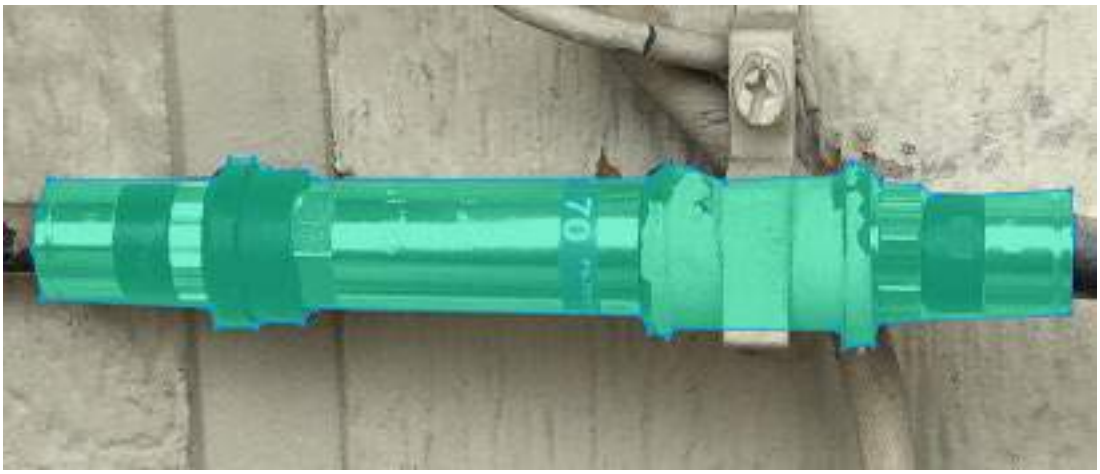

**Figure 5 - Example annotation of a House Box filter object of interest**

This annotation job must be done for each and every image that enters the visual database. Additionally, each annotation must be checked for accuracy, to ensure that any bad annotations do not negatively affect the accuracy of the system. After the images in the visual database have been annotated, and their annotations verified, they are finally ready to be shown to the Computer Vision system to learn the intricacies of the object.

To ease the burden of annotation, we made use of active learning (see Figure 6). Active learning is the process of training our Computer Vision system, first with a small subset of labeled images, and then using the system's learned ability to decide which new subset of images in the visual database should be annotated manually. We then annotated the new subset of images from the system manually, and repeated the process. This process of human-machine iteration is essential to reducing the cost of annotation, and overall improves the end result of system.

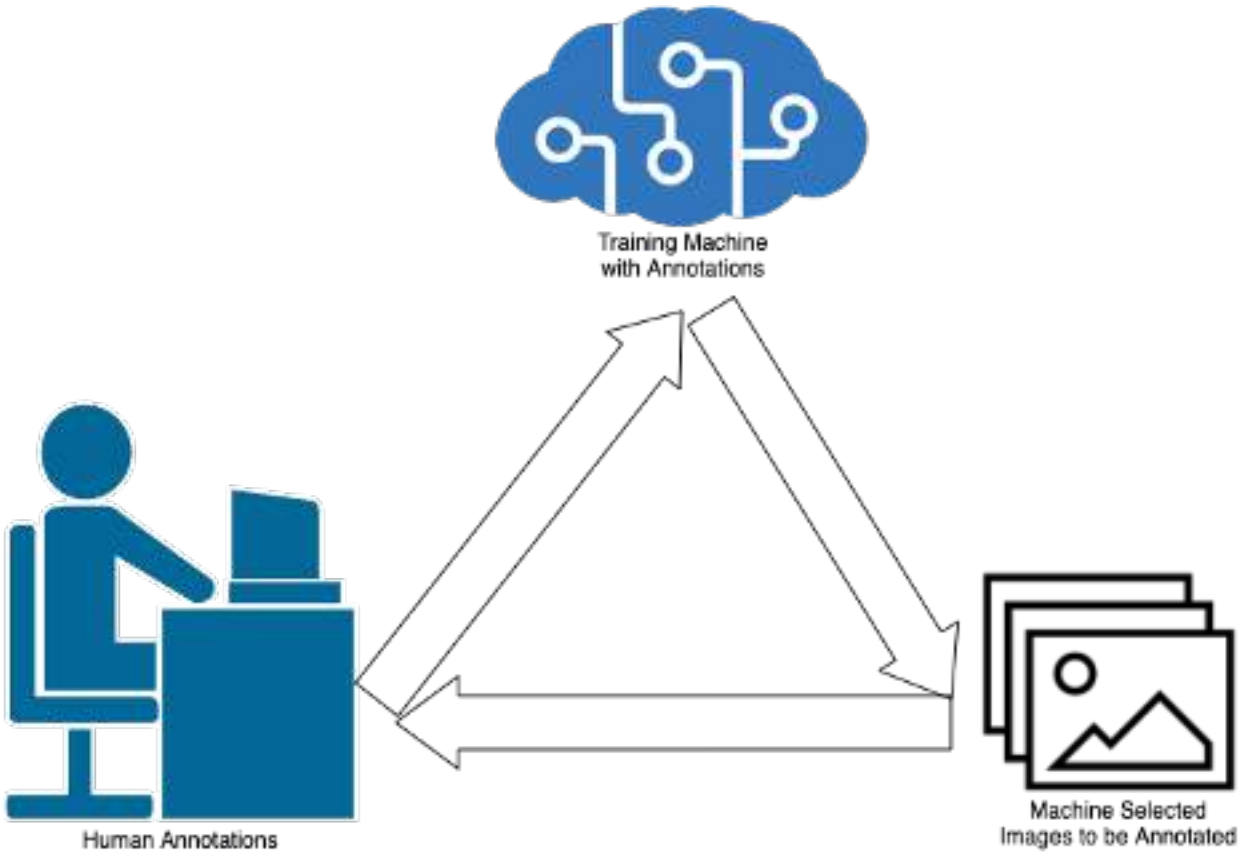

**Figure 6 - An active learning pipeline to reduce costs (time and money) of image annotations**

# 4. The App & How It Works

To approach the job of creating a Computer Vision-enabled means of visually verifying electrical grounds and bonds, we built two apps: a WebApp and an iOS App. Both use the same API endpoint to upload images to be inferenced to the Computer Vision model. This process leverages GPUs for detecting Filters and Ground Bonds. The CV model is coupled on what it detects, using rules to determine if a filter and ground block is wired correctly. Each image is captured, saved to our database and added to the ML training data. A feedback section indicates whether or not the CV model detected the image correctly.

Rules were developed to determine a simple validation for the house box and the power bond, as characterized below:

House Box

- Does a filter exist?
- Does a bond block exist?
- Bond block connected to filter?

Power Bond

- Does a tag exist?
- Does bonding hardware exist?
- No prohibited bonding locations?

Steps:

1. Snap a picture or upload an image of the House Box or Power Bond
2. Receive an answer if Ground Bond/Filter is properly installed

## 4.1. WebApp Version

This version was built specifically to run on a phone browser. We started with a WebApp to iterate quickly. This tool can be exceptionally valuable for testing (see Figure 7.)

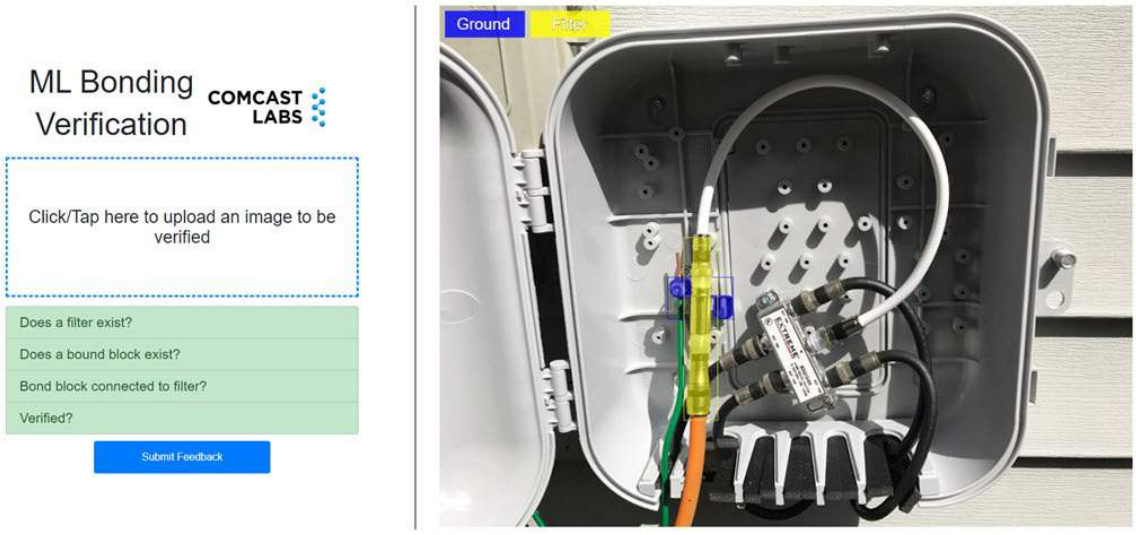

**Figure 7 - A view of the WebApp version for Computer Vision grounding/bonding**

### 4.2. iOS App

Our vision for building an iOS app was to make the user experience as smooth and easy as possible. This app makes it easy for users to point, click, and view results in a very user-friendly way (see Figure 8).

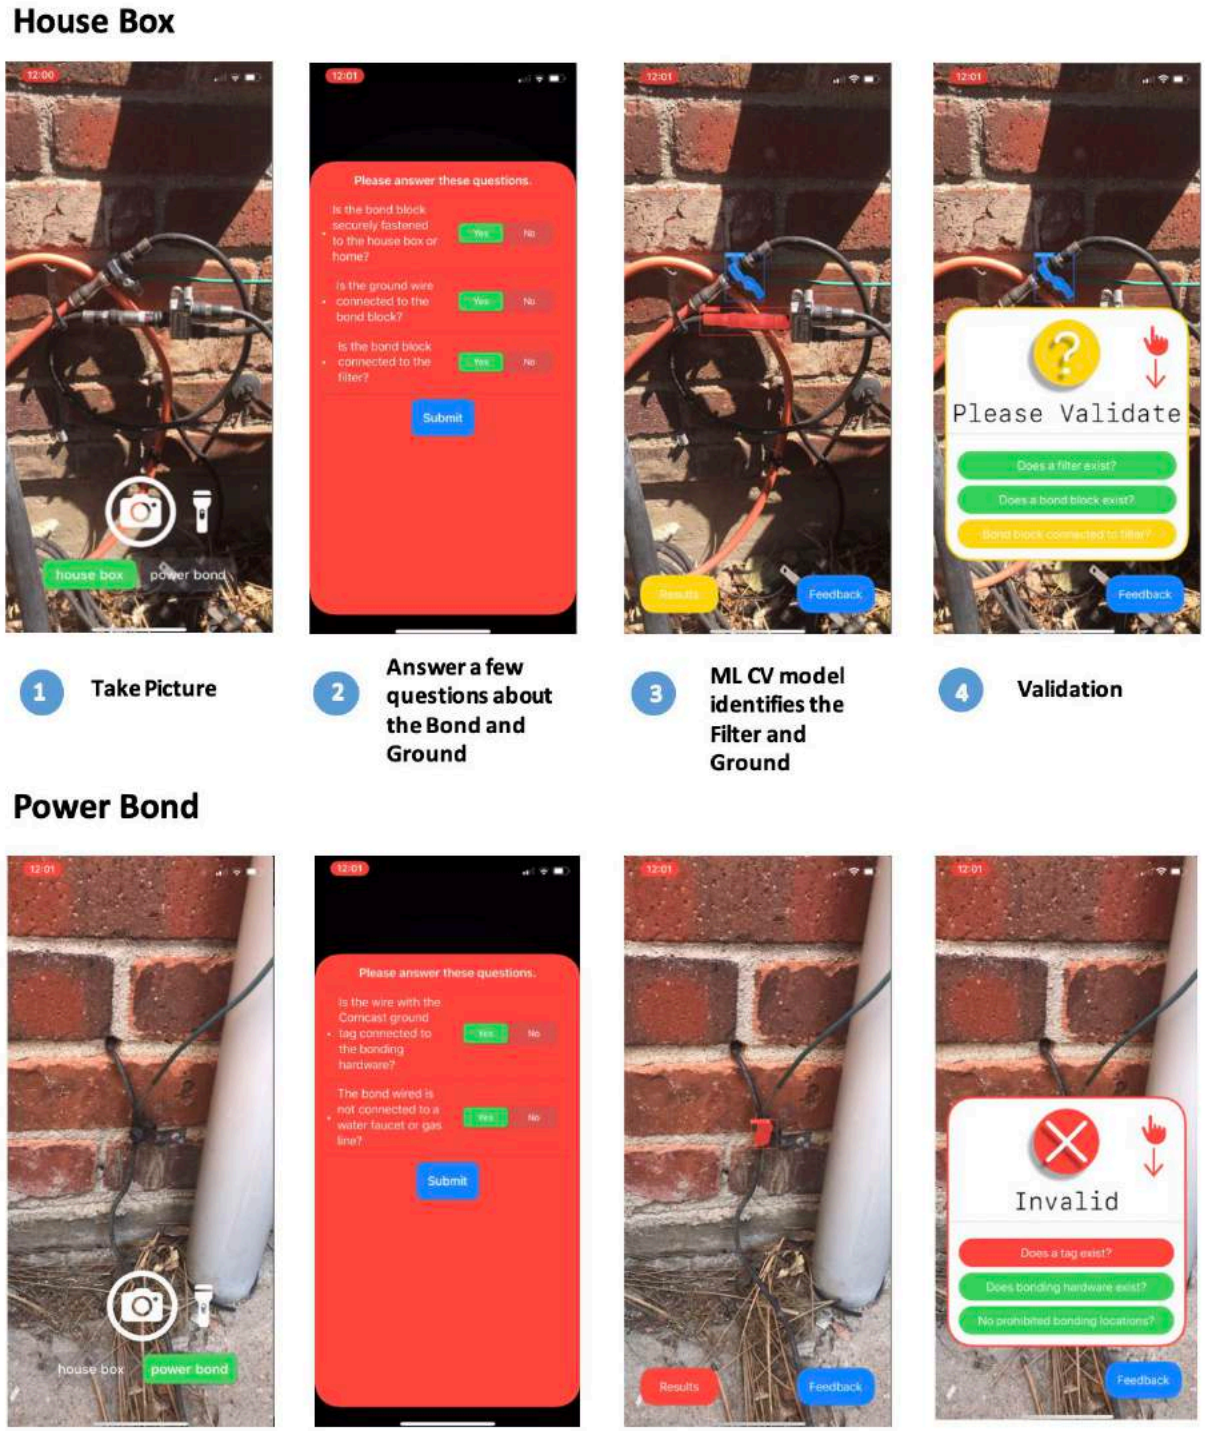

**Figure 8 - A view of the iOS app for Computer Vision grounding/bonding**

### 4.3. Trial

The Computer Vision app for electrical grounding and bonding verification is currently in trial in all three Divisions of Comcast, and specifically in systems within our Georgia, Florida and Colorado footprint. The app was successfully deployed to 50+ technician iPhones, used by technicians who are participating in the trial. So far, our feedback and learnings have been crucial to gain knowledge on how technicians are using the app, and to interpret different use cases we have not seen before.

Next steps are to integrate the app with an internally-developed digital tool, developed by and for technicians, called "Tech 360," and designed to give them a 360-degree diagnostic view of the homes and businesses they visit. That work is slated to be complete by year-end 2020, with anticipated availability to our 35,000+ techs by the middle of 2021.

### 4.4. Future updates

As the Computer Vision app expands in reach and usage, we are compiling a list of desired feature additions for the WebApp and iOS app. The list below represents a partial summary:

- *Development of an Image Queue*: If no mobile or WiFi network is available, enable the app to cache the images, then retry when connectivity resumes
- *Ease connection procedure:* Implement SSO and remove VPN
- *Implement wire tracing:* This will evaluate both RF and ground wires to ensure they are properly attached
- *Implement logic:* To determine if bond block is attached to the house box
- *Increase usability:* Add flags and notifications
- *Increase distinguishability:* Implement the ability to distinguish between six different filters that are deployed in the field.

## 5. Conclusion

Assuring the existence of a proper electrical ground and bond is a vital and longstanding best practice in cable telecommunications and broadband networks. What makes the task challenging is the simple fact that electrical grounds and bonds date back to the earliest days of homes with electricity. They're necessary to provide low-impedance electrical connections between two or more metallic bodies that are normally not current-carrying, to prevent circuit overloads and remove dangerous ground-fault voltage on conductive parts.

Good grounds mean that any current in the system goes to ground, and no voltage differences exist between them. Bad grounds can create voltage potential problems that appear to "drop the voltage" of anything connected, whether set-top boxes, modems, gateways, or, in the case of large MDUs, line extenders. Bad grounds can also wreak havoc when lightning strikes.

This paper described the use of Computer Vision, Artificial Intelligence and Machine Learning to provide technicians with a visual confirmation, intended to give them a high level of confidence about the ground andbond of a home or business. Using a WebApp and iOS app developed at Comcast Labs' Denver-area facility, technicians can verify grounds andbonds on their work-issued iPhone or iPad. It covers the background and history of grounding and bonding, why those activities continue to be important in communications network performance, and a discussion of the image collection and annotation necessary to build a production-grade visual database of proper grounds andbonds. This effort is in trial now (summer 2020), with plans to integrate this technology into a core digital diagnostics app used by field technicians following a successful trial.

# 1. Introduction

Assessing WiFi performance can be challenging, especially at scale. Most operators and service providers need provisions to understand the quality of delivered service to ensure customer satisfaction. In order to assess the service, we need to understand the requirements for consistent and reliable service offering over WiFi. Since WiFi can be used over both 2.4 GHz and 5GHz frequencies, they should be measured and assessed separately given there are different challenges per radio frequency. In this paper, each router that services a customer home will assume 2 connected radio interfaces. Once the 6GHz band is widespread, this will be an added (3rd) interface to quantify. Each connected client device, such as laptop or smart phone, will also have different bandwidth requirements to obtain the intended service, regardless of the connected interface. In this paper, we will talk through data sources and collected metrics. From those metrics, is it possible to make assessments at a aggregate level to infer reliable and consistent quality of service from poor or unusable service? Conversation pairings will refer to the transmit and receive between an access point (AP) and client device, such as a laptop. The idea here is to refer to this as a simple conversation. In order to have effective communication between both the AP and the station, the rules put in place by the protocols and the WiFi specification need compliance. Assuming compliance is met, measuring quality is the next step. WiFi quality depends on the specific conversation pairing requirements. Each pairing does not have the same time and bandwidth requirements, such as an IoT device compared to a 4K streaming device. They should not be treated the same when appraising the connection quality.

# 2. Data Sources

The Access Point (AP) to client station connection is typically a one to many relationship. As an operator, measuring data from the AP is typical since it is the central point of service in the home. It is also usually managed at the service provider level. The other main element in the equation is the client station device. While client station is not under the service provider control, it is important to recognize that the important role this device component has in this exercise. These measurements are solely to provide consistent and reliable connections to these client devices. While client devices have varying capabilities, it is fundamental to consider what is needed for each of the individual client types. Some of the most successful ways to rate the level of service is to be as individual as possible for all the requirements. Clients on a network have specific needs. As an service provider or operator, can we measure those needs at scale?

# 3. Metrics

Most measurements for WiFi quality of experience combine the same basic elements. The primary components consist of interface statistics, radio metrics and client connection statistics. The challenge with these elements are the fact they are constantly changing. WiFi is a very resilient protocol, as with most networking elements. These elements are constantly changing to meet the current conditions for service delivery. An example of the changing conditions is the rate adaptation mechanisms in video delivery to drop from HD service to SD service if HD service levels are not met. Adaptability is a key method for resiliency, but it poses challenges to understand when the quality of service compromises the customer experience. The components can be measured and assessed to provide feedback on that customer experience.

## 3.1. Interface Statistics

Interface statistics are useful in understanding what was successfully transmitted and/or received between the AP and the client station. How often were those transmission successful, filled with errors, or needed to be repeated? When we are quantifying applications, such as video, some retransmissions can be tolerated due to provisions such as buffering. While video is mentioned, each application for each client device type can be tailored to the the corresponding applications. The result is tailored to the specific service level requirement for a good user experience. Having a good ratio for interface statistics can help properly assess whether or not the current level of interface statistics are viable for a consistent user experience. Interface statistics consist of sent and received, as well as errors, retries and retransmissions. One of the key differences could be fine tuning ratios that can prove service level offerings. If it is known what is transmitted and received. Looking at the proportion of frames sent and received with respect to retransmissions and errors can yield insight into the quality of the connection. As such, measuring round trip time to assess latency is another potential method to assess the service quality between the AP and the client station. In gaming, most gamers will use latency as a measure of whether or not they are able to achieve consistent service.

## 3.2. Radio Statistics

One can argue that gaining access to the medium is the biggest challenge with WiFi today. In fact, from 802.11's beginnings, access control still presents a challenge. WiFi has always been a "listen before you talk" service. MU-MIMO was the long awaited feature in WiFi5. Most of the excitement for WiFi6 is OFDMA. Efficiency in admission control to the medium is sought after in WiFi implementations. If the AP can successfully group devices to transmit and receive at the same time within the group, this can free up more airtime to be used for even more transmissions. The number of concurrently connected devices in a home are growing as more and more devices are WiFi capable. Practices such as band steerring, pushing a client device on the 5GHz band is one way to make better use of a less congested frequency. The unlicensed 2.4GHz band is already over used and over crowded, especially in densely populated areas. Measuring the radio quality is key to understanding how much time is effectively being used for client connections. In 2.4GHz, there are only 3 non overlapping channels to use.

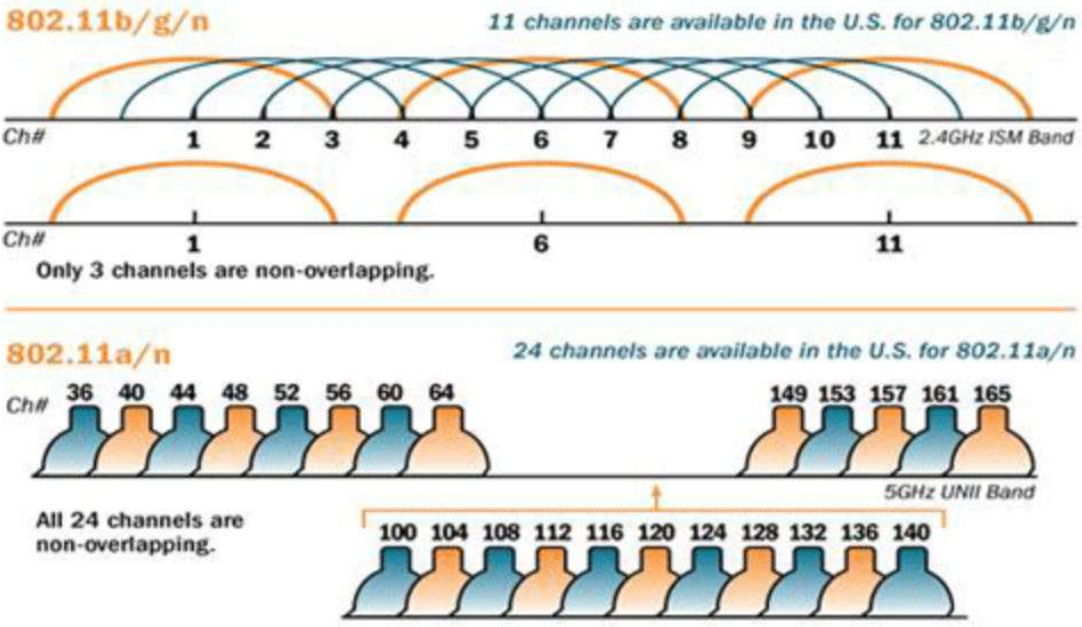

**Figure 1 - 2.4GHz and 5GHz available channels**

Given that WiFi operates in unlicensed spectrum, there is a lot of congestion in this space. As mentioned, it is typically worse in the 2.4GHz band, but congestion can still be an issue in 5GHz, especially in dense urban environments. This usually results in a lot of extra interference in this band that makes the signal to noise ratio for those connected clients lower than that in the 5GHz band. The noise from WiFi will results in interference.

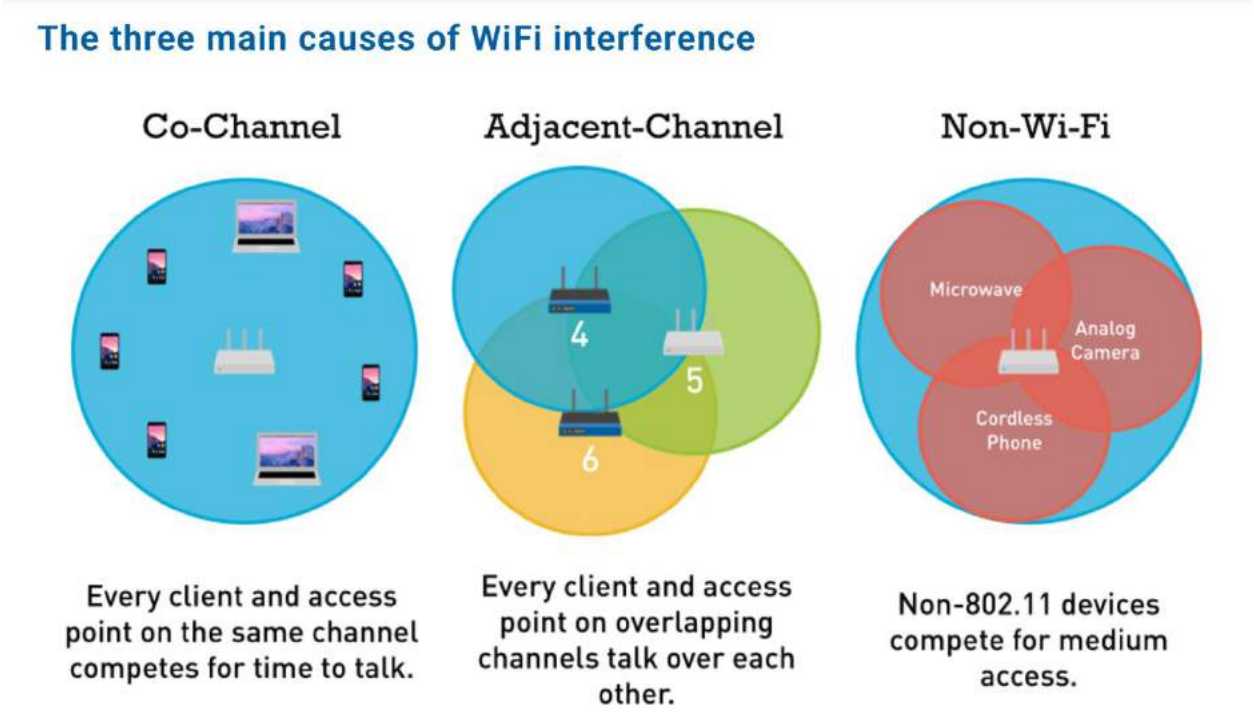

**Figure 2 - Interference**

In both bands, measuring the channel utilization where we can understand the amount of time used for servicing connected client stations is important for overall radio measurements. While there are some ways to do this in a standardized method, there are slight nuances that make normalization between APs necessary. Depending on the device, operators may see measurements such as transmit opportunity (TXOP) or free airtime (FAT) that begins to characterize the radio interface. These differences in the measurement will require normalization in a multi vendor environment. If we treat the radio measurement in the same fashion as the conversation pairing, it is a natural progression to normalize the measurement for aggregate trending.

## 3.3. Client Station Statistics

Client connection statistics that reflect signal levels of the current connection are always present in most quality of experience assessments. RSSI, PHY rates, MCS values, SNR values all provide feedback to estimate the AP to client station connection. Once again, there are nuances for these measurements. It is important to know what exactly is being reported. In WiFi, the management frames are transmitted and received at the lowest mandatory rates. If the reporting includes these management frames, this can skew the estimate of the connection quality. It is also worth noting that each client type is limited from the physical capabilities.

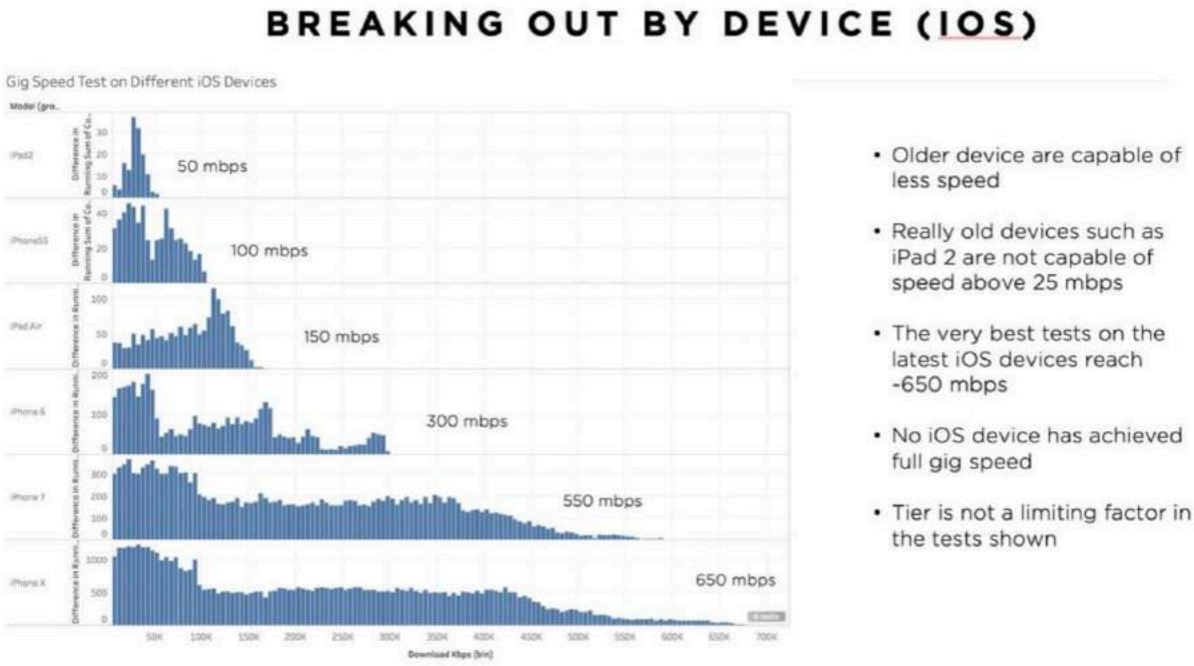

**Figure 3 - Client capabilities**

Not all client stations are created equal and should not be measured as such. As mentioned in Data Sources, operators can use the APs to take all these measurements so they know what is being measured and how often. Typically, APs have more transmit and receive antennas than the connected client devices. That imbalance of radio power needs to be recognized when evaluating these signal levels. Thresholds for these client types need testing feedback to ensure the levels are reflective of user experience.

## 4. Collection Interval

We mentioned earlier that WiFi is adaptive and constantly changing for current conditions. Collecting data at scale from moving targets should be considered when choosing collection intervals. Even if data storage and infrastructure is scaled well to collect these metrics often, it might not be necessary to collect data every minute or even every second to get reasonable measures of quality. In this conference, the idea of limitless possibilities is challenged. If that theme is extrapolated to the point where data storage and processing power is not an issue, do we want to collect data frequently? Does that make sense? In all computing systems, once mechanisms are built, efficiency is the next logical step, even if scale isn't an issue. Collecting data at the edge and aggregating into a cloud element is only meaningful if the right building blocks are in place. Beginning with the conversation pairing is fundamental to then build groups to count and ultimately trend and aggregate. Using that order of operations as a rule set can yield consistent aggregation points. If one can target the right thresholds for the individual conversation requirements, how often is necessary to check that connection? A good start would be hourly, if the infastructure can support the individual pairing data model. A more granular set of metrics has been found to roll up 15 minute intervals. There are some methodologies that will have localized collection agents at the WiFi interface to aggregate the data to be collected less often by centralized infrastructure.

 

Strategies for this type of data is important make sense of this at scale. If one keeps averaging or aggregating data, it will just make the measurements less meaningful and will not capture the experience properly. If we can divide the data into different compartments for each measurement, we can count those data occurrences while quantifying scale at that individual level. As a result, collection intervals can be done less often and aggregation can be scaled while still providing a meaningful experience gauge. The idea here is to expand vertically rather than horizontally. Limitless possibilities doesn't always mean expanding in the same direction.

## 5. Active vs. Passive Measurements

All of the data metrics and measurements discussed at this point are assuming that these measurements are passive. This means that we are going to watch active client station connections to a given AP and measure the primary components and report those measurements accordingly. Given that applications and client stations change hardware and software often, there is a need to pulse ever changing conditions. Having active measurements can aid in trending those changing conditions. If the endpoints are static to provide a baseline for each AP type and client station device type, that baseline can be trended for deviations. This will be instrumental in keeping the thresholds for the individual conversations meaningful.

## 6. Conclusion

Aggregating quality of experience data at scale can be done multiple ways. The interesting effect WiFi has on this quality of experience is that one to many or 2 way conversation is where the first operation is computed. Measurement data from specific thresholds for endpoint pairings will be the fundamental step before rolling the data into aggregate trends. Anything that is connected to the AP that has a cataloged resource is considered an endpoint pairing, such as AP to gaming device or AP to IoT device. The basic element to measure all of the following remain consistent in WiFi quality of service: interface statistics, radio metrics and client connection statistics. Counting the amount of occurrences where an acceptable service delivery was not met for those threshold pairings is paramount.

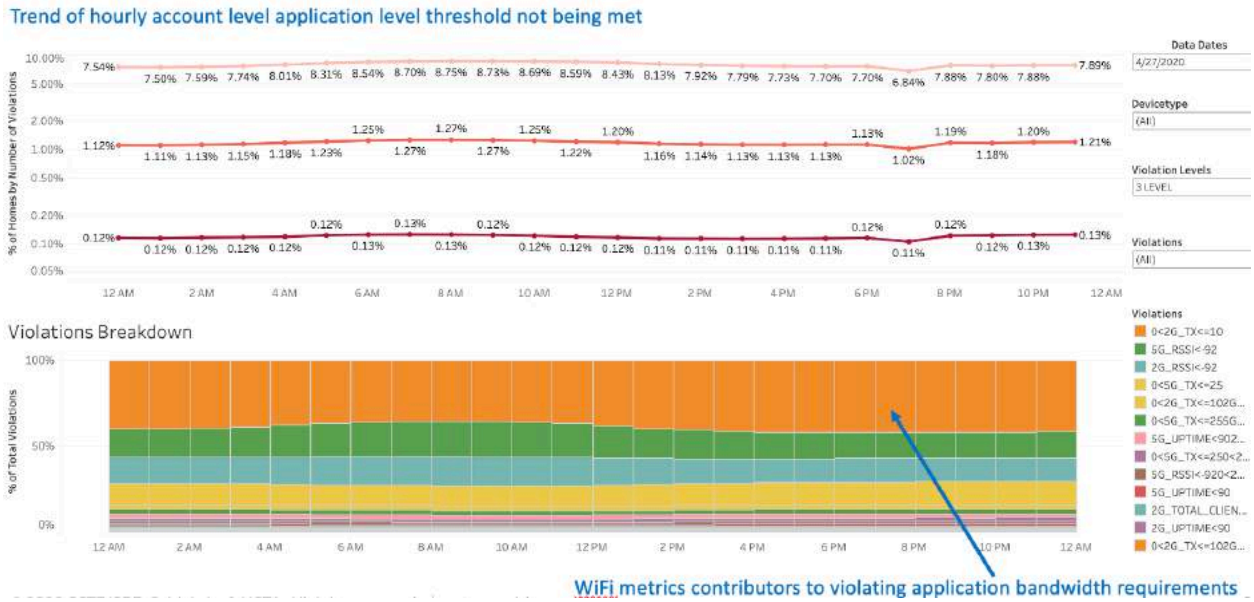

**Figure 4 - Aggregate Trending**

Once those counts are listed, it is important to give those counts context. Using those as a percentage in the overall service delivery can setup a baseline. In the above referenced figure, thresholds are applied across conversation pairings and counted as a percentage to assess impact on the wireless customer experience. The percentage of time polling systems captured the signal and bandwidth requirement below the configured threshold is trended. The bottom chart shows the distribution for the contributing reasons why the service delivery was not satisfied. If those endpoint pairings, such as service delivery for video streaming devices are contextualized, the ability to filter on those specifics can understand the trends for capacity management can be shown at an aggregate level. If that order of operations is not met, aggregate data will remain less meaningful.

# 1. Introduction

The proliferation of MSO-managed Wi-Fi devices has created a new set of challenges to define best install practices, capacity and troubleshooting. Modeling and characterizing capacity, as it pertains to multiple devices creating diverse traffic models, is challenging and evolving. Overcoming difficulty in the translation of a repeatable test lab environment, as a baseline to real world customer experience, will be discussed. This paper will focus on approaches to provide recommended device installation guidelines through a four-prong approach of prototyping, characterizing, baselining and real world testing.

This paper loosely follows the steps that Comcast took prior to the launch of the first wireless video settop. While Wi-Fi was not new, its application to a managed device was novel to the organization. Installation guidelines, much like those that existed for coaxial-connected devices, had to be developed based on new metrics which needed to be standardized across the various device combinations. Similarly, device settings needed to be adapted for this new medium through a cycle of prototyping and testing. Lastly, a new approach to whole home testing had to be taken to account for these new devices in the ecosystem.

# 2. Problem Statement

MSO-provided services over Wi-Fi create a unique set of challenges. On the radio interface, connected devices compete for resources. It is imperative to create a framework to bound the services that could be provided to a given home based on their type of service and equipment. Many Wi-Fi products are ubiquitous and have intensive bandwidth demands. Each MSO business unit looking to maximize its offerings to maximize its competitiveness – offer more devices with higher resolutions. Having a capacity model that translates to customer experience is imperative for scalable hardware and software support in a connected home. That capacity model must evolve in both terms of connected devices in a home as well as connected device traffic profiles and must be bound by installation guidelines.

# 3. Key Metrics

Through our research and testing we decided to use AirTime as the metric to quantify “how much Wi-Fi” a device or a service should be allowed in a home when installed at the recommended RSSI level.

## 3.1. AirTime

Wi-Fi began as a listen-before-talk service where only 1 device on the given channel can “talk” at a time. When a device is allowed to “talk” it will require a finite amount of time, AirTime, to complete its data transaction. The ability to transmit and/or receive data quickly and efficiently will determine how much AirTime a client will consume in a home.

### *3.1.1. Wi-Fi 6*

The charter for IEEE’s latest standard, Wi-Fi 6, benchmarks efficiency for high density Wi-Fi deployments. No longer was the goal to increase a given device’s bandwidth, but rather to have provisions in place to maximize the mechanisms to be as efficient as possible in high density environments. Features such as MU-MIMO and OFDMA are highly anticipated to aid in capacity demands on Wi-Fi’s radio interface. While OFDMA is not a new concept, it is new for Wi-Fi 6. This is a long awaited feature, where multiple client station devices can utilize airtime as a group, so as to be more efficient in an overcrowded environment. This will result in more throughput with less airtime.

 

*Table 1* below shows some sample data collected from the analysis of a Wi-Fi5 Xfinity Camera in an RF chamber operating in 2.4GHz. The signal from a conducted Access Point (AP) is radiated in an RF chamber containing with various degrees of attenuation to emulate distance and/or obstructions between the AP and the device under test. This type of anlysis allows us to understand the relationship between an installation closer to the AP (lower signal attenuation and higher RSSI) and the AirTime that the device will consume at that range.

**Table 1. Xfinity Camera AirTime utilization versus RSSI analysis**

| Chamber Attenuation dB | RSSI (Average) dBm | SNR (Average) | Average Channel Utilization (%) | Channel Utilization 90th Percentile (%) | Channel Utilization (%) Max | Channel Utilization (%) Min | Channel Utilization (%) STDEV | TX Rate (Max) Mb/s | TX Rate (Min) Mb/s | RX Rate (Max) Mb/s | RX Rate (Min) Mb/s |
|---|---|---|---|---|---|---|---|---|---|---|---|
| 0 | -56 | 49.28 | 6.26 | 8.1 | 24.7 | 3.1 | 3.09 | 144 | 122 | 144 | 78 |
| 5 | -61 | 44.5 | 5.81 | 6.9 | 17.6 | 3.9 | 2.02 | 144 | 132 | 130 | 77 |
| 10 | -67 | 38.5 | 5.98 | 7.3 | 11.3 | 4.7 | 1.42 | 144 | 121 | 129 | 78 |
| 15 | -71 | 34.2 | 5.93 | 7.3 | 11.3 | 3.1 | 1.31 | 144 | 117 | 124 | 78 |
| 20 | -68 | 37.3 | 6.72 | 9.0 | 22.3 | 3.5 | 3.42 | 144 | 133 | 116 | 77 |
| 25 | -72 | 32.97 | 6.19 | 7.4 | 20.0 | 3.9 | 2.36 | 143 | 121 | 103 | 58 |
| 30 | -76 | 28.69 | 6.07 | 7.1 | 16.5 | 3.5 | 2.25 | 125 | 106 | 89 | 52 |
| 35 | -81 | 24.15 | 7.45 | 11.3 | 21.9 | 3.9 | 3.60 | 102 | 82 | 77 | 39 |
| 40 | -86 | 19.86 | 8.60 | 12.3 | 16.0 | 3.5 | 3.08 | 69 | 56 | 52 | 29 |
| 45 | -90 | 15.91 | 10.65 | 18.3 | 42.7 | 3.5 | 6.69 | 58 | 54 | 26 | 13 |
| 50 | -93 | 15.06 | 13.06 | 23.4 | 41.2 | 5.8 | 8.01 | 52 | 44 | 26 | 6 |

Understanding not only the bandwidth requirements of the devices in a connected home, but also the time is takes on the air to get the required bandwidth, is a key metric for building a diverse capacity model. Breaking down what components are included in that measurement is pivotal. *Figure 1* below illustrates the various tasks consuming air time in the communications between an Xfinity Camera and AP and contrasts the differences between two beamforming settings. This analysis can help understand what elements, if any, beyond the data traffic are significantly contributing to the AirTime consumption of a given client. In this case, for a static device like the Xfinity Camera, the shorter beamforming interval was not only unnecessary but harmful to the overall performance of the home network by greatly increasing AirTime consumption.

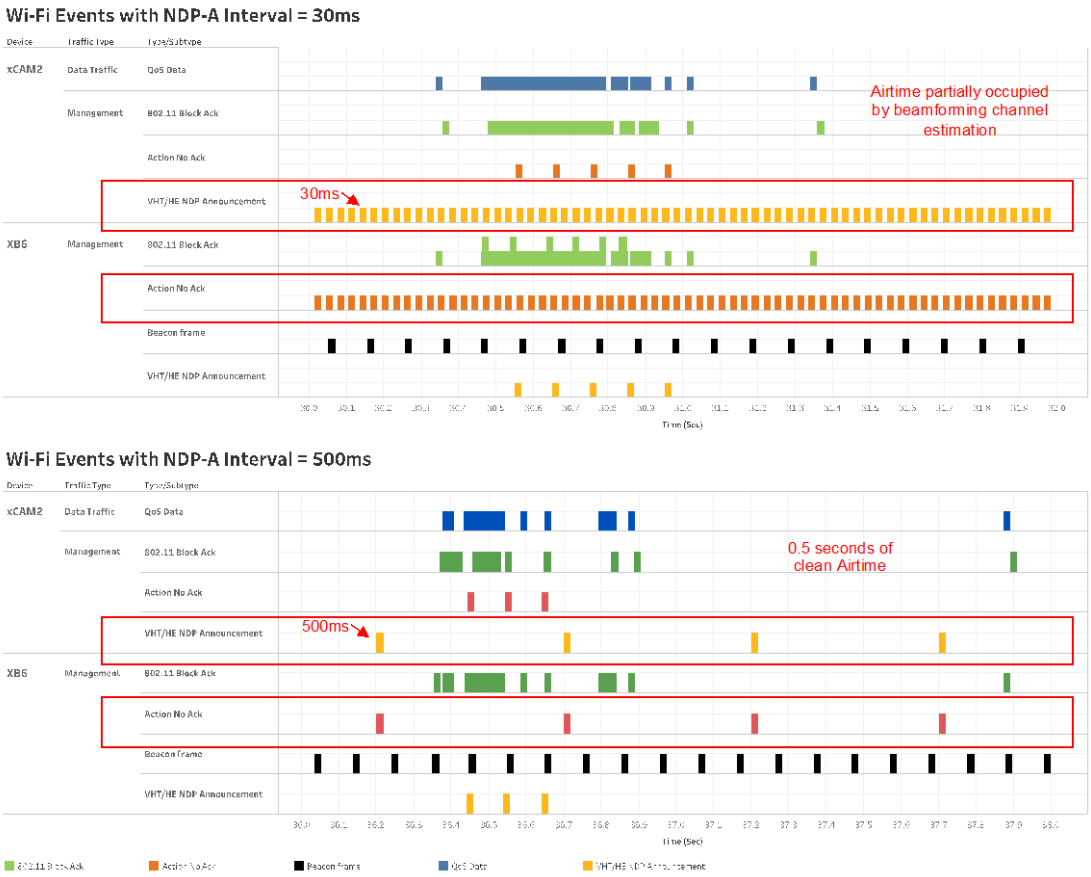

**Figure 1 - AirTime Analysis Between Xfinity Camera and AP with Different Beamforming Settings**

Once the AirTime model is properly measured it will provide a foundation for install guidelines. Airtime utilization has some nuances for the measurement across SoC platforms. Often SoC vendors report the AirTime consumed by their devices differently. By including variance of metrics into their reporting such as, management overhead frames inclusive of NAV times, probe responses, beacons, SIFC intervals, the collected data may have to be normalized as a result.

## 3.2. Received Signal Strength Indicator (RSSI)

More complex than defining "how much Wi-Fi" a device should be allocated was finding an installation guideline metric that would be both easily accessible and consistent across the various System On Chip (SoC) vendors that our devices employed. This metric needed to not only be easily understood by our customers, but also accessible to our technicians, via telemetry and/or on-screen diagnostics. RSSI measured from the access point (AP) can be used to determine the given attenuation in a model and is the basis for install guidelines. RSSI at the STA could be used but it is often more difficult to use for IoT devices that are not connected to a screen. Comcast agreed to use RSSI understanding its limitations.

With an understanding of the AirTime consumption of a managed device, or devices, at a given RSSI level it is possible to begin to model the approximate theoretical Free AirTime (FAT) available to a consumer that subscribes to various services.

## *4.* Prototyping

Early device prototyping became an integral phase of our characterization efforts, as it allowed us to verify our RF architectural decisions (2x2 / 3x3 / 4x4) as well as to begin the process of fine-tuning the settings of our devices firmware for an optimal user experience. Ensuring that the device hardware is capable of the theoretical maximum values provides the first step in Wi-Fi hardware verification. This is typically completed in a conducted laboratory setting. Adding attenuation to these test suites will yield valuable data points to build foundational measurements. These are usually referred to Rate vs Range (RvR) testing and Rate vs Orientation (RvO). At this prototyping phase, changing variables, such as driver settings and traffic models, is essential to qualify device behavior. Testing different protocols, such as TCP vs UDP, or modifying frame sizes, help prototype the device behavior.
Default driver settings for a Wi-Fi device can dramatically change the experience, depending on the overall desired application requirements. *Figure 2* below shows the impact of Wi-Fi frame size on the throughput capabilities of various Xfinity managed video clients. It is important to understand these impacts and bound the settings so that the devices will operate within their most efficient range.

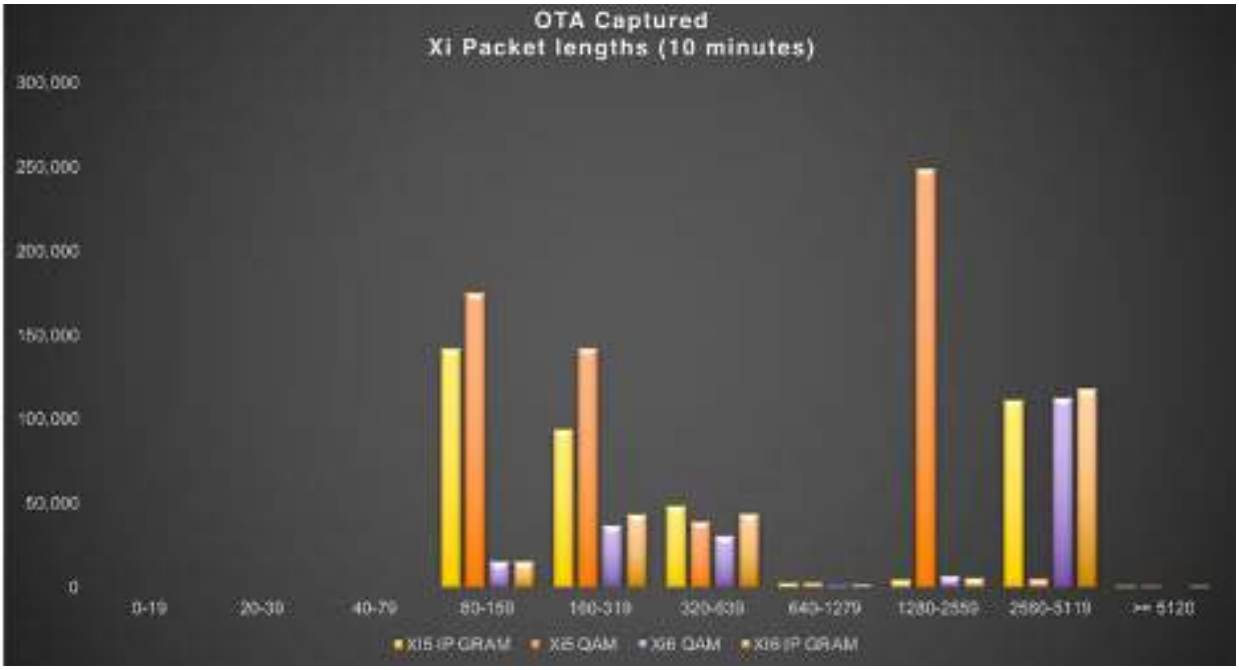

**Figure 2 - Throughput Versus Frame Size Performance for Various Xfinity Managed Video Clients**

Another setting we found to have a significant impact on the Wi-Fi performance of a device and/or home is frame aggregation. Wi-Fi uses frame aggregation to be more efficient with regards to airtime. This can come at a price. It noisy environments, there is a higher chance for a collision or error, which results in all aggregated having to be retransmitted again. This will take longer in an already overcrowded space. Some SoCs will have algorithms in place to dynamically measure the environment and aggregate only when the conditions are satisfactory.

*Figure 3* and *Figure 4* below illustrate the differences in throughput for a given AP when Frame Aggregation is enabled or disabled. It is important to understand the tradeoffs of this setting for various system load levels and frame sizes.

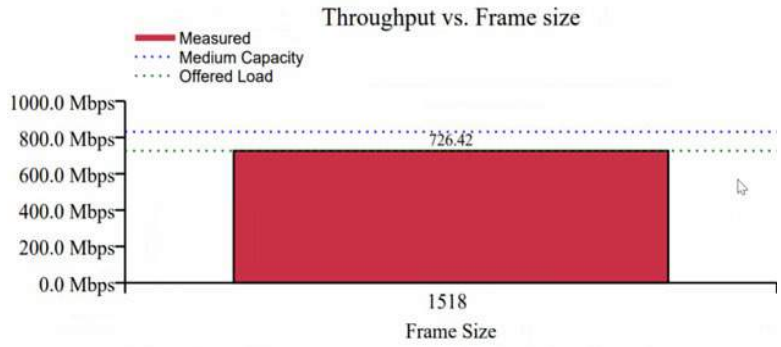

**Figure 3 - AP Throughput Versus Frame Size - Frame Aggregation Enabled**

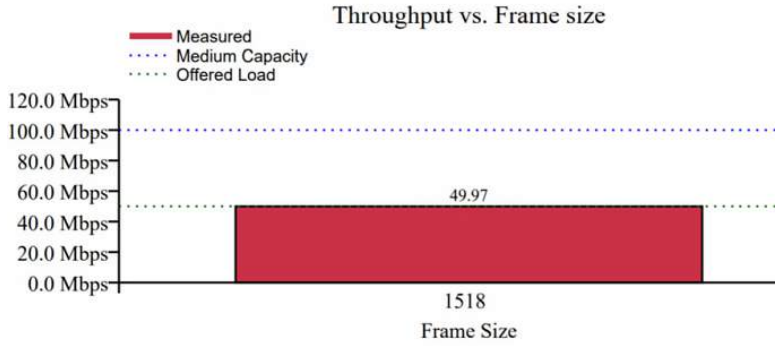

**Figure 4 - AP Throughput Versus Frame Size - Frame Aggregation Disabled**

## 5. Characterizations

Understanding how devices behave with the various APs and extenders is foundational for an operator to understand. Modeling can be challenging, given all the combinations and variables possible. In the prototyping phase, Wi-Fi specification compliance is mandatory. Achieving those theoretical maximum values will validate the hardware and the default driver settings for the conducted testing phase. In the IEEE Wi-Fi specifications there are also plenty of optional and other settings that can be tuned to achieve desired output, such as maximizing throughput or minimizing latency. As stated earlier, these settings can be adversely affected in noisy or crowded environments. How different settings affect the in home experience can produce different results, given the variety of different connected clients at varied RSSI levels. We instituted a rigorous and formal program to characterize each of our managed devices, (a) on its own with each of our APs and Extenders and (b) in the presence of our other managed devices. Individual characterization is performed pre-launch and frequently thereafter, as firmware, in either the managed device or APs, evolves. Whole home characterization is performed periodically in a radio silence test house such as one shown in *Figure 5* where all the metrics for the various devices are monitored and compared against the individual values.

**Figure 5 - Comcast Test House. Whole Home Setup. Cross-sectional view.**

## 6. Baselining

Through the characterization of the various devices the relationships between AirTime consumption and installation range, through the measure of RSSI, become apparent. This data in combination with the business goals allows the Product and Business owners to begin to define combinations of managed clients with a given AP that strike a balance between capacity and customer experience. This somewhat iterative, and often evolving process, will create baseline device configurations that can be reliably deployed and installed.

## 7. Testing

The capacity models and installation guidelines drawn from the characterization and baselining efforts need to corroborated in real world scenarios. This can be achieved via (a) controlled Test House tests and (b) device telemetry. A radio silent Test House can be converted into a real world scenario with the injection of noise and/or Wi-Fi traffic; device combinations can be tested against various APs with given software builds to confirm the recommended guidelines. Similarly, the real time telemetry provided by our APs can provide information to illustrate how given a device combination is performing under less controlled and more random scenarios. This test and telemetry data can be used as a feedback mechanism to further refine the characterization and baselining of the devices and software under design.

## 8. Conclusion

In spite of Wi-Fi being a live, shared medium, it is possible for an MSO to deterministically provide bounds to the number of managed devices and services based on Wi-Fi Airtime and RSSI installation guidelines.

A device design process based on prototyping, characterization, baselining and real world testing will provide product teams with the necessary information to provide capacity and installation recommendations that maximize both the number of services provided, and the customer experience.

# 1. Introduction

The COVID-19 (2019 novel coronavirus) pandemic caused governments around the world to issue shutdown orders resulting in a sudden shift in network traffic patterns as subscribers started using their broadband connections for tele-everything – working from home, remote learning, entertainment, social interactions, and commerce. As part of the crisis management effort, and to keep the public and various levels of government informed, operators posted reports of the status of their broadband networks in handling the increased usage.

To develop these reports, cable operators shared aggregated anonymized data with NCTA – The Internet & Television Association. In this paper, we first look at the data that the cable operators shared with NCTA as well as similar data from wireline and wireless operators. We then cross-reference the cable data with other third-party data to make some additional observations on the performance of the broadband access networks.

# 2. Cable Network Dashboard

NCTA worked with nine of the U.S.'s leading cable companies[1] to collect and aggregate anonymized network performance data for a publicly accessible network performance dashboard (NCTA, 2020). The dashboard reported on two metrics:

1. change in peak utilization
2. service group utilization grouped by state

The dashboard went live on April 4, 2020 and was still active at the time of the writing of this paper in August 2020. The data set for the dashboard includes data going back to March 1, 2020 – prior to when states started issuing shutdown orders. This was in order to measure and report on the impact of the orders on the network. The dashboard also provided insights into what happened when states started re-opening in late April 2020.

Change in peak utilization was chosen as the primary metric for the dashboard because networks are engineered for peak capacity, and this single metric provided the best snapshot of how well the networks were performing. Figure 1 shows the overall change in the peak utilization for both the upstream (US) and downstream (DS) traffic going back to March 1, 2020 to show the change from pre-shutdown levels. It is important to note that the change in utilization is not directly analogous to the change in consumption because the overall capacity of the networks are fluid; operators could be adding capacity each week. Even though a change in utilization is not the same as consumption, it still provides a good proxy for how data consumption changed as a result of the shutdown.

Peak upstream utilization occurred the week ending April 18, 2020, with a 35% increase over the pre-shutdown levels. For downstream traffic, the largest change in peak utilization occurred for the week ending March 28, 2020, at 20%.

[1] Companies who shared data included: Altice, CableOne, Charter, Comcast, Cox, GCI, Mediacom, Midco, and Sjoberg's.

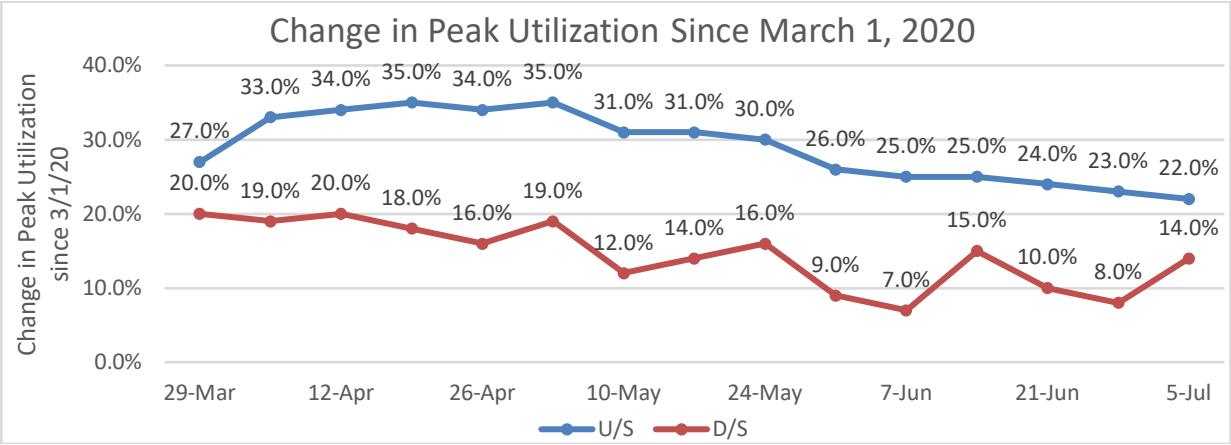

**Figure 1 - National peak utilization growth. Source: NCTA**

Figure 2 shows the week-over-week change in the peak utilization. The largest week-over-week change for the upstream occurred the week ending March 28, 2020, with a 7.3% increase and for the downstream the week of June 13, 2020, with a 7.8% increase. Again, it is important to note that this is the relative utilization of available capacity for that week.

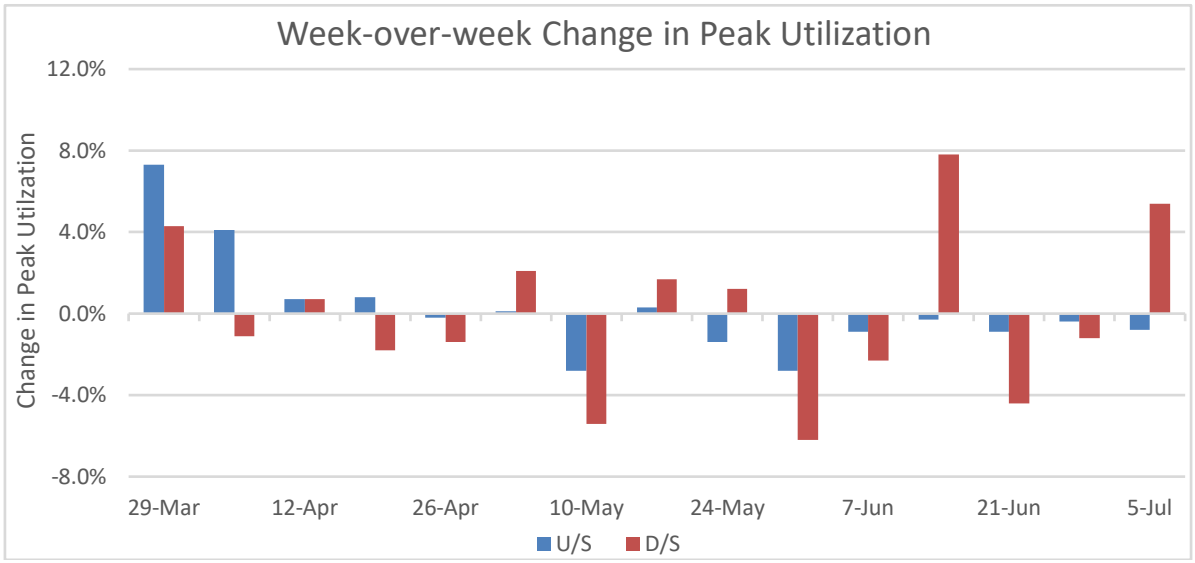

**Figure 2 - Week-over-week change in peak utilization. Source NCTA**

In addition to the aggregated change in peak utilization at the national level, MAC (medium access control) domain service groups utilization were collected. A DOCSIS (Data Over Cable System Interface Specification) service group is either a MAC domain upstream service group or a MAC domain downstream service group. A MAC domain downstream service group refers to the set of downstream channels from a port on a CMTS (cable modem termination system) line card that reach a fiber node and a MAC domain upstream service group refers to the set of upstream channels from the same MAC domain that are reached by a single cable modem. Operators shared the peak utilization levels for each service group and further grouped these by utilization level (<85%, 85%-95%, 95%-99%, and >99%) as shown in Table 1 and in Figure 3

Less than 0.35% of the service groups were ever above 95% utilization. For the dashboard, the service groups were aggregated by state to show how well the DOCSIS network was operating on a regional basis as shown in Figure 4.

**Table 1 - Aggregated service group utilization.**

| | Service Group Utilization Level | | | |
|---|---|---|---|---|
| ***Week*** | **< 85%** | **85% - 95%** | **95% - 99%** | **>99%** |
| *14* | 95.8% | 3.9% | 0.29% | 0.04% |
| *15* | 95.8% | 3.8% | 0.29% | 0.06% |
| *16* | 96.3% | 3.5% | 0.22% | 0.02% |
| *17* | 96.4% | 3.4% | 0.16% | 0.01% |
| *18* | 96.0% | 3.7% | 0.23% | 0.03% |
| *19* | 97.1% | 2.7% | 0.12% | 0.05% |
| *20* | 97.1% | 2.8% | 0.13% | 0.01% |
| *21* | 97.0% | 2.8% | 0.16% | 0.02% |

# 3. Other Open Source Data

The mobile wireless and wireline carriers, along with small cable operators, also shared network performance data via their respective trade associations.

## 3.1. Mobile Wireless

CTIA reported on the cellular network performance (CTIA, 2020). Mobile data use peaked at 22.6% above the pre-shutdown average on June 22, 2020.

**Figure 5 - Wireless data change from baseline. Source: CTIA**

## 3.2. Wireline

USTelecom reported on the wireline (DSL, fiber) network performance by reporting on the change in traffic (aggregated upstream & downstream) compared to the pre-shutdown level (USTelecom, 2020). The peak traffic change occurred the week of April 16, 2020, at 27% higher than the baseline, and then trended down to about 12%.

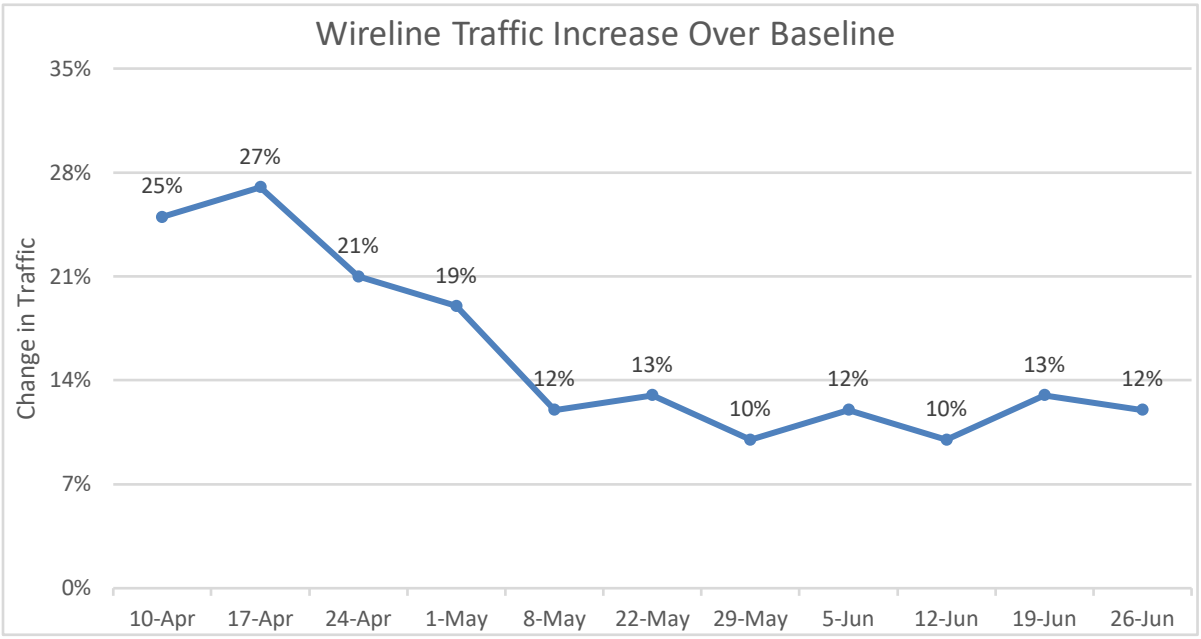

**Figure 6 - Wireline traffic change from baseline Adapted from USTelecom**

### 3.3. Small Cable Operators

ACA Connects, the trade association representing many of the smaller U.S. cable companies, reported that peak download usage was up 24% and peak upload usage was up 34% for its members (ACA Connects, 2020). Download consumption peaked at 44.7% (relative to February 1, 2020) on March 27, 2020, and the upload consumption peaked at 68.8% on March 24, 2020, as shown in Figure 7 and Figure 8.

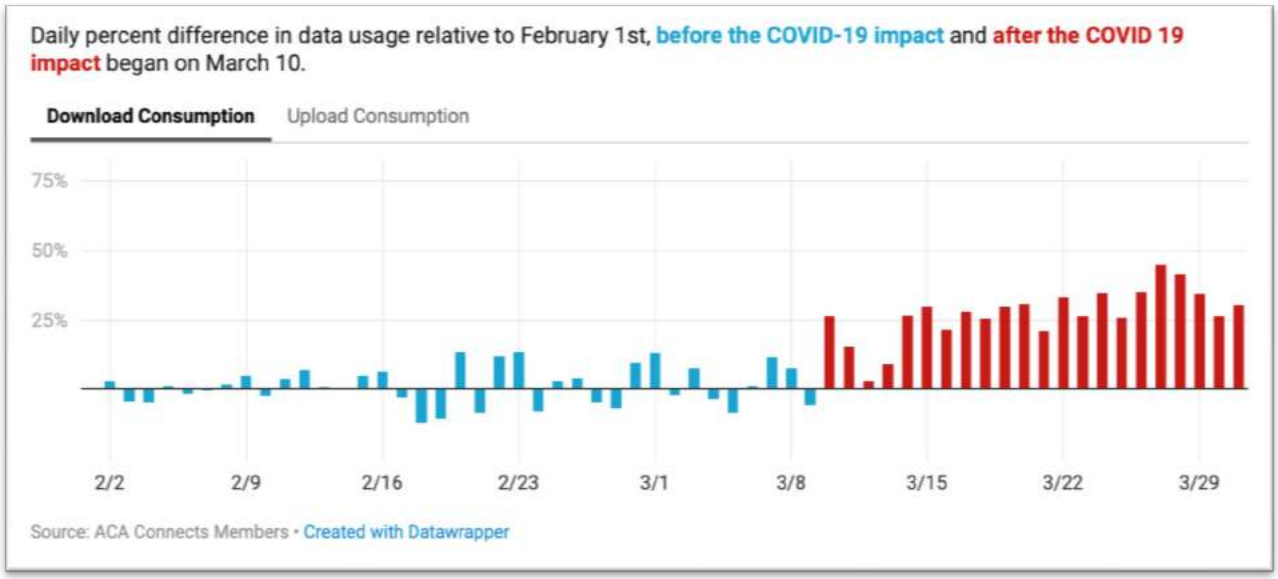

**Figure 7 - Download consumption. Source: ACA Connect**

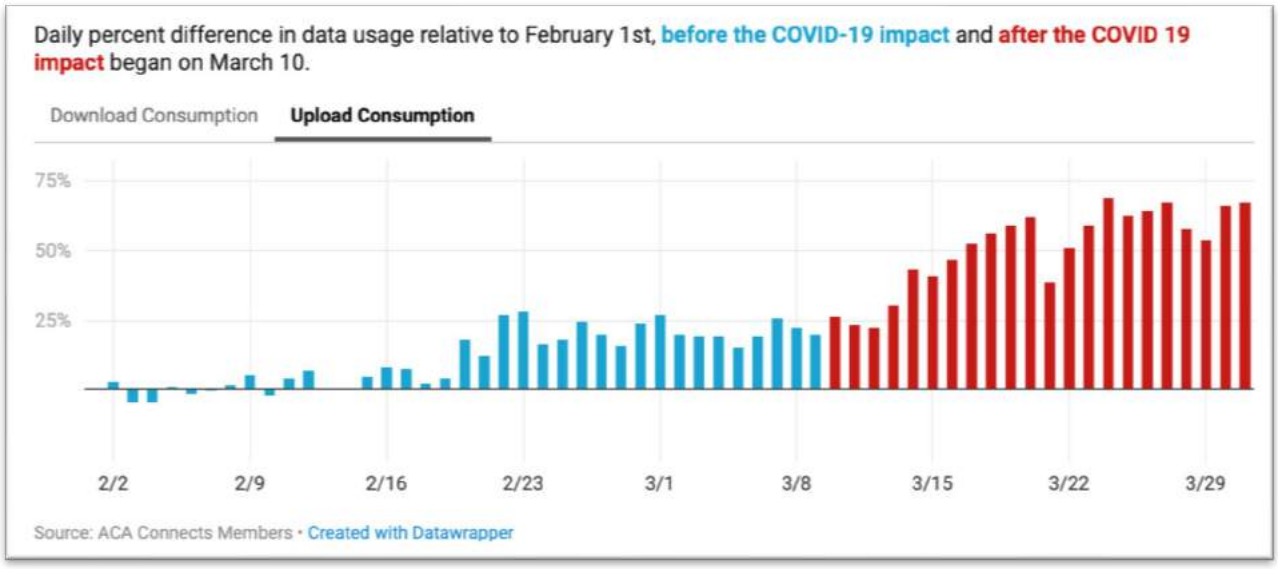

**Figure 8 - Upload consumption. Source: ACA Connect**

## 3.4. Global Internet

### *3.4.1. Nokia Deepfield*

At NANOG 79 (North American Network Operators' Group) in June 2020, Craig Labovitz of Nokia Deepfield gave a presentation on the impact of the pandemic on the internet on a global scale, in which he discussed impacts on networks both domestically and internationally (Labovitz, 2020). As shown in Figure 9, Labovitz reported that most networks typically have 40-50% traffic growth in one year, and many saw a 45% change during the first four weeks of the shutdown.

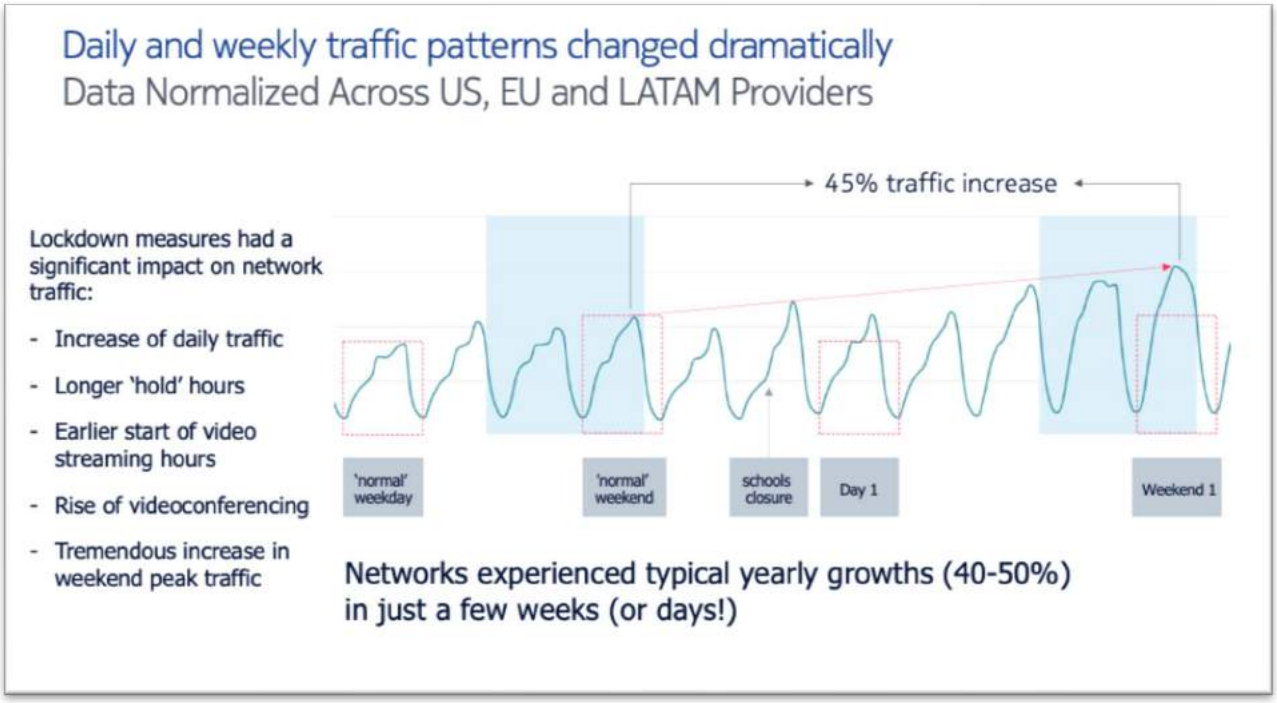

**Figure 9 - Reported change in traffic patterns. Source: Nokia Deepfield**

Labovitz also reported on the change in application usage as shown in Figure 10 after the first week of the shutdown, with the secure messaging app "WhatsApp" and videoconferencing apps in general showing the largest growth in usage. Figure 11 shows the growth in videoconferencing with Zoom usage growing as much as 700% on select networks. Figure 11 also shows how Zoom moved to a multi-CDN (content delivery network) strategy from a single CDN delivery strategy. Figure 12 illustrates how WebEx had somewhat consistent growth for each day of the week, while Zoom experienced its highest growth on Saturday and Sunday.

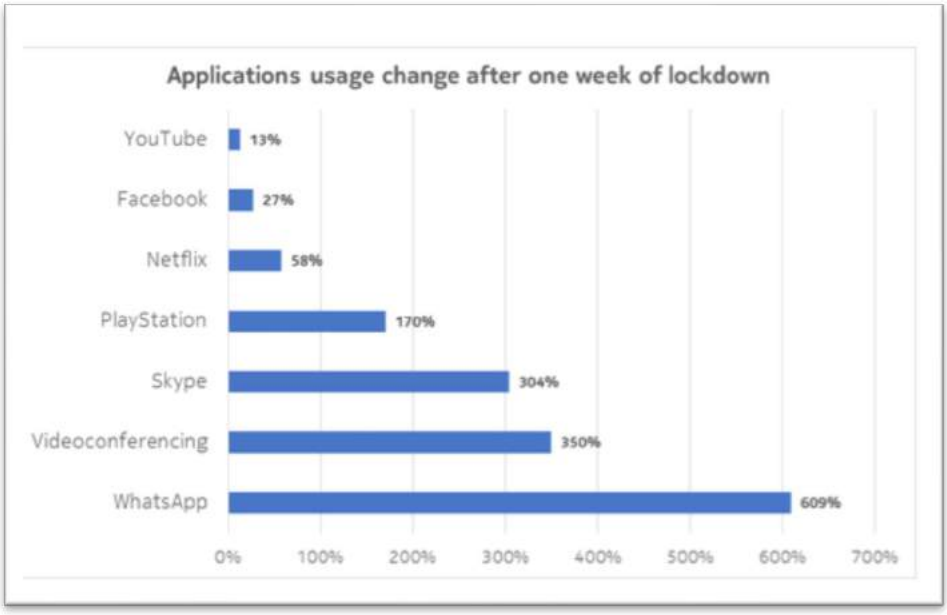

**Figure 10 - Change in application usage. Source: Nokia Deepfield**

**Figure 11 - Videoconferencing usage growth. Source: Nokia Deepfield**

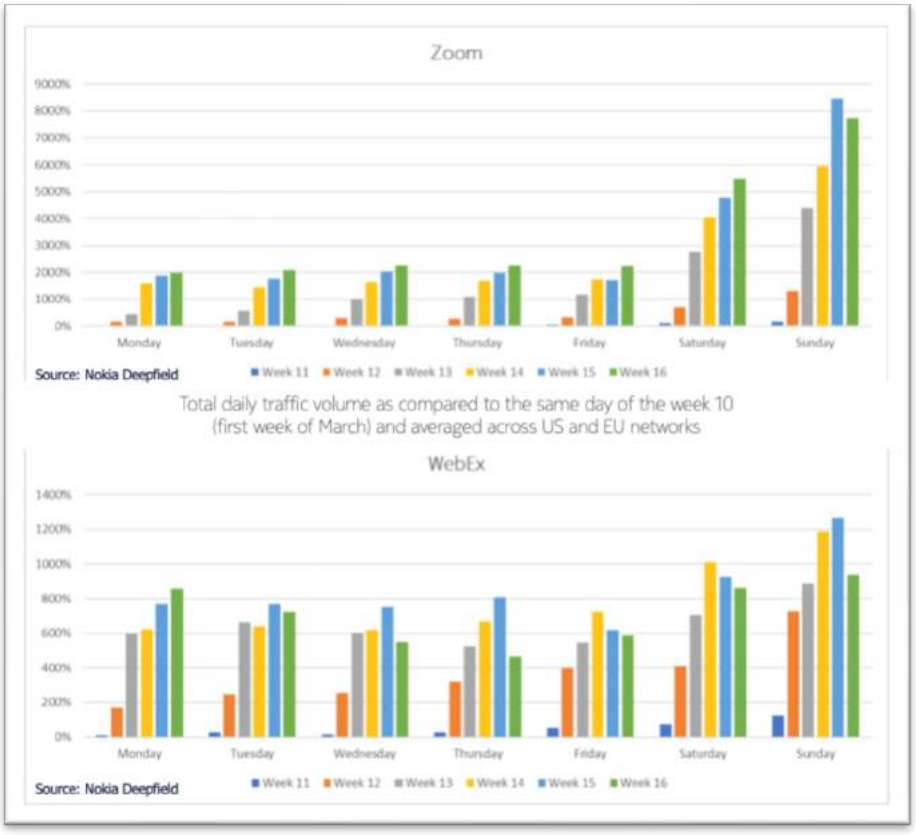

**Figure 12 - Change in Zoom and WebEx usage. Source Nokia Deepfield**

### *3.4.2. Sandvine*

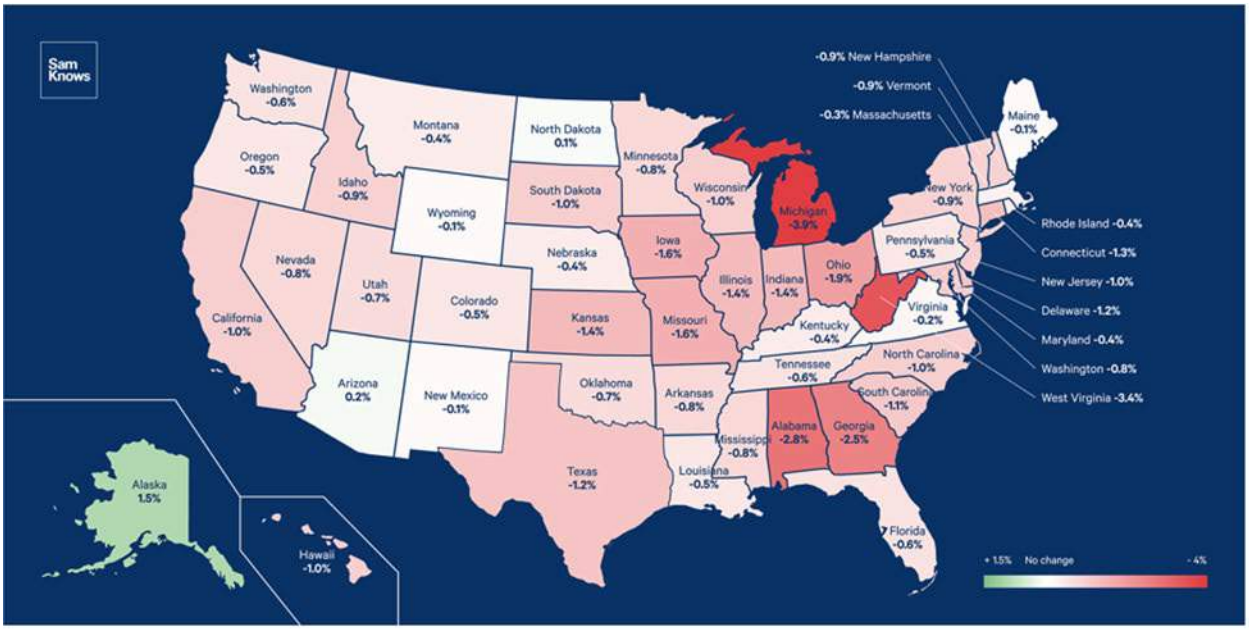
Sandvine reported that Internet traffic grew almost 40% due to the shutdowns (Sandvine, 2020). In addition, Sandvine also reported on the total traffic by application category during the shutdown as shown in Figure 13, with video streaming having the largest share of the traffic at 57.6% and growing 2.2%.

**Figure 13 - Sandvine global application category total traffic share Source: Sandvine.**

### *3.4.3. SamKnows*

SamKnows operates a large scale measurement platform that is used by ISPs, governments, academics and consumers. SamKnows gathered the test results from 500,000 homes that have a SamKnows-enabled router installed. These home routers run regularly scheduled speed tests to a major U.S.-based CDN every 10 seconds using multiple TCP (transmission control protocol) connections in parallel. SamKnows posted that most of the states only saw about a 1% decline in the download speeds as shown in Figure 14 (SamKnows, 2020). SamKnows did not provide any further explanation for what may have caused the 1% slowdown. Further it is unclear whether this reduction is within the margin of error or whether in fact the networks actually experienced a 1% decrease in downstream speed.



*Based upon a sample of more than 500k homes running automated download speed tests on a regular basis. Each speed test uses 16 concurrent TCP sessions and measures to a major US CDN. Measurements from 2020-03-12 were compared against measurements from 2020-03-24 to create this comparison.*

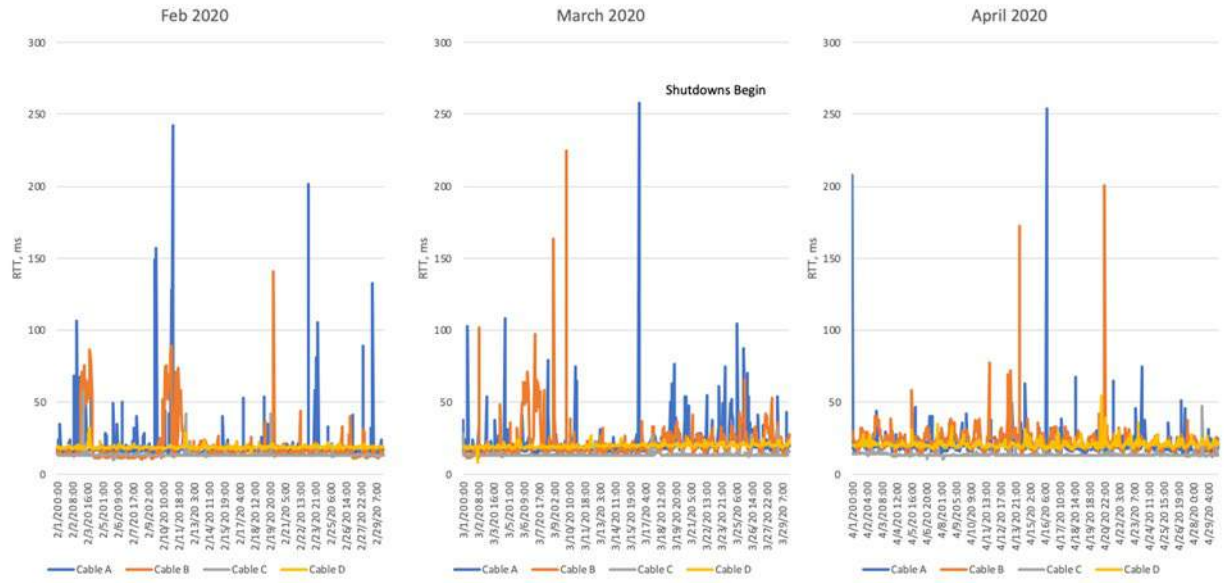
**Figure 14 - SamKnows measured change in download speed by U.S. state between March 12 and March 24 Source: SamKnows**

### *3.4.4. RIPE Atlas*

The RIPE Network Coordination Centre operates a large Internet measurement platform, RIPE Atlas, that employs a global network of probes that measure Internet connectivity and reachability. Each RIPE Atlas probe runs a set of built-in tests 24x7. One of the tests is for each RIPE Atlas probe to issue a set of pings every 15 minutes to each of the 13 root servers. The ping test results, in aggregate, can be used to monitor the latency on a network and as a proxy for detecting quality of service issues due to congestion or a change in routes.

To measure the impact of tele-everything, results were pulled from RIPE for the Atlas IPv4 ping test to the E-Root Server every 4 minutes for ten random Atlas probes on four of the largest U.S. cable networks for the period of February 1, 2020 to July 1, 2020. We grouped them by network operator to look at how the round-trip time changed from pre-shutdown to when the shutdown occurred. Figure 15 shows the round-trip times on an hourly basis for four of the major cable operators. For the most part, the round-trip time did not change very much between the pre-shutdown (February 2020) and when the shutdowns started (March 2020). During the first two weeks of the shutdown (March 15-30) we can see that there are periods when the round-trip times increase. Several of the spikes in the round-trip time occur during the early hours of the morning. Figure 16, shows the round-trip times for the last two weeks in March and we can see some spikes that could be correlated with a shift to tele-everything.



RIPE Atlas Probes Round Trip Time from Cable Networks to E.root-servers.net. E-root-servers.net uses IP Anycast to provider service from the closest location. All times shown are in GMT.

**Figure 15 - Round-trip time for major cable operators.**

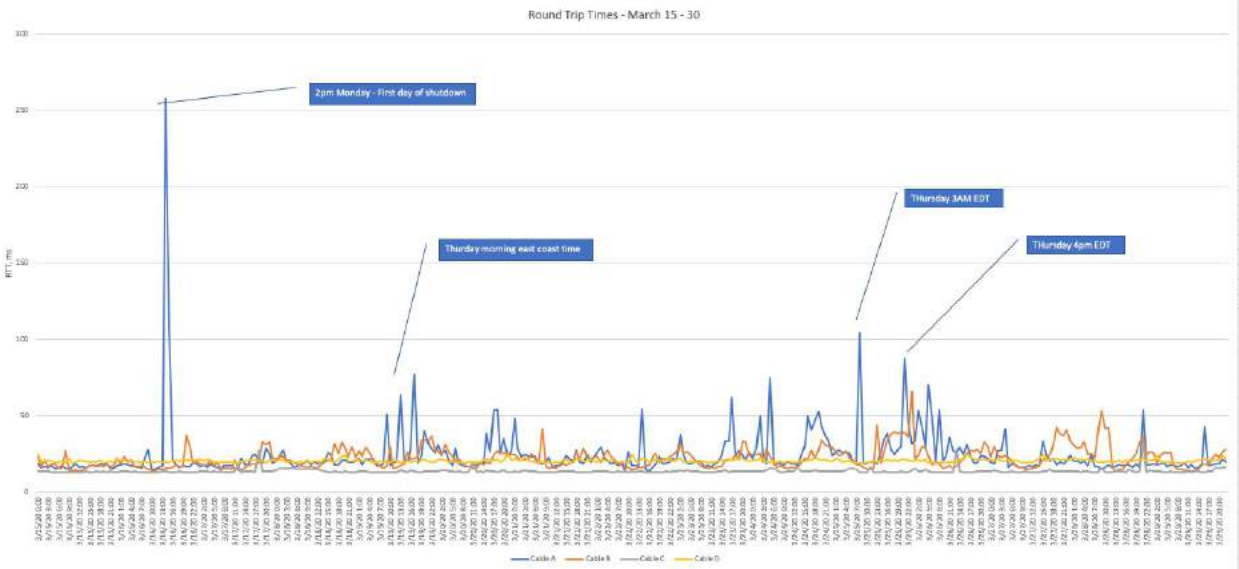


**Figure 16 - Round-trip times March 15-30.**

## 4. Observations

In addition to the published data above, we can glean some additional insights from other data that cable operators and others reported about network performance.

## 4.1. Traffic Growth

In general, overall broadband usage increased due to the shutdown. The NCTA Network Performance dashboard reported an increase in the peak utilization and others reported overall traffic growth between 20-50% ( (CTIA, 2020); (USTelecom, 2020); (ACA Connects, 2020); (Labovitz, 2020); (Sandvine, 2020)).

We can get an approximation of the magnitude of the traffic growth on the cable networks by comparing the forecasted growth of peak downstream and upstream bandwidth per subscriber with the observed growth in the peak utilization at the start of the shutdown. Ulm and Cloonan reported that in 2019 the downstream average bandwidth per subscriber during busy-hour (DS Tavg) was 1.97 megabit per second (Mbp/s) with a 5 year average CAGR (compound annual growth rate) of 37.8% and the upstream average bandwidth per subscriber (US Tavg) was 140 kbp/s with a 5 year average CAGR of 18.8% (Ulm & Cloonan, 2019). Using these numbers the DS Tavg is forecasted to grow about 3% each month and the US Tavg forecasted to grow about 1.5% per month on average. If we compare these with the observed change in the peak utilization on the cable networks of 20% in the downstream and 35% in the upstream, it becomes clear that traffic grew substantially as a result of the shutdown.

**Table 2 - Traffic engineering calculations for cable networks.**

| | Downstream | Upstream |
|---|---|---|
| **Tavg** | 1.97 Mbp/s | 140 kbp/s |
| **5-year CAGR** | 37.8% | 18.8% |
| **2020 forecasted monthly growth** | 3% | 1.5% |
| **2020 change in peak utilization** | 20% | 35% |

In addition to traffic growth, we can also infer that the shift to tele-everything resulted in cable networks experiencing about six months to a years' worth of traffic growth in a month and that this was consistent with what other ISPs around the globe experienced. We can also infer from the SamKnows download speed measurements that this growth did not have a measurable impact on the subscribers download or upload speeds. And finally, the shift to tele-everything caused a step-function in demand for bandwidth. It remains to be seen whether this is a temporary step function that will return to the pre-shutdown levels at some point, or if this is a permanent shift.

## 4.2. Service Delivery Infrastructure

ACA Connects posted peak transit network capacity utilized by day for its larger members as shown in Figure 17. We can see that the transit utilization did not change with the shift to tele-everything and we can infer from this that the service delivery infrastructure of content delivery networks, caches, and peering agreements with content partners worked well. This is consistent with a similar report by Labovitz, as shown in Figure 18 on the performance of the Netflix service delivery system where before the shutdowns Netflix had a 63% cache hit rate, and 46% cache hit rate once the shutdowns began (Labovitz, 2020).

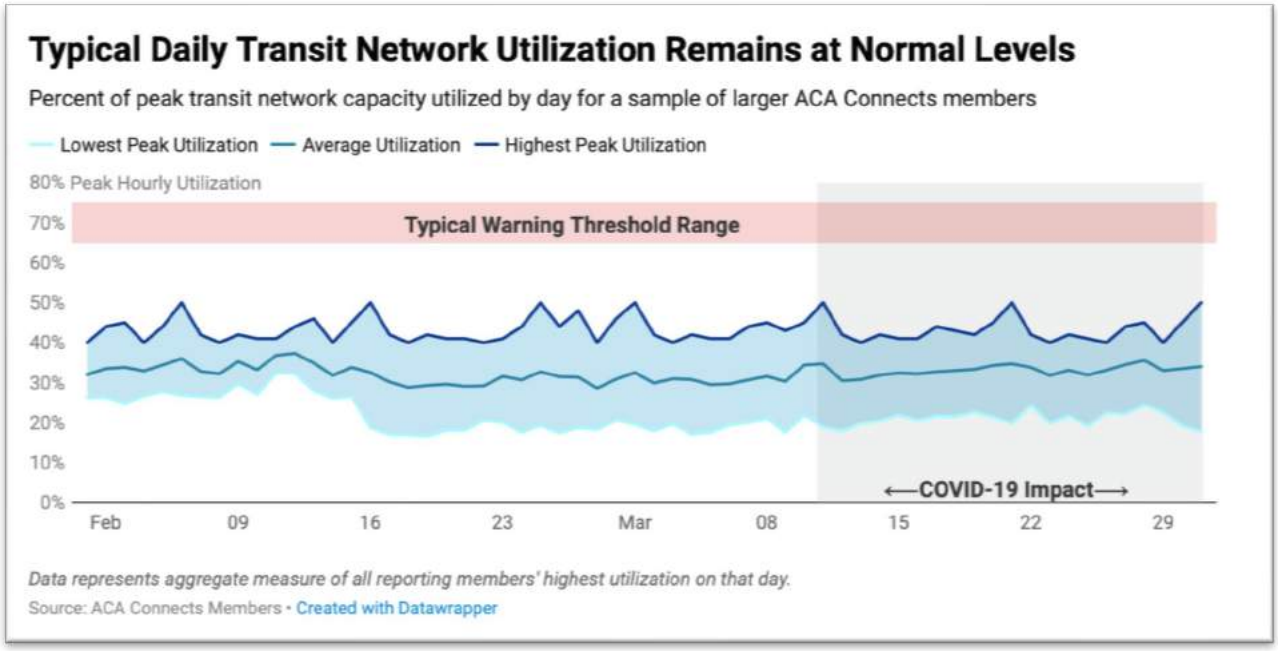

**Figure 17 - Small cable operator transit utilization.**

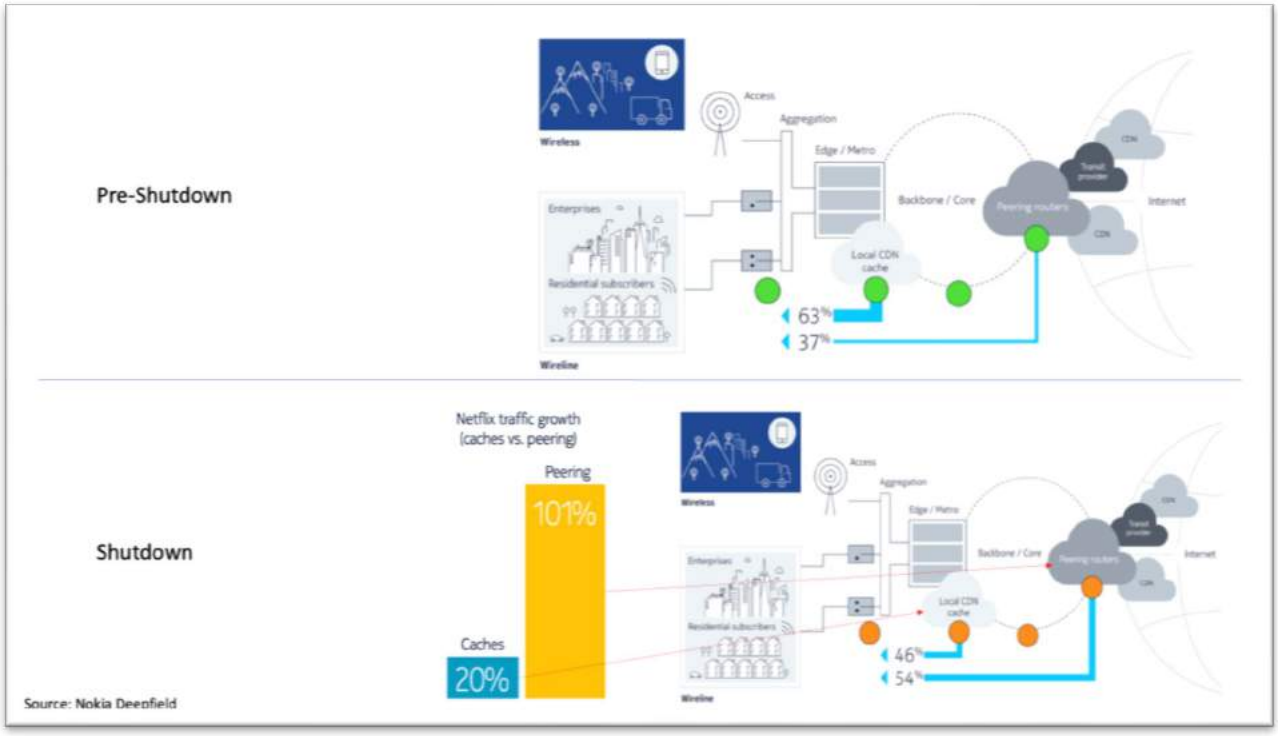

**Figure 18 - Netflix service delivery (CDN + off-net = via peering).**

## 4.3. Upstream Traffic and Telework

One of the big questions at the beginning of the shutdown was how would tele-everything impact the upstream traffic in the networks. We analyzed the data and attempted to correlate it with other data such as census data to see if geographic areas with high concentrations of occupations that can be done remotely might explain changes in upstream traffic. We cross-referenced service group utilization data with census data to generate the heat map shown in Figure 19. The heat map shows the states with the largest changes in upstream utilization combined with the largest percentage of the occupations that can be done remotely. The map was generated using data from March 1 and April 15, when most of the cases were still in the state of New York, and illustrates that there is some correlation between upstream utilization growth and tele-work. As much as there is high interest in such correlations, such conclusions are tentative at best. Time of year, weather, school and other factors can influence this. However, the heat map does seem to show some correlation.

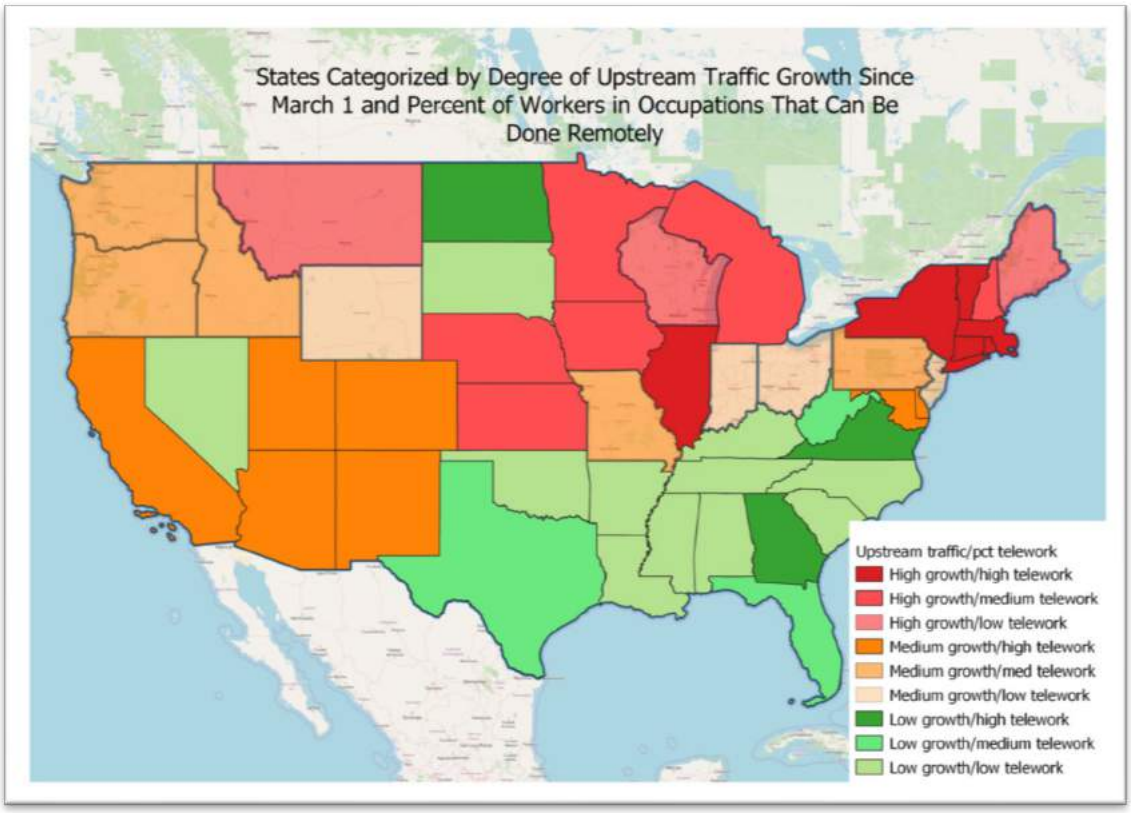

**Figure 19 - Upstream growth and telework by state combined for the period March 1, 2020 – April 15, 2020.**

## 4.4. Upstream and Vacation Homes

Similarly, we also looked to see if there was any potential correlation with areas experiencing large changes in upstream utilization due to subscribers migrating to their vacation homes to wait out the shutdown. Figure 20 shows utilization combined with vacation home data. The northern states with a large percentage of vacation homes experienced the largest increases in upstream peak utilization. This may be because many of the vacation homes in the north are three-season homes (spring, summer, and

fall) and therefore, what we may be observing is vacation homeowners moving to their homes earlier than normal as part of the shelter in place orders. Again, these types of correlation are suppositional.

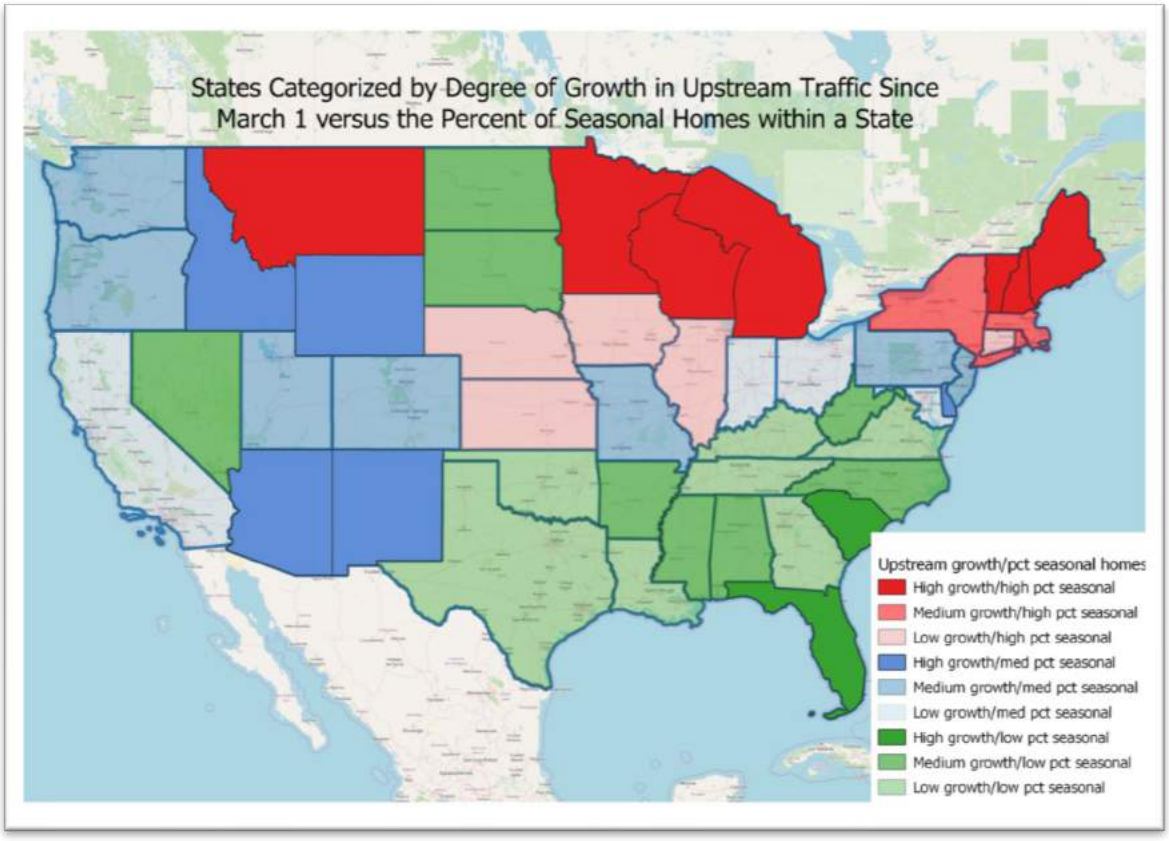

**Figure 20 - Seasonal homes and utilization combined for the period March 1, 2020 – April 15, 2020.**

## 4.5. Videoconferencing and Video Streaming

Another concern raised was the potential impact on upstream traffic with a high usage of videoconferencing for work, school, and entertainment. It was reported that videoconferencing applications such as Zoom, with symmetrical bandwidth requirements, experienced as much as a 700% growth with the largest growth occurring on weekends.

### *4.5.1. Average bandwidth per subscriber during busy-hour*

Using the average bandwidth per subscriber during busy-hour, Tavg, for the downstream and upstream from 2019 and the reported 5-year average CAGRs (Ulm & Cloonan, 2019), we can estimate the forecasted 2020 Tavg for the downstream and upstream around the time of the shutdown when consumers switched to tele-everything. In Table 3 we show the calculations for the forecasted Tavg and then extrapolate the change to Tavg as a result of tele-everything. We estimate that the downstream Tavg grew by 430 kbp/s, growing to 2,582 kbp/s, and the upstream Tavg grew by 51 kbp/s to 198 kbp/s.

**Table 3 - Average Subscriber Bandwidth During Peak Busy Hours.**

| | Description | Formula | Down | Up |
|---|---|---|---|---|
| **(A)** | 2019 average bandwidth/sub during busy hour (Tavg)[2], kbp/s | A[DOWN] / A[UP] | 1966 | 140 |
| | 2019 downstream-to-upstream traffic ratio | | 14 | |
| **(B)** | 2019 CAGR[3] | | 37.80 % | 18. 80 % |
| | | | | |
| **(C)** | Estimated monthly growth in Tavg | B/12 | 3.15% | 1.5 7% |
| **(D)** | Estimated growth in Tavg for Jan-Mar 2020, kbp/s | A*C*3 | 186 | 7 |
| **(E)** | Estimated Tavg at beginning of April 2020 | A+D | 2152 | 147 |
| **(F)** | Estimated DS:US traffic ratio for April 2020 | E[DOWN] / E[UP] | 15 | |
| | | | | |
| **(G)** | Change in peak due to shutdown[4] | | 20% | 35 % |
| **(H)** | Estimated growth in Tavg with shift to tele-everything, kbp/s | G*E | 430 | 51 |
| **(I)** | Estimated tele-everything Tavg , kbp/s | E+H | 2582 | 198 |
| **(J)** | Estimated tele-everything downstream-to-upstream traffic ratio | I[DOWN] / I[UP] | 13 | |

In relative terms the upstream's peak grew more than downstream. Converting the peak utilization to an absolute number allows us to take into account the asymmetrical nature of DOCSIS broadband connections and the fact that the upstream grew from a lower base. When we do this, we can see that in absolute terms that the downstream bandwidth usage grew ~9x the upstream.

Even though the usage of videoconferencing grew much more than the usage of video streaming, the fact that video streaming uses on average about five-times more bandwidth than videoconferencing, as shown in Table 4 and Table 5, contributed to the 9x growth in absolute bandwidth in the downstream.

**Table 4 - Videoconferencing bandwidth requirements.**

| | Upstream | Downstream | Average |
|---|---|---|---|
| **Zoom (Zoom, 2020)** | 600 kbp/s – 1.8 Mbp/s | 600 kbp/s – 1.8 Mbp/s | 1/1 Mbp/s |
| **WebEx (Cisco Webex, 2020)** | 500 kbp/s – 3.0 Mbp/s | 500 kbp/s – 3.0 Mbp/s | 1/1 Mbp/s |
| **MS Teams (Microsoft, 2020)** | 500 kbp/s – 1.5 Mbp/s | 500 kbp/s – 1.5 Mbp/s | 1/1 Mbp/s |

[3] Ibid, p. 8-9
[4] NCTA, "COVID-19: How Cable's Internet Networks are Performing,"

**Table 5 - Video bandwidth requirements.**

| Streaming Service | Downstream |
|---|---|
| Netflix | 5 Mbp/s |
| Hulu | 3 Mbp/s |
| Amazon Prime | 5 Mbp/s |
| YouTube | 7 Mbp/s |

### *4.5.2. Traffic Ratio*

The shift to tele-everything had minimal impact on the downstream-to-upstream traffic ratio. In 2019, the busy-hour downstream-to-upstream traffic ratio was 14:1. We estimate that it grew to 15:1 in 2020 prior to the shutdown and with the shift to tele-everything that it declined to 13:1. This is consistent with overall traffic ratio, as reported by OpenVault, which reported that it went from 20:1 down to 16:1 (OpenVault, 2020). The reduction in the overall traffic ratio can most likely be attributed to the increased use of videoconferencing during the daytime hours for tele-work and tele-school, while the smaller change during the peak busy hours is likely due to any increased upstream usage being offset by increased video streaming in the downstream.

## 5. Conclusion

The COVID-19 pandemic of 2020 caused a sudden shift to tele-everything that resulted in large changes in traffic patterns on the Internet and cable networks. In this paper, we looked at data collected and posted by the cable industry as well as data posted by other third parties on the performance of cable networks and the Internet in general with the shift to tele-everything. We observed that the shift to tele-everything caused internet traffic to grow 30-50% and that traffic on the cable networks grew 20-35%, with the traffic growth on cable networks somewhat independent of the size of the operator. We observed that the service delivery infrastructure of content delivery networks and caches worked well, with most of the traffic growth being observed in the access networks and not on the transit links. We also observed that even with the sudden growth in traffic, there was no measurable impact on the end user's quality of experience, as measured download speeds only declined about 1% and there was no measurable change in the round-trip time for the RIPE Atlas test probes.

We also looked at the impact of the shift to telework and the early opening of northern vacation homes on the upstream usage. We observed that there was a loose correlation between the two.

And finally, we looked at the impact of the growth in videoconferencing and video streaming on the network. We observed that even though the upstream in cable networks in relative terms grew more than the downstream, that the absolute bandwidth growth on the downstream was 9x the bandwidth growth in the upstream and that this is because video streaming uses about 5 Mbp/s per high-definition video stream compared the 1 Mbp/s in each direction used by the videoconferencing applications. The impact to the downstream-to-upstream traffic ratio was small as the growth of video streaming in the downstream was somewhat offset by the growth in video conferencing in the upstream.

Overall, U.S. cable networks have performed well during the pandemic.

**Title** **Page Number**

 

# List of Figures

# List of Tables

 

# 1. Introduction

Considering adding a wireless footprint to your network? Hear about the lessons which we have learned over the past three years of CBRS network researches, trials and how we are building a wireless network. What are the key challenges that have been overcome and the areas that need to be considered? As networks converge, wireless technology is becoming another tool to provide additional services and expand the network.

# 2. Utilization of CBRS Shared Spectrum

## 2.1. Citizens Broadband Radio Service

On recommendation of President's Council of Advisors on Science and Technology (PCAST) board advisory to lead innovation in wireless technology services, the U.S. government directed National Telecommunications and Information Administration (NTIA) to collaborate with Federal Communications Commission (FCC) to find possibilities for the commercial use of additional spectrum, which held by Federal and non-federal users. In 2015, the FCC adopted rules for commercial use of 3.5 GHz frequency spectrum in the range from 3550 to 3700 MHz for shared wireless access. The commission established Citizens Broadband Radio Service (CBRS) and created three-tier framework to accommodate shared frequency band for the commercial use. CBRS network devices use the LTE standards for radio access and core network as regular LTE devices. The main difference between traditional LTE and CBRS LTE operation is the spectrum access method that devices use. In normal LTE operation, wireless service operators buy license LTE spectrum and utilize the spectrum for an access. In CBRS LTE, a central spectrum assignment mechanism used to manage the spectrum utilization and access. This new central spectrum assignment mechanism known as a Spectrum Access System (SAS)

## 2.2. A novel three-tier paradigm, an industry first with CBRS

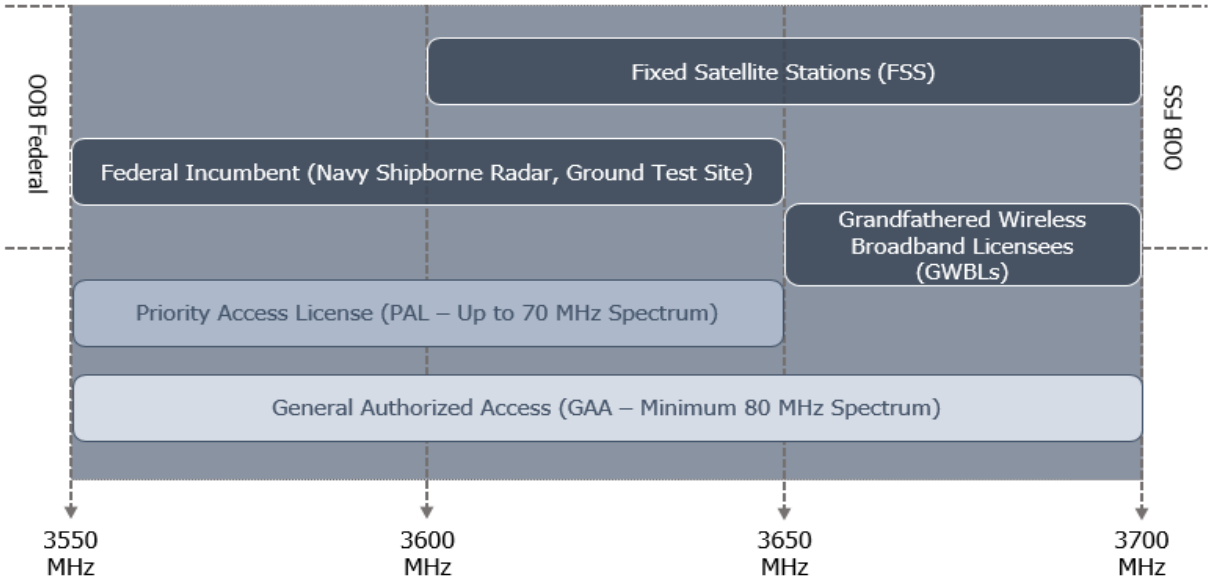

**Figure 1 CBRS 3.5 GHz Frequency Band**

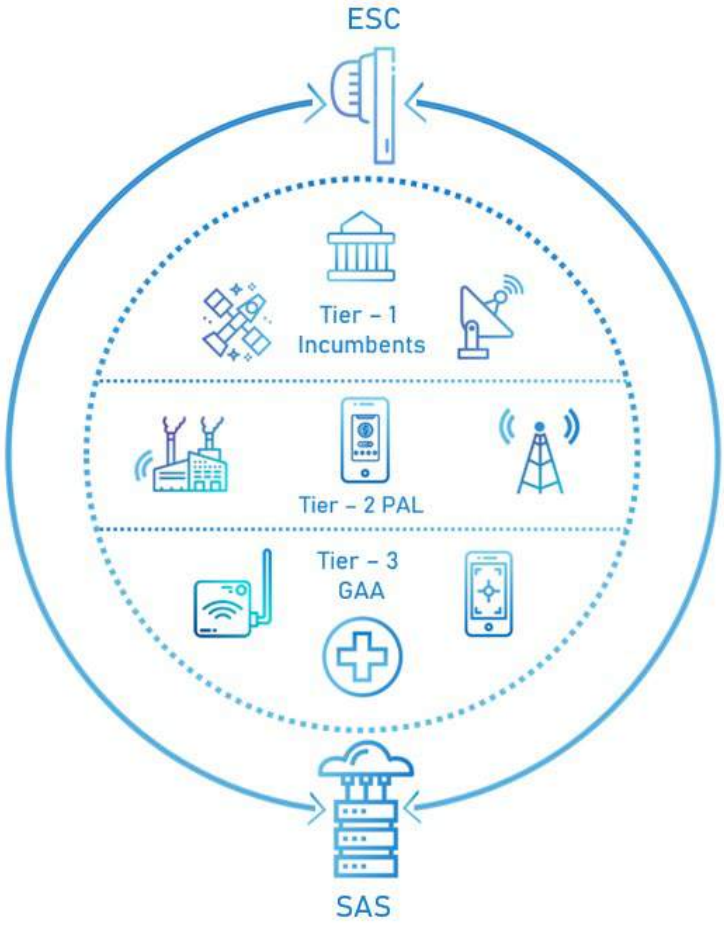

**Figure 2 3-Tier CBRS Structure**

A three tier-sharing framework, SAS enforced prioritization at all times.

**Incumbents:** US Military Radar/DoD, Fixed Satellite Station (FSS), Grandfathered Wireless Broadband Licensees (GWBLs) Highest priority access over PAL and GAA users.

**PAL:** Priority Access License, licensed tier. Licenses awarded via FCC Auction 105 for 3.5 GHz. Priority access to 70 MHz. Must register with SAS. Interference protected from GAA users.

**GAA:** General Authorized Access, unlicensed tier. Minimum of 80 MHz with an ability to float up to 150 MHz if PAL licenses are unoccupied. Must register with SAS. No interference protection. Opportunistic use, null priority rights.

## 2.3. Spectrum Access System

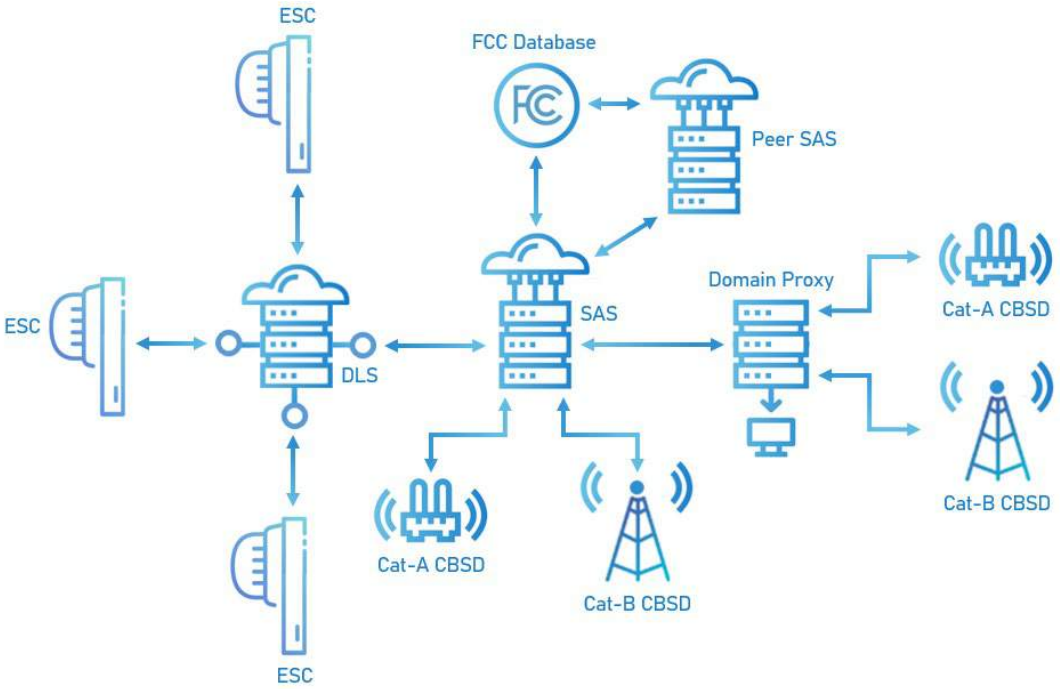

**Figure 3 Spectrum Sharing Ecosystem**

ESC: Environmental Sensing Capability
DLS: Decision Logic System
SAS: Spectrum Access System
CBSD: Citizens Broadband Radio Service Device

Spectrum Access System (SAS) is an entity authorized by the Commission to operate in accordance with the rules of part 96. It manages the assignment and distribution of spectrum to the users based on permissible frequencies at their location. Depending upon the user location, SAS controls and permits maximum transmission power level to protect higher tiers incumbent users and PAL users. All category CBSDs must register, authenticate identification and report its location with the SAS. An individual CBSD may directly communicate with SAS or CBSDs composed of a network may employ a system (Domain Proxy) for aggregating and communicating all required information exchange between CBSDs and SAS. On exchange of all necessary CBSD's information with the SAS, the SAS verifies requestor CBSD's FCC identifier with a FCC database and verifies CBSD's identity prior to authorizing the state where CBSD can start providing services. SAS is capable to determine available channels for users at any given geographic location and on the request of Spectrum Inquiry from CBSDs; SAS shall respond back to CBSDs with available spectrum for the requesting CBSD's geo location so CBSD can proceed with Grant request to SAS. CBSD would look for a channel grant from SAS by providing its maximum EIRP capability per MHz and on conforming to CBSD's EIRP capability with FCC database; SAS shall approve or reject Grant for requesting CBSD. For any new requesting CBSD, on successful Grant response, SAS would put CBSD in IAP pending until next Coordinated Periodic Activates among SASs (CPAS) window before giving Authorization to such CBSD. CPAS runs through every night from 12am PST to 3am PST. Post CPAS window; granted CBSD would be authorized to transmit by SAS followed by conditional exchange of heartbeats between CBSD and SAS at every 200 seconds time interval.

## 2.4. Environmental Sensing Capability

Environmental Sensing Capabilities (ESCs) sensors used to detect operation of Federal Incumbent in 3550 to 3700 MHz frequency band and it provides incumbent information back to SAS upon detection of any activity on any of the channels in the band. On receiving Incumbent detection information from ESC, SAS shall direct CBSDs for channel change or cease CBSDs transmission by suspending active grants of CBSD in order to protect federal incumbent's operation. On active Grant suspension by SAS, CBSD shall relinquish that grant and request new Grant for alternate channel recommended by SAS for immediate authorization. If no alternate channel available then SAS shall cease CBSD transmission by suspending its last active grant. On suspended grant, CBSD may continuously send heartbeats to SAS for suspended grant and resume operation when it receives success code (Code "0") from SAS in any of the heartbeat responses from SAS. In Release-1 of CBRS specifications, ESCs only monitor activity of Federal incumbent in 3550 to 3650 MHz of spectrum. ESC is a non-federal entity commonly operated by approved SAS administrators. Due to ESC's importance of detecting federal incumbents, SAS also protects ESCs against harmful interference which may be caused by surrounding CBSDs.

## 2.5. Incumbents

Incumbents are Tier-1 users of the CBRS frequency spectrum with highest priority over PAL and GAA users. There are Federal and Non-Federal incumbents. Federal incumbents are U.S. Navy's Shipborne Radar System that operates on any frequencies between 3550 to 3650 MHz. Federal incumbents also include some inland radar operation sites operating on any frequencies between 3500 to 3650 MHz. Non-Federal incumbents include Fixed Satellite Stations (FSSs) and Part-90 Grandfathered status Wireless Internet Service Providers. They are called as Grandfathered Wireless Broadband Licensees (GWBLs). FSSs are receive only earth stations operating on frequencies between 3600 to 3700 MHz. There are a few Out-of-Band (OOB) Registered for protection earth stations, i.e. TT&C (Telemetry, Tracking and Command) FSSs operate on frequencies between 3700 to 4200 MHz. GWBLs operate only on upper 50 MHz of CBRS spectrum, i.e. 3650 to 3700 MHz. These are all Tier-1 incumbents in CBRS shared model eligible for interference protection by SAS. Spectrum controller system retains information about these Federal as well as Non-Federal incumbents and their protection and exclusion zones in accordance with the rules of part 96. Depending upon CBSD's geo location and relation between non-federal incumbents (location of FSS and GWBL's active transmitter), SAS shall determine if the deployed CBSD location is an exclusion or protection zone for that CBSD to protect that non-federal incumbent from harmful interference. SAS also retains information about list of Exclusion Zones (EXZs) published by NTIA and shall not allow CBSD operation within 40kms radius of defined locations.

## 2.6. Protection of Federal Incumbents

Federal incumbents are-protected by SAS through the method of Dynamic Protection Area (DPA) activation. There are two types of DPAs. E-DPA and P-DPA. E-DPA is an ESC-DPA and an always-on DPA, monitored by ESC network. NTIA has provided the list of E-DPAs along the coastal boundary in the east and west coast of U.S. geography. Other than coastal areas, the additional list of E-DPAs provided by NTIA also covering the areas of Alaska, Hawaii, Puerto Rico and Guam. When federal Navy's radar system turn on its operation then SAS administrator's ESC sensor detects the active channel of radar system and the DPA zone where Navy ship operates. Upon detection, ESC provides that DPA ID and channel information to SAS. So within 300 seconds SAS shall re-assign CBSDs those are operating on the same channel as Navy's radar system and are under the protection zone of that DPA if there is any alternate channel available in that geographical area or may even cease those CBSDs' operation if no alternate channel available in order to protect federal incumbent from harmful interference. In order to protect in-land federal incumbents, P-DPAs (Portal-DPAs) are used. There are few P-DPAs published by NTIA for

 

federal's ground based radar test sites operate on frequencies in the range of 3500 to 3650 MHz. Also known as "Informing incumbents" where SAS gets testing schedule of ground based radar system 24 hours in advance. In order to protect in land federal incumbent, SAS shall re-assign CBSDs operating on the same channel as ground radar system's channel and located under that P-DPA zone.

## 2.7. Protection of Non-Federal Incumbents

Non-Federal incumbents such as FSSs and Part-90 GWBLs protected by SAS from harmful interference caused by low tiered users through the method of aggregate interference calculation as per rules defined in part 96. Aggregate interference calculations consider CBSDs within 40 to 150 kms radius depending on the type of protected entities and type of CBSD.

## 2.8. Commercial SAS Trial Obervations in New York City, NY

Charter deployed a cluster of 21 FCC certified Category-B outdoor CBSDs in New York City, NY area. All CBSDs are configured with single 20 MHz LTE channel transmitting at max power per Category-B CBSD limit defined in part 96 under general radio requirements. New York City, NY county area is within 150 kms radius of one of the registered for protection "Fixed Satellite Station" (FSS) located in The Bronx, NY. There is an unexpired GWBL's transmitter located within 40 kms radius of this FSS. Hence, this relation between FSS and GWBL makes the area of 150 kms radius of the FSS an "Exclusion Zone". Therefore, upper 50 MHz of spectrum found to be unavailable for CBRS services by SAS until the expiration of active GWBL's license. So CBRS services can only be operational in the spectrum between 3550 to 3650 MHz in the New York City county geographical area. As per NTIA's defined protection zones, the deployed geographical area covered by five E-DPAs and four P-DPAs. CBSD grant suspension observed by any of these five E-DPA activations whenever there is any incumbent activity detected by ESC network in these E-DPA zones. The only channel suspended by SAS where Navy's radar system is operating on. Due to unavailability of alternate channel re-assignment feature on SAS now, CBSD could not get instantaneous new grant authorization from SAS. CBSD stayed in grant suspended state while Navy's radar system was in operation and resumed its services back when SAS gets no further information from ESC about incumbent activity.

## 2.9. Conclusion

CBRS is technology agnostic so it's not only good for LTE services but also one of the best option to deploy 5G services today in mid-band range of spectrum because of possibility to have wider channel bandwidth up to 100 MHz in 5G as per FR1 specs of 3GPP. Use of CBRS will provide platform for high performance deployments of diverse use-cases. It can be as simple as point to point or point to multipoint deployments for a small networks to large complex networks. These use-cases can be fixed, mobility and even advanced standalone networks. Other than mobile and cable service providers, many other market verticals such as Medical, Industrial, Agricultural, Retail, Oil & Gas, Energy, Power utility, Transportations, Airport and Educational institutions can utilize CBRS spectrum and make best use of it for their private network, Internet of Things (IoT), Security and surveillance and much more.

# 3. Implications to the deployment strategies

This section covers the details of how Charter has leveraged it's all possible physical assets such as Cable strand, Towerstream buildings and valued SMB locations for strategic deployment of its wireless mobility network in CBRS across 5 different markets. The deployed networks have been fully utilized for Charter's extensive in depth testing of MVNO data offload use case.

## 3.1. Attached Mount Deployment (Rooftop)

47 dBm/10 MHz allowable power limit applies to this deployment type and it can support larger antennas e.g. 64T64R Massive-MIMO antennas, one CBSD can have multiple sectors, typically get mounted on the rooftops and connect to Charter's DOCSIS serving the building.

**Application:** Attach mount unit can be installed more strategically than strand mount or SMB to clear obstructions or point to a targeted hotspot with required down-tilts without limitations like the other two types (Strand, SMB). Attached mount will be more effective when advanced features like Antenna Beamforming, Sector Virtualization, and Dynamic Load Balancing etc. are tested. This type of deployment provides larger coverage and capacity than strand and SMB scenarios.

**Cost:** Attach mount deployment and radio costs are most expensive than other three types of deployment. High cost for this type of deployment due to site surveys, A&E (structural analysis, construction drawings, LPC, transit or any other permit required) and entering into lease agreement with landlord. Site installation and commissioning, city inspection and close-out.

**Figure 4 Attached Mount (Rooftop) Outdoor Deployment**

## 3.2. Strand Mount Deployment

Strand mount is the most cost effective solution for Charter where aerial cable strand lines exist. The size and power are lower than Attached mount CBSDs, but their biggest bottleneck is power consumption from

the HFC plant power supply. Charter's mandating vendors to stay under 100W, some vendors have come up with strategies like powering down the CBRS amp until traffic picks up to keep plant power consumption low.

**Application:** Another bottleneck of strand unit is the mounting orientation – It has to be always along the strand and thus hotspot-targeted deployment in this case might be challenging. To mitigate this, Charter has requested Quasi-Omni strand design that has dual sectors with two sets of antenna covering NE and SW directions. Their height is always 18ft and typically, comes with 2x2 MIMO capability.

**Cost:** Utilizing existing assets to mount, connect to, maintain and operate make these the most cost efficient and expedient deployment type for outdoor Cat-B CBSDs.

**Figure 5 Strand Mount Outdoor Deployment**

### 3.3. Small Medium Business (SMB) Deployment

Indoor low power Category-A devices have been installed as part of Charter's CBRS wireless trial on Charter business customer's premises. Mainly used to provide pedestrian coverage. This deployment type can provide blanket coverage when deployed every 400 - 500 ft. A Strand or Attach mount usually compliments SMB coverage by serving as an umbrella cell and fill in for any coverage holes. Charter has requested vendors for Tri-Star config which adds a third sector to cover indoor and two sectors pointing outside the stores from behind a glass window. Charter makes use of this deployment type where applicable to form a uniform layer of CBRS coverage targeting AOI's and have run trials confirming seamless connectivity and performance between the outdoor coverage and the indoor coverage.

**Inside Out:** Charter's initiative to provide outdoor / pedestrian street coverage utilizing business customers' locations tested to serve as a contingent layer of indoor Category-A devices under outdoor high power Category-B umbrella cell. Below is a snapshot of three different locations where Indoor units installed with

different heights and attenuation after the glass within 100ft was observed to be least at 18ft. This resulted in a larger footprint and relatively sustained coverage of the three scenarios.

**Figure 6 Indoor CBSD Deployment in SMB**

**Figure 7 Inside-Out Deployment in Spectrum Stores**

**Table 1 Inside-out Testing**

| Inside-Out Testing | Manhattan Spectrum Store | Astoria Spectrum Store | 7th Floor Charter Office |
|---|---|---|---|
| Coverage Radius | 1000 ft. | 485 ft. | 495 ft. |
| Throughput Outside | 67 Mbps / 19 Avg. | 74 Mbps / 17 Avg. | 49 Mbps / 9 Avg. |
| Throughput Inside | 77 Mbps | 74 Mbps | 72 Mbps |
| RSRP within 100ft. | -78 dBm | -95 dBm | -102 dBm |
| Height | 18 ft. | 8 ft. | 70 ft. |
| Clutter Type | Dense Urban | Urban | Dense Urban |
| Glass Type | Standard | Double glass panel | Standard |

**Conclusion:** Inside-out strategy requires optimal height (around 15 ft.) non-reflective and non-metal coated glass type and strategic placement of CBSD behind the glass in SMB location.

One of the most frequent issue noticed on SMB type indoor small cell is TDD time synchronization using external independent GPS antenna due to unreliable GPS signal with low SNR level in dense urban and urban locations in New York City and Los Angeles. It has been observed that small cells keep going into a GPS holdover state and out-of-sync state followed by out of service very frequently. It is unrealistic to use IEEE 1588PTP solution with independent grand master clock on each and every SMB locations. SMB small cells are wired using DOCSIS3.1 indoor CM for backhaul connectivity and hence it will be essential to have DOCSIS Timing Protocol (DTP) on such locations to mitigate timing sync related issues. DTP has been described in detail in section 8.1 of this document.

**Outside-In Tests:** The nature of the 3.5 GHz wave makes it less reliable when coverage target area is indoor and CBRS cell deployed outside. We conducted tests with a few types of inbuilding locations with an outdoor CBRS serving cell on Strand. Our tests include, location with Brick Wall and no windows in corridor, location with windows but obstructed for outside signal and location with windows and no obstructions to outside signal.

**Figure 8 Outside-In Test Locations**

**Table 2 Outside-In Testing**

| Outside-In Testing | High School (Inside) | Grocery Store (Inside) | Restaurant (Inside) |
|---|---|---|---|
| RSRP (dBm) | -112 dBm (best),<br>-135 dBm (worst) | -118 dBm to -135 dBm<br>(outside -99 dBm) | -105 dBm<br>(outside -100 dBm) |
| Throughput (Mbps) | 9 Mbps (avg),<br>0 Mbps (min) | 8 Mbps<br>(outside 39 Mbps) | 30 Mbps<br>(outside 39 Mbps) |
| Coverage Limiting Factor | Uplink timeout | 20-30 dBm Loss of RSRP | Glass type |
| Structure Type | Brick walls | Glass window + wall | Full glass windows |
| Clutter | Residential/Urban | Commercial/Urban | Commercial/Urban |
| Will Outside-In strategy work? | No | Weak | Yes (Rare case) |

**Conclusion:** Providing the coverage inside the building from outdoor CBSDs will not work effectively. If Area of Interest (AOI) is inbuilding then it has to be targeted within the building.

# 4. Performance Characteristics of CBRS LTE Network

CBRS is a beneficial platform to bridge the gap between low spectrum carriers and mmWave challenges. Below are some of the characteristics Charter has observed in their CBRS trails.

## 4.1. Characteristics of CBRS Wave

3.5 GHz electromagnetic waves are subject to increased propagation losses than say the signals of AWS 1700 MHz or GSM at 800 MHz in a cellular network. The CBRS wave is 8.5 cm in wavelength, compared to 17 cm (AWS) and 37.5 cm (GSM) at the above frequencies. Thus, a CBRS cell gets- 2 times more propagation loss from 1.7 GHz carrier and 4.4 times higher propagation loss from 800 MHz frequencies. Extrapolating these values, if we suppose 3.5 GHz Category-B CBSD's Cell Radius in a dense urban clutter is 1/4$^{th}$ mile (1320 ft.) would yield cell radius of AWS radio at about ½ mile (2650 ft.) and about 1.1 miles (5808 ft.) for GSM keeping same EIRP.

Antenna size advantage: CBRS has a cutting-edge advantage over low band carriers making it more favorable to rollout. Due to smaller wavelength, antenna size is typically 12" – 15" long and weighs 2 lbs. This has opened-up deployment possibilities /strategic venues that were not an option in lower band rollouts from an acquisition standpoint. Image below shows CBRS 3.5 GHz antenna to the left and 600 MHz antenna on the right on one of Charter's trial sites. CBRS antenna is 14.3" long, wights 2 lbs compared to 600 MHz antenna's 8 ft length and more than 100 lbs weight.

| | | |
|---|---|---|
| Frequency Range | MHz | 3300 - 3800MHz |
| Polarisation | Degree | +/-45° Slant Linear |
| Gain | dBi | 12.5 |
| Azimuth Beamwidth | Degree | 65° |
| Azimuth Beam Squint | Degree< | 3° |
| Elevation Beamwidth | Degree | 22° |
| Electrical Downtilt | Degree | T0° |
| Electrical Downtilt Deviation | Degree< | 1° |
| Impedance | Ohms | 50 |
| VSWR | < | 1.5 |
| Return Loss | dB> | 14 |
| Isolation | dB> | 25 |
| Front to Back Ratio: Total Power +/-30° | dB> | 28 |
| Upper Sidelobe Suppression, Peak to 20° | dB> | 18 |
| Cross-Polar Discrimination | dB> | 16 |
| Maximum Effective Power Per Port | W | 50 |

**Figure 9 CBRS 3.5GHz Antenna Properties**

**Decreased Obstruction Resistance:** CBRS wave is seen to incur abrupt attenuation when obstructed compared to AWS and GSM that could refract around obstructions, form a shadow and resume coverage in good RSRP range. CBRS however is observed to be very prone to obstructions. This can be seen in drive data when the cell is obstructed the coverage takes an abrupt hit i.e. 20-30 dBm attenuation.

**3.5 GHz coverage reliability:** CBRS wave is affected to a higher degree relatively when deployed in high foliage areas, hilly terrain obstructing antenna beam, downtowns or vertically layered dense urban clutter that obstructs the beam.

**Figure 10 Dense Urban Morphology**

## 4.2. mmWave Comparison

If an operator doesn't already own spectrum, then there are a few options which can be considered. The next auction which will be happening is the C-BAND auction. This spectrum will have very similar characteristics to CBRS and should be viewed in a similar manner. The other option is to look at mmWave. mmWave has two distinct advantages. The first advantage is large blocks of bandwidth which can be utilized versus sharing 150 MHz among many parties. The second advantage is the ability to radiate at higher powers due to the restrictions the FCC has placed on CBRS. Both of these are strong advantages for mmWave; however, mmWave has a major issue. It does not propagate very far, and it is easily obstructed by foliage, buildings, and windows. To show the differences, a theoretical comparison was performed between 5G CBRS and 5G 28 GHz mmWave. Table 3 below shows the baseline assumptions for the comparison and Figure 11 shows the results.

**Table 3 5G CBRS vs 5G 28 GHz mmWave Assumptions**

| | mmWave gNB | Sub-6 gNB | mmWave UE | Sub-6 UE |
|---|---|---|---|---|
| Combined transmission power (dBm) | 28 | 34 | 16 | 23 |
| Antenna gain (dBi) | 23 | 23 | 11 | 0 |
| Total EIRP (dBm) | 51 | 57 | 27 | 23 |
| BW (MHz) | 800 | 100 | 800 | 100 |
| Frequency (GHz) | 28 | 3.5 | 28 | 3.5 |
| Height (m) | 40 | 40 | 1.5 | 1.5 |
| DL/UL max layers | 2/2 | 8/4 | 2/2 | 2/2 |
| Propagation Model | Rma Rural NLOS | Rma Rural NLOS | Rma Rural NLOS | Rma Rural NLOS |

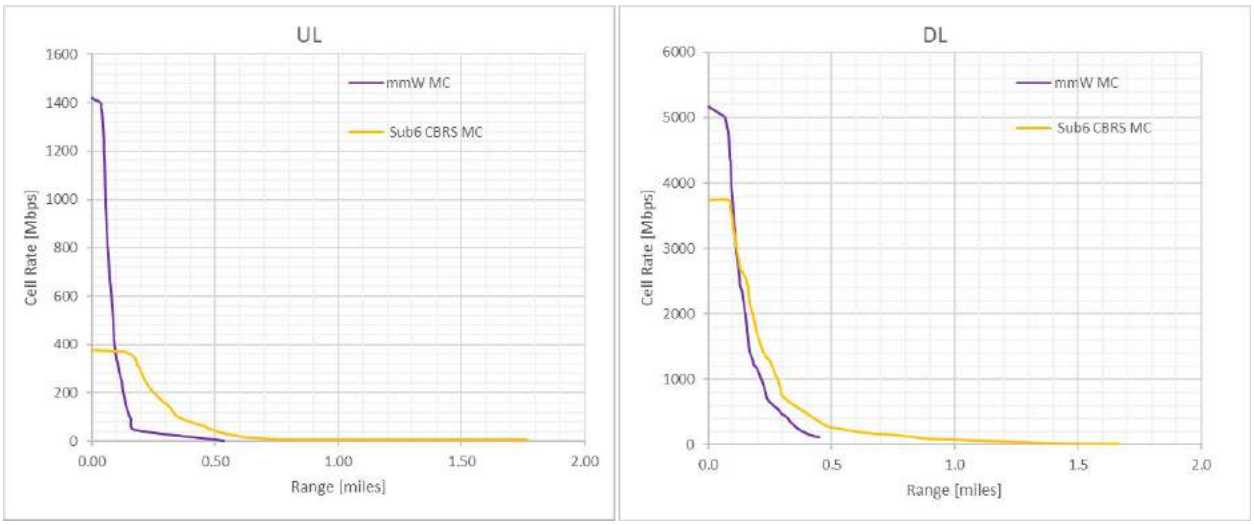

**Figure 11 5G CBRS vs 5G 28 GHz mmWave Results**

**Key takeaways from the results:** DL throughput is not significantly higher for the 28 GHz mmWave transmission versus the 5G CBRS product even though the bandwidth is 8X. 5G CBRS gets significantly more coverage (1.7 miles versus 0.5 mile); however, UL connectivity is very low just pass 0.5 mile. UL capacity below 0.2 mile is significantly greater in mmWave.

## 4.3. 5G CBRS vs 4G CBRS

Outside of the hype, does it make sense to deploy a 5G CBRS network versus a 4G CBRS network? There are many areas which need to be explored before making this decision. For the purposes of this paper, a short review of a few of the technical aspects will be performed.

From a theoretical comparison, spectral efficiency for 5G is slightly better due to a leaner carrier design which corresponds to roughly 15% improvement. Very similar improvement for 5G is also seen with Pathloss calculations.

General comparison between LTE and 5G –

**Table 4 LTE vs NR Comparison**

| | LTE | NR |
|---|---|---|
| Frequency Range | Sub-6 GHz | Sub-6 GHz and mmWave |
| Maximum CC BW | 20 MHz | 100 MHz or 400 MHz depending on frequency band |
| Subcarrier Spacing | Fixed 15 kHz | Scalable 2^μ 15 kHz |
| Waveform | DL: CP-OFDM<br>UL: DFT-s-OFDM | DL: CP-OFDM<br>UL: CP-OFDM/DFT-s-OFDM |
| TTI | 14 OFDM symbols in fixed 1ms | 14 OFDM symbols with scalable 1/2^μ ms |
| Channel Coding | Data: Turbo coding | Data: LDPC<br>Control: Polar code |

| | | |
|---|---|---|
| | Control: Tall biting convolutional coade | |
| Initial Access | Broadcast | Unicast |
| MIMO | 8 layers codebook and non-codebook precoding | 8 layers non-codebook precoding |
| Reference Signal | CRS, DMRS, CSI-RS, SRS | DMRS, CSI-RS, PTRS, SRS |
| Duplexing | FDD, Static TDD | FDD, Dynamic TDD |
| HARQ | Synchronous/Asynchronous with 8 processes | Asynchronous with 16 processes and CBG retransmission |

### 4.4. CBRS Coverage Reliability from Field Tests

Charter conducted tests to observe CBRS behavior and coverage reliability in different clutter types. It has been noted that CBRS is more prone to obstructions and cell radius is affected when path is obstructive. Phenomenon like refraction and scattering do not aid CBRS wave in an obstructed path.

**Figure 12 Field Drive Test Plot**

Site data shown in the Figure 12 where street to the north is obstructed. It has been observed the RSRP cannot sustain obstruction and degrades to sub -120 dBm zone very quickly right after (138 ft). Unobstructed path to the west is 736 ft. SINR also shows similar trend to RSRP degradation. This is typical behavior of CBRS 3.5 GHz wave when obstructed and reduces effective cell radius in non-LOS conditions.

## 4.5. Factor affecting throughput in CBRS network – Field Assessment

Charter tested various factors to observe effects on throughputs. Below is the analysis of data gathered. From the field we observed DL throughput has high dependency on RSRP. As CBRS RSRP fluctuates the affect is translated directly to the streaming UE. As seen from test results, depending on morphology of the clutter, below a certain RSRP the SINR takes a hit and throughputs plunge to single digits.

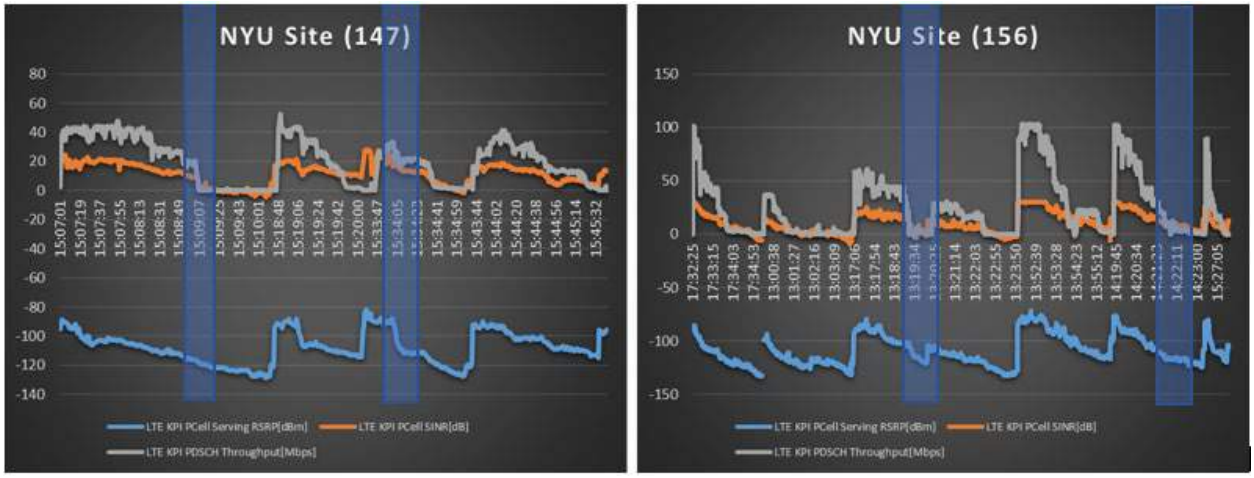

**Figure 13 Field Single Site Performance Stats**

In the left graph: As highlighted, when RSRP (blue) drops below -115 dBm, the DL Throughput is seen taking an abrupt hit (gray) to single digits. It rises again as RSRP goes up and again below certain RSRP the throughput nose dives. The second highlighted region from left to right, shows obstruction in coverage as RSRP taking a steep gradient downward, the throughput degrades but doesn't drop down to minimum until RSRP crosses neg 115 dBm. For this morphology, neg 115 dBm seems to be the point below which decent throughputs cannot sustain. In the right graph: In the second site region the throughput shows same trend as first region, as shown in highlighted area, as RSRP (blue) dips below neg 100 dBm, the SINR drops and Throughput take a steep slope downward to single digits (gray). As soon as RSRP exceeds -100 dBm, both SINR and throughput rise showing direct correlation. The second highlighted area shows similar trend when RSRP drops.

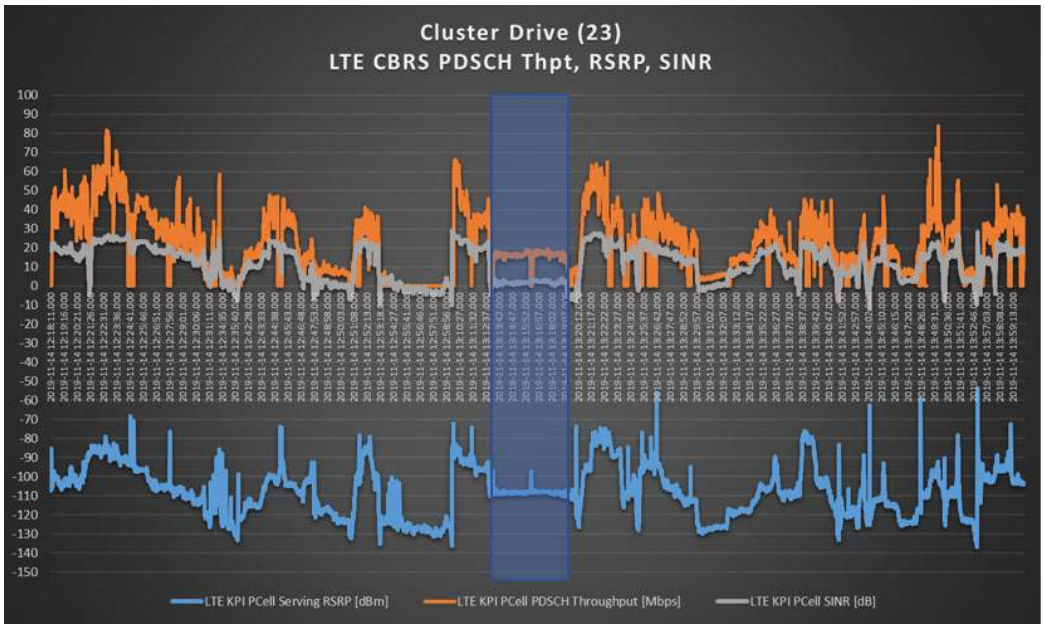

**Figure 14 Field Cluster DL Performance Stats**

In another area cluster drives were observed to show instances (left highlighted portion above) where RSRP stayed between -110 dBm to -112 dBm and throughputs were not severely affected even when SINR dropped to single digits. The right highlighted portion shows an abrupt drop in DL throughput as RSRP plunges but it regains and trends alongside RSRP rising trend.

Also this area was deployed with a different vendor equipment than the previous area so the chipset or equipment's receive sensitivity or processing power could be the factors differentiating from other area. In addition to this, this clutter morphology is denser with more shadowing, reflections, refractions and beam scattering phenomenon(s) coming into play.

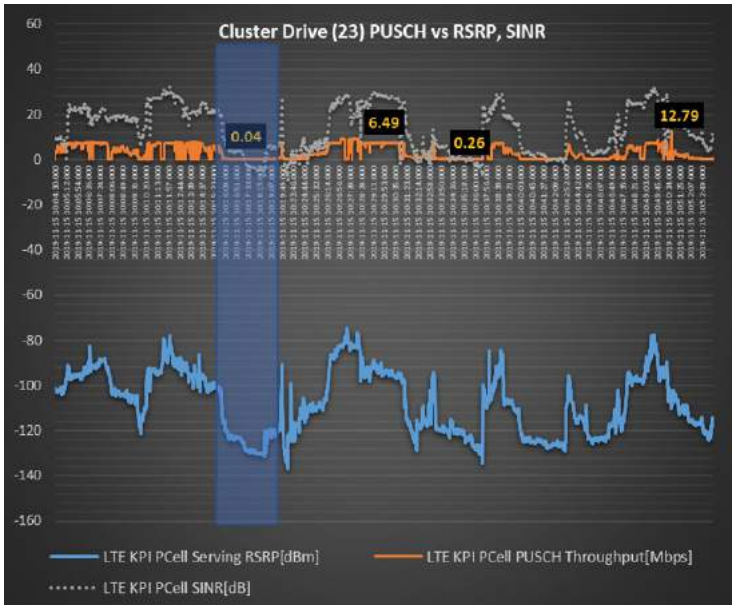

**Figure 15 Field Cluster UL Performance Stats**

In this graph UL throughput data is shown, collected during a field trial. It can be seen UL is more susceptible to degrade as RF conditions deteriorate. When DL RSRP dips below -100 dBm, the UL throughput lowers to under 1 Mbps. Although DL RSRP is uncorrelated to UL but the path loss scanario's are the same in both directions most of the time, as highlighted in the graph above show.

### 4.6. LTE Performance KPIs Observation from Field Trials

Performance KPIs for Strand network when tested yielded following –

Up to 14 Simultaneous UEs connected in dedicated mode, 14 GB Tonnage carried with 1% Drop Rate and 99% Establishment Rate and X2 HO Success rate of 95%

**Table 5 Cluster Performance KPIs**

| Strand CBRS Cluster KPIs | Max UEs Connected | Drop Rate (%) | ERAB Success Rate (%) | RRC Success Rate (%) | S1 Success Rate (%) | Tonnage (GB) |
|---|---|---|---|---|---|---|
| | 14 | 1 | 99 | 99 | 100 | 14 |

Attached mount cluster field tests showed following –

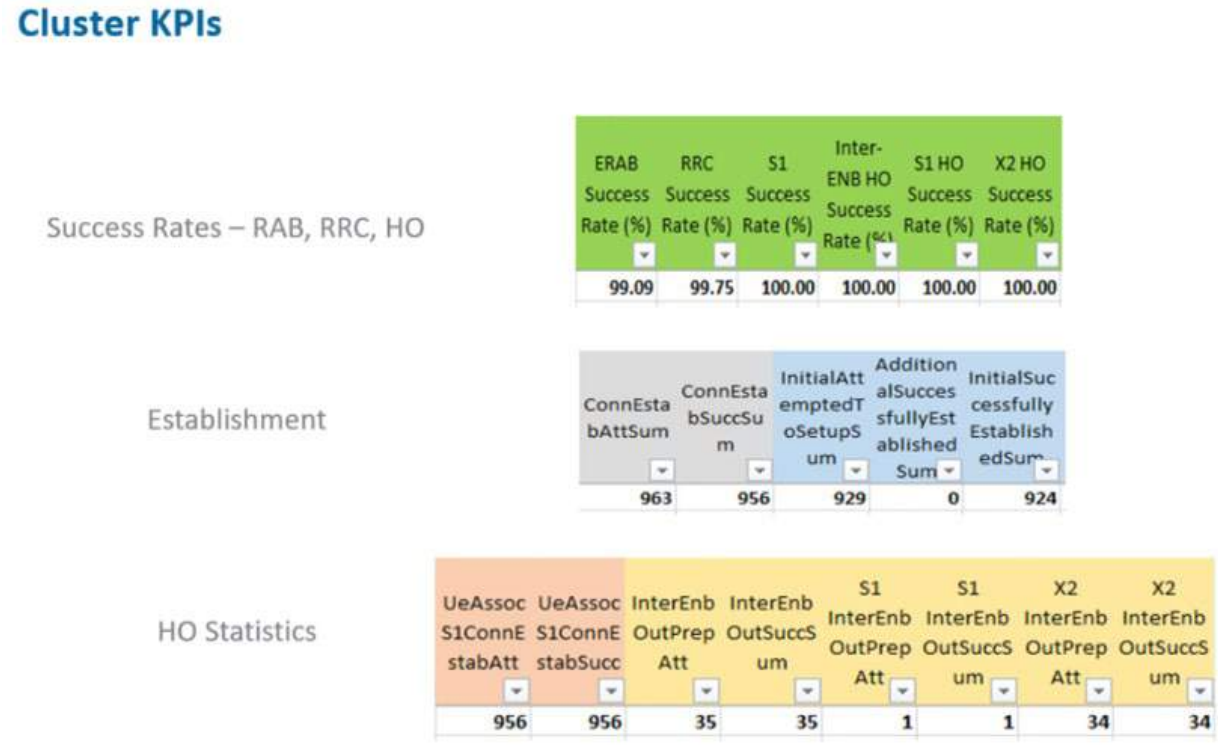

**Figure 16 Attached Mount Cluster KPIs**

In a single session 5.9 GB network tonnage was handled with 43 HO attempts in between 3 sites, 8 Sectors and 16 Carriers. Up to 14 UEs, 5 simultaneously attached to the network, peak data rates of

103 Mbps observed. 963 connection establishment attempts, ERAB setup rate, RRC Success rate, S1 & X2 HO Success rate and Inter-eNB success rates were all greater than 97%.

| RSRP | Percentage of Drive (%) | DL Thpt Avg (Mbps) |
|---|---|---|
| > -90 dBm | 11 | 41 |
| > -100 dBm | 17 | 35 |
| > -110 dBm | 37 | 25 |
| > -120 dBm | 21 | 16 |
| > -130 dBm | 14 | 5 |

**Figure 17 Cluster Drive RSRP and Throughput**

RSRP is the key driver of performance. Below graph is a plot of DL throughput per dBm and the steepest gradient is at -104 dBm. We've observed depending on clutter type and morphology the throughput is more affected as RSRP degrade from -104 dBm and drops to single digits as it nears -120 dBm as shown in 'Factor Affecting Throughput in a CBRS Network – A Field Assessment' section.

Direct correlation observed between throughput and RSRP however the degradation is seen when RSRP goes into triple digits

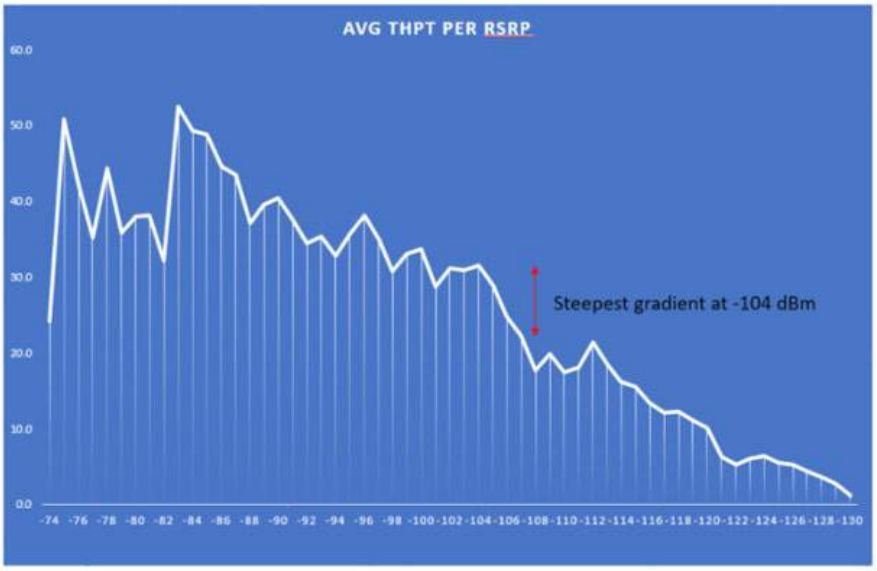

**Figure 18 RSRP to Throughput Function**

## 4.7. Capacity Testing

Charter conducted a field trial in Tampa, FL to test CBRS load bearing capability and effect on cell performance throughput. Field trial done at three distinct locations from the cell based on RSRP values referred as Cell Near, Cell Mid and Cell Edge.

*Figure 19 Load Test Setup on Field*

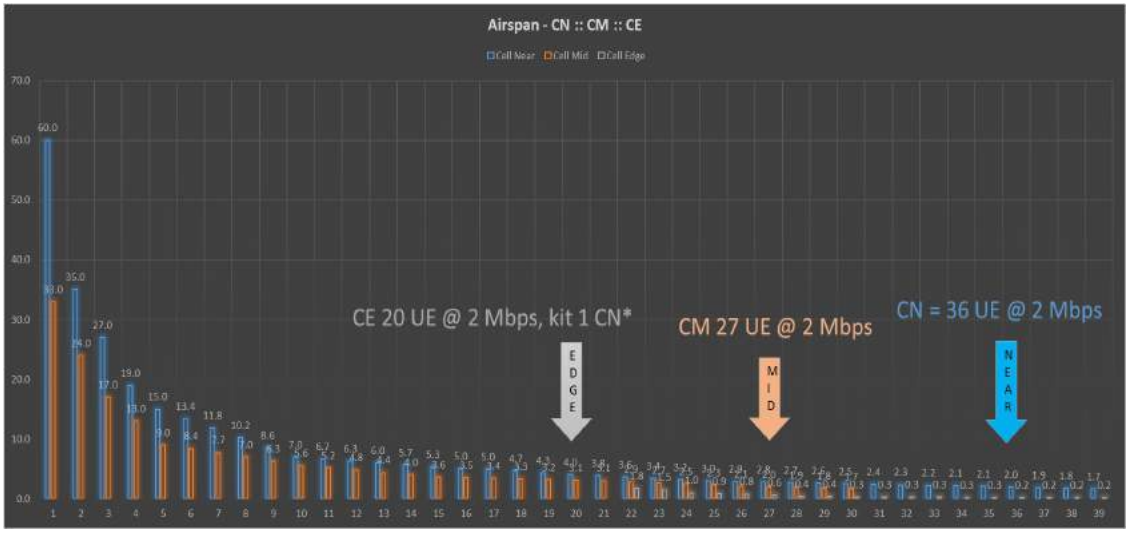

**Figure 20 Load Test DL Performance Stats**

In the graph above, when one UE attached at Cell Near location, the Downlink throughput was 60 Mbps. When second UE was fired up the Downlink throughput dropped to 35 Mbps Avg. Third one joined, and the throughput reduced to 27 Mbps and so on (blue). At the Cell Near location, up to 36 UEs simultaneously streamed above 2Mbps. At the Cell Mid location (orange), throughputs started at 33 Mbps and up to 27 UEs could stream above 2Mbps simultaneously. Lastly, at the Cell Edge (gray) location, 20 Simultaneous UEs could stream at and above 2 Mbps. Testing of another vendor showed slightly different results, consolidating all in the table below shows Cell Near of 34 and Cell Edge of 13 UEs maintaining 2 Mbps at all times.

**Table 6 DL Load Testing**

| DL Throughput | # UEs at Cell Near | # UEs at Cell Edge |
|---|---|---|
| > 20 Mbps | 4 | 0 |
| 15 – 20 Mbps | 2 | 0 |
| 10 – 14 Mbps | 4 | 0 |
| 5 – 9 Mbps | 7 | 4 |
| 2 – 4 Mbps | **34** | 13 |
| 0 – 1 Mbps | 0 | **33** |

Majority of UEs stayed within 2 – 4 Mbps at Cell Near.
Majority of UEs stayed under 1 Mbps at Cell Edge

In addition, from observation in the Field trials that as UEs are loaded up, the 2Mbps boundary threshold (DL) reduced virtually. Our test results shown in the table below:

**Table 7 Load Effect on Cell Radius**

| Loading effect on Geographical Radius of 2 Mbps DL boundary | | |
|---|---|---|
| **# of Simultaneous UEs** | **2 Mbps Radius (m)** | **% Loss of Radius** |
| 1 | 342 | |
| 5 | 277 | 19% |
| 15 | 205 | 40% |
| 30 | 64 | 81% |

## 4.8. Busy Hour Traffic Analysis

Busy hour changes dynamic of the cell, grade and quality of service. Below is a theoretical analysis of how busy hour affects end user throughputs. Input parameters in this calculation have been taken from our capacity testing field trial.

We assumed average throughput per user is 50 Mbps DL / 10 Mbps UL in non-busy hour. Using capacity trial results, we get average of 34 Cell Near and 13 Cell Edge, giving an average of 23.5 UEs Cell Mid for 20 MHz. At 40 MHz we took 1.5 times 23.5 UEs = 35 UEs per cell. Assuming 80% of users at busy hour, this comes to 28 UEs per cell in BH. Combining rates for different QAMs, throughput per user in BH comes out to be 5.8 Mbps. From 50 Mbps to 5.8 Mbps is the effect of busy hour on a CBRS cell. This analysis is theoretical.

**Table 8 Assumptions for Busyhour (BH) effect on Throughput**

| Per CBRS Cell 40 MHz BH Analysis | DL | UL | Unit | Remark |
|---|---|---|---|---|
| Avg. Throughput per UE (Product) | 50 | 10 | Mbps | 20% UL based on FC2 |
| # of UEs per Cell | 35 | | Avg | Per testing in 20 MHz:<br>CN 35 + CE 12 = 23.5 Avg UEs * 1.5 for 40 MHz = 35.2 UEs |
| BH Users | 28 | | UEs | 80% of estimated total UEs |
| Peak Throughput BH (256 QAM) | 300 | | Mbps | |
| Peak Throughput BH (64 QAM) | 220 | 35 | Mbps | |
| Peak Throughput BH (16 QAM) | 150 | 23 | Mbps | |
| Peak Throughput BH (QPSK) | 75 | 12 | Mbps | |

| | | | | |
|---|---|---|---|---|
| Peak Throughput BH (Consolidated) | 164 | 17 | Mbps | (Based on drive data: 30% for each DL Modulation except 10% for 256 QAM) |
| Throughput per User (BH) | 5.8 | 0.6 | Mbps | |
| Total Tonnage per User (BH) | 2.6 | 0.3 | GB | |
| Total BH Tonnage per Sector | 73.6 | 7.5 | GB | |

**Table 9 Busyhour (BH) Traffic Analysis - Strand Mount**

| BH Traffic Analysis – Strand | DL | UL | Unit |
|---|---|---|---|
| Avg. Throughput per UE (Product) | 50 | 10 | Mbps |
| # of UEs per Cell | 35 | | Avg |
| BH Users | 28 | | UEs |
| Peak Throughput BH (Consolidated) | 164 | 17 | Mbps |
| Throughput per User (BH) | 5.8 | 0.6 | Mbps |
| Total BH Tonnage per Sector | 73.6 | 7.5 | GB |
| Total BH Tonnage per Strand Site | 147.2 | 15.0 | GB |

**Table 10 Busyhour (BH) Traffic Analysis - Attached Mount**

| BH Traffic Analysis – Attached | DL | UL | Unit |
|---|---|---|---|
| Avg. Throughput per UE (Product) | 50 | 10 | Mbps |
| # of UEs per Cell | 35 | | Avg |
| BH Users | 28 | | UEs |
| Peak Throughput BH (Consolidated) | 164 | 17 | Mbps |
| Throughput per User (BH) | 5.8 | 0.6 | Mbps |
| Total BH Tonnage per Sector | 73.6 | 7.5 | GB |
| Total BH Tonnage per Attached Site | 220.7 | 22.5 | GB |

**Table 11 Busyhour (BH) Traffic Analysis - SMB**

| BH Traffic Analysis – Attached | DL | UL | Unit |
|---|---|---|---|
| Avg. Throughput per UE (Product) | 50 | 10 | Mbps |
| # of UEs per Cell | 17 | | Avg |
| BH Users | 14 | | UEs |
| Peak Throughput BH (Consolidated) | 164 | 17 | Mbps |
| Throughput per User (BH) | 12.0 | 1.2 | Mbps |
| Total BH Tonnage per Sector | 73.6 | 7.5 | GB |
| Total BH Tonnage per SMB Site | 220.7 | 22.5 | GB |

Average DL User throughput drops from 50 Mbps to 5.8 Mbps as traffic spike hits 80% of cell capacity. Cell overlap along with advanced load and spectrum sharing and congestion mitigation techniques can be employed to reduce this impact.

### 4.9. Conclusion

CBRS is more suited for hot-spot targeted and pocketed coverage applications with redundancy to fall back to alternate technology when needed like Charter's MVNO in DSDS configuration with the ability to transition to MVNO network to mitigate customer impact. In the event of blanket / cluster wide coverage requirement the ISDs will have to be no more than 1000 – 1400 ft. apart.

CBRS LOS vs non-LOS coverage, the loss beam incurred when subjected to obstruction due to its high propagation loss characteristics, makes CBRS radius shrink to a greater extent than low band spectrum carriers.

## 5. CBRS Radio Devices and RF Design of CBRS Network

### 5.1. CBRS Radio Devices

In CBRS terminology, an LTE eNodeB or base station is called Citizens Broadband Radio Service Device (CBSD). As per Code of Federal Regulation, Part 96, there are two categories of CBSDs defined, Category-A and Category-B devices. All CBSDs must register with and authorized by SAS prior to their initial service transmission. They must operate at or below the maximum power level authorized by SAS and must be in compliance with their FCC equipment authorization. For Category-A CBSD, the maximum EIRP and maximum PSD limits are 30dBm/10MHz and 20dBm/MHz respectively and generally deployed indoors. For Category-B CBSD, the maximum EIRP and maximum PSD limits are 47dBm/10MHz and 37dBm/MHz respectively and deployed outdoors.

### 5.2. CPE for Fixed Wireless Access

Selection of optimal Customer Premise Equipment (CPE) for Fixed Wireless Access (FWA) application is very crucial. High power, high antenna gain CPE device helps in network design for better uplink user performance perspective. Today, there are many OnGo certified, part 96 compliant CPEs available in the market to choose from for various different form factors for Fixed Wireless network application in CBRS. Charter has done FWA rural broadband trial in North Carolina with a couple vendor's CPE devices with capability of 1x4 and 2x4 MIMO configurations and high power up to 26 dBm and 15 dBi high gain antenna for better user experience. Their 3GPP device category information is very important and used to allow the eNodeB to provide compatible user services more efficiently. In other words, the user equipment category defines the overall performance and the capabilities of the UE. There are different UE categories that have a wide range of features supported for enhanced end user performance experience. Some of them are only capable of supporting SISO; some of them support 2x2 and 4×4 MIMO. The UE category defines a combined uplink and downlink capability as specified in 3GPP TS36.306

**Table 12 CPE Category**

| User Equipment Category | Downlink (Mbits/s) | Max # of DL MIMO Layers | Uplink (Mbits/s) | 3GPP Release |
|---|---|---|---|---|
| 1 | 10.3 | 1 | 5.2 | Rel. 8 |
| 2 | 51 | 2 | 25.5 | |
| 3 | 102 | 2 | 51 | |
| 4 | 150.8 | 2 | 51 | |
| 5 | 299.6 | 4 | 75.4 | |

| User Equipment Category | Downlink (Mbits/s) | Max # of DL MIMO Layers | Uplink (Mbits/s) | 3GPP Release |
|---|---|---|---|---|
| 6 | 301.5 | 2 or 4 | 51 | Rel. 10 |
| 7 | 301.5 | 2 or 4 | 102 | |
| 9 | 452.2 | 2 or 4 | 51 | Rel. 11 |
| 10 | 452.2 | 2 or 4 | 102 | |
| 11 | 603 | 2 or 4 | 51 | |
| 12 | 603 | 2 or 4 | 102 | |

### 5.3. RF Design

Various different strategic CBRS trials have been performed over the last couple of years. Extensive Continuous Wave (CW) tests performed in different morphological geography to understand 3.5 GHz signal propagation characteristics in all different areas like dense urban, urban, sub-urban and rural. Results have been studied thoroughly, data utilized for RF design model tuning to create our own optimal propagation model for each different morphological area. For an accurate and realistic RF design, the recommendation is to use 3D modeling with accurate and high definition 3D geo data for a better result. Foliage data consideration into RF design would give result that is more accurate. For the best RF design and propagation model tuning, adopt an advanced method to collect CW data with better equipment. The advanced method such as dead reckoning giving location information that is more accurate. This will be crucial for markets such as NYC, LA and Dallas or any downtown areas with high-rise buildings.

### 5.4. Conclusion

Plenty of RF drive tests and walk tests performed on the field on different types of small cells from multiple vendor equipment deployed on strand, rooftop and indoor locations. An average cell radius provided by strand mount small cell is approximately 300 meters. This is line of sight (LOS) radius and not a uniform radius of circular coverage as strand mount CBSDs usually deployed below clutter at 18 feet radiation point. The cell radius for line of sight coverage from an Attached mount (Rooftop) small cell is at least 1500 meters, diameter of cell coverage is 3000 meters. However, the overall non line of sight radius depends on height of attached mount CBSD and is relative to clutter and can vary from 300 meters to 700 meters radius (600 meters to 1400 meters diameter).

## 6. Introduction of 3GPP Virtual RAN Split Options

Virtual Radio Access Network (vRAN) is a new network deployment architecture that reduces the operational and capital expenditures of wireless network deployment. vRAN network architecture consists of mainly three parts, 1- Central Unit (CU), 2- Distributed Unit (DU) and 3- Radio Unit (RU). Each of these parts can execute different layer(s) of network communication protocol, and this is classified as ‘Split Options. In this part of white paper, we will explain what different split options are, and why Charter has selected split option 2 for DOCSIS based 5G CBRS wireless network deployment.

## 6.1. Split Options

In vRAN deployment model, there are seven main protocol split models used to execute different parts of protocol layers at Distributed Unit (DU) and at Central Unit (CU). Here is the list of protocol split options used today.

- Option 1: RRC/PDCP split
- Option 2: PDCP/RLC split
- Option 3: Intra-RLC split based on a split of the RLC functionality such that the entire RLC is located in the central unit hosted in the cloud
- Option 5: Intra-MAC split
- Option 6: MAC/PHY split
- Option 7-1: This split where the IFFT and cyclic prefix insertion/removal performed at the remote radio unit (distributed unit) and IQ samples in frequency domain exchanged over the Fronthaul interface
- Option 7-2 & 7-2a: These splits have the additional benefit that pre-coding and digital beamforming, or parts thereof, are performed at the remote radio unit (distributed unit)
- Option 7-3: This split option considered only for the downlink, further reduces bandwidth requirements on the interface as coded user data exchanged before modulation.

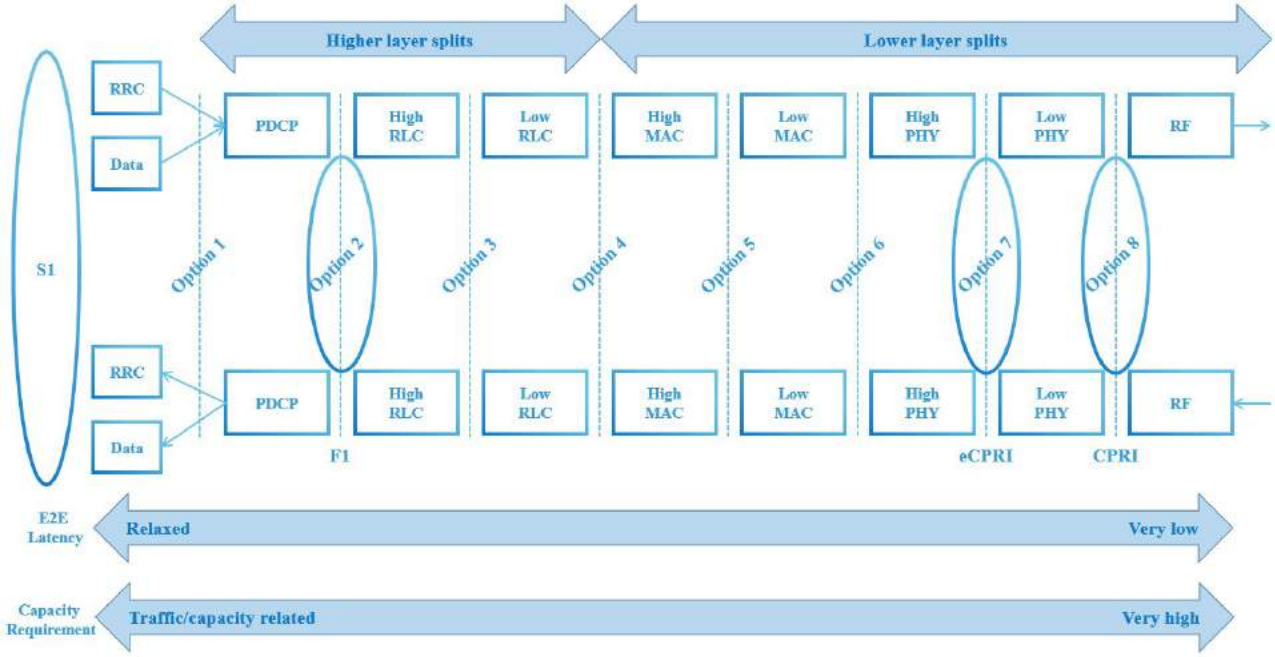

**Figure 21 Protocol Split Options**

Each protocol layer has a number of processes that perform the tasks of that protocol layer. In addition, these processes represented by the processing blocks. In Physical layer (PHY) of LTE standard, there are nine processing blocks and split options 7.1, 7.2 and 7.3 created based on splits between processing blocks.

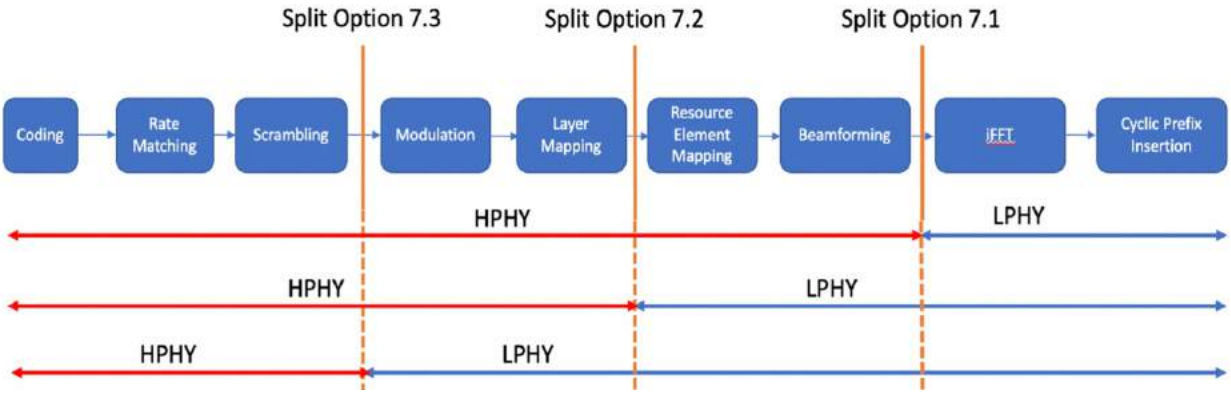

**Figure 22 Sub-splits for Split Option 7**

Processing blocks below split point are called Lower Physical Layer (LPHY) and processing blocks above split point is called Higher Physical Layer (HPHY). LPHY is executed in RU and HPHY is executed in DU.

## 6.2. Split Options and Latency Requirements

Latency requirements on the interface in general become tighter the further down in the protocol stack the split is, though one can classify two levels of latency requirements. For 3GPP, Split Option 1-3, where all RAN functionality that has to operate synchronously to the radio (i.e. in real time), the interface latency requirements are rather relaxed. Latency requirements are much more stringent for the other options where RAN split cuts in between synchronous functionalities. Recommendation to have Split Option 7-3 for CRAN deployment. Split Option 2 or Option 3 is preferred for deployment with DOCSIS since latency requirements is rather relaxed.

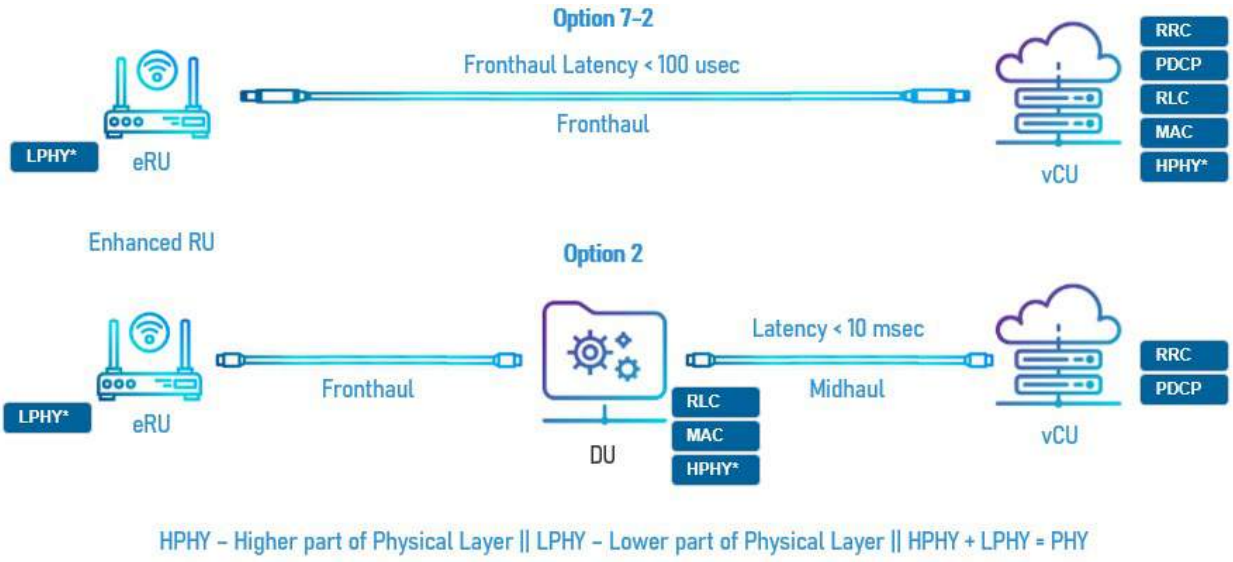

**Figure 23 Sub-splits Option 7-2 vs Split Option 2**

## 6.3. Split Option 2 vs Option 7-2

Split Option 2: As Charter, we selected split option 2 model for vRAN deployment over our widely available DOCSIS network. Split option two model has a separation at RLC layer, executes PHY, MAC and RLC layers at DU and RRC and PDCP layers at CU. Data transmission latency requirement for split option 2 is at most 10 msec. Any latency value of more than 10 msec. will degrade the quality of service delivered to our subscribers.

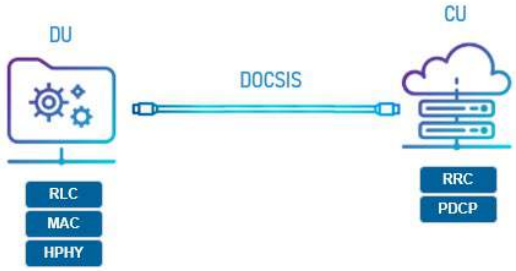

**Figure 24 Split Option 2**

Split option 2 has latency advantage over split option 7.2 in addition to the following advantages such as Mobility support. Handover between DUs will be similar to current intra-sector handover since DUs served with the same CU (same RRC layer). Link latency between DU and CU will affect the RRC messaging (required for HO) latency. No fiber requirements. Lower scheduling delay since scheduler runs in DU.

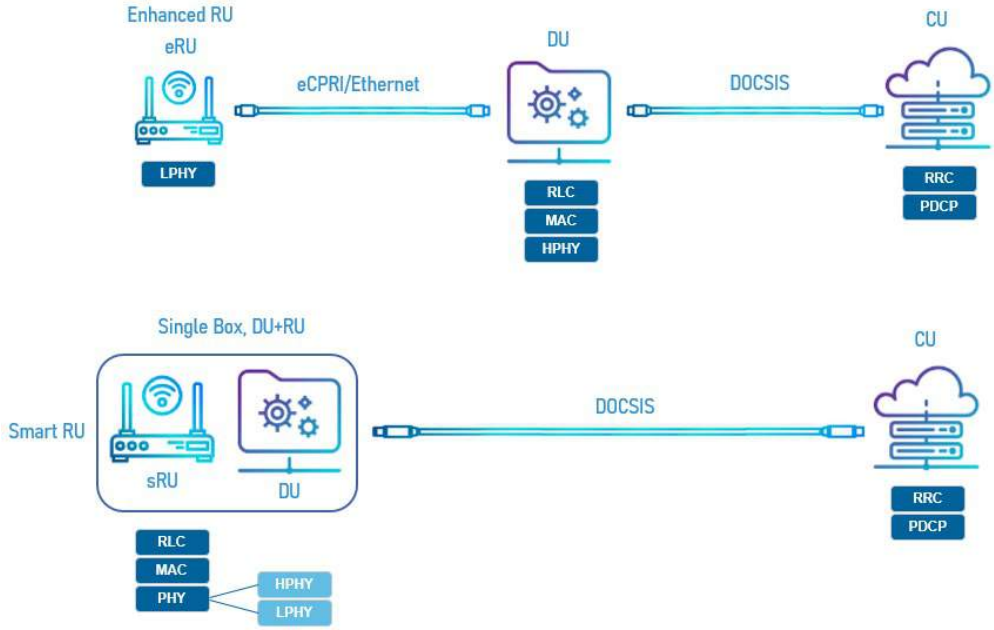

**Figure 25 Split Option 2 over DOCSIS**

Charter has selected combined RU and DU model for cable strand DOCSIS deployment. In this model, DU and RU is combined in a singled box executing PHY, MAC, HPHY (higher part of PHY layer) and LPHY (lower part of PHY layer) protocol layers.

Split Option 7-2: This model requires fiber deployment and we are considering using this split in markets where we have the required fiber coverage. Data latency requirement is 500 microseconds. Certain advantages of this split model are, but not limited to, Interference Management through Coordinated Multi-

Point (CoMP) and Inter-cell Interference management. SON features will benefit from central processing, and scheduling. Since eCPRI is not used, cost of CU will be lower.

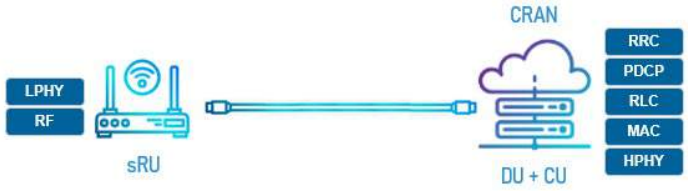

**Figure 26 Split Option 7-2 over Fiber**

### 6.4. Conclusion

Charter has selected Split Option-2 for its vRAN based 5G CBRS wireless network deployment over DOCSIS because of its data transmission latency advantages. Also, since DOCSIS network provides advanced latency reduction features such as Bandwidth Report (BWR), Charter is ready to leverage these features to further ease of its 5G CBRS wireless network deployment on cable strand. We will keep monitoring the latest advancements in vRAN field, and latest releases of 3GPP standards together with oRAN initiative to fine tune our vRAN network deployment strategies.

## 7. DOCSIS Backhaul

Near ubiquitous availability of Cable and DOCSIS assets in urban and suburban areas is one of the significant factors driving Charter's and more broadly cable industry's interest in Small Cell deployments for many years.

In anticipation of DOCSIS use as backhaul for wireless, the wireless technical leadership at Charter and CableLabs have been busy adding several critical and innovative features in DOCSIS.

In this section of the paper, we discuss these features.

### 7.1. Low Latency Xhaul (LLX)

LLX aims to reduce the latency for mobile traffic on the DOCSIS network to as low as 1–2.5ms. It uses mobile and DOCSIS scheduler pipelining to achieve lower latency. CableLabs issued LLX specification in 2019 in a document titled Low Latency Mobile X-haul over DOCSIS® Technology. As shown in the picture, LLX introduces a new interface called Bandwidth Report (BWR) for exchange between the scheduling functions of the mobile and DOCSIS networks, which produces the effect of one pipelined system rather than two independent systems.

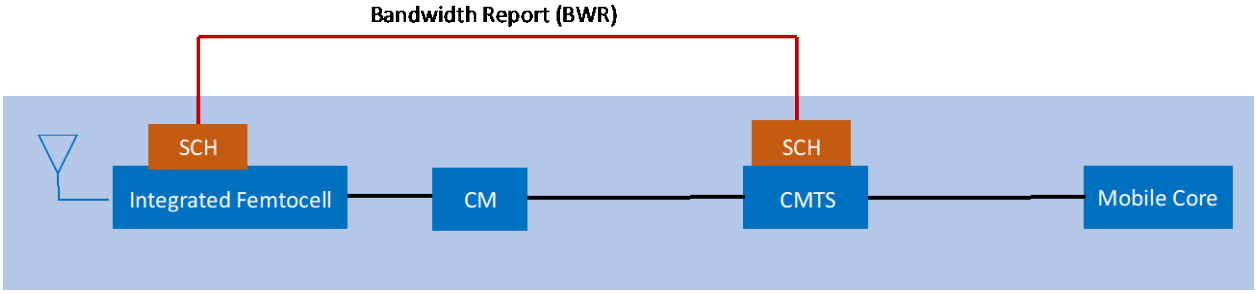

**Figure 27 Low Latency Xhaul**

The Bandwidth Report (BWR) is sent by the eNodeB scheduler to the DOCSIS scheduler and provides information about the amount of bytes eNodeB scheduler expects for some specific time in the future for the data transmission before the arrival of the actual traffic. Current LTE-DOCSIS systems do not have BWR and have a cumulative latency. The latencies of the eNodeB and CMTS systems are additive. Latency increases further with network congestion.

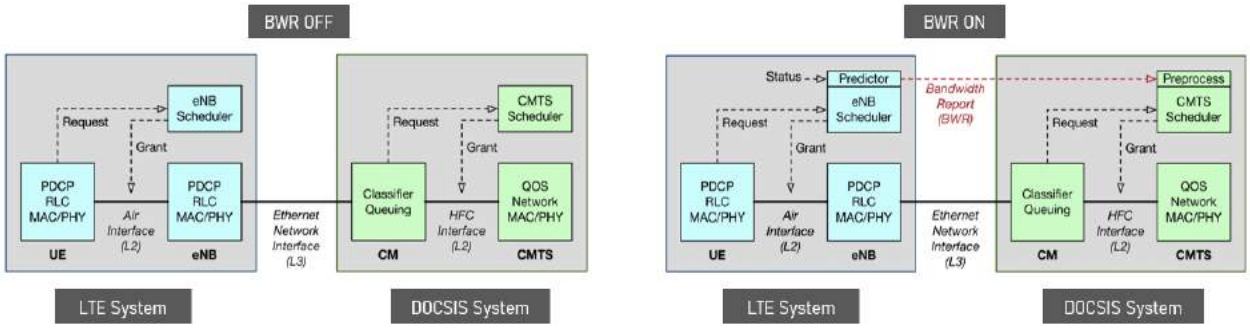

**Figure 28 Bandwidth Report OFF/ON**

For example, a 4G eNB or 5G gNB provides a future traffic profile through the BWR message, allowing the CMTS to make QoS and granting decisions earlier than it normally would. As a result, we can observe significant reduction in the variability in Jitter, improvement in average latency and smoothening of latency curve when BWR is ON. BWR works in 5G-NR similarly to the way it works in LTE for the majority of 5G traffic that employ larger slot sizes. 5G-NR URLLC (Ultra Reliable Low Latency Communication) latency requirements are 1-2ms. Using BWR the CMTS scheduler will have to predict the number of grants required per queue, verify this a few milliseconds later when the BWR arrives, and adjust as necessary.

## 7.2. Low Latency DOCSIS (LLD)

LLD is a CableLabs specification developed with vendors and operators. It focuses on lowering the latency by reducing queuing delay and media acquisition delay. The queuing delay is, lowered by using a different logical path for queue building vs. non-queue-building application traffic. In addition, the media acquisition delay is, lowered by using proactive scheduling mechanisms. LLD targets a reduction in round-trip latency in the DOCSIS network to below 5ms. It also targets a reduction in delay variation on the DOCSIS network by a factor of 100 compared to what is typical today. As a result, LLD promises to deliver significantly improved user experience for consumer applications, such as online gaming. Very importantly, the existing DOCSIS 3.1 equipment can include support for LLD with a software upgrade and without requiring hardware change.

## 7.3. Conclusion

Although Low Latency DOCSIS (LLD) and Low Latency X-Haul (LLX) have similar-sounding names, they are two different technologies with different objectives. While LLX reduces the latency for mobile user traffic on the DOCSIS network used as mobile X-haul (backhaul, mid-haul, or Fronthaul), the LLD reduces the latency in general on the DOCSIS network.

As the interest in Small Cell deployments is gaining momentum, operators are actively analyzing the LLX technology and inquiring the SmallCell vendors to support it. To operators' relief, the mobile eNB/gNB and the DOCSIS CMTS can add support for LLX via software upgrade without requiring hardware change.

As the Smallcell and CMTS vendor implementations of LLX become available in the next year, Charter looks forward to evaluating the technology in the lab and field.

# 8. Timing and Synchronization

Unlike Wi-Fi, the 4G LTE and 5G NR require stringent synchronization (Phase and Frequency) of wireless transmission to avoid interference between uplinks and downlinks. Since the CBRS is a shared band, the clock synchronization across basestations of the same and different operators is critical for full realization of the spectrum and avoid unwanted interference. As laid out in the table below, the synchronization requirements for TDD LTE and 5G NR are specially stringent.

**Table 13 Frequency and Phase Synchronization Requirements**

| | Frequency | Phase |
|---|---|---|
| 4G LTE TDD | ±50 ppb | ±1.5 µs |
| 5G NR TDD | ±50 ppb | ±1.5 µs |

These synchronization requirements are documented in 3GPP specifications – TS 36.133, TS 36.922, and TS 38.104.

As discussed earlier in this paper, Charter is pursuing both indoor and outdoor deployment of CBRS Smalcells. The acquisition of accurate phase and frequency for outdoor Smallcel deployment is rather straight forward and Charter is planning to use GPS.

On the other hand, the acquisition of accurate phase and frequency for indoor wireless deployment is much more complex and requires evaluation of multiple options.

As shown in the table, there are a number of options for timing and synchronization. For outdoor deployments, GPS is the most widely used timing source. However, for indoor applications such as Femtocell, the combination of PTP and DTP ranks higher on the list and is carefully studied and tested.

Table 14 Synchronization Types - Advantages and Disadvantages

| | Advantages | Disadvantages |
|---|---|---|
| DOCSIS Timing Protocol (DTP) with PTP | • Supports LTE TDD and 5G timing precision requirements [2]<br>• Timing from our Charter owned and operated network<br>• CableLabs standard promoted by cable vendors | • Requires significant changes to DOCSIS infrastructure, including hardware upgrade to CM<br>• Grand Master clocks in each headend<br>• Regular network calibrations may be required |
| Over-The-Top PTP | • No upgrades to DOCSIS network required | • Timing synchronization not precise enough for TDD LTE even with DOCSIS QoS. (5-10 millisecond range)<br>• Performance is negatively impacted with network loading and uplink packet delay variation (uplink BW limited) |
| Network Listen/Macro Sniffing | • No upgrades to DOCSIS network required | • Reliance on Macro network for timing<br>• Availability everywhere is an issue<br>• Out-of-band listen requires dedicated radio – additional cost & more space |
| Global Positioning System (GPS) | • No upgrades to DOCSIS network required<br>• Supports LTE TDD timing precision requirements | • Receive challenges indoors, susceptible to jamming<br>• Placement not in the control of the operator<br>• Installation and operation cost external antennas |
| Over the top Network Time Protocol (NTP) | • No upgrades to DOCSIS network required | • Timing synchronization not precise enough (100 millisecond) even with dedicated QoS on DOCSIS |
| TV Broadcast Listen | • No upgrades to DOCSIS network required | • Need a receiver for TV broadcast<br>• Femtocell must know location – own & TV tower |

## 8.1. DOCSIS Timing Protocol (DTP)

DTP is part of CableLabs' DOCSIS 3.1 specifications and further enhanced in CableLabs CM-SP-SYNC specification. DTP carries the IEEE 1588v2 protocol over the DOCSIS network without the influence of jitter from network buffering. Additionally, DTP accounts for plant and path asymmetry that over-the-top

PTP may not. Furthermore, DTP provides timestamp and determines the downstream timing offset, which PTP uses to calculate precise timing and synchronization.

The picture below shows the application of DTP and PTP when DOCSIS network is used as backhaul for the mobile traffic. As shown, the DTP used between the CMTS and CM and PTP is between the grandmaster clock and CMTS and between the CM and eNB. CMTS and CM essentially convert PTP to DTP on the DOCSIS link. Sync E makes the frequency synchronization performance of PTP better. In case of loss of the master clock, Sync E also helps eNB keep clock running longer in holdover mode without losing precision.

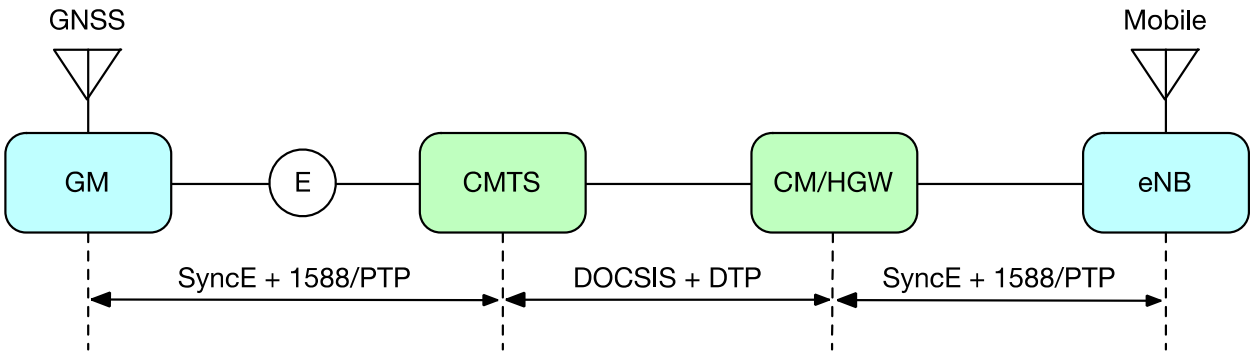

**Figure 29 DOCSIS Timing Protocol**

DTP is a new protocol and is currently not widely implemented or deployed. However, there is a keen interest in it from cable operators exploring indoor Small Cell deployments. Operators need a reliable source of precise timing and synchronization for both 4G TDD LTE and 5G NR deployments.

## 8.2. Assisted GPS

For indoor deployments, Charter is also evaluating "Assisted" GPS technology, which claims to provide accurate phase and frequency in challenging RF environments (e.g., building basement). In an "Assisted" GPS enabled system, DOCSIS backhaul could be used to feed the small amount of data carried by the satellite signals. This process makes it unnecessary for the "Assisted" GPS receiver to demodulate the data, allowing the system to provide accurate phase and the frequency at significantly low GPS signal levels.

## 8.3. Conclusion

The engineering teams at Charter are actively testing both PTP/DTP and "assisted" GPS technologies in collaboration with CableLabs and Cisco. We hope to publish results from our study in the next Cable-Tec-Expo for the benefit of the industry.

## 9. Wrap-Up

The rollout of a wireless network is a significant challenge. The wireless engineering team at Charter has dedicated the past three years to understanding the characteristics which are important to a successful wireless deployment. In this paper, we have covered the important deployment scenarios which should be understood for every deployment – Strand Mount (Outdoor Aerial Strand), Attached Mount (Outdoor, non DOCSIS), and Indoor Deployments. Strand Mount utilizes all of the advantages of the HFC/DOCSIS network such as power availability, wide coverage, and quick deployments. This does need to be countered with the additional power load on the network. The Attached Mount deployments are utilized for strategic applications such as hot spots which can not be reached via the HFC network. The most important consideration of an Attached Mount is power and permitting which can eat up months of time getting a unit deployed. Key to success though is ultimately the indoor coverage. A drawback of CBRS is the EIRP power limits imposed by the FCC. This significantly reduces the ability of a 3.5 GHz signal to enter most building structures; therefore, it is important to have a strong indoor coverage plan. Charter has found a significant advantage with an Indoor/Outdoor strategy where two sectors cover the street outside of a building and the third sector is for indoor coverage.

It is important to understand the RF properties of CBRS. The 3.5 GHz signal is in a sweet spot for new wireless spectrum. It has the advantages of small form factor versus lower frequency spectrum while still getting reasonable coverage versus mmWave spectrum. From our research, RSRP is critical to monitor and manage. An RSRP value which drops below -110 / -115 dB causes a significant drop in throughput. It is important to rely on accurate 3D modeling to make sure a reasonable RSRP is maintained throughout the network. With the timeline of a wireless network deployment, it is important to consider 5G in your decision. Most significant deployments of a wireless network will start in 2-3 years which will give time for the initial higher cost of 5G to align with present day 4G deployment costs. Organizations like ORAN are helping drive 5G costs down quicker through standards and interoperability.

With the deployment of a DOCSIS network, it is important to consider Split 2 versus Split 7.2. Our research and testing has shown that Split 2 or a full gNB is a more practical option for a DOCSIS network primarily due to the amount of capacity required to support Split 7.2. Latency is a challenge, but it can be managed for a Split 7.2 configuration via adoption of technologies such as Low Latency Xhaul (LLX) and Low Latency DOCSIS (LLD).

For indoor and dense urban environments, timing will be a challenge. There is research and new technology in development focused on supporting better timing in both of these environments. Our current focus is on DOCSIS Timing Protocol and Assisted GPS. Both technologies have proven to support a better timing signal indoors.

It is hard to put three years of research into a single paper. The focus of this paper has been on the technologies which we feel have the strongest impact on a new wireless network on a modern day HFC plant. Best of luck with your wireless deployment.

# 1. Introduction

Years after years, Wi-Fi has become the de-facto way to access Internet at home. Based on the IEEE 802.11 standard family, the Wi-Fi technology has experienced several major PHY/MAC updates during the last 20 years, each one defining a generation on its own. Not so long ago, the general public was still not aware of those gaps and just called "Wi-Fi" any one of them. The generational naming introduced by the Wi-Fi Alliance in 2018 was seen a better way to advertise each new release instead of relying on 802.11 amendments name.

Built upon the IEEE 802.11 ax amendment, Wi-Fi technology is currently at its sixth coined "Wi-Fi 6" which operates on the unlicensed 2.4 and 5 GHz ISM band with an extension into the 6 GHz territory called Wi-Fi 6E.

Each Wi-Fi generation brought an improvement in peak throughput: from the original 11Mbps back in 1999, Wi-Fi 6/6E now offers up to 9.6 Gbps. However, Wi-Fi 6/6E main target was not peak throughput increase but improved efficiency in dense environments.

Indeed, the success of Wi-Fi, due to its low cost, ease of use and performance led to an explosion of Wi-Fi devices, exhibiting the limits of previous generations in terms of congestion and channel access in such scenarios.

Prior to Wi-Fi 6, access points (APs) and stations (STAs) were contending to access the medium with similar priority. More and more end-devices being deployed, resulting congestion has led to a degraded experience in crowded places like multi-dwelling units (MDUs).

In this paper, we will briefly present the evolution of IEEE 802.11/Wi-Fi technology and its quest for more throughput. We will then present the main features of Wi-Fi 6 and the change of paradigm it brought to the table with a more AP-centric channel access. We will then discuss how Wi-Fi has changed the residential environment and the main uses cases it needs to address. We will then present how Wi-Fi 6 can change user experience at home today and how the opening of the 6 GHz band will drastically change the user experience tomorrow. With three times more spectrum available, results achieved in clean environment could be truly representative of the end user experience even in dense environment.

# 2. Evolution of Wi-Fi Technology

Wi-Fi technology, which brand is owned by the Wi-Fi Alliance (WFA), is based on IEEE 802.11 standard. While IEEE 802.11 develops the technology, the WFA aims to promote it and creates as such interoperability testing and certification programs to ensure the end-users of a certain level of performance and compatibility. While independent, both organizations are tightly linked in the way Wi-Fi became so successful nowadays. General public knows the brand "Wi-Fi" but is generally not aware of the main generations it has experienced in its life, partly because Wi-Fi has always been backward compatible with its previous generations. An equipment bought in 1999 could work today with the same performance even in the most advanced Wi-Fi network. The generational naming introduced in 2018 by the WFA with numbers is a step to better differentiate the Wi-Fi technologies. Before addressing Wi-Fi 6/6E, we will recall what are the different Wi-Fi generations and their quest to always increase the throughput.

## 2.1. Early Wi-Fi Generations

The first commercial success of the IEEE 802.11 technology was relying on the 11b amendment back in 1999. Operating on the 2.4 GHz industrial, scientific and medical (ISM) band, this technology was based on direct sequence spread spectrum (DSSS) and complementary code keying (CCK) modulations and offered up to 11 megabits per second (Mbps) at the physical (PHY) layer on channel occupying 22 MHz. Its inclusion in laptop's CPU helped democratizing what can be considered as the first generation of Wi-Fi.

While development started at the same time as 11b, products based on 11a amendment came later. This technology was solely operating on the 5 GHz ISM band where more spectrum was available. It was relying on orthogonal frequency division multiplexing (OFDM), which divides the bandwidth in smaller subcarriers for a transmission in the frequency domain. Back in that day 11a could delivered a throughput up to 54 Mbps at PHY layer through the use of higher order modulations (64 quadature amplitude modulation (QAM)) and a channel bandwidth of 20 MHz. This can be considered as the second generation of Wi-Fi.

The will to port most of 11a innovations introduced in the 5 GHz ISM band into the 2.4 GHz ISM band gave birth to the 11g amendment in 2003. The same OFDM and modulations as 11a were introduced, while keeping backward compatibility with 11b devices. Only the 20 MHz channel bandwidth from 11a was kept As such 11g offered up to 54 Mpbs at the PHY layer with 20 MHz channel and could be considered as the third generation of Wi-Fi.

## 2.2. Generational Wi-Fi

In order to increase even more the throughput and as computation capability was more affordable, IEEE 802.11 worked on a new amendment which would be defined for both 2.4 and 5 GHz ISM band. With 11n, peak PHY throughput was increased by doubling the bandwidth (from 20 MHz to 40 MHz, an option viable mainly in the 5 GHz ISM band which is larger) and introducing multiple-input multiple-output (MIMO) concept which allow the use of up to four antennas. If channel conditions permit, spatial multiplexing which is a mode of MIMO transmission allow the transmission on the same channel of different parallel streams, increasing the throughput. 11n could then offer a throughput up to 600 Mbps at the PHY layer. 11n was published in 2009 by IEEE 802.11, but some years before people could buy products supporting a draft version of 11n pushed by the WFA to respond to the public demand. 11n is the fourth generation of Wi-Fi and named as Wi-Fi 4 by the WFA.

As the most efficient way to increase throughput is to use more spectrum, the next IEEE 802.11 amendment was only operating at the 5 GHz ISM band where more than two 20-MHz channels could be aggregated. 11ac amendment use all possible dimensions available to increase its peak throughput: higher bandwidth (up to 160 MHz), higher modulation order (up to 256 QAM), higher MIMO (up to 8 antennas). A full feature 11ac could offer up to 6.9 gigabits per second (Gbps) at the PHY layer, while the vast majority of gateways were shipped with up to 4 antennas. 11ac was published in 2013 by IEEE 802.11. The WFA used only a subset of 11ac features for its wave 1 certification based on a stable 11ac draft, later completed with additional ones for its wave 2 program. The use of larger channel was possible because spectrum was made available in the 5 Ghz band. However, all 160 MHz channels available in this band overlap with incumbents (e.g. radar) which have primary access. The constraint made on the devices to detect those signature and move away in case of positive detection (process often called dynamic frequency selection (DFS)) is such that in practice only 80 MHz channels are really used in residential deployments. 11ac is the fifth generation of Wi-Fi and named as Wi-Fi 5 by the WFA.

 

After the completion of 11ac, IEEE 802.11 group was trying to address a problem which was more and more visible as Wi-Fi technology was more and more successful. Originally thought as a cable replacement, the issue of density of devices and congestion associated to it was not really part of the design. With the 11ax amendment, IEEE was targeting to improve efficiency in dense deployment scenarios, with a throughput increase measured this time not at PHY layer but above the medium control access (MAC) layer, i.e., at the application layer, directly related to the user experience in such deployment. Since no work have been carried out on the 2.4 GHz ISM band since 2009, it was decided from the beginning to define 11ax for both the 2.4 and 5 GHz band, with a later extension to the 6 GHz band. 11ax brings a lot of changes which we will detail in a later section, but it also increases the throughput by using four times more subcarriers within the same spectrum (guard band can be reduced while guard interval (typical of OFDM modulation) is proportionally smaller) and up to 1024 QAM modulation. Therefore, a full 11ax solution can deliver up to 9.6 Gbps. 11ax amendment is expected to be published in 2021 by IEEE 802.11, but products are already available. WFA release 1 certification is ready since mid-2019 based on a subset of 11ax features from a stable draft. This certification only covers the 2.4 and 5 GHz band and it is expected that the 6 GHz band will be covered soon. 11ax is the sixth generation of Wi-Fi called Wi-Fi 6, while Wi-Fi 6E is used to indicate support of the 6 GHz band.

## 2.3. Peak Throughput Evolution

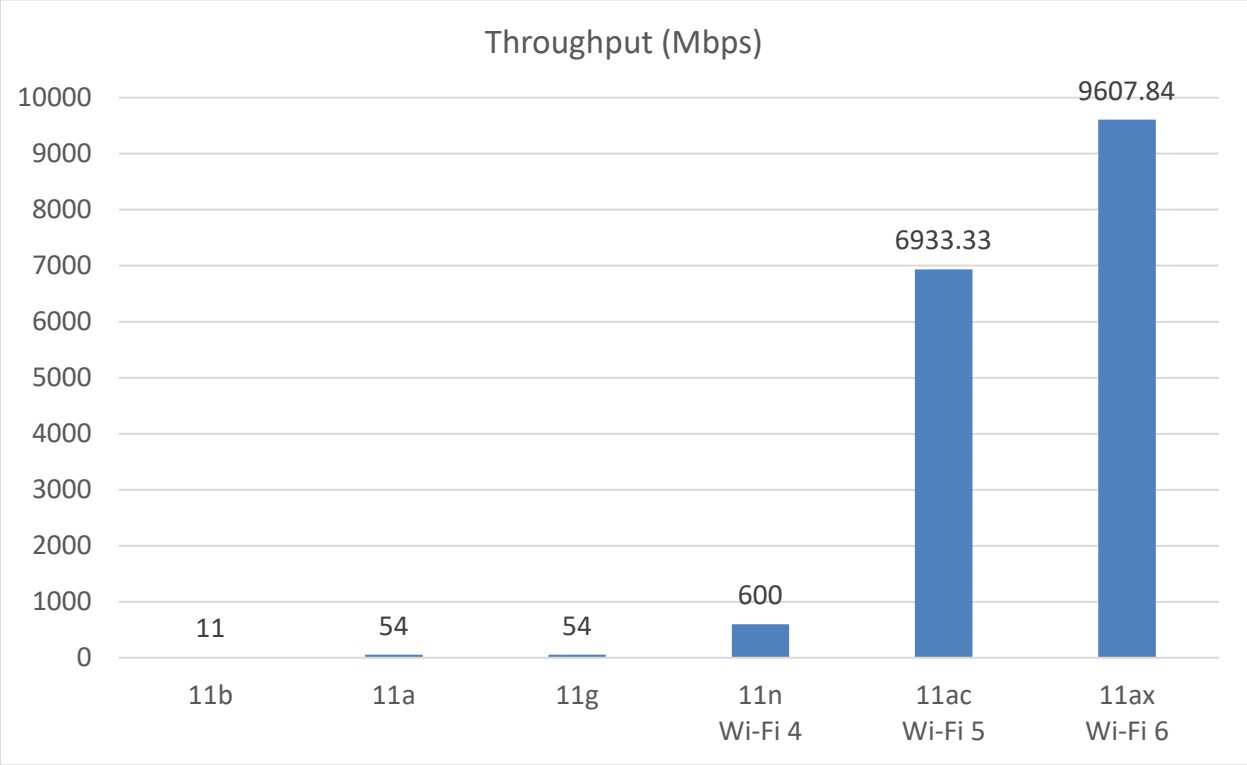

**Figure 1 - Throughput increase over the Wi-Fi generation**

As shown from Figure 1, Wi-Fi technology, like any successful wireless technology, has always known peak throughput increase though its various generations. Wi-Fi 6/6E is particular in the sense that this metric was not its primary objective. Wi-Fi 6/6E was developed to improve efficiency in dense environment like MDUs or stadium, where the limit come from too much devices trying to access a limited spectrum available at the same time.

# 3. Wi-Fi 6 Technology Overview

Wi-Fi 6 introduced many features to address the high density problem. In the following, we will detail the most important one when facing a residential unmanaged deployment.

## 3.1. Geared For Multi-User Transmissions

When too many stations are doing traffic at the same time, one solution to reduce congestion is to group them to either send them data (downlink) or receive data from them (uplink).

Wi-Fi 5 AP could already send data up to 4 STAs at the same time with a method relying on spatial separation called DL MU-MIMO. This technique is useful to exploit the asymmetry in antenna configurations between an AP (equipped generally with 4 antennas) and the STA (usually no more than 2 antennas) to send more streams to different STAs. However, this approach is heavily dependent on the radio conditions, topology and signal processing at the STA side.

To cope with this, Wi-Fi 6 introduced OFDMA as a way to group several STAs together in the frequency domain. Supported in both DL and UL directions, this method allocates group of (contiguous) subcarriers to different STAs.

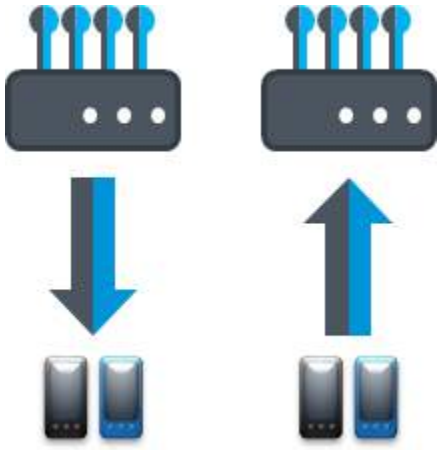

**Figure 2 - DL/UL OFDMA**

This technique is particularly efficient when packets to transmit are small, reducing the air time needed to send them.

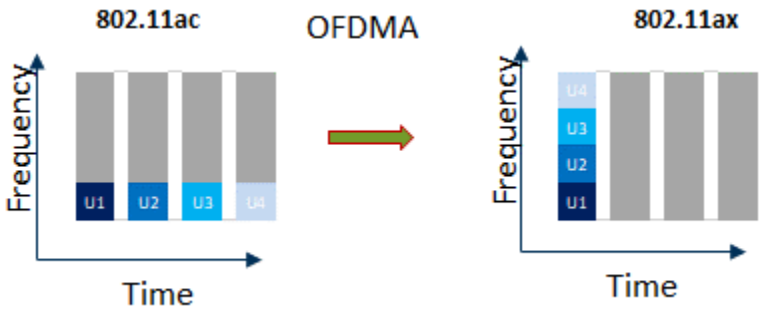

**Figure 3 - DL/UL OFDMA efficiency for small packets delivery**

If traffic is heavy with larger packet size, OFDMA could be less efficient due to the fact that the bandwidth is divided among the users. But Wi-Fi 6 can still use DL MU-MIMO transmissions to deal with such use case. Later Wi-Fi 6 products are also expected to be able to use this technique in the reverse direction as well with UL MU-MIMO.

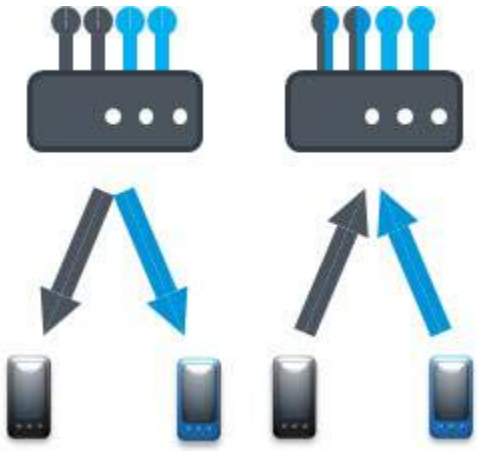

**Figure 4 - DL/UL MU-MIMO**

In Wi-Fi 6, scheduling at the AP side takes an even more important role as the AP is now in charge of DL and UL transmission. To make the STAs transmit in the uplink when the AP wants to, a new trigger mechanism is introduced which allow a more AP-centric medium access as we will discuss below.

## 3.2. Toward an AP-centric Channel Access

Before explaining how the trigger principle works and how it can improve efficiency at the network level, it is worth recalling how channel access used to work prior to Wi-Fi 6.

### *3.2.1. Classical Channel Access Mechanim*

During the history of Wi-Fi products, the channel access mechanism has been mainly updated from the distribued coordination function (DCF) access originally defined in the first IEEE802.11 standard from 1997[1]. Based on carrier sense multiple access with collision avoidance (CSMA/CA), each device wanting to transmit shall listen first to the medium to detect any energy above a given threshold. If none is detected, then it can transmit. Such principle is also known as the listen before talk (LBT) principle, terminology often used in regulation. Of course some refinements were added to this simple principle to avoid systematic collision between two devices such as the use of a backoff counter and an exponential contention window.

A device, being it a STA or an AP, shall pick a random value between 0 and the actual contention window size and store it in a counter. After sensing the medium for a fixed duration (DIFS), if the medium is idle (i.e. no energy detected above the threshold), then the device can decrement the counter by one for each time slot (lasting 16µs or 9µs) it senses the medium idle. When the counter reaches zero, the device can transmit. If energy is detected while the counter was not zero, then the device should stop until no more energy is detected and resume the decount after the fixed duration sensing (DIFS). If the frame sent is not acknowledged, then the device shall pick a new value but this time it shall double the

[1] Another mechanism based on polling, called point coordinated function (PCF), was also introduced but never encountered success through commercial products.

contention window size to reduce the probability of collision. Figure 5 shows an example of two STAs contending for the medium.

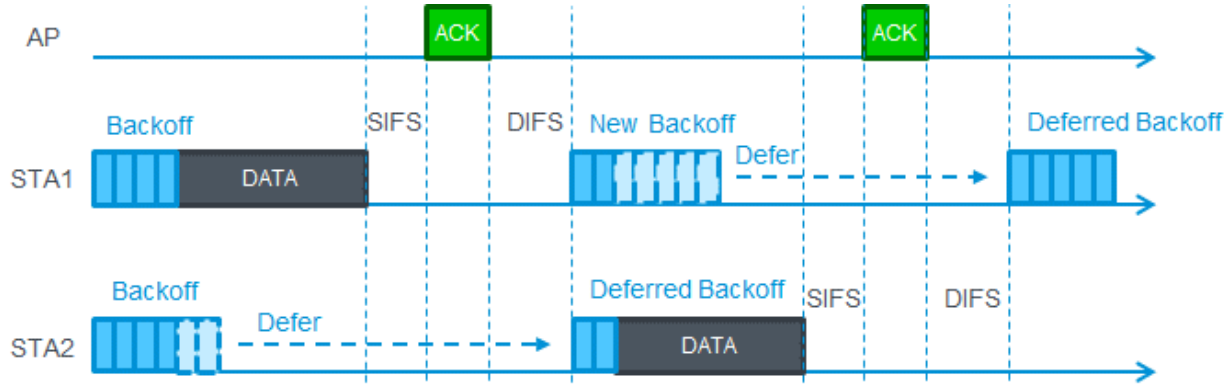

**Figure 5 - Channel access example (pre-11ax)**

Additionally to this energy detection mechanism, Wi-Fi relies also on a preamble detection PHY mechanism. Preamble is a part of each Wi-Fi frame which indicates the duration of the given frame. By successfully decoding it, the sensing device knows when it can resume its sensing if it wanted to transmit. This process is further refined by the fact that if the sensing device decodes the complete frame, then the MAC header contains information on the duration on the ongoing exchange (though the network allocation vector (NAV) field), i.e.; including duration of the next frames to be sent which helps the sensing device even more.

Modifications have been added to this channel access mechanism, in particular through the 802.11e amendment from IEEE 802.11 and the wireless multimedia (WMM) certification from WFA, like aggregation of MAC and service packets (AMPDU, AMSDU respectively) to increase the throughput of the support of quality of service (QoS). Qos is achieved by having different parameters for the contention window size minimum and maximum values and the fixed duration used for sensing (AIFS) leding to an enhanced distributed channel access (EDCA).

More details can be found in the relevant standards and specifications, but the main principle pre-11ax was that all devices should operate using this principle. This means that within in a Wi-Fi network, or basic service set (BSS), the AP and all its associated STAs contend equally for the medium. Note that when QoS is engaged, the AP may a slight advantage in terms of access with default parameters for:

- best effort category: with a maximum contention windows size lower than the one to be used by the STAs,
- voice/video categories: with a lower fixed duration used for sensing.

With more and more devices being deployed at home, AP is competing with more and more STAs increasing collision over the air and congestion. This become a greater problem when other Wi-Fi networks are deployed in the vicinity on the same channel. The networks, called overlapping BSSs (OBSS) have APs but also STAs connected to them. One can easily understand that such crowed environment could lead to bad user experience: all devices fighting for the medium with (almost) the same priority.

### 3.2.2. 11ax Trigger Frame Channel Access

To mitigate this effect, Wi-Fi 6 decided to shift the paradigm of the channel access to make it more AP-centric instead of device-centric for the uplink direction. Instead of having all STAs contending for the medium, only their AP will do so. For example, if we have 2 BSSs with *N* STAs associated to each one, instead of having 2*N*+2 devices trying to access the medium, only the 2 APs will contend for both downlink (DL) and uplink (UL) transmissions.

To coordinate multi-user transmissions in uplink the trigger frame (TF) was introduced. This frame, sent by the AP, schedules the next UL transmissions of all addressed STAs. Figure 6 shows an UL-OFDMA transmission on a 80 MHz BSS where STA1 is allocated the first 20 MHz, STA2 is allocated the second 20 MHz nd STA3 is allocated the remaining 40 MHz. The AP can acknowledge the reception of all uplink transmission with a single ACK frame (called M-BA). In this case instead of three stations contending for the medium, only the AP will to send its trigger frame

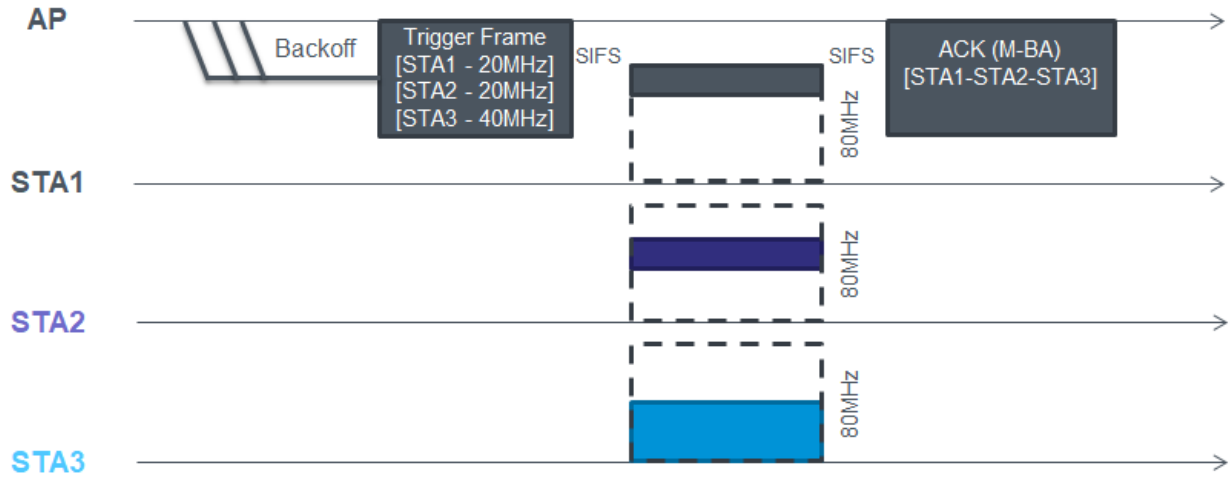

**Figure 6 - Example of a Trigger Frame exchange for UL-OFDMA transmission**

Once engaged at least once in such uplink procedure, the STAs will refrain to access the channel autonomously leaving only their AP in charge of gaining access to the medium for them.

Of course this mechanism can only be applied by Wi-Fi 6 STAs. But as more of them are entering the market right now, legacy devices will also see some benefits: the newer STAs will not contend for the medium but only their APs will. In fact, by choosing to address dense deployment, Wi-Fi 6 true potential will only be achieved if enough Wi-Fi 6 capable device are in the market. So while the trend is in favor of it, we have to remember that the vast majority of the devices at home are still Wi-Fi 4/5-only capable.

## 4. Wi-Fi Challenges at Home

Wi-Fi as a technology has become synonymous to internet both in residential and enterprise environments. From its inception in the late 1990s, Wi-Fi performance has improved by orders of magnitude as shown previously. The use cases supported by Wi-Fi has also significantly changed over the years. In a typical residential environment, Wi-Fi may support an average of 15 devices (2020), and up to 50 devices in a tech centric residence. The use cases supported by now includes internet access, gaming devices, IoT devices, mobile devices with varied used cases. The following sections detail some of the key use cases that Wi-Fi as a technology needs to address

### 4.1. Entertainment

With streaming services that are available, home entertainment has moved to wireless from the earlier fixed media devices like DVD, CD etc. Supporting robust streaming services require dedicated bandwidth to media consumption devices including TVs, Roku, media players and mobile devices used as media consumption devices. Simultaneous media consumption with multiple devices also needs to be supported by Wi-Fi technology. Additional support for newer use devices that support augmented reality(AR) and virtual reality (VR) is also a requirement for Wi-Fi technology.

### 4.2. Smart Home

Smart Home include variety of devices including video devices (video doorbell, cameras) and IoT sensors (Wi-Fi and other technologies). Smart video devices require sufficient bandwidth to support video upload/download. IoT sensors based on Wi-Fi require technology support for long battery life and reliable communication at the edges of the residence.

### 4.3. Internet access

The requirements of internet access to homes has gone up significantly over the years. As mentioned earlier, the number of devices in many US homes is 15 and in many cases approach 50 devices. The increase in devices places significant burden on the network to provide great connectivity to devices. In addition, due to the shared nature of the access medium in Wi-Fi, additional technologies have to be developed to support the increase in number of devices. Multi-dwelling units present additional challenges since the number of devices that are in proximity can be significantly higher than in standalone residences. New technologies and best practices have to be developed to support internet access in multi-dwelling units.

The recent introduction of Wi-Fi 6 should help addressing the previous use cases while the opening of the 6 GHz band should alleviate the most critical issue in MDUs which is congestion due to lack of spectrum.

## 5. How Wi-Fi 6E Will Change Experience in Dense Residential Areas

### 5.1. Experience in Legacy Band

Where Wi-Fi 6 really shines, to the point of improving the user experience by a factor 4, is really in the heavy congested environments with lots of users sending small packets. The trigger frames sent by the AP to schedule uplink transmissions of its associated STAs dramatically reduces the congestion otherwise observed with the classical EDCA mechanism where all STAs contend for the medium.

However, you do not need a dense deployment to see the benefit of Wi-Fi 6 which may be not throughput related. To demonstrate it, we set ourselves in a clean environment (i.e. no neighboring networks). We set up an 11ax 4x4 Wi-Fi 6AP configured on a 80 MHz channel, similar to what is available in the 5 GHz band without having to rely on an DFS mechanism. We associated to it :

- two 2x2 160 MHz-capable Wi-Fi 6 laptops, and
- one 4x4 Wi-Fi 6 160 MHz-capable router set as a station (think of it as an extender for instance).

The devices are close to the AP with equivalent received power. Figure 7 shows our setup which is an interference free one.

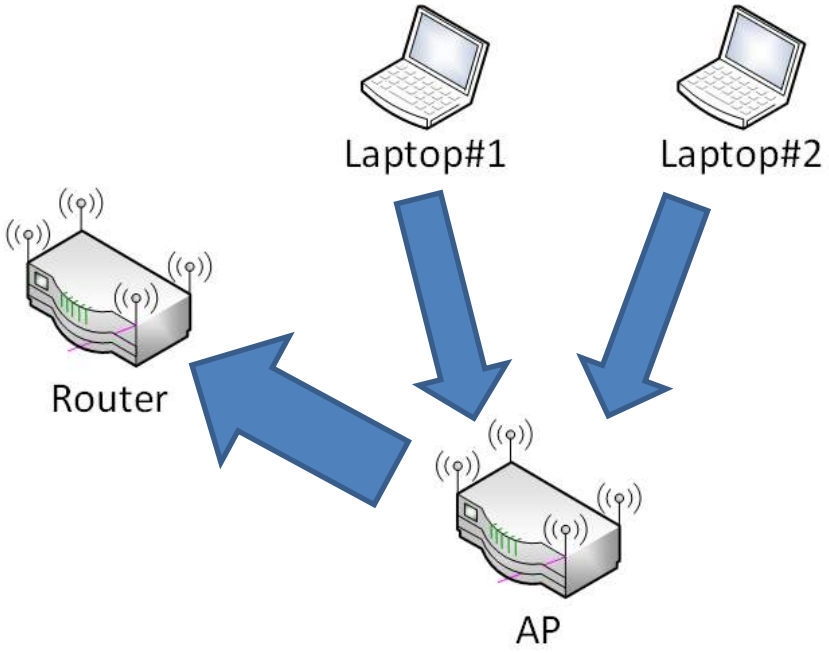

**Figure 7 - Interference Free Setup**

To evaluate any benefit of Wi-Fi 6 in such scenario, we run throughput tests (using IxChariot) when setting the AP first in Wi-Fi 5 mode then in Wi-Fi 6 mode. For both runs, we use the following traffic profiles at the same time:

- a UDP uplink transmission with a throughput target of 250 Mbps for each laptop,
- a UDP downlink transmission with a throughput target of 500 Mbps for the router.

UDP is used to show to see Wi-Fi 6 benefits at MAC/PHY layer without any recovering protocol from upper layers. We use the same quality of service for all traffics (Best Effort).

### *5.1.1. Inteference free setup*

Table 1 shows the average throughput obtained after 1 minute of traffic.

**Table 1 - Wi-Fi 5 vs Wi-Fi 6 Average Throughput (Interference Free Setup)**

| Device | Traffic Direction | Throughput Target (Mbps) | Wi-Fi 5 (Mbps) | Wi-Fi 6 (Mbps) |
|---|---|---|---|---|
| Laptop #1 | Uplink | 250 | 238 | 209 |
| Laptop #2 | Uplink | 250 | 156 | 217 |
| Router | Downlink | 500 | 491 | 494 |

We see that in both mode downlink traffic is almost the same, the 500 Mbps target is almost honored for Wi-Fi 5 and Wi-Fi 6. However, the uplink results show a different story. In Wi-Fi 5 mod, one laptop is getting significantly more throughput (238 Mbps) than the other (156 Mbps). The radio conditions being the same, this demonstrates that some STA implementations could be more aggressive than others in their channel access mechanism (with use of frame bursting for instance). In Wi-Fi 6 however, both STAs have

equivalent uplink throughput (209 Mbps vs 217 Mbps) which is controlled by the AP. Both do not reach the target throughput (250 Mbps) though.

The full story is shown by the throughput curves during the time which are given in Figure 8 and Figure 9 for Wi-Fi 5 and Wi-Fi 6, respectively.

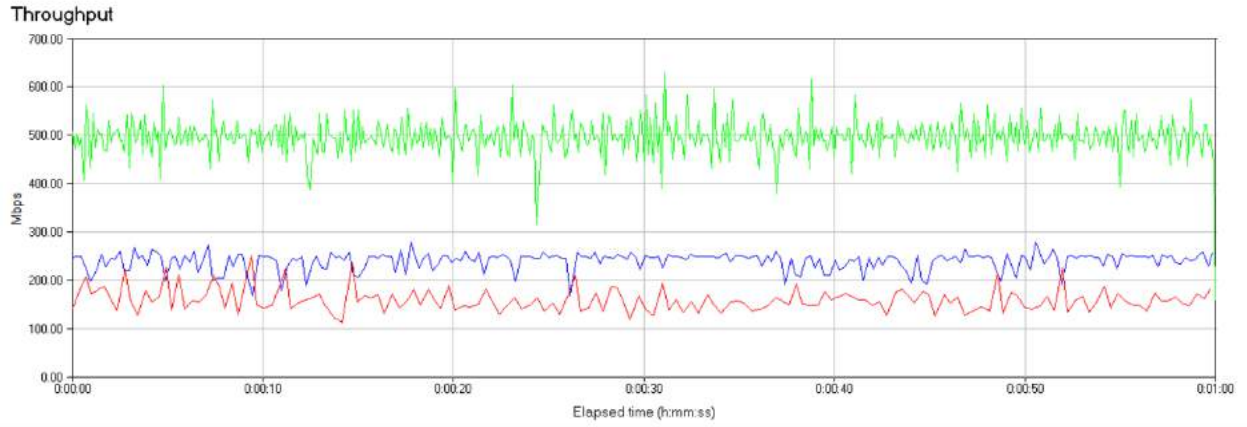

**Figure 8 - Wi-Fi 5 Throughput Evolution (Interference Free Setup)**

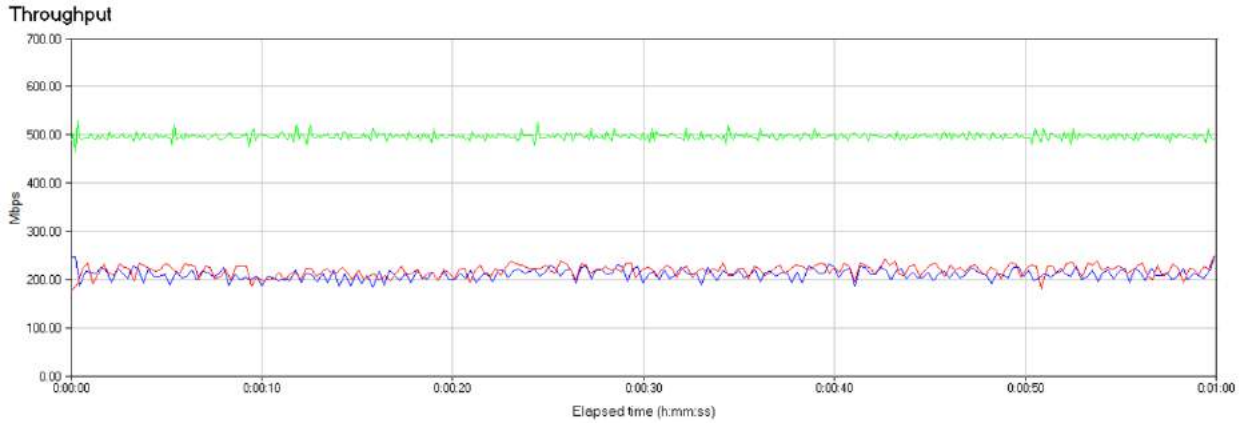

**Figure 9 - Wi-Fi 6 Throughput Evolution (Interference Free Setup)**

All Wi-Fi 5 curves are more impacted by the lack of coordination between the three sources of traffic which all contend to access the medium. Wi-Fi 6 curves are less prone of such variation since only the AP controls the traffic by triggering the two laptops and instructing them to use UL OFDMA transmissions while it serves also the third device in downlink. One can see that both STA curves (blue and red) are almost the same leading to a better fairness. Ultimately, this will also result in better latency for all three devices with a service delivery more stable thanks to Wi-Fi 6.

### *5.1.2. OBSS Setup*

In an MDU type of deployment however, you are usually not alone on an 80 MHz channel. To see the effect, we introduced an interfering network on the same channel as our setup (OBSS) but at a reasonable distance from it. In the lab, we reduced the transmit power of such interferer to simulate distance. On this

setup we run a continuous TCP full-buffer traffic (iperf) to create a Wi-Fi noise to which our setup has to defer (mainly due to preamble detection).

We ran the same experiment in both Wi-Fi 5 and Wi-Fi 6 to check the effect of OBSS in way which is closer to what people are experiencing. Results are given Table 2, Figure 10 and Figure 11.

**Table 2 - Wi-Fi 5 vs Wi-Fi 6 Average Throughput (OBSS Setup)**

| Device | Traffic Direction | Throughput Target (Mbps) | Wi-Fi 5 (Mbps) | Wi-Fi 6 (Mbps) |
|---|---|---|---|---|
| Laptop #1 | Uplink | 250 | 132 | 168 |
| Laptop #2 | Uplink | 250 | 68 | 176 |
| Router | Downlink | 500 | 479 | 486 |

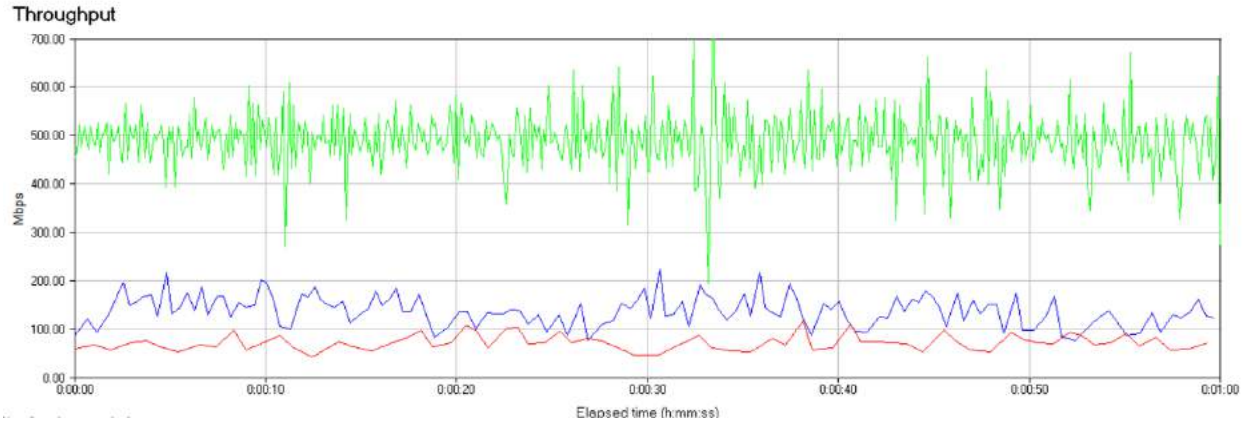

**Figure 10 - Wi-Fi 5 Throughput Evolution (OBSS Setup)**

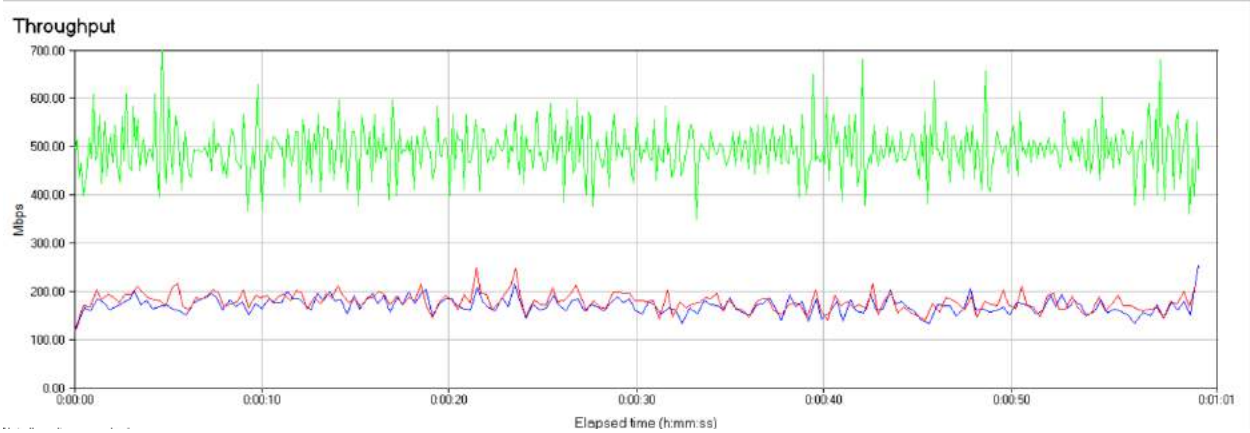

**Figure 11 - Wi-Fi 6 Throughput Evolution (OBSS Setup)**

As one can see, both setups are affected by the OBSS and none could reach the throughput target, but the Wi-Fi 6 one offers more stability to both uplink transmissions with fair access of the spectrum to both of them.

## 5.2. The 6 GHz Experience

With the recent FCC decision to open the 6 GHz band to wireless devices, more than 1.2 GHz band will be made available for Wi-Fi 6E I nthe US. It is envisaged that residential AP deployment may choose to use low-power indoor model to avoid the access to a geolocation database for automatic frequency selection (AFC). Under such conditions, the whole 6 GHz band is available without any constraints à-la DFS. To put it simply, seven 160 MHz channels will be available for a Wi-Fi 6E AP to choose from, greatly reducing the risk of OBSS really affecting the performance.

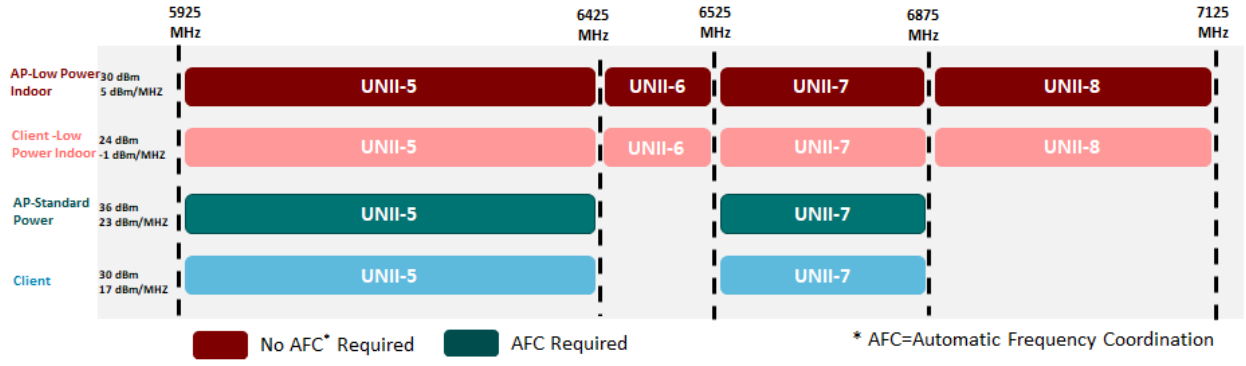

**Figure 12 - 6 GHz Spectrum (US)**

In dense residential deployment, most of the congestion/collision will then come from inside the BSS itself. Higher frequency means more wall attenuation and with 7 channels to choose, overlapping should not be experienced in the near future on this band. With no legacy devices present, STAs will most likely choose to be controlled by the AP for a better user experience.

It is envisaged to have 160 MHz channel bandwidth as the norm in 6 GHz band. If we take our previous interference free setup to make it operate in a 6 GHz-like environment, then we can setup our AP with a 160 MHz channel bandwidth and repeat our measurements. Table 3 shows that in this 6 GHz-like environment targets are reached on average for the three devices (less than 2% deviation) while Figure 13 shows the throughput evolution and its stability

**Table 3 - Wi-Fi 6 Average Throughput (6 GHz-like Setup)**

| Device | Traffic Direction | Throughput Target (Mbps) | Wi-Fi 6E (Mbps) |
|---|---|---|---|
| Laptop #1 | Uplink | 250 | 168 |
| Laptop #2 | Uplink | 250 | 176 |
| Router | Downlink | 500 | 486 |

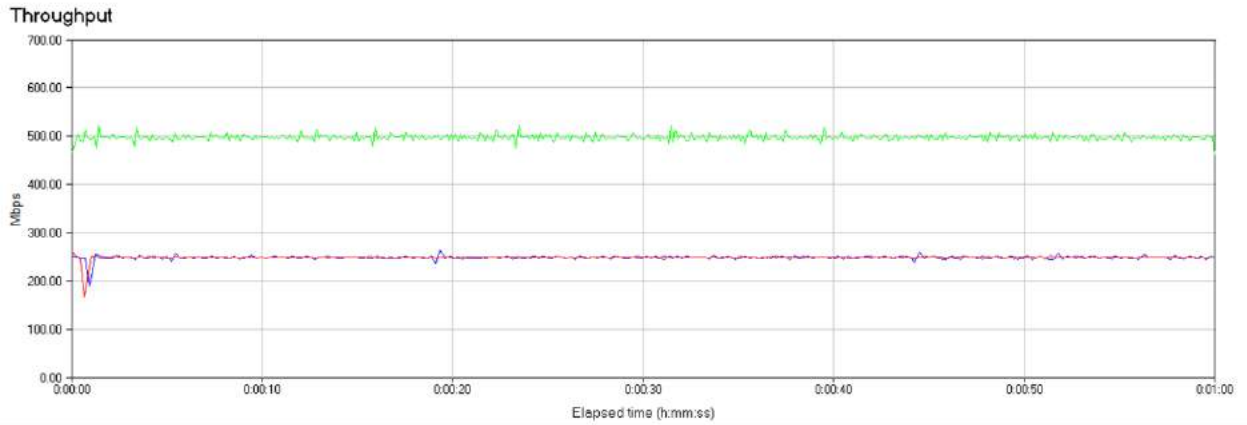

**Figure 13 - Wi-Fi 6 Throughput Evolution (6 GHz-like Setup)**

6 GHz opening is also considered in Europe, but on the lower 500 MHz band first. Recent decision from Ofcom UK to open it by end of this year provides three 160 MHz channel to Wi-Fi 6E devices for operation. While this is less than what the US are opening right now, the key advantage of Wi-Fi 6 are still there to improve experience at home.

# 6. Conclusion

In this paper we reviewed the evolution of Wi-Fi technologies over the years and the challenge it should address in dense residential scenarios. If the introduction of Wi-Fi 6 technology certainly helps in providing unique features to improve user experience in dense deployment, the wireless systems are still bounded by the spectrum available to them. Fortunately, the recent opening of the 6 GHz band in the US, paving the way to others countries (Europe, South Korea, …), allows Wi-Fi 6E to really be able to change user experience at home, even in dense areas since Wi-Fi 6 key features are more effective in Wi-Fi 6 only ecosystem. Indeed, IEEE 802.11 operation on 6Ghz band is restricted to Wi-Fi 6E devices only (i.e. no Wi-Fi 4/5 or even 11b legacy to take into considerations).

# 1. Introduction

How does one go about optimizing the most extensive public Wi-Fi network in the nation? That was the task we were asked to perform. Comcast XfinityWiFi network is a vast Wi-Fi overlay network, with close to 21M access points. These Access Points are deployed outdoors, inside small and medium businesses, and in subscriber's homes. The purpose of this ongoing project is to improve the customer experience of the XfinityWiFi network and increase the overall traffic usage, and increase the data offload of Xfinity Mobile users over the XfinityWiFi network.

The fundamental impact when customer faces a bad experience on Wi-Fi is that they may decide to turn off Wi-Fi on their mobile devices and may use valuable LTE data. While they may do so while outdoors, our data shows that sometimes these customers will continue to use LTE data while in their own homes and would not connect to their home Wireless Gateway provided by Comcast.

Some of the challenges facing the optimization of XfinityWiFi network, apart from the sheer size, were the fact that no central or distributed controller manages and coordinates the system from a Wi-Fi perspective. The Access Points are not aware of each other and have no communication path between them. The network was never designed for complete coverage or even to allow seamless roaming between Access Points. Also, over 98% of the network comprises of residential Access Points that act as a Home Hotspot (HHS). We had minimal control over what Wi-Fi configuration changes can be applied to these devices.

The first step we took was to break the optimization of a nationwide network into smaller, more manageable zones. We took several of such zones and used them to prove the methods, processes, and tools. We broke the process into multiple iterations, using traditional RF planning, measurements, and predictive tools to test after each iteration. Thus, establishing a baseline and iterative improvements as we progressed.

In parallel, the CommScope team developed a Big Data pipeline to ingest data from multiple sources of measurement; Multiple Network telemetry data, Access Point telemetry, enriched with geographic information data. This Big Data Analytics platform is turning discrete sources of data into powerful insights and recommendations.

This paper will describe in detail the methods, processes, and tools we developed to address this challenge and the results observed so far.

# 2. Testing and Methodology

Working with Comcast's XfinityWiFi team, we agreed to address the problem of optimization of this nationwide network by breaking it into smaller geographical areas. The logic behind this approach is the fact that it is local radio interferences and environmental conditions that impact Wi-Fi Access Points (AP).

Comcast team selected several outdoor areas, with different characteristics, all had a mix of outdoor, and indoor APs; the indoor APs were a combination of the residential home hotspot (HHS) and business hotspot (SMB). Each of the selected areas had a Primary and Secondary zone. Manual testing were conducted in the primary zones.

We used different approaches for the optimization per designated primary zone:

1. Tuning Zone – No physical change to an existing outdoor network. (e.g., No adding of new Access point). Only modifications allowed were configuration changes.
2. Densification Zone – Allow changes to the existing outdoor network by adding new outdoor Access Points. Include configuration changes.
3. Greenfield Zone – A complete redesign of the outdoor access point deployment. Include configuration changes.

We established a Test Methodology and perform identical RF testing in each of the Primary zones. Third-party testers were using a combination of mobile clients (iOS and Android) to perform walking and stationary tests. Conducting standard RF measurement and Over the Air packet capture tools (Ekahau, Omnipeek, Accuver (Android only)). They measured RSSI, SNR, Noise Floor, and Throughput test while walking and in stationary locations. The tests establish baseline conditions in each Primary zone. The same testing repeated after each iteration and produced a detailed test report. A team of CommScope experts analyzed the raw data, and results and suggested modifications for the next iteration.

**Figure 1 Breaking up the problem – optimization zones (Primary Zones are highlighted)**

The main tools used in the iteration process, based on the limitations of the network design, were fundamental Wi-Fi configuration changes such as RF channel planning, channel width, transmit power, and modification of Wi-Fi cell size. In the Densification and Greenfield zones, we were able to add AP to ensure better coverage, and in the Greenfield even created an overlap between the outdoor AP.

Note, no changes were made to any of the indoor hotspots, residential or SMB.

Below is a visual description of the activity (connected clients and tonnage of usage) of the network during several months before the COVID-19 pandemic.

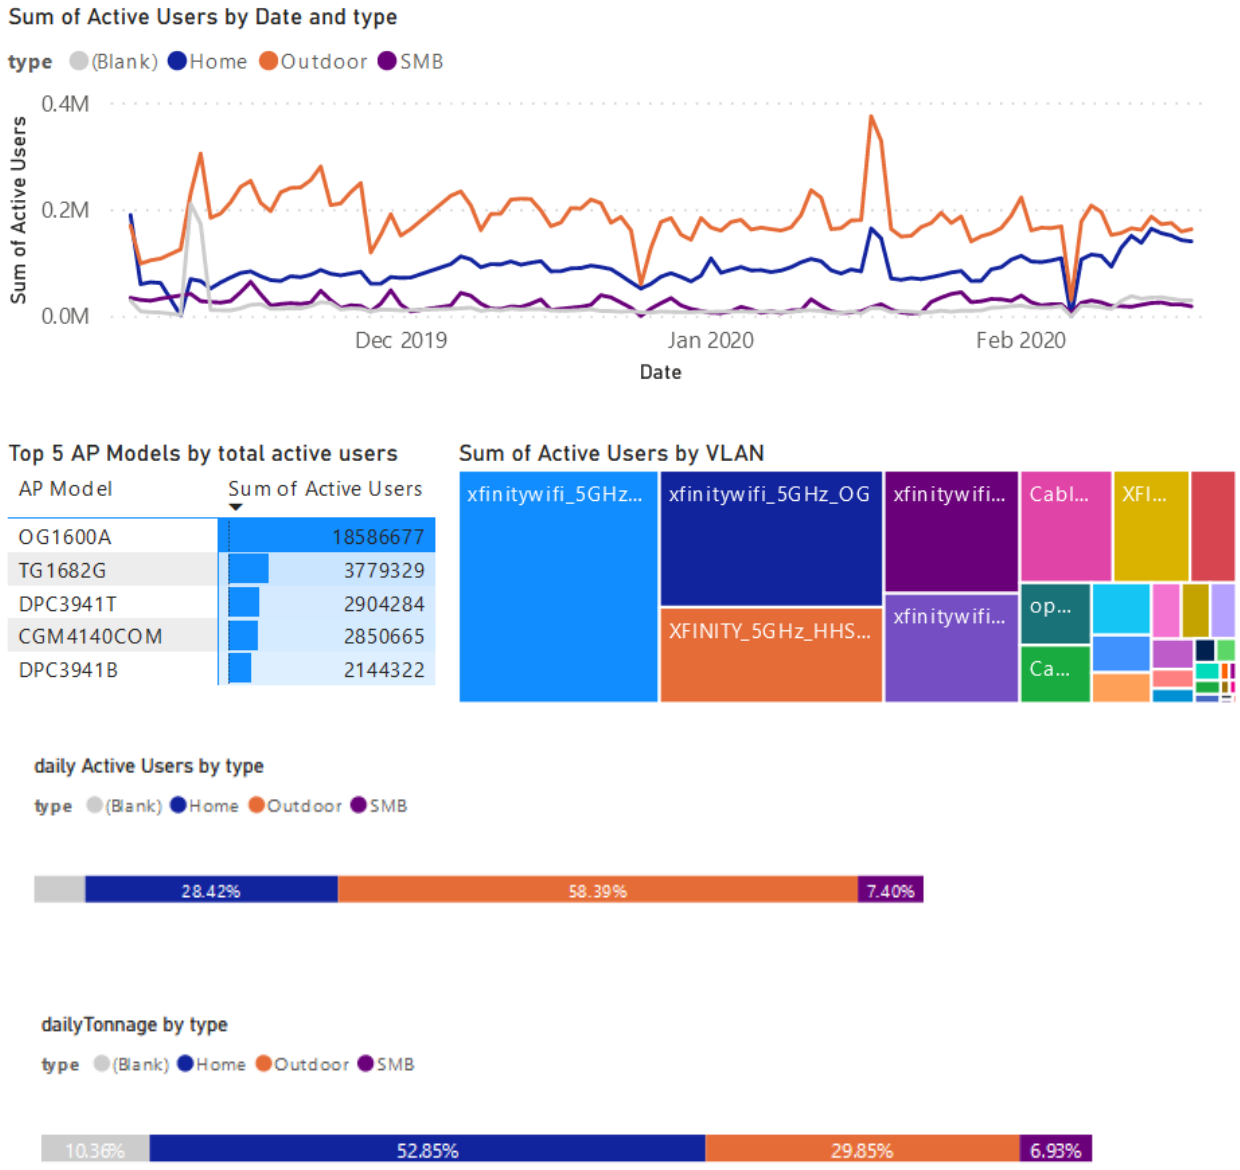

**Figure 2 High-Level view of the usage of XfinityWiFi network**

## 2.1. Manual vs. Automated Methodology

The problem with the method and testing methodology described above is that it does not scale. It relies on testers walking the areas, and a manual process that cannot be scaled nationwide.

Our proposed solution was to augment manual RF testing with measurements collected from the network. This includes using Netscout network probes reports and collecting relevant data from outdoor AP. This approach obtained data from network assets, independent of testers walking the areas. And thus, has the advantage of looking at real customer data vs. test client's data. To collect and make use of all this data, we created a Big Data Analytics platform and pipeline to ingest, and analyze different sources of data, cross-correlate multiple measurements into a comprehensive view. And use the manual testing process to "verify" our automated network results and insight.

The main goal of the big data approach and tools is to show how we will be able to answer the following questions:

- How to optimize and automate the process of "making XfinityWifi network better"?
- How to identify where and how the currently deployed network should be augmented?
- Help identify where Comcast should deploy the new XfinityWifi network/APs to offer more offload opportunities to Xfinity Mobile customers.
- Identify Bad Client Experience events, characterize and group them into subcategories
- Show some correlation between Netscout records and Wi-Fi RF (SNMP logs) records relating to the Bad Client Experience events and subcategories.

Several Machin Learning methods and algorithms were used on the existing data. Clustering, anomaly detection and co-occurrence were used to analyze the existing network; Identify areas of over coverage, under coverage, patterns of client movement across the network deployed in the zone and more.

## 2.1. Current Sources of Data for Analytic system

All the traffic in the XfinityWiFi network traverses the network over softGRE tunnels that are established between the Access Point (AP) and the Wireless Access Gateway (WAG). By placing Netscout probes in the network close to the WAG, which monitors all TCP traffic inside the tunnel; The Comcast team was able to collect and report in 5-minute intervals several TCP measurements.

In addition to the TCP traffic reports generated by the network probes, we collected measurements from the outdoor APs that represent the Wireless performance. The outdoor Wireless Access Points reported a vast number of Wi-Fi RF and network statistics in 15-minute intervals.

We enriched the information provided by Netscout and the APs with geographic information about the AP location, either by GPS coordinates or other GIS data.

**Table 1 Sources of Data**

| Devices | Information | Source |
|---|---|---|
| Device location | Geo Location | Google Earth map (KMZ) and GPS coordinates |
| Outside plant location | Geo Location | Google Earth map (KMZ) |
| Ruckus Outdoor AP | Usage and Statistics | Netscout and SCI/Druid |
| OG1600 Outdoor AP | Usage and Statistics | Netscout and SNMP logs |
| Indoor HHS | Usage and Statistics | Netscout only |
| Indoor SMB | Usage and Statistics | Netscout only |

The above different sources of data accumulated to 250+ days of data, 4000+ geographic locations, 10k-100k records per site per day. 10 TB of compressed data/month. 4 disparate data sources (csv, json, mib, log, kmz). With different types of triggers, event-based, 5 minutes, 15 minutes, and daily time windows.

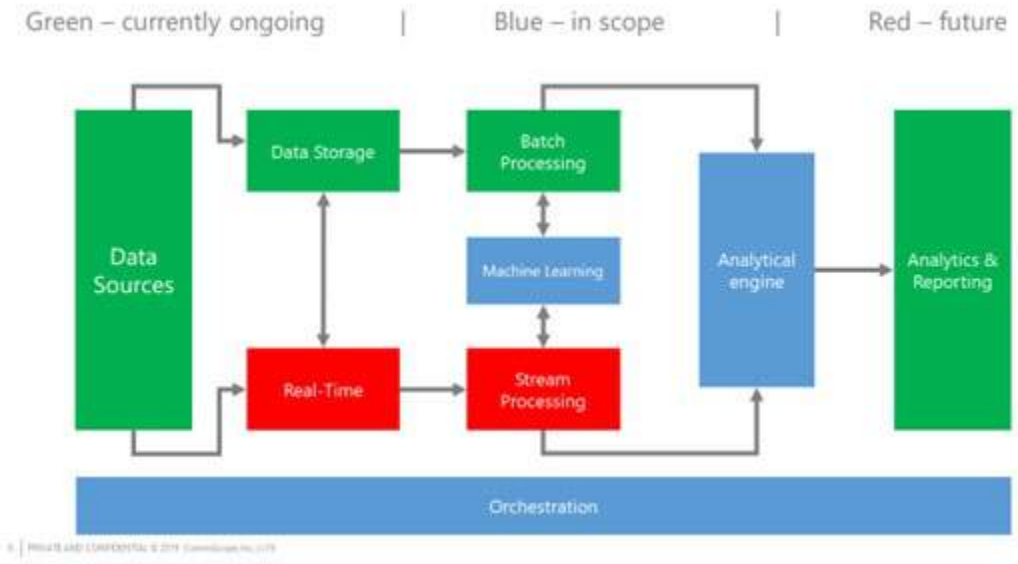

**Figure 3 High-Level description of a big data analytics platform**

## 3. Defining and Measuring User Experience

One of the main objectives of the project is to improve the overall Wi-Fi customer experience. But how do we define good customer experience? Customers usually do not know or care about any of the RF parameters that govern wireless communication. Often, the user's subjective assessment of the quality of the service boils down to a few essential characteristics.

- Connection reliability, is the connection easy? Is it fast? Is it repeatable?
- Latency, do I get a snappy response from the network?
- Throughput, is there an adequate minimum throughput guaranteed?

Our challenge is how to quantify these subjective assessments, by translating them into parameters we can measure and control.

From the network side, we can measure many aspects that enforces the above assessment of quality:

- Packet loss and packet retransmission
- Airtime utilization
- Throughput
- Latency
- Consistency

Assuming we can measure, how do we know what constitutes Good or rather Bad Customer Experience? For that, we need to understand the use case and expectations from the service this network provides.

## 3.1. Use Case for XfinityWiFi network

There are fundamentally two distinct use cases for the XfinityWiFi network. It may serve as a well-known "Guest Network" for visitors that come into your home or business. In this case, residential or business owners do not have to create a unique guest network and remember the credentials that would allow the visitor to join the network. All the access points broadcast the same SSID name (aka. Network name), and all Xfinity customers can join them for free. These users tend to be stationary users with mobile or handheld devices and laptops.

The second use case serves customers that are mainly outdoor; these are pedestrians with mobile or handheld devices. As such, the XfinityWiFi Network aims to create a continuous coverage in designated outdoor areas. And serve these pedestrian users' data applications such as web browsing, video and audio streaming, IP voice application such as WhatsApp, Facetime, etc.

By having a good understanding of the above use cases, we can provide a good foundation for defining the Key Performance Indicator (KPI) that will be measured, their expected values and acceptable range.

## 3.2. Key Performance Indicator

Netscout data provided by the Comcast team collected and reported in 5-minute intervals the following TCP measurements:

DHCP Time- Measure how quickly a customer can get an IP from the network by recording the time it takes to complete a DHCP complete DORA (discovery, offer, request, and acknowledgment) exchange.

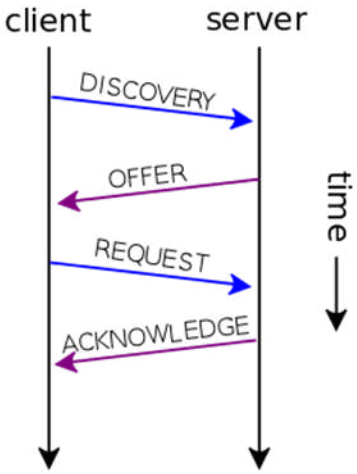

**Figure 4 DHCP DORA 4-way exchange**

Client Latency- Measures the initial TCP 3-way handshake between client and server and calculates the client-side latency (time elapsed between the Syn-Ack and Ack)

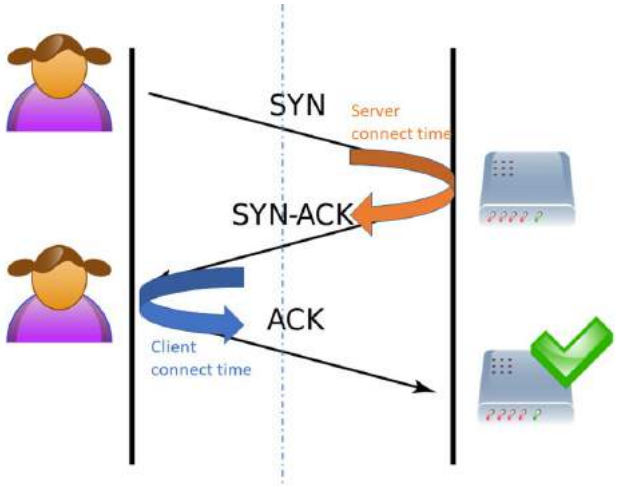

**Figure 5 TCP 3-way handshake**

Average Throughput- records the TCP throughput in each direction (Upstream and Downstream) within a 5-minute measuring interval. Throughput is calculated by dividing the sum of bytes in each direction by the number of milliseconds of activity in the corresponding direction.

TCP Retransmission- Number and percentage of TCP packets that were retransmitted in each direction i.e, from the client towards the server, and from the server towards the client.

While the first two measurements (DHCP Time and Client Latency) only represent a brief snapshot in time, the other two are ongoing and provide much more detailed measurement of all active TCP sessions between the client and the network.

The Average Throughput report is also used to sum the total of traffic (Tonnage) that traverse the network over a period.

In addition to the TCP traffic reports generated by the network probes, we collected measurements from the outdoor APs that represent the Wireless performance.

The outdoor Wireless Access Points reported a vast number of RF and network statistics in 15-minute intervals. Below are some of the relevant measurements collected.

**Table 2 Example SNMP information elements provided by the Access Point**

| Group | Information Element | Description |
|---|---|---|
| Client information | Client IP address | |
| | Client MAC Address | for all clients associated with the AP |
| | Client State | Authenticated, Associated, Authorized, Secure or Unsecure |
| | Client RSSI | the last Received Signal Strength Indicator (RSSI) of the wireless client device. |
| | Min RSSI | the minimum RSSI of the wireless client device through the 15-minute interval. |
| | Max RSSI | the maximum RSSI of the wireless client device through the 15-minute interval. |
| | Client Last Transmit Rate | the transmit rate of the last MPDU sent to the client |
| | Client Last Receive Rate | the receive rate of the last MPDU sent from the client |
| Active Wi-Fi Channel quality statistics | Min Noise Floor | the minimum noise floor (dBm) on the serving channel across the measurement interval. |
| | Max Noise Floor | the maximum noise floor(dBm) on the serving channel across the measurement interval. |
| | Median Noise Floor | the median noise floor (dBm) on the serving channel across the measurement interval |
| | Activity Factor | percentage of airtime the radio was actively utilizing the channel across the measurement interval |
| | Channel Utilization | percentage of time the medium was utilized on the channel across the measurement interval |

| | | |
|---|---|---|
| | Retransmission | percentage of packets that had to be retransmitted during the measurement interval |
| | Busy by Other Radio | percentage of each second that the transmitter is busy by another Radio |
| | Average Tx Mod Rate | a weighted average of the Tx modulation rate for data MPDU in Mbps |
| | Average Rx Mod Rate | a weighted average of the Rx modulation rate for data MPDU in Mbps |
| Radio based statistics | Radio Tx OK | number of successfully transmitted MSDU (data MPDU) |
| | Radio Tx Fail | the number of hardware Tx errors and excessive retries for MSDU (data MPDU). |
| | Radio Rx OK | number of Ethernet frames forwarded to stack by wifi MAC |
| | Radio Rx Fail | number of data MPDU missed by sequence number gap |
| | Tx MCS | the number of Data MPDU transmitted for each MCS (modulation and coding scheme). |
| | Rx MCS | the number of Data MPDU received for each MCS (modulation and coding scheme). |
| SSID based statistics | SSID Tx OK Bytes | per SSID number of bytes in successfully transmitted MSDU (data MPDU). |
| | SSID Tx OK | per SSID number of successfully transmitted MSDU (data MPDU). |
| | SSID Rx OK Bytes | per SSID number of bytes in Ethernet frames forwarded to stack by wifi MAC. |
| | SSID Rx OK | per SSID number of Ethernet frames forwarded |
| | SSID Successful Auth | per SSID number of wifi clients successfully authenticated |
| | SSID Auth Failure | per SSID number of wifi client's authentication Failures |

# 4. Identifying Bad WIFI Client Experience (Bad WCX)

To provide a better user experience, we had to define what does “good user experience” means. And therefore, what are the bad cases we wish to identify, eliminate, or correct.

DHCP Time and Client Latency only represent a brief snapshot in time; however, they provide insight into the Connection reliability and the perceived latency. We were aiming for a fast Authentication (802.1x or Open SSID), and fast DHCP response (less than 1Sec). These parameters of Authentication and DHCP response, are entirely under the network operator control. As a rule of thumb, we also defined expectable latency as less than 150ms.

In order to measure latency, throughput, and reliability on an ongoing basis, we used the following criteria’s as “good user experience”:

1. Less than 4% of TCP packet retransmission,
   Measurements conducted by Comcast identified 4% as the threshold where clients start noticing network delay and slowness.
2. A minimum downstream throughput in the coverage areas,
   We were aiming at HD Video quality inside cell coverage (>5Mb/s) and SD Video quality at cell edge (>3Mb/s).
   Note, Outdoor AP may serve up to 100 active clients per Radio, 50 per SSID.

Evidence of Bad WIFI Client Experience (Bad WCX) can be gleaned from records of a high percentage of TCP packets retransmission. Another proof of Bad WCX is slow average throughput for lengthy sessions. We should look for a combination of indications from the Netscout reports of the same client MAC at the same 5 min bin.

## 4.1. Criteria’s of Bad WIFI Client Experience (Bad WCX)

1. Percentage of Server Retries ≥ 4% AND Number of packets retries > 2 (packets)
2. Percentage of Client Retries ≥ 4% AND Number of packets retries > 2 (packets)
3. Video sessions that are longer than 2 minutes AND average downstream throughput less than 3Mbps

## 4.2. Types of Bad WCX events

Looking at the total Bad WCX events based on the above criteria, we can group them into different types of events, which may require different resolutions.

1. Moving Client
   - records identify client on Multiple AP during the 5 min bin
2. Client on a Single AP, Single VAP/VLAN.
3. Client on a Single AP, Multiple VAPs/VLAN.

Note – in order to create this classification of events; we would need to add within the 5min bin all records of the client that experienced a Bad WCX within that 5min bin.

### 4.2.1. Example of identifying type of Bad WCX

As seen in Table 3 below. At 11:45 The client 48:BF:6B:92:FB:D8 is connected to an OG1600 with AP_MAC_Address of a8:9f:ec:da:b2:6a, experienced a Bad WCX while connecting to the 5GHz xfinitywifi VAP. However, the same client also registered on the 2.4GHz VAP during the same time. And exchanged most of the traffic on this VAP. This is a case of **Client on a Single AP, Multiple VAPs/VLAN**

At 13:50 and 14:05 the same client experienced 2 Bad WCX events. These are cases of the **client on a Single AP, Single VAP/VLAN.**

At 16:10 we see the same client registered on multiple AP, experiencing 2 Bad WCX events. On TG34862G with AP_MAC_Address 88:ef:16:dd:b0:01. And on TG862G AP_MAC_Address cc:a4:62:af:68:d4. This is a case of **Moving Client**

**Table 3 Example of classification to the type of Bad WCX**

| Time Line | 5 Min | MAC Address | AP Model | VLAN | | TCP_retries_From_Server | From Server Packets Count | %TCP Server Retransmission | TCP_retries_From_Client | To Server Packets Count | %TCP Client Retransmission |
|---|---|---|---|---|---|---|---|---|---|---|---|

## 4.1. Correlating Bad WIFI Client Experience with WIFI SNMP Data

Utilizing telemetry, currently in the form of SNMP polls or Ruckus SmartCell Insight (SCI) reports. Allows us to make measurements without the need to have testers on the ground. Furthermore, collecting data in small intervals, over a long period enable us to identify trends in behaviors. And avoid any transient events that may impact test results of a specific day.

The main trends we were looking for were Channel Utilization, Activity Factor, Wi-Fi Retransmissions, and calculated Average Modulation Rate.

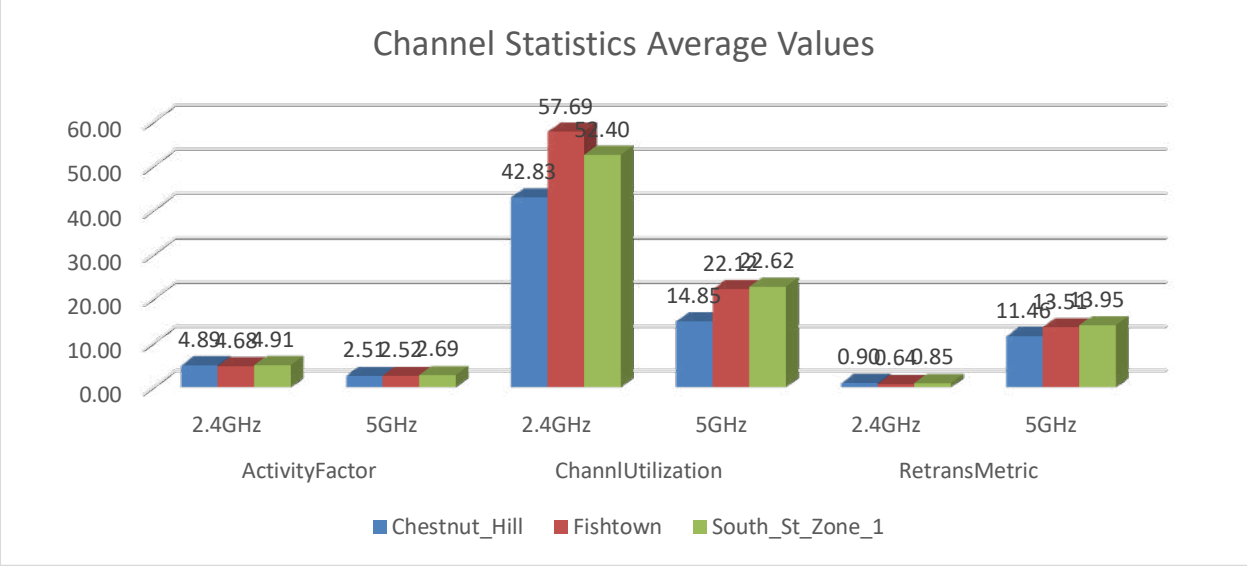

Figure 6 Average Channel Health Statistics

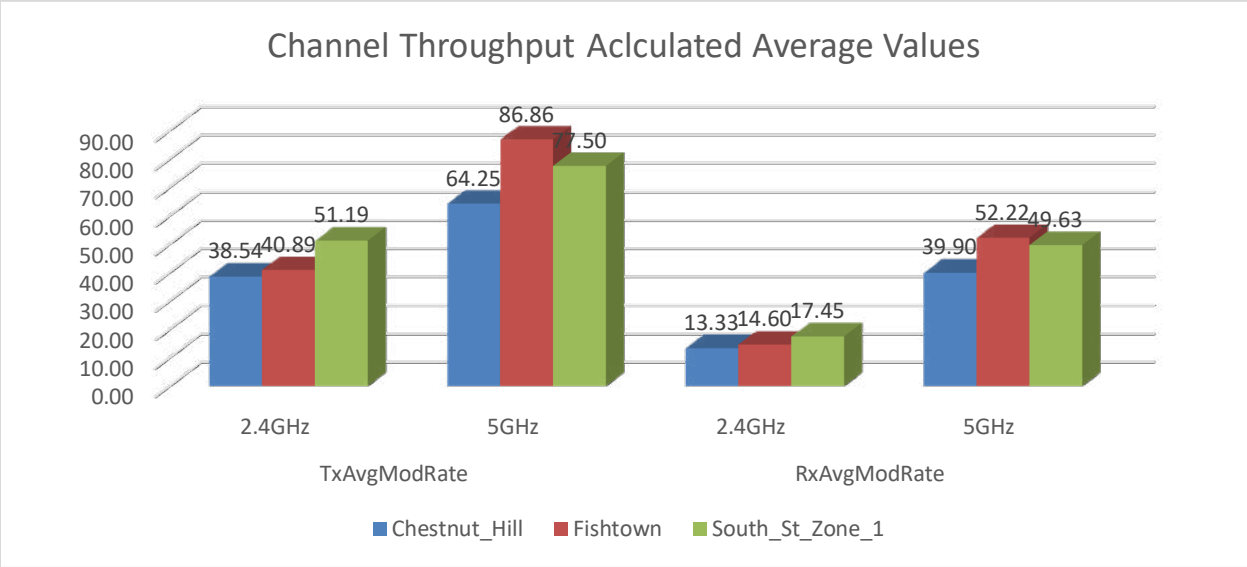

**Figure 7 Average Calculated Channel Throughput**

For each of the areas, we also identify the outliers AP. This insight helped in the channel planning, as well as with decisions about turning 2.4GHz radio off entirely in some cases.

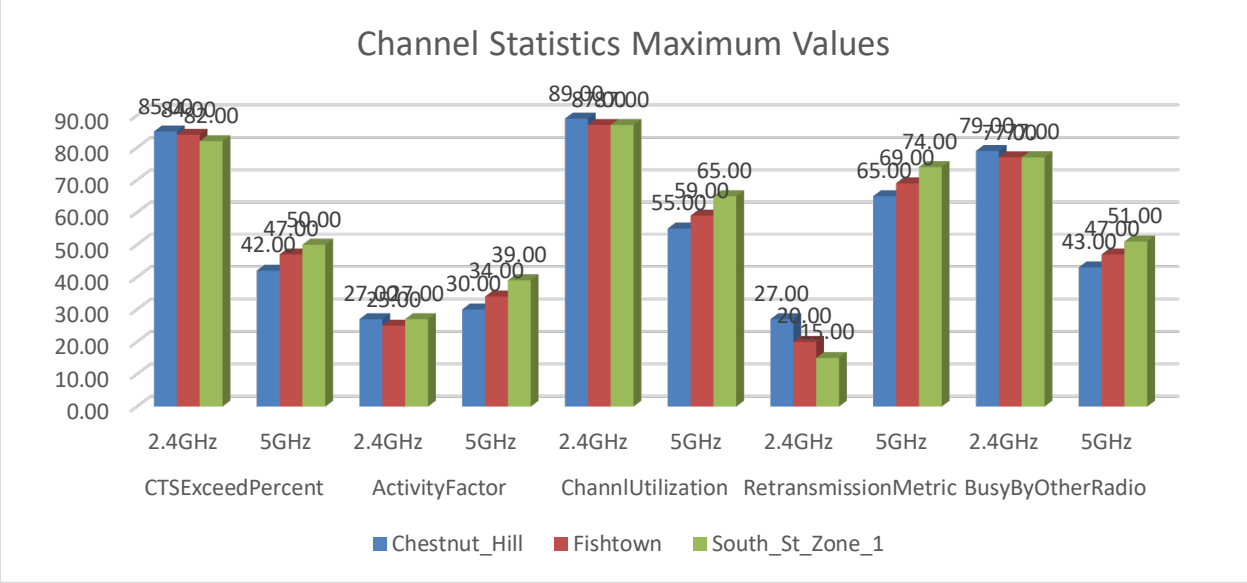

**Figure 8 Outliers of Channel Health Statistics**

One of the indications that would provide insight into the way client interact with the AP, in terms of good Signal to Noise Ratio (SNR), Signal Strength Indicator (SSI), and throughput; is the distribution of Data MPDU across the different Modulation and Coding Scheme (MCS) indexes.

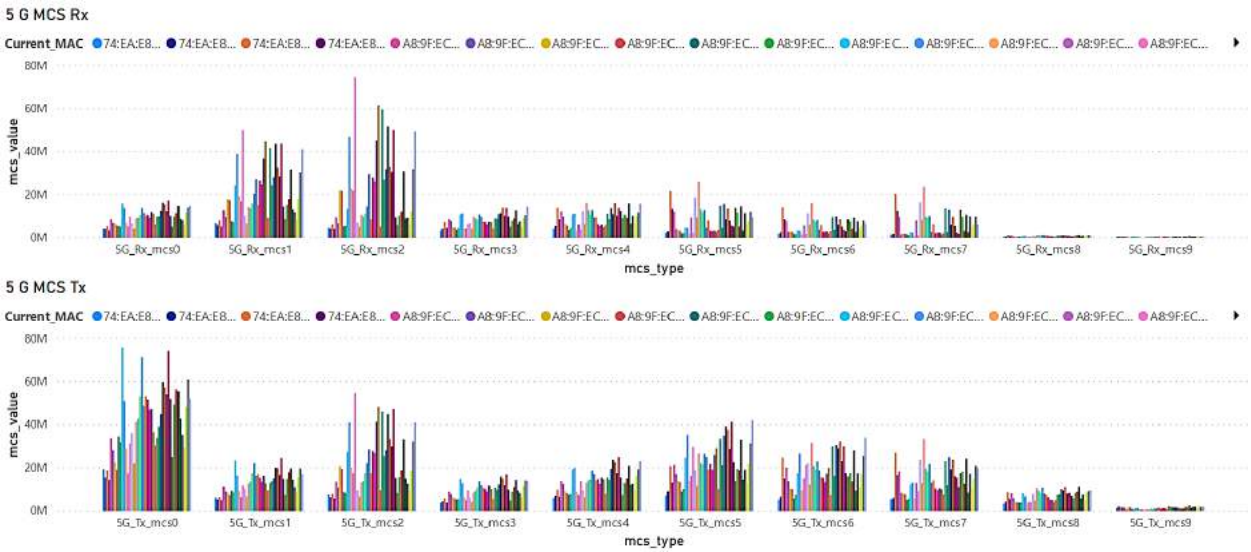

**Figure 9 5GHz Radio Data MPDU distribution across MCS**

# 5. Current Results and Findings

## 5.1. Baseline state

First, we needed to establish the percentage of sessions with Bad WCX out of all client sessions.

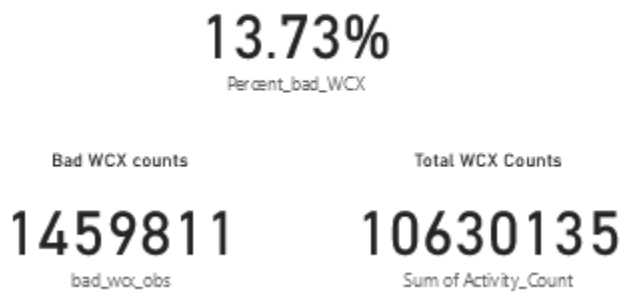

Figure 10 Percentage of sessions with Bad WCX out of all client sessions – Baseline state

Looking at the breakdown of Bad WCX based on the three types defined above. We can see that moving clients represent the smallest group of bad experience events. Even when looking at outdoor AP exclusively, this non-intuitive fact holds.

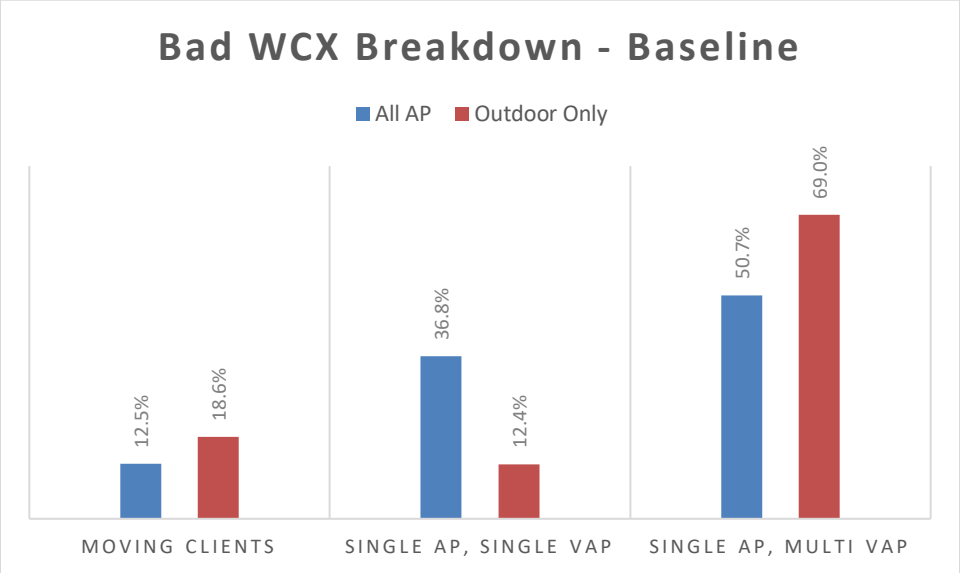

Figure 11 Bad WCX breakdown per type – Baseline state

A second insight is that there is no real difference in the Bad WCX due to TCP retries when we look at the percentage of retries compare to all TCP packets in that direction. As expected, the traffic patterns are heavily skewed in favor of downstream. In other words, much more traffic is going from the server towards the client. At first glance, this may be non-intuitive, given the differences in transmit power and receive sensitivity between the client and the AP.

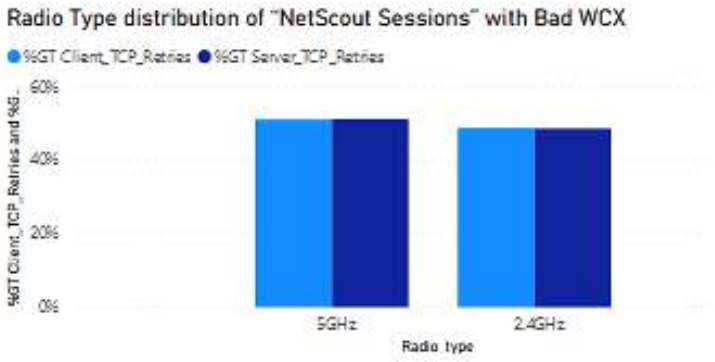

Figure 12 Bad WCX distribution per Radio – Baseline state

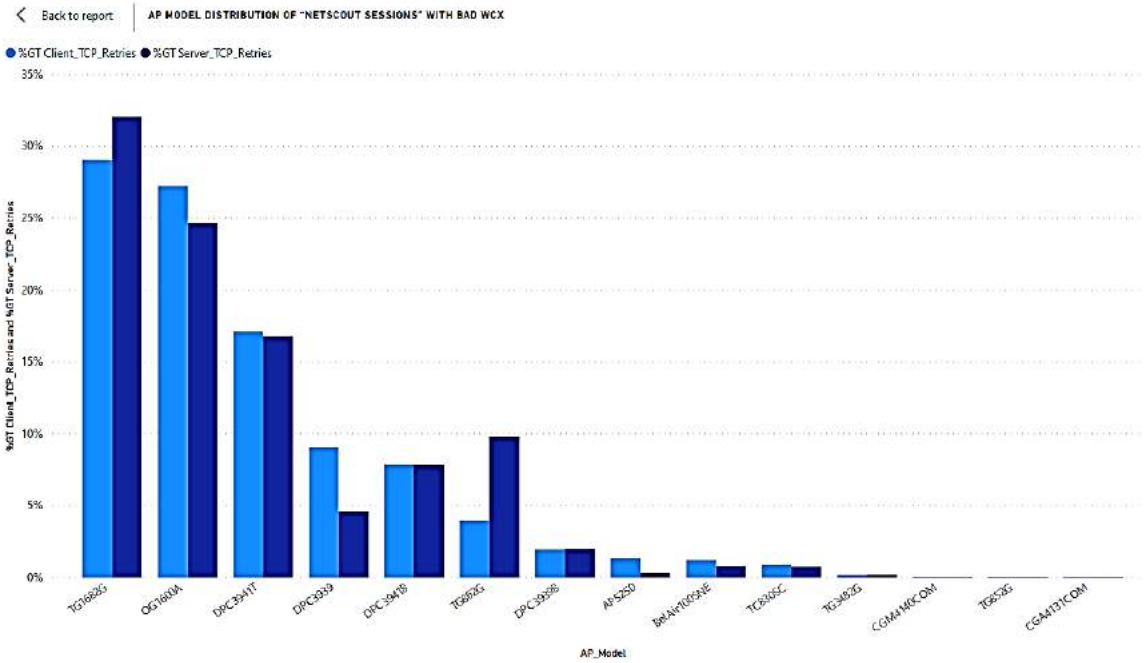

Figure 13 Bad WCX distribution per AP Model – Baseline state

## 5.1. Current state

For each of the areas, CommScope has defined several iterations of configuration changes and for the areas that allowed, added coverage by additional outdoor AP or a complete redesign. While COVID-19 shelter-in-place impacted our ability to conduct many of the iterations and significantly reduced the number of observations (client activity, sessions of outdoor activity, etc.). We were able to drive many of the changes based on the insights we gathered by the big data analytics systems.

Using cross-correlation between our defined criteria of Bad WCX, AP SNMP, and telemetry reports. We were able to drive the following improvements on the network. Note the significant improvement in the outdoor AP (OG1600), and the smaller improvement in the average of all models.

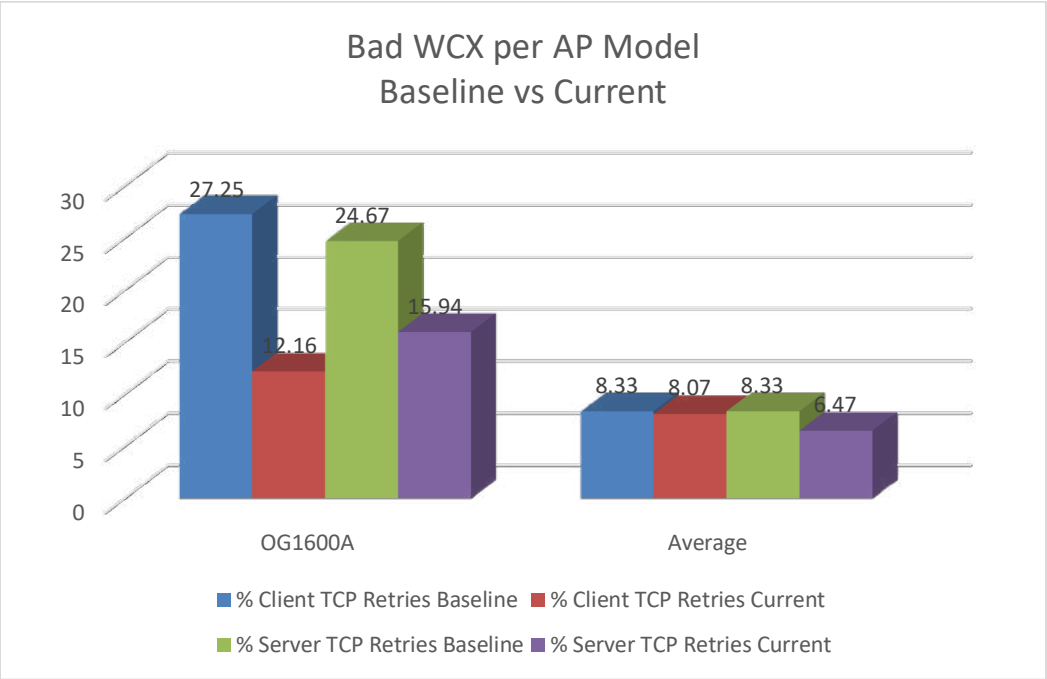

Figure 14 Bad WCX distribution per AP Model – Baseline vs. Current

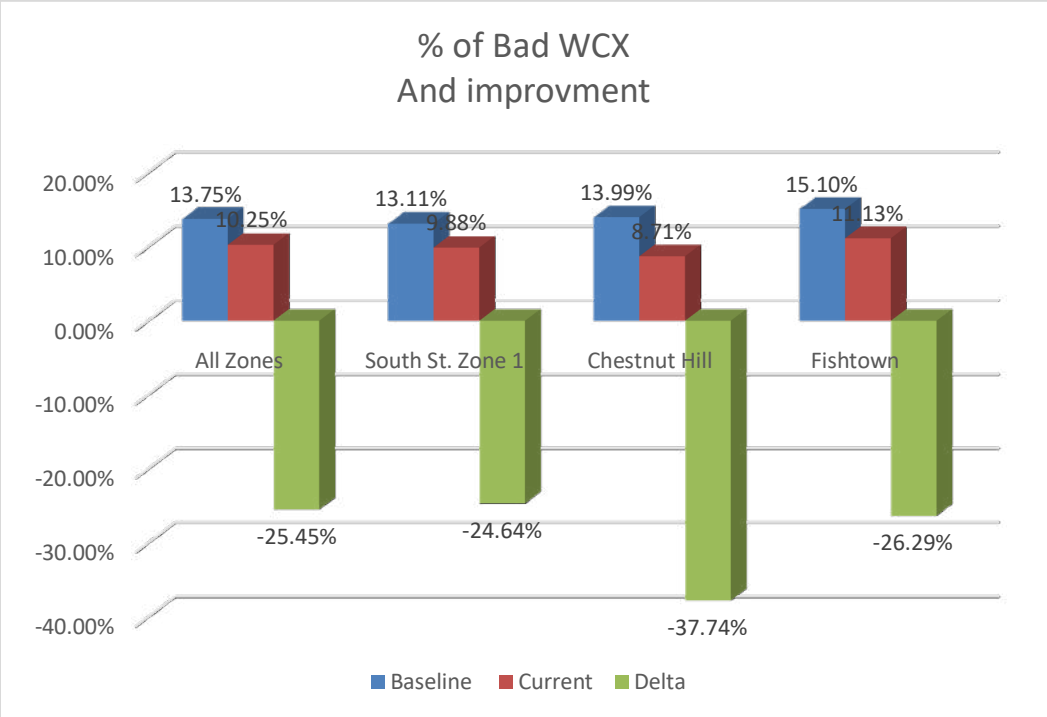

Figure 15 Percentage of sessions with Bad WCX out of all client sessions and improvement

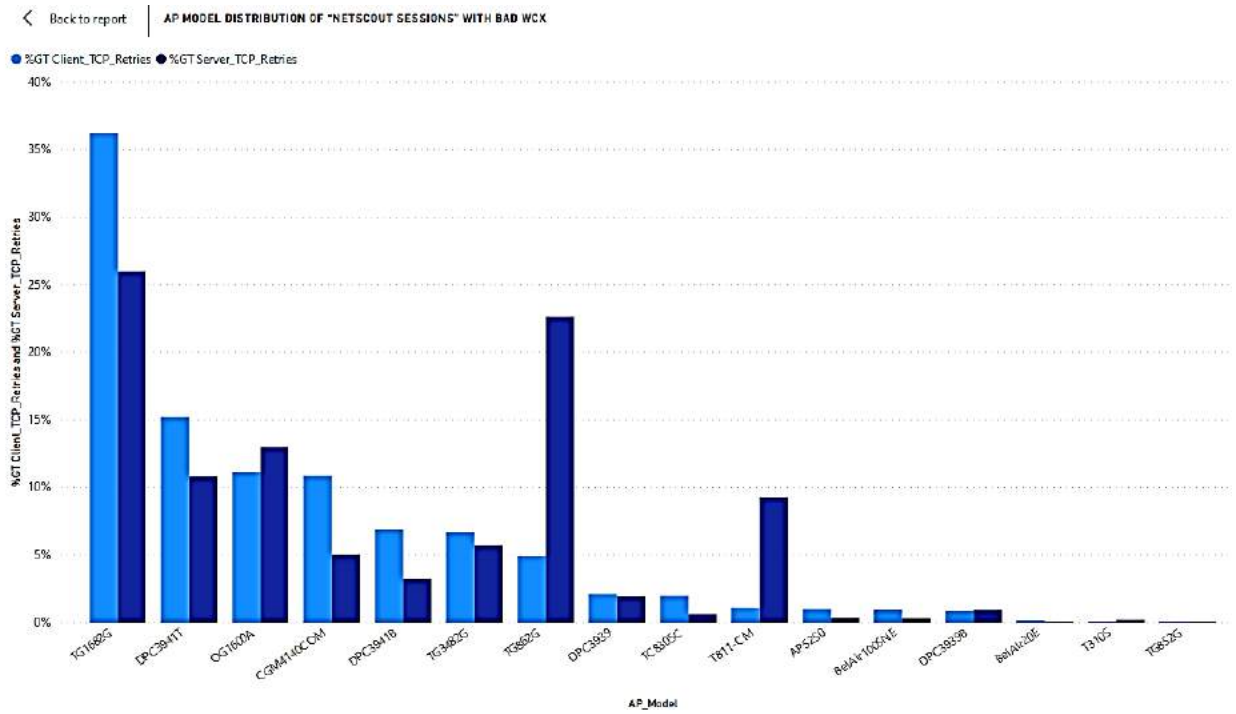

Figure 16 Bad WCX distribution per AP Model – Current state

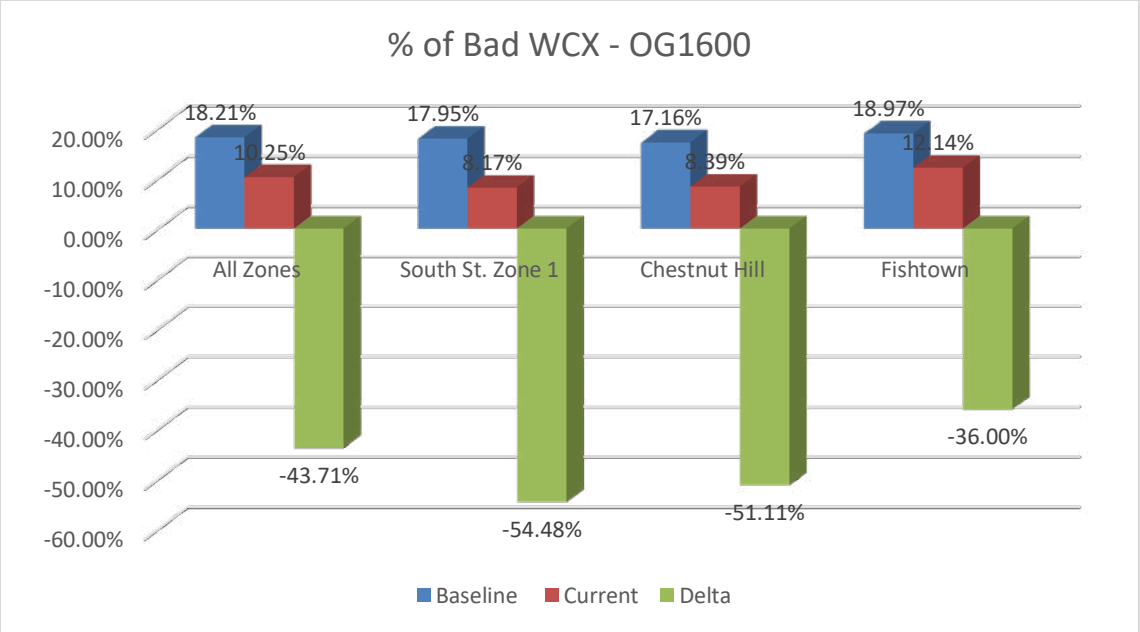

Figure 17 Percentage of sessions with Bad WCX out of all client sessions and improvement – OG1600s

## 6. Conclusion

Utilizing an automated big data analytics system that collects, correlates, and provides insight into users' experience, even for a nationwide network, is achievable.

Bringing together the right subject matter experts in the areas of data science and Wireless; Operators can use the insights generated by the big data analytic system to identify possible causes of bad user experience. Through recommendations and applying the right actions and implementation, we can eliminate or significantly reduce the number and frequency of these bad user experience events. Paving the way to a more optimized network that can serve more customers and provide significant data offload opportunity for an LTE usage.

Future enhancement of this platform includes more sources of data (e.g., indoor Access Points) and real-time telemetry, which will increase the ability to predict where optimization and intervention are needed. The platform and architecture developed to provide the foundation for a machine learning platform. Such machine learning capability would be able to establish thresholds, identify anomalies, and automate the identification and prediction of user experience. Future enhancement is to close the loop by turning the insights and recommendations provided by the system into an engine that would apply the right configuration changes to the network and continue to optimize the performance.

# 1. Introduction

Over the past year wireless operators around the world have focused on the deployment of broad 5G coverage. As we are just now beginning to see true 5G devices enter the consumer market, these recent upgrades will support new spectrum options and greater spectral efficiency provided by the 5G standard. The near-term objective is simple: make sure network capacity keeps up with consumer demand.

As we look beyond near-term consumer demand, the 5G standard includes a series of Key Performance Indicators (KPIs) to address a series of use cases beyond today's wireless networks capability. Consider remote driving or e-health use cases where not only bandwidth but also ultra-high reliability communications are required. And possibly the use case supporting rapid forms of transit such as high-speed trains travelling up to 300+ miles per hour. Finally, consider the use case of remote driving cars where one millisecond of latency is critical to avoid a disastrous accident.

Each of the use cases noted and many more can be summarized into three categories: Ultra-reliable and low-latency communications (URLLC), Enhanced mobile broadband (eMBB) and Massive machine type communications (mMTC). Figure 1 shows how the 5G KPIs are assigned to aforementioned categories. To achieve the full potential of one or more categories operators will need to acquire new spectrum and deploy fiber-based radio access network (RAN).

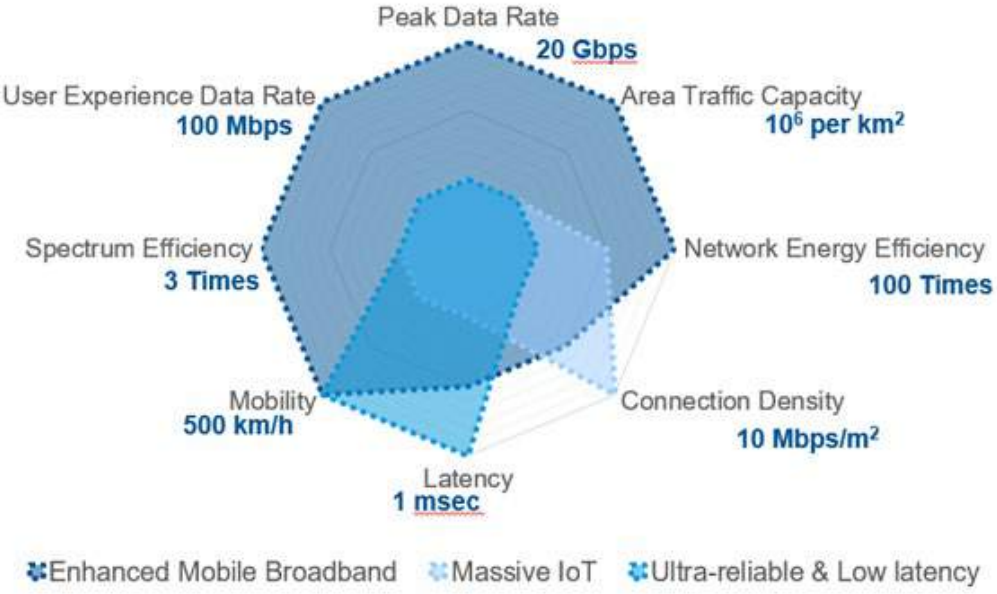

**Figure 1 The 5G KPIs help define a set of categories which can be applied to use cases for the deployment of 5G services as depicted on this graphic**

Existing spectrum deployed today by operators can support 4G subscriber's user experience; however, to address many of the 5G KPIs operators will need to look at new spectrum options such as higher frequency spectrum typically referred to as millimeter wave (mmWave). The mmWave part of the spectrum has large (measured in hundreds of Megahertz(MHz)) available spectral bands to achieve user experience capacity demands. However, mmWave spectrum is more impacted by environmental factors such as rain and snow. In order to overcome those challenges operators must densify their wireless network deploying small cell radios along roadways rather than traditional towers which today have an

Inter Site Distance (ISD) in urban areas on the order of 1,500 feet. The next section will describe a series of architectures that provide the necessary capacity and performance requirements to meet the 5G KPIs. Each of the sections will provide an overview of the architecture, describe some of the salient features of the architecture and provide some guidance on when an architecture should be considered.

## 2. Optical architecture considerations to support 5G deployments

As operators look to densify their wireless networks to support 5G small cell technologies, transport of network capacity from radio head to extensible Radio Access Network (xRAN) locations is predicted to grow at a rate of ~32% per year between 2019 and 2025, according to the Ericsson Mobility Report[1]. (Corning research). This increased demand for 5G transport drives operators to deploy an optical infrastructure. Figure 2 illustrates how the different architectures to be discussed provide support for the various KPIs associated with 5G. The following sections provide guidance on network architecture considerations when densifying a 5G network.

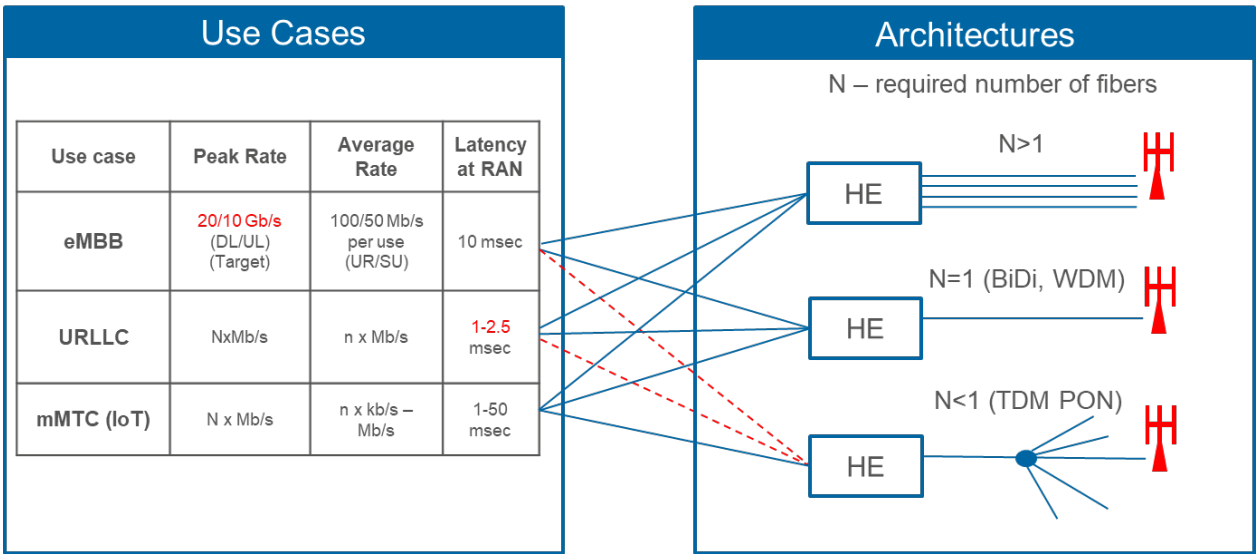

**Figure 2 High-level overview of the various use cases or categories for 5G services and how they align with different architecture choices (adopted from ITU G.sup.5GP draft)**

### 2.1. Network architecture: Point-to-point or point-to-point WDM

The most direct way to provide a high-performance link for mobile transport (from xRAN to the radio) is a fixed, dedicated point-to-point (P2P) architecture. Historically, this is the de facto solution for mobile transport. This architecture requires a dedicated fiber connection from the xRAN location to each drop fiber serving the 5G radio. The optical fibers may reside within a dedicated cable supporting xRAN transport or may reside alongside other optical fibers in the cable supporting other services such as fiber to the home or enterprise-based services. The fiber, cable, connectivity, and infrastructure costs of a dedicated P2P architecture scale as demand for network connectivity grows. Proper up-front planning and over-provisioning of the infrastructure is critical to ensure that long-term growth opportunities will be accommodated with costs.

[1] Ericsson, "Mobile data traffic outlook". June 2020. https://www.ericsson.com/en/mobility-report/reports/june-2020/mobile-data-traffic-outlook

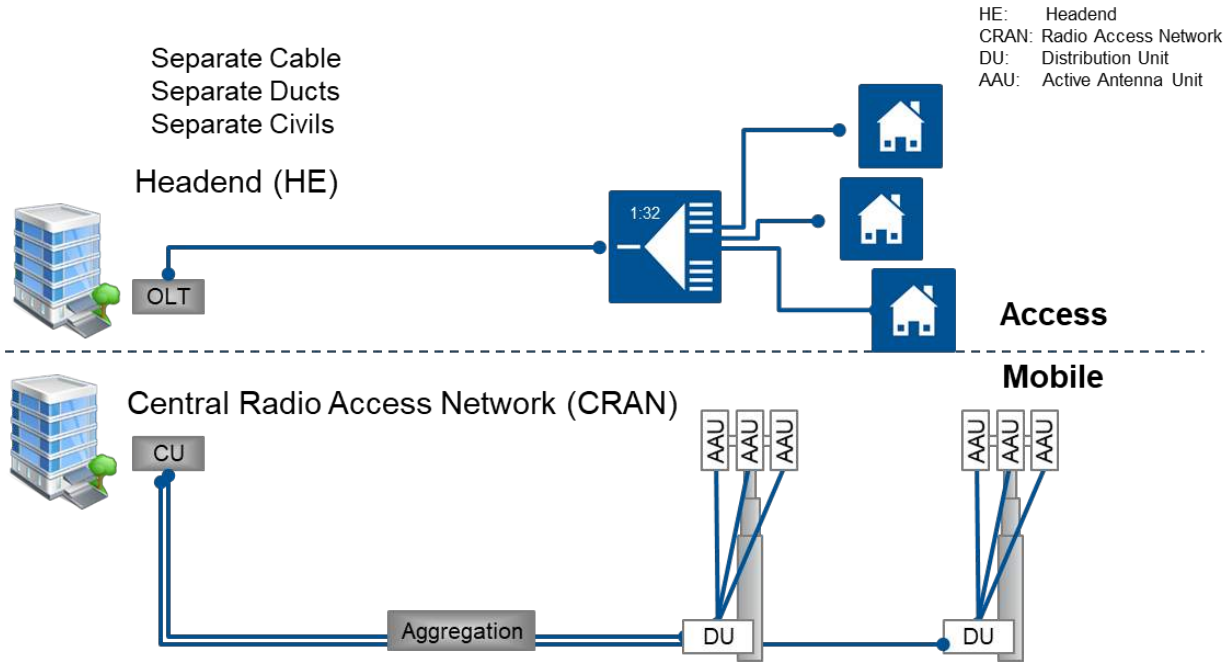

**Figure 3 - A dedicated point-to-point network architecture employs a separate ODN for access and mobile radio connections**

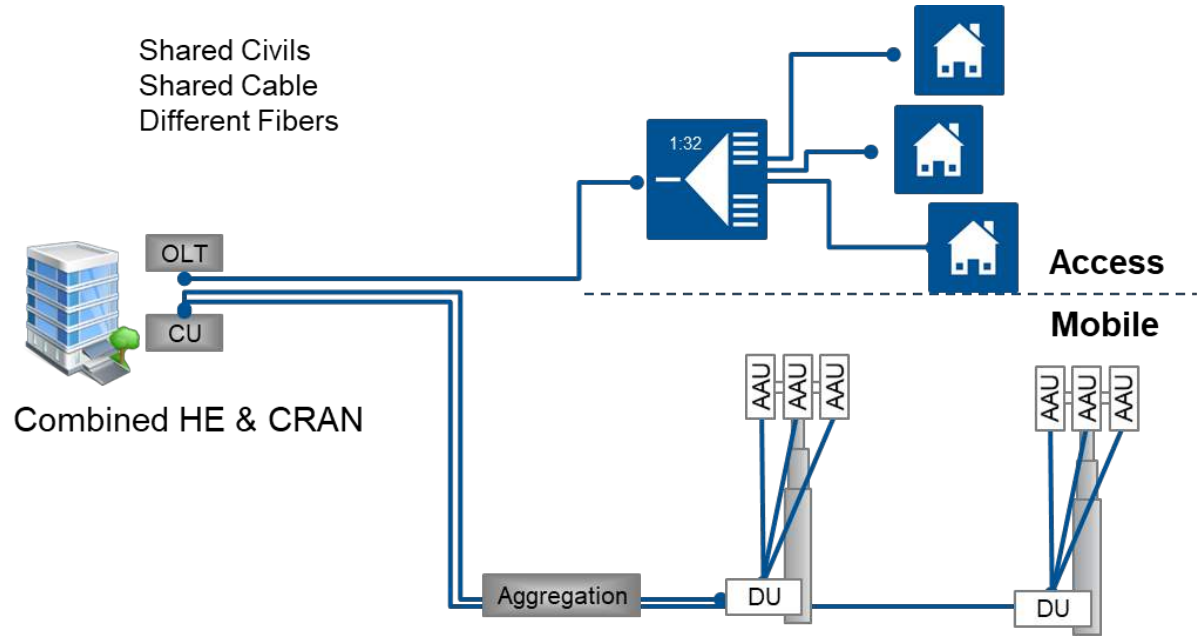

**Figure 4 - A shared point-to-point network architecture has common infrastructure and cable in the feed portion of the ODN for access and mobile transport**

If an operator's existing infrastructure has additional dark fiber within the feeder and distribution cables available for 5G transport or the operator has decided to deploy a new network, a P2P shared architecture is more viable for mobile transport. The low incremental cost and flexibility of dark fiber in a high fiber count cable to support network growth can help manage the uncertainty of future demand (new subscriber

transport, connectivity, mobile densification). Since the incremental cost of fiber is small, sharing cable minimizes incremental cost in the feeder, and sharing duct avoids costly civil work and delays to acquire construction permits if duct capacity is available. Network access points that are already in place might also defer the cost of connectivity if they are adequately sized.

Both dedicated and shared P2P architectures as depicted in Figure 3 and Figure 4 benefit from commoditized, relatively low cost actives, utilizing standardized optics that don't require precise wavelength control or temperature control.

Sharing a cable sheath clearly reduces cable and installation costs in a fiber rich environment, and savings are improved as the number of antennas in the mobile transport links grows. In many markets the availability of dark fiber is low in distribution areas which have experienced significant demand for network infrastructure. These are typically areas where network densification is necessary challenging operators to deploy new optical fiber to support small cell deployment. Hence, operators are very interested in reusing installed fiber in more fiber-lean transport options such as wavelength division multiplexing (WDM) and bi-direction transceivers (BiDi).

## 2.2. Network architecture: xWDM and BiDi technology

In situations where fiber planning cannot or did not over-provision fiber and cable, or where fiber is exhausted, a dedicated or shared P2P architecture will necessitate new cables and the possibility of significant civil costs if existing duct is not available. An alternative path operators may consider is leveraging WDM technology to extend the capacity carrying capability of exhausted or limited fibers deployed. These technologies enable multiple data channels at different wavelengths to be transmitted through one optical fiber simultaneously. The first and simplest example is the use of Bidirectional optics (BiDi), where two simplex fiber connections for carrying upstream and downstream signals are combined into a single fiber. BiDi technology utilizes a pair of distinct optical signal wavelengths for transmission in downstream and upstream directions. Because the wavelengths are different, upstream and downstream traffic do not conflict. This approach is similar to that used in a Passively split Optical Network (PON), which employ bidirectional transceivers with integrated WDM multiplexers (diplexers) to separate upstream and downstream channels. Since synchronization of upstream and downstream data streams is critical between an adaptive antenna unit (AAU) and distributed unit (DU), BiDi optics minimize the asymmetry in propagation delays since both upstream and downstream signals share a common optical fiber.

BiDi optics are more costly as a result of integrated transceivers with WDM multiplexers, but duplex transmission in a single fiber delays or avoids fiber exhaust, offsetting that cost. BiDi optics also help preserve space in the headend (HE) terminal, providing more shelf space for expansion. BiDi optics are increasingly common, relatively simple to implement, and can be installed in a greenfield or brownfield environment because no additional external optical modules (like WDM multiplexer) required.

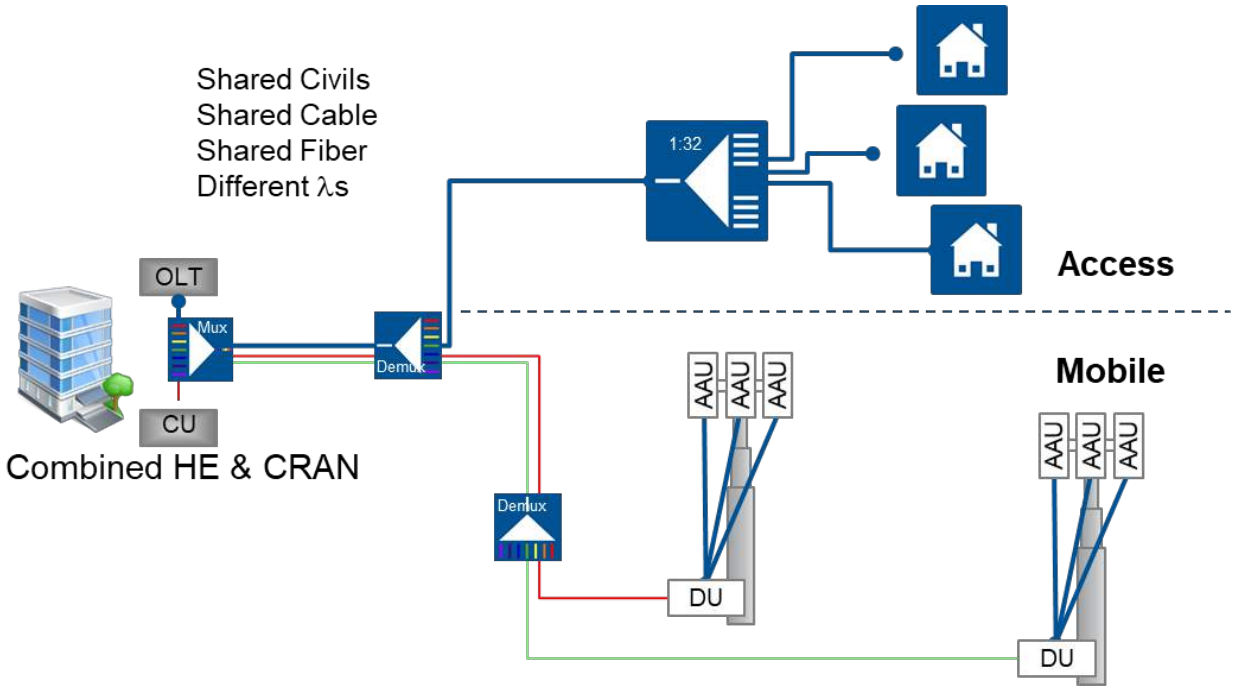

**Figure 5 - xWDM converged access networks share infrastructure fiber and connectivity in the ODN extensively**

Both Coarse (CWDM) and Dense (DWDM) xWDM technology are emerging in radio access networks, including unidirectional or BiDi optics. At the transmitter, a xWDM multiplexer combines the output from several optical transmitters for transmission over a single optical fiber. At the receiving end, a demultiplexer separates the combined optical signals and passes each channel to a matched optical receiver. Only one optical fiber per transmission direction is needed between multiple xWDM transceivers, unless BiDi optics are employed, in which case both directions are supported with a single fiber. Since multiplexer and demultiplexer channel ports are specific to a wavelength, transceivers must normally be manually selected to match a specific port's wavelength channel.

Adding an additional mobile transport connection involves connecting a new optical transceiver at the HE or xRAN core to an open optical multiplexer port, and a new optical transceiver to a matched optical demultiplexer port at the radio head. While CWDM technology commonly supports 4, 6, 8 or 12 channels, the much high channel density associated with DWDM technology provides extensive capacity growth for areas with extremely high connection density or where cabling/infrastructure costs/civils are prohibitive.

Most optics in xRAN networks are being deployed at or below 10 Gbps today. More recently, 25 Gbps optics have emerged utilizing CWDM and Local Area Network WDM (LWDM) channel plans, leveraging cost reduced optics resulting from massive deployment of 25 Gbps in hyperscale data center applications. LWDM optics can operate in the O-band where fiber chromatic dispersion (CD) is low, minimizing chromatic dispersion penalty at longer distances, extending the reach of the Optical Distribution Network (ODN).

xWDM technology enables xRAN densification with ODN infrastructure costs that grow as the network grows. WDM multiplexer and demultiplexer technologies increase capital expenses, and xWDM transceiver optics are more costly than standard optics, especially at higher channel density, but once the

initial capital expense is invested, adding additional capacity-becomes a matter of purchasing additional xWDM transceiver channels as densification increases.

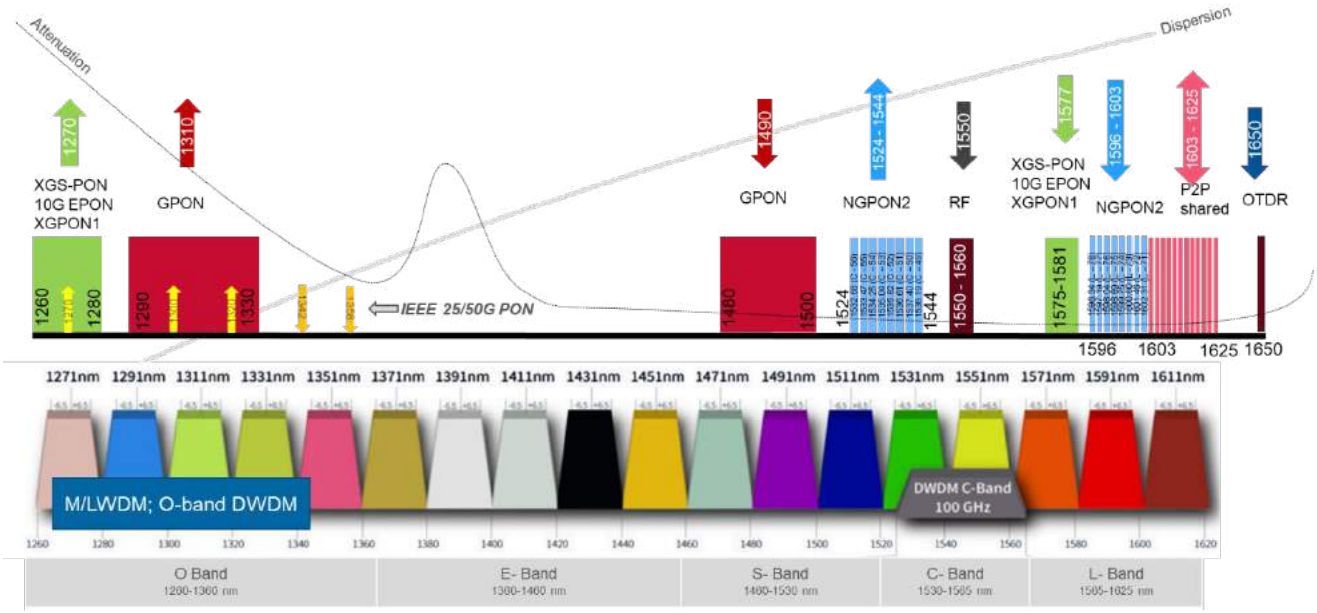

**Figure 6 - Illustration of the various wavelengths utilized within the access network including IEEE and ITU-T PON standard wavelengths and xWDM (illustration courtesy of Mark Hess from Corning Optical Communications)**

A xWDM based architecture also offers potential flexibility that cannot be achieved with a fiber rich P2P architecture utilizing standard optics. The origin and destination of traffic in the optical transport layer is normally fixed and inflexible in a dedicated or shared P2P architecture. Since the path in a xWDM architecture is dictated by the wavelength channel selected, multiple mobile antenna sites can be fed from a Macro or xRAN core over a common transport fiber. Extending this futher, technology such as reconfigurable add-drop multiplexers (ROADMs) may also be considered to support network topologies with path redundancy enabling the ability to route critical mobile traffic around failure points in the network.

Tunable and auto-tuned optics also offer the potential for simplifying implementation and maintenance through no-touch provisioning. Transport service to a new antenna or other end point can be turned up without having to carry stock and manually select or match transceiver wavelengths to specific WDM ports.

WDM convergence has emerged as way to further extend the capacity and performance of mobile transport networks. Employing a xWDM architecture retains an independent P2P connection from each xRAN terminal at the HE to each radio head, while sharing a common optical fiber in the feeder network.

## 2.3. Network architecture: Passive split optical networks (PON)

Since the early 2000's operators have been deploying fiber to the home networks utilizing passively split optical technology typically referred to as Passive Optical Networks (PON). The attraction of a PON network is the ability to deploy a single optical fiber deep within the network, passively splitting the fiber to support a number (e.g. 32 or 64) of subscribers. In comparison to a point-to-point active ethernet network where there is a dedicated optical fiber from the headend to the subscriber in a 1:1 ratio, within a

PON network the ratio is on the order of 1:32 or 1:64 thereby reducing the electronics needed at the headend and fiber capacity within the feeder network.

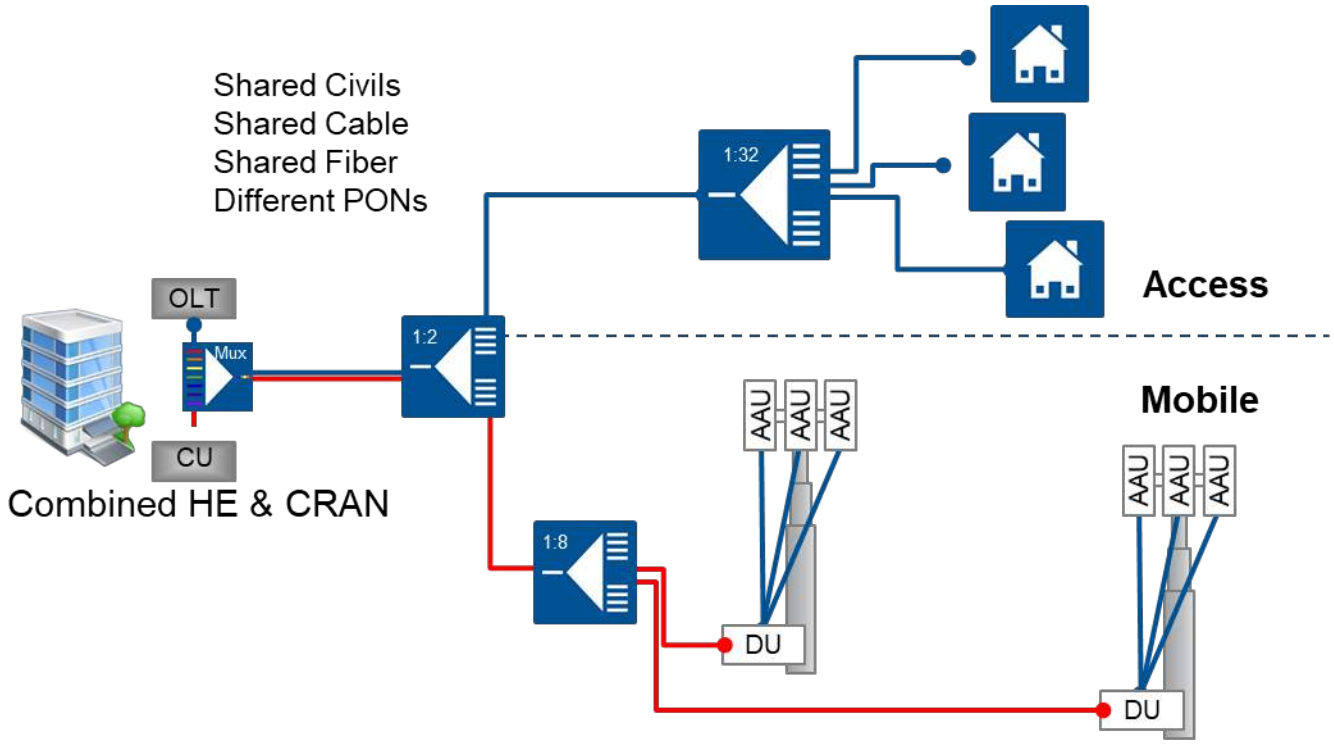

**Figure 7 - Increases in capacity by PON standards allow for mobile transport and converged residential networks over a common ODN**

Because a single fiber provides connectivity at the headend to multiple subscribers both ITU-T and IEEE have defined a series of standards to enable a one-to-many Time Division Multiplexing (TDM) (and more recently adding WDM) based communication protocol. This protocol is necessary to ensure upstream traffic from one subscriber device does not conflict with another subscriber. Both standards organizations have continued to evolve their PON standards to increase overall capacity provided over the PON while looking at ways to reduce latency and improve throughput.

Today many operators are deploying symmetrical 10Gbps defined by standards such as IEEE's 10Gbps E-PON or the ITU-T XGS-PON. Other operators are considering much higher capacity PON standards such as NG-PON2 also defined by the ITU-T to provide up to 40Gbps of symmetrical bandwidth over four separate 10Gbps wavelengths. Recently the IEEE released a new standard providing support of either 25Gbps or 50Gbps symmetrical bandwidth. These significant increases in speed provide operators with excellent capacity headroom for the residential subscriber but in many cases are being considered for a converged network supporting both residential subscribers, small enterprises and 5G transport for small cells.

In recent standards development attention has been made to ensure backwards compliance with existing standards or providing multiple wavelengths over a common ODN. Operators could consider utilizing the 10Gbps E-PON standard for residential services while looking at 25G or 50G NG-EPON to provide transport of small cell radios leveraging a common ODN.

As noted above, a PON network utilizes TDM arbitration to ensure each device has a clear channel for upstream communication. This arbitration does highlight a downside of PON networks, increased latency and in some cases increased jitter. In some of the 5G use cases noted above where millisecond latency is critical for communication, a PON based network may not be able to meet the end-to-end service objectives.

The jury is still out as to whether PON can meet the requirements for KPIs that would support all three eMBB, URLLC and mMTC categories in 5G networks. Operators will need to decide on the trade-offs inherent to PON based networks: cost advantages and efficient use of feeder fiber versus increased latency and potential long-term capacity constraints as compared to point-to-point-based architectures. Each operator will need to evaluate these trade-offs and decide what is best for their 5G objectives and network environment.

In Table 1 the authors have summarized a series of different attributes for operators to consider as they look to prepare for the build-out of a 5G transport network. Each of the different architectures have various salient features which will guide an operator on how to proceed based on their current capital constraints and network infrastructure in place.

**Table 1 - Summary of the various attributes of different mobile transport architectures to address 5G network deployments**

| | **Dedicated PT-PT** | **BiDi PT-PT** | **Shared PT-PT** | **xWDM** | **PON** |
|---|---|---|---|---|---|
| **Application** | Transport | Transport | Transport & FTTH convergence | Transport & FTTH convergence | Transport & FTTH convergence |
| **Fiber count** | Highest | High | Highest | Lowest | Low |
| **Adoption** | Standard | Emerging | Common | Standard | Under Evaluation |
| **Complexity** | Moderate | Moderate | Moderate | Complex | Moderate |
| **Flexibility** | Low | Low | Moderate | High | High |
| **Path Redundancy** | Low | Low | Low | Capable | Low |
| **Construction cost** | Highest | Higher | Lower | Lowest | Lower |

## 3. Conclusion

The growing demand by consumers on the mobile network is predicted to increase at a rate of 30% per year. This demand alone will push existing wireless technology and architectures to the brink of capacity. The deployment of 5G wireless networks does provide operators an opportunity to gain additional spectral efficiency; however, this alone will not be enough. Further, emerging use cases are pushing additional capacity, latency and connectivity requirements, demanding new spectrum and increasingly dense radio networks.

This paper provided an overview of essential architectural approaches, describing deployment issues to consider based on a carrier's use cases. The authors are also aware that combinations of these architectures as well as other technologies are worthy of consideration. These may include the possible use of Cable Labs Data-over-Cable Service Interface Specifications (DOCSIS®) or Integrated Access-

Backhaul (IAB) technology to provide this transport from the radio site to the xRAN location (or intermediate location). Although these are acceptable technologies, we challenge each operator to look over the 10-year horizon to ensure the infrastructure dollars spent today are capable of meeting the demands of the longer-term network demands.

## List of Figures

 

# 1. Introduction

The networking software industry is experiencing an accelerating technology shift from centralized data center application delivery models to a distributed edge computing paradigm. In this new computing paradigm, cloud infrastructure and services are delivered from multiple distinct and geographically distributed locations in closer proximity to the end user or data source. The drivers for this shift are the emergence of advanced Enterprise use cases & applications, network infrastructure convergence and operator digital transformation initiatives. These applications require deterministic latency and ultra-fast response times, distributed processing of large volumes of data near the source and flexible scalability across network and computing ecosystems. Included in this transition, the convergence between wireless & wireline, combined with increased hub-site network capacity in cable Distributed Access Architectures (DAA) and the drive to centralized mobile Radio Access Networks (cRAN), are making distributed edge computing more feasible for operators.

This computing paradigm is enabled by cloud-native principles and application containerization & orchestration technologies that promise new operational efficiencies and agility to develop innovative services. We see this trend across Enterprises and network operators that want to accelerate software delivery while maintaining a consistent quality of experience from applications & data to devices and end-users alike, independent of location. 5G and high-speed fixed broadband connectivity services are acting as catalysts to enhance the underlying network performance and agility using a cloud-native services-based architectures. This in turn poses a challenge of operationalizing an applications-first approach in the operator's network to facilitate open, modular, and portable multi-vendor networking software across their distributed edge compute infrastructure platforms.

Advanced cloud-based management & orchestration systems, however, were not designed for distributed edge computing. These systems were optimized for very large compute environments where server clusters are co-located and mesh inter-connected by an over-provisioned data center fabric. In edge centric architectures, compute & network nodes are geographically distributed and inter-connected by multi-layer access and aggregation networks with varying degrees of capacity, latency, and flexibility. This creates the opportunity to adapt and optimize the use of containerization and cloud orchestration technologies to meet the needs of embedded real-time network functions and edge business applications.

This paper will delve into emerging edge computing infrastructure architectures, available open-source software to enable distributed edge computing, and key technical considerations to accelerate adoption of new software-based operational methods. This paper evaluates the use of open-source projects from the Linux Foundation Edge (LF Edge) and Cloud Native Computing Foundation (CNCF), such as Akraino Edge Stack and Kubernetes, to build and operationalize distributed edge computing networks. This paper will also explore how hyperscale cloud platforms are addressing this technical challenge and how cable MSOs can leverage a rich technology ecosystem to architect open edge technology systems, implement software defined network operations, and monetize new edge-based business services.

# 2. Drivers for Access Network Modernization

In the ever growing quest for delivering higher reliability, higher speed connectivity services to residential and business customers, MSOs are overhauling their traditional Hybrid Fiber Coax (HFC) networks along three key dimensions: (1) disaggregation and distribution of vertically integrated, proprietary functions of the CMTS previously located at headend or hub locations; (2) deeper fiber-based Ethernet/IP connectivity to remote access infrastructure nodes where MAC and PHY layer processing occurs; (3) convergence of service functions & infrastructure for both wireline and wireless services.

Functional disaggregation based on the DOCSIS DAA specifications allow for splitting of MAC & PHY layers from the CMTS, driving either a Remote MACPHY Device (RMD) or a Remote PHY Device (RPD) deeper into the access plant (Levensalor & Stuart, 2020). DAA extends the digital processing of the headend and hub domains out to fiber nodes, pushing intelligence closer to the end user and offering the opportunity to leverage generalized compute platforms, NFV and SDN. This in turn facilitates flexible deployment, optimized infrastructure and automated operations which would otherwise be increasingly complex due to the distributed nature of this architecture (Evolution to Distributed Access Architectures, n.d.). This is illustrated in **Error! Reference source not found.**. Additionally, since these locations are typically constrained in space and power, there is a need for light-weight, high-performance compute resources and efficient virtualization technologies such as Linux containers to maximize use of CPU and network resources.

Pushing fiber and Ethernet/IP connectivity deeper in the access plant has the effect of increasing the available access network capacity to a smaller number of homes or businesses in a service group. This in turn allows operators to boost service bandwidth and reliability, while guaranteeing SLAs via increased levels of visibility and control in the physical network underlay. A unified and automated physical & virtual network underlay is a critical component of orchestrating edge compute & storage infrastructure in support of dynamic infrastructure and overlay end-user applications and services (The Converged Interconnect Network, 2020).

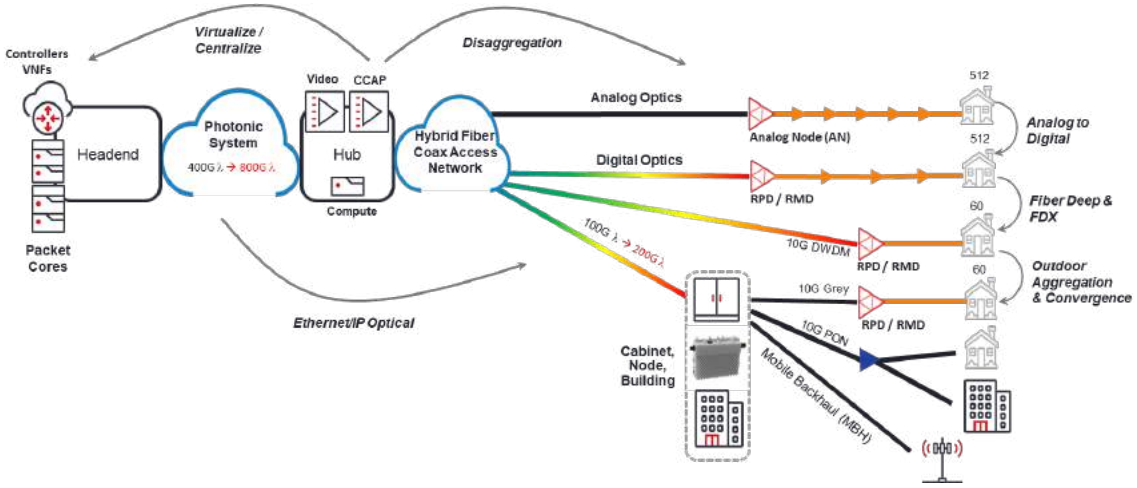

**Figure 1 - MSO transition to DAA and fiber deep**

Finally, Packet Core functions delivered via a virtualized CCAP such as user management and authorization are non-data/user plane software-centric capabilities that can be delivered out of a centralized location leveraging the economies of scale offered by cloud-based IT platforms. These functions can be placed in headend or regional data center locations but would necessitate a unified approach to manage the end-to-end lifecycle of open, modular, multi-vendor software components that ran as a monolithic application in a single-vendor CMTS system. This comes with the added benefit of enabling the convergence of service delivery functions across different access medium, such as FTTH and 5G RAN.

# 3. Cloud Native and Edge Computing Architectures

## 3.1. Distributed Edge Computing

As the cost of commodity computing hardware continues to decline and smart devices and sensors shrink in size, it becomes economically feasible to build connected infrastructure that is continuously monitored and optimized using data-driven insights and intelligent automation systems. In addition, 5G technology promises to enable the interconnection of tens of billions of devices, sensors, and things, so we are going to see an exponential increase in endpoints coming online and generating massive amounts of data that need to be processed closer to its source.

When we overlay this technology landscape with new kinds of business oriented real-time, low-latency applications, like self-driving cars, robotic manufacturing, industrial process automation, and augmented/mixed reality, it becomes critical to segment the application space based on bandwidth and response time requirements. See Figure 2 - Edge Application Segmentation. This high-level segmentation provides a framework to think about applications in terms of its functional components, communications requirements and where these components need to be located to meet the end user experience. Since most public cloud regions are within 60-100 msec of high-density population centers, it becomes clear that a good subset of these high intensity applications is not feasible with today's centralized cloud model.

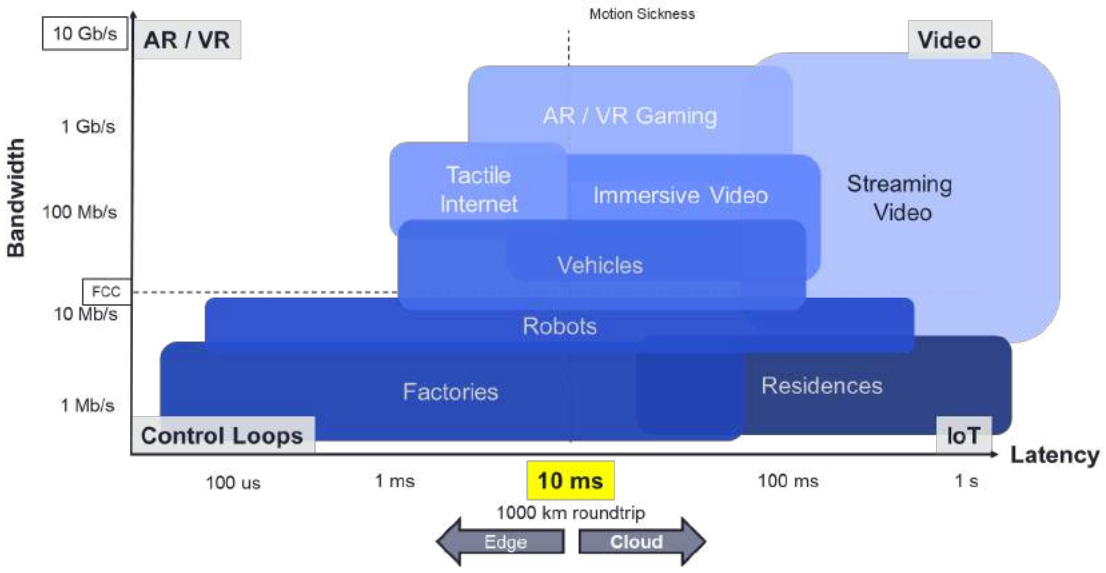

**Figure 2 - Edge Application Segmentation**

Centralized cloud computing has been a huge success by all measures, and businesses continue to migrate both generic IT and specialized workloads to public clouds. These businesses include Communication Service Providers (CSP) and network operators who are embracing cloud-native technologies to virtualize their networks, modernize operations, accelerate the pace of service innovation, and dramatically reduce costs. The resulting cloud workloads range from business-oriented IT applications such as planning, order management and service assurance, to network-centric software applications such as network service orchestration, virtualized routing and other CPU-based data / user plane functions. These workloads will be distributed across heterogeneous central and edge-based data centers that require a unified approach for software management and operations.

On the technology front, one of the corner-stone technologies of cloud computing – server virtualization or virtual machines – is increasingly being replaced by Linux container technology which has three compelling advantages: rapid workload deployment, better CPU utilization and lighter-weight resource footprint. This container technology supported by tools like Docker have the added benefit of simplifying application life-cycle, from creation and packaging, to testing and delivery across any infrastructure running a Linux OS.

These trends are helping drive an industry shift to create a more distributed and infrastructure optimized computing model, which moves cloud-style consumption of compute, storage, and network resources closer to the end-user or data source. We call this new computing paradigm Distributed Edge Computing (DEC), whereby a software-centric approach facilitates dynamic placement of application components across a heterogeneous environment of connected compute & storage resources, while abstracting the complexities of operating these resources from the application developer. These resources may reside on a smart sensor powered by an ARM processor, an IoT gateway running on a network appliance or a data center located within a hub location of an MSO network. See Figure 3 - Edge Locations.

This DEC approach is also fundamental in the move towards virtualization and distribution of CMTS functions that must be dynamically, but intelligently placed across Hub and access infrastructure with the right resources to meet performance requirements, such as Low Latency DOCSIS (LLD) specifications. LLD targets 1ms queuing and overall less than 10 ms round trip time in the access network (Whie, Sundaresan, & Briscoe, 2019).

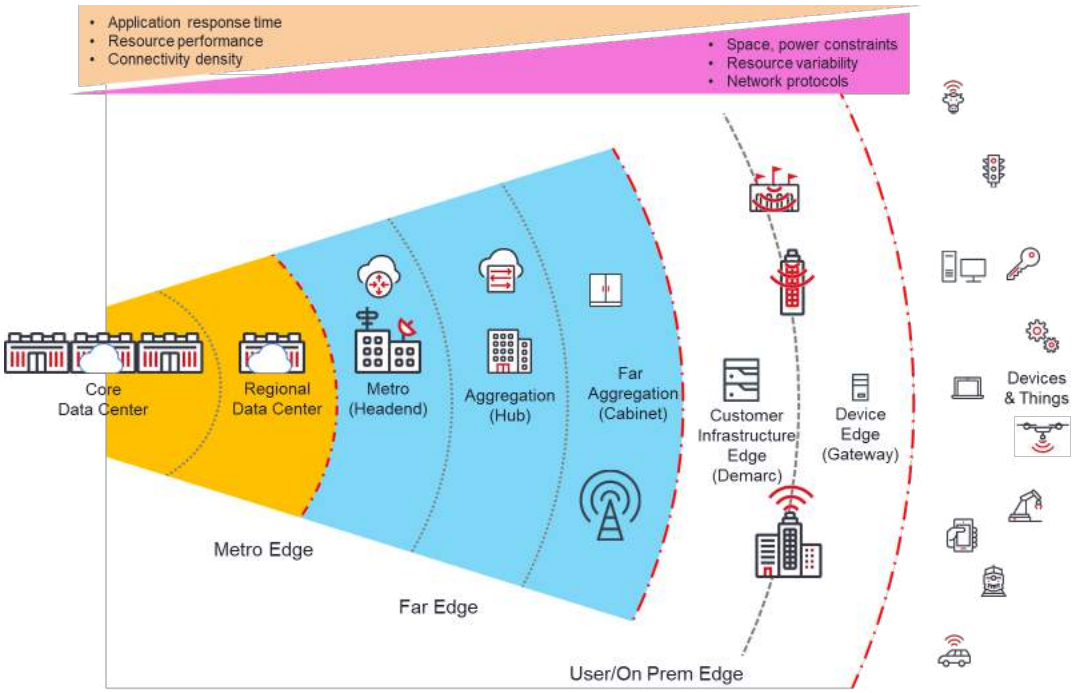

**Figure 3 - Edge Locations**

### 3.1.1. Properties of Distributed Edge Computing

There are in fact multiple names and definitions of this style computing, so we propose that there are three key properties shared across the spectrum of edge-centric computing architectures.

- *Location*: physical location of a compute node in a distributed environment defines communications latency, data sovereignty and ability to perform specialized hardware-assisted processing. This covers a spectrum of compute capabilities from a sensor/device in a mining field to customer premise and operator network infrastructure hosting network and application services within a metropolitan area.
- *Heterogeneous cloud:* distributed edge computing is an optimization of central cloud computing, and as a result it inherits properties such as shared resource pooling, elasticity, and application agnostic infrastructure. This is often overlooked but it emphasizes the need to support a holistic and cloud-native approach to containerized application delivery and multi-location data processing according to resource constraints, performance & quality of experience.
- *Network diversity*: as application components and supporting resources become more distributed, the underlay communications network becomes more diverse, and increasingly critical, in terms of protocols, technology domains, application awareness and transport flexibility. This is in contrast with network applications that run within a server cluster in the same core data center.

## 3.2. Cloud Tiering Reference Model

### 3.2.1. 3-tier Cloud Model

From a software application standpoint, edge computing infrastructure fits into a 3-tier system, where the edge tier is located between the hyperscale cloud and devices to perform specialized functions. This 3-tier system limits the extent to which device level applications need to communicate with a centralized cloud for active data storage, processing and other services, as illustrated in **Error! Reference source not found.**.

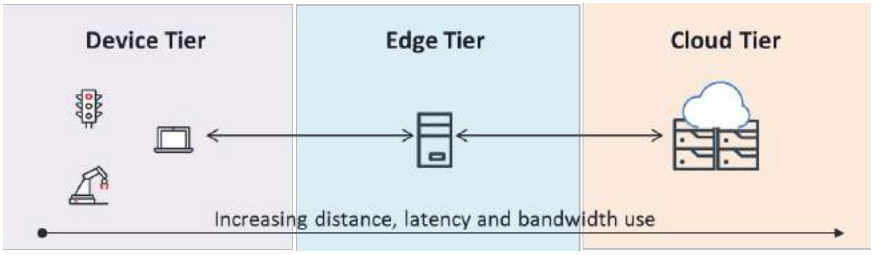

**Figure 4 - Three-tier Cloud System**

When this edge tier is missing, which by and large is the norm today, the system becomes a traditional cloud computing environment whereby all the application intelligence is centralized and possibly assisted by smart devices. From an application perspective, the edge tier can play a dual role to deliver network services and application services. In a 5G RAN, the edge can host radio signal processing functions and user plane functions (UPF) for local traffic breakout and termination at the application layer. Another key

role is to bring compute resources closer to the device tier to improve application response time, reduce unnecessary data transfers to the cloud tier and enhance communications security.

### 3.2.2. Elements of the Edge Tier

The edge tier's functional role also varies according to the capabilities and ownership of the underlaying communications network. The edge compute tier sits between the enterprise LAN and operator's metro core to leverage last mile networks and enable local traffic breakout functions for general traffic off-load, time-sensitive end-user applications as well as network-centric protocol processing supporting higher-level applications. As a result, the edge tier can be further decomposed into the Device Edge and the Infrastructure Edge as illustrated in **Error! Reference source not found.**.

The purpose of the Device Edge is to host a Device Edge Cloud or sometimes referred to as On-Prem Edge Cloud where enterprise owned devices can benefit from proximity and security of an on-net cloud environment for local application processing and storage serving the enterprise environment. This is particularly useful where enterprises need to retain control of their network traffic and where their data is processed and stored.

The Infrastructure Edge is located on the operator side of the last mile network and typically hosts an Edge Cloud environment for Telco-centric workloads, or what is commonly called a Telco Cloud. These environments are owned and operated by last mile network operators and are becoming increasingly attractive to offer internal network services, shared infrastructure wholesale services and enterprise business services in collaboration with hyperscale cloud providers. The infrastructure edge is where we see the potential for MSOs to differentiate their network services by creating access on-ramps onto an edge cloud for running gaming, AR/VR, Smart City IoT and other real-time analytics intensive applications near the data source.

The Edge Cloud represents not just an architectural choice, but also a system that encompasses storage and compute assets located at the edge of the network, and interconnected by a scalable, application-aware network that can sense and adapt to changing needs, securely and in real-time.

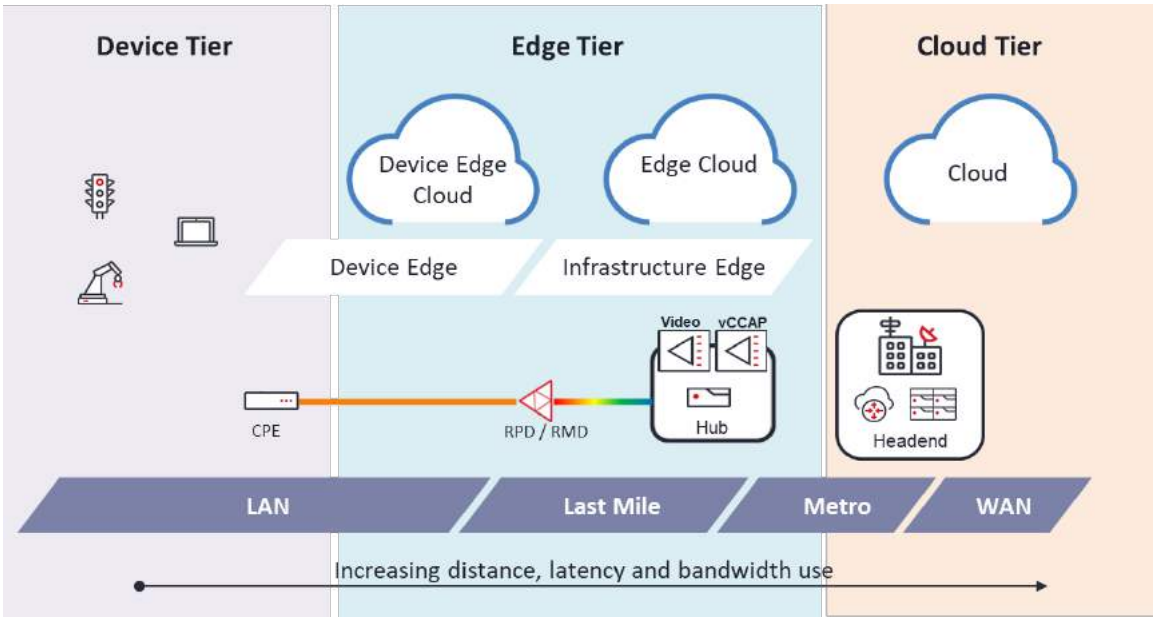

**Figure 5 - Edge Cloud Network Reference Model**

From an infrastructure perspective, the same cloud networking model can be applied to an MSO network, with the device tier defining the subscriber's domain and the edge tier encompassing the outside plant passive equipment, RPD/RMD nodes as well as hub locations hosting vCCAP systems. The hub and headend locations are equipped with data center infrastructure such as server clusters and cloud-native platforms to deliver the compute and networking environment for virtualized packet core and video functions. These are considered edge data centers due to proximity to the subscriber, footprint requirements and variety of network functions requiring specialized hardware depending on DAA design choices.

On the other hand, RPD/RMD nodes are not multi-server clusters, but they can be considered generalized compute node extensions of the infrastructure at the hub or edge data center, and therefore can participate in the end-to-end orchestration of resources allocated to user plane network functions in the last mile. Due to the nature of MAC/PHY processing functions, such as FEC and MAC scheduling, these nodes can benefit from having specialized accelerators like GPU, TPU, FPGA and smart NICs with very efficient techniques for pooling and scheduling micro-workloads is a distributed fashion. These edge nodes are typically in space and power constrained locations but can also be deployed in edge data center environments where a remote CMTS is desired due to population density.

One key property of these edge nodes and small edge data centers is their highly dispersed physical locations, which require high degrees of autonomous operation and resilience. Given the underlying Ethernet/IP fabric, there is an opportunity to turn a mesh of edge nodes and data centers into one pool of resources for dynamic orchestration of virtualized edge functions, when and where they are needed, thereby reducing the total cost of ownership for the operator.

# 4. Cloud Native Technologies

## 4.1. Cloud Native Applications

With the development and proliferation of hyperscale cloud platforms from Amazon, Microsoft, Google and others, a new kind of software development and delivery paradigm has emerged called *cloud native* applications. This approach is based on the principle of decomposing an application into a set of microservices that can be developed and deployed independently to accelerate & optimize the DevOps life cycle of software systems. These microservices are packaged into light-weight containers which are scheduled to run on compute nodes by a container orchestrator. There are many advantages of containers

vs virtual machines, but the principal ones are portability, low resource usage, dynamic horizontal scalability, and fast restarts.

*Cloud native* applications are built to run and scale in public, private, and hybrid clouds and they use the following constructs to deliver on the promise of a developer-centric approach to enable cloud scale agility, scalability and flexibility of software systems. See Figure 6 - Cloud Native Constructs.

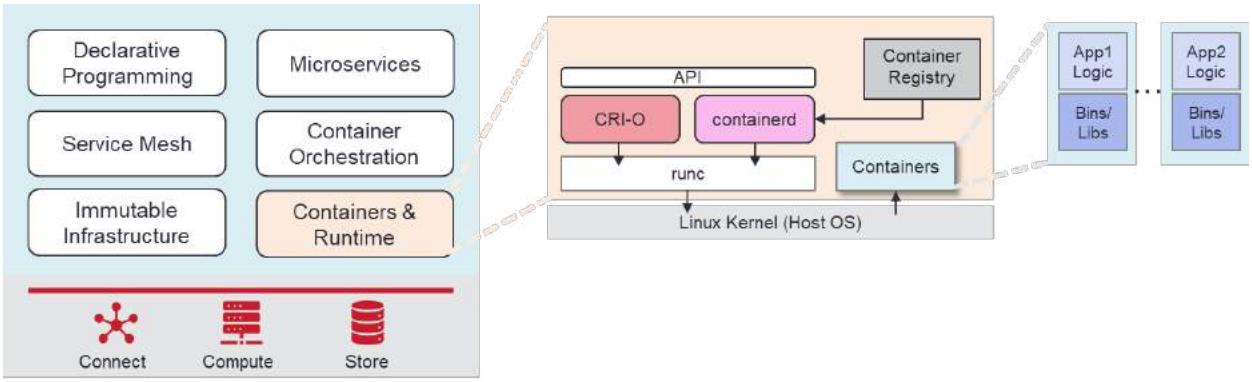

**Figure 6 - Cloud Native Constructs**

*Containerization* is an operating system virtualization paradigm in which the kernel supports multiple isolated user space instances or namespaces. From an application perspective, a container is an executable binary packaged with its lib dependencies and intended for execution in these private namespaces with resource constraints such as CPU, memory and storage. The lifecycle of a container is managed by what is commonly called a container runtime. There are several container runtime implementations, each with their own approach at managing the end-to-end lifecycle of a container. In Linux, the execution phase of a container is generally performed by runc (github.com/opencontainers/runc, n.d.), an Open Container Initiative compliant implementation, but alternatives such as *rkt*, pronounced "Rocket" (coreos.com/rkt/, n.d.), are also available. The configuration and image management are performed by applications such as docker, containerd and cri-o which interact with runc. In an effort to simplify the integration with the different container runtime flavours, the Kubernetes Container Runtime Interface (CRI) offers an abstraction layer to interact with the underlaying container runtime.

Using containers instead of virtual machines increases CPU utilization and significantly reduces disk space requirements. This is because containers running on the same host share the operating system (OS) while virtual machines have their own OS, providing complete isolation between apps. This property makes containers a more attractive choice for running software-based network functions and applications at the Edge Tier's compute, power and space constrained hardware.

*Service mesh* is a dedicated infrastructure layer for service-to-service communication. This infrastructure includes not only network connections between containers and services they form, but also a means of discovering services. This layer makes possible direct communications between containers under policy control (therefore the term *mesh*).

*Microservices* are loosely coupled fine-grained services with lightweight communication protocols. This architectural style was developed as an alternative to large, tightly coupled services. It brings not just

modularity and scalability vital for applications at the edge cloud, but also supports incremental integration with legacy systems and distributed, parallel development of software (Namiot & Sneps-Sneppe, 2014).

*Immutable infrastructure* is the concept of never requiring server infrastructure to be modified to support new requirements, but rather new servers are built to replace the old ones. This approach reduces operational complexity by eliminating the need to deal with differently upgraded systems and makes possible quick and fully automated recovery from faulty software that was rolled out to customers. Also, when implemented as the foundation for container images and their workloads, immutable infrastructure removes from consideration the difference between development, test, and production environments.

*Declarative Application Programming Interface (API)* is a design style that avoids specifying *how* to perform described functions, instead, it describes *what* needs to be done. This style allows understanding and consuming of services without knowledge of the services implementation. This reduces integration complexity and promotes service modularity and scalability, simplifying operations.

Cloud native applications consist of loosely coupled, resilient, manageable, and observable container-based microservices. DevOps teams use automation to make high-impact changes frequently and predictably with minimal effort within large scale data centers. Applications designed for the Edge Tier infrastructure use the same cloud-native principles, but must take into account the resource constraints and location context characteristics mentioned in Properties of Distributed Edge Computing.

*Edge Native* applications are impractical or undesirable to run in centralized data centers at public, private, and hybrid clouds. These applications are developed with proximity and specialized resources in mind as well as different security, compliance and networking requirements due to location. Edge-native applications use the infrastructure edge to provide large-scale data ingest, data reduction, real-time decision support, bandwidth savings or to retain sovereignty over critical data.

In the spectrum between Edge Native and Cloud Native Applications, Edge Enhanced is a set of applications that can operate in a centralized data center, but would gain performance, typically in terms of latency, or functionality advantages when operated using edge computing. These Edge Enhanced applications may be adapted from existing cloud native applications or may require no changes if the edge cloud environment is abstracted by the container runtime engine and associated container networking facilities.

## 4.2. Virtual and Cloud Native Network Functions

Cloud-native principles can be applied to enterprise and consumer-oriented applications, as well as communications and networking software that we refer to as Telco or MSO workloads. These workloads can be broadly classified according to the function and services offered in the network operator's stack:

- *Management*: Business Support System (BSS) and Operations Support System (OSS) are software solutions that help operators manage the customer experience, network offerings and network operations for planning, engineering, ordering, activating, and assuring communications services. This type of application is non-real-time and does not interact with the user / data plane & network traffic directly.
- *Control*: network management, signaling & control plane software solutions provide network device inventory, discovery, configuration, performance, fault and resource management capabilities in support of user / data plane services, but are not directly involved in processing the subscriber's / customer's traffic. This includes systems such as user authentication & session management, service policy enforcement, and DHCP services for IP address assignment. These

 

network functions are considered management and control functions that can be deployed as virtualized or containerized applications without significant differences in network user plane performance.

- *User plane*: these are multi-layer network traffic processing functions that operate at the network layer and below for the purposes of packet inspection, encapsulation, transformation, QoS treatment, forwarding, and filtering among other functions. These are the most-real-time intensive network functions that can operate in a subscriber's cable modem or uCPE, RPD/RMD node or headend location. This is the type of networking software stack that is impacted the most when migrated to a virtualized or containerized environment due to its performance and reliability requirements, but more importantly the life-cycle management processes and techniques used by the vendor and network operator community.

Network Function Virtualization (NFV) has been in production networks for several years now, including data plane functions such as virtual routing (vRouter), virtual firewall (vFW) and virtual Broadband Network Gateway (vBNG). These software-based data plane functions, or Virtual Network Functions (VNF), evolved from their dedicated physical appliance counterparts. When a network function is implemented as a software stack that runs in a virtualized compute environment, as a Virtual Machine (VM), it is referred to as "virtual" or "virtualized network function" (VNF). In many cases, several VNFs will operate in an edge cloud as part of a network service chain that provides a composite service to the end customer.

Network functions can run inside a virtual machine or a container. When a network function is built and deployed as a cloud-native application it is referred to as "cloud native network function" (CNF) or "containerized network function". See Figure 7 - VNF vs CNF. This means that the software is distributed as a container image and deployed, managed, and orchestrated by tools like Docker and Kubernetes. Both VNFs or CNFs support lifecycle operations that enable frequent and automatic deployment and updates of the software; this is fundamentally different from traditional processes where network operations update network elements on a controlled and infrequent basis.

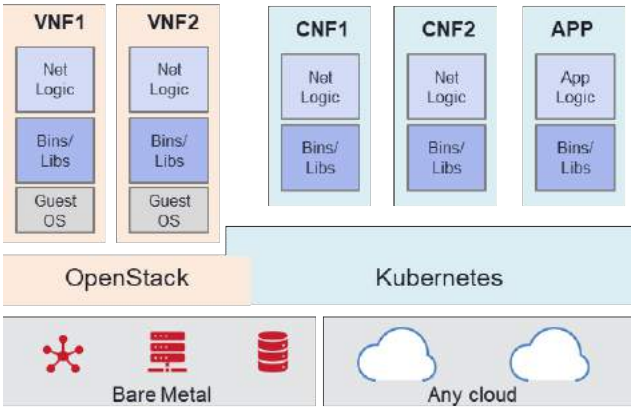

**Figure 7 - VNF vs CNF**

It is important to note that even though the software capabilities of a VNF may be containerized, the VNF itself is not orchestrated as a containerized application because the delivery mechanism for deployment is a VM image. In other words, containers inside the VM are not exposed to an external container orchestration system. Container orchestration or lifecycle management inside a VNF is typically handcrafted by the VNF vendor using tools like Docker compose and therefore container resource management is limited to the resources allocated to the VNF instance at deployment time. The

implication is that mechanisms for the operator to deploy, scale, monitor and heal these software-based network functions are very different and they operate at different abstraction levels, VM-based VNFs running on virtualization systems such as OpenStack or VMware vs container-based CNFs running on a container runtime such as Docker and orchestrated by Kubernetes.

These differences are critically important at the infrastructure edge where real-time user plane functions need to make optimal use of resources and require direct access to acceleration hardware, where containers can be much more efficient. Another key consideration for edge network functions is the location of the control plane responsible for lifecycle operations across a distributed set of compute elements hosting VNFs or CNFs. In the case of containerized functions, this control plane is increasingly based on Kubernetes which is based on a collocated server cluster concept. More on this in the next section, but the reliability and make-up of underlaying network infrastructure will impact the control plane design.

## 4.3. Container Orchestration

### *4.3.1. Kubernetes*

Kubernetes is one of the most widely used container orchestration and management platforms in the Enterprise IT industry (Alusha, 2019). The rise of Kubernetes (K8s) has enabled cloud providers to offer managed K8s services that allow enterprises to create a hybrid / multi-cloud environment for their applications. K8s is an open-source system for automating deployment, scaling, and management of containerized applications (Kubernetes, automated container deployment, scaling, and management, 2020). K8s simplifies the deployment of scalable, distributed applications by managing the lifecycle of containers, including scheduling, load balancing and distribution across different server nodes.

Kubernetes was designed for large scale cloud environments, and it works well out-of-box only when the infrastructure edge consists of one or more Kubernetes clusters and their master nodes have a fast and reliable connection to worker nodes. The Kubernetes master node (or control plane) is relatively heavy, and while its worker nodes are less resource demanding, they are still not lightweight at all. While specific sizes vary depending on its distribution and version, Kubernetes best practices for running large clusters (Kubernest Best Praactices, n.d.) recommends at least 4 GiB of RAM and a single core Intel Xeon CPU for a master node that controls up to 5 worker nodes. When the number of nodes grows, so grows the RAM and CPU requirements for the master node, getting to 60 GBytes and 36 Intel Xeon CPU cores for more than 500 nodes.

A Kubernetes cluster consists of the components that represent the control plane and a set of machines called nodes, sometimes referred to as worker nodes (Kubernetes Overview, n.d.). See Figure 8 - Kubernetes Components, taken from (Kubernetes Components, n.d.).

A pod is the smallest scheduling unit in Kubernetes and represents a set of containers that are tightly coupled, share resources and therefore run in the same worker node. Kubernetes runs workloads by assigning pods to nodes based on the resource usage and limits from the application. Each pod has its own IP address, and a default Kubernetes control plane runs its own DNS service for service to address resolution.

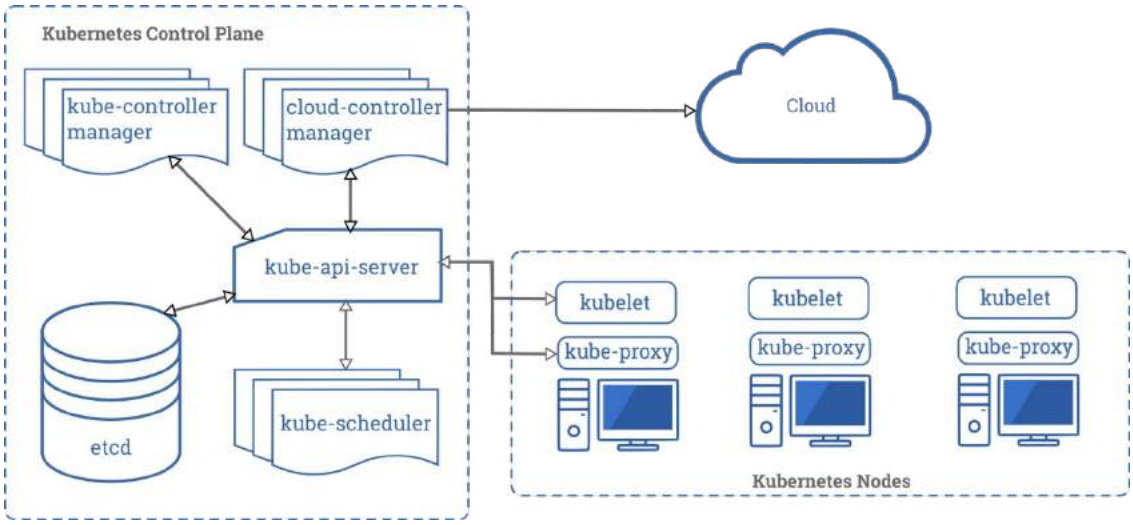

**Figure 8 - Kubernetes Components**

The Kubernetes control plane (master node) consists of:

- the database (etc. by default) that stores all cluster data,
- the API server (kube-api-server) that exposes the Kubernetes API and serves as its frontend,
- the scheduler (kube-scheduler) that watches for newly created pods and selects a node for them to run on,
- the controller processes runner (kube-controller-manager) that runs node, replication, endpoints and other controllers responsible for managing different elements of the cluster,
- the cloud-specific processes runner (cloud-controller manager) that runs processes specific to the cloud provider,
- for high availability deployments, the master node is configured on three separate machines.

The Kubernetes data plane (worker node) consists of:

- kubelet is the agent that accepts pod specifications from the control plane and runs them on the local container runtime (e.g. docker),
- kube-proxy is a network proxy that implements the Kubernetes Service concept, where one or more pods can sit behind a network service for load balancing purposes.

Kubernetes uses Network Plugins that run at the node level to configure container & pod network interfaces in the Linux OS and perform IP address management. By default, the kubelet is assigned with a plugin that supports a cluster-wide IP network. Container Network Interface (CNI) is a CNCF project that provides the specification and tools required to implement plugins to manage the allocation and deallocation of network resources for a container. Kubernetes supports plugins that adhere to the CNI specification and support can be extended as required by introducing new plugins for specific network functionality such as supporting container communications over VXLAN and MACVLAN (github.com/containernetworking, 2020).

Vanilla container-level networking is not suitable when orchestrating containerized data plane network functions (CNF) in a service chain or when more complex network overlays are required, such as creation and management of VXLAN tunnels that extend beyond a single Kubernetes cluster. Network Service Mesh is a cloud-native project that adds network capabilities to the Kubernetes ecosystem to enable dynamic cross-connections between local and remote CNFs (network service mesh, 2020). It offers an

 

API to establish connectivity between network services in an abstract way and provides policy-based service function chaining.

### 4.3.2. Kubernetes Distributions

Since a default Kubernetes installation (often referred to as "vanilla" Kubernetes) cannot be used without installing additional components, it is recommended to use one of the free or commercial Kubernetes distributions. A well-chosen Kubernetes distribution instead of the "vanilla" one reduces the operator's dependency on Kubernetes experts and offloads a lot of installation and configuration work, this is definitely a preferable choice, at least until the operator develop in-house expertise and automation tools with Kubernetes. A broad categorization of distributions is illustrated in Figure 9 - Kubernetes Distribution Models.

There are several dozen Kubernetes distributions recognized by the (CNCF), and it is recommended to select from this list according to the operator's requirements (CNCF Cloud Native Landscape, n.d.). We describe a couple of distributions below that are relevant for edge cloud.

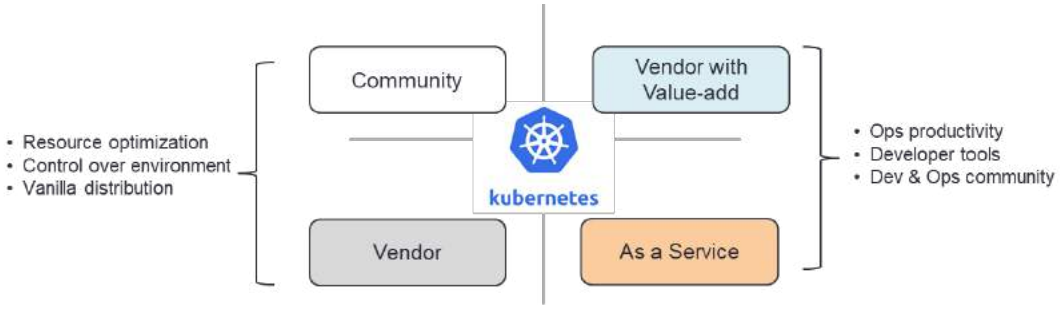

**Figure 9 - Kubernetes Distribution Models**

### 4.3.3. Vanilla Kubernetes Distribution

Kubernetes sources are available at GitHub (https://github.com/kubernetes/kubernetes) and many organizations take this source "as is", build it for different platforms and distribute it without any significant addition. This form of distribution makes it more convenient than building it from the source and has a clear correlation between such distribution and a tagged Kubernetes version (see https://github.com/kubernetes/kubernetes/tags). Canonicals "Charmed Kubernetes" distribution (https://jaas.ai/canonical-kubernetes) is an example of a vanilla distribution. This distribution has broad applicability across Telco and MSO workloads without specialized compute requirements for containers.

### 4.3.4. Kubernetes with Value-add Capabilities

Some commercial organizations take the Kubernetes source and add significant functionality to it, making a commercial distribution with dedicated support. Kubernetes distributions such as Red Hat OpenShift (https://www.openshift.com/) and Rancher (https://rancher.com/) provide installers for fully automated cluster deployment as well as abstractions and tools for DevOps processes and CI/CD pipelines.

Both Red Hat OpenShift and Rancher use special, container-oriented Linux distributions for worker nodes (CoreOS and RancherOS respectively). Some of these distributions offer a Cluster API capability to manage multiple Kubernetes clusters that can be deployed on-prem, private cloud or public cloud.

### 4.3.5. Kubernetes as a Service

Kubernetes as a service is offered by all major cloud providers, AWS, Microsoft Azure, IBM and Google Cloud Platform. In this kind of distribution, the cloud service provider takes care of everything related to the Kubernetes version, allocation, and installation of master (control planes) and worker nodes, and all the underlying compute, storage and network resources. This type of managed Kubernetes service is managed from the cloud providing the ability to unify on-prem and cloud hosted clusters and flexibly deploy containers across a hybrid cloud.

This type of Kubernetes deployment makes practical sense for back-end management workloads that oversee an operator's network but are not suitable for infrastructure edge user plane workloads. In some cases, the cloud provider supports edge cloud environments that can be collocated in a hub/headend or operator edge data center to run enterprise services or network control plane functions at the metro level. When considering this service, one must clearly understand the operational benefits, managed services costs and the tradeoffs associated with lack of control and visibility of the underlying infrastructure.

### 4.3.6. Lightweight Kubernetes for Edge Cloud and IoT

A Kubernetes cluster consists of one or more master nodes and one or more worker nodes. Each node has Kubernetes binaries that dictate the role and behavior of the node. These binaries come with significant overhead, which makes them impractical for certain edge deployments where the underlying hardware is limited in compute and memory resources. Lightweight Kubernetes distributions address this class of hosting environment by stripping off functionality that is not required in small scale, single node use cases.

One of such distribution is k3s by Rancher built for IoT and edge compute (k3s.io, 2020). This distribution builds Kubernetes from a reduced source tree and changes its binaries structure with the single goal of making it as small as possible. It replaces the *etcd* database with reduced storage based on *sqlite3* and removes in-tree storage drivers and cloud providers. Also, it reduces the memory footprint by running many components inside a single process. This results in a "lightweight" distribution that is suitable to run both control and user planes on devices with limited resources, making it a great fit for Edge Cloud nodes to coincide with RPDs/RMDs.

Canonical makes another "lightweight" Kubernetes distribution called MicroK8s (MicroK8s, 2020). This distribution also targets IoT and edge computing. It makes most of Kubernetes options default, resulting in simplified installation, configuration, and updates.

### 4.3.7. Kubernetes for Distributed Node Clusters

One more specialized Kubernetes distribution (or at least its approach) that should be considered. By default, Kubernetes requires a reliable connection between its master and worker nodes. KubeEdge is designed for environments where this connection may be intermittent and the Kubernetes master node (or control plane) is at the Cloud Tier while worker nodes are at the Edge Tier.

This distribution replaces the worker node's *kubelet* software with its own lightweight node agent called *edged*, and adds a special software layer on top of the master node. It changes how a worker node communicates with its master node located at the Cloud Tier, enabling it to work across non-reliable network conditions which the default Kubernetes control plane cannot tolerate.

Consider this alternative when there is a requirement for hosting the control plane in a central cloud location. The tradeoff for this is increased complexity and a significant deviation from the default Kubernetes, which locks the operator to this specialized distribution.

# 5. Building out a Distributed Edge Cloud

It is important to highlight the technical considerations in the deployment of virtualized infrastructure and network software applications such as in a DOCSIS DAA network. A proposed framework for this discussion is shown in Figure 10 - DAA Orchestration Framework.

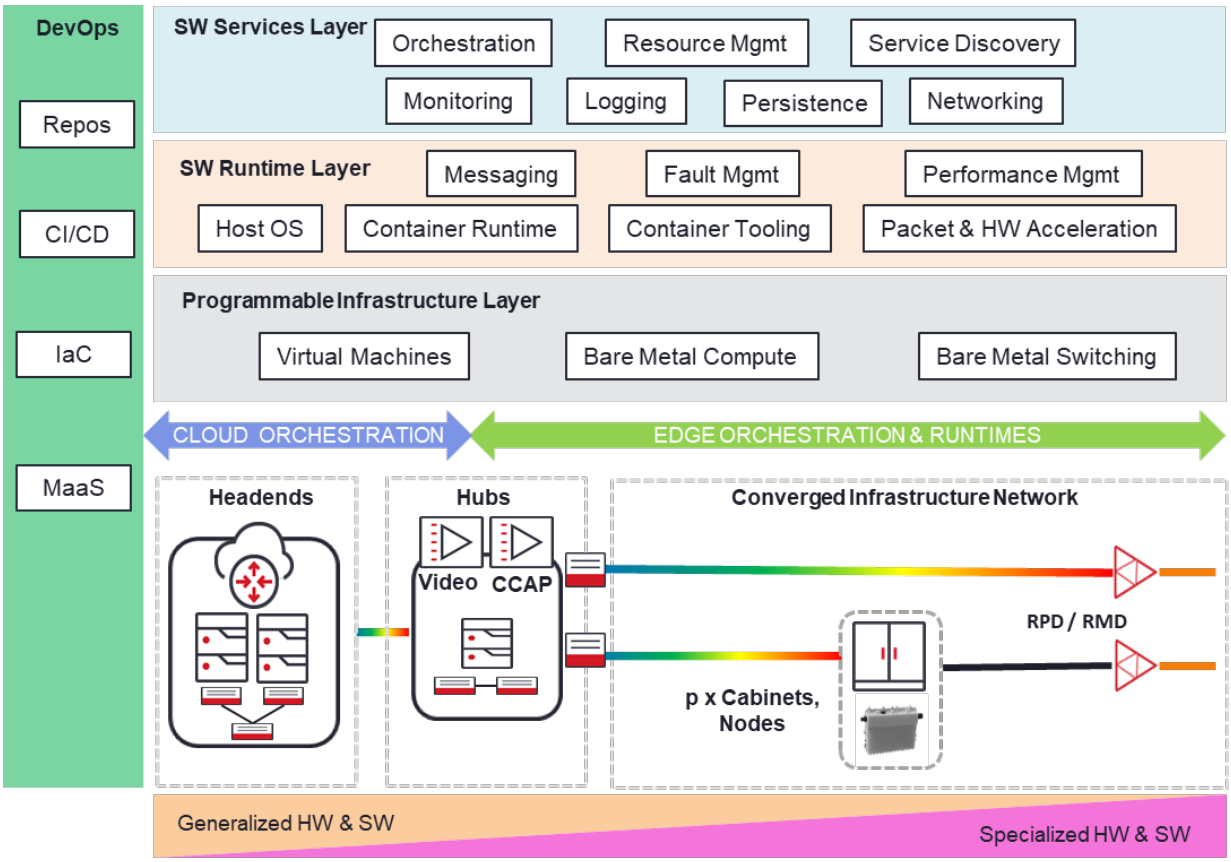

**Figure 10 - DAA Orchestration Framework**

## 5.1. Cloud vs Edge Orchestration

As discussed before, Kubernetes orchestration of containers/pods has some underlying assumptions about homogeneity, network underlay and proximity of worker / compute nodes. The Kubernetes scheduler needs reliable and fast connectivity to its compute nodes, in this case across the access network to reach Hub and RPD/RMD nodes. Kubernetes networking also assumes that the underlying switching infrastructure support a flat IP domain interconnecting the physical host nodes.

There are primarily three design alternatives:

1. Define Kubernetes clusters according to homogeneous resource type and functional requirements: e.g. nodes with specialized resources to support RPD/RMD functions belong to the same cluster. This means multiple edge clouds consisting of either general purpose compute or specialized compute & accelerator are managed by different Kubernetes instances. This adds complexity to managing distinct clusters, but it allows for independent scaling of cluster and the interconnection network
2. Define Kubernetes clusters according to a flat physical topology of the interconnection network and including heterogenous resources within the same cluster, i.e. general and special purpose resources. This simplifies the management of the centralized Kubernetes control plane itself, but complicates the scheduling algorithms needed to make container/pod placement decisions
3. Hybrid approach of the above two options to allow for incremental scaling and performance management of the network as services and subscriber density increases.

Similar issues arise with the default deployments of OpenStack because it was not designed for distributed edge clouds; resource heavy control planes need to be deployed at multiple locations with another management layer required to coordinate between different clouds. An end-to-end network service orchestration capability can be used to unify and stitch together services across multiple edge clouds.

## 5.2. Network Functions and Runtimes

One of the most important techniques for working with network functions at the edge is to treat them as individual building blocks or "microservices" with well-defined interfaces for configuration and user plane stitching. This provides operational flexibility to introduce new services and software updates, when and as needed, in an automated fashion.

Whether network function is control or user plane oriented, they will rely on standard communications protocols for interfacing with platform services or other network functions. Data transfers using RESTful mechanisms is the most widely used style implemented as JavaScript Object Notation (JSON) over HTTP/1.1. While this provides simplicity for clients, it does require a web server embedded in the network functions. Messaging using Remote Procedure Call (RPC) is protocol agnostic and offers direct communication between clients and server applications. Brokered messaging is another alternative usually used in high performance publish-subscriber communication models that requires a message broker. And lastly for monitoring applications the Message Queuing Telemetry Transport (MQTT) protocol is typically used. It is critical that VNF and CNF vendors align on standard protocols and interfaces to simplify integration and allow for optimization of messaging systems in the runtime environment.

Selection of the runtime environment for VNFs and CNFs is dependent on whether network functions are optimized for central cloud, edge cloud or specialized appliance environments. While these choices provide similar deployment agility from a Kubernetes scheduler, the runtime OS, guaranteed priority scheduling, and HW acceleration abstraction capabilities are critical for real-time sensitive network functions. Servers with accelerators (GPUs, FPGAs) or specialized ASIC-based appliances with generalized compute need a high reliability runtime to guarantee network and CPU resources, and provide a high-performance data channels between VNF/CNFs. RPD and RMD nodes with limited resources can use lightweight Kubernetes distributions and a specialized runtime for access to packet processing, HW acceleration features and policy-driven CNF chaining.

## 5.3. Automated Operations & Business Network Intent

Manual deployment and operation of edge cloud infrastructure is not practical, especially with the scale of MSO networks, services and subscribers. Software delivery, VNF/CNF instantiation and replacement must be fully automated by a software services, orchestration, and monitoring layer. This is one of the reasons Kubernetes adoption has risen quickly; changes in the infrastructure, application scale up/down and recovery on failures are fully automated based on application intent provided through a manifest.

Modern automation tools can be classified as supporting declarative or imperative style of programming. With declarative style, the infrastructure is described as "what" needs to be built, vs the imperative – "how". In order to support immutable infrastructure concepts described earlier, a declarative "what" style of tools (like Terraform) that support the notion of "Infrastructure As Code" should be used for managing infrastructure. This approach decouples infrastructure description from the tools used to build it, making it possible to automate across different compute and network systems. This is beneficial to maintain a common baseline of infrastructure software across a heterogeneous environment of Headend/Hub and remote RPD/RMD nodes.

A network fabric supporting edge cloud needs a holistic, data-driven closed loop approach that automates key business processes that span IT systems like planning, fulfillment and assurance and network lifecycle operations such system connectivity & network functions configuration, scaling and healing. Describing network intent in the form of operational state allows network algorithms to determine whether or not the network is deviating from its intended state and therefore take corrective actions, such as proactively re-routing traffic to avoid congestion or alerting the operator of impending network outages before they occur. Kubernetes intent-driven orchestration of containers is well suited to support this model as long as the scheduling of end-user applications can influence the allocation of the underlying network infrastructure, whether physical or virtualized. This enables optimal use of network resources based on application needs from core cloud to edge cloud to access.

One key area that requires special extensions to Kubernetes is the scheduling & placement of containerized functions based on not only CPU, memory, and specialized HW availability but also networking constraints that exist in a distributed edge cloud environment across headend/hub and remote nodes. The basic Kubernetes scheduler assesses in real-time CPU and memory resource requests and limits to decide on resource allocation and contention management. This works well in data center applications where the cluster fabric is overprovisioned and fully meshed, so placement decisions can be made virtually ignoring available bandwidth or effective round-trip-time between nodes. A network aware scheduler is required to maintain not only container resource usage and limits for compute and memory, but also topological constraints, specialized accelerators, network capacity, packet loss, latency and jitter metrics.

## 5.4. Application Repositories

Each application and virtual network function need to be placed in one or more repositories where the orchestration layer can retrieve and deploy across the infrastructure. This repository provides a controlled place where version-controlled artifacts can be maintained. This capability is vital for mitigation of issues that arise after a botched deployment. Automation must be able to restore a system to the last working state without network operator intervention. It is highly desirable to have this repository integrated with a software development Continuous Integration/Continuous Delivery (CI/CD) process or vendor pipelines to accelerate tactical deployment of new features and fixes.

Another proven practice in automated software operations is the blue-green model of deployment, where two identical software stacks are maintained, with the first (blue) being alive and the second (green) being on standby. Switching between stacks should be automated and without any downtime to the end-user or network service. When new components are released, they are added only to the green stack which becomes operational, while the blue remains on standby. Once the green stack has demonstrated no production issues, the blue stack is updated. However, if the green stack fails, then "old" blue stack becomes operational, while the green one is taken offline for troubleshooting.

## 5.5. Undercloud Architecture

In advanced software-driven networks, there is an expectation that the end-user applications riding over the network can influence network behavior and resource allocation to meet QoS, security and reliability requirements. The dynamic nature of containerized multi-cloud applications necessitates a flexible and intent-driven approach to automatically allocate, configure, monitor and scale compute and network connectivity resources between the physical infrastructure underlay and the network functions overlay as depicted in Figure 11 – Intent-Driven Undercloud.

The Physical Infrastructure Underlay (PIU) is made up of all the physical resources installed at headend/hub and remote node locations for the transmission, switching and processing of video and data services delivered to subscribers. This physical underlay is SDN-controlled and highly instrumented to enable high fidelity telemetry to be used by the Containerized Network Overlay (CNO) to ensure network applications and functions are meeting the demands placed on them by the End-User Application Service Mesh (ASM).

The CNO is made up of CNFs, and VNFs where appropriate, to deliver network control and user plane services such as vBNG, 5GC and UPF, vRouting and vCMTS. Due to the multi-layer nature of the Converged Interconnect Network (CIN), a Network Service Mesh (NSM) associated with the networking Kubernetes clusters can be used to drive policy-based service chaining and configuration of the CNO and PIU layers. These service chains, both control and user-plane centric, support specific services that are specified as "network intent" by the Application Service Mesh. This technique ensures that the CNO layer is making closed loop decisions with dynamic network information to operate within the policies specified by the operator while maintaining the intent of the network services specified by the ASM. This coordination of intents is based on the use of application manifests that specific resource requirements and constraints to the Kubernetes control plane.

It should be noted that the CNO and ASM layers are orchestrated and managed by different Kubernetes control planes which may be operated by the network operator or a separate application/cloud provider with integration into the operator's Intent-Driven Undercloud (IDU) and direct network peering into the Headend/Hub sites.

The Intent-Driven Undercloud (IDU) is a policy layer that maps application networking intent into a Network Service Mesh (NSM) intent that oversees multi-domain, multi-vendor, multi-layer functions such as available inventory and capacity of resources, resource management, orchestration and monitoring of end-to-end connectivity services. The IDU initiates real-time deployment & configuration, automatically allocating physical compute, store and network resources and stitching an end-to-end connectivity service that supports the CNO layer.

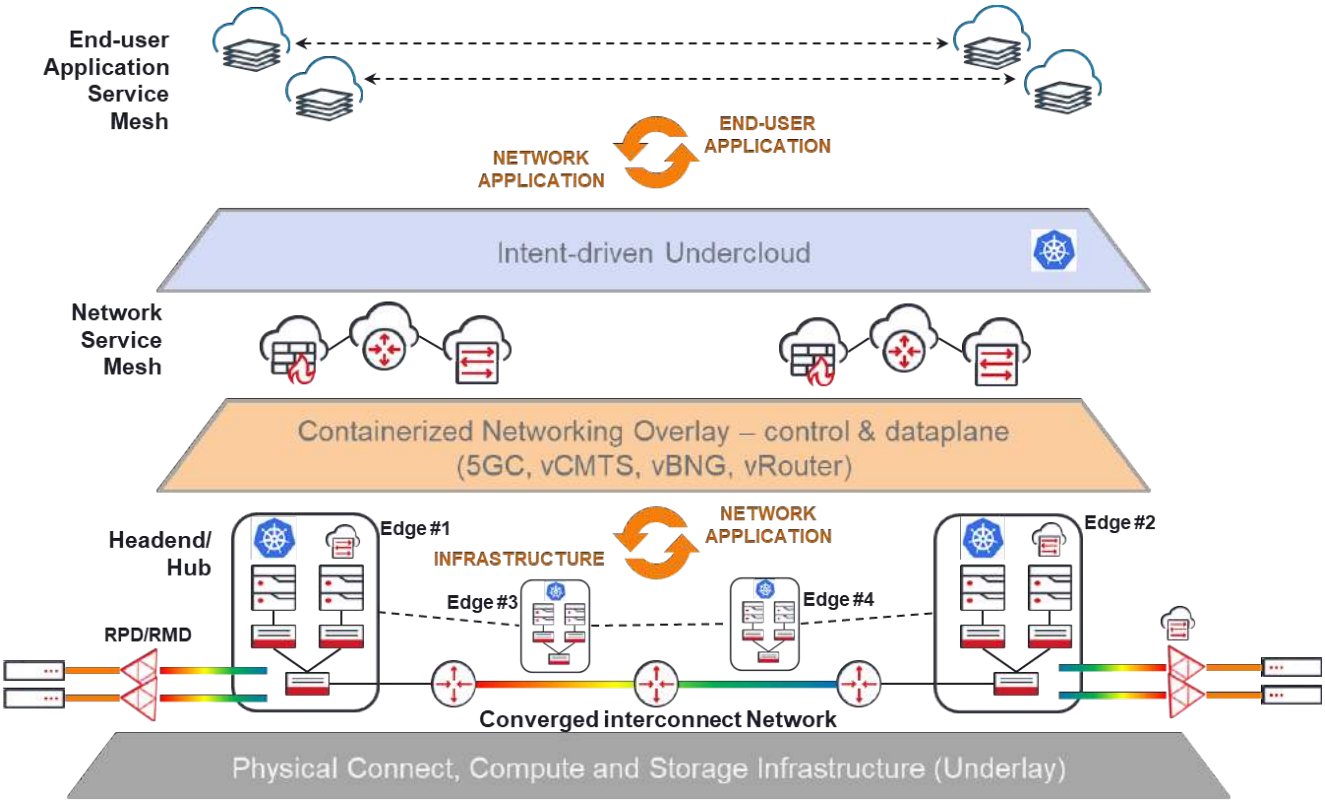

**Figure 11 – Intent-Driven Undercloud**

### *5.5.1. Undercloud Control Plane*

When orchestrating the undercloud with Kubernetes, each cluster is part of a headend/hub data center, where the master nodes (or control plane) reside. This control plane site uses the undelay CIN network for reliable and fast connections to the remote worker nodes or RPD/RMD nodes. This centralized architecture enables the master nodes to be configured for high availability and to scale where compute resources are homogeneous and plentiful.

Two approaches can be used to cluster compute nodes in the DAA network:

1. Organize clusters by resource type constraints
2. Organize clusters by physical connectivity constraints

The first approach, as illustrated in Figure 12 - Homogeneous Resource Scheduler, takes advantage of native Kubernetes scheduling features for deploying CNFs within the same pool of resources allowing an external end-to-end service orchestration component to abstract the physical topology dependencies in the access network and request CNF deployments according to network centric constraints such bandwidth availability, latency, packet loss, and jitter. This method allows for independent scaling & replacement of cluster nodes, clear separation of concerns between localized compute functions and decentralized network connectivity and enables independent scaling of the CIN topology. The end-to-end Service Orchestration component is responsible for calculating network paths and ensuring application intent is met through the interconnection of physical and virtual/container functions across clusters.

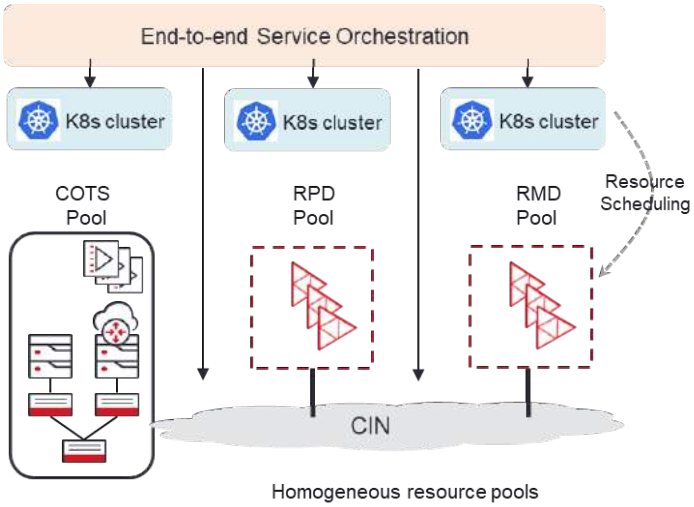

**Figure 12 - Homogeneous Resource Scheduler**

The second approach, as illustrated in Figure 13 - Heterogeneous Resource Scheduler, requires that Kubernetes be aware of network topology to make pod scheduling decisions. As discussed before, when Kubernetes is used for orchestrating the CNO across a heterogeneous network pool, its scheduler assigns pods to remote nodes based on CPU and memory resources only, potentially making sub-optimal decisions due to dynamic network latency and performance characteristics that it is not aware of.

To overcome this problem, the Kubernetes scheduler can be extended with capabilities to make network-centric decisions (Kubernetes Scheduler Extensions, 2020). This network-aware scheduler can use labeling mechanisms across the physical underlay to build a view of network topology, latency & BW utilization underpinning worker nodes. Additionally, it can label specialized resources such as FPGAs, GPUs and smart NICs to filter and select nodes given the CNF resource requirements.

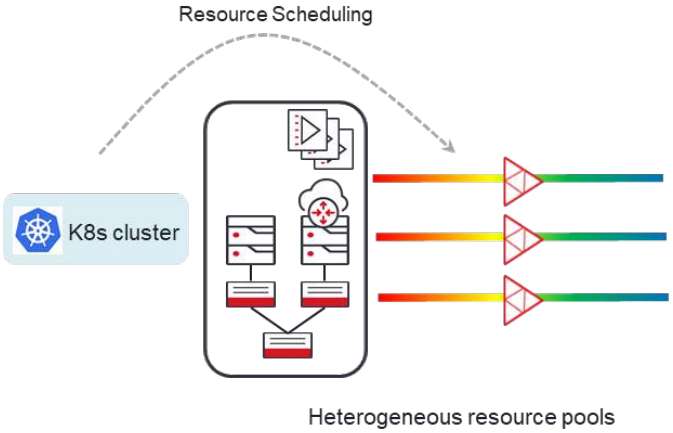

**Figure 13 - Heterogeneous Resource Scheduler**

This label-based, custom scheduler extension mechanism can be used to place CNFs to highly optimized nodes with run-time operating systems, available specialized software as Data Plane Development Kit (DPDK), Single-root input/output virtualization SR-IOV and various accelerators.

### *5.5.2. Undercloud Resources & Edge Optimized Runtime*

The resource-constrained reality of the distributed edge cloud nodes means careful consideration must be given to CPU, memory, and storage requirements for Kubernetes. Since centralization of the control plane is possible, the remaining concern is with the runtime environment footprint and Kubernetes agents to coordinate with the centralized master.

We have discussed several options in this paper, including lightweight Kubernetes distributions such as k3s, MicroK8s and KubeEdge to address Kubernetes agents running on worker nodes. The other challenge is addressing the container runtime itself, as discussed in Virtual and Cloud Native Network Functions. This runtime package should be based on a real-time Linux distribution built using the Yocto Project (Yocto Project, 2020).

As mentioned above, highly optimized resource nodes with real-time operating systems and specialized software and hardware can be included into pod scheduling decisions using Kubernetes labels and custom scheduler extensions.

Within CableLabs, there is a new initiative, called Project Adrenaline, which is harnessing momentum to address the management of heterogeneous accelerators available at different locations in the cable access network. This project aims to promote technologies and architectures that enable a distributed & heterogeneous edge compute fabric to support dynamic placement of workloads (Levensalor & Stuart, 2020). The ability to orchestrate workloads and abstract the use of accelerator resources through an edge optimized Kubernetes runtime is extremely beneficial for the application developer community; this initiative will accelerate application design cycles and deployment of new features and bug fixes, independently of the underlying infrastructure allowing for concurrent innovation and cloud-style delivery.

## 5.6. Open-Source Building Blocks

In previous sections, we have described the use of certain open source software components to build edge cloud infrastructure. In this section, we will provide a high-level overview of relevant open source projects and pointers for additional information. Open source software greatly reduces the price for solutions and components when the same codebase is used by several businesses, and these businesses coordinate the development effort and prioritization of features. Several organizations provide a means for coordination of development of open source software, usually in the form of a membership. The Linux Foundation is one of the largest and best known open source organizations and it includes several “suborganizations” with focus on specific areas of technology, one of which is edge.

### *5.6.1. LF Edge*

The Linux Foundation *Edge* was announced in Jan 2019 as an “umbrella organization to establish an open, interoperable framework for edge computing independent of hardware, silicon, cloud, or operating system” and includes over 30 “Premier” members from the operator, cloud and vendor community and over 40 “General” and “Associate” members (Linux foundation edge, 2020).

One of the most relevant for cable MSOs is the Akraino Edge Stack project.

#### *5.6.1.1. Akraino Edge Stack*

The Akraino Edge Stack intends to develop a fully integrated edge infrastructure solution for the Edge tier (LFEdge Akraino, 2020). This project consists of two main elements:

1. Blueprints as declarative configurations of entire software stacks to address specific use cases,
2. Software for common components declared in blueprints

The Akraino edge stack is an open-source software stack that improves the state of edge cloud infrastructure for operators, service providers and IoT networks. This edge stack can be viewed as the runtime and infrastructure layers for VNFs and CNFs. Akraino Blueprints are divided into two groups: approved and proposals, that are structured into several families. Each blueprint targets a very specific use case and a very specific deployment size, referred to as "Point of Delivery" (Akraino PODs, 2020).

Each blueprint uses the Akraino reference software stack illustrated in Figure 14 - Akraino Software Stack (The New Intelligent Edge - Akraino Edge Stack Overview, 2018).

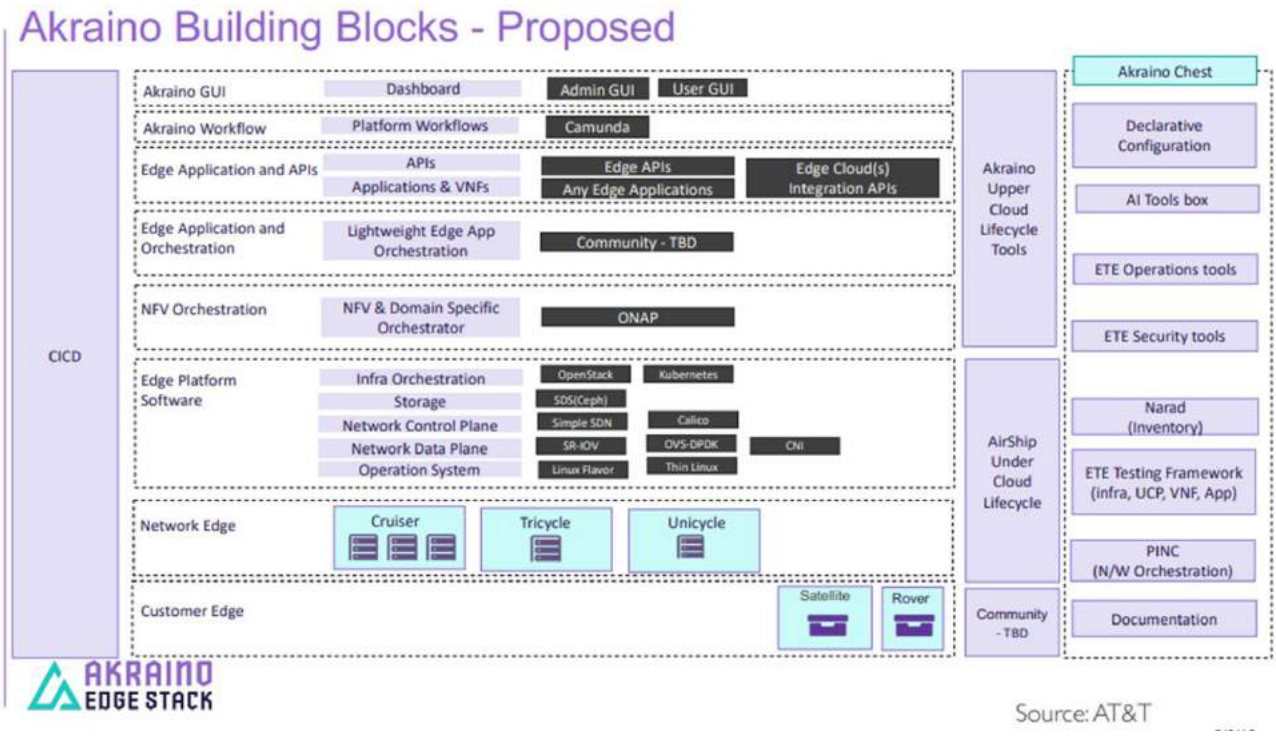

**Figure 14 - Akraino Software Stack**

Akraino uses an edge cloud architecture model with the full control plane located at the infrastructure edge. A blueprint represents a standard model of deployment for various operator sites: central regional and edge. While the blueprints cover a wide range of use cases with Multi-access Edge Computing (MEC) and 5G vRAN (Virtualized Radio Access Network) applicable to cable MSOs, there are no blueprints to address different control plane deployments.

A relevant blueprint for this paper is the Kubernetes-Native Infrastructure (KNI) Blueprint Family. The KNI is optimized for Kubernetes-native workloads and also allows hybrid deployments (CNF & VNF) using KubeVirt, a technology that allows VMs to run as a pod inside a Kubernetes cluster. There are currently two KNI blueprints in progress:

- Provider Access Edge (PAE) optimized for real-time and high performance vRAN and MEC workloads
- Industrial Edge (IE) optimized for small footprint and low latency for IoT, serverless and machine learning workloads

It is noteworthy that KNI uses a commercial Kubernetes distribution called "Red Hat OpenShift" (https://www.openshift.com/) and the Cluster API (https://cluster-api.sigs.k8s.io/) to deploy a Kubernetes cluster. The Cluster API is declarative and uses tooling to simplify provisioning, upgrading, and operating multiple Kubernetes clusters. This makes it much more suitable for the distributed edge computing deployments.

#### *5.6.2. Cloud Native Computing Foundation*

The Cloud Native Computing Foundation (CNCF) hosts open-source software components for cloud native applications (https://www.cncf.io/). CNCF hosts Kubernetes, however there are over 1,400 projects, product, or technologies under the CNCF umbrella, see (CNCF Landscape). It is recommended to get familiar with categories of technologies and products and to see how CNCF suggests combining them into a solution.

### 5.7. Commercial Cloud Platforms for Edge Computing

In its simplest form integration with a cloud platform is a matter of accessing specific endpoints on the internet, but most of cloud platform providers offer more tightly coupled software supporting computations at the Edge Tier.

When looking at this software it helps to understand that the Internet of Things (IoT) was the very first use case for edge computing that was offered by commercial and open-source cloud platforms. The IoT use case requires very specific cloud-based components (like a thing registry) and messaging protocol (MQTT), and Edge Tier nodes usually serve as IoT gateways. Also, this use case requires data processing as close as possible to the source. Such processing can be done as a dedicated process at the edge node, in the form of a standalone application, a container, a virtual machine or a serverless application. Serverless application frameworks are increasing in popularity because they do not require packaging, easily fit into event-driven design and use compute resources only when active.

#### *5.7.1. AWS IoT Greengrass*

The AWS IoT Greengrass consists of a binary that is installed on a node (a Linux server, for instance) at the Edge Tier. After installation and registering with the AWS IoT cloud service, it provides MQTT messaging service to IoT devices. Messages can be processed right at the node by a serverless application (integrated with AWS Lambda service) or forwarded to the cloud for consumption by other AWS services. AWS IoT Greengrass also integrates with artificial intelligence software, providing means to run models pre-trained at AWS or elsewhere.

### 5.7.2. AWS Outpost

AWS Outpost is a ready-to-use edge cloud infrastructure. It provides several compute, storage and networking services that are enough to run an Edge Tier based datacenter. Typically, an Outpost rack of server is deployed on the enterprise premise or the operator's network to peer directly with access networks such as 5G and perform real-time edge processing functions. Outpost is offered as a managed service and is considered an extension of AWS cloud regions, making it possible to seamlessly deploy applications across core and edge clouds.

### 5.7.3. Azure IoT Edge

Microsoft Azure IoT Edge is a binary that extend the Azure IoT Hub to the edge. As AWS IoT Greengrass, it can serve as IoT gateway, and can run containers and artificial intelligence software, all integrated with respective Azure services.

### 5.7.4. Azure Stack Hub

Microsoft Azure Stack Hub is another ready-to-use edge cloud offer, very similar to AWS Outpost, except that it is only a software stack that run on commodity servers. It provides several compute, storage and networking services that are enough to offer IaaS and PaaS services at edge locations or local zones.

### 5.7.5. Google Cloud Anthos

Google offers a different approach to enable edge and multi-cloud environments. Google Anthos is a control plane and run-time Kubernetes environment that unifies delivery of containerized applications across a wide variety of public (e.g. AWS) and private cloud (e.g. VMware) environments.

## 6. Conclusion

Cable operators' investments to modernize access networks and move towards DAA is opening up new opportunities to transform their operations models and differentiate their network services with support for edge-centric Enterprise applications. Embracing cloud-native principles and an applications-first mindset is critical to the success of this transformation while simultaneously creating new revenue streams for Edge Cloud applications. Adapting Kubernetes orchestration and containerization of network and application functions are foundational first steps, which when coupled with an Intent-Driven Undercloud as defined in this paper, creates an adaptive and application aware network built for dynamic scale, business agility, operational efficiency and service innovation. This strategy enables low-latency and high bandwidth on-ramps to edge cloud resources at Hubsites and DAA locations where dynamic application demands can be satisfied through intelligent placement of network & application topologies.
