With Dennis Botman, we did more than simply play around with a Chatbot as a side-project. We, in essence, created another teammate. A teammate that could make all of our jobs easier, but only after we spent time training it, as well as making our customers comfortable with getting help from a bot. In the end, we were able to free up more time to tackle larger, more interesting problems.

Tasks to improve engineering efficiency can have a huge impact on how you grow and operate your engineering teams. Setting aside time for your engineers to solve their own problems should always be looked upon as an investment of time or resources that carries many beneficial outcomes.

Abbreviations

API	application programming interface
ATM	automated teller machine
CLI	command line interface
DNS	domain name system
DM	direct message
FAQ	frequently asked question
FQDN	fully qualified domain name
IP	internet protocol
RDEI	rapidly deployed elastic infrastructure
ROI	return on investment
NLP/NLU	natural language processing / understanding
NLU	natural language understanding
VIP	virtual ip (internet protocol)

Abstract

Artificial Intelligence (AI) and cloud computing are two factors (among others) that allow Communication Service Providers (CSPs) to become Digital Service Providers (DSPs). CSPs, through AI, have the possibility of transforming their networks, and the operation of services. The natural evolution of applying AI to our networks ("knowledge plane"), is what has been called Autonomous Networks. Networks that can be self-configured, self-healing, self-evolving and self-optimizing. In this paper we will present the journey that we have started in the data-driven operation of our networks and services (AIOps) and the use cases with which we seek to reach autonomous networks. Like also the discussion of some frameworks, the challenges and how long this evolution will take.

Content

1. Introduction

AI Operations (AIOps) is one of the most talked-about acronyms in the IT world these days. In the last year, the term AIOps has been introduced strongly in the Telecommunications industry and has become a special topic in the main conferences [1] [2].

The term AIOps was originally coined by Gartner in 2016 and have pushed the concept into the marketplace. “AIOps combines big data and machine learning to automate IT operations processes, including event correlation, anomaly detection and causality determination” [3].

This definition applies to AIOps in enterprise IT environments: CSP typically have bigger and more complex IT environments with multiple sets of IT challenges. For a long time at the SCTE Cable-Tech Expo and other conferences, data analytics and AI / ML applications have been presented that today we would call AIOps.

A first definition of AIOps in the telecommunications industry is the use of AI for the operation of networks and services. In some way the automation of many of the processes of the operation, being the long-term objective to reach what is called autonomous networks.

Certainly, there has been a lot of activity in trying to use AIOps to improve cable network operation and customer experience. On the other hand, future networks (full virtualization and containerization) and services will generate a volume of data with exponential growth, and this poses a great challenge.

In 2018, after the merger of Cablevision S.A. (MSO) and Grupo Telecom (Telco, MNO), Telecom Argentina began a process of digital transformation, which has accelerated since the COVID 19 pandemic. We are going from being an MSO and MNO, that is, a Communication Service Provider (CSP), to a Digital Service Provider (DSP). Telecom is going to a Multiservice Convergent Network and Multi devices approach, where the Client / User can consume their own and third-party services (platforms) from any device and connected to any of our access networks.

The DSP is not merely a dumb pipe offering shared access to a common utility; it is an online, real-time business that deals with countless transactions every day, managing high volumes of data traffic and

multiple devices per user, and often multiple users per account. The mobile and fixed landscape has changed dramatically and CSP's are fine-tuning their businesses, and their network infrastructure, to cater for the digital needs of the data-hungry customer.

In our networks and services, AIOps has the potential to change, the way we operate, and to become the foundation of the transformation that leads to the fourth industrial revolution. But this requires hard work, a long-term commitment, and a deep cultural change. All Operations Support Systems (OSS) in our current and future networks generate a huge amount of data.

The final aim of all these efforts is to be able to offer our services in an adequate way for our next generations of clients. They are nowadays putting the requirements in the market and driving the evolution of technologies. Our clients do not buy technologies, they buy services. Operating, managing, and provisioning future services with automation processes becomes essential. If we want a complete automation, we will need AIOps.

This technical paper proposes a comprehensive overview of frameworks and applications of AIOps, and we will present the journey that we have started in the AI-driven operation of our networks and services (AIOps) and the use cases with which we seek to reach autonomous networks. This technical paper is organized as follows. Following this section, we introduce AIOps. In section 2, we expose AIOps Service Management Framework. In section 3, we present the state of the art in the evolution towards autonomous networks, the concept of the knowledge plane and our reference architecture. Section 4 we present the AIOps use cases in Telecom Argentina. The last section, which is section 5, outlines the key challenges in our digital transformation journey that we started in 2018.

1.1. AIOps Overview

While AIOps was developed to give scalability to the management of IT systems, given their increasing complexity, the associated platforms and the AIOps framework, we can extend its applications to Telecommunications operations. AIOps has 3 main parts: *observe*, *engage,* and *act*. (Figure 1).

AIOps brings together three different IT disciplines - Service Management, Performance Management, and Automation - to achieve your continuous improvement and information goals. AIOps is the recognition that in our new accelerated and hyper-scaled IT environments, there must be a new approach that takes advantage of advances in big data and machine learning to overcome legacy tools and human limitations.

Implementing an AIOps strategy goes beyond obtaining better analysis of existing data. To create the foundation of a machine learning system that provides continuous information, you need:

- Open access to data including multiple consumable sources of streaming and historical IT data
- Machine learning and algorithms that learn behavior patterns from data and generate automated information
- Automation to act on analytical information and collaborate with the ITSM customer service center

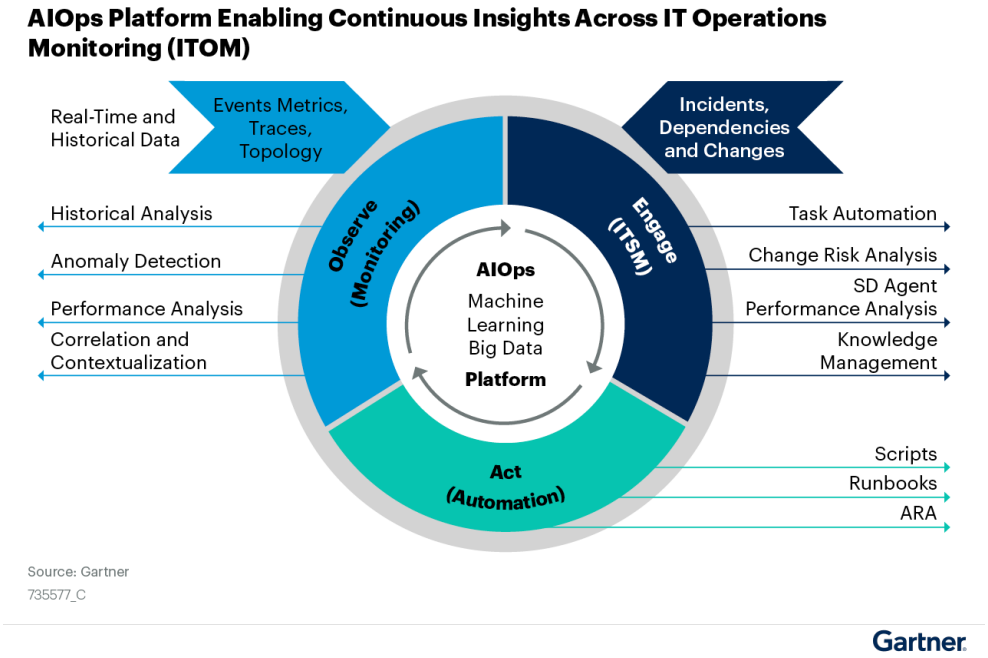

Figure 1 - AIOps for ITOM by Gartner

Various AIOps platforms have been developed in the IT world. “Nowhere is this more evident than in the world of DevOps, a data-rich, back-office practice that presents a perfect sandbox for exploring the power of artificial intelligence. The teams in charge of operations now have a burgeoning collection of labor-saving and efficiency-boosting tools and platforms on offer under the acronym AIOps, all of which promise to apply the best artificial intelligence algorithms to the work of maintaining IT infrastructure” [4].

AIOps platforms enhance decision making across I&O personas by contextualizing large volumes of operational data. I&O leaders should use AIOps platforms to improve analysis and insights across the application life cycle, in addition to augmenting IT service management and automation.

Enterprises are increasing their use of AIOps across various aspects of IT operations management (ITOM) and maturing their use cases across DevOps and SRE practices.

Enable continuous insights across ITOM by supporting these three aspects of AIOps platforms: observe, engage and act [5].

In Figure 2, we present where the AIOps platforms are in the Hype Cycle for Monitoring, Observability and Cloud Operations.

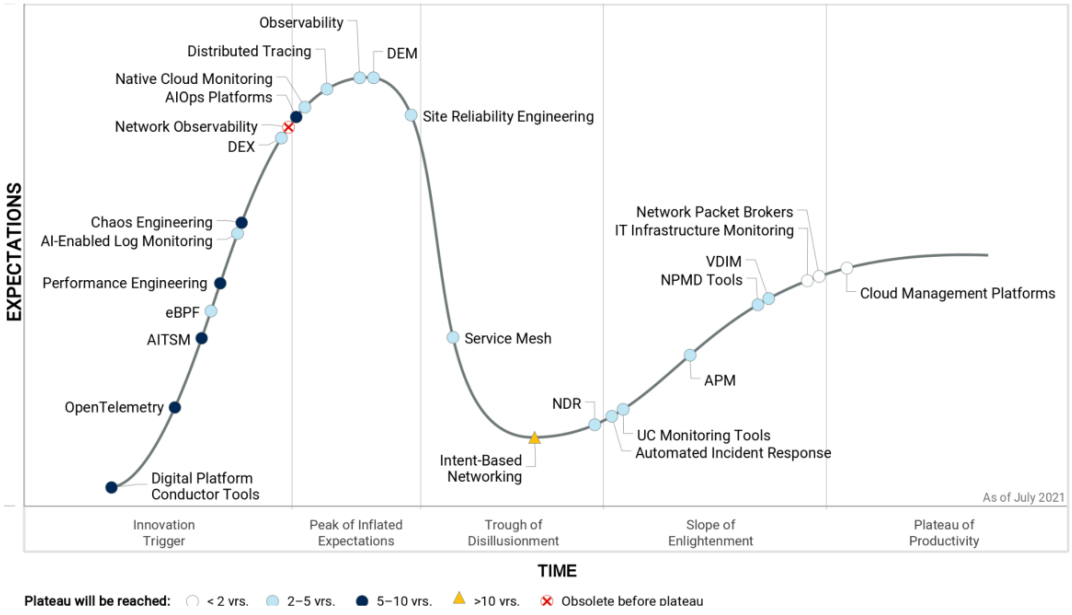

Figure 2 - Hype Cycle for Monitoring, Observability and Cloud Operations, 2021
Source: Gartner

1.2. AIOps and Cloud Native

We are building cloud native applications as a collection of smaller, self-contained microservices has helped organizations become more agile and deliver new features at higher velocity. In the Figure 3 we present the evolution in the IT world from a traditional architecture to one based on containers and the role of AIOps.

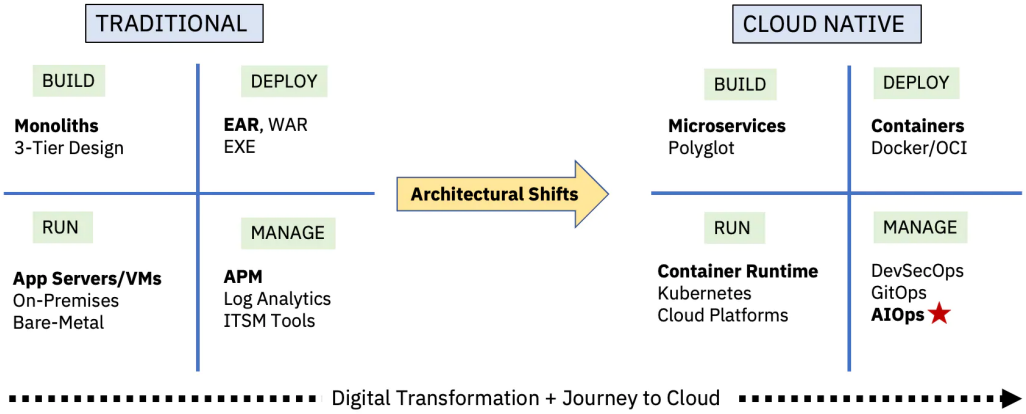

Figure 3 – Evolving IT landscape
Source: IBM[1]

[1] https://www.ibm.com/cloud/blog/aiops-a-path-to-reliability-at-cloud-scale

1.3. Future Networks and AIOps

According to the Ericsson Mobility Report [6] in 2026, 3.5 billion 5G subscriptions are forecast. The Massive IoT technologies NB-IoT and Cat-M1, in 2026, these technologies are forecast to make up 46 percent of all cellular IoT connections. Two-thirds of the world's data didn't exist five years ago, and the datasphere will grow more than 5X by 2025, according to IDC.

At Telecom Argentina our vision of 10 G and 5G is that it is not just an access technology, it is a *digital ecosystem* to create services tailored to our clients, end to end.

"5G promises to be revolutionary if CSPs, vendors, application developers and companies find how to co-create, manage and participate in a digital ecosystem" [7].

The 5G ecosystem is conceived with the technologies and architectures used by the "cloud natives[2]", its functions, services and attributes are controlled by software applications and can be exposed as an "API" or as a service adjusting to the measure of each need. Allowing to expose network capabilities and combine them with AI.

Figure 4 shows the journey towards a native cloud architecture and the level of automation, which was presented in "CableLabs Envision Vendor Forum 2021 Mobile and Convergence".

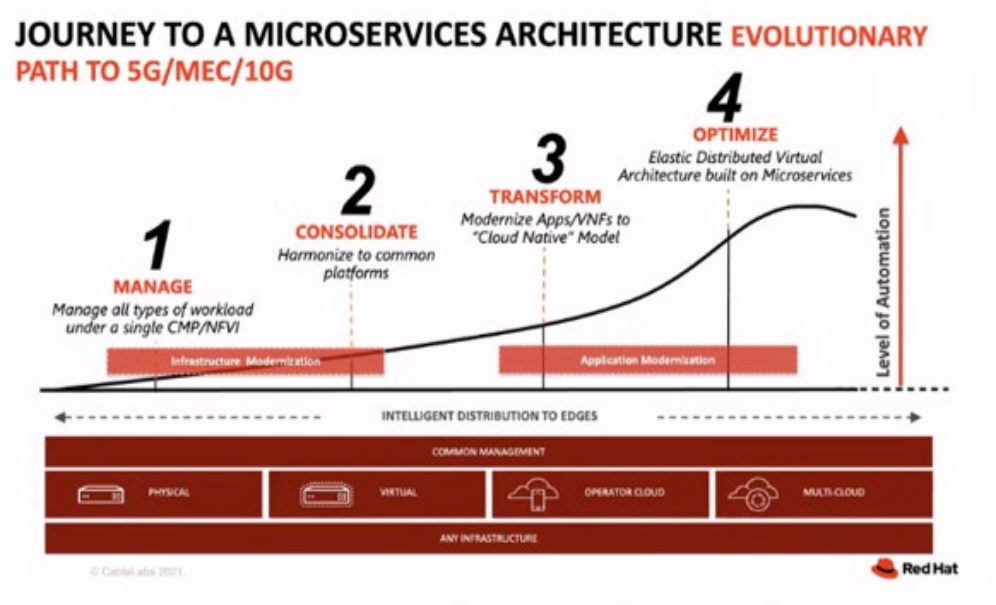

Figure 4 - Journey to a Microservices Architecture
Source: CableLabs[3]

[2] When we deploy network functions in the cloud, we must distinguish between cloud ready, that is, network functions on virtual machines (Virtual network functions, VNFs) with deployment automation and cloud native where network functions are based on containers (cloud-native network functions, CNFs).
[3] https://community.cablelabs.com/wiki/display/COMMUNITY/Envision+2021 (members only)

The computing capacities necessary to generate the services are also distributed and can be located where it "makes the most sense" according to the need.

5G was born AIOps, since from its conception the so-called *plane of knowledge* has been included. That is, a layer within the architecture oriented to the operation and orchestration of networks and services.

1.3.1. Future Networks and AI

Although AI / ML is part of the architecture of future networks, it is important to highlight the combination of 5G, 10G and AI for the generation of new services. Future networks will provide the scalable bandwidth and remote computing power needed to collect and process the growing volumes of data that will drive the proliferation of artificial intelligence, distributing intelligence everywhere. Figure 5 shows the economic value generated by 5G and AI.

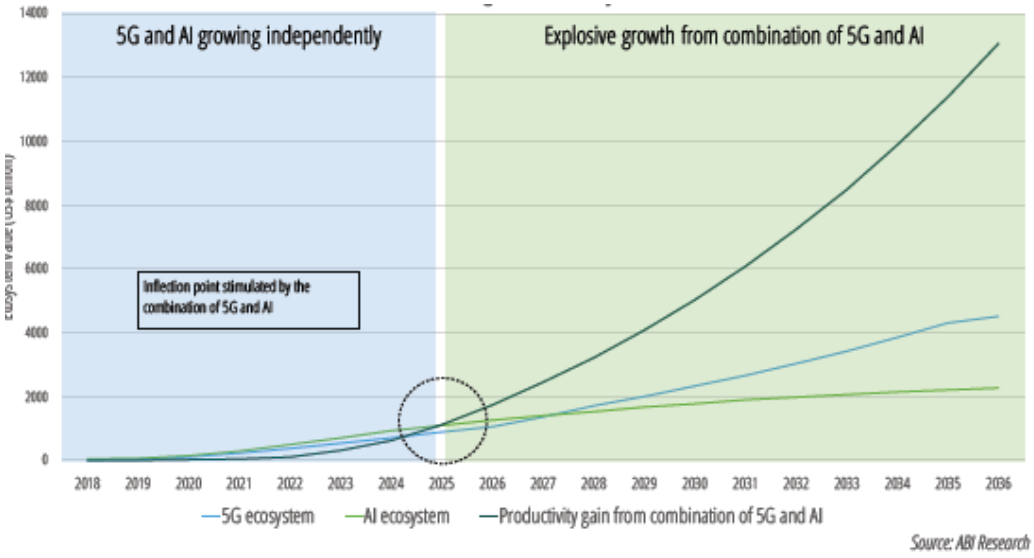

Figure 5 - Economic value generated by 5G and AI

2. AIOps Service Management Framework – TM Forum

The transformation affects all aspects of a CSP business, including operations that have undergone constant change since a few decades. CSP's role has shifted from offline records related to telephony services to processes that design, install, provision, activate, maintain, and manage inventory for each network-based service. AIOps, envisions a high level of AI-assisted or driven automation in IT and network operations [8].

In addition to the challenges faced by any large enterprise, CSPs include specific business and operations systems and processes, as well as new software-defined and controlled networks. Each of these environments is in flux, moving toward cloud-native architectures that can run on public, private, and hybrid (a mix of public and private) clouds. Automation of operations is the scope of AIOps for CSP,

[4] https://www.intel.la/content/www/xl/es/wireless-network/5g-ai-foundations-business-society-abi-report.html

although the teams working on AI and automation are largely separate today. Additionally, data tends to be disparate, processes can be semi-documented and inconsistently automated, and organizations tend to work in silos.

It is important to understand how different is working with AI from traditional operations. It is based on intention rather than procedure and employs non-deterministic logic and non-predictable outputs from specific inputs.

2.1. AIOps motivation

AIOps envisions a high level of AI-driven or assisted automation in IT and network operations. It's a radical leap, but critical if CSPs want to achieve their automation goals. How they get from here to there is the most important question that AIOps helps to answer.

While current technology (without AI) can automate nearly 75% of manual effort, AI is the best choice for processing extremely large data sets that combine heterogeneous data from multiple sources and where multi-domain, or cross-functional correlation is required.

In the context of our work, we adopt AIOps definition as in Figure 6, where Operations include:

1. Business processes enabled and driven by AI.
2. Service Management frameworks, processes, and tools that have been properly reengineered and adapted to support the operations management of AI-based applications and their components in Production. We call this layer *AIOps Service Management*.
3. AI-based applications that are actively running delivering business and operational services. In AIOps, we assume that key systems and their components in Production are deeply infused with AI capabilities forming a blend of AI and traditional software. In figure 1 we indicate these systems as AI-based BSS, AI-based OSS, AI-based Data Analytics, AI-based ERP, third-party AI platforms, other AI applications.
4. Infrastructure components where automation is driven by AI.

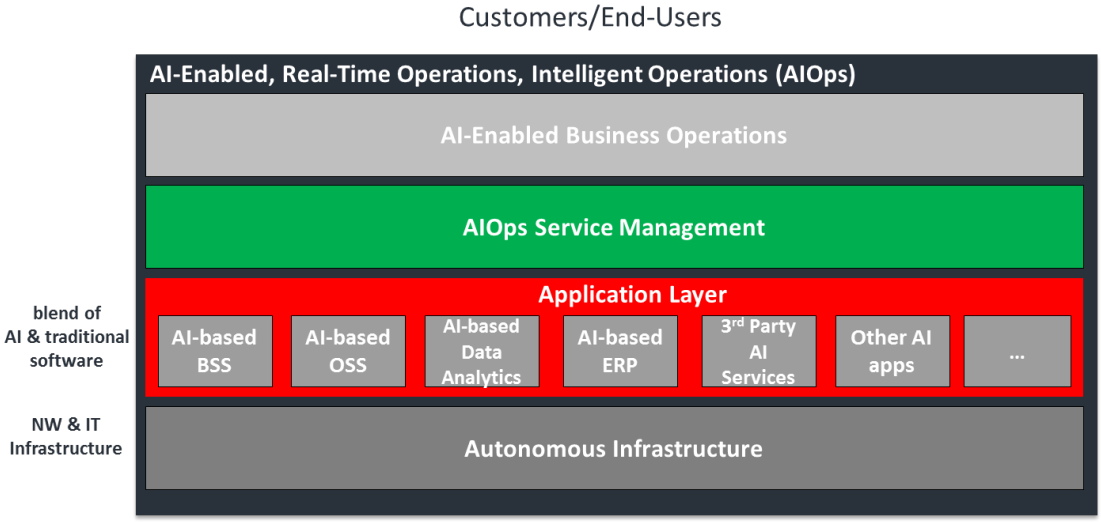

Figure 6 - AIOps and AIOps Service Management
Source: TM Forum

AI can also be a better fit than traditional software to automate responses to both repetitive analytical requirements and ever-changing network configuration and customer experience requirements.

Figure 7 – Goals for AIOps
Source: TM Forum 2020, ACG Research

CSPs should take a few steps on the automation path to increase the degree of hands-on service they can deliver, regardless of the achievement of large-scale autonomous networks - many more milestones remain on that path.

2.2. AIOps Service Management processes

Within the life cycle of traditional software there are two stages: Implementation and Production.

- *Implementation*: it is the set of all the processes and activities that carry a given software and its corresponding components from the Development stage to the Production stage of the life cycle, making that software and its capabilities available to end users.

- *Production:* is the set of processes and activities that operate, monitor, support, maintain all applications and all their components in live production environments, and ensure that the capabilities and services provided by those applications are available and appropriately consumable by end users in accordance with SLA. Production is usually the stage where apps spend most of their life. We design and develop applications in days, weeks, or months. We then deploy them to Production in minutes or during an overnight rollout deployment. There, in production, applications can last for years and even decades.

In AIOps this segmentation is indistinguishable. The dynamic nature of AI software and its ability to learn and evolve autonomously while running in Production create a continuum between the Implementation and Production stages. AI components will permanently move from the deployment state to the live state and vice versa, challenging the distinguishable boundaries that currently exist between the deployment and production stages.

2.3. Real-world use cases

Some use cases based on the real-world business needs of CSPs have been developed. They are focused on customer experience, service quality, business performance, and efficiency.

These include:

- Prevention and prediction of poor customer experience
- Prediction of churn and proactive customer retention
- Accurate service level monitoring
- Proactive root cause identification, communication, and resolution in 5G networks
- Customer complaint prevention
- Preventive Maintenance
- Smart Operations and Maintenance (O&M) for Broadband Services in the Home
- Closed-loop service assurance

2.4. AIOps and Automation

The information provided by machine learning and analytics can drive automation to save time and reduce costs. An AIOps solution can provide functionality for high-value use cases, such as automated event remediation, closed-loop compliance processes, and event-driven automation. Smart ticketing can be particularly valuable as it automatically generates service tickets based on automatic anomaly detection and then optimally routes the tickets to the expert who can best fix the problem or fix the problem automatically. As a result, operators can manage a growing number of assets without increasing labor costs, freeing up staff for more valuable activities, and delivering better quality to customers.

2.5. How to start

AIOps continues an evolution in operations that began some decades ago, when teams focused primarily on offline record keeping, increasingly automated processes. This journey started with observability, moved to actionability, and now culminates in closed-loop automation. The solutions used to implement AIOps fall along similar lines.

- Analyze complex data sets to identify patterns in monitoring, capacity and automation data in hybrid on-premises and multi-cloud environments.
- Provide information that guides immediate actions to reduce costs, solve problems more quickly, and improve quality.
- Closed-loop automation: artificial intelligence and machine learning enable problems to be predicted, found, and solved without human intervention, often before they affect service quality, and to improve quality in a modern environment of software defined networks (SDN).

3. Autonomous Networks

Given the growing virtualization and cloudification (Telco-Cloud)[5] of our networks make possible the evolution towards autonomous networks. At Telecom we adopt the AIOps framework, understanding that it is the from automation path to autonomous networks (AN). "Autonomous networks, put simply, enable our engineers and technicians to go off and chase really interesting problems, leaving the less interesting problems to be operated by software systems" [9].

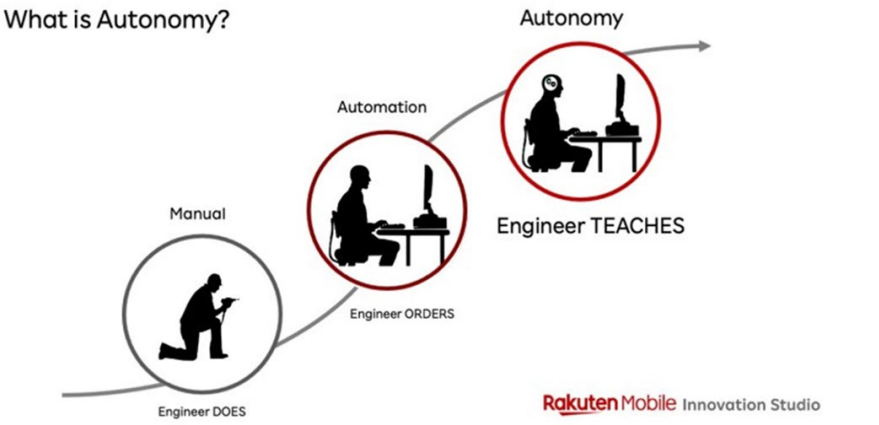

Figure 8 – What is Autonomy?
Source: Rakuten Mobile

We understand AIOps as the way to automate autonomous networks. Although today there are no autonomous networks (AN). Rakuten is the first fully virtualized network in the world, they have the privilege of being able to begin the journey of creating a truly autonomous network [10].

There are several organizations and working groups proposing frameworks, standards and how to apply the AI to automation in the networks. There are three main thrusts of AN: ETSI, ITU, and the TM Forum, which are driven by operators and vendor (Telecom Argentina is participating or is in consultation with them).

- TM Forum - Autonomous Networks Project [11].
- ITU Focus Group on Autonomous Networks (FG-AN) [12].
- ETSI Experiential Networked Intelligence Industry Specification Group (ENI ISG) [13].

3.1. Definitions

We have taken some definitions from those working groups and we started to build our own AIOps and AN framework.

- **Data Analytics**: monitoring data to look for patterns and anomalies (without applying intelligence) and applying those patterns towards effective decision making.

[5]Much of our core of the mobile network is virtualized, however the APIs are proprietary to the vendor.

- **Artificial Intelligence**: the development of computer systems capable of performing tasks that normally require human intelligence; this includes visual perception, speech recognition, decision-making, and translation between languages.

- **Machine learning**: a type of AI that gives machines the ability to learn automatically and improve from experience without being explicitly programmed.

- **Deep learning**: takes machine learning further by processing information in layers, where the result or output from one layer becomes the input for the next.

- **Automation:** within MSOs and MNOs, this means automation of processes that were previously carried out by people; AI is an enabling technology that may (or may not) help with the process of automation. Within MSOs and MNOs, this means automation of processes that were previously carried out by people like configuration, management, operation and testing of physical and virtual devices within the network. With growing costs and the daily emergence of bandwidth-hungry applications, networks cannot be managed manually. Increased levels of network automation help to reduce complexity and are essential for businesses to keep up in the digital world. AI is an enabling technology that may (or may not) help with the process of automation. What it culminates is a network that is highly predictable and highly available improving the business outcomes.

- **Cognitive computing:** like AI, cognitive computing is based on the ability of machines to sense, reason, act and adapt based on learned experience, but whereas AI acts on its analysis to complete a task, cognitive computing provides the information to help a person decide. Like AI, cognitive computing is based on the ability of machines to sense, reason, act and adapt based on learned experience. Cognitive computing refers to computing that focuses on reasoning and understanding at a higher level and in a manner that is analogous to human cognition, rationale, and judgement. Applications of cognitive computing include speech recognition, sentiment analysis, face detection, risk assessment and fraud detection. The difference between AI and cognitive computing lies in the way they approach the purpose of simplifying tasks. AI is used to augment human thinking and solve complex problems. Cognitive computing mimics human behavior and reasoning to solve complex problems like the way humans solve problems.

- **Autonomous networks:** are those that possess the ability to monitor, operate, recover, heal, protect, optimize, and reconfigure themselves; these are commonly known as the self-properties. The impact of autonomy on the network will be in all areas including planning, security, audit, inventory, optimization, orchestration, and quality of experience. At the same time, autonomy raises questions about accountability for non-human decision that affect customers" [14].

3.2. Intent-Based Networking

"Intent" is the keyword in this technology, which describes a network's business objective or an outcome.

Intent-based networking (IBN) is an emerging technology concept that aims to apply a deeper level of intelligence and intended state insights to networking. Ideally, these insights replace the manual processes of configuring networks and reacting to network issues. The goal is networking that uses machine learning and cognitive computing to enable more automation and less time spent on manual configuration and management. With intent-based networking, network administrators define the intent and the network's software finds how to achieve that goal using AI and ML by

performing routine tasks, setting policies, responding to system events, and verifying that actions have been done.

These systems not only automate time-consuming tasks and provide real-time visibility into a network's activity to validate a given intent, but they also predict potential deviations to that intent, and prescribe the action required to ensure it. This greater intelligence makes the network faster and more agile and reduces errors [15].

3.3. Levels

Six levels of autonomous networks were defined by the members of the TM Forum. As shown in Figure 9.

Autonomous Levels	L0: Manual operation & maintenance	L1: Assisted operation & maintenance	L2: Partial Autonomous Networks	L3: Conditional Autonomous Networks	L4: High Autonomous Networks	L5: Full Autonomous Networks
AN services (Zero X)	N/A	Individual AN case	Individual AN case	Select AN cases	Select AN services	Any AN services
Execution	P	P/S	S	S	S	S
Awareness	P	P	P/S	S	S	S
Analysis/ Decision	P	P	P	P/S	S	S
Intent/ Experience	P	P	P	P	P/S	S

Personnel (manual) Systems (autonomous)

Figure 9 – Six Levels of Autonomous Driving Network

Source:TM Forum

Level 0 - manual management: The system delivers assisted monitoring capabilities, which means all dynamic tasks must be executed manually.

Level 1 - assisted management: The system executes a certain repetitive sub-task based on pre-configured to increase execution efficiency

Level 2 - partial autonomous networks: enables closed-loop O&M for certain units based on AI model under certain external environments, lowering the bar for personnel experience and skills.

Level 3 - conditional autonomous network: Building on L2 capabilities, the system with awareness can sense real-time environmental changes, and in certain network domains, optimize and adjust itself to the external environment to enable intent based, closed-loop management.

Level 4 - high autonomous network: Building on L3 capabilities, the system enables, in a more complicated cross-domain environment, analyze and make decision based on predictive or active closed-loop management of service and customer experience driven networks.

Level 5 - full autonomous network: This level is the goal for telecom network evolution. The system possesses closed-loop automation capabilities across multiple services, multiple domains (including partner's domains), and the entire lifecycle, achieving autonomous networks.

3.4. The Knowledge Plane

The research community has considered in the past the application of AI techniques to control and operate networks. In 2003 David Clark et. al propose the knowledge plane (KP) as a *pervasive system within the network that builds and maintains high level models of what the network is supposed to do, to provide services and advice to other elements of the network. The knowledge plane is novel in its reliance on the tools of AI and cognitive systems* [16].

The knowledge plane (Figure 10) paradigm proposes the evolution to a cognitive network, where the devices learn, decide, and act to achieve end-to-end goals. This emerging paradigm is clarifying a set of new cognitive-based protocols and algorithms that optimize network's performance.

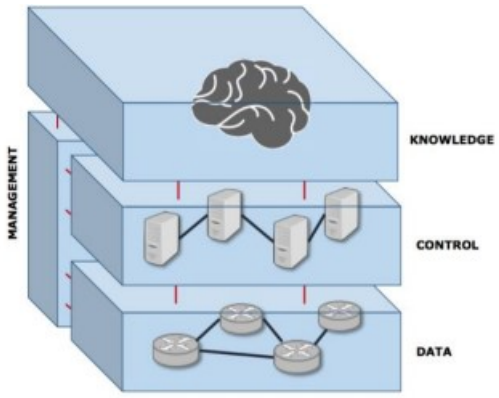

Figure 10 - The four planes in network architecture.
Source: TM Forum.

Several different KP based approaches have been proposed [17]. But it is not until the development of NFV and SDN that such proposal once again takes hold in communities such as the TM Forum, IETF, 3GPP, ETSI etc and the Industry.

In [18] progress is made in the definition of a new paradigm based on this plane. This is knowledge-defined network (KDN) operates by means of a control loop to provide automation, recommendation, optimization, validation, and estimation. The KDN paradigm is also taken by the TM Forum, ETSI and ONAP as a proposal to specify future architectures.

An example of the plane of knowledge in an SDN is presented in Figure 11 [19].

The introduction of AI and automation using AI, in short, seeks to ensure greater performance and efficiency of networks.

The paradigm shift that will be brought about by the introduction of these new technologies includes a substantial shift from a focus on network operations to a focus on the user experience.

We have conceptualized these AIOps tools that interact with the different types of networks as Knowledge Plane, a "place" where the massive amount of data obtained from the network is processed with the different

AI tools, either in real time or in a post-processing, and that, based on results, produces modifications in the network itself. This is called closed-loop automation[6].

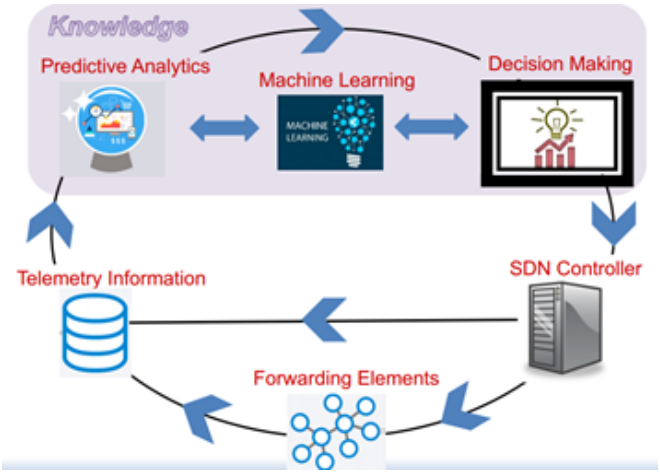

Figure 11 – Knowledge Plane in a SDN

3.5. The Knowledge Plane at Telecom

More than a decade has passed since the emergence of a paradigm of autonomous computing in the world of telecommunications. Back then, there was a gap between that paradigm and the capacities of the networks. However, a path has been taken in recent years with the adoption of cloud computing, NFV and SDN.

These technological advances have made available a more agile infrastructure, computing capacity and storage as resources more abundant than ever. Motivated by this evolution, together with the ever-growing need to improve the management and administration of networks and services, we present this first approach to the plane of KP. We adopt the knowledge plane paradigm for our Telco Cloud project.

We define a reference architecture (Figure 12) with the purpose of automating the services from end to end, with a holistic view of the network and services. It is based in the different WGs and other initiatives of other CSPs and vendors.

At the beginning, and to have a common language, a framework was defined in which the preponderance of the knowledge plane in the different layers of the network, both virtual and physical, is highlighted.

[6] Note: There are many different names for closed loop, cognitive loop, Monitor Analyze-Plan-Execute over a shared Knowledge (MAPE-K), observe–orient–decide–act (OODA), etc.

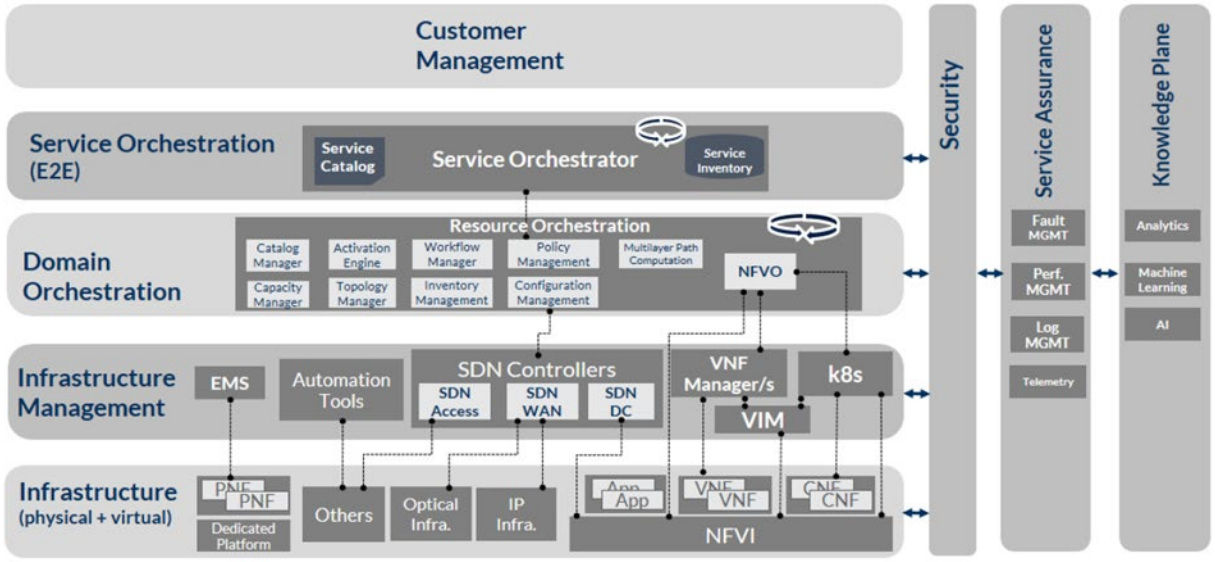

Figure 12 - Knowledge Plane Integration

There is no doubt that in the course of time this general vision will not only be modified but also specified. A result that only experience can provide.

3.6. An outline of Knowledge Plane architecture

Based on the different standards and our own experience in recent years, we can propose a conceptual architecture where two modalities of KP and Close Loops are distinguished.

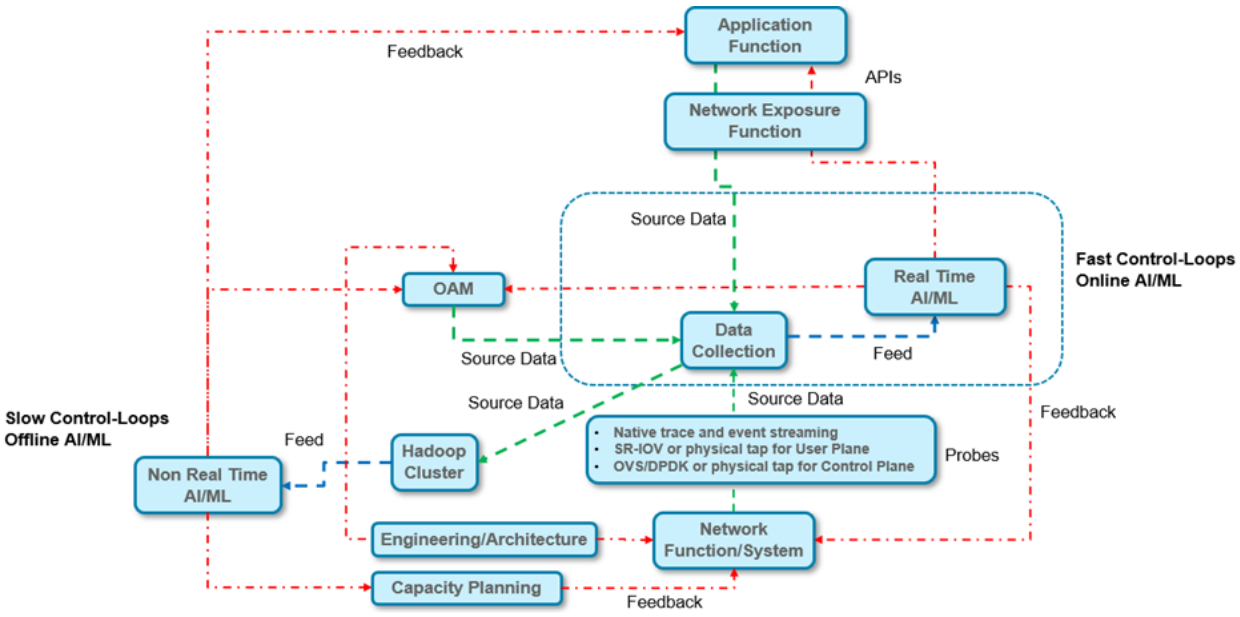

Figure 13 - Knowledge Plane architecture

Offline AI/ML (or Slow Control-Loops): based on a large amount of historical data, stored in a data lake, statistical models or other algorithms are applied (for example, time series) and the results obtained by data scientists lead to implement changes in the network, in OAM and in the long-term architecture.

Online AI/ML (or Fast Control-Loops): This instance is very dependent on:

- type of network to which it is applied
- if it is Access or Core

The information obtained from the network through probes, applications and OAM is stored in a Data Collection in real time. Then they could be combined in new tables to feed AI/ML algorithms (note that we are not putting training because it could be that the algorithm is a type of Clustering).

The Data Collection and Real Time AI/ML could be embedded in a network element or could be external to it.

As the algorithm works in real time, it would be necessary to prepare it, to test it with real data, making a pre-processing in laboratory before taking it to production, with a portable solution (for example Kubernete/KubeFlow) in a process of continuous improvement of the software. The result of the algorithm feeds back directly to the network elements, OAM, and applications. Obviously, the supervision of a human expert should be constantly validating the automated work of the algorithms ("He Teaches").

3.7. AI Techniques in Network Automation

Many techniques that can be used for decision making with each providing different cognitive capabilities. Many offer inference capabilities and only a few offer perceptive capabilities, so it is important to identify the problem requirements to choose the right technology. Figure 14 summarizes the comparative capabilities of the technologies [20].

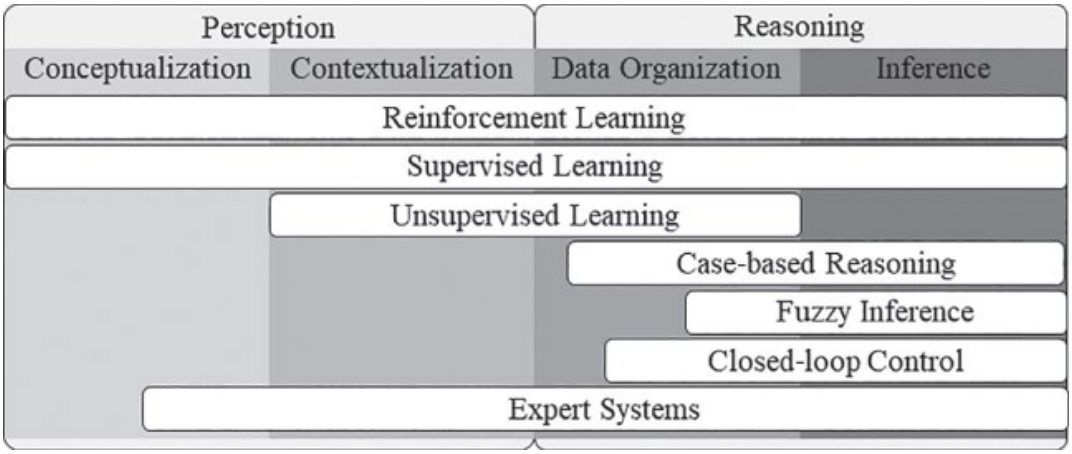

Figure 14 - Capabilities of the different automation techniques.

4. AIOps at Telecom Argentina

At Telecom, there are a few initiatives that we have considered within the AIOps framework. We believe that it is important that they are seen under the focus of Augmented Intelligence. Nowadays, as a STEM team one of our missions is to lead AIOps in our current and future networks. Our recipe within STEM team is diversity, work in cells, agile mindset, and self-learning. In the following sections we present two of the initiatives we have been working on.

4.1. Ada

At Telecom Argentina, we have been working on a tool for network dimensioning for some time now [21]. In 2017 we developed STEM-ML for Cablevisión, a tool that assisted the decision-making process for the dimensioning of the HFC network. Later, we decided to incorporate data from the radio-access network (RAN) and relaunched the project under the name Ada[7]. The goal is to have a tool that combines machine learning and SME input to assess decisions on CAPEX and OPEX investments.

Historical data is collected for every HFC node, as well as for every cell on the mobile network. The idea is that for decisions in the short term (up to a year from the present), ML-based forecasts are provided, and the role of experts is to set priorities and act based on them. For long-term decisions (5-10 years periods), on the other hand, ML-based forecasts would require a longitude of history that hasn't yet occurred. In our experience, however, it is possible to provide reasonable approximations if forecasts are supported not only by historical data but also by experts' knowledge. Hence, we are currently working on finding ways for the experts to pass input to ML algorithms.

In the past, planning engineers used to research on potential scenarios and make a series of calculations to approximate what they thought was going to happen in the long-term, based on their knowledge of the average client and use cases. Working together, we built profiles for the operating sectors, so they can refine on what would be expected from a variety of use cases. To better understand this, let's see that for example, the case of a group of households where the service is mostly used to check social media, and the income is low will not be the same as in another group of households where there are heavy streamers, and the income is higher. We are providing the planning teams with better information to start with.

As this paper is being written, we are working on how to enable engineers to pass information to a model about what they expect the CAGR would be at different kinds of operating sectors, in the next 5-10 years. This will involve a combination of simulation and forecasting techniques. Also, it will require a certain level of automation that would not be achievable outside a ML framework.

4.2. Customer claim prediction

Within the domain of AIOps one of the most popular use cases is customer claim or tickets prediction [22] [23]. The main idea is to use information derived from different elements of the network, such as: CMTS, cablemodems, electronic devices, etc. to estimate the probability of a customer to generate a complain.

Information is generally collected through OSS systems and ingested in a machine learning (ML) pipeline where preprocessing, analysis and ML model testing is performed. We are currently developing this kind of solution to ultimately increase customer satisfaction.

[7] The Ada name of the AIOps tool for planning the mobile network and HFC, is in honor of who is considered the first programmer in history, Ada Lovelace (1815-1852)

Using hourly collected information from over 1.2 million DOCSIS 3.0 cablemodems we are trying to anticipate customer complains two days in advance. To handle this amount of data we have partnered with Google[8] to develop and deploy this project using Google Cloud Platform (GCP) services. Although we are in preliminary stages (MVM1), many steps have been given towards the final implementation.

Potentially relevant variables (e.g., signal to noise ratio, consumed bytes, average Rx, t3 and t4 time outs, etc.) have been identified and our Service Assurance team have been able to efficiently transfer these data, collected by our OSS systems, to GCP.

Daily, cablemodem and customer claims are transferred to a relational database mounted on GCP. After the data is successfully ingested, an automated data cleansing process is run using Big Query[9] to guarantee a proper information quality level. In addition, a Data Studio[10] dashboard has been created to double check this already curated information. We have found very useful to quickly visualize quality KPIs, such as: MAC Addresses count, percentage of missing values, customer claim evolution, etc.

Even though the data cleansing stage is run over the whole data set, we are using a different strategy to develop and test different ML models. Two random samples containing 10,000 and 50,000 cablemodems are being taken to accelerate the processes of feature engineering, hyper parameter tunning, model evaluation and model selection.

We are exploring different approaches to maximize precision and recall metrics[11].

At time this document is being written, we have tried a series of XGBoost models with different sets of hyperparameters[12] and feature engineering scenarios. We are also working on a different approach, reframing the whole task as a survival analysis problem. Furthermore, we are considering using recurrent neural networks to capitalize the sequential structure of the cablemodems metrics data.

Regarding technical challenges, two of the most difficult tasks have been dealing with an extremely unbalanced dataset and label noise. Although from a business perspective having a low proportion of customer claims is a good indicator, some ML models can struggle to learn from these kind of data sets. In our case, after filtering the target population (DOCSIS 3.0 residential customers), the positive class dropped to 0.1%, which added more complexity to the problem. To reduce the impact of this issue on model performance we applied hyperparameter tunning[13] and a technique called SMOTE [24] combined with an under sampling of the majority class. Both approaches led to improvements in model performance.
On the other hand, records are not always properly labeled. Some customers, for example, don´t make a complain, even when their cablemodem is not working adequately. This leads to label overlapping. Some cases that should have been labeled as positive get labeled as negative, hence, remaining in the same region in the feature space of the positive class with the opposite ground truth label. To handle this problem, we have used a Python package for confident learning called Cleanlab [25]. The main idea of this approach is to run a model and remove cases that have been confidently classified within a class when their ground truth label corresponds to another class.

[8] Telecom Argentina adopted a multi-cloud strategy On-Premises, Amazon, Azure and Google.
[9] As stated from Google in their web page, Big Query is a: “Serverless, highly scalable, and cost-effective multicloud data warehouse designed for business agility”
[10] Google tool for data analysis and visualization.
[11] We found these two metrics to be the best way to measure model performance based on the characteristics of the data set (e.g., highly unbalanced) and business needs (maximize precision to avoid as many false positives as possible)
[12] We have performed random search, and we are currently changing to a Bayesian optimization approach.
[13] We searched for the best value of “scale_pos_weight”, the hyperparameter used by XGboost to handle unbalanced classes.

We have been able to overcome many challenges and, although we are still in initial phases of this project, we hope to deploy a state-of-the-art ML system to give one more step towards AIOps goal: fully automated networks.

Finally, with the aim of showing a high-level view of our project, the Figure 15 below describe the data flow and the desired outcomes.

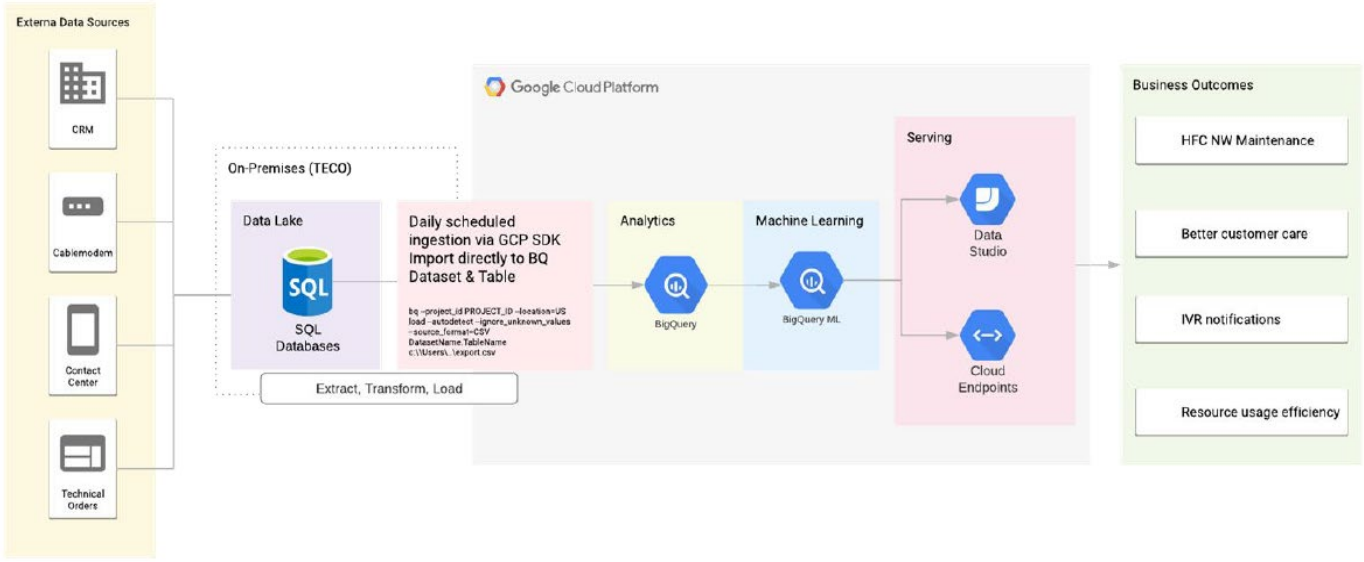

Figure 15 - Data Flow and outcomes

We are currently including DOCSIS 3.1 cablemodems in the first model (MVM 2) and starting field tests working with Service Quality, Field Service and Customer Experience teams.

On the other hand, we are beginning to define the MVM 3 related to a closed loop system to impact the QoE of some of our services. That is, with AIOps frameworks, starting our journey from automation to autonomous networks.

5. Conclusions

Throughout this technical paper we have seen the need to automate the operations of our current and future networks using artificial intelligence, presenting the AIOps framework that we have adopted in Telecom Argentina. This adoption was accelerated during the beginning of the pandemic that has produced an enormous change in our organization. However, we are still on the path of digital transformation and AIOps plays a fundamental role.

Within this transformation, however, there is something in which we cannot apply AIOps, it is in interpersonal skills that will not be able to be replaced. We must develop the empathy, collaboration, and autonomy of our work teams. On the other hand, although the path of AIOps is from automation to autonomous networks, we must not forget that we must see it from the perspective of Augmented Intelligence (AgI).

"While Artificial Intelligence is creating machines to work and react like humans, Augmented Intelligence is using those same machines with a different approach to improve human capabilities. In fact, AgI involves people and machines working together, leveraging their own strengths to achieve greater business value. In other words, the primary goal of AgI is to empower humans to work better and smarter" [26].

The Path to 100 Gbps DAA Nodes

Analyzing DOCSIS Bandwidth and its Impact on the CIN

A Technical Paper prepared for SCTE by

John T Chapman
CTO Broadband Technologies & Fellow
Cisco Systems
jchapman@cisco.com

https://www.linkedin.com/in/john-t-chapman/

1. Introduction

This white paper will look at DOCSIS bandwidth as it relates to a DAA (Distributed Access Architecture) node. Although similar to an Integrated CMTS (Cable Modem Termination System), there are some additional design considerations to be aware of. The first section looks at various design considerations. The second section then goes right into the bandwidth calculations.

Specifically, the following goals will be addressed with this white paper:

Network Design Considerations

- Review channel and port differences between an integrated CMTS (I-CMTS) and a DAA node
- Discuss a new concept of DS:US bandwidth ratio (DUCR) and peak versus average capacity

Bandwidth Studies of DAA Nodes and its CIN requirements

- What is possible today (with some DOCSIS 3.1 and video)
- What is possible with DOCSIS 3.1
- What is possible with DOCSIS 4.0
- What is possible after DOCSIS 4.0

This white paper will establish a set of metrics and then use them along with an extensive bandwidth analysis of DOCSIS to provide guidelines on what technology direction operators may decide to go.

All calculations are supported by a publicly available spreadsheet as show in Figure 20 by contacting the author. The numbers capture in the while paper are supportive of general conclusions. As time goes on, the spreadsheet may contain more exact bandwidth numbers for a given upstream and downstream channel configuration.

2. Network Design Considerations

2.1. Review of I-CMTS channel/port configurations

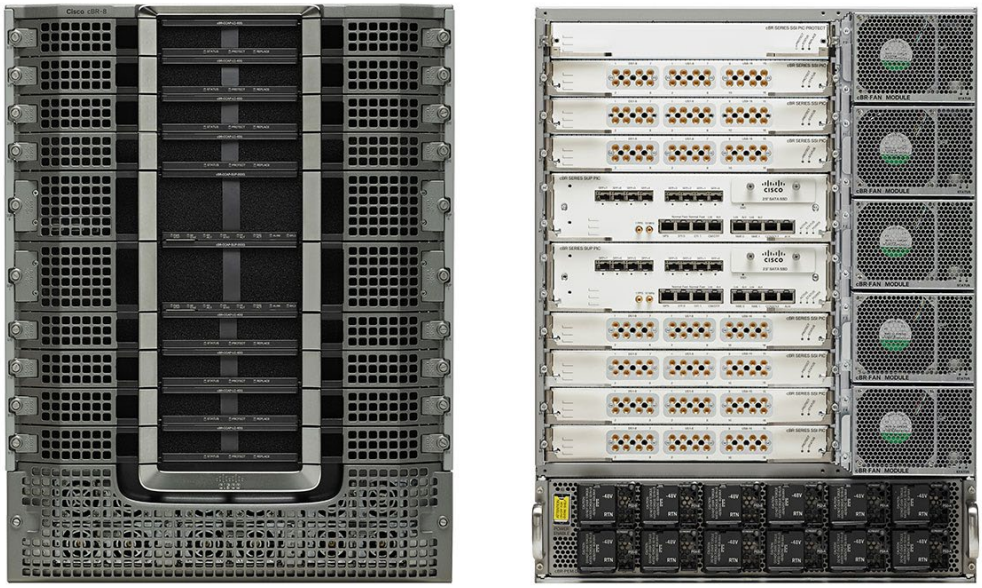

Figure 1 - Example of an I-CMTS

To start the analysis, we first begin with the Integrated CMTS (I-CMTS). A typical I-CMTS is shown in Figure 1. The I-CMTS was designed to connect to separate radio frequency (RF) downstream (DS) combining and upstream (US) combining network. As such, the DS and US RF ports are separate and do not contain a diplexer.

The I-CMTS also contains RF redundancy. In this example, there are eight line cards (8 LCs) but only seven RF physical interface cards (PICs). Internally, there is a 7+1 redundancy scheme that allows one LC to replace any of the other seven line cards without changing the external RF path.

Here are some example I-CMTS capacity values

CMTS Ports

- 7 LC @ 8 DS ports x 16 US ports = 56 DS ports and 112 US ports per I-CMTS chassis

Channels per I-CMTS Port

- DS: 96 SC-QAM and 2 OFDM
- US: 8 A-TDMA and 2 OFDMA

The SC-QAM and A-TDMA channels are for DOCSIS 3.0 and earlier versions. OFDM and OFDMA channels are added for DOCSIS 3.1 and DOCSIS 4.0

Ethernet Capacity

- Dual 100 Gbps

The Ethernet connectivity represents the total aggregate capacity of the chassis. The DOCSIS protocol allows for over subscription on the HFC (Hybrid Fiber-Coax) plant. In addition, the I-CMTS allows for some oversubscription on the CMTS chassis. Thus, the total RF capacity may be greater than the Ethernet capacity. Over-subscription is important as each Ethernet port needs to connect to a router port, so each port has a cost associated with it. Over-subscription both keeps costs down and represents proper traffic patterns.

Internal Constraints

- Bus and backplane bandwidths, various memory sizes, packets-per-second (PPS) limitations of data and control planes, CPU core count and clock speeds, software architecture, etc.

These internal constraints lead to DOCSIS performance constraints such at the number of service groups (SGs), classifiers, and data throughput.

2.2. DAA Node channel/port configurations

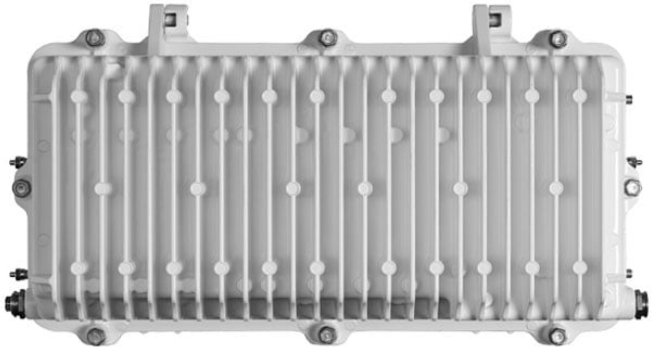

Figure 2 - HFC DAA Node

There are two types of DAA nodes defined at CableLabs.

- The first type is the Remote PHY (RPHY) system. The RPHY design takes the PHY chip out of the I-CMTS and puts it in the RF node. The MAC chip remains in the I-CMTS and is connected to the PHY chip in the node with a 10 Gbps (or higher) link. [1][2][3]
- The second approach is a Remote MAC and PHY (RMACPHY) system where the entire layer 1 and layer 2 CMTS is placed in the node. Layer 3 connectivity is supplied by a leaf router. Aggregation of RMACPHY nodes replies on system software known composed of a MAC Manager and a PacketCable Aggregator.

Both RPHY and RMACPHY are part of the Flexible MAC Architecture (FMA), although FMA commonly refers to RMACPHY as RMACPHY is its first system deliverable. Additional non-DOCSIS features such as MPEG-TS video, narrowband digital forward (NDF), narrowband digital return (NDR), out-of-band (OOB) channels, are all managed using the RPHY protocols and add to the Ethernet bandwidth requirements.

For the analysis in this white paper, which focuses on RF channels, RF ports, and Ethernet ports, both the RPHY and RMACPHY systems are identical. Hence forth, the term DAA node equally applies to an RPHY node or a RMACPHY node. A typical RF node is shown in Figure 2. A breakdown of the connectivity of that node is shown in Figure 3.

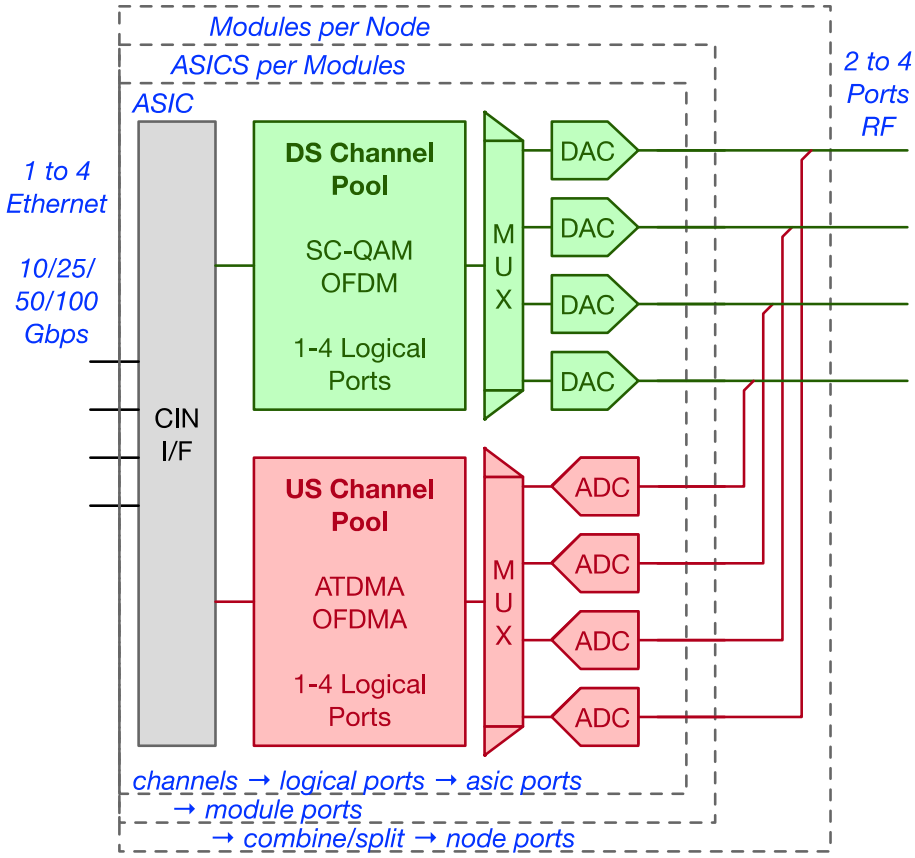

Figure 3 - DAA Node channels and ports

A DAA node has two to four RF ports. These RF ports after a diplexer, so they contain both DS and US spectrum and channels. That is different than an I-CMTS. There is also no RF redundancy which simplifies things.

A DAA node is composed of:

- One or more RF ASICS that fit into a module
- One of more modules that fit into a node

The DAA ASIC contains a pool of RF channel for SC-QAM, OFDM, ATDMA, OFDMA as well as resources for NDR, NDF, OOB 55-1, OOB 55-2, and the upstream spectrum burst receiver. This pool of resources can be organized into one or more port groups which are then mapped into DS digital-to-analog (DAC) and US analog-to-digital (ADC).

Now, here is a tricky part. Say that the chip supports a 1x2 port config (so 1 DS and 2 US). That could map to one DAC and two ADC. Or, it could map to four DAC and four ADC. Now, why would that be interesting? There is an additional function that DAA silicon may provide called digital pre-distortion (DPD).

The downstream power amp is a class A amplifier which means it does not run anywhere near saturation. DPD pre-distorts the DS signal in the opposite manner that the DS power amp may distort it. When combined, the linearity of the power amp is increased. This allows the output power amp in the node to be biased at a lower voltage and thus the power amp runs at a lower power level for a given output level. To make this all work, the ideal DPD circuit has to monitor all four DS power amps. It does with an extra four set of full range ADC converters.

In the upstream direction, a node would normally combine RF inputs from four down to two or one and then connect to an ASIC. This creates noise funneling where the noise floor from multiple inputs is combined. Instead, if each RF upstream input is received on a separate ADC, and then digitally processed, then the impact of noise funneling can be reduced.

The DAA module acts like a small CMTS. There can be one or two modules in DAA node. The modules may be split across downstream ports or directly connected. The upstream ports may be combined or directly connected to the US ports on the modules.

2.3. DAA Node CIN connectivity

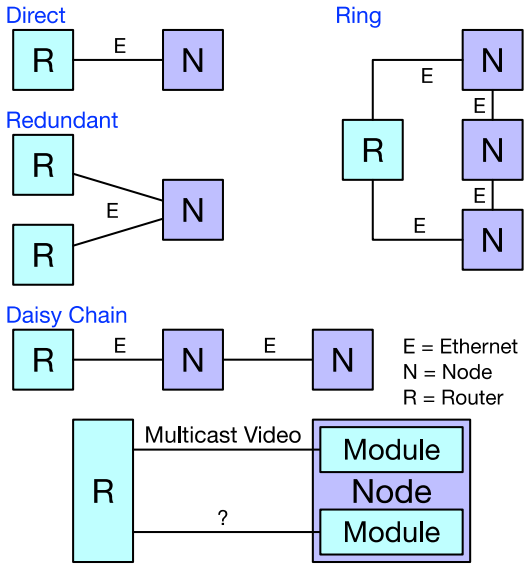

Figure 4 - DAA Node Ethernet Connectivity

The aggregate of all bits from all the DS and US RF channels pass through the Ethernet ports and through the Converged Interconnect Network (CIN). The definition of the CIN is in part defined by the use of the Ethernet ports.

The various Ethernet configurations are shown in Figure 4.

- Direct is most common
- Daisy chain allows multiple nodes to share a common 10 GE link. This may become a less popular option as node bandwidth increases
- Rings are rare but they do provide a redundant path on a common 10 GE link. Rings may become less popular use as the node bandwidth requirements increase. Or, the rings could just move to higher bandwidth
- Redundant connectivity is rare today, but may become useful in the future for a CIN.

Imagine a DAA node that connects to separate hub sites. If one hub site fails, the DAA nodes remain connected to the other hub site. In fact, since the DAA nodes are now IP connected, each DAA node connects to all hub sites, not just the next hop hub site. This is a powerful concept as it allows DAA nodes that might not fit on one hub site to be connected to another hub site.

Backhaul may be one or more Ethernets per Node, in addition to the above configurations. This presents both an opportunity and a dilemma for MPEG-TS video. Linear video which can consume 64 SC-QAM channels is usually sent using IP Multicast.

- Multicast video may be shared across network ports of the same module if designed to do so
- Multicast video cannot be shared across network ports that go to separate modules

So, if you have to 1x2 modules to make a 2x4 node, then the multicast video will have to be sent separately to each. If you have one 2x4 module, and if the ASICs permit sharing of video, then you may only need to send one multicast video stream to the node.

This is a very important consideration for DAA node planning as it could double the number of Ethernets you require. For denser DAA node configurations, like for DOCSIS 4.0, it may be necessary to move to 25 Gbps Ethernet or higher.

Make sure to work out these considerations on the DAA bandwidth spreadsheet.

2.4. DUCR – Downstream to Upstream Capacity Ratio

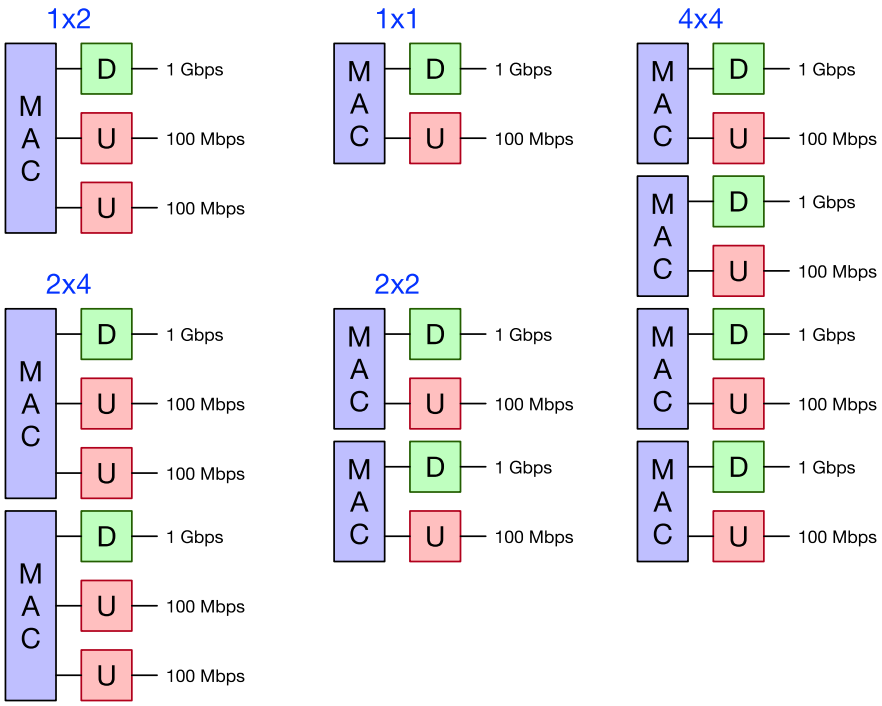

Figure 5 - DAA Node Ethernet Connectivity

As mentioned before, even though a DAA node may have four physical DS and US ports, it has an effective number of ports depending upon the internal configuration of resources. Figure 5 shows these various combinations with example bandwidth numbers. Here are the important points to keep in mind.

1x1 modules

- One module creates a 1x1 node
- Two modules create a 2x2 node
- The 1x1 module may be a 1x2 module with one port disabled.

1x2 module

- One module creates a 1x2 node
- Two modules create a 2x4 node
- This is the current state of the industry in 2021

2x2, 2x4 module

- Next generation chipsets contained in a single module
- Targeted at one module per node.

4x4 module

- Not available or deployed yet, but could be with future ASIC densities. ADC and DAC density is already here.
- Also, two 2x2 modules could form a 4x4 node.

These port configurations can be further sorted into two classes:

- Single-return: 1x1, 2x2, 4x4
- Dual-return: 1x2, 2x4
- Quad-return: 1x4 (not in actual use)

A single-return system has the same number of DS and US ports; a dual-return system has twice the upstream ports as downstream ports. Quad-return is not in use but is included for consistency. (the usage of these terms are defined here)

So, when should you use a single-return system versus a dual-return system?

The first reason may be cost. If you as an operator are paying a license per channel or per port, a dual-return system will cost more money. However, if you are paying a license per customer, then a single-return and dual-return system may be the same price if the hardware is the same.

The second reason is peak capacity versus total capacity.

The peak capacity is set by the port capacity, and any one particular CM is only connected to one physical port of a DAA node and thus one DS port and one US port. Thus, a single-return system and a dual-return system have the same peak capacity.

The total capacity is set by the aggregate bandwidth of all ports and how they fit within the Ethernet port bandwidth. In this scenario, a dual-return system has twice the upstream capacity as a single-return system, although they both have the same amount of downstream bandwidth.

Here is a potential conclusion.

- If a significant number of your customers are running at an upstream rate that is higher than say 50% of the upstream bandwidth (say 1 Gbps service rate on a 1.4 Gbps port), there are a low number of CMs on a node, and sales are based upon good speed-test performance, and then you may want to go with a single-return system.
- If a significant number of your customers are running at an upstream rate that is lower than say 50% of the upstream bandwidth (say 300 Mbps on a 1.4 Gbps upstream), there are a high number of CMs on a node, and sales are based on connectivity and overall throughput, then you may pick the dual-return system.

The third reason is if there are not enough OFMDA channels. For example, the silicon may support two upstream ports at 2 OFDMA each, but only one upstream port at 4 OFDMA each. Both solutions have the same average capacity, but the single upstream port has higher peak capacity.

The fourth reason is to get to a desired DS:US capacity ratio (DUCR) for a DAA node. DUCR (*pronounced "duck-r"*) is a proposed definition originating in this white paper.

- Average DUCR takes into account the total bandwidth from the total number of DS ports and US ports. This is a measure of the capacity of the HFC plant from the CMTS viewpoint.
- Peak DUCR only takes into account the bandwidth of one DS port and one US port. This is a measure of the capacity of the HFC plant from a CM viewpoint.

A single-return system will have the same value for average and peak DUCR. A dual-return system, the average DUCR will be half the peak DUCR.

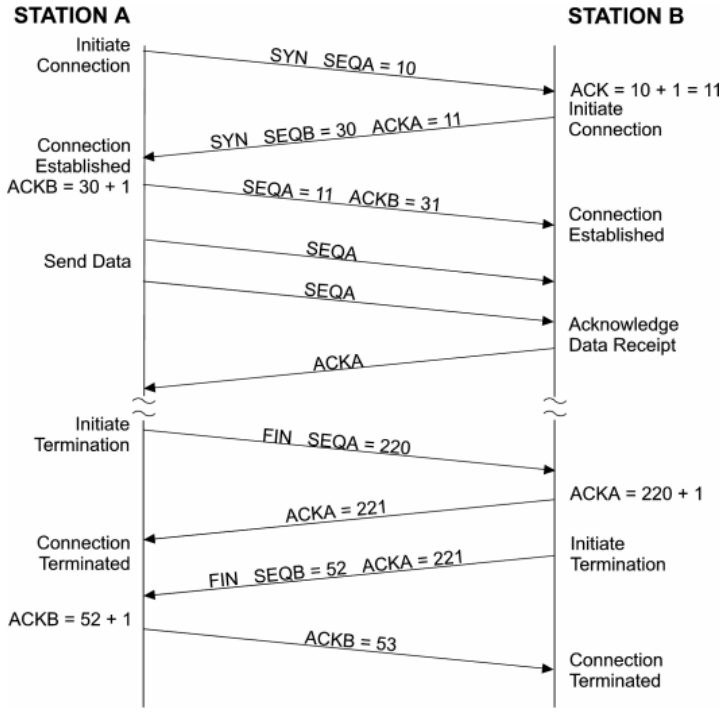

Figure 6 - TCP Handshakes

So, what is a good value DUCR? That depends upon the nature of traffic being run over the DOCSIS interface. About 75% of Internet traffic is TCP (transport control protocol). To understand this, let's do a quick re-hash on how TCP works.

A set of TCP signaling actions are shown in Figure 6. Typical TCP stack implementations try to send one ACK for every two data packets. TCP will fragment files into max MTU (about 1500 bytes) packet sizes with the last packet being a remainder. Note that Ethernet packets on an Ethernet interface have a 12-byte inter-packet gap (IPG). When the Ethernet frames are put on DOCSIS, that IPG is removed by replaced with DOCSIS framing overhead which is 13 bytes or more.

- DS: (1518 + 12 bytes IPG) x 2 = 3060 bytes
- US: 64 bytes + 12 bytes IPG = 72 bytes
- TCP DS:US ratio 3060 / 72 ~= 40 (most extreme case)

Shorter TCP transfers from web pages can dramatically reduce this ratio. The remaining UDP traffic and upstream TCP traffic also reduces this ratio. The DUCR value of the DOCSIS system should be less than the TCP ratio in order to all the downstream to fill with TCP traffic and still allow room in the upstream for non-ACK traffic.

Cable Modems (CM) contain a TCP ACK suppression mechanism that removes redundant TCP ACKs, which in term allow for a higher ratio to work. Ack suppression will remove an older ACK from a TCP flow if a new ACK comes along, if there is upstream queuing in a CM, and if the ACKs are in a burst. A nice side effect is if the upstream queue begins to build up due to upstream compression, the probability of a redundant ACK being present goes up.

5G TDD (time division duplex) systems share the same spectrum for downlink and uplink transmissions. The proportion of bandwidth between downstream and upstream is set by a frame structure configuration. The typical profile used in 5G is the so called "DDDSU" where D = downlink, U = uplink, and S = 10:2:2 (D:G:U) where G is guard time. Thus, there is a time ratio of about 3.25:1 for DL:UL. Ignoring overhead, that would correspond to a DUCR value of 3.25 if the modulation was the same. If the mobile downlink has a higher modulation that the mobile uplink, then the mobile DUCR value could be closer to 4 or 5.

Table 1 - Proposed DUCR Guidelines

DUCR		Usage Notes
Average	Peak	
40	80	• Downstream may not get fully utilized as there is not enough upstream bandwidth to support TCP ACK traffic. • Not recommended • ACK suppression in the CMs allow this extreme condition to work and this does represent some
20	40	• At the edge of working for DS and US. • This is what is often deployed today but really only works because of ACK suppression.
10	20	• Good balance between DS and US bandwidth for asymmetric traffic.
5	10	• Better balance between DS and US bandwidth for asymmetric traffic that also allows for upstream originated TCP transfers • Average DUCR on DOCSIS matches 5G TDD systems
< 2.5	< 5	• Upstream may not get fully utilized in the presence of asymmetrical traffic • Allows high symmetrical SFs to be sold. • Peak DUCR on DOCSIS matches 5G TDD systems

Based on upon these data points, Table 1 provides some guidelines for picking the right DUCR value.

A high DUCR means the downstream may not get full utilized. A low DUCR means the upstream will may get fully used (unless there is a lot of upstream TCP transfers).

Note that the asymmetry of a CM service flow may be different that the asymmetry of the DOCSIS channels. For example, say there is a 1 Gbps downstream and a 100 Mbps upstream with a 1x2 node. Thus, the upstream capacity is really 200 Mbps, the average DUCR is 5 and the peak DUCR is 10. Meanwhile, the CM has been configured to use 200 Mbps downstream and 10 Mbps upstream which is a DUCR of 20. How does that play out?

The CM will follow its individual CM DUCR, and either the downstream or upstream service flow will max out first. The DOCSIS channel, however, is an aggregate of all CMs, and of CMs are different rates. Thus, the aggregate traffic will ultimately shape to the channel DUCR.

3. DOCSIS Bandwidth Basics

3.1. Baseline assumptions

Summary	Explanation
2 x 4 Node Capacity	Number of DS and US ports on Node
Scenario	Reference number
DS End MHz	DS Spectrum upper limit
DS Start MHz	DS Spectrum lower limit
US End MHz	US Spectrum upper limit
VOD/SDV MPEG-TS	VOD used in calculation
Linear Video MPEG-TS	Linear channels used in calculation
DOCSIS DS port Gbps	DOCSIS Downstream Port
DOCSIS US port Gbps	DOCSIS Upstream port
Ethernet DS Gbps	Ethernet Downstream (DOCSIS + Video)
Ethernet US Gbps	Ethernet Upstream (DOCSIS)
DUCR, Avg	Node Ratio for DS:US capacity
DUCR, Peak	Port Ratio for DS:US capacity
ODFM ch per Node	DS OFDM channels needed per node
OFDMA ch per Node	US IFDMA channels needed per node
DOCSIS DS BW MHz	Total DS DOCSIS RF Bandwidth
Cross-over MHz	Cross-over band
DOCSIS US BW MHz	Total DS DOCSIS RF Bandwidth

Figure 7 - Spreadsheet Inputs/Outputs Explained

The study in this paper is contained within a spreadsheet. The outputs of the spreadsheet and what they represent are summarized in Figure 7 and the common set of input assumptions is in Figure 8.

32	VOD/SDV MPEG-TS	1794	DS Stop MHz for D4.0	ESD	ESD or FDX for D4.0	4096	OFDM Mod
64	Linear Video MPEG-TS	16.4	US Start MHz	YES	Video in FDX Trans Band	2048	OFDMA Mod
2	DS ports per Node	32	ch SC-QAM @ 6 MHz	120	MHz FDX Trans Band	256	SC-QAM Mod
4	US ports per Node	4	ch ATDMA @ 6.4 MHz	24	MHz DS unused < 108	64	ATDMA Mod

Figure 8 - Spreadsheet Common Inputs with default values

VOD/SDV MPEG-TS

- Unicast video services that are reserved on each downstream. The analysis is that VOD is carried on IP unicast on Ethernet and delivered to one downstream. SDV may be on IP multicast on the Ethernet, but is also delivered to only one downstream. For 6 MHz video spacing, 32 channels of video will be 192 MHz.

Linear Video MPEG-TS

- Also known as broadcast video. The analysis assumes that linear video is carried on IP multicast so there is one copy on a shared Ethernet for two DOCSIS downstreams.

Ports per node

- The number of unique downstream and upstream ports per DAA node.

DS Stop MHz for D4.0

- This allows the ending frequency for DOCSIS 4.0 to be manually set higher or lower

US Start Frequency

- Common starting point for the upstream. The spreadsheet will subtract out ATDMA channels and then fill the remaining upstream spectrum with OFDMA. To prevent OFDMA being calculated below 42 MHz, specify 4 channels of ATDMA (default is 6.4 MHz each), and a start frequency of 16.4 MHz (42 – 4*6.4).

Channels of SC-QAM

- These are downstream channels. DOCSIS 3.0 CMs have/had configurations of 8x4, 24x8, and 32x8. SC-QAMs are retained for legacy CMs.

Channels of ATDMA

- Typically, four upstream ATDMA channels were used for DOCSIS 3.0 and this occupied all available bandwidth in the upstream.

ESD or FDX for DOCSIS 4.0

- Changes the downstream starting frequency. You can tell FDX is being used when the "cross-over MHz" is negative.

Video in the FDX transition band

- FDX excludes 684 MHz to 804 MHz. That band can be used for MPEG-TS video or for legacy CMs. This is usually a yes.

FDX Transition Band

- This is defined as 120 MHz in the specification and is included here in case operators need to change it.

DS MHz skipped below 108 MHz

- 72 MHz to 76 MHz is used for the legacy OOB channel, and 88 MHz to 108 MHz are used for the FM band. Typically, these bands are not available for DOCSIS downstream or MPEG-TS video. This totals to 24 MHz.

Modulation

- The average QAM modulation level used for DOCSIS 3.0 and DOCSIS 3.1
- ODFM and OFDMA have profiles which can be configured to optimize modulation levels per subcarrier [4][5]

Note that if the upstream was configured for no ATDMA channels, and there would be seven full 96 MHz channels of OFDMA between 12 and 684 MHz, and if the modulation of each data subcarrier was 4K QAM, then the theoretical throughput of the upstream channel would be 6 Gbps. This matches the 10G

vision in the Cable industry [6]. The analysis in this whitepaper, however, assumes four ATDMA channels for backwards compatibility below 42 MHz.

3.2. Acceptance criteria

Scenario	1	2	3	4	5	6	7	8	9	10	11
DS End MHz	1002	1002	1002	1218	1218	1794	1794	1794	1794	1794	1794
US Rtn Path MHz	42	42	85	85	204	85	204	300	396	492	684
1) DS Path ≥ 5 Gbps	54%	54%	49%	92%	62%	207%	177%	154%	130%	108%	62%
2) 2 < avg DUCR < 20	148%	148%	131%	246%	52%	181%	149%	91%	56%	36%	14%
3) US SF 1 Gbps, 0.4 K	7%	7%	33%	33%	106%	33%	106%	151%	209%	268%	385%
4) 100% > 85 MHz US	-78%	-78%	0%	0%	217%	0%	217%	350%	526%	701%	1051%
Combined Results:	-78%	-78%	0%	0%	52%	0%	106%	91%	56%	36%	14%

Acceptance Criteria	1)	5	Gbps DS path min					Success Critieria	
	2)	2	DUCR min	20	DUCR max	avg	based	success if >	100%
	3)	1	Gbps US SF with	40%	of additional headroom (K)			borderline	
	4)	100%	more BW than a	85	MHz return path			reject if <	90%

Diplexer ratio %	29%	29%	27%	27%	26%	27%	26%	24%	24%	23%	22%

Figure 9 - Acceptance Criteria

One of the extended features of the spreadsheet is to evaluate each scenario against a set of criteria. These criteria so far are.

How close is:

- the downstream above a desired speed?
- DUCR between two level for peak or avg?
- the headroom of a service flow?
- how much better is the proposed return path compared to another return path solution?

The results can then be ranked within an upper and lower percentage.

There is also a diplexer ratio calculator. Negative values indicated FDX operation.

3.3. QAM/ATDMA calculator

Table 2 - QAM Configuration

Country	USA	USA	Europe	Europe

3.4. OFDM Configuration

Table 3 - OFDM Configuration

Downstream			
Scenario	**A**	**B**	
Size of channels (MHz) - 24-192 MHz[1]	192	192	MHz
FFT size (4K or 8K FFT)	4096	8192	subcarriers
Subcarrier spacing	50	25	kHz
Cyclic prefix (Ncp)	192	192	samples[2]
Roll-off (Nrp) - must be less than Ncp	128	128	samples[2]
Ncp overhead	4%	2%	
Guard band override (leave blank if not used)[3]	1	1	MHz
Guard band on upper and lower edge (MHz)[4]	1.000	1.000	MHz
Number of active subcarriers	3800	7600	subcarriers
PLC overhead (number of subcarriers)	8	16	subcarriers
Continuous Pilot Scaling (48 - 120 subcarriers)	48	48	subcarriers
Continuous Pilots (include pilots for PLC)	56	56	subcarriers
Scattered Pilots (estimate)	29	59	subcarriers
Num of NCP - must be >0 (estimate)	4	4	
QAM order of NCP (QPSK, 16QAM, 64QAM)	6	6	bits / sym
NCP overhead (including CRC)	40	40	subcarriers
FEC overhead	12%	12%	8/9 code
Data QAM order (bits per symbol)	12	12	bits / sym
Data Rate (Mbps)	**1844**	**1911**	**Mbps**
Overhead % based on active subcarriers	19.1%	16.2%	
Efficiency	80.9%	83.8%	
Adjusted bits/second/Hz	9.61	9.95	

Notes

1. If using exclusion bands, reduce channel size by amount of spectrum excluded for data rate
2. Sampling rate is 204.8 MHz (based on OFDM spectrum - FFT size x subcarrier width)
3. Note that maximum active OFDM spectrum is 190 MHz so must have 1 MHz or higher guard band if channel is 192 MHz
4. Note that guard bands are based on Appendix V of D3.1 PHY spec based on roll-off period samples shown below (rounded to whole number of subcarriers)

OFDMA for DOCSIS was first introduced for DOCSIS in [6]. For a great discussion on OFDM and OFDMA settings, refer to [8].

3.5. OFDMA Configuration

OFDMA Upstream			
FFT size (2K or 4K FFT)	2048	4096	subcarriers
Subcarrier spacing	50	25	kHz
Size of channels (MHz) - 7.4 - 96 MHz[1]	96	96	MHz
Exclusion bands (or unused bands)			MHz
Guard band on upper and lower edge (MHz)[3]	0.5	0.5	MHz
Number of active subcarriers	1900	3800	subcarriers
Cyclic prefix (Ncp)	96	96	samples[2]
Roll-off (Nrp) - must be less than Ncp	64	64	samples[2]
Ncp overhead	4.48%	2.29%	
Maximum K values based on channel size	18	9	
OFDM symbols per OFDMA Frame (K)[4]	18	9	
Minislot size (400 kHz)	8	16	subcarriers
Minislots per OFDMA frame - (minimum 25 or 16 to ASIC)	237	237	
Edge minislots per OFDMA Frame (estimate)[5]	23	23	
Unused subcarriers (assumes continuous exclusion band)	4	8	
OFDMA frame duration	376.88	368.44	µsec
Pilot pattern	1	8	pattern
Pilots per minislot (body)	2	2	pilots
Pilots per minislot (edge)	4	4	pilots
complementary pilots per minislot (body)	2	2	comp pilots
complementary pilots per minislot (edge)	4	4	comp pilots
Total data carriers per OFDMA frame	33088	33088	
Total complementary pilots per OFDMA frame	520	520	
Data QAM order (bits per symbol)	10	10	bits / sym
bits per minislot (body) - no FEC overhead	1412	1412	bits
bits per minislot (edge) - no FEC overhead	1384	1384	bits
FEC overhead (long codeword)	11.11%	11.11%	8/9 code
FEC overhead (medium codeword)	15.15%	15.15%	28/33 code
FEC overhead (short codeword)	25.00%	25.00%	3/4 code
bits per OFDMA frame	296889	296889	bits
Data Rate (Mbps)	**788**	**806**	**Mbps**
Overhead % based on active subcarriers	17.08%	15.18%	

Table 4 - OFDMA Configuration

Notes

1. Valid channel sizes 11 - 96 MHz for 50 kHz; 7.4 - 96 MHz 25 kHz (includes 0.5 MHz guard band per edge)
2. sampling rate is 102.4 MHz (based on OFDM spectrum - FFT size x subcarrier width)
3. Note that guard bands are fixed at 0.5 MHz on cBR-8
4. K values must fall in range from table on right
5. Edge minislots occur at start of OFDMA frame, after excluded or unused spectrum, and at start of modem burst (10% might be a good estimate - has minimal impact on estimate)

4. DAA Bandwidth Studies

Figure 10 - Bandwidth today with low-split

Deployment scenarios today are generally with a 1x1 or 1x2 DAA node with newer ones using a 2x2 or 2x4 DAA node. This scenario looks at a 2x4 node on an existing 1002 MHz HFC plant, with and without MPEG-TS video, and with a 42 MHz return path.

DOCSIS 3.1 CMs are capable of receiving 32 6 MHz SC-QAM channels (192 MHz total) plus two OFDM channels (192 MHz each), for a total of 576 MHz of DOCSIS spectrum. That is over half of the available spectrum on the HFC plant today. At this time, few deployments are fully utilizing that available DOCSIS capacity on their HFC plant.

In scenario 1 (a) with video and on a 1002 MHz plant, there is 96 SC-QAM carriers (576 MHz) of MPEG-TS video is present, resulting in only 348 MHz of remaining spectrum available for DOCSIS. The resulting DOCIS downstream bandwidth is about 3 Gbps which can be implemented a partial OFDM channel (132 MHz) and 32 SC-QAM channels (or a full 192 MHz OFDM channel and 26 SC-QAM channels).

The total Ethernet DS bandwidth, including video, is about 10 Gbps. If the multicast video cannot be shared across the RF downstream ports, there is an additional about 2.5 Gbps (64 x 38.5 Mbps) load on the Ethernet. This exceeds a single 10 Gbps backhaul, so two 10 Gbps backhauls may be needed or one 25 Gbps backhaul.

The upstream is 100 Mbps and the resulting average DUCR is around 14 and peak DUCR is around 27. These are reasonable ratios.

In Scenario 2 (a), only 58 channels of video are deployed, so DOCSIS can now be allocated a full 576 MHz. That equates to two OFDM channels (2 x 192 MHz) and 32 SC-QAM channels (192 MHz). The DOCSIS downstream increases to about 5 Gbps per DS port. The avg/peak DUCR jumps to about 25/50. This is high but in alignment with today's practices.

In scenario 1 (b), the upstream is changed from the default four ATDMA channels below 42 MHz to only 2 A-TDMA channels, while ODFM fills in the gaps down to 10 MHz (19.2 MHz). The average modulation was dropped to 1024-QAM. The resulting theoretical throughput is 200 Mbps, although in practice it may be slightly less than this due to plant noise. Bear in mind with a 2x4 node, that is the equivalent of 400 Mbps of capacity for each 5 Gbps downstream. This shows up with slightly high but good DUCR values.

In scenario 2 (b), all MPEG-TS video is removed, and 948 MHz (54 MHz to 1002 MHz) is used for DOCSIS. The DOCSIS downstream is about 8.5 Gbps per port. This could be used to drive two banks of CMs that share a common set of 32 SC-QAMs but separate pairs of OFDMA channels. Or, the 32 SC-QAM could be used for legacy CMs and there would be two banks of DOCSIS 3.1 CMs, each connected to two OFDMA channels but not the SC-QAM channels.

The doubling of the US throughput has kept the DUCR values from getting too high which would mean the upstream may saturate and the downstream may not get fully utilized. The DAA silicon should be able to support this scenario. Without the increase in upstream bandwidth, this may not make sense. Instead, it shows that the upstream return path needs to be increased, and that is the subject of the next section.

The observation from these scenarios is that video could be reduced to 58 or so channels on a 1002/42 MHz plant to allow the full potential of a DOCSIS 3.1 CM to be used. Further, if OFDM is placed below 42 MHz, then the upstream can be almost doubled. If video is entirely removed, DOCSIS can be increased three-fold from about 2.8 Gbps to about 8.5 Gbps. There is a lot that can be done for DOCSIS without changing the HFC plant.

4.2. DOCSIS 3.1 with 1218 MHz, mid/high split and 2x4 DAA Node

2 x 4 Node Capacity	DOCSIS 3.1			DOCSIS 3.1

Figure 11 - Bandwidth with DOCSIS 3.1 mid-split and high-split

This section exams the move to an 85 or 204 MHz return path. There are three deployment plans suggested and are shown in Figure 11.

Scenario 3, looks at the impact of moving to an 85 MHz return path but retaining the 1002 MHz downstream. This can be a reality of the downstream RF limit that is imposed by the HFC amps and/or the CMs, rather than the DAA node. The return path now has four times the capacity with over 450 Mbps rather than the previous 100 Mbps.

Scenario 3 with video has a decent 2.5 Gbps downstream with low DUCR values. Low DUCR values in theory allow for symmetrical bandwidth, but in practice may mean that the US is under-utilized. When MPEG-TS video is completely removed from the HFC plant, the DOCSIS downstream bandwidth can go to over 8 Gbps. The DUCR values are almost ideal at 10 and 20. With no video, the Ethernet backhaul barely fits into two 10 Gbps links. With video, it fits.

Scenario 4 increases the downstream to 1218 MHz with an 85 MHz return path. The downstream bandwidth goes up to about 4.5 Gbps and the DUCR values increase to the ideal zone where both downstream and upstream can be fully utilized. With no video, the downstream goes to about 10 Gbps and the DUCR values are still excellent. Note that the OFDM channel count is getting high. The Ethernet bandwidth crosses 20 Gbps which is not good as it does not allow headroom for signaling and there could be the multicast video hit. This is a good place for a 25 Gbps Ethernet serving both downstream ports.

Scenario 5 increases the upstream return path to 204 MHz. This allows a 1 Gbps upstream service tier to be sold. But it also ends up decreasing the DS spectrum and throughput somewhat. The downstream is about 3 Gbps with video and 9 Gbps without video, which is quite decent. The DUCR values are on the low side so the upstream may not be fully utilized, and the Ethernet bandwidth falls back into a dual 10 Gbps target.

The observation here is that DOCSIS 3.1 provide a huge amount of bandwidth growth in both the downstream and upstream, especially if video is removed.

4.3. DOCSIS 4.0 with ESD 1794 MHz and 2x4 DAA Node

2 x 4 Node Capacity	D4.0 ESD with video						D4.0 ESD with no video

Figure 12 - Bandwidth with DOCSIS 4.0 ESD at 1794 MHz

Six scenarios, each with a different upstream split (85, 204, 300, 396, 492, 684 MHz) but a common downstream cap of 1794 MHz are shown in Figure 12, with and without MPEG-TS video. This version of DOCSIS 4.0 is referred to as extended spectrum DOCSIS (ESD). [6] The 85 MHz return path is not an actual DOCSIS 4.0 use case, but is included for comparative purposes.

The DUCR values are very telling here. For almost all the higher splits, the ratios are so low that it is likely that the upstream will get fully utilized, unless all the traffic was symmetrical, which it is not. In fact, for a 684 MHz 1x2 or 2x4 node, DUCR drops below one which means there is more upstream capacity than downstream capacity. For 1x1, it is still low. So, 684 MHz may not be a good choice. The 492 MHz upstream also has low ratios.

Note the impact on the Ethernet backhaul per node. In general, two 10 Gbps backhauls for a 2x4 node are no longer enough. 25 Gbps is likely needed or even 40 Gbps. At 25 Gbps and a 2x4 node, both downstream paths could not be saturated at the same time, although that is probably acceptable. Not that this analysis is not included downstream bandwidth for OOB and NDF, so some headroom is required.

The 396 MHz upstream is right in the middle. It has twice the upstream bandwidth of 204 MHz. But remember 204 MHz already did a 15x increase over 42 MHz, so is another 2x worth it? The driving goal would have to be the ability to offer a 2 Gbps upstream service. Note that the OFDM channel count without video is high and may not fit some silicon implementations.

With no video, and at lower return paths, the DOCSIS downstream goes past the 10 Gbps mark. With a 204 MHz upstream, and no video, the DOCSIS downstream is about 15 Gbps, which could allow a 10 Gbps x 1 Gbps service to be sold to the home. That's interesting for competitive purposes.

The observation here is that 204 MHz looks like a great choice for asymmetrical traffic and for a potential 10 Gbps x 1 Gbps service offering. 396 MHz is a second choice for more symmetrical traffic and a 2 Gbps upstream service offering.

Figure 13 - Bandwidth with DOCSIS 4.0 ESD at 1602 MHz

What if the HFC plant can't make it to 1794 MHz and only gets to say 1602 MHz? or even 1506 MHz or 1554 MHz? All is not lost. The results are shown in Figure 13 for 1602 MHz. Both the 85 MHz and 204 MHz cases have good DUCR values. Above that, the DUCR values are too low.

The observation here is that the DUCR values suggest that the 204 MHz upstream in this scenario is the way to go. DOCSIS 4.0 CMs would still be required.

Figure 14 - Bandwidth with DOCSIS 4.0 FDX

DOCSIS 4.0 full-duplex (FDX) with a downstream limit of 1218 MHz, a maximum upstream return path of 204 to 684 MHz, and with and without video is shown in Figure 14. [9][10][11][12][13]. The 85 MHz return is not an FDX use case an dis included here for comparative purposes.

The DUCR values are low and suggest that a 684 MHz return will not fill the upstream with asymmetrical traffic. A 1218 MHz downstream with two 85 MHz upstream has very nice DUCR values, although it is not FDX. The FDX choices would be a 204 MHz return path for 1 Gbps subscriber service or 396 MHz return path for a 2 Gbps subscriber service.

The downstream bandwidth is about 4.5 Gbps with video present and about 9 Gbps with all video removed.

The OFDM channel requirements are high and care should be taken on silicon choices. Alternatively, using more than 32 channels of SC-QAM for DOCSIS is an alternative.

The Ethernet bandwidth should be doable with two 10 Gbps interfaces or one 25 Gbps. Again, be careful of how multicast MPEG video is shared as this could make two 10 Gbps Ethernet saturate and the DOCSIS downstream would not be fully utilized.

Figure 15 - Bandwidth with ESD + FDX, 2x4 DAA Node

The following post DOCSIS 4.0 scenarios are not official CableLabs projects, and are thus theoretical and for discussion and planning purposes.

The scenarios in Figure 15 combines FDX and ESD from DOCSIS 4.0. The upstream return path would be 204 to 684 MHz and the downstream path would extend to from 108 MHz to 1794 MHz. This could be an achievable design goal by combining the best of ESD and FDX. With video, there is enough downstream spectrum for a shared 10 Gbps and without video, there is about 15 Gbps of bandwidth. The upstream is about 5 Gbps. This could allow service offerings of 10 Gbps x 4 Gbps.

The DUCR values are low suggesting that all the upstream bandwidth may not get used. The OFDM channel count is high and could be a challenge for ASICs. The Ethernet bandwidth also exceeds the 25 Gbps limit, so either a 25 or 40 Gbps Ethernet would be needed.

Figure 16 - Bandwidth with 3 GHz ESD, 2x4 DAA Node

The scenarios in Figure 16 is a 3 GHz version of ESD [14]. The value of 2946 MHz is derived from taking 1794 MHz from DOCSIS 4.0 ESD and adding six more 192 MHz OFDM channels.

The downstream bandwidth is nice and high and is around 25 Gbps with no video. What is interesting with the DUCR values is that 204 MHz is a good choice, especially if it is a dual-return upstream. However, this would limit service offerings to 1 Gbps. Alternatively, a single 396 MHz would work which could allow a 20 Gbps x 2 Gbps service to be sold.

The OFDM channel count is very high indicating yet another generation of silicon, which would be needed anyway to hit 3 GHz. The Ethernet bandwidth is hitting the 50 Gbps level now.

Figure 17 - Bandwidth with 3 GHz FDX, 2x4 DAA Node

The scenarios in Figure 17 are a 3 GHz version of FDX, with and without video, on a 2x4 DAA node.

The bandwidths are higher than the 3 GHz ESD case since there is more downstream spectrum on each of the downstream ports (606 MHz per port). However, the downstream is slightly above 25 Gbps and will likely be held at 25 Gbps due to the Ethernet backhaul which will be dual 25 Gbps or 50 Gbps.

Figure 19 - Bandwidth with 3 GHz ESD, 4x4 DAA Node

The scenarios in Figure 18 is a 3 GHz version of FDX with a 4x4 DAA node.

The downstream DOCSIS speeds are a healthy 25 Gbps per port which adds up to 100 Gbps downstream for the node. FDX has an extra 606 MHz per port which adds up across four ports. The DUCR levels are the same for average and peak since the number of downstream and upstream ports are the same.

100 Gbps per DAA node is impressive and an indication of where the CIN network may need to scale to in the future.

Figure 20 - DAA and DOCSIS Bandwidth Calculator

5. Conclusions

The future of DOCSIS is inter-twined with the DAA Node. The bandwidth and port density calculations that used to be done for a I-CMTS are now done for the DAA Node.

For any frequency plan, DAA has benefits over a conventional CMTS.

1. By placing the modulation in the node where there is a lower noise floor, high modulations can be run.
2. The number of nodes that a single physical CMTS can support increases, sometimes 4x or more
3. The fiber network is converted to a Ethernet based CIN which can now support PON, business services, and mobile backhaul.

Care must be taken that the DAA node has enough OFDM channels to support a particular configuration. The CIN network has to be designed to support the Ethernet capacity of the Node. DOCSIS 4.0 breaks through the 10 Gbps Ethernet capacity boundary. In the future, DAA nodes could approach 100 Gbps in downstream capacity.

DUCR was defined in this white paper as the ratio of downstream to upstream capacity of a node. The average DUCR took into account the number of ports and looks at the HFC plant from the CMTS perspective. The peak DUCR only looked at one downstream port and one upstream port and looks at the HFC plant from the CM perspective. High DUCR values indicate the downstream may not get fully utilized while low DUCR values indicate the upstream may not get fully utilized.

DUCR is a good tool for evaluating the usefulness of a deployment plan and is a measure of asymmetry. 5G uses a DUCR value of 5. A good target for cable would be 5 to 10 for average capacity. Too low a value indicates the upstream may not be fully used. Too high a value indicates that the downstream may not get fully used. CM ACK suppression allows this value to be artificially high.

Removing MPEG-TS video from the downstream spectrum works well to increase DOCSIS bandwidth. The example used in this white paper showed an increase of 3x in bandwidth, from 3 Gbps to 9 Gbps, on a 1002 MHz plant by just removing video. The 1218 MHz plant for DOCSIS 3.1 was useful for retaining the same downstream spectrum size as 42 to 1002, but with a 204 MHz lower limit. DOCSIS 4.0 ESD added even more bandwidth, but went over the 10 Gbps Ethernet backhaul ceiling.

The 42 MHz return path can be increased by 50% to 100%, from 100 Mbps to 200 Mbps, by removing two of the A-TDMA channels, adding OFDMA, moving the modulation to 2048-QAM, and starting at a lower frequency. An 85 MHz return path provided excellent return path bandwidth with great DUCR values. The 204 MHz return path added more bandwidth than needed on DOCSIS 3.1 and worked well for DOCSIS 4.0. DOCSIS 4.0 would benefit from two 204 MHz return path ports.

For 204 MHz to be deployed, all OOB signaling for video has to be removed from the plant, and OUDP updates have to be done to accommodate signal leakage detection. Return paths greater than 204 MHz have diminishing returns in a 1x2 node configuration, but are more attractive in a 1x1 configuration. Note that two 204 MHz return paths are roughly equivalent to one 396 MHz return path from an average capacity viewpoint.

It was also demonstrated that future silicon solutions could sub-split a node to 4x4 and if the plant went to 3 GHz, then nodes could approach 100 Gbps of capacity.

Abbreviations

ADC	analog-to-digital converter
ATDMA	advanced time division multiple access

1. Introduction

The hybrid fiber coaxial (HFC) network has served as both a reliable and flexible architecture which has enabled cable operators to continue to migrate their networks to meet the exponential growth in bandwidth demanded by both commercial and residential customers. This architecture has supported cost effective capacity increases with minimal disruptions to the network and end-users. While more recent efforts have focused on building fiber-to-the-home (FTTH) networks, they are generally quite expensive with cost estimates often nearing $1000 per household passed (HHP) or greater. Given the long-term capacity of an all-fiber network, it may be considered the obvious choice for green field deployments. However, for brown field areas, the cost of a FTTH network upgrade drives the continued evolution of the existing HFC architecture as a better choice.

The introduction of extended spectrum Frequency Division Duplex (FDD) Data Over Cable Service Interface Specification (DOCSIS) within the DOCSIS 4.0 specifications enable that continued evolution by defining standards that for Cox would support capacities as high as 12 Gbps on the downstream and 3 Gbps on the upstream across the legacy HFC node and amplifier (N+X) architecture.[CM-SP-PHYv4.0] The strategy for operational implementation of this upgrade will be a critical component to the success of multi-Gig deployments over HFC.

This paper will explore several considerations for upgrading the HFC network to 1.8 GHz FDD DOCSIS 4.0 including a drop-in amplifier approach, intermediate upgrade steps, amplifier gains/tilts, and other operational aspects.[1]

2. Requirements and Constraints

A key challenge for cable system operators is the ability to transform the HFC network to meet the growing bandwidth demands while simultaneously continuing to provide reliable services to a large existing customer base. In fact, many of these customers have service level agreements (SLAs) in place which prohibit significant down time in the network. As a result, it is almost always the case that an operator cannot upgrade an entire market or, in some situations, even a single node within a maintenance window of a few hours. The ability to execute an upgrade to a network in incremental steps while continuing to support legacy devices and services is critical to the success of the operator, and the evolution to 1.8 GHz extended spectrum DOCSIS will be no exception to this requirement.

2.1. Tap Output Radio Frequency (RF) Levels

The DOCSIS 4.0 specification was developed with an assumption that extended spectrum DOCSIS 4.0 FDD signals operating up to 1.8 GHz would be communicating with a single point of entry (POE) device in the home. That is, there would be no splitters, drop amplifiers, or pass-through devices between the tap output and the DOCSIS 4.0 customer premise equipment (CPE) device. For extended spectrum FDD, this assumption was based upon the need to provide adequate forward signal levels at the CPE to support up to 1.8 GHz in spectrum with higher order quadrature amplification modulation (QAM) levels. Historically, operators have modeled drops with 2 or 4-way splitters and a 100-150 ft of cabling. With a POE device, at a minimum, the 2 or 4-way splitters are no longer necessary providing an additional 4 to 8 dB of signal level to a DOCSIS 4.0 device. However, that signal level increase does not carry-over to

[1] The authors wish to acknowledge and express their appreciation to others in the Cox Outside Plant Engineering team who also contributed to the technical work presented in this paper

legacy devices in other homes. It will take significant time for operators to migrate their in-home CPE to DOCSIS 4.0, and, as a result, the network will be required to support both single DOCSIS 4.0 POE device homes and legacy homes with multiple CPE devices including legacy video.

2.1.1. Legacy Levels

Video service offerings were the driver for the birth and growth of the cable industry during the 70's, 80's and 90's. The incorporation of data services (DOCSIS) was first introduced in the late 90's long after video services provided in the form of set tops were prolific within the network. While many operators, including Cox, are developing roadmaps to replace proprietary video CPE devices with Internet Protocol Television (IPTV), it is both cost prohibitive and infeasible to do a wholesale replacement of millions of these legacy devices within a short time. As a result, operators are required to continue to support both legacy video and data services to set tops and cable modems at their current location within the home as they migrate the network. This requirement constrains the architecture as tap output power levels in the legacy spectrum must be kept close to what they had been prior to the upgrade. When tap levels change, legacy CPE devices within the home are at risk of no longer receiving the minimum signal level required, driving the potential for a poor customer experience and truck rolls.

During Cox's initial experimentation with node plus 0 amplifier (N+0) architectures in 2017, early attempts were made at minor reductions in tap output levels to increase the reach or HHP per node. (See Figure 1) Early trials revealed a more than 20% increase in truck rolls and while there are a number of factors which can contribute to truck rolls when migrating from a N+X to a N+0 architecture, subsequent trials with restoration of design tap output level targets to more closely match legacy levels brought the number of truck rolls back in line with historical levels.

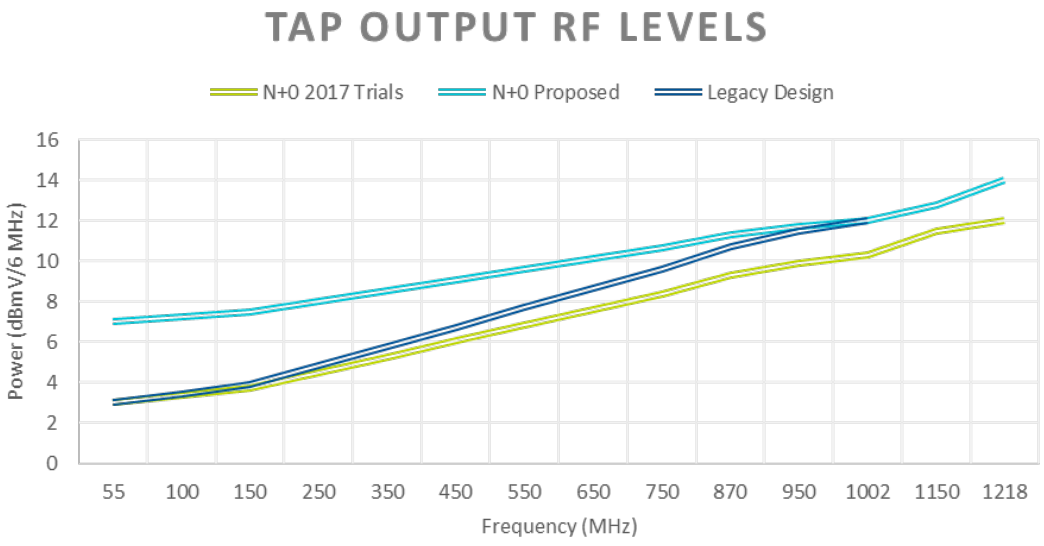

Figure 1. Previous Cox Trials Revealed the Importance of Maintaining Legacy Levels

2.1.2. In-House Conditioning

In addition, a more subtle dependency in tap output levels also exists. While HFC plant design constraints dictate a minimum tap output level, fielded implementations generally yield levels that are

above that minimum. See Figure 2 for an example of output levels for a series of 5 consecutive taps on a cable run between amplifiers. Actual output levels are provided in blue and minimum design requirements are provided in red. If a future change or upgrade to the plant results in the output levels changing, for example, if any of the actual output levels are reduced and brought closer to the design minimum levels, then any homes/devices connected to taps whose output levels were reduced might be at risk of no longer functioning properly.

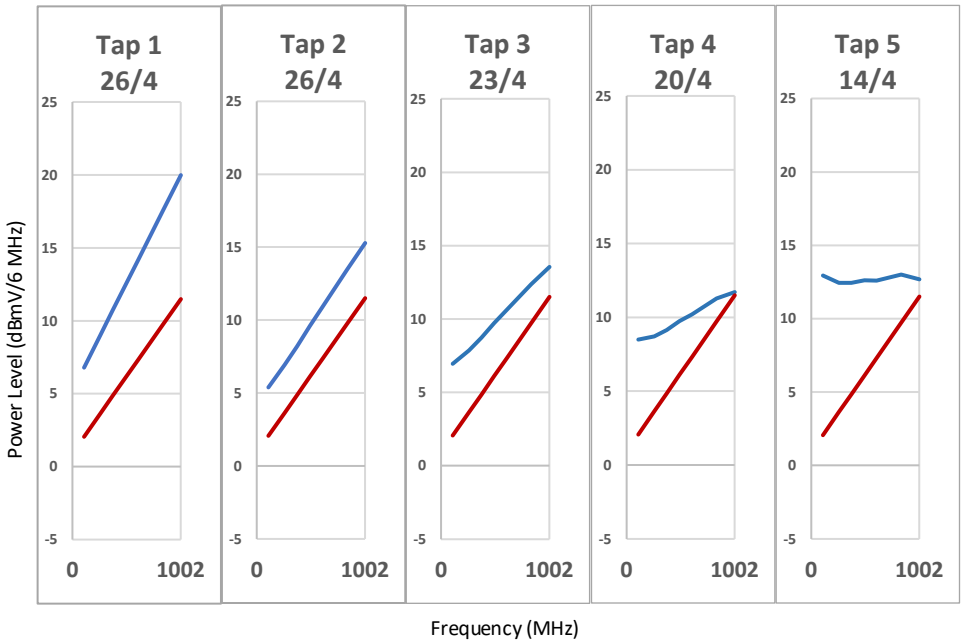

Figure 2. Example Tap Cascade Output Levels (Blue) versus Minimum Design Spec (Red)

While the red curve meets minimum design constraints, there is a risk that in-house wiring may have leveraged the additional power previously provided at that tap to deliver adequate levels perhaps deeper into the home. That is, either the operator or the homeowner may have placed devices within the home that leveraged this additional power. Alternatively, technicians may have installed in-home attenuators to force levels closer to what they considered to be optimum. If the levels are subsequently lowered (but still at or above spec), adequate signal level may not be present for those devices, driving the need for possible in-house amplification, splitter reconfigurations, or attenuator removals that were not required before. From the homeowner's perspective, his service was working before the upgrade but no longer functions properly afterward. This situation can be referred to as in-house conditioning and is quite common.

2.2. Mainline Amplifier Considerations

During most prior HFC downstream bandwidth upgrades, a "drop-in" approach was used. The drop-in term was meant to convey that legacy amplifier locations were maintained and that new amplifier modules/stations with increased downstream bandwidth were dropped in as replacements at those locations. Mainline passives (taps, splitters, and directional couplers) also maintained their legacy locations and were only replaced if needed to support the increased downstream bandwidth. The drop-in approach minimized the need for extensive plant construction/redesign that would have been required if amplifier locations were moved, which in turn helped minimize downtime during the upgrade.

When considering a 1.8 GHz upgrade, the drop-in approach continues to be attractive in that upgrades to passives (which far outnumber actives) could be accomplished regardless of whether the amplifiers in the area have been upgraded or not. This increases the flexibility to efficiently deploy resources for that part of the upgrade and enables small sections of plant (down to individual feeder legs) to be upgraded without the long duration outages inherent in upgrades where actives move locations, requiring the passives to be changed along with the actives.

Historically, both downstream amplifier gains and downstream amplifier RF output levels were increased to help facilitate drop-in upgrades while maintaining amplifier and tap RF output levels in the existing legacy band. Each are discussed next in more detail.

2.2.1. Downstream Amplifier Gain

To facilitate a drop-in bandwidth upgrade, the downstream gains of the mainline amplifiers were increased to offset increased cable losses at the higher frequencies. Table 1 below shows the downstream amplifier gains for many of the amplifiers commonly used in North America, and how they increased as downstream bandwidths increased.

Note that downstream amplifier gain generally refers to the gain at the downstream upper band edge (highest rated frequency). It is important to keep in mind that sufficient gain is required to offset the coaxial and passive losses between amplifiers (to achieve unity gain) and that gain requirements are not directly linked to amplifier RF output levels.

Table 1 – Amplifier Gains for 750, 870, 1000, and 1218 MHz Amps

Manufacturer	Amplifier Type	Operational Gain at Rated Frequency (dB)

For a full drop-in type of upgrade to 1.8 GHz to be supported, the downstream gains for the amplifiers would need to increase even higher.

Figure 3 shows the historical gains for Line Extenders plotted against cable loss increases. The frequency axis was extended to show the associated gains that would be required for drop-in upgrades to 1.8 GHz. A cable length and type (1360 ft of PIII .500 cable) whose loss matches the legacy gains at various lower

frequency points was selected to graphically show the increased gain versus increased cable loss relationship. This shows the gains required if the span loss preceding the amplifiers were all coax, and if the amplifiers were at maximum spacing.

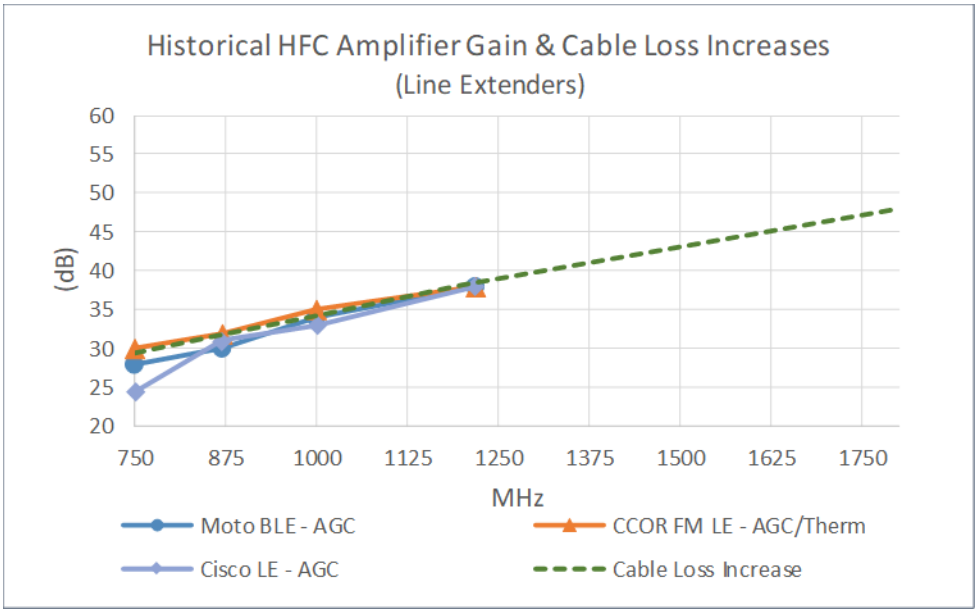

Figure 3. Line Extender Gain & Cable Loss Increase

For Line Extenders, the gains shown are for automatic gain control (AGC)/Thermal types. Based upon this information, gains at 1.8 GHz of approximately 48-49 dB may be required for full drop-in capability for these type amplifiers. There appears to be some consensus in the industry that this amount of gain is feasible for 1.8 GHz Line Extenders.

An internal Cox study was also performed to estimate what Cox's actual 1.8 GHz spacings would be for AGC/Thermal Line Extenders. Information from Cox's design data base was used to determine the existing 1 GHz coax and passive losses preceding each Line Extender. Based upon vendor data sheets, coax losses were increased by 40 percent and passive losses by 20 percent and summed to estimate the expected total loss at 1.8 GHz. The results are shown in histogram format in Figure 4.

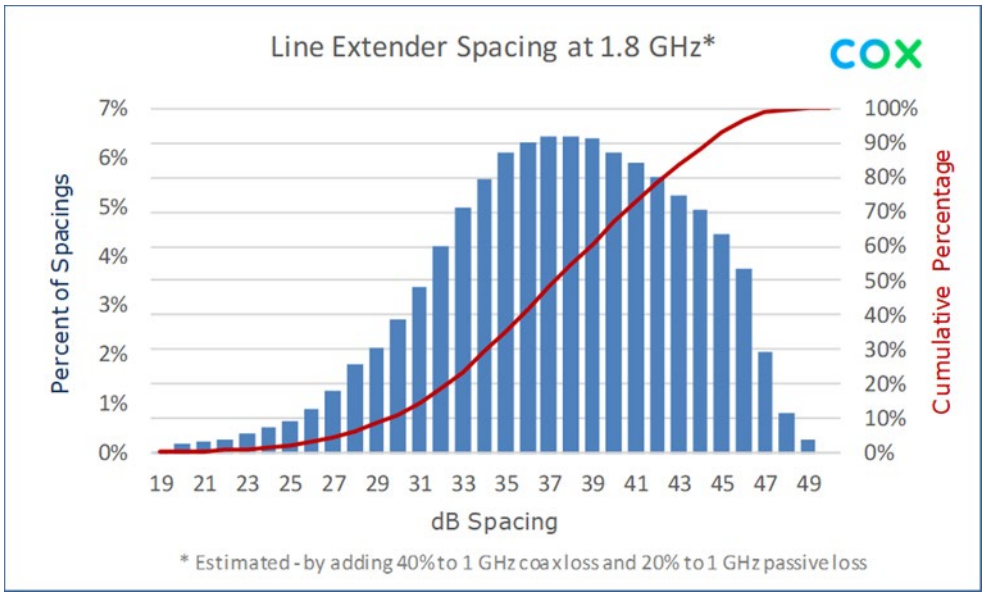

Figure 4. Estimated 1.8 GHz Line Extender Spacing for Existing Cox Spans

The histogram correlates the above assumption that AGC/Thermal Line Extenders with 48-49 dB of gain at 1.8 GHz should cover the vast majority of spacings for these type amplifiers using a drop-in upgrade approach.

Figure 5 shows the historical gains for high gain Multiport Bridger amplifiers plotted against cable loss. The frequency axis was extended to show the associated gains that would be required for drop-in upgrades to 1.8 GHz. A cable length and type (2450 ft of PIII .750 cable) whose loss matched the legacy gains at various lower frequency points was selected to graphically show the increased gain versus increased cable loss relationship. This show the gains required if the span loss preceding the amplifiers were all coax, and if the amplifiers were at maximum spacing.

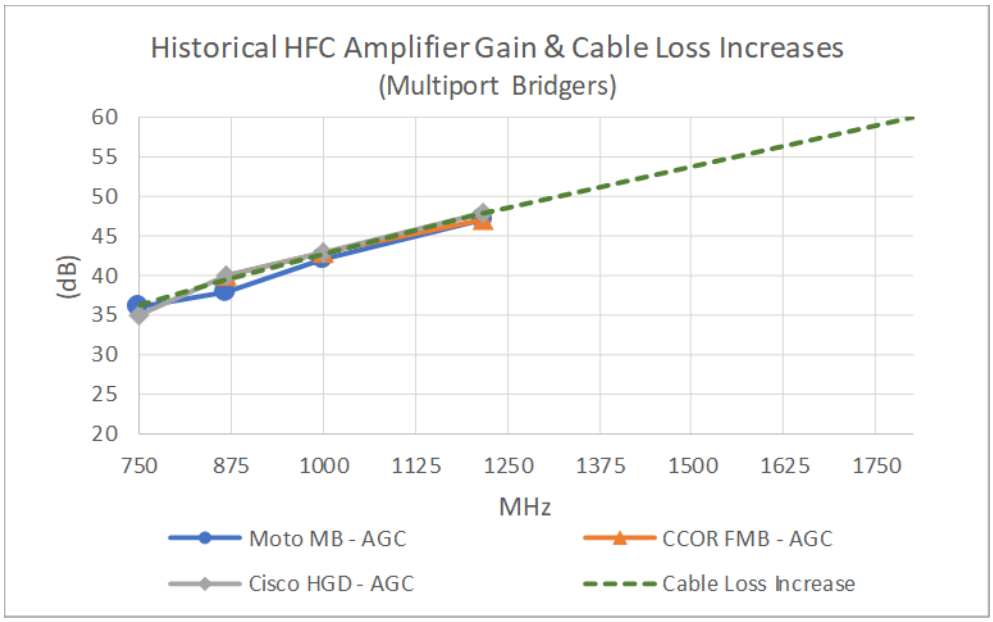

Figure 5. Multiport Bridger Amplifier Gain & Cable Loss Increase

For Multiport Bridgers, the gains shown are for AGC types. Based upon this information, gains at 1.8 GHz of 59-60 dB may be required for full drop-in capability for these type amplifiers. There appears to be consensus that this amount of gain would not be feasible for these types of amplifiers. For one, Carrier to Noise Ratio (CNR) would suffer due to the extremely low input levels that would need to accompany amplifiers with such high gains. Additionally, it would be very difficult to achieve sufficient closed loop isolation in a station with so much downstream gain combined with an increased upstream gain. There appears to be some consensus in the industry that 48-50 dB gain would be feasible for these types of amplifiers, but in systems that had made use of maximum spaced amplifiers with high coax losses in their legacy plant that would not be enough gain to overcome losses at 1.8 GHz. This led to the consideration of ways to address this concern.

The Booster Amplifier concept was conceived based upon the realization that there could be a 10 to 12 dB gain shortage in some cases where high gain Multiport Bridgers had been deployed at or near full spacing where most of the loss was coaxial. At Cox, this is called an express application, where the RF from the node was fed deeper into the network to efficiently reach tapped feeder areas by using lower loss express cable in conjunction with high gain amplifiers. In scenarios where the 1.8 GHz drop-in amplifier would not have enough gain to cover the high express losses, Cox initially considered adding a Line Extender, but realized a preference to use a smaller, lower gain, lower cost amplifier placed in the express cable route to supplement the drop-in amplifier's gain. Currently several amplifier manufacturers are planning to make such amplifiers which have come to be known as Booster Amplifiers. Cox recognizes that installing these type amplifiers will be much easier in aerial plant than in underground, but even in underground there are often locations along long express runs where the cable run is interrupted to accommodate a splitter, coupler, or splice block.

An internal Cox study was also performed to estimate what Cox's actual 1.8 GHz spacings would be for AGC Multiport Bridger amplifiers, to determine what percentage of those amplifiers might need Booster Amps added. Information from Cox's design data base was used to determine the existing 1 GHz coax and passive losses preceding each amplifier. Based upon vendor data sheets, Cox increased those coax

losses by 40 percent and passive losses by 20 percent and summed them to estimate the expected total loss at 1.8 GHz. The results are shown in histogram format in Figure 6.

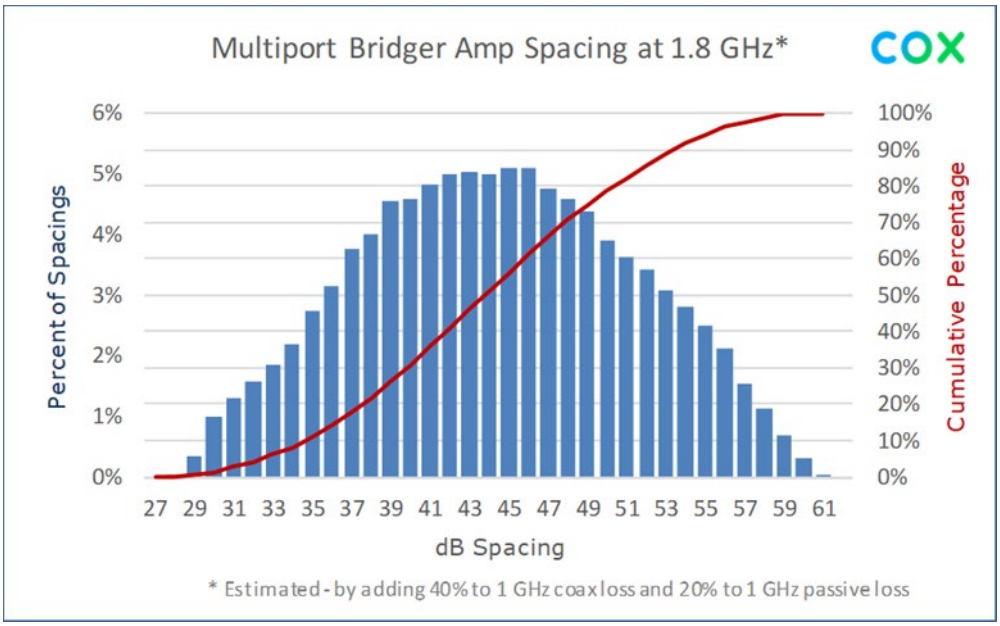

Figure 6. Estimated 1.8 GHz Multiport Bridger Spacing for Existing Cox Spans

The histogram shows that Multiport Bridgers with 48-50 dB of gain at 1.8 GHz should cover roughly 75 to 80% of Cox's spacings for these type amplifiers using a drop-in upgrade approach. The remaining 20 to 25% would require the addition of a Booster Amplifier. With Multiport Bridger amplifiers representing about 32% of the network, Cox's expects to need booster amplifiers for approximately 8% of the network spans.

2.2.2. Downstream Amplifier RF Output Levels

When considering downstream amplifier RF output levels for plant upgrades to 1.8 GHz, two important aspects must be considered. One is how closely the tap RF output levels after the upgrade should match the current tap RF output levels in the legacy band, and the other is the total composite power (TCP) constraints that exist when operating amplifiers with significantly greater channel loading at high output levels. When considering a drop-in upgrade approach these two factors are inherently linked.

The expectation that both legacy CPE and the new extended spectrum D4.0 CPE will need to co-exist in the same network for years to come should be well understood. With that comes a requirement to consider both the downstream RF levels that will feed the legacy CPE and the new extended spectrum CPE. As was mentioned prior, Cox learned that in order to minimize the potential for service complaints and associated truck rolls when performing a plant upgrade, it is best to keep the downstream RF levels feeding legacy CPE very close to what they were.

If the assumption is to leave the downstream RF output levels of the taps nearly unchanged in the legacy band, and to replace the existing taps with 1.8 GHz taps using the same tap values (which looks possible based upon 1.8 GHz tap insertion losses), then it follows that the downstream RF output levels of the replacement amplifiers should remain nearly unchanged in the legacy band. At Cox, the legacy band is 54 or 108 MHz to 1002 MHz for most of the network. Existing typical node/amplifier RF output levels in

that band are shown in Figure 7. Note that actual signal level per 6 MHz is shown (not analog equivalent).

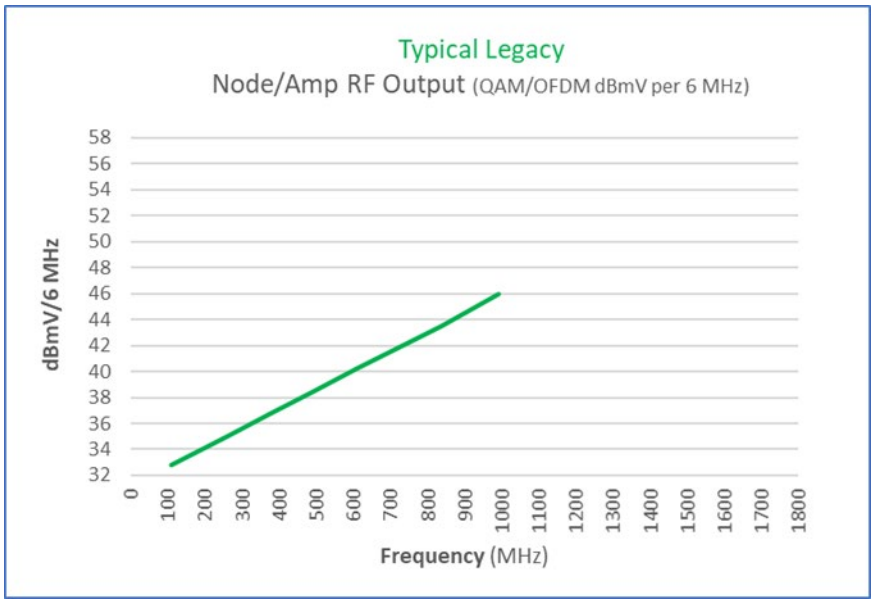

Figure 7. Typical Node/Amp RF Output Levels

In drop-in plant upgrades from 750 or 870 MHz to 1002 MHz, traditionally the amplifier RF output levels were increased along a common output tilt line. This trend also applied to some earlier plant upgrades that started at 550 MHz and has recently been incorporated for upgrades to 1218 MHz. Evidence of this approach is shown in Table 2 and Figure 8. Table 2 shows the reference output levels on the published data sheets for two major manufacturer's amplifiers. Figure 9 shows the same information in graphical format. While not all operators ran the exact reference RF output levels that were specified on published data sheets, most did tend to use similar RF output tilts as those shown.

Table 2 – Amplifier Data Sheet Reference Output Levels/Tilts (dBmV/Channel – analog equivalent)

Mfr	Rated Frequency (MHz)	Amp Type	54 MHz	750 MHz	870 MHz	1002 MHz	1218 MHz
S-A	**750**	**LE, HGD, HGBT**	36	46			
S-A	**870**	**LE, HGD, HGBT**	35	45.7	47.5		
S-A	**1002**	**LE, HGD, HGBT**	35	45.7	47.5	49.5	
Moto	**750**	**BLE, MB, BT**	37	47			
Moto	**870**	**BLE, MB, BT**	37	47	49

Moto	**1218**	**BLE, MB**	38	48.2	49.9	51.8	55

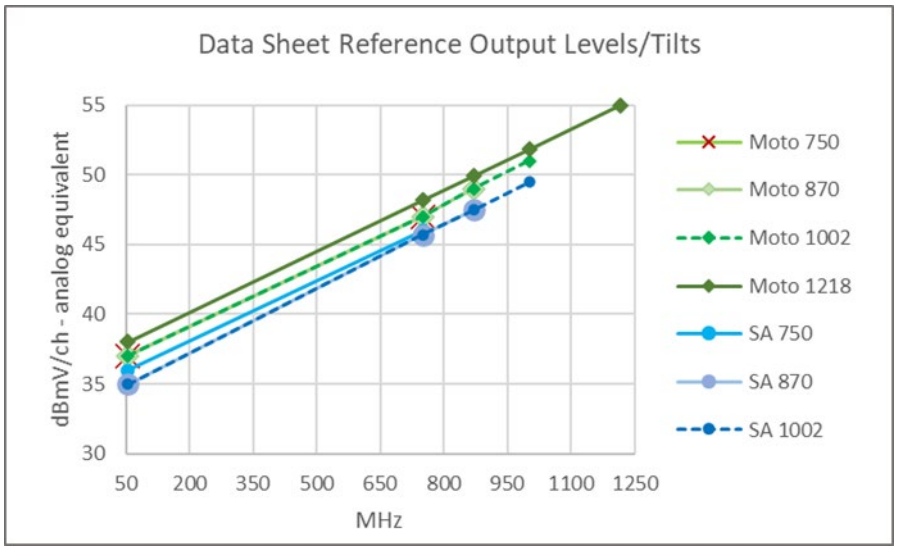

Figure 8. Amplifier Data Sheet Reference Output Levels/Tilts

Cox followed the trend of increasing the RF output levels along a common tilt line during upgrades to 1002 MHz; however, using a similar approach for upgrades to 1.8 GHz introduces a problem. Figure 9 shows what that would look like.

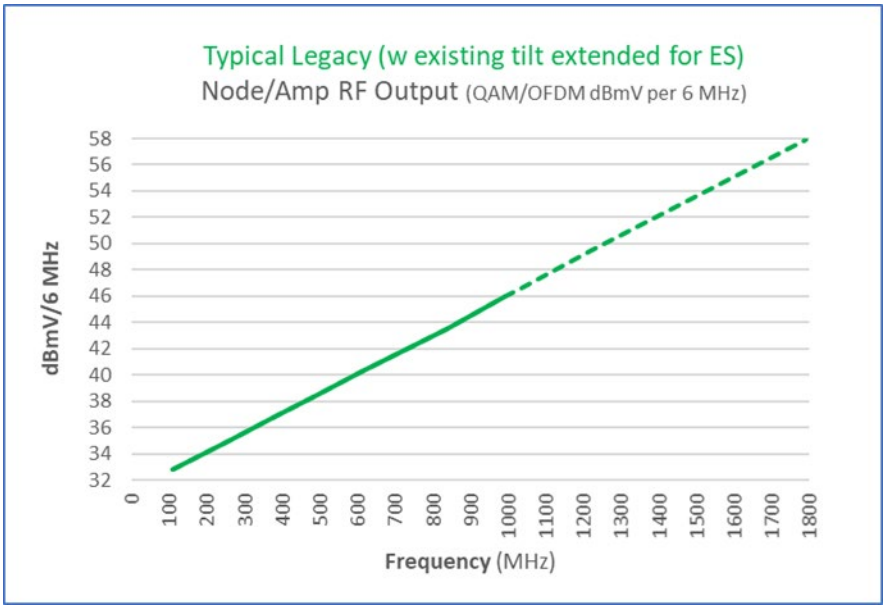

Figure 9. Typical Node/Amp RF Output Levels - if extended to 1.8 GHz

If the tilt line representing Cox's typical amplifier RF output levels in the legacy spectrum was extended out to 1.8 GHz and the band was fully loaded at those levels, the total composite power (TCP) at the amplifier output would be excessively high reaching 74.8 decibels relative to one millivolt (dBmV). It is worth noting that the associated TCP for the legacy band in this case is only 62.7 dBmV. If you consider that there may be roughly 4 dB of loss from the output of the final amplifier gain stage (commonly referred to as the power amplifier) to the station RF output port, 74.8 dBmV TCP at the port would equate

to ≈ 78.8 dBmV TCP at the power amplifier output. That is much higher than any power amplifier can currently support while outputting usable signals.

The TCP limitations of state-of-the art broadband power amplifiers were recognized early on during the extended spectrum discussions, as similar discussions had gone on previously in association with the very high RF output powers required for N+0 architectures. All broadband amplifiers have limitations on how high they can run before distortion becomes excessive. The question of how high the new amplifiers will be able to run with extended spectrum loading is under investigation but gain block manufacturers are diligently working to optimize and characterize their output power capabilities. While beyond the scope of this paper, it is worth mentioning that there's more than one aspect to consider, as in some cases better performance may come at the cost of higher power consumption.

For reference, amplifier output TCP can be calculated by converting the output signal level (in dBmV per 6 MHz for each 6 MHz of bandwidth that will be occupied) to power (typically expressed in milliwatts), summing those powers, and converting the summed power to dBmV.

When the limitations due to TCP were discussed in conjunction with the desire to keep RF amplifier output levels near to what they have been in the legacy band, the idea of reducing or stepping down the RF power in the extended spectrum became a widely discussed topic. Various output power profiles for the extended spectrum were suggested, such as making use of multiple step downs; up to one per 192 MHz orthogonal frequency division multiplexing (OFDM) channel (referred to as zig-zag or lightning bolt), or shaping the amplifier RF output power in the extended spectrum to be flat while keeping the legacy spectrum tilted (referred to as tilt-flat).

After much discussion, most operators coalesced around the idea of having one or possibly two step downs in the extended spectrum, with all output power levels referenced to a virtual linear tilt line from lowest to highest frequency (referred to as tilt-tilt). This concept was not new, as prior to conversions to "all-digital" signal carriage, cable operators ran amplifier RF outputs referenced to what was called an "analog equivalent" tilt line - with analog video carriers ran at the levels shown on the tilt line and digital (SC-QAM256) signals typically ran 6 dB lower relative to the tilt line.

The ability for the DOCSIS 4.0 remote PHY device (RPD) / remote MACPHY device (RMD) in a distributed access architecture (DAA) node to make use of a step down (or multiple step downs) in the extended spectrum was written into the D.4.0 PHY specification. Up to 10 dB of step-down capability was mandated. The step-downs, once created at the RPD/RMD module, would pass through amplification and tilt stages in the node so that the tilted RF output with associated extended spectrum step-downs would be outputted at the node RF output ports. With this approach, the broadband amplifiers following the node in N+X architectures would not have any part in producing the RF profile with the step downs, and would just need to make use of equalization, amplification, and internal tilt to allow the duplication of the tilted RF output with associated extended spectrum step downs at their RF output ports.

With the extended spectrum step-down capability, operators will need to work to optimize a variety of factors. If it is desired to maintain legacy band amplifier RF output levels near to what they have been, the amount of step down for the extended spectrum can be adjusted to align the output TCP of the amplifier to a place that the operator deems to be optimum. That will require interaction with amplifier station manufacturers familiar with the output level capabilities of the amplifiers.

Some of the trade-offs to consider are that increasing the amount of extended spectrum step down lowers the TCP and increases the RF power margin between design operating levels and the point where significant ill effects from amplifier overdrive occur – such as 4-5 dB reduction in modulation error ratio

(MER) with only 1 dB increase in levels, or the onset of significant bit errors. That margin needs to be considered because real world amplifiers and networks will have some inherent factors that could cause amplifier output levels to be higher than targeted. Those factors include the accuracy of the actual RF output levels versus the programmed RF output levels, the AGC's ability to hold output levels over temperature, and the fact that frequency response build-up in the network can increase the TCP even when high and low frequency output levels are held tightly at target levels. On the flip side, increasing the amount of extended spectrum step down reduces the RF input levels to amplifiers and the DOCSIS 4.0 modems in that spectrum, which can reduce overall carrier to noise and potentially reduce the order of modulation that the extended spectrum OFDM signals can support.

At Cox, based upon vendor feedback concerning power amplifier performance and on Cox's plant performance modeling, Cox identified two potential initial target profiles for amplifier RF output levels, shown in Figure 10 below. The green trace represents holding Cox's RF output levels in the legacy spectrum where they are now, extending that virtual tilt line, and using a 6 dB step down in the extended spectrum from 1 to 1.8 GHz. This represents a total virtual tilt of 25.1 dB from 111-1791 MHz. The blue trace shows what is Cox's preferred option, where the legacy RF output level at 1 GHz is held, but the overall virtual tilt is reduced and again a 6 dB step down is used in the extended spectrum. This represents a total virtual tilt of 21 dB from 111-1791 MHz.

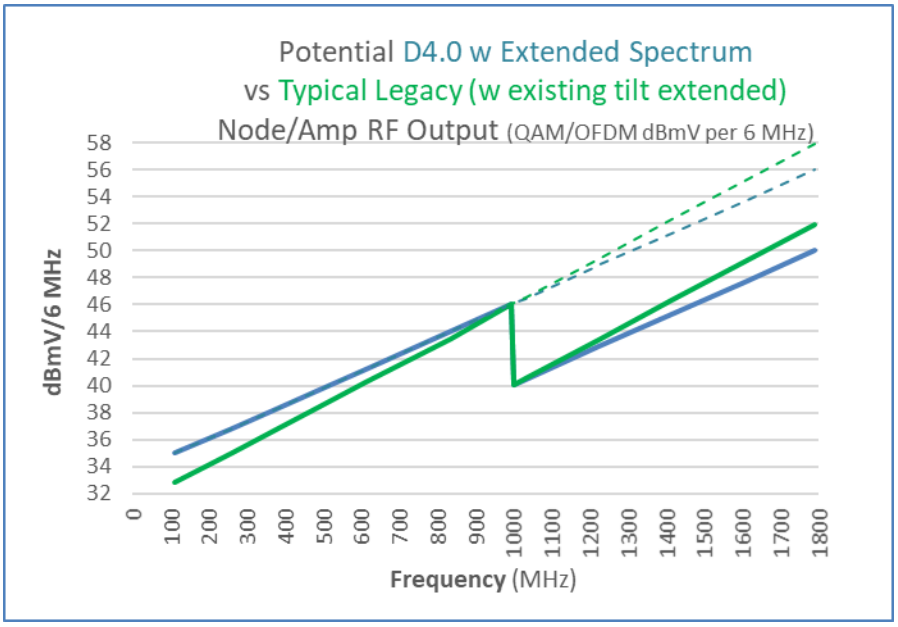

Figure 10. Potential Amplifier RF Output Profiles for 1.8 GHz

There are three potential advantages to the reduced tilt option:

1. Cox learned from amplifier gain block manufacturers that not all TCP is created equal. While it is true that conceptually, amplifiers with lower TCP also produce lower distortion, it has been found that the RF power at the highest frequencies has a disproportionate effect on distortion that is not captured via TCP differences alone. The RF energy at those very high frequencies can cause significant effects on the overall distortion, and it appears that keeping the RF energy lower at those frequencies is beneficial. In the blue reduced tilt trace the RF output power per 6 MHz at 1791 MHz is 2 dB lower than in the green trace.

2. There is also an improvement in TCP for the blue reduced tilt trace (68.6 dBmV) compared to the green higher tilt trace (69.5 dBmV).

3. The first incarnations of 1.8 GHz taps available on the market have "flatter" insertion losses than legacy taps, i.e., less tilt from low to high frequency across the band. Since the losses at 1 GHz are no greater than the losses of the legacy taps they will replace, and they are flatter, that means that the losses at the lower frequencies for the new taps end up being somewhat higher. With the blue reduced tilt profile, the higher outputs from the amplifiers in the lower frequency range help to offset the effect of a tap cascade having higher insertion losses in that band.

Based upon modeling, the slight reduction in RF power per channel at the higher frequencies with the detilted blue trace profile does not appear to be enough to alter the supported order of OFDM modulation in that region; however, Cox will continue to work with amplifier manufacturers to monitor measured performance attributes and further adjustments to the extended spectrum step down may be needed.

One final input on this topic. Since Cox's initial efforts to develop a target amplifier RF output profile, a new wrinkle came up, which was the need to plan to support 1.2 GHz high-split in portions of the network. Understanding that RF output levels in the new 1 to 1.2 GHz spectrum will become a legacy condition to deal with on the road to 1.8 GHz, Cox put careful thought into what should be done in that spectrum. Many of today's DOCSIS 3.1 RPD's and the software applications used to configure them do not currently support the 6 dB step down shown above while continuing to provide quality overall performance. Cox also realized that if that spectrum was deployed with no step down, it would be painful to later reduce those levels significantly to match the 6 dB step down with the migration to 1.8 GHz. After careful consideration, Cox's current plan is to introduce a 3 dB step down, which is more readily available in RPD products today, in the new 1 to 1.2 GHz spectrum. With respect to how that will play into the eventual migration to 1.8 GHz, the target RF output profile (with the new double step approach), is shown in Figure 11 below. This did increase TCP slightly (by 0.3 dB to 68.9 dBmV) relative to the initial target shown above. There is a benefit in that OFDM signal in the ≈ 1 to 1.2 GHz spectrum is now expected to have better MER than anticipated in the original single stepdown profile. The virtual tilt from 111-1791 MHz remains unchanged at 21 dB.

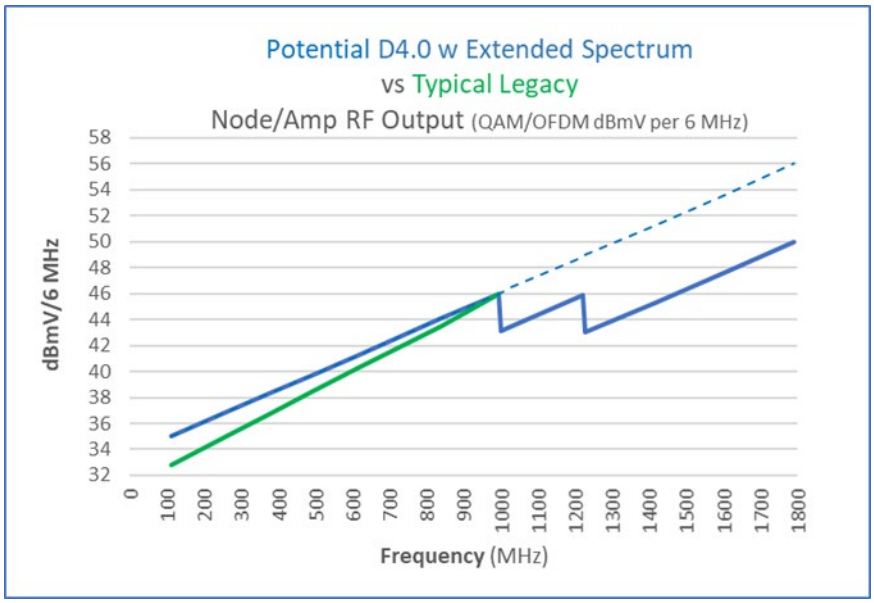

Figure 11. Current Potential Amplifier RF Output Profile for 1.8 GHz

2.3. Impacts of Spectrum Changes

Cable operators have a great deal of experience over the years with frequency expansion upgrades, i.e., increasing the top end frequency of the network (e.g., 550, 750, 870, 1000 MHz); however, these upgrades have always targeted increasing the downstream bandwidth and have rarely modified the upstream/downstream frequency split until recently. The transition from sub-split (42/54 MHz) to mid-split (85/108 MHz) represents one of the first times that operators are moving that upstream/downstream frequency split. Movement to mid-split is a minimal impact upgrade as most services that are locked into a particular frequency do not fall in the affected range or, if they do, the services were agile enough to allow movement beyond the band of change. With the transition to a high-split configuration (204/258 MHz), operators can no longer expect minimal impact as several downstream services are fixed in the spectrum below 204 MHz which will transition to upstream.

2.3.1. Service Impacts

One cannot say that DOCSIS has not been a resounding success. Cable was once a video only service that is now a majority data service. The compounded annual growth rate (CAGR) of data services continues to be in the 30% range, putting pressure on the need for more and more bandwidth devoted to data. This has led to an unprecedented number of node splits annually and the move to mid-split to relieve upstream congestion. Mid-split and the move to high-split and eventually ultra-high-split reduces the available downstream bandwidth below 1 GHz. While the higher spectral efficiency of DOCSIS 3.1 has helped significantly, it is not enough by itself.

2.3.1.1. QAM Video

To compensate for the reduced downstream bandwidth, Cox has converted QAM based video from MPEG2 to MPEG4, reducing the number of QAM video channels from approximately 70 to 42. Cox has already made extensive use of switched digital video (SDV) to reduce the number of QAM channels devoted to video. The MPEG4 conversion allowed the move to mid-split and the addition of another 96 MHz DOCSIS 3.1 OFDM block with no reduction of video services. Eventually, over a several year

period, Cox plans to eliminate QAM based video services in favor of IPTV. Approximately 10% of our video base is already IPTV only. Based on current utilization, an all IPTV 250 HHP node would consume approximately 450 Mbps of IPTV traffic at peak busy hour. That is equivalent to ¼ of a DOCSIS 3.1 OFDM block, or 48 MHz (8 QAM video channels). However, the conversion to all IPTV comes at a significant price, the retirement of QAM only STB's and a much larger population of DTA's. The newest generation of QAM enabled STB's include bonded DOCSIS 3.0 modems and can be converted to IPTV.

There is also significant interest in being able to offer a symmetric gigabit service prior to the availability of DOCSIS 4.0. There are two paths using DOCSIS 3.1 to achieve this. The first is to move to high-split and increase the upper end of the downstream spectrum to 1.2 GHz to recover the lost downstream bandwidth. This requires that not only actives in the plant be upgraded, but passives will have to be upgraded beyond their current 1 GHz limitation. A second approach would be to accelerate the move to IPTV, removing QAM video from the network and devote that bandwidth to DOCSIS. This would require retiring all QAM-only CPE including the millions of DTA's in the network. The plant upgrade would then touch only actives and would be similar in cost to a mid-split upgrade. The tradeoff is then the cost of the passive upgrade vs. the cost of retiring CPE. Both must be done eventually to meet the final DOCSIS 4.0 ultra-high split (UHS) end state. A "halfway" solution is also possible; Cox dedicates 16 of the QAM channels to SDV/VOD. Retiring the QAM only CPE would allow removing the SDV/VOD QAMs from the network, keeping the broadcast QAMs and DTAs. This would allow high-split on 1 GHz plant with only a slight limitation in DOCSIS capacity while minimizing the amount of retired CPE.

2.3.1.2. Legacy OOB STBs

The upstream move to high split or ultra-high split introduces several issues. The first is the legacy out-of-band (OOB) downstream for STB's. Downstream OOB is limited to a highest frequency, by specification, of 130 MHz, which now falls in the upstream spectrum. Cox has retired all legacy OOB STB's in favor of DOCSIS Set top Gateway (DSG) STB's, however customer owned UDCP devices, such as TiVo, that use CableCards are required by regulation to be supported using legacy OOB. Several approaches to a solution have been proposed, such as moving the OOB to a higher frequency in the downstream and providing an in-home down converter for devices needing legacy OOB. Cox has chosen another approach, along with other operators, in developing a DSG to legacy OOB converter to be placed in the homes of UDCP customers. This eliminates the need for OOB support within the coaxial network.

2.3.1.3. Impacts of HS and UHS Devices

Large numbers of sub-split and mid-split STB's and modems will continue to be in the network, potentially for years, after high-split or ultra-high-split (UHS) networks are enabled. A high-split DOCSIS 3.1 modem or an UHS DOCSIS 4.0 modem could be transmitting upstream with levels bursting as high as 65 dBmV, with a significant portion of that energy falling within the downstream passband of the sub-split or mid-split devices. For a STB or modem, the total composite power (TCP) received from the network may be on the order of 20 dBmV. The automatic gain control (AGC) on the front end of those devices reacts relatively slowly, and the bursting upstream from the high-split or UHS modem, even through the isolation of a splitter, may overload the front end of the older device causing dropped packets or macro blocking. For this reason, Cox is recommending that all homes that are high-split or UHS enabled, should be single point-of-entry, and any video services should be IPTV only using wired or WiFi connectivity to the gateway. A potential similar problem exists for adjacent homes off the same tap of a high-split or UHS home. However due to drop cable loss and better isolation in the tap, analysis

estimates this to be a problem in less than 5% of adjacent homes. Remediation could be through conversion of that home to HS/UHS or the installation of upstream blocking filters in that home.

2.3.1.4. MoCA Networks

Cox, along with other operators, has a significant footprint of Multimedia over Coax Alliance (MoCA) enabled homes used for multi-room DVR or in some cases WiFi extensions. Nominally, MoCA point-of-entry (POE) filters are used to isolate MoCA signals from the network and from interfering with adjacent MoCA networks. Once the downstream spectrum is extended above 1 GHz, to 1.2 or 1.8 GHz, MoCA will be incompatible with the network. Homes that have only 1 GHz CPE and MoCA, can continue as is if the MoCA POE filter provides adequate isolation. Homes using spectrum above 1 GHz cannot use MoCA, and any existing POE filters will have to be removed and the MoCA network replaced with WiFi or other compatible network technology within the home.

2.3.2. The Downstream Bandwidth Squeeze

In order to execute the migration process of increasing both the upstream and downstream frequency spectrum, two options are available as illustrated in Figure 12 and Figure 13. Figure 12 illustrates one option which provides for the lowest cost and lowest network downtime, as it benefits from completing the construction process (upgrading the node, and amplifiers for both upstream and downstream with the desired upstream/downstream frequency split) as a single step. However, by executing the entire construction change as a single step, the network maybe temporarily forced to operate with reduced downstream bandwidth, referred to here as the “squeeze”. The operator can avoid the squeeze by deploying an adequate number of CPE supporting the higher downstream frequency prior to the upgrade to absorb the lost bandwidth incurred by raising the split. Some limited modeling has indicated upgrading 20% of the CPE deployment should provide adequate congestion relief. However, the fact that these devices will need to be single point of entry (and drive the need to swap other sub-split and mid-split in-home devices) may limit early customer acceptance and thusly, the ability for an operator to deploy CPE early.

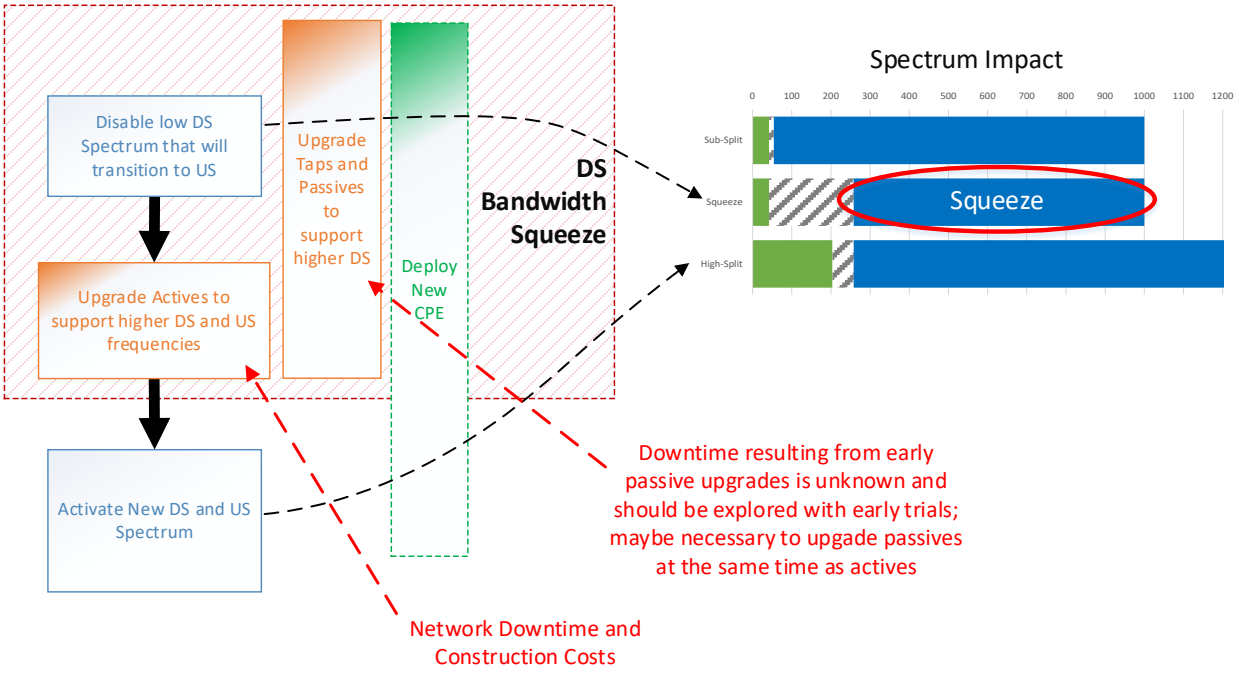

Figure 12. Migration Option to Support both DS and US Frequency Expansion with Minimal downtime but possibly incurring a Bandwidth Squeeze

Figure 13 illustrates a second option which eliminates the downstream bandwidth squeeze by executing the construction process as two steps. First the operator replaces the active and passive components to handle the higher downstream frequencies and activating that new downstream prior to changing the upstream/downstream frequency split in the actives. In parallel, the operator would be upgrading the CPE population to accommodate the increased downstream spectrum until an adequate number of high frequencies devices are deployed to eliminate the possibility of congestion when lower downstream spectrum is disabled to make room for upstream. Once an adequate number of new CPE were deployed, the operator would execute a second step to upgrade the active components a second time with the desired upstream/downstream frequency split and activating the new expanded upstream bandwidth.

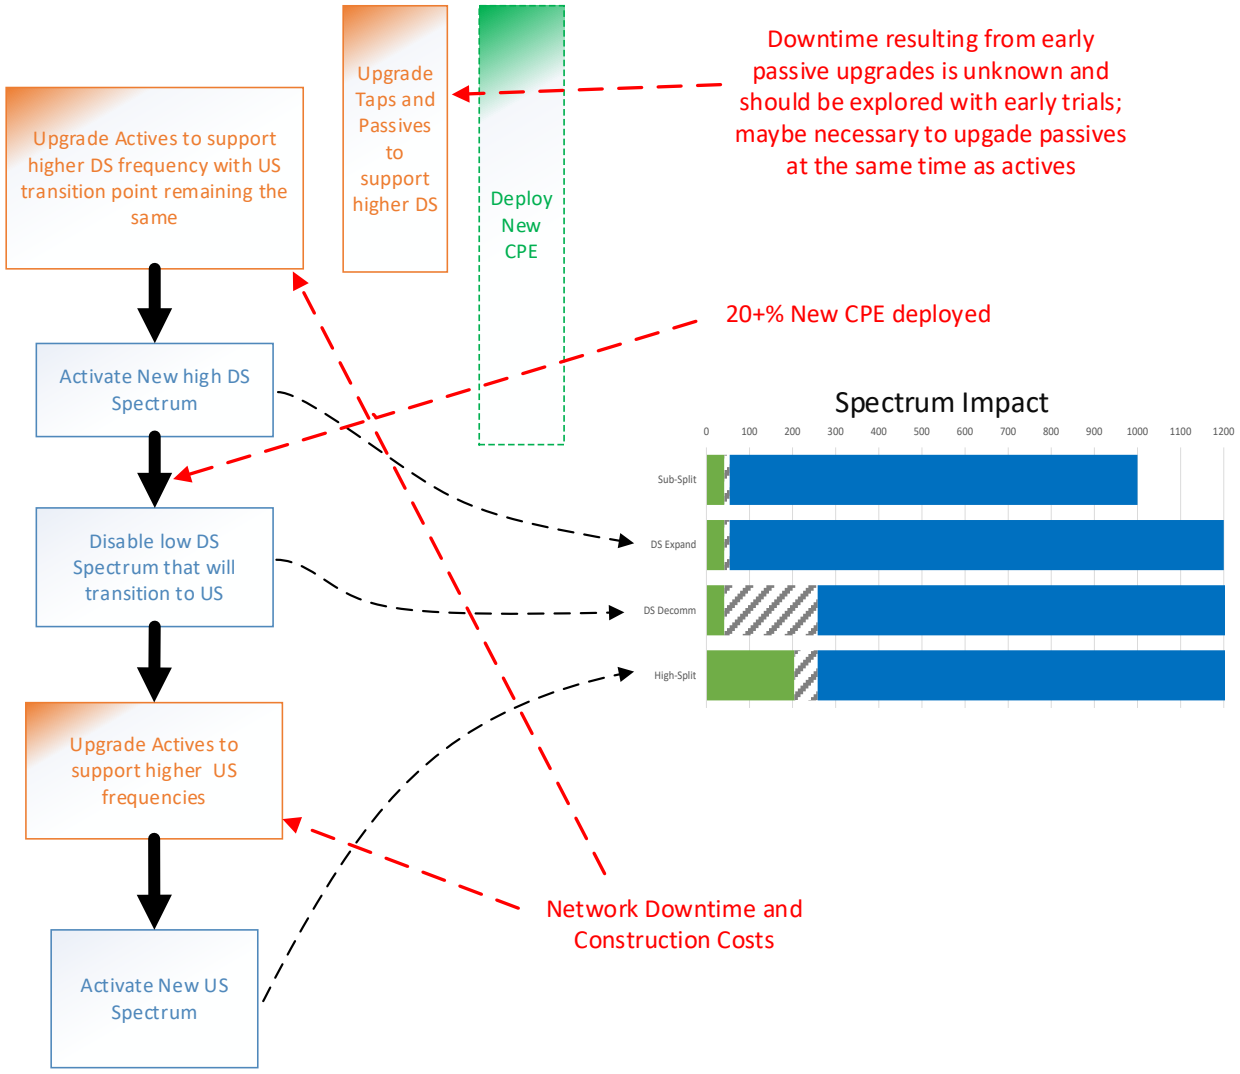

Figure 13. Migration Option to Support both DS and US Frequency Expansion with Increased Costs and Downtime but without a Bandwidth Squeeze

The increased costs and extended customer impacts in network down time, make the second option an undesirable choice. As a result, cable operators are strongly incentivized to identify ways to temporarily absorb the lost downstream bandwidth during the migration process. In the case of Cox, efforts are currently underway to look at accelerating the retirement of legacy video spectrum and replacement with IPTV which will provide some downstream spectrum relief during this transition period. Alternatively, operators may want to investigate accelerating their high-split upgrades prior to downstream congestion problems to also enable some absorption of this spectrum squeeze.

2.3.3. FCC Requirements for Leakage

Signal leakage is another factor which introduces significant challenges for operators as they move to DOCSIS 4.0 FDD, and, in particular, increased upstream spectrum. In the United States, the Federal Communications Commission (FCC) mandates that operators actively monitor their networks for signal leakage to assure that HFC network signals don't interfere with wireless services. While the FCC's requirement extends to many wireless services and frequencies, aircraft navigational signals (ranging

from 108 to 137 MHz) are of particular concern and as such, operators are required to provide documentation annually to the FCC to assure compliance.

Historically, this frequency band overlapped with what is the downstream spectrum on the cable plant (sub-split or mid-split spectrum plans). (See Figure 14) As such, vendor solutions relied on reference leakage test signals either generated by specialized equipment feeding the combining network in a headend or by RPDs in the case of DAA. With the consideration of high-split and ultra-high-split spectrum configurations, the lower edge of the downstream moves to 258 MHz or higher. The leakage reporting region of the aeronautical band is then clearly in the middle of the upstream frequency spectrum.

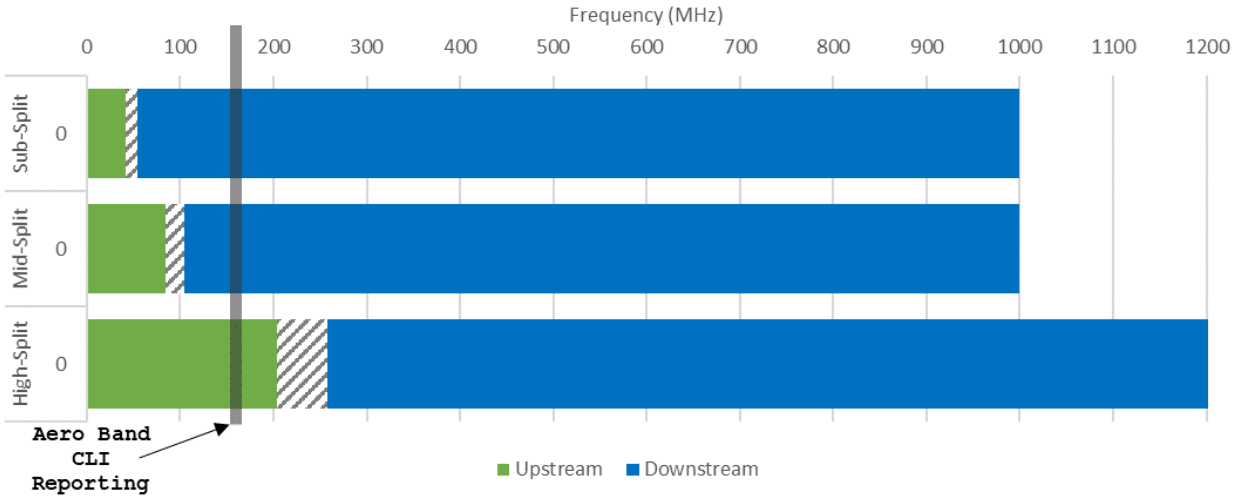

Figure 14. Leakage Reporting Spectrum Relative to Upstream/Downstream Split Configurations

This is a fairly dramatic paradigm shift for the leakage problem in that historically downstream signals are at their peak at the outputs of nodes and amplifiers in the network and are weaker as they progress through the tap outputs and onto the drop and in-house wiring. Conversely, upstream signals are near their peak at the cable modem output (on the order of 40 dB stronger than the downstream signals at the same point in the network). As a result, the signals in the aeronautical band are stronger in the house and on the drop, which is also the most common location of leaks.

High-split leakage solutions require a reference signal sourced from within the home to manifest these leaks within the network. An upstream signaling protocol called OUDP, that was part of the initial DOCSIS 3.1 standard, was leveraged to generate this reference signal. With some minor enhancements to the DOCSIS specifications, the industry enabled any DOCSIS 3.1 or 4.0 CPE device to function as a leakage reference signal source.[MULPIv3.1][CCAP-OSSIv3.1][MULPIv4.0][CCAP-OSSIv4.0] While requiring only firmware updates to CPE and CMTS devices, this solution does require hardware upgrades to leakage meters in order to detect this new signal. As a result, operators will need to lead their network upgrades with leakage meter upgrades to their truck fleet prior to enabling high and ultra-high-split configurations. It is generally expected that leakage meter vendors will provide solutions that function in both high-split and mid/sub-split networks enabling operators to continue to meet FCC reporting requirements during the transition period of upgrading from sub/mid-split to high/ultra-high-split on their network.

3. DOCSIS 4.0 Migration Strategy

The optimal strategy for upgrading a cable operator's network depends upon several factors including initial architectural state, network congestion conditions, competitive positions, as well as planned future product offerings. In addition, standardization of an architecture is highly desirable providing an operator with economies of scale in all aspects of business operations including volume pricing, flexibility in supply chain management, market product offerings, organizational knowledge, network maintenance, and technical expertise. However, the diverse set of factors affecting the strategy means that operators must plan the execution at a global level while realizing that they will often need to respond in a local market to unique competitive situations.

With Cox's EON (Extended Optical Network) program which began in 2007, Cox became one of the first cable operators to migrate their network to a 1 GHz design; however, Cox chose to remain at a sub-split configuration (42/54 MHz upstream/downstream frequency split) during that upgrade primarily due to its large base of legacy video CPE requiring significant amounts of downstream QAM video spectrum. As time progressed, due to other efficiency upgrades such as MPEG4, Cox remained fairly well positioned relative to downstream capacity; however, in more recent years, Cox has begun to experience the pressure of upstream bandwidth demand with more and more nodes encroaching upon upstream congestion.

The most common tool readily available to operators to address congestion problems is a node split. (See Table 3) Node splits are a rather coarse tool that divides the serving area in half providing the same capacity to both serving areas, each with half as many users. It effectively provides a doubling of capacity for both the downstream and upstream. However, node splits are a congestion relief tool only as they cannot provide for an increase in individual maximum customer rates since the total spectrum allocation remains the same.

Table 3 – Relief Levers Available to Operators to Address Bandwidth Challenges

Bandwidth Challenge	Target Issue	Relief Action
Congestion Relief	Upstream and Downstream	Node Split
Congestion Relief	Upstream	Mid-Split
Product Competition	1 Gbps Symmetric	High-Split
Product Competition	2 Gbps Symmetric	Ultra-High-split

In recent years, Cox has experienced an enormous growth in necessary node actions with more than 90% of those driven to address upstream congestion issues. Initially, Cox leveraged node splits, however, beginning in 2020, Cox turned toward mid-split plant upgrades as the preferred course of action. Mid-split upgrades provide an additional 150% of upstream spectrum (from 30 MHz of usable upstream spectrum to nearly 75 MHz) providing greater upstream congestion relief while also providing for a greater maximum sustained data rate.

3.1. Capacity Milestones

While a mid-split configuration provides for significant runway for operators dealing with the tactical problem of upstream node congestion, it fails to address some of the key upstream data through-put milestones such as 1 Gbps upstream which may be desired due to competitive threats. Table 4 provides the expected maximum sustained data rates for various split configurations under consideration by Cox. Similarly, Figure 15 provides for possible Cox frequency allocations for these split configurations. Table 4 illustrates that the capacities provided by DOCSIS 4.0 enable HFC to remain competitive with all-fiber networks. High-split and ultra-high-split configurations enable operators to offer 1 Gbps and 2 Gbps

symmetric speeds respectively through their networks. As such, it is the DOCSIS 4.0 1.8 GHz ultra-high-split configuration that is the end game for this plan.

Table 4 - Split Configuration Maximum Sustained Data Rates

Split Config	Upstream	Downstream
Sub-Split (42/1002 MHz)	0.1 Gbps	5 Gbps[1]
Mid-Split (85/1002 MHz)	0.5 Gbps	5 Gbps[1]
High-Split (204/1002 MHz)	1.5 Gbps	6.5 Gbps[2]
High-Split (204/1218 MHz)	1.5 Gbps	9 Gbps[2]
Ultra-High-Split (396/1794 MHz)	2.5 Gbps	12 Gbps

2 Assumes all DOCSIS 4.0 4k-OFDM DS

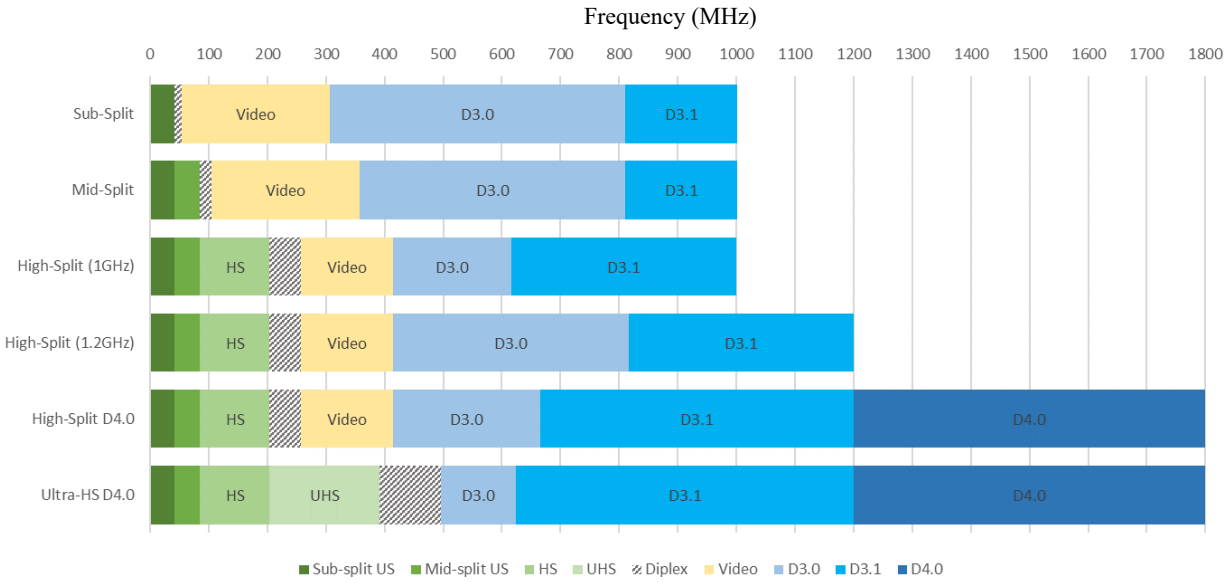

Figure 15. Possible Cox Spectrum Allocations for Various Split Configurations

3.2. Cost Implications

One important element to consider when evaluating migration paths is cost, and for the purposes of this analysis, Cox considered 8 alternatives for reaching a 1.8 GHz ultra-high-split target. (Figure 16). Each colored column in Figure 16 represents a network capacity as identified in Table 4. The circles in Figure 16 represent the network state of the plant where the letters represent the upstream/downstream frequency split (SS is sub-split, MS is mid-split, HS is high-split, and UHS is ultra-high-split) and the numbers represent the highest frequency supported by the actives and passives respectively. For example, the orange circles represent a network state with a high-split configuration and with nodes/amplifiers supporting 1.2 GHz, and taps/passives supporting 1.0 GHz (referred to as 1.2/1.0). Such a network would only run signals up to 1 GHz. While such a combination may seem odd to the reader, such states are incorporated into the plan to represent transition milestones that also minimize regrettable spend. Cox's network is primarily a sub-split 1.0/1.0 plant; however, as mentioned above, Cox is in a multi-year process of upgrading the network to mid-split 1.2/1.0. With Mid-split representing approximately 12% of the Cox network, starting points of both sub-split and mid-split were used as migration path options. In addition, remaining states were selected based upon vendor guidance concerning likely future product offerings and timelines.

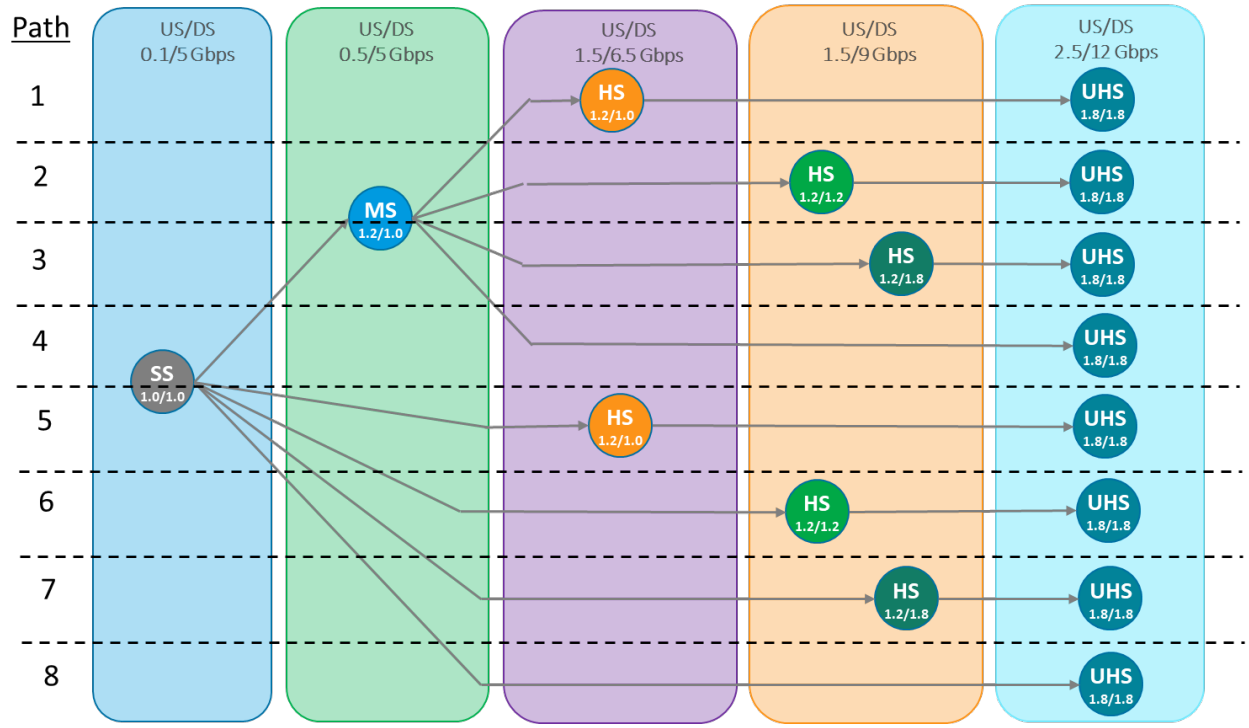

Figure 16. Cox Progression Path Options to Achieve 1.8 GHz UHS

Cox then developed an outside plant cost model for each of the transitions between states in Figure 16. It was then possible to sum those transitions to estimate total cost for each of the path options. (In order to remove proprietary cost data within this paper, all cost numbers were scaled relative to the cost of the transition of Sub-split 1.0/1.0 to Mid-split 1.2/1.0. The expectation is that other operators, equipped with their own unique costs for a mid-split upgrade, may then leverage the cost model results for their own unique circumstances.) Figure 17 provides the estimated total cost relationships for each of the 8 migration paths. In addition, the primary driver for high cost is provided for the more expensive paths.

As shown in Figure 17, paths 2 and 6 are significantly more expensive driven by the need to revisit all passive elements in the network twice for upgrades; first to 1.2 GHz and subsequently to 1.8 GHz. In addition, path 3 is quite expensive primarily because of the need to revisit the actives three times for bandwidth changes and twice for sweep and rebalancing to accomplish the upgrades; however, depending upon competitive circumstances, path 3 may still be necessary in some competitive market situations.

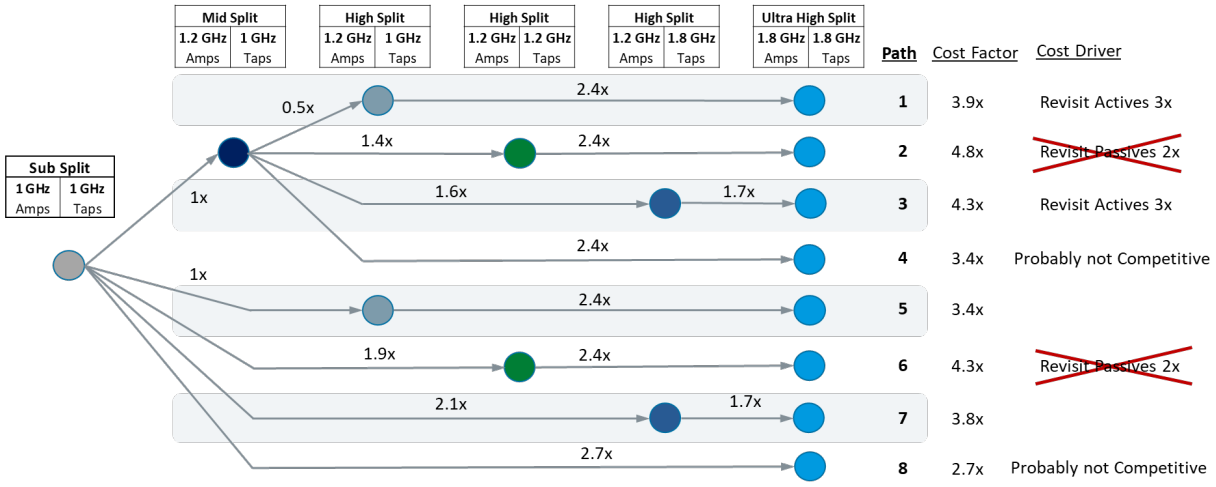

Figure 17. Estimated Cox Cost to reach DOCSIS 4.0 UHS for Eight Migration Paths

3.3. Product Availability and Path Implications

In addition to cost, commercial availability of products within the timeline demanded by competitive situations is also an important factor. As of the release of this paper, mid-split 1.2 GHz nodes, amplifiers, and passives are readily available. High-split 1.2 GHz nodes and amplifiers are expected to be readily available in 2022. However, as described above in sections 2.3.1 and 2.3.3, legacy video services and leakage monitoring need to be addressed in order to field a high-split network. Each operator must estimate their unique time implications to swap CPE to address service impacts; however, at a minimum, leakage aspects are likely to slow any large scale high-split deployments until at least late 2022 or early 2023 in order to deal with hardware upgrades of leakage meters and cumulative leakage index (CLI) reporting applications as well as CMTS modifications required in the enhanced DOCSIS specifications. 1.8 GHz nodes and amplifiers will likely not be available much earlier than late 2023 and more than likely middle of 2024 driving deployments into late 2024 to early 2025.

Relative to 1.8 GHz taps and passives, these are commercially available today with a cost premium over existing 1.2 GHz taps. However, this cost premium is more than offset by the high labor costs associated with revisiting passives twice in migration paths 2 and 6, driving a preference for a strategy where passives are only updated once in any timeline. In addition, based upon vendor feedback, 1.8 GHz passives are expected to require new housings. As such, there is some debate within Cox as to how disruptive a 1.8 GHz passive upgrade will be on network downtime, especially when considering the effects of power passing on other portions of the network. Given the raw number of passives within a node (Cox averages ~150 passives/node), it seems desirable for operators to begin passive upgrades significantly earlier than the rest of the plant upgrade; however, excessive network downtime might drive operators to a single cutover time for all actives and passives for a given node. Cox will need to pursue early trials using both a precursor and a concurrent upgrade process to better understand this impact and drive the scaled approach.

Migration paths 4 and 8, which basically capture jumping straight to a fully ultra-high-split 1.8 GHz configuration, are likely not competitively viable as it is quite likely that significant deployment penetration of symmetric 1 Gbps products beyond trials might be required earlier than 2025.

As a result, 4 recommended paths (1, 3, 5, and 7) (Figure 18) are left for consideration, costing between 3.4x and 4.3x the cost of a mid-split upgrade.[2] Cox is continuing to investigate the possibility of accelerating the replacement of legacy video CPE with an IPTV-based solution which may be required for paths 1 and 5, both of which provide substantial cost savings. Depending upon the competitive urgency to move to high-split, there may not be adequate time to replace CPE, and as a result, Cox would need to pursue paths 3 and 7. However, paths 3 and 7 drive the need for accelerating and targeting 1.8 GHz passive upgrades as activating a high-split for these paths requires these new taps and passives. Selection between the options 1 and 5 or 3 and 7 is driven by whether the node faces more immediate upstream congestion in which case a mid-split upgrade would be needed and paths 1 or 3 would be taken.

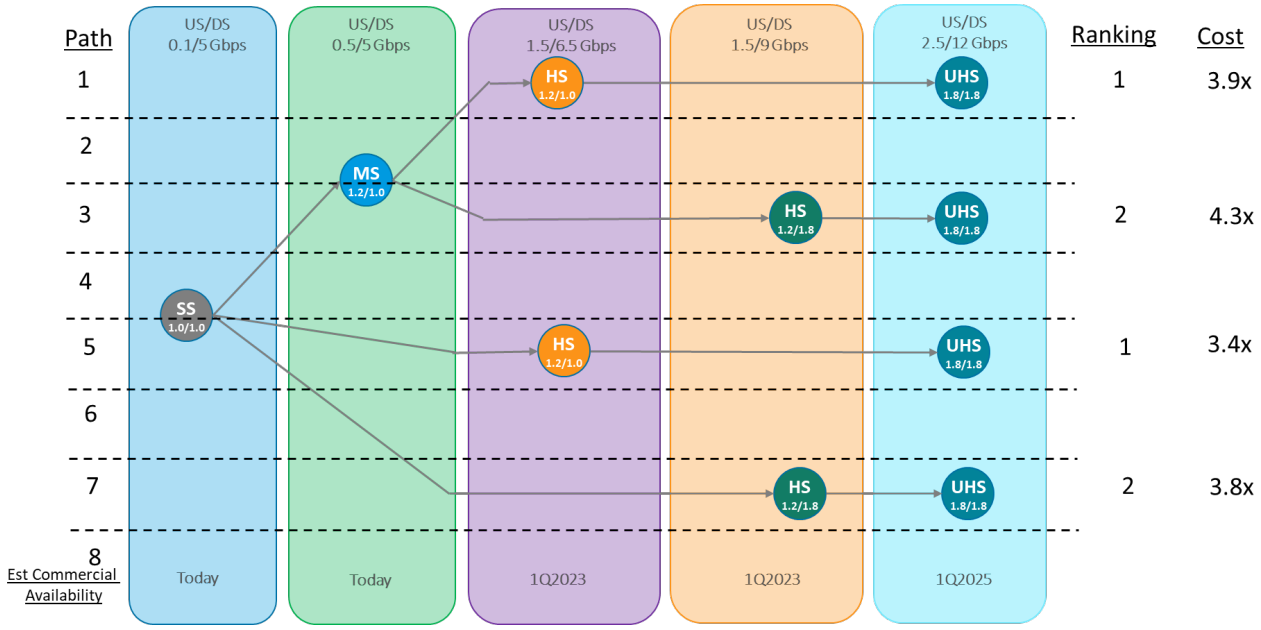

Figure 18. Recommended Migration Path Options to 1.8 GHz UHS

Figure 19 provides a possible timeline for paths 1 and 5. Key highlights of this process include the need to retire SDV/VOD or execute an IPTV upgrade to provide adequate downstream spectrum to achieve a high-split on a 1 GHz network as well as the need to upgrade homes with high-split service to a POE CPE device to eliminate in home interference with legacy devices. As mentioned earlier, there are some questions that will need to be resolved during trials as to the impact of earlier passive deployments on network downtime.

Figure 20 provides a possible timeline for paths 3 and 7. One key requirement in this process is the need to upgrade to 1.8 GHz passives much earlier in the process during the actual 1.2 GHz upgrade step; whereas that was a flexible option in Figure 19 assuming it didn't contribute to significant downtime.

[2] A key parameter in estimating the overall upgrade cost is cable replacement. The multipliers provided represent a 2% cable replacement assumption; however, Cox is currently performing tests in various markets to attempt to better refine that estimate. Any change in that percentage will impact the overall cost multiplier for each path but the relative differences will remain the same as the total cable replacement cost would be constant for all eight paths.

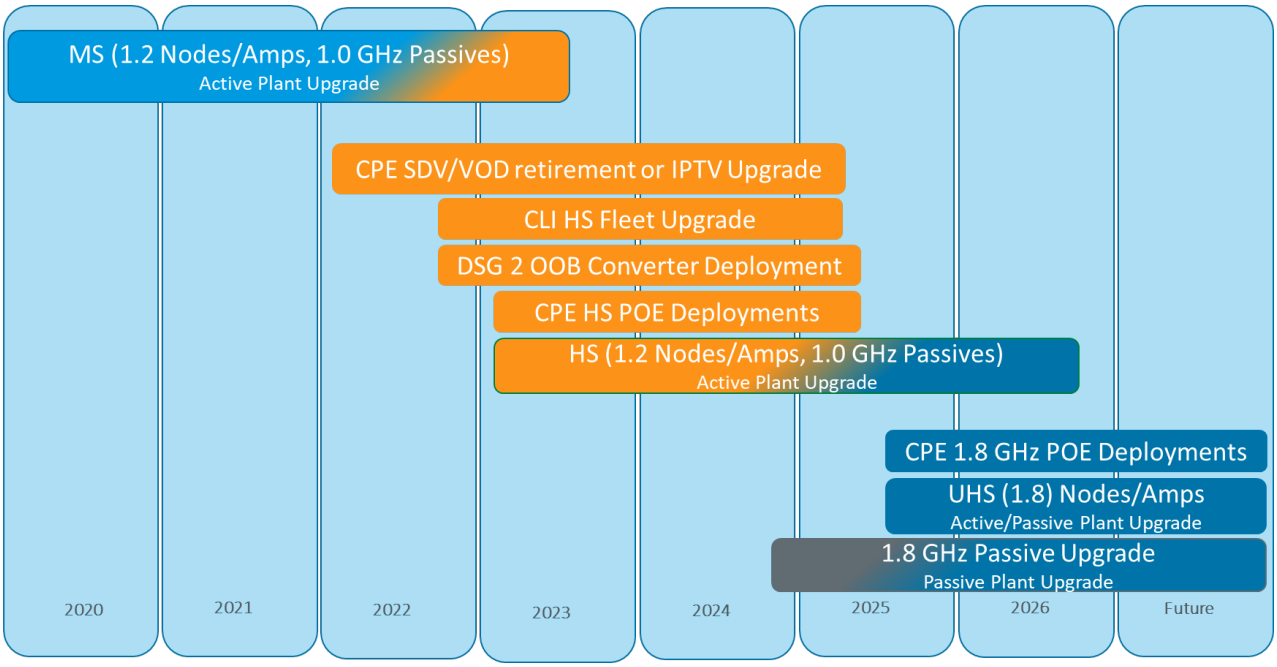

Figure 19. Possible Cox Migration Roadmap (Paths 1 and 5) with a 1.0 GHz Intermediate Spectrum Limit

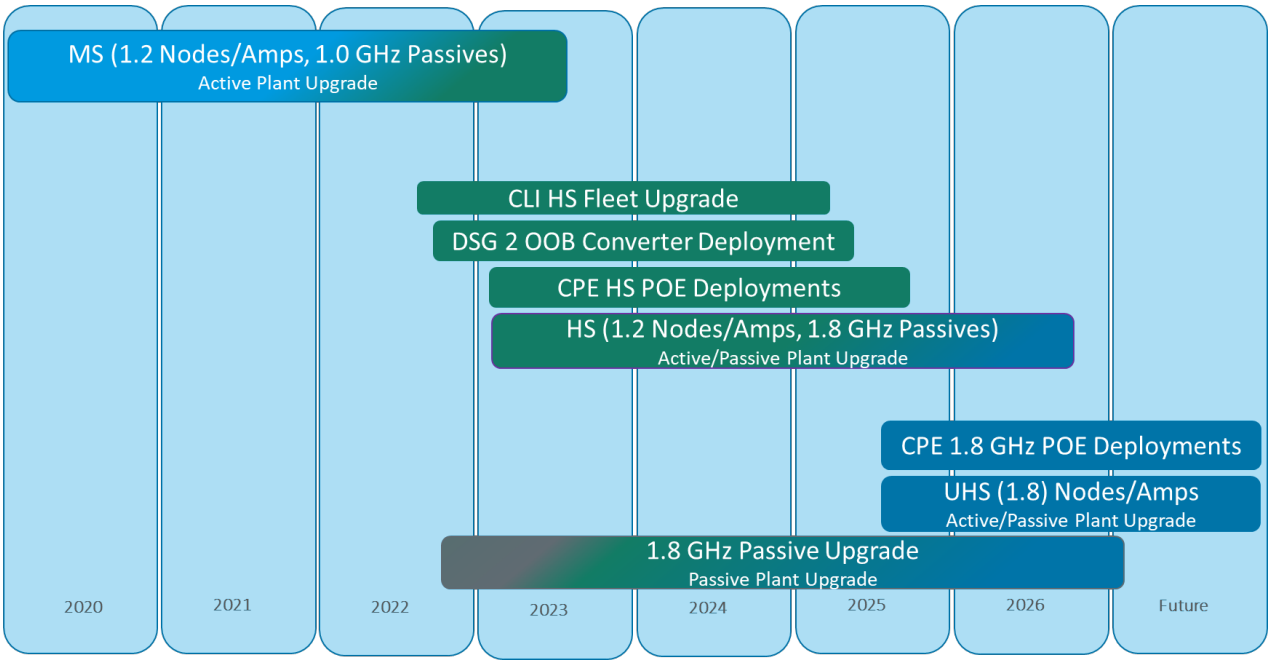

Figure 20. Possible Cox Migration Roadmap (Paths 3 and 7) with a 1.2 GHz Intermediate Spectrum Limit

4. Conclusion

In summary, there are many important aspects to consider in association with potential bandwidth upgrades made possible by FDD DOCSIS 4.0. In the paper we explored many of those aspects and:

- Pointed out the rationale for maintaining legacy band tap RF output levels during plant upgrades.
- Described the historically used drop-in approach to plant bandwidth upgrades, and its benefits.
- Explained likely 1.8 GHz amplifier downstream gain requirements for drop-in upgrades and why Booster Amps may be needed.
- Provided for consideration, proposals for amplifier RF output profiles with associated rationale.
- Described some of the major items to consider associated with spectrum changes, with potential methods for handling them, including:
    - Reducing QAM Video
    - Meeting CableCard Regulations and Addressing Legacy OOB (55-1, 55-2)
    - Requiring POE for HS and UHS homes
    - Retiring MoCA
    - Meeting FCC Leakage Regulations
- Pointed out the potential requirements for a downstream spectrum “squeeze” associated with the plant upgrades and offered alternative mitigation approaches to consider.
- Shown a variety of potential approaches making use of progressive steps leading up to ultra-high-split 1.8 GHz and presented associated rationales and cost factors.

1. Introduction

The death or end of coaxial cable transport has been predicted in the past on more than one occasion to give way to fiber-to-the-home. The resiliency of coaxial transport, however, has proven to be quite enduring. Coaxial cable itself has not yet been used to its full potential and operators have demonstrated that with the always improving operational practices in addition to the robustness and flexibility provided by the evolving transport technologies, there are still effective means to get value out of our coaxial infrastructure investment. A key factor in this equation is that under several operator starting point scenarios, fiber-to-the-home (FTTH) deployment requires significant investment and coaxial based evolution alternatives can still address most subscriber requirements.

As it appears that coaxial based transport in the access will still be with us for quite some time, it behooves us to think how coaxial transport would look like 10+ years from now. This paper explores how a coaxial based future could evolve in the long run, what would be the implications on topology, spectrum, and technologies that we could see taking shape under the pressures of deployment costs, service offerings, operational efficiency, reliability and market competition.

Today demand for capacity and consumption patterns from subscribers is quite varied. Unfortunately, in deployments, where serving area sizes until recently consisted of about 400+ households per fiber node, there has been little flexibility to design based on the traffic characteristics that we experience. Instead to maintain acceptable levels of customer experience, we have been designing these serving groups driven by peak user speeds and competitive forces. The diversity of our subscribers' usage patterns indicates that peak-capacity based design can leave a good amount of resources and investment on the table. Service elasticity and resulting in network elasticity to flexibly support our subscriber diversity becomes more relevant in our environment that not only caters to residential subscribers but also small businesses and wireless connectivity sharing the same coaxial infrastructure.

1.1. Capacity Improvement Mechanisms

Our industry has leveraged 3 ways of improving HFC capacity. First is by improving efficiency, second through segmentation and third by increasing the amount of spectrum we use. We have been using all three tools available at our disposal as we have evolved our cable networks.

In cable, we have used several efficiency improvements tools. We have improved the efficiency of how we carry video leveraging more efficient compression techniques. We have introduced profiles in our DOCSIS 3.1 systems so that if a CM is closest to an amplifier or a fiber node, this CM could transmit at greater speeds/efficiencies and not at the lowest common denominator as was the case in earlier implementations. Cable has done a very good job at cleaning the HFC plant, improving channel conditions so that we could carry higher order modulations, reaching up to 4096 QAM in the upstream and up to 16384-QAM in the downstream. Distributed architectures have helped in that they eliminated noise and distortion contributions of the analog optical link, thereby facilitating higher modulation transport. Figure 1 shows a 16384 QAM DOCSIS constellation example.

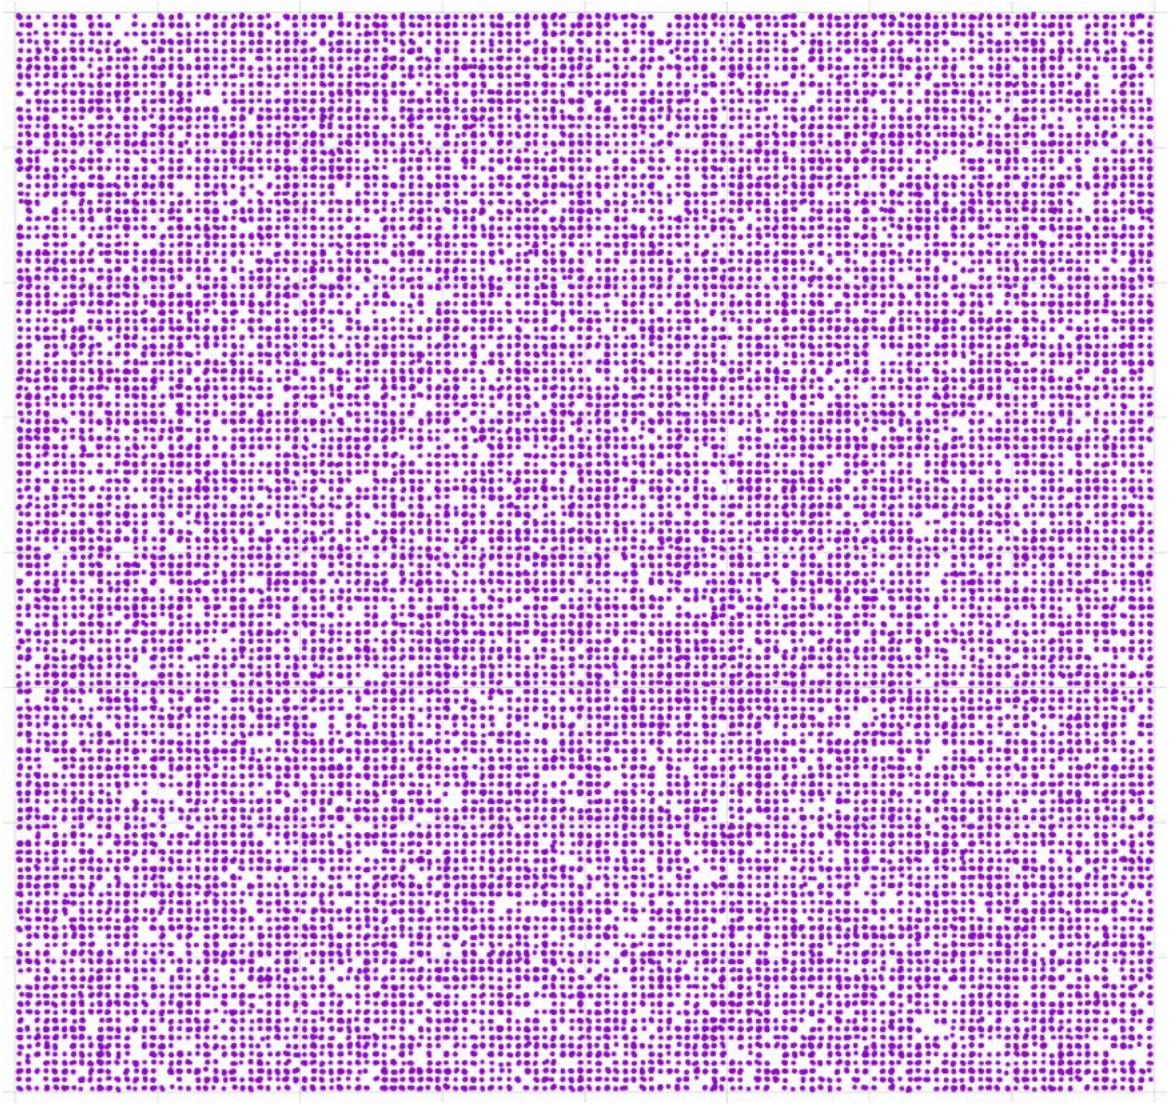

Figure 1 - Highest Efficiency 16384-QAM DOCSIS Downstream Constellation

We have an RF domain peak capacity limitation imposed by the amount of spectrum available. Still by dividing this RF domain into smaller serving areas or segments the amount of capacity per user can be increased. Segmentation in cable has been used on an "as-needed-basis" for quite some time, relying on node splitting to address capacity shortages. The growth in demand for capacity has reached a point in which a surgical approach to segmentation may not always be sufficient as this increase in capacity is more widespread and the rapid growth in demand may require longer term solutions. These solutions consisted of an HFC architecture migration from the original Node+4/Node+5 500 HHP architectures to the smaller Node+2 to Node+0 architectures. In addition to increases in aggregate capacity, they also bring improved performance and higher reliability. Figure 2 shows a Node +0 network migration from a legacy 500 HHP node.

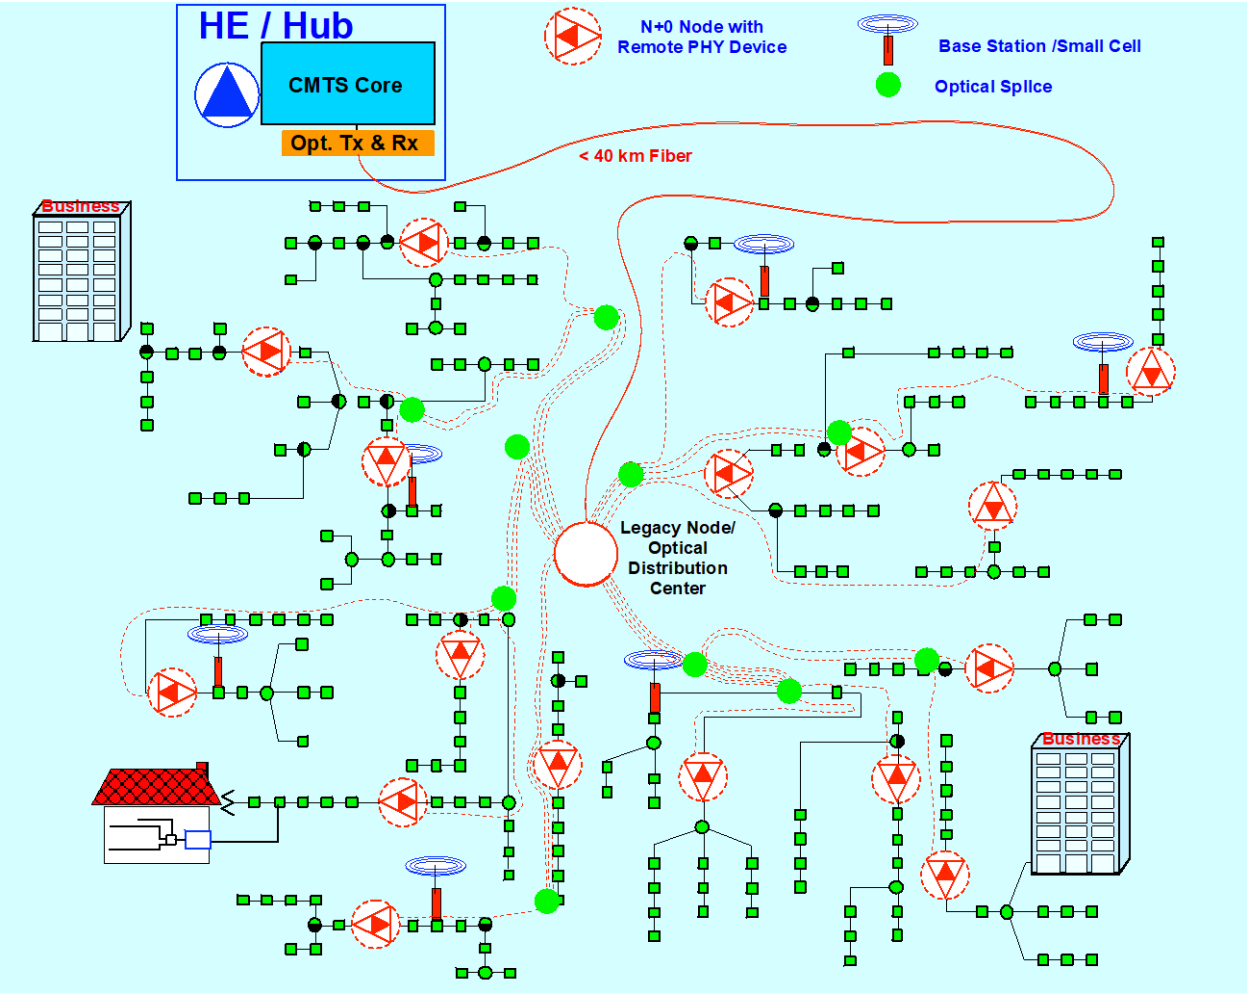

Figure 2 - Legacy/Original Node Segmented Into Node+0 Child Nodes

The changes that have been taking place regarding segmentation and efficiency improvement are quite transformational. The area that perhaps has shown a steady improvement is spectrum enhancement. In the past, it has been somewhat limited by regulatory forces but also by demand, operational complexity and ultimately by cost.

We mentioned earlier how spectrum could enable peak service capacity. In the past peak capacity has been increased by aggregating/bonding more channels within the overall available spectrum. Now however, we have reached the point that the maximum number of channels used by CMs is quickly approaching the maximum amount of spectrum we have available. Therefore, in order to increase service tiers, we need to increase our coaxial RF spectrum. DOCSIS 4.0 addresses this need but at a service tier CAGR of 25% to 40%, we need to start thinking about longer term options. We will discuss the paths we could take to address this demand.

2. Ultimate Coaxial Spectrum Resources

In the early days of cable, only video was carried over the network, video content was limited and the demand to support higher frequencies was also limited. Support to carry the highest practical frequency was also impacted by the attenuation of coaxial cable, the need for multiple amplification stages and the noise and distortion amplification introduced. In this early all-coaxial transport, cable networks evolved from maximum frequencies of 250 MHz to 350 MHz, 450 MHz up to 550 MHz. It was in the 1990's when the transformation of cable networks into a Hybrid Fiber Coaxial (HFC) architecture took place. At that time the HFC network typically consisted of fiber serving areas of 500 households passed (HHP). Instead of having up to 30 amplifiers in cascade, many fiber nodes serving areas were upgraded to 4 to 5 amplifiers in cascade before reaching the furthest subscriber. This network transformation also included the transport of digital video and bidirectional transport to carry data and video at a highest downstream frequency of 750 MHz. With IP-data becoming the dominant use of cable networks, DOCSIS system capabilities evolved along with plant frequency upgrades. DOCSIS versions included 860 MHz, 1002 MHz, 1.2 GHz and with DOCSIS 3.1 and DOCSIS 4.0 specifications 1.794 GHz became the next high frequency target.

The questions that we want to ask ourselves are: How high in frequency can we leverage our coaxial infrastructure? What are the challenges that we need to consider and are there potential approaches to address these challenges?

Coaxial transport relies primarily on the transverse electromagnetic (TEM) mode of propagation. In coaxial cable, TEM mode is radially symmetric and propagates along the direction of the center conductor (Figure 3).

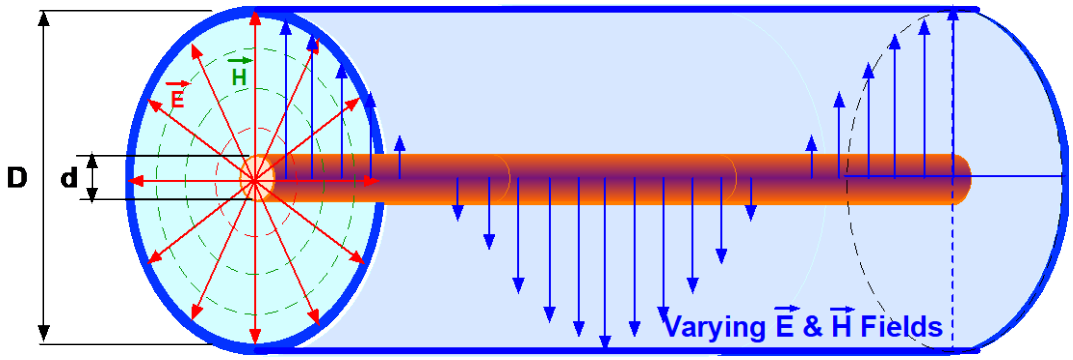

Figure 3 - TEM Propagation Mode in Coaxial Cable

As the frequency increases and the wavelength approaches the dimensions of the radius of the coaxial cable, other modes of propagation are excited. The transverse electric TE_{11} mode is the first to appear. When these modes are allowed to propagate with the TEM mode, they interfere with each other. The frequency at which TE_{11} appears is called the cut-off frequency (f_c) which for TE_{11} mode is given by:

$$f_c = \frac{c}{\lambda_c} = \frac{c}{\pi\left(\frac{D+d}{2}\right)\sqrt{\mu_R \varepsilon_R}}$$

where c is speed of light, D is the inner diameter of the outer conductor, d is the outer diameter of the center conductor and μ_R and ε_R respectively are the relative permeability and relative permittivity of the

dielectric material. Table 1 shows the estimated cut-off frequency for different cable types we use in our industry.

Table 1 – TE11 Coaxial Cable Cut-Off Frequencies

Cable Type	Cut-Off Freq
RG6	29.1 GHz
RG11	18.6 GHz
0.5"	11.5 GHz
0.625"	9.3 GHz
0.75"	7.7 GHz
0.875"	6.6 GHz

As you can see with 0.625” and 0.5” hardline cables which are common in the distribution portion of the network, have cut-off frequencies of 9.3 GHz and 11.5 GHz providing significant opportunities for higher bandwidths. This opens up attractive potential resources we could leverage. Nevertheless attenuation, implementation, operational costs, service tier and aggregate capacity are also factors that need to be considered.

3. Legacy of Analog Video Transport

Transport of analog video was required to transmit at a very a high carrier-to-noise ratio. The downstream plant required very clean maintenance and other services had to coexist well with analog video. The channel spacing used by analog video was adopted by newer data services, and out-of-band emissions of the new tenants of cable’s coaxial spectrum were also tightly controlled. There have been numerous decisions that have been made in cable based on analog video transport, not only in the design of services that share the same spectrum as analog video, but also decisions in the transport infrastructure itself so that it can optimally support analog video.

The original cable industry plant was designed around one type of service, mainly the delivery of broadcast analog video services. A Cable Television (CATV) service provider frequency-multiplexed a lineup of analog video channels from a central location such as a hub or headend. It transmitted the video signals to subscribers connecting to the coax network within a fiber node serving area. In order to have suitable reception of analog video, each home had to ideally receive the video channel signal at about the same target power level. Cable accomplished this with an RF distribution network where taps coupled RF energy out of the hardline into drop ports to connect to the subscribers’ homes via drop cables. Each successive tap following a fiber node or an amplifier, has a specific coupling loss to the drop port so that even after the attenuation of coaxial cable, the power reaching the end-device, such as a set-top-box, is about the same for all subscribers. Figure 4 shows a schematic representation of a coaxial segment with taps of decreasing values.

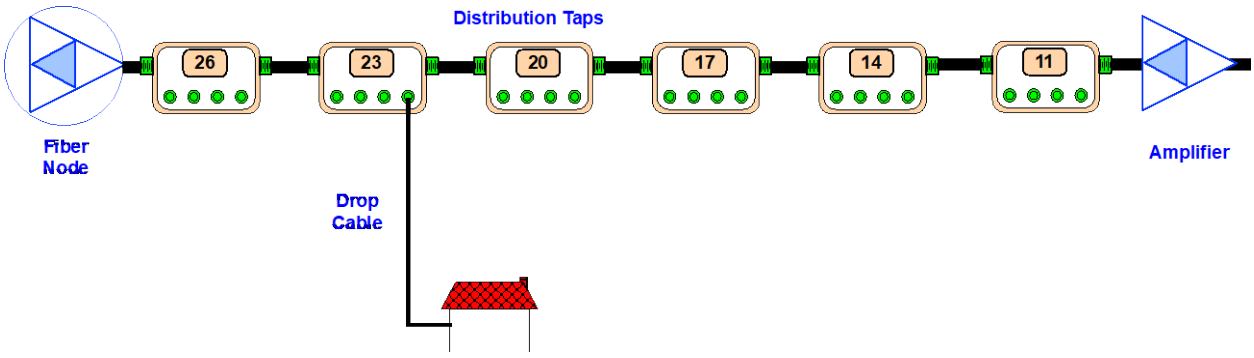

Figure 4 - Fiber Node-to-Amplifier Coaxial Segment With Tap Values To Provide Similar Power Levels Per Video Channel

Over the relatively narrow band that the upstream occupies, differentiation in channel conditions can depend on the amplifier cascade value and specific impairments which predominantly impact one or more cable modems. There is also some frequency dependence when comparing the edges of the upstream band with the middle of the upstream band. The downstream also imposes larger frequency-dependent behavior due to cable attenuation, however this behavior is typically ameliorated by an up-tilted downstream signal and by the decreasing tap values which effectively equalizes the power levels for all customers along the coaxial segment.

4. Evolving HFC Environment

While early in Cable, the focus was on having every analog video channel be received by every Set Top Box (STB) and TV receiver at approximately the same power level, an allowance to deviate from that philosophy of operation has been enabled with the introduction of channel conditions' dependent profiles in the DOCSIS 3.1 specification. Another trend worth noting is that more traffic in cable networks has steadily moved from broadcast to unicast. This has been due to the way services are delivered such as video on demand as well as IP video services. Therefore, the need of having one stream having to be received by all receivers is disappearing.

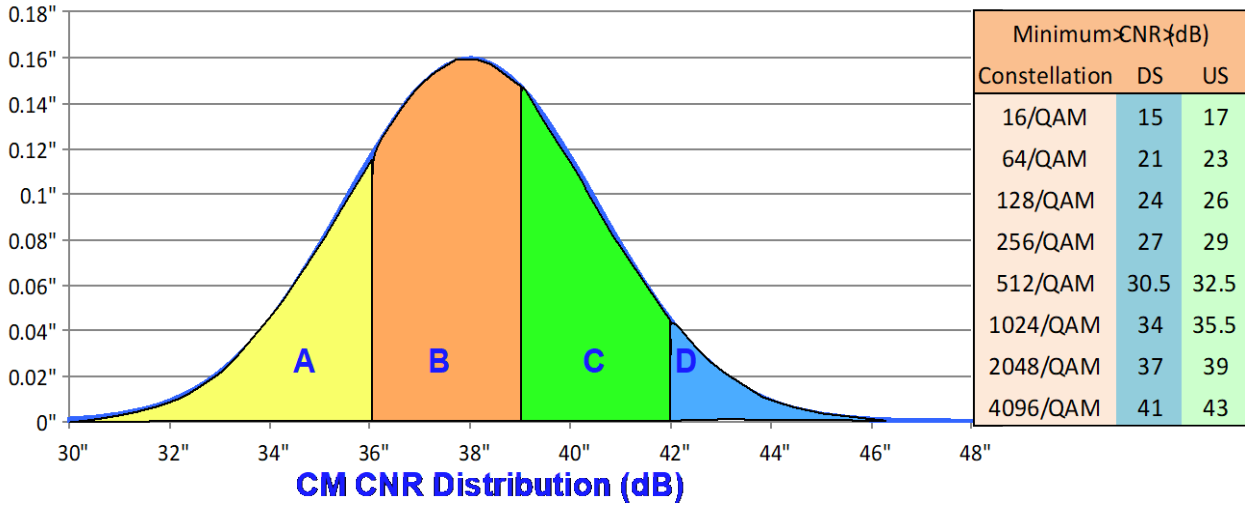
About a decade ago, the transition to digital video broadcast started in the United States which, except for low power TV broadcast stations, has now been completed. This transition also impacted "must carry" rules. When analog is no longer transmitted, there is no longer the requirement to carry broadcast channels at the over-the-air frequencies. For example, Channel 2 does not need to be carried at 50 MHz in our cable networks when only carrying digital video channels. For all practical purposes, we live today in an all-digital world. Not only video but also voice and data are carried over bit streams. We are no longer required to optimize our networks to distribute video signals so that their service endpoints are at about the same power levels. This is a brand-new ball game; the change in conditions allows us to break free from the restrictions of analog video distribution and everything it entails. The consequences of analog video distribution are not just limited to reclaiming coaxial RF spectrum by replacing analog video with the more efficient digital video. The change in conditions is significantly more encompassing—. Think about revisiting all the network design decisions that have been made since the early days of community antenna television.

4.1. A Step Beyond DOCSIS Profiles

As we move to an all-digital transport, our criterion needs to shift from the optimal transport of analog video to the optimal transport of bits. No longer are we required to deliver every analog channel at about

the same power level. Now we need to focus on how to transport the highest number of bits across our entire spectrum.

When we introduced the DOCSIS 3.1 version of the specification, instead of treating all CMs the same, the concept of transmission profiles was incorporated. This meant that CMs that could perform at a higher efficiency level due to a more benign channel would be placed in a profile where higher order modulation would be used. Figure 5 highlights the variation in CNR of a population of CMs and an example of how they could be grouped in different efficiency buckets.



Minimum CNR (dB)		
Constellation	DS	US
16/QAM	15	17
64/QAM	21	23
128/QAM	24	26
256/QAM	27	29
512/QAM	30.5	32.5
1024/QAM	34	35.5
2048/QAM	37	39
4096/QAM	41	43

Figure 5 - CM CNR Distribution and Modulation Order Thresholds

The assignment of profiles is adaptable to the current conditions of a CM. Today, a CMTS is specified to support up to 16 downstream profiles and 7 upstream profiles. These profiles are defined within the downstream channel with subcarrier granularity and in the upstream with minislot granularity since the modulation order is defined on a per minislot basis. CMs could go to a higher or lower efficiency profile depending on the channel conditions and leveraging the ranging response mechanisms and MER and codeword error metrics.

4.2. Higher Frequency Off First (HFOF)

In a DOCSIS OFDM downstream, resources exist in symbols (time) and subcarriers (frequency). In the upstream, minislots consisting of symbols and subcarriers are also allocated in time and frequency. As we use higher frequencies, the variation of CNR versus frequency is more evident. The attenuation in hardline and drop cables versus frequency becomes the dominant factor determining the MER and CNR in a CM. Figure 6 shows coaxial attenuation versus frequency and Figure 7 highlights how such losses may impact CNR at higher frequencies on a CM attached to a coaxial segment.

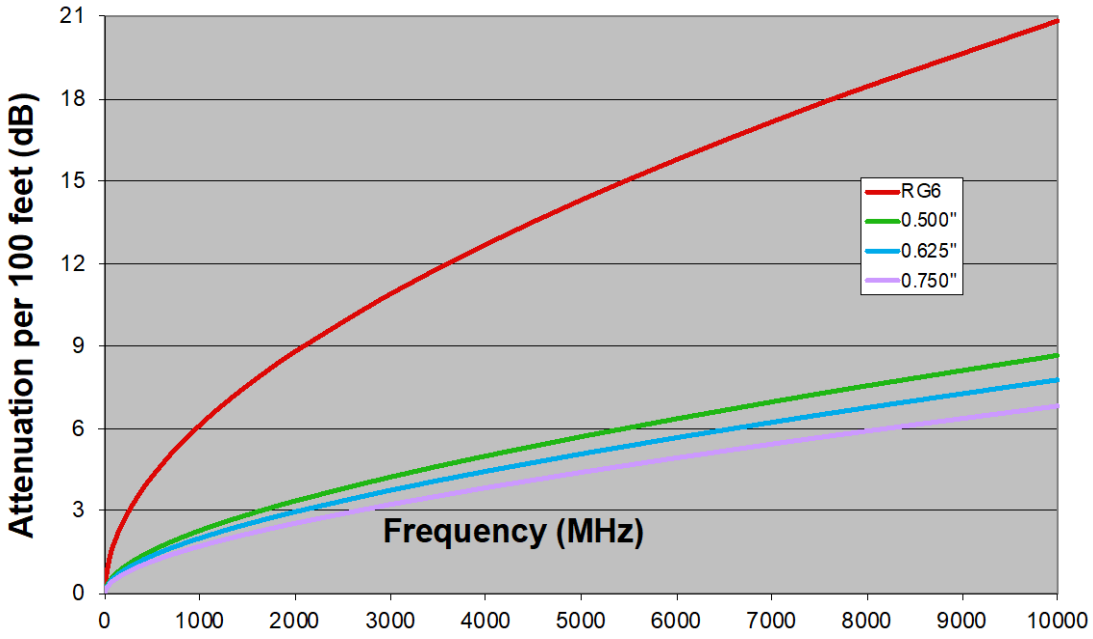


Figure 6 - Hardline And Drop Cable Attenuation Versus Frequency

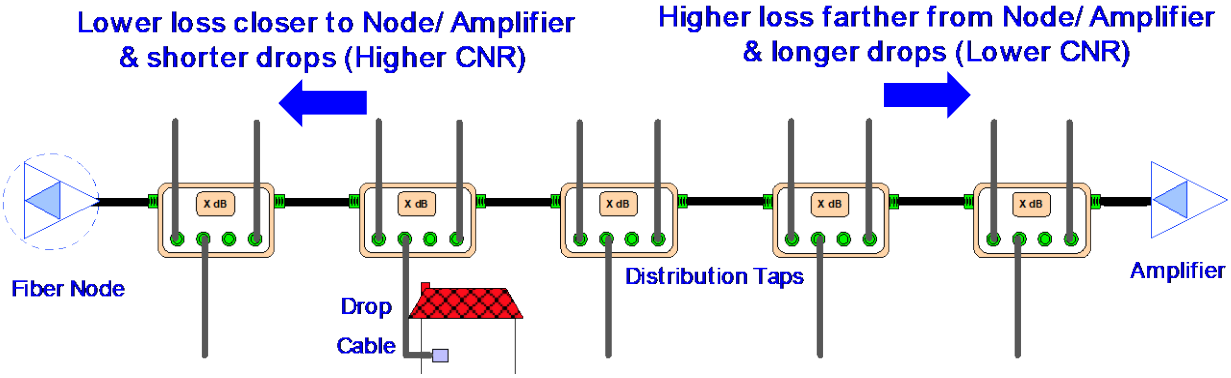

Figure 7 - CM Higher-Frequency CNR Based on Topology Location and Drop Length

Figure 7 shows that, at higher frequencies, CMs that are closer to the fiber node and with shorter drops will enjoy better CNR while CMs that are further out from the node and with longer drops cables will have lower CNR. This effect is due in large part to the fact that Total Composite Power for the transmitted signal from any Node/Amplifier is limited to "reasonable" levels on the order of ~70 or so dBmV, so the received power at higher frequencies is reduced by the combination of limited transmit power at the higher frequencies and increased attenuation at the higher frequencies. This qualitative assessment is quantified using the topology example of Figure 8. This coaxial segment consists of 4 taps in cascade and 12 CMs attached to these taps through drop cables. The drop lengths have been selected on purpose with great diversity of lengths so that we can better observe the significant effect that drop cable attenuation can have on performance. In this analysis, a hardline feeder cable of 0.5" and an available bandwidth of 11 GHz are assumed.

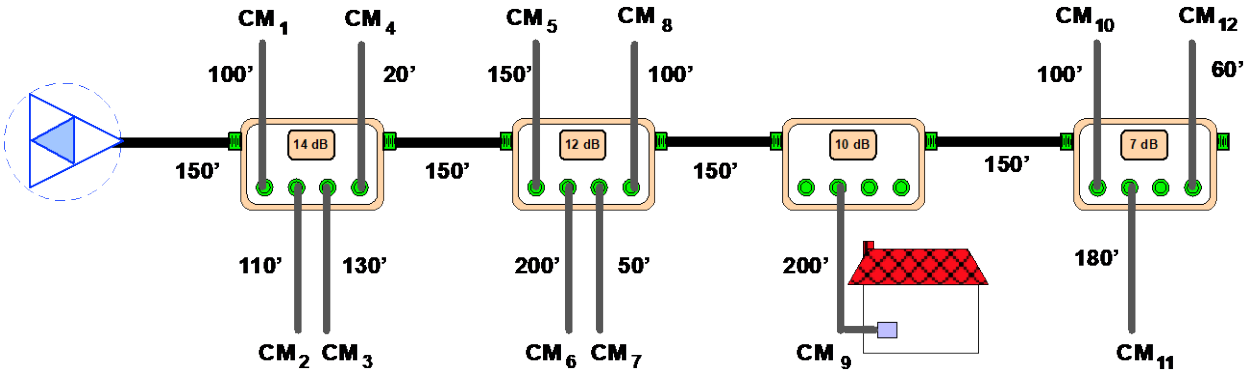

Figure 8 - Sample Coaxial Segment For Ultimate Capacity Estimation

Table 2 shows the total capacity that the CMs within the sample coaxial topology in Figure 8 could have if each CM has access to the entire 11 GHz spectrum.

Table 2 – Full Bandwidth Capacity Of CM Within Sample Topology

Modem	Full Bandwidth (Gbps)
CM_1	134.3592
CM_2	129.5459
CM_3	118.1095
CM_4	146.1113
CM_5	105.6579
CM_6	75.2112
CM_7	145.609
CM_8	134.6757
CM_9	74.7192
CM_{10}	134.053
CM_{11}	85.2012
CM_{12}	144.8434

As you can see the capacity that each CM could obtain varies widely from a lower 74.7 Gbps value to a higher 146.1 Gbps rate. In general, CMs that are close to the Node/Amp and CMs with short drop lengths tend to experience much higher capacities than the others. The average aggregate capacity is 112.14 Gbps which results in an average capacity per CM of 9.345 Gbps if it would be equally shared. If we assign spectral efficiency according to the downstream CNR table in Figure 5 and assuming a 3 dB receiver noise figure, the resulting efficiency versus frequency for the different CMs within the sample topology is shown in Figure 9.

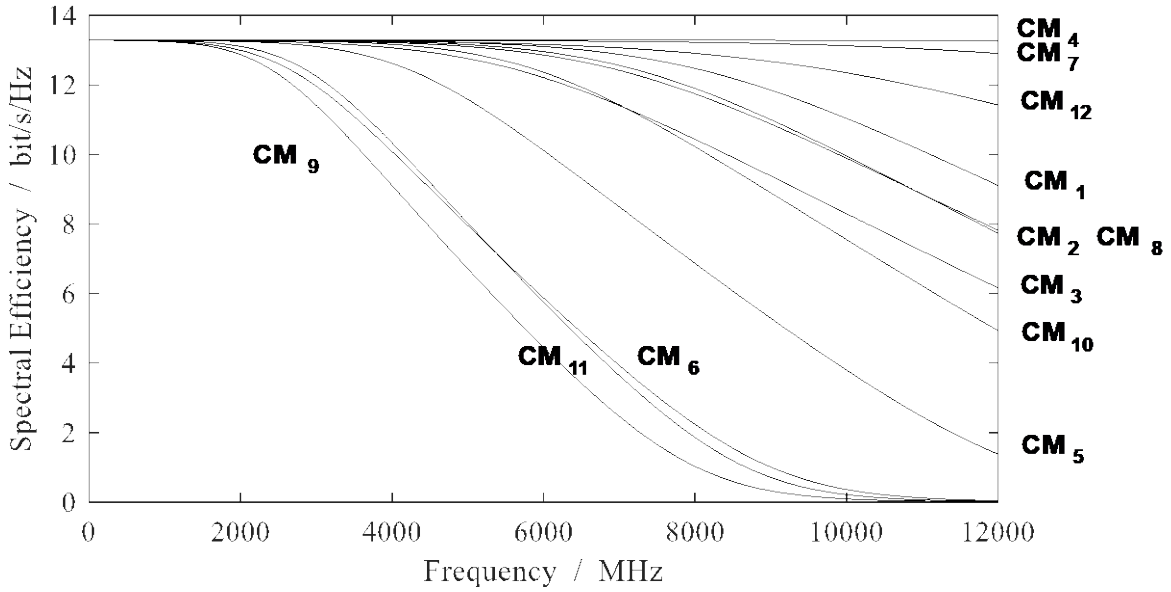

Figure 9 - Spectral Efficiency Versus Frequency Of CMs Within Sample Topology

As observed in Figure 9, CM_4 with a short drop and closest to the fiber node enjoys the best performance while CM_9, which has the longest drop and is located after 3 hardline segments, has the most limiting performance. The performance of CM_{12}, that is located in the last tap but has a short drop highlights the impact that drop cable can have as well as the fact that there is plenty of capacity left for the amplifier that sits behind the cascaded hardline segment.

If one would have the capability of flexibly assigning capacity on a frequency basis to the different CMs that enjoy different channel performance the overall aggregate capacity could be optimized. This mechanism is what we call "higher frequency off first" (HFOF) mechanism, which assigns the higher frequencies to the CMs that enjoy best higher-frequency CNR performance and leaves the lower frequencies for the CMs that have limited higher-frequency CNR performance. Figure 10 shows the allocation of capacity according to frequency bands. The capacity allocated to each CM is the same so there is some variation in the bandwidth allocated to each CM. An overall aggregate capacity of 142.81 Gbps is obtained which represents an improvement of 27% compared to the traditional approach calculated by averaging values in Table 2. (Note: If a particular CM is not utilizing its assigned spectrum, then the CMTS scheduler would be able to re-assign that spectrum to one or more other CMs. This intelligent scheduling would likely be typical in real-world scenarios).

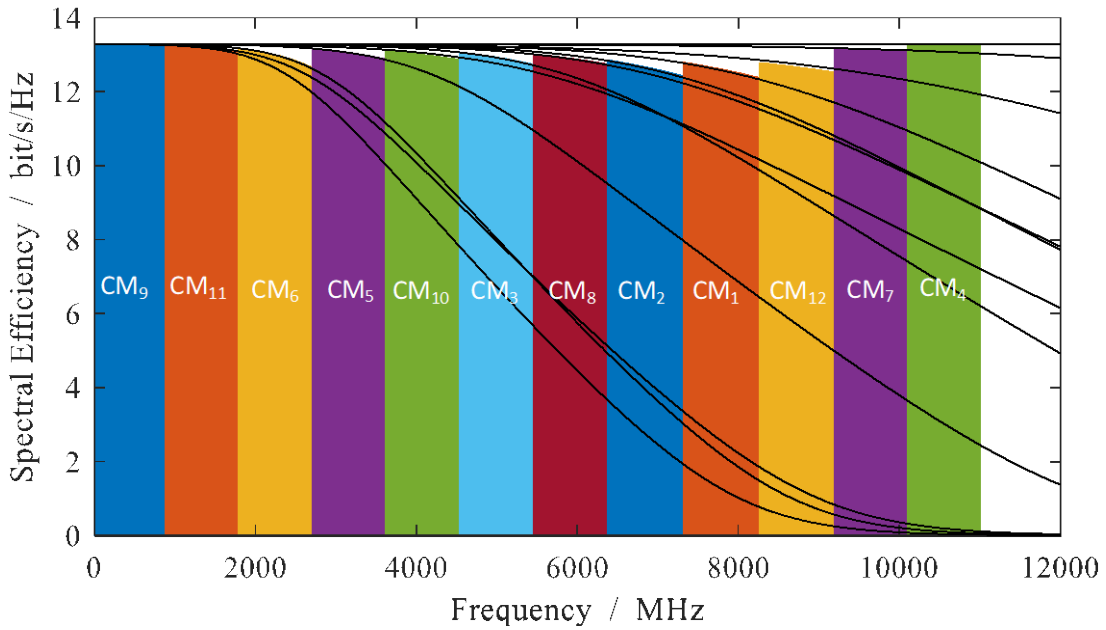

Figure 10 - CM Capacity Allocation Following HFOF Approach

A second simulation was conducted using 200' coaxial segments for a total of 800' total segment length. In that scenario using the traditional approach an average aggregate capacity of 105.888 Gbps was achieved or an average capacity per user of 8.824 Gbps. When leveraging the HFOF approach an aggregate capacity of 139.992 Gbps or 11.666 Gbps per user was obtained. This represents a 32% improvement of HFOF over the traditional approach.

4.3. Dynamic Range

The attenuation of hardline and drop cable versus frequency as shown in Figure 6 can be significant. In Figure 11, we combine the frequency response of all CMs along the coaxial segment. As you can see the loss across the entire 11 GHz bandwidth can be significant, but the loss across the portion of the spectrum allocated to each CM according to HFOF is bounded, resulting in a significant relaxation of dynamic range requirements. The blue and red segments on the CM loss curves stay within a limited loss range, highlighting the dynamic range benefits of the HFOF approach.

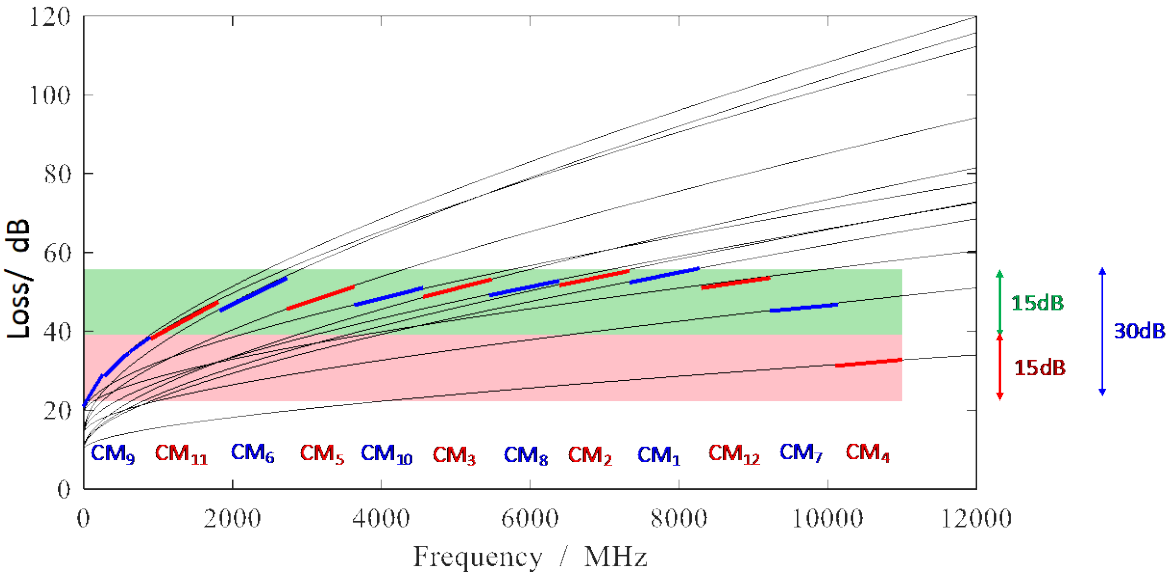

Figure 11 - End-to-end CM Attenuation Within Allocated Frequency Band

4.4. Implementation Implications Of Peak And Aggregate Rates

In the earlier sections, we have seen how a large amount of coaxial spectrum can be made accessible to CMs. In this section, we explore techniques in making this accessibility cost effective. In WiFi and mobile applications, we have systems with limited amounts of bandwidth available out of a diverse selection of spectrum bands. The accessibility to the many options of spectrum bands is achieved through the tuning capabilities of the receiver. How much bandwidth can a receiver simultaneously capture, process and aggregate, is an indication of the peak capacity a handset could reach.

A similar approach could be followed in cable where CMs could have accessibility to a wide spectrum while the bandwidth capture capabilities would indicate the potential peak bandwidth a CM could reach. Figure 12 shows an example of the cable analogy where 10.8 GHz of coaxial spectrum is available. This amount of spectrum is consistent with the cut-off frequency of 0.5" hardline cable. In this example a CM capture bandwidth of 1.8 GHz is assumed. The total amount of spectrum available for the downstream in this example is 10.2 GHz. Leveraging HFOF techniques and assuming a clean plant, a modulation order of 2048 QAM can be reached which leads to a 17 Gbps capacity per 1.8 GHz capture bandwidth and an aggregate capacity out of the entire 10.2 GHz of spectrum of approximately 100 Gbps assuming DOCSIS 3.1 level overhead. The CM capture range could be adjusted based on the target peak rates and implementation cost complexity criteria. Figure 12 depicts the scenario just described where some CMs, depending on where they are within the coaxial segment topology, are assigned certain frequency bands.

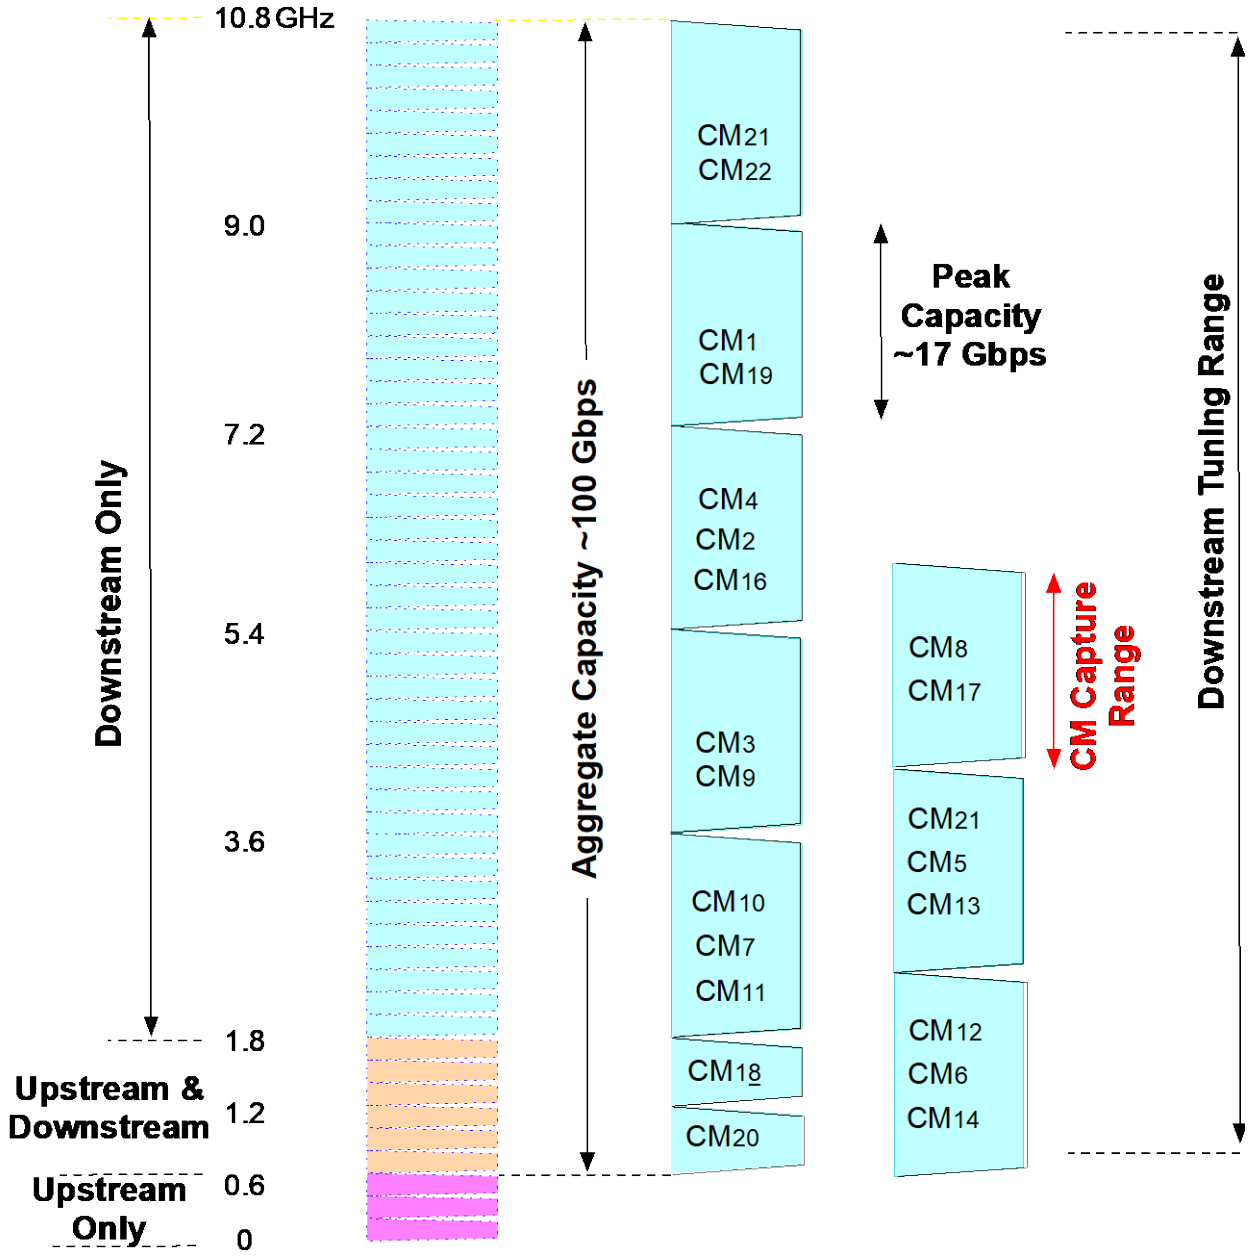

Figure 12 - CM Spectrum And Bandwidth Allocation Example

5. An Evolved Scheduler

In an environment such as the one depicted in section 4 where much higher frequencies are used, such as the case of coaxial spectrum above 3 GHz, subscribers' frequency-dependent performance becomes more noticeable. This behavior becomes highly dependent on which tap they are connected to and how long the drop cable is. In this environment, the importance of having an evolved scheduler that can allocate resources based on frequency and Modulation Error Ratio (MER) is very important.

We introduced profiles in the DOCSIS 3.1 specification which allows custom mapping of subcarrier modulation order versus frequency for groups of CMs associated to a profile. Figure 13 shows an example describing its implementation.

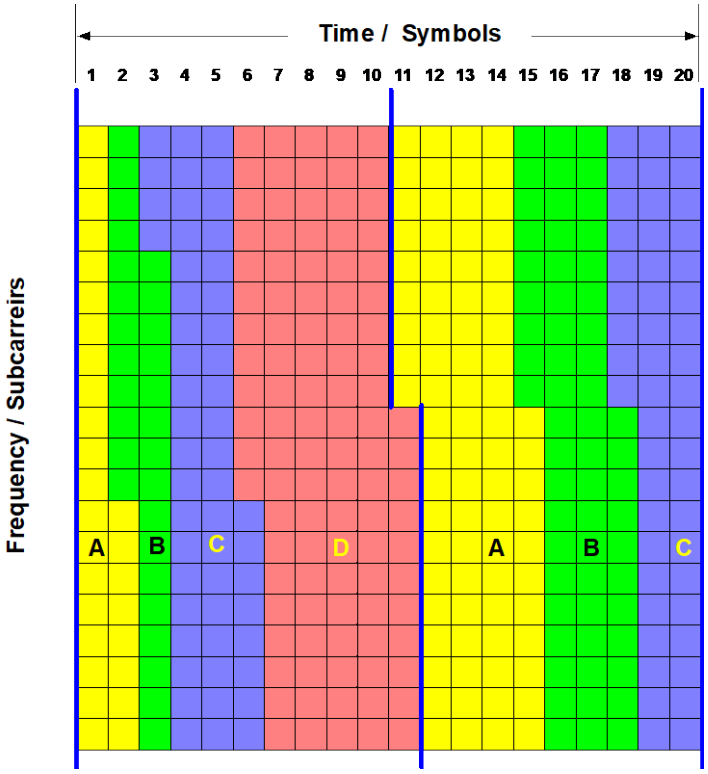

Figure 13 – Conventional Implementation of Downstream Modulation Profiles, A,B,C,D

The profile, however, covers the entire range of frequencies within a channel. In an environment with strong frequency dependent behavior, having the capability of limiting users under the same profile within a certain frequency range would be advantageous to more flexibly implement the HFOF concepts and improve overall system performance. If the channel could be flexibly split in two or three frequency segments as shown in Figure 14, one could optimize overall network performance.

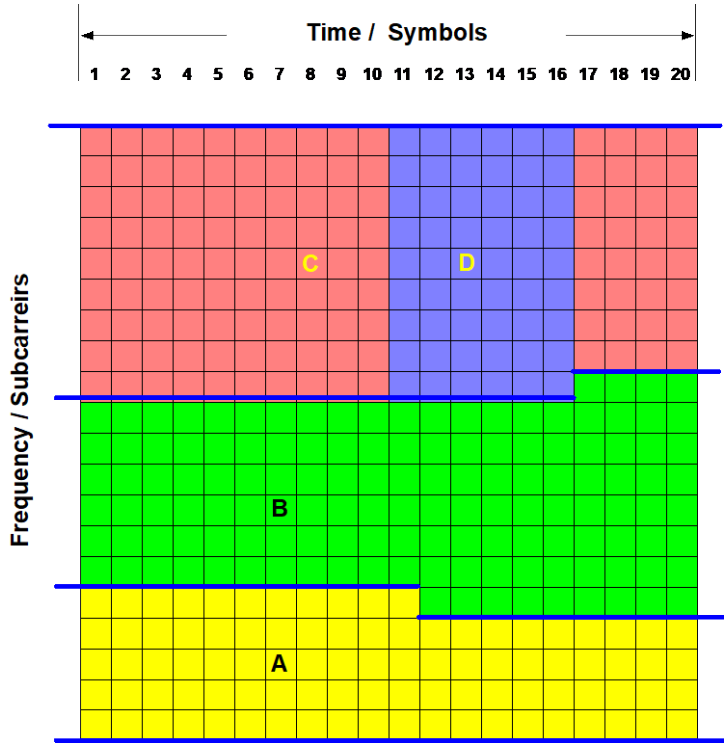

Figure 14 – Frequency Dependent Implementation of Downstream Modulation Profiles, A,B,C,D

Figure 14 shows a downstream frequency-dependent implementation of profiles. A similar capability can be implemented in the upstream

5.1. Additional Frequency Aware Scheduling Benefits

In addition to capacity optimization, having resource allocation control based on frequency and SNR provides other operational benefits. With efficient allocation, a user's capacity is less sensitive to the length of cables and location. Therefore, we could have a system implemented with more flexible coaxial reaches. As operators migrate to N+0 topologies, it is advantageous to split the original HFC node into as few child nodes as possible. To that effect operators can smartly reposition child node locations, not necessarily coincident with former amplifier locations leveraging longer coaxial segments.

Leveraging frequency dependent resource allocation of a next generation scheduler, you can have, for example, a 1.8 GHz coaxial segment with 6 taps supporting 9 192 MHz DOCSIS 3.1 channels. In such a scenario, you can have CMs connected to the first two taps allocated to use channels 5 through 9, CMs attached to the next two taps could be allocated resources from channels 3 through 7 and the CMs attached to the last two taps could be allocated resources from channels 1 through 5. Since the CMs that are farther away use the lower frequency channels one can afford much longer coaxial segments. Another way of looking at this is requiring only lower gain amplifiers resulting in overall lower power consumption.

6. Conventional Taps and Connectors

We mentioned earlier that in order to distribute analog video channels such that they arrive at approximately equal power levels to our subscribers, our coaxial networks were designed with decreasing

tap values so that the attenuation of coaxial cable is somewhat compensated by the tap value. In this original approach, a tap in proximity and following a node or an amplifier would have a higher coupling loss than a tap that is farther away from the node or amplifier so that the impact of longer cable attenuation is compensated.

According to the old paradigm, every end device such as a TV set, a set-top box or a cable modem would receive about the same power level per channel. Operators would use RF distribution taps that consisted of a housing structure and a faceplate. Typically, the housing included ports to connect to the hardline cables or the rigid portion of the coaxial network. The faceplate, on the other hand, included ports that connected to the flexible portion of the coaxial network, the drop cables (Figure 15). The faceplate also included coupling and splitting circuitry to provide specific coupling loss values to the drop ports. These faceplates are removable and designed with different coupling loss values to reach the subscriber's premises at the target power level. If different coupling values or tap values are desired, the faceplate is replaced by another one with the desired coupling values.

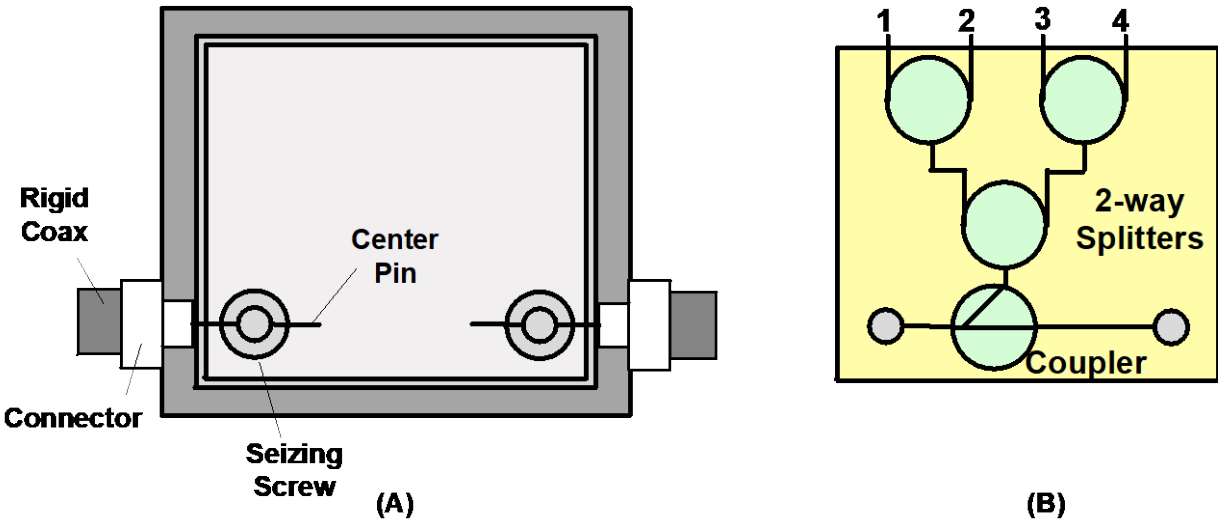

Figure 15 – Tap Housing (A) and 4-Drop-Port Removable Faceplate (B)

One reason to have the tap consist of two components, the housing and the faceplate, is so that faceplates with different tap values can be easily interchanged.

Another reason to have removable faceplates is so that during installation, technicians could have access to the internal structure of the tap. This would allow them to set/configure the tap to receive the center pin of an external KS connector attached to the hardline cable. The connector could attach from a vertical direction when used in pedestals with an underground coaxial distribution network, or from a horizontal direction when the transmission cables are inline as is the case of an aerial distribution network (Figure 16).

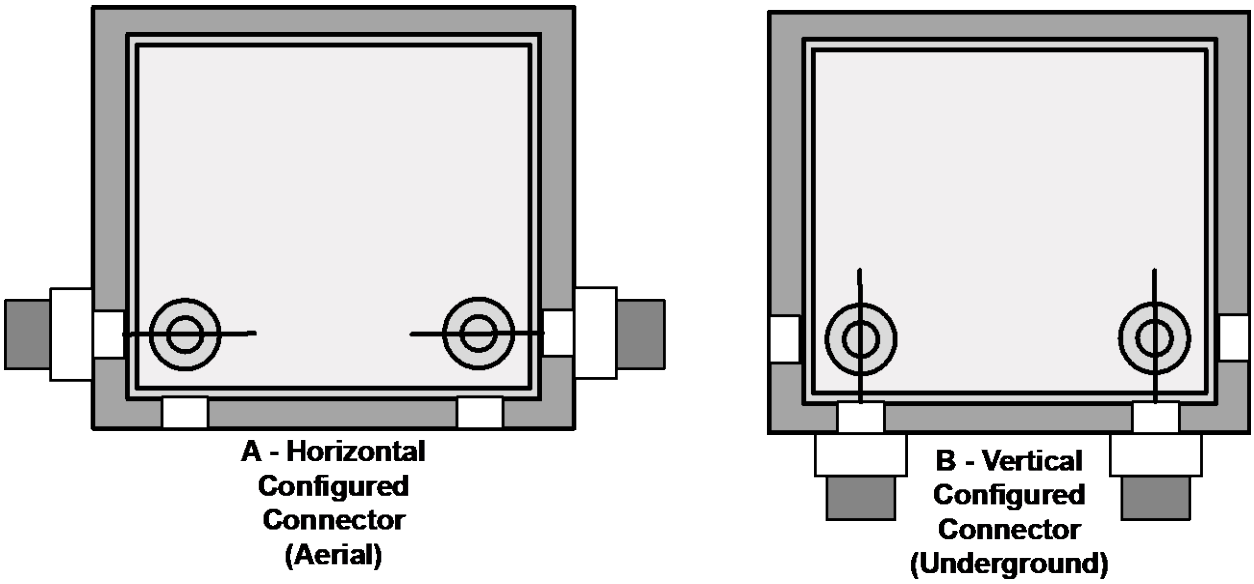

Figure 16 – Horizontal/Aerial (A) and Vertical/Underground (B) Configuration Of Traditional Tap Housings

With a faceplate removed, one can also verify that the long center pin of the KS connector is trimmed to the right length (different tap vendors require different center pin lengths and technicians adjust by manually cutting the center pin) and adjust the seizure screw to make sure a good contact is made with the center conductor of the KS connector.

A fourth reason is to change faceplates with a larger or smaller number of drop ports. This occurs when new customer premises are built and/or a greater number of ports are required.

One challenge that comes from having removable faceplates is that when the faceplate is removed the RF transmission to the elements downstream from the tap is interrupted. The industry solved this by including a conductive path that switches in place enabling an alternate path between the taps' input and output ports, therefore avoiding interruption of AC and RF transport. This alternate path is often implemented using a metal strip which has suboptimal performance at higher frequencies (Figure 17).

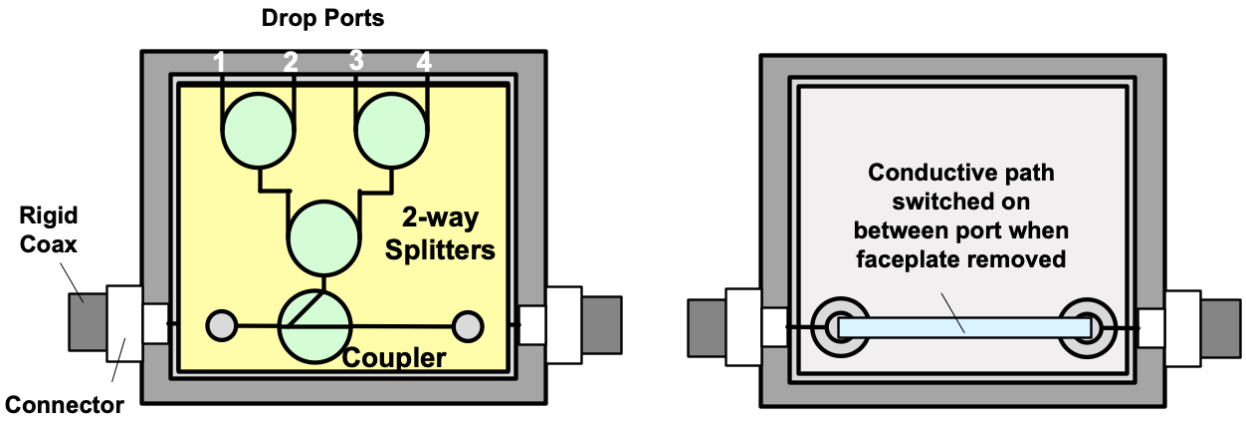

Figure 17 – Tap With And Without Faceplate Showing Conductive Path Switched On When Faceplate Is Removed

7. Revisiting Cable Distribution and Network Components Design

In today's digital age, if we want to control capacity that each subscriber could ultimately consume, we would ideally leverage digital tools that control resource allocation, mainly the CMTS scheduler. If possible, we should avoid using infrastructure means that impact resource allocation when digital means are available. It has been a long time since we moved away from using inline RF notch filters to control premium content access. We have evolved to using digital encryption tools instead. For resource allocation tasks we must also leverage as much as possible our digital domain tools.

Therefore, for the taps that are closer to the node or amplifier we can use a much lower value tap than what is conventionally used (Figure 4). Figure 18b, shows an alternate coaxial segment to the one presented earlier in Figure 4 and Figure 18a, with tap values adjusted so that subscribers leverage the channel conditions and performance they have available in their transmission medium to the node or amplifier.

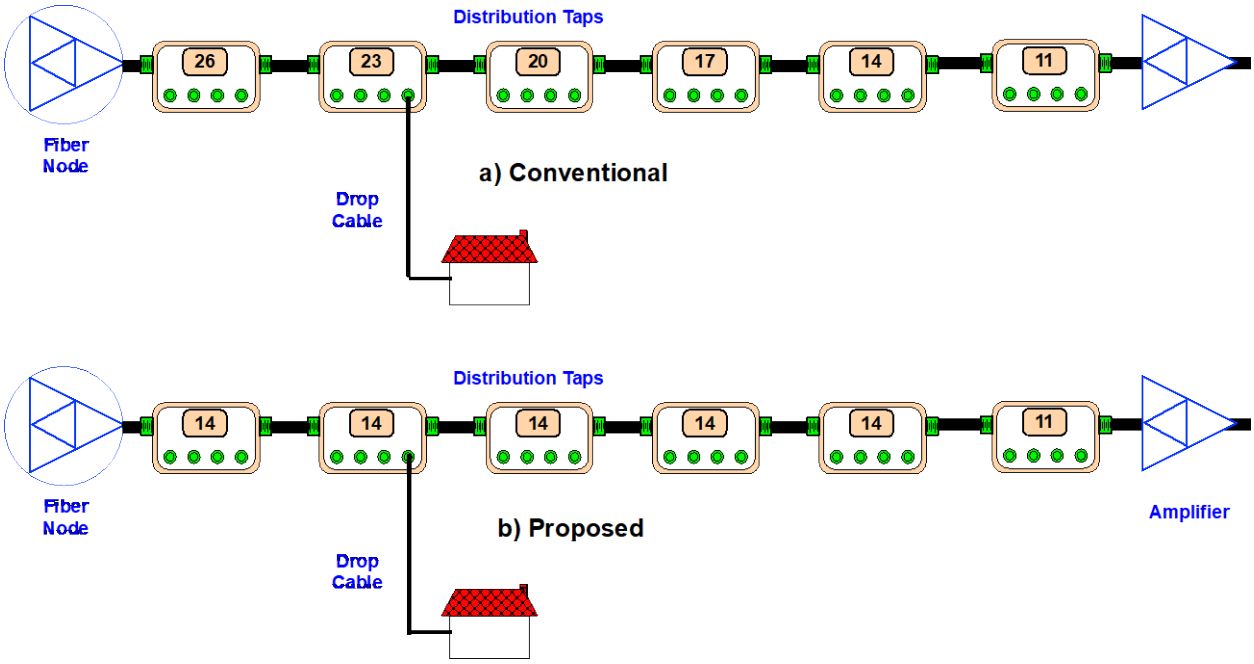

Figure 18 – Coaxial Segment With Adjusted Tap Values Optimize Subscriber Capacity

In Figure 18, the first four taps have decreased their tap values to 14 dB, the 5th tap remains at 14 dB and the last at 11 dB. At lower frequencies, the insertion loss of taps with values 17 dB or higher is dominated by the implementation or excess loss. The insertion loss value for the 14 dB four-port tap is still below 2 dB even after adding excess loss. At higher frequencies the tap implementation becomes more complex and there is a small, gradual excess loss that increases with frequency.

7.1. Single Value Tap

In Figure 19, all the taps for this 4-drop-port scenario, have the same coupling loss value of 14 dB. It does not represent a drastic change, even for the last tap where only a small capacity penalty is incurred. An

exception can be made with the end-of-line "tap" when we are actually dealing with a splitter. Keep in mind that not all end-devices or cable modems need to have the same RF power level. The scheduler is in charge of controlling the capacity that the CMs receive, even though the RF receive power may vary among end-devices. Figure 19 shows the implementation of the coaxial segment using only one tap value.

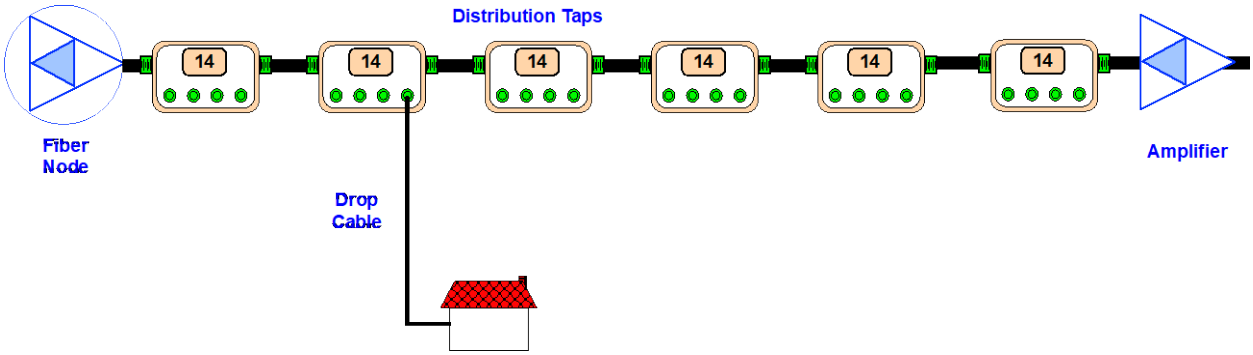

Figure 19 – Single Value Tap Segment For A 4-Port Tap

Using only one tap value for a type of tap significantly simplifies operations. The stocking of taps is much easier. Table 1 shows typical options for tap types and values commercially available.

Table 3 – Typical Tap Types And Coupling Loss Values in dB

2-port	29	26	23	20	17	14	11	8	4
4-port	29	26	23	20	17	14	11	8	
8-port	29	26	23	20	17	14	11		

The 14 dB tap coupling value shown as an example for a 4-port tap has not yet been optimized. Its optimization will depend on the spectrum bandwidth, lengths of coaxial cables and the number of taps that the operators are targeting in a coaxial segment. However, a suboptimal tap value should not significantly affect performance, according to our recent study.

With this in mind, it is safe to assume that there could be a single tap value for 2, 4 and 8-port taps in addition to an end-of-line splitter. This approach would result in the types of taps shown in Table 4.

Table 4 – Modified Tap Types And Coupling Values – Last Column For End-Of-Line Taps

2-port (dB)	11	4
4-port (dB)	14	8
8-port (dB)	17	11

The number of spare taps that a technician would need to stock has been greatly reduced. Without counting the end-of-line splitters, we are dealing with the implementation of a single-value tap for each number of port types.

In this new environment, can the tap performance be improved? One of the challenges when implementing taps is its port-to-port isolation. A simplified traditional tap circuit can be represented by a coupler followed by a splitter. We represent a 2-port tap by a coupler followed by a 2-way splitter, a 4-

port tap by a coupler followed by a 4-way splitter and an 8-port tap by a coupler followed by an 8-way splitter.

This configuration has a potential isolation issue between splitter ports. Isolation between drop ports is not optimal and degrades at higher frequencies. Figure 20 shows a design alternative for a 4-port tap.

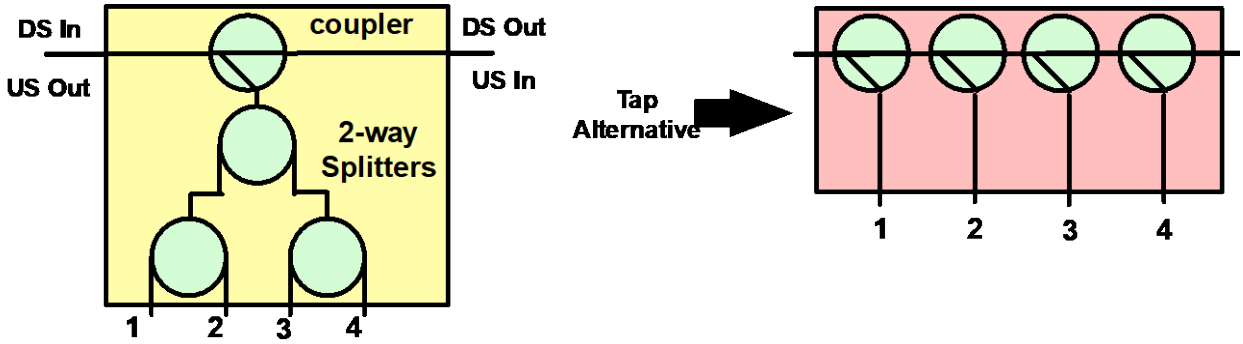

Figure 20 – High Isolation 4-Port Tap Design Alternative

7.2. Revisiting Need For Removable Tap Faceplates

Now that we have an approach to drastically reduce the inventory of taps, we need to ask the question again. Do we really need removable faceplates? Earlier, we discussed some of the reasons why we have removable faceplates. We will now explore the impact of not having them.

Properties of taps with removable faceplates include:

1) Changing tap values

2) Changing the number of drop ports

3) Switching the tap configuration between vertical and horizontal

4) Verifying proper length of center pin

5) Verifying proper contact of seizure screw

6) Maintaining connectivity to the elements downstream during faceplate removal

Changing tap values may no longer be necessary in an environment with a reduced number of tap types. The burden on inventory has been reduced with single-value taps for different numbers of ports. A reduced number of tap types also facilitates the development of a vertical-only housing and a horizontal-only housing. This provides the opportunity to explore using two types of tap housings, mainly horizontal and vertical connector entry tap housings (Figure 21).

Separate vertical and horizontal housings eliminate the need for technicians to mechanically configure a horizontal or a vertical connector entry option. The mechanism that enables dual connector entry options makes operation at higher frequencies more challenging.

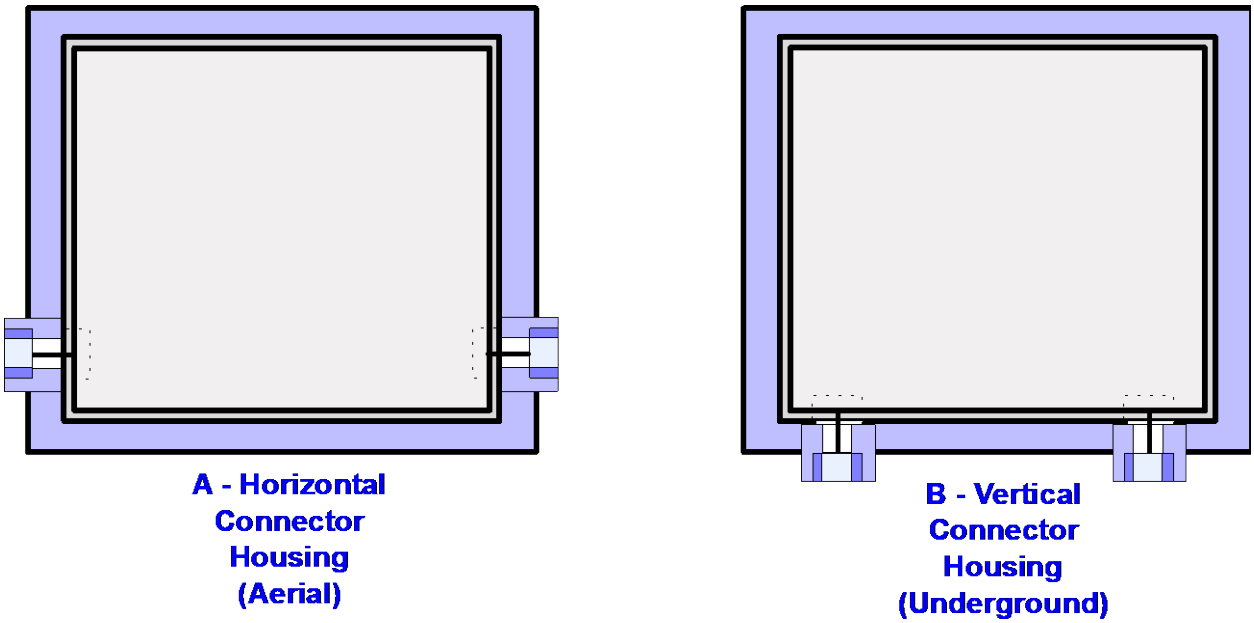

Figure 21 – Separate Housing SKUs For Horizontal (A) And Vertical (B) Taps

Specific connector entry (horizontal or vertical) implementation enables a mating tap connector permanently attached to the tap circuit board. This means that technicians do not need to trim the center pin at vendor specific lengths. It actually enables the use of a connector with fixed length center pin that screws to establish connectivity without the need for seizure screws. You can use a female connector attached to the tap and the board inside the tap and a male connector that attaches to the hardline cable (Figure 22).

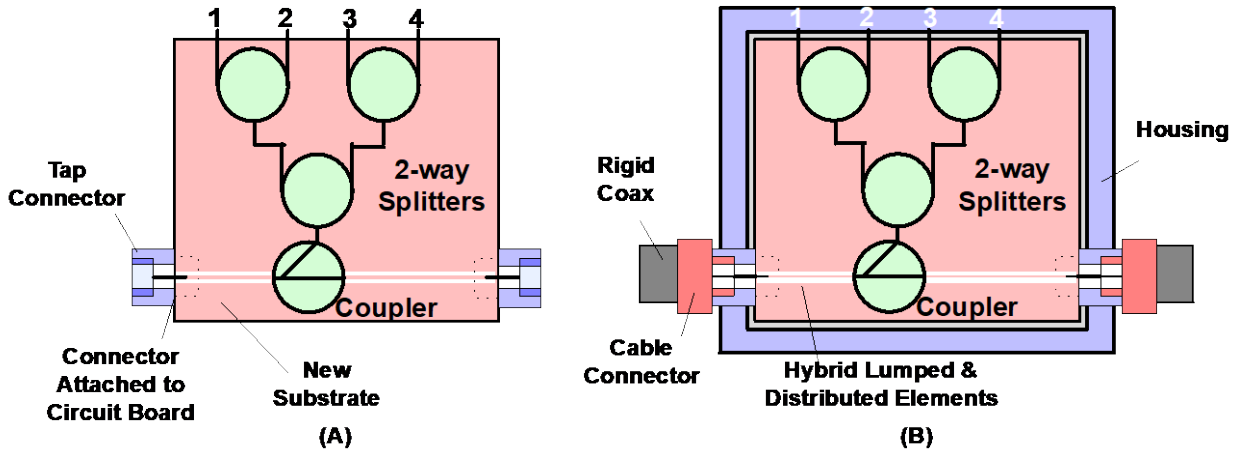

Figure 22 – Updated 4-Port Tap Design

There is no longer a need to verify contact and center conductor length by removing a faceplate. The tap can be implemented as a closed unit. Water leakage and radio frequency ingress problems would be drastically diminished. Challenges in implementing the switchable conductivity path when faceplates are removed are avoided. All circuitry can reside in one board and the assembly of a permanent connector that mates to a hardline connector would enable much higher frequency implementations.

One drawback of this proposed approach is that tap replacement results in a service outage for subscribers downstream from the tap. Reasons to require the changing of taps are diminished with the use of enclosed taps. In the rare event when a new premise needs connectivity. which was not anticipated during the original network design, and no spare drop port is available, you would need to replace the tap. Tap failure would also require a tap replacement, but in an environment where the taps are never opened this would be rare. In a fiber deep architecture, tap replacement is less of an issue as the network affected area is smaller. To replace a tap, two of these next generation hardline connectors are unscrewed to remove the whole tap, estimated at less than 1 minute of interruption.

As we move to higher frequencies, we need to be mindful of the natural tendency to hang on to traditional approaches. We have an inertia to continue using techniques that may no longer be the most efficient. Our environment is changing, we have been gradually pushing to higher and higher frequencies and the way we manufacture taps needs to evolve as well.

In the past, tap circuitry has been implemented using lumped circuit elements. However, as we look to support higher frequencies, incorporating distributed elements may be necessary. Similar questions must be asked regarding the tap circuit substrate. Fiberglass-based substrate, FR4, has been used in the past. Its low permittivity may result in higher loss and leakage at higher frequencies. Ceramic and PTFE (Polytetrafluoroethylene) based substrates should be explored. Their higher permittivity helps confine the RF energy and reduce leakage. While cable's traditional support of lower frequencies (< 1GHz) takes advantage of lumped element circuit components, hybrid lumped and distributed circuits next-generation designs could provide good performance at both higher and lower frequencies.

8. 100+ Gbps Experimental Setup and Demonstration

At this point, the discussion has focused on theoretical aspects of using higher portions of the coaxial spectrum leveraging simulations and modelling of a coaxial segment with cascaded taps. This section discusses experimental results obtained from an actual coaxial segment that has been built using cascaded taps linked by rigid coax cable. This network is actually a 50-ohm network, although the cables that were selected, have the exact attenuation versus frequency behavior of 0.54" rigid coax and RG6 flexible coaxial cable. This network leverages two types of transmitters. From 500 MHz to 3000 MHz a single-frame DOCSIS signal was composed in MATLAB and generated from an arbitrary waveform generator (AWG). This signal was configured with DOCSIS 1024 QAM subcarriers and the output was received in the last tap by a Rohde & Schwartz DOCSIS analyzer. A raw rate of 20 Gbps was estimated at the DOCSIS receiver.

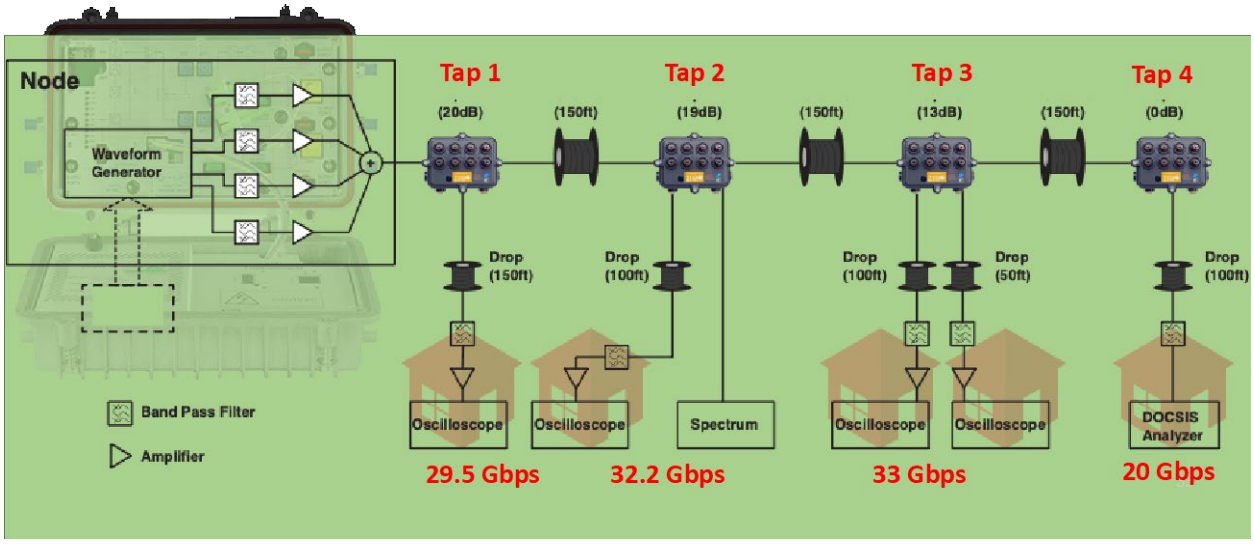

Figure 23 – Experimental Setup of > 100 Gbps Coaxial System

The rest of the spectrum covering frequencies of up to 12 GHz was occupied by re-designed DOCSIS-like OFDM symbols generated from AWGs (Figure 24).

Figure 24 – Spectrum Allocation Of Experimental Setup

A transmission band from 3 GHz to 6 GHz was assigned to Tap3, a band from 6.5 GHz to 9.5 GHz was assigned to Tap 2, and a band from 9.5 GHz to 12 GHz which was assigned to Tap 1 which enjoys the best CNR at higher frequencies. The portion of the spectrum between 6.0 GHz and 6.5 GHz was not used due to the aliasing signal from the AWG module operating at 12 GS/s. An optimized custom design could avoid that frequency gap. Capacity was estimated at 29.5 Gbps at tap 1, 32.2 Gbps at tap 2, 33 Gbps at tap 3 and 20 Gbps at tap 4. An aggregate capacity of 114.7 Gbps was obtained.

9. Node+1 Architectures

The analysis in previous sections examined a single coaxial segment. This capacity is therefore accessible to a Node + 0 architecture. Nevertheless, the use of higher frequencies doesn't have to be limited to N+0. In fact, as you further examine the performance of CMs that connect to the last tap and have a shorter drop length, such as in the case of CM_{12}, the spectral efficiency is quite high. An equivalent longer hardline segment with no drop connecting to an amplifier that follows can take advantage of an N+1 architecture. To highlight that higher cascade use, the spectral efficiency in CM_{12} is shown in red in Figure 25.

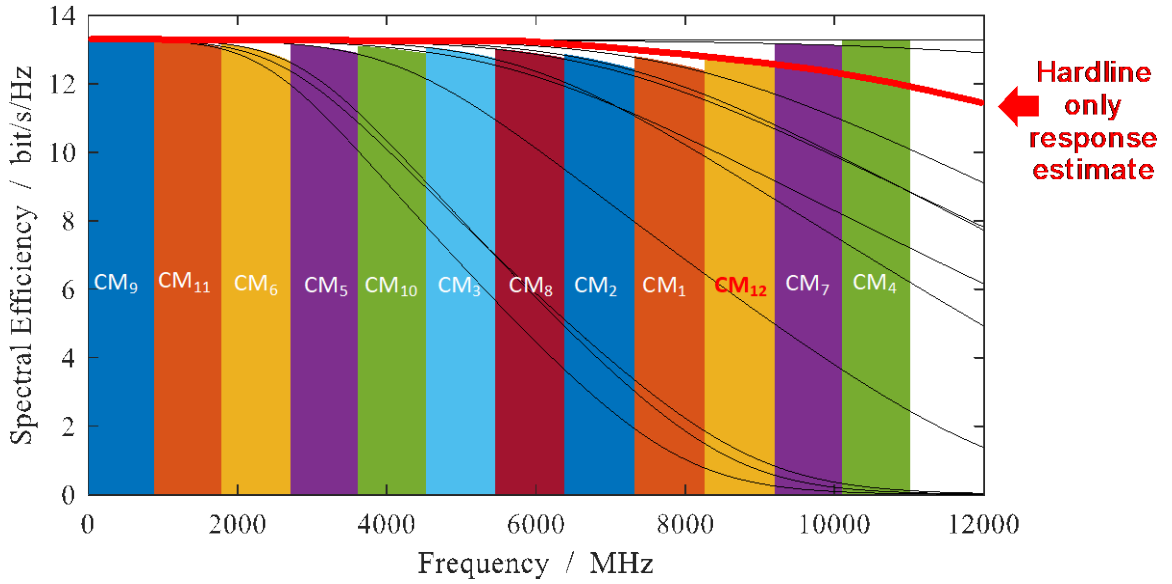

Figure 25 – Spectral Efficiency Available At End Of First Coaxial Segment N+1 HFOF Implementation

Figure 26 shows a N+1 concatenated coaxial segment with some sample scenarios regarding the bandwidths that could be implemented in the segment that follows the fiber node and the one that follows the N+1 amplifier. Figure 26 includes an aggressive scenario with 10 GHz bandwidth following the fiber node (Option 1), in addition to a more conservative 6 GHz bandwidth implementation (Option 2). Keep in mind that higher bandwidths are feasible if lower efficiencies are allowed or in shorter drop length scenarios.

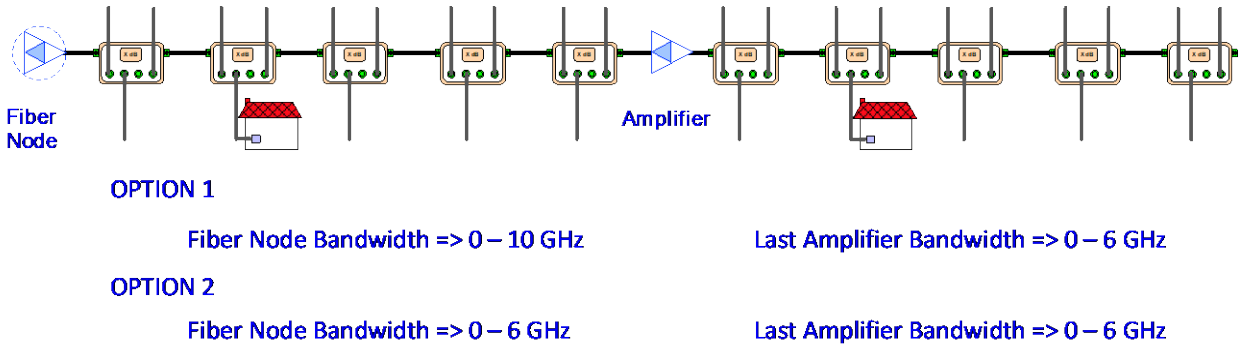

Figure 26 – Coaxial Segments in N+1 HFOF Implementation

9.1. Longer Coaxial Segments

As HFC networks evolve to fiber deeper. An alternative to Node+1 is to use longer coaxial segments. In order to avoid having too many optical nodes in a N+0 architecture, we have been pushing very high gains and power levels out of our optical nodes. We are doing this so that the furthest home can access all the resources that the CMTS or the RPD or RMD makes available. If we submit to the HFOF philosophy, you don't have to expect that every CM can handle the entire spectrum available. It is OK not to be able to consume all the resources. A consequence of this is that you could afford longer passive segments. We

are calling this topology “N+0-Long”. The intelligence of the evolved scheduler will help you with the appropriate resources based on the capabilities of each endpoint.

10. New Kind Of “Hybrid” Fiber Coax

As we have seen how we can still achieve significant capacity leveraging coaxial resources, in order to balance the cost-complexity of the end devices or CMs, one has to determine how much coaxial aggregate capacity and how much peak capacity are practical. Even though 100 Gbps is achieved as an aggregate from a coaxial serving area, the complexity of a CM capturing significant RF bandwidth has to be assessed when determining its practical peak rate. We estimate that 25 Gbps could be a practical peak rate target or 50 Gbps when stacking two receivers. An alternative to coax is the use of coherent PON or CPON. The emergence of coherent optical innovations in the access environment along with the cost reduction trends of coherent optical components, make CPON an attractive long term access solution. The cost of deploying fiber deeper and fiber-to-the-home varies significantly among operators and even within an operator, which may lead an operator to different coax versus fiber deployment strategies. This will depend; on the specifics of the starting point scenario to evolve towards FTTH, on the availability of conduits, on the cost of deploying fiber drops, on economical and operational aspects for extending the life and frequency range of coax and many other dependencies. For some operators, it may make sense to migrate directly to FTTH and for others leveraging the existing coax may make economical sense. The evolution of fiber deeper and FTTH could be made on an as needed basis. A technology like CPON which allows users to reach 100 Gbps on typical Hub-to-subscriber lengths, supporting split ratios of up to 512, could be leveraged to support subscribers demanding higher peak rates. There are many users that may not need peak rates above 25 Gbps for quite some time. Now that fiber is penetrating much deeper in cable networks, the high-end users requiring high peak rate services are a long optical drop away which could be implemented on a success basis. Operators can design the ultimate fiber-to-the-home network but only deploy it partially based on where the high-end customers are. This would result in a gradual transition towards FTTH depending on where the demand is. In some places, there may not ever be such a demand. A CPON network could feed “Extreme Coax” nodes, base stations, enterprise and residential high-end users. Figure 27 shows such a “Hybrid” network where CPON and an N+1 “Extreme Coax” network are jointly leveraged to address subscribers’ long term demand of peak and aggregate data rates.

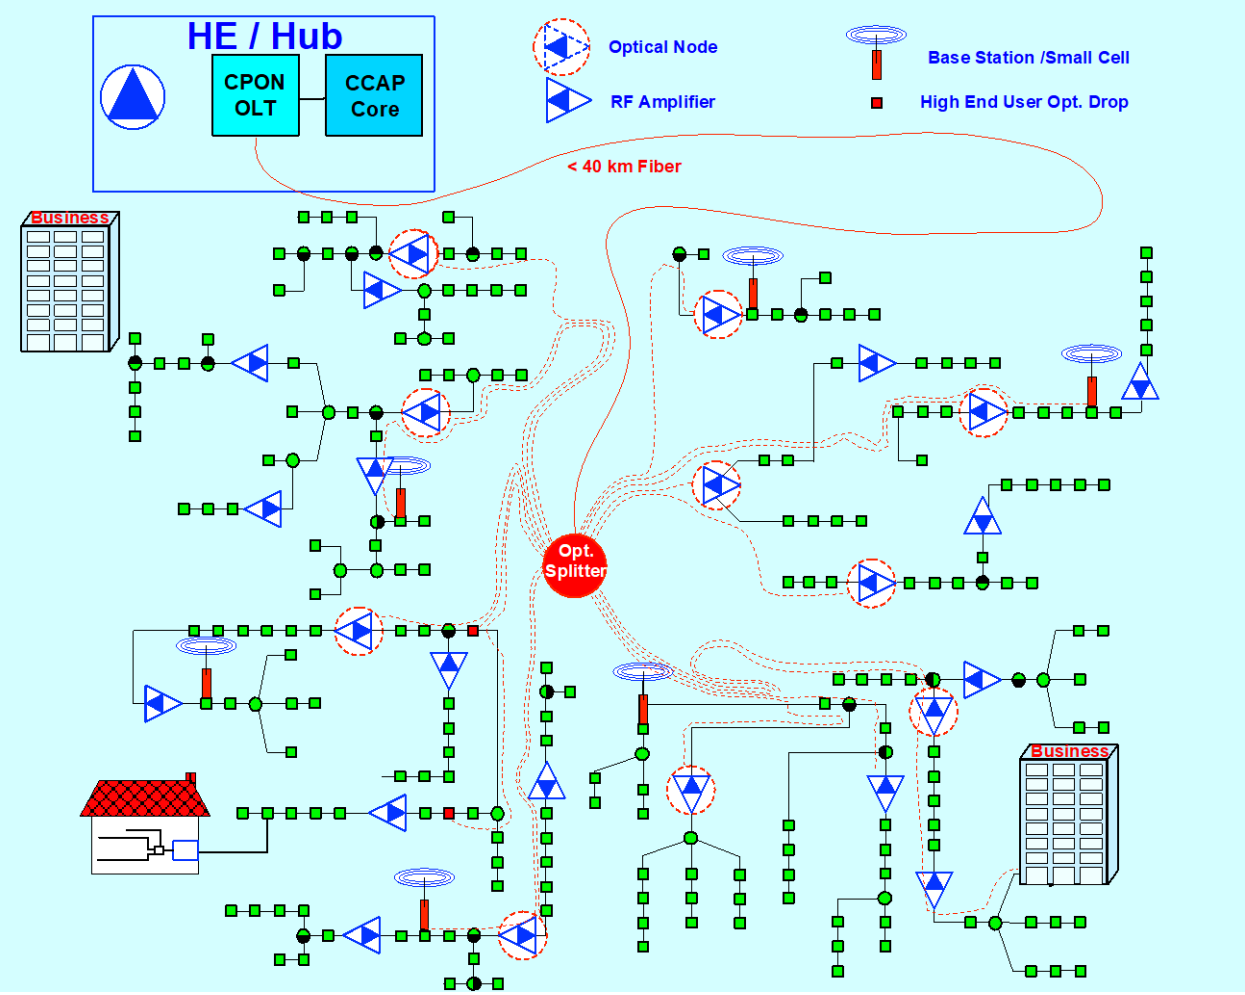

Figure 27 – Ultimate CPON/Extreme Cable "Hybrid" Fiber Coax Network

11. Conclusion

We have finally said goodbye to analog video and we need to fully embrace the digital era with all of its benefits, including the opportunity it provides in re-designing our coaxial network. The CMTS being the device that controls resource allocation still has plenty of room for improvement in this new environment.

As Cable entertains the support of 1.8 GHz, 3 GHz and even higher frequencies, the coaxial cable medium exhibits greater dependency in frequency. Having frequency-aware resource allocation provides great strategic advantage, helping enhance our data delivery capabilities over coax. Being free from analog video restrictions provides Cable the opportunity to drastically simplify the implementation of its coaxial infrastructure while preparing it to evolve to higher frequencies. Except for end-of-line taps, Cable can follow a single value tap for each tap type with the same number of ports. This reduction in inventory makes attractive horizontal- and vertical- specific taps, as well as taps without removable faceplates, avoiding many of the challenges in the evolution to higher frequencies.

A Higher Frequency Off First (HFOF) approach to allocating bandwidth has been proposed to optimize how we can use higher frequency resources as well as to facilitate the extension of coaxial segment lengths. This approach is not limited to N+0 architectures but can also be used with N+1 and higher

cascade scenarios. Coaxial bandwidths greater than 100 Gbps have been demonstrated over a coaxial segment using HFOF and leveraging frequencies approaching the cut-off frequencies of the hardline cable (11 GHz). Balancing the capture bandwidth of the CM versus its tunability allows the optimization in the system's cost-complexity through peak versus aggregate rate assessment. The proposed HFOF approach also bounds the system's dynamic range. Frequency aware scheduling, HFOF, single value tap and high frequency tap redesign are key ingredients to this Extreme Cable approach. Together these concepts are powerful, but they could also be used independently and provide benefit to the evolution of our coaxial environment.

A new "Hybrid" Fiber Coax environment where CPON and Extreme Cable join forces to deliver data services is considered as a gradual, success-based transition to FTTH in the areas where it is needed.

Abbreviations

AWG	arbitrary waveform generator
CAGR	compound annual growth rate
CATV	cable television
CCAP	converged cable access platform
CM	cable modem
CMTS	cable modem termination system
CNR	carrier to noise ratio
CPON	coherent passive optical network
dB	decibels
DOCSIS	data over cable service interface specification
DS	downstream
FEC	forward error correction

Joann_Shumard@cable.comcast.com

1. Introduction

System support tools can be a vast ocean of internally-developed and externally-purchased groups of software solutions. This paper will focus on drivers and solutions to an organizational problem, the tooling abyss, that centers around the dual impacts of pace and sprawl of tools created and utilized to keep in stride with the innovation growth of the technology of our industry. This document will clarify the definition of what a tool is for our industry, identify the business impacts of our decisions, and recognize the perspectives of the user community.

"Just build a new one" is a typical response to developing tools to support new technology. This mantra has defined many aspects of the transformative technology growth in the industry. The "build a new" strategy, without a plan for the old, has led to an exponential growth of complex tools required to operate the business. This methodology increases user complexity and causes operational inefficiency. Technology innovation has unlocked an expansive sea of data and knowledge, but this simultaneously created a myriad of tools making it more complex for the user communities. Increasing complexity can result in inefficiency, such as when a single team member must reference multiple interfaces to troubleshoot a single problem. This complexity creates and exacerbates perceptions of information overload. The concept of "adding new to old" has also shaped new challenges, like a sense of searching through an abyss of information when trying to find critical troubleshooting data. The influx of added information and operating multiple interfaces causes challenges for teams responsible for managing the customer experience, maintaining the plant, and monitoring system events.

The persistent launch of new technologies in the industry has driven a constant change in the tools needed to operate them. This paper will focus on building a strategy around making instrumental tooling decisions, concentrating on when to develop new, when to integrate, and when to sunset tools. Tooling culture will be discussed to delve into the psychology of change, and the navigation of managing evolution, including the emotional attachment to tools team members, have historically known. This paper and presentation will review strategies on tool development that are based on operational efficiency while supporting new technology and driving overall business strategies.

The purpose of this paper is to understand how more effective development methods can lead to improved team performance across multiple technology tooling systems. Evaluating real-world organizational problems provides a pathway to investigate a specific business problem and seek opportunities that shape future business goals or strategies. The information will enhance the understanding of how business evolution, financial requirements, and consumer needs have led to the multitude of systems utilized in today's operations. The paper will focus on the history of how the tooling abyss has been created and the impacts on the user community. It will propose new opportunities in managing tooling systems to support the development of plausible and implementable solutions.

2. History Of Industry Technology

To help understand today's issues of the complexity of the tooling abyss, we can review the pace of innovation of the industry because every "chapter" brought with it a corresponding increase in tools. Cable television dawned in the 1940s when cable became the connection into the homes that could not be easily reached by standard over-the-air broadcast capability [2] (Cable History, 2014). Through the years, the technology evolved through amplifiers and the continuing focus to reach more people. The 1960s was an innovation milestone with the introduction of the Jerrold Channel Commander headend signal processor, the first pay-for-view (PPV) event offering, solid-state technology, and the enhancement of aluminum-shielded foam dialectic distribution cable. In 1969 the Society of Cable Television Engineers (SCTE) was established, focused on training and educating the industry's technology professionals. The innovations of the 1970s brought new concepts of two-way addressability and enhancements in drop

cable to improve in-home quality. Video evolution continued to grow through the years, and the expansion of the industry continued through compression technologies, industry channel expansions, and innovation in delivery systems.

The 1990s accelerated the pace of technology innovation with the introduction of the fiber to the node methodology or Hybrid Fiber Coax (HFC) [2] (Cable History, 2014). The innovation of the return spectrum opened the door for two-way communication that would support PPV revenues, telephony voice, and the ability to deliver the internet to homes. In 1995 copper-wire phone lines provided 14.4 kbps internet, while the then-new cable modems would provide 4000 kbps which, at the time, was groundbreaking. In 1997 CableLabs emerged as a governing presence to align broadband standards for manufacturers and operators to ensure consistency in the business. Since the beginning of DOCSIS 1.0 in 1997, these standards and the industry have grown exponentially. DOCSIS 1.0 became 2.0, 3.0, 3.1, and laid the future for 10G and beyond. Analog delivery systems have transformed into fully digital architectures, providing a stream of innovative technical data. All of this evolution transformed the experience for all internal users.

3. Tool Development Influence

The historic pace of innovation is a significant factor in recognizing how the tools needed to operate them have also transformed. The first 50 years of evolution centered primarily on video technology. The catalyst of the evolution of the cable modem created a pace of innovation in the next 25 years that has dramatically altered the amount of software development and tooling innovation required to keep pace with the accelerated growth. In early history, basic measurements of levels were the primary performance indicators compared to today's expansive data capabilities that provide insight into the customer premise equipment in the home. This history of acceleration is a primary contributor to the exponential growth of support tooling in the industry.

4. Industry Tooling

Some may ask: What is considered a cable tool? The focus of this paper is on the software developed "electronic toolbelt" [1] (Breymier, 2020) rather than the hands-on physical tools used by field teams. If starting from the catalytic point of the introduction of cable modems, that question can be answered by the desire to understand the state and levels of the cable modems when troubleshooting. Early troubleshooting would require logging into the CMTS (Cable Modem Termination System) and looking for a specific modem that required its MAC (Media Access Control) address. The use of the "show cable modem" feature and directly logging into the CMTS became quickly identified as a non-scalable way to gather and interpret information for troubleshooting.

As the technology and customer base have grown at an accelerated pace over the past 25 years, so has the technology of the tools that support it. Tools in the business can be those used for monitoring the systems, databases that store information, back-office systems, or tools used by front-line team members who work in the home or the plant. New user interfaces (UIs) are tool interfaces created using data pulled from the CMTS and developed into a more consumable view. As the technology evolved and new data became available, in many cases, new tools were created to support it. The answer to the question about what constitutes a necessary tool must acknowledge certain contributing factors. The next sections describe the vast amount of tools utilized in the course of supporting business needs to identify opportunities to optimize strategy for future development.

5. Organizational Importance

The purpose of this review of industry tooling strategy is to investigate the impact development decisions have on team performance, tooling development environment, and intra-organizational communication. The problem identified is that the methodology of creating tools in multiple departments to meet only specific needs, and potentially without a long-term strategy, can negatively impact team performance. When tools are created without a centralized, defined strategy, the organization is impacted by wasted investment tech debt due to software teams duplicating work effort. Team performance is negatively impacted when information does not directly aid internal users to efficiently complete their tasks. Cross-department team conflict leads to organizational impacts on performance and job satisfaction.

There are multiple inputs into what is needed for system tooling, such as new technology, process change, and internal operational-user requests. When internal departments do not have aligned priorities, this can lead to challenges with professionals and software-development engineers working with conflicting priorities resulting in resource inefficiencies. Understanding the drivers for tooling development within the organization and the various business departments are imperative when recognizing what influences the tooling strategy.

6. The Tooling Abyss

To support today's technology, the parallel rise in tooling can cause many internal users to feel like they are swimming in an unending deluge of information. There is an endless stream of new data driving constant change. New tools are developed to support new technology, while legacy tools are sometimes not decommissioned. Some methodologies add new data or widgets to existing tools, making them large and complex to operate. There are three notable areas where the growth of technology creates the pathway for this number to continue to grow:

- Centralized Tooling System Management
- Decentralized Tooling System Management
- Tool Ownership Conflict

Centralized Tooling Systems

Many organizations promote the centralization of tool development to control the development lifecycle. However, it is essential to recognize that the technology in and adjacent to our industry is advancing at an exponential rate. It is critical to understand that a centralized approach to tooling development may not result in one specific strategy. In essence, even centralized organizations may not always have a consistent strategy for tool development.

Commonly, organizations focus on launching new technologies and products to their internal users from a central viewpoint. However, not all have a centralized strategy for tooling, nor a software development plan for operating tool readiness. An increasingly common challenge that illustrates this is a new technology that becomes available to external users, but the tooling is not fully developed for the internal operators that support them. One practice commonly used is "just add new," where engineering organizations feel compelled to not only build the new capability but also create a tool to support it. New architectures and components may take years to completely roll out throughout a large system, which leaves the operators and technicians with no choice but to use multiple sets of tools. In this situation, one tool supports the new architecture, while one remains to operate the legacy. Further complicating this issue, by the time one "new' technology rollout is nearing completion, the following new technology is waiting to ramp up. Tooling never ends; the parallel strategic goal that is continuous integration/continuous development (CI/CD) assures it.

The negative impact to the teams responsible for operations and the technicians is this constant swiveling and cross-referencing of tooling information to complete everyday tasks. Advocates of the centralized model tend to focus on security standards as well as enhancing and growing existing operational toolsets. The risk and challenge with this methodology are that without discipline and long-term strategy, a system's code-stack can become obsolete. It can become so monolithic that continuing development becomes less agile and stability questionable. The thought in this method is that maintaining a centralized toolset reduces the swivel, but as technology data increases, the tool can become more complex to operate, and the amount of information contained in it can become overwhelming. Overall, technology and innovation are great things that drive growth, but there is an impact on the operations when the tools needed to support it are not available.

Decentralized Tooling Systems

Most of today's largest service providers are a product of acquisitions [2] (Cable History, 2014). That creates an increased number of tools integrated into the organization, some developed in-house and some contract acquired through business acquisition. The challenges consolidating organizations face include what to do with the newly acquired tool. Is its function duplicative? What is the cost to sunset the old one? Without a consistent strategy on organizational tooling systems, many choose to simply keep everything and operate in segments.

The broadband communications industry was started by and continues to attract an amazing talent pool that is capable of innovating new ideas, especially when it comes to supporting software-developed tools. Many talented teams have taken it upon themselves to create "gap solvers" where there may be centralized or common systems, but to operate them more effectively, they develop secondary enhancements. These individual solutions developed across the organization can create quick short-term solutions to a current business problem. They are also one of the highest contributors to the tooling sprawl. This methodology creates challenges in operational consistency, security, and system consistency, as well as hinders the ability to make future system changes.

Tool Ownership Conflict

Pride in ownership is a valued characteristic. People involved in the ideation and development of new tool ideas are no exception. Being competitive is a cornerstone of our business. Metrics commonly drive our teams to work hard and strive to be the best. In many business areas, this is a practice that has determined constant operational improvement through the years.

However, in the tooling and development space, this mindset can also be a contributor to conflict. It can perpetuate the keeping of obsoleting systems because of emotional attachments from those who created and used them. In organizational terms, dominant or competitive conflict culture is a winner versus loser strategy that can lead to negative, organizational influences [3] (Choi & Ha, 2018). The competitive conflict culture applied in the software development space leads to inefficiency and negative employee experience. In contrast, the collaborative conflict culture is a partnership-oriented culture focusing on coordinating the best outcomes for the business.

In both centralized and decentralized examples, leaders are responsible for the technology that overlaps with other teams. This overlap can result in continuous conflict, even when attempting to be effective and productive. This dynamic creates both a task and a relationship conflict for the teams that manage the tooling systems. When there is a lack of a clear strategy, negative team impacts can include job dissatisfaction and team inefficiency [3] (Choi & Ha, 2018). Negative individual behaviors are caused by a lack of direction as well as a competition where people are diligent in keeping what they own. It also means some tools may stay in operation because of a lack of willingness to let go of obsolete and antiquated electronic software systems.

Cost of Inconsistency

Job dissatisfaction is not the only business challenge created by competing or unclear tooling strategies. Another is duplication. Tooling duplication is a common result of the decentralization of operational support tools, where the same data is used in multiple ways. For example, different groups may download data on customer premise equipment, then use that data to create a plan of action, or evaluate a system's status. In doing this, developers create duplicate data stores for the information. This duplication creates a cost to the business in multiple ways.

- Multiple data stores mean replication on multiple platforms and systems, which take up much more storage space
- Multiple support teams are required to maintain the data and UI, or one support team is required to support multiple similar tooling systems
- Replicated system upgrades and security requirements
- A technical debt of overlapping and duplicated operational systems
- Inconsistent user experiences

Technical user inefficiency is an increasing cost to the business, especially when the abyss of tools and complexity requires team members to swivel to multiple interfaces to troubleshoot system issues. Team and individual metrics are impacted. As an example, time-per-task increases when the tooling lacks stability, speed of response, or contains more information than is needed for the task. When the utilization of the tool or tools to complete the work is inefficient, its users will avoid adoption. When complex information flows disrupt a tool user's ability to work swiftly and accurately, they will disregard it.

The pace of new consumer and system architecture technology has reached extraordinary heights. This timeline requires system tooling to innovate at the same pace to support the operational needs of the business. When there is system tooling duplication, lack of a focused strategy or extremely large monolithic systems, the ability to maintain pace is reduced. Reduced agility, when launching new features and technology, can result in products becoming available to consumers before they can be effectively supported, from an operations perspective.

7. Information Overload And The Human Factor

Understanding the user experience is an essential concept in any tool's development. The accessibility of data through the internet and system technology has created a rich opportunity to connect and collaborate in extraordinary ways. Recognizing the power of data, however, needs to be balanced with the human factor. Essentially, the cognitive value in the information relies on the design, structure, and quantity of the information shared with the user [6] (Voinea, Vică, Mihailov, & Savulescu, 2020). Cognitively people are likely to take mental shortcuts because, at any given time, the human brain can only process so much complex information. Information overload is a phenomenon that emerges when the amount of information and choices become so expansive that they impact the user's cognition. The psychology of how people process information is a critical understanding point in tool-development concepts. That is because simply adding new data, new widgets, and new information can ultimately have a significant impact on how the internal users adapt to the technology change.

The constant evolution of tooling and strive to drive more data to the internal users also create challenges in the best way to train new tooling technology. In an interview to inform this paper with Walter Breymier, a veteran technician at Comcast, he observed that the constant pace of change and volume of information impacts team members in different ways [1] (Breymier, 2020). The technician perspective must be a key factor in evaluating how a tool will be adopted:

- There is not always a clear understanding of who and what the software tool is for
- Technicians are not given time to truly absorb the best way to utilize the tools
- As a direct result, the tendency is to "stick to what you know" and avoid utilizing the new information.

It is worth noting that it can be the team members with the longest tenure who are the most resistant to change. They may also need more time to comprehensively understand the newest technology. Understanding the human factor is critical to ensure the information in the tooling is comprehended and utilized by all team members.

A study in information-avoidance behavior substantiates this view by modeling a stressor-strain-outcome framework. The intent is to qualify this avoidance as a consideration of network fatigue in comparison with social networking [4] (Guo, Lu, Kuang, & Wang, 2020). This concept evaluates the thresholds in which the time pressures, data irrelevance, information overload, and data fatigue indicate the predicted result of information avoidance. The study illustrates that stressors are created through information irrelevance, information overload, and social overload. These stressors become a strain when the individual reaches the point of network fatigue. When time pressures are factored in, the rate of information avoidance also increases; the calculation is noted in Figure 1 below.

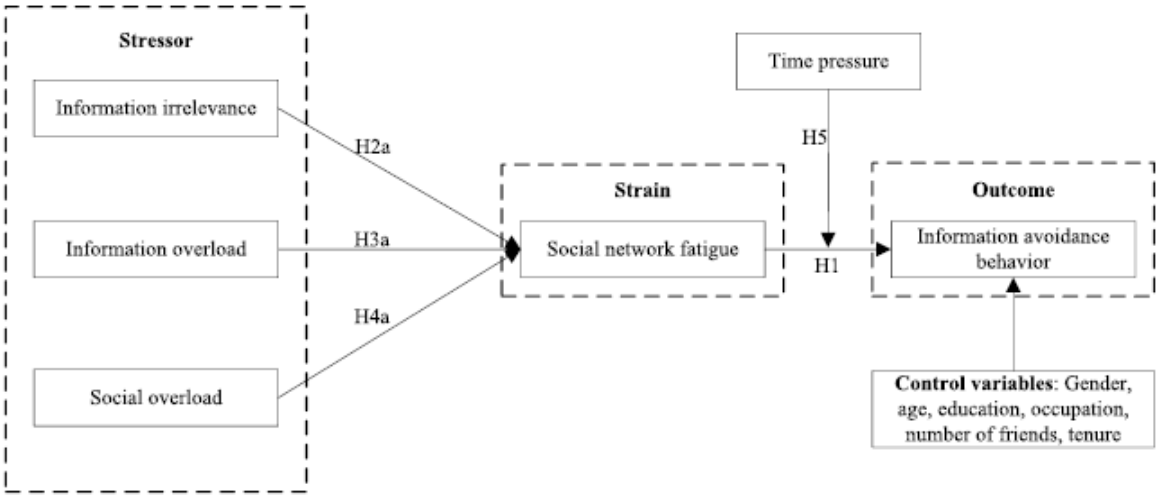

Figure 1 - Information Avoidance Calculation

This study is relevant to the concepts of exposing large quantities of information through system tooling with added time pressures. As an industry, the teams that utilize the system tools are typically held accountable to a very high level of time pressures, intrinsic with responding to system or customer issues. There is likely to be a broad and deep spectrum of data available to our team members that may not be the most relevant to the issue they are working on at that moment. The constant interaction with the networking data can conceptually be an aspect of network fatigue. All of these elements are factors in the introduction of tooling technology to ensure they are not creating even higher incidents of information avoidance.

8. The Solution

Creating a solution to the complex world of supporting tools for advanced technologies relies on multiple factors. The initial assessment comes from a survey of operational teams to identify how many system tools the team members are using and what information they value. Depending on the organization's

history and tooling strategy, it is entirely possible that a single department team could use up to 100 different electronic system tools to complete their work.

As a result, organizations must not only invest to advance network and consumer technology, but must also commit to the system tools needed to support it. Definition of the development culture, blended with leadership influence, creates the foundations of agility and success. Figure 2 shows a view of a tool development ecosystem. It begins with the need to ensure that regardless of what changes are being made, the tenet of operational reliability and stability are foundational to the business.

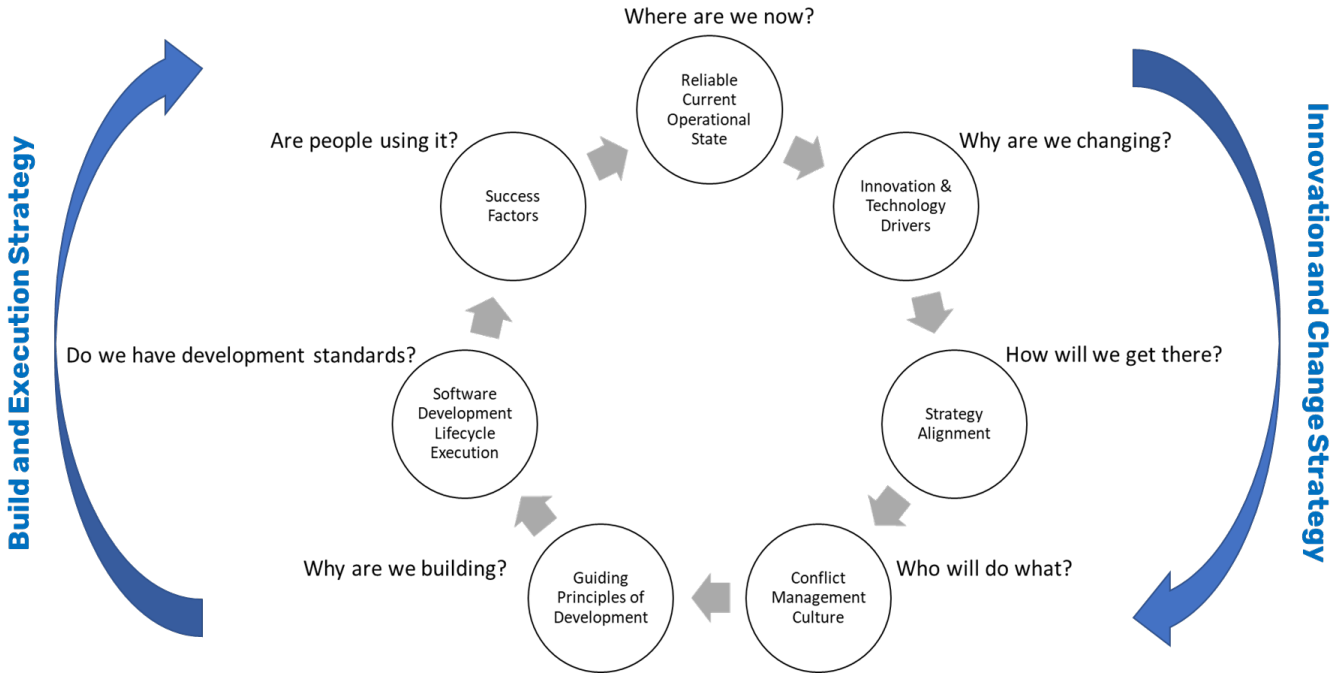

Figure 2 - Software Tooling Development Strategy

Change Drivers

The pace of innovation has primarily driven the need for tool evolution. The history of the technology evolution creates the basic drivers for much of the need to evolve the tooling systems. Comcast colleague and Engineering Fellow Larry Wolcott (2021) [8], a recognized industry expert on the topic of Proactive Network Maintenance (PNM), shared his insights about tooling for this paper. He noted that it is critical to recognize the drivers of the development changes and to be sure to integrate ideation and capability requirements when operationalizing a tooling system or update.

There are typically four primary drivers of change in tooling evolution: new industry technology, tool infrastructure technology, organizational process improvement, and enhancing the user experience.

Figure 3 - Drivers of Tooling Change

Strategy Alignment

The first step in optimizing tooling development for both the development teams and the teams that ultimately use the tools is to agree on a unified strategic planning process, specifically for software-developed systems and electronic tooling. Simply deciding if the organization will be centralized or decentralized will aid strategic alignment. As previously discussed, methodologies can and do differ from department to department, and there are various visions on what is valuable in the data that is presented to internal users.

Coordinating on any strategy, including tooling, starts with leadership alignment, both top-down, and ground-up. Department and area leaders need to be committed to a discipline that outlines the requirements for tooling development. Governance matters for the organizational accountability that integrates all of the change drivers into a cohesive strategic plan. The strategic plan should address standards for tooling technology, coding languages, reliability requirements, financial payback, and business value determination.

The strategy and structure for governance require a collective of experts representing the knowledge wheelhouses of engineering, software tooling development, finance, and operations. All must be equally represented to ensure that the expertise of each discipline is integrated, which creates a balanced business strategy. Engineering experts are responsible for the architectural vision of the technology that supports products. The software development experts are responsible for maintaining tooling technologies that support the monitoring and operations of the engineering systems. The operations experts utilize the software-developed systems and electronic tools needed to maintain and operate the engineering systems. The finance team is responsible for maintaining overall business financial objectives. Each of these groups is critical. Collaboratively, they create a comprehensive business strategy that directly influences the creation of operational support tools.

When the strategy is well balanced, the tools that are used to operate these systems are fully adopted, truly optimized, and streamlined. Each team has a critical role in creating a highly collaborative and focused strategy that optimizes overall business strategy and value. When they are not in balance and the strategy is not aligned, the abyss of tools grows, complexity increases and conflict can slow down the pace of innovation and development.

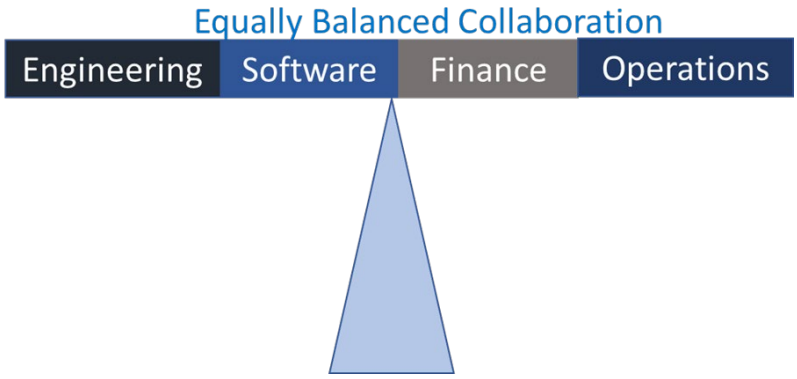

Figure 4 - Balanced Business Strategy

Conflict Management Culture

To maintain a balanced strategy, an organization needs to define expectations for resolving inevitable conflicts so that working teams have a clear path to work together positively. A collaborative conflict-management culture can have a positive impact on organizational effectiveness and improve job satisfaction [3] (Choi & Ha, 2018). Successful conflict navigation relies on cognitive flexibility, self-awareness, and commitment to collaboration. When the teams have more clarity on aligned goals and operate collaboratively, there is an opportunity to enhance innovation and create healthy tension. In this application, teams working in technology need healthy tension to innovate and strive for constant improvement. When there is trust and willingness to be more flexible, individuals feel that their contributions are valued. In turn, job satisfaction will be higher, and internal users will adapt to change and resolve conflict most effectively.

Executive leaders are tasked to define organizational responsibilities and create a process to entrench an inclusive and collaborative conflict-management culture into the entire organization. A collaborative conflict-management culture relies on individual cooperation to create a compromising versus competitive method for deriving agreements [3] (Choi & Ha, 2018). As a metric-driven industry, this concept for tooling development represents a notable shift from the competitive dynamic. An innovation strategy that is only focused on what is best for the technology, for purposes of a competitive result, can create conflict with financial standards, or challenges for operations. A compromise-oriented solution provides the potential to create a healthy tension in the organization that can lead to innovative breakthroughs and positive organizational influence.

When there is a non-competitive, collaborative environment, innovation is maximized, and integration is optimized. Larry Wolcott, mentioned previously, notes the engineering concept that "just because we can, doesn't mean we should" mindset. This concept means that even groundbreaking technology can be available, but if operational teams find it too complex or there are conflicts with operational efficiency, it may not reach its full potential. To ensure that balance is maintained between engineering and operations, there must be a focus on collaborative problem solving and conflict management.

Development Principles

The technical sprawl of tooling is expanded or contained by the software and electronic tool development strategy. Eric Wall (2021) [7], a leader of the support teams that develop several of Comcast's widely utilized operational tools, shared the perspective that the growth of tool development must have a clear, collaborative strategy. Without recognizing business benefits and how operators utilize them, the software developed may not have the intended impact. To aid in ensuring the strategic direction of development, below are a few guiding questions to drive the most efficiency in software tool development.

- Is this requirement strategically aligned and governed?
- What is driving the change or the problem that needs to be solved?
- Who and what development team is responsible for solving it?
- How will the user behavior be influenced, and what is the behavioral expectation?
- How does this fit in the business financial model?
- Should this be developed internally or purchased?

The answers to those questions will clarify new tooling initiatives and align with the expressed strategies of the business. As noted previously, the drivers for creating a large set of tools are driven by many factors: Building new without a plan for the old, "because my team can," and gap functionality all contribute to the steady growth in tools volume. To resolve this continuous sprawl, discipline and commitment adherence to guiding principles are paramount.

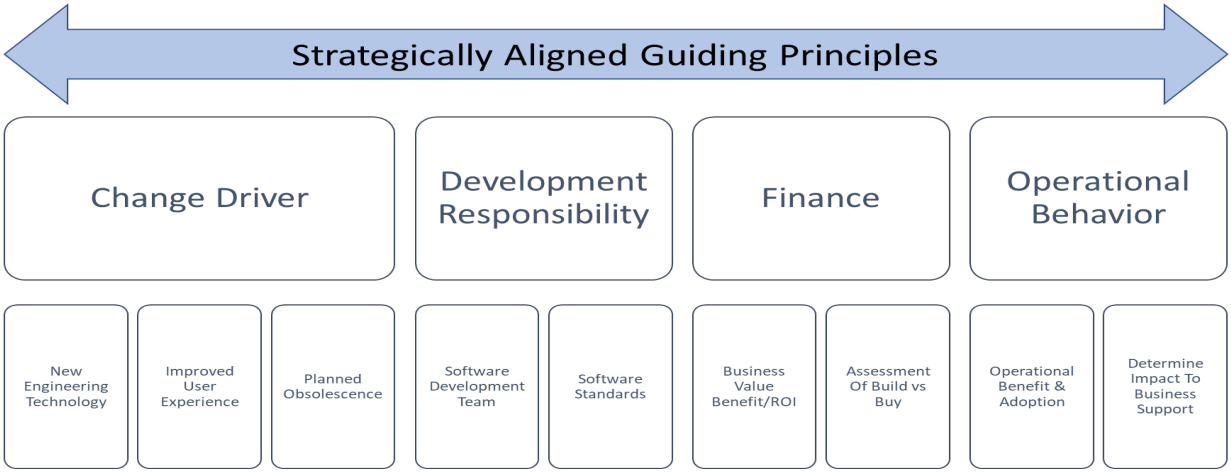

Figure 5 - Strategically Aligned Guiding Principles

Lifecycle Development Execution

Lifecycle execution for tools and tooling should be a structured approach based on the resources available and the overall business requests. The concepts of people, process, and technology are critical components to prioritizing work for development [7] (Wall, 2021). Development standards are set by software engineering experts to ensure a commitment to security and development standards. The challenge that developers face is that of a large number of requests to complete work versus a set amount of dollars to accomplish them.

"Cost modeling can lead strategy" is a common axiom in determining business value drivers for development [7] (Wall, 2021). Cost modeling is a strong influencer of development prioritization, along with engineering, tooling software, operations, and finance, all are essential parts of a comprehensive strategy. With this in mind, the recommendation is to create a foundational basis for development work prioritization by clarifying how each influences the lifecycle.

- Engineering Deployment Of New Technology
  - If tooling systems are not built or updated for the new technology, what experiences would fail?
- Software Development
  - If there was no investment into the systems to maintain reliability, modernize, and grow in capacity, would the system tools become unreliable or unusable?
- Operational Requirements

    - How will features and functionality improve the experience and drive business value?
    - Will there be improved efficiency or saved time per task?
- Financial Requirements
    - Is there a positive return on investment (ROI) analysis of the cost to create the tool or enhancement compared to the value benefit for the business?

Overall, even when the answers to some, or all, of these questions, are yes, the development work still needs to be prioritized to optimize developer time. All of these factors require equal consideration when planning the development work. Discipline in the business strategy and execution lifecycle is the best way to ensure the internal users of the tools are utilizing them most effectively.

Success factors

In the overall business strategy, success factors can rely on many considerations. The first leading indicator of successful development is whether or not the tool has been adopted and utilized by its internal users. Simply put: Are people using it beyond the break-in period? Positive feedback would indicate that the work completed has made their job simpler or better in some way. The success criteria of adoption and utilization is a leading indicator of success, because if people are not using it, then there was no value in building it.

"Success equals adoption. If they adopt it quickly, they value it, therefore, they're less likely to work around it."

-Larry Wolcott, Engineering Fellow, Comcast

The second leading success factor is recognizing how the development of the tool is benefiting the business. This factor requires evaluating that the desired impact was achieved and is positively influencing user behavior. Too much information at the wrong time, or the creation of swivels, can cause team members to take more time to accomplish a task. Therefore, success comes from the reduction of time per task by improving the efficiency of the person using the tool. This reduction in time also creates a component of the payback model by illustrating the cost of build versus the improvement in technician efficiency. A hypothetical example of the influence of calculating task time is in Table 1, below. If in pre-development a task takes 5 minutes to complete, and post-development it takes 3 minutes to complete, the savings are demonstrable.

Table 1 - Business Benefit Calculation (Average Cost Is Illustration Only, Not Actuals)

	Task Quantity	Time Per Task	Average Hourly Cost	Task Cost
Pre Development	100,000	5 min	$60	$500,000
Post Development	100,000	3 min	$60	$300,000
Total Business Benefit				**$200,000**

The third success factor is confirmation that the tool developed achieved the intended expected results and business behaviors without creating more tools for the technicians and other internal users to use in the course of completing their work. The strategy to innovate and create new must be balanced with the roadmap of the legacy technologies and not perpetuate information overload for the users. The success could be measured by a metric to create more technician efficiency, such as reducing the time per task and thus improving operational metrics.

"The gauge of success is when the tool accomplishes a meaningful task and the percentage of users is high".

-Walter Breymeir, Field Operations Comtech, Comcast

The perspective of the end-user is the final success factor. The tool must be easy to use and provide the best information at the right time, without overwhelming, and be quickly adopted. The tool must be viewable in a consolidated way, to 1) minimize swivel, 2) reduce confusion on when to use the tool in what situation and 3) be easy to learn for its users.

As well, and from a good sense perspective, the tool must be cost-effective to be available to the broadest number of users for the least amount of cost. Choosing the right balance of information and finding the most cost-effective way to reach the largest number of users provides an avenue to optimize adaptability and usability. The information provided is a vital factor in preparing the training for new technology and supporting tools. The tooling systems must be intuitive and easy to learn. Training must be provided to the end-users to not only teach them new technology but to provide the team members time to absorb and learn.

"A tool could be great, but without training and it being easy to learn, it will likely fail to be used by the majority."

-Robert Snare, Field Operations Comtech, Comcast

9. Conclusion

The tooling abyss is a real and reasonably universal consequence of industry consolidation and the after-effects of growth-by-acquisition. There are the tools traditionally used by the field, then there are the "new" tools that come in through the different (acquired) doors. The tooling abyss is similarly fed by the technological advancements in adjacent and over-arching technology sectors, thus creating a myriad of information that needs to be quantified and managed to operate the business.

It is a top-down and bottom-up challenge: Large companies that became larger because of industrial and geographic consolidation are particularly susceptible to performance challenges associated with duplicative tooling. And, strong emotional attachments to favored or long-used tools, at the individual and small-group level, as well as the earnestly-developed patches and workarounds developed over time, can make it difficult to "centralize" tooling and related support.

The outcome is "tool sprawl," which is evidenced by the amount of new swiveling teams need to do across multiple applications, which serves only to add time to task completion and raise frustration. While it is true that as service providers, we "sit on" mountains of actionable data, the definition of "actionable" requires continuous attention. Too much information at the wrong time can lead to information avoidance and overload, both of which hinder operational performance.

When cross-department technology teams are not aligned, tool development can overlap, which also drives inefficiency for the business. There is a business cost when there is competitive conflict, inadvertently causing developers to work against each other, usually to achieve a desired or published performance metric. Strategic alignment is crucial to ensuring a collaborative instead of conflicting culture exists for the teams.

Therefore, a clear and comprehensive business strategy needs to provide clarity to streamline both the overall technology development process and the tooling process. Collaboration within a cohesive strategy is what generates an environment of optimized innovation. When the development lifecycle is optimally

based on a balance of experiences and wisdom representing engineering, software, operations, and financial elements, the resulting tooling products will drive business benefit most effectively.

Success factors hinge on meeting the needs of the internal users and business operations. Development teams need to ensure that system reliability is a foundational cornerstone because unreliable systems will not be adopted and utilized by users. Listening to feedback provides insight into why or why not the tool is being used. Two-way communication provides a conduit for information sharing for both the developers and the users. This avenue allows developers to aid in training and learning while receiving critical feedback on improvement opportunities.

"The measurements of reliability, adoption, and feedback determine why or why not tools are utilized and successful in meeting the needs of the business."

-Eric Wall, Executive Director Software and Development Engineering, Comcast

The tooling abyss can be avoided through an overall alignment in business strategy that integrates the views of multiple teams. Engineering, tooling software developers, operations, and finance teams must work together to commit to a business strategy that is effective for all. When there is a strategic commitment, innovation is increased, conflict is positive, complexity is reduced, and the overall health of the business improves. The tooling abyss ultimately becomes a manageable pool of critical resources widely adopted and utilize to optimize business initiatives.

1. Introduction

During the 2018 SCTE Cable-Tec Expo, panelists in a "birds of a feather" RDK session introduced the concept of a "Wi-Fi Happiness Index," abbreviated WHIX. Described as a weighted, realistic view of Wi-Fi behavior in a home, the WHIX index may involve more than 50 parameters, and very large quantities of machine-derived data. Since then, the WHIX concept has grown in breadth and depth, and is the topic of this paper.

The paper will cover what it takes to deliver per-device WiFi metrics, normally gathered across the industry, that contribute to an aggregate / whole house WiFi health assessment; what factors shape high and low WiFi performance; algorithmic detail regarding the non-linear aspects of whole-home "happiness;" and the value of customer feedback in informing health-centered WiFi metrics.

The paper will also cover best practices that can be proactively applied to WHIX assessments, in terms of recommended next steps. For instance, in situations where the WHIX score may indicate a suboptimal WiFi experience, a series of complementary algorithms can be run to evaluate different recommendations for improving the WiFi connection. For example, an algorithm can be run to determine if Wi-Fi extender "PODs" are recommended for this WiFi network. Attendees will also learn how WiFi health assessments can be applied to triage situations, and for engineering-level troubleshooting of new software releases.

1.1. The WiFi Happiness Index

WiFi is complex: The user experience of someone using WiFi is affected by multiple different WiFi conditions, occurring simultaneously. Even a WiFi subject matter expert can find it difficult to consider all the various WiFi conditions, assess the health of the WiFi network and determine how these conditions interact to affect the user experience. WHIX can be designed to process this complexity, with a goal of making it easy to understand whether a customer is having a good or bad experience. WHIX can also provide details on what is affecting each customer's WiFi experience.

WHIX can measure how well a WiFi network is working by modelling the WiFi user experience. It can provide details on specific WiFi conditions and how they correlate to good or bad WiFi connectivity. WHIX can assess the WiFi user experience at two levels: Per client device and for each WiFi network as a whole. Specifically, it can measure the WiFi connection on every client device in every network, every hour. It may also use this client device information to measure the user experience of each WiFi network. As API-based software, it may run in the cloud and can be integrated into other internal tools and UIs, including those used by field technicians to find and fix customer problems.

This may be used to assess the user experience for each specific WiFi client device. WHIX may also make it possible to understand the overall user experience provided by that WiFi network. Together, the per-device and per-network assessments may inform and model the WiFi user experience in a way that is intuitive and comprehensive.

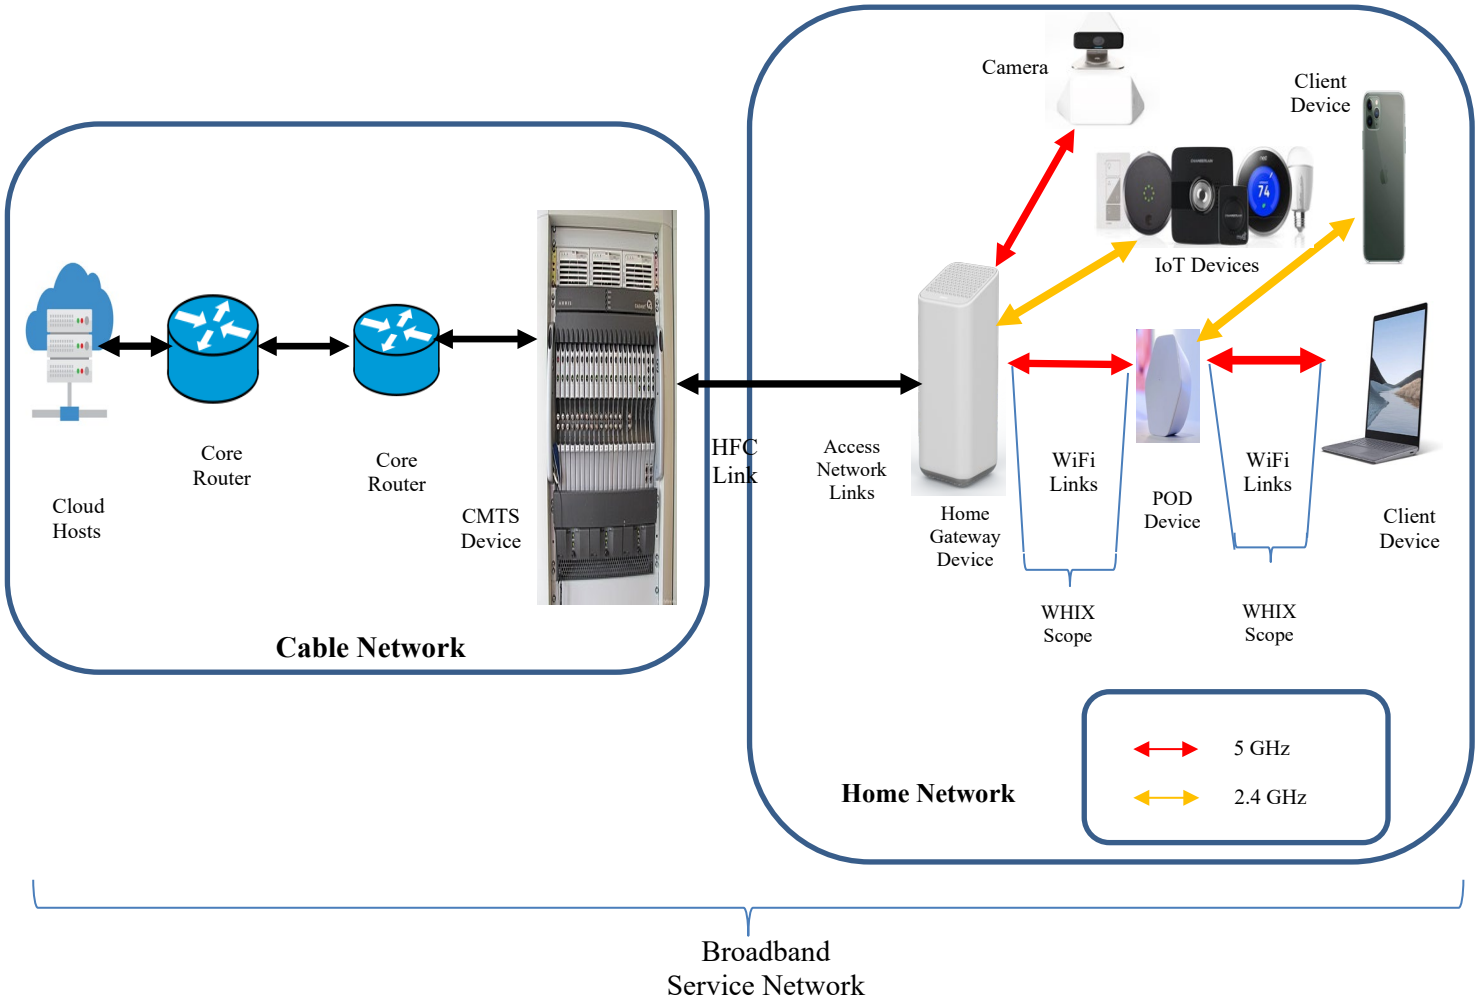

Figure 1 - The scope of the WHIX in an end-to-end broadband network

Figure 1 shows a typical end-to-end residential WiFi network. The cloud hosts the WHIX server components. The cable network component shows the typical network components, such as Core Routers and Cable Modem Termination Systems (CMTSs.) The "last mile" is over Hybrid Fiber-Coax and is connected to the Home Gateway Device (a WiFi router). Together, the Home Gateway and the WiFi extender "PODs" provide the WiFi service.

The WiFi router and WiFi extender PODs may use either dual-band (2.4 GHz + 5 GHz) or triple-band (not shown; 2.4 GHz + 5 GHz + 6 GHz) WiFi technology to provide high-speed connectivity. The WiFi extender (POD) is optionally used to improve the signal strength of WiFi in specific locations of the house. The various client devices shown in Figure 1 include a mobile phone, laptop, camera, and home automation devices, including a touch screen and various sensors. The Home Gateway device is

connected to the POD, client laptop and to the mobile device(s) on the 5GHz channel; the touch screen and the camera over the 2.4 GHz channel.

The scope for the WHIX WiFi assessment is all the WiFi connections (both the 2.4 GHz and the 5GHz) that form the end-to-end path between the WiFi gateway and each WiFi client device. Other links, including the core network and access network, are not in scope for the WHIX WiFi assessment.

WHIX uses a machine learning (ML) model to process raw telemetry data and create WHIX "scores" that can model the user experience. Each score is based on a 0 to 100 range. 100 may indicate the best possible user experience, and 0 may indicate the worst possible user experience. In practice, most scores fall on a sliding scale between these two extremes. Different industry implementations could use different score ranges based on the granularity of the score that is desired and the data available.

Figure 2 shows a sample of score interpretations.

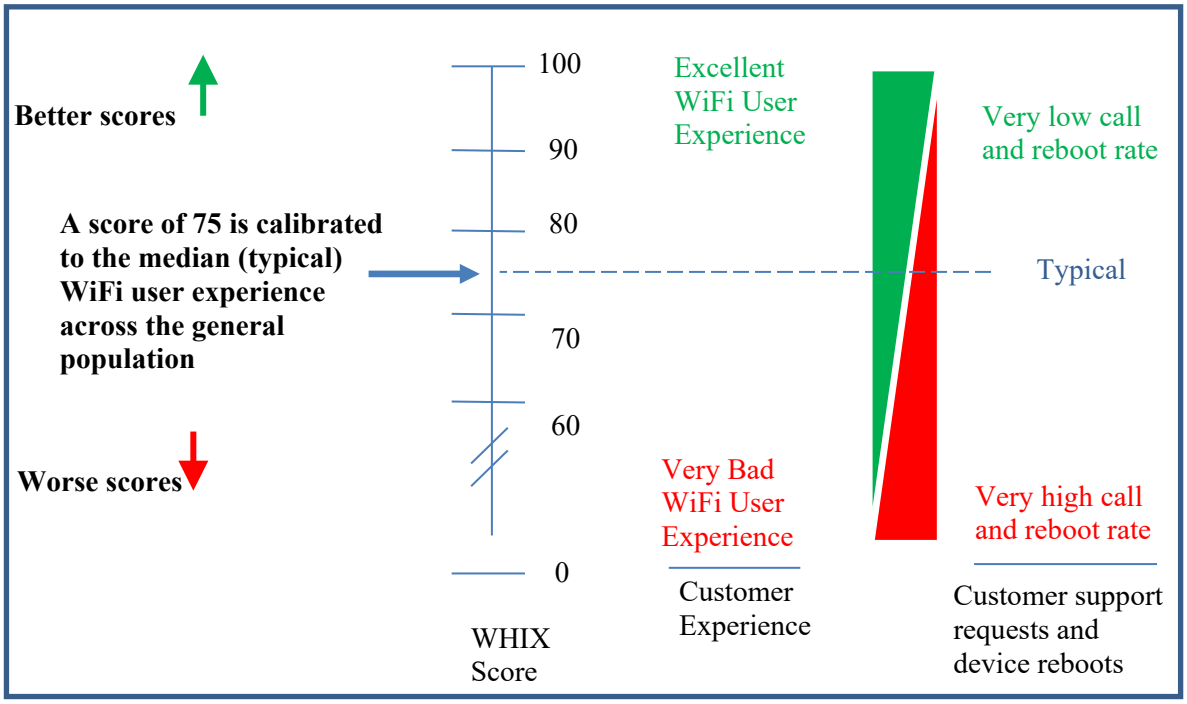

Figure 2 - The WHIX Uses Human-Readable Labels

The WHIX machine learning (ML) model can be trained using billions of historical WiFi data points collected over time from millions of WiFi networks. The ML model can be calibrated to provide a score of 75 when the user experience matches the median (typical) user experience. Scores greater than 75 may indicate a better than typical WiFi user experience. Scores less than 75 may indicate a worse than typical WiFi user experience.

A low WHIX score generally indicates a poor user experience and often results in a higher rate of customer support requests to the connectivity provider.

WHIX Scores may be mapped to human-readable labels. These labels may include:

- Excellent (scores >= 90 and <= 100)
- Very good (scores >= 80 and < 90)
- Good (nominal) (scores >= 70 and < 80)
- Bad (scores >= 60 and < 70)
- Very Bad (scores >= 40 and < 60)
- Extremely Bad (scores >= 20 and < 40)
- Worst (scores >= 0 and < 20)

Multiple factors simultaneously affect the user experience on a WiFi network. The WHIX assessment can consider both positive and negative factors to create these scores. When the positive factors are more significant than negative factors, the WHIX assessment score may be greater than the median score of 75. Conversely, when negative factors outweigh the positive factors, the WHIX score may be less than 75.

2. Telemetry data used by WHIX

One of the most common problems seen with WiFi is the change in the signal strength at different locations within a residence. WiFi signal strength can be a problem when the signal is too weak -- and can also be a problem when it is too strong. Weak signal strength can be caused by longer distances between WiFi devices and by obstacles that impact signal strength. Weak signals can be difficult for the receiver to reliably discern from background noise and interference. Very strong signals can sometimes occur when WiFi devices are too close to each other. Strong signals can overwhelm the dynamic range of some WiFi receivers and cause errors. WiFi tries to adjust for poor signal strength by changing how the WiFi signal is modulated. A lower signal modulation index can improve the reliability of the WiFi reception, but can have adverse effects, like lower throughput and higher channel utilization for a given bit rate.

Another common WiFi problem is high WiFi channel utilization. This is often expressed as the percentage of airtime used on the WiFi channel. The available airtime on a channel is finite, yet is used for multiple reasons. Airtime is used by the WiFi stations and access point(s) (APs) in the WiFi network being assessed; by WiFi networks in neighboring homes/businesses; and by non-WiFi RF sources such as baby monitors and microwave ovens. When a greater percentage of the available airtime is consumed, WiFi devices must contend with other WiFi devices to access the WiFi channel. As a result, the WiFi channel utilization increases. High WiFi channel utilization can cause the following undesirable scenarios:

1) *It becomes more difficult for WiFi stations and access points to send traffic.* During periods of high channel utilization, WiFi devices often wait for other WiFi devices to finish transmitting before the begin sending their data.
2) *There's a greater chance that multiple WiFi devices will attempt to begin transmission at the same time*. This can cause collisions, such that none of transmissions can be received.
3) *It can cause higher latency*. Higher latency means that packets incur longer delays. This reduces the user experience of delay sensitive applications like interactive games.

It follows that lower WiFi channel utilization can cause improved latency, improved throughput, fewer dropped packets -- and an improved customer experience.

Many other factors can affect someone's WiFi experience. These include downlink and uplink PHY rates, MCS (Modulation and Coding Scheme) levels, the background RF level (also called the "noise floor"), and Signal to Noise Ratio (SNR). Also impactful: The rate of packet re-transmissions on each client device; the rate of lost packets (when all retransmissions fail) on each client device; service availability (percentage uptime) of the access points in the WiFi network; and the ability (or inability) of WiFi clients to sustain the WiFi connection (measured as "rapid reconnects"). The total number of WiFi clients on each WiFi channel can impact performance, as can the rate of WiFi password failures, the configured maximum channel width, the operating channel width for each client device, media access delay for transmitted packets, the ability (or inability) of the network to steer each client device to a closer AP or steer that client device to a better WiFi band, QOS configuration/usage -- and more. It's a long list!

These WiFi factors tend to affect different WiFi client devices in different ways. This is because different types of client devices use WiFi very differently. For example: WiFi cameras use more uplink bandwidth (in the direction toward the access point) than downlink bandwidth. This makes WiFi cameras more susceptible to problems that impair uplink data transmission. WiFi media players and set-tops use more downlink bandwidth, so these are more susceptible to downlink-related problems. Other devices, like IoT sensors and thermostats, use very little bandwidth and can successfully operate at low PHY rates -- but must have extremely reliable connections. Still other devices, like game consoles, tend to be more sensitive to latency. WHIX may use a mapping of client device "fingerprint" data to categorize client devices into one of multiple WiFi device categories. WHIX may consider the WiFi device category when analyzing the WiFi user experience for each client device.

These factors can work in combination to affect multiple WiFi links used to create the end-to-end connection for each client device. For example: when a client device is connected to a gateway that provides both a WiFi Access Point and the home's WAN service connection, then only a single WiFi link is used in the end-to-end path between that client device and the WAN connection. In the case where a client device is connected to an access point provided by a WiFi extender POD, additional WiFi link(s) can be used to backhaul traffic to the WiFi gateway that includes the WAN service connection. In this case telemetry data from multiple WiFi links may be analyzed to understand the user happiness for that client device.

This telemetry data may be collected by both main WiFi gateway access points and WiFi extender POD access points. WHIX may import this data and use it to measure how well WiFi is working for each client device and for each WiFi network as a whole.

3. WHIX algorithm overview

The algorithms that can be used to create a WiFi Happiness Index may use a supervised ML training model based on this WiFi-related telemetry data. Telemetry data may be sourced from each of the Home Gateways and WiFi extender PODs, in millions of homes, and aggregated as anonymized high level statictics to train the ML model.

Client types spanning nine WiFi categories may be derived from device fingerprint data (see Table 1). In a typical iteration, the training model may examine >4K specific WiFi conditions over these nine different client device types. This model may form the core of the WHIX analysis and feed the outputs of the WHIX API.

Table 1 - Types of WiFi client device categories assessed by WHIX

WiFi Client Device Types Categories Assessed by the WiFi Happiness Index
1. Broadband Devices: Smartphones, laptops, tablets
2. Media Players: Smart TVs, streaming video devices, streaming dongles
3. Media Sources: Cameras, streaming servers
4. IoT / Printers: Thermostats, lightbulbs, sensors, and networked printers
5. Managed Set-tops
6. Managed WiFi Extender PODs
7. Audio Devices: Smart speakers, connected audio devices
8. Network Devices: Customer-owned WiFi extenders, etc.
9. Game Consoles

4. Training the Machine Learning Model

Multiple feedback mechanisms can be used to determine WiFi conditions associated with user happiness (or pain) with WiFi connectivity. These feedback mechanisms can include User Contact Rate statistics and Unscheduled Reboot Rate statistics.

Customers contact their service provider for many different reasons. Some contacts are for questions about billing or if the customer wants to upgrade/downgrade service. Other contacts occur when the customer needs help to resolve a WiFi-related problem. As an indication of WiFi-related user happiness, customer contacts may be filtered for contacts related only to connectivity problems. After filtering, connectivity-related contact rates may be compared with connectivity-related contact rates for the general (total) population of all customers. A higher rate of connectivity-related contacts may be associated with a poorer WiFi experience. A lower rate of connectivity-related contacts may be associated with a better WiFi experience.

Gateway reboots can occur for a variety of reasons. These may include “scheduled” reboots that coincide with software upgrades during a late-night maintenance window. Reboots can also occur during “unscheduled” times. Unscheduled reboots can occur as a result of power outages, software “self-heal” mechanisms and because a customer reboots the device. Many customers may reboot their WiFi gateway when experiencing a WiFi related problem. A higher rate of unscheduled gateway reboots may be associated with a poorer WiFi experience. A lower rate of unscheduled gateway reboots may be associated with a better WiFi experience.

WHIX ML models may be trained using statistical feedback from both user contacts rates and unscheduled reboot rates. Different ML models can be trained for different WiFi client device categories.

First, each WiFi-related condition (WiFi criterion) may be mapped into a range of values called a "bin". Bins may be constructed based on the distribution of telemetry data, so that enough Boolean "matches" occur within a bin range (where possible) to have sufficient data to avoid noise. For example: a bin may be used to characterize channel utilization (CU) criteria in the ML model might include all CU telemetry values greater than 22% and less than or equal to 25% for the client device category of "Media Player" devices.

Next, correlation may be measured for each WiFi criteria bin with customer contacts related to connectivity. For each bin (range of values for a single WiFi criterion), the percentage match rate in the population that made contact with the service provider for connectivity-related issues within the previous 24 hours may be calculated. This may be calculated by dividing the number of criteria matches for this bin range (which occur in the customer population that made a connectivity-related contact in the previous 24 hours) by the total number of telemetry reports received for any value of this WiFi criterion.

Then, the "Criteria Match Difference" (CMD) may be calculated to compare this match rate by this criteria match rate in the total general population. For example, if the criteria match rate for this bin range in the population with connectively-related contacts is 10% higher than the criteria match rate for this bin range in the general population, then Criteria Match Difference = 110%. CMD values equal to 100% may indicate that when conditions match this criteria bin range, there may be no effect on customer happiness. CMD values higher than 100% may indicate a poorer customer experience compared to the general population. CMD values lower than 100% may indicate a better customer experience compared to the general population.

The same process may also be applied using feedback from unscheduled reboots. This may establish correlation between each specific WiFi criteria bin range and customer happiness as indicated by unscheduled reboots.

This process may be repeated for more than 4,000 combinations of WiFi criteria bins across the 9 client device types.

Based on this correlation data, an algorithmic weight may be calculated for each of the 4,000 WiFi criteria bins. Positive weights may indicate WiFi conditions that correlate to WiFi user happiness that is better than the general population. Negative weights may indicate WiFi conditions that correlate to WiFi user happiness that is worse than the general population. Zero weights may be used to indicate correlation with the typical WiFi user happiness level (same user happiness as the general population). For each WiFi criteria, the weights for all bins in the ML model may be normalized such that positive weights offset (balance) negative weights across the total population.

The ML models may be re-trained for every WHIX software release. This may recalibrate WHIX to support and track with all new WiFi Gateway models, extender PODs models and software versions. Each new WHIX software release may typically also expand the ML model, to include new WiFi telemetry data that may become available since the previous release.

5. How WHIX uses the Machine Learning Model

After the ML model may be trained and validated, it can become available for use by WHIX. The following is a description of how WHIX could use this ML model.

On each telemetry interval (currently each hour), WHIX may use the ML model to assess the WiFi conditions for every client device in every home. First, all available WiFi telemetry can be collected from

the WiFi gateway and from all extender PODs in that home. Telemetry for device fingerprinting can also be collected and used to map each client device into one of the 9 WiFi device categories. The WiFi telemetry data may be used to create a Boolean match for a specific bin range of each WiFi criteria.

- For example, if fingerprint data maps client device "A" to the WiFi device category of "Media Player" then the section of the ML table for Media Player devices can be used.
- Then all WiFi telemetry may be compared to the bins defined in the ML model. For example: telemetry for 2 GHz Channel Utilization is collected for all access points used in the end-to-end path for client device "A". If the telemetry indicates 10% channel utilization on the WiFi gateway access point and 42% channel utilization on a WiFi extender POD used in the end-to-end path for this client device, the larger (worst) telemetry value from these 2 WiFi link may be used.
- In this case, a channel utilization telemetry value of 42% may match the 2 GHz channel utilization criteria bin may be defined as "greater than 40% and less than or equal to 45%". Once this Boolean match is determined, the weight for this bin may be used to indicate the user impact of this individual WiFi criterion. In this case, the weight may be -2 for this bin range of Channel Utilization for media player devices. A weight of -2 may indicate that this condition may correlate with a very slight negative impact to the user's WiFi experience.

Next, the process may be repeated for all other telemetry data that was collected on all WiFi link(s) used for the end-to-end path to client device "A". Each additional telemetry data value may be processed by the ML model to add an additional weight for each WiFi criterion.

All weights for all criteria matches for client device "A" may then be summed and added to a value of 75 that can be used tonormalize the WHIX score to the typical score in the general population. This calculation may provide the WHIX score for client device A for the most recent hour. If the WHIX score is greater than 75, this may indicate that WiFi conditions on the links used for this client may provide a better-than-typical user experience. If the WHIX score is less than 75, it may indicate that WiFi conditions provide a worse-than-typical user experience. Previous scores may be retained to support historical views and trend analysis for this client device.

Next, the WiFi network for that home as a whole (WHIX account score) may be evaluated. This process may use the client device scores in that home to calculate an overall WHIX account score for each hour. This may involve analyzing the client device scores to determine which client devices provide the worst WiFi experiences in that hour. The set of these worst devices may then be used, along with an adjustment to recalibrate the median (typical) account score to 75, to create the WHIX account score for that hour.

WHIX can be analyzed over time. Various statistical analysis methods may be used to aggregate WHiX time series data and characterize the WiFi user experience over extended time periods. Statistical methods that provide the best predictor that the customer will/will-not contact the service provider and/or reboot their gateway device within the next 24 hours may have the best correlation with user WiFi happiness.

6. Benefits of WiFi Performance Monitoring

The WHIX concept may enable service providers to determine the quality of each customer's WiFi experience, per connected device and for every customer's account as a whole. This can enable service providers to see the most sample interval (based on available telemetry data) and also see a timeline that shows historical views, including any times when the customer's WiFi experience was materially better

or worse. Data may also provide indications of what caused the customer's WiFi experience to be better or worse for each hour. The detailed data may indicate the root cause of what affected the customer's WiFi experience, and can be used to troubleshoot and remediate any problems. WHIX output data may be provided via an API that supports integration into various user interface tools.

Incremental software upgrades dispatched to Home Gateways and WiFi extender PODs may also have an impact on WHIX scores due to changes that have been incorporated into a software version. By monitoring highlevel statistics based on WHIX scores, service providers can determine if the WiFi quality has changed. If the WiFi quality has degraded, coincident with a software upgrade, the problem can be proactively identified, triaged, and remedied with new software that includes the appropriate fix. This may reduce customer contact rates and may help provide a quick fix to a potential customer-impacting problem.

Monitoring the WiFi Happiness Index may help in troubleshooting difficult issues that normally surface over time. It may also help to narrow down whether problems are intermittent or persistent.

WHIX can also be used with other cloud-based tools to create automated recommendations to improve the WiFi user experience for each home. This can include automated recommendations to perform specific targeted action(s) designed to improve the WiFi network in each individual home.

7. Conclusion

This paper illustrates a comprehensive concept for monitoring and assessing the user's WiFi experience at the per-user and per-client device level. The concept provides details that can be used to troubleshoot common customer WiFi problems. WiFi Happiness Index (WHIX) can be based on a Machine Learning algorithm that models how various WiFi conditions can affect user happiness with each of multiple WiFi client device categories, ranging from laptops and phones to IoT devices, for every account holder, every sample interval.

By using this concept, technician and care agents may identify specific client devices and specific accounts that are may experience WiFi-related issues, and, importantly, may recommend solutions to solve those problems.

WHIX can also be used to measure the aggregate user WiFi experience in WiFi gateway and extender POD software releases. This can be measured in early trial groups and/or in lab test environments. By comparing the aggregate WiFi experience on successive software releases, service providers can identify hidden software problems and prevent problematic software releases from being widely distributed. Conversely, it can be used to identify software releases that improve the user's WiFi experience and/or confirm the customer experience benefit from correcting previous software bugs.

The Zen of Ticketing

Operational Transformation

A Technical Paper prepared for SCTE by

Melissa Wood
Sr. Director Reliability Engineering, Program Management
Comcast
183 Inverness Drive West, Englewood, Colorado
719-491-0457
Melissa_wood@cable.comcast.com

1. Introduction

Enterprise ticketing systems are among the vital subsystems that "keep the lights on" for broadband service providers – or, more accurately, keep service-related lights off. Service-related tickets, not unlike the complex and interwoven landscape of "tools," in general, are foundational for identifying, tracking, and resolving internal and external operations, from scheduled maintenance to incident handling. For those reasons, ticketing systems are often as layered and difficult to detach as multiple layers of wallpaper on a wall -- they got that way through decades of growth, patches, ownership changes, and management shifts (e.g. from centralized to decentralized and back again).

As the title of this paper indicates, this paper is about how to get to "zen" when it comes to incident and trouble ticketing. We define zen as a general state of enlightenment attained by summing the parts, which in this case, are the many different ticketing systems acquired through decades of individual acquisitions that helped defined our industry's consolidation.

In this paper, we will share how and why Comcast pivoted toward a unified ticketing system -- including what constitutes realistic expectations, lessons learned, useful metrics, and best practices. We will characterize what it takes to unify multiple ticketing systems, so as to attain the benefits that come from operational scale.

2. Ticketing Infrastructures: The Backstory

Comcast provides multiple services to customers to help keep them connected, everywhere, all the time, across a large geographical footprint. From traditional cable television, to Internet, phone, security, and wireless, Comcast and the cable industry deliver products every day that consumers expect to 1) be there when needed, which is all the time, and 2) evolve gracefully.

Overall consumer desires for service availability and speed puts extra emphasis on our engineering and operations teams to execute reliability measures in ways that get a "thumbs up" from consumers every time. Moreover, managing changes to the network production environment, so as not to cause self-inflicted outages, is part of what prompted Comcast to move towards a unified and enterprise-wide ticketing infrastructure.

Why does this matter now? The complexity of the network topology, coupled with heightened consumer expectations, requires a scalable solution. We can no longer "throw more people at it," when it means trying to manually understand all the many cross-departmental tickets and alarms, all firing inside an increasingly complex network topology. The answers require people and technology.

Like many of you reading this, Comcast "got here" through multiple acquisitions, as a result of a heavy few decades of industrial consolidation. This coupled with understandable and necessary localized network requirements at the regional and divisional levels, produced differing hardware, software, and – tantamount to this discussion – ticketing systems, especially as it relates to managing outages and network upgrades. As a direct result, processes and tools vary across our different engineering and operations teams.

Collaborating during an upgrade or outage event demands teams chat on different platforms, and to document ticket information in multiple places to keep stakeholders informed. These variations cause unintended delays to resolve the customer's impairment, resulting in their inability to use services they pay for. The ability to scale and reliably manage the network is more important than it has ever been.

Basically, to provide new and highly reliable services to customers, at scale, requires pioneering towards one network, end-to-end -- including ticketing -- across people, processes, and technologies.

Moreover, our employees provide great feedback on a regular basis about on-the-job processes that are difficult or could be approved upon. Now is the time to make those processes straightforward with the same execution regardless of the geographic location. Building a unified enterprise ticketing infrastructure sets the tone and removes assumptions, which gets us closer to full operational transparency.

3. The Challenges of Managing Outages and Network Upgrades

Tools and processes across Comcast vary when it comes to managing outages and performing network upgrades. Any service provider that grew its geographic footprint by acquisition, then resolved to consolidate and cluster its holdings, invariably faces an avalanche of tools, like ticketing systems, that are used regularly, thus are familiar, yet they all do essentially the same thing. Our internal analysis, for instance, revealed numerous siloed applications that existed to support teams doing incident and change management. Such replication of records adds risk to delivering reliable services -- risks that are potentially service-impacting, thus customer-impacting. Like all service-minded broadband providers, we continually upgrade our network to provide more products and services, with the very specific intent to be "always on." This good work can be overlooked, especially if an outage accompanies an otherwise proactive change.

Data or configuration items (CI) tend to be stored in many different tools and can lack a standard way of providing relationships between them. A CI represents service components, infrastructure elements that need to be managed for successful delivery of services. An example is network components, such as, routers, hub, gateway, etc. Technologies vary greatly from group to group, when it comes to how hardware and software is monitored. Teams tend to work outages from the same CI, producing up to 20 tickets for a single impact, which also produces multiple instances of repeat communications.

Impacts in the network drive impairments to applications that both customers and employees use. When individual teams are working in a silo to conduct incident and change management, the number of incident tickets are inflated, and duplicate technical and executive communications are distributed. Change tickets themselves can result in an outage, due to not having robust conflict assessment across the company. While we are in a far better place than we were 5 to 10 years ago, when it comes to "swivel chair" operations, engineers still spend time manually looking up needed information to solve an outage, having to swivel between tools to manually enter data needed either in an outage or change ticket.

Another contributing factor is alarm correlation across topologies and different activities. When alarm correlation is weak, it is often because root cause analysis is often only done on "severity one and two" tickets, which only equates to about a quarter of the workload. Lower-level severity tickets are created only to form documentation to identify patterns and trends. "Parent" and "child" tickets aren't always properly linked, which puts a weak spot again on correlation. The amount of manual work performed by engineering and operations teams can delay outage mitigation, degrade the customer experience, and limit the ability to scale needed changes within the network.

The guiding principle towards any major overhaul to how development and operations teams work together is to create a vision with shared visibility, communication and collaboration that embraces working together in a blameless culture to drive continuous improvements, always.

4. Transparent Ticketing Processes Create Reliability

Developing a transparent ticketing process for higher reliability is easier said than done! Assessing the nuts and bolts of how your organization is operating today to the desired future state will create a shared vision for alignment utilizing best practices others have identified.

A reliability vision spans people, process, and technology. From a people perspective, there is a need to have clear, accurate and timely communications to the appropriate technical, executive and customer audiences. Processes should establish a robust, data-driven culture to drive resource allocation appropriately. The technology should provide a framework to build automation that decreases outage impacts and reduces unnecessary and especially duplicative labor.

There are several steps outlined in this section that helped to organize the Comcast journey. These steps provided a framework that guided teams through design, to the transition into the zen of ticketing, and eventually to operationalizing ongoing practices.

4.1. Analysis Overview

The first step in this zen of ticketing journey was to identify a solid framework (or two!) to manage the enterprise architecture. The three most common that engineering and information technology (IT) leaders lean towards to accelerate automation of things are information technology infrastructure library (ITIL), site reliability engineering (SRE) and development and operations (DevOps).

Our approach involved blended principles from SRE and ITIL to drive innovation through an agile continuous learning model. ITIL has provided common best practices helping across many operational teams, while SRE brings to light self-service tools and automation scripts. The models together increase reliability and performance of applications and services as manual work decreases. With a constant eye toward automation of manual processes brings the ability to auto-mitigate, remediate, and removes manual labor.

First, we will address the ITIL model. The ITIL is a five-step process to measure, report, plan and implement quality improvement cycles for ticketing operations. Its core components, including Service Strategy, Service Design, Service Transition and Service Operation, provide the framework for continual service improvement. The ITIL service management lifecycle provides guidance for implementation of a configuration management database (CMDB), event, incident and change management with policies, guidelines, and streamlined processes. The is extremely important, as it provides the capability to build physical and software configurations items into relationships that serve as the base for incident and change tickets. It also sets the foundation for automation, and aids in understanding customer impact. Figure 1 shows the ITIL core components (Ghadi, 2011).

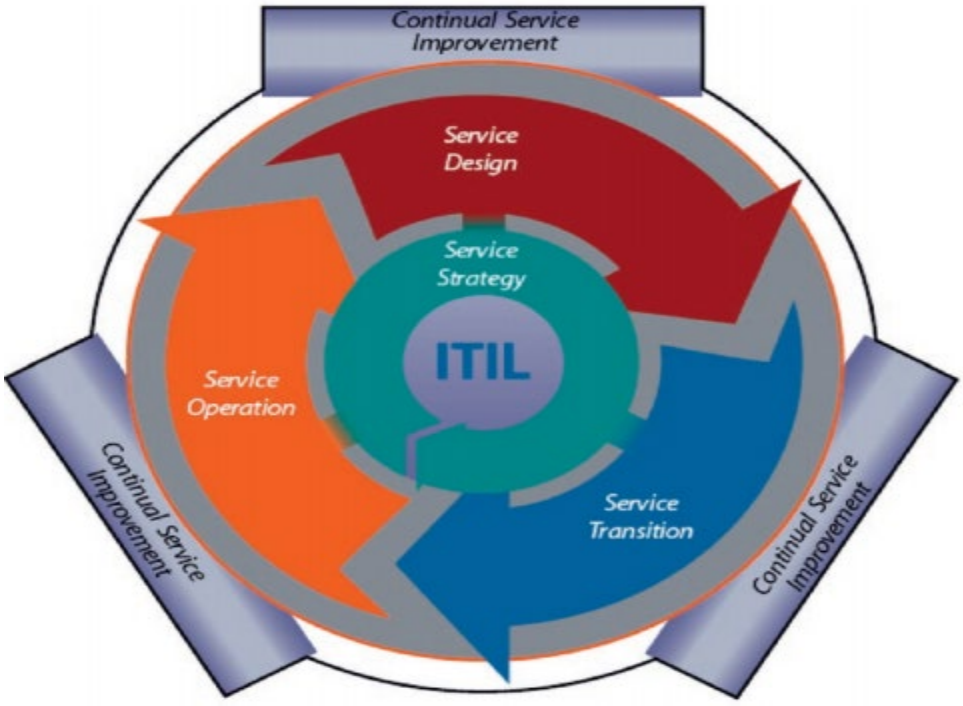

Figure 1 – ITIL Core Components

The ITIL components guided us through the common network enterprise architecture layers of business, data, solution, and technology. The focus on the four common network enterprise architecture layers was intended to reduce duplication, and to set the stage for automating certain repeatable tasks. The layers, informed by the focus needed to achieve a single ticketing platform, included:

- Business architecture or processes to define the strategy for moving people, process and tools to a single ticketing platform. Such as "governance" to inform key business processes.
- Data will include a standardized CMDB to identify physical assets, with relationships that tied to incident, change and problem management tickets.
- A solutions architecture to provide a blueprint of the end-to-end ecosystem, especially with regard to how applications will connect and get deployed.
- A technology architecture to assess what software is appropriate to support the evolution of a single ticketing platform. This view defines applications, databases and how they bridge together.

Each layer provided a different view to achieve the desired ITIL enterprise architecture. The viewpoints consisted of the following components:

- Business
    - A detailed vision to achieve best practices to transform the enterprise to a single ticketing platform

    - An ITIL Service Strategy to guide the design, development, and implementation of service management lifecycle with policies, guidelines, and processes

    - A review of current practices to understand “must have” end user requirements to align to future state
- Data
    - CMDB model with relationships diagramed
    - Schema of Incident, Change and Problem workflows
- Solution
    - Ecosystem design to map out process and software connections
    - Defined service level agreements supporting Incident, Change and Problem processes
- Technology
    - Identification of tools and service delivery platform

The second model we utilized is at the heart and soul of Google as they discovered a need to manage risk and growth called “Site Reliability Engineering” or SRE. SRE goes down the path of having software engineers that have the drive and ability to automate across complex architectures. Scale and reliability are created to manage higher volume of changes to your network with this methodology.

Figure 2 – SRE Key Principles

As shown in Figure 2, SRE drives resiliency into infrastructure and workflows that provide automatic responses with code to what humans have previously done (Site Reliability Engineering, 2020). This practice can transfer operational work into development tasks. As with the ITIL framework, SRE has five base elements to guide towards a software engineering model:

- Business communication for clear alignment on the definition of reliability with service levels that have associated impact.
- Architecture creation of scalable systems that have resilience to reduce outages.
- Build and run using automated toolchains for provisioning and deploying code is the foundation of automating manual work.
- Operating and monitoring aspect to measure everything that matters via service level indicators (SLI) and service level objectives (SLO) to assist with business impact.

- The SRE culture is set up to define a mix around 40% software and 60% administration system capabilities, with each SRE having accountable SLOs.

Implementing an SRE environment provided a higher ability to complete errorless transactions with proactive monitoring that frees the team to work on structural improvements at a more rapid pace. SRE provides not only definition for how to improve reliability, but also provides engineers with the opportunity to build and design instead of just putting out fires. Google has taken lead with the SRE role and methodology to foster sustainability and operational resiliency of all digital assets. Figure 3 provides a sample of what a SRE engineer focuses on (Feoktistov, 2021).

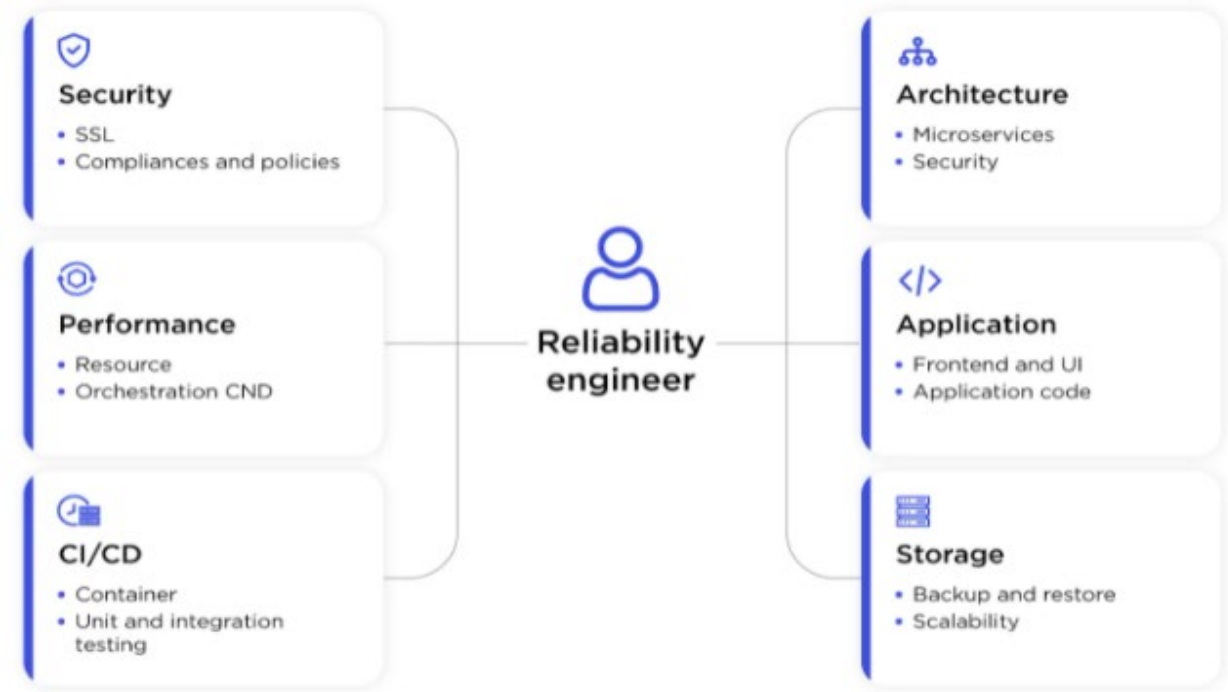

Figure 3 – Site Reliability Engineer Responsibilities

Comcast benefited from a blend of ITIL and SRE to address processes across the organization, as well as the complexity of the CI that existed, with a focus on eliminating manual work. The next step involved mapping out the benefits of this approach, in order to address the question of why any company would break down their current ticketing infrastructure and drive their teams into a single platform. Streamlining incident and change tickets to lower the amount of manual work, improving communications and building an ecosystem to remove toil to help set the stage for scalability are but a few answers to that question. To get to where you are going, you must understand where you have been. Table 1 defines the who, what, why, when, how and where of mapping the current state of ticketing to the future zen state of ticketing. This exercise is intended to understand the different audiences and how they will be impacted.

Table 1 – The Zen of Ticketing Platform Analysis

Classification Names / Audience Perspective	**Who** People, resources	**What** Entities involved in each perspective	**Why** Goals, objectives & business plan	**When** Time and performance criteria	**How** Functions in each perspective	**Where** Locations and interconnections within the enterprise	Classification Names / Model Names
Executive Perspective	List of all teams doing Incident and Change tickets.	List of what each team is responsible for, inventory list and best practices for Incident and Change tickets.	List of benefits for moving to a single ticketing platform.	SLAs for managing the Incident lifecycle from open to mitigation to close; Change ticket lifecycle.	List current & future state to identify transformations to include governance process for future state.	Map of geographical locations to show how they are interconnected.	**Scope Contexts**
Business Management Perspective	Define roles and responsibilities across teams.	Process flow diagrams showing inventory across processes, to include CMDB	Remove duplicate tickets; Create change risk model and conflict assessment.	Determine time needed to get to future state.	Diagram inputs and outputs across process transformations.	Define distribution.	**Business Contexts**
Architect Perspective	Understand system roles to define CMDB for inventory to feed Incident and Change tickets.	Schematic showing inventory across processes, to include CMDB.	Diagram showing system end state CMDB lifecycle.	System timing representation.	System process representation.	System locations.	**System Logic**
Director Perspective	Technology role diagram.	Inventory configuration.	Software selection.	Timing to implement technology.	Software process representation.	Technology locations.	**Technology Physics**
Engineer Perspective	Tool and security roles.	Data definition	Rules for software implementation.	Timing to implement technology.	Process configuration.	Distribution configuration.	**Tool components**
Enterprise perspective	Organization	Data	Strategy	Schedule	Function	Network	

4.2. Future State Network Enterprise Architecture

As stated, ITIL provides a recipe for reliability practices. Figure 4 shows the main areas of focus to improve incident and change management processes. Comcast chose a third-party platform with plugins to align with overall business strategies, including financial planning, applications testing, agile development, and project management, to name a few. The Service Strategy, Service Design, Service Transition and Service Operation guided the team toward agreed-upon implementation plans. An internal SRE team was created to configure the platform towards the aligned future state with a focus in the following areas (IT Service Management, 2019):

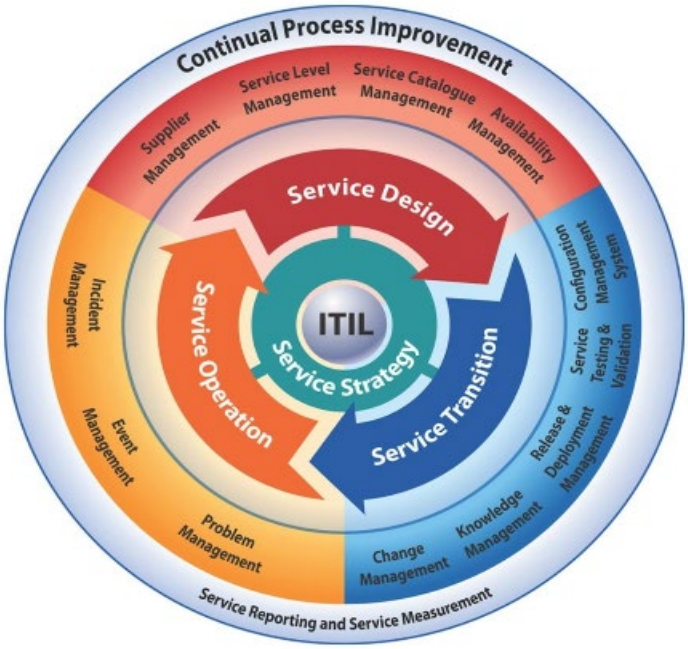

Figure 4 – ITIL Lifecycle Architecture Support

- **Configuration Management Database (CMDB)** – provides the capability to build physical and software configuration information into and between relationships that will be the base of incident and change tickets. This sets the foundation for automation and aids in understanding impact.
- **Incident Management** – provides a single platform for cross-departmental teams to work in unison on outages, with a focus on improving time to engage, time to mitigate and time to restore an outage with strong reporting.
- **On-Call Scheduling** – provides automated escalation from an incident ticket for fix agents to get engaged on an outage.
- **Problem Management –** provides the ability to perform trend analysis, within the same single platform, while tracking internal and third-party vendor action items
- **Change Management** – provides a single platform with a systematic, trackable and controlled approach to the lifecycle of all changes, enterprise-wide, to understand conflicts and customer impact.

4.3. Implementation Plan

Migrating to a zen of ticketing state requires a lifecycle strategy. Collaboration between the team managing the business change, and stakeholders of all impacted teams is key. The zen of ticketing strategy, goals and teams were documented and approved by senior leadership to ensure alignment with the future state. Figure 5 provides an example team structure to build a focused team.

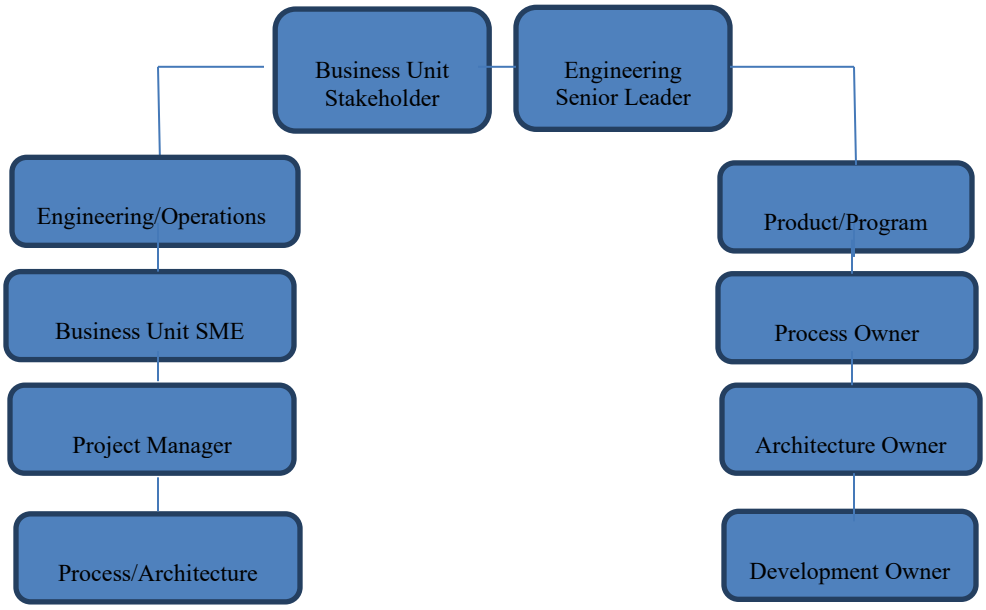

Figure 5 – Implementation Team Structure

Implementing the role of a "product owner" provided a liaison structure across multiple teams to learn and decide how to move through the lifecycle implementation plan. As the discovery process took place, the product owner facilitated the conversation to understand each team's current as-is state, mapping to the future state. With the support of senior leaders, the business goals identified a future visionary state that included the benefits of implementing a new architecture. One might call this a product roadmap and/or charter that is then socialized with teams during a kickoff session. The product manager worked with stakeholders to identify what the "day one" experience would look like, and the architecture team gathered the information it needed to draft different viewpoints to illustrate the alignment.

As the experts on the new technology, the process team mapped current workstream processes to the future state, being careful to identify areas where people would need to change what they were doing. Once the new architecture is approved, the product team will create and submit "stories" for the development team. A story in this context describes what the business is aiming to achieve with incremental code development. The number of stories identified will determine length time needed for development.

The development methodology is necessarily agile and iterative. As functionality is ready to be reviewed, visual demos and user acceptance testing will commence. As each functionality piece is finalized in the lower-level environment, process documentation is created, which will also support training efforts. Training needs may vary by team; therefore, this segment is handled uniquely to ensure the "people readiness" aspects cover awareness, desire, knowledge, and reinforcement. The overarching goal is that teams understand the "why" behind the change. Figure 6 displays the milestone implementation steps for the focused areas each team will need to accomplish.

	Workstreams	Discovery (3 months)			Design (3 months)				Development (3 months)			Onboarding (3 months)		Gating Dependency	Risks	Mitigation
		Kickoff	CMDB Current	Process/ Tools Current	Access Setup	CMDB Future	Process/ Metrics Align	Prod Day 1 New	Req Stories	Arch	Dev UAT	War-game	Training

LEGEND: On track; At risk; Blocked; Completed; Not Started

Figure 6 - Enterprise Architecture Implementation Plan

The mission-critical business drivers encompass improvements that are required in the data and process sections of the workstreams. This, along with developing the overall technology ecosystem, will drive duplicate tickets to one in the single zen platform. Repeatable steps will be identified through discovery, with a focus on automating where it makes sense. The implementation lifecycle can vary depending on the complexity of the network topology and availability of source data. Designing a governance process will help manage the aligned continuous improvements, timeline, and resources required. Finally, regular communications are critical to keep the program team engaged along with leadership across the enterprise. Long term programs can easily succumb to distractions if there is not discipline around program and communication management dwindles.

5. Agile Solutions With Continuous Learning are the Way

Organizations that adopt learning as a practice increase the chances of continuous improvement, while promoting a culture of knowledge and innovation. Leading with a mantra of transparency in all operational and engineering practices also helps to cultivate a blame-free culture. Agility sets boundaries for how to work, in preparation for being able to pivot to new processes and technology. Those pivots may arise because of business needs or competitive threats; in all cases, the customer always plays the primary role. As a result, team environments that achieve shared milestone objectives are more productive, and more emotionally satisfied with their work. A scaled agile framework provides three critical dimensions to help build a learning culture, as shown in Figure 7 (Continuous Learning Culture, 2021). All three dimensions speak to employees at every level to foster growth and transformation.

Figure 7 - The Three Dimensions of a Learning Culture

5.1. Lessons Learned and Pro Tips

As we continue our journey towards the zen of ticketing, we identify a few pitfalls to help our readers avoid those things that can disaffect their single zen ticketing aspirations.

The first lesson learned involves the objective, the goal, and the timeline for a single zen ticketing initiative. Most cable operators already have a ticketing system (or 20!) in place that may have been created over the past 15-20 years. Be sensitive to the time and people that it took to build what worked well until now. Set smaller and realistic timelines that create incremental improvements over time. A governance process will help keep those involved grounded as to what the next quarter's commitments will bring.

A second lesson learned involved the CMDB. As described earlier, the CMDB provides the capability to build physical and software configurations items into relationships that serve as the base for incident and change tickets. It also sets the foundation for automation, and aids in understanding impact.

"Do not underestimate the value in moving towards a single solution that can provide automation and correlation of events, so that engineers can focus on the problem instead of being ticket jockeys," noted Rich Massi, VP, Reliability Engineering Residential Products and Services, who shared his viewpoints during an interview. Build a process to stay current, because the CMDB is never done. Also important is how and who best maintains the CMDB's governance and data quality processes.

Automation is a key aspect of moving into a single zen ticketing platform. Covet all insights about how to perform a task, should automation break or go down -- it happens. Ensure everyone understands manual processes from the beginning, before automating tasks. (You can thank us later for this one!)

Call it what it is. The bigger the organization, the higher the likelihood that big software initiatives like ticketing will come with a fancy name, a logo, stickers and more. Just call it "ticketing"! This will reduce

financial and capital expenditure discussions to come, allowing you to focus on the incremental improvements.

Product and process are alignment upfront. The process should drive the implementation as opposed to the tool trying to drive the process. It is important that there is alignment on the process before the tool is adapted. Otherwise, just another problem is created when multiple groups are trying to modify the tool in competing ways.

Lastly, and speaking of the finances: think about the big picture. Larger companies going through large transformations like moving towards a single ticketing platform should anticipate funding requirements. Considerations like vendor support versus in-house work, i.e., "buy versus build," will depend on what skill competencies exist to start such a major program. A multi-year program, unified ticketing is best approached as an endeavor that is forecasted and budgeted to cover operational and capital expenditures.

5.2. Success Stories

We're starting to gather the success stories that come with moving our teams onto a single ticketing platform. We're not all the way there yet – about halfway, at the time this paper was written. Yet so many wins have been and have yet to be celebrated! Results so far clearly indicate that moving incident and change tickets into the single zen ticketing platform is reducing "swivel" and the time it takes to manage those processes.

The voice service engineering and operations team were the first to embark, diving headfirst into the single ticketing platform. Frances Augustine, Executive Director Reliability Engineering, led the vision to reduce the number of alerts engineers were managing. She was relentless that "eyes on glass" was going to become a thing of past, and that managing with a proactive mindset would be a much healthier work environment. Through the automation associated with a single ticketing system supported by a mature CMDB, the "Voice team" was able to do just that and move from a reactive to proactive operation, focusing on a sustainable level of logged alerts to tackle before an outage occurs. This includes internal alerts, to ensure voice services are always on, to providing automated reporting to the Federal Communications Commission (FCC) for its required outage notifications. This automation enabled engineers to pivot from being reactive to being proactive, finding issues from logs before they became outages. It also enabled a reduction of Tier 1 vendor support.

Another early adopter was in our residential services and products team. Early on, this team aligned with the single ticketing platform, spending hours to build out its CMDB so that all the appropriate software, hardware and respective locations were identified, connected, and correlated when doing incident and change tickets. The extensive time spent to build (while knowing that CMDB work is never really done; see section 5.1) also enabled automation of incident and change ticketing. As a result, the team was able to eliminate an entire vendor team that had provided manual triage support. This team not only tackled the single tools aspect but is also now ensuring that all teams performing incident management are doing it the same way, so as to harvest additional business improvements.

As part of the journey to adapt to a single ticketing platform, having key performance indicators (KPI) per team, across a collective set of teams, will help measure the success in a few sample areas:

1. Mean time to mitigate and resolve incidents
2. Change success percentage (number of changes executed/not executed flawlessly)
3. Number of changes automated
4. Number of incidents created automatically from event management logging and correlation
5. Percentage of time team spends in reactive versus proactive tasks over X Time

6. The Future of Ticketing

The future of the ticketing, zen or otherwise, is really all about scalability. It's about acknowledging industry consolidation, building smart network platforms, and utilizing intelligence in the right way to ticket the things that matter. Tickets are not necessary for every logged event -- but every logged event can provide trend and analysis to move towards managing proactively. Simply put, our networks are smart and intelligent -- but if we're not smart about our networks, we can't let them show their intelligence. Single ticketing is the path to network intelligence.

The nirvana towards moving into a single ticketing platform, besides the obvious benefits of removing unnecessary duplication and effort, is the uplift to overall reliability. "Spend a little bit of time on Incident Management, police Change tickets that fall out from automation, and spend 80% of your time doing problem management to enable even more automation," advises James Manchester, our SVP of Core Platform Technologies.

What's next? Everything that enables reliability to be "always on" and flourishing. As incident and change ticketing puts firm solid practices in place for ticketing, next steps will likely include moving teams into a single problem management space. Doing so will enable further analysis to ensure an outage, if it happens, only happens once.

Cybersecurity is another realm to explore with respect to unified ticketing. Knowing what is happening in the network is always important, and more so in digital times. Professional hackers continue to advance where and how they can breach systems. It's entirely plausible for managed ticketing practices to also advance, to keep would-be interlopers out.

7. Conclusion

Getting to a "zen state" as it relates to change and incident ticketing, or any type of ticketing, is really about "keeping the lights on" and driving reliability as a core service, at a fundamental and strategic level. This is especially true for large companies, like ours, that grew as a result of multiple decades of system acquisitions and geographic clustering, then remained "siloed" through onboarding and corporate integration. As it continues to become mainstream within Comcast, the unified zen of ticketing approach will bring valuable intelligence to understanding topology and automating remedial tasks.

We'll close with this list of tips, when considering a unified ticketing environment where you work:

- Think about a unified enterprise ticketing infrastructure as a way to create alignment on tools, processes, and people.
- Have a vision to steer teams towards.
- Know that transparent ticketing processes create reliability.
- Adopt a framework such as ITIL and/or SRE to design, transition, and operate into a single ticketing platform.
- Analyze the current and future state of tools, processes, and people, to understand what's going on.
- The right team and leadership support structure is crucial for stakeholder support.
- Under-commit and over-deliver wherever possible!
- Go slow to go fast in an agile continuous learning environment.
- Perform retrospectives with a culture of learning; be an advocate for learning.
- Celebrate the successes and continue to look to the future.

1. Introduction – The Why

The cable broadband industry has had a tremendous expansion of products and services since its initial launch. With each expansion of service, the importance of having a plan to help contend with threats has grown. Technology in general has flourished and impacted societies greatly, and cable has been impacting and often driving a lot of that change. Let's take a moment to review some history.

Cable was born to bring better television experience to communities. Reception was poor down in valleys and technology solved that problem of getting to local programming. Next was the expansion of access to more television content, where content providers leveraged the controlled means of signal delivery to the paying customer in an effort to protect their private programming. The third phase of growth marked the first tipping point of criticality of service offering by the industry – voice service. With the advent of voice service, cable began to expand beyond the world of entertainment and increased the importance of the connection. Calling 911 depends on a reliable voice service, so providers needed to pay closer attention to the target of 100% availability. Legacy copper telco phone service was one of the last things that didn't work during a local subscriber power outage and cable voice subscribers desired the same level of service. The fourth phase of cable evolution is high speed Internet access. With the expansion of e-commerce and migration from physical to "digital everything," subscribers could realize an almost unlimited resource that can reshape everyday lives. Today, we are in the midst of the fifth phase of our industry's expansion and continued rise of criticality of service with the promotion of the 10G Platform. With 10G our subscribers will depend on information and services enabled such as telehealth/telemedicine, home/business security monitoring, e-education and a host of undreamed critical Internet based services.

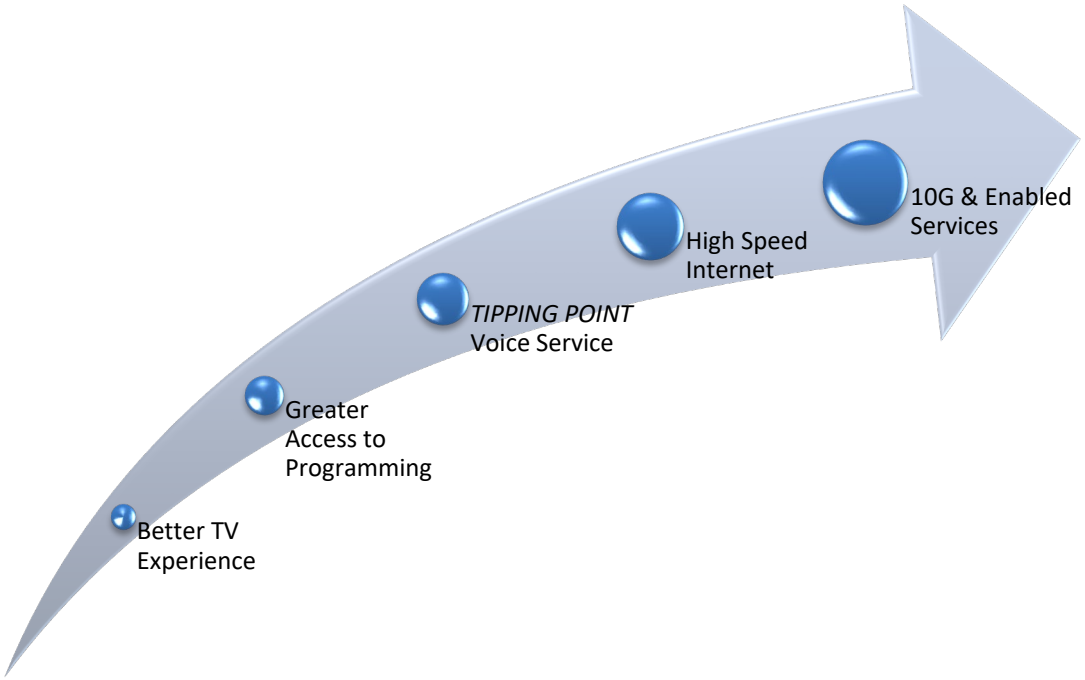

Figure 1 - Cable Industry Importance of Service Milestone Markers

Given this next phase of the cable broadband evolution, let's ask, "What is our game plan when threats to our infrastructure strike?" Natural events, such as earthquakes, hurricanes, fires, floods, winter weather and solar storms; along with manmade threats such as physical attacks, cyberattacks, and electromagnetic

(EM) attacks posing risk to the electric grid could have cascading effects and leave our critical facilities and networks requiring their own power generation and energy storage capabilities for an extended period of time. We are doing a good job at preparing and deepening our resiliency as an industry, however even the strongest plans can and will be tested by unpreventable natural events. This paper will outline high frequency (HF) radio based resources (in particular SHARES) broadband providers can leverage (with proper upfront planning) when all traditional lines of communications are down and we need to reach out for information and request aid typically in the form of security, access, and fuel.

2. What is SHARES?

The SHAred RESources (SHARES) HF radio United States government program administered by Department of Homeland Security (DHS) provides a means for users with a national security and emergency preparedness mission to communicate when all traditional means of communications are unavailable. SHARES members use existing high frequency radio resources to coordinate and transmit messages needed to perform critical functions, including leadership, safety, maintenance of law and order, finance, and public health. SHARES is available on a 24-hour basis to provide an emergency communications link to support intra or inter-sector mission requirements. The use of SHARES requires no prior coordination or activation to transmit messages. A signed non-disclosure agreement (NDA) submitted to DHS is required to obtain proper call sign and access to net frequencies, the SHARES participation directory, and key SHARES resources.

More than 1,400 HF radio stations—representing 104 federal, state, and industry organizations located in all 50 states, the District of Columbia, and several locations overseas—are resource contributors to the SHARES HF radio program also referred to as the SHARES HF network or net for short. Nearly 500 emergency planning and response personnel participate in SHARES. Approximately 200 HF radio reserved channels are available for use by SHARES members. SCTE is the recognized coordinating registration lead for the cable broadband industry. Cable broadband providers interested in deploying a supporting station can contact me for assistance submitting the necessary paperwork and station planning. There is no associated membership or participation fee to get involved.

Membership in the SHARES program is voluntary. As mentioned, the SHARES network is available on a 24-hour basis and requires no prior coordination or activation to transmit messages. Members consult a SHARES handbook hosted at the SHARES private website to find stations, frequencies and/or automatic link establishment (ALE) addresses of participating organizations they need to communicate/coordinate with. Participating SHARES HF radio stations accept and relay messages until a receiving station is able to deliver the message to the intended recipient.

The SHARES program has three operating levels:

- **Operational Level 3** - No emergency exists. The allocated frequencies may be used for training, the weekly SHARES net, on-the-air testing and configuration of SHARES stations, and exercises.
- **Operational Level 2** – An emergency potential exists. Non-essential on-the-air activities on some or all SHARES net channels may be suspended. The SHARES coordinating network monitoring is increased, and regional coordinators for SHARES (RCS) are contacted and advised of potential US Emergency Support Functions (ESF) #2 activation. SHARES net control stations may maintain watch on designated channels to provide stations with an opportunity to test their equipment, and to receive or relay situational awareness messages.
- **Operational Level 1** – An emergency exists, or the potential for an emergency is enough to warrant net activation.

The SHARES Program is organized into several regions and Table 1 represents the geographic breakdown of how the states are organized. The organization is aligned with the Federal Emergency Management Agency (FEMA) regions.

Table 1 - SHARES to FEMA Regions Breakdown

SHARES Region	FEMA Region/States & Territories
Northeast	*FEMA: I, II*, III* CT MA ME NH RI VT NJ NY DC DE MD PA VA WV * PR and VI are in FEMA Region II but are in SHARES Region SE
Southeast	*FEMA: IV* AL FL GA KY MS NC SC TN PR V
South	*FEMA:VI* AR LA NM OK TX
Southwest	*FEMA: IX* AZ CA HI NV American Samoa, Guam, Northern Mariana Islands, FM (Federated States of Micronesia (FM) is not a U.S. Territory but receives certain government services from the U.S.)
Northwest	*FEMA: X* AK ID OR WA
North	*FEMA: V, VII, VIII* IL IN MI MN OH WI IA KS MO NE CO MT ND SD UT WY

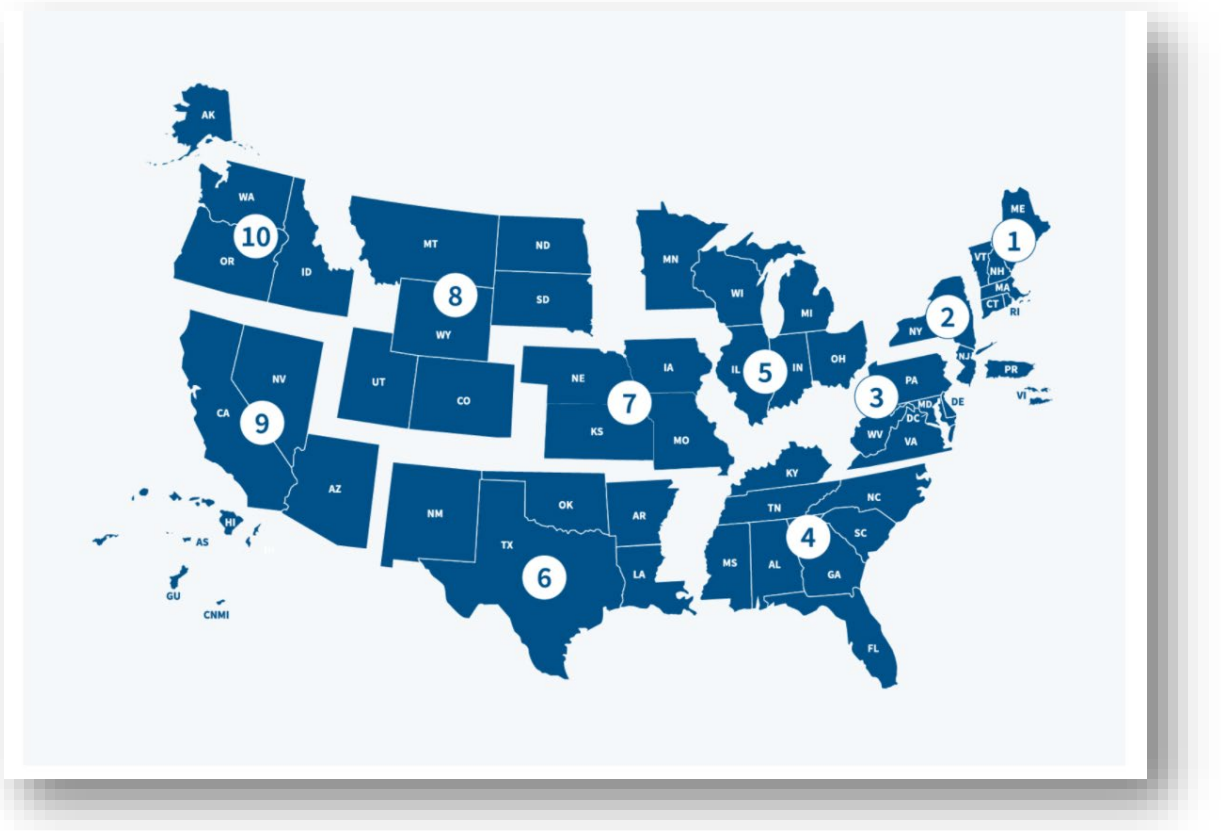

Figure 2 - Federal Emergency Management Agency Ten Regions

Cable broadband providers are present in all ten regions and ideally each operator should evaluate and deploy where they have a need to cover both areas prone to natural disasters as well as zones that could act as critical information relay stations throughout the country.

3. What is HF?

HF operates from 3MHz to 30MHz bands and can be found right above the medium frequency and below very high frequency (VHF) spectrums. Each band has its advantages and use cases. The HF space is used by military, police, emergency services, disaster relief organizations and SHARES. The transmission of communications is called propagation, that is moving of transmissions across the open air. Note there is no physical infrastructure required to carry the message. Up to 1.5 kW single side band (SSB, a form of modulation) and 1 kW carrier wave and data modes can be utilized to get the communication on the net. The national net frequencies often have the capability of transmitting messages coast to coast.

3.1. Propagation Methods

Ground wave propagation takes place when the antenna is configured parallel to the Earth's surface and the range decreases as frequencies increase. The terrain will determine how far the signal will travel. Line-of-sight waves travel point-to-point and are typically found in use for air traffic communications. HF is able to leverage a powerful mode of propagation that takes advantage of the Ionosphere in Earth's atmosphere to refract signals from one point to another. This is called sky wave propagation. Performance using this method will vary by hour of the day, night-day, winter-summer, and allocated frequencies.

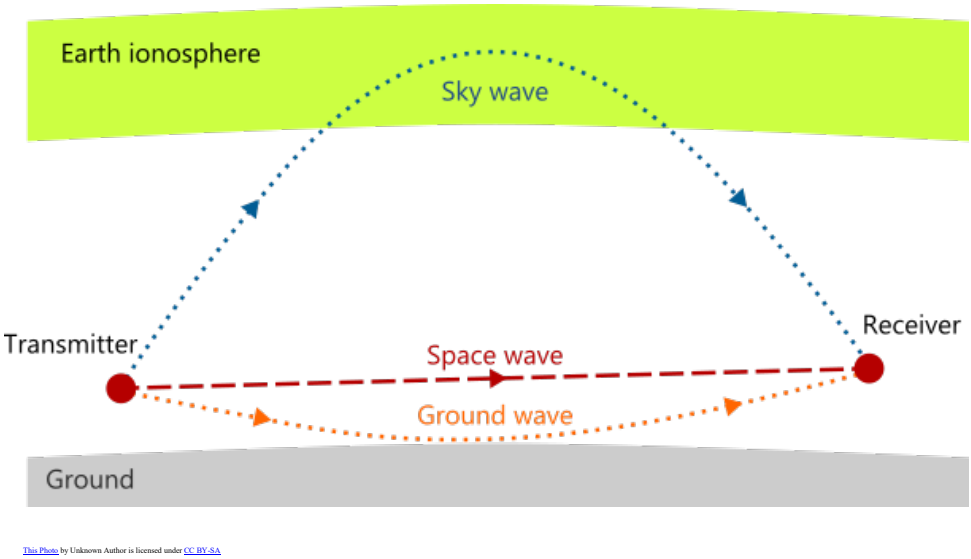

Figure 3 - Common Modes of Propagation

The Earth's magnetic field can play a role in propagation as well. This phenomenon is witnessed in the aurora borealis (northern lights). Space weather or solar winds impact not only the aurora but HF propagation as well. There is a US government service that tracks the space weather conditions like traditional weather forecasting. The United States Space Weather Prediction Center that is part of National Oceanic and Atmospheric Administration (NOAA), has an email alert service that will provide statistics for planetary A and K indexes. These indexes help station operators get a sense of space

weather conditions that could be impacting propagation. It is helpful to subscribe to the service at: https://pss.swpc.noaa.gov/ProductSubscriptionService/RegistrationForm.aspx. The K index is computed every three hours by readings of magnetometers, and conditions tend to be more favorable when K is 3 or lower on a scale of 0-9. The A index is calculated from the previous 8 K index readings and favorable A conditions would be a value of 15 or lower in a recognized range of 0-400. If you like to learn more about space weather, NOAA has released a short video https://www.youtube.com/watch?v=HrloxznL93s.

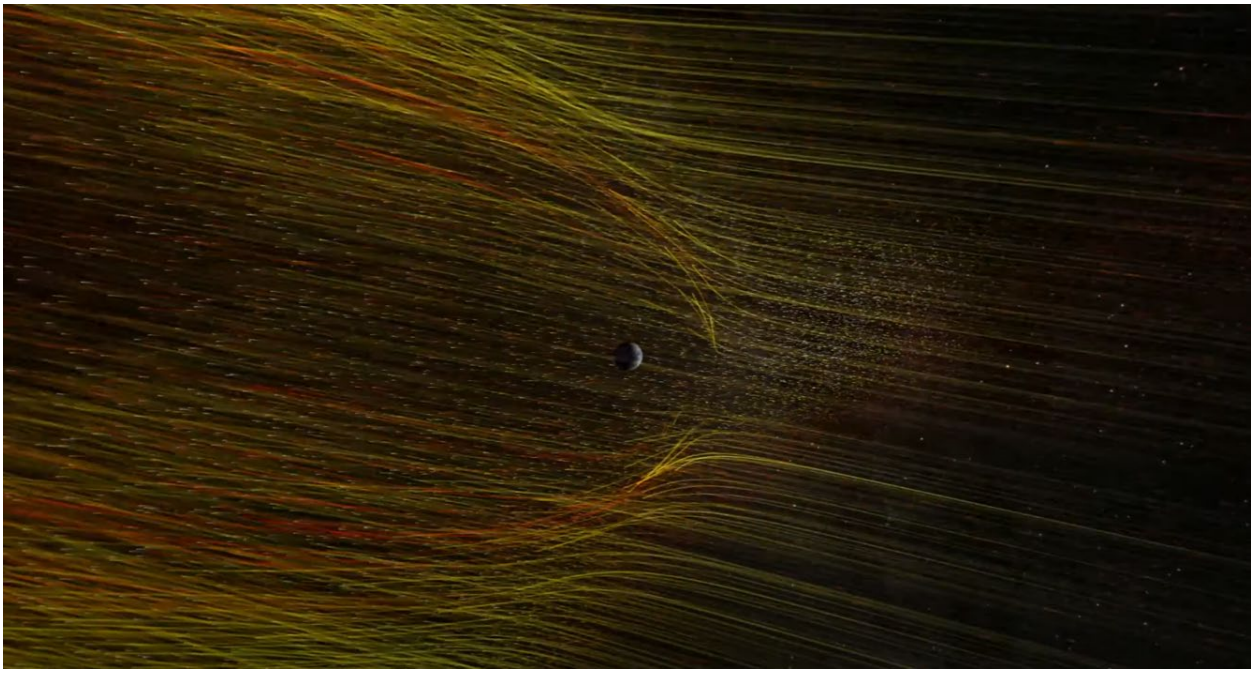

Figure 4 - Space Weather Simulated NOAA Example

When leveraging sky wave propagation, use of an antenna designed for maximizing near vertical incidence sky wave (NVIS used interchangeably with sky wave) will help achieve the receipt of signal. On average NVIS propagation can cover distances between 30-400 miles. The angle of the antenna in comparison to the sky will affect how close/far the signal will return to the earth. It is possible to "bounce" the signal up and down however, strength of signal will diminish with each hop. NVIS frequencies for SHARES will be found between 3 and 12MHz. It is important to note that there is an area between ground wave propagation and the HF hop called the skip zone. In this area, there could be no HF signal received. Alternate means of radio communication could be used to fill in these "HF dead zones." Ionosphere HF conditional monitoring can be found at https://www.sws.bom.gov.au/HF_Systems/6/5.

4. Station Operator Needs

One of the most essential pieces of the SHARES radio station is the operator. Proper planning for the human factor cannot be overlooked or under-planned. This planning begins at home. Before you depart to tend to station needs during times of activation, be sure to have your home plan in order. If you are unable to dedicate focus on your safety and mission of relaying message during incident because your thoughts are trying to react to needs at home then there may be gaps in your own home care planning. Proper home planning is beyond the scope of this paper but is important and worth the mention. Please have a home plan in place to provide peace of mind.

For station deployment needs, simple everyday items should be included in a key assets bag. A search online search for "emergency survival bag/kit –with 72 hours of disaster preparedness" can provide many pre-built options. Suggested items in such a kit can include:

- hammer/mallet
- gloves
- masks
- nylon rope
- bottles of water/water filtering device
- first aid kit
- shade/rain canopy
- rechargeable weather radio
- three days of food and water/water purification system
- sunglasses/safety glasses
- sleeping support needs (bag, tent, etc.)
- personal hygiene support items such as toothbrush/paste, TP, extra socks, undergarments, and showerless cleaning towels
- chair
- small table if possible
- pen and pad of paper
- LED flashlight or evening lighting/battery powered lantern
- waterproof storage bag
- insect repellent
- duct tape and/or electrical tape

5. Station Hardware

As the SHARES Program implies, it depends on access to appropriate hardware to transmit and receive HF signals. Stations generally consist of the person operating the hardware, the HF/RF unit itself and the supporting antenna. When selecting the necessary hardware, it is important to consider the use case and location the station will be deployed. For example, an urban major city with skyscrapers will limit the amount of physical space an antenna can be erected. Please examine the location before making the antenna selection. SCTE has secured both fixed and portable versions of SHARES station equipment to allow for optimum flexibility of deployment. Also, when matching antenna to RF until capability, be sure to analyze the output power of the transmitting equipment to what the highest power capacity of the antenna is rated for. The SCTE equipment can produce transmissions as great at 125 watts; therefore, our antennas should be able to transmit signals output power of at least 125 watts.

5.1. Radio

When selecting a radio for SHARES one should ensure the feature set matches capabilities of other key stations on the network. For example, the ability to store frequencies (software defined radios) in a list format and rapidly change from one frequency to another can save a lot of time and limit frustration especially during challenging times like net activation. Other commonly deployed station qualities include rugged construction (not necessarily military grade but approaching that quality of construction). During activation, having well built equipment will relieve some anxiety about station reliability and allow the operator to perform the key task of relaying information.

Another consideration when choosing an HF radio is how easily can the radio be changed without needing to replace the entire device. Typically, this is accomplished via a software defined method and many of the higher end devices support the ability to manipulate the handset appearance, what features are restricted/enabled, and many more operating functions. A good practice would include a plan to purchase this equipment once and anticipate having this gear in service for many years (unlike laptops or cell phones). Finally, a built-in standing wave ratio (SWR) meter is very handy to help troubleshoot antenna issues to help optimize power throughput to the system. Standing wave ratio meters help determine how much of the RF unit's output power actually gets transmitted, and the optimum meter ratio is 1:1. A solid target of 1:3 or less is optimal. If the ratio is much higher, antenna adjustments are needed such as adjusting the mast height, ends of antenna height or distance of feedline run.

Figure 5 - SCTE Portable Radio and Power Supply

Assembling the radio should be practiced and familiarized by the station operator. A common setup will have: copper ground wire connected to the ground screw, HF 50 Ohm antenna feeder coax cable, power supply, handset connector cable and audio out like a small speaker or headphone connection. Make sure the surrounding area is clean and without obstruction of airflow. Also leave room for a pad of paper and pen to capture notes. Remember, the area may be lacking good light and air conditioning due to the situation that warrants the operator being at the station. If there is notice that wind-based storm could be the cause of the deployment do not deploy the equipment until after the storm has subsided. If the antenna (in particular) is exposed to the elements during storm conditions, it could be subject to serious damage or even blown away.

5.2. Antenna

The SHARES program has many frequencies allocated for use by authorized licensed participants. Versatile antenna systems should be secured to allow for transmission across many of the confidential frequencies. Some antennas are deployed and configured to transmit optimally on a particular frequency. That approach is good for the national net that will leverage one or two frequencies. However, to have the greatest flexibility and readiness to deal with the unknown of the deployment as well as propagation

conditions, it is recommended to select an antenna system that is either tunable or broadband in nature. Tunable antennas can match the maximum output power to the frequency the radio is set to transmit on.

A broadband antenna is very flexible. Usually this is a terminated folded dipole (TFD or T2FD). These are available in many lengths and while all will work, length determines the lowest effective frequency supported by the antenna. Typical TFD lengths can be 60, 90 or even 120 feet long. For NVIS communications the TFD should be mounted in an "inverted V" configuration with the center apex up about 5-10m with the ends sloping downward to a height of about 2-3m from the ground. Precise height values and shape are not critical, often deploying the emergency station will present unique installation opportunities and antenna manufacturers will also offer installation recommendations. The antenna is connected to the transceiver using coaxial cable. A high-quality double-shielded 50 Ohm cable such as RG-214 or LMR-400 is recommended. Up-front planning is essential to ensuring readiness in time of true need.

Figure 6 - SCTE Portable Broadband Antenna and Mast Kit

One item to note, HF communications is subject to propagation condition changes that are impacted by time of day, sun activity, time of year and station location. Propagation is probably the biggest wildcard in the art of emergency HF communications. SHARES leverage many HF channels to help offer various opportunity to find a frequency where propagation is less of an interference factor. As mentioned above, online solar index resources such as the United States Weather Prediction Center

(https://www.swpc.noaa.gov/products/planetary-k-index) offers reports of geomagnetic conditions that can impact station experience. Another notable resource to have programmed in the radio is the United States National Institute of Standards 5MHz 10MHz 15MHz and 20MHz channels. This service will help give station operators a sense of how that range of frequencies are performing at that time. The government service announces the time along with other important information such as Atlantic high seas warnings at 8 and 9 minutes after the hour, and a Pacific high seas warning is broadcast at 10 minutes after the hour.

6. Station Powering Considerations

As mentioned in the introduction, power is essential to the services we provide. Looking at the current state of the utility grid here in the US, as our importance of service to our subscribers increases so shall the level of preparedness be adjusted to match that expectation. The good news is that deepening our power resiliency for our last lines of communication does not need to drain capital budgets. Looking at flexible, renewable, portable, power stations to support an "off grid" mentality to our last line of communications is commercially viable at the time of this publication. A search for 2000kWh with peak power output of 4000W would provide a good reference point to power the station for several days with moderate use. Some of the newer portable power stations can incorporate multi-modes of charging to include solar, traditional AC and even DC from automobiles.

By way of reference, Cybersecurity and Infrastructure Security Agency (CISA) has released recommended guidelines for critical communication infrastructure. This can be found at: https://www.cisa.gov/sites/default/files/publications/Factsheet%20Resilient%20Power%20Best%20Practices.pdf. As suggested, there are various levels of power preparedness that are recommended when removing risks for vital communications. This breakdown provides different levels of backup to grid power that can be considered:

- **Level 1**– Least-cost best practices that provide a commercially reasonable chance of maintaining power for at least **three days/72 hours** under all-hazard conditions (for example, three days of fuel is stored onsite to maintain critical loads).
- **Level 2**– Provides a best-efforts approach to maintain power for at least **seven days** under all hazards.
- **Level 3**– Generally covers the most critical infrastructure where power should be sustained under all-hazard conditions for a minimum of **30 days**.
- **Level 4**– Typically limited to the most critical military/federal/National Essential Functions communications infrastructure where power should be sustained with no unplanned downtime under all hazards in **excess of 30 days**.

Ultimately it will be up to each of the broadband providers to determine what level of readiness each station should adhere to. History has demonstrated that having 72 hours of standby off grid power is a good model.

7. SHARES Station Setup

Pre-planning for this all-important asset is vital. Identifying who in the employee pool will be authorized (both at the company level and SHARES NDA level) and familiar with the equipment before deployment is critical. It is important to plan for both a fixed and portable station to help ready your organization for the disaster that warrants the activation of the SHARES network. Flexibility of the portable kit enables the operator to move the asset into and out of areas of need. Having a lightweight mast, antenna, hardened radio, and power source will provide the reliable equipment in time of need. Practicing setting

up and properly packing up the station during non-activation days will provide the operator skills necessary to deal with the stresses of getting vital information in and out of areas impacted by incident. A permanent station located at a mission critical building that already has plans for continuity can extend its value during disruptions. The roof can serve as a good permanent deployment location for an antenna and proper site survey is advised prior to selecting an antenna. Be sure to secure the station equipment as you would any valuable network asset.

Turning to the portable deployment needs, procedure wise, setting up the station in a logical manner can help ensure quick readiness to get on the air. First, identify available space for the antenna, RF unit and power supply. This will normally be limited to how much length coax feed line that connects the antenna to the RF unit is on hand. Experience has demonstrated that 100' is a practical length of a portable setup. Also, try to select an area where shade is readily available. Being present at the station for long hours and the added impact of the sun could result in additional bodily stress. Having a portable canopy is recommended.

The next steps involve setting up the station and all its components. After the location for the station has been determined, begin to setup the mast, necessary guy wires and antenna. Remember to connect the coax to the antenna before hoisting the antenna. Next connect the coax feedline to the RF unit. This will prevent accidental transmission by the RF unit without a load attached that may result in equipment damage. After the RF unit is connected to the antenna, connect the RF unit to the power supply. Finally, refer to the radio manufacturer's manual/recommendation for proper grounding technique as this will vary from radio to radio. However, typically there is a grounding screw on the back of the power supply that would allow for copper ground wire to be attached to a metal ground rod.

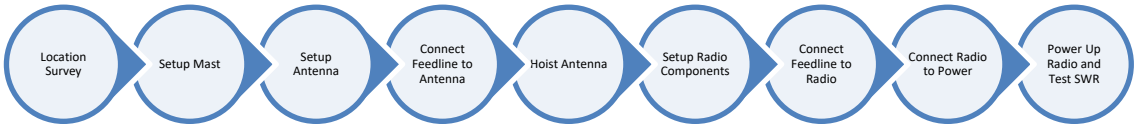

Figure 7 - Simplified Portable Station Deployment Steps

These basic steps should allow an operator to now transmit and receive signals on the SHARES frequencies. If performance is poor, conduct a simple SWR test and adjust the antenna as necessary. Actions could include raising/lowering the center mast or ends of the antenna or confirming a good dry fit of the feed line to the connections on the RF unit and/or antenna. Another opportunity to help improve performance is to run a simple metal cable on the ground under the antenna from one end to the other.

8. Digital Modes

In this section some common modes of digital communications or non-push-to-talk methods of message delivery are discussed.

8.1. HF Email

Email is such a valuable asset. It is hard to imagine conducting business without this method of communication. Disaster communications can leverage Winlink Global Radio Email®. Winlink is an all-volunteer project of the Amateur Radio Safety Foundation, Inc. (ARSFI), a non-profit public benefit corporation with no beneficial owners. Its original purpose (started in 1999) was to provide a very long-

range radio path for radio amateurs who did not have access to “land-line” communications needed to send and receive email messages. Subsequent uses have been oriented toward providing partial backup of email services for emergency communication service agencies during a local commercial communications outage or communications overload. Transfer speeds and available bandwidth do not allow for complete replacement of traditional Internet based email services but when essential messages need to be relayed reliably, Winlink can get the job done.

SHARES Winlink HF email system operates on approximately 80 dedicated channels which are not listed in the SHARES channel list or net list. The channels are known to the SHARES Winlink Express software and are updated electronically via Internet on a regular basis (preferred) or over the air (very slow). Winlink needs to be downloaded off the Internet to a viable laptop/desktop in advance, configured and tested. An authorized and registered separate call sign is required for the Winlink station. Like traditional Internet based email, Winlink requires a unique email address that is routable by both the Winlink platform as well as traditional Internet based email. When local Internet access is down, the email client will communicate via a HF modem connected to the computer and HF radio. Mail routing can leverage BOTH traditional SMTP and Winlink delivery methods. The Winlink client is configured to connect to a remote Winlink email gateway where the message can be properly relayed to either another operator on the Winlink network or Internet.

Figure 8 - SCTE HF Enabled Email Station

During a “worst case scenario” where traditional Internet/email is unavailable, station operators can leverage the radio-only Winlink mode. Messages are transferred to remote message servers (RMS) designated by the recipients as their message pickup stations. Each Winlink user can register up to three message pickup stations for redundancy. Modems specially designed for HF transmission (Pactor for example) are used to establish and route the traffic over the specific frequencies.

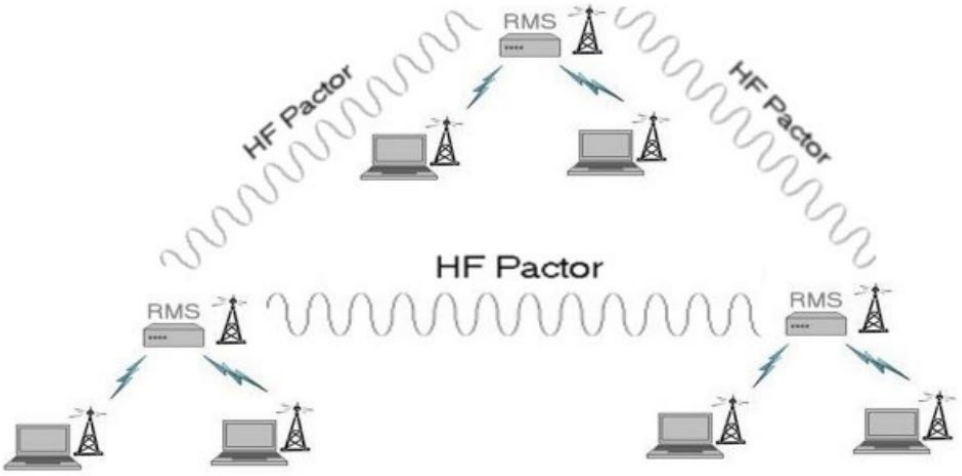

Figure 9 - Winlink HF Email Routing

Note, using this method of moving messages will be slower than what we are accustomed to with highspeed based Internet mail routing. Wherever possible the message should be plain text, simple and to the point as to avoid congesting the remote message servers.

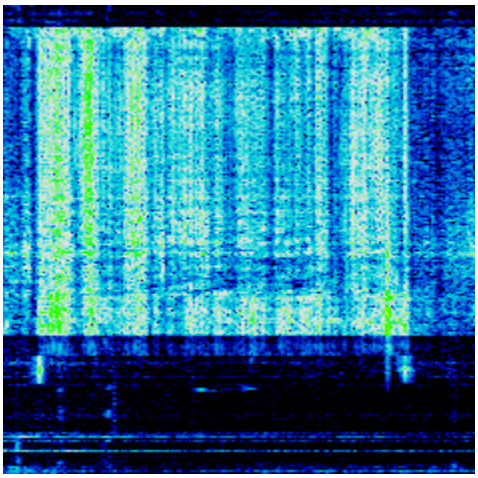
8.2. Automatic Link Establishment

Automatic Link Establishment (ALE) is an automated calling system that brings telephone-like functionality to HF communications. Instead of forcing operators to listen for calls, ALE uses digital signals to indicate that one station wishes to connect/call another. The receiving transceiver then alerts its operator (much like a ringing telephone), who can then accept the call. Once the call is accepted the two stations can use voice communications or switch to a digital mode, e.g. MT63, to transfer data, much like using a modem on a telephone call.

ALE is designated for use on the channels designated “SHARES ALE Net.” SHARES stations are encouraged to program these frequencies into their ALE radios. Sounding is a process to determine link quality analysis can be enabled to measure connectivity with other ALE stations. The ALE radio should not exercise its sounding function more than one-hour interval (ninety minutes is the preferred setting for equipment that supports it). ALE address codes and ALE frequencies are provided to licensed SHARES operators when completing their application to the program. The availability of ALE operations may be different from the hours of operation for voice nets. One of the strengths of using ALE is the radio will help optimize the experience/voice performance based on up to the minute propagation conditions.

8.3. MT63

During times of poor propagation, station operators and SHARES net controllers can leverage a broadcast technique to help get the important message through. SHARES has standardized on MT63 modulation/demodulation methods for this use case. MT63 is an orthogonal frequency division multiplexed (OFDM) digital data mode aimed for use in high noise environments. MT63 was developed by Paweł Jałocha. MT63 is designed for keyboard-to-keyboard (like text messaging) conversation modes on HF bands. MT63 distributes the encoding of each character over a long time period and over several tones. This code and symbol spreading implementation is key to its robustness under less than ideal conditions. The MT63 mode is very tolerant of mistuning, as most software will handle 120 Hz tuning offsets under normal conditions. MT63 uses 64 binary phase shift keying (BPSK) (2-PSK) channels placed in 500, 1000, and 2000Hz of bandwidth. There are 2 main modes of transmission: short interleaving and long interleaving. With short interleaving, MT63's robustness is somewhat compromised in exchange for lower latency (time to end of transmission). With long interleaving (what SHARES leverages), MT63 operates at its best robustness in exchange for a longer latency (about double the latency of short interleaving). Figure 10 represents the source broadcast visual and the computer converted text.



BT
UNCLAS
SUBJ: MT-63 Broadcast - 23 June 2021
1. Conditions continue to be very poor so please listen for stations attempting to c,k 3YJ?;(_GM3=▯(2N\`XfUi8nJUroI station does nop get back to a station please advise you have a "relay" and Net Control will get you to check that station into the net.
2. Please keep an eye on the weather; as noted this week there has been several severe storms that moved through the various parts of the country causing much property damage and the cost of approximately 13 lives. Please use caution if storms are or move into

Figure 10 - Visualization of MT63 Transmission

8.4. Encryption

The SHARES network does permit the use of encryption of messages. Traffic exchanged should be unclassified in nature. The use and access to the encryption software is restricted to SHARES members. Note, if a message is being encrypted, be sure that employees having the authority to permit such a message to the SHARES recipient is approved by senior company employees. Remember, the nature of SHARES is to exchange important information pertinent to the continuation of restoring conditions to business as usual.

9. Voice

The most common mode of communication for SHARES is voice. When operating the station, it is important to remember this service has a mission of safety and vital information exchange so providing the minimal amount of information that is required to get the message across is key. A typical exchange would be:

"This is SHARES CALL SIGN (spelled out phonetically) I repeat SHARES CALL SIGN (no phonetical spelling) in STATE of OPERATION (physical location) with the following priority traffic for the SHARES NET: insert message."

Listening stations will often acknowledge the message and request additional information such as how long you will remain on frequency, status of station power (estimated runtime) and wellbeing of people/operator at the station.

It is important to log any corresponding messages and call signs that are engaged with the exchange of information. Several hours could pass, conditions may change, or additional information could be received that impact an initial touch base with another SHARES operator and it is important to remain in contact with the NET for proper up to the minute information relay.

10. Local Communications

In the area where the HF skip zone is experienced (region under the NVIS propagation where there is very little to weak signal) an alternate supporting means of radio communication is required. This could be a man-pack designed for short distance HF communications (like in the military). This solution would be very tactical in nature supporting the actions of actual restoration processes. Key for this plan is not to depend on towers like in the case of cellular infrastructure as this infrastructure may not be present (why SHARES is being activated).

11. Conclusion

A key provision to having a solid plan for business continuity is to have the necessary tools for addressing the situation ahead of time and not trying to scramble and find the tools needed DURING an incident. SHARES station deployment needs to be planned for ahead of time, coordinated with team members on when to exercise (ideally monthly) the equipment and keep up to date with the SHARES coordinating office to ensure the latest frequencies/information is at hand when and where it is needed.

In summary, here are key components required to get on the SHARES network:

1. ALE ready HF radio

2. Broadband HF antenna capable of transmitting and receiving on frequencies between 3 MHz and 30 MHz
3. Antenna mast system
4. Proper space and elevation of 10 feet or higher to enable radio signal propagation
5. Necessary coax cabling to connect antenna to radio
6. Reliable power supply compatible with the selected HF radio
7. Backup power in the event primary power fails
8. Laptop computer with digital broadcast demodulation software such as MixW or Fldigi configured to receive MT63 transmissions

Finally, when evaluating the setup of radio stations, consider securing both a fixed and portable solution. The portable solution can be shipped/setup when and where needed. A logical location for a fixed station should be at a hardened facility such as a data center, network operations center (NOC) or other strategic critical facility designed to meet SCTE 226 Class A specifications. This 2021 Cable-Tec Expo paper along with SCTE 206 and SCTE 239 best practices will assist cable broadband providers optimize their readiness of major disasters.

1. Introduction

Forget throughput – latency is the new standard of internet quality. Whether it's a glitchy videoconference or a "laggy game," it's increasingly important to know how latency is impacting customers, and how it interacts with the network components we control. In this paper we will describe work done with Raspberry Pi-based test points that measure roundtrip time, jitter and packet loss, using realistic UDP streams. We will also share some of the early data we've collected and discuss what we've learned so far.

2. Lag Overview and Project Motivation

Subscribers use "lag" to describe an aggregation of latency, jitter, and packet loss; a poorly performing service or application is described as "laggy". Historically, subscriber internet use was dominated by HTTP web browsing and streaming protocols that download a video segment at a time – neither of which is particularly sensitive to lag. Today, popular applications like real-time video conference and online gaming are extremely lag sensitive. In addition, the FCC SamKnows program now tracks latency in addition to speed.

CableLabs is addressing this need in the Low-Latency DOCSIS (LLD) program, and vendors are introducing various product features intended to improve lag. But how can operators know if these new products are effective? Lab testing can help of course, but there is no substitute for field loading and actual customer traffic patterns. Many new features over the years have shined in a lab and provided less-than-stellar results once deployed. Likewise, every new product comes with a slew of configuration parameters … are these parameters tuned correctly? Vendors typically provide recommended starting values, and often these values persist into perpetuity without being critically examined to ensure that they're optimal. We can do better, but only if we can measure the results each time we turn a knob.

Just as operators have monitored node utilization for years, operators need a platform to monitor and track lag over time throughout the network. Thus, the Cox LagSpy program was born.

2.1. LagSpy Goals

Cox has the following goals for the program:

- Use realistic UDP streams to measure latency, rather than ICMP pings.
- Ability to distribute test points widely throughout the Access Network.
- No special configuration of subscriber CPE equipment (e.g. no need for port forwards.)
- Upgradable with ability to add new features and test protocols over time.
- Low hardware cost.
- Configurable network utilization.
- Portable software

2.2. LagSpy Overview

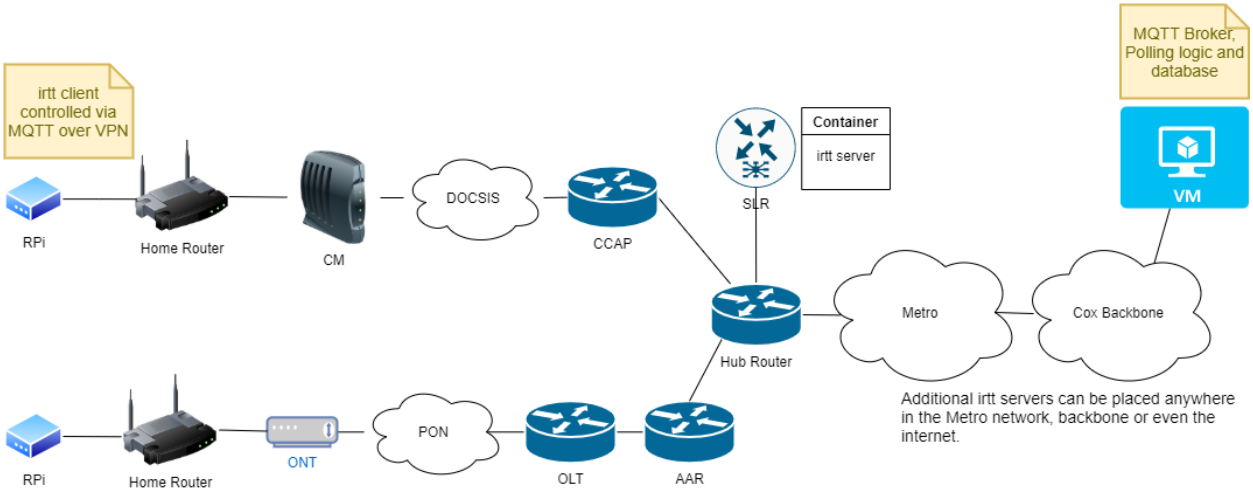

Figure 1 – LagSpy Proof of Concept Architectural Overview

In the proof of concept architecture, Raspberry Pi single board computers were mailed to employee volunteers. These Raspberry Pi devices are nicknamed “Lag-Pis”. Each Lag-Pi implements a network test client called IRTT (Isochronous Round-Trip Time). The Lag-Pis are controlled by a virtual machine on the internet known as the Poller, which also aggregates and stores the test results. The Poller instructs each Lag-Pi when to perform a test and specifies the IRTT server to test against.

The IRTT test involves a client and a server (similar to IPERF). The Lag-Pis implement the client role, and the servers are set up at interesting points in the Cox network. For the proof of concept trial, we are setting up IRTT servers at the Service Layer Router (SLR) connected to the Hub Router. The SLR was selected since neither the Access Router itself (CCAP or OLT) nor the hub router can act as an IRTT server. To minimize latency to the Lag-Pi, we wanted something as close to the access network as possible. We are also setting up IRTT servers at two of our Regional Data Centers (RDCs) for comparison to the SLR.

While our primary focus in the proof of concept is the DOCSIS Network, the architecture is transport agnostic and can run on any access network (DOCSIS, PON, Cellular Data, etc.)

2.3. Why IRTT?

IRTT is a widely available open-source package which generates a customizable UDP stream to measure route trip time and jitter, among other things. Here is an example of an IRTT test and its results:

```
irtt client -i 20ms -l 172 -d 30s --fill=rand --sfill=rand --hmac=0x<redacted> -q irtt-
telemetry.coxlab.net:22112
[Connecting] connecting to irtt-telemetry.coxlab.net:22112
[184.176.185.20:22112] [Connected] connection established
[184.176.185.20:22112] [WaitForPackets] waiting 352ms for final packets

                         Min     Mean   Median      Max  Stddev
                         ---     ----   ------      ---  ------
                 RTT  78.92ms  84.55ms  83.55ms  117.3ms  3.17ms
          send delay   -1.24s   -1.23s   -1.23s   -1.21s  2.25ms
       receive delay    1.31s    1.32s    1.32s    1.35s  2.22ms

       IPDV (jitter)   1.93µs   2.32ms   1.13ms  34.77ms  3.15ms
           send IPDV    110ns   1.89ms    925µs  19.11ms  2.41ms
        receive IPDV    754ns    740µs    274µs  34.42ms  2.31ms
```

```
    send call time   12.9µs     72µs             932µs  46.5µs
       timer error    100ns    129µs             827µs   107µs
 server proc. time   4.45µs   9.39µs             128µs  4.86µs

              duration: 30.3s (wait 352ms)
  packets sent/received: 1471/1471 (0.00% loss)
server packets received: 1471/1471 (0.00%/0.00% loss up/down)
    bytes sent/received: 253012/253012
      send/receive rate: 67.5 Kbps / 67.5 Kbps
          packet length: 172 bytes
            timer stats: 28/1499 (1.87%) missed, 0.64% error
```

In this example, the UDP payload size was set to 172 bytes, the inter-packet interval is 20 ms, and the test ran for 30 seconds. The total bandwidth was 67.5 Kbps, approximating a UDP audio stream. The round-trip time was on average 84.55 ms with an average jitter of 2.32 ms. These are the parameters Cox is currently using in the trial, but we are investigating other streams to model (see Section 3.3.2).

IRTT is launched in either client or server mode. The client generates the test traffic, which is reflected back by the server. The client compares the original packet to its reflected version to calculate the performance statistics. In our architecture, the Lag-Pi is acting as the client.

IRTT is extremely easy to deploy. On a Debian/Ubuntu Linux VM, you can install it simply by running `apt-get install irtt`.

2.3.1. UDP versus ICMP for Latency Testing

Many tools (e.g. the Ookla Speed Test) use an ICMP-based tool like ping for latency measurements. We selected a UDP-based tool as we believe this more accurately reports the subscriber experience.

UDP based measurements are more accurate because:

- Different QoS is generally applied to UDP versus ICMP.
- Internally, many devices implement ICMP as a control plane protocol and UDP as a data plane protocol. So for example, many devices employ hardware acceleration for TCP and UDP, but hardware acceleration is rare for ICMP.
- Real applications use TCP or UDP to transmit data. No common applications deliver user data using ICMP.
- Many devices rate limit ICMP handling for DDOS protection. IRTT sends a continuous stream of UDP data, but this is impossible in ICMP. A high ICMP packet rate is often treated as a ping flood DoS attack and will be blocked.

2.4. Why Raspberry Pi?

Raspberry Pis were selected for the pilot based on their low cost and small form factor. They can be cheaply mailed in bubble envelopes. We used the 2GB model of the Raspberry Pi 4B. Note that the networking is significantly improved from the Raspberry Pi 4 versus the 3. Specifically, the Raspberry Pi 4 can support gigabit ethernet speeds while earlier models were throttled by a slow USB 2.0 bus connecting the main SoC to the networking chip. This architecture limited the ethernet throughput to about 300 Mbps.

We will not use Raspberry Pis for large scale deployment. For mass deployment, we will incorporate a LagSpy client into Cox managed gateway devices.

2.5. Employee Pilot

We solicited 19 employee volunteers for the pilot from a DOCSIS working group and mailed pre-configured Lag-Pis to them. The volunteers simply plugged in the power adaptor and connected the Lag-Pis to an ethernet port on their LAN. The volunteers are distributed across multiple Cox markets.

Note that while the Raspberry Pi 4 supports Wi-Fi, we have disabled it and are relying exclusively on gigabit ethernet for LAN connectivity. Wi-Fi introduces a significant amount of latency and jitter, and the focus of this project is on the access network. However in a future project, we could easily measure Wi-Fi latency and jitter in this architecture simply by enabling the Wi-Fi on the Lag-Pi, and setting up an IRTT server on the access point.

3. LagSpy Technical Deep Dive

3.1. Software Architecture

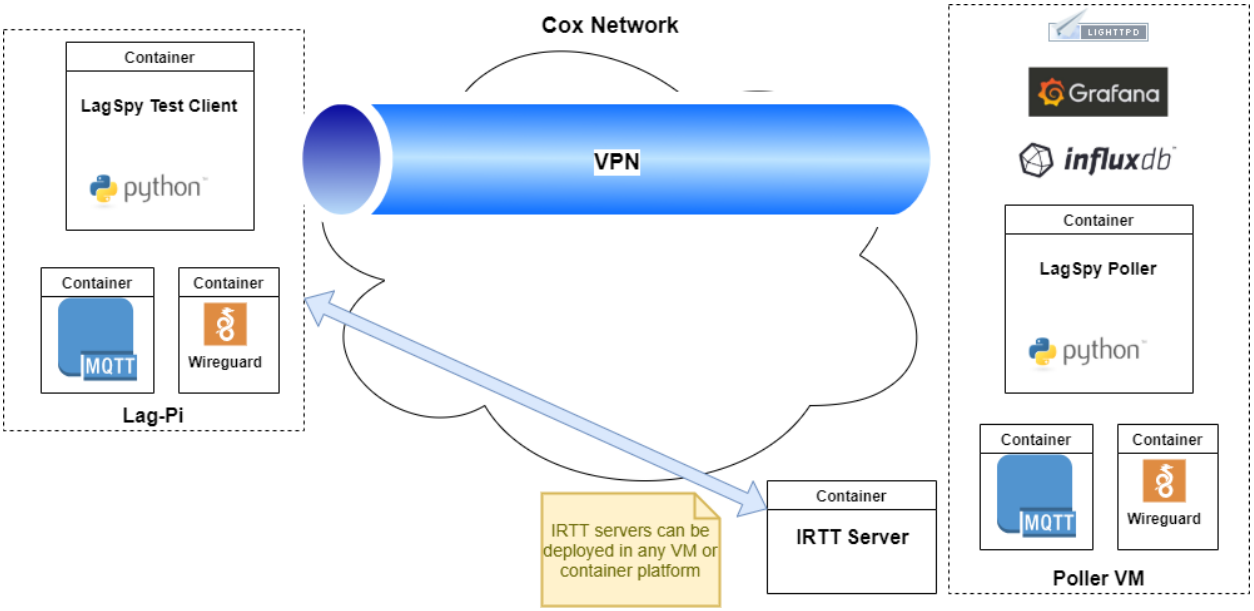

Figure 2 – LagSpy Software Stack

The principal components of the Lag-Pi are:

- The LagSpy Test Client, written in Python 3.8.
- Eclipse Mosquitto to implement an MQTT client.
- Wireguard to establish a VPN connection to the Poller for command and control.

The principal components of the Poller are:

- The Lagspy Poller, written in Python 3.8.
- Eclipse Mosquitto to implement an MQTT broker and localhost client.
- Wireguard for a VPN endpoint.
- InfluxDB to import and aggregate data from the Poller for visualization.
- Grafana for visualization of test results.

- Lighttpd (primarily used to upgrade the Lag-Pi.)

Note that MQTT and Lighttpd are only exposed over the VPN interface over the 10.13.0.0/16 subnet.

The IRTT Servers are implemented in containers, which can be deployed virtually anywhere as IRTT is a simple protocol that only exposes a single UDP port. Docker (and other container frameworks) can strictly limit the resources available to an applications, including memory, CPU, and network sockets, greatly reducing the risk to the platform.

3.1.1. Connectivity Driven by Client

The VPN tunnel is initiated from the subscriber side, meaning that no special configuration is required on the home gateway. The connection is initiated from the LAN side. The Wireguard `PersistentKeepalive` feature prevents the home gateway's NAT state from timing out due to inactivity.

Once the VPN tunnel is established, the Poller can initiate MQTT traffic at will to the Lag-Pi. No port forwarding is required.

Likewise, IRTT traffic is initiated by the Lag-Pi (client) and does not require special forwarding rules.

3.2. Command and Control

MQTT, a popular IOT control protocol, is used to manage the Lag-Pis. MQTT is a Publisher-Subscriber (Pub/Sub) protocol. Clients publish messages to named channels called "topics". Clients can subscribe to any topic of interest. MQTT creates a reliable mechanism to establish both 1:1 communication with individual Lag-Pis, and also to send messages to multiple Lag-Pis at once.

The MQTT Broker coordinates the message forwarding and is implemented on the Poller.

For LagSpy, all message payloads are in JSON format.

Table 1 – LagSpy MQTT Topics

Topic	Arguments	Direction	Description
connect/hello	n/a	Lag-Pi → Poller	Register with poller and keepalive
connect/enroll/<mac>	MAC address of Lag-Pi	Poller → Lag-Pi	Provide VPN credentials to Lag-Pi
connect/link_ok/<mac>	MAC address of Lag-Pi	Poller → Lag-Pi	Keepalive response
irtt/start/<mac>	MAC address of Lag-Pi	Poller → Lag-Pi	Start IRTT test
irtt/results	n/a	Lag-Pi → Poller	Results of IRTT test
iperf/start/<mac>	MAC address of Lag-Pi	Poller → Lag-Pi	Start IPERF3 test
iperf/results	n/a	Lag-Pi → Poller	Results of IPERF3 test

3.2.1. Wireguard Certificate Enrollment

The Wireguard VPN requires that each peer have a unique Private Key and a statically assigned IP address in the VPN subnet. As we did not want to manually provision each Lag-Pi with VPN credentials prior to shipment, we implemented a dynamic VPN credential mechanism over MQTT.

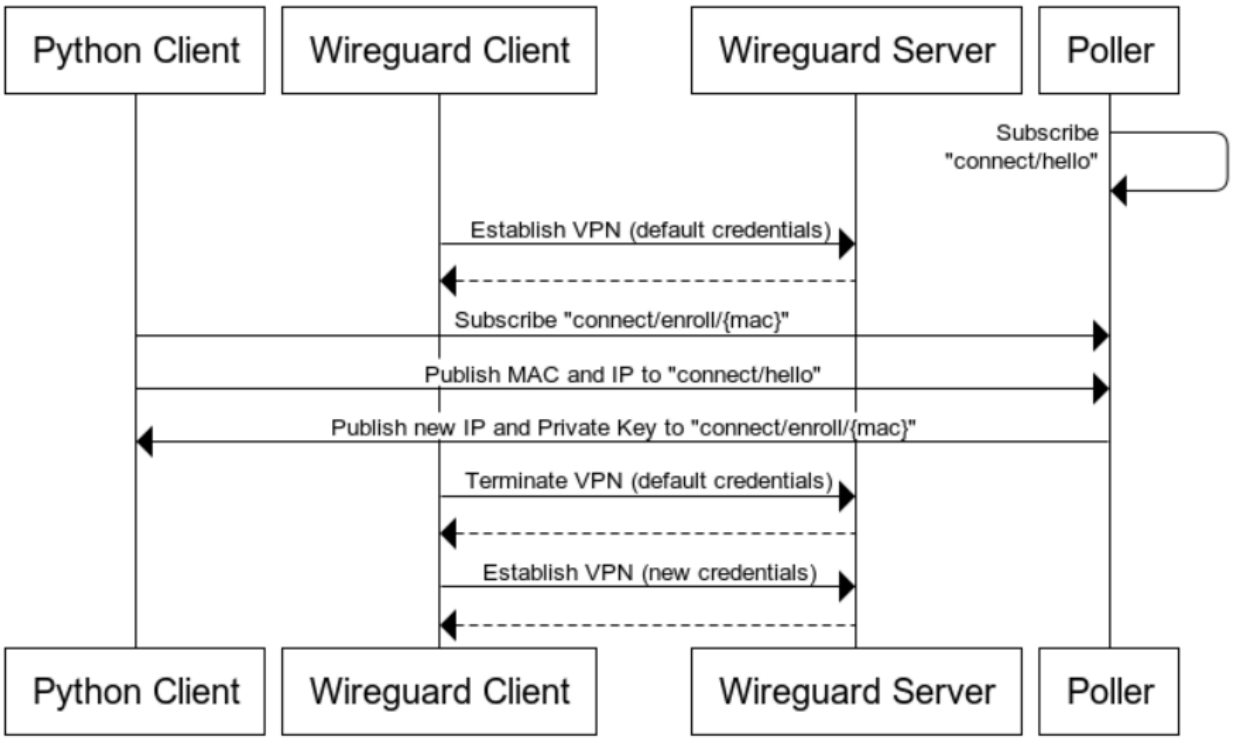

Figure 3 – Wireguard VPN Enrollment Process

A default set of credentials are used to establish the permanent credentials. Wireguard only allows one endpoint at a time to connect with the default private key. This enrollment process can gracefully handle a small amount of contention for the default credentials, but this algorithm will need to be revisited as we increase scale.

3.2.2. Network Failsafe Keepalive

If the Wireguard VPN fails, then the Lag-Pi becomes unmanageable. To mitigate this, each Lag-Pi runs a cron job that verifies the ability to download a small file from the Poller. If the file download fails, the script ensures the Wireguard container is running.

3.2.3. Debugging with Mosquitto

MQTT is a pub-sub protocol, meaning that any authenticated party can subscribe to a topic. Therefore a user on the Poller can subscribe to interesting topics for debugging purposes, and sniff the control messages sent over the VPN. This is very useful for troubleshooting.

In the example below, we can observe the “connect/hello” messages received from the Lag-Pis.

```
lagspy@poller-dt1-phx-0:~$ docker exec -it mosquitto mosquitto_sub -t
"connect/hello"

{"publicIpv6": "::", "publicIpv4": "68.109.32.146", "ip": "10.13.0.16", "mac":
"e4:5f:01:3b:18:23", "topic": "connect/hello", "message": "hello", "seqNum":
5393, "timestamp": "2021-07-19 15:27:49.829820"}

{"publicIpv6": "2600:8800:1a1:1a00::b71a", "publicIpv4": "", "ip":
"10.13.0.12", "mac": "e4:5f:01:21:a0:d4", "topic": "connect/hello", "message":
"hello", "seqNum": 2924, "timestamp": "2021-07-19 15:27:54.517621"}
```

3.3. IRTT Deep Dive

3.3.1. Limitations

IRTT attempts to break up the measured Round Trip Time (RTT) into "Send Delay" and "Receive Delay". However this decomposition is based on injecting a timestamp into the test packets, which requires precise time synchronization between the client and server. This doesn't seem to work in any practical environment that we've tested using Raspberry Pis or even Windows PCs. If the RTT is low enough, one of the components will be reported as a negative number. As we are fairly confident that the Cox network does not support time travel, we must conclude that this is due to clock skew between the client and server.

We have attempted to achieve better time sync by using GPS modules without success. We also tried to use NTP, where the NTP peer, the NTP server, and the NTP client were all on the same ethernet switch. This didn't work either.

We suspect the only way to get this to work is to use IEEE 1588 (Precision Time Protocol) with IRTT endpoints that use precision real-time clocks. This is out of scope for the LagSpy program, since our long-term plan is to use consumer grade internet gateways. Integrating LagSpy into a cable modem that implements DOCSIS Time Protocol could provide a way to get this precision.

IRTT sends symmetrical bidirectional test traffic. For example, if IRTT is configured to send 60 kbps upstream, then an identical 60 kbps stream is generated in the downstream direction as well. Unlike iperf3, it is not possible to perform unidirectional testing.

However, due to the nature of the DOCSIS protocol and the use of TDM in the downstream vs. TDMA in the upstream, the major contribution of latency and jitter is in the upstream. Downstream traffic of this nature will simply be forwarded along by the CMTS into the plentiful frames available to each modem's SFID (assuming the modem is below its QoS limit). This generally happens at or very near real time. In the upstream, however, the modem must request a timeslot in a contention-based interval first, then wait for the CMTS scheduler to allocate a timeslot, then wait for the MAP message to arrive, and finally send the data. This process is more sensitive to network congestion and has more possibility of variation due to limited contention intervals. Therefore, we make the assumption that the changes in latency and jitter over time are primarily due to the fluctuating conditions of the upstream.

3.3.2. IRTT Traffic Profiles

IRTT streams are highly customizable, so we can model a number of latency sensitive applications. Currently we are using a profile that simulates an audio stream, but we plan to add more profiles to our testing toward the end of 2021.

CableLabs has studied typical data streams from collaboration apps (see References). Their summary findings are below.

Table 2 – CableLabs Video Confrerencing Bandwidth Summary. Applications were anonymized by CableLabs.

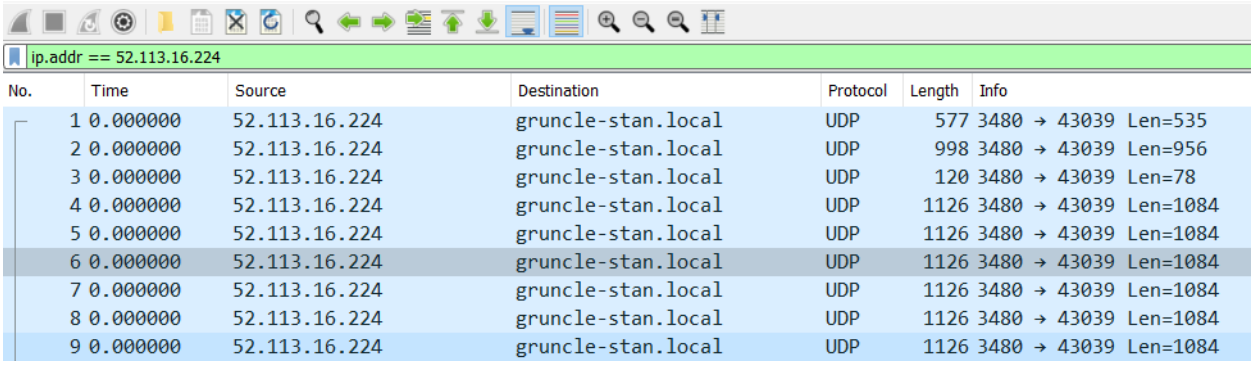
Application	Typical Upstream	Typical Downstream
Application A	< 500 kbps	Between 1 and 2 Mbps
Application B	200 kbps typical; one outlier at 2 Mbps	Approx. 1 Mbps
Application C	Approx. 350 kbps	Approx. 2 Mbps
Application D	Between 200 kbps and about 1.8 Mbps	Cluster at 500 kbps and cluster at 3 Mbps

While video conference traffic is highly asymmetrical, IRTT can only model symmetric streams. We recommend modeling the upstream data rate since most latency and jitter should be introduced in the upstream.

3.3.2.1. Characterizing Application Streams

Characterizing application streams is straightforward with a packet sniffer application such as Wireshark.

- Optional: place an ethernet switch with a mirror port between the device under test (DUT) and the LAN. These switches are widely available for under $50.
- Launch the app generating the traffic on the DUT.
- Start a Wireshark capture. For apps that run on a computer, you can run Wireshark on the same machine. For something like a game console, the optional ethernet switch must be used. Or, many prosumer/commercial home routers have a sniffer capability.
- Collect data for several minutes, then end the capture.
- Identify the traffic of interest and apply a display filter. The filter can be applied in the upstream, downstream, or bidirectional as desired. In this example:
    - Use `ip.addr==52.113.16.224` for bidirectional.
    - Use `ip.src==52.113.16.224` for downstream.
    - Use `ip.dst==52.113.16.224` for upstream.
    - Take care to filter based on the remote application server (public IP address) rather than the LAN device.



- Go to Statistics→IO Graphs in Wireshark. Set up Display Filters for upstream, downstream, and bidirectional. You can inspect both bitrate and packet rate by selecting the appropriate option for the Y Axis.

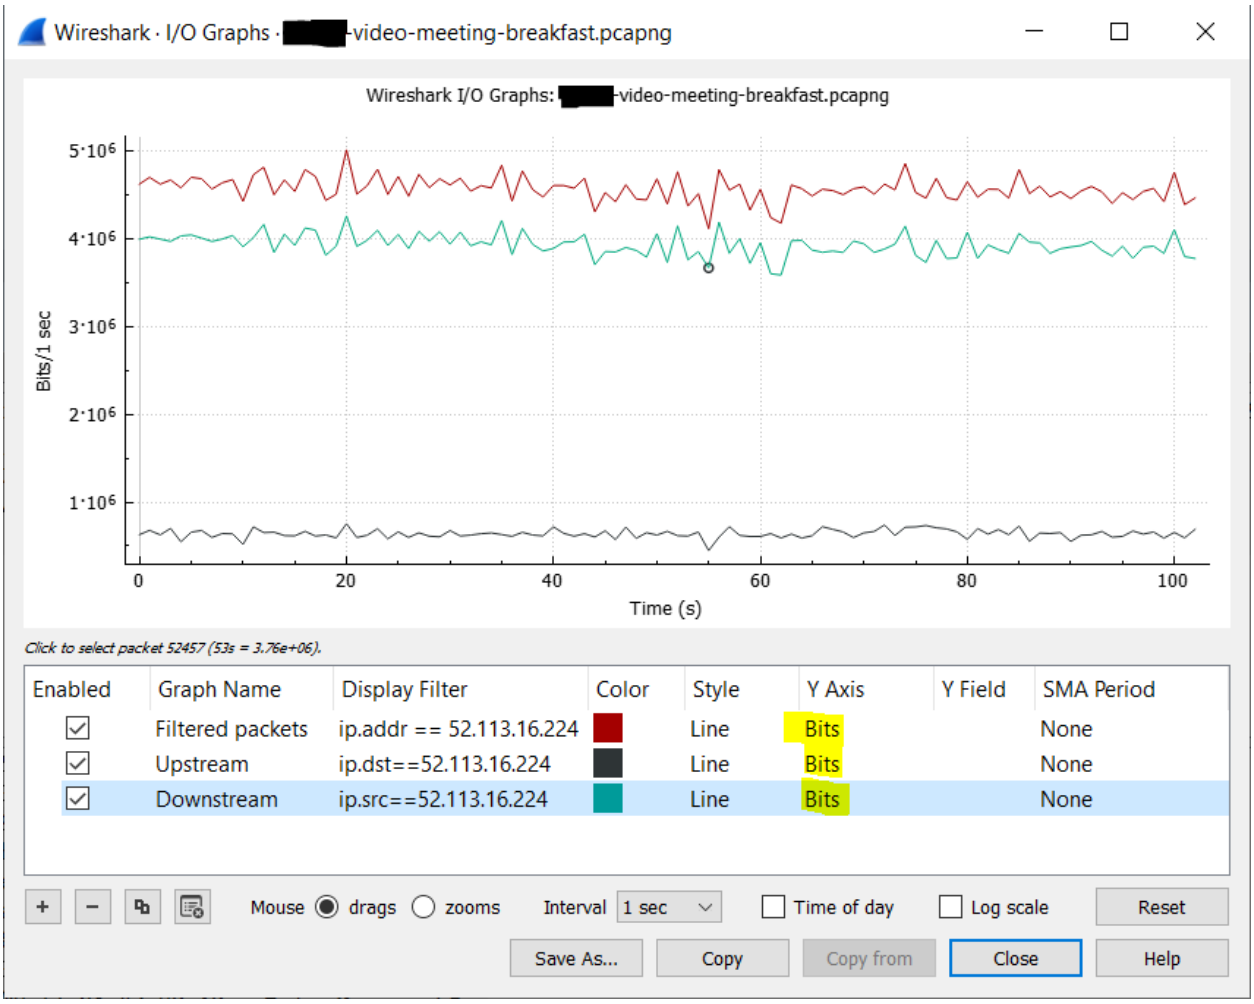


Figure 4 – Example video conference data rate. Note that "Bits" is selected on the Y Axis, and the Interval is set as 1 second. This is an asymmetric stream, with a typical upstream rate of 500 kbps and a typical downstream rate of 4 Mbps.

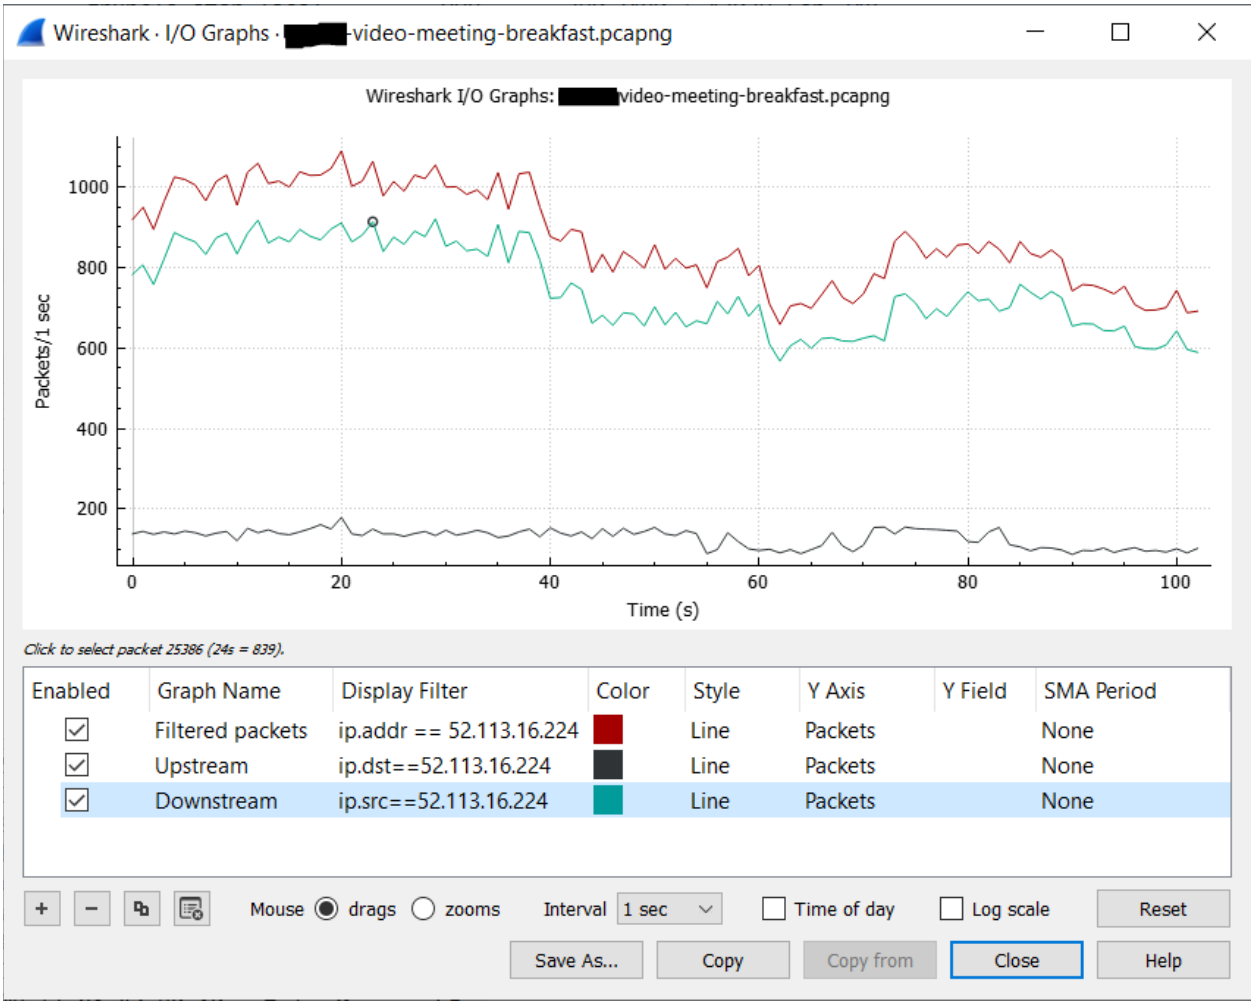

Figure 5 – Example video conference packet rate. Typical upstream rate is 100 pps, and typical downstream rate is 800 pps.

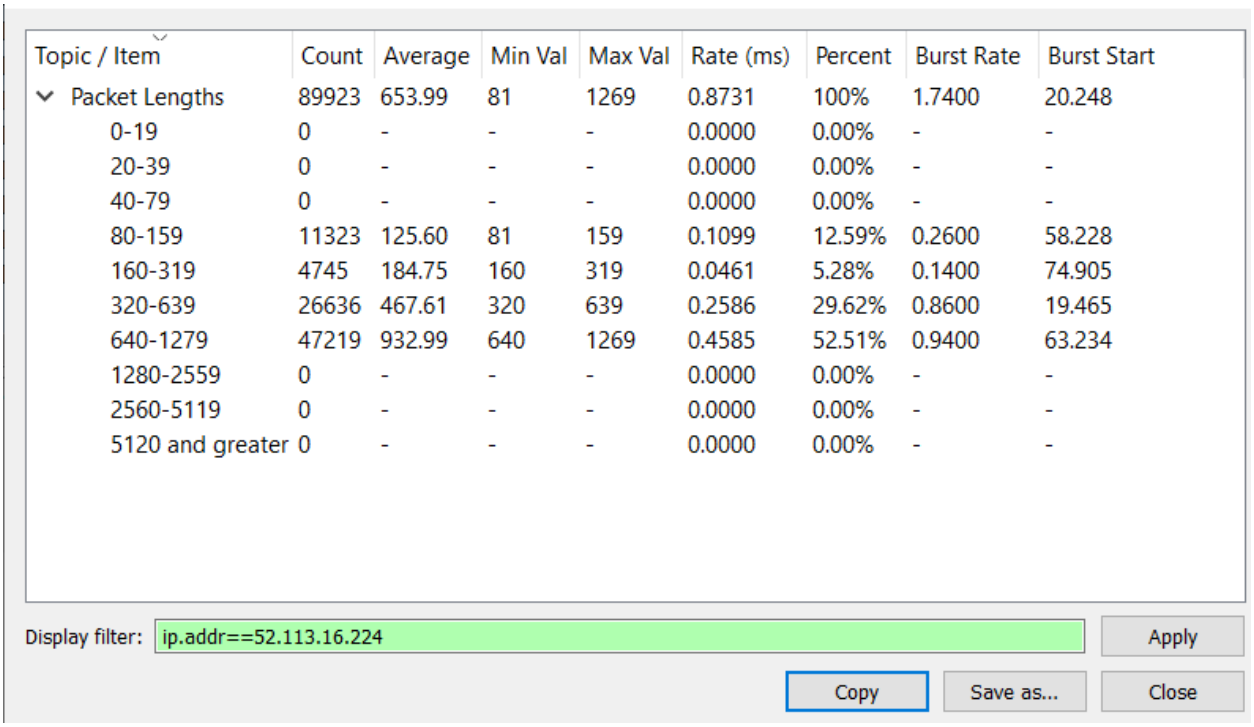
- Inspect the packet length in Wireshark using Statistics→Packet Lengths. Apply the desired Display Filter.



Topic / Item	Count	Average	Min Val	Max Val	Rate (ms)	Percent	Burst Rate	Burst Start
Packet Lengths	89923	653.99	81	1269	0.8731	100%	1.7400	20.248
0-19	0	-	-	-	0.0000	0.00%	-	-
20-39	0	-	-	-	0.0000	0.00%	-	-
40-79	0	-	-	-	0.0000	0.00%	-	-
80-159	11323	125.60	81	159	0.1099	12.59%	0.2600	58.228
160-319	4745	184.75	160	319	0.0461	5.28%	0.1400	74.905
320-639	26636	467.61	320	639	0.2586	29.62%	0.8600	19.465
640-1279	47219	932.99	640	1269	0.4585	52.51%	0.9400	63.234
1280-2559	0	-	-	-	0.0000	0.00%	-	-
2560-5119	0	-	-	-	0.0000	0.00%	-	-
5120 and greater	0	-	-	-	0.0000	0.00%	-	-

Figure 6 – Example video conference packet size. Typical packet size is 933 bytes. Since upstream and downstream histograms were very similar, only the bidirectional analysis is shown here.

From this analysis and focusing on the upstream, this application can be modeled in IRTT using the following parameters:

- Interval (`-i` parameter): 1 / 100 pps = 10 ms
- Length (`-l` parameter): 933 bytes – 28 bytes = 908 bytes. Note that we subtract the IP and UDP header size to calculate this parameter.

As a sanity check, IRTT reports a throughput of 733.5 Kbps, which is reasonably close to the observed value of approximately 500 Kbps.

3.4. Security Considerations

3.4.1. Lag-Pi (IRTT Client)

The Raspberry Pi is not a hardened hardware platform (e.g. it does not have secure boot or secure storage.) We are only using Raspberry Pis for a limited employee trial and will migrate to managed and secured hardware in the next phase.

The LagSpy application does not listen on any open ports. All command and control traffic is secured over a Wireguard VPN tunnel.

3.4.2. Poller

The Poller is listening on a Wireguard server port. All other services (MQTT, HTTP) are restricted to the VPN interface. In other respects, the same hardening considerations apply to the Poller as any standard server with an open port.

3.4.3. IRTT

The IRTT application is written in Golang and is not subject to the buffer overflow-based attacks that plague C/C++ applications.

By default, the IRTT server listens on UDP port 2112 and is discoverable using standard network scanning techniques (including Shodan.io). At a minimum, this allows an attacker to waste network resources by sending test traffic to the server, and could be the basis for a reflection attack.

To mitigate this risk, we recommend the following:

- Override the default port number
- If possible, disable IPv4 on the IRTT server and use IPv6 for IRTT testing. The IPv6 address space is sparse and more difficult to scan.
- Use the IRTT `-hmac` option to enable the HMAC feature. When enabled, the server will not establish a connection or otherwise respond to client traffic that doesn't use the same HMAC value. This means that the port will appear to be blocked by a firewall (filtered) in a standard nmap scan.

3.4.4. SLR

Cox utilizes routers at each hub site that are dedicated to hosting ancillary (non-data path) services. These routers are known as Services Layer Routers (SLR) and are deployed in pairs, directly connected to metro hub routers. The SLR is an appealing place to host an IRTT server because:

- The Docker implementation on the SLR imposes resource limits to mitigate against DoS and other resource-based attacks.
- The underlying router platform supports access controls that block traffic arriving on the IRTT address from impacting the other router functions.

3.5. Test Policy Configuration

Different Lag-Pis operate in different environments and some populations need to execute differents tests. Thus there is a need to implement a flexible policy framework to control how and when tests are executed on a given Lag-Pi.

Our current policy file subdivides testing into 5 different groups, as shown in Figure 7. Our two main group categories are testing groups and server groups. Testing groups specify tests for a member device to run and the server groups provide addresses of available servers.

For testing groups, each group has a list of devices with defined mac addresses. The devices with those mac addresses will run specific tests and write those results to a file in accordance with the permissions of the group. The irtt-testing group sets the mac address as "default", assigning all devices to the `irtt-testing` group automatically; this will require any connected devices to perform irtt tests. In contrast,

the `iperf3-testing` group requires that devices with mac addresses defined in the group, such as "ef:5f:01:3b:18:23", execute iperf3[1] tests in addition to irtt tests.

For server groups, each group contains a list of IP addresses running case-specific servers. These groups allow devices within the testing groups to obtain a list of Ips to run their tests against. For example, the `irtt-IPv4-server-Ips` group contains IP addresses running an IPv4 irtt server. As a result, when a device using IPv4 in the irtt testing group is looking for a server to run a test against, it would get the necessary IP from the `irtt-IPv4-server-Ips` group. Likewise, the `iperf3-server-Ips` group contains a list of Ips running an iperf3 server and the `irtt-IPv6-server-Ips` group contains Ips running an IPv6 irtt server.

```
groups:

        irtt-testing:
                group-name: irtt-testing
                permissions:
                        - run-irtt-tests
                        - write-irtt-results
                enabled: true
                devices: default

        iperf3-testing:
                group-name: iperf3-testing
                permissions:
                        - run-iperf3-tests
                        - write-iperf3-upstream
                        - write-iperf3-downstream
                enabled: true
                devices:
                        - e4:5f:01:3b:18:23
                        - e4:5f:01:3b:17:43

        irtt-IPv6-server-IPs:
                group-name: irtt-IPv6-server-IPs
                IPs:
                        - irtt-telemetry.coxlab.net
                enabled: true

        irtt-IPv4-server-IPs:
                group-name: irtt-IPv4-server-IPs
                IPs:

                enabled: true

        iperf3-server-IPs:
                group-name: iperf3-server-IPs
                IPs:
                        - 192.168.0.43
                enabled: true
```

Figure 7 – Policy file containing different testing and server groups.

[1] Iperf3 testing is not part of the core LagSpy functionality, but we are leveraging the LagSpy command and control framework to automate some iperf3 testing we are doing for product acceptance.

3.5.1. Server Autodiscovery

To avoid the need to manually assign each Lag-Pi to the closest server, we are implementing a simple autodiscovery algorithm to find the nearest server. Once per boot, the Lag-Pi will perform a traceroute to each server in the pool and will select the closest (by hops) for IRTT tests.

3.6. Data Visualization

To gather and present the metrics received from MQTT we have a three-part architecture. First, the metrics sent over the MQTT `irtt/results` topic activate a Python listener that decodes them, normalizes the data, then sends each measurement to an InfluxDB instance. Second, InfluxDB collects the data and applies any active retention policies, then makes the data available for consumers.

Lastly, we assembled a Grafana Dashboard to display a subset of the measurements returned by IRTT. Thanks to both Grafana and the InfluxDB query language (Flux), we're able to not only display the metrics as returned but also partition and display them however we wish. This includes building composite metrics, windowing, and aggregation across the whole metric population to make trends clearer or weed out noise that may be present in the data set.

Our current visualization tools plot results for individual Lag-Pi test points. As we increase scale and deploy more test points, we will need to develop tools to analyze the data in aggregate.

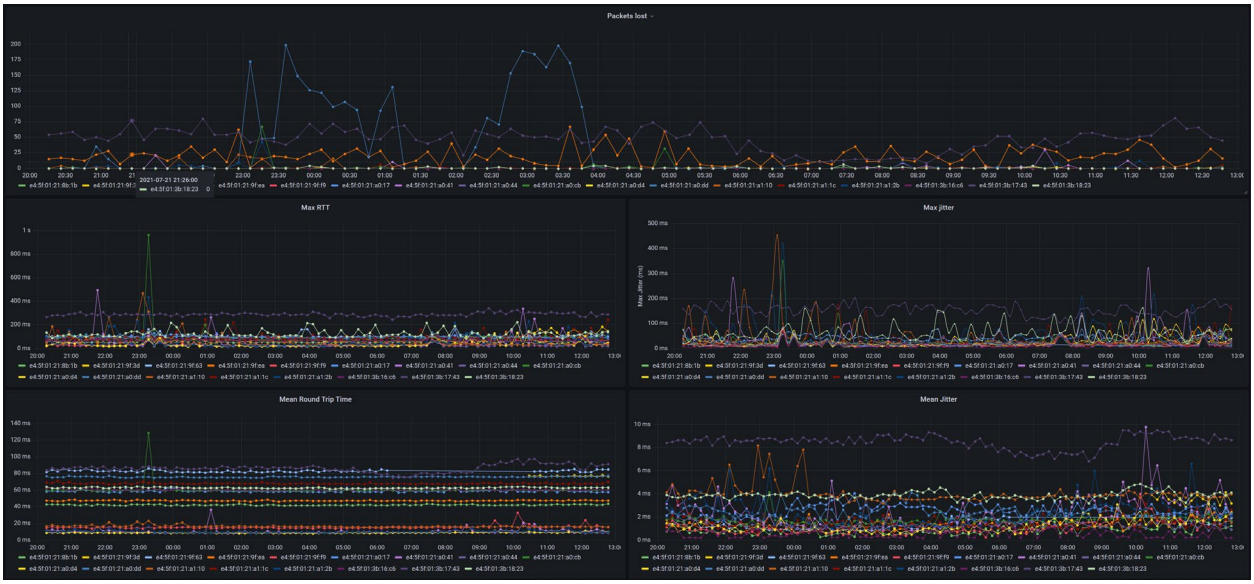


Figure 8 – Grafana Dashboard illustrating: Packet Loss, Max Round Trip Time, Max Jitter, Mean RTT, and Mean Jitter

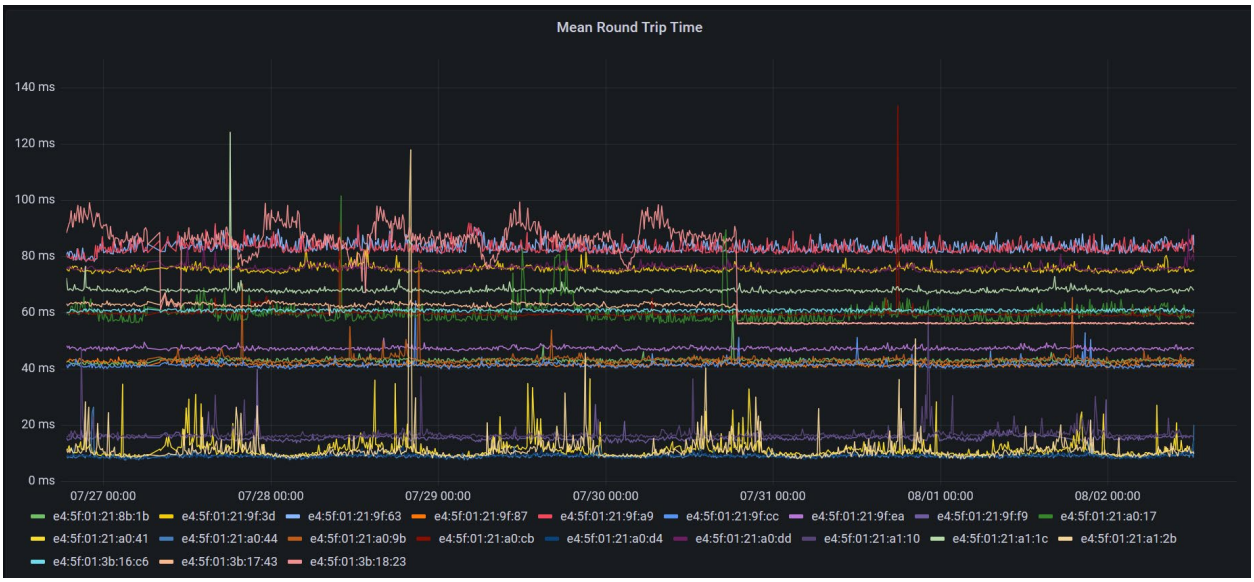

Figure 9 – Mean round trip time over several days of data. Note the cyclic increases for some devices (e.g. the yellow line near the bottom.)

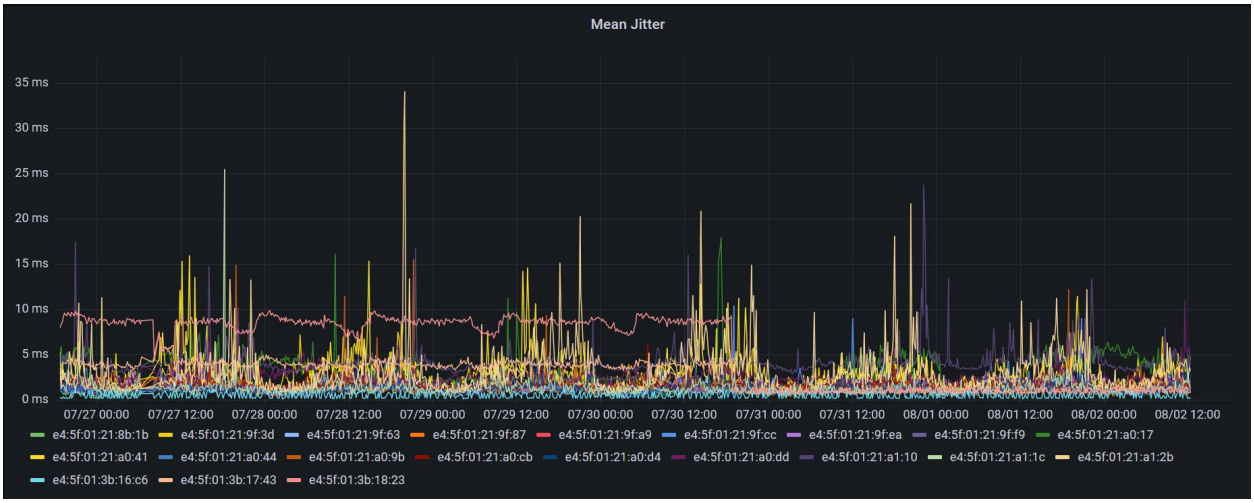

Figure 10 – Mean jitter over several days of data. Again cyclic behavior is evident for a few Lag-Pis.

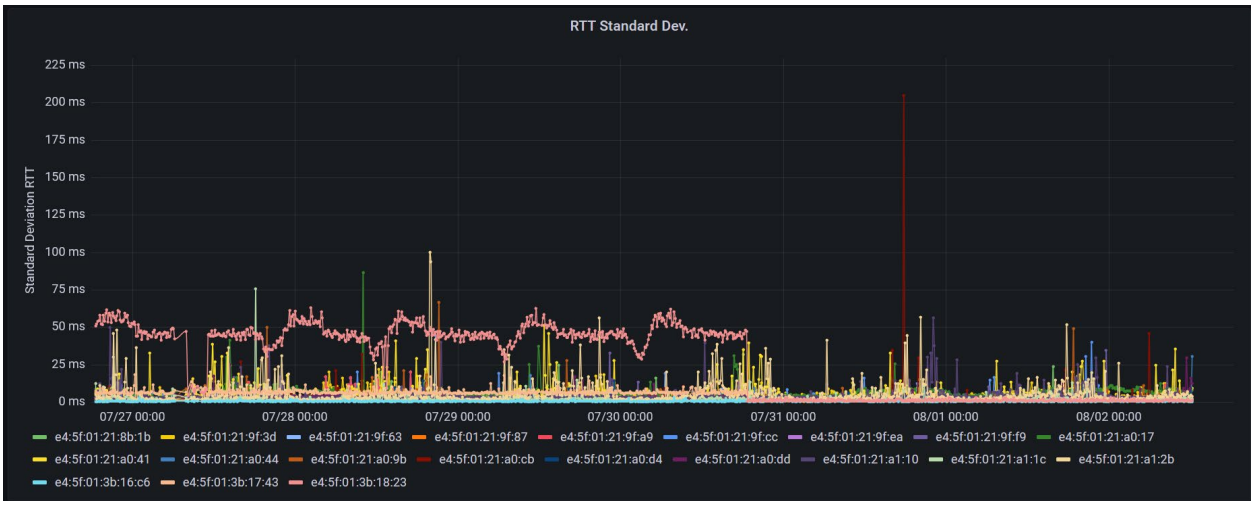

Figure 11 – Round trip time standard deviation across several days of data.

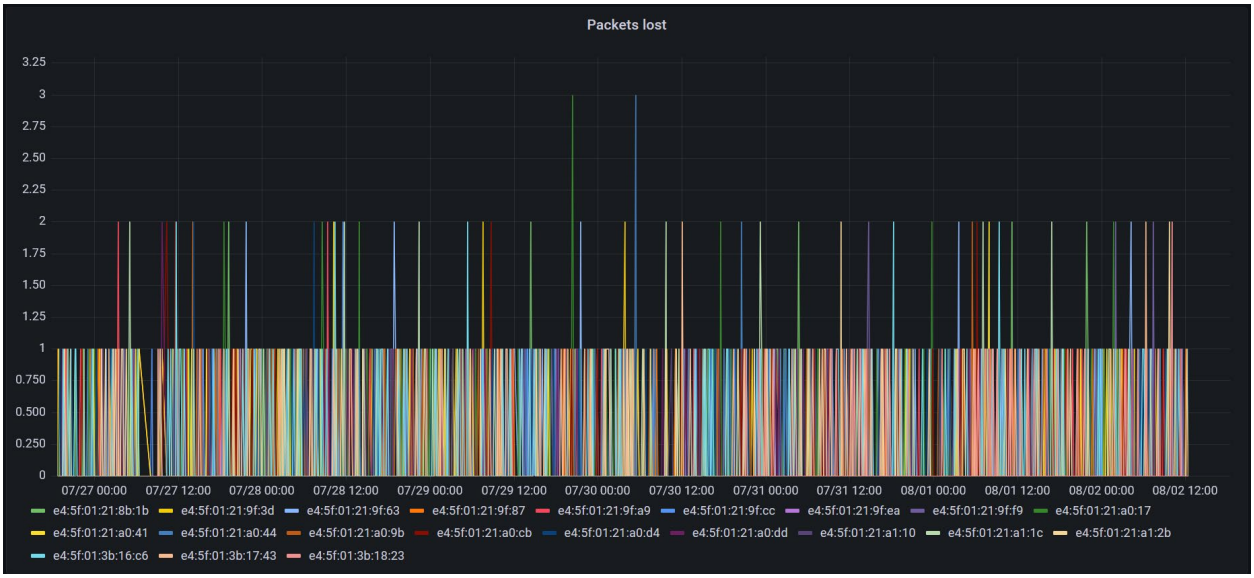

Figure 12 – UDP packet lost during test. Over this test interval, at most 3 packets were lost (out of 1500 sent during the test.)

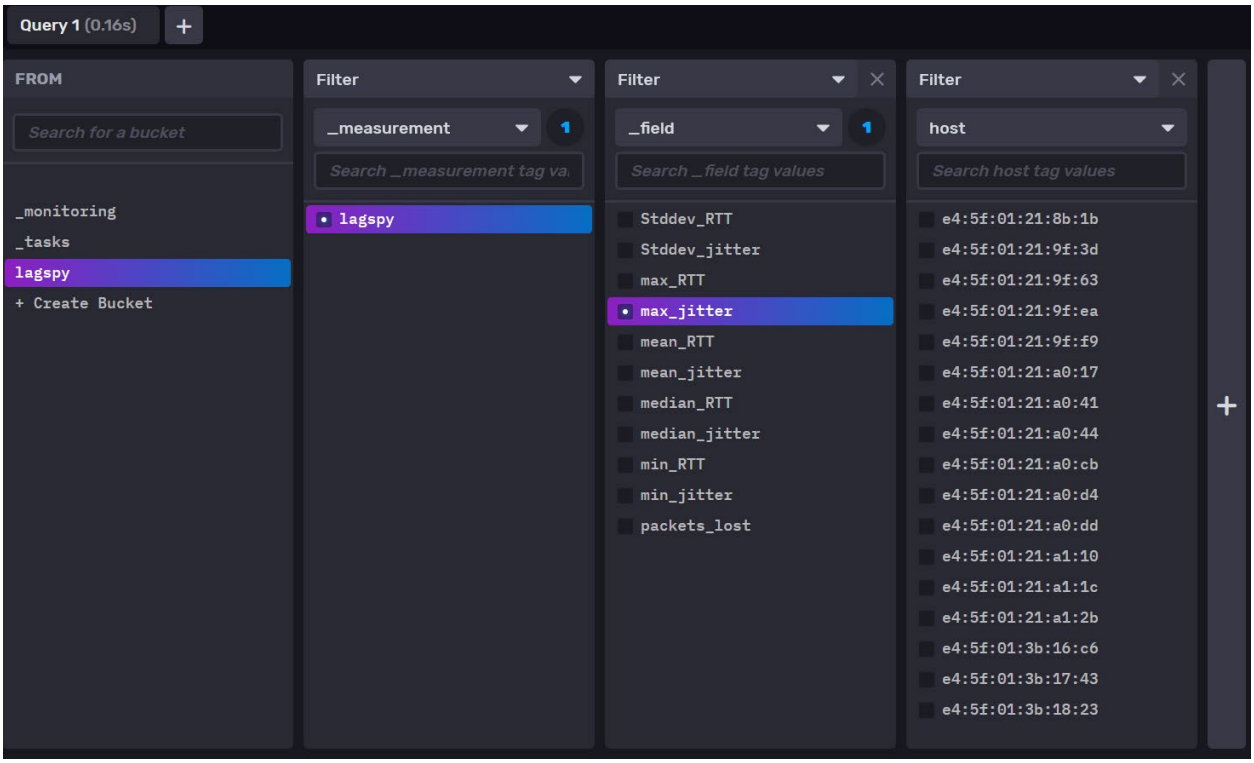

Figure 13 – InfluxDB Fields and Query Generator

3.7. Resource Usage

Application CPU and memory usage is minimal on the Lag-Pi. When idle, the CPU is 99.7% idle and there are 1.372 GB RAM free (on a 2 GB device). During an active IRTT test, 4.3% CPU is consumed by the IRTT process.

Table 3 – Application Resource Usage

Component	% Memory	Virtual Memory
Docker overhead (containerd, dockerd)	6.2%	3.4 MB
Python Test Client	0.6%	52 KB
IRTT Client	0.1%	879 KB

LagSpy is a lightweight application, especially on a platform that already has Docker running. This supports the long term goal of contributing LagSpy to a Linux-based gateway stack such as RDK-B or DD-WRT.

Note that Wireguard resource usage is primarily in kernel space and can't be easily measured.

4. Conclusion

This has been a project of discovery for our team, and we have learned the following lessons thus far:

- Approximately 50% of our Lag-Pi are deployed in an IPv4-only environment. Since Cox has enabled IPv6 for years, this was surprising to us. Many home routers still disable IPv6 by default.

- The Wireguard VPN implements an effective NAT keepalive using the `PersistentKeepalive` keyword. However this keepalive is disabled by default.
- There is a lot of variation in home network configuration, especially among our enthusiastic engineering volunteers. The sooner this functionality can be integrated into the home gateway, the better.
- The ability to remotely upgrade the Lag-Pi software has been critical even at this very early phase.
- Never underestimate the number of hurdles to jump through (e.g. security reviews) when setting up a server with a public IP address, no matter how trivial the service.
- There are still routers out there with outbound firewall policies.
- There is a software compatibility issue with NOOBS 3.5 and the Raspberry Pi 4B impacting about 10% of devices. Avoid this issue by installing Raspberry Pi OS directly onto the SD card.

Transitioning Advertising to IP Video

Technical Strategies for Migrating from QAM to ABR Video Advertising

A Technical Paper prepared for SCTE by

Jim Owens
Sr. Director, Video Advertising Solutions Product Management
CommScope

jim.owens@commscope.com

1. Introduction

Ever since the first cable networks launched in the 1970s, a major trend driving the programming of pay tv providers has been targeting. As more and more channels have launched to target specific interests, viewers have self-segmented. This, combined with the ability of cable networks to segment their networks into ad zones has enabled advertisers to target their ad dollars with increasing precision.

Today, the rise of Internet Protocol television (IPTV) and over-the-top (OTT) video has allowed content to be delivered to a growing array of connected devices. The transition to IPTV and the subsequent development of IP advertising technologies now enables service providers to take their advertising precision (and value) to a new level.

Many multiple system operators (MSOs) are betting on a transition from traditional quadrature amplitude modulation (QAM)-based cable TV to IP video based on adaptive bitrate (ABR) streaming using Internet-based approaches. To do so successfully, cable providers need a strategy that will enable them to gradually transition their legacy set-top box (STB) advertising platforms to the newer adaptive bitrate (ABR) dynamic ad insertion (DAI) systems without disrupting their existing, successful advertising businesses.

This paper provides an overview of how MSOs can prepare for the switch to IP video advertising while continuing to maximize the return on their legacy set-top box platforms.

2. Growth of IP Video

The use of IP and ABR video is increasingly prevalent. The IPTV market was valued at USD 72.24 billion in 2020 and is expected to reach USD 194.21 billion by 2026, at a compound annual growth rate (CAGR) of 17.89% over the forecast period 2021 - 2026.

Parks Research shows that 76 percent of consumers have an OTT service and 22 percent of broadband households have four or more services. As a result, some of the country's largest multichannel video programming distributors (MVPDs) have launched their own IP-based video services. In November 2016, AT&T introduced its DirectTV Now service (now AT&T TV), and Comcast followed suit in September 2017 with Xfinity Streaming service for existing Xfinity customers. In February 2019, Spectrum debuted its TV Essentials service.

One of the benefits of IP video is the ability to target addressable ads. Even today, the addressable ad market is well-established. According to USIM, currently, there are about 54 million MVPD (cable, telco or satellite) households that are linear addressable and 35 million that are ad supported video-on-demand addressable households.

However, the ability to target using traditional video delivery techniques to STBs is limited. Transitioning to ABR-enabled dynamic insertion offers more precise targeting and allows operators to charge more for the ads they deliver. Ultimately, the newer technology will provide benefits that the traditional set-top box can't offer. But as MVPDs build up the number of streaming subscribers to fully leverage this new technology, they need a strategy that allows for a graceful and gradual transition.

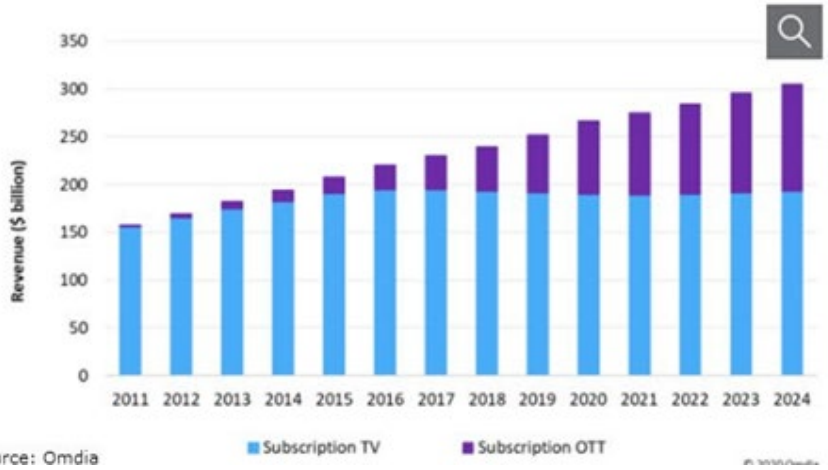

Figure 1 – Subscription TV and OTT Revenue Trajectory, 2011-2024

3. Legacy QAM STB Advertising vs. IP/ABR Advertising

While there are solutions for enabling limited addressable advertising capabilities in traditional STBs, this paper will focus primarily on network-based ad insertion techniques and their evolution as the industry migrates to IP video.

Today the majority of MVPD advertising dollars and subscription revenues come from the traditional set-top box platforms. Using MPEG-2 transport streams, ad servers and splicers, the platform inserts ads in pre-defined ad zones. The ad schedules, which are negotiated and bought, are locked 24 hours in advance. While the legacy STB platform still commands the bulk of the revenue for service providers, it is far from perfect.

For starters, ad zones are defined by geography, which is based on the service provider's access network topology and covers a relatively large area. Negotiating and selling the available ad space is also labor-intensive, involving advertising sales reps working with potential advertisers to fill all the available time slots. Because ad commitments must be locked in at least 24 hours in advance, service providers miss out on potential last-minute ad buys. Finally, the STB solution relies on a number of components that are hardware-based.

Conversely, IP-enabled advertising is a software-driven technology that offers more granularity and flexibility. It is enabled by adaptive bitrate technology that allows service providers to deliver multiple video quality levels within a video stream. Data within each stream is separated into fragments, each containing blocks of video encoded at different bit rates. The varying bit rates enable the media player to choose the appropriate bit rate based on the connection's performance level. The player relies on a manifest, which is essentially a list of available segments. At the simplest level, IP advertising is enabled by customizing this manifest for each stream and either adding or replacing existing segments to introduce ads that can be targeted down to individuals and sessions.

Beyond the technical performance advantages of ABR-enabled IP advertising, there are several significant business advantages. The IP-based technology works across any video device that connects to the internet. Therefore, service providers and their advertisers can reach viewers on whatever platform or

device they may be using. Because the technology is fully dynamic, ad decisions can be made in real-time, enabling advertisers to maximize their ad buy and helping service providers capture more last-minute sales. Ad sales can also more easily be automated using targeting criteria and real-time auctions.

The ability to target households, or even individual subscribers, with surgical precision is perhaps the most significant advantage of IP advertising. Addressability can be enabled via individual app and device-level data. Common targeting parameters include device, demographics, time of day/day of the week, content and category, location, etc. Advanced targeting can include content and purchase behavior, household income, product interest, and any other information available through the use of first and third-party data.

The advantage of this investment is obvious: providers can charge much more for addressable ads on IP—studies estimate up to 4-5 times more than for a regular ad. They can target down to the individual user and optimize ad delivery in real-time. This means higher ROI and the ability to capture new, hyper-targeted ad revenue streams.

The business case for making the transition to IP advertising is strong, but the market is still in the early stages. While IP offers better targeting and more dynamic sales models, the majority MVPD subscribers and ad revenue is associated with traditional STB advertising. Operators eventually need a unified solution that can address both markets.

The more immediate question for providers is how to make the switch in steps as they prepare their networks and organizations for the future while getting as much value as possible from their legacy STB platform. IP ad delivery utilizes entirely different technology, sales processes and ad decisioning. Implementing and adapting to these changes will take time, but there are steps that providers can take now and in the near future to prepare.

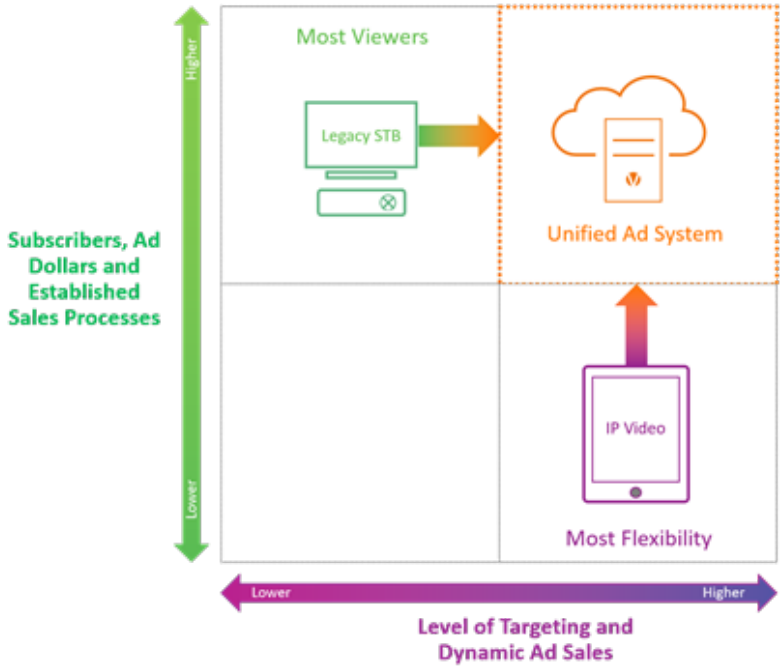

Figure 2 – Creating a Solution that Combines the Strengths of Traditional QAM and IP Advertising

4. Technology Overview

4.1. QAM Advertising

The QAM ad insertion stack consists of the ad insertion server and the splicer. Designed to perform frame-accurate operations on MPEG Transport Streams, the splicer can take an ad stream from the ad insertion server and replace the original bits in a live program stream. The ad insertion server is responsible for preparing and streaming the ads to the splicer, based on schedules published for each channel. The ad breaks are precisely signaled in band via the SCTE 35 standard. The splicer and ad insertion server use the SCTE-30 protocol to coordinate the timing of their activities.

Ad schedules are traditionally generated by a Traffic and Billing system, the function that resides in the ad sales operation and optimizes the placement of advertiser spots within the constraints of the ad buy.

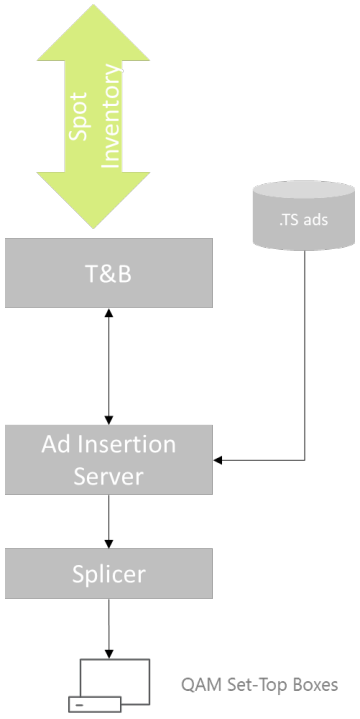

Figure 3 – QAM Advertising Stack

4.2. IP Advertising

There are two main approaches to inserting ads into ABR video, Client-Side Ad Insertion and Server-Side Ad Insertion. Both rely on the content being prepared so that segments align with ad insertion points and the appropriate markers identify the location of the ads. Client-Side Ad Insertions works by having the

client call to an ad server to obtain the correct ad. IP ad insertion is increasingly driven by Server-Side Ad Insertion, which will be the focus of this paper.

In IP video using ABR, the video segments are represented in a manifest, which lists the names of all of the segments that represent a live or on demand video stream. Each segment is also represented in multiple bitrates that can be selected based on the client's assessment of network performance and other factors.

In Server-Side Ad Insertion when an ad event is present, the Manifest Manipulator, using VAST or SCTE-130 standards, passes metadata from the client to an Ad Decision Service (ADS) and requests a decision on which ad to insert. The Ad Decision Service (sometimes just referred to as the Ad Server) identifies campaigns that are looking to target that particular client metadata and responds with one more targeted ads. The Manifest Manipulator then customizes the manifest with pointers to the new ad content segments and returns it to the client. Using this new manifest, the client then retrieves a personalized mix of content and advertisements (or other content).

Note that there can be multiple ADSs involved for a single piece of content that can be called depending on the ownership of the ad inventory. While the mechanics of that flow are outside of the scope of this paper, the Manifest Manipulator must be able to support multiple ADSs.

A separate process may be triggered to prepare the ads for delivery, particularly if they are retrieved from third parties dynamically. This may involve transcoding an ad from a mezzanine format into acceptable codec and bitrates or applying standard content profiles to an existing third-party ad.

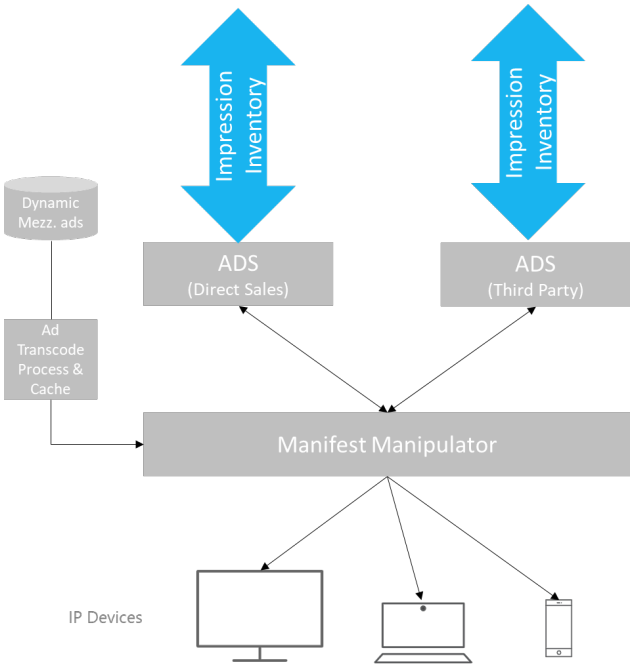

Figure 4 – IP Advertising Stack

4.3. Challenges of the Current Siloed Model

If treated independently, implementation of QAM and IP advertising models results in a siloed architecture, with lack of communication between the two and significant replication of resources. For example:

4.3.1. Separate Ad Decision Infrastructure

The separation of the ADSs for IP ad campaigns and a distinct Traffic and Billing system for scheduled ads limits the ability to generate revenue from the two systems:

- Difficulty in executing campaigns that address both IP devices and QAM STBs
- No opportunity to supplement local scheduled ads with dynamic impression-based ads
- Inability to sell unsold scheduled inventory with dynamic ads

4.3.2. Separate Ad Insertion Systems

The requirement to run and maintain two separate ad insertion systems duplicates operational and capex costs. Both a Server-Side Ad Insertion system based on Manifest Manipulation and a traditional QAM Ad Server and Splicer system need to be procured and maintained.

4.3.1. Parallel Ad and Entertainment Content Preparation

Just as the infrastructure to deliver the ads is replicated, duplicate systems exist to retrieve, process, and deliver entertainment content and ads. The cost of this delivery pipeline grows with the amount of content, the number of ads being targeted and the architecture of the network.

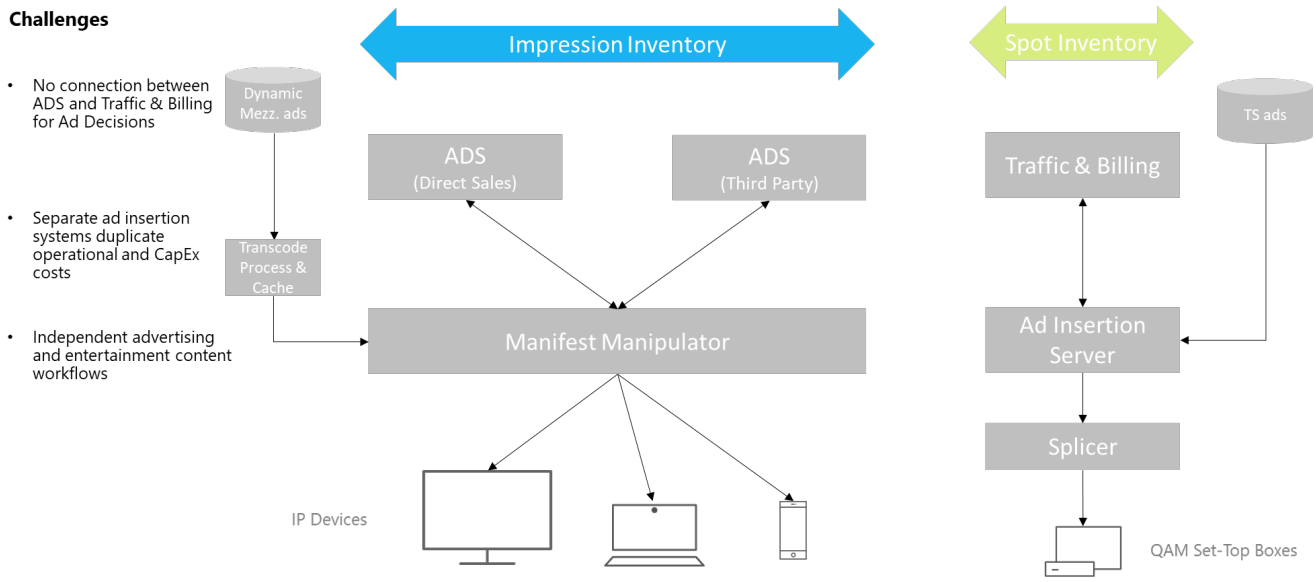

Figure 5 – Parralel IP and QAM Advertising Stacks

5. Business Goals for the Transition to IP

As operators make the transition to IP video and IP advertising, they must consider that traditional QAM video will continue to be delivered for some time and ensure that their existing advertising business is still efficient, profitable, and relevant. At the same time, they must invest in new solutions that leverage the capabilities of IP video, knowing that the number of viewers might remain relatively small for a period of time. This requires trade-offs and a concerted strategy that optimizes the existing business while positioning for the future.

Some of the business goals operators must consider when making this transition include:

5.1. Defend current QAM Advertising Business

As mentioned above, a key goal must be to defend the current advertising business while making the transition to IP video. This includes:

- Maintain existing business processes and ad revenue
    - Ideally the transition should allow for a period of time where existing ad sales, operations and technology can continue to run effectively on the existing QAM network without major changes.
- Extend zone-based ad sales to IP devices (IP Parity)
    - A common first step is to extend the current schedule-based ad sales to IP devices, often referred to as “IP Parity”. This means that ads purchased targeting QAM STBs by Ad Zone will appear on IP devices in that Ad Zone on the same services. This approach allows operators to establish an advertising system for IP devices without interrupting the existing business model. In this way, for a time the same ad sales process can address customers as they move to IP STBs and other IP devices.

5.2. Maximize Revenue

Once an IP advertising process has been established, operators can begin to not only take advantage of the new IP video capabilities but also optimize their legacy QAM advertising solutions to increase revenue. As will be outlined in more detail below, this involves leveraging the strengths of both platforms, beginning to unify some of technologies and enhancing the QAM advertising system to add some of the flexibility and targeting capabilities that are associated with IP advertising. These goals include:

- Monetize unsold ad inventory
    - Removing limitations on QAM ads sales that impose a 24-hour window. Operators can get an immediate revenue boost by making ads targeting QAM STBs more dynamic. Previously unsold inventory can be sold at the last minute, possibly using automated, programmatic techniques
- Enable a mix of scheduled and dynamic ads
    - At the same time, continue to support current ad sales and business processes, so that the system supports a mix of traditional schedule-based ads and dynamic ad placements
- Extend advertising to more channels
    - In many cases there are channels that are properly conditioned for ad insertion but due to low viewership or inadequate ratings data ads are not inserted by operators. The system

should be able to measure the viewing audiences on these channels and, if necessary, aggregate these viewers to make ad insertion on these channels profitable.

- Improve QAM advertising targeting capabilities
    - Leverage changes in the hybrid fiber coax (HFC) network architecture to enable finer-grained targeting of traditional QAM ads at the political precinct or neighborhood level.
- Enable campaigns across QAM and IP footprints
    - While transitioning from QAM to IP video, the solution should allow for operators to execute campaigns that address all device types (though not necessarily with the same targeting precision). This opens up opportunities for new types of campaigns and provides a model that is difficult for other players to offer.

5.3. Improve Operational Efficiency

Addressing a new IP video service that has different technical requirements and capabilities will require new technology and processes. Key to the success of this new advertising initiative will be the ability to optimize the different operational models to find efficiencies. Some of the critical areas include:

- Unify Ad Decisions
    - Eventually the solution should leverage a single "source of truth" for the subscriber data, targeting criteria and the campaigns that are available for execution. This system will incorporate both traditional schedules and dynamic campaigns and address all device types.
- Unify Entertainment/Ad Preparation
    - Great efficiencies can be found in standardizing on one video preparation workflow that can deliver entertainment content with advertising to QAM STBs and IP devices. Standardizing on ABR video formats as the source for both entertainment content and ads can reduce the costs of running two parallel video processing and preparation systems and prepare the operator for the all-IP video future.
- Unify Ad Insertion Systems
    - Similarly, relying on a single system for ad insertion/ad execution represents opportunities for opex and capex reductions versus purchasing and maintaining separate products.
- Transition to Virtualized Solutions
    - All of these migrations can also accelerate the move from hardware-based products to virtualized, software-based solutions that can reduce opex, capex and offer other advantages such as elastic scalability.

5.4. Enable New Business Models

Though not directly tied to the transition to IP video, operators are also looking to capitalize on new business models that leverage their unique knowledge of the end customer and position as owners of the delivery network.

- Insert ads on behalf of Content Partners
    - Cable operators are increasingly applying their ad insertion capabilities beyond the traditional inventory allocations on cable channels. Operators can insert targeted ads on national ad breaks on behalf of programmers and broadcasters on both traditional QAM STBs and IP devices inside and outside of the home. This opens up a new and very large part of the television advertising market.
- Enable Programmatic Sales Through Third Parties

- Operators can supplement their in-house ad sales with third party advertising networks to programmatically sell ad inventory that may previously have gone unsold.

6. Transition Strategy

6.1. Siloed Model

The siloed model represents serious challenges to achieving the business goals set out previously. However, there are some concrete steps operator can take to move their IP video advertising strategy forward.

6.1.1. IP Parity Through Processing of Existing Ad Zones Outputs

A common way to initiate IP advertising through IP parity in this model is to take the existing spliced channels and transcode and package them as separate IP video streams. In this model each ad zone becomes a separate version of the IP channel and is offered only to IP clients in that ad zone. As IP clients service by a CDN different techniques are employed to determine the location of individual clients and map them to existing ad zones. Support for out of home streaming may require additional sophistication. However, the goal of replicating Ad Zones on IP devices can be achieved without major changes to the existing systems.

Pros:

- Defend current QAM advertising business by extending scheduled ads to new IP subscribers
- Requires few changes to existing systems

Cons:

- Maintains dual processes for both QAM and IP video delivery
- Does not take advantage of the dynamic, targeted nature of IP clients
- Requires replicating video processing that may not be practical with large numbers of ad zones

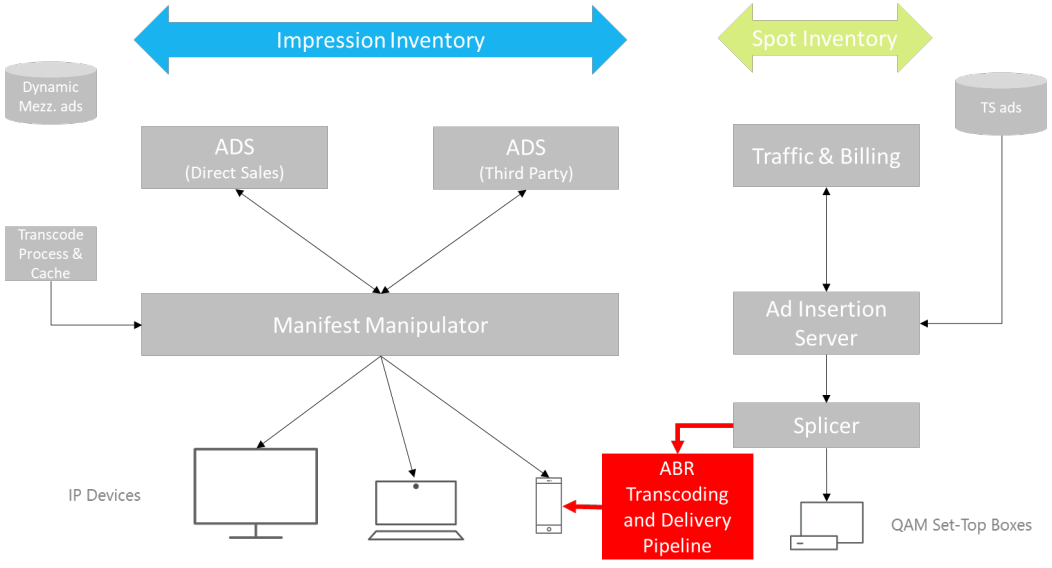

Figure 6 – Achieving IP Parity in a Siloed Model

6.2. Hybrid Model

The next step in the transition is a hybrid model, where both the IP and QAM advertising systems exist side-by-side but start to exhibit coordination and see reduction of redundant processes and components.

Some key steps in this stage are outlined below:

6.2.1. IP Parity Through Integrating Schedules into the ADS

A more sophisticated and efficient model of achieving IP Parity is by ingesting schedules into an ADS (or a component that can act as an ADS for schedule-based ads). The ADS processes the schedules and responds to queries from the Manifest Manipulator with the appropriate ad or ads. This approach has several advantages over the siloes model. First, it requires processing of only one version of each channel into the ABR format regardless of the number of ad zones. Second, it leverages a Manifest Manipulator for the ad insertion, establishing the infrastructure for future IP addressable ad insertion using standards-based protocols and processes. Third, it allows for the use of ABR content for IP ads, again leveraging a standard IP advertising process.

6.2.2. Add Dynamic ADS Integration to Existing Ad Insertion Servers

Just as a process can be established that delivers scheduled-based QAM ads to IP devices, the reverse can be enabled to allow the delivery of dynamic, impression-based ads to legacy ad insertion servers. By adding support for protocols such as VAST or SCTE 130 to the existing Ad Insertion Servers, the Ad Servers can identify ad avails that have not been sold and reach out to an ADS for a real-time (or near real-time) decision to fill the available spot. The ADS responds with ads that are part of campaigns targeting this inventory.

In conjunction with making the ad decision process more dynamic, the ability to collect real-time data from two-way STBs improves visibility and precision in ad measurement, which means that impression-based campaigns can be more dynamically interwoven with scheduled spots to better leverage inventory and increase ad revenue. It also expands the number of channels on which ads can be sold, due to precise viewership information for long-tail channels. This is accomplished by integrating with other elements of the video network, such as SDV servers that already aggregate channel tuning information.

This begins to accomplish the business goals of:

- Allowing unsold inventory on QAM STBs to be sold dynamically near the time of the ad placement
- Support a mix of schedule-based and dynamic impression-based ads on QAM STBs
- Begin to unify the IP and QAM decision systems
- More easily allow for the execution of campaigns across all device types
- Expand the number of channels that can support advertising

6.2.3. Add Support for IP Content to Existing QAM Ad Servers

Independently, or in conjunction with the integration of the Ad Insertion Server to the ADS, a further enhancement adds the ability of the QAM Ad Insertion Server to ingest ads in ABR format and stream them as MPEG-2 Transport Streams to a splicer. To do so, it may leverage the ad preparation process from the IP system, including transcoding and re-packaging.

This capability begins to achieve the business goal of unifying the ad preparation process and increases the universe of ad inventory available to the QAM ad insertion system.

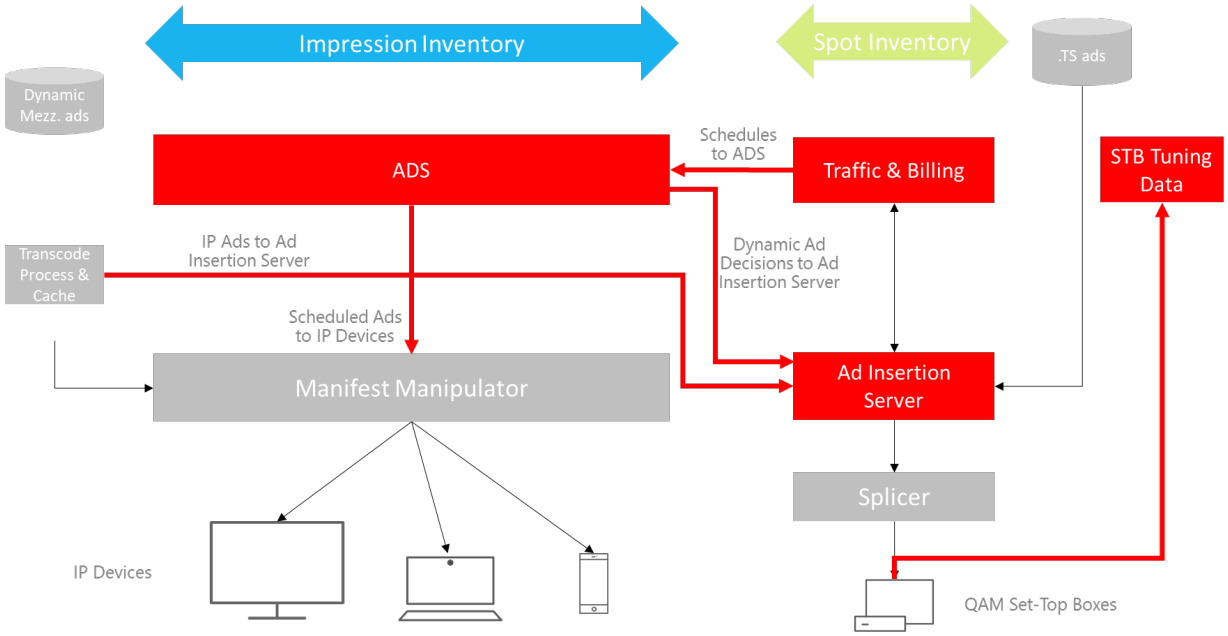

Figure 7 – Summary of Enhancements Possible in the Hybrid Model

6.3. Unified Model

The final model on the path to a full IP video delivery system is a unified model in which the advertising ecosystem has been consolidated into shared systems that support both IP and QAM devices yet fully support the capabilities of IP video advertising.

The characteristics of this model include:

6.3.1. Unified Ad Decisions Through the ADS

The ADS is the central point for all ad decisions, both IP and QAM. Dynamic ad decisions are used for ads delivered to both IP devices and QAM STBs. Scheduled ad sales may still be supported, but the system of record for these ad buys has shifted to the ADS. Note that multiple ADSs are still supported, as advertising inventory may be split between owners, and operators may call out to third party ADSs for decisions on ads sold by other parties in the ecosystem.

6.3.1. Unified Ad Insertion System

The unified model leverages the Manifest Manipulator for ALL ad insertions, using ABR video as the mezzanine format for all ad execution. Based on decisions from the ADS, the Manifest Manipulator generates both personalized manifests that establish a unicast stream to a specific device, but also "channel" manifests that can generate an ABR stream targeted by traditional Ad Zone or any other criteria desired. Similar to the way IP ad content support was added to the Ad Insertion Server in the hybrid

model, now the segments that comprise these ABR channels are converted to Transport Streams for delivery over the HFC network to QAM STBs. The result is a common ad execution platform based on virtualized software products, eliminating the need for traditional ad insertion servers and splicers.

6.3.1. Unified Ad and Content Preparation

Because all ad insertion is now done using ABR video as the mezzanine format, content preparation can be consolidated to a single workflow that uniformly processes and delivers video to QAM and IP devices. This step sets the business on a sustainable path of growth by further improving operational efficiency and adding flexibility to continue building the IP video network.

6.3.2. Enhanced Targeting of QAM Ad Insertion

Current Ad Zones offer powerful local targeting capabilities but are relatively broad compared to power of addressable IP advertising and are “hard wired”. Changes to the HFC architecture, such as switched digital video (SDV) (including the option of switching all QAM channels) and Distributed Access Architectures (DAA) represent opportunities to develop much more granular targeting for legacy STBs. For example, unique multicasts could be targeted to individual SDV service groups or DAA nodes, greatly enhancing the targeting capability of network-based ad insertion. The composition of the Ad Zone can also be flexible, dynamically assembled from the component service groups or nodes using software configurations.

The unification of content preparation and the efficiency with which channels variants with unique ads can be generated by the manifest manipulator make it relatively easy to generate the large number of targeted channels needed to take advantage of the greater number of smaller Ad Zones.

The unified model addresses the business goals of improving operational efficiency through:

- Unifying ad decisions
- Unifying ad insertion systems
- Unifying ad and entertainment content preparation
- Migrating all systems to virtualized solutions
- Taking advantage of enhanced targeting capabilities enabled by changes to the HFC architecture

Finally, the unified model establishes an advertising system that supports both IP and QAM devices, but is ready to transition to a full IP-only world without requiring any additional changes.

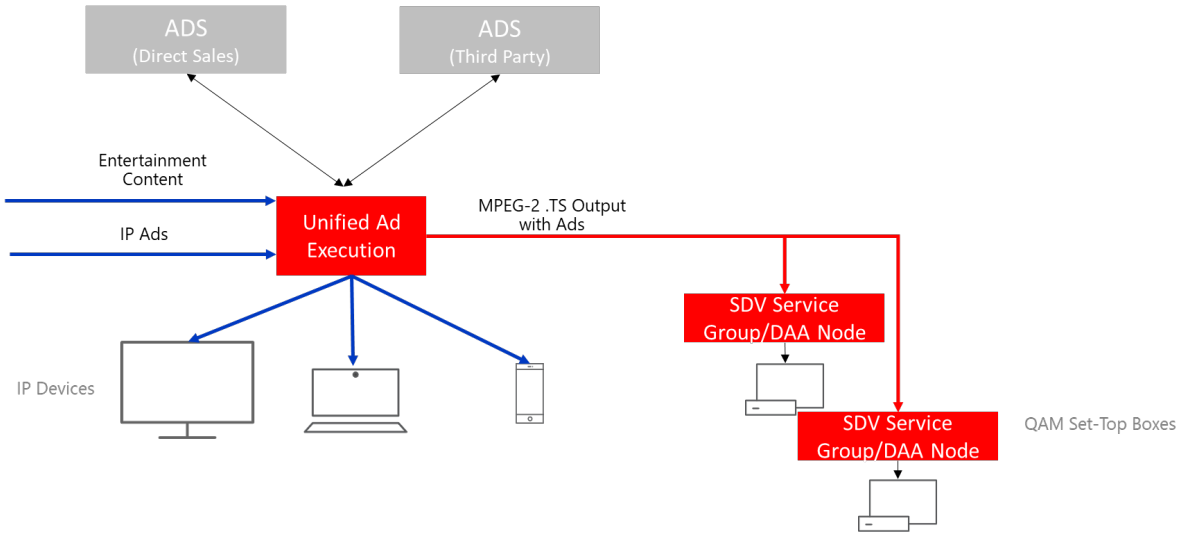

Figure 8 – Summary of Enhancements Possible in the Unified Model

7. Conclusion

As the chart below shows, different models address different business goals. The decision of how fast to proceed must be based on the return on investment, which will be unique for each operator based on factors such as the size of their subscriber base, sophistication of data collection and analytics, the maturity of their existing advertising business and the speed with which they intend to migrate to IP video.

	Transition Strategy						
	Silo	Hybrid			Unfied		All IP
	IP Parity - Xcode Ad Inserted Channels	IP Parity - ADS/Schedule Integration	Add Dynamic ADS Support to Legacy Ad Server	Add Support for IP Ads to Legacy Ad Server	Unified Ad Insertion Platform	Target QAM by SDV Service Groups/DAA Nodes	IP Advertising Platform
Business Goals							
Defend Value of Current Business					X		n/a
Extened QAM Advertising to IP Devices	X	X					
Maximize Revenue							
Improve Legacy Targeting Capabilities						X	n/a
Extend Advertising to More Channels			X		X		X
Leverage Unsold Advertisign			X		X		X

1. Abstract

This quantitative study considers the perceived effectiveness of virtual training events from the learner perspective. Data considered as part of the study include post-training participant evaluations gathered through the learning management system (LMS) of a large telecommunications operator, for both pre- and post-pandemic courses. Courses provided by eleven trainers from one geographic region were included as part of the study, and responses to evaluations were analyzed to identify whether a relationship exists between the trainers who received developmental training on adult learning theories and practices in the virtual classroom and participant perceptions of effectiveness. The findings indicate that participants have a more favorable perception of some elements of virtual training classes, when provided by instructors who have received additional training, and that instructors who have not received training receive lower scores in some categories. These findings indicate that adult learning theories and practices, if applied properly in the virtual classroom, create a learning experience that is just as effective as the traditional in-person classroom.

2. Introduction

Prior to the start of COVID-19 pandemic, the prevailing belief of many educators and business leaders was that in-person instructor-led training was far superior to virtual or online learning. Online learning experiences were considered a substandard or fallback option for workplace learning, and in many K-12 and post-secondary settings were often not considered at all. A report from the US Department of Education (2020) found that in the 2018 school year, 64.7 percent of post-secondary students were not attending any distance education or online courses, and only 16.6 percent were exclusively attending distance education courses. This paradigm shifted almost overnight, when the need for social distancing forced widespread migration to virtualized teaching and instruction for all learners, from K-12 and post-secondary to adult learning experiences in the workplace.

As a result of the shift, learning organizations have been challenged to re-evaluate how we transfer knowledge and specialized skills. Technologies such as Zoom, Microsoft Teams, and Cisco WebEx have replaced the traditional classroom environment in all levels of education. After a full year of distance learning, opinions vary widely on whether remote learning meets the needs of learners, or whether this learning modality should remain relegated to the role of a backup or emergency solution.

Modern theories of adult learning, known as andragogy, provide important insights into this question. Research indicates that effective and positive learning experiences can still occur in a virtualized delivery model. A 2010 meta-analysis of thousands of empirical studies by the US Department of Education found that students in online learning experiences performed slightly better than those in instructor-led events. Further inquiry is needed to gain additional insights specifically related to the pandemic and the experience of adult learners in the workplace, and could help expand the collective understanding of this important and timely topic.

3. Literature Review

The need for alignment to core andragogical theories in the online classroom is not a new concept. Malcolm Knowles, widely considered the founder of modern theories of adult learning, predicted in 1983 that the significant increase in electronic delivery of training would require adult learning professionals to learn how to “use the technology in congruence with principles of adult learning” (Blackwood & White, 1991).

3.1. Adult Learning Theories

The topic of how adults experience learning and transfer knowledge is a well-researched and robust area of study. Early works by Knowles (1975; 1980) outline the foundational principles that most subsequent studies have sought to prove or refine. The common characteristics of adult learners as understood within the profession (Merriam & Bierema, 2014; Abdullah, et al, 2008) are as follows:

- Self-Direction: Adult learners must be actively involved in the process of learning and have agency over the direction of the course, and in some cases, the selection of content.
- Experience: Adult learners bring their own life experience and knowledge to the learning environment, and effective facilitators of adult learning must recognize this and seek to connect the learners' experience to the topic being taught.
- Goal-Orientation: Adult learners have a goal in mind when attending learning experiences, whether that is to broaden their knowledge for a job or profession, or simply for personal development.
- Relevancy-Orientation: Adult learners must recognize the value or reason for the topic being taught, and tend to be more problem centered.

These principles have been further studied, refined and expanded upon since their introduction, but are commonly considered the core of adult learning practices, and apply in learning environments ranging from formal learning experiences such as post-secondary education to informal experiences found in social or community programs. Research on the use of these theories in the workplace learning environment is a fast-growing area of study (Caruso, 2018; Hendriks et al., 2018; Cookson, 2001; Grow, 1991), and the inquiries found in this study offer a meaningful addition to the literature.

3.2. Conversion to the Online Classroom

While the need for social distancing during the height of the pandemic required an immediate change to delivery methods, in many cases the content and learning outcomes were not in alignment with the modality. Davis and Arend (2013) clearly outline the different ways of learning and how a careful alignment between instructional methods and desired learning outcomes is critical to the success of any learning experience. Specifically in the context of online learning, Fein and Logan indicate that instructors must not directly transfer content originally designed for the in-person classroom without making the adjustments to the activities and program to better align with the learners' needs (2003). Further findings from Fein and Logan (2003) indicate that students rated courses more highly where the instructor made appropriate changes to adapt the course to the online environment.

Independent of the content itself, changes are required for the instructor in terms of methods and practices used for delivery. One of the notable challenges related conversion to online instruction is the complexity of the computer based classroom when compared to the traditional classroom. Instructors need to facilitate an environment where learners experience self-direction and construct meaning during the learning process, and must work to create meaningful discussion through improved listening skills and asking more facilitative questions to create dialogue (Davis & Arend, 2013; Fein & Logan, 2003). Realism of the learning environment is also key to success and learners benefit from the content being more project- and activity-based (Fein & Logan, 2003)

3.3. Andragogical Principles in Online Classrooms

Adult learning theory's application in virtual classroom environments is vast in scholarly literature. Arghode et al. (2017) and Deineha et al. (2020) have conducted systematic reviews on andragogical

learning principles that examine student's perceptions of excellent online instructional delivery. Findings suggest that instructor involvement is equally important and relevant when aligned with deep content (Arghode et al., 2017). Further evidence supports the theory that an online instructor can operate as a facilitator within the online student population by running activities and providing immediate feedback; this gives the students feel of control over their understanding and improved guidance throughout the course (Arghode et al., cites Yamagata-Lynch et al., 2015). Adult learning principles, when applied correctly, aid knowledge transfer by satisfying basic student needs. On the other hand, Arghode et al. (2017) and Deineha et al. (2020) also noted conflicts between students' perceptions when andragogical principles are applied for online classrooms in the same way they would be applied for in-person classes; resulting in negative student perceptions. Furthermore, the collaboration between teacher-to-student or student-to-student showed not to be perceived as necessary, stating that students were likely to favor individual work in an online setting (Arghode et al., 2017; Deineha et al., 2020). The literature analysis on adult learning theory in virtual classroom delivery shows a theme that adult learning practices for online environments require specific curating, similar to in-person adult learning. Likewise, a perceived gap suggests that little study has been done specifically for adult learners in a technical field under a large telecommunications operator.

The purpose of this quantitative study is to investigate the inclusion of foundational adult learning theories and practices in the virtual classroom for technicians of a large telecommunications operator, and analyze whether use of these methods in remote learning experience proves just as effective as in-person learning. To do so, we pose the following questions:

- Does the perceived effectiveness of virtual training change based on the use of adult learning principles/methods by the trainer?
- Do trainers who have received additional training themselves on adult learning in the virtual space receive better scores from participant on level 1 evaluations?

4. Research Methods

As detailed in the literature review, sources exist relative to the topics of adult learning theories and practices and the synchronous online environment, but limited research exists that specifically links the training of instructors back to the evaluation scores of learners. To that end, a quantitative method was selected for this study, in order to consider the existing data set related to learner reactions that is already captured in the Learning Management System (LMS).

4.1. Participants

The population considered in the study is comprised of employees within the field operations business unit of a large telecommunications operator, with the representative sample drawn from employees who completed any courses, both ILT and VILT, between July 1st 2019 and July 1st 2021.

The nonprobability sampling method was used to select one geographic region to consider as part of this study. This method was selected largely due to availability of data and because the particular region represents the phenomenon being studied (Creswell, 2003; Creswell & Guetterman, 2019). The region selected has a staff of eleven technical and safety instructors, some of whom received additional training and coaching on core adult learning theory and instructional methods in the virtual classroom, and others who did not.

4.2. Data Collection

The concept of levels of evaluation for learning experiences was first outlined by Kirkpatrick (1959, 1976, 1996) and is still a common method used to quantify impact of training. Kirkpatrick's model is comprised of four levels, typically explained as reaction (level 1), learning (level 2), behavior (level 3), and results (level 4). For purposes of this research, we are considering the level 1 evaluations for the selected group of learners. After completion of training courses, data were collected using a survey link sent via email to participants. Participants are not required to complete level 1 evaluations, and do not receive any follow up reminders if the evaluation is not completed. While the learner identities are captured automatically within the LMS, that information was removed from the data set for purposes of this study to maintain full anonymity of learners.

The evaluations contain a combination of question types, including traditional and modified Likert scale, Yes/No, multiple choice, and open-ended responses. For purposes of this study, the open-ended responses are not considered, due to the notable challenge with qualitative methodology and large numbers of responses which require significant time for accurate and meaningful coding and analysis to identify themes (Creswell, 2003; Creswell & Guetterman, 2019).

Question across the three evaluations ranged from the topic of pace ("The pace of the learning was…" with learners given modified Likert scale options) to topics of applicability ("Select the statement that best reflects your ability to apply the information"). In addition, one evaluation included questions that were specific to the performance of the instructor ("Did the facilitator of the course…Create an environment where I could ask questions and provide input?") answered using a traditional Likert scale.

4.3. Data Analysis

The data were exported into a spreadsheet from the Cornerstone™ LMS. Information that could be used to identify individual respondents (e.g. employee number) was removed from the data set. The trainers were each assigned a number (e.g. Trainer 1) which was used throughout the rest of the analysis. As noted above, the open-ended text responses are not considered within the scope of this study, and were removed from the data set. All Likert scale responses were coded using numeric values (e.g. 5 - Strongly agree, 4 – Agree, 3 - Neither agree nor disagree, 2 – Disagree, 1 - Strongly disagree) and Yes/No responses were coded as Yes=2 and No=1. A modified Likert scale was used for multiple choice questions with four possible answers, where 4 represents the positive response and 1 represents the negative response.

The database also required cleanup activities to remove responses not relevant to this study, such as questions asking for the name of the instructor. In addition, all non-answers/non-responses were removed from the data set.

The data were organized into four discrete groups, representing the time frame of pre- and post-pandemic, and further into groups representing those trainers who received additional training themselves on incorporating adult learning theories and practices into the virtual classroom, and those who did not. The groups were labeled Group 1, Group 2, Group 3 and Group 4 to enable simple comparative analyses of the data. See Table 2 for detail on group designations.

Table 1 – Group Designations

Group	Description	Start Date	End Date
1	Pre-COVID ILT	July 1, 2019	March 1, 2020
2	VILT, Prior to additional training being offered	March 1, 2020	May 1, 2020
3	VILT, Trainers who received additional training	May 1, 2020	October 1, 2020
4	VILT, Trainers who did not receive additional training	May 1, 2020	October 1, 2020

Trainers from the selected sample were assigned to groups based on specific criteria. All trainers from the selected sample were assigned to both groups 1 and 2, since all trainers delivered ILT prior to the pandemic, and all trainers delivered VILT sessions without receiving additional training during the early months of the pandemic. The trainers were then assigned either to group 3 or 4, based on whether they received developmental training in the following months. See Table 3 for detail on group assignments.

Table 2 – Trainer Group Designations

Code	Group 1	Group 2	Group 3	Group 4
Trainer 1	x	x		x
Trainer 2	x	x	x	
Trainer 3	x	x		x
Trainer 4	x	x		x
Trainer 5	x	x		x
Trainer 6	x	x	x	
Trainer 7	x	x		x
Trainer 8	x	x	x	
Trainer 9	x	x	x	
Trainer 10	x	x	x	
Trainer 11	x	x		x

After separating the data into four groups, the Likert scale questions were separated from the other types of scored questions, to enable numeric analysis using the same 1-5 scale for Likert, and the 1-4 and 1-2 scale for multiple choice and yes/no, respectively. Lastly, in the final data analysis all numeric values were converted to a percentage (e.g., for Likert scale the maximum number of points available is 5, so the final score for each category was divided into 5, while the multiple choice maximum score was 4, so the final score for those categories was divided into 4, and so on). This method enabled a more mathematically accurate comparison of participant response patterns.

As noted earlier, participation in level 1 evaluations after course completion is voluntary, so the results represent only those learners who chose to provide feedback. A total of 98 unique participants provided responses for courses attended during the considered time. Gathered responses were separated into the group categories identified in Table 2. In analysis of the four groups, no responses were received for any VILT courses provided during the identified time period for group 2. VILT courses were offered during this time period by the identified instructors, but no participants responded to level 1 evaluations for the VILT courses. As a result, group 2 data was not used as a comparative for the purpose of this study. Data were able to be considered related to group 1, identified as the pre-pandemic traditional ILT classroom. This dataset is used for the control in order to have a meaningful comparative for groups 3 and 4.

During the time period considered, data was collected using three different level 1 evaluations. To combine these data sets, all individual questions from the three level 1evaulations were reviewed and assigned to one of three possible categories, and one of ten possible subcategories. This categorization aligns with the foundational adult learning principles related to the questions, and enables us to consider the unique participant responses independently of the specific evaluation used, and thus identify trends in the responses. The three categories questions were mapped to are learner needs, learning technology, and adult learning theories and practices. Some subcategories may align with multiple higher-level categories, to enable deeper analysis of topics as aligned to adult learning theories. See Table 3 for detailed category and subcategory mapping.

Table 3 – Evaluation Questions and Categories

Categories	Subcategories
Adult Learning Theories & Practices	Instructor Overall Satisfaction
Adult Learning Theories & Practices	Classroom Management
Adult Learning Theories & Practices	Learning Objectives
Adult Learning Theories & Practices	Instructor Communication
Adult Learning Theories & Practices	Instructor Knowledge
Adult Learning Theories & Practices	Learning Pace
Learner Needs	Content Related to Job
Learner Needs	Learning Pace
Learner Needs	Overall Satisfaction/Recommendation
Learner Needs	Instructor Interaction
Learner Needs	Instructor Overall Satisfaction
Learner Needs	Learning Objectives
Learning Technology	Learning Technology

After mapping all questions to these ten subcategories, we identified significant challenges with categories of instructor interaction, instructor knowledge, instructor overall satisfaction, learning pace, and overall satisfaction/recommendation. Earlier level 1 evaluation models containing questions with these topics used a Likert scale, affording participants more range of possible answers; while the later version of the evaluations changed this concept to a yes/no question. The change in question and answer criteria caused significant variances between the two data sets, and we determined that the best and most accurate way to address this was to remove these categories from consideration within the scope of this research to avoid any potential inaccuracies in findings. Additionally, the subcategories of classroom management and instructor communication were not able to be mapped to the newer questions in the later level 1 studies, so these were also removed in order to avoid errors. The three remaining subcategories are considered within this study: content related to job, learning objectives, and learning technology.

5. Results

As noted in the literature review, adult learners tend to be practical and have a need for their learning experience to be relevant to their life or work (Merriam & Bierema, 2014). The subcategory of "content related to job" contains all questions from the three different level 1 evaluations that were determined to align with this concept. See Table 4 for all included questions for this subcategory. Participant mean

responses in group 1, the pre-pandemic traditional ILT group, were 86.53 percent positive, while group 3 and 4 responses were 89.29 percent positive and 87.50 percent positive respectively.

Table 4 – Content Relevance to Job Category

Question Text
I had sufficient opportunities during the training to apply and practice the concepts and skills presented.
This session has increased my ability to perform my current job.
Training activities reflected real world, on-the-job situations.
I plan to use this information in my current job.
The material covered is relevant to my job.
I would recommend this training program to a colleague in a similar position.
Select the statement that best describes examples and activities in the course.

The second subcategory analyzed was learning objectives, aligning with the adult learner's need for clarity on the goals and intended objectives of their learning experience (Merriam & Bierema, 2014). The questions included in this category address both the participant perception of their understanding of the objectives (e.g., "I had sufficient opportunities during the training to apply and practice the concepts and skills presented") and the participant perception of the facilitator's ability to clearly explain the objectives (e.g. "The facilitator clearly explained the program objectives"). See Table 5 for all included questions in this subcategory.

Table 5 – Learning Objectives Category

Question Text
The learning objectives were clear.
The facilitator clearly explained the program objectives.
I had sufficient opportunities during the training to apply and practice the concepts and skills presented.
Select the statement that best reflects your ability to apply information.
The facilitator clearly explained the program objectives.

For group 1, participant mean response was 87.20 percent positive, compared to 78.57 percent positive and 75.00 percent positive for groups 3 and 4 respectively.

The final subcategory of questions considered within the scope of the research was learning technology, which included questions designed to gather participant perceptions of whether the use of technology supported or detracted from their learning experience. See Table 6 for included questions in this subcategory.

Table 6 – Learning Technology Category

Question Text
Did the learning environment and/or technology support your learning?
Select the statement that best describes the use of technology in this course (if applicable).

The mean participant response for group 1 in the learning technology subcategory was 84.78 percent positive, compared to 82.14 percent and 98.75 percent for groups 3 and 4 respectively.

5.1. Discussion

While we anticipated that the mean evaluation scores for ILT (group 1) compared to VILT (groups 3 and 4) courses would show a higher positive response for ILT; that was only found to be the case for the subcategory of learning objectives, with the ILT group having a mean score of 87.20 percent compared to the much lower scores in groups 3 and 4 (78.57 and 75.00). This may indicate that instructors are more accustomed to clearly identifying the desired outcomes or objectives of the course in the traditional classroom compared to the VILT environment. Another interpretation could be that the participants scored this category higher for ILT because they were better able to understand and identify the objectives of the course, related to greater opportunities for hands-on practice of skills. Group 4, the trainers who received less developmental training on adult learning theories in the VILT environment, were lower than their peers who received the additional training, implying that they were less proficient at recognizing and including the importance of reinforcing learning objectives within this type of environment.

The category of content relevance to job was marginally higher for group 3, the group of trainers delivering VILT courses who received additional training on adult learning theories and practices. This finding implies that even in an online environment where learners are afforded limited opportunities for practice of the skills learned in the course, an instructor who uses techniques to engage the learners and construct meaning is able to foster an environment where learners are able to identify how they can use the information back on the job. An interesting pattern that also emerged in this category was that those trainers receiving this additional training scored higher in this category for VILT courses, even when compared to traditional ILT courses. Additional developmental training for instructors on adult learning theories and practices had an overall positive effect on learner perceptions, regardless of the type of classroom environment.

The final category, learning technology, provided surprising and important insight into learners' perceptions of the role of technology in the ILT environment compared to VILT. The ILT course perceptions related to technology use represent participant impressions do not relate to the use of an online/virtual teaching medium (e.g. Webex), but rather are connected to the use of technology labs or other materials found in the ILT setting. As such, this data point is less effective when used in comparison to the learner perceptions recorded for groups 3 and 4, in the exclusively VILT settings. What is unexpected about this data is the significantly higher (>10 percent) favorable scoring for group 4, the trainers who did not receive additional coaching on adult learning practices prior to delivering these courses. The trainers in group 3 who received additional developmental training on adult learning in the VILT environment also received coaching on use of tools within the online training platform, such as breakout rooms, polling, and other features. It is likely that these trainers subsequently utilized these tools during their sessions; and the participants' lower positive score may indicate that the use of these tools distracted them from the learning. The findings may also indicate that group 4 instructors relied more heavily on their instructional techniques rather than the online tools, again creating less distraction for the learner.

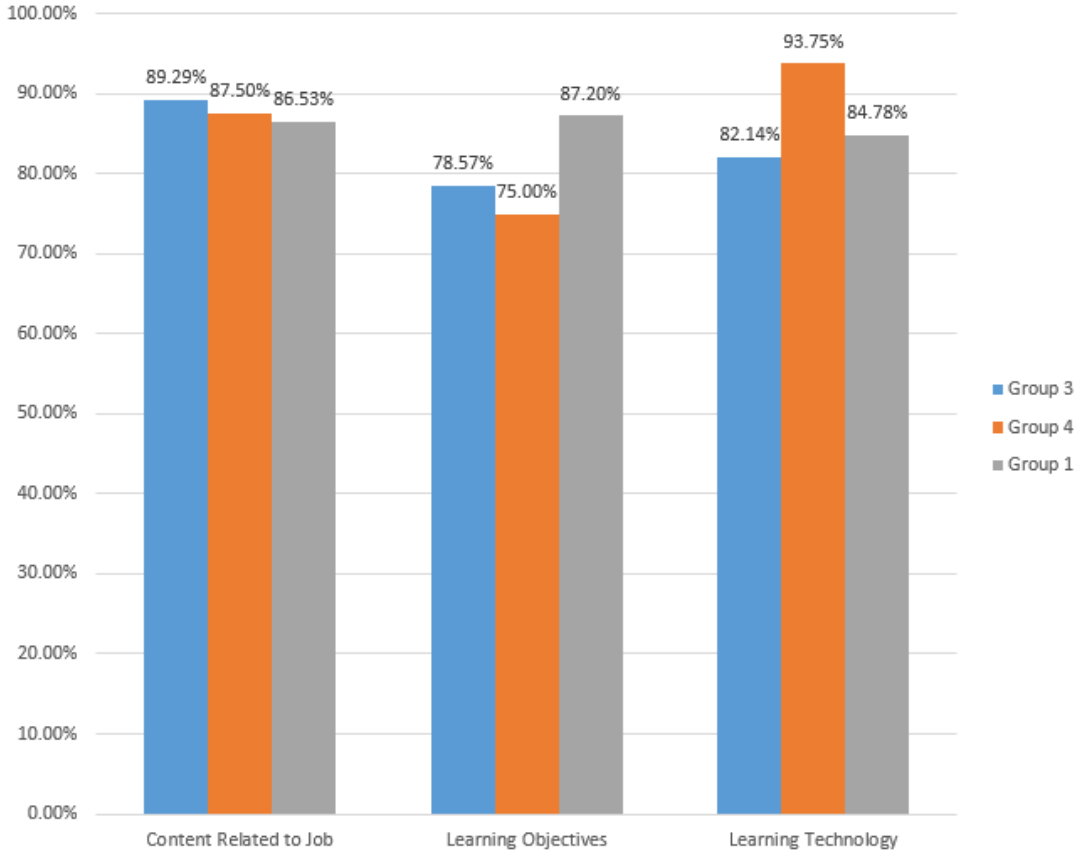

Figure 1 – Category and Group Comparison

5.2. Study Limitations

While this study provides a fascinating starting point for inquiry into this topic, some limitations exist related to the data available. The first consideration is related to the sample, and whether it accurately represents the population considered. Specifically, since level 1 evaluations are not a requirement of learners but are considered optional, we are only gathering the opinions and perceptions of those learners who felt strongly enough to take the time to respond. As a result, the responses may be skewed either towards a more positive angle (learners who felt strongly that the course went well and wanted to provide this feedback) or a more negative angle (learners who had a poor experience and want to share this). Greater accuracy could be obtained by sampling a set of the larger population and requiring learners to respond within the sample, to ensure that positive, negative, and neutral responses are all gathered and considered.

Another limitation of the study is related to the technology and the function of the LMS used to gather the data. Learners are not issued the level 1 evaluation invitation until the trainer providing the training marks the course roster as complete. As a result, if there are any issues with the roster close-out process, the learner may not even be given an opportunity to respond.

We were also challenged by the change of the level 1 evaluation questions during the time period considered. While the overarching topics were generally similar, as evidenced by the ability to categorize the questions for scoring analysis, it is certainly a challenge to have the required level of clarity on the data when there are significant differences in the data set. Specifically, several of the categories changed

from a 5-point Likert scale to a 2-point yes/no scale between iterations of the report, which rendered meaningful analysis within these categories impossible. Future studies of this type would be enhanced through the use of a consistent set of questions and question categories for the entire time period considered; which was not a possibility for this particular inquiry.

Lastly, the subjective open-ended responses that participants provided were not analyzed in this study. To appropriately code qualitative data, researchers must perform extensive review and analysis to ensure accuracy and objectivity (Creswell, 2003). Future studies of this type would benefit from a mixed-methods approach in order to gather both the quantitative responses that can be more easily analyzed, alongside open-ended qualitative responses from learners. Greater triangulation by considering perspectives from different sources beyond just the learners (e.g. trainers, operational leaders) could also strengthen the data and findings.

6. Conclusion

The findings of this research show a pattern of positive learner perceptions of virtual courses after the trainer has received additional training on virtual facilitation techniques and adult learning theory. Concepts from the literature related to application of adult learning principles in general, and specific guidance for the online classroom were supported in the findings. Although future study is needed to further explore this topic, the present study has enhanced the understanding of the relationship between application of adult learning principles in the online learning space, and positive participant experiences.

Abbreviations

LMS	Learning management system
ILT	Instructor-led training, used to indicate in-person/classroom training
VILT	Virtual instructor-led training, indicates online training
K-12	Kindergarten through twelfth grade school setting

Michael.Wang@sjrb.ca

1. Introduction

Network operators must modernize their networks to support the growing demand for faster internet connections, mobile backhaul and fronthaul, and business services. Universal aggregation is a converged networking approach that uses a shared coherent Dense Wavelength Division Multiplexing (DWDM) core with Internet Protocol (IP) routing and switching platforms.

As is the case for other Multiple-System Operators (MSOs), Shaw must remain competitive while striving to meet the intense challenges of delivering a better user experience during the COVID-19 pandemic. The pandemic has put increasing pressure on many operators and universal aggregation could prove to be a valuable tool for their current and post COVID-19 challenges. It provides the right speeds, footprint, aggregation, and automation capabilities with the ability to integrate Internet Protocol/Multi-Protocol Label Switching (IP/MPLS) with transport infrastructure.

This paper outlines Shaw's work to provide universal aggregation under its modular, coherent DWDM platform while providing greater capacity and significant network cost reduction. The legacy approach to deploying multiple interconnected and complex platforms for each type of service—such as residential, mobility, and business—often results in increased operational cost and difficulty troubleshooting.

For operators, universal aggregation creates a smarter, simpler, and more agile network. Shaw's universal aggregation network supports 100 Gigabits Ethernet (100GbE), Optical Transport Unit 4 (OTU4), 10 Gigabits Ethernet (10GbE), and Optical Transport Unit 2/2e (OTU2/2e) over 100Gbps & 200Gbps wavelengths. It uses a Zero Touch Provisioning (ZTP) system that simplifies operations and allows Shaw engineers to automate most of the deployment tasks. Currently, its maximum bandwidth capacity is 1 Terabit Per Second (Tbits/s) in a single rack unit at 224 watts. The paper will present a comprehensive overview of the implementation process and important considerations for the industry to replicate Shaw's success.

2. Drivers for Convergence

Operators' economic environment has changed significantly over the last two years.

Firstly, there has been a dramatic increase in traffic due to the explosion of residential data/video/voice, mobile xHaul, and business services. It has significantly reduced the spare capacity in the deployed networks and making it necessary to overbuild and introduce new transport technologies to satisfy projected traffic demand. Secondly, most operators are experiencing a need to reduce their operational costs, particularly in building and managing complex multilayer, multivendor networks. To simultaneously satisfy these two trends, operators need to integrate residential, mobility, and business traffic under a single transport network while also providing a simple and automated way to manage that network.

In network infrastructure, where in the past it may have been necessary to use separate equipment for optical transport (layer 1), Ethernet switching (layer 2), and IP/MPLS routing (layer 3), there is an evolution toward a model where all three tiers are integrated. The trends show a convergence of DWDM with Ethernet/client Optical Transport network (OTN)-Synchronous Optical Networking (SONET) as the initial step, and the integration of DWDM/Ethernet-OTN-SONET with IP/MPLS in the future. Separately, there is also a trend toward integrating three types of network services onto common infrastructure: residential, mobility, and business. Furthermore, network-layer convergence will integrate photonic with Ethernet/client OTN/client SONET and IP/MPLS.

Tables 1 and 2 demonstrate the concepts of traffic-type convergence and network-layer convergence, respectively.

Table 1 – Traffic Convergence

	Traffic Categories
Traffic Convergence	Residential
	Mobility
	Business

Table 2 – Network-Layer Convergence

	Network Layers
Network-Layer Convergence	Tier 1 - Optical Photonic
	Tier 2 - Carrier Ethernet
	Tier 3 - IP/MPLS (Future)

2.1. Convergence of Traffic Types

Since March 2020, cable networks have seen a 30.8% growth in downstream traffic and a 54.8% growth in upstream traffic (**ref. [9]**), and the enormous growth in the three service types is exacerbating network silos for operators. The convergence drivers for different traffic types will be discussed in detail below.

2.1.1. Residential Traffic

Over the years, the MSO landscape has proven itself to be dynamic. Residential triple-play once dominated revenue opportunities. Although cable operators are turning their attention to new revenue-generating opportunities in wireless and business services, residential is still a crucial revenue source. Now, operators are focused on aggressively reducing the operational costs of delivering residential services while continuing to meet customer demands for faster speeds.

Residential broadband services are generally carried over a separate DWDM/MPLS network from other types of services, managed by distinct network monitoring systems and, most importantly, live in their own priority structure. They have their own service tier, service-level agreement (SLA), latency requirements, and so on. The residential offerings act as an independent silo with the potential for significant operational inefficiencies.

If operators continue to operate their residential broadband products as separate silos they are at risk of failing to achieve the operating margins necessary to remain competitive due to a duplication of efforts and lack of focus. This could allow telcos that *can* offer multiple services on a converged platform to take their market share.

2.1.2. Mobility Traffic

After significant growth and success in video, data, and land line voice services, wireless is the next frontier for cable. Quarter over quarter, the US cable mobile virtual network operator (MVNO) business continues to see mobile subscriber growth (**ref. [1]**). As of 2021, less than four years after the launch of the first MVNO by Comcast, three US cable MVNOs combined have amassed millions of customers. Comcast and

Charter MVNOs utilize Verizon as the mobile network operator (MNO). Recently, Cox Communication also demonstrated an interest in starting an MVNO. The momentum is there, and executive leadership at cable companies has consistently shown strong support for and interest in growing the wireless business.

Comcast and Charter have been signaling for some time that they intend to build Citizens Broadband Radio Service (CBRS) based mobile networks in their existing cable footprints in an effort to reduce the compensation given to Verizon and other MVNO partners for use of their networks **(ref. [2])**. Their MVNO operations were intended as a way to build a subscriber base and brand in advance of owning their own wireless networks, despite incurring consistent Earnings Before Interest, Taxes, Depreciation, and Amortization (EBITDA) losses for an extended period of time. Cox—which had entered the wireless space a decade ago, only to exit after disappointing results—has signaled its intention to re-enter the wireless market through the purchase of a significant number of CBRS licenses across its cable footprint. The largest cable operators already have a dense network of millions of Wi-Fi hotspots that can easily be turned into 5G small cells to create a mobile network.

In contrast to the US, virtually all of Canada's largest cable and telco operators offer residential wireline, business wireline, and mobile services on their own infrastructure (**ref. [1]**). Rogers, Canada's largest cable and mobile operator, has been offering mobile services since 1985, with Vidéotron launching its wireless services in 2010, and Shaw acquiring Wind Mobile in 2015. The Canadian market faces strong competition from Canada's large incumbent telco operators, which have invested heavily in fiber to the home, connecting more than 60% of their broadband homes directly to fiber, and leveraging a robust Radio Access Network (RAN) sharing agreement to minimize their infrastructure costs.

Today's cable operators are tomorrow's mobile operators **(ref. [3])**, and behind every efficient wireless network, there must be a converged wireline network. The industry has reached the consensus that optical DWDM transport's capability of transmitting a large number of information streams simultaneously over a single optical fibre makes it the best possible solution for the most demanding xHaul needs. Operating separate residential and mobile optical cores is prohibitively costly for operators, while converging optical networks into a single, common core will significantly cut costs and improve network agility. A converged network will manage peak traffic load more effectively, improving both speed and performance.

2.1.3. Business Traffic

Operators of all sizes have found growing opportunities to take part in the lucrative and ever-evolving business services space. While the battle for the wireless dollar has gotten most of the ink in the trade press recently, the traditional telcos and cable MSOs are waging a war on another, less publicized front: the small and medium-sized business market. The telcos are moving aggressively into the residential video services market, where cable operators currently enjoy a high penetration rate. To compensate for the loss of residential video customers, operators have chosen to pursue perennially underserved small- and medium-sized businesses. And they are winning over these customers with Carrier Ethernet.

Operators typically deliver business services over disparate architectures. A high-security application, for example, runs over its own DWDM wavelength. Schools, financial institutions, and telephony that require fast switching (50-millisecond) protected services would be typically served via a SONET network. And low-priced Ethernet services run over shared bandwidth tunnels using Layer 2 or 3 architectures. In addition, business customers may favour symmetrical services, while residential customers are well served by DOCSIS, which is currently asymmetrical, typically offering 5:1–10:1 ratios in the downstream/upstream bandwidth. With business customers driving cable operators to better utilize existing

fibre plant and invest in new FTTP deployments, the trend is to offer multiple broadband pathways over existing fibre using DWDM.

2.2. Convergence of Network Layers

The layer-1 photonic network, the layer-2 carrier Ethernet network, and the layer-3 IP/MPLS network are designed, built, and expanded independently, and are often maintained by teams working in complete silos. This results in each layer being over-provisioned to cope with uncertain network demands (**ref. [4]**) and the networks being overprotected due to overlapping and redundant resiliency schemes on each layer.

This also results in additional Capital Expenditure (CAPEX) and Operational Expenditure (OPEX). In terms of CAPEX, transponders, switch ports, and router ports—the most expensive parts of the core of the network—become layered and the siloed infrastructure relies on large volumes of line cards for traffic hand-off between networking layers. Additionally, OPEX is increased because multiple teams are required to handle the provisioning and maintenance of a single service. Inefficiencies can also be seen in other areas, including a loss of time because of the need to deploy multiple processes and teams, and high complexity due to multiple independent network management systems (NMS) associated with each network layer, which results in high costs and poor network resource utilization and leads to poor monetization.

Multiple trends are driving operators to integrate DWDM optical transport with Ethernet/client OTN-SONET technology, primarily in metro and more recently in long haul networks. These trends include the demand for more bandwidth and greater agility with key applications, including cloud connect services, fixed broadband aggregation, mobile xHaul, and SONET migration.

2.3. Six Mandatory Attributes of The Unified Transport Platform

Operators have been asking for simpler, more cost-efficient converged network architectures that will enable them to concentrate on innovating revenue-generation services (**ref. [5]**). Based on Shaw's modeling, the converged agile optical framework must have following six attributes:

1) High bandwidth densification per rack space

For mobility operators, network densification means adding more cell sites to increase the amount of available capacity, which demands high bandwidth densification per rack space of the unified transport platform that contains Mobility xHaul, with a minimum threshold of 800Gbits/s per 1 Rack Unit (RU).

2) Building-block-approach scalability

Scalability is the ability of a system to expand without major modifications to its architecture. The concept implies the ability of a network system to accommodate a sudden increase in traffic volume gracefully and rapidly. After meticulous modeling by Shaw, it was found that the unified transport platform must be able to handle the unpredictable growth pattern of residential, mobility, and business traffic with building-block-approach scalability.

3) Full-set client interface support

The unified transport platform is required to support residential, mobility, and business services. Such a platform must be able to provide all required standard client interfaces, including Ethernet, OTN, and SONET.

4) Full-featured General Communication Channel (GCC0)

The unified transport platform has to integrate business services. Because of the power and rack space restrictions of business customer premises, installing an out-of-band management switch is usually not a viable option, or at least a very expensive one. Shaw's assessment concludes that in-band full-featured

GCC0 is a vital attribute of the converged agile optical framework. For a detailed explanation of GCC0, please go to Section 3.4.

5) Zero Touch Provisioning (ZTP)

Because the unified transport platform converges all service types, deployments are almost always multi-sited. Traditional turn-up based on manual initial configuration requires highly trained field personnel who are often difficult to find, and therefore multi-site deployment without ZTP tends to be slow, costly, and highly error prone. However, Shaw's analysis indicates that ZTP is a mandatory attribute for the unified transport platform.

6) Flex-grid

The concept of Flex-grid is related to the first attribute—high level bandwidth densification per rack space. To achieve high bandwidth densification, operators have to look beyond 100Gbps using a fixed grid. Only Flex-grid DWDM systems support 400G+ with high spectral efficiency. While fixed grid DWDM systems can still support "fat channels", it is at the expense of significantly lower spectral efficiency. Spectral efficiency is an important measure of how effectively or efficiently a fiber network transmits information.

3. Classic Optical Network

Classic Optical Networks are based on Legacy DWDM technology, which are hostile environments for service convergence. It is exceedingly difficult to implement service convergence in a classic optical network, if not entirely impossible. Legacy DWDM networks have the following defining features:

- It uses a chassis-based platform with low level bandwidth densification per rack space.
- Its scaling is inefficient.
- It is limited to SONET and 10GbE/40GbE client interfaces.
- It does not support line-side GCC0.
- It does not support ZTP.
- It uses a Fixed Grid (50 – 100GHz).

All the above characteristics present severe restrictions for network convergence. These characteristics are discussed in detail in the following sections.

3.1. Chassis-Based Platform and Low-Level Bandwidth Densification

All classic DWDM equipment manufacturers have chosen a chassis-based platform. In such a platform, each DWDM component is devised as a card to be installed in an empty slot of the chassis. For example, Arrayed Waveguide Gratings (AWG); Wavelength Selective Switches (WSS); Erbium-Doped Fiber Amplifier (EDFA); and most transponders/muxponders are typically constructed as individual cards. Figure 1 shows a typical 14 RU monolithic chassis.

A transponder/muxponder card is commonly installed vertically but still roughly takes about 1 RU. A typical legacy transponder/muxponder only has the bandwidth density of up to 100Gbps per 1RU. 100Gbps is significantly less than the minimum requirement of 800Gbit/s per 1 RU for a converged platform.

The transponders/muxponders work in pairs in a point-to-point system. At a specific source, the destinations for residential service, mobility service, or business service are usually different. Therefore, in a classic system this would require three pairs of transponder/muxponder cards at the source and destination, resulting in 3RU per site.

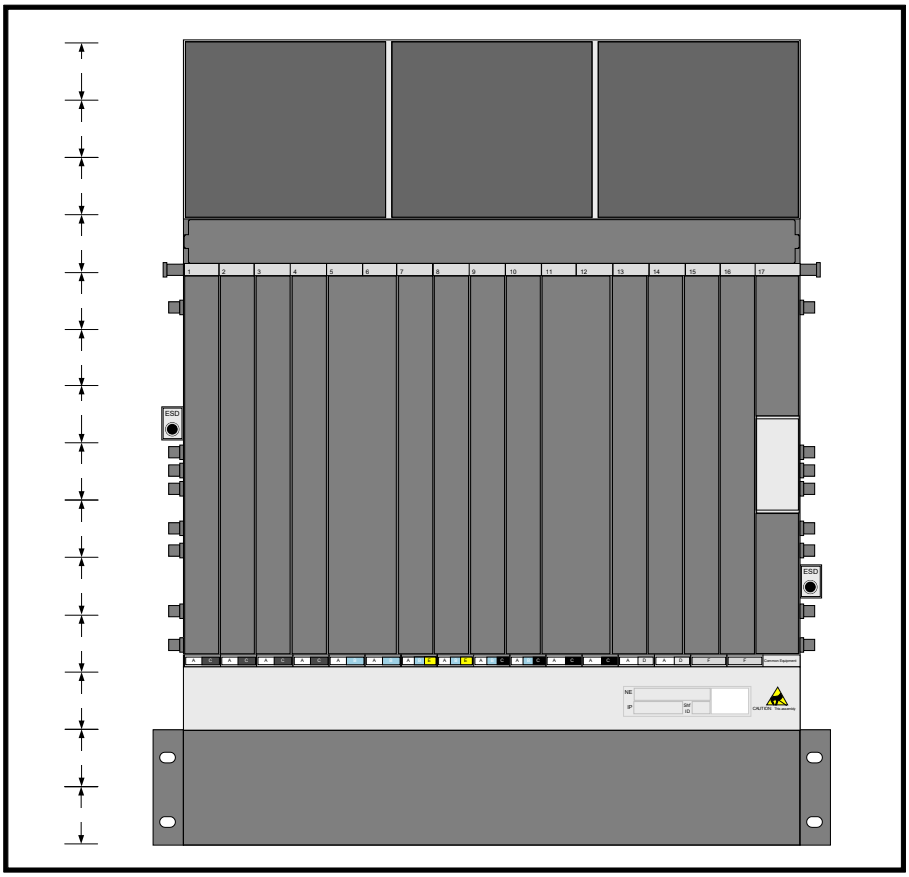

Figure 1 – Chassis Based Platform

3.2. Inefficient Scaling

The legacy monolithic-chassis DWDM systems are able to handle future traffic volumes on day one, but also require a large up-front investment for capacity that may not be needed for several years. This is particularly true for chassis equipped with specialized hardware such as terabit scale switching fabrics, as the fabric is part of the initial installation, even though transponders may be added over time. As for operators, space and power are also always at a premium, and classic optical networks require large space and power budgets at the beginning of deployment. The issue of inefficient scaling is particularly acute for remote mobility sites and business customer premises.

In order to achieve service convergence for mobility and business, MSOs need to examine modular DWDM systems with smaller footprints. For example, 1RU pizza-box blades that offer the advantage of efficient scaling for all operators.

3.3. Client Interface Limitations

Classic DWDM systems usually only support SONET client interfaces and low-rate Ethernet client interfaces. For a legacy transponder/muxponder, only three client formats are typically supported, including SONET OC192, 1GbE, and 10GbE, with only a few legacy DWDM vendors offering 40GbE and 100GbE

client interface support. While these three client interfaces are often sufficient for residential traffic, they fall short of the requirements for mobility and business traffic, which both require 100GbE and OTU4. In addition, many business customers also need OTU2/2e.

Because of the limited client formats, MSO operators are forced to move mobility and business traffic away from legacy optical networks and onto IP/MPLS networks. The traffic migration to IP/MPLS is considered suboptimal due to DWDM offering the most efficient use of optical fibre throughput capacity, as well as lower price points. As far as the client ports are concerned, classic optical network focuses on residential customers, while overlooking mobility and business customers. The client interface format limitation is a serious roadblock to service convergence.

Table 3 and Table 4 list the key parameters for OTN Frames and SONET OC192, for reference.

Table 3 – OTN Frames

OTUk	Bit Rate (Gbps)	Payload Rate (Gbps)	Payload Types
OTU4	111.809973	104.355975	100GbE
OTU2e	11.095730	10.356012	10GbE LAN, 10GFC (TTT)
OTU2	10.709255	9.995277	10GbE WAN, 10GbE LAN (GFP-F), STM-64/STS-192

Table 4 – SONET OC192

Acronym	Bit Rate (Gbps)	DS0	DS1	DS3
OC-192	9.9953	129,024	5,376	192

3.4. Client-Side GCC0 Only

General Communication Channel 0 (GCC0) is used for overhead communication between network nodes. GCC0 has operations, administration, and management (OAM) functions such as performance monitoring, fault detection, signaling and maintenance commands in support of protection switching, fault sectionalization, service-level reporting, and control plane communications. GCC0 has two bytes within OTN overhead. GCC0 is terminated at every 3R (re-shaping, re-timing, re-amplification) point and used to carry management information and GMPLS signaling protocol.

Legacy DWDM transponders/muxponders only support client-side GCC0. Optical Transport Network (OTN) standards define the GCC0; it is an in-band channel used to carry management information between transponder/muxponder pairs. GCC0 is a critical method to manage an optical device for a business customer site. Because of power limitations and rack space restrictions, it is very difficult to install a layer-2 management switch for out-of-band management in a business customer site. Figure 2 represents a schematic diagram on client-side GCC0.

Although client-side GCC0 is a useful feature, it is considered as only a partial implementation of GCC0. In client-side GCC0, the network interface device (NID) at the far-end site encapsulates management information into the GCC0 bytes of each OTU2/OTU2e frame. The NID sends out the OTU2/OTU2e frames from its network-side port, which has a grey (black and white) wideband pluggable, most likely at 1310nm. When the near-end transponder/muxponder receives the frames on its client-side port from the far-end NID, it decapsulates the GCC0 bytes from the OTU2/OTU2e frames and recovers management information from the GCC0 bytes.

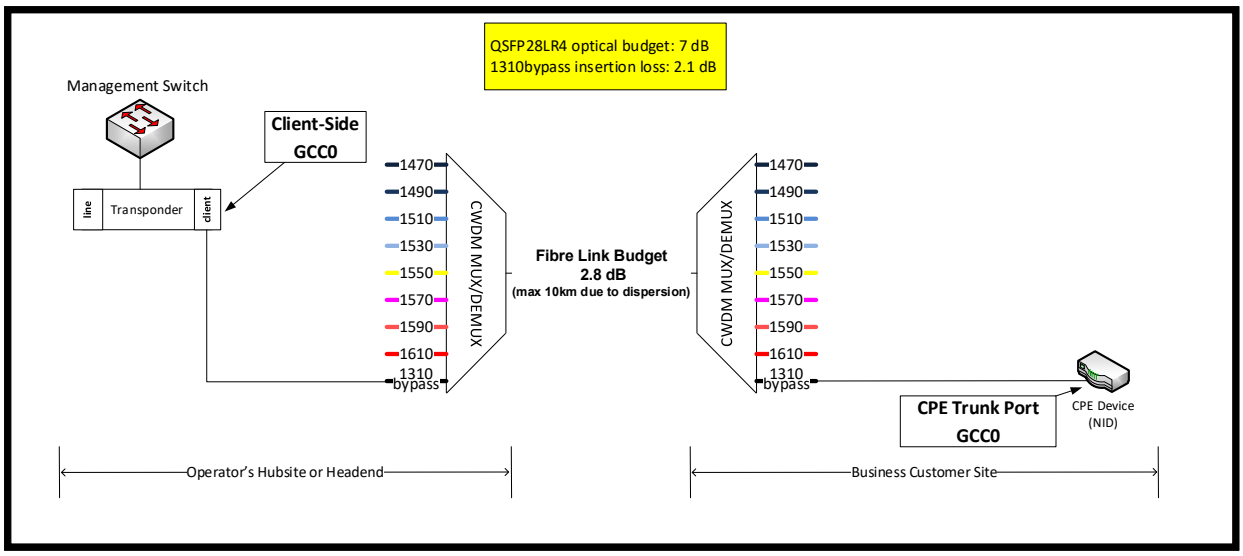

Figure 2 – Client-Side GCC0

While a management switch is necessary for the near-end site, it can be skipped for the far-end site when client-side GCC0 is supported on the near-end transponder/muxponder. It should be noted that the limiting factor for client-side GCC0 is the distance between the near-end and far-end. If there are only dark fibres between the near-end and far-end, the maximum distance for client-side GCC0 is approximately 10km, depending on the fibre rating. If CWDM is inserted between the near-end and far-end, the maximum distance is reduced to 5km. Though client-side GCC0's maximum distance is adequate for residential service and mobility service, it is insufficient for most cases of business service.

In summary, due to the aforementioned factors, legacy DWDM devices' lack of line-side GCC0 support considerably hampers the potential for service convergence.

3.5. Manual Turn-up Initial Configuration

As the name suggests, the goal of Zero Touch Provisioning (ZTP) is to install a networking appliance without the need for local configuration by a trained individual, making it possible for a new or replacement device to be sent to a site, physically installed, and powered up by a locally present employee without technical skills. The ZTP feature carries out the configuration and connection to the management system.

Legacy photonic-layer devices do not support ZTP, and therefore extensive manual configuration is required to turn up a new device in a classic optical network. Manual configuration is laborious, prone to errors, costly, and time-consuming. In this scenario, an individual with basic configuration skills and a laptop has to go onsite and configure the device for basic operation before its configuration can be completed remotely using the central management system **(ref. [6])**. Alternatively, the device can first be sent to a central location where it is staged before being sent to its final location for installation. This is also costly as it requires shipping the device twice, which could potentially mean passing through customs twice. And there is the risk of accidentally shipping an appliance with an IP-address destined for a different site.

For residential service, ZTP is helpful but it is not always needed. However, for mobility service at a remote site and business service at a customer premise, ZTP is critically important. With ZTP, a device can be shipped directly from any warehouse to the remote site or customer premise and installed as soon as it

arrives and be up and running within minutes of installation. This dramatically reduces the lead time, time spent on an installation, and number of configuration errors, which are significant benefits for mobility and business services.

Because legacy DWDM's chassis does not support ZTP, operators must look into next generation optical devices for service convergence. ZTP is becoming more widely supported as next generation optical equipment vendors realize their equipment can now be installed by local techs who may not be trained on provisioning and configuration.

3.6. Fixed-Grid Photonics

Older generation optical networks are based on 100 Ghz or 50 Ghz spaced photonic systems. These gridded networks can offer forty-eight or ninety-six fixed grid optical channels within the total 4800 Ghz C-Band Spectrum. This fixed grid spacing is based on the International Telecommunication Union (ITU) standard and has been the norm for most photonic systems for over 20 years. These systems use passive, ITU grid filters to provide wavelength ingress/egress. Second and third generation optical transponders running at 35 GBaud typically require 37.5 Ghz of optical spectrum, which fits perfectly into these ITU gridded filters. This version of the DWDM network has served the industry well for years.

As next generation transponders are moving towards 400GbE, they bring with them the need for larger per channel spectrum. This larger channel spectrum requirement exceeds that of what is available on these ITU gridded filters. The Fixed-Grid paradigm cannot support them, making this method obsolete.

4. Universal Aggregation

Universal Aggregation is a converged networking approach that enables the aggregation of traffic from SONET, Ethernet, and OTN services using shared fibre and the same optical DWDM platform. Under the Universal Aggregation paradigm, the DWDM systems are considered as both core technology and access technology. Behind the SONET, IP/Ethernet, and OTN services, the traffic sources include residential, wireless, and commercial.

In a traditional network, it is no wonder that performance and reliability are increasingly valued as operators must configure, shape, and optimize each service type individually on separate platforms, with each platform having its own vendor-provided technical support. Sometimes, this means dealing with multiple platforms with the same vendor. However, in the majority of cases, operators must deal with several different platforms from separate vendors. Managing multiple interconnected hardware deployments across diverse vendor environments significantly increases operational cost and makes troubleshooting a very complex task. Traditional separated network architectures are simply unable to scale quickly enough, negatively impacting time-to-market for new service revenues.

In traditional network architectures, each of the three network layers has its own network silo. There is growing evidence against siloed networks, contributing to its inherent weakness as part of the network architecture. Disadvantages of network silos include:

- An inability to better utilize or share the silo's resources.
- The extended period of time needed to deploy, manage, and upgrade in the siloed environment.
- Rising operating costs, given each silo's unique processes.
- The redundant building of each silo's own protection systems to meet availability requirements.

Recent developments in coherent optical technologies provide greater opportunities for operators to move toward comprehensive network convergence. In network converged systems, residential, mobility and business services coexist over the same fibres, forwarding tables, data planes, servers, etc. However, getting to this point will take time and careful planning. To help support the shift towards full network convergence, operators need a robust platform framework.

Universal Aggregation breaks up the aforementioned silos by converging all into a single, unified platform. This means aggregating mobile, residential, and enterprise traffic vertically, while at the same time aggregating SONET, Ethernet, and OTN services horizontally. Universal Aggregation enables a simple, compact, scalable, and efficiently converged infrastructure with coherent optic transport, saving operators from having to build different networks for different services. By supporting all services on a unified platform, Universal Aggregation reduces operational cost considerably and expands competitiveness substantially.

Table 5 – Universal Aggregation

	Traffic-Type Convergence	Network-Layer Convergence
Universal Aggregation	Residential	Tier 1 - Optical Photonic
	Mobility	Tier 2 – Carrier Ethernet
	Business	Tier 3 - IP/MPLS (Future)

Shaw has successfully implemented Universal Aggregation on a blade-centric architecture. It is a converged framework spanning access, transport, packet, and optical, and combining fast, simple deployment with a wide range of options for right-sizing capacity. Residential, mobility and commercial services are aggregated into one unified platform supporting SONET, Ethernet, and OTN. Shaw's implementation of Universal Aggregation has the following technical characteristics:

- High Bandwidth Density per Rack Space
- Efficient Scalability
- Full-Set Client Support - SONET, Ethernet, and OTN
- Line-side GCC0
- Zero Touch Provisioning
- Flexible Grid

Shaw's successful experience indicates that the most efficient unified technical platform of Universal Aggregation is a modular, coherent DWDM system with Ethernet/OTN/SONET client interfaces. In the section below, we will discuss the blade-centric platform in detail.

4.1. Overview of Blade-Centric Platform

As mentioned previously in Section 3, over-engineered, restrictive, chassis-based systems are not adaptable in the converged environment. A typical chassis is shown on the left side of Figure 3, and a typical modular blade is shown on the right side. The typical DWDM chassis is of 14RU, while the typical modular pizza-box is only of 1RU.

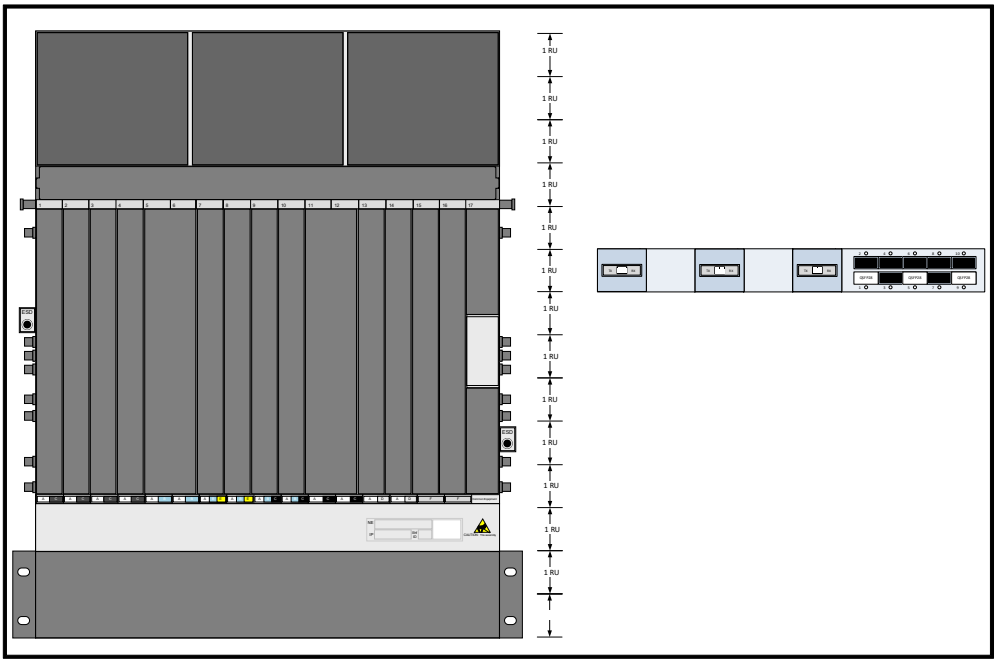

Figure 3 – Chassis vs Blade

The modular product line divides DWDM functions into three areas: ROADM blades, Splitter/Coupler blades, and Transponder blades, as shown in Figure 4. The ROADM-on-a-blade provides wavelength selective switching and amplification. While Figure 5 only shows two ROADM blades, our platform currently supports a maximum of eight ROADM blades (one main blade and up to seven tributary blades) that can be interconnected as a single Network Element (NE). A Splitter/Coupler blade has the main function of channel add/drop and replaces legacy static filters in CDC (Colorless, Directionless, Contentionless) configurations. Splitter/coupler blades are interconnected with the ROADM blades as one NE, and the Transponder blade is a transceiver with very high port density on both network and client sides, which in the future could be part of a single NE as well.

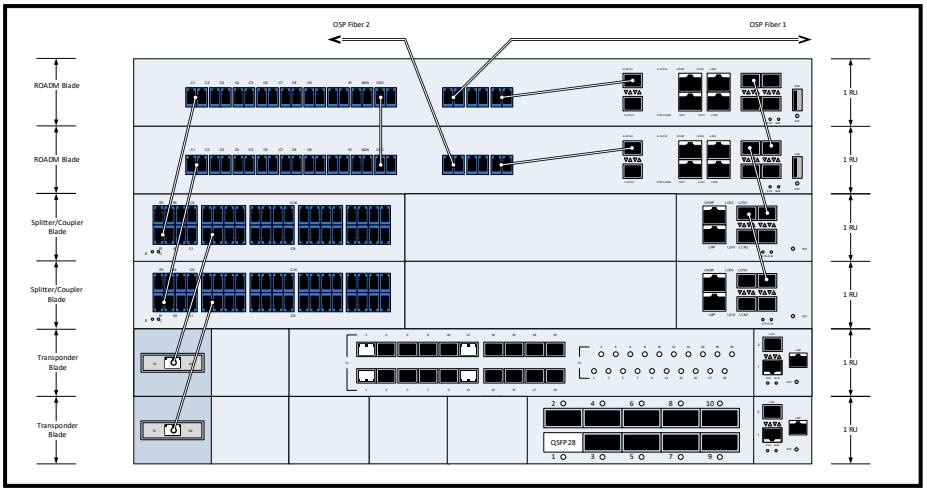

Figure 4 – ROADM Blades, Splitter/Coupler Blades, and Transponder Blades

This isolation approach allows vendors to rapidly implement and deploy new features in each secluded functional area when and as much as needed. Because of the modularity, vendors tend to be much more responsive to feature requests from operators.

4.2. High Network Densification

The blade-based platform is a simpler, more agile approach to creating an optical network for Universal Aggregation of residential, mobility, and business traffic. The blade paradigm is the only feasible platform for universal aggregation at this point in time due to the exceptionally high bandwidth density per 1RU. Figure 5 shows a typical implementation of Universal Aggregation on a modular platform. The transponder blade at the bottom of Figure 5 aggregates residential, mobility, and business into one 1RU pizza-box at the source. To achieve the same goal, the typical chassis-based platform would have to use three transponder cards, which means approximately three times of power consumption and rack space.

The transponder blade's line port bandwidth capacity can either be 100Gbits/s or 200Gbits/s, depending on the modulation on the line port, which ultimately depends on the fibre span loss and OSNR (Optical Signal to Noise Ratio) of the system. If the distance between the source and destination is shorter than 230km, it is likely that 200Gbits/s would suffice. If the distance is longer than 230km, however, capacity would have to be 100Gbits/s.

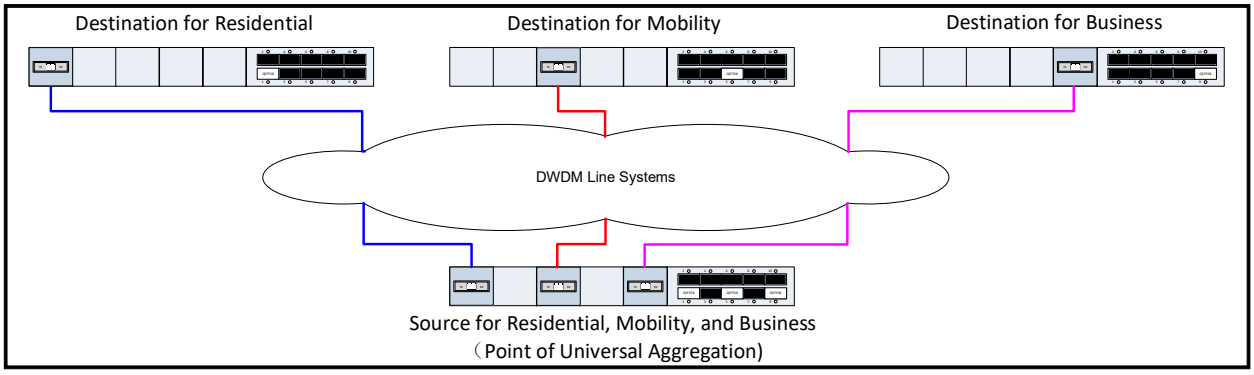

Figure 5 – Universal Aggregation on A Modular Platform

Figure 6 shows a typical transponder module with QSFP28 client interfaces. It has five line ports, and each line port has a maximum bandwidth capacity of 200Gbits/s. The total maximum capacity for the 1RU module is 5x200Gbits/s, which is 1Tbits/s.

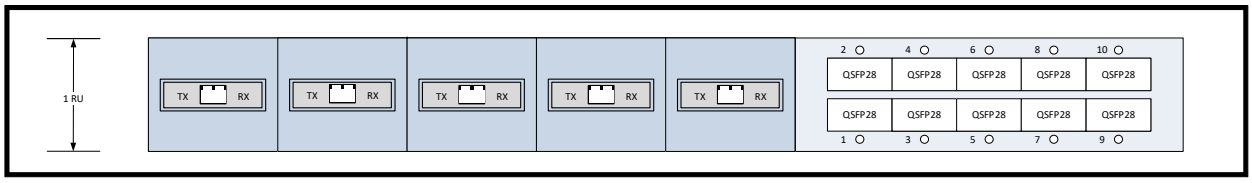

Figure 6 – Maximum Bandwidth Capacity of a Transponder Blade

While 1Tbits/s bandwidth capacity per pizza-box is considered extraordinary for a 1RU rack space, the power consumption is about 224 watts, which is on par with shelf-based transponder cards. In the blade-centric paradigm, the transponder blades consume a larger percentage of total power as compared to ROADM blades and splitter/coupler blades; this fact enables vendors to focus on independent improvements in power for transponder blades without the constraints of traditional converged shelves.

Most operators should be able to achieve an overall 30% power savings per 100Gbps bandwidth compared to legacy systems.

4.3. Efficient Scalability with Building-block-like Infrastructure

Traditional chassis-based platforms represent a significant initial capital outlay and the chassis backplane is inherently inflexible. On the contrary, a blade-based modular system requires a smaller, granular initial investment while allowing for a pay-as-you-grow approach. With single rack unit sized blades, the system is also space efficient and flexible.

The paradigm offers the advantage of efficient scaling for all operators. Scaling efficiently is one of the key network requirements for operators in the era of Universal Aggregation. The building-block approach to hardware allows for a low initial spend for year-one deployments with the ability to grow incrementally as traffic increases and more capacity is required. Many converged, monolithic-chassis DWDM systems, by contrast, are able to handle future traffic volumes on day one, but also require a large up-front payment for that capacity even when the capacity may not be needed for several years. This is particularly true for chassis equipped with specialized hardware such as terabit scale switching fabrics, as the fabric is part of the initial installation, even though transponders may be added over time.

4.4. Full Set Client Support - SONET, Ethernet, and OTN

Each service type demands a unique set of client interfaces from DWDM transponders. For residential landline telephony, SONET OC192 is needed. For residential Internet, both 10GbE and 100GbE have to be supported to communicated with CMTS. For mobility xHaul, 100GbE and OTU4 are required. Business customers request the widest range of client interfaces: SONET OC192, 10GbE, 100GbE, OTU4, OTU2/2e.

Table 6 summarizes the client interface formats required by each service type.

Table 6 – Service Type/Client Interfaces

Service Type	Client Interface Formats
Residential	SONET OC192,10GbE, 100GbE
Mobility	100GbE, OTU4.
Business	SONET OC192, 10GbE, 100GbE, OTU4, OTU2/2e

Chassis-based legacy platform only supports a limited subset of the client interfaces listed in the above table, ruling out monolithic chassis as a platform for Universal Aggregation. However, the blade-centric platform supports all client interfaces in Table 6. As listed in Table 7, Module A supports SONET OC192, 10GbE, and OTU2/2e, while Model B supports 100GbE and OTU4. Two models of modular blades are also shown in Figure 7, below.

Table 7 – Model/Client Interfaces

Model Type	Client Interface Formats
Model A	SONET OC192,10GbE, OTU2/2e
Model B	100GbE, OTU4.

Comparing Tables 6 and 7 confirms that together, Models A and B will provide full set client interfaces for residential, mobility, and business services, and that modular blades are ideal for Universal Aggregation of these three types of traffic.

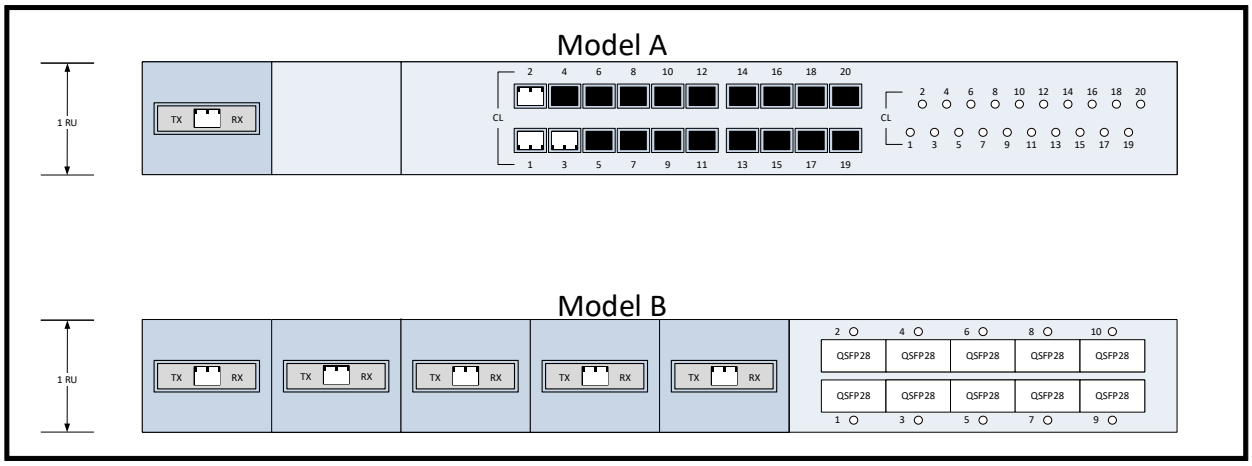

Figure 7 – Model A and Model B

4.5. Line-Side GCC0

As discussed in Section 3.3, legacy DWDM systems only support client-side GCC0. Blade-based next-generation DWDM systems support both client-side GCC0 and line-side GCC0.

For line-side GCC0, the transponder/muxponder in the far-end site encapsulates management information into the GCC0 bytes of each OTU4 frame. The OTU4 frame then goes through the electrical-to-optical conversion and is sent out of the line port of the far-end transponder/muxponder on a specific DWDM wavelength. Upon receiving each OTN frame by the near-end transponder/muxponder, the GCC0 bytes are extracted and the management information is retrieved. In using line-side GCC0, there is no need for a management switch in the far-end site, although a management switch is still necessary for the near-end site. The maximum distance for line-side GCC0 is about 80km depending on the fibre rating, even with CWDM inserted. This distance is adequate for most business services.

Figure 8 below is the schematic diagram of line-side GCC0.

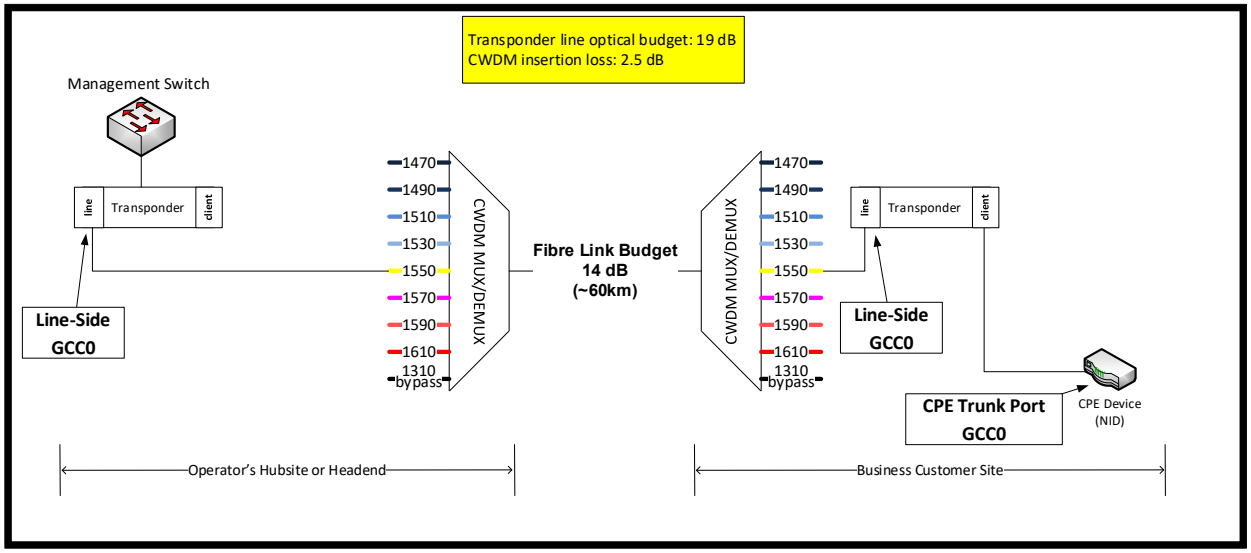

Figure 8 – Line-Side GCC0

4.6. **Zero Touch Provisioning (ZTP)**

The blade-centric next-generation platform also supports ZTP. Shaw has set up several pre-staging centres in various regions. Before shipping a blade to the site, Shaw engineers will pre-provision the blade and save the configurations to the USB key attached to the blade. The blade will then be shipped with the USB key to local technicians. When the local technicians receive the blade and USB key, all that is required is a plug-and-play. Figure 9 shows a typical set-up of a pre-staging lab.

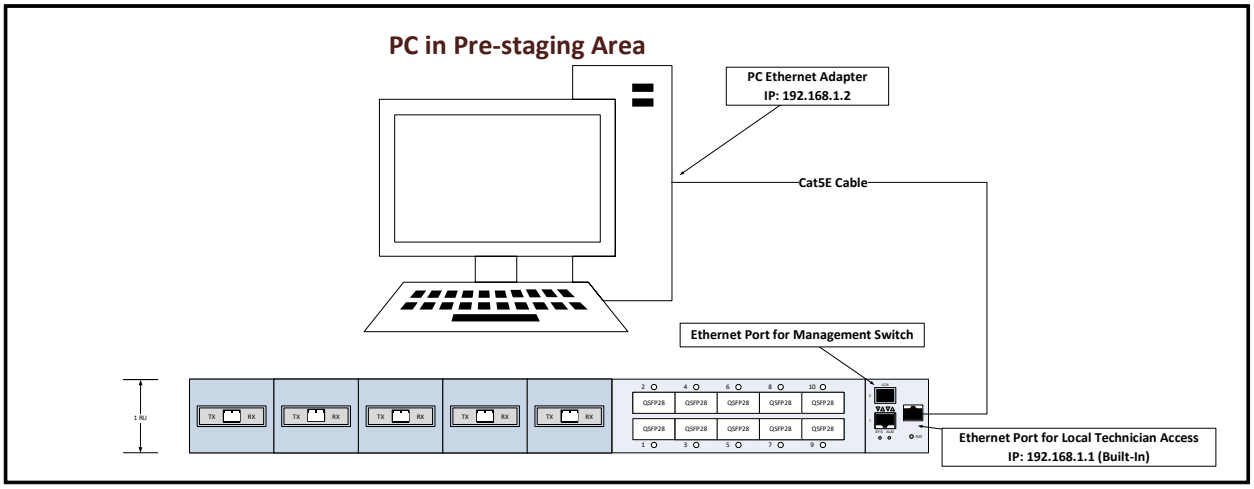

Figure 9 – Zero Touch Provisioning

4.7. **Flexible Grid**

Flexible Grid, also written as Flex-Grid, is in contrast to Fixed-Grid which was discussed previously in section 3.6. Flex-Grid combines two concepts together: finer wavelength granularity and the ability to join adjacent wavelength slots together to form arbitrary sized channels. From hardware perspective, Liquid Crystal on Silicon (LCoS) based Wavelength Selective Switch (WSS) makes a ROADM Flex-Grid.

Universal Aggregation requires 400Gbps transponder/muxponder because residential, mobility, and business each normally requires 100G client bandwidth. The blade-centric next-generation modular platform provides a 400G transponder blade with Flex-Grid. With the 400G blade, operators will be able to transport more than twice the information within the same spectrum on Fixed-Grid. Operators can actually further increase the spectral efficiency by 25% with the use of Flex-Grid by allowing the subcarriers in DWDM superchannels to be squeezed more closely together. While Flex-Grid drastically improves spectral efficiency, the modular 400G transponder pizza-box does not require Flex-Grid as absolute pre-requisite, it will also work on existing legacy Fixed-Grid for backward compatibility.

The superchannels enable operational scaling by allowing operators to turn up optical capacity in larger increments with the same effort. Going forward, next-generation optical transport networks will need to make the most use of the flexibility of advanced coherent modulation technologies. More advanced flexible coherent modulations will support a wide range of modulations tailored to specific applications of residential, mobility, and business. Flexible DWDM grids will enable more efficient and flexible use of optical spectrum to maximize capacity.

5. Conclusion

This paper has outlined the benefits of Universal Aggregation on a modular platform, which is a promising paradigm for Cable operators.

Under the paradigm of Universal Aggregation, it is unnecessary for operators to build separate networks for different traffic types of residential, mobility and business. By aggregating all three types of service on a unified platform, Universal Aggregation reduces operational cost considerably and expands competitiveness substantially.

In traditional systems, each network layer has their own network silo. In the Universal Aggregation model, these silos are all broken down. The consistent unified platform across optical, Ethernet, and IP/MPLS will smash down all network silo walls.

Shaw's Universal Aggregation utilizes a blade-centric platform with the following features:

- It has astoundingly high bandwidth density per 1RU with a 90% increase in available system bandwidth comparing with legacy systems.
- It uses a building block approach to scalability, which only requires a small initial spend while allowing for continuous growth through pay-as-you-go.
- It supports 100GbE, OTU4, 10GbE, and OTU2/2e over 100Gbps and 200Gbps wavelengths.
- Its line-side GCC0 offers in-band management for remote mobility sites and business customer sites.
- It implements a Zero Touch Provisioning (ZTP) system that simplifies operations and allows engineers to automate most of the deployment tasks.
- It supports Flex-Grid which increase the spectral efficiency by 25% for 400G blades.

Abbreviations

3R	Re-shaping, Re-timing, Re-amplification
10GbE	10 Gigabits Ethernet
100GbE	100 Gigabits Ethernet
CAPEX	Capital Expenditure
CBRS	Citizens Broadband Radio Service
CPE	Customer Premise Equipment
DSP	Digital Signal Processor
DWDM	Dense Wavelength-Division Multiplexing
EBITDA	Earnings Before Interest, Taxes, Depreciation, and Amortization
EDFA	Erbium-Doped Fiber Amplifier
GCC	General Communication Channel
GMPLS	Generalized Multi-Protocol Label Switching
IP	Internet Protocol
IP/MPLS	Internet Protocol/ Multi-Protocol Label Switching
ITU	International Telecommunication Union
LCoS	Liquid Crystal on Silicon
MSO	Multiple-System Operators
MVNO	Mobile Virtual Network Operator
NE	Network Element

NID	Network Interface Device
NMS	Network Management System
OAM	Operations, Administration and Management
OPEX	Operational Expenditure
OSNR	Optical Signal to Noise Ratio
OTN	Optical Transport Network
OTU2/2e	Optical Transport Unit 2/2e
OTU4	Optical Transport Unit 4
RAN	Radio Access Network
ROADM	Re-configurable Optical
RU	Rack Unit
SONET	Synchronous Optical Networking
Tbits/s	Terabit Per Second
UA	Universal Aggregation
WSS	Wavelength Selective Switch
ZTP	Zero Touch Provisioning

1. Introduction

Not so long ago, the CMTS was all about the hardware, the chassis, the cable line cards with embedded CPU, memory and storage. It had long development cycles and expensive/lengthy processes for deployment and upgrade. The virtualization of the CMTS removed the need of the specialized hardware by providing the CMTS services in software running on generic servers. By doing so, it has greatly improved the efficiency of the CMTS hardware infrastructure and started the cloud native transformation of the CMTS software.

With the virtualization laying out the foundation, moving the CMTS to the cloud is a natural step forward to scale the CMTS beyond the on-premises physical servers. Cloud provides on-demand compute, memory and storage resources with high scalability, availability and security. It offers users the economies of scale and better cost efficiency with a pay-as-you-go cost model. It reduces the application development time and simplifies the deployment/upgrade processes by managing the underneath infrastructure and platform on behalf of the users.

CMTS cloudification is not just a rehosting effort, it is an optimization process that requires proper service decoupling and workload placement. The cloud computing services can be “resource-aware” or “serverless”. The resource-aware service, such as Amazon Elastic Compute Cloud (EC2), allows users to control the resource allocations and autoscaling at a relatively coarse granularity.

The serverless service, such as AWS Lambda or Amazon DynamoDB, fully manages the resources on behalf of the users with built-in fine-grained auto scaling capabilities. The geographical location of the cloud platform also matters as it impacts the network latency and the data transport cost. The distributed and inhomogeneous cloud environment presents an interesting and challenging problem for the cloudification of the CMTS.

In this paper, we explore the cloudification solutions for the CMTS. Following the introduction, we first overview the vCMTS structure in Section 2 and the public cloud infrastructure in Section 3. We then explain the cloudification motivations in Section 4 and describe the different architecture choices in Section 5. We examine the different cloud hosting options in Section 6 and explore the CMTS service placement strategies in Section 7. In section 8, we show an example for deploying the CMTS services on AWS. In Section 9, we explore how to take advantage of the serverless platform by converting the stateful DOCSIS processes into stateless functions. In Section 10, we discuss how to start the cloudification with a proof-of-concept (PoC) effort. In Section 11, we study how to deliver CMTS as a service by using CI/CD and the cloud powered multi-tenant architecture. Finally in Section 12, we conclude the paper.

To simplify the text and precisely describe the intended cloud entities, we use the Amazon Web Services (AWS) terminologies in this paper and provide links to AWS original definitions in the Reference Section. Similar terminologies and definitions can be easily found on other public cloud providers’ platforms such as Microsoft Azure, and Google Cloud platform,

2. vCMTS Architecture Overview

The vCMTS virtualizes the physical CCAP core in the DOCSIS distributed access architecture (DAA) [1] as shown in Figure 1. It is typically installed in a headend or hub that is connected to both the converged interconnect network (CIN) and the service provider (SP)’s core network. Function wise, the vCMTS contains the following service domains with distinctive timing requirements:

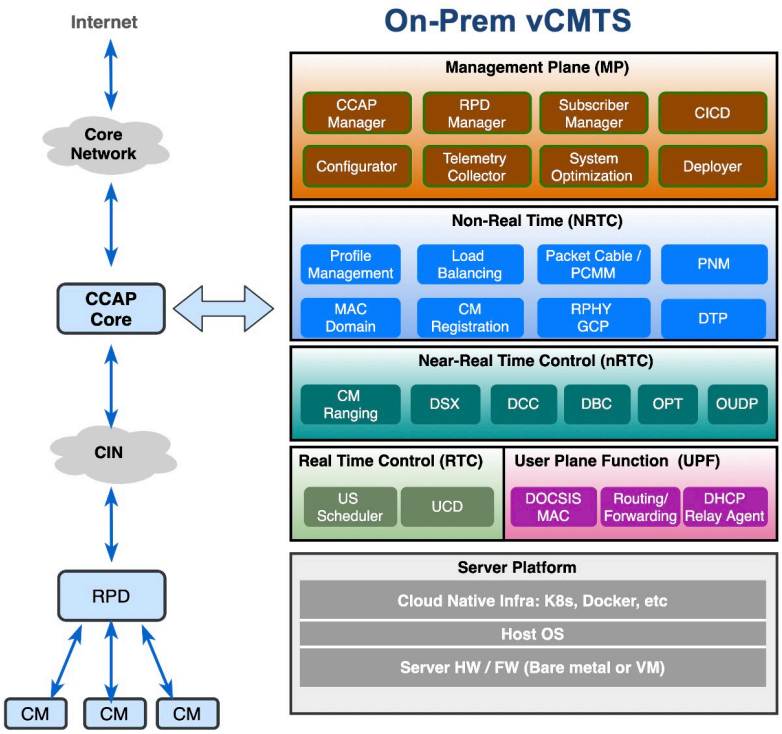

Figure 1 – vCMTS in Cable Distributed Access Architecture

Management Plane (MP)

MP contains the non-real-time (latency > 1sec) management functions to control/optimize the CMTS network elements, for deployment, configuration, health monitoring and carrying out any corrective actions if needed.

Non-Real Time Control (NRTC)

Non-real time (latency >1sec) control, NRTC, refers to the CMTS control functions that have a timing budget of 1second or above, such as CM registration, load balancing, profile management, and proactive network management etc.

Near-Real Time Control (nRTC)

Near-real time (10ms – 1sec) control, nRTC, refers to the CMTS control functions that have a timing budget of a few hundreds of milliseconds, such as DOCSIS ranging, DSX and DBC etc.

Real Time Control (RTC)

Real-time (<10ms) control, RTC, refers to the CMTS functions that have a timing budget of single-digit milliseconds, such as DOCSIS upstream scheduling and functions, UCD update transaction and MAP replications.

User Plane Functions (UPF)

> The term of UPF is borrowed from mobile for describing the data plane functions that require high-throughput and low latency, such as DOCSIS MAC frame processing, packet routing/forwarding, and DOCSIS downstream scheduling.

The latency values for RTC, nRTC, and NRTC are adapted from the Open Radio Access Network (ORAN) Alliance [2].

The vCMTS today is hosted by a dedicated server or a server cluster on premises that contains the compute, memory, storage and networking resources, and certain server/platform applications, such as Docker, Kubernetes, Radis, Kafka etc., to run the containerized CMTS microservices.

3. Public Cloud Infrastructure

Public cloud delivers virtualized computing services on-demand globally through internet and/or direct connections. Today the major public cloud platforms have practically covered all locations that have a critical mass of Internet users.

Depending on the distance relative to the end users, the public cloud infrastructure can be either in the Region or at the Edge using the AWS terminologies, defined as below.

Region

> A Region is a physical location around the world that contains multiple data centers within a geographic area, such as US East (Northern Virginia), US West (Northern California) etc. Each Region consists of multiple, isolated, and physically separate Availability Zones (AZs).
>
> Each AZ has one or more discrete data centers with redundant power, networking, and connectivity in a Region. Within the Region, an AZ is physically separated by a meaningful distance, many kilometers, from any other AZ, although all are within 100 km (60 miles) of each other.

Edge

> The Edge infrastructure provides the computing services as close to the endpoints as necessary, deployed as the cloud-managed hardware and software in locations outside the Region and even onto the customer owned devices themselves. Edge is typically used by latency sensitive or data intensive applications which would benefit from the local processing for avoiding the latency or network cost for shipping the workload to the Region.
>
> AWS edge offers multiple edge computing solutions including AWS Outposts for on-premises, AWS Local Zones for metro areas, and AWS Wavelength for the 5G Edge.

Figure 2 shows the AWS Region map and edge networks in North America [3]. Similar coverage can also be found on other public cloud platforms. For a vCMTS, both the Region and the Edge may be used for cloudification.

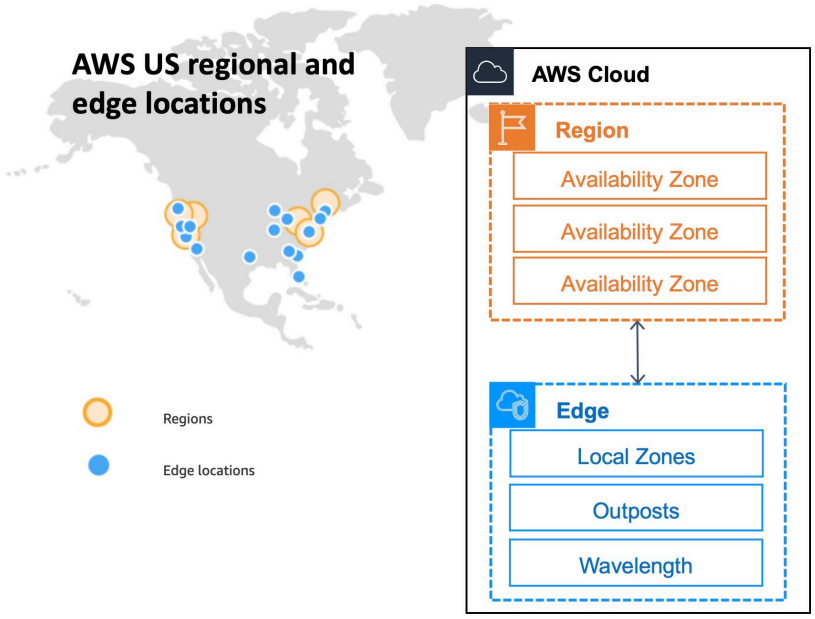

Figure 2 – AWS Infrastructure and Region Map in North America (2021)

4. Moving the vCMTS to Cloud

Just like virtualization removes the need for the specialized hardware, cloudification aims to remove the need for owning the physical servers, instead use the cloud compute services with a consumption-based cost model.

Moving to the cloud benefits both the CMTS vendors and the operators. For the CMTS vendors, cloudification simplifies the infrastructure/platform development, so they could have more time/resource innovating on their unique market differentiators. For the CMTS operators, cloudification promises global coverage, built-in high availability and rapid scaling capabilities. With on-demand cloud computing, operators have less risk for over-provisioning or under-provisioning, no need to worry about upfront costs and on-going server maintenance (provided by the cloud provider), or patching and software upgrades (provided by vendor).

The chosen public infrastructure / platforms should best suit the CMTS workloads in terms of proximity, performance and cost efficiency. Hybrid and multi-cloud strategy may be used to adapt to specific CMTS deployment needs.

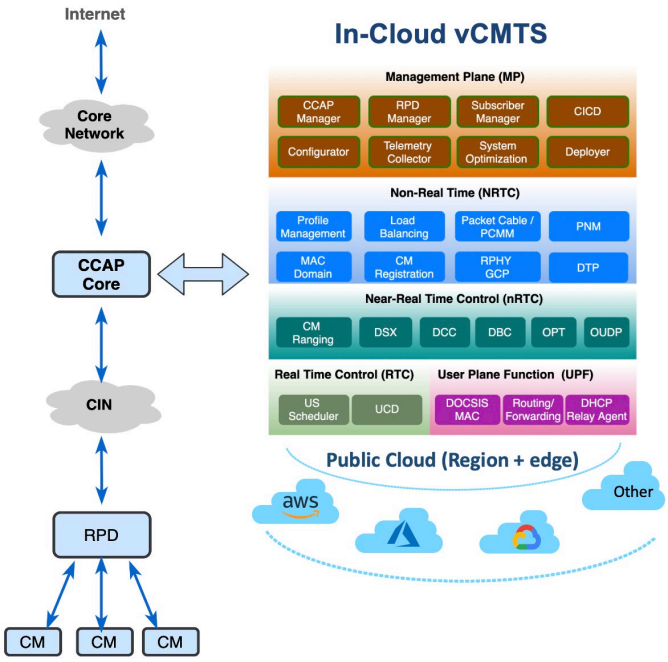

Figure 3 – vCMTS Hosted in Public Cloud

5. Cloudification Archtecture Choices

Migration to the cloud is hardly a one-step move. It involves multiple iterations to achieves the optimum efficiency. Figure 4 shows the typical architectural choices that may be used along this journey.

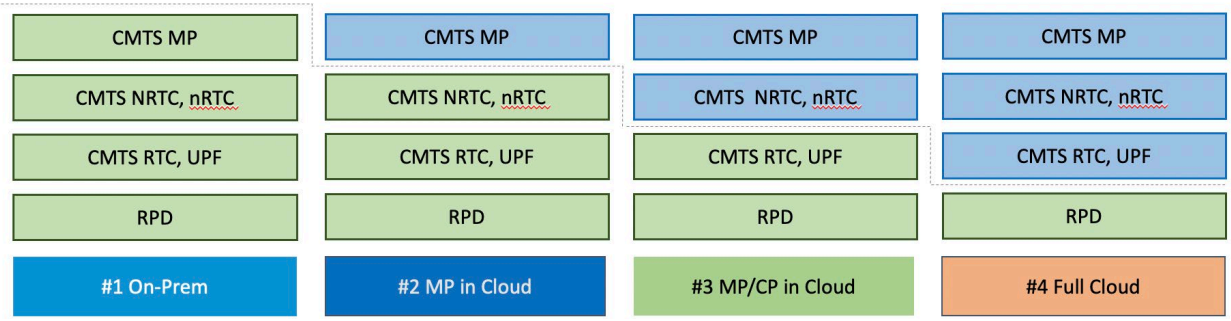

Figure 4 – CMTS Cloudification Choices

#1 On-Premises

This is the vCMTS with all the CMTS service domains hosted on premises and no cloud involved. This represents the majority of vCMTS deployments today.

#2 MP in Cloud

By simply moving the MP to the cloud, this could be a phase-one approach for cloudification. It also accomadates the FMA DAA where DOCSIS is built in the Nodes attached to the plant.

#3 MP and CP in Cloud

This is a hybrid development/deployment environment involving both cloud computing and the private on-premise compute platform. Specifically, the MP and the DOCSIS control plane (CP), including the NRTC and nRTC functions, are in the cloud, while the UPF and the RTC functions remain on-premise. This option requires that the DOCSIS control and user planes are separated with proper interface definitions.

#4 Full Cloud

The CCAP core is fully moved to the cloud. More details can be found in Section 8 where a full cloud deployment example is presented using both the Region and the Edge platforms. A Region-only full cloud setup can be found in Section 10 to test drive the cloud computing platform. This scenario applies if the cloud provider is providing Internet transit services or if the vCMTS is paired with a test harness that includes virtual DAA nodes and virtual CMs.

6. vCMTS Hosting Options

The cloud environment offers a variety of hosting options for the vCMTS services, as shown Figure 5. This includes the options of physical servers on premises, a "resource-aware" virtual server platform, or a "serverless" platform.

The vCMTS today typically uses the physical servers on premises, owned and managed by the service provider. It scales statically by the number of physical servers, with each server as a pooling unit for all resource types including compute, memory, storage and network interfaces. Once installed, the vCMTS capacity is fixed regardless the actual workloads. Provision is typically needed based on the workload in the worst case scenario, resulting in wasted resources during idle time.

The on-premises hosting option does have its advantages for handling the latency sensitive and data intensive workloads, such as UPF and RTC. Because of this, all major cloud platforms have the on-premises extensions, either as physical servers, such as AWS Outposts, or software agents/packages running on the user-owned servers.

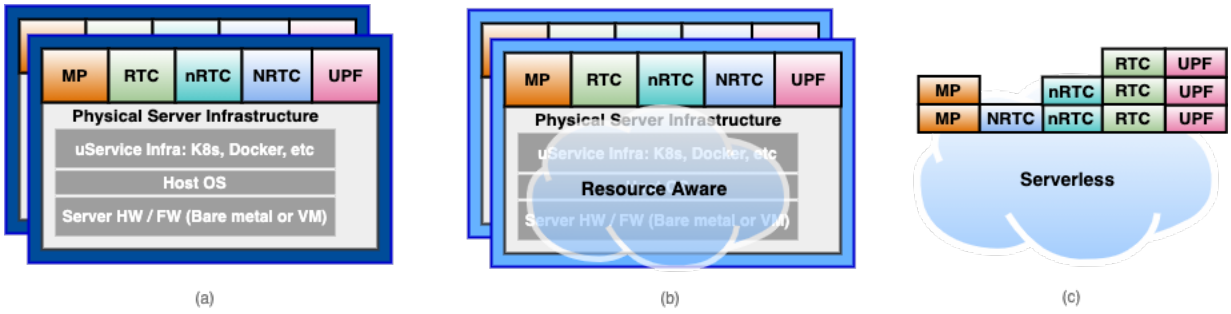

Figure 5 – vCMTS Server Platform Options

The “resource-aware” platform is the traditional cloud computing platform provided by virtual machines (VMs) overlaid on physical hardware, such as Amazon EC2 [4]. On this platform, users can configure the VM instances and organize clusters without the need to own the underneath physical server. In fact, they only rent a fraction of the cloud infrastructure to run the workload and achieve the economies of scale of sharing the infrastructure with others. Since users can control the resource type and running time, this platform is suitable for long-lasting or stateful workloads. However, there is the overhead to configure the VMs and the autoscaling is in the number of VMs, a coarse granularity comparing to the next serverless platform.

“Serverless” is a new cloud computing technology that keeps the infrastructure/platform completely hidden from the user [5]. It aims to simplify the application development/deployment processes, and enables a fine-grained, transaction-based consumption model. The serverless resources are automatically scaled on the user’s behalf as the workload changes. The serverless platform started with AWS Lambda, a function-as-a-service platform, and later expanded to include any resource-unaware backend services, such as Amazon DynamoDB for database, Amazon Simple Storage Service (Amazon S3) for binary storage, and AWS Fargate for running the containers.

The serverless platform is rapidly evolving but is comparatively less mature. For example, it is limited today in hosting stateful or latency sensitive applications, as the underneath compute resource is ephemeral and invisible to user applications. To take advantages of serverless platform, applications need to be stateless, event driven and able to tolerate the invocation delays.

7. CMTS Workload Placement Strategies

CMTS is a complex system, producing a wide variety of workloads that have diverse requirements on the infrastructure/platform, such as the distance/latency to the cable modems (CMs), processing speed, memory size, I/O performance, and CPU types etc. On the other hand, the cloud environment is distributed and inhomogeneous in nature. Having an optimum workload placement is critical to minimize cost, ensure the CMTS performance.

Figure 6 shows the mapping of the key workload requirements (y-axis) to the available cloud platform types (x-axis). It reveals the suitability for placing a CMTS workload onto a specific platform, as described below:

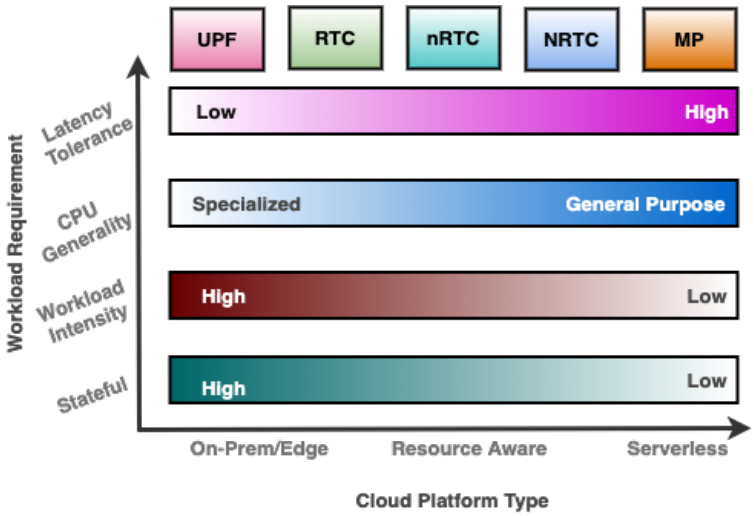

Figure 6 – CMTS Workload Placement Strategies

UPF and RTC

The UPF and RTC workloads are suitable for the on-premises/edge platform, as both types are latency sensitive and/or data intensive.

The UPF workloads are time sensitive and data intensive, up to millions packets per second per Service Group (SG). The RTC workloads are timing sensitive and compute intensive. The DOCSIS US scheduling decisions need to be made every millisecond with a processing time limited to the low hundreds of microseconds. Accurate DOCSIS timing is also required to align MAPs with the US physical layer. The RTC relies on the UPF for forwarding the real-time signaling traffic. The combined platform service access delay must not exceed the overall latency budget of low single digit of milliseconds.

nRTC

The nRTC workloads are the DOCSIS control protocols with a time budget of a few hundreds of milliseconds, including the signaling propagation delay and the processing delay. Examples of the nRTC workloads include ranging request handling, dynamic service flow addition/change/deletion (DSX), and dynamic bonding group change (DCC). The nRTC timing requirement is more relaxed than the UPF and RTC requirements, but tighter than the NRTC and MP workloads.

As an optimization strategy, the nRTC workloads can be placed in the Region to free up the Edge resources for UPF and RTC. Since the in-region serverless platform today have non-negligible invocation delay that may exceed the nRTC timing budget, the in-Region resource aware platform, such as Amazon EC2, may suitable for the nRTC workloads.

NRTC and MP

The NRTC workloads, such as CM registration, MP workloads, and as SG configuration, are typically infrequent and latency tolerant (minimum one second). Occasional usage spikes may occur, for example, during a planned upgrade/maintenance window or upon an unexpected power outage. In which case, the NRTC may experience a CM registration storm with potentially thousands of CMs trying to register at the same time.

These characteristics match well with the serverless platform, where the NRTC and MP would benefit from the built-in elasticity and the economics of the fine-grained cost model. During the normal operation time, the serverless platform may not incur any cost as the NRTC or MP workloads are very low and may well be within the free tier of the serverless services. During the rare event like the CM registration storm, the serverless platform can rapidly scale up to meet the demand and scale down once as storm fades away.

In summary, the CMTS workload placement is an optimization process to minimize cost within the boundary conditions for the CMTS to perform at a given scale.

8. Full Cloud CMTS Deployment Model

A full cloud CMTS may be deployed on both the edge and the Region for an optimum workload placement. Figure 7 shows a full cloud CMTS deployment example on the AWS platform, where the UPF and RTC functions are placed at the edge and the nRTC, NRTC, and MP functions are placed in the Region.

The AWS virtual private cloud (VPC) service is used to form a virtual network to logically isolate the edge and Region resources for the CMTS. The CMTS VPC is connected to the on-premises network via an AWS Local Gateway, which further connects to the CIN and the SP core network via a SP router (SPR). This setup allows the DOCSIS upstream and downstream data traffic to traverse the same path as in the vCMTS today. For the CMTS control and management traffic, a dedicated connection known as AWS Direct Connect, is used between the Region and the edge to reduce the transport latency and jitter.

Within the Region, multiple AZs are used to add geo-redundancies for the control and management plane. The nRTC is placed on the resource-aware platform meet to the near-real time latency requirement. With explicit configurations, auto-scaling can be enabled for the nRTC across multiple AZs. The NRTC and MP can be placed on the serverless platform, thanks to the extra timing budget, which has built-in auto-scaling capability and better cost efficiency with its fine-grained, transaction-based cost model.

To support the user plane and control/management plane separation, the following interfaces/protocols are used to facilitate the communication between the CMTS service endpoints across the Edge and the Region. Each CMTS endpoint is assigned with an IP address from its hosting subnet reachable by other endpoints through the border gateway protocol (BGP).

Punt Path:	For the US UPF to punt the upstream DOCSIS signaling to RTC, nRTC or NRTC via TCP or UDP, such as CM Bandwidth Requests to RTC, Ranging Requests to nRTC, and Registration Requests to NRTC.
Inject Path:	For the CMTS control plane to inject the DOCSIS signaling messages to the DS UPF via TCP or UDP, such as MAP and UCD messages from RTC, Ranging Response messages from nRTC, and Registration Responses from NRTC.
Rest API:	For MP to configure/manage the CMTS control plane and user plane services. The REST APIs can be carried over HTTP and leverage existing interface definitions based on the DOCSIS YANG data models.
Telemetry Streaming	For MP to monitor the CMTS control plane and user plane operations. The telemetry data can be carried in GRPC and using the existing DOCSIS model driven telemetry interface definitions.

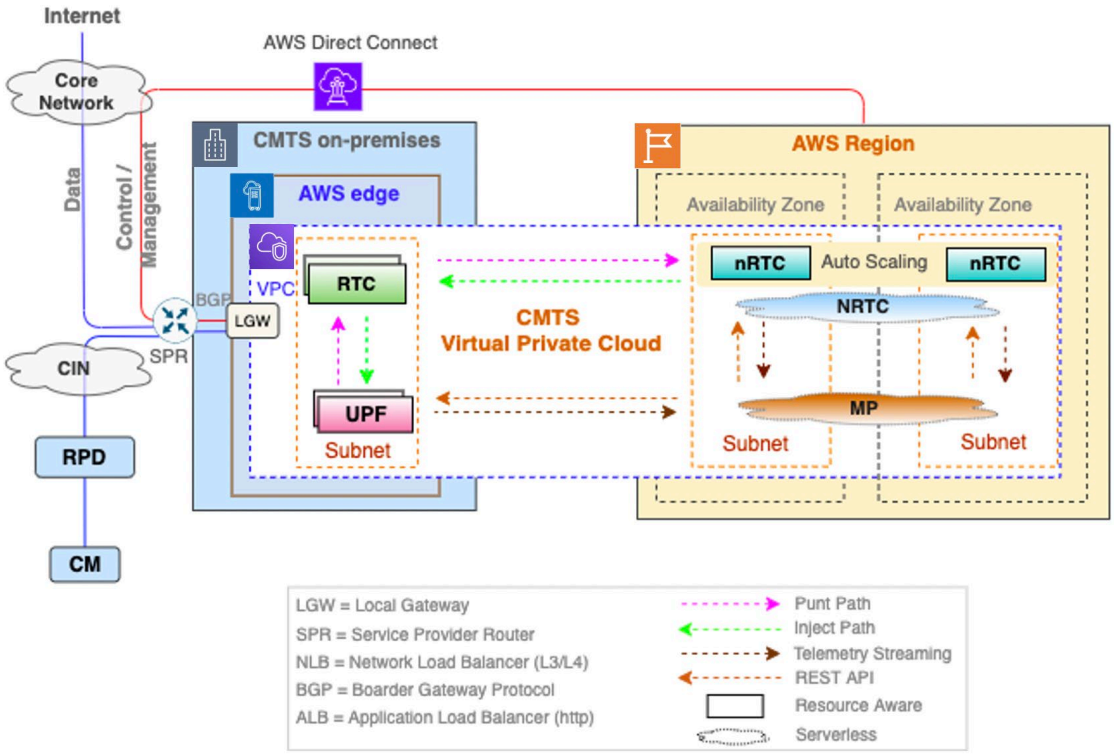

Figure 7 – Full Cloud CMTS Deployment Example on AWS

9. Serverless DOCSIS State Handling

Given the simplicity and economics appeal of the serverless platform, we are interested to explore how it can be used to support DOCSIS which is known for being deeply stateful. The DOCSIS control protocol is based on states of several DOCSIS entities, such as service groups (SGs), cable modems (CMs) and service flows (SFs). DOCSIS applications are multi-step procedures, such as profile management, load balancing and channel resource management for resiliency. The cloud serverless platform on the other hand has no affinity to the underlying compute infrastructure, and it is not possible to hold states across invocations. To provide serverless DOCSIS services, the code needs to be written in a stateless style.

Given the serverless technologies available today, the following two methods can be used for DOCSIS state handling,

- using the serverless data stores to persist the states externally, and
- using the serverless workflows to orchestrate the stateless functions.

This stateless approach to programming is also required to implement horizontal scalability which provide elasticity and thus better economics with resource-aware platforms.

9.1. Using the Serverless Data Stores

This is a key technique in the cloud native design that uses the external datastore to persist the states across function invocations. States are externalized as events passing between the functions through the data store while the functions themselves remain stateless. Examples of the datastores on a serverless

platform include Amazon DynamoDB, an NoSQL database with single-digit millisecond access time or microsecond access time with cache accelerations, and Amazon S3 for large binary object storge.

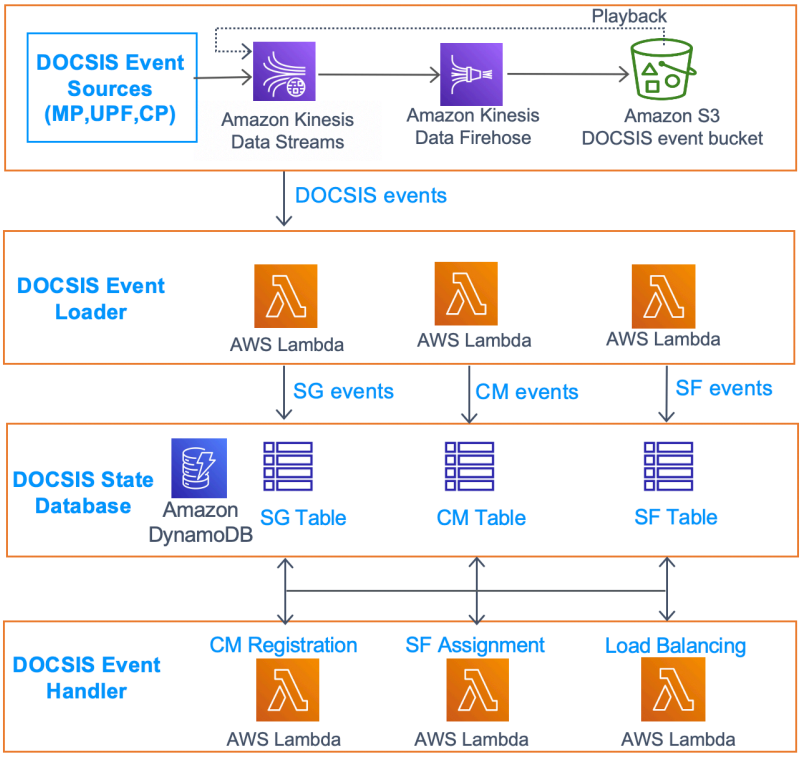

Figure 8 – DOCSIS State Handling Using Stateless Datastore

Figure 8 shows an example for using the serverless data stores to handle states of the non-RTC workloads. It uses an AWS serverless platform that contains AWS Lambda for serverless compute, Amazon DynamoDB for serverless database, Amazon Kinesis for serverless streaming, and Amazon S3 for serverless storage.

The design is based on an event driven architecture where the state information is passed as events between the stateless functions. The state changes of the DOCSIS SG, CM, and SF entities are represented as events from the management, user plane and control plane. These events are pushed into Amazon Kinesis, a data streaming service that keeps the event sequences in different shards or service groups.

These events are then pulled by the DOCSIS event loaders (implemented as AWS Lambda functions) and sorted into the corresponding Amazon DynamoDB tables. The loaded events will then trigger the DOCSIS Event Handler (also implemented as AWS Lambda functions) that watch the tables to process the state changes.

As an optimization, multiple handlers can be triggered for a single event. For example, a CM REG-REQ arrival event will trigger the CM Registration handler to process the REG-REQ, the Load Balancing handler to process the CM's load balancing group configuration, and the DS/US resiliency function to provide the channel list for the CM's transmit and receive channel sets.

In this example, there is also an Amazon S3 bucket to store the event history in longer term, which serves as the single source of truth that can be used to derive the DOCSIS states for debugging, fault recovery and AI/ML analytics.

In summary, by converting states into events, a stateful DOCSIS microservice can be disaggregated into a set of serverless functions. The fine-grained stateless functions then allow the serverless platform to quickly adapt the computational resource allocation to the shifting workload requirements, therefor achieving higher resource efficiency and lower cost comparing to the resource-aware platform.

9.2. Serverless Workflows

The DOCSIS application is typically a higher-level construct that contains various functions working in coordination with each other to accomplish the desired tasks. The execution order of the functions reflects the application states and the state transitions as the dependency or precedence of the execution of one function to another.

On the cloud serverless platform, there is a workflow service that can be used to record the function execution sequence, such that individual functions do not need to know about the application states. Additionally, since the workflow captures the prior knowledge of the execution order at runtime, it can be used for the platform level optimizations, for example, by warming up functions, pre-fetching data and instructions to achieve better performance.

Figure 9 is an example of using the AWS step function to implement DOCSIS profile management. AWS Step Functions is a serverless workflow service that can be integrated with other AWS services, such as AWS Lambda, Amazon DynamoDB, Amazon Kinesis, and Amazon SNS to accomplish a complicated procedure with many logical steps.

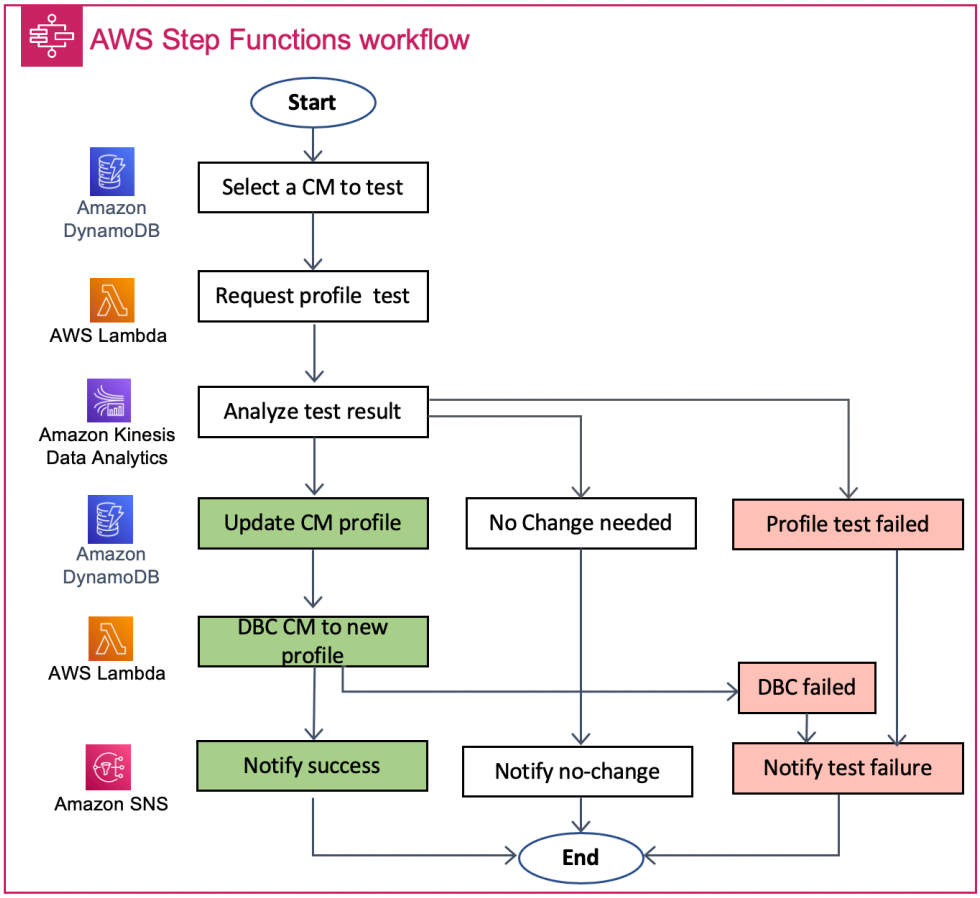

Figure 9 – DOCSIS Profile Managment Using Stateless Workflows

10. Getting Started

Moving to cloud is an interesting and challenging paradigm shift. It requires deep understanding of both the cloud services and the CMTS resource usage characteristics to maximize the cloud benefits. Since it may take years to mature to that level of understanding, cloudification is an iterative optimization process that requires learning while doing.

Given the on-prem CMTS has already been virtualized, a lift and shift strategy to the cloud is feasible to jump start the cloudification by moving a copy of an existing vCMTS and data to public cloud with minimal or no redesigning or modifications. This essentially is a test-driven development model to identify issues caused by the cloud hosting environment, and resource consumption hotspots for targeted redesign and optimizations.

This cloudification strategy motivated us to start a proof of concept (PoC) project using AWS as shown in Figure 10. In this setup, the vCMTS, the Cisco cnBR and the cnBR manager, are placed in an AWS Region that covers the on-premises lab location where the RPD and CMs are located. The cnBR in the Region is connected to the lab's router via an AWS Direct Connect. The PoC is used evaluate all vCMTS workloads in the cloud environment. Finding of this study will help refine the cloudification strategy and determine the architecture choice.

The in-region full cloud solution as used in this PoC can also be used as a convenient testing/development environment, which can be quickly created on-demand without the expansive lab expansions.

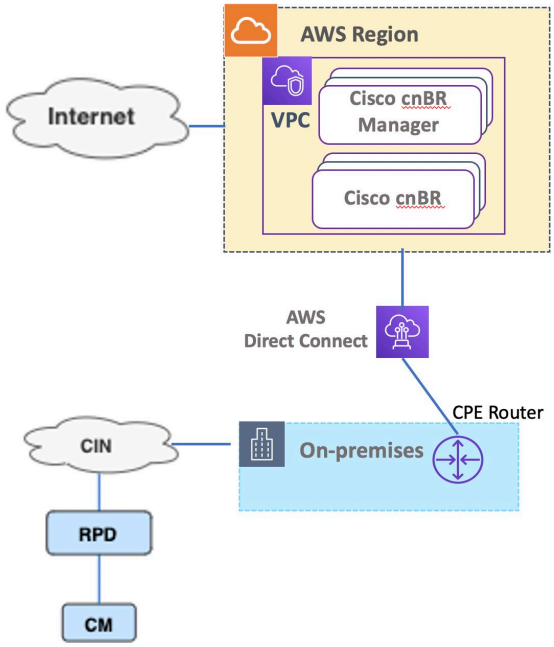

Figure 10 – Poof of Concept for CMTS Cloudification

11. CMTS-as-a-Service

With cloudification, the CMTS can be delivered as a service to the cable operators through the Internet or the direct connect services offered by the cloud providers. To make the CMTS-as-a-Service successful and sustainable, multi-tenancy is the key to bring down the CMTS development and maintenance cost.

In its basic definition, the CMTS multi-tenancy is an architecture in which a single CMTS entity serves multiple cable operators. Such entity can be the continuous integration and continuous delivery (CI/CD) pipeline that produces the production software and various cloud resources required to execute the CMTS functions.

11.1. CI/CD Simplification

CI/CD can be pictured as a pipeline, where new code is submitted on one end, tested over a series of stagers (code, build, test, release, deploy) and then published as operation-ready code. In the traditional single tenant environment, the complexity of the CI/CD pipeline goes linearly with the number of tenants. The CMTS vendor needs to maintain separate pipeline for each operator, slowing down the CI/CD life cycle, and wasting development /deployment resources.

With multi-tenancy, only one CI/CD pipeline is required as shown in. Figure 11, which can dramatically reduce the CI/CD complexity, improve quality and accelerate innovations, as all tenants would use the same code, the same operational infrastructure, and the sane deployment procedures.

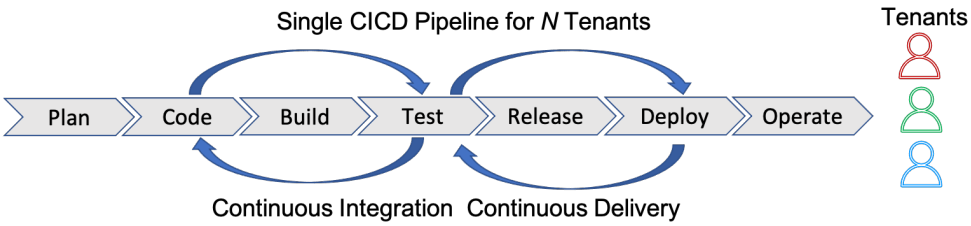

Figure 11 – CI/CD Simplification With Multi-tenancy

11.2. Multi-tenant CMTS Resource Sharing/Isolation

A multi-tenant CMTS achieves the cost and operational efficiency by sharing the same CMTS software and the cloud infrastructure among multiple operators, while keeping the tenants from accessing another tenant's resources. It boils down to a constrained optimization issue to properly partition the CMTS resources among the tenants either statically and/or dynamically.

There are a wide range of factors to consider for the resource partitioning across different tenants [6]. For example, a big operator who has large and constant workloads may be suitable for dedicated resources, a small operator on the other hand may find it more feasible to use the multi-tenant pooled resources. The workload characteristics also impact the partition strategy. For example, it's more economical to use the pooled resources for the DSX transactions, as they are only triggered occasionally. The goal of the multi-tenant CMTS is to efficiently serve everyone and automatically scale up and down based on current requirements demanded by the tenants.

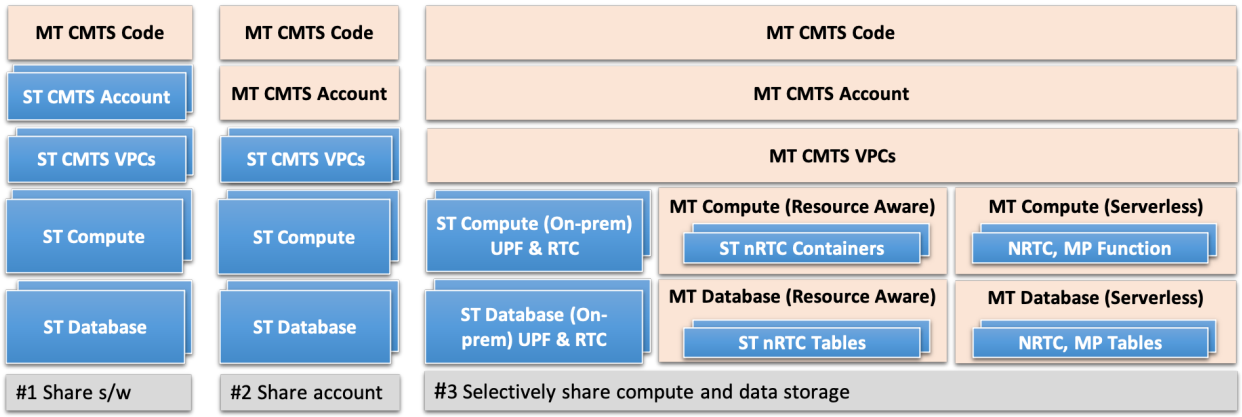

Figure 12 – Multi-tenant CMTS Resource Sharing and Isolation Options

Figure 12 shows three different resource partition options of the tenant stack including CMTS software, CMTS account, the VPC network construct, and the compute/data storage resources. These options may be applied in any combination to fit various tenant requirements.

The first option is the most isolated approach, where tenants only share the multi-tenant (MT) CMTS software. A single-tenant (ST) account is assigned to each tenant to keep all the moving parts of the tenant stack in complete isolation.

The second option pushes the isolation to the next level with all tenants running the same code in the CMTS provider's account. One or more unique ST CMTS VPCs are assigned to each tenant to enforce the isolation with the network boundaries. VPC based isolation avoids the certain account provisioning

restrictions and gives the CMTS provider more centralized control across all tenants' deployment and operation. However, this option also has the same scaling issue as the first option, as the number of VPC grows, the management agility and resource efficiency decrease.

The third option has much more granular resource partitions among the tenants. It offers the best efficiency, agility and cost benefits among the three options. However, it requires a much more comprehensive tenant isolation strategy. Since operators are only naturally separated by their headend/hub locations, the on-premises UPF and RTC functions are completely isolated in compute infrastructure and data stores. For the CMTS services hosted in the Region, tenants are isolated by containers on the resource aware compute platform, and by functions on the serverless compute platform.

For the data stores, tenants can be isolated by tables or even table entries via the tenant identifier. Multiple cloud utilities are available to simplify tenant isolations. For example, using AWS Identity and Access Management (IAM) to implement run-time, policy-based isolations, using Amazon Elastic Kubernetes Service (Amazon EKS) namespace to isolate the ST container groups, and using the Amazon DynamoDB partition key to isolate ST tables.

12. Conclusions

The decision for moving the CMTS to the cloud is obvious: you pay for what you use, scale when you need, and spend less time managing the infrastructure/platform, and end up with more time to innovate for your business.

Cloud is different from the on-premises server environment with its distributed Region and edge locations and various resource-aware and serverless compute/storage platforms. Moving the CMTS to the cloud cannot be a simple rehosting process. Instead, it requires iterative optimizations to make most of the cloud environment.

With cloudification, the CMTS can be delivered as a service, enabled by CI/CD and the cloud based multi-tenant architecture. This opens new business opportunities for both CMTS vendors and cable operators improving business agility, productivity and cost efficiencies.

With the virtualization laying out the foundation, the cloudification of the CMTS can start with a lift-and-shift followed by a test-driven development model for targeted redesign and optimizations.

It is the time to unleash the power of the cloud computing for the CMTS.

Abbreviations

API	Application programming interface
AWS	Amazon Web Services
BGP	Boarder Gateway Protocol
CM	Cable modem
CCAP	Converged cable access platform
CIN	Converged interconnect network
CI/CD	Continuous integration, continuous delivery
CMTS	Cable modem termination system
CP	Control Plane
DS	Downstream
DSX	Dynamic service addition/change/deletion
FMA	Flexible MAC architecture
GCP	Generic control protocol
gRPC	Google RPC
MAP	DOCSIS bandwidth request
MP	Management Plane
MT	Multi-tenant
nRTC	Near-real time control plane
NRTC	Non-real time control plane
RPD	remote PHY device
RTC	real-time control plane
SG	Service Group
SF	Service Flow
SP	Service Provider
ST	Single tenant
UPF	User plan function
vCMTS	Virtualized CMTS
YANG	yet another next gen (data modeling language)

1. Introduction

This is being written in the summer of 2021, a year-plus since the global pandemic that sent many of us home to work, and created an entire category of 2020 memories – "my/our COVID project" – ranging from sourdough bread to bathroom remodels to fitness journeys. If there was such a thing as an unofficial, job-related COVID project, automation would assuredly qualify! From plant maintenance to residential product support, circumstances arose over the past year that catalyzed us to align processes and achieve automation.

Maybe this feels familiar to you: Volumes upon volumes of tickets. Late night/early morning pages and dispatches. On-call team member burnout. All are symptoms of large, complex systems, built and patched and rebuilt over decades, and probably showing multiple signs of wear. You, of course, "just" want to ensure you know what is going on, where, and when.

But how do you sort what is truly an impacting event that requires immediate attention, from the what can be a daunting level of "informational noise"? How do you get the right eyes on the right problem at the right time?

The answer that worked for us was a duet of process alignment and automation. In this paper, we will review some of the automation opportunities we identified, how we identified them, and the impact they had on our teams and business operations functions. We will review two different approaches to address these opportunities – informational noise reduction, and optimization by correlation -- in two quite different areas of our operation: first, by our field plant maintenance technicians, supported by our XOCs (eXcellence in Operation Centers), and second, in our national Residential Product Support team.

2. Getting Started – Process Alignment

In consolidating and post-consolidating environments, a necessary course of work is to find "sameness," for purposes of scale. For our national and field teams, we have been focusing on sameness across all functions. However, overall "sameness" only delivers that initial goal of industry consolidation and geographic clustering -- scale. As important as scale, and the next step after achieving it, is internal synchronicity. We define that here as "the best of best practices, applied at scale," across the consolidated organization. Internal synchronicity optimizes how things are done, and it does so at scale. It's why we're on a quest, partly characterized in this paper, to identify best practices/processes/ solutions and implement them everywhere.

As we identified areas of differences, an initial area of activity we believed could serve large benefits to customers and employees was identifying and implementing best practices around node outage treatments. When we dispatch plant maintenance technicians for node outages during the day, we are pulling them off other work that is in their queue. When we dispatch plant maintenance technicians after hours, we incur overtime, and when there is enough on-call activity, those technicians can burn out. It is therefore important that we dispatch them only to nodes where they can take action to fix problems. It is about getting the right technician to the right place at the right time. It is worth noting, plant maintenance technicians are the more expensive technicians, with the pricier bucket trucks, as compared to fulfillment technicians. And we all know that when dispatched at night, technicians deserve for it to be a legitimate issue.

We needed to determine what steps we could take to reduce the number of times plant maintenance trucks get dispatched, only to find that the node was out because the power was out, or some other event the technician was not able to repair – the classic "NTF" (no trouble found). We have three different divisions and as we looked at node outage practices, we found different processes for each of the divisions.

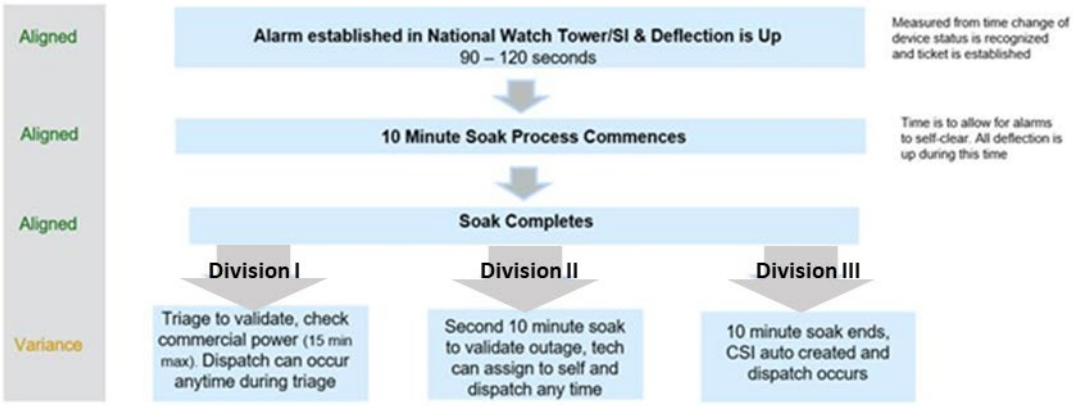

Figure 1- Traditional Division "Node Soak" Process

As we see in Figure 1, above, there was alignment in three areas, but variance existed once a node completed the initial 10-minute "soak," a term we use to indicate the period of time during which node components self-clear any alarms. It is important to note that nodes go into soak when a certain percentage of modems served by that node go through a registration state change (to offline).

The division teams came together to review their processes and resulting data, comparing apples to apples, to see who had the most efficient plant maintenance dispatch records, based on total dispatches, fix codes, and NTFs. Perhaps not surprisingly, folks can have a good bit of passion for their individual tools and/or processes. So, after a notable amount of review of data and discussion of the data, the node outage process utilized by Division I was identified as the best solution for the customer, the employees, and the company. We referred to the activity as "outage pre-verify," because the XOC was verifying that the outage exists before dispatching staff. Once we had a process name and agreement, the team then focused on developing a thorough implementation plan which included detailed training and communication plans; a review of the LOQs (Lines of Questioning) used by the Division I team during the triage activities; determining and preparing for expected HFC (Hybrid Fiber-Coax) desk task increases because of the triage activity; and expected truck roll decreases related to plant maintenance. Once we had developed this detailed plan, we launched it on a region-by-region basis across divisions 2 and 3. In some areas, we launched more quickly than originally planned, because it was such a good story, from a plant maintenance perspective.

3. The Results of Process Alignment

How has the Outage Pre-Verify work been received by the two other division field teams? Charles Detwiler, a Comcast Maintenance Supervisor in the Pittsburgh area summed it up this way:

"Outage Pre-Verify has reduced overtime and man hours drastically. HFC techs are putting information in tickets, so we now have a better understanding of what we are going to be troubleshooting and there is also much more trust that this is a legitimate outage. We just had a regional call and reviewed the significant truck roll reductions since rolling out Outage Pre-Verify. Lastly, our techs are less stressed because we are rolling fewer trucks at night, so we are getting more rest."

Steven Musembi, VP (Vice President) of XOC for Comcast's Central Division credits the introduction of Outage Pre-verify as *"a direct contributor to node performance in the Central division. OPV (Outage Pre-Verify) freed up labor via transaction reduction to help find and address plant issues, improving the customer experience for all of our customers."*

Issues that are detected via our tools and rule sets, which become tasks for our HFC technicians, are referred to as Dashboard Tasks. Whenever there are node issues that hit our thresholds, that creates a dashboard task. The numbers speak volumes. Figures 2 and 3, below, show the total number of dashboard tasks and the number that were cancelled as a result of XOC outage pre-verify work. The overall result was reduction of all dashboard tasks by nearly a third (29.32% and 28.5%.) Internally, we were also able to break these out by daytime and after-hours Plant Maintenance dispatches, to show the overtime savings. Again, these reductions happened and continue to happen because the HFC desk technicians are following through on the same set of OPV (Outage Pre-Verify) LOQs (Lines of Questioning) to properly triage a node outage.

OPV Details - Division 2 Fiscal June 2021			
Region	**Total Dashboard Tasks**	**# Cancelled Dashboard Tasks**	**% Canceled Tasks**
1	14765	3847	26.05%
2	11679	3620	31.00%
3	8105	1624	20.04%
4	7807	3326	42.60%
Totals	**42356**	**12417**	**29.32%**

Daytime Savings – Division III

Region	# of Dash Tasks between 8 am and 5 pm	# Canceled WT Tasks between 8 am and 5 pm	% of Canceled WT Tasks Relative to the # of Dash Tasks (8 am to 5 pm)	Total Tme Savings in Hours (Tasks 8am-5pm *1.5 hours)
1	2,924	852	29.14%	1,278
2	2,343	888	37.90%	1,332
3	1,672	507	30.32%	760.5
4	1,661	563	33.90%	844.5
5	911	239	26.23%	358.5
Total	9,511	3,049	32.06%	4,573.5

Figure 5 – Breakdown of Another Division's Plant Maintenance Cancelations – Daytime hours

4. Additional "Sameness" Opportunities

The Division I team also shared its operating practice for MSOs (Multi-Soaking Outages). A multi-soaking outage is the term used to describe a node that drops into soak, which as a reminder occurs when a certain percentage of modems associated with that node experience a registration state change, indicating that "something is up" at the node. What's different in a multi-soak outage is that the node self-clears before the 10-minute soak time elapses, but alarms and re-soaks itself again, in short order. The division's process was to triage and dispatch help to nodes that dropped into soak, and then cleared, four or more times in any rolling 24-hour period. Because we were going to be reducing plant maintenance truck rolls with our Outage Pre-Verify work, it made sense to also implement this same practice across all three divisions. We knew that implementing the MSO functionality would drive additional HFC technician tasks as well as additional plant maintenance-related truck rolls. However, the HFC leadership teams were gaining efficiencies by reducing tasks in other areas, and the Plant Maintenance teams were very capable of taking on this work, given the significant reductions in truck rolls as a direct result of the Outage Pre-verify work.

Figure 6 shows that our plant maintenance teams are, on average, finding and correcting node multi-soak issues more than half (57.5%) of the time. Again, these are intermittent outages that we are correcting before they become a larger outage – a big lift for the customer experience.

Division II	Region	Tasks	% Region
	1	137	54.80%
	2	102	72.30%
	3	160	57.60%
	4	77	72.00%
Division Total		**476**	**61.30%**
Division III	**Region**		
	1	177	48.10%
	2	136	58.10%
	3	145	63.60%
	4	132	54.30%
Division Total		590	57.50%

Figure 6 – Multi-Soaking Outage (MSO) Repair Results

With the solid progress being made for MSO with the setting of 4 times in a rolling 24 hours, we are poised for the divisions to move to 3 times within 24 hours, to drive even more reliability into the infrastructure – which automatically means fewer outages for our customers! One division has already moved to 3 times in 24 hours, while our two other divisions preparing to make the move as well.

5. Align the Process, Then Automate – One Way

Once the teams aligned on the process, we needed to lighten the load for our HFC technicians, who had taken on a great deal of additional triage activities. And now that we were all on the same process, we could build consistent automation. All those canceled jobs were canceled because of the excellent work performed by these HFC technicians – and we did not add headcount to our HFC desks to support the outage pre-verify or the MSO work. Together, the division and national team developed a user story to capture a description of a software feature from an end-user perspective. This allowed us to to reduce "eyes on glass" time for the HFC desk technicians. Considerations for the user story included:

- Utilizing automation and other tool inputs to validate node outage events and reduce pre-verify questions, using already-available data for:
    - Verification of device registration state
    - Confirmation of no upstream activity – flatline node
    - Validation of power supply status
    - Determining "storm mode" status
    - Verification of headend or CMTS (Cable Modem Termination Server) alarm
- Saving an estimated 3 minutes per pre-verify task (on average, a pre-verify task takes 7 minutes prior to the automation), by reducing the number of manual actions needed for task completion
- Saving an estimated 30K+ hours per year at the XOCs, on eliminated workflows.

This automation work is in progress for implementation in 2021. Future automation enhancements will include checks of Xfinity Home devices served by a node, to determine connectivity type (backup / cellular), to further the accuracy of automated checks related to commercial power availability.

6. How Covid Impacted Automation Activities

When you are supporting the flagship products for a major cable/broadband company, it is imperative that they work at or better than the expected 99.999% of the time. This certainly made 2020 a year to remember! The pandemic required teams and companies to shift perspectives, cultures and make some really challenging decisions. Employees were having difficulty with the lack of in-person social engagement, hallway conversations and the biggest issue, the blurring boundary between work/life hours.

7. Necessity: The Mother of…*Automation!*

We had to find those solutions fast! But first we had to identify what could be automated. We looked at redundant tasks such as pulling logs from devices, ticket entry, ticket assignment and triage. Previously, our offshore team did the ticket creation, while another offshore team did the initial triage. Outsourced resources also played a major part in "air traffic control" - assigning tickets to the correct teams for mitigation, as well as escalating to on-call resources when needed. Fortunately, our teams were slightly ahead of the curve here and had been doing the data analysis prior to this occurring. This event just fast-tracked the groundwork we had already laid out.

Having a head start in finding and implementing automation drastically reduced our fears about team burnout and not being able to support our products at the same level. While there were obvious candidates, we were still faced with the challenge of *how* we find automation opportunities.

The undisputed answer: data analysis and best practices.

Specifically, we built reports to understand what our biggest drivers were, and what could we do to streamline our workflows. We also looked for "low hanging fruit," or, the quick wins. We engaged with our engineering teams to dive into what was important and what was lower priority that could wait until business hours. We worked to create a portal so that our internal customers could create tickets on demand and escalate if needed. We worked on auto-assignment, auto paging and correlation. We developed "soak" periods for alarms and alerts, to give electronics a grace period to reset themselves. Not only did we work to make our processes and systems more efficient and user-friendly, but we also worked to make them smarter.

We also needed to understand who our internal customers were and what needs they had. Any solution we developed needed to be user-friendly and convenient. What existing tools could we share with them to help them do their jobs, and potentially prevent the escalation in the first place? What opportunities are "hiding in plain sight," for anomaly detection and/or reductions in MTTM (mean time to mitigate)?

8. How We Automated It

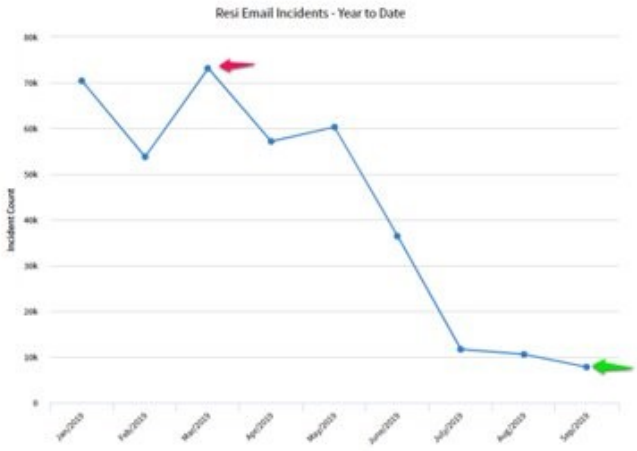
In March of 2019, we started taking a hard look at the volume coming into the Production support team. We broke it down by the primary service, looking at each individually. We ran ticket reports to understand volume, trends, and commonalities. Our highest volume related to an email platform. In March of 2019, there were over 74,000 tickets created for this platform alone. Once we did the analysis, we discovered that a majority were auto-resolving, when the main event resolved. In other words, we

were generating tickets for events where they were not the primary issue, but rather an impacted service. It was informational noise.

One of the other findings was that, the outsourced team was largely serving as a pass-through for tickets. An alarm or alert would trigger and be assigned to the Tier 1 queue. The Tier 1 team would respond by reassigning the ticket to a Tier 2 team. Ahem: If no investigation or triage is happening, then why is a ticket entering any queue?

These top-two findings guided our actions and next steps. Our first action was to correlate events with primary drivers. As an example, if one VM (Virtual Machine) went into an alarm start and there were 50 affected applications on that VM (Virtual Machine), we will generate 51 tickets. In the updated noise reduction effort, we now have 1 ticket that has 50 events appended. This reduces volume while still tracking impact. It significantly reduced overall volume and allowed us to find and trend the truly impactful events before they became major incidents.

Based on our analysis of the data, we were able to identify and define this correlation solution, which we presented to our engineering partners. We wrote out exactly what problem we wanted to solve, and what our desired outcome would be. Once we had these defined, we were able to figure out the actions needed to get from the problem statement to the solution. We then presented this to our engineering teams to kick off our efforts and garner buy-in. During this collaboration process, we also developed a deeper understanding of the platforms we support, strengthened our relationship with the engineering partners and most importantly, provided results. This also allowed the engineering teams to focus on the stability of the product rather than sort through a high volume of informational noise.



Created	Incident Count	Percentage of Incidents
Jan/2019	70,429	18.47%
Feb/2019	53,794	14.11%
Mar/2019	73,147	19.18%
Apr/2019	57,165	14.99%
May/2019	60,299	15.81%
June/2019	36,449	9.56%
July/2019	11,676	3.06%
Aug/2019	10,582	2.78%
Sep/2019	7,792	2.04%
Total	381,333	100%

Figure 7- volume reduction via correlation

The impact of this implementation also had other benefits. By limiting what alerted to the affected service, application, or infrastructure, the mean-time-to-mitigate was reduced and customer NPS (Net Promoter Score) saw a rise in positive feedback.

"I lead an engineering and operations team for enterprise-scale complex applications. Large events would often lead to a storm of alerts making root cause analysis slow. Nancy's team came in and implemented automatic correlation that minimized the noise to just the important alerts. This has significantly reduced our MTTM (mean time to mitigate), which improves our customer NPS."
– Gabriel Satterlee - Director of Engineering Operations

This process was the beta, or proof-of-concept (PoC), and was proven to work. Based on these results, we began to push correlation activities out to our other supported products and applications. When we trended the data, post implementation, we noted that there was significant reduction in both MTTT (mean-time-to-triage) and MTTM (mean-time-to-mitigate).

Part of the overall reduction effort involved reviewing the alerts we had in place. By reviewing these alerts, we were able to understand what was actionable, as opposed to a warning or for awareness. We developed a better understanding about how to adjust thresholds where it made

sense, and anticipate what related events could be correlated. We were effectively able to reduce the noise and focus on hidden problem areas via deep dive investigations.

Most of the automation efforts involved escalation reduction, by looking at three factors:

> *1- Are these escalations actionable or not? If not, we can adjust thresholds to ensure actionable next time or remove them entirely.*
>
> *2- Reduction of duplicate escalations/tickets: Do we need 5 tickets for the same issue? Typically, that answer is no. Our approach was to merge similar alerts into the same ticket to reduce toil and escalate a single time for a single issue.*
>
> *3 – Using problem management to focus and deep-dive on the top "repeat offenders." This helped to prioritize Engineering/Developer teams around specific issues to improve customer experience and reduce load on our teams.*
>
> *These three factors were key in both deprecating our offshore resources and improving quality of life (work/life balance) for our teams.*
>
> ***~Brian Seeley, Sr. Manager Production Support***

As this process unfolded, we realized that we were able to automate a lot of the manual work – meaning that our Tier 1 , serving as a catch-and-dispatch team, was not required to support the internal product team, because we were directly assigning to the responsible resolver teams. Those that were not directly assigned to an engineering team went directly to our Tier 2 Triage desk for a more technical review. In some instances, we were even able to move resolution steps all the way to Tier 1 customer Care and, eventually, a customer-facing application, so that they could "self serve" for issue resolution, without having to call us. More on this later.

We did still have the challenge of ticket entry. We lacked a means for our field teams or other business partners to report an issue to us, beyond email. The process involved emailing our Tier 1 team, which would acknowledge the request, create the ticket and assign it to our Tier 2 team for initial review, while pulling of necessary log files. After Tier 2 completed its work, it would be assigned to an incident management team or engineering team, depending on the triage steps. After the Incident Management or Engineering teams completed their piece, the ticket went back to Tier 1, to follow up with the issue reporter. The number of exchanges between assignment groups caused a lag in final root cause or mitigation of the issue.

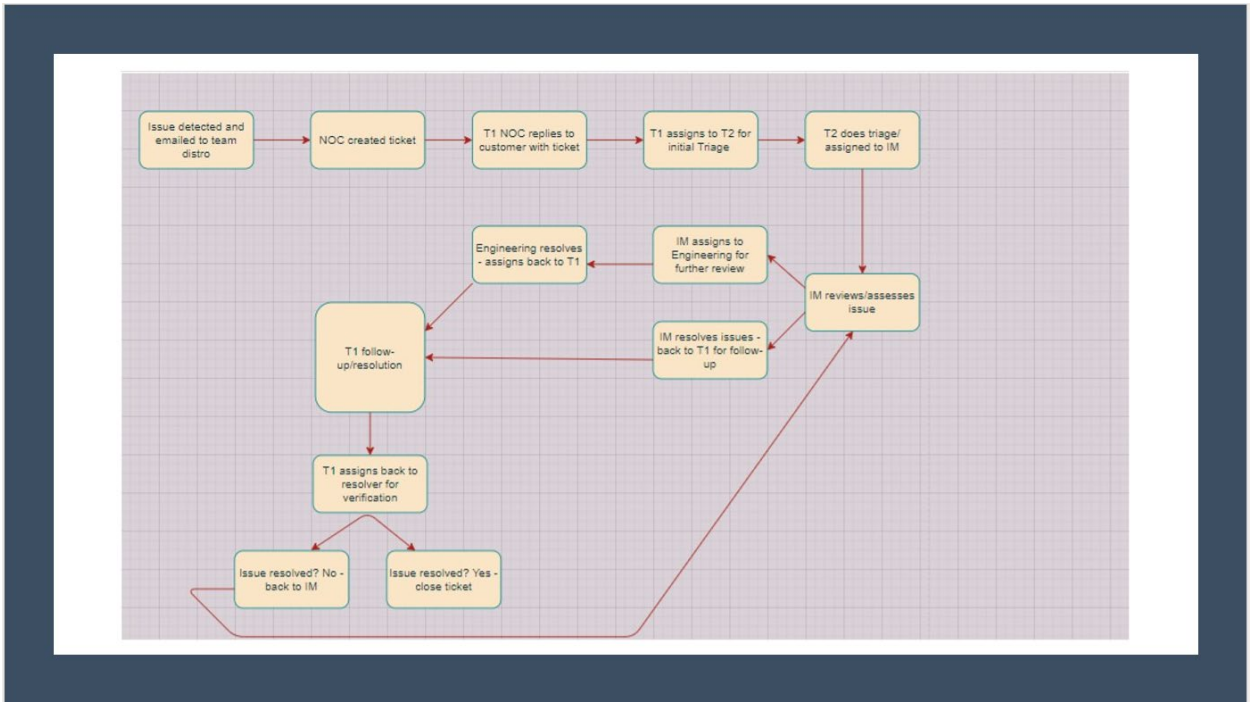


Figure 8- Pre-portal Workflow

Working with our ticketing tools team, we were able to provide requirements for a ticket portal that anyone with the organization could access. This allowed users to directly submit their issues and receive a ticket number at time of entry. We also allowed a user reporting an issue to escalate to the on-call resource, which is especially important after hours or on weekends. ***Note, we did include a disclaimer to "use with discretion," as it will generate a page to the on-call resource's phone.*

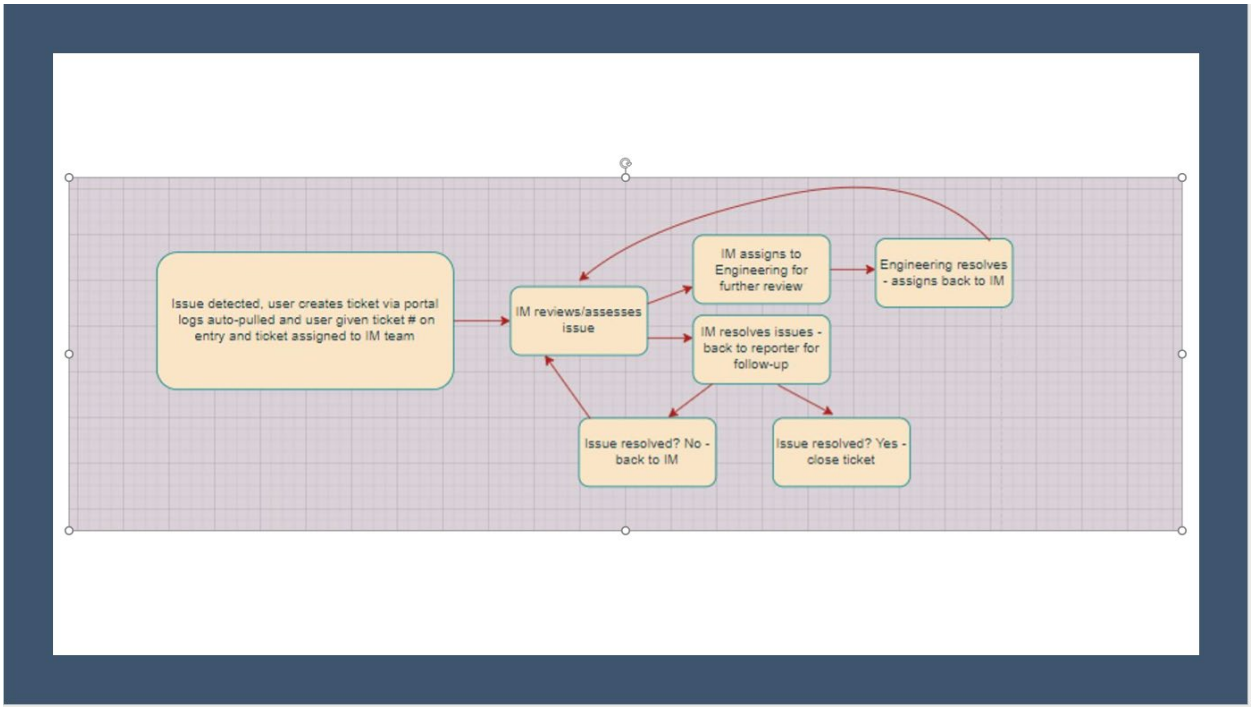

Figure 9- Post-portal Workflow

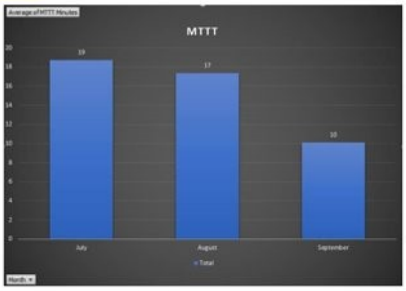
The portal allowed us to simplify and streamline the ticket process, lessen the number of reassignments, and reduce the MTTM. In addition, the portal and auto-assignment work, we were able to automate pulling device logs when needed (typically a single-customer reported issue). By automating the log pulls, we were able to demonstrate a fair reduction in MTTT and MTTM. We also saved upwards of 2,000 hours (about 2.5 months) of manual labor, and automated most of the Tier 2 work, increasing the opportunity for cost savings.

Mean Time to Triage:
We see an approximate 8-minute decrease for the month of September when comparing to July & August.



Mean Time to Mitigate:
We see an approximate 30-minute decrease for the month of September when comparing to July & August.

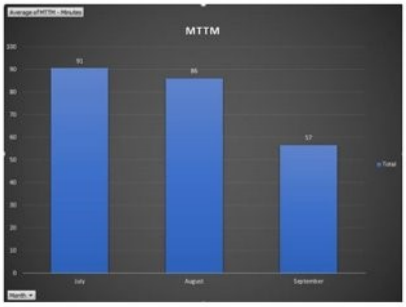


Figure 10 - Mean Time Graphs

Previously, we mentioned tool-sharing and being able to get fixes out to Tier 1 care agents, and eventually directly into our consumers' hands, via an app. When we subsequently analyzed volume, we started seeing trends. What we noticed was that two API (Application Program Interface) functions accounted for most actions taken to fix a customer's escalated issue. This required them to call Tier 1 support, which then escalated to the advanced team, which created a ticket for us to email to the Tier 2 team. That is a long way around, when the task is to quickly escalate!

We worked with our development engineering team to safeguard the API and make it accessible to our Production Support team. We validated the functionality of the tool into which these APIs were integrated. Once we signed off on it, we opened it up to the advanced care team. This prevented escalations to us and our engineering partners, but still created an escalation to the advanced care team. It saved mitigation time for the customer -- and we knew we could do better. Comcast uses ITGs (Interactive Troubleshooting Guides) for our Tier 1 agents, so we worked to get the correct LOQ (line of questioning) into the ITG, with a wrapper around the APIs so that Tier 1 agents could execute and resolve the customer's issue at point-of-contact, by clicking a link. This readily reduced the mean time to resolve as well as escalations – but what if we could help the customer and prevent the call altogether? By leveraging our existing technology and available customer-facing applications, we did just that. We made these functions available directly to the customer in the Xfinity App.

9. Conclusion

A careful review and analysis of your network, systems and applications helps identify areas of sameness, best practices, and resultant opportunities for process alignment and automation. When these opportunities are missed, it can slow the process of automation, potentially causing re-work. Categorizing your findings helps define your proof of concept and identify the low hanging fruit (the quick wins). We found it helpful to write out a problem statement, including an anticipated solution or expected result. From there, determinations can be made about what tools to leverage, to get from problem to solution, and to start defining the "How" of automation opportunities.

In reviewing the automation journey, we categorized opportunities into three "buckets." The first was the "low-hanging fruit" / quick wins, which in our case was the ticket auto assignment. The second was event correlation, which involved a comparatively medium level of effort. We had the foundation already available but needed to ensure that we had proper mappings and service flows in place before implementation. The third was the more difficult, longer-range automation plan of getting resolutions pushed out customer-facing tools, like our customer care app, Xfinity Assistant. This was a multi-phased approach that took a lot of coordination with various teams.

What drove our decisions was the result of extensive, targeted data analysis, which identified the redundant task-type work. If automation is on your to-do list, start by looking for repetition – what tasks are team members are being asked to perform over and over? This also helps to prioritize your automated efforts. By analyzing our email platform, for instance, we were able to determine that there were two main functions, or API calls, that were leveraged to resolve in the range of 90% of customer reported issues. This was a separate opportunity, of the windfall variety, that was identified while we were reviewing options for event correlation.

One consistent theme that emerged throughout all our automation efforts was that it must be measurable. We have the data to baseline where we started, and can continue to measure results to prove (and occasionally disprove) the value of the work being done. Are we seeing the benefits of this effort, as we anticipated? If yes, proceed. If no, re-evaluate: Either we are missing a key component, or this really does not have the ROI (return on investment) we originally envisioned. In which case, it may make sense to deprioritize this automation task and move to something that will have greater impact.

Keep in mind: Data can come from a lot of sources. It can also be a combination of different source types that can give you what you need to measure performance and results accurately. Sometimes, you'll find that you have this great idea, but no way to prove it because the data does not exist. That does not mean you throw away your idea! Reframe the question. Work to identify, define, and implement the right logging to build your data. It is likely a gap that needs to be addressed.

Last not least: Stay agile. Flexibility and adaptability should be the forefront of any effort. Remember to identify the big wins as well as the low-hanging fruit. Ensure that your data tells the story and paints your vision, which will help you to garner the support of your teams for buy-in. Because ultimately, talking about automation is great, and we can sing its praises -- but without stakeholder and customer buy-in, it is not going anywhere. It is extremely difficult to enact change. Most employees, team members and even family members are resistant to changing the way they do their daily tasks. By understanding other teams' processes and procedures, you can highlight the benefits they will see by implementing the

suggested methods. You will also find that they have critical processes that you may want to leverage into your playbook – which brings us back to pollinating best practices throughout the organization.

1. Introduction

Upstream Orthogonal Frequency Division Multiple Access (OFDMA) technology in DOCSIS 3.1 is starting to be rolled out in the field. Operators are beginning to test Upstream OFDMA channels in the lab and in the field and are discovering various intricacies in getting the upstream OFDMA to work robustly. Lower frequencies in the upstream spectrum can be noisy and making use of those portions of the spectrum tougher. Upstream RxMER looks very different than the Downstream RxMER, due to the noise funneling characteristics on the HFC plant, the additive nature of noise has a large impact at the CMTS upstream receiver.

As operators roll out OFDMA technology, they are starting to collect data on the performance of these OFDMA channels. This includes the US RxMER data, IUC usage hours, profile definitions etc. As a cable industry we are just starting to comprehend the OFDMA channel performance. Analyzing the US RxMER data and the IUC data is a powerful tool in understanding the performance of each of the node segments and the individual modems. This paper will discuss methods on how to analyze the upstream network data. It will discuss algorithms on how to logically extract the outlier modems and node segments. This paper will discuss methods for anomaly detection, historical behavior analysis, pattern recognition, classification and condition evaluation in the access network data. Combining the analysis of data along, with network topology and device location, it is possible to create a general view of the plant condition and isolate problem sources. The paper will implement methods on how to assign a health score to modems and network segments in an effort to triage which are the top priority nodes that operators need to work on. All this will enable operators to reduce upstream OFDMA troubleshooting and problem resolution time, reducing operational costs and enhancing network reliability.

2. Upstream Background

DOCSIS® 3.1 is now largely deployed in the field. This has primarily focused on a very successful roll out of the Downstream Orthogonal Frequency Division Multiplexing (OFDM) technology. Operators now are beginning to test Upstream Orthogonal Frequency Division Multiple Access (OFDMA) and are now deep into understanding the various intricacies in getting the US OFDMA to perform robustly. The first step is for an operator to get a good stable initial configuration of the OFDMA channel (location channel parameters, IUC definitions etc.). Once an operator can get CMs operating reliably on the OFDMA upstream channel, the operator can then start thinking about how to improve the reliability and efficiency of that upstream channel.

In the upstream direction, the cable system may have a 5-42 MHz, 5-65 MHz (Europe), 5-85 MHz, or 5-204 MHz pass bands. While a DOCSIS 3.1 CM supports a minimum of two independently configurable OFDMA upstream channels with each occupying a spectrum of up to 95 MHz, the challenge has been to find appropriate space in the spectrum to locate these channels. Operators who are running a 5-42 MHz plant are trialing out OFDMA in the space available after the spectrum used by 3 or 4 SC-QAM channels. Operators with mid split (5-85) plants usually have up to 10 SC-QAM channels and are making space for an OFDMA channel by using some of the spectrum just below 85 MHz and turning off a few SC-QAM channels. Operators in Europe with a 5-65 plant typically have 3 or 4 SC-QAM channels are using the remaining space an OFDMA channel, either the OFDMA channels go from 20-45 MHz or 45-65 MHz, depending on where the SC-QAM channels are.

The OFDMA upstream multicarrier system is composed of either 25 kHz or 50 kHz wide subcarriers. For a 95 MHz channel, this equals 3800 25 kHz spaced subcarriers or 1900 50 kHz spaced subcarriers. DOCSIS 3.1 Upstream transmission uses OFDMA frames. Each OFDMA frame is comprised of a configurable number of symbols (K = 6 to 36). Several transmitters may share the same OFDMA frame

by transmitting on allocated subcarriers of the OFDMA frame. The upstream spectrum is divided into groups of subcarriers called minislots. Minislots have dedicated subcarriers, all with the same modulation order ('bit loading'). OFDMA minislots are 400 kHz wide and have either 8 (50 kHz) or 16 (25kHz) subcarriers. The modulation order of a minislot, as well as the pilot pattern used may change between different transmission bursts and are determined by the profile definition.

2.1. Upstream Network Data

CMTS and CM support features and capabilities that ca be leveraged to enable measurement and reporting of network conditions. These Proactive Network Maintenance (PNM) features deliver metrics which operators can use to identify undesired impacts such as plant equipment and cable faults, interference from other systems and ingress noise. With this information operators can make modifications necessary to improve conditions and monitor network trends to detect when network improvements are needed.

The OFDMA technology comes with a few different PNM measurements: Upstream Capture for Active and Quiet Probe, Upstream Triggered Spectrum Analysis, Upstream FEC Statistics, Upstream RxMER Per Subcarrier, Upstream Equalizer Coefficients, Upstream Impulse Noise Statistics, Upstream Histogram, Upstream Channel Power. These eight features are detailed in the [PHYv3.1] specification. The purpose of these upstream PNM functions is to analyze the upstream in various ways. These goals include measuring the plant response, understanding the underlying noise floor, having a wideband spectrum analyzer function on the CMTS, gathering statistics of burst/impulse noise occurring in a selected band, understand the linear response of the upstream cable plant, monitoring upstream link quality via FEC and related statistics, understanding the nonlinear effects in the channel such as amplifier compression and laser clipping, providing an estimate of the total received power in a channel and becoming aware of the upstream receive modulation error ratio (RxMER) for each subcarrier.

2.1.1. US RxMER

A CMTS uses upstream probes for ranging-related functions such as determining transmit pre-equalizer coefficients. A CMTS also uses the upstream probe to take an RxMER (received modulation error ratio) measurement. The CMTS grants probe opportunities to a CM in a P-MAP message with the "MER" bit set. When the CMTS receives the probe transmissions from the CM corresponding to such a grant, it performs the RxMER measurement and uses the results in its decision making. It also populates the corresponding MIB object or can upload a RxMER per subcarrier file via TFTP, for the operator's information. Some CMTS implementations also measured the RxMER in an alternate fashion, they are using the actual data transmission bursts from a CM to do a measurement.

2.1.2. Other US PNM data

The other Upstream PNM features (Upstream Capture for Active and Quiet Probe, Upstream Triggered Spectrum Analysis, Upstream FEC Statistics, Upstream Equalizer Coefficients, Upstream Impulse Noise Statistics, Upstream Histogram, Upstream Channel Power) are in various stages of maturity on different CMTS platforms.

As of the writing of this paper, we have had access to a lot of Upstream RxMER data, but have not been able to gather a meaningful set of samples from the field for any of the other PNM data types. In the future, as we get access to more data samples of those types from CMTS in the field, we can start analyzing those (for a future paper). For this paper, we focus on the US RxMER data that we have and start building methods and tools and ways to visualize and analyze this data set and figure out what kinds of upstream evaluation we can perform.

3. Upstream Observations

3.1. Introduction to Upstream RxMER Data

The upstream RxMER data is a PNM metric measured by the CMTS to report receive modulation error ratio on a per subcarrier basis. Similar to the downstream RxMER data, the upstream RxMER data can be helpful in identifying upstream impairments over frequency as well as performance fluctuations over time. The following is an upstream RxMER capture measured from 23.9 MHz to 51.4 MHz. Typically, noise floor is higher at lower frequencies. Although Pre-Equalization can help compensate the tilt, we still observe a slight inclination in the data from the lower frequencies to the higher frequencies.

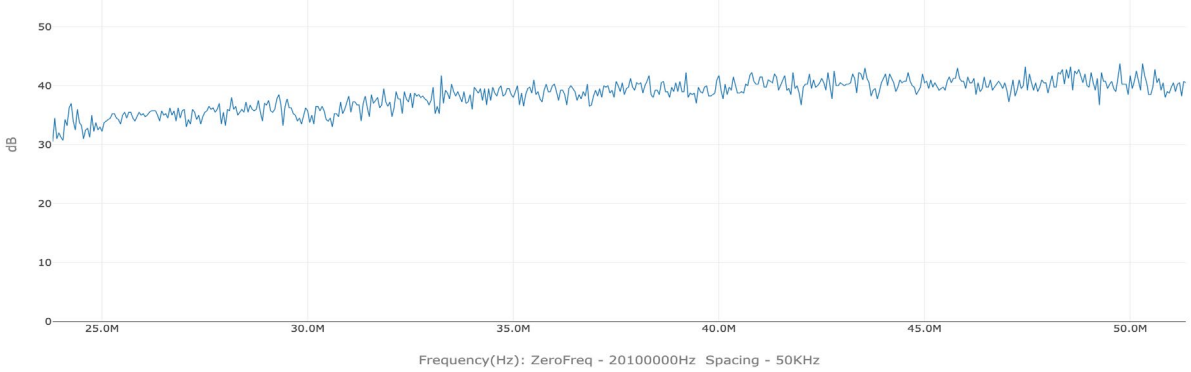

Figure 1 – An US RxMER sample on a OFDMA channel from Single CM

When more samples are captured over time and are displayed in one plot, we can observe the changes of RxMER values over time. By capturing more upstream RxMER samples and analyzing the over-time features of the data, there is opportunity that intermittent impairments and field events can be observed and categorized. In this paper, the discussion is focused an upstream RxMER dataset that was collected from multiple OFDMA interfaces during a 2-week timeframe.

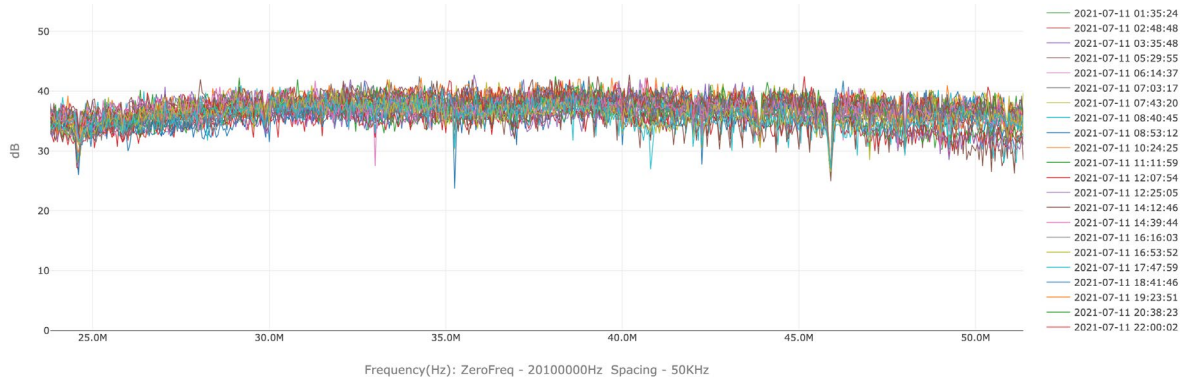

Figure 2 – Multiple US RxMER samples, OFDMA channel, Single CM (lab)

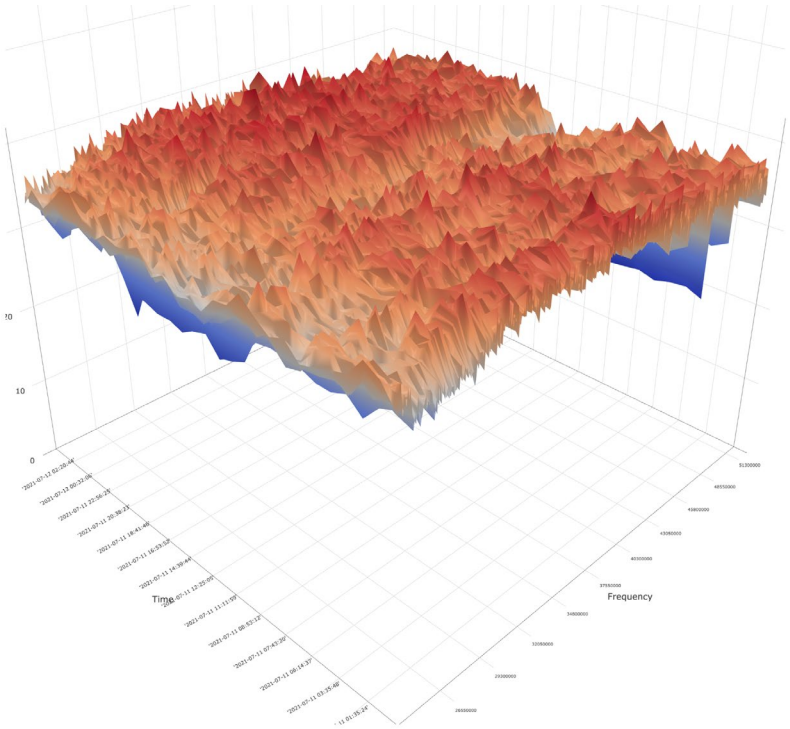

Figure 3 – 3D view of US RxMER samples, time versus frequency

3.2. Variations and Impairments

The following figure shows upstream OFDMA RxMER samples collected from a CMTS in the field. A lot of variation in RxMER values is observed in this visualization. The RxMER values of unused/inactive subcarriers are reported by the CMTS as 0xFF (63.75 dB), which are the spikes seen in the graph. The maximum difference between the RxMER values on a same subcarrier can be as much as 20 dB, which indicates that the condition of the upstream OFDMA channel is constantly changing. Ingress noise can also be observed on captured samples.

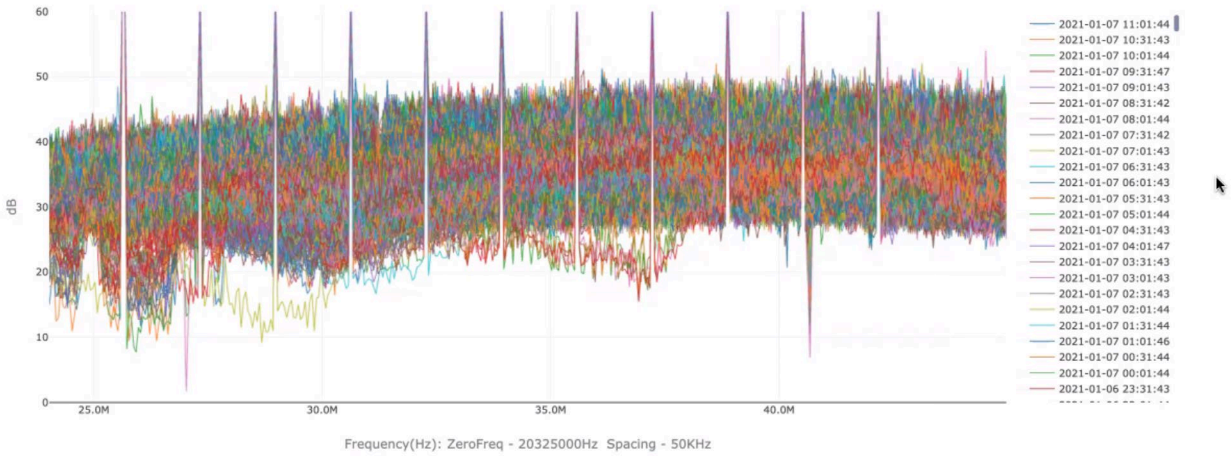

Figure 4 – Multiple US RxMER samples, OFDMA channel, Single CM (field)

In the RxMER captures collected from a different CM, we observe less variation in RxMER values. We also observe standing waves across the spectrum.

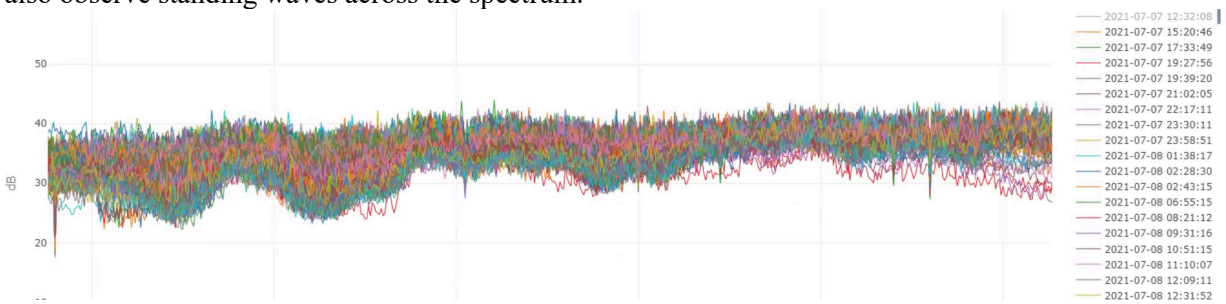

Figure 5 – Multiple US RxMER samples, OFDMA channel, Single CM (field)

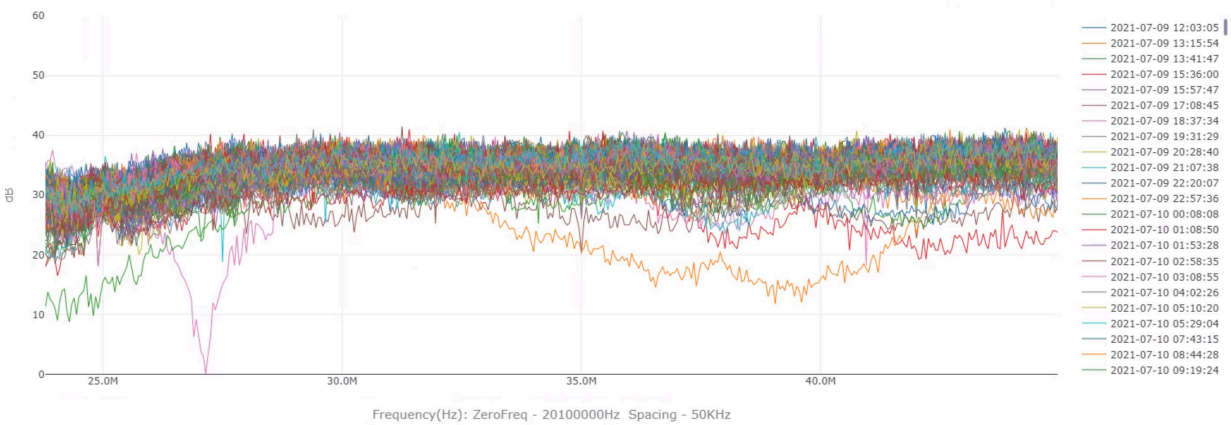
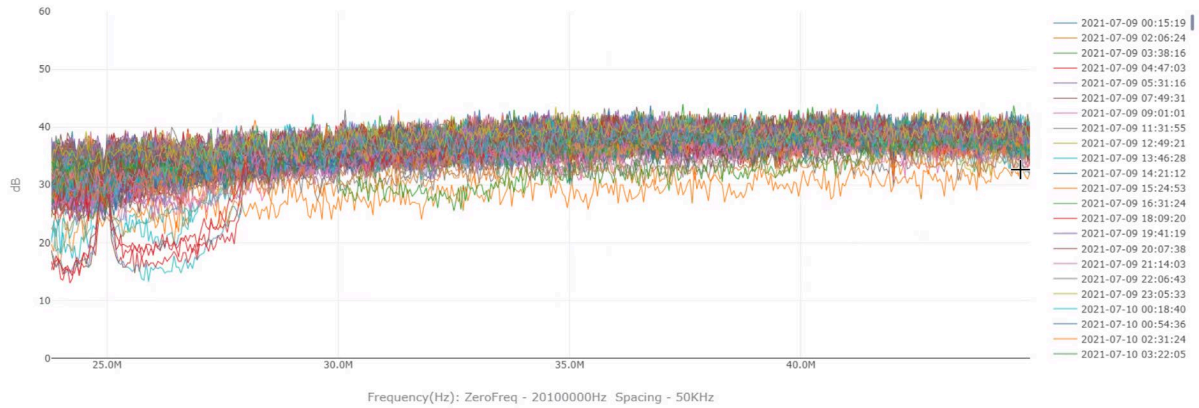
The following RxMER captures show relatively tight value distribution but have many outliers throughout the capturing period.





Based on the observations of such variations, we develop statistical analysis methods to further extract information from the upstream RxMER data, which are discussed in the following section.

4. Statistical Analysis

When assuming that the RxMER values captured from each subcarrier are following normal distribution while the impairments are absent, it is helpful to use percentiles, variance, skewness, and kurtosis calculated from the RxMER values over time to summarize the distributions and provide insights into the behavior of the impairments. Each of the statistical calculations is discussed in the following sections. We also discuss initial use cases of the statistical metrics, observations of RxMER time series on different frequency ranges, and why the data suggests that PMA is necessary for the robustness of the upstream OFDMA deployment.

4.1. Percentiles

In order to analyze the upstream OFDMA RxMER values captured over time for each CM, we calculate different percentile values from each of the subcarrier's historical RxMER values. We calculate 1%, 2%, 5%, 10%, 15%, 20%, and 50% values from all the RxMER values captured on each subcarrier and include the minimum and maximum values to illustrate the range and distribution densities. By calculating the delta values between the percentile traces, one can automatically identify frequency ranges that may need attention as well as intermittent impairments on the data captured over time, as highlighted in the following figures.

For example, when we calculate the deltas between the minimum value, 1%, 5%, 15%, 50%, and the maximum value, and observe large differences between 1% and 5% traces while seeing smaller delta values between the other percentile traces, such as the condition indicated in the third highlight in the following figures, an intermittent impairment can be identified. On the other hand, if the percentile values are evenly distributed but the averaged percentile delta values are high, such as the condition shown in the first highlight, a persistent impairment can be identified.

Figure 6 – RxMER over time with persistent impairments and intermittent impairments

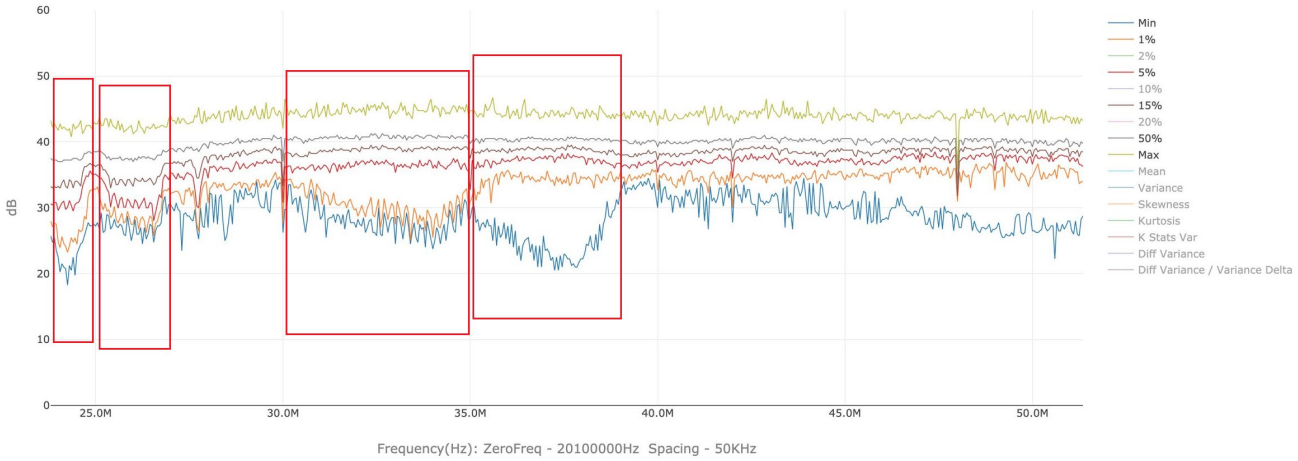


Figure 7 – Percentiles and min, max values calculated for each subcarrier

4.2. Variance over Time

It is well known that variance is a statistical measurement of the spread between numbers in a dataset. In the application we developed for this research, other than calculating the percentiles we calculate the variances of the RxMER values captured from each subcarrier and visualize the variance calculation results over frequency.

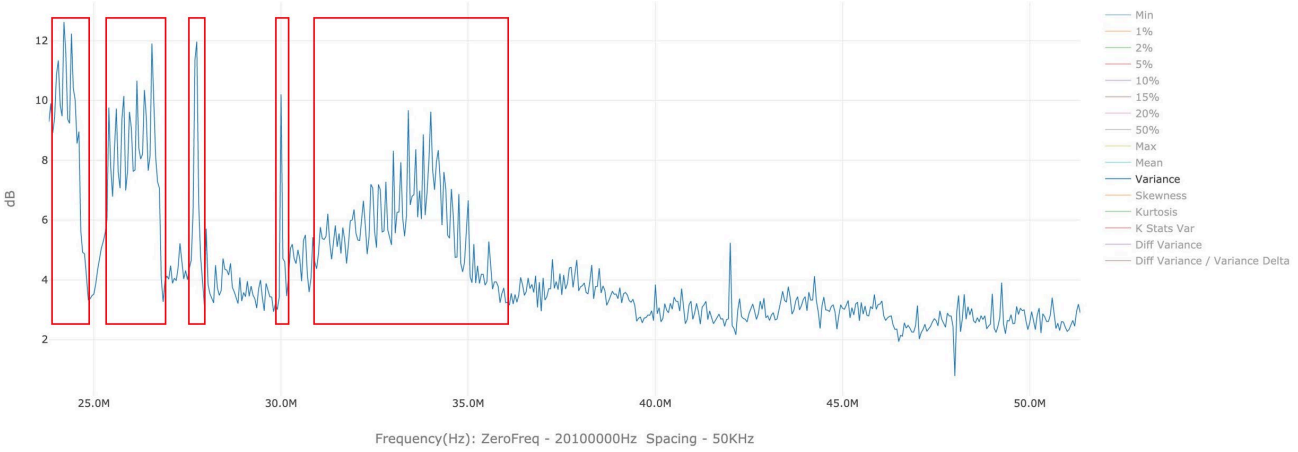

Figure 8 – Variance values calculated for each subcarrier

Relatively high variance can indicate that the RxMER values captured from the subcarriers are unstable over time. However, variance by itself would not provide sufficient information to differentiate persistent impairments and intermittent impairments/events, as both can cause instability of subcarriers' RxMER values which leads to high variance values. By defining thresholds for the variance, it can be used as the first step of selecting unstable subcarriers based on their upstream RxMER values captured over time. And in order to extract sufficient information for categorizing the impairments observed over time at

high-level, such as identifying persistent impairments versus intermittent impairments, we introduce skewness and kurtosis calculations of the RxMER values from each subcarrier.

4.3. Skewness over Time

Skewness is a measure of the asymmetry of the probability distribution. The value of skewness can be positive, zero, or negative. Positive skewness indicates that there is more weight in the right tail of the distribution, whereas negative skewness indicates the opposite.

Figure 9 – A CM with persistent impairments and intermittent impairments

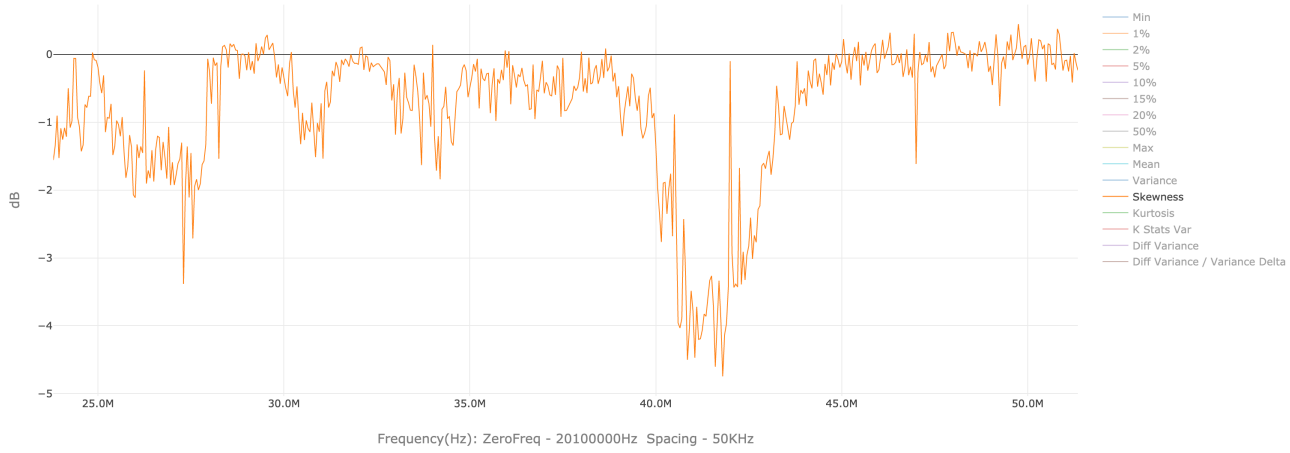

Figure 10 – Skewness calculated for each subcarrier

Considering that the distribution of a subcarrier's RxMER values over time should be approximately symmetrical when no impairment is present or only persistent impairments present, large absolute skewness values (especially when the skewness is negative) can be used to identify subcarriers affected by intermittent impairments/events.

Combining skewness with variance, it can be inferred that when both of the variance value and the absolute skewness value are large, the subcarrier is primarily being affected by intermittent impairments;

and when the variance value is large and the skewness value is close to zero, the subcarrier is primarily being affected by persistent impairments.

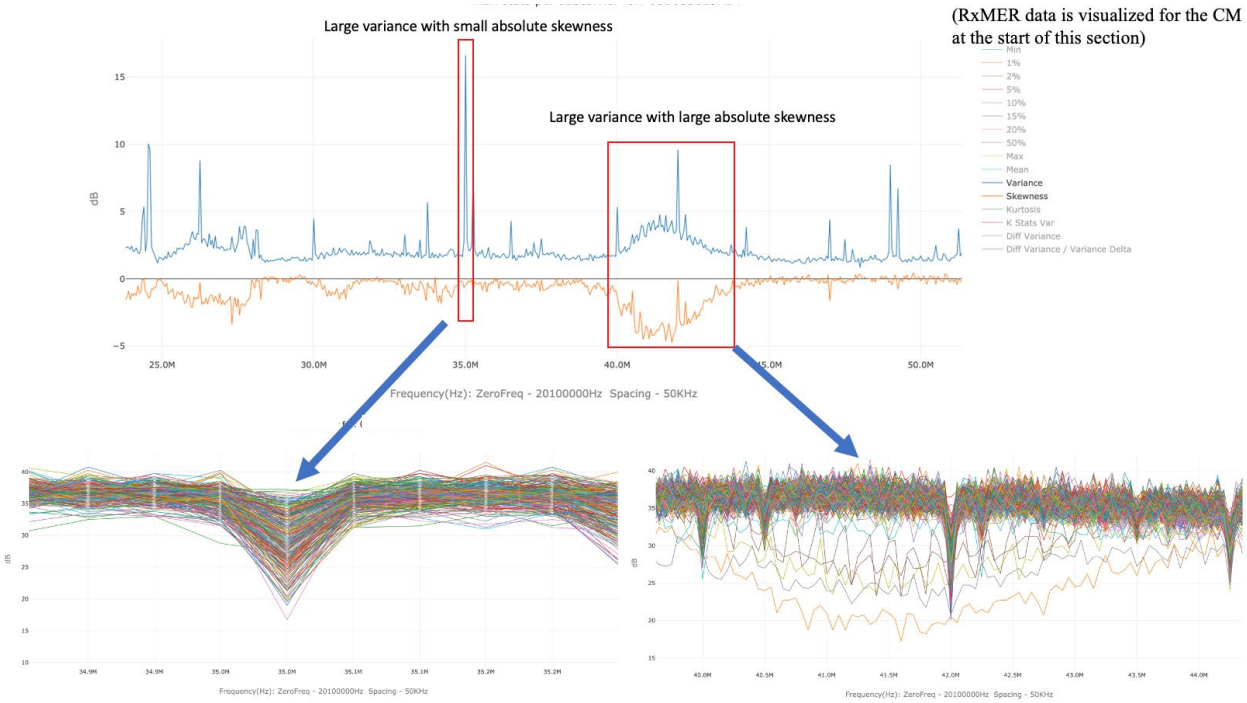

Figure 11 – Persistent and Intermittent Issues identified by variance & skewness

The bottom of Figure 11 shows that a persistent issue presents and is identified by using the combination of variance and skewness at 35 MHz of the spectrum. The variance of this subcarrier's RxMER values is large, however, the skewness is close to zero based on the calculation and the observation that the RxMER values are evenly distributed under the impairment.

Another impairment between 40 MHz and 44 MHz is identified as an intermittent issue since the variance values and absolute skewness values are large. The behavior of both of the identified impairments can be further confirmed when we visually check from the bottom of the 3-dimensional graph (Figure 12) generated from the upstream RxMER samples captured over time.

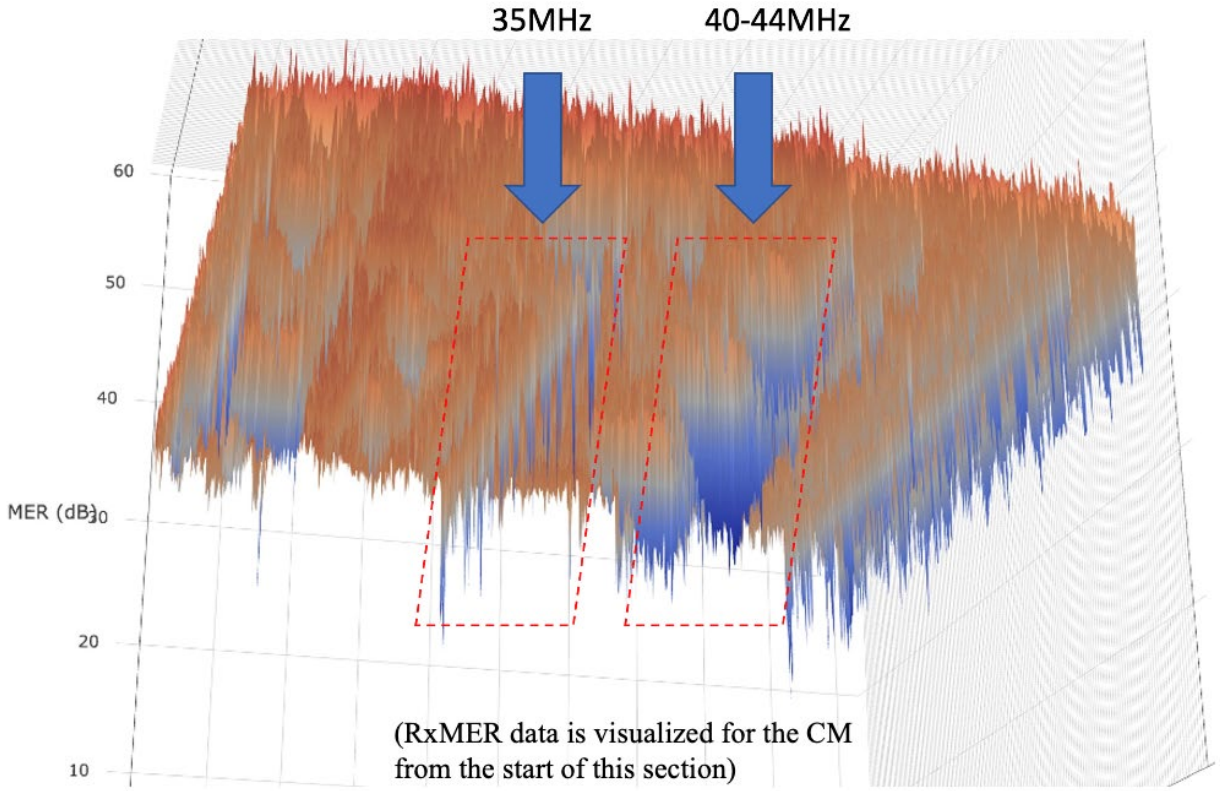

Figure 12 –3D graph of the RxMER samples captured over time

At 35 MHz, the impairment is persistent. It constantly affects the RxMER values and is almost captured by every RxMER sample. On the other hand, the impairment between 40 MHz and 44 MHz can be considered intermittent since it only presents occasionally in the 300 RxMER samples visualized in the 3D graph.

4.4. Kurtosis over Time

Kurtosis is a measure of the "tailedness" of the probability distribution. Higher kurtosis corresponds to greater extremity of deviations, which can be correlated with variance and skewness to further confirm if an identified impairment/event captured by the RxMER data is persistent or intermittent.
In our application, we calculate excess kurtosis (the value is 0 when the distribution is normal) of RxMER values over time for each subcarrier. From the observations, the combination of large absolute skewness values and large kurtosis values emphasizes the intermittent behavior of an impairment. This can be a promising technique to process a large number of RxMER samples captured from each CM over time, remove the noise, and filter out information that can be used for potential automatic anomaly detection in OFDMA, as demonstrated in Figure 13.

(RxMER data is visualized for the CM at the start of this section)

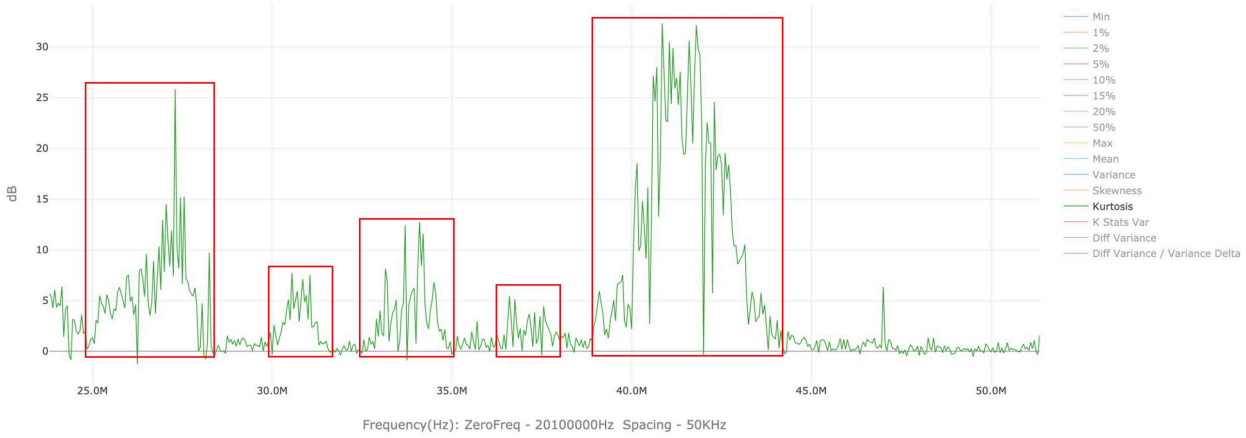

Figure 13 – Intermittent issues identified by kurtosis

4.5. RxMER Time Series on Different Frequency Ranges

Another way to analyze RxMER data is to view the variations of small frequency range (practically a multiple of the subcarrier size). Here we choose a unit of 1 MHz, which for the 50 kHz spacing is 20 subcarriers. The idea is to take an average of the RxMER for those twenty subcarriers and then plot that average value as it changes over time. We do this for every 1 MHz of the spectrum, and then certain patterns become more apparent. In order to observe RxMER value changes over time sequentially, we calculate the average RxMER values of each 1 MHz frequency within the channel and visualize the averaged RxMER values with the sample capture timestamps (as shown in Figure 14).This visualization method provides insights into the unstable nature of the upstream and helps us identify issues that can be potentially identified by algorithms we may develop.

Figure 14 – Averaged RxMER time series for one CM

One of the patterns (see Figure 15) we observed is periodical changes across the whole channel over the course of the day, and these varying RxMER patterns repeat every day. The variation is significant, anywhere from 5 to 10 dB.

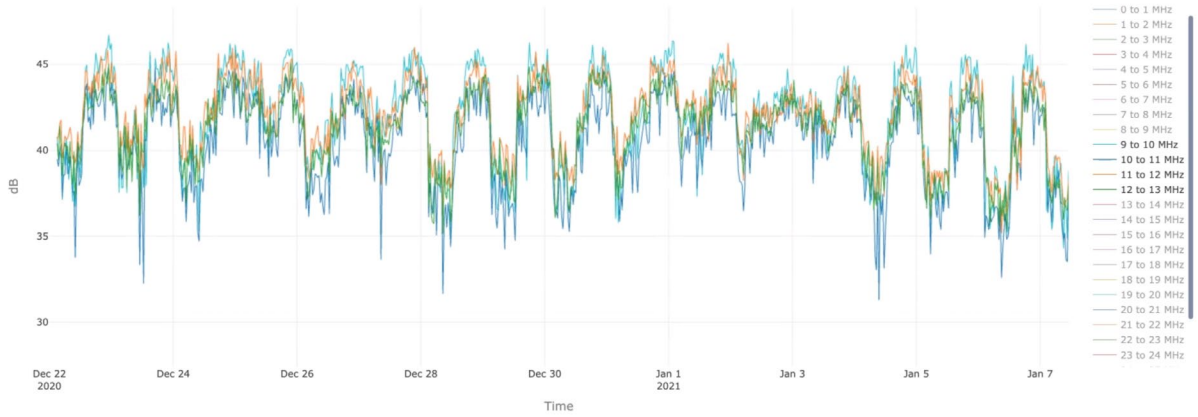

Figure 15 – Recurring daily variation in RxMER

In another example, (see Figure 16), an intermittent issue happened on July 5th can be identified between 11 MHz and 15 MHz of the OFDM channel (34.9 MHz – 38.9 MHz), where there is a sudden drop in the average RxMER values by about 18 dB.

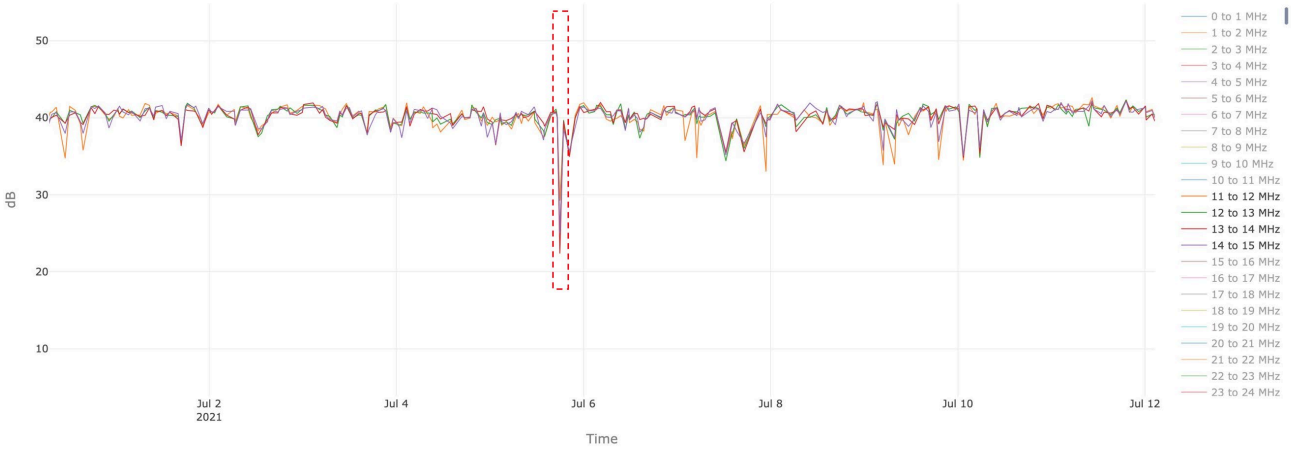

Figure 16 – Intermittent issue observed on RxMER time series

We can then target the problematic RxMER sample using the timestamp, as shown in the top half of Figure 17. Comparing the RxMER sample that has issues (the yellow trace) with a clean sample captured on the same day (the red trace), it indicates that an intermittent issue happened and significantly affected the result of the RxMER measurement.

In addition, because of noise funneling in the upstream, such an issue may also be captured by the measurement of upstream RxMER on a different CM around the same time, as shown in the bottom half of Figure 17.

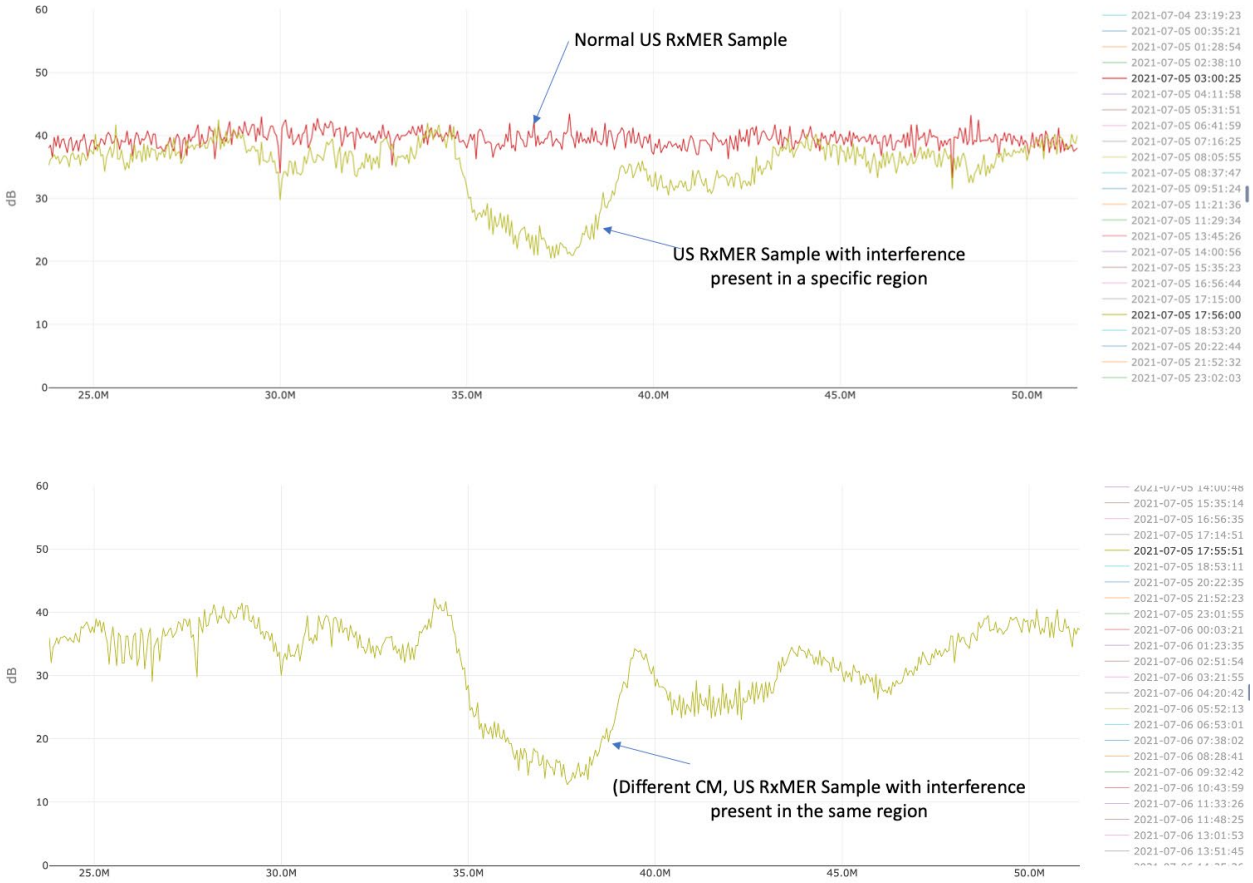

Figure 17 – A problematic frequency region on multiple CMs

To provide another example of such intermittent issues being highlighted by RxMER time series, as shown in the top of Figure 18, a significant event is identified using the data collected from a different CM where all subcarriers had a 30 dB drop in their RxMER values. This outlier sample is as shown in the bottom half of Figure 17. The cause of this outlier sample is under investigation, this could be a CMTS measurement bug or it could be the nature of the plant noise manifesting itself as a low RxMER.

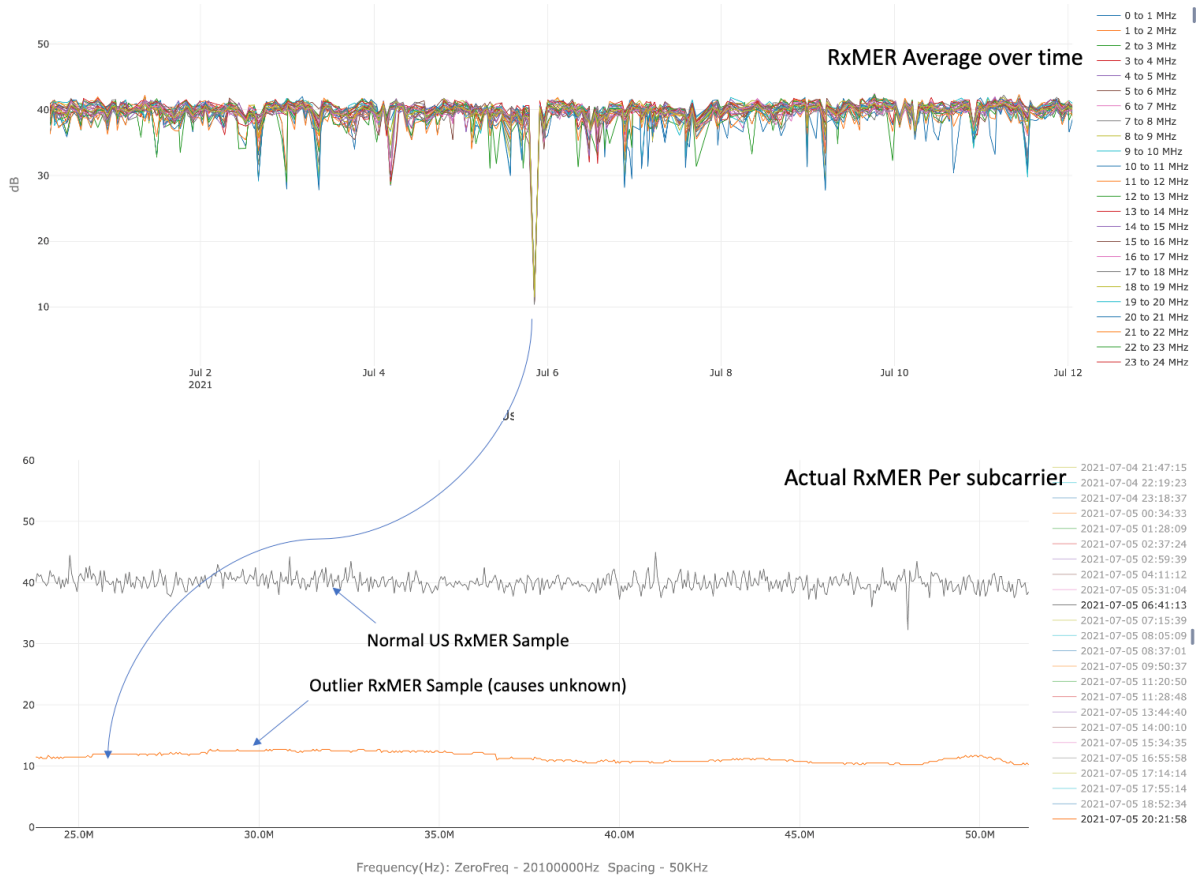

Figure 18 – A different intermittent issue observed on RxMER time series

In another example, one of the observations we made were sudden drops in average RxMER across the whole channel. For example, in Figure 19, we can see on Dec 27th the RxMER for the CM drops down by 10 dB, and then a few days later goes higher and fluctuates between two or three levels.

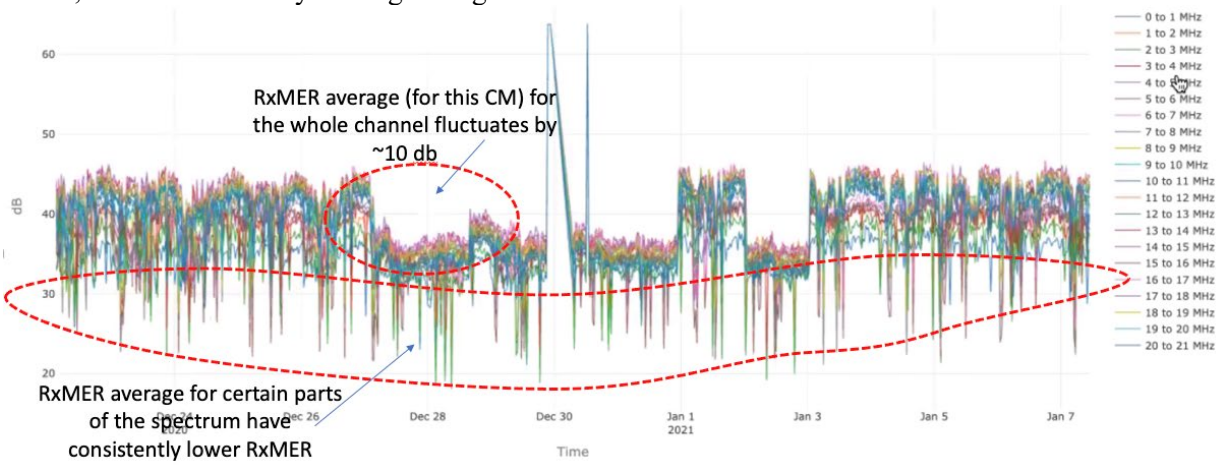

Figure 19 – RxMER Variation across time.

By using the average RxMER time series data, intermittent issues (both unknown issues and repetitive issues) can be identified with low computational cost. For the goals of proactive network maintenance (PNM), such identified issues can be characterized and categorized for the operators to be aware of and potentially reduce maintenance time and cost. In addition, when the root causes of the issues are located and isolated, the features of these issues can be fed into advanced models such as machine learning based classifiers for automatic anomaly detection and root cause inference.

4.6. Clustering Analysis on Statistical Measures

In order to analyze the features extracted from the upstream RxMER data collected over time using variance, absolute skewness, and kurtosis, and research how the impairments can be automatically isolated and categorized, we first calculate the statistics for all of the subcarriers of CMs on multiple OFDMA channels, and then generate a 3-dimensional graph to show if the statistics of the subcarriers' RxMER data are naturally clustered in 3D space.

As shown in Figure 20, there are two main clusters in the 3D graph, one of which has relatively large variance values and small absolute skewness and kurtosis values, whereas another cluster has small values in variance but relatively large values in both absolute skewness and kurtosis.

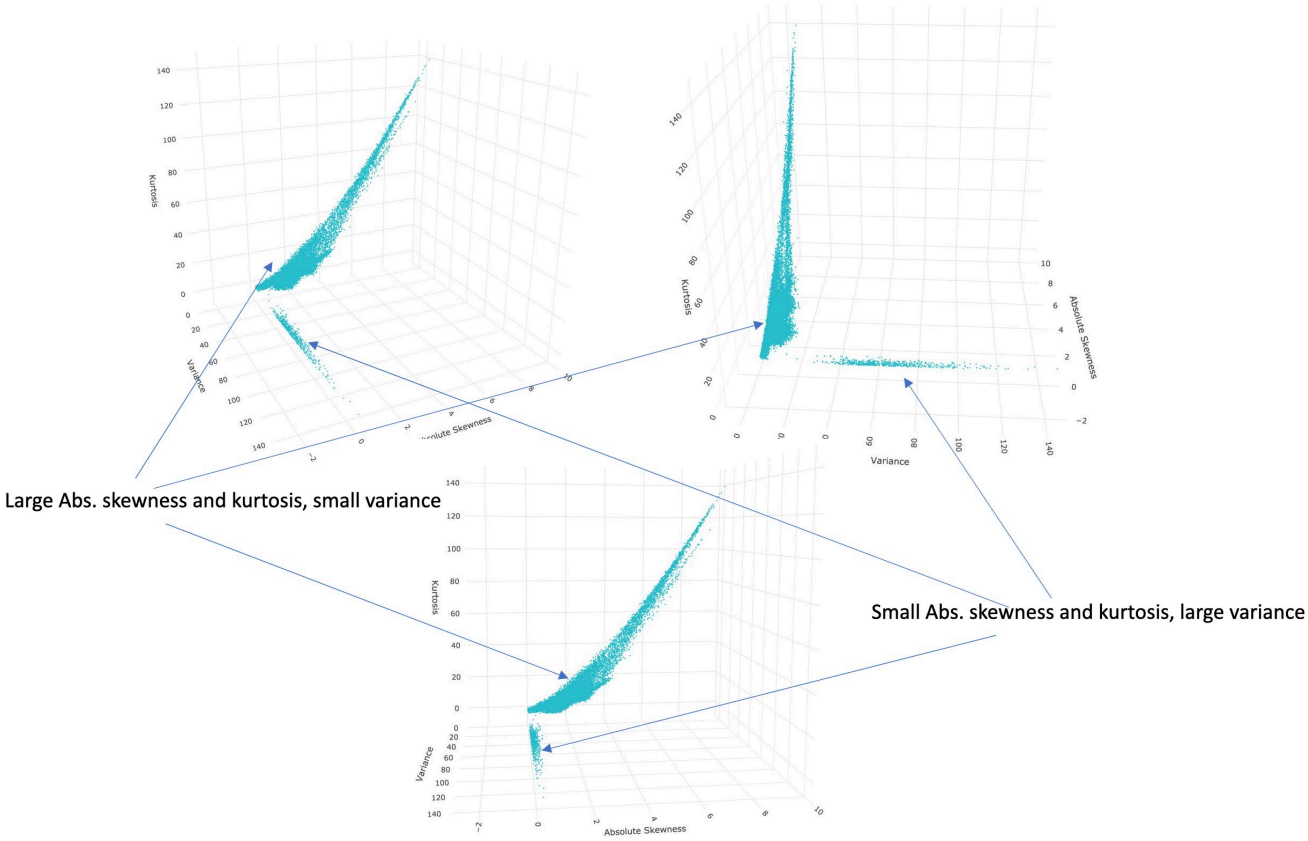

Figure 20 – 3D graph of variance, absolute skewness and kurtosis values

It can also be inferred that the cluster that shows significance in absolute skewness and kurtosis suggests positive relationship between the two statistics. In other words, large kurtosis and absolute skewness both can be used as criteria to identify intermittent impairments on the OFDMA channel, and they potentially reinforce each other.

In addition, this analysis helps identify thresholds that can be applied to the statistics in creating a threshold-based method to automatically detect subcarriers under impairment. Also, centroids can be calculated for these clusters to categorize the impairment types.

More research is ongoing around understanding the impairment types in upstream OFDMA channels. Calculating the statistics of upstream RxMER values over time can be a promising feature extraction method for machine learning models. For example, a 1-dimensional convolutional neural network can use the normalized variance, skewness, and kurtosis traces over frequency as input taken from 3 different channels. A regression model (see [ANOMALY DETECTOR ICPHM 2020]) can be developed to automatically localize and classify impairments observed by RxMER data in upstream OFDMA.

4.7. Time Clustering – PMA Use Case

By analyzing the upstream RxMER data collected from the field, an important note can be made that the condition of the OFDMA channel can vary significantly from moment to moment, which can lead to frequent IUC shifting if the CMTS is enabled to automatically adjust upstream IUCs for CMs based on FEC error rates and RxMER measurement results. To automatically create a set of IUCs that can provide optimal operational robustness and channel capacity, upstream PMA can be adopted. The upstream PMA algorithm uses time clustering to group all upstream RxMER samples collected from all CMs over time in order to automatically design optimal IUCs, which has been proven to be beneficial in field trials.

There are 2 algorithms that are implemented in upstream PMA which we call algorithm 2b and 2c, see [US PMA SCTE 2020]. Algorithm 2b is more aggressive in capacity improvements compared to algorithm 2c, whereas algorithm 2c designs more robust IUCs. To provide examples, we calculate and visualize the time each CM spends on each IUC to provide insights on how the CMs may utilize the IUCs based on simulated CMTS criteria. As shown in Figure 21, IUCs created by algorithm 2b are used by the CMs evenly in time, as the IUCs are designed to prioritize channel capacity gains. In Figure 22, CMs use IUC 5 and IUC 6 primarily, as the bit loadings of the IUCs are lower to ensure robustness and fewer IUC shifts.

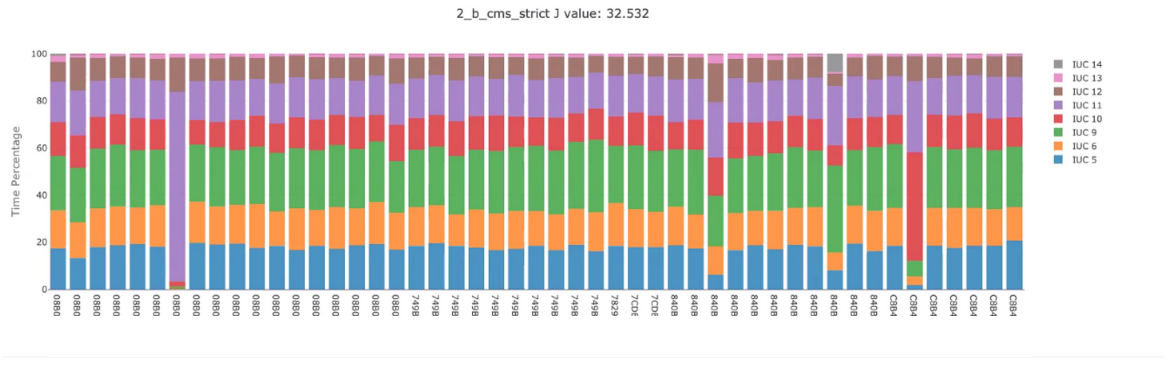

Figure 21 – IUC usage time distribution per CM (method 2B)

Figure 22 – IUC usage time distribution per CM (method 2C)

5. Data Analysis

We have observed some interesting patterns in the OFDMA channel data collected by the CMTS on modems in the field. These include "outage" patterns on a particular modem on a particular OFDMA channel, or invalid RxMER values for a CM across the channel etc. To categorize the issues in data reporting, we label them as "measurement discontinuities".

5.1. US RxMER Measurement Discontinuities

The first pattern that we see is that some modems have no RxMER entries for large parts of the data collection timeframe. As an example, in the figure below, during a data collection period of two weeks, we see that for a period of four days the modem does not respond and so the CMTS has no RxMER samples for that modem. This may be caused by but true outage or an issue at the cable modem or it could also be that the user just turned the cable modem off. Some data analysis would need to be done to correlate the outage with say data traffic on the modem and tease out the root cause of this outage. A second issue that we observe is when the CMTS reports value of 0xFF for all the subcarriers off that modem. Based on some discussions with the operator on the status we believe that this condition is when the CM is in partial service on that OFDMA channel but is maintaining data connectivity with the CMTS on the other channels.

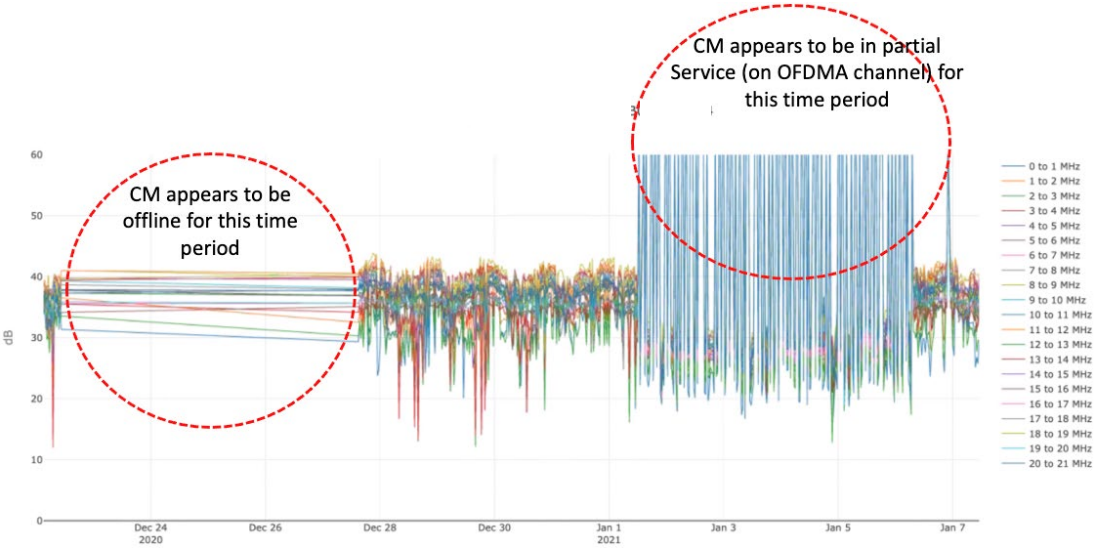

Figure 23 – One CM offline or in partial service

5.1.1. CM Outage Issues

Based on examples we saw in the previous section we know that multiple modems have outages at different points in time. This leads us to the next step of analysis by aggregating all such outage data from modems on the same node. The idea is to observe each of the individual CM outages on the node and try to correlate them over time to identify any meaningful events on the network.

Here we aggregated all the offline outage events (i.e., no RxMER samples) from the modems and are plotting them as a bar graph over time. Given that the data collection frequency was every hour we consider each gap in the data set as one event for that one modem. We calculate the number of such outage events and plot them on the graph below as an aggregate of all modems in the service group. The graph below shows that between Dec 24th and 28th there were many hour-intervals where up to 13 to15 modems in the service group were unable to respond to the RxMER request and work offline during that interval

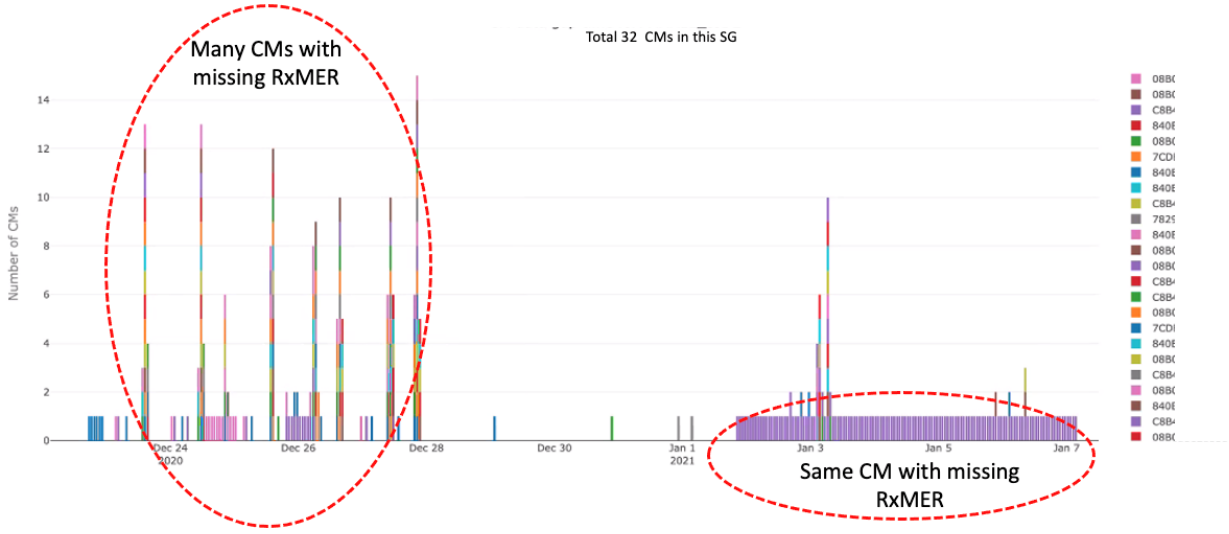

Figure 24 – Num of CMs Missing Data Samples across SG

We also looked at the amount of time each modem was missing data and plotted a histogram of the outages. The graph below shows the number of events which lasted from ~50 minutes to ~3 hours.

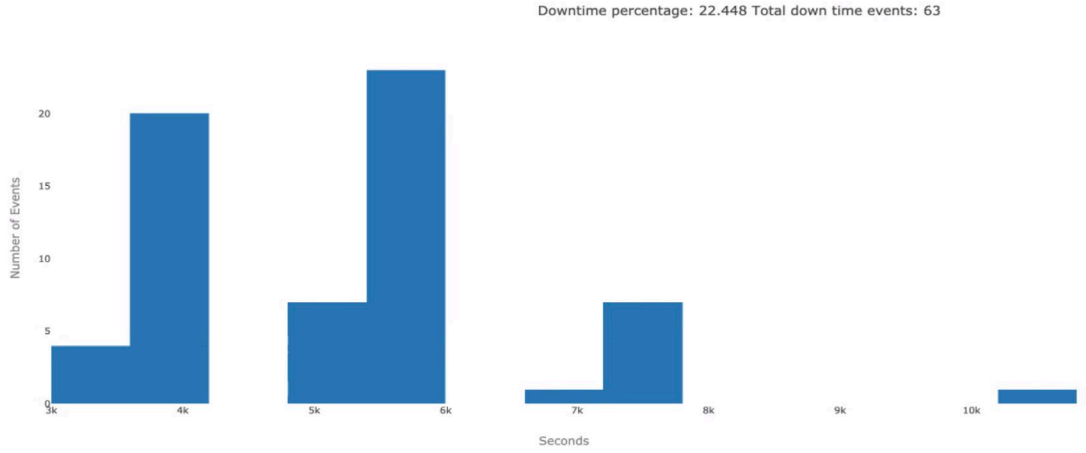

Figure 25 – Characterizing outage times

5.1.2. CM Invalid RxMER

The second type of measurement discontinuity are the events when the CMTS returns all 0xFF values (i.e., invalid samples) for US RxMER from the modems. Any collection interval which has a US RxMER file but with the data set to all 0xFFs counts as one event for that one modem. We calculate the number of such outage events and plot them on the graph below as an aggregate of all modems in the service group. The graph below shows that between Jan 1st and Jan 7th, there were many hour-intervals a few different modems (different colors for the actual CM MAC address), up to 2 at a time, were unable to respond to the CMTS request appropriately to get valid RxMER measurements. In particular two CMs, in green and gray looked to be struggling during that week.

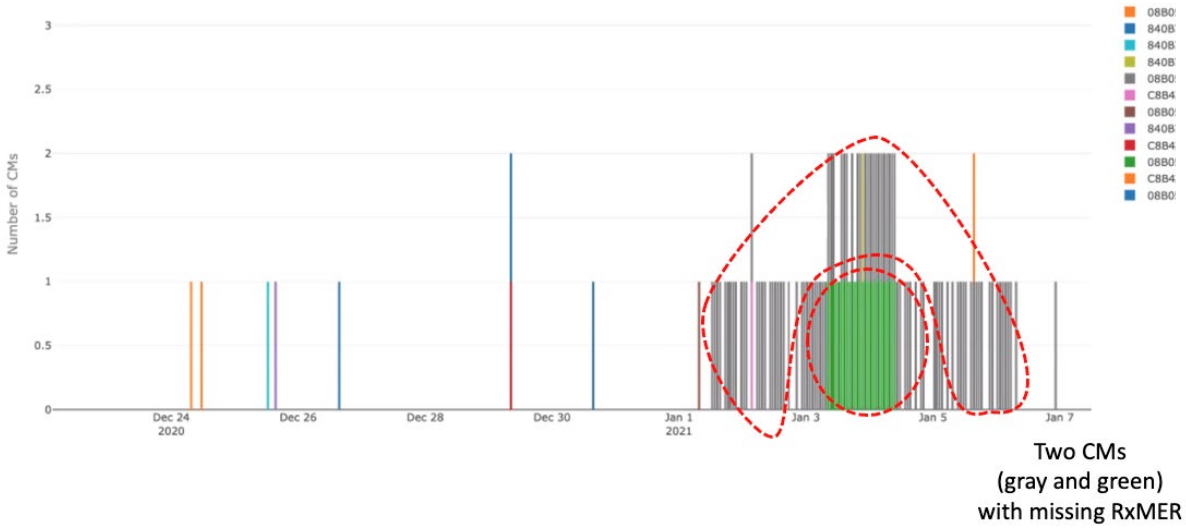

Figure 26 – Num of CMs offline across the whole SG (FF)

5.2. Health Score

Operators have identified a need to develop a set of metrics from the network which reflect how they affect the customer's network connection (speed, reliability, latency). Operators want to identify which factors have an impact on the service. Any network health metric needs to be ultimately linked to the customer impact.

A health score allows an operator to discern which alarms/events from the network are relevant. An operator would like to use a health score to prioritize problems and help triage problems and identify which areas/problems need truck-rolls.

One can think of various components to the health score, including downstream metrics upstream metrics node level metrics etc. Here we are just focused on the upstream component of an overall health score. We look at the individual CM level score and add a service group or node level score. At this point these upstream scores themselves could consist of multiple components though for this paper we are focused only on the RxMER data.

5.2.1. CM Score Upstream

Each of the parameters that we discussed above such as variance skewness, kurtosis, percentile, could all have different thresholds or areas of interest where we could flag the particular modem. One can also look at FEC statistics or profile/IUC statistics, and combined them into a CM score

5.2.2. Node Score Upstream

One can also aggregate all the measured metrics from all the modems on a given node and come up with an aggregate node score. The benefit of this view is for an operator to prioritize how a particular node is doing and how healthy is a node as compared to other nodes on the plant. This gives and operator a prioritized list of nodes which they can then work through the top issues.

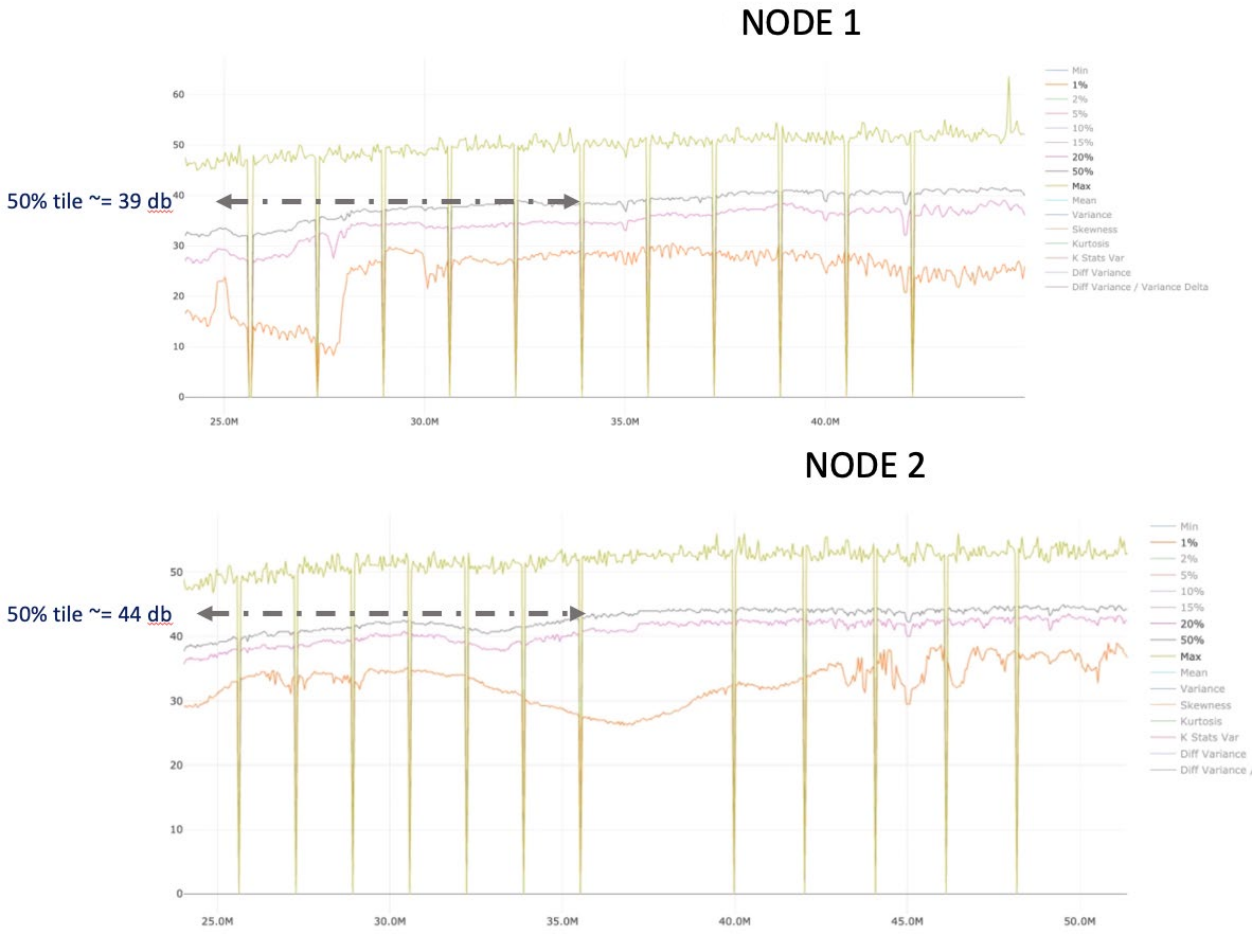

Figure 27 – All CMs All RxMER samples, Percentile, Node 1 vs Node 2

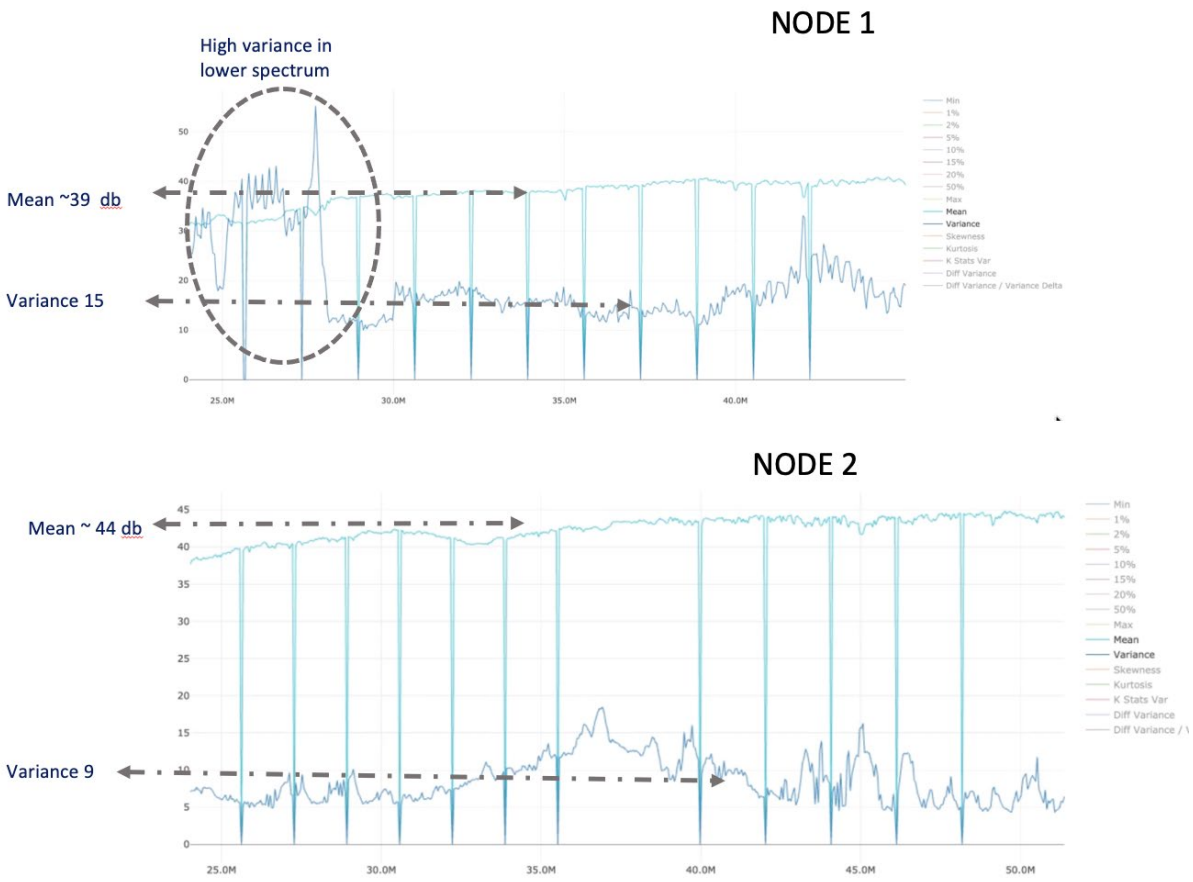

Figure 28 – All CMs All RxMER samples, Variance, Node 1 vs Node 2

5.2.3. US RxMER Data Analytics Application

CableLabs has developed an upstream RxMER data analysis application which can be used for a variety of functions [C3 CableLabs]. As shown in this paper one can visualize the RxMER of a cable modem, all the RxMER samples of a CM, all the RxMER samples of a node. There is also a table view off a service group where you can CB statistics off each individual cable modem. An operator can obtain the average variance, skewness, kurtosis in each part (frequency ranges) of the channel. An operator can also sort the CMs based on those values.

This is a very powerful tool in identifying the "outlier" CMs in the node/segment and then use that information for further analysis/ triaging of truck rolls etc.

5.3. Future Work

There are future topics we will continue to research on in order to develop advanced methods for automatic upstream OFDMA anomaly detection for cable operators to gain more visibility into the upstream OFDMA performance, potentially guide truck rolls and reduce network maintenance cost. These topics include defining anomaly categories in the upstream, anomaly detection methods, and correlations of different measurement data.

5.3.1. Defining Anomaly Categories in the Upstream

We observe many common impairments in the upstream RxMER such as the ingress-like noise observed between 15 and 27 MHz of the OFDMA channel as shown in Figure 30. However, the sources of the impairments mostly remain unknown today. Apart from this, the types and features of the upstream impairments vary from interface to interface, node to node, and area to area. In order to categorize the observed anomalies in the upstream, one may define the labels of the impairments in a hierarchical way. For example, the two parent categories could be persistent impairment and intermittent impairment. Under each of the parent categories, there could be sub-categories such as ingress, echo, or loose connector etc.

Defining impairment categories in the upstream OFDMA can provide critical insight into understanding performance affecting issues and how they need to be prioritized. It also guides the development of feature extraction methods and anomaly detection methods.

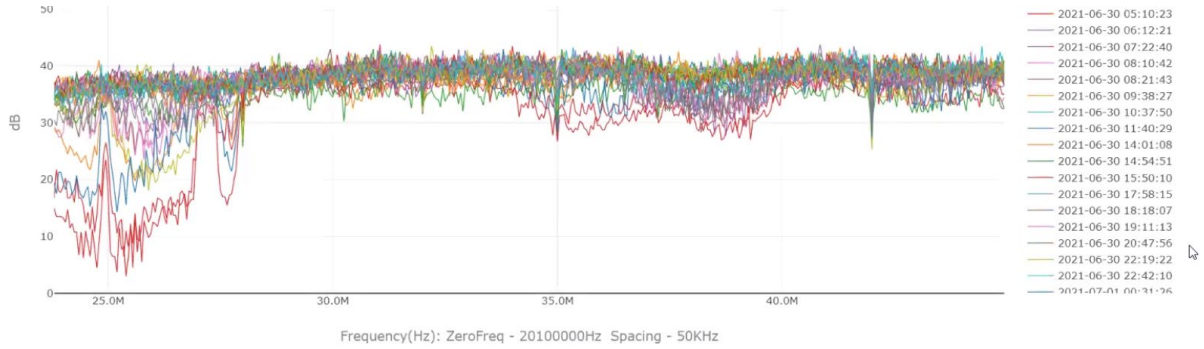

Figure 30 – Impairments at lower frequencies

5.3.2. Anomaly Detection Methods

Several different types of anomaly detection methods can be applied to the upstream RxMER dataset. Threshold based algorithms can be used to label impaired subcarriers and differentiate intermittent issues and persistent issues; 1-dimensional convolutional neural networks can be used to detect patterns over time (RxMER time series) or over frequency; 1-dimensional convolutional neural networks that has multiple input channels can be used to take aggregated data as input, for example, variance, skewness, and kurtosis of each subcarrier's RxMER values over time to perform pattern recognition of the anomalies; 2-dimensional convolutional neural networks can be used to directly consume RxMER sample captures over time (the 2 dimensions are frequency and time) and identify events with their frequencies and timestamps, similar to recognizing objects on pictures; Recurrent neural networks can be used to recognize patterns on RxMER time series. All of these candidate methods depend on well-defined categories/patterns and labeled datasets.

5.3.3. Correlation of Different Measurement Data

While the upstream OFDMA RxMER data already provides much information for performance monitoring, correlating it with other measurement data could have enhanced benefits. Upstream Pre-Equalization data can provide insights into how the CMTS configures the CMs to compensate impairments or other channel attributes; upstream triggered spectrum captures can provide detailed views of the upstream transmission status; upstream FEC error rates can be correlated with RxMER captures over time to analyze how much a certain impairment/event is affecting the robustness of the communication. All of these can be interesting research topics in upstream data analytics.

6. Conclusion

As OFDMA becomes more and more widely deployed, the upstream RxMER measurement capability is becoming available and mature on the CMTSs and MSOs have started to leverage this capability to gain visibility into the status and performance of OFDMA. By visualizing the upstream RxMER captures and producing different views of data, information such as upstream impairments and RxMER variations can be captured to support and drive research of upstream data analytics. In this paper, we discussed how statistical methods can be used to analyze RxMER values captured over time from each subcarrier and extract useful information from noisy upstream datasets. Intermittent issues and persistent issues can be isolated and differentiated by calculating variance, skewness and kurtosis on the upstream RxMER data captured over time. And by plotting the statistics in 3-dimensional space, we discover clusters that can potentially be leveraged to support automatic impairment detection/categorization. Analyzing the RxMER data captured over time by creating average RxMER plots for different frequency regions can provide views from another aspect of the data. Combining the RxMER over time data with identified CM reporting issues, MSOs can gain more visibility into the history of OFDMA channels' performance on individual CM basis as well as at node level. As of the goals of future research of upstream OFDMA data analytics, it is possible that more methods for feature extraction can be developed to simplify and aggregate measurement information. And intelligent models can be built to localize and classify upstream OFDMA impairments accurately and efficiently.

1. Introduction

There are two main sets of costs in network planning that can be reduced through automation and artificial intelligence (AI):

- First, the process today is highly manual. It takes up the time of personnel who could be better utilized if the process was highly automated. Think of network planners with intrinsic knowledge of their network who spend most of their time updating Excel spreadsheets by hand. Their valuable experience could be used much better to maintain the network and to ensure that the customers are happy. ***Automation*** is a tool that can help reduce this set of inefficiencies.

- Second, network planning depends on the ability to forecast network traffic demands. Today this is typically done in an ad hoc fashion where an initial guess of the future network traffic demands is adjusted by essentially a gut feeling from multiple stakeholders. The problem with this approach is that it may result in many inaccuracies in the forecast. Overestimates in the forecast result in too much bought or deployed equipment and then underutilization of network resources. Underestimates in the forecast result in too little deployed equipment, lowered quality of service (QoS) observed by the customer and delayed service deployments, which must wait for equipment to be installed. ***Artificial intelligence*** (AI) is a tool that can reduce this set of inefficiencies.

We note that the two problems feed on each other and prevent either from being solved effectively. The first problem, which is one of automation is more obvious to network operators. As a network equipment vendor, we often hear of the customer woes caused by complicated planning spreadsheets. Through planning network deployments, we also observe first-hand the impact of inaccurate traffic forecasts. The two problems feed on each other as follows: the logic in one direction is “since we have to manually forecast network traffic there is no point automating the rest of the process as there will always be manual steps anyway” and in the other direction “since we manually do planning, there is no point automating the forecasting”. It is also quite possible that network operators are not fully aware of the latest forecasting tools, some of which we talk about in this paper and which can break this cycle of circular logic.

Our hypothesis is that increased automation and the use of artificial intelligence can reduce planning costs, while increasing service provider’s velocity and agility. The focus of this paper is on artificial intelligence and its automation, which should be a medium-term target for the industry. Network planning automation is a near-term topic which many vendors are addressing with their software solutions. There are many vendors advertising their ability to import spreadsheets and incorporate them into automation software, so we will not talk about this topic anymore.

Our main focus is on how AI can be used to automate the process. The goal of using AI technologies is automate as much of the network planning process as possible. Figure 1 shows how this could be done.

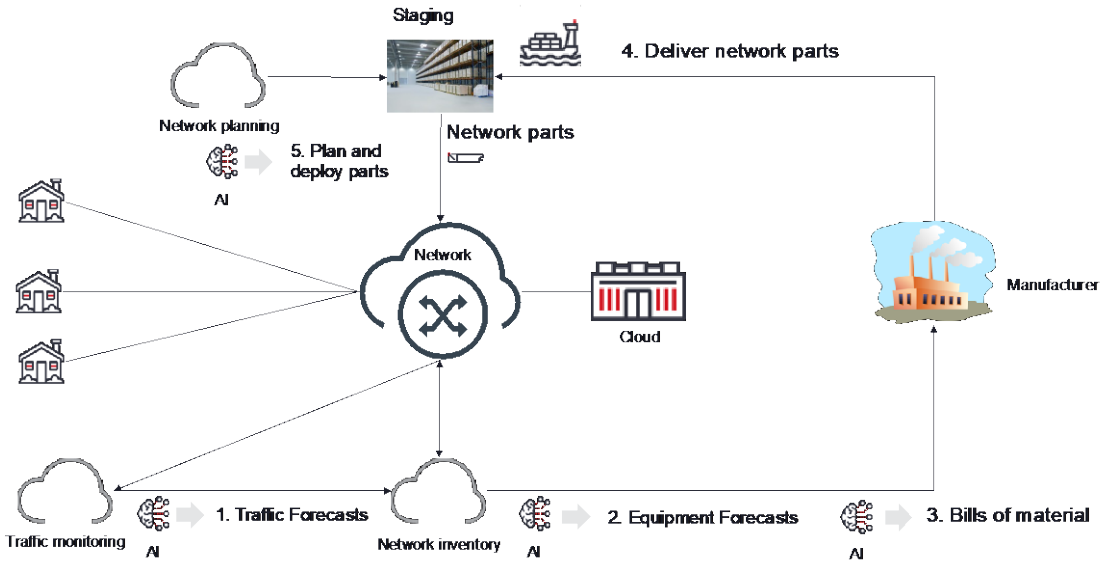

Figure 1 A Vision for a self-planning network

In Figure 1, the network connects the users to the cloud, where most of today's services reside. The traffic monitoring module collects network measurements, such as packet counters and network conditions (e.g., on fibers, or with IPFIX) and uses AI to create traffic forecasts (1). The traffic forecasts are passed to the network inventory module, which uses AI to create equipment forecasts – how much equipment to buy (2). The equipment forecast is passed on to another AI module, which optimizes costs and delivery times for equipment and creates bills of materials, which are sent to manufacturers (3). The manufacturer delivers network equipment to a staging area (4). Meanwhile, the network planning module uses AI to plan network deployments and dispatches technicians to install equipment from the staging area. Ideally, the only manual process is to install equipment and other parts of the process are fully automated with software and AI.

The rest of the paper is organized as follows. We start with a short description of how AI is implemented using deep neural networks (DNNs), following a description of a software architecture which is required to incorporate DNNs into network planning processes. Then we talk about forecasting techniques for network measurements, and we show some performance results using DNNs to forecast network traffic.

Throughout the paper we cite Wikipedia and AI blogs for various AI concepts. While this may appear to not be the most scientifically sound, we found these articles easy to follow and they always link to the more complete computer science papers for the keen reader. There is much DNN jargon used in the paper. We introduce DNN-specific terms in quotes "" to emphasize their jargon origins.

2. Foundations of AI technologies

AI technologies are based on the use of deep neural networks (DNN) for machine learning (ML). Machine learning is a computer science concept in which functional blocks are created by showing the computer examples of correct outputs from inputs, instead of explicitly writing functions that instruct the computer on how to produce outputs from inputs in structured programming (Wikipedia, n.d.). Instead of coding the algorithm, a generic machine learning algorithm is "trained" with examples of what the correct outputs are for given inputs. In recent years, DNN technology has elevated machine learning cognition to the level of human capability. For example, it is now possible to train a DNN-based machine learning algorithm to read a paragraph of text and answer questions about it more accurately than humans, or to categorize x-ray images better than radiologists (Zhang, et al.).

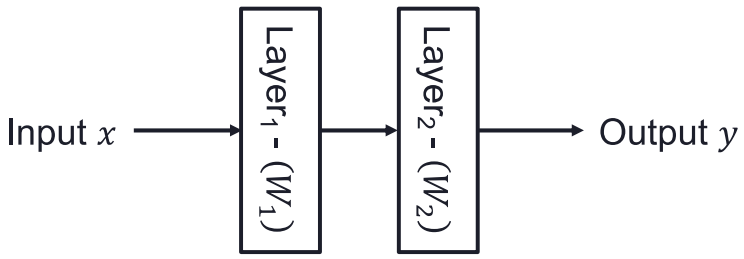
DNN technology is based on basic linear algebra components – matrix multiplication and addition and basic calculus –derivatives. Most of the knowledge required for DNNs has been around for hundreds of years since the time of Carl Friedrich Gauss (Wikipedia, n.d.) and Issac Newton (Wikipedia, n.d.). What is new at this time is that the advances in parallel computing have made it possible to deal effectively with large matrices and train very large DNNs. The most common computing platform are the Graphic Processing Units (GPUs) (Wikipedia, n.d.), which can be used even beyond DNNs, and they are now being complemented with Tensor Processing Units (TPUs) (Wikipedia, n.d.), which are specialized computing units for DNNs. AI accelerators such as TPUs are now found almost anywhere from being embedded in laptops, cellphones, and dedicated data center servers.

DNN-based AI technologies are bringing two main advantages to machine learning. First, as we mentioned DNN-based techniques are starting to perform tasks better than humans. Even though these tasks are limited in nature, it is still impressive to see this, and it opens the question of what other tasks DNN-based ML do better than humans. This is one of the questions we want to answer in this paper. Second, unlike other ML techniques DNN-based ML algorithms are highly automatable. This means that the role of humans in ML is now transferring from traditional manually intensive tasks such as feature engineering, feature selection and tuning of algorithms performed by data scientist, to more traditional software building, which automates these tasks. We explain these concepts shortly. An astute reader will notice that automation of ML is as important as the automation of the network operations to produce a self-planning network. The difference is that in ML this problem is well on its way to being completely solved.

For completeness and interest of the reader we now give a simplified overview of how DNNs make predictions and how they are trained. This is followed by an overview of the different aspects of DNN ML automation.

2.1. How DNNs make predictions

A DNN is a set of algebraic equations that describe how outputs are determined from inputs using matrix operations. A graphical version of the DNN representation is shown Figure 2a, which shows the most basic type of building block for DNNs, known as "dense blocks". The 2-layer DNN shown in the figure is shallow. A typical may have dozens of layers.



a) Graphical Description of a 2-layer neural network

$$y = \max(0, W_2 \times \max(0, W_1 \times x + b_1) + b_2)$$

b) Mathematical Description of the 2-layer neural network

Figure 2 An example 2-layer DNN used for forecasting

The network in shown Figure 2a evaluates an equation involving linear algebra shown in Figure 2b. In this example equation, $W_1 \times x$ is a matrix multiplication (Wikipedia, n.d.) and the max function ensures that the result of all operations is positive. Terms b_1 and b_2 are called bias for the layer. The input to the network is x, while the output is y, so the equation describes the functional block performed by the DNN. The output y is also called a prediction and in the case of forecasting, x is the historical time-series we are trying to predict while y is the future value we need to know for planning purposes. The input x is a mathematical vector whose components are called "features". Each feature is a separate input variable contributing to the output of the DNN. In the case of forecasting, "features" are past samples of the observed network measurements.

The simple set of algebraic transformations in this example is very powerful as it can be shown mathematically that a neural network with enough layers – depth – can approximate any function. For this reason, DNNs are known as "universal approximators" (Hanin & Sellke, 2018).

A pictorial description of a DNN shown in Figure 2a can be translated into the above equation in Figure 2b by an AI engineer and then made into a software program that performs the set of algebraic equations. In practice, the software piece is simple to write using libraries such as TensorFlow (Abadi, et al., 2015) and PyTorch (Paszke, et al., 2019). The DNN can also be exported into the Open Neural Network Exchange (ONNX) (Open Neural Network Exchange, n.d.), which describes the equations and can be loaded into many DNN software frameworks.

Going even further than the simple daisy chain we used, more complex structures could be built by using feedback – Long short-term memory (LSTM) networks and sparse matrices – convolutional neural networks (CNNs). LSTM networks are thought to be good for forecasting as they can model sequential nature of time-series where past values are related to future values. As it turns out, LSTM is not particularly good for network time-series as we show later in the paper. A more promising area for network time-series forecasting is the recent development of matrices that perform inverse fast Fourier transform – IFFT, matrices that perform the inverse

discrete wavelet transform – IDWT and matrices that perform polynomial functions. We talk about these later in the paper.

2.2. How DNNs learn

So far, we described the prediction or inference part of the DNN use. If we know the weights of the DNN (e.g., matrices W_1 and W_2 in Figure 2) then upon receiving the inputs, the set of matrix calculations described by the DNN is performed to determine the outputs. The outputs of the DNN are called the "predictions". This process of making prediction is sometimes called "inference". Weights are determined during a process of training.

For example, if we have the function

$$y = 2x^2 + 3x,$$

we can generate a dataset of training samples shown in Table 1 in the two left-most columns. With the dataset we can use a training function provided in open-source software such as TensorFlow (Abadi, et al., 2015) to determine a set of matrices W_1 and W_2 that result in the best approximation of the function. This function is called "fit" as it fits the weights of the DNN to the dataset during the training. The fit function minimizes the error of the predictions $\hat{y}$ for the dataset compared to actual values in the dataset y. The error can be measured with the Mean Absolute Percentage Error (MAPE) shown in the right-most column of Table 1.

Table 1 Example training dataset for $y = 2x^2 + 3x$

Input x	Actual output y	Predicted output $\hat{y}$	MAPE $\frac{\|\hat{y}-y\|}{y}$
1	5	4.5	10 %
2	14	15.6	11.5 %
3	27	25.4	5.9 %

This simple example may make it seem odd. Why is a DNN learning a known function when we could just be using the function itself? The true power of DNNs comes in when the function is not known but has been observed. In this case, the dataset is a set of observed values coming from the network and the underlying process that models it is not known. For example, the observed values could be packet counters or SNR measurements. In the forecasting case, the training procedure will determine a relationship between the past and future observed values. Once the DNN is trained it can be used for forecasting, by taking in past values and then giving out future values.

The great DNN research achievement in recent years has been to devise a training procedure that uses a set of inputs and outputs of a function to find the set of internal weights W to approximate the function. The training procedure uses "stochastic optimization" whose understanding essentially requires a PhD in mathematics or computer sciences. However, this understanding is not necessary to use DNNs as almost anyone who understands software development can write approximately 10 lines of code to create the DNN and train the function.

The training procedure is iterative and takes in a set of examples of inputs and outputs in batches. For each batch, the training procedure takes in the inputs and generates predictions using the current matrices. The predictions from the DNN are compared with the known outputs to find the error in the predictions (the "loss" function) and this error is used to adjust the weights. The adjustment is usually done using a gradient descent that takes a learning rate as an input and calculates the error of the predictions from the weights and number of predictions. The learning rate determines how quickly the descent happens and how closely to the best fit the training gets. The gradient of the whole DNN is calculated using "backpropagation" (Wikipedia, n.d.), which is an algorithm applied backwards through the DNN to differentiate it. Backpropagation is one example of automatic differentiation using the chain rule (Wikipedia, n.d.).

2.3. Tunning DNN Models

A DNN model is a trained DNN. A single DNN may have multiple models for different versions of the dataset, or different versions of the training algorithms. Each version may have the same structure (number of matrices, size of matrices, and flow through the matrices), but the weights may be different. In a parallel to software development, DNN models have different versions, which presumably improve with higher version numbers. Unlike software, a DNN model is not guaranteed to work well over time, as the inputs may have significant changes in their statistical properties. An example would be traffic demands changing if a new data center peering point is added to the network.

Tuning DNN models has historically been the task of data scientists. The tuning process involves four parts: feature engineering, feature selection, optimization of training hyper-parameters and selection of the DNN architecture. The reliance on data scientists for tuning of DNNs is now waning due to the introduction of automation, as we show in the next section.

Feature Engineering

Feature engineering is the process of modifying input variables to make them better during training and prediction. Historically, this was a very important part of machine learning and data scientists spent a lot of time on it. With the improvements in DNN technology, which during training learns the best representation of input variables, this process has become almost irrelevant. However, it is still important to scale the input and output variables to small range (typically between 0 and 1) to avoid numerical issues.

Feature Selection

Feature selection removes unimportant features. As the number of features increase so does the size of the DNN as each of the weight matrices needs to have the width of the vector it is multiplied with. A larger DNN size results in a longer time to make a prediction (and therefore to train the network). Most importantly, larger size means that the DNN training requires a larger dataset due to the "curse of dimensionality" (Wikipedia, n.d.). For example, if a DNN requires 300 samples per feature to be trained, adding 10 new features means that we need to have available another 3000 new training examples to get the equivalent performance. As the training data used for forecasting accrues historically, adding 10 new features to the inputs means that more measurements are required to train the DNN. Getting an extra 3000 new 15-minute

network samples for training may take as long as 4 weeks, so reducing training dataset size is a very important problem.

Feature selection is based on the premise that not all DNN inputs contribute equally to the output of a DNN. The basis of this premise is that during training, DNNs use the statistical correlation between input and output variables to deduce the best weights. Input variables uncorrelated to the outputs are not needed at the input to make predictions. Over the years, many feature selection approaches have been developed and this process can be automated through a search of required features (SciKit Learn, n.d.).

Selection of training hyper-parameters

Recall that during training input examples are grouped into *batches*, and that for each batch a gradient of the DNN is calculated using backpropagation and applied to the weights with a *learning rate*. The weights of the DNN are called "parameters" as they are determined during training, while the batch size and the learning rate are "hyper-parameters" as they are inputs to the training procedure.

Selecting the right batch size and learning rate are the easiest way to improve the performance of DNN during training. The process used for this is called hyper-parameter optimization or hyper-parameter tuning (Brownlee, n.d.) and is highly automatable and easily parallelized.

In the rest of the paper, we do not distinguish between training and hyper-parameter tuning. In practice, they are often combined into a single procedure.

Selection of a DNN architecture

The simple DNN example in Figure 2 uses two matrices of matrix weights W_1 and W_2, which are determined during the training process and tuned during the hyper-parameter search. However, the choice of the number and size of matrices may not be obvious for each data set.

At least two architectural parameters are unknown for even the simple example in Figure 2: the number of matrices and the size of each matrix. We used 2 matrices, which was easier to explain in this paper, but a typical DNN may have many more layers than that. The height of each matrix is also not readily known as only the width of each matrix is known (the height of the previous matrix). For more complex internal structures it gets complicated in terms of how the architecture is selected, and there is even an area of DNN techniques dealing with measuring the difference between architectures, called ablation (Wikipedia, n.d.).

To find the best architecture, in parallel to the hyper-parameter a network architecture search (NAS) (Wikipedia, n.d.) is also needed. The NAS space is much larger than the space of hyper-parameters, so this is much bigger problem to automate effectively. Typically, the search is done in unique directions, for example one direction could be a daisy chain of dense layers (shown in Figure 2a), while another direction may be a network with daisy chains of LTSM layers. In each direction the NAS is restricted to the number of layers and the height of each layer. Recently, this has been generalized in open-source software (OSS) by Google's Model Search (Google, n.d.).

3. Operationalizing DNNs with AI Software

We now pivot to perhaps a more interesting set of topics for network operators – how DNNs are operationalized with software. The main set of software available is free OSS. The AI software stack has evolved over the last 3 years in conjunction with the developments at the Cloud Native Computing Foundation (CNCF) (Cloud Native Computing Foundation: Building sustainable ecosystems for cloud native software, n.d.). The two main drivers are TensorFlow (Abadi, et al., 2015), which implements DNNs, and KubeFlow (Kubeflow: The Machine Learning Toolkit for Kubernetes, n.d.), which is a set of Kubernetes services used to create AI-specific distributed applications. Both OSS projects were initiated and are still strongly supported by large cloud providers (e.g., Google).

3.1. Microservices

The AI software stack is based on the concept of "microservices" (Wikipedia, n.d.), which are meshed with networking into distributed AI applications. This follows today's architectural patterns, where distributed applications based on microservices underpin today Software-as-a-Service (SaaS) software delivery model (Wikipedia, n.d.).

Microservices are implemented with Linux containers, which group Linux processes to have common permissions and resource limits. Communications with microservices are implemented with networking and commonly with a higher layer protocol such as the Hyper-text Transfer Protocol (HTTP) implementing a Representational State Transfer (REST) architectural style (Wikipedia, n.d.). The microservices are also called RESTful as they are assumed to not hold state between subsequent REST application programming interface (API) calls. Each micro-service exposes its API through Uniform Resource Locators (URLs) corresponding to each of its available functions. Microservices in the same distributed application communicate through networking, so they are not guaranteed to run on the same server, or even in the same datacenter.

Microservices can be combined into distributed applications, where there may be layers implementing different functionalities (e.g., the web interface layer and the database layer). To improve security inside the distributed applications, microservices-based distributed application use a "service mesh" (Wikipedia, n.d.) – an overlay topology interconnecting the microservices in a security conscientious way. As the RESTful communication approach does not provide stateful transfer of data, a messaging bus (service) may be employed to simplify communications between microservices in the same distributed application.

The distributed microservices application architecture is very common in cloud applications, and it has been driven by OSS delivered through the CNCF (Cloud Native Computing Foundation: Building sustainable ecosystems for cloud native software, n.d.). The key contribution to CNCF came from Google in the form of Kubernetes (Kubernetes: Production-Grade Container Orchestration, n.d.), which is container resource orchestrator. Most of the work of the CNCF revolves around building software required to make distributed applications managed by Kubernetes easy to make.

3.2. DNN models as microservices

A trained model is described with an ONNX file, which contains the description of the DNN layers and the weights of each layer. ONNX files can be read by all major DNN software libraries and the used to make predictions. An ONNX file does not make predictions, it only describes a network and its weights. When loaded into ONNX hosting software, the software provides a way to make predictions with the stored DNN model. Inside software, a DNN model is used with a function "predict", which takes as an input features x and outputs an estimate $\hat{y}$.

The functional DNN model fits with the RESTful approach of stateless services. The DNN model does not hold state between subsequent prediction calls. The model can be served on a unique URL with an HTTP post request carrying x and the serving microservice returning the prediction $\hat{y}$. This serving functionality is available in all major DNN software distributions. For example, TensorFlow Serving (Tensorflow: Serving Models, n.d.) and TorchServe (PyTorch: TORCHSERVE, n.d.), provide generic serving containers, which can load a DNN model from an ONNX file and then provide a service access point for the model's predict function. In a distributed application, a serving container becomes is a microservice serving multiple models, each with a unique URLs.

3.3. AI architecture

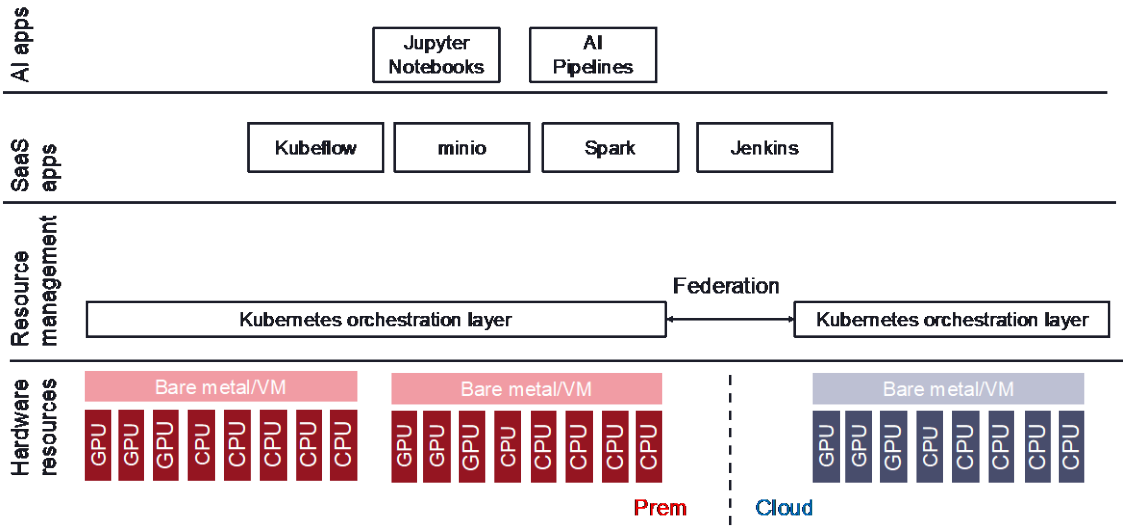


Figure 3 Example AI software stack

The AI software stack is shown in Figure 3 and contains several microservices-based distributed applications running over a distributed hardware architecture. All architectural components in the figure are OSS and are taken from CNCF and TensorFlow family of software. The main AI OSS component, KubeFlow, is spearheaded by major cloud companies, who use it in their cloud and are the basis of their automatic ML (AutoML) offerings. Only the knowledge of Kubernetes is required to setup and maintain the software. It does not take very long to install and set up the stack, or to apply software upgrades. In our opinion, building AI software without using the

Kubernetes and KubeFlow OSS ecosystem would be a strategic mistake, which may result in much unneeded development efforts and may likely result in a complete overhaul of AI software architecture a few years later.

3.4. Architectural Layers

The “hardware resources” are shown at the bottom of Figure 3. They may reside in a private cloud, on the premise close to networking equipment (the edge cloud), or in the public cloud. Hardware resources are made available through the Kubernetes API. We note that the hardware resources are not homogeneous or equally distributed. For example, there would be many more compute and storage resources in the cloud then on the premise (“infinitely” so). The Kubernetes resource manager uses the resources according to their cost and latency requirements of the distributed application. Specifically, one would expect to use edge or network resources first if they are available, to achieve best latency, and spill over other less latency constrained workloads into the cloud.

The “resource management” layer in Figure 3 is a federation of Kubernetes container orchestrators, which manages the hardware resources across multiple clouds. There is a Kubernetes instance associated with each separate set of hardware resources (e.g., cloud or edge). The Kubernetes orchestrator keeps track of available hardware resources and allocates the resources requested for each microservice and spins up the microservice on those resources. Separate instances of Kubernetes can be federated to allow for a seamless use of resources regardless of their location. Kubernetes also provides services useful for a microservices-based architecture: a domain name service (DNS) which maps service URLs to IP addresses, load balancing, automatic scaling based on measurements of service latency, monitoring of microservices health, and restarting them when necessary, and a global registry implemented as distributed key-value store. In terms of resource separation and security, Kubernetes provides namespaces which are logically separated groups of microservices.

The “SaaS apps” layer in Figure 3 is a set of distributed applications installed on top of the Kubernetes resource manager, which are required to build distributed AI. For illustration purposes, we show some of the more useful services for AI: MinIO (MinIO: Object Storage for the Era of the Hybrid Cloud, n.d.) can used to store datasets, by providing an S3 (Amazon S3: Object storage built to store and retrieve any amount of data from anywhere, n.d.) compatible object storage, with the ability to store objects (files) transparently on the local servers or in the private or public cloud; Spark (Apache Spark: Lightning-fast unified analytics engine, n.d.) is a distributed in-memory analytics engine capable of processing vast amounts of data, so it can use to process datasets; Jenkins (Jenkins: build great things at any scale, n.d.) is an integration and delivery automation software; and KubeFlow is an AI pipeline orchestrator and DNN model tracker. A Kubernetes cluster may have many other services co-existing with these, depending on how it is used.

The “AI apps” layer is at the top level of the AI software stack in Figure 3. AI apps are built using the KubeFlow SaaS layer. KubeFlow provides facilities for launching of AI specific containers hosting Jupyter Labs Notebooks (Jupyter: Project Jupyter exists to develop open-source software, open-standards, and services for interactive computing across dozens of

programming languages, n.d.) and for creation of AI pipelines, which are distributed applications used for training and validation DNN models. KubeFlow also contains services for tracking and delivery of DNN models.

3.5. AI Pipelines are DNN model factories

AI pipelines are dynamic distributed applications that train DNN models. Each model has its own pipeline, which includes data processing, training with NAS and hyper-parameter selection, and validation steps. Figure 4 shows an example AI pipeline. A pipeline is specified using KubeFlow's domain-specific language (DSL), which describes the containers to be used at each stage of the pipeline. In the example, there is a container for processing data, container to train a model and a container to test a model. When the pipeline is started, Kubeflow spins up the containers in the order specified and ensures that each part of the pipeline finishes before containers for the next part of the pipeline are spun up.

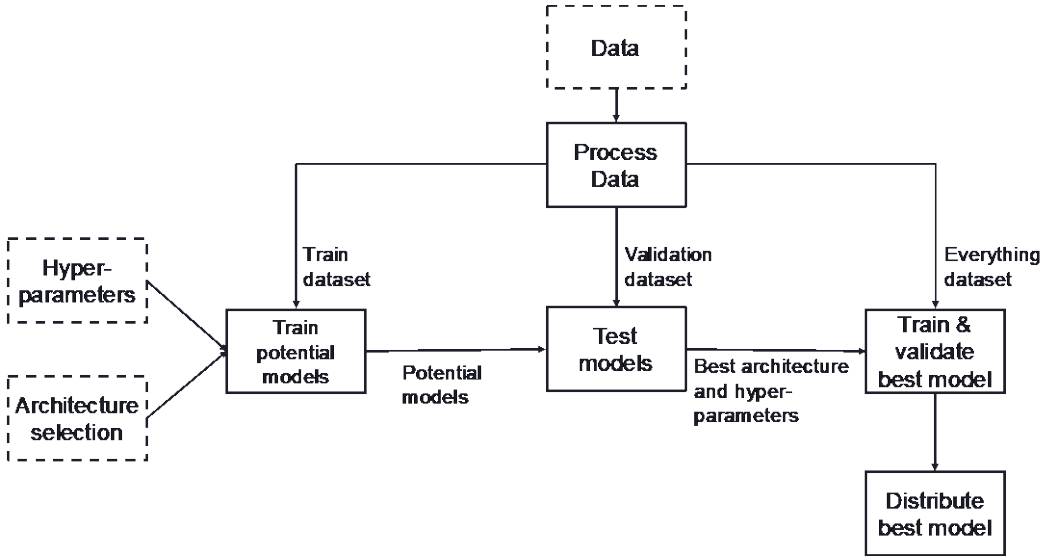

Figure 4 An Example AI pipeline

In the example, data is input to the "process data" step, which requires KubeFlow to provide the data to the process data container, which it also spun up for the pipeline. In practice, data may be in an S3 bucket stored locally or in the cloud. This data processing step may use SaaS services of Spark to process a large volume of data. Note that the data is split into a training and testing dataset to follow common machine learning methodology. The test dataset is provided to the training step, which uses NAS and hyper-parameter search to train many DNN models. This part of the pipeline uses Katib (Kubeflow, n.d.) to create many instances of the same training container with different inputs and runs them in parallel on the Kubernetes cluster. Potential models are evaluated using the validation step. The models are ranked based on the performance of the loss function (error) as shown in Table 1. The DNN model with the lowest error corresponds to the best architecture and hyper-parameters for the training dataset. These are passed to an instance of the training container, which trains the best model with all available

data. The model is validated using hold out data from the dataset. The final step is to distribute and serve the best model.

Figure 5 shows the relationship between AI pipelines and the regular network applications. On the left side of the figure, AI pipelines are a special type of distributed application, used specifically for DNN model search with NAS and hyper-parameter tunning. In our software stack, AI pipelines exist in their own Kubernetes namespace. Each pipeline implements a specific AI use case. For example, network traffic forecasting, which is the topic of this paper, is one use case, which is quite different from other use cases. We show two other use cases in Figure 5: an AI use case that trains a DNN for optical signal-to-noise SNR calculations; and an AI use case that trains a DNN model for network design and planning. The latter may be a DNN model implementing a reinforcement learning approach for path selection in the network. The output of an AI use case is a DNN model. As the DNN models are trained in a namespace different from where they run, then stored in a DNN model registry, which is accessible from all namespaces.

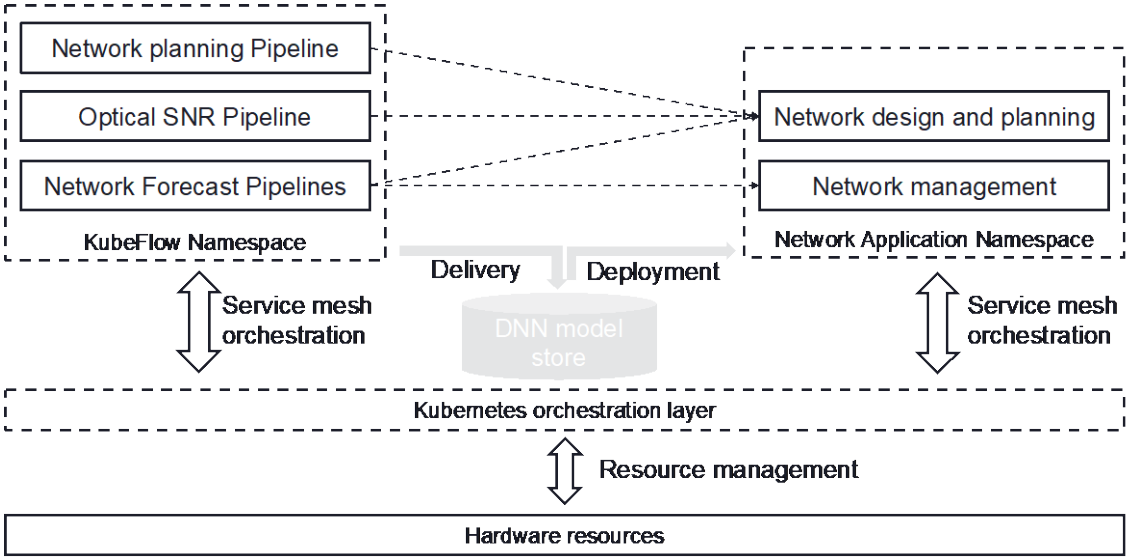

Figure 5 AI pipelines and other distribute network applications

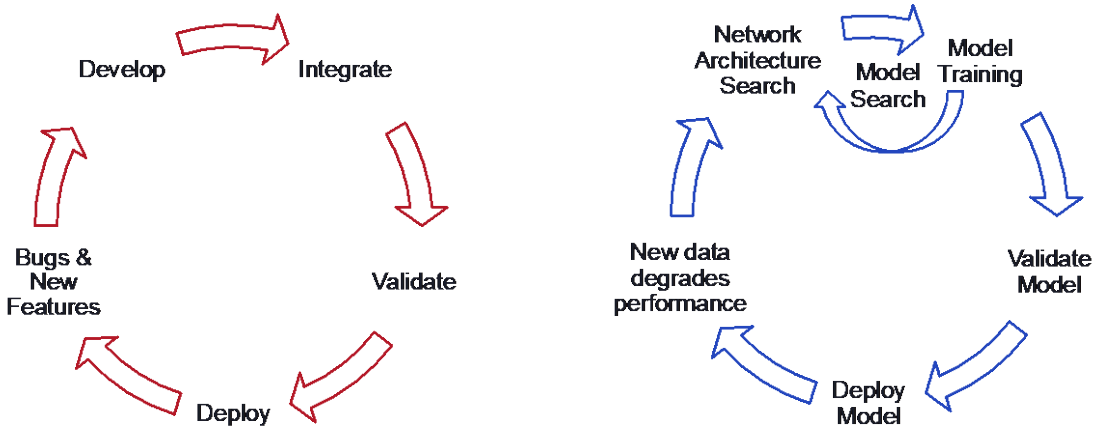
The right side of Figure 5 shows the network applications using the DNN models trained by the pipelines on the left side. The dashed arrows indicate where pipelines deliver models. Note that the network forecasting is many applications, as forecasting could be done at different scales for planning, or management. The model is delivered to the DNN model store and then it is deployed in the corresponding network application.

In the example, we assume that the network applications are hosted on the same Kubernetes cluster. This could be done in separate namespaces as shown in the figure to assure that the network applications are secure and have guaranteed resources. The figure shows several pipelines, the “network planning pipeline”, the “optical SNR pipeline” and the “network forecast pipeline”. Each pipeline produces a DNN model for a specific purpose and with a separate

dataset. To produce the model, pipelines may use the same pipeline template (e.g., template in Figure 4), or they may have different pipeline templates. For example, one of the pipelines may use transfer learning (Wikipedia, n.d.), while other pipelines may use reinforcement learning (Wikipedia, n.d.) to produce their DNN models.

3.6. The MLOps Cycle

The architectural relationships in Figure 5 create an opportunity for MLOps. MLOps (Google) are the equivalent of DevOps (Wikipedia, n.d.) for AI. DevOps is generally accepted way of creating cloud-based software application with a tighter integration of software development and delivery, than what has been done historically. Integral to DevOps is the concept of combined Continuous Integration (CI) and Continuous Delivery (CD). The process is typically done with an automation tool like Jenkins. The CI/CD process is shown in Figure 6a. As the code is being developed, it is automatically tested and integrated and then validated. Testing and integration are done in the development environment, while the validation is done in the testing environment. If the new software is compliant with validation tests it is transferred to the production environment. Even in the production environment the software can be tried out before full deployment. This can be done with Kubernetes, which is instructed to only deploy some portion of the newly created containers into production and load-share application between the new and old containers. Only if the new containers perform satisfactorily, the new containers replace all the containers.



a) DevOps Cycle with CI/CD b) The MLOps Cycle

Figure 6 DevOps vs. MLOps

DevOps are enabled by the ability to automate testing, integration and validation and then automatically deliver containers to the cloud. This ability is right now coming directly from the use of microservices and Kubernetes, combined with CI/CD automation. Microservices architecture allows incremental upgrades (one micro-service at a time). Kubernetes provides a platform to test microservices through namespaces. For example, with Kubernetes it is possible to easily create namespace where different versions of the same microservices are logically separated on the shared hardware and incremental testing of new features and bug fixes can be

done. Kubernetes also provides facilities to gradually upgrade a microservice in production by gradually replacing copies of old versions with new upgraded ones and to monitor the new versions and to roll them back if problems are noticed.

The MLOps cycle is shown in Figure 6a. This is the equivalent to CI/CD for DNN models, with some fundamental differences. The first difference is that the DevOps cycle is triggered by bugs in the code or new features, while the MLOps cycle is triggered by new data, which degrades the performance of the existing DNN model. The second difference is that the DevOps cycle starts by development of the code, while the MLOps cycle starts with a network architecture search and model training, which includes hyper-parameter optimization. Instead of coding a new DNN model, the new model is found automatically using new data. Validation and deployment parts of the cycle are essentially the same. The new model is packaged as a microservice and is updated in the service mesh just like any other microservice.

3.7. Automatic Machine Learning (AutoML)

The combination of AI pipelines with NAS and hyper-parameter search is known as automatic machine learning (AutoML). The search for the best combination of data processing, network architecture and hyper-parameters is completely automated and the DNN model factory in Figure 5 can produce DNN models without human input.

While this may sound magical as the data scientist expertise and experience is greatly reduced and removed from the ML process, we note that there are several points to AutoML that require some human input:

- First, the NAS and hype-parameter space may be quite large. This means that the search space could be so large that the time to create a new model may exceed operational needs. A data scientist or an AI Engineer would be involved to decide on the *reasonable* search space that may generate *good* DNN models.
- Second, model performance in production must be monitored and evaluated as data coming from the network changes over time. A sufficient change in the network data will trigger the MLOps cycle. However, a data scientist still needs to monitor the performance and its trends and make judgment calls when to trigger the MLOps cycle or debug DNN model performance for causes of degradation.
- Third, the role of AI models in the distributed network applications needs to be well understood. This requires a human contribution in understanding the domain of application and to design the system that automates downstream actions of network operators.

So, while data scientists will still be needed in the world of AutoML, their role in the process will change. Instead of each data scientists training a single model over a period of weeks or months, that data scientist will be able to train hundreds of models in a day and debug the select few for performance issues. Data scientists may also take on the role of a translator (Analytics translator: The new must-have role, n.d.) to bridge the gap between business needs and AI technological capabilities.

4. Forecasting the Network Demands with Artificial Intelligence

So far, we have talked about existing and soon-to-be-available AI architectures and components. This section talks specifically about how DNNs can be used for forecasting in the network.

Forecasting is the process of taking in historical values for a network measurement and producing estimates of future values. Network measurements are stored in databases as time-series, "series" is used because measurements are collected uniformly, so only a sequence of measurements is required and time can be calculated by a position in the series.

Several kinds of forecast are possible, depending on what the inputs and outputs are:

- Single-variate forecasts are for time-series containing a single measurement, for example packet counts from a single router link.
- Multi-variate forecasts are for time-series containing multiple measurements, for example packet counts from multiple links on the same router.
- Single-step forecasts produce the next value in time, so if packet counters are collected every 15 minutes, a forecast at 8:00AM will be for the packet counter at 8:15AM.
- Multi-step forecasts produce a sequence of future values, so if packet counters are collected every 15 minutes, a forecast at 8:00AM can be for the next day and produce 96 values (for every 15 minutes in a 24-hour period).

There are only 4 valid forecast types, given the two kinds of inputs and outputs.

The content of this section is best suited for single-variate forecast of single-step or multi-step kind. However, we also show results for multi-step forecasts.

4.1. Forecasting network traffic

Forecasting approaches are based on behavioural models of underlying processes that reflect in the data. For example, some generalities about human generated data are almost always true: human activity almost always increases, and human activity is seasonal. The growth in human activity is especially reflected in the growth of Internet traffic, which seems to only go up (Cisco, n.d.). There is also seasonality in the Internet traffic (Hen & Karlesson, 2019) reflected both in which direction the network traffic flows and in the volume of traffic. For example, the difference is pronounced during a single day with high business traffic during work hours and low business traffic during the evening and high entertainment traffic during the evenings, which are also temporarily different across the world. Generally, seasonality is also noticeable during different days of the week with weekends and holidays showing high consumption of entertainment and low business traffic.

4.2. Traditional forecasting approaches

A generally accepted forecasting approach is to decompose the time-series and extract the trend and seasonality components (Hyndman & Athanasopoulos). The reminder of the time-series includes noise, which needs to be smoothed out. Figure 7 shows the decomposition process. The input is historical time-series. The trend is extracted first, followed by the seasonality. The remainder of the time-series is smoothed. The trend can be used to make long-term forecast (in the order of months, quarters, and years), while the seasonality can be used to make forecasts for

repeating patterns in the time-series (daily, weekly). The smoothed remainder can be used to make short-term forecasts.

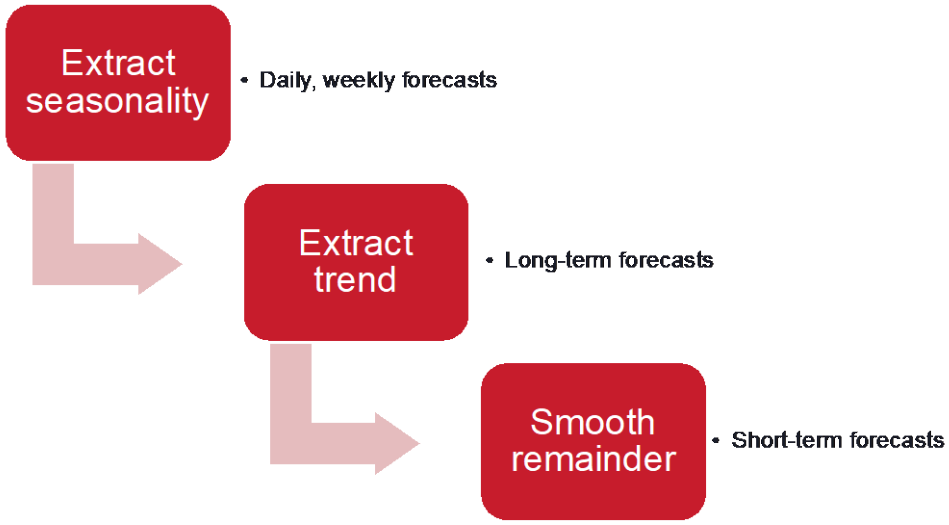


Figure 7 Forecasting time-series decomposition

Traditionally, time-series decomposition has been a highly manual process. The time-series structure is not known before analysis done by someone with a lot of forecasting expertise. The decomposition can be done automatically using one of the newer tools (Prophet: Forecasting at Scale), however a forecasting expert should still ensure that the automation has gone smoothly as the forecasting model in (Prophet: Forecasting at Scale) makes very specific assumptions about the time-series. The forecaster makes an informed decision for each of the time-series components trend, seasonal and smoothing. A typical forecasting expert works with a small dataset and uses judgment in deciding which forecast makes the most sense. For example, forecasting quarterly GDP over the last 50 years only has 200 points and a forecasting expert may use their knowledge of economics and information available outside of the time-series to decide if GDP will go up or down in the next quarter. Compared to network data, this is very small dataset – there are close to 200 data points in two days of 15-minute bins. So, some of the analysis done by traditional forecasting technique doesn't translate well into the networking domain.

In terms of time-series feature, an expert forecaster may use some of the following approaches:

- Seasonality can be estimated in many ways including taking averages at repeating time, e.g., by find an average traffic on Monday 9:00AM-9:15AM, by isolating data in this repeating period of time and then averaging, or with more complex approaches such as estimating the periodicity in the frequency domain.
- Trend is typically chosen as the best line that fits through the data. To make things simple to understand, a forecaster usually picks linear or exponential trend (Wikipedia, n.d.), but more complex methods such as piece-wise linear trends (Hyndman R. J.) are also possible.

- Smoothing is used to remove the noise from the time-series. A familiar from of smoothing may be the moving average (MA) smoother available on stock tracking platforms (Ermey, 2019). The moving average is also statistically the most likely estimate of the next value in the time-series. More sophisticated smoothers also exist, namely the auto-regressive moving average (ARIMA) family of estimators (Wikipedia, n.d.), which model temporal relationships between samples of a time-series. Some forecasters feel confident in using
  ARIMA forecasters for multi-step forecasts, however assumptions on the underlying data should be checked before getting overconfident with this method.

It is important to take stock of the state-of-art in existing forecasting approaches: they are highly dependent on matching the model in the forecasting algorithm to the time-series, because historically there wasn't that much data available for forecasting. Both reasons are why human intervention is required for traditional forecasting approaches.

As we have shown earlier, one of the advantages of using DNNs is that they can learn the best model for a time-series, given enough data. In the networking use cases, there is enough data. We now go over some of the approaches that can be used to automate forecasting with DNNs.

4.3. Forecasting with DNNs

Probably the most accepted DNN forecasting approach is to use recurrent neural networks (RNNs) (Wikipedia, n.d.). RNNs use recursion to pass data from the previous step to the current step as shown in Figure 8. In the figure the DNN block is identical throughout the network, meaning that recursion happens, and the last output is the function of all inputs. The RNN structure models time dependencies in the time-series. The block could be made from anything, but a popular structure long-term short memory (LSTM), which is numerically stable.

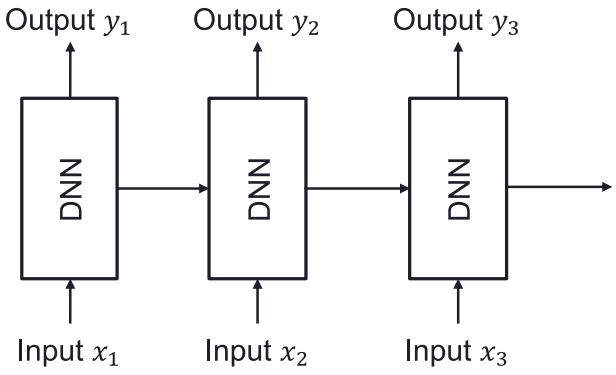

Figure 8 Recursive Neural Network

The assumption of the recursive relationships of time sample is reminiscent of that ARIMA forecasting models. As we already mentioned, this approach is valid for short term forecasts (smoothing) after trend and seasonality have been removed. The assumption of the recurring

relationships in the time-series isn't always true, or important for time-series forecasting. The more important assumptions are around trend and seasonality, which should be accounted for.

Recently, a residual network structure (Wikipedia, n.d.) was used to model this behaviour. In a residual network, it is possible to have skip connections, that allow addition or subtraction of various output blocks. The N-BEATS doubly residual network architecture (G, n.d.) for time-series forecasting is shown in Figure 9. Following from left to right, on the bottom, it can be seen that what is happening in the network is a trend estimate being determined first and then being subtracted from the input. Then the seasonality estimate is determined and subtracted from the "residual" of the input (input with trend subtracted). Finally, the residual of both of those is smoothed out. On the top of the network, the outputs of the three estimates are combined for the forecast.

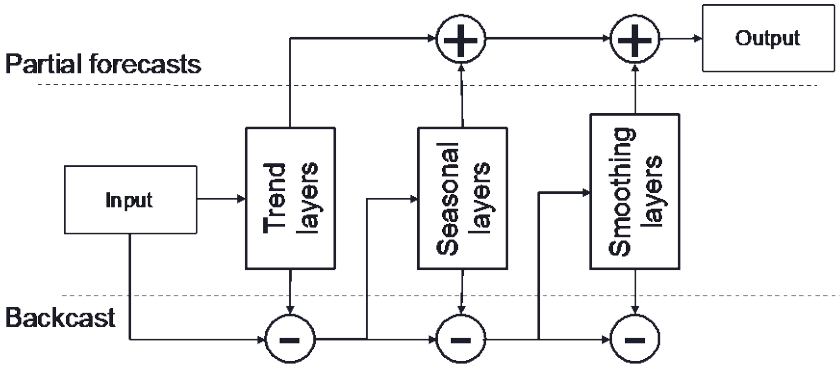

Figure 9 Time-series decomposition

As an example, we used the NBEATS (G, n.d.) network and compared it to the winner of the M4 forecasting competition (The M4 Competition Team, n.d.) dataset. The winner of the competition was a modified LSTM, which was used to win the competition and it required human intervention to perform well. The M4 forecasting competition dataset has over 100,000 financial and manufacturing time-series. Algorithms are compared against a simple baseline, which is used to ensure that there is something to learn in the dataset. The baseline algorithm uses the last seen value as the forecast of future values. It may be hard to believe, but this simple baseline is very hard to beat on real-life datasets.

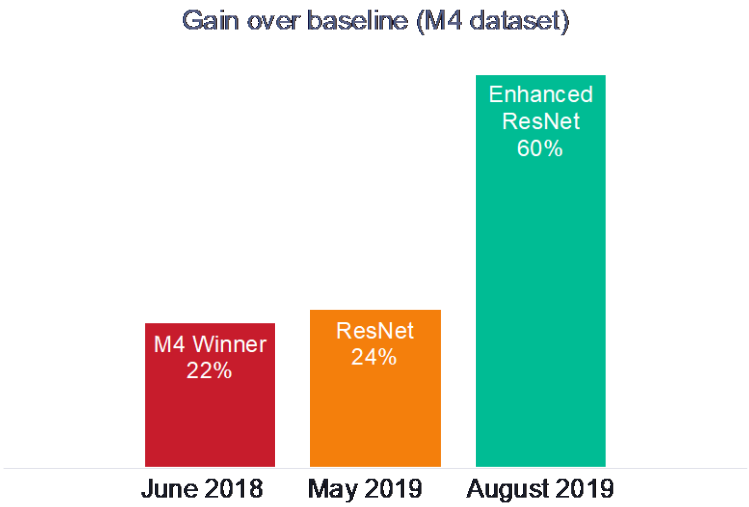

Figure 10 Performance comparison of DNN approaches (public dataset)

In the Figure 10, NBEATS is labeled as ResNet. The relative gain is measured on the error of one method over the other method. So, 22 % gain of the M4 Winner over the baseline means that the error (MAPE) of the winner is 22 % less than the winner. It should be observed that NBEATS improves upon the M4 Winner, but not by a lot. Based on our observations of the NBEATS performance, we developed a new ResNet based algorithm and it shows an improvement of 60% over the baseline (labeled Enhanced ResNet). As far as we can tell, the Enhanced ResNet is the world's best forecaster as it works better than the M4 competition winner and the next best forecaster.

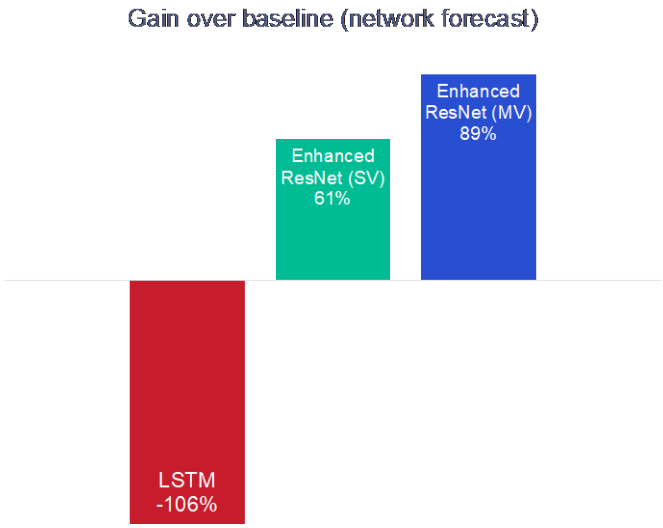

Figure 11 Performance comparison of DNN approaches (network dataset)

Real-world network datasets are quite different from the financial series in the M4 dataset. For the most part, financial time-series are smooth and without sudden changes. On the other hand, network time-series often have unexpected steps and spikes. We tested the LSTM and Enhanced ResNet algorithms on a network time-series in our possession. The data was collected from a large service provider. The results are shown in Figure 11. Note that LSTM does not work well on this dataset. It performs much worse than the baseline. We are confident this is because LSTM assumes too many dependencies on time, so it doesn't work when the time-series have abrupt changes.

On the other hand, the Enhanced ResNet algorithm (shown as "Enhanced ResNet (SV)") works much better than the baseline. Furthermore, the Enhanced ResNet algorithm can be extended to forecast from multi-variate inputs (shown as "Enhanced ResNet (MV)"). Network time-series have dependencies on other time-series, so it is advantageous to combine them during the forecasting process.

5. Summary

This paper has talked about forecasting in the context of network operations. We have made the argument that network operations, especially its planning functions, need to automate all parts of their processes and that this cannot be done without automated forecasting. We have shown how automated forecasting can be done with DNNs and AutoML. We have also used network time-series from an actual network to show the power of forecasting with DNNs.

We believe that DNNs and AutoML have the potential to revolutionize the network planning process and make it more accurate and less costly than today.

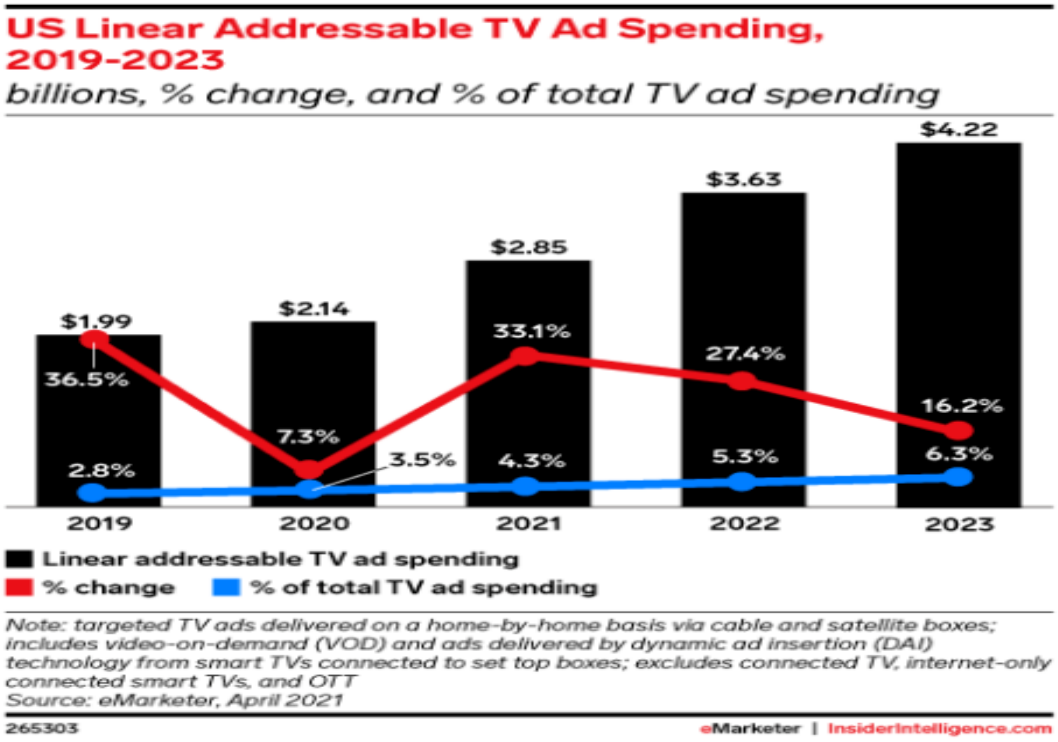
1. Introduction

The popularity and adoption of the SCTE 224, Event Scheduling and Notification Interface (ESNI) is opening new use cases where the protocol is a great fit. One new and exciting use cases is for addressable advertising where content providers and operators can use static, national ad inventory which are more targeted to the viewers and therefore potentially generate higher CPMs. Addressable advertisements, in this context, means replacing advertisements sold on broad age/gender demographics with advertising sold on more specific audience definitions. This evolution in ad avails has both content providers and operators excited for revenue growth potential in this relatively untapped market. According to eMarketer, U.S. addressable TV advertisement spending is expected to grow 33.1%, 27.4%, and 16.2% respectively in 2021, 2022, and 2023 and will eventually represent 6.3% of the total TV ad spending.



SCTE 224 has proven itself as an efficient and effective means for machine-to-machine communication of out-of-band (OOB) linear rights management. Additionally, combining of SCTE 224 with SCTE 35 to trigger the in-band signaling allows precision execution of linear rights for content substitution and addressable advertising management. ESNI is well known as the solution of record for content embargos and alternate content, however, content providers are now using ESNI for addressable advertising,

The ESNI protocol is perfectly well suited to communicate rules and policies at an audience-based level, thereby providing a substrate to implement addressability. Two critical requirements within the addressable advertising workflow are 1) identifying which slots within the content provider's 14-15 minutes per hour are addressable and 2) conveying ad information specific to those slots. ESNI is the key mechanism to communicate slot schedules for addressable slots versus national advertisements. ESNI also communicates specific rules for the addressable inventory on behalf of the content provider to the

distributors' Advertising Decisioning Service (ADS). ESNI therefore facilitates appropriate ad avail decisioning, providing information for ad spot inclusion and exclusion.

ESNI objects are extensible markup language (XML) messages with relevant fields for advertising such as ViewingPolicy actions for ad inclusion, exclusion, and ADS directives. These ESNI messages are managed with a representational state transfer (REST) interface for exchange between the operator and content provider. SCTE 35 markers in the stream trigger these breaks as they have done in the past. The out-of-band ESNI execution components then link these in-band SCTE 35 markers with the ESNI instructions.

2. Addressability Background

Let's start with a high-level description of addressable advertising: Linear-based television advertising (cable or satellite TV ads) has been essentially sold the same way for years. The operator/distributor typically has the ability to sell 2 to 3 minutes of commercials per hour per program – historically called the local avails – and the content provider sells the rest of the ad inventory per program per hour – roughly 14 to 15 minutes of commercials. In this workflow, the local avails inventory has been classified as addressable ads, targeted and sold at a local level vs. ads sold by the content providers which are national ad campaigns that are "locked and loaded" to be seen by everyone watching that particular program.

The buzz around the industry is the transition of taking those 14 to 15 minutes of content provider-owned national inventory and converting it into "addressable" ad inventory. Addressability has both content providers and operators interested because of the potential revenue and growth of this relatively untapped market.

There are also a few industry consortiums focused in this area, such as Go Addressable and Project OAR that are working to tackle both business and technical challenges to grow the space. Additionally, the SCTE Digital Video Subcommittee working group five recently released a best practices document around using SCTE 224 for advertising (SCTE 268, Operational Practice on the Usage of SCTE 224 for Advertising Information).

3. SCTE 224 Context

The SCTE 224 Event Scheduling and Notification Interface (ESNI) is an XML-based standard that provides a defined protocol for carrying machine-to-machine metadata for video. There are five basic constructs within SCTE 224, as shown in Figure 1. Each of these constructs work together to provide a content provider with a means to convey video rights for content replacement as well as advertising instructions on the operator side of the workflow. These five constructs are Media, MediaPoints, Policy, ViewingPolicy, and Audiences. We describe each of these here, and then tie them all together with the underpinning for the advertising use case in the following section.

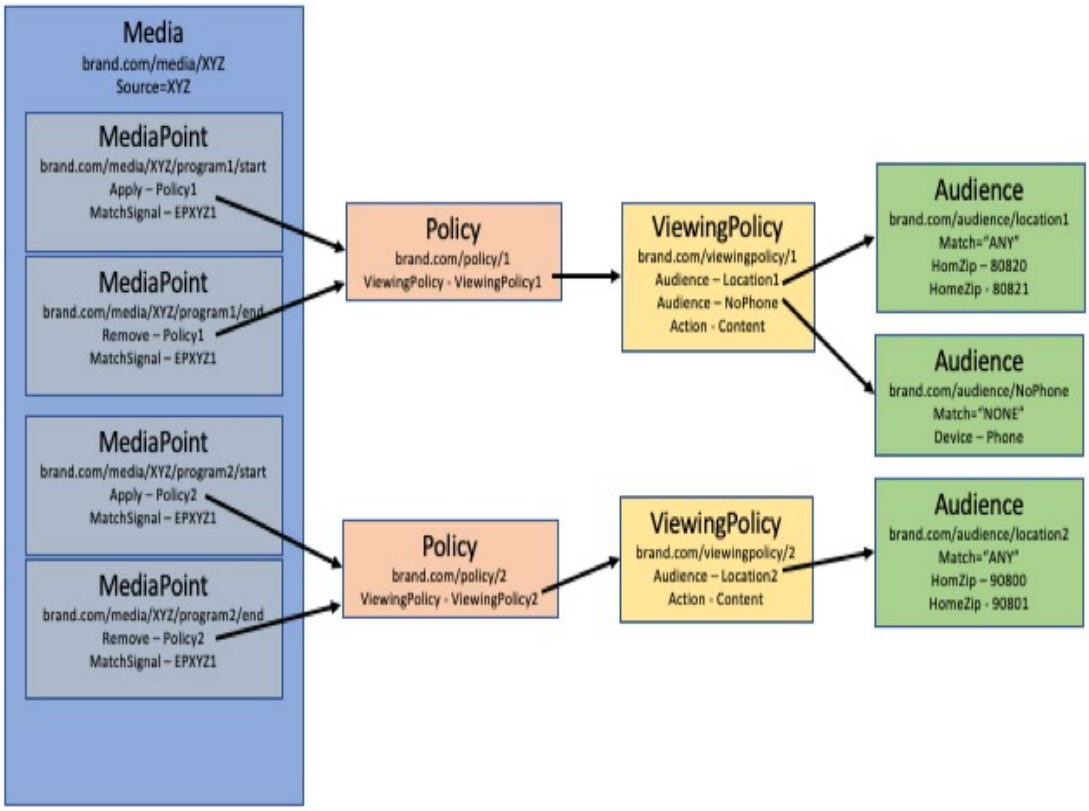


Figure 1 – SCTE 224 Constructs

3.1. SCTE 224 Media

The Media object is a top-level container representing a linear channel whose primary function is to carry all the MediaPoints, so it contains an ordered list of MediaPoint elements as shown in Figure 1. The Media object also contains a few key elements like a description and source for the linear channel it represents.

3.2. SCTE 224 MediaPoint

The MediaPoint object describes a point in the Media when a decision needs to be made or an action needs to be taken. These points in time can either be time-based (i.e., the presence of a @matchTime attribute in the MediaPoint) or SCTE 35 in-band signal based for frame accuracy. The signal-based MediaPoints contain a MatchSignal element with XPath matching logic to link the MediaPoint to the presence of the in-band signal. Signals can be reused, because MediaPoints also have an effective/expires window constraining when the MediaPoint can be evaluated.

When a MediaPoint is triggered, based on time or signal, it can either "Apply" or "Remove" one or more Policy objects which effect the state of the linear playout. See the Policy object description below for more details. MediaPoints that "Apply" a policy do so until another MediaPoint explicitly "Removes" that Policy or they time out based on the duration indicated in the "Apply" statement.

3.3. SCTE 224 Policy

A Policy object is nothing more than a container for defining a set of ViewingPolicy elements to be acted upon based on this Policy being "Apply" or "Removed" from the Policy stack. The "Apply" or application of a Policy means putting that Policy on that Media's stack via first-in-last-out queue. All policies currently on the stack that affect a particular Media are aggregated together, so multiple Policies can be affecting the state at one time. The removal of a Policy then takes it off that stack and out of the state of that Media. SCTE 224 has explicit rules about how to manage the Policy queue in a SCTE 224 execution engine.

3.4. SCTE 224 ViewingPolicy

The ViewingPolicy object is the key SCTE 224 object that associates one or more actions to an audience. These "Actions" can range from directing an audience to alternate content, restricting trick mode, or restricting resolution. For ads specifically, these actions can contain information about the Advertising Decisioning Service (ADS) to use for a particular audience, or various advertisement conflicting rules for a particular audience. The key to a ViewingPolicy is that if the "Audience" criteria is met, then the action must be taken. The SCTE 224 maintains a list of actions, many of which apply to the ad use case such as allocation and break owner, allowed within the ViewingPolicy object, many of which are specific to addressable advertising

3.5. SCTE 224 Audience

The Audience object is a set of characteristics that define a subset of viewers based on certain aspects of their device type (tablet, phone, etc.); device characteristics (local storage, mobile, etc.); or location information (such as zip codes, postal codes, latitude/longitude, market areas); or even receive categories such as Distributor or Virtual Integrated Receiver Decoder (vIRD). Audience objects can contain other Audience objects, making for compound Audiences. Additionally, logic to associate a client with an Audience is based on matches of ANY, ALL, or NONE of the characteristics outlined, for easily including or excluding specific characteristics. For example, you can say Match="ANY" for a list of zip codes to characterize the audience within that area, or Match="NONE" to characterize an audience outside that area.

3.6. SCTE 224 Example Logic

So now let's take those five objects from Figure 1 and run them through a scenario. A video signal acquisition system (SAS) sees an in-band SCTE 35 signal. It calls a signal decisioning system (SDS) to figure out what it should do. When the SAS calls the SDS it tells the SDS which source it was on, what time it saw the signal, the binary signal, and the client characteristics. If it could talk, it would say something like "I just saw the signal 'UhJeasfojoihe23edde' on source XYZ, at 1:00pm and I am encoding for zipcode 80820." The SDS then looks through all the out-of-band SCTE 224 and its Media to find the one for that source (i.e., XYZ). Once it finds the correct Media, it examines its MediaPoints to find those that fall within the designated time window. Once it has the list of MediaPoints, it evaluates each one to see if there is a match with the signal. For a MediaPoint that matches, it either performs an "Apply" or "Remove" of the associated Policy. It then goes from that Policy to the ViewingPolicy, where it determines whether a match exists between the audience and the designated zipcode, based on the Match criteria. If yes, the SDS would return the "Action" of the ViewingPolicy to the SAS for that audience. In the case of alternate content, for instance, it might tell the SAS that it needs to switch over to another source and start encoding the alternate source.

4. Addressable Advertising Specifics

How does SCTE 224 support this new dynamic with addressable ads? The exciting news is that the SCTE 224 standard is set up to communicate rules and policies at an audience-based level, which is exactly what addressable advertising needs to make it work.

Within the addressable advertising workflow, the first critical decisioning point is for the content provider and operator to know which advertisements are addressable, within the content providers' 14-15 minutes of ad avails per hour. To do that, SCTE 224 is used as the communication protocol between the three parties. The content provider's ad schedule is converted into SCTE 224 and then distributed throughout the value chain in SCTE 224 format. Figure 2 shows the video and SCTE 224 information being sent from the content provider to the operator and the Advertising Decisioning Service.

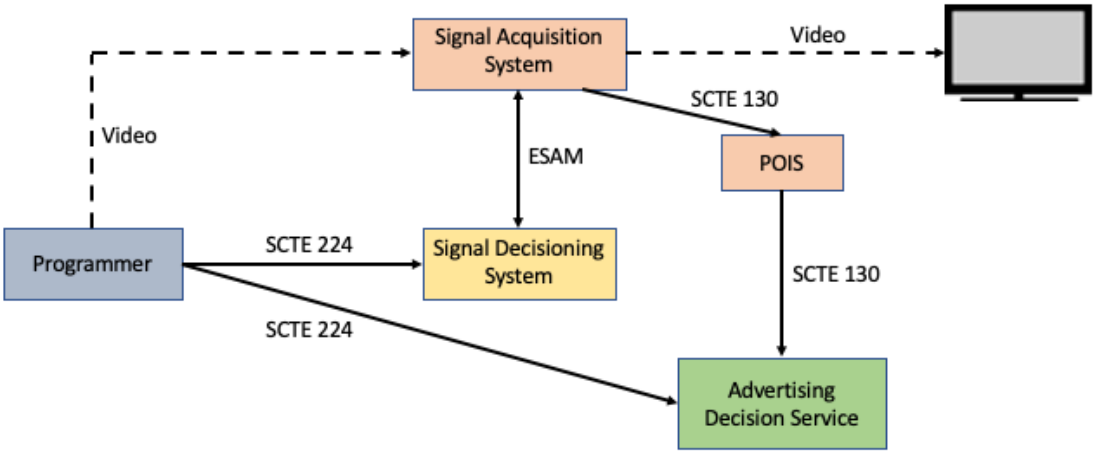

Figure 2 – SCTE 224 Advertising Use Case

4.1. Identifying Addressable Slots

This SCTE 224 message set is sent to the operator's signal decisioning system (SDS) to work with the signal acquisition system (SAS), which is watching for the SCTE 35 in-band signal in the video. When the SAS sees an SCTE 35 marker for the start of an avail break/pod, it calls the SDS to see if that is an addressable ad slot or not. The SDS logic then looks for the corresponding MediaPoint to "Apply" the policy and then validate the operator against the ViewingPolicy Audience and resulting action. For example, if the operator is ABC and the "ABC" is in the content provider's audience, and the action is "LinearDAI (Digital Ad Insertion)", then it is addressable. The SDS then will return the "LinearDAI" back to the SAS as the decision response, which means the SAS now knows that it is an addressable advertising slot, so it then calls the Placement Opportunity Information Service (POIS) to get an advertisement to play. If, on the other hand, the operator is "DEF" and is not in the Audience, the SDS would return a "noop," to mean "no opportunity," which tells the SAS to do nothing and/or keep doing what it was doing, which results in it playing out the baked-in advertisement. It should be noted that there could be other actions like "SignalDeletion".

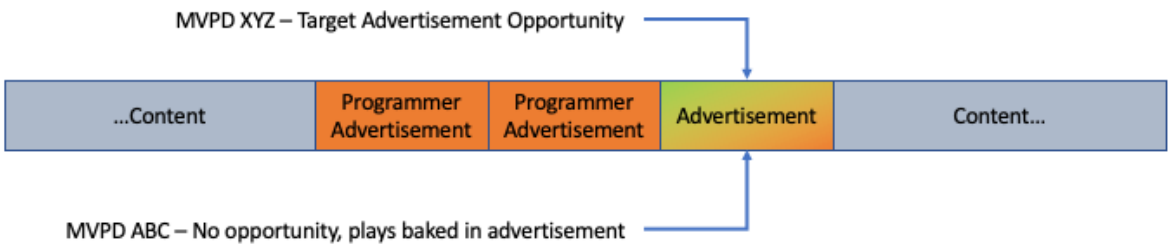

Figure 3 -- Identifying Slots

This might sound like a capability that SCTE 35 has today, but the benefit of out-of-band SCTE 224 is that it is unlimited in capacity and ability to match audience and action pairs. Because the signaling happens out-of-band, it does not impact the frames in the video by trying to cram everything into a SCTE 35 signal, so it greatly reduces the SCTE 35 work required with the video. In fact, it allows a single, simple SCTE 35 marker to be sent to multiple operators and have multiple meanings, which results in individual playout payloads to multiple operator recipients. Because content providers innately serve multiple operators and audiences, this is a highly desirable feature.

4.2. Addressable Advertising Rules

The second major addressability use case for SCTE 224 is providing specific ad rules for the addressable inventory on behalf of the content provider to the operator and its Advertising Decisioning Service (ADS). There are many advertisement rules, but two constitute the main rules conveyed from the content provider to the operator. One involves which ADS to use, whether there are campaign/order codes associated with that slot that the ADS needs to know. The second involves advertisement inclusion and exclusion, or whether there are conflicting rules, based on what advertisements the content provider already has slotted in its linear feed. In this case, a common language like SCTE 224 can facilitate the appropriate advertising placement with correct ad decisioning rules applied. Each of these types of advertisement rules can easily be carried by SCTE 224 and conveyed to an operator by or for the content provider, on a per-operator basis. Below are more details about these rules.

4.2.1. ADS Rules

Because SCTE 224 information is sent out-of-band and can be used differently for each operator, a content provider can set up different Advertisement Decisioning Systems for each operator. The content provider can use a SCTE 224 MediaPoint that has a Policy for audience “Comcast,” for instance, and action “use FreeWheel” and another operator with audience “Charter” and action “use Google DFP”. The SCTE 224 actions have been expanded in 2020/2021 to handle just this use case. This means that with a single, simple SCTE 35 in the video identifying the ad break, a content provider can tell different operators to use different ADSs.

Additionally, because the content provider now has individual direction capability for different operators, they can direct more than just *which* ADS to use. They can also include varying order numbers or varying campaign attributes that are different for each operator. This can result in a tighter coupling of addressable advertisements and the operator, leading to potentially higher revenue upsells.

4.2.2. Advertisement Conflicting Rules

Again, because the SCTE 224 signal path is out-of-band, it is not limited in size or what it can carry, compared to a SCTE 35 in-band signal. As a result, a content provider can include extensive metadata about an advertisement – or, more importantly, about what targeted advertisement(s) cannot be used, to avoid placing ad within the same ad break that conflict with one another. Because the content provider knows about the baked-in advertisements in the feed, it can provide rules to the operator or the operator's ADS about what advertisements would fit great in the pod -- it can say which advertisements to include. Or, a content provider can say which type or category of advertisements *not* to include (to exclude), because they would counter the previous or consequent advertisement that had been identified as addressable.

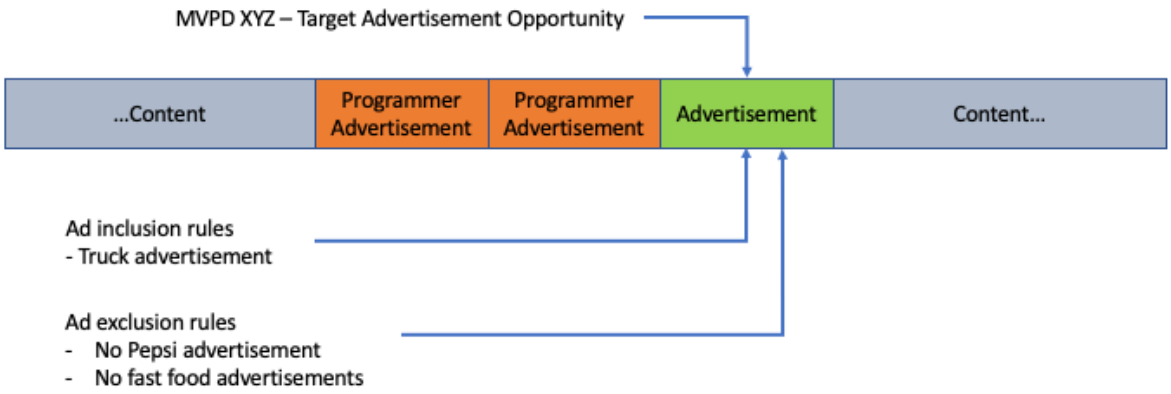

Figure 4 -- Conflicting Rules

Examples of these rules include, but are not limited to, the following:

1. Showing a specific number of advertisements or limiting the number of ad spots for a specific product group
2. Specifying a minimum spacing between advertisements belonging to a specific product group
3. Specifying that an ad spot may only be replaced by campaigns that's a member of a specific product category
4. Excluding particular products or categories that might not align with other advertisements in the advertisement pod.

Some real-world application of these types of rules includes not wanting to have a Brand A, a soda ad, and Brand B, another soda ad, appearing in the same advertisement pod. Or showing a national car advertisement followed by a local car dealer advertisement, or not showing an insurance advertisement in every pod.

4.3. Advertising Metadata Information (Intelligent Ad Insertion)

Because of its aforementioned large capacity and flexibility, SCTE 224 can also carry a great deal of information about the advertisements or the content around the addressable advertisement. Examples of these additional use cases include:

1. Scene information - Often ad campaigns are set up on overarching show genre, category, or age group, but if a content provider could convey more information at the scene level, it could be that

much more valuable for the slot. For example, what was last viewed by the audience in the last scene before the break: Maybe it was a car chase. Tying the next advertisement to that visual context, and scheduling into the next appropriate advertisement break a car dealer advertisement would more maximize effectiveness. This linkage could lead to greater CPM values.

2. Actors or other action-based metadata – Similar to the above example, product placement or metadata derived from action within a show (either live or pre-recorded) could be used to drive more intelligent ads and higher CPMs. Examples of this could include knowing the actor or additional scene information.
3. Ad Creative metadata – Using metadata from the previous ad or other ads from the advertisement pod could lead to a more intelligent ad break and higher CPM.
4. Technical ad metrics – Data such as ad duration could be used to ensure ad breaks are not missed, which could result in loss of revenue for the content providers and operators.

5. Conclusion

Ultimately, the benefits of using SCTE 224 to implement addressable advertising are plentiful and could enrich the ad environment for both content providers and operators/distributors. A short list includes:

- Addressable ad slots can be identified uniquely for different operators
- Different ADS can be supported by different operators
- Inclusion and exclusion rules can be conveyed machine-to-machine
- Different inclusion an exclusion rules can be executed for different operators
- Advertisements can be enriched with scene, actor, or creative metadata in ways that strengthen visual ties and could improve overall effectiveness/CPMs.

All of those benefits come with reduced complexity within SCTE 35, because they all can be done with a single simple SCTE 35 trigger; the rest is carried in the SCTE 224 Audience, ViewingPolicy, and Policy construct. This provides a content provider with control and execution within its linear feed. No more multiple versions of a video, just to carry different SCTE 35 markers to different operators, or multiple complex SCTE 35 markers into the video, leading to confusing and problematic interpretations by operators.

The addressable advertising eco-system is still highly complex. It involves and needs much more than SCTE-224 to solve its many nuances, but hopefully we have provided a glimpse into how much it plays a critical role in enabling addressable advertising — for both content providers and operators.

Larry Wolcott, Fellow, Comcast

1. Introduction

The cable industry started taking advantage of proactive network maintenance (PNM) nearly a dozen years ago, and has shared results at many previous SCTE Cable-Tec Expos – so what's new in PNM for 2021? Water. Not the liquid itself, but what it can do to our subscriber drop plant and the services we provide over that plant. Operators have long been haunted by coaxial cable water ingress – since the very first days of the industry. Water ingress is nothing new, but it now has its own special tool in the PNM toolbox. In the grand scheme of things, that tool is a way to sharpen the focus on enhancing the customer experience and network performance, which is where PNM tends to take center stage. (Even, and perhaps especially, when it's raining.)

This paper reviews the progress of water detection, location, and severity assessment in the cable plant. The authors explore the background, motivation, theory and provide an outline for operators to evaluate their networks. In addition, there are field and lab examples which clearly illustrate the importance to customer experience, using customer testimony and speed test results as points of validation. Lastly, the authors provide information to help operators determine the future impacts when considering DOCSIS 4.0's features, such as extended spectrum (ES) DOCSIS and full duplex (FDX) DOCSIS.

2. Background

It has been said that one of the most versatile pieces of test equipment available to the cable industry is the spectrum analyzer. These are instruments that display signals in the frequency domain, and have been used for decades to install, validate, and troubleshoot service on cable networks.

Starting November of 2012, the DOCSIS 3.0 specification was expanded to include spectrum analyzer-like functionality in cable modems (CMs). This feature is known as full band capture (FBC) and is supported by most DOCSIS 3.0 and all 3.1 CMs. Since this time, most cable operator-deployed modems now have the FBC spectrum analysis capability.

This was an important moment for cable operators, creating the opportunity to automate a long-time manual process, known as sweeping. Prior to this time, technicians were required to manually connect broadband test equipment to take measurements of the RF plant. In addition to significantly improving operational efficiency and reducing costs, FBC allows cable networks to be monitored constantly, without a technician being present. This is important for diagnosing intermittent issues which can occur at odd times, often as the result of temperature or weather changes.

Among the earliest recognized impairments (Figure 1) was the standing wave, or more accurately, amplitude ripple which is caused by standing waves. These are characterized by a periodic, or predictably repeating waveform in the frequency response, which may be sinusoidal or scalloped. Standing waves can be classified by a number of parameters including their periodicity and magnitude.

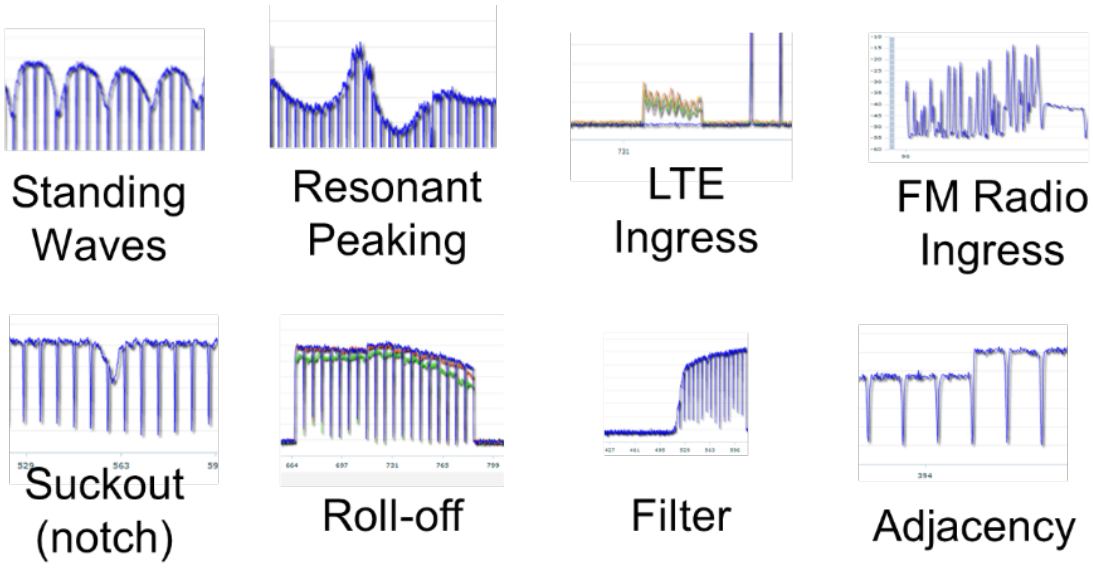

Figure 1 - Examples of impairments found using FBC (Source: Comcast)

As illustrated in Figure 1, there are several common RF impairments which can be detected and classified using FBC. However, there are a few impairment types which do not clearly fall into these general impairment categories. This typically occurs in the case of multiple problems resulting in a compound impairment. The detection software algorithms can become ineffective, sometimes detecting one or the other.

3. Cable RF Spectrum Fundamentals and Water

Some of the basic concepts of cable RF spectrum are illustrated in Figure 2. The horizontal axis represents the frequency spectrum, starting from 5 MHz and ending above 1000 MHz [1000 MHz is the same as 1 gigahertz (GHz.)] RF signals are precisely modulated and transmitted at specific frequencies, and their quality is measured using a variety of metrics: RF power, carrier- or signal-to-noise ratio, frequency response, and more.

For instance, we measure RF power (signal strength) using the decibel millivolt (dBmV) rather than watts. This is because the range of RF signal power in cable networks is very large, so, expressing those numbers in units of watts gets unwieldy. When comparing two values, we use units of the decibel (dB) because it represents a ratio, although it is logarithmic. One simple rule-of-thumb to remember when using decibels is that a 3 dB change in signal level represents a doubling or halving of RF power. For example, 50 dBmV is twice the power of 47 dBmV.

Notice in Figure 2 that all the RF signal levels across the spectrum are similar, making a nice flat line across the peaks of the signals. However, in Figure 3 there are significant power variations at different frequencies within the spectrum. When things are working properly, the levels should be relatively flat and sometimes may have a tilt in one direction or the other. The overall amplitude-versus-frequency performance of the spectrum is known as the “frequency response.”

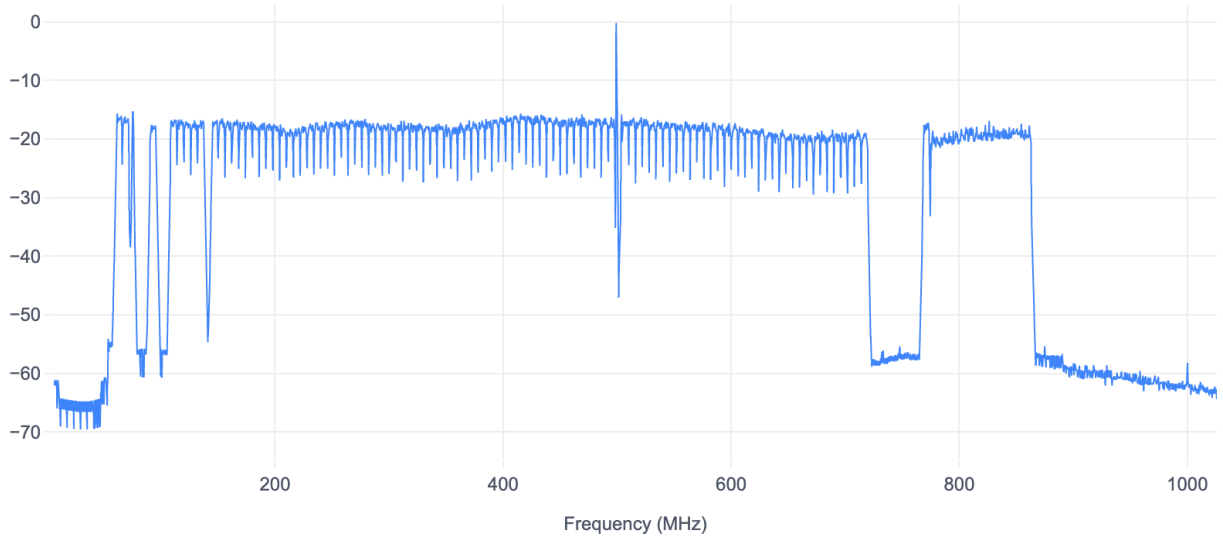

Figure 2 - Unimpaired frequency response

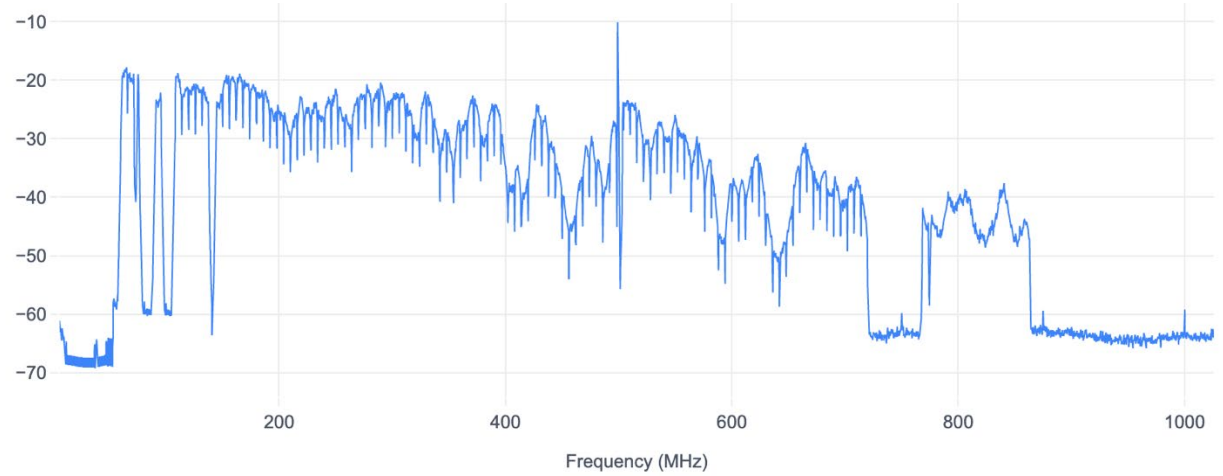

Figure 3 - Water impaired frequency response

When water enters coaxial cable, several things happen to create the distinctive frequency response shown in Figure 3. Why does water in coaxial cable have that effect on RF? The presence of water in the cable's dielectric changes the dielectric constant, which changes the velocity factor, characteristic impedance, and attenuation (see the Appendix for more information on the characteristics of coaxial cable). Further complicating the water-related degradation is the fact that the water is not uniformly distributed throughout the length of the cable. That, in turn, results in randomly distributed, localized variations in the cable's velocity factor, impedance (think micro-reflections) and attenuation, causing a non-periodic shape in the frequency response.

The severity of this problem will depend on the amount of water present in the cable and other factors such as temperature and system RF levels. These problems have been observed to coincide with rainy weather and tend to be variable, sometimes completely clearing when the water drains or evaporates. The

amount of customer impact can be measured with downstream receiver power levels, tilt, per-channel RxMER, and codeword errors or packet loss, which may inform the repair prioritization.

To avoid confusion, another related but different impairment you should be familiar with is known as an amplitude ripple, commonly referred to as a "standing wave." This is especially important because the standing wave is somewhat like our water signature, but there are subtle and not-so-subtle differences. Standing waves are also caused by impedance mismatches and the resulting micro-reflections, but water is not present. Because there's no water to add *random* attenuation, the signal bounces and attenuates in a predictable manner. In the case of a standing wave, a repeating and *periodic pattern* can be seen in the frequency response. Standing waves tend to have a sinusoidal wave shape, but can sometimes have a sharp, scalloped appearance. A standing wave may affect all or part of the RF spectrum. These problems tend to be constant (non-variable) or change very little. The changes in standing waves are subject to environmental influence such as wind or temperature, which can influence the mechanical properties of the plant.

It is most common for our drop cables and taps to be impacted by the presence of water, but it could be feeder or distribution cable affecting multiple locations. Drop cables are easily damaged by squirrels chewing on the jacket and shielding and is very common in some areas. Hardline is also subject to animal chews, radial cracks and holes caused by all manner of hostile forces. It is important to distinguish between drop and hardline because these are sometimes two different repair categories, each requiring a different type of technicians to fix the problem. Generally, a drop cable signature will be common to all devices within a single location and would be repaired by an install/repair tech or business partner (contractor). Larger plant issues would be repaired by a network maintenance technician and can disrupt service for a larger segment of our network. The latter often requires additional attention to scheduling and notification to help limit the negative impacts to customers.

From the customer's perspective, excessive RF signal attenuation is typically experienced as diminished quality and reliability of their internet or video experiences – or, in some cases, it renders those services unusable. What gets affected depends on the specific frequency which is impacted by the impairment. Conventional DOCSIS, video or other system signals can be used to evaluate the severity of the problem. However, given the transient nature of water in our cable systems, these types of problems can be temporal and associated with weather. Therefore, time and environmental components can be used to help with predictability. For example, additional resources may be allocated to a service area in advance of a rainy season.

3.1. Water Migration - Peripheral Damage

In addition to the cable, which is often a primary victim of water ingress, it's also common for the water to migrate and damage peripheral components. When additional network elements are damaged, multiple problems can become compounded and worsened. Among the most common examples are taps, splitters, splices, block splices and all the different filters and pads installed in the drop network.

3.1.1. Water Damaged Tap

In the following example, a water-soaked drop was the primary source of water ingress. However, the tap was physically located at a lower elevation on the pole than where the water entered the cable. With water accumulating over time and the influence of gravity, the water eventually migrated into the tap. A closer look at Figure 4 clearly shows water droplets in the upper left and lower right corners of the tap faceplate. The circuit also shows rust and other signs of corrosion. The subsequent frequency responses were captured before and after the faceplate was replaced. The FBC spectrum in Figure 5 represents a typical high-frequency roll-off starting around 500 MHz, becoming dramatically worse at 750 MHz (nearly 30

dB). In this case, the OFDM channel was significantly impacted, causing severely degraded service performance. Figure 6 shows the frequency response improvement after replacing the water-damaged faceplate.

3.1.2. Water Damaged MoCA Filter

Virtually any passive or active network element can become subject to water migration. In some cases, the water can indirectly affect the network elements, resulting in unexpected impedance mismatches. The following example shows an in-line MoCA point-of-entry filter located at the ground block. Like many other types of filters, these passive devices are sealed against water ingress. However, when the drop cable jacket is compromised, the water can easily migrate along the center conductor or dielectric, where there is no water barrier. In the example shown in Figure 7, the filter became filled with water, froze, and expanded, causing the press-fit housing to become separated. The entire assembly was recovered from the field including the drop cable, filter, and ground block. Upon inspection, the Series 6 drop cable was damaged near the tap-side fitting (Figure 8) which is highly consistent with rodent chew marks, commonly seen on drop cables (Figure 9). In this case, there was no water immediately present at either connector interface. However, when a vacuum was applied to one end, the water quickly migrated and became evident at the connector (Figure 10).

The condition and integrity of the outer jacket is critically important to protect the cable plant from water ingress. While evaluating several damaged filters, water ingress and freezing could readily be attributed as the cause. In each example, the water ingress point could be located. Figure 11 shows more examples of typical jacket damage.

3.2. Test Results

A number of field trials were conducted in 2020 resulting in a large number of cable samples recovered from the field. In one trial, over 100 drop cables were located and replaced, providing a substantial sample group. Other control groups of bad drops were also brought in from the field. In the latter group, the damaged drops were not necessarily associated with water.

In the example, Figure 12 shows the frequency response of a water-soaked drop cable (bottom) compared with the same type and length of new, unimpaired cable (top). Pockets of severe attenuation can be observed.

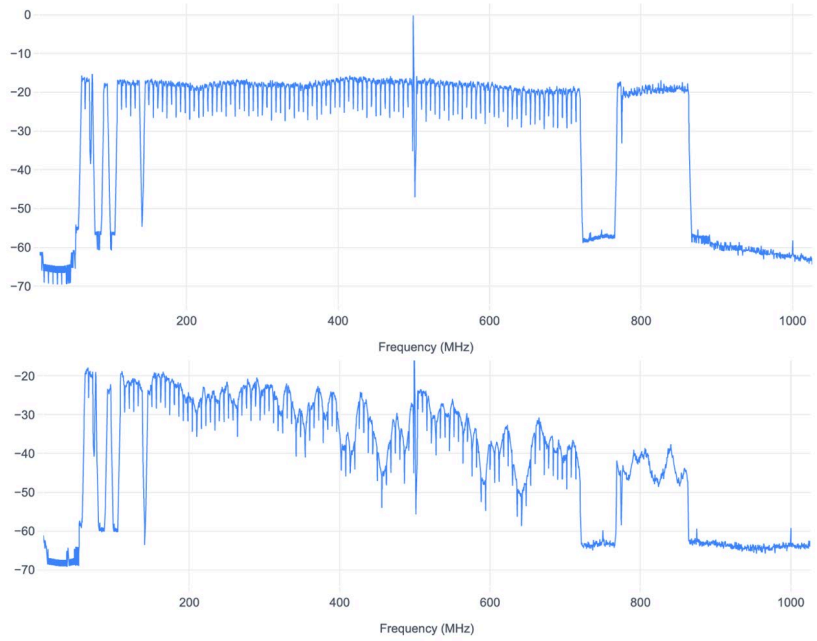

Figure 12 - New drop cable (top) compared to water-soaked cable (bottom)

These two cables were analyzed with test equipment including a speed test which closely approximates the experience a customer would have. A number of these tests were run and Figure 13 shows a typical result. The top value of 1262.7 Mbps download speed is consistently achieved using a new 95-foot RG6 drop cable. Then, when using the same type and length of cable with water damage, a speed of 179.3 Mbps is achieved. This is significantly below the provisioned speed of 1200 Mbps, delivering only 14% of the provisioned performance.

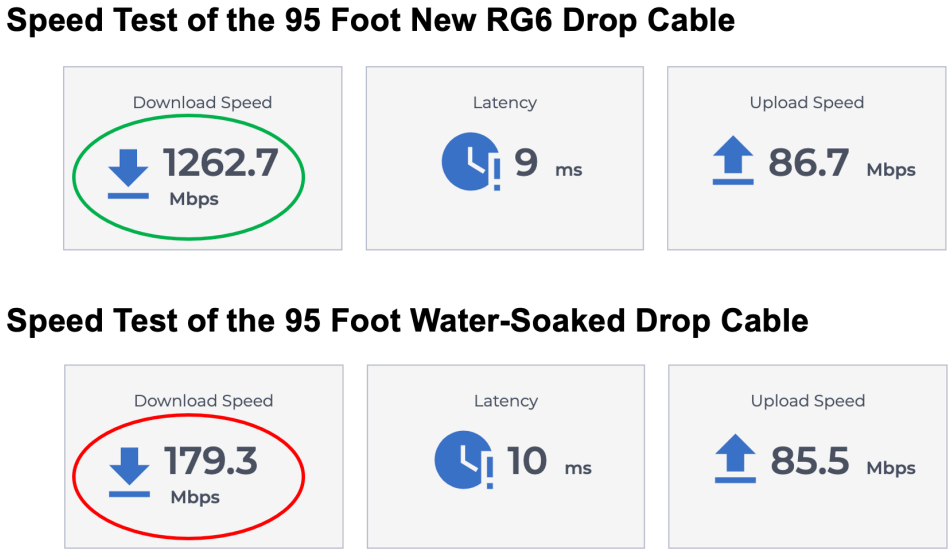

Figure 13 - Speed test comparison of new vs. damaged drop cable

To examine the influence of temperature, the same damaged cable was frozen (Figure 14) at -10 degrees Fahrenheit. After freezing, the frequency response was measured (Figure 15) and the attenuation greatly improved, having well over 25 dB improvement at certain frequencies.

At the same time, speed tests were run, and the results are show in Figure 16. When the damaged cable is frozen, the speed test results improved dramatically. A speed of 1078.4 Mbps was achieved, reaching nearly the same speed of a brand-new cable. Then, within minutes, the cable thawed and was retested at 68 degrees Fahrenheit. When the frozen water returned to a liquid state, diminished speeds returned. In this example, a paltry 70.9 Mbps was the peak download speed.

4. Customer Impact

4.1. About Customer Experience

As previously discussed, water-soaked cables are a regular occurrence in most cable systems. Regardless of underground or overhead construction, cables can become damaged or otherwise deteriorate, allowing

water to ingress and eventually migrate through the length of cable. Depending on the cable's exposure to the elements, the impact on the customer experience can be highly variable.

4.2. Customer Experience – A Typical Example

In the presence of water damage, it's common to hear from our customers that their service was poor and unreliable. In the following example, FBC was used to identify an individual subscriber drop that had water damage, specifically by the unique signature in the displayed frequency response. As Figure 17 shows, the response has a non-periodic wave shape, and attenuation increases dramatically at higher frequencies. Remote polling of the modem showed that most of the downstream SC-QAM signals had poor performance, as shown in Figure 18. The upstream was relatively unaffected.

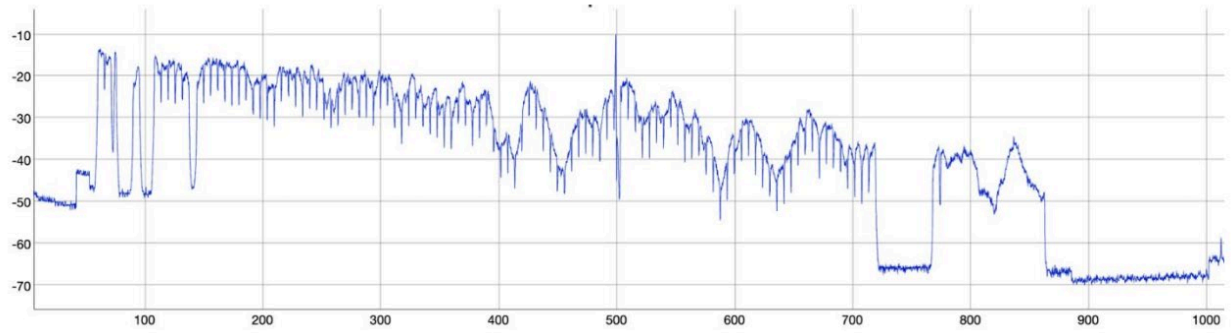

Figure 17 - Water damaged cable frequency response, prior to repair

Note the non-periodic wave shape in the FBC response in Figure 17 and the higher attenuation at higher frequencies. This example occurred when abrasion damaged the cable's jacket, allowing water to enter the cable.

Figure 18 - Impaired downstream SC-QAM power and RxMER levels, per channel

As seen in Figure 18, most of the downstream SC-QAM signals have low signal level and degraded RxMER, indicated in red shaded boxes. The upstream was relatively unaffected.

Technicians went to the subscriber location and were able to find and fix the problem without having to enter the premises. Figure 19 shows the coax jacket, which had been damaged by abrasion from the electrical service drop. The damaged coax jacket allowed water to enter the cable and travel inside of the cable all the way to the ground block. Figure 20 shows water coming out of the connector at the ground block end of the drop.

Figure 19 - Damaged coax jacket where water was able to enter the cable

Figure 20 - Water coming out of the end of the connector at the ground block

The fix was to replace the subscriber drop from the tap to the ground block. Figure 21 shows the FBC screen shot after the new drop was installed, and Figure 22 the post-repair SC-QAM performance.

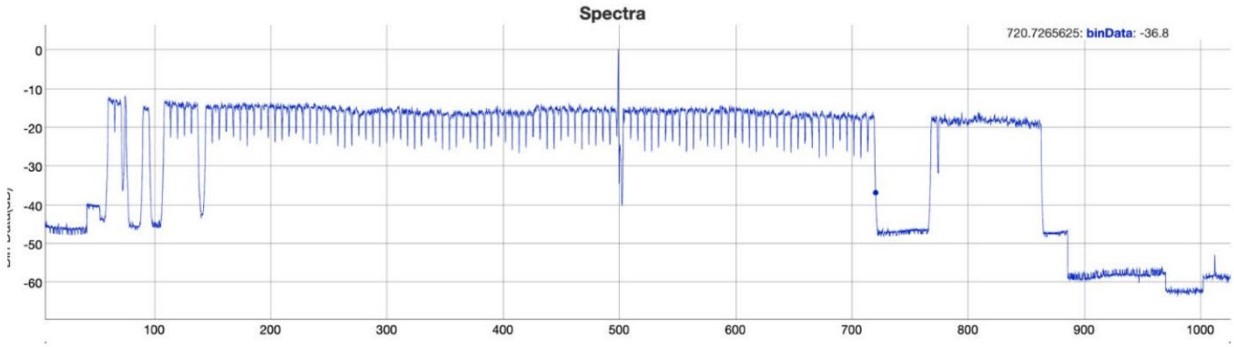

Figure 21 - FBC response after drop cable was replaced from the tap to the ground block

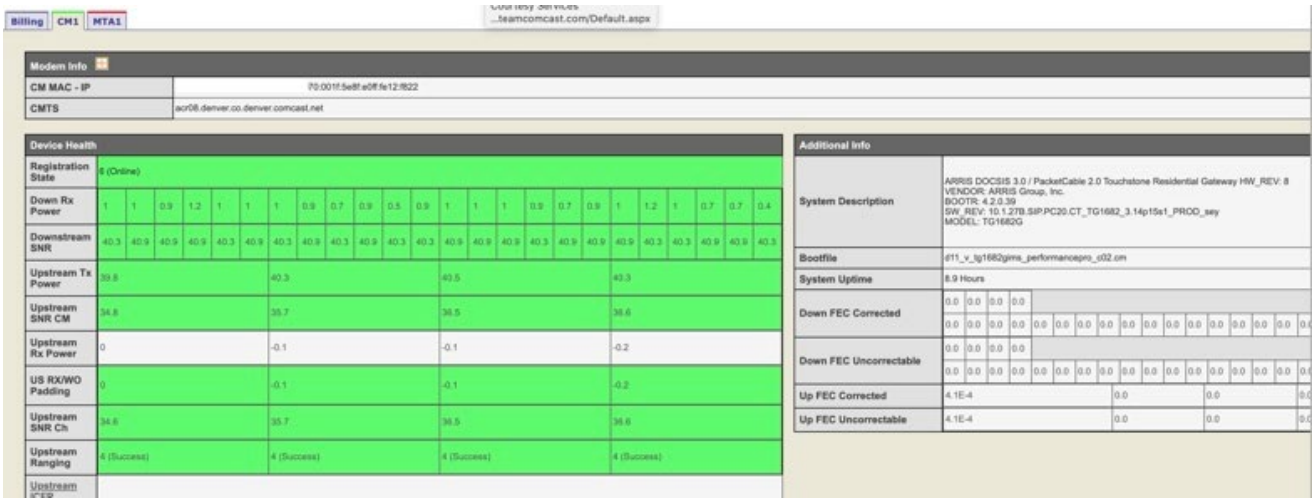

Figure 22 - 40+ dB RxMER, signal performance after drop cable replacement

4.1. Environmental Influence

The impact of temperature and thermal influence on cable networks is well-known. When the cable plant is structurally intact, the system is designed to cope with hot and cold temperatures. However, when the characteristic impedance is compromised, things can become predictably unpredictable.

4.2. Severity Assesment

Fortunately, as illustrated in Figure 23, our fundamental DOCSIS signal quality measurements are excellent for determining the customer impact. The water causes a directly observable degradation in downstream signal power, which can result in degraded receive modulation error ratio (RxMER) and ultimately poor, unreliable performance. Figure 23 enumerates the basic order for conducting a customer impact and severity assessment.

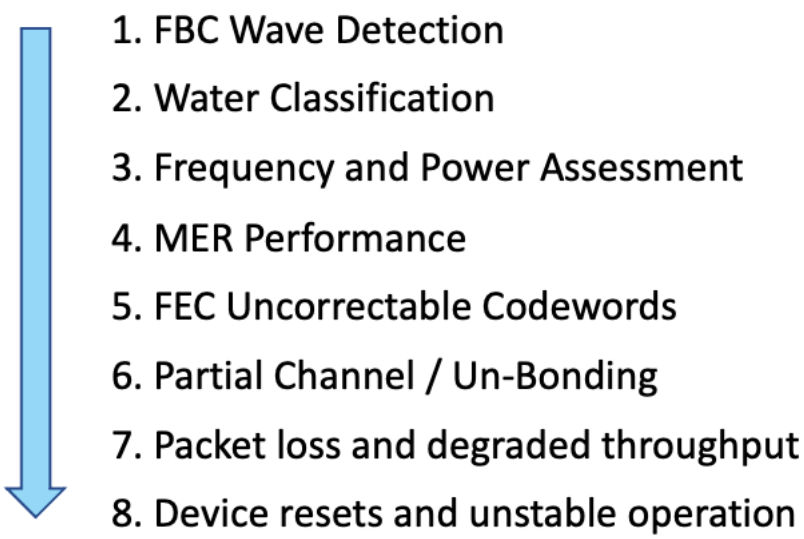

Figure 23 - Severity assessment

Beginning from step 3 in Figure 23, it's common for operator tools to provide some if not all the information. It's fair to say that operators have already been dealing with the outcome of water-soaked cables. Unfortunately, lacking the detection and classification of water damage, the repairs can be inconsistent and often-times, unpredictable. And when the technician has some information about the likely cause of the problem, knowing what to look for is easier so troubleshooting can be faster, and repairs are more likely effective.

4.3. Proactive Repairs

By adding steps 1 and 2 in Figure 23, operators can proactively identify and attribute water damage as the cause. One of the common effects of water damaged cables is a progressive decay of service quality. This is influenced by a number of factors including the amount of moisture, freezing, thawing, heating and cooling. These environmental influences contribute to water migration and accumulation. In some circumstances, these damaged cables can be detected, located and repaired prior to affecting the customer's service.

5. Water Wave Detection Methods

This section covers the methods defined for automatically differentiating between impedance mismatch-related standing waves and water in a coax cable. When it was discovered that there were visually discernable differences between the two impairment types, work began to algorithmically differentiate between the two impairment types. With a few known results to start with, we have tested these methods enough to develop them. After applying the methods to known test results, one known wet drop was added to the PNM test rack at CableLabs and further confirmed after time, after some drying of the cable, too.

5.1. Generalities

Figure 24 shows a typical standing wave in downstream spectrum capture data on the top, while Figure 25 shows the same for a water-soaked cable. The second plot in each figure shows the respective spectrum data after inverse Fourier transform (IFFT) filtered autocorrelation time domain values, and the last graphs in each are cumulative distribution functions (CDFs) of the time domain values obtained by ordering the values after the IFFT from largest to smallest and taking the cumulative values for each observation. Note the differences between the standing wave and water wave plots. First, the waves in the spectrum data are scalloped and repeating in the standing wave case (standing), but do not follow closely any repeating pattern in the water-soaked cable case (wet). Looking at the transformed data in the middle plots of each figure, the standing case appears to have a strong peak, whereas the wet case is more spread out. Translating these data into CDF plots at the bottom of each figure, we see that the standing case has an initial spike and then a more gradual curve up, whereas the wet case starts lower and has a steeper initial climb.

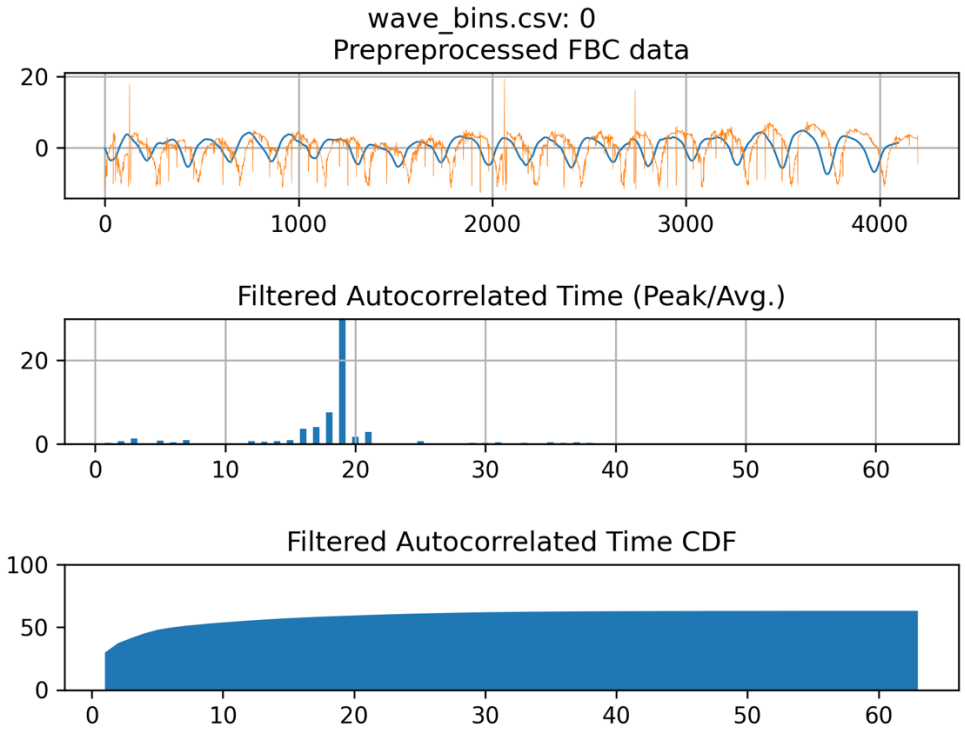

Figure 24 - Standing wave spectrum capture plot, IFFT transformed time domain plot of that same spectrum data, and a CDF of the time domain data

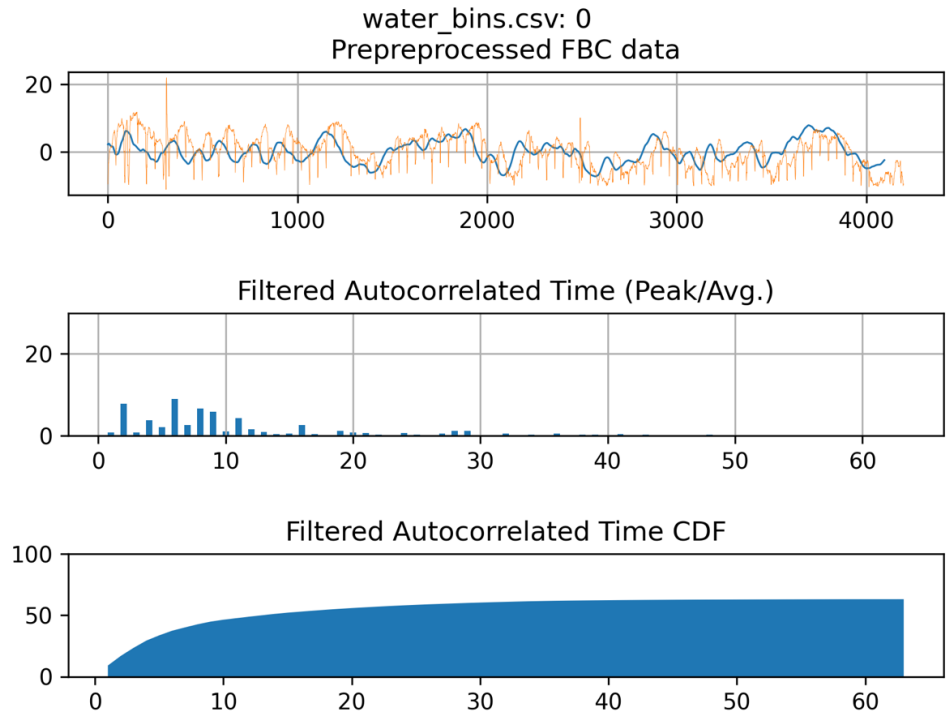

Figure 25 - Water wave spectrum capture plot, IFFT transformed time domain plot of that same spectrum data, and a CDF of the time domain data

5.2. Test 1: Comparisons of a known wet drop and a like section of drop cable.

We obtained a drop from the field which we could visually confirm the existence of water in the drop. We then created a new drop using the same cable length and type for comparison in the tests that follow.

For another indication of the existence of water in a coax cable, see the S_{12} measurements for a normal unimpaired section of coaxial cable (Figure 26) versus the same type of cable that has been affected by water (Figure 27). Note the loss as a function of frequency is rather smooth in an unimpaired cable, but it is not smooth at all in the case of a wet cable. For a treatment of S-parameters including S_{12}, see the PNM point of view document on full duplex DOCSIS® or Ron Hranac's *Broadband Library* article on the subject (https://broadbandlibrary.com/a-quick-look-at-s-parameters/).

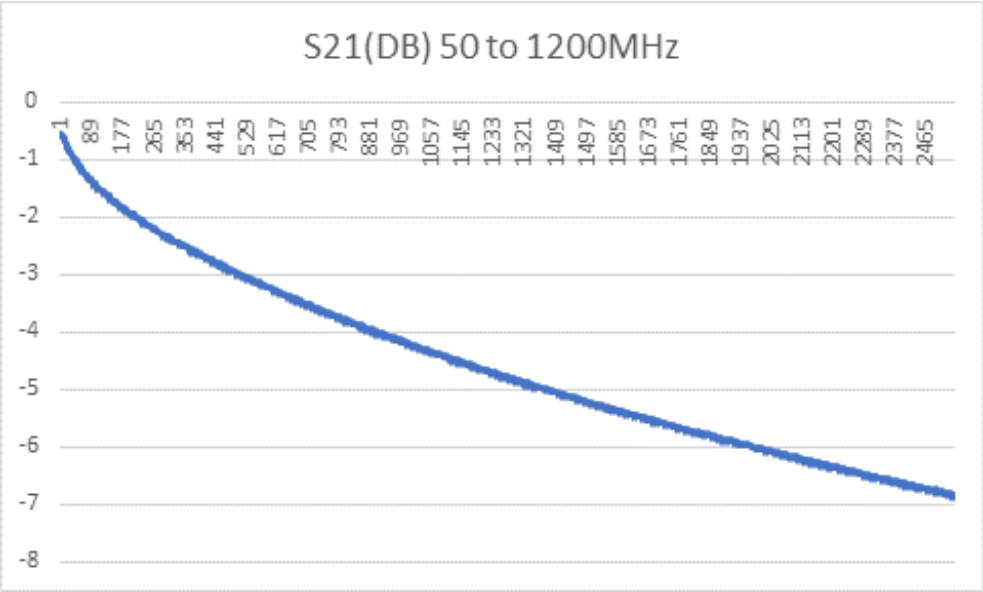

Figure 26 - S_{21} for a normal, unimpaired drop

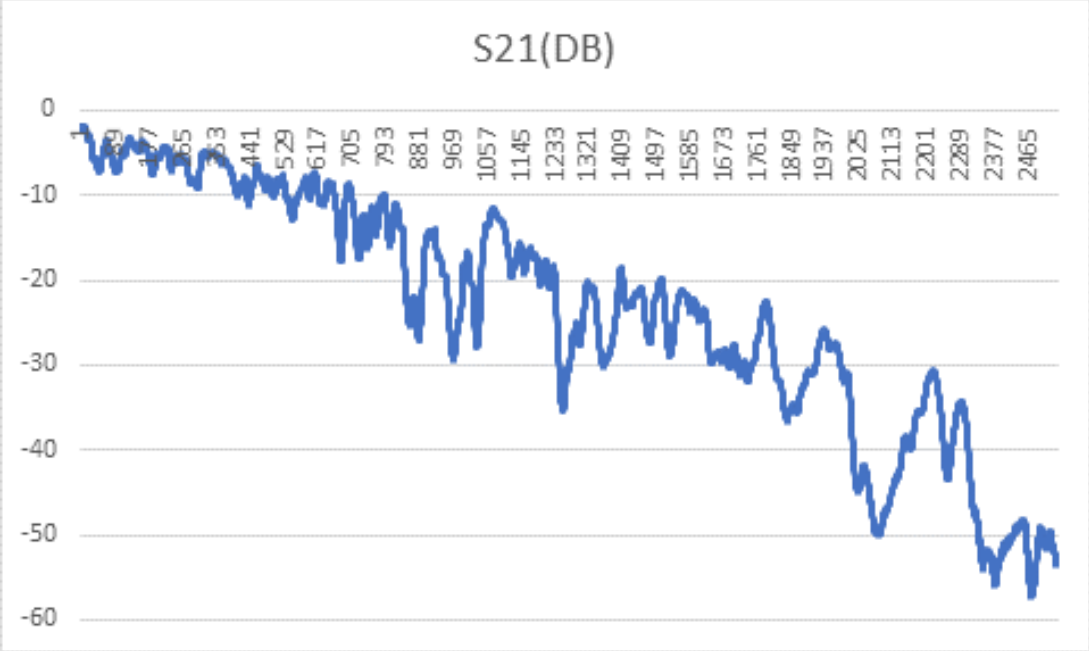

Figure 27 - S_{21} for a water-soaked drop

Next, we examine the group delay of the wet cable, as shown in Figure 28. Note that the group delay is uneven to a small degree over the measurable frequencies, and then at about 1500 MHz measurement isn't possible so the plot shows much higher variability. Ignoring the portion of the plot that is noise and not measurable above 1500 MHz, we see that group delay variation appears in wet cables.

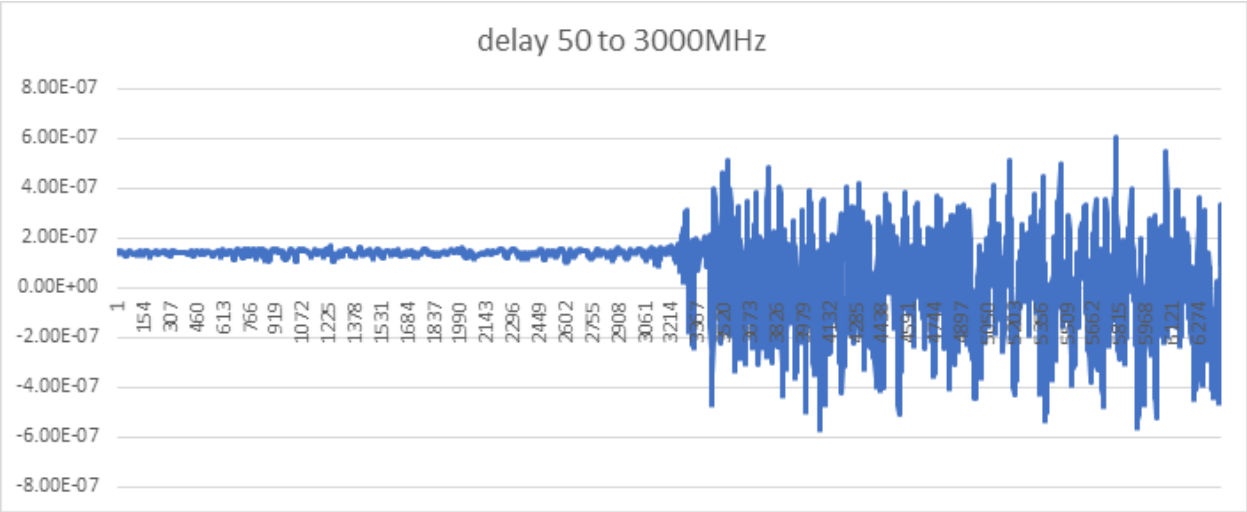

Figure 28 - Group delay for a water-soaked cable

Next, we apply a time domain reflectometer (TDR) to a pair of cables, one wet (WWI cable) and the other in good health (100 ft Series 6), both the same type and length of cable. Here we display the S_{11} and S_{22} values which are reflection coefficients. We see that more energy is reflected in the wet cable compared to the dry cable. Note that we aren't claiming that the entire length of the wet cable is filled with water; we have no way to measure how much of the cable is water soaked and to what degree. We are only showing that some amount of water in the cable will appear differently in reflection measurements (S_{11} and S_{22}).

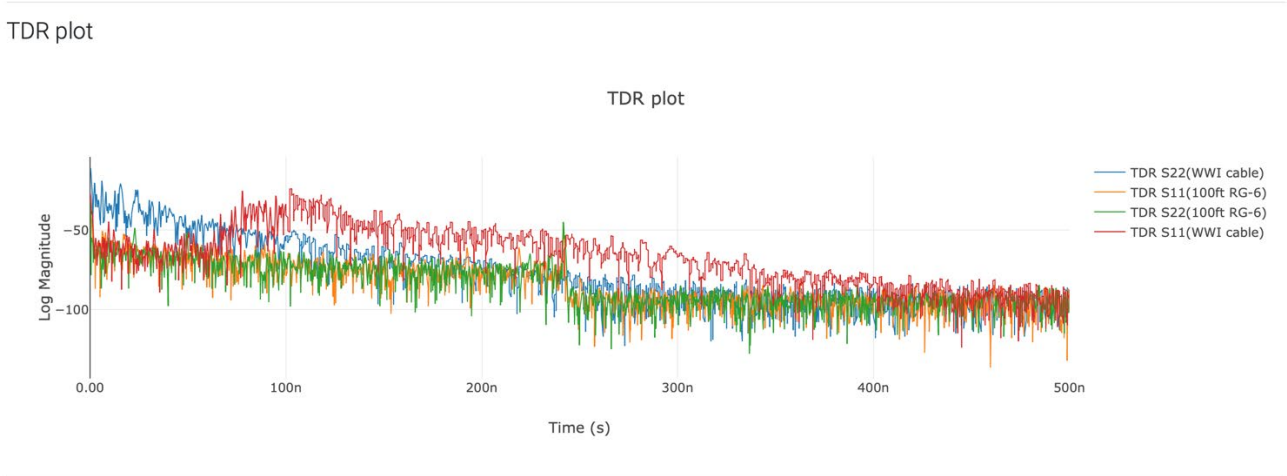

Figure 29 - S_{11} and S_{22} measurements of wet (WWI cable) and dry cable, both 100 feet of Series 6 cable.

Next, we compare the same two cables' S_{11} group delay values. Note again that the wet cable shows variability over the measurable frequencies before about 1.5 GHz, and lots of noise over the higher frequencies that are not reliably measurable. But the unimpaired cable shows nearly flat across the entire

plot, at both lower and higher frequencies. Clearly, wet cable has reflective properties, and impacts group delay as well.

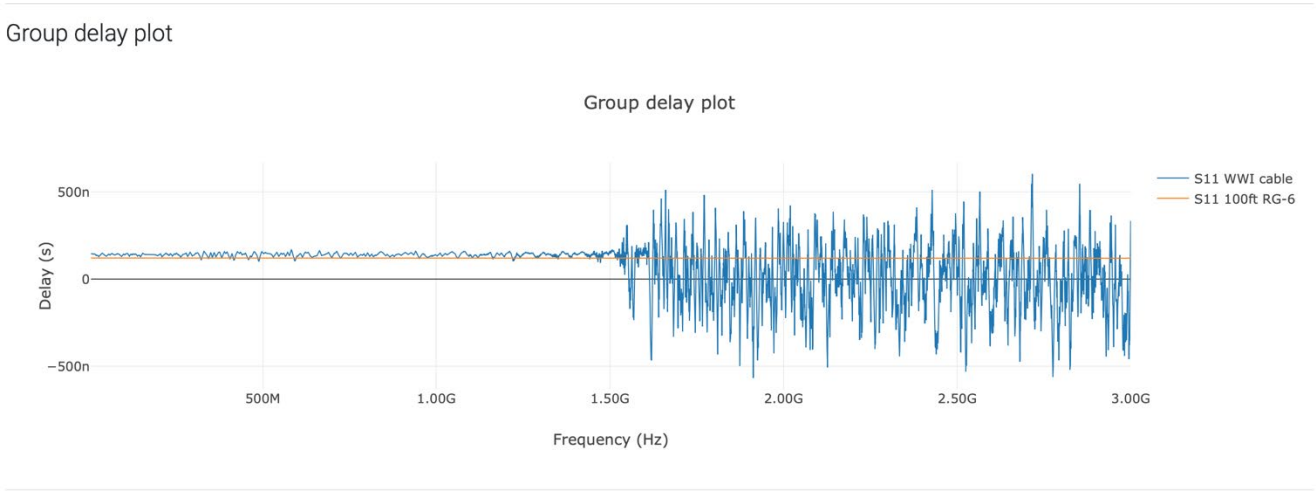

Figure 30 - Group delay plot of S_{11} values for a water-soaked cable (WWI cable) and a clean, unimpaired, dry cable, both 100 feet of Series 6 cable

Looking at the magnitude S-parameter values for these two cables, shown in Figure 29, we see several differences.

- Comparing S_{11} values, the wet cable's values (blue) are higher and slightly more variable than the dry cable's (orange).
- Comparing S_{12} values, the wet cable's values (green) are highly variable and are lower values than the very stable and higher values for the dry cable (straight red line).
- Comparing S_{21} values, the wet cable's values (purple) are again highly variable and are lower values than the very stable and higher values for the dry cable (straight brown line).
- Comparing the S_{22} values, the wet cable's values (pink) are higher and a bit less variable than the values for the dry cable (grey).

While any of the S-parameters can be used to differentiate a wet cable from a normal dry cable, S_{12} and S_{21} appear to show the difference most clearly.

Note: We have not tested and shown a cable with a standing wave for comparison. A follow up step would be to include other types of cable impairments to see if S-parameters can be used to differentiate between different types of impairments. But because the S-parameters can technically define whether a cable is impaired or not, the exercise would be only to determine if S-parameters can be used to differentiate between different types of impairments.

Our primary concern with this test is to find data we can utilize to differentiate between an impedance mismatch-related standing wave and a wet cable. Both are impaired, but a wet cable may be more difficult to spot visually in the field, yet likely isolated to a small span of hard line or a single drop and may be easy to isolate using FBC in CMs.

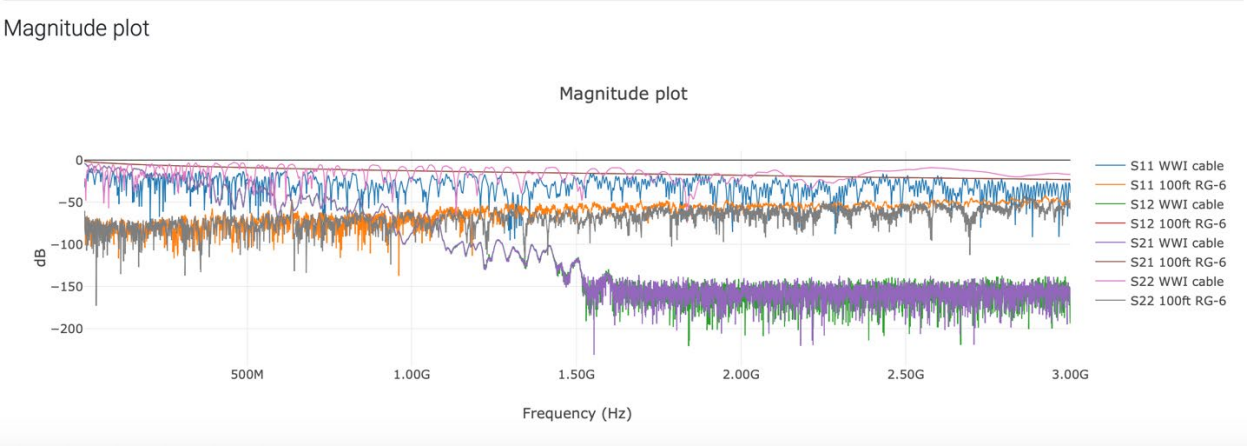

Figure 31 - S-parameters for a wet cable (WWI cable) and a dry, unimpaired cable of the same length and type: 100 feet of Series 6 cable

5.3. Methods for differentiating water from standing waves in coax

The previous test results suggest a few competing methods for determining whether a coaxial cable has been impaired by water intrusion versus is damaged in a way to cause a standing wave. In this paper, we show three promising methods.

We outline two early methods here, and show evidence of their utility, with the expectation that future tests will allow us to compare the effectiveness of these methods and perhaps develop improved methods. Both methods rely on spectrum data obtainable from the CM but can be applied to spectrum data from other sources. An advantage of these simple methods is that they rely on common modem spectrum capture data, and complex data. But we intend to research other methods and data sources for comparison and to improve the reliability of our methods. The intent of these two methods is to identify impairments that can be quickly found and repaired with a clear net positive impact on service and plant health.

Both methods explained here rely on removal of spikes and other noise in the data through smoothing methods, and then the samples are normalized for processing.

A third method is explained here as well, which takes a TDR-like approach and applies a simple threshold, which is consistent with other methods in use, and will be easy for technicians to follow.

5.4. Tom's IFFT method

CableLabs' Tom Williams suggested a simple IFFT of the spectrum data, then to manually look for the clear difference in the time domain data. Group delay in the wet cable should reveal more energy later. Tom's method is essentially as follows.

1. Take a spectrum response, then filter, flatten, and interpolate to remove high level responses such as pilot signals, and low-level responses such as unused spectrum.
2. Apply an IFFT to produce an impulse response to look for dispersion.
    a. If one or two narrow lines are found, this indicates a standing wave.
    b. If the time response is distributed beyond one or two lines, water in the cable is indicated.

3. To improve detection, apply autocorrelation to the time response data. Measure the impulse response coefficients relative to the DC term, remove the two largest coefficients, and remeasure the coefficients. Search for a small drop from these two coefficients to the third as an indicator of water.
4. Search for a downward tilt in the spectrum plot, from low frequencies to higher frequencies. If this tilt is not intended in the plant design (which should be very rare), this is another indication of water in the line.

Tom further tested his method on several suspected CMs whose data were obtained from the field but not all confirmed as standing wave versus wet. Using the suspected impairment categories, he plotted the tilt and an error ratio improvement relative to DC, then drew a line between the categories to form a function that can serve as a threshold for differentiating the two impairment types. The method is updated then as follows.

1. Remove tilt from spectral response. Record the tilt.
2. Perform an IFFT to get time domain data.
3. Select time samples <65 to eliminate the tallest wave response.
4. Record error ratio improvement relative to DC term.

Figure 32 shows a plot of the resulting tilt and ratio statistics from 10 standing waves (as seen in the spectrum data manually) and 10 wet waves (also as seen in the spectrum data).

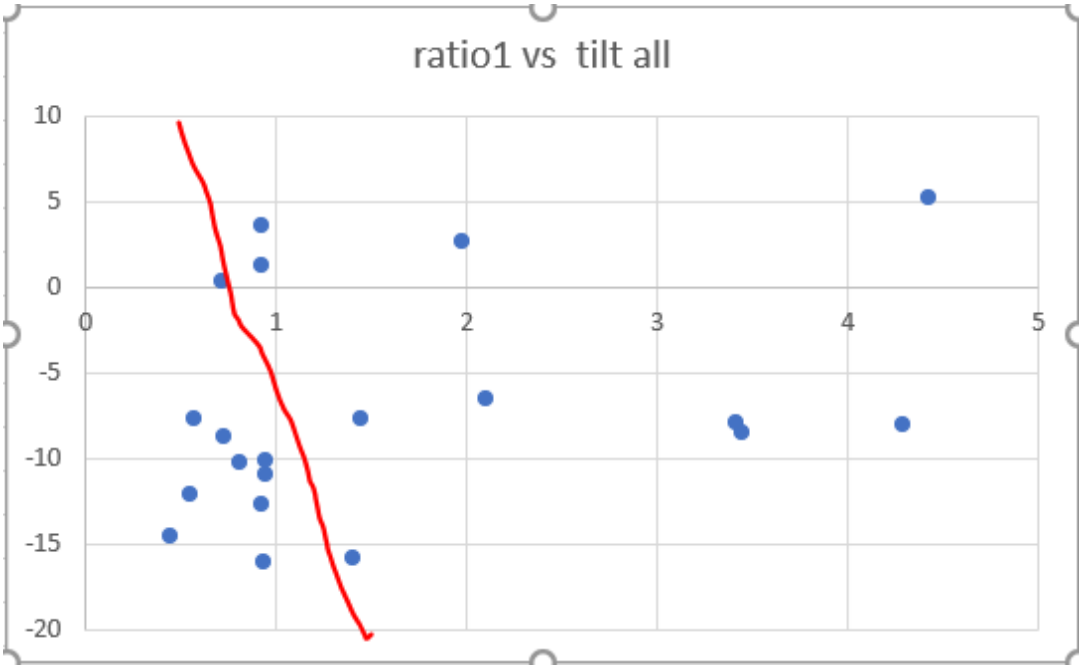

Figure 32 - Error ratio versus tilt, showing a red line that differentiates between a wet cable (left and below) versus a cable with a standing wave (above and right)

Because these 20 spectrum captures are from CMs that have not been confirmed to have standing waves versus water waves, we can only say that they were impaired, and that the two impairment types were

visually clustered. Further, these 20 results were picked from a much larger pool of CM responses for their obvious impairments and strong visual differences in the two types of impairment patterns (standing versus wet).

To be certain of the effectiveness of this method, more field data must be collected, and confirmation of the cause should be conducted if the difference is important.

5.5. Jason & Jay's method

CableLabs' Jason Rupe and Jay Zhu, purposely working independently from Tom Williams to come up with a different method, developed a method very similar to Tom's method and extended it to better enable computer programs to differentiate between the two impairment types, relying on proven machine learning and statistical methods to identify that the spectrum data shows an impairment. Once an impairment is discovered to exist, we want to determine whether it is a wet cable or a standing wave primarily.

This method extends off the first by calculating a CDF, then fitting a curve to the resulting data, and using the resulting parameters to differentiate between a standing wave and a water wave. Recall Figure 24 and Figure 25 which showed the CDFs and the initial jump in a standing wave versus the slower climb of the water wave data. By fitting a function to the CDF, we obtain parameters that describe the desired CDF pattern which can then be mathematically compared to rules that will be statistically determined later from field data and can be initially determined using the same data used in Tom's method. The method steps are as follows. This procedure picks up after the spectrum data are cleaned, and an IFFT is performed to obtain the time domain data, which are used in the procedure.

1. In this step, we preprocess the data for additional clean up, and apply Tom's method to get the autocorrelated magnitude values.
2. Calculate the CDF from the time domain data. This requires taking the IFFT results from the spectrum data, in the time domain, and sorting from largest to smallest, then calculating the cumulative of the current and all previous observations for each observation.
3. After calculating the CDF, we fit an exponential curve of the form $a*e^{(-b*x)}+c$ and keep the three parameters.

The parameters of the curve fit are then used to characterize the captured spectrum data from each CM. In the figures that follow, we show a few plots of data from CMs, some with standing waves and others with water waves. Figure 33 is a set of plots from the water impaired drop obtained from the field and then placed in the PNM lab at CableLabs. The data were captured months after placing the drop cable in the lab, and after some drying has taken place. Note that the spectrum plot at the top left almost shows a repeating scalloped pattern, and the filtered autocorrelated time domain values show much energy in a narrow area. This cable may appear almost like a standing wave. This result suggests that a cable that cycles between being heavily water intruded and drying out some may actually look like a standing wave at times. Collecting data over time might confirm the issue, but a CM with this severe of an issue, with neighbors who indicate no issue, should be quick to repair with a drop replacement, regardless of the cause.

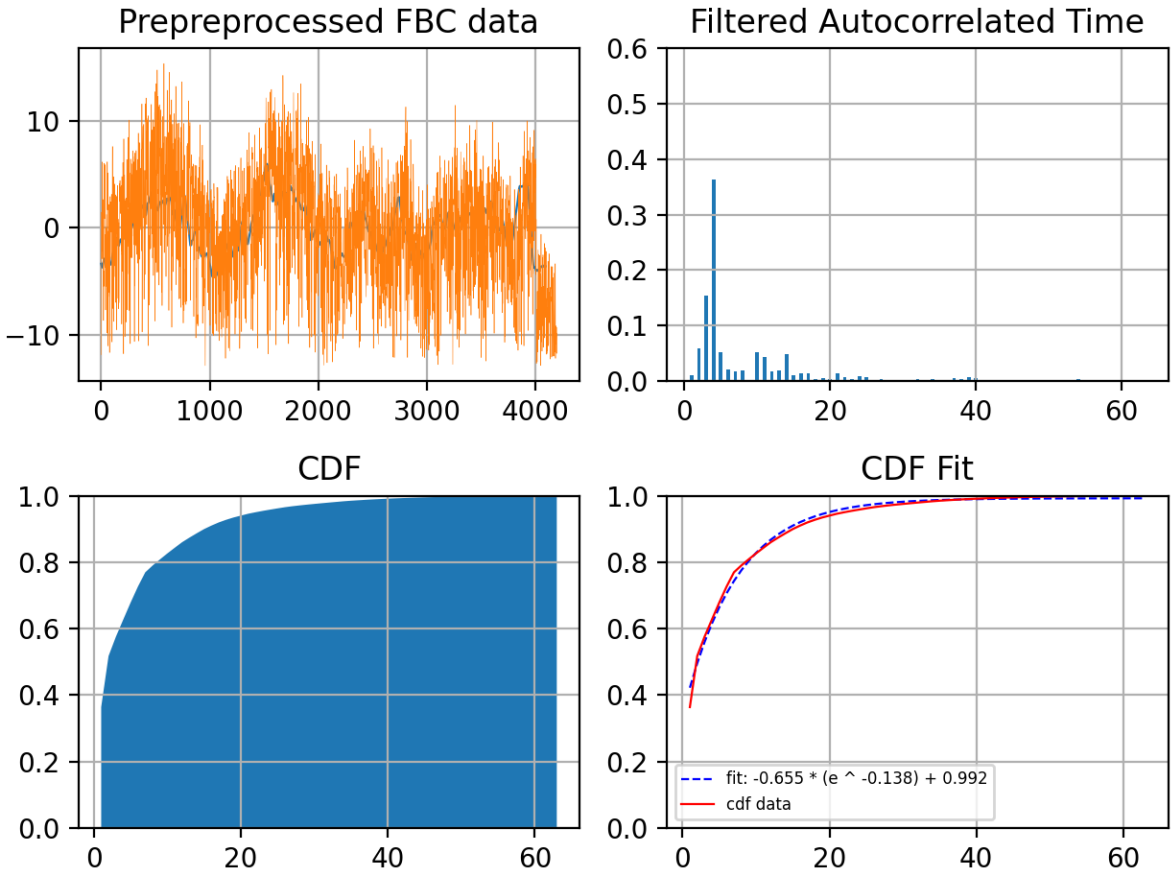

Figure 33 - A confirmed wet drop from the field which has been installed in the PNM lab at CableLabs, and the CM on the end of the drop used to gather spectrum data then processed with the CDF curve fitting method

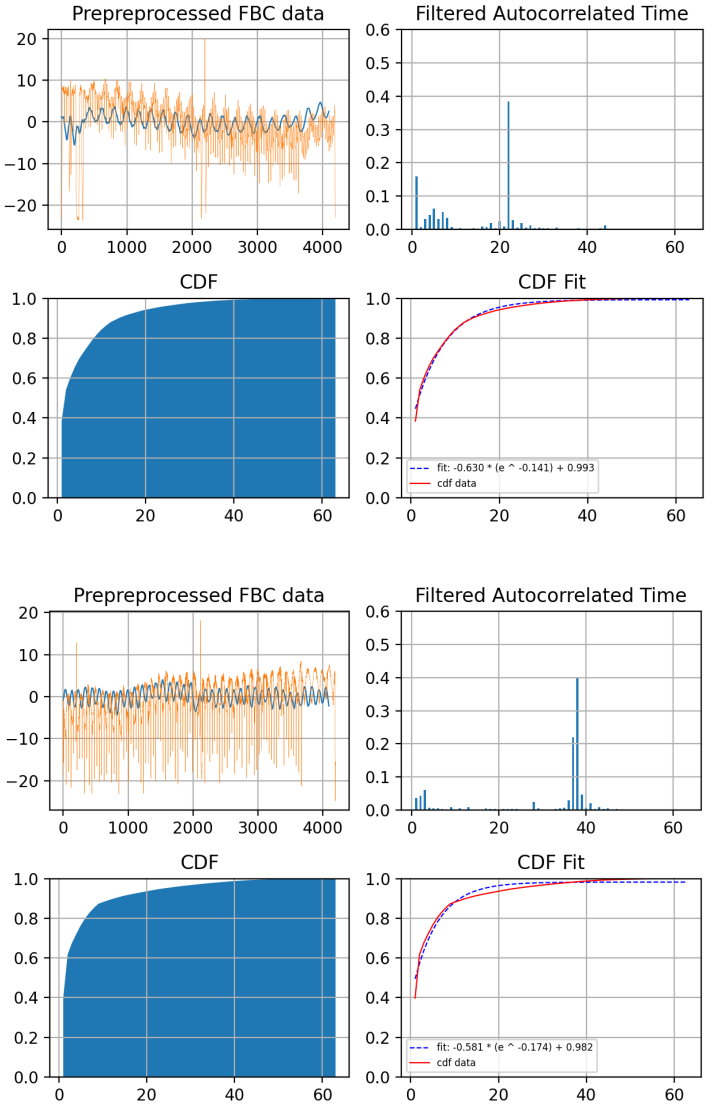
Figure 34, and Figure 35 show a few CMs with standing waves, and water waves respectively, all sampled from the same 10 used in Figure 33 of Tom's method. Note that, as expected, the standing waves show a sharper CDF curve than the water wave CMs do. While subtle, we expect that the CDF parameters will show this difference and allow us to create, through a large sample of confirmed cable sections, a statistical model that can, based on the parameters of the fit, assign a likelihood of water intrusion versus a standing wave in the cable.



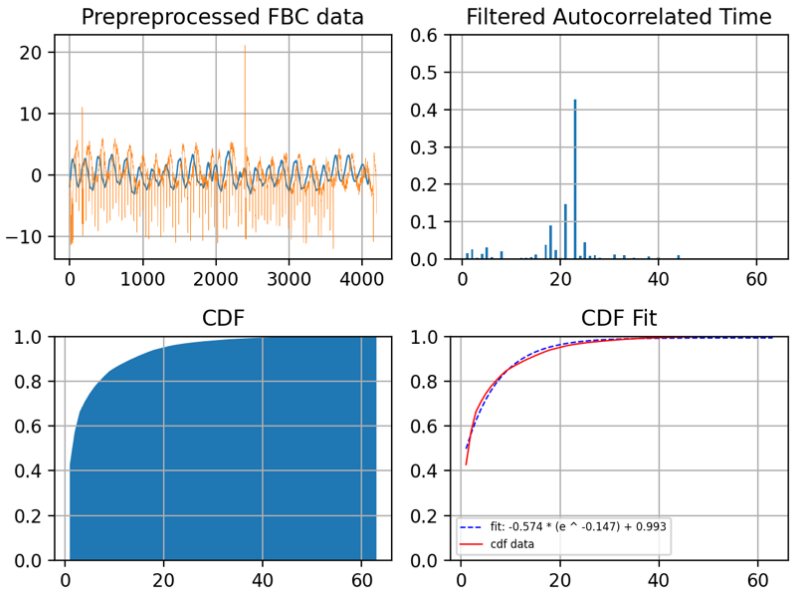


Figure 34 - Three selected suspected CMs with apparent standing waves

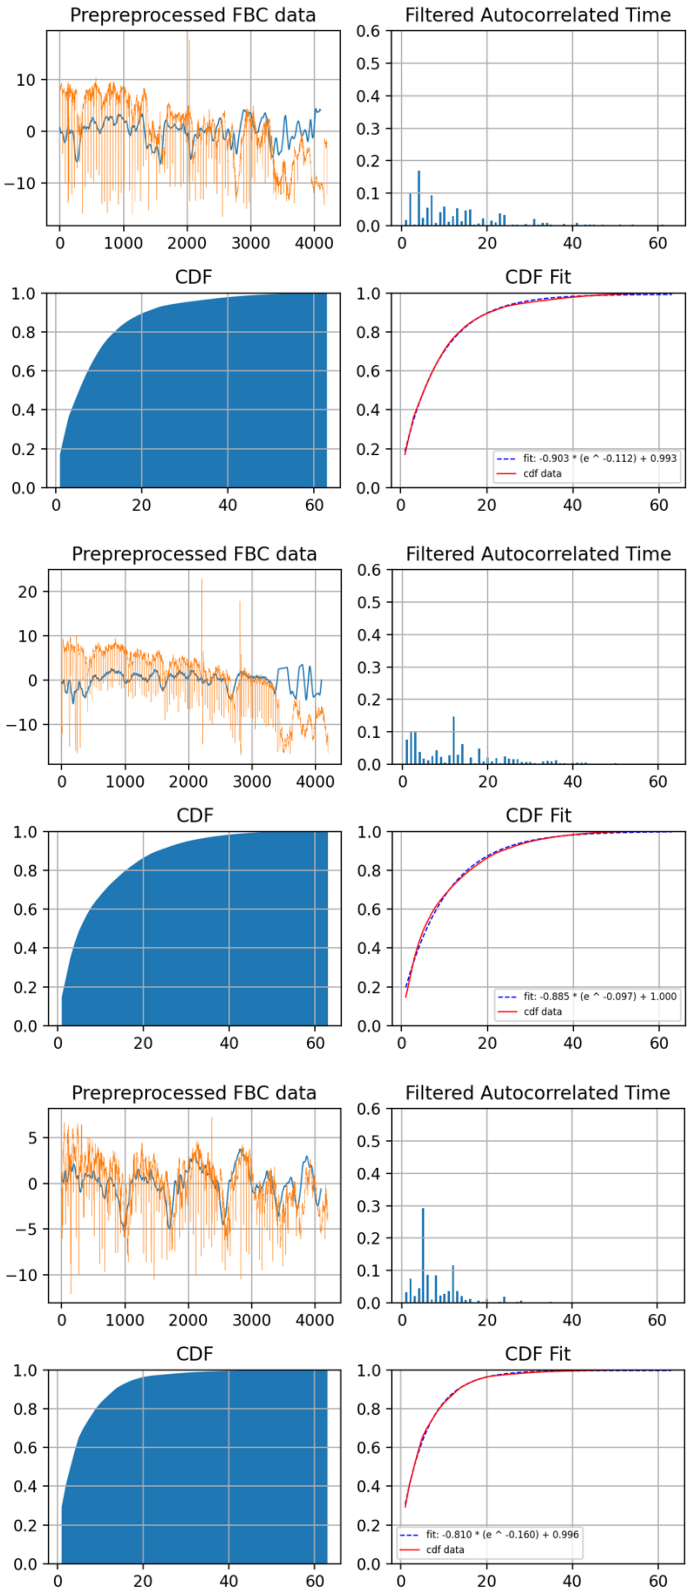

Figure 35 - Three selected suspected CMs with apparent water waves

Extracting the three fit parameters from each of the 20 CMs (10 each believed to have standing waves or water waves), plotting these in 3D in Figure 36, and coloring the point for each CM by the believed class of impairment each has, we see a clear pattern again. Note we show the 3D plot twice in the figure, from different angles, to better show the delineation.

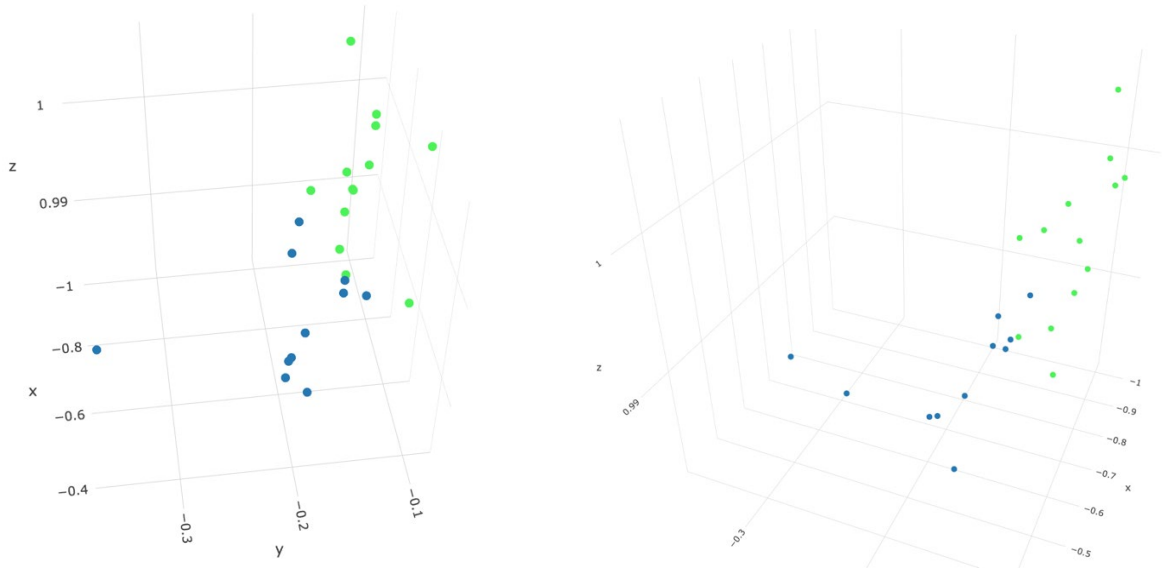

Figure 36 - Curve Fit Plot of Wave Parameters

Figure 36 is a plot, from two perspectives of the three parameters from curve fitting of the 10 CMs with standing waves (blue) and 10 CMs with apparent water waves (green); X=a, Y=b, and Z=c, with X, Y, Z being the plotted values for the parameters a, b, c in the curve fit.
Note that the CMs with suspected water waves tend to have higher (less negative) Y=b values, higher z=c values, and often smaller (more negative) x=a values than those labeled to have standing waves. This pattern can also be seen in the data shown in Table 1, from these same 20 CM spectrum captures (one from each of 20 CMs identified as having either a standing wave or a water wave in the spectrum data) plotted in Figure 33.

Table 1, exponential function fit parameters from the CDFs of time domain data obtained though IFFT method applied to the spectrum capture data from 20 separate CMs, selected from a large group of field data as indicating an impairment, 10 with suspected water waves, and 10 with standing waves. Fitting function: a * e ^ (-b * x) + c.

5.6. Larry's Method

One of most common methods for field technicians to validate the presence of water is by use of a time domain reflectometer (TDR). It is common for a TDR to transmit a fixed-width impulse and capture the reflected response, or echo. The response can be analyzed, in conjunction with the known parameters of the cable (Appendix A) and typically display the fault distance(s). In the case of water reflections, the time domain impulse response shows a distinctive signature compared to a singular point of damage.

By using the full spectrum amplitude bins with some additional processing, the functionality of the TDR can be approximated. Figure 37 shows 3 FBC traces, the top is unimpaired, middle is water damage and bottom are a typical amplitude ripple caused by a standing wave.

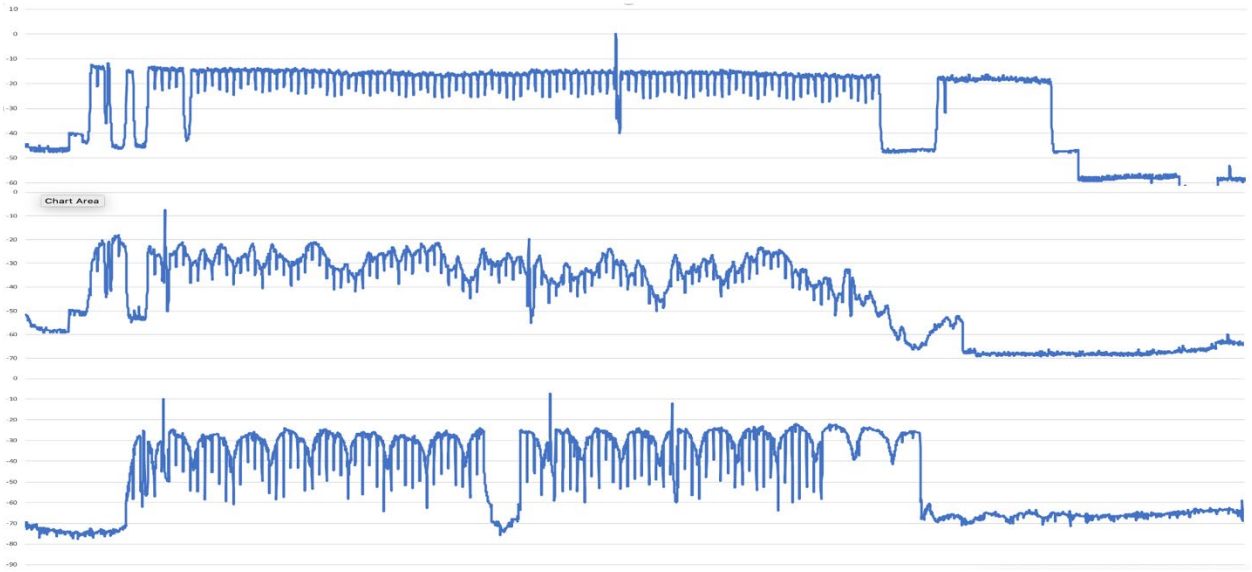

Figure 37 - FBC samples compared, unimpaired (top), water damage (middle), standing wave with amplitude ripple (bottom)

A bit of pre-processing the amplitude bins produces an improved result. The next step illustrated in Figure 38 demonstrates the frequency spectrum with guard band and vacant spectrum being interpolated, or "filled in." In these examples, a simple linear interpolation is done between the SC-QAM and OFDM channel alpha region. This is done to minimize the effect of unoccupied spectrum that would otherwise result as noise in the result. Figure 38 shows unimpaired, water damage and amplitude ripple (top to bottom), after interpolation between the known signal energy.

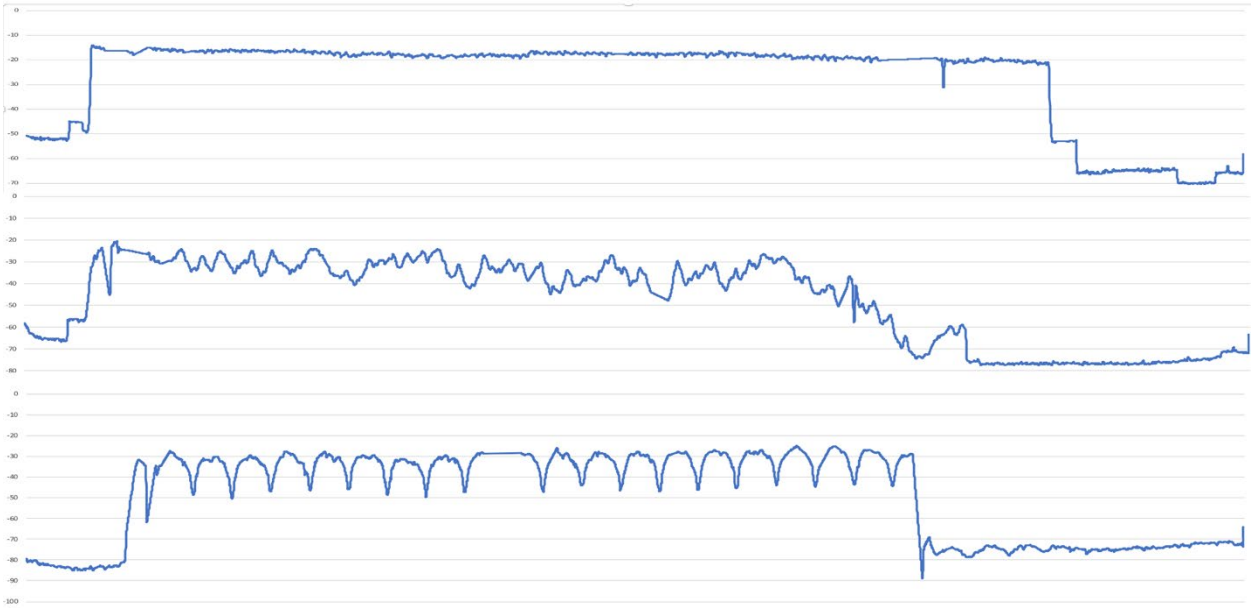

Figure 38 - Interpolated FBC samples with guard bands and vacant spectrum "filled"

After interpolation, the unoccupied spectrum can be cropped, leaving a contiguous block of signal energy, removing any remaining noise floor spectrum. Figure 39 shows the center 4096 bins after removing the other bins. Again, similar to Figure 37 and Figure 38, the top trace is unimpaired, center contains water and bottom is an amplitude ripple caused by a standing wave.

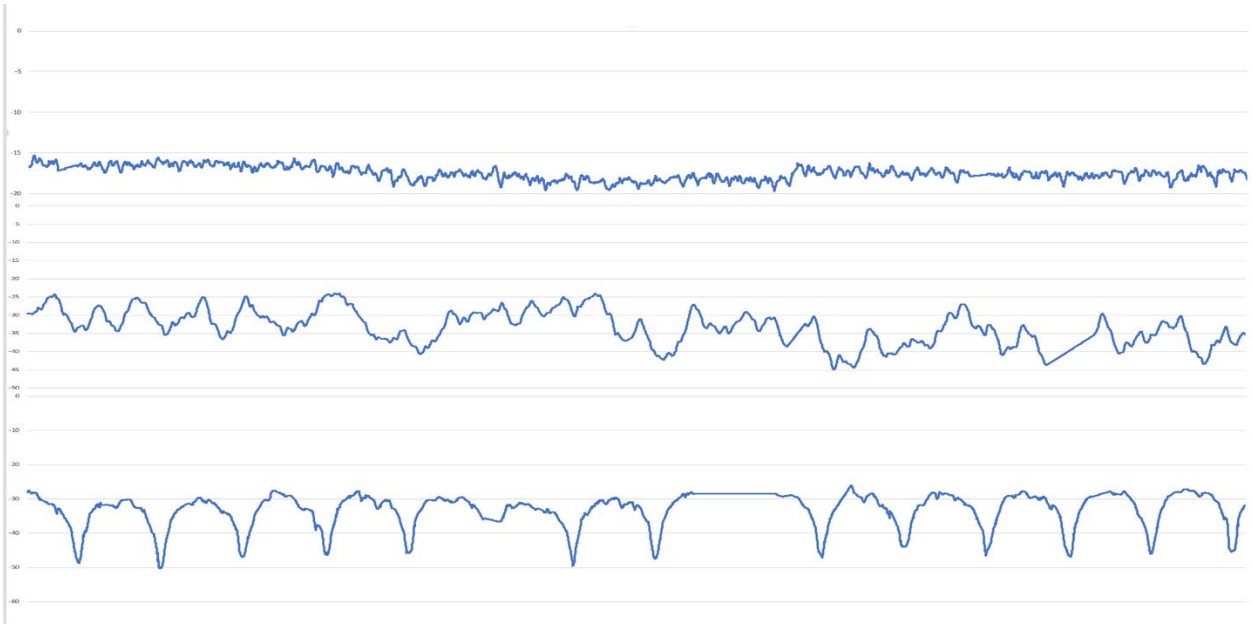

Figure 39 - Samples are cropped to 4096 bins of occupied spectrum

After some pre-processing, the amplitude bins can now be projected to the complex plane, using digital signal processing (DSP). The intent is to perform a Fourier transform to render a time domain impulse response, like the previously discussed TDR. However, the full band capture bins are represented as logarithmic magnitude, meaning the in-phase and quadrature (I&Q) have already been summed and squared. While it is impossible to recover the actual I&Q values, minimum phase assumptions are sufficient derive a reasonable impulse response. This is achieved by instantiating a complex number with zero phase component, uniformly for each bin. Then using an IFFT, the impulse response is obtained (Figure 40). Notice that the top unimpaired trace shows no echo, center trace shows energy spreading and bottom has a singular echo response.

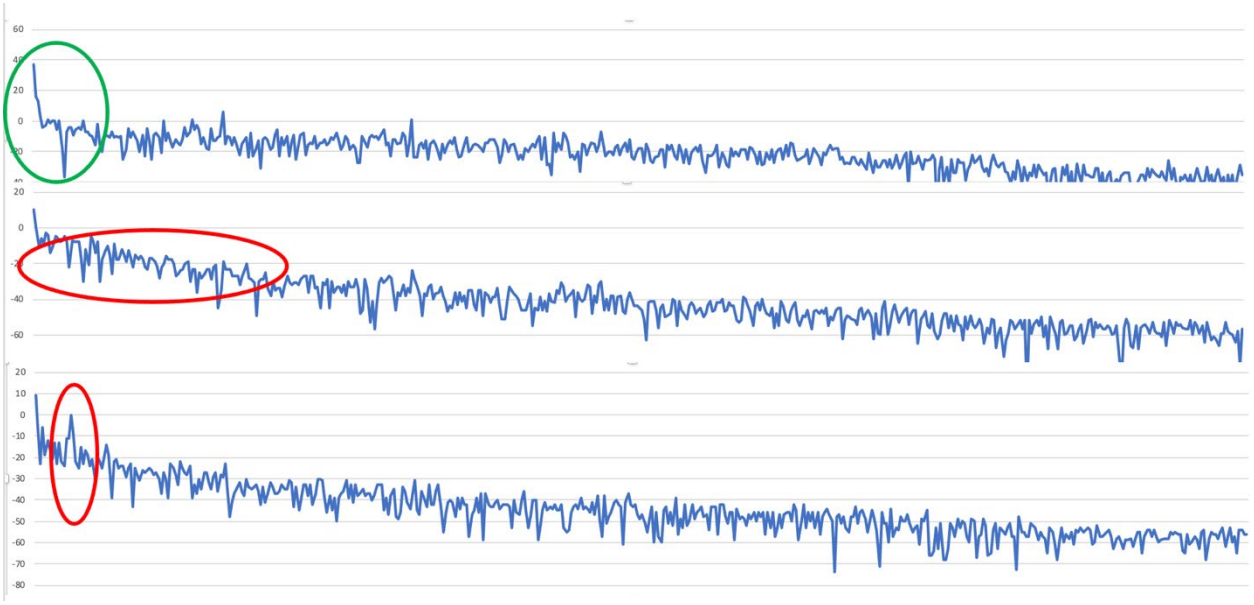

Figure 40 - Log magnitude bins are converted to time domain using zero-stuffed IFFT technique, using minimum phase assumptions

Finally, when multiple time domain impulse responses are overlayed in Figure 41, the spreading becomes more obvious. The red line indicates a threshold that correctly distinguishes between water and amplitude ripple on 100% of the examples provided.

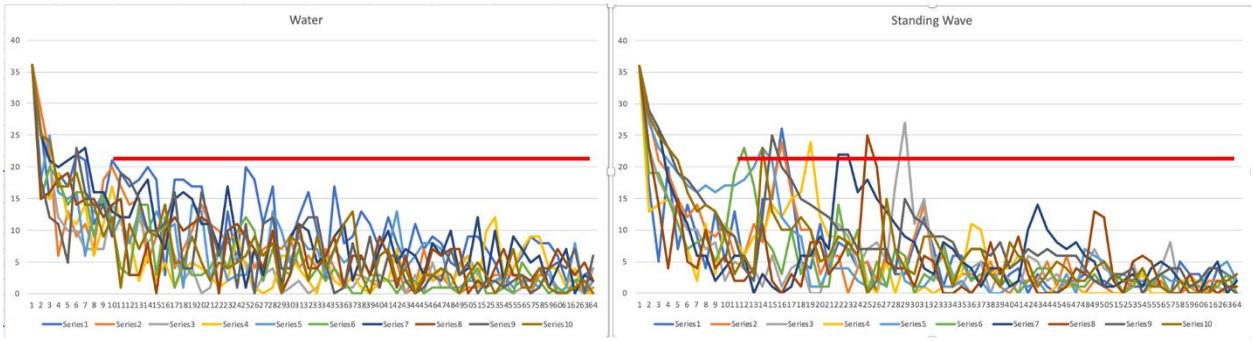

Figure 41 - Time domain spreading in water (left), and peak threshold detection (right)

6. Operational Practice Consideratons

Of the samples recovered in the field trials, virtually all the water damage could have been avoided. There are a number of recommendations discussed below to help reduce the occurrence of water damage.

6.1. Materials Selection

When installing the drop system, consideration of the cable and components are key in the performance and life expectancy of the system along with the methods and practices used for installing it. Our focus for this section will be on how to maintain a weather tight drop cable network.

Let's begin with material selection. When selecting RF cable ANSI/ SCTE 74 2011 Specification for Braided 75 Ohm Flexible RF Coaxial Drop Cable can provide the information needed to ensure that you select the correct cable for the proper use and purpose. Two of the key components of the standard will be jacket construction, designed for either aerial or underground and flooding compound for both aerial and underground cables. Before we get too far, we should discuss flooding compound. Flooding compound in both aerial and underground cable is meant to help preserve against rapid degradation due to corrosion only. It is not intended as a self-repair component and therefore any damage to the jacket of aerial or underground cable should be replaced.

Connectors used should be of the 360-degree compression style with integrated weather seals to limit water migration. The other component that we need to maintain a weather tight, moisture-proof drop cable network would be weather seals for RF port connections. These port seals may be integrated as part of the connector or a separate piece. In either case it is important that we are using the proper seals whenever the connection may be exposed to outside elements or fluctuations in temperature or areas of high moisture such as basements, garages, crawl spaces, pedestals, lock boxes, house boxes etc.

6.2. Installation Practices

Now that we have the materials let us look at how to install them to ensure the integrity of the drop system for years to come. The points that we will cover are those specific to the weatherproofing of the drop system and is not meant to reflect all considerations when installing the drop system.

When preparing the cable for installation we need to be careful with the tools we use and how we use them as damage to the jacket can easily happen. Let's start with proper fitting, preparation, and installation. Using the correct prep tool for the cable size and fitting style as well as ensuring that the tool is sharp will ensure a good fit between the connector and the cable being used. Next is the compression of the connector. For this to be successful we need to be sure we are utilizing the correct compression tool for the fitting being used and that it is in good working condition. A visual inspection of the compression shall be made to ensure that there is a complete and even compression of the fitting to the cable.
RF Port seals, when installing the seal, we need to ensure that the seal extends past the threads of the RF port and contacts the smooth portion of the barrel connection. If the seal is not integrated with the connector the seal should be installed so that the leading edge of the connector is in direct contact with the seal. The seal does not need to be compressed between the connector and the body of the component of the barrel connector to be properly installed.

Regarding the cable itself there are several practices we need to consider as well. Water will follow the route of the cable, riding the exterior jacket looking for a point of entry and/or flowing on the interior of the cable. Therefore, we utilize the practice of installing drip loops along the pathway of the cable to provide a means to displace the exterior water. Drip loops should also be utilized to ensure that any connections or drop components are always higher than the lowest point of the cable. Utilizing gravity to keep all moisture away from connections and components.

Care must be taken on how we attach the cable and methods used for attachment so that the jacket is not damaged. Attachments such as clips and hangers should not have hard or sharp edges that could damage

the jacket during installation. In addition, care must be taken during installation as a slip of a tool or improper use can also result in damage to the jacket of the cable.

Something as basic as removing the messenger from aerial cable, if done incorrectly, can also lead to damage of the jacket. By utilizing the vertical pull method, not the horizontal “wishbone” method, the jacket will remain intact during the removal process. Extra care must be taken when preparing a mid-span drop so as not to damage the jacket during messenger wire separation.

When installing aerial cable, the pathway of the cable should be such that the cable does not come in contact with objects that could wear against the jacket and compromise the integrity over time. If such contact cannot be avoided, the use of a protective barrier such as tree guard should be used. With underground cable the best way to protect the jacket is the use of conduit. This would protect the jacket from hard sharp objects below the surface that may damage the jacket, provide a means of protection if there is any digging in the area and finally protect the cable at the critical points where it enters or leaves the ground. If conduit is not used to protect the complete path of the underground cable, then it is a must to protect the cable at the points where it enters and exits the ground. This can be done by using smaller sections of conduit or U Guard. This protection should extend 8 inches below the ground and should extend to at least 3-4 feet above ground.

6.3. Inspection for Damage

We should always be performing a visual and tactile inspection of the cable. We need to be on the lookout for cable that does not look or feel right and completing a further inspection based on these observations. All knicks or cuts in the cable jacket can and in time will permit a pathway for water intrusion and therefore must be dealt with. Remember flooding compound is not meant to be a self-repair method. Whenever you see physical signs that water has entered the cable, this may be corrosion, discolored center conductor or moisture, the cable and / or components must be considered compromised and correctly remedied.

6.4. Repair vs Replace

Replacing the damaged section of the drop system should be the preferred method. By repairing or splicing of the damaged section we cannot be sure that there is not still the presence of moisture that will continue to degrade the cable.

6.5. Cable Handling and Storage

How we store the cable prior to use can also have a significant impact on its performance as well. If possible, all cable should be stored inside of the vehicle prior to use. If this is not possible care must be taken to properly protect the cut end of the cable from taking on moisture as it is exposed to the environment. The cable should also be protected from unintended damage from other items that may be stored around it.

7. Future

Water entering our cables is a common problem with unpredictable impacts to our customers. However, rain being the most common cause is somewhat predictable using national or local weather data. We can imagine a future opportunity to get ahead of water related problems by proactively repairing damaged cables in advance of rainy seasons with prolonged precipitation. In addition to weather, other causes such as sprinkler systems can have predictable periodicity and should also be considered.

Another important observation about this type of impairment is that it affects high-frequency spectrum, worse than low-frequency spectrum. This could influence an operators DOCSIS evolution strategy and how to prioritize cable replacements. For example, if considering using RF spectrum above 1.2 GHz, and operator might decide to increase the priority of replacing these damaged cables.

8. Conclusions

Proactive network maintenance has come a long way in the past 11 plus years but has more valuable but hard work ahead.

As CableLabs focused on achieving accurate impairment detection using PNM, SCTE has been developing operational practices that help operators make PNM actionable and affordable. Partnering with Comcast, over 100 water-damaged subscriber drop cables were recovered from the field. The cable samples were then sent to Comcast's Physical and Environmental lab for testing and characterization of the cables' physical condition and RF parameters. The result of this effort is a new, comprehensive understanding of how water, rain, and freezing impact our networks' coaxial cables.

Using spectrum captures from CMs in the field, we created approaches for differentiating water waves from standing waves (amplitude ripple). The unique frequency response signature created by water in a subscriber drop cable provides an easy way to quickly identify affected drops remotely, without a truck roll. Once a water-damaged drop has been identified, a technician can be dispatched to replace it. The result is a new PNM tool, and more efficient field practices to come.

A strong standing wave as well as a strong water wave both can have significant impact on a customer's service, so both must be addressed. But knowing the difference is important. While on the surface it may seem that knowing the difference between a standing wave versus a water wave in the coax plant is a secondary concern, the difference has at least two key important
values.

1. Knowing that the impairment is a water wave versus a standing wave tells the technician what to look for, and where to look for it. A drop affected by water can quickly be replaced once identified. Water-damaged passives can as well, and technicians can look for corrosion, water, nicks in cable, and other plant failure modes that are the causes for the water wave indicated. In contrast, an echo cavity that creates a standing wave may be harder to find and will be indicated by different failure modes in the cable plant.

2. Water in the cable plant can get worse with time. Therefore, early detection is an opportunity to be truly proactive. Removing the problem before it impacts service is best. And if you can identify and remove the problem before it worsens, even better. Early detection affords the opportunity to remove a small problem from the network before severe damage in amplifiers, taps, and other components happens. A quick fix early avoids a lengthy, more costly fix later.

We presented three methods in this paper for finding water in drops using RF spectrum data. We intend to collect validated field data and perform a comparison of the methods in the future, and report on the benchmarking results in an update of the Primer for PNM Best Practices document published by the PNM working group at CableLabs, and expect to reflect the best methods in a future SCTE NOS Working Group 7 field practice. Work is underway now to develop a PNM benchmarking tool for general comparison of PNM methods, allowing us to provide a benchmarking data set to certify and test any packaged PNM algorithm, starting with these water wave methods. A test report will be the output, based on the number of false positives, false negatives, and potential severity weighting of the results. Once

demonstrating the value in this use case, we expect to offer the same benchmarking approach for other PNM methods.

This work was the result of continuous improvement in how the industry develops and uses PNM. Working closely among operators, vendors, CableLabs, and SCTE, we were able to shift to a DevOps approach to PNM, with continuous cycling between the operations in the field with research and development. While simultaneously collecting experience and validating ideas in the field, the tools were developed in software, using the PNM test methods available, to create this new tool for improving network quality and customer services.

We intend take this work further to align the causes with various cable types, ages, and other factors to determine whether certain cable types in certain environments or use cases are better than others, and what this means for future cable plant deployments, maintenance, and the useful lifetime of coax cable plant.

9. Appendix

9.1. Characteristics of coaxial cable

Coaxial cable is a two-conductor transmission line. One of the conductors is called an inner or center conductor and is "…surrounded by a concentric conducting shield, with the two separated by a dielectric (insulating material); many coaxial cables also have a protective outer sheath or jacket. The term 'coaxial' refers to the inner conductor and the outer shield sharing a geometric axis."[1] See Figure 42.

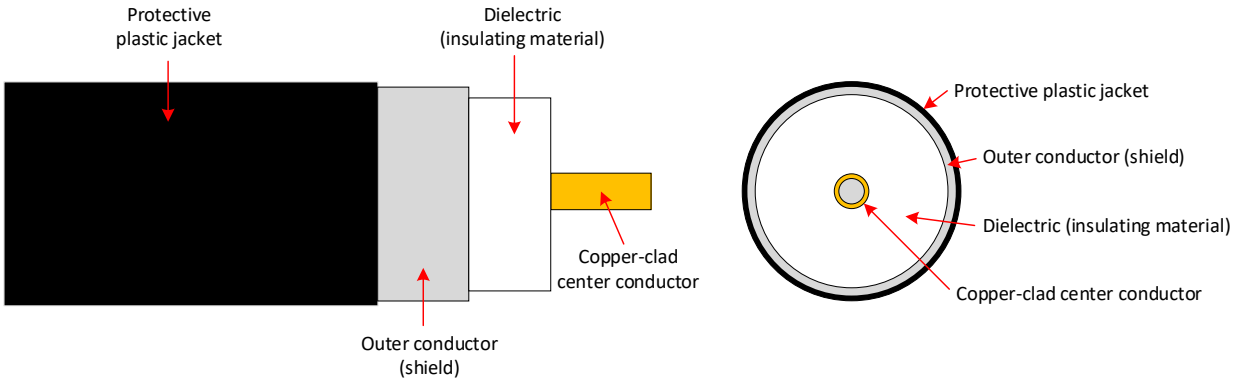

Figure 42 - Coaxial cable side view (left) and end view cross-section (right)

There are two major types of coaxial cable found in cable networks. One type is known as hardline cable and is used in the distribution plant that is attached to utility poles or buried underground. The center conductor is typically copper-clad aluminum (but can be solid copper in some applications), and the shield an aluminum alloy. The name comes from the semi-flexible solid tube-like outer conductor (shield). Hardline cables distribute RF signals throughout the community being served by the cable operator, and in many cases also carry 60 volts to 90 volts AC to power nodes and amplifiers. Figure 43 shows two examples of hardline coaxial cable.

[1] From Wikipedia: https://en.wikipedia.org/wiki/Coaxial_cable

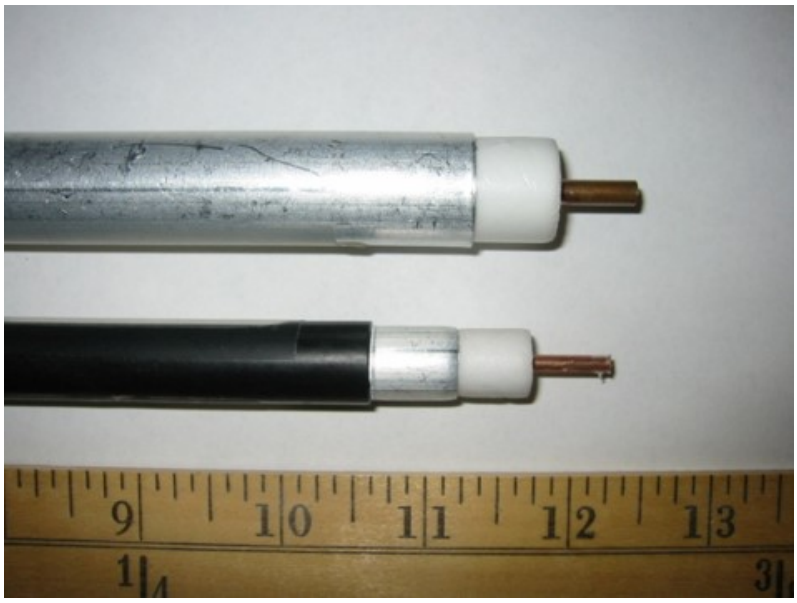

Figure 43 - Examples of hardline coaxial cable: unjacketed 0.750 inch diameter (top) and jacketed 0.500 inch diameter (bottom)

The second type is a smaller diameter, flexible coaxial cable used for the subscriber drop, which is that part of a cable network between the hardline distribution plant and the customer premises equipment inside the home. The center conductor is typically copper-clad steel, and the shield a combination of Mylar-backed aluminum tape and braid. See Figure 44.

Figure 44 - Series 6 coaxial cable with the end prepped for installation of a connector

In both hardline and subscriber drop cables used in cable networks, the dielectric is a closed-cell gas-injected foam. The protective jacket can be polyvinyl chloride (PVC) or polyethylene (PE) plastic, depending on application.

The following summarizes some of the electrical characteristics of coaxial cable. When any of these parameters deviates from desired nominal values, the performance of the coaxial cable and the cable network can degrade.

9.1.1. Impedance

Generally speaking, *impedance* is the combined opposition to current in a component, circuit, device, or transmission line that contains both resistance and reactance. Impedance is represented by the symbol Z and is expressed in ohms. Impedance is further defined as the frequency domain ratio of voltage to current, $Z = E/I$. Impedance in an alternating current circuit, including RF, is a complex value and includes both resistance (the real part of complex impedance) and reactance (the imaginary part of complex impedance) – that is, both magnitude and phase. Impedance can be thought of as a way to describe the concept of AC resistance.

The *characteristic impedance*, Z_0, of coaxial cable is expressed in ohms, and is related to the outside diameter D of the inner or center conductor, the inside diameter d of the outer conductor or shield, and the dielectric constant ϵ (relative permittivity) of the insulating material (dielectric) separating the two conductors. Cable networks use coaxial cables with a nominal characteristic impedance of 75 ohms. As long as the characteristic impedance of the signal source, coaxial cable transmission line, and load or termination to which the cable is connected is the same (that is, 75 ohms), essentially all RF power from the source is delivered to the termination or load, except that which is lost to attenuation.

The following formula can be used to calculate the characteristic impedance of coaxial cable.

$$Z_0 = \frac{138}{\sqrt{\epsilon}} log_{10} \frac{D}{d}$$

where
Z_0 is the cable's characteristic impedance in ohms
ϵ is the dielectric constant of the insulating dielectric material
log is base 10 logarithm
D is the inner diameter of the shield
d is the outer diameter of the center conductor

The calculated characteristic impedance of 0.500 diameter hardline coaxial cable, assuming a dielectric constant of 1.32, a shield inner diameter of 0.452 inch, and a center conductor outer diameter of 0.109 inch, is 74.2 ohms. Anything that affects the cable's dielectric constant and/or the ratio D/d will change the impedance. Figure 45 illustrates the D/d relationship in coaxial cable. Figure 46 shows coaxial cable that has a kinked shield, resulting in a different D/d ratio, which in this case would cause the impedance at the point of damage to be reduced from what it is in the rest of the cable.

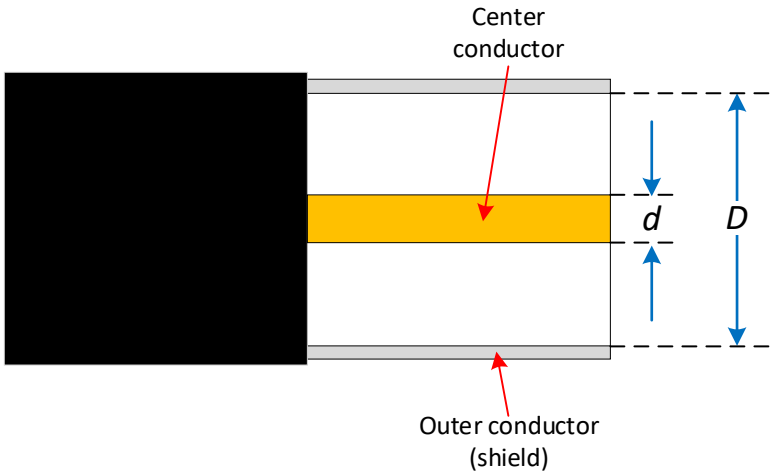

Figure 45 - Illustration of the D/d relationship in coaxial cable

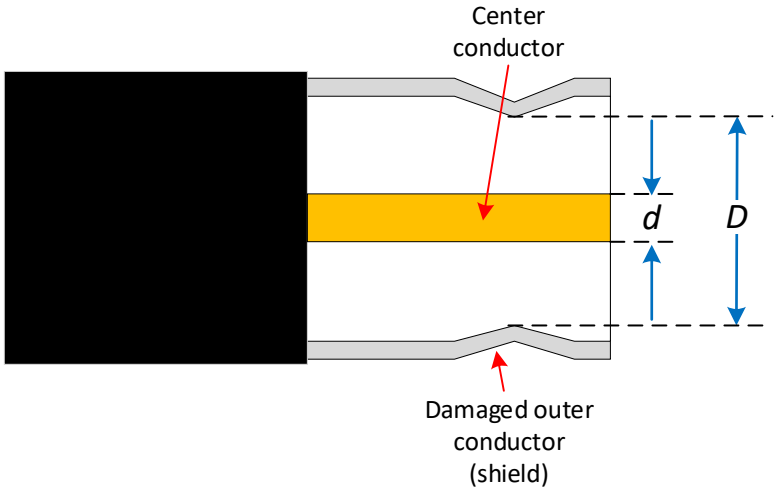

Figure 46 - Damage to the shield in this example changes the D/d relationship, resulting in a change of impedance at the point of damage relative to the rest of the cable

9.1.2. Attenuation

Attenuation (also called loss) is a decrease in the power of a signal or signals, usually measured in decibels. Expressed mathematically, $\alpha_{dB} = 10log_{10}(P_{in}/P_{out})$, where α_{dB} is attenuation in decibels, P_{in} is input power in watts, P_{out} is output power in watts, and $P_{out} < P_{in}$. When signal power is stated in dBmV, $\alpha_{dB} = P_{in}(dBmV) - P_{out}(dBmV)$.

According to *Modern Cable Television Technology, 2nd Ed.*,

> Signal loss (attenuation) through coaxial cable can occur through any of four principal means:
>
> - Radiation out of the cable due to imperfect shielding

- Resistive losses in the cable conductors
- Signal absorption in the dielectric of the cable
- Signal reflection due to mismatches between the cable and terminations or along the cable due to nonuniform impedance

Assuming signal leakage (radiation) from the cable is negligible and there are no significant impedance mismatches, resistive losses in the metallic conductors are the dominant contributor to attenuation, followed by signal absorption in the dielectric.[2] Coaxial cable attenuation is greater at higher frequencies than at lower frequencies, as shown in Figure 47.

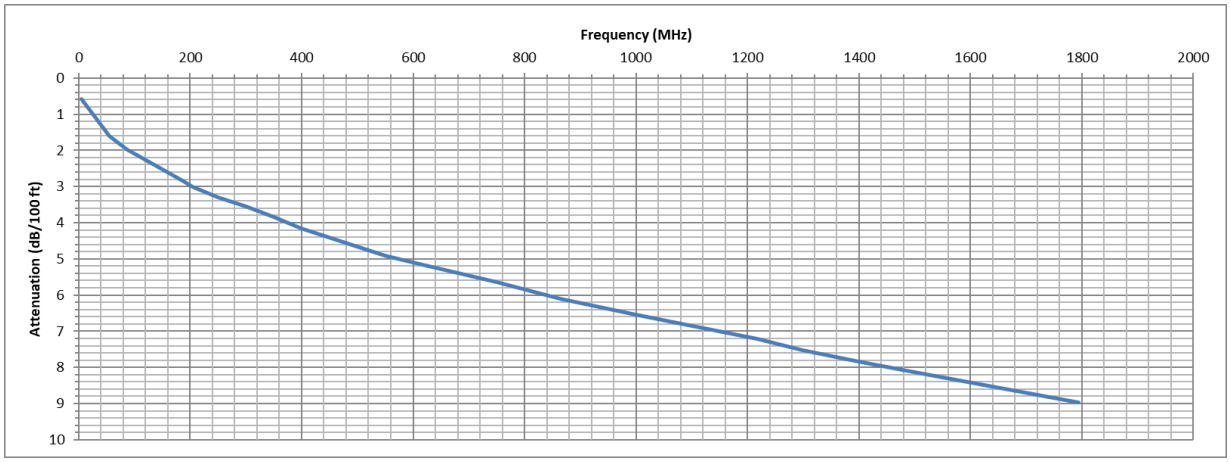

Figure 47 - Plot of typical attenuation in dB/100 feet for Series 6 subscriber drop cable, from 5 MHz to 1794 MHz

Coaxial cable attenuation in decibels changes about 1% per 10 °F temperature change (as the temperature increases, attenuation increases; as the temperature decreases, attenuation decreases).

For more information, see "Coaxial Cable Attenuation" in the Summer 2021 issue of *Broadband Library*.[3]

9.1.3. Dielectric constant

Dielectric constant is a parameter that applies to the dielectric in coaxial cable, and typically refers to relative permittivity.[4] Dielectric constant is related to coaxial cable's velocity factor using the following formula:

$$\epsilon = \frac{1}{VF^2}$$

[2] Note: An increase in the dielectric constant means a lower velocity factor, which increases signal absorption in the dielectric, and increases attenuation for a given size and impedance coaxial cable.
[3] https://broadbandlibrary.com/coaxial-cable-attenuation/
[4] This usage is considered obsolete by some standards bodies in favor of *relative static permittivity*.

where
ϵ is dielectric constant (relative permittivity)
VF is velocity factor

For example, the dielectric constant of hardline coaxial cable with VF = 0.87 is about 1.32. As mentioned previously, anything that changes the dielectric constant will change coaxial cable's impedance (and its attenuation).

9.1.4. Velocity factor

Velocity factor is the ratio – in decimal form – of the velocity of an electromagnetic signal propagating through coaxial cable to the speed of light in a vacuum. A common VF for hardline coaxial cable is 0.87, and for drop cable is 0.85. Mathematically,

$$VF = \frac{c}{c_0}$$

where
VF is velocity factor
c is the velocity of the electromagnetic signal traveling through coaxial cable
c_0 is the speed of light in a vacuum,[5] in the same units as c

Another formula for velocity factor is

$$VF = \frac{1}{\sqrt{\epsilon}}$$

where
VF is velocity factor
ϵ is the dielectric constant.

9.1.5. Velocity of propagation

Velocity of propagation (VoP) is velocity factor expressed as a percentage. For example, a VF of 0.87 equals a VoP of 87%. The latter means that RF signals propagating through the coaxial cable have a velocity that is 87% of the speed of light in a vacuum.

9.1.6. Return loss

When the impedance of a load or termination equals the characteristic impedance of the transmission line connected to that load, an incident wave is completely absorbed by the load. In the real world, there are no perfectly reflectionless loads, which means impedance mismatches exist. Impedance mismatches cause reflections. Reflected waves interact with incident waves to produce a distribution of fields in the transmission line known as standing waves. The presence of standing waves in coaxial cable can cause

[5] According to the National Institute of Standards and Technology, c_0 is 299,792,458 meters per second.

amplitude ripple in the frequency domain.[6] There are several ways to characterize the severity of impedance mismatches, among them is *return loss* (R).

Return loss (which is not the same thing as attenuation in the return or upstream spectrum of a cable network) is the ratio, in decibels, of the power incident ($P_{incident}$) upon an impedance discontinuity to the power reflected ($P_{reflected}$) from the impedance discontinuity. Note: When $P_{reflected} < P_{incident}$, return loss is a positive number.

Return loss is used to characterize network components such as active and passive devices, connectors, customer premises equipment, etc. Return loss has sometimes been used to characterize coaxial cable, although structural return loss is far more commonly used. The following is one formula that can be used to calculate return loss:

$$R = -20log_{10}\left(\left|\frac{Z_{device} - Z_0}{Z_{device} + Z_0}\right|\right)$$

where
R is return loss in decibels
log is base 10 logarithm
Z_{device} is the complex characteristic impedance of a device, in ohms
Z_0 is 75 ohms for cable networks

Hardline coaxial cable used in cable networks is typically specified to have a characteristic impedance of 75 ohms ±2 ohms, so the calculated return loss would be at least as good as about 37.4 dB.

9.1.7. Structural return loss

As mentioned in the previous section, return loss is one way to characterize the severity of impedance mismatches, especially in active and passive devices, connectors, and other components used in cable networks. *Structural return loss* (SRL) has been used for decades for coaxial cable, in large part because SRL deals with return loss at specific frequencies caused by evenly-spaced repetitive impedance discontinuities arising during the manufacturing process.[7] The following is from Technical Note 1069, "Testing CATV Cable to 1 GHz," published by Times Fiber Communications, Inc., in April 1999:

> As coaxial cable is manufactured, a number of variables can cause the impedance to change. Recall, the cable's impedance is a function of the cable's physical properties (conductor diameters, insulation's dielectric constant), and if any of these properties change, the impedance will change. For example, the dielectric material is extruded over the center conductor during the manufacturing process. As the dielectric is extruded, its diameter or dielectric constant can change and cause the impedance to change. This impedance change is extremely small and difficult to measure. If only one of these impedance changes occurs in the cable or if they occur at random intervals, the return loss will be good; but due to manufacturing processes, there may be many evenly spaced

[6] The term *standing wave* is often used to describe *amplitude ripple*, although technically speaking amplitude ripple is not the same thing as a standing wave.
[7] Pulley diameter and spacing, non-uniformity of line speed through extruders, vibrations, and other factors contribute to the creation of periodically-spaced, almost microscopic physical dimension variations in the center conductor, dielectric, and shield during the manufacture of coaxial cable.

> impedance changes and return loss problems will arise. Reflections from these evenly spaced impedance changes add together at a frequency corresponding to a half wavelength spacing. Although each impedance change may be very small, when they all add together, they cause a return loss "spike." These spikes can be narrower than 200 kHz. The return loss from these impedance changes is called the structural return loss because the impedance variations are due to structural nonuniformities in the cable.

In the past, a broadband sweep generator in conjunction with a variable bridge and variable termination were used for coaxial cable SRL measurements. As the operating bandwidth of cable networks increased beyond about 600 MHz, the aforementioned method could no longer provide accurate results. New measurement techniques were developed, based on the use of a fixed bridge, network analyzer, a set of calibration standards, and calculations to determine the SRL. A test procedure is described in the standard ANSI/SCTE 03 2016 Test Method for Coaxial Cable Structural Return Loss. The following is an excerpt from ANSI/SCTE 03.

> The purpose of this procedure is to provide instructions to measure cable structural return loss (SRL). The cable impedance as a function of frequency is calculated from a vector (magnitude and phase) return loss. The average of this impedance across the desired frequency range is the "cable reference impedance." The structural return loss is calculated from the cable impedance as a function of frequency and the cable reference impedance. This may be automated, but requires a vector network analyzer, and may be subject to errors due to the cable connection.

Figure *48* shows an example of a measurement of average impedance for a reel of coaxial cable. The top trace is the measurement from one end of the reel of cable, and the bottom trace is from the other end. Figure *49* shows a measurement of the same reel of cable's vector return loss from both ends of the reel.

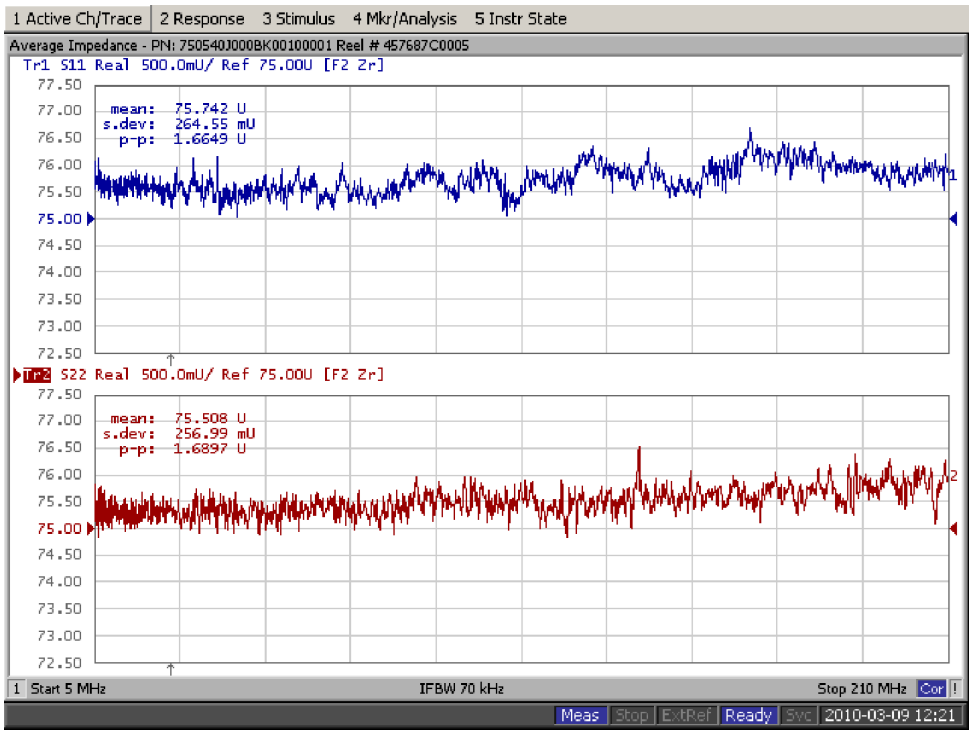

Figure 48 - Example measurement of the average impedance of a reel of coaxial cable, using the method described in ANSI/SCTE 03 2016. (Screen shot courtesy of Amphenol Broadband Solutions.)

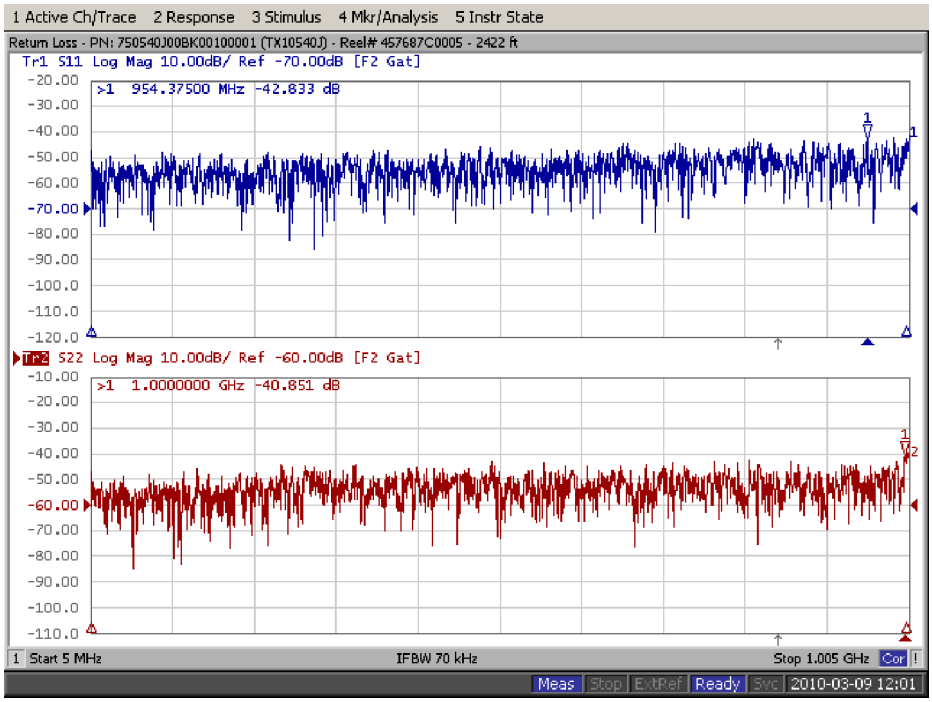

Figure 49 - Measurement of return loss of the same reel of cable in the previous figure. (Screen shot courtesy of Amphenol Broadband Solutions.)

Figure 50 shows the calculation of SRL from the parameters in Figure 48 and Figure 49.

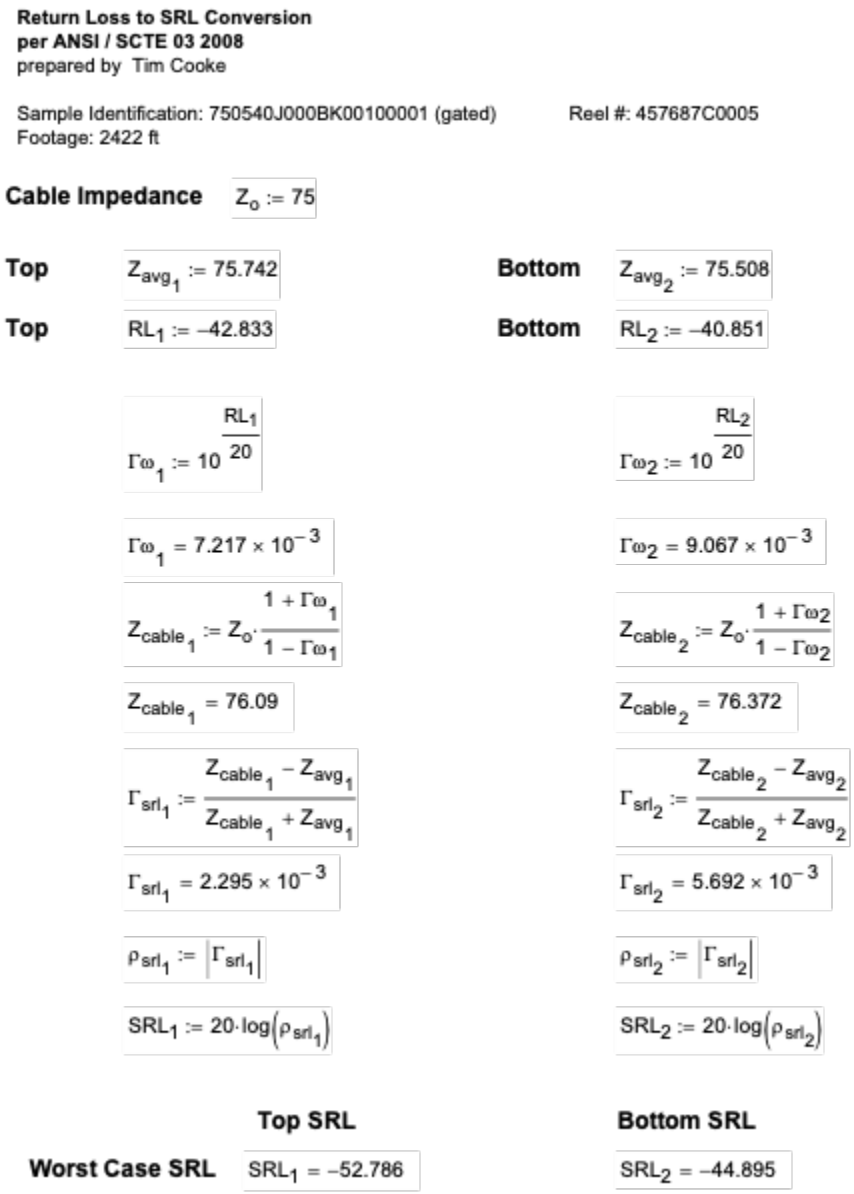

Figure 50 - Calculated worst case SRL for the reel of cable discussed in this section. (Courtesy of Amphenol Broadband Solutions.)

9.1.8. DC loop resistance

Loop resistance – more accurately, DC loop resistance – is a parameter usually specified in ohms per 1,000 feet, and is important for cable network powering purposes. Typical published DC resistance values for 1,000 ft. of 0.500 hardline cable are 1.35 Ω for the center conductor (measured end-to-end), 0.37 Ω for the shield (also measured end-to-end), and 1.72 Ω for the loop resistance. For loop resistance, imagine shorting one end of a 1,000 ft. length of cable, and measuring the DC resistance between the center conductor and shield from the other end.

What's important here is that the resistance values are at DC – the resistance one would measure with a conventional ohmmeter – and not at the frequencies of the RF traveling through the coaxial cable. Direct current travels through the entire cross section of a conductor. Alternating current, which includes RF, travels on and near the surface of a conductor, a phenomenon known as skin effect.

Abbreviations

AC	alternating current

1. Introduction

Understanding the traffic consumption trend is one of the essential elements in network capacity planning. We have seen an exponential traffic growth for long periods and a huge step function increase during the COVID-19 pandemic period. In the first part of the paper, we present the historical traffic growth over the past years, especially emphasizing the impact of COVID shelter in place in various ways.

The next part of the paper, we will examine the ongoing analysis, innovation, strategic direction, and how all those factors and components materialize as actionable plans using our patent-pending planning tools. We will also examine how our scalable suite of tools was a key driver in staying in front of COVID, as we were able to make fast decisions with near-real-time data in the ever-evolving early days of COVID-19 lockdowns in the United States

2. Deep Analysis

Internet peak traffic has increased exponentially over the years. Figure 1 shows the internet peak traffic increase over the past 10 years. Peak traffic is calculated based on the aggregated 95th percentile peak traffic volume measured at the northbound Gigabit ethernet ports in each CMTS device. It includes residential and business customer traffic and a new customer growth on top of the organic traffic growth.

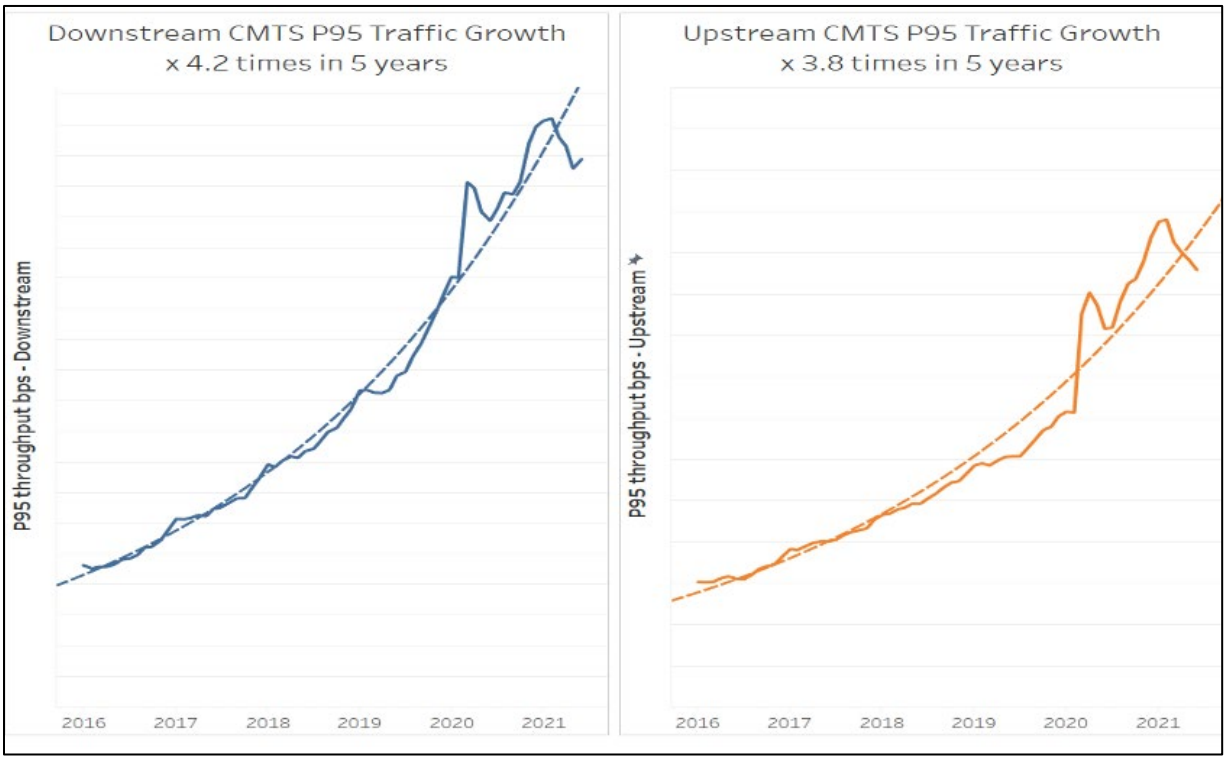

Figure 1 - Aggregated Peak Traffic Growth

Figure 2 shows the year over year (YoY) peak traffic growth rate. It had increased by 40-50% YoY growth until 2016 when major streaming service providers re-encoded the contents with optimized encoding algorithms and reduced the bandwidth usage. Since then, we have seen the traffic YoY growth rate to be about 30% until COVID-19 shelter in place started in March 2020.Traffic increased dramatically in a short period of time when shelter in place began. Upstream traffic growth is higher than downstream growth. Cox networks experienced 22% growth downstream and 34% growth upstream in 2 weeks after COVID-19 stay at home started.

As shown in Figure 2, upstream traffic grew about 70% and downstream traffic grew about 67% in April 2020 from April 2019. Downstream traffic growth continued to decline after it hit the highest point in April 2020. YoY growth rate since March 2021 significantly reduced because the latest value in the YoY calculation is compared to the surgical value after COVID-19 in 2020.

Figure 2 - YoY Peak Traffic Growth Rate

Figure 3 presents peak hour usage increase relative to pre-COVID-19 in February 2020. It compares the historical YoY growth trend and the actual growth rate. The recent downstream growth rate is smaller than the historical growth pattern. Upstream traffic continues to be growing and the recent trend shows 15% points above the historical YoY growth rate.

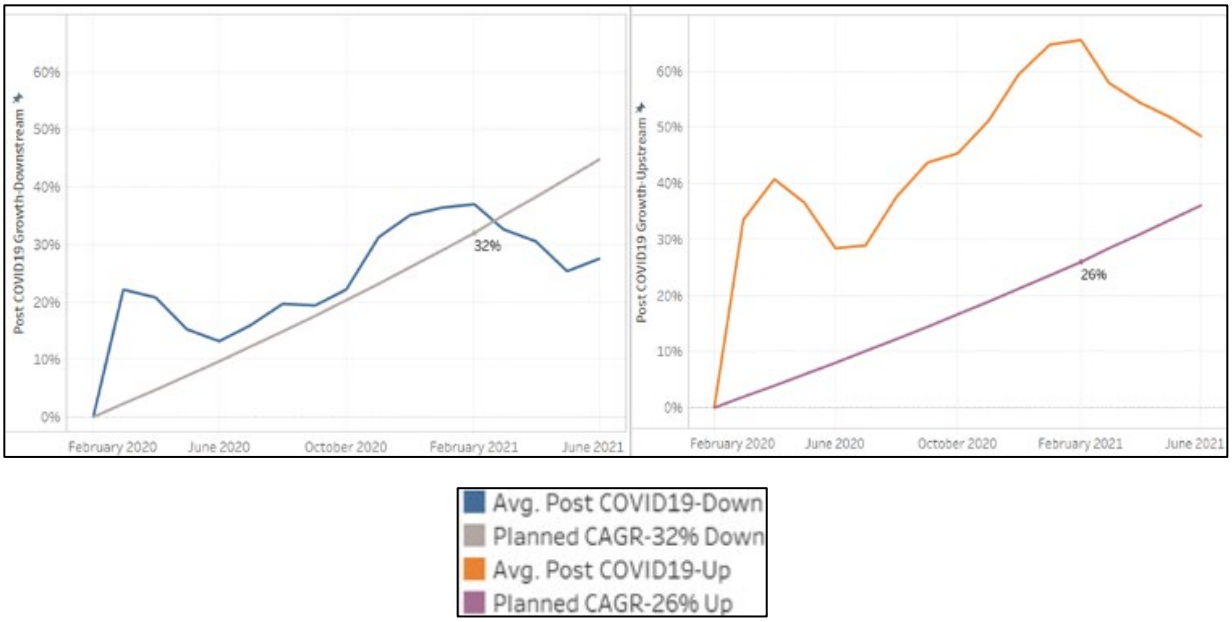

Figure 3 - Post COVID-19 Traffic Growth: Actual vs Expected

During COVID-19, the residential upstream traffic usage pattern has changed due to WFH (work from home) and SFH (study from home). In addition, upstream peak hours of residential customers have shifted to the daytime as shown in Figure 4. Recently it has returned to late evening, especially when the summer started, however, the daytime upstream usage pattern is still higher than pre-COVID-19.

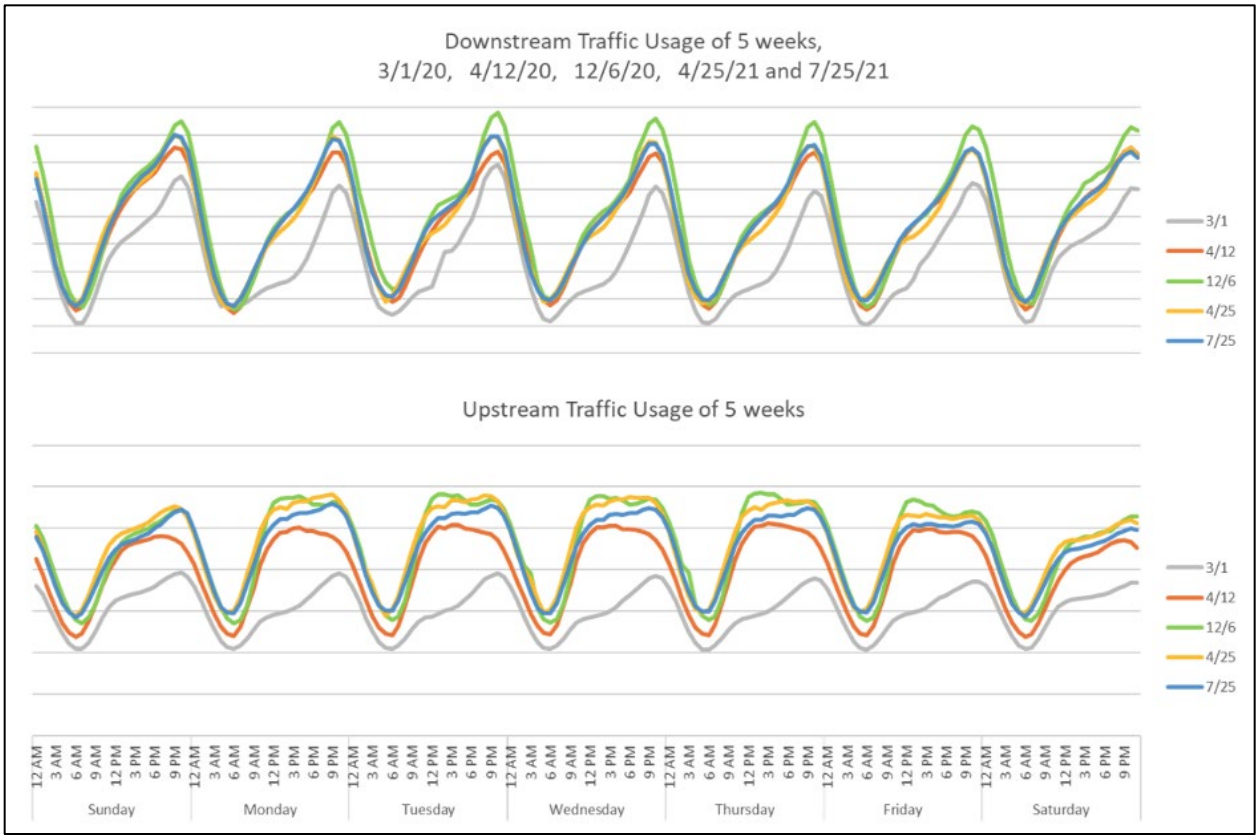

Figure 4 - Traffic Usage Pattern by Time of Day

The residential customers' peak traffic ratio of downstream to upstream is presented in Figure 5. It has grown to almost 19:1 since downstream traffic growth rate is higher; however, it reduced to 16:1 because upstream growth rate is higher after COVID-19 started. Currently the network has plenty of downstream capacity and relatively lower upstream capacity. Since Cox is building a mid-split plant, the capacity ratio of downstream to upstream will support the demand substantially.

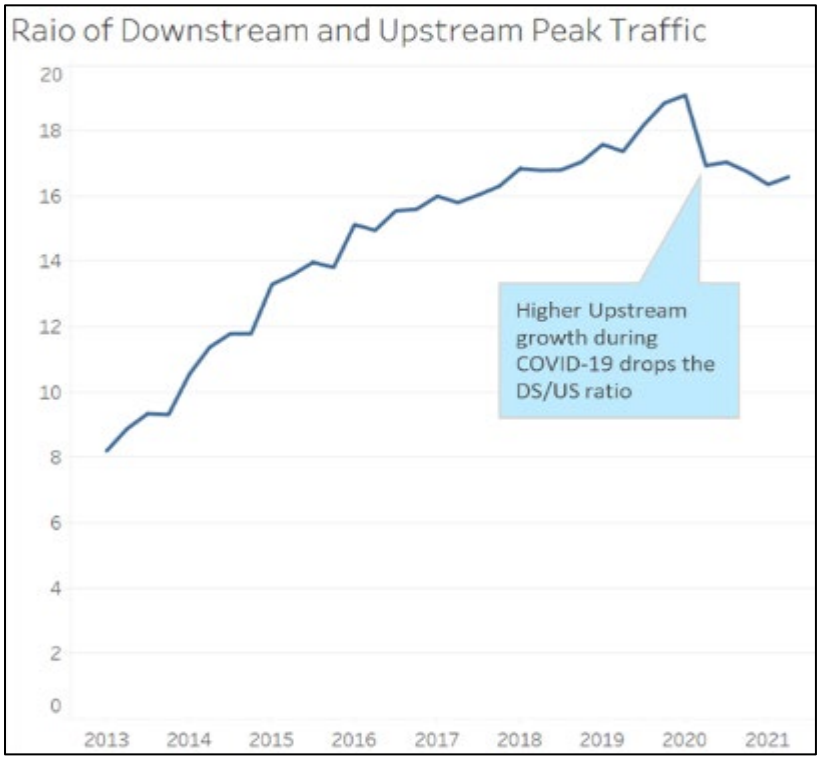

Figure 5 - Ratio of Downstream and Upstream Peak Traffic

Figure 6 displays the traffic category mix since March 2020. There has been a significant increase in WFH, and moderate increases in video, web, gaming and social since COVID started. The overall traffic remains dominated by video and web. Peak usage growth was still driven by traditional drivers such as OTT (over the top) video. In early 2021, WFH traffic increased up to 400% from the baseline of March 2020. Recently it went down to a 150% increase from the baseline.

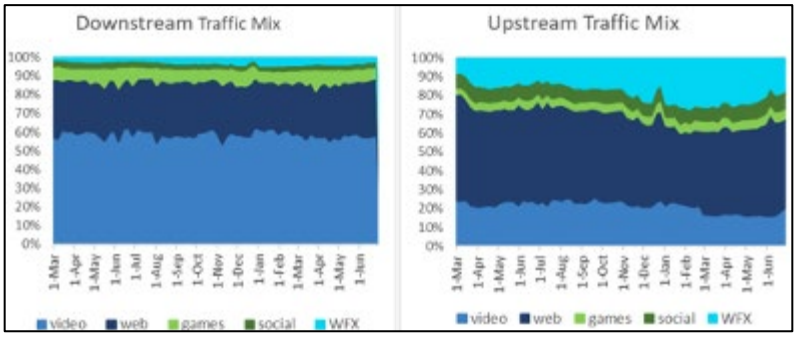

Figure 6 - Traffic Mix by Category

It would be interesting to see how business customers and residential customers consume network bandwidth differently. Figure 7 presents the average usage pattern of business and residential customers by the time of day. Business customers' usage peak hours are from 10AM to 4PM, while residential customers' peak hours are from 7PM to 10PM. Business customers consume less downstream traffic and more upstream than residential customers. Business customers' usage ratio of downstream to upstream is 5:1, while residential customers' usage ratio is about 16:1 as of time of authorship (August 2021).

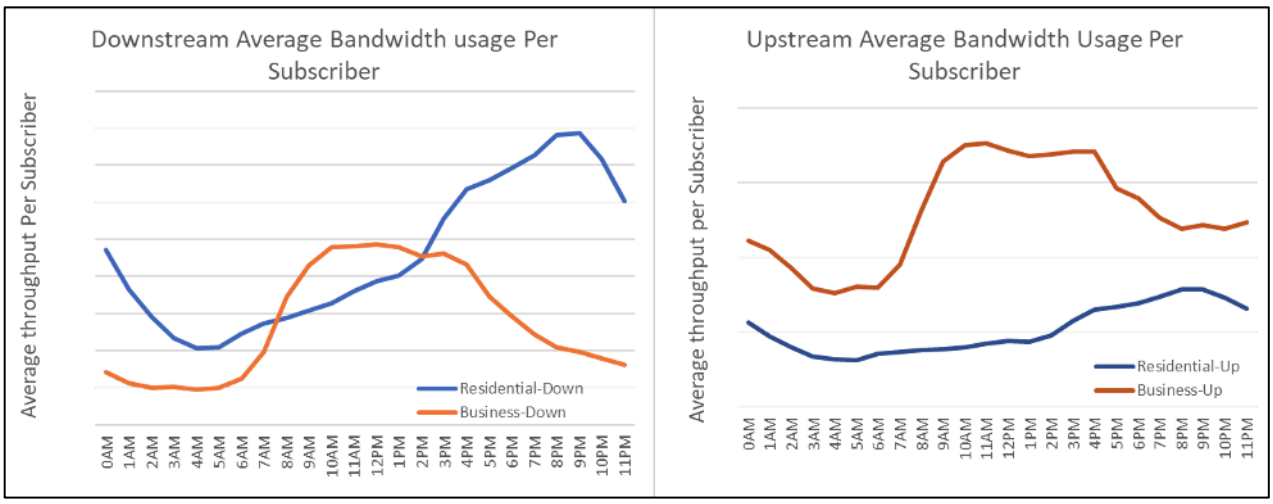

Figure 7 - Usage Pattern of Residential and Business Customers

Figure 8 shows the average usage throughput per customer by different tier speed, with the most popular tier, the first and second highest tier and the lowest speed tier. Basically, the average time of day usage patterns are almost the same across all of the different tiers. Figure 8 shows an example of the average throughput by speed Tier. The higher speed tier consumed more bandwidth, but not proportional to the maximum speed it can use.

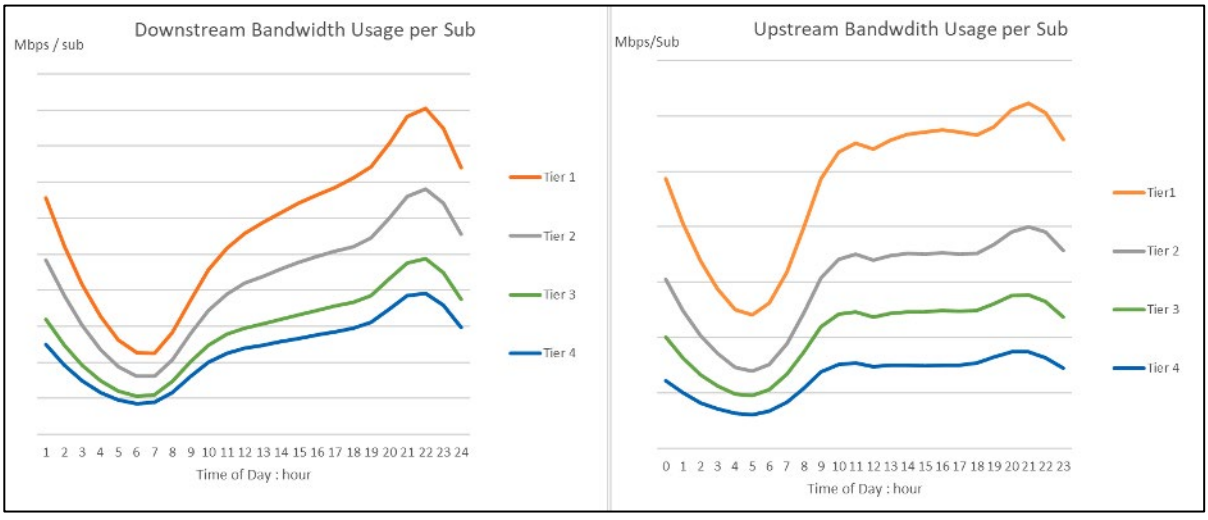

Figure 8 - Average Throughput of each Customer

3. Modeling and Planning

Translating network analysis into actionable information and data is the next facet of our teams. Implementing insights from our network analysis, in partnership with other industry experts such as CableLabs, has cultivated into a robust automated pipeline for the access network, and automated connectivity with other areas of network planning, such as backbone planning tools. These tools are developed on Cloudera, but built modularly for simpler migration as Cox's data strategy shifts

These modeling efforts were designed leveraging big data concepts and presented at SCTE in their infancy a few years back. As a recap, prior to the current methods, a series of manually generated Excel workbooks were used to infer a static CAGR-based growth rate for planning. These workbooks were first automated into workflows, connecting source data into a single schema, then logically joining and cleaning data. Within the workflow are tools designed to statistically identify anomalies, using kernel density and analysis of variance (ANOVA) to detect and alarm issues in the data. In addition to triggering external teams to research root cause and correct data issues, if possible, there are alternate "corrected" data tables generated. The corrected data uses interpolation methods to correct the gaps and errors until any corrected data loaded into the base (untouched) tables.

The final dataset, consisting of telemetry, topology, geospatial, upstream and downstream load, capacity, product and revenue data all on a time series basis, are loaded with node and market-level keying. That weekly utilization table is then used to infer node-level forecasts using an array of statistical and machine learning methods, specific to each node's specific growth pattern(s). From there, each node, with all its detailing attributes and forecasted load, are passed through a robust rules-based optimizer to determine the growth path, again, on a by-node basis.

This rules-based optimizer, dubbed the capacity response engine (or CRE) is one of the most important apprentices of the planning tools. The CRE can apply "if then" based business logic, simply applying business rules to grow node capacity, or it can use constraints such as budget, costs, manpower, ROI, customer counts, and other customizable variables to return strategic-based network growth views; and it can deploy combinations of business logic and constraint-based functions. With the data and information about the node, the CRE uses the current node topology and the various attributes of the node to determine the best series of node actions to both manage congestion, as well as selecting the shortest and/or most economic path to fulfil Cox's strategic network initiatives.

With the CRE completed, applying node actions to the 10 plus years of forecast, the results are used to create reports, as well as used to create the Volume Model (VM). The VM is our resource management model that feeds directly into our cost models. Here, we determine the license and physical equipment needed to grow the network. These outputs are also used to determine field headcount resources and critical facilities needed, with automations to link that data to their respective models, as well.

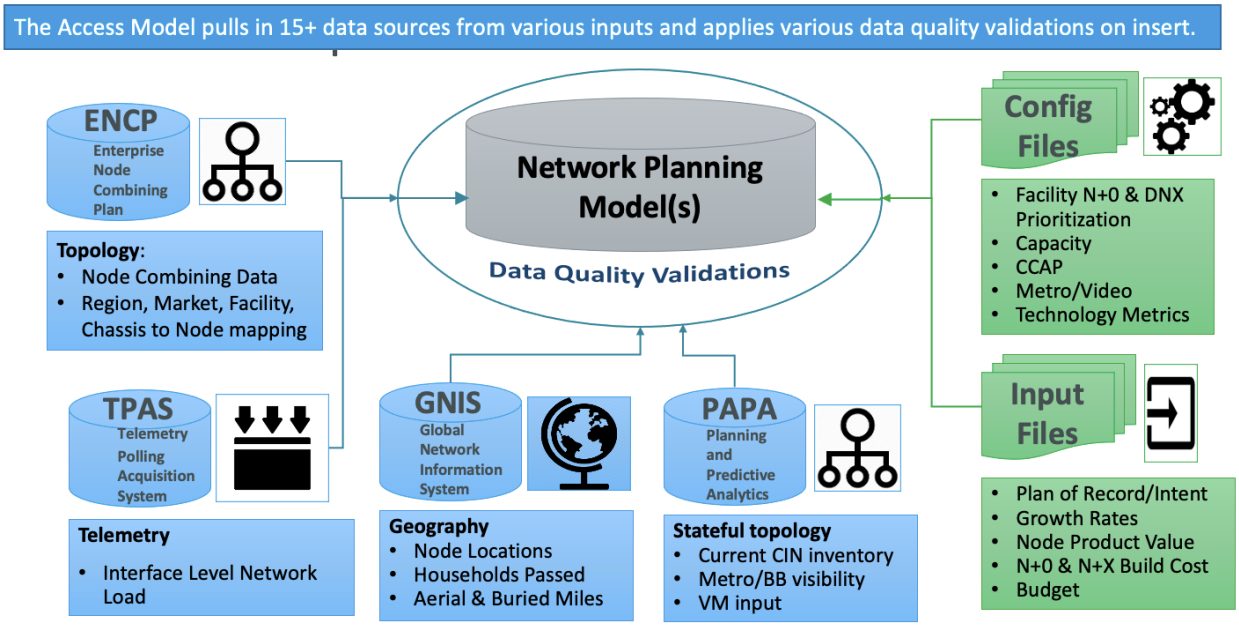

Figure 9 - General Overview of tooling

4. Business Continuity and COVID

Coupling our analysis and understanding of network and customer behavior has been vital for planning the network and keeping in front of the growth triggered by COVID. In the early days of COVID, in the beginning of lockdowns, we experienced a shift from the norm where customer-heavy nodes saw drastic decreases in usage while residential nodes saw a full year of growth, >30% year over year, in a few weeks' time frame (reference Figure 2).

With the robust pipeline of automated processes, we were able to marry the rapidly evolving data and analyses related to COVID and utilize insights from those analyses to quickly spin up forecasts to help us understand what "could" happen, as well as how we would need to grow the network to respond, thanks to the CRE. Data was used in creating hundreds of scenarios, and vital in determining courses of actions needed to address the elevated number of highly congested nodes* (see Figure 3). As well, leaders were able to assess costs near real time and make decisive decisions to keep up with this new network demand.

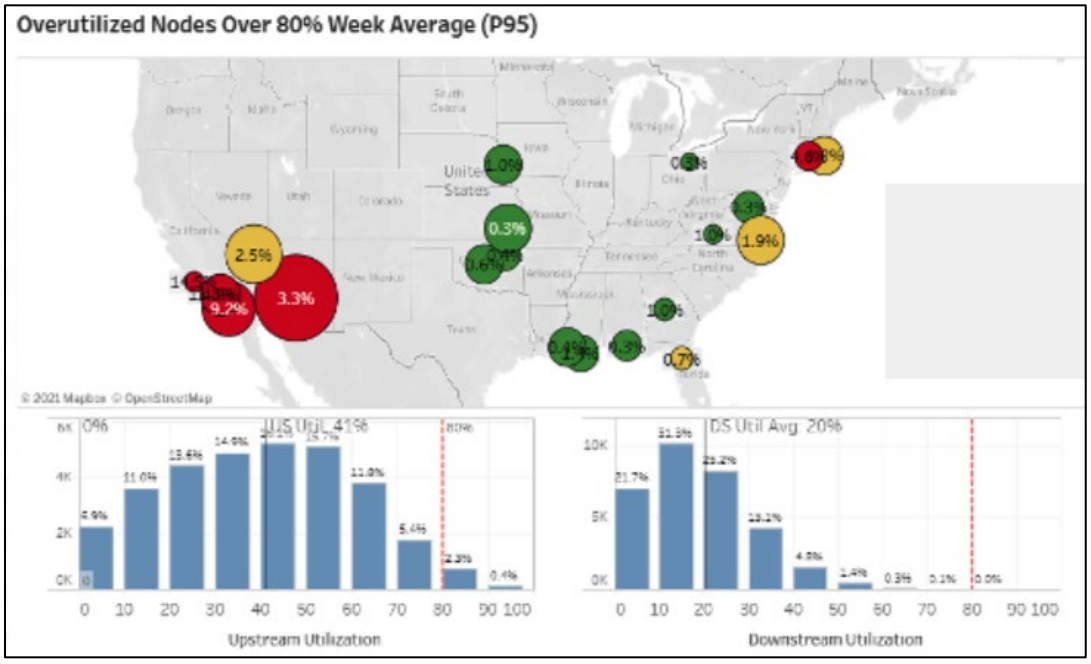

Figure 10 - COVID Related Network with High Congestion Nodes

Understanding the increased congestion was just a small portion of what was required. Next, we needed to be able to forecast and predict where we would see sustained growth, where we could expect less growth, and when we should see the effects of COVID decay from our growth curves. With our pipeline in place, we were able to increase the accuracy of our forecasts by implementing what we had learned so far, as well as reviewing and implementing assumptions regarding what we 'think' may happen. Of course, forecasting models weren't always 100% correct. Since we didn't have prior pandemic data to inform our models on the impact to network usage and node growth, we had to cycle input data in as fast as we could obtain it. From there, the models were updated on an ongoing basis. We were then able to add and control the COVID related variation by calculating a coefficient for the increased growth over what was expected (i.e. COVID growth over baseline expectation) then adding them into our Auto Regressive Integrated Moving Average models

(ARIMA, expressed: $Y_t - Y_{t-1} - \mu = \phi_1(Y_{t-1} - Y_{t-2} - \mu) + a_t - \theta_1 a_{t-1}$) and controlling with future assumptions and COVID decay with indicator variables (sometimes referred to as dummy variables or one-hot encoding in computer science). Figures 11 – 14 show some of the evolution of our assumptions, as well as the increased accuracy as we integrated more and more data after the mass lockdowns started.

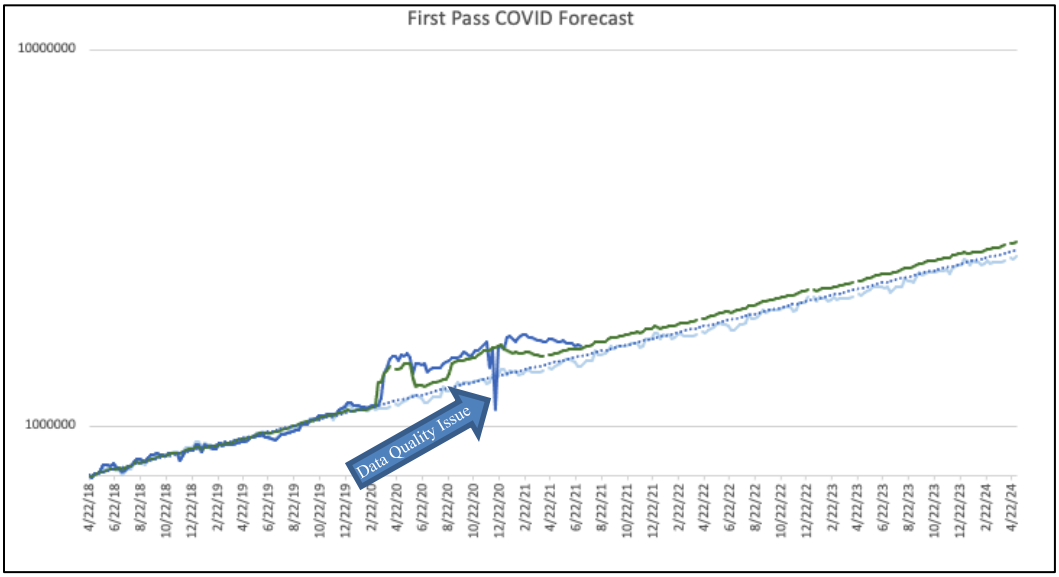

Figure 11 - Forecast post COVID W/O Forecasting COVID Effect

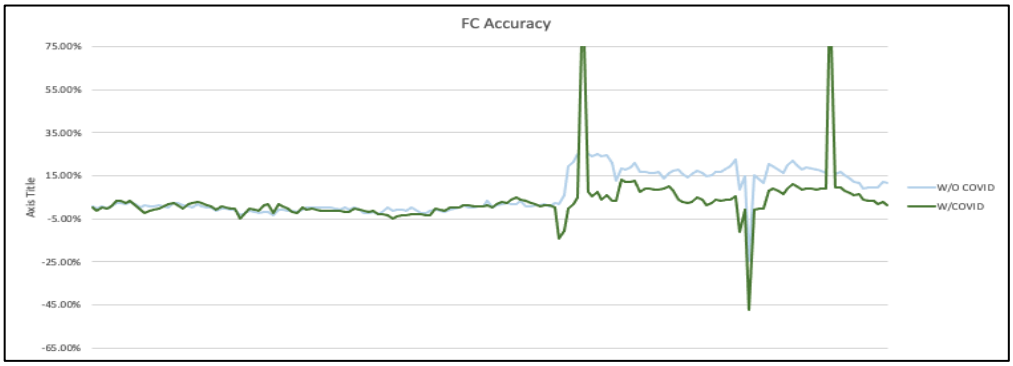

Figure 12 - First Pass Forecast post COVID

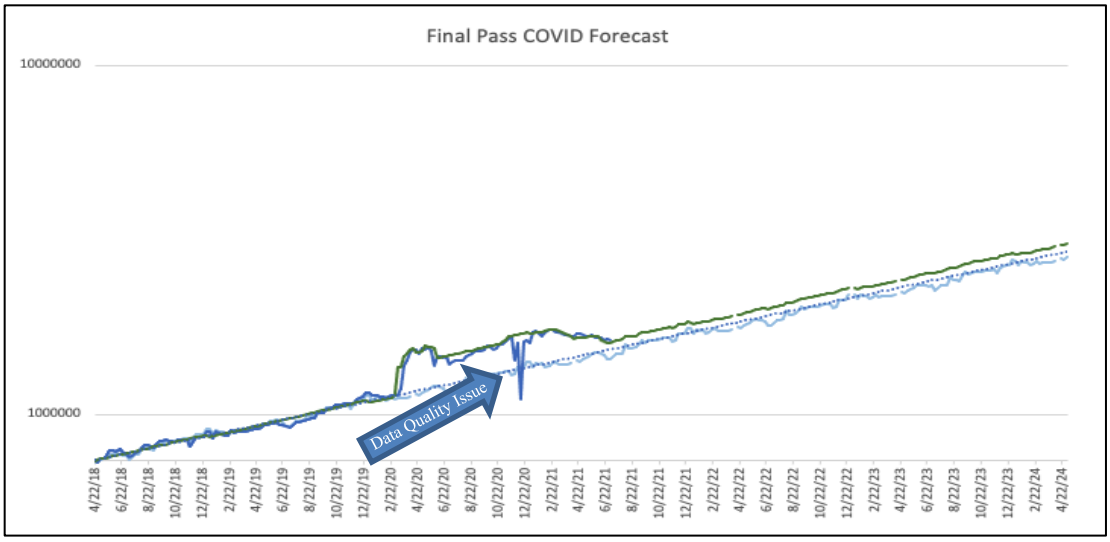

Figure 13 - Forecast post COVID with COVID Effect Forecasting

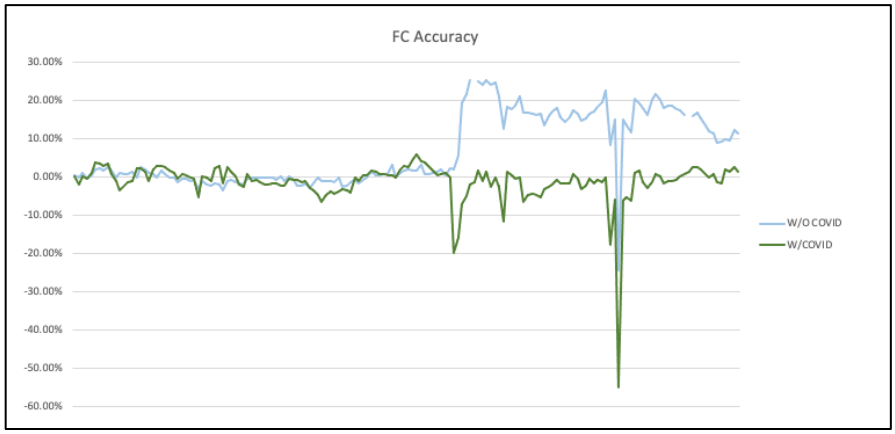

Figure 14 - Final Pass forecast with improved accuracy

With that, we were able to update and publish the models regularly. These published models are output into reports or used to generate costs and resource models, which are used in decision making about the direction of growing and planning the network. At first, we were updating the forecasts models weekly and communicating the findings to the broader teams. Despite the robust tasks of computing all the predictive models on a by-node basis, our scalable pipeline was always up to the task, and our planning teams were able to respond quickly. When we would see large shifts in the forecasts due to variations in the COVID related traffic, we would push the forecasts through the CRE to the outcome for our near-to-short-term plans.

This led to a need for complete network/model reworks of the full 2021 calendar year node growth plans, directly effecting outside plant and critical facilities executional plan of record. Utilizing our tools, we were able to re-work about year in just a few months, leaving more time for our field partners to adjust and react to the updates. To put this in perspective, our BAU (business as usual) policies require 18 months advanced planning “locks”, worked one quarter at a time over a period of a quarter. Achieving a

re-work of majority of the plan in the midst of the plan's deployment required solutions that not only work at scale, but can also be quickly adapted to unforeseen events, such as the COVID pandemic.

But just adjusting the plans also wasn't enough to address this congestion. Our engineering partners engineered solutions to address congestion; network solutions we had never modeled or deployed before. As these solutions were defined, we were able to model them. These solutions included spectrum actions, such as the implementation of 5th carrier and SOFA (sub split orthogonal frequency-division multiple access), to add fast and lower cost relief to highly utilized nodes. Being able to model these solutions as they were developed meant our leaders could measure the cost and benefits within days of the details being finalized so they could be integrated into planning for testing and deployment. Figure 15 below is an example of the output after a scenario run, implementing 5th carrier and SOFA to shoe the decreased need in other more invasive and expensive actions.

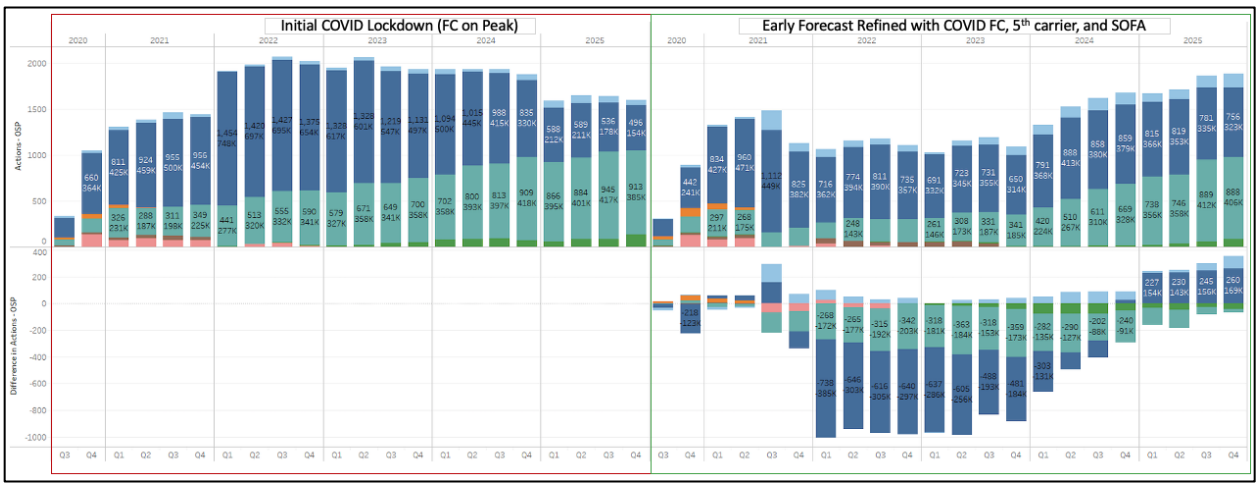

Figure 15 - Planning Scenario Implementing 5th carrier compared to predecessor

Conclusion

Cox's advanced network planning tools are where the rubber meets the road. A few years ago, the idea of these tools in their early developmental stages were presented at SCTE. Since then, we have been maturing the tools and increasing the capabilities and functionalities. Over the past few years, our planning teams have continuously developed and refined our tools to meet the needs of the business. In an extremely robust application, much of our analysis and planning components are automated, and automated with the flexibility to adapt quickly to changing business needs. The 2020 pandemic lookdowns tested our tools and infrastructure, but thanks to the scalable architecture, Cox was able to deliver refined plans to keep our customers connected.

Abbreviations and Definitions

ANOVA	analysis of variance

What's Smart About Smart Power?

Modernizing the Power Grid and HFC Networks: Power Outage Notifications and Advanced Sensing

A Technical Paper prepared for SCTE by

Dr. Robert F. Cruickshank, III
Gridmetrics™ R&D Liaison
Cable Television Laboratories, Inc.
Louisville CO, 80027
+1-703-568-8370
r.cruickshank-c@gridmetrics.io

1. Introduction

This paper calls the cable broadband industry to action to investigate and capitalize on the increasingly important intersections between grid/utility power and cable network power. Managing the intersections of power and communications across the landscape and throughout our respective infrastructures—from communities to forests—is fundamental to improving network reliability and cost-effective operations. Additionally, working with organizations responsible for emergency response, corporate security, situational awareness, public safety, and business resilience is fundamental to preserving our way of life and preventing catastrophic loss of life and property.

The paper begins with motivational examples related to grid outages caused by severe weather and cyber-attacks, their exponential rise, and troubling forecasts for increasing numbers of issues. A deep dive into the failures of supply and demand during the February 2021 Texas Power Crisis includes a spatiotemporal summary of issues in Houston and sheds light on the global nature of the many grid operational challenges ahead.

The background on powering the grid and how it connects to the Hybrid Fiber-Coaxial (HFC) network includes a discussion of the connection points of HFC power supplies and the possibility for fatal back-feeding from misbehaving power electronics in the growing base of solar photovoltaic inverters, battery walls, and electric vehicles. The sea change of implications of the grid incorporating renewable energy sources and transitioning from 1-way central-station delivery of power to two-way flows among distributed energy resources are discussed.

The Gridmetrics™ Power Event Notification System (PENS™) is introduced as the most capable, fastest, and lowest latency system for monitoring the massive sensor-starved grid edge. Also discussed is Gridmetrics' role in U.S. Department of Energy (DOE), Office of Cybersecurity, Energy Security, and Emergency Response (CESER), Cybersecurity for Energy Delivery Systems (CEDS) R&D program. The new American National Standards Institute (ANSI), Society of Cable Telecommunications Engineers (SCTE) Standard 271 2021 is discussed along with a few of the plethora of anticipated operational applications in the field.

Readers focused on how to better access utility power data, improve relationships with utility ecosystems, and create new business opportunities will benefit greatly from this paper and the accompanying presentation and panel session.

2. Motivation: Operational Costs and Network Reliability

Issues resulting from outages and poor power quality affect everyone and directly impact cost and service reliability. Outages and poor power quality issues are on the rise and are expected to increase.

2.1. Outages

At best, outages are expensive and disrupt cable broadband operations and the customer experience. At worst, outages lead to property damage, human suffering, and lives lost. Outages from 2002 to 2020 are shown in Figure 1 [1].

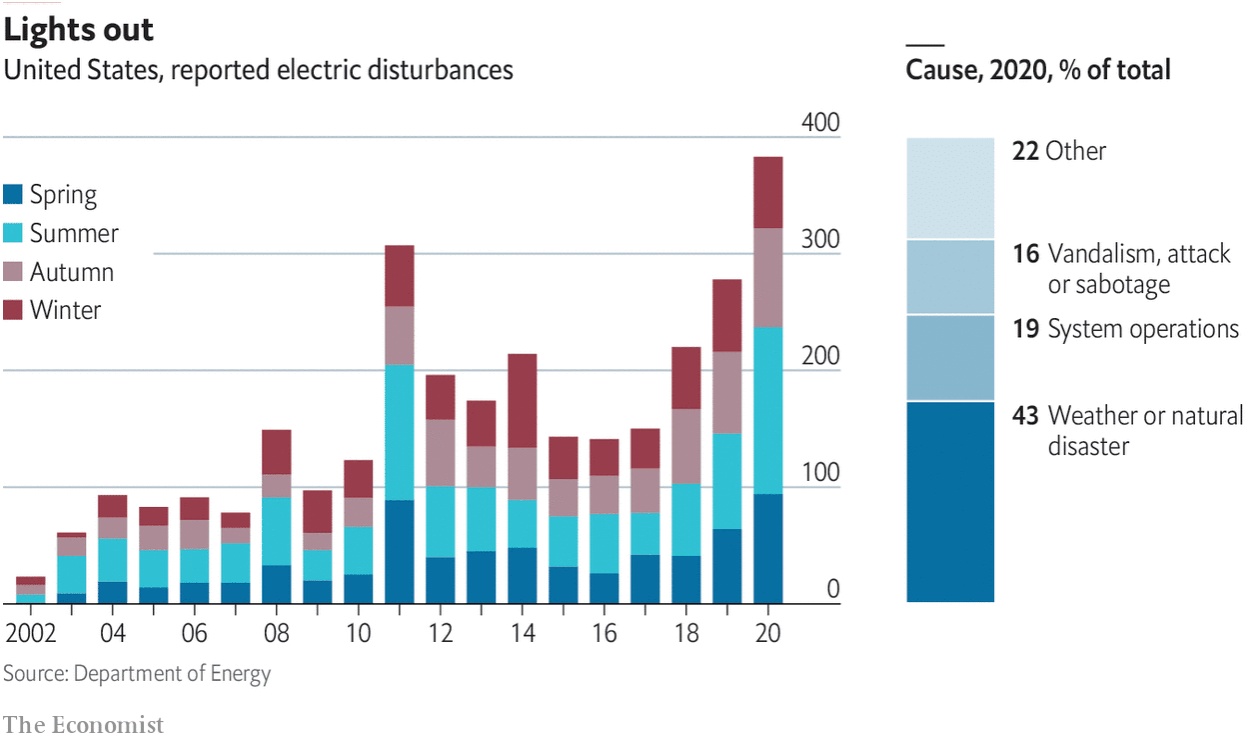

Figure 1 – U.S. Power Outages 2002 – 2020

Outages most often occur at the grid edge [2], and utilities are way behind the cable broadband industry in terms of being mostly unaware of an outage until customers call to report a loss of service. While both industries have made advancements in automatic outage detection and declaration, cable's battery-backed broadband networks are far superior to utility wireless mesh networks in terms of latency, loss, throughput, and jitter—and hence are the best alternative for monitoring grid voltage, phase, current, and on/off status.

2.2. Power Quality

Poor power quality is a silent and stealthy foe that is largely unmonitored. The American National Standards Institute establishes nominal voltage ratings and operating tolerances for electric power systems in ANSI C84.1-2016 provided by the National Electrical Manufacturers

Association [3]. The upper and lower acceptable voltage limits are 105% and 95% respectively, and there are additional considerations for the frequency, intensity, and duration of voltage excursions [4].

Within normal operating voltages, the customer experience is acceptable. Above or below voltage limits, issues arise with billing, resilience, safety, and equipment longevity. For example, high voltages lead to higher energy usage and higher electric bills and may damage capacitors on electric motors widely used in refrigeration, heating, air conditioning, and pumping water--and low voltages lead to overheating and a shortened lifespan of motors.
Unfortunately, utility "smart meters" are not up to the challenge of reporting costly power quality issues such as voltage spikes and sags. By design, all smart meters in the U.S. are limited to 240 VAC split-phase leg-to-leg measurements, providing no measurement of the performance of ground or neutral circuits. In every cable shop throughout the world, there is likely a prominently displayed section of melted in-home coaxial cable that serves as a warning to technicians of the fatal perils of unbonded neutrals and intermittent grounds.
While more than half of U.S. households have smart meters deployed, the capability is often unused in daily operations due to bandwidth limitations in the backhaul mesh communications infrastructure that results in bottlenecks in utilities receiving and processing smart meter data.

3. February 2021 Texas Power Crisis

The February 13–17, 2021 North American Winter Storm Uri, was a major winter and ice storm that had widespread impacts across the United States, Northern Mexico, and parts of Canada. The storm resulted in over 170 million Americans under various winter weather alerts and caused blackouts for over 9.9 million people in the U.S. and Mexico, most notably in the 2021 Texas power crisis [5]. The blackouts were the largest in the U.S. since the Northeast blackout of 2003 and resulted in economic costs, human suffering, lives lost. Losses were greater than Hurricane's Harvey and Ike.

3.1. Severe Storms

The Texas Power Crisis came about as a result of three severe winter storms sweeping across the United States from February 10–20, resulting in massive electricity generation failures, and resultant shortages of water, food, and heat [6]. Nearly than 4.5 million homes and businesses were left without power for four days of freezing darkness [7]. At least 210 people were killed directly or indirectly, with some estimates as high as 702 killed as a result of the crisis [8].

3.2. Failure of Generation and Fuel Supply

As shown in Figure 2, the arctic temperatures resulted in the failure of 48% of electricity supply as generators and fuel supplies for generators froze and were unable to operate to meet the unprecedented rising demand of heating loads. The February 15–18 gap between (colored) supply and demand depicts massive declines in hundreds of natural gas and coal-powered generators along with lesser declines in wind and increases in solar generation.

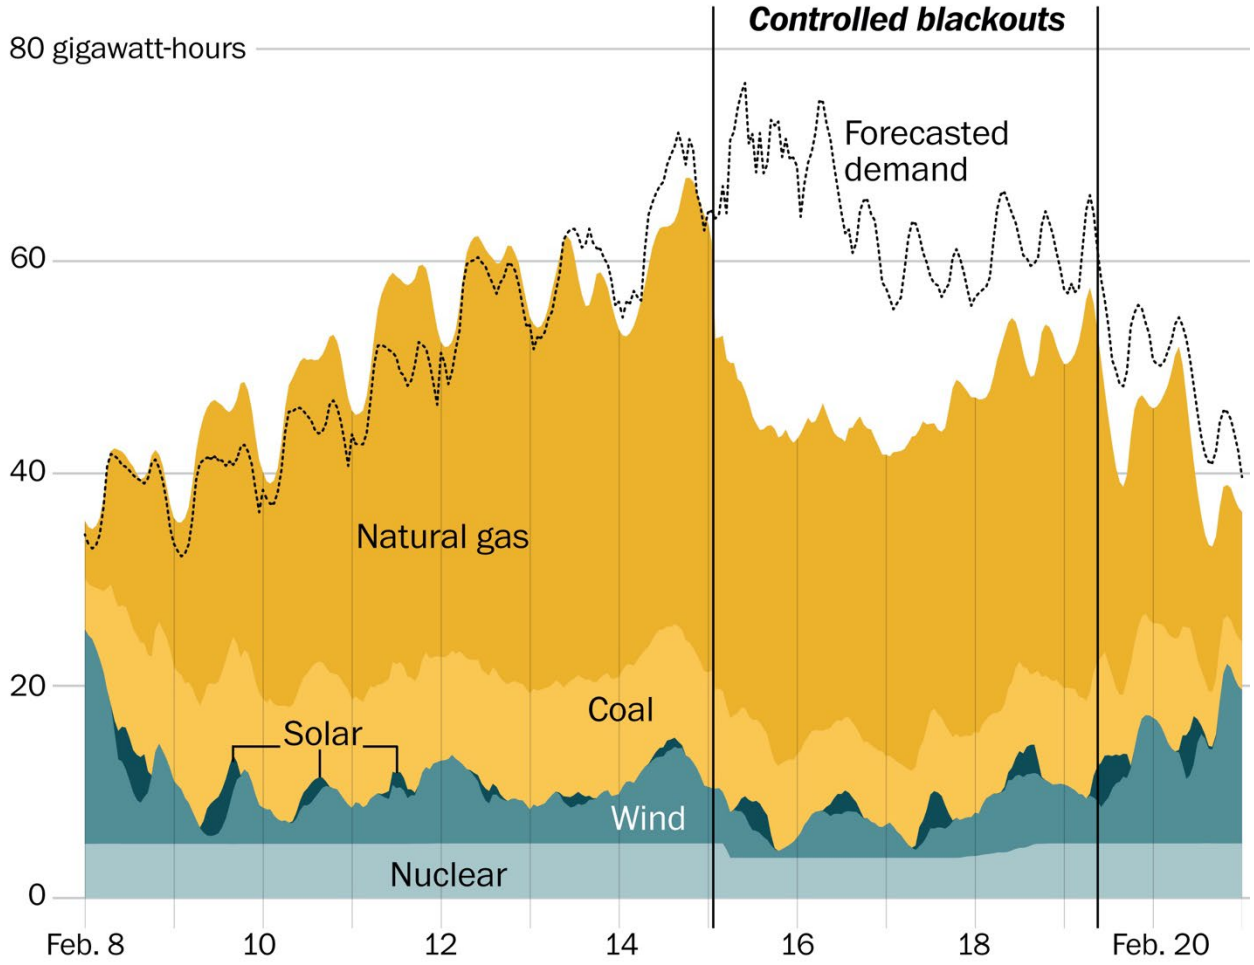

Figure 2 – Texas Electricity Supply and Demand February 8-20, 2021

The observations presented in Figure 3 are based on measurements from over 10,000 HFC power supply sensors distributed across the low-voltage distribution grid in the Houston, TX area. The sensors provide a voltage reading (± ~1.2 volts) at a particular latitude and longitude at 5-minute intervals. For the purposes of this analysis, power sensors have been aggregated and mapped to the U.S. National Grid, (USNG) a standard 1 km x 1 km square. The color scale at right is an index that denotes outage duration, where red denotes sensors out all three days.

3.3. Spatial and Temporal Analysis

In the data, both macro and subtle patterns can be seen as the widespread power outage and subsequent recovery unfold. The exact cause of an outage at any particular sensor cannot be inferred directly from the data—i.e., whether the outage was due to downed lines or due to operator-controlled power shutoffs (aka load shed)—but analyzing temporal and spatial behavior of voltages and power conditions reveals a new, independent lens to view and understand the severity and duration of outage events across the city and within particular neighborhoods. In addition, analyzing voltage trends prior to outage events, as well as residual voltage readings on de-energized lines during outage events, highlights an urgent need for better real-time situational awareness of the distribution grid to anticipate localized grid stresses and to manage utility

worker and public safety. A special thanks goes to Dr. Scott Clearwater and the team at CableLabs for the analysis.

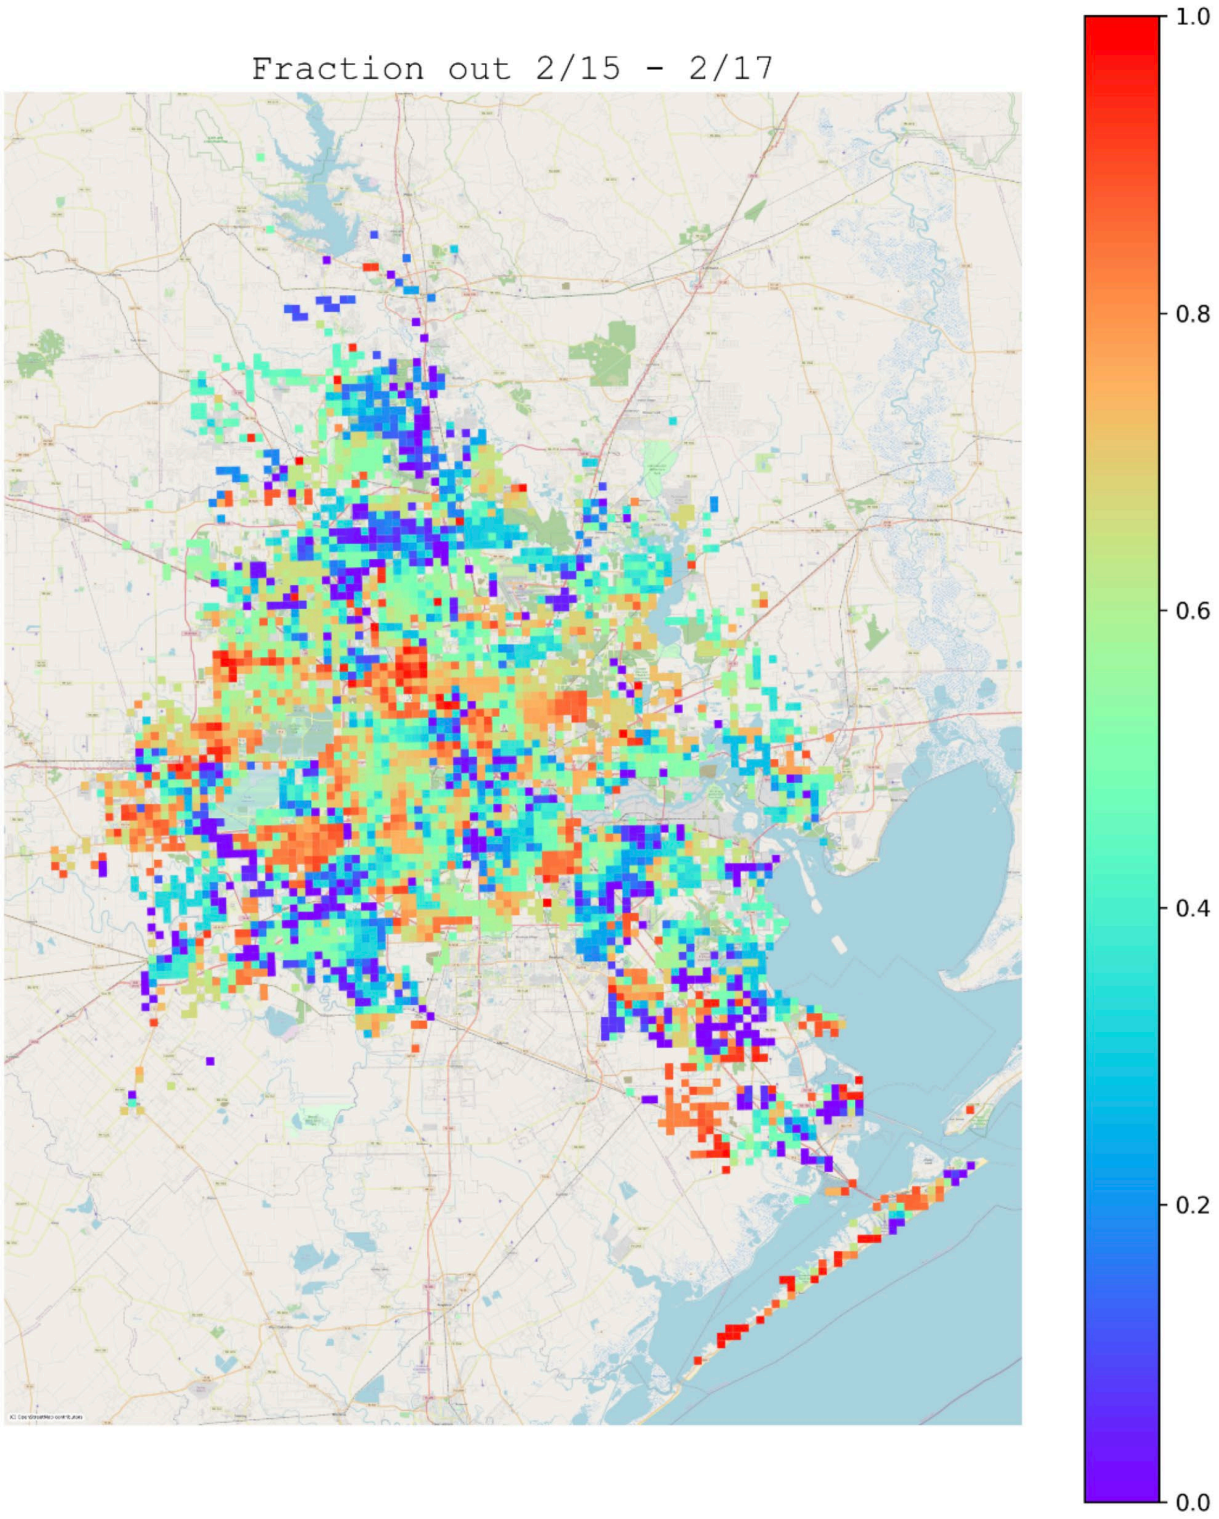

Figure 3 – Spatiotempotral view of Texas Power Crisis, February 15-20, 2021

3.4. Missing Focus on the Demand Side

The February Texas Power Crisis along with two more Texas blackout close calls in April and June resulted in a focus on improving the nexus of natural gas and power generation, better public communication, more power plant weatherization/protection, and new power transmission projects. Demand-side work has been ignored and missing to date is a focus on shoring up the grid by aggressively managing load [9].

4. Background on the Grid and HFC Powering

Situational awareness of the electric power grid is gaining in importance with the increasing number of power generators, power consuming devices, and power infrastructure failures. In the United States, 200,000 miles of well-instrumented high-voltage transmission lines make up the grid core, or backbone. However, lower voltage, local distribution lines connect the remaining 96.5% of the grid, accounting for 5.5 million miles of poorly instrumented grid infrastructure as shown in Figure 4. [2].

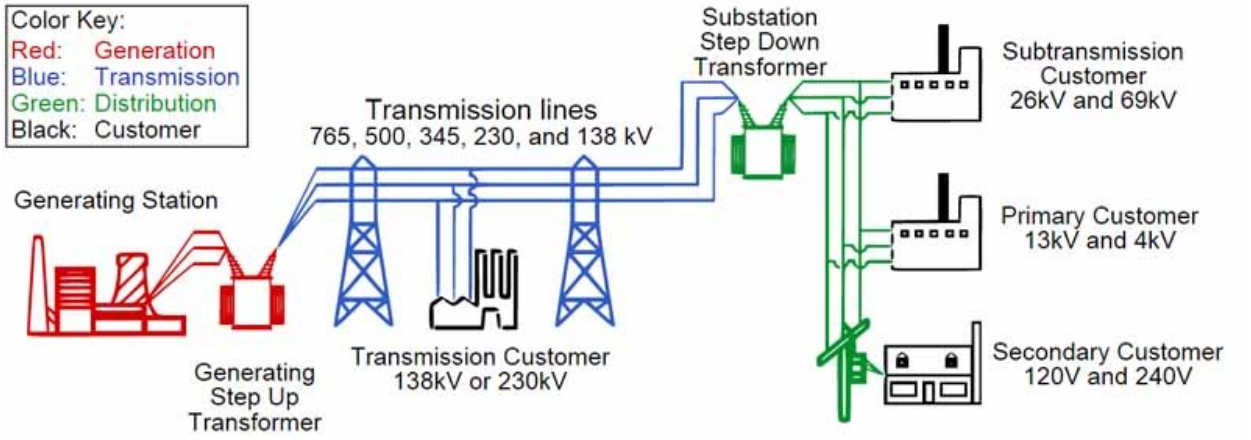

Figure 4 – Power Grid Schematic

The connection points for HFC power supplies, electric vehicle (EV) chargers, and photovoltaic systems are located in the distribution grid shown in green in Figure 4.

5. Solutions for Monitoring the Grid and HFC

There are inevitable requirements to get new, real-time instrumentation deployed into the last miles of the distribution grid, and the broadband industry already has a great head start.

5.1. Gridmetrics™ and PENS™

Gridmetrics is the premium supplier of power event notifications. Gridmetrics was born at CableLabs and inspired by 2017-2021 conversations with the National Renewable Energy Laboratory. Gridmetrics makes grid insights available via the Power Event Notification System (PENS™). PENS Aggregates unique data from ~300,000 sensors in HFC power supplies and provides an unmatched observational view of the state of power in the last mile of the distribution grid. PENS alerts are available via email, Esri, and an API for use by emergency

response, public safety, FEMA, DHS, business resilience, and other users. The nationwide footprint of Gridmetrics sensors is shown in Figure 5, where red the notes outages.

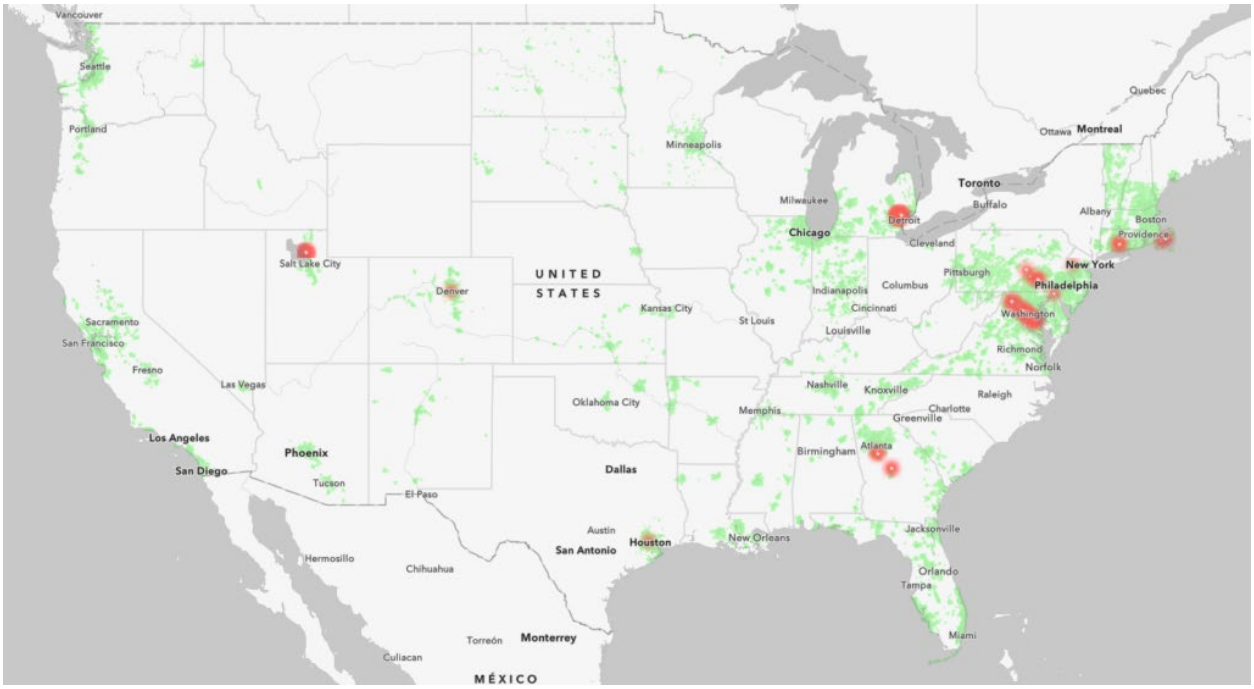

Figure 5 – Gridmetrics™ U.S. Map

Figure 6 shows an example of a PENS Alert for an area to the West of Tallahassee, Florida. Note how the event, the population, and Gridmetrics sensors are alongside the edge of a wildlife area.

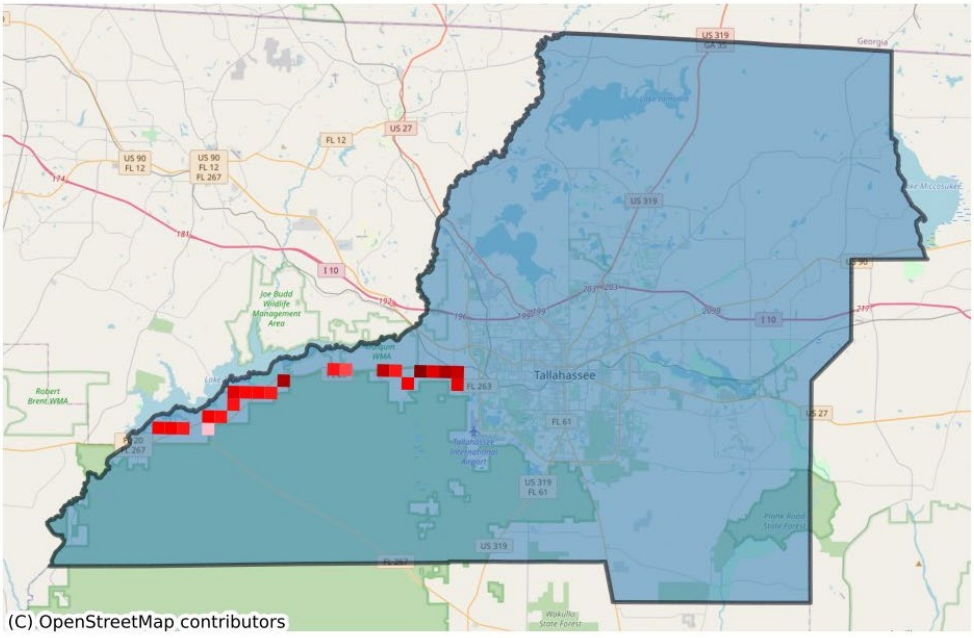

Figure 6 – Example PENS™ Alert

Figure 7 provides an additional example of Gridmetrics sensors tightly aligned with population. Darker green denotes denser populations and darker red denotes outages affecting more people.

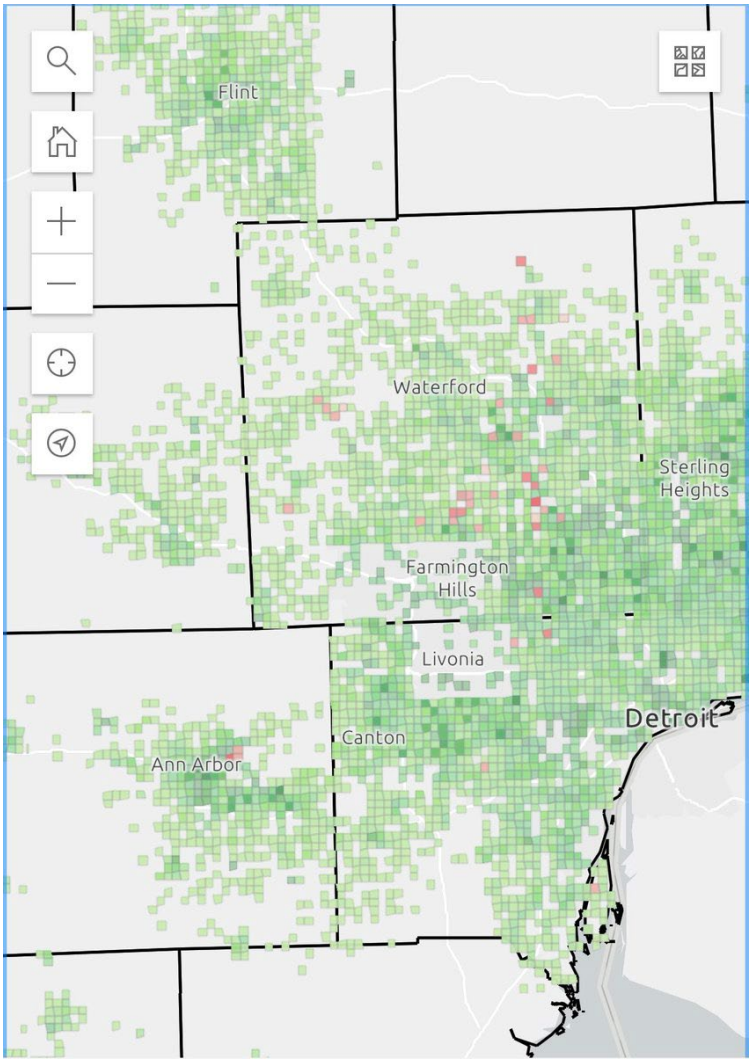

Figure 7 – July 21, 20201 PENS™ Detroit Outage

Today, there is no comprehensive, independent source for power event insights. Most solutions offer insights only at the county level. As mentioned previously, PENS provides insights using the USNG 1km x 1km grid overlay projection. In addition, most solutions offered by utilities and other entities provide updates only every 15 minutes. PENS scans the broadband sensor network every 5 minutes looking for events.

PENS Email Alerts are unique in that they provide: 1) Initial Alert, 2) Update Alerts over time, and 3) Closing Alerts to indicate service is restored. The combination of the three types of Alerts allows for automatic opening and closing of network incident tickets in different operations centers within a utility, broadband provider, emergency responders, etc. Interested users may sign up for alerts and more information at www.gridmetrics.io.

Gridmetrics is part of the Esri partner network and provides a Feature Service Layer view in Esri Marketplace [10]. For existing Esri users, the set-up is simple, and a no-fee trial version is available.

5.2. SAGA - Situation Awareness of Grid Anomalies

Another powerful solution for monitoring the power grid and HFC networks as SAGA, Situational Awareness of Grid Anomalies. SAGA is a $3M, 3-year project to develop near real-time cyber-physical resiliency through machine learning—using existing infrastructure. The U.S. Government funding for SAGA came in 2019, after several joint proposals were developed by the National Renewable Energy Laboratory (NREL) and CableLabs, submitted, and evaluated by the U.S. Department of Energy and the Advanced Research Project Agency.

SAGA identifies anomalous behavior using cable broadband's secure out-of-band in-service network and rapidly detects cyberattacks dynamically and in near real-time through machine-learning. The SAGA learning-aided low-voltage estimation framework is shown in Figure 8.

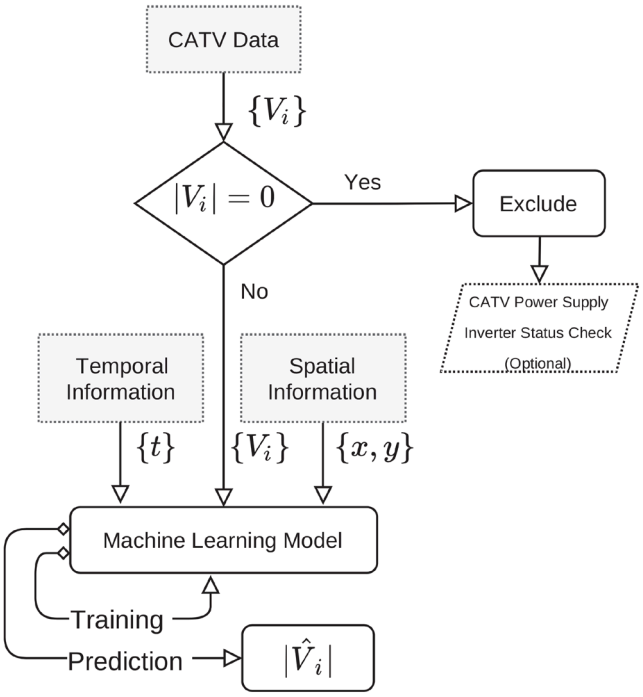

Figure 8 – SAGA learning-aided low-voltage estimation framework

The goals of SAGA include demonstrating a disruptive technology for power system data analytics using existing infrastructure while providing commercialization and product feature roadmaps. SAGA builds upon NREL's extensive collection of power system state estimation and mapping tools and integrates the growing set of Gridmetrics 'situational' data. SAGA assimilates other time-series geospatial data such as weather and cyber-physical phenomena, distribution infrastructure maps, and tax lots. To ensure the ongoing evolution of SAGA and global impact

on operational efficiencies and network reliability, lessons learned inspired the development of a new next-generation ANSI/SCTE grid and HFC sensing standard.

6. New U.S. National Standard: ANSI SCTE 271 2021

Motivated by the successes of PENS and SAGA and recognizing that existing sensing capabilities are out of date, the new ANSI SCTE 271 2021 standard specifies requirements for Power Sensing in Cable and Utility Networks. SCTE 271 specifies additions, without replacing prior sensor specifications developed in the late 1990s during the development of DOCSIS 1.x.

SCTE 271 specifies how to monitor HFC and Grid for voltage and current anomalies and send *raw* waveforms to the cloud for further processing. The importance of the ability to observe, communicate, and then cloud-compare multiple high-resolution traces of voltage and current in real-time cannot be overstated. Secure backhaul of streaming continuous point-on-wave (CPOW) power observations is a quantum leap beyond phasor measurement units that assume a sine wave and then compress and distort all data before backhauling, as shown in Figure 9 (note the phaser approximation completely misses and misrepresents the voltage spike anomaly).

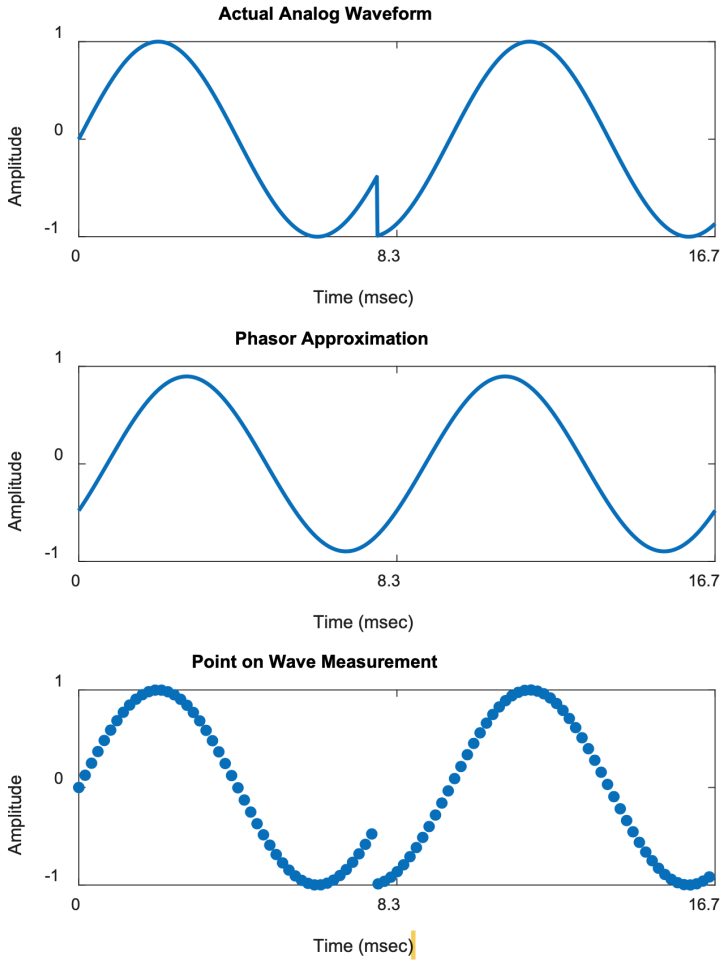

Figure 9 – SAGA learning-aided low-voltage estimation framework

SCTE 271 measures the 60/75/90 VAC quasi-square wave HFC network and the 120/240 VAC power grid. Goals include: 1) reducing network element reboots, outages, and issues that cause wildfires, and 2) improving the customer experience and the lifespan of the HFC, Customer Premise Equipment, and the grid. SCTE 271 can be used to identify voltage and current highs, lows, fluctuations, as well as outage and voltage sages that indicate grid congestion—that can be used to actively manage load and increase use of renewables.

The following requirements are included in SCTE 271:

1. If voltage or current is sensed, it ***shall*** be measured with a precision of 0.002 per-unit (0.2% of nominal value), e.g., +-0.24 volts at 120 VAC
2. If CPOW capture is provided, the sampling rate ***shall*** be a minimum of 10k samples/second = 166 samples/period at 60 Hz (more better)
3. If observation timestamp provided, the resolution ***shall*** be <= 1 microsecond. Clock accuracy ***shall*** be <= ½ microsecond, which is ~ 1/100th of a degree at 60 Hz
   (1 sec / 60 cycles) * (1 cycle / 360 degrees) * (1 degree / 100) = .46 microsecs
4. If configurable remote reporting is provided, control plane ***shall*** enable a) a 1-time poll reply, b) continuous replies and/or c) fixed interval replies
5. If a communication plane is provided, it ***shall*** use IETF/APSIS YANG model and SSL or TLS for authentication & encryption. No SNMP is required.

The new capabilities specified SCTE 271 are expected to unleash a plethora of opportunities for proving value in advanced grid sensing that helps modernize and manage the grid by predicting catastrophes and advancing grid state estimation with visibility to two-way electricity flows.

6.1. The Aging and Failing Grid: Predicting the Next Catastrophe

Figure 10 shows additional examples that reinforce the need for and benefits of advanced grid sensing. Both images were taken from *in-service* conductors and were made possible by developing and applying grid sensing capabilities in Australia in the wake of catastrophic wildfires. The image at left is a wire-rope conductor that is unravelling mid-span. Imagine looking up from a chairlift or gondola, that you are riding on, and seeing the wire-rope unravel! The image at right is a flat “Licorice” drop cable that is often used in direct burial applications.

Figure 10 – Examples of failing in-service conductors

6.2. The Changing Grid: Advancing State Estimation by Monitoring Two-Way flows at the Grid Edge

The grid edge is constantly changing. From with a historical perspective, in 1882, Thomas Edison installed generation in New York City and London using coal fired power plants, which use the thermoelectric Rankine cycle—and haven't changed all that much. All electricity delivered from power plants travelled outward through the grid to customers; this is referred to as a one-way delivery of central station power. And that's how the grid operated for the next hundred years; there was organic load growth in the sense that, new appliances, housing subdivisions, power substations were developed, but behavior was mostly predictable, and the grid had one normal state. It was either on or it was off.

Then came the Public Utility Regulatory Policies Act in 1978, which for the first time allowed non-utility generators to market their power to utilities. Suddenly, anybody could build and operate a generator, not just utilities. Fast forward to today where every state and nation has renewable portfolio standards, trying to achieve, say, 30% renewables within five years, 50% renewables within 10 years, etc. But that means generators are everywhere. And now we have not just one-way flow, we've got two-way flows at the grid edge! If the solar panels on your house make more energy than you're using, then grid electricity is not flowing into your house—it's flowing out of your house. And that's great, but the problem is, the sun and the wind are intermittent and variable. They're uncertain and forecast error is on the rise in the face of climate change and severe weather.

So, we're not certain what the production and demand at the edge is going to be; we do our best to forecast it, but we don't know for sure and that makes these two-way flows, even more unpredictable. The net effect is, it's much harder to "see" and estimate what's going on in the grid today—than in the old grid with one normal state—where you could easily tell if it was on or off based on customer call volume. Today, there's an unlimited number of dynamic normal states and that thwarts detection of non-normal conditions—caused by something really being wrong. For example, is a voltage sag or spike in a neighborhood just because a cloud went over the sun or because the sun came out again—or is it the result of a coordinated outside-in cyber-attack against thermostats, HVAC controllers, "smart" inverters at the edge with the intent of taking down the core?

Today, we struggle to identify failures and cyberattacks. It's difficult to detect cyberattacks and here's why: If you found the keys to a car and you were mischievous, you might wait until midnight, and then, lurk around and figure out which car those keys fit—very quietly and unobtrusively. Once you had access and you were in, then you'd wait until the owners left and then you'd steal the car. And that's the fear with cyberattacks; attackers constantly try to get in and might make only small disturbances—until they know that they're in. But the disturbance they create can be so small that we won't be able to detect their presence until they come back and do something terrible and bring down the grid. And we all know in the pandemic and severe weather, that the reliability of the network is extremely important, and we simply cannot have energy and communications networks go down—ever!

7. Conclusion

As the number of distributed energy resources and two-way electricity flows rapidly increase, the aging grid infrastructure elements that are supposed to keep the grid safe are failing and causing unprecedented loss of life and property. While the enormity of the electric power grid is such that in the U.S. alone, the 5.5-million-mile distribution network is long enough to reach the moon nearly 21 times—the performance of the last mile of the grid is sparsely monitored and hence unable to be optimally managed. Gridmetrics sensor readings fill the immediate need to augment utility supervisory control and data acquisition systems by rapidly improving the monitoring of the secondary distribution portion of the grid.

The growing and evolving Gridmetrics data set is available to aid in monitoring and managing the secondary distribution networks that make up the last mile of the grid. The locations of specific anomalies worthy of investigation are available for use in the utility ecosystem including emergency response, public safety, the Federal Emergency Management Agency, the Department of Homeland Security, business resilience, and other entities.

Through maintenance and repair efforts, infrastructure aging, wear, and tear—and local weather—the location and severity of anomalies will change over time, supporting the case for the real-time Gridmetrics API and real-time data feeds. Through collaboration with the utility ecosystem and sharing best practices for anomaly detection and classification, it is expected that anomalies that foretell of impending infrastructure failures and safety issues, and high-risk for loss-of-life can be identified. In addition, the criteria used to identify anomalies can be expanded, refined, and validated to achieve maximum benefit from Gridmetrics data.

Data from next generation broadband power quality sensors can help pinpoint existing portions of the grid that can be inspected for high, low, and fluctuating voltages—and high-impedance faults—which can cause unsafe conditions, poor customer experiences, and premature failures of customer equipment. In addition, outage data from broadband sensors can be correlated with existing data sets to create a more comprehensive understanding of distribution network performance and frailties. Combining insights from utility supervisory control and data acquisition systems and Gridmetrics data will help improve network reliability, resilience, and safety.

1. Introduction

There are many ways to model advanced broadband networks, and a growing number of ways to simulate their behavior, based on available information about performance characteristics. This paper, co-authored by Comcast's Ramya Narayanaswamy, Karthik Subramanya, Richard Prodan and Larry Wolcott, will explore the intersection of theoretical modeling, practical proactive network maintenance (PNM) and modern data science – a potent combination that is well suited for the sophisticated modeling and simulation needs of cable 10G networks.

Using traditional RF reflection measurements like scattering parameters / S-parameter matrices, fed by real-world field PNM (Proactive Network Management) data into a graph topology, the authors will show how advanced 10G networks, and particular bidirectional signal flows, can be simulated for both existing and proposed networks.

Having a graph topology of the network, along with cable and component specifications, provides a means to apply transmission line theory as never before. Most cable operators have this RF and reflection data readily available for their systems. This simulation of cable systems, as-built, can predict end-to-end performance which can be compared against actual measured performance using PNM tools. This technique can provide a method for the evaluation of full-duplex (FDX), extended spectrum (ES) and traditional RF transmission performance of existing plant, as well as experimental designs. Beyond that, it can solve for fault detection, and many other previously unsolvable RF mysteries within our cable universe.

2. Background of Network Modeling

Scattering parameters or S-parameters are commonly used to model the electrical behavior of radio frequency (RF) communications networks when stimulated by electrical signals. The S-parameters are used to form a scattering matrix or S-matrix, that collectively describe the behavior of a network or circuit at different frequencies. These parameters are convenient for high-frequency RF design because they are easily measured by standard lab equipment such as a vector network analyzer (VNA). Coaxial S-parameters are further described in section 7.2.

There are alternatives to S-parameter modeling, which can be used to understand the transfer function of communications networks. Analysis of the frequency response including signal levels transmitted from the node and received by the cable modem or vice versa is described. This approach allows the use of log magnitude values versus frequency from component spec sheets to model the transfer function of each section of transmission line (i.e., cable) terminated at either end with an impedance (i.e., a tap, node, or cable modem) characterized by its magnitude return loss versus frequency. Note that this formulation provides the complex frequency response with only the scalar amplitude versus frequency of the cable transmission line and the magnitude return loss and insertion loss versus frequency of the tap terminating impedances. This provides a convenient alternative to S-parameter and T-parameter measurements, which are difficult to measure on existing networks.

3. Network Modeling and Simulation

3.1. Physical Layer (PHY) Model

Traditional hybrid fiber/coax (HFC) cable distribution networks have been built as tree and branch networks consisting of a fiber node connecting multiple cascaded amplifier coax cable sections. Each section connects to a series of multiport taps transmitting signal to and receiving signals from drop cables

to customer premise equipment. An example of one coax branch of a conventional Node + N HFC architecture shown in Figure 1. The node span contains multiple amplifier spans, each with multiple taps between amplifiers.

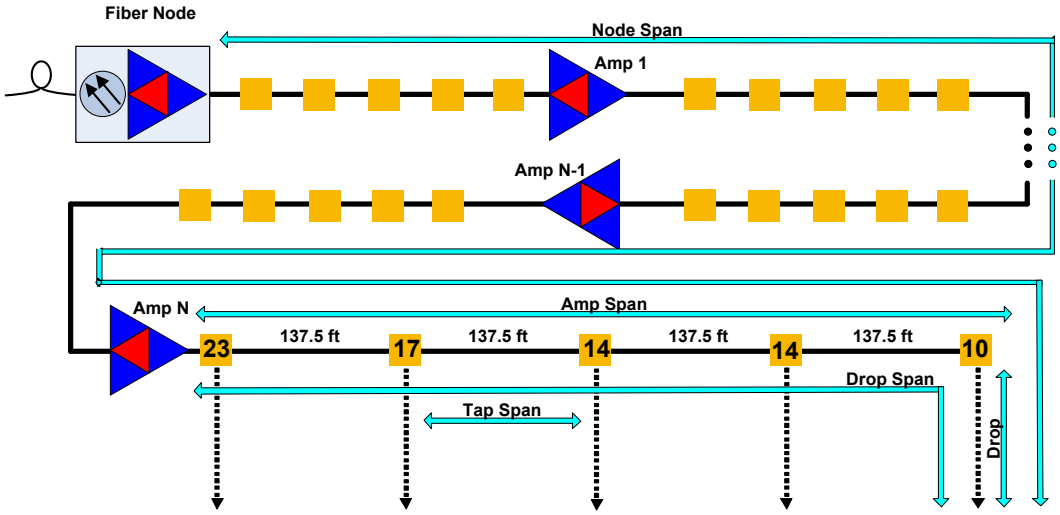

Figure 1 - Conventional node plus N network architecture

This conventional architecture provides two-way signal transmission on separate spectral bands using frequency division duplex operation. Each amplifier section uses diplex filtering to separate upstream transmissions toward the node in the narrower lower frequency band (typically 85 MHz or less) from downstream transmissions from the node in the much wider upper frequency band (up to 1.2 GHz). Such diplex filtering prevents two-way transmission within the same bandwidth. Each multiport tap contains a directional coupler that diverts a portion of the downstream signal to the drops connected to the tap ports and injects the upstream signals present on the tap ports toward the node. The directivity of the directional coupler prevents upstream signals from propagating in the downstream direction or from diverting to other drops upstream from that tap port.

The design of a hybrid fiber coax (HFC) network requires specifying the individual components and their values to obtain consistent signal levels across all the subscriber drops. These include:

- hardline cable (trunk and express feeder) and drop cable type and parameters
- tap parameters (insertion loss, tap loss, return loss, isolation)
- downstream and upstream node and tap equalization type, frequency range, and tilt value
- tap spacing
- drop cable length
- amplifier output (level and tilt)

Analysis of the frequency response including signal levels transmitted from the node and received by the cable modem or vice versa is described. This approach allows the use of log magnitude values versus frequency from component spec sheets to model the transfer function of each section of transmission line (i.e., cable) terminated at either end with an impedance (i.e., a tap, node, or cable modem) characterized by its magnitude return loss and insertion loss versus frequency.

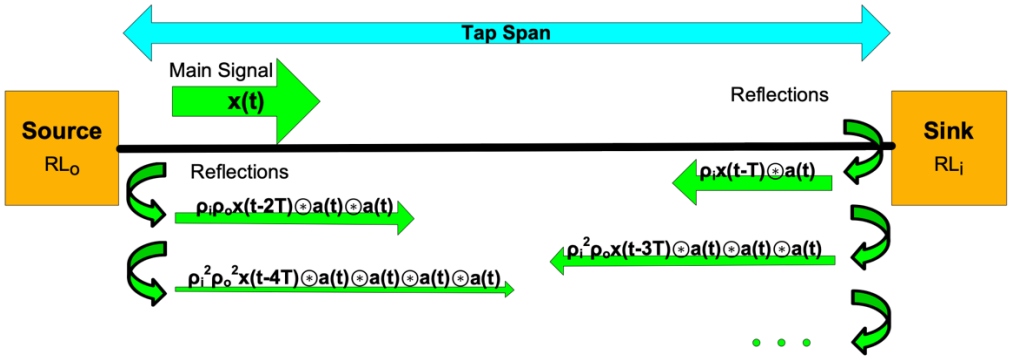

Figure 2 – Signal reflections in a cable between adjacent taps

Consider a signal transmitted downstream from a tap output to the adjacent tap input as shown in Figure 2. with amplitude response $A(f)$ and linear phase response which has the corresponding impulse response of the cable denoted by $a(t)$. The transmitter at the signal source has (nearly) matched impedance to the drop cable but with a return loss RL_o (dB). In general, the return loss is also a function of frequency $RL(f)$. The signal traverses the cable to the tap with propagation delay T which has a (nearly) matched impedance to the cable with return loss RL_i (dB). A portion of the signal equal to the reflection coefficient $\rho_i = 10^{-RLi/20}$ is reflected back to the source, which in turn a portion of the reflected signal equal to the reflection coefficient $\rho_o = 10^{-RLo/20}$ is re-reflected back toward the tap, and so on ad infinitum. This can be represented as a sum of the incident signal x(t) and the infinite series of reflections each delayed by the round trip (i.e., twice) the propagation delay T of the cable.

The same analysis applies to a drop cable section between a tap port and the cable modem F-connector port where the attenuation model and propagation delay are specified for the drop cable instead of the hard-line cable and the input and output return losses are specified for the tap port and the cable modem F-connector port respectively. The network simulation will require each of these transmission lines to be cascaded from the node to each cable modem attached to the network.

3.2. Network Topology as a Graph

Cable operators typically have some electronic form of system design, usually rendered by computer aided design (CAD) systems. These electronic representations of the network are used throughout the lifecycle of the network, from design to construction, upgrades, maintenance and so forth.

One of the major goals of the graph system is to map the physical and logical topology of the access network into a graph database that will allow querying paths between the physical and logical objects of the access network. There is no single dataset or database that currently has the required data compiled with common keys, instead the data is distributed across different units of the org among databases currently in use for services with differing goals. The lack of common keys and differing identifiers and definitions for the same objects in different databases present a challenge. The initial goal is to achieve mapping 95% of an access network node in the graph. To overcome this challenge, we develop and implement algorithms that check for availability of an access network object in multiple databases and when found confirm matches to the same vertex, when not-found provides an edge to the nearest vertex with a score that provides the strength of the attribution.

The goal is to map the following path: Device → Household (HH) → Tap → Amp → Buss Leg → Node using the following 3 data sources:

1. *CAD* provides detailed data on the physical design topology of serviceable addresses. Attributes reported include model, type, and location coordinates for CMTSs, Nodes, Taps, Amps and Serviceable Addresses: This is used for HH → Tap → Amp → Buss Leg → connections
2. The node combining plan *(NCP)* provides billing information presenting currently active services serving subscribers with activated devices for each location. Providing for Device → HH connections
3. *CM Topology* provides CMTS registry, and the devices connected to the CMTS at the given moment. Used to validate online inventory from Device → CMTS

While CMTS naming is conventional and CM Topology can be matched to NCP rather easily, the main difficulty is identifying the activated addresses in physical design topology in CAD and matching them with the addresses from the billing data. The matching algorithm consists of the following steps:

Step 1: Filter the CAD dataset for HH's using a node ID and account numbers with corresponding Addresses and Devices in the network data aggregator

Step 2: Use an enhanced fuzzy matching algorithm on the address fields of CAD data and network data aggregator to get high confidence matches for same addresses.

Step 3: Use lon/lat coordinates as reported in CAD data and network data aggregator to match records based on geographical proximity. We match coordinates that are closest to each other using a threshold for maximum distance.

Step 4: When no match can be made between CAD and network data aggregator records, get the records for all the taps with their coordinates attached to the node from CAD. Match all the network data aggregator records to the nearest tap using lat/lon coordinates. All the addresses from network data aggregator gets a match at the end of this step, all the unmatched addresses from CAD are tagged as inactive/passed addresses.

Step 4: Merge all the matched addresses to CM Topology data using media access control (MAC) addresses. Anything unmatched on left and right side are tagged accordingly and will be passed off to related teams for further review.

3.2.1. Graph Topology Data Structure

The graph data used in the simulation consists of a set of vertices/nodes that represent the hierarchical elements of the network, and a set of edges that represents the relationships in this hierarchy. A high-level example is illustrated in Figure 3. Figure 5 shows the details of the graph structure which contains a cable modem (Device), equipment location (HH), drop cable (Drop) and tap (Tap) which are connected. Figure 4 shows a more complex example of the CMTS topology mapping to the RF active ports.

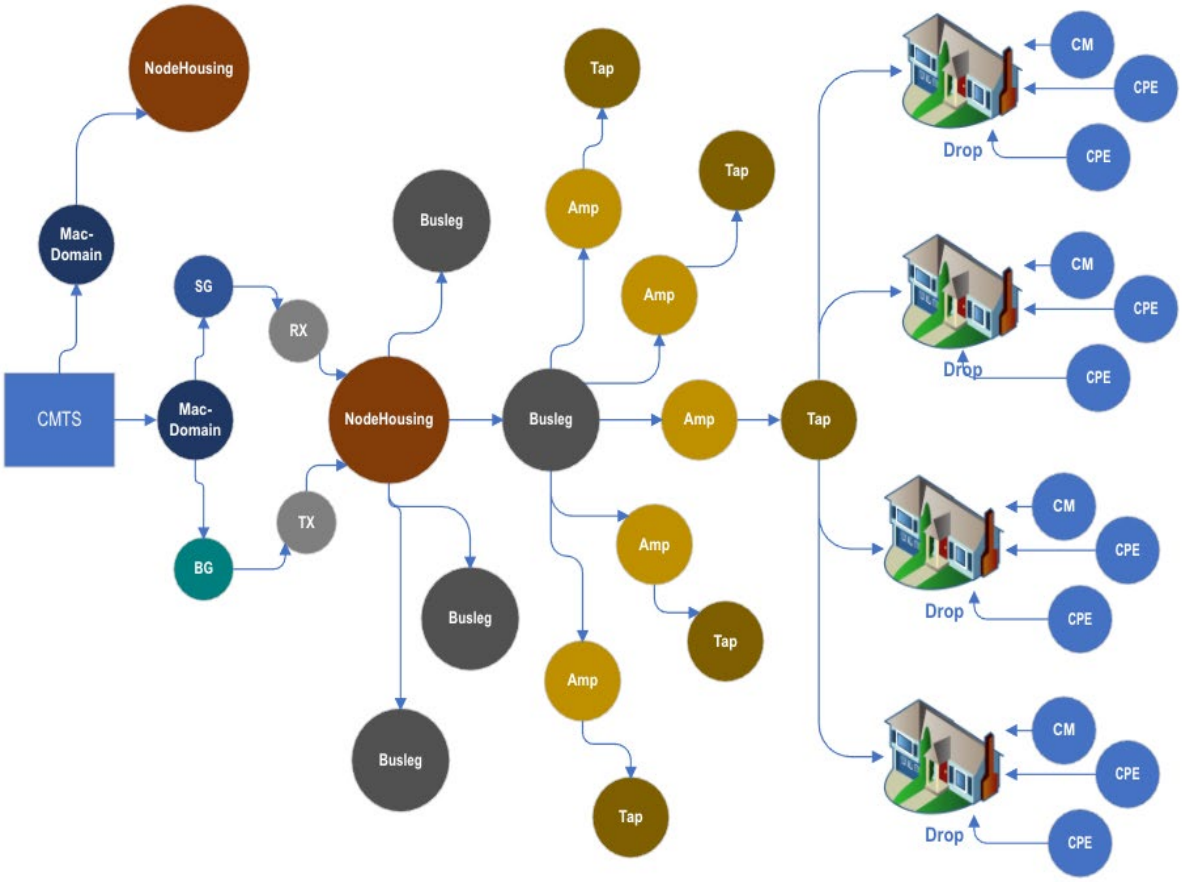

Figure 3 – High-level graph model example

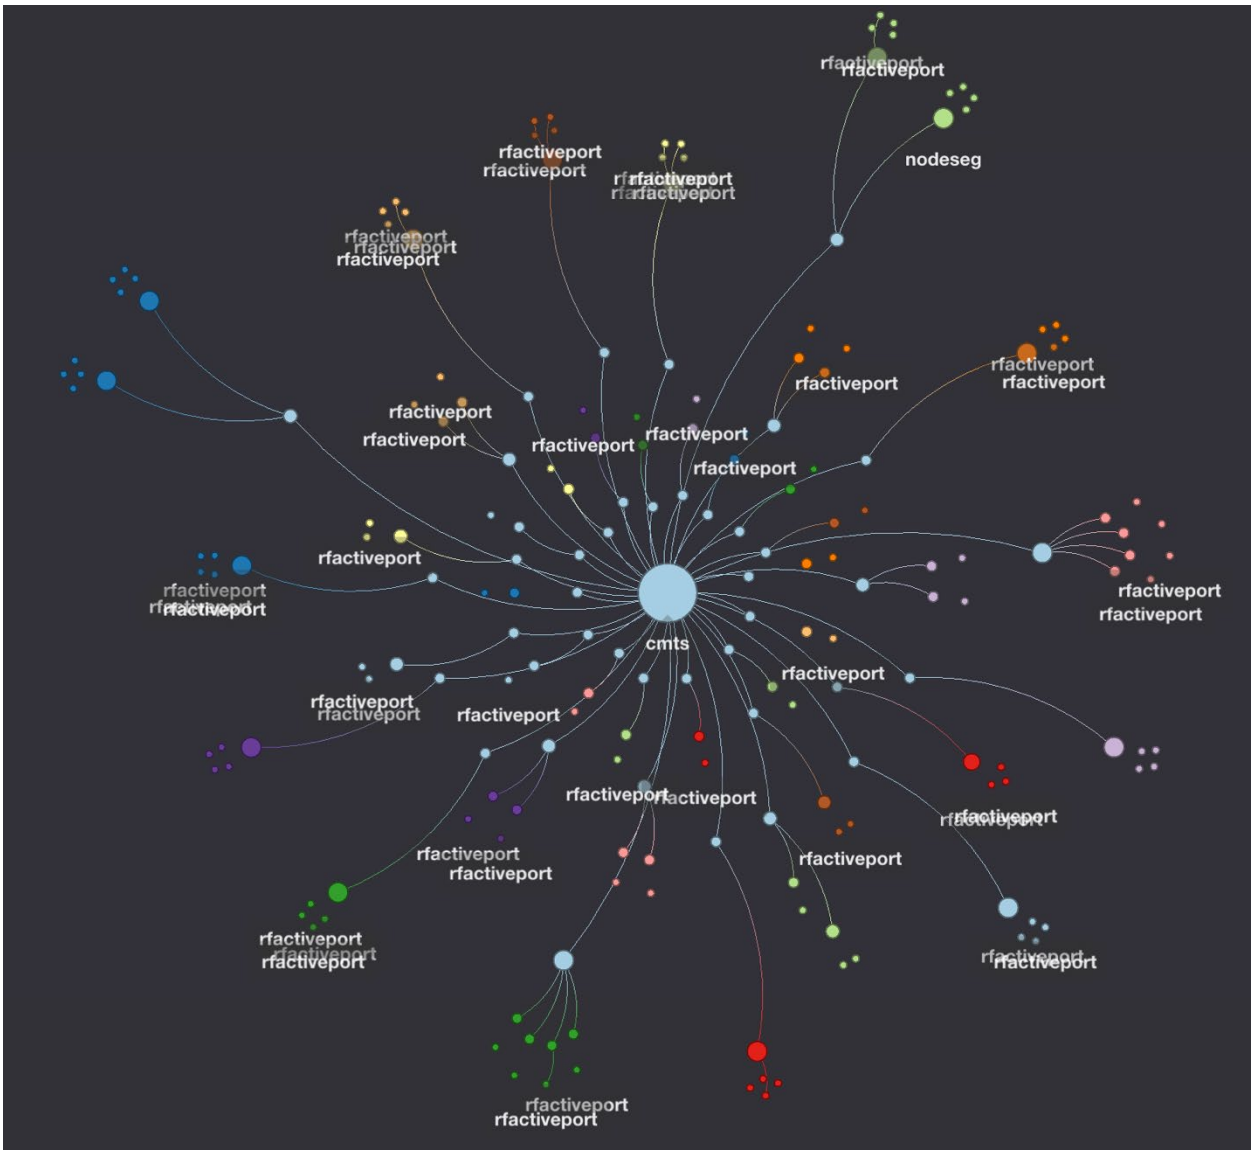

Figure 4 – Example graph terminating at Rfactiveports/busleg

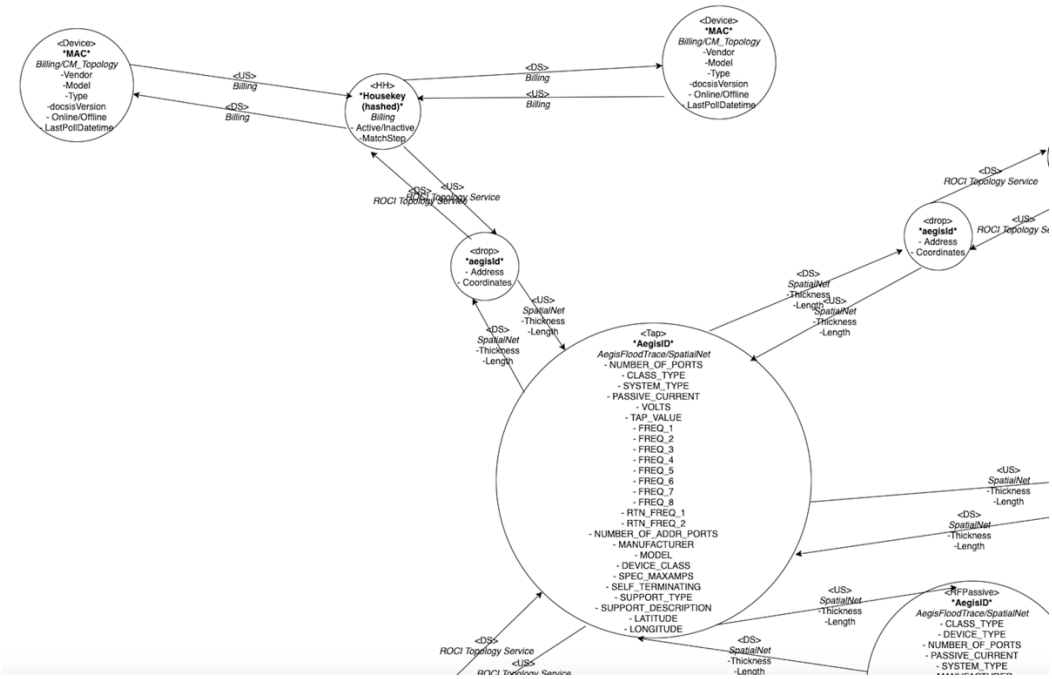

Figure 5 – Detailed graph model (tap, drop, modem)

1. Vertices
    a. The graph vertices are elements from the Division to a site, a CMTS in the site down to the individual devices in a subscriber's home.
    b. Division, Region, Site, CMTS, Headend Tx/Rx. US/DS Port, MAC Domain, Service/Bonding Group, Clamshell (node housing), Bussleg, Active (Amp), Passive, Tap, Design Address/Drop, Billing Address/HH, and Device.
    c. Labeled as:
    'division', 'region', 'cmts', 'headendTx', 'headendRx', 'usport', 'dsport', 'macDomain', 'servic eGroup', 'bondingGroup', 'clamshell' is the node housing, 'bussleg' is the fiber node in the node housing, 'amp', 'passive', 'tap', 'drop', 'billingaddress', 'device'
2. Edges
    a. Edges exist between vertices in the graph that denote the relationship between the vertices.
    b. The edge type depends on the data source that creates the edge, the context of the edge in terms of direction, or physical nature of the relationship between vertices.
        i. US - an upstream edge. This exists from device upstream through the flood trace all the way to MAC Domain and directly from MAC Domain to the CMTS.
        ii. DS - a downstream edge. This exists from the CMTS directly to Mac Domain down through the flood trace to device.
        iii. NCP_US - this is an edge created based on a confidence metric that we can map NCP reports of CMTS US ports to RX to the correct MAC Domain and bonding groups.
        iv. NCP_DS - this is an edge created based on a confidence metric that we can map NCP reports of CMTS DS ports to TX to the correct MAC Domain and Service Groups.

v. resides_in - Used for busslegs and optical rx/tx that physically exist inside a node housing.

3.3. Software Simulation

After reviewing the physical layer model and graph topology, we now have sufficient context to begin the simulation. Each of the previously discussed models and network elements are implemented as software components. The software objects are used to instantiate the network topology and gather the required parameters to build transmission line segments. These transmission line segments can then be cascaded to simulate a complete network that is redrived from the network design and specifications.

3.3.1. Database of Component Specifications

The graph network topology provides information that identifies the equipment types, which are used to assemble the required specifications. The product specifications are usually provided in the form of human-readable documentation such as portable document format (PDF). These specifications need to be converted to a database format that can be referenced by the software. To support this simulation exercise, the scope of equipment was limited and generalized to reduce the amount of document translation required. The list network elements and their required specifications are as follows:

- **Cables** - Diameter, length, structural return loss, nominal velocity of propagation (NVP) and attenuation vs frequency
- **Taps** – Return loss vs. frequency, attenuation vs. frequency, tap loss, port-to-port isolation, port-to-tap isolation, tap-to-tap isolation
- **Conditioners and pads** – Attenuation vs. frequency
- **Amplifiers** – Return loss vs frequency, gain vs. frequency
- **Splitters (and directional couplers)** – Through loss vs. frequency, tap loss vs. frequency, return loss vs. frequency

3.3.2. Network Object Model

The software object model looks a lot like the network physical model in terms of equipment and their connections. All the typical network elements have corresponding classes which are extended from a parent class of `NetworkElement`. The abstract class of `NetworkElement` contains all the functionality that is common to all network elements, such as their graph relationships (parent-child or node-edge), attenuation vs. frequency and return loss vs. frequency.

The abstract class of `NetworkElement` is extended by all the subclasses that provide their extended implementations. Our model contains `Cable`, `Node`, `Splitter` (inclusive of Directional Coupler), `Tap`, `Amplifier` and `CableModem`, which each have unique characteristics beyond the abstract `NetworkElement`. The `NetworkElement` is an abstract class which is extended by several inheriting subclasses including cables, taps and so forth. An example of this class diagram is shown in Figure 8.

3.3.3. Transmission Line Object Model

Figure 6 shows a common schematic symbol for a coaxial transmission line. The source impedance is ZS, characteristic impedance of the transmission line is Z0 and sink impedance is ZL.

Having the instantiated network elements, equipment specifications and connection topology (Figure 7) allows for transmission lines to be modeled and simulated. These are the minimum parameters required to perform a simulation using the proposed model: cable length, cable velocity of propagation, cable attenuation vs. frequency, source output return loss vs. frequency and sink input return loss vs. frequency.

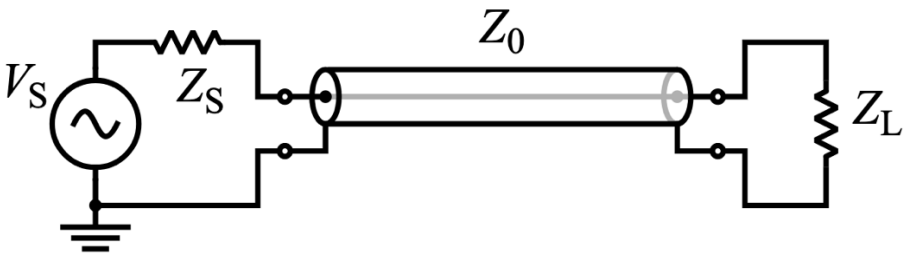

Figure 6 – Schematic symbol for a coaxial transmission line

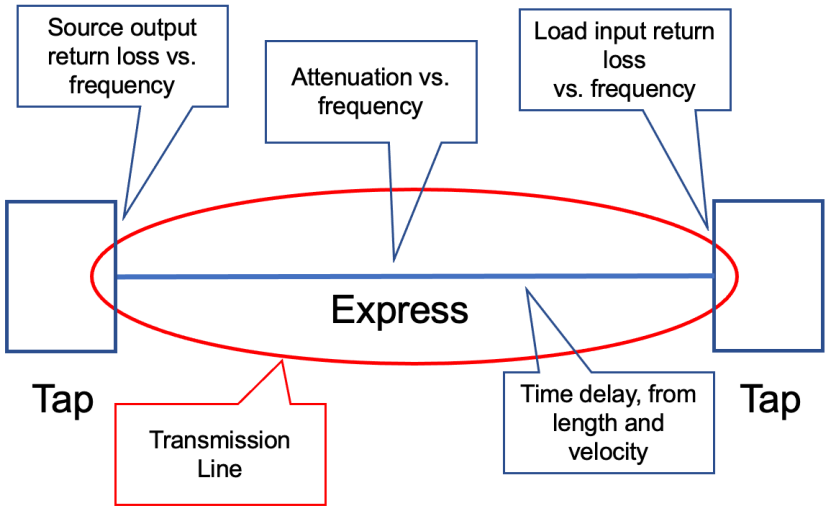

Figure 7 – Parameters required for S21 equivalent of a transmission line

To support the assembly and cascading of the transmission line parameters, a transmission software package is created to provide the implementation. Our TransmissionLine objects are constructed by traversing the fully assembled network graph, extracting the connected network elements (example, Figure 7) and copying the required parameters (Figure 7) to the `TransmissionLine` object.

3.3.4. Simulation of a Transmission Line

Transmission line transfer function is described earlier by Dr. Prodan in Figure 2. Recall that there is an infinite series of reflections interacting with incident signals. The series of reflections might imply that a recursive software routine could be useful. Fortunately, because of attenuation, the loss associated to the infinite recursions does eventually become insignificant (or having a practical limit). Because of this, there is a math shorthand which can be used, known as the Euler summation. This is a handy way to accelerate the summation of an infinite series.

for a length of trunk cable with cable propagation delay T, cable amplitude response A(f), and tap input/output port return loss RL = -10 Log(ρ) where ρ = reflection coefficient, that the transfer function H(f) for the tap span cable transmission line is given by:

$$H(f) = \frac{A(f)\, e^{-j2\pi fT}}{1 - A^2(f)\, 10^{-\frac{(\mathrm{RLi+RLo})}{20}} e^{-j4\pi fT}}$$

This formulation provides the complex frequency response with only the scalar amplitude versus frequency of the transmission line and the magnitude return loss versus frequency of the terminating impedances. This avoids the need to measure complex valued S-parameters versus frequency for each component. It also avoids the conversion to t-parameters for transmission frequency responses that would be cascaded to compute the end-to-end transfer function between any two points in the network.

3.3.5. Running the Simulation

3.3.5.1. Instantiating the Network Graph

To be useful in the network simulation, the network objects need to be instantiated and assembled dynamically, driven from the graph model discussed in section 3.2 and section 3.3.

Fortunately, coaxial cable networks adhere to a tree-and-branch structure, so graph models are easily traversed without concern of recursion or circular referencing (circular dependencies). This cardinality is strictly enforced by the `NetworkElement` object having only a singular, mandatory parent with zero-to-many child relationships. Each graph vertex can be used to instantiate the object from its respective class using a factory software pattern. The unified modeling language (UML) diagram in Figure 8 helps illustrate the factory pattern.

Converting to-and-from graph and tree-branch networks may seem like an anti-pattern. However, a good way to think about the network topology is having a physical vs. logical duality. The graph model better serves the network's logical model with properties such as multiple combining of ports, service groups and MAC domains. At the same time, HFC's physical network elements are designed and built in a tree-branch structure with elements such as nodes, cables, splitters, and taps.

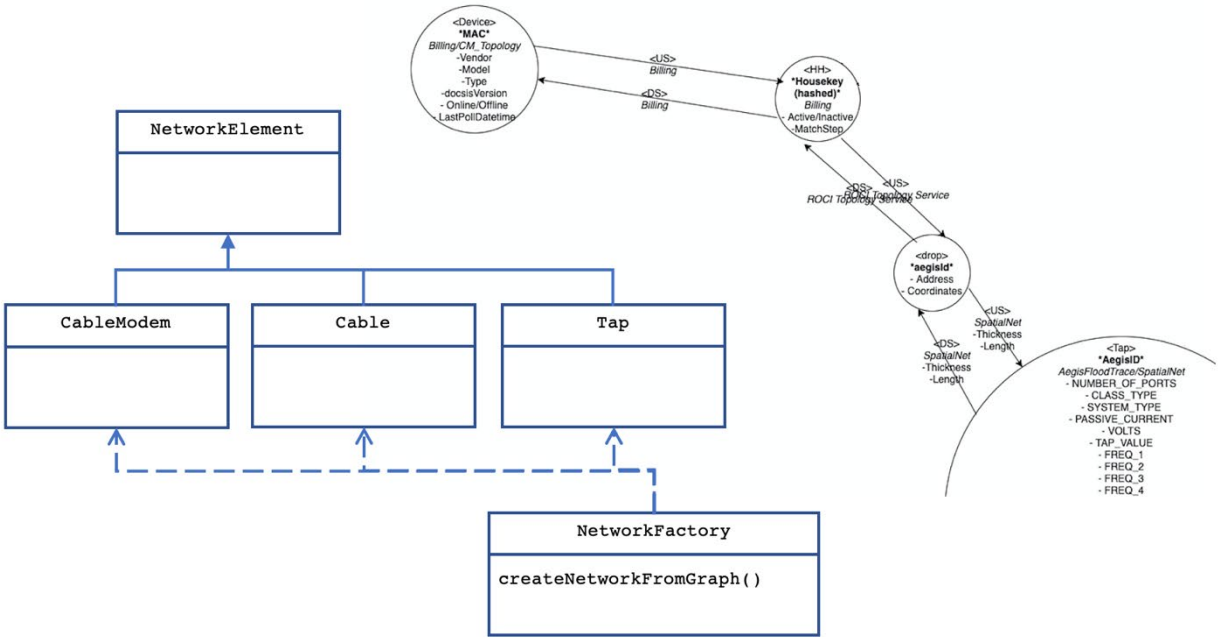

Figure 8 – UML diagram of network factory from graph

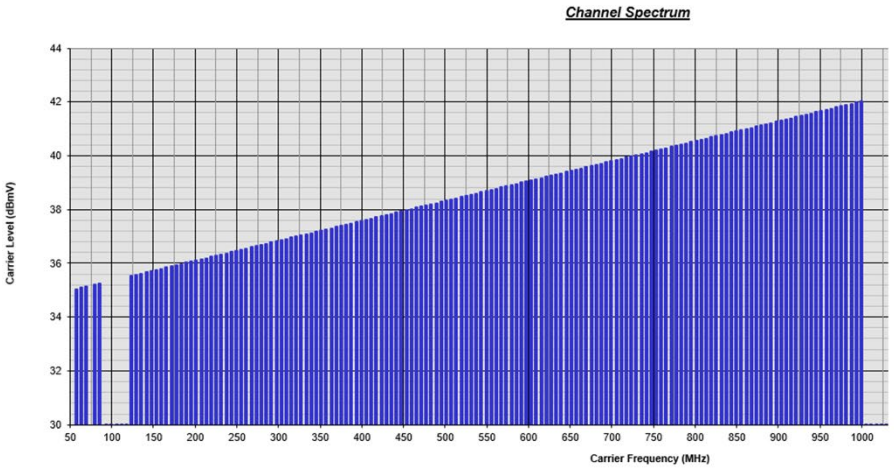
3.3.5.2. Operational Power Profiles and Launching

When simulating the transmission of RF signals on a cable network, the power levels and tilt are required. There are several different variables that go into operational launch power configurations. Especially when considering existing cable networks, different types of equipment, lengths, and types of cables, taps and architecture all influence the launch power selection. At Comcast, nearly 50 different variations of operational power launch profiles exist. As a practical matter in the simulator, the top 6 profiles will be generalized, allowing for additional power profiles to be added as needed.

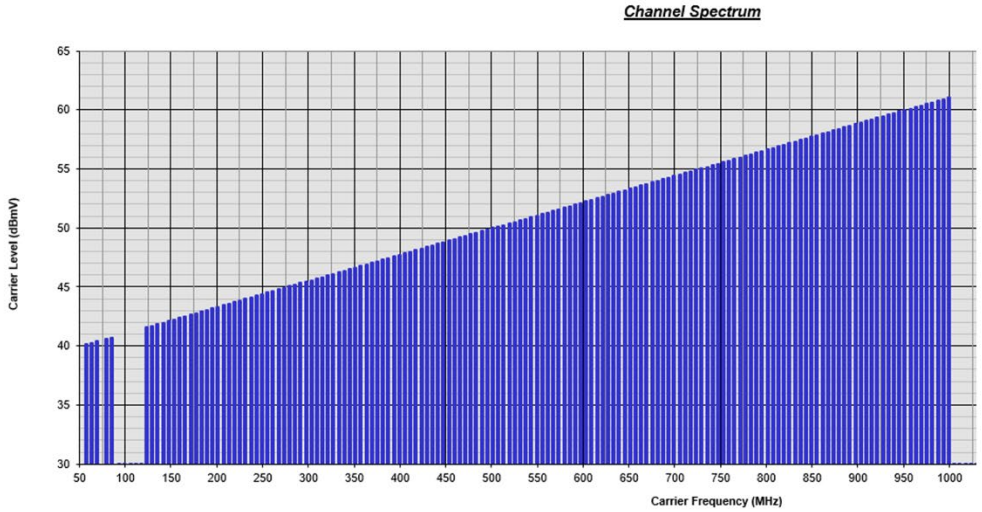
The operational launch power is expressed as power levels at given frequencies, resulting in a positive tilt. This tilt is designed to accommodate the anticipated attenuation of the passive components. When designing the systems, the operational tilt is optimized to deliver a flat RF spectrum at the end of the line(s). Additional tilt can be removed by conditioning and equalizing the signal, which are also accommodated in the software model, described later.

Figure 9 and Figure 10 show two examples of operational power profiles. The tilt is measured as the difference between the 6 MHz channel power measured at 57 MHz and 873 MHz respectively. Notice that the frequency spectrum is fully occupied up to 1 GHz. In both examples, the full-spectrum tilt is higher than the specified profile tilt value. When comparing the two figures, note the power per-division on the y-axis is 2 and 5, Figure 9 and Figure 10 respectively.



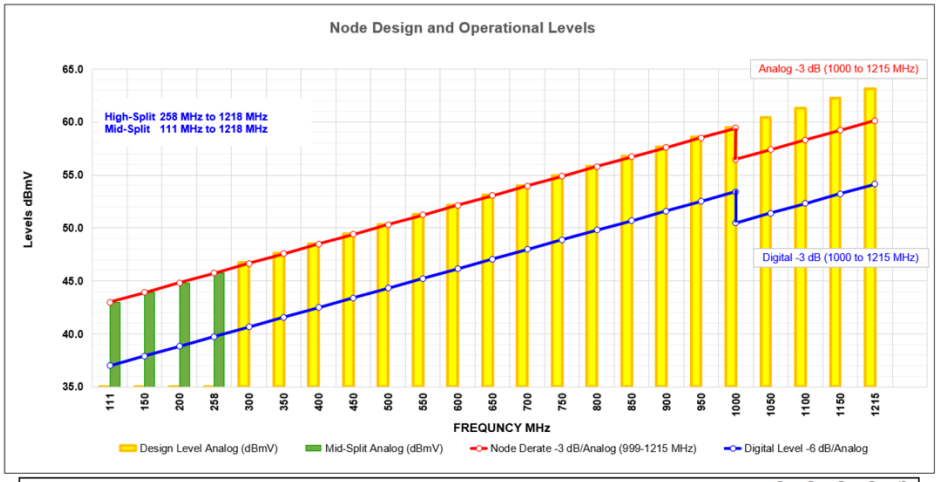
Frequency	RF Level
57 MHz	35 dBmV
549 MHz	39 dBmV
753 MHz	40 dBmV
873 MHz	41 dBmV
999 MHz	42 dBmV
Tilt @ 750 MHz	5 dB
Tilt @ 870 MHz	6 dB
Tilt @ 999 MHz	7 dB

Figure 9 – Operational power profile with 6 dB of tilt



Frequency	RF Level
57 MHz	40 dBmV
549 MHz	51 dBmV
753 MHz	56 dBmV
873 MHz	58 dBmV
999 MHz	61 dBmV
Tilt @ 750 MHz	15 dB
Tilt @ 870 MHz	18 dB
Tilt @ 999 MHz	21 dB

Figure 10 – Operational power profile with 18 dB of tilt



MHz	111	150	200	258	300	350	400	450	500	550	600	650	700	750	800	850	900	950	1000	1050	1100	1150	1215
Design Level Analog (dBmV)	43	44	45	46	47	48	48	49	50	51	52	53	54	55	56	57	58	59	60	61	62	63	64
Operational Node Derate -3 dB/Analog (999-1215 MHz)	43	44	45	46	47	48	48	49	50	51	52	53	54	55	56	57	58	59	57	58	59	60	61

Figure 11 – Operational power profile with 1 GHz derating of -3 dB

Operational power profiles become further complicated when considering designs using frequency spectrum above 1 GHz. In contemporary system designs, RF output ports can be set with a 19 dB linear tilt from 258 MHz to 1,215 MHz (measured from CTA carrier center frequency to CTA carrier center frequency).

In this example (Figure 11), the node operating levels include a 3dB derate for all signals above 1000 MHz and for each RF output port set to:

- 43 dBmV analog-equivalent NTSC level at 111 MHz. Single-channel, 6-MHz 256-QAM level shall be 6 dB lower, or 37 dBmV at 111 MHz for initial mid-split deployments.
- 46 dBmV analog-equivalent NTSC level at 258 MHz. Single-channel, 6-MHz 256-QAM level shall be 6 dB lower, or 40 dBmV at 258 MHz.
- 60 dBmV analog-equivalent NTSC level at 1000 MHz. Single-channel, 6-MHz 256-QAM level shall be 6 dB lower, or 54 dBmV at 1000 MHz.
- 61 dBmV analog-equivalent NTSC level at 1,215 MHz. Single channel, 6-MHz 256-QAM level shall be 6 dB lower, or 55 dBmV at 1,215 MHz.

3.3.5.3. Channel Plans and Lineups

For modeling purposes, it's typical to use a standard channel plan and fully populate the RF spectrum model with 6 MHz power equivalent SC-QAM channels. In Figure 9, Figure 10, and Figure 11, it can be seen that the operational power profiles are often expressed as such. However, the simulation will be required to support all common forms of cable signal transmissions such as SC-QAM, OFDMA, SCTE-51 out-of-band (OOB), analog channels and continuous wave (CW) pilots. This makes it possible to simulate and compare channel lineups and power loaded scenarios that are found in deployed networks. Figure 12 shows 2 examples of different channel lineups. The top graph shows a simulated RF spectrum, fully loaded with SQ-QAM from 57 MHz to 1 GHz. The bottom graph shows the same frequency spectrum, mixed with SC-QAM and OFDM which are sparsely loaded. In this example, there are 5 channel blocks of SC-QAM and 1 block of OFDM.

Figure 12 –Examples of channel plans and lineups

3.3.5.4. Echo Transfer Function

Consider a signal transmitted downstream from a tap output to the adjacent tap input as shown in Figure 2 with amplitude response $A(f)$ and linear phase response which has the corresponding impulse response of the cable denoted by $a(t)$. The transmitter at the signal source has (nearly) matched impedance to the drop cable but with a return loss RL_o (dB). In general, the return loss is also a function of frequency RL(f). The signal traverses the cable to the tap with propagation delay T which has a (nearly) matched impedance to the cable with return loss RL_i (dB). A portion of the signal equal to the reflection coefficient $10^{-RLi/20}$ is reflected back to the source, which in turn a portion of the reflected signal equal to the reflection coefficient $10^{-RLo/20}$ is re-reflected back toward the tap, and so on ad infinitum. This reflected signal can be represented as a sum of the infinite series of reflections each delayed by the propagation delay T plus multiples of the round-trip time (i.e. twice the propagation delay or 2T) of the cable.

3.4. Simulation vs. Measured Performance

Having the measured values that can be compared with simulated values enables several use-cases. Implementors can evaluate designs vs. specifications, locate significant impedance mismatches and identify unanticipated path loss or gain. In the simplest form, this can be used to improve the classification if impedance mismatches such as faulty or damaged cable and equipment. In more complex scenarios, new designs can be simulated and validated, comparing with pre-existing network designs.

3.4.1. PNM Spectrum measurements

As of November of 2012, the DOCSIS 3.0 specification was expanded to include spectrum analyzer-like functionality in cable modems. This feature is known as full band capture (FBC) and is supported by most DOCSIS 3.0 and all 3.1 cable modems. Since this time, most cable operator-deployed modems now have the FBC spectrum analysis capability. This offers a convenient tool for measuring RF spectrum performance at the location of the cable modems and CMTS.

3.4.2. Configuring, enabling, and measuring the RF spectrum

Information about controlling PNM spectrum measurements is provided in [CM-OSSIv3.1], Section D.2.4, "CM Spectrum Analysis Objects." The spectrum analyzer control parameters, defined by Table 1, are used to configure and enable the FBC. Most of the implementations have default values, so simply enabling the spectrum analyzer should result in usable information for testing the basic functions of TFTP and SNMP. The measurements are configured and enabled by using SNMP with the following MIB objects.

Table 1 - Spectrum analyzer control parameters

Attribute Name	Type	Access	Type Constraints	Units	Default
Enable	Boolean	R/W			False
InactivityTimeout	UnsignedInt	R/W	0..86400	seconds	300
FirstSegmentCenterFrequency	UnsignedInt	R/W		Hz	93000000
LastSegmentCenterFrequency	UnsignedInt	R/W		Hz	993000000
SegmentFrequencySpan	UnsignedInt	R/W	1000000..900000000	Hz	7500000
NumBinsPerSegment	UnsignedShort	R/W	2..2048	bins-per-segment	256
EquivalentNoiseBandwidth	UnsignedShort	R/W	50..500	hundredths of bin spacing	150
WindowFunction	Enum	R/W	other(0), hann(1), blackmanHarris(2), rectangular(3), hamming(4), flatTop(5), gaussian(6), chebyshev(7)		
NumberOfAverages	UnsignedShort	R/W	1..1000		1
FileEnable	Boolean	R/W			False
MeasStatus	MeasStatusType	R/O			
FileName	AdminString	R/W	SIZE(1..255)		

The spectrum measurement output is obtained either through SNMP or TFTP file transfer. Table 2 describes the structure of this file, including byte offsets for each of the discrete values reported by the test. See [CM-OSSIv3.1], Section D.2.4, "CM Spectrum Analysis Objects," for the MIB details for implementation.

Table 2 - Spectrum analysis response format

Element	Size
Size File type (value = 504E4D09)	4 bytes
Major Version (value = 1)	1 byte
Minor Version	1 byte
Capture Time	4 bytes
Channel ID	1 byte
CM MAC Address	6 bytes
FirstSegmentCenterFrequency	4 bytes
LastSegmentCenterFrequency	4 bytes
SegmentFrequencySpan	4 bytes
NumBinsPerSegment	2 bytes
EquivalentNoiseBandWidth	2 bytes
WindowFunction	2 bytes
Length (in bytes) of SpectrumAnalysis Data	4 bytes
SpectrumAnalysisData	BinAmplitudeFileData

Described in Table 2, the PNM spectrum measurements are expressed as log magnitude power, per bin. Bins represent a range of frequency spectrum, given a center frequency and frequency span. The frequency span is sometimes referred to as the resolution bandwidth (RBW) and is used to specify the width of the measured spectrum.

For further details about the PNM spectrum capture capabilities, refer to [PNM Best Practices Primer: HFC Networks (DOCSIS® 3.1)], Section 5.2.8, “How to Implement”.

3.4.3. Simulated launch of the RF spectrum

The input of the simulator begins with a channel lineup, which has an operational power profile. Then, as the mathematical models are applied and cascaded, a resulting amplitude vs. spectrum is calculated. The amplitude vs. spectrum can be calculated anywhere within the network graph, at the input or output of the transmission line segments. Figure 13 shows the output of the simulated launch of a channel lineup, using the 18 dB tilt operational power profile shown in Figure 10. The simulated channel lineup includes both SC-QAM and OFDAM channels, fully occupying a 57 MHz to 873 MHz channel plan.

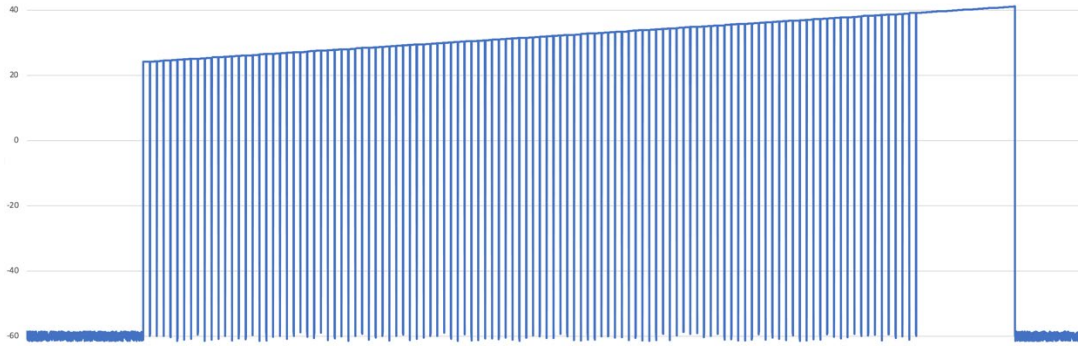

Figure 13 – Shows the simulated launch of an RF channel lineup with 18 dB of tilt

To simplify the comparison of the measured vs. simulated RF spectrum, the log magnitude power values should be scaled to the same RBW. This is a straightforward exercise using the following conversion equation. To change from a power spectral density (PSD) measured in RBW1 (i.e., dBmV/RBW1 MHz) to RBW2: PSD2 (dBmV/RBW2 MHz) = PSD1 + 10*LOG(RBW2/RBW1)

The process for generating simulated bins is as follows (including code examples). Note that this example does not contain any accommodating for spectrum shaping, such as a square-root raised cosine (RRC) filter. This may be a feature available in a future version.

1. Construct an array of bins using the frequency span divided by the target RBW. Our examples will use 6 MHz to 1026 MHz (1020 MHz total width) at 117187.5 kHz which results in 8704 total bins.

```
Bin[] bins = new Bin[(int)((endFreq - startFreq) / resolutionBandwidth)];
```

2. Initialize the bins with a simulated random noise floor.

```
for (int i = 0; i < bins.length; i++){

       bins[i].setLogPower(randomNoise);

       …
```

3. Enumerate the channels from the simulated launch plan and render the bins from each, interpolated at the center frequency from the operational power profile. Note that different channel types may have different rendering rules, such as SC-QAM and OFDM. For example, SC-QAM will have a simple roll-off factor and OFDM will have raised pilots.

```
bins[i].setLogPower((double) interpolatedBinPower);
```

3.4.3.1. Attenuation vs. Frequency

The linear attenuation versus square root frequency characteristic of coaxial cable is predictable. This useful property simplifies modeling the behavior of signal attenuation of the interconnecting hardline cable between taps or between a tap port and the terminating device on the drop cable.

Tap parameters including insertion loss, tap loss, return loss, and tap-to-output isolation are also specified as attenuation versus frequency. Figure 14 shows the proposed attenuation model (left) compared to the simulated output of the same model (right). Both charts show the attenuation vs. frequency on 100 meters

of series 11 coaxial cable, and they agree. Further, the chart in Figure 15 shows a channel lineup using the 18 dB launch profile (green trace), compared with simulated attenuation from 100 meters of P3 .875 (amber trace), P3 .500 (blue trace) and RG6 coaxial cables (grey trace). The attenuation parameters were extracted from the component parameter database discussed in section 3.3.1.

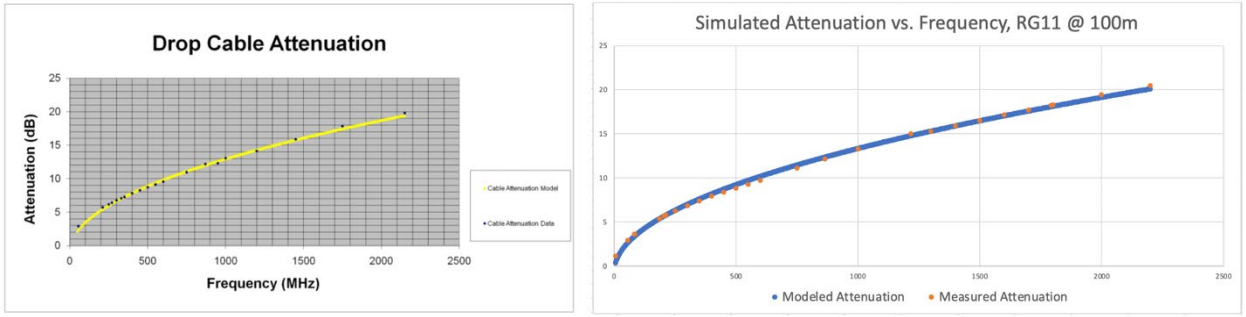

Figure 14 – RG11 attenuation model compared to RG11 simulated attenuation

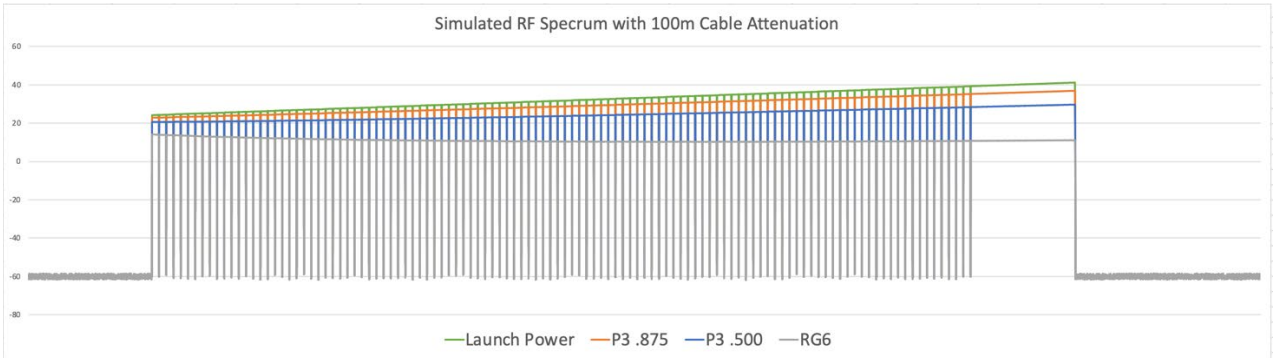

Figure 15 – Simulated launch RF compared to attenuation on P3 .875, P3 .500 and RG6 cables

3.4.3.2. Tap Equalization and Signal Conditioning

An important consideration for supporting the wider bandwidth on the passive fiber deep plant is the use of tap plug-in equalizers. Such equalizers provide either upward or downward attenuation (tilt) with increasing frequency. The amount for each tap is determined to provide approximately the same output levels versus frequency at all tap ports. An example of tap equalizer magnitude frequency (amplitude) responses is shown in Figure 16 and the simulator response in Figure 17.

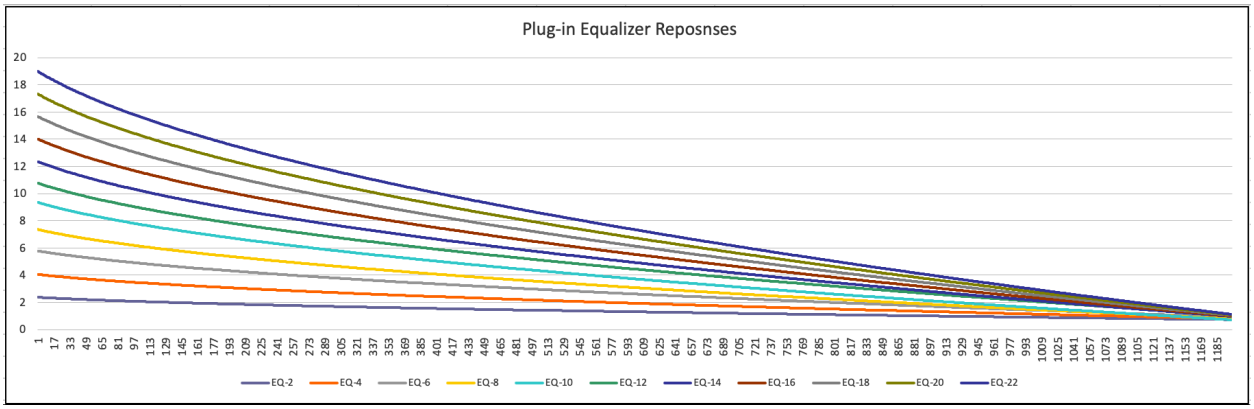

Figure 16 – Tap equalizer response vs. frequency

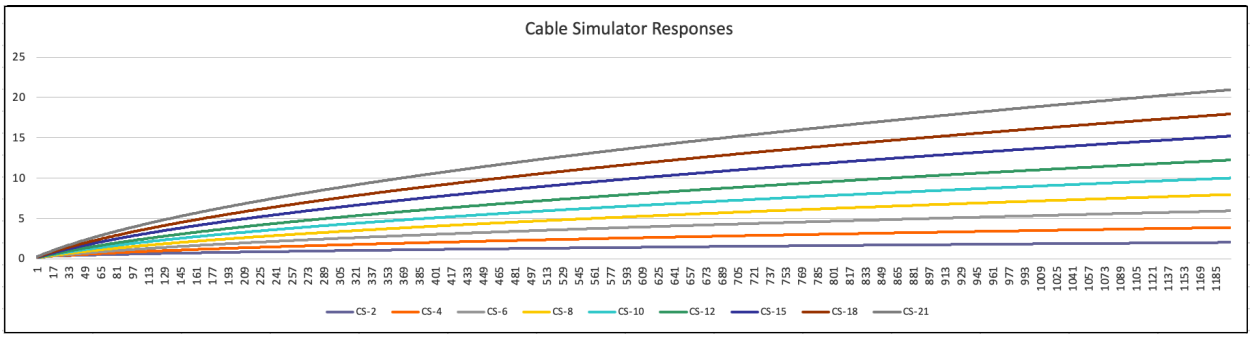

Figure 17 – Cable simulator response vs. frequency

3.4.3.3. Return Loss vs. Frequency

As seen in Dr. Prodan's model, tap parameters including insertion loss, tap loss, return loss, and tap-to-output isolation are also specified as attenuation versus frequency. Figure 18 shows an example of such tap specifications.

2-Way Maximum Insertion Loss (dB)										
Number of Ports (#-Way),Tap Value (dB)										
Frequency ≤(MHz)	2,4	2,7	2,10	2,12	2,14	2,17	2,20	2,23	2,26	2,29
5		3.9	2	1.8	1.3	1.2	1	0.7	0.7	0.7

4. Implementation and Results

4.1. Examples

When the simulation is implemented as described in the previous sections, a number of use cases can be satisfied. At the time of writing, the simulation software and analysis were just being completed so we will review 3 preliminary results. Further development will continue, including material described in Section 5. Future

4.1.1. Plant fault isolation

PNM continues to be one of the most important tools for operators to proactively monitor and maintain their networks. By enhancing PNM with an RF transmission line simulation, its classification and accuracy can sometimes be improved.

Among the most commonly detected PNM signatures using FBC are amplitude ripples, often caused by standing waves. Standing waves are caused by impedance mismatches somewhere between the node and the modem. Having a minimum of 2 impedance mismatches, energy reflects off the second mismatched impedance, back to the first, and then some of that energy continues downstream, but delayed. This causes an impact to the signal that appears as a standing wave in the spectrum amplitude. When observed in a spectrum display, the standing wave will appear as a periodic amplitude change. This is precisely what the physical layer modeling and simulation are doing. However, in an ideally designed and deployed cable plant, there should be no amplitude ripple.

This example (Figure 19) shows log magnitude frequency response obtained using the FBC feature of PNM. In this example, the PNM measurement data has 8704 total bins representing 6 MHz to 1026 MHz frequency spectrum. Each bin spans 117.1875 kHz, or .1171875 MHz of frequency spectrum. In this case, an amplitude ripple is clearly present throughout the occupied frequency spectrum. Then in Figure 20, the

network response is simulated including transfer function of the distribution cables, tap and drop cables. The simulation is configured to match the channel plan, launch-power profile and similar output resolution bandwidth of 117.1875 kHz.

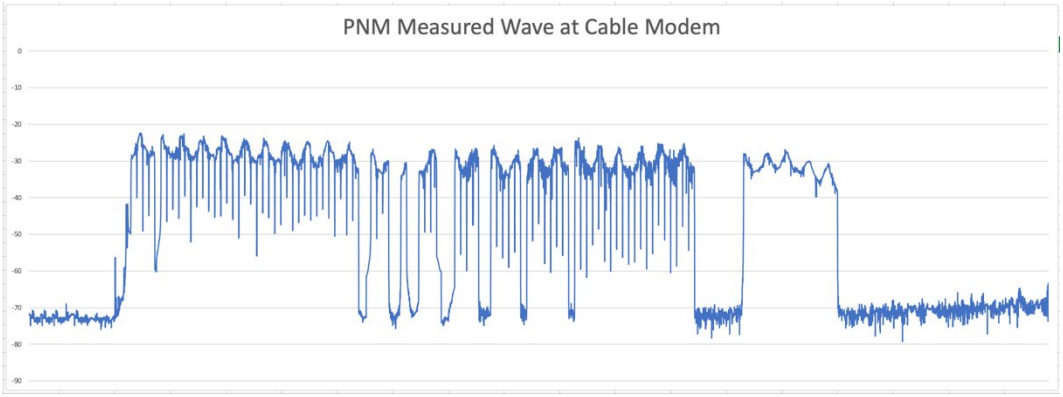

Figure 19 – PNM measurement of amplitude ripple from cable modem using PNM

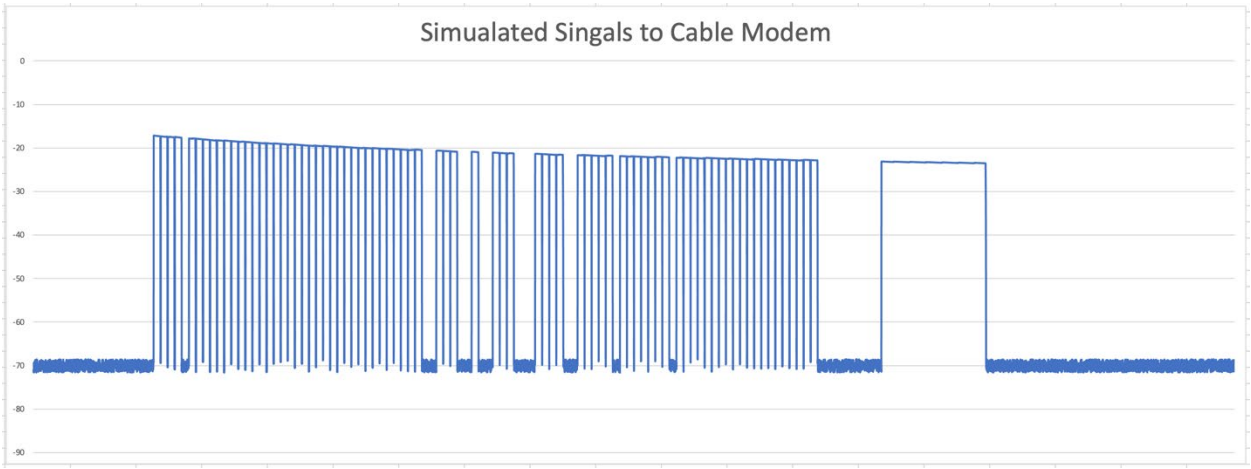

Figure 20 – Simulation of launched signal with cable, tap and drop attenuation

The resulting log magnitude bins from the PNM measurement and simulation cab be processed using common digital signal processing (DSP) techniques using fast Fourier transformations (FFT). The following results were achieved by projecting magnitude-only amplitude bins to the Complex number plane. This can be achieved in a number of ways, demonstrated here and discussed further in Appendix 7.1.

This method uses “zero stuffing” of the phase component which achieves a satisfactory result, assuming that the cable plant exhibits minimum-phase characteristics.

First, the bins need to be converted from logarithmic to linear form.

```
double power = Math.pow(10.0, (0.1 * decibels));
```

Next, an array of Complex numbers is instantiated by constructing each Complex value with the magnitude and a zero-value phase component.

```
Complex[] c = new Complex[linearBins.length];

for (int i = 0; i < linearBins.length; i++){
    c[i] = new Complex(linearBins[i], 0);
}
```

The resulting Complex arrays can then be used to perform Complex division, resulting in the frequency-domain Complex quotient seen in the top section of Figure 21.

```
Complex[] quotientArray = new Complex[complexArray.length];

for (int i = 0; i < complexArray.length; i++){
    quotientArray[i] = complexArray[i].divide(denominatorArray[i]);
}
```

Finally, using the inverse fast Fourier transformation (IFFT), a time-domain response of the Complex quotient is produced (bottom of Figure 21). In this case, the frequency and magnitude accuracy of the impairment is increased by referencing the impaired signal with the simulated signal, which are otherwise unknown to the PNM analysis.

```
Complex[] complexTimeDomain = fourier.transform(getPaddedArray(binsComplex),
TransformType.FORWARD);
```

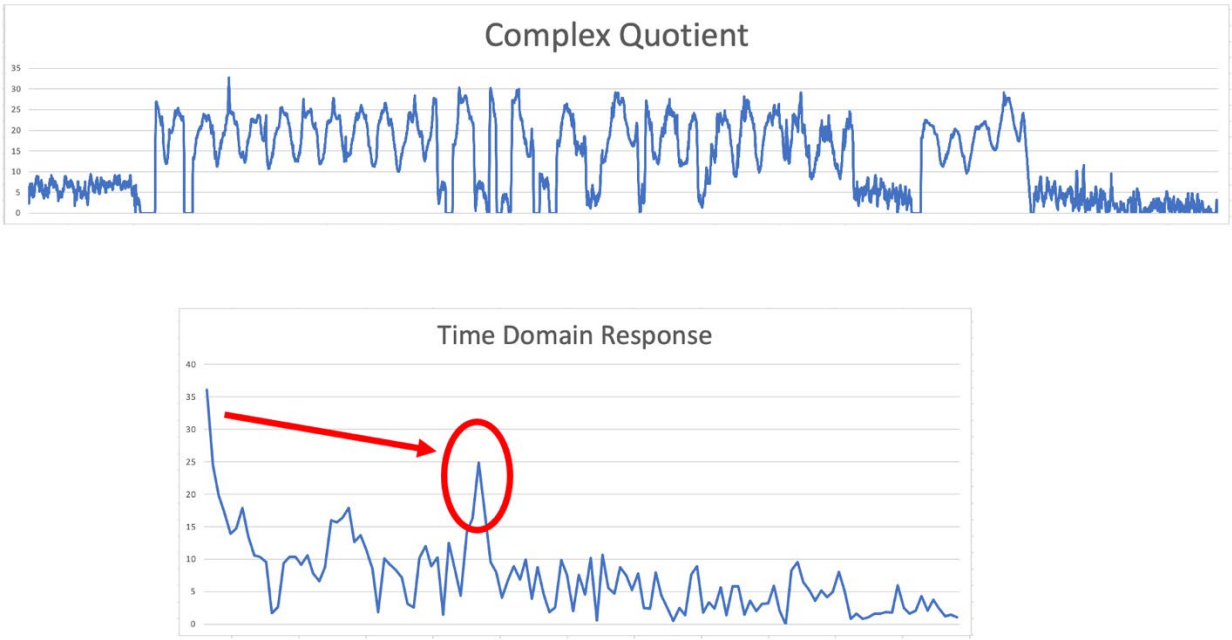

Figure 21 – Frequency(top) and time domain (bottom) analysis of Complex quotient

Having the improved frequency and time accuracy of the fault results in more precise fault lengths which can be calculated in either frequency or time.

This example was calculated, starting with the speed of light in feet per microseconds, rounded for simplicity to 983.571. The number is then divided by 2 for round-trip time and multiplied by the velocity factor of the drop cable, which is 0.85. Finally, the number is divided by the peak-to-peak ripple length of 19.28 MHz. The resulting calculation reveals that the faulty cable length is 21.68 feet, or perhaps the distance of the reflective fault from the cable modem F-connector.

4.1.2. System Design Verification

Another interesting and potentially valuable use case for simulation is to evaluate the quality and completeness of system designs. This simulation can predict end-to-end performance which can be compared against the design specifications. By traversing the network graph and comparing against PNM measurements, deviations and threshold violations can help identify inconsistencies in the designs.

4.1.3. In-home (drop) Amplifier Detection

The third example of the simulation is to help operators identify the presence of in-home (drop) amplifiers. These small amplifiers have been around for decades, used by operators and customers to add gain to the signal received by the modem. There are many different types of amplifiers including those with active and passive returns (upstream), passive, balanced and unbalanced active port configurations. In some cases, depending on equipment and configuration, it will be difficult or impossible to detect the presence of an amplifier. This method does not suggest an all-inclusive way of detecting every amplifier, rather it does propose a method that will work in some common configurations.

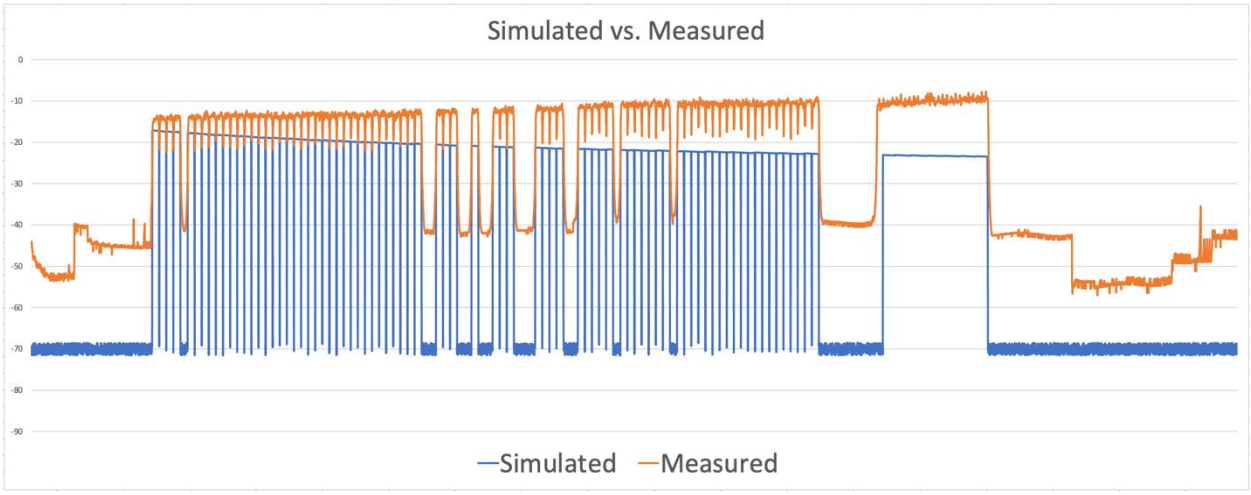

Figure 22 – Drop-amplifier detected: 15 dB gain measured vs. simulated

5. Future

5.1. FDX and ESD PNM extensions

Future versions of FDX DOCSIS technology will be supporting architectures beyond node+0. To support amplifier cascades in FDX, the amplifier technology will be equipped with echo cancellation. This complicates the physical model, which is well suited for this simulation exercise. There are several different amplifier design proposals, each making different claims about bit loading vs. distance, cascade depths and other significant performance implications.

ESD DOCSIS technology is far simpler to model, having very little change in the simulation other than the equipment specifications. Most of the cables already specify upper frequencies in the range of 2 GHz to 3 GHz. However, many of the active and passive components such as nodes, splitters and taps remain to be designed. When complete, adding their specifications to the existing simulator database is trivial.

In Figure 23, the simulated launch and attenuated signals can be compared when expanding from DOCSIS 3.1 to DOCSIS 4.0 frequency spectrum. The top chart is 5 MHz to 1 GHz of fully occupied spectrum using SC-QAM and one 192 MHz wide OFDM channel. The bottom chart shows the same lineup, adding 4 additional 192 MHz wide OFDM channels up to 1.8 GHz. This simulation was run using the 18 dB launch profile (green trace), compared with simulated attenuation from 100 meters of P3 .875 (amber trace), P3 .500 (blue trace) and RG6 coaxial cables (grey trace).

The TCP of the simulated node launch and cables are easily calculated by summing the log magnitude bins at the output of each.

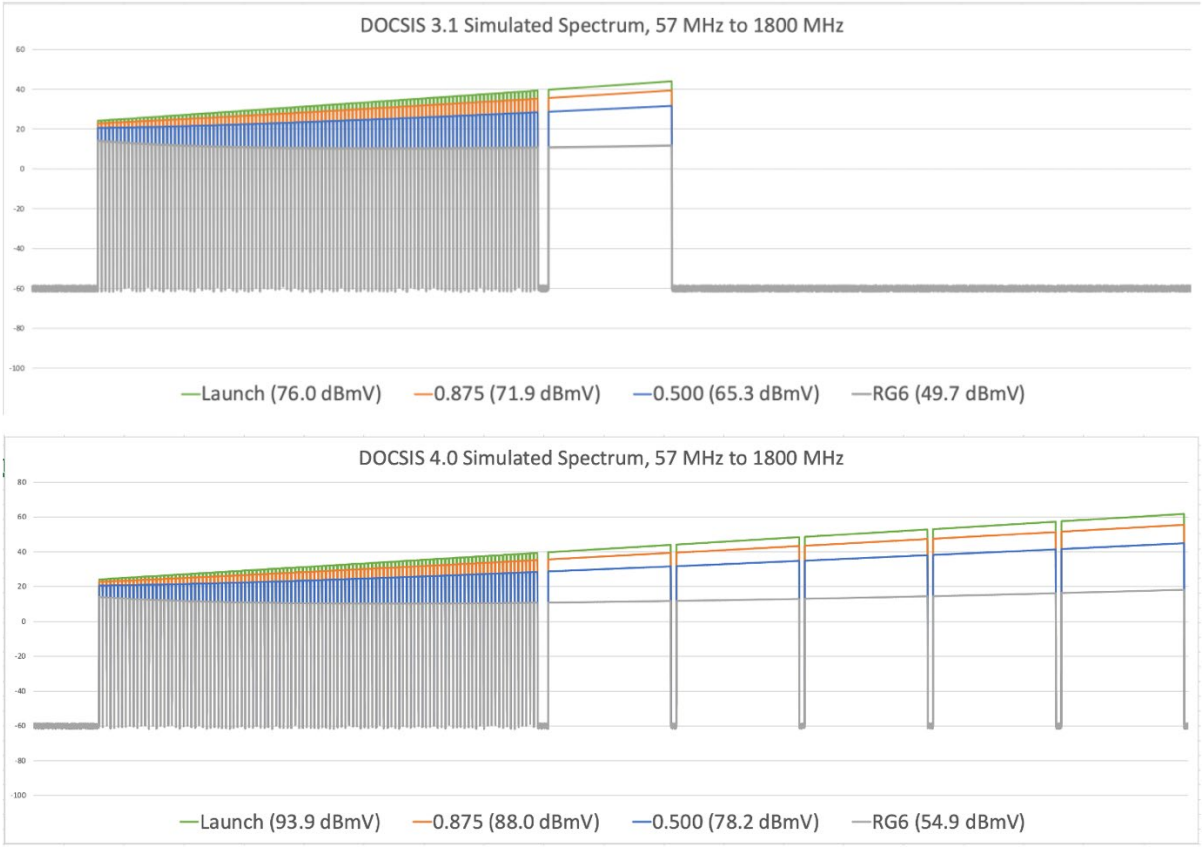

Figure 23 – Simulated spectrum of 1 GHz and 1.8 GHz compared, with TCP

Table 3 – DOCSIS 3.1 and DOCSIS 4.0 simulated output TCP compared

	18 dB Launch	**P3 0.875 (100m)**	**P3 0.500 (100m)**	**RG6 (100m)**
1 GHz	76.0 dBmV	71.9 dBmV	65.3 dBmV	49.7 dBmV
1.8 GHz	93.9 dBmV	88.0 dBmV	78.2 dBmV	54.9 dBmV

6. Conclusion

As our 10G networks continue to evolve and increase in complexity, so does our need to improve the sophistication of our modeling and simulations. This paper by Comcast's Ramya Narayanaswamy, Karthik Subramanya, Richard Prodan and Larry Wolcott, examine a practical approach to doing that. They prove that software, data science and graph theory can be used to advance the theoretical FDX and ESD physical-layer models previously proposed by Dr. Prodan.

By using a graph topology of the network, paired with PNM software, cable specifications, and data science, simulating cable networks just "got real". The simulation examples show that evaluating as-built

vs. simulated RF performance will be valuable for a number of use cases. Among them are the evaluation of full-duplex (FDX), extended spectrum (ES) RF performance. Also, traditional RF transmission performance of existing plant, as well as experimental designs. Lastly, it improves PNM fault detection, classification, and many other previously unsolved mysteries of RF.

7. Appendix

7.1. Phase recovery of magnitude-only measurements

Common digital signal processing (DSP) techniques exist to facilitate the analysis of digital signals. The PNM and simulation measurements discussed in this document are represented as magnitude-only power measurements. These measurements do not contain the constituent phase and amplitude information required to instantiate a Complex number, required for many DSP routines. There are several methods for projecting a magnitude value on to a complex plane, one of them is the Hilbert transformation.

Let G[k] be the minimum phase magnitude response. First convert magnitude to nepers using the natural (base-e) logarithm.

$$H[k] = \ln(G[k]) \qquad 0 \le k \le \frac{N}{2}$$

Next mirror the first half into the latter half (the latter half of the DFT corresponds to negative frequencies or negative times):

$$H[k] = H[N-k] \qquad \frac{N}{2} < k \le N-1$$

There are 3 steps to compute the Hilbert transform.

$$h[n] = \mathcal{DFT}\left\{ H[k] \right\}$$

$$= \sum_{k=0}^{N-1} H[k] e^{-j2\pi \frac{nk}{N}}$$

Then, multiply every positive time index ($n<N/2$) with $-j=e^{-j\pi/2}$ (or spin those complex values by -90°) and multiply every negative time index ($n>N/2$) with $+j=e^{+j\pi/2}$ (or spin those complex values by +90°). $h[0]$ and $h[N/2]$ (if N is even) should be set to 0.

$$h[n] \leftarrow \begin{cases} 0 & n = 0 \\ -j \cdot h[n] & 1 \le n < \frac{N}{2} \\ 0 & n = \frac{N}{2} \\ j \cdot h[n] & \frac{N}{2} < n \le N - 1 \end{cases}$$

Finally inverse transform that result and negate.

$$\phi[k] = -\mathcal{IDFT}\left\{ h[n] \right\}$$

$$= -\frac{1}{N} \sum_{n=0}^{N-1} h[n] e^{j2\pi \frac{nk}{N}}$$

$\phi[k]$ is the phase, in radians, of the minimum-phase system. The complex transfer function is:

$$G[k]\, e^{j\phi[k]}$$

7.2. About S parameters (Courtesy of Ron Hranac)

Consider a component or device being evaluated as a "network" with some number of ports N, and a characteristic impedance Z_0. For instance, a terminator can be considered a one-port network, as shown in Figure 1.

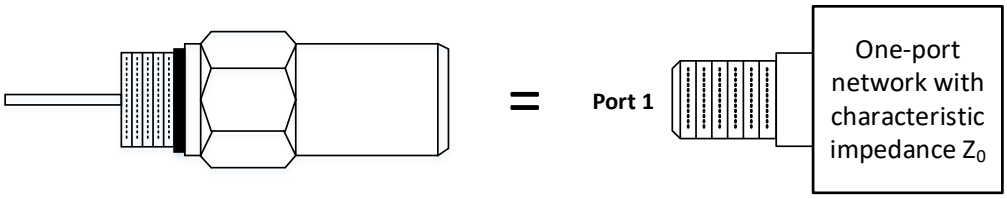

Figure 24 - Cable equipment chassis terminator represented as a one-port network.

Likewise, an in-line attenuator (or amplifier, tap, etc.) can be considered a two-port network, as shown in Figure 2.

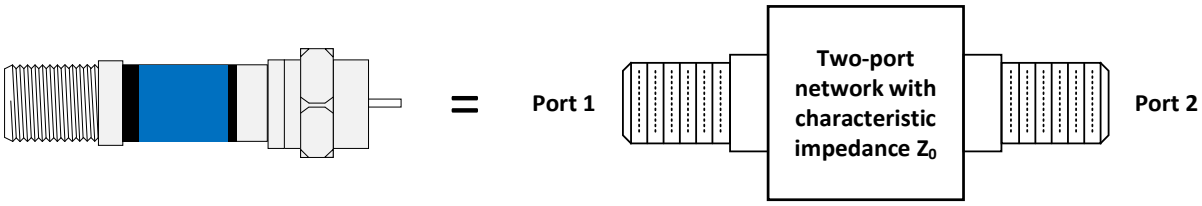

Figure 25 - In-line attenuator represented as a two-port network.

Among the metrics that can be used to characterize N-port networks are scattering parameters, or S-parameters. S-parameters are complex numbers usually expressed in the format S_{mn}, where m is Port 2 (the output port) and n is Port 1 (the input port). The remainder of this discussion focuses on two-port networks.

Assume that a two-port network such as an attenuator is being characterized. A test signal is applied to Port 1, and that signal measured at Port 2. From an S-parameter perspective, this gives us S_{21}, the forward voltage gain or transmission coefficient. See Figure 3.

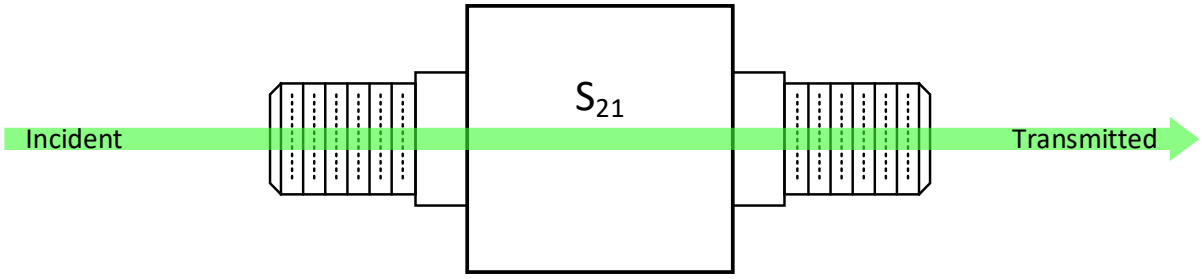

Figure 26 - Testing the two-port network from Port 1 to Port 2 gives the S-parameter S_{21}.

While the incident signal is being applied to Port 1, we can also measure any reflection from the two-port network. The reflection is a combination of reflections from Port 1's connector and all of the components inside of the two-port network. Here, the S-parameter is S_{11}, the voltage reflection coefficient for Port 1. See Figure 4.

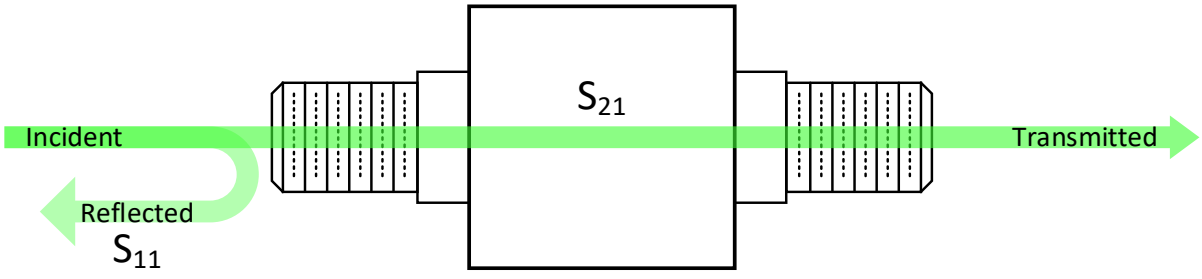

Figure 27 - Measuring the reflection from Port 1 gives the S-parameter S_{11}.

Note: When performing a measurement of S-parameters, the port(s) other than the one(s) being measured should be terminated in the network's characteristic impedance (typically 75 ohms for cable systems). An example is shown in Figure 5 for the case of a reflection measurement on Port 1, with Port 2 terminated.

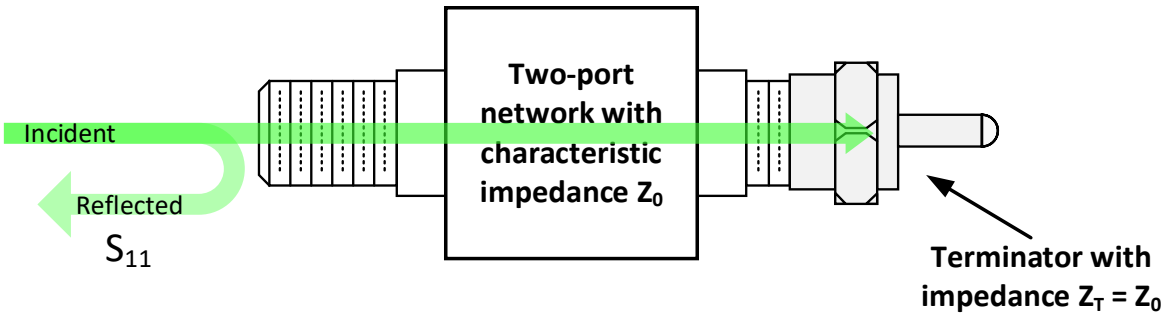

Figure 28 - It is common when measuring S_{11} to terminate Port 2 in an impedance equal to Z_0.

Next, apply a test signal to Port 2, and measure at Port 1. This gives us the S-parameter S_{12}, the reverse voltage gain or transmission coefficient. See Figure 6.

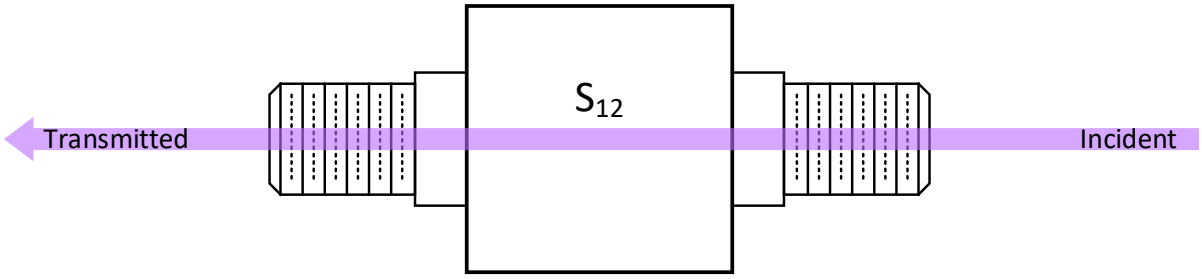

Figure 29 - Testing the network from Port 2 to Port 1 gives the S-parameter S_{12}.

Here, too, a reflection measurement can be made at Port 2, as shown in Figure 7. This gives us the S-parameter S_{22}, or Port 2's voltage reflection coefficient.

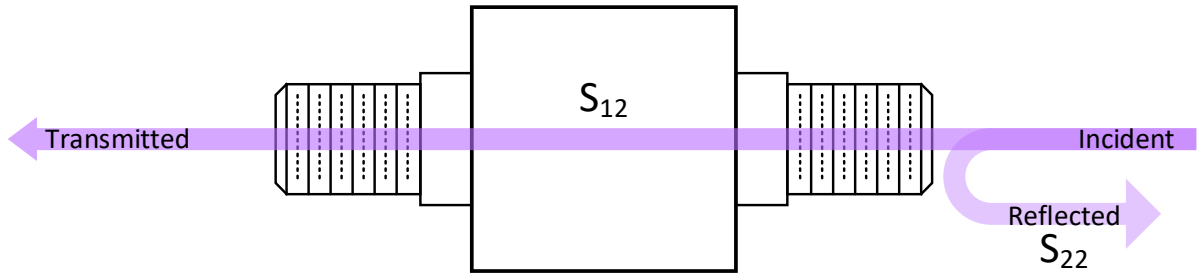

Figure 30 - Measuring the reflection from Port 2 gives the S-parameter S_{22}. In many cases Port 1 would be terminated in an impedance equal to Z_0 while performing this measurement (not shown).

In an operational FDX DOCSIS network, the FDX node's echo cancellation circuitry characterizes the network from the perspective of S_{11}, similar to the example shown in Figure 8.

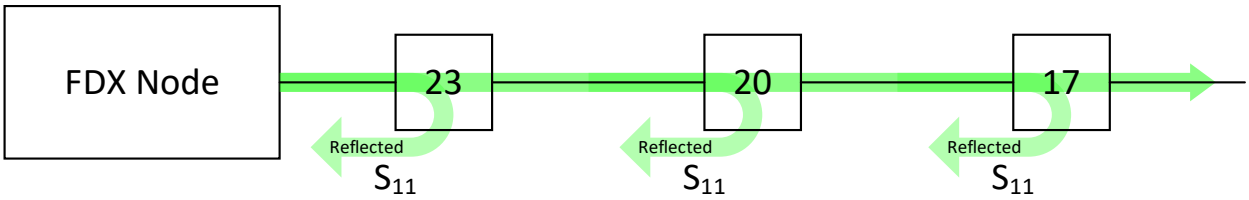

Figure 31 - FDX DOCSIS node S_{11} characterization of the cable network.

The following table summarizes the S-parameters just discussed.

Table 4 – Two-port S-paramters

Two-Port S-Parameters	
S_{11}	Port 1 (input port) voltage reflection coefficient
S_{12}	Reverse voltage gain or reverse transmission coefficient
S_{21}	Forward voltage gain or forward transmission coefficient
S_{22}	Port 2 (output port) voltage reflection coefficient

For S_{11} and S_{22}, the voltage reflection coefficient is the ratio of reflected voltage $E_{reflected}$ to $E_{incident}$. For S_{12} and S_{21}, the transmission coefficient is the ratio of transmitted voltage $E_{transmitted}$ to incident voltage $E_{incident}$.

Figure 9 shows the relationships of $E_{incident}$, $E_{reflected}$, and $E_{transmitted}$ when measuring from Port 1 to Port 2. Here, $E_{transmitted}/E_{incident} = S_{21}$ and $E_{reflected}/E_{incident} = S_{11}$.

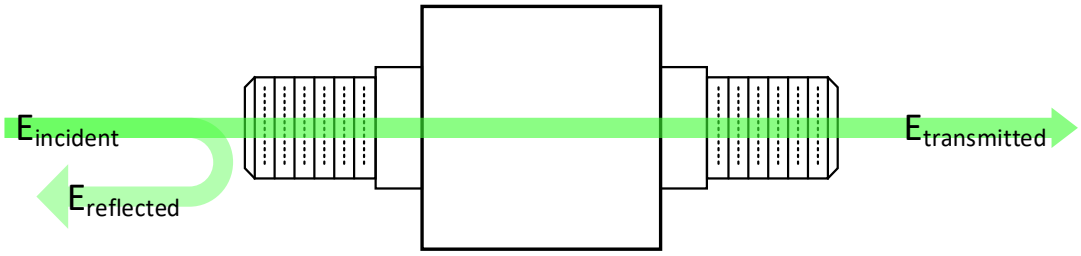

Figure 32 - Relationships of $E_{incident}$, $E_{transmitted}$, and $E_{reflected}$ when measuring from Port 1 (input port) to Port 2 (output port).

Going the other direction, from Port 2 to Port 1, $E_{transmitted}/E_{reflected} = S_{12}$ and $E_{reflected}/E_{incident} = S_{22}$. See Figure 10.

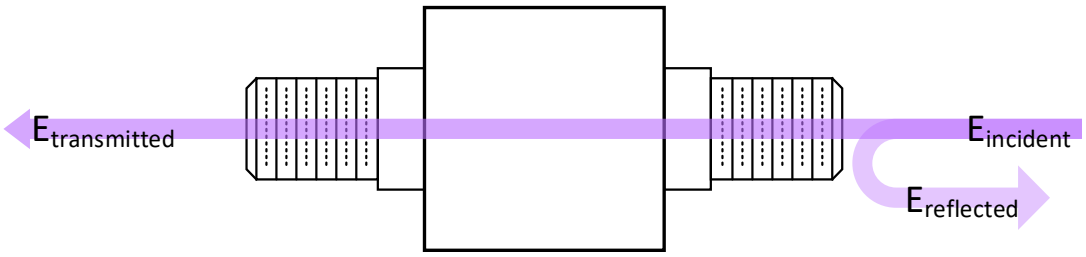

Figure 33 - Relationships of $E_{incident}$, $E_{transmitted}$, and $E_{reflected}$ when measuring from Port 2 (output port) to Port 1 (input port).

Cable operators are usually more familiar with characteristics such as gain, insertion loss, and return loss. Here are some common relationships derived from S-parameters (referenced to a two-port network, and assuming Port 1 is the input port and Port 2 is the output port).

Input return loss in decibels
$R_{in} = -20\log_{10}|S_{11}|$

Output return loss in decibels
$R_{out} = -20\log_{10}|S_{22}|$

Gain in decibels
$G_{dB} = 20\log_{10}|S_{21}|$

Insertion loss in decibels
$L_{dB} = -20\log_{10}|S_{21}|$

1. Introduction

We have an exemplary beachhead for better in-home Wi-Fi coverage with the instantiation of a low power indoor (LPI) effective isotropic radiating power (EIRP) spec (5 dBm/MHz power spectral density (PSD)) for access points (APs) by the FCC which promises a Gbps+ link budget for in-home data distribution (and scavenging) over 6E wireless networks. But the FCC also opened the door to standard power in that band (up to 36 dBm EIRP) for indoor use with the adoption of a spectrum coexistence scheme it refers to as automated frequency coordination (AFC). Using AFC and the higher power, we can now consider trunked indoor links which meet (or better) a 2.5 Gbps PHY for even large floorplan homes and perhaps enable mixed-power and mixed-band in-home mesh architectures. This enthusiasm is tempered somewhat by the observation that battery-powered clients are currently restricted by silicon to 20 dBm footprints at 6 GHz and as such, may determine extender density in the home for particular service mounts. However, alternating current (AC)-powered clients capable of power upticks (above LPI even if shy of standard power) – which include set top boxes (STBs), video streamers and gaming hardware – imply that we should be able to exploit link modulation and coding scheme (MCS) to fairly dense quadrature amplitude modulation (QAM) spectrum efficiencies for streaming and gaming services to these fixed endpoint clients – especially those of a heavy downstream data delivery bias.

This paper will examine the opportunities to be found in a standard power Wi-Fi 6E regime, discuss AFC implications (for cloud portal and AP endpoints) and suggest possible in-home architectural leverages of this substantial uptick in AP EIRP.

2. The LPI Reference Point

2.1 Availability of FCC-compliant Test Devices

6E consumer premise equipment (CPE) has begun to enter the market and it is obviously relevant to gauge the impact of LPI's allowable power in real scenarios which feature appropriate spatial stream (SS) scaling alongside the 6 dB client "power penalty" between client devices and APs -- and against path losses normally associated with various endpoint locations in a common floorplan. As in previous years, the 5300 square foot Commscope/Arris Wi-Fi house affords us the opportunity to test wireless links which emulate endpoint placements in homes up to that footprint in size and explore rate/reach and latency performance against these placements.

An available 6E-compliant smartphone was tested against a multi-band 4x4 AP to evaluate rate/reach throughout the Wi-Fi house. The results of these tests are shown below.

2.2 Early 6E Device Performance Data

Measurements were conducted early last year for nascent 6E devices (4x4 AP and 2x2 smartphone). These yielded the following measurements in the house at close operating range:

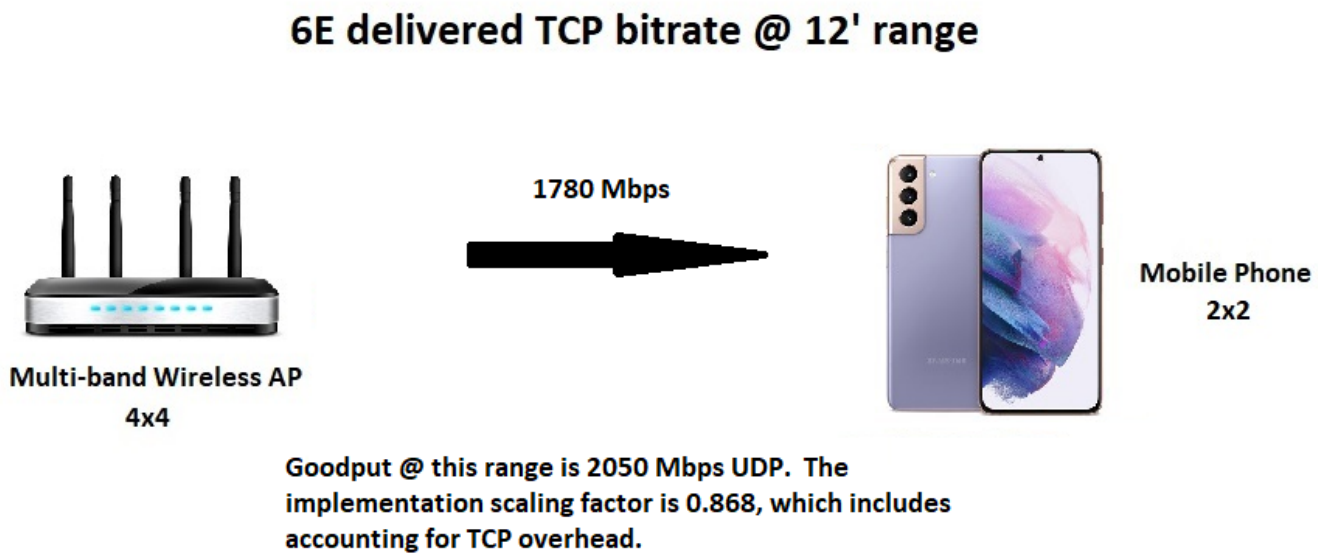

Figure 1 - Measured Close Range 6E LPI TCP Performance Between the AP and a Mobile Client

The testing was conducted across an open room at a radius of 12 feet or less (to establish a low path loss but far-field result which was expected to produce maximum MCS). The mobile was operating at backed off EIRP, relative to the AP, as mandated by the FCC. Free-space path loss (FSPL) at mid-band 6 GHz and that distance amounts to 60 dB (~49 of which gets you 3 feet off the antennae). Referring to the bitrate waterfall curve (goodput rate versus path loss) for 4x4 <-> 2x2 (albeit at equivalent powers, AP and client), we see that the link should support a goodput (bitrate accounting for Wi-Fi framing) of just over 2000 Mbps, with a TCP accounting moderating that to around 1800 Mbps or so (using 10% TCP overhead as a reference). Note that battery-powered mobile clients are likely limited even more -- to a maximum of 20 dBm EIRP -- which pushes the connection penalty to at least -7 dB relative to the AP. The operating points are captured on the waterfall curve for Wi-Fi 6 bitrates at LPI for 2x2 clients, leveraging the maximum 160 MHz channel bandwidth (note that the abscissa of the graph shows path loss off the antenna – which means you are actually down 49 dB at the leftmost point):

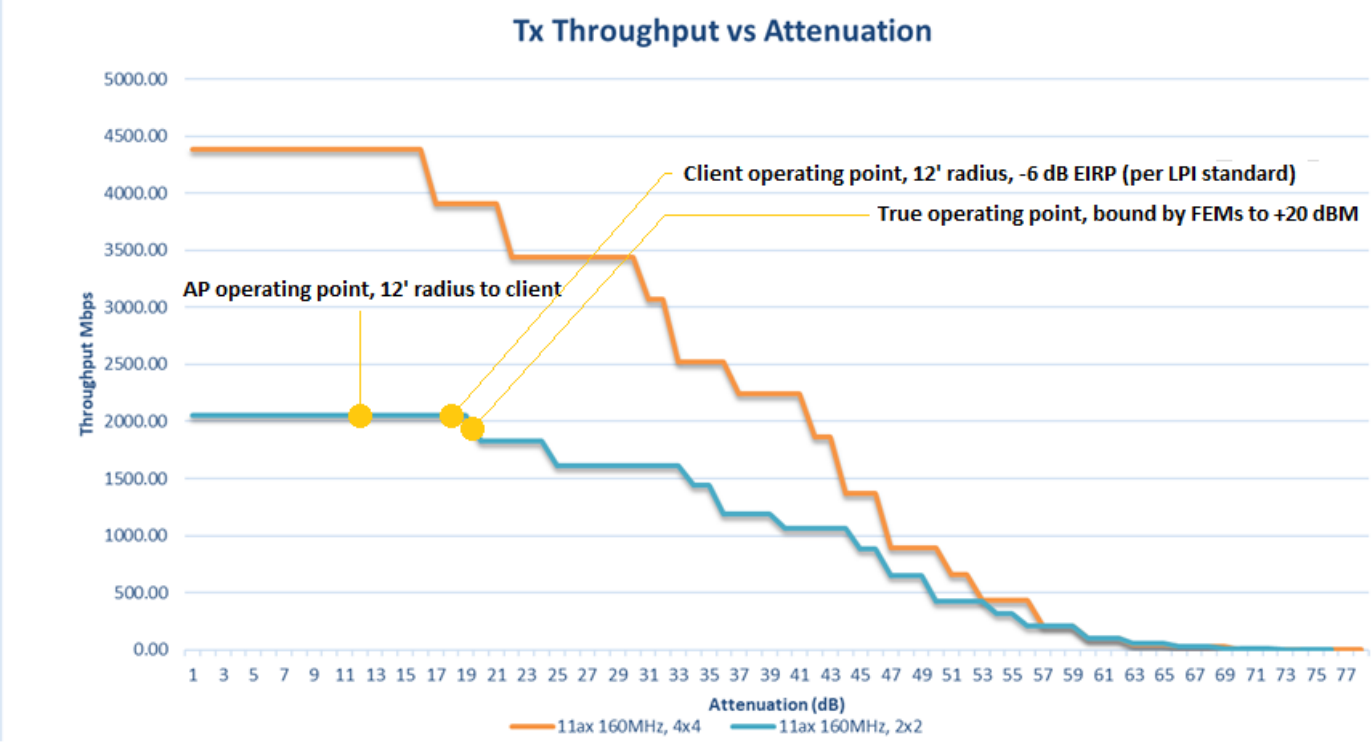

Figure 2 - Differential MCS Operating Points, Downlink and Uplink @ 12'

Note that the client – 6 or 7 dB down in power -- is operating at a mostly equivalent link budget to the AP at this close range, with a max compromise of one lower MCS step. This is not unusual behavior – and clients are almost universally the more restrictive on MCS setting than APs (certainly guaranteed when their transmit footprint is managed 6-7 dB below the AP).

2.3 Whole Home Performance

To get a feel for LPI coverage from an optimum AP location in the Wi-Fi house, the multi-band wireless router was placed in the central living room on the main floor. The mobile smartphone client was then moved room-to-room to measure data exchange rates and paint a coverage map for the house. Per housing floor, the TCP rates are shown below:

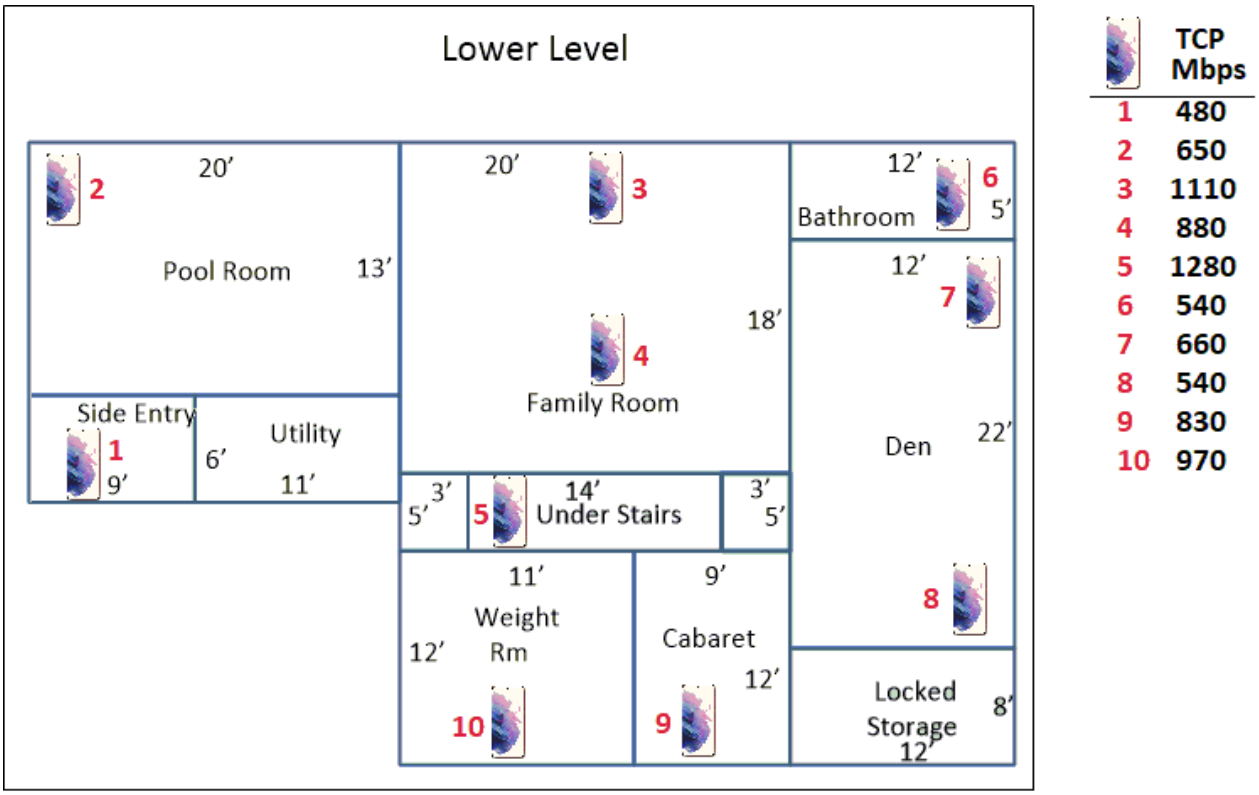

Figure 3 - Wi-Fi Hous Lower Level 2x2 Client Performance

22	870

Figure 4 - Wi-Fi House Main Level 2x2 Client Performance

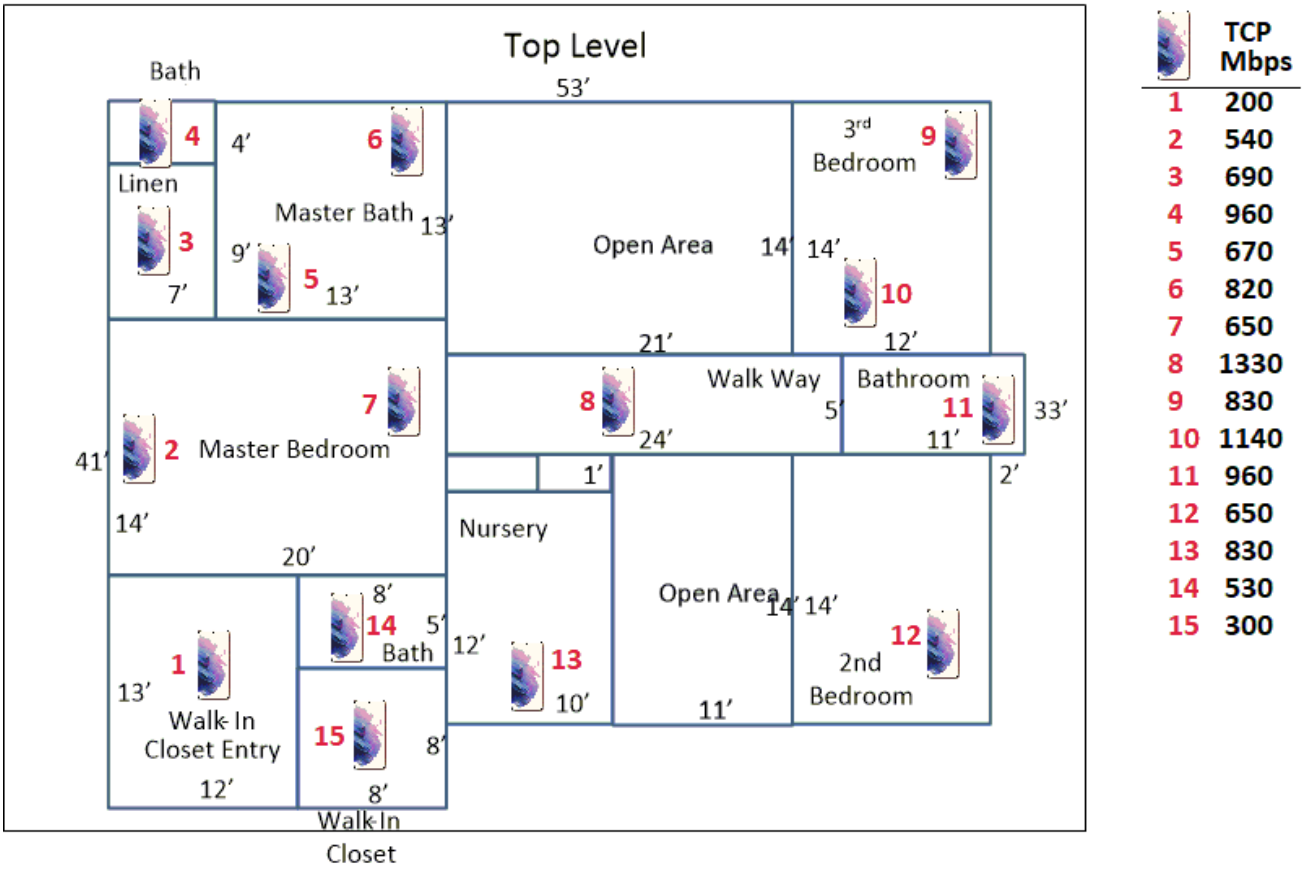

Figure 5 - Wi-Fi House Upper Level 2x2 Client Performance

These collections of data yield the following “heat maps” of the LPI-backed off mobile smartphone around the whole of the Wi-Fi house:

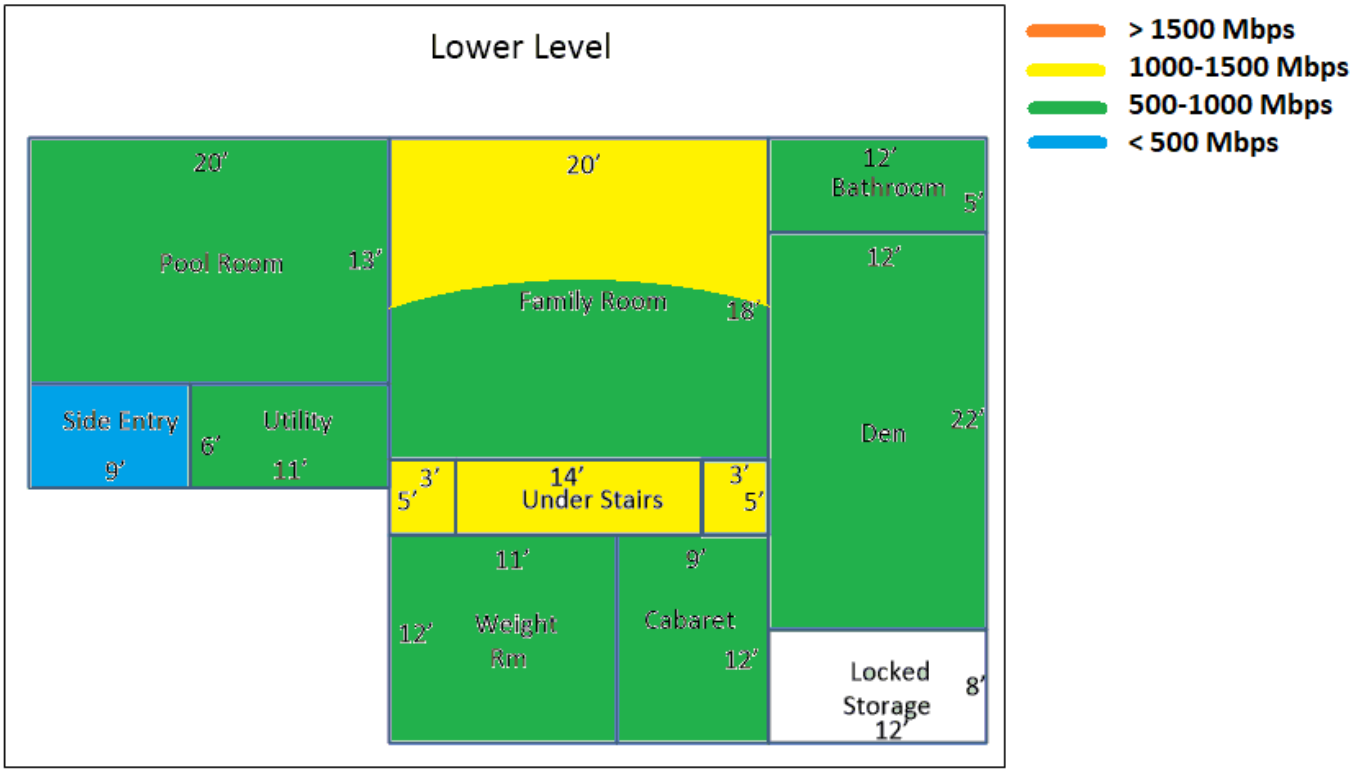

Figure 6 - Lower Level Heat Map

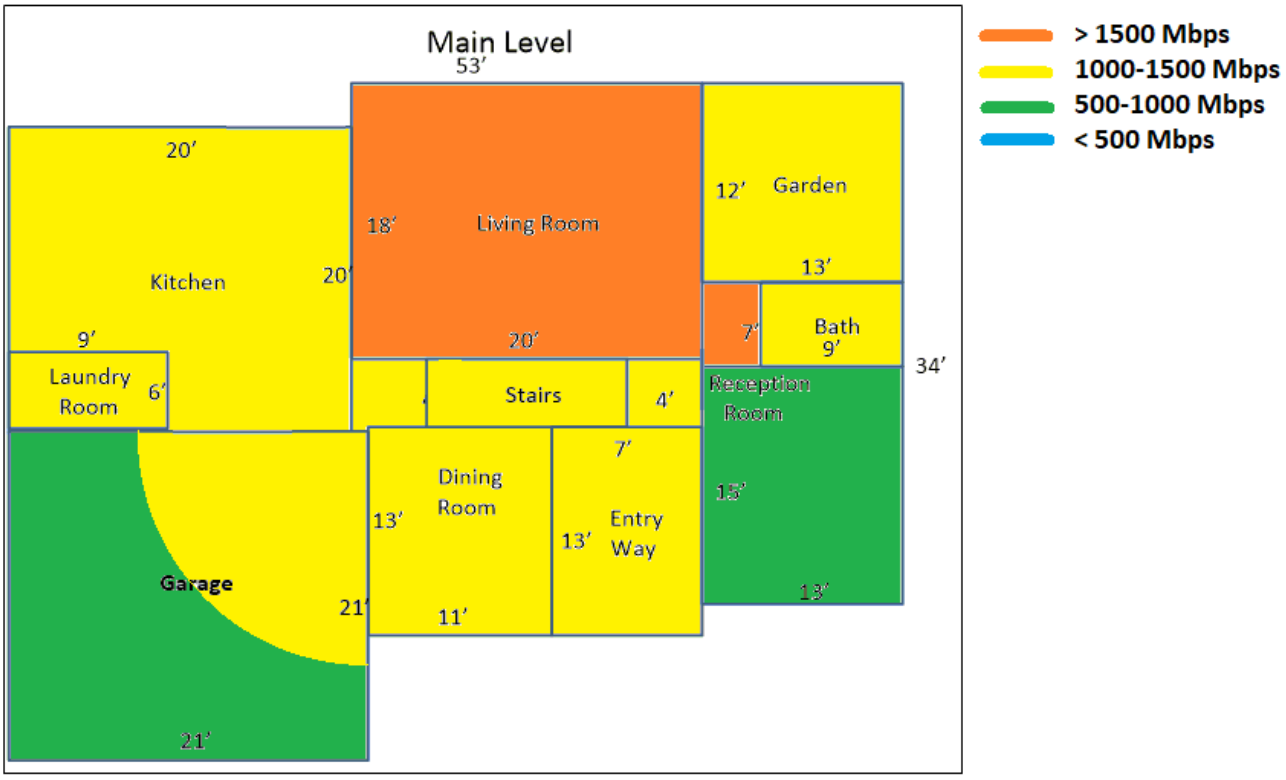

Figure 7 - Main Level Heat Map

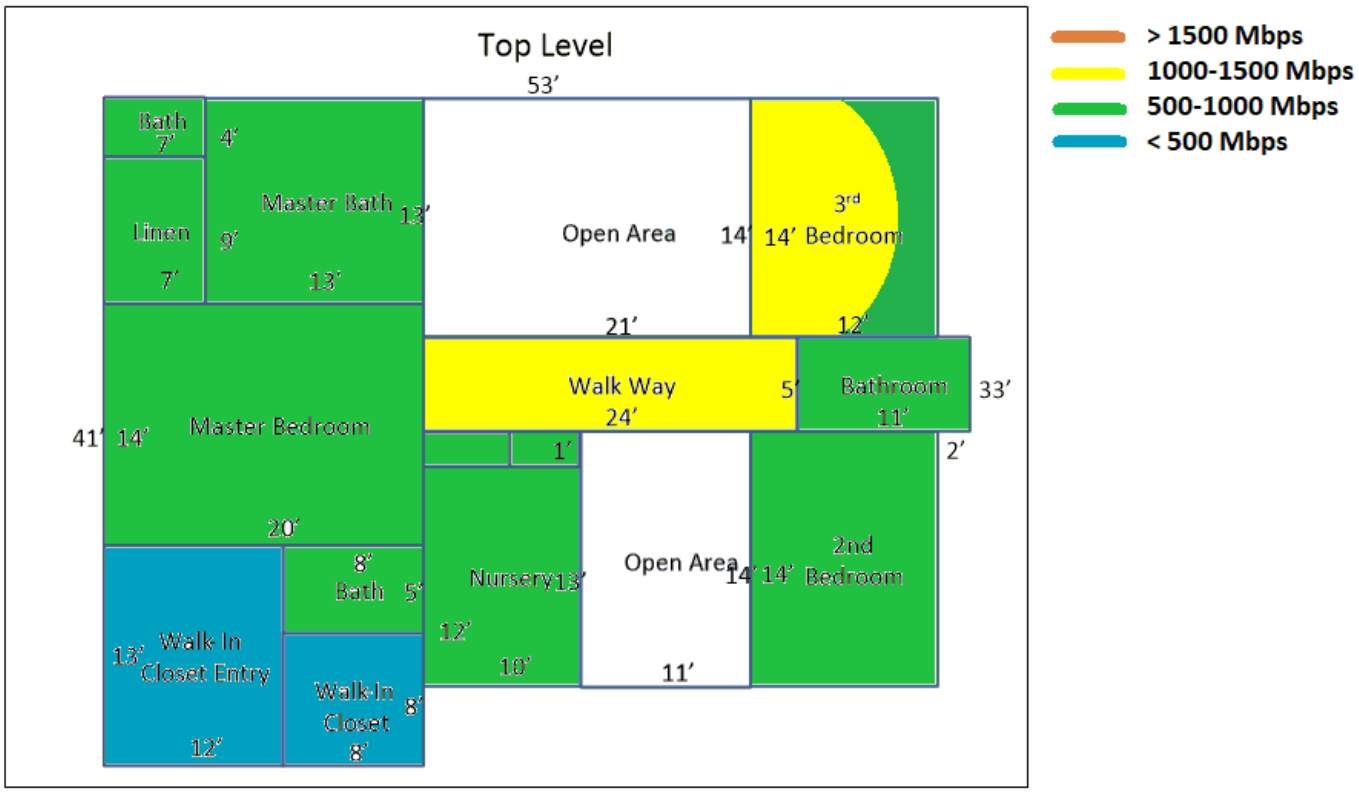

Figure 8 - Top Level Heat Map

Note that, on the lower level, there was a service null directly below the AP – likely a result of a compromised antenna gain pattern along the central vertical axis of that device. In any event, armed with these results, we can lay out expectations for coverage if we bump the AP power up to an AFC-approved 4W.

3. The Standard Power Prospectus

The fundamental tenet of higher EIRP is the notion that over identical path geometries, more transmit power means higher received power, better carrier-to-noise ratio (C/N) and better spectral efficiency (higher link MCS) which then sustains higher bitrate coverage over a greater service area.

3.1 Implications of the Power Gain

The bump from 27 dBm at 160 MHz BW in the 6 GHz band (LPI EIRP) up to 36 dBm is obviously significant. To put it in perspective, this implies a link linear throw increase of 2.8x to sustain at least the same MCS provided by LPI at a given service radius from client to selected AP or a service footprint up to almost 8x the coverage achieved at LPI for a selected reference bitrate – *provided the client can track the AP EIRP by no less than -6 dB*. (These are best-case numbers, essentially just FSPL without consideration for drywall and flooring – which, per transition, add lumped losses to the FSPL for a given radius). On the face of it, such an uptick suggests you can service a 10,000 square foot, multi-floor mansion from a single AP or gateway and achieve the same bitrate performance you would obtain throughout a 1500 square foot bungalow at LPI levels.

A couple of qualifying footnotes need to be appended at this juncture, however, to dampen and rationalize the more enthusiastic of these expectations.

3.2 Signal Propagation Considerations

The principal point of allowing standard power indoors (with an AFC system) is an acknowledgment that interior wall and flooring transitions will serve to attenuate and scatter 6 GHz Wi-Fi energy on its outbound journey. Further, depending upon exterior construction, building entry loss (BEL) anywhere from 6 to 30+ dB will constrain the radiation footprint on its inside-to-outside propagation. In prior testing at the Arris Wi-Fi house, multiple path tests indicated that, at mid-band 6 GHz, 4.5 dB drywall losses and 9 dB flooring losses could be inferred. (This will obviously vary somewhat with construction differences in other homes but seems a reasonable anchor in calculating available power at a given client location throughout the house, given the AP's own position and orientation.)

As a point of reference, it should be noted that these line-of-sight (LOS)-based calculations start to lose their predictive capability once you transition perhaps 3 walls/floors and get more than 40 feet from the AP – multipath effects not being accounted for (and one accumulates new signal energy vectors based on the dielectric thickness and size of every medium being traversed – as well as the sheer number of these transitions.) The best analysis involves a ray-tracing-based simulator (similar to the overlaid lighting effects summed in every computer-generated imagery (CGI) frame of a movie) but these can be expensive; lumped propagation channel models for in-home projection exist but require parameter tuning (related to the transition geometries associated with the main propagation path and the relative orientations of transmitter and receiver). All of the predictive work here is based on simple LOS analysis (to produce the most conservative link throw expectation); the bookmark is to just be aware of the sources of error in predicting more far-flung receive client behavior. Actual results at the range extrema would be better than our predictions.

Now, the setting of a goodput asymptote for a bitrate expectation versus path loss can overestimate the delivered signal footprint from AP to client if the spatial stream counts on both sides are equal. This is due to less-than-perfect antenna orthogonality and the effects of polarization mismatch (due to device orientation or path effects) between transmitter antenna farm and receiver antenna farm. In the cases where a 4x4 AP is lighting up various 2x2 clients, these diversity losses are washed out by what amounts to spatial oversampling available to the link by virtue of the spatial stream mismatch. However, this also means that the goodput expectations will scale to the least common denominator (2x2 in this case) – though the rate achieved will be closer to expectations in this scenario than for the case of a 4x4 device linking with another 4x4 device. (And all of this assumes fixed radiation patterns – i.e., no presumption of any type of antenna beam steering capability).

3.3 Qualifications for Standard Power Benefits

Using both the recorded LPI device performance at various in-home waypoints along with predictions for the same, and couple this with what amounts to a vernier or gain factor between expectation and measured performance at an open-look short link path, we can then begin to predict performance at standard power levels. Referring to our prior LPI measurements and projections at a small path loss in the Wi-Fi house yields the following observations: 1) Client spatial stream specification will define the rate multiplier (and hence, maximum asymptote) for delivered goodput bitrate performance; 2) Battery powered clients – with the constrained EIRP set by frontend module (FEM) thermal considerations (driving a more modest bias rail in pursuit of lower operating temperatures) – will not be able to track the increased output level of a standard power AP and hence these links will be compromised at large service radii as clients disconnect due to Wi-Fi framing loss; 3) AC-powered clients will benefit greatly from the

power uptick, if they can attain a 30 dBm EIRP (24 dBm conducted with a maximum antenna gain of 6 dBi – which amounts to a much less demanding conducted power budget than that provided by the typical -1 to 2 dBi gains of small form factor client devices). Put another way, if portable client electronics can achieve a 20 dBm footprint with a 0 dBi antenna gain factor, then fixed AC clients can bridge 6 of the 10 dB power gap from tracking standard power client to portable levels (30 dBm down to 20 dBm) and establish the necessary standard power with only antenna changes and 4 dB worth of additional conducted power.

It is worthwhile to also note that these range considerations anticipate full leverage of the 160 MHz BW available at 6 GHz; the client connect limitations become dramatically more concerning if narrower BWs are employed on the links (leading to reduced client EIRPs – potentially down to 12 dBm if the channel operates at 20 MHz BW).

These observations produce an interesting set of architectural permutations of in-home Wi-Fi networks, as we shall see. Standard power goodput bitrate achievable for both 4x4 and 2x2 links is captured immediately below, along with operating points for the various uplink and downlink power budgets:

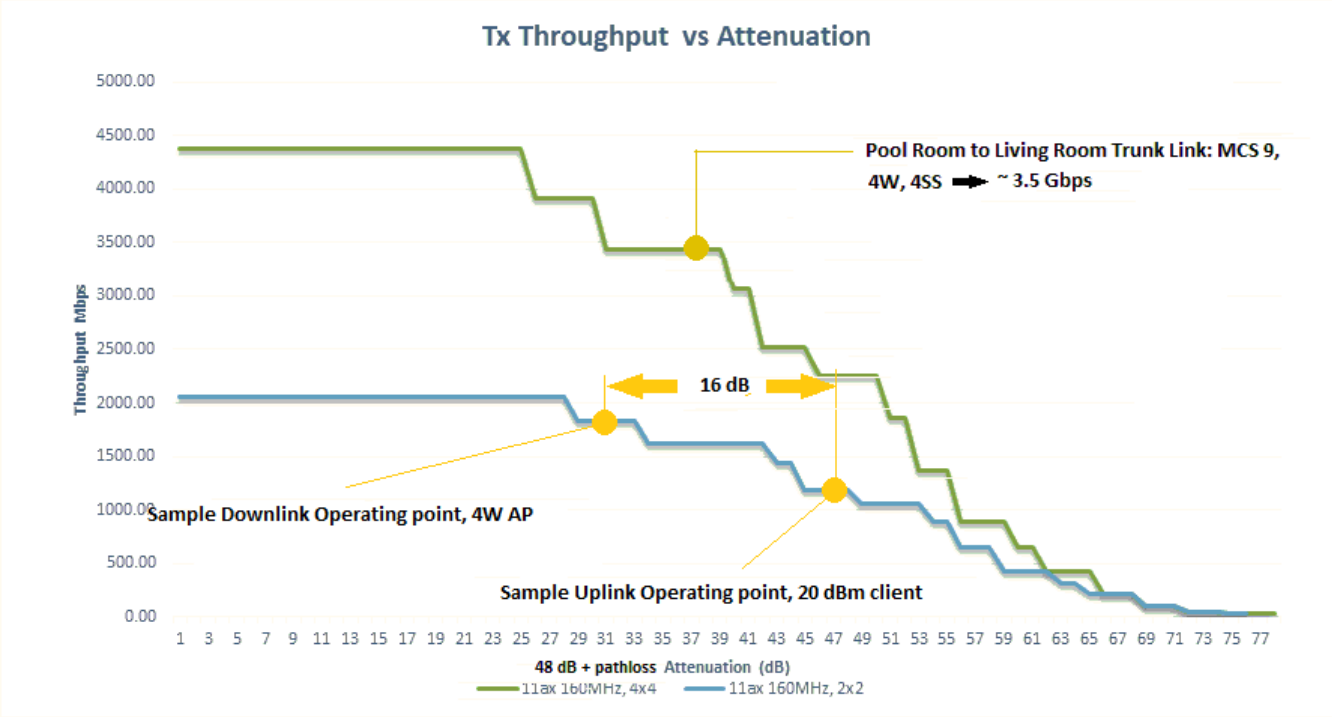

Figure 9 - Bitrate Waterfall vs Path Loss for 4W AP

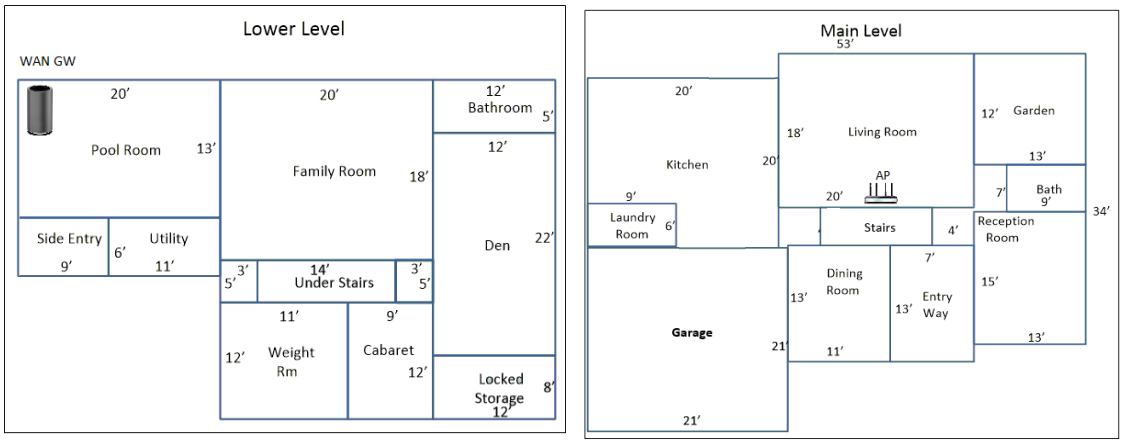

Figure 10 - Proposed Trunk Link Endpoints, Lower and Main Levels

As before, the ordinate axis assumes an antenna-launch loss of around 49 dB as a starting point and the values listed are essentially distance, in pathloss dB, from the antenna(e) to the client. Fundamentally, the move to higher power represents a push (reach expansion) on the pathloss axis by 9 dB:

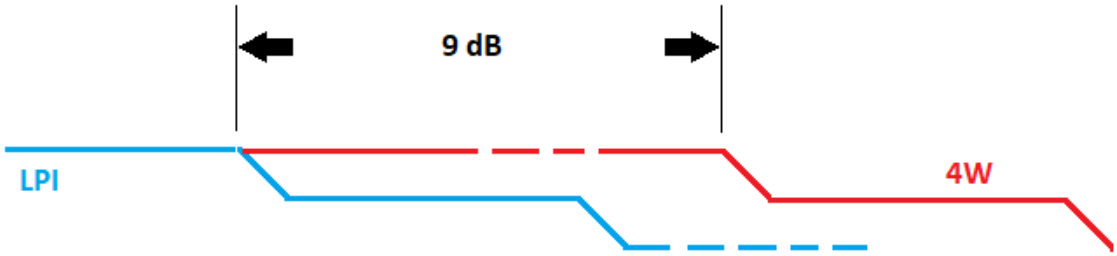

Figure 11 - Effect of Increasing EIRP on Delivered Bitrate

The constrained radiation footprint of portable, battery-powered client devices puts a damper on the more inflated of the coverage aspirations one would otherwise assign to a 4W EIRP, servicing AP, then. But the more robust (4x4) trunk performance and ability to reach more 1W-capable (largely fixed location) clients remains. The question arises: at what size in home floorplan would one want to invest in 4W APs, and what strategies on LPI and 4W mix might make sense? These considerations for in-home wireless service mounts are addressed in detail in section 7. But first, the machinery of AFC, its motivation and operational implications need to be understood (if only as background detail).

4. Potential for Interference

The operational "hall pass" granted Wi-Fi exploit of the 6 GHz spectrum at up to 4W EIRP levels comes (rightfully) with accommodation for exploits of that spectrum by existing communications infrastructure. It is in this accounting and policing of the asset by the FCC that we can arrive at fair use of 6 GHz, so it is worthwhile examining the known fixed wireless access (FWA) actors in the space.

4.1 The Contenders for Common 6 GHz Spectrum

While a reasonable directive for oversubscribed spectrum amounts to "listen before talk", the fact remains that simultaneous access to the same piece of the 6 GHz band for different unlicensed communication systems would be problematic absent some appreciation (and interdiction) of the opportunities for one system's transmissions to compromise the receptions required of an alternate system. The spectral region of concern here involves the 850 MHz worth of U-NII-5 and U-NII-7, where the FCC is now granting Wi-Fi the opportunity to extend its reach by leverage of AP power up to a 4W footprint. The contending system cases can be shown as follows:

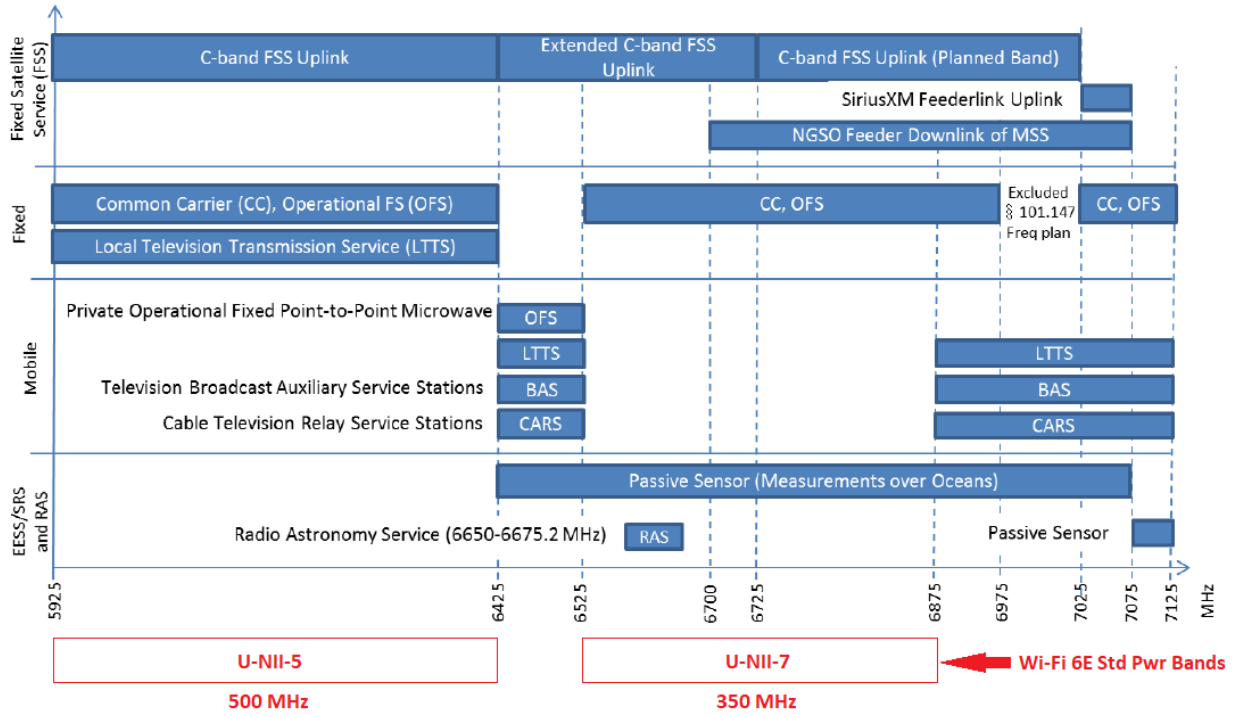

Figure 12 - Legacy FWA 6 GHz Spectrum Use

Note that the services described encompass both fixed service (FS) and C-band fixed satellite service (FSS) mounts, along with some mobile point-to-point (P2P) links as might be employed by news services with "on the scene" coverage. Given the predominant population of FS clients (which are also increasing in number, where C-band satellite growth shows a -2%/year reduction) and the fact that the much smaller number of mobile services (MS) have the ability to re-orient antennae to mitigate interference at the

deployment site, we will focus on the impact to FS infrastructure. However, low-horizon satellite positioning (in the norther latitudes) can potentially expose the satellite receivers to rogue, unlicensed ground link propagation paths at low elevation offsets (presenting much less than orthogonal look angles) and so an effort should be made in establishing the relative heft of 6 GHz indoor energy impinging on the geosynchronous equatorial orbits (GEOs) used by C-band satellites (whose uplink band overlays U-NII-5 and -7 as shown above).

4.2 Dismissing Satellite Interference Concerns

In the report *Frequency Sharing for Radio Local Area Networks in the 6 GHz band, revision 3,* prepared by RKF Engineering Solutions for the 6USC, there is an exhaustive simulation assigning 6 GHz devices (as either small cell or Wi-Fi devices) on a per-person basis, with historical representations on device use cases which serve to estimate the concurrent, accumulated radiation from all indoor standard power devices across the continental United States (CONUS) and estimate the interference-to-noise ratio (I/N) as presented to the GEO-parked C-band satellites in use. Fundamentally, duty cycles of use on high power devices, based upon inferred link capacities and data consumption per hour were assigned. The upshot of the protracted chain of assumptions was that ~ 1 billion devices could be involved across CONUS, with the instantaneous overlay of around 400,000 standard power ON cycles. (The report spells out all assumptions used in the simulation and the reader is invited to download the paper – which is available on the internet in the public domain.) For comparative purposes, the report also estimated the impact to satellite receivers of the legacy 6 GHz infrastructure (which obviously is already operating concurrently with C-band satellite without measurable negative findings). A key figure of the study shows the following impact to receivers on the GEO arc from both legacy systems and the expected high indoor use of 6 GHz standard power Wi-Fi:

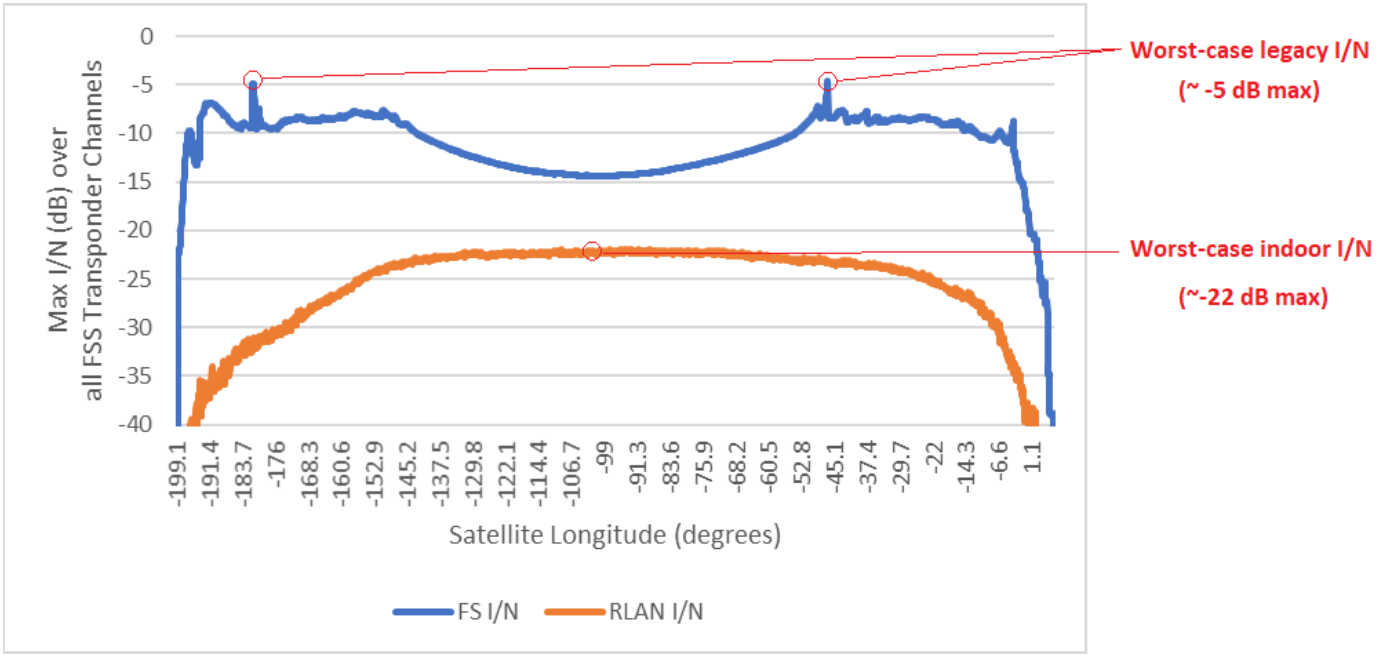

Figure 13 - Relative Obscurity of Potential 6 GHz Indoor Wi-Fi Interference to Satellites on the GEO Arc

The estimated 17 dB lower I/N due to indoor standard power Wi-Fi – versus what the satellites experience already from legacy 6 GHz outdoor links – is a telling graphic (and allows us to concentrate on interference implications to land-based FS links only). This consideration summons AFC exclusion zone calculation around these legacy endpoints and as such, will be addressed in the following section on AFC.

5. Band Management: Automated Frequency Coordination

5.1 The Premise

The intention of AFC to create an FCC-supervised gate into unlicensed indoor exploit of 6 GHz begs elaboration. In order to instantiate this higher performance gate, a specification has been developed which merges several databases, an exclusion zone calculator, the presumption of default LPI behavior by APs seeking higher EIRP, a restriction on indoor-only AP use and a messaging exchange function (between a cloud supervisory portal and those APs). The block diagram manifests as follows:

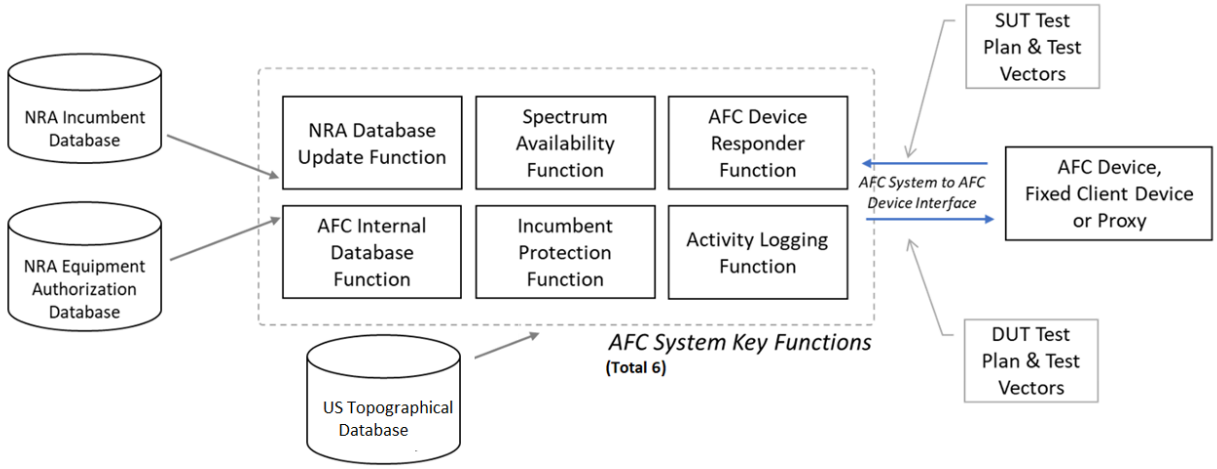

Figure 14 - AFC Block Diagram

As the diagram indicates, there have been six System Key Functions identified for the specification-in-progress, along with three reference databases. The intention of this organization is to support a bilateral data exchange with AP's soliciting the AFC for permission to operate at standard power; by and large, this exchange consists of a query from the AP which provides its latitude, longitude and operating height information to the AFC, which then references its databases for identification of the location of potential co-channel interference (CCI) targets and delivers a mask of available band and power back to the AP. The abbreviated schematic also points the way to certification – system under test (SUT) and device under test (DUT) test vectors at the point of data exchange (interface to the right in the above figure).

Key to all this is the presumption that, unless the appropriate provisioning message (parameterized permission) is received by the AP, its default operating EIRP envelope will be constrained to the LPI-specified 5 dBm/MHz PSD. Furthermore, the permission assigns a lease timeout period after which even approved standard power devices are required to revert to an LPI emissions envelope. (This can obviously be forestalled by periodic queries to the cloud AFC, which would then serve as renewals of the

standard power lease). The buried requirement here is that the AP must be able to access the AFC portal at least once per day (the currently mandated expiration timeout) – and must repeatedly guarantee its lease renewal in order to maintain permission to operate at a standard power envelope.

As of this writing, many implementation details for AFC remain unsettled (key among these being the hosting question for the application – which then begs additional work on whether the service is industry-sponsored or a private affair -- the latter, then, invoking appropriate subscription or licensing). As might be expected, multiple stakeholders in the venture are currently deeply involved in finalizing details, since the goal is to have an operational AFC some time in 2022.

5.2 Operational behavior

The following outlines the specific functional parsing associated with the cloud-based AFC (pertinent to block diagram above):

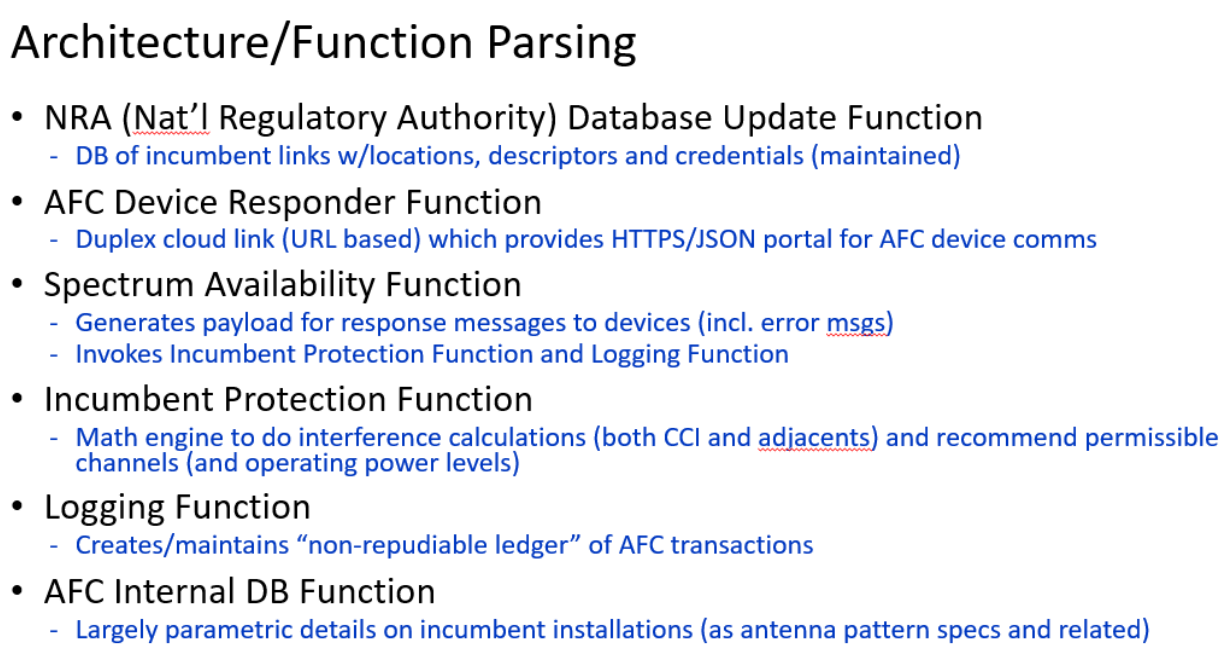

Figure 15 - System Key Function Responsibilities

Message exchange details provided below:

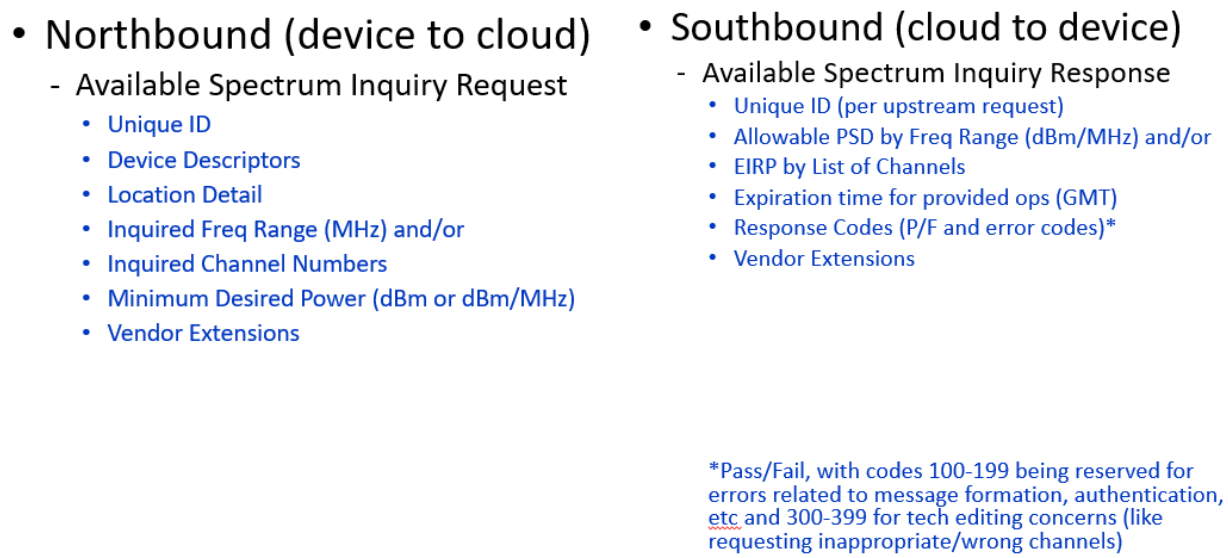

Figure 16 - Messaging Details Between AP and Cloud AFC

Additional messaging clarification is provided by the following:

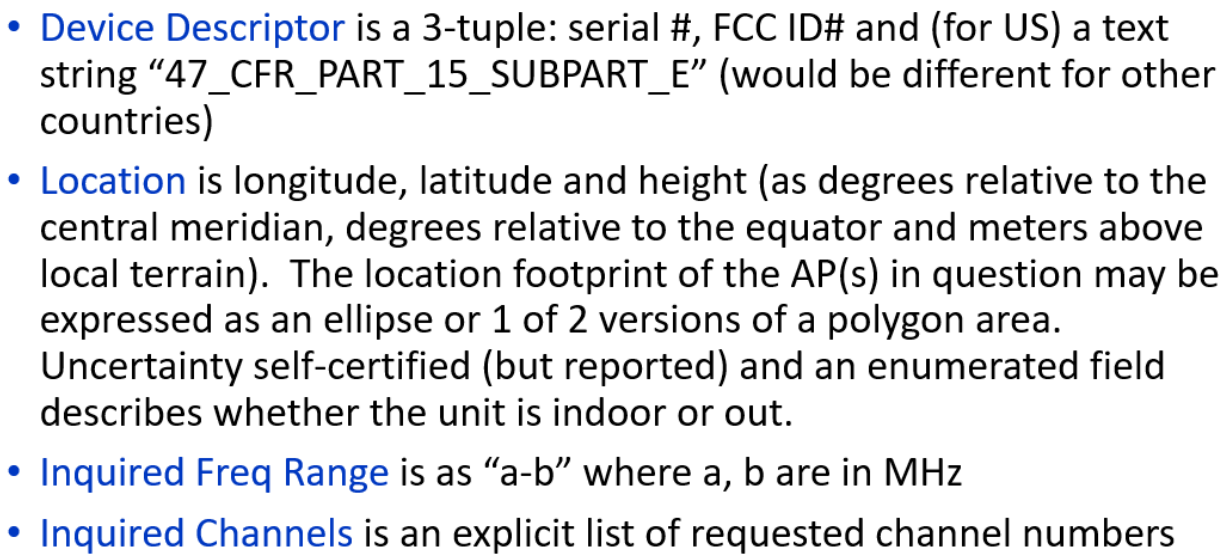

Figure 17 - Messaging Supplemental Definitions

Note that the exchanges listed may be executed by a proxy device (mobile, for example) on behalf of the AP. This would be accomplished with an NFC link between AP and proxy which would facilitate the cloud link connection and grant a pathway for user options and supplemental data entry on device location. The proxy shim would appear as follows:

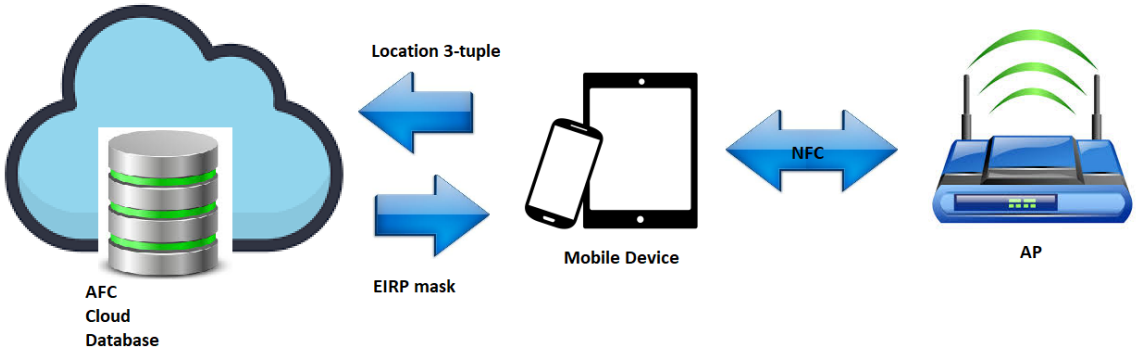

Figure 18 - AP Proxy Arrangement

The motivation for this added proxy lies in leveraging various methodologies to extend GPS position indoors, away from building apertures such as windows and to the immediate proximity of the AP (which, in a buried interior placement, may otherwise be blanked for GPS coverage). It also provides an application hosting environment where additional location data (height in floors or feet) may be inserted via the user (to improve on three-dimensional (3D) AP location uncertainty).

5.3 Nuances and Potential Optimizations

The operational dynamics of the AFC system suggest that, in the interest of speedier resolution of atomic requests from APs for access to standard power operation and a reduction in the query traffic impinging on the AFC from a nationwide population of devices, some amount of "query triage" might be considered. The driving consideration in this is that for a vast number of the requesting APs, lack of proximity to fixed wireless 6 GHz links guarantees deep marginalization of CCI possibilities which might otherwise negatively impact operation of the legacy fixed wireless links. In fact, CCI requires a multilateral conspiracy of overlaid/adjacent channels in the band, aligned FWA antenna aperture (as both azimuth and elevation above ground) and minimal geographical offset of the two contending endpoints in order for concern over potential CCI to be realized. These observations present the opportunity to streamline determination of exclusion zone limitations (reduce calculus overheads) and perhaps extend standard power AP leases past the 24-hour limit presently in the specification (in cases where the potential for interference is effectively and persistently nonexistent). Both efficiency gambits invoke some subtle tradeoff considerations, however.

5.3.1 Radius of Interference

First, as regards the reduction of calculation overhead, is the observation made above that the potential for CCI involves competitive channel access, unfortunate alignment of the FWA antenna with the source of possible interference and geographical proximity of the two potentially interfering endpoints (legacy FWA and Wi-Fi AP). Of these three parameters, inter-endpoint distance is easily the most significant contributor to CCI. It is only when this radius falls below some minimum that additional calculation need be performed to ascertain the possibility of CCI at a level which threatens operation of the FS or FSS link. For example, free-air LOS path loss over the radius involved (assuming optimal coupling of antenna apertures) and a conservative assignment of only a 10 dB penalty for dwelling egress (likely values will fall in a range of 10-30 dB at 6 GHz, depending upon exterior wall construction details and proximity of a

standard – non-e-glass -- window) generate the first cut at the potential for CCI based solely upon proximity of the FS receiver to the Wi-Fi AP.

Some example numbers would be helpful: at 6.5 GHz (mid-band 6 GHz) free-air path loss amounts to 113 dB at one mile. Coupling this with the maximum indoor AP power of 36 dBm and a building entry loss (BEL) of 10 dB suggests the propagated Wi-Fi signal amounts to no more than -83 dBm at a one-mile radius in any direction. The goal, however, is to get to I/N to -6 dB at the nearest FWA antenna (i.e., no closer than 6 dB below the noise floor at a particular BW). To be especially conservative on this gambit, we will neglect the interference moderating effects of clutter, scatter, terrain blanking (available in several standard outdoor propagation models) and narrow antenna aperture (assuming, in this case, no azimuth selectivity in the FWA antenna systems). For a 160 MHz overlaid band (between FS and AP) and a presumed 4 dB NF on the FS receiver, we get a maximum allowable interference footprint of -174 + 10*log(BW) + 4dB receiver NF – 6 dB minimum desired I/N ratio – 33 dB (FS boresight antenna gain for a small dish), or -127 dBm. Translating this to path loss of the AP signal (and accounting for benefitting only 10 dB on the BEL), the distance would have to amount to +36 – (-127) – 10, or 153 dB. At mid-band, this free-space loss comes at 102 miles displacement! Clearly, a single distance-to-FS receiver metric (under these stacked, overly conservative presumptions) does not represent much exclusion zone calculation triage benefit.

Perhaps a more realistic approach would be to find the distance at which a 4W AP presents no worse an interference candidate than an LPI device (which is permitted an indoor EIRP of 27 dBm @ 160 MHz BW *anywhere* in the US) – and then append a keep out area which, at its periphery, represents no greater a threat to FS operations than the energy footprint of an indoor LPI device exiting its enclosure (to a total throw of 300 feet or so) through an especially stout BEL. To set that energy threshold, one can conservatively set the BEL for the building housing the LPI AP to 30 dB (assumes stone exterior construction and e-glass windows), add 300 feet of arbitrary FSPL (as nearest proximity to an FS endpoint) and then use this abated field strength as the target value for a 4W AP to hit (under a less beneficial BEL of 10 dB, just to bake in margin). In round numbers, the target signal strength ends up being 27dBm – 88 dB (FSPL for 300 feet, mid-band) – 30 dB (BEL), or -91 dBm. This implies that one requires the FS spacing to the standard power AP to account for 117 dB worth of path loss (36 dBm – 10dB BEL – (-91 dBm target)). This arrives at a throw of 8500 feet (1.6 mi) at mid-band 6 GHz. This makes for a more manageable first cut.

So now the first triage step is to determine if the AP is further away from the nearest FS receiver by at least 1.6 miles; if this is the case, then the entirety of the U-NII-5 and U-NII-7 bands could be released for use by the petitioning AP – and the concern for interference potential relegated to being no worse (and this, actually by a fair margin) than that supplied by an equivalent indoor LPI device located in a stone home 100 yards from the FS receiver.

5.3.2 Antennae Alignment

Now the notion of antenna selectivity can be introduced. Note that with the 1.6-mile approximation above, all signal loss was put down to FSPL and BEL. With one additional step, APs which locate themselves less than 1.6 miles from a potential FWA site may be cleared to operate at standard power by evaluating whether the combination of FSPL, BEL and antenna pattern misalignment could defuse the possibility of interference. Note that FS endpoints have antenna radiation parameters logged into the Universal Licensing System (ULS, also referred to as national regulatory authority (NRA) in separate documentation) database referenced by the AFC. For the prevalent class A and B antennae, the pattern is

fairly narrow around the boresight direction of the element (for both azimuth and elevation). (In situations where sectorized coverages are combined – as would be the case for point-to-multipoint (P2MP) systems -- it is straightforward to select the most aligned element(s) of the array). An example of the most common apertures deployed in the field is captured below:

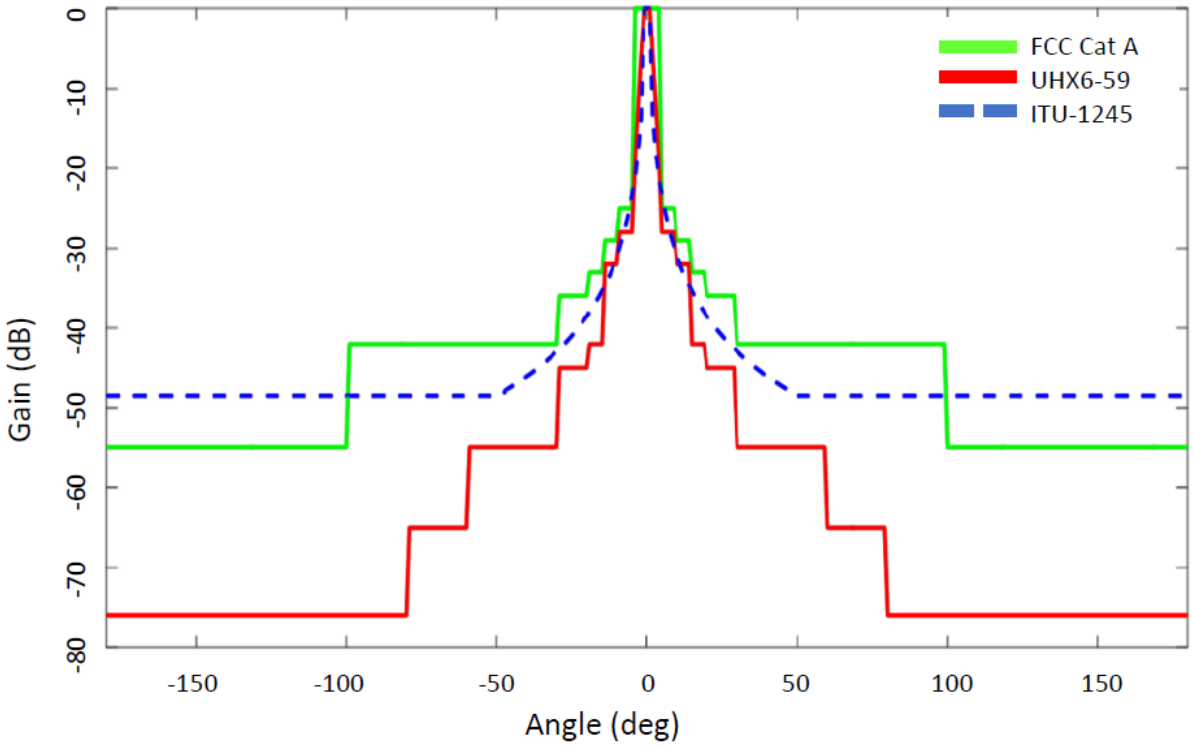

Figure 19 - FS Antenna Apertures (Azimuth Look Angle)

Zoomed in, the aperture looks like this:

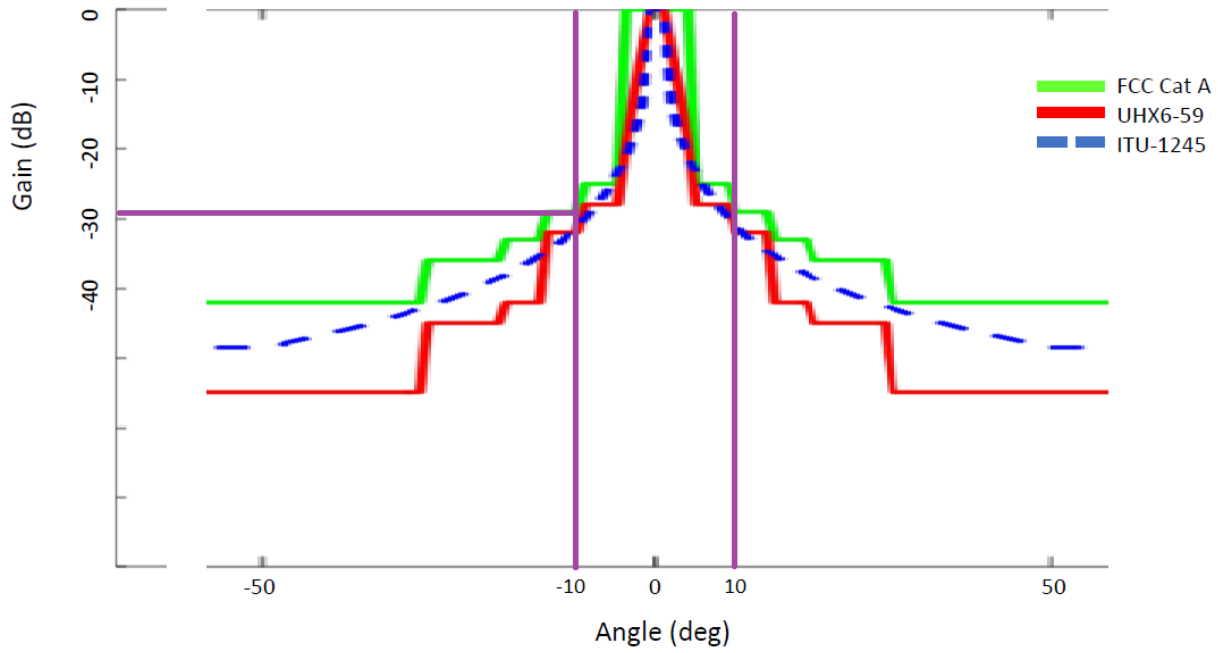

Figure 20 - Antenna aperture zoomed

Note that such performance is representative of 83% of the FS antenna population (per Commsearch research in 2011 – such not being recently re-evaluated, however). Even a cursory examination of the figure reveals that, once off-boresight by as little as +/- 10 degrees, any of the commonly used FWA antenna masks shown exhibit an azimuth selectivity which will produce > 30 dB loss relative to the aligned gain. Normally, one would consider boresight gain as the reference against which, would be applied the selectivity offset loss; however, recall that the distance calculation above applies to any angular displacement of AP-to-FS receiver, including exact boresight. Referencing our prior interference radius calculation, if we can count on an *additional* interfering signal loss due to the FS receive antenna's look angle to the candidate AP, our FSPL budget reduces to 117 – 30, or 87 dB. In mid-band, this would allow Wi-Fi AP's full rein on standard power as long as the AP distance from the FS endpoint is greater than 270 feet and the look angle exceeds 10 degrees on either side of target system antenna bore sighting. But (though in a significant minority) there are other antennae in use by legacy 6 GHz FWA infrastructure which feature a broader aperture and we will consider them, despite a low representation in the total number of target antenna systems, as the least common denominator default in calculating a conservative exposure profile for nearby FS receivers.

A representative sample of a popular (smaller) 0.9m diameter antennae, the Andrew VHLP3-6W, exhibits the following selectivity for horizontal and vertical, single polarizations:

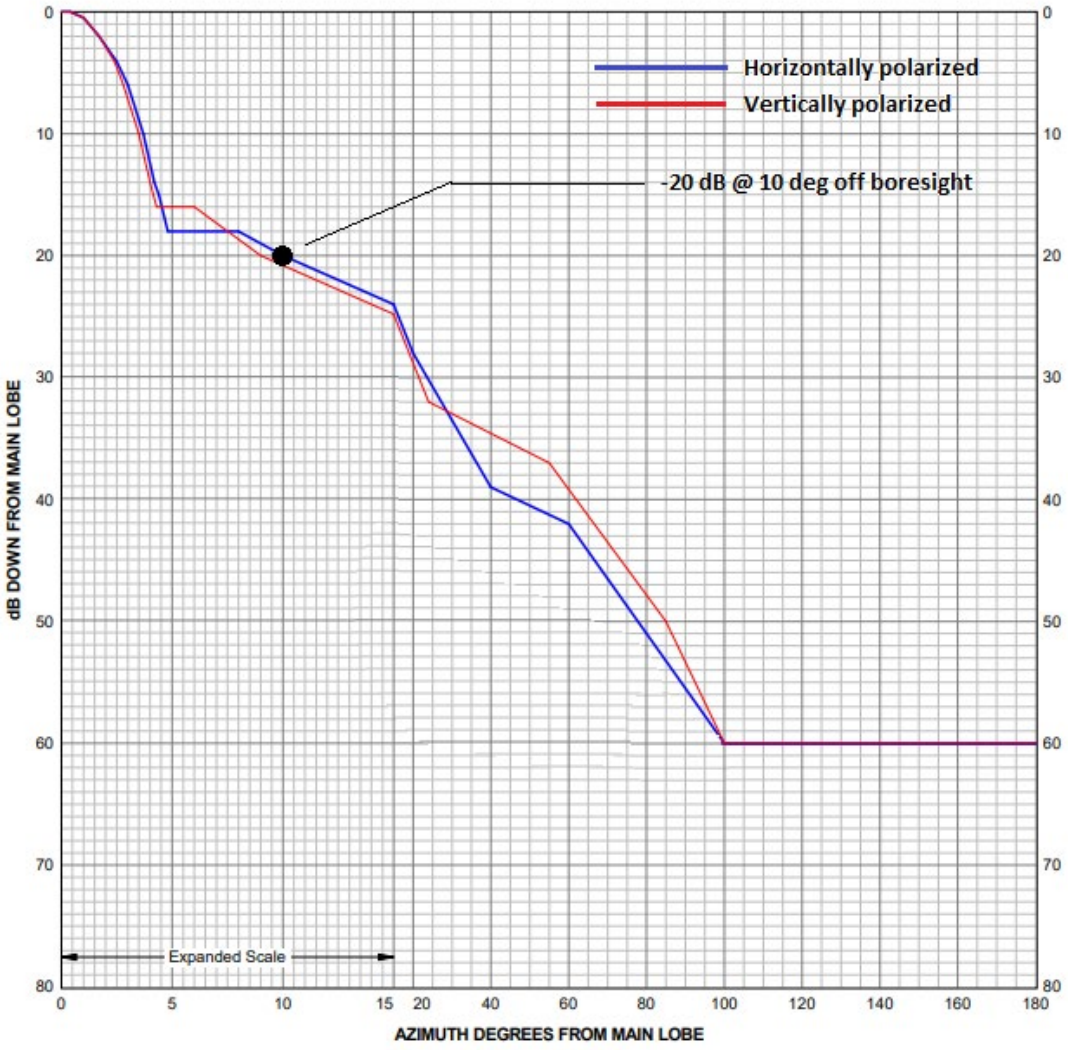

Figure 21 - Representative Small Diameter Antenna Single-Sided Selectivity @ 6 GHz

If we peg look angles > 10 degrees (between AP and FWA antenna) as a reference point, this smaller antenna exhibits worse selectivity than larger units (only ~ -20 dB or better, relative to the main lobe – versus the -30 dB exhibited by the majority of the FS antenna population). Using this as our generic interference possibility, our margin to interference collapses to 117 – 20, or 97 dB of required FSPL. The mid-band proximity associated with this number amounts to 850 feet (0.16 miles). The second "shortcut", then, for releasing the full extent of U-NII-5 and U-NII-7 spectrum for standard power use of APs has the dual qualifications that the distance to FS antenna must be > 0.16 miles *and* be off-boresight by at least 10 degrees.

Outside of these calculation shortcut cases, the AFC system would likely have to perform a full exclusion zone calculation (using distance, look angles, FS receiver link details and related) to evaluate whether Wi-Fi interference is a consideration.

5.3.3 The Argument for Variable Lease Duration

As regards the notion of extended leases, the FCC has decided that 24 hours (with an additional 24 hours grace period in the event of AFC system connection failure) will be the norm. This is based on the mere possibility of the ULS database being amended on 24-hour boundaries. Originally, the 6USC consortium had proposed a 30-day lease, projecting that the potential for interference nationwide would not significantly alter within a one-month timespan. It seems very likely that, in rural and suburban areas, the pace of 6 GHz infrastructure build-out will see a rate of database change very much slower than every 24 hours. It may be worthwhile for the FCC to re-examine standard power lease epochs – if for no other reason than this would greatly down-scale the communications traffic from APs to the AFC system (though, in fairness, this economy of communication does not appear to be an impediment for the system to operate, given the vast number of network paths in place to gather the AP solicitations and the ability to map AFC from the single cloud portal to multiple network edge locations). There certainly seems to be a case for applying some variation in lease lengths, depending upon location parametrics associated with the petitioning APs – especially if a case can be made to the AFC system that the device location is fixed (i.e., not a portable device).

Referring to our section on AFC calculation triage, a great many of the soliciting APs (perhaps as many as 90%), should require no full calculation of interference potential – which suggests longer leases may serve adequately.

5.3.4 Apportioning the Shared Spectrum

The final option we consider here is that, if the probability of the two wireless systems interfering with each other is not easily dismissible based upon proximity and alignment, we can examine the leverage of alternate in-band spectrum (non-overlaid assignment of spectral resources) to resolve the issue (and so grant some amount of leeway to the requesting AP(s), based upon available contingency spectrum). By appending guard bandwidth on either side of the incumbent system's operational link bandwidth, an exclusion portion of the spectrum for the soliciting Wi-Fi AP may be determined. (This would have to be done for every exposed FS node within a 1.6-mile radius -- depending upon boresight offset – each potentially with a differing link spectral profile.) Note that legacy FS links typically feature system BW << 100 MHz and there is 850 MHz of standard power 6 GHz spectrum across the two leverageable U-NII bands which can provide the frequency-division multiplexing (FDM) options desired – so the opportunity for mutual avoidance is quite high in all but the most crowded urban environments. Further, the Wi-Fi APs are already required to meet beyond-band-edge transmit power rolloffs which conform to the following out-of-band (OOB) energy mask:

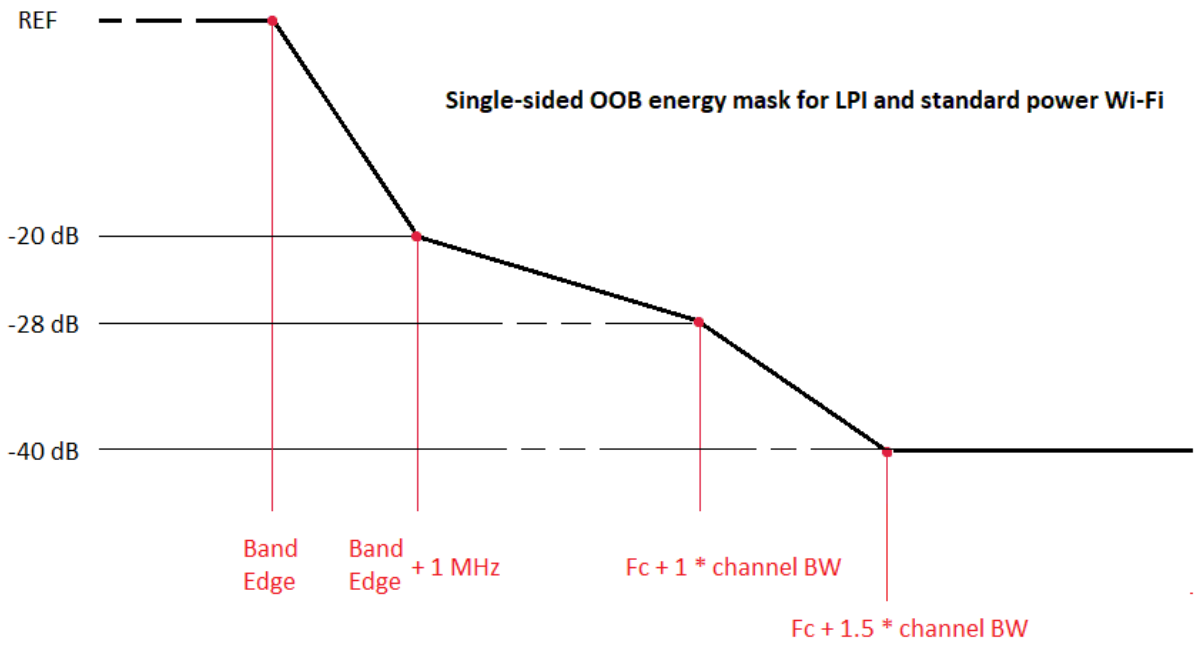

Figure 22 - Required OOB Energy Suppression by Wi-Fi APs

With 20 dB of specified OOB suppression at +/- one MHz from either band-edge of the AP's channel, and presuming 160 MHz of AP BW to set guard bands, one is tempted to represent the AP's spectral footprint as 162 MHz and have that augmented edge-of-band be no closer than the FS receiver's own band edge, to (conservatively) guarantee that the offset frequency AP's energy footprint within the FS link band is at least 11 dB lower (36dBm – 20 = 16 dBm) than that of a corresponding LPI footprint centered precisely on the FS link's center frequency. (As noted in prior sections, such is ubiquitously permitted without operational sanction anywhere in CONUS). So, a 1 MHz guard-band on either side of the FS channel to define a keep out region for overlaid AP energy is certainly sufficient. This has the takeaway specification that the nearest AP center frequency (Fc) for a 160 MHz channel can be no closer (on either band-edge side of the legacy FS link) than 81 MHz away to guarantee the necessary suppression. This can be shown pictorially as follows:

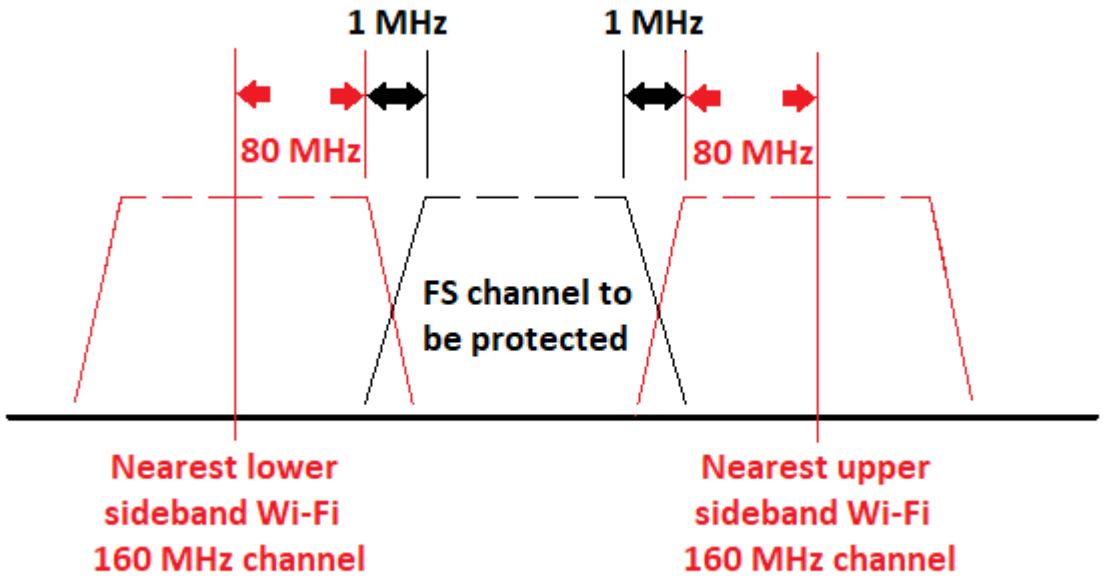

Figure 23 - Suggested FDM Keepout for Adjacent Wi-Fi Channels

In a spectral asset pinch (and as a last resort), Wi-Fi channel BWs less than the full 160 MHz may be considered for "spectrum puncturing" opportunity.

5.3.5 Ancillary AFC Services

The operational aspects of the AFC system in the prior sections have dealt exclusively with AP and cloud considerations for manufacturers and service providers. However, there is a consumer-facing aspect which needs to be acknowledged and dealt with: absent some type of *a priori* analysis, how could a consumer be assured that they would be able to leverage the standard power AP they are considering for purchase? The obvious answer seems to be that, like an AP, they should have the ability to query the AFC system (with appropriate geolocation detail) and have it deliver a verdict on the usability of a standard power device at the location they specify for use. Simply put, if they would not be permitted to exercise the standard power option where they reside, there would be no point in investing in a more powerful (and expensive) AP than one which exploits LPI.

The AFC specification also permits what amounts to a private data channel (vendor-specific extensions) which could be leveraged (along with a log of prior AFC communications) for client applications to provide some monitoring capability of the AFC interactions with the AP; such would be useful for determining the cloud-to-ground behavior of the AFC system and perhaps also assist with fault analysis.

5.4 AP Behavior Under AFC Management

The touchstone for managed AFC operation (and prerequisite for AP certification) is the compliance of the AP to the operating transmit power mask delivered to it from the cloud portal. That is, absent AFC connection and mask delivery, the AP cannot presume to operate at greater EIRP than that allowed for LPI operation. Further, it must default to no more than the LPI specification at lease timeout (currently specified to be 24 hours); finally, if granted a mask (as either available channels or frequency spans), it will not presume to a standard power EIRP in those spectral regions specifically masked off by the AFC query response and only leverage the spectrum allocated. In all cases, however, the AP will adopt a "listen before talk" spectrum deference posture (to mitigate interference from alternate, non-Wi-Fi, unlicensed links). This layered approach to spectrum exercise elicits several algorithmic methods to tune AP behavior for compliant operation and are examined below.

The following segments detail potential AP operating behaviors above the foundation presumptions just detailed above. Note that references to other bands besides 6 GHz are included only for completeness and acknowledge that 6 GHz band assignment for clients necessarily must account for the impact of mapping traffic to clients across *all* available Wi-Fi bands serviced by the AP.

5.4.1 Wi-Fi Airtime Engine (WAE)

The AFC-bound APs seeking to leverage standard power may comprise any of several multiband Wi-Fi options (up to, and including what some tag as "quad-band" APs – 2.4 GHz, 5 GHz low band, 5 GHz high band and 6 GHz). Assignment of multiband clients to 6 GHz (which define the magnitude of the exploit of 6E standard power) will require assessment by the AP regarding allocation of its band resources based upon projected bitrate consumption and the parametric contribution of several considerations. Among these are airtime budget/band available and in-use, desired margins to known airtime limits, band-use and bitrate-use profiles of the prospective client population, status of per-band data queues in the AP, limitations of the AFC-derived channel power mask, historical time-of-day prior behavior and detected desired-channel interference from other Wi-Fi APs or unlicensed 5G/LTE transmitters. The core determination effected is an assessment of airtime burn in each of the bands (especially 6E, given its higher degree of scheduling determinism and ultimate rate/latency performance). This evaluation we will refer to as the WAE.

As previously alluded to, consumed airtime per band is a result of supported bitrate at a particular set of MCS values; these latter are sustained by good C/N in the bandwidth being used – which itself is a function of radiated power and link length. The greater the EIRP and the shorter the path length (loss), the higher the potential MCS – and the less the airtime used to transmit the data packets. The reverse is obviously true: lowering the EIRP or extending the service radius to a far-flung client will lower the delivered signal C/N at the endpoint, reduce the operating MCS for the link and increase the airtime consumed to deliver the data packets (associated with that client, but nonetheless deducted from the overall airtime in the standard case of a single channel/band). Note that these aspects define the viewpoint from the AP to clients or peers (downstream traffic). Because the links support duplex operation, the corresponding upstream MCS and packet sizes must also be accounted for in the channel airtime usage. (And the upstream MCS will be lower than downstream in the 6 GHz band – given the Wi-Fi 6 FCC-mandated 6 dB backoff in client EIRP relative to the AP). The goal of the WAE is to canvas the available operating parameters and balance Wi-Fi band use to achieve best overall duplex data throughput (up to the SLA limits of the WAN).

The following diagram describes the algebra around estimations of band capacity (presume single channel/band) and band availability for future service mounts:

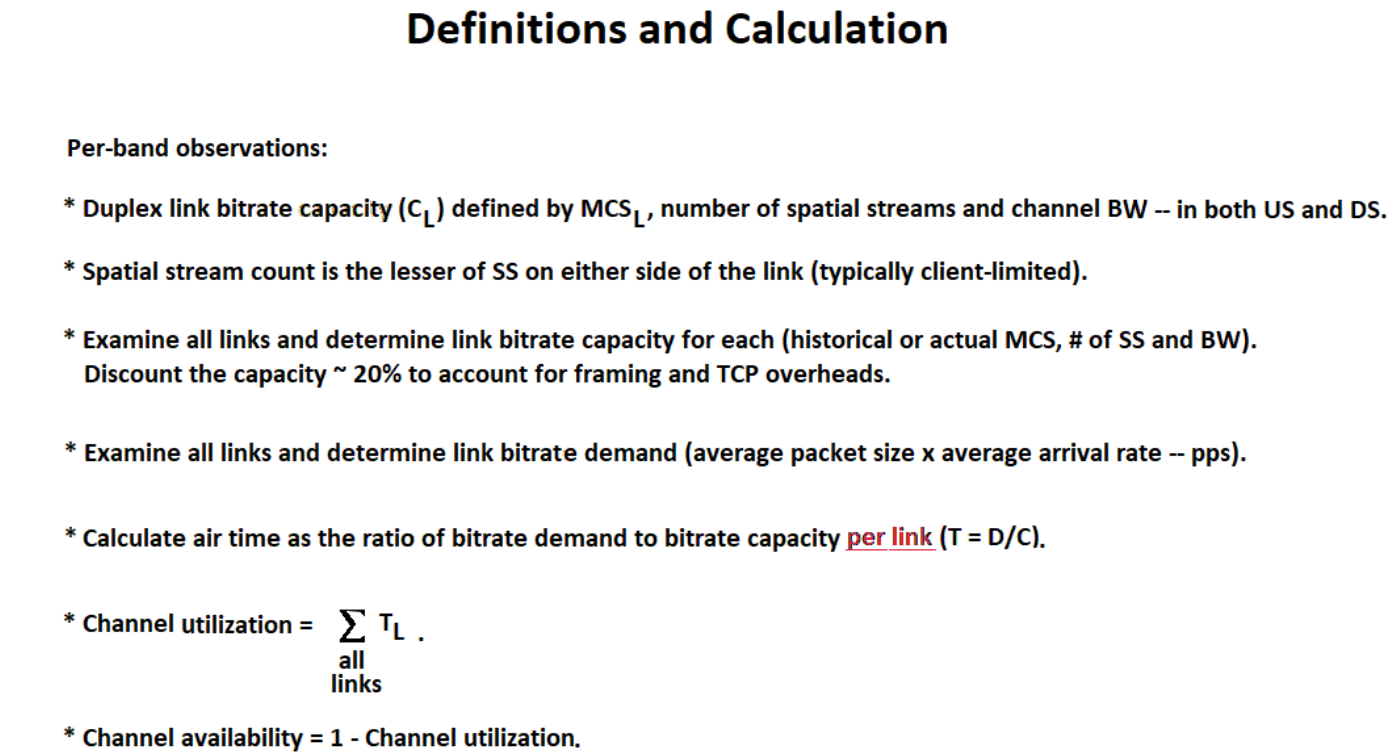

Figure 24 - WAE Term Definitions and Airtime Calculus

Note that the calculation involves acknowledgment of some amount of Wi-Fi framing overhead, coupled with TCP loop closure (as roughly 10% of available goodput airtime). This allows us to estimate goodput bitrate limits when calculating MCS-based link spectral density (as bps/Hz of channel BW) and then have the framing overhead count against that calculated link capacity. Using these calculations per band allows the AP to weigh service mounts based on actual available capacity (versus merely physical layer (PHY) expectations) per supported Wi-Fi band.

The general mechanism of consulting cached (historical) service mounts on a per-client basis would allow the WAE to do an initial assignment of client device to band based upon detection of the client's presence in the network, said client's own supported bands (and MACs) and a review of the client's recent past data consumption. The key historical factors are observed link upstream (US) and downstream (DS) MCS and data rate (calculated as a rolling average of packet size and arrival interval) historically associated with the client(s) in question. Actual MCS detail will be sounded out when the client attaches to its assigned band and may differ from historical indications for the case of a different applications environment, relocated mobile client devices or assignment to a different band (whether the device is mobile or fixed). By invoking historical record, the WAE can make a predictive estimate of the band availability impacts when a particular client lights up on the network.

Two diagrams immediately follow, one dealing with the static interplay of entities or parameters which influence the WAE and a second to demonstrate band assignment strategies for given mounts of clients/services. The third consideration (accessing 6E standard power against a stored mask of available power/channel in the 6 GHz band) will be detailed after these two.

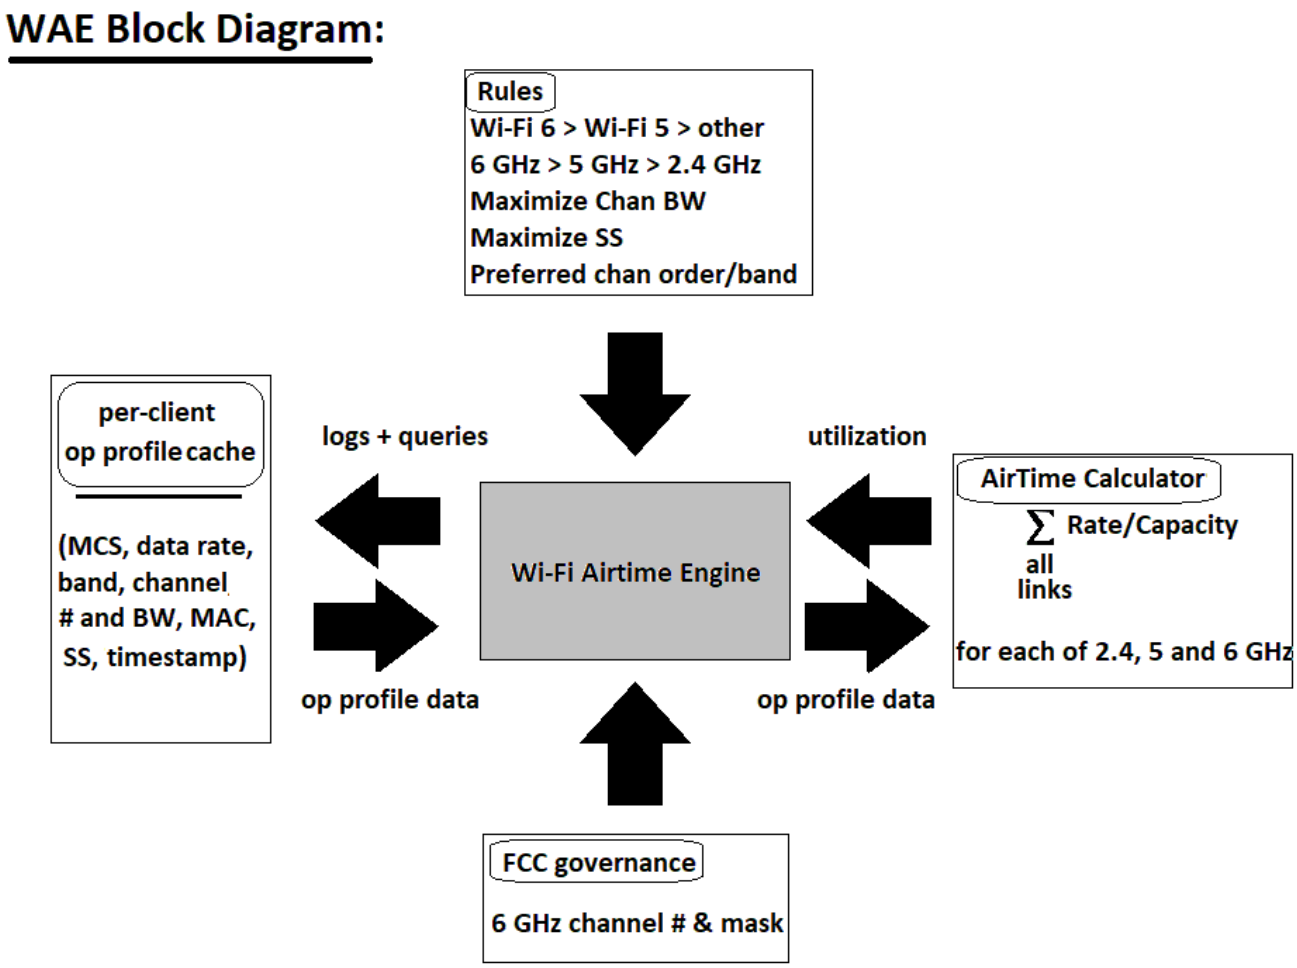

Figure 25 - WAE Interactions

The block diagram lays out the dependencies and interactions of the WAE and four operational data repositories: the profile cache, FCC governance, airtime calculator and client link parameter assignment rules. The rules block is essentially provisioned into the device in one of several ways: via cloud-based remote radio management (RRM), core software (and upgrades) or application-solicited user preferences and directives. The nature of the rules is to establish an order precedence to be used in the WAE's assignment of client operating parameters. Examples of these are shown in the diagram above; Wi-Fi 6 supported connectivity has a higher precedence than Wi-Fi 5 (especially at 6 GHz, where MAC homogeneity guarantees excellent, ungroomed, latency performance); which itself is the intermediate choice before indulgence of airtime-robbing older legacy Wi-Fi MACs. In similar fashion, where client band operation offers options, the preference would be to assign clients to 6 GHz before 5 GHz – with the 2.4 GHz band being reserved for devices which can only operate in that band. Generalized rules would be captured by notions such as maximizing channel BW and SS for any given link (to invoke the best bitrate – and hence, shortened airtime to deliver packets – for each client link). Other rules might establish channel number assignment in each band (based on prior attachment successes, say).

As regards the operating parameter cache, this defines a collection of most-recent client link parameter assignments over some finite rolling period with tagged timestamps. The cache reflects productive historical assignments which the WAE can reference in assigning initial operating points for a client link ahead of calculated airtime ratios based on the anticipated demands of any new service session. (This permits profiling of clients in terms of their data ingestion and production stochastics.) This should prove hugely beneficial for client devices which are single-purpose network mounts and unlikely to exhibit a wide spread of operating demands.

Finally, the airtime calculator maintains a monitor on the sum of all client link ratiometric (as rate/capacity) performance. Typical margin determination would assign a percentage (in the region of 20-25 %) of airtime excess in each band and the airtime calculator would establish band congestion based upon the available excess airtime available per band after the margin and all calculated airtime ratios are accounted for. This provides the WAE with an airtime budget per band which it utilizes in determining optimal client-to-band assignments (transferring bitrate loads as necessary to keep all bands at reasonable utilization levels).

5.4.2 Client Mounting Process

It follows then that these data repositories defined above can be leveraged in a controlled order to effect client band assignment for the AP WAE. An illustration of this follows:

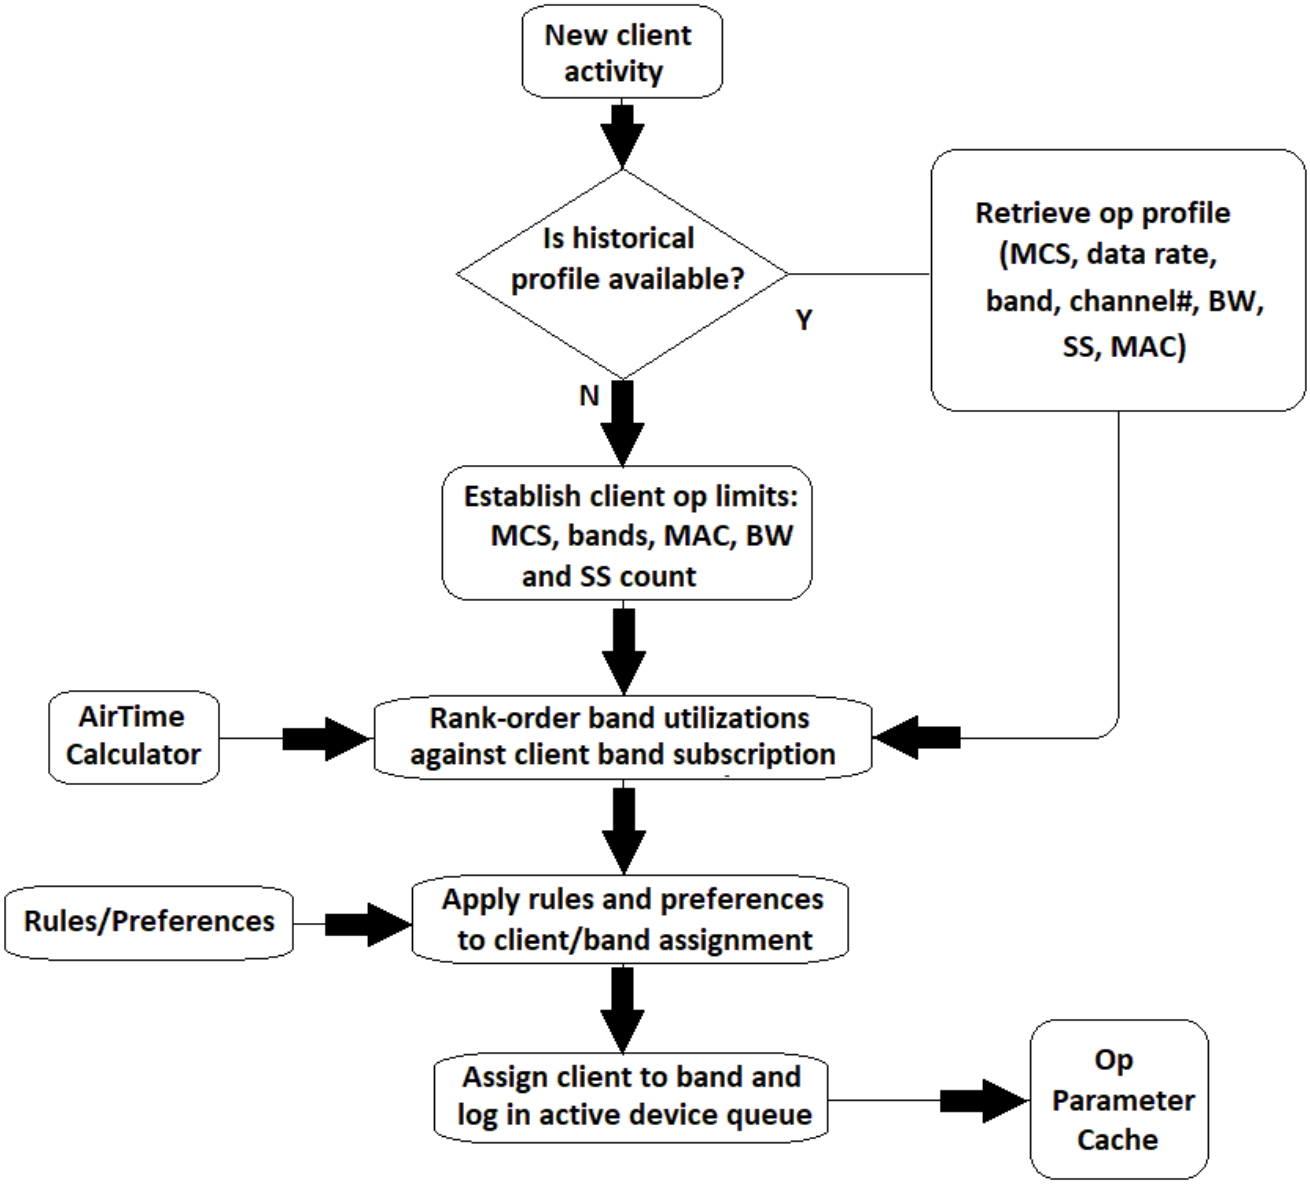

Figure 26 - Wireless Client Mounting Process

Note that housekeeping for the Op Parameter Cache is not included here but can be assumed to include retirement of latent client parameter detail for situations where the timestamps of the data exceed some "hold" timeout period.

The AP's decisions on band use and power/channel assignment are associated with time-of-day historical set points and available empty (or low CCI) channels. As regards the former, the WAE would make use of the Op Parameter logs and interpolate between those timestamped captures and the present time-of-day (TOD) to determine a matching set of parameters (modulo-24 hour).

5.4.3 The Importance of Channel Scanning

In the creation of an available channel map at 6 GHz the AFC-provided channel mask is the starting point of the process. However, responsible stewardship of the channels provided also requires the AP to develop a view of potential unlicensed competitors for the Wi-Fi channels granted it. (There is the unintended consequence, in multiple dwelling unit (MDU) situations, that nearby Wi-Fi customers may all receive the same AFC mask, which unfortunately serves to increase the risk of CCI on the available channels). RRM can assume the mantle of direction of the spectrum decisions; however, the process offered for consideration here is for the cases where RRM is either not available for the AP or there exist disparate, non-aligned RRM orchestrations proximate to the AP. The implication for the WAE is that it must maintain a background scanning function to determine a rank-order of acceptable channels to use (based upon detection of energy during the scan). The scan may be optimized for efficiency (time required to distill the exploitable spectrum) versus "freshness" of the available data. One such optimization would be a progressive triage of available channels based upon initial scanning at maximal bandwidth for the AFC-granted channels (from the collection of all but the current channel in-use) and then progressively narrower scans (by factors of 2, down to a limit of 20 MHz) of those channels which exhibit energy below some set threshold. The outcome could be used to create a candidate channel ranking down to an ultimate resolution of 20 MHz. (or to that bandwidth which has been determined – or commanded – to be the minimally acceptable one. It is certainly possible that, due to bitrate demands at 6 GHz, only options at 80 and 160 MHz may be considered). The algorithm (for determining the best option for a new channel in a single band) is logically illustrated as follows:

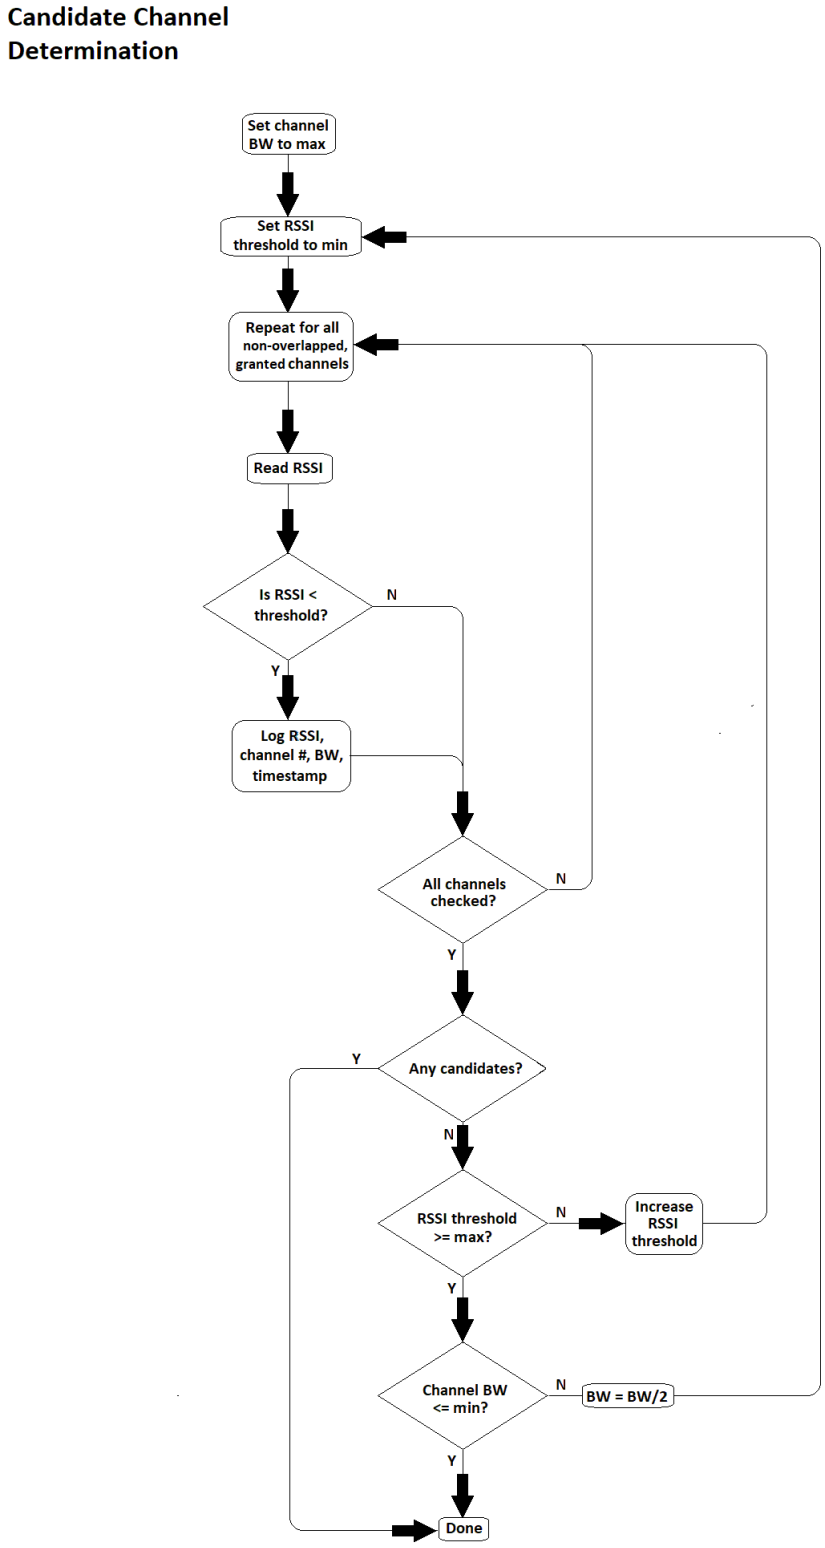

Figure 27 - Scanning Algorithm for Determination of Unconstested 6E Wi-Fi Channels

Given the still-pending maturity of the AFC specification, some of the details above are speculation – but in general, they represent the type of calculus and behavior a 4W AP would have to maintain to warrant its exploit of Wi-Fi 6E.

6 The Emerging Option of Indoor Adaptive Antenna Patterning

A brief aside on antenna developments appropriate to the various service mounts in Wi-Fi 6E is appropriate. Fundamentally, there are two classes of antenna arrangement which serve the interest of robust indoor Wi-Fi distribution: isotropic and narrow-beam patterns. As regards the former, it is expected that both client and AP groups will continue to support multi-direction antenna footprints for major slices of Wi-Fi airtime (to account for random AP-to-client spatial distribution and promote the least expensive method to implement fixed, full azimuth and elevation reach). Narrow-beam near-line-of-sight (nLOS) radiation patterns are, however, useful for P2P home inter-mesh trunk hauls, given that these endpoints are spatially fixed relative to each other. Their directional pattern distributes the allowed EIRP across a reduced spatial cone (improving link margin to one preferred, fixed receiver at the expense of sensitivity for multiple others) and thereby limits the scattering which promotes multipath-based symbol spreading. This unwanted aspect of isotropic radiation can dictate use of wider timing guard band intervals (for expansive floorplans) which can rob goodput throughput. It also inflates error vector magnitude (EVM) at a particular link operating point and hence, represents compromise of the delivered bitrate through potentially unwarranted MCS reduction.

In the scenario where bookended APs are used to establish a trunk haul between meshes (and involves at least a moderate concentration of 6E clients), it makes sense to consider smart antenna switching which, on a per client basis, alternates between isotropic radiation at some inclusive EIRP (which does not tax client receiver dynamic ranges for the respective -- likely 2x2 or even 1x1 -- clients of each AP endpoint), and a 4W, directionally specific, full spatial-stream-exploiting trunk link. The combined efficiency of sharing single-channel airtime between the two modes implies that a second channel (and radio) need not necessarily be resorted to; it is, at minimum, an option to consider for a high-end class of standard power AP.

7 Service Mount Considerations for Standard Power Operation

With the available recourse of higher EIRP, considerations of how best to integrate such a capability within a home Wi-Fi fabric can be evaluated. More transmit energy begets much-improved home wireless coverage, but there are architectural nuances to be evaluated. In addition to the increased bitrate comes the assurance of much better latency performance (between 10x and 100x, versus 5 GHz) for 6E links, primarily due to the single Wi-Fi media access control (MAC) to which every band participant must exclusively subscribe. At standard power, it should be possible to link large client populations throughout a spacious multi-story floorplan and still meet < 2 msec latency for all client links.

7.1 Client Backoff

By far the biggest impact on in-home Wi-Fi service throw at 6 GHz involves the FCC-mandated 6 dB backoff in client EIRP versus its servicing AP (whether this device operates at LPI or 4W). And it is at the point where client transmissions – even down to MCS0 – cannot be recovered by the AP that Wi-Fi framing collapses and the client is disenfranchised by the mesh. At this point in uplink communications,

the downlink is still capable of decent performance – so the argument goes that downlink-biased services (most are of this type; the exceptions being media backhaul for home security or work from home – WFH – scenarios) will not sputter and burn airtime on retries but more abruptly, simply (and prematurely, perhaps, from the transmitting AP's standpoint) fail.

The implication to whole home LPI wireless service is clear: once a client outreaches the service throw, the user has no other choice than to insert a wireless extender into the mix. But as pointed out earlier, at standard power operation, these service radii easily accommodate very large floorplans even when the single AP is not optimally located (i.e., in a lower corner of a multi-story home, for example). So perhaps the better way of viewing standard power is that it affords the opportunity (up to well above American average home floorplan size) to obtain the desired WAN-matching service-level agreement (SLA) with only a single AP whose location is determined solely by convenient access to its WAN. For larger homes, a summary takeaway might be that one could guarantee > 1 Gbps client service everywhere throughout the home, even with a corner basement mounted wide-area network (WAN) gateway.

7.2 Subordinate APs

It is noteworthy that the FCC has created an exception category to the backoff for what it deems "subordinate APs" – essentially peer nodes on trunk links who themselves have one or more clients to service. For these devices (think "extender" in the case of a large home) EIRP need not be reduced. This has the effect of providing for exceptionally robust connections between mesh nodes simultaneously serving proximate battery-constrained clients and implies that the insertion of an intermediate hub is almost always guaranteed to enfranchise clients whose path loss to a single, non-optimally placed, AP renders them otherwise "unreachable". In doing so, it also appreciably raises the average link MCS throughout the whole home, which pares the overall airtime spend and makes single-channel radio extension at least conceivable.

Note that this exception to EIRP backoff establishes standard power Wi-Fi as a less costly option for large homes. Simply put, even if the standard power AP is a bit more expensive than an LPI-constrained one, it costs less (in dollars and APs) to cover a whole home to a given aggregate bitrate service level than to attempt multiple LPI extensions to keep the wandering low-power clients happy. And not to put too fine a point on it, fewer (or no) linked extenders imply a much more robust network availability factor.

7.3 Standard Power Deployment Opportunities

So now we come to advised exploit of 4W indoors for Wi-Fi 6E APs. Certainly, the span of client capabilities (and service bitrate expectations) will define the most efficient leverage of multi-power Wi-Fi meshes for given service mounts. Using the testing at LPI and the projected improvement in reach afforded by standard power, we can imagine several architectures which would efficiently serve even the largest home layouts and unlock advantages of 6E. We already have data which indicates mobile client support anywhere in the Wi-Fi house based upon the servicing LPI AP being located at the home midpoint; when this AP is promoted to standard power, the rates cannot help but improve (up to the uplink starvation case previously mentioned). But this turns out to be a needless worry.

Some examples of the expectation for client devices in the Wi-Fi house if the central AP is bumped to 4W would clarify the monstrous benefit of a 4W midpoint AP in the 5300 square foot home. Referring to our data, a repainting of obtainable TCP bitrates for 2x2 mobile devices scattered throughout the Wi-Fi house

becomes a monotonous affair. No room on any floor is served with less than at least 1.4 Gbps downlink bitrate – and the entirety of the main floor (where resides the AP) sees the maximum 1780 Mbps. The tiling looks as follows:

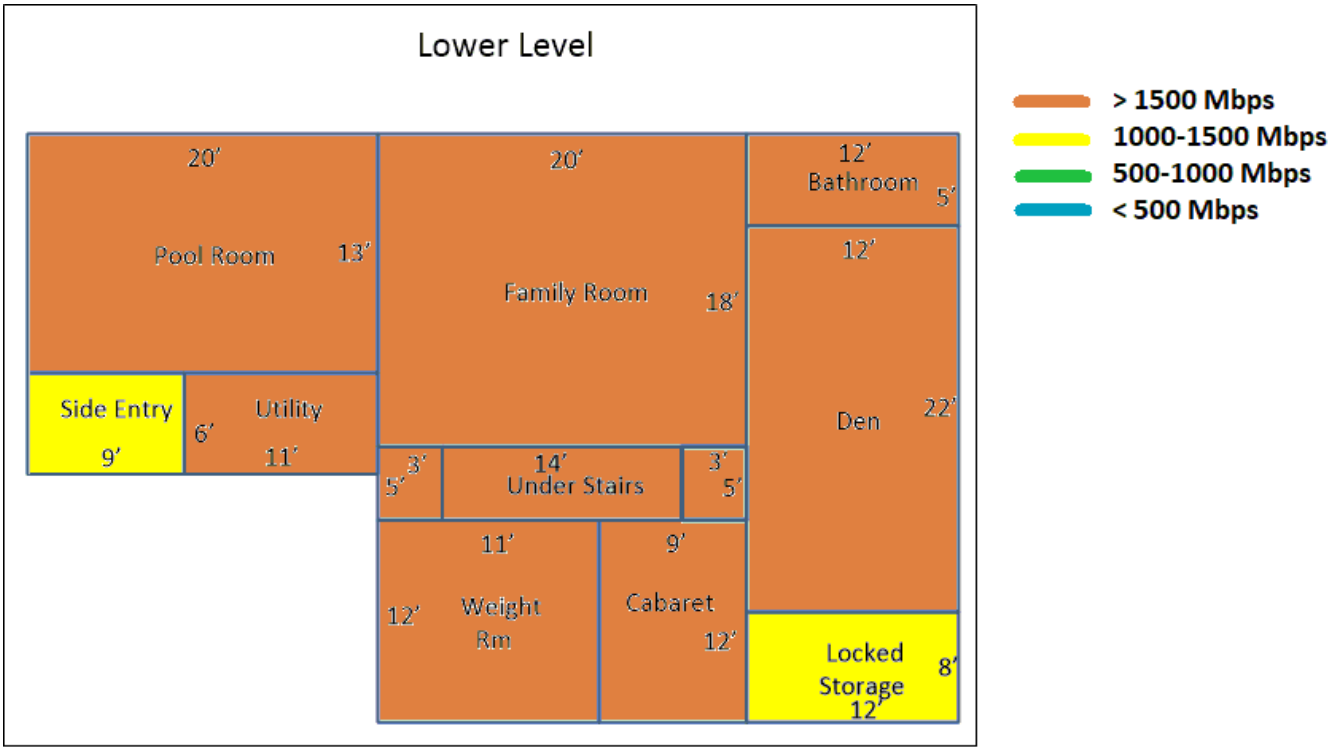

Figure 28 - Lower Level Service Coverage with 4W AP

In fact, though clients at the side entry and locked storage locations on the lower floor would be constrained to just under 1.5 Gpbs with an AP association from the home midpoint, in the case of the side entry location clients would be steered to a binding to the WAN gateway. Under this presumption the full 1780 Mbps becomes available there. Signal throw to the locked storage area, however, is actually worse to the WAN endpoint than the living room AP, so the modest attenuation of bitrate to 1.4 Gbps would remain.

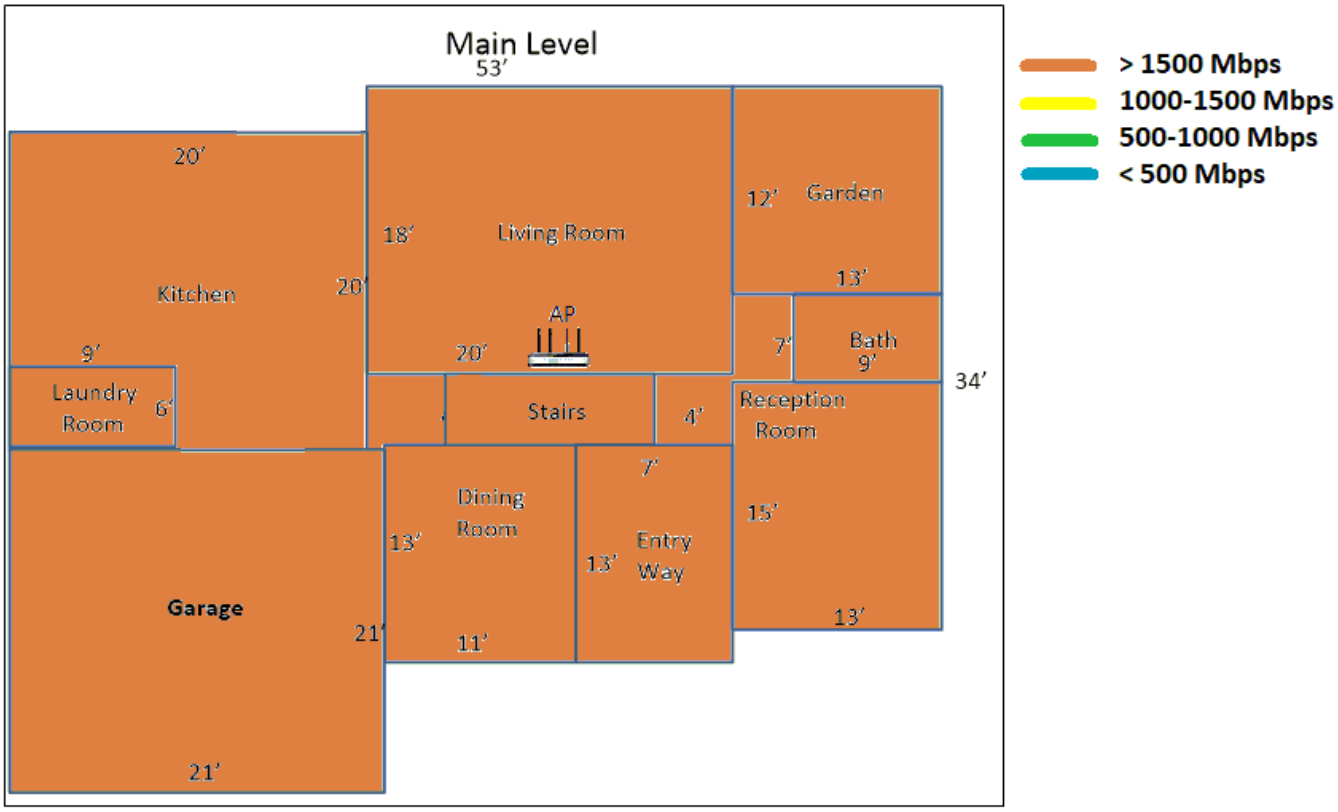

Figure 29 - Main Level Service Coverage with 4W AP

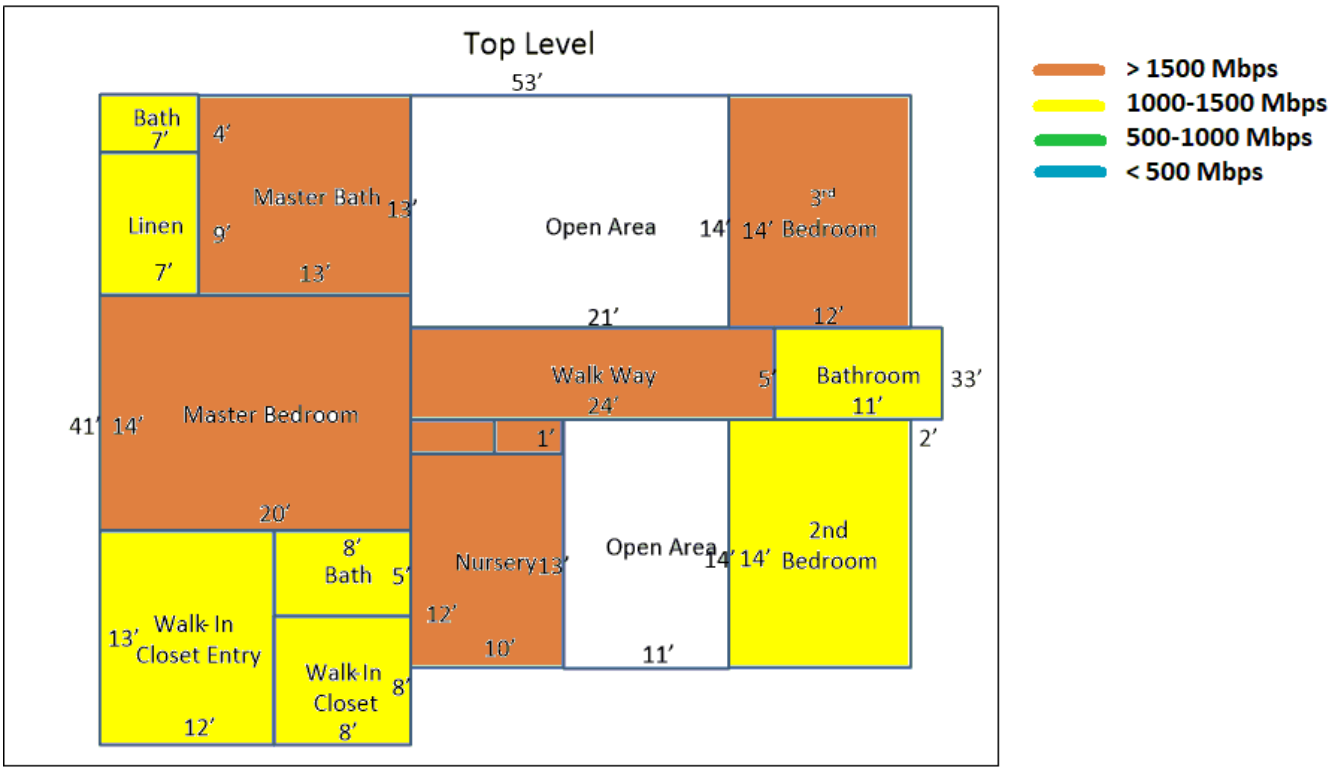

Figure 30 - Top Level Service Coverage with 4W AP

Noteworthy in all of this downlink behavior analysis is the comforting realization that, despite the rather onerous limitation of 20 dBm of transmitter power, the roaming mobile clients never experience uplink service anywhere in the house to < 550 Mbps (so the prior bookmark on potential uplink starvation may be retired).

But the midpoint approximation – not a bad alternative and easy enough to implement -- is likely not the best coverage option for extremely large floorplans. As the WAN attachment is in the basement pool room (a common enough home topology for connecting an outside WAN), it would make sense to move the extender all the way to the upper floor and closer to the two Jack/Jill bedrooms. This has the airtime benefit that more clients can be steered to the WAN-attached gateway, such steering subtracting airtime from the 4x4 trunk (and eliminating one link latency/client for those which can so attach). These latter outcomes are most welcome, in that the movement of the extender AP endpoint further away from the WAN will (slightly) penalize the trunk bitrate performance (so it having to carry less backhaul/fronthaul traffic tends to somewhat balance the capacity drop). The modified layout looks as follows:

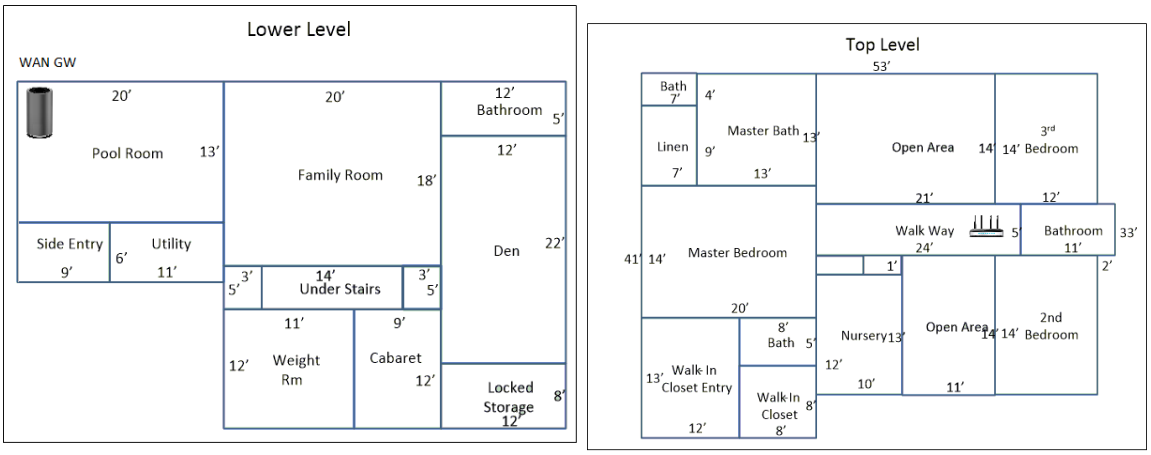

Figure 31 - Modified Trunk Topology to Improve Whole Home Coverage

In this scenario, trunk performance is somewhat degraded (recall the midpoint extender placement allowed for a 3.5 Gbps goodput carry) to something more like 2.5 Gbps. However, the client coverage everywhere in the Wi-Fi house (except for that poor locked storage location in the basement, which achieves "only" 1.25 Gbps now) easily averages 1.7 Gbps. For the case of low numbers of 6E clients in a home (as will be the norm for the next ~5 years), this ability to roam (or set up a fixed client endpoint) anywhere in the home and not experience rate throttling manifests obvious value. Note that, in terms of present-day services, there are precious few application bundles which, even in simultaneous aggregate on one device, approach a 100 Mbps/client downlink service requirement – so having 1.5-2 Gbps at your disposal everywhere in the home is a bona fide lottery win.

This client "overindulgence", then, begs the question of whether a single 4W WAN gateway in the low corner of the house could blanket it with sufficient signal throw to enable excellent (or even more-than-adequate) service bitrate in a home the size of the Wi-Fi house. Without performing a full volume analysis, it is instructive to examine what the worst-case client downlink/uplink support appears to be, given the geometries in play. Selecting the far corner of the second bedroom on the top level as a checkpoint, the service radius amounts to ~ 62 feet from the WAN gateway (with two floors and perhaps 3 walls to penetrate – though the two large open areas facilitate multipath reach to this client placement). In this far corner of the house, downlink would be expected to be 1030 Mbps and uplink, ~ 275 Mbps – a fair margin to uplink starvation which would otherwise defeat persistent client attachment. The clear implication is that one would have > 1 Gbps everywhere in such a large home, even with a single, inconveniently located, AP. And let's be clear – the Wi-Fi test house represents a floorplan which is 2x the US national average for size of new construction, single dwelling units (SDUs).

It appears, then, that the recourse of two 4W APs is not obviously necessary in up to at *least* 5300 square feet of living space -- which means we would reserve that strategy for extremely large floorplans (realtor estimation of the mansion footprint, for example, sets an 8000 square foot expectation on qualifying space to earn that moniker). And it is not clear that the recourse of 2 standard power APs to blanket such a homestead would represent much of an investment concern for users well-heeled enough to own it.

Statistically speaking, given the predominant 6E client target capability of 2SS/device (which bounds the 160 MHz BW delivery of services to around 1.8 Gbps TCP), the overwhelming majority of US homes would *at most* require a single standard power wireless gateway – no additional wireless meshing required.

8 Conclusion

There is great value to be had in policing and permitting standard power operation in the highly scheduling-deterministic Wi-Fi 6 GHz band – and so extend the promise of this vast spectral asset which the FCC released last year. Though limited-power mobile clients represent a challenge to the brute force expectation that standard power APs should always be considered, it is nonetheless true that the advantages of the expanded coverage footprint over LPI suggest that a standard power "lynchpin" AP find representation in all floorplans more than perhaps 1500 square feet, to properly anticipate and lever the multi-Gbps WANs which are in the offing. Furthermore, floorplans in the 6000-10000 square foot range can make use of a single, very robust 4x4, 4W trunk (with bookended -- full 4W EIRP at each endpoint -- APs) to seamlessly connect meshes with client devices up to the periphery of the expansive floorplans (and minimize the peppering of LPI extenders everywhere throughout the footprint). The FCC and the greater industry at large have taken great precaution in defining and (soon enough) implementing a 6 GHz band coexistence scheme which simultaneously protects legacy microwave infrastructure investments and liberates all the promise of Wi-Fi 6E. The in-home high speed wireless future has never looked so bright.

Why Scale Needs Unity:

One Operator's Journey

A Technical Paper prepared for SCTE by:

1. Introduction

The “heavy lift,” when industries like ours consolidate though acquisitions and geographic clustering, is almost always carried by engineering. Why, because the biggest physical asset is the plant. And it wasn’t that long ago when dozens of different operators made hundreds of different decisions about capacity expansion methods, network topology, node sizes, even amplifier spacing and drop materials. Big decisions, that necessarily last for decades.

Then, one day, the convergence activities wind down, giving way to the undiluted pursuit of scale – scale of the network, and, by extension, to operations and “the field.” The pursuit of scale is a perpetual transformation, and involves aligning many of those previous decisions, made in previous times and under previous ownership. It’s a different kind of heavy lift because it’s as people-impacting as it is equipment-impacting. If you’ve ever tried to replace a favorite tool or dashboard with another one, for any reason, you know how what we’re talking about. Unity through scale is about aligning people with tools, processes, and standards.

Comcast’s unification blueprint focuses on three core areas: technology convergence, tools alignment, and process alignment. It’s more transformative process than organizational location, centered on a highly reliable, self-healing network. It uses real-time data to enable automation, and it’s all supported by the same tools, processes, and practices.

2. Compelling Case for Change, Vision and Guiding Principles

Background:

The Comcast network, like many other industry leaders, has grown through acquisition. While we have a single network, there is procedural variation in how work is executed. Individually, Divisions and Regions are highly successful. However, as we look to scale and optimize network performance, we are hampered by procedural and tool differences. If our tools and inputs into those tools are not the same, we are less able to take advantage of automation.

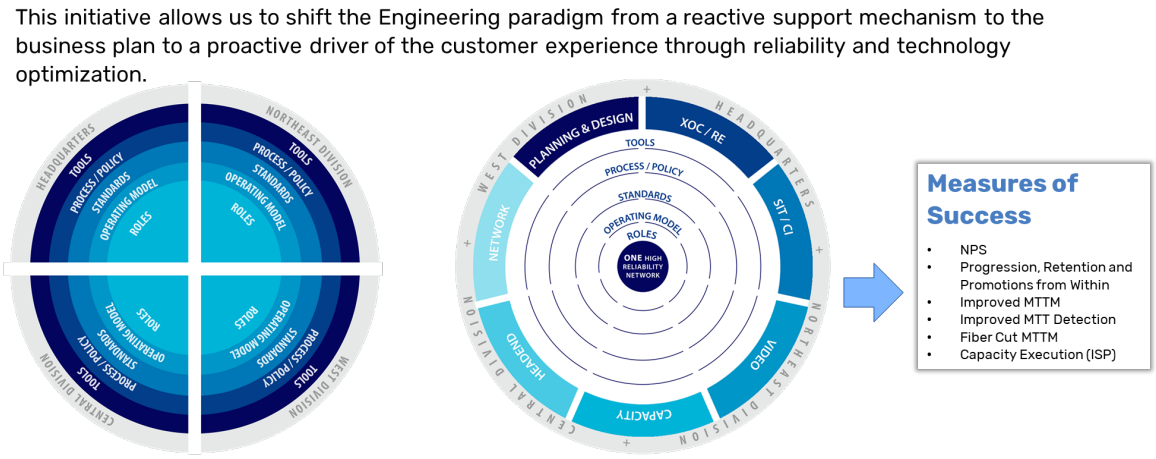

Figure 1 - Our Transformation Journey

Given the evolution of new technologies and tools, we now have the opportunity to shift the engineering paradigm from a reactive support mechanism to the business plan, to a proactive driver of the customer experience through reliability and technology optimization. Seeing the technology opportunity, the need to scale, and to evolve our tools, Tony Werner, President of Comcast Technology, and his engineering leadership across the network took two critical steps to prepare the organization to meet growing consumer demand on the network. In 2018, the company's three divisions began the process of developing division-specific standard operating models for Strategic Infrastructure/Critical Infrastructure (SIT/CI) Headend, Video, Network, XOC Planning and Design. In some locations, this also included shifting process ownership and accountability from regions to divisions. Simultaneously, Werner also asked his headquarters engineering teams to start to develop next generation tools that optimize cloud technology to better harness the power of automation and build a self-healing network.

- Our network operating **model** is fundamentally **changing**
- Moving **from 15 regionally diverse** networks **to a homogenous enterprise cloud-based** technology permitting unparalleled scalability
- Optimization of automation will **reduce escalations** and **trouble calls**
- **The pace** of the transition is **happening fast**

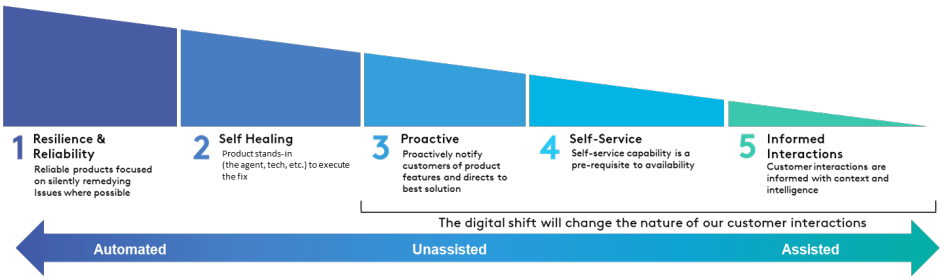

Figure 2 - Technology Transformation

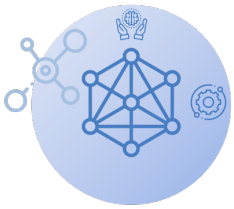
In late 2019, it was increasingly clear that the development of technologies and tools was outpacing the development of common processes and the expressed elimination of redundant tools across the network. Divisional leaders were asking for tool customizations that would fundamentally undermine the potential power of the tools and network. This was the ideal time for the organization to launch an initiative that would ensure a clear understanding of our long-term vision and the pace with which we needed to realize our vision. To drive this change, Werner established an executive leadership coalition made up of headquarters engineering leadership and a representative of the division presidents to sponsor the change. They asked Shane Portfolio, SVP of Reliability Engineering, and his team to provide leadership for the change in partnership with his Engineering peers from headquarters and the 3 divisions (4 Engineering Leaders = E4). As VP of Consumer & Strategic Programs, I was asked to provide change management support for the initiative. The focus of this paper is on this second wave of change.

Common Vision and Guiding Principles: Based on leadership interviews and an organizational assessment, it became evident that each leader had a different vision and understanding of the guiding principles we would use to support decision-making and how we worked together. To that end, the E4 and Leadership Coalition developed the following vision and critical operating and design principles.

Vision: *We will design, build, and operate a highly reliable, self-healing network of unprecedented scale, that utilizes real-time data to enable automation supported by the same tools, processes, and practices. To realize this vision, we will move from regionally diverse networks to a homogeneous cloud-based technology providing scalability and efficiency to existing processes providing greater field focus on customer experience. The transition will align career and talent with our evolving technology. To be successful, our talent transition needs to leapfrog the technology transition. To fully capitalize on the technology available, in service of our customers, employees and shareholders, it is critical that we operate as one network to best position the company for the future.*



We will design, build and operate a highly reliable, self-healing network of unprecedented scale, that utilizes real-time data to enable automation supported by the same tools, processes and practices.

To realize this vision, we will move from regionally diverse networks to a homogeneous cloud-based technology providing scalability and efficiency to existing processes providing greater field focus on customer experience. The transition will align career and talent with our evolving technology. To be successful, our talent transition needs to leapfrog the technology transition.

To fully capitalize on the technology available, in service of our customers, employees and shareholders, it is critical that we operate as one network to best position the company for the future.

One Vision, One TEAM

Operating Principles

- Build and earn trust and respect
- Be system thinkers
- **Play our future into being by taking every opportunity to implement our vision**
- Be a coach for our teams and our peers
- Be authentic, honest and value constructive conflict
- Have a clear vision and strategy for the team
- Be transparent
- Get out of our own way
- Value collaboration, we will not act in silos

Design Principles

- **Same** Processes and Tools
- **Same** Architecture
- Data Inputs and outputs will be the **same** for each tool
- **Same** Deployment Practices
- **Same** Methods and Procedures

2020 Focus

- Business Case
- Executing on the tools strategy
- RE Realignment
- Skill and Career Development

Measures of Success

- eNPS
- tNPS
- rNPS
- Progression, Retention and Promotions from Within
- Improved MTTM
- Improved MTT Detection
- Fiber Cut MTTM
- Capacity Execution (ISP)
- TC Reduction
- Contact Rate Reduction
- Outages Due to Changes

Figure 3 - Our Vision

Operating Principles: Given that each engineering function rolled up under different P&L leaders, identifying and holding ourselves accountable to a set of operating principles was critical. Leaders quickly realized that trust, transparency, and a commitment to act together rather than in silos was essential.

Design Principles: In the organizational assessment, leadership realized that while their processes had become more aligned, they were still very different, and that in order to optimize new technology and tools, they needed sameness at each level of their work. So, the leadership agreed that all future work would focus on achieving sameness of architecture, process, tools, methods, procedures, and roles across the divisions and headquarters.

3. Campaign Approach to Change

Defining the critical path and the roles to achieve sameness was fundamental to getting started. We had 9 functions across headquarters and divisions with different levels of process alignment and tools. We also knew if we were going to have the leadership and talent to lead and manage the future network, that this transformation gave us the opportunity to grow our team capabilities rather than asking external consultants to "swoop in" to fix us. To transform the organization, we couldn't just focus on the operational processes, we needed to optimize enabling systems like goal setting, performance reporting, budgeting, talent management, training, etc. Fundamentally we needed to "play with other people cards" and enlist them to support and nudge our vision along. We couldn't be an island. The whole system needed to drive the change. In addition, we knew that we couldn't wait till the change was fully baked to

move forward we needed to "play our future into being," which meant every decision and action moving forward needed to be in support of sameness. We needed a multi-level approach.

We also understood that we needed to evolve into a culture of sameness. Culture is not something we or anyone could mandate. Culture is something we needed to grow over time, through the adoption of practices and new procedures that could be reinforced, supported, and adopted. We also knew that our future was not dependent on a single solution or action, but rather on the combination of elements that we would implement to create it.

Our transformation approach needed to focus on both building the organization's **capacity and capability to change.** To do this, we utilized a campaign model to design our change approach. To build our organizational capacity to change, we identified three levels of change: 1) organization design level - which focused on the redesign of processes, tools, and talent for each function; 2) macro change level - which focused on the optimization of the enabling functions and organization events to reinforce the change; and 3) micro change level - which focused on the individual workstream initiatives. As a technology organization we utilize agile design, however, to gain leadership support for major process changes we knew that they would need to see the end-to-end process design before we could implement. So, we agreed to utilize a fast-cycle redesign methodology that optimized a waterfall methodology.

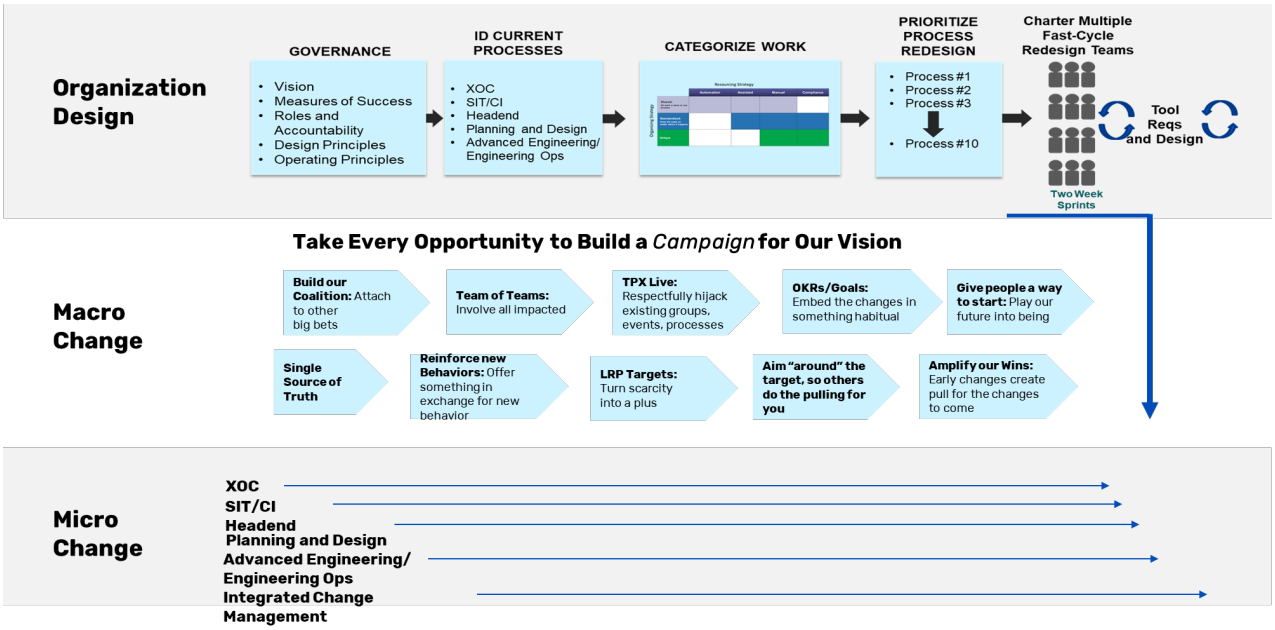


Figure 4 - Our Plan to Build Capacity

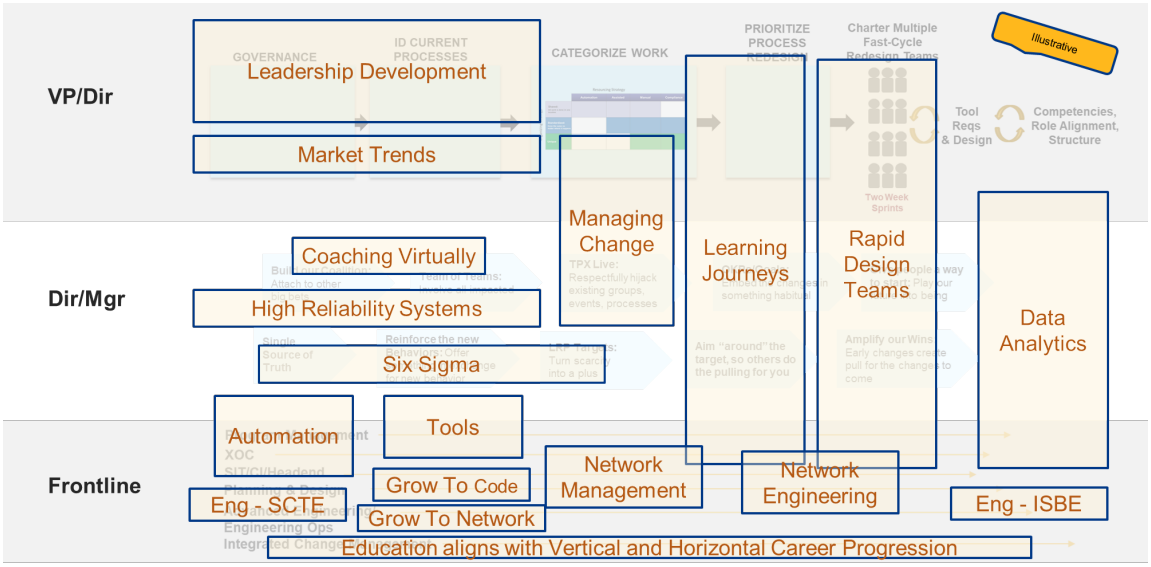

Figure 5 - Our Plan to Build Capability

To build capability, we agreed we would utilize an action learning approach and bolster our work with development at each level of the organization. From one vantage point, we were a transformation process. From another vantage point, this was a major leadership and skill development process.

The Executive Leadership Coalition, the E4 and the division Presidents gave their support for moving forward. The E4 as sponsors met with the leadership of each functional team to kick-off the work. The first step was for each functional leadership team to categorize the work, to identify what work needed to be the same, and whether the work should be done by a single team across the Divisions or needed to be done within the Divisions. In addition, we began to map current state processes to prioritize the work. Then, in late March 2020, COVID 19 hit.

4. A COVID Detour that Solidified Leadership Commitment and Approach

With COVID 19 came the retrenchment of consumers to their homes and significant dependency on networks for work, school and staying in touch with loved ones. Foreshadowing the increased need for scale, the Leadership Coalition asked leaders to explore options for accelerating the plan. To respond to the request, the team developed a business case for change and possible options. In July 2020, Leadership agreed to stay the course and because of a better understanding of the technology, tools, talent implications and transition timing, the division Presidents recommitted the strategy of sameness. The development of the business case surfaced several opportunities. First, we needed to solidify the return on investment (ROI) for the 10 most critical tools that our strategy was dependent on. Second, we needed to fortify the trust and transparency between headquarters and division partners. In particular, division leaders needed to feel confident they would achieve their targets even if they changed the processes that today were enabling them to be highly successful, or relinquished ownership of other processes to enable efficiencies and optimize automation. Finally, we needed to have headquarters technology and division presidents jointly signal their sponsorship.

5. Establishing a Center-Led Approach

To move forward, the E4 developed an approach which focused on accelerating decision-making, growing the partnership between headquarters and division teams and the operational discipline necessary to enable clear understanding of the changes as well as a highly reliable consumer experience. The approach had the following components:

Center-Led Leadership: In August 2020, The E4 agreed to implement a "Center-Led" operating model, to create a system of accountability to drive sameness. Being Center-Led meant that all changes moving forward within the 9 Pillars, nationally or within a division, needed to be agreed to by the three division and headquarters leaders. The objective was to focus our energy and resources to move towards sameness, not further apart.

pillar Role and Co-Leadership: The first step the E4 took was to identify the 9 functional Pillars, their role and strategy in the realization of the initiative vision. The E4 then identified a division and headquarters leader to co-lead each pillar on a yearly rotation. The objective was to create a single voice for each pillar to help drive requirements and prioritization. The role of the pillar co-leads is to create a "virtual cross functional leadership team" and facilitate the creation of process, tool, key performance indicators (KPI) and role sameness nationally within their pillar. A critical measure of success is to facilitate decision-making that reflects the operational discipline that drives transparency and builds a foundation of trust across the pillar. pillar co-leads were identified and announced in September 2020.

Three-Legged Support: To support the Pillars, each pillar was assigned 3 resources: Integration Lead, Organization/Change Management Lead, and Project Manager. The Integration Lead is a subject matter expert accountable for cross pillar integration. The Organization/Change Management Lead is accountable for ensuring a common operational problem-solving approach and real-time action learning. Project Manager is on point to support pillar Leadership. This 3-legged stool (Integration, Organization/Change and Project Management Leads) plus the Integrated Program Management (IPM) Lead are critical to success. All resources are internal.

Domain Integration: To ensure tight coupling across the 9 pillar teams the E4 decided that each Executive leader would provide sponsorship for 6 that are common cross the 9 pillar domains: Reliability, Talent, Partnership, Tools, Quality and Engineering Architecture.

Prioritized 90 Day Sprints: The E4 agreed to facilitate the transformation in 90-day sprints. Each quarter the pillar Co-leads were asked to prioritize their pillar's focus in partnership with their pillar leadership. During September 2020, the pillar Teams identified their priorities and developed a detailed charter for each priority that included: objective, scope, measures of success, design criteria, required resources and date driven workplan. In October 2020, each pillar team presented their recommended priorities and charter for review, feedback, and support to move forward. The E4 approved 24 Initiatives for the first 90 sprint (Q1 of 2021). In mid-November 2020, each pillar "kicked-off" their initiative workstreams. In Q2 2021 29 Initiatives were approved and in Q3 2021 17 Initiatives were approved.

Common Goal: In support of our collective success, the E4 agreed that each of their Senior Leadership Teams would have the following common goals for 2021.

1. Deliver the same highly reliable network experience across the enterprise by completing the 2021 pillar priorities.
2. Improved Partnership Scores

Linking Mechanisms: The E4 established regular weekly, bi-weekly, monthly, and quarterly connection points at the division President, E4, Integrated Program Management and pillar level to ensure transparency and thoughtful decision-making and change management. The Organization Development and Program Management team partnered to support each forum.

Sponsorship: Based on the E4's work and mutual commitment to success, on 11/30/20 the headquarters Leadership and division Presidents sent a joint letter to all leadership signaling their sponsorship that we will have common processes across the network:

> "The strategy represents a historic milestone within our company – an inflection point to change the way we manage our network that will have tremendous impact on our ability to continue providing the fastest broadband service to our customers and increase our agility to respond to the growing needs of the business. By developing strong partnerships among headquarters and division teams and implementing the exact same tools, technologies, and processes across all teams, we will continue to build the network of the future.
>
> This strategy hinges on partnership and 100% alignment. All of us are committed to the success of this initiative and dedicated to doing what it takes to make it happen. Now we are asking you to join us."

6. Disciplined Approach: Process, Tool, Function, Role Sameness and KPIs

As we began the initiative, one of the concerns expressed was regarding the pace of decision-making. Based on interviews with leaders at all levels, it became evident that when recommendations were presented, they lacked the back-up detail to allow for efficient decision-making. To help remediate this, we made a commitment to utilize process design best practices. To support each team's work and ultimately integration, the Organization Development/Change Management Team developed a process redesign toolkit to guide each team's work and to ensure we have the necessary documentation of decisions to develop the requisite business case and change management plans. One of the challenges we needed to navigate was helping teams to understand the type of work they were focused on and applying the right set of tools to help achieve their goal. For example, a sub process that needs to be redesigned requires a certain set of tools vs if the process needed to be completely redesigned. The need to apply these best practices has required "muscle building" and has met resistance. However, we have had several cases where the E4 has said, we like the vision, but we need the detail, or teams have spent months discussing strategy change and finally realized that they really didn't agree. The E4 has continuously shared that details matter and that "it is better to do it right the first time than having to do the work twice."

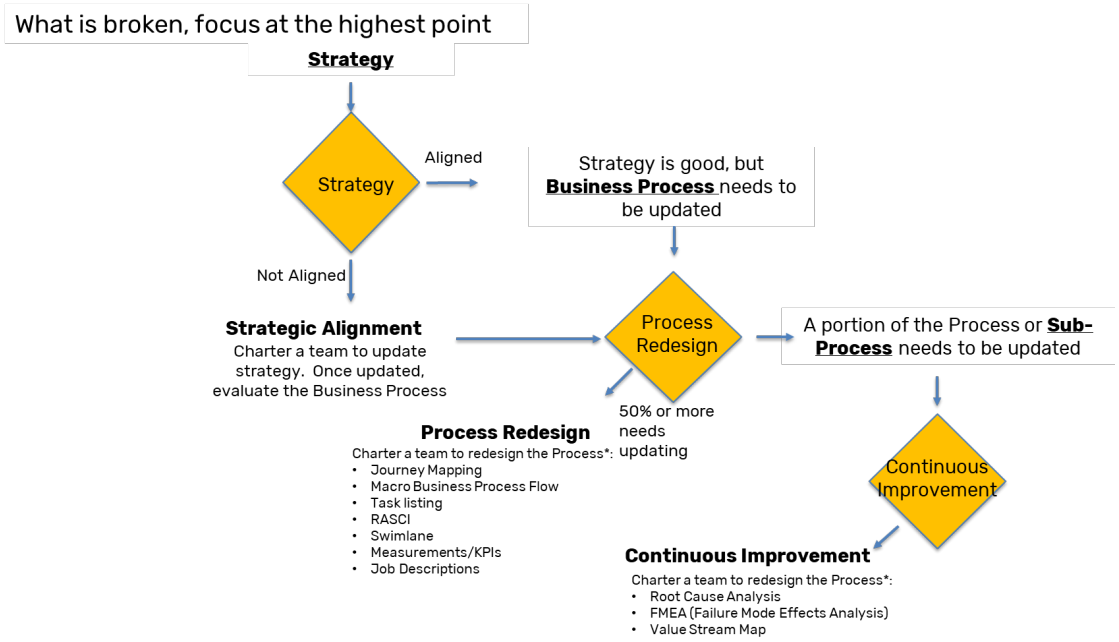

Figure 6 - What is the Right Approach

As a complement to each pillar's process work, they also worked on removing tool differences, ensuring that pillar KPIs are the same, developing talent strategies for each pillar and developing strategies to continuously improve employee satisfaction.

7. Building Trust and Partnership

To grow the headquarters and division pillar partnership, the E4 committed to regularly facilitating a partnership survey. The focus of the partnership survey is to ensure that headquarters and division Leaders are mutually living to our sameness principles and delivering what each other needs to be successful. So, we developed a short survey that as of the summer of 2021 has been administered twice to Director and above leaders. The survey results and the comments are reviewed openly with all partners and each pillar is asked to develop an action plan to improve results. The first survey surfaced several opportunities particularly around role and process. For example, we learned that division partners perceived that the headquarters agile sprint approach to development did not meet the planning and operational needs of their division partners. We also learned that a headquarters team's "big picture view" of customer outages did not feel customer-centric to their division partners, who are responding to the unsatisfied customer. Subsequently, we discovered that our division partner's need for data-driven specifics on what is changing was perceived as resistance to change. Virtually all organizations that have a division/region structure experience similar differences in experiences. What is different in this case is that we agreed to start myth busting to grow the partnership vs. ignoring it.

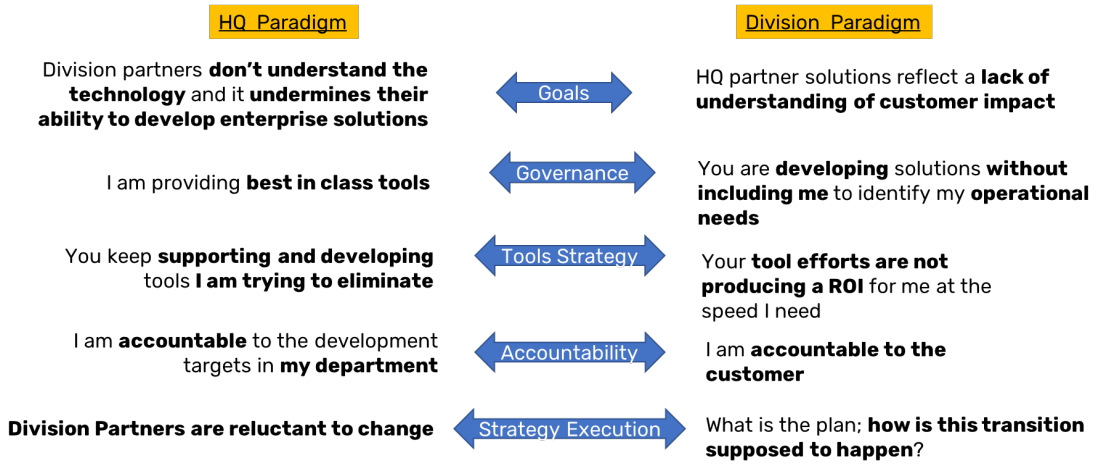

Figure 7 - Partnership Opportunities

8. Decision Protocol

In May of 2020, the Co-leads asked for clarity from the E4 about their decision-making protocol, the criteria necessary for the E4 to support a recommendation. Some of the co-leads expressed frustration with decision-making efficiency. In response the E4 developed a protocol to help facilitate decision-making. They perceived that there was an opportunity to help the teams better understand what they need, as leaders, to take the risk to change their processes. They felt that there were several case studies they could point to where decisions were expedited because the detail was fully developed and recommendations appropriately "stakeholdered." The E4 used these case studies to develop their protocol. Once they developed the protocol, they met with the Co-leads to share it with them. There were several themes in the protocol: 1) the foundational process, task and accountability level detail needs to be completed; 2) recommendations to the E4 need to be supported and presented by each of the four leads for the pillar (headquarters and 3 division Leads); 3) all recommendations should be stakeholdered with the E4 prior to the meeting; and 4) the E4 will not make decisions on the spot, they will confer and come back with recommended next steps.

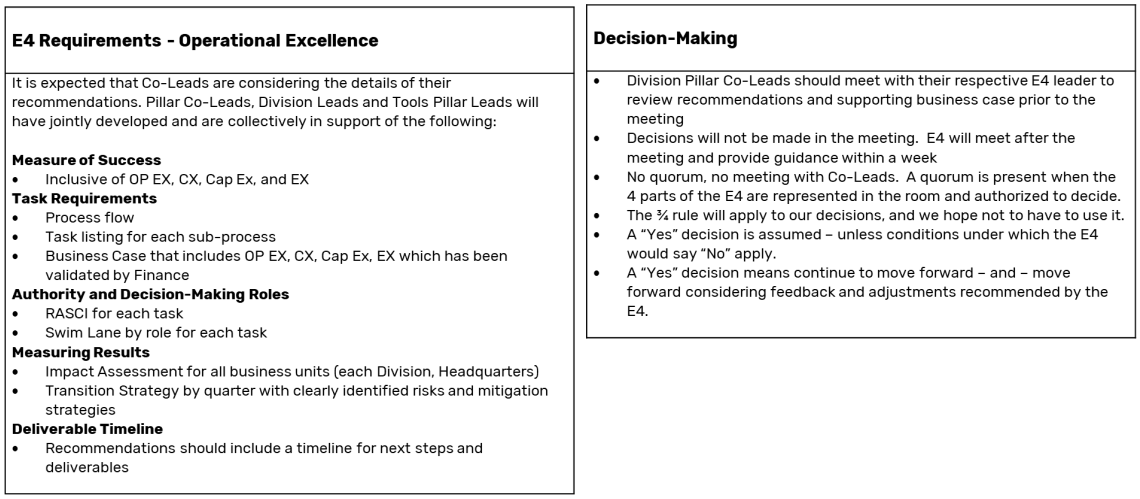

Figure 8 - Decision-Making Protocol

9. Creating our Future

To help build a high reliability culture that would propel our work, we agreed to create a "History of the Future." The state of any organization at some future time is a function of the interplay of three forces: its history, market events that are not in your control, and choices that a leadership team makes about its own future. A "History of the Future" exercise asks a leadership team to imagine their future success and identify the critical elements that enabled them to achieve success. (CFAR, 2003)

After understanding the partner survey feedback and meeting with each engineering leader, the E4 came together in March of 2021 to visualize their future and identify the critical elements of success. A primary theme that surfaced was an opportunity to increase VP ownership for the future. In addition, 6 future opportunities were revealed (below). To help build leadership and develop the future culture, pillar leaders were asked to develop recommended protocols that they could be implemented for each of the 6 future states below identified by leadership:

1. Create a protocol that would guide teams to design their vision, but incrementally implement with embedded opportunities for adjusting and readjusting to ensure reliability
2. Create a protocol to guide decision-making that enables an enterprise solution while caring for organization P&Ls
3. Design a feedback system that allows us to capture and respond quickly to front-line concerns and recommendations
4. Identify the operating practices we need to adopt, that will accelerate future development and allow us to pivot easily
5. Design a protocol for identifying talent within the divisions that we want to lift and shift and that provides relief for division P&Ls

6. Identify the practices we need to have in place to grow a culture that honors innovation without blame if it fails

In June 2021, the pillar leaders presented to the E4 recommended protocols for how the teams could move forward to create the culture and future the E4 visualized. In July 2021, the E4 Leadership supported all pillar lead recommendations and asked two Executive leaders to develop a strategy to implement the recommended practices as part of the reliability and quality domain.

10. Leapfrogging Our Talent in Front of the Technology Transformation

Early on, the E4 made a commitment to ensure we have the talent to manage our future network. In addition, they committed to ensure we grow our current talent into the future roles. To transition our talent, we developed a 4-phase process: 1) How We Operate Together; 2) Assess Change, Skill, Close Gaps and Align Talent; 3) Plan and Build Pipeline; and 4) Monitor Progress. Given that, the unification of tools and processes will drive enterprise-wide consistency. That automated and center-led systems will provide standardized workflows across the enterprise. We recognized that our engineers will become enterprise-wide subject matter experts who will problem solve across the system. In Phase 1 to support and proactively guide the talent needs across the Engineering organizations, we agreed to establish a single talent governance structure over the headquarters and division functions. To guide our work, we identified the following intention and design principles.

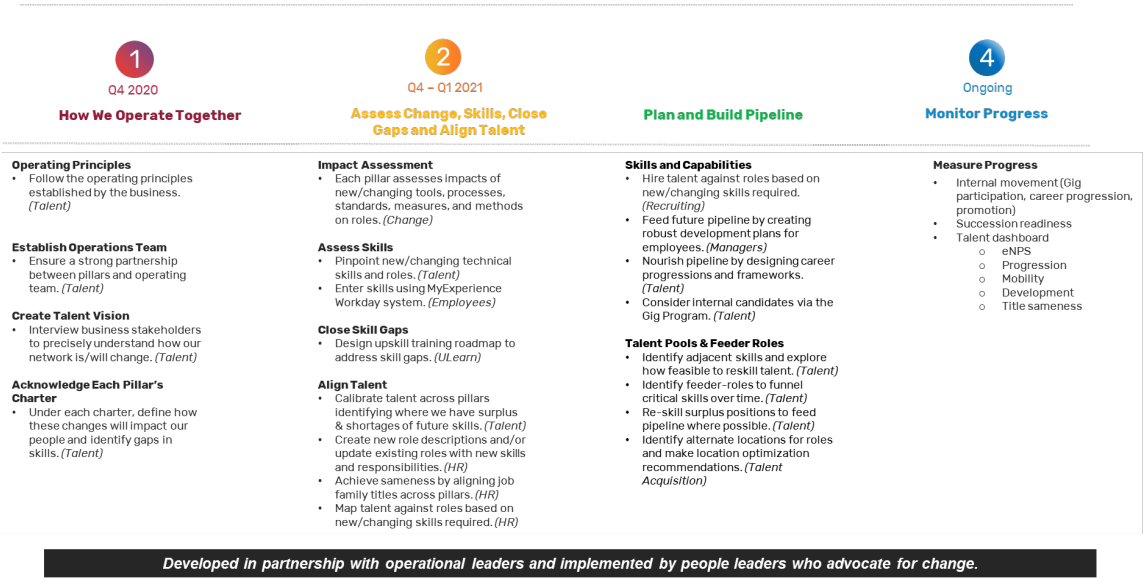

Figure 9 - Our Talent Approach

Our Intention:

- We are committed to enriching the careers of our people while elevating their confidence and motivation.

- We will achieve this by investing in career development opportunities while aligning role accountabilities across organization boundaries.
- This will allow us to mobilize our workforce with the right people in the right roles at the right time enabling organizational effectiveness and growth.

Our Design Principles:

- We align on the same titles, roles, responsibilities, & levels
- We design career movement the same and use the same standard approach
- We follow the same execution strategy (approvals, deployment practices, and communication methods)
- We don't act in silos
- We agree to use the same calculation to determine our Resource Needs

In Phase 2 we intricately are weaving in the updating of role profiles and career strategies with each process redesign. One of the first things we did was facilitate a title audit by function to understand how different we were across the organization. In Phase 3 we are developing pipeline strategies to ensure that as each new technology is rolled out, we have the talent to support it. We have completed the development of progression strategies for headend and engineering.

Our strategy is to resource new enterprise opportunities with current high performing talent from across the organization. Given that new technologies are still in their infancy and not widely understood by our front-line teams, we have developed a process for partnering with current managers to "tap high performers on the shoulder" to ask them if they are interested in new roles. This strategy was developed as part of our History of the Future work and has been highly successful. One of the bigger learnings in the development of this strategy was that we thought that normal recruitment processes would attract internal talent. We discovered that the information about new opportunities was not reaching the right talent and that there was not a clear understanding of the opportunities. Thus, the need to overtly reach out to the managers of high performers and mutually meet with them about future opportunities.

11. Evolving Operating Model

All of these elements combined are evolving into our new operating system. Fundamental to this new operating model has been establishing clear roles and a governance model for process changes.

In response to the Partner Survey, we focused on putting in place critical elements

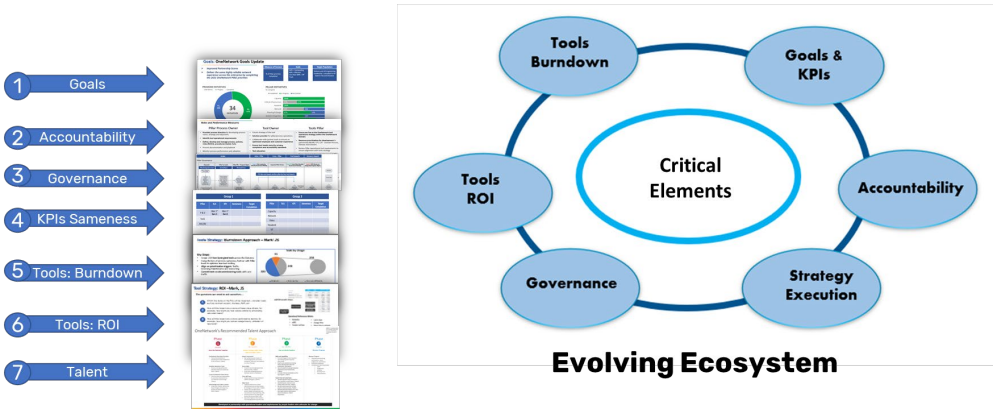

Figure 10 - Our Evolving Ecosystem

Accountabilities: To help clarify roles we adopted a business process management model. In this model **the Business Process Owners** come together to define the common workflow process, KPIs and creates a single set of requirements for tools. They are responsible for the decommissioning of legacy tools to ensure there is a single set of tools for each pillar. They are on point to monitor and continuously improve process performance.

The **Tools Owners** are solution providers. They develop, integrate, and operate the tools. They are on point to make sure our tools meet security, privacy, compliance, and accessibility standards.

The **Tools pillar Leads** coordinate and operationalize our tools strategy. They facilitate resource prioritization and manage intra tool dependencies. monitor tool decommissioning.

Roles and Performance Measures

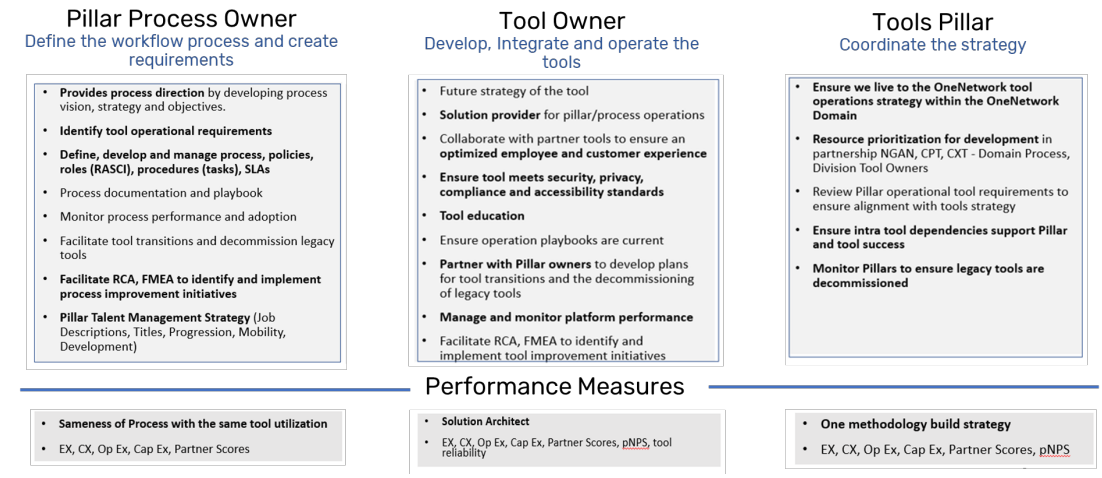

Figure 11 - Business Process Management

Clarifying roles and accountabilities has been critical. It has forced process owners to take up their responsibility to be clear about their process strategy. It has also been clear that it is their responsibility to live and enforce the tools strategy. Previously the tools owners were left to negotiate tool requirements across the multiple headquarters and divisional process owners. In addition, to support innovation, they were allowing independent tool development rather than coordinating pilots with tools partners.

KPI Reporting: We have established and resourced a **Reporting pillar** to ensure that we drive KPI sameness and primary source reporting. We have recently reached agreement that we will grow into a single reporting group.

Governance: To sustain our gains, we have established a **pillar governance model** that we are growing into. In this model we continue to position Process Owners as accountable for process design. However, to ensure integrated development across the functional pillars it forces process owners to gain support from other Pillars, and tools owners as well as the tools pillar support before making any changes to agreed-upon processes. Once any recommended change has support from all stakeholders it is presented to the E4 for final approval.

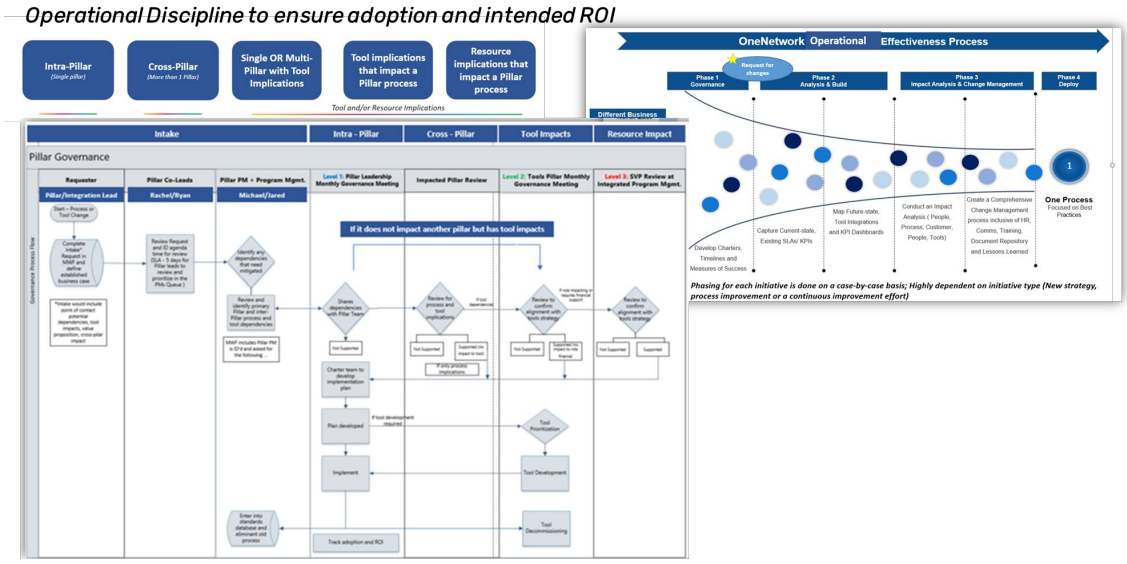

Figure 12 - pillar Governance Model

12. Program Maturity & Results

To date (summer 2021) this initiative has chartered and launched 66 initiatives in 2021. To date we have a 94% completion rate.

More importantly, we have a better understanding of where we are not the same, have clear accountabilities and agreement that sameness is our mutual goal, and have a status report of sameness maturity by pillar for Process, KPI, Tools and Talent.

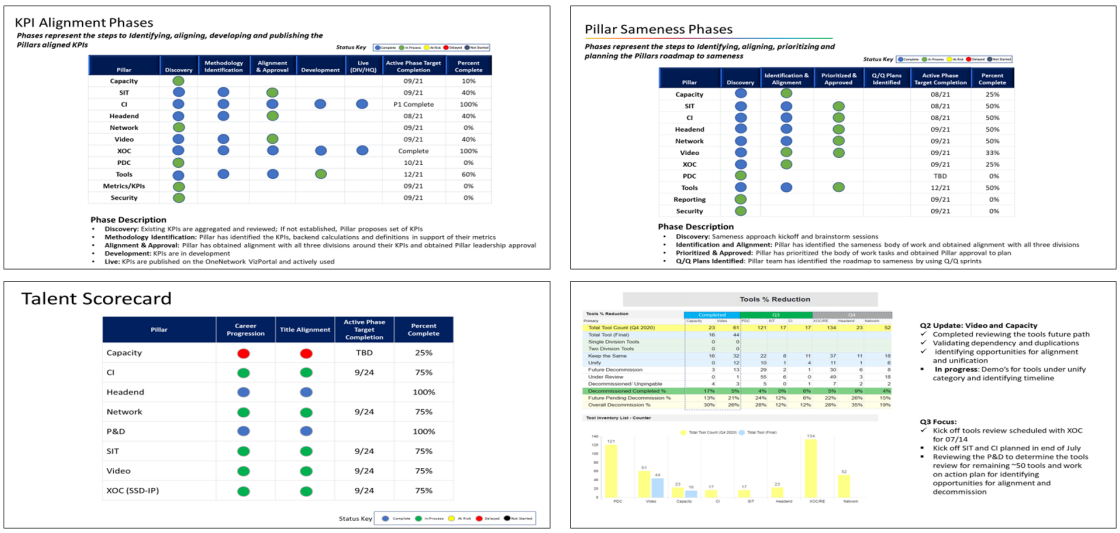

Figure 13 - Maturity Status

In addition, we are seeing improvement in our Partnership Survey scores.

13. Conclusion

Our experience over the past year has reinforced critical organization design practices that we learned we shouldn't take for granted. As a team we have reconfirmed the value of these practices and that we need to reinforce the need to apply them in everything we do.

Practice #1: Organize for the future you want. We reminded ourselves that if we wanted sameness, we needed to organize for sameness and have a set of principles that leadership was committed to.

Practice #2: Start with Sameness. We reminded ourselves that we needed to plan for strategy execution prior to design, that it could not be an afterthought. We needed to understand the variability of process prior to design and ensure all stakeholders included in the development of design requirements if we want to have a single playbook.

Practice #3: No process is an island. We reminded ourselves that Process design requires a cross pillar approach. Process design needs to consider the hand-offs between Pillars and tool integration points. For example, when redesigning our node split and headend processes, we need representation form multiple other Pillars at the table.

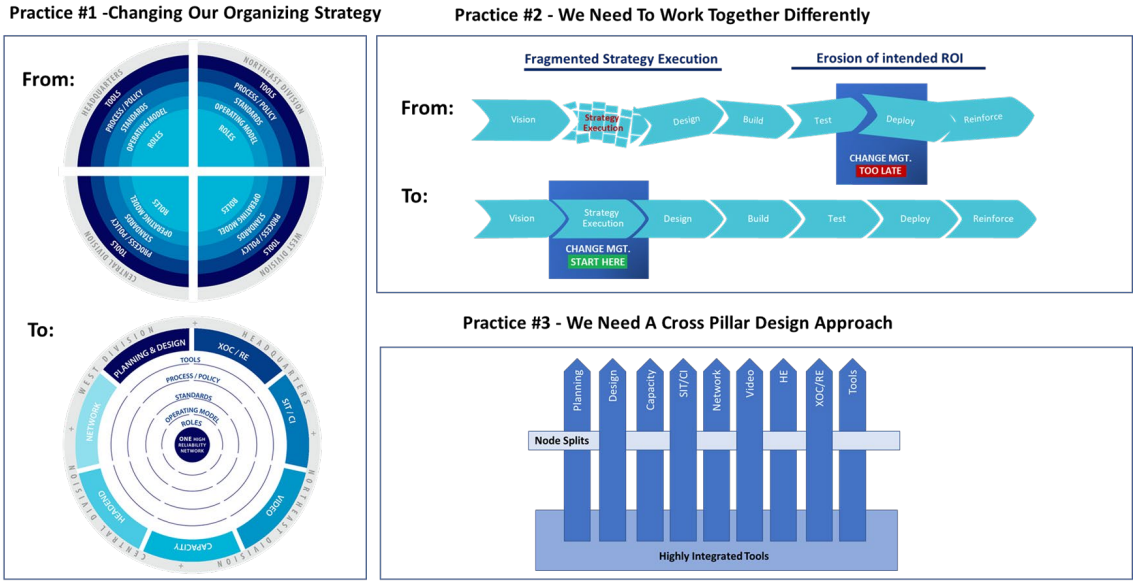

Figure 14 - Evolving Practices

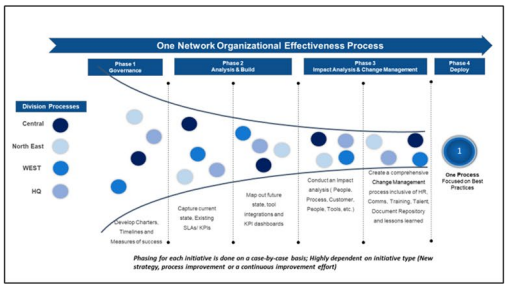
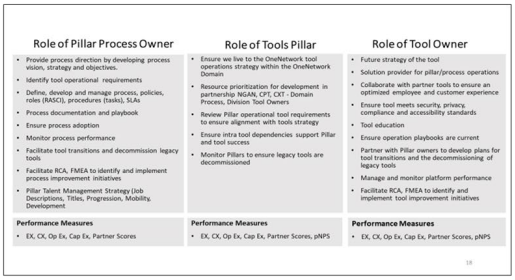
Practice #4: There is a science to organization design. We reminded ourselves that if we want a highly reliable system, we need to use the right tools. We needed to recommit to operational excellence and the tools that would enable us to ensure clarity of process, roles, and accountabilities. As we evolved as a leadership team, we began to realize that when we thought we had commitment, we really didn't because we were not discussing the process with enough detail on the table. As a team, we needed to learn that detail was our friend, not a burden that made the decision-making process longer. It reduced rework. We also began to realize that our leaders needed the detail to feel comfortable with the changes we were asking them to make. So now we do detailed macro process maps, a "swim lane" view of task listings and role and accountability charts for each task.

Practice #5: Role clarity is essential. We reminded ourselves that not everyone is clear about their roles. That we need to take the time to be overt about our expectations of each other and respective decision rights. This practice has been applied in several areas. We applied this practice when chartering each pillar, the role of pillar leaders, and roles within each process. But we also discovered that it was important to identify the roles of multiple levels of leadership. We clarified that executive leaders focus on a 3–5-year planning cycle. Senior Vice Presidents focus on the operationalization of strategy with a 2–3-year planning horizon and Vice Presidents focus on the near-term operationalization of strategy. Prior to this, our leaders were waiting for decisions to be made rather than feeling authorized to come together to develop and drive strategy.

Practice #4 – We Need to Adopt Operational Effectiveness Process/Tools



Practice #5 – We Need Role Clarity



Practice #6 – Tight Coupling is the Key to Reliability

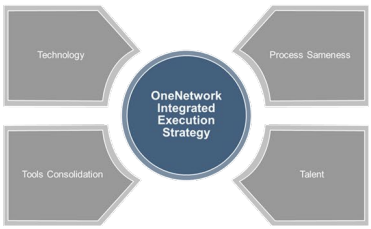


Figure 15 - Evolving Practices #2

Practice #6: Tight coupling and appropriate sequencing of process, tool, technology, and talent is critical to realizing consumer reliability. We reminded ourselves that we always need to start with the process.

We see ourselves as learning how to be a learning organization. We are actively developing the culture we need to grow into the phase of our future. We are looking forward to seeing how we can grow into our new practices.

1. Abstract

Smart cities and communities is a concept that is gaining more attention because of its potential to enhance citizens' lives and make cities and communities more efficient. Rural America can also benefit from leveraging new technologies like IoT (Internet of Things) and Fixed Wireless Access (FWA) to achieve better operational efficiencies.

In this paper we present findings in a Proof of Concept (PoC) project that demonstrates how technology can help an equestrian farm transform into a smart farm. We discuss the details of connecting the farm with high-speed broadband using FWA in the Citizens Broadband Radio Service (CBRS) frequency band then meshing the barn with high-speed Wi-Fi using Point-to-Multipoint unlicensed band.

Within the project, we also deployed LoRaWAN technology to provide early-warning detection of potential illness in the horses on the farm through the use of a water intake monitoring solution in addition to LoRaWAN environmental sensors installed to monitor the horses' surroundings. Another use case is deploying a mix of LoRaWAN and video analytics to detect unauthorized access to facilities.

2. Introduction

The Wireless Technologies R&D team at Charter is executing a PoC trial at a local Colorado Equestrian Farm ("Farm") to ascertain the viability of IoT technology through a variety of Smart Farming use cases, using multi-access technologies, including access technologies such as LoRaWAN, FWA in CBRS, Wi-Fi, and application technologies like video surveillance and license plate recognition.

The primary goals of the Smart Farming use cases include:

- Providing early warning detection of potential illnesses in the horses on the farm through the use of a water intake monitoring solution.
- Improving security on the farm through LoRaWAN sensor monitoring and alerting and video surveillance.
- Providing Spectrum Internet ® Wi-Fi connectivity at the Farm

In this paper, we will describe the Farm layout, which is essential in the design of the system, followed by the logical network setup description. Both the CBRS main FWA connectivity to the Farm as well as the wireless mesh connectivity to the different barns are detailed in the next section along with the broadband use case of video surveillance. Next, we will describe the IoT network based on LoRaWAN and the associated use cases for the farm. Finally, we will conclude with the summary and next steps in the research and PoC.

2.1. PoC Venue – Equestrian Farm

The PoC venue is an Equestrian farm outside of the Denver area. Overview:

- 120 Acres
- 55 Total Horses
- 3 Barns – used to stable horses (includes both leased stalls and leased horses)

    - Main barn attached to indoor training arena
    - Upper barn located 200 feet southeast of the main barn
    - Lower barn located .25 miles south of main barn
- Large indoor training arena attached to main barn
- Outdoor training arena
- Outdoor horse walker
- 4 Pastures
- Security gate at entrance with minimal security
- Farm is set up on a hill with line of site to a CBRS FWA RAN (Radio Access Network) at Charter's Spectrum's CTEC office in Englewood

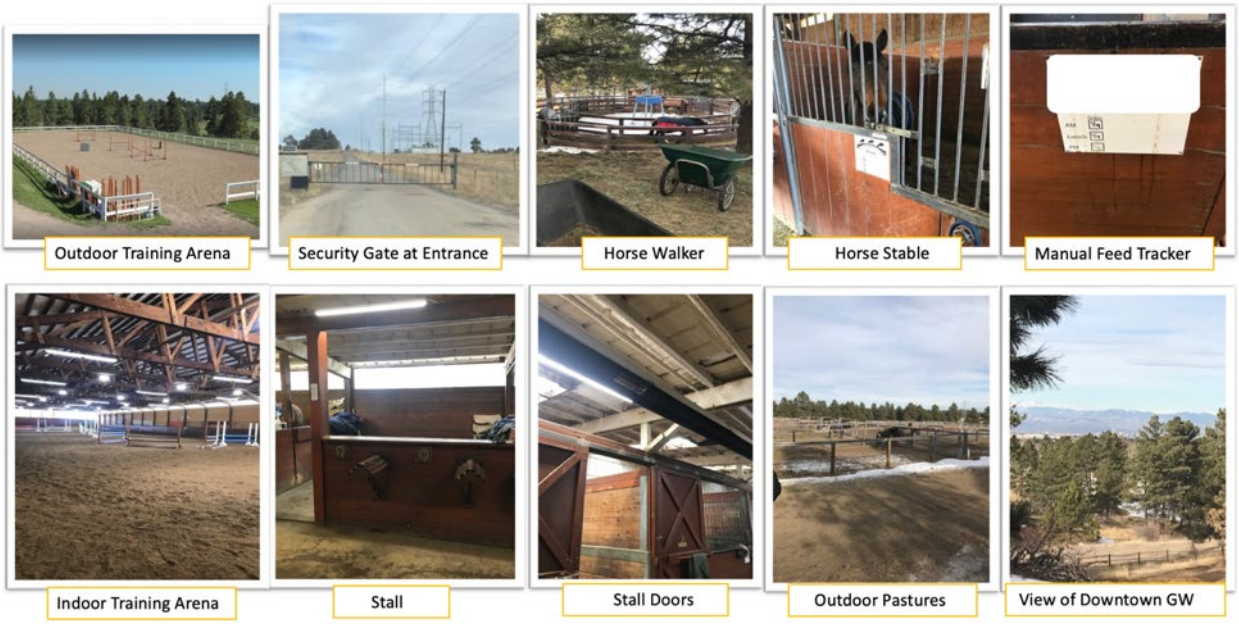

Figure 1 - Farm areas

3. Use Cases and Utilized Solution

The following figure depicts the logical network setup.

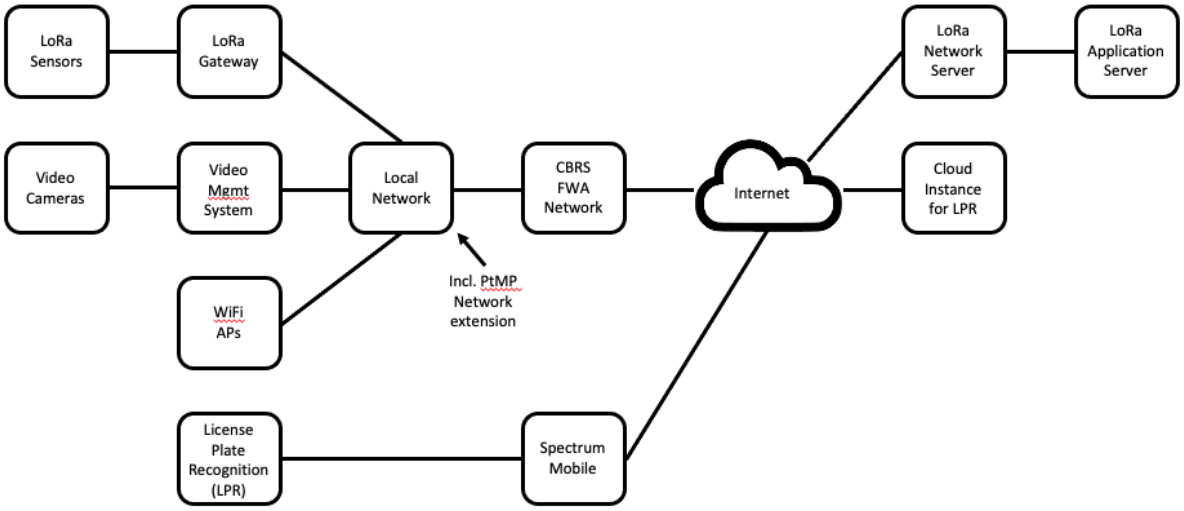

Figure 2 - Logical Network Setup

3.1. Internet Backhaul – CBRS Fixed Wireless Access

As a main 'anchor' to the internet, a Fixed Wireless Access link to the local Charter CBRS test network is utilized. The receiving eNodeB is located at Charter's CTEC1 building (5.5 miles away). Since line-of-sight conditions are available, the achievable throughput performance is close to ideal.

The 'FWA access link' is primarily used to transport traffic to the LoRaWAN network and application server, end-user internet backhaul via the Wi-Fi access point and other equipment cloud portals, but also provides the option to retrieve video streams from the local video management system. The License Plate Recognition system will have internet connectivity via Spectrum Mobile™ service.

Due to the superior Radio Frequency (RF) conditions and achievable performance results, the link to CTEC was selected.

Main Barn to CTEC Tower					
PCI	Distance	SINR	RSRP	Download	Upload
120	5.5 Miles	26 dB	-92 dBm	240 Mbps	11 Mbps

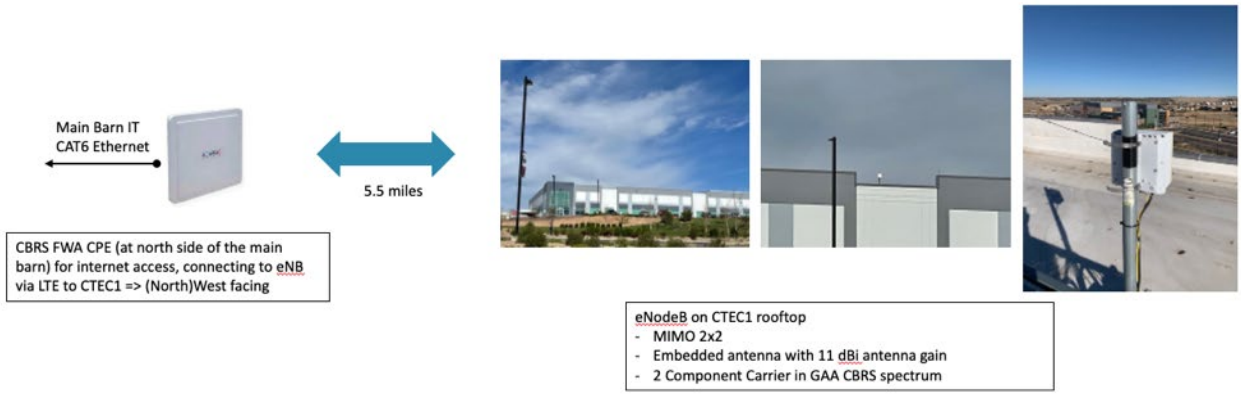

Figure 3 - eNodeB deployment at Charter CTEC1 building

3.2. Local Network Extension and Access for Farm Owner and Customers

Due to the distribution of Farm buildings – main/upper barns and owner's house – a wireless extension of the local network is required, mainly to achieve the following:

- Transport of the camera feeds from the upper barn stalls to the video management system (VMS) at the main barn
- Remote Wi-Fi access point at the farm owner's house to be able to access the system

For that purpose, a Point-To-Multipoint unlicensed 5GHz wireless system was chosen. The Base Station is mounted at the main barn and connected to the main distribution network switch. The subscriber units are installed at the upper barn and the farm owner's house.

In addition to the Wi-Fi AP at the farm owner's house, another unit is deployed inside the main barn for access to the network.

3.3. Video Surveilance

For the purpose of giving the option to the Farm owner and farm personnel to visually monitor designated areas in the farm complex, the following areas were equipped with cameras and connected to a video management system with integrated DVR:

- 4 horse stalls in main barn
- 5 horse stalls in upper barn
- Indoor training arena (4 cameras total) in the main barn
- Outdoor facing horse walker

3.3.1. Use Case 'video surveillance horse stalls':

Farm owners and personnel have the ability to remotely monitor the conditions of select horses for improved welfare and security. In the future, this could be extended to provide the same access to the horse owners. Additionally, processing the captured and stored video feeds allows for implementation of further analysis and detection of unusual horse behavior via AI (Artificial Intelligence) and ML (Machine Learning).

Figure 4 - Horse Video Surveillance

3.3.2. Use Case 'video surveillance indoor training facility':

Farm owners and personnel have the ability to detect abnormal behavior or 'not permitted' jumping based on time (after hours), in combination with installed LoRaWAN proximity sensors, and general remote monitoring of activities.

Figure 5 - Training Facility Video Surveillance

3.3.3. Use Case 'video surveillance outdoor horse walker':

Farm owners and personnel have the ability to remotely monitor activities at the outside horse walker, in combination with LoRaWAN sensors, in order to detect equipment malfunctions, horses escaping or other general remote monitoring of activities.

Figure 6 - Horse Walker Video Surveillance

3.4. LoRaWAN® Network and Sensors

For the purpose of monitoring conditions and environments in the Farm area, a LoRaWAN network setup consists of various sensors and an outdoor gateway, interconnecting via the internet to a network and application server. Sensors that are part of the solution include:

- Open/close door for monitoring the selected horse stalls
- Temperature and humidity in main, upper and lower barns and TAC room (contains equipment for the solution)
- Proximity sensors for training facility and outdoor horse walker (use cases described earlier)
- Water consumption monitoring. This sensor solution consists of a water meter, which is in line with the water supply and the water bucket for the horse (automatically refilled via a floating valve) and connected to a LoRaWAN pulse sensor.

Figure 7 - Water meter and LoRa pulse sensor solution

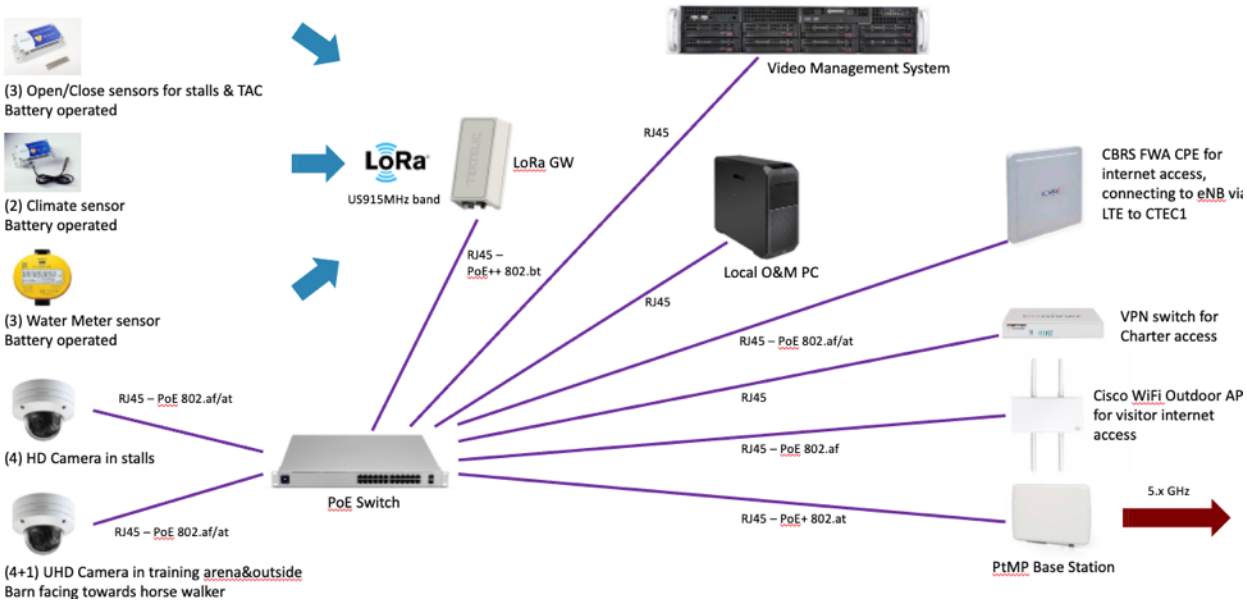

Figure 8 - Connectivity diagram example, here in the main barn

3.5. License Plate Recognition at Gate Entrance

The purpose of the license plate recognition (LPR) is to provide the Farm owner with the ability to monitor and track access, with dates and times, of visitors for potential later proof of entrance for those who entered the Farm area. As additional enhancement for the future, the LPR system could be linked to the gate control via a white/black list control.

Figure 9 - Example of outdoor LPR install

Figure 10 - Location of gate and existing poles

The LPR system is installed in close proximity to the gate, which is approximately 0.5 miles away from the Farm building complex.

The processing of the license plate recognition is done at the edge in a self-contained battery and solar powered system. The processed data is sent to a cloud portal via a cellular (using Spectrum Mobile service) link.

4. Conclusions and Next Steps

The proof of concept activities have already demonstrated that the use of hybrid wireless technologies combined with data processing at the edge and in the cloud is extremely helpful in a rural farm environment for its day-to-day activities. The trial will continue and learnings from the end users - farm owners and personnel - will be used to improve the overall solutions. Additionally, other use cases or enhancements to the existing use cases will be made as needed.

xGitGuard: ML-based Secret Scanner for GitHub

A Technical Paper prepared for SCTE by

Bahman Rashidi
Senior Security Architect
Comcast Cable
Philadelphia PA
bahman_rashidi@comcast.com

1. Abstract

Misused leaked secrets on code sharing platforms such as GitHub (GH) have caused some of the data breaches of our time. Unfortunately, this kind of credential leak is quite common across the code sharing platforms. Developers and code contributors are required in many cases by organization's security policies to comply with security practices and remove sensitive information before they push their code to GitHub. However, sometimes inadvertently developers neglect to remove sensitive information, such as API tokens and user account credentials, from their code prior to posting it. Malicious attackers crawl through GitHub, hoping to find these secrets and thus grab foothold into an organization's territory. Companies have limited ability to address this risk as given the scale of GitHub it is difficult if not impossible to find leaked secrets before malicious attackers. Some companies leverage bug bounty programs as a way to incentivize third party agents to manually look for and report these secrets through responsible disclosure. Unsurprisingly, this process can create unnecessary exposure. Consequently, we at Comcast Cybersecurity Research designed and developed "xGitGuard,"a Machine Learning (ML)-based tool that uses advanced Natural Language Processing (NLP) to detect organizational secrets and user credentials at scale and with appropriate velocity in GitHub repositories. This paper begins with a description of the problem statement. Next, we discuss the design of xGitGuard and how it improves upon current solutions, and the solution space. Finally, we provide details about how xGitGuard can be deployed in different scenarios.

2. Introduction

GitHub is the biggest open-source community with more than 200 million repositories (and of those, 30+ million are public) and over 65 million users [1] [2]. Users on GitHub publish the code of their projects, collaboratively develop software, and use the code from the platform in development. Given the open nature of GitHub, there is an opportunity to publicly disclose otherwise confidential data. [3] [4]. For example, a project may disclose login credentials for remote servers and service accounts or API tokens if such information is embedded in code distributed on the platform.

Although the risk of disclosure on GitHub and Stackoverflow is known, it is not known the extent of confidential information disclosed, and how efficiently that information is identified by attackers.

In this paper, we describe xGitGuard, an ML-based tool that detects exposed organizational secrets on GH both the public and enterprise versions. xGitGuard is designed and developed with the goal of addressing the existing challenges associated with classic regex scanning approaches (solutions relying on finding regular expressions). xGitGuard takes advantage of new text processing algorithms that can find secrets within files with high level accuracy. xGitGuard scans the entire GH for secrets efficiently using an agile scanning search approach. The agility of xGitGuard helps incident response teams to take proper actions in timely manner. In next sections, we detail how it works and can be deployed.

The rest of this paper is organized as follows: we introduce an overview of xGitGuard in Section 3, alongside a workflow overview. We then further detail the components of the xGitGuard and how they work with each other. We then discuss the related work in Section 4. We finally discuss different deployment scenarios for xGitGuard in Section 5.

3. xGitGuard

xGitGuard is an ML-based tool that detects organizational secrets, including API tokens/keys and user credentials exposed on both public and enterprise GitHub. xGitGuard has two separate models: one for detecting credentials, such as password-like secrets, and one for detecting API tokens and keys. Table 1

shows examples of such secrets. It is designed to be both scalable and accurate in scanning and detecting secrets. The rest of this section details the architecture of xGitGuard and all of its components.

Table 1 – Examples of secrets for each category

Credentials	Tokens & Keys
Username & passwords	API tokens (AWS, Azure, Slack, etc.)
Server credentials	Encryption keys
Account credentials	Session tokens
DB access credentials	Session IDs

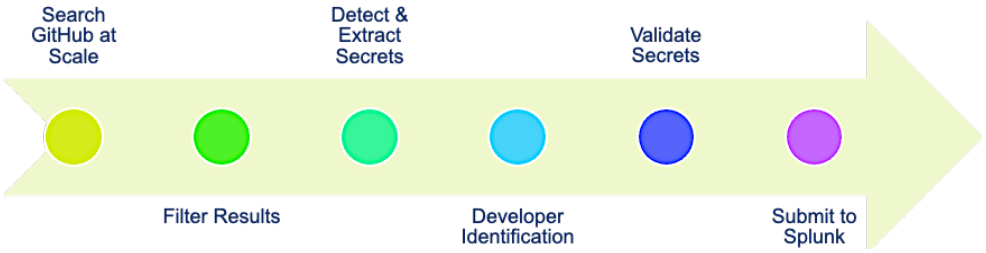

Figure 1 – xGitGuard workflow overview

3.1. Architecture

xGitGuard scans GH repos for documents potentially related to an organization and containing secrets. It also processes candidate documents for secrets, identifies developers using commit history, validates detected secrets using an ML component, and then calculates a confidence level for every detection to submit to a dashboarding tool. Figure 1 shows an overview of xGitGuard's overall workflow. The implementation of xGitGuard includes six main components. Figure 2 and Figure 3 show overview architectures of xGitGuard's workflow for credential and token detection models:

Search: xGitGuard has a unique approach to searching GitHub: it uses two types of keywords to craft GitHub queries, each for a different purpose. i) Primary keywords (PKEY): helps to search for documents that are related to the organization. ii) Secondary keys (SKEY): are then used to target documents that potentially contain secrets. xGitGuard uses two different lists of secondary keywords for credential and token detection. The two lists are deliberately different, as each will detect different types of secrets (credentials and tokens). However, the primary keywords are the same between both. With this unique approach, we scan the entire GitHub but only target documents that are relevant and sensitive.

Query Engine: This engine implements a multi-processing system that runs multiple queries in parallel to reduce the time to detect a secret. This helps with scalability. xGitGuard also maintains a hash list of documents that have been processed in the past and skips them in the future scans if they show up in query results. This way a file will be processed once, which reduces the processing time in total.

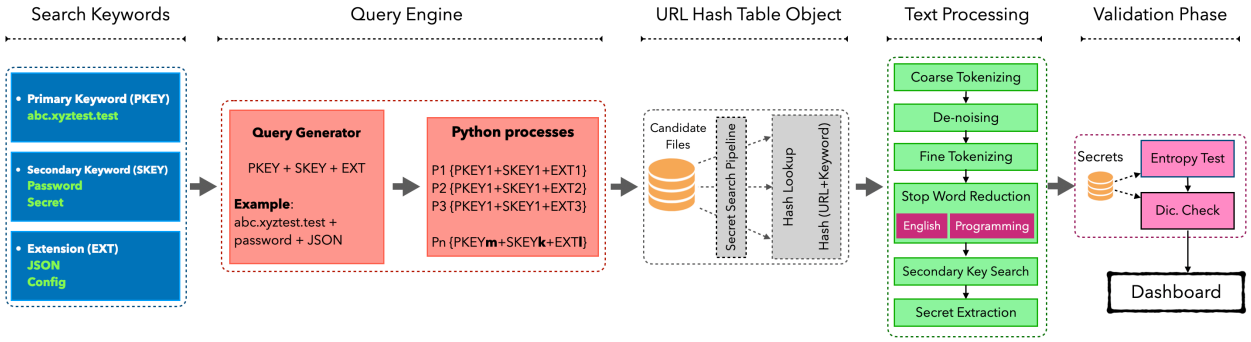

Figure 2 – Credential detection architectural overview

AI Model: This is the core of the xGitGuard, that processes the documents for secrets. This component is responsible for detecting the secrets within the documents. The core model of xGitGuard uses NLP and other in-house developed text processing algorithms to identify secrets. The model begins by breaking down documents to smaller tokens, then it removes the noise and stop words (meaning common English dictionary words, such as "the," "a" and "an," that are mutual terms/words among different languages, etc.), extracts the secrets and extra metadata (e.g., masked secret, line of code, etc.) around the detection. As Figure 3 shows, the only difference between credential and token detection models is that token detection model relies on using regexes (regular expressions) after de-noising the document.

Scoring: After detecting a secret in a document, this component calculates a confidence score for it. The higher the score, the more accurate the detection. This score is calculated based on several factors, such as the entropy of secret keys, n-gram similarity to English words, etc.

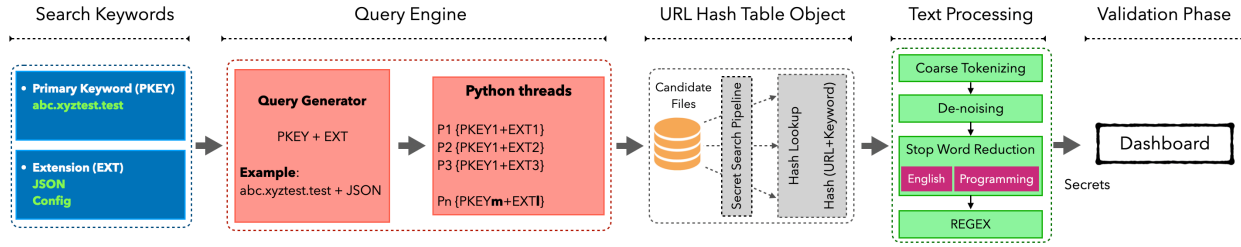

Figure 3 – Key & Token detection architectural overview

Validation Model: This ML-based model is responsible for validating detected secrets. The input to the model is a secret, and the output is whether the input is an actual secret or not. The model is built using a number of features, with the focus on the secret itself and the line of code where the secret was found. This model has an accuracy of above 90% in recognizing secrets from non-secrets text. The accuracy of the validator depends on how well we train the model and how comprehensive our training data is.

User Identification: xGitGuard is able to identify the developer who posted the code on GitHub, using commit logs related to the repos. This component extracts the email address and full name related to the developer.

3.1. Development and Deployment

The entire xGitGuard code base is developed in Python. This includes our algorithms, APIs, scanning and pre-processing documents, as well as submitting detections to dashboards. In order for xGitGuard to

perform better, all the text processing models and algorithms are persisted in the form of pickle files (serialized object models). This helps to avoid retraining our models every time a new cycle of xGitGuard starts. It also enhances agility and eases the process of deploying the final model. The modularity of pickle files helps to deploy the final model on many platforms.

4. Related Technologies

The problem of detecting leaked secrets within GH and other similar code-sharing platforms (e.g., Stackoverflow) is not a new problem in the information security community. In the past years, a number of tools from both the open source and commercial sectors tried to address such problems. However, existing solutions have some challenges, in particular scalability and accuracy.

There are three main limitations related to the existing tools. The first is that most of these tools, and especially the open source versions, exclusively focus on a single use case (they either focus on API tokens or passwords, not both). The second limitation is that almost all the solutions discussed here rely on pattern detection (regular expressions). This limits the types of secrets that are covered and only detects certain types of secrets. Finally, these approaches require users to point the tools to specific repos that they want scanned, because they lack scalability to scan the entire public or enterprise GH.

4.1. Truffle Hog

Truffle Hog is a free and open source tool that can help developers check for any hard-coded secrets. Truffle Hog is designed to scan for secrets through repositories (users need to point the tool to specific repos in order to scan them) and the entire commit history. The tool specifically searches for each diff (differences between file content) from each commit and evaluates them for secrets [5]. The Truffle Hog's core model relies on detecting high-entropy strings (average number of bits per symbol needed to encode a string) that could represent secrets, whether API tokens and keys or other types of credentials [6].

4.2. Nightfall for GitHub

Nightfall for GitHub is a commercial variant of similar tools that uses ML to detect secrets exposed on GitHub repos. Similar to Truffle Hog, this solution only works on manually-selected repos. Unlike Truffle Hog, this tool can be integrated with GH accounts in the form of an app and can automatically detect secrets as a user pushes code to repositories. This tool is an extension of Truffle Hog in terms of the approach to secret validation [7]. The main focus of Nightfall is to detect API keys and tokens and omits passwords and other credentials as a category of leak.

4.3. Gitguardian

Similar to Nightfall, Gitguardian is a commercial tool with a limited amount of publicly-available information. It describes the tool as ML-based and able to identify more than 200 types of API tokens. However, similar to Nightfall, Gitguardian exclusively targets API tokens and keys by relying on regular expression classifiers. Alongside the commercial variant that it offers, Gitguardian also provides a free service to scan one's repos on GitHub [8] [9].

4.4. EarlyBird

EarlyBird, developed by American Express, is another sensitive information detection tool relying on pattern detection (regular expression). EarlyBird exclusively scans repositories for clear text password violation, personally identifiable information (PII), sensitive file names and outdated cryptography

methods, etc. It functions on committed code (GH repos) and local files. Similar to Nightfall, it can also work as a pre-commit check. Besides the regular expressions that are used for secret detection, EarlyBird also uses entropy calculation for password detection [10].

5. Deployment

xGitGuard is a standalone and internally-developed and used application. Depending on the use case, it can be internally deployed and utilized in different ways. In this section, we discuss some of the ways that xGitGuard could be deployed.

5.1. Continuous Scanning

One way to deploy xGitGuard is to run it as a stand-alone application continuously running and scanning GitHub repos. This way, xGitGuard will continuously query GH in a cycle, receive documents and process them for secrets. This process continues until stopped manually. Using this approach, a longer time should be expected for the first cycle, as all the received files are new to xGitGuard and they all will be processed. In the second cycle and after, the previously processed files will not be processed (unless they have been modified) and it will take shorter time for xGitGuard to process the queries.

5.2. Git Hook

In this approach, xGitGuard is used as a hook integrated with GH. This approach will specifically be applicable on GitHub enterprise (GHE). The hook is responsible for intercepting new commits and processing them immediately for any hardcoded secrets. Depending on security operations center's (SOC) strategy, the commits containing secrets can be dropped or not.

5.3. BigQuery GH Datasets

GitHub has over 100 million repos with only ~30 million repos being public. The rest of repos on public GH are licensed. It is wise to scan not only the public GH repos, but also the licensed repos. GH provides weekly snapshots of open-sourced licensed repos that can be queried by Google BigQuery [11]. In this scenario, the scanned repos can be passed to xGitGuard for secret detection.

6. Conclusion

We developed an internal tool called xGitGuard to detect leaked secrets in open source code repositories, to keep our data safe from inadvertent leaks. It was designed to perform with a high level of agility and a low false positive rate. Its strength, compared to other methods using regular expression scanning, is its use of NLP and text processing to detect secrets, and machine learning/ML to validate the detections. Our in-house developed algorithms and technologies outperform existing solutions in this area. xGitGuard is a stand-alone model that can be used in different ways depending on the use case. If well-trained, the ML-based validator has a high level of accuracy. Such high accuracy reduces the rate of false positives.
