1. Introduction

The transition to open RAN (Radio Access Network) based on interoperable splits is gaining significant momentum across the mobile industry. Conventional composed base stations are being decomposed into separate radio units (RU), distributed units (DU) and centralized units (CU), as illustrated in Figure 1. However, where best to split the open RAN is a complex compromise between RU simplification, DU functionality, CU functionality, support of advanced co-ordinated multipoint RF capabilities, consequential limitations on transport delay budgets as well as interface bandwidth expansion.

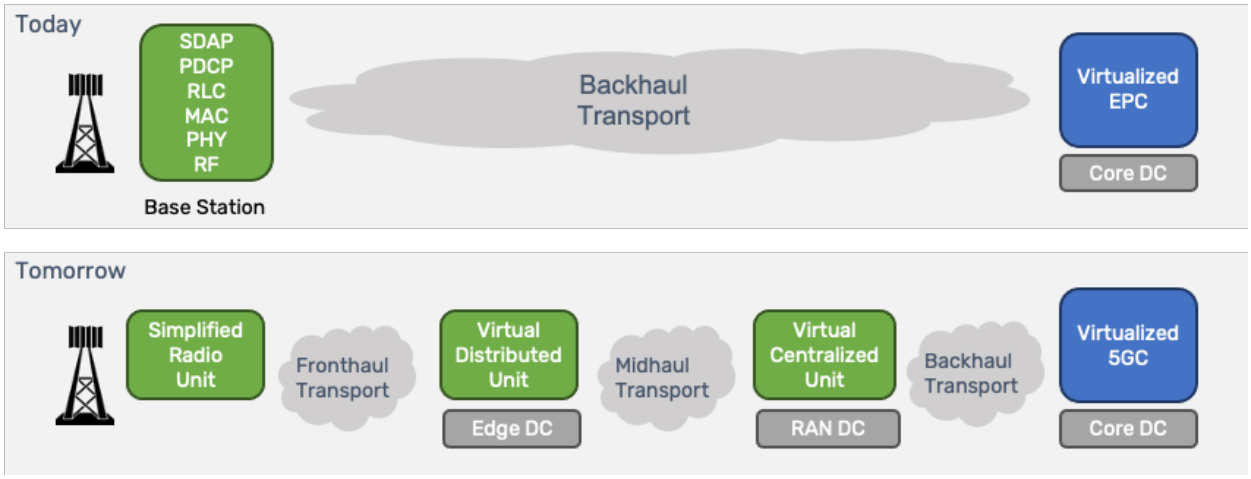

Figure 1 - The Transition to a Decomposed Radio Access Network

During the study into 5G's Radio Architecture, several alternative splits were analysed [1]. These were broadly categorized into "higher layer splits" (HLS) and "lower layer splits" (LLS). The demarcation between these two categories is the location of the scheduler, with the term LLS being applicable to deployments with lower latency transport where it is possible to realize enhanced performance through centralized scheduling, and HLS being applicable to deployment with higher transport latencies that operate with a distributed scheduler.

To help in comparing alternative options, different splits have been assigned numbers with higher numbers representing splits "lower down" in the protocol stack, meaning less functionality being deployed "below" the split in the RU. Lower layer splits occur below the medium access control (MAC) layer in the protocol stack which contains the scheduler functionality. Several lower later splits are possible, including Split 6 - between the MAC and physical layers, Split 7 - within the physical layer, and Split 8 - between the physical layer and the RF functionality. Interestingly, Split 6 is analogous to the Remote PHY interface as defined at CableLabs [2].

Before 5G's analysis into splits, the de facto approach to split the RAN was to use an interface based on the Common Public Radio Interface (CPRI). Back in 2003, the CPRI industry co-operation (www.cpri.info) had defined an interface between a Radio Equipment Control (REC) element implementing all the RAN baseband functions and a Radio Equipment (RE) element implementing the RF functions, to enable the RE to be located at the top of a cell tower and the

REC to be located at the base of the cell tower. This interface was subsequently repurposed to support relocation of the REC to a centralized location that could serve multiple cell towers via a fronthaul transport network. Using the split numerology introduced in 3GPP 38.801, with the RE implementing the RF and REC implementing the physical layer and above, the CPRI-based split is identified as a split 8 approach.

Split 8 has been characterized as requiring up to a 30-fold bandwidth expansion compared to HLS approaches [2]. Furthermore, in LTE the transport latency budget of all LLS approaches is constrained by the operation of hybrid automatic repeat request (HARQ) functionality in the MAC layer. This results in the oft-quoted delay requirement of 250 micro-seconds for one way transport delay budget between the radio and the element implementing the MAC layer's uplink HARQ functionality. Finally, with 5G's increasing focus on multi-antenna systems, the CPRI split 8 approach is hampered by the need to scale linearly with the number of RF elements.

With such extreme requirements, it is evident why the focus of DOCSIS based transport has been on HLS approaches to RAN decomposition, where there is nominal bandwidth expansion compared to conventional RAN backhaul systems and delay budgets can be measured in milli-seconds instead of micro-seconds. This paper takes an alternative view and compares the requirements for supporting two different lower layer splits, namely the network functional application platform interface (nFAPI) Split 6 as defined by the Small Cell Forum (www.smallcellforum.org) and the Split 7-2x as defined by the O-RAN Alliance (www.o-ran.org). Whereas the pre-conception is that lower layer splits are incompatible with fronthaul being transported using DOCSIS, this paper examines the LLS requirements associated with these splits and demonstrates how, given correct configuration, fronthaul deployments can be compatible with DOCSIS based transport.

2. Small Cell Splits

The Small Cell Forum (SCF) took the initial lead in defining a multivendor lower layer split, taking its FAPI platform application programming interface (API) that had been used as an informative split of functionality between small cell silicon providers and the small cell RAN protocol stack providers, and enabling this to be "networked" over an IP transport.

This "networked" FAPI, or nFAPI, enables the Physical Network Function (PNF) implementing the small cell RF and physical layer to be remotely located from the Virtual Network Function (VNF) implementing the small cell MAC layer and upper layer RAN protocols. First published by the SCF in 2016, the specification of the MAC/PHY split has since been labelled as "Split 6" by 3GPP TR38.801 that studied 5G's New Radio access technology and architectures. The nFAPI architecture is shown in Figure 2.

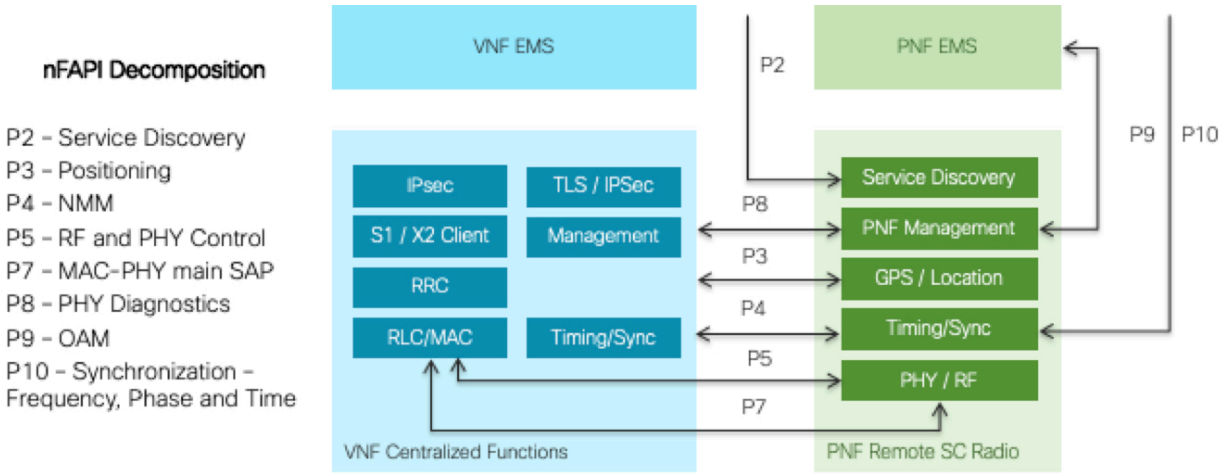

Figure 2 - Small Cell Forum's nFAPI MAC/PHY Split

The initial SCF nFAPI program delivered important capabilities that enabled small cells to be virtualized. Importantly, when comparing the transport bandwidth requirements for the fronthaul interface, nFAPI/Split 6 does not significantly expand the bandwidth required compared to more conventional small cell backhaul deployments. Moreover, just like the backhaul traffic, the nFAPI transport bandwidth varies according to served traffic, enabling statistical multiplexing to be used over the fronthaul IP network. This can be contrasted with the alternative CPRI/Split 8 that requires bandwidth expansion up to 30-fold and a constant bit rate connection, even if there is no traffic being served in a cell.

3. HARQ Latency Constraints

LTE contains a retransmit mechanism called the hybrid automatic repeat request (HARQ). DOCSIS does not have an equivalent mechanism. There is an uplink synchronous HARQ which has tight timing constraints and a downlink asynchronous HARQ that does not. The timing constraints discussed here are unique to LTE and do not apply to 5G. This is important as in the Cable industry, some operators may only consider deploying 5G on their DOCSIS network.

Whereas nFAPI/Split 6 offers significant benefits over CPRI/Split 8 in terms of bandwidth expansion, both splits are below the hybrid automatic repeat request (HARQ) functionality in the MAC layer that is responsible for constraining the transport delay budget for LTE fronthaul solutions. LTE-based Split 6, Split 7 and Split 8 all have a common delay constraint equivalent to 3 milliseconds between when uplink data is received by the RF to the time when the corresponding downlink ACK/NAK needs to be ready to be transmitted by the RF, as illustrated in Figure 3.

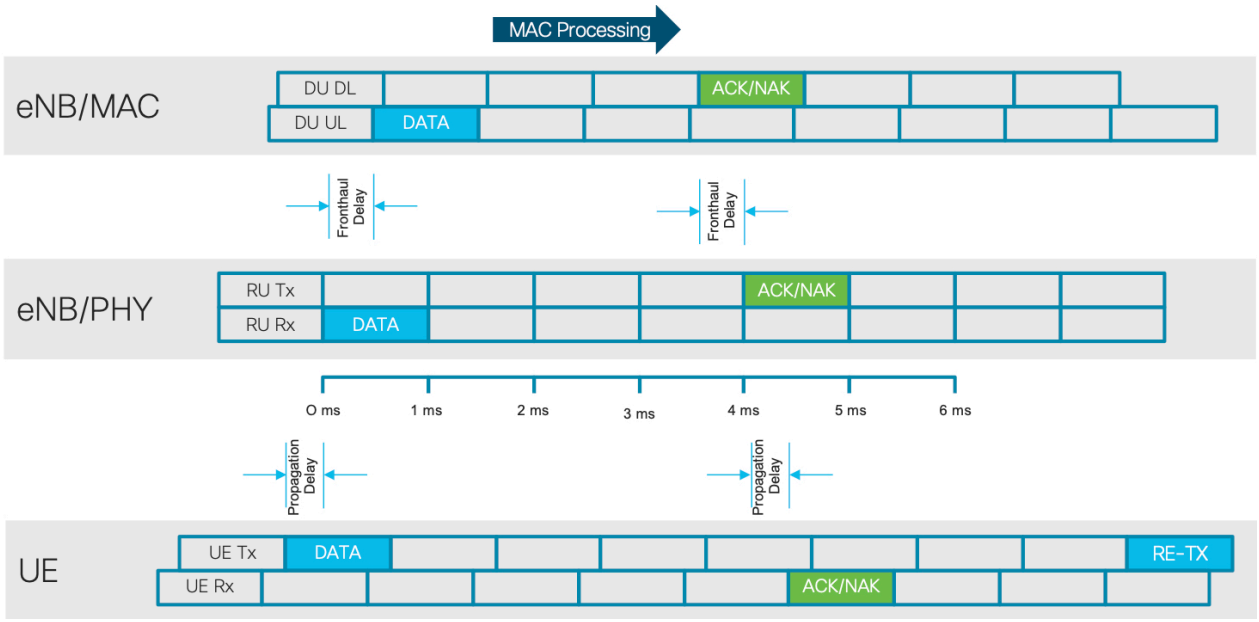

Figure 3 - HARQ Latency Constraints for LTE

These 3 milliseconds need to be allocated to HARQ processing by the MAC layer and fronthaul transport delay, with a common assumption being that 2.5 milliseconds are allocated to processing, leaving 0.5 milliseconds allocated to round trip transport, or 250 micro-seconds for one way transport delay budget between the element implementing the RF and the element implementing the MAC layer's uplink HARQ functionality.

The Small Cell Forum acknowledges such limitations when using its nFAPI split. Because the 250 micro-seconds one way transport budget severely constrains nFAPI deployments, SCF defines the use of HARQ interleaving that leverages standardized signalling to defer HARQ buffer emptying, enabling higher latency fronthaul links to be accommodated. Although HARQ interleaving buys additional transport delay budget, the operation has a severe impact on single user equipment (UE) throughput; as soon as the delay budget exceeds the constraint described above, the per UE maximum throughput is immediately decreased by 50%, with further decreases as delays in the transport network increase, as illustrated in Figure 4.

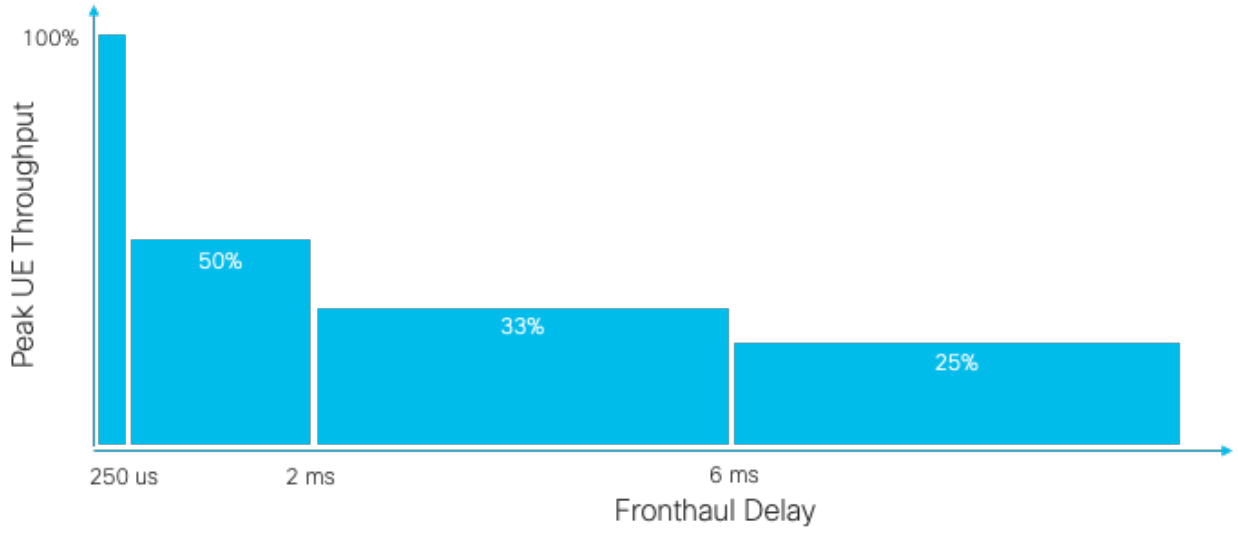

Figure 4 - Impact of HARQ interleaving on peak UE throughput

Some proponents have advocated that in certain LTE deployment scenarios, the operation of HARQ can be disabled to avoid the associated 250 micro-second delay constraint. However, analysis indicates that HARQ operation plays an important role in improving performance as signal to node ratio (SNR) falls below 8 dB [4], meaning that a significant number of cell edge users will likely be impacted if HARQ is disabled.

The restriction associated with the operation of LTE uplink HARQ is due to the definition of HARQ operation as being synchronous, whereby the identity of a HARQ process is derived from its transmission timing. This can be contrasted to the operation of the LTE downlink HARQ that defines the signalling of a HARQ process identity along with the data which means that there are no equivalent downlink timing constraints.

Importantly, 5G new radio (NR) does not implement the same synchronous uplink HARQ procedures, instead defining the use of HARQ process identities in both the downlink and the uplink. Consequently, 5G fronthaul systems do not suffer the same HARQ-based transport delay constraints as LTE. Instead, the limiting factor constraining the transport budget in 5G fronthaul systems is the operation of the windowing during the random-access procedure.

When a UE wants to establish a connection, it first recovers information on the system information broadcast type 2 (SIB2) message broadcast by the cell. SIB2 includes information about the random-access channel (RACH) configuration. The UE uses the RACH configuration to determine the time, frequency, preamble identity and repetition information to use when sending the physical random-access channel (PRACH) preamble, sometimes referred to as “message 1” (MSG1). If received correctly by the network, the base station will transmit a random-access response (RAR) message to the UE. The UE will monitor the physical downlink control channel (PDCCH) for reception of the RAR message sent by the network, sometimes referred to as “message 2” (MSG2). Importantly, the monitoring period is controlled by a

parameter termed *raResponseWindow* which has a maximum value of 10 milliseconds [5], as illustrated in Figure 5.

This maximum value of 10 milliseconds needs to be partitioned between the PRACH preamble processing by the MAC layer, round-trip transport delays and over the air delays. Allocating 2.5 milliseconds to PRACH preamble processing leaves 7.5 milliseconds to be allocated between the over the air transmissions and round-trip transport delay. This effectively means that fronthaul round-trip transport delays of up to 5 milliseconds can be accommodated without impacting the currently defined RACH processing.

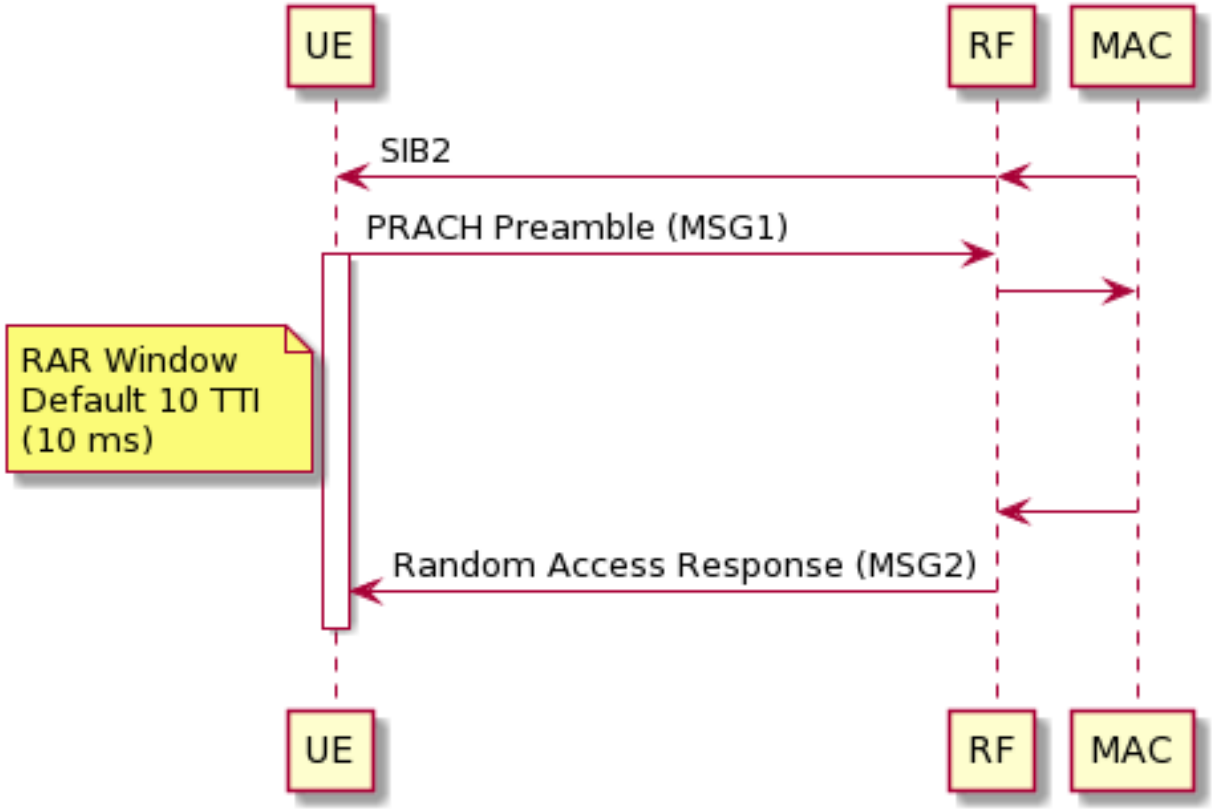

Figure 5 - Random Access Timing

Importantly, whereas the 500 microsecond round-trip transport delay requirement necessitated by LTE's synchronous uplink HARQ cannot be met by the DOCSIS system, the ~5 millisecond round-trip transport delay for 5G might be achieved with an optimized DOCSIS configuration, and thus splits 6 through 8, will work for DOCSIS, at least from the HARQ viewpoint. The Low Latency Xhaul (LLX) feature is targeted at getting the majority mobile traffic to be within 5 milliseconds round trip.

4. Split PHY Alternatives

Unlike in nFAPI/split 6 where there is a clear demarcation between MAC and PHY layers, the newer split 7 intra PHY approach can have multiple realizations. 3GPP 38.801 describes three alternative realizations:

- Split 7-1: whereby the FFT, Cyclic Prefix handling and uplink PRACH processing are distributed into the RU
- Split 7-2: In addition to those functions defined in Split 7-1, the RU additionally includes layer mapping/de-mapping and optionally the precoding functionality
- Split 7-3: In addition to those functions defined in Split 7-2, in the downlink, the RU additionally includes the modulator

These split PHY alternatives, together with the nFAPI/split 6 and the CPRI/split 8 are illustrated in Figure 6.

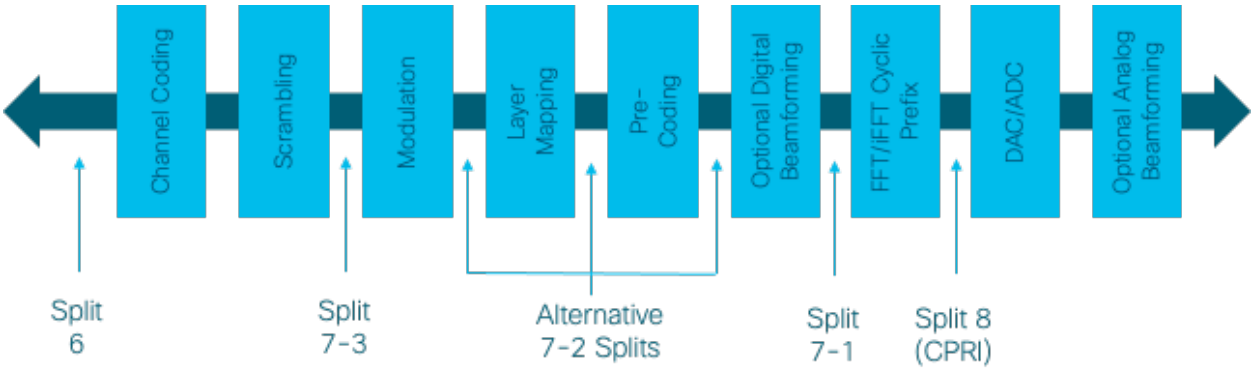

Figure 6 - Alternative Lower Layer Splits

As reported by the Small Cell Forum [2], these alternative split PHY approaches offer benefits in terms of advanced RF combining capabilities. Table 1 is taken from the Small Cell Forum's study into virtualization which highlights that "the lower down in the protocol stack the decomposition occurs, the greater the ability to benefit from the enhanced co-ordination techniques".

However, the alternative approaches to split PHY realizations risk fragmenting the industry in its effort to define a multi-vendor interoperable split PHY approach. This issue was taken up in 2016 by a group of operators and vendors in the xRAN Forum. The xRAN Forum worked on comparing alternative vendor views on split PHY realization and managed to coalesce these into a single approach. Then in 2018, the xRAN Forum announced its merger with the C-RAN Alliance to form a world-wide, carrier-led effort to drive new levels of openness in the radio access network of next-generation wireless systems named the O-RAN Alliance.

Table 1 - Comparing Advanced RF Combining Capabilities of Lower Layer Splits

Advanced RF Combining Capability	PDCP/ RLC	Split MAC	MAC/ PHY	Split PHY
Carrier Aggregation		x	x	x
Cross Carrier Scheduling		x	x	x
Higher order MIMO				x
Downlink Joint Processing- Joint Transmission			x	x
Uplink Joint Reception independent PHY decoding			x	x
Uplink Joint Reception joint equalization PHY decoding				x
Joint Processing – Dynamic point Selection		x	x	x
Co-ordinated Scheduling/Beamforming up and downlink	x	x	x	x

5. O-RAN Alliance's Lower Layer Split

Taking its lead from earlier xRAN work, the O-RAN Alliance published its "7-2x" Split PHY specification in February 2019 [6]. All Split 7 alternatives offer significant benefits over the legacy CPRI/Split 8, which includes avoiding split 8 requirements to scale fronthaul bandwidth on a per antenna basis, as well as introducing transport bandwidth requirements that vary with served traffic in the cell, compared to Split 8 which has a near constant network data rate even when there is no cell traffic. Moreover, when compared to Split 6, the O-RAN lower layer Split 7-2x supports all advanced RF combining techniques, including the higher order multiple-input, multiple-output (MIMO) capability that is viewed as a key enabling technology for 5G deployments.

However, instead of supporting individual transport channels over the nFAPI interface, Split 7-2x defines the transport of frequency domain IQ defined spatial streams or MIMO layers across the lower layer fronthaul interface. The use of frequency domain IQ symbols can lead to a significant increase in fronthaul bandwidth when compared to the original transport channels.

Figure 7 illustrates the bandwidth expansion due to split 7-2 occurring "below" the modulation function, where the original 4 bits "1110" to be transmitted are expanded to over 18 bits after 16-QAM modulation is applied, even when using the block floating point compression scheme defined by O-RAN Alliance.

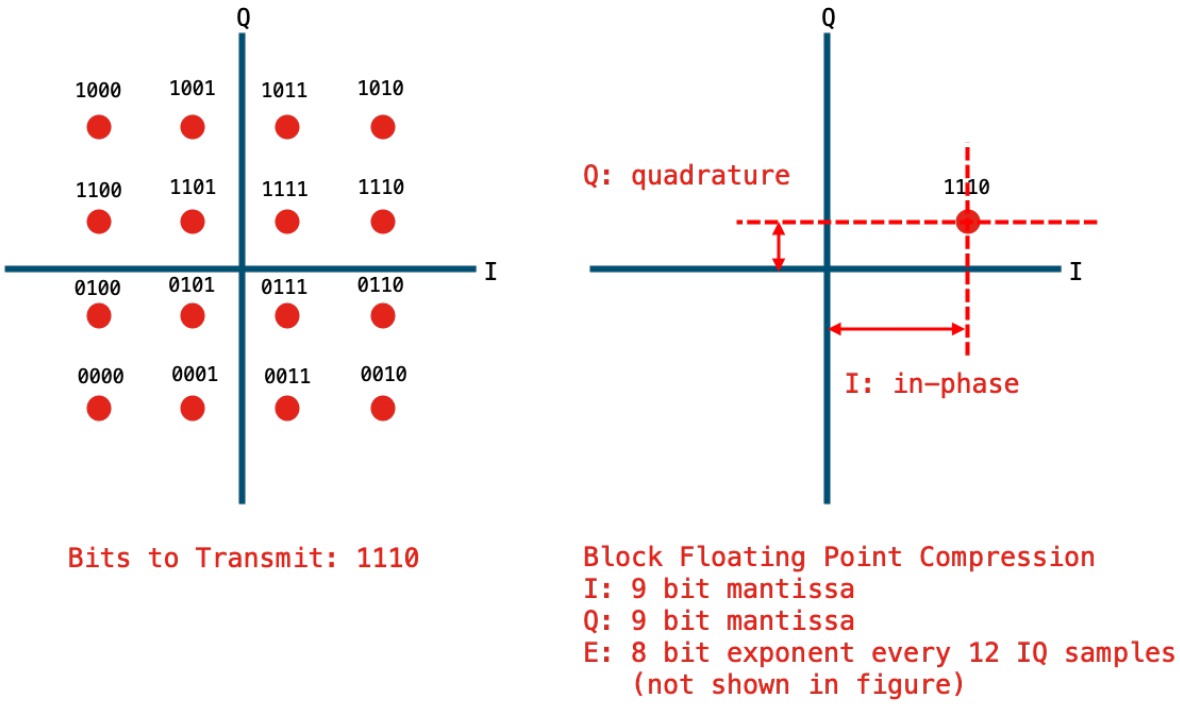

Figure 7 - Bandwidth Expansion with Block Floating Point Compressed Split 7-2x

The bandwidth expansion is a function of the modulation scheme, with higher expansion required for lower order modulation, as shown in Table 2.

Table 2 - Bandwidth Expansion for Split 7-2x with Block Floating Point Compression compared to Split 7-3

Modulation Scheme	Bits to modulate	Block floating point bits	Bandwidth expansion ratio
16 QAM	4	18.67	4.67
256 QAM	8	18.67	2.33

Such a bandwidth expansion was one of the reasons that proponents of the so called Split 7-3 advocated a split that occurred “above” the modulation/demodulation function. To address such issues, and the possible fragmentation of different Split 7 solutions, the O-RAN Alliance lower layer split includes the definition of a technique termed *modulation compression*.

The operation of modulation compression of a 16-QAM modulated waveform is illustrated in Figure 8. The conventional Split 7-2 modulated constellation diagram is shifted to enable the modulation points to lie on a grid that then allows the I and Q components to be represented in binary instead of floating-point numbers. Additional scaling information is required to be signalled across the fronthaul interface to be able to recover the original modulated constellation points in the RU, but this only needs to be sent once per data section.

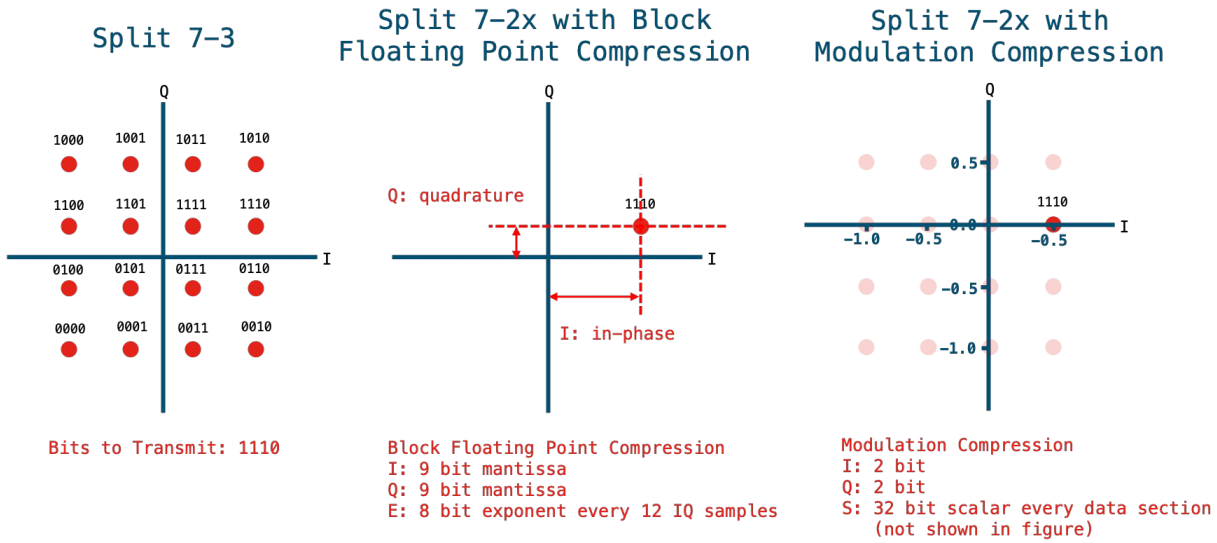

Figure 8 - User Plane Bandwidth Reduction Using Modulation Compression with Split 7-2

Because modulation compression requires the in-phase and quadrature points to be perfectly aligned with the constellation grid, it can only be used in the downlink. However, when used, it decreases the bandwidth expansion ratio of Split 7-2x, where the expansion compared to Split 7-3 is now only due to the additional scaling and constellation shift information. This information is encoded as 4 octets and sent every data section, meaning the bandwidth expansion ratio will vary according to how many Physical Resource Blocks (PRBs) are included in each data section. This value can range from a single PRB up to 255 PRBs, with Table 3 showing the corresponding Split 7-2x bandwidth expansion ratio over Split 7-3 is effectively unity when operating using large data sections.

Table 3 - Bandwidth Expansion for Split 7-2x with Modulation Compression compared to Split 7-3

Modulation Scheme	Bits to modulate	7-2x Block FP Compression BW Expansion Ratio	PRBs per data section	Modulation Compression (ModComp) bits	7-2x ModComp BW Expansion Ratio
16 QAM	4	4.67	1	6.67	1.67
			10	4.27	1.07
			255	4.01	1.00
256 QAM	8	2.33	1	10.67	1.33
			10	8.27	1.03
			255	8.01	1.00

Note, even though modulation compression is only applicable to the downlink (DL), the shift of new frequency allocations to Time Division Duplex (TDD) enables a balancing of effective fronthaul throughput between uplink (UL) and downlink. For example, in LTE, 4 of the 7 possible TDD configurations have more slots allocated to downlink traffic, compared to 2

possible configuration that have more slots allocated in the uplink. Using a typical 12-to-6 DL/UL configuration, with 256-QAM and 10 PRBs per data section, the overall balance of bitrates for modulation compression in the downlink and block floating point compression in the uplink will be (1.03 x 12) to (2.33 x 6), or 12.40:13.98, i.e., resulting in a relatively balanced link as it relates to overall bandwidth.

A more comprehensive analysis by the O-RAN Alliance has examined control and user-plane scaling requirements for Split 7-2x with modulation compression and compared the figures with those for Split 7-3. When taking into account other overheads, this analysis indicated that the difference in downlink bandwidth between Split 7-3 and Split 7-2x with Modulation Compression was estimated to be around 7%. Using such analysis, it is evident why the O-RAN Alliance chose not to define a Split 7-3, instead advocating a converged approach based on Split 7-2x that can be configured to address a variety of lower layer split deployment scenarios.

6. Comparing Split 7-2x and nFAPI

Material from the SCF clearly demonstrates that, in contrast to Split 7, their nFAPI/Split 6 approach is challenged in supporting massive MIMO functionality that is viewed as a key enabling technology for 5G deployments. However, massive MIMO is more applicable to outdoor macro-cellular coverage, where it can be used to handle high mobility and suppress cell-edge interference use cases. Hence, there may be a subset of 5G deployments where massive MIMO support is not required, such as 5G fronthaul over DOCSIS, so let's compare the other attributes.

With both O-RAN's Split 7-2x and SCF's nFAPI lower layer split occurring below the HARQ processing in the MAC layer, both are constrained by exactly the same delay requirements as it relates to LTE HARQ processing and fronthaul transport budgets. Both O-RAN's Split 7-2x and SCF's nFAPI lower layer split permit the fronthaul traffic load to match the served cell traffic, enabling statistical multiplexing of traffic to be used within the fronthaul network. Both O-RAN's Split 7-2x and SCF's nFAPI split support transport using a packet transport network between the RU and the DU.

The managed object for the SCF's PNF includes the ability for a single PNF to support multiple PNF Services. A PNF service can correspond to a cell, meaning that a PNF can be shared between multiple operators, whereby the PNF operator is responsible for provisioning the individual cells. This provides a foundation for implementing Neutral Host. More recently, the O-RAN Alliance's Fronthaul Working Group has approved a work item to enhance the O-RAN lower layer split to support a "shared O-RAN Radio Unit" that can be parented to DUs from different operators, thus facilitating multi-operator deployment.

Both SCF and O-RAN Split 7-2x solutions have been influenced by the Distributed Antenna System (DAS) architectures that are the primary solution for bringing the RAN to indoor locations. The SCF leveraged the approach to DAS management when defining its approach to shared PNF operation. In contrast, O-RAN's Split 7-2x has standardized enhanced "shared cell" functionality where multiple RUs are used in creating a single cell. This effectively uses the

eCPRI based fronthaul to replicate functionality normally associated with digital DAS deployments.

Comparing fronthaul bandwidth requirements, it's evident that the 30-fold bandwidth expansion of CPRI was one of the main reasons for SCF to embark on its nFAPI specification program. However, the above analysis highlights how O-RAN has delivered important capabilities in its Split 7-2x to limit the necessary bandwidth expansion and avoid fragmentation of the lower layer split market between alternative split PHY approaches.

The final aspect when comparing these alternatives is how much the bandwidth is expanded when going from Split 6 to Split 7-2x. Figure 6 illustrates that the bandwidth expansion between Split 6 and Split 7-3 is due to the operation of channel coding. With O-RAN having already estimated that Split 7-3 offers a 7% bandwidth savings compared to Split 7-2x with Modulation Compression, we can use typical channel coding rates to estimate the bandwidth expansion between Split 6 and Split 7-2x.

Table 4 uses typical LTE coding rates for 64-QAM modulation to calculate the bandwidth expansion due to channel coding rate, where the coding rate is the ratio of the useful data transmitted in a subframe to the total amount of data transmitted. This is combined with the additional 7% expansion due to Modulation Compression to estimate the differences in required bandwidth. This table shows that the difference in bandwidth between nFAPI/Split 6 and Split 7-2x is a function of channel coding rate and can be as high as 93% for 64QAM with $^{1}/_{2}$ rate code, and as low as 16% for 64 QAM with an $^{11}/_{12}$ rate code.

Table 4 - Example LTE 64QAM Channel Coding Bandwidth Expansion

Name	Effective Code Rate	Channel Coding BW Expansion	Channel Coding Expansion plus 7%
64-QAM $^{1}/_{2}$	0.554	1.81	1.93
64-QAM $^{3}/_{5}$	0.650	1.54	1.64
64-QAM $^{3}/_{4}$	0.754	1.33	1.42
64-QAM $^{5}/_{6}$	0.852	1.17	1.26
64-QAM $^{11}/_{12}$	0.926	1.08	1.16

Whereas the above analysis indicates that the cost of implementing the Channel Coding above the RU in Split 7-2x is a nominal increase in bandwidth, the benefit to such an approach is the significant simplification of the RU by removing the need to perform channel decoding. Critically, the channel decoder requires highly complex arithmetic and can become the bottleneck in physical layer processing. Often, this results in the use of dedicated hardware accelerators that can add significant complexity and cost to the Split 6 Radio Unit. In contrast, O-RAN's split 7-2x allows the decoding functionality to be centralized, where it is expected that it can benefit from increased utilization and associated efficiencies, while simplifying the design of the O-RAN Radio Unit. A summary of these comparisons is illustrated in Table 5.

Table 5 – Summarizing Differences Between nFAPI and Split 7-2x

Characteristic	nFAPI	Split 7-2x	Comment
Advanced RF Techniques	Supports 6 out of 8 RF techniques	Supports 8 out of 8 RF techniques	Split 7-2x supports higher order MIMO
Round-trip Transport Latency for LTE	Hard limit of 0.5 milliseconds	Hard limit of 0.5 milliseconds	Identical delay constraints as both splits are below HARQ
Round-trip Transport Latency for NR	Soft limit of ~5 milliseconds	Soft limit of ~5 milliseconds	Identical delay constraint
Bandwidth Expansion compared with HLS	Limited bandwidth expansion	~16-93% bandwidth expansion for 64 QAM	Split 7-2x has lower bandwidth expansion for higher modulation rates
MIMO Layer Bandwidth Expansion	None	Bandwidth scales with MIMO layers (Cat-B)	Key delta in bandwidth is due to expansion due to MIMO layers
Statistical Multiplexing in Transport	Yes	Yes	Both splits enable statistical multiplexing
RU Complexity	Similar to composed base station	Removes requirement for channel decoder in RU	Split 7-2x enables RU simplification

7. MIMO Layer Optimization

Both LTE and 5G define the use of MIMO that use multiple transmitting and receiving antennas and exploit multi-path to enable multiple MIMO layers to be supported. In cable, an analogy would be that each port on a fully segmented fiber node is a MIMO layer. The comparison above indicates that there may be limited bandwidth expansion possible with Split 7-2x compared with Split 6 when a single MIMO Layer is being sent over the fronthaul interface. However, where the RAN is configured to support multiple MIMO layers, then this will be the primary parameter that governs the effective bandwidth expansion of Split 6 versus Split 7-2x deployments.

The separate MIMO layers can be used in various configuration, including spatial multiplexing where different layers are used to transmit separate information in order to increase the capacity of the channel, and transmit diversity where different layers are used to transmit the same information in order to enhance the quality of the received signal. Earlier analysis of LTE field trials has compared the transmission modes used in a congested multi-cell environment, contrasting spatial multiplexing, transmit diversity and massive MIMO techniques [7]. These results indicate that the most common multi-antenna technique operated in the network is transmit diversity. Significantly, the O-RAN Split 7-2x supports 3 different transmission schemes:

- Spatial Multiplexing with Cyclic Delay Diversity
- Spatial Multiplexing without Cyclic Delay Diversity
- Transmit Diversity

Specifically, with transmit diversity, the two or four transmit diversity MIMO layers can be packed into a single physical resource block sent over the Split 7-2x interface, meaning that the fronthaul bandwidth is not expanded compared with Split 6, even when transmitting multiple MIMO layers. This is illustrated below for the downlink direction, showing a single set of resource elements (shown in yellow) being used to drive multiple antenna streams (green for antenna 0, blue for antenna 1) and where the individual antenna reference symbols necessary for the operation of MIMO are time multiplexed across the fronthaul interface and then unpacked into the separate streams used to transmit over the respective antennas.

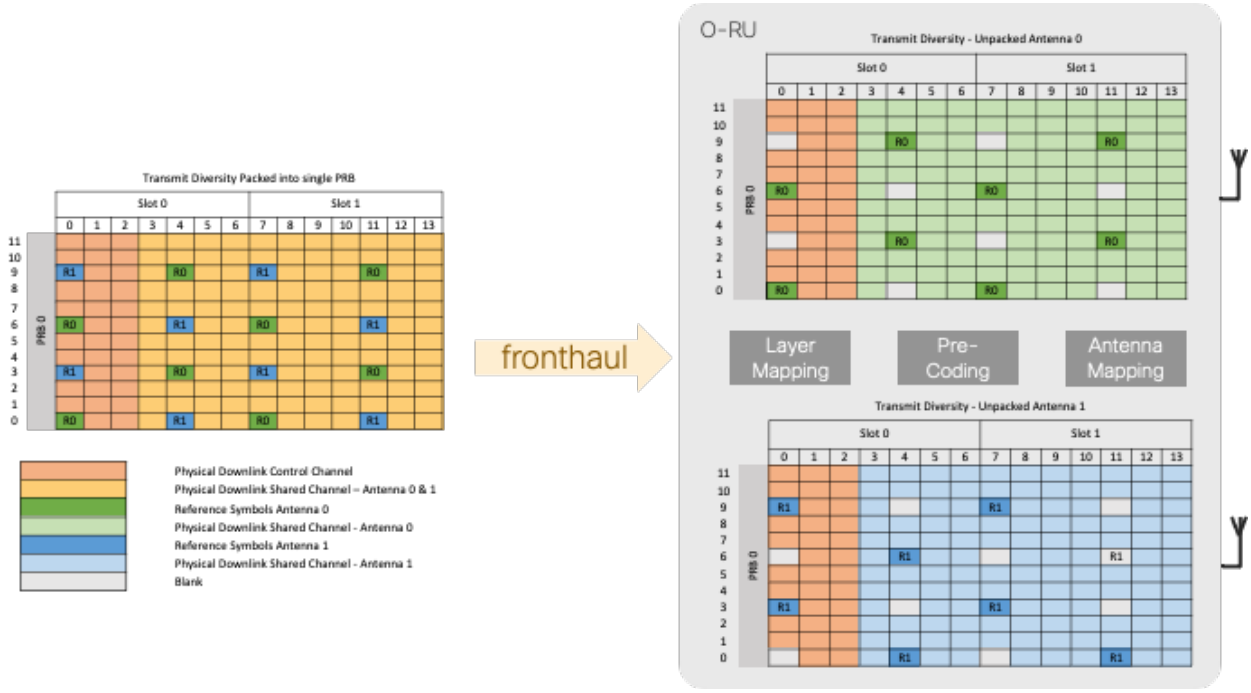

Figure 9 - Packing Multiple Transmit Diversity Layers into a Single Physical Resource Block

Hence, in scenarios where transmit diversity is the most common multi-antenna technique, the options available in O-RAN's split 7-2x avoids any additional fronthaul bandwidth expansion compared to Split 6.

8. Minimizing Transport Delays with Co-operative Scheduling

The above analysis has shown the variety of techniques embedded within the O-RAN fronthaul specification that are aimed at reducing the bandwidth requirements when transporting the multi-vendor interoperable Split 7-2x interface. The final aspect covered in this section deals with the

O-RAN Alliance specification for optimizing fronthaul deployments transported using resource allocation-based transport networks such as DOCSIS and passive optical networking (PON).

Heavily influenced by earlier CableLabs low latency mobile xhaul (LLX) technology [8][9] , O-RAN has specified a “co-operative transport interface” (CTI) targeted at minimizing transport delay requirements through the coordination of resource scheduling between the RAN elements and the transport network. Leveraging the same concepts in CableLabs’ bandwidth report (BWR) concept, the mobile scheduler in O-RAN’s O-DU can signal in real-time information such as fronthaul bandwidth and associated latency or QoS requirements to the transport scheduling entity in the transport node (TN). Here the reported information can be used to expedite resource allocation for the uplink RAN traffic, including adapting the transport control traffic sent to the distributed transport unit (TU) used to support the packetized xhaul traffic.

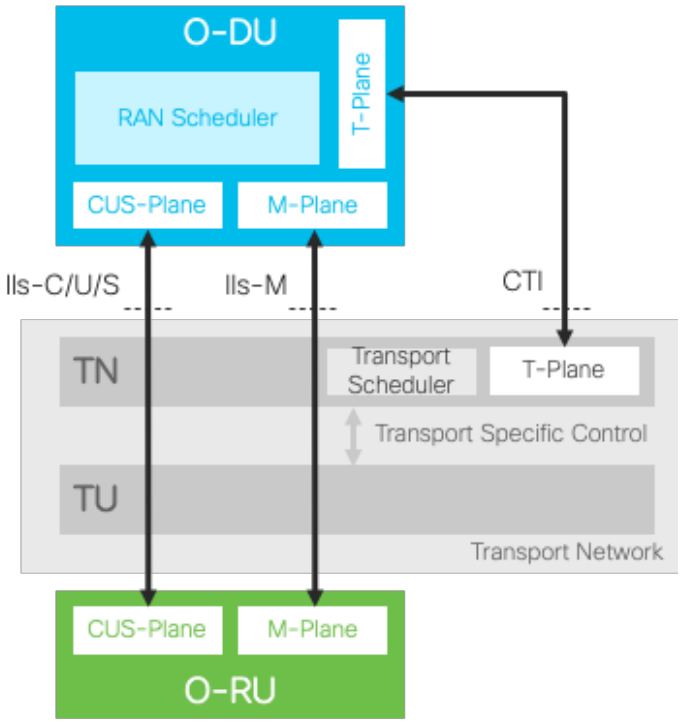

Figure 10 - O-RAN’s Co-operative Transport Interface

Earlier trials of the BWR system have demonstrated the benefits of scheduler co-ordination [10]. Trials have shown that even when channel utilization is high and many users are trying to access the channel, BWR ensures a 1-2 millisecond latency with a higher DOCSIS traffic priority applied to the BWR flow. Significantly, at the 95th percentile, BWR has been demonstrated to reduce DOCSIS upstream latency by almost an order of magnitude, from 22 milliseconds to 2.5 milliseconds.

With 5G new radio (NR) avoiding the strict sub-millisecond latency constraints associated with LTE’s synchronous uplink HARQ procedures, the specification of CTI by the O-RAN alliance,

coupled with the above delay measurement results, indicate that DOCSIS will be able to support the transport delay requirements associated with O-RAN's 5G fronthaul interface.

9. Scaling For Fronthaul Bandwidth

Network densification is a key driver for enabling 5G. This will see conventional cell tower sites be upgraded with 5G capability, but also a raft of new sites being deployed. These new sites will likely be targeted at delivering "hotspot" capacity to meet consumers' ever-increasing demand for more mobile broadband, or targeted coverage for supporting new vertical value chains which 5G aims to support. The 5G radio market can then be viewed as split into conventional "on-tower" based and newer "off-tower" based deployments.

The on-tower radios will be attempting to deliver increased capacity across the tower's coverage area through the use of MIMO. These MIMO systems could range from 8x8 MIMO up to 64x64 massive MIMO systems. Due to their larger radius, there will also be more UEs per radio which means the average traffic rate will be higher. The 5G on-tower market will almost always use a fiber-based fronthaul transport, although some instances do have radio backhaul.

The off-tower market is the emerging small cell market. The small cell will have a smaller radius with a less dense MIMO (2x2 or 4x4) and with fewer UEs, which means the average traffic rate will be lower. These small cells may be pole/building mounted, strand mounted, or indoor mounted. This is the market for HFC connectivity using the fiber or coax side of the hybrid fiber-coax (HFC) plant. The coax side of the HFC plant would use the DOCSIS protocol. This market segment is somewhat analogous to Wi-Fi with a potentially larger radius.

In order to understand the impact of fronthaul on the off-tower market, we first define the expected bandwidth model of the RAN system that will be backhauled over DOCSIS. Then we compare the bandwidth load to the service level of a cable modem.

With so many variations in how to configure an LTE or 5G system, it is further complicated by different approaches of how to configure the fronthaul. We will focus our attention on the split 7-2x Modulation Compression profiles approach that leverage the bandwidth saving capabilities described above.

Moreover, we will re-use a TDD test profile that looks to be applicable to the majority of new spectrum being allocated to 5G, using the so called "DDDSU" frame structure configuration. In this TDD frame configuration, D represents a slot configured for downlink operation, U represents a slot configured for uplink operation, and S represents a special slot that includes a number of symbols for downlink, a number of symbols for uplink and a number of symbols for a guard period between the downlink and uplink symbols. In an example the 14 symbol special slot can be configured as 10:2:2 (D:G:U) where G is guard time. So, this is equivalent to a time multiplexing ratio of approximately 4:1 for DL:UL.

An example LTE profile would be for 2x20MHz radio that uses 2x2 MIMO, for example corresponding to a CBRS deployment that uses 4 x 10 MHz licenses. Using Modulation Compression in the downlink and block floating point with 9-bit mantissa in the uplink, our calculations are that when considering control plane and transport overheads, a peak of 330

Mbit/s of throughput will be required on the downlink and a peak of 320 Mbit/s of throughput will be required on the uplink. Note, because of the unequal fronthaul compression techniques applied to the UL and DL, the 4:1 time multiplex results in a roughly symmetrical fronthaul bandwidth being transported over Ethernet.

An example 5G NR profile using the same 40 MHz of spectrum would be for a 40 MHz radio that uses 4x4 MIMO. Using Modulation Compression in the downlink and block floating point with 9-bit mantissa in the uplink, our calculations are that when considering control plane and transport overheads, a peak of 950 Mbit/s of throughput will be required on the downlink and a peak of 690 Mbit/s of throughput will be required on the uplink.

Whereas these rates represent the peak uplink and downlink speeds, it is recognized that real-world deployments operate with a non-uniform spatial distribution of traffic such that not all radios will be simultaneously operating at their peak capacity. The SCF analyzed such a phenomenon as part of their nFAPI virtualization deliverables [12]. While the exact peak-to-mean spatial distribution across a RAN will be a function of the deployment, e.g., including the use case being address (e.g., residential/enterprise/urban), the SCF report that a value of a peak-to-mean ratio of 3.5-to-4.0 across a 200 radio node "off-tower" network can be used to help dimension the virtualized RAN.

The bandwidth of the DOCSIS plant is well documented in [13] and results are show in Figure 11 with 96 channels (6 MHz per channel) of MPEG video, and in Figure 12 with no MPEG video. Figure 11 represents a typical case today on the HFC plant while Figure 12 represents a point in 3 to 5 years when MPEG video has been retired from the HFC plant and video services are all video over IP over DOCSIS.

The bandwidth numbers in the table represent the peak bandwidth of the DOCSIS spectrum. Each cable modem (CM) will be provisioned with some value less than this. The Distributed Access Architecture (DAA) nodes are described by the number of unique DOCSIS ports in the downstream (DS) and upstream (US) direction. A 2x4 DAA node has two unique DOCSIS DS (equivalent to a downlink) and four unique DOCSIS US (equivalent to an uplink) ports.

2 x 4 Node Capacity	User	DOCSIS 3.1 with video					DOCSIS 4.0 ESD with video

Figure 12 - DOCSIS Bandwidth for a 2x4 DAA Node

The DOCSIS plant, as are all networks, is built with over-subscription in mind. In Figure 11, scenario 1, the DOCSIS plant supports 3 Gbps DS and 100 Mbps US. This is a typical deployment in 2021. As a typical example, this bandwidth may support 200 CMs with highest provisioned rate of 1 Gbps DS and 20 Mbps US for about 10% to 20% of the CMs, while the majority of the CMs are 200 Mbps x 10 Mbps and 100 Mbps x 5 Mbps. This defines an over-subscription case that recognizes that not all CMs will transmit or receive at the same time.

As discussed before, the small cell will not use all four of its MIMO channels simultaneously all the time. Nor will it use its full spectral capacity all the time. In fact, it depends upon the reach of the small cell and how many subscribers it connects to. Since the CM is part of a large service group (SG) of say 200 homes, the reach of the small cell and any other small cells on that node, will have the same geographical footprint. An analysis of the number of small cells per fiber node and small cells per macro-cell can be found in [14].

So, at a first pass, if a DOCSIS SG shares the same region as a set of small cells, and hence the same customers and same traffic load, then their traffic patterns will be similar. In this scenario, think of Wi-Fi connected laptops to a DOCSIS network, mixed with cell phones that are either Wi-Fi to DOCSIS connected or mobile connected.

At a second pass, the small cell fronthaul downstream bandwidth (950 Mbps) matches the max CM bandwidth (1 Gbps) and thus fits. The small cell fronthaul upstream (650 Mbps) does not match the upstream bandwidth of scenario 1 (100 Mbps). Instead, the DOCSIS upstream spectrum will have to increase from 42 MHz return (100 Mbps) to 204 MHz return (1.48 Gbps). This assumes a common spectrum starting point of 16.4 MHz.

The tables show that the DOCSIS DS bandwidth can be increased dramatically to about 10 Gbps with DOCSIS 3.1 by removing the legacy MPEG video. DOCSIS 4.0 with extended spectrum DOCSIS (ESD) can take the DS limit further as well as increase the upstream bandwidth.

Another issue that arises in support small cells, especially if they are in the home, is the support of IEEE 1588 timing. The DOCSIS Time Protocol (DTP) provides this service and is defined in [15] with further support in [16][17][18][19][20].

10. Conclusion

Fronthaul is perceived as being synonymous with fiber-based transport systems; extreme bandwidth requirements and sub-millisecond latency requirements may cause many to reach the conclusion that DOCSIS is only suitable for transporting higher-layer splits. However, in this paper we have described the enhanced capabilities in O-RAN's Split 7-2x lower-layer split architecture that are targeted at minimizing the impact on transport networking requirements.

Standardized techniques have been described that enable the bandwidth expansion of a single fronthaul stream to be reduced to low percentages when compared to alternative higher-layer split alternatives. Moreover, spatial stream optimization techniques have been described that enable a single transport stream to drive certain MIMO antenna configurations. The hard delay requirements for LTE fronthaul are deprecated in favour of soft delay requirements for 5G New Radio, with delay constraints now measured in milliseconds instead of microseconds.

Taking the lead from earlier CableLabs BWR concepts, O-RAN has fully specified a co-operative transport interface to link the RAN and transport schedulers, an approach that has already demonstrated low millisecond transport latencies and, at the 95th percentile, a reduction in DOCSIS upstream latency of almost an order of magnitude, from 22 milliseconds to 2.5 milliseconds.

Finally, we use example LTE and 5G profiles to set the parameters used in fronthaul bandwidth calculation and compare them with existing and evolving DOCSIS bandwidths. It was clear that the DOCSIS downstream had ample bandwidth, but the HFC plant needs to be upgraded to 204 MHz to allow for small cell fronthaul.

1 Abstract

Cable companies offer multiple services – TV, broadband (cable, fiber, ethernet), voice, business services, home security and many others. And Cable companies now offer mobile service. They have purchased CBRS spectrum and are developing 5G service offerings for a Quad-Service play.

Mobile is an entirely new technology area for the industry and the service must be brought online in double-quick time to meet market demand, monetize CBRS spectrum purchases, and meet business commitments. At the same time, they must invest in the mobile network which is evolving to 5G. Operators must also be in position to offer these three (3) major 5G communications use cases: Ultra Reliable and Low Latency (URLLC), Massive Machine Type (mMTC), and Enhanced Mobile Broadband (eMBB).

5G is complex:

- New User Endpoints (UEs in 5G speak)
- New radios (CBRS), DOCSIS/PON backhaul and/or hybrid RAN (own & partner)
- An SDN/NFV-based Core, both centralized & distributed and/or hybrid Core
- Edge clouds and cloud-based environments (mix of bare-metal, VNF, & CNF deployments)
- A diverse network with a multitude of vendors & customers
- New, unique use cases including but not limited to Fixed Wireless Access (FWA), network "slicing", autonomous vehicles, IoT etc.
- Exposure to developer APIs (for even more app use cases) and many others
- Subscriber needs are changing, and new experiences are being created at a rapid pace

Security is critical in such a diverse, evolving, and complex 5G network while at the same time these services must be bought online faster to market with limited budgets and strained resources.

Traditional Enterprise-based security solutions will not be adequate based on the scope of the challenge, the size, diversity and scale of the network and the numerous new, unique & evolving use cases.

A 5G-based security solution requires not only adherence to traditional IT concepts of availability, integrity & confidentiality but also provide:

- A centralized, multi-vendor, end-to-end network control & management ("single pane of glass")
- Be adaptive, self-learning (AI/ML) with real-time threat updates
- Highly-scalable to support millions of diverse (UE & network) elements
- Customizable and automated (auto-discovery, audit & auto-remediation) to handle the volume of threats & scale and extent of the 5G network

2 5G: Key Security aspects

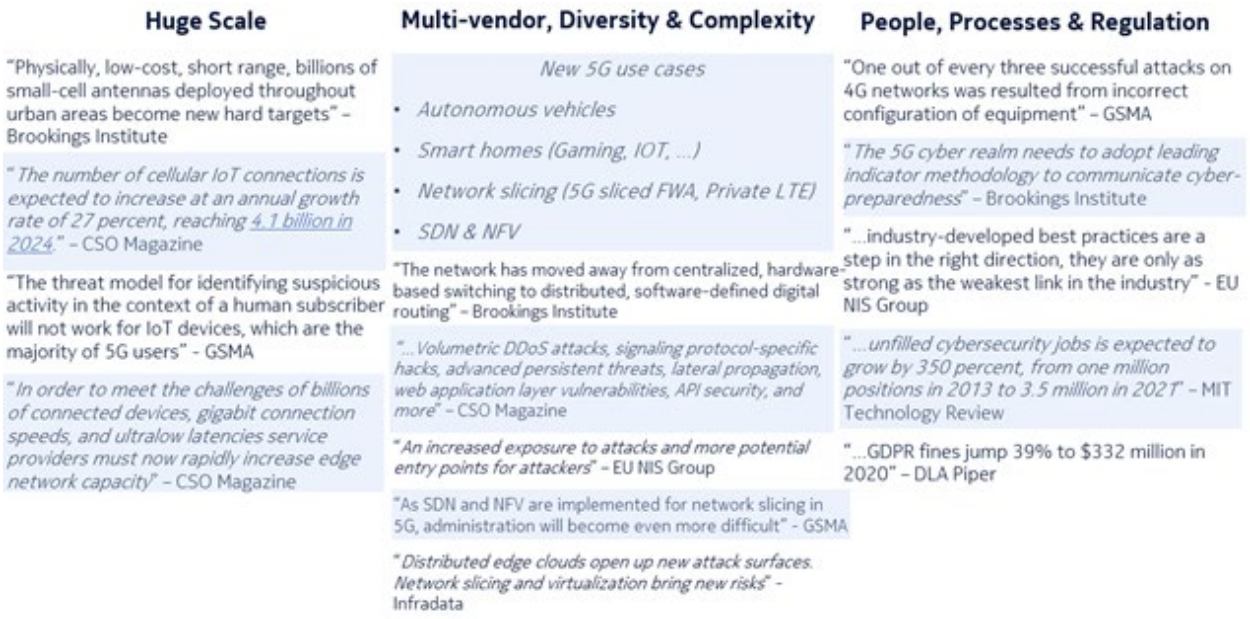

Figure 1 – 5G: Key security aspects

The key 5G security aspects can be summarized in three broad categories

1. Stringent requirements (latency, reliability & security) at high scale
2. Multi-vendor, Diversity & Complexity
3. People, Processes & Regulations

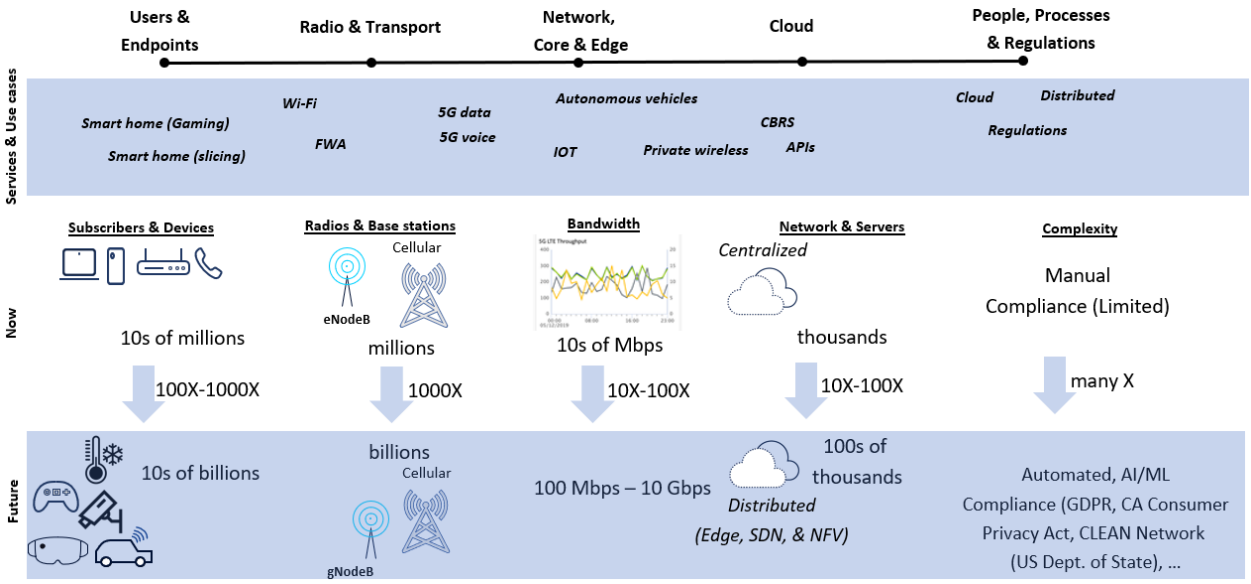

Figure 2 – Scale challenges at a glance

2.1 Stringent requirements (latency, reliability & security) at high scale

Table 1 - Speeds, Latency, Reliability requirements & Security implications

	Use-Case	DL	UL	Network Latency	Reliability	Cost Sensitivity	Security
Consumers	Mobile Broadband	100-300M	10-50M	15-25ms	Medium	Medium	Medium
	Fixed Wireless Access	1-5G	100-200M	1-20ms	High	High	Medium
	Event experience	1-100M	1-5G	1-5ms	Medium	Medium	Medium
	In-vehicle Infotainment	5-100M	1k-1M	1-20ms	Medium	Medium	Medium
Industries	Critical automation	1M	1-10M	1-5ms	Very high	Low	Very High
	Tele-operation	1M	1-10M	1-25ms	Very high	Low	Very-High
	Highly interactive AR	5-100M	1-100M	1-10ms	High	Medium	High
	Mass sensor arrays	1k-1M	1k-1M	200-500ms	Low	Very High	Medium-High

CBRS & 5G network requirements are in order(s) of magnitude higher in terms of # of UEs, # of radios, a software-based Edge, Core & Cloud network compared to prior networks (fixed or mobile). This compounded with the scale and new use cases leads to stringent security implications.

2.2 Multi-vendor, Diversity & Complexity

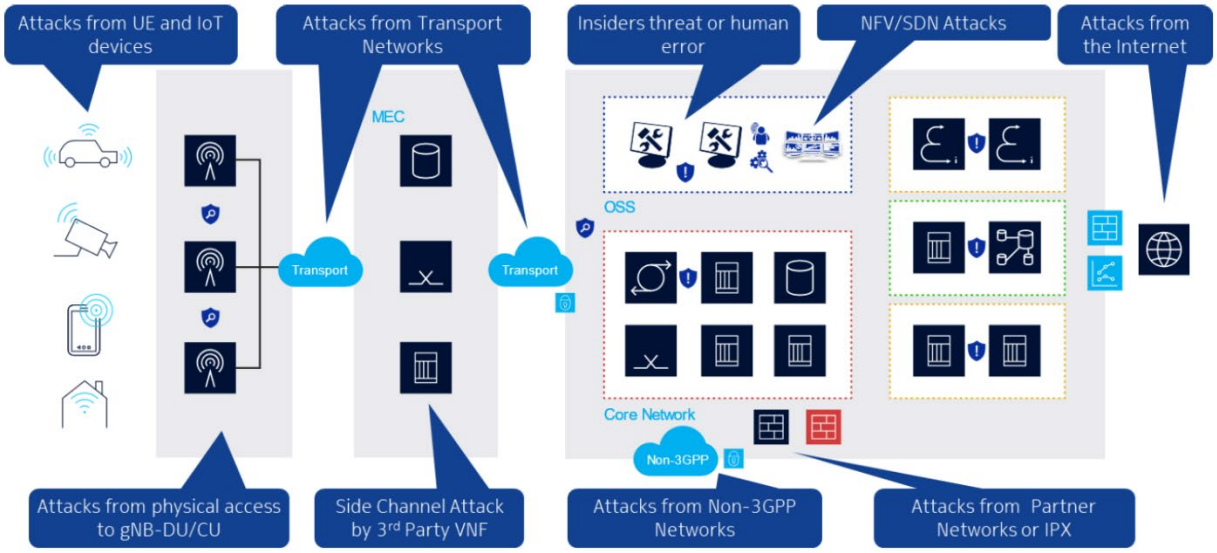

Figure 3 – Multi-vendor, diversity & complexity

Rather than having single monolithic providers controlling everything from the infrastructure up to the service layer, there are multiple stakeholders involved. The cloud, mixed edge/cloud and hybrid cloud environments have changed the notion of a perimeter. With 5G, there are many more players involved in the delivery of a service, with a much more diverse set of roles, and different understanding of risks.

Disaggregated network with lots of software solution components, new, & complex use cases (network "slicing", augmented reality, V2X, IoT & APIs).

Specific attack threat vectors for 5G networks include, but are not limited to:

- Users, Devices & Endpoints
    - Protection against eavesdropping, DOS, traffic injection, & rogue gNB attacks
    - Many times, attacks may occur without the owner of the device even being aware of it. It could be triggered by malware that has infected the device. Botnets are among the biggest threats. For example, large sets of infected devices that are controlled by an attacker and used to carry out large scale attacks, such as distributed denial of service attacks (DDoS). Such attacks can happen in 4G, too. But in 5G, we assume a different level of magnitude with higher speeds and larger device numbers. Many of them will be cheap and poorly managed IoT devices, which may easily become part of a botnet, possibly due to missing security patches, for example

- UE interaction is complex with DSDS-controlled handoff between CBRS <-> 5G (MNO) <-> 5G (MNO roaming)

- CBRS/5G Radio, Network and Transport
  - Network distribution & 5G services increasing the overall attack surface (DU, CU, (v)CMTS, OLT, IWF, MEC, Edge, Core, Cloud, IoT)
  - Transport technology is a mix of DOCSIS & PON backhaul for the CRBS radio sites where traffic will be backhauled over broadband (BB) networks to the Hub (or Headend). And the distributed user plane with IWF function at the interconnect point to the 5G Core network
  - Attacks may also derive from transport networks, as in 4G. Base stations are physically exposed, and therefore particularly endangered. That the base station may be split into a central unit (CU) and several distributed units (DU) is an infrastructure feature that is specific to 5G. In this case, it is mostly the DUs that will be physically exposed, but the network interconnecting CU and DUs is also at risk
- Edge, Cloud & Infrastructure Security

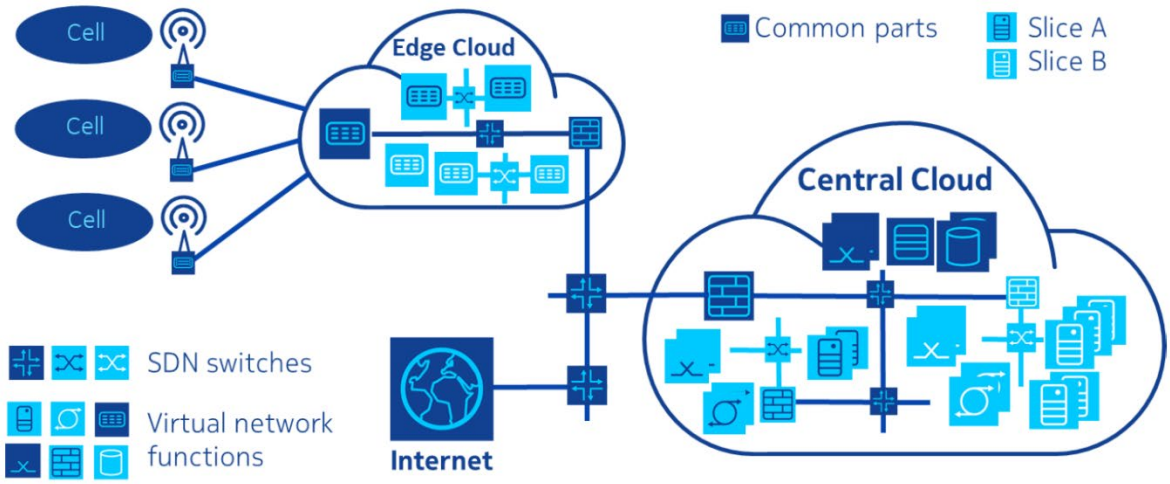

Figure 4 – Edge, cloud & infrastructure

  - 5G networks will adopt new networking paradigms. Network Function Virtualization (NFV) with both CNFs & VNFs and Software Defined Networking (SDN) will make networks much more dynamic. Cloud-centric networking is characterized by massive-scale, software-driven infrastructure and continuously shifting traffic flows, bandwidth demands, and network topologies. New attack vectors come up due to the use of Network Function Virtualization and Software Defined Networking. In particular, the sharing of infrastructure may allow so-called ‘side channel attack’. When two different applications share common hardware, for example a CPU, there is always a risk that information may leak from one application to another. Other side channels may be opened by flaws in the virtualization layer. For example, a hypervisor may have a flaw that allows one virtual machine running on said hypervisor to access the memory of another virtual machine

running on the same hypervisor. Such side channel attacks have the potential to break the isolation between different applications or slices, and they can be very subtle and hard to detect.

If only trusted software under the control of one organization (e.g. the network operator) runs in a cloud, the risk of side channel attacks may be low. However, in 5G low-latency scenarios, third party software, such as AR/VR applications, may need to be deployed on the same edge computing infrastructure as the operator software. In this case, the side channel attack threat becomes a very real one.

- Scale
  - Discrete physical devices replaced by multiple VNFs & CNFs
  - Number of network entities under configuration management increasing dramatically
  - Expansion in the # of VNFs, CNFs & NEs requiring authenticated communications
  - Dramatic increase in volume of security information & alerts generated across the 5G network
  - Dramatic increase in the number & type of user accesses to the 5G virtualized infrastructure
  - Large increase in the amount & type of logs & data generated across the distributed network

- New, complex use cases (network “slicing”, IoT & APIs)
  - Given that more and more parts of the overall solution are accomplished in software and the "web speed" need for CI/CD, means even more attack vectors. Security must be designed in.

2.3 People, Processes & Regulations

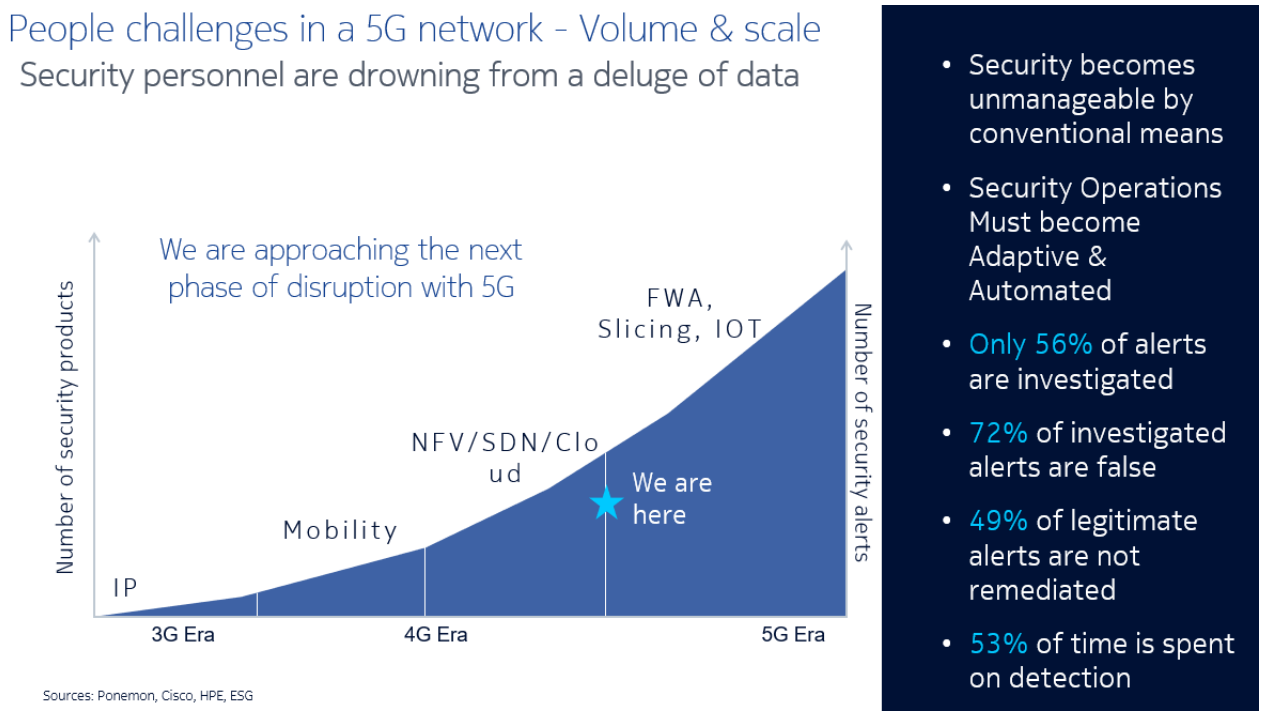

Figure 5 – People, processes & regulations

There is always the threat of security breaches by human errors or by malicious insiders. This is so in all networks, but considering mission critical 5G services, the impact of insider attacks may be even more devastating than in earlier mobile network generations.

- 65% of cyberattacks exploit configuration-related vulnerabilities
- 62% of causes of downtime are configuration errors (user error)

As the security threat landscape of mobile network is evolving very fast, it creates a lot of concerns on industries and governments and drives need to impose stricter security regulation on critical information infrastructures (CII) including mobile networks.

Many countries have passed cybersecurity or privacy laws which have important implications on the design, implementation, and operation of mobile networks. Examples include:

- EU issued a report on 5G risk assessment in Q3 2019 which identifies the main threats and threat actors, the most sensitive assets, the main vulnerabilities, and strategic risks Mitigating measures will be announced end 2019 to address the identified cybersecurity risks at national and union level
- General Data Protection Regulation (GDPR) in EU is passed in April 2016 and implemented in May 2018. GDPR has global significance as it governs not only EU companies but also all companies that process EU resident's data

- In France, law has been issued in August 2019 to preserve the interests of defense and national security in connection with the operation of mobile radio networks (5G and further) It modifies the Posts and Electronic Communications Code to introduce an authorization request for the operation of radio network equipment (BTS and core).
- China Internet Security Law enacted in November 2016 and in force in June 2017.
- Canada's Personal Information and Electronic Documents Act (PIPEDA)
- In USA, if government project is involved, contractors need to comply with Federal Information Security Management Act (FISMA) and National Institute of Standards and Technology (NIST) requirement FIPS 200 and SP 800-53
- California Consumer Privacy Act (CCPA)
- Clean Network (US Department of State) and many others

Finally, there is a geo-political and nationalistic aspect to 5G, and supply-chain provenance must be evaluated in depth.

Before 5G, mobile network was primarily focusing on voice and internet services. Moving toward 5G, mobile network operators will unavoidably get into other business segments such as banking, energy, healthcare, public safety or even military. Network operators must be ready to comply with all industry specific and government regulatory security requirements.

3 5G Security Framework

3.1 Vision

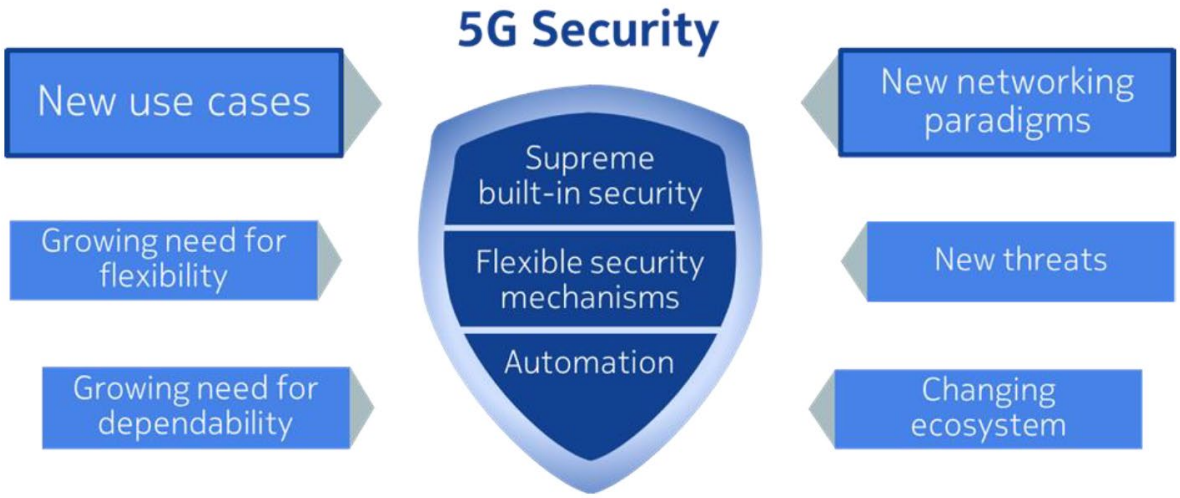

Figure 6 – 5G Security framework

Mobile networks are moving into a post-perimeter world where the network boundaries have disappeared, and the difference between insiders and outsiders has been eradicated. Given this situation there is pressing need to gain total visibility and intelligence on what is happening within service provider infrastructures, services, applications, data and people, to detect security breaches and respond to them.

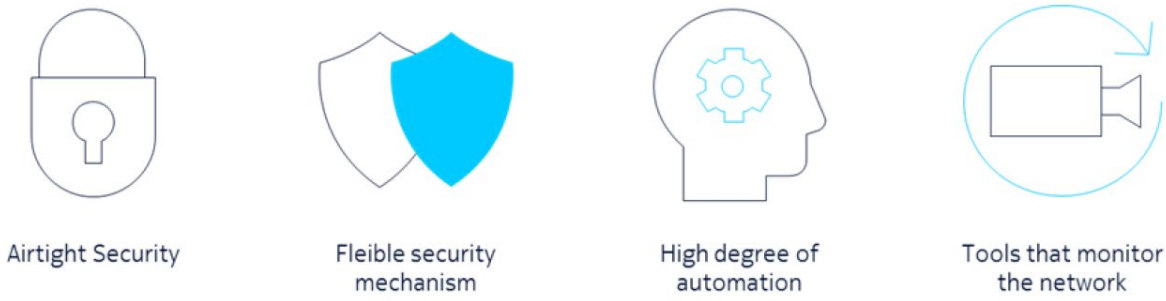

Figure 7 – 5G Security vision

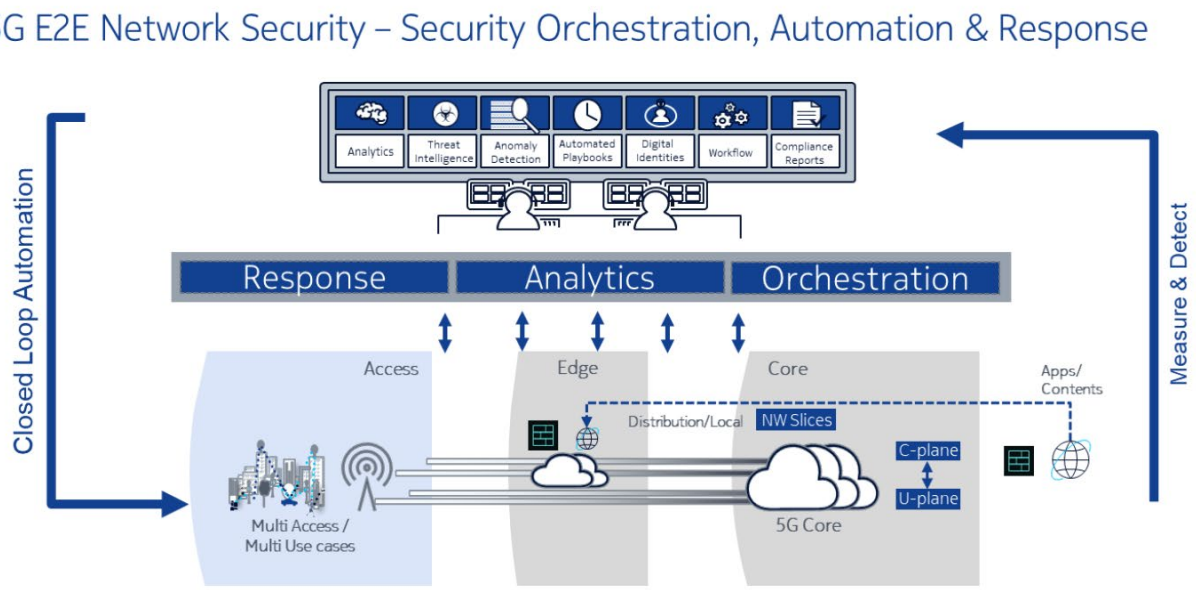

Figure 8 - SOAR

A Security Orchestration, Automation & Response (SOAR) strategy provides a centralized security command-and-control structure to protect the network from the most advanced persistent attack with the fusion of threat intelligence, analytics, machine learning & automated response.

Security must limit attack vectors, detect all threats when they do occur and respond faster to eliminate time between detection and mitigation.

Some of the key themes include:

- Constantly measure your security posture and risk levels. This is more than compliance auditing, but rather an ongoing near real time assessment of your network security posture. To do this effectively requires automated software security systems
- Control and limit access to key operational systems and assets. In addition to perimeter security defenses, this includes access governance and management
- Detecting threats earlier in the kill chain requires an ability to perform multi-dimensional analytics across a variety of systems and resources in order to identify threats that may be otherwise missed. The goal is to identify anomalies from normal behavior, and this is where data analytics and machine learning (ML) for security are emerging. Analytics and machine learning (ML) are needed to spot indicators of compromise, proactively identify harmful actors, help security analysts prioritize risk and initiates the appropriate rapid response

Rapid response is key to minimize the impact of cyber-attacks. The time between detection and mitigation needs to be eliminated. One of the big challenges security teams face is the inability to keep pace with the diversity and velocity of threats.

Combined with a global cyber skillset shortage, traditional incident response strategies rely on too many manual processes performed by limited security expert resources. This is where security process automation or orchestration plays a key role.

Adaptive security is about transforming security operations to be predictive & automated by using machine learning and multi-dimensional analytics and threat intelligence in order to drive rapid, automated, and predictive responses to threats.

3.2 Security Orchestration Analytics and Response (SOAR)

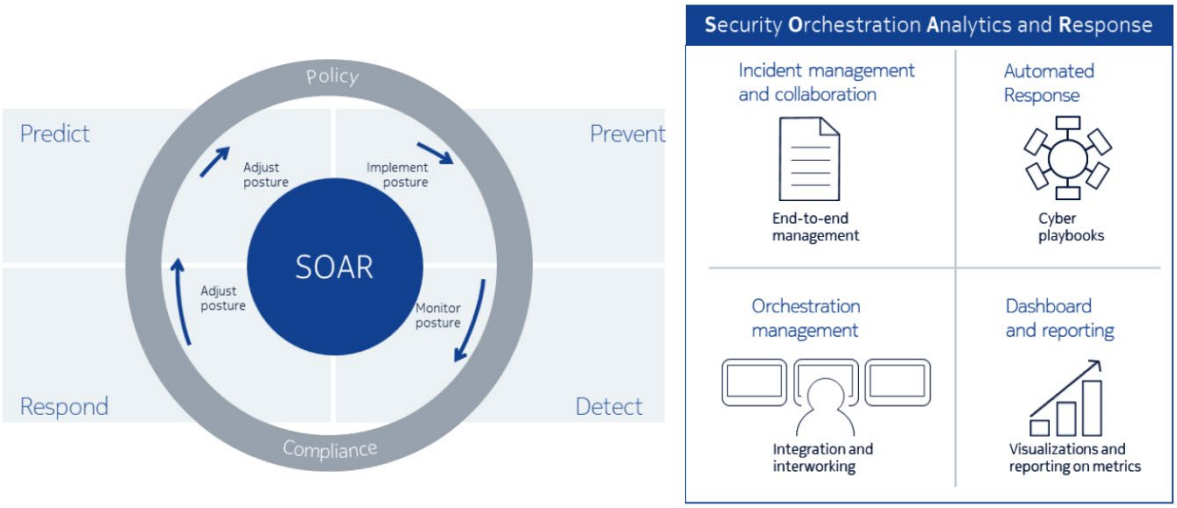

Figure 9 – SOAR in action

An "optimized" state cannot be achieved using conventional approaches to security operations. The priority for any digital strategy is to build an adaptive security architecture that automates security driven by intelligence and analytics.

These are the basic principles of Security Orchestration, Analytics and Response (SOAR): using security analytics in order to drive an orchestrated automated response.

SOAR systems aggregate, correlate, and analyze data from disparate point tools into cohesive and enriched security intelligence with business-specific context.

By analyzing user behavior to identify bad actors and providing threat indicators to potential insider threats. These capabilities help security professionals prioritize risks and automate security operations activities in the context of the attack surface and business and improves alert management by correlating and consolidating alerts from existing systems.

Security operations workflow automation and orchestration are at the heart of the transition from static defense to agile and adaptive response. Security automation involves more than just operations; it must be aware of and encode business processes, regulations, and customer-specific policies. Automation is the

process executing repeatable actions without human intervention while orchestration is the concept chaining these automated tasks into executed playbooks to perform workflows to accelerate both investigation and mitigation.

3.3 5G Security Architecture

3.3.1 Defense in Depth

Below is how the 5G architecture is depicted by 3GPP in its Technical Specification TS 23.501.

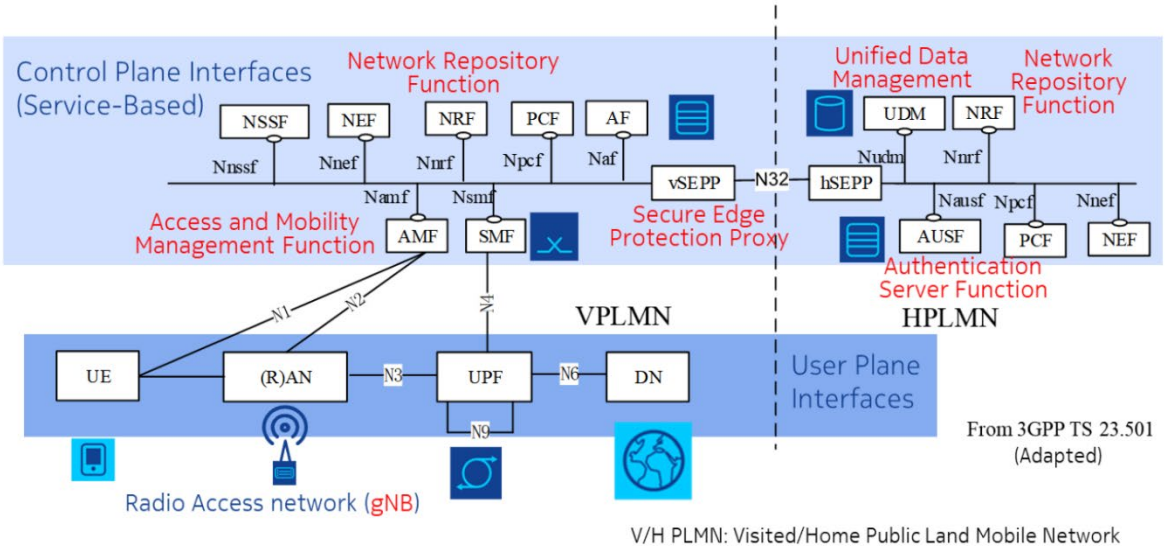

Figure 10 – 3GPP specifications

The basic concept of 5G Mobile Network Security is known as “Defense in Depth”. This describes multiple layers of overlapping security measures protecting the valuable assets, preventing from potential attack, and causing impact to the important asset of the network.

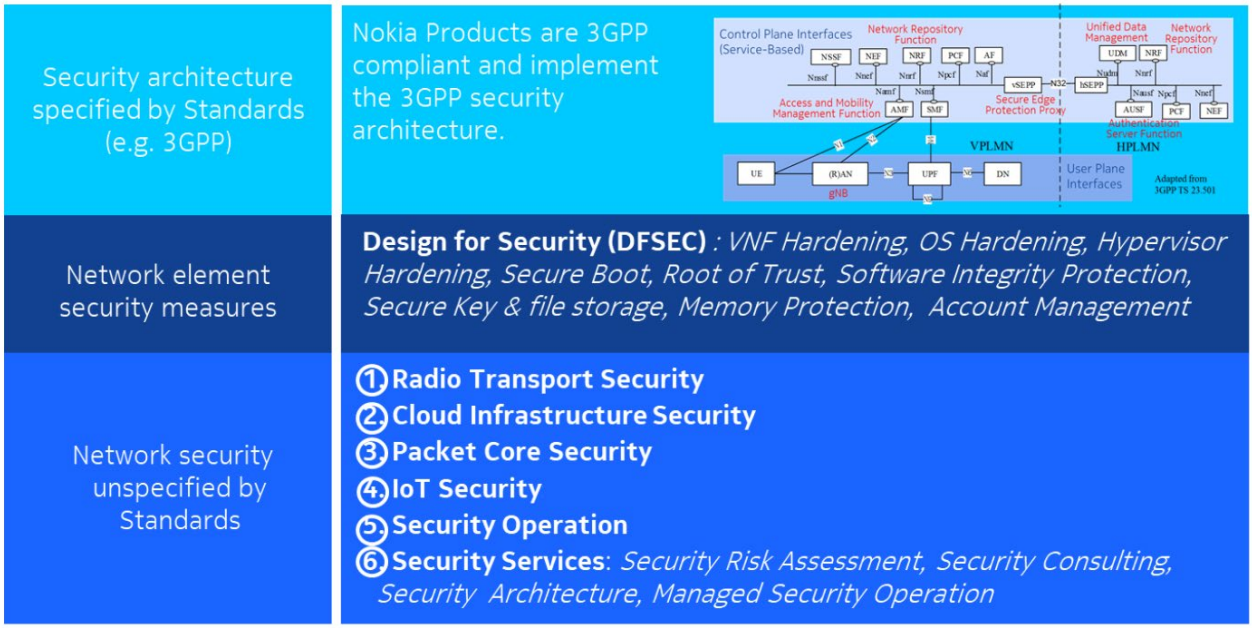

Figure 11 – Defense in Depth

The 1st layer is the 3GPP specified security architecture. Security features are implemented in most 5G solutions and products, supporting 3GPP-recommended security architecture.

The 2nd layer is the hardening of the Virtual Network Function & cloud infrastructure and is vendor and network dependent. Vendors require well-defined security management processes built into their Design & Development. This ensures all products in the portfolio are implementing a baseline set of security features and hardening according to best practice within the industry. Examples include secure key and file storage, secure boot, root-of-trust, account management, and Software Integrity Protection.

The 3rd layer is also vendor and operator dependent. Vendors must identify gaps that are not covered by 3GPP and standard VNF & CNF hardening steps and fill the gaps by offering comprehensive security solutions and services.

The diagram below illustrates the essential elements of a security architecture for a 5G network implemented on distributed service provider networks:

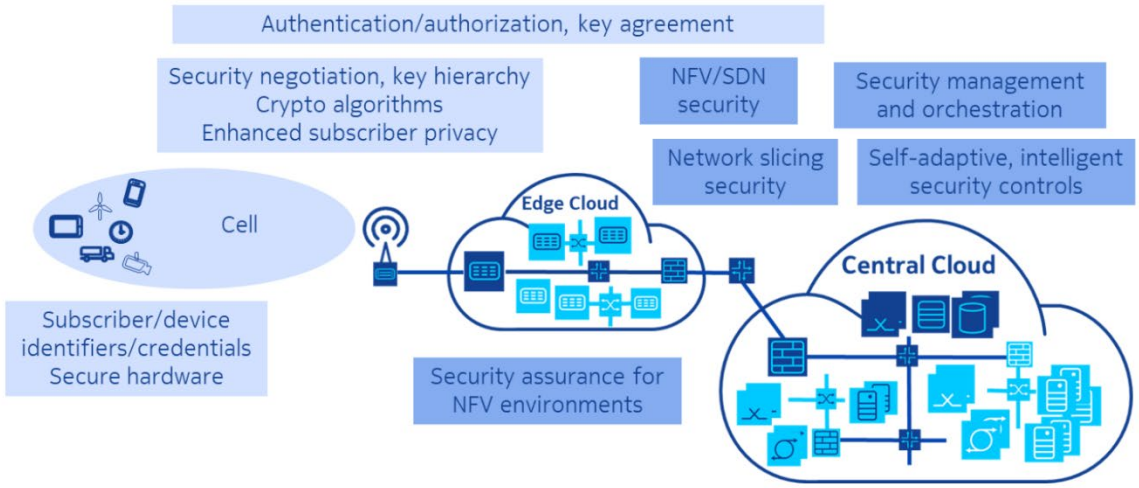

Figure 12 – Edge, infrastructure & cloud security

The key security areas are split into Radio Transport Security, Network & Packet Core Security, Cloud Infrastructure Security, Network Slicing Security, Security Operations, Design for Security (DFSEC) and last but not the least are the security professional services which help operators to understand their existing security risks, to design, implement and operate their network the most secure way.

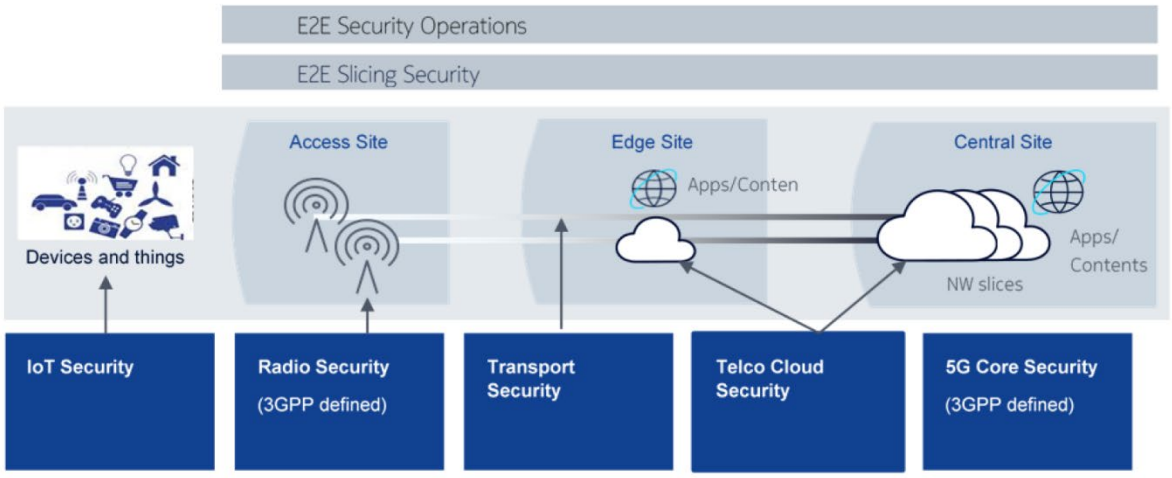

Figure 13 – 5G security overview

3.4 Key defense building blocks

Defense is the deployment of security controls in layers to eliminate or mitigate against threats. Defense includes:

- Layered protections – security layers complement one another, such that what one layer misses, another layer will catch
- Defense in multiple places – security defenses are pervasively located in different places within the network
- Defense through diversification – when possible, using different security controls will limit the effect that a fault or a vulnerability in one part of the network will have on the rest of network

3.4.1 Identity

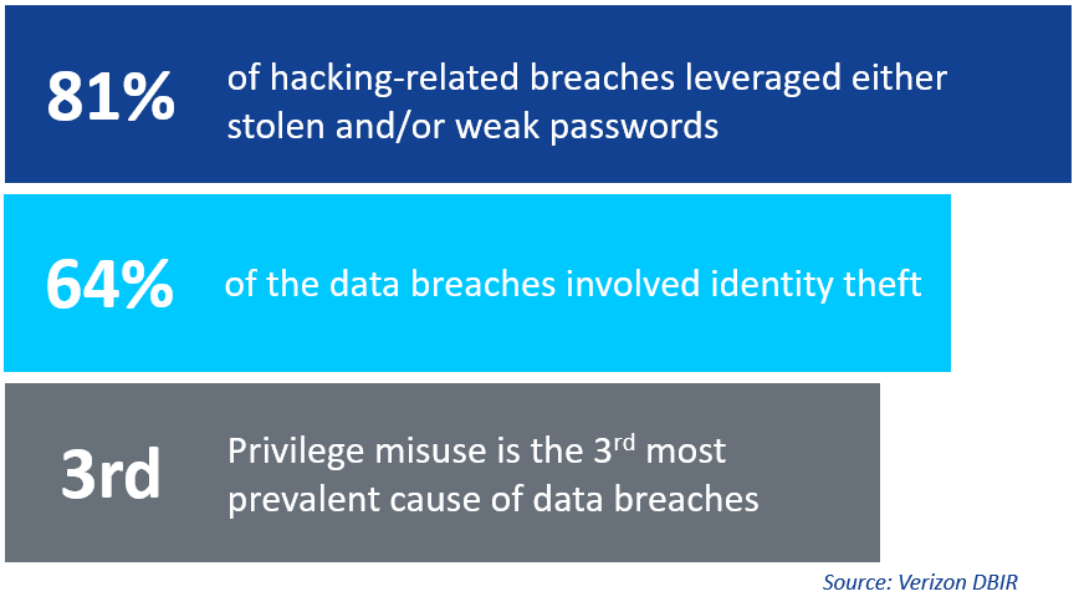

Figure 14 - Identity

Identity is the basis of any sound defensive posture. One must know who a threat is (and who isn't) with certainty, quickly and robustly at scale.

Two primary functions required to maintain identity in the end-to-end network:

- Certificate issuance
- Certificate deployment & Lifecycle Management

These tasks are performed by a Certificate Authority (CA) which must be:

- Centralized

- Issues certificates to NFs for NF-NF mutual authentication
- Certificates enable TLS and IPSec for secure NF-NF communications
- Highly scalable – support millions of certificates

3.4.2 Abstraction (or Zoning)

Abstraction is the classification of objects into security classes or groups and assigning security controls, rights, permissions and privileges to these classes or groups. An object in a 5G network could be any network element, application, device or asset which is part of the infrastructure providing the mobile service.

The classification of objects in mobile operator networks should be made based on their criticality to the business and their level of exposure to external threats.

Examples of abstraction in a mobile operator network include division of the network into security zones and the assigning of security controls to mitigate threats specific to each zone. Abstraction also involves the methods used to control how access to different domains of the network is controlled for administrators and network operations personnel, along with controls which are applied to ensure security of the network element configurations.

3.4.3 Zero Trust

As 5G networks are being exposed to a large array of threats, classification of objects based on a "Zero Trust" concept is required.

In response to the NIST RFI for Developing a Framework to Improve Critical Infrastructure Cybersecurity (RFI # 130208119-3119-01), Forrester Research introduced the security concept of "Zero Trust"

For years in information security most security concepts were designed based on a model of a "hard shell and soft core". Alternatively called the "castles-and-moat" framework. This model is based on threats always coming from outside the network, requiring a "hard shell", while permitting loose controls on the inside of the network "soft core", where free access to systems is generally employed. This concept has become outdated for many reasons, including:

- The distributed & hybrid nature of the network with edge, core & cloud locations
- The model does not consider or expect internal threats, where "trust" is implicitly granted. However, the reality of the last few years is that internal threats are a significant attack vector into networks, including not only malicious employees, but also human error and identity spoofing. Once in the internal network, the attacker has a free reign to penetrate other systems with almost no risk of detection. And the attacker can stay in the network for extended periods of time, sometime even years
- The model does not account for machine-to-machine/IoT communication, as well as complex automation processes, which cannot be trusted by default just because they are "internal"

The Zero Trust model is straightforward:

- Zero Trust implies that there is no such thing as a pre-granted trust status – nothing and no one is trusted – not even inside your network. This applies to everything in the network including

traffic, machines, devices, and people. Zero Trust mandates that since nothing is trusted, controls must be implemented on a per service per request level to protect the business. This is unlike a host or IP-based security mechanism where trust is wholesaled to anyone with a hostname/IP and thus to any application running on that device.

Zero Trust requires that security professionals protect internal data from insider abuse in the same manner they protect external data on the public Internet, following three main principles:

1. All resources must be accessed securely, regardless of their location (logical or physical) in the network
2. Access control and least privileges are key security mechanisms to employ across the entire network
3. The security framework for the network is built based on all available "if-then" scenarios. Logs are gathered, making sure all traffic is inspected, to cover future "what-if" scenarios

Zero Trust also means that security controls are not built on top of each other, but rather controls are built from the inside out, starting with each system and network element, and using that as the basis for building security across the complete network.

3.4.4 Data Hiding

Data hiding is the concept of revealing to any subject only the minimum level of information the subject requires to perform their task. System hardening standards must also be employed to ensure that only the required minimal number of services for a specific implementation are running, thereby reducing the attack vector open to malicious traffic, and minimizing the potential for widespread disruption of service.

3.4.5 Encryption

Information in a mobile operator's network is a combination of data in transit, as well as data at rest. Some of this data is sensitive subscriber data, while other data is critical information needed to configure and manage the network. To protect against attack vectors attempting to exploit this data, encryption is used to control sensitive and critical information while the information is traversing the network (in-transit) or is stored (at rest).

3.5 UEs, Radio & Transport Security

In every mobile network, there is a radio interface. This interface is inherently exposed to attacks and must therefore be secured carefully. Traffic over the radio interface is already encrypted as publicly known, but radio air interface security must go beyond encryption.

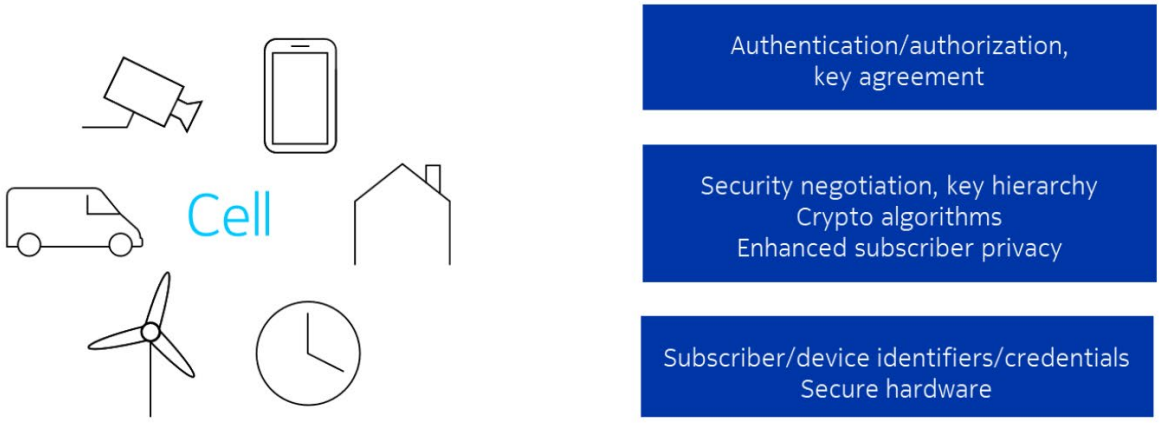

Figure 15 – UE security & privacy protection

First, UEs (mobiles) must be authenticated and authorized to use the network or specific services. The authentication relies on means to identify subscribers or devices, and on credentials that should be stored on the devices securely, making use of specific secure hardware, such as the SIM card. The SIM card is technically called UICC, or Universal Integrated Circuit Card, on which a USIM (Universal Subscriber Identity Module) is implemented. During authentication, a key is agreed upon, from which a hierarchy of session keys is derived to secure the subsequent communication. How security is applied must be negotiated, for example, determining which type of traffic will be secured and by which crypto algorithms this will be achieved.

“Enhanced subscriber privacy” refers to the fact that in earlier network generations, an attacker can trick mobiles into revealing the true identity of the subscription, a practice known as “IMSI catching”, one that is applied not only by attackers but also by law enforcement. In this mechanism, the subscription identifier is never passed in the clear over the air but encrypted. Protection against this kind of attack is considered a requirement for 5G. All falls under the scope of 3GPP.

The attacks on the confidentiality and integrity of the traffic can be mitigated by state-of-the-art cryptography. This has been standardized by 3GPP for many interfaces.

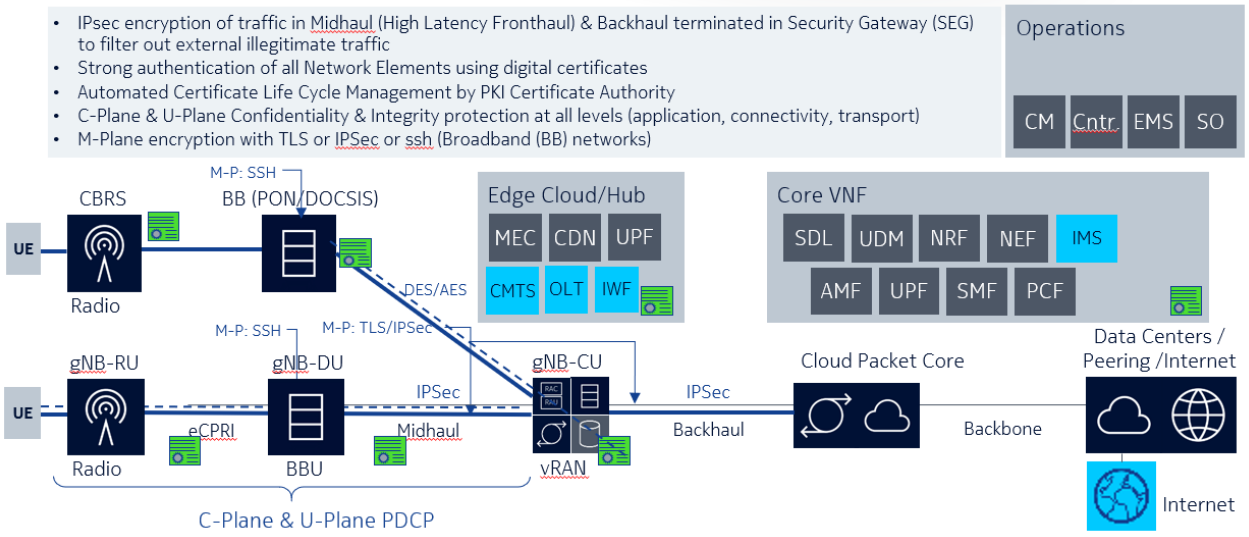

Figure 16 – UE, radio & transport security

Next-generation Node B (gNB), especially CBRS radios, gNB-CU & gNB-DU are located in unsecured locations. Hackers can easily attack the core network from any unsecured DU or CU through the transport network interface. In order to protect the edge cloud and cloud core data centers from illegitimate traffic, the best practice, as recommended by 3GPP, is to encrypt the traffic between gNBs and the core network using IPSec. The concept to encrypt all traffic from DU or CU is not only to ensure confidentiality and privacy of user traffic but more important to ensure all traffic entering the core network is not tainted by hackers in any way. The 3GPP recommendation to filter out unwanted traffic is to encrypt the legitimate traffic with IPSec and authenticate with asymmetrical keys using with Public Key Infrastructure (PKI).

Key solution components for this include:

- Security Gateway (SeGW) devices with GTP firewall and IPsec capabilities
- the centralized security gateway management system and
- PKI, or Public Key Infrastructure. Public Key Infrastructure consists of the Certificate Manager, which is served as the PKI certificate authority. A strong authentication of gNBs is provided with PKI certificates
- Automated Certificate Life Cycle Management is also required to be provided by the Certificate Manager/Authority

3.6 Network & Packet Core Security

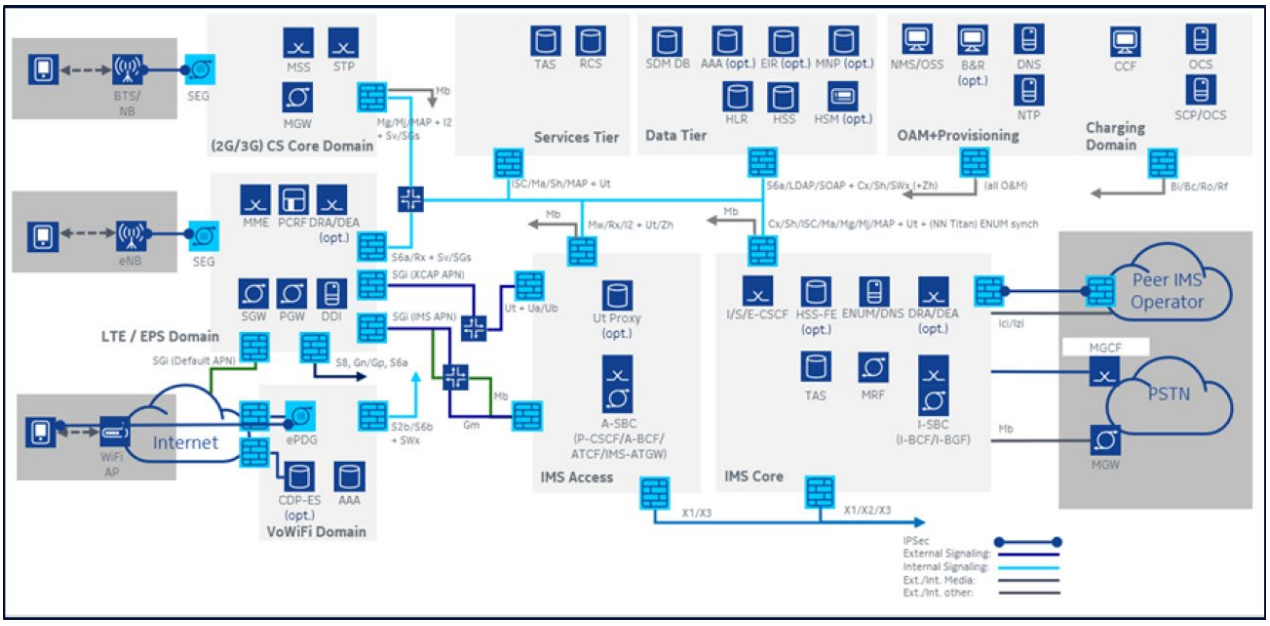

Figure 17 – Network & Packet Core security

A comprehensive security architecture meeting stringent data and roaming security standards includes:

• E2E traffic separation and zoning are mandatory to isolate high exposure equipment from high value assets. In case one security zone is compromised, the exposure can be easily contained before the high value asset is also compromised. Security Zone must be implemented from the beginning or retrofit will be difficult and costly

• Virtualized security appliances provide isolations between security zones or domains

• GTP, SCTP firewall to protect the eNB or gNB interface from radio access network

• Diameter firewall is required to protect the DIAMETER roaming interface

• Physical or virtualized firewall with Intrusion Detection System and Intrusion Protection System (IDS/IPS) is required at DN or SGi interface to internet

• Secure DNS to protect against infiltration of network via DNS

• Protect network from DDoS volumetric attacks

3.7 Cloud Infrastructure, NFV & SDN Security

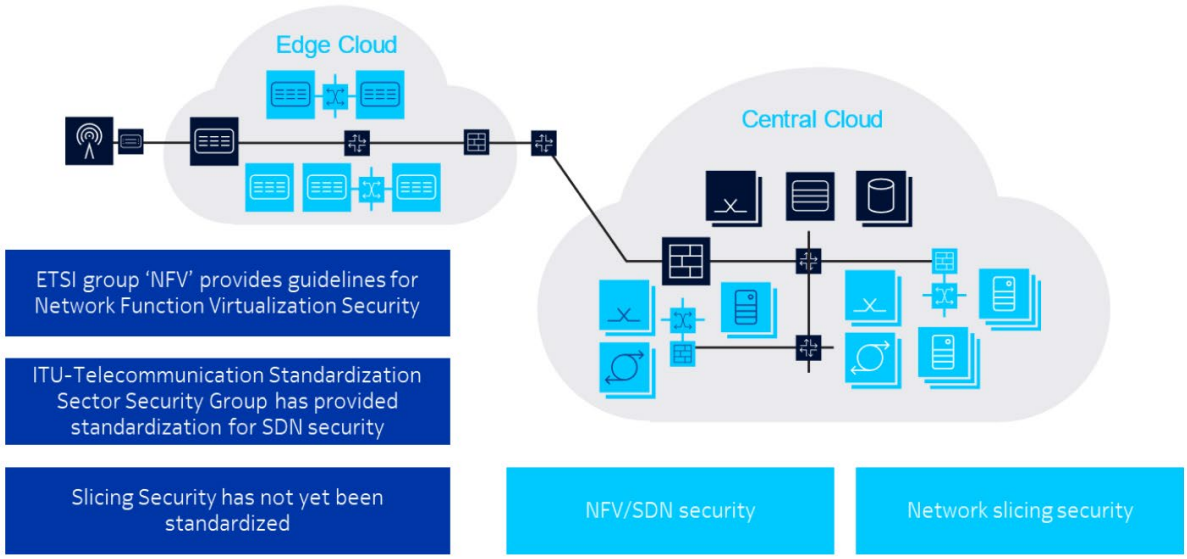

Figure 18 – Cloud, NFV & SDN security

Cloud infrastructure using NFV and SDN technology is crucial in 5G as it enables the flexibility and the elasticity needed for the diverse use cases.

All 5G networks adopt the new networking paradigms Network Function Virtualization and Software Defined Networking, as well as supporting slicing. In this section, we do not cover specific NFV and SDN security measures but only the threat of side channel attacks in NFV environments.

One can conclude that it is important to design and implement the shared cloud platform with a high degree of care, in a way that keeps the residual, exploitable vulnerabilities to a minimum, whilst still being prepared to patch the system quickly, in case one of these residual vulnerabilities are detected. SDN and NFV security are not specified by 3GPP. It is the security group of ETSI that provides guidelines and recommendations for Network Function Virtualization security.

To secure a network implemented in an NFV environment, the following security measures are recommended:

• Secure implementations of the virtualization layer and the overall cloud platform software. The focus here is about implementing a robust hypervisor and good isolation of traffic data. Examples include:

- Root of Trust: software integrity protection, secure boot, & vendor certificate
- Security hardening including zoning, segmentation & traffic filtering
- Security management: Certificate management, malware protection, identity management, & image signing
- Security orchestration: automation of security policies, breach remediation, monitoring & API security
- Robust security implementation of the VNFs & CNFs

- Good logical separation of VNFs provided by the virtualization layer. It is possible to have a physical separation of VNFs, but this comes at a cost and less flexibility
- Traffic separation by dedicated virtual switches, VLANs and wide-area VPNs
- Perimeter security and network internal traffic filtering by virtual firewalls
- Logically or even physically separated security zones
- Secure operation and maintenance, secure operation of IP services (e.g. DNS)
- Cryptographic protection of traffic and of data on storage

To ensure the SDN is secure, the SDN controller must be secured. Implement important measures, such as:

- Cryptographic protection
- Authentication and authorization
- Robust implementation of overload control

Microservices architecture introduces different requirements around how applications are developed, deployed, and managed across their lifecycle. It presents new attack vectors – need to be concerned with the fact that containers share a common kernel. Keeping malicious container applications from exploiting kernel and container security holes is a top concern.

All CNF (Container Network Functions) owners must run security audits and security scans on all container images which are produced. The audits must include:

Container provided default security mechanisms e.g. process restrictions, file & device restrictions, sandboxing using Linux namespaces, & Linux kernel hardening

Image provenance: Check if images and packages inside images are up-to-date and are free of security vulnerabilities

Namespace quotas

Application separation by namespaces or clustering or zoning (Kubernetes provided)

- Audit automatization, we must be able to automatize all checks. That will save precious time and one can run it as often as one requires. Manual audit is not an option unless one is just testing or learning
- Container links and volumes. If you use read-only filesystem in your running container “docker diff” can help you to find issues
- The bigger an image is, the harder the audit will be. Reduce the size of your images as much as you can
- The host kernel is the shared point between all containers in the same server, keep that kernel up-to-date

3.8 Self-adaptive security management and orchestration

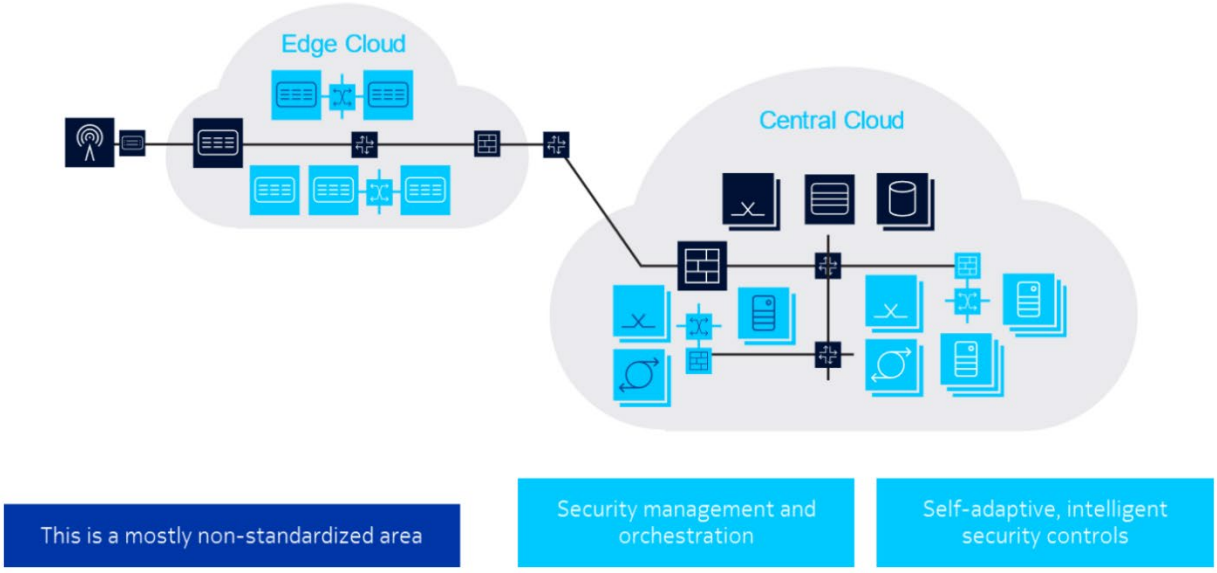

Figure 19 – Security management & Orchestration

There are two key parts of the 5G security architecture Security Management and Orchestration, and what is known as “self-adaptive, intelligent security controls”, which describes tools that monitor the network pervasively, analyze the information gained to detect anomalies and attacks, and trigger suitable countermeasures, with as little need for human interaction as possible. Again, this is an area that is mostly non-standard.

3.9 Network Slicing Security

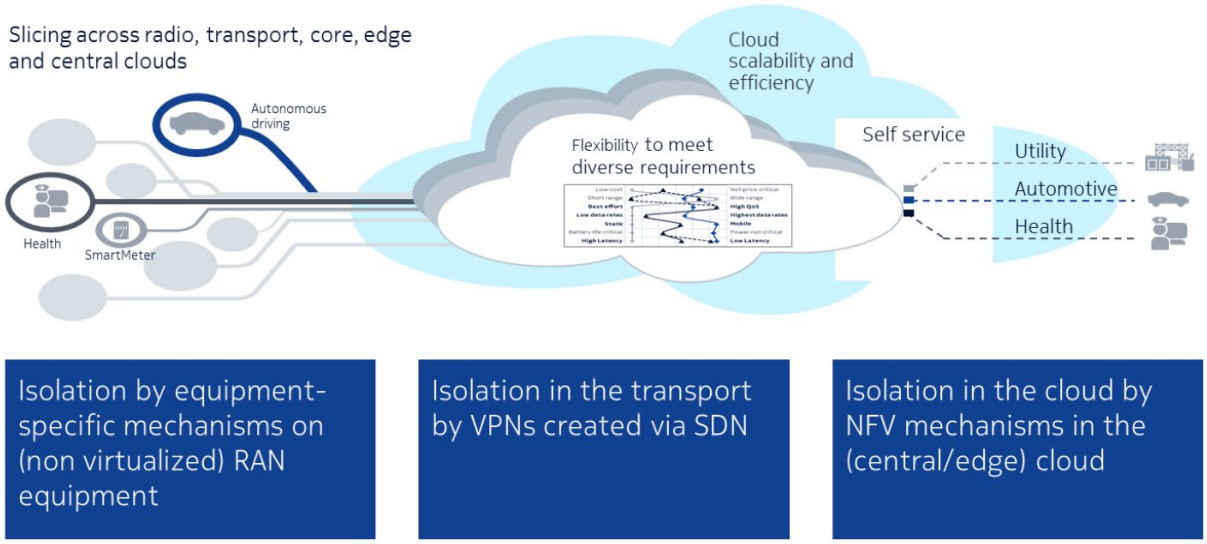

Figure 20 – Network slicing security

The crucial aspect in slicing security is slice isolation. Isolation has two angles:

- Availability: resources dedicated to one slice cannot be consumed by another slice
- Confidentiality: data/traffic cannot be intercepted/faked by entities of another slice

Network Slice Isolation = Resource Isolation + Security Isolation

Isolation will confine any effects of a potential cyber-attack to a single network slice. It is obvious that perfect isolation is required in a multi-tenant setup, where tenants may be competing organizations, such as different manufacturers running each running its own industrial automation slice.

As mentioned earlier, 5G security must be flexible. Instead of a one-size-fits-all approach, the security setup must optimally support each application. In a sliced network, this can be achieved by customizing the security setup per slice. Security features subject to this flexibility may comprise the mechanisms for identifying and authenticating mobile devices and/or their subscriptions, or for determining the way that user traffic is protected. For example, some applications may rely on security mechanisms offered by the network. These applications may require not only encryption, as in LTE, but also user plane integrity protection. However, other applications may use end-to-end security on the application layer. They may opt out of network-terminated, user-plane security because it does not provide additional security in this case (but rather increases the energy consumption of mobile devices).

Below are recommendations for network slicing security:

1. Better isolation if less components are shared

No side channel attacks if computer hardware and hypervisor are not shared

Tradeoff between resource usage efficiency and degree of isolation

Sharing increases the resource usage efficiency but potentially lowers the isolation

In a big central data center, there may be abundant physical resources, so some physical resources may be dedicated exclusively to one application, e.g. the UDM or a network management system. In small (far) edge cloud deployments, it may not be possible to set aside part of the physical resources for a single application only

2. Cloud Infrastructure security is mandatory. Cloud infrastructure must be carefully designed, implemented, and hardened to minimize vulnerability and side channel attack

3. Secure, trusted parties operating the shared parts are required

In most cases, a mobile network operator MNO may be considered a trusted party by its customers. There can also be use cases where the tenant cannot afford to rely on the security provided by an MNO, but needs to establish its own security mechanisms, including the use of tenant-owned infrastructure (for sensitive data, e.g. subscription data), where the MNO has no access at all

If untrusted parties need to deploy their application in a shared infrastructure, for example, online game vendor may want to install their gaming software in the Mobile Edge Compute (MEC) platform in order to reduce network latency, it is suggested operators must have a well-defined onboarding process to ensure the 3rd party software is fully tested and validated in a sandbox environment before deployment

4. Security automation & orchestration is needed to cope with dynamic nature of slicing. Security management and orchestration must be aware of slicing, same for the reactive security controls. Some security tools may only run within one slice, not aware of other slices, but there must be others that have the complete network view

3.10 Design for Security (DFSEC)

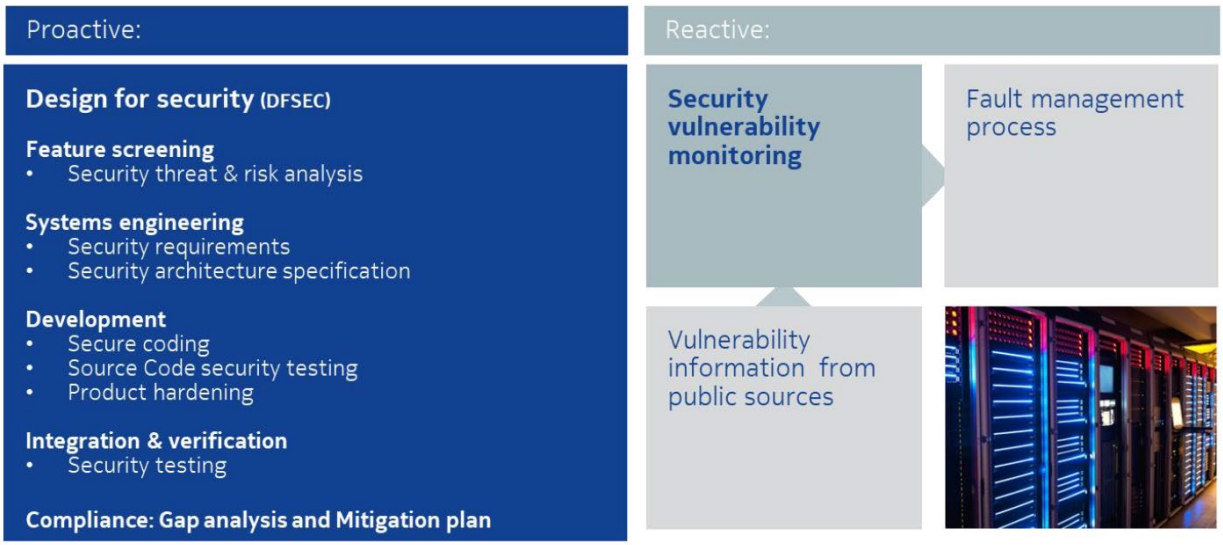

Figure 21 – Design for Security (DFSEC)

The vendor community recognizes that product security is not limited to security functions and protocols implemented in the product itself. Product security is strengthened and augmented by information security, incident response/vulnerability management and independent checks and audits.

Vendors must be capable to comply with legal and regulatory requirements around the world. And implement a security management processes and contractual security requirements for their internal teams and suppliers. Privacy by design is a part of Design for Security (DFSEC). Data privacy modelling and security features must be inbuilt to protect sensitive and private customer information in their products and ensure that product design complies with applicable regulatory requirements such as GDPR.

DFSEC is based on standards, industry best practices and customer requirements. Vendors' processes must be aligned with global security assurance frameworks from 3GPP (GSMA NESAS), TL9000 etc. Products must undergo customer acceptance tests, and security is a part of this testing. Below is a list of industry standards that must be employed in different phases of the Design & Development process.

Table 2 – DFSEC requirements

DFSEC Phase	Standard Compliancy
DFSEC	• SSE-CMM (SSE-CMM)
Threat / Risk Analysis	• ISO/IEC 27001 • 3GPP TS 21.133 Security Threats and Requirements • ITU-T X.805 (threat categories) • Guidance on the Privacy and Electronic Communications (EC Directive) Regulations 2003 Part 2
Security Requirements	• ISO/IEC 27001 • ISO/IEC 17799
Security Architecture	• ITU-T X.805
Secure Coding	• MISRA C
Security Testing	• NIST-1 (2003). NIST Guideline for Network Security Testing.
Security Auditing	• Common Criteria, Common evaluation methodology
	• ISO/IEC 19011 Guidelines for quality and/or environmental management system auditing.

Vendors must have a Design for Security (DFSEC) process embedded in the product development lifecycle and applies security requirements and security architecture at the beginning of the lifecycle, shifting the product security process from being reactive to proactive. DFSEC covers all the product development phases from feature screening, systems design, software development, integration, to verification processes.

Security is never a one-time effort. Every modification makes it possible for software bugs and security vulnerabilities to emerge. Therefore, security development must be process-oriented. Every release will undergo same threat & risk assessment, security checks, tests etc.

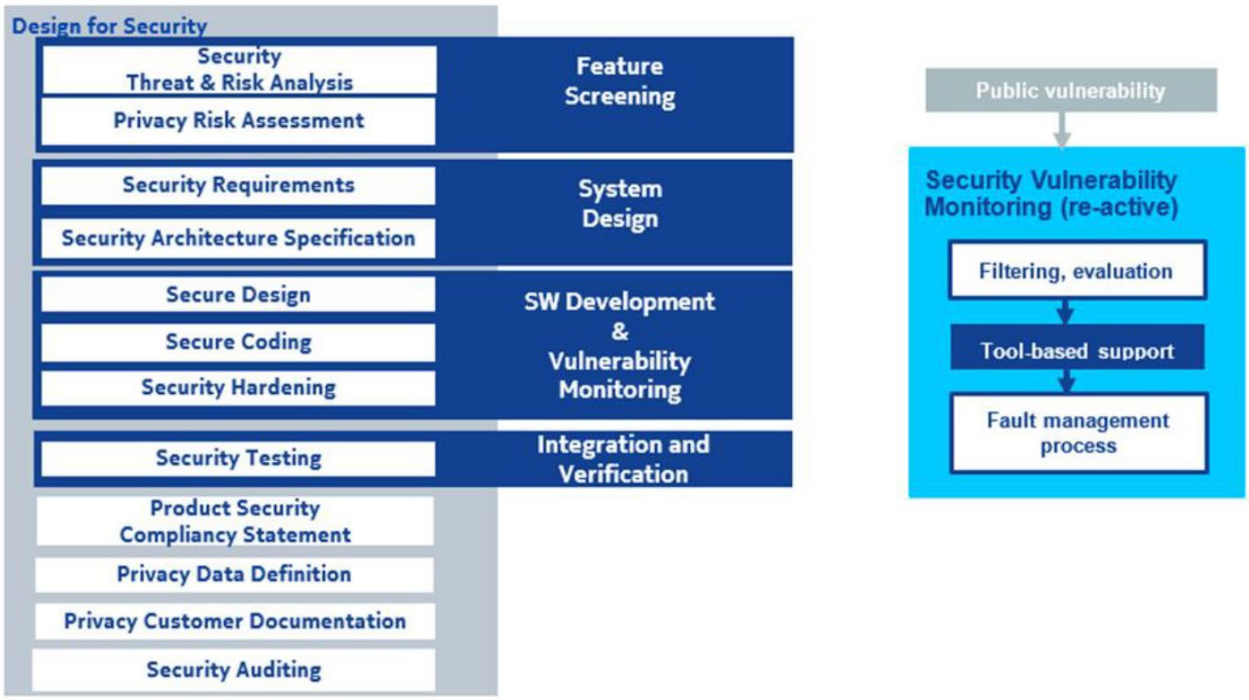

Figure 22 – DFSEC in action

Independent audits give customers further confidence in security promises and helps vendors identify areas where they can improve to meet the latest threats. Vendor must conduct third-party vulnerability scanning and penetration testing for their product samples. And ensure that operations support centers are certified to ISO 27001 standards.

3.11 Security Operations

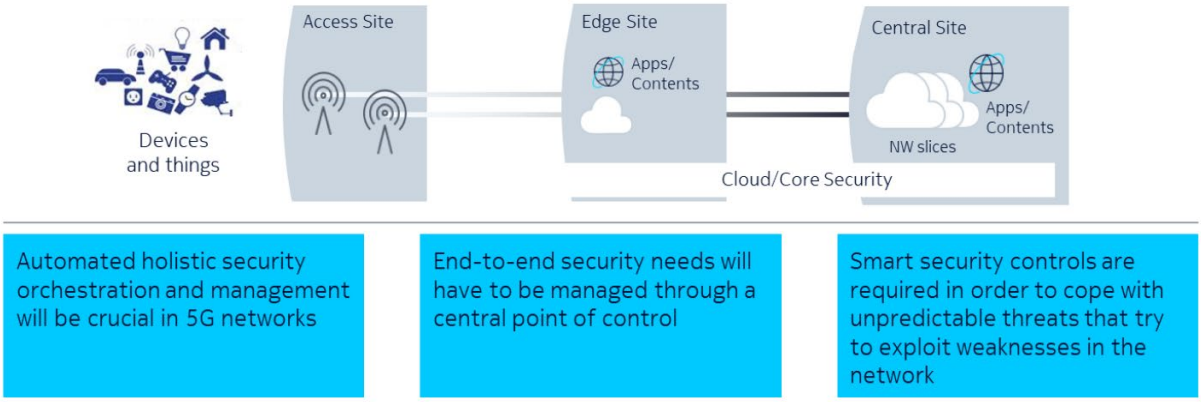

Figure 23 – Security Operations

Today, security professionals monitoring service provider and critical infrastructure networks often get thousands of cyber security alerts each day. Many are false alerts and duplicates. Yet, the sheer number of alerts can overwhelm a company's security team, resulting in incidents that are not investigated. For example, the "2018 Ponemon Security study" found that on average, 44 percent of alerts are not investigated, and of those investigated and deemed legitimate, nearly half (49 percent) go un-remediated. Teams need better ways to automatically prioritize alerts that allows them to focus on the most severe ones first. It is not an option to stay with the manually-intensive approach in the 5G era and must be migrated to an automated approach supported by artificial intelligence, data analytics and machine learning.

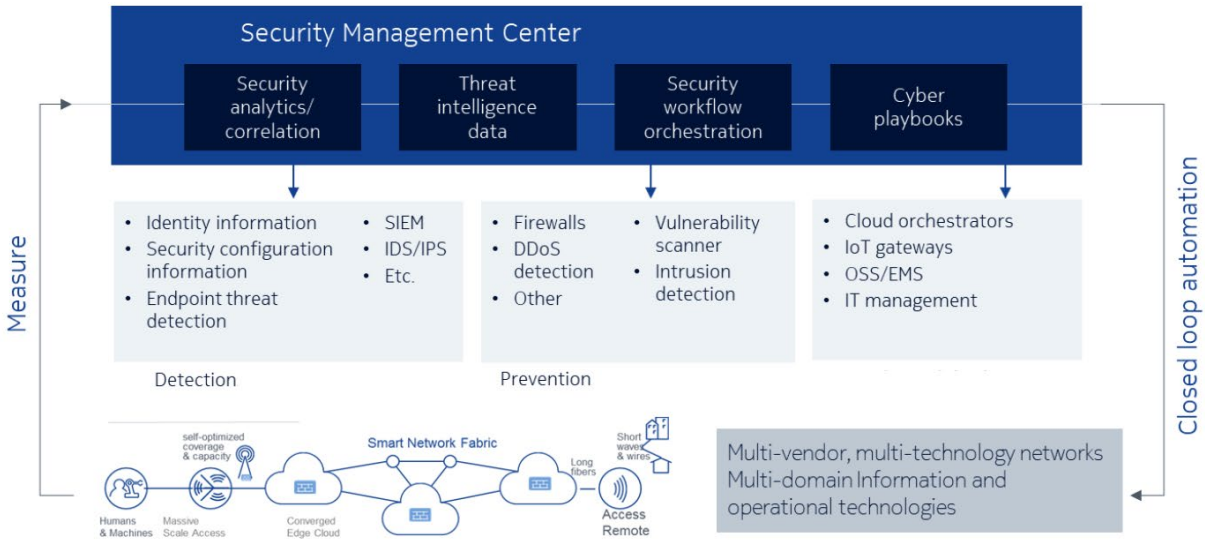

Figure 24 – Security Management & XDR

SOAR solution has been developed to replace today's manually-intensive approaches with security systems built on three pillars – intelligence gathering and analysis with machine learning and automation.

Intelligence gathering and analysis correlates data from across the network, devices, and cloud layers to spot suspicious anomalies, and provide insight into the nature of the threat, the associated business risk, and the recommended response.

Security Orchestration, Analytics & Response (SOAR) must be supported by an umbrella of security applications covering all aspects covered earlier in the paper:

1. Identity Access Manager

implements access controls to ensure least privileged access to key operational systems. It provides jump-host for CLI and GUI access to all (physical or virtual) network elements. i.e. no direct access from operator's consoles to management interfaces of the network elements. Human credentials are segregated from network elements' credentials. It also assures traceability of operator actions

2. Audit Compliance Manager

automatically and continuously audits the configurations of network entities for compliance with golden configuration

3. Certificate Lifecycle Manger

automates certificate enrollment and deployment, discovery, and audit

4. Endpoint Security

- analyzes network traffic in order to detect malware and anomalies of all end-user devices

5. Security Management Center

- aggregates logs and data for real-time monitoring & management. It provides a consolidated view for efficient reporting and simplifies incident management and forensics

3.12 Extended Detection & Response (XDR)

A fragmented security posture must move towards integration across Security Operations, Security Tools and Threat Intelligence. Extended Detection and Response (XDR) enables all three areas of integration. XDR takes security orchestration, automation, and response (SOAR) to even greater effectiveness through a cloud-native architecture built to accommodate the ever-growing and increasingly complex volumes of data coursing through 5G networks. XDR-based security operations are anchored by a robust data pipeline. That makes it possible to collect more data from more sources, all processed and analyzed through one cohesive security management system — so threats can be acted on faster and more effectively than ever before.

With machine learning (ML), the effectiveness of intelligence gathering, and analysis will improve continuously. Having access to a massive amount of high-quality data is the basis for training an AI/ML system. When using a security product that includes ML, you will want to augment the things you have

done in the past, like signature collection and automated malware analysis, and combine them with the machine's capability to determine new, malicious content.

A data pipeline also allows XDR to provide overarching security lifecycle management, orchestrating and automating all aspects of risk and threat prediction, detection, and response. Security teams can more easily integrate disparate threat intelligence data that is tailored to their unique requirement, model specific threats and attacks to their networks, and automatically apply the most appropriate preventative controls.

XDR solutions should provide the following features:

- Integrated security operations: End-to-end visibility across networks, clouds, and endpoints through a "single pane of glass" management interface — allowing security teams to quickly pinpoint the exact source of any potential breach
- Integrated security tools: Manage and administer disparate point products in a coherent and consistent way, providing a library of interfaces and connectors that bring a range of end-to-end infrastructure components and multi-vendor security tools under a single security management platform
- Integrated threat intelligence: Cognitive threat detection analyzes network sessions for malware or anomalous device behavior, and interprets the global threat landscape in a consistent, actionable way. Automated alert prioritization and classification eliminate the need for security teams to investigate redundant or lower-priority notifications so they can focus on blocking legitimate attacks

1. Summary

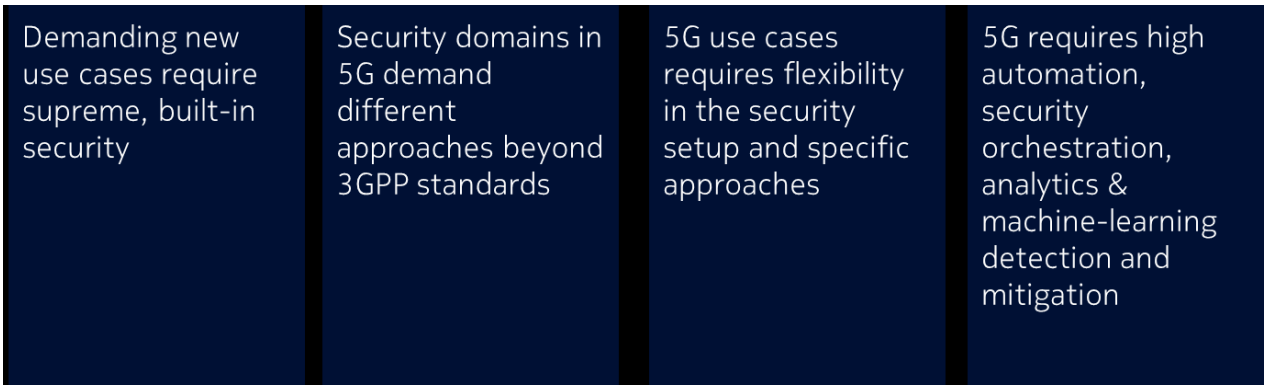

Figure 25 – End-to-end 5G security

End-to-end holistic security is mandatory in 5G network deployment and it is clear that:

1. 5G has a lot of mission critical use cases requiring supreme, built-in security. All network functions in the system must be hardened to avoid known vulnerabilities. Retrofit is always challenging and costly and, in some cases, service impacting
2. Number of network functions in a typical 5G network will be an order of magnitude more than 4G or fixed (cable or fiber) BB networks. Number of incidents and security logs will increase in the same order of magnitude. Adding the dynamic nature of the network configuration, 5G requires automation, security orchestration and machine-learning to identify and mitigate security threats
3. Different use cases may have different security requirements in different domains. Additional or overlapped security measures need to be implemented on top of recommendations from 3GPP standard
4. Because of dynamic nature of 5G network slicing, 5G use cases require flexibility in the security configuration

By introducing the security solution early on, operators can leverage security from the very beginning of their 5G rollout, rather than shelling out for an expensive retrofit further down the line. Operators can start to enrich security workflows, analytics, and training prior to the mass-deployment.

Security is a process (not a destination). Operators require a partner who is experienced in both 5G and security realms who has the skills, deployment experience in numerous 5G networks to be on top of any evolving threats and strong engineering and financial capabilities to continue investing in the 5G.

And most of all, a partner who is aligned in the overall goal to make 5G a secure, safe environment for everyone.

4 Acronyms

3GPP	3rd-Generation Partnership Project
AI	Artificial Intelligence
AKA	Authentication & Key Agreement
AMF	Access & Mobility Management Function
AR	Augmented Reality
AUSF	Authentication Server Function

10G And FTTP:
Drivers, Considerations And Strategies

A Technical Paper prepared for SCTE by

Michael T Scardina

Introduction

Armstrong is well recognized as America's 11th largest multiple system operator (MSO), serving thousands of homes and businesses across Pennsylvania, Ohio, West Virginia, Kentucky and Maryland. Their first broadband Internet customer was connected in 1997 and over the years they've earned a reputation as a fast-to-market and efficient disruptor.

As other MSOs debate fiber-to-the-premise (FTTP), Armstrong actually made the decision to build FTTP – 15 years ago … using radio frequency over glass (RFoG) technology to reach down to ten homes per mile in rural areas. With over 27,000 RFoG FTTP customers, four years ago Armstrong made the switch to light up the same 1x32 distributed split passive optical network (PON) infrastructure with gigabit passive optical networking (GPON). In fact, in dense areas, Armstrong activates GPON on the same glass as RFoG allowing one customer at a time to be moved from RFoG to GPON.

Why did Armstrong pursue FTTP in the first place and what drove the later transformation with XGS-PON? In this paper, we will explore the business, network, operations and financial reasons as to why Armstrong pursued this path to 10 gigabits per second (10G) and bypassed other options. We also outline how these network advancements and market factors have caused consumers to enhance their home wireless fidelity (Wi-Fi).

The Original FTTP Decision by Armstrong

Armstrong has experienced an impressive compound annual growth rate (CAGR) of combined bandwidth consumption for all Armstrong customers across the entire network. Historically, it had been 42%. More recently, the average usage CAGR has been 55%; daily average usage jumped from 290 Gbps (gigabits per second) in Feb 2020 to 450 Gbps a year later, (Gbps) on 2/1/2020 to 450 (Gbps on 1/31/2021 as shown in Figure 1.

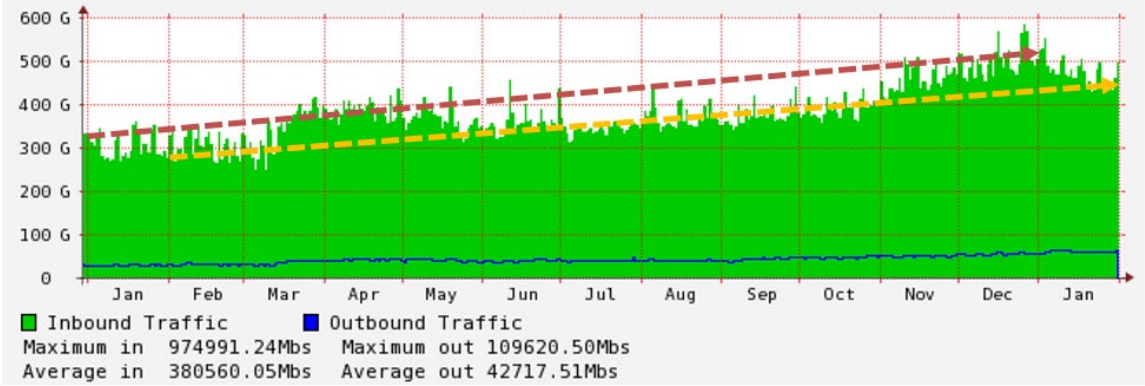

Figure 1 - Cumulative Usage for (Wide Area Network) WAN Plus (Content Delivery Network) CDN and Peering Cumulative Ports (Jan'20-Jan'21). (Source: Armstrong)

To achieve and sustain the stated goal of "growth in perpetuity," the company pivoted to a fiber-fueled growth strategy. Armstrong realized that each Data Over Cable Service Interface Specification (DOCSIS®) upgrade would be costly and, at the current growth rate, could likely be over subscribed upon being fully rolled out.

Even though FTTP was not the lower cost solution Day 1, it would be Day 2. To reach a fact-based decision, Armstrong created a spreadsheet containing all available historical data. “All the numbers proved out the fiber decision,” according to Michael Scardina, Director of Network Strategies and Technologies at Armstrong. Mid-term and long-term evaluations showed FTTP to be both the lower cost and longer life solution – enabling Armstrong to remain highly competitive long into the future.

Power Savings

A significant HFC and DOCSIS operating expense is electricity (e.g., powering the nodes and the downstream amplifiers.) Switching to fiber and PON would yield a substantial energy savings in millions of dollars annually. Then, there’s the labor savings resulting from a major decrease in the need for hybrid fiber-coaxial (HFC) plant maintenance (e.g., avoid ingress/egress leakage repair, eliminate battery upkeep).

Customer Premises Equipment (CPE) Costs

Another financial factor in Armstrong’s decision process involved CPE costs as they form a significant part of any network upgrade. Upgrading to DOCSIS 3.1 (then 4.0) or FTTP requires replacing CPE. For Armstrong, a GPON ecosystem was more mature and costs were more predictable. And a GPON 1Gbps system is easily upgraded to a XGS-PON 10Gbps system, with no change to outside plant necessary. XGS-PON also provides higher capacity and, like GPON, offers a very simple and scalable method to extend high throughput layer 2 connectivityto enterprise customers on the same fiber route. Armstrong uses these layer 2 connections to extend a full suite of enterprise services by virtually and securely connecting the customer to the hub distribution router. There are substantial financial and operational benefits to this as it typically removes the need for dedicated direct fiber with MPLS CPE routers. According to Scardina, “The cost of XGS-PON CPE is $1/10^{th}$ that of MPLS CPE used for enterprise customers.” For Armstrong, it was a more economical use of last mile fiber.

Upstream Limitations

Consumers and their behavior also played a key role in Armstrong’s decision. The need for speed applied not only to the downstream, but also the upstream. Inherent upstream limitations made DOCSIS technology a less viable path on which to continue. Upgrading to DOCSIS 3.1 technology would be “a stopgap solution at best” says Scardina. “Moving to orthogonal frequency-division multiplexing / orthogonal frequency-division multiple access (OFDM/OFDMA) is one thing, but moving the forward/reverse split to add upstream spectrum is a much more complex problem with compounding effects.”

Scardina continues, “For example, while Armstrong’s HFC plant architecture from the mid-1990s would allow amplifier module-only change to move from 5-42 megahertz (MHz) sub-split to 5-85MHz, because of limits in the legacy set-top box command and control downstream channel, upstream frequencies above 85MHz would require new diplex filter technology to notch the upstream to support a small amount of downstream. 5-85MHz isn’t enough upstream spectrum to support growth demands and 5-204MHz isn’t either in the long term. For the time being, Armstrong uses node/distribution leg splits to reduce the number of modems sharing the 5-42MHz upstream as FTTP replacement of HFC fully ramps.”

The HFC plant change from sub-split to mid-split, as shown in Figure 2, enables up to 300Mbps in the upstream. However, for the reasons articulated by Scardina above, the shift to a high-split to support symmetrical 1Gbps speeds is more complex and costly.

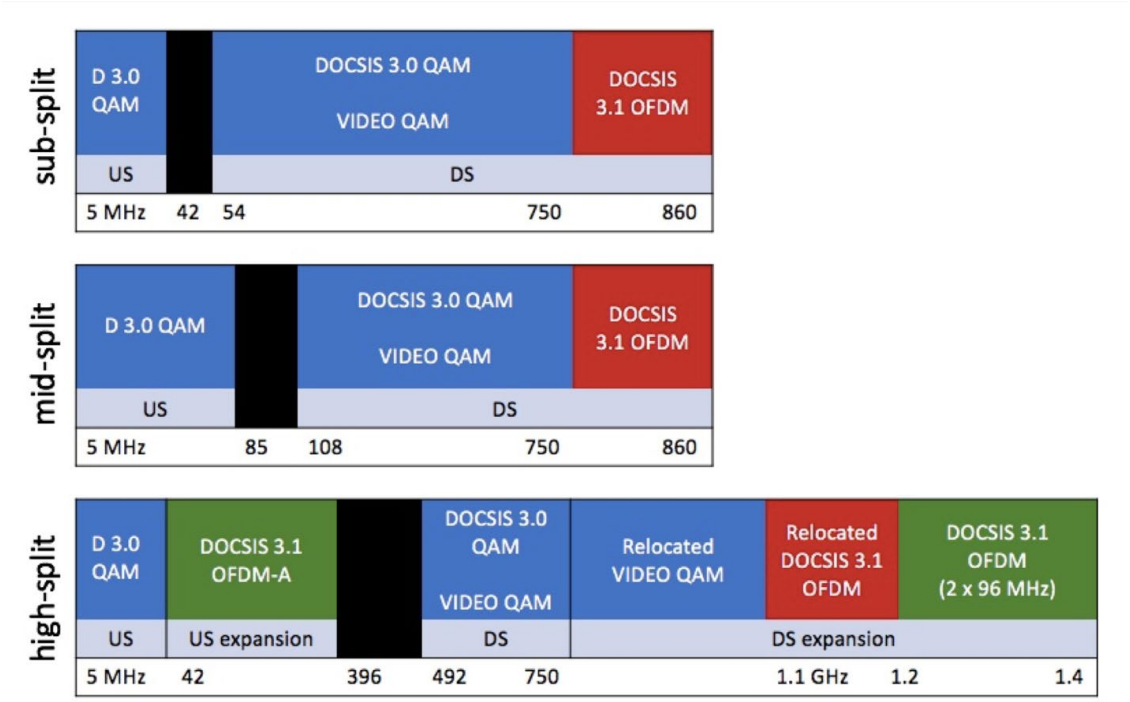

Figure 2 - HFC Spectrum Impact of Support for Higher Speed Services

The Consumer Electronics Show (CES) Horizon

The annual CES show in Las Vegas also provided ample proof that this was the right decision. Viewing the event as a "weather forecast" of what is on the horizon, Scardina took note of what the Armstrong network would need to support with the emergence of augmented reality (AR) and virtual reality (VR) centric gaming applications. Beyond software used in the home, there's the proliferation of devices. "On average, four new devices entered each home in one month earlier this year," according to Scardina. Washers, dryers, dishwashers, exercise equipment have all evolved into IoT devices – connected to the network. "There are so many new bandwidth uses that we simply didn't have in the past."

Field Tech Training & Equipment

In deciding upon fiber, Armstrong had an important operational consideration: the degree of difficulty to transition from DOCSIS technology to FTTP. What impact would this decision have upon the people, the processes and the equipment? Armstrong discovered that the technical skill sets honed through years of DOCSIS deployments could fairly easily be transferred to the deployment of fiber. Many of the same basic concepts applied. The move to fiber yielded a simpler process in the field as handheld splicing tools took the place of complicated connectorized cables. As for the use of spectrum analyzers, the technique that puts radio frequency (RF) signals in a radio spectrum for DOCSIS signals applies in a very similar way to optical signals in a fiber. And PON meters are simpler to operate than RF signal level meters.

The rationale for Armstrong's FTTP decision has been validated time and time again. An additional lesson that has been learned is that the company could have deployed FTTP even faster. With Rural Digital Opportunity Fund (RDOF) and other broadband initiatives driving increased fiber rollouts, Armstrong now competes with new and existing fiber entrants for the same labor and materials,

challenging the rate that fiber expansions can be built. However, broader operator adoption of fiber is a double-edged sword and Armstrong benefits from lower technology prices as a result. In fact, cost declines contributed to Armstrong's move from GPON to XGS-PON.

Provisioning: DOCSIS to GPON

"We initially started with Ethernet passive optical network (EPON) because of the DOCSIS Provisioning of EPON (DPOE) standard", says Scardina. "However, EPON didn't work out. DPOE and its virtual cable modem approach performed as expected, but the available CPE and services delivery did not. So after investing many months and the need to pacify angry customers, we switched to GPON due to its proven track record. A GPON system utilizes its own set of service templates for provisioning customers and a DOCSIS Provisioning of GPON (DPoG) standard never came to fruition. Nonetheless, by layering in commercial middleware, we were able to convert DOCSIS service codes to GPON templates; an outcome that surprised us in its simplicity."

Scardina continues, "Manual provisioning just wasn't an option, so we initially purchased middleware to marry our back office DOCSIS provisioning system to the GPON Network Management System (NMS). That worked very well and remained in place for more than a year. We then explored replacing the commercial middleware with internal resources for OpEx savings. In less than a week, an in-house developer was able to replace the commercial middleware with our own adapter. Additionally, designing our own middleware to interface between our traditional billing and CPE provisioning systems created an agnostic approach to flow-through provisioning. This allows field premise techs to provision a cable modem, GPON ONT, Wi-Fi, Telephony multimedia terminal adaptor (MTA)/number porting, and video set-top boxes all from one mobile application on their smart phones. Change can be hard, but it doesn't have to be as hard as you think."

The 10G Platform with XGS-PON and Combo PON

Armstrong's innovation with FTTP did not end with their original decision. For some Armstrong customers, GPON fits their needs perfectly. But, for the high-bandwidth consuming customers, there was a need for a smooth shift to accessing higher speeds. Service providers can co-mingle GPON and XGS-PON on the same fiber strand to provide more network flexibility and better address customer demands. For example, you can maintain customers on GPON while utilizing XGS-PON as a higher-end option for commercial customers (Figure 3). According to Scardina, "there's no need for a dedicated fiber using different technology to a single customer. Instead, we use an XGS-PON wavelength to deliver prioritized services."

"Armstrong was able to simplify its deployment process of XGS-PON over its existing GPON network through the use of Combo PON technology, which allows providers to combine these disparate technologies over the same infrastructure – from a single OLT port," according to Jess Beihoffer, Director of Sales Engineering at ADTRAN.

The need for separate overlay networks to serve homes and businesses can now be avoided. The technologies can be converged on the same platform. A single fiber. A single PON (up to 128 customers). All yielding economies of scale. Armstrong recently announced the launch of 10Gbps services starting in the town of Wexford, Pennsylvania using this architecture on a 32 PON split.

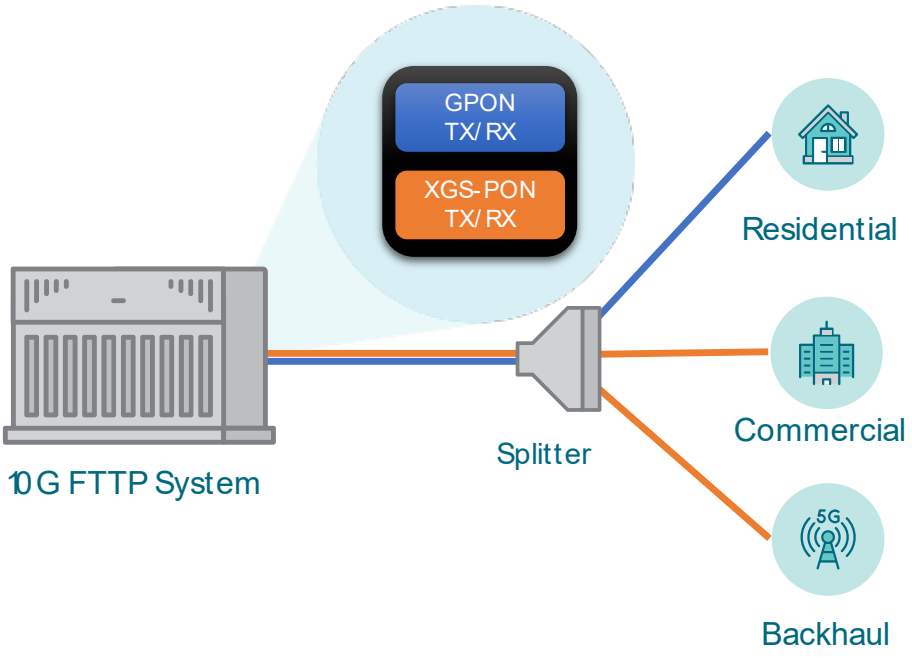

Figure 3 - Combined XGS-PON and GPON technologies on a common optical distribution network (ODN) and optical line terminal (OLT) system. (Source: ADTRAN)

The co-existence of PON technologies enabling backward compatibility has been a point of discussion since the inception of 10G PON standards in 2009. By combining both wavelengths within the OLT optics, Armstrong not only simplified the optical distribution network (ODN) when introducing higher capacity XGS-PON, but also took advantage of added port density as a single port can now simultaneously support both GPON and XGS-PON. Armstrong was able to gain greater network flexibility. The growing popularity of this technology has led industry and analysts such as Omdia to converge around the term Combo PON. Refer to Figure 4.

This technology is seen as key to simplifying the path to 10Gigabit networks, as well as providing improved economics for operators building new FTTP networks or modernizing existing GPON fiber networks to support the economic and social development of the communities they serve.

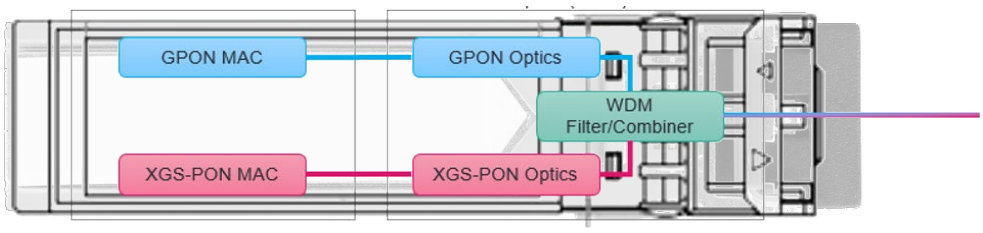

Figure 4 - Combining XGS-PON and GPON technologies within a common OLT module. (Source: ADTRAN)

Some of the immediate economic benefits that providers are seeing is a reduction in power consumption (50+%) as well as rackspace (up to 50% lower), mitigating two of the major concerns that providers face in their hubsites.

A more flexible network contributes to higher customer satisfaction. Moving high-usage GPON customers to the XGS-PON overlay alleviates congestion for customers staying on the GPON network and results in improved performance for those who remain and those who migrate. As Scardina explained, “If you have one customer on a street that is a very high bandwidth consumer, you can easily shift them over to XGS-PON to better fit their broadband needs without causing any disruption to your other customers in the area.”

Next generation FTTP technology like Combo PON provides all of the XGS-PON capacity and operational benefits, affords the opportunity to leverage the full value of mass market GPON technology, while further simplifying fiber network modernization processes. The promise of such a network should serve to “demystify the perceived level of effort and lessen intimidation,” according to Beihoffer of ADTRAN. “It’s not a forklift upgrade. Folks shouldn’t be scared to touch PON.”

With 10G networks historical bottlenecks no longer exist in the access network. The bottlenecks have migrated into the home and the backbone. Regarding the home, a stellar Wi-Fi experience is all-important – especially since most consumers view Wi-Fi as the Internet.

Delivering the In-Home Gigabit Experience

The in-home experience is critical. “If 10G is at the side of the house but can’t be accessed by the client device, what’s the point?” Scardina noted. The importance of excellent home Wi-Fi was recently confirmed with executives at Tier 2-3 service providers. They cited that the primary benefits of offering a residential managed Wi-Fi solution are Improved Customer Experience and Reduced Churn – two sides of the same coin. Not surprisingly, every executive said “Wi-Fi coverage throughout the house” is a very important to their residential customers.

Managed Wi-Fi

As MSOs increasingly focus on being broadband-first providers, they are focusing on providing a high-quality managed Wi-Fi service within the home. They also know that their customers view Wi-Fi as synonymous with the Internet and a Wi-Fi issue often triggers a customer service call. By providing a managed Wi-Fi solution, the service provider can ensure that their customers are leveraging the latest technology (currently Wi-Fi 6, soon to be Wi-Fi 6E), and placing advanced Wi-Fi system components throughout the house to ensure maximum coverage.

Analytics and Insight

Leveraging cloud-based data and analytics packages integrated into the Wi-Fi system solution, operators are given a window into the customer’s network, behavior, and experience. They are then equipped to efficiently provide enhanced customer service and present new offerings tailored to the subscriber.

The Core Network: Scaling to 100G

The backbone network between the OLTs and the core is another area that requires focus. As the last mile access network scales to 10G, Armstrong also is further strengthening and scaling core network and

transport systems to support the growing needs of the last mile. “Don’t just look at your last mile, it all comes back to your core. Build your core and make sure it’s highly scalable and redundant”, said Scardina. Several years ago, Armstrong began upgrading its core network backbone links from multiple (N) x 10 gigabit Ethernet (Nx10GE) ports to (N) x 100 gigabit Ethernet (Nx100GE). As XGS-PON deployments increase, Armstrong is preparing for similar upgrades to the uplinks from their 10G fiber access, aggregation and transport platform. Refer to Figure 5.

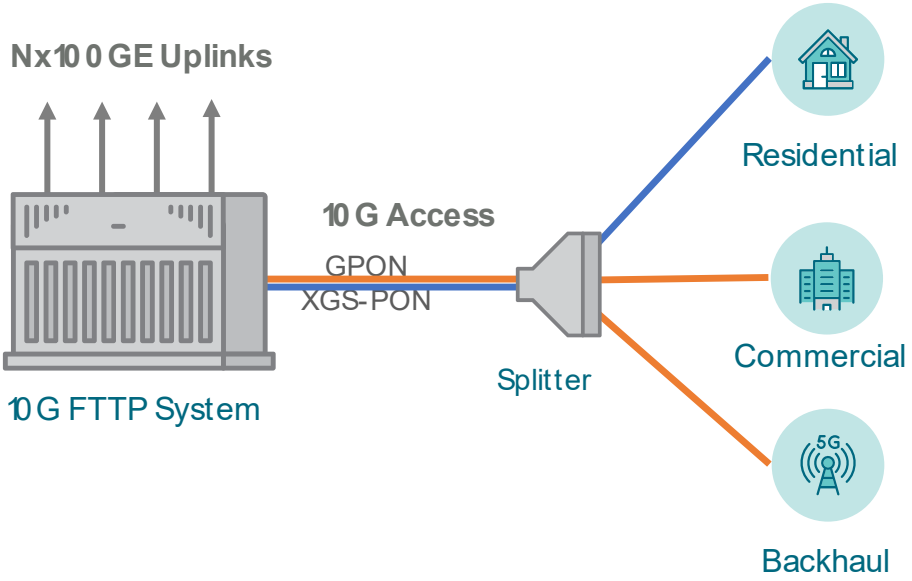

Figure 5 - Strengthening the Network Core for 10G Access. (Source: ADTRAN)

Why Not DOCSIS 3.1 / 4.0 (with fiber deep)

If service groups are kept small enough, DOCSIS 3.1 technology can reliably support the speeds that GPON enables (at least in the downstream direction), but not those delivered with XGS-PON. To achieve speeds approaching 10G, DOCSIS 4.0 Extended Spectrum or Full Duplex DOCSIS techniques are required. These are certainly valid choices for some, but many will find that the plant upgrades required to extend the spectrum to 1.8 GHz and beyond, and to modify the split and/or change the architecture to Node + 0 can add these complications that are not found with an FTTP overlay, or with an upgrade from GPON to Combo PON:

- Service disruption during upgrade activities;
- No operating cost reduction;
- Disruption of legacy services due to interference from new upstream channels (requiring installation of filters or change of CPE), and
- Multiple upgrade steps may be required on the way to 10G.

Conclusion

The Armstrong FTTP story is a compelling one. The business, network, operations and finance reasons as to why Armstrong pivoted to FTTP long ago are ones which other MSOs could well use today to make a strong argument in favor of this transformative move. These are just some of the reasons which are as relevant as ever:

- Performance of bandwidth-hungry (gaming) applications and escalating volume of connected internet of things (IoT) devices;
- Long-term, competitive, lower cost solution;
- Lower labor expense with reduction in plant maintenance;
- Significant energy savings, and
- Maturity of fiber and PON ecosystem due to greater FTTP adoption by more operators.

That argument is only bolstered by the advantages realized with XGS-PON together with Combo PON technology. Service providers can co-mingle GPON and XGS-PON on the same fiber strand to provide more network flexibility and better address customer demands. Combo PON technology yields a significant reduction in space use, power consumption and capital expense which enabling a longer GPON life span and an increase in gigabit service coverage.

As Scardina states, “The time for XGS-PON is now. Find a way to do it that makes financial sense. Spend the capital expense (Capex) once and be prepared for when customer demands increase. Be proactive, not reactive.”

10G Full Duplex DOCSIS Implementation Exceeds Expectations

A Technical Paper prepared for SCTE by

Richard S Prodan, Ph.D.
Engineering Fellow
Comcast Cable
1401 Wynkoop Street #300

rich_prodan@comcast.com

1. Introduction

The advent of DOCSIS 4.0 Full Duplex (FDX) technology has arrived after several years of industry collaboration and the publication the DOCSIS 4.0 FDX specifications. Implementation of an FDX node reference design incorporating the remote PHY ASIC SoC has been initially evaluated in the Comcast labs. The key technology to enable simultaneous transmission and reception in the same spectrum requires real-time removal of the high-power cable plant reflections of the transmitted downstream signal from the low-power upstream signal received using “echo cancellation”.

The successful performance of this enabling technology demonstrates the potential for greatly increasing upstream throughput in an additional nearly 600 MHz of spectrum shared concurrently with the transmission of the downstream signal. Evaluations indicate increased spectral efficiency beyond the minimum performance requirements in the FDX specification. This paper will analyze the implied capacity limitations in the specs. A comparison to the measured performance is made which demonstrates exceeding these limits. This comparison will conclude that the performance limits in the FDX specification should be reexamined to update the expected efficiency gains enabled by full duplex echo cancellation technology as currently realized.

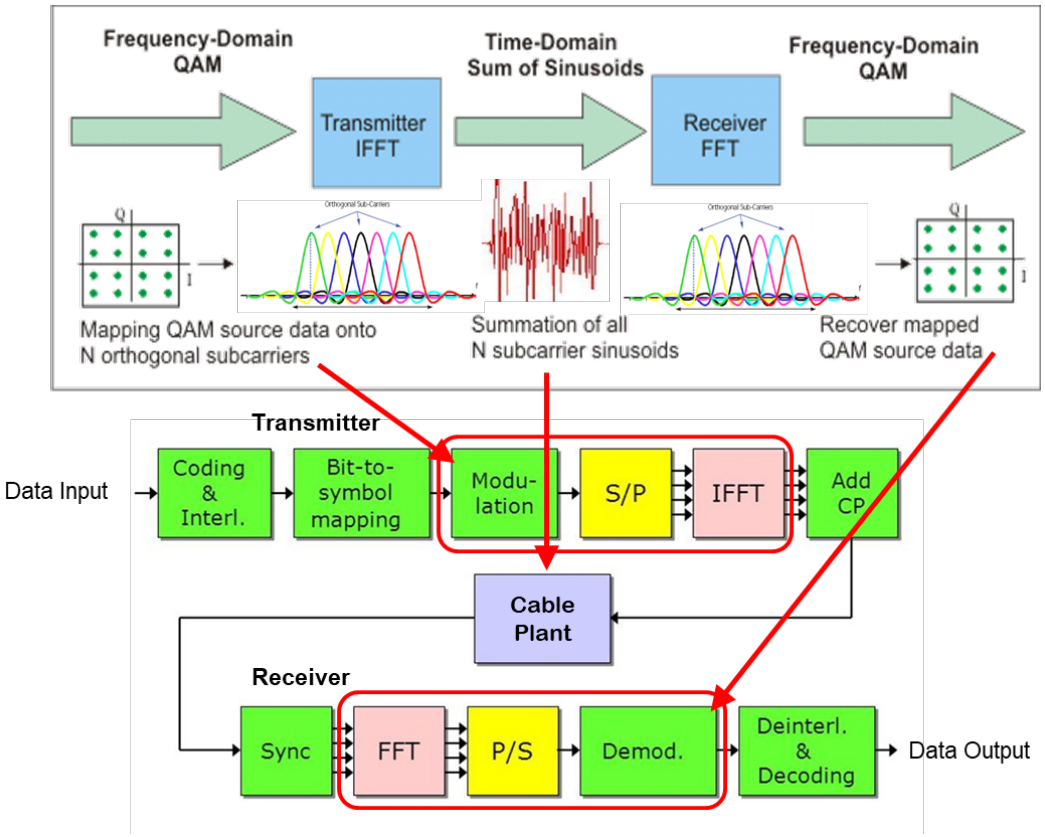
2. DOCSIS 3.1 – The Basis of DOCSIS 4.0 Full Duplex Modulation

DOCSIS 3.1 provides higher throughput and greater flexibility for cable data systems. The PHY layer based on Orthogonal Frequency Division Multiplexing (OFDM) differs significantly from that in previous generations based on Single Carrier Quadrature Amplitude Modulation (SC-QAM).

OFDM is a modulation scheme where many closely spaced, complex valued, harmonically related (orthogonal) QAM data subcarriers of various modulation orders are transformed into a time domain waveform or OFDM symbol. The resulting OFDM symbol in the time domain can be reversibly transformed back into the original QAM data subcarriers in the frequency domain. This reversible process uses the mathematically efficient implementation of the Discrete Fourier Transform (DFT) called the Fast Fourier Transform (FFT) to accomplish this reversible transformation. The N-point FFT transforms a group of N time samples into an equal number of N frequency domain complex valued subcarriers. The inverse FFT reverses this transformation from the frequency domain into the time domain.

As shown in Figure 1, forward error correction (FEC) coding and interleaving is applied to the input data bits. The error protected data bits are mapped into N frequency domain QAM symbols modulated onto N orthogonal subcarriers. These QAM subcarriers are serial-to-parallel converted and input into an inverse Fast Fourier Transform (iFFT). This transformation produces a single time domain OFDM symbol comprised of the summation of all N subcarriers. A portion of the end of each OFDM symbol known as a cyclic prefix (CP) is prepended to the beginning of the same symbol to prevent inter-symbol interference (ISI) due to signal micro-reflections or “echoes”.

Any contiguous group of samples within each OFDM symbol can be used to recover the subcarriers using the periodicity property of the DFT. If the latter part of the symbol past the prepended cyclic prefix is used, and the micro-reflections are confined in time to the duration of the cyclic prefix, then the remaining samples in the OFDM symbol are free of inter-symbol interference. Consecutive groups of QAM subcarriers are thus transformed into OFDM symbols and transmitted successively over the cable plant.

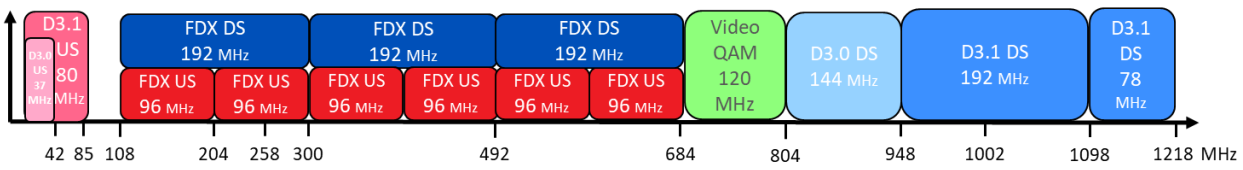


The reverse process at the cable modem receiver synchronizes the ISI free portion of each OFDM symbol, performs an FFT and parallel-to-serial conversion to recover the QAM modulated data subcarriers which are then demodulated, deinterleaved, and FEC decoded to recover the error-corrected data bits. Details of the DOCSIS 3.1 OFDM/OFDMA transmission and reception are described in a prior paper [1].

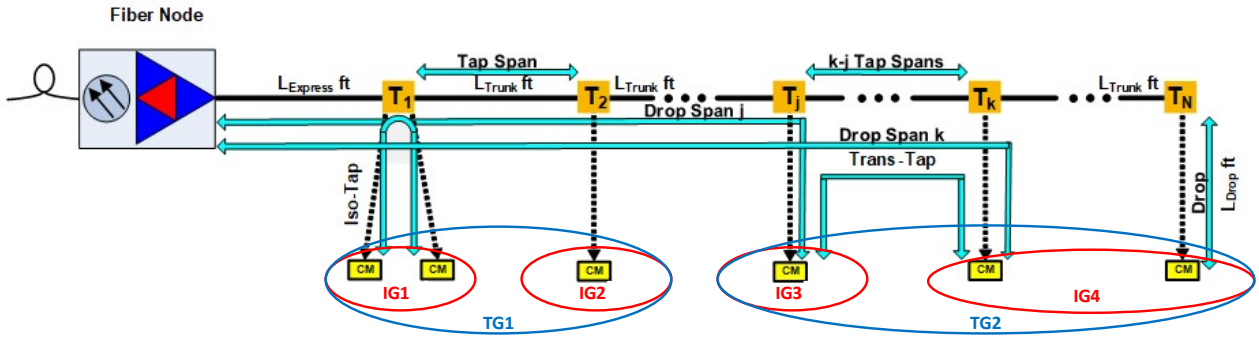
3. DOCSIS 4.0 - Full Duplex Spectrum Sharing

Full Duplex DOCSIS 4.0 uses the same OFDM/OFDMA modulation as DOCSIS 3.1 but overlaps downstream transmissions from node to modem and upstream transmissions from modem to node within the same frequency spectrum in the 108 MHz to 684 MHz FDX band. This greatly increases the upstream bandwidth yielding a total channel data rate up to 5.7 Gbps with 1024 QAM subcarriers and over 4 Gbps total data payload rate without overhead.

Legacy upstream DOCSIS 3.0 and 3.1 signals remain in the 5 to 85 MHz (mid-split) band. Legacy downstream DOCSIS 3.0 and 3.1 signals occupy the 804 MHz to 1002 MHz band, and only DOCSIS 3.1 OFDM signals occupy 1002 MHz to 1218 MHz. An example of such spectrum allocation is shown in Figure 2 with downstream (DS) and upstream (US) frequency bands.



The FDX band is divided into three 192 MHz sub-bands in the FDX band containing three downstream OFDM channels overlapped with six upstream OFDMA channels. The FDX node simultaneously transmits and receives these channels within the FDX band. Cable modems operate in a dynamic FDD mode with the direction of each sub-band upstream transmission or downstream reception dynamically assigned with a Resource Block Allocation (RBA) message allocating the upstream or downstream capacity within the FDX band in a flexible manner as capacity demands require.



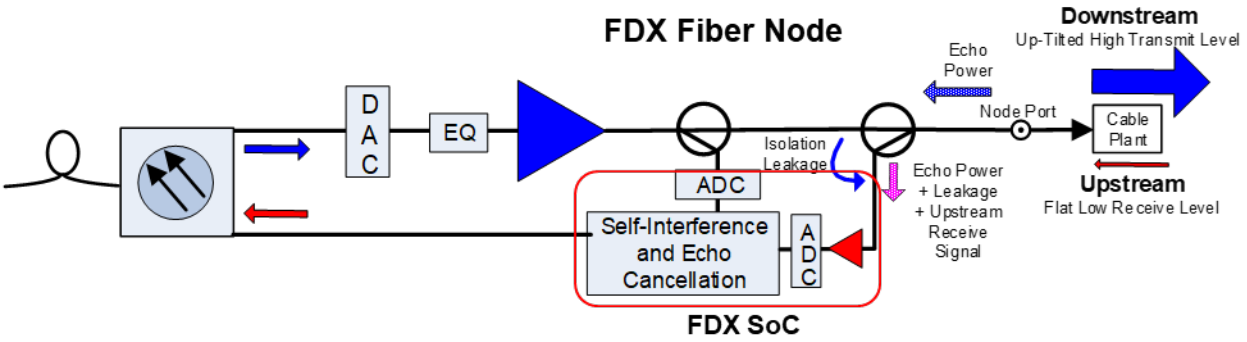
Tap Position (Highest to Lowest):	Tap 1	Tap 2	Tap 3	Tap 4	Tap 5	Tap 6	Tap 7
Tap Type (Number of Ports):	4	4	4	4	4	4	4
Tap Value (dB):	29	29	29	26	20	17	8
Tap Conditioner Type (CS or EQ):	CS	CS	CS	EQ	EQ	EQ	EQ
Tap Conditioner Value (dB):	12	6	6	4	10	10	22

Full Duplex DOCSIS 4.0 was originally specified for a Node + 0 plant without amplifiers beyond the node. The Node + 0 cable plant architecture is shown in Figure 3. When a modem transmits in an FDX sub-band, modems on the same tap (Iso-Tap) cannot receive on the downstream in the same sub-band due to the high upstream interference introduced across tap ports into the low downstream receive level of the other modems on the same tap. These modems are said to belong to the same interference group (IG). However, modems separated sufficiently apart across different taps can have sufficient isolation to interference. Such separated modems can belong to different IGs where the transmission of a modem in a sub-band does not significantly interfere with the reception of other modems in other IGs within the same sub-band. Identification of each modem IG is performed in the “sounding” process in which each modem in turn transmits a test upstream transmission while all other modems measure the received level relative to the downstream received level in a modulation error ratio (MER) triggered measurement window. Low received MER modems are placed in a common IG while higher MER modems remain in other IGs that are isolated from the test modem interference.

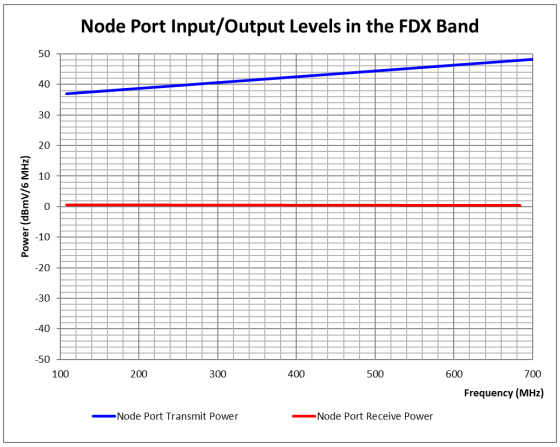
Modems in different IGs can be grouped into a single Transmission Group (TG) with common sub-band RBA transmit/receive assignments. Other TGs can operate with complementary RBA assignments providing full duplex simultaneous transmission and reception across all TG sub-bands at the node. A detailed treatment of FDX PHY layer operation of interference management is described in [2].

4. FDX Node Evaluation in the Comcast Lab Cable Plant

The operation of the simultaneous transmission and reception in the FDX node reference design that was evaluated in our lab. The 7 tap Node + 0 cable plant design used in this evaluation is shown in Figure 3. The FDX node reference design is depicted in Figure 4. The Remote PHY device (RPD) containing the FDX system-on-chip (SoC) in the FDX node receives legacy upstream below 85 MHz and legacy downstream from 804 MHz to 1218 MHz (not shown). These legacy bands are needed to initialize the node as well as cable modems in DOCSIS 3.1 mode prior to adding DOCSIS 4.0 FDX functionality in the FDX band.

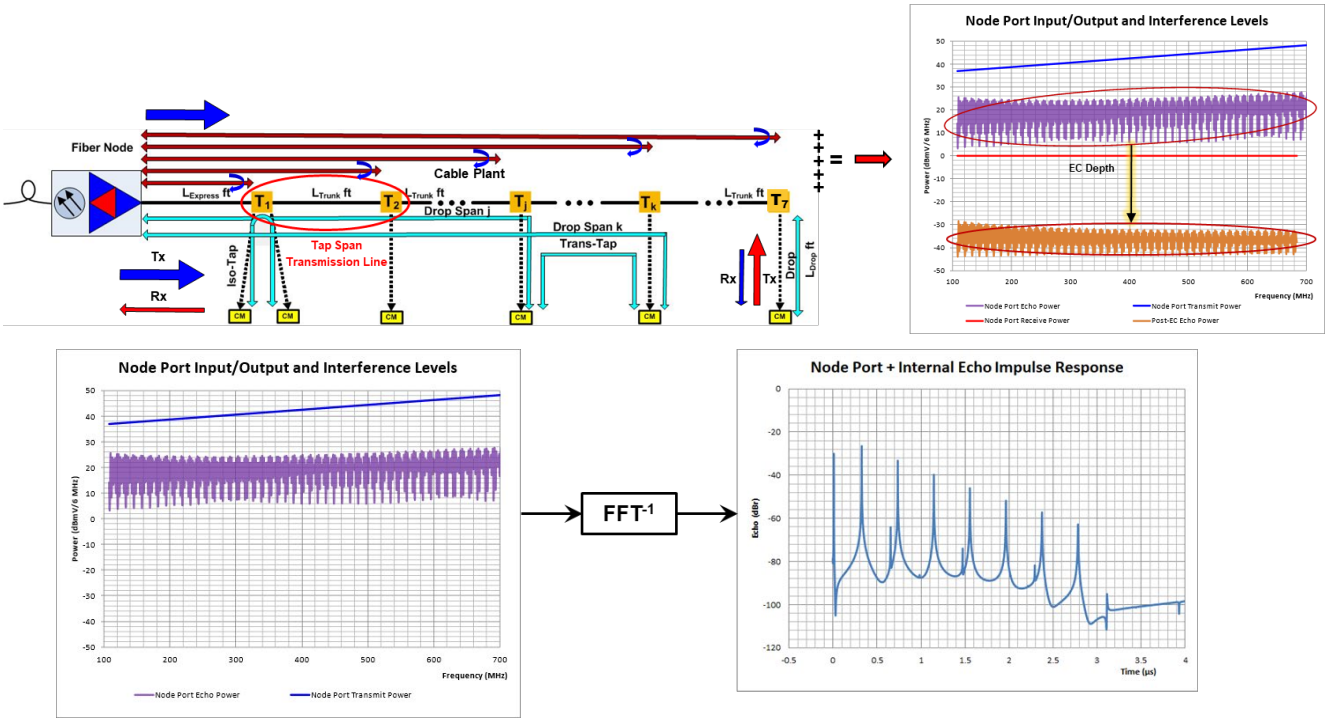


The downstream continuous OFDM signal is launched from the node port at a level from 37 to 48 dBmV/6 MHz with a 10 dB uptilt in the FDX band (see Figure 5). The downstream level determines the maximum reach (number of equalized taps and feeder plus drop cable lengths) for a modem receive level of 0 dBmV/6 MHz across the entire FDX and legacy bands.



The combined upstream burst OFDMA signals of all granted modem minislots arrives at the node port without significant tilt at a low level near 0 dBmV/6.4 MHz. The upstream receive level is limited by the 65 dBmV total composite power (TCP) of the cable modems in the highest loss path from the modem to the node. Thus, the upstream path being essentially equal path loss will transmit with the same power spectral density resulting in the same 0 dBmV/6.4 MHz across the FDX band at the node port.

The high-level downstream signal launched into the cable plant will result in reflected signal energy back toward the node due to tap return losses causing impedance mismatches with the cable characteristic impedance in the cascade of connected tap-to-tap transmission lines. The node echo paths and the resulting reflected signals or echoes are shown in Figure 6.



Note that the downstream echo power is below the downstream launch power at the node port but the echo is higher than the received upstream signal at the node port. Taking the inverse FFT of the reflected signal power shows the distribution of the relative echo level and delay of the echo path components from the node port and each tap relative to the 0 dB node launch signal reference. This echo level being higher than the received upstream signal at the node port results in a negative signal-to-noise ratio (SNR). The upstream signal would not be recoverable with a negative SNR. Hence echo cancelation technology of sufficient cancelation depth to suppress this interference and increase upstream received SNR is required.

5. Echo Cancellation Performance Exceeded

The RPD SoC in the FDX node reference design of Figure 4 reduces the echo level below the upstream receive level using self-interference and echo cancelation of the downstream echo. The node downstream signal is sampled and digitized as a reference for echo cancelation. The upstream signal with the

downstream echo through and the leakage across the FDX node port directional coupler of Figure 4 (replacing the frequency division duplex diplexer) is also digitized. Using the downstream reference signal, the echo cancelation operation within the FDX SoC subtracts the echo plus leakage signals from the upstream input plus interference.

The evaluated performance of the echo cancelation is shown in Figure 7. The resultant bit-loading achieved was 1024-QAM subcarriers in the received OFDMA symbols with zero codeword errors after LDPC decoding. The echo is substantially cancelled. The residual post EC signal to echo ratio is increased to 35 dB to support 1024-QAM an shown in Table 2, Upstream CNR Performance for D3.1 – a significantly positive upstream receiver SNR!

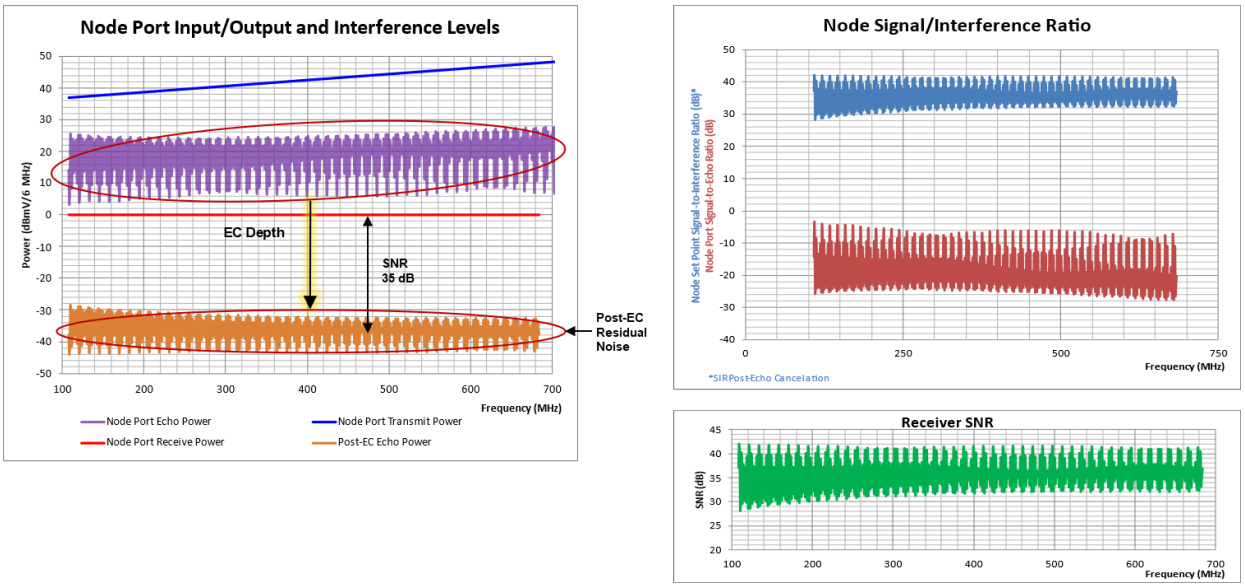


Figure 7 – Node Signal to Echo Interference (Pre and Post Echo Cancelation)

The upstream and downstream data rates per channel type and the total aggregate data rates for the channel plan of Figure 2 are calculated in Table 1.

Table 1 – FDX Cable System Data Rates

The upstream bit-loading is a function of the echo level present relative to the minimum upstream receive level. This relationship is illustrated in Figure 8 where lower echo levels yield higher bit-loading post echo cancelation and vice versa. The assessment of this trade-off for a given minimum upstream receive level is ongoing for a more complete characterization of the echo cancelation performance as implemented.

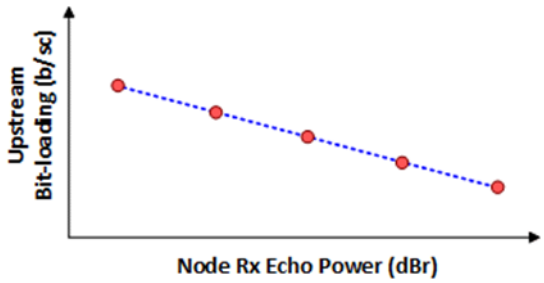

Figure 8 – Upstream bit-loading vs. relative echo power

6. The Future Evolution of FDX Technology

The demonstrated results of this technology in our labs indicates a path forward to extend the reach of echo cancelation beyond all-passive Node + 0 cable systems. The depth of echo cancelation with the system designed transmit and receive signal levels and resulting echo levels shows 1024-QAM OFDMA modulation is achievable in a Node + 0 cable system. The use of this technology in FDX amplifiers can extend the reach into Node + N system designs.

Managing downstream output and upstream input levels in amplifier cascades such that the upstream signal to echo ratio is reduced below that of the node can increase the achievable SNR at the upstream amplifier output for the same echo cancelation depth in the node. Longer amplifier cascades will accumulate the reduced echo cancelation residual interference lowering the received SNR and achievable bit-loading at the node. But as shown in the Table 2 SNR vs. bit-loading, a 6 dB decrease in SNR to 29 dB lowers the modulation efficiency from 10 to 8 bits per subcarrier. This compromise could enable the use of FDX amplifiers with echo cancelation in limited cascade depths for a 20 percent decrease in overall upstream capacity over the 576 MHz wide FDX band. Such a compromise may be entirely acceptable in exchange for the still very significant increase in wideband upstream capacity with amplifier cascades extending the reach of FDX technology to Node + N cable systems.

7. Conclusion

The initial evaluation of echo cancelation technology of an ASIC SoC enabled RPD in a DOCSIS 4.0 FDX node reference design was described. The performance in a representative Node + 0 cable system design in our labs demonstrated the successful implementation of FDX echo cancelation in a representative but challenging Comcast Node + 0 cable system design. The measured 1024-QAM OFDMA error-free performance exceeded the upstream capacity of 64-QAM OFDMA in the DOCSIS 4.0 FDX PHY specification – a 67 percent capacity increase.

The echo cancelation performance utilized in a future FDX amplifier can extend the reach of FDX beyond all-passive Node + 0 cable systems. A trade-off of amplifier cascade depth vs reduced upstream spectral efficiency could provide significant increases in total upstream capacity in existing 1.2 GHz Node + N cable systems.

1. Introduction

We have all heard the term “Software Fragmentation”, especially in the context of mobile device applications. Software fragmentation occurs because of the variety of hardware and software platforms. As a consequence, applications may not be compatible with that new hardware, forcing the need for application changes or the need for another application altogether.

The above also happens with Remote PHY Devices (RPDs). A single cable MSO will typically deploy RPDs from multiple suppliers, each with a different application software, and even multiple RPDs from the same supplier that have different hardware components and require different application software. Although RPD software design is based on common specifications, the behavior of the software differs between RPDs implemented with different hardware components and/or by different suppliers. As these differences accumulate, managing the system and maintaining interoperability becomes more complex.

How can this be mitigated?

A common software base can be shared between RPDs, even when they come from different suppliers. This paper will explain how sharing a common software base is implemented, and how it is applied to the RPD platform and supplier ecosystem.

2. Typical Cable Access Network

Most MSOs’ hybrid fiber-coax (HFC) networks have been designed with an upper spectral boundary of 750 or 860 MHz, while some are designed to support 1 GHz and other newer networks designed to support 1.2 GHz. For the more abundant 750 or 860 MHz networks, if not already fully utilized, it is expected that the use of their capacity will soon be increased to the point of exhaustion.

The increased utilization of this access network capacity has been driven by the success of cable MSOs’ service offerings.

As it is well known and understood, for many years the growth in, and demand for, more video programming resulted in the need to allocate large numbers of EIA (Electronic Industries Association) channels for video services, mostly known for their fixed, 6 MHz size, and used both for BC (Broadcast) and NC (Narrowcast). These 6 MHz EIA channels have filled every available portion of the spectrum.

Additionally, the success of, and growth in, HSD / broadband services continues. Most, if not all, operators offer increased service tiers and observed a growth in the use of HSD service capacity for well over a decade now, which amounts to a significant year-over-year compounded growth. This phenomenal success drives the need for increased network capacity, which is implemented by either expanding the spectrum allocation for HSD, or continuous service group segmentation, to reduce the number of users per service group. Or both.

In a separate but parallel trend, operators have been actively converging video and data services into a common Converged Cable Access Platform (CCAP) platform. This evolution, which has been underway for many years now, is intended to reduce the environmental requirements in HEs (headends) that result from service group segmentation. This is because as more service groups are added through segmentation, more HE equipment is needed, which drives the need for space, power and cooling. These trends imply an evolution towards newer, more modern, and denser equipment.

However, as the success of high-speed data and on-demand services continued, the evolution of the access network progresses towards further expanded capacity and ever-smaller service groups. For the

former, the spectrum allocated to narrowcast services increases, driving operators to deploy Data Over Cable Service Interface Specification (DOCSIS©) services including more SC-QAM (Single Carrier Quadrature Amplitude Modulation) channels, and more recently, with DOCSIS 3.1, the allocation of network spectrum for more or wider OFDM (Orthogonal Frequency Division Multiplexing) channels, as well as more narrowcast video services. For the later, more CCAP ports are needed, which drives the deployment of more line cards and eventually more chassis. These expansion trends result in a continuous growth of headend equipment, which is already starting to exceed the capacity that headend facilities can support.

3. Benefits of DAA

The above trends are now intractably linked to two additional evolutions: distribution of components of the access network, implementing a Distributed Access Architecture (DAA), and virtualization of the core network functions.

There are many benefits from the implementation of DAA. One key benefit is the improvement on performance, which is achieved in multiple ways, including: improved SNR characteristics, enable longer link distances between the headend and the nodes, provide higher service reliability, better use of capacity, etc. Beyond the performance improvements, a key benefit of DAA is the increased headend capacity. The implementation of DAA makes it possible to improve the density of CCAP devices in several ways, including the implementation of denser equipment, the use of Ethernet technology which is simpler and smaller in footprint, which more than doubles the capacity as compared to traditional CCAP chassis.

DAA can be implemented in many ways. As the optical link from the headend to the node is converted from analog modulated forward to digital, using Ethernet as the transport, several approaches can be taken for the implementation of the remaining headend components. One approach, for which a key goal is to convert all required components into functionally individual software pieces implemented independently, is to implement DAA in various discrete SW components as shown below.

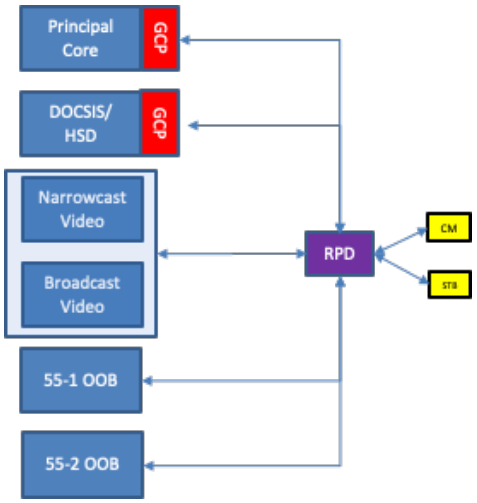

Figure 1 – DAA Implementation Components

The key components depicted in the DAA implementation above include:

- The Principal GCP Core, or GCPP, is the first component that the RPD will contact after receiving an IP address. GCPP is implemented such that it will configure all the RPD functions except DOCSIS channels and behavior, which will be implemented by the DOCSIS CMTS. As the name implies, GCPP communicates with the RPD using the GCP protocol. Included in the GCP Principal Core are all the non-DOCSIS command and control functions for the RPD, including configuration, management and reporting.

- The DOCSIS Core, which is the second component that the RPD will contact in the network. The DOCSIS Core also communicates with the RPD using GCP, and provides all configuration, command and control for DOCSIS channels, both downstream and upstream.

- Narrowcast and Broadcast Video engines, which can be implemented as separate components or combined into a single device, provide all the video content services for the various RPDs in the network. It is important to note that neither the Narrowcast nor the Broadcast Video engines communicate with, nor have knowledge of, the RPDs. Instead, services are configured statically in the Narrowcast and Broadcast Video engines upon their bring-up, and are multicast to all RPDs, which listen for these services as configured by the GCP Principal.

- Out-of-Band engines or cores are implemented separately from the video engines. Given that video systems are implemented using a single encryption and command/control technology, only one (i.e., either SCTE 55-1 or SCTE 55-2) of them is deployed in any one system. The OOB function may or may not implement GCP for communicating with the RPD. When GCP is implemented the OOB server is a Core, and it will configure the OOB downstream and upstream OOB channels in the RPD. However, when GCP is not implemented the OOB server is an engine, and the GCP Principal will configure the downstream and upstream OOB channels.

- Finally, not depicted in Figure 1, is a very important component: the Timing Server. Also known as the Grand Master, the Timing server provides the critical timing synchronization for all the DAA components. Each of the DAA components will include a Timing Client, which will communicate with the Timing Server to maintain timing synchronization. While timing synchronization is not absolutely critical for video services, it is imperative for DOCSIS service to operate. Therefore, video services may be initiated before timing synchronization is achieved, but DOCSIS services will not.

The key advantages for the above architecture are: implementation consisting of a multi-supplier platform where each component can be developed independently, smaller functional components with simpler implementation, and generally reduced time-to-market. However, implementation of smaller discrete components has its downsides, such as: the implied requirement to more tightly specify the behavior of each component to ensure that the overall system will operate as intended, management of the various components including their configuration and upgrade, and the need for more elaborate orchestration.

4. Common Issues Faced with RPD Deployments

The base implementation of a DAA system is generally simple. However, significant complexity is introduced when interoperability with different suppliers' components is introduced.

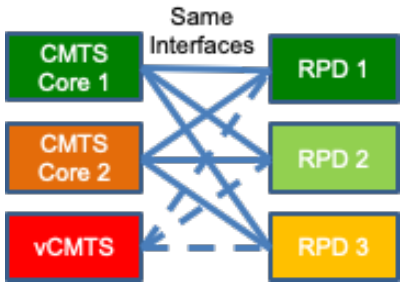

Figure 2 – Functional CMTS-RPD Interoperability Matrix

When considering the overall CCAP system, the complexity to achieve multi-supplier interoperability is even larger. Over the years, larger MSOs have deployed multiple CMTSs, and eventually multiple CCAPs, experiencing the complexities associated with such equipment implementation interoperability.

As depicted in Figure 2, the number of combinations of interoperable components increases geometrically as additional components are added on either side of the interoperability matrix. Having a single CMTS to interoperate with multiple suppliers' RPDs is complex and requires a lot of careful planning and implementation. But if the number of CMTS implementations is increased to 2 or 3, the interoperability complexity doubles and triples respectively. Furthermore, in the case of DAA, if multiple GCP Principals and/or multiple DOCSIS cores, and/or multiple video engines, and/or multiple OOB engines/cores are introduced into the mix, the amount of complexity and work required for lab and field testing to maintain interoperability increases by orders of magnitude.

Therefore, a multi-supplier RPD deployment coupled with a single headend implementation is a sensible approach to an interoperable DAA ecosystem. In this way, the HE components of the DAA, which are deployed in the hundreds, are kept the same for all MSO sites, but the component that is deployed in the thousands, tens of thousands, or even hundreds of thousands, are obtained from multiple sources, ensuring an innovative and competitive ecosystem.

Finally, it is important to recognize that there are numerous types of HFC nodes and network use cases, which will drive the need for an even larger variety of RPD types.

In the same way as there are different kinds of nodes for different HFC network applications, there are also Remote PHY devices with different characteristics that are best suited for each of the specific HFC network use cases. For example, nodes that are best suited for N+x network architectures may have different RF characteristics, and their corresponding RPDs may be implemented to support more service groups. By contrast, N+0 network architectures have different node RF characteristics and require RPDs that are intended for fewer subscribers.

Similarly, while there are use cases for RPDs in the outside plant, there are also applications for RPDs in headends, or "inside plant" as it is frequently called, which will have different implementation characteristics. This use case diversity has driven suppliers to offer RPDs packaged for nodes, where there is a single RPD, or in some cases 2 RPDs, and the only opportunity for cooling is through convection by contact with the outside node enclosure, while other RPDs are packaged in shelves, where the number of RPDs is much larger, even requiring the need to support line-cards, and it is possible to implement cooling through forced air movement.

Therefore, while it is possible to maintain the HE equipment constant, the variety of MSO's HFC networks and application use cases, plus the desire to maintain a multi-supplier RPD ecosystem, drives the need for a large number of RPD types (e.g. upstream/downstream port counts and frequency splits), models and suppliers.

5. Solutions Attempted To Date

Over the last few years, as the development of RPDs proceeded through more use cases and newer models, suppliers have made every effort to reduce the number of implementations, and to the extent possible maintain a single RPD design. While the RPD hardware implementation is different between RPDs intended for different use cases, it is especially beneficial to maintain the same software base. To that end, most suppliers have tried to implement a single software base for their RPDs.

This is possible while the key hardware components used in the implementation of RPDs are the same or are of the same hardware generation. However, when the hardware implementation is different, it is no longer possible to maintain the same software base. Such is the case for RPDs that were implemented initially with discrete hardware components, and eventually were migrated to functionality integrated transceiver-type hardware devices, it is especially the case when migrating to generations of RPD hardware components that implement newer versions of the DOCSIS specifications, as is the case now with the advent of DOCSIS 4. In such cases, a change in the software base becomes inevitable.

To mitigate the need for software diversity, an approach was launched within the industry, led by CableLabs® and supported by a multitude of suppliers and operators, known as OpenRPD. The approach, implemented as an open-source project, consisted of developing an application layer software, which interfaced with the RPD hardware via a hardware abstraction layer and device drivers, and operated above a lower-level kernel software.

While all the above efforts were intended to maintain and/or arrive to a single software base, various ecosystem situations and changes in the hardware approach made it difficult to succeed.

6. Collaborating on a Single Software Solution

Given our industrial experience throughout the evolution described above, it became clear that many of the issues stemmed from the differences in the software implementation of the standard. The variability of behavior increases the complexity of managing and debugging the devices. So how could this be mitigated? The answer is, once again, to move to a single RPD software base. To accomplish this, a common RPD application software program was created to include all suppliers developing RPDs for the operator.

The idea of RPD suppliers sharing a common software base is not new. As described above, CableLabs hosted a similar program known as OpenRPD. The OpenRPD program allowed participating suppliers to access a common software base as well as submit changes for features and fixes. These suppliers showed early successes during the Remote PHY interoperability activities at CableLabs. Issues were certainly found during these activities, as expected. But when solutions to these issues were found, all participants reaped the benefits.

6.1. Chosing the Target Hardware

Before beginning the architectural design of the software, it is important to decide on the initial hardware that will be supported. This decision will have a large impact on the software development scope of work.

The primary question here is, should the currently deployed devices be considered in the software implementation? Or should the focus of the software be on only on new hardware development? Targeting both existing and new hardware would certainly reduce the mix of implementations to support, which is the goal of the project. But at the same time, it would greatly increase the scope of work necessary to deploy the software.

On the other hand, supporting only new hardware development could simplify the software architecture by leveraging the design of the new generation of integrated silicon solutions. Additionally, the new devices would soon be replacing the previous generation in the field. And because of these reasons, it was decided that focusing on the next generation of RPDs was the way to go.

6.2. RPD Software Architecture

Proper architecture of the software is critical when supporting multiple hardware targets. It is important to separate the main components are shared and those that will differ between the various platforms. Figure 3 below shows the basic architecture of the RPD software:

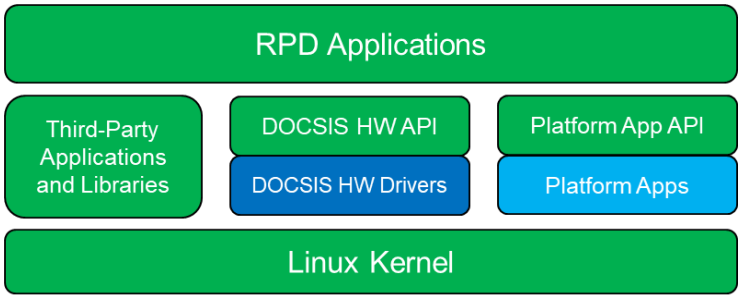

Figure 3 – RPD Software Architecture

The above blocks highlighted in green represent the functional components that are shared across all target platforms.

- **RPD Applications**: This is the collection of applications that provide the primary control interface and orchestrate control operations such as device configuration and monitoring.
- **DOCSIS HW API**: This specifies the programming interface for the DOCSIS-specific hardware. This includes operations such as DOCSIS channel and data-plane configuration.
- **Platform API**: This specifies the programming interface for the platform-specific hardware. This includes operations such as amplifier and attenuation configuration, LED control, timing configuration and monitoring, etc.
- **Third-Party Applications and Libraries**: This includes dependencies for features such as DHCP, SSH, 802.1x, etc.
- **Linux Kernel**: The distribution provides the supported Linux kernel version.

The blocks highlighted in shades of blue are specific to the hardware on the target platform.

- **DOCSIS Drivers**: These drivers conform to the interface defined by the DOCSIS API. They perform the low-level operations necessary to program the DOCSIS-specific hardware. Platforms that use the same DOCSIS hardware solution share the common drivers from the hardware provider.
- **Platform Applications**: These applications conform to the interface defined by the Platform API. These applications are specific to the each of the suppliers' hardware designs.

7. Managing the Software

The common RPD software will be used by multiple RPD suppliers targeting multiple platforms. This introduces some complexity when considering how the software base will be managed. Some of the questions raised are:

- Which build framework should be used to create the OS distribution?
- How should the software repositories be organized?
- How can each supplier separate their IP from the common software?

7.1. Deciding on the Build Framework

There are many choices when it comes to managing the project's build framework and operating system distribution. Some of the more popular frameworks for embedded systems are:

- Buildroot
- Yocto
- OpenWRT
- "Roll your own"

As expected, each of the choices come with its own advantages and disadvantages, briefly summarized below.

Buildroot is known for its simplicity. This means developers new to the framework can get started relatively quickly. However, precisely because of its simplicity, a significant amount of customization may be required to support many platforms within a single project.

The Yocto project, on the other hand, was designed with flexibility in mind. Yocto comes ready with a vast library supporting a large number of platforms. But with this flexibility comes complexity. Yocto is known for its steep learning curve.

The OpenWRT Project's primary focus is building firmware for commercial devices such as routers. It can be used for other types of embedded devices as well, but stepping away from its design for routers means additional customization.

Creating a custom distribution without a third-party framework is another option. This is something to consider if a project has very specific requirements that existing solutions do not provide. But this can introduce more overhead in maintenance when it comes to tasks such as keeping security patches up to date and resolving dependencies for upgrades.

Considering the choices above, the Yocto project was selected for managing the RPD program's OS distribution. In the end, it was decided that the time spent on learning the tools would be well worth the flexibility and hardware support required by the program.

7.2. The Yocto Project: Layers and Recipes

So, what makes the Yocto project flexible?

Let's start with what Yocto refers to as "recipes." A recipe is basically a script that provides instructions on how to build a particular entity (e.g. application, library, file system image, etc.). In its simplest form, a recipe for an application can just provide the location of the source software. Yocto can determine how to build the application and install it as long as the source is using one of the common automated build systems (e.g. autotools, cmake, meson, etc.).

Recipes are located in directory trees where the top directory is referred to as a "layer." A layer is a collection of recipes and configuration files. A single layer typically encompasses a particular category of recipes. For example, one layer might include recipes for shells, or even common RPD software applications. A typical project will have multiple layers, but will not necessarily use every recipe in every layer.

7.3. Organization of Layers in the RPD Project

The RPD project contains four categories of layers:

- **Third-Party Applications Layer**: This is actually several layers. The RPD project pulls in the existing layers from Yocto that provide the third-party open-source applications and libraries such as DHCP, SSH, and 802.1x. These layers are shared among all RPD projects.
- **Common RPD Applications Layer**: This layer contains the recipes for all of the common configuration and monitoring applications for the RPD. In addition, recipes for the DOCSIS HW and Platform APIs are provided. This layer is shared among all RPD projects.
- **SoC Applications Layer**: These layers contain the recipes for the various system on a chip (SoC) solutions available. They provide recipes for the required OS kernel and the DOCSIS HW drivers. Each RPD project selects the SoC layer associated with the hardware chosen for the target platform. Access control is necessary to restrict its use to suppliers that have the associated license agreements with the SoC provider.
- **OEM Applications Layer:** These layers contain recipes for applications, libraries, and drivers specific to the target device. Access control ensures that this layer is restricted to the associated supplier.

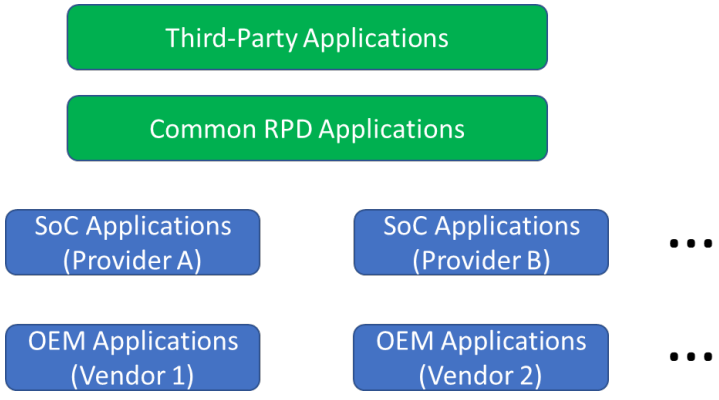

Figure 4 – Yocto Layers for the RPD Project

As described above, some of the layers are shared while others are selected based on the needs of the target device. For example, two different suppliers could use two different SoC solutions in their respective RPDs. Figure 5 below illustrates the combinations of layers required for an RPD developed by supplier "1" using SoC "B":

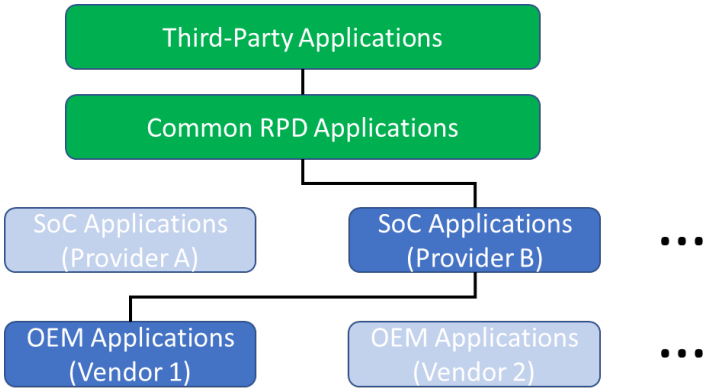

Figure 5 – Example Selection of Yocto Layers

7.4. Managing the Layers

As explained in the previous section, the Yocto layers are useful for organizing the build recipes into logical categories. These categories make sense from a software architectural standpoint. But they are also helpful when it comes to managing software changes and access control.

The layers in the RPD project have different access requirements depending on which category they fall into. For example, the common RPD applications must be accessible to all developers, but a specific supplier's OEM layer must not be available to other suppliers. To handle this requirement, each layer is placed in a separate repository. The proper access permissions can now be set uniquely for each repository.

One concern with this setup may be that developers now have to deal with a large number of repositories just for a single target. It is certainly true that the list of required layers can grow, especially given that just the third-party applications alone can be spread over many layers. But this is easily handled by using an application such as Google's "repo" command. Tools like this can take a single manifest that points to the collection of repositories for a project and manage any bulk operations such as checking out the software, branching, committing, etc. Operations on individual repositories can be performed as usual.

With the access controls in place for each of the repositories, this naturally decides which developers can see and make software changes as well as participate in software reviews for each layer. For example, only the suppliers with licensing agreements for a specific SoC can participate in the development for the associated layer. Likewise, all parties can participate in the development of the common RPD software layer.

8. What Comes Next?

Features continue to be added to the Remote PHY specifications that will need to be supported. The next big feature on the roadmap is streaming telemetry. This is a paradigm change from the pull model

supported today. Adding the vast number of statistics required for monitoring field deployments is no small task. But the results of this effort can be shared among those involved with the project.

Another task on the horizon is virtualization of the RPD control plane. Running the RPD software without the underlying hardware can have multiple uses. A virtual version of the RPD can be used for automated integration testing in the build environment. Additionally, initial development testing for some features can be started with the virtual RPD, reducing the time spent on lab resources.

Overall, the roadmap may be similar to other RPD software programs. The big benefit with this program is that the fruits are shared by all.

9. Conclusion

Managing a large deployment of Remote PHY devices is a challenging task. Problems will arise in any large network. Troubleshooting these issues become more complex when the devices differ in behavior, debug capabilities, and supported features. Moving to a common software base certainly will not solve all issues typically seen in deployments, but standardizing the implementation of the management interface will simplify the configuration, monitoring and troubleshooting of RPDs by reducing the supplier-specific behavior. Accomplishing this goal is possible with a software architecture and development environment that supports multi-supplier collaboration.

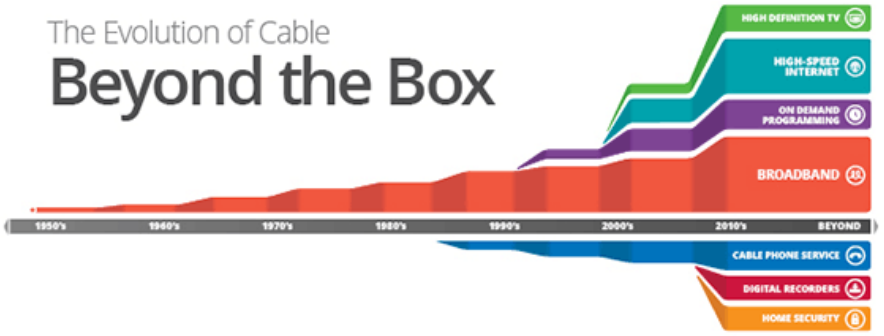
1. Introduction

The airwaves around us are continually filled with the invisible signals emanating from and between the Wi-Fi gateways and devices that use them for broadband connectivity, as well as from and between devices that use Bluetooth for connectivity. Naturally, techniques like Radio Frequency Identification (RF ID), which date back to the 1970s, were developed to use those radio waves for object identification. Commonly, you will see RF ID tags affixed as stickers or built into consumer devices, for the purposes of being read at a distance and without line of sight, as with highway toll readers, employee ID badges, etc. The ambient nature of these signals provides the opportunity to "piggy back" on the existing networks, which can reduce the overall power consumption of RF backscatter solutions. This paper examines the performance tradeoffs between different communication protocols used in both sensor and tracking solutions, including RF backscatter, Wi-Fi, Bluetooth, and LoRa (Long Range). The main area of focus will be around power consumption and data throughput for IoT type solutions. Readers will learn the basics of energy consumption and data transmission rate capabilities from these technologies, along with the power consumption baselines of mainstream IoT devices and how transmission protocols can impact the powering and life of the IoT devices.

Cable network operators are always looking for ways to add services for their customers, especially so since the 1990s. A couple of examples include: Data over cable, voice, and DVR(Digital Video Recorder) evolving to nDVR, were added to the service bundle. More recently, home monitoring and security services have also been offered by many operators. [1]



(Calcable.org, n.d.)

Figure 1 - Evolution of Cable

The Internet of Things is loosely defined as Internet-connected sensors in homes, businesses, and public spaces, as well as the data analytics monitoring of those sensors back in the data center. With the Internet of Things, there is an opportunity to rapidly open up entirely new service opportunities that can differentiate cable network operators from their competition. However, the primary challenge will be to smoothly install, operate and integrate these new services with the operator's existing service bundle.

Cable network operators are uniquely positioned to offer IoT services to new and existing customers. They have four characteristics that industry start-ups and OTT service providers covet:

- Existing service location in millions of homes, businesses, and public spaces

- High speed and reliable network connectivity
- Power for sensors and gateways
- An existing and localized/in-market fleet of fulfillment technicians

Cable network operators have a well-established presence in the home including cable modems, home gateways, set top boxes, Wi-Fi extenders and home security hubs, however the evolution to new services - such as connected healthcare, and smart homes – will require new devices and sensors, as well as increased care to ensure the highest network performance while preventing security breaches.

Where is the world of IoT going? According to a market report from Research and Markets "The total number of IoT connection worldwide will increase from 1.5 billion at the end of 2019 to 5.8 billion in 2029". Using that as a data point one can assume these devices will continue to show up in our daily lives in various locations, in a multitude of forms. Many of these devices are part of larger systems or add-ons to existing systems. In those cases, the powering of the devices come from wired sources or systems recharged on a regular basis. Additional implementations consist of stand-alone devices used for monitoring or tracking. These devices tend to be small and powered by batteries (think of door sensors, window sensors, outdoor sensors for temperature, humidity, noise…etc.). One of the biggest issues with the stand-alone IoT devices is maintaining power to the devices so they can do their job.

For systems or environments with large amounts of sensors, replacing batteries can be an endless task, making the labor cost to replace batteries or devices a non-starter. Just think about how often you swap out your remote batteries and multiply that by 5, 10 or even more for your home IoT devices. Now take that equation and move it to an outdoor or warehouse situation and the problem explodes one or two orders of magnitude. With that said, many IoT vendors target their designs to a single battery that will last the lifetime of the device, which can be anywhere from 3 years all the way out to 10-15 years in a low power wide area network solution (LPWAN).

So how can we extend the life of these devices? Doing so could be a game changer, depending on the application and the amount of data that is being sent out. There are a couple of ways this can be done: use larger batteries, leverage energy harvesting technologies to replace the batteries or extend battery life tend to be the most obvious. However, another interesting option is changing the data transmission protocol used to transmit the data to the access point/base station.

2. Communication Protocols used in IoT(Internet of Things)

IoT devices are ubiquitous and are part of our everyday life, from the smart home devices we use to the health and wellness devices that keep track of our overall health. Have you ever wondered what makes these devices smart? The simple answer is that these devices are now capable of communicating with a computer/machine/internet and provide critical data for algorithms and applications.

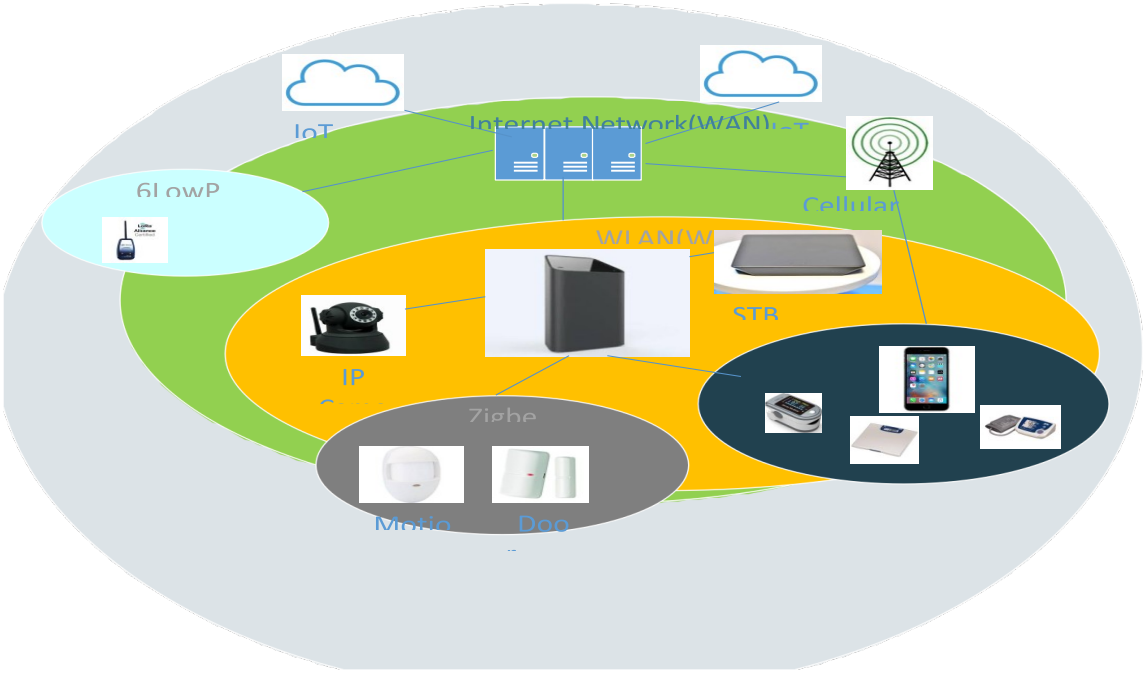


Figure 2 - Devices and Networks used on IoT Applications

Figure 2 shows multiple devices using different communication networks and protocols. The choice of the protocols and networks depends on the type of data involved, range of the sensors, and the applications these devices support. Some networks and protocols support data transfer at longer distances, while other protocols support larger data transfer rates at low range(distance). Depending on the range, these networks could be classified as WAN(Wide Area Network) or PAN(Personal Area Network). PAN includes networks like Bluetooth, Zigbee, Wi-Fi, which support very high data transfer rates, but their range is limited to probably a few meters. On the other hand, WAN include networks and protocols like LoRaWAN, NB-IoT, Mobile(LTE/5G), Cable/Fiber broadband, and can support connectivity at larger distances. Table 1 provides some key details of each of these network protocols. The sensor that uses these networks need to meet the power requirements of the network/protocol, as the sensor might need to engage the antenna and provide enough power to transmit and receive the data. Often, the power characteristics would depend on the data being handled and the distance the data is being transmitted.

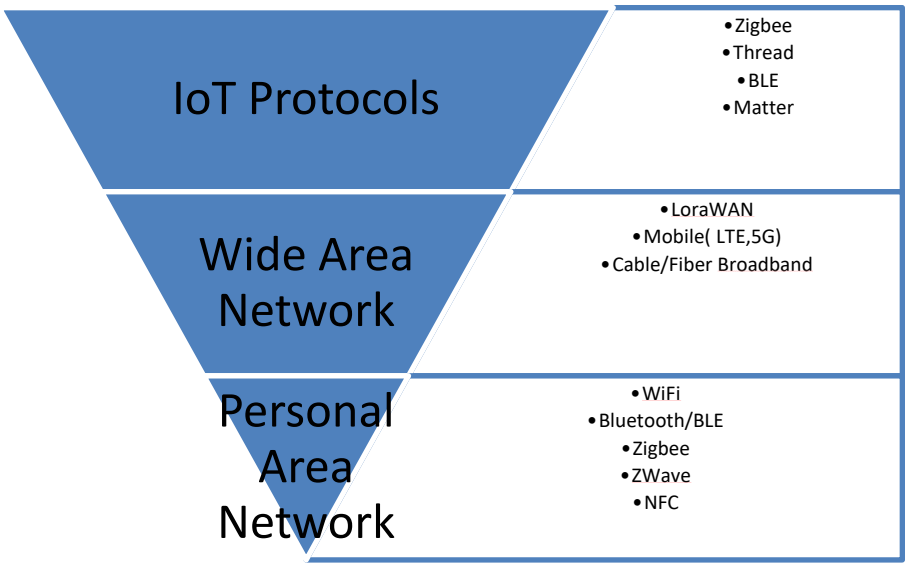

Figure 3 - Components of a typical IoT Application, Networks and Protocols used

As the penetration of these sensors/devices increase, it is critical to note the power consumed by these sensors, both from an efficiency and a sustainability perspective. Most of these sensors are often powered by batteries and the users would ultimately need to replace batteries on these sensors. This is a significant challenge in terms of a sustainable ecosystem. This paper compares the power characteristics of the different protocols and would seek methods to make the IoT ecosystem more sustainable. By understanding the power characteristics and requirements for these networks and protocols, we can explore augmenting the power from sustainable sources, such as ambient light. This would improve the battery life of the sensor, making it more sustainable and provide better customer experience.

Table 1 - Table showing operating conditions of IoT networks

	Personal Area Networks						*Wide Area Networks*	
	NFC	**BLE**	**Wi-Fi**	**Zigbee**	**Zwave**	**WiFi HaLow**	**Mobile(LTE, 5G)**	**LoRa**
Operating Freq	13.56 MHz	2.4 GHz	2.4, 5 and 6 GHz	2.4 GHz	908.42 MHz	< 1GHz	450 MHz to 6GHz and 24.25GHz to 52.6 GHz	902-928 MHz
Max Power	Low power needed	1mW – 100 mW	100mW – 4000mW	10mW – 100mW	10mW – 100mW	10mW – 100mW	Varies as per endpoint	
Battery Operated?	Yes	Yes	Possible	Yes	Yes	Yes	Yes	Yes
Range	10 cm	<100m	Around 50m	<100m	100m	Approx 1Km	Range varies. Up to a few Km. 5G bands offer very low range compared to LTE	Between 15 to 20 Km
Throughput	424 Kbps	2Mbps	WiFi ax max – 3.5Gbps	250kbps	40kbps to 100kbps	150kbps to 4Mbps	50Mbps to 10Gbps	300 bps to 37.5 kbp
Ease of Adaptation	Wide Adoption	Wide Adoption	Wide Adoption	Wide Adoption	Medium Adoption	Low Adoption	Growing Adoption	Low to Medium Adoption

3. Power Characterisctics

Table 1 provides us with some details on the metrics on the networks and protocols used. In this section, we will examine how some of these protocols are efficient with regard to power consumption.

As the world around us gets more complicated, the flow of information grows in importance as we become more connected. Someone is always checking their Facebook feed, e-mail, doggie cam, receiving alerts from their home systems, finding their car, checking the air quality, traffic speeds…etc. As the flow of information becomes increasingly more important for our daily lives, the need for these systems to be connected and always available becomes critical. The devices that make it all possible need to rely on some type of power source to keep us “in the know”.

The easiest power solution for all these are the devices already connected into the regular power grid. With wired solutions, the power usage isn't a big concern, other than a power outage, which can be handled by some type of battery backup, if necessary. Other solutions that tend to be more mobile (the main one being a smartphone) have rechargeable batteries that give the device portability but offer a very limited life before the user must recharge the system. The final case, which we are most interested in, is the IoT case where devices are deployed in a stand-alone fashion and expected to function for an extended period normally measured in years as opposed to days. This is where changes in power consumption can have enormous impacts on the life of the device.

There's a couple of ways to break down the power characteristics of the different devices and protocols. In general, the farther you transmit a signal, the more power you will need; the more data you transfer, the more power you will need; and the longer the device is "awake" and transmitting data, the more power you will need. This addresses the technologies employed with a very broad stroke, but with that in mind, we can break the different solutions down based on their reach, reliability, throughput, and power consumption. Each of these different parameters really speaks to the notion of there not being a "one size fits all" IoT solution.

In general, IoT devices have two main purposes: the first is to collect data and the second is to forward that data to a centralized system where the data can be stored, analyzed, and/or acted upon. Looking at the power budget for the endpoint, a large portion is expended in the transmission of the data back to the gateway. These networks consist of many endpoints to very few gateways. In some cases, a gateway can support up to and potentially over 1 million IoT devices. Here's some of the different networks these IoT devices can be deployed in:

3.1. Personal Area Networks(PAN)

PAN is a network that interconnects computers within a limited area such a residence or a small business facility. Primarily these networks were intended to be the data pipe between computers and modems and hence the focus was more on data throughput. As spaces like residences and businesses grew, the need to provide reliable data connectivity at larger distances became important. This resulted in increased power output on the radios. With the advent of IoT devices and networks, devices that are powered by batteries grew and this put a natural limit on the power we could transmit. There have been significant advancements on the power efficiency of these networks that consume less power, but still manage to support better data rates.

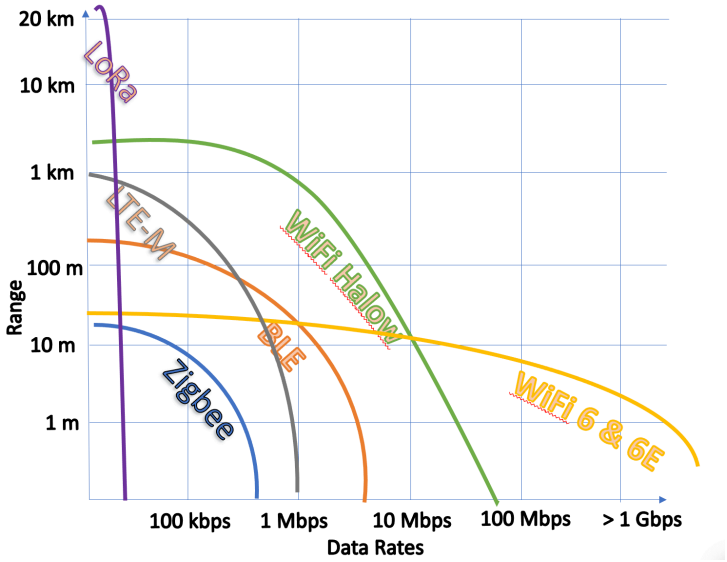

Figure 3 - Range vs Data rates of Wireless PAN

As shown in Figure 3, we see that the data throughput of the networks tends to drop down as the distance between two endpoints increase. The data rates supported at different distances depends on the protocol used and on the specific implementation of the standard. As protocols are pushed to the edge, the need to provide reliable connectivity often results in increasing the output power, which in turn puts a lot of stress on the endpoints, especially if they are battery-powered. Even within range, the pain point in managing battery life of multiple sensors and devices leads to an unpleasant customer experience. Hence, this paper looks at the power characteristics of these network protocols and where power performance can be optimized if we can augment the battery power with energy harvested from ambient power sources, like light, temperature differential, and power over RF. We will look at the power characteristics of some protocols in this section.

- ***BLE (Bluetooth Low Energy)***
  Compared to Classic Bluetooth, Bluetooth Low Energy is intended to provide considerably reduced power consumption and cost while maintaining a similar communication range. Mobile operating systems including iOS, Android, Windows-Phone and BlackBerry, as well as macOS, Linux, Windows 8, and Windows 10, natively support Bluetooth Low Energy.

  A typical BLE SoC (i.e. an all-in-one Application + Radio chip) typically consumes:

  - A few hundreds nA(Nano Amp) while in deep sleep,
  - 2 to 10 µA while a RTC tracks time (needed between radio events while advertising or connected),
  - 10 to 30 mA while CPU or Radio runs (computing data, TX, RX). RX and TX power consumption is roughly the same.

  The life of a BLE peripheral basically consists of 3 main states:

- Be idle (not advertising, not connected). The device would be in a sleep/standby state and consumes just over a few hundred nanoamps though.

- Advertise (before a connection takes place). Peripheral needs to be running approximatively 5ms every 50ms. This is the time when your device actually uses the most power because advertising requires sending many packets, frequently. Average power consumption is in the 1-10 mA range.

- Be connected. Here, consumption is application-dependent. If application is mostly idle, a peripheral is required to wake up periodically and must send a packet each time in order to keep the connection alive. Even if the peripheral has nothing useful to send, an *empty packet* is still sent. Side effect: that means low duty cycle applications basically transmit packets for free.

We could estimate the battery life of a BLE device using a typical BLE example:

- Radio power consumption = (5.4uA * 3V) * 1/2s = 8.1uW
- System power consumption = (2uA * 3V) = 6uW
- Total power consumption = 14.1uW
- Battery life = ((300mAh * 3V) / 14.1uW) * 0.7 = 44681 hours = 1860 days

If we can augment the battery with an energy harvesting source that can supply enough power for the SOC, we could either make the sensor battery free or extend the battery life.

- ***ZigBee***

  ZigBee is a mesh network protocol designed to carry small amounts of data across medium distances. It runs on a mesh topology network, meaning information from a single sensor node, travels across a group (or "mesh") of nodes until the transmission reaches the gateway.

  ZigBee is a local area network (LAN), so unlike BLE, it is not intended to connect to devices directly around a user. Instead, it connects to devices that need a wider range. Because of this, it's an ideal protocol for home automation[1] and smart lighting[2].

  As an example, battery life of a motion sensor with a ZigBee radio could be around 5-7 years, which is comparable to that of BLE

[1] https://www.link-labs.com/applications-of-home-automation/
[2] https://www.link-labs.com/smart-lighting/

- ***WiFi HaLow***
  WiFi HaLow is IEEE 802.11ah standard that uses the WiFi protocol characteristics, using a sub-GHz band. WiFi HaLow promises
    - Lower Power Consumption
    - Longer Distances
    - Better Penetration
    - Lower data rates (150 Kbps at longer range, 10+Mbps at closer range)

  Figure 4 shows the frequency bands used by WiFi Halow in the WiFi standards.

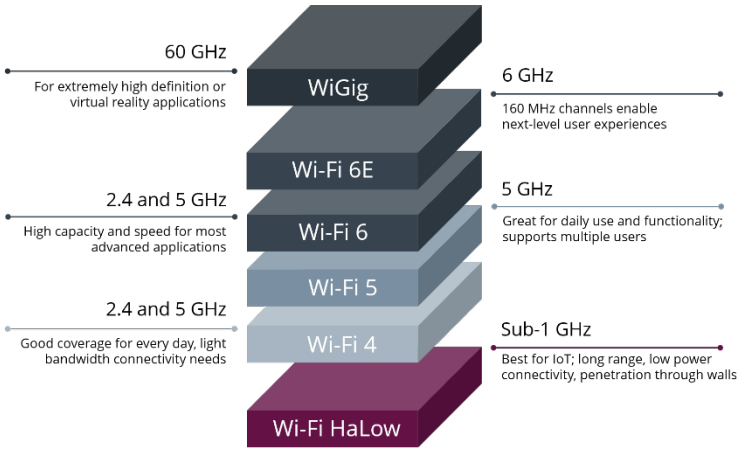

Figure 4 - Wi-Fi Frequency Bands

3.2. Wide Area Network (WAN)

(In the context of this paper, when talking about WAN, we are referencing wireless WAN solutions.)

Some of the most compelling deployment use cases for IoT revolve around the deployment of sensors and asset tags spanning large geographic reach (when the term WAN is used, a range of more than 2km is a good starting point). There are a multitude of use cases for these devices, but in general they can be categorized into a handful different areas…1) highly reliable data with large data throughput requirements, 2) small amounts of data that are not time sensitive and 3) small amounts of data requiring a high level of reliability. Additionally, from a technology perspective, there are two different solutions that are usually discussed for these transmission scenarios; cellular and non-cellular (sometimes referred to as licensed and unlicensed spectrum). Below is a chart that outlines some of the different characteristics of these systems

Table 2 - Characteristics of Cellular and Non-Cellular LPWAN Networks

Parameter	CAT-1	CAT-M1	NB-IoT	LoRa	SigFox
Bandwidth	1.4 - 20 MHz	1.4 MHz	180 kHz	125 kHz or 500 kHz	100 Hz
Data Rate	DL: 10 Mbps UL:5 Mbps	DL: 1 Mbps UL: 1 Mbps	DL: ~20 kbps UL: ~60 kbps	.3 – 50 kbps	100 bps
Latency	50-100 ms	10-15 ms	1.6 – 10 s	Topology dependent	Topology dependent
Spectrum	Licensed	Licensed	Licensed	Unlicensed	Unlicensed
Peak Transmit Power	23 dBm	23 dBm	23 dBm	20 dBm	22 dBm

- Cellular (Licensed spectrum)[3]
  Cellular WAN solutions have evolved with the changing cellular technologies, but the most common ones are CAT-1, CAT-M1 and NB-IoT. All three solutions leverage licensed cellular bands which provide a more controlled environment for the transmissions which give the data transmissions a higher reliability than networks using unlicensed spectrum.

  - CAT-1

  In the world of LPWAN CAT-1 would be considered a power hog but has some of the highest throughputs and lower latency.

    - ◊ Latency typically 50-100 ms
    - ◊ Throughput of 5 Mbps uploads and 10 Mbps downloads
    - ◊ Spectrum bandwidth of up to 20 MHz

[3] https://en.wikipedia.org/wiki/Narrowband_IoT

- ◊ Typical use cases include video surveillance, ATM communication and vehicle telemetry

- CAT-M1(LTE-M)

CAT-M1 or LTE-M uses existing LTE networks but consumes far less battery power than CAT-1 devices. The solution has the ability to handle moderate bandwidth applications with minimal latency requirements.

- ◊ Latency typically 10-15 ms
- ◊ Throughput of 500 kbps uploads and 1 Mbps downloads
- ◊ Spectrum bandwidth of up to 1.4 MHz
- ◊ Ability to handle cell tower handoffs
- ◊ Typical use cases include wearables, high value asset tracking and health monitors

- NB-IoT[4]

This protocol is designed for devices that transmit small amounts of data with fairly loose latency requirements. The solution still leverages the LTE network, but operates in the roll off of the licensed spectrum.

- ◊ Latency typically 1.6 – 10 seconds
- ◊ Throughput of 120 kbps uploads and 160 kbps downloads
- ◊ Spectrum bandwidth of approximately 180 kHz
- ◊ Typical use cases include smart gas, water and electric meters along with smart city applications such as street lighting and parking sensors
- ◊ Stationary application since it cannot handle cell handoffs

Table 3 - LPWAN Network Characteristics

	Data reliability	Data throughput	Power consumption	Endpoint mobility
Grid Powered Cellular	High	High	High	stationary
Battery Powered Cellular	High	Low	Medium	
LPWAN/NB-IoT	Low	Low	Low	broad

- Non-Cellular (Unlicensed spectrum)

In the unlicensed LPWAN space the main technologies used are LoRa and Sigfox. Both solutions are focused on data uplink, where a large number of sensors transmit data to a small number of gateways in a star type topology. With these solutions using unlicensed spectrum, interference in the form of noise and other signals is a much larger concern.

[4] https://www.siretta.com/2021/02/lte-cat-1-vs-lte-cat-4/

Data collected and used in these systems in most cases is slow changing and not latency dependent. Occasional missed data packets shouldn't impact the overall system. Applications like temperature monitoring, air quality and agricultural data are good candidates for both solutions.

- LoRaWAN or LoRa[5]

LoRa networks can be deployed in a very low-cost manner with a minimal number of gateways to support the network. Unlike licensed LPWAN solutions, network gateways are easily deployed and managed. With a focus on low power LoRa endpoints can see device lifetimes from 10-15 years depending on the data being transmitting, frequency of data updates and distance the sensor is from the gateway.

  - ◊ Latency of system is dependent on the number of packets a gateway can process in a day related to the number of endpoints being supported
  - ◊ Throughput of .3 kbps to 50 kbps
  - ◊ Easily transmits through physical barriers
  - ◊ Spectrum bandwidth of 125 kHz or 500 kHz uplink and 500 kHz downlink
  - ◊ Star on Star network topology

- SigFox[6]

SigFox uses a proprietary technology which is optimized for extended distance over LoRaWAN, where up to 10 km is urban and 40km is rural areas, where LoRaWAN would only be capable of roughly 5 km in urban and 20 km in rural areas.

  - ◊ Latency of system is dependent on the number of packets a gateway can process in a day related to the number of endpoints being supported
  - ◊ Throughput max of 100 bps
  - ◊ Easily transmits through physical barriers
  - ◊ Spectrum bandwidth of 100 Hz for the uplink and 600 Hz on the downlink
  - ◊ Star network topology
    - ◊ Limited to 140 messages a day for the uplink and 4 messages for the downlink

4. Energy Harvesting

Harvesting energy for IoT applications can done using a variety of sources. While some include using the ambient environmental conditions to harvest energy, other methods include transmitting energy using mediums like WiFi or RF. Candidates include sensors used in IoT applications such as temperature, humidity sensors, to motion sensors and cameras. The key here is to find the right energy source that can either power the sensor in a battery-free mode, or trickle-charge the batteries to increase the overall life of the sensor.

Figure 5 shows an example of a system that is capable of harvesting energy to augment the battery of a sensor using the BLE communication system.

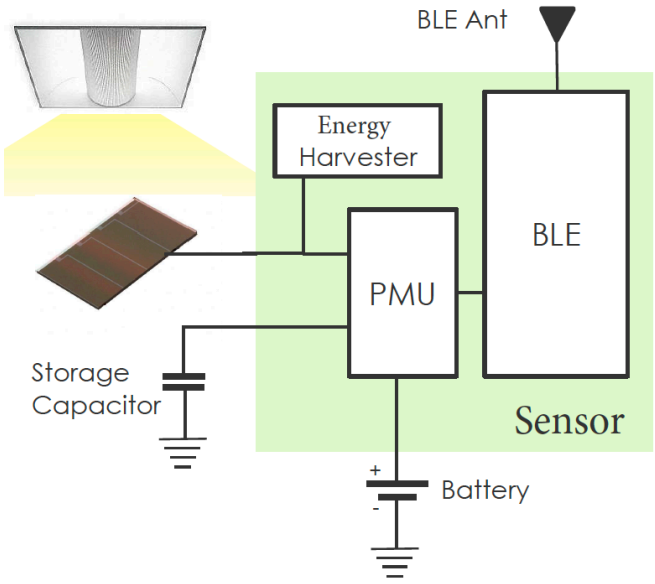

Figure 5 - Typical Energy Harvesting system

There are a variety of energy sources from which we could harvest energy. We will examine a few of the most application or common energy harvesting technologies next. Figure 6 illustrates how different energy harvesting technologies could support applications such as sensors, asset tracking application and many others. Table 4 shows the power density of the each of the energy harvesting technologies.

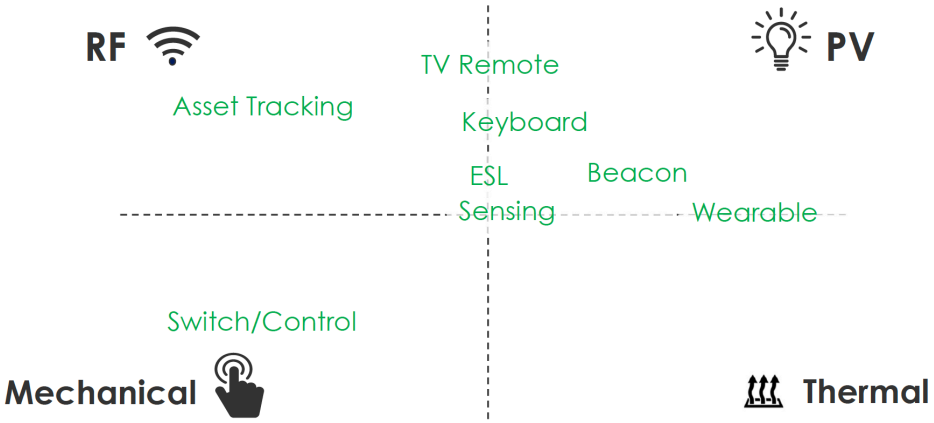

Figure 6 - Applications Supported by Energy Harvesting Technologies

Table 4 - Power density of various Energy harvesting systems

Source	Power Density
Mechanical/Piezoelectric	[0.11-7.31] mW g2/cm3
Radiofrequency	$1.2*10^5$–15 mW/cm2
Solar	[0.006–15] mW/cm2
Thermoelectrical	[15–60] _W/cm3
Wind	[0.065–28.5] mW/cm2

4.1. Photo Voltaic Energy Harvesting

The technology of using photons (sunlight) for generating power/energy has been around for millions of years. The ambient light available around us, even indoors, is sufficient to generate energy that can trickle charge a battery or power low-power sensors. Significant progress has been made in the form of organic photo voltaic cells that can generate sufficient power from indoor lighting conditions.

Figure 7 shows the power needed for various wireless protocols and how they could be powered by a 10 cm^2 IPV (Indoor Photo Voltaic) panel.

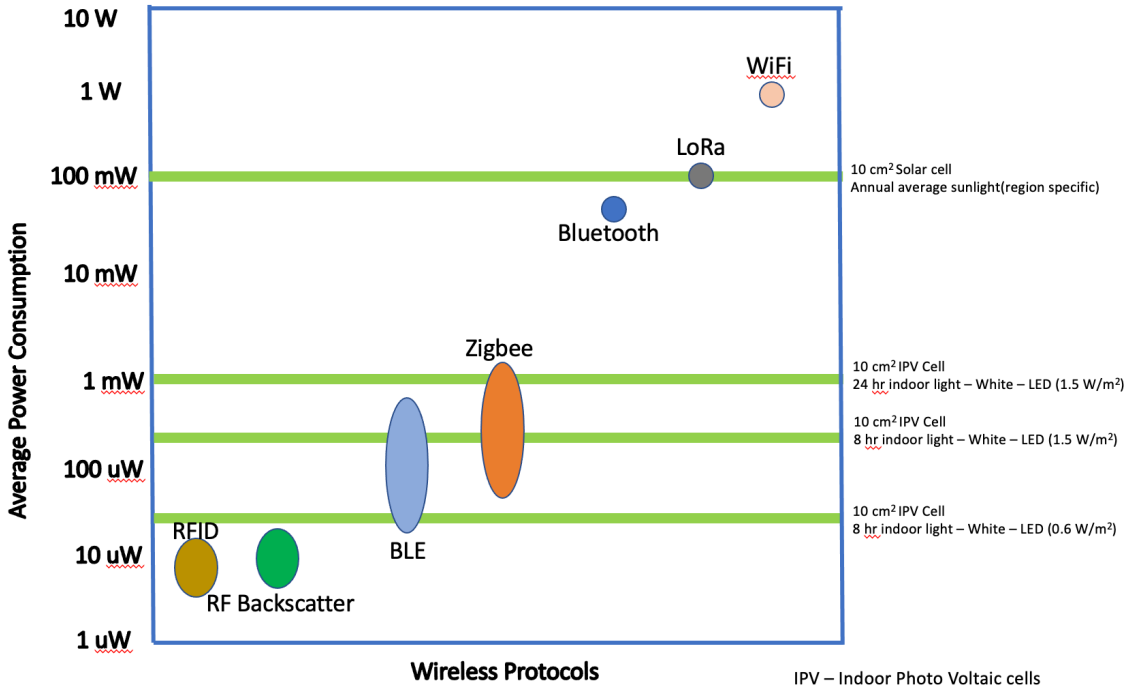

Figure 7 - Mapping wireless protocols to indoor photovoltaic cells based on power needs

4.2. Radio Frequency based Energy Harvesting

RF-based energy harvesting provides a controlled environment for charging/powering IoT devices/sensors over RF/Electromagnetic waves that propagate around us in the form of WiFi/Bluetooth or other wireless signals. RF-based energy harvested signals can carry the information along with the production of energy and can also process that information simultaneously. [7][8]The amount of RF energy available for harvesting at the RF harvester's antenna input will depend on the source's transmitter strength, RF frequency, duty cycle, and range to the receiver.

Figure 8 shows a typical RF harvester that receives energy on a particular frequency. There can be 2 types of RF harvester.

- Ambient RF harvesting: In this case, the receiver is capable of harvesting energy from ambient RF like Bluetooth and WiFi signals
- Active RF harvesting: In this case, a transmitter would send energy on a specific frequency and the receiver would tune to get power. This method offers a more controlled environment.

[8] https://ieeexplore.ieee.org/document/6623062 - **Wireless Information and Power Transfer**

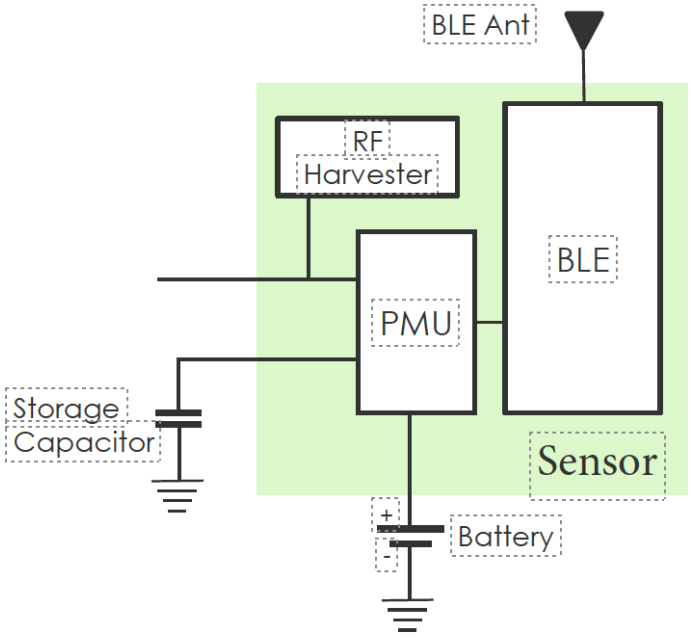

Figure 8 - RF based Energy Harvesting

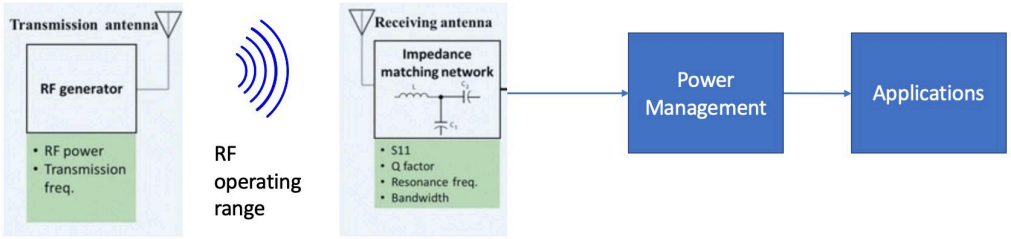

Figure 9 - Active RF based Energy Harvesting

4.3. Mechanical based energy harvesters

Devices called Nanogenerators can convert small amounts of mechanical energy into electric current. The very first nanogenerators were based on the triboelectrification and piezoelectric effect.[9]

Energy harvested from unintended mechanical vibration and abandoned heat can also be directed to low powered electronic devices. Conversion of energy from the ambient environment into electrical energy is known as vibration energy harvesting (VEH).[10]

[10] https://www.ingentaconnect.com/content/tandf/ginf/2019/00000201/00000001/art00010;jsessionid=35omsvrame402.x-ic-live-01

4.4. Thermal Energy Harvesters

Thermal energy harvester use "heat" and temperature variation as the main source to generate power. Two techniques are being used to harvest energy from a thermal source. The first is pyroelectric and the other is thermoelectric.

- The Seebeck effect[11] is used by the thermoelectric technique to convert the difference in temperature into usable energy forms directly. A 5–8% efficiency of harvesting is achievable by the thermoelectric technique of harvesting.
- In pyroelectric energy harvesting, the wasted heat energy is converted into electrical energy for battery-free IoT-based portable devices and wireless sensors. It can convert temperature fluctuations into electrical energy, and this makes it more attractive for harvesting energy.

5. Case Study

As discussed in the earlier section of this document, it is very important and critical that we innovate technologies that help us maintain the growing number of IoT devices and also provide a sustainable solution. Increasing battery usage creates challenges in recycling them. In the sections above we looked at how networking technologies, both PAN and WAN perform. As the number of endpoints and sensors grow, reliable communication at farther distances is a challenge. Increasing output power not only increases draw on the energy sources, but increases the noise in the system and makes it more susceptible to noise.

In this section, we look at technologies that can offer a low-power alternatives to some of the wireless PAN technologies. We will look at the network performance in terms of data throughput, range, efficiency, latency, and power consumption. As a case study, we look at RF backscatter technology to see if it has potential as a low-power, protocol-agnostic, secure network that could be used by IoT sensors to transmit data and stay connected.

5.1. RF Backscatter Network

In RF backscatter networks, multiple network topologies are possible. We will look at a few of those topologies, and one in detail, to evaluate its effectiveness in terms of data throughput, efficiency, and latency.

- Ambient - In the first network topology, the endpoints (backscatter devices) communicate with each other by reflecting either ambient signals or a dedicated carrier service, as shown in Figure 10. The challenge with this network topology is that the receivers exhibit poor sensitivity in the range of -40 to -60 dBm, which limits the operating distances between the endpoints.

[11] https://en.wikipedia.org/wiki/Thermoelectric_effect

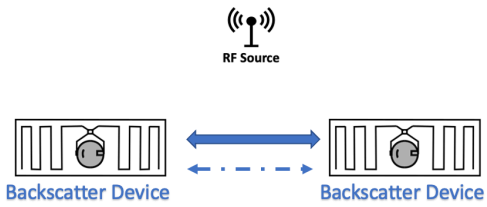

Figure 10 - Backscatter network using Ambient signals

- WiFi/LoRa: The second backscatter topology involves receiving backscattered packets on commodity radio receivers like WiFi or LoRa as shown in Figure 11. This topology is a significant improvement from the ambient backscatter, as the WiFi/Bluetooth/LoRa radios have better sensitivities. Using a LoRa receiver can further extend the range to 100s of meters.

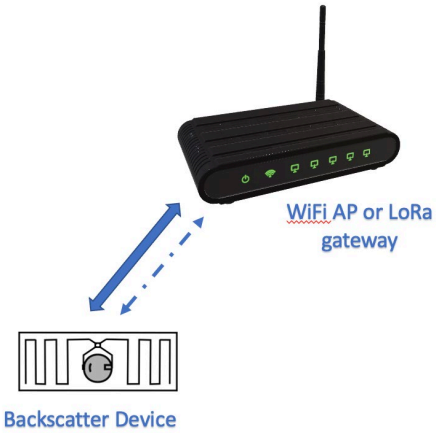

Figure 11 - Backscatter using Wi-Fi or LoRa signals

- Full Duplex: The third topology uses custom signal sources and custom receivers in a full-duplex configuration to operate the backscatter devices as shown in Figure 12. This configuration provides maximum flexibility.

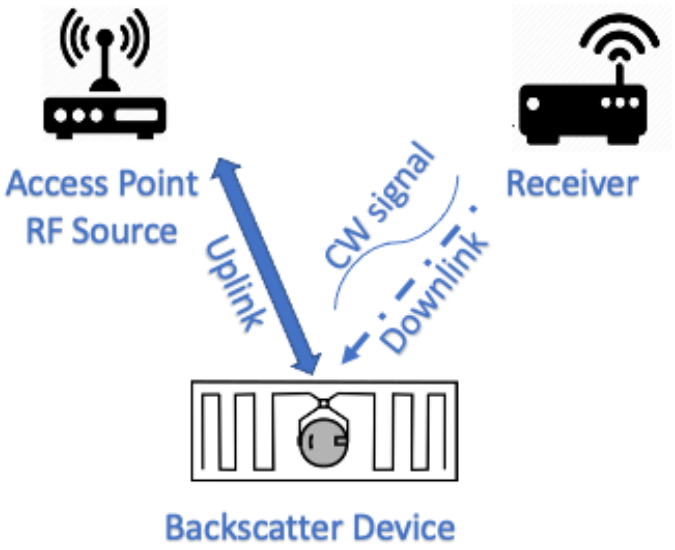

Figure 12 - Backscatter using Custom RF sources

While backscatter can be used with batteries, RF harvesting is still a popular choice for building battery-free systems since we can use the same antenna for both power and communication. Backscatter research is still in its infancy with primary focus on novel physical layer design. Recent research proposes solving some of the pressing networking and MAC-layer challenges of backscatter.[12]

Unlike a traditional wireless network that consists of solely a transmitter and a receiver, a RF Backscatter network consists of three distinct device roles: an Endpoint, a Gateway, and a Companion.

- ***Endpoint***
  The Endpoint a tiny, low cost, low power device that would be a sensor (such as a temperature sensor or smoke detector). The endpoint in a typical network (using WiFi/BLE) would have a wireless transmitter. However, in a backscatter network topology, the sensor achieves low power connectivity by using a backscatter uplink to transmit data packets to the gateway, as shown in Figure 12.

- ***Gateway/Access Point***
  The Gateway in this backscatter network takes the role of a traditional wireless receiver. It acts as a data sink for backscatter packets that are sent in from multiple endpoints. The gateway also serves as a bridge/hub between the backscatter network and another PAN or WAN or cloud server that can process the data generated by the endpoints. The gateway is shown as the RF source in Figure 12.

[12] M. Hessar, A. Najafi, and S. Gollakota. Netscatter: Enabling large-scale backscatter networks. In NSDI 19

- ***Companion/Receiver***
  The companion enables Backscatter communication by transmitting a brief CW (Continuous Wave) signal for each uplink transmission. The companion also coordinates Endpoint devices using a low power downlink signal.

In this network topology, the communication is initiated by the Companion. The companion first transmits a wake code to an Endpoint using On-Off Keying (OOK)[13] modulation. The Endpoint has an ultra-low power detector that helps it detect the wake code. Upon receiving the wake code, the Endpoint goes into a listening state/mode. An Endpoint in listening state would be able to receive data from the Companion via the downlink.

The Companion then transmits a downlink packet followed by a brief CW signal. The downlink packets instruct the Endpoint to transmit a backscatter packet during the subsequent CW signal. By selectively reflecting and absorbing the CW signal from the companion, the Endpoint is able to use backscatter to synthesize a wide variety of standard RF protocols (WiFi/LoRa) that can be received by the Gateway.

The Gateway can then bridge the data coming in from the backscatter network to a server that can process the data. Figure 13 shows the sequence followed by a backscatter network to transmit data from a sensor to an app on the customer's phone. Since the sensor/endpoint consumes low power, we could as well add any energy as discussed in the Energy Harvesting section of this paper.

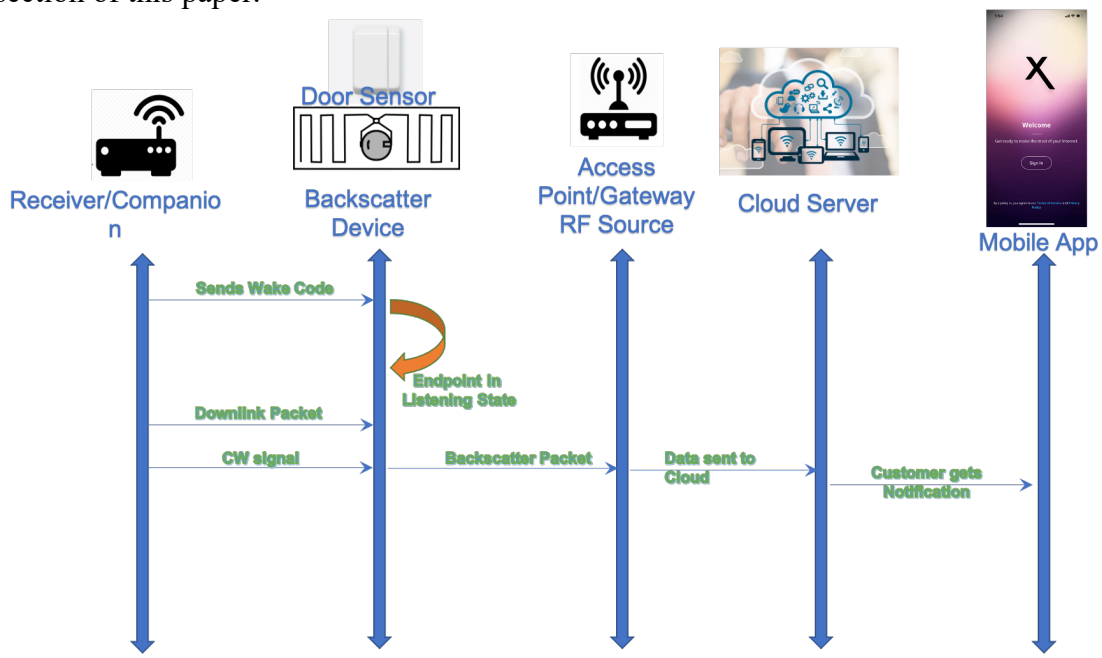

Figure 13 - Sequence diagram of a RF backscatter network packer transmission

[13] https://en.wikipedia.org/wiki/On%E2%80%93off_keying

RF Backscatter endpoints can achieve extremely low power to transmit the data generated by the sensor. A conventional radio actively generates and transmits RF signals for communication. Such system requires complex hardware and uses significant amounts of energy. See the comparison of power consumed, shown in Figure 7. Backscatter modulation utilizes reflected RF signals to communicate, which dramatically reduces all the systems needed to generate radio signals directly at an endpoint/sensor.

The reflections are produced by modulating the Endpoint's antenna impedance in the presence of a CW (Continuous Wave) signal, generated by the Companion. See Figure 14, when any type of wave encounters a boundary between two mediums that have different impedances, a portion of the wave is reflected. The reflection's magnitude is determined by the difference in impedance between those mediums. This is true for a mechanical wave traveling through a rope to a fixed point on a wall, or an electromagnetic wave encountering an antenna.

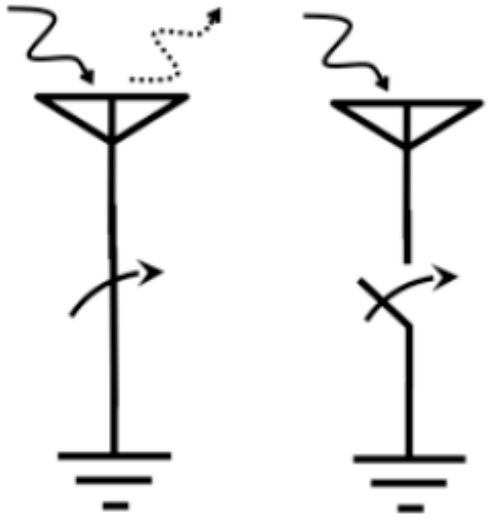

Figure 14: RF wave reflected/absorbed due to change in impedance

6. Conclusion

The world around us is becoming more connected on a daily basis; it is easier than ever today to grab information about the weather in your favorite destination, the air quality in your neighborhood, if you left a window open or a door unlocked and if you need to water your grass. In many of these cases, battery-powered IoT devices and their networks are supplying this information, but to keep the information flowing, these devices need to stay powered up and there's only so many options available. This paper has outlined some of the potential design considerations that could be implemented to extend the life of these devices either through improving the energy efficiency of the protocols used or additional technologies that could replace or extend the battery life of these IoT devices. In IoT applications and networks, where devices are deployed in a stand-alone fashion and expected to function for an extended period

normally measured in years as opposed to days. This is where changes in power consumption can have enormous impacts on the life of the device.

Innovation has been a constant in this industry, as we strive to bring in brand new technologies or improve existing ones to accommodate more use cases and help manage the ever growing number of battery-powered IoT devices.

The energy harvesting technologies mentioned in this paper have been deployed for many decades, and continue to evolve to address the pressing needs of a fast changing world.

The RF backscatter solution presented in this paper is promising and enables us to consider an ultra-low power, protocol-agnostic sensor portfolio.

1. Introduction

Low Latency is gaining importance amongst operators, and they are focused on reducing latency in each of part of the network including the Wi-Fi links in the home, DOCSIS links in the access network and core network segments. Providing lower latency and hence measuring the latency in each portion of network is a vital requirement for MSOs. Operators will need to troubleshoot latency issues and need the ability to identify latency within their networks vs. outside of their networks.

This paper aims to share the experience from developing a simple end-to-end latency measurement framework. A new measurement protocol defined in the IETF is STAMP (Simple Two-Way Active Measurement Protocol, RFC 8762). The paper will provide the lessons learnt from developing a proof of concept for latency measurement using STAMP. It will describe the high-level measurement architecture and locations for measurement agents and peers. A STAMP-reflector could be implemented in a gateway or a device behind it and a STAMP sender can be implemented somewhere in the network (e.g., in a hub, north of a CMTS). An operator can start with small number of measurement entities and scale up as needed. If a Session reflector can by dynamically instantiated in a gateway, then one can run measurements on-demand. The paper will also investigate methods to kick off different latency tests and have the measurement end points report latency data. It will also look into how latency data from various sources can be aggregated and reported. It will also discuss measurement control and reporting methods based on LMAP (Large-Scale Measurement of Broadband Performance). The paper will provide an understanding of MSO needs around latency measurement, an overview of the most appropriate metrics to report, and how to deploy measurement technologies to meet those needs. The paper also reports on a prototype STAMP measurement system which is deployed and collecting latency data.

1.1. Latency Metrics

One-way latency is the total time it takes for a packet of data to travel from the sender to the receiver, across one or multiple hops. Round trip time (RTT) or round-trip latency, is the total time it takes for a packet of data to travel from the sender to the receiver, across one or multiple hops, plus the total length of time it takes for receiver to send a packet back to the sender, through one or multiple hops.

Packet Delay Variation, PDV, is also derived from a sequence of latency measurements where a single reference latency is chosen from the stream based on specific criteria. The most common criterion for the reference is the packet with the minimum delay in the sample.

1.2. Latency Measurements

Active measurements are conducted by generating traffic between two end points for the sole purpose of measuring the latency. Passive measurements are done simply by observing normal host-host interactions. Instead of measuring the latency of specially created test packets like in active measurements, passive measurements are based on the normal user packets that traverse the network.

Active measurements are conducted by generating traffic between two end points for the sole purpose of measuring the latency. An Active measurement method depends on a dedicated measurement packet stream and observations of the packets in that stream. These packets are used to measure packet delay, and packet loss. One-way performance metrics need clock synchronization across the test points for measurements which are tough to implement. Active measurements can use protocols such as TWAMP/ TWAMP Light/STAMP.

1.3. Measurement Protocols

[IETF RFC 5357] TWAMP defines a standard for measuring round-trip network performance between any two devices that support the TWAMP protocols. TWAMP consists of two inter-related protocols: TWAMP-Control and TWAMP-Test. TWAMP Light is an alternative architecture which eliminates the need for the TWAMP-Control protocol and assumes that the Session-Reflector is configured and communicates its configuration with the Server through non-standard means.

Simple Two-way Active Measurement Protocol (STAMP) is a newer IETF standard [IETF RFC 8762] which provides a simpler mechanism for active performance monitoring. It separates the control functions (vendor-specific configuration or orchestration) and test functions. STAMP enables measurement of both one-way and round-trip metrics (delay, delay variation, and packet loss). It is intended to be used on production networks to enable the operator to assess service level agreements based on delay, delay variation, and loss.

2. STAMP

Simple Two-way Active Measurement Protocol (STAMP) is an IETF defined Standards Track RFC 8792[STAMP RFC]., which enables the measurement of both one-way and round-trip performance metrics, like delay, delay variation, and packet loss.

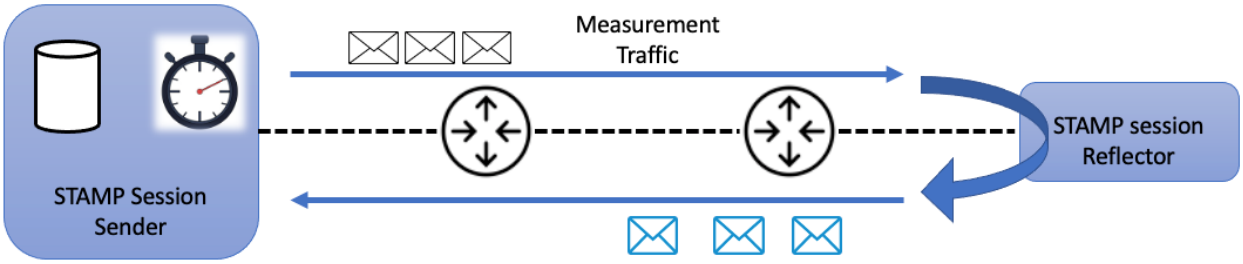

Figure 1 – Simple two way Active measurement protocol

A STAMP measurement session is a bidirectional packet flow between a Session-Sender and a particular Session-Reflector for a given time duration. A STAMP Session-Sender transmits test packets over UDP to the STAMP Session-Reflector. The STAMP Session-Reflector receives the Session-Sender's packet and sends a response per the configuration.

The configuration and management of the STAMP Session-Sender, Session-Reflector, and sessions are outside the scope of the STAMP RFC and can be achieved through various means. E.g., Operators could develop: Command Line Interface, Operational Support System (OSS) / Business Support System (BSS), SNMP, and NETCONF/YANG-based Software-Defined Networking (SDN) controllers.

2.1. Modes of operation

There are two modes of operation for the STAMP Session-Reflector, stateless and stateful per [IETF RFC 8762]

Stateless: The STAMP Session-Reflector does not maintain test state. It uses the value in the Sequence Number field of the received packet as the value for the Sequence Number field in the reflected packet. As a result, values in the Sequence Number and Session- Sender Sequence Number fields are the same, and only round-trip packet loss can be calculated while the reflector is operating in stateless mode.

Stateful: The STAMP Session-Reflector maintains the test state. This enables the Session-Sender to determine which direction the loss is happening by using the of gaps the Session Sender Sequence Number and Sequence Number fields. As a result, both forward path loss and return path packet loss can be computed.

STAMP supports two authentication modes: unauthenticated and authenticated. Unauthenticated STAMP-Test packets, ensure interworking between STAMP and TWAMP Light. As STAMP and TWAMP use different HMAC algorithms in authenticated mode interoperability is only in the unauthenticated mode.

2.2. Port number & Interop with TWAMP

A STAMP Session-Sender and STAMP Session-Reflector use UDP port 862 (same as TWAMP) as the default destination UDP port number. An implementation of the Session-sender and Session-Reflector can define the port number to receive STAMP-Test packets from User Ports and Dynamic Ports ranges.

One of the essential requirements to STAMP is the ability to interwork with a TWAMP Light device. For example, a TWAMP Light Session-Reflector may not support the use of UDP port 862, as specified in [RFC8545]. A STAMP Session-Sender is allowed to use alternative ports. If any of STAMP extensions are used, the TWAMP Light Session-Reflector will view them as the Packet Padding field.

2.3. Packet Format and Size

By default, STAMP uses symmetrical packets, i.e., the size of the packet transmitted by the Session-Reflector equals the size of the packet received by the Session-Reflector. The STAMP Session-Sender packet has a minimum size of 44 octets in unauthenticated mode (see Figure 2) and 112 octets in the authenticated mode (see [IETF RFC 8972]

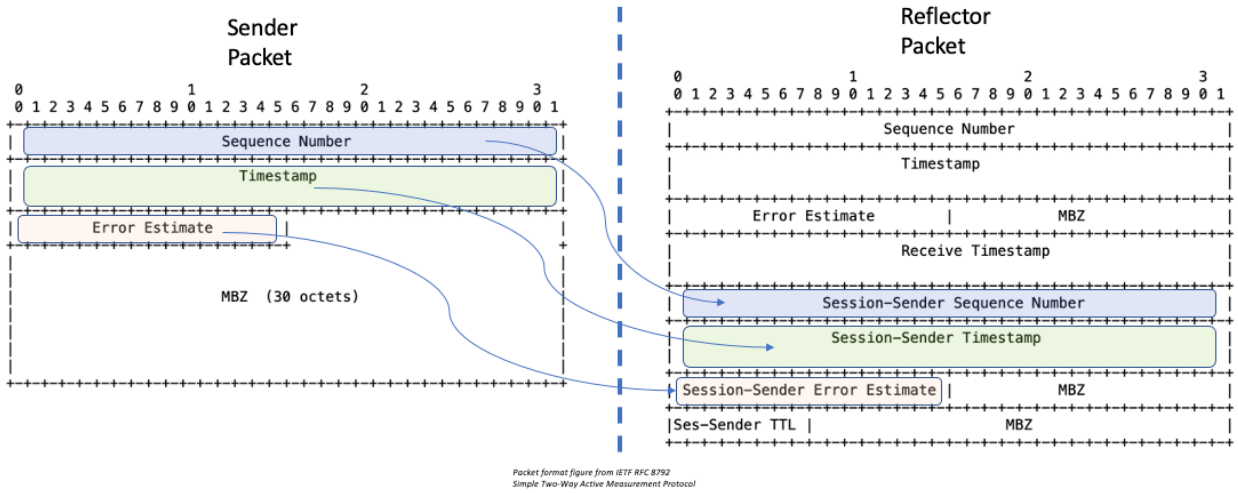

Figure 2 - STAMP Test Packet Format (Sender & Reflector)

STAMP supports symmetrical size of test packets, i.e., a reflected base test packet includes information from the Session-Reflector and, thus, is larger. To maintain the symmetry between base STAMP packets, the base STAMP Session-Sender packet includes the Must-Be-Zero (MBZ) field to match to the size of a base reflected STAMP test packet.

Generating variable length of a test packet in STAMP is defined in [IETF RFC 8972]

The field definitions for Authenticated mode are the same as the unauthenticated mode. The STAMP Session-Reflector test packet format in authenticated mode includes a HMAC hash at the end of the PDU. The detailed use of the HMAC field is in described in the [IETF RFC 8762].

2.4. STAMP Extensions

STAMP defines multiple extensions to give the operator additional functionality as related to latency measurement. Some of these extensions include functionality such as extra padding, location, timestamp information, class of service, direct measurement, access report, follow-up telemetry and HMAC. These are described in the [IETF RFC 8972].

Here is the format of the TLVs used within the existing stamp packet. [IETF RFC 8972]

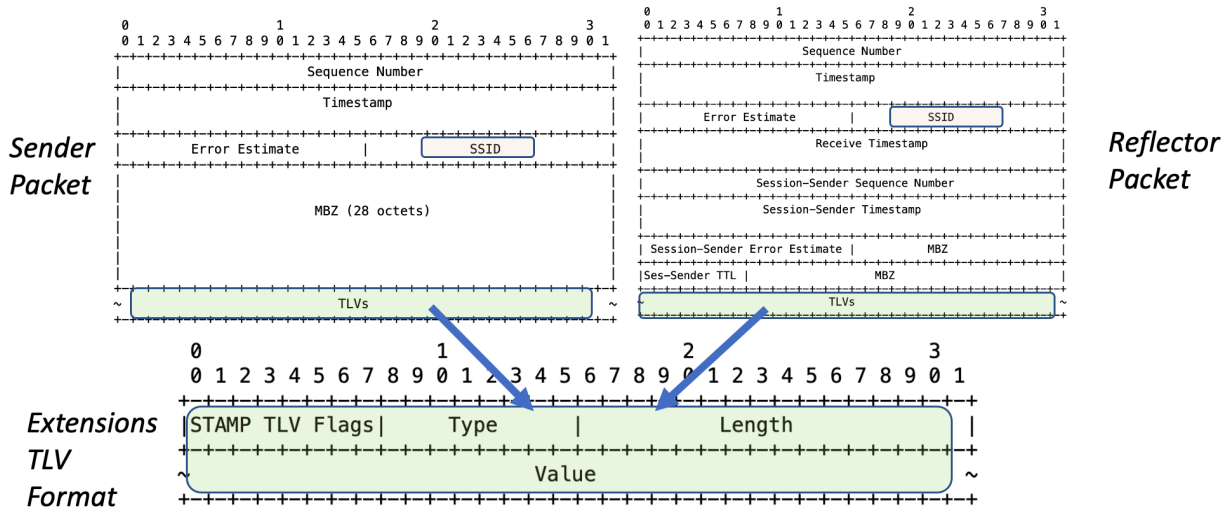

Figure 3 - STAMP Test Packet Extensions Format

Of the eight types of STAMP extensions, defined below are a couple of the extensions. The “Extra padding” TLV (Type 1) can extend the size of the STAMP packet, to allow an operator to test the network with different sized packets. The “Class of service” TLV (Type 4) can be used by an operator to check how the DSCP value of the IP test packet changes as it traverses different networks.

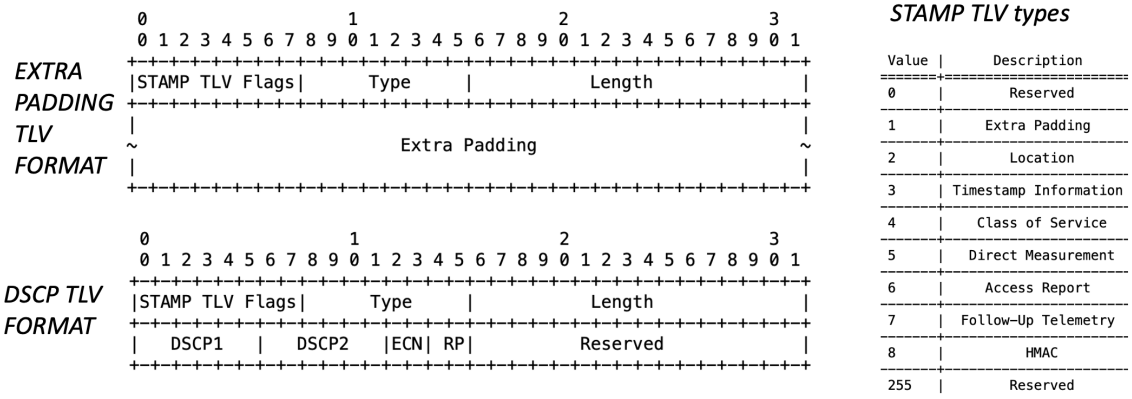

Figure 4 - STAMP Extra padding and DSCP Extensions

3. LMAP

The Large-Scale Measurement of Broadband Performance (LMAP) [IETF RFC 7594] developed by the IETF standardizes a measurement system for performance measurements of broadband access devices such as home and enterprise edge routers, personal computers, mobile devices, set top box, whether wired or wireless.

Measuring portions of the Internet on a large scale is essential for accurate characterizations of performance over time and geography, for network diagnostic investigations by providers and users. The goal is to have the measurements made using the same metrics and mechanisms for a large number of end points on the Internet, and to have the results collected and stored in the same form.

3.1. LMAP Architecture

A large-scale measurement platform involves basically three types of protocols, namely, a Control Protocol between a Controller and the Measurement Agent (MA), a Report Protocol between the MAs and the Collector(s), and several measurement protocols between the MAs and Measurement Peers (MPs), used to perform the measurements. In addition, some information is required to be configured on the MA prior to any communication with a Controller.

LMAP has defined the following

- A Control Protocol, from a Controller to instruct Measurement Agents what performance metrics to measure, when to measure them, how/when to report the measurement results to a Collector.
- A Report Protocol, for a Measurement Agent to report the results to the Collector.

The LMAP framework has three basic elements: Measurement Agents, Controllers, and Collectors.

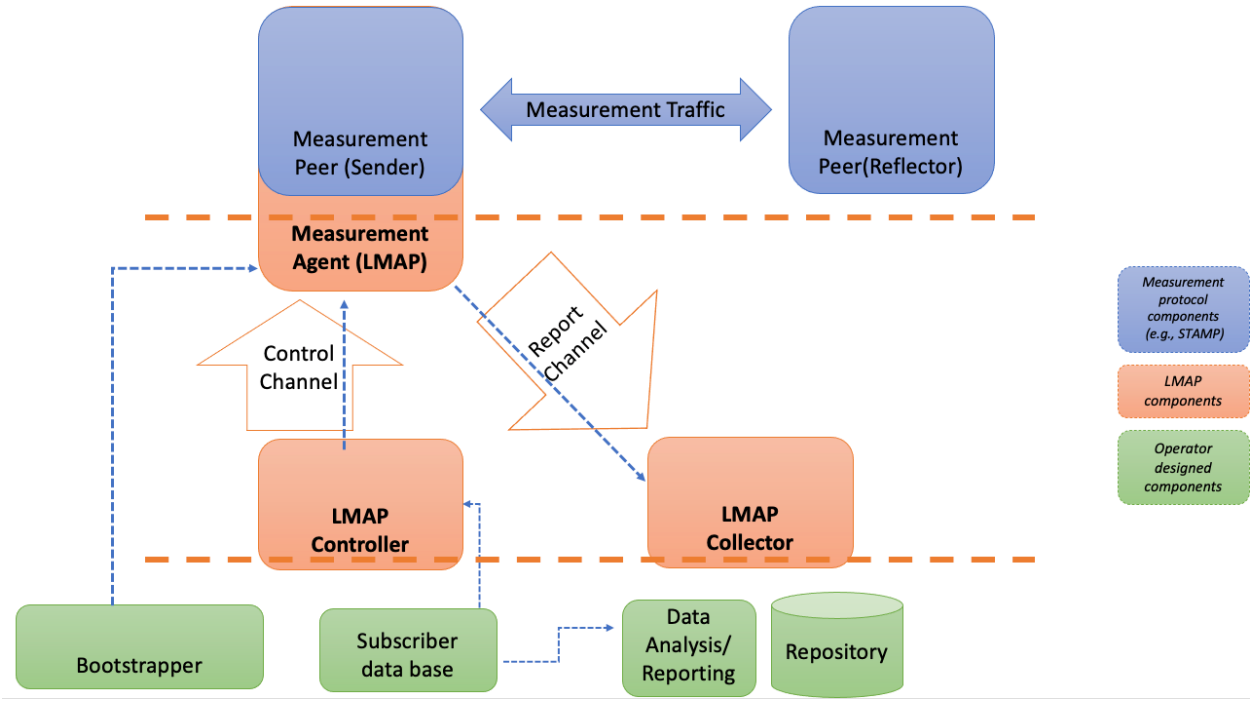

Figure 5 - Elements of an LMAP-based Measurement System

Measurement Agents (MAs) initiate the actual measurements, which are called Measurement Tasks in the LMAP terminology. In principle, there are no restrictions on the type of device in which the MA function resides.

The Controller instructs one or more MAs and communicates the set of Measurement Tasks an MA should perform and when. For example, it may instruct an MA at a home gateway: "Measure the 'UDP latency' with www.cableco.org; repeat every hour at xx.05". The Controller also manages an MA by instructing it on how to report the Measurement Results, for example: "Report results once a day in a batch at 4am" (a Report Schedule.)

The Collector accepts Reports from the MAs with the Results from their Measurement Tasks. Therefore, the MA is a device that gets Instructions from the Controller, initiates the Measurement Tasks, and reports to the Collector. The communications between these three LMAP functions are structured according to a Control Protocol and a Report Protocol.

The LMAP effort has specified an information model [IETF RFC 8193], the associated data models [IETF RFC 8194], and protocols for secure communication. Information Model applies to the Measurement Agent within an LMAP framework. It outlines the information that is configured on the Measurement Agent or exists in communications with a Controller or Collector within an LMAP framework. The purpose of such an Information Model is to provide a protocol- and device-independent view of the Measurement Agent that can be implemented via one or more Control and Report Protocols. The data models are extensible for new and additional measurements.

3.2. LMAP YANG model

The LMAP framework has three basic elements: Measurement Agents (MAs), Controllers, and Collectors. Measurement Agents initiate the actual measurements, called Measurement Tasks in the LMAP terminology. The Controller instructs one or more MAs and communicates the set of Measurement Tasks an MA should perform and when. The Collector accepts Reports from the MAs with the Results from their Measurement Tasks.

The YANG data model [IETF RFC 8194] for LMAP has been split into three modules: The common module (ietf-lmap-common.yang) provides common definitions such as LMAP-specific data types. The control module (ietf-lmap-control.yang) defines the data structures exchanged between a Controller and Measurement Agents. The report module (ietf-lmap-report.yang) defines the data structures exchanged between Measurement Agents and Collectors.

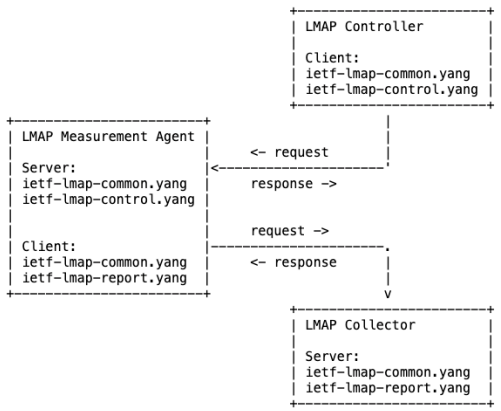

Figure 6 – High level view of the LMAP YANG model components

Below is a figure which describes the various components within the LMAP- Control and LMAP-Report YANG data modules.

Figure 7 – High level view of the LMAP-Control YANG model

(*) Figure 7 is built from views with the tools at https://yangcatalog.org/yang-search/yang_tree/ietf-lmap-control@2017-08-08

The LMAP Information Model [IETF RFC 8193] is divided into six functional parts mapped into the YANG data model as follows:

- Preconfiguration Information: bootstrapping information is outside the scope of the model
- Configuration Information: Modeled in the /lmap/agent subtree, the /lmap/schedules subtree, and the /lmap/tasks subtree

- Instruction Information: Modeled in the /lmap/suppressions subtree, the /lmap/schedules subtree, and the /lmap/tasks subtree.
- Logging Information: success/failure/warning messages in response to information updates from the Controller, will be handled by the protocol used to manipulate LMAP-specific configuration.
- Capability and Status Information: Capability is modeled in the /lmap/capability subtree. The list of supported Tasks is modeled in the /lmap/capabilities/task list. Status Information about Schedules and Actions is included in the /lmap/schedules subtree. Information about network interfaces can be obtained from the ietf-interfaces YANG data model [RFC 7223]. Information about the hardware and the firmware can be obtained from the ietf-system YANG data model [IETF RFC 7317]. A device identifier can be obtained from the ietf-hardware YANG data model [YANG-HARDWARE].
- Reporting Information: This is modeled by the report data model to be implemented by the Collector. Measurement Agents send results to the Collector by invoking an RPC on the Collector.

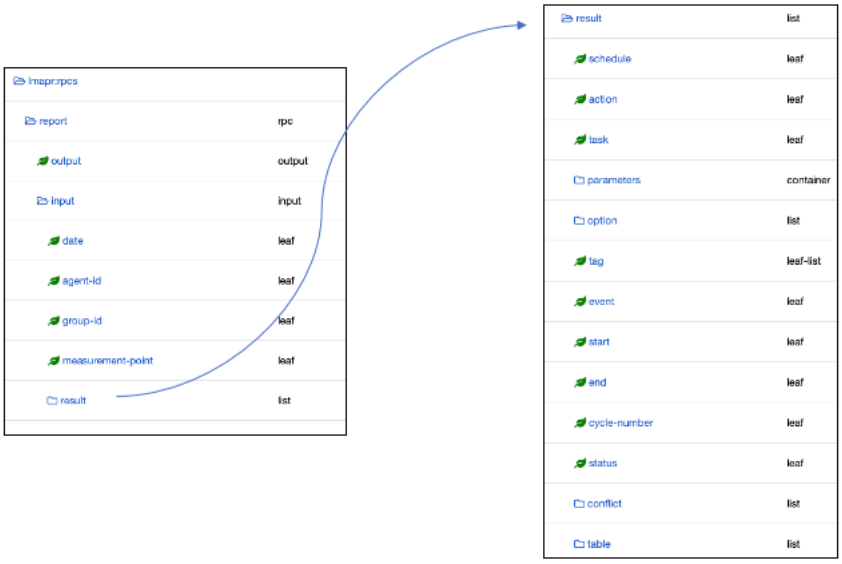

Figure 8 –Definition of the LMAP-REPORT YANG model

(*) Figure 8 is built from views with the tools at https://yangcatalog.org/yang-search/yang_tree/ietf-lmap-report@2017-08-08

4. Latency Measurement Architecture

The latency measurement architecture can be split into two parts as shown in the figure below:

Measurement Domain: This includes the measurement protocol itself and the measurement agent and the measurement peers. This domain performs the actual latency measurements/tests and calculate the latencies.

Large Scale control and data collection: This includes the large-scale latency measurement orchestration across the network by a controller/collector entity. The controller entity which coordinates the measurements across the various measurement agents in the network. The collector entity collects the data from the various measurement agents and then presents the aggregate data to the operator.

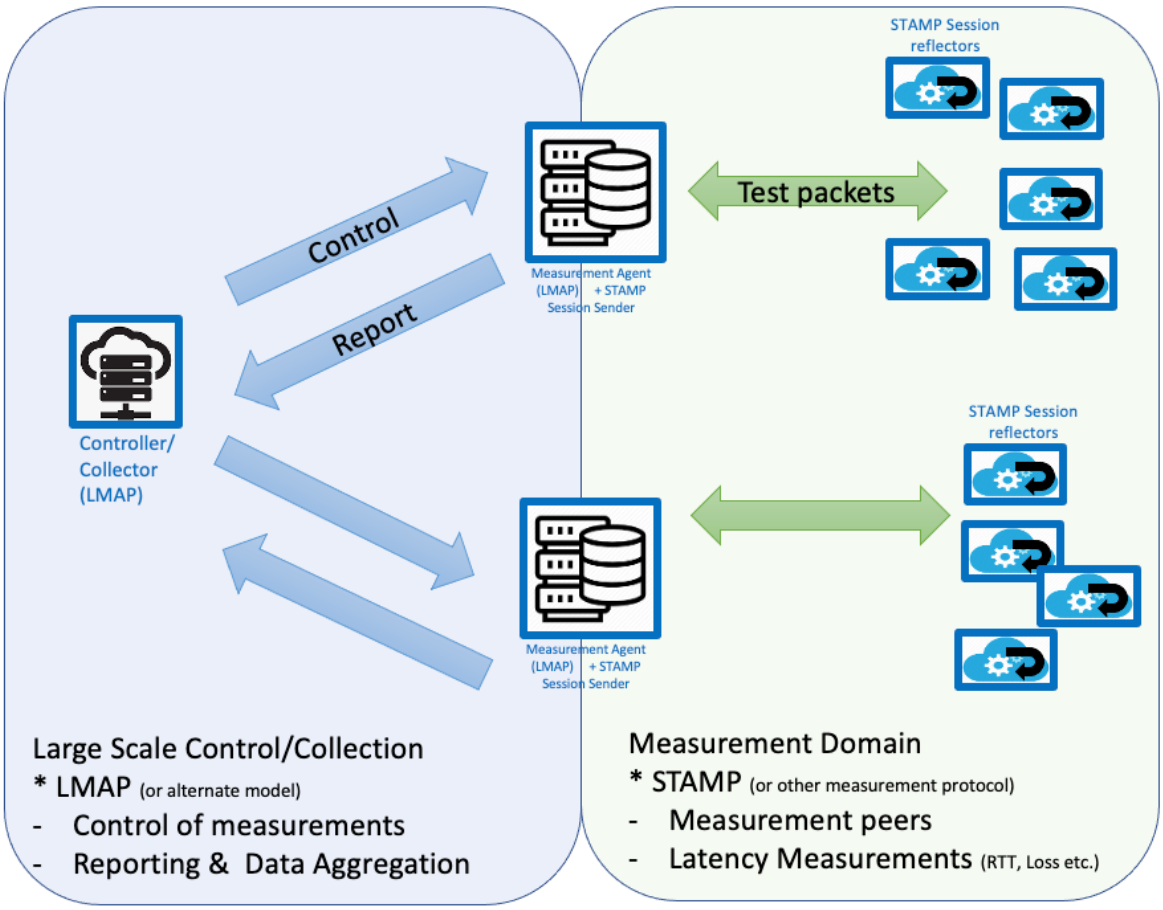

Figure 9 - Latency Measurement Architecture

Separating the data control and collection domain from the actual measurement domain allows the operator to make appropriate choices for both domains. The leading contender for large scale control and collection is the IETF LMAP model. For the measurement domain the IETF STAMP measurement protocol appears to be the best fit.

4.1. Measurement Architecture in a Cable Network

In a cable access network, the latency measurement architecture described above with and LMAP domain and the STAMP domain could be implemented as follows.

An operator could choose to deploy a measurement agent at each hub or headend location just north of the CMTS at that location. This way an operator can reliably measure the latency on the DOCSIS / access network portion of the network. STAMP session reflectors are lightweight entities and can be placed at the customer premise. This could be at the cable modem itself or on a gateway device which the operator installs at the customer premise.

To measure latencies in the core network and operator could also place the lightweight stamp session reflectors at locations close to the interconnection/ peering points to the Internet. Now an operator could deploy and LMAP collector and controller at a more centralized location for example the network operations center which oversees multiple hub/headend locations or perhaps even the whole network of measurement agents. See Figure below.

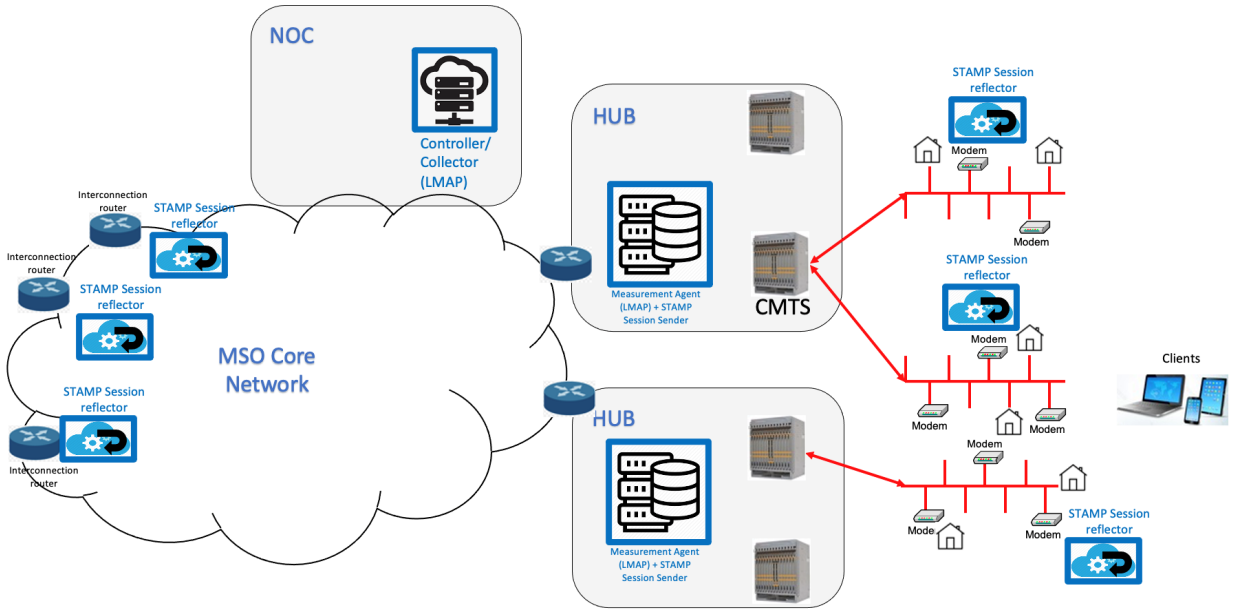

Figure 10 - Latency Measurement Architecture in a Cable Operator Network

4.2. Measurements in the Access vs Core vs Home Network

For the access network, each measurement agent at the hub locations would be responsible for running latency measurement tests to each of the session reflectors within its domain, i.e., within the part of the cable network to which it is connected.

For the core network, an operator could choose to run tests between every interconnection router and every measurement agent so that they can get a baseline understanding off the latencies across each of the potential paths across the core network.

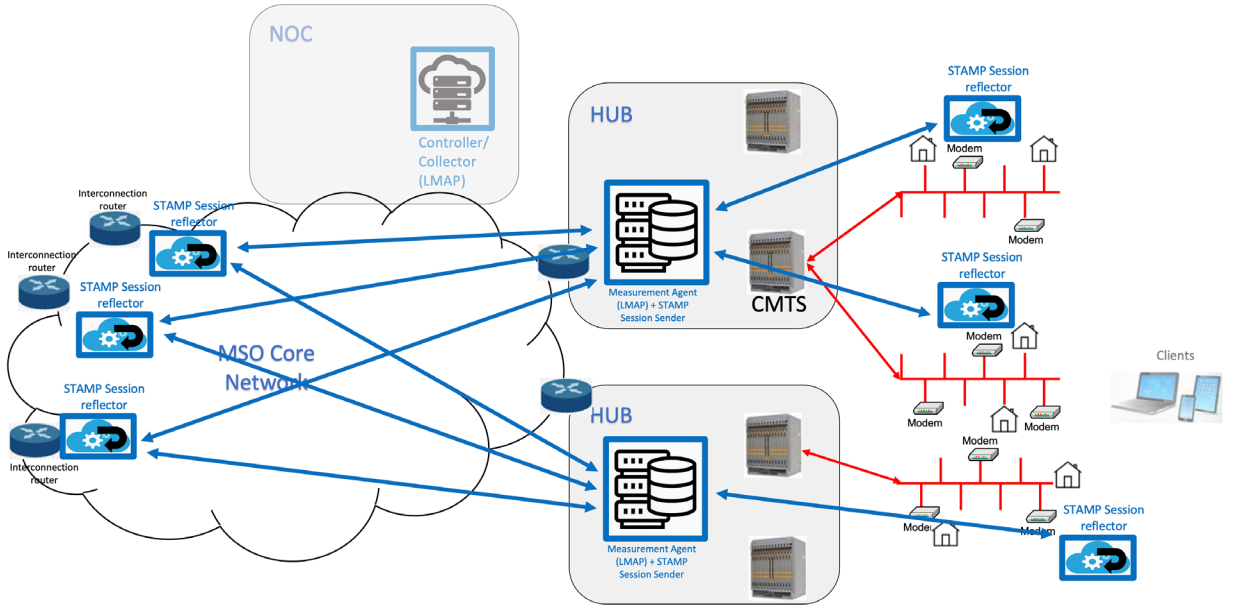

Figure 11 - STAMP Latency measurements (Access & core)

And operator can also instantiate a measurement agent within a client device for example a handheld device or a laptop which could be owned by a customer or by a technician. In this case this measurement agent within the customer's home can help measure latencies to each of the session reflectors within the network. In the case where this measurement agent talks to the session reflector within the gateway in their customer premise, this will this result in the operator understanding the latency in the home network (e.g., Wi-Fi). When the measurement agent in the handheld device runs latency tests with the session reflectors close to the interconnection points the operator can also get an understanding of the combined access and core network latencies from the customer location to the peering point.

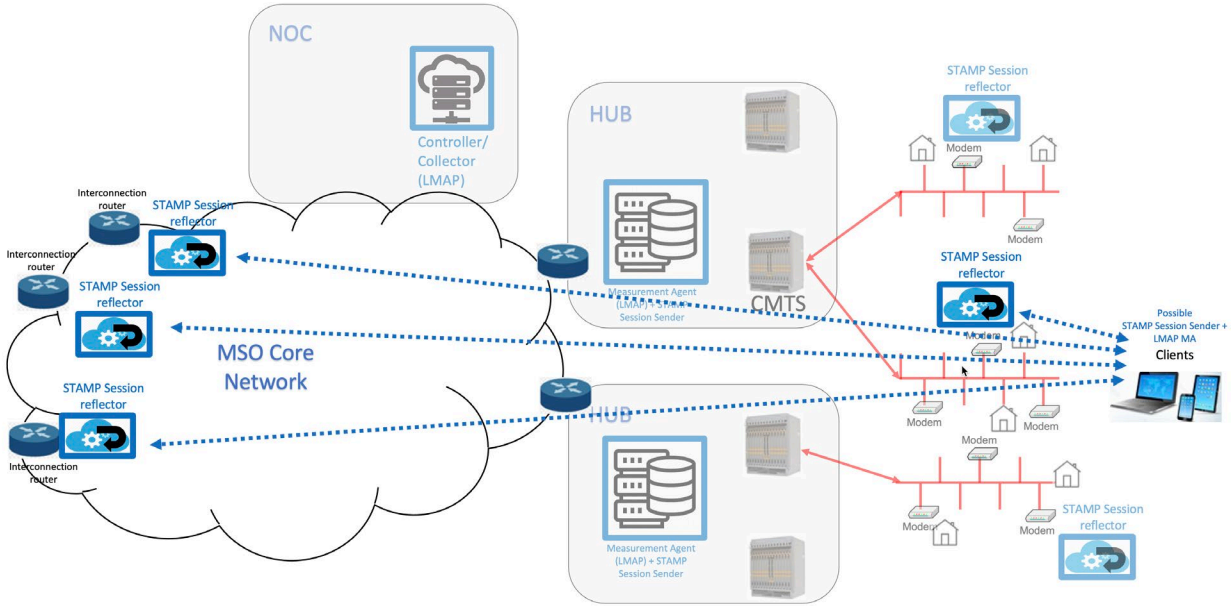

Figure 12 - STAMP Latency measurements from a Client-side MA

4.3. Measurement aggregation

Now for a large-scale measurement system the LMAP controller/collector will coordinate with each of the measurement agents in the network. The controller will command each of the measurement agents to run specific latency tests at a particular point in time or on a schedule. Each measurement agent will collect the set of latency measurements compute the requested statistics be it histogram counts or percentile data for that test. These results will be reported back to the collector. This way the LMAP controller/collector becomes the one central location where an operator can go to understand the latency performance across the whole network. All the data analytics and data aggregation off the latency measurements across the network both the access network and the core network and potentially the home network will be implemented at the collector.

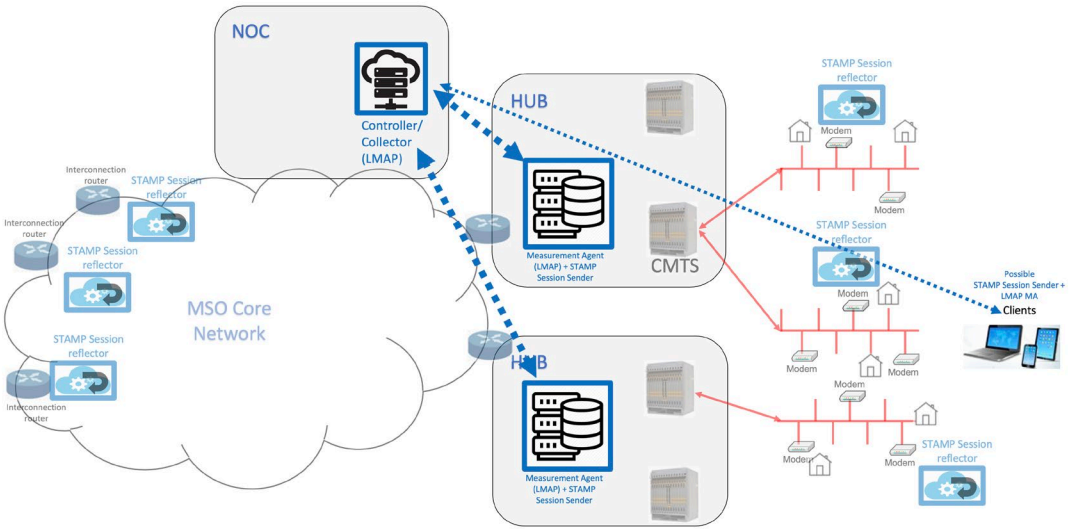

Figure 13 - LMAP Measurements control and reporting

4.4. Scaling Considerations

An operator would need to think through the scale of the measurement infrastructure that they deploy. The number of measurement agents and session reflectors needed will depend on the size of their network. An operator would need to account for the number of headend/hub locations they want to cover and the number of peering points they want to cover.

4.4.1. Core network Latency

As described above, for core network latency measurements, the operator would plan to have measurements from each hub or headend location to each of the Internet peering/transit points within MSO network. In an informal survey we found that each operator has on the order of 8 to 12 peering points and transit locations and while of the bigger operators having up to 30 interconnect locations (based on past mergers and acquisitions of cable properties). Typical operator networks vary from 100s to 1000s of CMTSs and this implies 10s to 100s CMTS hub/headend locations.

An operator would desire to get a full mesh of latency measurement of "CMTS" x "Interconnect" locations. For a small cable operator this would be in the order of 100 links and up to a 1000 links for a larger operator.

An operator will likely place one Session reflector at each interconnect location. An operator may choose to place a one Measurement Agent at each hub/headend location. Alternatively, they could place to near the Core/Aggregation router to reduce number of measurement agents, those this will lose the ability to truly isolate access network latency in the measurements.

4.4.2. Access network Latency

As per the previous section, the assumption here is that an operator places measurement agents at each hub/headend location. Now the question is how many section reflectors an operator wants in the access portion of the network. An operator needs to figure out if they want to perform latency measurements to every modem on the network or if they want to subsample the CM population.

If an operator decides to subsample the network, they need to decide what percentage of devices should be used in latency measurement, would it be 20%, 10%, or 1%? For e.g., for a mid-tier operator with 10 million broadband subscribers, a 10% choice implies: 1 million session reflectors and even a 1% sampling implies 100,000 session reflectors. If an operator decides to equally distribute these session reflectors across their CMTS footprint, let's assume a 1000 CMTSs and each CMTS supporting 50 nodes, then this is just about 2 session reflectors per node segment. These types of calculations give us an idea of the choices an operator will have to make in terms of the number of session reflectors the coverage of the modems that are needed and then start planning to scale the number of measurement peers accordingly. With Distributed CMTS architectures (Remote PHY or Flexible MAC architecture technology) with RPD and RMD devices in the network, an operator may choose to measure those links separately which means an additional layer of measurement agents at each of the nodes.

Once an operator gets comfortable collecting and understanding the latency measurements in a small part of the network then a phased approach to increasing measurement coverage across the network, will be the likely path than operators take.

5. Experimental results

To put all the latency measurement theory and protocols to test, we built an experimental latency measurement system prototype which was tested with measurement server and peer locations across the Internet.

5.1. Prototype Components

For the latency measurement system prototype, the following components were implemented: A Measurement agent (STAMP Session sender) and a STAMP session reflector. Additionally, an LMAP Controller + Collector along with adding LMAP functionality to the measurement agent are currently under development as well. These prototype components will be made available at [C3 CableLabs] after the development is complete.

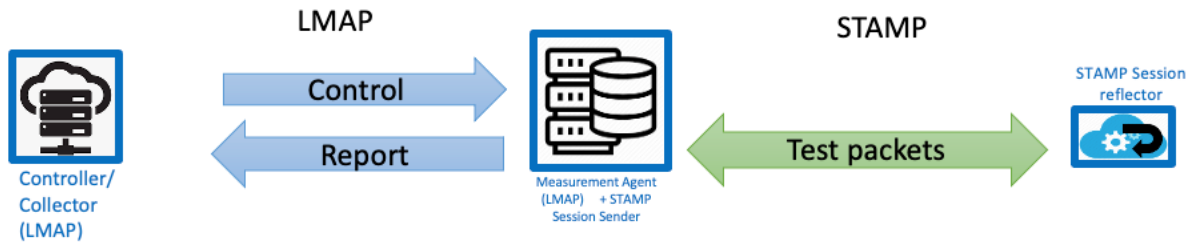

Figure 14 – Prototype components

5.1.1. Session-Reflector

The STAMP session-reflector software implementation was developed using C and built for a Unix environment. The Raspberry Pi platform was chosen for a session reflector. The idea is to create a lightweight stamp session reflector software which could potentially be embedded within a cable modem or a gateway device in the house or a Wi-Fi AP. Another option would be a stand-alone device which the operator installs as "probes" throughout their network.

5.1.2. Measurement Agent

The measurement Agent consists of two components, the STAMP Session sender and the LMAP Measurement Interface.

The STAMP session sender software implementation was developed using C and built for a Unix environment. The Measurement Agents were instantiated on AWS servers using Ubuntu Linux instances. The same version of the Measurement agent was also deployed onto the Raspberry Pi platform to run locally to test and debug. The idea here is to create a robust STAMP session sender software which could potentially be extended to support all the STAMP features and support a variety of latency tests for an operator. This Measurement Agent (STAMP session sender) will be controlled through the LMAP measurement Interface it implements.

The LMAP measurement interface was developed to support a NETCONF interface and support the LMAP YANG model. 'Netopeer2' is an opensource server for implementing network configuration management based on the NETCONF Protocol. The server uses 'sysrepo' (an opensource library for storing and managing YANG-based configurations for UNIX/Linux applications) as a NETCONF datastore implementation. The idea is that the measurement agent will interface with the LMAP controller using the NETCONF protocol.

5.1.3. LMAP Controller and Collector

The LMAP Controller and collector entity is being developed to support a NETCONF interface and support the LMAP YANG model. This communicates with the various Measurement Agents to configure tests and gather the results back. The additional data analytics and visualization happens hereat the controller/collector.

5.2. Test Metrics

There are various metrics which and operator could track when they are looking to understand the Latency performance of their networks, be it the access network, the home network, or the core network. each portion of the network needs to be measured to understand the current characteristics and then to improve on it.

The [LM SCTE 20] paper discusses the basics of latency and proposes some metrics to measure. The main measures which an operator should look at are

- Latency RTT (Round trip time)
- PDV (Packet Delay Variation)
- Packet Loss (and directionality of loss if available)

For the Latency and PDV measures, if an operator were to pick a number, the 99^{th} percentile value is a very good metric to track and is likely indicative of the customer experience especially in latency sensitive real time applications. To understand how the latency behavior changes over time it is also useful to track multiple percentile values, e.g. 0^{th} percentile (minimum), 25^{th} percentile, 50^{th} percentile (median), 75^{th} percentile, 95^{th} percentile, 99^{th} percentile, 99.9^{th} percentile, 100^{th} percentile (maximum).

To understand how the latency varies over time and visualizing it, a simple time series graph shows a lot of interesting patterns. Additionally, a histogram of the data set is a great place to start analyzing the latency performance. A cumulative distribution function (on a logarithmic scale) can show the operator the more interesting latency behavior regions.

5.3. Expermental Setup for Latency Measurement using STAMP

As a first step we decided to deploy the STAMP measurement agents and session reflectors in a network and work through the issues we would see with such a deployment on the Internet. Four different locations of the AWS servers were chosen, across the U.S, to give different sampling/variation of latency measurements. These server locations were in Oregon, N. California, Ohio, N. Virginia. There was a single session-reflector behind a DOCSIS 3.1 CM in a home in Denver. The session-reflector was connected via WiFi to the CM.

Figure 15 – Location of Measurement Agents & Session Reflector

5.4. Latency Measurement Test results

Each Measurement Agent ran latency tests to the Session reflector periodically. The interval chosen was every 5 mins, and tests were run over a period of a week. An individual 'test' consisted of 2000 to 5000 packets sent back-to-back.

Round trip latency and loss measurements were the focus of the experiments. The change in sequence numbers on the sender and received side also exposed packet loss in either direction.

As the clocks across the Session-sender and the Session-reflectors were not synchronized, one way latency measurements are not reported, though they were calculated.

5.4.1. Time Series view

The following figure shows a set of roundtrip latency measurements between a measurement agent in Oregon (STAMP Session sender) and a measurement peer (STAMP session reflector) in Denver. They're following figure shows about 75 hours of latency testing with 5000 test packets being sent every five minutes.

One can easily see that though the latency is around 35 ms for a lot of the time, there are some clear periodic larger spikes of latency up to 140 ms and then some even larger spikes of latency up to 2.5 seconds. The orange dots on the bottom of the graph indicate the number of packets lost during the test.

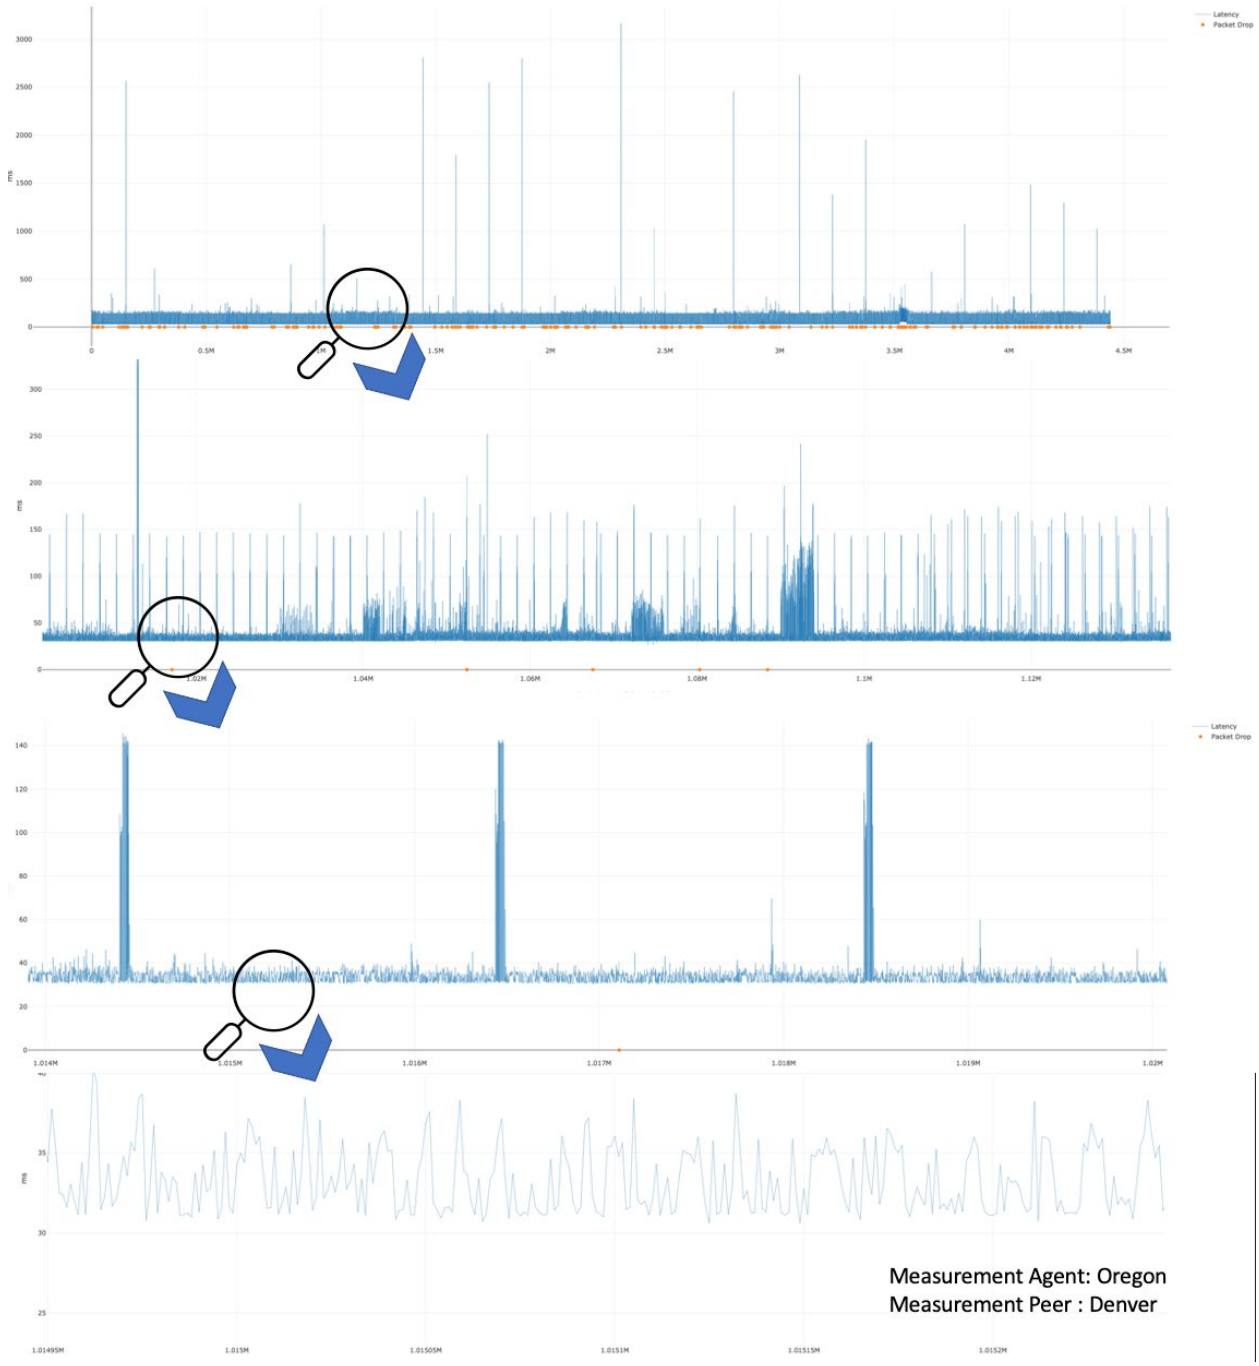

Figure 16 –Latency data - time series

5.4.2. Histogram view

The next figure below shows a histogram of latency, for each of the four links measured. The histogram bins are chosen to be one second each, do show with high granularity that different latency's that we observe to each of the measurement agents which are in different locations. As expected, the Ohio and N Virginia measurement agents have higher latencies (farther from Denver session reflector) compared to the measurement agents in California and Oregon (closer to Denver). As the histogram indicates, the

latency behavior is very different for different links and has multimodal distribution. Again, a reminder to network operators and users, to fight the urge to reduce latency to an “average” number or run a single test and take that to be latency number.

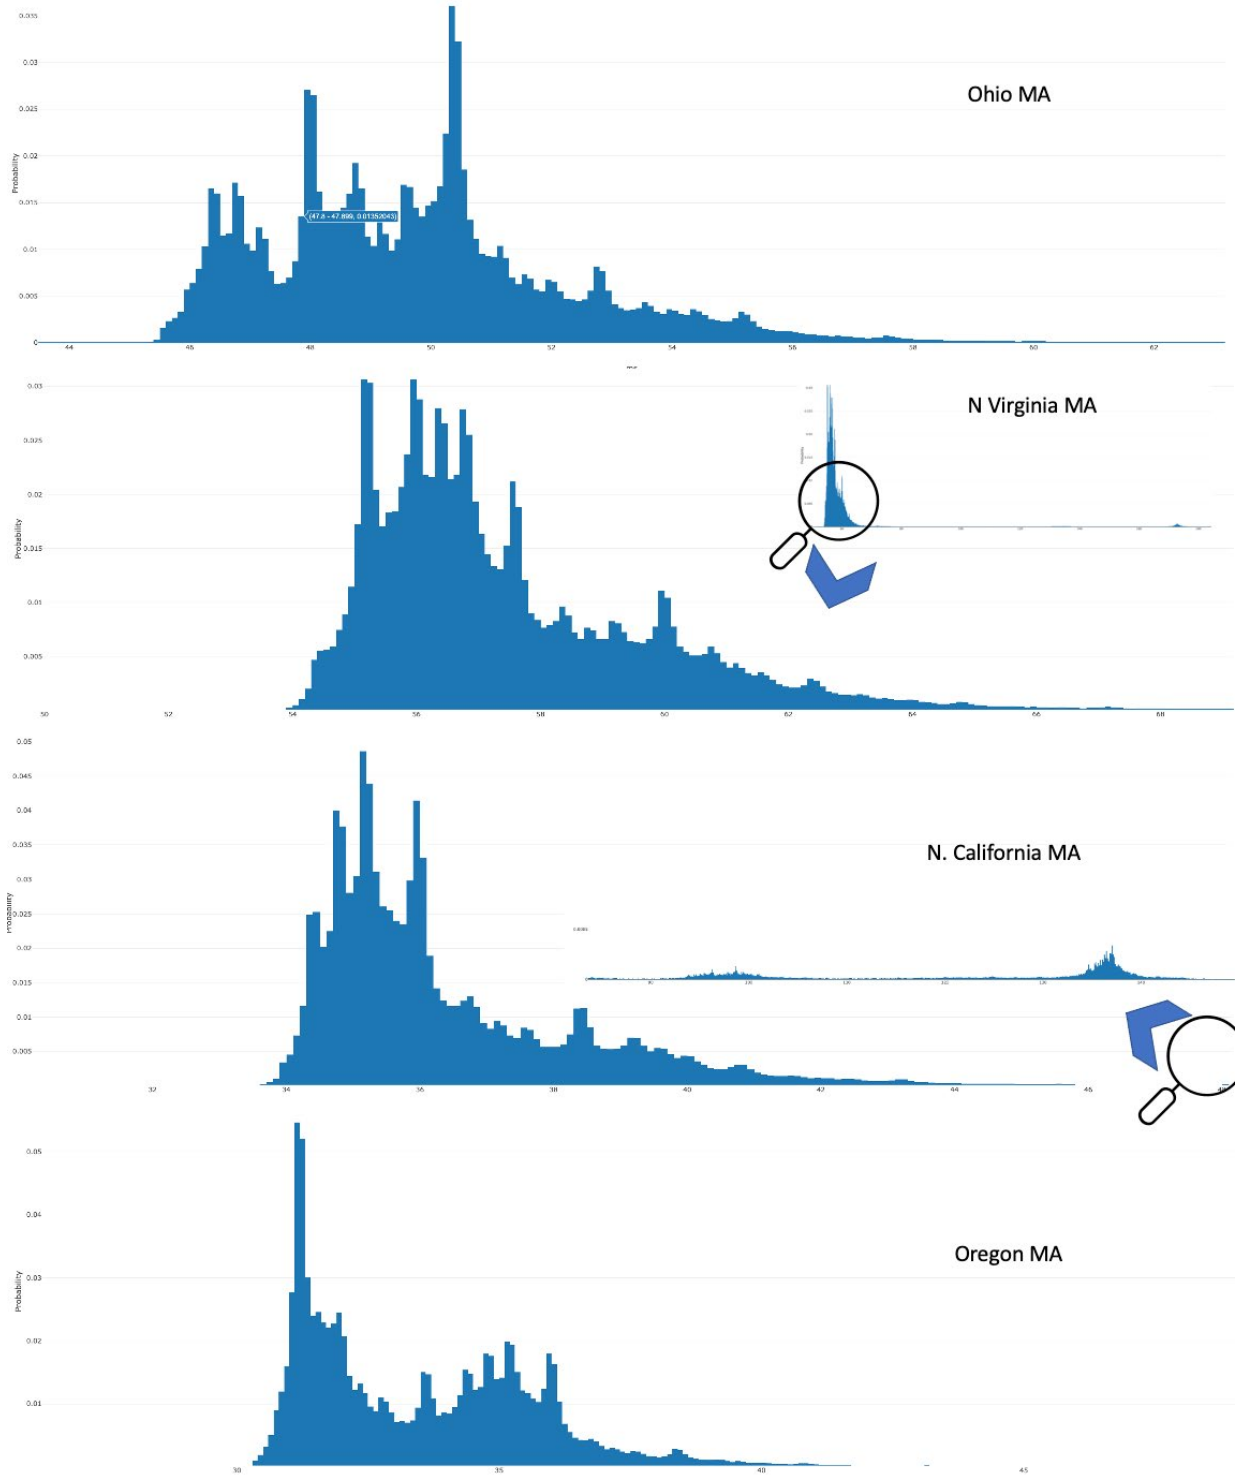

Figure 17 – Histogram of latencies from all 4 MAs

5.4.3. CDF view

The following figure shows a cumulative distribution function (CDF) graph of the latency data from each of the measurement agents. Here we look at the percentile values off Latency and use that as a metric to compare the different links. the scale on the Y-axis is logarithmic and the X-axis is zoomed in to the areas of interest. Operators are typically interested in the 99th percentile values of latency as that is shown to be indicative of the customer experience especially for real time applications such as gaming or real time communications. The table at the end of the section shows the 99th percentile, while the CDF graphs below show the 50th and the 95th percentile.

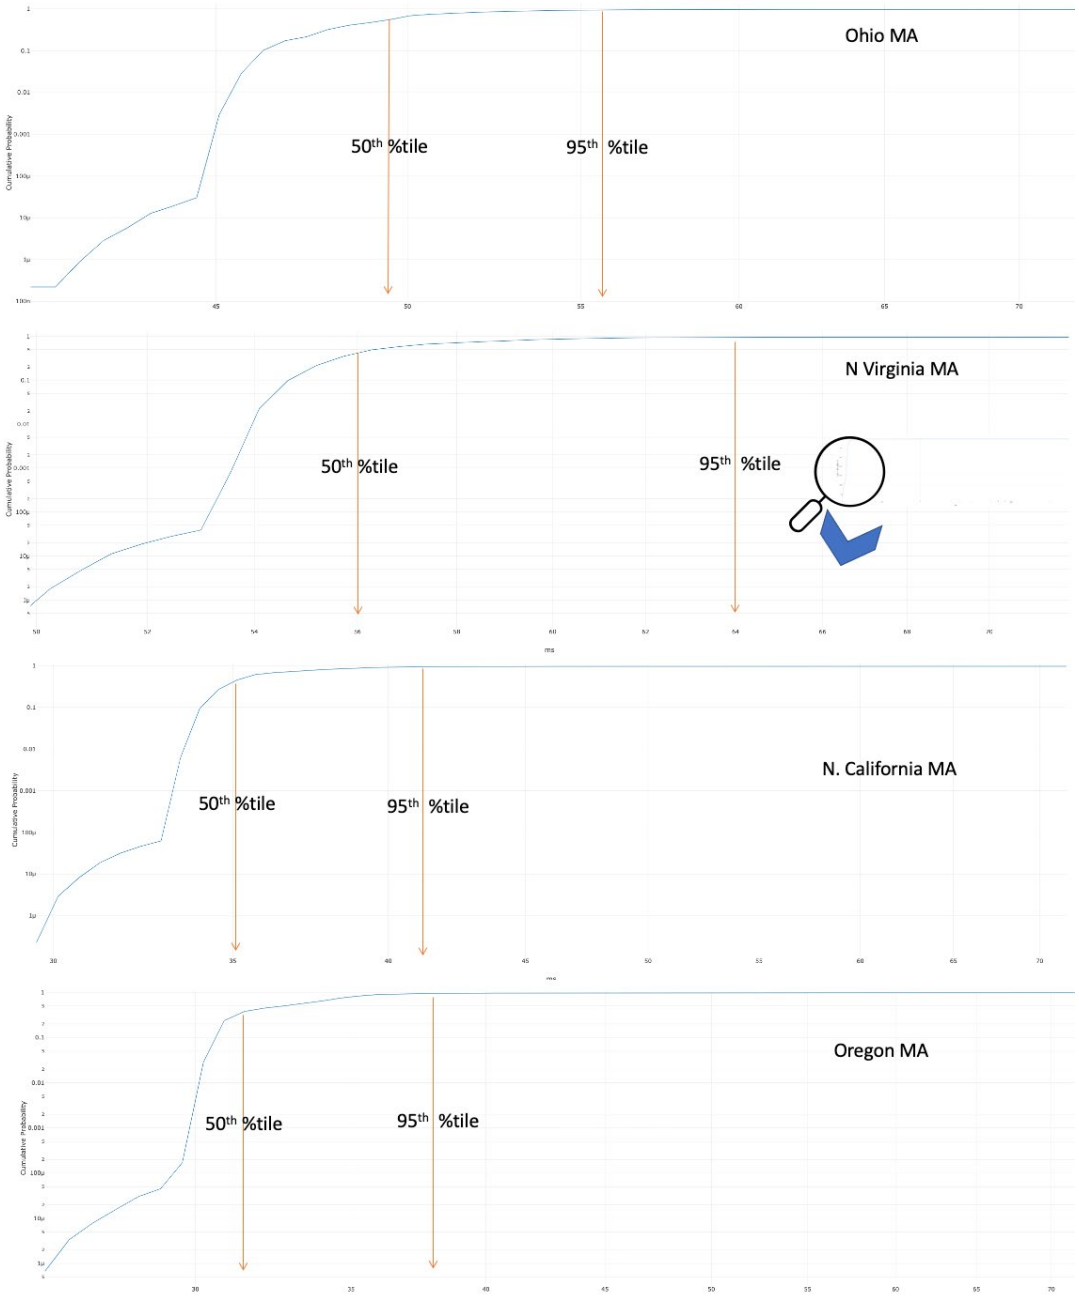

Figure 18 – CDF of latencies from all 4 MAs

5.4.4. Home Latency Testing

The next set of results below are for a measurement agent and a measurement peer located in the same home; this would be an example of testing the Wi-Fi latency within the home. the first graph below is a time series off a test run over 80 minutes, with 5000 packets being sent every five minutes. Again, while the nominal Latency hovers around the 5 ms mark, there are occasional spikes up to 14 to 16 ms and additional spikes of leading see up to 180 ms and some outliers of latency up to 1.2 seconds

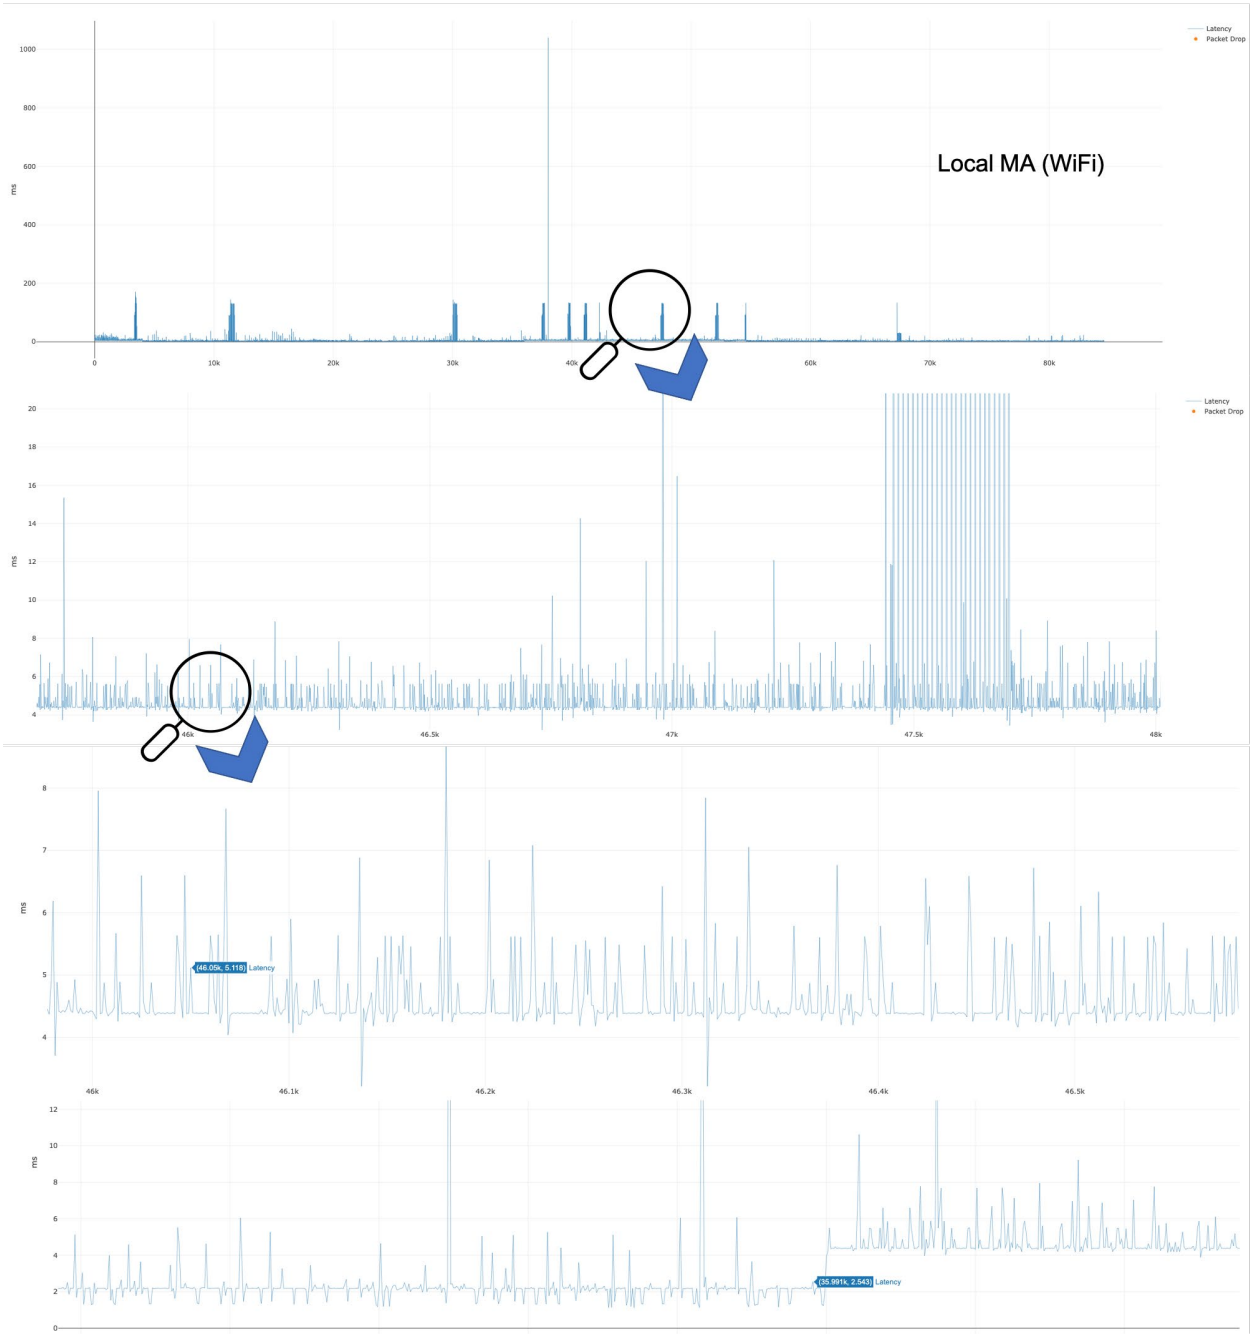

Figure 19 –LAN Wi-FI , Latency Time series

The LAN latency data, when distributed in two different bins and displayed as a histogram shows the 2.5 ms and 4.5 ms latency as the most common latencies observed in this test environment, and the CDF shows that the 50th percentile latency is around 2 milliseconds and the 95th percentile latency is around 5.3 milliseconds.

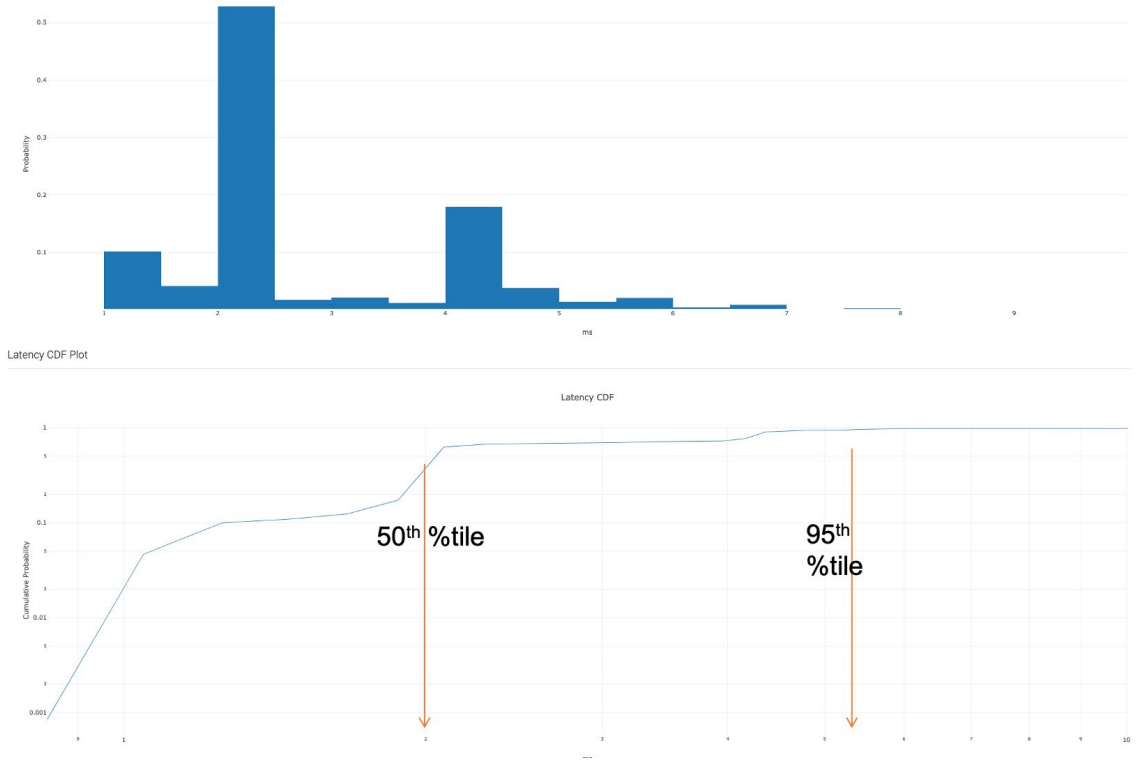

Figure 20 – LAN Histogram and CDF

5.4.5. Summary of results

The table below captures the Latency measurements percentiles of interest to the five different measurement agents four of which were spread across the country and the last was in the same LAN. Additionally, we also show the minimum and maximum latency observed across each of those five links.

Table 1 –Latency measurments to different locations

Server/Measurement Agent location (Measurement Peer in Denver)	**Min (0th percentile)**	**50th percentile**	**95th** percentile	**99th** percentile	**Max** (100th percentile)
N. Virginia	49.69 ms	56.3 ms	64.5 ms	172.2 ms	2.794 s
Ohio	40.63 ms	49.2 ms	56.6 ms	172.1 ms	2.812 s
California	29.56 ms	35.3 ms	42.5 ms	134.1 ms	2.808 s
Oregon	25.80 ms	32.7 ms	38.4 ms	116.8 ms	3.163 s
Local (LAN)	0.83 ms	2.02 ms	5.31 ms	13.41 ms	148.8 ms

6. Conclusion

Latency measurement is a vital requirement for operators deploying new low latency technologies going forward. Building a latency measurement system in hardware and software as a prototype can be relatively straightforward. Scaling it to production to measure the whole network needs planning and good engineering.

One main choice is that of a measurement protocol and here we successfully used STAMP across the Internet for latency measurement. STAMP is lightweight and easy to implement on existing hardware software platforms that it can be easily deployed by operators either in a standalone white box or as an add-on to existing devices (cable modems or gateways or APs). STAMP offers a variety of functionality (e.g., round trip and one-way measurements and loss, DSCP traversal, and different packet size testing) and can meet the needs of most Latency measurement requirements.

The second big choice is architecting the large-scale control and collection of data, and LMAP fits that bill quite well. The LMAP control and report architecture provide the operator with a well thought out set of information/data models to initiate latency measurement and collect data at scale. Understanding the CDF of the latency measurement and tracking a set of percentiles values should give an operator very good understanding of latency performance of their networks and how it changes as they deploy newer technologies.

Abbreviations

PDV	packet delay variation
RTT	round trip time
CDF	cumulative distribution function
DSCP	Diff Serv Code Point
ms	millisecond

1. Introduction

Network operators understand that an increasing number of discrepancies between their network and inventory databases can lead to (1) greater service fallout rates, (2) impact to customer experience and (3) potential significant loss of revenue from dissatisfied customers. While networks are evolving toward more “addressable” (e.g., discoverable) devices, there is still a significant amount of resource elements in the network that are non-addressable (e.g., patch panels, fibers) thus requiring manual tracking in databases. Furthermore, most existing inventory systems either do not, or cannot, stay in lockstep with the “as-is” state of the network and continue to impose on network operators a significant amount of error-prone manual tasks. While network-to-inventory “manual audits” can provide a snap-shot update in time, each audit can cost network operators millions of dollars in consulting/staff costs and expenses they can no longer afford. And, with networks and services evolving quickly to keep up with customer demand this only increases the number of yearly audits needed to stay up to date with the network. As a result, network operators find it increasingly difficult to reconcile their physical network with their network inventory databases leading to (1) increasing number of discrepancies that is no longer manageable through traditional manual corrective means; and (2) generating an increasing amount of stranded assets that may no longer generate revenue to the network operator while still consuming space, power, and HVAC expenses.

In this paper, we will describe an architecture that uses augmented reality (AR) and artificial intelligence (AI) [1] as part of a planned network maintenance or upgrade to reconcile the physical network with planned inventory. We propose a new inventory architecture in which AR is used to capture images of network devices, seamlessly and unobtrusively, in the field during regular maintenance tasks, which are then analyzed using AI to update the inventory. It will also describe how technicians are assisted in verifying that a task was performed correctly. Visual examples will show, in tutorial style, how the technologies blend together.

2. Present Mode of Operations

The operations context in which we introduce the new inventory architecture begins with an operator planning changes to the physical network, as part of end-to-end service setup, and dispatches technicians to implement the change at a central office (CO). The technician will most likely have a workforce order (WFO) describing the changes; specifically, the order may require the technician to connect fiber “Z” to

Port “2” of a patch panel to complete connectivity, as illustrated in

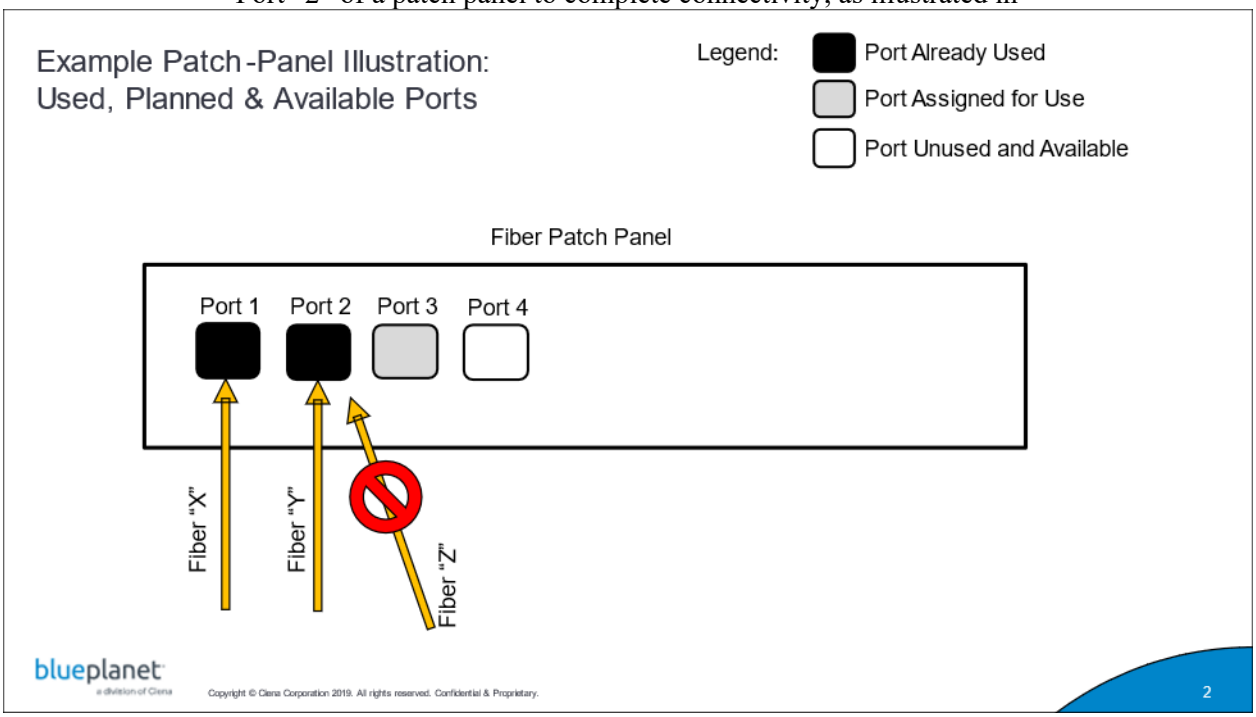

Figure 1. The problem begins that although the network operator planning team may have designed the end-to-end service based on inventory data showing port “2” available, the reality (“as-is” state) of the network shows that an existing fiber is already consuming this assigned port. Although this network discrepancy may have originated in different ways – e.g., terminated service but fiber not removed, previous workorder task assigned fiber “Y” to the wrong port, poor documented updates back into inventory… – the result is the dispatched technician will need to make a choice:

(1) Perform an ad-hoc change to the task, or
(2) Delay the task until the inventory and physical network match.

For most network operators, option (2) of first reconciling inventory with the network to then generate a new design and workorder for service introduces such delay and impact as to certainly jeopardize customer business, so option (1) becomes the de facto approach – Do what is necessary to deliver customer service now, update systems as best as possible later.

Present mode of operations (PMO) shows that network operators will define decision protocols for the technician to assist in option (1). For example, often the technician will not know if there is live traffic on the offending fiber (Fiber “Y”) consuming port “2” eliminating the possibility of disconnecting the fiber to release the port. As a result, a decision protocol may guide the technician that in case a port defined in

the workorder is already consumed, select the next available port on the panel, say port “3” in

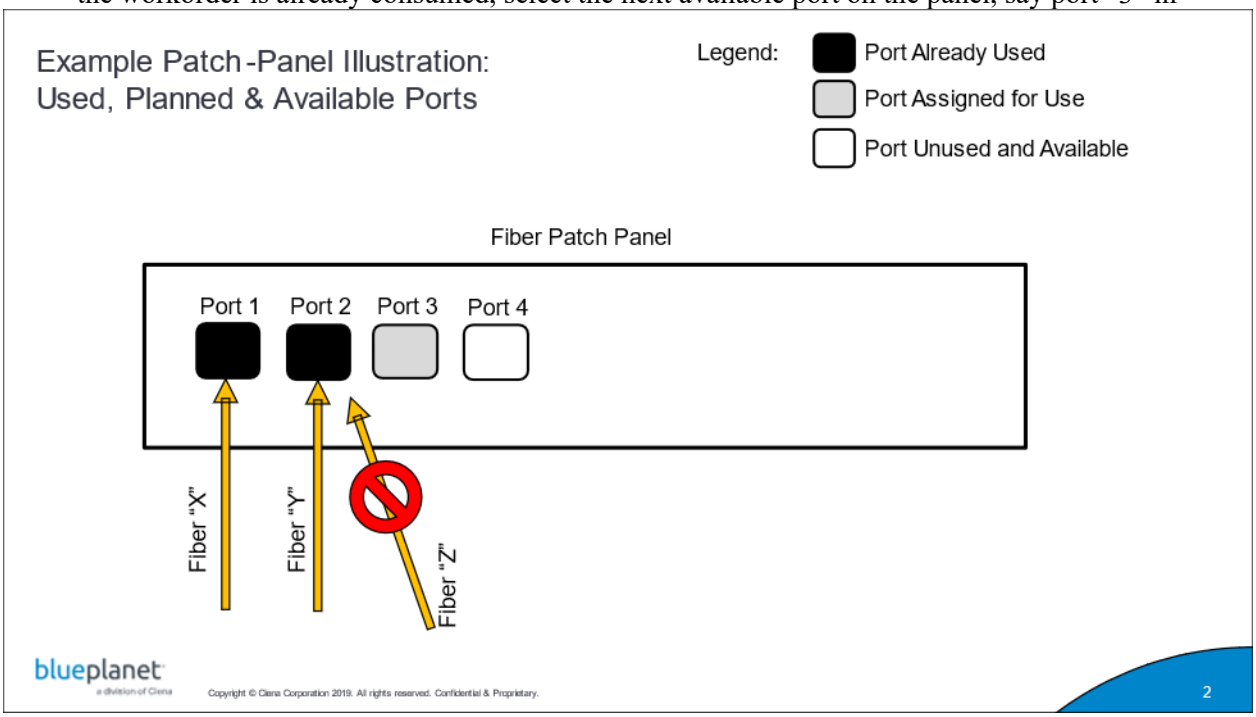

Figure 1, and document back to the planning team the newly selected port. What the technician will not know, and workforce order will not capture, is that port “3” may already be planned in inventory and assigned for another service to be connected in the field at a later time, making port “4” the next unused and viable port for service. This approach exacerbates the out-of-sync inventory problem and works against their efforts to plan network updates.

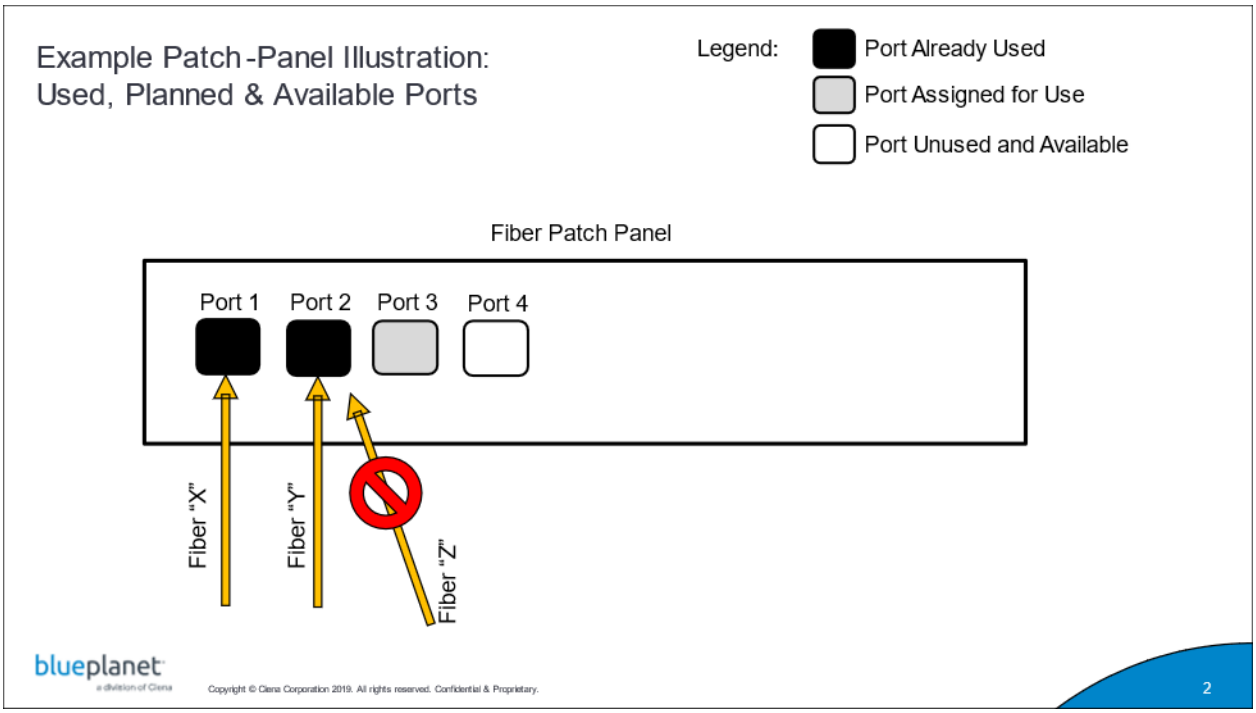

Figure 1: Patch Panel Illustration

Instead, what if we can use AR with physical visual devices such as phones, tablets, or "smart glasses" to superimpose real time digital records over the visuals of physical reality to guide operations and technicians to first time right service delivery [2]. And, if we can use AI with image processing and deep neural networks for object detection and image segmentation to convert physical reality into digital records ("as-is" network view) that can rapidly resolve discrepancies. Operators have a growing interest in using image capture, recognition, and AI [3] [4] to digitize inventory and track physical network assets while exposing any discrepancies in the network.

3. AR and AI for Inventory Synchronization

The first step in our proposed architecture approach is to enable the technician to quickly take stock of the "as-is" state of the resource elements and then compare with planned equipment for alignment before engaging any changes. Figure 2, provides an example network device as we would see in a CO, the device has several ports in use and cables dropping from the used connections. Here, some ports are used and cables that connect to the port overlap and sometimes cover available ports. The approach to capture and digitize the current port usage will need to determine which ports are used and which are available underneath the mesh of cables.

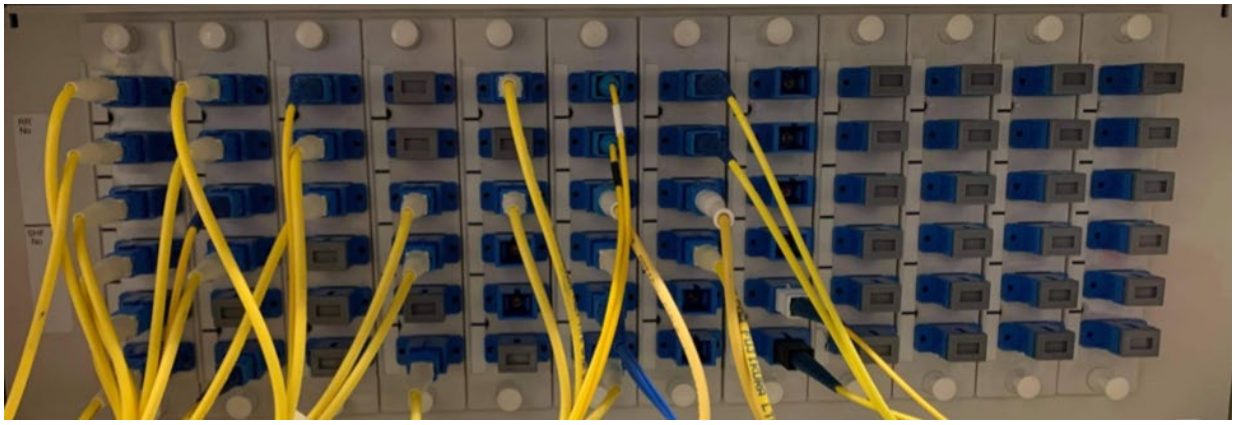

Figure 2: Example Network Device

For this we introduce the use of augmented reality (AR) combined with smart device enabling the technician to capture and digitize the target equipment as shown in Figure 3. The technician would aim the smart device camera toward the network device and ensure it fits within the boundary of digitization border of the application.

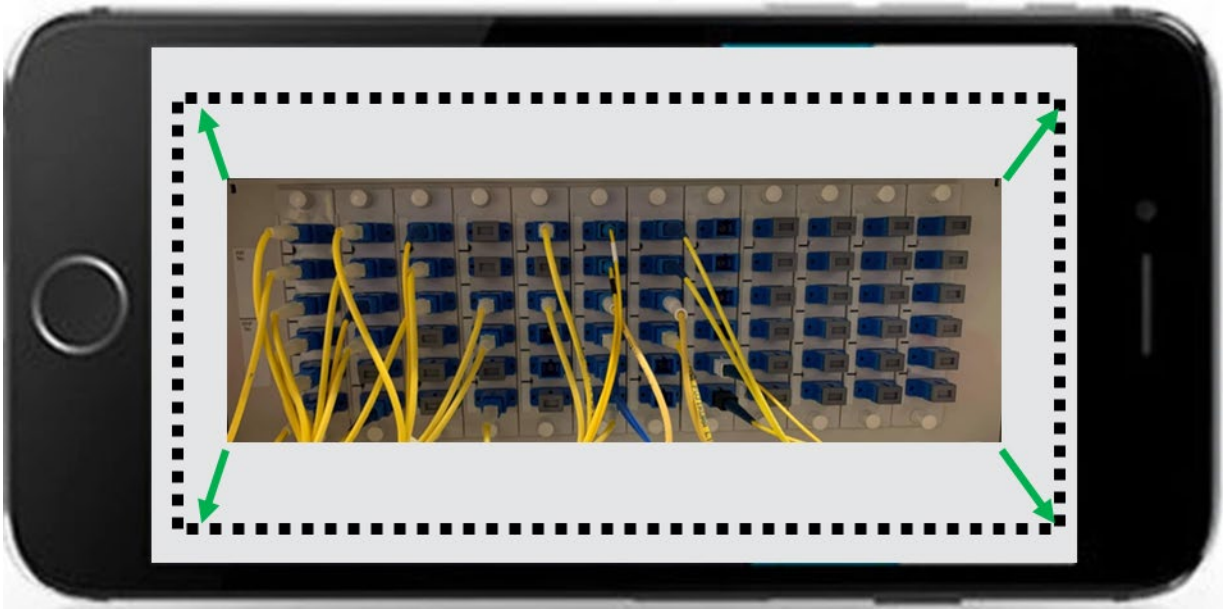

Figure 3: Device Capture with Augmented Reality

Because a single frontal picture would certainly not take a clear enough picture of ports through the cables, the augmented reality application would guide the technician to pivot the smart device in direction of the arrows shown on screen so the smart device can collect a series of picture or video from different angles creating a rich multi-perspective recording of the device before automatically closing the camera

indicating the capture process is complete. This image capture process would take less than a minute of the overall technician's time and have negligeable impact on his task schedule. The image capture has a dual purpose:

A) Digitize the "as-is" state of the device to be compared with the planned view of the device in inventory database and identify any potential discrepancies.
B) Become the reference image to guide the technician on the device tasks ahead.

Before we can identify any potential discrepancies, the digitized device must first be identified so the system knows what to compare with and what device to present back to the technician as operational guidance in next step tasks. For this, when the smart device captures the device image, it can also capture the device bar code, and/or the unique ID (combination of location, floor, shelf, etc.) many network operators stamp on devices today, and/or the physical characteristics of the device itself. The latter part means comparing the physical layout of the digitized device with digital reference pictures/models from device vendors themselves. When combining the above vectors of identifications with GIS (Geographic Information System) location the AI function can present back to the technician through their smart device an accurate determination of the network device discovered. In absence of enough identification vectors the smart device will ask the technician to enter a known ID code for the device to finalize selection.

The next step is for the image technology tied to digital image capture to determine what ports are used or available for use. This is done by extracting the features of the ports (used and available) and comparing them to models of available ports and computing their likely association to either available or used, as illustrated in Figure 4. This is where the importance of having created a stream of images or video by pivoting the smart device camera around the network device is key. As the image processing computes the likelihood across different image perspectives some ports will show consistently 100% available (green) or 100% used (red), while many of the ports that were "hidden" by cabling may be computed to higher accuracy as each perspective reinforces either "used" or "available". For ports that are not resolved as either 100% used or available, the smart device can allow the technician to "pinch-zoom" on the area of the device image they will work on and enable the technician to confirm by touch (yes/no) if the port is consumed or not. It is important to note that as technicians continue to take image captures over time as they work on the device the movement of cables, changes in connection and exposure to different angles will create an increasing accurate perspective of the as-is state of the device and phase out any potential differences across image captures.

Figure 4: Digital Image Map

At this point the resulting discovered digital image map is ready for comparison with inventory database to create a discrepancy map that will guide the network operator to correct and reconcile inventory to the network. The discrepancy map would list all the objects in database that do not match with the digital image map with associated probability based on the accuracy of the digital map. The network operator can take the discrepancy of highest to lowest probability and initiate reconciliation processes to correct discrepancies in future in-field work, or directly guide the technician on location to make the correction if in the

technician's remit. An example can be a cable is occupying a port that the inventory systems know the service was terminated and cable should have been removed but not completed by the last technician. By continually feeding image captures of network devices as changes are implemented the imaging technology and underlying AI engine creates a more accurate view of discrepancies and their associated probabilities. This enables the network operator to focus on correcting the discrepancies of greatest value to the business, all while the technicians continue their daily work orders with the addition of image capture.

While the AI system computes and updates the digital image map and probabilities of discrepancies continuously, the technician is guided in his workorder operations through the smart device without delay. Let's take the original example in

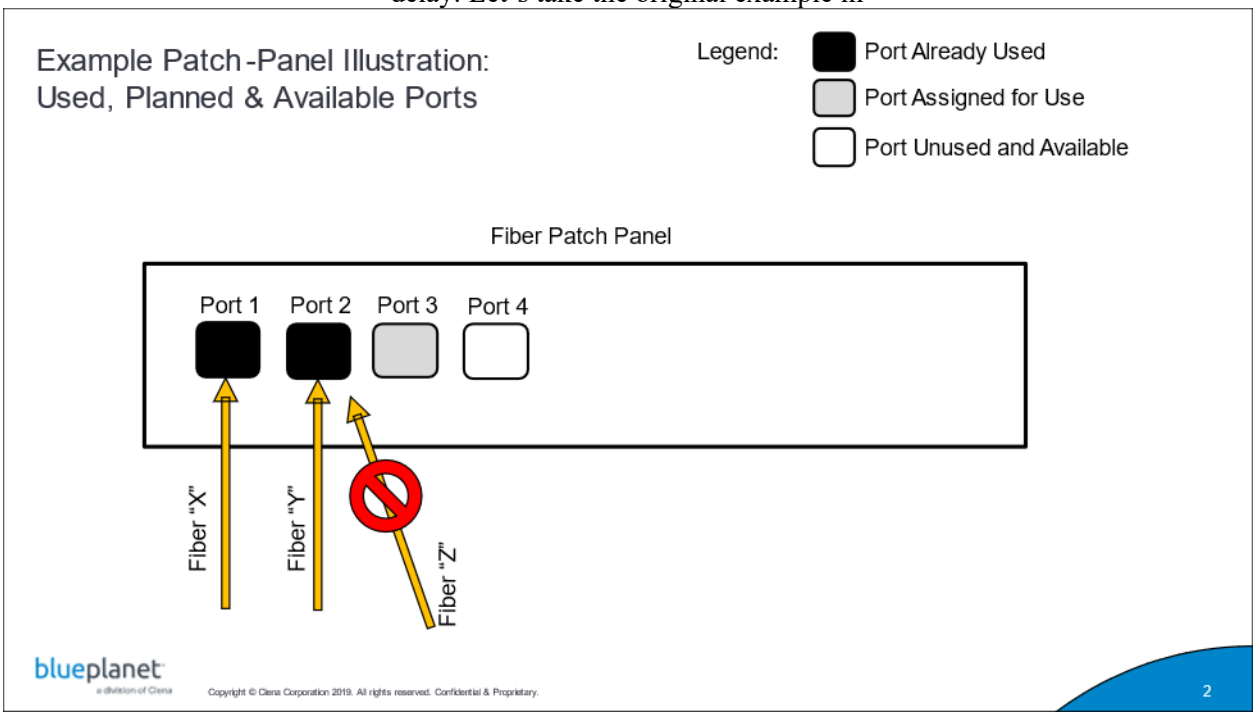

Figure 1: The technician has a workorder to connect a fiber cable to complete an end-to-end service. The workorder indicates that fiber "Z" should go to port "2" but the port is already used. Although the technician may have a protocol in place indicating he should use the next "available" port, the selection of the port will benefit from a guided operations approach from the combined AR/AI system. Because port "3" is already assigned for future service in the inventory database, the smart device will guide the technician to connect the fiber to port "4" as illustrated in Figure 5.

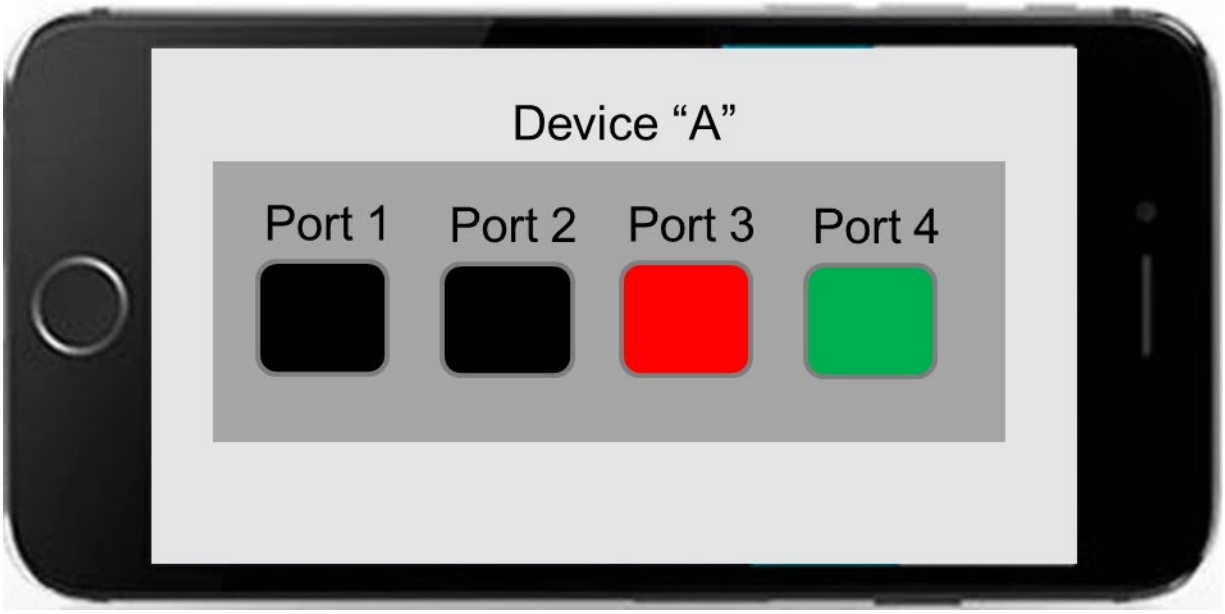

Figure 5: Guided Operations - Connections

Once the fiber connection is completed, the technician will capture another image of the device in its current “as-is” state which will update the inventory database with the new connection and can include communication to the planning team that an update to the original plan was required to complete the task.

The proposed architecture that captures the above AR and AI technology and guided operations can be illustrated as in Figure 6. At the heart of the architecture is the federation of data that that brings together under a common normalized information model, the following:

- Network operator defined device template used to model and identify the equipment to be analyzed for discrepancies.
- The Inventory “as-planned” view of the device to compare with the digital image map for discrepancies.
- The digital image map of the network device, generated by the imaging technology, from the captured smart device video/pictures.
- The federated data can also include vendor defined device templates that may be more accurate/complete than inventory models and when combined with GIS data enables very accurate determination of network devices across a wide range of resources in inventory.

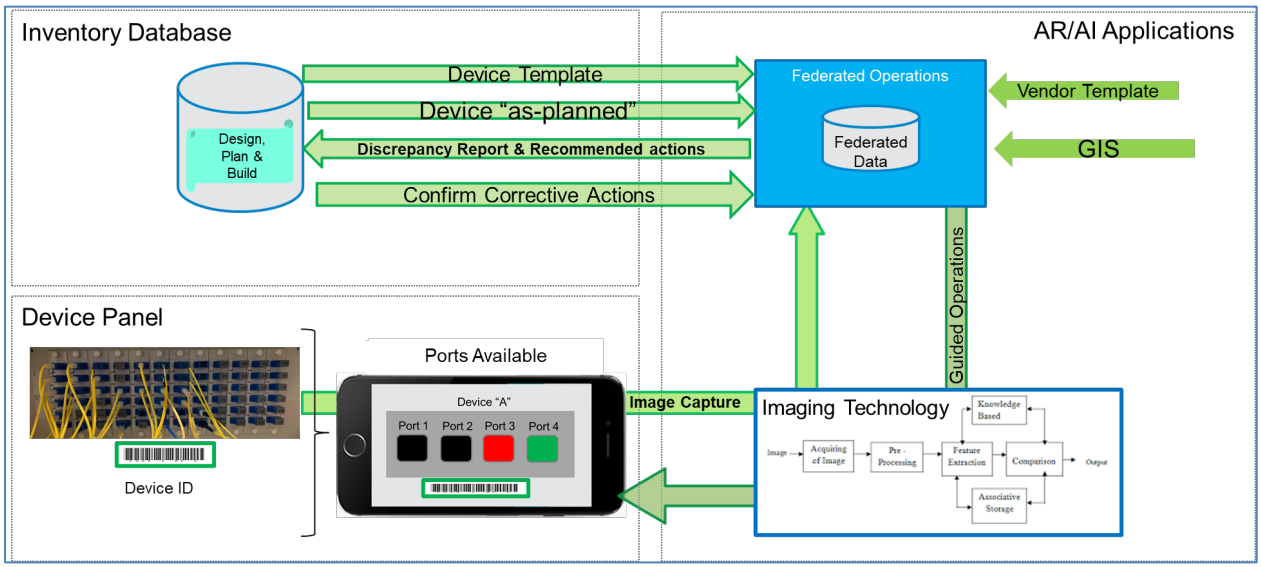

Figure 6: Proposed AR/AI based Architecture

Discrepancy detection rules are applied across the federated data to generate discrepancy reports where each discrepancy is mapped from highest to lowest level of accuracy and associated recommended action for remediation. Here the network operator can choose to either tabulate a series of reports into a dedicated workorder where a technician can be dispatched at a prescribed time and location to correct these discrepancies, or, the architecture allows the guided operations (as shown in Figure 6) where the corrective action is communicated back to the technician through the smart device and corrected in flight. Both approaches enable the network operator to achieve increased inventory and network synchronization (INS) toward eliminating device discrepancies that can impact their customer, their business, and their competitiveness in the market.

4. Future Mode of Operations

The AR/AI architecture presented in this paper is a proposed future mode of operations (FMO) to enable network operators in stopping and reversing the proliferation of network discrepancies that impact their business today. In this future mode of operations, the technicians in the field use readily available image capture tools like smart phones and/or tablets combined with existing AR software to provide a constant feed (crowd sourcing) of "as-is" state of devices as a constant stream of data complementing any traditional discovery process to keep the inventory database in lockstep with the network. The imaging technology and associated AI that creates the digital device map, and federated data infrastructure, can be cloud-based making the approach scalable to different business needs. Communications across image capture tools, imaging technology, federated data and Inventory databases can be achieved through open APIs for greater ease of integration. The result of this proposed architecture is to finally close, in as real-time as possible, the inventory and network synchronization loop that has eluded the industry for so long.

It is important to note that while the example used in this paper describes an approach to resolving discrepancies related to fiber connection, this same architecture can be used in wider context, for example:

- Equipment upgrade: Upgrading card, shelf, or device where the image technology is used to map the existing device to be upgraded against the new device characteristics to guide and confirm toward a successful upgrade.

- Initial equipment discovery: The digital image captured by the technician and resulting digital device map generated through AI can be quickly mapped to vendor templates that trigger the creation of accurate device object entries in inventory without lengthy or costly audit processes in the field.

Although the proposed architecture provides a promising approach to inventory and network synchronization, this future mode of operations would also need to fit within the following operational considerations:

- Recording devices: Not all network operators allow recording devices to capture network information. The off the shelf devices and software proposed with this architecture would need to be authorized on premises.
- Workforce: A technician's contracted responsibilities may not allow for the additional task of capturing images/video as part of workorder flow.
- Secure data/connection: The processing of images/video in the cloud would mean secure connection and possibly encryption between network operator and federated data.
- Inventory database access: Many existing and legacy inventory systems in network operators may not allow direct access to inventory data and could require multiple data exports that would be ingested into a federated environment.

5. Conclusion

This paper has proposed an AR and AI architecture approach to inventory synchronization. The approach shows that with off the shelf smart devices and the use of AR a technician can capture a rich set of multi-angle images/video data in very short time and effort that can be used by AI to quickly identify the device and generate an accurate digital image map for discrepancy detection between network and inventory. We also described how conversely AI and data federation can provide the technician, through AR, a guided operations approach to completing a workorder task without compounding network discrepancies and even correcting in real-time previously reported discrepancies. The proposed architecture can be either on-prem or cloud-based depending on the business needs of the network operator. The architecture approach applies to the connectivity example presented in this paper but also in wider context of device/equipment upgrade and maintenance. And the approach can be used as an initial network discovery and inventory setup method for network operators wanting to populate their new inventory system with a current view of network devices in the field.

Abbreviations

AR	augmented reality
AI	artificial intelligence
PMO	present mode of operations
CO	central office
WFO	workforce order
INS	inventory network synchronization
FMO	future mode of operations

1. Introduction

What initially started in early March 2020 as a multi-day trial to determine if the company could rapidly move to support a remote workforce, as part of emergency preparedness, quickly pivoted into a remote workforce for roughly 18-months in response to the pandemic. This was not only a radical change in the way we work, but also in the way our customers use our products. Disruptions in supply-chain, construction, and customer interactions added challenges to what would have otherwise required a tremendous-level of effort to ensure the customer experience remained as consistent and positive as possible.

Fortunately, we have a standing process for managing our bandwidth on an ongoing basis. This process has four components: (1) strategize, (2) model, (3) plan, and (4) deploy. This paper reviews each of these four components in general as well as how they enabled us to rapidly respond to the increased demand driven by the pandemic.

2. Strategize

The last decade has seen an evolution from planning for the co-existence of multiple products with discrete bandwidth requirements on the HFC network to all products utilizing IP transport on multiple access network technologies. Telephony evolved from circuit-switched telephony to IP/packet-switched. Video evolved first from analog to digital, then from MPEG-2 to MPEG-4, and dedicated QAM-based to shared IP-based delivery. This paper will focus on meeting the bandwidth needs resulting from the converged delivery of products over IP.

The general formula we use to determine the amount of bandwidth required (C, capacity) as being at least the sum of the Peak Traffic (we use P_{95}) and Max Tier (T_{Max}):

$$C \geq P_{95} + T_{Max}$$

The Peak Traffic is sometimes looked at as the product of the number of subscribers and the per-subscriber contribution to peak traffic, however, we use the measured value that the node is at or below for 95% of the time (P_{95}). When additional capacity is available, there are peaks in traffic that can be handled by the network without loss of data and which typically should not impact the customer experience, so we utilize this measure to prevent those peaks from driving unneeded capacity.

The maximum tier is typically the maximum advertised speed plus some overhead to ensure a positive quality of experience. Ulm & Cloonan (2017) list these as separate variables, and many argue that the overprovisioned we include in the tier is not the same as the quality of experience variable they intend. Cloonan (2014) refers to the QOE experience as K. Rather than treating these separately, we typically overprovision the customer by ~10% and use the overprovisioned value as T_{Max} in our calculations.

Capacity calculations for upstream and downstream are treated separately. For example, if the maximum tier on a node was 300/30 (300 Mbps downstream, 30 Mbps upstream), and these were overprovisioned by 10%, then we would use $T_{Max\text{-}D}$ of 330 and $T_{Max\text{-}U}$ of 33. In a node with 32 SC-QAM (37.5 Mbps) channels on the downstream and 4x6.4 MHz QAM (26.88 Mbps) channels on the upstream, then we can figure out the maximum amount of traffic that the nodes can bear before a node action is required as follows:

$$C \geq P_{95} + T_{Max} \xrightarrow{rearranged} P_{95} \leq C - T_{Max}$$

Downstream	Upstream
$P_{95} \leq C - T_{Max}$	$P_{95} \leq C - T_{Max}$
$P_{95} \leq (32 \times 37.5) - 330$	$P_{95} \leq (4 \times 26.88) - 33$
$P_{95} \leq 1200 - 330 \leq 870$	$P_{95} \leq 107.52 - 33 \leq 74.52$

For QAM, we use 7/8 of the raw throughput to estimate the available payload capacity. Although the traffic limits are based on these formulas, operations typically use a "70%" rule, which has worked as these numbers are close to 70% of the capacity, though in the future, this will need to be addressed as it is likely that this will not remain close to 70%. Today, nodes are considered targets for node-actions at 70%, congested at 80%, and heavily congested at 90%, with the latter two corresponding to increases in trouble-calls.

Approaching the target maximum P_{95} value in either the upstream or downstream will typically drive a node-action. In practice, we use a model to project when a node will approach the capacity limits to plan node actions much further in advance, and closely monitor actual data to make modifications to the plan based on changes that could not be predicted.

Downstream traffic is estimated to grow at a compound annual growth rate (CAGR) of 35% while upstream traffic grows at a 26% CAGR. It is not feasible for us to accommodate this type of growth in every part of the plant each year, instead we plan to address 20% of our footprint each year in anticipation of completing an upgrade cycle each 5-years. This means that our target design needs to result in an increased peak traffic capacity of about 4.5x on the downstream and 3.2x on the upstream. These targets do not include increases otherwise needed to support higher maximum advertised tiers.

Increases in product offerings don't follow the same growth patterns as usage. The maximum offered downstream speeds tend to increase at about 3.2x over a 5-year period. There appears to be pressure on the upstream to increase to symmetric speeds, but it is unclear if that will continue over the long term. It is probable that the primary driver is more likely to be around latency rather than sustained throughput, but marketing from competitors will likely keep the need for increased speed/bandwidth.

There are two types of bandwidth levers: optimize existing spectrum and increase available spectrum. Optimizing existing spectrum could be from optimizing the underlying technology, increasing the efficiency with regards to the payload, and/or by reallocating spectrum between services. Increasing available spectrum can come from repurposing spectrum, reducing the number of subscribers sharing the spectrum (segmentation/node-split), or increasing the frequency range (spectrum) that the plant is able to support.

If we assume that the downstream traffic was 870 Mbps and needs to accommodate growth of 4.5x over the next 5 years, and the maximum tier was 330 Mbps and needs to accommodate a growth of 3.2x over the next 5 years, we can apply our formulas as follows:

$$C \geq P_{95} + T_{Max}$$

$$C \geq (870 \times 4.5) + (330 \times 3.2) \geq 3915 + 1056 \geq 4971$$

This means that we would either need to increase the amount of downstream capacity to nearly 5 Gbps, segment the node, or do some combination of the two. Having the benefit of hindsight for this example, we knew that

over that timeframe we were looking to expand the downstream to 48-SC-QAMs and 192 MHz of OFDM, which would give us a downstream capacity of 3.6 Gbps, meaning that some degree of segmentation would be required. We also know that the T_{Max} was actually a 1 Gbps service with a 10% overhead, or T_{Max}=1100 Mbps. We assume that a simple node-split typically results in a 60/40 split in the traffic, a three-way split results in a 40/36/24 split, and a double split results in a 36/24/24/16 split in the traffic. T_{Max} remains unchanged.

$$P_{95} \leq C - T_{Max}$$

$$P_{95} \leq 3600 - 1100 \leq 2500$$

In order to achieve this the higher traffic leg of the segmentation would be targeted to grow to less than 2500 Mbps, which assuming a growth factor of 4.5x means it should be ≤ 555.5 Mbps, or 63.8% of current peak capacity, meaning that most simple node-splits should suffice.

2.1. CoVID Impacts

One of the major impacts of CoVID was to drive people to shelter at home, meaning all activities, including work and school, became dependent upon the residential network. Nearly overnight we noticed an increase in network utilization equivalent to what we would expect after a full year's growth, and at the 1-year mark we measured the expected 35% increase on the downstream but an unprecedented 55% increase on the upstream. The graph below shows a typical weekday before CoVID in orange and after CoVID in blue. It is also worth noting that while the downstream peak remains in the evening (and in-line with typical annual increases), the upstream peak moved to start in the late morning and usage remains significantly higher for roughly 10-hours.

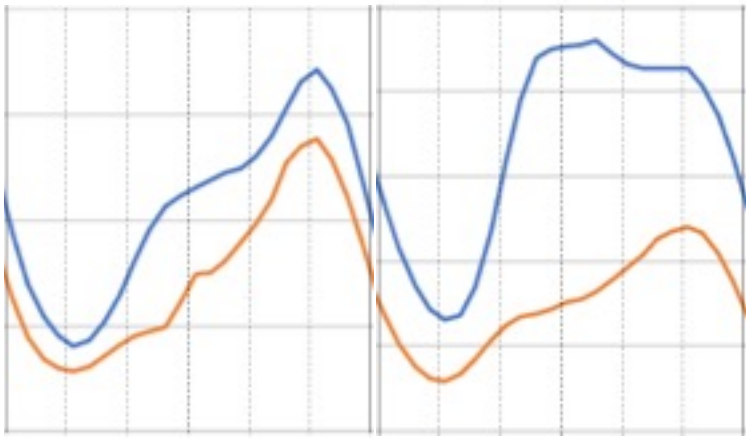

Figure 1 – Typical Weekday Bandwidth Impact, Downstream (left) and Upstream (right)

Our plans to accommodate downstream growth had already included reclaiming spectrum from other services and growing the amount of spectrum allocated to DOCSIS, especially focusing on DOCSIS 3.1 enabled devices that support OFDM capacity. Our plans to accommodate upstream growth were based on DOCSIS 3.1 and a migration to Mid-Split, including the use of OFDMA in the mid-split spectrum. We did not feel that accelerating the move to Mid-Split would enable us to respond as quickly as required to customer demand.

The first option that was proposed was to reallocate some of the ATDMA carriers to OFDMA to increase capacity. This is known internally as Sub-Split OFDMA (SOFA). The challenges with this approach were multi-fold, including requiring a higher penetration of DOCSIS 3.1 devices than was present at the time and a lack of maturity of OFDMA itself. While not implemented for this immediate circumstance, we kicked off a program that will allow us to implement SOFA should the upstream impact continue to last for many years.

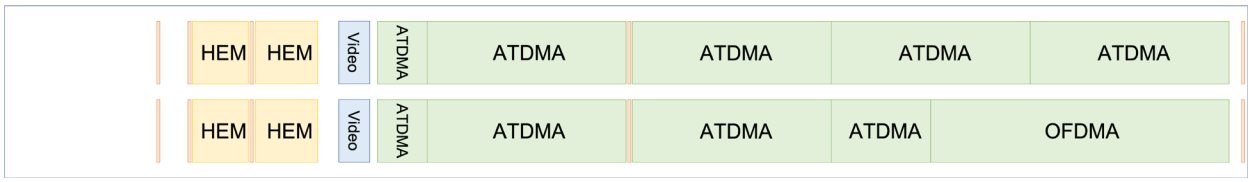

Figure 2 – Pre-CoVID Spectrum vs. Initially Proposed SOFA

We reached out to customers in heavily utilized nodes who were heavy users either intentionally (for example, to incentivize them to move to one of our Fiber products if that option was available) or unintentionally (for example, increasing outreach to customers whose devices may be impacted by malware or may be transmitting higher volumes of traffic due to configuration issues).

The option we ultimately implemented is known internally as fifth-carrier (5C) as it is the fifth carrier in the DOCSIS sub-split upstream that is intended to be used to deliver internet service (there is also a 1.6 MHz ATDMA carrier designated for DSG, which is why the initial state shows five items labeled ATDMA). This required us to work closely with all our markets to make alterations to how the upstream spectrum was utilized by non-Data products. Thanks to significant ongoing efforts resulting in moves from circuit-switched telephony to IP-Telephony, legacy video return to DOCISIS-based return, and dedicated telemetry return paths to using embedded DOCSIS modems in our plant gear, we had the opportunity to retire and/or relocate many legacy carriers, giving us enough spectrum to launch an additional 3.2 MHz upstream channel.

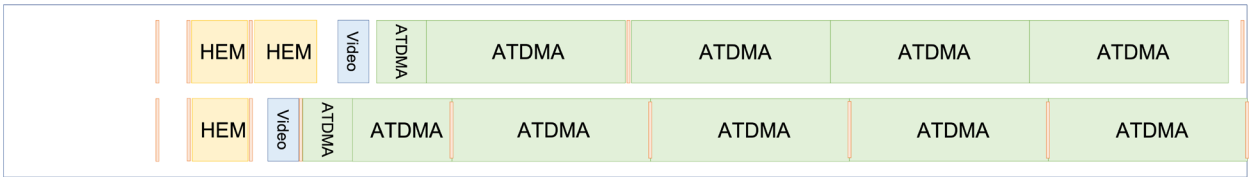

Figure 3 – Pre-CoVID Spectrum vs. Fifth Carrier

This brought along many challenges which will be discussed later in this paper, but this addition of 12.5% more raw spectrum gave us 18% additional capacity towards the P_{95} (as T_{Max} remained the same). This served to reduce the number of congested nodes back down to within 0.5% of the pre-CoVID levels, with an expectation that as this did not completely offset the 26% increase, the number of nodes approaching congestion could be expected to reach a level between 3% and 6% for the remainder of the 5-year upgrade cycle unless another activity brought additional relief. That other program is the previously mentioned SOFA program.

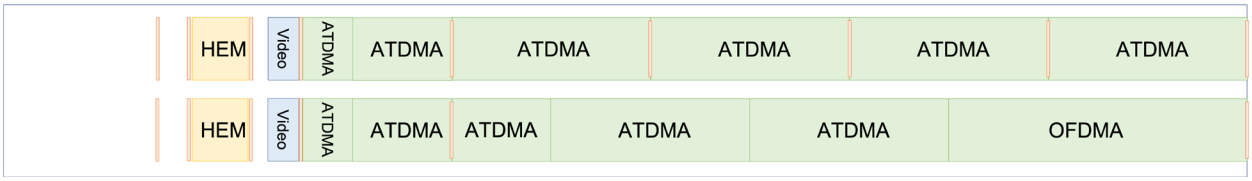

Figure 4 – Fifth Carrier vs. Fifth Carrier with SOFA

When coupled with the 5th Carrier, the newly proposed SOFA option has 2x3.2 MHz and 2x6.4 MHz ATDMA carriers in addition to the OFDMA in the subsplit spectrum region.

3. Model

Due to the sudden change in demand as customer behavior changed due to CoVID, it was crucial for our teams to quickly analyze the growing bandwidth concerns, predict the range of future growth patterns, and determine the impact of different strategies in handling each scenario. The automation of our planning tools allowed such a wide variance to be analyzed within days, and for solutions to be proposed and adjusted with similar speed.

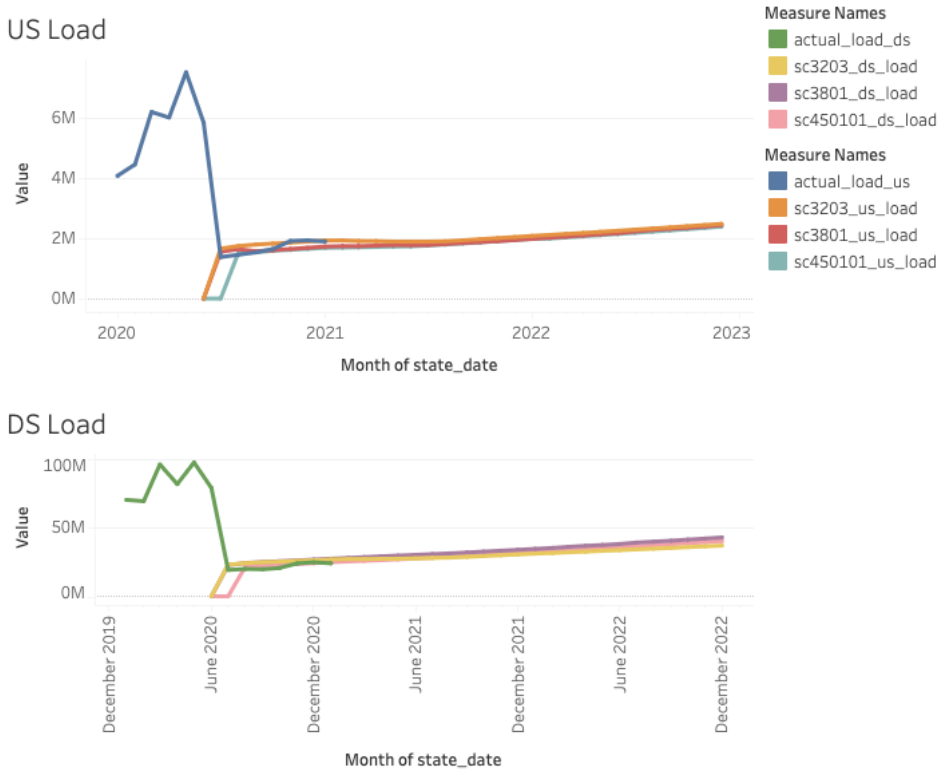

Figure 5 – Enterprise node load compared across forecast scenarios

Our forecasting model predicts network load based on historical node-level traffic data, weighted by seasonality and outlying factors, like the recent node action spike due to COVID. This predictive modeling is constantly updated to reflect new information, or to confirm existing patterns and narrow down the range of possible outcomes. Even with unexpected shifts to otherwise predictable data, the forecast gives a statistically sound expectation.

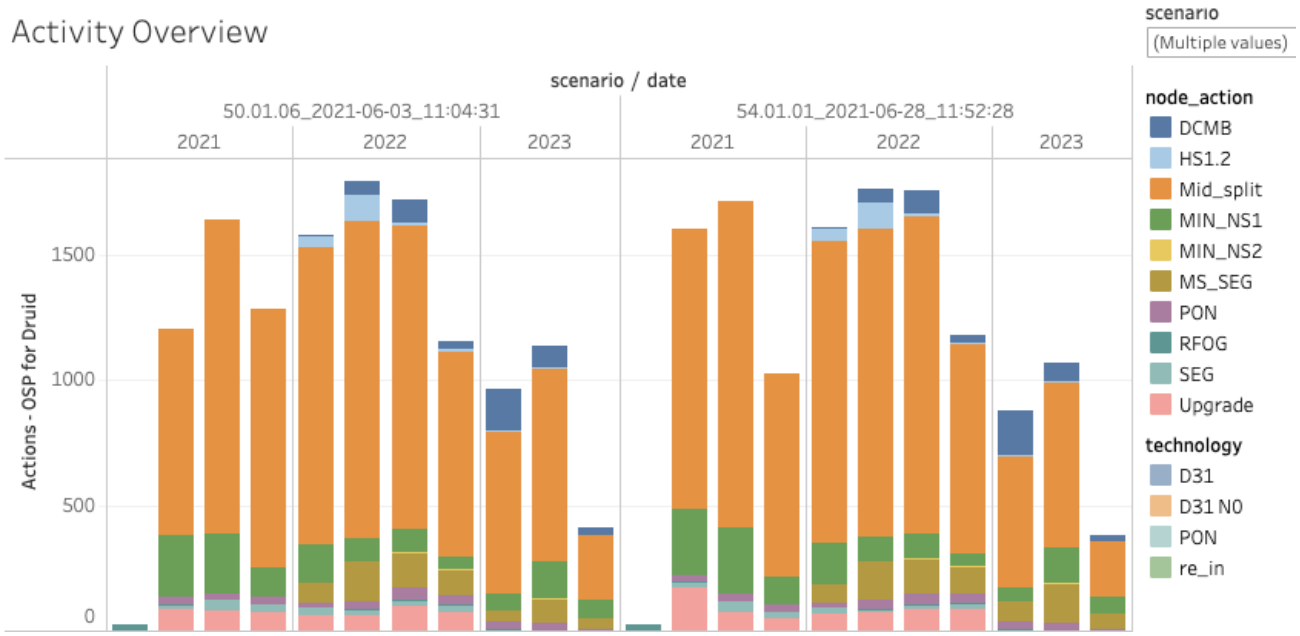

Figure 6 – Automated node action comparison example

Given any one set of expected network utilization, the Capacity Response module compiles a logical action priority based on a determined set of business requirements. As the strategy is adjusted by the planning team, the model us updated to reflect the appropriate action thresholds, technology definitions and restrictions, and deployment rates. The output of any given scenario provides an overview of the deployment schedule required at minimum to manage utilization, which is then processed through the Volume Model for the respectively required hardware and licensing per facility.

With these modeling capabilities, proposals for new technology considerations underwent rapid approval processes as we were immediately able to give relevant estimations of impact for each case. Ultimately, the abstraction of the underlying logistics to each solution allowed the planning teams to focus on solving these urgent problems at a much larger scale.

4. Plan

On Tuesday afternoon of March 10, 2020, we were told to pack up and head home early. The explanation was that the company wanted to conduct an emergency preparedness test with us working from home for a few days. By the end of the week, it was obvious that this was due to a virus with a peculiar name that was starting to get more headlines and an increasing sense of concern. By that weekend, it was clear that we would not be back in the office for at least a few weeks with few, if any of us, expecting that it would be nearly 18 months (or longer) before any of us were back at our desks.

By the following week, the node-action escalation team was seeing an uptick in node-action tickets as people started working from home and students began taking classes online and driving up upstream traffic utilization. Almost overnight, Zoom went from being a relatively obscure app to part of our lexicon. Daytime commercial usage shifted from high-capacity business infrastructure to residential nodes that until then were used primarily for daytime TV watching, personal email, and gaming. At nearly the same time, an internal node-action ticketing automation tool went live, and the node-action tickets went from a typical one or two a week to nine or ten per day, eventually averaging 24 per day in April. The small team responsible for processing the node-

action tickets was quickly overwhelmed, leading to recruiting other employees to sort and triage the incoming flood of tickets.

The months of March, April, and May of 2020 saw over 1,200 node action tickets processed in those three months alone, versus a total of 77 by the same team for all of 2019. The previously discussed traffic growth predictions had gone completely out the window as we experienced over a year's worth of demand increase in less than a month.

After it was decided to use a 5th upstream ATDMA carrier to provide more capacity, the initial thought was that we would add this to every node in all markets. This had the advantage of being a global response, however over two-thirds of our nodes were still below the node-action thresholds, and the 5th carrier would have simply been excess capacity. It also would have meant many nodes consuming an unneeded upstream license at a cost in millions for the unnecessary licenses. Thus, the decision was made to add the 5th carrier on a node-by-node basis.

Once that was decided, members of the bandwidth management team were tasked with reaching out to the markets, the video teams, and the regional DOCSIS teams to prepare them for the effort, while the EMO team began pulling the node utilization data from the ACOE group each week. As that was happening, trial nodes were being identified in multiple markets. Where needed, HEM channels to support the circuit-switched telephony were being moved or removed, and the non-DOCSIS based video-OOB signals were relocated (SCTE 55-1 and SCTE 55-2). This was across the enterprise and was a coordinated effort between multiple corporate and field teams and their boundary partners.

Figure 7 depicts a typical transition as it was implemented.

1. The top row represents a typical starting configuration prior to pandemic
2. Where applicable, plant sweep channels and telephony HEM channels were moved or removed
3. The legacy video upstream OOB was relocated
4. The DOCSIS carrier used for DSG was moved downward by the regional DOCSIS team to create a gap
5. New plant sweep channels were placed
6. Applicable nodes had the 5th DOCSIS ATDMA carrier added for use by cable modems and EMTAs

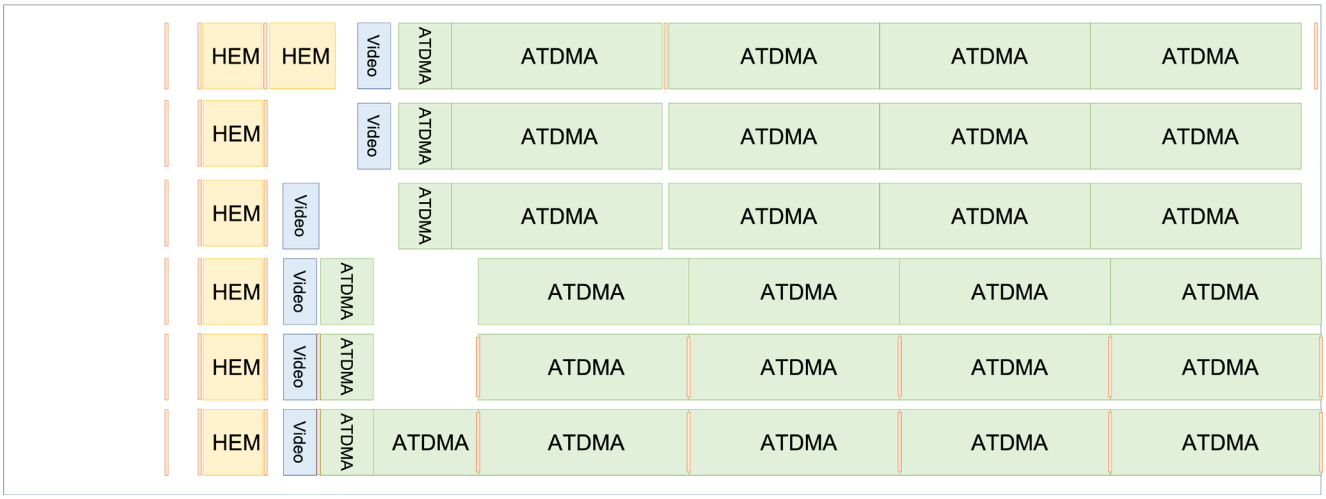

Figure 7 – Preparing to Implement 5th Carrier

The spectrum preparation (through Step 5) was implemented across all nodes in each market, leaving the space for the 5th Carrier to be inserted as required. As nodes hit the Upstream 70% utilization threshold, they were added on a weekly basis to a list to have the 5th carrier turned up. This response not only saved money but allowed for an agile response to prevent congestion where utilization approached node-action levels during the lockdowns. Such a measured response also kept the number of nodes per week manageable and prevented overwhelming the resources needed for deployment of the solution. For nodes not receiving a 5th Carrier, they will remain at the 5th row of configuration until such time as they are migrated to a new spectrum, such as mid-split or high-split. Current estimates show approximately half the enterprise nodes will eventually receive a 5th carrier.

Nodes continued to be added for the 5th Carrier throughout the year and the effort continues to this current day. At any point in time, the total number of 5th Carrier nodes is less than the total number of deployments as previously planned node actions have resulted in many 5th Carrier nodes being addressed with Mid-split.

The 5th Carrier solution is expected to run for the next several years but will gradually taper off as we execute on our plans to implement mid-split or higher capacity upstream solutions. Thus the 5th Carrier may have a fairly short duration within Cox network planning but is notable for the much-needed relief it provided at a critical time due to extraordinary and unforeseen circumstances.

5. Deploy

Typical pre-COVID deployments unsurprisingly involve high-level controls through program management and Engineering governance to standardize customer and employee impacting projects. The phase gates ensure cross-functional collaboration and awareness but also establishes metric baselines, success criteria, trial performance reviews, and early-life metrics to gauge deployment success. Our deployment process framework is internally referred to as Solution Certification. This framework integrates these cross-functional workstreams, fulfills governance requirements, and readies a service for production availability.

The Solution Certification process is used as an integration management tool to organize the Technology Readiness and Operational Readiness efforts through trials. The process' output is a scalable and sustainable deployment model to minimize operational exposures to critical activities. It combines the strategy, modeling, and spectrum planning outputs with the technology & operational readiness workstreams to culminate in production readiness of the deployment fulfillment and service guides. This process is used for large or small spectrum initiatives such as the plant and service enablement of Mid-Split with four ATDMA carriers or expanding the downstream OFDM from 96-192MHz. Overall, this process may take anywhere from 6 to 18 months depending on complexity and impact to field operations.

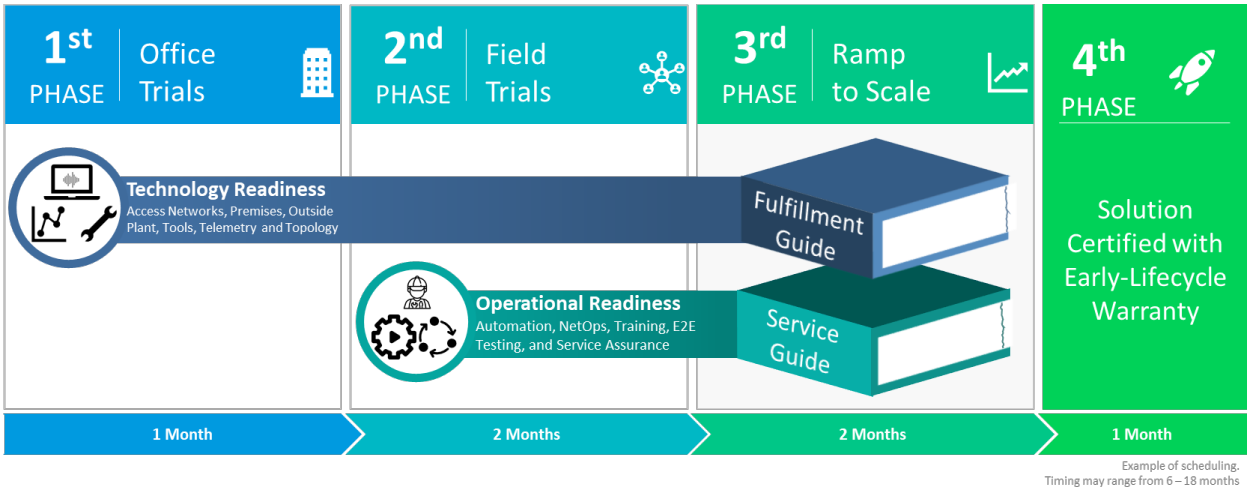

Figure 8 – Solution Certification Process

Office Trials: Technology Readiness' first major milestone that takes the lab-tested deliveries and converges multiple technical workstreams into an office test bed. Trial activities include end-to-end testing, speed tests, node validations, utilization rate checks, and validations for video, voice, and data devices. Pre-COVID, the office trial proved to be an ideal initial gate as employees quickly identify defects that could not be lab tested.

Field Trials: Ops Readiness converges on the certification path to include direct communication with local field teams to understand common issues, validate training, and identify defects that otherwise cannot be captured in analytics. Major activities include the second round of end-to-end testing, on-site node tests, residential & business test account validations, and automation initial testing iterations. Field trials may extend to soaks across multiple markets to widen the trial sampling as a final verification measure before scale.

Ramp to Scale: Handoff to Field Engineering & Operations begins when technology and ops readiness meet trial success criteria. This phase is focused to validate fulfillment and service guides operability in scaled deployment through iterative learning to refine operational processes and automation solutions. Additionally, it is used to test and improve reporting, management, and monitoring tool functionality before the solution is certified.

Solution Certified: Transition to the field is complete and the launch is functioning as designed while operating at full scale. The solution is warrantied for a minimum of 30 days by the program development team to monitor performance and address defects, however, a continuous feedback loop in place to ensure performance and enhance as the solution matures in lifecycle.

Dedicated analytics support is critical to the Solution Certification process for both technology and operational efforts. These reports are essential to trials in not only tracking utilization rates and customer transaction rates but also MER values, D3.1 penetration rate, ticketing, and even track devices in partial service. These trial-focused dashboards are continually modified to evolve it into an operational dashboard as the certification progresses in scalability. For demand-based programs, these dashboards are used as the input to identify node candidates, validate service changes, and also monitor performance to identify anomalies that require escalation to DOCSIS operations and Access engineers. This enables rapid response for our teams to review, troubleshoot, and action on nodes which may necessitate reverting nodes back to original configuration to ensure no harm is done. Ultimately, this dashboard is the key management and reporting tool through a project's lifecycle.

Automation is also a key operational readiness workstream in the effort to streamline changes and processes to meet the high operational tempo that are demanded by field engineering teams. Even small automation updates better enable enterprises to reach scale, improve efficiency, and stay ahead of the curve meet future bandwidth demand and ensure the quality of service expected by our customers. Early collaboration to standardize processes during Solution Certification with operations and engineering teams better enables automation effectiveness and increases agility of future deployments and automation updates.

5.1. Certifying 5th Upstream

COVID's demand for immediate bandwidth increase necessitated the prioritization of a technological solution. The executive leaders' *all hands on deck* call delivered the strategy, modeling, and spectrum plan but now required the development and deployment of more bandwidth. This top-down approach supported the teams by prioritizing this workstream over all others but also limited formalized project and program management as daily direct communication kept leadership abreast of 5th Upstream Carrier status.

Access engineers immediately configured 5th US Carrier in the lab, drafted a MOP in a half-day and worked alongside CPE engineers to form a test plan while outside-plant engineers tested thresholds to determine how to adjust for the low-end 3.2MHz ATDMA. Projects normally estimate 60 days for a single engineer dedicating 25% of their time for lab work, the COVID-team deployed 5th US at Cox Communications Atlanta office in three days. The greatest contributing factors for 5th US Carrier's development expediency were: 1) Leader-driven project crashing with multiple dedicated engineers, 2) standardized CMTS configurations enterprise-wide greatly limiting the volume of testing permutations, 3) and unoccupied offices permitting more aggressive entry to office trials. Labs and 5US carrier was ready for field trial in less than 10 days.

Field trial planning calls involved over a hundred engineers across Advanced Access, Outside Plant, and regional field DOCSIS teams. Each region volunteered to trial 5US, however, several markets required final spectrum alignment moves before it was 5US ready. Five markets across three regions were selected for field trials with Southern California heavily targeted due to exceptionally high utilization rates and heavy concentration of high-profile customers which would be a true test to 5US effectiveness. Overall, 5US was trialed on 15 nodes for a week before ramping to scale.

Concurrent with 5US Carrier's technology readiness workstream our analytics team, the ACoE, developed an MVP dashboard to assist teams to identify and prioritize 5US node candidates based off utilization rates and total customers in the early phases of COVID utilization. Progressive updates were added to develop a Node Prioritization dashboard to support the operational readiness to decisively target the most troublesome nodes with metrics that include high-speed subscription counts, average utilization rates ranging between 1-week to 3-months, and scheduled node actions.

By April 6th, 5US carrier graduated to the Ramp-phase and was soaking on 59 nodes. Engineering teams continued to improve 5US performance by adjusting thresholds but also addressed other issues like CSR VOIP performance, however, 5US full deployment management transitioned to Sustaining Engineering and the field's Bandwidth Management team.

By mid-April, 5US was at full-launch in spectrum-ready markets while the Bandwidth Management team coordinated with local teams to move HEMs, consolidate SCTE 55-1, and move the OOB/Upstream. They established a weekly cadence to review the Node Prioritization reports and queue nodes for the regional DOCSIS managers to review, schedule, and service enable with 5US. On April 20th, 5US had reached scale enterprise-wide with 2,291 nodes enabled by the end of the month.

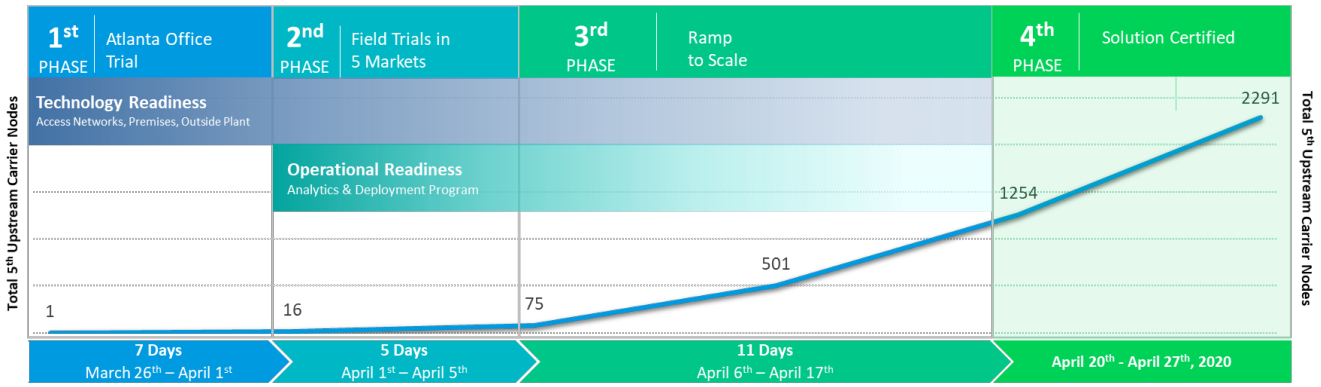

Figure 9 - 5th Upstream Carrier Solution Certification

5.2. 5th Upstream Carrier Deployed

By mid-May, the node volume utilization rates decreased to more manageable levels with teams gradually shifting focus back to the pre-COVID strategic roadmap with small contingents still focused on pandemic related demand. A total of 4,539 nodes were 5US enabled by end of May reducing the total volume of congested nodes (P_{95} ≥80%) from the 7.1% peak down to 2.6%.

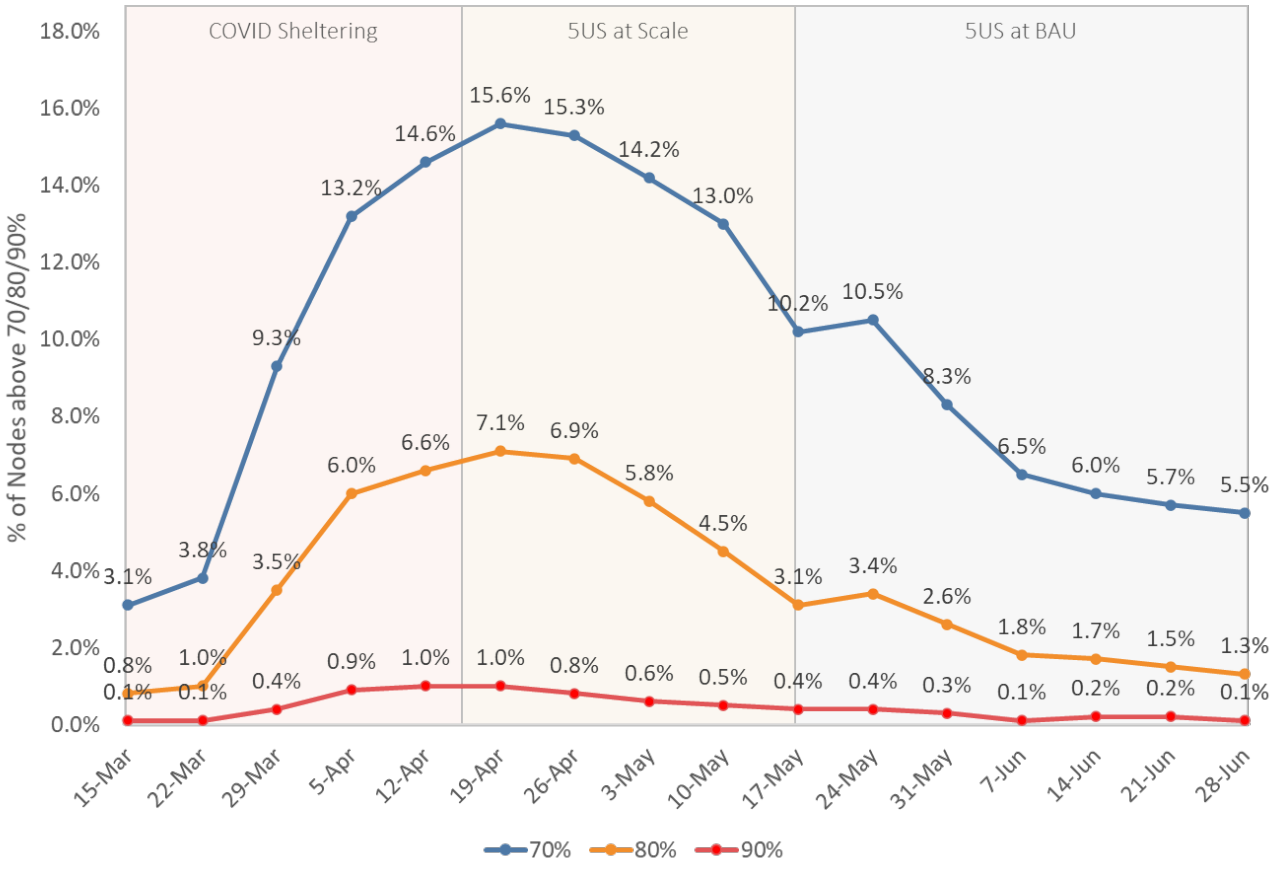

Figure 10- COVID-Driven Utilization and 5US Carrier

By Summer 2020, most nodes that could be addressed by 5US were already enabled and the team standardized the 5US enablement threshold to target nodes with a 4-week ≥70% P_{95}. Deployment rates sharply decreased to approximately 300 enablements per month but spiked to 645 once the remote-learning school year commenced. At the one-year Work from Home anniversary, 5th Upstream Carrier had been deployed to 9,958 nodes with over 42% of deployments occurring within the first 60 days of COVID sheltering.

As of Summer of 2021, the rate of 5th Upstream actions tapered off with some regions going weeks without enabling a fifth ATDMA channel. The total number of active 5US carrier nodes have progressively decreased over recent months as they continue to be consumed by mid-split migrations.

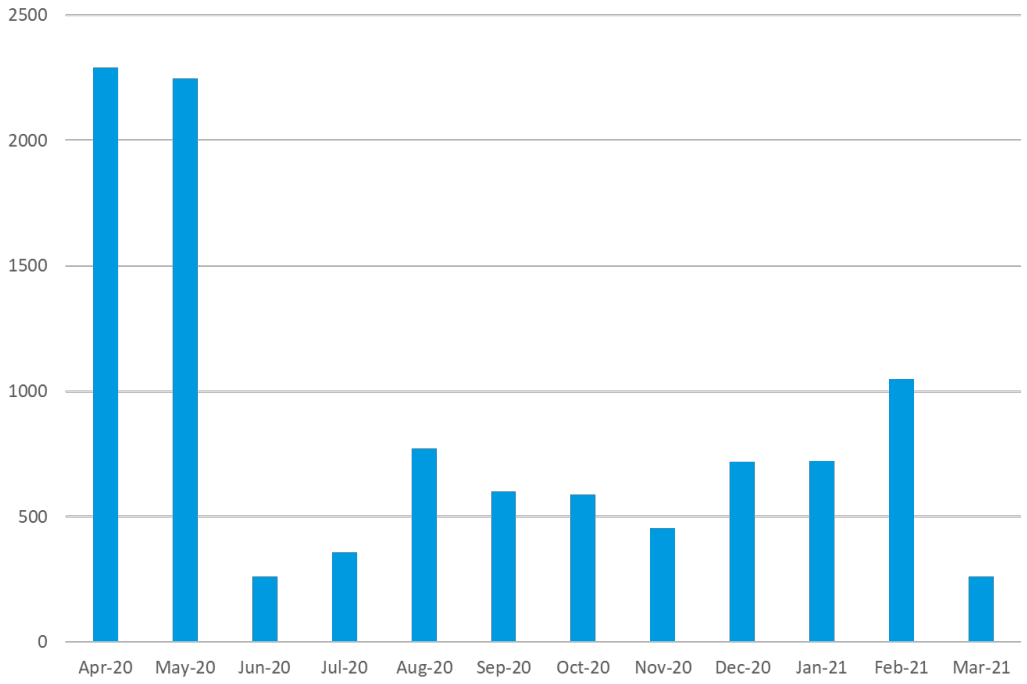

Figure 11- 5th Upstream Carrier Enablements

Operational readiness updates progressively rolled out to support the enablement process like Network Automation's service change update for 5US on RPD to enable scheduling and automated MOP execution. Additionally, the ACoE updated the Node Prioritization report to validate 5US enablements via utilization monitoring of the extra ATDMA channel. This removed the manual spreadsheet tracking of 5US nodes by both the deployment PM and the DOCSIS Operations managers. The Node Prioritization dashboard has since been expanded to also monitor downstream utilization rates and identify OFDM carrier widths to prioritize nodes that require expanded D3.1 capacity.

Figure 12– ACoE Node Prioritization Dashboard Example

In contrast to our typical Solution Certification which normally takes 6-18 months, 5US for the integrated chassis fast tracked the process in 23 days after entering the lab with 5US for RPD following three weeks later. This acceleration was due to a multitude of factors highlighted above, however, the greatest factor to the lightning-fast deployment was due to the strategic decision to use ATDMA. This proven and mature technology was developmentally and operationally less burdensome than OFDMA and could be deployed with minimal risk. Of particular note is that the 5th Carrier was implemented without any measurable impact to call volumes or truck rolls. To implement such a project without the customers noticing was an achievement in itself, and a testament to how the compressed schedule did not sacrifice attention to customer experience.

6. Conclusion

For the near future, Cox network planning will continue per capacity calculations as described in the early sections of this paper. As part of our efforts to accommodate constantly rising demands on utilization, we will be applying capacity levers such as 5th Upstream, SOFA, and Mid-split. In parallel will be the continued march toward the phase-out of legacy video to enable downstream OFDM expansions and transition to all-IP. The pandemic created an unforeseen spike in demand that likely will never be repeated, if only because post-pandemic trends indicate that many people will continue working from home, which will be factored into future growth models. However, for that once in a lifetime event, Cox had the resources, leadership, and corporate agility to able to react to the unprecedented growth and increase our network's resiliency to take care of our customers' needs.

Cable And Rural Broadband

How Cable Plays a Critical Role in Closing the Digital Divide

A Technical Paper prepared for SCTE by

1. Abstract

Cable was birthed in rural America. Cable grew up in rural America. Cable is still rooted in rural America with many rural American households serviced by a cable operator. The US is facing a broadband equity crisis in which nearly 20% of Americans, primarily in rural communities, do not have access to reliable broadband Internet. Cable operators are uniquely positioned to solve this problem once and for all.

This report will explain why rural broadband, like rural electrification in the 1930's and universal telephone service in the 1950's, is the most important societal technology issue of our time.

The report will further explore why delivering broadband to rural Americans is perceived as a challenging engineering and fiscal problem and will explain how innovative approaches to engineering, materials, construction practices, and business modeling can overcome those challenges. The advantages and disadvantages of these innovative approaches will be discussed.

Today, funding sources have expanded to include federal and state grants, broadband funds, and county and municipality initiatives which, when coupled with public / private partnerships, can easily tip the balance to a faster return on investment. Finally, the paper will discuss the financial opportunities and incentives that enable universally accessible broadband Internet to become a reality.

2. Introduction

What began as a pragmatic tool to enable researchers to communicate and collaborate more effectively has, today, become an essential tool for everyone's everyday life. Access to the Internet is as essential as electricity or the telephone and is more widely used for news and information than television and radio. With 90% of employment applications being submitted online, the Internet is an essential tool for seeking employment. For those currently employed, the number of people using the Internet to work from home has increased dramatically during the pandemic. While many private education programs were already exclusively using the Internet to deliver their curriculum, during the COVID-19 pandemic, the Internet became the essential tool for public education institutions. COVID-19 also brought about large increases in the use of telemedicine

However, an estimated 14 million to 160 million homes and businesses in the US do not have adequate access to the Internet. With an echo from the 1940's and rural access to electricity, 90% of those without access to the Internet live in rural areas.

In the 1930s electricity providers refused to deliver electricity to rural Americans. In the 1940s, telephone companies, and television broadcasters also refused. The cost was perceived to be too high to build each of these essential utilities and communication tools to rural communities. Cable, though, is rooted in bringing service to those that would not otherwise have it. Beginning in 1949, the pioneers of cable created cable to deliver television programming to rural America when no one else would.

Today, Cable faces another opportunity to serve its communities and to expand its networks. Many cable operators have been reluctant to build broadband services into rural communities due to poor internal rates of return (IRR). Conditions have changed, though, and Cable is well positioned to help eliminate this gap.

3. The Broadband Gap

The literature and media make frequent references to the “Digital Divide”, but what is this Digital Divide?

Generally, the Digital Divide refers to the gap between those that have access to information and communications technologies (ICT) and those that do not. In the past, the discussion about the Digital Divide was focused on access to computers and technology education. Recently, this is most often applied to describe lack of access to the Internet at broadband speeds, which is also referred to as the Broadband Gap.

The Broadband Gap, though, is not simply a technical or technological one. Those that lack access to broadband Internet are directly and negatively impacted because they are unable to fully benefit from educational, economic, and healthcare resources available on the Internet and they are unable to fully participate in the political and social aspects of their community, nation, and the world.

These are compounding disadvantages. Those that do not have access to the Internet are most likely to already be economically and educationally disadvantaged and their inability to reap the benefits of unencumbered access to the Internet creates a situation in which they are unable to pull themselves up and, instead, are simply drawn deeper into the chasm.

Some might be skeptical about the impacts of this Digital Divide. Consider that in 2015, 80% of Americans used the Internet to search for and apply for employment [1], but in 2020 reliable broadband Internet access was not available to tens of millions of Americans. Further, rural populations, less educated populations, low-income populations, and minority populations are less likely to have broadband access [2] and, therefore, do not have equal access to employment resources.

Education was in the spotlight during the COVID-19 pandemic. Prior to the COVID-19 pandemic, it was already well known that academic performance was better among those that have ready and reliable access to the Internet. According to a study by the Quello Center [3], students with no access to the Internet at home or who rely on a mobile phone for home Internet access will typically be ½-letter grade behind those students that have reliable Internet access at home. According to the US Census Bureau’s Household Pulse Survey [4], an estimated 2.5 million households with school-age children reported their Internet access was not reliably available for education purposes. With a virtually nationwide switch to online education in the United States, lack of reliable broadband Internet access caused significant impacts on academic achievement and disproportionately impacted rural populations and low-income and minority families.

Estimates range from 14 million to 160 million [5] Americans that lack Internet access at broadband speeds. This is a wide range that reflects the lack of accurate and standardized methods to identify the unserved.

Download and upload speeds are the most used standards for fixed broadband service. In the United States, the Federal Communications Commission (FCC) definition is the most referenced standard for broadband. The FCC’s definition has evolved over time, as demonstrated in Table 1, and as of July 2021 the FCC defined broadband Internet access as a service that delivers 25Mbps downloads and 3Mbps uploads.

Table 1 - History of Broadband Definitions in the US

Year Published	Source	Download Speed	Upload Speed
2021	US Treasury Department (minimum build-to, proposed)	100 Mbps	20 Mbps
2021	US Treasury Department (Eligibility)	Less than 25 Mbps[1]	Less than 3 Mbps
2018	USDA ReConnect (Build-To)	25 Mbps	3 Mbps
2018	USDA ReConnect (Eligibility)	Less than 10 Mbps	Less than 1 Mbps
2015	FCC	25 Mbps	3 Mbps
2010	FCC	4 Mbps	1 Mbps
1996	US Telecommunications Act	200 Kbps	200 Kbps

The FCC launched the Rural Digital Opportunity Fund (RDOF) program in 2019 and used Form 477 data, self-reported by Internet providers, to identify census blocks eligible for funding. This analysis resulted in the maps shown in Figure 1, and an estimate of 2,552,251 households without 25/3Mbps Internet access using a terrestrial network.

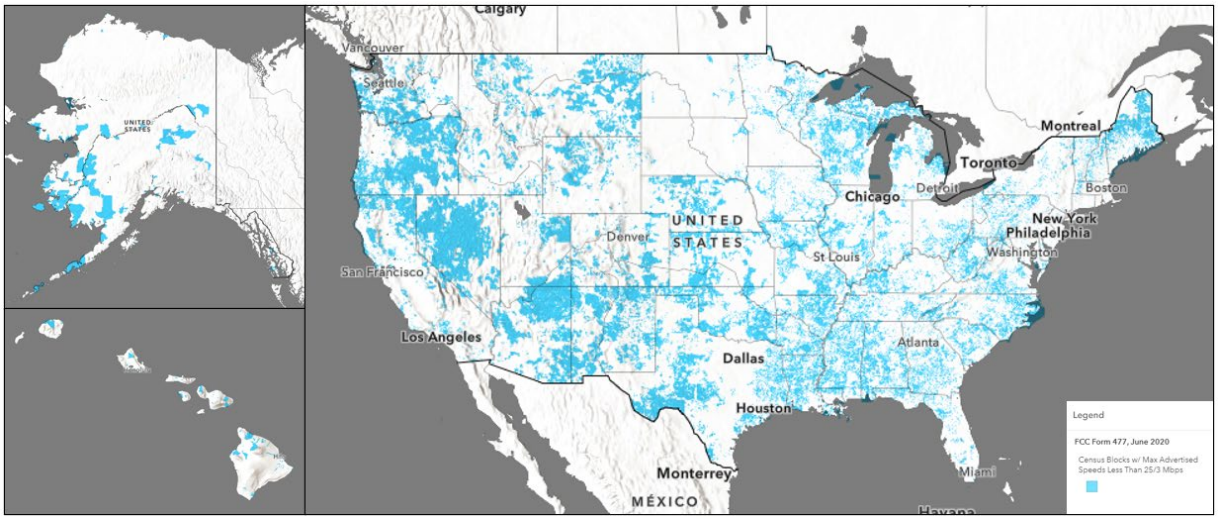

Figure 1- Census Blocks with maximum advertised terrestrial speeds less than 25/3 Mbps(FCC Form 477, June 2020)

With the introduction of the broadband requirements, including allowed overbuild of DSL networks[1], from the US Treasury and proposed legislation, the US has implicitly set the standard of broadband to be fiber-based or cable-based. This significantly changes the picture to show an estimated 10.6 million households without access to broadband.

[1] US Treasury has authorized the use of ARPA funds to overbuild DSL and older DOCSIS networks even though they might deliver 25Mbps/3Mbps.

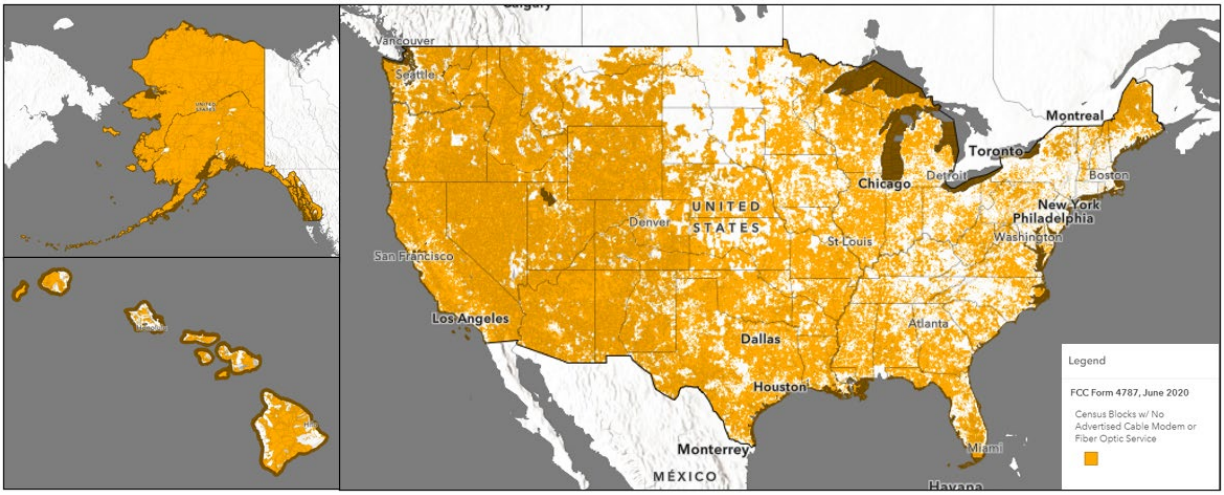

Figure 2 – Census Blocks with no advertised Cable Modem or Fiber Optic Internet Service (FCC Form 477, June 2020)

The US Treasury, in its guidance on use of American Rescue Plan Act (ARPA) funds, also empowered communities and governments to consider a wide range of information other than the FCC Form 477 as evidence that broadband networks were inadequate. These include data from other federal agencies like the National Telecommunications and Information Administration (NTIA), which recently released the Indicators of Broadband Need mapping application [6]. The NTIA map brings datasets together from the US Census (the American Community Survey), Department of Education, NTIA, Ookla Speed test results, Measurement Lab (M-Lab) speed test results, and Microsoft Broadband Usage Statistics.

A recent non-profit study [7] of Loudoun County, Virginia is an example of the significant difference these new data sources can make. Using Form 477 data, the FCC disqualified the entire county from the Auction 904: Rural Digital Opportunity Fund, presuming that all locations in the county have access to the Internet at 25/3Mbps (see Figure 3).

However, the local study shows that nearly 9000 households and businesses do not have access to the Internet at 25Mbps or higher (see Figure 5). Their study further shows that, on average, those households receive download speeds at 15Mbps or lower while paying almost 3 times more per month for Internet service than those that have access to cable-modem or fiber-based Internet access. This disparity between published coverage data and actual broadband accessibility is just one example of many that indicates that broadband coverage is significantly overestimated in the US.

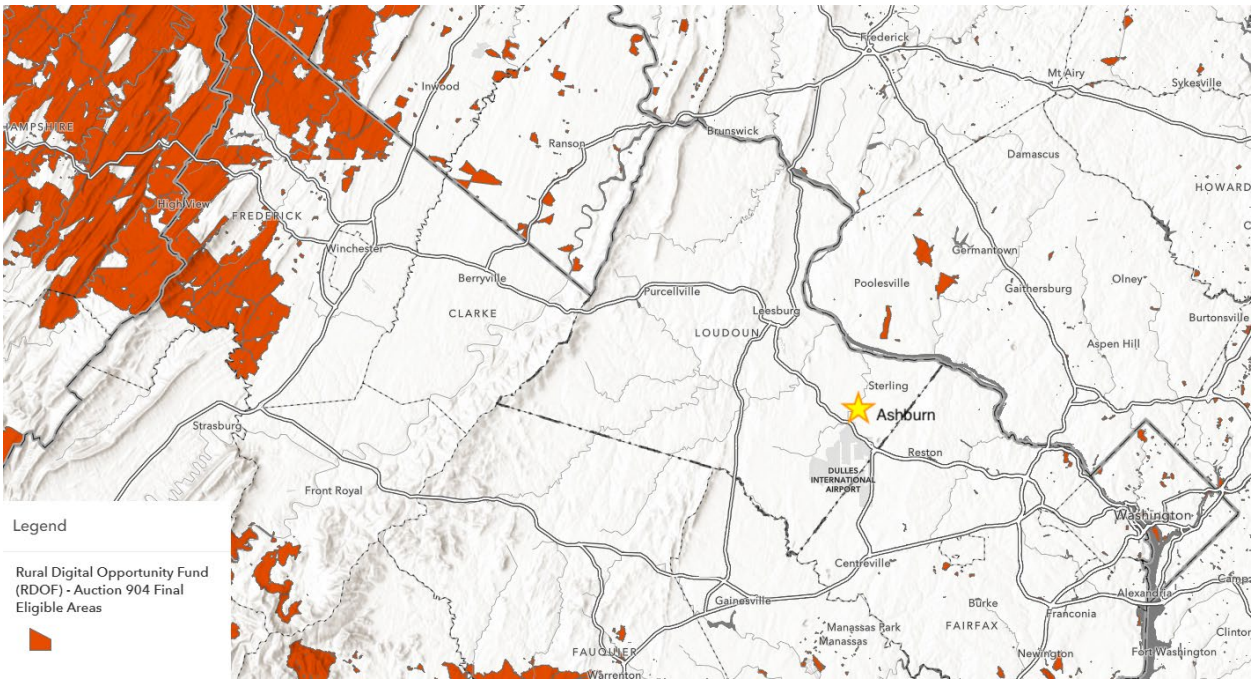

Figure 3 - RDOF Eligibility for Loudoun County, VA and Surrounding Areas

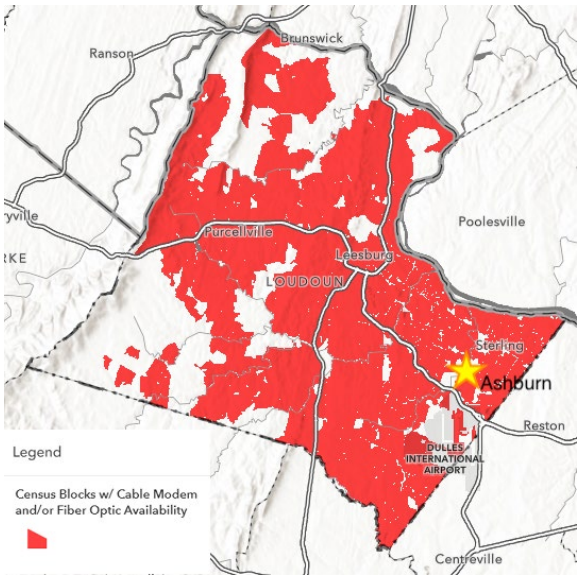

Figure 4 - Form 477 Data indicating accessibility to fiber or cable-based broadband in Loudoun County, Va.

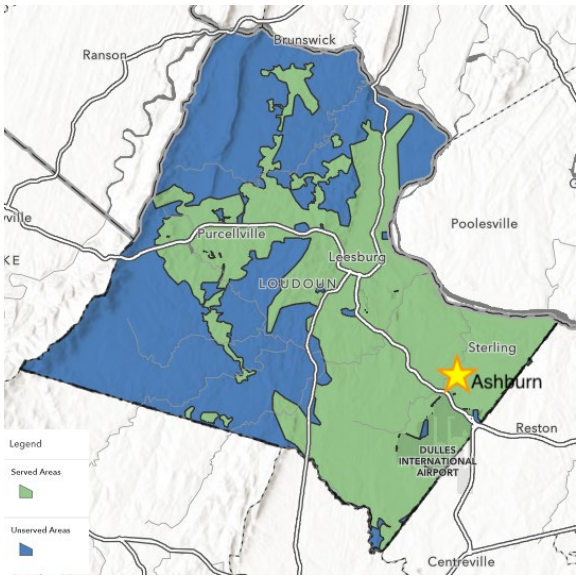

Figure 5 - Locally curated research indicating no broadband coverage (blue shaded areas) in Loudoun County, Va.

With estimates ranging from 14 million to 160 million homes and businesses that lack adequate access to broadband Internet, the available data clearly supports the claim that broadband access is severely lacking in rural areas.

4. Enabling Cable to Expand its Rural Footprint

Cable and other Internet providers have traditionally avoided serving rural areas due to technical or financial criteria. Based on business requirements and goals at the time, those criteria might have been perfectly valid. Conditions have changed and qualification criteria need to be re-evaluated.

Existing US cable franchise areas have very high penetration rates. Subscriber growth is slowing and is often driven only by churn between providers.

For US operators, there are four primary areas of company growth:

1. Growing penetration/stealing share for existing products
2. Introducing new products (e.g., mobile)
3. New home construction in existing footprint
4. Expanding footprint (mostly into underserved markets)

The most often cited reason for not building rural Internet access is that it is too expensive, but what are the factors that drive cost, and what are the characteristics of "rural" networks?

4.1. Construction dominates cost

It's important to understand when constructing rural broadband networks that build costs are dominated by construction labor. Materials and electronics, even sophisticated networking equipment, make up a very small portion of the network deployment costs. Construction is commonly outsourced to third-party contractors. Entering into these third-party relationships, it's important to obtain competitive pricing while at the same time not compromising on build quality. Often cable operators will be able to leverage numerous such relationships that they already have in place as part of their ongoing needs.

4.1.1. Logistical Factors

Logistics related to construction contribute significant overhead to the construction process. Before beginning construction, the operator must acquire permits from right-of-way owners such as local and state departments of transportation, easements where no existing access rights exist, and utility permits to connect to utility poles. Construction and safety permits must also be acquired. The application and permitting processes and requirements can be unique for each jurisdiction and can be tedious and require expertise in the specific jurisdiction.

These factors can be mitigated by considering cost sharing opportunities, reducing the number of times to "go to the well", building relationships with the permitting agents and agencies, and by coordinating construction with other utilities.

Previously, construction of new network infrastructure was planned on a 1-year cycle. This is no longer an effective strategy.

A one-year cycle was predicated on a "do-it-yourself" approach in which the operator designs, plans, and constructs the network as an independent and autonomous entity. This do-it-yourself approach is not cost effective for rural networks. Cost effective construction will require the operator to share the cost of trenching and boring. Municipalities are loath to have their roads disrupted and having each utility or communications provider running independent digs means multiple disruptions and more risk to the municipal infrastructures (like water and sewer).

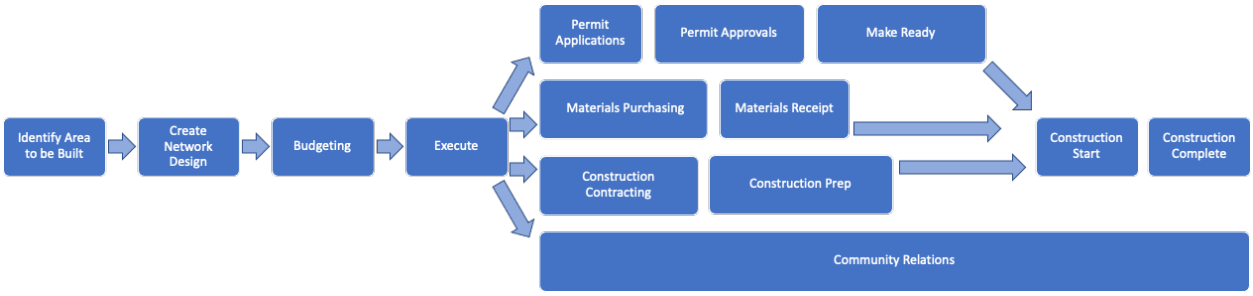

Figure 6 - Typical 1-year planning and construction cycle

Another factor to consider is availability of labor and materials. The industry is already experiencing shortages in skilled labor and materials, especially for fiber builds. As federal and state funding for broadband expansion ramps up in 2021 through 2024, these shortages will only get worse. The cable operator will need to order materials at least one year out, perhaps entering risk-buy situations. Recent experience has shown that even when pre-ordered, materials might not be delivered on time. Most publicly supported broadband expansion programs impose 2-year deadlines, so without flexibility in the cable operator's processes, network designs, materials choices, and construction practices, operators could find themselves facing penalties due to supply-chain issues.

All of this means that a 5-year planning cycle will be a necessary cost reduction strategy. This allows the operator to be opportunistic in construction – keeping an eye open for infrastructure projects where constructions costs can be shared (e.g. laying conduit alongside new water and sewer infrastructure, or coordinating water and road crossings with bridge and overpass replacements). With the federal funding for infrastructure being distributed in 2021 through 2024, these opportunities will be at a peak.

Becoming aware of potential cost-sharing opportunities will require planners to build relationships. Relationships with jurisdictional personnel are already a necessity to streamline permitting processes. Cable operators will need to foster new relationships in local and state planning offices and with planning teams in the various utility companies and possibly competitive broadband providers. These relationships will be critical to discovering future infrastructure actions that can be leveraged for the benefit of the cable operator through cost reduction and building goodwill among the participants. In fact, such relationships and coordination might become the new regulatory norm due to legislation introduced in 2021 [8, 9, 10].

Operators will often have choices to make in selecting which markets they chose to build. When a strong partnership is formed with the localities (both local and state), it can help foster an environment that facilitates and streamlines network construction. In the same manner, uncooperative localities can be a major obstacle to a successful build – and operators use this local cooperation criteria when selecting the areas that they chose to invest in.

Another factor will be the availability and willingness to take advantage of symbiotic relationships. As an example, Central Virginia Electric Coop (CVEC), responding to requests from its members to deliver broadband Internet access, started an initiative to offer zero-fee pole attachments to Internet providers. Through this program, CVEC formed a strong relationship that brought fiber-based broadband to 37,000 co-op members in rural Virginia [8] and also accelerated its smart-grid deployment. While the partner was not a cable operator, opportunities like this will be available to those cable operators that are alert and willing.

4.1.2. Improved Construction Techniques and Tools

Once the planning is complete construction can start, but it's not so simple as hanging or burying some cable. The art of network construction includes a variety of skills and requires an equally varying set of tools.

Advances in fiber cable have made it possible to fit more fiber strands into smaller and smaller cables. Ribbon cable makes it possible to fit, for example, 144 fibers into the same size cable as 72 fibers of loose-tube fiber. Unarmored cables are also available and can be a measured-risk for cable operators. These options can save space and reduce weight and wind loads on poles. Ribbon cable, though, has its own challenges since it typically requires special handling and splicing tools. In the past, splitting a ribbon cable in mid-span has not been practical. New tools, though, change this dynamic. Ribbon separation tools are available from multiple sources and enable crews to easily separate fibers from the ribbon. Ribbonizing tools and adhesives are also available to dress and complete ribbon splices. With new splicing kits, it is also now possible to splice whole ribbons or individual fibers.

Tools to bury cable have also advanced. Availability of tools like the vacuum excavator means that manually digging to avoid existing utility lines is no longer necessary. This is a significant time and cost saving tool.

Figure 7 - Examples of Vacuum Excavators[2]

Directional boring has been in use for many years. In the past, though, safely completing a directional bore was dependent on good documentation of existing utility lines (which is often incomplete or inaccurate) and could be quickly thwarted by unexpected geological features. They were also highly dependent on the skill of the operator to know the location and direction of the bit. Today's boring efforts, though, benefit from advanced tools like electric strike indication systems and proximity detection systems that significantly improve accuracy of the drill, but also reduce risks of injury and unexpected utility damage.

These are just a couple of examples of advancements in tools and techniques in construction.

4.2. Technology Considerations

Unless an area is directly adjacent to current hybrid fiber-coax (HFC) infrastructure, a service area expansion is typically going to best be supported by the deployment of an all-fiber network. Build costs are equivalent to HFC, and the result is a much more extensible, more fault tolerant, and less expensive to operate network.

For cable operators, while making a change to an all-fiber delivery, it will be important to continue to offer video services and leverage the substantial investments that have already been made in the video space. IP Video technology has matured, enabling cable operators to deliver nearly equivalent video services over fiber, albeit with some new challenges in service delivery. Video CPE and service activation, to name two, can look quite different from current practices.

Just as cable operators have started to embrace the push of some electronics deeper in the network (i.e. Distributed Access Architecture), the same movement is occurring within all fiber network architectures.

From a timing perspective (circa 2021), 10Gbps symmetrical PON (XGS-PON, or 10G-EPON) has become the technology of choice. Previously, the Optical Line Terminal (OLT) device was a monolithic modular chassis designed to be deployed in an environmentally stable environment like a data center. Recently, though, the remote OLT has become an enabling technology for lower-cost network builds. The OLT is now available and commonly used in several remote configurations, including node OLTs, outdoor cabinet OLTs, as well as compact OLTs designed for multiple dwelling unit (MDU) and high-rise buildings. Such configurations allow for the elimination of high fiber count trunks that must span the long distances to a hub or headend. These well-placed remote devices can also eliminate reach restrictions, since PON networks have distance limitations, often as low as 20km. Lastly, remote OLTs can eliminate or limit the needs for headend space or avoid the need for small electronics huts. All of these serve to save on construction cost.

Figure 8 - Traditional OLT Deployed Remotely

Figure 9 - Modern Remote OLT

Another enabler for lower-cost network builds is availability of many types of data, electronically, from so many sources. These include geocoding resources, address verification databases, geocoded census and consumer demographics, electronic network inventories (locating cable routes), satellite imagery and detailed topographical and soil-type maps.

In the past, with so much data available, subject matter experts would need to be employed to analyze the data and planners would need to interpret summaries provided from several sources to make build-out decisions. Often in-the-field surveys would need to be performed to verify the findings or to collect data that was otherwise unavailable. These processes often took months to complete. Today's modern planning and design tools, though, allow designers and planners to aggregate massive amounts of data, perform measurements and calculations, perform address density calculations, measure distances, and quickly run cost estimates simply by snapping out polygons on their computer desktop.

4.3. Workforce Challenges

Maybe one of the most significant concerns for expanding broadband service into rural areas is finding skilled labor. Especially with increased funding and mandates from the federal and state governments, demand for a workforce capable of building outside plant will be increasing and the existing workforce is already stretched.

Most operators no longer maintain dedicated construction crews. Instead, they might retain crews responsible for plant maintenance, and often will retain a contractor for repairs and hire other contractors to perform initial builds.

It will not be enough to have access to workers skilled simply in the art. Those workers will need to be trained in sound safety practices. Without this, the operator will be at risk for code violations, on-the-job injuries, or liability risks post-project completion. Skilled labor will be easiest found with a contractor.

With the growing emphasis on building fiber networks to previously unbuilt areas, a dearth of pop-up fiber construction outfits has surfaced. Often these crews are learning on-the-fly and have no first-hand experience nor quality training from the industry or from the manufacturer of the equipment they have chosen to use.

A reputable and quality network construction contractor will maintain continuous training in the art and safety for its employees. The contractor will have experience constructing infrastructure in the regions of interest. They will also be familiar with the safety protocols and permitting protocols of those regions and have the financial backing and stability to absorb changes in project schedules and unforeseen circumstances "on-the-ground".

For these reasons, choosing the least expensive contracting option on a per-job basis is not necessarily the best decision. Since longer-term planning is of growing importance, part of that planning will be to build relationships and retainers that ensure quality contractors are available and that they are able to plan their workforce development to match the operator's projected demand. These relationships are secured by committing to 5-year build plans and by forming long-term contractual agreements with contractors and suppliers.

Construction is not the only area of concern for the workforce, though. There are many connected processes that support construction. For example, prior to beginning construction, locators must be dispatched to locate and mark existing infrastructure (electrical, water, sewer, etc.). City, county, and state regulating offices must keep up with permitting and inspection volumes. These agencies might need to increase staff and provide education related to broadband to support increased volume of builds.

Another issue that operators must be prepared to manage is variations in regulations among jurisdictions and variations in enforcement within the same jurisdiction. The former is much more manageable and can be mitigated during the planning and permitting phases of a project. Variations in enforcement are caused by varying interpretation of regulations among inspectors or region-specific leadership. Such variations, though, often do not appear until after the project has begun and can result in construction activity being halted (while workers continue to be paid) and the project being delayed.

Anecdotes abound about such situations. One story related to the authors described a fiber project that required construction along a state right-of-way. The state regulating authority's (department of transportation, or DOT) safety rules made the use of an attenuator truck (crash truck) optional. During construction in one region, the local DOT personnel allowed the project to proceed without an attenuator truck being present. As the project moved into a neighboring region, the DOT personnel in that region would not allow construction to continue until an attenuator truck was present. The impact was a delayed project and additional cost for the truck and personnel to operate it.

A consistent and accurate inventory of broadband infrastructure is as important to bridging the digital divide as a complete record of serviceable locations (e.g., the locations of households and businesses). Historically, telecommunications companies have used an assortment of information systems – some developed in-house and some purchased – that were never designed to work together. When these systems were implemented, there was no perceived requirement for information sharing. Today telecommunications companies operate networks that have equipment from multiple vendors, lease bandwidth and antenna sites from other companies, and manage federal and state funding requirements. Mergers with, or acquisition of, other companies require the incorporation of different systems.

The provision of broadband connectivity is closely tied to geography. Location intelligence is fundamental to all communication services. A geographic information system (GIS) is a system that creates, manages, analyzes, and maps all types of data. It provides for data interoperability. GIS connects data to a map, integrating location data (where things are) with all types of descriptive information (what things are like there). This foundation provides for mapping and analysis that helps users understand patterns, relationships, and geographic context. The benefits include improved communication and efficiency as well as better management and decision making. Using the open data standards of a modern GIS promotes transparency, data sharing, and collaboration.

Dirty data and non-existent data that should have been collected (but was not) adds substantial cost to telecommunication projects. Mobile GIS workflows location-enable field activities, modernize data collection, and facilitate near real-time updates between the field and office. Authoritative geospatial data is key to support the work of broadband development and programs. Telecommunication providers and governmental organizations have a bottom-line interest in ensuring it's collection.

4.4. Financing Challenges

For many years, research has shown those that lack access to broadband Internet are directly and negatively impacted because they are unable to fully benefit from educational, economic, and healthcare resources available on the Internet and they are unable to fully participate in the political and social aspects of their community, nation, and the world. During the COVID-19 pandemic the world came to realize that access to the Internet can no longer be a benefit enjoyed only by urban and higher income populations, but it is an essential service that should be available to everyone.

Unfortunately, by their very nature, unserved and under-served areas are often rural and are expensive areas to build a network. A greenfield fiber build will often cost between $900 and $1200 per home passed, and even costlier for low density areas with costs up to $8000 per home passed. These costs have traditionally not passed the internal rate of return (IRR) tests of an operator. When building a greenfield network, fiber will likely be the best choice, particularly if in a low-density area. If cable operators build in an area adjacent to their current HFC network (aka "edge-outs"), it might behoove an operator to extend their existing HFC architecture.

As cable operators look for ways to grow subscribers, investing in under-served areas begins to be more attractive as a way to capture the pent-up demand for quality broadband. An operator will often enjoy significant service uptake in newly built areas because they have been inadequately served for so long. This helps support the business model around investing in the network build. Additionally, an all-fiber network will benefit from better economics from a total cost of ownership (TCO) point of view.

A major change in the environment for building broadband to rural areas is the availability of funding. Private investors have long been interested in building broadband to support their overall mission, and the changing environment over the past couple of years has made investment in rural broadband much more likely to pay off. Firms like Searchlight Capital [9] [10] [11] and GTCR [12] have been prominently investing in rural broadband because of this potential.

Recently available public funding has played a significant role in the decisions from private investors. It has also played a big role in decisions by some cable operators. For example, Charter Communications won $1.22B from the FCC's RDOF Auction 904 and plans to build broadband to up to one million currently unserved homes and businesses[3].

At the federal level, in the year 2020, the Coronavirus Aid, Relief, and Economic Security Act (CARES) act set aside $100M to be spent on broadband expansion and RDOF allocated up to $20.4B (to be distributed over 10 years) toward broadband expansion. In 2021, the US Congress passed the American Rescue Plan Act (ARPA), a $1.9 trillion economic stimulus program which allocates, through seven different programs, at least $20.3 billion and up to $265 billion that can be used for digital equity programs including broadband physical network buildouts. In addition to ARPA funding, it appears that another $65 billion will be made available in the infrastructure bill that is making its way through the US Congress in August of 2021 [13].

At the state level, 38 out of 50 states in the US have created funding programs specifically to support expansion of broadband service.

[3] Charter, and other Auction 904 winners, are revamping these estimates because the RDOF eligibility maps were based on incomplete data.

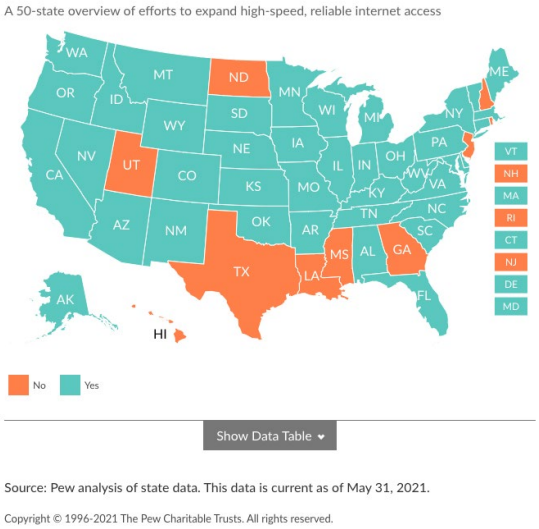

Figure 10 - US States with Broadband Funding Programs [14]

The structure and scope of these funding programs varies from state to state. The ARPA distributes much of its broadband funding directly to states and localities, so states' programs are currently undergoing changes to adapt to this influx of money. For example, the Commonwealth of Virginia's FY2022 budget initially allocated almost $60 million, but with the authorization of broadband funding from ARPA, Virginia will expand this to allocate $700 million over the next 3 years [15]. Further, many counties, towns and cities will receive ARPA funding and have the option to use that money to expand broadband infrastructure.

This influx of funding will change the way cable operators calculate the financial models for building to unserved and rural areas. In fact, these new funding options will directly impact the construction planning cycle because these funding sources impose delivery deadlines with penalties. Cable operators that develop, hire or contract expertise in broadband grant writing will have a distinct advantage over competitive providers that do not.

5. Conclusion

The utility of broadband Internet access has been studied at length and, by all measures, those that have access to broadband Internet are better off economically, educationally, socially, and health-wise. Those that do not have access to broadband Internet are disproportionately affected because they are already more likely to have lower incomes, more likely to live in rural areas that have fewer employment options, less access to basic healthcare, and access to fewer educational support resources.

Lack of broadband Internet access affects tens of millions of people in the United States, and approximately 90% of those affected live in rural areas. This is not a unique story. Rural broadband access has followed a similar storyline as rural electrification, rural telephone, and rural television. Internet access has simply failed to keep up with urban areas because Internet providers have failed to deploy newer technologies into rural areas.

Birthed in the mountains of Pennsylvania, the river towns of Oregon, and the plains of Wyoming, cable's history is rooted in rural communities. Over the last 30 years, cable has stepped up to the plate and delivered advanced services to the communities they serve. Modern-day economics has held back many cable operators from deploying their networks into rural communities.

Any incumbent network operator will be able to leverage advantages in building out rural broadband networks. They bring resources and knowledge to the challenge. Cable operators can bring this and more to the table. This is most profound when a new build area is adjacent to their current networks/footprint. Access networks (or "backhaul") can be a significant portion of both a network build and operation (if using leased fiber connections). As well, simply using existing people, processes, and resources will assist in building and running these networks.

Using a variety of new and even unconventional financial vehicles, these networks can easily be built and operated profitably. As discussed, there are a large variety of options available to enter into public-private partnerships, that not only make for good business for a cable operator, but also help to enable an essential service for these under-served communities.

Cable and Wireless Subscriber Management Convergence

A Common Approach to Identity Management

A Technical Paper prepared for SCTE by

Pablo Stalteri
Master Solution Architect
Hewlett Packard Enterprise
Mississauga ON, Canada, L4W 5G2
pablo.stalteri@hpe.com

1. Introduction

Most operators offering Cable and Wireless services have been implementing their Operations Support System (OSS) platforms using a silo approach, where different access technologies and business units resulted in the deployment of dedicated systems. Thus, to support wireline, broadband, cable TV, IPTV or wireless services, for residential or enterprise customers, multiple Billing, CRM, subscriber and identity management systems are being deployed. Furthermore, technology evolution and tactical execution methodologies when launching new services have contributed to produce different subscriber identification flows for the authentication and authorization required to access each service, as well as a plethora of subscriber data bases and data sources focused on solving the associated entitlement problem. Then the Cable and Wireless operator end up managing and maintaining multiple systems performing similar functions, with increased OPEX, offering different experience to the end customer depending on the service to be used.

In the next paragraphs we will describe the Subscriber Management Convergence solution that has been implemented in North American Triple and Quad Play operators, offering a virtualized consolidated 360-degree view of the subscriber profile for any type of access technology, type of device or type of service offered, encompassing both enterprise and residential customers, making use of legacy data sources to avoid the need of costly migrations.

2. Subscriber Management Convergence Solution

In the telecommunications market every operator tries to differentiate from competition by offering new services to their customers in the hope that they will adopt them if there is a real benefit for the subscriber and user experience is consistent with services already purchased. Most of the times, the real benefit is measured in terms of cost, and for that purpose operators try to bundle the new service with others the subscriber already has, to offer a cross-product discount, but this bundling is sometimes difficult to do from the OSS systems perspective, as there may be a subscriber database for Wireless services, another for Cable and another for Wireline services, making impossible for the operator to link all services of the subscriber during purchasing time. We have seen time and again cases where the CSP has defined an Account for Wireless services, another for Cable and another for Wireless, joining all this information together only during invoicing time, so the end customer receives only one bill. Therefor cross-product discounts are generally limited to services within the same technology: Cable services only (if you have HBO and Netflix service, then bundle package includes x% discount), or Wireless services only, etc. This silo approach ends up penalizing the customer that uses different access technologies, and so the real benefit is not materialized.

With regards to the end user experience, this one is also difficult to implement when the operator has different subscriber databases for each technology and business unit (residential, enterprise), as query entitlements to indicate if a particular service can be used by the subscriber generally

provides specific information associated to the silo that has been reached, without a full view of all services the subscriber has, and the application receiving this data differs from one another depending on the type of device the subscriber is holding. Some of these device applications require user identification and passwords to grant access, which are difficult to remember and maintain by the end user.

Some operators have tried to overcome these issues by consolidating all subscriber profile data into one big database, taking months and years to migrate data from legacy systems to the new one, which added to their OPEX and slow down the speed to which new services can be launched to the market. In these cases, changes done on legacy systems, such as Product catalogue QoS upload/download bytes, service monthly usage limit, throttling, etc, must be replicated in the centralized DB in a timely fashion to ensure consistency, adding complexity to the solution.

These challenges can be summarized as follows:

1. Integrate Subscriber's Data and Entitlements of all users, from cable, wireline and wireless into a single platform. Store identifiers available in user devices
2. Changes done on legacy systems (such as Product catalogue QoS upload/download bytes, etc) must be immediately available to external applications

Subscriber Management Convergence solution provides an answer to each of these requirements, by increasing flexibility in the creation of new services and fast integration with legacy data sources, without the need for long migrations or data consolidation implementation. The concept is based on "use the data that you already have" from legacy applications, accessing subscriber information via user equipment identifications readily available, and presenting each external application the data they need so that end subscriber always has the same user experience. The main advantages of this approach are:

- Abstracts data models from external applications, offering dedicated views to each of them
- Supports entitlement queries for all type of subscribers: cable, wireline and wireless
- Flexible business logic enabling sequential and/or parallel requests to data sources
- Easy integration with legacy data bases and platforms, with more than 100 protocols available
- No need of data consolidation or data migration
- Adaptable to Operators ecosystem: no impact on existing applications or legacy systems

The solution is based on two products that are integrated using 3GPP protocols, deployed in a virtualized environment and benefits from a micro service architecture, to pave the way to 5G implementation.

- **Data Federation** allows applications to query account, subscriber, service and device information from a set of downstream data sources, being the main one Unified Identity Repository (UIR). It federates external data sources via different protocols, to build a **consolidated XML response** and supports AuthN and AuthZ to allows the subscriber to access premium content (Entitlements)
- **UIR** provides an LDAP database which stores identification values (keys), that are used to access legacy data sources to obtain detail information

The outcome can be summarized as follows:

- Rapid adaptation to new business cases
- The data federation **abstracts query requests** so that applications do not need to care about data models and/or where data is retrieved
- Reduce implementation and maintenance costs: single platform across all access types, business units and services
- When legacy IDs are maintained, service catalogue **changes** are **reflected immediately**

3. Solution Architecture

Figure 1 shows the generic LDAP subscriber profile data model that has been implemented in several Quad Play operators using UIR.

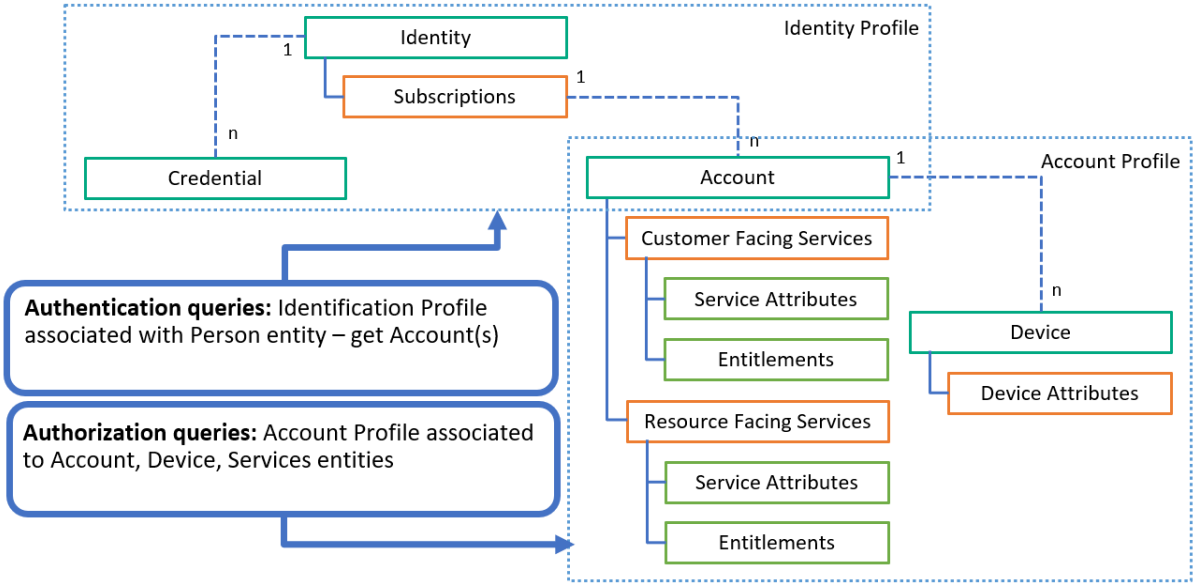

Figure 1 - UIR – Subscriber Profile Data Model

For every subscription, there is an Identity profile, storing different credentials, and an Account profile, which can be made up of multiples accounts (one for Cable, another for Wireless, another for Wireline, etc), which are keys to the corresponding legacy OSS systems the operator has. LDAP ensures the extensibility of the data model and we have found that it can adapt to the realities of any type of CSP.

The Identity profile is used in entitlement queries submitted by external applications, such as Video On Demand, wireless application or WiFi, to authenticate the physical subscriber (person) using a key that is provided by the device used. Thus, in the case of cable this can correspond to the MAC Address of the Set top box, IMSI for wireless, eSIM for Tablet, etc. In this way the subscriber does not need to memorize any userid / password to access the service: the device itself provides this key automatically when the service is selected. The result of the authentication query is the Account number.

The Account profile is accessed via the Account number previously retrieved for the authorization query, which with the input of type of service accessed and device used, allows to validate if the subscriber is entitled to use the service/device. Please note that in one account you may have multiple services (each one with several instances) and allow several types of devices/instances. Examples:

- A wireline Account may have Internet service, IPTV service, Digital TV service, Home Phone service, Home Alarm service, etc.
- A wireless Account may have Share data plan service made up of 2 smartphones (father-mother), each one with each own MSISDN, one Individual data plan service (son) with another MSISDN, etc

- Devices can be classified into access device (i.e GPON, FTTH, etc), consumer devices (set up box, smartphones, smartwatch, tablet, etc), each one with its own instance ID

The second component of the solution, Data Federation, is implemented in a layered architecture to provide flexibility in the northbound and southbound interfaces, as displayed in Figure 2. It consists of:

API Broker Layer

Logical component that hosts one or more API broker components. It provides HTTPS/REST based interfaces to which North Bound applications can authenticate, connect and query the system

Business Logic Layer

Based on API request type it triggers the flow selecting the Data Sources to consolidate the dedicated response:

1. Flow execution order in which each corresponding query needs to be executed according to business logic
2. Query in parallel and / or sequential order the different Data Sources using the appropriate protocol
3. Receive response from all Data Sources and keep them in memory
4. Compose all answers into a virtual data model to create the XML response (Payload)

Data Source Layer

Set of out of the box connectors to interface with each Southbound Data Source (ex. LDAP, JDBC, WebServices, HTTP/REST, SOAP/XML, etc) to acquire relevant information from keys retrieved from UIR and / or external data sources.

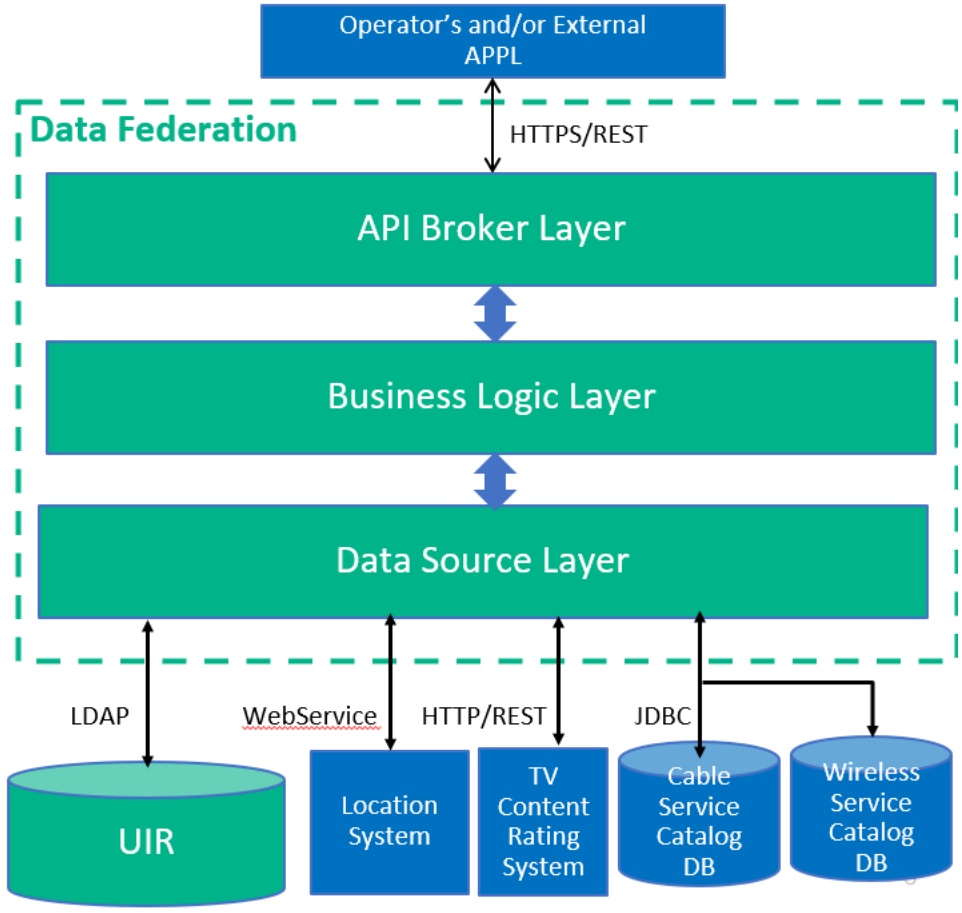

Figure 2 - Data Federation Architecture

It is important to mention that Data Federation is built using micro services technology provided by the enhanced Interactive Usage Manager (eIUM) platform. The rich set of out of the box connectors give the desired flexibility in both northbound and southbound interfaces, while its library of java classes provides the foundation for the business logic layer. Each of the layers are easily configurable, adapting to the realities of each operator in a matter of weeks. The Figure 3 presents an example of API implementation for Cable Enterprise application. Please note the sample list of external applications, some of them from the operator, some from partners (such as content partners), which make use of the authentication and authorization flows supported by the combination of Data Federation and UIR.

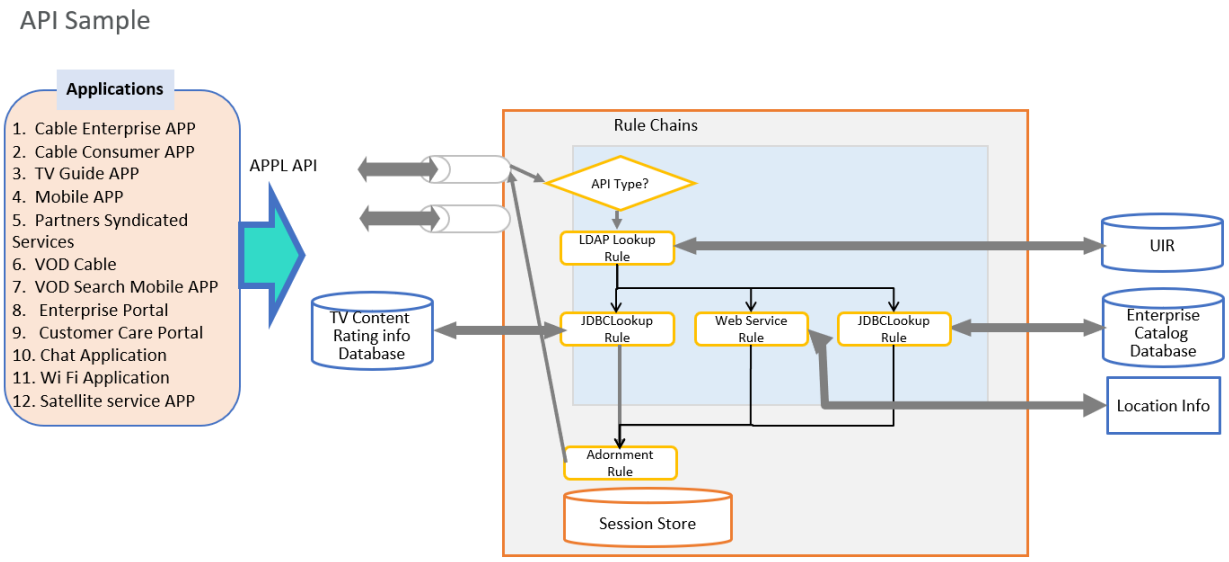

Figure 3 - Data Federation – API Sample

UIR data is populated automatically by the different legacy provisioning systems of the operator, using LDAP protocol. However, we have implemented in the Data Federation business logic layer of one CSP the ability to auto-provision new services in UIR if certain eligibility criteria are fulfilled for the same Person (Identity Profile), allowing cross-product discounts and loyalty programs. The case in question required to provision the entitlement to access for free a specific Sport channel from any wireless device if the subscriber has Service 1 (Wireless Data Plan of 10GB), Service 2 (Internet with no data limit), Account is active and residential and lives in states X,Y,Z. Please note that none of the legacy systems in the CSP were able to register this condition, as they were deployed with the typical silo approach, and only in UIR the operator was able to see for the first time all services the subscriber has purchased, and so offer a new service for free to create stickiness. This auto-provisioning is triggered by the provisioning of any Service 1, Service 2, Account update and/or location update.

4. Features

Data Federation key features are:

- Real Time Protocols for both Northbound and Southbound interface: HTTPS, REST, SOAP, JDBC, LDAP, Diameter, RADIUS client/server/proxy with advanced access control, TLS support
- Messaging format supported: XML, JSON, HTML
- Supports synchronous and asynchronous requests for both northbound and southbound interfaces
- Onboarding of Consumer Applications: Who access What attribute with What API

- OOB GUIs: Data Modelling Studio, Configuration Editor, File Service Workflow, Rule Chain Visualization, App Deployment Visualization, Operations Console, Deployment Manager, O&AM Workflow, Common Codec Framework
- NFV ready and cloud scalability: Level 3 Scale in/out
    - Dataless Micro service architecture, paving the way to 5G and Wi-Fi 6
    - VNF Manager (new component for NFV/MANO integration) and O&AM Workflow
    - EMS Management enhancement: NFV Templates and Operations Console Extensibility
    - Load Balancer for Real Time
- Management enhancement: statistics threshold with alarm, resource utilization chart, SNMP v2c and v3 support, Management HA support
- Reference Data Manager and Services enhancement: extend control for admin to manage reference data that drives business logic, advanced querying and caching

In addition, Data Federation provides optionally an Access Feature including the following two functions:

- **Access Control:**
    - Allow only **trusted clients/applications** to access UIR DF by providing mutual authentication using HTTPS Two-Way SSL
    - Authenticate and Authorize the users accessing UIR DF by checking against its LDAP database where user information, credentials and user's **access control list** (user, roles and privileges objects) data is stored
    - Provide **secure communication channel** between the clients and UIR Data Federation platform: TLS 1.2
- **Access Filtering:**
    - Ability to include service types / privileges / instructions as URL parameters, which enable a client to ask for a subset of the data that it is entitled to (e.g. {BASE_URL}/{RELATIVE_PATH_TO_ACCOUNT_VIEW}?pname=qamTV&pname=xyz)
    - Ability to include instructions, as URL parameters, which request UIR Federation to ignore one or more external data sources (e.g. {RELATIVE_PATH_TO_ACCOUNT_VIEW}?pname=qamTV&pname=xyz&exclude=LOCATION_SYSTEM&exclude=TV_RATINGS)

Access Control function:

- Allows only **trusted clients/applications** to access UIR DF by providing mutual authentication using HTTPS Two-Way SSL
- Authenticates and Authorizes the users accessing UIR DF by checking against its LDAP database where user information, credentials and user's **access control list** (user, roles and privileges objects) data is stored

- Provides **secure communication channel** between the clients and UIR Data Federation platform: TLS 1.2

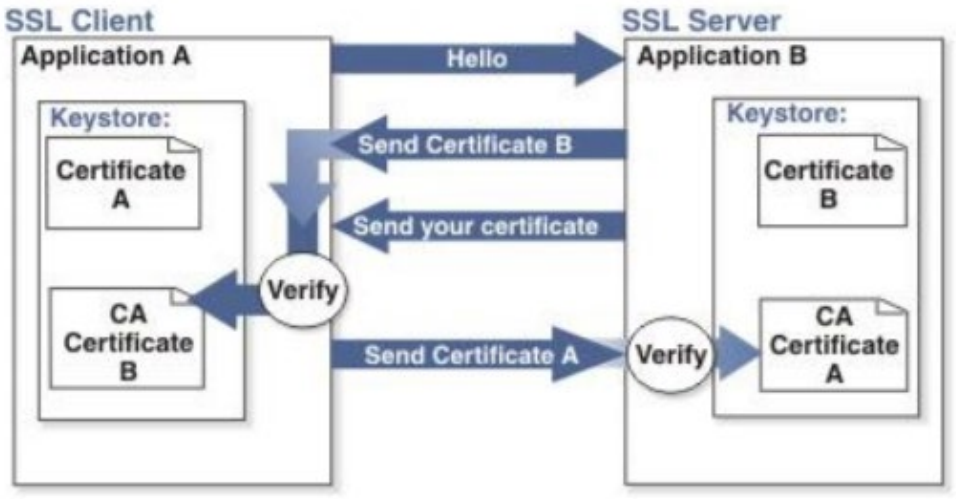

Figure 4 - Data Federation ACL Feature

Data Federation internally will leverage UIR LDAP Database where the Access Control List for a User is stored. The Access Control list would consist of User Role and Its Privileges and other artifacts. Data Federation will provide only those information elements to a user allowed by Access Control List, using the data model shown in Figure 5.
Data Access is enabled for the Account View to:

- Access to services, by type.
- Access to Service attributes, by name
- Access to Devices, by type.
- Access to Device attributes, by name
- Access to Person Role Map. By Id

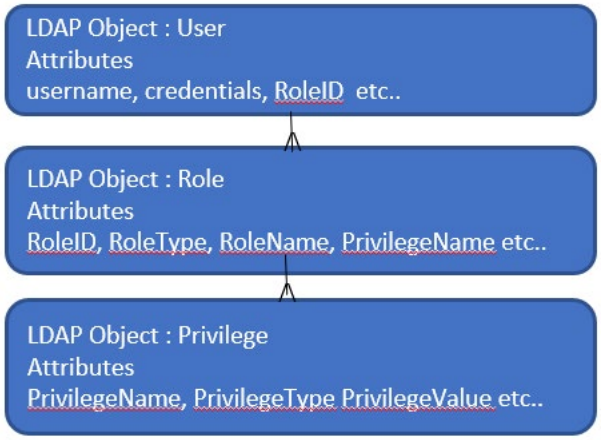

Figure 5 - Data Federation Access Control Data Model

5. Sample Deployment

This section describes a production implementation of the solution in one Quad Play operator in North America with 3 Million Subscribers. Here different provisioning, CRM and billing systems are implemented, for Cable, Wireless and Wireline access technologies, with dedicated flows for residential and enterprise customers. The main goal was to provide to any external application a consolidated view of the subscriber profile, accessed using different keys. Depending on the entitlement query type, defined by the external APP, a different view is presented.

Table 1 - Performance Metrics: Operator with 3M Subscribers - Payload

View	Average TPS	Max TPS	Average Response Time (ms)	Payload size
Account Lite View	5	80	75	Average – 405KB
Account View	19	300	200	Max- 3.3MB
Person View	7	20	10	Average – 1KB Max- 30KB
Mobile App View	4	73	188	Average – 2.5KB Max- 8KB
TV Guide View	9	290	200	Average – 18KB Max- 224KB
VOD Auth View	24	47	140	Average – 3.5KB Max- 17KB
Wifi View	2	26	2	Average – 1.3KB Max- 5KB
TOTAL	**70**	**500**		

As indicated in Table 1, two Account views were implemented, as there are APP that only require a “Lite” version of the account, indicating list of accounts associated to a subscriber ID, while the other version (called “Account View” in the table) lists all accounts, for each account all services and devices, for each service all instances, for each device all instances, etc. Therefor you can see that the payload for this full view is quite high, up to 3.3MB, and its data is retrieved in an average of 200 milliseconds. On the other side of the spectrum, you have the WiFi Application, that is just concerned about QoS associated to the subscriber, and so payload is just 5KB maximum. The platform was sized for 500 TPS queries, measured from the northbound interface, and each query can trigger multiple queries to the UIR, which in turn, according to the business logic of the entitlement query selected by the APP, can query one or multiple external data sources, some of them using JDBC protocol (i.e Oracle DBs), or webservices, for location information.

Figure 6 displays UIR LDAP reads and writes over time, where the number of TPS for reads is greater than the northbound entitlement requests, as the first query to LDAP is associated to Authentication, and the second and onwards with Authorization to retrieve details of the account, service and device.
Provisioning requests, coming from legacy systems, are classified into Inserts (ADD), Updates (MODIFY) and Delete (DEL).

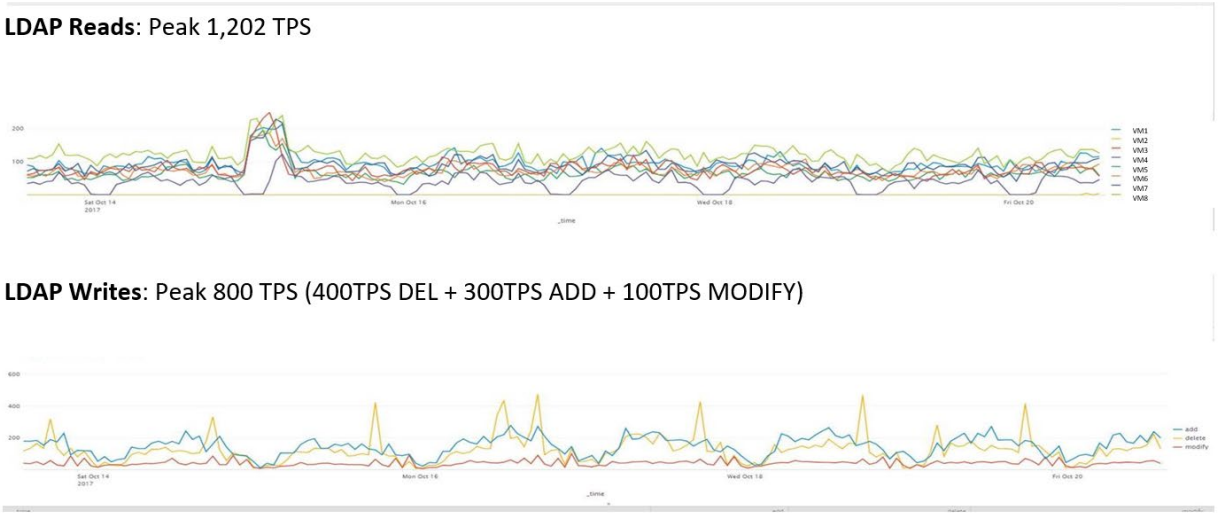

Figure 6. Performance Metrics: Operator with 3M Subscribers – LDAP

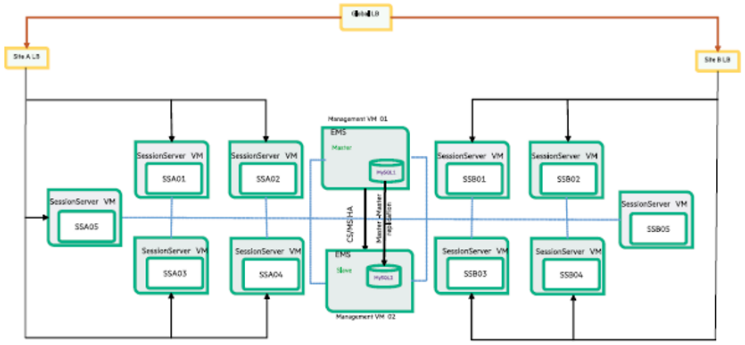
Finally, Figure 7 details the production deployment in two identical sites, where each site has five Virtual Machines with Data Federation, each one supporting up to 100 TPS query. The EMS component in each site is made up of an Operations Console, a web-based application designed for operators who need to monitor and manage micro services deployment on a daily basis. Among its capabilities, it can give you an at-a-glance, global view of the health of your deployment, view and monitor all the processes, as well as alarms and problems with your processes. You can also use it to create process groups for easier monitoring and management, and view history charts to show process activity over time. Operators can also perform routine

management operations, for example, starting and stopping processes and groups. The Operations Console also provides role-based security to limit operations capabilities for different users.

- Two identical sites
- Each site with 5 Session Servers VMs and 1 EMS VM, supporting up to 500TPS query
- Each VM with one Session Server containing the 3 layers: API Broker, Business Logic and Data Source Layer

	vCPU	vRAM (GB)	Disk (GB)
VM supporting 100 TPS	8	16	200
OS	RHEL 7.5 (x86-64)		
Hypervisor	VMWare		



• Multi site deployment is achieved with built in HA, that is, there is no need for third party clustering software (i.e. Red Hat Clustering)

• EMS: Single Config Server (CS) and Management Server (MS) run on HA mode with a replicated master-master MySQL database

Figure 7. Sample Production Deployment: Operator with 3M Subscribers

High availability is achieved by having each real time component (called Session Server, in eIUM) in active-active mode in both sites.

6. Conclusion

This paper described the HPE Subscriber Management Convergence solution, which leverages existing legacy data sources and streamlines the identity management process to produce a consistent customer experience across different access technologies and services involved. The solution introduces a centralized Subscriber Profile and Identity Repository along with Data Federation capabilities, so that when there is a need to check the authorization of a customer accessing a specific service from a particular device and location, this entitlement information can be retrieved from a single point. In addition, the authentication flow required to access the service will use the data already provided by the device making the request (i.e. IMSI in smartphone, eSIM in tablet, etc), without the need for the end customer to introduce user id and password whenever possible. These two improvements result in a better customer satisfaction and fast time to market to launch new services.

1. Introduction

Upstream broadband usage and network capacity have been increasing sharply in recent years, particularly under global pandemic lockdowns since March 2020 [NCTA/covid-19-overview]. The spread of COVID-19 around the entire world has placed upstream traffic growth on an extremely irregular pattern with fluctuations, posing great challenges to use conventional methods such as Auto-Regressive Integrated Moving Average (ARIMA) and other classical statical models to ensure accurate forecasts because those classical methods have been proven to be weak and inadequate for modeling non-stationary traffic flows.

In practical forecasting applications, the use of different modeling methods has become a popular research by many scholars [Chen, 2011; He and Zeng, 2021]. However, with the rapid development of cable companies' network, network traffic data scale is increasingly important in modern network traffic world. Just combining forecasts from different models with weighs allocated does not satisfy the need to model big traffic flow data more effectively.

In this study, we propose a clustering-based two-stage approach to build network traffic forecasting models using ARIMA, eXtreme Gradient Boosting (XGBoost) and Long Short-term Memory (LSTM) that includes data preprocessing and model building, as shown in Fig. 1.

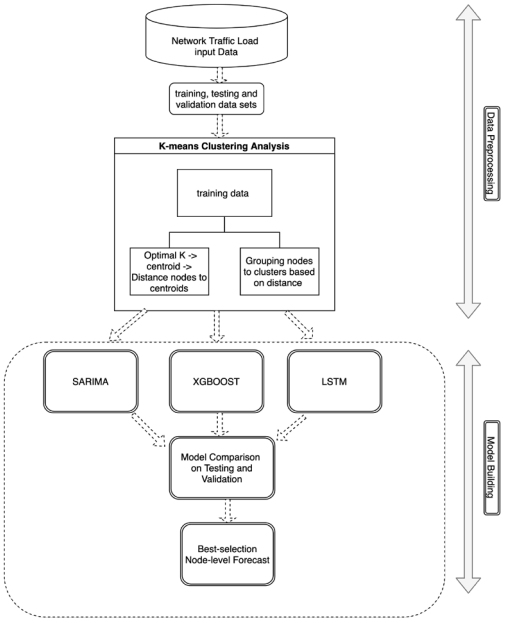

Figure 1 - The flowchart of the proposed best-selection forecasting

In the data preprocessing stage, using the training subset, we apply the K-means clustering method to find the K cluster centers to group a collection of network nodes into homogenous subsets based on intra-cluster similarity in traffic data [Vujicic et al., 2006]. K-means clustering is one of the most-commonly used data clustering algorithms, originally from signal processing. It aims to partition n observations into k clusters in which each observation belongs to the cluster with nearest mean (cluster centers or cluster centroid), serving as a prototype of the cluster [Anderberg, 1973, Kaufman and Rousseeuw, 1990]. A key assumption of applying forecasting models on clusters is the similarity of behavior patterns within a cluster. This algorithm is helpful to obtain computational efficiency when it comes to big data time series forecasting.

The paper is structured as follows: Section 2 explores the related studies and research gaps in existing literatures. Section 3 describes the methodology. Section 4 discusses the experimental results and Section 5 concludes the paper.

2. Background

Network traffic-related data are collected as time-series, hence time series analysis and forecasting techniques such as ARIMA modelling, XGBoost and LSTM can be employed for the traffic forecasting. In this section, we first review three modeling techniques applied: ARIMA, XGBoost and the deep learning-based Long Short-Term Memory (LSTM) model, then followed by review of related work.

2.1. Learning methods

2.1.1. ARIMA

The ARIMA model was pioneered by Box and Jenkins [Pankratz, 2008]. It is one of the most classical statistical models in time series prediction. This model can be presented as a linear regression function, in which lags and the lagged forecast errors are used for prediction. A standard ARIMA model can be expressed by three terms: autoregressive order (AR, p), moving average part (MA, q), and difference order (differencing, d). A seasonal ARIMA is an expanded version of a standard ARIMA model with information extracted from the seasonal parts that cannot be processed by the standard ARIMA model. To build a seasonal ARIMA model, finding the non-seasonal part (p, d, q) of ARIMA is the first step, and tuning the seasonality components (P, D, Q) is the second. Diagnostic checking of stationary and residual uncorrelation is vital for a good fit model. A simple ARIMA structure is illustrated in Figure 2 as follows:

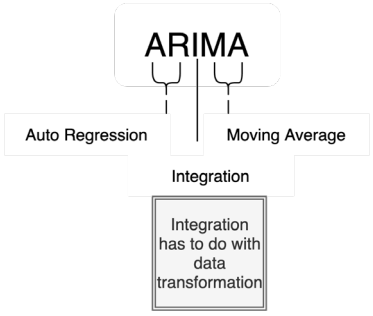

Figure 2 – ARIMA Structure

2.1.2. XGBoost

Extreme Gradient Boosting as one of the boosting algorithms in ensemble learning was first proposed by Tianqi Chen in 2015 and Carlos Guestrin in 2011. It is proved in the literature [Chen and Guestrin, 2016] that the XBGoost model has the characteristics of being efficient and scalable [Saeed, 2016]. The basic idea of the Boosting algorithm is to combine many weak learners to form a strong model that can predict accurately. Extreme gradient lifting tree [Wang et al., 2019] essentially is an integrated learning algorithm in which the number of decision tree keeps being added with each iteration till a strong classifier is found [Fabricius, 2000]. The XGBoost model has proved to have many advantages in model prediction, such as the lack of a need to preprocess the data, a fast operation speed, complete feature extraction, a good fitting effect and high prediction accuracy [Alim et al., 2020]. A simple XGBoost structure is illustrated in Figure 3 as follows:

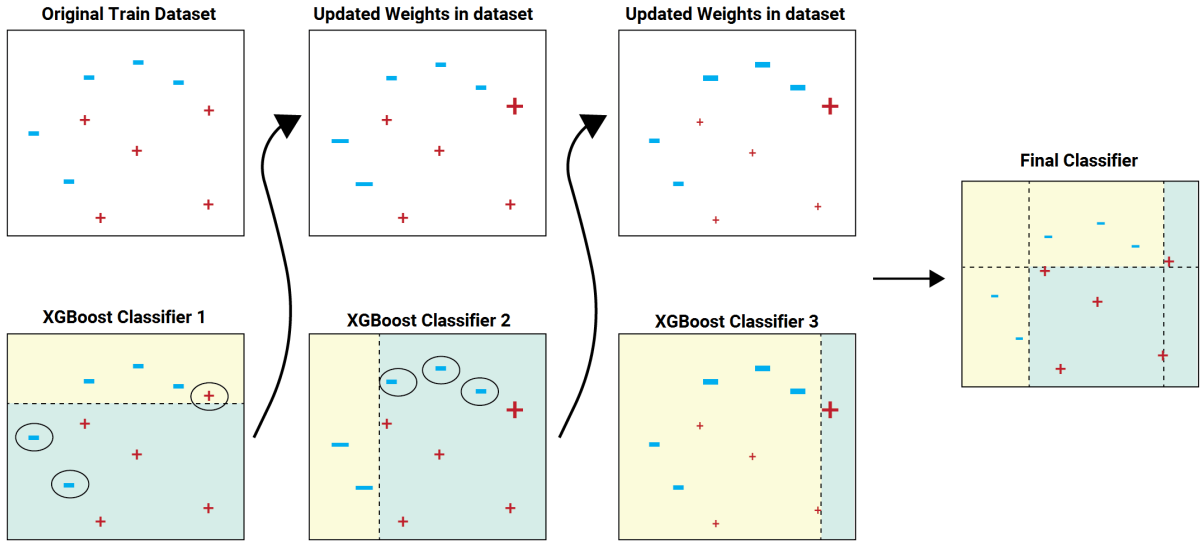

Figure 3 - XGBoost structure (https://blog.quantinsti.com/xgboost-python/)

2.1.3. LSTM

Long short-term memory networks (LSTM), proposed by (Hochreiter & Schmidhuber, 1997) is a special kind of recurrent neural network (RNN). Different from other RNN models that could easily suffer from the problems of getting small gradient loss (i.e., less than one), and multiplication of those gradient losses would vanish during training process, LSTM overcomes these problems by memorizing the prior stages' internal trend through a few different gates (i.e., input gate, forget gate, control gate and output gate) and optionally let data pass through or dispose of based on a sigmoidal neural network layer to predict future patterns. A simple LSTM network is illustrated in Figure 4 as follows:

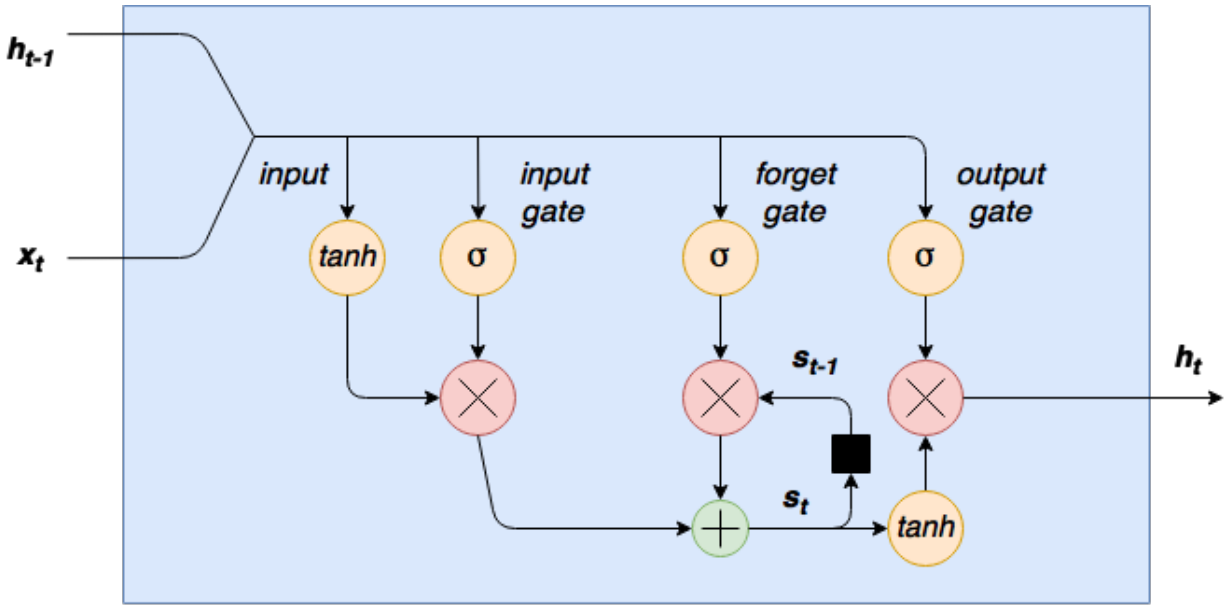

Figure 4 - LSTM structure (https://adventuresinmachinelearning.com/keras-lstm-tutorial/)

2.2. Related work

There are several works that have focused on comparing the performance of different forecasting techniques. He and Zeng (2021) have put forward a forecasting method of XGBoost-LSTM combination model based on a weighting method in forecasting product sales. The two years' sales time series data are modeled by using XGBoost and LSTM neural network models, respectively. They prove that the performance of using XGBoost-LSTM model to deal with time series is much higher than that of the original XGBoost single model, which maximizes the advantages of the two prediction models. Chen (2011) proposed to use the combination models that combine the linear model and the nonlinear model to predict tourism demand time series data. The results showed that the combination is superior to the individual models for the test cases of tourism demand time series. Alim et al. (2020) compared the performance of the XGBoost model a seasonal ARIMA model for human brucellosis in mainland China and used them to make short-term predictions. The results showed that the prediction accuracy of the XGBoost model was much better than that of the ARIMA model.

2.3. Research gap

From the above-mentioned research works, we have identified a couple of major research gaps. To the best of our knowledge, first major research gap is that there are very few research papers that have employed a clustering approach to perform classification of large quantities of network traffic data, grid search parameters or train model within a cluster. Clustering-based modeling approach can be very effective in terms of reducing computational cost for big data but still obtain decent prediction accuracy. Researchers in one study prove training the classical SARIMA models on clusters of public safety network users identified by the K-means algorithms performs well compared to the prediction based on the overall aggregate traffic [Vujicic et al., 2006]. With the data we have, at an individual node level, time series are very volatile, include a high amount of noise, and are unevenly and nonlinearly affected by different effects. However, most nodes in this study follow similar pattern and many series move in tandem, suggesting possibility to group those nodes into homogeneous clusters for hyperparameter search and model training.

Secondly, different from many relevant research studies recommending using combination of forecasting model: selecting appropriate weights to weight and average the results obtained from several different model, we propose to build different models separately and let three models compete to always select the best individual-level forecast in practical forecasting application. This will provide more reliable traffic prediction to the network management and the network capacity planning.

3. Methodology

11,738 network nodes' weekly upstream traffic load time series were selected into input for this study to test the performance of three models: ARIMA, XGBoost and LSTM. After replacing missing values with linear interpolation for each time series, 174 weekly data polls between 2018 and May 2021 were collected as the input data. During model development, 70% of the input data were used to train models, 20% is used as the testing data set, and the remaining 10% is used as the verification data set.

3.1. Data description and Pre-processing

The upstream traffic dataset used in the study was obtained from a cable company's network. It contains information regarding *site id*, *node description*, and *traffic loads* in weekly intervals, gathered from 11, 738 nodes. *Site id* and *node description* were concatenated to a string to label each network node in this study.

The significant problem forecasting is facing is the presence of missing values and outlier values in the observed historical traffic load data. In the dataset we collected, there exist missing values in weekly timestamp and traffic loads due to occurrences of data collection failures. Therefore, those missing values were linear interpolated based on historical trend. Linear interpolation is illustrated in Figure 5. In Figure 5, the left plot shows raw data weekly trend for one sample node but with missing polls highlighted with yellow arrows. After interpolation, those missing polls were filled with imputed values which can be seen on the right plot.

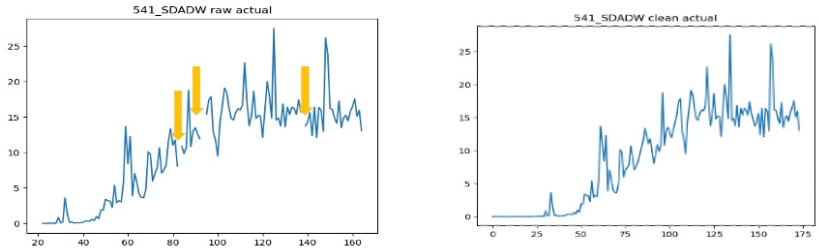

Figure 5 - Missing value linear interpolation

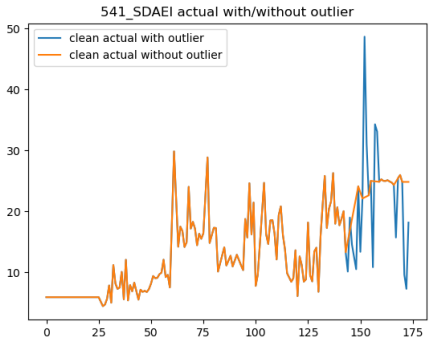

Figure 6 - Data with/without outliers

Outliers in time series can be grouped into two types: outliers affecting a single observation and outliers affecting a single observation and subsequent observations, which is true in our input data. In this study, we use a combination of statistical method to detect those anomalies and then apply linear interpolation based on time to replace them with imputed values. The effect is depicted in Figure 6.

3.2. Forecasting model set-up

Three different models based on the same input are proposed and fitted to predict future traffic loads. 70%-20%-10% of data partition is used for training, testing and validation purposes. The performance of all three models is presented based on the criteria of Mean Absolute Percentage Error (MAPE) as shown below:

$$M = \frac{1}{n}\sum_{t=1}^{n}\left|\frac{A_t - F_t}{A_t}\right| \quad (1)$$

where A_t is the actual value, F_t is the forecast value mean, n is the number of times the summation iteration happens. M stands for mean absolute percentage error used to evaluate prediction accuracy and is expressed in percentage. In this study, a value lower than 10 is said to be a fit model. The evaluation of all three models is done by preparing a model on a training dataset and by making predictions on a test dataset and a validation dataset. Training, test and validation MAPEs are calculated to measure model performance.

Before training each model, K-means clustering method was used to partition 11,738 nodes into 4 optimal clusters. In this study, we use Euclidean as a distance metric because we have normalized each time series to have the same length for all nodes selected after preprocessing. the node count distribution by cluster is summarized as follows: Cluster 0: 10,082 nodes; Cluster 1: 392 nodes; Cluster 2: 71 nodes; Cluster 3: 1,193 nodes. To intuitively observe the data characteristics of each cluster's traffic load, the sum of traffic loads by each cluster is plotted in the following figure:

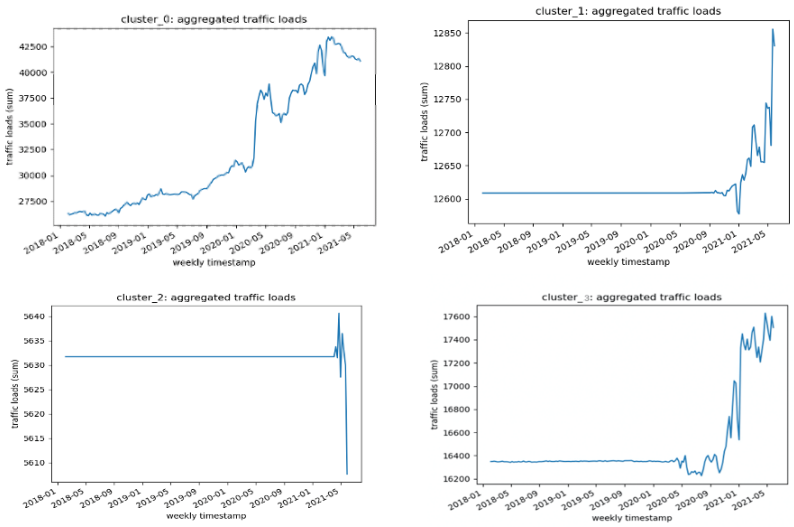

Figure 7 - Upstream Traffic Loads Trend by Cluster

As we can see form Figure 7, Cluster 0 shows much more volatilities and fluctuations since the start of COVID-19 compared to three other clusters. Clusters 1 and 3 experience more seasonal effect compounded with COVID-19 since late 2020. Cluster 2 has a relatively more peaceful trend compared to three others.

After K-means clustering, the main steps followed for the ARIMA model fitting as follows:

- Grid search was used to automatically discover the optimal order of non-seasonal and seasonable parameters at a cluster level. The combination of (p, d, q) that returns the lowest Akaike Information Criterion (AIC) and Bayesian Information Criterion (BIC) values are selected as the most optimal parameters for each cluster.
- Dataset is split into 70%, 20%, 10% training, test and validation sets, respectively.
- Stationarity of the series are checked using the Adfuller function with the P-value along with the autocorrelation function (ACF) and the partial autocorrelation (PACF) plots. Training data are transformed based on the stationarity check.
- SARIMAX models are trained and obtained to make estimation on fresh test data.
- To check the goodness of fit of the ARIMA model, MAPE values for both training dataset and testing data set are calculated.

After K-means clustering, the main steps followed for the XGBoost model fitting as follows:

- To obtain the best performance, the grid search algorithm is used to optimize the parameters: min_child_weight, gamma, subsample, colsample_bytree, max_depth and learning rate at a cluster level.
- Dataset is split into 70%, 20%, 10% training, test and validation sets, respectively.
- XBGoost models are trained and obtained to make estimation on fresh test data.
- To check the goodness of fit of the XGBoost model, MAPE values for both training dataset and testing data set are calculated.

After K-means clustering, the main steps followed for the LSTM model fitting as follows:

- Scale data using MinMaxScaler to speed up the learning process and help model.

- Hyperparameter such as number of layers, layer depths, activation functions, dropout coefficients are repeatedly tuned at a cluster. Manual tuning of LSTM hyperparameter is used instead of using automated tuning package such as SMAC3 to avoid common failure to find well-defined global minima with automated packages.
- Dataset is split into 70%, 20%, 10% training, test and validation sets, respectively.
- LSTM models are trained and obtained to make estimation on fresh test data. During the model training, the validation loss was monitored by early stopping call back function to halt the training if there is an increment observed in loss values. The number of epochs for the training was tested with different values.
- To check the goodness of fit of the LSTM model, MAPE values for both training dataset and testing data set are calculated.

4. Results and Discussion

In order to see the prediction effect of all three selected models, training, test and validation MAPEs are matched on 11,542 nodes for comparison. All three groups of MAPEs were classified into four groups: <= 5%, between 6 and 10%, between 11% and 15% and greater than 16%. Number of nodes were summarized for each MAPE group.

Tables 1 and 2 respectively present the comparison of the training and test prediction accuracy for three selected models.

Table 1 - Training MAPE by Models

Model	Training MAPE				Total
MAPE Range	<= 5%	>=6% & <= 10%	>=11% & <= 15%	>=16%	
SARIMA	1,360	2,828	2,059	5,295	11,542 nodes
XGBoost	11,333	55	20	134	11,542 nodes
LSTM	3,573	2,979	2,909	2,081	11,542 nodes

From Table 1, for the training set, the XGBoost model has the highest number of nodes with the MAPE value less than or equal to 10% than two other models.

Table 2 - Test MAPE by Models

Model	Test MAPE				Total
MAPE Range	<= 5%	>=6% & <= 10%	>=11% & <= 15%	>=16%	
SARIMA	982	746	1,175	8,639	11,542 nodes
XGBoost	2,244	2,228	2,870	4,200	11,542 nodes
LSTM	2,299	3,996	2,753	2,494	11,542 nodes

In Table 2, for the test set, the LSTM model has a higher number of nodes with the MAPE value less than or equal to 10% than two other models. Majority of the nodes with the LSTM showed the MAPE value less

than 15%, which shows the potential benefit of using the LSTM to predict network traffic. The ARIMA has the lowest number of nodes with a good fit, which might indicate the weakness of using conventional statistical models to predict for non-linear data.

To further evaluate model performance of all three selected models, we chose nodes with both training MAPE and test MAPE less than 10% to compare training MAPEs with test MAPEs. If the test MAPE is lower than training MAPE, we consider that node's forecast is a good fit. Vice versa, if the test MAPE is higher than training MAPE, we label that mode as overfitting training data but does not perform well on the evaluation data. Node counts for good fit and overfitting by different models are summarized in Table 3:

Table 3 - Node Counts with <= 10% MAPE by Models

Model	Node counts with good fit (Mape <= 10%)	Node counts with overfit (Mape <= 10%)
SARIMA	956	586
XGBoost	1,195	3,248
LSTM	2,129	2,278

As shown in Table 3, it is clearer that LSTM overall has less overfitting issues in network traffic forecasting than two other models. It further indicates that LSTM in this paper has higher fitness and predictive performance in network traffic prediction compared to ARIMA and XGBoost. XGBoost model has the most overfitting issues in this study.

To map model performance for the validation dataset, a comparison of 596 nodes validation MAPEs is shown in Table 4.

Table 4 - Node Counts MAPE by Models

Model	Node counts with Mape <= 10%)	Node counts with Mape >10%)
SARIMA	101	495
XGBoost	139	457
LSTM	346	250

Table 4 shows that LSTM has the most of number of nodes with validation MAPE less than 10%, followed by XGBoost and SARIMA.

According to the overall results, the performances of the ARIMA models were the lowest and the LSTM models performed the best. LSTM models produced the best results.

5. Conclusion

The author proposed to use K-means analysis to partition network traffic nodes to different cluster and apply seasonal ARIMA model (SARIMA), XGBoost model, and the Long Short-Term Memory (LSTM) model on clusters to reduce computational cost and predict effectively.

Three selected models are compared with respect to performance. According to the comparison, the performance of the LSTM network is better than ARIMA and XGB model. XBGoost model shows a reasonable performance but showed serious overfitting issues. Moreover, the classical data analysis model ARIMA has more obvious forecast error, which shows the disadvantage of classical parameterized approach faced with tremendous traffic data.

As for future work, the SARIMA model could be improved using one-step ahead forecast method. At the same time, LSTM models can also be improved by hyperparameter tuning such as the number of layers, learning rate, optimizers, etc. Overfitting with the XGBoost model could be avoided using the delta difference between time interval (i.e., lag term of the time series) as the input and let the input lag term predict the univariable time series. L1 and L2 regularisation can be introduced to the LSTM and XGBoost to address overfitting. Cross-validation can be tried with all three selected models to obtain more reliable forecasting models.

1. Introduction

Now that Low Latency DOCSIS (LLD) gear is certified and available, operators are beginning lab testing and field trials, and are working out how to deploy and configure the equipment to provide the best performance for their users. This paper provides guidance and best practices for network operators in the configuration and management of Low Latency DOCSIS services. It is essentially a cheat-sheet on the different provisioning modes available in LLD as well as a run-down of the various control knobs available to the operator - what they do, how they interact with one another, and what effect they have on the service characteristics. It introduces each of the features that make up LLD and lays out a template of recommended configuration settings, the reasons behind those choices, and how those choices might evolve over time. It provides MSOs with a step-by-step approach to turning on each of the LLD features to ultimately ensure that customers can enjoy the benefits of the technology. In addition, this paper discusses some of the end-to-end aspects of delivering on the low latency promise, such as DSCP and ECN traffic marking, and performance monitoring.

2. Brief overview of Pre-LLD latency management features

Applications today that use a transport protocol like TCP seek out as much bandwidth as possible and use a "congestion control" algorithm (most commonly "Cubic") to adjust to the available bandwidth at the bottleneck link through the network. Typically, this will be the last mile link—the DOCSIS link for cable customers—where the bandwidth available for each application can vary rapidly as the activity of all the devices in the household varies. The behavior of the Cubic congestion control algorithm is that it increases its sending rate (or, more precisely, the number of bytes in flight) until it experiences packet loss (generally due to the bottleneck link buffer overrunning), then it pauses sending for a short time (allowing the bottleneck link buffer to drain a bit) before ramping up its sending rate again. The result typically is that the bottleneck link buffer is kept nearly full whenever a TCP file transfer is occurring. This in turn results in latency (and latency variation) for all of the applications that are sharing that bottleneck link.

There are two features available in DOCSIS equipment that pre-date LLD, and that can help manage the latency caused by congestion controlled traffic. For reference, these two features are briefly described here.

2.1. Buffer Control

Past implementations of cable modems had upstream buffer sizes that were found to be quite large, much larger than they needed to be to ensure good TCP throughput. CMTSs similarly were built with over-sized downstream buffers. In many cases, these buffers could hold multiple seconds worth of packets. This phenomenon was referred to as "bufferbloat", and was not unique to DOCSIS equipment. The result was that applications would see highly variable latency, with huge latency spikes occurring whenever a sufficiently large TCP file transfer occurred.

DOCSIS 3.0/3.1/4.0 specifications allow a cable operator to tune the transmit buffer size for cable modems and CMTSs in their networks. The feature controls upstream buffering in the cable modem, and downstream buffering in the CMTS for each Service Flow.

The Buffer Control parameters limit the maximum queue depth of a Service Flow. The Service Flow buffer holds the packets that are enqueued for transmission and this parameter sets an upper limit on the amount of data that can be enqueued for transmission. By providing the ability to control per-Service Flow buffers, the Buffer Control parameters provide a means of balancing throughput and latency in a standardized and configurable manner.

In order to accommodate implementation differences (e.g., varying amounts of memory available for buffering) and to allow an optimized partitioning of buffering memory based on the number of active Service Flows, the main Buffer Control parameter for a Service Flow is referred to as Target Buffer (TLV [24/25].35.2), which the operator can use to set the desired buffer size in bytes. The implementation (CM or CMTS) is required to set the actual buffer as close to the target value as is reasonably possible.

In cases where more precise control of the buffer size is desired, there are two additional parameters: Minimum Buffer (TLV [24/25].35.1) and Maximum Buffer (TLV [24/25].35.3), both also specified in bytes. The implementation is required to reject the configuration if it cannot comply with the buffer size limits configured by these two parameters.

Alternatively, an operator can configure a Default Upstream Target Buffer Configuration (TLV 68) parameter that applies to all upstream Service Flows in the absence of the Buffer Control setting for the Service Flow. This parameter is only applicable to the upstream buffers in the CM. It is specified in milliseconds, and the CM is required to size each relevant Service Flow buffer by calculating the appropriate buffer size based on the Service Flow's Maximum Sustained Traffic Rate value.

CableLabs previously published guidelines on configuration of the Buffer Control feature [Buffer Control]. Here we provide some updated recommendations on setting buffer sizes.

In order to ensure that a single TCP connection can fully utilize the SF rate, the SF buffer size needs to be greater than or equal to the base RTT (i.e. the round-trip-time in absence of queuing delay) of the TCP connection, yet to minimize the latency and latency variation caused by TCP traffic, the buffer should be kept as small as possible. Thus setting the buffer size involves a tradeoff between ensuring good TCP throughput for long distance file transfers, and good quality of experience for latency sensitive applications.

Since many TCP connections are between a client and a local CDN node (perhaps 10-20 ms base RTT), and in many areas RTTs greater than 50 ms are fairly rare, it is recommended that operators set the buffer size to 50 ms, as a balance between good TCP performance for most file transfers and good QoE for latency sensitive applications. But, this value is region dependent. In regions where typical RTTs are significantly shorter (or longer) than 50 ms, a smaller (or larger) value can be used.

Table 1 – Recommended Buffer Control Parameters

Option 1: Per SF configuration		
Parameter	**Upstream Settings**	**Downstream Settings**
Buffer Control: Target Buffer	TLV 24.35.2 = 50 ms * MSR / 8 *MSR = Maximum Sustained Rate for the Service Flow*	TLV 25.35.2 = 50 ms * MSR / 8
Option 2: Default per CM or CMTS		
Parameter	**Upstream Settings**	**Downstream Settings**
Default Target Buffer Configuration	TLV 68 = 50 ms	CMTS vendor proprietary = 50 ms

2.1. AQM

While the Buffer Control feature allows the operator to set the buffer size to a more appropriate level, Active Queue Management (AQM) can work to reduce the buffering latency even further without sacrificing TCP throughput. AQM algorithms monitor the queue depth (or queue delay) in the buffer, and automatically make intelligent decisions to drop packets at appropriate intervals in order to send a congestion signal to the traffic senders (e.g. TCP senders) that results in the queuing delay being kept relatively low, while allowing the link to be fully utilized. Thus, a network device can support enough buffering so that it can absorb bursts of packets on the ingress but doesn't let a standing queue build up.

The DOCSIS 3.1 specification requires cable modems to implement a particular AQM algorithm called DOCSIS-PIE that is described in [RFC8034]. The DOCSIS 3.1 specification also requires CMTS equipment to implement an AQM algorithm, although it leaves the choice of that algorithm up to the implementer. Active Queue Management in DOCSIS is further discussed in [DOCSIS AQM].

By default, AQM is turned on for all Service Flows. It is a best practice to ensure that the CM Upstream AQM disable (TLV 76) in the configuration file is set to Enable, or absent (the default is enable). The Service Flows also have AQM encodings within the Service Flow set of parameters. It is also recommended to ensure that the SF AQM Disable (TLV [24/25].40.1) in the configuration file is set to Enable, or absent (the default is enable) for both upstream and downstream Service Flows. Also it is recommended to leave the Classic AQM Latency Target (TLV [24/25].40.2) at its default value of 10ms, unless experimentation is done to validate another setting.

3. Brief Overview of LLD Features

The LLD functionalities that were recently added to the DOCSIS 3.1 specifications recognize that even AQM isn’t enough to provide a consistent low latency experience for latency sensitive applications like multiplayer online gaming and cloud gaming. For these applications, the bursts of packets that AQM occasionally allows to queue up in the bottleneck link buffer, are disruptive to the Quality of Experience for the user.

The key insights that led to the development of LLD were: a) while the majority of application traffic uses traditional TCP and thus causes latency variation and packet loss, other applications (in particular many latency and loss sensitive ones) aren’t causing these degradations, but nonetheless suffer as a result of them; and b) there are TCP congestion control algorithms that don’t cause these degradations, but they are nearly impossible to deploy in the internet because they don’t work well with existing bottleneck link technology.

LLD seeks to address these two insights by allowing applications that don’t cause latency variation & loss to avoid being subjected to those degradations, and by introducing support for a new class of congestion control algorithm that can adjust to the available capacity of the bottleneck link without causing those degradations in the first place.

Further details can be found in [SCTE LLD], but the core of LLD consists of support for two queues in each direction, a “Classic” queue for traditional congestion-controlled traffic, and a “Low Latency” queue for traffic that doesn’t cause latency, latency variation and loss. The Classic queue has a comparatively deep buffer (along with AQM) that allows traditional congestion controllers to achieve high throughput while keeping latency reasonably under control. The Low Latency queue has a very shallow buffer along with some other features that enable “well behaved” applications to achieve ultra-low delay.

The key to LLD is that it doesn't differentiate between these two categories of traffic based on any kind of subjective judgement as to the importance of one application vs. another, or even the relative latency/loss sensitivity of one vs. another. Instead, the distinction is made based on the application sender's behavior: does it send data in a smooth and/or sparse manner that doesn't materially contribute to queuing delay and packet loss, or does it send data in such a way that it over-drives the link, causing a queue to build up, and backs off only when it senses severe congestion. A related aspect of LLD is that it doesn't prefer one type of traffic over the other. Instead the goal is to allow both types to coexist and share the link capacity in a fair manner, and to allow the application to make the decision as to how it wishes to behave, and thus which queue it should utilize.

DOCSIS equipment, going all the way back to DOCSIS 1.1 gear, supports the concept of Service Flows, which are uni-directional logical pipes set up on the DOCSIS link between the CM and CMTS. Each Service Flow is described by Quality of Service parameters that govern aspects like data rate, and packet classifiers can be set up to direct packets into the appropriate Service Flows. Low Latency DOCSIS uses this existing Service Flow (SF) functionality to create a logical pipe (SF) for the Classic queue and another for the Low Latency queue, and uses the existing classifier mechanism to direct packets into the appropriate SF. LLD then adds some new functionality that ties this pair of Service Flows together, referred to as a Low Latency Aggregate Service Flow (LL ASF), as well as some additional features that enable the LL ASF and its constituent LL SF and Classic SF to provide great performance for all of the different applications that make use of it.

One of those additional features is support for a new congestion control mechanism that allows applications to dynamically adjust their sending rate in order to fully utilize the available capacity in a fair manner, but without causing queuing delay or loss. This mechanism is referred to as the "Low Latency, Low Loss, Scalable Throughput" (L4S) architecture, and it involves the bottleneck link providing real-time congestion signals to applications via a single bit in the header of each IP packet. This "Explicit Congestion Notification" mechanism allows the sender to react to the initial onset of congestion, without triggering packet drops, and thus send at a data rate that keeps the congestion level (i.e. queuing delay) to an absolute minimum.

4. Low Latency Service Configuration

Low Latency DOCSIS service requires configuration by the operator in order for the feature to be enabled. Some of the service parameters require direct configuration by the operator, and others are specified to have useful default values, and may only require modification in certain exceptional conditions. This section describes the service parameters (configuration file TLVs) and the effect that those parameters have on the low latency service offering.

4.1. Service Rate Configuration

In traditional (single upstream/downstream SF) DOCSIS configurations, the tier of service is defined via three Service Flow rate shaping parameters (TLVs) in each direction: Maximum Sustained Traffic Rate (TLV [24/25].8), Maximum Traffic Burst (TLV [24/25].9), and Peak Traffic Rate (TLV [24/25].27). With an LLD configuration, the same three rate shaping parameters are used, however they are configured on the ASF (TLV [70/71]) rather than the Service Flows underneath the ASF. The CMTS scheduler will rate shape the aggregate of traffic in both the LL SF and the Classic SF to meet the limits set by those TLVs.

The individual Service Flow parameters for rate shaping are not expected to be configured in an LLD configuration, and equipment may or may not support configurations in which those TLVs are set.

4.2. Low Latency Classifiers

4.2.1. Packet Classifiers in LLD ASFs

Classification of traffic into the two SFs under the LL ASF is configurable by the operator using traditional DOCSIS classifiers. The DOCSIS spec does not allow definition of classifiers that direct traffic to an ASF, but rather only to a SF.

In cases where an operator would have traditionally defined a single SF in each direction, classifiers were not needed since all traffic would by default use the single (primary) SF. When that configuration is updated to LLD, Classifiers will be needed to direct a subset of traffic to the LL SF, with the Classic SF serving as the primary SF.

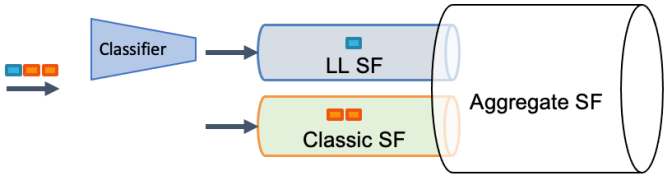

Figure 1 – Classifier Setup for US and DS Service Flows

In cases where an operator would have traditionally defined multiple SFs in each direction to carry traffic for different services (e.g. Community WiFi or voice signaling traffic), when that configuration is updated to support LLD (by replacing one or more of those SFs with ASFs), classifiers need to be defined - with appropriate Classifier Rule Priorities - such that the correct subset of traffic will be directed to the appropriate LL and Classic SFs.

The LLD-capable CMTS provides a feature referred to as "Classifier Merge" that can assist in the creation of these classifiers in certain cases. This feature is described in Section 5.5 of this paper.

4.2.2. Marking of Non-Queue-Building and L4S Traffic

There are two categories of traffic that are compatible with the LL SF: sparse "Non-Queue-Building" traffic (such as VoIP and traditional online games), and capacity-seeking (i.e. high data rate) L4S traffic (such as cloud gaming and video conferencing). These two categories use two different fields in the IP header to identify their traffic. Non-Queue-Building (NQB) traffic uses the 6-bit Diffserv field, and L4S traffic uses the 2-bit Explicit Congestion Notification (ECN) field. These two fields together form an octet that was formerly referred to as the Type of Service (ToS) octet, with the DS field being the upper 6 bits, and the ECN field being the lower 2 bits.

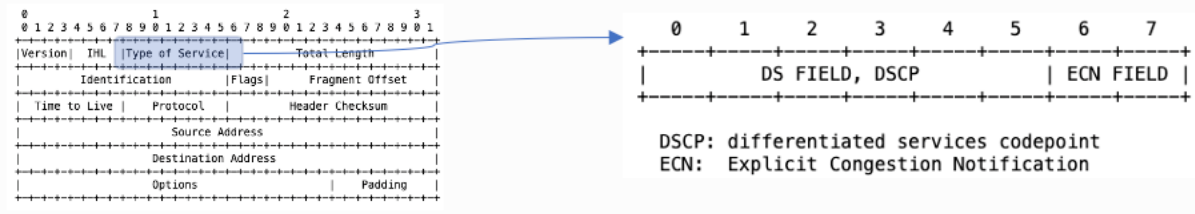

Figure 2 – The differentiated Services and ECN fields in the IP Header

4.2.2.1. NQB and DSCP

The DS field encodes a value between 0 and 63, where each specific value is known as a Diffserv Code Point (DSCP). There are several DSCPs that are used by applications today to mark sparse traffic that is generally compatible with the LL SF. It is expected that operators will wish to classify all such traffic into the upstream LL SF.

While multiple DSCPs are in use by applications in the home network, there is no requirement or expectation that an operator will carry these DSCPs into their core network. Rather it is expected that operators will select a single DSCP to be used as the NQB codepoint within their core network. Thus the configuration in the upstream is likely to include classification on multiple DSCPs and use of the DOCSIS ToS Overwrite feature to ensure that all LL traffic gets a consistent DSCP in the core network, just as the operator likely will want to configure DOCSIS ToS Overwrite on the Classic SF to ensure that all classic traffic gets a consistent default DSCP (e.g. 0) in the core network.

In terms of DSCPs that are compatible with LL, the Expedited Forwarding (EF) DSCP (46) is defined by the IETF to denote voice traffic, and is used by default by some VoIP applications, as well as for the audio stream of some video conferencing applications. Further, Windows 10 allows applications to mark "AudioVideo" or "ExcellentEffort" traffic as CS5 (40). Several multiplayer online games utilize this value for their game state update packets. Windows 10 also allows "Voice" or "Control" traffic to be marked as CS7 (56). (Note: other operating systems do not limit the choices of DSCP that applications can choose). The IETF is in the process of finalizing the assignment of an "NQB" DSCP (45) specifically for applications to denote Non-Queue-Building behavior (see [IETF NQB]). Additionally, the IETF recommends that network operators re-mark upstream NQB packets to the DSCP value 5 prior to an interconnection with another network, and that they re-mark downstream NQB packets to DSCP 45 prior to a user's home network. The rationale for this recommendation can be found in [IETF NQB].

As a result, it is recommended that upstream traffic marked by the source as CS7(56), EF(46), NQB(45), or CS5(40) be classified into the LL SF. It is also recommended that the LL SF be configured (via DOCSIS ToS Overwrite) to change the LL DSCP to the value 5, and the Classic SF be configured to change the DSCP on classic traffic to the value 0. The four recommended DSCPs for upstream classification (56,46,45,40) can be selected using two DOCSIS ToS Range and Mask classifiers, one that matches values 45 & 46 (0xB4 B8 FC), and one that matches 40 & 56 (0x28 28 2F). These classifier encodings are shown in the example in Section 4.2.3.

For downstream traffic, it is recommended that operators classify the NQB (5) DSCP into the LL SF, and use the DOCSIS ToS Overwrite feature to change it to 45. Note that the value 5 above is only a recommendation, an operator could choose a different value for use in their core network (even the value 45 if that works well). If a different value is chosen, it would be necessary to either re-mark NQB to 5 at interconnection, or negotiate with the interconnection partner on the use of the different value for NQB traffic.

4.2.2.2. L4S and ECN

L4S compliant senders mark their packets with the value ECT1 (0b01) in the ECN field. Additionally, it is possible that ECN traffic gets re-marked to CE (0b11) by a network element. As a result, it is recommended that operators classify both of these ECN values to the LL SF. These can be selected via a single DOCSIS ToS Range and Mask Classifier (0x01 01 01).

4.2.3. Recommendations for LL classifiers

Table 2 – Low Latency Classifiers

Classifier	Upstream	Downstream
IPv4 Classifier for DSCP 45 & 46	22.9.1 = 0xB4 B8 FC	23.9.1 = 0xB4 B8 FC
IPv4 Classifier for DSCP 40 & 56	22.9.1 = 0x28 28 2F	23.9.1 = 0x28 28 2F
IPv4 Classifier for ECN (ECT1 & CE)	22.9.1 = 0x01 01 01	23.9.1 = 0x01 01 01
IPv6 Classifier for DSCP 45 & 46	22.12.1 = 0xB4 B8 FC	23.12.1 = 0xB4 B8 FC
IPv6 Classifier for DSCP 40 & 56	22.12.1 = 0x28 28 2F	23.12.1 = 0x28 28 2F
IPv6 Classifier for ECN (ECT1 & CE)	22.12.1 = 0x01 01 01	23.12.1 = 0x01 01 01

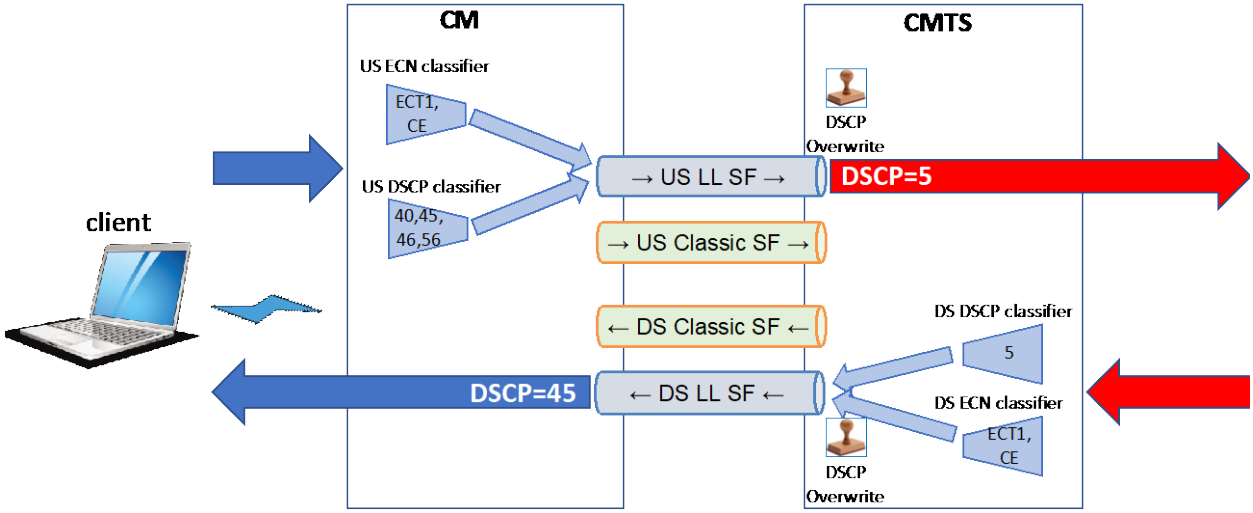

Figure 3 – Classifier Usage on CM & CMTS

4.2.4. DSCP Overwrite

Operators typically wish to manage the DSCP values that are utilized within the core network, and commonly mark all customer Internet traffic with a single DSCP (usually either CS0(0) or CS1(8)) so that it can be identified and handled appropriately in core network routers. This DSCP marking is usually set as packets ingress into the core network, both at interconnections (via router configuration), and at the access network (via the DOCSIS ToS Overwrite feature).

To support low latency end-to-end (including when one or both endpoints are outside the MSO's network) it is recommended that the operator use two DSCP values in their core network, one for default Internet traffic and the other for NQB Internet traffic. An operator can choose any pair of DSCPs that they wish, but as discussed in Section 4.2.2.1, the value 5 is recommended by IETF for use across interconnections. Here we will assume that the operator uses 0 for default Internet traffic and 5 for NQB Internet traffic in their core network.

For upstream SF configuration, it is recommended to use the ToS Overwrite feature to mark all traffic on the LL SF as NQB(5) and to mark all traffic on the Classic SF as CS0(0). Note that this will mark L4S traffic as NQB(5) as well, which is unintended. An alternative, in the case that the operator controls the home gateway software, is to selectively re-mark the four DSCPs 40,45,46,56 to 5 in the home gateway, and then just use DSCP 5 and ECN classifiers for the upstream LL SF in DOCSIS.

Current Wi-Fi gear does not yet support the same low latency features as DOCSIS (i.e. L4S, NQB isolation, Queue Protection). However, low latency traffic can be given a separate queue from classic traffic via the use of the WMM QoS Video Access Category. By default, most consumer Wi-Fi gear will map DSCPs in the range 32-47 to the Video Access Category. For upstream traffic, three of the four DSCP values that are recommended for low latency treatment (40,45,46) already get mapped into the Video Access Category by default, and the fourth DSCP (56) gets mapped into the Voice Access Category. It is recommended that operators mark downstream NQB traffic with the NQB(45) DSCP so that it is mapped to the Video Access Category by default in current Wi-Fi gear, and so that it can get full NQB treatment in future Wi-Fi gear that supports all of the features defined for the NQB PHB. Note that this will mark L4S traffic as NQB(45) as well, which is unintended. An alternative is to use selective re-marking in a router within the MSO core network (possibly even the CMTS router functionality) to change DSCP 5 to 45.

To summarize, the following DOCSIS ToS Overwrite settings are recommended.

Table 3 – DSCP TOS Overwrite Settings

Service Flow	Overwrite Setting	TLV
Upstream LL SF	set DSCP= 5 & don't modify ECN	24.23 = 0x03 14
Upstream Classic SF	set DSCP= 0 & don't modify ECN	24.23 = 0x03 00
Downstream LL SF	set DSCP= 45 & don't modify ECN	25.23 = 0x03 B4
Downstream Classic SF	set DSCP= 0 & don't modify ECN	25.23 = 0x03 00

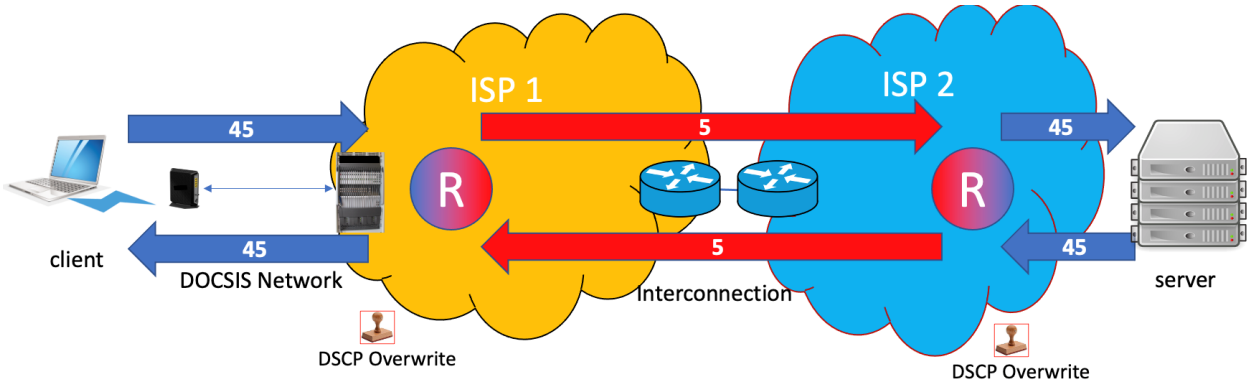

Figure 4 – NQB DSCP changes through the network

In the cases where the DOCSIS ToS Overwrite feature is used, it is noted above that this feature will overwrite the DSCP on L4S traffic as well. The implication of this is that in current Wi-Fi gear, the L4S traffic will be sent in the Video Access Category, which will give it higher priority across the Wi-Fi link than classic traffic by default. This may or may not be desirable. The IETF recommends that WiFi gear

be configured such that the Video Access Category is given equal priority to the Best Effort access category, by adjusting the "EDCA" parameters for AC_VI to match those for AC_BE.

4.3. Queue Protection

LLD supports a Queue Protection (QP) function that monitors traffic classified into the LL SF in order to ensure that those traffic flows are compatible with the low latency queue. The QP function identifies flows that are misbehaving (i.e. causing queue build-up) and redirects the packets of those flows into the Classic SF.

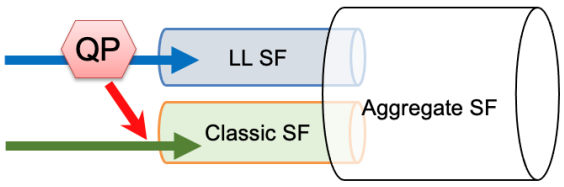

Figure 5 – Queue Protection

4.3.1. Algorithm Details

The three core concepts to understand about the queue protection function are:

1. What is a "microflow" in the eyes of the QP function?
2. What is the "congestion rate" of a microflow?
3. How does the QP decide whether to re-direct (sanction) packets?

The QP function defines a "microflow" as a stream of packets that share a common "flow ID" composed of elements of the packet header. The details of this functionality are described in Annex P.3 of [DOCSISv3.1 MULPI], but it can be summarized by the following. Implementations utilize the "5-tuple" of source IP address, destination IP address, IP Protocol (e.g. udp or tcp), and then the source port and destination port (in the case of TCP/UDP/UDP-Lite/SCTP/DCCP) or the Security Parameters Index (in the case of IPsec). In cases of un-encrypted tunnels (e.g. v4-in-v4, v4-in-v6, v6-in-v4, v6-in-v6, and GRE) implementations will parse into the inner header to find the appropriate fields. For protocols that lack a layer-4 header with meaningful flow identifiers (e.g. ICMP or IGMP), implementations will just use the 3-tuple of source-IP, dest-ip & protocol. Note that an **encrypted tunnel** (e.g. a VPN), obscures the microflows inside the tunnel, and so appears to the QP function as a single microflow.

As each packet enters the QP function, the algorithm calculates the packet's flow ID, updates the "queuing score" for that microflow, and then decides whether to put the packet in the low latency queue or the classic queue.

The queuing score for a microflow originates from a concept referred to as the "congestion rate" of the microflow. As a packet enters the QP function, the algorithm estimates how much queuing delay this packet would experience if it were to be enqueued in the low latency queue. That queue delay estimate is then used to select a "weight" for that packet between 0 and 1, using the ramp function shown in Figure 6 below.

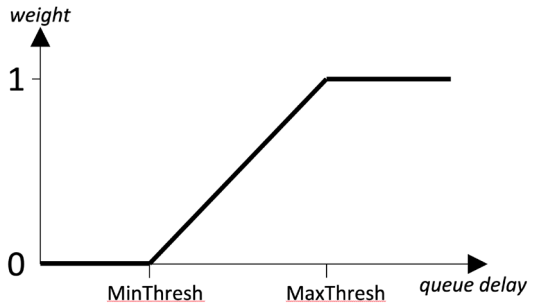

Figure 6 – Queue Protection Congestion Weight Function

This packet's size in bytes, times this weight value, is referred to as the "congestion bytes" for this packet. For example, if the packet's queue delay estimate is greater than MaxThresh, then all of the bytes of this packet are considered congestion bytes. Or, if the queue delay estimate is less than MinThresh, then this packet has zero congestion bytes. Finally, if the queue delay estimate is somewhere in between MinThresh and MaxThresh, then some fraction of the bytes of the packet are considered congestion bytes. The "congestion rate" for a microflow is then a measure of how quickly its congestion bytes are arriving. This is clearly a function of how bursty the microflow is (i.e. how much queue delay is it causing on its own) and any queue delay caused by other microflows.

The QP function mathematically 'filters' the arriving congestion bytes for a microflow through something that resembles a token bucket filter in order to generate the queuing score for that specific packet. In other words, each microflow is allowed to send at a certain congestion rate (default 4 Mbps), and any congestion bytes that arrive in excess of the allowed congestion rate 'queue up' virtually and form the basis for the queuing score. In fact the queuing score is simply the calculated time it will take for any queued-up congestion bytes (including the newly arrived congestion bytes for this packet) to drain out of this virtual queue.

The decision as to whether to re-direct the packet to the classic SF is made based on the current queuing score and the current queue delay estimate taken together. If the product of these two values (both are in units of time) exceeds the product of the two QP parameters: QPLatencyThreshold (default is equal to MaxThresh) and QPQueuingScoreThreshold (default 4 ms), and the current queue delay is greater than the QPLatencyThreshold, the packet will be re-directed. The significance of these two criteria are as follows. The 'product' criteria allows each flow to "burst" above the allowed congestion rate a little bit, but, if the queue delay grows, the amount that a flow is allowed to burst diminishes, thus causing the algorithm to more strictly enforce that allowed congestion rate. The queue delay criteria ensures that a packet arriving to a nearly empty queue won't be re-directed, even if it has a high queuing score.

This all may seem like a lot of state for the algorithm to track for the dozens or even hundreds of microflows that could exist at any point in time. But, the algorithm actually only needs to hold on to state for the microflows that currently have a queuing score. As soon as that queuing score expires (drains out), the algorithm forgets about the microflow.

Of note is the fact that the weight value used to calculate the congestion bytes for a packet is identical to the CE-marking probability used in the Immediate AQM algorithm described in the next section. This was not done simply for convenience or to reduce processing load. The result of using the same ramp function for both purposes is that the rate of CE-marked data arriving at the microflow receiver is a close approximation to the congestion rate calculated internally by the Queue Protection algorithm. As the next section describes, a responsive microflow will monitor the rate of CE-marked data arriving, and

automatically adjust its sending rate in order to (in effect) keep the congestion rate low, thus ensuring that its packets remain in the low latency SF and are not re-directed to the classic SF.

4.3.2. Configuration Parameters

The behavior of the QP function is affected by six configurable parameters:

- MinThresh – the queue delay threshold below which a packet's bytes are not considered to be congestion bytes. This threshold is identical to the MinThresh used for IAQM explicit congestion notification marking. See the IAQM section of this paper for a discussion of how this value is configured and its default value.
- MaxThresh (TLV [24/25].40.3) – the queue delay threshold above which all of a packet's bytes are considered to be congestion bytes. This threshold is identical to the MaxThresh used for IAQM explicit congestion notification marking. See the IAQM section of this paper for a discussion of the default value.
- Queue Protection Enable (TLV [70/71].42.7) – a Boolean value that can be used to disable the Queue Protection function for an ASF. The default is true (enabled).
- Drain Rate Exponent (TLV [70/71].42.10) – the "drain rate" (aka "allowed congestion rate") sets the congestion rate allowance for microflows. Microflows that maintain a congestion rate that is less than this value will never have packets sanctioned. Microflows that exceed this congestion rate can experience sanctioning. This parameter is expressed as a power-of-two exponent, which allows the divide operation to be implemented as a simple bit-shift. The default value is currently 19, which corresponds to 2^{19} Bytes per second, or 4.2 Mbps. The reason for this choice of default value is that, in steady-state operation, L4S flows are expected to aim for a maximum of 2 CE marks every 15ms. Assuming 1500 byte MTU-sized packets, this equates to a maximum congestion rate of 1.6 Mbps. The exponent value 18 (2.1 Mbps) may be sufficient to allow well behaved L4S flows to avoid sanctioning, but the value 19 gives a bit more cushion. As L4S congestion control designs evolve, it may be worthwhile to experiment with the value of this parameter. Additionally, for ASF configurations where the Aggregate Maximum Sustained Traffic Rate (AMSR) value is less than 4.2 Mbps / scheduling_weight (4.66 Mbps using the default scheduling weight – scheduling weight is discussed in Section 4.6), this default value will be too high to trigger any packet sanctioning. In these scenarios, it will be necessary to configure the Drain Rate Exponent to a lower value if Queue Protection functionality is desired.
- QPLatencyThreshold (TLV [70/71].42.8) – the queue delay threshold below which QP sanctioning is suppressed, regardless of the queue score for the microflow. This value is also multiplied with the QPQueueingScoreThreshold to form the threshold for packet sanctioning described above. The default value of QPLatencyThreshold is equal to MaxThresh. Setting this to a lower value may be beneficial to better protect low latency traffic from an unresponsive microflow flooding the LL SF.
- QPQueuingScoreThreshold (TLV [70/71].42.9) – the nominal queuing score threshold for packet sanctioning. This parameter provides a congestion burst allowance for each microflow. Setting a larger value will allow microflows to cause larger bursts of queuing delay without being sanctioned, and setting a lower value will enforce the allowed congestion rate more strictly. As described above, the queue delay of a packet is multiplied by the microflow's queuing score, and this product is compared against the product of QPLatencyThreshold and QPQueuingScoreThreshold. The default value is 4ms.

4.3.3. Implications for applications

So, what does this all mean to an application or microflow?

Since the congestion rate of a microflow is always less than or equal to its total data rate, any microflow that maintains an **instantaneous** data rate (i.e. packet size divided by packet interarrival time) that is less than the Drain Rate will **never** have its packets re-directed to the classic queue. Conversely, any microflow that bursts (or continuously sends) at a rate greater than the Drain Rate, could be subject to having its packets re-directed, depending on how much queue delay it and the other flows sharing the low latency queue are creating.

Any microflow that supports L4S ECN congestion signaling can (and should be), in effect, monitoring its congestion rate and using closed-loop feedback to adjust its sending rate to avoid QP re-direction.

4.4. IAQM & Coupled AQM

The Low Latency SF supports an Active Queue Management function which performs Explicit Congestion Notification marking of packets in accordance with the L4S Architecture. Packets that pass the QP function (and thus are enqueued into the LL SF queue) and are marked by the sender as L4S ECN Capable Transport (ECT1) can potentially be marked with a Congestion Experienced (CE) mark by the LL AQM function. The LL AQM function takes no action on packets that are not marked by the sender as ECT1.

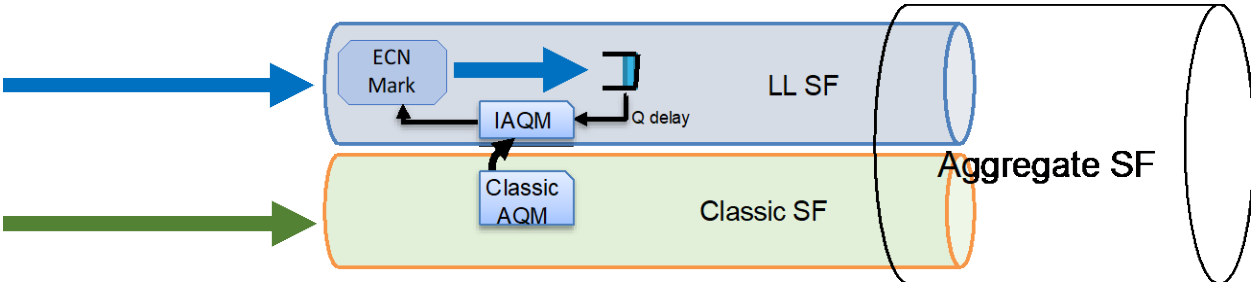

Figure 7 – IAQM in Low Latency Service Flow

4.4.1. Algorithm Details

The decision to CE mark a packet is driven by a coupling between two independent AQM functions, the "Immediate AQM" (IAQM) function and the Classic queue AQM function. The IAQM function uses the estimated queue delay of the packet to calculate a marking probability (probNative), the value of which is identical to the weight value used in QP.

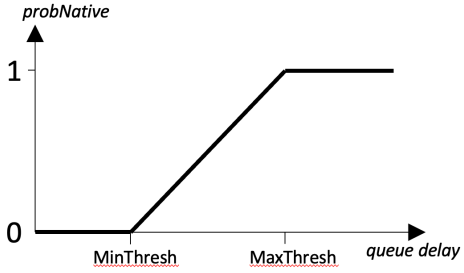

Figure 8 – IAQM Calculation of probNative

The two thresholds, MinThresh and MaxThresh, are actually configured by setting MaxThresh and the "range" of the ramp function (i.e. the difference between MaxThresh and MinThresh), where the range of the ramp function is represented by the base-2 log of the range in nanoseconds. This allows implementations to calculate probNative (and QP weight) using a simple bit-shift instead of a divide.

The Classic AQM function generates a separate probability value (drop_prob) as described in the next section. The LL AQM function calculates a CE-marking probability (probL) for the arrived packet using these two probabilities and a configurable coupling factor.

$$probL = \max\left(\text{probNative}, \min\left(1, \text{coupling\_factor} * \text{sqrt}\left(\text{drop\_prob}\right)\right)\right)$$

The purpose of this calculation, and of the LL AQM algorithm in general, is to send congestion signals to L4S capable transport protocols so that they can modulate their sending rates and bytes-in-flight to maintain both low queuing delay and a fair allocation of the link bandwidth.

When the drop_prob value is zero (i.e. there is very little traffic or queue build-up in the classic queue), probL is simply equal to probNative, and thus the LL AQM function sends congestion signals based on the instantaneous queue delay in the LL queue. By using low thresholds for the probNative ramp function, the AQM enables L4S senders to maintain low queuing delay.

When a queue forms in the Classic SF (e.g. due to classic congestion controlled traffic such as TCP cubic) the Classic AQM function will calculate a drop_prob that is appropriate for classic flows, and this value then dominates the probL equation and drives the CE-marking decisions. The result is that congestion in the Classic SF queue induces higher CE-marking in the LL SF queue, causing the L4S flows to slow down and yield capacity. The goal of this function is to balance the congestion signals for Classic flows and L4S flows such that all flows achieve approximately equal throughput.

4.4.2. Configuration Parameters

The LL AQM function is controlled by four configurable parameters:

- MaxThresh (TLV [24/25].40.4) – the queue delay above which the LL AQM would always trigger a CE-mark. The default is 1 ms.
- Range Exponent of Ramp Function (TLV [24/25].40.5) – the queue delay difference between the MinThresh value (below which the IAQM component of the LL AQM would not trigger a CE-mark) and the MaxThresh value, expressed as the base-2 log of the range in nanoseconds. The default value is 19, which equates to 524 μs.
- Coupling_factor (TLV [70/71].42.5) – the weight used to couple congestion signals from the Classic SF to the LL SF, expressed in units of tenths. Setting this to a higher value will result in classic congestion controlled flows getting greater throughput than L4S flows. Setting this to a lower value will result in L4S flows getting greater throughput than classic flows. Setting the value to 0 disables coupling. The default value is 2.0, which aims to achieve approximate fairness between classic and L4S flows in a range of conditions (see the Scheduling Weight section for further details).
- SF AQM Disable (TLV [24/25].40.1) – when set to True, disables CE-marking of packets by the LL AQM function. The default is false.

When the IAQM MinThresh value derived from the configurable parameters above equates to a value that is less than 4000 bytes divided by the AMSR, implementations will adjust the MinThresh and MaxThresh (leaving the range as configured) to ensure that MinThresh is equal to 4000 bytes divided by AMSR.

When using the default values of MaxThresh and Range Exponent, this occurs whenever the AMSR is less than ~67 Mbps.

4.5. Classic AQM

The Classic SF supports an Active Queue Management (AQM) algorithm that sends congestion signals to flows that utilize the classic SF. For cable modems, the required algorithm is DOCSIS-PIE [RFC8034], for CMTS/CCAP equipment, the choice of Classic AQM algorithm is left to the vendor. In DOCSIS-PIE, packet drops are used as congestion signals, regardless of whether the sender marks its packets as ECN capable.

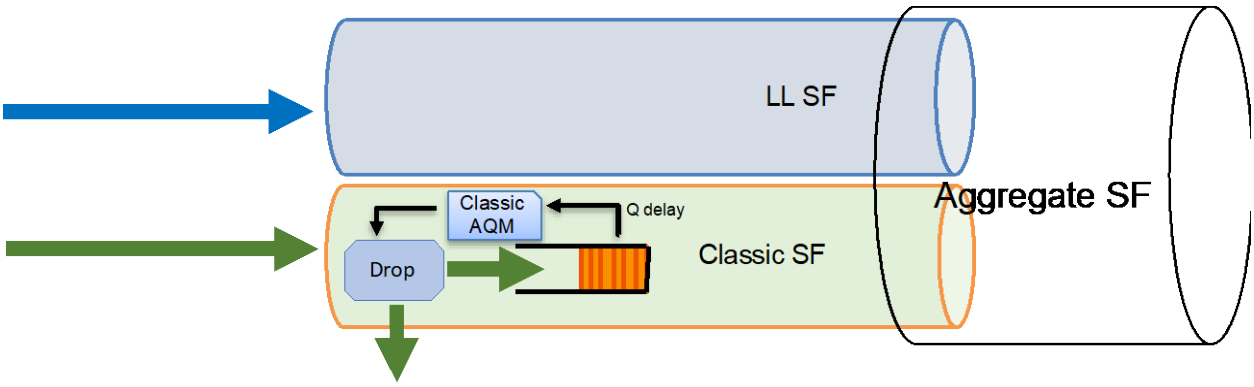

Figure 9 – DOCSIS PIE AQM in Classic Service Flow

The Classic AQM algorithm is controlled by two configurable parameters:

- Classic AQM Latency Target (TLV [24/25].40.2) – the average queue delay that the AQM algorithm is targeting. When the actual queue delay is less than the target, the AQM algorithm will reduce its drop probability, thus allowing classic congestion-controlled senders to increase their sending rate or bytes-in-flight. When the actual queue delay is greater than the target, the AQM algorithm will increase its drop probability, triggering classic senders to reduce their sending rate or bytes-in-flight, thus reducing queue delay. This value should be set to approximately one half of the expected base RTT (i.e. RTT in the absence of queue delay) that the majority of classic flows experience. The default for cable modems is 10ms. The default for CMTS/CCAP equipment is vendor-defined.
- SF AQM Disable (TLV [24/25].40.1) – when set to True, disables the Classic AQM function. The default is false.

4.6. Scheduling Weight

The two constituent SFs in the LL ASF compete for access to the bandwidth provided by the ASF rate shaper implemented in the CMTS. The CMTS scheduler is responsible for enforcing a configurable scheduling weight between the two SFs, both for downstream transmissions and for grants provided in the upstream. The scheduling weight is configured (TLV [70/71].42.6) as a value W between 1 and 255, where the LL SF is given W/256 share, and the Classic SF is given (1-W)/256 share of the bandwidth. The default value for W is 230, which equates to a scheduling weight of ~90% for the LL SF and ~10% for the Classic SF.

At first, it may seem that this parameter sets a hard partition in the capacity available to the two constituent SFs, and that the default value of (90/10) for LL vs Classic would result in LL traffic getting significantly greater throughput than Classic traffic (nine times as much!). Also, it may seem like a 50/50 ratio would be a more fair allocation. But this is not the case. The scheduling weight favors the LL SF, but is counter-balanced by the coupling mechanism described in Section 4.4 to enable per-flow fairness for all of the flows, both Classic and L4S. More detail on the coupled AQM mechanism and weighted scheduling can be found in [IETF dual-queue].

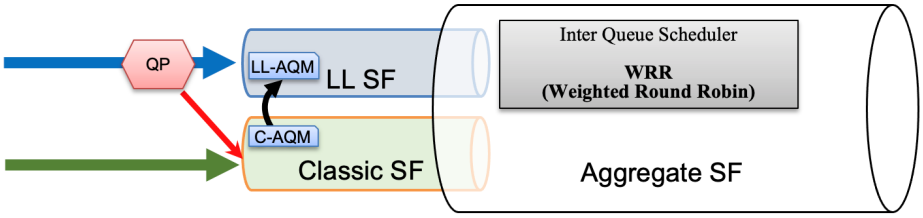

Figure 10 – WRR Scheduler

Without the coupling mechanism (e.g. if the operator disables coupling by setting Coupling Factor to 0), an operator wishing to provide "fair" allocation of bandwidth to flows utilizing the two SFs would need to predict the number of flows of each type that would likely be present, and set the weight accordingly. In essence, they would be forced to decide what fraction of the AMSR should be reserved for the LL SF vs the Classic SF.

So, when there is a mix of traffic utilizing both SFs, the default scheduling weight allows LL SF flows to consume up to 90% of the channel capacity, only as long as the Classic SF flows aren't pushing back via the coupled AQM. Thus per-flow fairness is provided as long as the ratio of L4S flows to Classic flows remains below 90/10. If the ratio of flows exceeds this value, then the L4S flows will be forced to share 90% of the capacity, and the much smaller number of Classic flows will share the remaining 10%, thus giving a throughput advantage to the Classic flows. It is expected that the ratio of L4S to Classic flows will grow over time as more operating systems and applications adopt an L4S congestion control algorithm, and thus there may be a point in time when a value for W greater than 230 would become more appropriate.

The above discussion assumes that the traffic sharing the ASF is responsive (i.e. it responds to congestion signals). However, one might wonder what would happen if unresponsive traffic were sent into one or the other of the SFs. If the unresponsive traffic is sent only to the Classic SF, it would consume whatever bandwidth that it consumes, and the remaining responsive flows (both the Classic and LL) would share the remaining bandwidth approximately equally. If the total Classic SF traffic (unresponsive and responsive) exceeds 10% of the AMSR (assuming the default scheduling weight), this would result in the Classic AQM generating a non-zero drop probability, which means that the unresponsive flow would experience a small amount of packet loss. On the other hand, if the unresponsive traffic is sent only to the LL SF, it would similarly consume whatever bandwidth that it consumes, and the remaining responsive flows (both Classic and LL) would share the remaining bandwidth approximately equally to a point. Due to the weighted scheduling, the total LL SF traffic cannot consume more than 90% of the AMSR (assuming the default scheduling weight) whenever there is capacity-seeking traffic in the Classic SF. So, if the unresponsive flow's traffic rate increases, it will eventually first squeeze the responsive LL SF traffic to zero throughput. If the unresponsive flow continues to increase its rate beyond 90% of AMSR, it will begin to have its packets sanctioned to the Classic SF, and only then begin to squeeze the responsive Classic SF traffic to zero throughput. So, in comparison, responsive traffic in the Classic SF

has slightly more protection than LL SF traffic does from an unresponsive flow that occupies the LL SF. If two unresponsive flows are sent, one to the Classic SF and one to the LL SF, and together they are sending at a rate greater than AMSR, the LL SF flow would be able to consume up to 90% of the AMSR, and the Classic SF would be constrained to 10%. If the LL SF flow's rate exceeds 90% of AMSR, it would have its packets sanctioned to the Classic SF, where it would compete with the other unresponsive flow for access to the 10% of AMSR allocated to the Classic SF. Overall, this situation isn't tremendously different from the traditional single-queue situation, where an unresponsive traffic flow can squeeze the responsive traffic down to zero throughput if it wishes.

4.7. Buffer Sizing

The configuration of buffer sizes for both the LL SF and the Classic SF is done via the Buffer Control TLVs. By default, LL SFs have a buffer size that equates to 10 ms at the configured AMSR (i.e. the buffer size in bytes is equal to AMSR in bps, times 10 ms divided by 8 bits/byte), whereas Classic SFs have a default buffer size equal to at least 50ms at the configured AMSR. Note that when both queues are fully utilized, the effective tail drop limit for the LL SF would be 10ms / scheduling_weight (i.e. 11ms), and for the classic SF would be 50ms / (1 – scheduling_weight) (i.e. 500 ms).

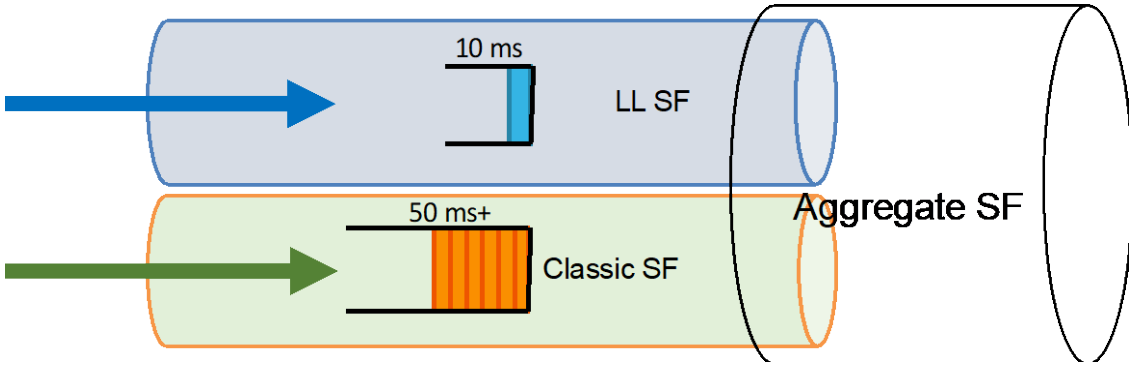

Figure 11 – Buffer sizing

For most deployment conditions, these default buffer sizes are expected to be sufficient. In many cases, the AQM and QP functions will prevent the buffers from reaching this tail drop limit. In particular, the QP function will generally keep the LL SF queue from significantly exceeding the MaxThresh value (i.e. 1 ms in the default configuration). For the Classic SF, the AQM algorithm will adjust drop probability in order to keep the steady-state queue delay at the target value (10ms).

4.8. Proactive Grant Service

The Proactive Grant Service (PGS) is designed to provide low latency for US Service Flows that may carry variable size data packets with random packet arrivals. With PGS a CMTS proactively schedules a stream of grants to the Service Flow. The intention is that the stream of grants is scheduled at a constantly adjusted rate that attempts to match or exceed the instantaneous demand. In doing so, the system ensures that the vast majority of packets carried by the Service Flow can be transmitted without being delayed by the Request-Grant process. If the traffic arrival rate exceeds the rate at which the CMTS is proactively providing grants, the CM will automatically piggyback requests for additional grants.

The bare minimum implementation of a PGS scheduler as described in the specification is the following.

There are three parameters for an upstream PGS Service Flow:

- Guaranteed Grant Interval (GGI) specifies the maximum interval (microseconds) between successive data transmission opportunities.
- Guaranteed Grant Rate (GGR) specifies the minimum granting rate, in bits/sec.
- Guaranteed Request Interval (GRI) specifies the maximum interval (microseconds) between successive request opportunities (unicast and piggyback).

If traffic activity is detected on a PGS Service Flow, the CMTS provides unsolicited data transmission opportunities at a minimum rate of GGR with an interval less than or equal to the GGI. The algorithm for detecting traffic activity on a PGS Service Flow is CMTS vendor specific.

The efficiency of a PGS service is highly dependent on the CMTS with its ability to detect inactivity and reduce the bandwidth usage to only the requests and shutting down any grants. There will always be a bit overhead in bandwidth lost, as an CMTS implementation may not be able to perfectly size the PGS grants to the varied type of traffic seen on the upstream.

Beyond this basic implementation, it is expected that CMTS schedulers will implement more sophisticated algorithms that can adjust the PGS grant rate automatically, in real-time, as demand for capacity fluctuates. Thus, the GGR value becomes a lower limit for the PGS granting, and when activity is present the CMTS grants at or above this level.

It is recommended that all Low Latency SFs be configured with PGS scheduling. For systems where the upstream capacity is constrained, it might be appropriate to set GGR to 0 (or a very low value), and allow the CMTS to dynamically adjust the actual grant rate without restriction. For systems which have sufficient upstream capacity, (and especially if the CMTS scheduler implementation is a basic one) an operator may choose to allocate some amount of bandwidth to the PGS Service Flows. GGR settings of 1-2 Mbps shows a lot of effectiveness in reducing they request-grant delay seen by the small packets that are typical of upstream voice services and online games.

Keeping in mind that the request-grant delay for an LLD-capable system might be in the range of 2-6 ms, setting the GGI value to something toward the upper end of that range may not provide much benefit. As a result, it is recommended that the GGI be set to a value less than 2 ms.

A PGS configuration of GGR = 2 Mbps and GGI = 1 ms will provide a 250 byte grant every millisecond, and thus can forward small packets (less than 250 bytes) with at most 1 ms of media access delay, and slightly larger packets (250 – 500 bytes) with at most 2 ms of media access delay. If a large packet (say 1500 bytes) arrives, the first 250 bytes will be sent in the first grant, along with a piggybacked request for 1250 bytes. It will take a full request-grant delay for the additional data grant to arrive, and in the meantime, multiple proactive grants may have been provided, which the CM uses to send further fragments of the original packet. As a result, the total media access delay for isolated packet arrivals is never greater than the request-grant delay.

The GRI value can be set by the operator to enable unicast polling (i.e. request opportunities that are dedicated to this Service Flow) that continue even during inactivity. This can be used to enable a SF to quickly restart PGS grants after a period of inactivity, even in the presence of heavy service group congestion. A value of ‘0’ for GRI disables this polling feature.

4.9. CMTS MAP interval

LLD lowers the request-grant delay by requiring support for a shorter MAP Interval and a shorter MAP processing time. The MAP interval is the amount of upstream time that each MAP message contains grants for and is also the time interval between consecutive MAP messages. Reducing the MAP interval means that the CMTS processes incoming requests more frequently, thus shortening the amount of time that a request might wait at the CMTS before being processed. A shorter MAP interval also means that grants are not scheduled as far into the future within each MAP message. Thus, for every millisecond that the MAP interval is reduced, the request-grant delay improves by 2 milliseconds.

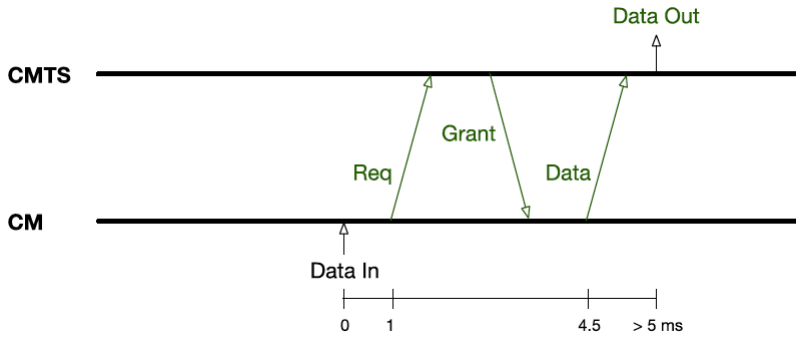

Figure 12 – CMTS Req-Grant Delay

DOCSIS MAP intervals have been in the 2 ms (typically) to 4 ms range for a long time. With LLD, CMTSs support a MAP Interval of 1 millisecond or less. Choosing a lower MAP interval for each upstream channel will reduce the latency experienced by all traffic, and is an important consideration for an operator.

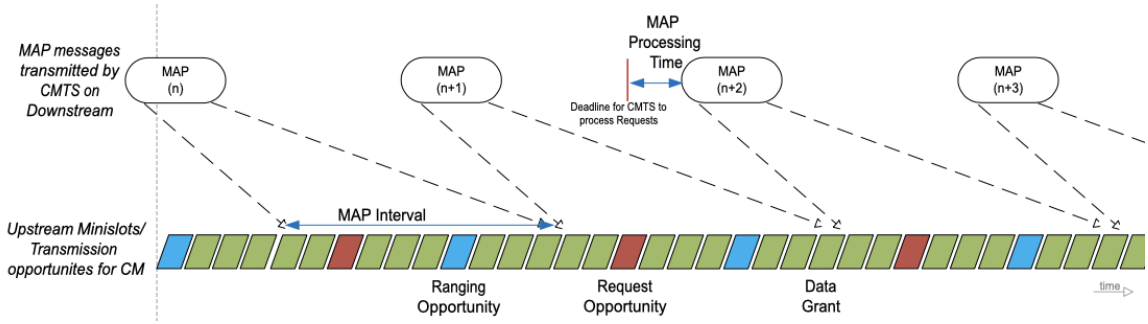

Figure 13 – CMTS MAP Interval

Decreasing the MAP Interval does increase the amount of downstream MAP message traffic, but in many systems the latency benefit outweighs the small impact on available downstream capacity.

5. LLD Configuration Mechansims

Low latency service is configured in the upstream and/or downstream direction by enabling an Aggregate Service Flow with two underlying individual Service Flows, a Low Latency Service Flow (LL SF) and a Classic Service Flow. There are a few different ways an operator can configure Low Latency DOCSIS services on a DOCSIS 3.1 or 4.0 CM.

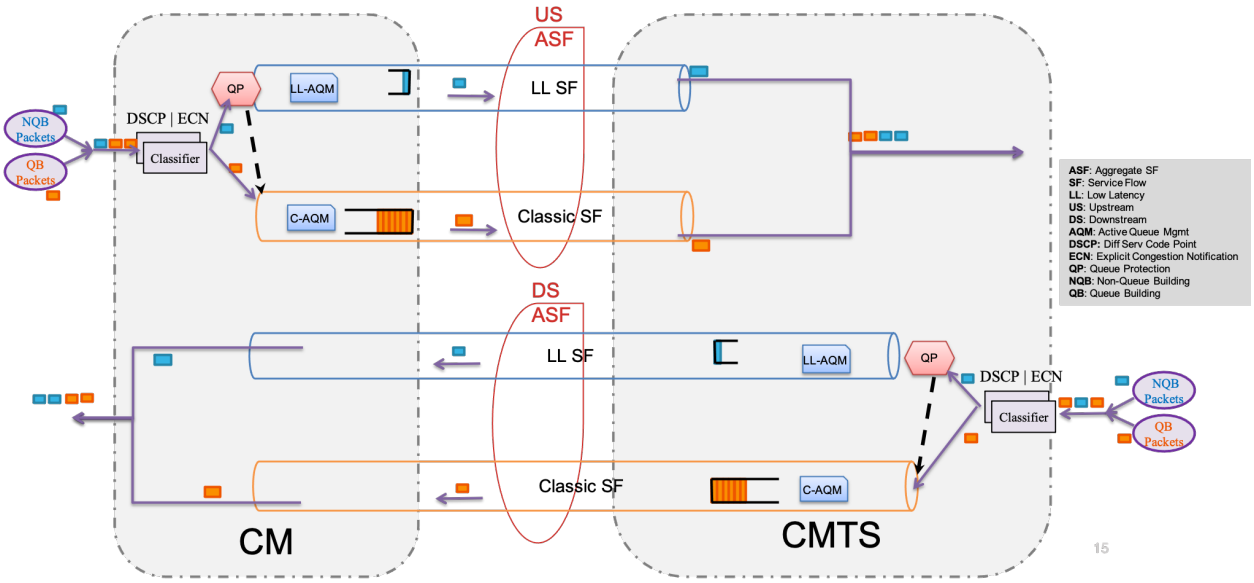

Figure 14 – Low Latency Provisioining : CM Service Flows

Enabling Low Latency services on a DOCSIS CM and CMTS involves the following components:

- Creating an ASF: An Aggregate Service Flow can be created by using explicit configuration file TLVs or by defining a template entry in the Aggregate QoS Profile (AQP) table that is then referenced in the configuration file. A separate ASF is needed for both the upstream and the downstream.
- Creating the individual SFs: Low Latency Service Flows and Classic Service Flows can be configured via explicit config file TLVs or by defining template entries in the Service Class table and then referencing those entries either in the configuration file or in an Aggregate QoS Profile (AQP) table entry. The Low Latency Service Flows and Classic Service Flows can be configured with different Quality of Service parameter sets. For example, in the upstream, the LL SF may use a scheduling type of PGS while the classic may use a scheduling type of Best Effort.

The following section describes the approaches an operator could take to configure these components.

5.1. AQP table with SF/SCN in configuration file

The primary goal with approach is to make use of existing config files and try to minimize changes to those provisioning process. This is possible in cases where the configuration file specifies a Service Class Name (SCN) for each Service Flow that the operator wishes to enable low latency services for. In this case, the current CM config file can be used as-is and the needed Low Latency DOCSIS feature configurations are made on the CMTS via the AQP table, using the Service Class Name from the config file as the AQP Name.

The provisioning system would need no changes and all CMs will boot up with the same config file as they did before the Low Latency DOCSIS features were turned on. For cable modems that support Low Latency DOCSIS, the CMTS will look up the Service Class Name in the AQP table first and expand the single Service Flow from the config file into an Aggregate Service Flow and the component Low Latency Service Flow and Classic Service Flow. For CMs that do not support Low Latency DOCSIS the CMTS will look up the Service Class Name in the Service Class Table and provision the appropriate single Service Flow.

Here is an example of the Service Flow parameters in a config file for the modem. In an actual configuration file, many other parameters will be present, this paper only shows the TLVs relevant to the LLD configuration.

Table 4 – CM Configuration File with TLV24/25 SCN

Config file parameter	TLV/Sub-TLV	Name /Value
Upstream Service Flow Encoding (TLV 24)	(Type 24.1) (Type 24.6) (Type 24.4)	Service Flow Reference = 1 QoS Parameter Set. = 07 Service Class Name = USBronze
Downstream Service Flow Encoding (TLV 25)	(Type 25.1) (Type 25.6) (Type 25.4)	Service Flow Reference= 2 QoS Parameter Set= 07 Service Class Name= DSBronze

Below are examples of an AQP & SCN definition on the CMTS, again we are focusing on the relevant LLD parameters.

5.2. AQP table with ASF/AQP Name in configuration file

The goal with approach is to make use of the new AQP definitions as defined in the Low Latency DOCSIS technology. The idea here is to align the changes with the new provisioning TLVs. The idea is to use the current CM config files with the new AQP definitions which now will be used only by the CMs which support Low Latency DOCSIS. The operator will also make the needed the Low Latency DOCSIS feature configurations on the CMTS side. An operator will use the new as the profile names for the AQP definition on the CMTS. The config file will point to the same profile name as defined on the CMTS.

The provisioning system would need to now accommodate these new configuration files and CMs with LLD support will boot up with the new config file. This makes things explicit for the operator and in the network. For cable modems that support Low Latency DOCSIS the CMTS will look up the AQP table first and provision the Aggregate Service Flow and the component Low Latency Service Flow and Classic Service Flow. For CMs that do not support Low Latency DOCSIS, would receive a different configuration file and the CMTS will look up the service class name table and provision the appropriate Service Flow.

Here is an example of the ASF parameters in a new config file for the modem that reference an AQP definition on the CMTS.

Table 7 – CM Configuration File with TLV70/71 AQPName

Config file parameter	TLV/Sub-TLV	Name /Value
Upstream Aggregate Service Flow Encoding (TLV 70)	(Type 70.1) (Type 70.4)	Aggregate Service Flow Reference= 1 ASF QoS Profile (AQP) Name= USBronze
Downstream Aggregate Service Flow Encoding (TLV 71)	(Type 71.1) (Type 71.4)	Service Flow Reference= 2 ASF QoS Profile (AQP) Name = DSBronze

The same parameters in the QP and SCN table can be configured as per previous section.

5.3. Explicit TLVs in CM Configuration file

This approach requires no configuration on the CMTS, rather it includes all low latency configuration including the ASF and the constituent SFs directly in the CM config file. These config files will only be usable by CMs that support Low Latency DOCSIS, so the provisioning system will need to ensure that such a config file is only given to CMs that report support for LLD in their CM Capabilities encoding in the DHCP Discover.

Here is an example of a new config file for the LLD CM.

Table 8 – CM Configuration File with TLV24/25 SCN

5.4. Parameter Overrides

When using an Aggregate QoS Profile encoding or a Service Class Encoding, it is possible to override the values of individual parameters configured on the CMTS by specifying the override values in the configuration file. When the CMTS finds a match for the SCN or AQP Name in the AQP Table or Service Class Table and there are overriding parameters in the CM Configuration file, the CMTS utilizes the parameter values from the config file in place of the values that were specified in the AQP table or Service Class Table.

In the case that the CMTS is expanding a Service Flow encoding into an ASF and two SFs as described in Section 5.1, the individual Service Flow parameters from the config file are distributed to the ASF and SFs as discussed in Section 7.7.4.2 of [DOCSISv3.1 MULPI].

5.5. Classifier Merge Operation

When using AQP expansion, as described in Section 5.1 and 5.2 above, the AQP Table includes an attribute that allows the operator to configure packet classifiers to select traffic that is directed to the low latency SF. When the associated Classic SF is the Primary SF, these classifiers may be sufficient for directing traffic into the LL SF, and the Classic SF itself would have no classifiers. In other cases, for example when the operator wishes to create two upstream Low Latency ASFs, it is necessary to craft classifiers that can appropriately select traffic for each of the three non-Primary SFs.

The CMTS supports a functionality called Classifier Merge that makes this process automatic and straightforward.

For each configuration file classifier that points to an ASF or points to a Service Flow that is expanded into an ASF via an AQP Name match (like discussed in Section 5.1), the CMTS will apply that classifier to the Classic SF under the ASF, and will merge in the classifier fields from the AQP table to build appropriate classifiers for the Low Latency SF.

As an example, consider the following upstream portion of a configuration file definition, which includes two upstream SFs and a classifier that directs traffic for the WAN subnet 11.12.13.0/24 into the secondary SF.

Table 9 – CM Configuration File with TLV24/25 SCN

Config file parameter	TLV/Sub-TLV	Name /Value
Upstream Service Flow Encoding 1 (TLV 24)	(Type 24.1) (Type 24.6) (Type 24.4)	Service Flow Reference = 1 QoS Parameter Set. = 07 Service Class Name = USBronze
Upstream Service Flow Encoding 2 (TLV 24)	(Type 24.1) (Type 24.6) (Type 24.4)	Service Flow Reference = 21 QoS Parameter Set. = 07 Service Class Name = USBronze
Upstream Pkt Classifier Encoding (TLV 22)	(TLV 22.1) (TLV 22.3) (TLV 22.9.5) (TLV 22.9.6)	Classifier Reference = 1 Service Flow Reference = 21 IPv4 Destination Address = 11.12.13.0 IPv4 Destination Mask = 255.255.255.0

In this configuration file, both SFs are configured with a Service Class Name that matches an AQP entry on the CMTS, so each of the two SFs will be expanded into an ASF and two SFs. Let's refer to these using reference numbers 1, 2, 3 for the ASF, Classic SF & Low Latency SF expanded from Service Flow Reference 1 (the primary SF), and reference numbers 21, 22, 23 for the ASF, Classic SF & Low Latency SF expanded from Service Flow Reference 21 (the secondary SF).

Referring to Table 5 in Section 5.1, the AQP entry for USBronze has six low latency classifiers defined (three IPv4 and three IPv6). The CMTS Classifier merge would result in the following set of ten classifiers:

Table 10 – Classifier Merge Example

Classifier for	Classifier reference	Service Flow Reference	Classifier TLVs
IPv4 DSCP 45 & 46	1	3 "Primary" Low Latency SF	IPv4 ToS Range and Mask= 0xb4, 0xb8, 0xfc
IPv6 DSCP 45 & 46	2	3 "Primary" Low Latency SF	IPv6 ToS Range and Mask= 0xb4, 0xb8, 0xfc

Note that the classifier provided in the config file was an IPv4 classifier, so the CMTS does not merge it with the three IPv6 Low Latency classifiers from the AQP table, since this "merge conflict" would create invalid classifiers.

The classifier merge process is described in Section 7.7.4.3 and Annex Q of [DOCSISv3.1 MULPI].

5.6. Primary Service Flow

Independent of the method of Low Latency DOCSIS provisioning, the CM and CMTS continue to activate the Primary Service Flows at registration time. Low Latency DOCSIS introduced new rules that the CMTS uses to determine which upstream and downstream Service Flows are the primaries based on the contents of the CM configuration file, and it introduced a new Registration Response TLV that the CMTS sends to inform the CM of this selection. The rules that the CM & CMTS use to select the primary upstream and downstream SF are as follows.

When the CM sends its registration request, it is required to send the configuration file TLVs in the order that they appear in the config file. The CMTS then selects the first SF or ASF encoding (either TLV 24/25 or 70/71) for upstream and for downstream, from the registration request. If the first selected Service Flow is an individual Service Flow (TLV 24/25), then this becomes the Primary Service Flow. If the first selected Service Flow is an ASF (TLV 70/71), then the associated Classic SF is chosen to be the primary Service Flow (even if that Classic SF TLV encoding comes much later in the registration request). If the first selected Service Flow is a TLV 24/25 that gets expanded via an AQP expansion, then the associated Classic SF after AQP expansion is chosen to be the primary Service Flow. For a CM indicating LLD support, the CMTS sends the Primary Service Flow Indicator TLV to the CM in the registration response, to identify the primary upstream and downstream Service Flow.

5.7. Device Capabilities

Configuration of Aggregate Service Flows and individual Service Flows for low latency services happens during the Registration process or can be dynamically initiated by the CMTS post-registration.

The CMTS will support at least one upstream and one downstream Low Latency ASF instance per CM. The CMTS optionally can support more than one Low Latency ASF instance in each direction per CM. A CM will support at least two Low Latency ASFs in the upstream direction. This is conveyed by the CM during the registration process, via the CM Capabilities encoding (TLV 5), in the Low Latency Support (sub-TLV 5.76). A value of 0 indicates Low Latency features are not supported and a value of 1 or more indicates the number of ASFs supported by the CM.

5.8. Compatibility Features with CMs Lacking Low Latency Support

A subset of the Low Latency features can be utilized in cases where the CM does not indicate support for Low Latency in its Modem Capabilities encoding. For example, Downstream Low Latency ASFs (and their constituent Service Flows) can be instantiated in order to provide isolation between queue-building and non-queue-building traffic in the downstream direction.

In the upstream direction, it is not possible to configure a Low Latency ASF for a CM that lacks support for Low Latency. However, it is possible to configure separate upstream Service Flows along with classifiers to direct NQB traffic to one of the two Service Flows. Keep in mind, this configuration lacks all of the functionality associated with a Low Latency ASF, i.e. aggregate rate shaping, IAQM with ECN marking, Coupled AQM, default buffer sizing, and Queue Protection, and so should be used with caution.

It is possible to configure PGS scheduling for CMs that don't support LLD. PGS scheduling is only enforced by the CMTS. For CMs that do not indicate Low Latency Support in CM capabilities, or for which Low Latency is disabled (TLV 91), the CMTS replaces the PGS scheduling type with the BE scheduling type and removes the GGI, GGR and GRI parameters in Service Flow definitions in the Registration Response that it sends to the CM. Regardless of whether the CMTS communicates the PGS configuration to the CM, the CMTS is expected to enforce the GGI, GGR and GRI parameters as configured for the Service Flow. This enables configuration of proactive scheduling on CMs that do not indicate Low Latency Support in CM capabilities. Note that the CM will report the SF as having BE scheduling type.

5.9. IPDR Ramifications

Some operators utilize Internet Protocol Detail Records (IPDR) to track per-customer data utilization stats (byte counts) for usage based billing or monthly byte cap accounting. With a Low Latency configuration, each customer will have two SFs in each direction instead of one. As a result, operators will need to consider what updates are needed in their IPDR collection and data processing implementations in order to identify both SFs and sum their byte counts.

In some cases, IPDR post processing functions key off of the Service Class Name to identify the broadband service for a customer. If the operator is using the explicit configuration file approach described in Section 5.3 above, they can include the same Service Class Name for both the LL and Classic SF (so, effectively, all of the explicit config file parameters are overrides to a basic Service Class configuration), and it may then be that no changes are needed in the IPDR post processing.

Alternatively, if the operator is using one of the AQP expansion options described in Sections 5.1 & 5.2, they could still use the same SCN for both LL & Classic, as long as they are ok with BE scheduling on the LL SF (as opposed to PGS), and default values for all of the buffering and AQM parameters.

Another approach could be to use a special character in the SCN to delimit between the “service” name and the Service Flow role, e.g. a colon as in “MyServiceClassUpstream:L” and “MyServiceClassUpstream:C”, and update the IPDR post processing function to look for a match up to the first instance of the delimiter.

6. Performance Monitoring

6.1. Service Flow Statistics

Low Latency DOCSIS technology also has added support for reporting statistics on Low Latency and Classic Service Flows. An operator may want to keep an eye on the IAQM Marking Rate, the number of packets undergoing sanctioning due to queue protection, AQM drop and tail drop statistics for the Service Flows when an operator has deployed LLD technology. These statistics are summarized in the table below and it would be good operational practice for an operator to track these statistics.

Table 11 – Service Flow statistics

Device	MIB Name	MIB Entries
CM & CMTS	DocsQosSfCongestionStatsEntry	docsQosSfCongestionSanctionedPkts docsQosSfCongestionTotalEct0Pkts docsQosSfCongestionTotalEct1Pkts docsQosSfCongestionCeMarkedEct1Pkts
CM & CMTS	DocsQosServiceFlowStatsEntry	docsQosServiceFlowPkts docsQosServiceFlowOctets docsQosServiceFlowTimeCreated docsQosServiceFlowTimeActive docsQosServiceFlowPHSUnknowns docsQosServiceFlowPolicedDropPkts docsQosServiceFlowPolicedDelayPkts docsQosServiceFlowAqmDroppedPkts

An operator using these statistics could be able to understand how Queue Protection is effectively working on the modems (upstream) or CMTS (downstream), and to help debug any issues that come up. Also once L4S traffic becomes more prevalent on the internet, the TotalEct1Pkts counter on the upstream/downstream will give the operator views into how much of the traffic is L4S compliant and the CeMarkedEct1Pkts counter will give the operators confidence that packets are being marked in the DOCSIS network and the network is supporting the L4S functionality appropriately.

6.2. Latency Histograms

Downstream Service Flows and Upstream Service Flows configured for BE or PGS scheduling support Active Queue Management (AQM) algorithms. As part of their operation, these AQMs generate estimates of the queuing latency for the Service Flow. The Latency Histogram Calculation function exposes these estimates to the operator in order to provide information that can be utilized to characterize network performance, optimize configurations, or troubleshoot problems in the field.

The ‘Latency Histogram Encodings’ parameter, when present, enables latency histogram calculation for the given Service Flow. The latency estimates from the AQM are represented in the form of a histogram as well as a maximum latency value. The operator configures the bins of the histogram, and the CM or the CMTS logs the number of packets with recorded latencies into each of the bins. The CM implements

histograms for upstream Service Flows, and the CMTS implements histograms for downstream Service Flows. While the latency histogram calculation function utilizes the latency estimation algorithm from AQM, the latency histogram calculation function can be enabled even for Service Flows for which the AQM algorithm is disabled.

6.2.1. Enabling Latency Histogram via CM Config file

The histograms can be enabled in the CM config file. The table below shows an example of a portion of a configuration file with the explicit histogram TLVs included within the SF definitions.

Table 12 – CM Configuration File Portion with Histograms Enabled

Config file parameter	TLV/Sub-TLV	Name / Value
Upstream Parameters		
Upstream Aggregate Service Flow Encoding (TLV 70)	(Type 70.1) (Type 70.8) (Type 70.9) (Type 70.42.1)	Aggregate Service Flow Reference= 1 Maximum Sustained Rate= 50000000 Maximum Traffic Burst= 50000 Low Latency SF Reference= 3

Upstream Service Flow Encoding (Classic SF) (TLV 24)	(Type 24.1) (Type 24.36) (Type 24.6) (Type 24.15) (Type 24.40.1) **(Type 24.40.6)**	Service Flow Reference= 3 Aggregate Service Flow Reference= 1 QoS Parameter Set= 07 Service Flow Scheduling Type= 02 SF AQM Disable = 0 (enabled) **Latency Histogram Encoding** (in unit of 0.01ms) = 100, 300, 500, 600, 700, 800, 900, 1200, 1500, 1800, 2500, 5000, 7500, 10000, 12500 (Enables 16 histogram bins from 1 – 125ms,)
Downstream Parameters		
Downstream Aggregate Service Flow Encoding (TLV 71)	(Type 71.1) (Type 71.8) (Type 71.9) (Type 71.42.1)	Aggregate Service Flow Reference= 11 Maximum Sustained Rate= 200000000 Maximum Traffic Burst= 200000 Low Latency SF Reference= 12

Config file parameter	TLV/Sub-TLV	Name / Value
Downstream Service Flow Encoding (LL SF) (TLV 25)	(Type 25.1) (Type 25.36) (Type 25.6) (Type 25.40.1) **(Type 25.40.6)**	Service Flow Reference= 12 Aggregate Service Flow Reference= 11 QoS Parameter Set= 07 SF AQM Disable = 0 (enabled) **Latency Histogram Encoding** (in unit of 0.01ms) = 50, 75, 100, 125, 150, 175, 200, 300, 400, 500, 600, 800, 900,1200, 1500 (Enables 16 histogram bins from 0.5ms – 15ms)
Downstream Service Flow Encoding (Classic SF) (TLV 25)	(Type 25.1) (Type 25.36) (Type 25.6) (Type 25.40.1) **(Type 25.40.6)**	Service Flow Reference= 13 Aggregate Service Flow Reference= 11 (Type 25.36) QoS Parameter Set= 07 SF AQM Disable = 0 (enabled) **Latency Histogram Encoding** (in unit of 0.01ms) = 100, 300, 500, 600, 700, 800, 900, 1200, 1500, 1800, 2500, 5000, 7500, 10000, 12500 (Enables 16 histogram bins from 1 – 125ms)

6.2.2. Enabling Latency Histogram via SCN

The histograms calculation can also be enabled using the service class name definition on the CMTS. the service class name MIB object (see [DOCS-QOS3-MIB]), can be configured with the appropriate settings. This service class name is then referenced from the config file either within the AQP or the SCN definitions.

Table 13 – SCN Latency Histogram definition on CMTS

CMTS MIB Name/entry	Value
docsQosServiceClassTable -- docsQosServiceClassLatencyHistBinEdges	The attribute is formatted as a string of unsigned 16-bit integers, each representing a histogram upper bin edge in units of 10 microseconds. (This matches the Config file encoding for the same)

6.2.3. Enabling Latency Histogram via SNMP

Once a cable modem is initialized the latency histogram calculations can also be enabled after registration. This is done by setting the histogram bin edges in the docsQosSfLatencyHistCfgTable, for a particular Service Flow on a particular modem. This is useful for testing on the fly where an operator would like to understand the latencies on a particular CM.

Table 14 – Enable Latency Histogram Calculation - Configuration

Device	MIB Name	MIB Entries	Example 1	Example 2
CM	docsQos SfLatency HistCfgTable	DocsQosSfLatencyHistCfgEntry ::= docsQosSfLatencySfLabel	 myUSLLSN	 US2LLSN

Device	MIB Name	MIB Entries	Example 1	Example 2
	(for Upstream Service Flows)	docsQosSfLatencyBin1UpperEdge	12,	10,
		docsQosSfLatencyBin2UpperEdge	20,	50,
		docsQosSfLatencyBin3UpperEdge	29,	100,
		docsQosSfLatencyBin4UpperEdge	37,	300,
		docsQosSfLatencyBin5UpperEdge	45,	600,
		docsQosSfLatencyBin6UpperEdge	53,	800,
		docsQosSfLatencyBin7UpperEdge	61,	1000,
		docsQosSfLatencyBin8UpperEdge	69,	1500,
		docsQosSfLatencyBin9UpperEdge	100,	--
		docsQosSfLatencyBin10UpperEdge	200,	--
		docsQosSfLatencyBin11UpperEdge	400,	--
		docsQosSfLatencyBin12UpperEdge	800,	--
		docsQosSfLatencyBin13UpperEdge	1000,	--
		docsQosSfLatencyBin14UpperEdge	1200,	--
		docsQosSfLatencyBin15UpperEdge	1500,	--
		docsQosSfLatencyBinEdgeNum	15	8

Note: This MIB table includes an SfLabel entry that the operator can set to a text string of their choosing. This string is used to identify the histogram data for a particular Service Flow in the histogram data files that are uploaded by the TFTP method described in Section 6.2.5. In the case that histogram calculation is turned on via the config file, the CM/CMTS will automatically populate the SfLabel field with the Service Class Name for that Service Flow (if one exists).

6.2.4. Querying Histogram Data via SNMP

Once the histogram calculations have been enabled either via the config file or via SNMP the operator can view the histogram of latencies via SNMP in the docsQosSfLatencyStatsTable. See [DOCS-QOS3-MIB] for the detailed definitions.

Table 15 – Latency Histogram Statistics

6.2.5. TFTP Reporting of Histogram Data

The CMTS and CM features and capabilities can be leveraged to enable measurement and reporting of latency estimates through each of the Service Flows. With this information, operations personnel can monitor latency trends and adjust network configurations as appropriate. Latency statistics include histogram counts, maximum latencies, etc., for each enabled Service Flow.

An operator can view the instantaneous statistics via SNMP as described in the previous section or they can have the CM & CMTS store the historical latencies observed and upload that data as a file to an external TFTP server. The following objects show how to enable this style of bulk data uploads on both the CM and the CMTS.

See [CCAP OSSI] and [CM OSSI] for the detailed definitions.

Table 16 – TFTP report of Latency Histogram - Configuration

Device	MIB Name	MIB Entries	Example Values
CM	docsCmLatency RptCfgTable for Upstream Service Flows	docsCmLatencyRptCfgSnapshotDuration docsCmLatencyRptCfgNumSnapshots docsCmLatencyRptCfgNumFiles docsCmLatencyRptCfgMeasStatus docsCmLatencyRptCfgFileName	300 288 7 ready CMUpstreamLLHist
CMTS	docsCmtsLaten cyRptCfgTable for Downstream Service Flows	docsCmtsLatencyRptCfgCmMac docsCmtsLatencyRptCfgSnapshotDuration docsCmtsLatencyRptCfgNumSnapshots docsCmtsLatencyRptCfgNumFiles docsCmtsLatencyRptCfgMeasStatus docsCmtsLatencyRptCfgFileName	CM-MAC-Addr-xxx 600 144 7 ready CMDownstreamLLHist

The operator can configure the duration of a snapshot, the measurement duration of Service Flow latency estimates. One row of statistics per Service Flow is captured during this snapshot interval and stored in the file. The number of Snapshots thus batched into a file can also be configured. E.g. If the SnapshotDuration is set to 300 seconds (5 mins), and NumSnapshots is set to 288, when enabled, the CM returns the latency data samples recorded once per 5-minute interval over the next 24-hour period. The NumFiles attribute controls the number of such files the CM uploads (0 disables, 255 enables unlimited number of files and 1-254 are other valid values). A FileName prefix can call be configured to customize the name of the files.

Statistics files can be enabled for TFTP /bulk file upload via the bulk data transfer mechanisms defined in [CCAP OSSI] and [CM OSSI].

Table 17 – TFTP /bulk file upload Configuration

		latencyRpt(9)
		}

6.2.6. Using the Reported Histogram Data

When commanded by the operator to upload histogram data the CM or the CMTS will upload a file to a TFTP server with the latency histogram metrics captured as per the snapshot configuration in the previous section.

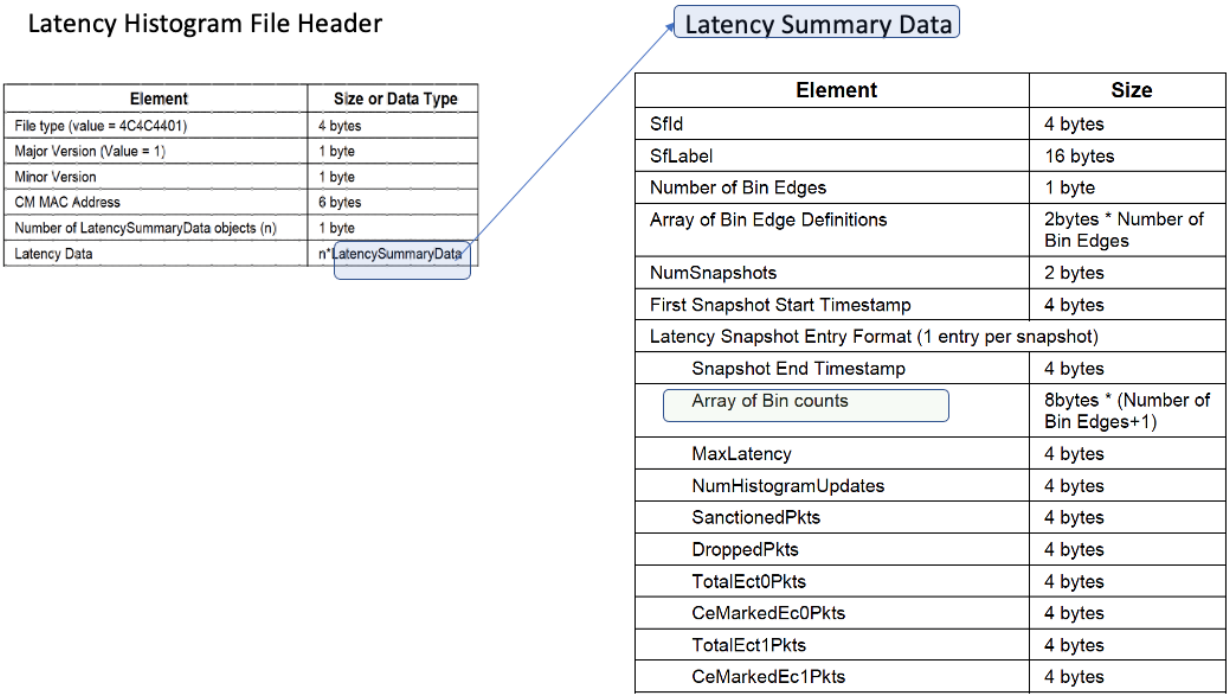

Figure 15 – Latency Histogram File format

Each latency histogram file from a CM or CMTS will have a standard file header as shown in the figure and will have a number of latency summary data entries. Each latency summary data entry will identify the Service Flow for which the latency histogram is being reported, the bin edge definitions and the number of snapshots with their timestamps, and for each snapshot will provide the count of packets in each of the bins and also some additional statistics such as the maximum latency, the number of

sanctioned packets within that snapshot, etc. CableLabs has developed a tool to decode these LLD Histogram files and this is available at the CableLabs [C3 Repository].

The histogram bin counts and bin edge definitions can be used to visualize the latencies seen by the Service Flow as shown below. The two graphs below show the latency data for an upstream Aggregate Service Flow which includes a Low Latency Service Flow and a Classic Service Flow. We can see that the majority of the packets in the Low Latency Service Flow have a latency between 1~2 milliseconds. In the Classic Service Flow we can see that the majority of the packets have a latency between 9 ~ 12 milliseconds. Building histograms like this with well-crafted bin edges will help an operator understand the latency performance of each of the CMs/CMTSs. this data can then be aggregated across the network to develop a baseline of latency performance

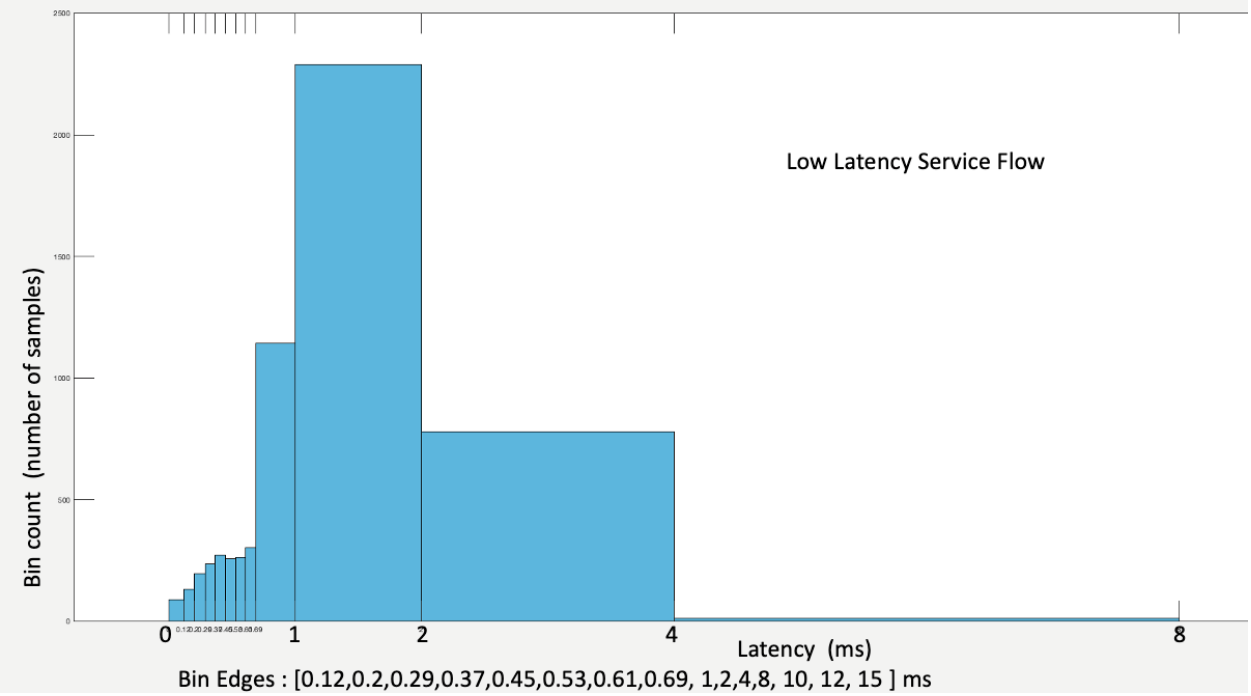

Figure 16 – Histogram plot Upstream Low Latency Service Flow

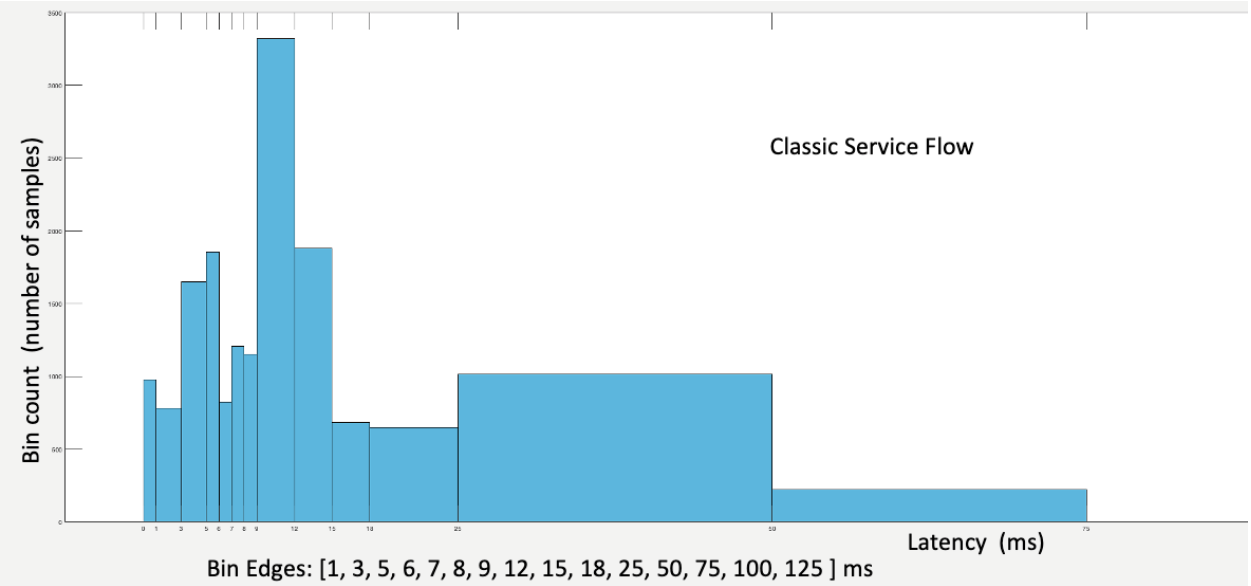

Figure 17 – Histogram plot Upstream Classic Service Flow

7. Conclusion

Low Latency DOCSIS technology (LLD) tackles the two main causes of latency in the network: queuing delay and media acquisition delay. In LLD, data traffic from applications that aren't causing latency can take a different logical path through the DOCSIS network without being stuck behind data from applications that are causing latency, as is the case in today's Internet architectures. In addition, LLD improves the DOCSIS upstream media acquisition delay with a faster request-grant loop and a new proactive scheduling mechanism.

While the LLD parameters can be tweaked to achieve the behavior that an operator wants, the specification already chooses default values for each the parameters based on the combined judgement of the LLD working group.

LLD can be deployed by field-upgrading DOCSIS 3.1 cable modem and cable modem termination system devices with new software. The technology includes tools that enable automatic provisioning of these new services. It allows for multiple ways to provision and enable the low latency services onto the CM/ CMTS. This ranges from methods which minimize the config file changes to methods which minimize the CMTS side configuration, and an operator can choose one of the methods to initiate field trials and ultimately finalize the configuration when deploying LLD across the footprint.

In addition, it also introduces new tools to report statistics of latency performance to the operator, which can be useful to validate configuration and functionality of implementations, as well as to monitor performance over time.

1. Introduction

The Cable industry continues to innovate on both technical and business fronts in their Access and Edge networks to meet and exceed ever-ascendant customer demands. Currently, Distributed Access Architecture, DOCSIS 4.0, Generic Access Platform, fiber deep, Wireless Access, and virtualization are all being deployed in various permutations in order to deliver on the promises of the 10G era – high bandwidth, low latency, seamless fail-over, single user profiles, and so forth. Looking at the evolution of the Cable Modem Termination System (CMTS) specifically, what was once a fixed, vertically integrated, HFC CCAP appliance from a single vendor has become a virtualized CMTS (vCMTS) appliance running on commercial off the shelf (COTS) servers. This transformation into the software domain has brought the agility needed to keep up with other upgrades to the network.

Along these lines, the vCMTS is now being broken into smaller component functions packaged in software containers that now can be deployed, managed, and scaled individually. In fact, some of those functions may be shared across other network functions or Access technologies to achieve some aspects of convergence and cost savings – for example, a DHCP server or a network telemetry database. The flexibility of such a decomposed, cloud-ready, vCMTS solution brings a lot of opportunities for the MSO in terms of hardware or software consolidation, placement of a workload to the "best" place in the network, individual scaling, and general positive reactivity to the real time needs of users or the operator.

These characteristics are also the promise from Cloud Service Providers (CSPs) when deploying a given application on their infrastructure. That is, they will manage the hardware, furnish a consistent pane of glass for management, and transparently provide redundancy and scale. This certainly sounds appealing! In fact, the Communications Service Provider (CoSP) industry is already familiar with moving enterprise workloads to the Cloud; but will this approach work for vCMTS – and the DOCSIS MAC dataplane in particular?

Figure 1 shows how a vCMTS solution could be deployed to Cloud infrastructure[1] and tie into the general MSO network. This approach moves the vCMTS functionality from equipment in the Headend/Hub in the RPD case or the Node in the RMD case owned by the network operator to servers and switches deeper in the network owned by a CSP. The upside is that the CSP handles the deployment and management of this hardware and provides a common software infrastructure, distributed backup capability, and other operational benefits to the network operator.

[1] Cloud can refer to Cloud Service Provider hardware located in the cloud providers datacenter or within a Telco or MSO providers premises. Section 1.1**Error! Reference source not found.** outlines various possible locations for cloud hardware.

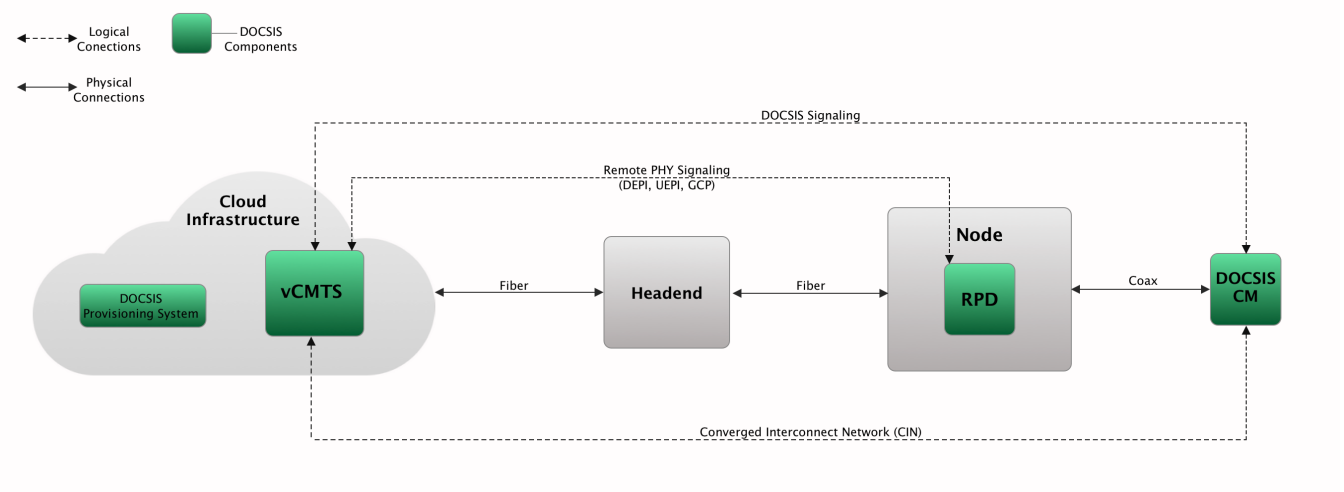

Figure 1 – vCMTS in the Cloud

For all the benefits, there are some trade-offs versus having the vCMTS running on local servers and switches in the Headend/Hub. While there are business and strategic considerations for moving a workload to the cloud – for example, costs, core competencies, and competitive circumstances – this paper focuses on technical questions of expected vCMTS dataplane performance and comparison to the same applications running on on-premise equipment. Just to be clear, the benchmarking and subsequent analysis described in this paper only looks at considerations for the DOCSIS dataplane as opposed to control plane elements of a full vCMTS solution (ex. availability of IEEE 1588), which is, itself, a topic ripe for further discussion.

- Section 1 lays out the test infrastructure and process used to evaluate the current Cloud offerings specifically for networking workloads like a vCMTS dataplane
- Section 2 presents the initial single Service Group benchmarking results across several cloud instance types and makes comparisons to on-premise solutions
- Section 3 describes considerations for effective and performant scaling of the vCMTS dataplane within the Cloud to work-around any per-instance performance limits
- Section 4 summarizes this testing and infrastructure analysis and recommends an “ideal cloud instance type” for the vCMTS dataplane or other similar Access workloads

In short, this paper will describe how a vCMTS dataplane workload can be run optimally in the Cloud, lay out benchmarks comparing various cloud products to on-premise solutions, provide a recommendation for an ideal instance type, and detail the full process from start to finish to allow this work to be generalized across other CSP offerings and workloads in the future.

1.1. Definition of the Cloud

A cloud instance is essentially a virtual machine that is hosted and managed by a CSP and can be rented to users. Each instance is defined by a set of properties, such as the number of virtual CPUs (including those with specific capabilities or instruction sets), the amount of memory or storage, accelerator

options (ex. GPUs, custom ASICs, etc.), and network connectivity. This analysis focuses solely on the offerings from Amazon Web Services (AWS) as being representative of the offerings from other CSPs.

The cloud products from AWS only continue to grow in number and to help customers determine the right match for their needs, AWS groups them into the families shown in Figure 2. Each family, and in many cases, sub-family (not shown), has a general set of workload requirements in mind, such as being optimized for machine learning algorithms or having large storage but low compute requirements. These attributes then translate into the actual instance configuration for compute, hardware accelerators, storage capability, number and size of network interfaces, and so forth.

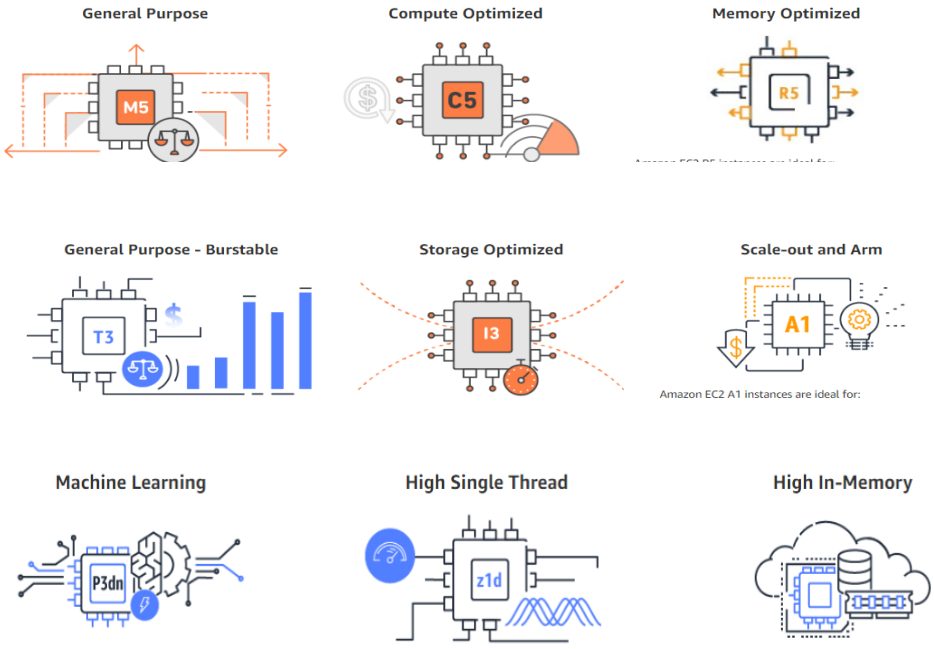

Figure 2 – AWS Instance Families[2]

The first criteria to filter the selection is knowing that vCMTS dataplane reference software used for this analysis was written and optimized for an x86 architecture and thus it will run best on instances based on the newest possible x86 processors with AVX-512 and AES-NI instructions. The second criteria is knowing that an on-premise server running this application can saturate 100Gbps per socket of DOCSIS traffic and thus would like to see instances with very high network connectivity.

Reviewing the options – and performing some baseline testing – the Compute Optimized family is most suitable for NFV generally and the vCMTS dataplane specifically because of its powerful compute capabilities. Within the Compute Optimized family is a sub-family known as "c5n" (the "n" is for networking), which pairs x86 compute from 1st Gen Intel® Xeon® Scalable Processors with up to 100Gbps of network bandwidth per instance. The instance configurations within this sub-family are shown in Figure 3.

[2] https://aws.amazon.com/ec2/instance-types/

Model	vCPU	Memory (GiB)	Instance Storage (GiB)	Network Bandwidth (Gbps)	EBS Bandwidth (Mbps)
c5n.large	2	5.25	EBS-Only	Up to 25	Up to 4,750
c5n.xlarge	4	10.5	EBS-Only	Up to 25	Up to 4,750
c5n.2xlarge	8	21	EBS-Only	Up to 25	Up to 4,750
c5n.4xlarge	16	42	EBS-Only	Up to 25	4,750
c5n.9xlarge	36	96	EBS-Only	50	9,500
c5n.18xlarge	72	192	EBS-Only	100	19,000
c5n.metal	72	192	EBS-Only	100	19,000

Figure 3 – Instance options within the c5n family[3]

All c5n instance types run on a single c5n server type that includes dual 18 core 1st Gen Intel® Xeon® 8124M Scalable Processors running at 3.0GHz (with up to 3.5GHz Turbo operation; Turbo cannot be disabled), 192GB of DDR4 memory, and a 100GBE network interface, as shown in Figure 4. The largest instances, c5n.18xlarge and c5n.metal, consume a complete server and hence are not co-resident with other c5n instances. Smaller instances consume sub-portions of the server resources and may be co-resident with other instances. Figure 5 shows the inverse relationship to the instance vCPU count to the number of such instances that will fit on a given c5n physical server. In other words, divide the total vCPU count of the hardware (72) by the number of vCPUs in an instance to calculate how many of the same instance can theoretically be deployed there.

[3] https://aws.amazon.com/ec2/instance-types/

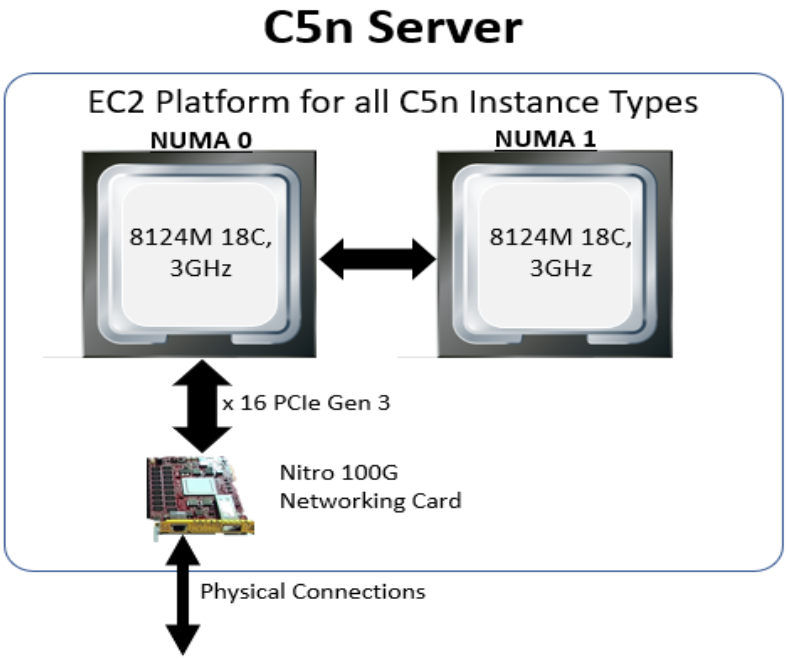

Figure 4 – AWS c5n server definition

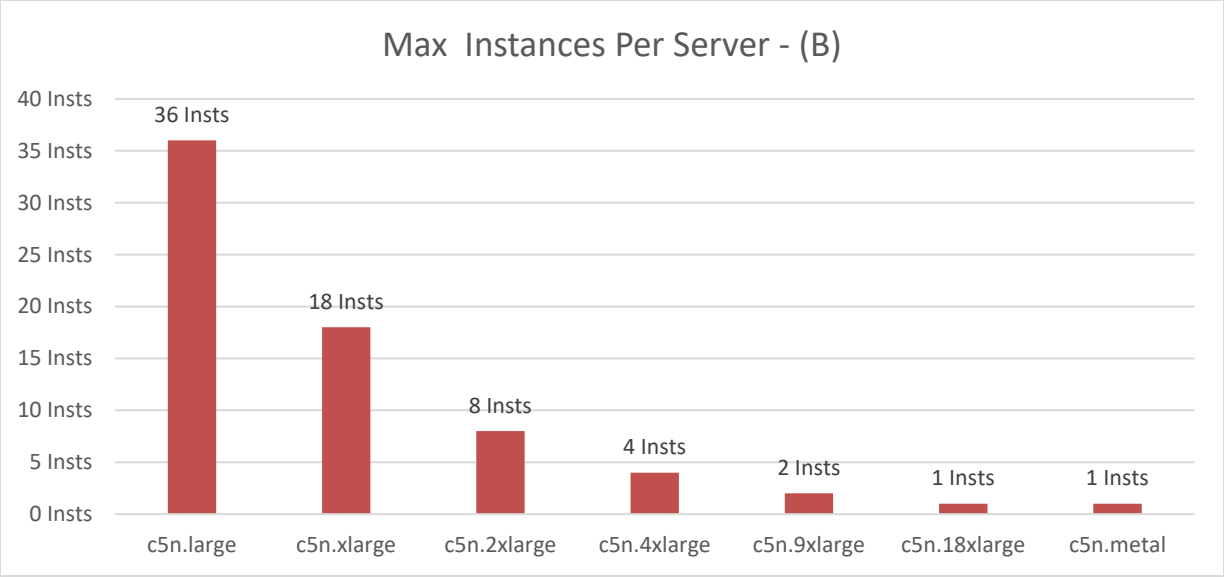

Figure 5 – Max number of instances per c5n server

Figure 3 is helpful to get a high-level understanding of the compute and memory resources per instance, however, what else can be said about the network bandwidth? This is key to set performance expectations correctly and perhaps even anticipate bottlenecks for a dataplane application. For example, is the defined bandwidth shared among other instances, are there limitations on packets per

second, are there any common packet offload features, how many ports/interfaces can be attached to an instance?

The network interfaces for the c5n family are provided through their own custom AWS Nitro System, which is a "combination of dedicated hardware and lightweight hypervisor[4]". This system includes a set of I/O acceleration cards for Virtual Private Cloud (VPC) and various storage options, a controller card that establishes a root of trust and interfaces to the control plane, and a few other elements designed for secure, accessible, and performant access to all cloud resources.

The main I/O card for network connectivity is called the Elastic Network Adapter (ENA), as shown in Figure 6. The ENA is a custom 100Gbps NIC supporting up to 15 physical interfaces (similar to VFs) per instance and up to 32 packet queues[5] per interface.

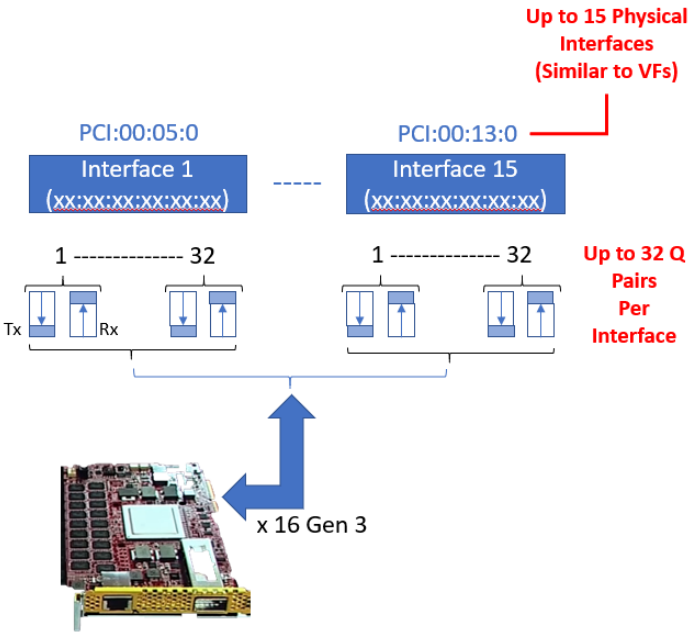

Figure 6 – Network connectivity via AWS Nitro ENA – c5n.18xlarge example

Even though all the c5n instance types make use of this 100Gbps ENA hardware, they do not have equal access to the bandwidth, the number of interfaces, the number of queues, or even if they need to share the bandwidth with other instances or not. Instances with less vCPUs and memory will have less networking bandwidth, less network interfaces (VFs), and less packet queues. This is important to note because of per-interface and per-queue performance limits that are discussed during later analysis.

Taking the public c5n instance listing and adding these key aspects for understanding the networking-related feature set yields the updated table shown as Figure 7.

[4] https://aws.amazon.com/ec2/nitro/
[5] https://aws.amazon.com/blogs/aws/new-c5n-instances-with-100-gbps-networking/

Model	vCPU	Memory (GiB)	Network Max Interfaces	Network Max Queues	Network Bandwidth (Gbps)	Network Shared or Exclusive	Number of Instances per Server
c5pn.large	2	5.25	3	96	Up to 25	Shared	36
c5n.xlarge	4	10.5	4	128	Up to 25	Shared	18
c5n.2xlarge	8	21	4	128	Up to 25	Shared	8
c5n.4xlarge	16	42	8	256	Up to 25	Shared	4
c5n.9xlarge	36	96	8	256	50	Shared	2
c5n.18xlarge	72	192	15	480	100	Exclusive	1
c5n.metal	72	192	15	480	100	Exclusive	1

Figure 7 – Adding ENA functionality to c5n instance definition

Finally, the software associated with the AWS Nitro system is generally lightweight since much of the control, management, and security of resources is done in the hardware of the various IO cards. That said, benchmarking shows notable differences in the performance of the standard ENA driver versus a standard DPDK-based PMD NIC driver and will be explored later.

Knowing how ENA resources are allocated to a given instance type along with ENA driver behavior will help explain the varied results across vCMTS benchmarking test configurations presented in subsequent sections. For example, is performance capped due to the compute capabilities of the instance, a bottleneck to and from memory, oversubscribing the ENA adapter in some way, or some other reason?

By definition, a networking application implies that data is being transported from one place to another, being "processed" (i.e., in this case, in the aforementioned cloud instances), and then, in most cases, sent somewhere else to provide some overall functionality. For this type of system, the topology of the network, complexity of the data transport layer, and location of compute resources, will all contribute to the expectations and limitations of deterministic behavior and a low end-to-end latency.

Early cloud options may have been limited, with servers and switches hosted in a far-off datacenter, but there are many more options today. As their real estate and infrastructure footprint has grown to accommodate a wide variety of workloads and markets, AWS offers compute, network, storage, and service products that can be located pretty much anywhere – including on a customer premise in various Enterprise and IOT form factors. Figure 8 shows several of the options relevant for Access network applications. The closer one gets the equipment and processing to end users, the lower possible latencies and higher potential for determinism for the application, but also the less possible abstraction and higher costs for hosting and management.

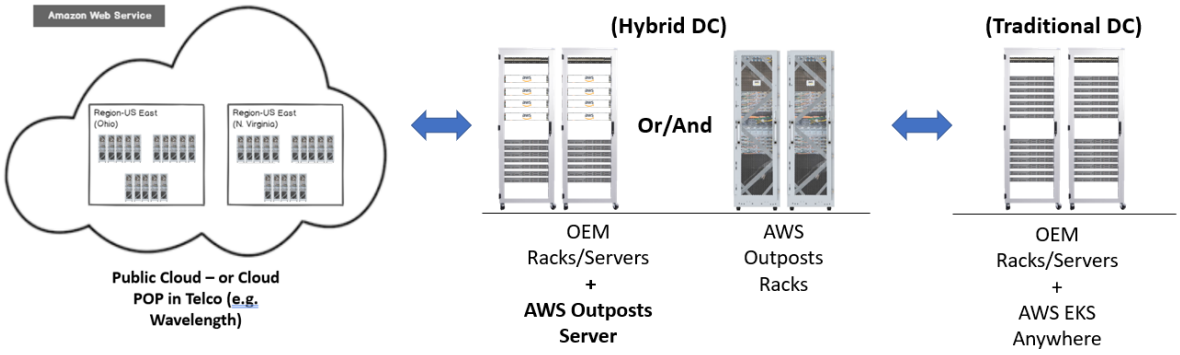

Figure 8 – AWS application continuum

AWS Regions define a physical location in the world where AWS clusters data centers[6]. Each Region is made up of so-called Availability Zones (AZs), which are one or more data centers logically connected for multiple layers of load balancing and redundancy. Some regions include ancillary Local Zones (LZs), which place AWS infrastructure and services even closer to population centers, enterprise customers, and IT centers to allow for single-digit millisecond response times. These concepts together allow for the scale, high availability, and relative localization CSP offerings are prized for and fit the needs of most applications.

But vCMTS or other Access dataplane workloads have more difficult-to-achieve requirements in terms of latency, jitter, and overall throughput than a typical Enterprise application. AWS is responding to this market by offering additional cloud deployment options. The first is called AWS Wavelength, which installs and maintains AWS equipment right inside the Edge Data Centers, Next Generation Central Offices, or Headends/Hubs owned by Communications Service Providers. This is a co-location network edge deployment model[7] and has "better together" benefits for the CSP and the network operator in being able to offer extremely low latency hosting or services for end users.

The second option, known as AWS Outposts, are packaged AWS hardware with AWS management infrastructure delivered onsite to a customer. The hardware could be a single server or a set of full racks, made for any instance type. From the technical perspective, AWS Wavelength is, perhaps, a scaled version of AWS Outposts that also includes an explicit agreement to resell or co-resell the use of this infrastructure to Enterprise customers as opposed to using to support the network directly. Given this paper focused on Access workloads (and vCMTS in particular) for an MSO, AWS Wavelength or AWS Outposts would provide approximately the same baseline performance in terms of latency and jitter.

The final option is to use non-AWS hardware running EKS, a Kubernetes offering from AWS, enabling a seamless workload orchestration across public, hybrid and private cloud. This provides an option to use

[6] https://aws.amazon.com/about-aws/global-infrastructure/regions_az/
[7] https://builders.intel.com/docs/networkbuilders/strategies-for-implementing-edge-services-in-the-10g-cable-network.pdf

familiar well proved and known quantity hardware where performance density and determinism are guaranteed while still availing of the flexibility and scalability offer by the cloud.

In short, AWS Regions, AZs, LZs, Wavelengths, and Outposts, as well as EKS Anywhere provide a gamut of options for hosting cloud instances and realizing a cloud deployment. The general interfaces and procedures to access and manage these resources is the same whether the associated server is local or (varying degrees of) remote.

In the context of the vCMTS dataplane and similar Access/Edge workloads, the main technical factors (i.e., ignoring cost) for choosing one over another are:

1. Meets or exceeds minimum required latency
2. Meets or exceeds maximum possible jitter
3. Maintains deterministic behavior for throughput/performance
4. Supports DOCSIS Time Protocol or underlying IEEE 1588 Precision Time Protocol (PTP)[8]
5. If going with onsite solution like Outpost, have the space, power, and skillset to host the infrastructure
6. Allows for required level of high availability/redundancy

Latencies and jitter are going to depend on distances, mediums, and network complexity (ex. switch hops, congestion, etc.) between the cloud site and end users. Deterministic behavior of the workload (i.e. beyond jitter on the network) will rely on having consistent access to compute, memory, and network resources with no major contention with other software applications. AWS provides several facilities for managing workload placement, which can constrain the variables for achieving solid and consistent performance. Two of these schemes are employed in this study.

The first scheme is Amazon ECS placement groups and specifically Cluster Placement Groups, which are logical groups of tasks or services[9] that can run on any type of AWS cloud location. In this way, a cluster can be defined to only run instances for the vCMTS dataplane and packet generators to achieve high and consistent throughput between deployed machine instances. Instances will be created within collocated Servers and Racks – maximizing communications efficiency. In this model is not possible to target specific servers within specific racks to host machine instances, AWS will manage the actual placement and hence actual location may vary as Instances are stopped and started.

The second scheme is the use of an Amazon EC2 Dedicated Host, which is a physical server with EC2 instance capacity fully dedicated for (one's) use. Dedicated Hosts support different configurations (physical cores, sockets and VCPUs) which allow (one) to select and run instances of different families and sizes depending on business need[10,11]. Though specifically designed for handling special Software licensing, in the context of this vCMTS dataplane analysis, it was used to run a number of c5n instances on the same physical server as shown in Figure 9.

[8] Technically DTP is part of vCMTS control plane and not strictly considered in this paper
[9] https://docs.aws.amazon.com/AmazonECS/latest/developerguide/clusters.html
[10] https://aws.amazon.com/ec2/dedicated-hosts/faqs/
[11] Note that there may be limited quantities and quotas for dedicated hosts in various regions.

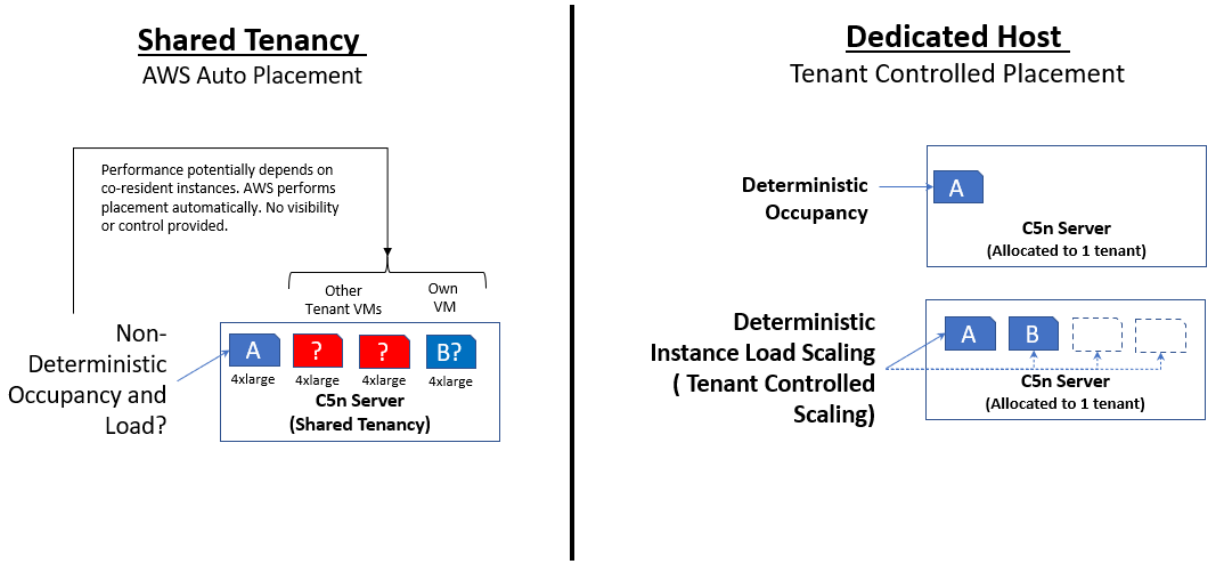

Figure 9 – AWS auto placement versus Dedicated Host

All that said, the cloud-based test setups described in the next section generally make use of AWS Regions as well as Dedicated Hosts to gather data and figure out the limits at each end of the spectrum of physical options. The other locations described in this section can be considered for future work but generally employ the exact same server hardware. As such, learnings in terms or throughput, scaling, and server capacity explored in this paper will translate to these locations too.

1.2. Application Porting and Test Setup

Intel had previously developed and released a reference vCMTS dataplane implementation to demonstrate the capability of various server hardware for the Cable Access network[12]. The reference package includes the vCMTS dataplane itself, packet generation and sink software, a cloud-native software infrastructure based on Kubernetes, and scripts for on-premise deployments. While there were some modifications that needed to be made for the cloud case (discussed later), all benchmarking was done using this vCMTS dataplane and existing packet generation software.

The on-premise tests were done on a server with the same CPU family that underlies the c5n instances – 1st Gen Intel® Xeon® Scalable Processors using the Skylake architecture. While this is an older platform than what is used for current vCMTS deployments[13], this apples-to-apples comparison makes it easier to identify underlying causes of unexpected behavior of the cloud infrastructure.

Figure 10 shows how the vCMTS dataplane and test software is deployed via Kubernetes across two different servers, one for the packet generation and sink facilities and one as the vCMTS dataplane device under test (DUT). These systems are connected back-to-back via Intel® 810 Series NICs and each SG is essentially assigned a dedicated 10GBE port (or equivalent VF). The traffic packet generation and

[12] https://01.org/access-network-dataplanes/overview
[13] https://networkbuilders.intel.com/solutionslibrary/maximizing-vcmts-data-plane-performance-with-3rd-gen-intel-xeon-scalable-processor-architecture

packet sink capabilities for a given vCMTS pod are provided by the same Traffic-Sim (DPDK pktgen) instantiation per SG.

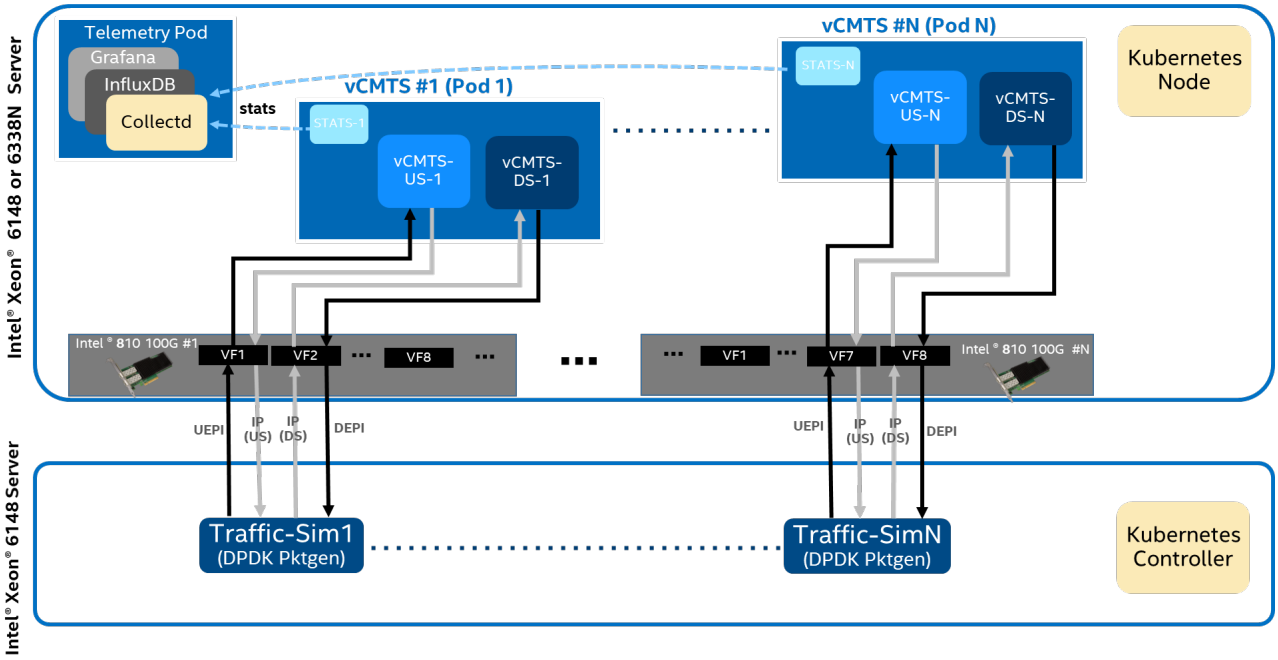

Figure 10 – On-premise vCMTS performance analysis setup

Figure 11 shows the test setup used for the AWS c5n performance analysis. At the high level, it is generally the same as the on-premise test setup insofar that the same vCMTS application and DPDK pktgen software is being used, however, there are a few key differences.

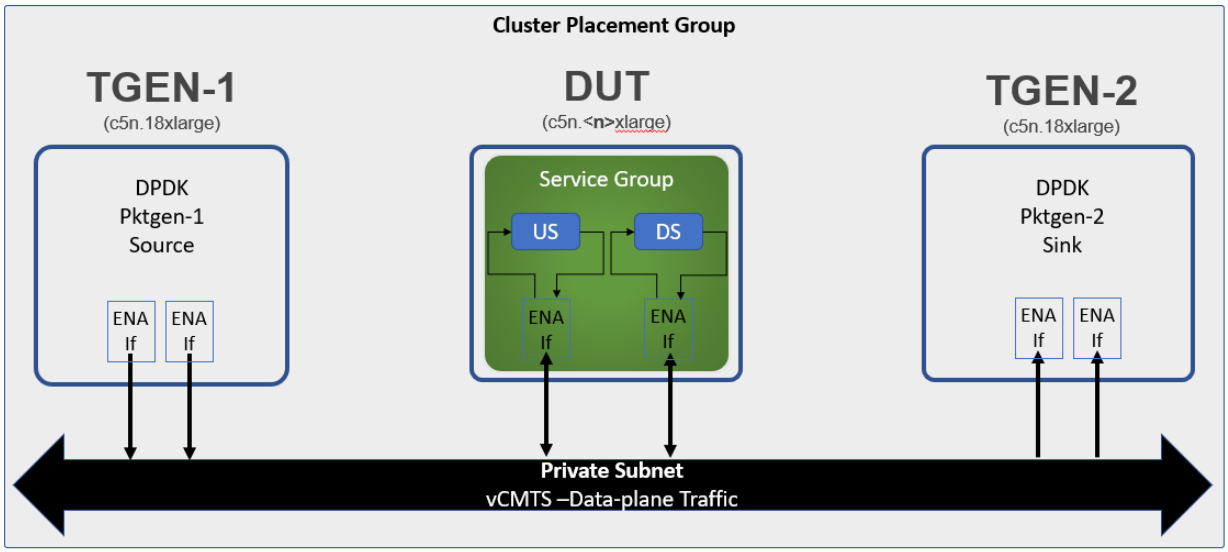

Figure 11 – vCMTS performance analysis set-up on AWS

From a system point of view, the packet generator and packet sink are running in different instances due to traffic throttling in the Nitro hardware observed during initial testing. That is, even though a single c5n.18xlarge instance has the raw compute capability to generate and receive the required number of packets, testing found there was a bottleneck through the networking sub-system that limited the bi-directional throughput. There will be more discussion of this finding later in the paper as it relates to scaling of the vCMTS dataplane itself.

On the infrastructure front, Kubernetes and the on-premise install scripts are not needed as the AWS Nitro system has its own hypervisor and application management facilities. In fact, the AWS cloud management tools were used to instantiate the desired instances and connect them via a Virtual Private Cloud (VPC) per the network diagram in Figure 12. Correspondingly, the existing reference testbed – which assumed that physical systems are connected back-to-back or through a simple switch – was modified so that L2TP tunnel and Cable-modem IP addresses were adapted to the sub-net properties of this VPC. At the network device level, the DPDK PMD for the Intel® NICs were switched to use the ENA PMD. This change also required the use of the DPDK out-of-tree IGB_UIO kernel module instead of the standard VFIO kernel module due to performance degradation with the ENA PMD.

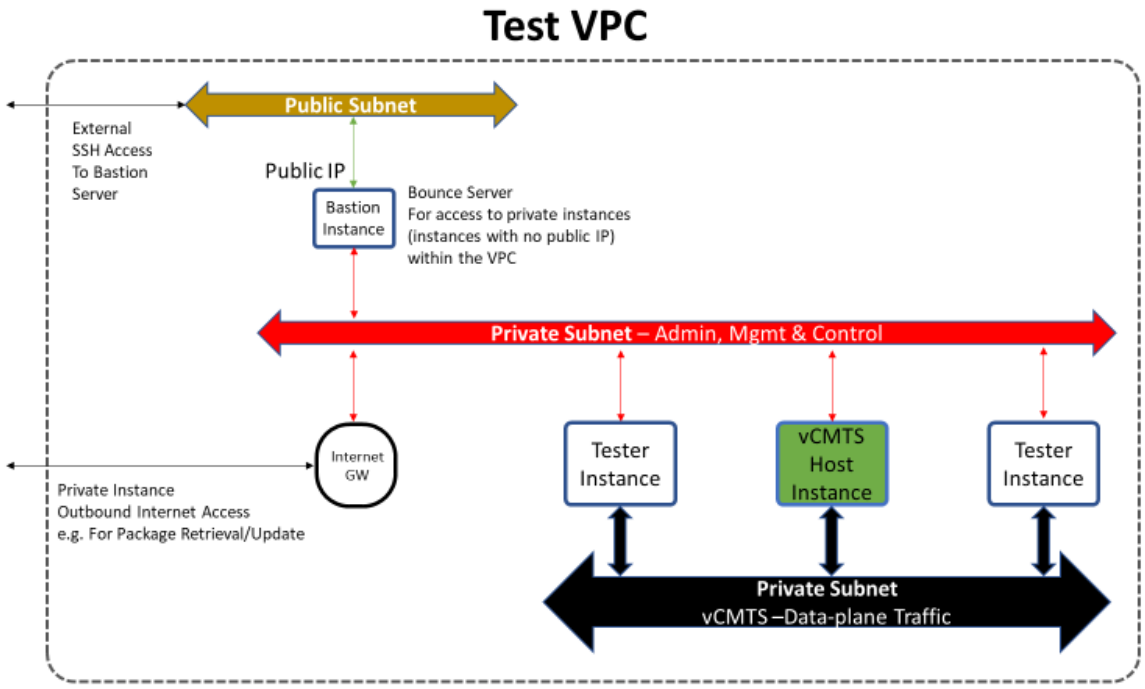

Figure 12 – VPC network architecture for vCMTS dataplane testing

All benchmarking, both on-premise and cloud setups, used the same general process as defined by RFC-2544[14], but limited to steady state load testing across a wide variety of packet sizes. In addition to the packet sizes recommended by RFC-2544, an iMix representative of MSO network traffic was also employed to replicate real-world circumstances. All tests were bi-directional in nature (i.e., sending traffic in both upstream and downstream directions simultaneously) and maximum throughputs were measured under zero packet loss conditions. Upstream traffic was configured to be a minimum of 10%

[14] https://datatracker.ietf.org/doc/html/rfc2544

of Downstream traffic for cloud performance tests. All tests employ the same number of (virtual) cable modems and use the same filter rules. In some situations, supplemental data, like per-pipeline-stage CPU cycle-counts, were captured later to the original test to help explain certain observations. Such data will be discussed in the relevant sections below.

2. Single-SG Throughput Analysis

Initial testing established single-SG performance across both the on-premise systems and the following AWS c5n instance types: c5n.metal, c5n.4xlarge, and c5n.2xlarge. The SG was chosen as the base unit of interest because a vCMTS dataplane would be scaled across vCPU cores based on the number of service groups required for a given network footprint.

Since all c5n instances make use of the same c5n server hardware it was expected that the single-SG performance would be similar across instances. It was also expected that this cloud performance would be similar to what is achievable on the on-premise platform. In both cases, there were surprises.

2.1. Comparing Instance Behavior to On-Premise

As mentioned in Section 1.2, bi-directional upstream and downstream throughput was measured for each test configuration with zero packet loss with traffic of several packet sizes and iMix types. Figure 13 plots the results for a c5n.metal instance.

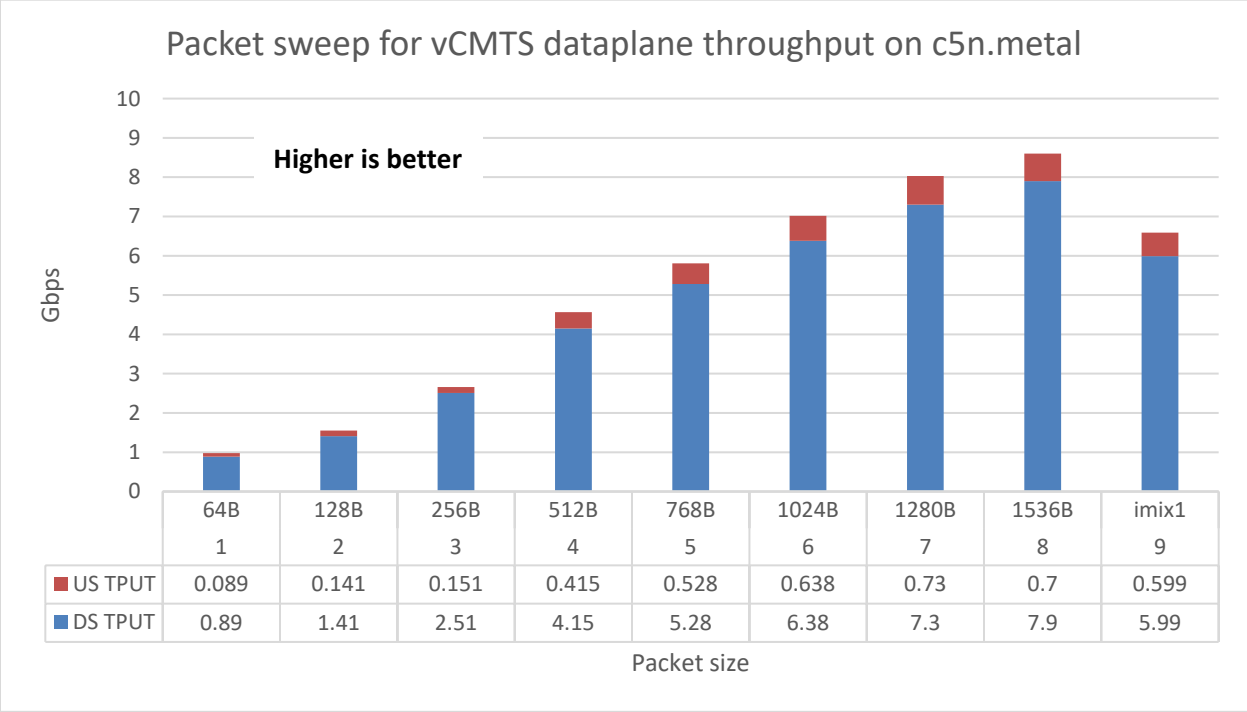

Figure 13 – Max bi-directional throughput for single vCMTS SG (c5n.metal)

The performance variance across packet sizes is expected and is a common phenomenon among any network function because smaller packet sizes at a certain network speed give less time to process that packet than larger ones. This behavior is seen in the other instances and both the on-premise platforms.

Since looking at any given packet size will yield the same themes, from here the analysis will use iMix data only. Figure 14 shows the iMix upstream and downstream aggregate throughput results across all tested instance types and on-premise platforms.

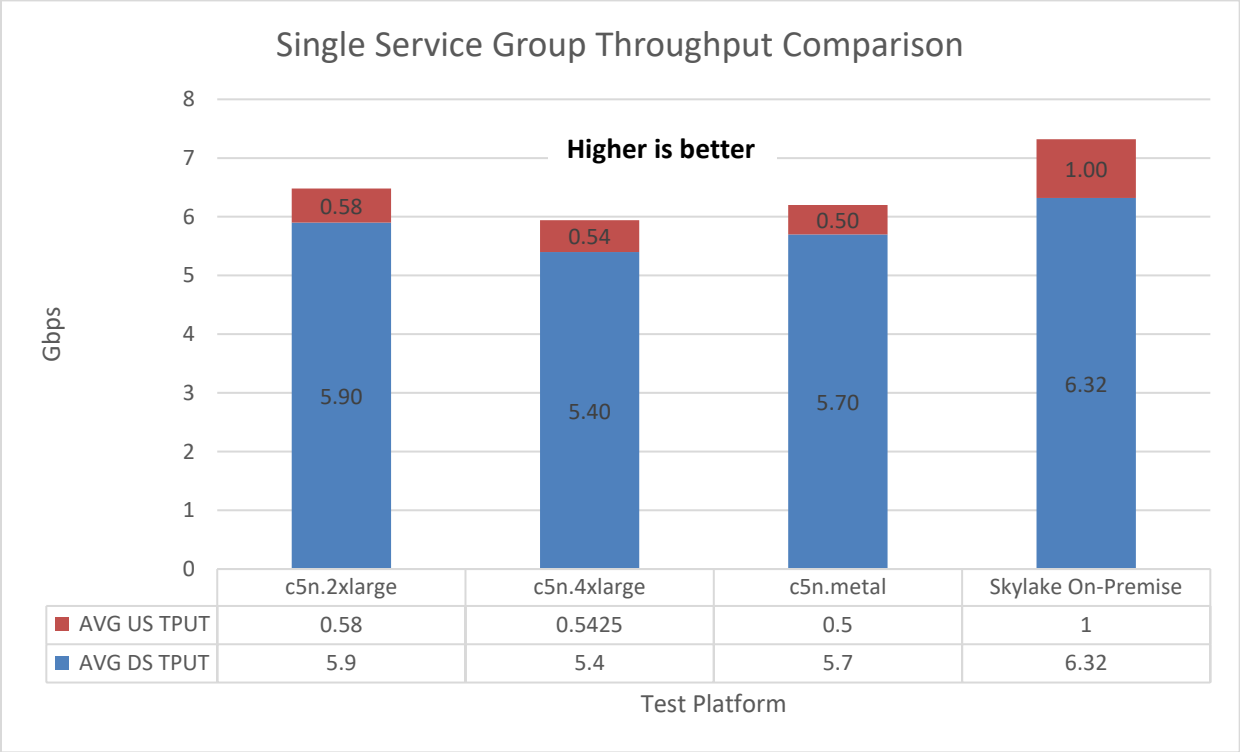

Figure 14 – Comparing per-SG vCMTS Dataplane Performance for iMix

The first observation is that the on-premise solution yielded the best performance at 7.32 Gbps of total upstream and downstream throughput. This was 13% better than the best cloud instance (c5n.2xlarge) at 6.48 Gbps. The result is surprising given that the cloud instances are running on CPUs with a higher base clock frequency than the CPU in the on-premise system, and the fact that the cloud instances may be able to take advantage of CPU Turbo operation for an even bigger boost (the on-premise servers disable Turbo in the name of determinism). Without mitigating factors in the memory or network, the performance of the vCMTS dataplane tracks linearly with the CPU speed. Thus, the cloud instances running at a minimum of 3.0GHz should get 25% better throughput than the 2.4GHz on-premise servers, but instead they are far in deficit.

How to explain this difference?

To answer this question, CPU cycle counts for each stage of the DOCSIS MAC pipeline were collected for both on-premise and cloud instance test systems. This was done in runs separate from the throughput measurements so one test did not affect the other. Figure 15 compares the results and sheds light on where each system is spending its CPU budget.

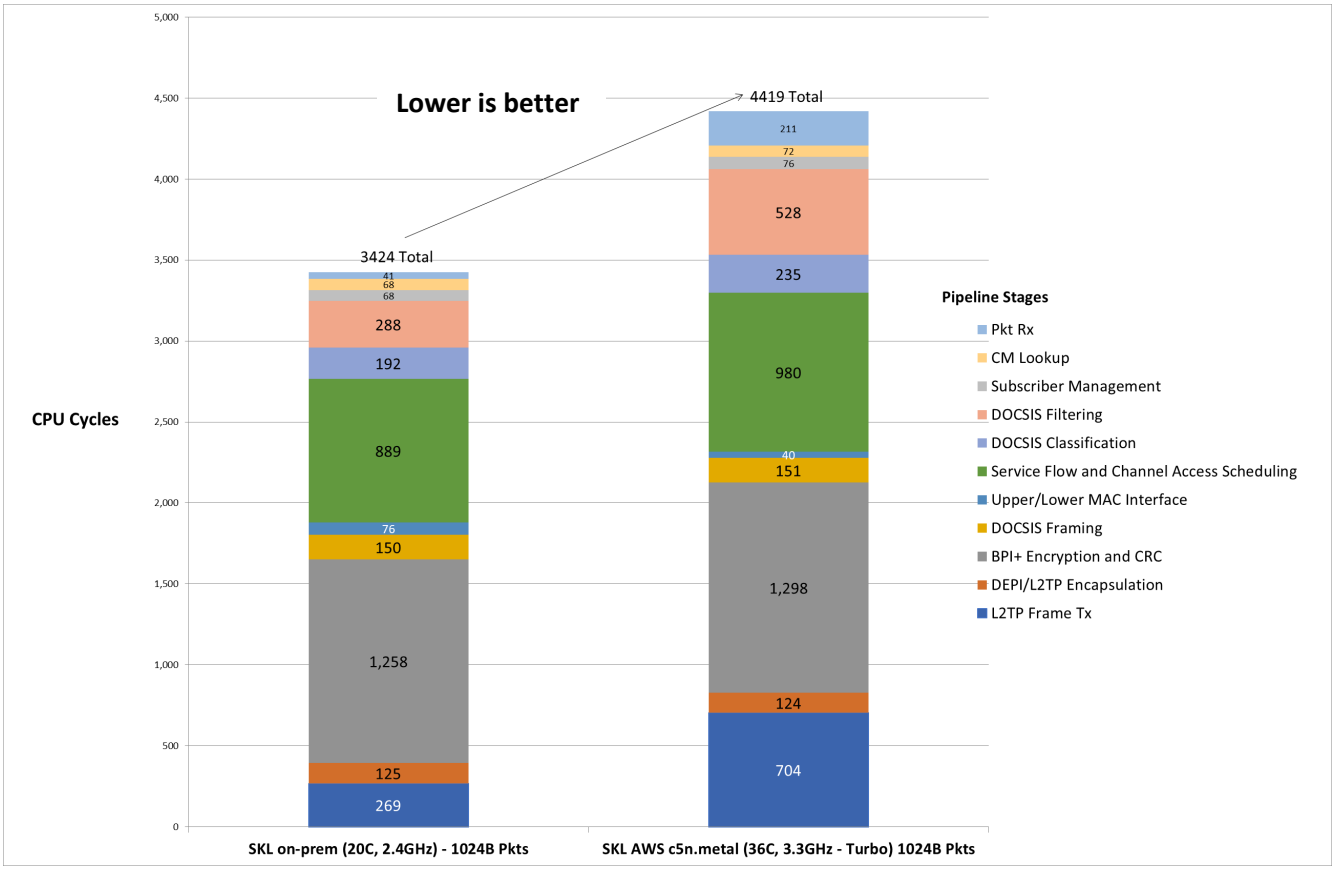

Figure 15 – DOCSIS MAC downstream CPU cycle count comparison – On-premise vs Cloud

Many of the pipeline stages have similar cycle counts. This means that both the cloud instances and the on-premise servers spent equal amounts of compute capability in those stages. However, the c5n instances took over 400%, 160%, and 150% longer in the packet receive, the packet transmit, and the DOCSIS filtering stages, respectively. Together this accounts for 29% more cycles and thus would process 29% less packets without even accounting for other possible bottlenecks.

The software part of the AWS Nitro system is generally lightweight; however, this data indicates that the ENA networking driver has quite a bit more overhead for basic receive and transmit functionality than a typical DPDK PMD in Linux. It is not clear what portion of this overhead can be won back with optimization to the ENA software driver or Nitro hypervisor (by AWS) and what portion is due to immutable behavior in the ENA/Nitro hardware itself.

The additional cycles for the DOCSIS filtering stage are not fully explained insofar that all tests use the same number of cable modems and the same filtering rules (i.e., parameters that are known to change the processing needs of this algorithm), but the current theory is that the significantly greater number of CPU cycles spent on packet receive is having some secondary effect on a shared resource in the CPU, for example, the L3 cache, instruction pipelines, or memory controller, and causing additional latency through the system.

The other main observation from Figure 14 is that the throughput was not consistent across the cloud instance types even though they are all running on the same underlying hardware and the throughput for a single service group should not be saturating the available network bandwidth. The c5n.2xlarge and c5n.metal data is approximately the same, within 5% variation, but the c5n.4xlarge performance was more than 10% worse.

2.2. Use of AWS Dedicated Hosts

Given that all c5n instances run on the same physical hardware and do not hit hard vCPU, memory, or network constraints to support a single SG, what could be the reason for the c5n.4xlarge performance difference? Looking back at Figure 5, four c5n.4xlarge instances can be instantiated on a given c5n server at any one time, and there are no guarantees where a given instance will be scheduled within an AWS Region (even if employing clusters). In other words, there could be other workloads from other AWS customers trying to make use of the same CPU L3 caches, memory, network interfaces, and other shared resources critical to vCMTS dataplane performance running on the same c5n server. These types of applications are known as noisy neighbors.

Per Section 1.1, AWS does provide a way to limit noisy neighbor risk via an AWS EC2 Dedicated Host. With a Dedicated Host, a customer reserves a whole server type (in this case a c5n) for themselves and therefore has full control on what instance types will be deployed there and what workloads will be running within those instances. Figure 16 shows how the initial single-SG test setup was modified from the original of Figure 11 to incorporate a Dedicated Host running the vCMTS dataplane in a c5n.4xlarge instance.

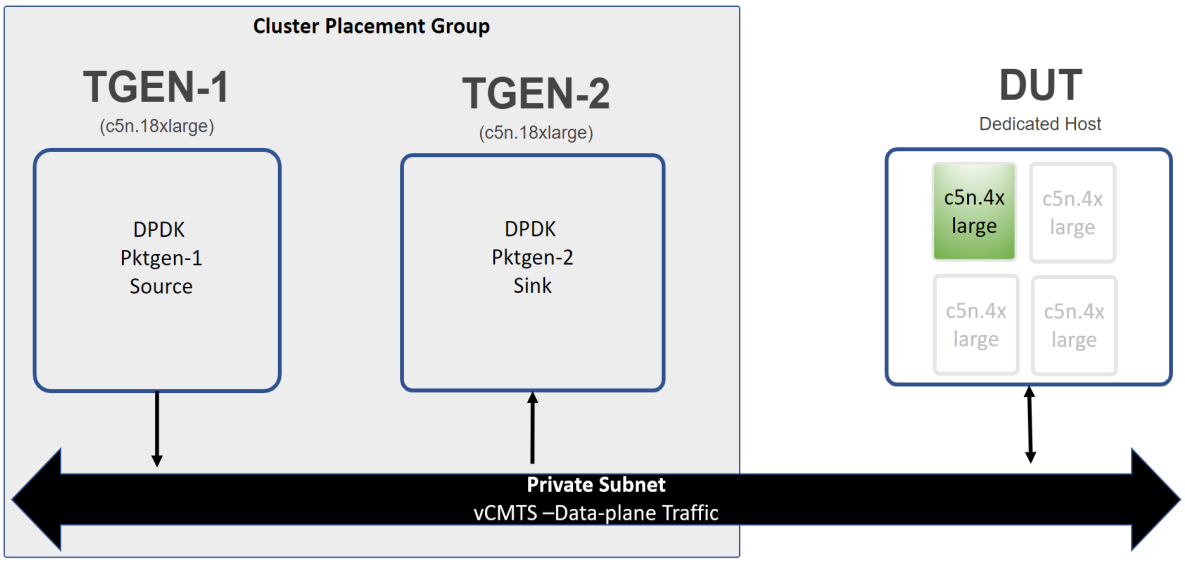

Figure 16 – vCMTS test setup with Dedicated c5n Host

Figure 17 shows the new c5n.4xlarge single-SG throughput test results alongside all the previous data.

Figure 17 – Affect of using a dedicated host on per-SG Performance

It is clear that using the Dedicated Host helped bring the c5n.4xlarge results in-line with the performance of the other c5n instance types, for example, within 1% of the c5n.metal bi-directional throughput. By definition a c5n.metal instance takes up a whole c5n server, so it makes sense that the behavior of a single known application in that environment would be consistent. However, in the c5n.4xlarge case, there are no guarantees on where and how AWS will schedule such instances in real time from any customer.

It is interesting to note, anecdotally, that during the initial single-SG cluster-based testing the c5n.4xlarge throughput would be in line with the performance of the other instances as if it was running on a Dedicated Host. However, it was uncommon and there was no discernable pattern to when the throughput would be higher and when it would be lower. A network operator cannot rely on a random best-case scenario when dimensioning cloud resource needs for critical Access infrastructure.

That said, why did the testing not show this same behavior in the c5n.2xlarge instance case? It, too, can share a c5n server with other instances; per Figure 5 a c5n server can host up to 8 c5n.2xlarge instances and chances are that at some point there will be a noisy neighbor application running in one of them. Without knowing the full details of the AWS instance scheduler, the main lesson is that without full control of the hardware performance cannot be guaranteed. With enough tests it is expected that the c5n.2xlarge instances would also see the same performance variability as measured in the c5n.4xlarge case.

Why wouldn't a user always employ a Dedicated Host then? While the benefits are clear, there are some trade-offs to using this type of cloud infrastructure that would need to be factored into a total cost of ownership calculation. First, AWS limits the number of dedicated hosts per account to two per AWS

Region. Perhaps exceeding that stated limit is due to the fact they their original intention is to support legacy software licensing models, or perhaps it puts the user into the realm of deploying their own AWS Outpost servers? Regardless, it is not an approach that scales on its own. In addition, for every dedicated host available a user will pay a higher per time unit fee versus equivalent EC2 product offerings (ex. c5n.metal) at the time of this writing[15].

While it was not originally designed for networking applications, the AWS Dedicated Host concept is very useful for workloads that prize deterministic behavior and/or have hard requirements on system resources to achieve key performance indicators (KPIs). However, their utility for large scale deployments may be limited due to higher cost and capacity constraints.

3. Per-Instance Throughput Analysis

The per-SG analysis uncovered functional differences between c5n instance types and comparable on-premise solutions for the vCMTS dataplane and subsequently, insights into the c5n hardware itself, how those servers are shared among multiple customers, and key insights for managing performance expectations.

The next phase of testing is designed to determine the following for each c5n instance type:

1. Scaling capability (i.e., throughput per SG)
2. Maximum throughput possible via multiple SGs
3. The limiting factor for performance (ex. vCPU, memory, networking)

This information will be used to deepen the technical understanding of each instance type and, ultimately, to plan effective vCMTS dataplane application scaling strategies.

3.1. Finding Performance Limitations

This scaling analysis uses the same testing set up that was used for the single-SG benchmarking. Data will be collected from c5n.metal, c5n.4xlarge, and c5n.2xlarge instance types, as well as the on-premise platform. In the ideal case, good scaling means that the throughput per SG stays as constant as possible as more SGs are added into the system. However, the reality is that the scaling is typically non-linear, in the negative direction, for any system with shared resources such as all of these under test.

The vCMTS dataplane reference application requires two network interfaces per SG (one for upstream and one for downstream), so the maximum number of SGs for a given instance type is the total number of network interfaces minus 1 for an administration port, then that number divided by two. For example, the c5n.4xlarge instance is allowed up to 8 total interfaces, so with 1 interface used up for administration, the maximum possible number of SGs for that setup is 3.

Figure 18 and Figure 19 below show maximum service-group scaling for c5n.metal and c5n.4xlarge instance types, respectively. The data for the c5n.4xlarge instance type was collected using the standard cluster setup versus using a Dedicated Host. Scaling data is not shown for the c5n.2xlarge instance since its 4 network interfaces limit it to supporting 1 SG at a time.

[15] https://aws.amazon.com/ec2/pricing/

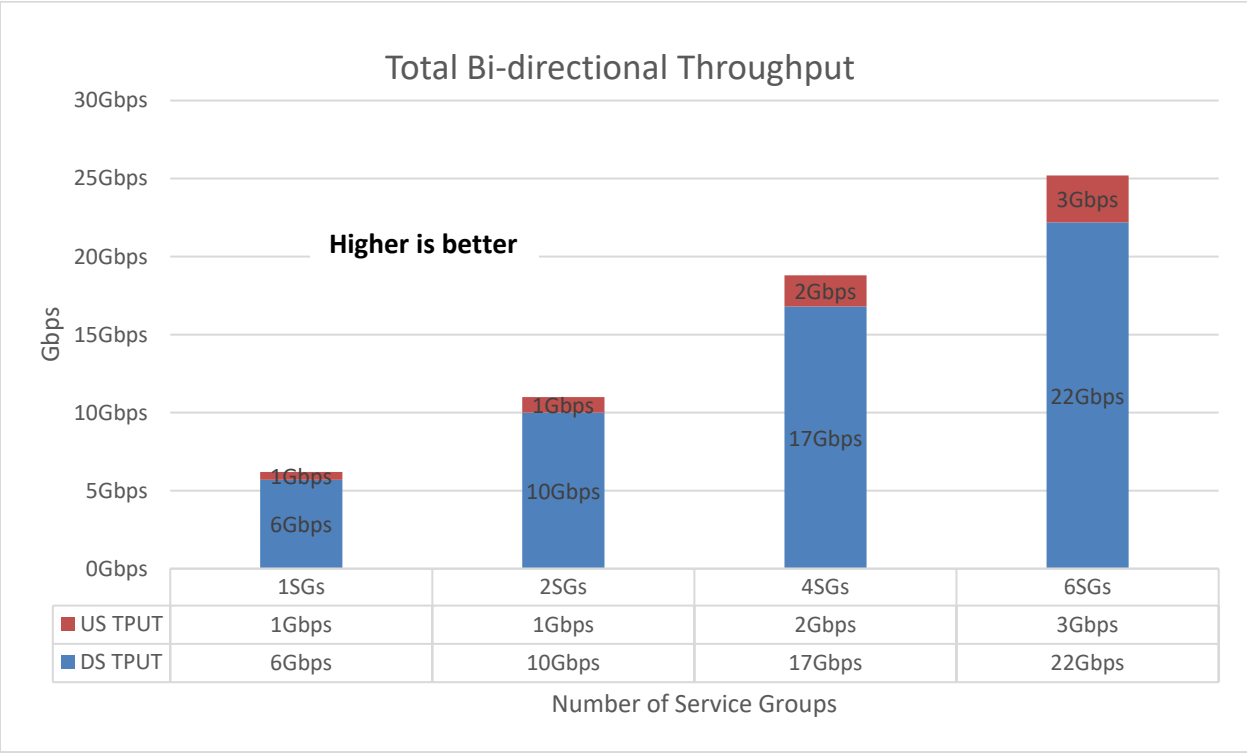

Figure 18 - Max bi-directional throughput for vCMTS service-group scaling (c5n.metal)

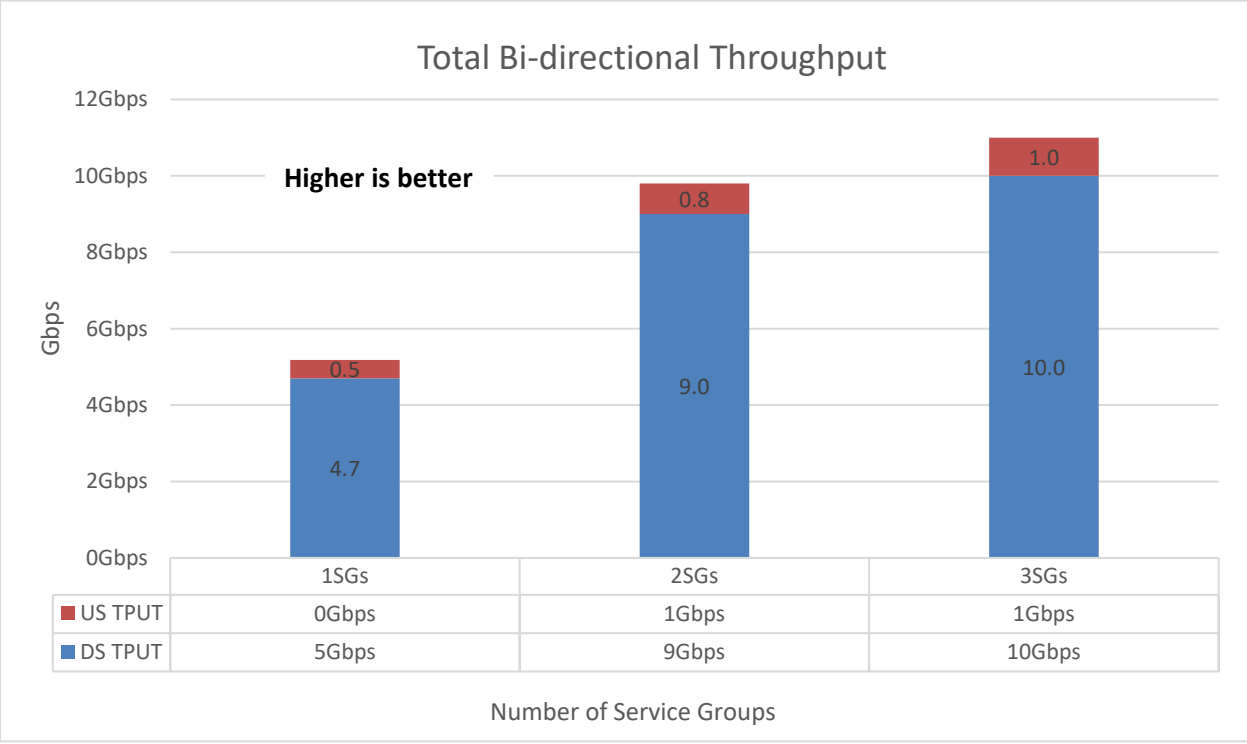

Figure 19 - Max bi-directional throughput for vCMTS service-group scaling (c5n.4xlarge)

The total bi-directional throughput of the c5n.metal instance shown in Figure 18 is not linear, but it tracks similarly to an on-premise solution insofar that it gets progressively worse as more SGs are added. The data points start at a single SG achieving 6.2 Gbps, then going to 2 SGs at 5.5 Gbps each and 4 SGs at 4.7 Gbps each, finally landing at 4.2 Gbps per SG in the 6 SG case. With 3 vCPUs supporting each SG, only 18 vCPUs were used out of the 72 available to achieve the total 25.2 Gbps bi-directional throughput for this instance type. Thus, the maximum throughput per instance is limited by the number of networking ports. Each additional two ports would allow the addition of another SG.

The story is different in the c5n.4xlarge case. There is decent scaling up to 2 SGs, with the throughput per SG at 5.2 Gbps and 4.9 Gbps in the 1 SG and 2 SG cases, respectively. However, the total throughput for the instance seems to be capped at about 11 Gbps, devastating the throughput per SG in the 3 SG case (bringing it down to 3.67 Gbps per SG). Prior testing showed that each network interface can only pass a maximum of ~4.0Mpps bidirectional or ~9.0Mpps unidirectional traffic, so total throughput for the system will be limited for small packet sizes. The iMix traffic in this testing averages ~1000 bytes in the downstream direction and ~300 bytes in the upstream direction and thus well outside of realm of possibility for saturating the theoretical 25 Gbps network bandwidth for the c5n.4xlarge instance type.

Bringing the on-premise platform into the picture, Figure 20 compares c5n.metal instance scaling to on-premise scaling and highlights the reasons for a huge difference in overall performance.

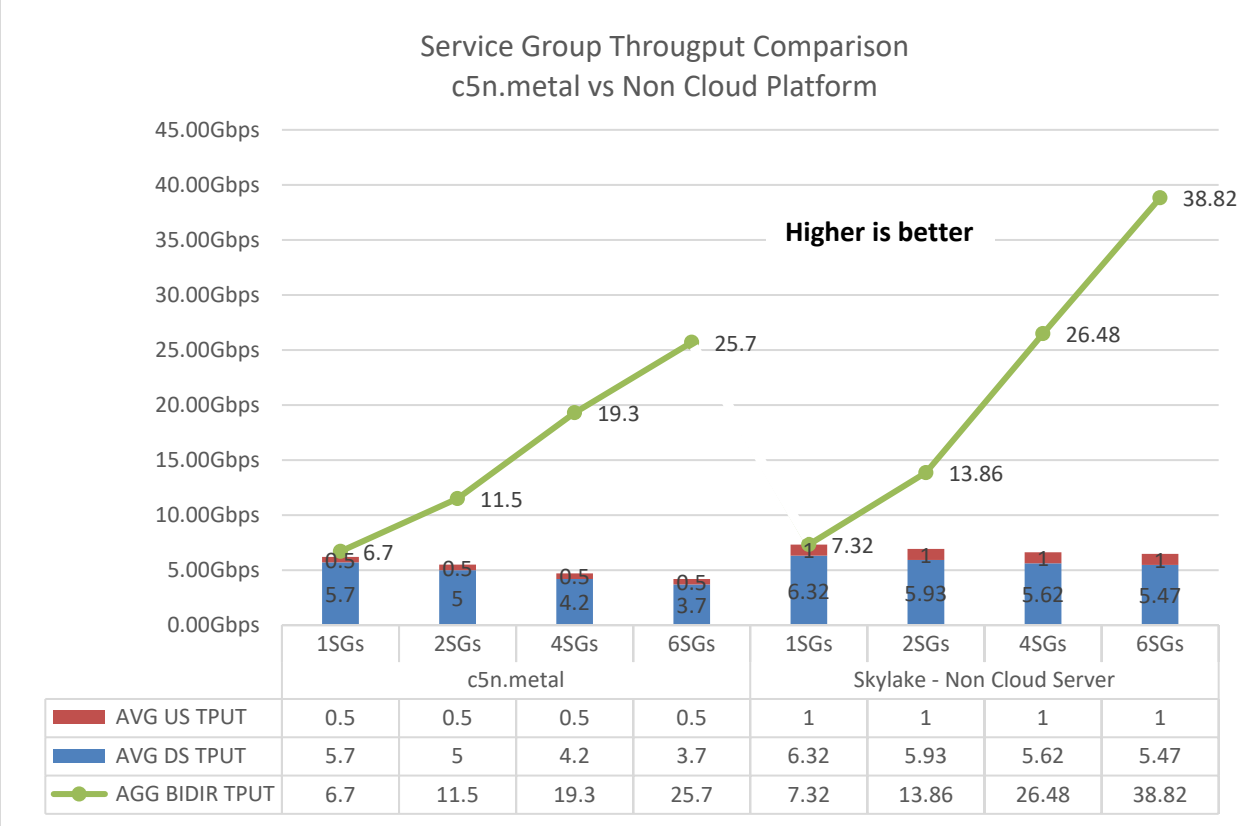

Figure 20 – Comparing on-premise to cloud scaling

There are three reasons why the on-premise platform scales better and achieves much higher overall performance than the c5n.metal instance. First is that the number of vCPU cycles needed per packet is

much higher for c5n instances due to large receive and transmit overhead in the ENA driver as described in Section 2.1. Second, the slope tracking the aggregate bi-directional throughput for the on-premise case in Figure 20 is much steeper versus the one tracking the c5n.metal performance, meaning that its average throughput per SG goes down at a slower rate (as seen in the per-SG bars). Finally, per prior analysis[16], the on-premise solution is only limited by the number of vCPUs and the amount of L3 cache; in the case of the Intel® Xeon® 6148 Scalable Processor with 20 physical cores (40 vCPUs) and 27.5 MB of L3 cache, the total achievable throughput per server with two sockets is ~100Gbps versus the ~25 Gbps for the c5n.metal case.

The main take-away is that the maximum vCMTS dataplane throughput for every c5n instance type is being limited by the networking sub-system. Specifically, the c5n.metal instance is limited by the number of networking ports and the c5n.4xlarge instance is limited by maximum packets per second in the ENA. Either way, this means that c5n instances, as defined today, have a mismatched compute-to-networking ratio and thus cloud resources that are being paid for (i.e., vCPUs) are not being used when the system is targeted at network-heavy applications.

3.2. Breaking Through Per-Instance Bottlenecks

Looking for clues in Figure 7, the compute to networking mismatch can be minimized with careful planning across multiple instances. In other words, can the c5n.metal bottleneck due to lack of network ports be solved by deploying multiple other c5n instance types with a better vCPU to port ratio (even if those instances have different per-instance limitations of their own)?

Figure 21 illustrates the example by comparing a single c5n.metal instance to four c5n.4xlarge instances, both of which fully occupy a single c5n server. These two system configurations are cost-equivalent in the financial sense, but also in terms of having the same amount of aggregate network bandwidth (100 Gbps) and a similar number of vCPUs (72 and 64). However, due to the greater total number of network ports available, the four c5n.4xlarge set up can support up to 12 SGs while the c5n.metal instance is limited to 7 SGs.

[16] https://networkbuilders.intel.com/solutionslibrary/maximizing-vcmts-data-plane-performance-with-3rd-gen-intel-xeon-scalable-processor-architecture

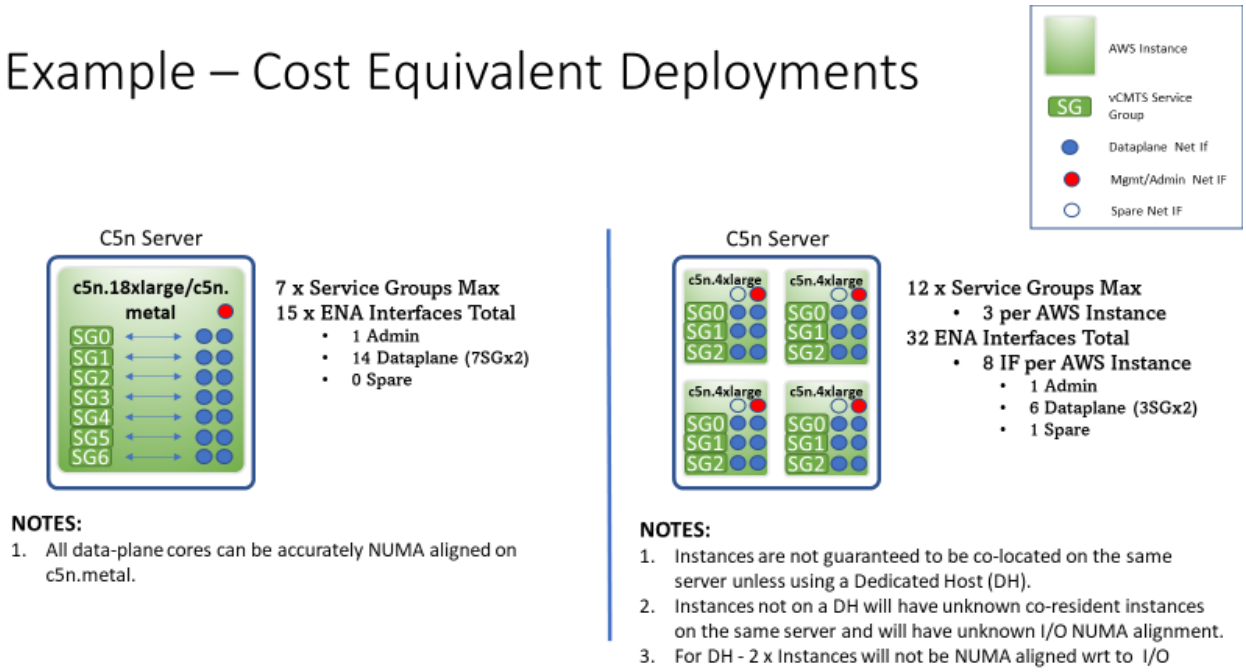

Figure 21 – Example of cost equivalent c5n instance configurations

Per the scaling data in the previous section, each c5n.4xlarge instance has a maximum possible throughput of 11 Gbps and therefore the maximum theoretical throughput for this system is 44 Gbps vs the 25.7 Gbps measured for the c5n.metal instance, a possible 71% improvement.

Taking the effect of real-life scaling factors into account, Figure 22 shows the total throughput measurements of two c5n.4xlarge instances. And while there is some degradation from the theoretical maximum, the data still demonstrates how compelling this approach can be. Note that due to organizational logistics (i.e., not any issue with the AWS infrastructure), benchmarking was completed with only two of the full four instance configuration.

	DUT_1 = 4SGs	DUT_1 = 6SGs	DUT_1 = 1SG, DUT_2 = 1SG	DUT_1 = 2SG, DUT_2 = 1SG	DUT_1 = 2SG, DUT_2 = 2SG
	1 Instances c5n.metal Cluster Placement		2 Instances c5n.4xlarge Dedicated Host		
AVG US TPUT	0.5	0.5	0.55	0.48	0.45
AVG DS TPUT	4.2	3.7	5.5	4.8	4.5
AGG BIDIR TPUT	19.3	25.7	12.1	15.84	19.8

Figure 22 – Throughput of two c5n.4xlarge instances to one c5n.metal

Starting with these measurements of 19.8 Gbps for two c5n.4xmetal instances supporting 2 SGs each, we see a 10% scaling penalty to the theoretical maximum of 22 Gbps. Conservatively assuming a further scaling penalty of 15% when going from two to four c5n.4xlarge instances, one could expect up to 33.6 Gbps of bi-directional traffic, which is over 76% of the theoretical maximum and still a 30% improvement over the c5n.metal capacity at the same cost.

Table 1 summarizes the vCMTS dataplane performance for each test setup alongside the resource usage for each scenario to give an idea of the constraint that is causing the bottleneck. It also calculates what percentage of the instance resources are being used and what is left unused – specifically for the vCMTS dataplane at least.

Instance Type	vCPU	Ethernet	Ports	Maximum vCMTS tput	Tput limitation	Used Resources	Unused Resources	% Unused Resources
Single c5n.metal	72	Shared 100G	15	25.7Gbps with 6 SGs	Number of ports	18 vCPUs, 25.7Gbps, 12 ports	54 vCPUs, 74.3 Gbps, 3 ports	75% vCPUs, ~74% network

Four c5n.4xlarge	64	Shared 100G	32	33.6 Gbps[17] with 12 SGs	pps per instance	36 vCPUs, 33.6 Gbps, 25 ports	28vCPUs, 66.4 Gbps, 7 ports	~43% vCPUs, 66% network
Two c5n.4xlarge	32	Shared 50G	16	19.8 Gbps with 6 SGs	pps per instance	18 vCPUs, 19.8 Gbps, 13 ports	14 vCPUs, 30.2 Gbps, 3 ports	~43% vCPUs, ~60 Gbps network

Table 1 - Scaling via multiple smaller instances

Clearly, aggregate performance of four c5n.4xlarge instances (based on the measurements from two c5n.4xlarge instances) is better than a single c5n.metal instance from both absolute throughput and percentage of resource usage perspectives. This configuration drives better utilization of vCPU cores by having a greater aggregate number of network interfaces to work with. That said, all c5n platforms used for vCMTS dataplane applications will not make use of all available compute and network capability.

So, what can be done with those unused resources? First, given that one type of bottleneck to scaling is the number of Ethernet ports per instance, a software vendor could modify the workload to use less ports overall. For example, the vCMTS dataplane application dedicates a port for US and a port for DS for every SG to optimize its transmit and receive logic, but this scheme could be modified to make better use of this constrained resource. Even if the new code to manage port usage adds more cycles per packet, the change would be well worth the effort in terms of maximizing overall throughput.

Second, unused vCPUs could be used for applications that do not require network access and do not otherwise interfere with the vCMTS dataplane resources, for example, to pre-process network or system telemetry. Alternatively, those unused vCPUs could be used in a high availability scheme, with backup vCMTS dataplane instantiations pointed to relevant databases and network ports but not actually processing packets until the primary applications fail.

No matter what is done with resources unused by the vCMTS dataplane, this testing shows that it is possible to use multiple smaller instances (in this example, c5n.4xlarge) to overcome sub-optimal compute-to-networking ratios and achieve better total bi-directional throughput for c5n-based infrastructure.

4. Conclusions

There is a lot of interest in moving applications found in the modern network into cloud infrastructure for all the typical reasons: offloading deployment and configuration of hardware, managing all infrastructure and over the top services though a consistent pane of glass, and having all needs for scale and multiple levels of redundancy taken care of by someone else. These are good and compelling reasons.

However, not all applications are created equal; each one must be evaluated to see if it makes financial, business, and technical sense to move from on-premise equipment to the cloud. This paper focused on only technical considerations related to making best use of cloud infrastructure for vCMTS dataplane

[17] Four c5n.4xlarge performance estimated based on the two c5n.4xlarge lab measurements

processing, with its challenging requirements for high throughput, cryptographic elements, low latency, and consistent performance, and leaves the rest to other venues. Only AWS product offerings were evaluated in this context, but the same methodology and criteria can be used to choose the best cloud infrastructure from any CSP.

The results were clear that even though the AWS c5n family of cloud instances was shown to be best among AWS offerings because of its high capability with Intel® Xeon® Scalable Processors paired with 100 Gbps network interfaces, there is a huge gap in their performance relative to a similar on-premise deployment. Per testing, there is too much overhead and a lack of performance guarantees that make it costly or operationally prohibitive to widely deploy the vCMTS dataplane to the cloud.

That said, AWS and other CSPs are continually innovating and introducing new cloud products; it is inevitable that they will address some of the observations described in this paper:

- Networking capability was not matched to the compute capability, limiting overall throughput
    - Networking ports per instance was generally too low
    - Compute cycles to support packet receive and transmit on the ENA was too high
    - Published bandwidth capacities had too many caveats to achieve in real-world tests (ex. packet per second limitations in the ENA capped iMix performance)
- Lack of resource isolation and/or control of workload placement leads to non-deterministic performance

A cloud instance (or rather, family of instance types) that addresses these issues would increase overall system performance, reduce custom software development efforts, assure customers with expected and consistent behavior, and generally give maximum value to the resources and services a network operator is purchasing to run an important part of their network.

In the meantime, even if not suitable for a large-scale vCMTS deployment, the convenience of cloud infrastructure still makes it interesting for other use cases, including the expansion of test capability, the enabling of remote collaboration, as a temporary solution for surge traffic, or to expand fail-over capacity.

Again, the most value from this work is in the education and process. The particulars (ex. test data for a c5n instance type) may have a limited lifespan, but the evaluation framework will help network operators make informed decisions on CSP offerings for any dataplane applications they are looking to move into the cloud now and into the future. On the flip side, it may help a CSP create the perfect cloud product optimized for the Access network.

4.1. Future Work

While cloud infrastructure in various forms has been around a long time and has proven its value in many business arenas, it is still early days for applying its underlying technologies and processes to the high demand needs of Access and Edge workloads like the vCMTS dataplane used in this study. There are many compelling topics in this domain demanding further research; some of these are: to expand this analysis to future AWS offerings (especially the next generation of the c5n family), to expand this analysis to similar products from other CSPs, to study questions around latency in the network by, for example, varying the location of the packet generator and sink relative to the dataplane function, and evaluate cloud offerings for vCMTS control plane needs.

Abbreviations

AWS	Amazon Web Services
AZ	AWS availability zone
bps	bits per second
CMTS	cable modem termination system
CoSP	communications service provider
COTS	commercial off the shelf
CSP	cloud service provider
DAA	distributed access architecture
DPDK	data plane development kit
DTP	DOCSIS time protocol
DUT	device under test
ECS	AWS elastic container service
ENA	AWS elastic network adaptor
KPI	key performance indicator
ML	machine learning
MSO	multi service operator
NIC	network interface card
PCIe	PCI Express
PMD	poll mode driver
pps	packets per second
PTP	IEEE 1588 precision time protocol
SCTE	Society of Cable Telecommunications Engineers
SG	service group
TCO	total cost of ownership
VF	virtual functions (in context of a PCIe device)
VPC	virtual private cloud

1. Introduction

By now the convergence of service signals over one digital MSO network needs no further motivation. Over the last some years there have been resources to describe the financial and engineering benefits of this transition (Chamberlain, 2017), (BAUMGARTNER, 2019), (Chamberlain, 2017).

In this paper we turn to the mechanism for creating the right form of infrastructure to make convergence an implementable reality. According to (Chamberlain, 2017) there are three requirements to make convergence successful: powering, backhaul and site availability. We find this a good generalization where power refers to the active power availability in the MSO outside plant, and site availability implies the fiber, coax, and pole access real estate to work with. In this paper we focus particularly on the backhaul section for successful convergence, which includes the connectivity of hubs and customer endpoints with the recent differentiator of digital fiber, see Figure 1 below.

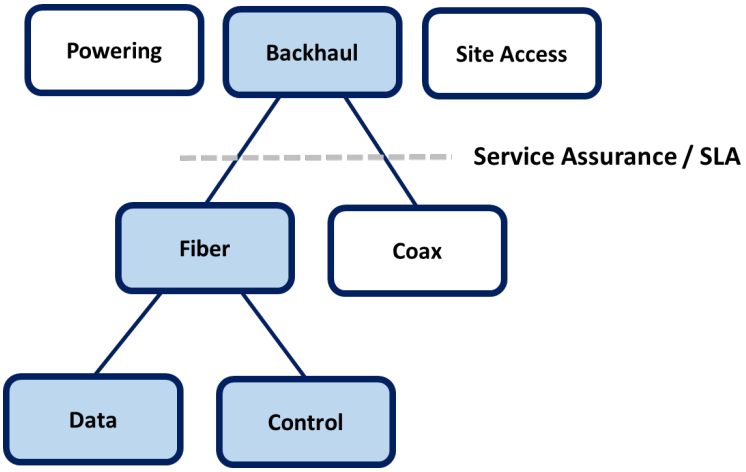

Figure 1, Infrastructure Needs for Convergence

This paper more specifically focuses on the transmission and management of multiple services over the fiber infrastructure, otherwise known as the converged interconnect network (CIN), spanning the fiber access endpoints or aggregation points to the signal packet cores at hubs or headends (Villarruel, 2020). While our focus is on the fiber networking, we go beyond to point out general implications and expectations for service assurance—code word for service layer agreements (SLA). The combination of transmission, management and sensitivities to service assurance is what drives the need for network slicing, thus the need for a paper that covers this topic.

Network slicing as a principle to streamline convergence of services for the cable industry has been described in useful detail in the reference paper: “Framework For Convergence Of Services On The MSO Network Using the Principles of Network Slicing” (Villarruel, 2020). This paper uses this reference paper as a launching point and further shows a practical implementation of network slicing on multiple services implemented in a laboratory setting.

We point out two disclaimers. First, we refer to network slicing as a general term, but the term network slicing also has a particular meaning within the 5G mobile space, as standard bodies like 3GPP have specific definitions for qualities of network slices for specific subservices. We use the generalized definition of network slicing because we can apply similar principles to a new space, in this case the MSO industry. Secondly, the work we show here is descriptive and not prescriptive in that there can be other ways to organize and share network resources and enforce service assurance.

2. Network Overview

The purpose of this paper is to position an end-to-end digital network that has the right sensitivities for convergence. At a high level we partition the converged network in two sections, access aggregation and core network transmission. See Figure 2 below. We position Flexible Ethernet (Flexed) technology for access aggregation and segment routing (SR) for the core network transmission. We also describe the principle of a Transition Map between FlexE and SR. This paper aims to describe the methodology for network slicing in the fiber backhaul and finally present a proof of concept from a lab buildout of the described principles.

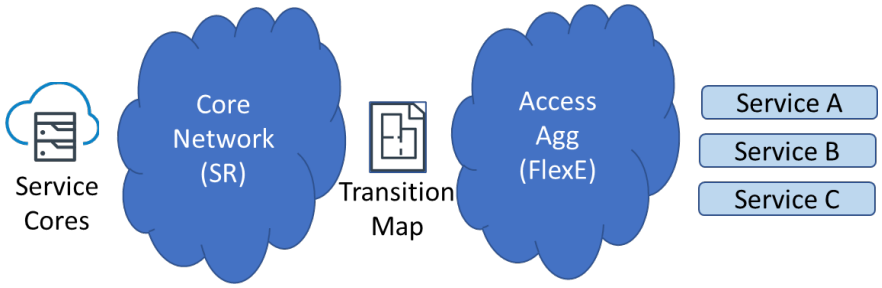

Figure 2, Network Overview

3. Convergence and Network Slicing

It is useful first review what we mean by service convergence and its relation to network slicing. Network convergence has been shown to include several access technologies with several services and subservices embedded, and span outside plant access and core networks, as seen in Figure 3 below (Villarruel, 2020).

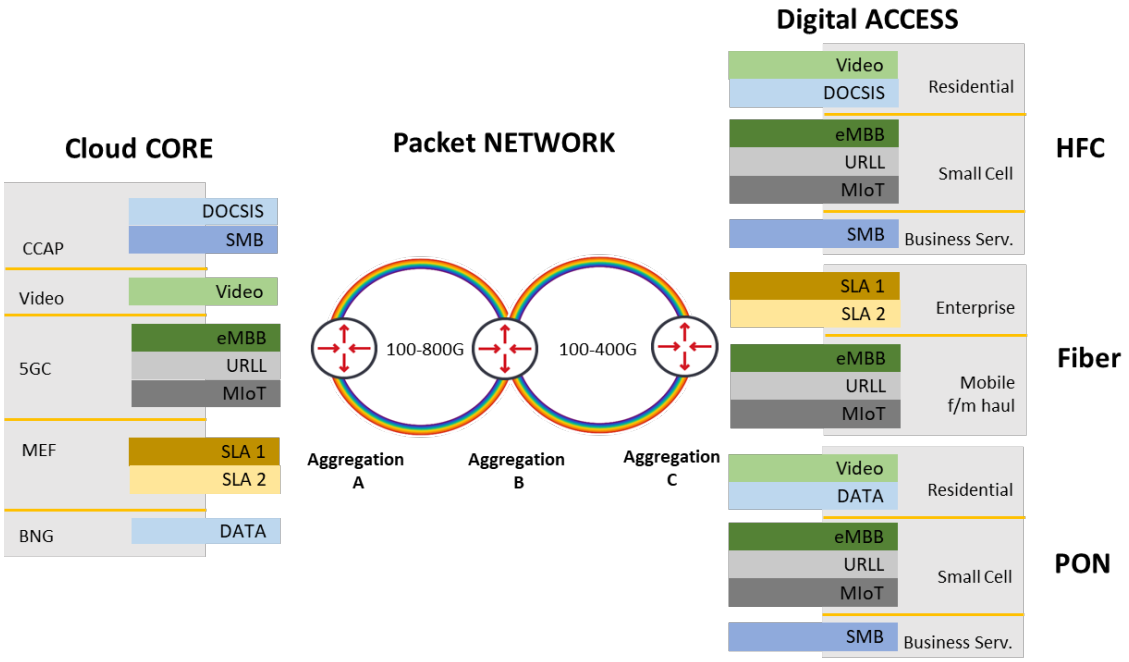

Figure 3, Convergence and Network Slicing

Notice that while Figure 3 is the view of an end-to-end system that works together, there is a delineation of domains, as each would have its own functions and expectations. See Figure 4. In the context of network slicing we call these resources the access would have its own resources, the network domain would have its resources and the core would have its resources. Connecting them might be a global orchestrator, but it is worthwhile to evaluate principles for each section in its own light. As alluded to in the introduction, the focus of this paper is on the network domain.

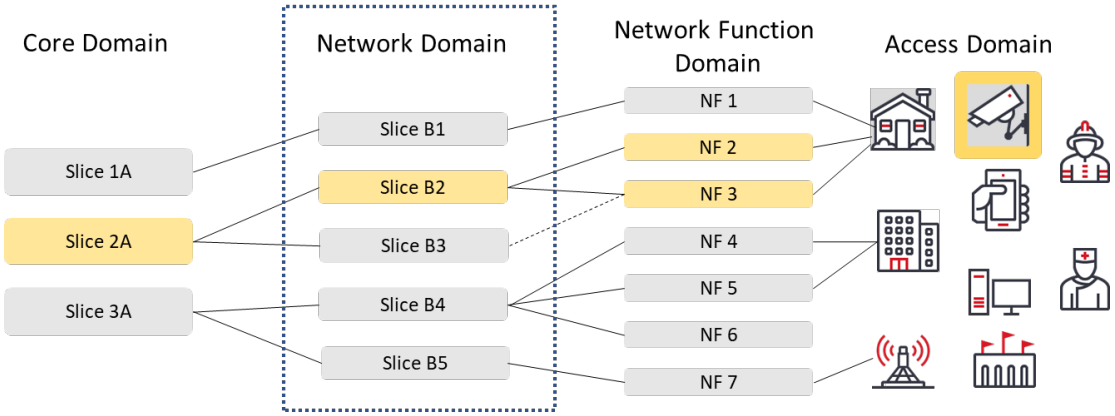

Figure 4, Slice Domains and Functions

Formally network slicing is: "a method to run multiple end-to-end logical networks on a common set of resources." But within and end to end framework there are domains which also have their own slices, so end-to-end network slicing is really a patch of slices from each domain to make a particular service. Using the example shown in (Villarruel, 2020), Figure 4, where each domain has a partition of resources that create domain slices, a subservice would use a unique collection of slices from each domain for end-to-end transmission of a subservice, otherwise known as a service blueprint. Consider the example

shown of a residential camera subservice, which might need a network function of face recognition and encryption, a tunnel from the network and a unique profile from a service core. The emphasis of this paper, if we take Figure 4 as reference, are the slice types available and created in the network domain. In this case the network domain is specifically the Ethernet and IP resources available to MSO systems that have evolved to a digital fiber plant, with the advent of distributed access architectures.

For a converged system it takes some effort to create the slice profiles and instantiate services as a collection of slices and manage their evolution through a lifecycle, but the primordial challenge is how to share sources in a way that allows legacy networks the same service assurance that they've had as independent networks. This is the fundamental challenge and so it must be addressed first, before any high-level orchestration or management is determined. The question is then, how does one converge services in a digital network such that they remain autonomous? The methodology for network slicing answers this question and is thus the kernel of this paper. We particularly revolve our work around utilizing concepts of soft and hard slicing, where hard slicing describes mechanisms that are rigid in how resources are dedicated, and soft slicing refers to mechanism that are made for flexibility in the sharing of resources. For the application of these hard and soft slicing concepts we leverage Flex Ethernet (Flex-E) and managed segment routing (SR) respectively. We now take a focused view of Flex Ethernet and Segment Routing.

4. Flexible Ethernet

Flexible Ethernet, otherwise known as Flex-E, is a mechanism that was created to provide transmission rate flexibility between client and line signals. This capability addresses the variety of client rates new and installed, along with line side transmissions and their ability to work together in a network. Flex-E dissociates the client rate from the physical interface. It does this by adding a shim layer to the 802.3, 100GBASE-R protocol stack and the 802.3bs 200/400GBASE-R protocol stack, separating the MAC from the PCS and PMA layers. See Figure 5.

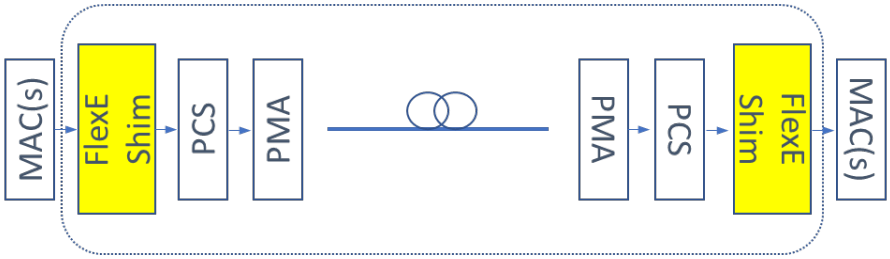

Figure 5, Flexible Ethernet Protocol

More generally, the Flex-E shim layer allows for not just one client MAC, but various, such that a collection of various clients at different rates can be transmitted over one or more Flex-E channels, see Figure 6. Specifically, FlexE clients have their own separate MAC, reconciliation layer and MII above the FlexE Shim layer, while layers below the PCS keep the intact rates as specified for their own Ethernet implementation (Optical Internet Working Forum, 22).

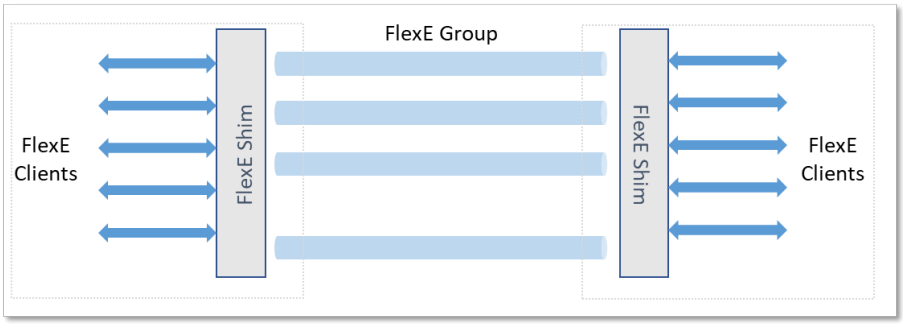

Figure 6, Clients and FlexE Group

The shim layer is shown in more detail in Figure 7; it shows the muxing function of a shim layer, where a collection of clients present themselves in a serial 66 bit stream, created from an ethernet MAC, operating at 10, 40 or mx25 Gb/s. Entering the calendar function, the client signals are adapted to the FlexE channel rate by a clock transition and an insertion or deletion of idle blocks. The calendar consist of 66 bit based time slots, and the control function controls the sequential insertion of client blocks to the calendar, along with insertion of necessary overhead. The subcalendars are logical groupings of calendar slots that prepare for interleaving that puts together signaling for the expected rate of the FlexE channel. Show in the Figure 7 is the description of the muxing function. There is also a demuxing function which is effectively the inverse of the muxing function.

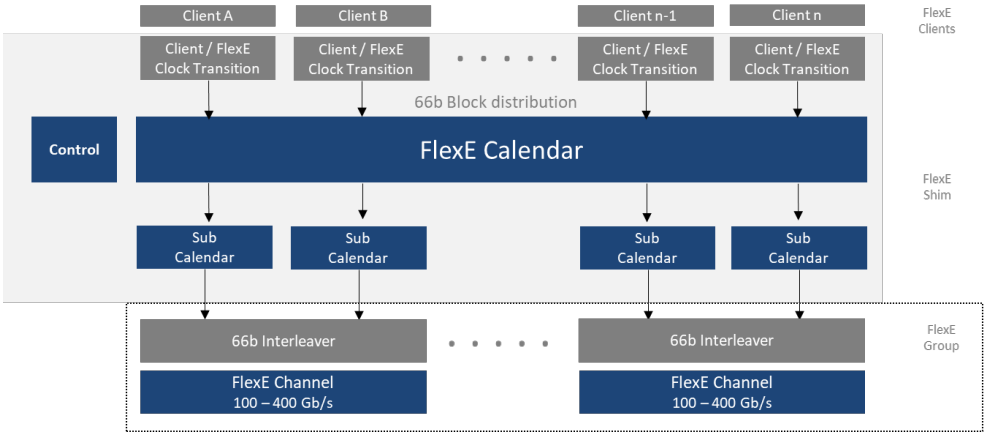

Figure 7, FlexE Shim Layer

The functionality of the FlexE calendar is interesting and a full treatment is beyond the focus of this paper, but as an example Figure 8 shows the calendar function in more detail for a 100Gb/s FlexE channel. Here the calendar has a granularity of 5G slots and every 20n slots create the sufficient 100Gb/s signal for a subcalendar. This calendar shows the serially inserted bitstream of mixed PHY clients at 10Bb/s and 25Gb/s. Similarly, the calendar can have up to 25G slots, a quality more natural for 25 G clients and greater speed FlexE channels at 200 or 400 Gb/s.

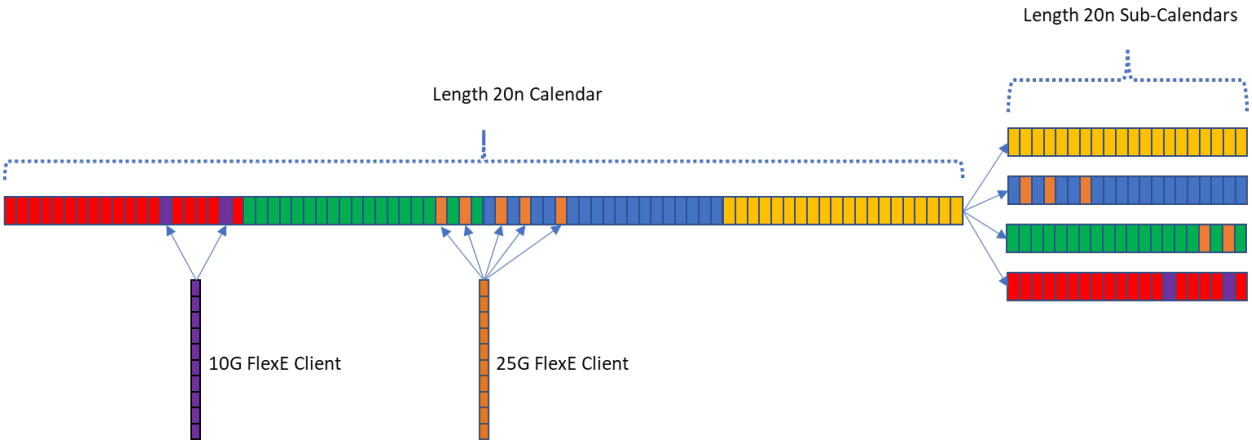

Figure 8, FlexE Calendar

With the presented characteristics FlexE has the capability of three basic functions, as shown in the Figure 9. Bonding allows the user to create a higher rate service, like 400G, with a collection of lower rate interfaces. The example shows 2, 100G Ethernet PHY signals carrying a 200Gb/s service. This is sometimes applied as an alternative to LAG without the extra layer of hashing algorithms. Subrating, service rates that don't match a greater service to be carried over on interface of a larger channel. More specifically the transmission rate is downsized in order to match the necessary client rate. In the example we show a 75G service utilizing a 100GB/s ethernet interface. And finally, there is the capability of channelization. which aggregates lower rate channels onto a higher rate interface. In the example we have clients of various native rates that manage to use one 100G FlexE channel. It is the case that these capacities can be mixed and matched depending on the circumstance.

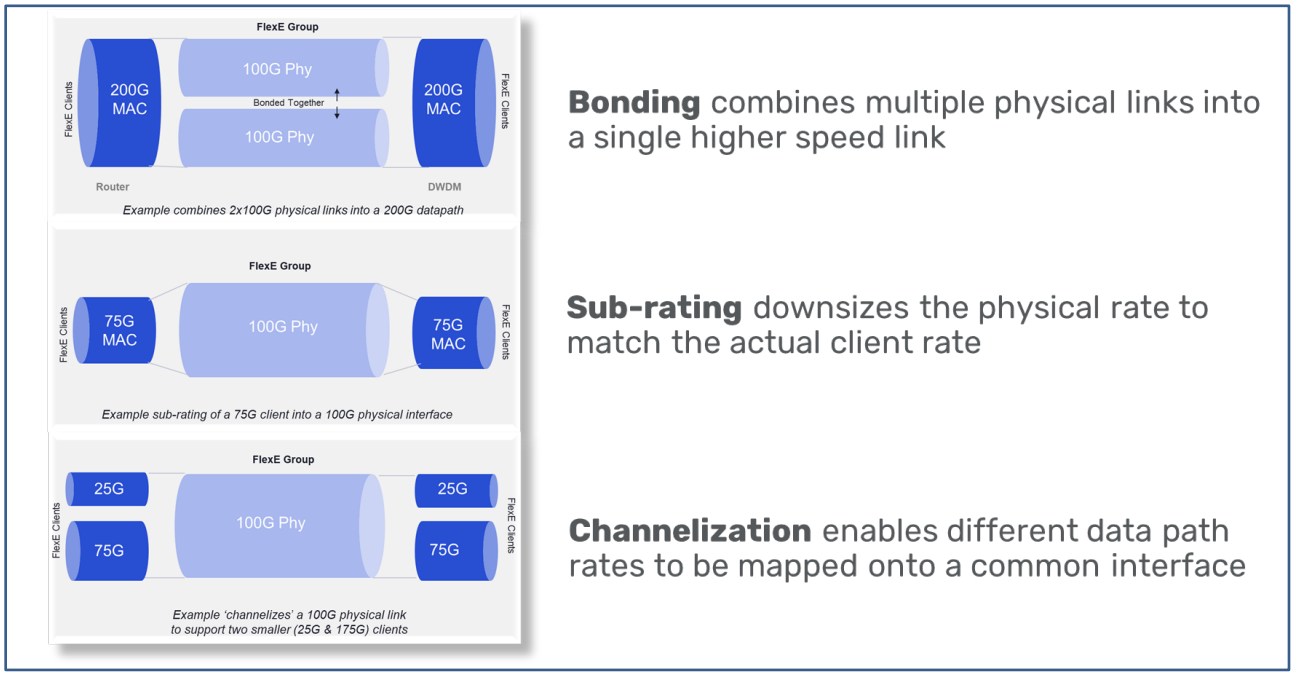

Figure 9, FlexE Functions

For our MSO convergence discussion channelization allows for the transmission of 10 and 25Gbs signals to leverage naturally higher rate backhauls, without having to go through an extensive forwarding plane, which is particularly useful in low footprint low energy platforms, such as outdoor shelves and nodes. Thus, FlexE is a good resource for the access outside plant, creating a robust combining mechanism that resembles straight forwarding muxing functions, like OTN, but with a more streamlined overhead.

But if FlexE is a good option for the outside plant access, what about the core network? This brings us to our next portion of end-to-end network slicing—segment routing. SR is an IP function which allows us to present a solution for soft network slicing.

5. Segment Routing – Data Plane

Segment routing is a topic that has been well described in other resources so here is a brief treatment reviewing basic principles (Bonica, 2017). SR has also started to show merit specifically in MSO networks as a way to enhance operational efficiencies for business services delivery (Yeo, 2019). SR per the name focuses on breaking down network topologies into segments, where a segment is a path between two routers. As seen in Figure 10, the router segments can be between two nearest neighbors like (AB) and (BC), and only need local awareness between nearest neighbors. Or segments can also describe routes that span across routers like (AC), and these segments need global awareness beyond just neighboring routers—these segments identifiers (SID)are described as adjacent SIDs or binding SID's respectively. Routing protocols can then be applied to segments as is done with regular routing that relies on unique addressing of source and destination. The routers that participate with capability to recognize SIDs and routes accordingly is called the SR domain.

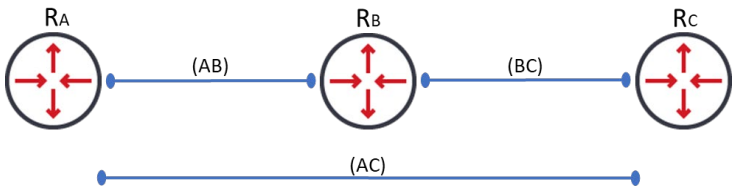

Figure 10, Segment Routing IDs

There are two methods for encapsulating SID's, one is to use labeling space in the MPLS header, and the other is for to use an IPv6 header with an SR extension. In either case the principles for inclusion of labels in headers throughout the life of a packet is the same. SR aims to keep the route of a packet known to the packet itself and reduce the calculation of routes as is done in legacy routing. This occurs by encoding the path of a packet with a stack of labels that describe the route to take and for the most part avoids large route calculations at every hop, as is done in regular routing by analyzing IP addresses and deriving paths from large look up tables.

In Figure 11 we show a very simple example of a six routers SR domain with a collection of local SID's, advertised and known only to individual nearest neighbors, and binding (global) SID's advertised and known to all (which allows packets to skip treatment at certain hops.) In Figure 12 and Figure 13 we show SR label stacks and accompanying payload progress through a route. In Figure 12 an instance using only local SID's shows a path from router Ra to router Rf. Note how the ingress packet from Ra has the whole path encoded on its label stack. At Rb, the router pops off the incoming label and forwards

the packet onto its next location, at Rc the router pops off the incoming label and forwards the packet onto its next location, and so on until it reaches Rf, where only the payload is left as was desired. In Figure 13 we note that the labels used include global SID's, where label processing skips over Rb and Re, with a local label between Rc and Rd. Here Rb and Re pass the packet onto the destination known globally without any manipulation of labels. At Rc and Rd however the label stack is depleted on route to Rf where it terminates as desired. Because of this simple approach, SR relies heavily on Interior Gateway Routing protocols, which simplify the necessity to know routes beyond local networks. There are other nuances and complications to label stack building and recognition, but this example highlights the general interworking of SR.

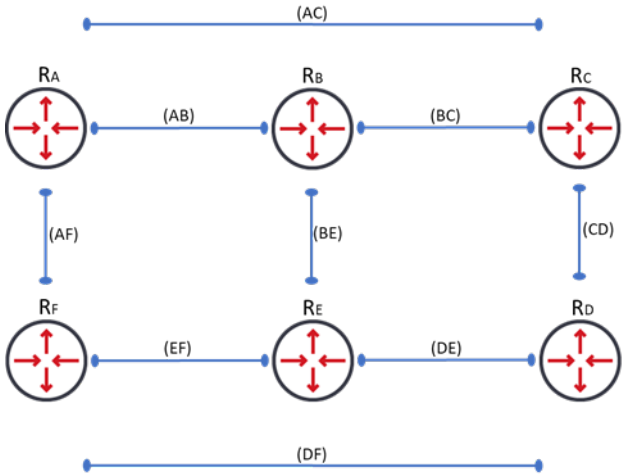

Figure 11, Routing Mesh and SID assignments

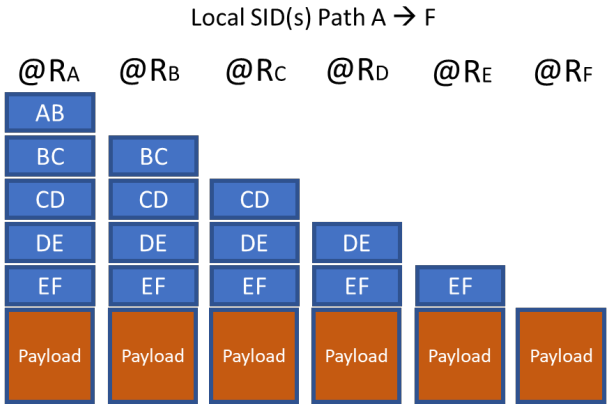

Figure 12, Local SID Path Progression

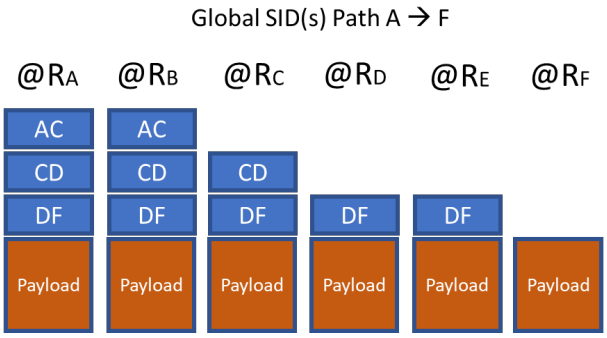

Figure 13, Global SID Path Progression

6. Segment Routing – Control Plane

In parallel to the data plane in SR there is also a control plane that calculates paths and decides what segments to visit, then communicates to routers instructions on how to build label stacks. The methodology used to control SR could allow us the ability to create an umbrella of reliable service assurance, which manifests itself as sellable SLA's, thus its importance. The decisioning of paths is done in path compute engines (PCE) where the cost of segments is evaluated according to variable state qualities such as latency or congestion, or other metrics. As shown in Figure 14, there are two schools of thought for location of path computation engines. One is to have path computation local, where each router participates in computing route characteristics and contributes cost of segments to a database that is available to all IGP participants. Each router then has the ability to influence SR labeling accordingly. The second school of thought is to have a centralized path compute engine which peers into networks and collates a global view of segment constraints based on telemetry and external influence and thus can create a wholistic cost of routes. The centralized PCE then has responsibility, not the local routers, for how label stacks are built and so directly controls the flow of information throughout the network.

For network slicing a centralized PCE, or "off-board" PCE is preferred because it can execute policy structures that could be missed if left to generic SR support mechanisms like Topology Independent Loop-Free Alternate (TI-LFA). A centralized PCE then takes control of creating SR stacks and distributing to origination points without burdening any path responsibility to middle hop routers. This is a particularly efficient way to meet service SLAs, particularly as SLA contracts can include certain non-typical networking constraints. For example, consider an example that has been considered recently, where a sensitive government service cannot cross country borders. If left to on board PCE it would be difficult to maintain data from crossing borders as pure networking mechanisms would not naturally digest that policy. With a centralized view of routes and costs expectations outside of typical network activity this important policy can be met.

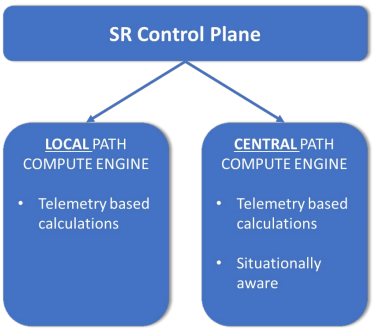

Figure 14, SR Control Plane Options

7. Transition Mapping

We have shown the operating principles of FlexE and SR, and while these are powerful independently in the case of a converged end-to-end network there needs to be an elegant and efficient, service aware, transition between the FlexE and SR domains, as shown in Figure 2. Figure 15 shows in more detail and how the Transition Map works in the context of an end-to-end network as it converges services. For Figure 15 this example we borrow some of the typical services and subservices listed in Figure 3. The transition function is a mapping between established FlexE channels and segment routed flows, where channels and flows have specific meaning and relationship to services and subservices carried by them from customer endpoints and handed off to service packet cores, then vice-versa.

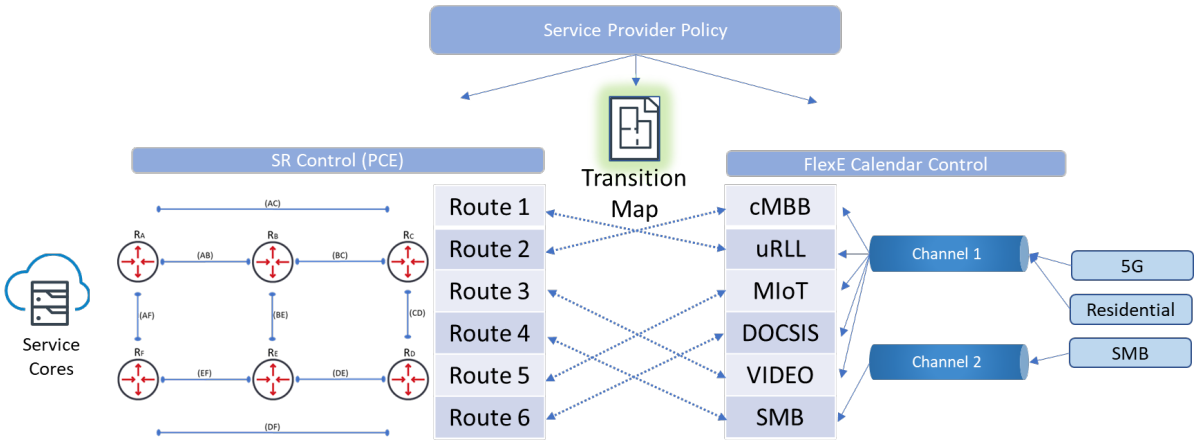

Figure 15, Transmission Mapping and Context

The transition function map executes a policy determined by the service provider which describes the relationship of subservices to SR labels and services to FlexE channels, in accordance to known SLAs. Note that the function map is intimately connected to the PCE and Calendar control functions, as they shed light to policy on how the map should be built.

In practice the transition function can be statically provisioned or dynamic. In a static set up very specific FlexE channels map directly to particular IP flows with variations over time executed by hand. On the other hand, in a dynamic state the mapping between Flex channels and SR labels could change depending on situations that allow services to best meet their SLA—again this points to the relationship of PCE and Calendar control with the policy mechanism and the transition map.

Note that SR and FlexE are well defined processes and mechanisms while the transition map is not. This implies that vendor differentiation is created around management of policy via PCE and Calendar control, and importantly the robustness of the Transition Map, how it is built and how it evolves as the system changes.

As an example, in the world of 5G, where the original work for formally defining network slicing, there is a standard list of attributes that define a slice, and that list is populated according to the particular needs of a service thus creating particular network slices, which then get assigned to subservices (GSMA, 2016). The service provider policy shown in Figure 15 would have an understanding of these slice definitions and their particular attributes and express this to the centralized PCE, the FlexE Calendar control and the transition Map where the policy is ultimately executed. In the MSO world, this is ripe definition work for CableLabs, where MSOs could benefit from Network Slicing attribute tables which could readily be assigned to subservice types.

8. Laboratory Set Up

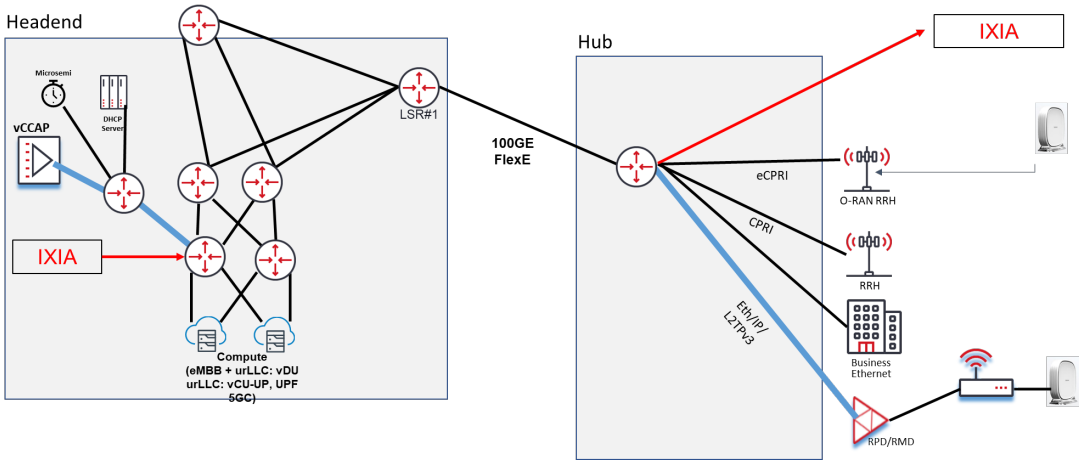

Figure 16, Planned Laboratory Setup

Figure 16 shows the planned laboratory setup with a convergence of mobile, residential and business services. Note that while this set up is built for this paper, it is also part of a more general laboratory set up for convergence in general, so some of the portions go beyond what would be needed for our testing, but useful in to verify other architecture questions.

The setup represents and-end-to end network with equivalents of outside plant, Hub and Headend. At the Headend there are the packet cores and supporting applications. There is cloud implementation of a 5G core and accompanying fabric, not in focus here. There is a virtual CCAP from a leading provider and supporting IEEE 1588 Master clock running ITU-T G.8275.2, and a DHCP server. There is also two entry routers to the Headend, an edge router located at the top, and the LSR#1 which is of our focus.

At the outside plant equivalent there is mobile signaling, from legacy backhaul in CPRI and next generation fronthaul in eCPRI supporting macro and microcells respectively. There is a point-to-point ethernet connection representative of business services. There is also a cable modem feeding into a Remote PHY Device, which ultimatately terminates at the CCAP. There is also an Ixia signal generator present to add rogue traffic which assists in testing the robustness of the FlexE and SR tunneling mechanisms.

We show that the service signals coincide on an aggregation switch, at the hub, which handles the execution of FlexE channels for all services. The aggregated signals are backhauled from the Hub to the Headend on a 100G signal, which is spent according to the FlexE channelization. The router at the headend LSR#1 terminated the FlexE channels and using a transition map executes service or subservice signals onto specific SR labels and flows, which have their own quality of service COS assignments. The flow prioritization is kept throughout the rest of the SR domain. Note that the signals are taking a non-direct path after LSR#1, as would be determined by typical routing protocols. This is to show the deliberate nature of the SR policy.

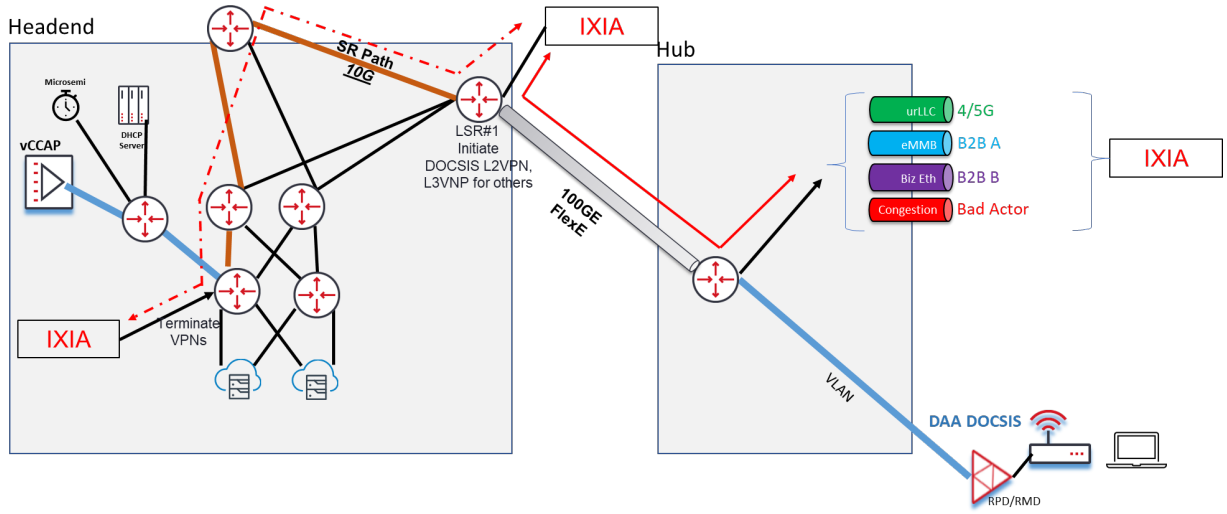

Figure 17, Actual Laboratory Setup

In Figure 17 we show the actual laboratory set up, which is a functionally networking equivalent to what is shown in Figure 16. Figure 17 shows the residential cable signaling is the only service that is running specifically on its native endpoints and cores. The system on the other hand mimics mobile and Business Ethernet flows via an Ixia traffic generator at the Hub. There is a 4/5G flow to mimic a signal from a wireless network source. The B2B-A and B2B-B signals represent enterprise grade circuits and the Ixia also provides a congestion flow to stress the FlexE channel—shown in the solid red line. In the Headend, at LSR#1 there is a breakout to another Ixia. This Ixia temporarily evaluates the FlexE signals and is the permanent stop for the congestion signal added to test the FlexE group. It is also the source for another "bad actor" signal into the SR domain in order to stress its class of service (CoS) mechanism—shown in the dot and slash red line. The LSR#1 is also where VPNs are originated, L2VNP for the vCCAP and RPD circuit, along with an L3VPN for the other signals. This is done to mimic typical business grade scenario in the case of L3VPNS, and in the case of DOCSIS signaling because we did not want to disturb same network settings for the vCCAP and the RPD. Note, that the FlexE segment relies on a 100G coherent direct connect signal, while the SR segment first path uses a 10G signal, for reasons that will be apparent in the next section. The VPNs are terminated ate the router before the last Ixia, through the representative cloud fabric.

The reason for differences between Figure 16 and Figure 17 was shortened set up and test time, a result of product transit, availability, and laboratory access in our current state with a pandemic.

9. Signal Settings and Test Results

	FlexE Settings	
Service Type	FlexE Group (Gbps)	FlexE Channel (Gbps)
B2B - A	100	5
B2B - B		5
4G/5G		5
DAA - DOCSIS		5
Bad Actor – FlexE*		75

Figure 18, FlexE Channel Settings

Figure 18 describes the FlexE bandwidth settings for each service type: Each service is assigned 5Gbps hard slices, and the "bad actor" congestion circuit is assigned 75Gbps, for a total composite of 95Gbps of client traffic and one backhaul signal and interface of 100Gbps.

Traffic Type	Tx (Mbps)	Rx (Mbps)
B2B - A	2G	2G
B2B - B	3G	3G
4G/5G	4G	4G
DAA - DOCSIS	25Mbps	25Mbps
Bad Actor	90G	75G

Figure 19, FlexE Throughput Results

Figure 19 shows the transmit and receive results for the Flex Ethernet group signal. We note three items. First when a bad actor that has a hard slice limit of 75G, as shown in Figure 18, tries to use more than its assigned SLA its signaling is curtailed back down to 75G, as determined by the FlexE channel setting, and second in this exercise of limiting the bad actor, none of the other service signals are affected. This is as expected. Third we note that the DAA DOCSIS signal is very low. This is per the one modem setting we had on the vCCAP. With more time we would have built a more extensive system. As it stand, with regards to bandwidth scale, the DDA DOCSIS signal is noise.

Service Type	DSCP	MPLS EXP	SR CIR	SR EIR (10G)
B2B - A	0 (Routine)	0	2G	8G
B2B - B	24 (Flash)	3	3G	7G
4G/5G	46 (Critical)	5	4G	0G (no burst)
DAA - DOCSIS	32 (Flash Override)	4	200Mbps	9.8G
Bad Actor – SR	1 (Priority)	1	200Mbps	9.8G

Figure 20, CoS Settings in SR Domain

Figure 20 shows the CoS settings for the service signals in the SR domain. The priority settings are expressed in the IP domain following the Differentiated Services Code Point (DSCP) structure. The MPSL priority settings are expressed in the MPLS Experimental bits mechanism (EXP), from lowest to highest. Basically, the MPLS priority structure can reflect the IP priorities to expedite any packet processing without digesting any IP headers. Note, the DCSP uses six bits and 64 possible values. The MPLS EXP on the other hand uses only three bits, and generally reflects the first three bits setting of the DCSP setting. Note, this allows for a further DSCP structure of priorities for subservices at the customer domain, to use as necessary.

Figure 20 also shows the bandwidth assignments for the different signals. The Committed Information Rate (CIR) shows the minimum bandwidth that the given signal will receive, this is typically a contractual SLA value. The Excess Information rate is the burstable rate possible, and it is the difference between the capable signal interface and the CIR. Note that the SR segment in egress from SLR#1 is 10G, thus the EIR values shows are calculated at 10G minus CIR. This is the nature of a flexible network slice as discussed earlier in the paper.

Traffic Type	Tx (Mbps)	Rx (Mbps)
B2B - A	2G	2G
B2B - B	6G	3G
4G/5G	4G	4G
DAA - DOCSIS	25Mbps	25Mbps
Bad Actor	10G	800Mbps

Figure 21, Transmission Results with SR CoS and FlexE

Figure 21 shows the end-to-end transmission results for the SR and FlexE segments. The focus here however is the priority structure set of the SR domain. Note the “Bad Actor” signal, which was assigned 200 Mbps, is trying to push 10G through the system which would take up all the line rate value. The output however shows the limiting nature of the soft slice as the system determined only 800 Mbps worth

of capability. Also note the B2B-B signal, which has a limitation of 5G in the FlexE domain, and a limitation of 3G in the SR domain. When it tries to put through its 6G signal, it gets throttled to 3G. Also note, that the DOCSIS signal is unaffected. Ultimately the 10G SR segment is all used up based on the decision structure set by CoS.

Figure 22 below shows a snapshot of the raw data presented above. The one item to note in the tests was latency nature of the DOCSIS signal. We conjecture that this loss value and the high latency is due to the very small nature of the DOCIS signal in this case. We describe it as being in the noise and thus prone to calculation error, which is not the case of all the other signals which show miniscule latency.

Figure 22, Raw Data Sample From Ixia.

10. Conclusion

This paper motivates the principles for hard slicing in an Ethernet domain via Flexible Ethernet, and soft slicing in a Segment Routing domain via the CoS structure. The paper then successfully shows these principles exercised on a laboratory system with multiple types of services. The systems shown is highly representative of what MSOs are trying to achieve with one digitized access and metro network. Please contact the authors for more information and context.

The authors would like to thank Regis Mounkala, Kaylan Kanchumarthy and Tina Wu, Solution Engineers at Ciena for their lab support and dedication to excellence.

Creating Confidence Among Subscribers Faced with Growing Cyberthreats

A Technical Paper prepared for SCTE by:

Bruce Van Nice
Senior Product Marketing Manager
Akamai
Santa Clara, CA
650-575-4008
hvannice@akamai.com

1. Introduction

Today people depend on the Internet for just about everything: transacting, interacting, learning, traveling, and a multitude of other activities. The Internet also allows businesses of all sizes to reach new and larger markets and provides opportunities to work more efficiently by using digital tools that are increasingly economical and targeted at organizations with limited technical expertise. One of the downsides is theft of digital assets has become commonplace and for many organizations it represents a greater threat than physical theft.

Remote work challenges that began in 2020 continue as cybercriminals take advantage of elevated stress and unprecedented focus on topics related to the pandemic to maximize the value of their exploits. They saw a good opportunity to launch attacks and profit from dependence on the internet and technology. They used phishing and other kinds of internet-enabled fraud to target everyone from workers searching for personal protective equipment to families looking for information about help paying bills, and many others.

For ISPs there are opportunities to help subscribers navigate the always changing security landscape with new services that deter internet threats and are easy to use. This paper will talk about the product development process behind a security service targeted at Small Midsize Businesses (SMB) that was launched across a major North American cable network. It will:

Summarize the threats internet users face which motivated product teams to evaluate potential services

Outline a service strategy developed to help small and midsize businesses deter internet threats

Offer perspectives on the threat intelligence used to support the new security service

Discuss go to market to build awareness of security services and extend the value proposition of reliable high speed internet access

2. Internet Users Face a Diverse Threat Landscape

Cybersecurity is a visible topic today, news reports in mainstream media highlighting internet related crimes have become commonplace. The news is fueled by a multitude of organizations that track and analyze malicious activity - there's lots of data about cyber threats.

The US Federal Bureau of Investigation is a widely respected organization that runs the Internet Crime Complaint Center (IC3) whose mission is "to provide the public with a reliable and convenient reporting mechanism to submit information to the FBI concerning suspected Internet-facilitated criminal activity, and to develop effective alliances with industry partners."

The IC3 tabulates the data they receive and publishes it in the Internet Crime Report every year. The chart on the following page, copied from the 2020 report[1], summarizes the year over year trends from 2016 to 2020.

[1] https://www.ic3.gov/Media/PDF/AnnualReport/2020_IC3Report.pdf

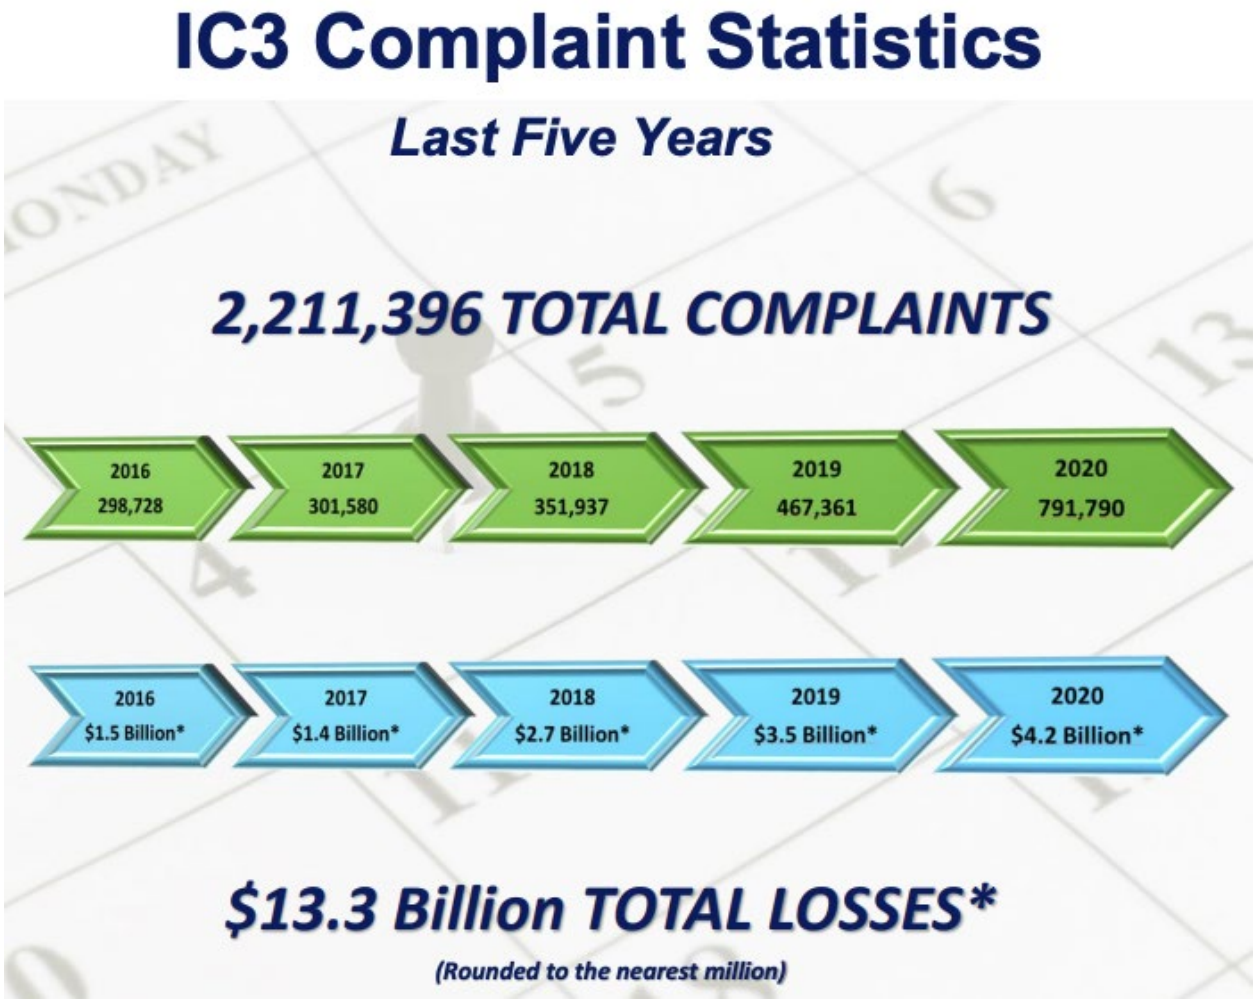

Figure 1 - Internet Crime Complaint Center (IC3) Internet Crime Report 2020 Summary of Complaints Received

The 791,790 complaints received from the American public in 2020 were a new record and represented a 69% increase over 2019. Reported losses exceeded $4.1 billion, a 20% increase over the previous year. The report also states: “These criminals used phishing, spoofing, extortion, and various types of Internet-enabled fraud to target the most vulnerable in our society - medical workers searching for personal protective equipment, families looking for information about stimulus checks to help pay bills, and many others. “

Another chart from the report summarizing threat vectors year over year is below. The 241,342 complaints tabulated for phishing scams more than doubled from 2019. To add color to the data and show how cyber criminals observe trends and tailor their exploits accordingly. The IC3 also received over 28,500 complaints about scams related to COVID-19.

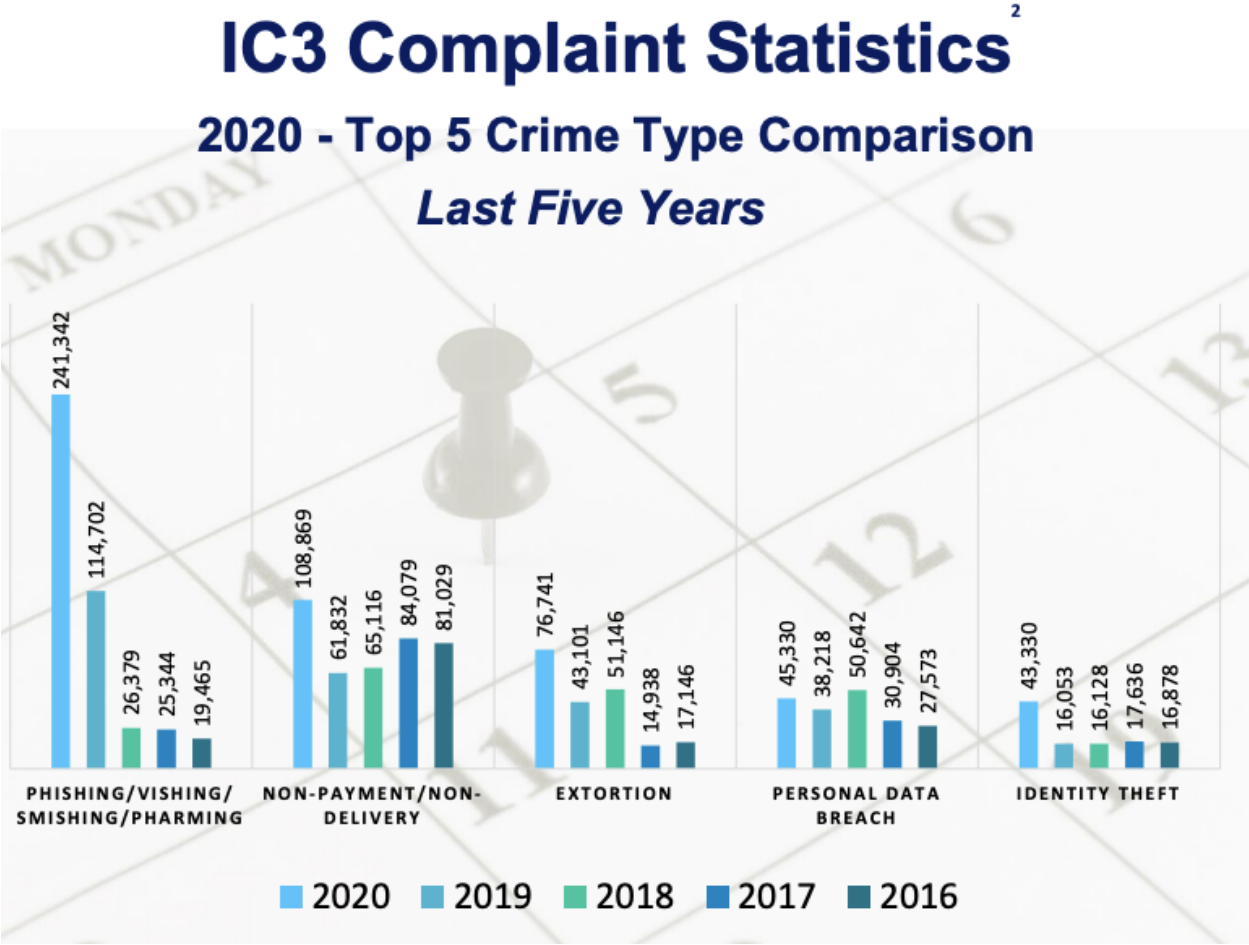

Figure 2 - Internet Crime Complaint Center Internet Crime Report 2020 Summary of Types of Internet Crime Reported

To add even more detail to this point, early in 2020 Akamai, a security company who participated in the development of the service covered in this paper, also showed a large amount of phishing activity focused on anything related to the pandemic[2]. The research showed hundreds of new COVID-related domains each day, most of which disappeared within 24 hours, which is consistent with longevity statistics they've historically gathered for names used for phishing.

Pandemic related scams are diminishing but hackers always innovate and find new themes to mine. Additional published research from Akamai shows a large increase in phishing prior to the holiday season last year[3]. Still more work discussed phishing campaigns modeled around cryptocurrencies and even Elon Musk[4]!

[2] https://blogs.akamai.com/2020/04/covid-19-phishing-exploiting-a-global-pandemic.html
[3] https://blogs.akamai.com/2021/02/phishing-holiday-season-attacks-on-the-rise.html
[4] https://blogs.akamai.com/2021/06/crypto-threats-surge-by-500-and-its-all-about-the-money.html

The point of these examples is not to offer a comprehensive overview of the threat landscape but to illustrate how hackers change their stripes to attract the attention of internet users and more importantly, get them to click on links and give up valuable data so they can make money. Diverse, fast changing exploits can make it hard for expert internet users to avoid being tricked, and it's even harder for average people.

3. The Road to Service Success

Like every company offering internet access services this organization was always looking for ways to improve their services. They were well known for performance and reliability and saw an opportunity to continue to contribute to online safety and help instill customer confidence with new security offerings.

The idea was to build on existing products which had embedded security features, like CPE for business customers with an integrated firewall and selectable levels of protection to control which kinds of protocol traffic are allowed or denied. Users can configure options to manage which protocol traffic will be permitted and blocked, like P2P applications.

More recently the team defined an optional DNS-based security service to defend workplaces against threats like malware, ransomware, phishing, botnets etc. The goal was to provide a foundational layer of defenses that take advantage of embedded network and operational strengths - such as scale, reach, reliability. This offering will be the focus of this paper.

In formulating product plans for this new service, initially targeted at Small and Midsize Businesses (SMB), several essential issues were considered to ensure success.

- Simplicity was paramount, surveys confirmed high awareness of cyberthreats but limited understanding of how to deter them - a service had to be simple to procure and operate.
- Complementing other security services was a critical consideration, most customers had security solutions and wanted to understand how anything new improved their posture
- Transparency was another requirement, subscribers had to be aware the service was operational, and what kinds of activity it was blocking.
- Customers had to have control and over time would expect even more "knobs and dials" to tune the experience

4. Keep it Simple

Large businesses are challenged dealing with internet security exposure but SMBs are even worse off because they may lack IT resources with specialized security expertise. A key product goal was to minimize the need for deep security expertise - with a model where the service "just works" after the service is activated (with some value add options discussed below) and covers all of the devices typically found in businesses today - PCs, phones, and even smart connected "things" like POS terminals, cameras etc. Other goals for the service included reducing installation overhead and ongoing maintenance - by eliminating software and hardware upgrades - as well as minimizing the expertise for configuring any optional features.

We provide every business subscriber with a graphical web portal that can be accessed anytime with a browser. The portal show's what's happening on their network and can be used to configure optional filters to manage what kinds of content is available on a workplace network, and what times certain websites are available to support Acceptable Use Policies.

5. Complementing Other Security Services

It was expected most business customers would already have security solutions and of course want to understand how anything new would improve their security posture. Examples of other services likely to be encountered include endpoint protection, specialized appliances, and “over the top” DNS-based filtering services. They considered how these options would shake out with respect to the planned service.

Endpoint software must be loaded on devices and requires ongoing maintenance, and it’s not available for smart connected devices. Appliances offer protection but web traffic on the internet is increasingly encrypted and malicious activity can be completely invisible to security appliances, especially lower end models that don’t have extremely sophisticated features to decrypt traffic (and experts to manage them). They also usually require periodic security expertise for ongoing care and feeding to be sure they operate properly. The user interface for security appliances is also typically aimed at someone with security knowledge, which an SMB may or may not have.

Security is about examining network traffic to determine whether it is malicious or legitimate. Approaches that operate in the data plane implement inline packet inspection to evaluate traffic. In the past it was possible to get visibility into most of the traffic on a network but the predominance of encryption has introduced significant limitations or complexity decrypting traffic. Inspecting packet traffic at line speeds has always been a costly operation, and inspecting encrypted traffic adds even more costs and operational overhead.

DNS filtering operates in the control plane. Incoming subscriber queries are matched against dynamic threat intelligence provisioned in resolvers, and policies can be applied to manage unwanted traffic. The team recognized attractive scaling capabilities since there is no need for pervasive monitoring and filtering of network traffic (and possibly decryption) and it can be layered on infrastructure already deployed and managed. Traffic from any device that makes DNS queries – the overwhelming majority – can be observed without the need for any client software. Threat coverage can be expanded by selectively forwarding suspicious traffic (typically domain names that point to both malicious and legitimate web resources) to proxies for further inspection. Experience has shown this is a small percentage of traffic, usually around 2%.

Based on these considerations DNS filtering was selected. The service is integrated with the subscriber internet access service (versus and off network “over the top” alternatives) to ensure performance and reliability.

6. Ensuring Transparency and Customer Control

Subscribers need a window into their service to understand how it is functioning. A portal user interface was specified to inform subscribers about their security posture and to allow them to configure other filtering features. Requirements included:

- Threat activity graphs showing threats blocked
- Configuration user interface for specifying web filters to support Acceptable Use Policies (AUP)
- Web filter graphs showing websites blocked by subscriber configured web filters
- Automated discovery of subscriber devices to support configuration of device-specific filters
- Subscriber-specified reports for archiving or offline analysis

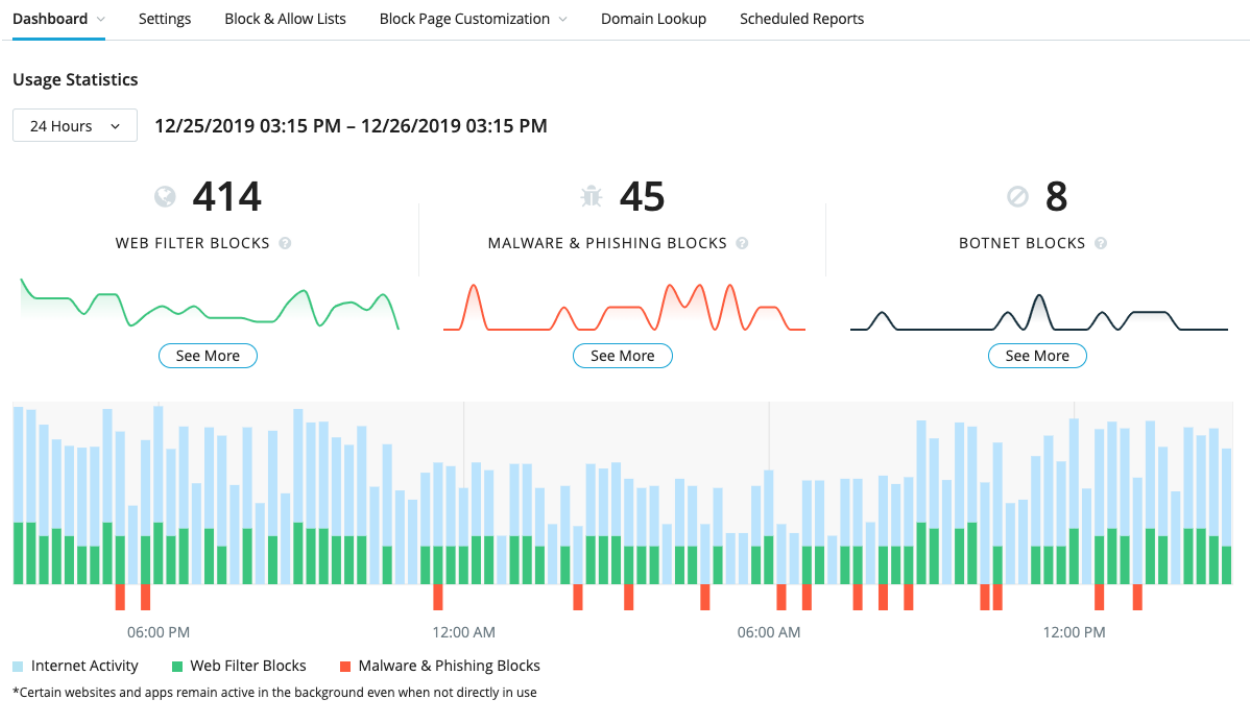

Figure 3 - Graphical User Interface Showing Internet Activity and Impact of Web Filters and Various Kinds of Malicious Activity

7. Sourcing Threat Intelligence

The value of security services is heavily influenced by the quality of the threat intelligence they employ. The threat landscape is incredibly diverse and it's simple for attackers to expose internet users everywhere to maximize the value of their efforts. Exploits also change quickly so attackers can stay ahead of security defenses that block their handiwork. For service providers in particular false positives can be extremely costly if subscriber access to favorite obscure websites is inadvertently blocked.

High level requirements for reconciling these objectives include:

- Large amounts of unencrypted raw data to maximize the coverage of increasingly sophisticated threats such as phishing, botnets and other kinds of malicious web resources
- High performance infrastructure to support near real-time processing of data to identify threats quickly and accurately to match the speed of change of today's exploits
- Machine learning algorithms that extend threat coverage by identifying subtle patterns and linkages in raw data that statistically match known threats used to train the algorithms
- Additional functions to validate threat entries are malicious to avoid blocking of legitimate web resources
- Software infrastructure to interconnect different processing systems so data flows among the "layers" in a structured way that allows inferences from one layer to the next

- Specialized processes to cull stale entries to keep threat lists from growing exponentially
- An iterative process to continuously refine, specialized algorithms that work together

Creating robust threat intelligence is complicated by the fact that some kinds of data is less available than in the past due to privacy regulations. More and more data is encrypted so it's opaque to analytical tools, and hackers increasingly use encryption to cover their tracks. Another advantage of DNS filtering is it overcomes these limitations. Unencrypted resolution data can be sourced from production resolvers or various kinds of network taps and anonymized to eliminate Personally Identifiable Information (PII).

DNS data has other useful characteristics for security research. Domain names and the Domain Name System (DNS) authorities and resolvers that support them, are fundamental to most security exploits. The DNS is widely used by malware developers because it connects everything on the internet from anywhere and virtually every network and device where an exploit might be activated will have access to the DNS. This means any device that emits a DNS query known to be associated with malicious activity can be identified as infected with the associated malware.

From a practical standpoint DNS queries are usually the first threat "signal" that's visible on a network where it can be detected remotely. Identifying activity at this stage is extremely useful as an exploit can potentially be disrupted before it does any real damage.

More details about how threat intelligence is developed can be found in a paper from SCTE 2018 "When Security and Privacy Collide New Approaches are Needed"

8. Marketing to Ensure Success

This is primarily a technical venue, but marketing is a critical part of any product launch process. Nothing sells itself anymore and building brand equity takes work - marketing investment helps ensure success. Product teams worked cooperatively with marketing to develop messaging that's aligned with other product and corporate marketing objectives.

For this service the marketing teams executed on a wide variety of initiatives. They built out a dedicated web presence in the commercial section of their website that provided all the information a prospective customer might be interested in. It highlighted all the major features of the service and offered complete descriptions of the value they offered to the intended customer base. Recognizing many potential customers were unlikely to be immersed in security jargon they used approachable language that was easy for typical SMB subscribers to understand. Other web pages present background information on security exposure so prospective customers can understand why protections are needed.

The marketing team also launched television advertisements across their US territory. Additional marketing campaigns reached customers directly with other media like email and marketing inserts as part of billing or other promotional packages.

There was additional effort for sales enablement. Teams were prepped on internet security basics so they could engage comfortably with prospective customers. They were equipped with simple product benefits they could convey and learned how to respond to questions about the service and how it compared with other security products prospects might already have. Business results

backed up the product development and marketing effort, with steady continuous growth in uptake.

9. Summary

Internet service providers everywhere are always looking for opportunities to improve their services. Speed and reliability aren't sufficient anymore. Awareness of security exposure on the internet creates an opportunity to contribute to online safety and help instill customer confidence with new security offerings. This DNS-based security service defends workplaces against threats like malware, ransomware, phishing, botnets etc., providing a foundational layer of defenses that take advantage of the power of network and operational strengths - scale, reach, reliability.

The product strategy for the new service considered several essential issues to ensure success:

- Simplicity was paramount because customers in the target segment often lack security expertise and specialized resources in general to oversee anything technically oriented
- It needed to complement other security services since most customers had security solutions and wanted to understand how anything new improved their posture
- Transparency was another requirement, subscribers had to be aware the service was operational, and what kinds of activity it was blocking.
- Customers had to have control and be able to tune the experience to match their business needs, preferences, and values

The new service was designed to complement other Small Medium Business (SMB) cybersecurity solutions such as firewalls and anti-virus. It adds threat defenses backed by machine learning algorithms that process live streamed DNS data in near real time to uncover new malicious activity quickly and accurately. Customized web content filters allow business managers to enable "Acceptable Use Policies" to manage the kinds of web content that are accessible on workplace networks. Investments in marketing and sales enablement were made to ensure good penetration of the service and attainment of business goals.

Delivering Access Beyond 10G

Coherent Subcarrier Aggregation as Backhaul for Next-Generation R-OLT, RMD, and Wireless

A Technical Paper prepared for SCTE by

1. Introduction

Over the last decade, the demand for network capacity has been continuously growing. This is particularly true in the last mile of the access and metro networks. This has been fueled by an unstoppable sequence of web-based applications such as video streaming, cloud services, mobile transport, and machine-to-machine communication. Recently, the traffic demand further increased driven by the ongoing pandemic though the impact has been, so far, manageable.

This growth was enabled by the wide deployment of broadband connectivity. This is an evolving landscape, which is now being addressed by the realization of newer technologies such as 10 gigabit per second (10G) capable Passive Optical Network (PON), DOCSIS 3.1, and fifth generation (5G) wireless, each offering access to subscribers at gigabit speeds. At the same time, the consolidation of hub sites and plant extensions are driving deployment of Distributed Access Architecture (DAA). As a result, the Converged Interconnect Network (CIN), the glue that connects these diverse access networks to the operator's headends, is being asked to provide more capacity to an increasing number of devices that are spread over an ever-widening geographic area.

Modern telecommunication networks transport Internet Protocol (IP) traffic utilizing primarily hub & spoke topologies. Here low-speed transceivers (spokes at the end user's location) are connected to high-speed transceivers (hubs). The optimal network topology for this would be point-to-multipoint (P2MP) and, usually, the physical plant is built as a P2MP architecture. However, the traffic is usually transported via point-to-point (P2P) architectures, such as those typically deployed for traditional telephony services, with the exception of PONs, where P2MP is realized using time-division multiplexing (TDM).

These network segments are the closest to the end users, and because of the large number of devices, cost and power consumption play a crucial role. At the moment, the preferred transmission method in access and metro networks is Intensity-Modulated Direct-Detection (IM-DD) systems, which employ modulation formats such as non-return-to-zero (NRZ) or pulse-amplitude-modulation (PAM)-4.

This technical solution has significantly contributed to the boom of the Internet, but initial doubts about its long-term sustainability – in terms of capacity – are arising as next-generation optical networks are being called upon to support even larger amounts of data. In fact, IM-DD is limited in spectral efficiency compared to the advanced modulation formats employed in coherent systems. Another strong limitation of the technology used in the access network is the utilization of TDM architectures, which significantly reduce the maximum throughput of the network and does not allow the usage of advanced digital signal processing (DSP) algorithms. These boundaries, and the underlying P2P network architecture, have resulted in a growing awareness in the industry that P2P 10G IM-DD systems cannot meet the requirements for backhaul while simultaneously making efficient use of network infrastructure, e.g., in the case of fiber scarcity.

In this context, coherent optics, as has happened in other segments, might come to the rescue where capacity and reach become the core concerns, but they still fall short where high device counts or simply geographic distribution are the key issues. A first important step towards a low-cost coherent marketplace is represented by the Optical Internetworking Forum (OIF) implementation agreement of 400ZR [OIFIA2020]. Coherent offers a wide array of advantages ranging from the ability to employ advanced DSP technologies – that can compensate for fiber propagation effects such as accumulated dispersion – to the enabling of wavelength division multiplexing (WDM).

This evolving storyline requires new solutions to address the given requirements. This paper provides operators with an evaluation of possible approaches to this issue ranging from higher speed IM-DD

systems to coherent optics with a special focus on the emerging concept of coherent P2MP transport using digital subcarrier multiplexing (DSCM) [Sun2020] for aggregation [Welch2021].

Fiber access links have traditionally been arranged in a P2P fashion, with paired electronics on each end of the fiber. If electronics are changed on one end, they must be changed on both ends to remain interoperable. Consequently, to combine low-speed interfaces to higher-speed ones, an intermediary aggregation device is required. In [Welch2021], a paradigm shift has been proposed that targets a universal approach to connectivity in telecommunication systems. This exploits DSCM to simplify the network architecture by removing the electrical aggregation layer and the bookended transceivers and replacing them with a simple passive optical combiner. Moreover, DSCM allows the realization of a truly P2MP network architecture [Welch2021].

This is relevant because most current-day last-mile architectures are broadcast in nature – meaning that transmitted downstream signals are "heard" by all endpoints. This is true for PON, DOCSIS, and Mobile networks. Wired networks (PON/DOCSIS) might be single or dual fiber. Whether one considers ring topologies, star topologies, passive tree architectures, PON overlay architectures, or enterprise/wavelength extensions, the deployment approaches are all similar. "Last mile" networks are predominantly P2MP in nature, but still served by P2P optics. Such designs tend to drive high optical port counts, while the solution based on DSCM might lead to significant savings [Bäck2020].

At the same time, that network capacity continues to grow, marketed network speeds are also growing, with 1 gigabit per second (Gbps) service now commonly available, and plenty of industry discussion around emerging multi-Gbps speeds on the horizon. We see this from a few perspectives, including residential broadband rates, demand from business customers, wireless capabilities now made possible via 5G, as well as an accelerating build rate of fiber networks. In addition, the cable industry has put forward its strong 10G mantra over the past few years. The discussion will address critical operator needs such as capacity, scalability, deployment lifespan, network reach, CIN aggregation architecture impacts, the convergence of DAA/wireless/business services, and operational simplification. A road map toward a new network paradigm will be also provided.

The remainder of this paper is organized as follows. Section 2 describes the state-of-the-art in terms of traffic, networks, integration with cable access technologies, and the reasons to move beyond 10G. Section 3 describes existing optical transmission technologies and how those can move beyond 10G. Section 4 presents a proposal that aims to cope with existing traffic patterns and high-capacity networks. Here, the concept of DSCM is introduced and we explain how this helps to realize fully capable point-to-multipoint optical networks. Section 5 provides a high-level qualitative comparison of technology options in moving beyond 10G before wrapping up.

2. Evolving Traffic and Deployment Requirements

In this section, we describe the evolving traffic and deployment requirements to serve various cable operator access solutions for HFC, PON, and wireless.

2.1. Network segments and traffic patterns

Figure 1 illustrates a generic tiered telecommunication infrastructure typical of systems deployed by cable operators today, spanning all the way from subscribers back to a wide area core network, with all links except for most subscribers, consisting of digital optical transport.

The access segment includes equipment such as Converged Cable Access Platform (CCAP) in DOCSIS hybrid-fiber coax (HFC), optical line terminal (OLT) in PON, and centralized unit (CU), distributed unit

(DU), radio unit (RU) in 5G wireless which provide last mile connections to users. Connections are generally tens of kilometers and limited to 80-120 km maximum.

The metro segment connects multiple access segments together across a larger, generally metropolitan area with links <200 km.

The core segment provides multi-city transport between different metropolitan areas covering hundreds or thousands of kms.

In this paper, we focus primarily on the access segment, but the solution described is also applicable to the metro segment.

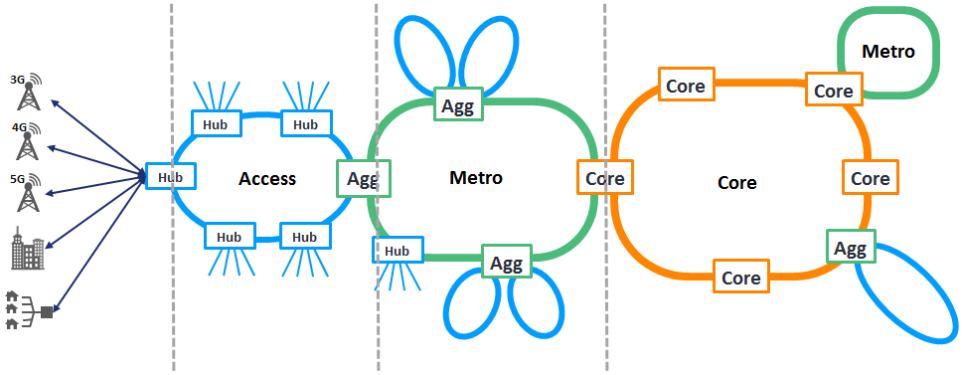

Figure 1 - Generic Cable Operator Network Architecture

A significant portion of the traffic within a cable operator's network is used for providing access from a large number of subscribers to a smaller number of service access points delivering services such as operator-delivered video content, streaming video providers, or general Internet services. This traffic is inherently organized in a hub and spoke pattern. Relatively low-speed (compared to optical transport) subscriber last mile interfaces connect to the Internet and other services via a high-speed hub, and traffic patterns resemble a point-to-multipoint (P2MP) network.

Today though, optical networks are still designed utilizing a point-to-point (P2P) approach, with the exception of access via passive optical network (PON). Figure 2 illustrates the differences between these traffic patterns.

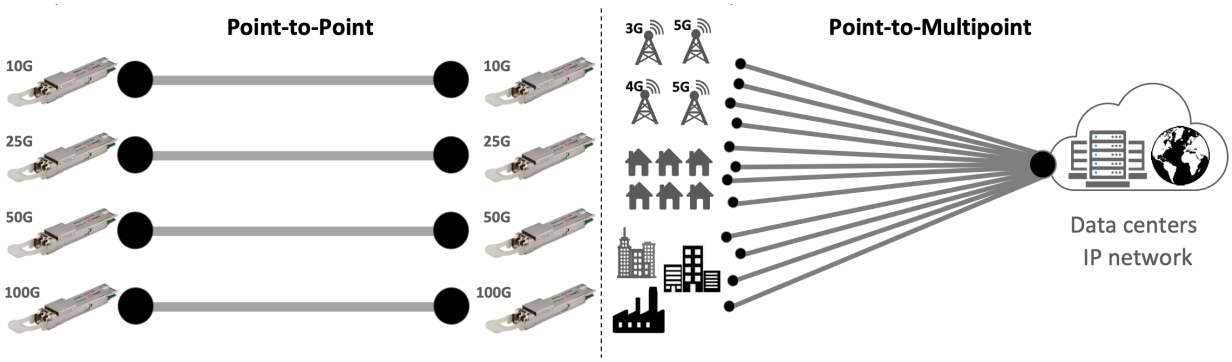

Figure 2 - Point-Point and Point-to-Multipoint Network Traffic Patterns

2.2. Evolving capacity needs for cable access segments

Over the last decade, the demand for capacity in the last mile access network has been growing continuously. At the same time, the access topology has also changed, with the "last mile" links becoming shorter, and active electronics being pushed deeper. Whereas fiber, coaxial, and twisted pair copper north bound endpoints previously terminated in facilities (headends, central offices, huts, etc…), it has become far more common for these termination points to be placed somewhere in the outside plant infrastructure.

Examples include:

- Cable operators' hybrid fiber coax networks have typically been fed by a combination of video QAMs (signal modulators) and Converged Cable Access Platform (CCAP) systems for broadband. These were typically rack mounted in an environmentally controlled facility. With the advent of DAA using Remote physical layer (PHY) or Remote media access control + physical layer (MACPHY) devices, those electronics take on a smaller more modular format that gets pushed out of the rack and into the fiber node installed in the neighborhood that is being served.

- Since the early 2000's, TelCo's have deployed remote digital subscriber line access multiplexers (DSLAMs) to deliver broadband over twisted pair copper.

- Mobile network operators (MNOs) have experienced a fast evolution of cellular radios and the radio access network (RAN) with electronics moving in multiple directions within the network topology. Increased use of virtualization and evolution of the location at which processing happens within the RAN has created increased need for a variety of optical transport solutions ultimately feeding radios located deep in the network.

- And for operators deploying fiber to businesses and residences, PON fiber terminations now frequently occur in remote OLTs that are pedestal or strand mounted, or within MDUs and office buildings.

The result is that the number of locations requiring fiber terminations is growing exponentially, while requiring higher and higher speed interfaces at the same time. Such network demands require a well thought out approach to connectivity.

Figure 3 below shows common scenarios for cable operators as they consider the required capacity in the access segment of their network.

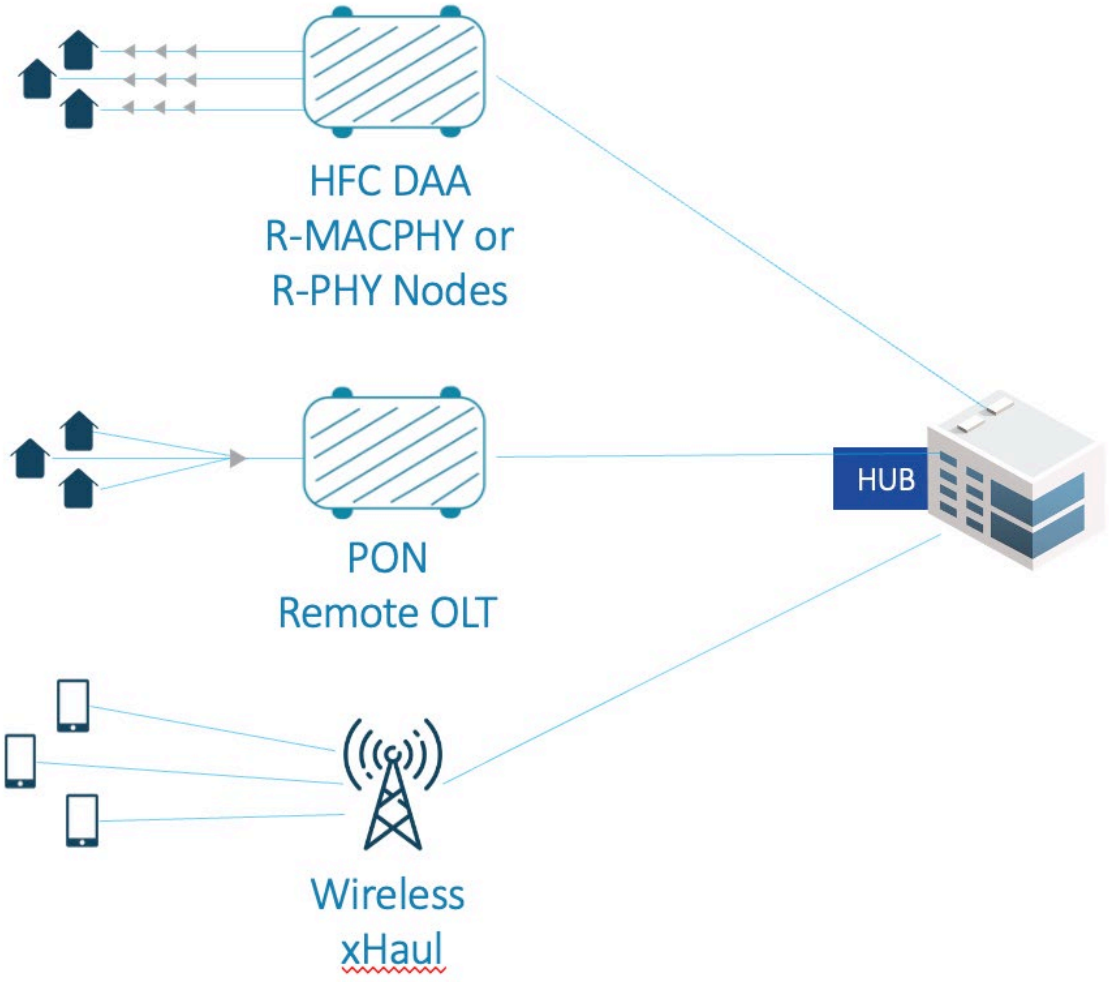

Figure 3 - Access Segment Transport Applications

2.2.1. HFC DAA

Many operators are evolving their DOCSIS and QAM video delivery infrastructure to DAA to:

- Save space and power in hub facilities as the number of HFC service groups expands with ongoing capacity growth
- Improve signal fidelity and resulting capacity by moving RF processing to the edge
- Converge HFC access backhaul with other forms of access backhaul by removing analog optics and replacing them with IP/Ethernet

DAA deployments today typically consist of 1 downstream (DS) service group with a mix of DOCSIS and QAM video. The total throughput required to feed a single DS service group with 1218 MHz of spectrum can theoretically exceed 11 Gbps but operators have generally coalesced around using 10G small form factor plus (SFP+) with 10GBASE-LR (long reach), ER (extended reach), or ZR/dense

wavelength division multiplexing (DWDM) optics based on IM-DD as a pragmatic, cost-effective solution.

The expense of updating the nodes once deployed leads operators to build outside plant (OSP) and the converged interconnect network (CIN) feeding DAA nodes for long term (5-10 year) capacity. Capacity needs are soon expected to exceed 10 Gbps in DAA nodes due to:

- Increasing desire to deploy segment-able nodes which provide an option to support 2 (or more) DS service groups in a single DAA node at 10 Gbps each (20 Gbps for 2 DS SG)
- DOCSIS 4.0 (D4.0) frequency division duplex (FDD) extension to 1794 MHz can support DS capacity in an individual service group beyond 13 Gbps; this allows D4.0 to exceed the capacity of 10 Gbps PON and offer true 10 Gbps service which may be an important marketing difference in years to come

As a result, 25G links to the DAA nodes is becoming a desirable target for the combination of D4.0 and multiple-downstream service groups in next-generation DAA nodes.

HFC DAA nodes are also generally power constrained, with increasing pressure to fit more and more processing or other features in a housing (in North America) which is thermally limited to 160-180 Watts in harsh outdoor environments. In many DAA node designs, pluggable uplink Ethernet optics are generally the constraint for maximum operating temperature. Larger and more thermally friendly pluggable form factors such as C form-factor pluggable half-size (CFP2) are favored in this environment over small form factor pluggable (SFP) or quad small form factor pluggable (QSFP) formats.

The upcoming standardization of a generic node housing with the SCTE Generic Access Platform (GAP) standard will drive this further by allowing other modules for edge compute or Ethernet switching in the same node. Power efficiency and power consumption are critical in DAA applications.

2.2.2. Remote PON

With advancements in IP video delivery and the ability for operators to deploy video service without traditional QAMs, cable operators are increasingly deploying more fiber to the home (FTTH) in the network. This is especially true in greenfield builds such as housing subdivisions, and also in rural areas fueled by government broadband funding. Common technologies for deployments today are 10G-EPON or XGS-PON.

Due to the nature of the cable network with long distance links to hubs and the desire for high split ratios of 64:1 or 128:1, many operators cannot easily support hub-based OLT. As a result, the emerging dominant deployment model is the Remote OLT (R-OLT), containing 4 PON segments within a single outside plant housing powered from the coax cable.

In terms of capacity, each PON segment is generally limited to ~9 Gbps of maximum throughput due to the nature of the PON system overhead. An R-OLT is typically fed using the same 10G SFP+ that would be used for HFC DAA including 10GBASE-LR/ER/ZR optics as a pragmatic solution. A one-to-one arrangement of SFP+ to PON segment is common, but some operators optimize cost using R-OLT platforms that support aggregation of the uplink interfaces to multiple PON segments.

R-OLT implementations could already use a cost-effective solution beyond 10G to support aggregation over a single interface for fiber/wavelength savings. Year over year capacity growth and evolution in the R-OLT is also expected to drive further need for capacity beyond 10G due to:

- Support for 25G-PON (25GS-PON or 25G-EPON)
- Potential increases in PON segments beyond 4 per R-OLT
- In some countries, cabinet-based deployments with up to 16 PON segments in a single chassis are also common

R-OLT are not as thermally or space constrained as HFC DAA nodes due to the lack of RF amplifiers, but pluggable uplink optics are still a significant design consideration.

2.2.3. Wireless xHaul

Many cable operators operate wireless networks directly or sell services to provide transport for wireless operators. With convergence of the access segment of the network to serve HFC and PON, it's natural to also consider wireless xHaul within that same network.

Figure 4 illustrates the split options in various 5G deployment architectures which differ in where and how functions are positioned between elements containing some or all RAN components consisting of CU, DU, and RU. Cable operators may deploy a mix of these architectures depending on the siting and capacity needs within a particular market.

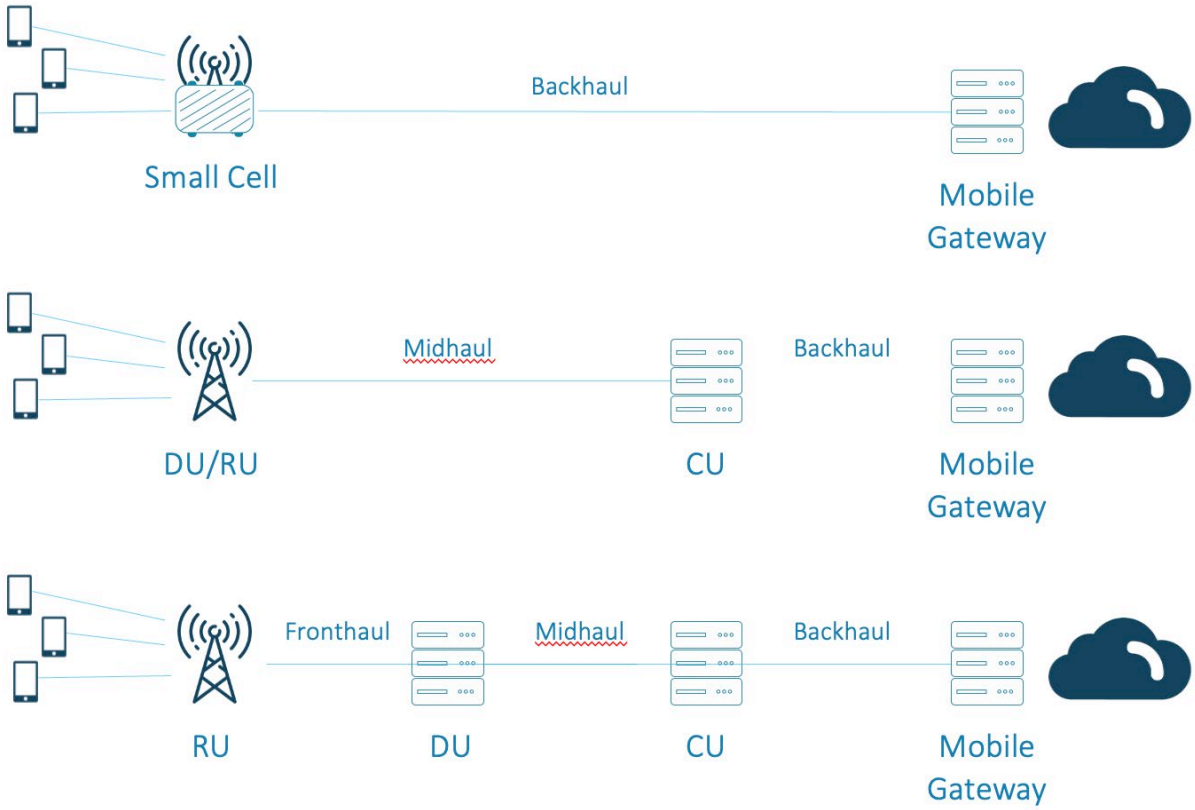

Figure 4 - 5G xHaul Transport Splits

Architectures feeding backhaul and common mid-haul options (F1 split, option 2) through the access segment will require overall capacity approximately equal to user bandwidth. Except in the case of massive multiple-input, multiple-output (MIMO) mm-wave bands, this capacity will generally not consume > 10 Gbps.

The increased use of virtualized RAN, with significant benefits in using elasticity to match capacity to where users move during the day, leads to growth in a fully disaggregated RAN with significant fronthaul usage possible through the access segment. While it is relatively common today to use dark fiber and gray optics with the need for fiber construction, an access segment which is naturally increasing capacity could allow for convergence and increased reuse of the existing fiber to boost wireless capacity.

Fronthaul bandwidth requirements, as indicated in [Cisco5G] can easily exceed 10G or even 25G as cell site capacity and the use of massive MIMO expands. An access segment architecture which supports endpoint capacities up to 100G could be well suited to serve these wireless needs.

Table 1 - 5G xHaul Transport Capacity Requirements

Band	Bandwidth	MIMO Layers	Fronthaul Data Rate for 3 Sectors No Compression	Midhaul/Backhaul Data Rate for 3 Sectors
850 MHz	10 MHz	4T/4R	7.35 Gbps	330 Mbps
1.8 GHz	20 MHz	4T/4R	14.7 Gbps	660 Mbps
3.5 GHz	100 MHz	64T/64R, 8 layers	57.87 Gbps	13.5 Gbps
28 GHz	400 MHz	64T/64R, 4 layers	82.32 Gbps	19.5 Gbps

2.3. Pushing beyond 10G

In the access space, service providers are faced with a challenging question – once an operator needs to upgrade or support capacities beyond 10G, should they upgrade to 25G or to 100G? If an operator upgrades to 25G, that increased capacity, as is often the case, will have a limited lifetime because there will be a need to upgrade soon again, assuming today's 30% yearly traffic growth persists. However, deploying 100G would likely be cost prohibitive today.

A quandary operators face in the "last mile" access network is that the number of network touch points far eclipses those of all other parts of the network. This leads to a situation where the operational expenses encountered for equipment upgrades drive costs that are often vastly more than for the equipment itself. Operators are well served to think this through and work to deftly address these ever-growing needs, going beyond just a repetitive process of constantly adding capacity in an incremental fashion. Minimally, such changes should have a lifetime of at least five years, and more ideally upwards of ten years.

Many choices have a ripple effect beyond just the end point solution. Commonly end points require an aggregation router at a hub/headend location. Aggregation devices with SFP/SFP+ interfaces usually have two or more 100G interfaces and those are used to communicate with two or more spine switches. When a network operator is considering bandwidths above 10G, each leaf switch is only aggregating four to seven 25G optics, or in other words, the cost of that leaf switch is applied to only six 25G end points on average. The hub facility at the edge of the network may also be experiencing space and power constraints so density of connections is increasingly important, especially when considering operator intention to add new functions like mobile edge compute (MEC). If an operator chooses to upgrade to 100G optics, then they might only be using 15%-20% of the capacity, so again, an aggregation device is needed higher up to drive more efficient port utilization on routers.

In HFC networks, it is becoming increasingly observed that fiber termination points at the fiber node demarcation points (where fiber transitions to coax occurs), are becoming an increasingly strategic point in the network that can be leveraged for a multitude of services. Fiber is such an important resource, as it represents an asset that was constructed at great expense. Furthermore, it is also a medium which is incredibly flexible and expandable at modest cost. These fiber end points represent the "new network edge" for MSOs that can be used to serve not only coax-fed residential and SMB customers, but also enterprise customers, cell backhaul services, as well as an operator's own RAN.

3. Existing optical transmission technologies

Direct detection (DD) was one of the first solutions to detect optical signals at the receiver. It is a technique where only the amplitude information is preserved after the photodiode optical signals are converted into electrical currents. The first commercial optical systems were realized with this technique, and DD dominated all market segments until approximately 2010. Up to that time, optical systems could transport 10 Gbps per channel over a total of 80 wavelength division multiplexed (WDM) channels on a single fiber.

Since 2010, there have been rapid advancements in coherent optical transmission technology to extract more and more capacity from a single channel. As a result, transmission systems with 800 Gbps or higher capacity are now commercially available. Coherent optics, in a similar way to the classical concept of coherent radio transmission, uses polarization along with amplitude and phase modulation to realize higher order quadrature modulations and provide higher capacity from a specific line rate or channel bandwidth.

3.1. 10G

10 Gbps per channel is widely used today. 10 Gbps Ethernet, first standardized as IEEE 802.3ae in 2002, is used widely in enterprise networks and access network backhaul especially for DAA in DOCSIS and fixed wireless networks. 10 Gbps was standardized as an option for FTTH in 2009 as IEEE 802.3av (10G-EPON) and in 2010 as ITU-T G.987 and is now the fastest growing access network technology in the world. 10 Gbps isn't just for fiber, either – DOCSIS support for DS speed approaching or exceeding 10 Gbps is becoming possible with DOCSIS 4.0 technology.

3.2. 25G (and beyond)

IM-DD has continued to evolve. 40 Gbps was the next step, with IEEE 802.3bg in 2011 creating the standard for single-lane 40 Gbps Ethernet (4 × 10 Gbps was standardized in 2010), but it is limited to a distance of 2km and is all but defunct in the market.

25 Gbps, as a by-product of 100 Gbps (4 × 25 Gbps) was the next step beyond 10 Gbps that was attractive to the market. IEEE 802.3by and IEEE 802.3cc standardized 25 Gbps in a single lane, and 32G Fiber channel (really 28 Gbps) was introduced at the same time.

25 Gbps has taken on a life of its own, independent of 100 Gbps. Economically 25 Gbps fits a sweet spot in network designs – fulfilling a need for more bandwidth but at a much lower cost than a jump to 100 Gbps. 25 Gbps per channel is now being applied to passive optical networking in the 25/50G EPON standard, IEEE 802.3ca. The limits of today's IM-DD technology began to be exposed in development of 50G PON at the ITU-T where 50Gbps over a single channel in the downstream was adopted for the ITU-T G.9804 series. Nonetheless, specification of 50 Gbps in the upstream was postponed in favor of 10 Gbps and 25 Gbps in the upstream due to the difficulties of burst reception at 50 Gbps.

Achieving 100 Gbps on a single channel with IM-DD was no small feat. In 2021, IEEE 802.3cu was able to achieve a standardized 100 Gbps on a single channel at a distance of 10 km. There are proprietary versions of single-lane 100Gbps that are able to achieve up to 40 km, but greater distances are relying on advanced modulations.

4. Future coherent transmission technologies

A race is on to establish the next-generation technology that will replace current P2P 10G optics based on IM-DD to support increasing capacity requirements for access and metro to serve DOCSIS, PON, and 5G wireless services. Among the most relevant challenges, one could single out bandwidth demands, compensation of the physical layer impairments, and continuous and dynamic network upgrades. Next, we will describe coherent systems in the form of single-carrier systems as well as DSCM.

4.1. Single-carrier coherent systems

Coherent detection has two key advantages over IM-DD. The first is that coherent detection preserves the phase information, and DSP algorithms can be applied within the transceiver to decode information embedded in the phase. Secondly, the local oscillator allows excellent channel selection. The first property was not fully exploitable until complementary metal–oxide–semiconductor (CMOS) and digital-to-analog (DAC) and analog-to-digital converter (ADC) technologies became mature. The second became less important after the introduction of the first commercial optical amplifiers. Because of this, coherent was not used during the first optical revolution that started with WDM systems and IM-DD. After the dot-com era and explosion of IP data traffic, the throughput of IM-DD systems became insufficient to cope with the exponential bandwidth growth.

This led to the rapid development of 100G thanks also to the implementation of the DSP algorithms and advanced forward error correction (FEC) code within the first generation of application-specific integrated circuit (ASIC) [Sun2008, Roberts2009]. These achievements led to the spreading of coherent technology from subsea to core and regional networks, where it replaced the IM-DD. Now, coherent transponders can achieve data rates beyond 1 Tb/s [Sun2020, Buchali2016], employing high-order modulation formats enabling a multitude of modes by varying the symbol rate, FEC overhead, and probabilistic constellation shaping (PCS). Although coherent has been so far confined to core and submarine networks, thanks to recent initiatives such as 400ZR, it is set to enter new markets such as data center interconnects.

IEEE 802.3ct has released a specification for 100 Gbps over a single channel for 80 km using dual polarization-differential quadrature phase shift keying (DP-DQPSK) (not direct detection). CableLabs® released a coherent optics specification in 2019 that describes the architecture and requirements for a 100 Gbps and 200 Gbps capable of up transmitting data up to 120km. As of today, though, only a handful of vendors are offering products that meet the 100Gbps requirements and fewer are offering a 200 Gbps option. The CableLabs coherent optics specification requires only a single fiber for transmission which is a big advantage over most other options that require 2 or more fibers. One potential disadvantage of coherent optical modules is that they incorporate a DSP into the housing which requires more power and a larger format due to the component size and required heat dissipation.

Type	Launch Power (dBm)	Loss Budget (dB)	Distance (km)	Speed (Gbps)	Fiber Count
10GBASE-ZR	0	25	80	10	2

Type	Launch Power (dBm)	Loss Budget (dB)	Distance (km)	Speed (Gbps)	Fiber Count
25GBASE-ER	-1	20	40	25	2
25GBASE-LR	-5	18	10	25	2
10GBASE-ER	-1	14	40	10	2
10GBASE-LR	-11	8	10	10	2
50GBASE-LR	-4.5	12	10	50	2
50GBASE-ER	-0.5	15	40	50	2
100GBASE-FR1	-2	4	2	100	2
100GBASE-LR1	-1	8	10	100	2
CableLabs P2PCO 100G	-6	21	80	100	1
CableLabs P2PCO 200G	-7.5	19	80	200	1
10GBASE-PR	2	30	20	10	1

Table 2 - Comparison of Single Channel Optical Systems

Coherent is also gaining momentum in the PON space with CableLabs recent kickoff of Coherent PON which is targeting 100Gbps PON using coherent optics as the underlying physical layer.

4.2. Digital subcarrier multiplexing based coherent systems

An alternative and more flexible solution to standard coherent is digital subcarrier multiplexing (DSCM), which creates subcarriers (SC) in the digital domain using only one laser. From a networking perspective, it is similar to the sliceable bandwidth variable transceiver (S-BVT) introduced by [Sambo2015]. The key difference between the single carrier of Section 4.1 and DSCM is that now the DSP operates at a symbol rate (R_s) of R_s/N, where N is the number of digital SCs. Clearly, in this case. the transceiver performance might be limited by the value of the laser linewidth Δf [Dris2013]. In fact, given the larger symbol period T_s, the $\Delta f \bullet T_s$ product for a DSCM signal with N SCs is N times larger than that of a single wavelength [Welch2021].

DSCM is used in P2P links [Sun2020], and it provides different benefits. First, it enables, by parallelizing with respect to the individual SCs, simplifcation of the DSP algorithms. For example, the compensation of accumulated dispersion. Second, it significantly reduces the impact of equalization enhanced phase noise (EEPN), which is relevant in the case of long-haul transmission. Third, by optimizing the modulation format of the SCs, it helps to increase the tolerance against filter cascade [Rahman2016]. Last, thanks to its intrinsic flexibility, it enables transmission to be adapted to the current traffic, thus reducing the power consumption [Velasco2021].

A pictorial representation of the spectrum of a 400G 16QAM DSCM signal – with 16 SCs at 4 gigabaud (GBd) each, and its equivalent single-carrier are depicted in Figure 5, where both channels occupy the same 64 GHz bandwidth. Only in case of ideal Nyquist shaping (i.e., roll-off = 0) there is no need for a guard band as there is no overlap. Roll-off = 0 is not possible, and therefore a guard band is needed [Welch2021].

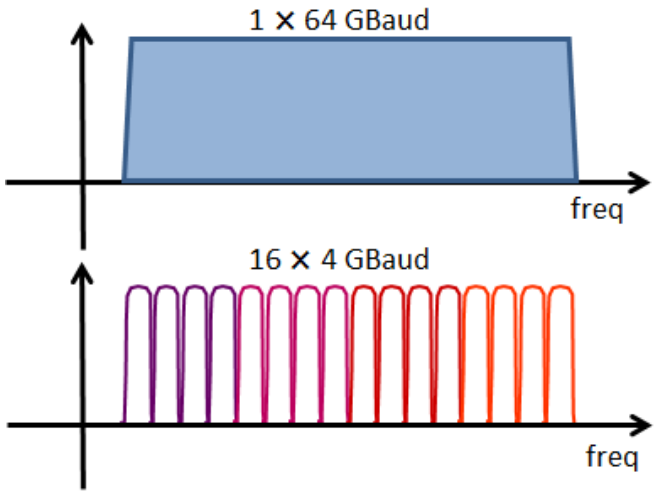

Figure 5 - Single Carrier and DSCM Spectrum

4.3. Enabling point-to-multipoint optical aggregation networks with DSCM

Beside the benefits described in Section 4.2, DSCM and coherent can enable the re-architecting and simplification of future optical networks. Figure 6 illustrates a simplified metro/access aggregation network realized with P2P transceivers (a) and with P2MP ones enabled by DSCM (b).

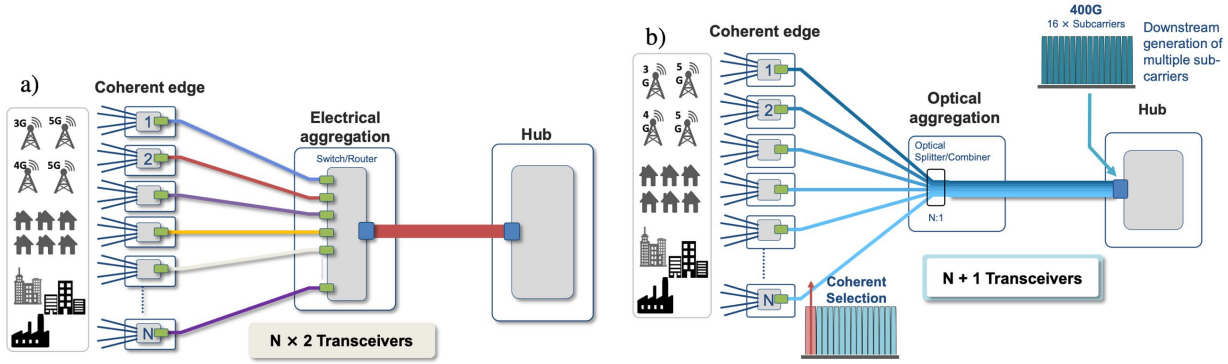

Figure 6 - Point-to-Point vs. Point-to-Multipoint Aggregation

In Figure 6-a, the N end users are equipped with N low-speed transceivers connected with their N pairs at the electrical aggregation stage. Next, a high-speed transceiver communicates to the hub, for a total of 2N

(low-speed) + 2 (high-speed) transceivers. The architecture shown in Figure 6-a can be realized by employing IP routers for aggregation and multiplexing of the low-speed into the high-speed transceivers, where each link uses the optimal rate P2P transceivers.

This approach is sub-optimal for hub and spoke traffic and is a major drawback of this solution. As optical spectrum in fiber is not scarce outside core networks, to achieve the lowest cost solution, we minimize the number of regeneration points. This approach hides a waste as there is no value to the end-users in regenerating traffic unnecessarily. In fact, this approach is constrained by decisions that are based on the peak traffic value. Consequently, operators will decide (1) to minimize the number of physical site visits, thus deploying higher-capacity transceivers – i.e., higher CAPEX or (2) to optimize the capacity of the transceivers; thus, increasing the number of truck-rolls, i.e., higher OPEX. Neither solution is economically optimal. With this architecture if an endpoint requires more capacity, the two transceivers in that link must be replaced. In the situation where the electrical aggregation devices utilize common port capacities, as is typical in most commercial high density devices, the entire aggregation device and all attached transceivers may need to be replaced. A typical example of this could include a DAA CIN built to support 10G with high density 10G switches for electrical aggregation; a need to change a link to the next step higher (25G) cannot be easily accommodated in the existing aggregation device.

Figure 6-b shows the same aggregation network realized with DSCM. The electrical aggregation stage is now replaced by a simple 1:N passive optical combiner, which greatly reduces the number of devices and stages needed to aggregate and up-speed the traffic to be transported to the next hub. In Figure 6-b, only N low-speed transceivers and 1 high-speed are required, i.e., 50% less than in Figure 6-a. This P2MP architecture connects multiple low-speed transceivers (spokes) to high-speed ones (hubs), breaking the bookended transceiver paradigm. These benefits directly translate into lower power consumption, smaller footprint, less sparing of parts and grooming equipment.

Furthermore, P2MP with DSCM enables cross-layer savings related to an efficient utilization of the optical transceivers, which can flexibly provide the required amount of capacity. For example, an operator deploys 100G (4×25G) P2MP pluggable optics in 12 leaf nodes. On day 1, only 1 SC per node is active, and all 12 SCs are terminated in a single 400G hub router port, which can receive up to 16 SC at 25G each. This is equivalent to approximately one-half (13 vs. 24) of the devices compared to what would be required with P2P optics on day 1. If the capacity grows in the edge nodes, then more SCs will be needed over time, and they can be activated via software. This operation is possible if the definition of SCs is maintained over more generations of P2MP optics, so that different versions of pluggable can interoperate, and operators can thus define multi-generational network architectures. By enabling this, routers and hubs can be independently upgraded, thus decoupling nodal upgrades from network-wide ones. Network operators can maximize the return on investment and ensure a smooth and cost-effective capacity upgrade of the network.

Nevertheless, there are challenges for P2MP architectures. First, it requires time to remove routers from the network, as these elements are rich in features, and operators use them for several network functions. Second, having fewer transceivers leads to network simplification, but if one device fails, the amount of traffic that is affected will be larger. A third challenge is the transmission of SCs over different light paths. If different SCs are propagated over different links, at the hub, they might suffer power imbalance. The pluggable will have an adjustable range to transmit and receive, and this will be monitored via a power control loop between the hub and each edge transceiver. Nevertheless, if the path loss difference exceeds the transmit output adjustment range, an external attenuator might be required.

As bandwidths increase and the number of devices in the geographic area expands, there may be a desire for protection or redundancy. The access network is typically unprotected over the last mile, but

redundant optics can be used at the hub location to protect against module failure; where there is an active/standby architecture deployed. If diverse fiber paths are available, then current protection mechanisms can be used to protect against fiber cuts. The cost of redundant equipment at the access edge of the network is typically prohibitive but for those applications that can justify the incremental expense that is also an option.

Overall, coherent with DSCM is a combination of mature technologies and it has been successful in high-end products, but when it comes to mass production, the required components, e.g., the laser, might have higher costs relative to traditional IM-DD or single carrier coherent solutions. On the other hand, coherent with DSCM significantly reduces the number of devices, eliminates the electrical aggregation stage and reduces the number of truck-rolls. It has been shown that, if the coherent pluggable price is below 50% of the existing pluggable, the solution presented in [Welch2021] brings cost benefits, when we consider the entire network [Marino2021].

4.3.1. Time-division versus frequency-division multiplexing

Time division multiplexing (TDM) and frequency division multiplexing (FDM) serve different scenarios with their advantages and disadvantages. In access, TDM – and its variants, e.g., statistical TDM – is used in PON networks before aggregation, where the multiplexing is carried out in time. This is a complex operation in the case of high data rates.

FDM – with DSCM – has been deployed in core networks [Sun2020] and enables Tb/s channels after aggregation via high-speed coherent transponders. In transport, the FDM-based channels are seen as one carrier by the remaining elements of the network. Hereafter, we compare TDM versus FDM, based on network application scenarios.

In PONs thanks to the application of statistical TDM, end users can receive streams down to Mb/s speed. This differs from the proposed coherent solution with DSCM approach, as the laser instability does not allow it to operate at symbol rate well below 1 GBd. From a transmission point of view, PONs today use the highly cost-effective IM-DD, whose transceivers are manufactured in volumes exceeding millions of units per year [Nesset2017].

On the other hand, in the case of data rate upgrade in a PON network based solely on TDM, all devices (hub + leaf modules) need to be replaced because the same peak communication rate must be supported. With FDM, the technology used and power consumption applicable to lower data rate locations can be optimized for that lower data rate. Transmission and reception at the peak rate is not needed. Maintaining high peak rates in all locations may increase costs and integration challenges for those optoelectronics in applications that do not need the full channel rate. .

Next, PON TDM transceivers cannot exploit the capability of advanced DSP techniques. DSP algorithms have difficulties in the learning phase required for burst mode transmission that is used in today's PON. For this reason, data rate upgrade might be limited for what concerns reach and synchronization. The last is particularly critical as the leaf modules will be placed at different locations before the aggregation stage. Because of these limitations, PON standards advance at a slower pace compared to other technologies.

In opposition to PON based solely on TDM, FDM simplifies data rate upgrades and enhances the network flexibility. By using DSP and continuous mode transmission/reception in both directions, it can extend the reach, and it supports DWDM. An FDM network enables different costs for users versus hub, the upgrades are independent, and they can be performed per individual end user (at a given coarse granularity). Thanks to these characteristics, P2MP based on DSCM and coherent can achieve a capacity

of 400G. P2MP optics based on coherent transmission with DSCM offers a roadmap to higher end user capacities than IM-DD implementations can achieve, and as traffic demands in access networks grow, the proposed implementation provides a number of other advantages, as discussed above.

5. Beyond 10G Solution Comparison

A flexible access segment optical network topology should provide:

- Cost effective technology
- Scalability as well as ease of upgrading
- Sufficient distance reach
- Integration into outside plant node platforms
- Service convergence to allow for a unified access network segment
- Efficient use of hub space and power
- Long deployment lifespan
- Operational simplicity

Table 2 provides the authors' view of a summary comparison of the available technologies with these criteria in mind . A "+" score indicates a technology which excel in a particular area while "–" indicates the poor ability to support the desired criteria. For single-carrier coherent, some criteria are greatly impacted by the use of electrical aggregation (EA) and the "with EA" variation covers the case where electrical aggregation in the outside plant is added.

Table 3 - Beyond 10G Solution Comparison

Criteria	IM-DD 25G	Single-Carrier Coherent 100G/200G+	DSCM 25G-400G
Aggregate Module Capex	+	-- - with EA	-
Scalability	-	Neutral + with EA	++
Reach	-	+	+
Node Integration	+	Neutral	Neutral
Service Convergence	Neutral	+	+
Hub Space/Power	Neutral	Neutral	+
HFC DAA Suitability	+	- Neutral with EA	Neutral
PON R-OLT Suitability	Neutral	Neutral	+
Wireless xHaul Suitability	Neutral	Neutral	+
Deployment Lifespan	-	+	+
Operational Simplification	Neutral	-	+

Aggregate Module Capex

- 25G IM-DD solutions provide very reasonable module costs while coherent solutions are expected to be significantly higher than IM-DD for some time

- DSCM allows for a significant reduction in the number of transceivers due to the P2MP operation and optical splitting/combining

Scalability

- The selective use of subcarriers in DSCM allows for a single module to support a range of total bandwidths while the capacity is fixed in IM-DD; this could allow for specific variants of the modules which only serve small numbers of subcarriers

- Single carrier coherent can scale in capacity through modulation, but does not generally support scaling below 100G per link without the use of electrical aggregation

Reach

- IM-DD solutions in the 25G and above range (and especially in DWDM configurations) are not readily available beyond 40km while coherent solutions can provide reach out to 120 km in point-point operation. P2MP operation with DSCM can be achieved beyond 40 km at rates up to 100G with split ratios of 32:1 or less

Node Integration

- IM-DD 25G solutions using SFP28 are nearly identical in space and thermal footprint compared to 10G SFP+ used for DAA and R-OLT nodes today

- The extra power in the optics and DSPs in coherent solutions drive increased power beyond 7W and require larger form factors for node integration such as CFP2 to support effective passive cooling

Service Convergence

- Moving past 10G generally allows service convergence but the maximum limit may prevent higher rate wireless fronthaul or business services from being offered over the same access segment optical network

- Coherent solutions allow for greater data rates to more easily aggregate multiple services and support higher xhaul capacity needs

Hub Space/Power

- The additional power consumed by single-carrier coherent solutions is offset by the reduction in total switch ports if aggregation of multiple services is possible externally (outdoor coherent termination device for example)

- DSCM provides significant benefits for hub space and power due to the P2MP operation which allows for aggregation of multiple end points into a single high-rate hub module along with simple optical passive combining/splitting

HFC DAA Suitability

- Single-carrier coherent, because it cannot scale down without separate electrical aggregation, is not well suited to the 20-25G requirements of segment-able D3.1 and D4.0 DAA nodes

- DSCM can scale down to a single subcarrier to suit 25G needs but does come with tradeoffs on power and space in HFC DAA nodes already constrained in those areas

PON R-OLT Suitability

- 25G IM-DD supports 2:1 aggregation relative to 10G PON technologies (peak capacity design targets)

- DSCM scales well through the range of possible uplinks in a typical 4 port R-OLT (40-100 Gbps), even considering some oversubscription while single-carrier coherent overserves capacity in today's 10G PON environments

Wireless xHaul Suitability

- DSCM supports lower scale than single-carrier and the dynamic P2MP operation is very well suited to the elasticity and number of radio endpoints that are served

Deployment Lifespan

- IM-DD will eventually bump into limits as 25G is no longer sufficient for transport to last mile access devices

- Coherent solutions provide significant capacity to cover near and long-term requirements

Operational Simplification

- IM-DD 25G operations are just like DAA and R-OLT today

- Single carrier coherent will generally require a coherent termination device to fit the wide range of devices driving up transceiver count and adding another layer of electrical aggregation devices into the network

- DSCM use of P2MP operation ideally suits the needs of the network and allows passive optical splitting/combining instead of electrical aggregation

6. Conclusions

This article presents a comprehensive discussion on why access segment optical transport Beyond 10G is required while reviewing the solutions available using IM-DD and coherent transmission technologies. A new concept of coherent digital subcarrier multiplexing (DSCM) provides benefits in scalability using individual subcarriers while supporting P2MP operation to allow for transceiver reduction and replacement of electrical aggregation from single-carrier coherent with passive optical splitting and combining.

The near future is sure to be very active in this area with interoperability and standardization happening on multiple levels including the newly created OpenXR Forum and just launched CableLabs 100G Coherent PON projects.

Elias Chavarria Reyes, Ph.D., Hitron Technologies, Inc.

John Chapman, Cisco Systems, Inc.

1. Introduction

This paper will detail the design and implementation of a cloud-based application to enable DOCSIS Time Protocol (DTP) deployment. This application is unique to the cable environment and its implementation can serve as a reference design for future cable cloud applications.

The key components of the app will be a database and an application programming interface (API). The application can be implemented on multiple cloud platforms. We chose to prototype our application on Amazon Web Services (AWS). The architecture design will follow the AWS Well-Architected Framework to leverage the benefit of the cloud and will provide horizontal scalability, pay-as-you-go cost structure, and high availability. The application will also be designed for service assurance, which is critical in field deployments. All cloud-based components and a CMTS emulator with the API client will be implemented on AWS.

DTP was invented in 2011 by John Chapman of Cisco [1], in anticipation of using the DOCSIS network to provide timing as a service (TaaS). In 2012, DTP was standardized as part of DOCSIS 3.1 [2]. This version of DTP defined the core algorithm and functionality. Since the primary use case for DTP is mobile backhaul over DOCSIS, CableLabs introduced the SYNC specification [3] in 2020 to address this use case. As part of the SYNC specification initiative, Elias Chavarria and John Chapman from Cisco redesigned the DTP algorithm to bypass a set of limiting assumptions in the original DTP design [4]. Also, in 2020, a group of companies, including Cisco, Hitron, Charter, and CableLabs, did a proof of concept (PoC) to validate the performance of DTP. The test results of the proof of concept are reported in a separate Society of Cable Telecommunications Engineers (SCTE) paper this year [5] and a CableLabs technical report [6].

At its core, DTP allows a DOCSIS network to interface its native timing and frequency to external timing protocols. To do this, DTP establishes a set of techniques and DOCSIS signaling messages between the cable modem (CM) and the cable modem termination system (CMTS).

In the original DTP design, the DTP messages contained CM and CMTS timing parameters. The underlying assumption was that the timing parameters for the CM could be measured separately from the CMTS ones before deployment. The timing parameters in the CMTS and CM would have been scalable in this distributed measurement model. For the assumption to be valid, a testing device capable of measuring those timing parameters needs to exist. However, no such testing device exists. Therefore, the usability of the original DTP design was limited. For this reason, DTP was redesigned as part of the SYNC specification effort [2].

In the redesigned DTP, the timing parameters are no longer measured separately for the CM and the CMTS, they are instead measured jointly. With this change, existing testing devices in the market can be used. A consequence of this change is that the number of measurements grows from linear to exponential. If n number of CMTS products and m number of CM products support DTP, the original DTP design required n+m measurements of timing parameters. The redesigned DTP calls for $n * m$ measurements of timing parameters.

The values of the DTP timing parameters that a DOCSIS network should use also depend on the CMTS and CM configuration, e.g. the interleaver configuration. For example, if there are w number of different interleaver configurations, the total number of measurements of timing parameters grows to $n * m * w$. In Phase 2 of the DTP PoC that Cisco, Hitron, Charter, and CableLabs are conducting [5], they will assess the impact of other configuration parameters, e.g., modulation, cyclic prefix, and frame size. If all these configuration parameters impact the DTP timing parameters, the total number of measurements will

continue growing exponentially. Assuming x different modulations, y different cyclic prefixes, and z different frame size, a total of $n * m * w * x * y * z$ timing measurements would be required.

The cable industry has two options to handle the measurement, storage, update, and accessibility of all the DTP timing measurements. One option is for every CM and CMTS vendor to do everything by itself, which would lead to a replication of effort and resource investments with little added value for the vendors. The second option is for a common entity, such as CableLabs, to lead the measurement, storage, update, and accessibility of the DTP timing parameters. This second option allows the cable ecosystem – both vendors and operators – to leverage a shared pool of resources. The opinion of the authors is that the second option is more feasible for the cable industry. To make this second option a reality, the authors propose a cloud application, as discussed in the following sections.

The DTP calibration includes three major steps: 1) collect the calibration data; 2) build a cloud app that distributes the data; and 3) a CMTS to access and apply the calibration data. The DTP calibration test could be conducted in many test labs. For example, CableLabs/Kyrio established a Network Timing Lab that could evaluate the DTP performance and collect the calibration data. One of the key contributions of this paper is to present the design of API and the AWS cloud server that distributes the calibration data. The CMTS will access the database to obtain calibration values in real-time via the API. Using these values, the CMTS will calculate the timing offsets for the CM and the 5G radios. CableLabs expects to continuously sponsor the application to enable the commercial deployment of DTP.

2. DTP Calibration Method

In this section, we further explain why DTP needs calibration and how to do the calibration. The DTP timing diagram is shown in Figure 1, where DS-T and US-T denote downstream (DS) and upstream (US) delays inside the CMTS, DS-H and US-H are DS and US delays in the hybrid fiber-coaxial (HFC) plant, and DS-C and US-C are DS and US delays caused by the CM. The CMTS sends the DOCSIS 3.1 timestamp. The timestamp is delayed when it arrives at the CM. In other words, the timestamp that arrived at the CM represents an early version of the CMTS timestamp. The time error (TE) is in the DS only. Ideally, DS-T, DS-H, and DS-C should be measured separately and used by DTP. However, DOCSIS does not provide the reference points to measure these delays. DTP provides a practical way to calibrate the DOCSIS 3.1 timestamp using the true ranging offset (TRO).

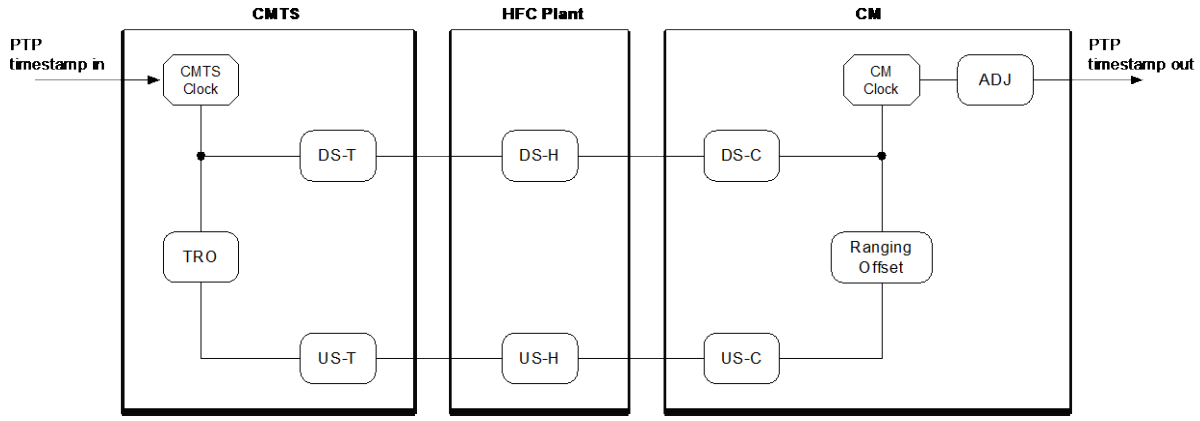

Figure 1 - DTP Timing [3]

DTP messages are exchanged between CMTS and CM, see Figure 2 for the case when the CMTS is the DTP master and the CM is the DTP slave. The CM measures the round-trip delay as the TRO. The CM

reports the TRO to the CMTS in the "DTP-Response" message. The CMTS sends the time adjustment *t-adj*, or *t-cm-adj*, to the CM using the "DTP-Info" message. The *t-cm-adj* is approximately equal to half of the TRO. The CM timestamp over its CM to CPE interface (CMCI) ports is equal to the DOCSIS 3.1 timestamp plus *t-cm-adj*. The *t-cm-adj* corrects the time error in the network. Note that the propagation delay through coaxial cable and fiber is theoretically symmetrical.

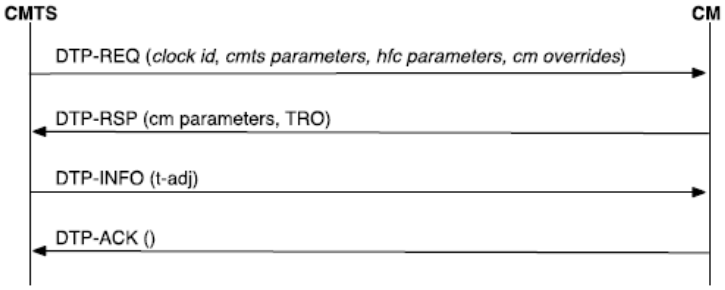

Figure 2 - DTP Message Flow [3]

If *t-cm-adj* is set to be half of the TRO, *t-cm-adj* cannot correct asymmetrical delay (different in DS and US). The asymmetrical delay is introduced by devices like CMTS, CM, remote physical RF layer (R-PHY) and remote physical and MAC layers (R-MACPHY), and any HFC elements. This asymmetrical delay needs to be measured in lab for each pair of CMTS and CM combos. The measured asymmetrical delay could be computed at the CMTS. For example, the following method is supported by the Cisco integrated CMTS (I-CMTS) cBR-8:

$$t\text{-}cm\text{-}adj = t\text{-}tro/2 + y, \quad (1)$$

where *y* is an additional time adjustment that applies in the CMTS to calibrate the DS delay in the DOCSIS 3.1 timestamp. This approach is described as method 2 in Section 5.4 in [6]. CM location, plant length, and other symmetrical TE are taken care of by the TRO. The asymmetrical TE is addressed by the additional time adjustment *y*. This additional time adjustment *y* can be mapped to formula (18) in the SYNC spec [3], which we copy here:

$$t\text{-}cm\text{-}adj = t\text{-}cm\text{-}adj\text{-}R + [t\text{-}tro + t\text{-}hfc\text{-}ds\text{-}o - t\text{-}hfc\text{-}us\text{-}o - t\text{-}tro\text{-}R]/2, \quad (2)$$

where *t-cm-adj* is the live time adjustment that the CMTS sends to the CM, while *t-cm-adj-R* is the value of the DTP time adjustment used in the calibration test that brings the average PTP two-way time error to zero [3]. Similarly, *t-tro* is the live TRO that the CM measures and sends to the CMTS. *t-tro-R* is the TRO reported by the CM in the lab calibration test. *t-hfc-ds-o* and *t-hfc-ds-o* represent any fixed delay elements in the HFC plant that contribute to delay [2], in DS and US, respectively. *t-hfc-ds-o* and *t-hfc-ds-o* are provided by the CMTS to the CM.

The above formula can be rearranged as:

$$t\text{-}cm\text{-}adj = t\text{-}tro/2 + [t\text{-}cm\text{-}adj\text{-}R + t\text{-}hfc\text{-}ds\text{-}o/2 - t\text{-}hfc\text{-}us\text{-}o/2 - t\text{-}tro\text{-}R/2], \quad (3)$$

Comparing Eq. (3) to Eq. (1), we get that:

$$y = t\text{-}cm\text{-}adj\text{-}R + t\text{-}hfc\text{-}ds\text{-}o/2 - t\text{-}hfc\text{-}us\text{-}o/2 - t\text{-}tro\text{-}R/2. \quad (4)$$

Note that if the HFC plant is assumed to introduce no asymmetry, i.e., *t-hfc-ds-o/2* = *t-hfc-us-o/2*, then Eq. (4) is further simplified as:

$$y = t\text{-}cm\text{-}adj\text{-}R - t\text{-}tro\text{-}R/2. \quad (5)$$

Eq. (5) captures the asymmetry in the reference-length plant (see Section 6.4.1.1 in [3]) introduced jointly by the I-CMTS and CM (in an I-CMTS architecture), or jointly by the RPD and the CM (in an R-PHY architecture). In DTP calibration, the values for *t-cm-adj-R* and *t-tro-R* that make the average PTP two-way time error to zero will be measured in the lab and the additional time adjustment *y* will be distributed by the AWS database. *t-tro* and *t-cm-adj* in Eq. (1) will be calculated lively in the field.

In summary, as shown in Figure 3, DOCSIS 3.1 timestamp is used in DOCSIS 3.1 networks that include a delay in DS. DTP uses TRO to correct the symmetrical part of the DS delay. DTP calibration further corrects the asymmetrical part of the DS delay. For example, DTP calibration reduced the time error from 3,223,800 ns to 13-31 ns as reported in Section 8.4 in [6].

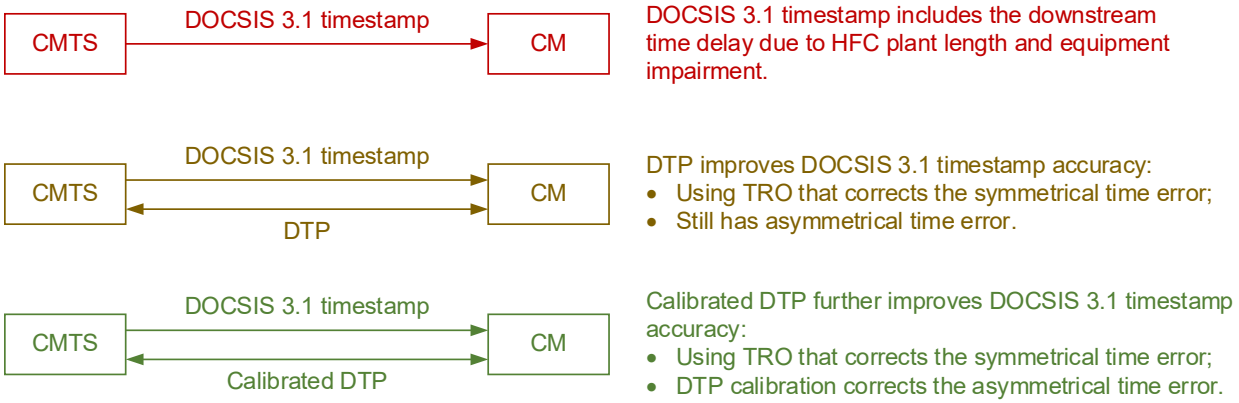

Figure 3 - DOCSIS 3.1 Timestamp, DTP and DTP Calibration

3. DTP Calibration Cloud Database Design

On a high-level, the primary components of the DTP calibration cloud database are – a database, a web-based graphical user interface (GUI) to provide a human interface for the lab engineer to add, read, and delete the DTP calibration entries, and an API framework to provide a machine interface for the CMTS to fetch the DTP calibration entries. Since the components to be implemented were functionally fairly uncomplicated, the decision to select a cloud provider was also relatively uncomplicated. AWS was selected as the cloud provider for DTP calibration since it is the most mature and enterprise-ready provider [7].

AWS provides multiple different methods to implement the abovementioned three components depending on the amount of modularity required in the system design. Figure 4 shows three possible system designs to implement a database, a web GUI, and an API in AWS with varying levels of modularity. Figure 4(a) illustrates implementing the three components within a single compute instance. While this approach provides vertical scaling capabilities, it offers limited flexibility and availability benefits. In Figure 4(b), the database is transitioned out to its own module while the web GUI and API reside on a single compute instance. Disaggregating the database offers added benefits of leveraging a database management system to abstract away the setup, operation, and scaling tasks. In Figure 4(c), all three components are implements in their own module. This approach provides the most modularity in terms of allowing

independent management and innovation of each component while hiding the complexity of each part behind an abstraction and interface.

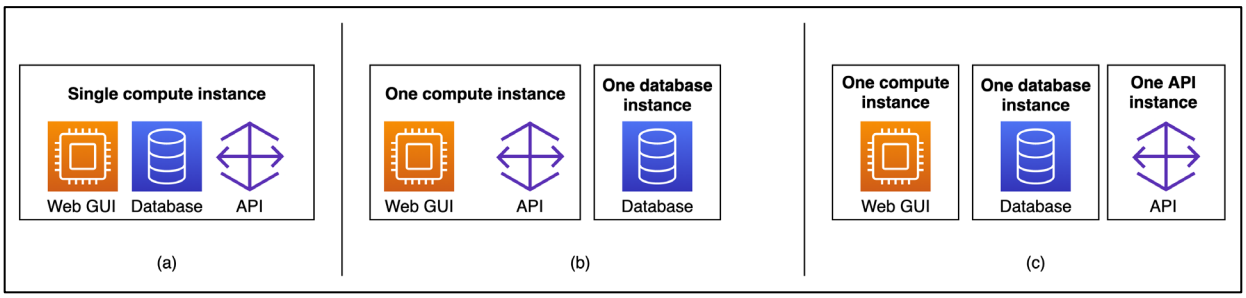

Figure 4 - Possible System Designs of the DTP Calibration Cloud Database

The complete framework of the DTP calibration cloud database is shown in Figure 5. The database is hosted using Amazon Relational Database Service (RDS), the web GUI is running on an Elastic Compute Cloud (EC2) instance, while the API framework includes Amazon API Gateway as the frontend and AWS Lambda service as the backend. To validate the end-to-end functionality of the cloud application, a CMTS emulator was developed to test sending requests and receiving responses from the cloud application.

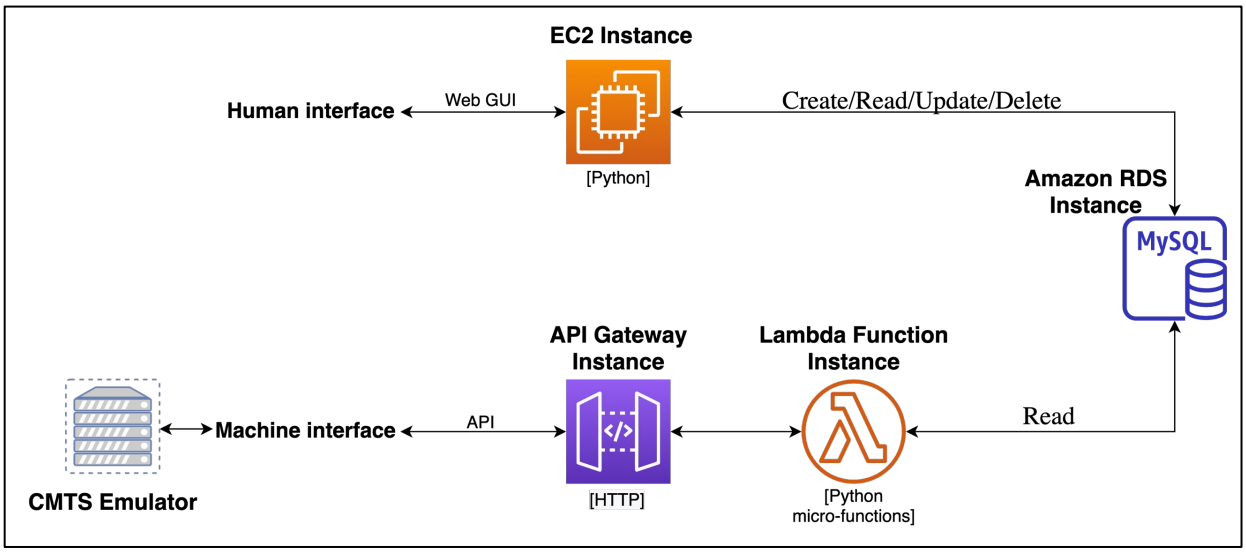

Figure 5 - Functional Design Diagram of DTP Cloud Calibration Database

Since the structure of the data to be stored in the database is not expected to change frequently, a relational database was selected as the database type. Amongst the different relational database engines available, MySQL was chosen as it is open-source and provides sufficient flexibility to run on any operating system. A Python script was developed to instantiate and create the database schema allowing for any possible changes in the future. Database reliability could be enhanced by utilizing the RDS Multi-AZ (Availability Zone) functionality provided by AWS wherein a standby database instance is automatically created in another AZ and data is synchronously replicated between the two instances.

The web GUI is implemented in Python using Flask [8]. Flask was selected as the web framework as it allows for easy addition of libraries or plugins for an extension and comes with a built-in development server and fast debugger. Additional modules for handling forms and enabling login using username and

passwords were implemented using Flask extensions. The web GUI provides the user with the capability to add new calibration entries to the database, read existing entries from the database, update existing entries in the database, and delete any existing entry from the database.

AWS offers two types of API Gateways – HTTP-based and websocket-based. HTTP APIs were selected as the API Gateway type since the communication between the CMTS and the cloud application is expected to be stateless and not based on stateful real-time two-way communication applications such as chat apps or streaming dashboards which require websocket APIs. Amazon's HTTP API Gateway provides API proxy functionality and low-latency, cost-effective integrations with other AWS services. Both HTTP GET and POST methods are implemented to enable sending query parameters via the URL of the GET request and the request body of the POST message. Since the connection between the CMTS and the cloud application is not expected to be persistent and would be infrequent (only when there is a new configuration pairing of CMTS-CM), the API backend also does not require persistent compute. Therefore, serverless Lambda functions are used in the API backend to consume compute resources only when needed – in case of an incoming request from a CMTS. The API Gateway is configured to pass the query/payload received from the client to the Lambda function and return the function's response to the client. A Lambda function is developed to run a database read query based on the received query/payload parameters (CMTS-CM Hardware-Firmware versions) and return the result (timing parameters) along with a valid HTTP status code.

The CMTS emulator is essentially an API client developed to test the responses of the cloud application by sending HTTP requests to the API Gateway with different Hardware-Firmware combinations. The content-type is set to application/json for these requests and responses. JSON is used as the payload format as it is lightweight and is suitable for both human reading and machine parsing. The motivation behind developing this emulator is to demonstrate the work needed by CMTS vendors to enable the remote collection of timing parameters from the cloud application.

The current application design also supports adding calibration entries, in addition to reading them, using the API Gateway and Lambda function framework. This would allow automation in the calibration process wherein a large number of timing entries could be added in the database without requiring manual work. Application security is considered at two levels: (i) API level: Access to the API can be restricted by either using HTTP request parameters-based authorization (such as username/password) or by using token-based authorization (such as JSON Web Token, JWT), and (ii) Network level: Access to the virtual network where the API framework is hosted can be restricted to known CMTS IP addresses only.

4. DTP Calibration Cloud Database API Design

4.1. Cloud App Message Flow

The message flow between the AWS server and CMTS is HTTP-based, as shown in Figure 6. HTTP uses TCP as transport layer to provide reliable network transmission using acknowledgments. Our DTP API uses "HTTP request" and "HTTP response" to exchange information between the CMTS and AWS server. The CMTS (client) sends Cal-data Request to the server that is contained in the HTTP Request. The Cal-data Request message includes network architecture and hardware/firmware combinations, see Section 4.2. The server sends Cal-data Response to the client that is contained in the HTTP Response. The data elements contained in the Cal-data Response message is described in Section 4.2.

The client sets a timer (i.e., 500 ms) using a status code when sending the Cal-data Request message. The client checks the status code and the received calibration data. If failure, the client resends the Cal-data Request message. The AWS server may provide multiple IP addresses for redundancy, and the client may

try another server IP address if failure over five times. There could be three failure reasons: 1) timer expired; 2) network architecture and Hardware/Firmware combinations do not match requested data; and 3) calibration data (test configurations or measured time error results) incomplete.

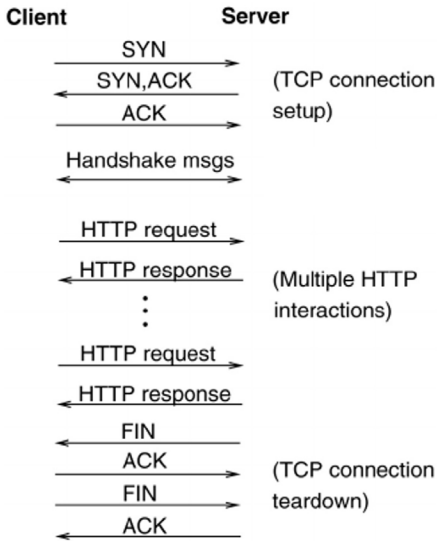

Figure 6 - HTTP and DTP Calibration Message Flow

4.2. Cloud App Data Structure

The data structure is illustrated in Table 1. Cal-data Request message only includes the first two data elements: network architecture and hardware/firmware combinations. Cal-data Response message includes all elements listed in Table 1. DTP could be deployed on the traditional network with I-CMTS and distributed access architecture (DAA). DAA also includes remote-PHY and remote -MACPHY. Network architecture is represented by two bits. Hardware and firmware combinations includes make, hardware and firmware version of I-CMTS chassis, I-CMTS line card, RPD (for DAA only), and CM.

Test configurations considered in the initial version of the cloud app include DS modulation scheme, DS interleaver, DS cyclic prefix, US modulation scheme, US cyclic prefix, and US frame size. DTP PoC [5] phase 2 testing is evaluating the impact of each parameter. Parameters that do not strongly impact DTP performance will be removed from Cal-data Response message. Other parameters that strongly influence DTP performance but are not listed above will be added to the Cal-data Response message.

Table 1 - Example Data Structure.

Network Architecture	Hardware & firmware combinations	Testing lab	Testing date	Test configurations	Additional time adjustment *y* (ns)	Constant Time Error (ns)
I-CMTS	Combo 1	CableLabs	11/1/2020	Config 1	200,000,000	-50
			11/1/2020		300,000,000	…
			11/2/2020	Config N	400,000,000	100
DAA	Combo 2	CableLabs	12/1/2020	Config 1	200,000,000	50
			12/1/2020		300,000,000	…
			12/1/2020	Config N	400,000,000	-100

5. Conclusion

4G/5G mobile networks require a high-accuracy synchronization source in the backhaul where the GPS signals are unavailable. DTP provides such sync signals in the backhaul over HFC networks. DTP needs automated calibration in the field to guarantee time accuracy.

This paper presented the DTP calibration method and design of a cloud app that distributes the calibration data. The cloud app is prototyped on AWS. A modular application design is developed allowing to leverage various cloud benefits such as abstraction, automation, and high-availability. The web GUI is implemented in Python using Flask allowing an engineer to add, read, and delete the DTP calibration data entries. The API uses HTTP protocol with JSON as the data format, and calibration data message flow was designed. Security and reliability enhancement features are considered and will be added based on costumers' requirements. Future work of automated DTP calibration includes collecting calibration data in test labs and adding them into the AWS database via the Web GUI. CMTS will need to add the corresponding feature to inquiry and apply the calibration data automatically. Proof-of-concept test for the AWS cloud app and automated DTP calibration is planned in the near future [5].

Abbreviations

API	application programming interface
AWS	Amazon Web Services
AZ	availability zone
CM	cable modem
CMTS	cable modem termination system
cTE	constant time error
DAA	distributed access architecture
DOCSIS	Data-Over-Cable Service Interface Specification
DS	downstream
DTP	DOCSIS Time Protocol
EC2	elastic compute cloud
GUI	graphical user interface
HFC	hybrid fiber-coaxial
I-CMTS	integrated cable modem termination system
PoC	proof of concept
RDS	Relational Database Service
RPD	remote physical layer device
R-PHY	remote physical RF layer
SCTE	Society of Cable Telecommunications Engineers
TaaS	timing as a service
TE	time error
TRO	true ranging offset
US	upstream

1. Introduction

Transparent Security is an open-source solution for identifying and mitigating distributed denial of service (DDoS) attacks and the devices (e.g., Internet of Things [IoT] sensors) that are the source of those attacks. Transparent Security is enabled through a programmable data plane (e.g., "P4"-based) and uses in-band network telemetry (INT) technology for device identification and mitigation, blocking attack traffic where it originates on the operator's network.

Cox Communications and CableLabs conducted a proof-of-concept test of the Transparent Security solution in the Cox lab in late 2020. Testing was primarily focused on the following major objectives:

- Compare and contrast performance of the Transparent Security solution against that of a leading commercially available DDoS mitigation solution.
- Validate that INT-encapsulated packets can be transported across an IPv4/IPv6/Multiprotocol Label Switching (MPLS) network without any adverse impact to network performance.
- Validate that the Transparent Security solution can be readily implemented on commercially available programmable switches.

CableLabs and Cox completed the lab trial in conjunction with Intel® and Arista Networks. Transparent Security was able to identify and mitigate attacks in less than one second as compared to greater than one minute for the leading vendor. We also validated that inserting and removing the INT header had no observable impact on throughput or latency.

Distributed denial of service (DDoS) attacks and other cyberattacks cost operators billions of dollars, and the impact of these attacks continues to grow in size and scale, with some exceeding 1 Tbps. The number of Internet of things (IoT) devices continues to grow rapidly, many have poor security, and upstream bandwidth is ever increasing—this perfect storm has led to exponential increases in IoT attacks, by over 600% between 2016 and 2017 alone. With an estimated increase in the number of IoT devices from 5 billion in 2016 to over 20 billion in 2020, we can expect the number of attacks and the size of attacks to continue this upward trend.

Detecting attacks is difficult, but mitigating them is even harder, and several solutions have been proposed with varying degrees of success. Typically, these solutions focus on blocking attacks that originate offnet and which targets an on-net resource. Even solutions that do identify attacks that originate on-net are limited in that they cannot block the attack traffic until after it has already traversed the access network. As such an operator's access networks can still be seriously affected, resulting in connectivity loss and quality of service (QoS) issues for customers.

Enhanced device visibility and packet processing can be used to identify the sources of such attacks. Leveraging programmable ASICs and P4 applications provides support for these enhancements by making the behavior of the data plane expressible in software and customizable without affecting performance. Specifically, this project will pair a DOCSIS modem with a series of P4-enabled devices connecting back to the operator headend via the P4 Runtime or Barefoot Runtime Interface (BRI). Both the P4 Runtime and BRI leverage GRPC as the underlying protocol. This architecture allows for visibility throughout the access network.

Transparent Security can leverage a machine-learning controller that has been trained with patterns to identify conditions and to perform dynamic operations by deploying new packet processing behaviors in the network (e.g., DDoS mitigation, virtual firewall, QoS detection/enforcement, and DOCSIS data plane functions). All operations will be performed at line rate while leveraging P4 in-band network telemetry

(INT), which allows data to be collected for reporting and analysis without control plane intervention. By inserting telemetry into the packet header, telemetry can be added to all packets rather than simply a sampling, which significantly reduces the time required to identify and mitigate the attack.

2. Motivation

As the proliferation of IoT devices continues to increase, the number of devices that can be compromised and used to participate in DDoS attacks also increases. At the same time, the frequency of DDoS attacks continues to grow because of the widespread availability of DDoS for-hire sites that allow individuals to launch DDoS attacks for relatively little cost. These factors contribute to a trend of malicious traffic increasingly using upstream bandwidth on the access network.

Typical DDoS mitigation solutions use techniques such as BGP diversion and Flowspec to drop traffic at certain parts of the network. However, mitigating outbound attacks using these techniques isn't entirely effective because the malicious traffic will have already traversed the access network, where it has the greatest negative impact before the traffic can be diverted to a scrubber or dropped by a Flowspec rule. Additional information on Flowspec can be found in section 4.2.2.2.

Transparent Security offers the promise of near-instantaneous detection of outbound attacks, as well as the ability to mitigate that attack at the source, on the customer premises equipment (CPE), thereby preventing that traffic from using upstream access network resources.

In addition to Transparent Security's DDoS mitigation capabilities, there are additional benefits to network performance/visibility in general. Implementation of Transparent Security on the CPE means that network operators can derive the specific device type associated with a given flow. This allows the operator to determine the type of IoT devices being leveraged in the attack.

This also opens myriad other possibilities—for example, reducing truck rolls by enabling customer service personnel to determine that a customer's issue is with one specific device versus all the devices on the internal network. Another example would be the capability to track the path a given packet followed through the network by examining the INT metadata.

Consumers will see a direct benefit from Transparent Security. Once compromised devices are identified, the consumer can be notified to resolve the issue or, alternatively, rules can be pushed to the CPE to isolate that device from the internet while allowing the consumer's other devices continued access. Such isolation mitigates the additional harm coming from compromised devices. This additional harm can take the form of degraded performance, exfiltration of private data, breaks in presumed confidentiality in communications, as well as the access network bandwidth consumed through DDoS. Less malicious traffic on the network provides for a better overall customer experience.

3. The History and Updates of Transparent Security

We initially released the Transparent Security architecture and open-source reference implementation in October 2019. Since then, we've achieved several milestones:

- Added source-only metadata to the P4 in-band telemetry specification, along with Transparent Security as an example implementation.
- Added support in the Telemetry Report 2.0 specification to collate multiple packet headers in a single telemetry report.
- Released a document titled "Transparent Security: Personal Data Privacy Considerations."

- Created a Transparent Security landing page.

Most proposed DDoS solutions fall into one of two categories, detection, or mitigation. This section discusses additional possible solutions in those categories and examines their advantages and disadvantages.

4. Existing Solutions

4.1. DDoS attack detection

DDoS attack detection is typically identified by an analytics engine identifying network traffic trends. These trends are based on routers sampling a summary of the packets as they enter the network. These samples can use IPFIX, NetFlow and SFlow to export this data.

The sampling technique cannot offer an operator a complete view of the network. Sampling is a statistics-based method for measuring network traffic by collecting, storing, and analyzing a sample of traffic data. This method has the advantage of allowing many interfaces to be monitored without significantly affecting network traffic.

IPFIX, SFlow and NetFlow are protocols used for sampling data. IPFIX and NetFlow are very similar, with IPFIX extending NetFlow v9 (https://www.oreilly.com/library/view/practical-network-scanning/9781788839235/1d6b69c7-62c3-40d0-be58-1ad82b22c115.xhtml). All these methods are limited to the data in the packet and do not contain any information about the network path used by the packet, validation for the source IP address or visibility to the source IP/device on a network behind a NAT.

Although the sampling method can effectively identify larger trends, it can miss anomalies that occur in a smaller portion of the traffic. That is, it can effectively detect a DDoS attack directed at a target, but it can miss or take longer to detect a DDoS attack originating at a given source. With source-based DDoS attacks, the system is trying to identify smaller anomalies, which are less likely to be captured in the sample.

4.2. DDoS Attack Mitigation

There are a wide variety of methods for mitigating DDoS attacks. A few of the common methods and the methods used by Transparent Security are highlighted below. This list is not exhaustive.

Also examined in this section are the points on the network where the mitigation is performed.

4.2.1. Network Locations for Mitigation

4.2.1.1. Out of Band

Out-of-band DDoS mitigations come in two flavors, appliances and scrubbing services. When an attack is detected against a host in the network, the traffic is routed through the out-of-band device, where it can remove or re-route the malicious traffic. An appliance routes traffic to the target to itself then removes the malicious traffic and provides a clean flow to the target. A service functions similarly except it routes target traffic to a mitigation center that cleans the traffic and forwards it to the destination.

However, both methods of out of band DDoS mitigation have downsides. The appliance is generally costly, and deployment can be complex. The service has difficulty defending low-bandwidth slow attacks,

and every interface must be protected, or it can fail to stop some attacks. Both methods can add latency to network traffic during an attack, and they generally rely on other methods for attack detection.

4.2.1.2. In Band

Traditional in-band DDoS mitigations are appliance based and work in the network path, comparable to a firewall, allowing the method to see all network traffic and react accordingly. As a result, in-band mitigation can provide detection as well as mitigation. However, it is costly, adds to network complexity and introduces another point of failure in the network.

4.2.1.3. At the Source

Transparent Security enables network operators to provide DDoS detection and mitigation at the source. This method protects target organizations with little to no effort on their part. It can also provide insight into hacked devices on the customer premises. This information can go a long way into preventing future attacks. Mitigation at this location has the added benefit of limiting attack traffic on an operator's network by blocking malicious packets before they enter the core network. Transparent Security mitigates primarily at the source, but the method is compatible with additional in-band target-based mitigation methods.

4.2.1.4. At the Target

While DDoS mitigation can be deployed at the target, it is generally of little use unless the attack is small (less bandwidth than the access circuit and less packets per second than the CPE is capable of processing).

4.2.2. Methods for mitigating DDoS attacks

4.2.2.1. Scrubber

As the name suggests, a scrubber cleans traffic to a specific host that is under attack. When an attack is detected, the traffic to that host is diverted to the scrubber—malicious packets are removed, and clean packets are forwarded. Different types of scrubbers have issues with either high-volume attacks or low-volume attacks. See Section 2.2.2.1, "Out-of-Band," for explanations of the weaknesses of out-of-band packet scrubbing. Scrubbers also require additional hardware in the network, which adds capital and operational costs for the service provider.

4.2.2.2. Flowspec

BGP Flowspec is an IETF specification (https://datatracker.ietf.org/doc/html/rfc7674) for diversion and filtering of malicious traffic. With Flowspec, the DDoS mitigation solution sends a BGP message to the routers which are forwarding the attack traffic. That router then blocks, rate limits, or forwards the traffic matching the Flowspec pattern.

4.2.2.3. Proprietary Matching Engine

Switch vendors have started developing proprietary packet matching and manipulation engines. Many of these engines could be leveraged to support DDoS mitigation.

5. Transparent Security Architecture

Transparent Security uses programmable data plane capabilities to enable real-time packet processing, high-resolution packet inspection, and in-band network telemetry (INT). INT allows MSOs to identify the compromised devices in milliseconds rather than minutes. This technology is enabled by new, currently available programmable chips that can process packets at line speed and be deployed at any point in the network, from the core network to residential and business customer premises.

Transparent Security is focused on inspecting, finding, and blocking malicious packets as close to the source as possible by adding details about the packet's source device, exact route through the network, and travel duration. INT can then be used by upstream processes to identify traffic patterns and then act on that information.

5.1. Data Plane Architecture

Figure 1 shows a typical data plane architecture of customer premises connected to the access network into an operator's core network. Any combination of the customer gateways, switches, and routers can be P4 enabled or not. By enabling P4, the available use cases increase substantially, but this architecture can be implemented in stages. Since the INT metadata is encapsulated in a UDP shim, there is no impact to L3 routing. Packets with the INT header can traverse network devices which do not support INT header insertion. Firewalls and other devices which use L4 headers will need to be updated to support INT to inspect the original L4 header.

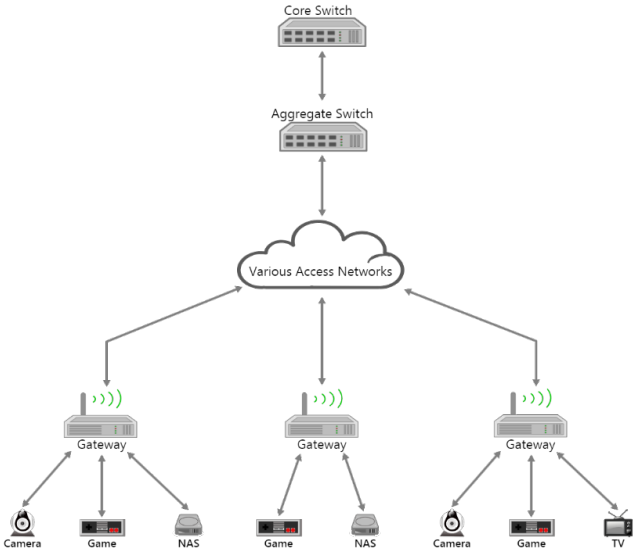

Figure 1 - General Architecture for the Data Plane in the Transparent Security Model

5.1.1. In-Band Network Telemetry

INT is a method for adding telemetry data to every packet at multiple points on the network. This approach can help determine things such as the path of a packet or the source device emitting packets. With INT, the packet only needs to be inspected at the edge of the network, which reduces the overhead and generates less traffic compared with sampling at multiple points in the network.

The P4.INT specification suggests a set of predefined fields:

- switch ID,
- control plane version,
- ingress/egress port,
- timestamp,
- RX packet count, and
- congestion status.

By leveraging P4 to implement INT, the data can be customized to meet the needs of a service provider. With this data, one can identify the source of a packet behind a firewall by including the originating MAC address in the INT header. With this data, one can obtain the specific source of a packet behind a firewall. Because customer premises and wireless networks are dynamic and multiple devices share the same ingress point on the gateway, knowing the ingress port is not sufficient when trying to identify the packet source. These extensions to the standard P4 INT data structure provide the packet source's MAC addresses, which are unique and are required to identify specific devices for customer premises and wireless networks.

One potential issue with INT is that it increases the size of the packet header. If this increase exceeds the frame size, it will cause packet fragmentation, which has a negative impact on network performance. This issue should not arise with Transparent Security, however, because the INT data is added at the gateway. With access networks, such as DOCSIS, the frame size is larger between the gateway and the core network than at the customer premises. Once the packet reaches the service provider core, INT metadata will not be added to the packet if doing so would cause the MTU size to be exceeded.

INT header uses UDP encapsulation and domain specific source only metadata. Transparent security is the reference example for source only metadata in the 2.1 version of the P4 INT specification (https://github.com/p4lang/p4-applications/blob/master/docs/INT_v2_1.pdf).

The INT header and metadata data will be removed after the telemetry report has been generated and before the packet leaves the network being monitored by transparent security.

5.1.2. Switch or Gateway with P4

The features available with networking hardware supporting the P4 language allow for the development of flexible, open, and consistent DDoS mitigation solutions. Using the information gleaned from the INT data, it is possible not only to detect an attack very quickly but also to identify the compromised device. Once identified, the switch or gateway can be notified to reroute or drop the problematic packets with a simple match rule performed at line speed when deployed with hardware acceleration in software on a gateway device containing a P4 chiplet. Additional information on P4 can be found at https://p4.org/.

5.2. Control Plane Architecture

Figure 2 depicts an example control plane architecture in which the analytics engine receives INT data from the core in-band as packets flow through the network. When malicious patterns are detected, the SDN controller is notified and updates the P4-enabled devices to handle the packets based on the pattern signature. The management interface between the controller and the P4-enabled devices can leverage a variety of protocols, including GRPC, Thrift, HTTP, or RPC. The protocol between the SDN controller and switches can vary, depending on the protocols supported by the switches and gateways. Telemetry data and alert notifications can optionally be sent to a dashboard or NOC server for integration with other analytics.

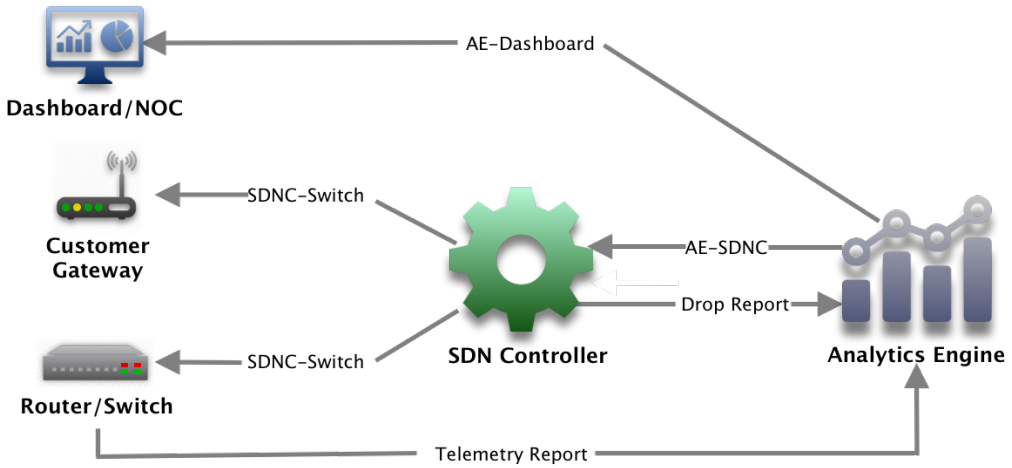

Figure 2 - General Architecture for the Control Plane in the Transparent Security Model

6. Components

6.1. Transparent Security Analytics Engine

The analytics engine (AE) serves as the intelligent core of the programmable data plane. Its purpose is to analyze telemetry reports and make inferences relative to generally defined patterns. For this use case, these patterns are limited to DDoS attack identification. The AE could be extended to manage Quality of Service (QoS), proactive network maintenance (PNM) or other use cases.

When an attack it identified, the AE informs the SDN controller, which is responsible for implementing network changes through the control plane.

The AE's include the following functions:

- identify DDoS attacks,
- mitigate the attacks, and
- remove inactive mitigations.

Multiple iterations of the AE have been tested as the project matures. The initial implementation was a Python service, which would parse the telemetry reports and identify the attacks. This solution was rigid and hard to scale. It was however able to detect and mitigate an attack in about 1 second and as such did meet our needs for detecting UDP flood-based attacks. This implementation can be found here: https://github.com/cablelabs/transparent-security/tree/master/tests/trans_sec/analytics

The second implementation leveraged a Painless pipeline to parse the telemetry reports and Elasticsearch was used to ingest the incoming data, visualize it and identity the attacks. This solution allows for multiple attack identification pipelines to use a shared parser. This architecture should scale without issues. The primary limitation of using Elasticsearch trend analysis is it took around 1 minute to identify an attack, which drove the minimum time to detect an attack outside of the target for transparent security. This implementation can be found here: https://github.com/cablelabs/transparent-security/tree/master/snaps-hcp

The current version of the AE is based on Siddhi. This solution provides modularity and scalability while still identifying attacks in about 1 second. Information on this implementation can be found here: https://github.com/cablelabs/transparent-security/blob/master/docs/SIDDHI_AE_SETUP.md

6.1.1. DDoS attack identification

Telemetry reports which include INT data are used to provide samples of the traffic running across the network. The telemetry reports use the telemetry report interface as noted in Figure 2 - General Architecture for the Control Plane in the Transparent Security Model. Telemetry reports are used instead of IPFIX since they contain the full packet header and a fragment of the data. With this richer data the AE will be able to employ attack identification techniques which are just not possible in DDoS identification applications that are limited to sampled flow data.

6.1.2. DDoS attack mitigation

The AE notifies the SDN controller of an active DDoS attack. This is sent over the AE-SDN interface as shown in Figure 2 - General Architecture for the Control Plane in the Transparent Security Model. This notification includes a signature of the attack, so that the SDN controller can mitigate it. The current implementation uses a rest call directly to the SDN controller. It is possible in production to have multiple SDN controllers. This interface may be updated to use a pub/sub model where SDN controllers can subscribe to message bus, such as Kafka (https://kafka.apache.org/protocol.html) or MQTT (https://docs.oasis-open.org/mqtt/mqtt/v5.0/mqtt-v5.0.html)

6.1.3. Remove inactive mitigations

The AE receives drop telemetry reports from the SDN controllers. These reports provide counters for all active mitigation rules on the network. These are sent over the drop report interface as shown in in Figure 2 - General Architecture for the Control Plane in the Transparent Security Model. The AE determines when the mitigation rule has not been used for a specific period which is an indication the attack has ended. Once an attack has ended, the AE will notify the SDN controller to remove the inactive mitigation rule.

6.2. SDN Controllers

The information used by the AE is captured by the P4 devices as part of the data plane and forwarded to the AE in line with the network traffic. When the SDN controller is informed by the AE that a DDoS attack has been detected, it updates action tables in the P4 devices through the control plane management interface (using protocols such as GRPC or Thrift). Thus, the P4 devices gain additional abilities in the data plane with a minimally intrusive controller activating them before consequences are experienced.

The controller's functions include the following:

- manage the network configuration on switches and gateways,
- push DDoS mitigation to managed devices,
- track which devices are participating in an attack by querying counters of dropped packets based on DDoS mitigation from the device preforming the mitigation,
- send periodic drop reports to AE with the dropped packet counters for each mitigation, and
- remove DDoS mitigation from managed devices.

6.3. Programable Data Plane

The programable data plane consist of routers, switches and customer gateways used in Transparent Security to add/remove the INT header, generate telemetry reports, and mitigate DDoS attacks. To date, the testing and development has focused on performance on devices which support P4. These devices provide a great deal of flexibility to quickly develop the data plane for transparent security. It is possible to deploy transparent security using other types of programable devices. See 4.2.2.3 for additional information on these types of devices.

The programable data plane functions include the following:

- manage the traffic across the network,
- add P4.INT data (source port, time, queue),
- add Transparent Security data (source MAC),
- remove P4.INT headers before they leave the service provider network,
- send telemetry reports to the AE and,
- mitigate DDoS attacks from the core network and the aggregate network.

6.4. User Equipment

The end user devices are the typical end units used by end customers, including IoT devices, phones, laptops, and an ever-increasing variety of devices. Many are connected to the gateway over Wi-Fi or LTE. Implementing transparent security does not require any changes to user equipment. The user equipment should not be able to detect if transparent security is deployed or not.

7. Message Flows

The following sections outline high-level message flows between the possible components.

7.1. Packet Flow and Alerts

7.1.1. Standard Packet Flow

Standard packet flow:

1. Customer device sends packets to the server provider network.
2. The packet will traverse a series of gateways, switches, and routers where some are aware of INT and others are not.
3. This first INT enabled switch will insert the INT UDP header and the metadata for that hop.
4. Incremental networking devices with INT support will add their node ID to the INT metadata.
5. Packet is forwarded to the final INT networking devices, such as a PE router.
6. Packet is cloned and sent to the analytics engine.
7. INT data are removed from the packet.
8. Packet is forwarded to the Internet.

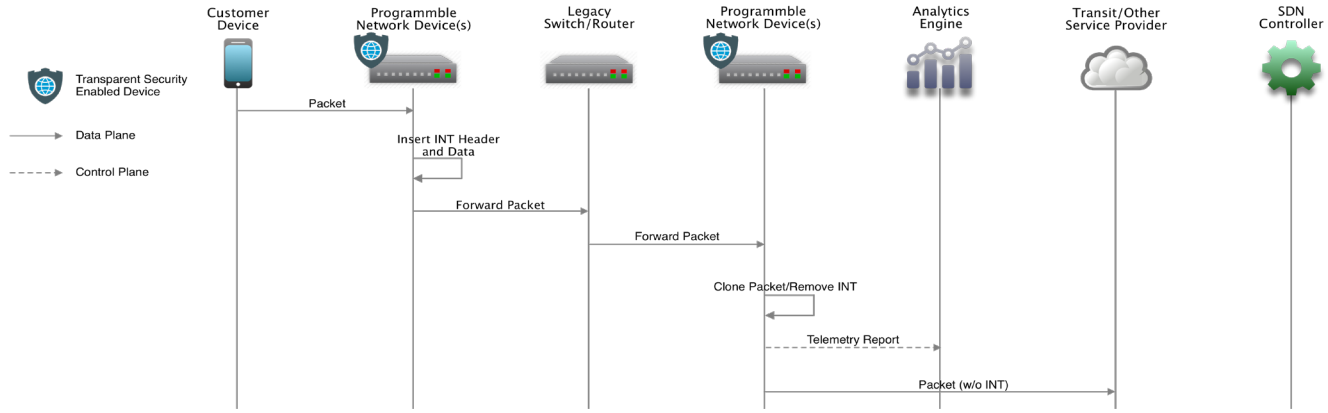

Figure 3 - High-Level Message Flow in the Control Plane and Data Plane when Packets Are Allowed Through.

7.1.2. DDoS Attack Identification and Mitigation

The following actions occur when an attack is detected:

1. Analytics engine recognizes an attack.
2. AE notifies the SDN controllers of the attack with its signature.
3. The SDN controllers notify the proper networking device to add an entry in the transparent security drop table for this specific attack signature.
4. The networking device add the entry into its transparent security drop table.

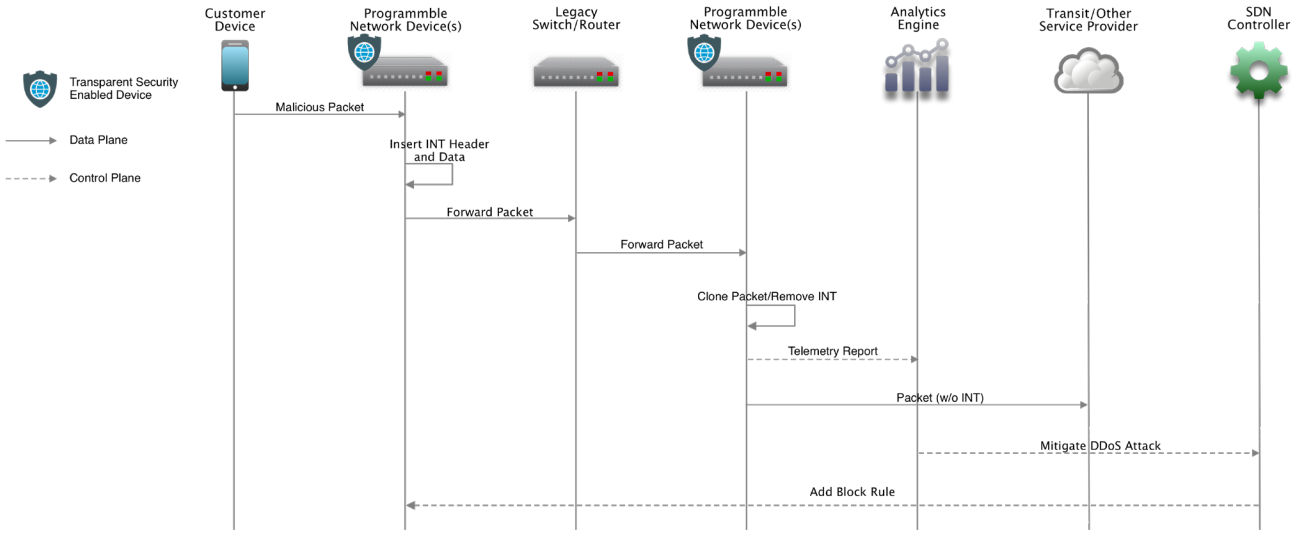

Figure 4 - High-Level Message Flow in the Control Plane and Data Plane during DDoS Attack Identification and Mitigation

7.1.3. Mitigated Attack Packet Flow

1. A packet as a part of the DDoS attack is sent to the service provide network.
2. The first transparent security enabled networking device with a drop rule drops the packet.
3. After the packet is dropped, the device increments the drop counter for that rule.
4. The SDN controller periodically collects the drop counters and sends them to the AE in drop telemetry report.

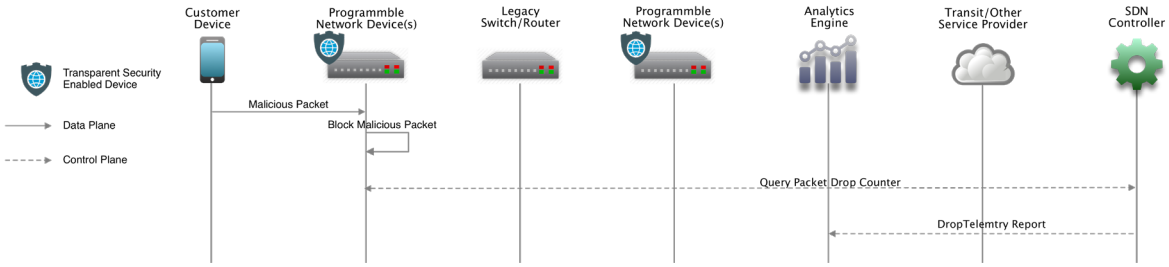

Figure 5 - High-Level Message Flow in the Control Plane and Data Plane while Mitigating an Attack.

8. Deployment options

Transparent Security can be deployed across the service provider network in several phases. A phased deployment makes it easier to deploy and realize many of the benefits while postponing any changes to cable modems (CMs). The process of a phased deployment begins at the hub or head end and moves to the customer premises at later phases.

8.1. Core/Head End/Hub Deployment

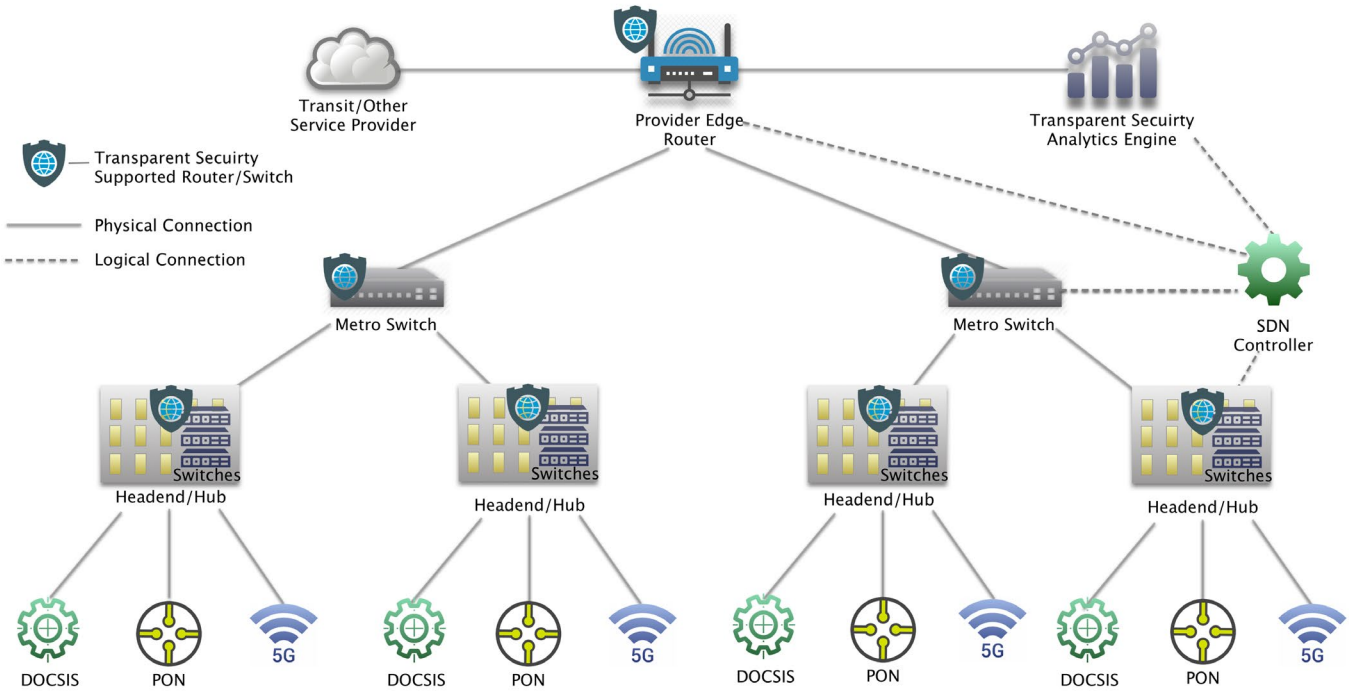

Figure 6 - Phased Deployment: Head End/Hub Updates

This deployment option focuses on the service provider's core network. Two classes of attacks can be mitigated. Attacks from this service provider's network against targets outside the network and attacks across the service providers network can be detected and mitigated with this model.

The first phase of deployment begins with upgrading the head end/hub by adding programmable switches with an analytics engine and an SDN controller. These switches can be included as part of distributed access architecture (DAA) upgrades. They provide the ability to mitigate a DDoS attack from a customer at the head end and identify which customer is the source of the attack.

This solution can also address ingress attacks from outside of the hub which is an advantage over a typical edge-based DDoS mitigation model.

There are no changes to the CM for this phase. The primary limitation to this solution is that it cannot identify the device originating the attack, only the customer. The compromised device remains active and continues to participate in ongoing attacks.

8.2. Customer Premisis

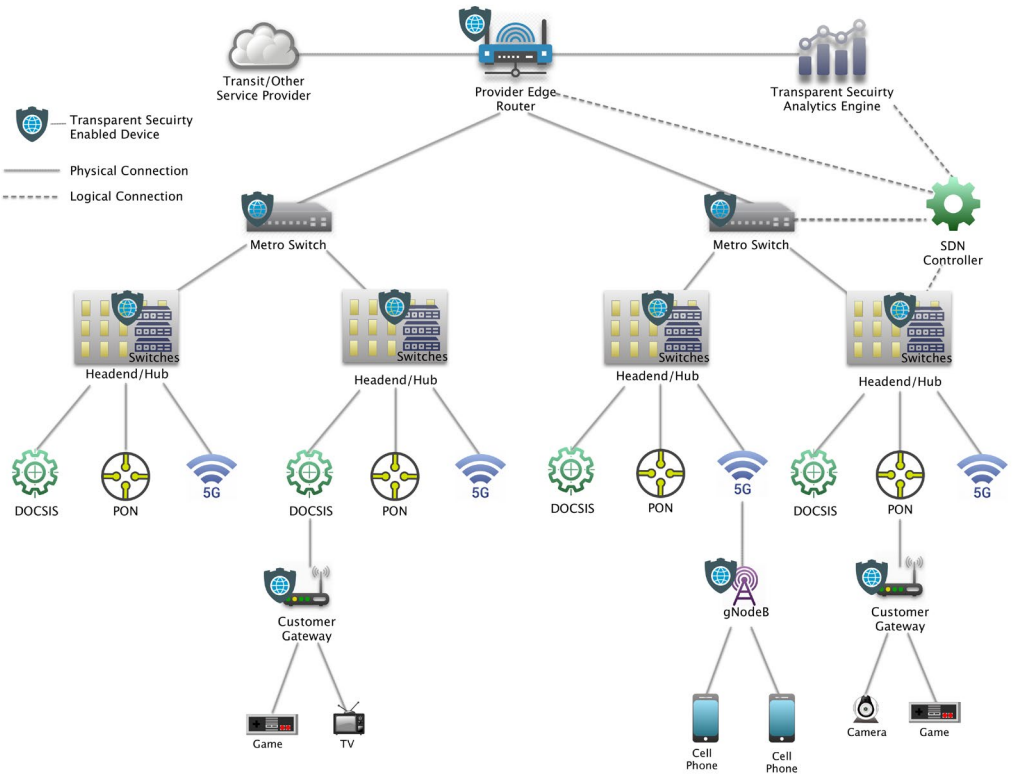

Figure 7 - Phased Deployment: Customer Premisis

In this deployment model, transparent security is deployed on a gateway device. For 5G, this can be deployed on a gNodeB. The initial INT insertion and DDoS mitigation is performed on the gateway device.

Once this model is deployed, the traffic on the access network will be scrubbed before it can impact any other customers, and customers will be able to address issues on compromised devices. The malicious traffic is dropped, and the count of blocked packets for each device is tracked. This model will not block benign traffic from the compromised device.

9. Lab Trial

To validate the viability and network impact for transparent security, Cox Communications conducted a lab trial with transparent security. This trial focused on a derivation of the Core/Head End/Hub deployment option. The goal of this trial was to validate that there is no adverse impact on network performance when adding transparent security. This includes latency, throughput and basic network routing.

9.1. Lab Trial Setup

The test environment was designed to simulate traffic originating from the access network, carried over the service provider's core backbone network, and targeting another endpoint on the service provider's access network in a different market (e.g., an "east-to-west" or "west-to-east" attack).

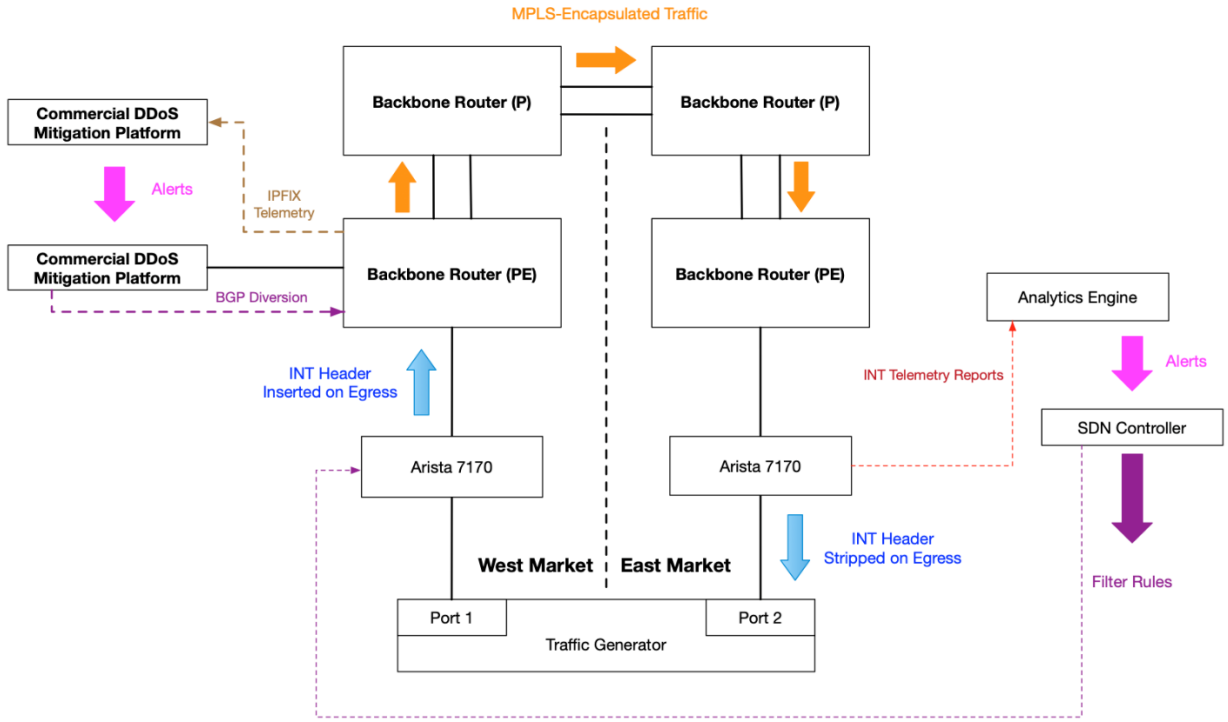

Figure 8 - High-level overview of the lab test environment

In the lab trial, various types of DDoS traffic (UDP/TCP over IPv4/IPV6) were generated by the traffic generator and sent to the West Market Arista switch, which used a custom P4 profile to insert an INT header and metadata before sending the traffic to the West Market PE router. The traffic then traversed an MPLS label-switched path (LSP) to the East Market PE router, before being sent to the East Market Arista, which used a custom P4 profile to generate INT telemetry reports and to strip the INT headers before sending the original IPv4/IPv6 packet back to the traffic generator.

9.2. Results

When comparing the performance of the Transparent Security solution against that of a leading commercially available DDoS mitigation solution, the lab test results were very promising. Detection and mitigation of outbound attacks was rapid, taking around one second. The commercial solution took 80 seconds to detect and mitigate the attack. Randomized UDP floods, UDP reflection and TCP state exhaustion attacks were identified and mitigated by both solutions. In this trial, only packets related to the attack were dropped. Packets not related to the attack were not dropped.

The Transparent Security solution was implemented on commercially available programmable switches provided by Arista. These switches are being deployed in networks today. No changes to the Networking Operations System (NOS) were required to implement Transparent Security.

The tests validated that INT-encapsulated packets can be transported across an IPv4/IPv6/MPLS network without any adverse impact. There was no observable impact to throughput when adding INT headers, generating telemetry reports, or mitigating the DDoS attacks. We validated that the traffic ran at line speed, with the INT headers increasing the packet size by an average 2.4 percent.

Application response time showed no variance with or without enabling Transparent Security. This suggests that there will be no measurable impact to customer traffic when the solution is deployed in a production network.

10. Conclusion and Next Steps

Transparent Security uses in-band telemetry to help identify the source of the DDoS attack.

This trial focused on using Transparent Security on switches inside the service provider's network. For the full impact of Transparent Security to be realized, its reach needs to be extended to gateways on the customer premises. Such a configuration can mitigate an attack before it uses any network bandwidth outside of the home and will help identify the exact device that is participating in the attack.

This testing took place on a custom P4 profile based on our open-source reference implementation. We would encourage vendors to add INT support to their devices and operators to deploy programmable switches and INT-enabled CPEs.

Take the opportunity today to explore the opportunities for using INT and Transparent Security to solve problems and improve traffic visibility across your network.

Distributed denial of service (DDoS) attacks and other cyberattacks can cost operators billions of dollars. With more and more devices coming into customers' homes and businesses, many of which with less-than-optimal security, this problem will only get worse. By quickly identifying attacks and blocking them before they reach the access network, Transparent Security can:

- reduce the operations impact of large-scale attacks by mitigating closer to the source within seconds of an attack starting,
- eliminate the risk of revenue impact resulting from a failure to meet service-level agreements,
- protect and enhance customer sentiments by avoiding large-scale DDoS attacks within a network, and
- provide a data stream from which new analytics and innovations can be built.

10.1. Alternate Applications for Programmable Data Plane

The Transparent Security source-based DDoS use case is just one of many that can benefit from the programmable data plane. Once deployed, this architecture can improve many of the operations performed today. It will also open networks to new waves of innovation and allow operators to provide such things as network optimization and additional customer services.

With the programmable data plane, it is possible to change the behavior of the network after hardware has been deployed. Use of an analytics engine and controller, as is done with Transparent Security, can

provide a closed-loop automation. Some of the network management capabilities available with the programmable data plane are listed below:

- packet flow tracking and optimization,
- prioritization on low-latency flows,
- active network monitoring/management, and
- traffic shaping.

Providing new services frequently requires installing new purpose-built hardware or deploying a virtual machine. With the programmable data plane, some of these services can be deployed on existing switches with very good performance. Some of the services that can be deployed with the programmable data plane include the following:

- firewalls,
- managed router as a service,
- Layer 4 load balancing, and
- SD-WAN (software-defined networking in a wide-area network).

Micronets is another CableLabs project that can leverage the programable data plane. Micronets creates additional layers of security within the customer premises and helps protect devices by using OpenFlow for the L3 traffic management. Transparent Security is focused on identifying devices participating in a DDoS attack and mitigating the attack at the source. The programable data plane, analytics engine, and controller used in Transparent Security can be leveraged by Micronets to improve packet processing performance and provide access to additional fields in the packet header. For more information on the Micronets project, visit www.cablelabs.com/micronets.

Matt Petersen, Charter Communications

1. Introduction

Nearly three years after the introduction of 10G, industry activity tied to this foundational next generation cable technology, known in technical circles as DOCSIS 4.0, is accelerating rapidly. The timing is well-suited to the moment. DOCSIS 3.1 has been in production for over 5 years. Newer features are now being exercised, such as 8k FFTs (25kHz) for OFDM and ODFDMA, Mid-Split and High Split networks to expand upstream, and the revolutionary Profile Management Application (PMA), the automated form of DOCSIS3.1 Multiple Modulation Profiles (MMP).

As DOCSIS 3.1 deployments continue, so do capacity growth and speed expectations for the network. DOCSIS 4.0 was developed to support relentless bandwidth consumption and speed trends, leveraging the DOCSIS 3.1 PHY basis for its bandwidth efficiency, resiliency, and backwards compatibility.

As with most cable technology evolutions, there is no "one size fits all" solution among, or often even within, a single operator. Each operator's current as-built networks have different starting points and range of other variables – region of the country, geography and topology, municipal and state make-ready differences and a range of aerial/underground construction techniques, to name a few.

In this paper, Comcast and Charter will provide a unified point of view on the rapidly approaching cycle of DOCSIS 4.0 upgrades. We will address:

- Implementation options in DOCSIS 4.0, including Full Duplex/FDX and Extended Spectrum/FDD
- Common use cases, with guidance on how DOCSIS 4.0 options may be applied
- The range of network variables and anticipated impacts
- How key dependent variables may drive evolution path decision criteria
- The complementary nature of the technologies

This is a useful and timely session for all operators, suppliers, and industry partners interested in how DOCSIS 4.0 will shape tomorrow, as envisioned by engineering leads of two largest cable operators in North America.

2. 10G Overview

2.1. Objectives

Cable operators have steadily increased bandwidth and speeds to subscribers since the launch of the DOCSIS high speed data services (HSD). Compound annual growth rates (CAGRs) and the appetite for more bandwidth-intensive applications, has made continuous investment in the network the cost of doing business. These trends have been reasonably predictable, allowing operators to be very efficient with their network investments and develop standard practices to manage growth. HFC continues to show the ability to adapt and increase capabilities to meet the needs of today's subscribers and businesses.

MSOs have historically been conservative in talking about their network capabilities. For example, technical terms such as "DOCSIS 3.1" and "DAA" represent some of the language of today's industry technology advances and foundational initiatives leading to 10G. However, the terms themselves are not particularly effective for describing what the network is capable of and what it can deliver for customers.

Building upon DOCSIS 3.1 and DAA, among others, the 10G aims to represent a technical benchmark but also be associated with what these new advances mean to services and to the customer experience. So what is 10G? The "pillars" of the 10G networks are defined as:

- Speed – Enabling of multigigabit symmetric speeds, raising the bar for consumer broadband.
- Low latency – Low Latency DOCSIS (LLD) is now incorporated into the DOCSIS 3.1 specification and carried forward into DOCSIS 4.0. Delivers a better customer experience, in particular for applications such as gaming and AR/VR.
- Reliability – Methods to proactively identify and address network issues before consumers are aware of them
- Security – Improve the confidentiality, integrity, and availability of safe communications.

Summarizing, 10G will offer up to 10 Gbps of intelligent, reliable, secure bi-directional capability that, coupled with decreased latency, will enhance the customer experience of today. The 10G network will unleash a new generation of capability that will drive innovative applications and create new digital opportunities, novel services, and impact lifestyles for the better.

2.2. HFC Challenges to 10G

With such a grand vision, what will it take for operators to move from PowerPoint (and white papers(!)) to implementation and field deployment?

Well, if 10G was simple to obtain and pedestrian in its objectives, it might already be available and there would not be multi-years of play-by-play media coverage and industry-wide excitement about its promise. Furthermore, painting the end state of a next generation network evolution is relatively straightforward. It is the transition from the current state to that end state that creates the challenges, consuming most of the energy that access engineers and business planners spend when debating network path and technology direction. The starting point for 10G comes with several interrelated obstacles:

1) *Coaxial Bandwidth* – First and foremost, the cable network spectrum is very broad, but there are still limits to the easily accessible bandwidth. For most HFC systems today, that bandwidth is either 750 MHz, 860 MHz, 1 GHz, and more recently to 1.2 GHz. The limit that applies for a particular plant is typically determined by the generation of RF amplifiers installed. With a downstream limit such as 750 MHz, for example, there is simply not sufficient spectrum to achieve 10 Gbps even in a complete DOCSIS 3.1 migration.

2) *Upstream Allocation* – Despite the scenario described above, the path to 10Gbps on the downstream is not too difficult to envision, even for 750 MHz. Simply add more very efficient DOCSIS 3.1 spectrum extending to 1 GHz or 1.2 GHz with readily available amplifier replacements, for example, and it is within reach, depending on other EOL fidelity variables. However, 10G is really setting its sights on massively expanding upstream bandwidth, which in North America is typically 42 MHz. Some MSOs have trialed upgrading to a Mid-Split Upstream, extending the return band to 85 MHz, to increase the capacity runway of the network and defer node splits. As can be observed above, the downstream-to-upstream (DS/US) ratio is highly asymmetrical. It is the primary goal of 10G to develop a more symmetrical DS/US ratio.

3) *Current DOCSIS Production Spectrum* – An assumption made above on the route to 10 Gbps is a "complete DOCSIS 3.1 migration." This is an unlikely scenario for many years. There will be relatively inefficient video QAM signals on the network for many years to support broadcast video services over many millions of existing set-top boxes (STBs) in the field today. In addition, while DOCSIS 3.1-capable devices are increasing in the field, DOCSIS 3.0 Cable Modems (CMs) still represent the majority in Comcast's footprint, and of the millions of DOCSIS 3.1 CMs in the field operate today, most operate in DOCSIS 3.0 mode, carrying the majority of traffic and accounting for most of the HSD spectrum. Other operators, including Charter, have activated more DOCSIS 3.1 upstream and are taking advantage of these additional efficiencies to add capacity and defer node splits. Existing services based on 256-QAM signals (as well as QAM VOD signals) put limits on how much spectrum can be allocated for DOCSIS 3.1, burdening some of the spectrum with less bandwidth efficiency.

4) *DOCSIS Capability* – The DOCSIS 3.1 standard limits the upstream spectrum to a maximum of 204 MHz – the "High Split" configuration. This configuration is designed to enable up to 1Gbps of upstream when carrying all DOCSIS 3.1 OFDMA signals. In this configuration, it is capable of up to about 1.5 Gbps. The definition of the DOCSIS 4.0 standard sets about to expand the amount of spectrum made available for Upstream, up to 684 MHz for either DOCSIS 4.0 option. This expansion is the major change that the standard is targeting towards the 10G network.

5) *Distributed Access Network (DAA)* – DAA is a definite "good" guy, so why is it listed here as a challenge? Well, the DAA journey has not begun with many operators, and is also fragmented in approach taken. For all of the discussion of DOCSIS 4.0, it is a consensus agreement that it will only be implemented via DAA. DAA is itself a complex, multi-faceted journey to production scale and as a prerequisite to DOCSIS 4.0, presents a large obstacle of a DAA plan is not first established and executed on.

6) *Business Case* – Plant upgrades have been part of cable network evolution for decades. Each upgrade cycle has undergone typical analysis of pro/con and meeting criteria for return on investment. Well-understood guidelines have been established over the years for node splits, spectrum addition, and other network augmentations, such as FTTH. Similar modeling will take place for DOCSIS 4.0 and be honed over time using empirical data.

2.3. Still Early in the Life of DOCSIS 3.1

Before expounding in the exciting technology and opportunities ahead with 10G, it is important to recognize that the DOCIS 3.1 journey is still early. Planning ahead for DOCSIS 4.0 does not mean things are standing still in the meantime – on the contrary, operationalizing and optimizing the advanced features enabled with DOCSIS 3.1 has really just begun.

2.3.1. 2020: Everything Changes

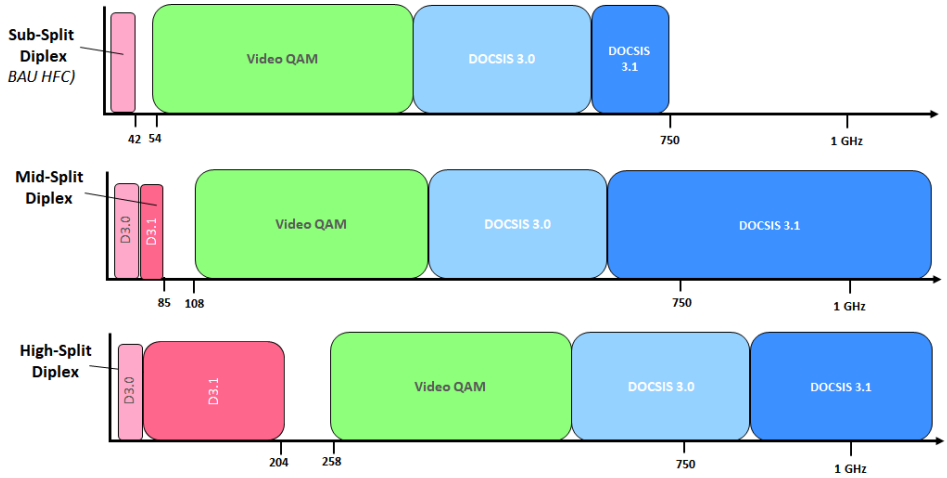
When it comes to the evolution of DOCSIS, each version seems to have a longer runway than the prior. That is certainly the case when we talk about DOCSIS 3.1, which can easily be considered to be in the infancy of its life span. Some operators began to roll out DOCSIS 3.1 OFDM downstream a few years ago, primarily to provide a Gigabit service offering. Like all versions prior, it is backwards compatible; however not until DOCSIS 3.1 CPE reaches meaningful penetration rates will operators be able to use it to its fullest capacity.

Recently with the COVID-19 pandemic we saw an increased number of people working from home and learning from home using video conferencing and real time communications tools. The industry shined in its ability to handle the increase in traffic due, but the pandemic did highlight the significance to optimizing how we leverage DOCSIS 3.1 increased bandwidth.

2.3.2. Pulling the Levers

A significant example of what is possible and still ahead for DOCSIS 3.1 is the expanded downstream and upstream spectrum it provides over DOCSIS 3.0. Current DOCSIS 3.1 has the capability to support a downstream frequency range up to 1.2 GHz and an upstream frequency range up to 204 MHz, better known as High Split. Today, a 42 MHz upstream bandwidth is the most common for North American cable operators, although some migrations to Mid-Split (85 MHz) have taken place. The expansion of frequency capability will allow operators more flexibility in how to leverage their networks for offering enhanced service tiers.

Figure 1 illustrates the differences between a standard HFC spectrum allocation today and the Mid-Split and High-Split architectures.



The majority of North American operators have deployed DOCSIS 3.1 downstream OFDM blocks. Some operators have also begun to leverage OFDMA in the upstream, which provides higher modulation schemes and greater bits per second per hertz (bps/Hz) when compared to the DOCSIS 3.0 A-TDMA Single-Carrier QAM (SC-QAM). As operators continue to increase the penetration of DOCSIS 3.1 CPE, some are opting to gradually remove ATDMA one service group at a time, replacing this spectrum with OFDMA because of the higher modulation profiles and increased throughput, and therefore longer capacity runway. Most node splits are driven by the upstream capacity utilization associated with the limited available 42 MHz of spectrum.

In the downstream path, operators are using the increased CPE penetration to further expand OFDM blocks and increase the total throughput made possible with 4096-QAM (12 bps/Hz) OFDM subcarriers as compared to 256-QAM (8 bps/Hz) of the legacy single carrier QAMs, a 50% increase in inefficiency. As downstream growth trends continue, there will be a reclamation of the legacy single carrier QAMs in the spectrum that are currently supporting DOCSIS 2.0/3.0 devices that, through attrition, are currently being

replaced with DOCSIS 3.1 CPE. The decreasing penetration of these legacy devices can be supported with fewer SC-QAMs occupying the downstream.

2.3.3. Increasing the Spectrum and Moving the Split

As shown in **Figure 1**, most HFC networks today are built with a 750 MHz or 860 MHz upper frequency range utilizing a 5 – 42 MHz "Sub-Split" return. This bandwidth cap of 42 MHz means a limited amount of DOCSIS carriers, and the amount of spectrum used for the upstream falls far short of the capabilities available in DOCSIS 3.1 devices that have now been available and deployed for years. There is ample opportunity to replace active components in the field with new nodes and amplifiers that support a downstream to 1.2 GHz, with either a Mid or High Split configuration. This extra spectrum will allow for the expansion of both OFDM and OFDMA carriers and greatly increase the total throughput capacity of the network in both directions.

Most operators, feeling the upstream growth constraints, now accelerated by COVID-19 and its implications [1][4] are already executing on these frequency expansion upgrades. Some are making these bandwidth changes in coordination with their Distributed Access Architecture (DAA) rollouts, minimizing outside plant impacts and making most efficient use of construction opportunities.

DAA itself can be considered another lever operators can use to increase signal fidelity and, with the available optimizations of bandwidth efficiency with DOCSIS 3.1, deliver greater capacity to the network, benefitting customers.

3. DOCSIS 4.0 Technology Options

3.1. Full Duplex DOCSIS (FDX)

Figure 2 illustrates the essential spectrum goal of FDX– enabling significantly more upstream. More interestingly, these new FDX upstream bands (Red "FDX" in **Figure 2**) are available for downstream. Huh? This is quite different than typical Frequency Domain Duplex (FDD) operation, the approach taken in DOCSIS 4.0 FDD. It is also begs the question – how can both downstream and upstream data exist in the same spectrum?

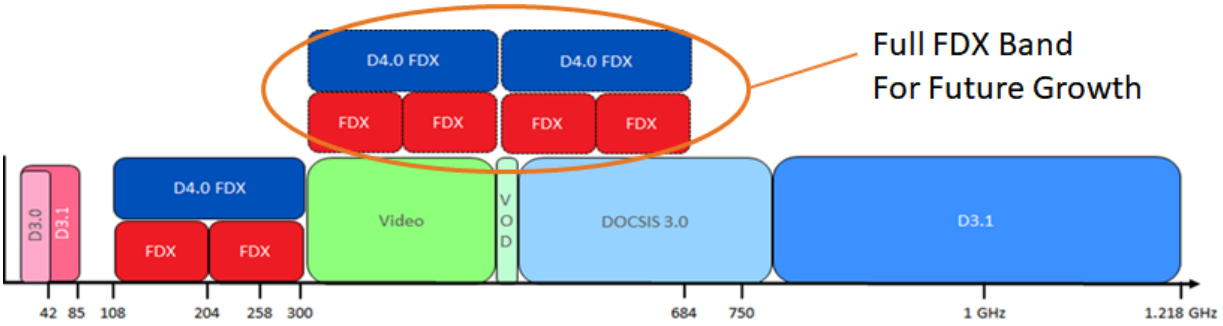


Figure 2 - Upstream Spectrum Added for DOCSIS 4.0 Full Duplex (FDX)

3.1.1. Key FDX Innovations

Although more upstream bandwidth is defined, it is the same 96 MHz OFDMA physical layer blocks as defined in DOCSIS 3.1. Thus, DOCSIS 4.0 leverages the power of the DOCSIS 3.1 PHY completely. Six additional 96MHz blocks are added across the 108-684 MHz band, complementing an 85 MHz "mid-split" system.

Downstream and upstream can occupy the same band with a technology known as Echo Cancellation (EC). Echo Cancellation in general is a mature technology used in other telecom networks, such as xDSL and wireless. It has not yet been implemented in cable networks. The EC concept is very similar, although the cable does introduce some new challenges. EC is the first of the two critical innovations that power FDX.

The second key innovation is based on an architectural difference in cable systems when compared to telco xDSL systems. Twisted pair telco networks are point-to-point from the DSL Access Multiplexer, or DSLAM, whereas HFC is a point-to-multipoint. This logical architecture difference creates the need for another layer of innovation for FDX. This is the creation of Interference Groups (IGs) and Transmission Groups (TGs) for the scheduler to manage.

Figure 3 illustrates these innovations from the CMTS perspective, using a passive coaxial network (i.e., N+0) for simplicity. N+0 is NOT a requirement for FDX, but the specifications were developed with N+0 as a baseline. FDX-capable amplifiers are being developed to support FDX signals over N+x networks, allowing FDX over a broader range of architectures. As in standard HFC networks, an RF amplifier cascade impacts quantifiably the network performance. With amplifiers for FDX, one of the impacts is the effect on IGs and TGs. As a result, additional considerations that account for the relationships among of maximum speed tier, penetration, and cascade depth have been developed. We will discuss FDX amplifiers in a subsequent section.

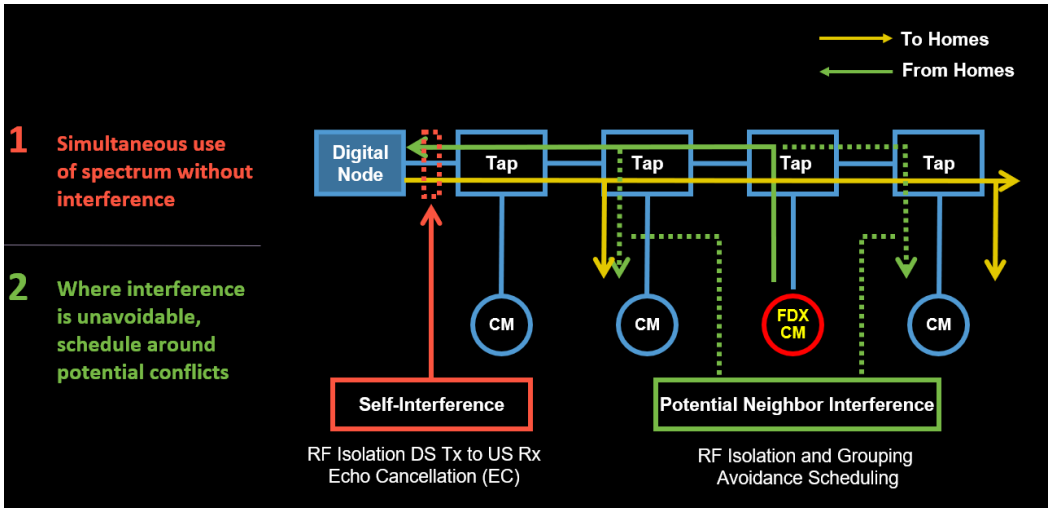

Figure 3 - Two Key New Innovations in DOCSIS 4.0 Full Duplex

3.1.2. A Closer Look Part 1 – Echo Cancellation

Referring to **Figure 3**, adding upstream where downstream exists requires that the downstream signal be "subtracted" before the US OFDMA receiver. This requires high RF isolation and strong EC of the much

higher downstream signal. While the implementation details may be complex, the EC concept is a quite simple, and the digital signal processing (DSP) principles to build it very mature. A simplified diagram illustrating the EC concept is shown in **Figure 4**.

The node downstream transmit signal will have some of its energy reflected back by the imperfect RF interfaces, such as described by the return loss of a tap, for example. These are the so-called "Echoes" that give the EC function its name. What is distinctive to EC for cable is the high cancellation required across a broad bandwidth. These cable specifics push the envelope.

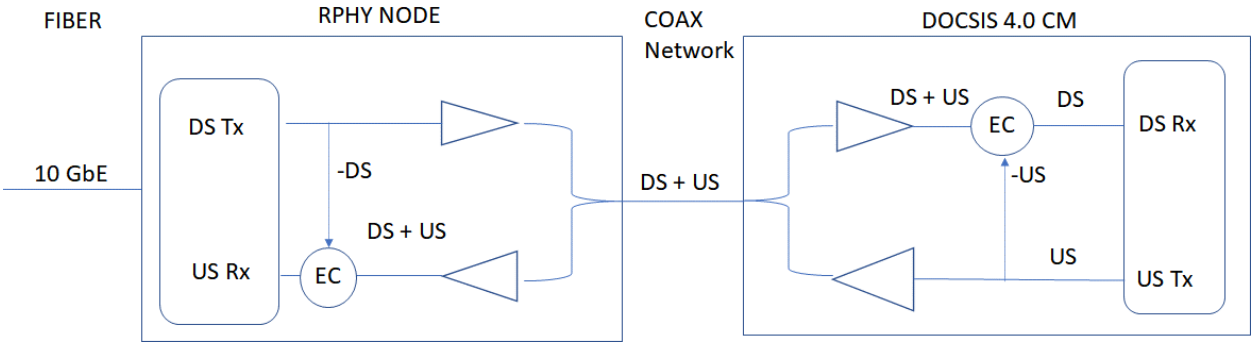

Figure 4 - Conceptual Basics of Echo Cancellation in a non-DAA Configuration

3.1.3. A Closer Look, Part 2: Interference Groups and Transmission Groups (IGs/TGs)

As noted, for HFC, the network is a point-to-multipoint architecture. While an FDX modem knows its own upstream transmission, it cannot know that of his neighbor. It requires sufficient RF isolation among neighbors to prevent FDX-band upstream users from interfering with a neighbor using that band for downstream. Unfortunately, RF isolation among homes cannot always be guaranteed to be high enough. The isolation relationships among homes a shared RF leg are determined as part of FDX "sounding" process.

Without sufficient RF isolation we can have the vCMTS scheduler designed to avoid this scenario. In an FDD system, the scheduler does not need to pay particularly close attention to the relationship of downstream and upstream access to the wire. This changes in FDX. During FDX "sounding," the FDX system determines these isolation relationships. Potentially interfering users are lumped into "Interference Groups," or IGs. A logical set of IGs is called a Transmission Group (TG), because not every IG needs to be treated independently – it depends on traffic. This scheduler assures that potentially interfering pairs are not subscribing the same spectrum in the same time slot.

Because there are six OFDMA blocks, the vCMTS can service multiple IGs with uniform capacity and speeds by assigning different Resource Block Assignments (RBAs) to each IG. **Figure 5** shows an example of how the 108-684 MHz FDX band might be allocated to simultaneously support a case with three TGs. These RBAs can adapt with time based on traffic demand.

Note that the FDX band is not all the DOCSIS spectrum available. Non-FDX DOCSIS 3.1 spectrum and DOCSIS 3.0 spectrum will also exist.

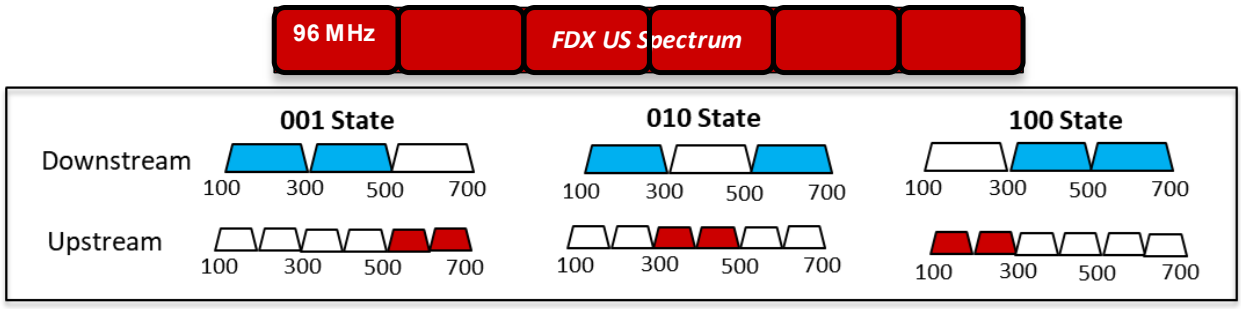

Figure 5 - OFDMA "Resource Blocks" Enabled in the FDX Band

3.1.4. DOCSIS 3.1 Compatibility / Coexistence

Because FDX is fundamentally based on DOCSIS 3.1, the FDX band can only be activated where the DOCSIS3.1 downstream is allocated. Existing DOCSIS 3.1 devices should be aware that they are part of an FDX system in order that they partake in IG/TG sounding and thereby be well-behaved co-existing devices in an FDX-enabled plant. This DOCSIS 3.1 device mode is known as "FDX-Light" or FDX-L. Obviously, DOCSIS 3.1 devices do not support FDX. They cannot transmit in all of the FDX band higher than 204 MHz. Nonetheless, it is important that the device be aware that it is operating on an FDX system. In this way, it can participate in network sounding, allowing the vCMTS to determine when it can schedule packets to be received by the device and avoid being interfered upon with by an FDX device that may be transmitting in the same band and at the same time.

FDX-L is a software-only upgrade to existing DOCSIS 3.1 devices. Without this mode, a separate DOCSIS4.0 band would need to be set aside, similar to what is done today with DOCSIS 3.0 and DOCSIS3.1 spectrum. Launching FDX and the much higher upstream speeds therefore implies a commitment to an amount of DOCSIS 3.1 downstream spectrum, within which the FDX upstream can operate. As with any spectrum allocation, this must be managed within the constraints of the HFC network's overall spectrum plan. Networks supporting FDX will all be a 1 GHz systems or 1.2 GHz systems, which are bandwidth upgrades from today's 750MHz systems and 860MHz systems. So, at first, the challenge to "find" spectrum is not as daunting considering that new spectrum that will be added as FDX becomes deployed when an amplifier is installed that adds new bandwidth above 750 MHz or 860 MHz.

3.1.5. DOCSIS 4.0 FDX is Coming to Life

The first DOCSIS 4.0 FDX RPD bring-up and characterization began in March of 2021, and the results were described in various media publications the next month [2].

Some hardware images of the first FDX RPD are shown in **Figure 6**. The RPD module shown on the right plugs into an FDX node, which is not shown.

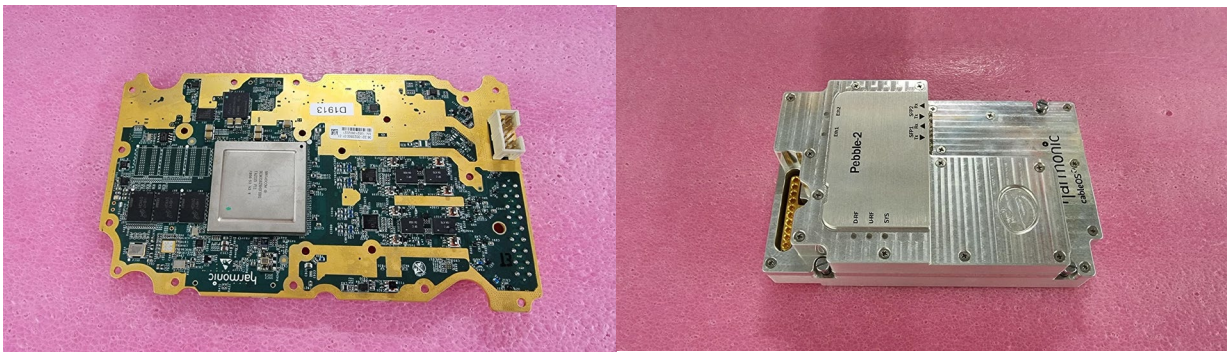

Figure 6 - DOCSIS 4.0 FDX RPD Hardware

Figure 7 shows the sample network's echo characteristics used for the test, as well as a simulation of how the FDX Band operates with both downstream and upstream present in such an environment. Also shown is the measured downstream and upstream throughput from the test, which includes block of DOCSIS 3.0 spectrum downstream and upstream (legacy), plus video carriers akin to today's channel line-up. The network achieved 7.6 Gbps downstream and 4.3 Gbps upstream, both in terms of net throughput. 1024-QAM was able to be successfully activated in the upstream, as shown, with performance similar to a typical DOCSIS 3.1 upstream receiver. The latter is of defined only to 204 MHz upstream.

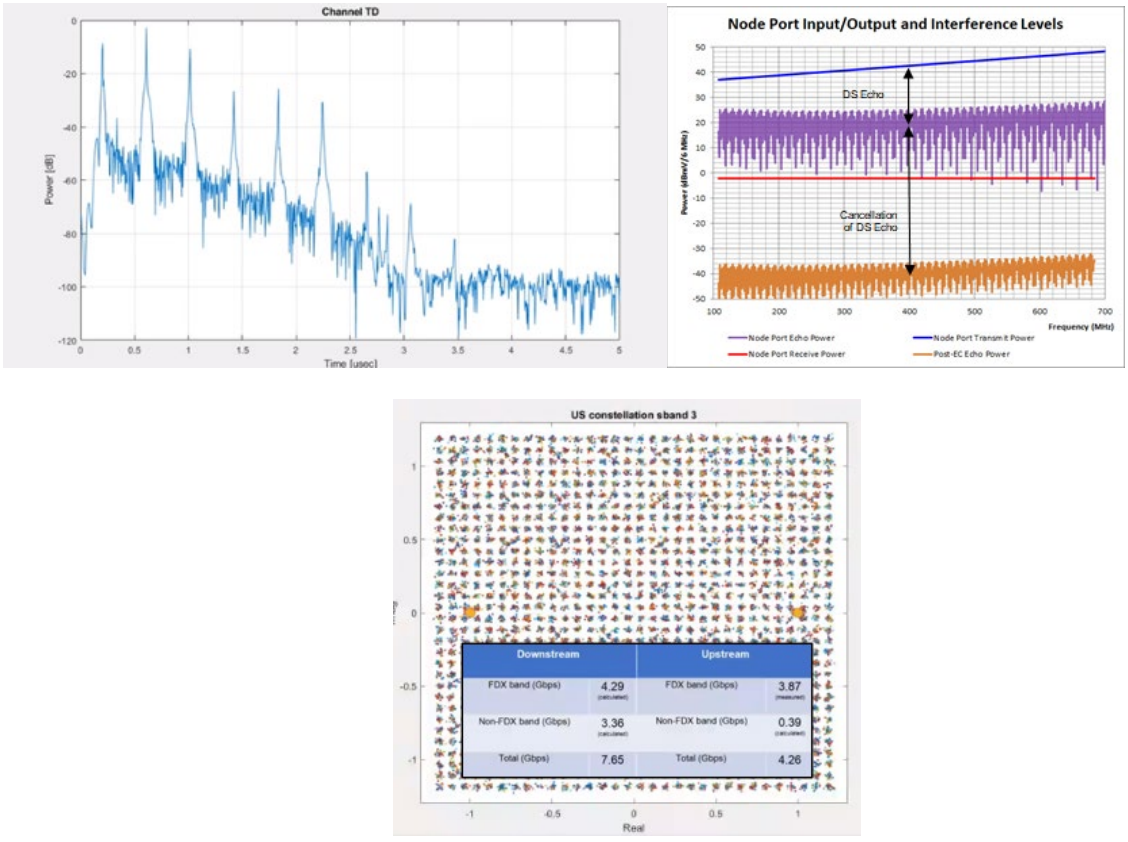

Figure 7 - DOCSIS 4.0 FDX RPD in Operation (clockwise from upper left): a) Plant Echo Response from Node Port b) Simulated Node Tx, Tx Echo, Node Rx, Cancelled Echo c) 1024-QAM US

The DOCSIS 4.0 specified minimum upstream MER requirements are higher than DOCSIS 3.1 in anticipation of noise contributions in the form of residual echo from the FDX band. Nonetheless, the test results observed and shown here using a "Model 1" plant and echo environment is delivering performance similar to a straight DOCSIS 3.1 US receiver, without needing any additional headroom for MER loss.

There will surely be more to come from the labs and shortly in the field as FDX is birthed in 2021!

3.1.6. FDX-Capable Amplifiers

The FDX system specifications were written using the assumption of an N+0 network. However, FDX is not technically limited to an amplifier-free plant and the specification does not prevent it. In fact, shortly after the FDX specifications were compiled, a CableLabs Study Group was formed to evaluate methods for implementing amplifiers that support FDX. The foundational EC technology developed for the FDX RPD can in principle apply at any point in the network to manage overlapping spectrum, and this can include amplifiers. Of course, these are therefore not traditional amplifiers, but a new class of device that includes this new digital signal processing (DSP).

An EC-based amplifier concept is shown in **Figure 8**. The nature of overlapping spectrum and gain in both directions creates a full-circle loop gain path. The EC must be capable of suppressing the FDX loop gain, such that the net gain around the path is < 0 dB to maintain a stable device. The EC must further be designed to act on the echo it is suppressing sufficiently that the aggregate residual echo noise, which becomes part of the amplifier's own noise floor, supports the US MER requirements effectively for DOCSIS4.0, without introducing unacceptable MER degradation and subsequent loss of bandwidth efficiency.

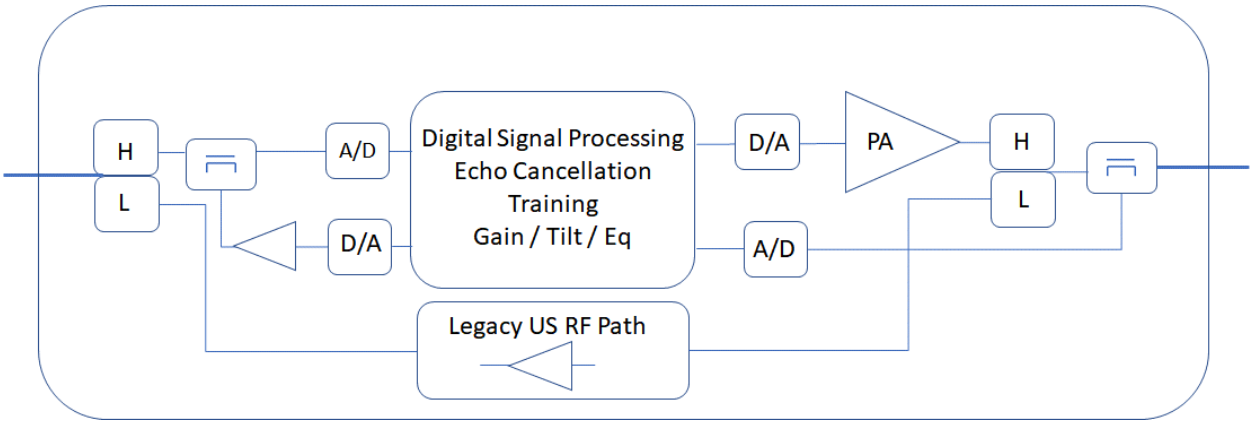

Figure 8 - FDX Over N+X Using an Echo Cancellation-Based Amplifier

The Echo Cancellation function required is similar to that of the node, except that for an amplifier it can exist on both sides. A sample of the upstream signal is taken so that an opposite phase, equal magnitude version can be added in front of the downstream amplifier. Similarly, the signal from the downstream amplifier is sampled and an anti-downstream version added at the input to the upstream amplifier.

As in HFC, as the cascade increases, noise contributions aggregate and the MER decreases. For an FDX amplifier, in the FDX band, there is an additional noise contributor to account for in the form of residual echo. The amount of acceptable degradation due to the amplifier is a system engineering parameter that flows from performance specifications ultimately to the performance of the EC itself. A significant advantage for amplifier EC when compared to N+0 is that the levels on the DS port are lower, and on the

US port higher. Thus, the DS to US level ratio is smaller, which is favorable for the EC that must subtract the downstream.

While noise analysis is relatively straightforward for N+x with FDX, the traffic engineering requires additional scrutiny due to the shared DS and US and the effects amplifiers can have in expanding the size of an IG.

Consider the N+1 system shown in **Figure 9**. When an amplifier is included, there is an expansion of Interference Group 4 (IG4) to the "south," or home-facing, side of the amplifier. These users become part of the last IG of the tap string before the amplifier. This is because of the limited drop-to-output isolation characteristics of today's taps. This parameter can be optimized for high drop-to-output isolation, but until there was FDX to consider, there was no reason to do so. Work in this area shows promise if the logistical and operational challenges can be managed.

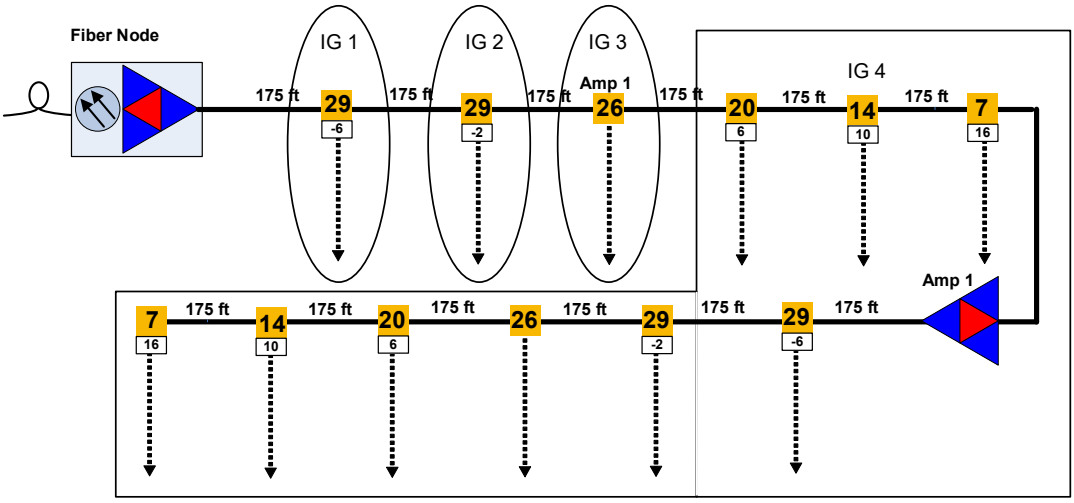

Figure 9 - Potential Interference Group Expansion due to Amplifier on an FDX Network

If we think about network segmentation triggers in current HFC networks, rules have been developed that link service group size, speeds, and percent capacity utilization and define total capacity required. Then, with an awareness of device penetrations, this can be translated to DOCSIS 3.0 and DOCSIS 3.1 spectrum requirements and the numerical thresholds that trigger a network augmentation.

Similar capacity-based analysis and empirical rule making will now apply to FDX, with one additional nuance. The FDX band is allocated for both downstream *and* upstream. The infrequent bursts of peak speeds can therefore be called upon to service the downstream *or* the upstream, but they have a new shared bandwidth dependency. Although from the node perspective there is full duplex spectrum operation, from the CM perspective the introduction of IGs places constraints on who can simultaneously access the spectrum. **Figure 10** depicts this observation.

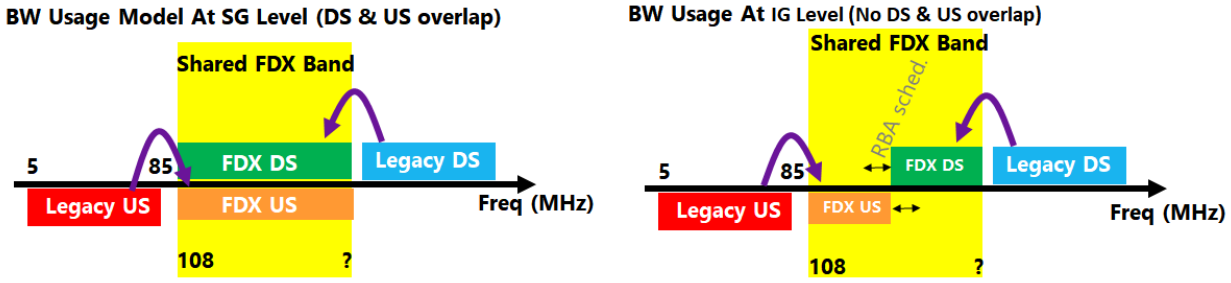

Figure 10 - Managing FDX Bandwidth to Guarantee Peak Speed Bursts [Courtesy CommScope]

The traffic engineering questions become:

1) How large can an IG be before there is an impact to the customer experience?
2) What service speed / IG size / spectrum rules exist when downstream and upstream traffic engineering become co-mingled in FDX?

Figure 11 shows a model assessing the subscriber count, spectrum, and QAM efficiency trade space for a set of input parameters projected to 2028 that includes average utilization with CAGRs of 35% downstream and 30% upstream, and speed tiers up to 4 Gbps/4 Gbps subscribed to by *every* user. The subscriber group (or IG size) sharing FDX spectrum can be as large as 64 and stay within 1200MHz of total spectrum, or even within 1 GHz for a relatively inefficient (for DAA) 9 bps/Hz net downstream throughput. The upstream, even for the 4 Gbps/4 Gbps (green) case, stays within the FDX band allocation for an IG size above 128.

What these studies reveal is that FDX bandwidth can be used extremely efficiently. Peak bursts are extremely infrequent and the collision of bursts from concurrent peaking users is rarer still. With an 85MHz legacy upstream, the upstream bandwidth is sufficient for peak-busy-hour (pbh) average utilization for up to 200 subscribers – where the red arrow points to the FDX bandwidth breach in **Figure 11**. The FDX upstream band turns out to be primarily a spillover reservoir for the occasional burst peaking user. Meanwhile, most of the daily grind for the FDX band is in delivering downstream capacity. This represents an extremely efficient use of precious HFC spectrum, which is precisely the principle that FDX was created on.

Reviewing, today's capacity management is based on assessing service group size vs available capacity vs utilization. At a certain empirically derived utilization threshold, a network augmentation is triggered. Typically, these are triggered by upstream utilization, and is a node split. However, it can also be new spectrum, more DOCSIS 3.1, or QAM reclamation.

The effect of FDX and the IG phenomenon is that now, in addition to the parameters above, network augmentation may be triggered by introduction of a new *speed tier*, and as a secondary factor the penetration of that tier over time. This will also ultimately be empirically derived, but initially be based on guidelines such as those given above. Network segmentation rules have been developed for services levels of 2/2 Gbps, 3/3 Gbps, and 4/4 Gbps.

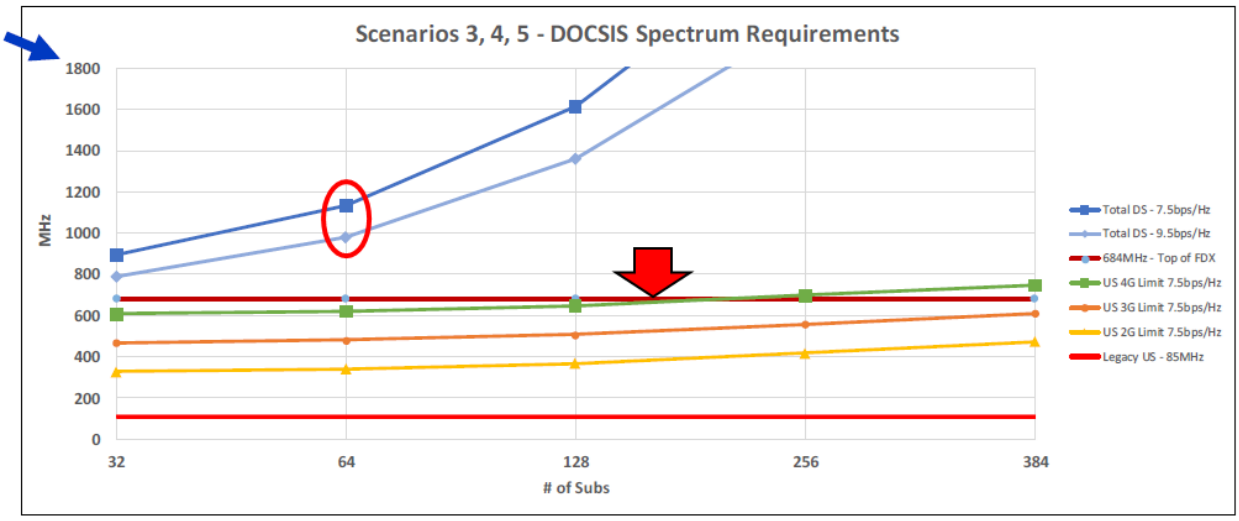

Figure 11 - Total RF Spectrum Required vs Subs Sharing a TG [3 Gbps/3 Gbps, 4 Gbps/2 Gbps, and 4Gbps /4 Gbps]

3.2. Extended Spectrum DOCSIS

3.2.1. What Is Extended Spectrum in the Plant?

The answer is simple! The cable industry has been executing HFC bandwidth expansion path for decades, so moving the spectrum to 1.8 GHz can be considered simply the next step in a well-established network evolution model. The next step in this path to higher bandwidth HFC has been coined *"Extended Spectrum"*. Looking back at the history of HFC plants, it was not so long ago that the upgrade was to 550MHz, then to 750 MHz, closely followed by 860 MHz, then 1GHz, and most recently to 1.2 GHz. Many "old-timers" can probably remember some of the incremental steps prior to 550 MHz, with long amplifier cascades – prior to adding the "F" in HFC. A step to 1.8 GHz from this perspective is just the next step in a spectrum and capacity expansion on the way to potentially a 3.0 GHz HFC network. In this manner we continue to leverage our valuable assets as has been done in HFC successfully for decades.

Recognizing the fact that HFC is going to be around for a very long time, cable operators are looking at what to do to keep moving on the path to 10G (10 Gbps). Prior spectrum expansion in the last two decades were primarily driven on the need for more downstream channel capacity; now, it is primarily upstream capacity, creating a more complex set of questions for what to do next.

There is increasing pressure on the physical layer of the network to create incremental capacity. Many networks may need additional interventions to keep up with new product and service offerings, but mostly to keep pace with the data traffic growth. The increase in Internet bandwidth demand is one of the primary reasons we touch the outside plant network today. Internet connectivity has become a very competitive landscape over the last decade, with the majority of the operators increasing data speeds on a consistent cadence. Had the role of data growth on network augmentation been understood 20 years ago at the dawn of HSD services, a more methodical and capacity engineering-based approach to place nodes could have produced more balanced service groups, evenly distributing data capacity. Nevertheless, over the last decade operators have learned the nature of capacity engineering and have been performing node segmentations, node splitting, and in some cases more aggressive steps, such as N+0 upgrades.

As expected, the results of these activities have benefited operators by systematically driving fiber deeper into their networks and closer to customer premises, thus reducing amplifier cascades and ultimately improving network performance and reliability. The segmentations have shrunk service group sizes sharing the bandwidth. Combined with aforementioned spectrum allocations, operators have a set of tools at their disposable to manage capacity, and with a range of impact suited to the incremental capacity upgrades of a simple node split, to tools suited to high growth, competitive footprint preparedness that include new spectrum, deeper fiber, and DAA.

3.2.2. Why Extend the Spectrum?

Leveraging the current assets of the HFC network in a manner that does not greatly change how operators invest capital is the key fundamental premise of *"Extended Spectrum."* Keeping network operations simple and familiar for the field operations teams is a key advantage of this approach. Extended Spectrum will allow cable operators to defer capital investments over a much longer period of time by using the "Business As Usual" (BAU) approach, while pragmatically driving fiber deeper into their networks. The improvements to amplifier technology will allow for continued use of most existing amplifier cascades, which fits into the current tree and branch topology of HFC networks.

Figure 12 shows how and Extended Spectrum allocation compares to today and to the High Split scenario that was shown in **Figure 1**.

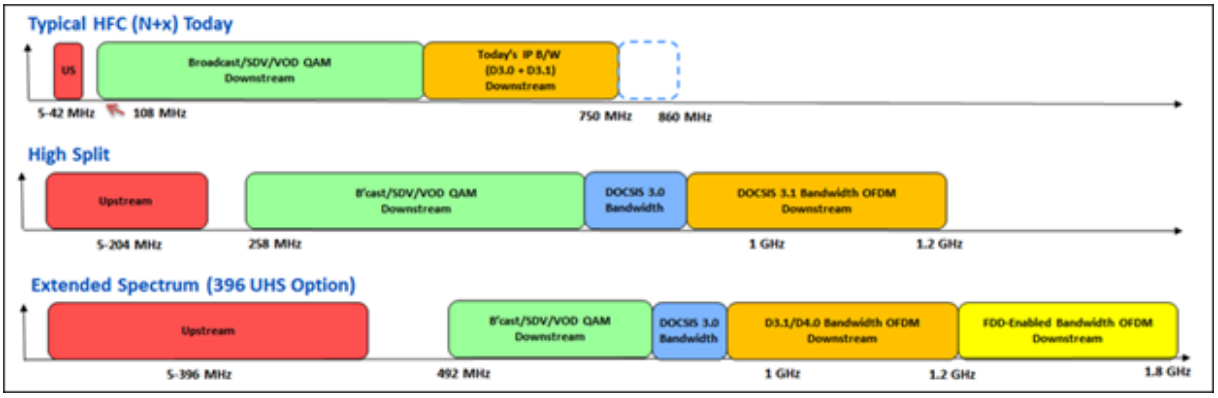

Figure 12 - Typical HFC vs High Split vs DOCSIS 4.0 Extended Spectrum

One of the biggest changes in future HFC plant upgrades will be pushing the upper limit of the carriers higher in the spectrum. Many details are still being worked out, but the goal is to perform drop-in upgrade to systems that were properly designed and built to a true 750MHz or higher. A properly designed and built system is highly dependent on the accuracy of the plant maps, the designer doing the work, the line equipment being used, and the distances in the spans of the coaxial cable. All of these potential uncertainties, plus the variables that went into the last system upgrade, can have an impact on this next step. With this in mind, operators will have flexibility to offer increased bandwidth in select locations to increase their speed to deployment.

So, how are operators looking at implementation of Extended Spectrum in practice? Below are some examples from an operator point of view in addressing some of the key changes introduced:

- *When is the right time to replace taps and passives*? The objective is for the frequency response of the housing to support 3.0 GHz now, with a 1.8GHz capability built into the device from day one. There is not an urgent need to put 1.8 GHz in place today, as most network upgrades are

beginning with a 750 MHz plant. Thus, even after an upstream split change, there is typically open and useable spectrum up to 1.2 GHz to consume, buying time to phase in taps and passives upgrades as the downstream bandwidth gets utilized.

- *How best to manage Total Composite Power over the extended bandwidth?* Maintaining a realistic Total Composite Power (TCP) while extending the spectrum to 1.8 GHz requires thinking about the tilt and output levels, because of the need to maintain legacy RF levels into legacy CPE. Working closely with the silicon vendors has been an important step to understand trade-offs between level and performance.

  Note that the RF amplification is being designed to drop into the current amplifier spacing and location currently utilize for 750 MHz plant. This creates the need for new RF hybrids that are capable of amplifying at much higher frequencies while maintain a Total Composite Power (TCP) that is acceptable to minimize all distortions while not exceeding a power budget. Given the magnitude of this challenge, alternatives are being considered while the amplifier efficiencies catch up, looking at ways to not exceed the TCP capabilities of the amplifier. A simple way this can be accomplished is to use a step-down approach of the signal at either 1 GHz or 1.2 GHz. This step down will maintain a TCP, while not impacting the amplifier linearity that would otherwise degrade amplifier MER we want to achieve.

- For the upstream split, what is the "right" ratio? 204, 396, 492, 684 MHz or beyond are all flexible and effective solutions for whichever direction various operators choose for their markets. Each must be evaluated comprehensively within the market of interest to ensure they do not break powering boundaries of the network, reduce overall performance, or dramatically increase complexity. **Figure 13** and **Table 1** [6] show the spectrum allocations for downstream and upstream based on the DOCSIS 4.0 standard "Ultra High Split "(UHS) options.

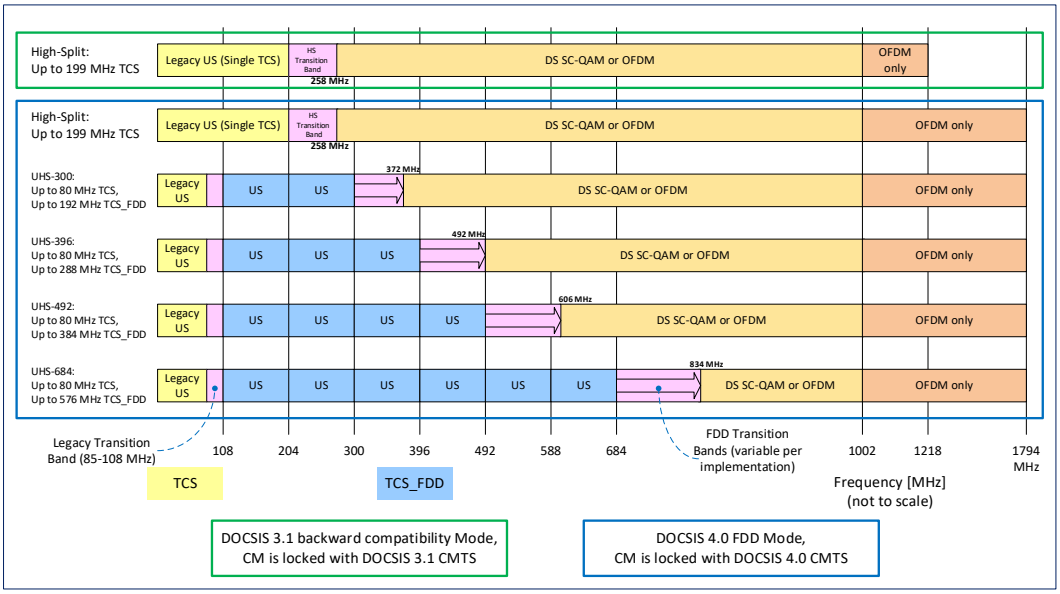

Figure 13 - DOCSIS 4.0 Extended Spectrum Allocation Options for Downstream and Upstream

Table 1 - DOCSIS 4.0 Extended Spectrum Ultra High-Split Options

Split Name	Diplex Filter Start Frequency (Upstream upper band edge) (MHz)	Diplex Filter Stop Frequency (Downstream lower band edge) (MHz)
High-Split	204*	258
UHS-300	300	300 MHz–372 MHz
UHS-396	396	396 MHz–492 MHz
UHS-492	492	492 MHz–606 MHz
UHS-684	684	684 MHz–834 MHz

Changes are coming to HFC networks over the next few years in order to deliver more bandwidth and prepare for 10G. Extended spectrum ensures that operators have a long-term cost-effective option. Continuing to leverage these assets in a strategic manner is one way in which we will remain competitive while meeting the growing demands and insatiable subscriber's appetite for more bandwidth. The path to 10G initiative announced by CableLabs has accelerated efforts to deliver 10 Gbps service over coaxial cable networks. This makes strategic research efforts a big part of how operators are planning to reach the 10G vision and which technologies will be best to use. **Figure 14** shows the first DOCSIS 4.0 Extended Spectrum DAA node SoC, now being brought up in labs.

As an industry, it is imperative to have a large selection of tools that allows cable operators flexibility and scalability for their specific operating models. When looking at all the different architectures and scenarios that exist across the globe, operators must consider how to best scale the available assets and when to do so. As has been the case for decades, this will include a mixture of tools that support implementing roadmaps, such as the path to 10G, with anticipation for key technologies on the horizon.

Figure 14 - First DOCSIS 4.0 FDD SoC

Recently CableLabs completed the specification work on DOCSIS 4.0, which includes Full Duplex DOCSIS (FDX) and Extended Spectrum DOCSIS (ESD). These DOCSIS 4.0 variants will support different options to increase bandwidth and capacity, and furthermore support convergence of the technologies over time.

3.3. FDD-FDX Synergies and Key Differences

The most important commonality between DOCSIS 4.0 FDX and DOCSIS 4.0 FDD is the use of the DOCSIS3.1 technology as the basis for their Physical Layers. DOCSIS 3.1, of course, was a major shift away from what had been exclusively Single-Carrier QAM (SC-QAM) modulation formats of limited maximum efficiency for both the downstream (256-QAM) and the upstream (64-QAM), and using a combination of Convolutional and Reed-Solomon coding for Forward Error Correction (FEC) to increase the robustness. DOCSIS 3.1 broke the precedent of compatible SC-QAM based versions of DOCSIS, embraced the fast-growing adoption of multicarrier modulation (OFDM/OFDMA), and updated the FEC to Low Density Parity Check (LDPC) that was, despite its computational complexity, now able be implemented in real time, delivering significant new coding gain.

Both DOCSIS 4.0 FDX and DOCSIS 4.0 FDD rely on these powerful DOCSIS 3.1 modulation formats and FEC. Furthermore, the same OFDMA and OFDMA "numerology" details are unchanged in DOCSIS4.0 – subcarrier spacings options, range of cyclic prefixes, FFT size, windowing, exclusion bands, pilots, PLC channel, etc.

Of course, the focus of DOCSIS 4.0 is the expanded spectrum range that these "DOCSIS 3.1" signals can be extended over, into frequency allocations where they had not been allowed before.

3.3.1. The Same Except Where they are Different

The discussion to follow will mostly take place from a network and DAA node point of view. However, a parallel discussion with many of the same characteristics apply on the CPE side, although the economic equation for CPE devices is very different. Technology parallels notwithstanding, the commercial differences and the premium value on the customer-facing LAN interfaces may lead to different business decision points on implementation and feature priorities.

For both FDX and FDD, upstream signals can extend beyond 204 MHz, up to 684 MHz. The required amount of OFDM and OFDMA resources is similar, as shown in **Table 2**. This is by design, enabling system-on-a-chip (SoC) suppliers to design and manufacture their chips which highly common blocks and functions for the most complex elements of the SoC. The common technology basis makes for an efficient and cost-effective ecosystem.

Where DOCSIS 4.0 differs from DOCSIS 3.1 more significantly are the differences between FDX and FDD that force changes at the "edge" of the SoC and outside of the SoC. However, the massive DOCSIS 3.1 processing engines required for either FDX or FDD are dominant features of these SoCs. Coupled with the common processing resources required, manufacturers of these devices may choose to implement the more moderate differences at the edge of the chip within a common SoC as configurable elements. This could be the case in the DAA node, or the CPE, or both.

Table 2 - Common DOCSIS Resources are Defined for FDX and FDD [6]

Item	Device	FDX OFDM/OFDMA	ESD OFDM/OFDMA	SC-QAM
Downstream Channel Support	CM	5 total OFDM channels; 3 channels capable of FDX operation; All channels capable of non-FDX operation up to 1218 MHz	5 total OFDM channels; All Channels capable of operation up to 1794MHz	32
	CMTS	6 total OFDM channels; 3 channels capable of FDX operation; All channels capable of non-FDX operation up to 1218 MHz	8 total OFDM All channels capable of operations up to 1794MHz	32
Upstream Channel Support	CM	At least 7 total OFDMA channels; 6 channels capable of FDX operation; 2 channels capable of non-FDX operation within the legacy diplexer configuration. (Some channels can be configurable to support either FDX or non-FDX operation. When supporting 6 FDX OFDMA channels, only 1 non-FDX OFDMA channel is required.)	7 total OFDMA channels	4 (or 8) SC-QAM channels, operating within the legacy diplexer configuration
	CMTS	8 total OFDMA channels; 6 channels with FDX operation; 2 channels capable of non-FDX operation based on operator deployment requirements.	8 total OFDMA channels	4 (or 8) SC-QAM channels, operation dependent on operator deployment requirements

The nature of the differences on the Original Equipment Manufacturers (OEMs) who build the FDX or FDD components around the SoC technology is more challenging than the SoC vendors. In FDD systems, the DAA node and CPE extends to 1.8 GHz, and includes diplex options for upstream settings. In FDX system, the typical 1.2 GHz bandwidth suffices, and there are no additional diplexers in the node beyond the standard Mid-Split one isolating the legacy upstream from the FDX band. FDX upstream is added by remotely configuring the vCMTS for the FDX band to activate the desired number of OFDMA blocks and extending the EC technology across these new blocks. The "Big Idea" is that this new massive upstream is added but where there is also downstream in use, thereby creating an extremely efficient use of coaxial spectrum without a large guardband penalty.

However, since OFDMA activation in the FDX band is not filter-based, an RF path at a node port, as shown in **Figure 15**, uses a *directional coupler* before the legacy diplexer in order to siphon off the upstream signal to send to an FDX band receiver. Thus, RF layout for an RF board in an FDX node is very different than in an FDD system.

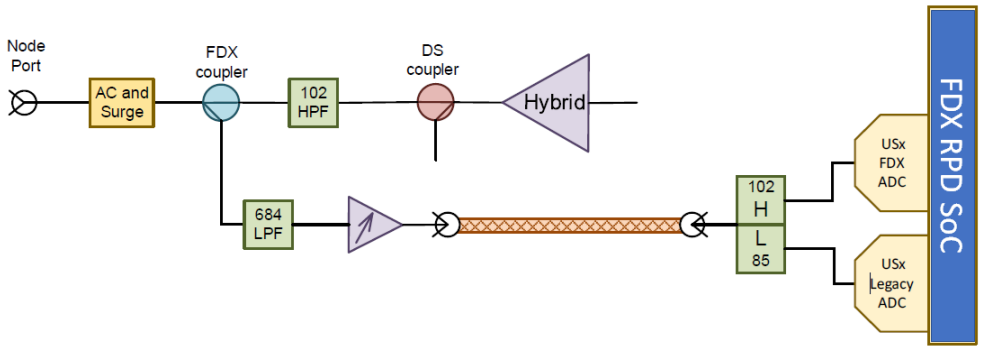

Figure 15 - RF Processing in FDX is Different than in FDD systems

Another change on the RF layout for FDX (not shown in **Figure 15)** are RF feedback traces from the downstream RF path, such as from the "DS Coupler" to sample and enable the signal so the EC can learn the interference and subtract it.

As described, in an FDD system, the RF processing chain is similar to today's nodes except for the much wider frequency response, and that it is expected that FDD nodes will incorporate a subset of the DOCSIS4.0 specification-defined diplexers to address upstream speeds by adjusting the diplex filter value remotely. The FDD "Big Idea" is then to enable this extended upstream-only spectrum, and downstream signals are extended up to 1794 MHz to make room for the shifted downstream to sit above the higher upstream plus ensuing guardband. FDD guardband is approximately 20% of the upstream diplex edge, for a maximum of 150 MHz in the 684 MHz case at the top end of the range. While 684 MHz is an available option, current usage and speed trajectories indicate this maximum upstream band edge may not be required, or at least not for many years.

Technically, 1794 MHz is the upper band limit defined initially for the DOCSIS 3.1 downstream. However, it had been largely deferred as DOCSIS 3.1 was developed (circa 2012) and the "I01" first release published. During that time, it was determined that quantifying the specification to this forward band limit could be deferred. This quantification is now taking place, and because of this, while the band edge of the frequency was identified by the DOCSIS 3.1 specification, it is the DOCSIS 4.0 work that is completing the requirements. Thus, 1794 MHz is typically identified with DOCSIS 4.0 Extended Spectrum and similarly, DOCSIS 4.0 FDX is associated with the 1218 MHz limit.

Figure 16 illustrates the commonality of DOCSIS processing resources from a spectrum utilization point-of-view between FDX and FDD.

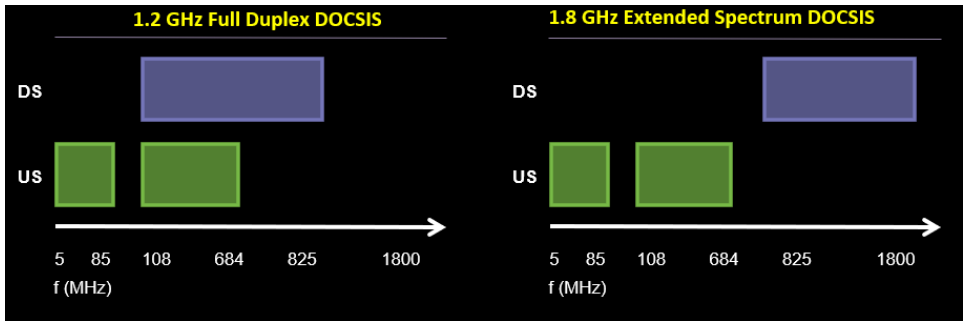

Figure 16 - DOCSIS Resources Downstream and Upstream are Common in FDX and FDD

3.3.2. Is this What DOCSIS 4.1 Might Look Like?

Observing the two DOCSIS 4.0 options, we see that both add a common set of upstream OFDMA blocks over a common frequency range. One, FDD, pushes a significant physical bandwidth extension into the network relying on common RF practices executed for several generations of HFC migration. The other, FDX, relies on the introduction of new DSP technology to complement the existing plant technology in order that the spectrum asset be operated more efficiently over a bandwidth that the plant is built to support.

Importantly, these are not mutually exclusive approaches! In fact, they are complementary technologies that, in principle, could be merged in some future DOCSIS extension, perhaps as shown in **Figure 17.**

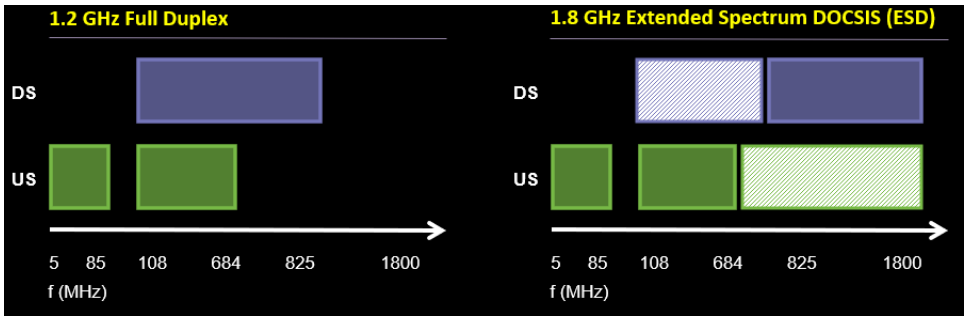

Figure 17 - The Potential Complementary Nature of FDX and FDD

With the DOCSIS 4.0 upstream capacity as defined for FDX or FDD in the 5-6 Gbps range, merging the two technologies may be next step toward push the upstream also towards the 10 Gig goalpost.

3.4. Characteristics and Attributes Summary

Table 3 summarizes DOCSIS 4.0 FDD and FDX comparative attributes discussed herein (most of them), side-by-side. This is a useful cheat sheet to have on a whiteboard (perhaps a relic of a pre-Covid era) to generate dialogue, inspire feedback, identify where information gaps exist, zero in on those that carry the most weight, and generally spark debate and pro/con scorecards . We will use it later to re-form from a side-by-side comparison into DOCSIS 4.0 NFEAQs – Not Frequently Enough Asked Questions.

Table 3 - FDD-FDX Attributes Comparison

Attribute	FDD/ESD	FDX
Strategy/Philosophy to 10G	• Based on access network BW extension upgrade, up to 1.8GHz, for existing actives and passives • Introduction of DAA to migrate to 10G, similar to previous HFC plant upgrades with a choice of diplex split configurations	• Based on access network technology upgrades to introduce new DSP (EC) into RPHY nodes and Amplifier platforms • Build on DAA production and scaling of vCMTS as the foundation for 10G
Migration Factors	• 1.8 GHz DOCSIS 4.0 DAA Nodes, Amps, Taps and Passives • Allows for cascade of amplifiers • New CPE	• RPD Nodes with DOCSIS 4.0 EC function • FDX-capable amps with DSP • New CPE
Complexity	• New tech challenges – BW and TCP extension • Use of "low power" amp extender for edge cases	• New tech challenges – EC function, CMTS scheduler, DSP-based amps • New capacity mgmt rule for IG/TG size for peak speed
Spectrum/Capacity	• 1536 MHz DS/656 MHz US (see **Figure 13** and **Table 1**) • Up to 15G/5G (all-DOCSIS 3.1) • DS/US: BW and Capacity per diplex selection	• 1110 MHz DS / 656 MHz US (see **Figure 2**) • Up to 11G/5G (simultaneous, all-DOCSIS 3.1) • FDX BW/speed by SW config
Operations	• Utilize existing common operational practices – FDD system with different possible split choices • New field tools	• New operational practices for handling of spectrum overlap and amplifier installations • New field tools
Network	• N+X • Cascade reduction/trade-off based market capabilities	• N+0 (optimal) • N+X – Cascade reduction/trade-off based on market speeds
As-Built Migration	• Continue node split and introduce DAA node splits, leverage for HFC migration activity, introducing components of FDD over time • Migration path and timing considerations for Underground vs Aerial and MDU vs SDU cost implications	• Introduce DAA for node splits with vCMTS, leverage for HFC migration activity and platforms that enable FDX activation • Migration path and timing considerations for Underground vs Aerial and MDU vs SDU cost implications

While capacity and data speeds often garner the most of the attention when discussing access network, other important attributes from **Table 3** that consume more attention when comparing the options above are alignment to long-term strategy for the access network, network upgrade costs, and operational implications. The latter two have corollaries the attributes "as-built" and "complexity," which we will dip into a bit deeper in the next section.

4. DOCSIS 4.0 Migration – Key Variables

Across a single MSO are a range of HFC architectures. Larger MSOs, such as Comcast and Charter, tend to have a very wider range of network variants, owing to the consolidation of many smaller operators over time and the exchanging of properties among MSOs to gain operating efficiencies. There are opportunities to reel in the range of variations with the introduction of new technology and defining new architectures as part of a Next Generation migration plan. It is an opportunity to build a more common end state. However, as noted, the difficult part is always in the transition *to* a desired end state. Several important network characteristics play a role in the cost, complexity, reliability, and performance of the end state achieved from a given HFC baseline architecture and physical network.

4.1. Network Bandwidth

Today's HFC networks come mostly in the 3 varieties of maximum bandwidth described earlier – 750 MHz, 860 MHz, and 1 GHz – with a fourth emerging at 1.2 GHz, which nearly all new actives and passives support today. Many of these networks, in particular 750 MHz networks, likely began their lives designed for much lower total bandwidth, such as 450 MHz or 550 MHz (even 330 MHz). RF signal loss over coaxial is frequency-dependent and has a predictable inverse root-frequency relationship. As such, the construction of the network led to a physical distance between actives and passives as well as feeder cable

requirements that could deliver a desired target end-of-line (EOL) performance – modest by today's standards – although at that time built around analog video requirements. Analog video is sensitive to noise and distortion, but these are pre-High Definition (HD) days with what would be considered low video quality expectations today.

This "spacing" generally was able to be held intact as RF amplification technology over time overcame the limitations of long spacing that was associated to an assumption of RF loss that may have fit for 450 MHz, but not for 750MHz. Bandwidth increments were relatively small steps, and broadband power amplifiers got better through the evolution from Silicon-based to Gallium Arsenide-based (GaAs) to Gallium Nitride (GaN)-based. By "better," we mean able to extend in bandwidth, but also able to extend in Total Composite Power (TCP), since more bandwidth to cover means more power to transmit. In addition, because RF transmission is launched on a tilt, the TCP is impacted disproportionately higher to the bandwidth added.

Lastly, most taps and passives on the network have upper frequency specifications such as 1GHz or 1.2GHz over which their RF parameter must be met. Passive devices can carry signals without guarantee of performance beyond these ranges with generally parasitic additional loss, to a point. With specification guaranteed only to 1.0 GHz or 1.2 GHz, there is a point above that at which the technology used in the design becomes incapable of supporting reasonable transmission with predictable loss.

The above variables have been part of the considerations for every HFC plant bandwidth upgrade over the years, and will be again as the network extension to 1.8 GHz is developed. How capable is the existing plant for supporting 1.8GHz and what are the cost / performance trade-offs and implications to prepare the network for this extension. There are no current HFC plants built with 1.8 GHz spacing in mind, and the disproportionate TCP due to tilted RF loading to 1.8 GHz places some constraints on the power spectral density profile.

On the FDX side, the RF design at the port of a node adds new passive components for feedback EC and a directional coupler to support the FDX band operation in both directions. These additional passive losses occur right at the output of the PA on the way to the port, contributing to launch power decreases that can reduce reach to homes on a passive network or decrease levels at the next active. The coupler designed loss also impacts the upstream signal at the node port in the FDX band that must be accounted for in the design and system engineering. These effects must be compensated for in the overall node design and accounted for in the system engineering. The trade-off space is typical in many ways - gains, levels, distortion, noise – towards an optimized FDX node design. What is different is that in the FDX band the trade-offs must have both DS and US in mind, since they share that part of the spectrum.

4.2. Cascade Depth

VERY long amplifier cascades were eliminated with the invention of HFC, allowing fiber to cover long distances and limit the coaxial cable portion of the plant. "Long" cascades today are much different. **Figure 18** shows a distribution of cascade depths across a sample within a region of the Comcast network used for a business modeling exercise. These distributions vary across regions with an operator as well as across operators. Comcast has builts million of homes passed to date in an N+0 configuration [3]. The sample selected in **Figure 18** is specifically outside of these N+0 build areas, but of course include some natural N+o as-built cases, such as MDUs. For this subset of the network, over 5 amplifiers in cascade would qualify as "a "large" cascade. Note that the "5" in N+5 merely refers to the maximum series cascade in the RF design. There could be 15 amplifiers off of a node port (near the median), but the number in cascade would be a maximum of 5.

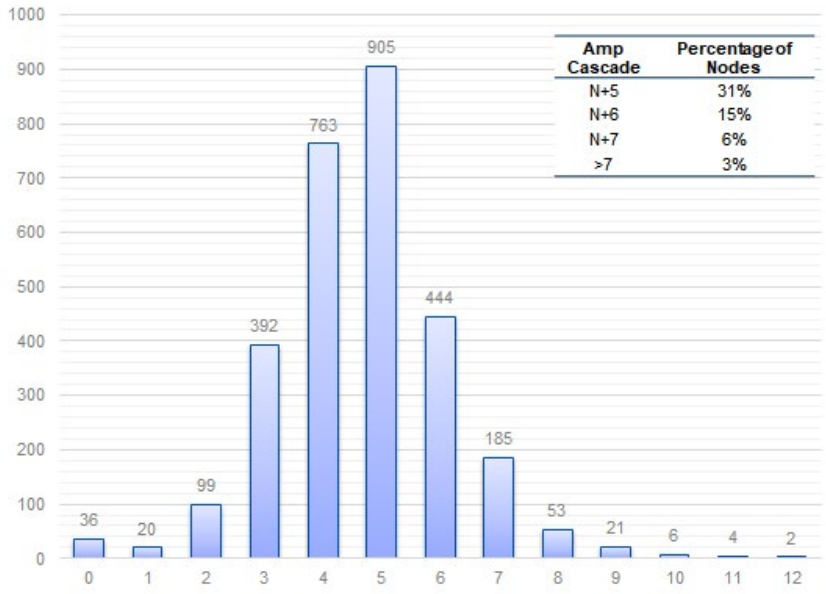

Figure 18 - Cascade Distribution – Comcast Sample

Cascade depth effects the same things it always has – MER degradation, frequency response, serving groups size (when combined with homes passed density).

For DOCSIS 4.0 cascade depth impacts are the same, only different. For FDX, as discussed, cascade depth includes the contribution of any residual noise of echo cancellation in addition to natural thermal noise. And, by the nature of the service group size relationship, cascade depth has a relationship to IGs and speed offering.

For FDD, the cascade depth drives the frequency response roll-off associated with the increased RF loss with frequency of existing feeder and drop cable, and taps and passives. Projected performance and the frequency extreme drive the minimum receive levels and ultimately bandwidth efficiency expectations.

For both cases, setting a maximum cascade design rule to offset the negative consequences of deeper cascades will drive cost into the migration plan in order to accomplish the segmentation needed. These costs can be modeled based on target objectives for the DOCSIS 4.0 network and the implications of those objectives on the cost of the network augmentation. In addition, as is always the case with network architecture, it can be phased over time to balance the deferment of upgrade cost with the need to achieve certain capacity and speed targets on Day 1 vs Day 1001. The flexibility to easily deploy new downstream and upstream capacity then becomes a consideration, always looking to eliminate or minimize physical plant touches.

4.3. Aerial or Underground Construction

For any network augmentation that involves pulling fiber or coax cable, there is a significant difference in the labor cost of this work between aerial and underground construction that is very favorable to the aerial plant style. The availability of conduit with unused carrying capacity underground helps to minimize this difference, where that is the case. Of course, not all underground is created equal either, such as augmentations that require tearing up concrete and crossing busy streets in metropolitan cores.

Operators know their own labor costs for these physical and regional variables, as well as any overhead costs associated with different municipalities, which can also vary widely. Sample network migration models can be created based on these known construction types. And, as pointed out in the discussion on "cascade depth," network augmentation can be phased as a function of time tied to capacity targets versus time, governed by CAGRs, and speed capability versus time, governed by the HSD business. The phasing has to be balanced by the opposing force of not creating too many network disruptions that are customer-impacting, and not creating excess inefficiency with too many ventures into the plant to take steps that were not sufficiently consequential the last time around in buying time to support traffic demand.

4.4. Homes Passed (HHP) Density

Not surprisingly, all else the same, it is more cost effective to upgrade a high-density area than a low density area, simply because the denominator is larger. Secondarily, there is a relative uniformity of higher density footprint that has a stabilizing effect on metrics, the customer experience and simplifying operations.

The boundary case of high density is the Multi-Dwelling Unit (MDU) environment. Unfortunately, and somewhat counterintuitively, such environments are also prone to be among the more challenging from an RF standpoint for a variety of reasons. MDUs will be discussed in more detail in the next section.

4.5. Network Powering

We will likely be asking more from the network power supplies that power the HFC plant when moving to DOCSIS 4.0. The DAA foundation of DOCSIS 4.0, the DSP that is introduced as part of FDX, or the extended bandwidth that is part of FDD all point towards taking a close look at the state of the existing network powering – voltage and amperage – as well as back-up power requirements.

Available power supply monitoring information has allowed Comcast to determine the percentage of upgraded footprint will require more current from existing supplies in a modest plant upgrade, and how many drive all-new power supplies to be added. Sensitivity analysis has been done around how many new amps of current drive power supply upgrades ($) or new power supplies altogether ($$$) given the known supply capacity margin going in.

4.6. Multi-Dwelling Units

When it comes to Multi Dwelling Units (MDUs), the "Good and Bad" are closely coupled. On one hand, an MDU can be considered the low hanging fruit for a DOCSIS 4.0 deployment given the high density and minimized cable lengths. It is that high density that makes these environments targets for competition. To add to the complexity, the FCC has rules (usually referred to as the "Inside Wiring Rules" 47 CFR 76.802) designed to enhance competition in MDU buildings. The FCC rules allow the MDU owner to gain control over Inside Wiring in order to make it available for use by a competitive service provider. It is these rules that make operators more reluctant to rewire the MDU or upgrade with fiber to each unit. A caveat to the FCC rules is that they are technology-agnostic and do not distinguish between the types of wiring that comprises the inside wiring. The applicability of the rules does not depend on whether the Inside Wiring is CAT-5, RG-6 or fiber optic cable.

The demographics of these properties vary greatly from location to location. Some utilize a campus layout, also known as a "garden style." Of course, the high-rise single building is usually what people think of when they hear "MDU." In any case, the density is typically much higher than serving single family units (SFUs), so an operator typically has opportunity for lower investment per living unit.

Servicing the MDU space is also unique in that the owner has the ability to grant exclusivity to the use of the inside wiring. This allows operators to sign "Bulk Agreements" to serve the entire building. Until recently buildings were often wired with coaxial cable. It is this wiring that DOCSIS 4.0 looks to leverage with symmetrical Gigabit speeds similar to fiber, without the costly expense of rewiring the building.

As with any HFC outside plant upgrade to increase bandwidth there will be some network and design challenges. With respect to MDUs, when compared to aerial or underground plant in easements or rights of ways, some of the challenges are similar. There are typically two types of environments, classified as either "Greenfield" new build or "Brownfield" existing network. The latter is the area that gives the greatest benefit to utilizing DOCSIS 4.0, given the re-use of the coaxial infrastructure that exists in a majority of buildings. The higher density of the MDU environment will allow operators to easily deploy in a cost effective and strategic manner. Operators have taken note of the power of fiber to the building, and thereby many sites are fed from a "Dedicated Node" that serves the complex only. These dedicated nodes can be upgraded incrementally by only making changes to that location. Even in the garden style layout there are very few actives and much less cable than single family units. The latter is of high importance given the higher attenuation of coaxial cable at upper frequencies. These shorter coaxial runs would also benefit from a future 3.0 GHz Extended Spectrum for the same reason.

In Greenfield, more builders and owners are opting to install fiber or Ethernet cable as they build the units. These will typically be fed using a Passive Optical Network (PON) technology which is not the focus for this paper. However, cable operators have equalized the conversation around fiber vs coax with respect to HSD speed offerings with DOCSIS 3.1 and DOCSIS 4.0.

Experienced field personnel will attest to the fact that MDUs have their own set of challenges related to maintaining the integrity of the RF performance. These units typically have high churn with people moving in and out more often. This creates more opportunities for loose connectors, open terminations, damaged inside wiring, etc. These types of issues can result in a trouble call or truck roll to resolve. Note for DOCSIS 4.0 Extended Spectrum, the new bands will be occupied by OFDM carriers only, which are much more resilient than SC-QAM signals, with better error correction and with the ability to change modulation profiles when needed.

The above MDU variables can be considered in the MDU design during the deployment. DOCSIS 4.0 has some requirements that will change how these buildings are served. Two of the biggest DOCSIS 4.0 changes are:

1) DOCSIS 4.0 must be deployed as part of a *Distributed Access Architecture* (DAA). With this requirement, there will no longer be a reliance on analog optics that serve nodes today. This will result in improved signal fidelity to the property and into the unit, and thus more DOCSIS 4.0 capacity.

2) The DOCSIS 4.0 modem will be a *Point of Entry device* when used in DOCSIS 4.0 mode, meaning that it will be the sole HFC-terminating device in the unit. There will be no need to be concerned with the splitter network to feed other boxes, such as STBs, and in many cases also the cabling inside the unit. These fundamental changes reduce the concern that we typically have when dealing with insertion and attenuation loses.

As stated in the beginning, MDU environments could be considered the low hanging fruit for initial DOCSIS 4.0 deployments to provide multi-gigabyte services without the need to re-wire the inside of the units. We even see a possibility of leveraging 3.0 GHz in the future in the MDU space.

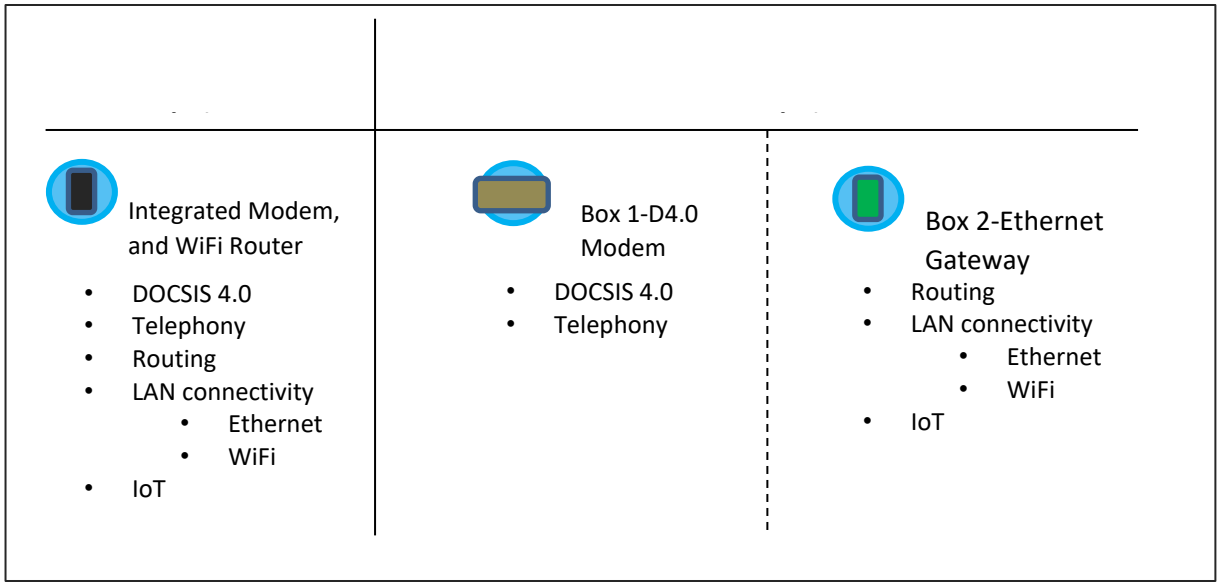
4.7. The Home Network

With increasing numbers of Wi-Fi devices within home networks (on average, there are currently 15.8 Wi-Fi connected devices per home, and current projections have these numbers doubling to above 36 devices per home by 2025), the strong preference for the convenience of wireless over wired by customers, the increase in IP traffic to and within the home, and the move to higher speed WAN solutions such as DOCSIS4.0, it is imperative that the industry collectively start assessing the various options for in-home devices to meet these evolving customer needs. Operators and technology partner experts who are focused on the customer experience, premise equipment, technical operations, and fulfillment operations are well aware of one of the fundamental questions around in-home device architectures; whether to deploy a single integrated Gateway box (device) or a dual box solution that separates the WAN modem from the LAN gateway. The advent of DOCSIS 4.0 has reignited that discussion, largely due to the value of locating the DOCSIS 4.0 modem near the home's demarcation for improved DOCSIS performance.

In considering the CPE options for a DOCSIS 4.0 solution, there are a number of tradeoffs that need to be contemplated. The primary consideration is the customer experience from ordering the service, to unboxing the devices(s), to installation and activation, to performance and reliability, and if there is an issue, how the customer can identify and quickly resolve the issue. Other key considerations include the cost of the device(s), as well as operational costs of managing SKUs including supply chain, Technical Operations, and care.

When talking about a 1-Box or 2-Box solution, the first consideration is to decide what functionality goes in each device. For the 1-Box solution, everything is integrated into a single device, so this is more straightforward. However, when this functionality is split across two boxes, the split of the integrated functionality across two devices as well as the connectivity between those devices must be considered. **Table 4** below shows one option for the separation of functionality; however, other options are possible depending on specific services that need to be supported as well as operational considerations.

Table 4 - DOCSIS 4.0 CPE 1-Box vs 2-Box Considerations



As noted previously, there are pros and cons to either the 1-box or 2-box approach. A single box configuration enables the Service Provider to offer a single device (gateway) to deliver the customer's connectivity and all of their IP-based services. This option makes an SIK installation process relatively simple, assuming no RF-related issues at the premises (note – a 2-box solution can also be based on an SIK model). However, it also can introduce some additional complexity around in-home/Wi-Fi connectivity. The connectivity issues are generally related to the location of the RF outlet within the premise, which is often not centrally located within the dwelling. The advancement in Wi-Fi and mesh technologies has helped alleviate the wireless connectivity challenges of the past.

Consider **Figure 20**. When considering a 2-box solution, one of the advantages, if properly executed, is that it can allow the router to be placed in a more central location in the home. This will likely provide a better in-home connectivity experience, as the Wi-Fi functionality in the gateway can be more centrally located within the home. Another advantage of the 2-Box configuration is the ability of the DOCSIS 4.0 device to be located at the demarcation, which will improve DOCSIS 4.0 performance by avoiding any additional passive losses or impairments from actives withing the home, as the in-home wiring is uncontrolled and can create installation and troubleshooting challenges. Avoiding this potential unnecessary degradation to the DOCSIS 4.0 solution can be beneficial to both operators (consistent performance, straightforward operations) and customers (higher speeds, more consistent performance, fewer technician visits). This is true from DOCSIS 3.1 as well, but the value of a demarcation installation with DOCSIS 4.0 is amplified since we are pushing the limits of the RF capabilities of the coax network.

The industry has been fortunate for some time in that the core WAN and Wi-Fi technologies have not been changing (individually or jointly) historically at the pace being observed today. The recent launch of WiFi6 (2019), the approval for Wi-Fi 6E (2020), and pending Wi-Fi 7 specification ratification suggest Wi-Fi is iterating at an accelerated pace, which is a good reason to consider a 2-Box solution. A 2-box solution allows the WAN and LAN functionality to be updated independently since this functionality is physically separated between two devices. As always, however, it comes with a cost that must be considered. These costs could manifest negatively on the operator side and the customer experience side. Some of these implications are discussed below.

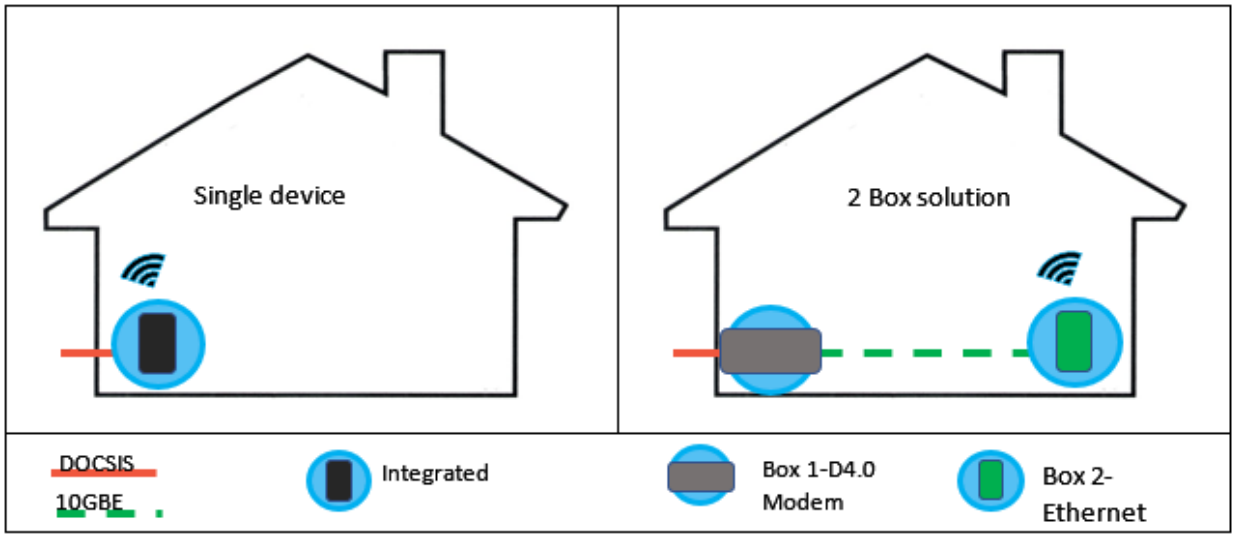


Figure 19 - DOCSIS 4.0 CPE 1-Box vs 2-Box Installation

As an example, an interesting challenge with a 2-box configuration is related to the connectivity between box 1 and box 2. As we look to moving to multi-gigabit speeds within the home we are faced with a couple of choices.

1. Leverage a 10Gbit Ethernet connection between the devices, which provides a robust connection but introduces complexity around running Ethernet cables and could compromise the ability to locate box 2 (router) with Wi-Fi in a central location within the home. This potentially undermines one of the key advantages of a 2-box solution, which is flexibility in the location of the Wi-Fi AP.

2. Consider leveraging a wireless medium (mmWave or Wi-Fi) for backhaul. Wireless backhaul introduces other challenges from cost on each device to managing Wi-Fi congestion within customer premises and guaranteeing reliable multi-Gigabit performance.

Another interesting item for consideration in the 2-box architecture, with its own "pros" and "cons," is whether the WAN (box 1) could be hardened and sit outside the customer premise or if it should be located within the dwelling. Locating the DOCSIS 4.0 eMTA outside the home has operational benefits as the Technician is now able to troubleshoot DOCSIS issues without having to enter the customer's home. However, in addition to the cost of hardening a modem to work in an outdoor environment, powering this device and how to get the LAN connected from outside the home to the Wi-Fi router in the home can be a challenge. Having the DOCSIS 4.0 eMTA outside the home also has some potential security risks because the LAN will be exposed outside the home. With all of these constraints in mind, it has been difficult to date to justify mounting the DOCSIS device outside the home.

With the increasing demands on our networks, the need to move to DOCSIS 4.0 longer-term is clear, and while this will take some time, it is important to plan how this technology will be deployed. While there are significant considerations for the DOCSIS networks as part of this transition, we must also be thoughtful about the CPE solution, as it is not likely to be cost-effective initially to deploy only DOCSIS 4.0 devices as this new technology is being launched. With that in mind, the customer impact and operational impact of the CPE decisions must be considered.

5. Planner's Guide to DOCSIS 4.0 Migration

There are reasons that North American cable operators, although generally aiming for similar service objectives, operating in similar competitive environments, and with common ecosystem technology options to choose from, have deviated in their architectural solutions and directions over time. Looking back to the mid-2000's, the popular debates of the era were many. Perhaps most prominent was around how to future-proof the downstream – the concern of the time – with increasing demand for HD channels, which consumed significantly more bandwidth per HD program (4-5x) than standard definition (SD) video. Back then, the discussions were around upgrading plant spectrum, deploying Digital Terminal Adaptors (DTAs), deploying Switched Digital Video (SDV), and transitioning to IP Video. Note these are also mostly complementary initiatives (SDV or IP Video being the exception).

More broadly, invest in FTTH now or double down on coax technologies was a hot topic. This perhaps sounds odd, given the 15+ years of continued successful coaxial strategy. But this period of time was also the launch of major Telco-based FTTH initiatives that signaled the "end" of cable services, again.

For MSOs, and again in particular large MSOs with broad and diverse geographical footprint, there are also many different starting points of HFC networks. Other initial conditions include existing portfolios of CPE devices with ranges of capabilities, critical OEM partners with varying roadmaps and unique expertise, different internal viewpoints on where the investment focus should be, and different perspective on near

term and long-term architecture. Capacity-building investment does not have simple, direct revenue tied to it the way new service opportunities do. Yet supporting capacity growth and demand is the cost of doing business as a network provider.

Furthermore, across operators and within a single operator, there are

- Different network architectures, often related to the range of per-homes passed (hhp) densities
- Different construction practices
- Zip-code, neighborhood, and property-specific demographics
- Different municipal operating environments
- Regionally varying competitive environments

These variables make it challenging for simple-to-state guidelines to easily apply and be executed. For example, a Comcast axiom previously mentioned was that the upgrade approach selected for an area must ensure at least a 5-yr lifespan before it would project to be augmented again. These types of principles are based on a combination of both network traffic and business modeling of executing various upgrade options.

The list above could surely be expanded upon, but it suffices to say, as the clichés go:

1) Cable solutions are rarely one-size-fits-all
2) Operators need a variety of "tools in the toolbox"
3) Evolution over Revolution

DOCSIS 4.0 is aligned to these well-worn principles.

5.1. DOCSIS 4.0 Begins with DAA

A major technology upgrade consensus "mandate" among operators is that the DOCSIS 4.0 roadmap will be based on DAA. Of course, this itself has tentacles that have been covered many times over in previous technical conferences, panels, the media, etc. There are different options within DAA. Comcast chose the Remote PHY (RPHY) path over 5 years ago, and has been successfully deploying DAA via RPHY in production scale for over 3 years. Some of this success can be attributed to moving the RPHY platform onto a virtualized CMTS core (vCMTS), decreasing interoperability permutations, and simplifying SW upgrades and changes through this centralized platform. With a node platform significantly more SW-based than its predecessors, this direction and migrating to agile development within the vCMTS was viewed as a critical step.

Since the standardization and deployments of RPHY, the Flexible MAC Architecture (FMA aka R-MACPHY) initiative at CableLabs has continued and matured. Some MSO's envision FMA as their DAA vehicle. There is a pro-con set of attributes to weigh between RPHY and FMA that is well-worn. For the topic of this paper, it is considered mostly orthogonal – DAA of one form or another must be in place for DOCSIS 4.0. RPHY vs R-MACPHY is not a significant consideration with respect to the DOCSIS 4.0 options. FDX or FDD can be implemented without any major dependencies.

5.2. Building a DOCSIS 4,0 Plan? Ask these Questions….

The debate over whether to move ahead with FDX or FDD is not likely to result in a crisp answer soon (if ever.) The reason is simple – there is no statistically meaningful data from which to make comparisons of the two, or to compare the projected results versus actual. There has been excellent DOCSIS 4.0 progress,

as we have discussed herein, but sample size and trial variety progress, not results of scale or statistical significance. FDX proof-of-concept field trials were executed in 2018 and 2019 using modified DOCSIS 3.1 devices with FDX EC designs from key technology partners. In addition, FDD field characterizations across multiple MSO networks to quantify the extended bandwidth behavior of various architectures and passive components of today's networks have also been completed.

A major milestone in 2021 shed some light on how the slideware is comparing to the reality using the first true DOCSIS 4.0 FDX RPD production SoC vehicle. Thus, the era of minimal information is coming to an end. The DOCSIS 4.0 RMD for FDD is now also in labs today. By the end of 2021, we will see DOCSIS4.0 FDX end-to-end modem registration, and in 2022 have a first look at FDX performance in the field from vCMTS to RPD to CPE. So.…we are on the verge of learning A LOT about the reality of both of these DOCSIS 4.0 options technically over the next 12-18 months.

Genuine technical capability and more confident, empirically-based extrapolations, based on real measurements, against the range of environments and conditions described will add significant insight in this time frame. However, it will be longer than 12-18 months to compare projected versus actual with respect to upgrade costs and operational challenges, since production at scale takes a few iterations to get right and production field teams take time to get ramped up, while incubation teams manage early technology introductions. Scale is a slowly ramping process where new technology and operational processes are concerned, as efficiency is a lower priority early on. And many fundamental components of construction, and upgrade costs, *are* well-understood. This includes items such as BAU node splits, DAA node splits, RF amplifier swaps, tap swaps, pulling fiber, upgrading coaxial cable, power supply augments, CMTS ports, spectrum addition, CPE installs, etc. Most MSOs have a good handle on these activities and mature budgeting around them. It is because of this that MSOs are able to form reasonable models, adding assumption figures or ranges to capture unknowns and sensitivity to unknowns of a DOCSIS 4.0 upgrade. And, like any new technology, DOCSIS 4.0 FDX and DOCSIS 4.0 FDD will bring their share of unknowns.

With this in mind, lets return to the attributes comparison of **Table 4** and try to reduce the broad implications of a single table of high-level attributes into a few succinct questions that can be used as a guide, as shown in **Table 5**. From there, we'll attempt to narrow these to what's really at the junction of Analysis Paralysis Avenue and Religious Belief Boulevard.

Table 5 - DOCSIS 4.0 Attributes Comparison - FAQs

Attribute	FDD/ESD	FDX
Strategy/Philosophy to 10G	• Based on access network BW extension upgrade, up to 1.8GHz, for existing actives and passives • Introduction of DAA to migrate to 10G, similar to previous HFC plant upgrades with a choice of diplex split configurations	• Based on access network technology upgrades to introduce new DSP (EC) into RPHY nodes and Amplifier platforms • Build on DAA production and scaling of vCMTS as the foundation for 10G
Key Questions	• What is the confidence level for efficient, quality spectrum to 1.8 GHz? • Is changing every active and passive in the plant non-regrettable capital?	• What is the confidence in broadband Echo Cancellation? • Is adding new EC to RF amplifiers too complex a device?

Attribute	FDD/ESD	FDX
Migration Factors	• 1.8 GHz DOCSIS 4.0 DAA Nodes, Amps, Taps and Passives • Allows for cascade of amplifiers • New CPE	• RPD Nodes with DOCSIS 4.0 EC function • FDX-capable amps with DSP • New CPE
Key Questions	• What are the projected new costs, cost premiums, and construction cost for FDD migration?	• What are the projected new costs, cost premiums, and construction cost for FDX migration?

Attribute	FDD/ESD	FDX
Complexity	• New tech challenges – BW and TCP extension • Use of "low power" amp extender for edge cases	• New tech challenges – EC function, CMTS scheduler, DSP-based amps • New capacity mgmt rule for IG/TG size for peak speed
Key Questions	• What are the practical limits of freq response and TCP for most of the targeted upgrade area? • Do all Taps and passives get swapped?	• What is the risk associated with the new technology of FDX? • What are the new algorithms for Capacity mgmt?

Attribute	FDD/ESD	FDX
Spectrum/Capacity	• 1536 MHz DS/656 MHz US (see **Figure 13** and **Table 1**) • Up to 15G/5G (all-DOCSIS 3.1) • DS/US: BW and Capacity per diplex selection	• 1110 MHz DS / 656 MHz US (see **Figure 2**) • Up to 11G/5G (simultaneous, all-DOCSIS 3.1) • FDX BW/speed by SW config
Key Questions	• What are the real BW efficiencies in the new US bands and DS bands for FDD?	• What are the real BW efficiency in the new overlapping US and DS bands for FDX?

Attribute	FDD/ESD	FDX
Operations	• Utilize existing common operational practices – FDD system with different possible split choices • New field tools	• New operational practices for handling of spectrum overlap and amplifier installations • New field tools
Key Questions	• What are the alignment and maintenance implications for support downstream bandwidth to 1.8 GHz?	• What are the setup and maintenance implications to supporting FDX actives and overlapping spectrum on the plant?

Attribute	FDD/ESD	FDX
Network	• N+X • Cascade reduction/trade-off based market capabilities	• N+0 (optimal) • N+X – Cascade reduction/trade-off based on market speeds
Key Questions	• What are the realistic N+x limitations for 1.8 GHz? • For different generations of plant design? • How does that translate to Capacity Q above?	• What are the realistic N+x limitation for FDX? • For what service speeds and penetration? • How does that translate to Capacity Q above?

Attribute	FDD/ESD	FDX
As-Built Migration	• Continue node split and introduce DAA node splits, leverage for HFC migration activity, introducing components of FDD over time • Migration path and timing considerations for Underground vs Aerial and MDU vs SDU cost implications	• Introduce DAA for node splits with vCMTS, leverage for HFC migration activity and platforms that enable FDX activation • Migration path and timing considerations for Underground vs Aerial and MDU vs SDU cost implications
Key Questions	• How are actives and passives upgraded over time? • How much additional cost is associated with N+x caps, new cabling, or remediating poor frequency response	• How are amplifiers upgraded to FDX? • How much additional cost is associated with Amplifier DSP or N+X caps?

Table 4 and **Table 5** cover many variables, and yet, as anyone who has engaged with field teams and network construction personnel can attest, beneath each of these are additional layers of detail owing to the aforementioned variability of architecture and plant in an MSO network. DOCSIS 4.0 implementation will at least establish an HFC demarcation at the DOCSIS 4.0 CPE device and eliminate all or most of the home coaxial network variability, which today is technically, unfortunately, part of the HFC network.

If we were to consolidate the 20,000 ft. list of **Table 5** list into what "really really" are DOCSIS 4.0 FDX and FDD decisions hinging on – what consumes the majority of the dialogue when drawing up the internal pro-con table for the mighty offsite whiteboard sessions (in a nod to the impact of Covid – this actually sounds attractive!)– it might look like **Table 6**.

Table 6 - Debate Kindling Top 3

Challenges	FDD/ESD	FDX
1	Total Composite Power limitations for 1.8 GHz	N+0 foundation implications for cost
2	As-built freq response over N+x	New technology risk
3	Upgrade and replacement of all taps and passives	FDX amp and N+x operation

6. Summary

The 10G network is perhaps the most recognizable industry-wide initiative today. Its vision has been organized around four key pillars of service – capacity/speed, latency, reliability, and security. For the access network, it is the capacity and speed objective, in particular symmetrical multi-gigabit capability that represents the most directly addressable. It is a shift from existing BAU network migration strategies, because of its dependence on physical network changes over and above node splits, and because of the massive service payoff in the form of significantly more capable HSD services.

From the first established at the Consumer Electronics Show (CES) in 2019, the details of the visions gave way to the development of the technical requirements to achieve it, which is DOCSIS 4.0. The FDX specification actually began its life as an Appendix to the DOCSIS 3.1 specification aimed at optimization capability for N+0 systems. The DOCSIS 4.0 specifications are now completed and released for both FDX and FDD. For "FDX, the Appendix," was a "lift and shift" operation into DOCSIS 4.0. The FDD specification was then completed, with the latest release that includes both (I03) publishing in December 2020.

In this paper, we tried to objectively, but (of course) through individual company lenses, articulate common and differentiating characteristics of FDD and FDX, compare the implications of the most important characteristics beyond the slideware and into real upgrade consequences, and bring to the external whiteboard some of the discussion points that have been occurring in internal and cross-MSO network brainstorming sessions. Hopefully this paper has provided a peek into these dialogues.

Lastly, while some of these activities are clearly multi-year endeavors and apt to adapt with learnings over time, there is always a need for a "North Star" target. Among most (but not all) cable operators, DOCSIS 4.0 is this North Star. There is an early fork of implementation paths, but many MSOs have assessed which trail makes sense for them at the outset of their DOCSIS 4.0 journey. Breadcrumbs recommended!

Abbreviations

A-TDMA	Advanced Time-Division Multiple Access
BAU	bits per second
CAGR	forward error correction
CES	high definition

1. Introduction

A large-scale production Distributed Access Architecture (DAA) footprint in terms of both homes connected and the number of digital nodes is being built by Comcast right now. Comcast began deploying DAA in 2018, focusing on the mature, multi-vendor Remote-PHY (RPHY) standard. The company continues to aggressively deploy DAA across all regions. A core premise of RPHY is that because it is a CableLabs standard, devices from different manufacturers of CMTS and Digital node are interoperable. Comcast has succeeded in delivering on this promise with Digital Nodes from three technology partners connected to its virtual CMTS (vCMTS) platform.

Many of today's DAA deployments are in areas with an N+0 (node plus zero amplifiers) architecture, which is sometimes referred to as "Fiber Deep." There is also an existing footprint of N+0 based on traditional analog fiber nodes. In both cases, there are no actives between the fiber node and customer homes. This creates the perfect opportunity to make A/B comparisons between the best-in-class analog HFC and DAA technology. Without RF amplifiers "watering down" any differences between the two networks, such as might exist in N+x deployments, we can attain a clear and unvarnished, side-by-side view of yesterday's and today's cable access technologies in production scale.

In this paper we will compare observations and numerical results obtained from operating these two N+0 variants. We will:

1) Describe lessons learned building both architectures, and adjustments made along the journey
2) Describe the transitional operational challenges and best practices
3) Quantify key performance metrics
    a. EOL MER (End of Line Modulation Error Ratio)
    b. Capacity
    c. Network power consumption – a critical area of focus for 1.2GHz DAA over N+0 in particular

This paper will address the journey, results, and future expectations of the industry's largest known initiative to take DAA from concept to reality..

2. Why DAA?

A Distributed Access Architecture (DAA) breaks the CMTS function into two components and distributes one part of it into the HFC network, typically the fiber node. The functionality distributed has narrowed to two DAA options. These are Remote PHY (or RPHY) and Remote MAC-PHY (known interchangeably as "RMD" for Remote MAC Device, or FMA = Flexible MAC Architecture). Figure 1 depicts the variations. Also shown is the fully Remote CCAP (R-CCAP) approach, which has faded from consideration among most cable operators due to the complexity.

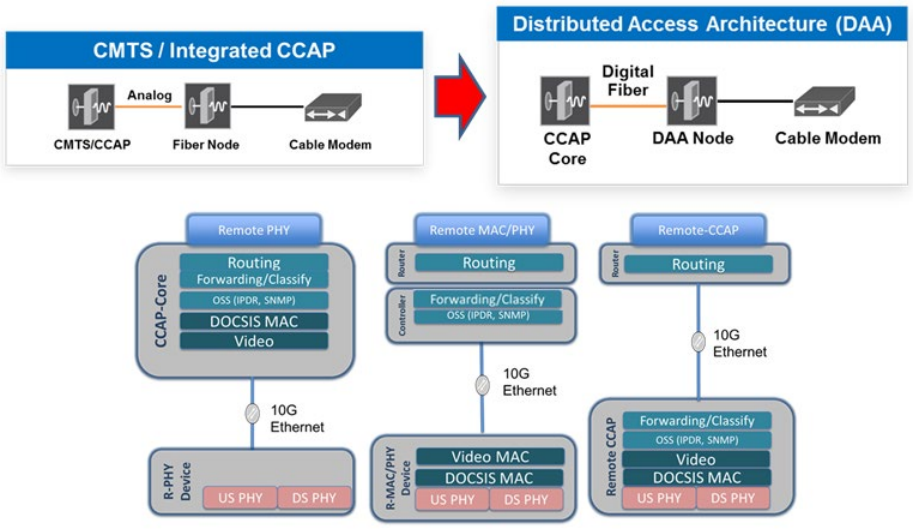

Figure 1 - Distributed Access Architecture Variants: RPHY, RMD, and R-CCAP

Remote PHY is currently the dominant deployed architecture, with tens of thousands of RPHY DAA nodes deployed in production networks in the US market alone, while only a relative handful of RMD devices have been installed. The FMA specification governing RMD interoperability got off to a later start, and this architecture takes on additional HW and SW complexity at the node. These two factors and forward-looking capacity advantages are contributing to the slower uptake of this technology. Whether this technology is brought to market in volumes will be determined over the next few years as more MSOs embrace DAA in their next generation architecture plans.

2.1. Key Benefits

Regardless of the amount of DOCSIS processing functionality distributed, DAA delivers powerful advantages associated with the standard digital Ethernet optics that are fundamental to the architecture. Until DAA came along, every node was implemented with Amplitude Modulated (AM) optics, created by, and unique to, the cable industry. Until that time, fiber optics had been based on binary digital transport only. A DAA node, fed by digital optics, offers significant network, infrastructure, and performance benefits over traditional AM-based optical links.

These chief advantages are:

1) *DWDM Wavelength Efficiency*

The use of digital optics means that there is a path to 80 DWDM wavelengths/nodes on a single fiber. Typical HFC AM optics are restricted to 16 wavelengths, depending on reach, to manage nonlinear effects that degrade MER. More than 16 are possible but they come with compromises in performance and distance. These nonlinear effects are much less significant in digital optics.

2) *Link Reach*

Using AM optics, as the link from Headend to node increases, fewer wavelengths can be used to meet a fixed end-of-line (EOL) MER requirement. HFC networks are constructed around these limitations. Digital optics eliminate this dependency for typical HFC reach requirements and enable link distances much longer than AM optics. The above aspects of reach and wavelength multiplication taken together simplify

and add significant flexibility to network architecture, promote cost savings due to the reduced fiber construction entailed, and enable the potential for consolidation of physical sites.

3) *EOL MER performance improvement*

DOCSIS 3.1 enables higher order modulation profiles, increasing the bandwidth efficiency up to 50% over DOCSIS 3.0 downstream and 67% in the upstream. Typically, EOL MER in HFC is dominated by the performance of the AM optics and degrades a little with each ensuing amplifier. In an Integrated CMTS, the fidelity requirement at the RF port feeding the optical transmitter is very high – 43 dB minimum for DOCSIS 3.0 and up to 48 dB for DOCSIS 3.1. The AM optical link then degrades the MER delivered to the node. It is a common node requirement to achieve a 38 dB minimum MER at the RF output port. This represents a significant fidelity loss of 5-10 dB. The MER degrades more as it is passed through HFC amplifiers.

Implementing DAA eliminates this AM Optical MER degradation situation completely. Instead, the CMTS fidelity requirement is met at the RPHY device (RPD) RF interface inside of the node. This increases the margin available to deliver DOCSIS 3.0 capacity, while increasing the capacity available for DOCSIS 3.1.

A similar situation exists for the upstream. Elimination of HFC upstream technology, whether an analog or digital return, occurs by placing the DOCSIS US Receiver in the node within the RPD, which recovers significant (67%) upstream MER.

4) *Space, power, cooling efficiencies in the Hubs and Headends*

Moving CMTS functionality to the node leaves less Headend components to power, cool, and consume space in a Hub site. Some of this power is distributed into the plant, which, as we shall see, quantifiably can provide a net positive return to the outside plant (OSP) due to the overall technology upgrade over the equipment it is replacing.

With respect to space, with the RF ports of the CMTS distributed, the connector density of the DOCSIS processing core can now be bounded by a higher density of optical connectors.

As traffic continues to grow, and new ports and computational power are necessary to support new demand, the incremental increase in footprint, power, and subsequent cooling needed to deliver the necessary processing power can be more granular, in particular as DAA leads to a virtualized processing core.

5) *Alignment with virtualization and convergence across last-mile access technologies*

As the HFC architecture evolves to DAA, nodes are more readily adaptable to other last mile access technologies that leverage Ethernet connectivity. Wireless, PON, and direct Ethernet services are all applicable, enabling convergence opportunity in the processing core.

Figure 2 shows the simple example of a Passive Optical Network (PON) Remote Optical Line Terminal (R-OLT) module. The concept is similar in principle to a plug-in RPD module, distributed to and backhauled from the same Ethernet-connected DAA architecture to deliver last mile residential and business services, but over an FTTH network.

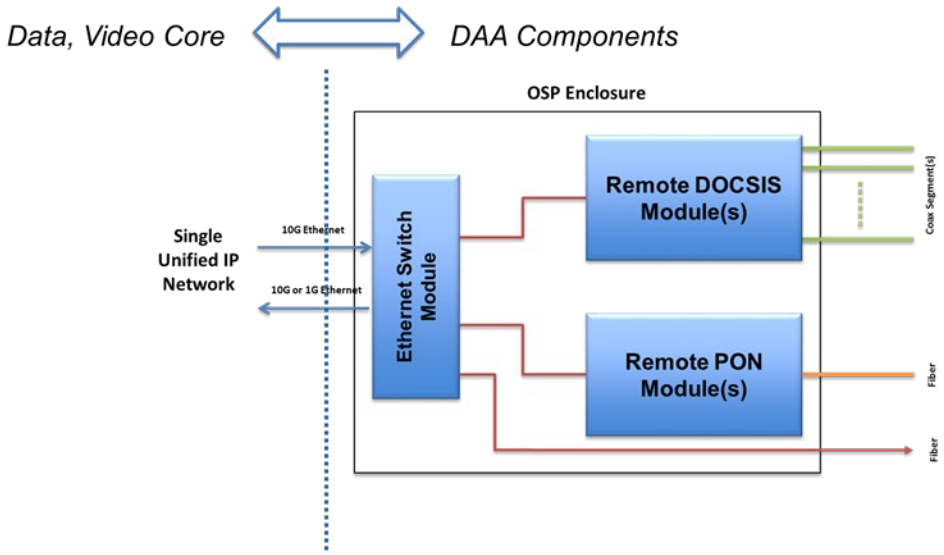

Figure 2 - DAA Enables Access-Agnostic IP Network Architecture Convergence

2.2. DAA as a Path to Virtualization

DAA can be considered the starting point of a larger shift in the HFC technology ecosystem away from purpose-built cable hardware where possible, and embracing the broader trends towards digital processing, software, and cloud-based services and applications. With the CMTS packet processing function in the headend separated from major DOCSIS-specific functions now implemented in the RPD, the CMTS can be revisited in the context of packet processing, switching, storage, and its DOCSIS scheduling role, all of which can be translated into virtualized real-time computational resources. With today's compute power, and the capability of software to deliver real-time services, a purpose-built DOCSIS machine is no longer required.

Instead, commercial off-the-shelf (COTS) servers and switches, combined with software running the required DOCSIS MULPI layer, can be used to implement the CMTS function. This leads to a simplified and more flexible virtualized CMTS platform, or vCMTS. Significant benefits can be leveraged over time through Moore's Law, delivering ever more compute power in increasingly dense physically dense footprints. Comcast introduced its first production DAA deployment hosted by a vCMTS in 2018, and since that time every DAA node has been connected to the Internet via a vCMTS, as the architecture has rapidly scaled.

Figure 3 conceptualizes DAA and its alignment to virtualization and vCMTS. As noted in the figure and pertaining to the idea of an access-agnostic last mile enabled by DAA, virtualization can apply to DOCSIS or PON / FTTH last mile, or other natural alternatives such as wireless. The virtual platform itself is not access-specific when it comes to the switching and routing of packets, simplifying the path to convergence of access technology at the packet processing layer when the access technology specific-SW is abstracted.

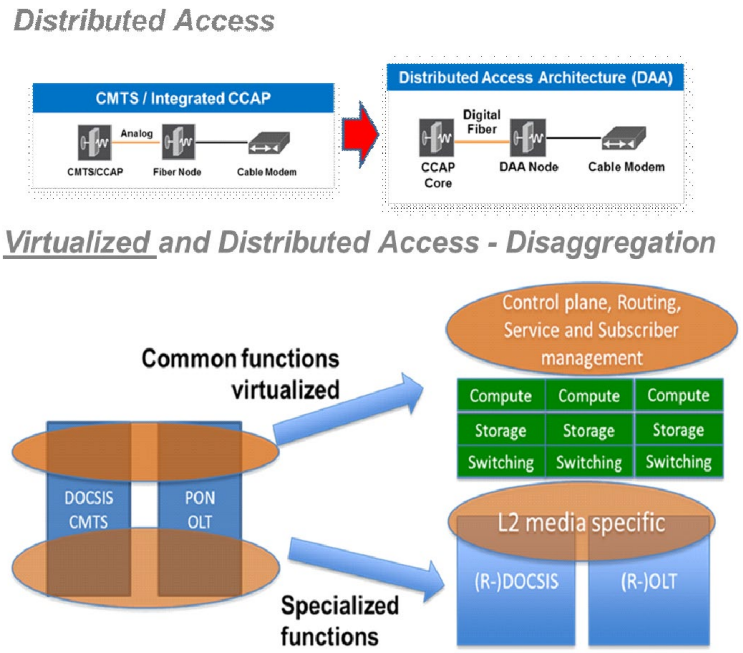

Figure 3 - DAA and Alignment to a Path Towards Virtualization and vCMTS

3. DAA-Powered Next Generation Access

3.1. Architecture Migration

Like most MSOs, Comcast is constantly assessing its access network upgrade strategy, adapting accordingly to changes in services, customer demands, traffic, and business priorities. The environment has never been more dynamic and perhaps – as the pandemic-related impacts blend into a new normal – never less certain. And, like all MSOs, while many network tasks are well-exercised muscles that are developed over years of experience, upgrades effecting the access network are generally not quick to implement nor simple tasks. Adding to the degree of difficulty is the need to make these upgrades and transitions as seamless as possible to customers.

Given that access network upgrades are multi-year initiatives, there is a need to prioritize accordingly. There is also a need to recognize that the pace of upgrades plays a role in applicable "tools in the toolbox." Considering the relatively long-term nature of an upgrade cycle, it is important there are not "starving" areas of the network left unattended until the upgrade comes along. No part of the network can afford to stand still. While it varies across the footprint, the pace of traffic growth and service demand outpaces upgrade pace, forcing repeated touches. This limitation of physical hardware and construction is also one of the drivers for introducing more software into the network through DAA and virtualization, which we will discuss shortly. Lastly, it is important that there be simplicity and repeatability in the operation to make these upgrades seamless, efficient, and delivering the benefits expected.

With the above dynamics in mind, a multi-pronged strategy was developed to make sure network upgrades are in-tune with growth and service requirements, as they vary by region, and the projected timing and scale at which the network must be upgraded to do so. **Figure 4** outlines a strategy based on these objectives.

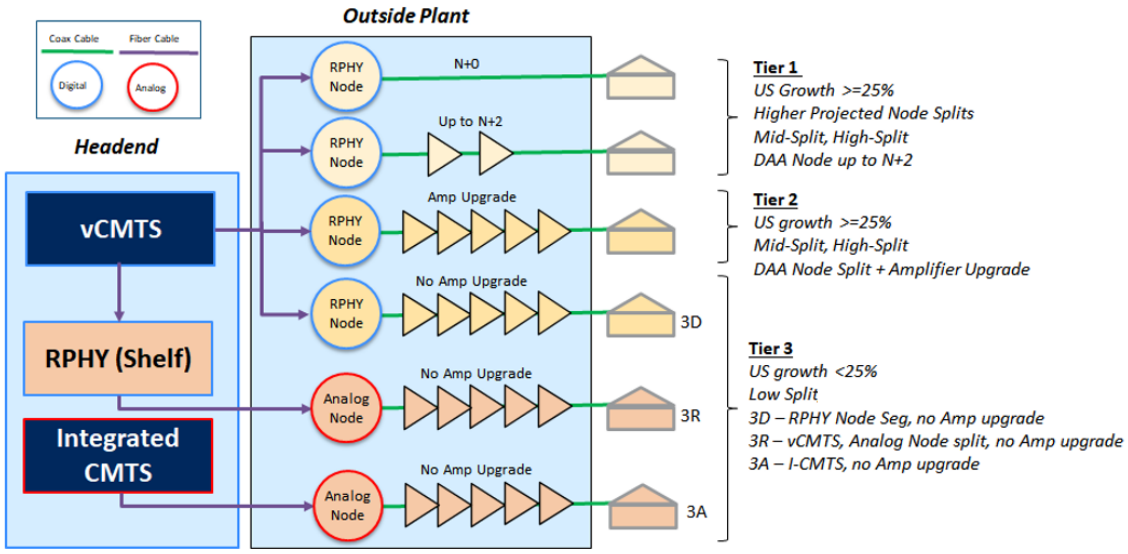

Figure 4 - Breakdown of Upgrade Approaches by Tier, Criteria, and Technology

In **Figure 4** we can observe that, across the roughly 60M homes and businesses passed by the Comcast network, the variations have been categorized into three Tiers of defined activity. Within the three Tiers, five migration options depend on various criteria and existing conditions. These are summarized as follows:

Tier 1 – The very highest HSD utilization and highest growth areas require the most aggressive change to network to stay ahead of demand – pulling new fiber deeper into the network, maximizing the downstream available bandwidth out to 1.2GHz, and decreasing the node size to a maximum allowable homes past while building more headroom into the capacity runway, deferring subsequent upgrades.

Tier 2 – High utilization in % growth, although not as high overall as the Tier 1 category. This approach defers subsequent upgrades for at least five years. For this category of network, this deferment can be accomplished with less aggressive means and can be done more quickly and more broadly by continuing to use node splits, but in doing so convert the network to vCMTS and DAA, while adding spectrum downstream and upstream via RF amplifier upgrades.

Tier 3 – Lower upstream growth and utilization than Tier 1 and Tier 2. Splitting of nodes "BAU" is sufficient to stay ahead of demand. However, while doing this work, begin introduction of key new enabling technologies of Tier 1 and Tier 2 (DAA and vCMTS) to place the foundation for a subsequent technology upgrade wave via Tier 1 or Tier 2 when necessary.

3.1. Spectrum Migration

As mentioned above, while migrating the access network to DAA, taking the opportunity to adjust the spectrum allocation is a practical and efficient way to increase long-term capacity. In addition, in order to provide higher upstream speeds and service tiers, a wider upstream path is required to deliver the instantaneous capacity necessary. With the commitment to install new equipment into the access network, it is the ideal opportunity to ensure that this equipment has a long runway of traffic capacity.

Figure 5 depicts stages or options available within the DOCSIS standards by which the upstream and downstream can be defined. It also indicates the HSD speeds available with these implementations for residential services under typical serving group sizes and capacity utilizations. Cable operators have been living in the "Low Split" (5 MHz – 42 MHz)_world for decades and have now begun moving to these higher upstream spectrum options.

While the Mid-Split architecture (upstream extended to 85 MHz) will cover an extended capacity runway for typical node sizes, its maximum speed, when carrying DOCSIS 3.0 traffic in the Low Split band, will be limited to about 300 Mbps. This increases to about 500 Mbps with an all-OFDMA upstream in the years ahead as DOCSIS 3.1 penetration continues to grow and eventually dominates the available bandwidth.

Both High Split (with an upper boundary of 204 MHz) and DOCSIS 4.0 Full Duplex (10G) provide the opportunity to offer, respectively, Gigabit and Multi-Gigabit symmetric services. Not shown below is a DOCSIS 4.0 Extended Spectrum DOCSIS (FDD) spectrum allocation, which, like FDX, can take the upstream as high as 684 MHz. However, as a Frequency Domain Duplex (FDD) architecture, it requires replacing all actives and passives in the plant, to extend the network to 1.8 GHz. That's necessary to provide sufficient downstream spectrum to offset the loss due to the added upstream allocation, plus the increased diplex crossover guardband.

By contrast, FDX uses common spectrum for both downstream and upstream to maximize efficiency in this known, mature, well-behaved RF spectrum.

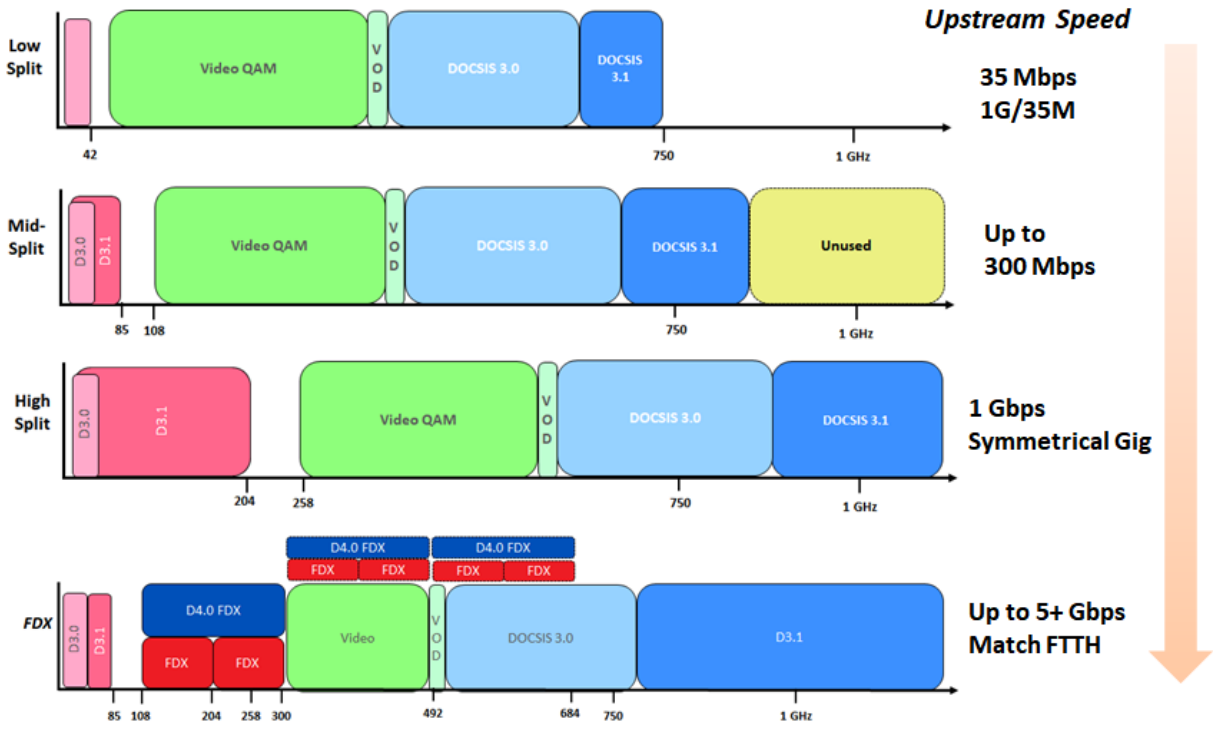

Figure 5 - Migration Options for HFC Spectrum Allocation

4. DAA Node Design Principles

4.1. Leveraging a Connected Platform

A DAA node has many of the expected essential features of an HFC node on the coaxial side of the device. It must place high fidelity RF signals onto the coax to reach the customers connected to its port, and it must receive RF upstream signals from those same customers. However, a "BAU" HFC node is a "dumb" transducer device, converting an analog optical waveform on fiber to an RF waveform on coax, and the opposite in the return path. Digital return upstream systems are a nuanced exception – they translate the RF waveform, but do so by digitizing it into a series of numbers and transmitting those numbers digitally before re-creating the waveform at the end of the optical link.

By contrast, a DAA node's RPD is a smart and IP-connected device. The DAA node design can take advantage of this connectivity. To start with, common node functions can be accommodated without the RF plug-ins that are often used in traditional HFC nodes. These plug-ins can tempt technicians, resulting in excess tweaking flexibility that can be misused without careful guidance. This is particularly the case for attenuation pads and tilt equalizers. Furthermore, local control using plug-ins results in loss of traceability, and unknown equipment settings. Instead, a DAA node can implement remote configuration of gain and tilt, enabling centralized power profile management, including outage-free spectrum enhancement and lineup changes. This provides state visibility and tracking, and can be enabled (or not) to technicians at the expertise depth of the control desired.

In the RF chain leading to and from the node ports, a DAA node that provides per node-port US attenuation can be controlled to identify a port experiencing an abnormally large ingress, minimizing triage and recovery. Moreover, if the RF launch amplifier includes an US RF switch matrix, mitigation schemes can be used to minimize the group of subscribers experiencing service reduction. For example, in a 4-port node segmented to 2 US service groups, the node port suffering ingress can be segregated to be on its own US service group while the other 3 node ports are combined to share the other US service group without interference from the ingress. This preserves the highest possible level of service for the most customers until the issue can be resolved.

In terms of inventory management, a "smart" DAA node can be designed to enable remote module inventory by reporting the model and serial numbers of every pluggable module in the node as well as other factory parameters. In addition, status monitoring of various module parameters enables tracking the component and node health.

Lastly, and perhaps the most powerful benefit of a DAA architecture and as previously described, is introducing the ability to easily alternative last-mile access technologies, such as PON, Ethernet services, or wireless. DAA can go beyond just DOCSIS-based RPHY and RMD nodes. Devices implementing an outdoor switch (aka "Switch On A Pole" or SOAP) functionality can provide OSP IP-link aggregation for other OSP devices, as well as access points for Metro Ethernet subscriber lines. A SOAP device can share the same DAA node with an RPD or be independently housed in an RF-less node housing. In both cases, the enclosure for the SOAP device should have similar traits to a "regular" DAA node.

Moreover, as MSOs deploy more FTTH PON to their customers, a Remote-OLT device housed in an OSP DAA node is becoming many MSOs' preferred approach. It provides both success-based deployment granularity, and serves as a more localized intermediate point from which to launch fiber-budget limited PON signals that may not be able to be passively delivered from the site where a typical chassis-based OLT would reside for a cable network. Similar to the Ethernet case, whether the R-OLT device shares the same DAA node with an RPD or is independently housed in an RF-less node housing, the DAA node should utilize the same key principles of resilient powering, remote monitoring, and control.

In short, the smart and connected nature of the DAA node, in particular the use of standard Ethernet optics for transport and virtualization, opens up a wealth of new architecture flexibility and operational benefits to DAA nodes that cannot be achieved in a typical HFC node.

4.2. New Powering Challenges

DAA nodes can drive an already existing N+x HFC system, be part of the more aggressive "Fiber Deep" migration that removes RF amplifiers (N+0) and extends downstream and upstream spectrum, and of course can also support anything between those two boundaries of plant state. The most challenging of these cases is the DAA node that powers the N+0 system, because these systems rely on higher RF output power to maximize reach, have the highest tilt to cover the longer length of coaxial cable that accompanies this reach, extends the downstream spectrum to 1.2 GHz, driving the Total Composite Power (TCP) higher than any previous node. It subsequently draws the most AC power to achieve these goals. Therefore, if a DAA node can support fiber deep, it will support all possible N+x variants it is likely to be deployed in with different RF configurations aligned to those architectures.

4.2.1. Node Power Design Considerations

The upgrade of a traditional N+X HFC system to a N+0 DAA requires paying even closer attention to plant powering. The DAA nodes that effectively replace (not 1:1) existing amplifiers are likely to consume significantly more power, and care should be taken not to surpass the line power supply's rating or the hardline current carrying limit. DAA nodes can implement several key features to help mitigate such issues as part of an upgrade.

In a typical older N+X system, power is passed from a line power supply to a node, and through it to multiple amplifiers. A node is rarely fed power which first passes through another node. If, as a result of bringing down a node for maintenance that power to the amplifiers is also lost, no additional subscribers are affected. However, in N+0 systems with smaller node domains, a single line power supply often feeds multiple nodes, often passing through one node to reach another. In such cases, it is very desirable to maintain uninterrupted power passing through a node even when it is undergoing maintenance (such as a module replacement), such that a service interruption due to maintenance is not extended to other node domains that are not undergoing maintenance.

Note that while the customer-facing blast radius may be similar from a numerical perspective because of the smaller number of customers per N+0 node, DAA nodes are less tolerant to short outages, due to the possibility of a reboot being triggered, than their traditional HFC node or amplifier counterparts. In addition, node outages create new software challenges in the back office for state management and recovery that could be otherwise avoided with thoughtful OSP design practices. Accordingly, it is desirable for fiber deep nodes to support power passing even while their internal modules are swapped.

4.2.2. Node Power Efficiencies

In a node's RF sections, most of the power is consumed by the output hybrid amplifiers. However, due to the insertion loss of a 4-way split as well as gain and tilt temperature compensation circuitry normally built into such an amplifier, it typically requires significant power to be allocated to drive these output hybrids. A DAA node with a smart RPD can significantly reduce this power requirement by implementing gain and tilt control in the RPD itself. Similarly, in the US, including configurable step attenuators prior to the return amplifiers enables the RPD to keeps tight control on the signal level at these amplifiers, thus reducing the dynamic range requirement for them, allowing them consume significantly less power. In an N+0 node, about 15~20 watt can be saved with such schemes, which is significant savings for a device that in the 100-140W range, depending on configuration.

Power delivery of both line power supplies and hardline cable is limited by delivered current, not delivered power. Implementing power factor correction (PFC) in the DAA node, which aims to align the phase of the AC voltage and current waveforms, reduces the quasi-square-wave current at the given power it consumes. Therefore, a DAA node implementing power factor correction enables more power to be delivered by the existing system. Moreover, by implementing power factor correction to reduce the quasi-square-wave current, additional efficiency is achieved by reducing the power loss on the hardline itself due to its loop resistance.

4.2.3. Practical Considerations and Solutions

One of the lessons learned in early DAA deployments is the importance of immunity to short power interruptions, as mentioned previously. The HFC plant is prone to split-second power interruptions, with most happening as a result of tap faceplate removals. In a traditional node such an interruption likely results in a split-second signal loss to customers, an event which is hardly noticeable. However, in a DAA node this can cause the RPD to reboot, extending the signal loss to several minutes. A solution we Comcast utilizes a capacitor-based scheme which can maintain power to the RPD for a few seconds during power interruption. Unlike battery backup, capacitor-based backup is maintenance-free and its lifespan surpasses the node's.

Another lesson learned is the need for a temporary node powering option *during* installation, burn-in and provisioning. Upgrading a traditional HFC plant to a DAA system typically involves installing a new DAA node in parallel to an active old node, burning in the new DAA node, provisioning it, and only then cutting it in instead of the old node. Often, there is not enough available power in the active system to power the DAA node on top of the existing system, and thus typically a generator is used to power the DAA node during these stages. However, it is desirable that the node be independently ready for plant power in advance, without causing interruption when moving from temporary generator power to permanent plant power. A solution we used involves a special temporary-powering power pack (PP) that is mounted in the second PP position in the node. Examples of the temporary power packs are shown in **Figure 6**.

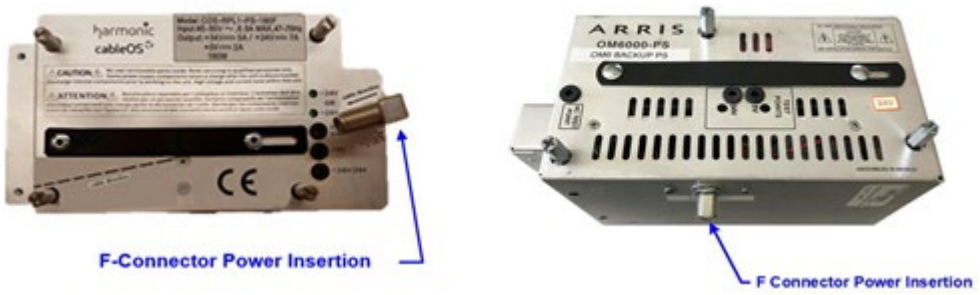

Figure 6 - Temporary Power Packs for DAA Nodes Simplify Cutover

The temporary PP drives the node's internal DC power rails as any PP, but gets its QSW power through a directly connected coax from an external generator, and not through the plant's and node's permanent power. During cutover, when the primary PP first gets its power from the plant, a node is operated briefly with redundant power (permanent and generator), and thereafter the temporary PP is removed (to be reused in the next node to be installed). **Figure 7** illustrates this temporary installation arrangement.

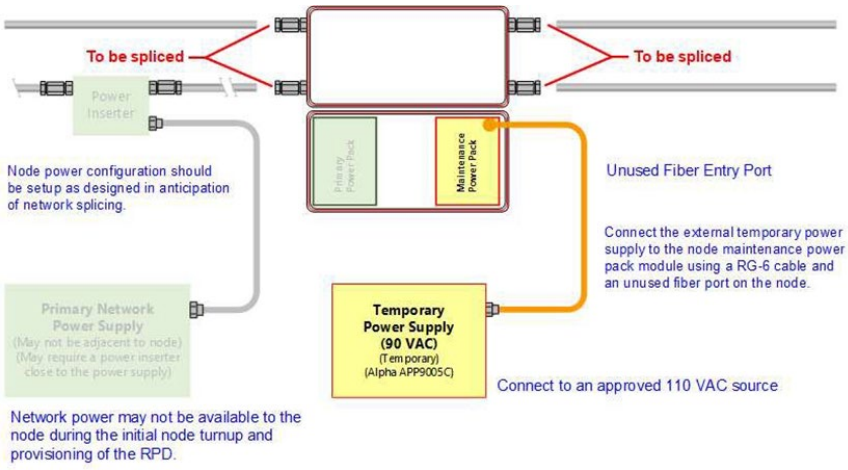

Figure 7 - Deployment Model of Maintenance Power Supply for DAA Node

5. Network Powering Implications for DAA

In a typical Comcast N+X deployment, it is common to have three power supplies providing AC to the network actives. Management of the distribution of power is provided by blocking power at strategic points to best utilize the available power. In an N+0 architecture there are three primary methods of distributing power to the nodes and other active devices (non-amplifiers) attached to the plant:

1. Centralized power using parallel feeds of 0.875" or 23-ohm power hardline cable to distribute power independently of the RF distribution.
2. Utilize power straps to connect node service areas to existing power supply locations.
3. Deploy independent, low wattage power supplies for each node service area.

There are advantages and disadvantages to each power architecture. To minimize the amount of parallel cable placement, permitting and construction activities, power straps were used to distribute power in the Comcast N+0 network. Simply put, a power strap is a power-only connection using 0.875" cable or 23-ohm power cable to route power from node area to node area. **Figure 8** is a simplified drawing of a power strap.

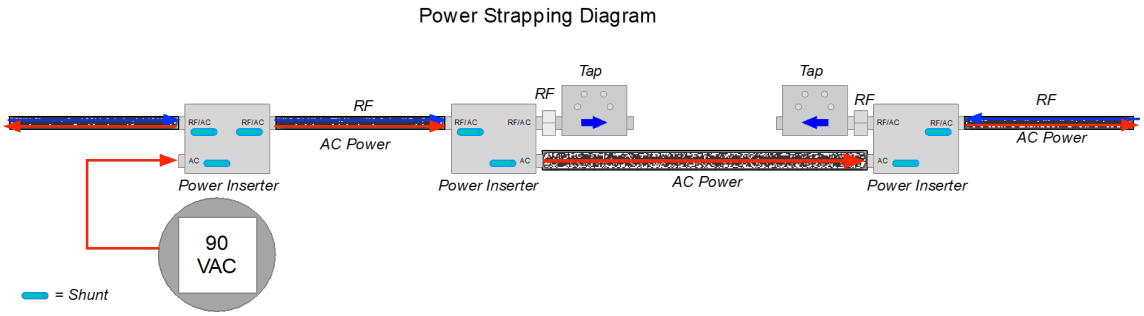

Figure 8 - Use of Power Straps in HFC Networks

Power straps provide a low-cost solution to manage power in a N+0 architecture but introduce a more complex network for maintenance teams to manage, troubleshoot and maintain. In addition to the potential for power glitches previously described, the common practices of pulling fuses or shunts to isolate plant issues now can shut down many nodes at once. Because of this, the power network design for DAA requires some additional levels of resilience to ensure a more robust experience.

5.1. Example Power Interruptions Example Power Interruptions

Typical holdup time for the AC power packs in DAA nodes extends from about 75ms to 250ms. The holdup time is defined as how long the power supply can maintain the DC voltage in the node after the input AC is interrupted. Loss of DC to the RPD initiates a reboot that can take many minutes to re-establish service to devices in the serving area. **Figure 9** is a capture of an oscilloscope displaying the impact of loss of input AC waveform and the ability of the node power supply to hold up the DC voltage.

Figure 9 - AC Interruption to Node Power Supply

Several common maintenance practices can also interrupt the AC waveform. Replacement of a tap faceplate or shorting a nut driver while tightening a seizure screw can occur during maintenance. **Figure10** illustrates examples where a tap faceplate removal or installation can impact the AC waveform enough to cause an RPD to reboot.

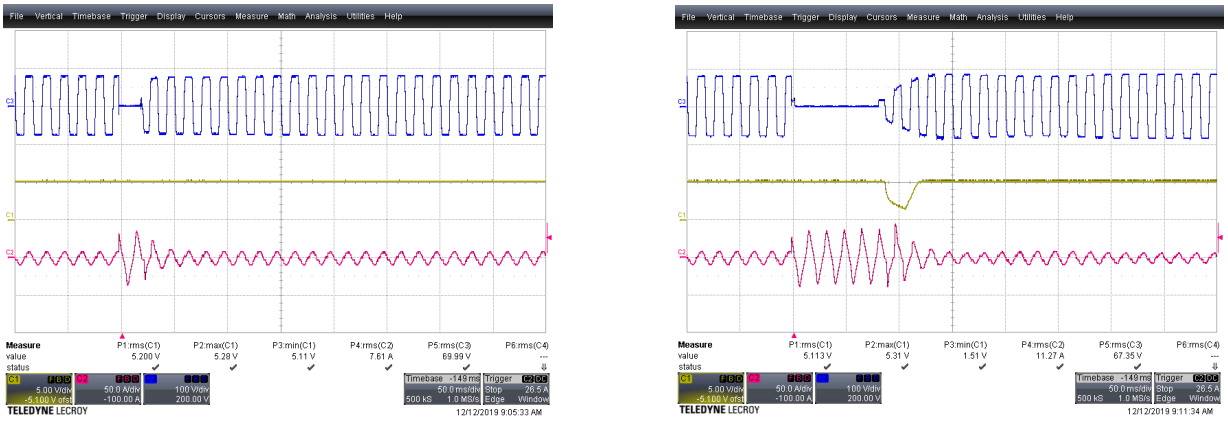

Figure 10 - AC Interruption to Node DC Power Supply Caused by Tap Plate Removal

In the example on the left, the faceplate was removed with little interruption to the AC waveform and no RPD reboot occurred. The example on the right demonstrates where a tap faceplate change took longer,

and the DC voltage was not able to be maintained to the RPD. In this case, an RPD reboot would be initiated.

AC interruptions impacted the nodes downstream of where the maintenance was being performed. Shorts, however, impact all nodes being fed from a common network power supply. **Figure 11** is an example of a technician accidentally shorting a nutdriver while tightening a seizure screw. As shown, there are several interruptions to the AC waveform eventually leading to an RPD reboot.

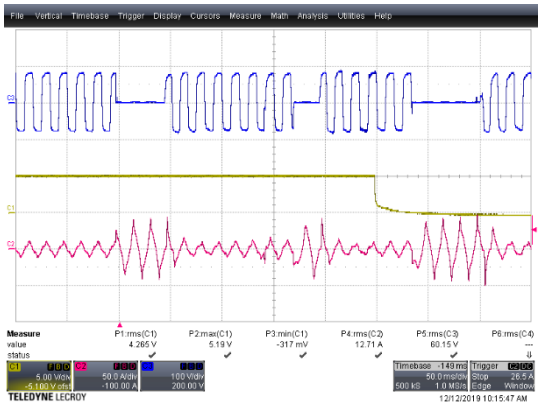

Figure 11 - AC Interruption to Node DC Power Supply Caused by Short at Seizure Screw

5.2. Design and Processes for DAA Power Resilience

To reduce the impact of normal maintenance procedures on the DAA nodes and improve the customer experience, several elements of the RPD deployments were focused on to improve the resiliency of the power network.

The impact on power from network passives and taps was reviewed. Currently available network passives are designed such that when the faceplate is removed, RF and Power continuity is interrupted. This is an undesirable characteristic in DAA deployments. Comcast is working with vendors to redesign the network passives to allow for cover removal and troubleshooting without impacting RF or Power to all ports.

In addition, taps were evaluated to measure their make-before-break characteristics. These characteristics vary by manufacturer and specific tap design. Processes were established to ensure that taps have no more than an 8 ms impact on the AC waveform when removing or installing a faceplate.

From a network powering point of view, some power supply models can be deployed with a fault-isolating dual output controller option that can limit the impact of a short. This controller allows the nodes to be split into two fault-isolated groups. When a short is detected on one leg, the device isolates that leg from the others in order to protect one group from the effects of the short. To fully utilize the feature some additional coax should be placed to maximize the coverage of the power supply.

6. DAA Production Findings

As of June 30th, Comcast has thousands of DAA RPHY nodes deployed, with the majority of these in an N+0 architecture, servicing over 1.5M homes passed across about 10k miles of plant. Beginning in 2021, DAA nodes are being deployed in traditional HFC architectures to accelerate capacity expansion and vCMTS footprint. These will number in the thousands this year and will consist of nodes with a single or two RPDs installed.

6.1. Fidelity Metrics

As noted in the overview describing the advantages of DAA, one of the key benefits is End-of-Line (EOL) MER. By eliminating the analog optical link, the MER loss that accompanies that fiber connection is eliminated. The MER generated by the RPD is essentially the same as the MER that would be delivered from a legacy I-CMTS port in a Hub site prior to traversing the AM Optical link into the field. It is therefore a high-fidelity signal placed onto the coax by the DAA node.

With the large scale of production of DAA nodes in the field there is now sufficient statistical sample size to do A:B MER comparisons among BAU HFC, N+0 with analog nodes, and DAA nodes.

Figure 12 shows distributions of Rx MERs of DOCSIS 3.1 OFDM for "BAU" HFC networks (top), analog N+0 networks, and DAA nodes (bottom).

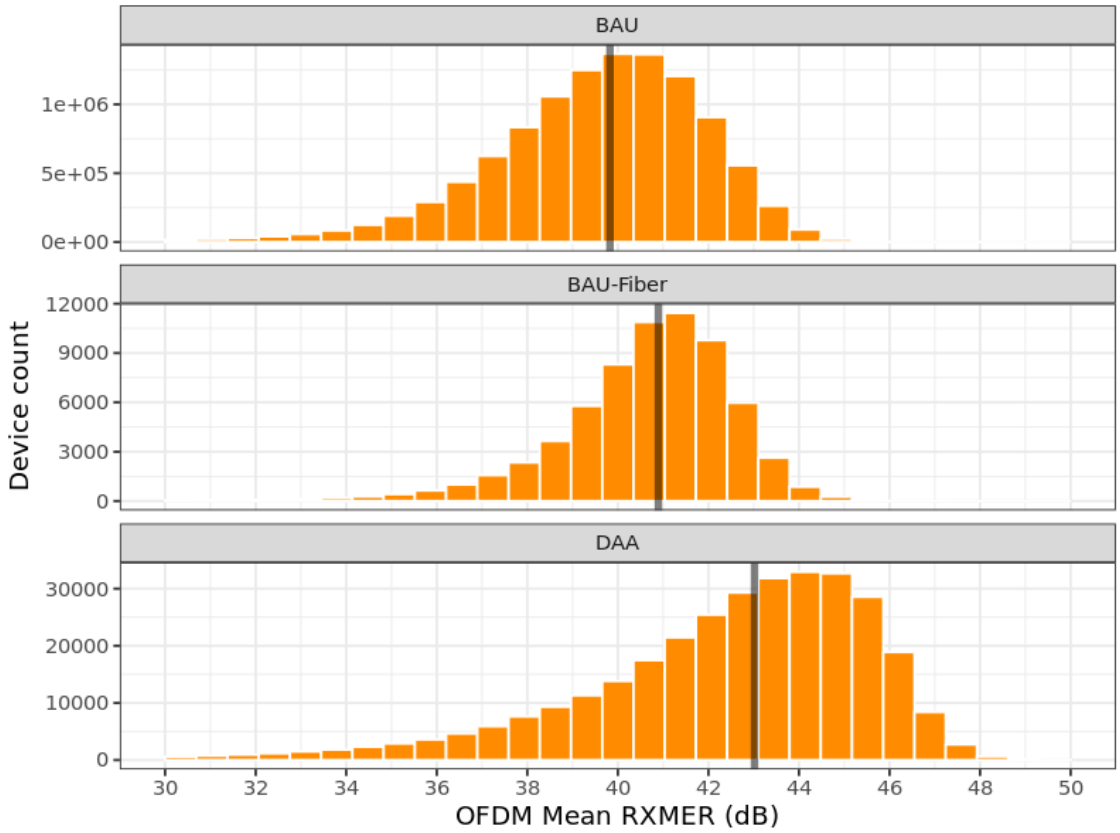

Figure 12 - Downstream Rx MER Comparison: N+x HFC, N+0 Analog, and N+0 DAA

Figure 12 trends exactly as would be expected. Analog N+0 has a better EOL MER than BAU HFC N+X MER, and DAA N+0 has a better EOL MER than Analog N+0 MER. There is a noticeable and quantifiable MER improvement in the bottom plot of **Figure 12**. The average MER increases with Analog N+0 over HFC N+X is a little over 1 dB. The MER gain from HFC N+X to DAA N+0 is over 3 dB. A 3 dB increase is equivalent to one modulation order of efficiency, such as the difference between the fidelity needed to support 512-QAM, for example, and 1024-QAM, which is a more efficient modulation in bps/Hz.

The numbers shown here are measured at the CM downstream receiver, and as such include all channel impairments up to that point, including the Noise Figure of the CM itself. The minimum DOCSIS 3.1 MER requirement for 4096-QAM is 41 dB at -6 dBmV/6 MHz. The minimum requirement for 2048-QAM is 37 dB @ -9 dBmv. Thus, these distributions would suggest that the DAA N+0 case will enable the 4096-QAM modulation profile *on average*, while for non-DAA there is a bandwidth efficiency penalty of about 9%. Whereas MER differences did not translate to anything except for performance margin in DOCSIS 3.0 systems, the use of DAA can add nearly 200 Mbps per OFDM block allocated in the downstream. With the use of multiple modulation profiles supported by the DOCSIS 3.1 Profile Management Application (PMA), this incremental new capacity is added to the network, optimizing coaxial bandwidth efficiency.

Lastly, note that the DOCSIS 3.1 downstream has MUST QAM formats up to 4096-QAM, but also offers optional profiles of 8192-QAM (8K-QAM) and 16,384-QAM (16k-QAM). The incremental capacity of increasing QAM formats is relatively modest (about 8%) for the increased MER needed to achieve them. However, with DAA, once impossible MERs are now within reach. While the full system specifications were not completed at the time of the DOCSIS 3.1 standards development for these QAM formats, based on the 4k-QAM requirements for the DOCSIS 3.1 downstream, the 8k-QAM MER requirement is likely to be in the range of 45 dB. From the distribution in **Figure 13**, a substantial number of CM MERs could reach this profile if it became available.

Now, pivoting to **Figure 13**, we see the side-by-side for the upstream, in this case only comparing BAU HFC vs DAA N+0.

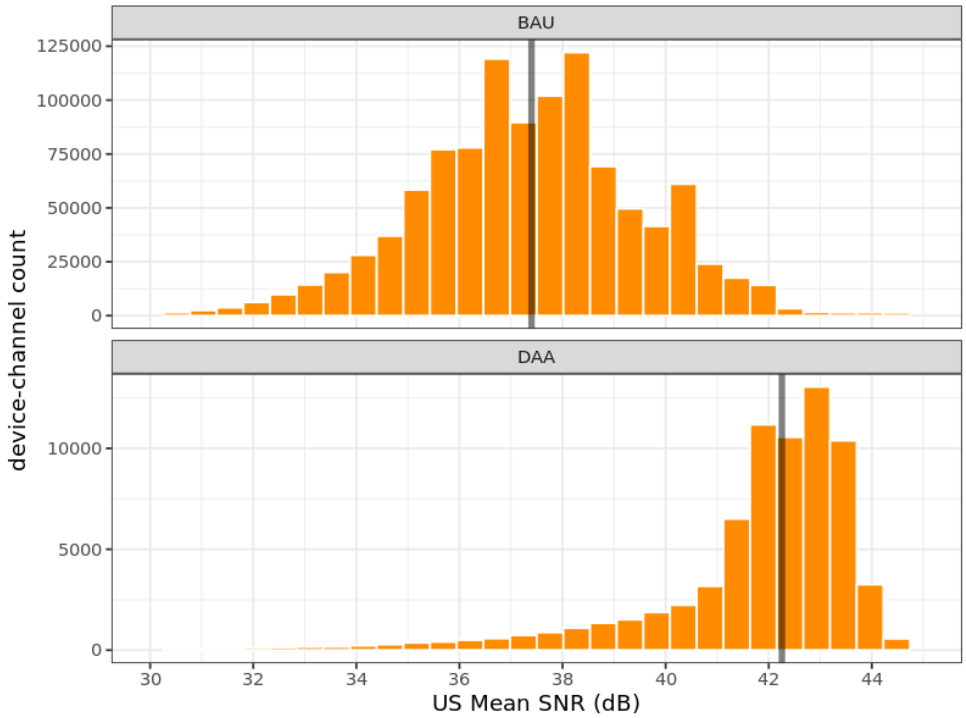

Figure 13 - Upstream Rx MER Comparison: N+x HFC (top) and N+0 DAA (bottom)

The large majority of node splits are driven by upstream capacity limitations, so we will consider the impacts of higher MER on capacity of the upstream.

The increase in bandwidth enabled by DAA in a production upstream is not determined completely by the capacity multiplier noted above for DAA and DOCSIS 3.1. There is an existing DOCSIS 3.0 traffic load in the Low Split band that will work to limit the percent capacity gain, as these carriers deliver a fixed DOCSIS 3.0 64-QAM maximum capacity regardless of network architecture. However, since we are considering Mid-Split, which delivers a long-term capacity runway, we can project that these DOCSIS 3.0 QAMs will be gradually reclaimed for DOCSIS 3.1 as those devices begin to dominate the CPE footprint, and base the analysis on the all-DOCSIS 3.1 case.

Thus, considering the use of Mid-Split supporting OFDMA, the DAA benefit of 3 dB can be used to estimate the impact on timing of a node split due to Compounded Annual Growth Rate (CAGR). For exemplary purposes, assume that the DOCSIS 3.1 upstream QAM format can be 256-QAM, where once it was 64-QAM for DOCSIS 3.0. The more powerful FEC of DOCSIS 3.1 delivers most of the additional QAM efficiency for "free" due to the extra coding gain. Improvements over time in the network RF quality that occur via node segmentation and noise funneling effects since the launch of DOCSIS 3.0 create additional dB benefits. Introducing the DAA gain to this situation, and the MER assessment above, suggest that we can improve to 512-QAM, or a 12% capacity gain.

An US CAGR of 25% is the current working assumption for business planners and capacity managers. This is a monthly growth rate of about 1.02%, and 12% capacity translates to 6-7 months. When considering the expense of tens of thousands of node splits per year, along with factoring in the time value of money, while it may be undramatic, this represents a quantifiable savings of capital by deferment to the node split budget.

In addition to capacity implications, this unavailable bandwidth must be accounted for when considering the penetration of speed tiers in a service group. As higher speeds are offered in the Upstream via Mid-Split, for example, increasing the peak burst, the remaining capacity during peak bursts must be shared by the other users in the service group. When the total available capacity is lower, there is less headroom above the peak, and this can impact the guidance for the number of users that can be added at the peak available tier. In addition, empirical data shows that when a subscriber upgrades to a higher speed tier, there is a predictable increase in their average utilization. As an example, the net result of these phenomenon, based on modeling for 300 Mbps US speeds, suggests that up to 6 users can have this speed tier in a Mid-Split system if utilization is below 60%. However, if the available payload is 9% lower, this number may be reduced to 4 or 5 users in a SG.

Furthermore, increasing US speed tiers has historically also increased utilization by freeing up latent demand. This again puts a premium on maximizing available capacity.

6.2. Customer Experience Metrics

Now consider Figure 14, which shows a common maturation trend observed when introducing the DAA platform followed by increasing production volume over the course (in this example) of a year. Statistically, the majority of customer trouble calls (TCs) are associated with issues that occur within the home, not the network. However, changes of any type on the network often results in interim jumps in TC activity. It is typical that as the DAA ecosystem components – vCMTS and RPHY Nodes – are rolled into new areas, there is an activation and support learning curve before returning to a "business-as-usual" state of health with respect to the customer experience. In some cases, this manifests itself as a temporary uptick in TC rate, which over time, as shown, returns to the mean.

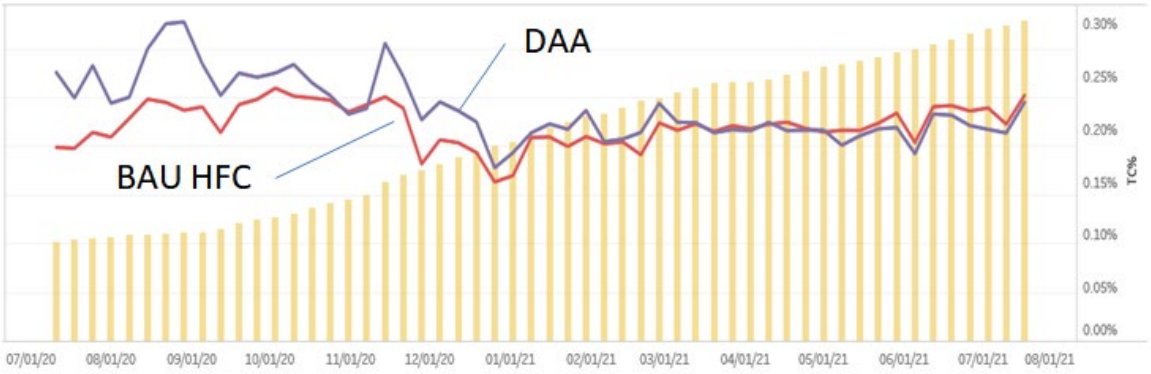

Figure 14 - Operational Metrics Proceed to Maturity as the DAA Platform Grows in Scale

As the DAA footprint continues to expand, availability and customer experience metrics are being carefully tracked and itemized so that any network-related causes are understood and addressed. Decreasing network maintenance activity and associated operational costs over time is cautiously expected, and saving targets established to quantify the costs removed from the operation. Observing network-related ticket root causes, improvements are anticipated for several reasons:

- Analog fiber links, prone to thermal variations and RF alignment sensitivity, become digital
- Large and more bug-prone monolithic SW releases of I-CMTS platforms become more incremental and agile
- The virtual implementation lends itself better to proactive measures and self-healing
- The virtual implementation lends itself better to smaller blast radii
- More robust DOCSIS 3.1 signals take over more of the spectrum allocation in both directions

We will continue to update the industry as DAA continues to scale across the enterprise, improving the network everywhere it is deployed.

6.3. Network Power Consumption Metrics

Returning to the topic of power consumption, one important original question about DAA networks, and in particular the very challenging N+0 DAA network – was what the impact would be on network power usage. RMD devices, with the added processing capability, distibuted into the node, would increase the power consumption challenge further.

A power study was devised to measure the true impact of the DAA architecture on a section of an N+0 DAA network built in Denver in 2020. Five nodes were selected which contained 18 network power supplies. The 18 power supplies contained a mix of Alpha XM2 and XM3, 15 and 18 amp, 120 and 240 VAC variants. At the input and output of each power supply, measurements taken pre- and post-construction:

- Power
- Voltage
- Current
- Power Factor

All measurements were taken with a FLUKE 345 PQ CLAMP METER.

The N+0 architecture took advantage of the high RF output levels previously discussed. Four specific drop models were developed based on a majority of residential builds. All taps include the capability to shape the RF to provide an optimized DS and US RF profile.

Table 1 depicts characteristics of the five nodes selected. The power boundaries are restricted to the node boundaries in the design effort, so power distribution was not changed from a pre and post construction point of view allowing for an apples to apples comparison.

One of the most significant items from the data in **Table 1** is the reduction in the number of actives, which is facilitated by the high RF levels utilized in the fiber deep design. This reduction creates several operational benefits in the plant, including lower mainteance, less failure points and lower power consumption.

The results of this study are shown in **Figures 15-19.** Assessing the results of the trial, there was a significant reduction in overall utility power usage in the plant. We can see a net reduction of input and output power from most of the power supplies studied and a net reduction in input and output power in every original node boundary area. This is most welcoming news. While using less power is always an excellent result, another practical point of view exemplified by this result is that it has once again been shown that over time we can accomplish much more for a fixed amount of power, as network services continue to be added. Effectively, the bits-per-second-per-kilowatt-hour (bps/kwh) continues to improve. This has led to the deployemnt, for example, of outdoor WiFi Access Points (APs) or APs supporting CBRS (Citizens Broadband Radio Service) coverage.

Additionally, while cutting the total number of actives is the cause of the most significant decrease in power usage in this study, the effect of reduced transmission power loss in the cable plant is also to be noted. When current is drawn through the coax network, power losses defined by Joule's Law ($P=I^2R$) are incurred based on current (I) and loop resistance of the network (R). As the number of actives is reduced, and the current required to run actives in the plant is also lessened, so is the total power dissapated by transmission. Reducing this dissapated power is key to overall plant efficiency because, unlike power driving nodes or other actives, the power consumed due to transmission creates no value.

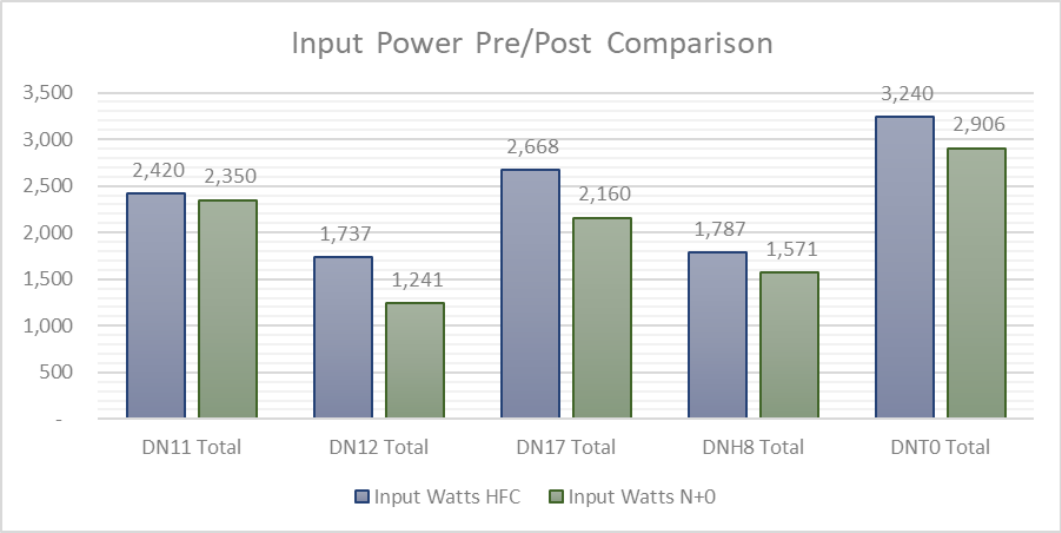

Figure 15 - Pre/Post Input Power Comparison by Original Node Boundary

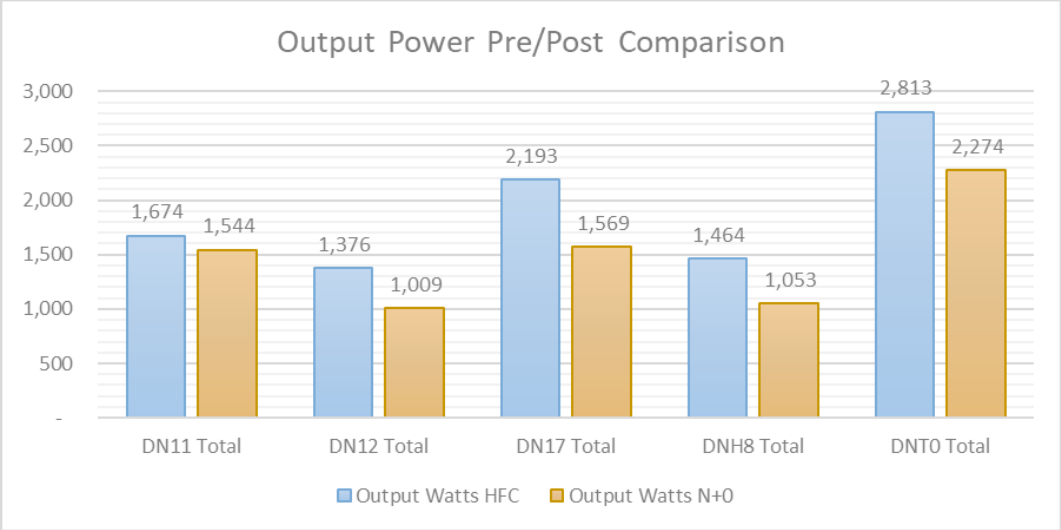

Figure 16 - Pre/Post Output Power Comparison by Original Node Boundary

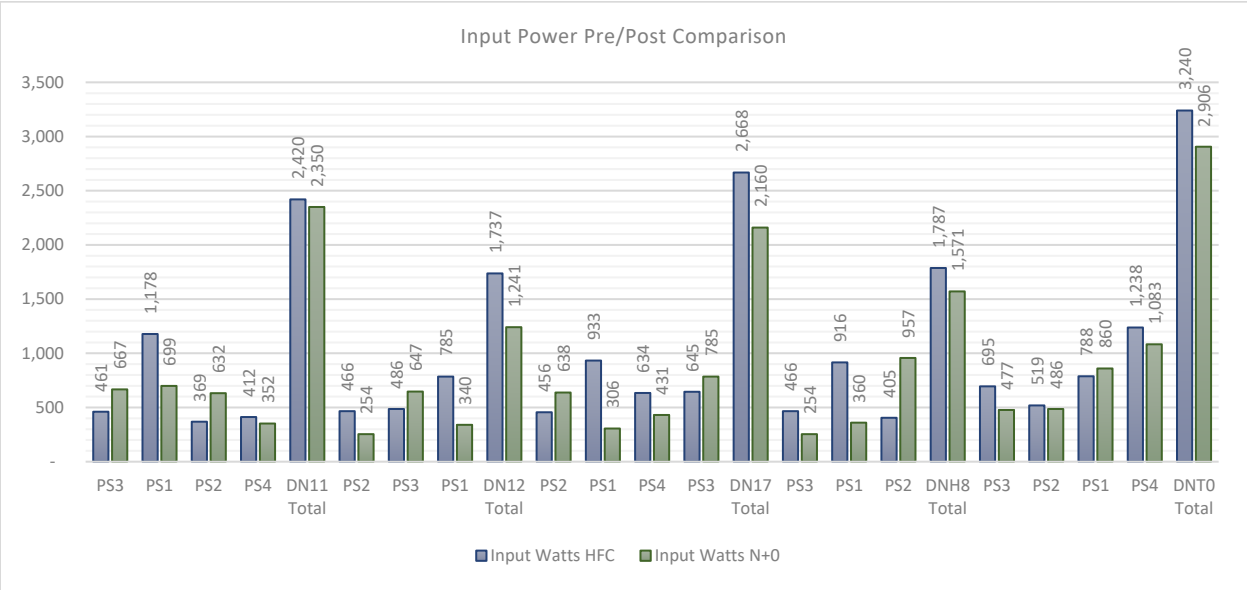

Figure 17 - Pre/Post Input Power Comparison by Power Supply

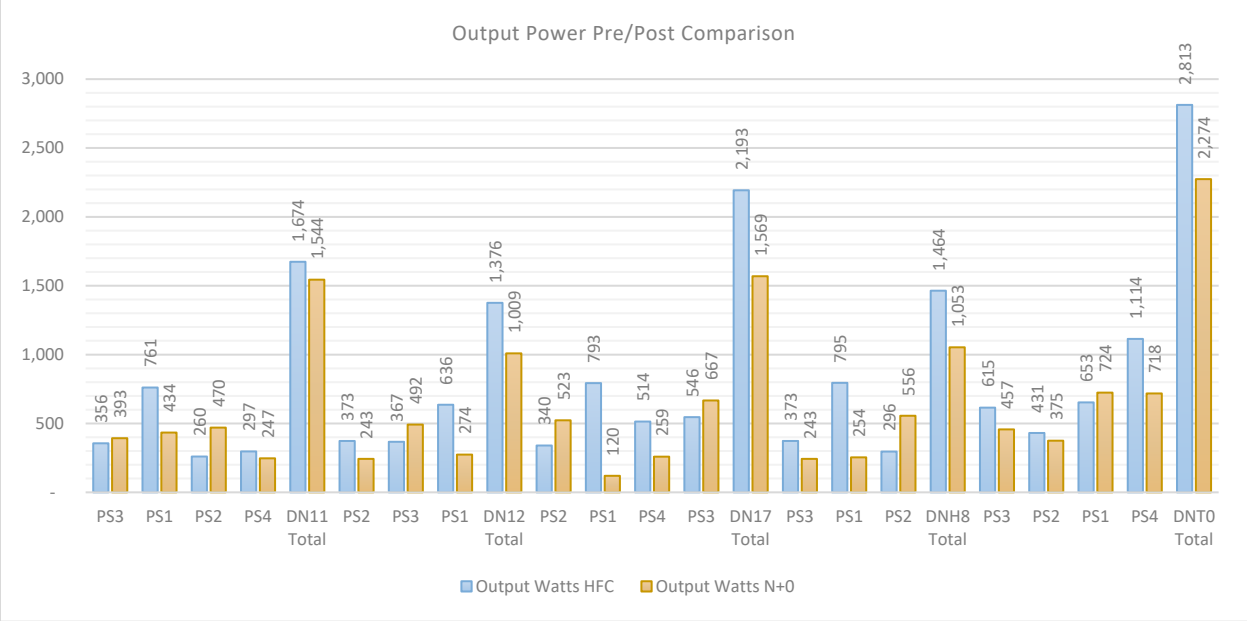

Figure 18 - Pre/Post Output Power Comparison by Power Supply

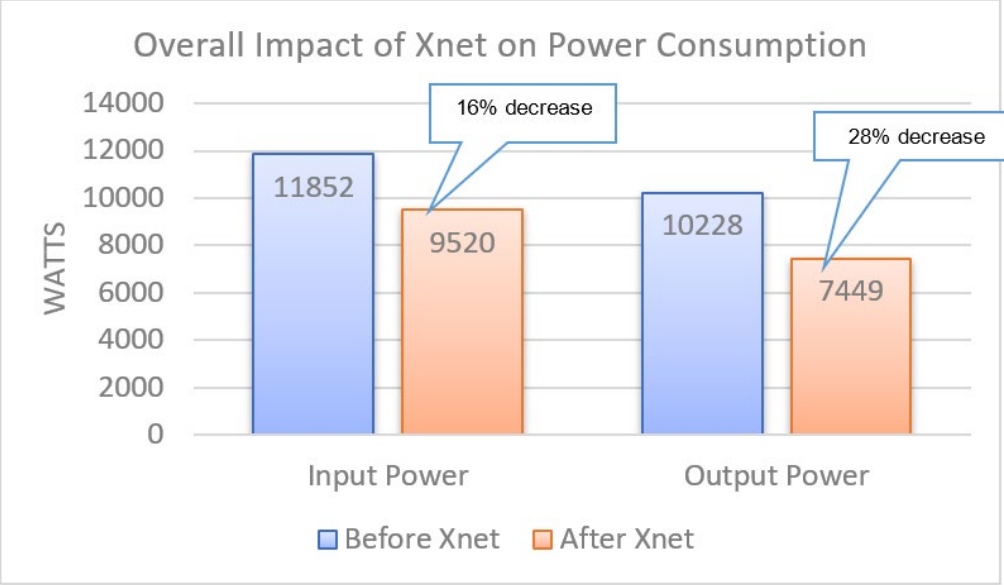

Figure 19 - Pre/Post Input Power Comparison Consolidated

An additional benefit derived from a reduction of plant actives and the resulting power savings is the positive impact on plant backup times. Using the powering data collected, and a 3-battery string of 114 Ah batteries, the sites in this study would experience an average of a 30% increase in battery backup time. This is shown in **Figure 20**. This additional runtime will reduce operational costs of additional backups to these sites during outages and decrease the risk of these outages becoming customer affecting.

Alternately, where current backup times are adequate, there may be opportunity to realize savings by either deploying a smaller, lighter, more cost-effective battery or by reducing battery string counts.

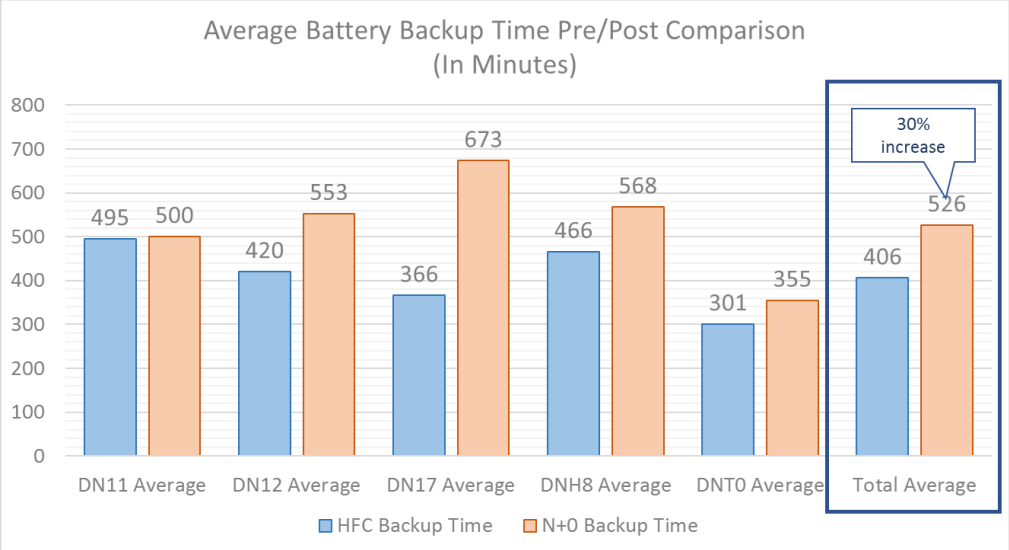

Figure 20 - Average Battery Backup Time Pre/Post Comparison

Finally, beyond the savings in network power, the reduction in network actives decreases the number of active failure points in the network. As with any system, reducing the number of potential failure points within the system, reduces the overall likelihood of system failure and, in this case, impact to customers.

7. Conclusion

Comcast began its DAA journey into the production network in mid-2018. By 2019, in every location that a Tier 1 or N+0 upgrade took place, it was done with vCMTS and DAA nodes. Remote PHY went from a CableLabs standard and PowerPoint to reality. There are now three production OEM partners producing DAA nodes in this interoperable ecosystem.

The scale of the deployment is now significant, yielding scale metrics of statistical significance, and validating projected performance improvements. We observed MER improvements that were anticipated with DAA, driving more capacity into the plant when it is combined with the more bandwidth efficient capabilities of DOCSIS 3.1. The capacity gains translate both to deferred costs of node splits, or other augmentations, that are driven by high utilization thresholds.

This added bandwidth can also translate to service speed scalability. While the added capacity technically could represent an opportunity for higher speed offerings, the difference is relatively modest for it to be a meaningful difference. For example, does it make very much difference to the customer or to the business if a service tier is 250 Mbps vs 280 Mbps (a 12% difference)? Probably not. However, the added capacity headroom will mean that more users can be added onto a higher speed tiers before a plant augmentation must occur to support the penetration – again, savings by deferring cost.

One of the initial uncertainties, and ultimately better than anticipated result, is how the introduction of DAA via RPHY nodes, as part of an N+0 upgrade, is, as it turns out, actually reducing power consumption of the serving area. This is a combination of the evolution of available technology replacing much older equipment in the field and incorporating efficient power network design as a priority from the outset. In the case of RF amplifiers that are eliminated in an N+0 build and effectively replaced by nodes, the amplifiers being replaced can be over 20 years old, and thereby relatively inefficient technology by today's standards.

Comcast is still relatively early in the DAA journey, but the engine is in 5th gear. The data from these upgrades is and will continue to be being collected and analyzed. This will drive optimizations and investment decisions going forward, such as the path to deployment of 10G and the evolution of the access network edge for alternative last mile technologies. Comcast will continue to keep the industry abreast of the observations and findings from the world's largest cable DAA network, fed by the world's most subscribed virtualized broadband platform.

Acknowledgments

A big thank you to the two Comcast technicians: Seth Williams, CommTech 5, Network Maintenance and Mike Torrez, CommTech 5, Network Maintenance. These talented gentleman collected all of the data for the power consumptions study.

Special thanks to Maher Harb and Ramya Narayanaswamy from Comcast's Next Gen Access Networks team for their support in providing dashboard readouts for the DAA production fidelity and customer experience metrics.

1. Introduction

There is no doubt that Fiber to the Premise (FTTP) is the very long-term end goal of every operator. The questions of when and how to move to FTTP within a cable brownfield is the billion-dollar question. It is widely recognized that FTTP is expected to cost more than a comparable upgrade to DOCSIS 4.0 using *Extended Spectrum DOCSIS (ESD)* – yet both will yield similar speed tiers and revenue from a residential service perspective during the 2030's and into the early 2040's.

In Australia, nbn™ (National Broadband Network) is a government-business enterprise that has recently completed the rollout of a ubiquitous broadband network. This national broadband network is leveraging copper, coax, fiber, Fixed Wireless and Satellite assets, and has used a truly technology agnostic approach to servicing 100% of the population. Like other operators in the post-COVID world, nbn is driving its broadband infrastructure efficiently to meet traffic demands and expected performance, and nbn has one of the most extensive DOCSIS 3.1 deployments in the world. Coupled with fully segmented (4x4) nodes over a fully analogue forward and return path architecture, nbn is now evaluating what the next significant investment cycle, expected in 2025/26, will entail and is asking the hard question as to whether this is the right time to overbuild FTTP to every residential home or to do another round of DOCSIS investments using Distributed Access Architectures (DAA) and DOCSIS 4.0.

This is a multi-billion-dollar question that has implications over the next two decades. nbn's investigations and analysis has concluded that the overall cost of deploying FTTP to their residential footprint would be about 5 to 6 times the cost of rolling out DOCSIS 4.0 with DAA. Figure 1 shows the FTTP journey that nbn envisions for its residential subscriber base.

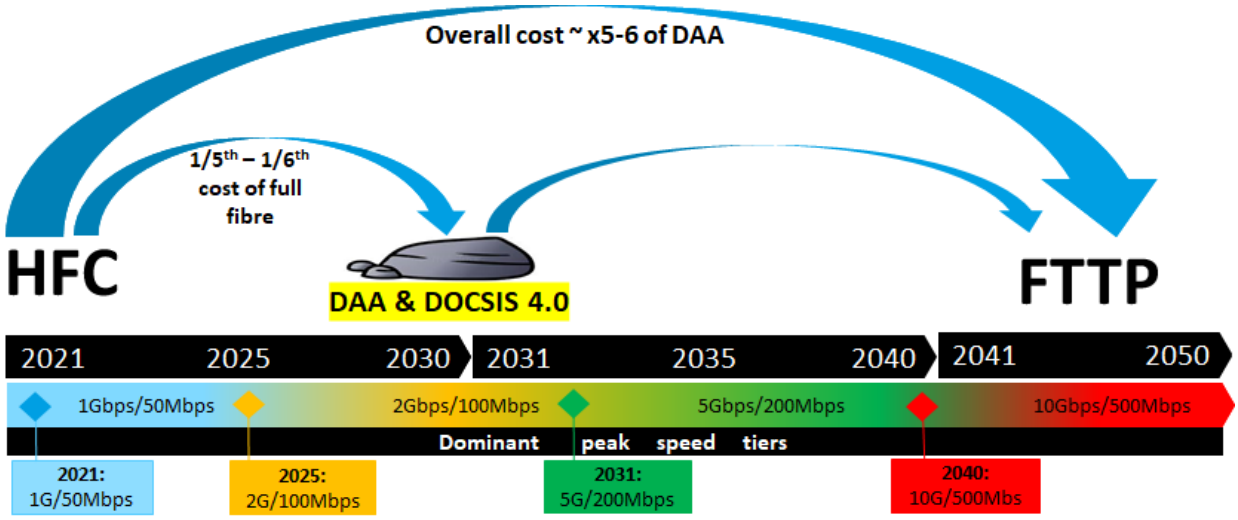

Figure 1 – The *nbn™ Residential* FTTP journey

In Australia, nbn still sees very asymmetric service tier offerings in the future serving the residential market. The main benefit that DOCSIS 4.0 brings to their table is the extended 1.8 GHz spectrum and additional downstream (DS) capacity to get through this decade and next. For other operators in highly competitive environments with fiber-based competitors, DOCSIS 4.0 enables multi-gigabit upstream (US) tiers.

For the next 5-10 years, nbn will be prioritizing major uplifts to FTTP in area's served by copper infrastructure (Fiber-to-the-Node/FTTN), namely, to address demand for higher speed services (> 50 Mbps or > 100 Mbps) which come with associated revenue uplifts and ceases further investment in copper remediation required to maintain the network. These copper areas will utilize existing Distribution Fiber Network (DFN) that nbn has already deployed to serve the DSLAM nodes, essentially extending the fiber deeper to pass all the premises served by the copper Distribution Area (DA). Fiber drops to homes will be built when customers order services of 100 Mbps or more; essentially using a demand driven approach.

Unlike copper-based services, nbn's HFC services do not suffer from the inability to reach Gigabit speeds or require intense and expensive remediation activities to maintain those speeds. For this reason, there is no major uplift in revenue expected from offloading HFC services to FTTP. When coupled with the recent large scale DOCSIS 3.1 investment and deployment, the nbn HFC network has adequate headroom in capacity to defer the next major investment cycle for several years.

There is no doubt that fully symmetric services will become an important offering for business in the near future. Fibre based 1 G and 10 G Ethernet are commonly deployed for businesses as well. However, DOCSIS-based alternatives with lower deployment costs might also have a great appeal - to business customers and operators alike.

For operators, DOCSIS 4.0 is a compelling proposition. It allows them to remain competitive, by delivering reliable high-speed residential services well into the 2030's across a wide footprint. As an interim technology, it allows operators to strategically deploy deep-fibre and FTTP where needed, while enabling the evolution of the HFC network towards N+0/N+1/N+2 DAA deployments. The reality is that most operators don't have the funds and resources to deploy FTTP to every customer in a short time frame – this is evident from the efforts of many companies who have attempted full fibre overbuilds.

This paper provides a case study of possible network evolution steps on an actual node; and then looks at the Total Cost of Ownership (TCO) for each option. This will show others the same steps that nbn went through in their decision-making process. The three approaches considered are:

- Full FTTP overbuild and offload.
- DOCSIS 4.0 Extended Spectrum DOCSIS (ESD) using DAA
- A hybrid approach - where deep-fibre DOCSIS 4.0 DAA deployments are coupled with selective/targeted FTTP offloads – to provide an optimum outcome that minimizes upfront CAPEX and maximizes the longevity of operator Investments in the DOCSIS part of network

The paper also considers network power consumption, material and truck roll costs for actives, passives, fiber and coax maintenance, as well as for the drop line maintenance and replacement, and give overview on how to make estimates for the costs over an extended period of performance.

The net present value (NPV) of the expected OPEX savings is the dollars-and-sense measuring stick against the investments required to achieve the savings - similar to calculating a payoff for a solar-powered home system without giving credit to all the environmental benefits. (Going green while collecting greens, that is.)

2. Network Evolution: Drivers and Timing

2.1. The 10G™ Initiative

The 10G Initiative within the Cable Industry is a key focal point for future vendor product developments and for future Multiple System Operator (MSO) architectural plans. At a high level, 10G defines the simple goal of providing 10 Gbps to subscribers in the future. In addition to speed increases, 10G also defines important goals of improving latency, security, and reliability within future Cable Industry service platforms. As a result, 10G will undoubtedly drive innovation on many fronts into the Cable Industry.

The upcoming arrival of DOCSIS 4.0 equipment (both Full Duplex, FDX, and Extended Spectrum DOCSIS, ESD) within the next few years will mark the next step in the quest for 10G - with a focus on providing the bandwidth via HFC plant augmentations. Since DOCSIS 4.0 equipment deployments will begin in the near future, it is imperative that we begin studying the timing and magnitude of the associated bandwidth capacity needs to ensure that the DOCSIS 4.0 equipment can support the required bandwidths.

These future capacity needs are being partially driven by subscriber demands (higher average bandwidth consumption resulting from higher resolution IP Video and larger subscriber numbers). But as we move forward towards 10G services, the biggest drivers for 10G operation will likely materialize from market challenges instead of subscriber demands. These challenges may result from competitor technologies that are capable of offering service level agreements (SLA) with bandwidths exceeding the typical maximum SLA of 1 Gbps offered by many Multiple System Operators (MSOs) today. Last-mile technologies that may be competitive to DOCSIS over the next 10-15 years include Passive Optical Networks (PON), 5G wireless/fixed wireless, and satellite services.

Satellite services are becoming more ubiquitous with more broadband-oriented, low-earth orbit satellites being launched on a regular basis. However, large latencies (due to the lengthy round-trip path) and relatively low bandwidth capacities (< 100 Mbps) would likely preclude these systems from competing with fiber and DOCSIS in a high-bandwidth marketing war of the future [SATELLITE].

5G wireless/fixed wireless can potentially offer competitive bandwidth capacities, and it has much more bandwidth capacity than satellite services. For sub-6 GHz 5G operations, capacities are expected to reach 500 Mbps. However, mmWave 5G technologies using 24-39 GHz ranges could offer 1.5 Gbps service level agreements or higher that could leap-frog the current DOCSIS 1 Gbps capacity [FORBES]. Limitations in current DOCSIS upstream capacity may be another area where fixed wireless service providers may attack.

PON is the most competitive to DOCSIS of these last-mile technologies. Several variants of PON already support 10 Gbps services. These include 10G EPON (10G x 10G), XG-PON (10G x 2.5G), XGS-PON (10G x 10G), NG-PON2 (multiple 10G lambdas), and NG-EPON (25G x 25G or 50G x 50G) [ITU]. Coherent PON services are also being studied that may eventually support even higher capacities.

Thus, 5G and PON are both technologies that could launch capacity-oriented marketing campaigns against DOCSIS in the coming years. It may prove beneficial to use forward-looking estimates of likely bandwidth capacity rollouts to predict when DOCSIS 4.0 augmentations may be required in the future.

2.2. Traffic Engineering For the Future

Previously, [CLO_2014] introduced traffic engineering and quality of experience (QoE) for broadband networks. From there, the paper went on to develop a relatively simple traffic engineering formula for

service groups that is easy to understand and useful for demonstrating basic network capacity components. It is still extremely relevant today.

The "Basic" formula shown below is a simple two-term equation. The first term (Nsub*Tavg) allocates bandwidth capacity to ensure that the aggregate average bandwidth generated by the Nsub subscribers can be adequately carried by the service group's bandwidth capacity. The first term is viewed as the "DC component" of traffic that tends to exist as a continuous flow of traffic during the peak busy period.

The "Basic" Traffic Engineering Formula (Based on Tmax_max):

$$C \geq (Nsub*Tavg) + (K*Tmax\_max) \quad (1)$$

where:

C is the required bandwidth capacity for the service group
Nsub is the total number of subscribers within the service group
Tavg is the average bandwidth consumed by a subscriber during the busy hour
K is the QoE constant (larger values of K yield higher QoE levels),
where $0 \leq K \leq$ infinity, but typically $1.0 \leq K \leq 1.2$
Tmax_max is the highest Service Tier (i.e. Tmax) offered by the MSO

There are obviously fluctuations that will occur (i.e., the "AC component" of traffic) which can force the instantaneous traffic levels to both fall below and rise above the DC traffic level. The second term (K*Tmax_max) is added to increase the probability that all subscribers, including those with the highest service tiers (i.e., Tmax values), will experience good QoE levels for most of the fluctuations that go above the DC traffic level.

The second term in the formula (K*Tmax_max) has an adjustable parameter defined by the K value. This parameter allows the MSO to increase the K value and add bandwidth capacity headroom that helps provide better QoE to their subscribers within a service group. In addition, the entire second term is scaled to be proportional to the Tmax_max value, which is the maximum Tmax value that is being offered to subscribers.

In previous papers [CLOONAN_2013, EMM_2014], found that a K value of ~1.0 would yield acceptable and adequate QoE results. [CLOONAN_2014] goes on to provide simulation results that showed a value between K=1.0 and 1.2 would provide good QoE results for a service group of 250 - 400 subscribers. Larger service groups (SGs) would need even larger values of K while very small SGs might use a K value near or less than 1.0.

2.3. Some Potential Future Service Tier Use Cases

Forward-looking predictions are always difficult to make, but we can bound these future challenges with reasonable assumptions for various cases. Figure 2 displays some downstream (DS) and upstream (US) average peak busy hour bandwidth consumption data that has been collected from the same four MSOs over a 12-year period. This data has then been corroborated with other MSOs globally. This gives us an unprecedented look into Tavg history. The DS compounded annual growth rate (CAGR) has been gradually slowing over the last half-decade. Based on this, the Tavg growth estimates are expected to be ~20% CAGR for both US + DS over the foreseeable future.

Figure 3 shows the extrapolated predictions for Tavg. DS Tavg is expected to grow from ~3 Mbps in '21 to almost 40 Mbps in 2035. US Tavg starts at 0.25 Mbps in 2021 and ends up around 3 Mbps in 15 years.

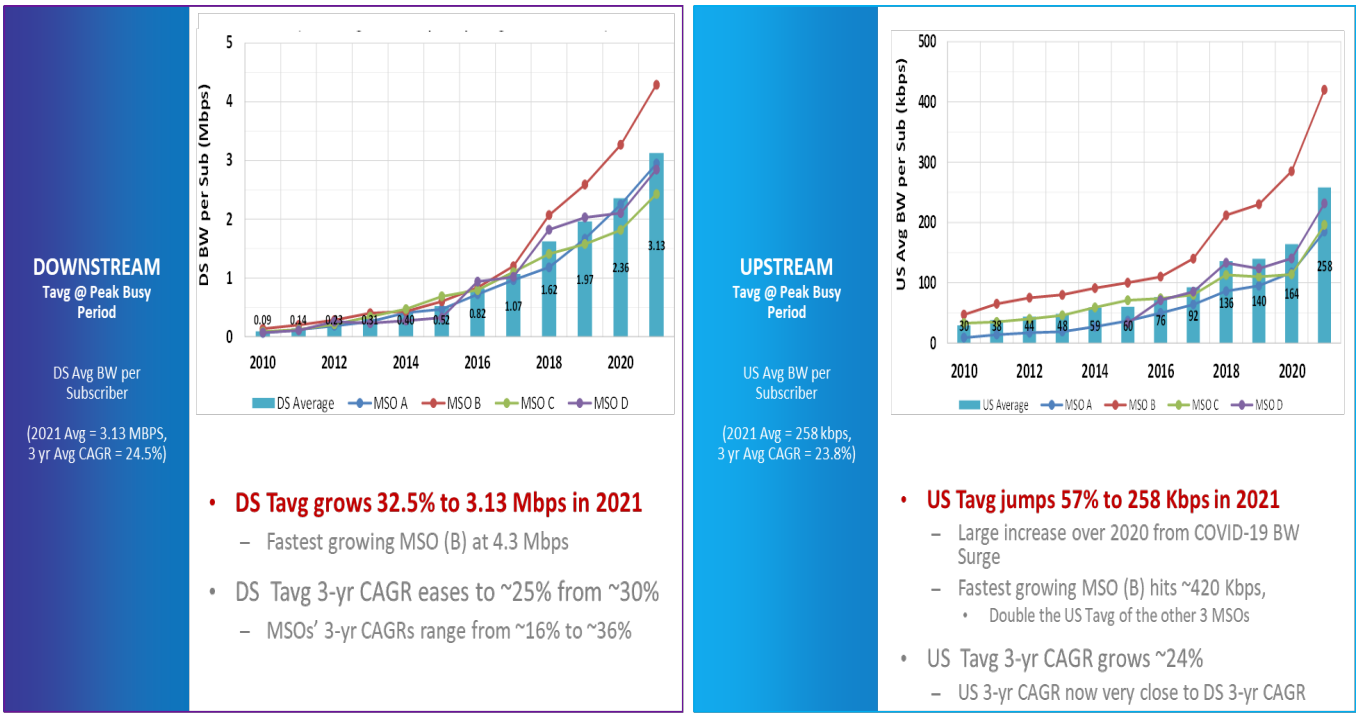

Figure 2 – Past Downstream and Upstream Average Bandwidth Usage Trends

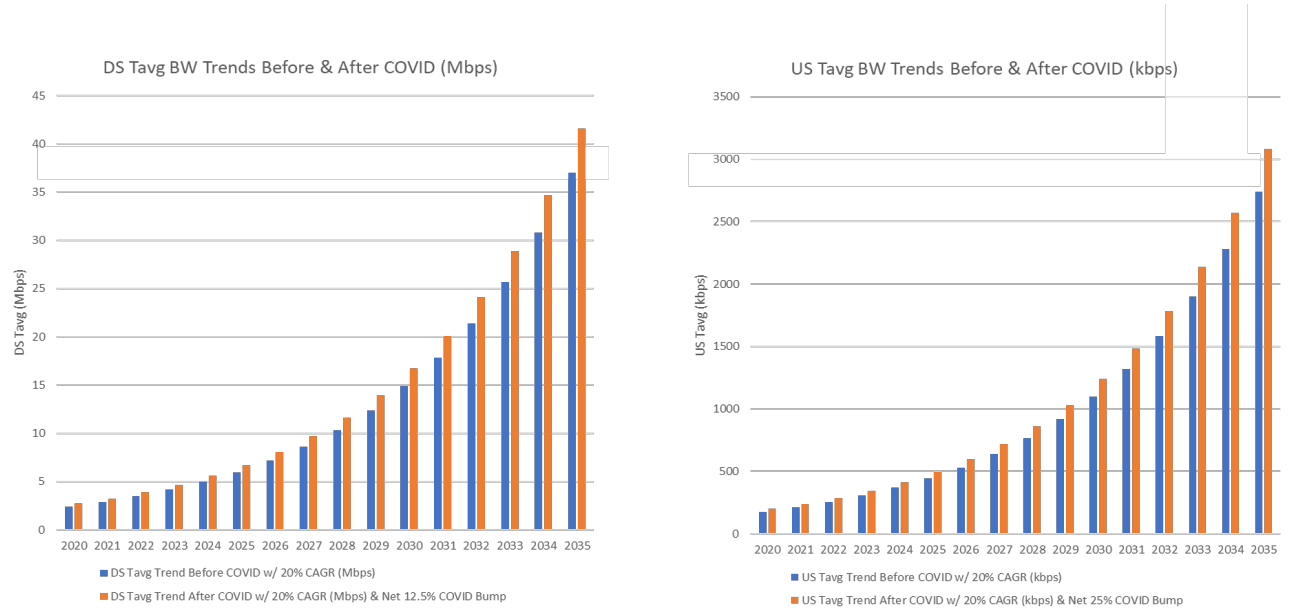

Figure 3 – Future Downstream and Upstream Average Bandwidth Usage *Predictions*

The maximum offered service tier, Tmax_max, had followed Nielsen's Law for many decades, growing at a 50% CAGR. However, this rate has significantly tailed off once Gigabit tiers were reached. The US tiers have been held artificially low due to the 42 MHz constraints. Typical DS:US tier ratios have been in the 10:1 to 25:1 range. As the US split is moved higher, the expected US tiers will jump as well. We do

not expect it to become fully 1:1 symmetric, but rather a much closer 2:1 to 4:1 ratio of DS to US. Going forward, it is estimated that Tmax_max will double roughly every five years for an effective 15% CAGR. This is shown in Figure 4.

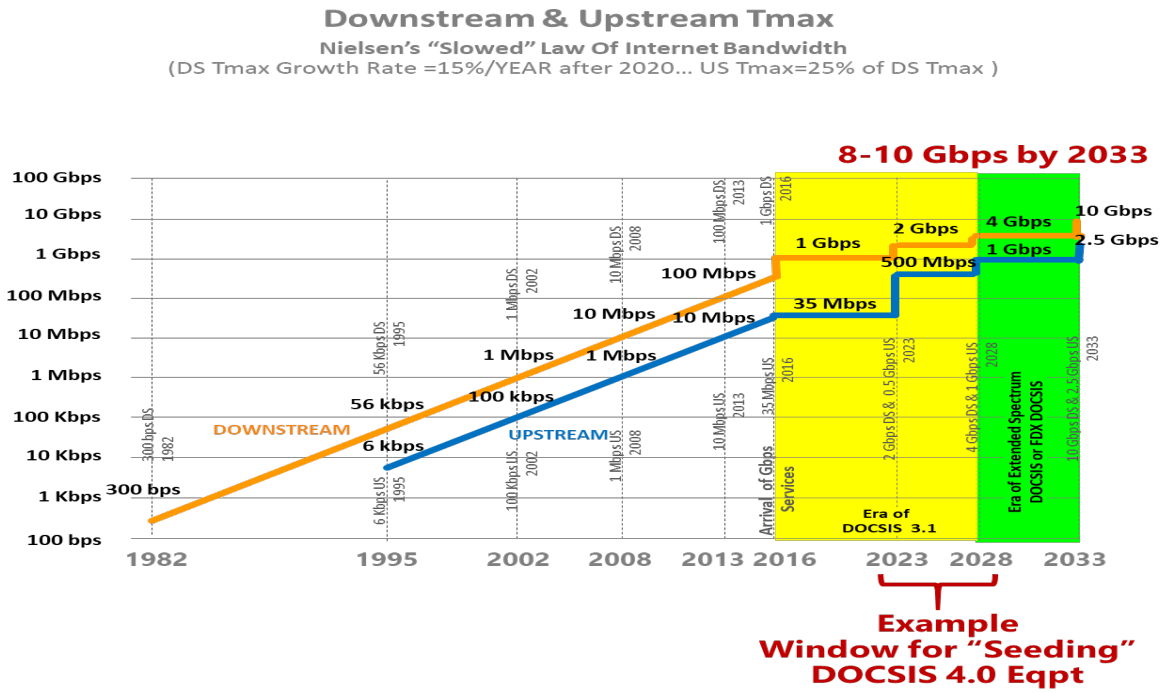

Figure 4 – Future Downstream and Upstream Maximum Service Level Agreement Trends

Previously, [ULM_2019] discussed how a 1218/204 MHz plant can support a 10G migration over the '20s decade. The 1218/204 MHz upgrade is still a strong viable option for networks needing immediate bandwidth capacity relief. However, with DOCSIS 4.0 products becoming closer to reality, some operators are wondering if they can get by with existing plants and then make a giant leap up to a 1794 MHz ESD plant. The CommScope Network Capacity Planning model that leverages the QoE-based Traffic Engineering formula helped us analyze several interesting use cases as the network migrates from 860 to 1794 MHz.

For our analysis, the timeframe is extended out 15 years, to 2035. The network starts with 300 MHz of legacy video spectrum and 30 bonded DOCSIS 3.0 SC-QAM channels. By 2033, the legacy video spectrum is removed in favor of IPTV over DOCSIS. Also, by this time, all 2.0/3.0 modems are assumed to be removed such that the network is now 100% OFDM/OFDMA channels. The model uses an effective DS OFDM bit rate of 8.8 bps/Hz and an US OFDMA bit rate of 7.7 bps/Hz.

The first two use cases shown in Figures 5 and 6 are for a CMTS Service Group (SG) with 120 subscribers (e.g., 240 HP, Homes Passed, @ 50% penetration). The next two use cases in Figures 7 and 8 assume a much smaller 60 subs per SG that an MSO might see from a fiber deep deployment.

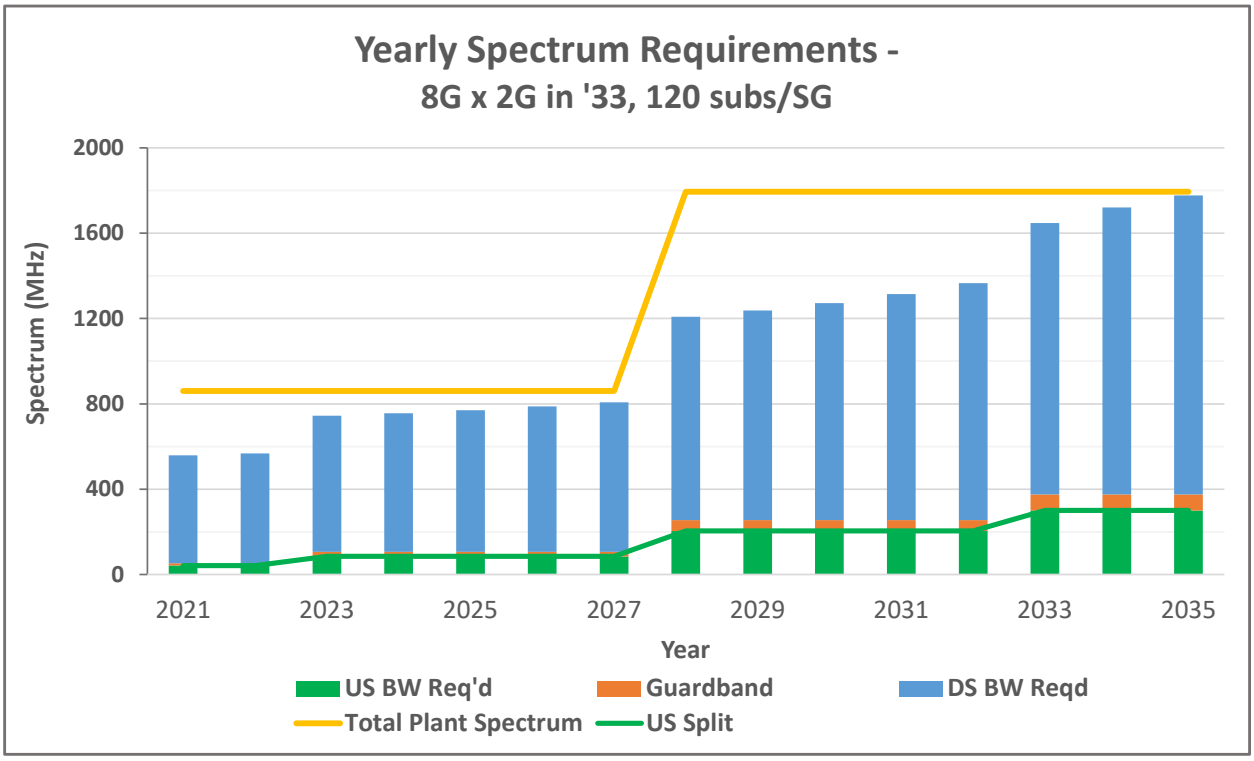

Figure 5 – 1794/300 MHz migration with 8G x 2G Service Tier, 120 subs/SG

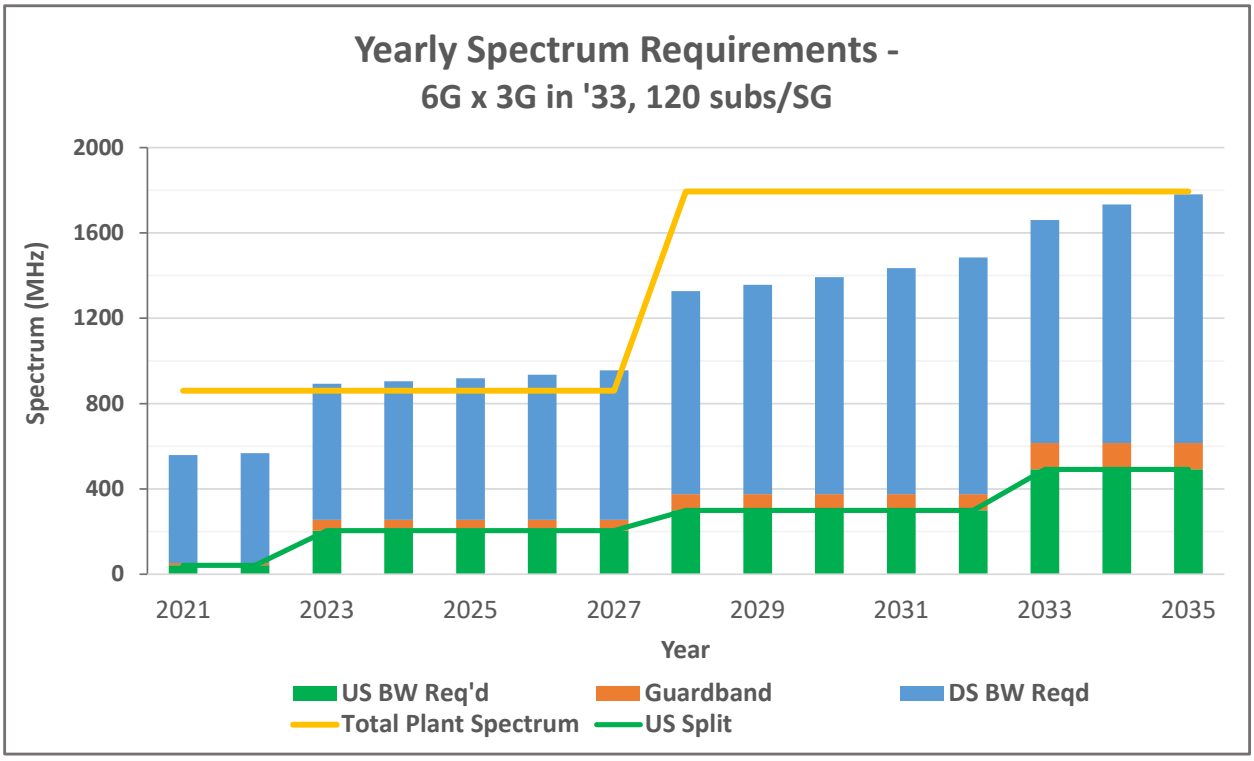

Figure 6 – 1794/492 MHz migration with 6G x 3G Service Tier, 120 subs/SG

The use case in Figure 5 assumes a 4:1 DS:US ratio with 120 subs/SG. The max service tier progresses to 2G x 500M, 4G x 1G and finally 8G x 2G. The 860/85 MHz plant can carry the operator through 2027. In 2028, the introduction of the 1G US tier forces an upgrade to 204 MHz at which time the downstream is also upgraded to 1.8 GHz. Note that a 1218 MHz plant would still be viable through the end of the decade. By 2033, the 2G US tier requires the US split to be changed to 300 MHz. Room is made for the 8G DS tier by the IPTV savings and removal of 2.0/3.0 SC-QAMs. By 2035, both the US + DS spectrum are filling up for this SG size.

Operators will need to install DOCSIS 4.0 equipment prior to enabling it, because the installation of the various components may take years. That installed equipment may be operated in a DOCSIS 3.1 mode for a while before being configured to enable DOCSIS 4.0 bandwidth capacities whenever the needs arise. Also note that some existing “1GHz” taps can actually operate at much higher frequencies. Depending on the tap type, they may not need to be replaced until the year 2033 jump in service tiers. This would give the operator a 12-year window to make the tap replacements.

The use case in Figure 6 assumes a 2:1 DS:US ratio with 120 subs/SG. The max service tier progresses to 2G x 1G, 4G x 2G and finally 6G x 3G. This use case requires a 204 MHz US split once the 1G US tier is introduced. An 860/204 MHz plant can be stretched for a couple more years by using the roll-off region above 860 MHz. Note that only the limited number of 2G subscribers might need to infrequently use that roll-off bandwidth. By 2028, the introduction of the 4G x 2G tier forces the network to upgrade to 1794/300 MHz. Later, the 3G US tier causes the US split to move to 492 MHz. This reduces available DS spectrum which is why the DS tier is limited to 6G.

The use case in Figure 7 assumes a 4:1 DS:US ratio with a fiber deep 60 subs/SG. The max service tier progresses to 2G x 500M, 4G x 1G and finally 10G x 2G. Even though the SG size is half of that in Figure 5, it does not change the date on when the 1.8 GHz upgrade is needed. That is because Tmax_max is dominating our traffic engineering formula rather than Nsub * Tavg. The SG size is hitting the point of diminishing returns for node splits as usual. The smaller SG size does buy some added capacity in the later years, enabling the operator to offer a true 10 Gbps DS service with a 1794/300 MHz plant!

The use case in Figure 8 assumes a 2:1 DS:US ratio with a fiber deep 60 subs/SG. The max service tier progresses to 2G x 1G, 4G x 2G and finally 7.5G x 3.5G. This use case is similar to Figure 6 except the smaller SG size provides enough capacity usage savings in later years to enable the higher 7.5G x 3.5G tier. Note that this is effectively what 10G PONs can offer too.

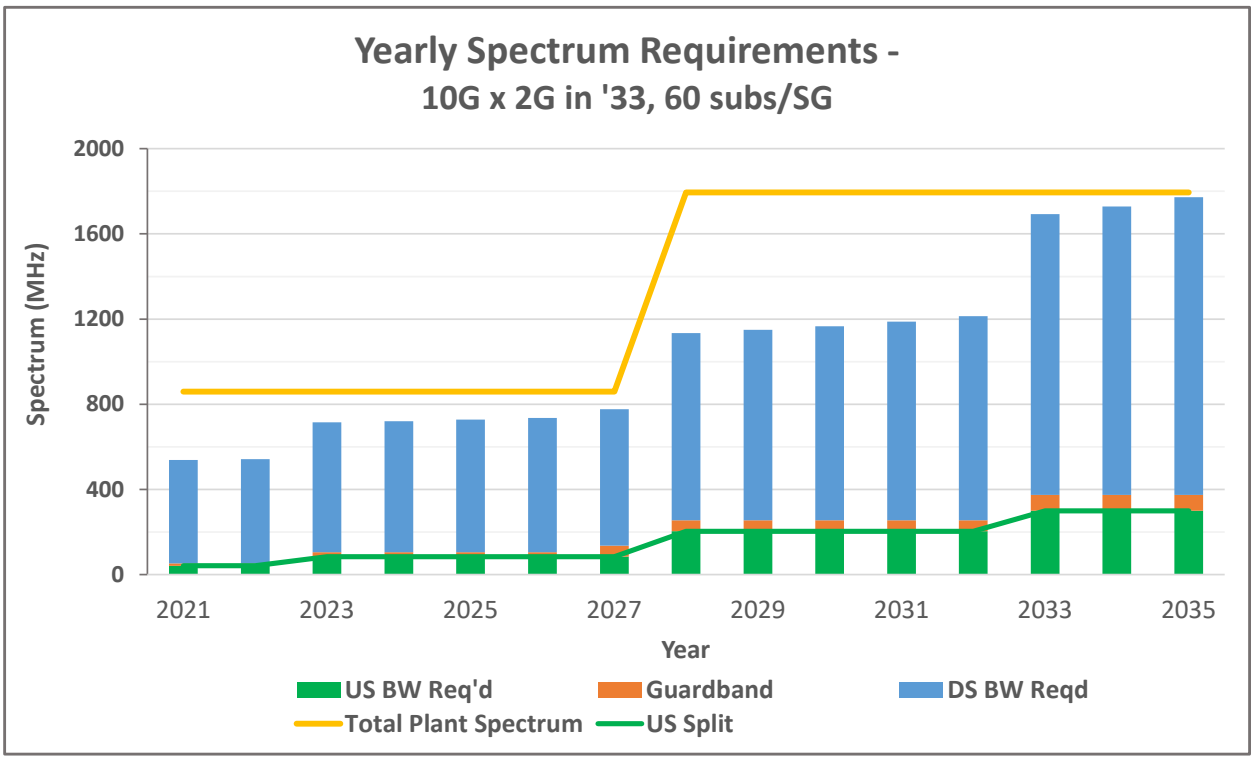

Figure 7 – 1794/300 MHz migration with 10G x 2G Service Tier, 60 subs/SG

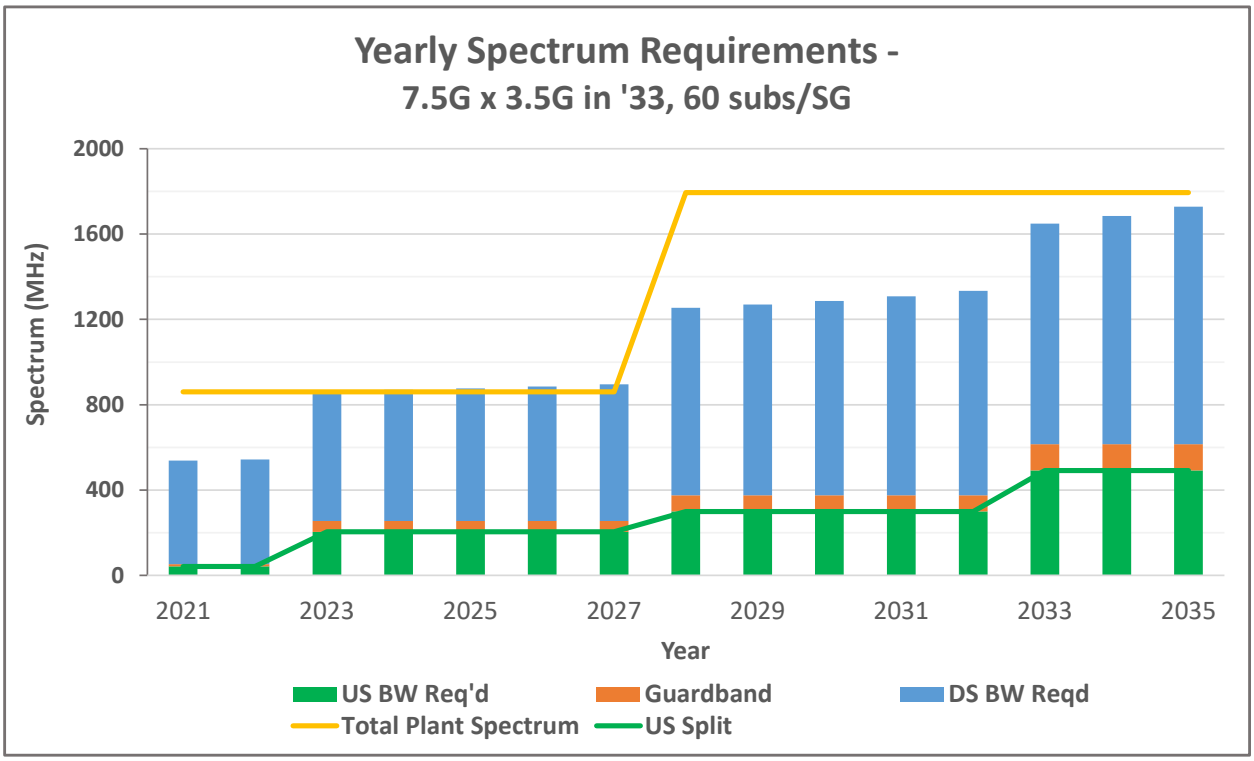

Figure 8 – 1794/492 MHz migration with 7.5G x 3.5G Service Tier, 60 subs/SG

3. Network Evolution: Various Paths Considered

In this section, we examine a sample HFC network area and look at the ways it can evolve, to keep up with subscriber capacity demand.

3.1. Baseline – an N+5 node area to start from

Figure 9 shows a single service group comprised of a single fiber-node serving 945 HP, in "N+5" topology, with 5 to 42 MHz upstream and 54 – 860 MHz downstream frequency bands. 300 MHz of DS is dedicated to legacy digital video, as in 50 SC-QAM channels of 6-MHz width. Assuming 50% subscription take rate, there would be 473 subscribers (Nsub) off this node, but in some scenarios, it could be even higher. These are very high subscriber counts for a single service group (SG), so our baseline scenario starts with 2x2 segmentation of the node into two roughly equal SG. This can be a challenge when the number of homes passed (HP) varies significantly across each RF leg of the fiber-node.

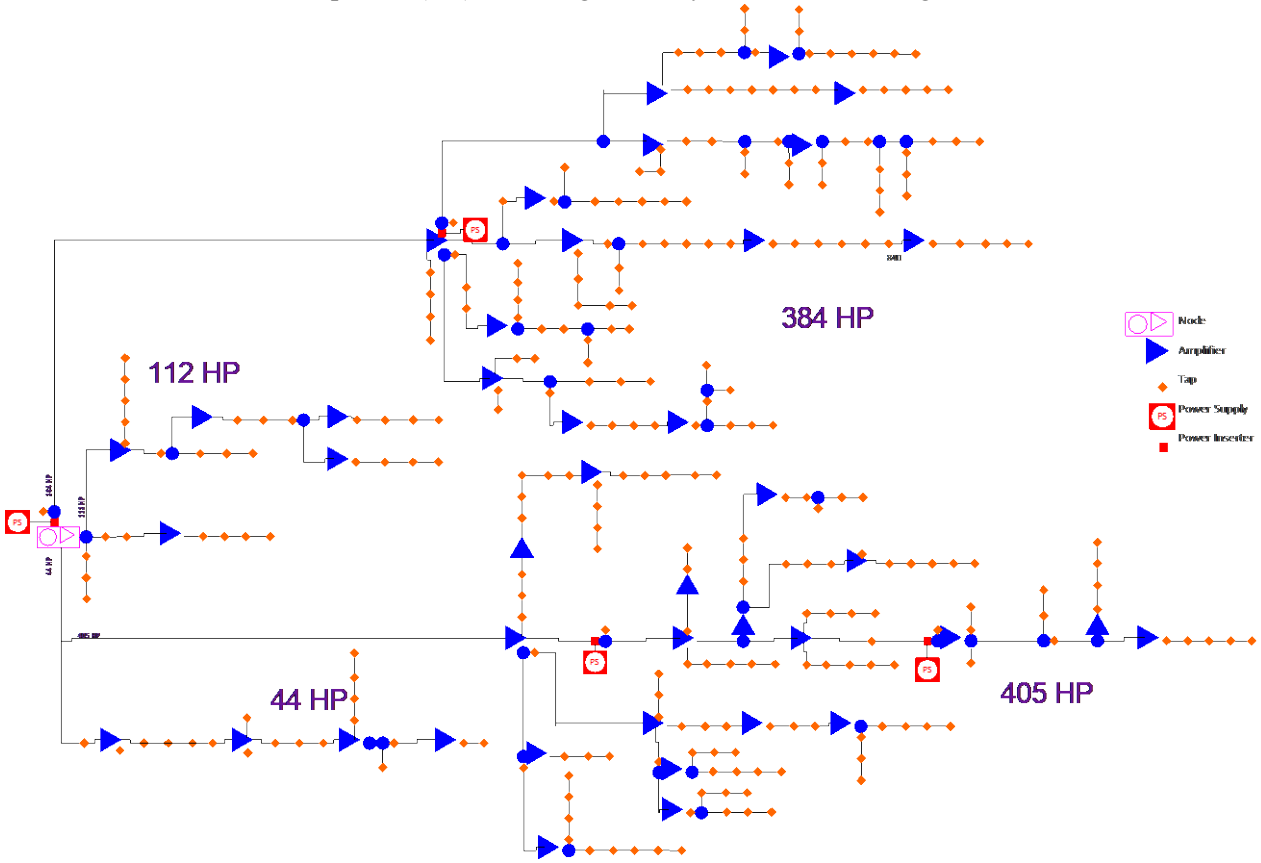

Figure 9 – HFC area under study, 945 HP, uneven distribution across node ports

Grouping node legs with 112 HP and 384 HP in one case, and 44 HP and 405 HP in another gives a balanced 496/449 HP split and is a reasonable step to make. This might mean two SG with roughly 250 subs per SG. As shown in Figure 6, a SG with 113 subs needs an 85 MHz upstream by 2023 and then jumps to a 1794/204 MHz plant by 2027. A larger SG size might push these dates even sooner.

If our example fiber-node is segmented again, going from 2 to 4 SGs, this step would not yield as much of a capacity improvement, given the unevenly distributed number of HPs on the four ports. The two larger RF legs might still have close to 200 subs/SG each, or more. Other options besides business-as-usual node splits need to be considered to meet our bandwidth needs.

3.2. Network evolution options

What upgrade options are available then? Figure 10 shows 3-dimensions to consider: US bandwidth augmentation, DS bandwidth augmentation, and how deep into the network the MAC/PHY functions are placed. There is, however, a network aspect to consider – to reduce "X" in the "N+X" topology, by stringing "fiber-deeper" into the network, and thus to reduce what was here an N+5 topology to N+2 and N+0, for example.

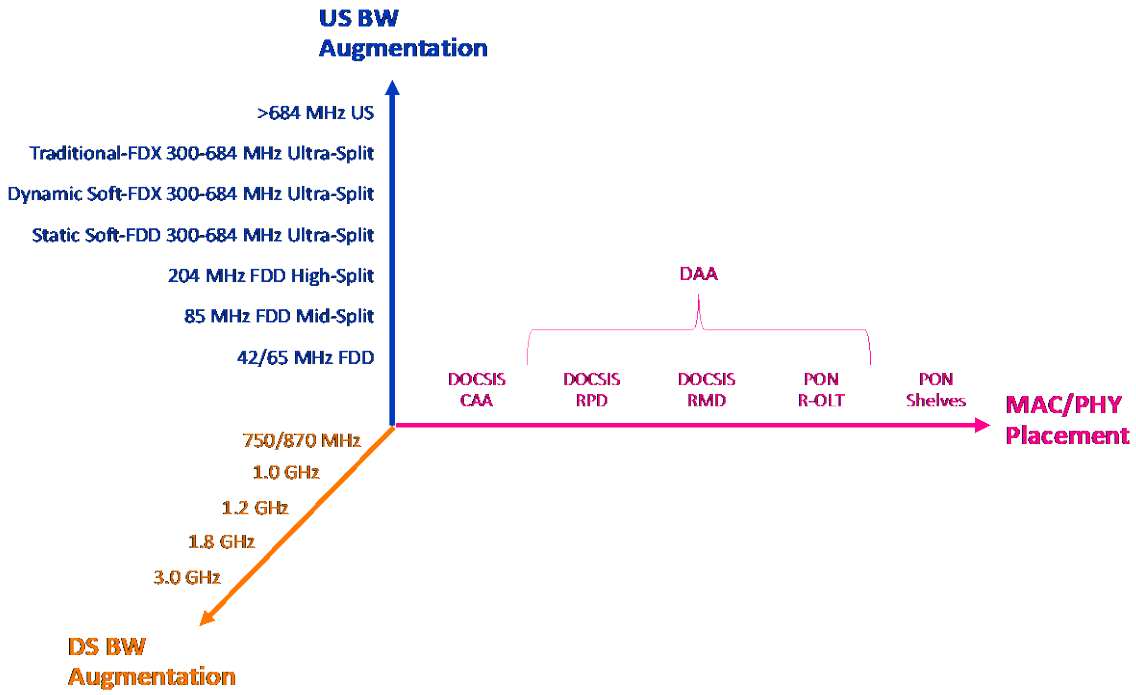

Figure 10 – Possible future evolution path directions for a typical HFC network

3.3. N+2 and N+0 upgrade options

Figures 11 and 12 show how the above baseline fiber-node area under study might evolve to get to an 8-node N+2 or a 15-node N+0 topology, respectively. Lots of changes happen with this topological progression. Table 1 lists the key ones and helps us comprehend the trade-offs involved. As fiber goes deeper, and the RF cascade gets shorter, from N+5, to N+2 and N+0, the number of nodes goes up, from 1 to 8 to 15, and the number or RF amps goes down from 42 to 34 to 0, respectively.

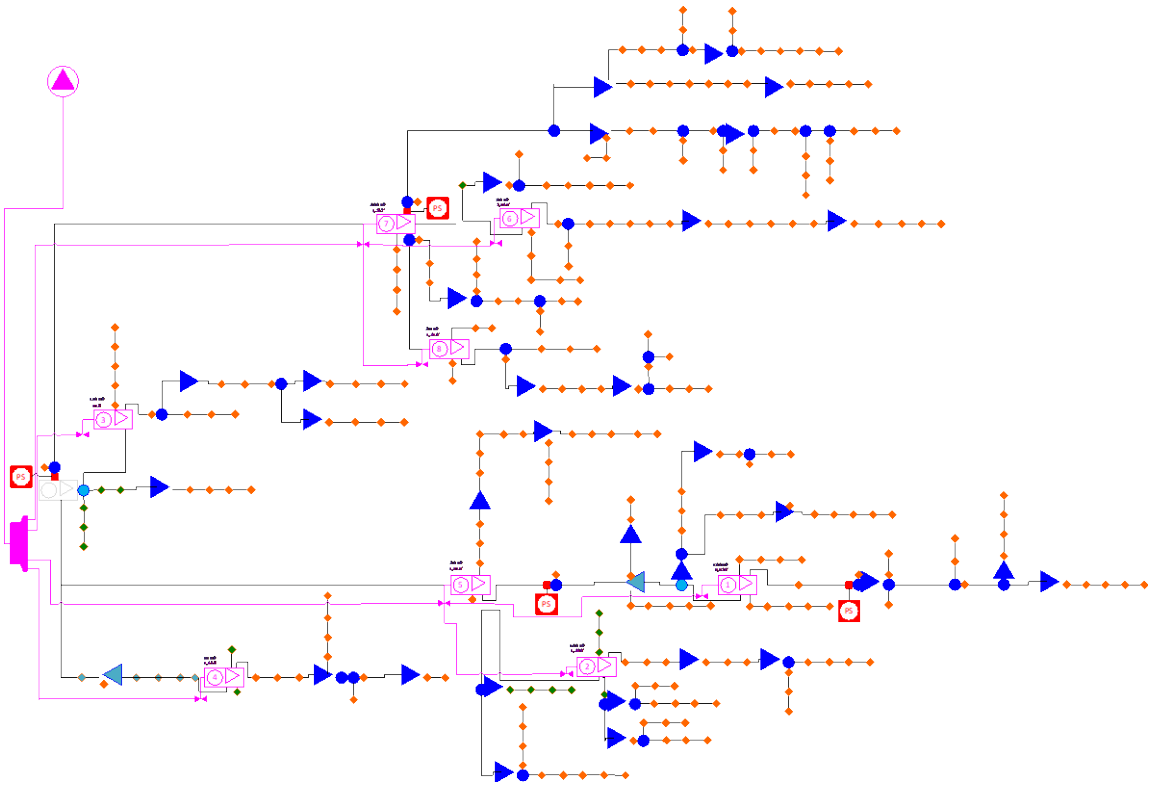

Figure 11 – Single node area under study converted from N+5 to N+2 topology

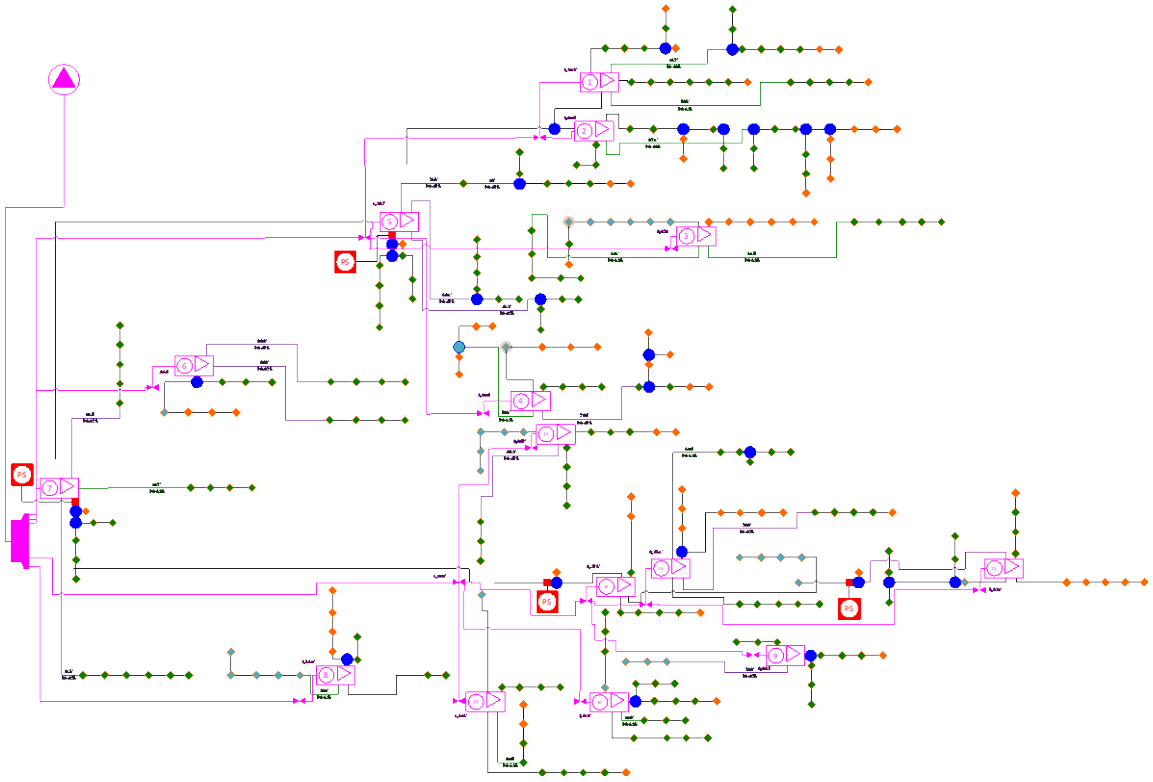

Figure 12 – Single node area converted from N+5 to N+0 “fiber-deep” topology

Repositioning of actives also causes changes to the taps: 34 out of 286 need a new faceplate for N+2 while as many as 208 out of 286 taps need the same for N+0. A 1.9 miles portion of the hardline coax needs fiber overlash for N+2, and as many of 6.5 miles of new coax/fiber for N+0. As a result, the distance from the furthest subscriber to the nearest fiber point/node reduces from 7,000 to 2,500 and 1,600 feet away, for N+5, N+2 and N+0 respectively.

Table 1 – How HFC network attribute change with upgrading N+5 area to N+2 and N+0

Topology:	N+5	N+2	N+0
Number of Standard **Nodes**	**1**	**8**	**15**
Number of RF amps	42	34	0
Number of tap faceplate changes out of # of taps	0/ 286	15/ 286	208/ 286
New plant; miles/ %	0	1.9 miles/ 19%	6.5 miles/ 67%
Fiber to the last subscriber	<7,000 ft	<2,500 ft	<1,600 ft

Note, this is an important point to consider for a future FTTP evolution. Installing new fiber is beneficial, in the sense that it gets the operator closer to the goal of getting fiber all the way to the customer premise. Figure 13 shows what percentage of the hardline plant gets over-lashed with fiber for various N+X scenarios: N+5, N+2, N+1, N+0, fiber to the last active (FTTLA) and fiber to the tap (FTTT), with some of these explained in detail in reference [Venk_SCTE_2016]

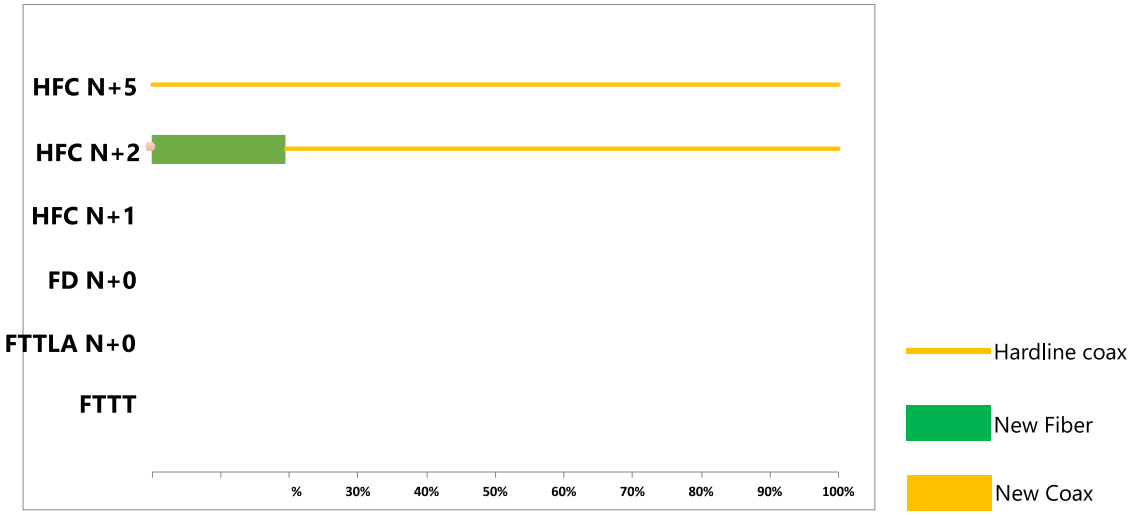

Figure 13 – Percentage of New Fiber + Coax required for various Upgrade Options

However, installing new fiber can be a costly proposition. This is especially true when dealing with underground plant that does not have any preinstalled conduits and thus where substantial digging and trenching is required. How does this cost compare to making improvements along the three dimensions shown in Figure 10? That is what the next section considers.

4. Network Evolution: Total Cost of Ownership Compared

To make sense of the myriad of tradeoffs involved, we present a simplified "total cost of ownership" (TCO) model for various upgrade options. Figure 14 shows an overview of the access network elements accounted for in this cost exercise, as well as a starting point from which to migrate this 5-42 MHz upstream, 54-860 MHz downstream, I-CCAP network. Furthermore, the taps in the network are assumed to need a faceplate upgrade for 1.2 GHz and a complete tap upgrade for 1.8 GHz.

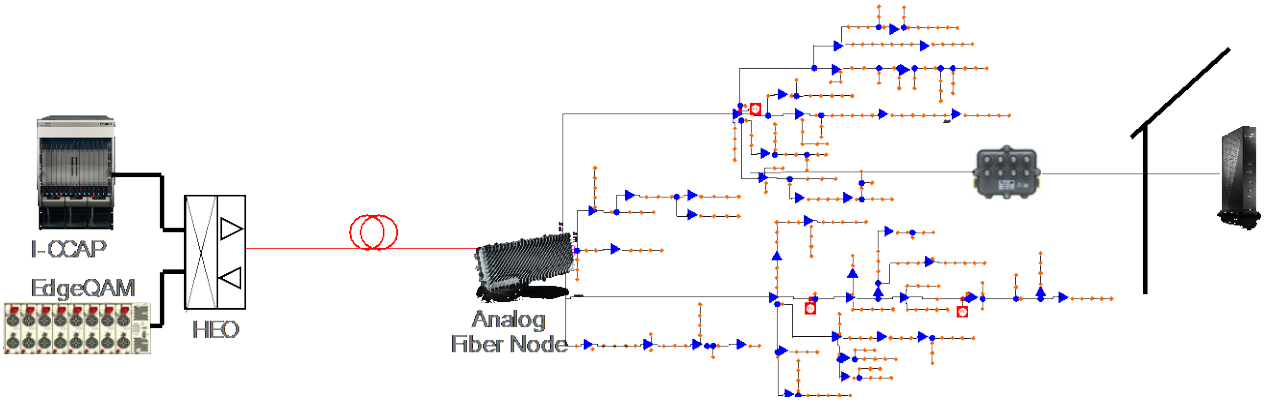

Figure 14 – Overview of Upgrade elements considered in CAPEX calculation

If the topology were to change from N+5 to N+2 or to N+0, the field portion of the network would get upgraded. The field portion would change from that in Figure 9 to that of Figures 11 and 12, respectively. If the I-CCAP were to get converted to DAA, the left-hand portion of Figure 14 would change to that of Figure 15.

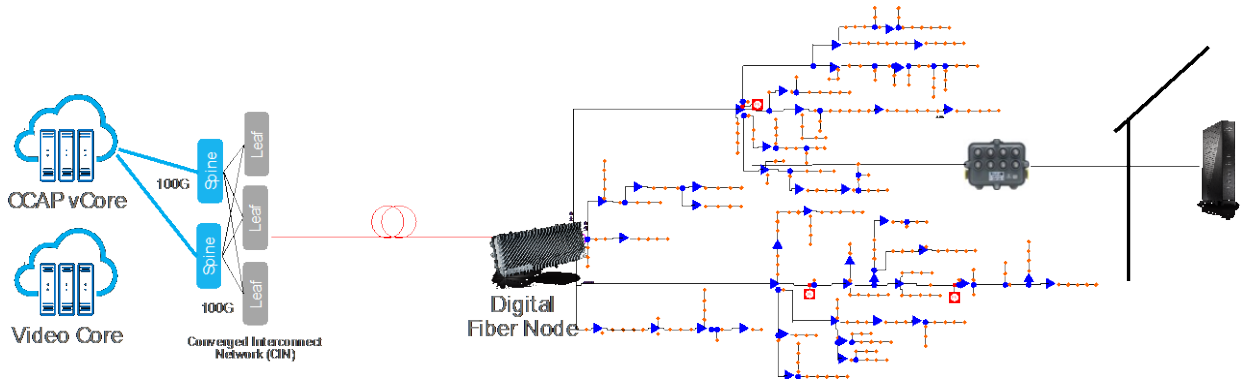

Figure 15 – Network upgraded from I-CCAP to DAA

4.1. Network upgrade paths considered

The nine upgrade scenarios analyzed are shown in Table 2. The names were selected for brevity, so they correspond to labels in the resulting plots. Other elements of the table include: architecture type (i.e. centralized I-CCAP, distributed DAA and PON), number of serving groups (SG), homes passed per SG (HP/SG) and number of nodes. The RF split and top DS frequencies, if applicable, are also shown.

Table 2 – Network upgrade scenarios considered

Name	Architecture	# of SG	HP/SG	# of nodes	RF split	DS BW
CCAP N+5	I-CCAP	2	~480	2	Mid or high	1,218 MHz
CCAP N+2	I-CCAP	4	~240	8	Mid or high	1,218 MHz
CCAP N+0	I-CCAP	4	~240	15	Mid or high	1,218 MHz
FDX N+0	DAA	4	~240	15	108-684	1,218 MHz
FDX-Lite N+5	DAA	2	~480	2	108-396	1,218 MHz
ESD N+5	DAA	2	~480	2	396/492 UHS	1,794 MHz
ESD N+2	DAA	4	~240	8	396/492 UHS	1,794 MHz
10G PON	OLT in hub	15	64	N.A.	N.A.	N.A.
10G R-PON	OLT in node	8	128	N.A.	N.A.	N.A.

4.2. Capital Expenditures (CAPEX)

Figure 16 shows the one-time capital expenditures (CAPEX) for each of the options. These are then normalized to the highest-cost case – that of the 10G Remote-OLT PON (R-PON). The legend shows a breakout for various cost components. On the headend side, there are CMTS (or OLT if PON) and head-end optics (HEO) – which includes SFPs for DAA and PON. On the field side, categories are: node hardware; field hardware consisting of RF amplifiers and fiber enclosures; labor expense to install nodes/amplifiers/fiber enclosures; then new fiber, material and labor; and taps, material and labor (or splitters, material and labor, if PON). On the customer premise side drops, material and labor and CPE – the ONUs for PON – are included.

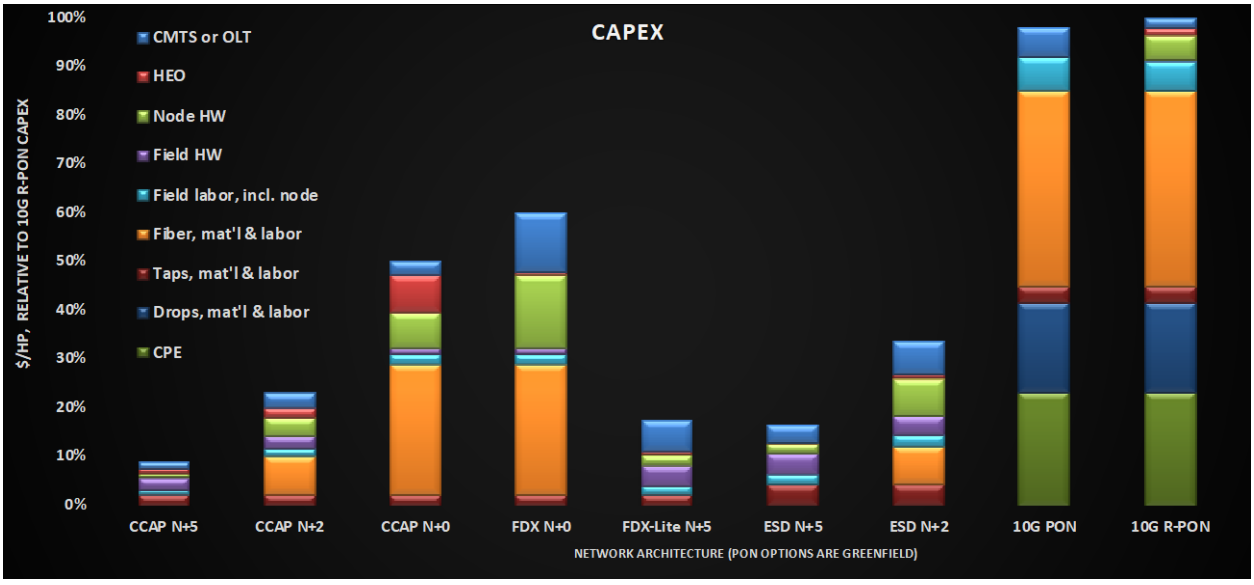

Figure 16 – Normalized CAPEX in $/HP for each of 9 upgrade paths

For I-CCAP, each service group gets 32x4 DSxUS D3.0 SC-QAM channels and 192x48 MHz DSxUS wide OFDM/A D3.1 channels. For DAA, it's 32x4 DSxUS D3.0 SC-QAM channels and 192x96 MHz DSxUS wide OFDM/A D3.1 or D4.0 channels. The fiber – material & construction labor estimates - shown in orange, are dominant in some upgrade cases and are based on $2 per foot for aerial and $12 per

foot for underground, with 80/20% mix of aerial/underground assumed, for a blended cost of $4 per foot. For CCAP N+5 and N+2, only the RF amplifier modules get replaced while the housings remain as they are. For all other cases which contain RF amplifiers, the complete old housing cutout and replacement with a whole new RF amplifier station is assumed. For FDX N+5, ESD N+5 and N+2 cases, given that no FDX nor ESD field RF hardware exists yet, a 40% HW cost premium is assumed over a comparable 1.2 GHz RF amplifier unit. For the PON cases, only the cost of subscriber drops and ONU hardware and install is included – which represents 50% of homes-passed - in order not to overburden PON CAPEX estimates.

4.3. Operating Expenditures (OPEX)

Operating costs are another significant part of the total costs of running a network and are calculated for a certain period of time. When combined with capital expenditures, CAPEX and OPEX add up to the "total cost of ownership" (TCO) over that same period. We select 15 years as a reasonable timeframe to consider, in part because the field hardware upgrades approximately coincide with this 15-year window. The operating costs considered include field network components power consumed, field actives hardware maintenance, hardline coax and/or fiber maintenance and drop lines repair and maintenance. Figure 17 shows these costs normalized to the same CAPEX 10G R-PON costs the y axes of Figure 16 were normalized to.

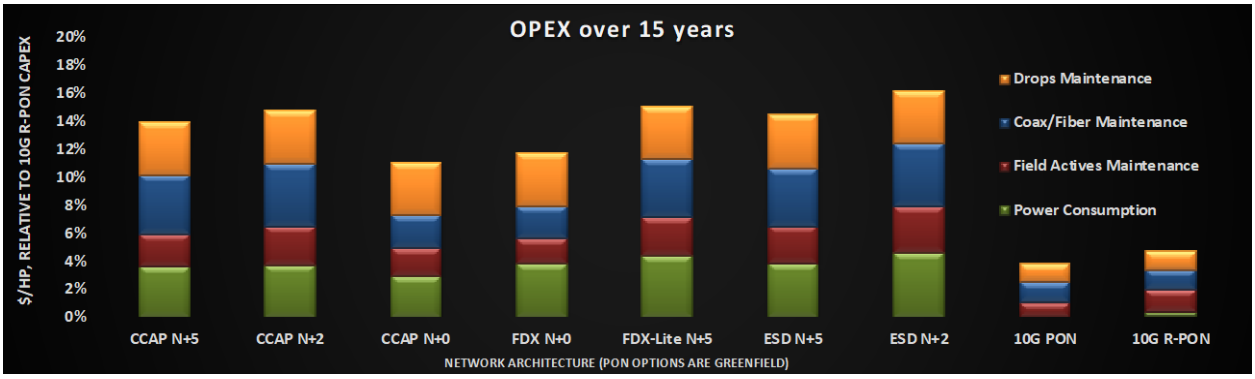

Figure 17 – 15-year Normalized OPEX, in $/HP, for each upgrade path

Power consumption is based on $0.12 per kWh; field actives (nodes and RF amps) are assumed to exhibit % failure over time as shown in figure 18; old coax replacement is based on 1% per year and the new coax/fiber at 0.35% per year; drops maintenance similarly is based on replacing 1% per year. The full costs from the year one is included, however, the costs from years 2 to 15 are time-value-of-money discounted with 5% per year discount rate. The values in Figure 17 is the OPEX cost normalized to the same value the CAPEX costs in Figure 16 are normalized – that of 10G R-PON CAPEX.

With these assumptions, Figure 17 shows that FTTP/PON upgrades have the lowest OPEX coming in at 3% - 4% normalized to the CAPEX costs while the cable options are in the 12% - 16% range. This is not surprising, as the PON options have a significant ~70% reduction in OPEX. So, how critically important is this?

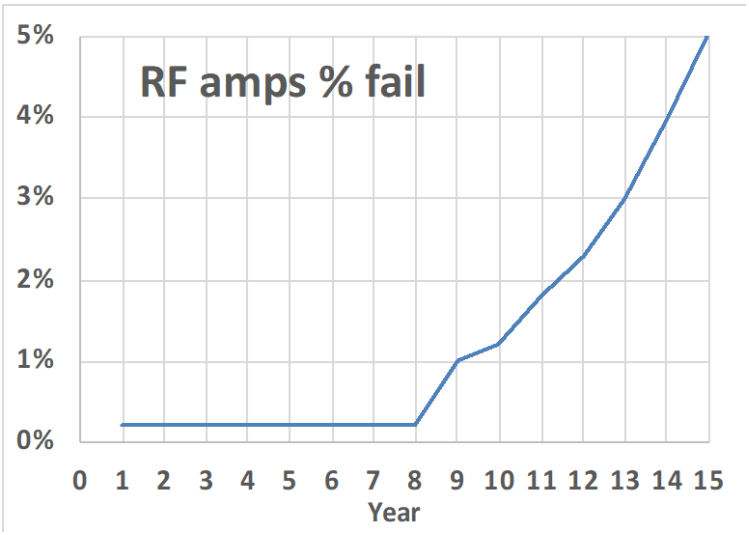

Figure 18 – Field actives failure over time, for estimating maintenance cost

4.4. Total Cost of Ownership (TCO)

The answer is provided by adding CAPEX and OPEX together, resulting in the TCO, as shown in Figure 19. At a first glance, no free lunch opportunity is detected, because those low operating expenses for the PON upgrades sit on the top of a very tall "candlestick" of the PON capital expenses. Nevertheless, TCO ratios did significantly reduce, as compared to those of CAPEX: take 10G R-PON vs. ESD N+5 for example: the CAPEX ratio was ~6, while the TCO ratio is down to ~3.

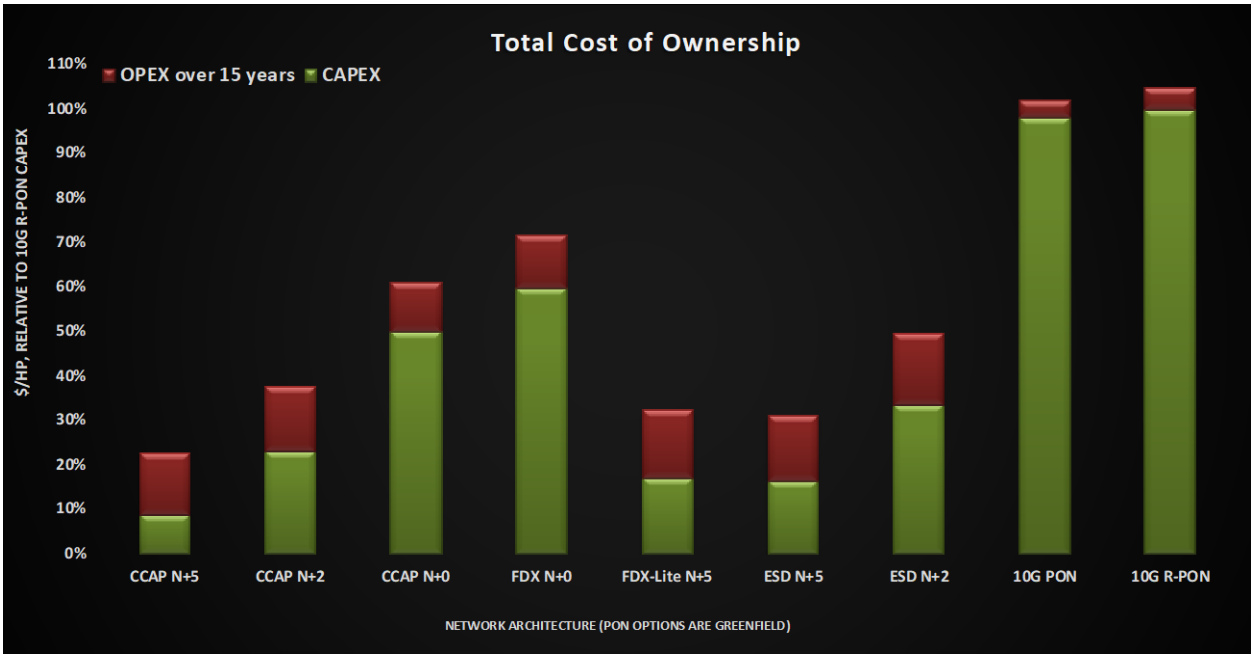

Figure 19 – 15-year Normalized TCO, in $/HP, for each upgrade path

Figure 19 gives the impression that staying with longer cascades (N+5) is the lower cost thing to do, as compared to progressively more expensive N+2, N+0 and FTTP. However, this does not consider the

potential network capacity gains from the other options. Would the network capacity gained justify these additional upgrade costs? The answer to this question is in a later section. However, let's first consider why should one trust these comparisons and numbers anyhow?

There are many factors that go into calculating TCO with many associated assumptions. Isn't there a way to give the reader some additional insights into the assumptions made, and what happens if those assumptions are changed? Monte-Carlo variability analysis comes to the rescue – and to getting these questions answered.

4.5. Sensitivity Analysis - CAPEX

The left sides of Figures 20, 21 and 22 show results of a 100,000-trial run Monte-Carlo analysis for CCAP N+5, ESD N+5 and 10G R-OLT CAPEX, comparatively. The blue areas give "95% confidence interval", based on input parameter assumptions made. Also shown are "base case" numbers – the numbers of Figure 16. What was 100% base case for the right-most 10G R-PON CAPEX, actually ranges from 86.8% to 126.8% for that 95%-confidence-interval, with an average of 105.8%. The ESD N+5 reports base case of 17.1% but ranges from 15.5% to 20.6%; the CCAP N+5 reports 6.7% base case but ranges from 5.9% to 8.5%. Thus, taking the numbers from Figures 16, 17 and 19 as fixed would indeed be a wrong thing to do.

Showing the variability helps but showing where the variability is coming from helps even more. That's why we include the "Tornado charts" on the right side of Figures 20, 21 and 22 – charts that show how much a change in the assumed input variables affect the results. The top variable for the two HFC cases is number of homes passed per study area. We used the 945 HP as the "base case" but allowed the range of 700 to 1,100 HP to also be considered, and that range changes HFC CAPEX significantly. The quantity of bridger and line extender amps follows; then, for ESD N+5 there is "ESD HW addition factor", followed by the labor cost to replace RF amps. For PON, the base case of 20% of underground plant, if changed from 0% to 40%, is the most CAPEX affecting, followed by fiber material and labor and how large of an area under study.

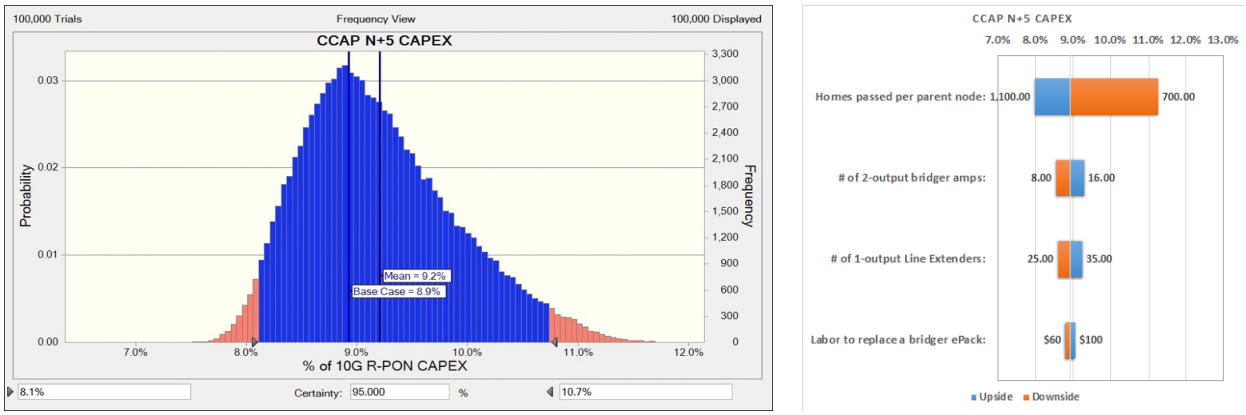

Figure 20 – Monte-Carlo variability and sensitivity analysis of CAPEX for CCAP N+5

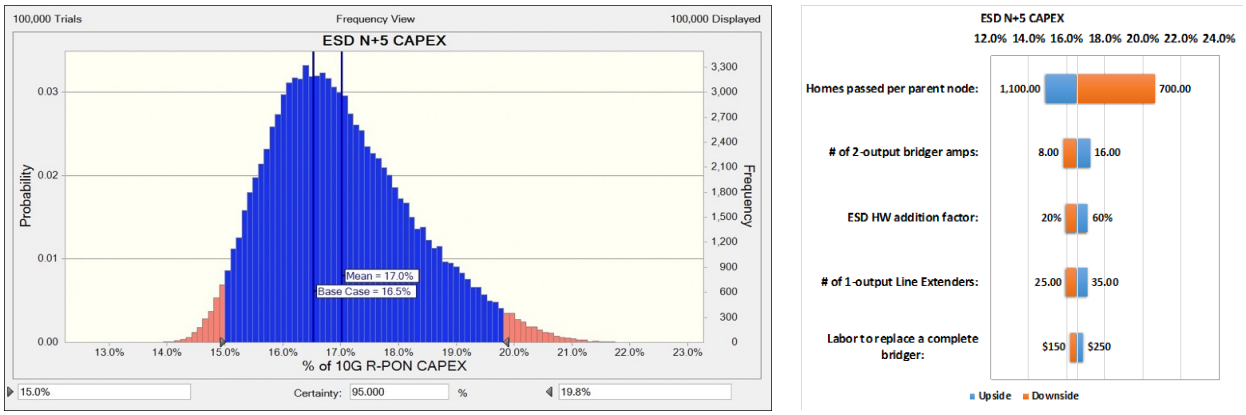

Figure 21 – Monte-Carlo variability and sensitivity analysis of CAPEX for ESD N+5

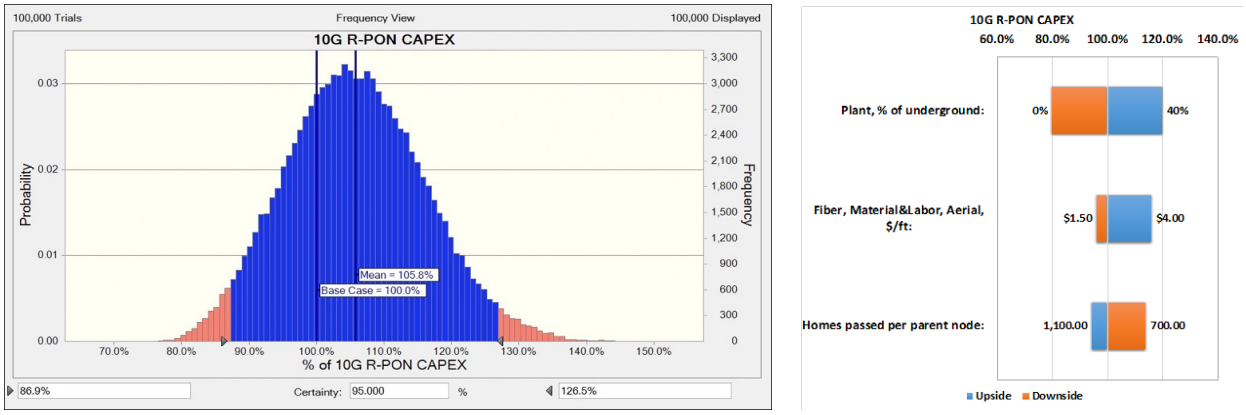

Figure 22 – Monte-Carlo variability and sensitivity analysis of CAPEX for 10G R-PON

4.6. Sensitivity Analysis - OPEX

Given the above insights about CAPEX variability and the causes of the same, it's only fair to look at variability of the OPEX too. Figure 23 shows variance of the average of all HFC upgrade cases and compares it to the variance of the average of the two PON cases. PON average base case numbers were 4.3% (of the 10G R-PON) for PON and 13.9% for the HFC upgrades overall. The 95%-confidence intervals, however, range from 3.1% to 6.4% for PON upgrades and from 11.2% to 19.1% for the HFC ones.

The sources of this variability are shown in Figure 24 – via tornado chart sensitivity analysis for PON and HFC upgrades on average, respectively. Some of the top affecting OPEX variables were educated guesses: how much less of repair and maintenance is the new fiber/coax going to have in comparison to previously installed one, what % of existing plant mileage gets maintained/repaired each year, and the same for the drop cables. In any case, even if some inputs were pure guesses, Figure 24 answers how those factors influence the overall OPEX outcome.

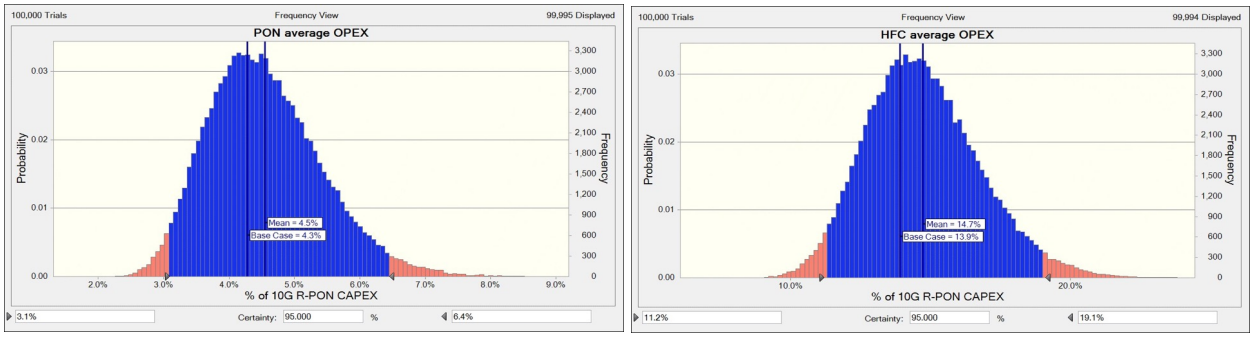

Figure 23 – OPEX variability of PON upgrades and HFC upgrades

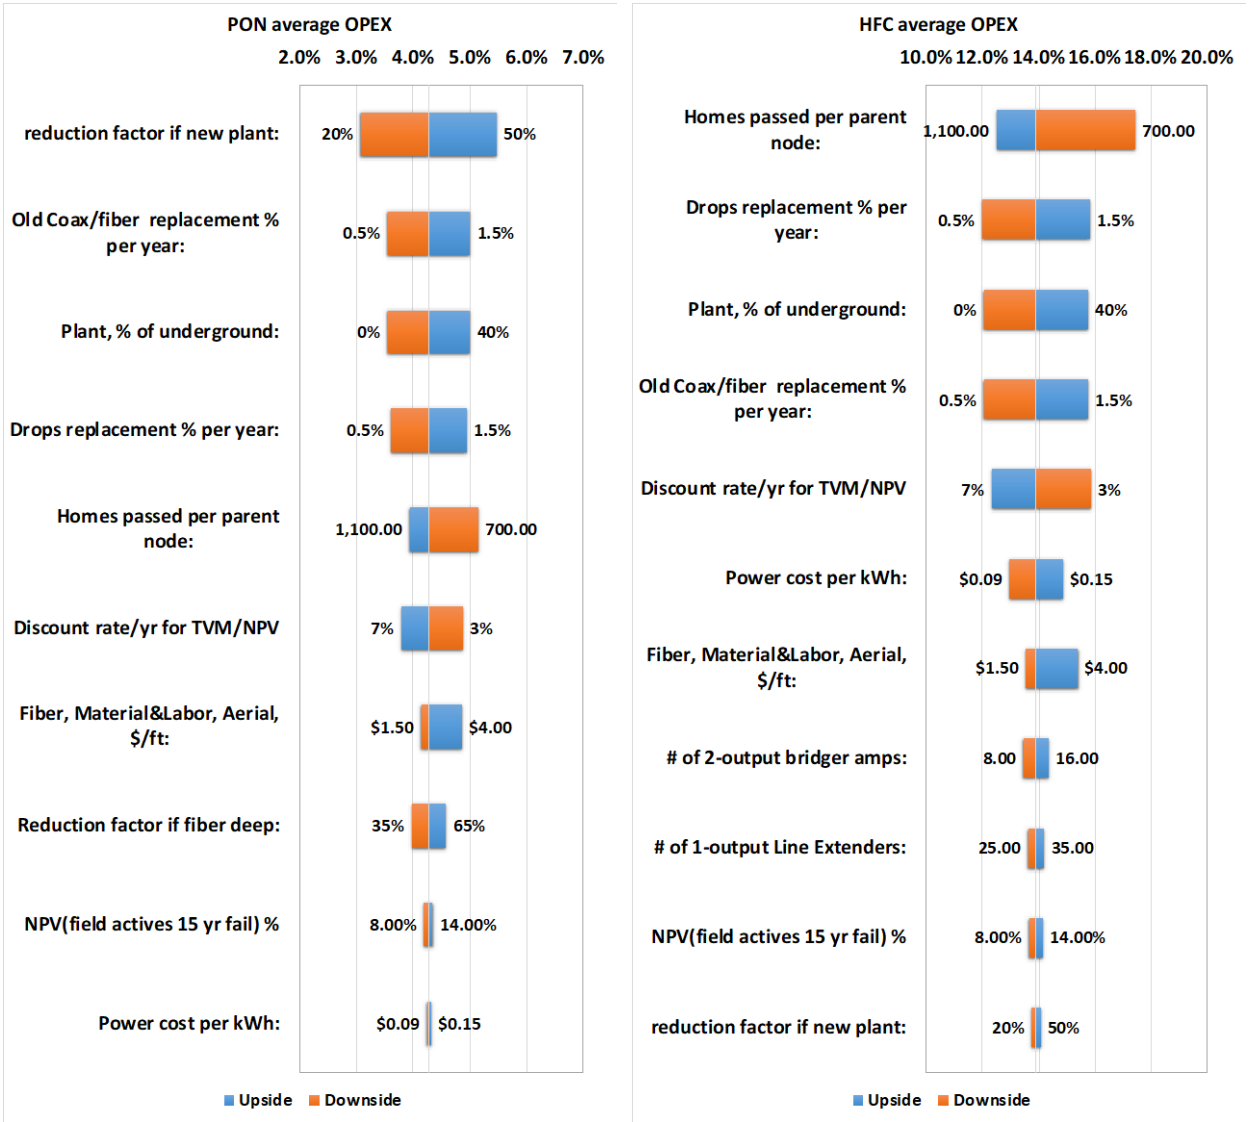

Figure 24 – OPEX sensitivity analysis for PON and HFC upgrades

4.7. Sensitivity Analysis – TCO

With separate variability analysis of OPEX and CAPEX, it may be interesting to see how the variations and sensitivities add up. Figure 25 shows variability of ESD N+5 for CAPEX next to the OPEX, and the resulting overall TCO. The sum of CAPEX & OPEX mean (17% & 15.4%) and base case (16.5% & 14.5%) do add up to the mean and base case of the TCO – 32.4% and 31%, respectively.

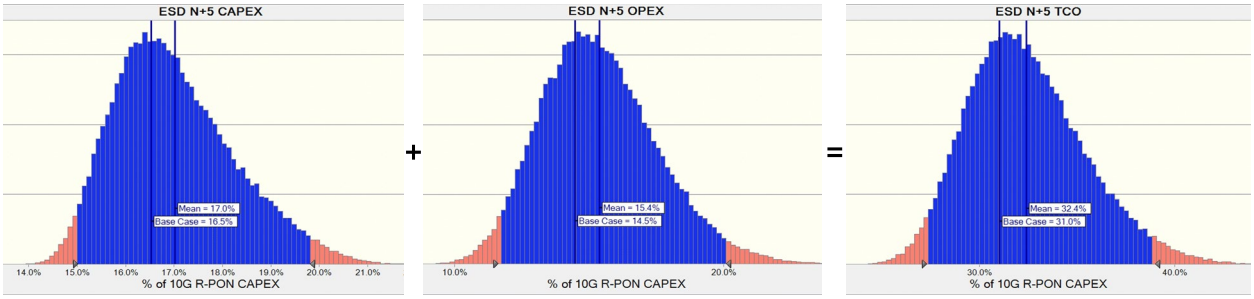

Figure 25 – CAPEX + OPEX variability adding to TCO variability

Figure 26 – Sensitivity of ESD N+5 TCO to various assumption ranges

The most contributing assumptions to the overall variability of ESD N+5 TCO are shown in the "tornado chart" in figure 26. The divisor of homes-passed per parent node features prominently, primarily because of the wide 700 - 1,100 HP range considered, as compared to the fixed 945 HP in the node area under study. Five other factors are OPEX; the rest are CAPEX driven. Hardline coax % replaced, 0.5% to 1.5% range per year, is the next most contributing, the % of underground plant enters via cost of old coax replacement – more costly if more underground; and so on.

The above sensitivity analysis, done by introducing variability into model's assumptions and then detecting what changes and by how much in the model's outputs, helped us gauge the reasonableness of the modeling process. That was but one of the ways of keeping "GIGO" (Garbage In, Garbage Out) from affecting our reasoning. The other way was to "keep it sophisticatedly simple (KISS), but not too simplistic". Thus, KISS and no-GIGO were our guiding principles in making these models.

4.8. Will network capacity gains justify various upgrade costs?

It depends… Figure 27 displays the 2021 max DS + US service tier rates (Tmax_max) that each of the upgrades can potentially support. Since no FDX nor ESD products are available yet, those estimates are left blank. Tmax_max rates are calculated by rearranging basic traffic engineering SG capacity formula of section 2.2 into:

$$\mathbf{Tmax\_max = (C - Nsub * Tavg) / K}$$

The 2021 Tavg values, as in Figure 2, are taken to be ~3 Mbps DS and 0.25 Mbps US, with K = 1; the CCAP 1.2 GHz mid-split options potentially give 6 to 7 Gbps Tmax_max in DS and 500 to 600 Mbps Tmax_max in US – and much more than that (8 x 8 Gbps DS/US) with the two FTTP options.

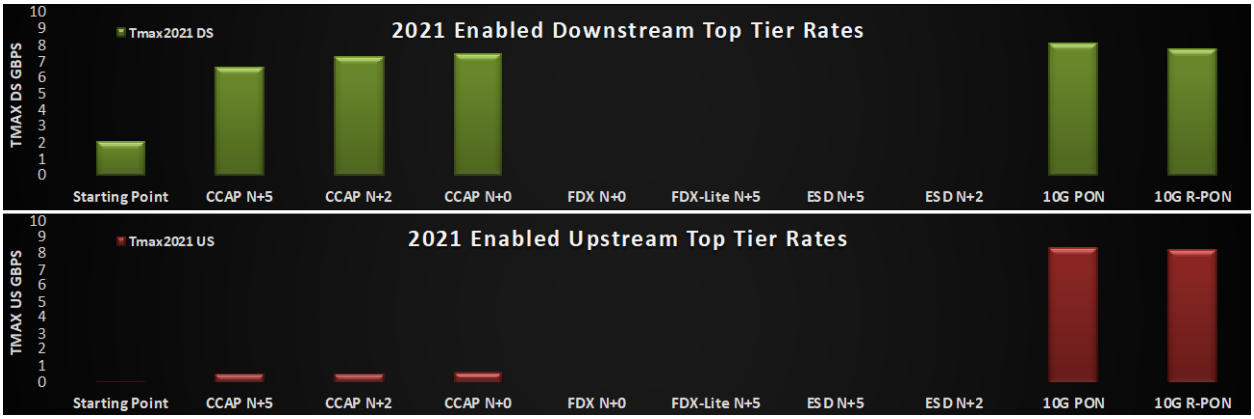

Figure 27 – Year 2021 DS/US Top Tier Rates enabled (FDX, ESD not yet available)

Figure 28 shows what the possible Tmax_max rates would look like in year 2036, for the 9 upgrade options, if next 15-year CAGR were 20% in DS and US, as was assumed in Section 2.3. The 2021 DS Tavg of ~3 Mbps thus grows to ~40 Mbps by 2036, the 2021 US Tavg of ~0.25 Mbps grows to ~1.3 Mbps by the year 2030 and to ~3 Mbps by the year 2036. In the DS, only the ESD version of N+5 has >1Gbps of capacity left for Tmax_max. The other two N+5 cases, CCAP and FDX-Lite, have their capacity drained by Tavg * Nsub (Nsub = 237 subscribers/SG for N+5, while N+2 and N+0 have Nsub = 118 subs). However, both N+2 and N+0 options in the DS seem fine and will still provide 5-6 Gbps Tmax_max. In the US, all three mid split CCAP upgrades tap out. Under the 20% US CAGR, mid-split will hold for US Tmax of 400 Mbps until 2030 but will run out of gas by 2036 – as the lower part of the

Figure 28 shows. This, as well as the ability to offer one gigabit US service, are the reasons to consider going high-split vs. mid-split for the 1.2 GHz upgrades.

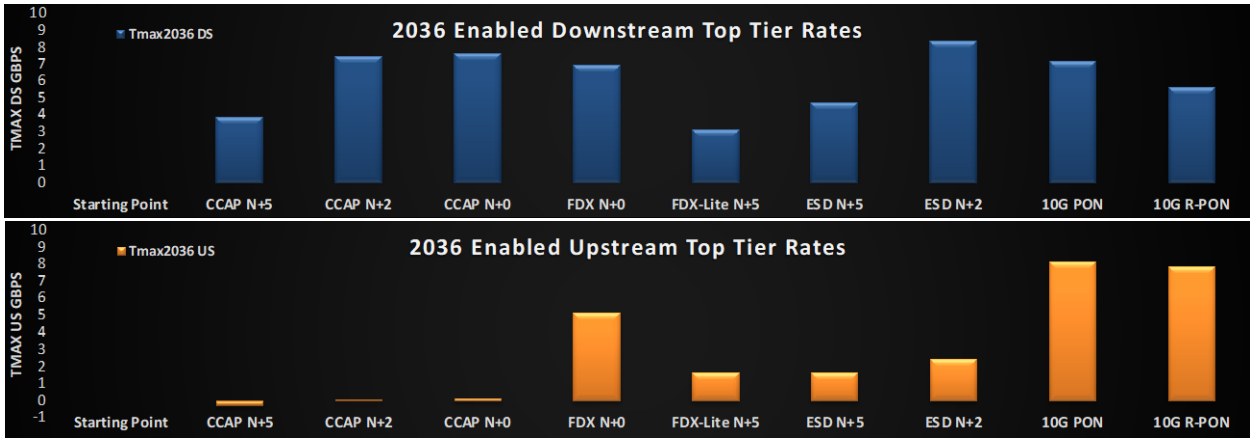

Figure 28 – Year 2036 DS/US Top Tier rates enabled; CCAP mid-split US out of gas

For the next scenario shown in Figure 29, the CCAP supports high-split US instead of mid-split. This step makes the gigabit upstream rates still a reality in 2036 with N+2 and N+0, and while N+5 CCAP, limited by its large SG size, is limited to a Tmax_max of only 600 Mbps.

Furthermore, the DS scenario in Figure 29 shows what happens if the DS CAGR slows and only reaches Tavg = ~25 Mbps. At this DS Tavg, all DS options still have multi-gigabit Tmax_max rates to offer, in 3 to 8 Gbps range. For FDX and ESD, both DS and US look promising – able to support max advertised rates up to 3-8 Gbps in DS and 2-4 Gbps in US. For FTTP/PON, 5-7 Gbps Tmax_max is available in the DS. In the US, Tmax_max of PON is 4x all the other options, other than FDX N+0, where the ratio is closer to 2x. It is interesting and not intuitively expected, however, that by 2036 the 10G PON Tmax in the DS is going to lag - ever so slightly - behind Tmax of ESD N+2 with 396/492 MHz ultra-high-split – granted; under the above assumptions.

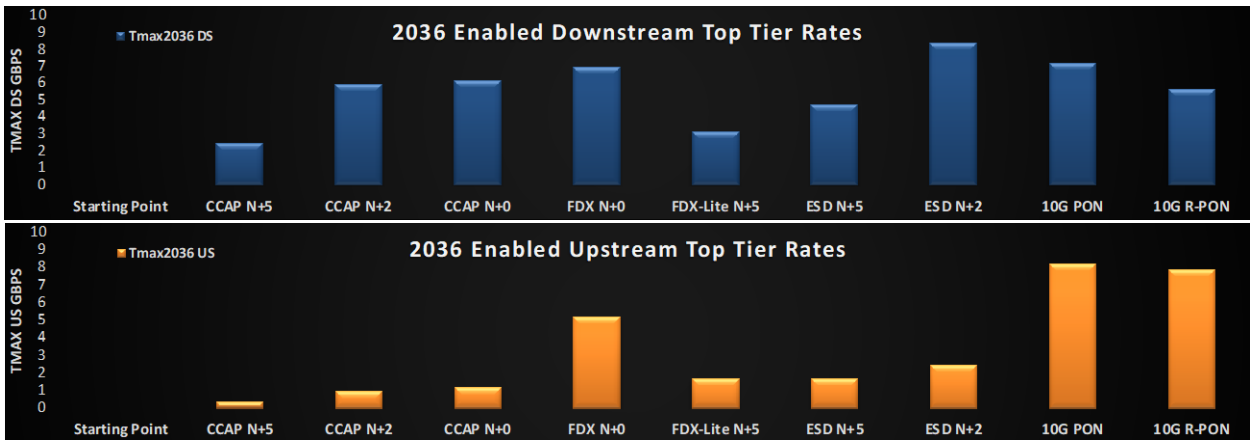

Figure 29 – Year 2036 DS/US Top Tier rates enabled; 15% DS CAGR + high-split CCAP

4.9. TCO analysis Takeaways

If DS capacity remains king, then ESD N+2 provides the highest DS capacities, even better than 10G PON, yet only has a TCO that is half that of PON. The N+2 architecture also leaves the network in an easy position to segment SG size if needed. Fiber is now much closer to every home, so a selective subscriber migration to FTTP now becomes feasible for any customers needing >10 Gbps connectivity. Finally, the deeper fiber from the N+2 HFC network aligns fiber nodes nicely with 5G Mid-band small cells. [ULM_2021] details several case studies showing the convergence of HFC and 5G Mid-band small cells.

The above analysis (with a DS Tavg = 25 Mbps and US Tavg = 3-4 Mbps over the next 12-15 years) shows that the CCAP N+2, FDX-Lite N+5 and ESD N+5 upgrade options are still able to deliver multi-gigabit service DS and at least 1 Gbps (CCAP high-split) or 2 Gbps (FDX-Lite, ESD) in the upstream. TCO for those three options are each roughly at 1/3 of the TCO of the PON - yet are expected to get the job of keeping up with the BW demand done over the next 12-15 years. This in short is the business case for “DOCSIS is here to stay”.

D3.1 or D4.0 or both? Under certain Tavg CAGR assumptions, D3.1’s “fuel tank” has enough gas to last into mid 2030’s, and especially so with the high-split 204/258 MHz option. Under those same assumptions, D4.0 has a potential to meet customer demand into 2040s.

As for comparing the two D4.0 options - The TCO for FDX-Lite N+5 is slightly higher than that of ESD N+5. The key difference, however, is in the DS Tmax_max – ESD N+5 will support 5 Gbps in 2036 while FDL-Lite N+5 can do ~3 Gbps. Upon closer inspection of the CAPEX cost contributors for these two (shown in Figure 16), the CCAP Core for FDX-Lite shows as more costly (and complex) than that for ESD, while upgrading taps as faceplate only for FDX-Lite shows as less costly (and complex) than the whole housing taps upgrade required for ESD. This tradeoff still made ESD CAPEX lower than that of FDX-Lite. The same follows for the TCO comparison, given relatively comparable OPEX for the two.

Why do we call FDX N+5 the FDX-Lite? Because, technically speaking, FDX has been envisioned as applicable to the N+0 topology only, and in order to use it with N+X, some type of “FDX amplifiers” would have to be required. Those could be implemented with echo cancelation, or, given the interference group (IG) elongation issue, via other options, as elaborated in [AYHAM_SCTE_2019]. As a result of IG elongation, however, with these amplifiers, some portions of FDX spectrum may end up getting used in the half-duplex mode only; therefore, the FDX-Lite designation. If the duty-cycle and simultaneity of Upstream and Downstream peak bandwidth bursts ever increase due to new applications (ex: AR or VR apps), then this half-duplex mode of operation required for FDX-Lite may become an impediment in the future that is not existent in the ESD solution. Nevertheless, time will tell when either ESD and/or FDX amplifiers will become available and what the burst requirements will look like for future applications. Additional conclusions can be drawn as this information becomes available.

4.10. Scenarios in which going straight to FTTP/PON makes more sense

There always will be some low-hanging-fruit opportunities in the networks, for example:

- where the total mileage of fiber build required is much lower than in the above study
- where the HP/mile density is much higher
- where the fiber construction cost may be lower than assumed above, either because of lower labor rates and/or because pre-installed conduit runs already exist and running fibers through those will cost significantly less and/or because of predominantly aerial plant

- Where existing fiber routes, perhaps installed with some other purpose - like those fiber routes to the two wireless towers in Figure 30 – can be repurposed for FTTP/PON use
- Innovation driven "disruptive" change in how fiber routing is done, as in this [THEGUARDIAN] article titled: "UK launches £4m fund to run fibre optic cables through water pipes"

Under those conditions, going FTTP would be the right thing to do, both for capacity gained and total cost of ownership reasons. Some of these conditions, dense urban customer base and pre-existing fiber conduits especially, may be behind the recent UK Virgin Media announcement "*Under an ambitious scheme announced today, Virgin plans to upgrade its entire network to full-fiber technology by 2028*", [VIRGIN].

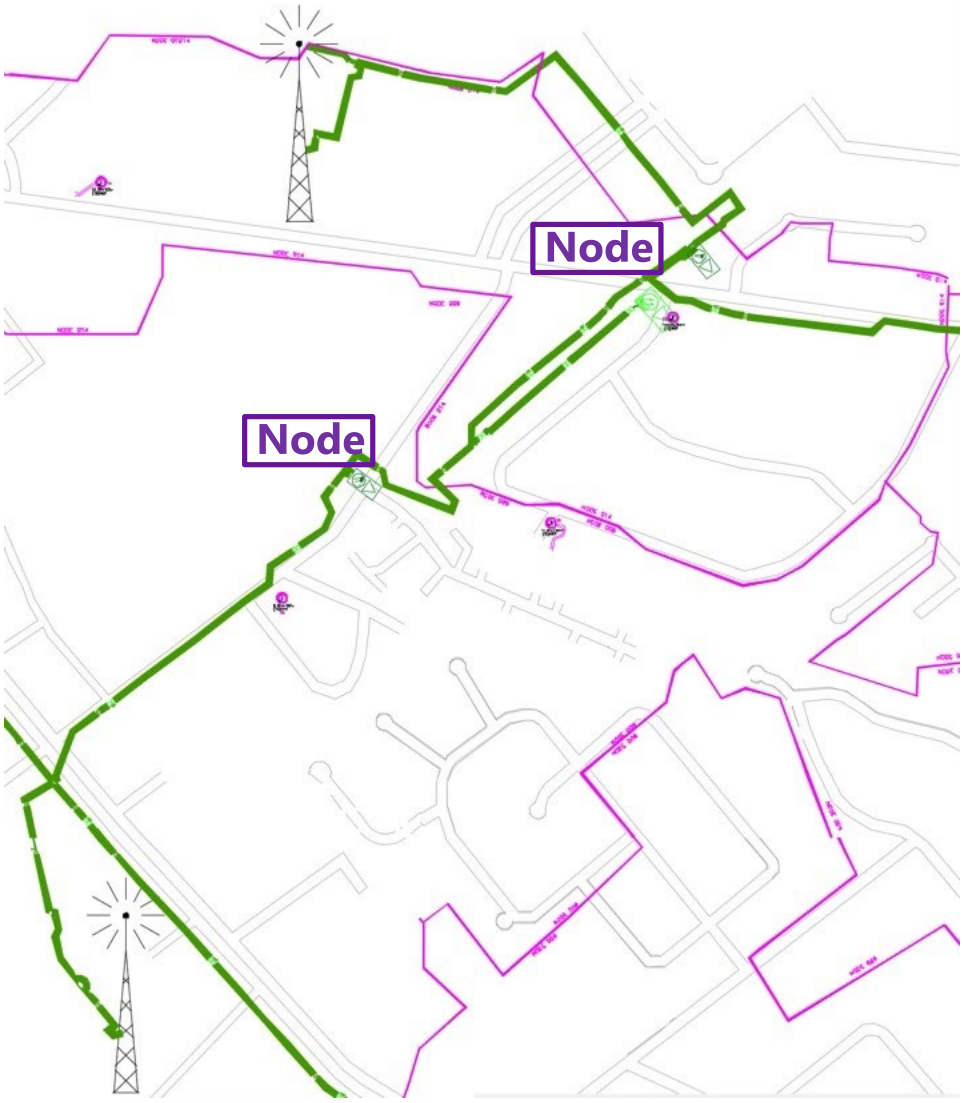

Figure 30 – Example of pre-existing cell-tower fiber routes, with "dark fiber" strands available to support FTTP/PON

4.11. Greenfield scenarios – business as usual or FTTP/PON?

Furthermore, what to build in the green field is the question to revisit often and to revisit hard. Based on our analysis, CAPEX for new builds HFC vs FTTP way - are on par – provided legacy video issues and back-office compatibility are taken out of the discussion. It comes down to the operations folks deciding to continue business as usual or to remove all the obstacles for going the "brave new world" way, and to start doing fiber all the way for all the new / greenfield builds

5. Discussion – The Steps to Get There

5.1. The name of the game is optionality

As many Operators contemplate the jump to FTTP, DOCSIS4.0 continues to offer an extremely viable and cost-effective upgrade path, comfortably enabling multi-gigabit services, including symmetric gigabit services for business and enterprises.

To maximize their optionality in the coming years, operators are beginning to seed new Extended Spectrum DOCSIS (ESD) passive components in their networks as part of their regular preventive network maintenance (PNM) programs. These new passives are emerging with 1.8GHz rated faceplates and housing supporting 2GHz+, and will enable operators to expand their plant's spectrum as required; and as they evolve from centralized CCAP platforms; which today are limited to 1.2GHz operation, to distributed access technologies like Remote MACPHY which are evolving to support ESD operation to 1.8GHz.

The deployment of distributed access architectures will drive fiber deeper into HFC footprints and strengthen the future economics behind fiber to the home and business. This non-regret investment in their footprints will also provide operators with powerful optionality that allows them to choose the right technology for the right place at the right time.

Operators have many options to choose from as they upgrade their networks to support the bandwidth demands of the future. Their choices will likely be different depending on their particular constraints, challenges and expected Return-on-Investment (ROI). In addition, they may opt to utilize one option for some period of time, and then switch to a different option at a later point in time. Some operators may even choose two or more options to utilize in different markets at the same time.

Faced with the potentially expensive decision of deploying FTTP, one approach to making a sound decision may include an economic cutoff analysis where the level of investment required for FTTP overbuild deployment in a HFC node serving area is compared against the uplift in revenue expected from that investment of fiber coupled with the OPEX savings from not having to maintain an HFC plant; which can be subject to variation by different area's depending on the geographic and environmental factors (e.g. is the plant overhead or underground? Is it in or adjacent to a coastal location? Is it a high traffic area prone to damage?). This investment analysis should be performed over the expected life of any uplift in HFC plant, which is typically 10-15 years.

Below is a list of potential options, divided into several different constraint types.

- Near-term and Long-term Greenfield Deployment Areas
  - In these areas, operators may opt to roll out FTTP. This is the logical choice, as it provides long-term bandwidth capacities for the deep future. Since connections must be pulled to each

home anyway, it makes the most sense to utilize the technology with the longest lifespan ahead of it (FTTP).

- Near-term Non-Greenfield Deployment Areas with D3.1-capable HFC plants already in place with needs for ~3 Gbps (or less) Downstream SLAs and ~1 Gbps (or less) Upstream SLAs
  - In these areas, operators may decide to utilize combinations of several near-term D3.1-enabled techniques to augment both SLA capacity and per-subscriber average capacity to extend plant life. These techniques can include:
    - Traditional Node-splits that move towards N+3 or N+2 cascade depths (which can especially help give more per-subscriber average Upstream Capacity which may be required in the future due to COVID bandwidth demand increases)
    - Moving the Upstream split from 42 (or 65) MHz up to 85 MHz or 204 MHz (high-split)
    - Moving the top-end Downstream frequency from 750 (or 860) MHz to 1.2 GHz (Note: Getting to 1.2 GHz Downstream/204 MHz Upstream is a valuable interim step, as it will yield:
      - ~1.1-1.3 Gbps of Upstream Capacity (supporting ~1 Gbps Upstream DOCSIS SLAs)
      - ~5.5-7.5 Gbps of Downstream Capacity (maybe limited to ~2-3 Gbps DS DOCSIS SLAs due to some of the capacity being used by Legacy QAM Video))
  - In these areas, operations can use combinations of several approaches to reduce the spectrum required to support video, including:
    - Using Switched Digital Video (SDV) to reduce spectrum that must be dedicated to Legacy QAM Video
    - Moving to IP Video (which offers some of the same benefits of SDV with the transmission of only requested video streams).
    - Use more efficient video coding schemes to reduce spectrum that must be dedicated to video
  - In these areas, operators may use "Selective Subscriber Migration" to move selected subscribers from the HFC network to a parallel FTTP network that only needs to be installed with adequate infrastructure to support the small subset of subscribers selected for this treatment. These selected subscribers will tend to be those who select the highest SLAs and/or those who consume inordinately large amounts of average Bandwidth Capacity. This approach will extend the lifespan of the HFC network for the majority of "normally-operating" subscribers.

- Long-term Non-Greenfield Deployment Areas with D3.1-capable HFC plants already in place with needs for ~4 Gbps (or greater) Downstream SLAs and/or ~2 Gbps (or greater) Upstream SLAs.
  - Several approaches are permissible, depending on the constraints and challenges facing the MSO.

  - Approach #1 (HFC Focus):
    - Operators can begin by deploying 1.8 GHz-capable taps (in 3 GHz housings) to seed the network. This may be a lengthy activity to ubiquitously cover a majority of HFC plants, so it may need to be started many years before the actual 1.8 GHz service is to be enabled. Prior to D4.0 enablement, these taps can be used to transport traditional D3.1 bandwidth capacities peaking at 1.2 GHz Downstream frequencies and 204 MHz Upstream frequencies.
    - Alternatively, MSOs can begin deploying 1.6 GHz-capable faceplates in existing tap housings to seed the network. This reduces the maximum Bandwidth Capacity by a

small amount, but it could reduce costs and reduce installment times. Prior to D4.0 enablement, these taps can be used to transport traditional D3.1 bandwidth capacities peaking at 1.2 GHz Downstream frequencies and 204 MHz Upstream frequencies.

- At the same time (or slightly later), MSOs can begin deploying D4.0 1.8 GHz-capable/Ultra-High-Split-capable amplifiers (in 3 GHz housings or in existing housings that can support 1.8 GHz operation) to seed the network. This may be a lengthy activity to ubiquitously cover a majority of HFC plants, so it may need to be started years before the actual 1.8 GHz service or Ultra-High-Split service is to be enabled. Prior to D4.0 enablement, these amplifiers can be used to transport traditional D3.1 bandwidth capacities peaking at 1.2 GHz Downstream frequencies and 204 MHz Upstream frequencies.
- At the same time (or slightly later), MSOs can begin deploying D4,0 1.8 GHz-capable/Ultra-High-Split-capable DAA Nodes (in 3 GHz housings or in existing housings that can support 1.8 GHz operation) to seed the network. This may be a lengthy activity to ubiquitously cover a majority of HFC plants, so it may need to be started years before the actual 1.8 GHz service or Ultra-High-Split service is to be enabled. Prior to D4.0 enablement, these DAA Nodes can be used to transport traditional D3.1 bandwidth capacities peaking at 1.2 GHz Downstream frequencies and 204 MHz Upstream frequencies.
- At the same time (or slightly later), MSOs can begin deploying D4.0 1.8 GHz-capable/Ultra-High-Split-capable CM/Gateways into homes to seed the network. This activity can be done in a ubiquitous fashion or can be done in a targeted fashion, targeting the high-end users who are likely to require D4.0 BW capacities in the future. Prior to D4.0 enablement, these CM/Gateways can be used to transport traditional D3.1 bandwidth capacities peaking at 1.2 GHz Downstream frequencies and 204 MHz Upstream frequencies. It is even possible that these D.40 modems can be used on the D3.1 networks to increase the number of bonded OFDM blocks that the CM can feed into a single home.

- Once the D4.0-capable taps and amplifiers and Nodes and requisite CM/Gateways are deployed within a particular HFC network, the higher capacity 1.8 GHz Downstream operation and Ultra-High-Split Upstream operation (up to 684 MHz) can be enabled whenever subscriber bandwidth demands and SLA requirements demand the higher capacities. The need for higher SLAs is likely to dominate this activity. Higher SLAs could be required to support subscriber demands, but it is more likely and expected that higher SLAs will typically be required to respond to marketing challenges from other competing Broadband operators offering high-bandwidth service (>3 Gbps) in the same geographical area. The time-frames for the development of these marketing challenges (and the time-frames for the enablement of D4.0 bandwidth capacities) will obviously vary from area to area depending on the nature of the competition in each area. Each MSO will need to predict when these challenges will arise to permit them to properly phase and schedule their D4.0 rollout activities with adequate lead time.
- As was the case for near-term HFC plants, MSOs can still use combinations of several approaches to reduce the spectrum required to support video in their long-term HFC plants, including:
    - Switched Digital Video or a move to IP Video (which offers some of the same benefits of SDV) to reduce spectrum that must be dedicated to Legacy QAM Video

        - Use more efficient video coding schemes to reduce spectrum that must be dedicated to video
    - As was the case for near-term HFC plants, MSOs can still use "Selective Subscriber Migration" to move selected subscribers from the HFC network to a parallel FTTP network that only needs to be installed with adequate infrastructure to support the small subset of subscribers selected for this treatment. These selected subscribers will tend to be those who select the highest SLAs and/or those who consume inordinately large amounts of average Bandwidth Capacity. This approach will extend the life-span of the HFC network for the majority of "normally-operating" subscribers.

- Approach #2 (FTTP Focus)
    - Operators can begin by targeting high-density subscriber areas (ex: MDUs, high-rises, some city dwellings) for 10G-capable FTTP deployments where the business case analysis indicates there is value. (Note: The business case analysis should be focused on subscriber density, fiber-pull complexity, cost of labor, and whether opportunities exist to share costs of fiber-pulls with other initiatives such as fiber deployments to support cell-tower installations). This FTTP network can initially be built as an overlay to the already-existing HFC network.
    - Operators can extend the above FTTP deployment activities to all other areas, extending the 10G-capable FTTP connectivity to all subscribers in high-density subscriber areas, medium-density subscriber areas, and low-density (rural) subscriber areas. This FTTP network can initially be built as an overlay to the already-existing HFC network.
    - Operators can begin deploying PON ONT Gateways into homes to seed the network. This activity can be done in a ubiquitous fashion or can be done in a targeted fashion, targeting the high-end users who are likely to require higher BW capacities in the future. Since having both PON and DOCSIS CPE equipment co-existing within a home is probably undesirable to subscribers, the FTTP system must be enabled and operational the moment that the first subscriber in the area receives their PON ONT Gateway equipment. It should be clear that during the transition from HFC to FTTP, the two networks will both be operational and running in parallel. A subset of subscribers will be connected to the HFC network, and a subset of subscribers will be connected to the FTTP network. Over time, more and more subscribers will be moved from the HFC network onto the FTTP network.

- Approach #3 (Blended HFC/FTTP Focus)
    - This approach permits the MSO to use both Approach #1 and Approach #2. Each of their subscriber areas can be upgraded using a different approach depending on the particular constraints and challenges in that particular area. Business case analyses will need to be done to determine which approach is most suitable for any particular area.

6. Conclusions

This paper has studied many different evolutionary paths that MSOs can choose to utilize as they evolve their networks to the higher bandwidth capacities needed for future 10G operations. Each operator will clearly choose the path that yields the best return on investment for their own situation, and each operator

will undoubtedly find themselves with different sets of constraints and challenges as they select their future paths.

In general, this study tended to show that for markets where HFC networks already exist, operators will likely want to augment their existing HFC infrastructure to provide the types of bandwidth capacities that are anticipated to compete in the late 2020's and 2030's. Several phases of upgrades are likely. Operators may find a very good return on their existing investment by utilizing DCOSIS 3.1 technologies and traditional node-splitting activities for as long as permissible. This should carry them a long way into the 2020 decade. But to support the bandwidths of the late 2020's and 2030's, operators will likely need to begin seeding DOCSIS 4.0 technologies coupled to DAA architectures into their existing HFC networks, perhaps operating the equipment in a DOCSIS 3.1 fashion for a while before enabling the DOCSIS 4.0 operations. This permits the MSOs to seed the DOCSIS 4.0 equipment over multiple years before having to enable it, which is required since it does require changes to many network elements (Nodes, Amps, Taps, and CPEs). Each DOCSIS 4.0 technology has its own strengths and weaknesses. FDX requires less work on taps (although taps will still likely need to be upgraded to 1.2 GHz operation) at the expense of an N+0 plant. ESD operation may be simpler to diagnose (since it uses familiar FDD technologies) and it may yield higher downstream throughput capacities when N+2 plants are permitted. ESD may also provide cost benefits over FDX.

For Greenfield markets, the study showed that it is beneficial to consider FTTX as a starting point, because the higher cost of initial deployment is a given, and the FTTX technology provides larger bandwidth capacities for the long-term.

In either case, it is clear that MSOs have many good options from which to choose as they augment their networks to support the 10G services of the future.

Abbreviations

10G	10 gigabits per second
5G	5th generation mobile network
AR	augmented reality
BW	bandwidth
CAGR	compound annual growth rate
CAPEX	capital expenditures
CM	cable modem
CMTS	cable modem termination system
COVID	corona virus disease
CPE	consumer premise equipment
D3.1	DOCSIS 3.1
D4.0	DOCSIS 4.0
DAA	distributed access architecture
DFN	distribution fiber network
DOCSIS	data over cable service interface specification
DS	downstream
ESD	extended spectrum DOCSIS
FDX	full duplex
FTTN	fiber to the node
FTTP	fiber to the premise
FTTT	fiber to the tap
FTTX	fiber to the "X"
GIGO	"garbage in, garbage out"
HEO	head-end optics
HFC	hybrid fiber coaxial
HP	homes-passed
I-CCAP	integrated converged cable access platform
IG	interference group
IP	internet protocol
IPTV	internet protocol television
KISS	keep it sophisticatedly simple; or, keep it simple and straightforward
MAC	media access control
Mbps	megabits per second
MDU	multi dwelling unit
MSO	multiple system operator
NPV	net present value
OFDM	orthogonal frequency division multiplexing
OFDMA	orthogonal frequency division multiple access
OLT	optical line terminal
ONT	optical network terminal
ONU	optical network unit
OPEX	operating expenditures
PHY	physical layer
PNM	proactive network maintenance
PON	passive optical network

QoE	quality of experience
RF	radio frequency
ROI	return on investment
SC-QAM	single carrier quadrature amplitude modulation
SDV	switched digital video
SFP	small form factor pluggable
SG	service group
SLA	service level agreement
TCO	total cost of ownership
US	upstream
VR	virtual reality

1. Introduction

Demand for broadband services continues to grow. While wireline access technologies have supported traditional broadband services, a significant amount of broadband traffic is supported by wireless access technologies. Multiple System Operators (MSOs) have deployed Data-Over-Cable Service Interface Specification (DOCSIS) networks for many years to provide wireline broadband access for their customers. Because of the increasing demand for wireless broadband access, MSO interest has grown in deploying and backhauling their own 5G wireless access networks using their existing DOCSIS infrastructure.

Radio access technologies such as the fifth generation (5G) New Radio (NR) require accurate alignment in frequency, phase, and time of day to minimize interference and improve efficiency. Several MSOs have recently acquired Citizen Broadband Radio Service (CBRS) spectrum licenses to deploy time division duplex (TDD) 5G base stations (BSs). 3rd Generation Partnership Project (3GPP) standards specify a time difference of no more than 3 µs between cells which requires timing accuracy to be within 1.5 µs of a Primary Reference Time Clock (PRTC) [1].

Outdoor base station antennas can be oriented to be line-of-sight with Global Positioning System (GPS) satellites for the reception of timing signals. If line-of-sight cannot be achieved, as in the case of indoor base stations (e.g., Femtocells), an alternative timing source with 1.5 µs accuracy is required. IEEE 1588 Precision Time Protocol (PTP) [2] can provide this level of accuracy.

PTP was developed and specified frequency and phase synchronization across Ethernet transmission links using timestamps to address latency and jitter issues. PTP enables Ethernet-based networks to be used as backhaul links for 3GPP Long-Term Evolution (LTE) and 5G systems. However, PTP was not designed for DOCSIS networks.

When DOCSIS is lightly loaded, it is possible to support PTP "over-the-top" of DOCSIS [3]. However, DOCSIS was not designed to support highly accurate PTP "over-the-top". Therefore, a highly loaded DOCSIS system will not be able to support PTP to the accuracy levels required by TDD 5G base stations without the use of DOCSIS Time Protocol (DTP). DTP was introduced in DOCSIS 3.1 to reliably support PTP on DOCSIS networks.

DTP, invented by Cisco [4] and included in CableLabs DOCSIS specifications [5] and [6], enables DOCSIS networks to deliver PTP to wireless base stations. DTP establishes PTP-to-DOCSIS interfaces at the Cable Modem Termination System (CMTS) and at the Cable Modem (CM). DTP allows the timing and frequency system of the CMTS, the Hybrid Fiber Coax (HFC) plant and the CM to be a timing bridge. DTP accurately takes the PTP timing source at the input of the CMTS, and replicates it at the output of the CM with the correct timing offsets to take into account all the delays through the DOCSIS system. Figure 1 shows PTP and DTP operating on a DOCSIS system. Components of a generalized DOCSIS system are shown in green.

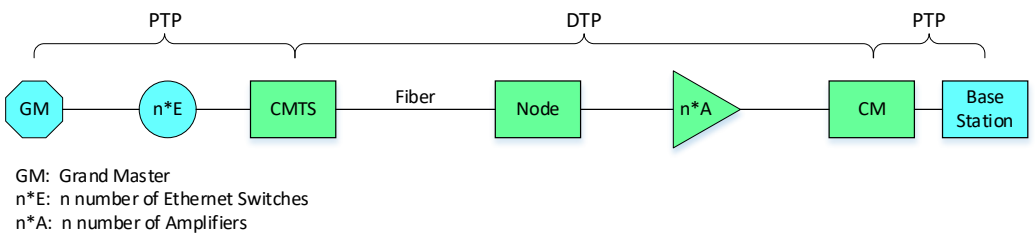

Figure 1 - PTP and DTP on an Integrated CMTS Architecture

The DTP protocol runs between the CMTS and the CM. The CMTS receives a PTP timestamp on a PTP slave port and synchronizes its internal clock to that timestamp. The CMTS synchronizes all DOCSIS timestamps to this internal clock, making the DOCSIS timestamp traceable to a PTP timestamp. The CMTS uses the ranging capabilities of DOCSIS, and delays through the CMTS and CM, to calculate timing offsets for an accurate PTP timestamp at the CM. The CM then regenerates PTP and sends it to the BS.

Many vendor companies have developed or are developing solutions that support DTP. Support for DTP is planned for the Cisco CMTS (cBR-8), and remote PHY device (RPD) products in a future software release (targeted for 2022). In January 2021, Hitron launched the ODIN-1112, the world's first DOCSIS 3.1 modem to support DTP. The ODIN-1112 supports operating as either a DTP master or a DTP slave. By pairing the ODIN-1112 with a small cell gateway, cable operators can leverage their existing DOCSIS networks to offer 4G/5G services. Hitron is dedicated to helping cable operators capture new opportunities in 5G and will continue expanding its product portfolio to enable not only outdoor but also indoor small cell deployments.

CableLabs, Charter Communications, Cisco and Hitron initiated proof-of-concept (PoC) testing for DTP in Q2 2020. This paper presents the DTP PoC test plan, methodology and up-to-date status.

2. DTP PoC Test Plan

DTP PoC testing started in September 2020 at both CableLabs and Charter. Cisco also conducted tests in their lab. The DTP PoC testing has three phases. Phase 1 evaluates the DTP time error in a lab environment with minimum fiber and coaxial cable length, without amplifiers, without traffic load, etc. The CM synced with DTP is plugged into an LTE base station to test the wireless signal time accuracy over the air (OTA). We also verified three manual calibration methods that allow changing the true ranging offset (TRO) or DTP time adjustment in the CMTS and the CM. The time error (TE) for all test scenarios and cases is compared with the DTP time error budget as defined in [5]-[9]. Phase 1 testing concluded in July 2021. The phase 1 methodology, setup, and results are reported in [9].

Phase 2 is designed to evaluate DTP performance in sophisticated configurations that are representative of anticipated field deployments. Different downstream (DS) and upstream (US) loads will be added to the

Table 1 - Phase 2 Test Plan

Parameter		Baseline test value	Comparative test values	Extreme value (optional test)
DS load		0	25%, 50%	75%
US load		0	25%, 50%	75%
Coax length (R-PHY to CM)		a few meters	1/4 and 1 mile	
Fiber length (Router to R-PHY)		tens of meters	25 km	
Number of amplifiers		0	1, 2	
CMTS config change (DS)	Interleaver	2	1	16
	Modulation	4096-QAM	1024-QAM, 256-QAM	
	Cyclic prefix	1 (1.25 µs, 256 samples)	2 (2.5 µs, 512 samples)	3 (3.75 µs, 768 samples)
CM config change (US)	Frame size	K = 6	K = 9, BW ≥ 72 MHz K = 18, BW < 48 MHz	
	OFDMA modulation	256-QAM	64-QAM	1024-QAM
	Cyclic prefix	6: 256 samples	4: 192 samples	

HFC plant to assess DTP and PTP performance. The coaxial cable and fiber length and number of amplifiers will be adjusted to determine DTP performance. The impact of HFC network configurations will be evaluated. These configurations include: DS interleaver, modulation and cyclic prefix, US frame size, modulation, and cyclic prefix. The phase 2 test plan is summarized in Table 1. For each parameter, a set of baseline, comparative, and extreme test values is defined. The extreme values are optional for phase 2 testing. Only one parameter will be changed for each test case to reduce the number of network configuration combinations. Phase 2 testing is planned for Q3 and Q4 2021.

The DOCSIS 3.1 timestamp transmitted from the CMTS to the CM is delayed while propagating downstream through the HFC network. DTP is designed to calibrate the DOCSIS 3.1 timestamp by using the TRO. DTP automatically compensates for the symmetrical (identical in DS and US) time error in the HFC network. However, the CMTS, RPD, and CM could introduce asymmetrical time errors that reduce the time accuracy of DTP. If pre-calibrated asymmetry values are known, DTP also compensates for asymmetrical time errors. Such asymmetrical time errors need to be measured in the lab before deployment for each combination of CMTS, RPD, and CM hardware and software versions. CableLabs/Kyrio established a Network Timing Lab to conduct these kinds of tests and collect data to calibrate the asymmetrical time error. This calibration data will be distributed by an Amazon Web Service (AWS) cloud server to enable the CMTS to calibrate the asymmetrical time error in the field automatically. The AWS cloud server design is presented in [10]. Once the AWS cloud server is developed and the corresponding automatic calibration feature is added to the CMTS, phase 3 tests will be started to validate the concept of this feature.

3. DTP Performance

3.1. Test Setup

The measurement setup for DTP performance testing is illustrated in Figure 2. Because there is no time measurement equipment available that supports DTP, DTP performance is measured between the input PTP timestamp to the CMTS and the output PTP timestamp of the CM. The Calnex Paragon-X is used to measure the DTP performance. Port 1 (PTP master) on the Paragon-X is connected to the Cisco integrated CMTS (I-CMTS) cBR-8 using PTP. The cBR-8 is connected to a Network Convergence System (NCS) router and a Cisco RPD via fiber. The RPD connects to the Hitron ODIN-1112 CM via a coaxial cable.

DTP is used between the cBR-8 and the CM. The CM is connected to port 2 (PTP slave) on the Paragon-X using PTP. The Paragon-X uses GPS and a Rubidium (Rb) clock to calibrate frequency. The Paragon-X compares the PTP timestamp received on port 2 against the timestamp generated by port 1.

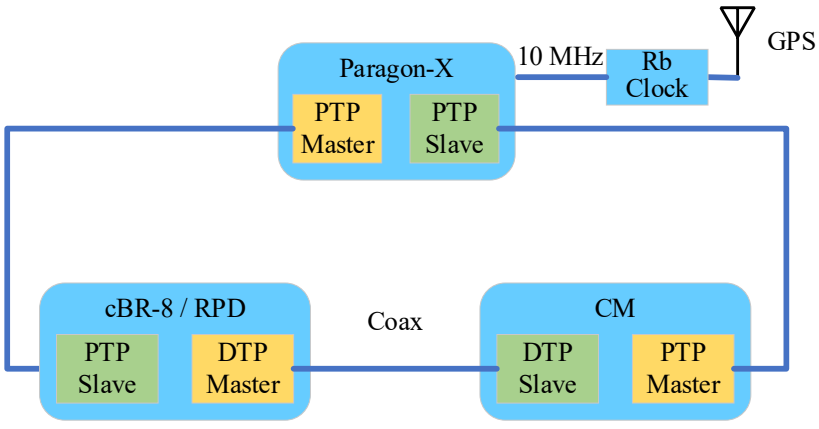

Figure 2 - Block Diagram of DTP Performance Test Setup [9]

The measurement accuracy of the Paragon-X is ±5 ns. CableLabs verified the performance of the Paragon-X before the DTP performance test. The method and results are reported in [9].

3.2. Time Error Budget

3GPP technical specifications 36.133 [1] and 38.133 require LTE and 5G NR base stations to have phase synchronization better than 3 µs between BSs. It indicates that each BS must have synchronization better than 1.5 µs. PTP (IEEE 1588) and ITU-T G. 8271 require a synchronization better than 1.5 µs.

The DTP TE budget for a typical Distributed Access Architecture (DAA) scenario is provided in Table 2, along with the TE budget calculated for the actual DTP test setup with an RPD used in the PoC testing. The clock used in the Paragon-X is compared with a delayed version of itself, so the PRTC does not apply. The test setup only uses one Class B boundary clock (BC) in the NCS. The total "Ethernet and Dynamic Aspects of Ethernet TE Budget" is 470 ns in total. The RPD is Class A. No node or amplifier is used. Hence, the "DOCSIS Network TE Budget" is 510 ns. A base station is not included in this test setup. The total TE budget is 980 ns which is much smaller than the required 1500 ns in PTP and 3GPP specifications. The DTP performance TE test results will be compared with this 980 ns TE budget as a pass/fail criteria.

Table 2 - DOCSIS and HFC TE Profile for the DTP Performance Test Setup with RPD [9]

Budget Component	DAA			DTP test setup		
	n	@	TE	n	@	TE
PRTC *(Class A is 100 ns, Class B is 40 ns, ePRTC is 30 ns)*	Class A		100	Class A		0
Network holdover and PTP rearrangements			200			200
Network dynamic TE and SyncE rearrangements			200			200
T-BC *(Class A is 50 ns, Class B is 20 ns)*	4	50	200	0	A@50	0
T-BC *(Class C is 10 ns, Class D is 5 ns)*				1	B@20	20
Link asymmetry			50			50
Ethernet and Dynamic Aspects of Ethernet TE Budget			**750**			**470**
I-CMTS/RPD/RMD *(Class A is 200 ns, Class B is 100 ns)*	Class A		200	Class A		200
DTP			50			50

HFC node			10	DAA		0
HFC amp/LE	N+3	10	30	N+0	10	0
CM *(Class A is 250 ns, Class B is 100 ns)*	Class A		250	Class A		250
DOCSIS Network TE Budget			**550**			**510**
Rearrangements and short holdover in the end application			0			0
Base station slave or intra-site distribution	Class A		50	Class A		0
Base station RF interface			150			0
Base Station Network TE Budget			**200**			**0**
Total TE Budget			**1500**			**980**

3.3. Phase 1 Test Results

DTP performance tests were conducted in CableLabs, Charter, and Cisco. The testbeds used an upstream Orthogonal Frequency-Division Multiple Access (OFDMA) channel. DTP is manually calibrated by setting the TRO at the CM to compensate the asymmetrical constant TE. Five runs of data were collected at CableLabs, five were collected at Charter, and one was collected at Cisco. Each test is set to either 1076 s, one hour or three hours. The results are summarized in Table 3.

Many TE statistical results were analyzed by the Paragon-X including two-way time error, constant time error (cTE), which is the average two-way TE, maximum and minimum two-way time error, dynamic TE (dTE), maximum time interval error (MTIE) and time Allan deviation (TDEV). Descriptions of these concepts and results were presented in [9]. In this paper, we only focus on the most important parameters, as listed in Table 3.

The results show that the cTE is smaller than 31 ns. The max TE and min TE results are within ±200 ns, which meet the 980 ns TE budget requirement discussed in subsection 3.2. The only exception is run 4 in the Charter testbed. A PTP Delay_Response message in run 4 arrived at the Paragon-X approximately 9 s later than expected. This was not observed in the other four runs in the Charter and CableLabs data and is likely a test anomaly that can be discarded.

Table 3 - Time Error Results with RPD [9]

All TE results unit in ns			Test setup with RPD				
			Two-way Time Error				Peak-to-peak dynamic TE
	Run	Time duration	Mean (cTE)	Max	Min	Max-Min	
CableLabs	1	3600 s	30	46	-47	163	157
	2	3600 s	13	146	-94	240	220
	3	3600 s	31	118	-47	165	144
	4	3600 s	21	138	-67	205	183
	5	3600 s	29	125	-81	206	190
Charter	1	3 hours	-29	97	-151	248	226
	2	3 hours	-30	102	-146	248	225
	3	3 hours	-19	110	-183	293	231
	4	3 hours	13607	9,404,370,078	-147	9,404,370,224	9,449,878,963

Cisco	1	1076 s	-20	121	-122	242	225

4. LTE Timing Performance Using DTP in Backhaul

Section 3 verified that DTP provides synchronization much more accurately in a lab environment than the required TE budget of 980 ns. In this section, DTP is used in mobile backhaul to check the LTE OTA signal time accuracy.

4.1. Test Setup

The test setup is illustrated in Figure 3. The grand master (GM) clock connected to a GPS receiver provides the PTP time source for the DOCSIS system. Both I-CMTS and DAA R-PHY architectures use PTP as an input timing source. In the I-CMTS architecture, the CMTS exchanges DTP messages with the CM. In the R-PHY architecture, the CMTS Core exchanges DTP messages with the CM. The CM uses DOCSIS 3.1 timestamps and DTP as its timing source, and provides a synchronization signal for LTE BS1 by PTP. We set up another LTE base station, BS2, that is synchronized to a GPS clock to compare

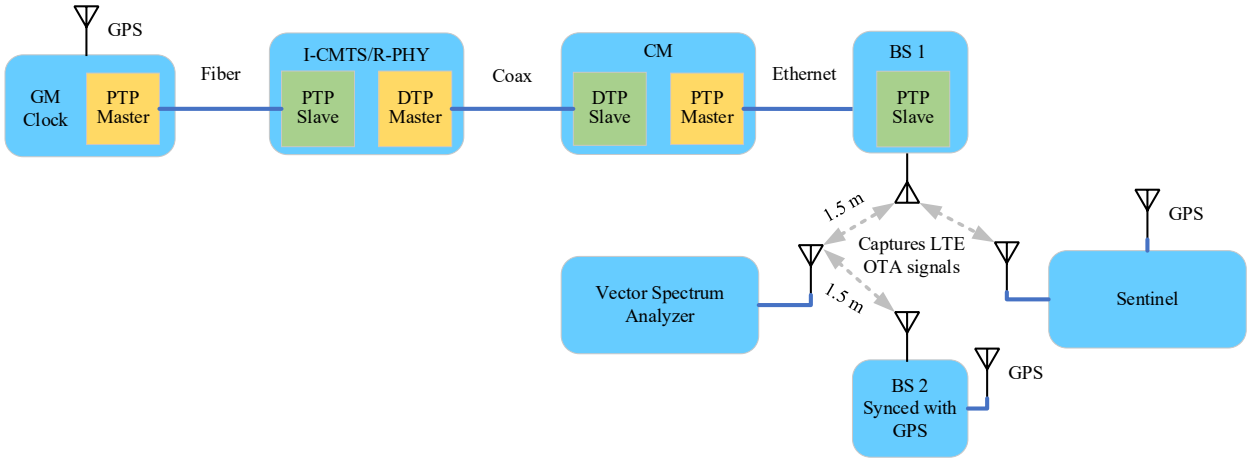

Figure 3 - Block Diagram of LTE OTA Setup

Total TE Budget			1580			1280

with BS1. The two BSs radiate LTE signals over the air. The Calnex Sentinel collects the LTE primary synchronization signal (PSS), the secondary synchronization signal (SSS) and decodes the time of day from the BS1 LTE signal. The Sentinel uses GPS and an internal Rubidium clock as a reference to evaluate the accuracy of LTE timing. The measurement accuracy of the Sentinel is ±100 ns.

A vector spectrum analyzer (VSA) is used as another LTE OTA measurement method. It collects the spectrum of both BS1 and BS2, then converts them to the time domain by an inverse fast Fourier transform (IFFT). Thus, the downlink (DL) time-domain bursts in the TDD LTE signals can be compared. The VSA antenna is equal distance from both BS1 and BS2 antennas. By properly selecting the measurement bandwidth and fast Fourier transform (FFT) size, the VSA measurement accuracy achieved was on the order of tens of ns. The measurement accuracy of the VSA method is constrained by the LTE signal burst uncertainty due to the BS amplifier and local oscillator performance, which can be off by as much as 10 µs. BS1 and BS2 are the same model from the same manufacturer using the same hardware and software, so the relative uncertainty is much smaller than 10 µs. With the VSA method, it is straightforward to check the TDD-LTE signal bursts in the time domain, but it is not a high-accuracy method to judge if the LTE OTA signals meet the 3GPP synchronization requirement.

4.2. Time Error Budget

The TE budget for the LTE OTA setup is listed in Table 4. In comparison to the TE budget for the DTP performance test listed in Table 2, the LTE OTA setup includes extra TE budget for the PRTC and base station. The TE budget for BS1 is 200 ns, and for BS2 it is 300 ns. Since BS2 uses GPS, that introduces an additional 100 ns into the TE budget. Given that the VSA test compares the relative TE between BS1 and BS2, the total TE budget is 1580 ns which is smaller than the 3 µs (air to air) TE budget required by 3GPP specifications. The Sentinel only uses BS1. The total TE budget is 1280 ns which is smaller than the 1.5 µs (air to GPS) TE budget required by 3GPP specifications.

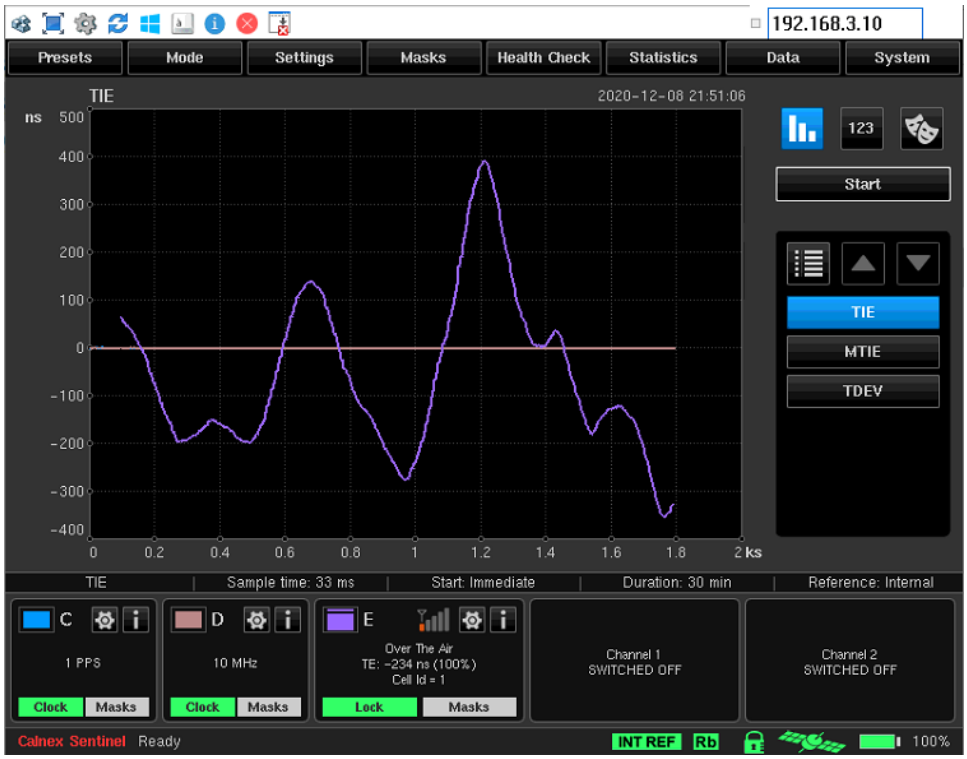

Figure 4 - RPD Sentinel OTA Measurements [9]

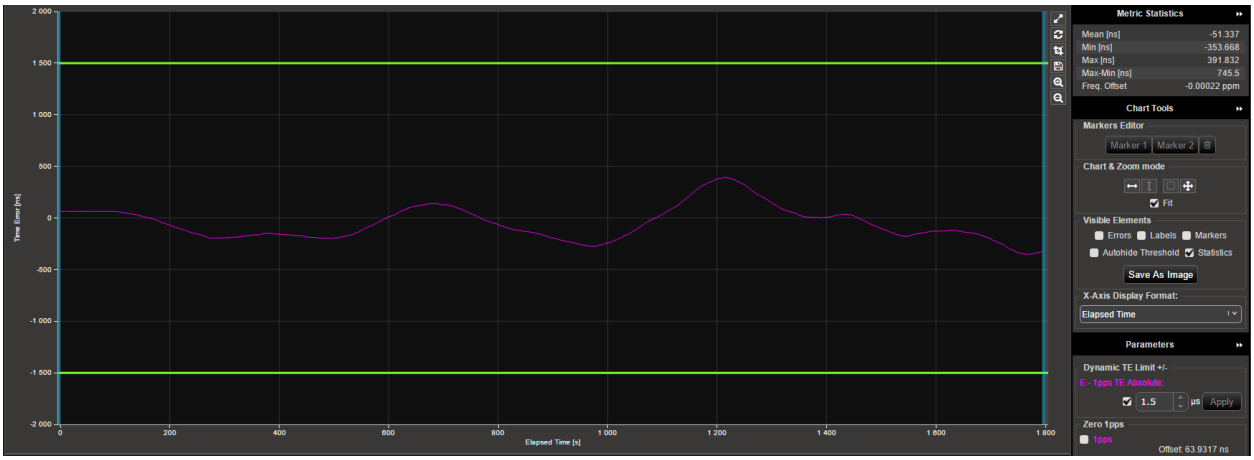

Figure 5 - Sentinel OTA Results [9]

4.1. Sentinel Measurements

The eNodeB (eNB), using DTP in the DOCSIS backhaul, radiates an LTE signal from 3620 to 3630 MHz with a cell ID of 1. Channel E on the Sentinel decodes the time of day on the LTE signal. This time of day is compared with the GPS time of day. Figure 4 shows an example of Sentinel measurement data. The OTA LTE signal TE varies from -354 to 392 ns, with a mean value of -51 ns. Figure 5 shows statistical results that are further processed by the Calnex Analysis Tool (CAT).

Five sets of Sentinel data were collected. Table 4 lists the results. The average LTE signal TE is between -71 and 9 ns. The largest peak-to-peak variation is 746 ns. All the TE results meet the ±1.5 µs 3GPP requirement.

Table 5 - Sentinel OTA Results Summary [9]

Run	Time duration (s)	Two-way Time Error (ns)			
		Mean (cTE)	Max	Min	Max-Min
1	1800	-51	392	-354	746
2	1800	-25	269	-255	524
3	1800	-41	186	-286	472
4	3600	9	159	-107	266
5	3600	-71	131	-332	463

4.2. VSA Measurements

The VSA measures LTE signals in the frequency domain and converts them into the time domain. To avoid mutual interference between the two LTE signals, the two BSs are configured on two separated channels: BS1 uses 3620-3630 MHz and BS2 uses 3690-3700 MHz. The VSA compares LTE signals from BS1 and BS2 in the time domain. As shown in Figure 6, the upper two subfigures (yellow and blue) are the frequency domain magnitude spectrum, and the lower two subfigures (green and red) are the time domain waveforms. The left side two subfigures (yellow and green) are BS1 signals using DTP in the backhaul, and the right side two subfigures (blue and red) are BS2 signals synced to GPS.

Both BS1 and BS2 employ LTE TDD configuration 2 and special subframe configuration 7. The subframe structure of TDD configuration 2 is provided in Figure 7, where D represents downlink, U represents uplink, and S means special subframe. The time duration of each subframe is 1 ms. The special

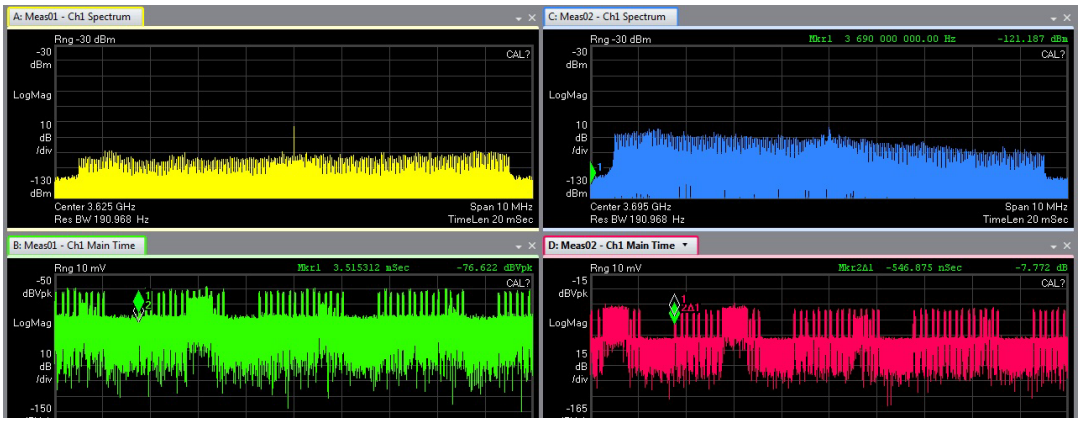

Figure 6 - VSA OTA Results [9]

Subframe number									
0	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**
D	S	U	D	D	D	S	U	D	D

Figure 7 - LTE TDD Configuration 2 Subframe Structure

subframe consists of 14 symbols, where 10 symbols are allocated for the downlink in special subframe configuration 7. So each of the downlink signals should last $3\frac{10}{14}$ ms. There were no UEs in the lab, and no traffic in either the downlink or the uplink during the VSA OTA measurement. BSs only transmit reference signals and control channel information in downlink subframes.

The lower two subfigures in Figure 6 present bursts with a period of 5 ms, each group of bursts lasts for less than 4 ms, which agrees with theoretical TDD LTE downlink signals. Marker 1 is placed on the rising edge of the burst for the BS1 signal (green), and marker 2 is place on the rising edge of the burst for the BS2 signal (red). VSA syncs markers are placed in both channels so that they are comparable. "2Δ1" represents the time difference between markers 1 and 2. 2Δ1 is 529 ns. The relative time error between BS1 and BS2 LTE signals is 529 ns which is much smaller than the required TE budget of 1580 ns as listed in Table 3 and the 3 µs requirement in the 3GPP specifications.

5. Conclusion

DTP is designed to provide accurate synchronization for the backhaul of TDD mobile networks. DTP PoC testing was conducted by CableLabs, Charter, Cisco and Hitron. PoC testing was divided into three phases:

- Phase 1 validates that DTP works in a basic lab environment.
- Phase 2 evaluates DTP performance in sophisticated environments that mimic field deployments.
- Phase 3 verifies automatic DTP calibration in field deployments by using an AWS cloud server to distribute calibration data.

This paper reported up-to-date progress of DTP PoC testing, and key findings in phase 1 testing. The results successfully demonstrated that DTP works in a lab environment. The measured DTP time error results meet the time error budget. Using DTP and PTP in the backhaul, LTE over-the-air signals meet the 3GPP synchronization requirement. DTP is being evaluated in various HFC network configurations. An AWS cloud server is being developed to enable automated DTP calibration.

1. Introduction

It was the summer of 2017, Hamilton was the hottest show on Broadway. Data hungry consumers were straining the network and there was one looming question the Broadband provider couldn't answer: How can I build my existing network to be bigger, better, faster?

In a company built by acquisitions, network construction knowhow was managed by local knowledge, teams and antiquated systems running DOS. The organization was anxious for change. The company had to prepare and scale the next generation of construction to accelerate growth.

Enter a young(ish), scrappy and hungry crew that never spliced cable but needed a job. Management gave them 5 months and bowls of cashews to fuel their mission. Look three years into the future, assess how the birth of a workflow management platform became the center of the construction universe and, in the words of the C level execs resulted in "not too many complaints."

This paper will test a basic hypothesis of organizational change management: do people, process and technology have to move together in the same direction to drive change? It will argue that technology can drive organizational change and it will outline the inputs necessary to do so. It will further demonstrate that a group does not need to "own" the work to transform the work. It will articulate a bold approach to the routines and rituals required for agile technology development to translate into incremental organizational changes. Most importantly, it will challenge its readers to re-think their methods of driving change with construction and design resources in an ever-evolving race to construct the fastest data delivery network.

2. Building a National Tool Started With a Pivot

The first attempt to build a tool was called Polaris, referring to the North Star sailors would use to set their course. Polaris was conceived to set the course for how capital expenditures would be managed to build out network infrastructure. This tool was intended to help standardize the way the enterprise works with 3rd party Business Partners, and to become the source of truth for all construction activity, capital dollars spent, duration and quality of work completed. But after some time and substantial software investment, Polaris was still just an idea – or rather, a conglomeration of ideas collected over time, without any unifying vision or purpose.

While the Organization developed a nationwide infrastructure strategy, its 15 regions had uniquely different ways of managing the day-to-day of it, from walkout surveys to permitting and plant construction. Every region agreed that a national tool could be helpful, but none wanted to change the way they were operating. Regions would commit to getting their teams to use Polaris only if their specific, ever-growing list of features were delivered. In an effort to gain user adoption, the Polaris team had implemented somewhat arbitrary capabilities, based on disparate requests, from the most vocal regional users. The irony is that while trying to build a tool that would work for everyone, they built something that didn't quite work for anyone. The pressure to on-board Regions into Polaris was mounting, but the tool had only a handful of test users and the executive team couldn't get a clear answer on what was needed to launch.

In the summer of 2017, Polaris was handed off to a new software development team, with instructions to "fix it, fast." A technical deep dive yielded the brutal truth: it was not usable. Not even the technical foundation was salvageable. Neither the development team nor potential users seemed to know the answer to the question: what problem are we trying to solve? Without any reusable code, clearly documented requirements in place, or shared vision, the new leadership team recognized that "fixing" Polaris was an impossible task.

Lesson 1: Know When to Pivot

In August, Polaris was shut down. In September, P2 was born. By January 2018, P2 would need to support a Pilot market with an actual workflow. The bold decision to shut down a 3-year effort and task a new team to build a working tool in 4 months' time was the catalyst to *fan this spark into a flame*.

P2 (short for Polaris 2) began with a clear mission in mind: build a national tool that would help manage the flow of construction, with a common set of goals and language.

> Mission Statement: P2 is an enterprise-wide integrated workflow orchestration tool that tracks the progress of all construction job types – providing visibility into status of milestones, accurate cost of each project, the data to build forecasts, and the ability to roll up those metrics to a national view.

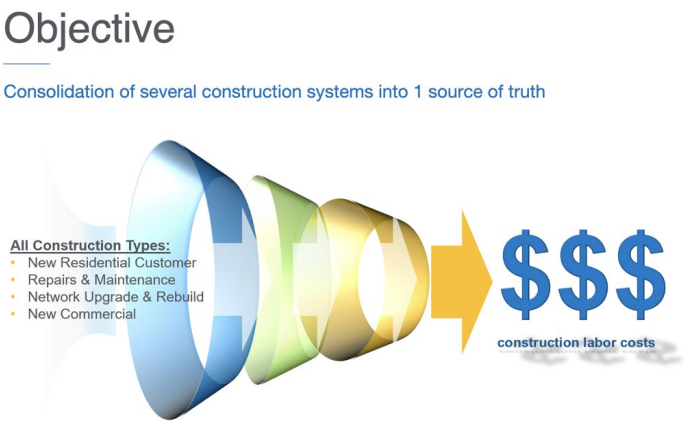

Figure 1: P2 Platform Objective

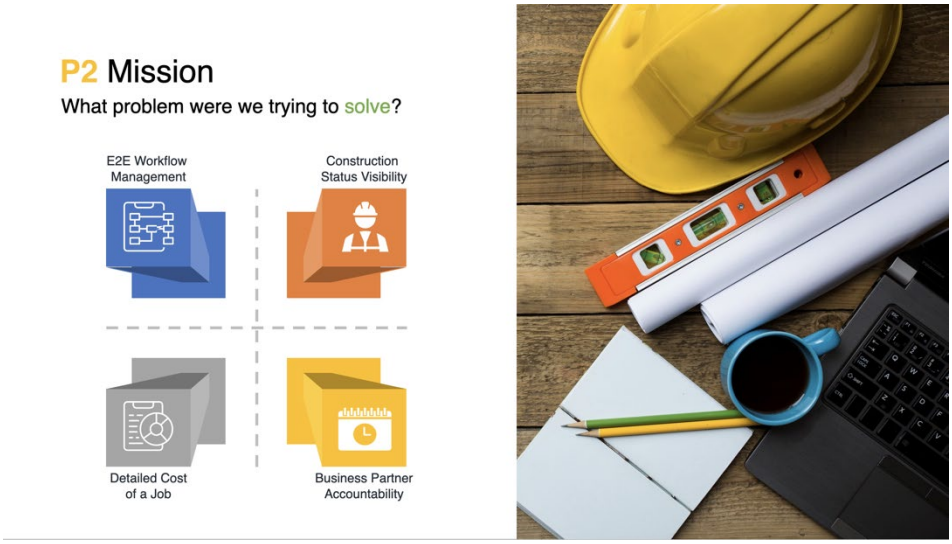

Figure 2: P2 Problem Statement

The plan was to build on that belief shared by all 15 regions that a single tool, that provides a national view of all construction builds, would be useful. But, moving 5,000+ users onto a new standard platform meant that many of the teams across those regions would need to change certain processes and ways of doing things. And change is hard.

Comcast's construction teams had been building out the network for years, which meant they had well established ways of managing phone calls, marked-up paper maps, post-it notes, spreadsheets, and local databases to keep the flow of production moving. In their minds, this insider know-how, sometimes collected over decades, had been optimized for their circumstances. Aerial coax construction to replace a span? Who else could more efficiently complete this build than the guys who pull cable in their towns every day? The original Polaris team struggled to find a meaningful benefit for end users to transition to a new platform; what incentive existed to drive change? With a pivot to P2, there was an opportunity to clearly identify and communicate "the why" and benefits of change.

The "why" was a parallel initiative called Fiber Deep. Comcast was about to deepen its investment in constructing a proactive network upgrade architecture that would increase capacity in the short term and pave a way for growth in the long term. The challenge was that this was a new kind of cable construction that was unfamiliar to many. It was massive in scale, impacted entire geographic areas, and the volume of this type of work was expected to grow with time. As work was increasing, it was clear that phone calls and post-it notes wouldn't be enough to keep these large-scale projects moving on time and budget, and the existing databases couldn't be refactored quickly enough to support this use case. Visibility of related work and automation to speed up data entry or help with calculations were identified as critical needs. The development team realized that building an intuitive way of managing these types of projects in a set of workflows would be compelling enough to persuade users to adopt the tool.

Lesson 2: Talk Less, Smile More… Ask Many Questions

The P2 team set out to build this new tool, that would support a new process, managed by new teams. Given the specific scope (Fiber Deep), but with many unknowns and open questions, it was a perfect situation to apply a *Design Thinking* framework. In Design Thinking, the goal is to use the following process to design a solution:

1. Empathize – to think about the community of people needed to be served, the roles they play, the challenges they'll have and what they'll care about
2. Define – based on their challenges, identify what will that community need, what is a problem that needs to be solved?
3. Ideate – brainstorm to come up with a wide range of ideas to tackle the problem identified
4. Prototype – build a small proof of concept that can be demoed, and that allows user interaction
5. Test – run experiments to test the hypothesis, allow users to engage with the prototypes to validate if the idea really solves the problem

In the months that followed, the P2 Team spent hours, days, weeks with the Construction experts. This was a small team of software developers who didn't know the first thing about construction, but knew how to really listen to people in order to *Empathize, Define,* and *Ideate.* These rich discussions gave the team enough direction to start iterating on a prototype of a single Fiber Deep workflow. During this time together, the P2 Team continuously strove to do two things – 1) show incremental progress, no matter how small, and 2) build trust by always delivering on a commitment and being transparent about the process and any mistakes or missteps. These frequent discussions, small feature demos and iterative development based on their feedback, gave the Regional Construction teams a sense of ownership in the workflow that was being built. By December, the P2 Team had built enough of a workflow framework, and enough advocates, to bring key Regional team members together in Philadelphia to demo the *Prototype* to prep for a January trial.

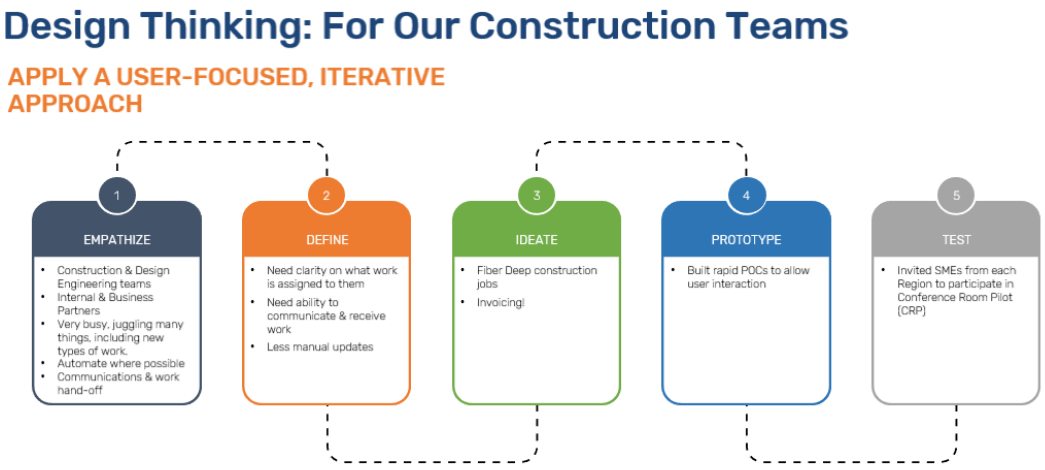

Figure 3: Design Thinking Applied to Construction Workflow

Lesson 3: Build Advocates… *in the Room Where It Happens*

Although constructing Fiber Deep builds involved a new process, a few Regional teams had already begun their projects and had strong opinions about how to implement these outside plant changes. The P2 Team knew that in order for a National tool to succeed, these Regional teams would have to develop a common language and come to an agreement on what really matters when managing these projects. The purpose of this large meeting was not only to demo the prototype, but to have the local experts and decision makers from each Region sit in the same room, debate the controversial topics, but leave with a shared commitment to live with whatever compromise they made. These sessions, which were called *Conference Room Pilots (CRPs)* allowed stakeholders to have a seat at the table, to voice their point of view on construction nomenclature, or the kind of specific attachments a vendor should load when submitting an invoice, and everything else. But, no matter what was debated, a decision was required at the end.

When decisions were needed on topics that reached an impasse, the only way to move forward was to vote. The vote was a sacred ritual, each of the three divisions got two votes, representing their Finance and Construction organization, as well as the voice of their regions. Once a vote was cast, and a decision was made, it was prioritized. Some change requests, like field labels, were quick to change and if a decision was reached in the room, an engineer made the change on the spot. Some requests, like standardizing construction quality audits, were agreed to be important but could be addressed outside of P2 in the short term and added later. Finally, a handful of decisions would require Executive Leadership input prior to implementation.

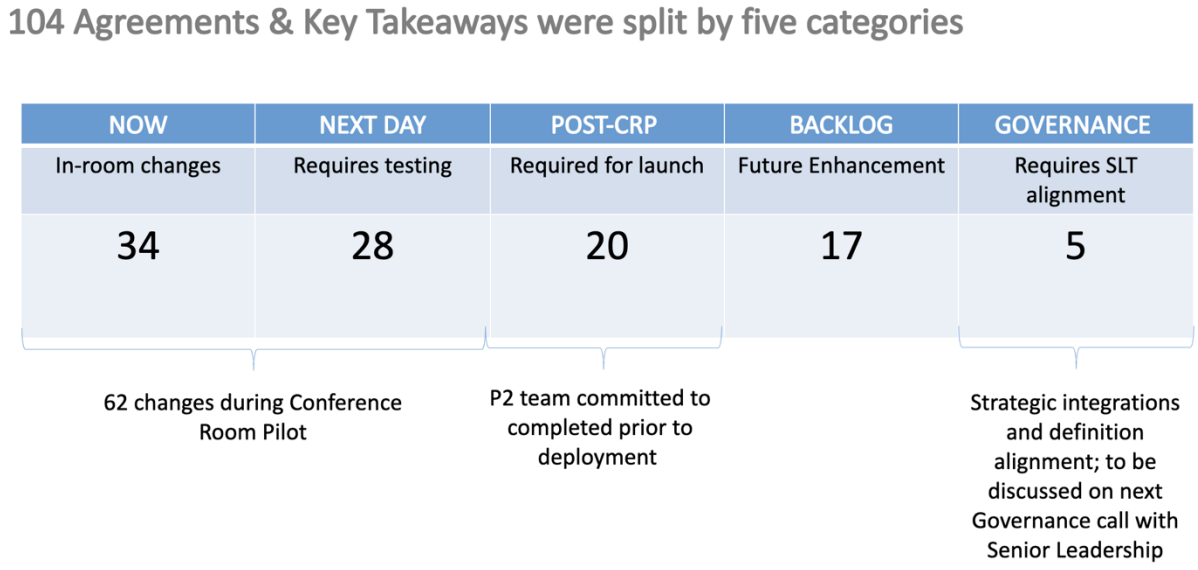

Figure 4: Conference Room Pilot Agreements Output

The Conference Room Pilots gave an opportunity for the people *in the room where it happened* to own the process that was being built into the tool. Debating the topics made their ideas and concerns feel heard, and voting gave them agency, even if the outcome wasn't exactly what they had proposed. As the team closed out on its first of many CRPs to come, they got the commitment from one of the Fiber Deep Project Leads to run a Pilot of the tool in their Region. A Pilot would allow the team to take their prototype and *Test* whether they got the solution right. What many folks did not know is that that in those early days, the P2 Tool only supported one Workflow, in one Region, for one Design Business Partner, and one Construction Business Partner. Yet, it was enough to run a Pilot. In software product development, there is a concept called "MVP," which stands for Minimum Viable Product. Building an MVP workflow, with continuous demos of small incremental progress, and by building trust in local advocates, was enough to prove out the value and benefit of managing Fiber Deep in a single tool. At the launch of the Pilot, the tool still had many gaps in functionality and many unanswered questions about process, but it didn't matter. The development team continued to iterate, develop and deploy new functionality each week, closing these feature gaps in both small and meaningful ways.

The Pilot began with a handful of Users in the production tool and the P2 team talked with them every single day. Users would join each day to let them know which buttons they clicked, which ones they couldn't find, which headers were confusing, and about a plethora of missed requirements. Each Pilot User had the personal cell phone numbers of the product development team. The development team ate feedback from this pilot community for breakfast, lunch and dinner. The P2 team continued to build on the trust and transparency established during the initial engagements. They always fully embraced and encouraged criticism and feedback about the tool, the process, the interactions with the Users. Both internal Construction team members and Business partners trusted the team enough to immediately inform them if a feature wasn't working. They all knew that sharing that feedback, however rough, was the only way to get better.

Lesson 4: ***When You Got Skin in the Game, You Stay in the Game***

As the Pilot continued, additional Regions agreed to come on-board. New requirements were identified with each new project, but decisions were always brought back into weekly calls where all Regional experts had a chance to weigh in and vote. The development team continued to work closely with each new Regional team to understand their challenges and needs, and fix things that weren't working for them. By November of 2018, the P2 Tool had become the national workflow tool for all teams that had Fiber Deep projects to manage. It had grown from 10 Users to about 150 Users across the country, all executing the same construction workflow in in P2.

With the Pilot, and incremental, iterative changes, P2 had managed to drive standardization across 15 Regions using technology to pave the way. Change was starting to happen. But the majority of new build construction workflows still needed to be accounted for. The number of Regional teams, decision makers, feature gaps, process changes needed to support all construction, increased exponentially. The development team continued to leverage the CRP format to quickly *Empathize, Define, Ideate, Prototype,* and *Test* workflow changes needed to support the variety of workflows needed. They spent the final few months of 2018 in a full-blown marathon to develop and deploy all the capabilities needed to manage all construction in P2. Local advocates built over the course of the Pilot evangelized the benefits of the Tool and helped strengthen the call for everyone to transition over to the new way of working.

By 2019, all three Divisions agreed to launch P2 across all their Regions in the first quarter of the year. The transition to National deployment, where all 5000+ Users across every Region and Business Partner were on-boarded to this new platform was not easy. For one Division in particular, adopting P2 meant migrating away from an existing legacy tool that had been in use for over 10 years. But the Construction

teams that had helped to build this tool could see the value of a single platform, and made the commitment to push through the challenges and adapt to the process changes that came along with it.

Lesson 5: "Aim" for "Not Too Many Complaints"

Immediately following the full adoption of the P2 Tool, the development team met with the Cable Division Finance Executives for a progress briefing. As the team gave a demo of the tool and an update about the launches, an Executive remarked – "based on where you are in this process, I haven't received too many complaints." In this meeting, it became clear that one indicator of success was not how many praises P2 received, but that it didn't draw, "too many complaints...." The motto became an anthem.

3. Piloting is Easy, Scaling is Harder

Lesson 6: When You need to Operate at Scale, Process Must Also Be a Product

The successful launch and adoption of the P2 Tool had much to do with the trust that was built between the Users and the development team. Thanks to the frequent touchpoints through the CRPs, daily chats and regular meetings, the Users felt like their needs and requests were always being heard. This feedback loop gave the Users and the development team comfort in knowing there was clarity on the list of problems that needed to be solved, and the path to ideate and validate different approaches. However, as P2 was adopted as the National Construction Tool, the User community grew from 150 to 5,000 users in a matter of weeks. At that scale, personal phone numbers and chat messages to the development team would not work; the product development process needed to maintain that trust and User engagement also needed to evolve.

To that end, the P2 Team added a Product Operations group, whose objective was to build the processes and communications channels needed to support a User community at scale. Rather than have people pick up a phone or send an email, the Product Operations team built out a self-service ecosystem that gave every User a path to look up release notes, FAQs, read documentation, watch training videos, and submit enhancement ideas. CRPs evolved into Product Trials, where the *Test* part of the product development lifecycle now included more structure around how to collect feedback, measure success, and how to troubleshoot issues when something didn't work as expected.

Product operations is critical to ensuring the platform can build with empathy at scale – supporting all Users where they are and giving them an equal voice, even if they don't have the phone number for a member of the product development team.

Lesson 7: *Every Action's an Act of Creation* – The Criticality of Process, Post-Launch

By using software to identify the work being performed, P2 became the center of the construction ecosystem. Technology had fanned the flame of change by bringing all regions together to loosely follow a high-level set of processes. Furthermore, having everyone work in a single tool provided an opportunity to use consistent language to talk about construction activity. The P2 platform provided the foundation to align around one national strategy to deploy a proactive network upgrade architecture. While P2 could provide data on how construction was progressing, it became clear that a governing body was needed to determine how to measure if the enterprise was successful in its implementation and create a forum to adjust policies around process and compliance collectively.

In early 2019, just as P2 was getting deployed nationally, Construction 2.0 (C2.0) was born. Just like P2, Construction 2.0 had a clear mission statement:

> "Construction 2.0 is a construction business operations ecosystem that compliments the strategy of fast, efficient growth through standardization and alignment of roles and responsibilities, processes and procedures, tools and reporting, and performance management."

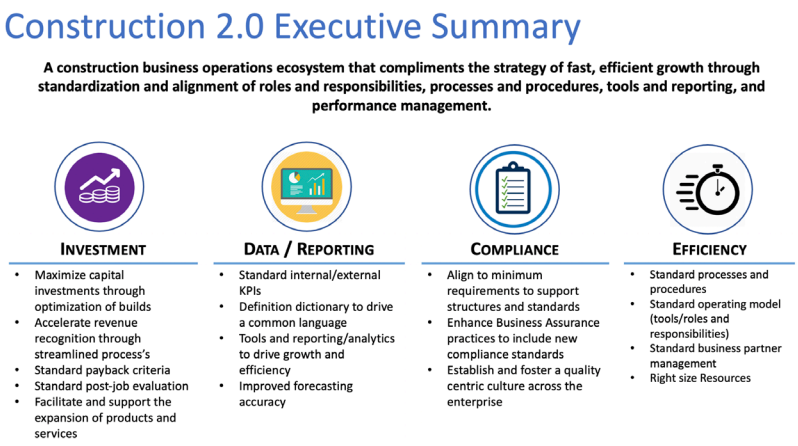

Figure 5: Construction 2.0 Charter

The inaugural C2.0 summit was the first time in the enterprise's history when Regional and Divisional representation came together to prioritize a construction process improvement roadmap and establish and agree on an approach to execution. The summit was the first deliberate step towards organizational sameness.

After the initial summit, the C2.0 team quickly discovered that gaining alignment to process, policies and standards would take a different level of effort to achieve sameness across the enterprise. Rather than starting with a focus on Roles and Title alignment, C 2.0 rationalized that by prioritizing the standardization of processes most critical to the business, those politically stickier issues would naturally follow.

Working teams were established with key Divisional and Regional representation, and facilitated by a member of C2.0. The working sessions were bucketed into four main categories to work through the prioritized list of national process changes and included:

1. Business Partner Process Standards
2. Sales Interaction Process Standards
3. Construction Standards
4. Strategic Software Integrations Standards with other National tools that impact Construction

The P2 Team was brought in if an organizational process change necessitated changes in the tool. This integrated approach allowed C2.0 to marry process and policy decisions back into the existing P2

workflows. For example, in the early development stages of P2, there was general consensus that quality audits were critical to construction workflow but it would require a process change. That process change was managed in the Construction Standards workstream discussions and the P2 team was present to collect requirements for development.

In addition to the working meetings where all the "sausage making" was occurring, governance and update forums were stood up. The Governance meeting facilitated fast alignment, and brought the most important decisions to leadership coming out of the working teams. The update meetings consisted of monthly program calls to keep the broader stakeholders informed and quarterly updates to keep senior leadership in the loop.

The governance structure was critical. Each Division had a voter and a proxy voter for both Construction Ops and Finance to ensure the organization was making well-rounded decisions and created more meaningful meetings; it was consensus driven decision making.

Lesson 8: Make Progress to *Get a Lot Farther by Working a lot Smarter*

At first, the governance decision making process was clunky, and the conversations were spent trying to understand the problem and the solution being solved for, versus making a decision to implement a new national process or standard. To address agility, C2.0 had to change the way it presented recommendations during governance.

To address quicker decisions making monthly Governance forums were limited to one hour and only included two topics: Decisions and Ideation items. For quicker decision making, a "pre-voting" process was implemented. The process involved all governance decisions and supporting documentation to be sent to leadership one week in advance of the meeting. Each division workstream lead was instructed to meet with their leadership on upcoming topics to inform the vote. Each voter would respond to the template via e-mail with their verdict. Anything aligned to pre-governance no longer required discussion, which saved time for topics where alignment was more challenging to garner. The ideation section consisted of strawman proposals to ensure the workstreams were solving the highest priority items with a general identification of the problem that required solving. Once prioritized and ideated, most all of the heavy lifting and debate on process change happened within the workstream teams.

Once decisions were made, several ways to communicate the change were implemented. To support the change management process more locally, a core group of division leads received launch documents. Each document provided pertinent information to support the communication of the change such as background of what is being launched, intended audience and FAQs. Internal stakeholders had access to a standards portal housing national standards and The Construction Hub portal that housed national policies. A Business Partner Portal providing standards and policies for design and construction business partners was also created. Where process changes impacted P2, the Product Operations team would build Job Aids or Awareness documents to summarize impact to P2 Users.

These structures enabled C2.0 to solution quickly, garner the appropriate approval from leadership to implement, disperse information to stakeholders and partner with P2 team as the solution unfolded. This cross-pollination of process and technology allowed C2.0 to care for the most important items in a manner that would yield quick wins in terms of user functionality, tool compliance and overall standardization sameness. It created a formalized way to share best practices and either adopt or augment those practices to fit the enterprise. It pushed the organization towards the sameness in a way that was agile and manageable for the ecosystem to consume.

4. You fought in this war, what was it all for?

Once the entire construction community is in one system, it created fractal changes within the organization. The C2.0 governance forum created a place to assess priority of new system integrations to trigger an action or provide status to other orgs that had interaction with the outside plant design and construction community. Within the 18 months of launch, P2 integrated with other national applications to process:

- Sales orders that required construction plant extension to new customers
- Capacity augmentation work that required outside plant design/construction activities
- Survey requests to determine total cost of construction prior to a customer sales commitment
- Procurement warehouse data to cost out materials required for a construction build
- Purchase order balances ensuring fund availability to complete a build
- Visibility of construction status to all construction activity to anyone in the enterprise
- Maintenance requests requiring outside plant construction resources to address

Three years post the initial pilot, the C2.0 governance process is continuously prioritizing additional integrations to ease communications across the organization.

5. Conclusion

Change is often difficult to accept. When a large organization is facing the need for meaningful change across the enterprise, it can be a challenge to get existing teams on-board to implement them effectively. In more traditional approaches to change management, the people, process and technology need to be fully defined in order to execute the asks. With P2, the team proved that Technology can be used to drive organizational change, even if the organization wasn't ready to answer every process and people related question. By allowing Technology solutions to remain agile, to flex and change to prioritize the highest impact needs of the organization first, you can get people to join the movement. With time, the incremental changes in behavior and process, driven by small, iterative changes in the Technology, will build up to the meaningful change you were striving for.

Using an agile approach, local knowledge can be leveled up and turned into enterprise best practices. This can, in turn, be used to propel the organization towards sameness, and drive compliance of tool usage and standards application. Facilitation of a collaborative approach, fostering a growth mindset, making it safe to fail fast and course correct while in flight can drive consensus and alignment needed to manage change effectively.

As your organization and solutions scale, process becomes more critical to the success of its growth. At a certain inflection point, a more formal process will begin to drive the change, with Technology supporting both. The results of weekly incremental change over a period of three years for the enterprise resulted in an ability to scale the network nationally, in a standard way for years to come.

6. Acknowledgements

The P2 and C2.0 efforts wouldn't have gotten off the ground without the vision, courage and executive decision prowess of Elad Nafshi, Tim Nester, Meena Soleiman, Larry Beauchamp and Doug Czekaj. The P2 platform could never have become a reality if it wasn't for the sheer brilliance, continuous cheerleading, coaching and sponsorship of Bruce Bradley. The P2 platform wouldn't have accelerated its growth and scaled properly without the incredible product operations team, envisioned and led by Chau

Phan. This paper wouldn't have been written without the encouragement of Bob Gaydos. This journey would have been lonely if it wasn't for the friendship the co-authors developed because of it.

1. Introduction

Trillions of gigabytes of data is being generated/captured by devices and network systems, which need to be analyzed and processed. Forbes estimates [1] that in the year of 2025, 150 zettabytes of data will need to be analyzed and processed. Over half of this data is expected to come from the edge of the network (79.4 Zetta bytes by 2025 [2]). The world's most valuable resource is no longer oil, but data [3, 4]. While oil is a limited natural resource which needs to be preserved and conserved. On the contrary data is experiencing explosive growth and showing no signs of slowing down anytime soon. Data need to be managed, processed and analyzed to derive value from it. Conventionally, this data is sent to the centralized systems usually in the cloud for processing, analyzing and deriving insights. It is an enormous task at hand. This method of processing the data incurs significant latency and huge amount transport cost. Which often renders the derived stale insights not useful for most latency sensitive applications.

Edge computing (EC) addresses and mitigates some of these issues. In this paper we look at different aspects of EC, comprising of addressing the latency in data processing, analyzing and deriving insights; architecture, standards and deployment considerations.

2. Motivation For Edge Computing

EC supports placement of compute, storage and other processing resources needed for performing analytics and deriving insights in a given scenario, along a wide spectrum of deployment scenarios ranging from centralized data center to individual devices or somewhere in between either extreme, to address the latency, storage and any special processing needs of a given application or service. The key motivators of EC are latency reduction, enhanced privacy and security, backhaul bandwidth optimization and enabling autonomous decision making at the edge of the networks [5]. This is depicted in Figure 1.

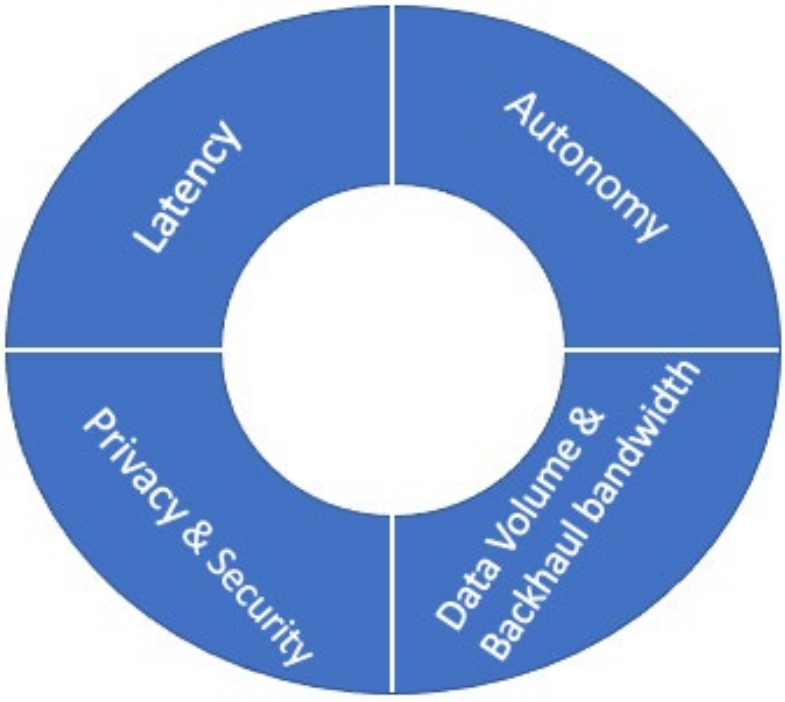

Figure 1 - Key motivators for Edge Computing

2.1. Latency

Zettabytes of data is being generated [2] at the network edge. Often there is a time-critical need to process and analyze these data, derive insights and take actions based on the learnings from these insights. It may not be viable to transfer this data to a central core and wait for the decisions to be made as there may be opportunity costs and safety issues because of this latency. Reducing latency is imperative[9] for many applications in Industry 4.0, healthcare, smart cities, aviation, autonomous driving, enterprises, entertainment, and augmented reality/virtual reality (AR/VR). Data need to be processed with a deterministic latency in a timely manner and EC addresses this critical need. We will look into various EC architectures and deployment scenarios currently being explored in various standards bodies and in the industry at large to meet different latency requirements. The EC enables agile service response and facilitates logic execution closer to the end users and devices both temporally and spatially.

2.2. Privacy & Security

In many centralized data processing scenarios such as cloud-based services, the user and/or device-generated data is transported to the central data center for processing, deriving analytics and taking actions. There are many regulatory requirements to ensure the privacy of the data as to origin, identity of the users/devices, etc. For instance, the energy/water usage reports from individual meters, if associated with an individually identifiable user may impact the privacy and security of this person. Another instance can be getting a count of number of vehicles in a road transport network without sending individually identifiable information about any vehicle or person, aggregating their number per segment/area, deriving analytics and insights to formulate a strategy for optimal traffic management. Further, these regulations vary widely across different sates/counties/municipalities, each requiring compliance with its own set of rules and regulations. This phenomena in not unique to smart cities scenario; it extends to other verticals such as healthcare and enterprises.

EC can act as an intermediary between the user data and centralized servers in the cloud or on premises. The EC can provide the desired anonymity for the sensitive data of the individual devices and users; and aggregate such data to minimize the processing at the central servers and reduce the costs of raw data transportation. It also can facilitate implementation of local rules and policies, and ensure compliance with regulations of the individual administrative domain (cities, healthcare systems, enterprises etc.). Additionally, EC provides autonomy and control often needed by these entities which are responsible for the data generated by users and devices in their respective domains.

2.3. Data Volume And Backhaul Bandwidth

Large, continuous data streams from huge number of devices/end-points can be burdensome on backhaul networks [5]. The overhead associated with the transfer of data from the devices to the central application servers, increases manyfold. Each data point being transported incurs overhead at each of the protocol layers, often these are small amounts of data compared to the transport overhead associated with it. In many instances, applications can benefit from aggregation of these data in edge nodes before being sent to the central servers. For example, a water meter can continuously collect the consumption data, while it probably needs to send them to the central server few times a day to meet the desired application processing needs. In some industrial 4.0 applications, the control may need to be gathered and logged, but may not be need to be reported to central servers for each individual data point. However, any exceptions, such as the temperature of a control unit becoming unusually high and needing immediate attention, may be sent immediately as a high-priority message by the edge node. Also, during normal course of operation, many systems collect large number of data points which are of interest for a short duration, after short life this data may lose it relevance, EC can address processing this type of data effectively. The

EC can act in this manner and conserve bandwidth usage on the backhaul, reduce the transportation costs and decongest the transport network while effectively meeting the application needs.

2.4. Need For Autonomy

Often the regulatory requirements for data autonomy, where the data is generated vary widely. This is the case for smart cities in which each city and local governments are responsible to define the regulation for maintaining the data and ensuring that it is secured. This calls for autonomy to do certain processing locally where the data is generated. Also, many applications in areas such as industry 4.0, need local context aware data processing, which are not suitable for central cloud computing. The EC enables meeting the local processing needs, also facilitates data processing per local policies and compliance with local regulations. The same needs exist in many other verticals, such as hospitality, health care, industry 4.0, enterprises and smart cities.

With the above-mentioned characteristics, EC is an enabler and plays a pivotal role in transitioning from centralized to distributed computing. It also makes it a key component of transition from centralized Industry 3.0 to distributed, data-driven and latency-sensitive Industry 4.0 paradigm. The same can be applicable to many other verticals. It minimizes time-to-insight, time-to-action by an order of magnitude, also minimizes cost-of-insight, in the process enabling timely and effective decision making and opening many new avenues of opportunities.

3. Edge Computing Architecture & Standards

3.1. 3GPP

Figure 2 and Figure 3 [14] provide a reference architecture for supporting EC per 3GPP specifications. The Figure 2 reference architecture depicts 5GS architecture for roaming scenario supporting EC with uplink classifier/branch point (UL CL/BP) support.

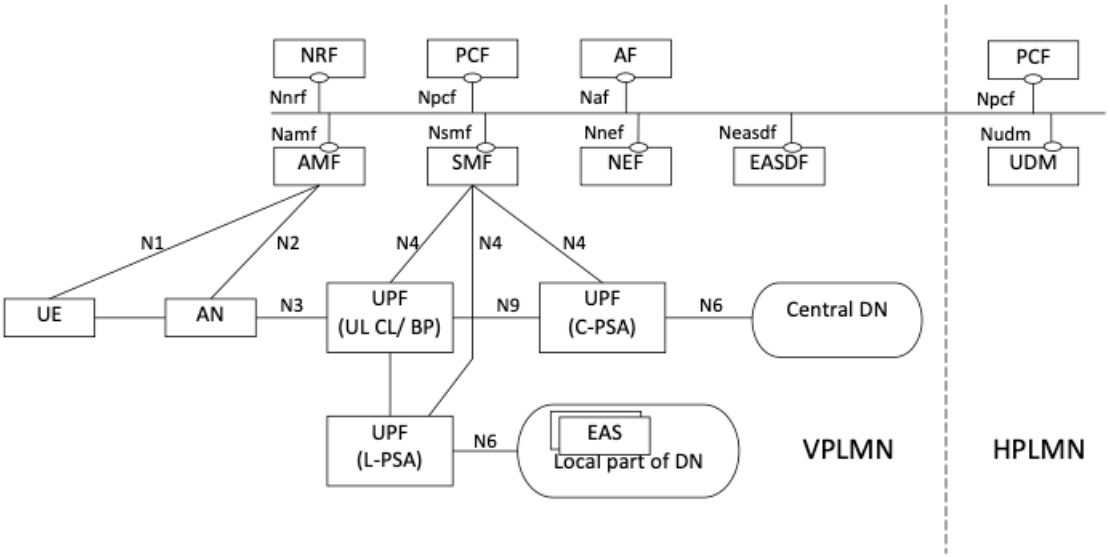

Figure 2 - 3GPP Edge Computing Architecture - Roaming with UL CL/BP

The 5G core per 3GPP standards specifications [14] supports the following connectivity models to enable EC:

- *Distributed anchor point*: For a protocol data unit (PDU) session, the PDU session anchor user plane function (PSA UPF) is in a local site, i.e., close to the UE location. The PSA UPF may be changed due to UE mobility.
- *Session breakout:* A PDU session has a PSA UPF in a central site (C-PSA UPF) and one or more PSA UPF in the local site (L-PSA UPF). The C-PSA UPF provides the IP Anchor Point when UL classifier is used. The EC application traffic is selectively diverted to the L-PSA UPF using UL classifier or multi-homing branching point mechanisms. The L-PSA UPF may be changed due to UE mobility.
- *Multiple PDU sessions:* EC applications use PDU Session(s) with a PSA UPF(s) in local site(s). The rest of applications use PDU session(s) with PSA UPF(s) in the central site(s). Any PSA UPF may be changed due to e.g., UE mobility and using session and service continuity (SSC) mode 3 with multiple PDU Sessions.

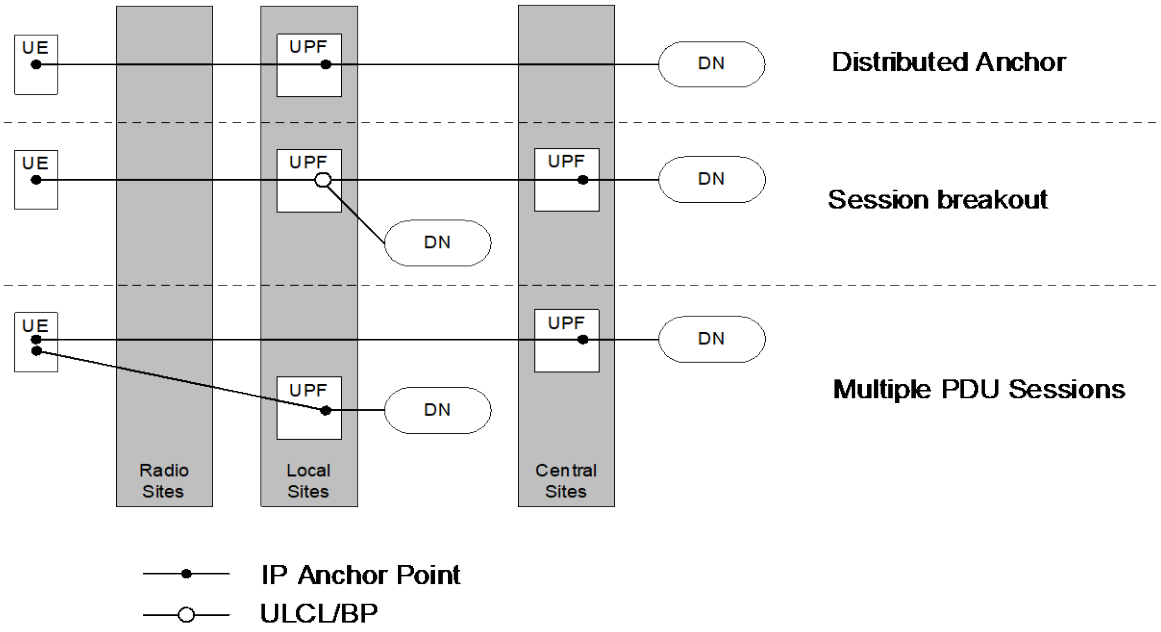

Figure 3 - 3GPP Edge Computing Connectivity Model

The following are some of the salient features of 5GS [14] support for EC:

- Flexible placement of UPFs in the network, which provide IP anchor point or different branch points in the network
- Simultaneous connections to multiple data networks
- Support for multi-homed PDU sessions, using either UL CL or BP
- Enhanced SSC: a connection through a new PDU session anchor point is established before the previous connection is terminated
- The application function (AF) can make a request to influence traffic routing for a given UE

Standardization efforts are currently ongoing for the 3GPP Rel.17 of the specifications [14]. The scope for Rel.17 includes:

- Edge application server (EAS) discovery and re-discovery
- Edge relocation
- Network exposure to EAS
- Support of 3GPP application layer architecture for enabling EC
- Services of EAS discovery function (EASDF) for EAS discovery, DNS etc.

3.2. ETSI

Figure 4 provides the framework of ETSI multi access mobile edge computing (MEC) for the deployment in a network functions virtualization infrastructure and virtualized network functions (NFVI/VNF) environment [15]. MEC offers to application developers and content providers cloud-computing capabilities and an information technology service environment at the edge of the network. MEC is access agnostic, providing flexibility in the operator network; managing different types of sites where the location of the edge will depend on the use case and needed activities to be performed. MEC system incorporates two levels: the MEC host level and system level. The former consists of the MEC host, the platform and the virtualization infrastructure manager, while the latter is composed by the MEC orchestrator, the operations support system.

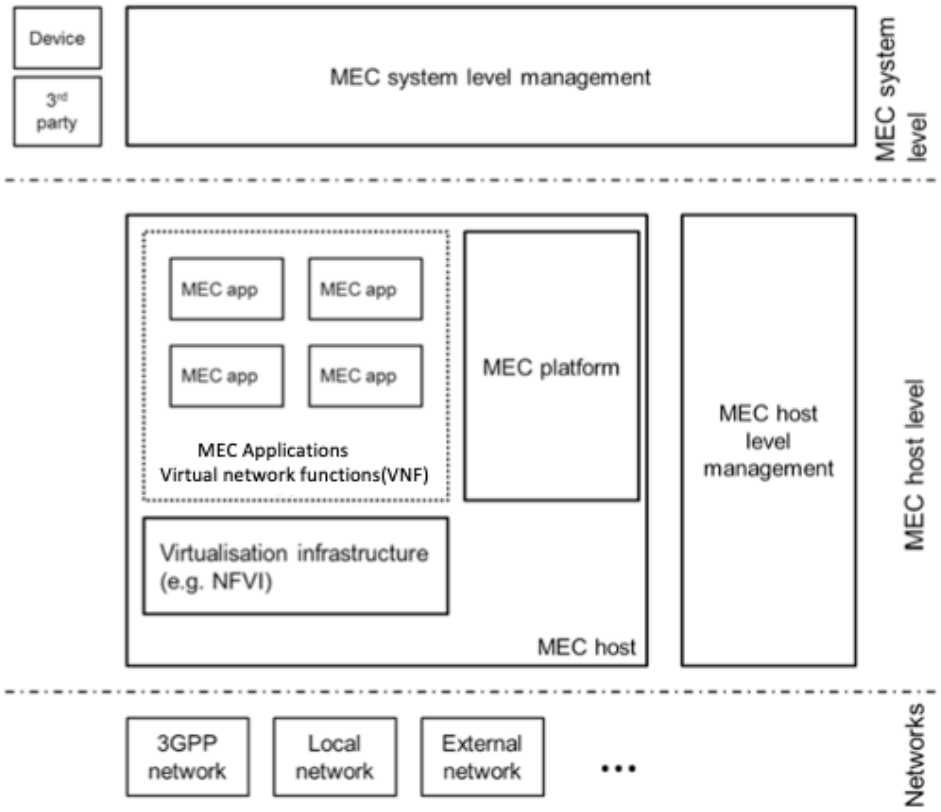

Figure 4 - ETSI Multi Access Edge Computing framework

3.3. IETF

The motto of IETF for beyond edge computing (BEC) methodology is – "Distribute as much as you can, centralized only if you must" [13]. IETF BEC aims to further research and standardize the protocol between multiple BEC gateways, common API across various BEC platforms, user mobility: edge to edge, edge device configuration/management, light-weight virtualization technologies (container/uni-kernel) and local edge security. BEC platform is depicted in Figure 5. The approach here is push the applications and use cases which are latency sensitive towards the edge of the network i.e., edgification of the system. On the other hand, system which scale well, benefit from clustered or centralized processing pushed deeper into the core of the network, i.e., cloudification approach for the system is adapted.

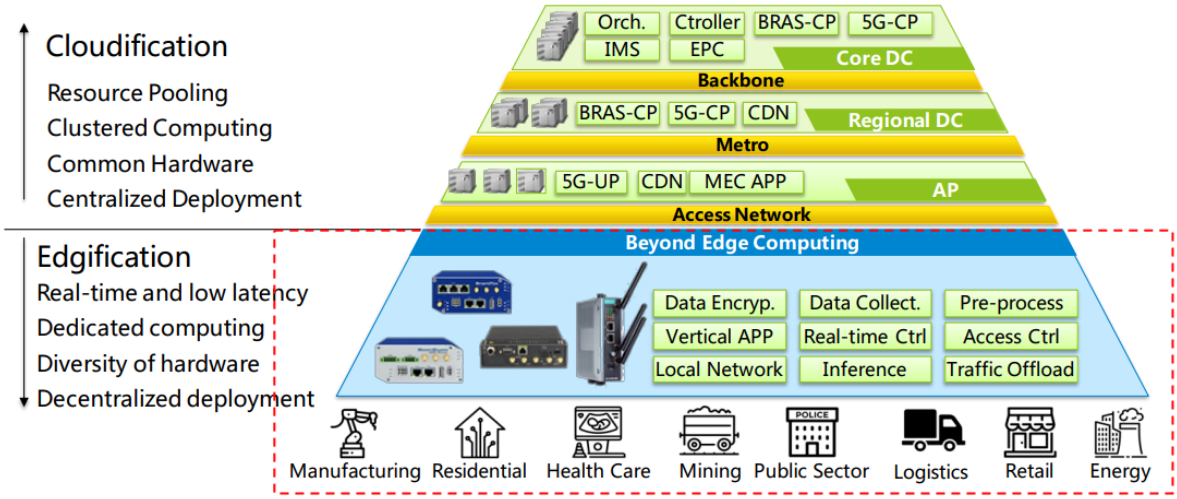

Figure 5 - IETF Beyond Edge Computing

4. Dimensions Of Edge Computing

Figure 6 below (adapted from [10]) depicts different dimensions of EC, the degree of importance these dimensions assume in catering to the needs of different verticals differ. The dimensions of EC are:

- *Time scale/Responsiveness* – real-time, near-real-time, and non-real-time.
- *Communication span* – device-2-device (D2D), device to near edge, device to center of network. How many other entities a given entity interacts with to perform its function, determines the amount of data exchanged and mutual dependence between the systems. Some of the devices may act independently and report their state (e.g., temperature sensors, humidity sensors etc.); while a cooling system may take all this info from multiple sensors and coordinate with coolant, fans etc. to achieve desired temperature control. Similarly, traffic sensors and traffic control systems act in tandem but with different degrees communication span.
- *Degree of control/autonomy* – fully autonomous entities which act independently based on local info such robotics systems, connected vehicles etc.; Systems with some autonomy and local decision making based on predefined policies and rules; and centrally controlled system which collect the data and report to central system and act as per instructions from central system.
- *Location* – immediate vicinity/local/confined to the entity, regional and global. The sphere of influence of a given entity in performing its function.

To this end while connected vehicle, critical healthcare, Industry 4.0 equipment may need real-time responsiveness together with a large degree of autonomy to respond to changes, other applications such as traffic control systems may function well with near real-time response and regionally coordinated control, some enterprise applications may be processed with centralized services as to the response time and processing needs. A given EC deployment for specific requirement need to be tuned based on the processing needs, need for autonomy, sensitivity to response times and specificity for location.

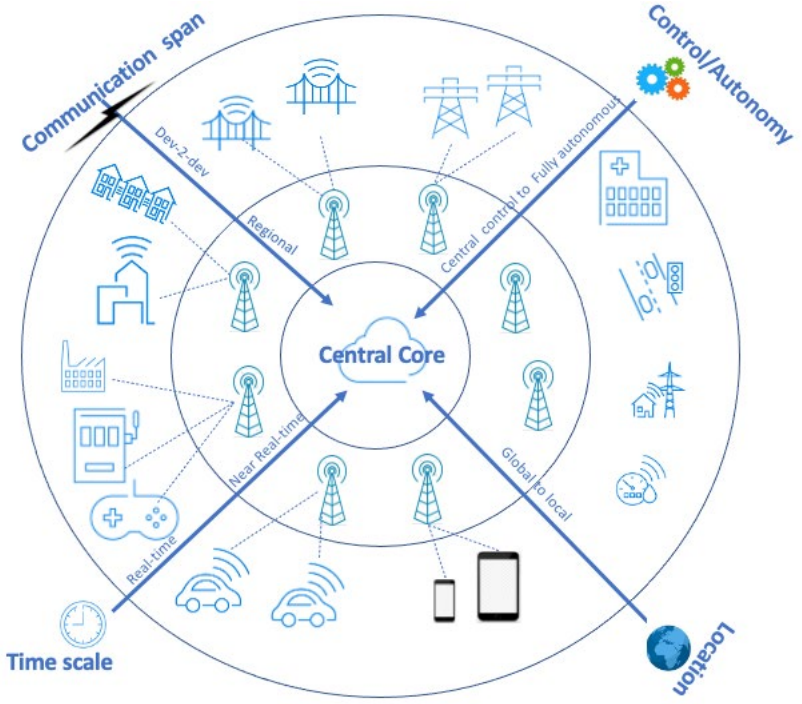

Figure 6 - Verticals that may benefit from Edge Computing

5. Edge Computing Continuum

EC is the key technology, that can support innovative services for a wide ecosystem, stakeholders for EC range from operators, infrastructure providers, application and content providers in the continuum as depicted below. It can span a variety of network locations, form factors, network, and application functions. Centralized computing is performed deeper into the network possibly in the cloud if it suits a given application, and is often used for latency tolerant bulk processing for large number of users. In contrast for latency sensitive tasks requiring some autonomy and local decision-making EC works better. In EC storage and analytics of data is performed closer to end users and devices, in close proximity to where such data is generated. This may differ for different applications, sometimes for the same application there may be multiple points of EC for different types of data in the continuum of the EC depicted above. The 3GPP and ETSI architectures depicted in Figures 2-3-4 enable realization of any combination of this as needed for an application, service or enterprise use case such as industrial control, healthcare, hospitality industry, video analytics, smart city functions, AR/VR/XR applications. Figure 7 describes the EC continuum based on latency and processing needs, assumes ultra reliable low latency communication (URLLC) for access network.

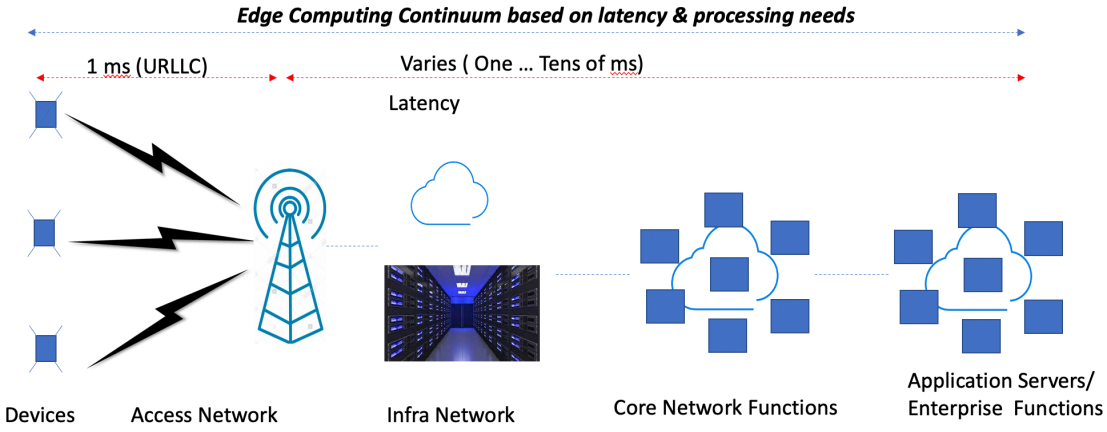

Figure 7 - Edge Computing Continuum

The spatial and temporal proximity needs between devices and application services and systems offering these services is determined by the characteristics of the services under consideration. These include real-time responsiveness, mobility, interactivity, criticality of the function (Industry 4.0, healthcare etc.). These characteristics together with the costs and affordability of a given solution shall largely influence EC deployment in the continuum depicted above. The Figure 8 adapted from [5] depicts continuum of EC from physical end point to central data center, and potential ways to instantiate and scale these. For instance, the edge instances from physical endpoint through compute edge may be singular nodes, the edge deployment from local data center through central cloud could be a cluster of nodes or cloud, based on resource needs and cost considerations.

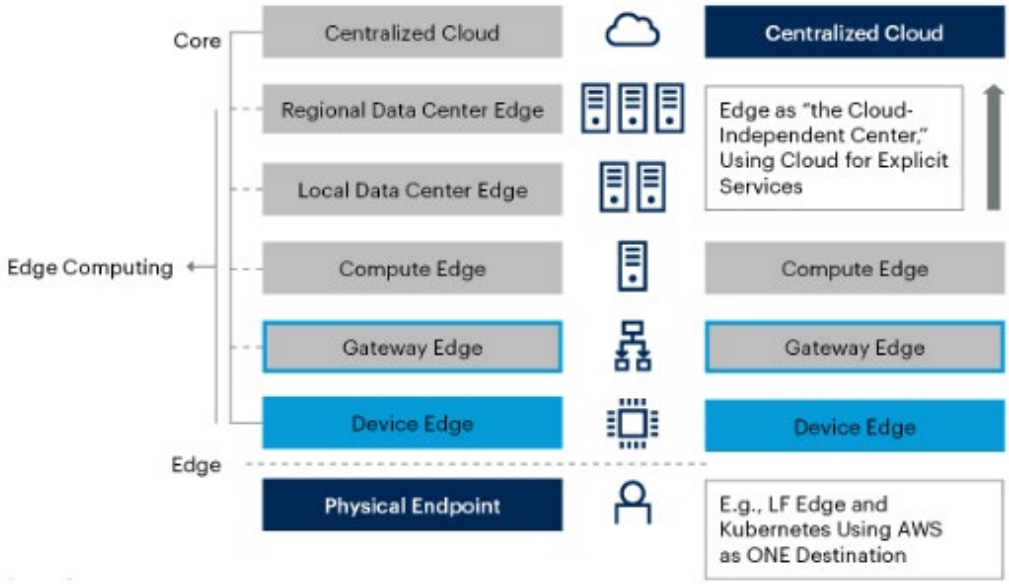

Figure 8 - Edge Deployment Continuum

The original vision for EC is to provide compute and storage resources closer to the user in open standards and in a ubiquitous manner [11,12]. EC is a crucial computing paradigm for multiple verticals IoT, AR/VR/XR, Industry 4.0, and smart cities. The basic characteristics of EC, compute, storage and latency vary widely among these verticals. The specifications from standards bodies like 3GPP and solution offerings from service providers and equipment vendors also have evolved to fulfill these needs. EC specifications from 3GPP currently can support positioning of multiple instances of UPF function at different points network to address latency and data processing needs. Similarly, solutions from vendors provide edge cloud services (e.g., AWS outpost, Azure edge etc.) and standalone servers conducive for EC from many providers.

6. Analytics And Intelligence At The Edge

There is a huge amount of data being generated by the large number of devices connected to the network both through wired and wireless networks. This data is often transported to the central core for processing, analysis and to discern insights and act on them. Often due to the latency of the transport networks and delay in processing, the full potential of this data remains untapped. Therefore, the processing of this data at the edge of the network using various analytics and deep learning (DL) techniques enables deriving insights performing timely actions to realize the value.

Edge computing enables incorporation of DL analytics technology such as computer vision (CV) – in a parking lot to detect expiry of parking duration for a car, to detect availability of parking spot, and natural language processing (NLP) – to provide context sensitive localized information about certain operations. EC can also be beneficial to many applications such as AR/VR/XR, gaming, Industry 4.0 applications, smart cities, health care and hospitality are only to name a few. Incorporation of DL into edge is a huge enabler, can make it possible many previously not feasible applications and use cases, also enhance the quality of experience for existing applications e.g., online gaming.

To realize this potential, there needs to be a match between the capability of the EC nodes, and services, DL processing needs and adequacy of the offered accuracy, latency, energy, memory footprint [9]. The available processing power, energy (battery powered devices/small nodes) and memory in the EC are often the bottleneck. Some of them can be addressed by training the models in a central location in the cloud doing much of the heavy lifting and deploying the trained models at the edge to process the locally generated data and derive insights. The key is tailoring the EC resource and DL models to match one another and meet the needs of the applications. 3GPP has intimated an effort for analytics and machine learning based insights using a federated learning (FL) model, which can potentially fulfill some of these needs.

7. Edge Orchestration And Deployment

EC imposes a few unique challenges to orchestration. Namely:

- *Resource constraints:* resources such as power (e.g., battery powered edge devices/systems), CPU, storage may be severely constrained at the edge
- *Scale:* the number of edge instances may be large, ensuring consistency and coherence across several instances may be difficult
- *Autonomy:* due to resource constraints and loss of communication may necessitate autonomous operation at the edge for extended periods of time

The degree of importance of above-mentioned factors needs to be taken into account in orchestration and deployment of an EC instance. The leading orchestration tools (OpenStack, Kubernetes, ONAP) are

currently focusing on large scale cloud deployments, some these are being adapted for edge orchestration and are still evolving.

ETSI MEC deployment model [16] allows EC to be accessible to a wide range of mobile devices with reduced latency. Figure 9 below depicts, how to make the edge services accessible to large number of devices even when the devices' current access network does not offer the service. While the device during its mobility reaches the target network, which does not offer the application services previously availed by the device, as depicted in Figure 9-II (b) the target MEC host can reach to the application services in prior serving network or alternatively as depicted in Figure9-II (c) the UPF in the target network can reach the application server through the UPF in the prior serving network.

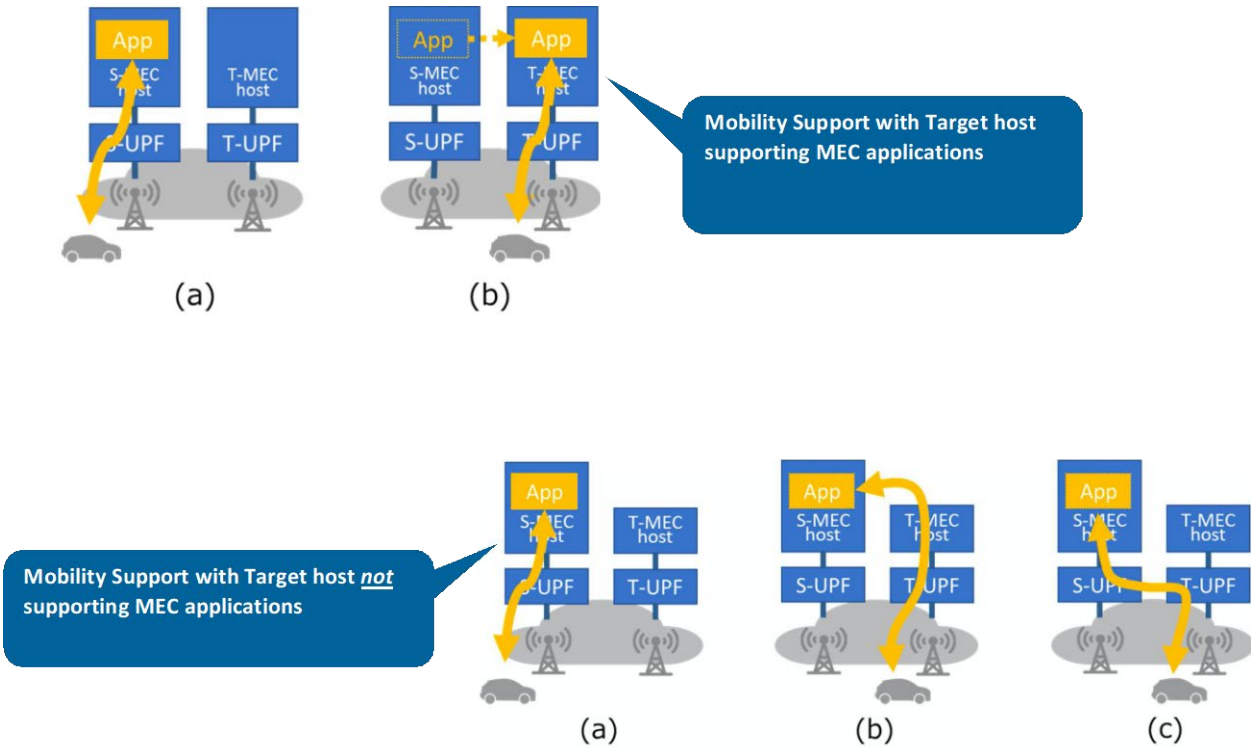

Figure 9 I & II - ETSI MEC Deployment

8. Conclusion

In the last few years significant strides have been made in enhancing the EC architecture, yet there is a need for more improvement. Currently some of EC efforts appear to be in specific silos marked for specific applications, software stacks, sources of data being used, specific cloud and network service providers. This fragmentation across different silos, service providers and multitude of software stacks constrain the stakeholders from realizing the full potential of EC. There is a need for holistic integration of these diverse domains through standardization, industry alliances and market forces. Some of it is being addressed in various standards bodies such as 3GPP, ETSI, IETF and various industry alliances and projects (MANO, ONAP, Kubernetes, etc.). It is imperative on all the stake holders to harmonize and accelerate these efforts across different standards bodies and industry alliances to realize the full potential of EC. EC is already delivering on its promise by significantly optimizing on time-to-insight, time-to-action and cost-of-insight, in the process enabling timely and effective decision making and opening new avenues of opportunities.

1. Introduction

Established MPEG-2 TS based video workflows have been used for distributing content in traditional consumer delivery ecosystems such as QAM-based cable, satellite, ABR Streaming, as well as over-the-air broadcast. With the advent of adaptive streaming technologies such as MPEG DASH and Apple® HLS, these same content video workflows have been adapted to these new types of video distribution. With that said, manual workarounds are often needed to fit in the new features enabled by adaptive streaming. Thus, the ABR distribution workflows may still depend on MPEG-2 TS source content delivery systems for several years due to existing equipment and network tools, and the need to provide traditional QAM linear services [4]. It is expected that backend systems of MVPDs will change as third-party content contribution and demultiplexed media component delivery becomes more widely used.

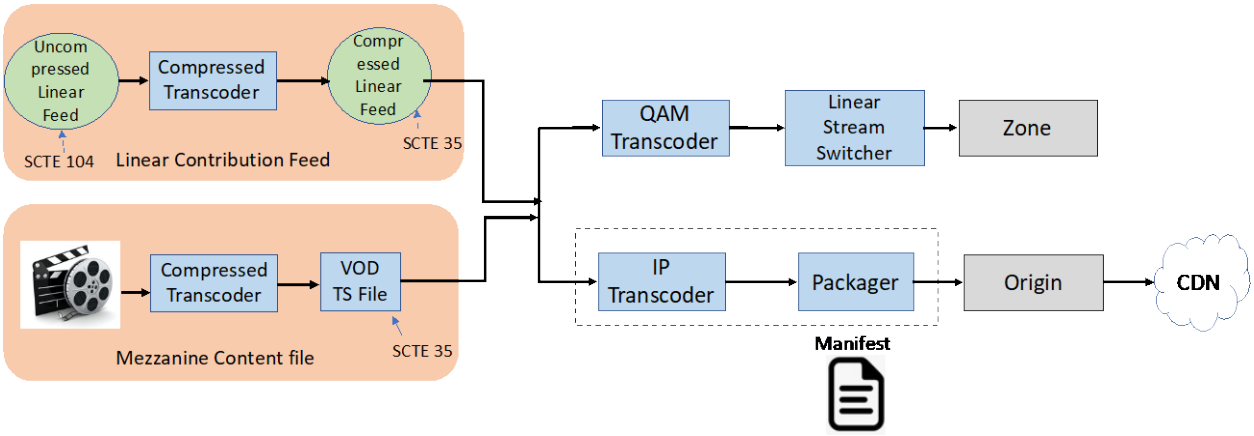

Figure 1 – Source Content workflows for contribution linear feeds and mezzanine files to distribution ABR Streaming and QAM services

This paper describes new mechanisms in existing structures added, proposed or planned in the MPEG-2 Systems (ISO/IEC 13818-1 8th ed) [9], SCTE 214 (DASH constraints) [3]. These additions to existing specifications can then be used in adapting the infrastructure to allow for better automation in mapping of source content into DASH structures for distribution of ABR streaming services.

2. Problem Statement

Between providing MPEG-2 TS source content to the MVPD through traditional source linear channels or VOD mezzanine files and then transcoding/packaging/ and distributing that content for adaptive streaming services, there is no clear mapping from source to distribution that can adjust to source content variations and automate this into adaptive streaming services while providing DASH-enabled, enhanced consumer experiences to the content.

Adaptive Streaming technologies can provide a more individualized customer experience for an asset with choices to match accessibility, language, commentary choices of the viewer. With that said, this is predicated on media content being identifiable and available for these purposes. For example, a selection of English, Spanish, French, and Chinese subtitles assumes that the player is aware of their existence, while a good user experience also depends on a sensible default client behavior. The contribution video ingest infrastructure for video feeds or VOD mezzanine is still operating on an MPEG-2 TS format, be it via fiber, satellite, or IP using TS-over-UDP, SRT, or RIST delivery protocols.

The MPEG-2 TS structure is more geared towards ingestion for QAM-based linear channels and VOD assets where language offerings are more static and limited to 1-2 choices which are determined by hard-coded PID convention ordering (e.g.,101- English, 102-Spanish). Automatically mapping these existing methods over to DASH Role and Accessibility constructs would limit players to static configuration of the channel or the VOD Asset unless a assets specific specialized workaround is done [4]. Additionally, accessibility services such as Audio Description (AD)/ Descriptive Video Services (DVS) are gaining popularity [10]. Initially accessibility tracks were represented using the same hard-coded audio PID construct and often signaling dead or archaic languages (e.g. Middle English) was needed to distinguish between these and the secondary language. Automatically mapping such a setup into DASH constructs is predominantly a manual process because the orthogonality between language and accessibility characteristics of audio streams were determined through PID numbering conventions and overloaded use of the ISO_639 language codes carried in the audio descriptor in the PMT. Often accessibility features would differ program by program on the channel which would require manual per-channel configuration which is usually limited to be a channel configuration instead of a program configuration. Moreover, this approach does not scale.

Lastly, the consumer experience from switching from a main program to an ad needs to be consistent. Achieving consistency becomes harder as the number of player options increase. Similarly, ads also need the same information for smooth playback experience. At the streaming player, another factor needed is the default playback mode set by the customer [10]. Once the player default playback information is known, the switching behavior between the main program and ad, and the playback behavior, can be deterministic and consistent even if the content experience between the main program and the ad do not overlap. But the current mechanisms cannot carry this information dynamically so it can change program to program. An understanding of the content experience offerings in the main program and the default consumer experience of the main program is needed to provide a deterministic behavior for the customer experience as the program moves into an ad or alternate content situation.

3. Latest additions to the MPEG-2 TS language descriptor

The MPEG-2 TS specification contains an ISO_639_language descriptor which has a three-character ISO 639-2 field for the language and an 8-bit audio_type field. [9][15].The descriptor resides in the PMT section. This information can change every PMT occurrence but should be limited to program boundary changes. The descriptor can add multiple table entry pairs of ISO 639-2 languages codes and audio_type codes, but current usage anticipates a single language-audio_type pair. In earlier editions of the MPEG-2 Systems standard, the audio_type codes were limited to accessibility roles -- visually impaired commentary (0x03), hearing impaired (0x02), clean effects (0x01), in addition to undefined (0x00) used for all other audio roles. In past common usage, a single occurrence of the language was used but the audio_type was limited to the undefined values [9][15]. If there was further need to define the audio, the bsmod descriptor values were used but were limited to specific types of Audio formats. These were tolerable in QAM delivery but become more of an issue with multiple different audio formats needing to be carried in adaptive streaming environments [3].

With the 8th Edition of ISO/IEC 13818-1, the structure of the ISO_639_language descriptor was not changed as it is ubiquitously used throughout the ecosystem. However, more values were added to the audio_type table [9]. The resulting efforts provide a clearer approach to map information from the MPEG-2 Stream into DASH values for audio services and accessibility associated services.

Table 1 – Mapping source audio_type values or bsmod descriptors (for (E)AC3) to Role and Accesibility values for audio services

Source Audio_type or bsmod descriptor	Role@value	Accessibility@value
Audio default (audio_type = 0x00 | bsmod [ST] = 000)	Main	N/A
Clean effects (audio_type = 0x01 | bsmod [ST] = 001)	SCTE: Music & Effects	N/A
Primary Audio (audio_type = 0x80)	main[i]	N/A
Native Audio (audio_type = 0x81)	absence of dub	N/A
Emergency (audio_type = 0x82 | bsmod [ST] = 110)	Emergency	N/A
Primary Commentary (audio_type = 0x83 | bsmod [ST] = 101)	main[ii], commentary	N/A
Alternate Commentary (audio_type = 0x84)	alternate, commentary	N/A
Bsmod [ST] = 100 or 111	TBD	N/A

Table 2 – Mapping source audio_type values or bsmod descriptors (for (E)AC3) to Role and Accesibility values for accessibility associated services

Type	Role@value	Accessibility@value
Audio description (audio_type = 0x03 | bsmod [ST] = 010)	alternate	description
Clean audio (audio_type = 0x02 | bsmod [ST] = 011)	alternate	enhanced-audio-intelligibility
Closed Captions[1]	main	captions
Sign language[2]	supplementary	sign

Tables 1 and 2, above, exemplify how one can map the signaling in the MPEG-2 TS mezzanine to the DASH Role or Accessibility values in the DASH MPD for consumer delivery. A similar mapping can be constructed for HLS which uses a different vocabulary for the purpose. It is also possible to map the bsmod values in (E-)AC-3 bitstreams to the DASH constructs if the information is not provided through the ISO_639_language descriptor. AAC provides functionally similar accessibility parameters. Given a basic pair of language code and Audio_type (set to undefined), this would allow the manifest to define a main role for each audio component using a specific language. With the addition of multiple pairs of Language-Audio_types, these same media components could also additionally define the stream as containing AD/ DVS. The tables provide a reference to automatically map what is listed on the transport stream, to role and accessibility assignments in the manifest. To be noted, this mapping in Table 1 and Table 2 is compatible with the role assignments and accessibility assignments of DVB in areas where these configurations overlap [7].

[1] Closed captioning is an accessibility component for a video or text track indicated by the caption service descriptor in the PSI. The equivalent audio_type value would be 0x00

[2] Sign language is identified through the @lang attribute (e.g. “ase” or “bfi”, as defined in ISO 639-3). The proper audio_type value would be 0x00.

In the 8th edition, the audio_type now has additional values of *primary, native, emergency, primary commentary, and alternate commentary*. With these additional values and the use of multiple language-audio_type pairs, there is even more that can be automatically transformed into DASH contexts [9]. For instance, using an audio_type value of "native" can distinguish between original and dubbed audio tracks in a manner that can be automatically processed. With the use of primary and alternate content, a sporting event could have more than one announcer, or just stadium sound, depending on the preference of the listener. In VOD assets, the number of audio experience choices can keep growing but with some direct mapping these can be automatically captured within a single manifest. But even for linear channels, these additional values for audio_type can be beneficial to indicate things like sporting event, native audio, emergency channel audio, and primary audio of the channel. Furthermore, additional information on the audio tracks can benefit DASH constructs by providing a way to have continuous audio media components in the created period, through avoiding overloading of the ISO 639 language value to additionally indicate audio streams with properties like audio description.

Figure 2 and Figure 3 show how the MPEG-2 TS language descriptor values could be set to dynamically provide several playouts, for both linear channels and mezzanine files. These can vary from program to program on a linear channel, or asset to asset on VOD services, so the customer experience offerings can be tailored to the content as well as the experience. For VOD services, there are fewer limitations on customer experiences. The number of languages allowed, for instance, can make a content asset more worldly. Distinguishing between dubbed and native sound, and additional accessibility options, can enable people to hear dialogue more clearly. This benefits both the hard of hearing, and people wanting to watch loud action movies at 2am without disturbing the rest of the family.

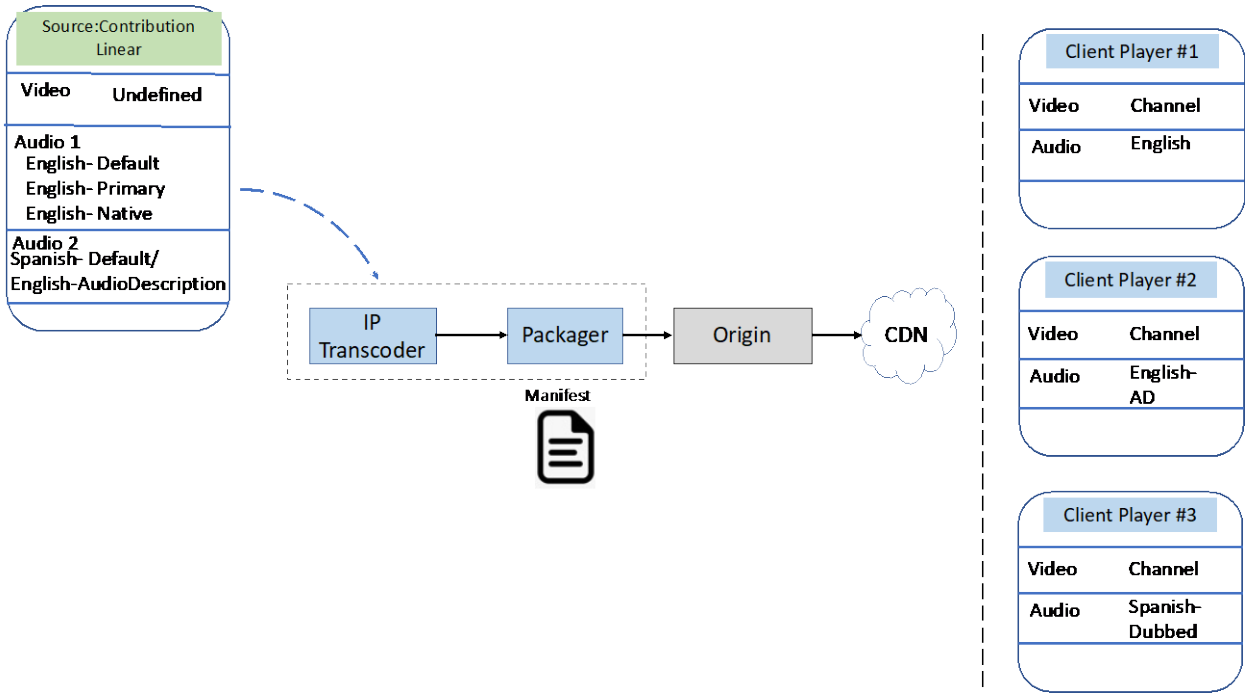

Figure 2 – Example of contribution feed configuration and resulting player options

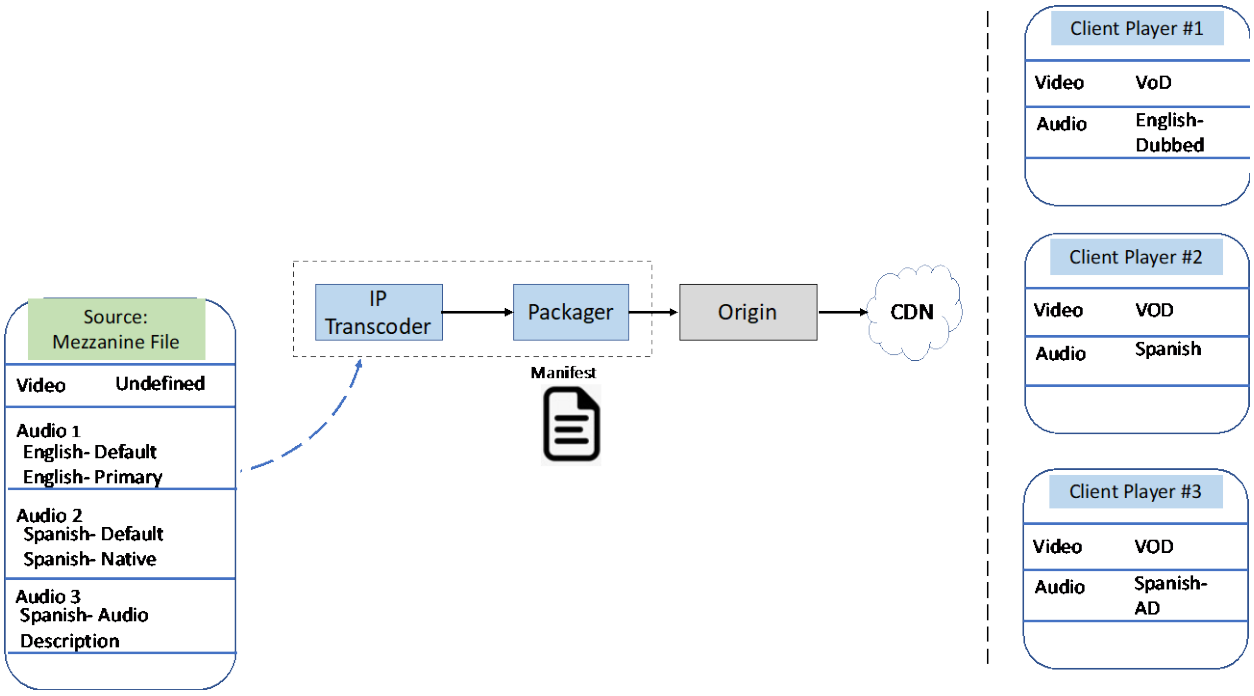

Figure 3 – Example of mezzanine file configuration and resulting player options

Figure 4 shows how the audio_type values can be set to handle different customer experiences for a sporting event. In this case, a sporting event can be offered with two different announcers, or just ambient stadium sound. This can be tailored to use cases like supporting a home announcer and an away announcer (including using different languages), or none at all, or including 3rd party commentary during a sporting event. For example, sourcing comedians for color commentary on sporting events is increasingly popular, as evidenced by the Olympic games.

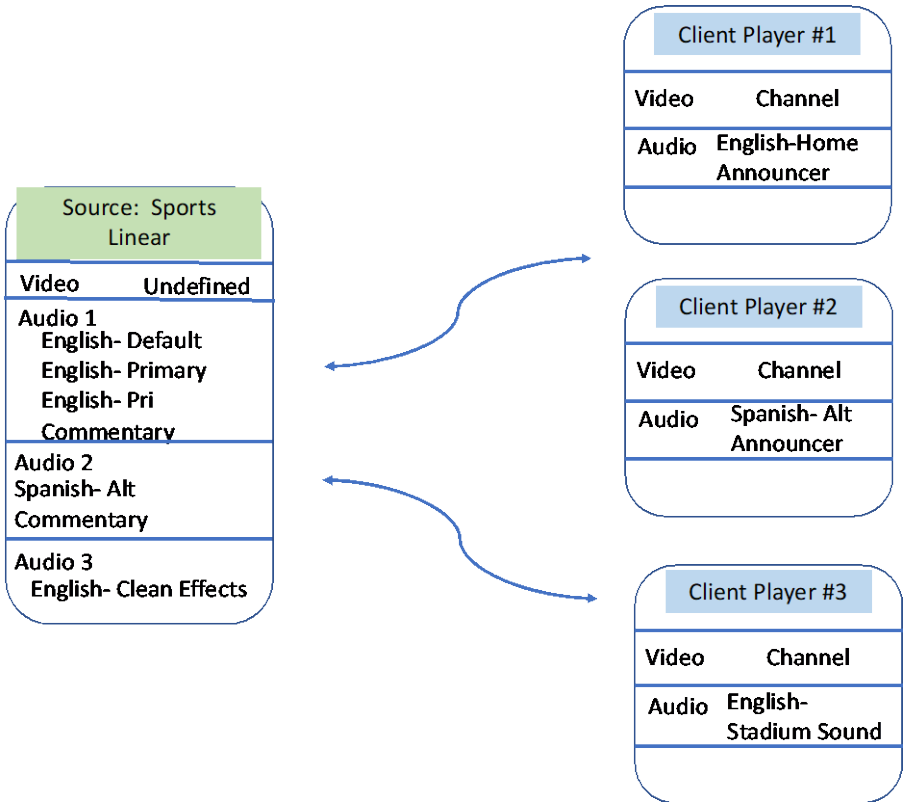

Figure 4 – Sport event contribution feed configuration and resulting player options

4. Using planned modifications to SCTE 214-1

The upcoming SCTE 214-1 revisions have proposed a supplemental property for media language defaults. From a DASH perspective, the player can set consumer preferences for media languages. The NorDig IRD specification provides an example of such logic [16]. From the content side, there was also a media language default that can be indicated in the ISO-639_language descriptor through assigning an audio_type *primary* value, but there is no way to reflect this in the DASH manifest until the media language default supplemental property was proposed. Knowledge of this information helps ad insertion where the language options may not exactly match the main content primary languages. With expanded choices in languages for the content asset, the playout experience can be disruptive between the main program and the 3rd party ad (e.g., switching from French main program to a Spanish ad) and inconsistent depending on implementation. With the primary language of the channel known, this can allow for deterministic ways to map to the customer experience at the client player. Even with an assigned language default language option at the player side, this information is useful especially when no languages overlap -- which can happen during an ad since the ad is independently prepared from the program or asset content. This supplemental property can be placed at the MPD level to indicate language default of the entire content, or provide a language default at the period level, which can override what is set at the MPD level. This supplemental property can also be indicated at a period level as well to indicate in cases of inserted ads what default language to use especially if there is no overlap with the main program [1][2]. From an automation perspective, providing this language default information in the manifest allows an

approach that provides consistent and deterministic playout behavior for the customer experience, even across main program and alternate content such as Ads. Examples of this are shown in Figure 5.

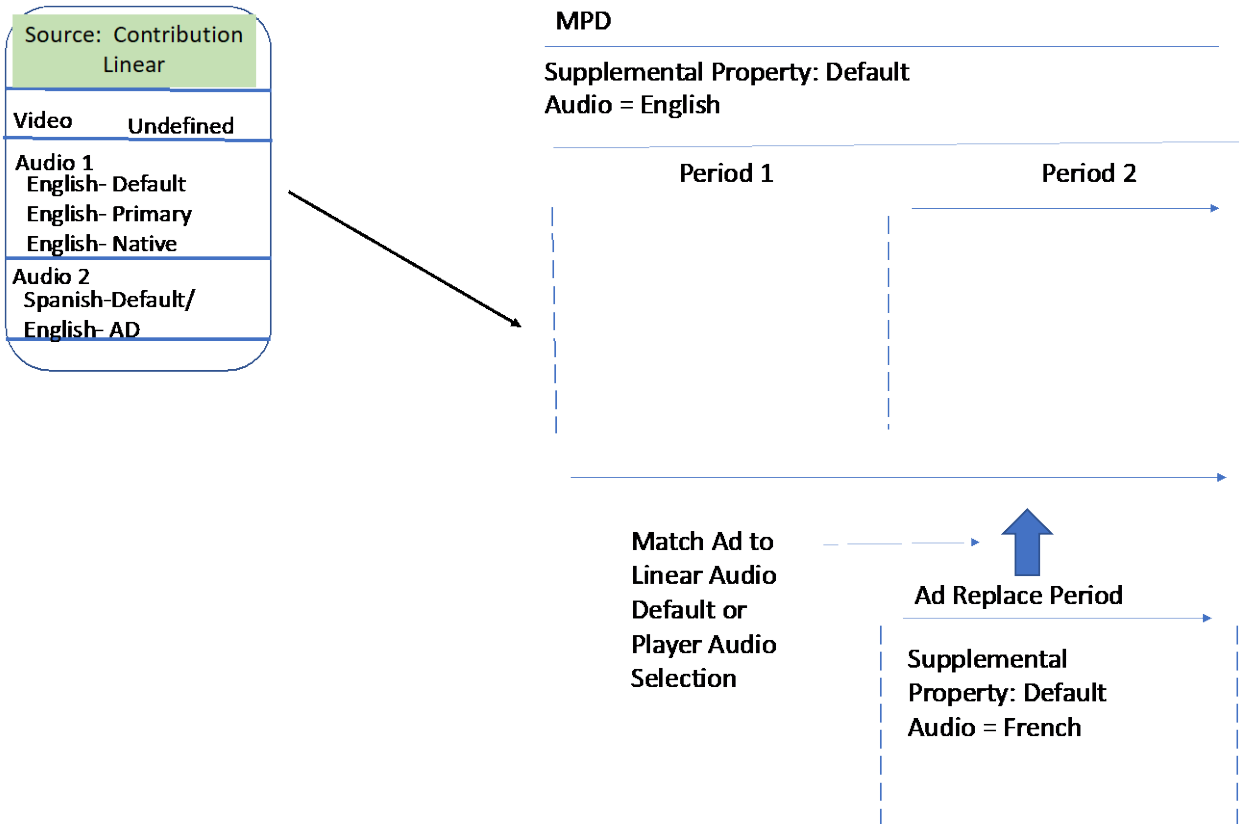

Figure 5 – Use of Media Language Defaults to Align Playout of Main Program and Ads

5. Future and International Extensions

The initial modifications described here worked by only adding additional values to the ISO_639_language structure [11][12]. But the makeup of content assets and linear feeds is expanding and evolving which can go beyond the ISO_639_language Descriptor structure on the audio stream. For instance, more accessibility features such as Video Sign Languages which is placed on the video stream cannot be well described just using the ISO_639_language descriptor. It also introduces the shift from having the content asset built around a single video stream to having several dependent video streams from 3rd parties as part of the content asset. With adaptive streaming there is also a shift to demuxing the media components which may manifest upstream delivery as demuxiplexed MPEG-2 TS streams which may originate from different parties (e.g., multi-language subtitles, dubbed audio, multi video sign languages).

In the next amendment of 13818-1, a new descriptor is proposed called the *Media_service_kind* descriptor that can co-exist with the ISO_639_language descriptor. This allows for a transition strategy from the old descriptor to the new descriptor depending on equipment software modifications. This new descriptor

expands from the ISO_639_language descriptor by applying to video and text streams as well as the audio descriptor and provides a main and dependent relationships between the different media components of the content asset. It also provides more additions to the media_type (similar to audio_type but extended to additional types of media components such as video or text) to address a more complete match between the full set of DASH roles and what is carried in the transport stream which includes values such as forced subtitles, substitution and dialogue. This also accommodates the future trends of having the media components of content being delivered on separate paths by multiple parties.

For the international requirements, the language code will be referencing ISO 639-3 to accommodate multiple sign languages and more dialects with BCP 47 extensions to handle regional dialect languages and scripts [5][6]. Furthermore, it will handle multi-language native audio tracks that may differ from a program-to-program basis but always provide the native audio of the program (ISO 639-3 “mul” code point.) In different parts of the world, this can be a differential playback mode for individuals who know multiple languages and would prefer the program to be played in the native language.

6. Conclusion

Enabling automation needs to define a clear path from mapping content source transport streams to distribution adaptive streaming manifests. With the additional values of audio_type in the ISO_639 language descriptor, adding the supplemental property media defaults in SCTE 214 [3]. We believe these enhancements will provide a clearer path from mapping information carried from the content source into its equivalent DASH roles and accessibility values.

The benefits of having this automation are clear. With DASH Role and Accessibility elements, the content is well described which benefits the customer by providing many more different types of experiences with the same asset and making it more accessible. In the past multiple assets of the same content had to be created separately and displayed differently to capture the different ways of viewing the content asset. But unless there is a way to automatically map this information from MPEG-2 TS structures, the presentation of the content would be limited to avoid the complexities of manually and correctly adding this information to each linear feed or VOD asset. The need to map from a MPEG-2 TS structure is needed due to the existing ingest system that is in place.

Furthermore, there needs to be an approach for this that works for inserting local ads, replacing national ones, or providing alternate content. The content experience can be affected by the ad playout of 3rd party content. Minimal disruption of the experience should be provided as an ad gets played out and when there is no way to avoid disruption of the experience during an ad then the behavior should be deterministic and consistent (e.g. keep the ad in Spanish even if the Spanish audio description is not available).

As content gets more internationalized, the customer experience expands, and these approaches provide a way of including these experiences while still providing a way to put this under the same manifest without changing backend operations.

Lastly in the future content assets and experiences will be expanding to include demuxed media component delivery and things like 3rd party independent signing tracks or new sporting or live event experiences. In anticipation of this, we believe the development of the media service kind descriptor in the next MPEG-2 TS systems standard edition will be needed as well as an approach to have these two descriptors co-exist for some time.

m.pala@cablelabs.com

1. Introduction

The cryptography world is going through a revolution. As new computation paradigms emerge and rapidly advance, like quantum computing (QC), the broadband industry needs to start planning how it will address the new security threats that are on the horizon.

Most of the public key cryptosystems like RSA [Rsa16] or ECDSA [Ec05] will not be considered secure when (and if) a large quantum supercomputer is ever built. For the broadband industry this means that, because of the dependency on X.509 [X509] certificates and the RSA algorithm, to provide devices with secure and verifiable identities, the protocols that are used today, e.g. DOCSIS® protocols [Doc31; Doc40], will need to support new algorithms and identities. In fact, network elements like cable modems or Remote PHY (R-PHY) nodes [RPhy18] use, today, their RSA private key and associated certificates chain to prove they are a legitimate and registered entity on the network. To continue to benefit from the security and usability advantages of public-key cryptography (PKC), the broadband industry must provide a mechanism for transitioning to quantum-resistant solutions *in a cost-effective manner*. Although our previous results on Composite Crypto (or Hybrid certificates) provided a promising path forward for the deployment of multiple keys associated with a single identity, our work still left some important questions. For example, an area that was still left to be explored was how to handle complex crypto policies for algorithm validation and deprecation. Because of these limitations, encryption was also left out of scope.

This paper describes our new results in multi-key environments that address the open issues from our previous work and update its technical details [Pala04]. Specifically, in this work we extend the initial proposal and introduce the explicit separation of “AND” and “OR” logic operations across the multi-key signature components. Additionally, our work enables encryption for multi-key certificates (e.g., for S/MIME or document multi-signing purposes) that was, up to now, still an open problem. Together with these important results, this paper also describes our proposal for algorithm revocation and how we leverage the details of X.509 certificates’ public key structures together with extensions in CRLs and/or OCSP responses to provide a dynamic, centrally managed, and easy to deploy algorithm revocation mechanism.

The rest of the paper is organized as follows: Section 2 provides an overview of the current landscape of Post-Quantum (PQ) cryptography and how it addresses the quantum threat. Section 3 describes the composite crypto solution and highlights current limitations of multi-key certificates when it comes to validations or encryption; Section 4 describes the new results that stem from the introduction of Combined Crypto alongside Composite Crypto; Section 5 provides the details on our algorithm revocation mechanism. Section 6 addresses the multi-key encryption conundrum and, finally, Section 7 provides our conclusions and envisioned future work.

2. The Post-Quantum Cryptography Landscape

Although the standardization process that is currently undergoing at NIST has not yet completed, there are interesting trends and practical long-term considerations for PQ algorithms deployment within the broadband industry that we can already highlight.

In order to understand how the new algorithms address quantum resistance, it is important to look at the principles behind solving the Hidden Subgroup Problem (or HSP) and how quantum computers can leverage superposition, entanglement, and interference to efficiently solve HSP for relevant domains.

2.1. The Hidden Subgroup Problem (HSP) and Factoring Keys

When it comes to the link between "classic" cryptography, like RSA or ECDSA, and quantum-based factorization algorithms, such as the one proposed by Schorr, it is not always easy to understand how periodicity comes into play and how post-quantum algorithms address quantum-resistance.

In this section we provide a qualitative explanation of HSP for the classic and post-quantum use-cases by introducing group theory concepts and their intersection with cryptography.

2.1.1. Groups, Cosets, and H-Periodic functions

With the use of modular arithmetic, a cornerstone in modern cryptography, we introduce, de facto, periodicity in the form of cyclic groups. These mathematical constructs consist of a set (e.g., "integers mod N") and a binary operation that takes two inputs and generates outputs in the same set:

$$G \times G \longrightarrow G$$

A group is characterized by three fundamental properties: (a) associativity, (b) a neutral element, and (c) all elements in the group have an inverse. Commutativity is not a core characteristic of a group and this, specifically, is a key differentiator when looking at quantum-resistance as explained in the rest of this section. A commutative group is also called an Abelian group.

When it comes to group theory, there are two definitions that must be well understood: subgroups and cosets. A subgroup H of a group G is defined as a group that still satisfies the group properties and is generated by one or more elements of the group (e.g., "h"). A coset is a similar concept to a subgroup in the sense that it can be seen as "translated" subgroups with respect to an element of the group G. For example, given a subgroup H generated by two elements (h_1 and h_2) and a third element "x" in the group G, the "coset of H with representative x (element of G)" is generated by applying all the permutations starting from the element "x" instead of starting from the neutral element.

The definition of H-periodic functions is strictly connected to the definition of cosets. When a function maps the values of a group to a set, it is said to be H-periodic (H is a subgroup) if, for all cosets xH, the value of the function is the same on all the elements in xH and differs on all elements of the other cosets.

2.1.2. The Hidden Subgroup problem and classic cryptography

The solution to HSP over specific groups can lead to breaking classic and post-quantum cryptography by leveraging the ability of a quantum computer to efficiently find the period of the underlying H-periodic function.

An example of this approach is explained in the famous Schor's paper from 1997 [Shor97]. In his work, Shor teaches us how to use quantum computers to efficiently implement the period finding function which is at the core of the factorization problem. In the case of "classic" algorithms, like the RSA or ECDSA, the underlying groups are commutative and, therefore, easier to deal with. For example, the group definition for the RSA case is $G_{RSA}= (\mathbb{Z}_N, +)$, while $G_{ECDSA}= (\mathbb{Z}_N \times \mathbb{Z}_N, +)$ provides the definition for the ECDSA one. The commutative property of these groups allows us to use the Fourier analysis on Abelian groups by using the Quantum Fourier Transform operation. In the RSA case, for example, given access to the function f that computes exponentiation modulo n, the factorization problem can be reformulated as finding a generator of the subgroup $H = \varphi(n)\mathbb{Z} \in \mathbb{Z}$, where $\varphi(n)$ is the group order and $\mathbb{Z}/n\mathbb{Z}$ is the set of integers modulo n. We can then use the function f as the oracle function for the subgroup H as:

$$f: \mathbb{Z} \to \mathbb{Z}/n\mathbb{Z} : x \mapsto a^x mod\ n$$

Once the generator $\varphi(n)$ is found through repeated sampling, computing the factorization of n can be accomplished by using the greatest common divisor (GCD) technique to find the non-trivial factors from the measurements.

2.1.3. The Dihedral Hidden Subgroup problem and Lattices

An interesting group that is relevant for post-quantum cryptography is the symmetry group. This group is defined as the set of all the possible elements permutations π (i.e., N-1 rotations, N reflections, and the neutral element) together with the functional composition operation. The neutral element is, in this case, the permutation that maps everything to itself, i.e., the identity element.

When looking at post-quantum algorithms and their relationship with HSP, we need to start from Regev's 2002 work on HSP. In his paper on Quantum Computation and Lattice Problems [Reg02], Regev shows how a solution to the Unique Shortest Vector Problem (SVP) can be obtained under the assumption that an algorithm that solves the hidden subgroup problem on the dihedral group by coset sampling exists. Regev's work demonstrates the equivalence between solving SVP on lattices and solving HSP on the dihedral group. The main difference with the classic use case is the fact that the group (i.e., domain and operation) for which a solution of the HSP is needed are non-commutative. As a reminder, the dihedral subgroup is a subset of all the permutations that are automorphisms (or symmetries) of the N-cycle (i.e., all the permutations that preserve the structure of the N-sided regular polygon) which include rotations and reflections. The Hidden Subgroup Problem for the dihedral subgroup can be defined as "given an H-periodic function, find H (or find the generators of H)".

Although also in the noncommutative subgroup problem the use of the Fourier analysis is at the center of efficient quantum-based solution, the difficulties of performing it on noncommutative groups makes the noncommutative version of the problem very challenging. Ettinger and Høyer [HeHø04] showed that efficiently solving the HSP for noncommutative groups is possible. More precisely, they show that it is possible to obtain sufficient statistical information about the hidden subgroup with a polynomial number of queries (similarly to the "classic" use case) … However, no known efficient algorithm exists that can leverage this information to find the generator for the subgroup. In their paper, Ettinger and Høyer state:

"Our main result is that there exists a quantum algorithm that solves the dihedral subgroup problem using only a linear number of evaluations of the function which is given as input [...] However, we hasten to add that our algorithm does not run in polynomial time. […] the algorithm applies a certain quantum subroutine a linear number of times […]. We know how to find the subgroup from the data in exponential time, but we do not know if this task can be done efficiently."

The original algorithm from Kuperberg from 2003 to solve HSP on the dihedral group runs in sub-exponential time $\widetilde{O}(3^{\sqrt{2\log_3 N}})$. Known improvements on these constructions are due to Regev [Reg04] and again Kuperberg [Kup13] where the total computation time is estimated to be $\widetilde{O}(2^{\sqrt{2\log_2 N}})$. Table 1 provides the group details (i.e., domain and operation) and specific application of HSP for different groups and well-known applications. For example, solving the HSP for the group of the integer numbers domain ($\mathbb{Z}_N$) with the addition ($+$) operation and (0) as the neutral element can be used in RSA factorization, while ECDSA and El-Algamal algorithms can be broken by solving the HSP for the group identified by the $\mathbb{Z}_N \times \mathbb{Z}_N$ domain with the addition ($+$) operation. In this case, the operation is the component-wise addition, and the neutral element is the pair (0,0).

Table 1 - List of Hidden Subgroup Problem definition and their applications

HSP Group	Operation	Application
$\{0,1\}^n$	XOR	Simon's Algorithm
$\mathbb{Z}_N$	$+ \ mod \ N$	Period Finding Function
$\mathbb{Z}_N$	$+$	Shor's Factoring Algorithm (RSA)
$\mathbb{Z}_N$ x $\mathbb{Z}_N$	$+$	Shor's Discrete Logs (ECDSA, El Algamal)
"Dihedral Group"	Composition of Symmetries (rotations, reflections)	Approximate SVP (and CVP)

2.2. Quantum-Resistant Cryptograpy

As we have seen, lattice-based cryptography does not come, so far, with efficient algorithms, quantum or classic, that can solve the underlying problem efficiently. That is why some of the most promising algorithms that are still present in the final round of the NIST competition are lattice-based. These mathematical objects are, in practice, regular collection of equally spaced vectors or points. In other words, lattices are regular arrays (or grids) of points that are generated by a combination of basis vectors. Lattice-based cryptography properties are rooted in the hardness of solving certain topological problems for which we do not have an efficient algorithm for, like finding the Shortest Vector Problem (SVP) or the Closest Vector Problem (CVP) given a specific basis for the lattice. Algorithms like Falcon [Fa17] or Dilithium-Crystals [Di17] fall in this category and produce the smallest authentication traces overall (i.e., signatures range from 700 bytes to 3300 bytes).

Another class of algorithms to keep an eye on is the Isogenies-based ones. These algorithms use a different structure than lattices and have been proposed for key-exchange algorithms, namely Key

Encapsulation Mechanisms or KEMs. Specifically, isogeny-based cryptography combines morphisms (or isogenies) among elliptic curves to provide Perfect Forward Secrecy (PFS) properties. Although Isogeny-based cryptography is computationally very heavy, it uses the shortest keys in the post-quantum algorithm landscape. SIKE is an example of such a class of algorithms.

Together with these two classes of algorithms, there is another type of algorithm that should be kept in our minds as a possible alternative: hash-based signature schemes. These algorithms rely on very different security property and data structures that are not tractable via HSP. The main issue with stateless hash-based schemes is the size of signatures: the lack of structure in the data comes at the expense of very large cryptographic signatures (although public keys are extremely small). Although the size of signatures hinders, today, their adoption, the security of this class of algorithms is not affected by advancements in HSP solving for non-commutative groups. A well-known hash-based algorithm that will probably be re-included in the NIST standardization process because of its security properties is SPHINCS+ [Sp15].

3. Multi-Keys Trust Environments

X.509 certificates have, so far, been used to link one public key to a single identity. This is true for Trust Anchors (or TAs), Intermediate CAs (or ICAs), and End-Entities (or EE). However, because the encoding of public key data structures inside certificates depends solely on the specific OID used to identify them, the inner BIT STRING that encodes the key value can be re-engineered to accommodate for any data structure. In our original work that was presented at SCTE Tech Expo 2020, we used the algorithm agility feature built in into X.509 certificates and defined a new OID to identify a key structure which implements a `SEQUENCE of SubjectPublicKeyInfo` structures. Each of the structures in the Composite Key encodes a specific public key which encompass the algorithm identifier together with parameters and the key value.

Practically, when a `compositeSignatures` schema is used to encode multiple signatures at once, the value for the algorithm identifier associated with the signature is defined as follows:

```
compositeSignatures OBJECT IDENTIFIER ::= {iso(1) identified-organization(3)
                dod(6) internet(1) private(4) enterprise(1) OpenCA(18227) 11 }
```

The `compositeSignatures` identifier is used to identify the type of signature, and the corresponding value, encoded in the `signatureValue` field, contains multiple signatures and associated parameters. Each of these individual `SignatureInfo` entries carry the information about one of the signatures applied to the certificate in the same order the corresponding public keys appear in the multi-key issuer's certificate.

3.1. Current Limitations

When we first drafted the public release of Composite Crypto, there were still few unresolved issues that were associated with the use of multiple keys in a single certificate. The main issues were related to (a) handling error conditions when only some of the signatures are reported to be bad, (b) the complexity of enabling encryption in multi-key environments, and (c) how to handle ecosystem-wide algorithm revocation.

At the time of publication, specifically, some argued that, although using multiple keys of different type is a valuable feature (not only when it comes to backward compatibility or future-looking deployments), the complications introduced from the use of multiple keys to validate a single object required the deployment of some complex validation policy and additional infrastructure elements. At the same time, a second argument against the standardization of multi-key certificates was related to the impracticality of modifying current crypto libraries to accommodate for new types of error conditions and API changes. A final argument against our idea was based on the difficulty of guaranteeing the correct distribution of validation policies across entire ecosystems, like the broadband one, without the need for deploying additional infrastructure elements.

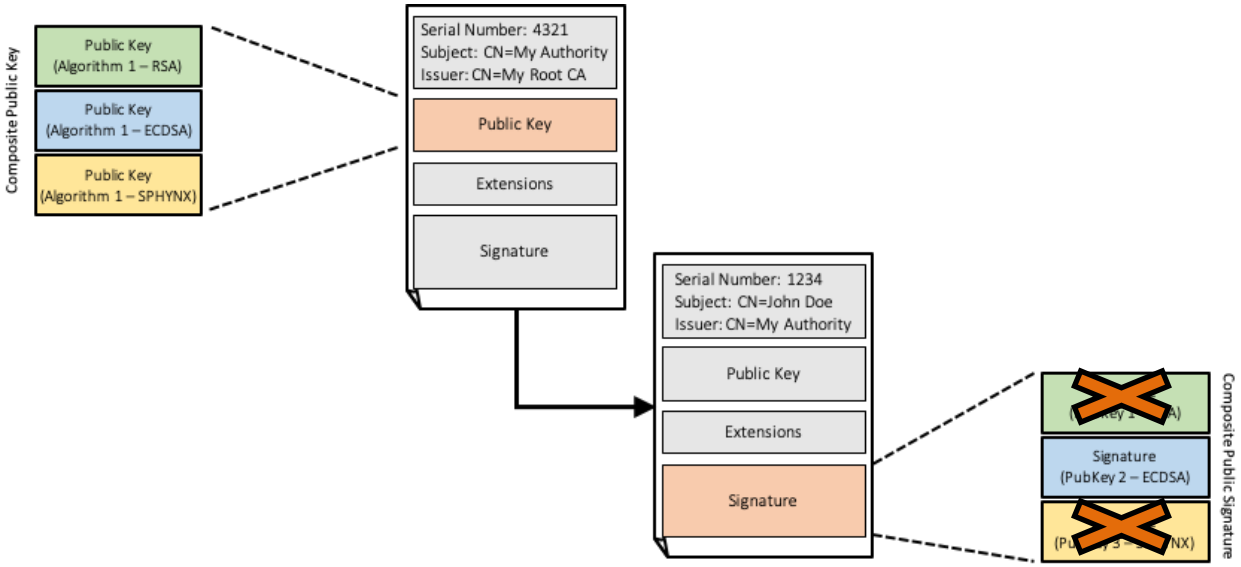

Figure 1 - Example of new error paths introduced with the use of multiple keys

Figure 1 sketches an explanatory error scenario where a composite signature, in this case on a certificate, has only one valid signature component. In our original work, the decision about the overall validity of the signature was left to the crypto library. This ambiguity posed a serious issue for consistency in how applications deal with these new mixed error states. In some scenarios, you want the possibility for the components of a composite signature to be “alternatives” so that a relying party can use the keys they prefer and/or understand (any of the signatures are equivalent). In other situations, instead, you want the possibility to report the signature to be valid only if all the components of signatures verify correctly. In other words, by providing an underspecified behavior, we inadvertently introduced, from an ecosystem perspective, the possibility for unpredictable results.

A problem that did not have a solution until now.

Another aspect that must be considered for signature validation is the level of trust in the algorithm throughout time. In the above example, let’s imagine that two out of three components of the signature are reported to be erroneous. Let’s also imaging that at time t_0, the use of ECDSA alone provides enough security for the identified application and ecosystem. Let’s now move the clock 3 years forward at a time

$t_1 = t_0 + 3$ years. Is the signature still to be considered valid? Without additional indications from a trusted source, applications and users are faced with an impossible task that cannot be easily resolved.

The next section explains how we solved the identified problems by introducing a second data structure that explicitly defines the relationship across the different key and signature components.

4. Composite Crypto vs. Combined Crypto

As described in the previous section, the fact that there were no clear semantics associated with the Composite Crypto was the source of the issues we were facing. This was reflected by the need of requiring crypto libraries to change their current APIs to support different validation policies. Because this might not be practical and might hinder adoption, we defined an alternative mechanism to drive the deterministic behavior when validating multi-key signatures. The core of our solution turned out to be extremely simple: defining, on top of the current ones, a new set of algorithm identifiers for keys and signatures that we call *Combined Crypto*.

With the introduction of these new OIDs (one for `subjectPublicKeyInfo` identifiers and one for `Signature` identifiers), we now have the possibility to explicitly define, via OIDs, the logic operations that crypto libraries must apply when validating the multi-key signatures.

When the *Composite Crypto* identifiers (also referred to as `compositeOr`) are used, the relationship across the different signatures is a logical “OR”. This means that the crypto library can use ANY of the signature components to determine the validity of the entire signature. A simple deterministic algorithm can be defined that goes through the list of signatures and stops at the first correctly validated one. If no signatures are correctly validated (i.e., because the values are corrupted or because the entity does not support the specific algorithm), the overall signature is not valid.

When the *Combined Crypto* identifiers are used instead, the relationship across the different signatures is a logical “AND”. This means that the crypto library must, in this case, positively verify ALL the signature components before being able to declare the whole signature valid. Also in this case, a simple deterministic algorithm can go through the list of signatures and stop at the first incorrectly validated one. If even one signature is not correctly validated (e.g., because of erroneous calculations or unsupported algorithm), the overall signature is not valid.

4.1. Advanced Key Structures

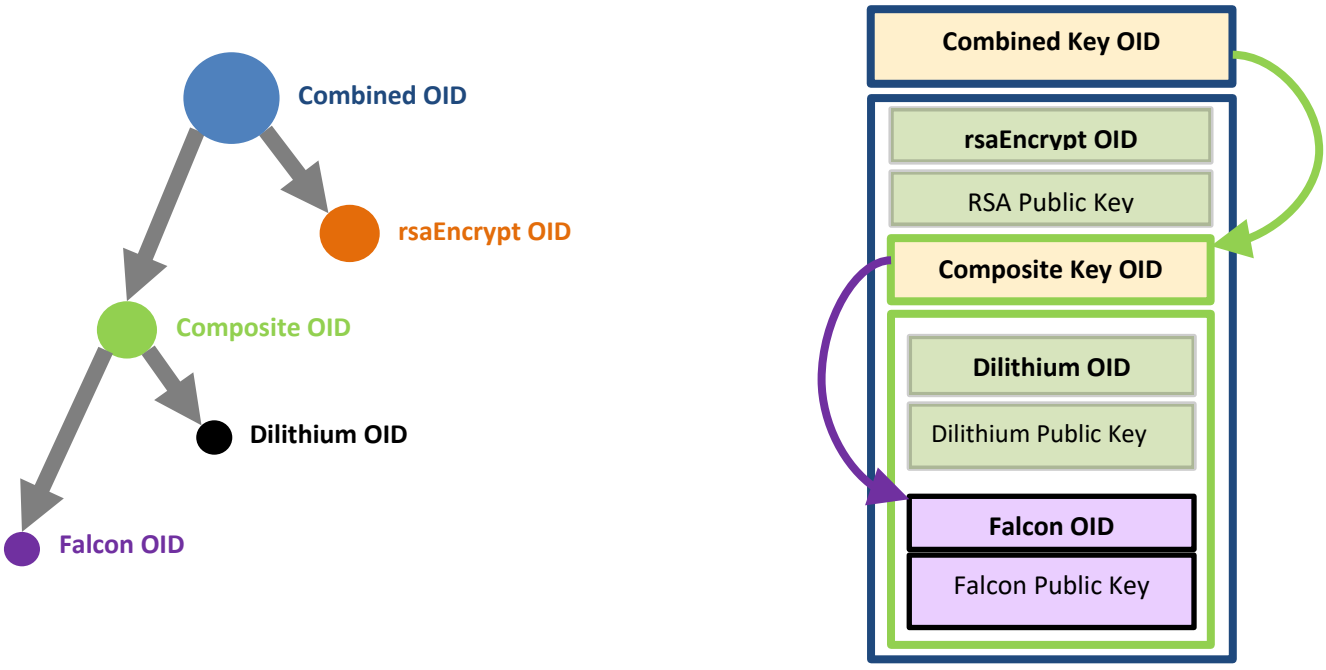

Figure 2 - Tree Representation of a Multi-Key Public Key Info structure

Figure 2 provides a tree representation of a key structure where the use of the “AND” and “OR” logical functions are leveraged. In the provided example, the represented key structure mandates for the use of an RSA component in the Combined Key container together with one of the two components from the Composite Key one. In fact, as previously discussed, when validating the components of a Combined key (as in this example), all of them must be validated correctly and that requires both the RSA and the Composite Key signatures to be valid. Back to the specific example, this translated to the need for the RSA signature to be valid together with, at least, one of the components in the Composite Key, i.e., the Dilithium or the Falcon signatures.

By following the described approach, CAs and PAs can design their certificate profiles with specific key structures for their certificates with deterministic behavior. For example, PKI architects can now decide to use a classic algorithm as the first element in a Composite Key to maximize backward compatibility. Another optimization strategy could be to maximize efficiency by using the fastest algorithm, from a validation standpoint, as the first element in composite keys, while using other FIPS and/or non-FIPS algorithms in combined keys to enforce the use of both types of cryptography together (i.e., classic and post-quantum).

4.2. A Deterministic Algorithm for Multi-Key Signature Validations

When using multi-key certificates, the `subjectPublicKeyInfo` structure of the certificate can have two different types of OIDs. The first type of OIDs is a container OID (i.e., the Composite or Combined ones) while the second type is a "real" algorithm OID such as, for example, rsaEncryption. Equation 1 provides a deterministic algorithm for validating multi-key signatures in pseudo programming language.

```
FUNCTION: Validate Signature Component

-------------------------------------------------------------------------

If Signature OID is Combined:

    For Each Component in Combined:
        If Signature Component is Combined:
            ERROR: Recursion
        End If

        If Validate Signature Component is NOT Valid
            Return False
        End If

    End For
    Return True

Else

    If Signature OID is Composite:

        For Each Component in Composite:
            If Signature OID is Composite:
                ERROR: Recursion
            End If

            If Validate Signature Component is Valid
                Return True
            End If

        End For
        Return False

    Else

        If Validate Signature Component is Valid
            Return True
        Else
            Return False
        End If

    End If
```

Equation 1 - Multi-Key Signature Validation Algorithm

For each of the nested components in combined signatures we evaluate it. We stop the validation process as soon as one component does not verify correctly. In this case the full combined key is invalid. On the other hand, if all components of the combined signature verify correctly, the combined key is considered valid.

For each of the nested components in composite signatures, we also evaluate it. However, differently from the combined key container, in this case we consider the composite key valid if at least one of the components is valid. The algorithm goes through the list of components and considers the composite key valid as soon as one component validates correctly. Conversely, the composite key is invalid if all the components (and not just one as in the combined key case) do not validate correctly.

5. Algorithm Revocation Via CRLs and OCSP Responses

With the possibility of algorithms being completely compromised overnight by quantum computers, PKIs are faced with a new problem: distrusting certificates that use a specific public key algorithm. Independently from the use of multi-key or single-key certificates, the inability, today, to provide such a mass-revocation tool can hinder our ability to effectively revoke the use of an algorithm.

---

*We are missing, today, an important tool in PKIs that is relevant for Post-Quantum algorithms deployment efforts, and that is **Algorithm Revocation**.*

We can easily see the impact of the lack of such tool with the latest example of algorithm deprecation that required a long time to complete (SHA-1). Specifically, when looking at the evolution of the deprecation process, we notice how it has happened very slowly and its resolution used ad-hoc criteria and deployment strategies instead of delivering formal ways to revoke its use across entire ecosystems. As a result, Certification Authorities, although they are there to guide the ecosystem and have the authority to revoke identities as needed, they still lack practical tools and options to enforce algorithm deprecation.

5.1. Policy Authorities as Sources of Trust

Since we introduced the concept of algorithm revocation in conjunction with multi-key environments, some critiques have been directed at the chosen trust model arguing that an external authority should be the one to provide algorithm deprecation information. Because this is an important governance principle, we want to provide additional considerations that can help understanding the principles we rely on when extending existing revocation mechanisms.

The trust model that is usually assumed in PKIs mandates for CAs to keep all participants in the ecosystem behaving according to a common policy. Therefore, CAs are already entities with a clear mandate to protect the integrity of the ecosystem by following verifiable procedures - this includes the possibility to revoke certificates. CAs are, therefore, the entities that, in accordance to defined policies, should provide indications about which type of keys should not be trusted throughout the PKI lifecycle.

In a trust infrastructure, besides the set of CAs that provide their services to the community, it is common practice to deploy a Policy Authority that is responsible for the ecosystem Certificate Policy (CP). When available, the content of the policy document is used to align CAs requirements across the whole ecosystem. In the DOCSIS PKI, the Policy Authority is operated by CableLabs on behalf of the entire ecosystem and is appointed with the task of making sure that the whole PKI is secure. As this governance model has been successfully exported to other ecosystems of interest for the broadband industry, our work can be extended and adopted in other device-centric ecosystems where a common trust infrastructure enables interesting and effective crypto-migration strategies (e.g., Wi-Fi Alliance/Passport 2.0, CBRS-A, etc.)

5.2. Algorithm Revocation vs. Certificate Revocation

When considering revocation and its practical impact over the ecosystem, an important consideration to make is related to the scalability of algorithm revocation vs. certificate revocation. Today, when a crypto algorithm needs to be replaced because of possible security risks or compromises, CAs must revoke every single affected certificate to make sure that the faulty algorithm is not used anymore.

Even when the higher levels of the PKI are protected with quantum safe algorithms (i.e., Root and Intermediate CAs), the option of using traditional revocation mechanism, i.e., via serial numbers, comes with very high costs related to adding many certificates to the revoked lists – both CRLs and OCSP servers are negatively impacted by these massive revocation events and can easily collapse under this added load (e.g., in the DOCSIS PKI the number of active certificates to revoke can be in the hundreds of millions). Conversely, the revocation mechanism described in this invention provides a very efficient way to mass-revoke certificates when and if needed. The mechanism is lightweight both on the Certificate Service Providers (or CSPs) when creating and distributing this information, and on the client when validating certificate chains and signatures. The rest of this Section provides a detailed description of the data structures, procedures, and extensions we defined to enable algorithm revocation.

5.3. Algorithm Revocation and Multi-Key Environments

The lack of standardized secure mechanisms to provide algorithm revocation is not a new problem. However, with the introduction of multiple keys within a single certificate, the problem of algorithm revocation becomes more evident.

In our work we focus on revocation of key structures, rather than a simply focusing on algorithms, to provide the possibility to better manage algorithm trust. For example, there might be the need to revoke a specific key configuration across the whole set of issued certificates (i.e., a specific algorithm or a specific algorithm hierarchy) without having to completely revoke its use in other cases. To address all these use cases, our work allows the ecosystem administrators to revoke, for example, the use of RSA as a primary key type in certificates or within Composite Key containers, but still allow the use of the RSA algorithm when used as a component of a Combined Keys (e.g., RSA + Post-Quantum Algorithm).

An example of the complexity that raises with the introduction of multi-key certificates can be easily shown by looking at the evolution of algorithm deprecation over an extended period. Let's imagine the case where a relying party correctly verifies the signatures on a specific document or certificate and let's also imagine that this process is repeated over and over – while the validation results do not change, the trust in the algorithm itself can change. For example, one of the algorithms used in the PKI might be compromised or there might be a new requirement, during uncertainty, to prevent the use of classic and/or post-quantum algorithms by themselves (e.g., you must use a combined RSA and Falcon signature).

The mechanism described in this work addresses all these cases.

5.4. Key Configuration Revocation

The key configuration revocation mechanism we introduce in this paper focuses on revoking specific key configurations via the use of key configuration revocation lists. To this purpose, we needed to provide a way to identify key configurations that must be distrusted. As discussed in Section 4.1, we can represent

key configurations as binary trees where the Composite and Combined nodes provide the bifurcations in the tree structure, while the individual components represent the end nodes (or leaves) of the tree. Few example configurations are provided in Figure 4.

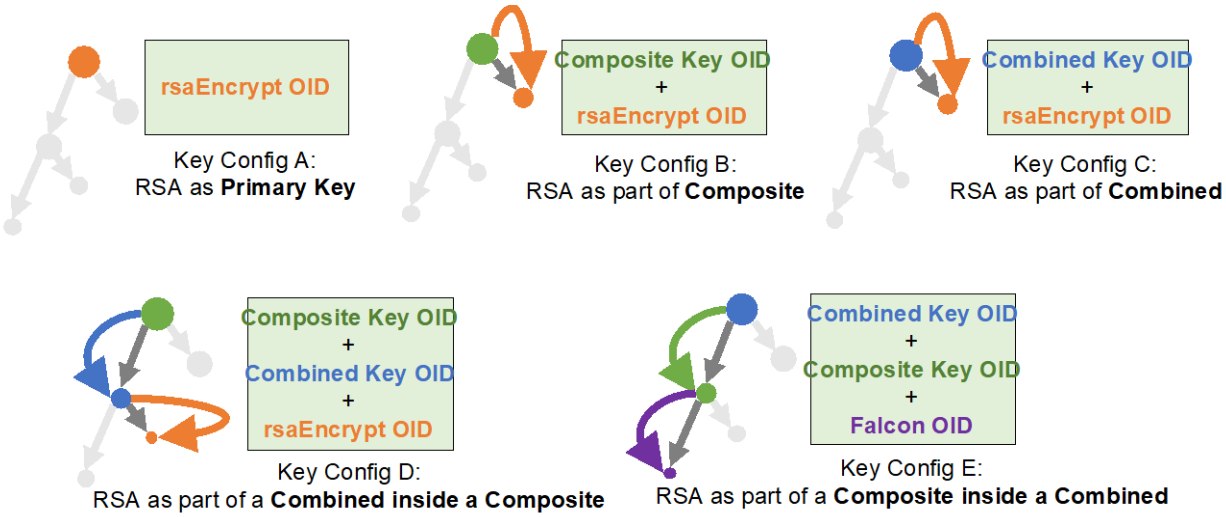

Figure 3 - Example Key Configurations for different types of primary algorithms.

For each of the key configurations that the CA wants to deprecate or revoke (or is instructed to do so by the PA), the CA generates a sequence of OIDs that we refer to as the `KeyConfigRevocationData`. This list of algorithm OIDs is then embedded as the value of an extension in OCSP responses and CRLs that are issued from the CA (or the delegated signer). The value of the `KeyConfigRevocationList` extension is implemented as a `SEQUENCE OF KeyConfigRevocationData`.

More specifically, each of these entries provides information about how to uniquely identify the specific key configuration (e.g., "(Start) → RSA" or "(Start) → CompositeCrypto → RSA"). Additionally, it is possible to specify an optional trust period for the algorithm in the form of `doNotUseBeforeDate` and `doNotTrustAferDate` fields.

The `KeyConfigRevocationList` data structure and associated identifier(s) are defined as follows:

```
keyConfigRevocationList-id OBJECT IDENTIFIER ::=
         {iso(1) identified-organization(3) dod(6) internet(1)
          private(4) enterprise(1) OpenCA(18227) 13 }

KeyConfigId ::= 1..MAX OF OBJECT_IDENTIFIER

KeyConfigRevocationData  ::=  SEQUENCE  {
        keyConfig               KeyConfigId,
            --- Identifier of the specific Key Configuration
            --- identified by this data structure
        doNotUseBeforeDate   [0]  GENERALIZED_TIME      OPTIONAL,
            --- Time before which the key configuration
            --- should not be used
        doNotTrustAferDate   [1] GENERALIZED_TIME    OPTIONAL,
            --- Timestamp after which the key configuration
            --- identified by keyConfig should not be trusted
            --- by the ecosystem clients anymore }

KeyConfigRevocationList  ::= SEQUENCE (1..MAX) OF KeyConfigRevocationData
```

To deprecate a specific algorithm when validating certificates (e.g., RSA), the data structure of the key revocation extension (i.e., the `keyConfigRevocationList`) carries the specific algorithm identifier as the only value in the `keyConfig` field. This configuration would not prevent, however, the use of the identified algorithm inside Composite or Combined keys because the algorithm identifier's list would be different. To deprecate both the use of an algorithm as a primary key in the certificate and as a component of Composite Keys (but leaving the possibility to leverage it in a Combined Key), the CA would generate two entries. The first one carries a sequence that comprises only a single identifier, e.g., the RSA algorithm identifier. This sequence deprecates the use of the algorithm as a primary key. The second one carries the sequence "Composite Crypto OID → RSA algorithm OID". This sequence deprecates the use of the algorithm as a component of Composite Keys (i.e., using RSA inside Composite Crypto keys).

5.5. Deprecating the use of multi-key certificates

CAs might also need a mechanism to deprecate the use of Composite Crypto or Combined Crypto within the ecosystem for when, for example, a transitioning period is over, and infrastructures and devices have fully transitioned to the new algorithms.

In this case, no additional mechanisms are required because the very same approach described in this paper can also be used to deprecate multi-key certificates: the CA generates a `KeyConfigRevocationData` entry where the `keyConfigId` carries only the Composite Crypto or the Combined Crypto object identifier(s) as needed.

6. Solving the Multi-Key Encryption Conundrum

Multi-key environments can provide interesting options to address encryption under today's cryptographic uncertainties. For this discussion, we choose the use case that deals with encrypting a document for a specific recipient as the explanatory relevant use-case. Specifically, the open problem we are focusing on is how to determine which key or set of keys should be used to encrypt a document for a recipient in the presence of multiple certificates and algorithms.

Similarly to the algorithm revocation case, linking multiple keys to the same identity is not a new problem and still we have no standardized solutions for it. In fact, there is no accepted procedure, today, to securely link together identities contained in different certificates that might even be issued from different CAs or different PKIs.

6.1. Encryption, Certificates, and Multiple Algorithm Support

To better explain the issues that crypto libraries and applications need to address when supporting multiple algorithms to encrypt data, let's go back to our example and describe the process of encrypting a document that is to be shared with a single recipient. In our example, let's assume that multiple algorithm support (e.g., RSA and Dilithium-Crystals) is required but only single-key certificates are deployed. This can happen, for example, when encrypting an e-mail for a recipient that might have multiple certificates, i.e., one with an RSA key and another with a Dilithium-Crystals one. For brevity and clarity, in the rest of the discussion we omit the description of the procedures for encrypting the data via a symmetric algorithm (not relevant for our discussion) and focus on the differences, when considering the encryption process, between single-key and multi-key certificates.

Before encrypting, applications must validate the revocation status of the recipient's certificate by accessing the certificates' revocation information (i.e., CRLs or OCSP responses) from the appropriate URL for all the certificates in the validation chain of the recipient. This is an essential step that prevents the leakage of the encrypted information for compromised certificates or keys. Without any indication of what the status of the algorithm (or key configuration) is or might be in the future, applications will happily encrypt the data for each of the certificates and possibly leak the encrypted content if one of the algorithms is broken.

This simple example shows the two main issues that the industry faces under the current crypto uncertainty when single-key certificates are used: dealing with the inefficiency of using multiple certificates connected to a single identity (i.e., need to interact with multiple infrastructures/services for a single encryption/validation operation) and the inability of efficiently communicating how to leverage the security of multiple algorithms together (i.e., "AND" or "OR" operations).

When looking at the first issue, multi-key certificates provide a distinct advantage: the need for less queries to the infrastructure. Specifically, because applications have to validate only one certificate chain per recipient, the number of requests to OCSP and CRL servers is greatly reduced. For example, in a three-tier infrastructure (i.e., Root CA, Intermediate CA, End-Entities) with three different algorithms deployed via single-key certificates, applications might need to perform up to six different OCSP or CRL queries and securely store 3 different Root CAs, while when multi-certificates are used, applications might need up to only 2 different queries and securely store a single Root CA. When looking at the second issue, the application that is performing the encryption is faced with the same uncertainty we noticed in the first formulation of our composite cryptography proposal (i.e., lack of deterministic behavior) because there is no possibility to dictate if the keys in the different certificates are equivalent or if they must be used together.

Ultimately, this one-to-one paradigm (i.e., one key for one identity) is also reflected everywhere in X.509 trust infrastructures where the assumption is that different certificates are associated with possibly different identities. Multi-key certificates solve the underlying conundrum by using a single identity, thus enabling the use of multiple algorithms across the board: from network functions to document signing.

6.2. More Efficient Encryption Process with Multi-Key Certificates

As described earlier, the ambiguity that was introduced with the initial proposal for multi-key certificates is completely resolved in this work by using explicit logic operations across keys and signatures that are completely defined by the specific OID used (Composite or Combined). Also in the encryption case, we leverage the separation of "OR" and "AND" logic operations to provide crypto libraries with deterministic encryption and decryption behavior. Table 2 provides a summary of the differences between Composite and Combined crypto when it comes to encryption options. Specifically, a Composite Key is enabled for encryption if at least one of the components algorithms supports encryption while a Combined Key is enabled for encryption if all the components' algorithms support encryption.

Back to our example, by providing algorithm deprecation information together with certificate revocation information, the encryption process can be performed even more securely than we do today and increase flexibility by supporting forward-looking or backward-compatible key structures. Even

outside the multi-certificate use-case, the availability and use of key configuration deprecation enhances the security of the whole ecosystem and help to prevent possible data breaches.

Table 2 - Encryption Operations for Composite and Combined Crypto

Composite Crypto	Combined Crypto
When Encrypting for a Composite Key, the encryption is performed with ***all the public keys SEPARATELY***	When Encrypting for a Combined Key, the encryption is performed with all the ***keys in a COMBINED way***
When Decrypting with a Composite Key, the decryption ***can be performed with ANY of the private keys*** related to the single public key components (OR)	When Decrypting with a Combined Key, the ***decryption must be performed with ALL the private keys*** related to the single Public Key components (AND)

7. Conclusions and Future Work

In this work we provide a description of the latest results when it comes to Composite Crypto and deployment of post-quantum algorithms. Specifically, we extend our original proposal to address the origin of the processing uncertainty that affected our original proposal: an incomplete design.

By adding a new set of OIDs, we can now express what the relationship across signatures (or keys) should be, thus providing a deterministic validation and encryption process. This simple enhancement unlocks deterministic behavior for crypto libraries without the need for deploying complex validation policies as it was initially envisioned. In other words, with the discussed new additions to our framework, the key structure of multi-key certificates itself provides clear validation, encryption, and decryption processing rules for crypto libraries.

On top of these important results, we identified CRLs and OCSP responses as the preferred mechanism to carry sequences of OIDs (and validity periods) to deprecate individual key configurations. This mechanism for algorithm revocation can be used in conjunction with both single key and multi key certificate environments.

Ultimately, the considerations contained throughout the paper show that the use of multi-key certificates can lower the cost of multiple algorithm deployment and provide the possibility to better manage, at the ecosystem level, the risks related to cryptographic failures. As we continue to evolve tools and specifications for multi-key environments, we envision that their deployment might become a common mechanism for delivering dynamic crypto-agile ecosystems in the future and, at the same time, simplifying new algorithm deployments and support algorithm migrations processes.

End to End Telecom for Healthcare Architecture

A Cable Industry Perspective

1. Executive summary

The COVID-19 pandemic forced people to consider new ways to manage healthcare and wellness care. One of the first places people turned was to online solutions. Video conferencing provided a way for physicians and other healthcare workers to provide remote care for patients even though opportunities for meeting in-person were limited. This provided a basic form of Telehealth. Many people had to manage their personal health and wellness conditions while primarily remaining at home. Again, network connectivity became essential for these rudimentary Aging in Place (AIP) use cases. While people relied on networking services, most did not really take advantage of the true possibilities of networked services. There are numerous networked sensors available that can measure many important parameters. There are smart home devices that can automate common tasks. More importantly, networks of family, friends and caregivers can be provided with information and contacted under common management. AIP and Telehealth has not nearly met its potential. This is an opportunity for cable operators. While there are piece parts that are available from specialists for smart home components, health management and communication, nobody has yet really integrated these parts into a cohesive service. Cable operators provide networking services to the home, work with existing familiar interfaces (like television) and aggregate services for consumers as core competencies. Therefore, cable operators are well-positioned to work with various partners to provide complete integrated AIP and Telehealth packages. This can increase convenience, reduce costs and improve care for all stakeholders in the healthcare value chain.

2. Introduction

The Healthcare industry is going through a major transformation to modernize the infrastructure, reduce the cost and increase the quality of care. In a series of articles, we have suggested how the Telecom industry can assist the Healthcare industry [1][2][3]. We call this inter-industry collaboration Telecom for Healthcare (T4H). Even though the T4H opportunity is not limited to these two major intersection points, we focus on Aging in Place (AIP) and Telehealth use cases to illustrate our thoughts on the end-to-end T4H architecture. (Refer to [4] for six different opportunities that a Telecom operator can address through the T4H architecture covered in this paper.) The SCTE Data Standards Subcommittee, in which the authors are members, is actively working on T4H solutions for the AIP and Telehealth areas in working groups three [5] and four [6].

Figure 1 provides a quick summary of the T4H opportunity and challenges from AIP and Telehealth points of view. Many of the needs, challenges, and Telecom opportunities of both markets are similar (refer to the SCTE working group analysis at [5][6]). Some of the high-level use cases that need to be supported for these two markets include:

A. Providing basic communication between the subscribers (users) and the providers/caregivers
B. Providing seamless communication between the users and the stakeholders
C. Monitoring the subscribers (users) for health, mobility, fall detection, etc.
D. Analyzing the data collected from the subscribers (users) and properly notifying the stakeholders
E. Assisting the T4H service providers with claims by documenting accountability
F. Offering managed services to support installations, product support, and other services to improve adoption and retain customers

The goal of the paper is not to elaborate on the use cases but to use them to motivate the end-to-end architecture. For additional information refer to the working group documents.

In the next sections, we elaborate on the T4H architectural needs, provide a framework, discuss details on individual components, summarize the findings and propose next steps.

3. End-to-end high-level T4H architecture

Figure 2 provides a high-level end-to-end architecture proposed by Duke Tech Solutions (DTS) in their market analysis [4] based on different T4H market opportunities. The framework is further elaborated in this paper with a second level of architectural details.

To understand the end-to-end T4H architecture, first, we need to understand the users, the service providers, and the other stakeholders (refer to Figure 1).

	Aging in Place	Telehealth
Subscribers (Users)	Older adults (65+), caregivers	Individuals, providers
Stakeholders	Family members, care givers, doctors, service personnel etc.	All family members, providers, (payors)
Needs	Communicating, monitoring, service, support, integration	Communicating, monitoring, integrating with provider systems
Challenges	Ease of use, provider network integration, problem solving	Ease of use, device and EMR integration, remote monitoring,
Telecom opportunity	End to end solution, managed services, provider integration	End to end solution, managed services, provider integration

Figure 1 - Telecom for Healthcare opportunity and challenges summary

Subscriber or Users: These are the folks who are the primary subjects of the T4H platform. For AIP, the elders who are aging at home are the primary users. The service infrastructure revolves around the elder's needs in the AIP use cases. For Telehealth, the users are typically the family members who are using the T4H platform at home or the patients who use the platform in the care centers (such as Veterans Administration (VA) satellite healthcare facilities [7]).

- Service providers: In the traditional healthcare industry physicians and nurses in offices and hospital systems are primary service providers. In the proposed T4H emerging system, the intent is to go beyond healthcare to wellness. Here it is important to realize that doctors are not the sole provider of wellness services. Hence, we introduce the concept of T4H service providers. For AIP the service providers include the caregivers (both healthcare and non-healthcare related), network providers and technicians. For Telehealth use cases, doctors are still included. This distinction is important for understanding the relationship between the users and the service providers from different architectural points of view.
- Other stakeholders: In the T4H environment, other stakeholders are also interested in the wellness of the users. These include, for example, family members, friends, and payors.

Understanding the classification of different stakeholders, we proceed with an explanation of the components in the T4H solution. We adopt the architectural framework provided in [4], DTS's Telecom for Healthcare Environment Framework (DTEF), to evaluate the end-to-end solution components proposed in this paper. We will use AIP and Telehealth use cases (as provided in section 2) in oder to do this.

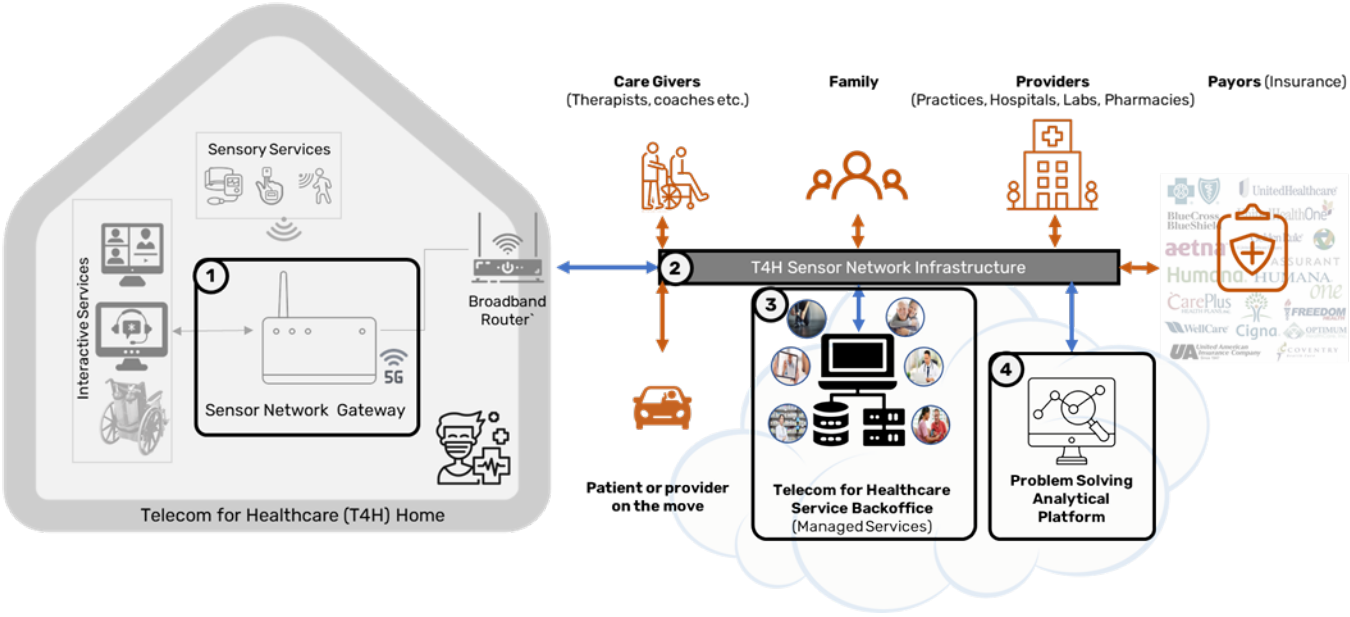

Figure 2 - DTS's Telecom for Healthcare Environment Framework (DTEF) based components

1. In-home healthcare/wellness aware gateway: From use cases A, B, C, it is clear that there needs to be a gateway in the T4H home. This gateway, as shown in Figure 2, acts as an integration point for monitoring the sensor devices (e.g., motion sensors, remote patient monitoring equipment) and integrating with the interactive services endpoints (such as unified communication services). This **Sensor Network Gateway** can be a standalone device or integrated with other vendor equipment such as the set-top box or residential gateway. In this paper, we treat it as a logically separate device.
2. T4H aware network infrastructure: Again from the use cases A, B, C it is clear that the T4H requires to connections between the users, the providers, and the other stakeholders. This requires not only reusing the exiting telecom infrastructure, but will also need to meet reliability, security and privacy requirements specified by the T4H architecture. The communications infrastructure will have to meet the needs of the sensor network traffic, unified communications traffic, and notifications to the different stakeholders. To differentiate (or to keep the focus on) the T4H needs, we call this the **T4H Sensor Network Infrastructure**.
3. T4H aware service back office: The cable operators have all the required infrastructure for managing end-to-end services. As mentioned in use case F, it is essential to turn the fragmented, gadget-oriented point solutions into a well-oiled managed service. This can only be accomplished by Telecom operators who have access to such infrastructure and have been managing communications infrastructure for 90+% of the households in the US. We call such infrastructure as **T4H Service Backoffice**.

4. T4H aware problem solving analytical platform: Finally, as mentioned in use cases D and E, this infrastructure attempts to solve the problems stakeholders are facing. These problems and related algorithms may be unique to the healthcare/wellness industry, but the infrastructure is similar to infrastructure the telecom operators use today. We call this repurposed analytical platform the **T4H Problem Solving Analytical Platform**.

These solution components are explained in the following sections. Note that in this paper we provide a block diagram level architecture. The detailed architectural specifications will be worked out in more detail at the SCTE DSS WG3 [5] and WG4 [6].

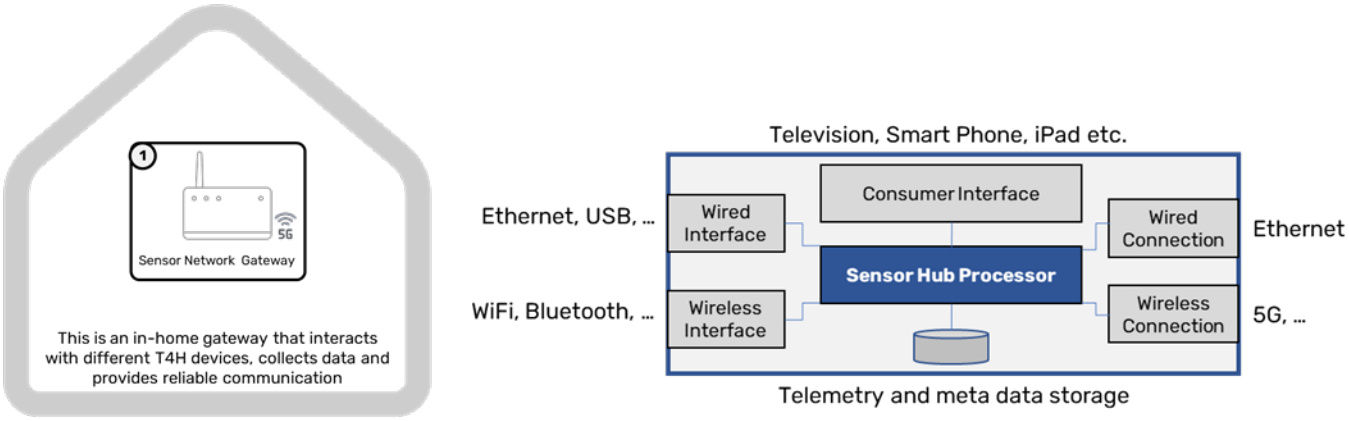

Figure 3 - Sensor Network Gateway architecture

4. In-home T4H architectural components

Figure 2 shows different tasks that need to be done in a T4H capable home. These tasks include:

- Support for different data streams: The AIP and Telehealth infrastructure needs to support typical data streams generated in a T4H home. These include sensor and actuator data streams, streams to record events and real-time streams such as video and audio communication between T4H stakeholders.
- Communication with existing in-home broadband devices: These might include consumer consoles (such as TVs or smart speakers), and smart home devices (such as smart locks, lights or video doorbells).

To increase the adoption of T4H solutions and for ease of use, the T4H in-home components need to be on the same logical network.

- The T4H physical networking can be dependent upon the use case for any particular device. Most components are likely best connected with an in-home broadband network, but certain devices (such as a locator device) may need to be connected even if the user is beyond the limits of the in-home network. The important thing is that the networked devices can communicate with each other on a secure logical network. Critical components may require a secondary backup network connection in case the primary network fails. Cloud-based services also protect against exclusive dependency on the in-home network.

    - The in-home solutions shall integrate remote patient monitoring devices, sensor devices (such as fall detection, motion sensors, etc.), and other IoT devices that are used for wellness needs.
    - Additionally (to increase the utility and ease of use of the system), the T4H solutions shall be integrated with the frequently used consumer consoles (such as Television for the elderly), smartphones, and other handheld devices. Again, a cloud-based solution simplifies and experience that can be duplicated on whatever console is convenient.
- Provide installation and support services: The operator shall also streamline the installation and support services to improve the ease of use of the integrated solution.

Based on the above high-level needs, we propose that a Sensor Network Gateway functionality be developed for supporting T4H solutions. The block diagram of such a gateway is presented in Figure 3. This gateway will have wired (Ethernet, USB, etc.) and wireless (WiFi, Bluetooth, BLE, etc.) interfaces to integrate the T4H devices and other IoT devices (such as turning on light, placing a phone call to the family member). They will need limited internal storage for the temporary storage of sensor data and to perform local analytics on time-critical events. The gateway will also need to integrate the consumer access interfaces (TVs, smartphones, iPads, etc.). The gateway shall provide redundant Internet connectivity with an Ethernet interface to wired broadband and a 5G or other wireless connection as a backup. The gateway shall offer an easy installation process and support self-install where possible.

5. T4H communication architecture

Although cable operators already own a capable end-to-end Telecom infrastructure, it may need to be adapted to meet T4H needs. That is the focus of this paper. The T4H sensor network infrastructure is used to provide communication between stakeholders and users, to collect in-home sensor information, to provide intelligent notifications, and to offer T4H managed services. This infrastructure, as shown in Figure 4, will be used in the T4H case for the following:

- Unified communications infrastructure: This is the collaborative software (similar to [8]) that is used to create a communication environment for different players in the T4H ecosystem. The challenge of offering UCC software is the ability to scale it to the individual consumer level and

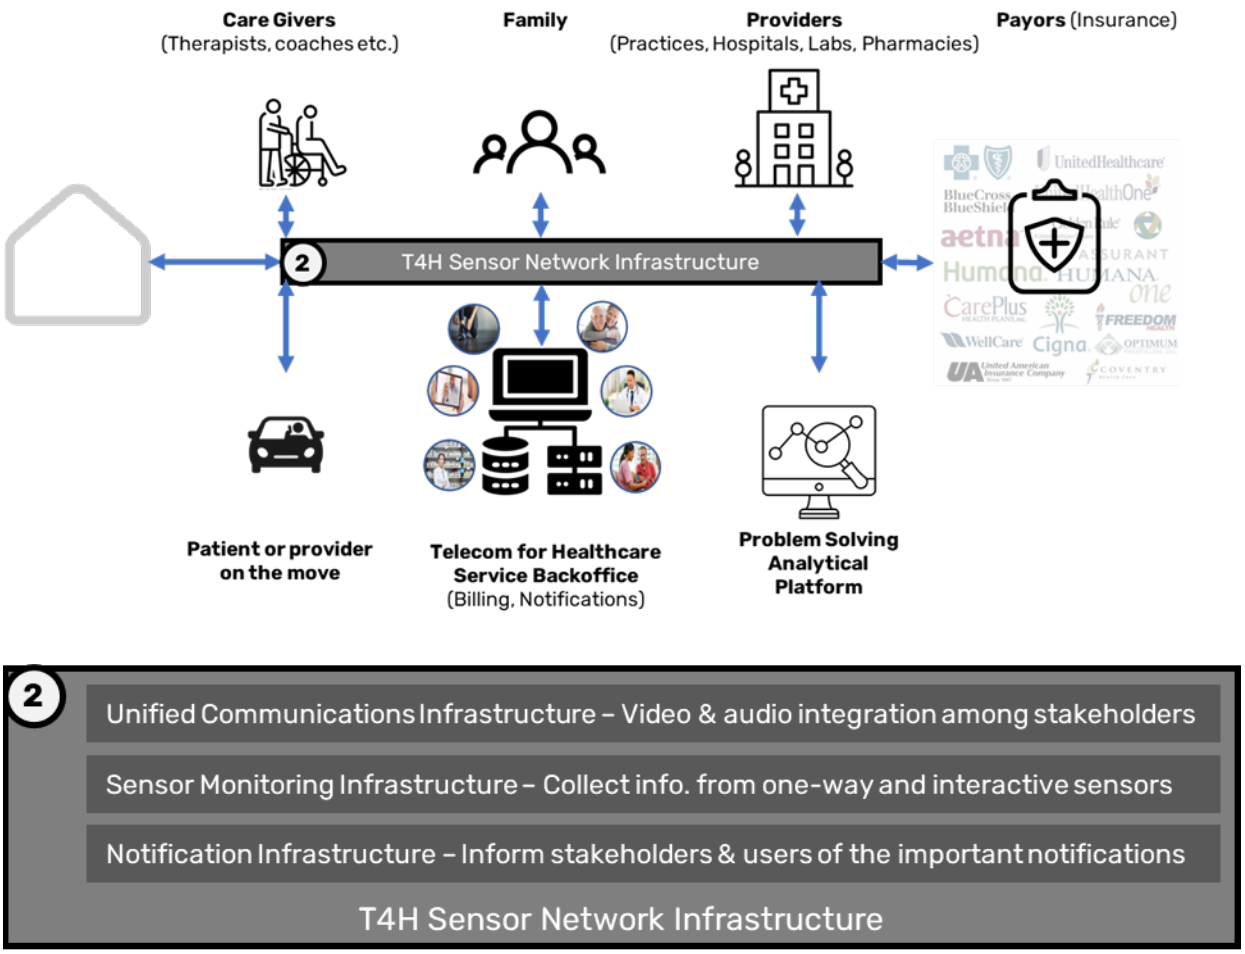

Figure 4 - UCC, sensor monitoring, and notification traffic on T4H Network Infrastructure

still host it for a large volume of deployments. Current UCC software may need to be enhanced for the healthcare market in order to be compliant with HIPAA. UCC software must seamlessly offer secure communication between parties in the communication session and still provide privacy to protect the shared and recorded content. Launching the UCC solution on different consoles (such as TVs, smart devices, etc.) is also an important requirement.

- Sensor monitoring infrastructure: This is a stream of information coming from the T4H from sensor devices. The traffic can be from remote patient monitoring (RPM) devices (typically medical devices), and other sensory devices (such as motion sensors, door openers, etc.) used for both AIP and Telehealth. The communication infrastructure will need to assist in bringing the devices online, providing secure communication of the information to the analytical platform, and potentially track metadata from the sensor devices. The platform must implement HIPAA requirements and offer privacy similar to what operators provide for PII. In healthcare, privacy extends to PHI (Personally identifiable Healthcare Information). Note that the overall QoE (Quality of Experience) for such streams is essential to understand. We refer you to [9] for our preliminary thoughts on consumption patterns for the T4H data.
- Notification infrastructure: The other major data streams included in the T4H communication infrastructure are the notifications. To enable this notification infrastructure, the endpoints (stakeholder, software, etc.) shall be registered to receive specific events. The infrastructure will

need to provide secure communication between the communication platform and the stakeholders.

6. T4H service back-office architecture

The T4H service back office, as shown in Figure 5, is used for providing managed T4H services. This includes installation, support, troubleshooting, connectivity management, billing, and more importantly business rule management. Note: The Cable operators already have much of the T4H infrastructure in place for managing their existing broadband and other in-home services. In the remainder of this section (as shown in Figure 6) we provide a discussion on what tasks need to be completed in order to implement the above-mentioned service components. We also discuss why cable operators are suitable for providing these services and what additional capabilities they need to develop.

- Connectivity management: The operator needs to manage basic connectivity services. These include the UCC, in-home sensor devices, notifications, etc. Cable operators have already been

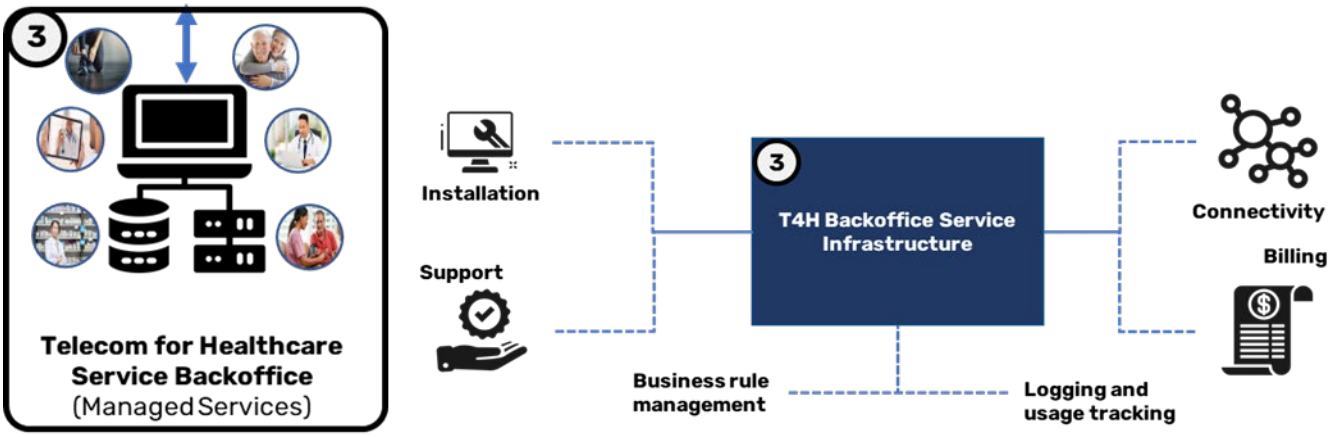

Figure 5 T4H service back-office infrastructure components

- managing such in-home services in many cases. Lately, operators are assuming the management of more extended services such as video surveillance, IoT-based services, etc. for a large customer base. The connectivity services that are offered to regular customers need to be extended for T4H services.
- Business rule management: Managing T4H customers, stakeholders, and service providers is done through business rules. This requirement will add new rules-based management. These include the user service enablement, the stakeholder notification management, and other per user management. This is similar to the Cable operator subscriber management. The cable operators have been managing such business/subscriber rules for more than 70M subscribers in the US. Extending similar concepts to T4H healthcare/wellness needs is the new challenge that cable operators face.
- Logging capabilities: Metadata and telemetry data collection are essential for T4H services. This data is required to enable new problem-solving capabilities for AIP and telehealth use cases. Additional information on such data gathering requirements can be found in [10]. Cable operators are used to gathering and analyzing gigabytes of customer and network-specific daily data. Extending the same capability for T4H services is a new opportunity and challenge for cable operators.

- Installation and support services: One major issue facing the T4H industry is their fragmented way of handling the market space. No single company is responsible for the quality of care. We recommend that Telecom companies extend their installation and support services to include T4H. Refer to [2][3] for the business case behind such an offering. Cable operator's experience in providing end-to-end installation services, their service assurance tools, and their "boots on the ground" to manage on-premise services can be effectively leveraged to support T4H services. This will require cable operators to expand the use of some tools and train additional teams to handle T4H services.
- Billing services: One of the challenges facing the next generation healthcare and wellness industry is billing capabilities for next-generation products. The Telecom industry is experienced in creating products for in-home services, billing for them, and collecting payments from customers. Extending the same capabilities for T4H services is required.

7. T4H analytical service architecture

It is necessary to tune the analytical platform to meet the needs of the T4H problem space by collecting the right data [10], providing appropriate analytics to solve problems, and offering a flexible notification engine for stakeholders. Such a platform is essential to add value to the raw data.

Some of the reference AIP and Telehealth problems that need attention include:

- Trend analysis: Providing trend analysis for basic time-series information gathered from an IoT

	Connectivity	Rule Management	Logging	Installation	Support	Billing
Tasks to perform	UCC, In home sensor devices, end to end services	Service, notification, PHI, and other per sub rules	Different T4H related meta data and Telemetry info.	UCC, IoT (Healthcare and non-healthcare devices)	T4H healthcare and non-healthcare services	User and stakeholder service billing and collection
Why Cable operators?	Extensive experience with in-home service mgmt.	Have been managing 70M+ customers	Used to managing tera bytes of customer specific info.	Highly experienced with in home, e2e service installs	Boots on the ground, service management tools and org.	Elaborate systems to offer and manage service models
Capability development for Cable operators	Need to tune the connectivity focus to T4H	Healthcare/wellness related rules	Collect T4H specific data and address the right problems	Repurpose to T4H vertical (RPM, monitoring installs, ...)	Repurpose to manage T4H	Repurpose to manage T4H

Figure 6 - Why MSOs are suited for T4H services, and what capabilities do they need to develop?

- sensor or telemetry information gathered from different RPM systems.

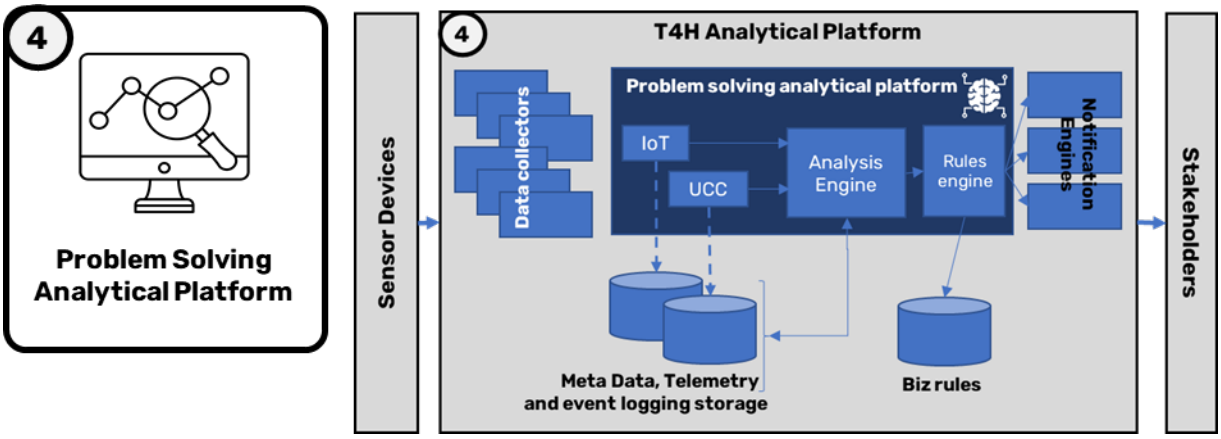

Figure 7 - T4H analytical plaform that manages problem-solving notification infrastructure

- Anamoly detection: Identifying different anomalies such as fall detection, etc. based on the collected sensor data.
- Correlation: Correlating different health and wellness-related conditions with indicative data.
- Resolution analysis: Assisting with different analytical algorithms and the data collected, then tying that data to T4H problem resolution.
- Quality of care forecasting: Providing different success metrics to quantify the quality of care provided by the cable operator's T4H solution.

To meet the above needs the cable operator will have to create the following architectural components, as shown in Figure 7:

- Metadata collectors: Collectors for different types of metadata for interactive systems (such as UCC), sensor networks (such as IoT), and telemetry data per customer. The operators need to adjust their existing monitoring capabilities to meet T4H needs.
- Analytical engine: An analytical engine is required to solve the problems highlighted earlier. This is accomplished using data collected from the various sources. These analytical tools need to consider the Protected Health Information (PHI) [11] restrictions and offer solutions for the classes of problems considered previously.
- Rules engine: Different business rules must be programmed for classes of services offered to the T4H customer for different classes of problems the platform needs to solve.
- Notification engines: The relevant observations from analysis must be communicated to the stakeholders through this infrastructure. Such a notification infrastructure is generally present and tuned for the SLA (Service Level Agreement) needs of the customers.

8. Conclusion and next steps

In order to realize the promise of Aging in Place and Telehealth, all parts of the ecosystem need to be integrated in a way that is convenient for all stakeholders. Cable operators are well-positioned to be this integrator because they already provide network and television services to customers and they have the underlying infrastructure that can install, support and manages such services. However, there is still a lot of work to be done to realize this vision.

In this paper, we propose and architecture capable of supporting AIP and Telehealth use cases and providing key features to users, caregivers, payors and other stakeholders. Some companies will undertake this integration opportunity eventually, but there is currently an opportunity for cable operators to step up and assume this role.

The challenges are not insignificant, but the cable industry has already shown an aptitude for this sort of work as they have created widely adopted standards, aggregated services, created an army of installation and support personnel, and formed trusted billing relationships with millions of consumers and businesses.

SCTE is already working on AIP and Telehealth within their standards development organization. With serious engagement and active participation, cable operators can agree on the problems that need to be solved and come up with solutions and strategies to create a new and potentially lucrative revenue source in AIP and Telehealth for operators around the world.

1. Introduction

High-speed Internet is ingrained in our culture. From email and social media to videos and entertainment, the online experience is part of everyday society. One primary enabler of high-speed Internet is the cable broadband network, a collection of Hybrid Fiber Coax (HFC) networks connecting residential and business users to the Internet. In the US alone, the cable broadband industry has over 78 million high-speed Internet connections.

The Covid-19 pandemic made these broadband connections even more essential. As much of the workforce transitioned to work-from-home status, businesses became reliant on stable Internet connections to perform core functions. Parents depended on these connections to support remote learning for their children. The line between business services and residential customers blurred, transforming high-speed data connections into a universal requirement.

Because the traffic flowing across broadband connections are vital for business, school, and health in general, the need for dependable service has become even more critical. Yet, at the time when we seem to need it most, our utility grid was exposed as a potential weak link for network resiliency. Across the United States, there have been waves of multiple day power outages, with reasons stemming from tropical storms, snowstorms, fires and freezing temperatures. Due to the susceptibility of the grid to severe weather, natural disasters, and planned outages, customers are purchasing home generation solutions at record rates. However, electricity at the customer's premises exacerbates the broadband problem, since TVs and laptops are functional, but without a connection to the Internet.

As performance of the grid brings to question the reliability of the HFC network, government entities have begun to legislate network backup time. High-speed Internet connections are so important that Multiple-System Operators (MSOs) are being mandated to keep their networks online, regardless of the utility grid. These mandates present a fundamental question for network reliability: How can we ensure power availability for critical HFC services during extended outages?

There are several potential solutions that continue to be explored, however, in many situations the simplest and cost-effective answer is adding batteries to existing HFC network elements to extend run time. However straightforward the concept may be, these batteries require space, environmental protection, thermal management, ongoing maintenance, budget, and end-of-life management. Solutions are heavily dependent on run time requirements, battery selection and, in many cases space limitations at existing broadband power system locations. Which battery chemistry provides the best run time? Which meets the budget? Which can be maintained by MSO technicians?

This paper explores various extended run time solutions using both Lithium Ion (Li-ion) and Thin Plate Pure Lead (TPPL) batteries. For each battery chemistry, comparisons are presented for run time, space requirements, thermal management, relative cost, and perspective comparison to higher total cost of ownership (TCO) for on-site generation solutions.

2. Extended Run Time

For discussion purposes, this paper will consider an "extended outage" as a utility outage that lasts longer than the average run time of the installed backup batteries plus run time of an average portable generator. This is assumed to be approximately 12 hours. For the last two decades, a three to four hour backup run time was typical for many cable outside plant (OSP) sites. This amount was determined to be sufficient for the operator to roll a truck with technicians, replacement equipment, or a generator. But with severe

weather and natural disasters causing longer grid outages across broad swaths of the network, standard run times have been questioned.

The California Public Utility Commission (CPUC) has been at the forefront of investigating these requirements. Since the state had experienced several instances of prolonged outages driven by utilities de-energizing sections of the grid to prevent possible wildfires, the CPUC created a new extended backup requirement. This was specifically developed for wireline carriers to enact "comprehensive resiliency strategies to prepare for catastrophic disasters and power outages." The new requirements adopted a 72-hour backup power requirement for the wireline providers' facilities in Tier 2 and Tier 3 High Fire Threat Districts[i]. This new requirement is far from the three to four-hour historic backup standard for which HFC sites were initially designed.

Not all regions will follow the CPUC's lead, but many areas are ideal candidates for extended run time. Texas was in the news for outages caused by freezing conditions, the Midwest and Southeast US are vulnerable to hurricanes, tornadoes or winter freezes and Northeastern US and Canada experience frequent extended outages due to annual winter storms. With the HFC network becoming increasingly important for society, it is likely some form of run time extension will be adopted in these regions as well.

While adding energy storage seems like a straightforward method of compliance, there are many challenges to overcome. Some reasons existing locations do not always lend themselves to easy upgrades include:

- Currently most sites have been designed specifically around the form-factor of three or six batteries in case size 27 (306 x 173 x 225mm) or case size 31 (330 x 173 x 240mm)
- Sites are often in easements in front of residences or on utility poles, so there is usually little or no space for additional battery cabinets to extend run times
- Many areas have height restrictions for cabinets making it impractical to add battery extensions to existing locations
- In locations where space does exist for additional battery enclosures, re-permitting can cost $10K or more per site and could add up to 6 months to install
- When upgrading existing sites with established utility service connections, it is often a requirement to maintain that connection to reduce costs and minimize logistical issues with local electrical utilities.

These hurdles are not show-stoppers but do eliminate the opportunity for a one-size-fits-all solution. The result is to look at the application, the location, and the installation to determine the right fit. The analysis starts with diverse options for energy storage and backup. After establishing different backup alternatives, the paper looks at the key factors for determining the best fit per application.

Figure 1 - Example cable broadband powering sites. The variability in available space, loading, and local regulations makes a one-size-fits-all solution for extended run time nearly impossible.

3. Backup Power Methods

There are a variety of possibilities available when considering how to provide backup power to the outside plant broadband network, including batteries, generators, fuel cells, and flywheels. Solar power is also a consideration when combined with an energy storage solution. While solar power, fuel cells, or flywheels could fill a niche, they do not currently present a viable solution for the broad deployment required to meet the new governmental mandates. These options must continue to be explored as their technologies mature, however they currently present significant issues regarding deployment and scalability. For this reason, this paper focuses on more prevalent alternatives – generators and batteries.

3.1. Generator Overview

Generators convert fuel (diesel, propane, natural gas, etc.) via internal combustion engine into electricity. The output can be either alternating current (AC) or direct current (DC), depending on the type of generator. A major advantage for generators is the ability to deliver power and keep the network running

as long as they have fuel. This becomes a key factor in the viability of generators as a solution for extended run time scenarios.

There are two broad categories of generators that can be used for extended run time scenarios in the cable broadband network: portable generators and curbside or stationary generators. Portable generators are designed for deployment during extended outages and provide flexible run time augmentation, then retrieved and stored until the next outage. Curbside generators are permanently stationed at the site to provide additional backup when needed. Most major operators have deployed both types of generators for extending run time in outage situations and have strategies for when and where to deploy based on unique site requirements.

3.2. Portable Generators

Portable generators have been broadly used in OSP for years as a flexible option to add backup time only when and where it is needed. Nearly all MSOs have an operational strategy for deploying portable generators to extend plant backup time during an outage. These strategies usually start by assuming a baseline backup time that is resident at each site based on the batteries installed. From there, remote status monitoring tracks the duration of the utility outage. Once an outage duration reaches a critical point set by the operator the site is at risk of dropping plant power and a network management system will trigger a technician to deploy a portable generator to the site to augment run time.

This strategy has proven effective over the years but has its limitations when dealing with outages of an extended nature. Portable generators are designed to be relatively small to be easily transported and deployed, and most suitcase style generators are optimized to completely enclose the engine to reduce noise. A standard 2 or 3kW suitcase style AC portable generator ranges from 50 to 100lbs. and will provide six to ten hours of backup per tank of gasoline for an average plant load of 600W. Due to this limitation, extended outages often require portable generators to be refueled multiple times, adding significant operational cost and environmental risk of technicians spilling gasoline in the field. Additionally, the flexibility and portability of generators make them an easy target for theft, often requiring additional cost and effort to secure. Another drawback to portable generators is that their output voltage quality is typically less stable than utility power. Variations in frequency and fluctuations in voltage can interact with the broadband UPS, causing the UPS to switch between utility line mode and battery backup mode. To avoid this undesirable behavior, modern UPS systems employ an AC input desensitizing feature to overcome poor input voltage quality typical of portable AC generators.

Portable generators can be staged from an operators' regional facilities to be within physical proximity of UPS locations that may require extended backup power. A typical portable generator staging approach utilizes trailers with multiple generators that are ready to deploy when needed. An example of a portable generator trailer is shown in Figure 2.

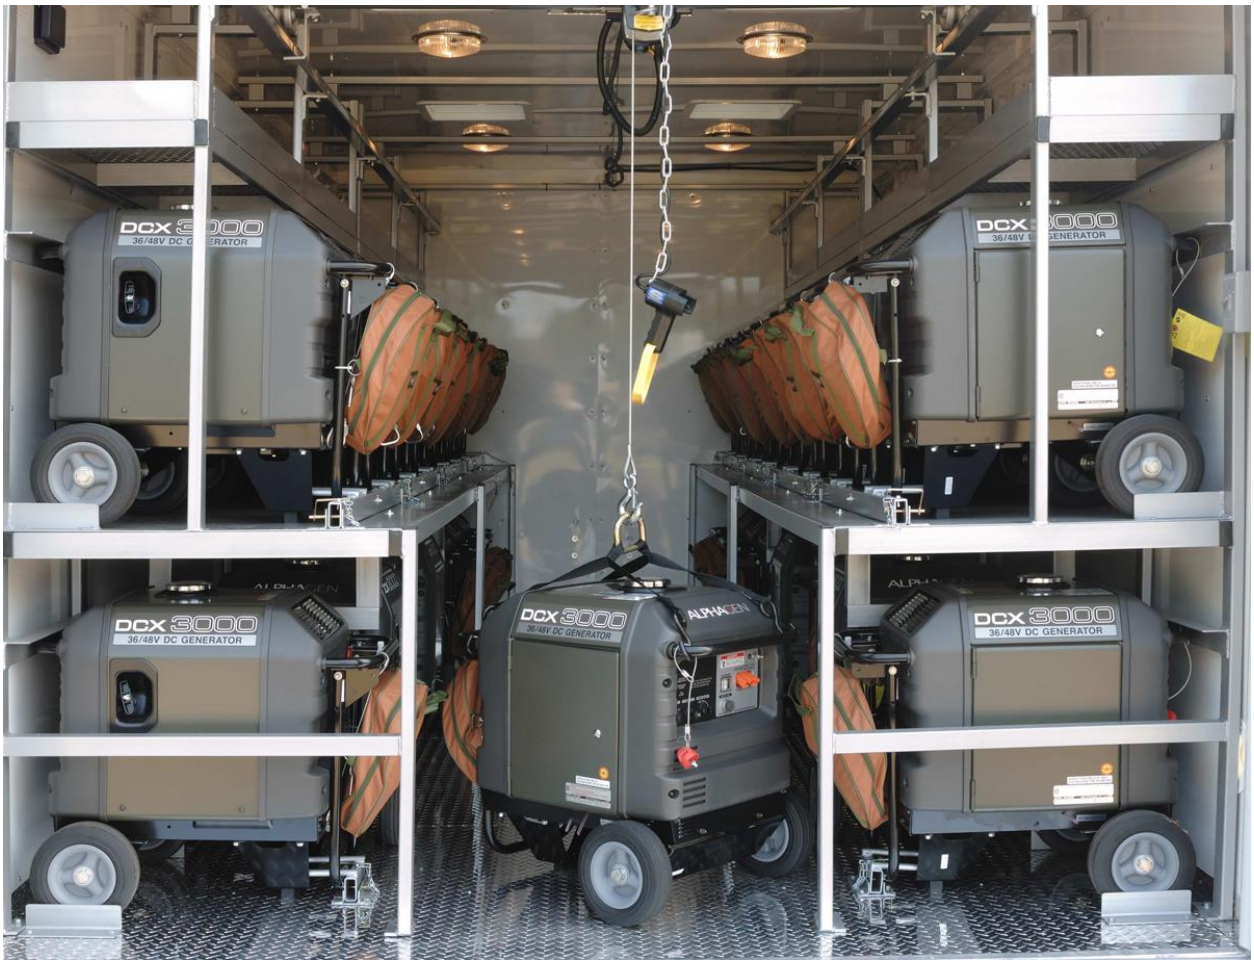

Figure 2- Portable Generators Staged for Rapid Deployment During an Outage

Run time limitation and theft risk of small portable generators can also be mitigated by using larger, tow-behind portable generators designed for construction sites. These larger generators can be capable of storing more than 50 gallons of gasoline allowing them to provide significantly more backup time, and due to their size, there is a reduced risk of theft. Larger generators do, however, have some drawbacks. Once again, due to their size and design, they can only be deployed one-at-a-time, meaning activation in a widespread outage can take a small army of technicians or making dozens of trips to and from the operator's warehouse. In addition, the amount of space required to store a fleet of large generators can be prohibitive and carry higher costs to maintain. In conclusion, larger portable generators are sized for larger loads than what's typically needed for cable, making them highly inefficient in this application.

3.3. Curbside (Stationary) Generators

Curbside or stationary generators are permanently stationed next to an existing cable powering site with critical loads to provide consistent support for extended outages. Historically, curbside generators were deployed in centralized powering architectures, where multiple power supplies were installed in a single location which fed power to the plant in multiple directions like the hub of a wheel. This allowed the significant cost to purchase and install the generator, and connect fuel to the site, to be distributed across multiple power supplies, making the cost per supply more reasonable. Stationary generators used in OSP powering applications provide DC voltage and connect directly to the system's DC bus with the battery

string and power supply inverter. This allows the generator to avoid frequent stops and starts from momentary outages by only starting when DC voltage drops below a certain level. A typical curbside generator installation included multiple enclosures: one enclosure houses the power supplies and limited battery backup. A second enclosure houses the generator. Some installations include a third enclosure to house propane fuel tanks for locations where natural gas is not available. A typical curbside generator installation is shown in Figure 3.

Figure 3 - Typical Curbside Generator Installation Using Natural Gas

Stationary generators are likely fueled with plumbed natural gas or with liquid propane cannisters. Of these two, generators that operate on natural gas are better candidates for delivering extended run time. When generators are fed natural gas via a pipeline it is less likely to be affected by a power outage. The drawback is many sites are not in locations with access to natural gas, and most sites that could have access are not currently equipped with natural gas due to upfront costs of digging a trench, running a new gas line to a site, installing and certifying a metered service, and permitting. Combined this process can add months of delays and thousands of dollars to site turnup and eliminate financial viability to add natural gas connection to meet the extended run time requirements. Liquid propane is used when natural gas is not available and the inherent limit to the amount of fuel that can generally be stored on-site for backup makes propane a less desirable fuel for extended outages of more than 24 hours.

Another factor to consider when looking at curbside generators as an option is the amount of maintenance required for proper functionality during extended outages. Since generators run on an internal combustion

engine, which is a complex system of moving parts, it is necessary to perform maintenance at least twice annually. An increased number of extended outages may also necessitate more frequent maintenance visits. Because of this additional maintenance requirement, TCO models should always bear this in mind.

One other key factor that cannot be overlooked when deploying portable or curbside generators is the noise level of the engine and its impact on overall customer satisfaction. As shown in Figure 1, many OSP powering sites are adjacent to customer residences or within utility easements on customer property. This alone can be a point of frustration, but when generator noise is added, it can often lead to customer complaints and, in some cases, customers lobbying local governments for restrictive ordinances to be placed on cable installations. For this reason, potential impact to customers is a primary factor when considering generator-based solutions.

4. Battery Overview

Batteries, the most common source of backup power, provide DC power to a standby power supply to be converted to AC plant power in times of utility outage. Batteries come in many shapes, sizes, capacities, and chemistries. Lead-acid chemistry has been a fundamental stalwart of energy storage for many decades. Traditionally, indoor applications were supported with flooded lead-acid batteries. These batteries have a liquid electrolyte, generate oxygen at their positive electrodes and hydrogen at their negative electrodes. Over time, water loss occurs, which requires the electrolyte to be topped off with water on a regular basis. A byproduct is the production of hydrogen and oxygen gas which must be ventilated to avoid hydrogen accumulation and the potential of combustion.

Both outdoor and indoor applications use valve regulated lead-acid (VRLA) batteries. The electrolyte is not liquid, but instead is immobilized with either a gel or absorbent glass mat (AGM). The result is less water loss, eliminating the need for topping off with water. Gas emissions are much lower in this solution, therefore ventilation requirements are far less than flooded lead acid batteries. Additionally, VRLA AGM batteries are generally rated non-spillable per UN 2800, which reduces regulations required for safe shipping.

The arrival of TPPL technology, a type of AGM VRLA battery, transformed lead-acid battery performance. TPPL batteries have thinner, high purity grids meaning more of them can be stacked into the battery. The result is increased surface area contact between the grid and active material boosting power densities. Therefore, TPPL batteries can deal with much higher current peaks and have faster charging capability. Standard TPPL batteries in case sizes designed to fit in most standard OSP cable enclosures, generally have higher capacities than other equivalent AGM VRLA batteries. For Extended Run Time applications where space is available for additional ground-mount cabinets, larger, high capacity TPPL batteries can be an additional high-value option.

Positive attributes for VRLA batteries include ease of transport, ease of installation, reduced maintenance, and higher energy densities compared to their flooded counterparts. A 98% recycling rate at end of life is also beneficial to the environment. Technicians in general like working with VRLA batteries, as they are typically non-spillable, include handles for improved installation and handling, and require limited maintenance. TPPL versions include greater temperature tolerance, higher energy density and longer life.

Two key downsides of VRLA batteries are slightly higher costs measured against flooded batteries and heavier weights associated with increased energy density. The high purity of TPPL models also increase initial cost, but the TCO is favorable due to the improvements in energy density and battery life.

4.1. Lithium Ion Batteries

Lithium Ion (Li-ion) batteries were originally conceived in the early 1970's and first commercialized by Sony 30 years ago[ii], but even as a result of continued research, development, and investment, they are still in infancy. Although there is still a positive and negative electrode, separator, and electrolyte similar to traditional lead-acid batteries, the key method of operation is the shuttling of Lithium Ions between electrodes. Temperature, charge voltage, end of discharge voltage and impurities limit the shuttling ability over time resulting in the loss of battery capacity.

The positive and negative electrodes of Lithium Ion batteries vary by technology and application, with this variance defining cell voltage and energy density. More research has been conducted on the positive electrode with Nickel-Manganese-Cobalt (NMC) and Iron Phosphate (LFP) being the most common, however research to improve the negative electrode is equally promising for the future.

Since multiple Lithium Ion chemistries exist, selecting the right one for an application is important. In Figure 4, the selection of chemistry will determine the voltage operating window and can impact the system cell count. LFP for instance operates at a lower voltage, therefore, to meet a higher system voltage, more LFP cells will be needed over other chemistries, such as NCM or NCA to meet the same system voltage window.

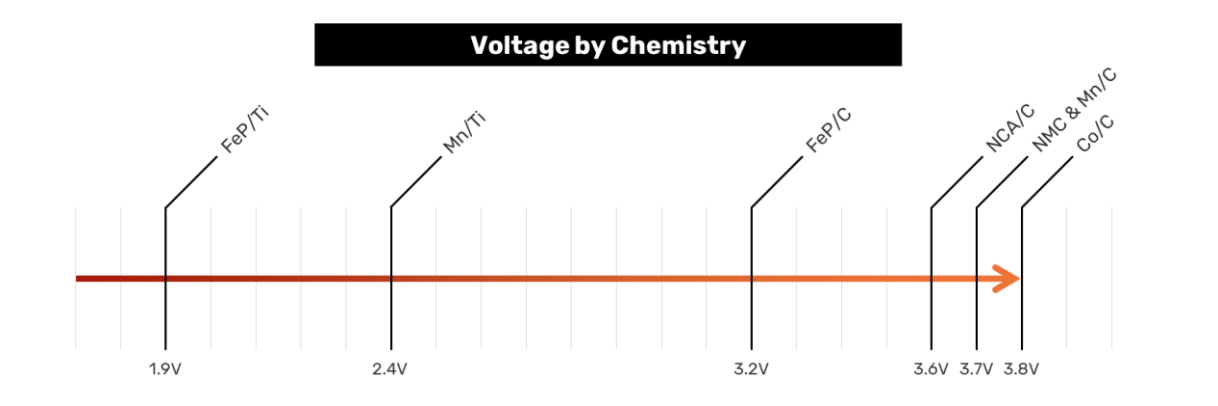

Figure 4- Standard Voltages of Lithium Ion Battery Cells based on Chemistry

Some key attributes for LFP and NMC chemistry batteries are depicted in the spider chart shown below. Since the CPUC project requires the providers to maximize run time and local jurisdictions would prefer as little physical presence as possible, NMC is a desirable choice to meet these goals. It also offers both cold and warm temperature tolerance and suggests long life in this type of application.

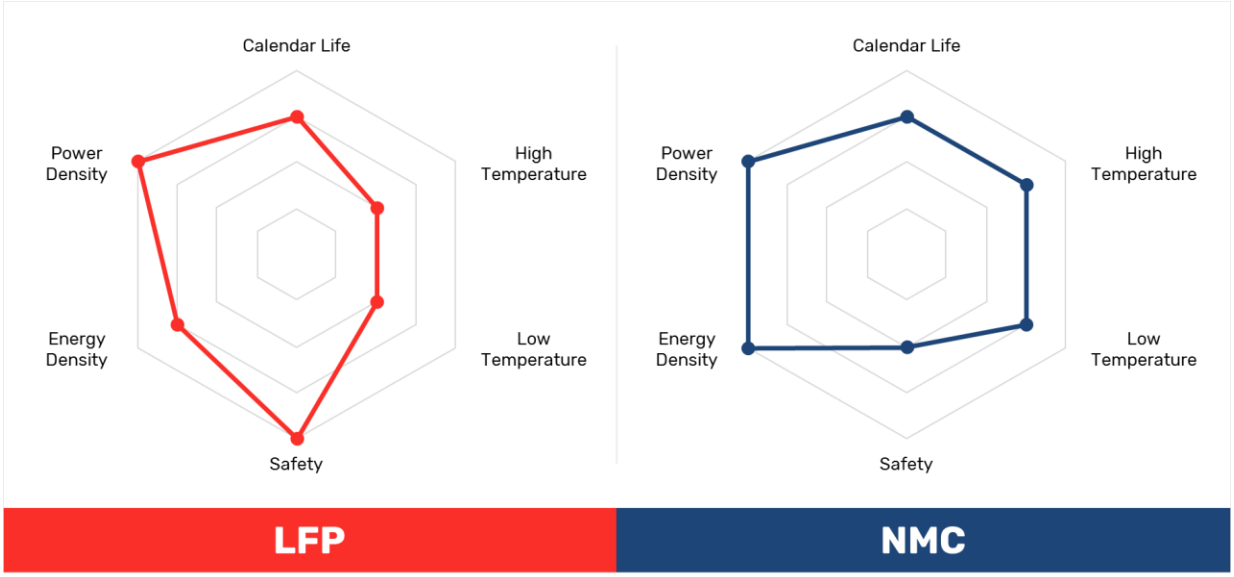

Figure 5- Spider Chart Showing Key Attributes of LFP & NMC Lithium Ion Batteries

4.2. Safe Lithium Ion Battery Design

When building Lithium Ion battery modules and systems, product developers must incorporate varied and numerous safety layers into the design as the battery needs to have optimize life, performance, and most importantly, safety. A graphic representation of these safety layers is shown in Figure 6. The Western Automotive-Grade Cell is the high-quality center of the layered approach. This is the optimal starting point for any designer as they develop an integrated system. Mechanical Safety System layers are designed to fit the battery housing, while providing physical protection for the critical internal elements. Operating the system in a safe way, while monitoring the key diagnostic parameters adds the Application-Level Software and Functional Safety Layers to the design.

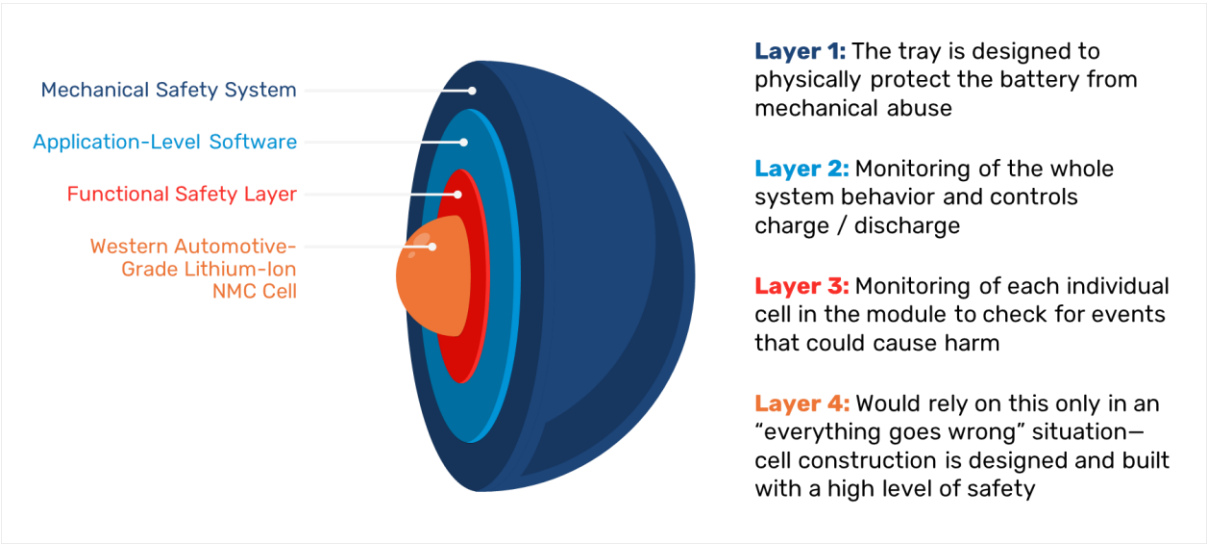

Figure 6- Graphic Representation of Layered Safety Design for Lithium Ion Batteries

Lithium Ion batteries require a Battery Management System (BMS) since, unlike lead-acid batteries, individual cells in a Lithium Ion system do not inherently work with each other to maintain system harmony and balance. The BMS can be active or passive, but it is critical to safe operation and application of the battery for successful system design. As a BMS gathers data, it raises alarms and makes critical decisions. With the proper communication protocols and interaction, the BMS can input information to the network operation center to allow assessment of battery health and overall system readiness prior to, during, or after an outage.

4.3. System Design for Lithium Ion Batteries

When designing any power system that integrates energy storage, it is always recommended to consider how battery performance, life and safety can be maximized by the broader system. This concept becomes significantly more important when considering lithium battery deployment in the OSP, where there is limited environmental control and most power supplies have been designed to manage unintelligent lead-acid batteries with brute force charging methods. Elements such as the system enclosure, power supply charger, internal infrastructure, and remote monitoring systems should all be optimized for integration with Lithium Ion batteries. Simplicity and safety for Lithium Ion products comes through a fully-integrated, engineered system.

First, it is vital to see if there is ample space for proper airflow between lithium batteries, and any necessary passive or active heating and cooling to maximize battery life and performance for outdoor systems. Next, the intelligence inherent in the BMS, required for safe deployment of a Lithium Ion battery, presents an opportunity to use the power supply charger as an additional safety layer. By creating a coordinated communication path between the Lithium Ion BMS and power supply, charge currents can be safely managed and optimized for the battery modules. Additionally, a Lithium Ion BMS should have the ability to provide valuable information that can be leveraged by remote status monitoring such as state of charge and state of health of the battery modules. Conversely, adding lithium batteries to an OSP power supply that has not been designed and tested for interoperability and communication can be potentially dangerous as the potential exists for the power supply charger to provide improper charge current to the BMS and harm Lithium Ion batteries. For these reasons, it is of the utmost importance that Lithium Ion batteries be designed into, and thoroughly tested with their intended OSP power system before being deployed in the field.

4.4. Comparison of TPPL and Lithium Ion Batteries

TPPL and Lithium Ion batteries have unique attributes, yet many applications will see the combination of both chemistries drive value for the application:

Physical Attributes:

Chemistry	Energy Density	Form Factors	Weight	Physical Orientations	Include BMS Electronics
TPPL	High	Many	Heavier	Most	Not required
Lithium Ion	Higher	Limited	Lighter	All	Yes, required

Operational Attributes:

Chemistry	Ventilation	Cut Off Voltage	Cycling Capable	Partial SoC Operation	Recycling
TPPL	Limited	Variable	Limited	Limited	98%
Lithium Ion	None	Fixed	Significant	Excellent	Limited

Figure 7- Comparison of the benefits of TPPL Lead-Acid and Lithium Ion Batteries

With noted differences above, each chemistry has physical and operational advantages depending on the application. Every day more applications arise where a Lithium Ion solution is the most viable solution because of energy density, longer life and greater cycling capability. However, in many situations TPPL remains the most cost effective and flexible solution available.

5. Requirements for Extended Run time Solutions

Generators and/or batteries (TPPL or Lithium Ion) can be used to meet extended run time requirements, but the right selection depends on analysis of several factors:

1. **Required backup time**: *The CPUC requires 72 hrs., however this may vary as other states develop backup recommendations around their unique needs.*
2. **Real estate:** *How much space is available at the site for additional enclosures or generators. Many sites have limited space and would require significant redesigns to create additional space.*
3. **Existing cabinet space:** *Using the existing cabinet where utility connection has been established is often paramount to avoid significant costs for running a new service. Maximizing energy density within an existing cabinet is the best strategy in these situations.*
4. **Location of the existing plant (aerial/underground)***: Generally, this determines the location of the established cabinet.*
5. **Power system load***: OSP power system loads can vary substantially where two sites with virtually identical systems can require drastically different upgrades for extended run time capability.*
6. **Fuel availability***: Primarily, is natural gas readily available at or near the site? This is one of the biggest questions when determining curbside generator viability.*
7. **Local regulations***: Local laws can restrict everything from the height, width, or weight of an enclosure to the type of fuel you are allowed to use and the permits required to do so.*
8. **Security concerns***: Sites at risk for theft can have unique challenges securing batteries, portable generators, or propane tanks. Additional security measures can drastically change TCO.*

9. **Total initial system cost**: *Upfront spend for the system cabinet, equipment and turn-up. This is often the biggest limiting factor for traditional extended run time solutions like curbside generators.*

5.1. Scenario Solution Comparisons

There are many different scenarios to consider when defining solutions. For brevity, this paper addresses several popular scenarios using common loads and varying available space, fuel, and security needed at each system location. Some assumptions were made for scenario comparisons:

- All loads are critical for support as driven by customer agreement or government regulation, therefore allowing the network to go down has significant financial consequence
- At least one extended outage greater than 12 hours occurs annually
- Costs for all equipment are based on currently deployed products plus known installation expenses
- Cost per truck-roll for generator maintenance or refueling is around $200 USD
- Impact of security concerns will be higher for lead batteries and portable generators having greater potential for reuse or value from recycling
- Lead-acid battery weight and energy density calculated from known TPPL configurations
- Lithium Ion battery weight and energy density is based on known NMC cell configurations
- Lithium Ion battery useful life assumed to be approximately two times that of TPPL

Scenario 1:

First, let's look at the run time capabilities for lead-acid batteries, lithium-ion batteries, and portable generators when the load is 4 Amps and there is only enough space for one pole mounted cabinet with a weight limit of approximately 600 lbs.

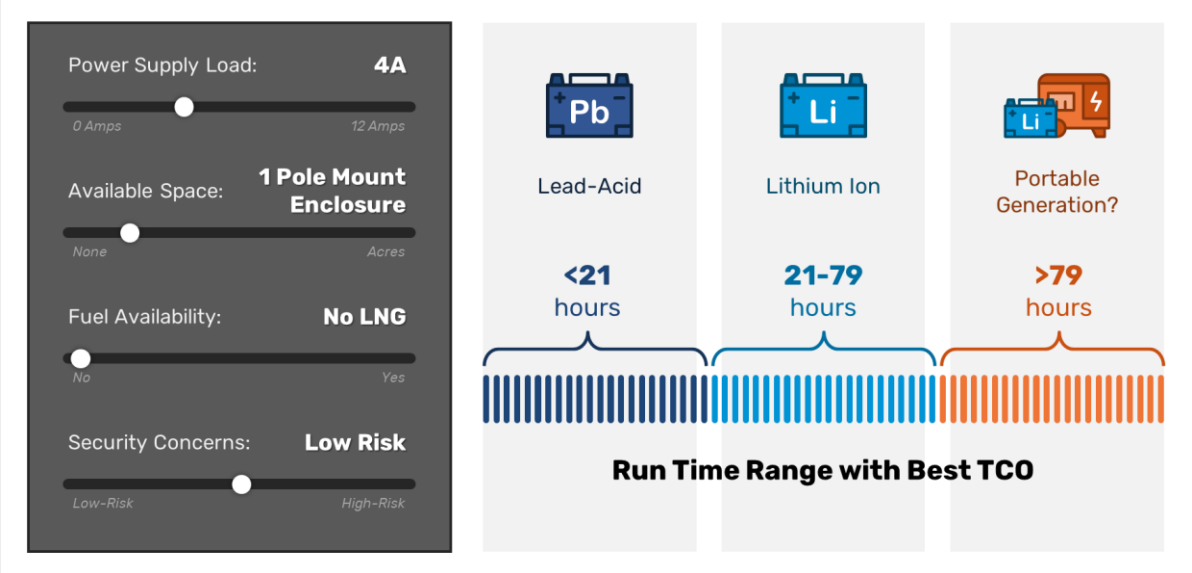

Figure 8- Run Time Ranges for Solutions in Extended Run Time Scenario 1

Due to space and weight restrictions of many pole mount installations, Lithium Ion batteries can play a key role in meeting extended run time requirements in this application and avoid the significant operational costs of portable generator deployment and refueling. However, as with any situation where

space is limited, after a certain run time threshold, the ability to continually bring new fuel on site to keep a portable generator running will be the only available tactic.

Scenario 2:

The next hypothetical scenario involves a ground mount site with an 8A load allowing space for one additional cabinet and an available natural gas hookup for a curbside generator. It is assumed this is a roadside deployment with little potential for noise to impact customer perception.

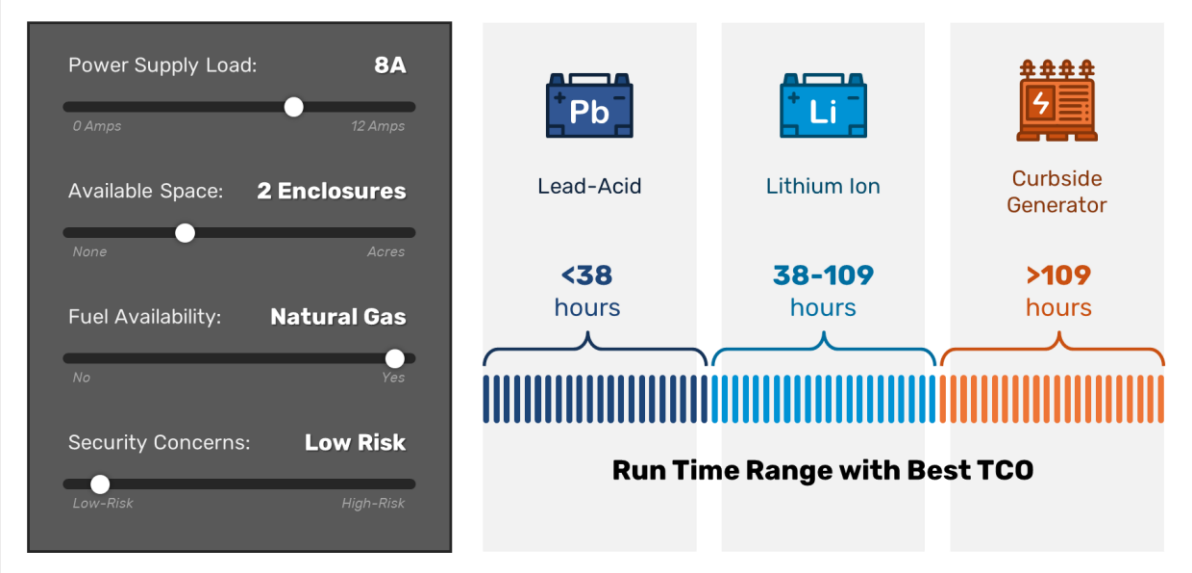

Figure 9- Run Time Ranges for Solutions in Extended Run Time Scenario 2

In this scenario, additional space afforded has an impact on useful range of battery solutions, as the amount of energy that can be stored on site is significantly increased. All three solutions can now be considered with using a second ground-mount enclosure on site. The TPPL solution no longer needs to be limited to case size 31 batteries and can now leverage an additional enclosure with High-Capacity TPPL batteries that may have been too heavy or taken up too much space for a pole mount application. The availability of a natural gas connection supports an on-site generator solution for extreme outages and does not require an army of technicians to refuel portable generators. Once again, Lithium Ion batteries show great promise as an alternative to a curbside generators in this extended run time scenario.

Scenario 3:

The first two scenarios considered common loads on the lower end and middle end of the load spectrum. This scenario has a higher site load of 12A, there is some restriction in available real estate, and an available natural gas line near the site. For this scenario we will assume this site has a history of frequent battery theft.

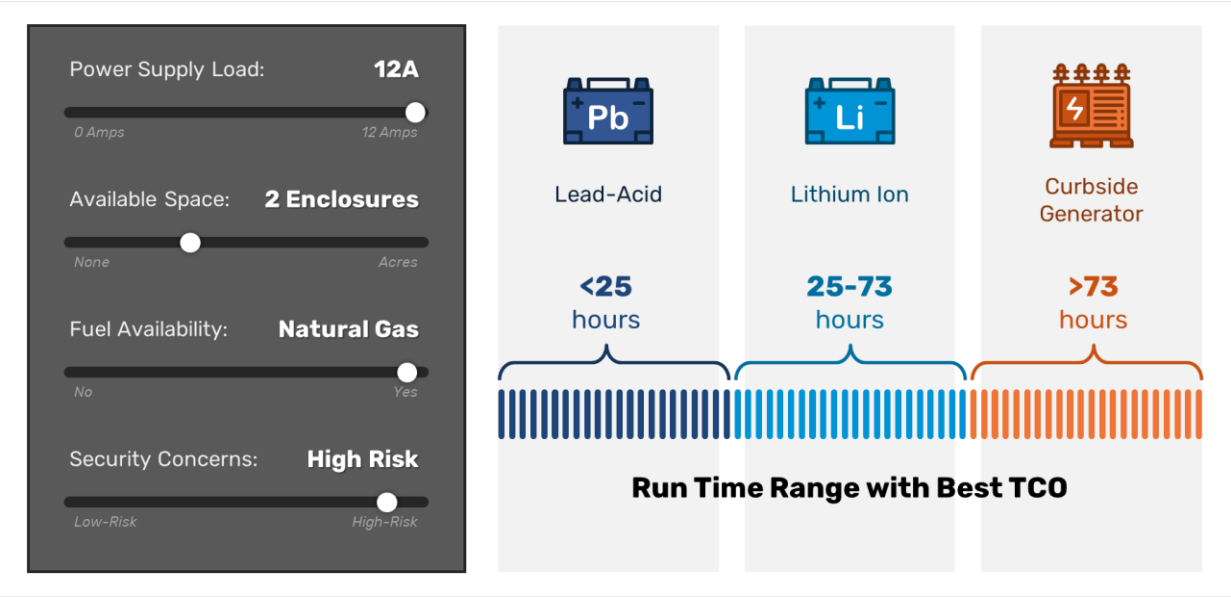

Figure 10 – Run Time Ranges for Solutions in Extended Run Time Scenario 3

The increased load on the power supply has an obvious effect on the available run time from battery-based options where Lithium Ion continues to show promise as the best TCO option to protect against extended outages. A subtle point to be understood here is the higher threat of theft could change the viability of lead acid, by building significant cost into the model for site security options. It could also mean planning multiple replacement cycles for the TPPL option, which also brings risk of the site being without backup during a critical outage.

5.2. Scenario summary

The number of variables in the explored scenarios further emphasizes the fact that there is no one-size-fits all solution for extended run time outages. Each variable needs to be carefully considered in order determine the best solution at each site. The key to having a solution for every site is to have a variety of tools to adjust for variability in site dynamics and run time requirements.

6. Conclusion

Power availability for critical HFC service during extended outages has become increasingly vital for operators because of new government regulations and greater global reliance on the broadband network. Simultaneously, the problem of extended outages does not seem to be going away any time soon. Data from the U.S. Energy Information Administration shows from 2018-2020 there were 164 extended outages in the U.S. alone that impacted more than 50,000 customers at a time, the largest of which impacted more than 1.4 million homes. [iii]These outages have begun to garner the attention of state and federal lawmakers and, in the case of California have driven strict wireline resiliency regulations.

Current available solutions addressing the challenge of extended outages have their own unique set of benefits and limitations, so having a suite of solutions to address the nuances of varied existing HFC powering deployments is imperative. High capacity TPPL lead-acid batteries will allow for adequate run time extension in a number of scenarios. And, while portable and stationary generators will continue to be useful in limited situations, advancements in Lithium Ion battery technology, and economies of scale driven by electric vehicles, have broadened the applications where lithium has a better TCO. Due to its

extreme energy density, light weight, cycling capability and advanced intelligent diagnostics, Lithium Ion technology as a part of an integrated, engineered system will become the keystone of many operators extended run time network resiliency programs.

Abbreviations

AC	Alternating Current
AGM	Absorbent Glass Mat
BMS	Battery Management System
CPUC	California Public Utility Commission
DC	Direct Current

1. Introduction

With the advent of smartphones and widespread deployment of mobile technologies like 4G LTE (and now 5G NR), wireless connectivity is becoming an integral part of a connectivity service offering for multiple system operators (MSOs). Several MSOs that lack mobile network infrastructure have relied on the mobile virtual network operator (MVNO) model to supplement their connectivity offerings with wireless. New entrants like DISH in the United States and Rakuten[1] in Japan (who are deploying their own mobile infrastructure) are also taking advantage of MVNO arrangements to supplement their network coverage.

As the name suggests, an MVNO is a wireless service provider that does not own the end-to-end mobile network; instead, it leverages a portion of a mobile network operator (MNO) network via a business agreement. Typically, MVNOs focus on the marketing, billing, and customer facing aspects and rely on the MNO network and/or services infrastructure to deliver the connectivity and/or services.

The MVNO's payments to the MNO are typically based on usage by the MVNO's customers. Although voice usage has stabilized, data usage continues to grow at a compound annual growth rate (CAGR) of more than 25%.[2] This makes the offloading of data for MVNOs even more important to remain profitable in the long run. The continued success of MVNOs is also important to MNOs in terms of sustaining their wholesale revenues (resulting from the MVNO data usage).

Until now, MVNO offerings from MSOs have relied on Wi-Fi to offload data usage from the MNO's network. Shared spectrum such as the Citizens Broadband Radio Service (CBRS) is significantly reducing the barriers for new entrants and small operators to further offload data usage and improve the economics of an MVNO offering. Deployment of shared spectrum will require MSOs to build their own cellular infrastructure to enable offload using CBRS in areas of high usage.

As MSOs look to deploy their own wireless infrastructure, they will have to contend with three disparate sets of wireless infrastructures—the MSO's community Wi-Fi network, the MNO's 4G/5G network, and the MSO's own 4G/5G network. Maximizing offload via the MSO's own wireless assets, ensuring a consistent user experience, and enforcing uniform and personalized policies as users move in and out of coverage of these three networks will require deployment of new converged network architecture and related capabilities.

This paper is focused on describing options for these evolutionary converged architectures that can be utilized by the MSOs as they progress in building out their own 4G/5G networks.

2. Overview of MVNO Models

Globally, several different MVNO models have been implemented and can be broadly classified as depicted in Figure 1. The classification is based on the amount of mobile network infrastructure owned by the MVNO and the degree of control over the management of different aspects of MSO subscriptions and their service offerings.

[1] "Rakuten Mobile Completes Connection of MMEs with KDDI Roaming Areas Through S10 Interface," press release, April 2020, Rakuten Mobile
[2] Figure 13 of "Ericsson Mobility Report," November 2020, Ericsson

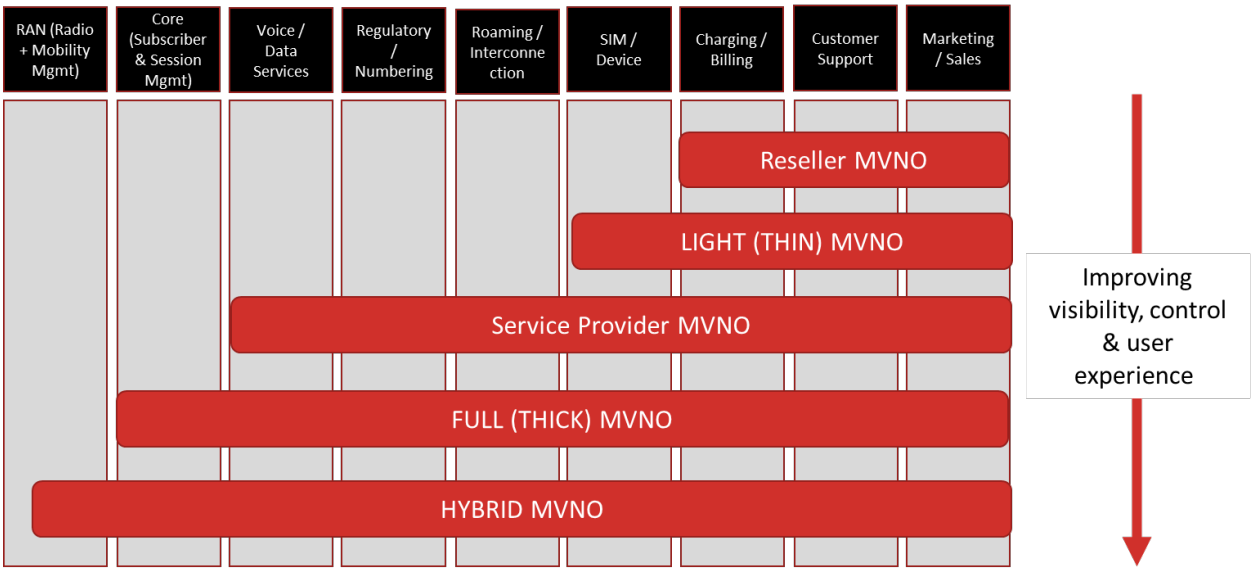

Figure 1: MVNO Types and Degree of Control

Reseller MVNO

A reseller MVNO manages the billing and customer network support functionality while utilizing an MNO for subscriber identity module (SIM) management, device management, core network, and radio infrastructure. The MVNO has no control over subscription, policy, and mobility management and lacks visibility into a subscriber's usage pattern to customize the service offering.

Light (Thin) MVNO

The light MVNO model is like the reseller model, except the SIM and handset are managed by the MVNO; all other aspects remain unchanged. The MVNO still has limited to no control on network policies, subscription, and mobility management of the subscriber on the cellular network and lacks visibility into data usage by its customers.

Service Provider MVNO

In comparison to the first two types of MVNOs, a service provider MVNO is responsible for deploying, operating, and managing its own service platform, thereby enabling the MVNO to differentiate its service offering from that of the MNO. However, the radio and core infrastructures still belong to the MNO, and the MVNO still has limited control on network policies, subscription, and mobility management of the subscriber on the mobile network.

Full (Thick) MVNO

In addition to the service platform, a full MVNO deploys certain mobile core network nodes, such as packet gateways and policy controllers, to have more control over the policy and session management of its customers while allowing the MVNO to leverage the MNO radio and mobility management infrastructure. The data traffic is routed back to the MVNO's mobile core network.

The MVNO manages billing, customer network support, SIM credentials, handset functionality, subscriptions, and policies and has full visibility into data usage. However, the MVNO has limited to no control over mobility management of the subscriber on the cellular network. This model is like the traditional home routed (HR) roaming model specified as part of 3GPP standards.

Hybrid MVNO

A hybrid MVNO (H-MVNO) is a relatively new model wherein the MVNO owns a mobile radio network deployed in specific geographic areas. These networks could be small cell hotspot deployments or traditional regional mobile deployments.

Like the full MVNO model, billing, customer network support, SIM credentials, handset functionality, subscriptions, and policies are managed by the MVNO. Additionally, the user device is prioritized to access and utilize the MVNO radio network when available and to use the MNO radio network only when it is outside the coverage of the MVNO radio network. This model can be of particular interest to many MSOs who may have or are planning to have hotspot and/or regional mobile deployments.

To deliver a seamless (converged) experience across the two wireless networks, a varying degree of convergence (interoperability) between the two networks is required. The degree of convergence and interoperability between the networks will depend on the type of applications used by the end users, types of services to be provided by the H-MVNO network, and the desired level of visibility into the subscriber usage to enable customized service plans, as well as the amount of operational coordination that is acceptable to both the H-MVNO and the MNO.

The hybrid MVNO model and associated converged architecture options are the focus of this paper. The next section covers the converged architecture options for evolving a traditional reseller or light MVNO into a hybrid MVNO.

3. Architecture Options for a Hybrid MVNO (H-MVNO)

The architecture options outlined below are categorized into two broad categories based on device capability regarding SIM support.

1. Architecture options for devices with dual SIM support
2. Architecture options extending support to single SIM devices

3.1. Architecture Options for Dual SIM Devices

In this section, we analyze the architecture options available to H-MVNOs for dual SIM devices.

3.1.1. Architecture Option 1: Independent Mobile Core Networks

Dual SIM devices have been around for some time. Traditionally, dual SIM devices were used to manage two separate phone lines with a single device (e.g., one for personal use and the other for business use or while traveling internationally). With the advent of embedded SIM (eSIM) technology, most smartphone manufacturers now support at least two SIMs—a physical SIM and an eSIM. With two SIMs in a device, the device can be configured to connect to two different networks from two different operators, making it a logical option for H-MVNOs to consider.

Most devices that operate in a dual SIM dual standby (DSDS) mode have two radio receivers but a single transmitter (although this may change with the proliferation of 5G), implying that the user can actively transmit data on only a single network at any given time. While on an active data session on one network, the DSDS device remains in standby mode on the second network, continuing to listen to paging messages. Upon receiving a page, based on service settings, the device either provides an indication of the incoming page to the user or automatically connects to the standby network while transitioning to standby on the first network.

Using DSDS-capable devices is the simplest way for an H-MVNO to maximize the use of its own network and utilize the MNO's network only when the user is outside the coverage of the H-MVNO's own mobile network. Figure 2 shows the network architecture for an H-MVNO utilizing DSDS, where both the MNO and H-MVNO have independent mobile cores and subscriptions. The MNO SIM is configured in the MNO Home Subscriber Server (HSS), while the H-MVNO is configured in the H-MVNO's combined unified data management (UDM) + HSS system. The transition between the H-MVNO and MNO networks in this architecture is controlled and managed by the intelligence in the device.

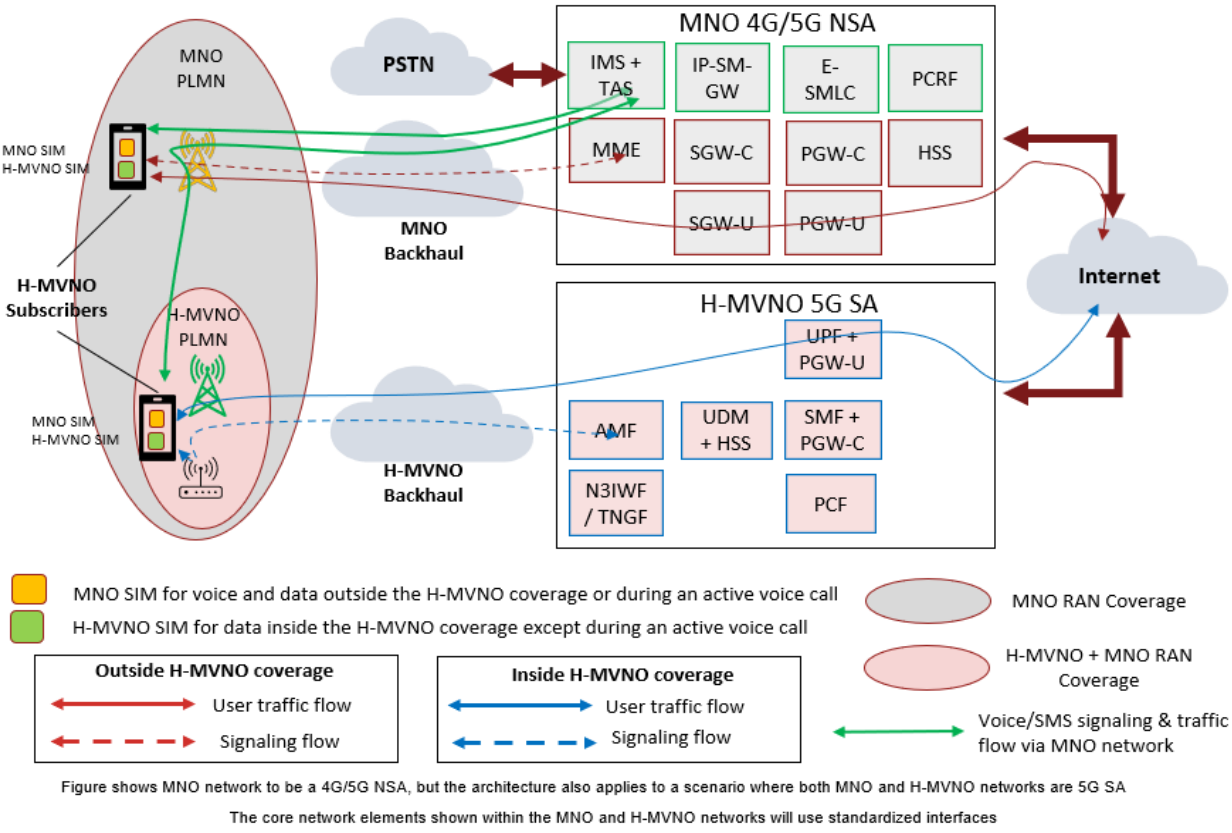

Figure 2: Hybrid MVNO Architecture Option 1—DSDS-Based Architecture

When the H-MVNO subscriber is inside the H-MVNO network coverage area, the user device connects to the H-MVNO network via the H-MVNO SIM (active SIM) to access the Internet while the MNO SIM is in standby, significantly reducing the time spent on the MNO network. On the other hand, when the H-MVNO subscriber is outside the H-MVNO coverage footprint, the H-MVNO SIM is not connected, and the device connects to the MNO network via the MNO SIM (active SIM) to access the Internet. Because of

the limited coverage of an H-MVNO network and the lack of a seamless handover between the two networks in this architecture, voice service will be over the MNO network.

The transition between the two SIMs (and the associated networks) while a user is active on one network is critical. It occurs in two cases.

- Paging-based—the device inside H-MVNO coverage receives a paging message from the MNO network for voice related service, and the user accepts it.
- Coverage-based—the device active on the H-MVNO network moves outside H-MVNO coverage or the device active on the MNO network moves inside H-MVNO coverage.

In addition to having to depend on dual SIM devices, this H-MVNO architecture option faces the challenge of the DSDS switching between networks. The custom intelligence built into all dual SIM devices before the finalization of the 3GPP Release 17 (Rel-17) standard will have vendor-specific implementations, which can result in a variety of user experiences. In June 2019, CableLabs conducted testing[3] on a subset of commercially available dual SIM phones to analyze the behavior and impact on user experience with regard to network connectivity, data-session transition, and paging on a non-active network. The test observations and results indicated that user experience varies significantly depending on the vendors' implementations on the dual SIM devices. The implementations supported paging-based scenarios but were not efficient for coverage-based scenarios, requiring user intervention and impacting user experience when switching between the networks corresponding to the two SIMs .This is because the device implementation assumes overlapping coverage from both the networks.

An H-MVNO needs to work closely with device vendors to customize the devices for effectively managing the transition between the two networks, specifically for hand-in/hand-out of H-MVNO network coverage and paging-based scenarios.

The H-MVNO network also needs to be able to gracefully become aware of the DSDS switching events (responding to either a mobility event or the user accepting a voice call through the MNO network) so as to avoid degrading the key performance indicators (KPIs), perform internal context cleanup (discard buffered download data, delete bearer context, etc.), and avoid wasting system resources. 3GPP is trying to address some of these issues related to the use of multiple SIMs. However, because of the ongoing pandemic, finalization of 3GPP Rel-17 has been delayed, and the earliest availability of these standards-based features in devices and infrastructure will likely be in 2023–2024.[4]

The voice and messaging services, including emergency calling/texting, will be provided via the MNO network utilizing the MNO SIM. While in H-MVNO coverage, the data services are via the H-MVNO access network except when active on a voice call. While on the voice call, the data services will be via the MNO access network utilizing the MNO SIM. While outside the coverage of the H-MVNO network, the data services will be via the MNO's network.

Finally, H-MVNOs lacks real time visibility into their subscribers' data usage statistics and patterns over the MNO network and have no control over policy, subscriptions, mobility, and user experience management when its subscribers are outside the H-MVNO network coverage. To overcome these data visibility and policy challenges resulting from having two separate anchor points with their own policies, user traffic needs to be routed back to the H-MVNO network. One way this can be achieved is via an over the top (OTT) VPN-like solution comprising a custom device-side application (e.g., connection manager) and a server-side application located in H-MVNO's cloud platform (private or public). Another is a

[3] "Dual SIM—An Alternative to 3GPP-Based Roaming Models," technical brief, June 2019, CableLabs R&D Wireless
[4] 3GPP Release 17, Study on System Enablers for Devices Having Multiple Universal Subscriber Identity Modules (USIM), TR 23.761, v1.5.0 (June 2, 2021)

standards-based approach that does not require a custom device client. There are two different standards-based ways (that do not require a client-side application) to achieve this and are described in sections below.

3.1.2. Architecture Option 2: Enabling S8 Interface Between Networks

One evolutionary approach to overcome some of the limitations of the above architecture option is shown in Figure 3.

This architecture evolution relies on implementation of standards-based interfaces between the two networks. The H-MVNO subscriber traffic across both the H-MVNO and MNO SIM connections is always anchored within the H-MVNO mobile core (routed from the MNO to the H-MVNO via the S8[5]-based interface). This ensures full visibility into subscriber data usage, irrespective of which network is used. The H-MVNO and MNO SIMs continue to be configured in their subscriber databases (HSS for MNO and UDM+HSS for H-MVNO) within their own respective mobile cores. The mobility management entity (MME) within the MNO mobile core selects the H-MVNO packet gateway (SMF+PGW-C) based on the default access point name (APN) value specified in the connection request from the device and the APN subscription data from HSS. The DNS query from MME will include both the tracking area code (TAC) and the APN to pick the nearest SMF+PGW-C to the end user. The SMF+PGW-C then selects a corresponding UPF+PGW-U network element nearest to the end user (from a latency perspective). Termination of S6a and S8 in different administrative domains has not been contemplated within 3GPP and will have to be agreed to and coordinated between the MNO and the H-MVNO.

[5] Although MNO network is depicted as a 4G network, this can easily be extended in a similar way for a 5G System deployment

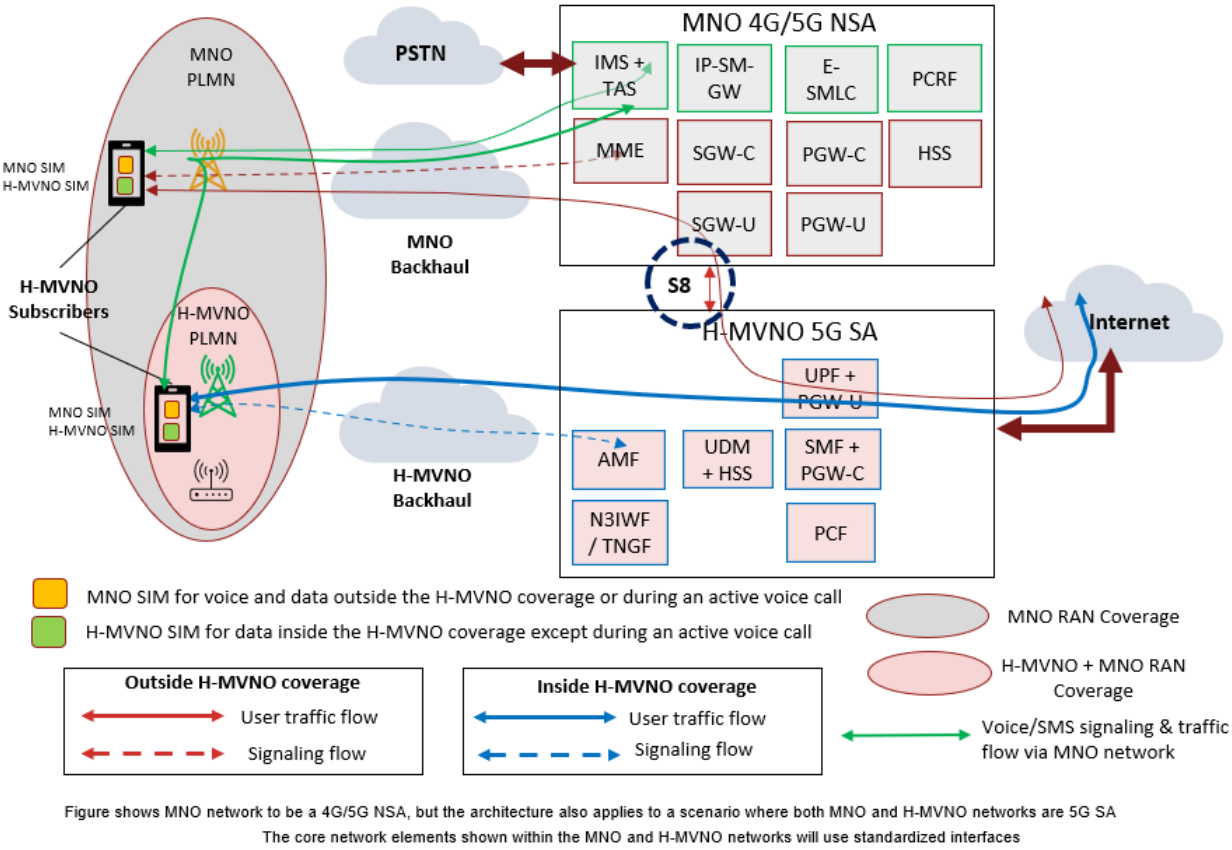

Figure shows MNO network to be a 4G/5G NSA, but the architecture also applies to a scenario where both MNO and H-MVNO networks are 5G SA
The core network elements shown within the MNO and H-MVNO networks will use standardized interfaces

Figure 3: Hybrid MVNO Architecture Option 2—Evolved DSDS Architecture

In this architecture option, like Option 1, the MNO SIM continues to be provisioned in the MNO HSS. Like Option 1, the voice and messaging services, including emergency calling/texting, continue to be provided via the MNO network utilizing the MNO SIM. While in H-MVNO coverage, the data services are via the H-MVNO access network except when active on a voice call. While on the voice call, the data services will be via the MNO access network utilizing the MNO SIM. While outside the coverage of the H-MVNO network, the data services will be via the MNO's network. However, unlike option 1, this architecture option uses a common data anchor point located within the H-MVNO network, thereby providing full visibility into the data usage patterns and statistics.

Some coordination to set up the connectivity between the MNO and H-MVNO networks will be required. Additionally, in this architecture, the MNO serving gateway (SGW-C) may have to generate the charging records for H-MVNO subscribers.

A key difference between the traditional 3GPP specified roaming architecture (home-routed) and this converged architecture (Option 2) is that while the roaming interface (S8) is utilized to interconnect the two domains for user data, the user subscription continues to be provisioned in the MNO HSS, resulting in continued use of intra-domain S6a interface for the control plane. The inter-domain interfaces between the MNO and the H-MVNO can be secured in the same way as they are done today for roaming, by using a secured connection.

Because the H-MVNO has control over the data traffic irrespective of which access network the subscriber is on (MNO or H-MVNO), it can implement uniform policies and functionalities in the H-

MVNO core network to manage steering/switching traffic, not only between the two 3GPP access networks, but also between the MNO's 3GPP network and the H-MVNO's non-3GPP (Wi-Fi) network.

In this architecture, it is possible to support access traffic steering, switching, and splitting (ATSSS) functionality across the H-MVNO's non-3GPP (untrusted, trusted Wi-Fi) network and the MNO's 3GPP network (even when the MNO 3GPP network is 4G[6]). While on the MNO's 4G network, the ATSSS traffic rules on the devices will be updated through the non-3GPP leg of connection. This will require some additional functionality within the H-MVNO infrastructure, as the SMF+PGW-C will have to retrieve information about the serving SMF+PGW-C and UPF+PGW-U and ensure that the same ATSSS anchor is assigned. The ATSSS capability will have to be enabled across both SIMs. However, unlike architecture option 1, no client-side application will be required.

By enabling ATSSS functionality across the H-MVNO's wireless (cellular and Wi-Fi) assets and the MNO's cellular network, a fully converged standards-based architecture could be realized, giving H-MVNOs tremendous flexibility in utilizing all available wireless access networks for user data transmission.

Additionally, capability to transfer the 3GPP leg of ATSSS-compliant Multi-Access Protocol Data Unit (MA-PDU) session from the H-MVNO's 5G network to the MNO's 4G network can also be contemplated as a custom capability within the H-MVNO mobile core; no enhancements are required in the MNO's 4G network. Depending on the implementation of the device IP stack, device side enhancements may not be necessary.

The next architectural option depicts a solution to enable ATSSS between the H-MVNO's Wi-Fi and the MNO's 4G network without requiring enhancements within the H-MVNO's core network or requiring ATSSS to be enabled across both SIMs. It also facilitates use of Wi-Fi connectivity when available, irrespective of whether the user is in the H-MVNO or MNO coverage.

3.1.3. Architecture Option 3: Enabling S6a and S8 Interface Between Networks

Figure 4 depicts further enhancements to architecture option 2. In this architecture option (option 3), the H-MVNO SIM is configured to roam onto the MNO's network when outside the coverage of its home network (H-MVNO network). Therefore, in addition to the S8 interface, this option requires support of inter-domain roaming S6a interface between the MNO and the H-MVNO networks for the H-MVNO SIM.

In this option, the data sessions are established using the H-MVNO SIM irrespective of whether the device is inside or outside the H-MVNO's network coverage area. The MNO SIM is utilized only for data sessions during an ongoing voice session. As in previous architecture options, the voice sessions continue to be established using the MNO SIM.

The roaming S6a interface is used by the MNO's core network to authenticate access via the H-MVNO's SIM. In the event an MA-PDU session was previously established, the anchor SMF+PGW-C is retrieved by the MNO's MME from the H-MVNO's network via the S6a interface. Otherwise, the PGW selection is done by the MME in the same way as described in option 1. The only time ATSSS MA-PDU will not be utilized is when the user is accessing data services during an ongoing voice call and Wi-Fi coverage is unavailable.

[6] 5G defined ATSSS capability is transparent to the 4G from a signaling perspective and does not require any modifications to the MNO deployment

In this option, since data is via the H-MVNO SIM across both networks, this option requires ATSSS configuration only for the H-MVNO SIM. Additionally, no customization for ATSSS across multiple SIMs is required in the H-MVNO's core network to utilize Wi-Fi connection irrespective of whether the user is in the MNO or the H-MVNO coverage. Furthermore, since a single SIM is used for data across the two networks, data session management can be more gracefully managed as the device transitions in and out of H-MVNO coverage. However, in option 3, when UE switches between the two SIMs (based on network availability), UE has to de-register from the source network and register on the target network and may experience a longer interruption to reestablish the session as opposed to Option 2, where separate SIMs are used for data operation on each network and both SIMs are registered to the networks simultaneously.

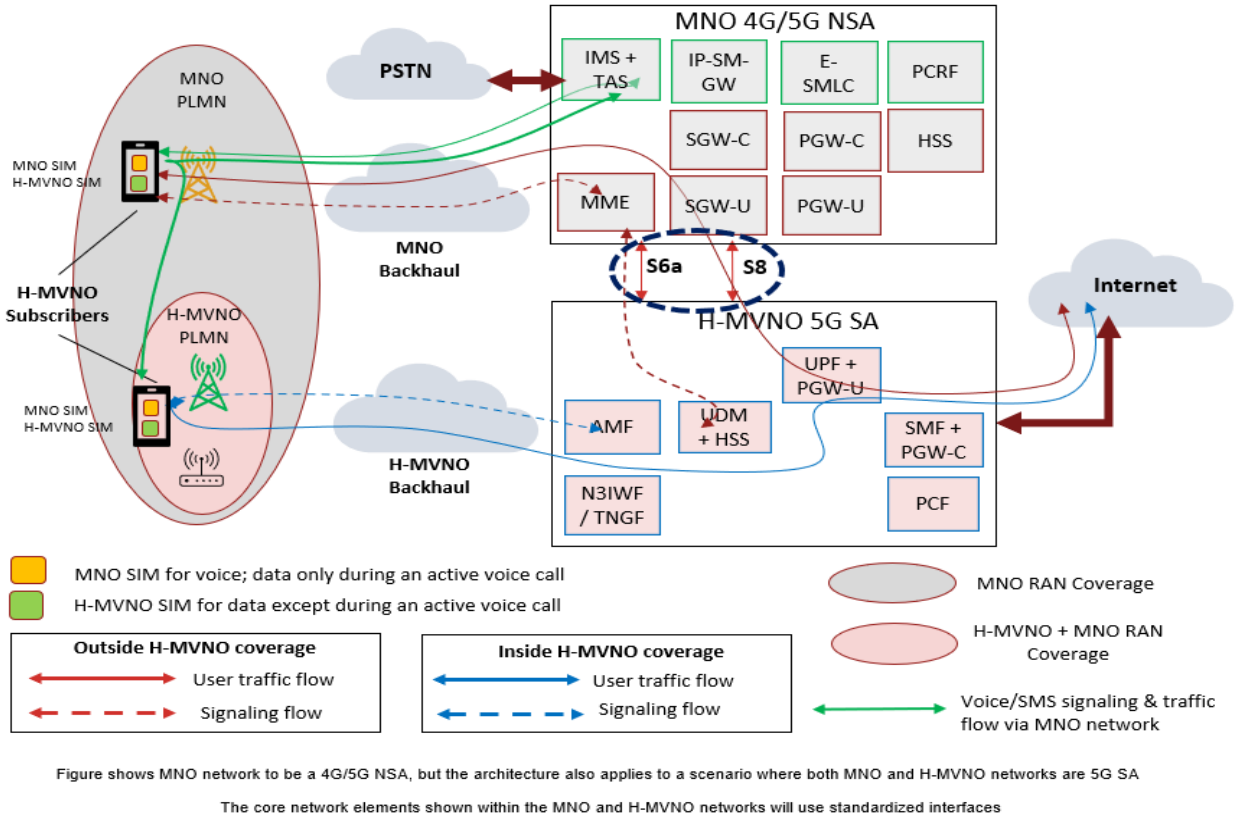

Figure shows MNO network to be a 4G/5G NSA, but the architecture also applies to a scenario where both MNO and H-MVNO networks are 5G SA

The core network elements shown within the MNO and H-MVNO networks will use standardized interfaces

Figure 4: Hybrid MVNO Architecture Option 3—Evolved DSDS Architecture

Table 1 compares the key salient features of the DSDS and evolved DSDS architecture options.

Table 1: Comparison of H-MVNO Architecture Options 1, 2, and 3

Attributes	H-MVNO Dual SIM Architectures		
	Option 1 (DSDS)	Option 2 (Evolved DSDS)	Option 3 (Evolved DSDS)
Enforcement of uniform policies irrespective of the serving network without device/network customization	×	✓	✓
Uniform traffic policy management regardless of the SIM or associated network without device/network customization	×	✓	✓
Full visibility into data usage statistics and pattern irrespective of the network used without device/network customization	×	✓	✓
Use of standardized ATSSS feature to improve session continuity across all accesses	×	×	✓
No need of coordination of roaming interfaces between MNO and H-MVNO	✓	×	×

Though the evolved DSDS architectures solve the issues of converged policy, full visibility into subscriber usage statistics and patterns and leveraging Wi-Fi connection when available, the following challenges still remain.

- Support for dual SIM is needed across the H-MVNO's device portfolio. There are also related concerns (i.e., efficiently managing transitions between the two SIMs as the subscriber moves in and out of H-MVNO access network coverage, especially if two separate SIMs are used for data sessions across the H-MVNO and MNO networks).

- The device on the MNO network is unable to immediately switch back to the H-MVNO network as soon as it moves inside the H-MVNO access network coverage without customization on the device side. One approach to facilitate this transition in the evolved DSDS architecture is to build intelligence in the anchor point (PGW/SMF/UPF), either through custom signaling or further enhancements to standards based ATSSS signaling.

The next section presents additional standards-based architecture options to overcome these challenges.

3.2. Architecture Options Extending Support for Single SIM Devices

In this section, we analyze the architecture options available to H-MVNOs to enable low-latency handovers between their networks and that of MNO networks. Even though the architecture options presented below are focused on single SIM devices, they are backwards compatible with above DSDS architecture options and will also be able to support dual SIM devices.

3.2.1. Direct N26 Interface Between H-MVNO and MNO Networks

One way to facilitate seamless handover of devices between MNO and H-MVNO access networks is through the implementation of the standards-based N26 interface. This architecture option is depicted in Figure 5. In this architecture, the H-MVNO SIM is provisioned within the H-MVNO network. Through the roaming interfaces, S6a and S8, the device can obtain the service by connecting through either the MNO or the H-MVNO access network. What separates this architecture option from the previous options is the introduction of the mobility interface, N26, between the two networks. With this interface, the device will be able to seamlessly move between the two networks through the execution of inter-PLMN (public land mobile network) handover procedures. The networks will be able to control the mobility aspects (connected mode handovers and idle mode cell reselection) as the device moves in and out of the H-MVNO coverage footprint rather than relying on the device to switch the data sessions between the two SIMs, as was the case for the dual SIM architecture options 1 to 3.

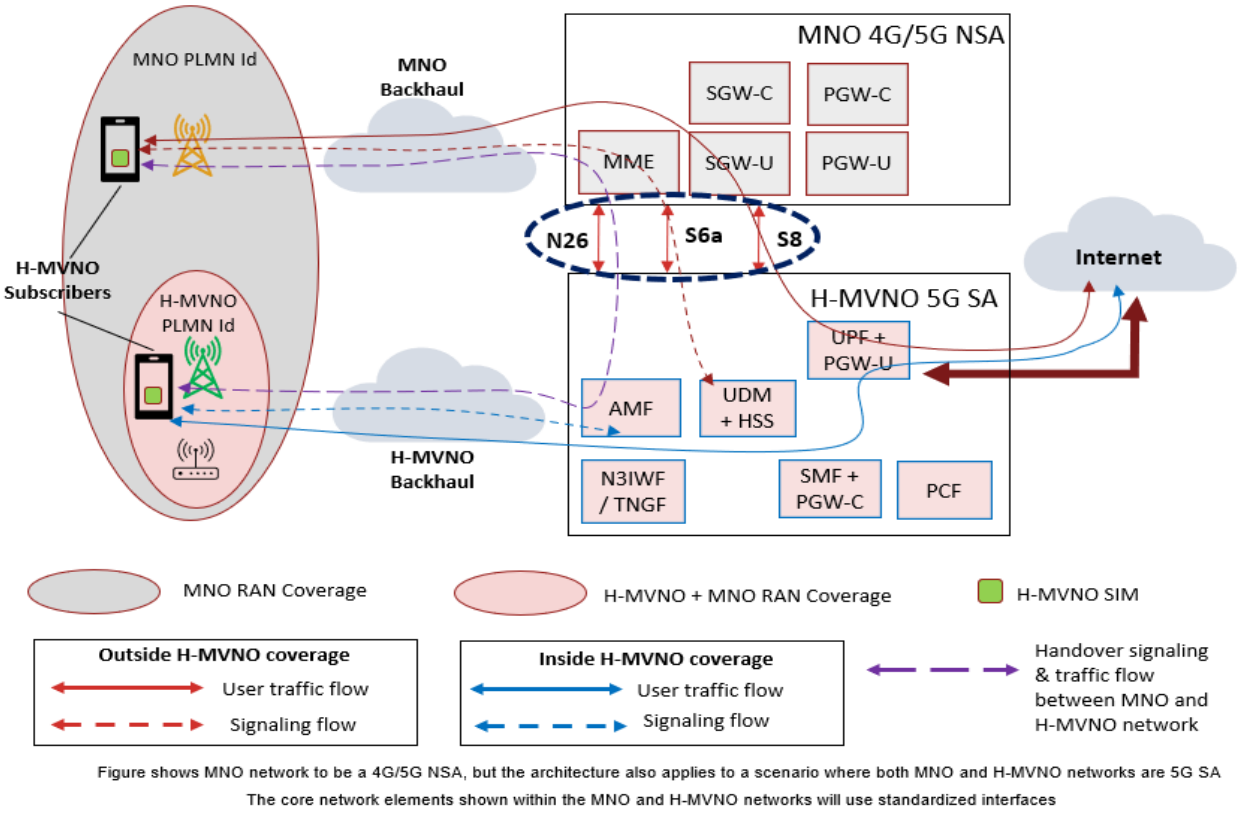

Figure 5: Architecture Option 4—Handover Interface Between MNO and H-MVNO

To enable option 4, several potential operational issues have to be addressed.

1. Securing the handover interface between the two networks
2. Having the appropriate mobility configuration and parameters (e.g., connected-mode and idle-mode configurations, event thresholds) for H-MVNO devices in the MNO network, taking into consideration the differences in the spectrum bands in the two access networks and the overlapping network coverage
3. Ensuring minimal impact to the MNO users from the additional signaling traffic in the core network caused by potential ping-ponging between the two access networks as the H-MVNO device frequently transitions in and out of the H-MVNO footprint
4. In case of multiple H-MVNO partners, the MNO core serving its subscribers having to interface with multiple core networks, creating significant operational challenges and risks

The first issue is similar to option 3 with regards to enabling secured connection with inter-domain S6a and S8 interfaces between the two networks. The same techniques used to interoperate and secure those interfaces also can be utilized for the N26 interface. The Rakuten network is based on this hybrid MVNO architecture option. Rakuten has an MVNO arrangement with KDDI and has enabled the S10 interface between its 4G core and KDDI's 4G mobile core.

The second issue can be addressed with custom configurations within the radio access networks for access barring, handovers, and redirection using RAT Frequency Selection Priority ID (RFSP ID) that has been specified in the standards.

Regarding the third issue, the actual amount of increase in excessive handovers and ping-ponging in the MNO core network will depend on the degree of contiguous deployment in the region by the H-MVNO (i.e., the number of handover boundaries between the two networks). Indoor/outdoor transitions could also result in many handover boundaries depending on the type of spectrum (low- or mid-band).

One way to address this issue of ping-ponging and corresponding signaling overload on the MNO's core network is by using a dedicated core for the H-MVNO traffic. This use of dedicated core also allows us to address the fourth issue. This architecture option utilizing a dedicated core is described below.

3.2.2. Dedicated Core for H-MVNOs

The dedicated core architecture option depicted in

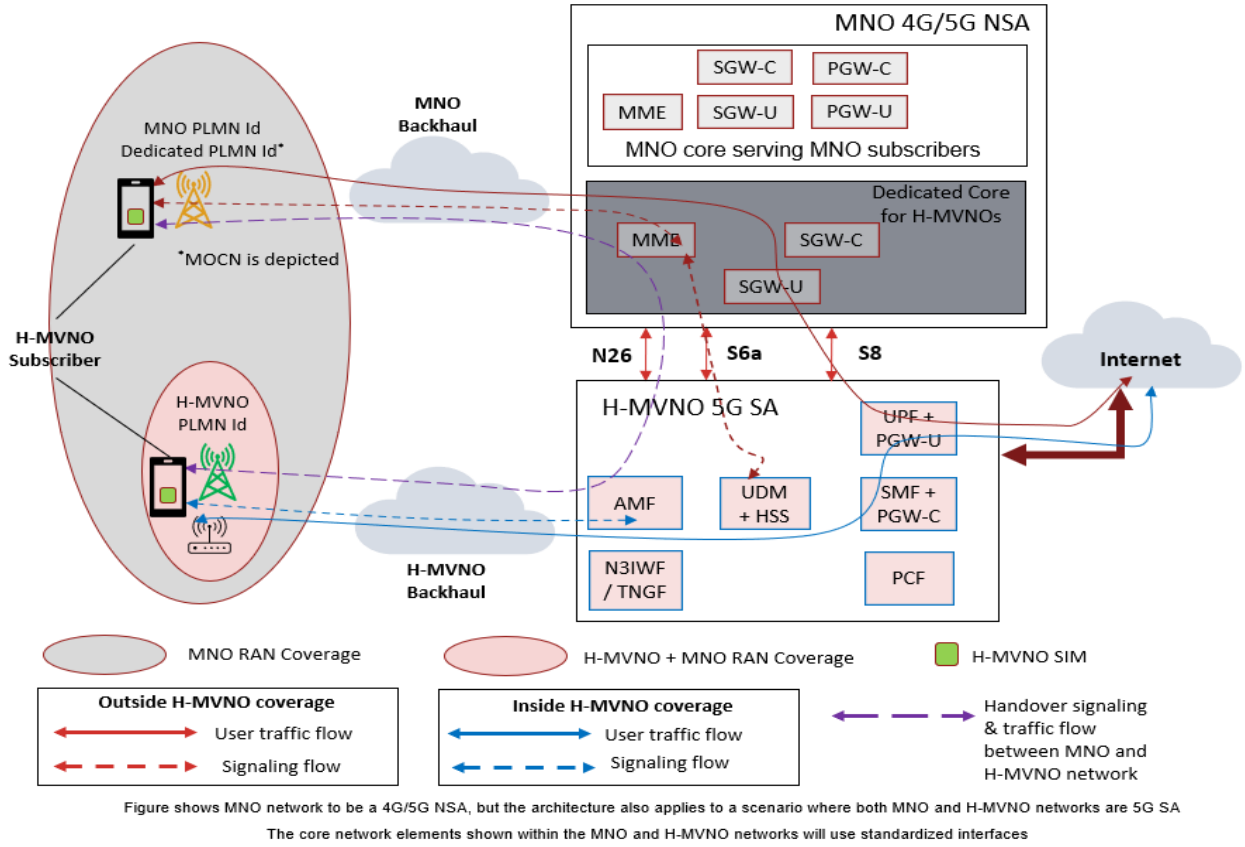

Figure shows MNO network to be a 4G/5G NSA, but the architecture also applies to a scenario where both MNO and H-MVNO networks are 5G SA

The core network elements shown within the MNO and H-MVNO networks will use standardized interfaces

Figure 6 helps alleviate the impact of ping-pong handovers and the risk to MNO core operation. The H-MVNO users' signaling, and user traffic streams will be processed within the dedicated core rather than the MNO's core, thereby isolating signaling load generated from the mobility of the H-MVNO's user devices from that of the MNO's user devices. The dedicated core comprises a dedicated mobility management entity (MME) and, optionally, an SGW (SGW-C + SGW-U).

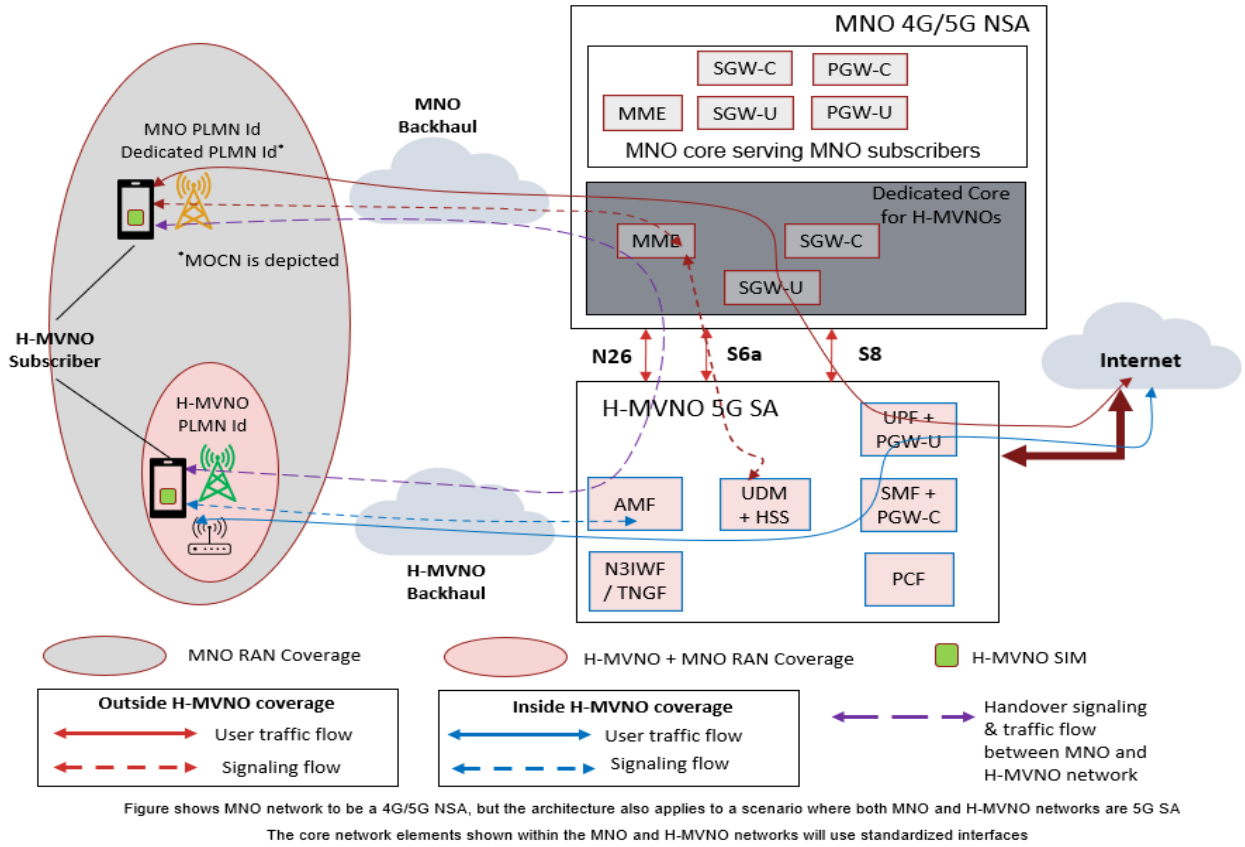

Figure 6: Architecture Option 5—Dedicated Core for H-MVNO

The dedicated core can be deployed and managed within the MNO network (as shown in Figure 6) or externally, depending on the MNO's operational policies. A key aspect of this architecture is that a single dedicated core can be shared across several H-MVNOs having an agreement with the MNO. The dedicated core would separate the traffic of each H-MVNO through the PLMN identity (part of the international mobile subscriber identity, IMSI) and route it to the appropriate anchor points in the H-MVNO home networks. The MME hosted within the dedicated core will perform a DNS query to select the SMF+PGW-C in individual H-MVNO networks, giving them full control over their subscribers' traffic.

Depending on the capabilities of the H-MVNO devices and the MNO access network, the dedicated core can be implemented using one of the following standards-based options.

Multi Operator Core Network (MOCN) specifications: In this option, the MNO access network broadcasts two PLMN IDs—one for its core network and one for the dedicated core. The dedicated core PLMN ID broadcast by the MNO is distinct from that used by the H-MVNOs in their home networks. The H-MVNO user devices are programmed to access the dedicated core PLMN ID when outside of H-MVNO access network coverage. As described previously, the dedicated core uses the home PLMN embedded in the IMSI to route the traffic to each H-MVNO network. The MOCN feature has been available since 3GPP Release 8 and is currently supported by most access vendors. Several advanced MOCN features, such as PLMN-specific configurations, parameters for access barring, handovers, and redirection, are likely to be available from access vendors, allowing for distinct handover settings for MNO and H-MVNO user devices. This can enable handover parameter configurations to be customized,

facilitating handovers between MNO and H-MVNO networks that do not impact the handover operation and performance for MNO user devices.

- **Standardized 3GPP feature—Dedicated Core (DECOR) or Enhanced Dedicated Core (eDECOR):** Implementing the DECOR feature in the MNO core and access network redirects traffic to the dedicated core based on information received in the subscription profile from the H-MVNO HSS. eDECOR-aware user equipment provides the dedicated core network ID (DCN-ID) when it is accessing the MNO network, which uses it to route traffic to the dedicated core. A key advantage of this approach is that the MNO does not have to broadcast multiple PLMN IDs. However, MNO access and core networks need to support the DECOR redirection/routing capabilities to have H-MVNO users serviced by the core dedicated to the H-MVNOs. In addition, to isolate the handover configurations for MNO and H-MVNO devices, additional functionality will be required in the MNO access network. One standards-based approach is to tie custom handover configurations by using a standardized index called the RAT Frequency Selection Priority ID (RFSP ID). One limitation of DECOR, compared to MOCN, is that the MNO will be unable to configure separate access barring settings for H-MVNO user devices. It may not be critical, however, given that MNOs do not currently require separate access barring configurations for their MVNO user devices.

The selection of one of these options will be based on the capabilities of the MNO access and core infrastructure and the H-MVNO devices.

Note: These options can be viewed as precursors of the network slicing concept specified as part of 5G. In the MOCN option, the network slice identifier is the PLMN ID. In the DECOR/eDECOR option, the slice identifier is either the DECOR parameter specified in the user profile, or the dedicated core network identity (DCN-ID) provided by the device.

Table 2 compares the salient features of the inter-network handover and dedicated core architecture options.

TABLE 2: COMPARISON OF H-MVNO ARCHITECTURE OPTIONS 4 AND 5

Attributes	H-MVNO Single SIM Architectures	
	Option 4 (Inter-Network HO)	Option 5 (Dedicated Core)
Seamless handovers	✓	✓
Minimizes signaling traffic impact on MNO core serving MNO subscribers due to handovers	✗	✓
No additional complexity within the MNO network to support multiple H-MVNO networks	✗	✓

Though the dedicated core architecture solves issues related to seamless handovers, it does introduce the following operational overheads in terms of network planning and configuration.

- The MNO needs to enable either MOCN or DECOR to facilitate isolation of the signaling traffic and minimize signaling load (caused by potential ping-ponging between the MNO and H-MVNO networks) on the MNO core control functions.

- The MNO needs to verify interoperability between the MNO access network and the core dedicated for the H-MVNOs.[7]
- The H-MVNO needs to ensure interoperability of the N26 between the dedicated and the H-MVNO core networks.
- The MNO needs to configure H-MVNO-specific mobility parameters in its access network; the H-MVNO needs to configure MNO-specific mobility parameters.
- Support for additional interfaces for supporting voice calls and SMS (described in the following section).

3.2.3. Voice and SMS Services Implications

Voice and SMS services are expected to be an integral part of all mobile service plans; therefore, it is critical to evaluate the ability to support them in the context of architecture options 4 and 5. Voice and SMS services require additional architectural components in the mobile core network that are not required for data services. This additional functionality is required to support i) voice and SMS applications, ii) mobile number portability (MNP), iii) interconnection/ interwork with PSTN, and iv) emergency services as required by the local regulator.

Given the widespread deployment of voice over LTE (VoLTE), 3GPP has defined several ways to leverage it for enabling voice service over 5G NR. Voice services likely will be enabled using VoLTE until 5G deployments become more ubiquitous. 3GPP has specified redirection from the 5G network to the 4G network for voice sessions to facilitate use of VoLTE. One way to redirect is through handover at the time of the voice media setup procedure, and another way is through radio channel redirection. The method of deployment is left up to the MNO operators and will depend on their network capabilities and configurations.

Described below are several ways to facilitate voice and SMS services as part of architecture options 4 and 5 using MNO's LTE deployment.

3.2.3.1. Voice/SMS Services Architecture Option A

One option is for an H-MVNO to support voice and messaging services via its own or a partner's voice/messaging platforms, as shown in Figure 7. In addition to showing the architectural impact, Figure 7 also depicts voice and SMS data flows when the device is in the coverage region of H-MVNO+MNO and MNO-only networks.

i) The voice traffic flow after the redirection to the MNO network (i.e., when the user is inside the H-MVNO coverage) and/or when camped/connected to the MNO RAN (i.e., when the user is outside the H-MVNO network coverage) is depicted by the solid green line.

ii) The voice handover/redirection signaling flow when camped on the H-MVNO is depicted by the dashed purple line.

[7] Problems surrounding interoperability can be minimized by ensuring that the MME and the MNO radio access network is from the same vendor.

iii) The SMS traffic flow after the redirection to the MNO network (i.e., when the user is inside the H-MVNO coverage) and/or when camped/connected to the MNO RAN (i.e., when the user is outside the H-MVNO network coverage) is depicted by the dashed yellow line.

iv) The SMS traffic flow when camped/connected to the H-MVNO RAN is depicted by the solid yellow line.

In voice/messaging architecture option A, the mobile connection for voice and SMS is always anchored at the H-MVNO's UPF, irrespective of whether the UE is located within the coverage area of MNO or H-MVNO's RAN. One perceived disadvantage of this option is that H-MVNO will have to deploy the voice and SMS infrastructure and manage the additional functionalities around MNP, emergency calling and interconnection to the PSTN. Using a voice service partner capable of supporting mobile voice and messaging can overcome these drawbacks.

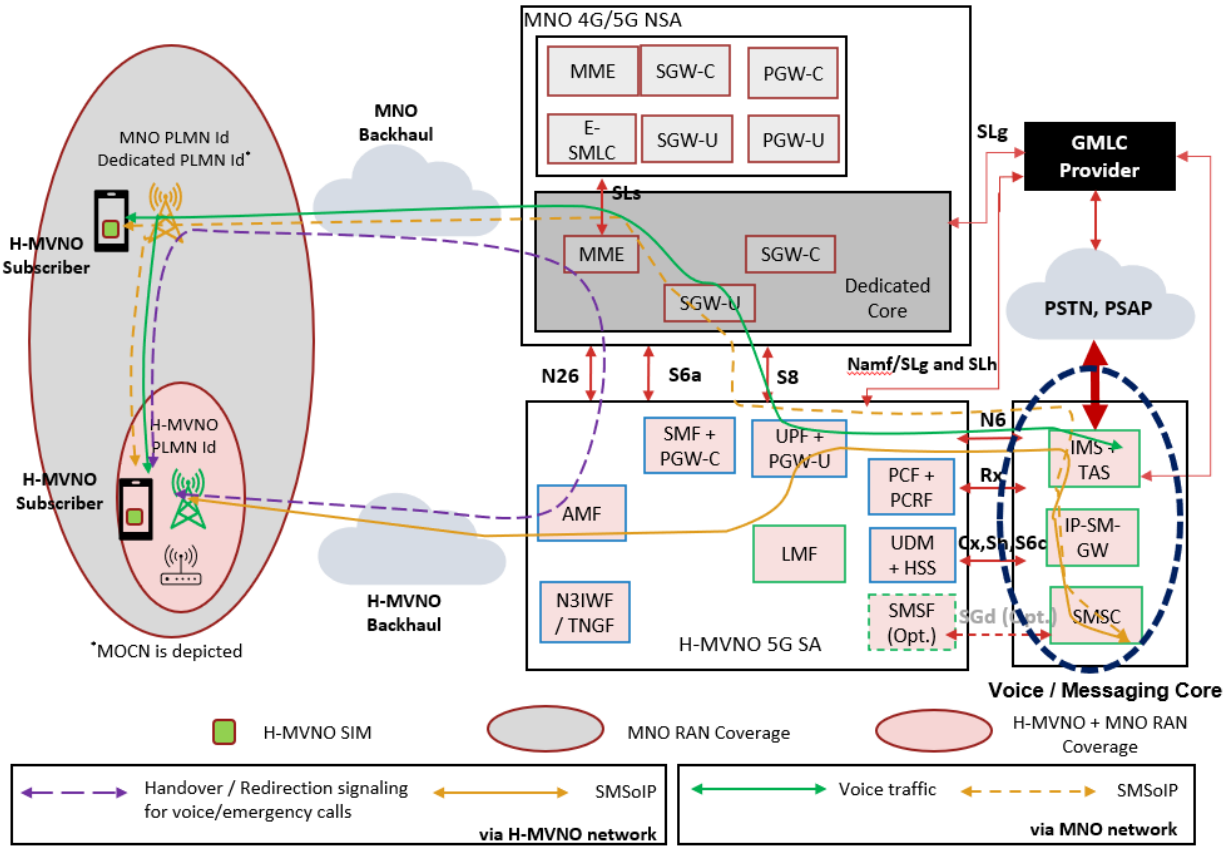

Figure depicts Single SIM Architecture (Option 5), but the voice option described is also applicable to Option 4*

Figure 7: Voice Architecture Option A for Single SIM Devices

An alternative to option A is to leverage MNOs' voice and messaging platforms (i.e., effectively, the MNO becomes their voice service partner). Given that all MNOs have a robust voice and SMS platform, this could be an attractive option for H-MVNOs, especially those who do not have the scale to deploy their own. As described below, there are two ways to leverage MNOs' infrastructure—voice/messaging architecture options B and C.

3.2.3.2. *Voice/SMS Services Architecture Option B*

As shown in Figure 8, in voice/messaging architecture option B, MNO's voice/SMS services platforms are used while the voice subscription and related credentials are configured in the H-MVNO UDM+HSS. In this architecture, additional 3GPP interfaces between the MNO's IMS, IP-SM-GW, and SMSC and the H-MVNO's UDM+HSS, PCF+PCRF, and SMSF are also configured as depicted in Figure 8. The MNO's voice and SMS platforms will use these interfaces to authenticate/authorize the user and retrieve the subscription and registration status/info (using the MCC+MNC from the IMSI of user device). This will ensure successful registration for voice and SMS services within the MNO's IMS and IP-SM-GW. It will also ensure proper forwarding of the incoming calls and text messages, irrespective of whether the user is camped on H-MVNO or MNO radio access network (RAN). Like in option A, the voice and SMS data connection will always be anchored in H-MVNO's UPF. The voice traffic and SMSs will be transferred from an H-MVNO's UPF to the MNO's IMS voice and SMS platforms through a secure data connection. The MNO's IMS will interface with the H-MVNO's PCF+PCRF (either directly or via a local MNO PCRF) through the Rx interface to set up dedicated bearers for the voice media traffic.

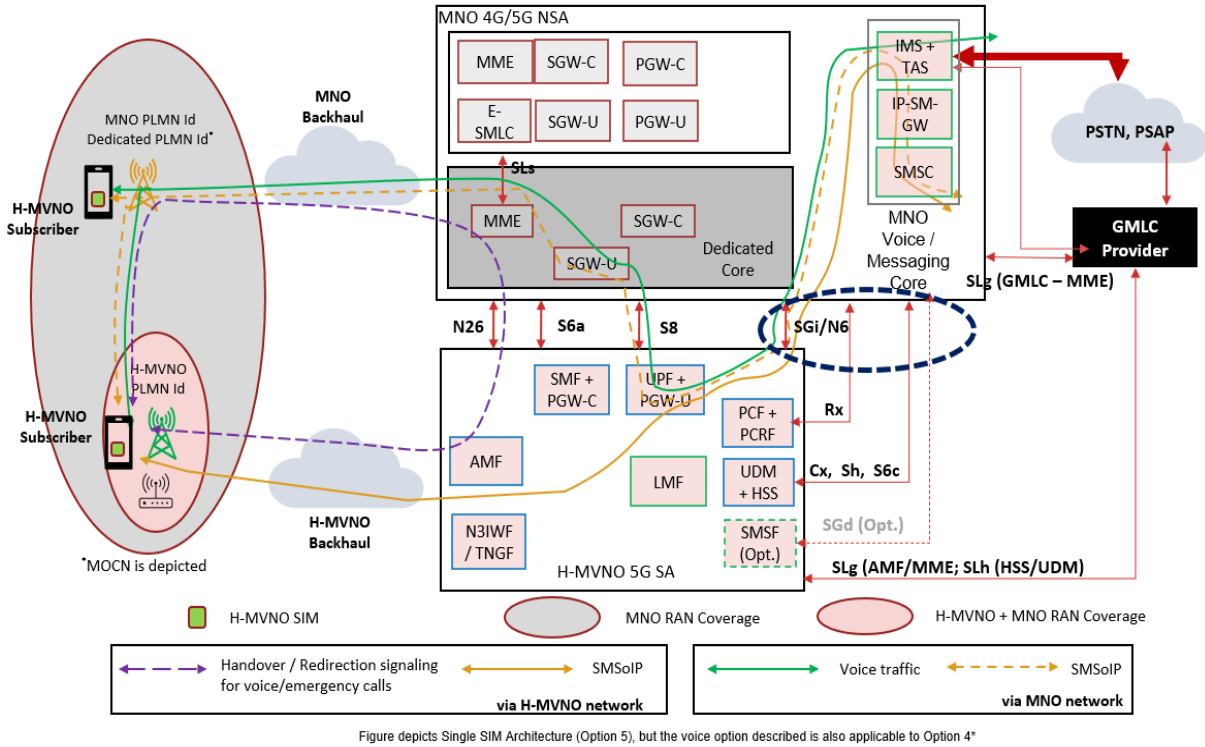

Figure depicts Single SIM Architecture (Option 5), but the voice option described is also applicable to Option 4*

Figure 8: Voice Architecture Option B for Single SIM Devices

Like option A, Figure 8 depicts the voice and traffic flows related to voice handover/redirection signaling (dashed purple), voiced traffic (solid green), and SMS flows (solid and dashed yellow).

User Connected to H-MVNO RAN

The voice call will be initiated, then redirected or handed off to the MNO's RAN. If an emergency call is initiated by the user, it will be redirected to be initiated via the MNO's network. The data anchor will continue to be the H-MVNO's UPF via the dedicated core. The voice signaling and media will be routed from the H-MVNO's UPF to the MNO's IMS.

The text messages will not result in redirection or handover to the MNO's RAN. The text messages will be forwarded via the H-MVNO's UPF to the MNO's IP-SM-GW via the IMS, which will then forward it to the SMSC for delivery to the target user. If a 5G control plane (NAS) is used to transfer the SMS (in the event IP-SM-GW is unavailable), then an additional interface between the MNO's SMSC and the H-MVNO's SMSF will have to be configured.

One aspect of voice and text services is the ability to accurately determine the user location during emergency calls and texting. The Gateway Mobile Location Centre (GMLC) must be able to query the serving control node (AMF/ dedicated MME) from the UDM+HSS to request the location of the user device from the serving control node. The MNO's GMLC partner must be capable of routing the query to the H-MVNO's network. Alternatively, the MNO network must be able to forward or redirect the query from the GMLC provider to the H-MVNO's UDM+HSS.

For emergency voice calls, the dedicated MME will retrieve the location from the MNO E-SMLC to deliver it to the GMLC. However, for text to 911, the H-MVNO will have to deploy its own LMF in its core as the user will not redirected to the dedicated MME for text service while in the H-MVNO coverage.

User Connected to MNO RAN

Even when the user is in the coverage of the MNO's RAN, it will continue to be anchored in the H-MVNO's UPF via the dedicated core (architecture option 5) or through a direct interface (architecture option 4). The voice call and text will be routed back to the IMS via the H-MVNO's UPF to the MNO's IMS platform. IMS will continue to interact with the H-MVNO's PCF+PCRF to set up dedicated bearers for the user traffic. Similarly, SMSC will continue to query the UDM+HSS to identify the serving node (either SMSF or the IP-SM-GW) so that the incoming text can be sent to the serving control node for delivery to the user's device.

The location retrieval by GMLC for emergency calls will be performed in the same way as described above. The text to 911 will be delivered via the dedicated core and the location retrieved using dedicated MME and MNO's E-SMLC

3.2.3.3. Voice Option C

If the H-MVNO operator is using a separate ISIM instead of deriving the IMPU from the USIM, one could also consider provisioning the ISIM in a separate HSS located within the MNO network or in the dedicated core as shown in voice architecture option C in Figure 9. This will allow the MNO's IMS functions to authenticate locally without having to interact with the H-MVNO HSS. Furthermore, if the IMS APN is anchored in the MNO's PGW, it will also eliminate interaction between the MNO's PCRF and the H-MVNO's UPF for the setup of the dedicated bearer.

Like options A and B, Figure 9 depicts the voice/SMS signaling and traffic flows when the device is in the coverage of MNO and H-MVNO networks. The color scheme used for the traffic flows is identical to that for options A and B.

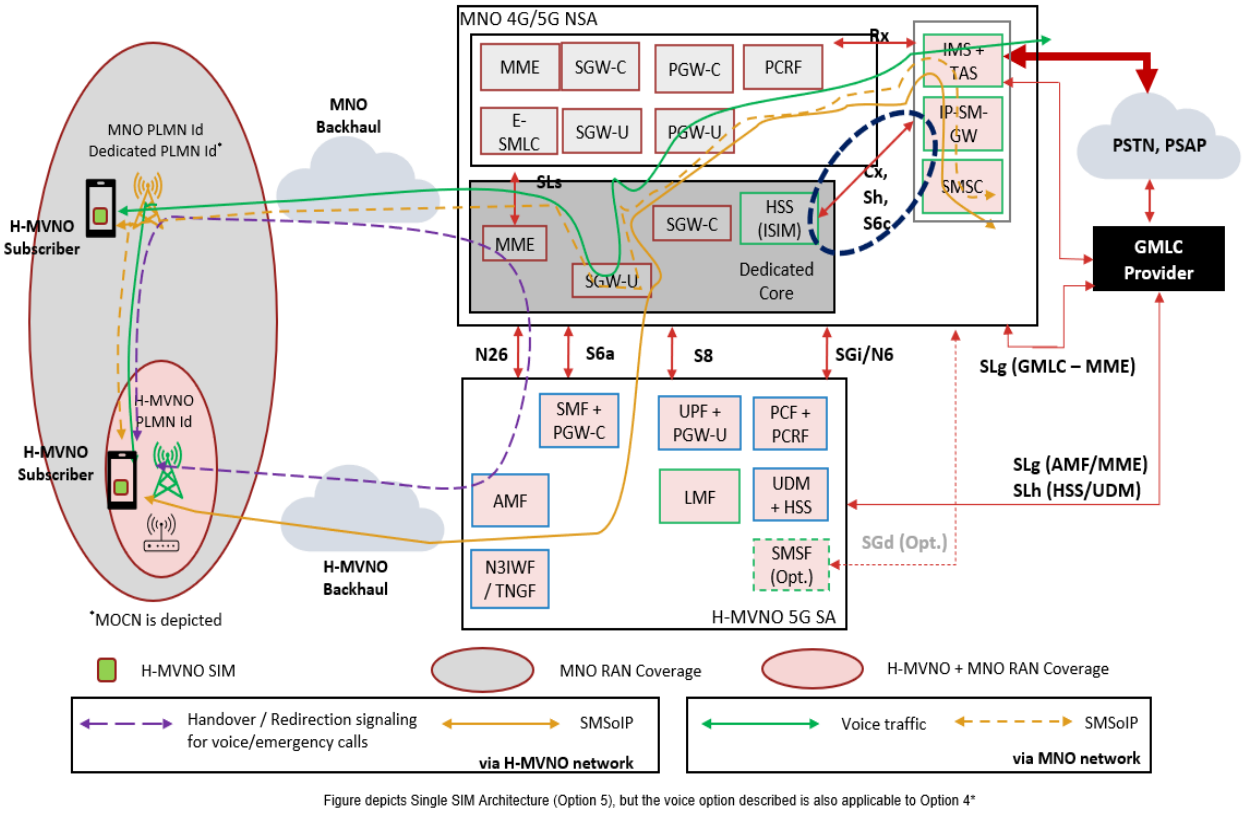

Figure depicts Single SIM Architecture (Option 5), but the voice option described is also applicable to Option 4*

Figure 9: Voice Architecture Option C for Single SIM Devices

One drawback of anchoring IMS APN in the MNO's PGW is that if the MNO has deployed 4G EPC core only, then the dedicated core needs to incorporate an interworking function to translate HTTP interface based 5G session control signaling messages received from the H-MVNO AMF into GTP-C based 4G EPC signaling messages to successfully set up the MNO's PGW as the anchor. To circumvent the need for this new interworking function, a dedicated UPF for voice could be deployed as part of the dedicated core.

In this architecture, the SMSC will still have to interact with the H-MVNO's UDM+HSS to determine the SMS serving node(s) (SMSF or IP-SM-GW). In addition, the GMLC provider will still have to interact with the H-MVNO's UDM+HSS to query the serving node (AMF/MME) to retrieve the location of the user device during text to 911 sessions while the UE is connected via the H-MVNO's RAN. Like option B, H-MVNO will have to deploy the LMF in its core to determine user location during text to 911.

Table 3 below summarizes the pros and cons for the above voice architecture options.

Table 3: Benefits and Impacts of Various Voice Architecture Options

Voice Options	Benefits	Impacts
Option A	• No coordination required with the MNO	• Requires H-MVNO to deploy IMS, TAS and SMSC (or partner with a voice/SMS service provider). • H-MVNO (or its voice partner) will have to support MNP, interconnectivity with PSTN, emergency calling, and associated location requirements. • H-MVNO (or its voice partner) needs to enable interconnection with PSTN and for outbound roamers.
Option B	• H-MVNO does not have to deploy voice and SMS platforms—IMS, TAS, IP-SM-GW, and SMSC. (SMSF may be required to facilitate delivery of SMSs when IP-SM-GW is unavailable.)	• Coordination is required with the MNO to enable interfaces between MNOs' IMS and SMS platforms and H-MVNOs' 5G core systems. • H-MVNO will still have to deploy location management function (LMF) (i.e., location server) to deliver location for text to 911 initiated by the user over H-MVNO's network. • MNO needs to enable forwarding/redirection of queries from GMLC provider to the appropriate function in the H-MVNO network and the dedicated core network.
Option C	• H-MVNO does not have to deploy voice and SMS platforms—IMS, TAS, IP-SM-GW, and SMSC • Fewer interfaces required between the MNO and H-MVNO networks compared to option B	• Dual provisioning required (USIM to be provisioned in H-MVNO network, while ISIM to be provisioned in MNO network). • If MNO has not deployed a combined 4G/5G core, an interworking function is required to translate session management messages. • Interface between SMSC and HSS+UDM will still be required to retrieve the serving SMSF if it is deployed in the H-MVNO network and not statically configured. • H-MVNO will still have to deploy LMF (i.e., location server) to deliver location for text to 911 initiated by the user over H-MVNO's network. • MNO needs to enable forwarding/redirection of queries from GMLC provider to the appropriate function in the H-MVNO network and the dedicated core network.

4. Conclusion

CableLabs recognizes the evolving mobile industry landscape driven by the introduction of 5G and the availability of new and innovative spectrum options. Many of our members are either MNOs supporting MVNOs or MVNOs looking to deploy their mobile networks. Globally, MVNOs have been around for some time, with varying degrees of control being made available to them. As regulators are also looking to facilitate increased competition, MVNOs are expected to play an integral part in that effort.

In a data-centric connectivity environment, because of continually growing usage and a lack of control over subscribers, MVNO arrangements have typically constrained the MVNOs' mobile service plans. As the data usage continues to grow, it is generally recognized within the industry that data offloading onto Wi-Fi and/or own mobile network is necessary for the success of an MVNO.

This paper presents evolutionary converged MVNO architectural blueprints that will allow CableLabs members who are MVNOs or are considering becoming one to converge their wireless connectivity service and maximize the offload onto their own mobile and Wi-Fi deployments while improving MVNO user experience. They will also allow an MNO member to differentiate itself from its competitor by offering greater flexibility to its MVNO customers and creating a win-win strategy for itself and its wholesale partners (MVNO). **Error! Not a valid bookmark self-reference.** and Table 5 summarize a comparative assessment of the different architecture options.

Table 4: Comparative Assessment of Architecture Options

Attributes	Dual SIM Architectures			Single SIM Architectures	
	DSDS	Evolved DSDS		Inter-Network HO	Dedicated Core
	Option 1	Option 2	Option 3	Option 4	Option 5
Support for dual SIM devices	✓	✓	✓	✓	✓
Support for single SIM devices	✗	✗	✗	✓	✓
No need for customization on the device to manage network transition	✗	✗	✗	✓	✓
Enhanced user experience through full data visibility, uniform policy, and subscription management	✗	✓	✓	✓	✓
Maximized use of H-MVNO access network when available without a connection manager client in the device	✗	✓	✓	✓	✓
Seamless low-latency mobility	✗	✗	✗	✓	✓
No interfaces needed between the two networks	✓	✗	✗	✗	✗
Minimizes signaling traffic impact on MNO core serving MNO subscribers due to handovers	✓	✓	✓	✗	✓
Use of standardized ATSSS solution for improved session continuity across all accesses	✗	✗	✓	✓	✓
No custom configuration of mobility related parameters in MNO's access network	✓	✓	✓	✗	✗

Table 5: Comparative Assessment of Single SIM Architecture Voice Options

Attributes	H-MVNO Single SIM Architectures (Voice)		
	Option A	Option B	Option C
No coordination required for enabling interfaces between MNO IMS and H-MVNO network	✓	✗	✗
No need for H-MVNO to host voice and SMS platforms	✗	✓	✓
No need for additional interface to authenticate H-MVNO subscribers	✓	✗	✓
No need for dual provisioning (USIM and ISIM separately provisioned across the two networks)	✓	✓	✗

The blueprints presented in this paper are standards based and evolutionary in nature. Members could start with the evolved DSDS option, then evolve to implement full mobility between their and MNO deployments by using the dedicated core option. The dedicated core architecture allows MNOs to isolate their infrastructure and customers from any excessive MVNO-related signaling or user traffic resulting from mobility between the MNO and MVNO access networks.

For dual SIM architecture options, voice is always carried over the MNO SIM utilizing the MNO network. This dual SIM approach can also be considered as an alternative to voice options A-C for architecture options 4 and 5 whereby N26 is used to enable low-latency data-centric applications (e.g., VR/AR applications) while the voice/SMS is supported using the second SIM via the MNO network. For single SIM devices requiring voice/SMS support, one of the voice architecture options will have to be considered.

Members could leverage the architecture options discussed in the paper to converge policy and subscription infrastructure across all access networks (MNO, MVNO, Wi-Fi) and enable a seamless user experience to their customers irrespective of the underlying wireless access technology.

1. Introduction

For decades, and within the halls of this very event (Cable-Tec Expo), technologists, being a practical bunch, described the substantial task that is widening the 5-42/54 MHz upstream signal path, as the kind of monumental event that would happen but once in a lifetime. This was usually expressed as "not in my lifetime," or variants.

The title of this paper, and the breadth of technical literature happening concurrent with this paper, is, first, an acknowledgement that widening the reverse path is very much going to happen in our lifetimes. It's also an assurance that while going to a Mid-Split (85 MHz) or High-Split (204 MHz) upper spectral boundary for the upstream, home-outwards signal path is a network makeover, it is not a network rebuild. There are ways to accomplish a larger upstream signal path that are precise, reasonably swift, and forgiving – all vital elements to a "makeover without scars."

Informed by substantial lab, field and live/production environment experiences, this paper aims to illuminate why a roomier upstream path is happening now. It will describe the major things that matter, when preparing for and enacting a systemic widening of that narrow sliver of upstream spectrum at the low end of the frequency band, between 5-42 MHz. A spectral area renowned for its many signal-squelching quirks, like impulse noise. The intent is to share what works and what doesn't, when it comes to accomplishing an upper spectral boundary of 85 MHz or 200 MHz.

Because, unquestionably, the upstream path is intrinsic to all two-way applications: It is one of the two ways.

Mid- and High-split upstream configurations coincide with increasingly powerful DOCSIS 3.1 options, even as DOCSIS 4.0 is emerging. The optimal near-term expansion and long term DOCSIS 4.0 migration varies by operator. Each operator must necessarily consider its network starting point, given the interdependency of bandwidth initiatives such as node splits, Distributed Access Architectures (DAA), upper spectral boundaries, and fiber-deeper topologies. It's also worth noting that DOCSIS Annex-A (conversationally known as "Euro DOCSIS") reflects the fact that our colleagues "on the other side of the pond" send signals upstream in the spectrum between 6-65 MHz and do so very successfully.

The mathematics of Compounded Annual Growth Rate (CAGR) provide a straightforward way to quantify capacity growth and network lifespan. "Billboard speeds" must also inform the upgrade roadmap, but generally the "What" of traffic engineering and lifespan management is tractable analyses.

The "How-to" of spectrum migration is where it gets complicated. Operators understand investments in node and amplifier upgrades from previous cycles. However, these cycles didn't address upstream spectrum, largely because usage patterns didn't warrant it. The 42/54 MHz split has been in place for decades, and devices that adhere solely to it, particularly set-top boxes (STBs), are in many millions of homes. Production-scale tools, techniques, and processes must be developed to ensure that a new, wider upstream path can be efficiently operationalized, while being transparent to customers.

This paper will describe the analysis, tools, techniques, and processes to enable this upstream bandwidth transformation, focusing on production operationalization of an 85 MHz Mid-Split including:

- How homes may be impacted by a mix of device spectrum capabilities
- Mid-Split activation using SC-QAM and OFDMA
- Existing metrics and tools to assess home health

- New automation techniques to enable a seamless transition for customers with the activation of new upstream spectrum
- Cross-functional tools and processes for Tech Ops, Care, and Serviceability
- Identify and discuss some of the differences between Mid-Split and High Split (204 MHz), and of DOCSIS 4.0

Widening the upstream to stay ahead of heavy bidirectional consumption is a multi-dimensional topic. Readers will learn about new tools and operational practices that can smooth this transformation.

2. A Brief History of Cable's Upstream Path

The term "upstream path" is synonymous with the "reverse path" and the "return path" because it came second, after the "forward" signal path, from Headends to homes. For the first few decades of cable television's evolution, from the late 1950s to the late 1970s, the upstream signal path wasn't necessary. Television signals were broadcast downstream, through the plant, to homes; subscribers turned on their TVs, and watched. Nothing was "clicked," and none of those clicks moved upstream, from homes to Headends, because nothing was clickable.

In the late 1970s, some operators experimented with televisions and rudimentary data services that encouraged consumers to interact. Coincident with that, attention started to focus on building a two-way path to augment the existing one-way, downstream plant. That involved installing modules into existing amplifiers that fed a signal upstream, to the headend, then balancing that two-way signal path. From the late 1970s until the mid-90s, in fact, operators expressed their two-way-readiness in terms of what percentage of amplifiers were "two-way-capable." This meant that the amplifier housing had an empty slot for the reverse module.

Spectrally, the 5-42/54 MHz reverse path is an inhospitable zone, highly susceptible to signal ingress and impulse noise. What makes it worse is that most noise – upwards of 70%, by some estimates – originates inside homes. Because the upstream signal path is a multipoint-to-point architecture (the exact opposite of the downstream signal path), any noise generated in a home is funneled upstream, through taps to nodes, getting amplified as it moves to the headend. This effect is called noise funneling. Noise funneling is bad.

The harsh conditions of the upstream path required a sturdy modulation type, relative to the QAM-styled modulation used to carry signals downstream, towards homes; QPSK was an early workhorse. Using a lower-order modulation, like QPSK, is not unlike slowing down when driving on a road with deep potholes: It's the only way to get to the destination, without gaining any unplanned "adventure badges" on your vehicle.

Over time, as fiber reached deeper into neighborhoods, which shortened amplifier cascades, it became possible to move to higher and higher orders of modulation in the 5-42 MHz upstream: 16-QAM and 32-QAM and 64-QAM via DOCSIS 3.0 SC-QAM. Today using DOCSIS 3.1 OFDMA, up to 1024-QAM will be viable, especially in DAA systems. Use of 2048-QAM may also be achieved, and 4096-QAM is within the standard. These increasingly bandwidth efficient formats allow ever-increasing amounts of data to be carried from homes outwards, to the Internet or cloud.

3. Differences Between the Upstream and Downstream Signal Paths

There are a few notable differences between the forward/downstream signal path, and the reverse/upstream signal path. They are briefly noted here.

One is channel widths. Because the upstream path was never envisioned (or designed) to carry video, its channel widths aren't a static 6 MHz, as they are in the downstream (home-facing) path. Upstream channel widths typically use one of three sizes: 1.6 MHz, 3.2 MHz, and 6.4 MHz.

The upstream signal path was envisioned as a way to move small amounts of information, such as a click to order a movie, or, later, a click of a mouse to request a web page. When voice-over-IP entered the service mix, audio signals began moving upstream. All are negligible, relative to the "carrying size" of broadcast video. So, until recently (hello, webcams!), traffic type was also a differentiator between what moved upstream vs. downstream.

Modulation is a third difference between the downstream and upstream signal paths. The width differences are to accommodate multiple modulation rates for sending traffic: QPSK, 16-QAM, and 64-QAM.

A fourth difference – and an omnipresent conversation – is the matter of noise and ingress funneling in the upstream direction, which makes upstream more susceptible to over-the-air (OTA) signals. As the upstream bandwidth grows, some OTAs flip from downstream phenomenon to upstream, and in doing so become more troublesome. In the lower spectral regions, it used to be the off-air analog channels, which vacated the band coincident with digital. There's the FM band, which sits between 88-108 MHz. Potential issue: Interference. There's also the Aeronautical Mobile and Radio Navigation, between 108-137 MHz. Potential issue: Signal leakage. And let us not forget legacy out-of-band signaling, used by some set-tops and modems to move things like guide data, and command-and-control information.

Some readers may remember the big-growth days of high-definition TV, and the concerns about having enough downstream capacity to carry them all. Suddenly, we needed to add capacity, adjust channel lineups, advance another leap in video compression (at the time, to MPEG-4), and roll out things like Digital Terminal Adaptors, or, for some operators, Switched Digital Video.

These days, downstream capacity is reasonably under control (even as 8K TVs started rolling into retail this summer). It's keeping ahead of the growth in upstream demand that drives a larger part of our plant augmentations. As it turns out, after DOCSIS 3.1, the only viable tool in the non-fiber-deep playbook, besides constantly splitting nodes (which is increasingly inefficient) is to add spectrum.

Ironically or not, while this paper was being written (summer 2021), the author was participating in nightly overnight maintenance window sessions aimed at bringing to production the new "scar detector" tool on live nodes to activate on the Mid-split band. It was about as good as it gets for upstream geeks!

4. HFC Spectrum Relationships: Mid-Split, High Split and DOCSIS 4.0

The HFC network in North America has been limited to 42 MHz or less in the upstream direction since there has been HFC plant. The launch of HSD services increased the focus on the upstream because of the central role it now plays in providing a quality Internet experience for the ever-increasing range of demanding real-time applications. Fortunately, the growth of Internet traffic per year has been generally quite predictable, although slightly less so in the upstream than the downstream. In the upstream, year-on-year fluctuations historically experienced periods where traffic has been more dynamic, and periods where it has been flat. It all nets out to an average usage per year that is predictable enough to let capacity planners do their jobs effectively.

There has been over 20 years of growth managed almost exclusively by a fixed amount of upstream spectrum between 5-42 MHz. The amount and type of traffic moving upstream largely populates the quality spectrum available and managing new growth has transitioned from new QAM carriers and node splitting to node splitting and more node splitting. The COVID-19 pandemic accelerated this activity [2]. DOCSIS 3.1 can be used below 42 MHz, but better QAM bandwidth efficiency is no match for spectrum when it comes to adding capacity – according to that Shannon guy (http://www.inf.fu-berlin.de/lehre/WS01/19548-U/shannon.html). For high SNR (Signal-to-Noise Ratio) cable networks, Capacity ~ [BW/3] * SNR [dB]. The key thing to note is "dB." Capacity increases directly proportionally to bandwidth, and only logarithmically proportional to SNR.

As nodes get split smaller and smaller, it tends to become less efficient to continue to split. It is less likely to yield a 50/50 split, so the full benefit of the split is not realized. Whereas a 50/50 split buys ~3 years of growth at a CAGR of 25%, if the node is split 60/40 or 70/30, it is less. It is not unusual for one port of a node to be naturally more heavily loaded with traffic than another, since these ports feed different neighborhoods, and one, for example, may include a student housing complex or have a high density of business customers, while another may service less online-active customers.

Figure 1 shows a set of upstream expansion options available for MSOs. Many are active or imminent. They can be viewed as sequential in time, with some overlap and market-based criteria informing the timing and path to 10G. The architectures are described further below.

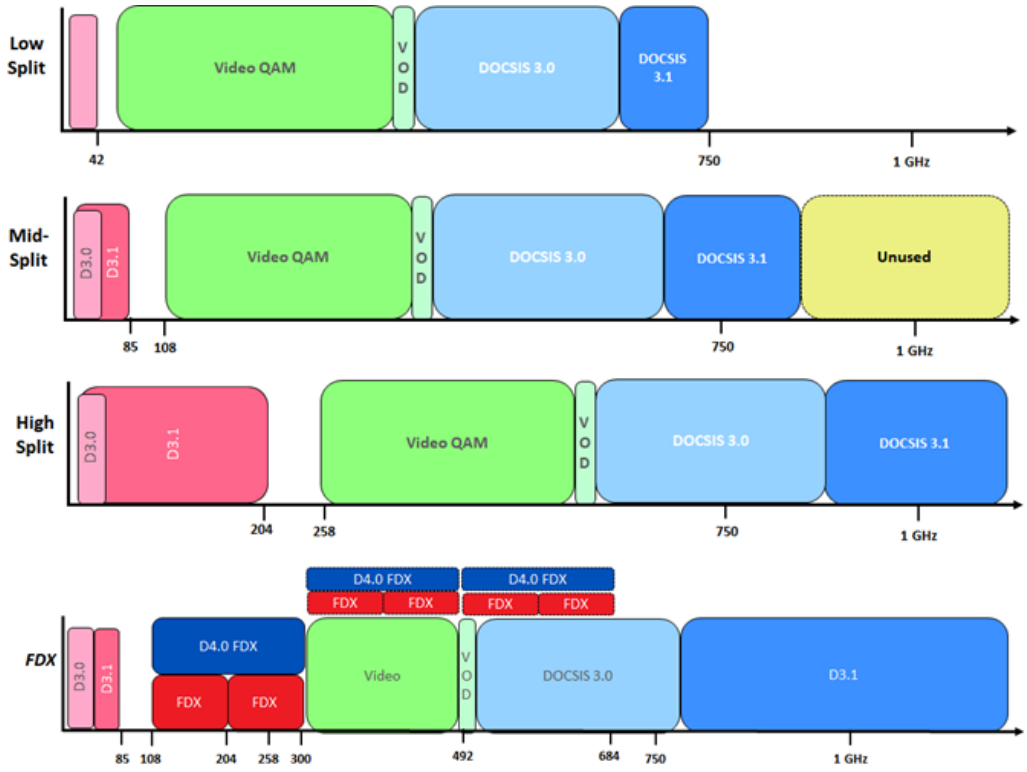

Figure 2 - Spectrum Migration Options through DOCSIS 4.0 (FDX only)

4.1. The Mid-Split: 5-85 MHz (defined initially in DOCSIS 3.0)

The Mid-Split is viewed as a practical steppingstone and with a relatively light touch because it resolves the upstream capacity challenge as we mathematically know it today. When combined with a node split, it defers additional augments to address congestion for at least 5 years, typically more (depending on D3.1 vs D3.0 assumptions). Furthermore, with an all-OFDMA channel, it can support around 600 Mbps. With a 4xSC-QAM DOCSIS 3.0 payload in the 5-42 MHz portion, about 450 Mbps is expected. Speeds up to 300 Mbps are expected in scale, under some traffic engineering guidelines tied to new utilization patterns.

An 85 MHz payload consistent with most MSO DOCSIS 3.0 usage today is 4x64-QAM DOCSIS 3.0 carriers, and a single OFDMA block from approximately 40 MHz to 85 MHz. This configuration is shown in **Figure 2.**

At this time (summer 2021), the Time and Frequency Division Multiplexing (TaFDM) feature, which allows spectrum to be DOCSIS 3.0 in some time slots and DOCSIS 3.1 in other time slots, has not been enabled. This remains an option, depending on the penetration mix of DOCSIS 3.0 and DOCSIS 3.1 modems and the net efficiency provided.

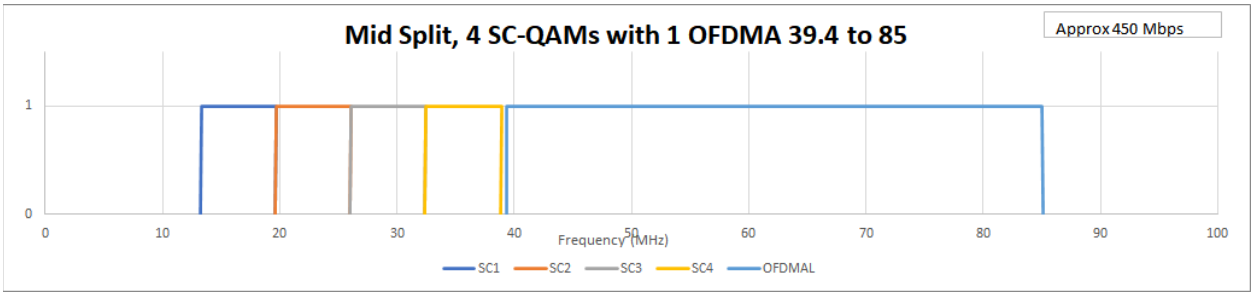

Figure 2 – Mid-Split DOCSIS 3.0 + DOCSIS 3.1 Loading Configuration

4.2. The High-Split: 5-204 MHz (efined initially in DOCSIS 3.1)

The High-Split is another popular option, as it stretches the speeds possible in the upstream to 1 Gbps or slightly more, as was demonstrated in the fall of 2020 [3]. Since the Mid-Split is such a powerful solution itself for capacity, going to a High-Split is a potentially very long-term solution with respect to capacity. However, practical capacity benefits are driven ultimately by the number of High Split-capable devices that can access that spectrum. There are many more Low-Split and Mid-Split modems deployed today compared to High Split, although this could change over time, and in particular for those that deploy with High Split.

4.3. DOCSIS 4.0

Like the High-Split, the primary value of DOCSIS 4.0, FDX or FDD, is upstream speeds. DOCSIS 4.0 fully attacks the historical asymmetry of downstream and upstream capacity, bringing multi-Gigabit symmetric capability to HFC. As it is defined today, the upstream will achieve 5-6 Gbps when fully activated. A path to 10 Gbps upstream is available by extending the bandwidth in FDX or FDD above today's 684 MHz limit with two more OFDMA blocks, to 1068 MHz. While this is easy to draw on a diagram, it creates challenges like upstream transmit power from a cable modem to overcome high coaxial losses.

Figure 3 summarizes the speeds associated with the options shown in **Figure 1**.

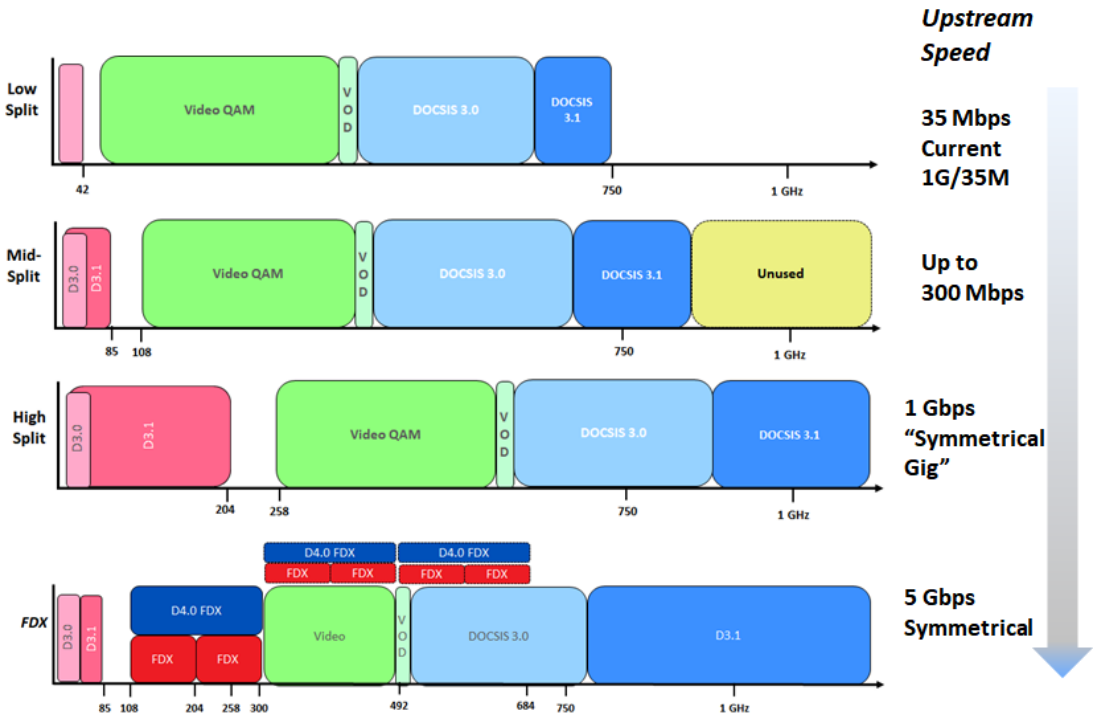

Figure 3 – Spectrum Migration and Implications to HSD Speed Tiers

We will get into the nitty-gritty details of the paper from this point on by mostly examining the Mid-Split scenario. Many of the same concepts are applicable to High Split, although there are some important differences that we will call out in the next section. There are deeper details, software and tool development, and mature processes that can be explained more readily using the Mid-Split case study due to its longevity, so we will lean on that for the bulk of the deep dives.

4.4. The Math

Mid-Split expansion takes the available upstream bandwidth from 37 MHz to a limit of 80 MHz. It was defined in DOCSIS 3.0, with the upper limit selected in part to fall just below the FM radio band in the US, while preserving the important downstream video out-of-band (OOB) signals widely used by legacy QAM set-top boxes (STBs). Per the earlier discussion, it is typically the upstream that drives network upgrade activity.

Because of the average per-user peak-busy-hour (pbh) upstream is still in the hundreds of kbps range, the upstream payload generally grows more slowly than downstream. Plus, because the new upstream spectrum is much cleaner, the Mid-Split impact on network lifespan is extremely powerful.

Figure 4 shows the time runway generated by three options – node split, node split plus upgrade to Mid-Split, and finally N+0 with Mid-Split. While N+0, with smaller service group size, offers the longest runway of the three, an N+x migration tied to a node split is also a very effective way to extend HFC lifespan to nearly 7 years in this analysis.

A key benefit of N+x with spectrum migration is its ability to add capacity quickly when compared to N+0. With the Covid-19 spike eliminating months of CAGR lifespan, N+x upgrades bring more US bandwidth to the network quickly to reset the lifespan timeline. The naturally slower pace of deeper fiber construction

will leave too many areas without an augment for too long of a period of time. With the capacity growth "time" erased due to the pandemic, alternatives such as drop-in HFC upgrades that are both fast and effective make a sensible augmentation step. Having a diverse strategy, not one-size-fits-all, adds important flexibility to deal effectively with adjustments for situations like Covid-19.

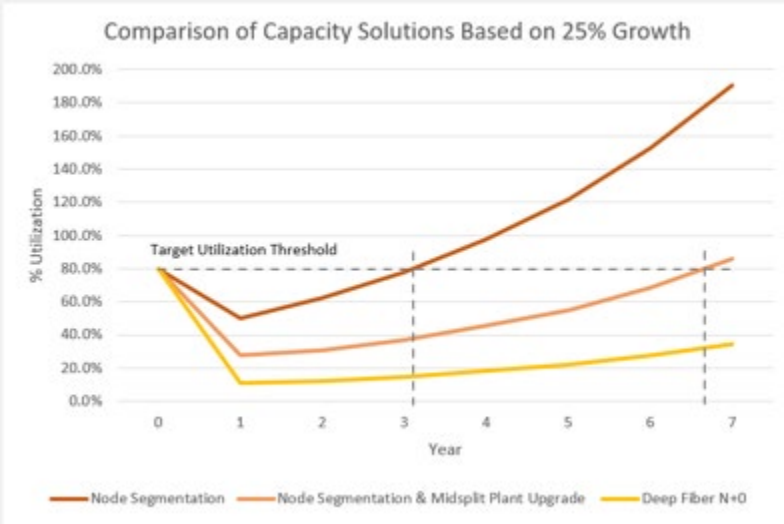

Figure 4 – Upstream Lifespan Expansion Options [2]

Lastly, looking ahead to future capacity and speed demand, and coupled with the objective to push fiber deeper into the network whenever possible, adjustments are being made to the architecture where it makes sense. For example, adding fiber in an underground network without the benefit of conduit is an inherently slow process. However, by providing the flexibility to allow a strategically placed amplifier (e.g., to allow an N+1 network) or two, there will be less construction, increased node size, and decreasing cost per household passed (HHP.) Combined, all speed the pace of the network upgrade and deliver the added bandwidth to more HHPs/year.

4.5. How About Some Real Visuals, Larry?

Comcast and other MSOs, such as Shaw Communications, have been building and activating Mid-Split spectrum for about 5 years. As much as can be gleaned from the crisp PowerPoint visualizations that led up to this moment is not nearly as exciting as displaying the real thing! **Figure 5** shows an activated Mid-Split upstream of 4xSC-QAM and the rest OFDMA. Upstream traffic is bursty, so this spectrum tool, the Yeti upstream spectrum analyzer application, has been placed in Max Hold mode to show the full 85 MHz band over time being utilized by the CM traffic. Most of the traffic is still in the DOCSIS 3.0 SC-QAM – the "Heatmap" view would show this – because most of the CMs in the system are DOCSIS 3.0. This balance is changing rapidly but DOCSIS 3.0 CMs are still the majority.

Figure 5 – Activated Mid-Split of 4xSC-QAM + OFDMA

5. New Spectrum, New Challenges

It is a sizeable project to upgrade the access network to support a new spectrum split. While some of the equipment is hosted in Hubs and Headends, where it is more easily accessible and centralized, upgrading outside plant (OSP) is more challenging. It requires going into the field, to every active device which has a diplexer – which is to say, every active device – and upgrading it to the new split. In some cases, this is something that can be done by changing a plug-in filter inside of the housing (not a live housing, removed from network) but in most cases it is not this simple. Many amplifiers in the field are decades old, made by vendors who no long support the product line, requiring swapping of devices altogether. Regardless, many operators have made the decision that the time is now for a frequency split upgrade and are committed to executing it.

Most of the above applies directly to an upgrade to a High-Split when it comes to upgrading actives in the field. However, the nature of the upgrade to Mid-Split is a lighter touch, with respect to other important variables. These are important to understand as part of a decision criteria on the upstream plan.

The seemingly intuitive “if more spectrum for Mid-Split is good, then even more spectrum for High-Split must be better” runs up against some significant new complications, outlined below.

5.1. Legacy QAM STB OOB Carrier

QAM video STBs that do not have a DOCSIS STB Gateway (DSG) control channel utilize the SCTE 55-1 or SCTE 55-2 protocol to get the necessary information to the STB. Signals returned from the STB over the upstream path in the 8-12 MHz range, typically. For fellow upstream geeks – yes, that part of the spectrum is terrible, but the protocol calls for very simple, robust modulation that is inefficient, but the traffic requirements of this modem are very low by today's HSD standards.

In the downstream, however, the "out-of-band" (OOB) carrier must be in the band 70-130 MHz according to the standard. When the upstream stops at 85 MHz, there is plenty of spectrum to place the OOB signal. When the spectrum extends to 204 MHz, legacy QAM STBs are stranded unless they can receive this OOB channel some other way. There are creative ways to do that, however it is some version of one-off solution.

Some of the thinking at the time of the DOCSIS 3.1 standard was that legacy QAM STBs were on the decline and would largely be out of the network by the time the High-Split was deployed. In addition, there was a move towards all-IP video delivery, which is still true today - although with somewhat less urgency based on changing business dynamics of the 10 years since the specification was being developed. One such class of box (General Instrument / Motorola DCT2000) is a model old enough that its tuner is at a fixed frequency and will not tune up or down from this frequency, which is about 72 MHz. Because it cannot tune up, it is incompatible even with Mid-Split. As a result, where Mid-Split is deployed, a pre-requisite is to swap these STBs out of the network. Due to the age of these STBs, the number of these STBs are very small, and the burden thus relatively low.

This is one of the very important aspects of High-Split compared to Mid-Split. Eliminating the OOB can make it a more invasive procedure for customers, as the best operator option is to extract these non-DSG-capable STBs, and this is more likely to "leave scars." The other import aspect attributable to High-Split is the Neighbor Interference (NI) phenomenon, which we will discussed later in this paper.

5.2. Aeronautical Leakage Band

The Aeronautical band, 108-137 MHz, is one in which there are requirements on operators to ensure there is not egress above a certain amount that could interfere with over-the-air (OTA) users in that band. Operators have mature processes and equipment to monitor this, placing "leakage carriers" in and around this band (and others) to measure leakage systemically to ensure compliance. It acts inherently as plant hygiene, so there is substantial benefit to operators - because where there is egress, there is the possibility of ingress. Ingress, of course, has been haunting the upstream for many years, and especially as the DOCSIS HSD upstream has grown more critical.

In practice, tones are placed close to the 108-137 MHz band in the downstream spectrum line-up and measured by specialized equipment. Of course, this works fine for Mid-Split. Mid-Split ends at 85MHz and the leakage band begins above that. However, this band, for High-Split is now in the upstream. To the letter of the FCC requirements, the upstream transmit power of a specification-compliant DOCSIS 3.1 modem cannot exceed the FCC limit, even at maximum transmit power. However, rather than do away with this aspect of plant maintenance altogether and lose the value it brings to operators and regulators alike, leakage measurements in this band will continue. Techniques which can measure leakage coming upstream from the modem are required, however, which is much different than today. Since these transmissions are bursty and short, the probability of catching them using today's auto-pilot drive-by method is not sufficient. Instead, techniques that use probe signals sent from CMs that are scheduled, and such that burst detecting equipment – also new for these meters – can capture the burst and assess the

leakage performance is needed. It is a more complex and intricate solution than is needed on the downstream, but early proof-of-concepts have shown it viable.

5.3. Cable Modem Maximum Upstream Transmit Power

The maximum Total Composite Power (TCP) of a DOCSIS 3.1 cable modem is 65 dBmV. An "average" upstream transmitter in our footprint launches at about 43 dBmV/6.4 MHz. Extrapolating to 4x SC-QAM carriers, this becomes a TCP of 49 dBmV, still plenty of headroom to 65 dBmV. Extrapolating a uniform Power Spectral Density (PSD) over Mid-Split, this becomes roughly 53 dBmV using the Mid-Split configuration of Figure 2 – again, still plenty of headroom, but keeping in mind that 43 dBmV was the average.

The 90% point for upstream TCP is about 51 dBmV/6.4 MHz, meaning 90% of cable modems transmit 51 dBmV/6.4 MHz or lower. Extrapolated to Mid-Split, this is a TCP of about 61 dBmV. Our headroom is disappearing! Indeed, the 55 dBmV/6.4 MHz case, which would be the limit of the TCP that the modem can transmit, when extrapolated to Mid-Split, is about a 99% point on the cable modem upstream, Tx power cumulative distribution function (CDF). Of course, 1% represents a very small relative likelihood of running out of gas, but it is certainly not negligible for a large DOCSIS footprint when the population of DOCSIS 3.1 devices (all Comcast Mid-Split capable devices are DOCSIS 3.1) in the field is growing.

Now consider these extrapolations for the High-Split case:

Average US Tx: 43 dBmV → TCP (High-Split) = 58 dBmV

90% Point US Tx: 51 dBmV → TCP (High-Split) = 66 dBmV

This suggests that there could be a significant increase in the number of CMs that will be transmitting at their maximum and more, reaching the amplifier or node port at lower than designed levels, all else the same. This may impact network performance (lower MER) and throughput, in addition to creating challenges for operations and maintenance in aligning the network. It is unlikely this would be noticeable to a customer during normal use of Internet applications. But it could increase slightly the probability of a speed test failure for a 1 Gbps upstream service, which does not have a lot of capacity headroom above 1 Gbps.

5.4. FM Band

One of the benefits of the Mid-Split spectrum stopping at 85 MHz is that the FM radio band begins at 88 MHz. Indeed, by the time discussions about an expanded DOCSIS 3.0 spectrum were happening, the role of plant ingress and impact on the upstream was beginning to be felt and understood. FM radios broadcast from 88-108 MHz and can be very powerful signals when nearby transmitting antennas on major stations with the most powerful signals. It is expected that this band will suffer in terms of guaranteed MER across part of the network.

There is no better option for working effectively through an FM band with residual radio noise ingressing onto the cable than using DOCSIS 3.1 OFDMA. However, if FM radio signals create high interference, as reflected by a low MER, there is only so much that can be done by OFDMA. The 88-108 MHz span is a modest chunk of spectrum – about 12% of the newly added capacity for High-Split, so the impact also is expected to be modest.

As with the Total Composite Power (TCP) case, this scenario could also make it more difficult for the High-Split solution to achieve the 1 Gbps or greater target, given the small amount of headroom that exists.

6. Tool Time !

A suite of existing Comcast tools is essential to Mid-Split activation, which will become apparent as we describe the new tool development and tech ops processes supporting the initiative. This section is an introduction to the essential tools that we will reference along the way.

6.1. Premise Health Test (PHT)

Premise Health Test is a tool used to assist technicians in the diagnosis of any customer premise. PHT has evolved over nearly a decade, beginning as Home Integrity Check (HIC), starting with DOCSIS-only measurement values. It has been expanded to be more comprehensive, including many Proactive Network Maintenance (PNM), Wi-Fi, MoCA, EPON and other measurements. The test is usually invoked before and after installs and repairs to provide outlet-level readings from the installed equipment, where available. In addition to pass-or-fail, PHT also provides details about the service to facilitate the troubleshooting process. **Table 1** has a complete list of pass-or-fail criteria.

Table 1 – PHT Pass-or-Fail Criteria

Metric	Upper Fail	Lower Fail	Single Threshold Fail
Actual US TX	> 54 dBmV	< 25 dBmV	
Partial Bonding			Registration state <>4 Downstream state <>1
FLUX ICFR			>= 3 dB ICFR (ICFR Indicators)
DS RX	>13 dBmV	<-13 dBmV	
DS SNR			< 33 dB
SpectraCM Impairments*	* Full Spectrum Devices Only		Any Individual Impairment <>ACP
MoCA PHY Rate * MoCA Network *	* MoCA Capable Devices Only * MoCA Segmented Network Devices * MoCA Unexpected/Foreign Devices		< 200 Mbps (XG to XI, XB to Xi, XG to XB devices only; Xi to Xi or RNG150 to RNG150 not in scope)
FM Ingress	* All DOCSIS Devices		Severe Ingress Condition
EPON	>-8.0 dBm >-4.0 dBm	<-28.5 dBm Downstream <-28.0 dBm Upstream	Please Refer to Market RTM Process for any Failing Light Level Conditions
All Out			All Devices are Unresponsive
Wi-Fi – RSSI	* Re-Launch 10-29-19; None Pass/Fail		< -70 dBm RSSI Range at Xi5/Xi6

6.2. Yeti

The Yeti tool comes from the PNM suite, providing real-time upstream spectrum capture information to users. Historically, operators have relied on hardware-based spectrum analyzers to perform this function. Since the advent of PNM, spectrum capture capabilities are now available in the cable modem, from both downstream and upstream burst receivers. Upstream spectrum capture implemented within the burst receiver provides several distinct advantages over external, hardware-based solutions. First, it eliminates

the need for additional hardware, which typically occupies valuable headend space and requires facilities power and cooling. It also allows operators to take advantage of the powerful burst receiver demodulators and CMTS core scheduling information. For example, in-channel demodulator performance metrics can be displayed along with the spectrum capture traces, with thresholds and colorization to aid in human interpretation. Another powerful feature is the CMTS scheduler's "quiet time" mode, which captures spectrum traces when no modems are transmitting. This provides users with a "noise-only" view of the upstream spectrum, simplifying the troubleshooting process by removing the cable modem bursts. **Figure 6** shows an example of the Yeti display, including SC-QAM and OFDMA bursts, in-channel demodulator statistics and threshold-based colorization.

Figure 6 – Yeti Upstream Spectrum Capture Display with SC-QAM and OFDMA

6.3. SpectraCM

This downstream spectrum capture tool provides a cable modem-oriented view of the RF spectrum. In the PNM suite, it's referred to as Full Band Capture (FBC) and provides the modems with downstream receiver spectrum capture. It's especially useful when upgrading from Low-Split to Mid-Split operation because of the switchable diplex filters in the cable modems. With the diplex filter operating in Low-Split mode, the cable modem is very effective at capturing the noise environment from within the home, which, as mentioned earlier, is often the source of RF ingress. Then when upgrading to Mid-Split operation, the frequency spectrum up to 85 MHz changes direction, creating a notorious funnel effect, which complicates troubleshooting. Having the ability to switch between diplexer modes of operation allows operators to automate this traditionally difficult troubleshooting process. **Figure 7** illustrates an example of SpectraCM being used with Yeti to match and locate ingress of VHF television signal ingress.

Figure 7 – SpectraCM (bottom) Locates Ingress with Yeti (top)

7. Activate Spectrum So No One Will Notice

It is an axiom of good network strategy and upgrade practices to think of success like a baseball home plate umpire does: You've had a good game when nobody notices that you were there. This is absolutely the case for migrating spectrum, with the caveat that they will notice in a good way that you were there, as the products enabled by these network upgrades – in particular upstream HSD speeds – become available. Until then, though, the internal satisfaction that is flat trouble call metrics and meeting schedule and budget targets will have to do.

We describe below the potential issues to manage and share practices that help to achieve a seamless customer experience.

7.1. Activate Spectrum So No One Will Notice

With the decades of spectrum split in North America being set at 42 MHz/54 MHz, all QAM video STBs deployed are configured this way. They were built to receive video channels beginning at 54 MHz. When the network is NOT configured this way, and instead is upgraded to enable the diplex split to expand the upstream and activate new spectrum above 42 MHz, the QAM STB's point of view for Mid-Split or High-Split changes. This is shown in **Figure 8**.

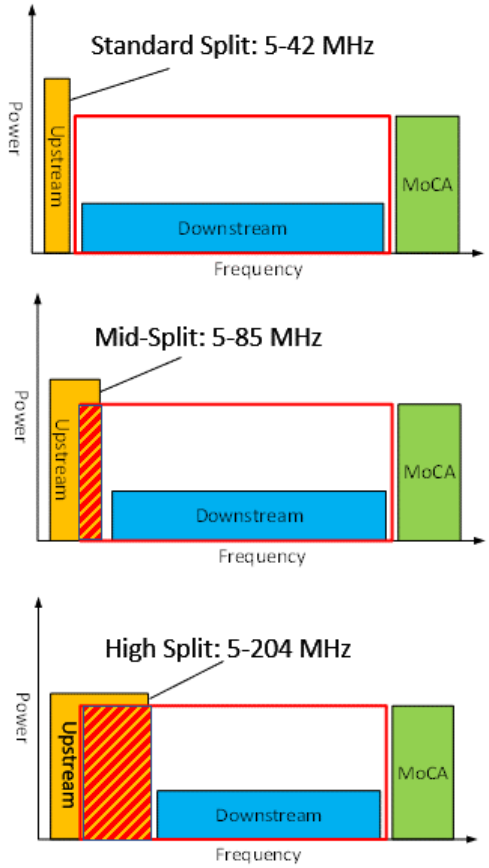

Figure 8 – New Spectrum Splits vs. Standard Deployed Equipment

The red cross-hatched areas in **Figure 8** represent the spectral overlap imposed on a QAM STB by a Mid-Split capable cable modem when utilizing that band. Any signal energy that appears above 54 MHz can be seen by the STB downstream receiver, because it is built expecting to operate on downstream signals that begin at 54 MHz. Unfortunately for the STB, in a home that also contains a Mid-Split capable cable modem (CM), the CM sees that band as "eligible" for placing carriers when the CMTS is configured to allow CMs to use it. In a CMTS that is properly load balancing, with much of the existing traffic volume generated by devices with a 42 MHz limit, and OFDMA turned on above 42 MHz, the Mid-Split capable devices would expect to be utilize the 40-85 MHz spectrum for transmissions.

Note that the RF processing front-end of the STB is not acting on any specific signal type – it is simply adapting its front-end gain to deliver the ideal level to the A/D converter using its Automatic Gain Control (AGC) function. AGC measures the total energy in the downstream band and doesn't care about its origin. It adds or subtracts gain to deliver the signal intact and at the optimized level – a balance between Signal-to-Quantization-Noise Ratio (SQNR) and clipping distortion – to the A/D converter, on its way to the digital processing. Thus, if new Mid-Split upstream energy on the STB receiver is very high, the STB receiver will add attenuation to keep the right operating point on the A/D converter. When this happens, the *desired* video channels will inadvertently be pushed into the noise floor through a phenomenon called "Adjacent Channel Interference" or ACI. If it attenuates too much, then the QAM video signals can be pushed down enough to cause low SNR in these channels, and video pixelization could ensue. Potential makeover scarring alert!

Note the above description is a "static" or time-fixed snapshot view of upstream energy and spectral overlap with signals moving downstream to a STB. Actual upstream traffic is called "bursty" because it bursts on and off. This is important because the AGC function has dynamic characteristics, but they tend to be slow (levels don't change very much, typically). As a result, the duty cycle (off/on ratio) and burst duration of upstream signals is a factor that can impact the AGC implementation of different STBs.

Note that, as represented in **Figure 8**, the nature of the levels is not favorable – the downstream receive level is low (DS Rx), while the upstream transmit level (US Tx) is high. Until now, there was a diplex filter to separate them, but now, between 54-85 MHz, this is no longer the case. As discussed, the US Tx average level is about 43 dBmV/6.4 MHz, with the vast majority at 51 dBmV/6.4 MHz or less. By contrast, downstream receive levels typically target 0 dBmV/6 MHz, but range widely by design from a minimum of about -12 dBmV/6 MHz to a maximum of +10 dBmV/6 MHz.

Fortunately, between a CM and a QAM STB there will be an RF splitter, the design of which will inherently isolate the port of a CM from the port of a STB by some amount. This scenario is illustrated in **Figure 9**, showing just one isolation path between modem (MTA) and a STB's RF inputs.

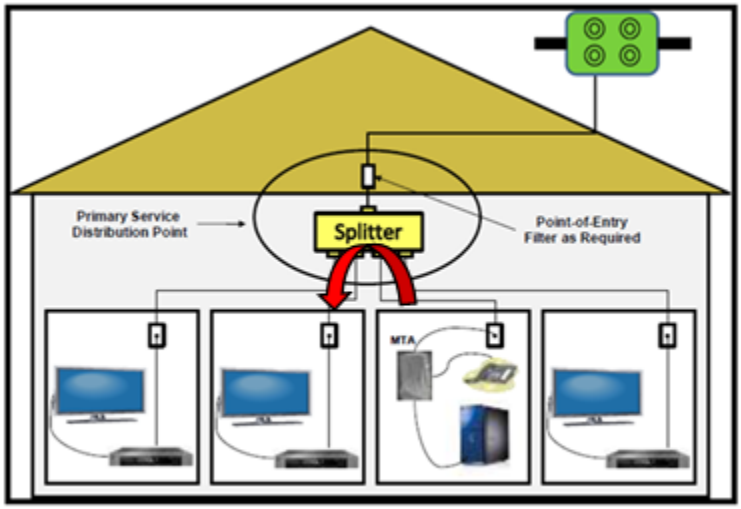

Figure 9 – Mid-Split Band Energy Isolation Path Across and RF Splitter

How much energy leaks through to the STB? That question depends directly on the splitter and home wiring shown in **Figure 9**. Home wiring – RG6 cable – has a very predictable dB/loss per foot and is easily modeled, from which some basic assumptions can be made about the range of run lengths in non-celebrity, which is to say "reasonably sized" homes. The most important factor with respect to the ACI phenomenon is the splitter(s) used to distribute RF to devices for video and data services. **Table 2** shows the specification for the isolation parameter (paragraph 13.0) for approved Comcast splitters.

The parameter used to evaluate the relative risk of video interference is called Carrier-to-Adjacent-Channel-Interference Ratio (CACIR). The threshold at which video degradation can be observed varies by STB model, and these have been individually characterized for every model still in use. Automated tools can discover the model type directly or through information in the billing systems and can apply a CACIR threshold according to the model type. For purposes of this paper, we will use the worst case empirically observed lab test value of -22 dB CACIR as the threshold value for deriving statistics. It seems like a 20 dB higher signal should completely blow up an RF front-end, right? However, note that the -22 dB is a

single carrier-to-single carrier comparison. There is, of course, more total bandwidth in the downstream than the upstream, so the total difference in power of the interfering energy to total downstream energy is less than this.

Testing was done as both "always on" and over a range of fixed duty cycles meant to emulate the "on/off" bursts of real upstream traffic. It is only when the upstream is bursting on, of course, that there are signals that can interfere with a downstream STB.

Table 2 – Port-to-Port Isolation of Comcast Approved RF Splitter

COMCAST

Field Equipment Specification: Mid-split Passive RF Drop Splitters

ID	Specification	Requirements				Test Method / Other References
12.0	Return Loss	**Minimum RF Port Return Loss, All Other Ports Terminated (MHz)**				ANSI/SCTE 144 2007
		5-1002	**1003-1218**	**1219-1675**		
		≥ 18 dB	≥ 15 dB	≥ 5 dB		
13.0	Isolation	**Minimum Output Port to Output Port Isolation (MHz)**				ANSI/SCTE 144 2007
		5-10	**11-85**	**86-1002**	**1003-1125**	
		≥ 25 dB	≥ 35 dB	≥ 25 dB	≥ 20 dB	
14.0	Maximum Output Port to Output Port Isolation 1,125 MHz-1,675 MHz	**Splitter Device**		**1126-1,675**		ANSI/SCTE 144 2007
		2-way		≤ 28 dB		
		3-way (unbalanced)		≤ 30 dB		
		4-way		≤ 30 dB		

Comcast specifies a minimum isolation through the Mid-Split band of 35 dB. That says that a lot of the upstream transmit power is going to be attenuated on the way to the STB. (Yay!) Is it enough? Usually. And, fortunately, when it is not, it is discoverable and easily remediated. For a scar-free upstream makeover, the key statement is "discoverable."

Because of the importance of quantifying the potential for ACI, an existing model of Comcast-approved splitters was measured for actual performance. Practical performance of these splitters is shown in **Figure 10**. Note that the band between 54-85 MHz is, in the case of this model, the "sweet spot" of RF isolation, with 45 dB being more characteristic of splitter performance. This is an extremely valuable 10 dB with respect to quantifying the potential to impact video.

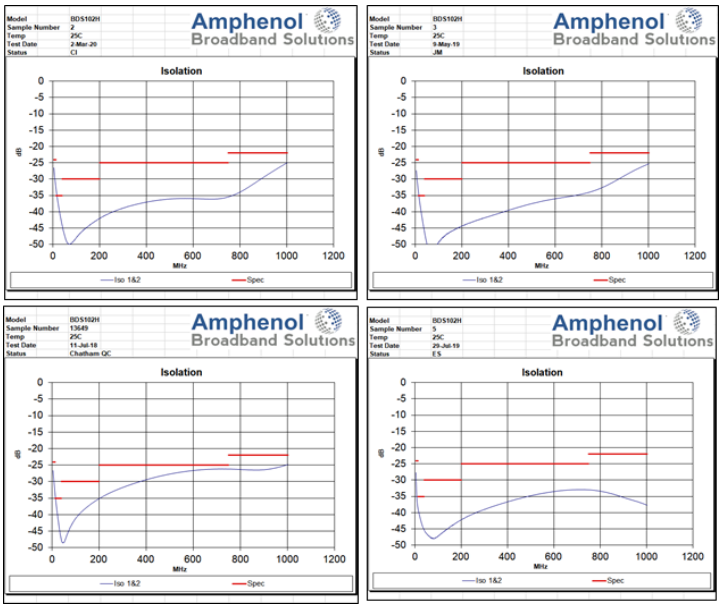

Figure 10 – Measured Port-to-Port Isolation of Comcast Approved RF Splitter

For every "sweet spot," there is of course a counter example. In the ACI scenario, the most concerning counter example, with respect to video service impact, is the use of a low-cost, off-the-shelf splitter that might be found in the cable TV accessories section of a home improvement store, such as Lowe's or Home Depot. (For old timers, this is where we used to say, "Radio Shack," but you may be hard pressed to find anything related to radio on the shelves there anymore ... if you can even find a storefront.)

Figure 11 shows the isolation performance of this type of splitter.

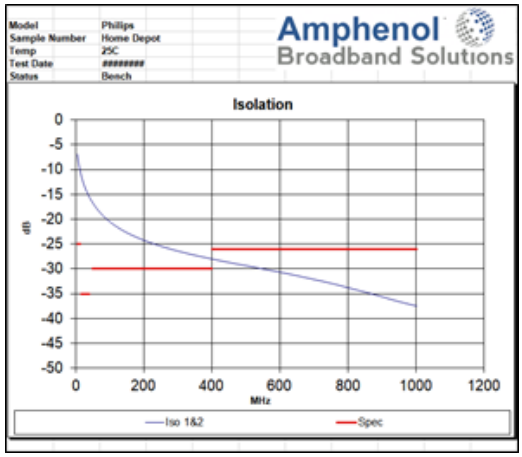

Figure 11 – Measured Port-to-Port Isolation of an Off-the-Shelf RF Splitter

We believe these retail splitter scenarios create the most likely risk to STB video degradation, as they perform with 15-20 dB worse isolation than the Comcast requirements. This in-home scenario is easy to envision occurring in practice and is generally out of the operator's control. Through the automated diagnosis of homes slated for a wider upstream, we can find such scenarios and take proactive measures prior to activating the Mid-Split spectrum.

Eliminating the possibility of video interference attributable to the activation of Mid-Split spectrum is a primary criterion for smooth spectral transition. Using empirical data of measured Comcast DS Rx and US Tx from production CMs, and typical home network assumptions for splitter and coaxial LAN runs, **Figure 12** shows the probability of ACI reaching the threshold for video interference to be 1.29% for the worst-case sensitivity among all STBs tested. This number looks small, and it is. However, when measured against the total number of broadband subscribers with video service, it is not negligible, and needs to be managed with proper tools and processes.

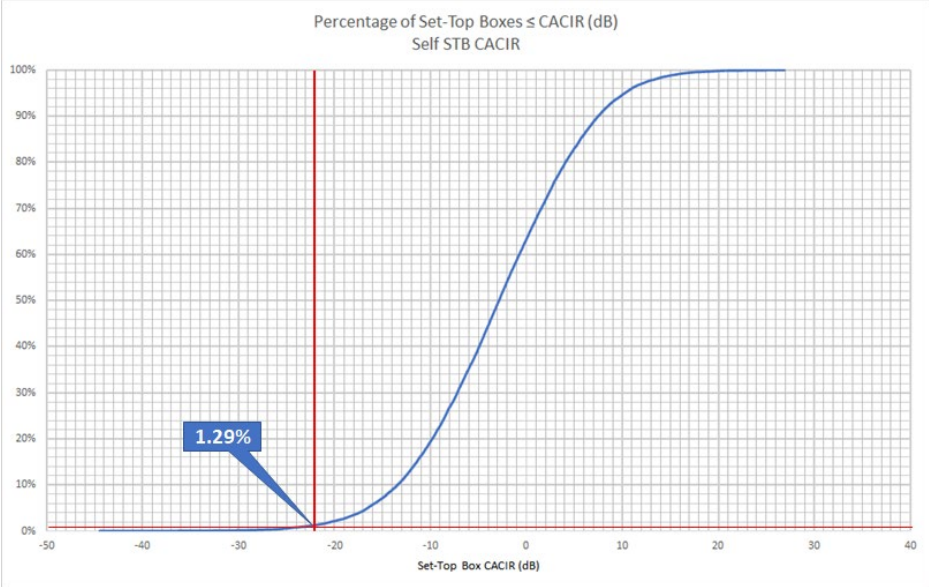

Figure 12 – Probability of Interference ≥ ACI Threshold of STB

One important note is that **Figure 12** shows the correlation of measured dB relationships with a lab-observed video impairment, under a set of fixed upstream transmission patterns. In real life, the upstream duty cycle is low, and the transmissions are relatively random in both size and duration. It is difficult to precisely correlate RF impairments measured in dB, to customer-impacting video degradation from real traffic, and further, to degrade it enough to generate a trouble call (versus the so-called silent sufferer – a worse scenario). While it is straightforward to create an impaired condition in the lab, how this translates to field exposure will be something that will be continually learned over the course of trials and the scaling-up of Mid-Split activation. That is the genuine way to test the hypothesis and lab measurements when encountering real traffic.

7.2. In-Home Amplifiers

In addition to OSP and traditional CPE devices that provide residential services that only know the 5-42 MHz Low-Split, many homes also use drop amplifiers to overcome losses across the in-home coaxial network. As you might expect, these are also built with a Low-Split diplexer.

These devices must come out…eventually…. but because they may or may not be customer-impacting, they do not *necessarily* have to be tackled coincident with the activation of Mid-Split spectrum. From a capacity perspective, every drop amplifier that can be removed so that it doesn't block Mid-Split energy from exiting the home is good for capacity. The operations perspective depends on the percentage of homes that include a drop amplifier – estimated at 15-20% but can cluster depending on geography and practices.

Methodically removing in-home drop amps over a period of time may make more sense than dealing with amplifiers transactionally, meaning only as part of a service call or product upgrade. A proactive plan to address drop amps will eliminate the perpetual limbo state that is mixed-mode devices working in mixed-mode spectrum.

With capacity and product in mind, we can itemize home amplifier management into two buckets:

1) Capacity-driven – Referring again to **Figure 4**, the coaxial lifespan when doing digital node splits and upgrading the network to Mid-Split is shown to be almost 7 years. This includes new capacity made available by Mid-Split (450 Mbps used), which depends on the DOCSIS 3.0 QAM bandwidth consumed and no considerations for TaFDM. Again, this only works if modems can access the Mid-Split bandwidth, which only happens if the CM is capable (new enough) of doing so. All DOCSIS 3.1 CMs we use are Mid-Split-capable, and our DOCSIS 3.0-only CMs are not. CMs are migrating to DOCSIS 3.1 status steadily, so over the 7-year period it is safe to assume the vast majority will be installed and capable of Mid-Split upstream connectivity. However, even if a Mid-Split-capable CM is present, any home that cannot allow the spectrum to pass out of the home is one that cancels the capacity gains. The "real" penetration of DOCSIS 3.1 OFDMA is decreased accordingly, and the 7-year lifespan is compromised. Thus, as mentioned, over time, these amplifiers must be removed, so that the capacity plan can deliver on its lifespan promise. How quickly this must be done is a mathematical analysis of utilization vs the "real" penetration trajectory.

2) Product-driven – One of the key benefits of the Mid-Split is the ability to deliver HSD speeds in the upstream such as 100 Mbps, 200 Mbps, 300 Mbps, even higher, as OFDMA begins to replace DOCSIS 3.0 QAMs in the upstream. Traffic engineering rules developed for these speeds account for utilization and total capacity and are considered reasonable expectations for potential product offerings. Once such products are made available, customers with home amplifiers will be (self)-blocked from receiving them. Interest in speeds that require Mid-Split would trigger immediate action, to remove the blocking amplifier. The challenge is how to manage this efficiently and, more importantly, in a way that is impact-free to the customer. The good news is these blocking devices (amplifiers or any filtering within the band that may have been installed inline) can be discovered remotely and in real-time. While the customer cannot get the new upstream speed immediately, a rapid and transaction-based process can serve to notify the customer that additional steps are required to support the speed upgrade. That we have detected the need for additional steps is a communications decision that is out-of-scope for the purposes of this paper. Either way, appointment scheduling can commence to eliminate the problem and get the new product speed to the customer.

   The product case is a different kind of operational task than the "capacity driven" case and is difficult to pre-plan because it is impossible to predict exactly which customers seeking the new upstream speed will also have in-home amplifiers. This adds to the long and growing list of reasons to proactively replace drop amplifiers during, for example, scheduled truck rolls to homes that also have been discovered as having a drop amp. Or, as mentioned above, build a program to recover in-home amplifiers proactively, over time, in a way that spreads out the cost of the effort, controls it better, and unifies the network for all homes -- rather than during product requests, which introduce a reactionary mode.

In a nutshell, the problem statement for Mid-Split activation caused by the 54-85 MHz spectrum overlap identified in **Figure 8**, is to develop a way to unobtrusively discover the state of a home with respect to these two criteria:

1) Potential for video interference
2) Ability to support DOCSIS upstream pass-through in the Mid-Split band

To enable this home-by-home assessment in scale, we developed an automated in-Home Assessment Test – aka iHAT – to enable a seamless migration of capable CMs to utilize Mid-Split when conditions 1 and 2 above are satisfied, as shown in **Figure 13**.

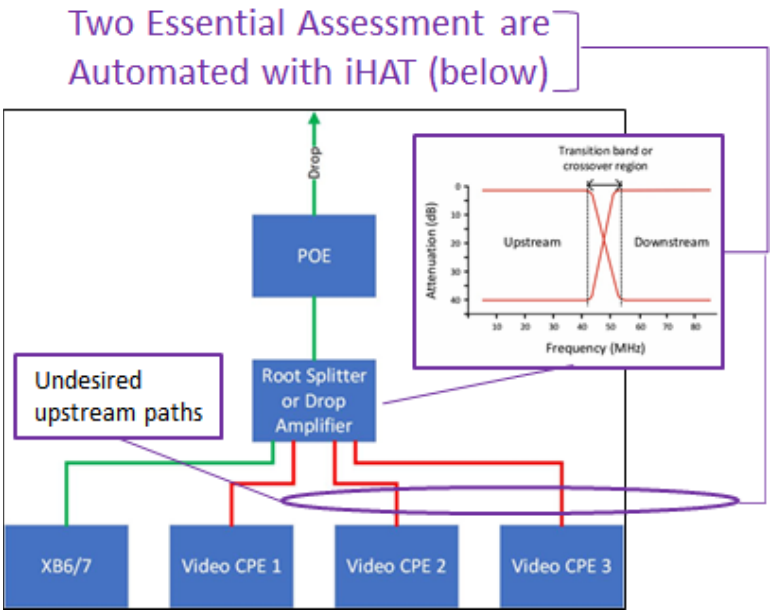

Figure 13 – The Two Basic RF Assessments Evaluated by iHAT

7.3. What's Under the HAT?

The "Black Box" view of iHAT that includes its functional core is shown in **Figure 14**.

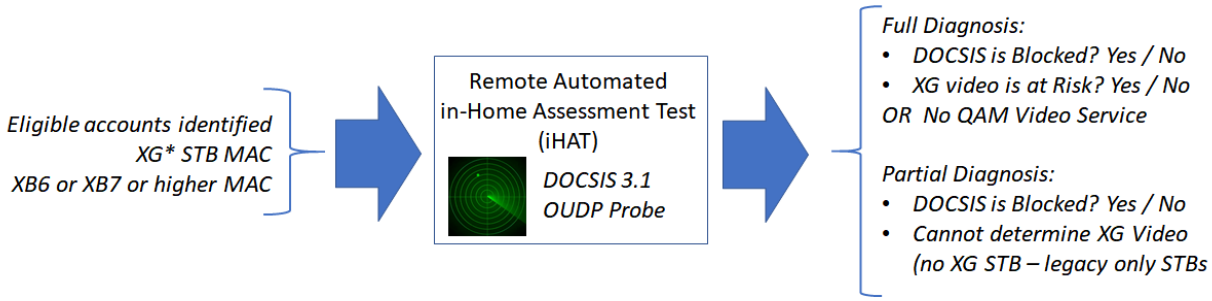

Figure 14 – The iHAT "Black Box" – Method and I/O

7.3.1. Incoming !

As shown in **Figure 14**, iHAT retrieves a list of devices, by account, on a particular Mid-Split-enabled RemotePHY Device (RPD) node, after the node is cutover, activated, and services restored that meet a pre-cutover state of performance (we are activating Mid-Split with OFDMA-only on DAA platforms). When an account is identified as having a Mid-Split-capable CM – for us, this includes the DOCSIS3.1 gateway family of XB6, XB7, and XB8 – it is deemed eligible for an iHAT test. With one of those devices present, it will be possible to place the CM in Mid-Split mode to determine whether its upstream transmissions in the Mid-Split band are able to be seen and received by a Mid-Split enabled vCMTS and DAA node, or if they are blocked.

When an account also includes the "XG" class of QAM STB, the iHAT evaluation will look both for DOCSIS Mid-Split pass-through and the potential for video interference. This XG family, the majority of QAM STBs in the Comcast network, supports the proactive network maintenance (PNM) and SpectraCM functionality needed to capture RF measurements that are the basis for iHAT scoring of video interference potential. Older QAM STBs do not support this capability. In a home that includes an XG class STB, that measurement taken is a reasonable proxy for the expectation for other non-XG STBs with respect to their isolation from Mid-Split spectrum energy.

If there is no XG-class STB present at all, but "legacy" QAM STBs are present, then no iHAT assessment can be made with respect to the potential for video degradation. At the outset, these homes will default to Mid-Split activation as data is accumulated. After some scale of statistical significance is built up, the policy will be revisited to determine if a course correction is needed. Also, as we observed in **Figure 12**, the risk of video impairment is very small. By NOT defaulting to activating in these homes, the alternative being committed to is to roll a truck to each home that only has QAM STB and take "iHAT" style isolation measurements manually when only a very small fraction may be impacted.

7.3.2. Start Your Engines

The method iHAT uses to make its determination is based on the DOCSIS 3.1 OFDMA Upstream Data Profile (OUDP) feature, which allows a pre-defined "probe" signal to be scheduled by a CMTS and generated as a test signal. The probe can be defined by center frequency, bandwidth, and duration. When iHAT runs, it schedules this probe signal, home by home, to be burst into a portion of the Mid-Split spectrum.

Figure 15 shows the probe signal centered at about 80 MHz. It is 1.6 MHz wide (a common reference bandwidth for OFDMA bandwidth used in the DOCSIS 3.1 requirements), has a PSD at the ranged OFDMA power, and lasts 3-5 seconds. These are empirically-derived values through trial-and-error testing and optimization in the lab.

Figure 15 – Probe Signal Used in iHAT via DOCSIS 3.1 OUDP Feature

When the probe is fired, the time stamp is used to instruct the XG STB when to execute a Full Band Capture (FBC), and with that capture, samples are returned to that include levels of the OUDP probe and the first few downstream QAM channels. By determining the relative levels of these components and comparing them to an interference threshold value, making offset adjustments that account for the test probe not occupying the Mid-Split band completely, the home can be classified as to whether it needs remediation.

The OUDP method provides three major advantages:

1) It is part of the DOCSIS 3.1 specification, so a required featured to be compliant to the specification (when asked for!)
2) It can be a scheduled event within a system's normal operation, and therefore is very non-intrusive, happening without a customer's awareness or service interruption
3) As a scaled down (in total power) representation of an actual upstream signal, it does not actually create enough interference to impact video. Instead, it emulates what a small portion of the filled spectrum would look like and extrapolates mathematically to draw the proper pass/fail conclusion.

Iterative optimization of the parameters yielded a repeatable, reliable result that correlates well as a mathematical extrapolation with the video threshold testing that forms the foundation of ACI analysis.

The probe signal can also be used to evaluate blocking of the Mid-Split upstream by a drop amplifier, because if this is so, the CMTS will not be able to observe the probe. However, as part of the iHAT test, Mid-Split becomes active on a modem prior to an OUDP probe being launched, once the CMTS has a configuration that supports it. Ranging information of the OFDMA band (DOCSIS 3.1 ranging) is available to determine if the upstream was successfully sounded. If not, this is typically sufficient cause to identify a home with a drop amp issue, at which point the CM can remain in partial service or reverted to Low Split mode. In either case, the home state is logged as "remediation required."

In future iterations of iHAT, a time-out on partial services re-tries will be used to force an auto-revert of the modem into the Low Split band. However, it is anticipated that, rather than do this with filter switching in and out, the vCMTS will support multiple bonding group (BG) operations that include both a 4-channel BG of all-DOCSIS 3.0 QAMs, and a 5-channel BG that is the former plus one OFDMA block of 40-85 MHz. This will simplify iHAT testing and shorten time consumed by avoiding modem reboots that force a diplex filter switch to Mid-Split, in order to execute the test. Instead, CMs will arrive on the scene in Mid-Split mode, by default, and if conditions such as drop amps block Mid-Split signal passage, then the lower 4-Channel BG will be deployed on that modem. In the case of a product need for that device (100Mbps upstream, for example), there will, of course, still need to be a rapidly-executed action scheduled for a good customer experience, to eliminate the blocking amplifier or filter, and to provide the service speed requested.

Figure 16 shows two sample outputs from iHAT. In these screen captures, the test was launched locally. To support deployment in volume production, these tests will run from the cloud.

In the top screen capture in **Figure 16**, we see the measurements being made by the iHAT tool. Notice the 2nd to the last value, which is what is compared to the 22 dB threshold "US OUDP Power minus DS Rx Power." This is well below the threshold and thus this measurement is a "pass." These values are stored for trend analysis and optimization. Another one of the values of particular importance for this is the last row, "Isolation." With iHAT, we now have the game-changing tool of being able to see the RF isolation between a gateway and XG STB in every home. Note also that 35.84 dB is very close to the Comcast isolation spec observed in Table 4.

In the bottom capture of **Figure 16**, we see the explicit result: "video interference was above threshold for at least one set top box," and also the isolation value, in this case called out by its variable name in the actual code as "dbCDelta" of 24.16 dB – above threshold.

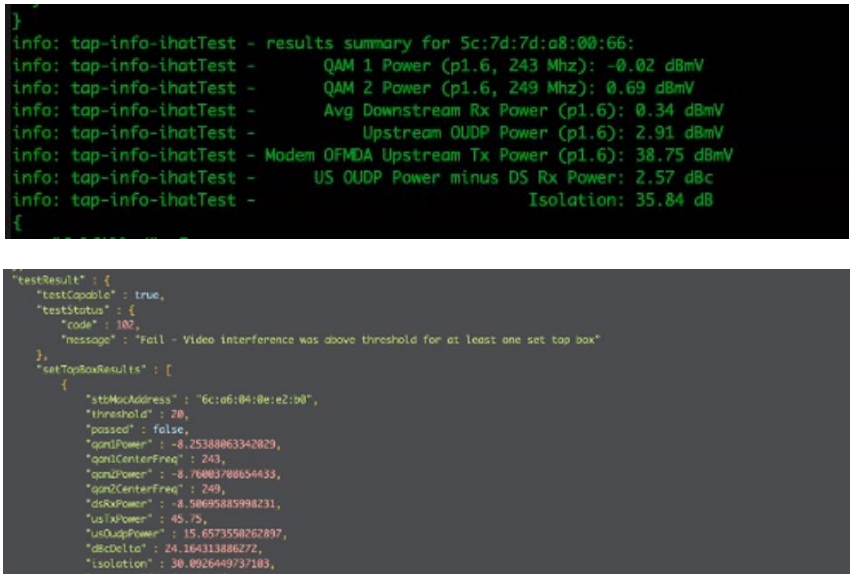

Figure 16 – iHAT Screen Captures of Video Assessment: Pass (Top), Fail (Bottom)

7.3.3. The Answer is…..

As shown in **Figure 14**, the output of iHAT is straightforward:

- DOCSIS Mid-Split pass-through (pass/fail)
- Potential for video degradation without intervention (pass/fail)
- Partial diagnosis – DOCSIS Mid-Split compatibility only; this is the case of a customer that has video services but no XG STB to support the telemetry needed to run the video assessment of iHAT

For a home to be declared ready to be activated, both DOCSIS and video tests must pass. If either does not pass, the home is left in Low-Split mode, and the home is dispositioned for remediation with the associated reason code (DOCSIS or video). How to optimally process the remediation queue itself is a discussion among many stakeholders. In addition to the pass/fail "answer" at the heart of iHAT, the RF measurements taken in the home, such as the isolation measured from the CM to the STB, are recorded and stored for purposes of trend analysis and iHAT optimization.

A fourth "state" that iHAT technically discovers is that the home is simply "ineligible" for Mid-Split because it has a CM which is only capable of Low-Split. In this case, the RF test engine does not run at all. This discovery occurs on the front-end, during the filtering of accounts connected to the RPD to only those that include a Mid-Split-capable CM.

Note that for a fully automated solution, iHAT receives input account/device data and develops output conclusions and an accompanying set of numerical parameters associated with the result for use elsewhere. In this sense, iHAT is the test function, with appropriate interfaces into other key back-office tools and subsystems, to operationalize the completely automated solution into the end-to-end ecosystem. In this context, iHAT is the "engine" of the overarching *Mid-Split Spectrum Upstream Launch* (MUSL) method, which we shall discuss next.

8. The Muscular Frame Supporting the iHAT Engine

8.1. MUSL-Up: End-to-End Device Activation Overview

As described above, the innovative iHAT tool provides a relatively non-intrusive view into a customer's home, and, on a home-by-home basis, will make a Go-No Go declaration with respect to readiness for activating spectrum in the Mid-Split band. iHAT scores a home's DOCSIS readiness for passing spectrum to 85 MHz, and its likelihood of creating video interference.

Referring to **Figure 17**, we can show how iHAT fits within the broader operational perspective, going from the trigger of a DAA Mid-Split node cutover on the far left, to the completion of activation on the far right. Note that "Tier 1" and "Tier 2" refer to different categories of markets which inform the upgrade strategy used at Comcast, however they have no real bearing on the flow otherwise.

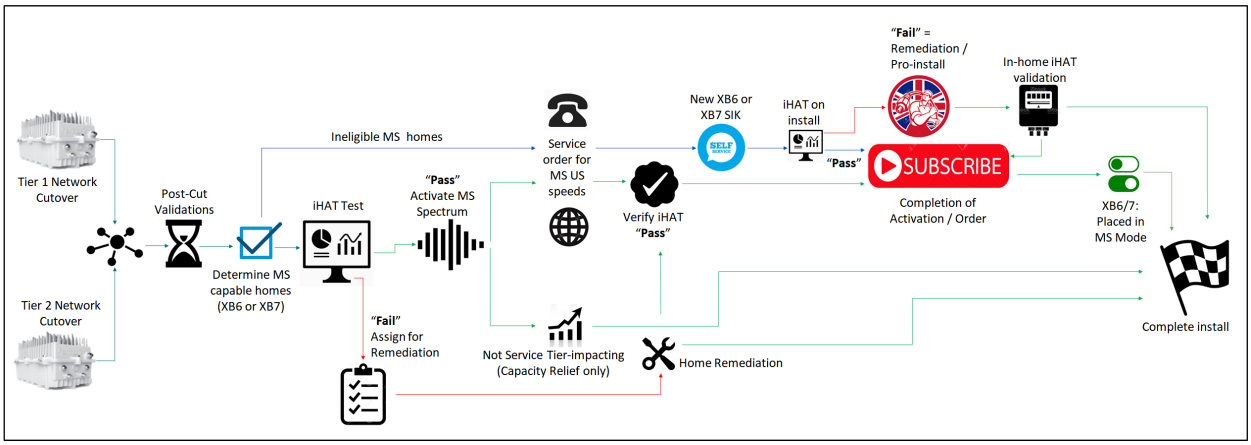

Figure 17 – Simplified Mid-Split Activation Flow: Cutover Through Activation

Beginning on the left, when a Mid-Split network upgrade occurs, internal tools will notify systems when construction is complete and officially closed out. This triggers the spectrum activation process, notifying other tools that the network is now be able to take this step. Two things must happen prior to letting iHAT sweep across the node and validate homes where Mid-Split can be turned on. They are:

1) *Post-Cut validation* – Ensures that the network has resumed to BAU metrics after the cutover. It is not uncommon to have a short period of elevated network activity shortly after a cutover, and it is desirable to resolve any residual cutover issues prior to moving to Mid-Split. This can be time-based, or it can be directly associated with, for example, observation of trouble TC metrics, pre-cut vs post-cut.

2) *Determine which homes are eligible for activation* – This boils down to whether the DOCSIS CPE is capable of Mid-Split. At Comcast, all DOCSIS 3.1 Gateways are Mid-Split-capable.

On item 2) above, if a home is ineligible, then iHAT does not run. Following this arrow to the top path in Figure 2, there is no immediate required step to get that customer a Mid-Split-capable modem. There is an effective loss of capacity for every CM that cannot access the DOCSIS 3.1 spectrum, because it forces utilization in the Low-Split band, rather than accessing the faster and wider OFDMA spectrum.

There is guidance in the in the field on what triggers a DOCSIS 3.1 upgrade for a customer – a particular speed tier for example. Over time, DOCSIS 3.0 CMs will organically disappear from the field, and it is likely at some point there will need to be a proactive effort to remove the older CMs in the network to maximize the DOCSIS 3.1 capacity.

Now, as shown in **Figure 17**, when a customer decides to upgrade their speed tier to one that requires Mid-Split, then getting them a gateway capable of that becomes a priority. Also, this customer's home needs to be evaluated for its ability to be placed in Mid-Split mode. So, as a new Mid-Split-capable gateway is brought onboard, one of the first things it needs to do is call upon iHAT to determine the state of the home for Mid-Split. If the iHAT "pass" is recorded, then the activation process continues, and iHAT sets the device into Mid-Split mode. It then becomes capable of using the OFDMA spectrum between 40-85 MHz. If iHAT records a "fail," then the customer is notified that a technician must come to the home to complete their install, and that their new speed tier will not be available until this "Pro Install" step happens. When the remediation is complete, the technician will validate onsite with iHAT, in this case triggered locally from the Performance Health Test (PHT) application.

If the eligibility conditions are in place – Mid-Split capable CM, and a STB model with the necessary telemetry capability – we move to the right of the blue checkmark of **Figure 17**: "iHAT Test." Let's now follow the lower path under the iHAT test icon – "iHAT fail."

8.1.1. The Remediation Queue

As noted, unless there is a speed upgrade required by a customer, there is not necessarily an immediate need to provide them with a Mid-Split capable gateway. However, it is still important that the iHAT score be logged. The fact that the home needs to be remediated is documented and populated into tools used by agents and technicians. Homes in this category are placed into a "Remediation Queue." iHAT will identify the specific failure mode, so that technicians know what needs to be done when they arrive. In general, remediation tasks are well-understood and known to technicians, and include changing out home amplifiers for alternative devices, checking home splitter configuration, models, and wiring, to bring the home to Comcast compliance standards. After remediation is performed, the iHAT test is run to validate readiness for Mid-Split spectrum, and the activation then completed.

When to schedule a home for remediation, assuming there is no speed tier motivation, is a business decision. They can remain in Low Split mode until that time, with some impacts on the network side. There are multiple variables to consider that have to do with capacity, efficiency, and proactive expense. Ultimately, however, all homes in the remediation queue will need to get serviced to extract the full DOCSIS 3.1 capacity and maximize the upstream runway these architectures are made to deliver.

Also note that a customer's iHAT "score" is not necessarily static. This is a very important point – the home has never been static, but now there is quantifiable information that can be used and leveraged to account for this, to improve the customer experience. Changes to the coaxial network in the home made by the customer, or new CPE brought into the home, can both affect the iHAT score. These events are "on demand triggers" that will call on iHAT to run off-cycle even after the initial iHAT sweep of the node at cutover.

8.1.2. iHAT Pass

The most straightforward flow in **Figure 17** is down the center, left to right. Both branches are logical and easily understood. An iHAT "Pass" means that the DOCSIS signals up to 85 MHz are able to be received by the vCMTS receiver, indicating that there is no home amplifier or filter blocking this transmission. AND it means that the home has been checked for RF isolation between the CM and the STB and determined not to be of concern.

Going to the lower green flow down the center of **Figure 17**, this is the case where there is no speed upgrade involved. The spectrum is being turned on to maximize efficient use of upstream capacity. The Tier 1 and Tier 2 plans are counting on use of this capacity to defer any future network augmentation by at least 5 years. So, while it may not be noticeably service-impacting to a customer, it is network- impacting. It may be indirectly service-impacting by lowering the congestion on that node overall (a good thing) and providing lower utilization spectrum for that customer to take advantage of for their current services.

The upper green flow is the case when a speed tier upgrade request is made, and there is already a Mid-Split-capable device present. Because a home's iHAT score is not static, a new iHAT score is taken prior to upgrading the customer. The customer expectations for the new service will be higher, and the awareness will be acute to service-impacting issues, so it is prudent to be certain that the home is still in a "ready" condition. In addition, because the customer now has, for example, a speed tier of 200 Mbps, they will have bursts of energy more likely to utilize a wide chunk of the Mid-split band at once, a condition that more aggressively exposes the STB to energy that can cause video degradation. If this "updated" iHAT result is still "pass," then activation is completed. If not (this is not shown), this home reverts to a

Remediation state, and because of the desire for a new service tier, it is a Remediation Queue with a higher priority.

8.2. MUSL-Building Logic

As powerful as the iHAT engine is, to use it in a production flow such as **Figure 17**, and, as importantly, seamlessly in production scale, it cannot be done on a home-by-home basis via human interaction. The information iHAT needs to run and the information needed by other systems to act on the iHAT outcome must be automated, and the interfaces to these other functions built for production scale. A logical flow diagram for the overarching MUSL ecosystem is shown in **Figure 18**. As shown, within the MUSL framework, like its role in **Figure 17**, iHAT is the engine. **Figure 18** speaks more to the software logic and definition of the adjacent subsystem interfaces that are implied by the flow of **Figure 17**.

The interfaces for iHAT for use in production are highlighted in the red box at the bottom of **Figure 18** and briefly described below. These represent interfaces for MUSL to distribute this important information to stakeholders, for the end-to-end operational success of Mid-Split activation.

Customer Accounts – Serviceability: When there are new upstream speeds that only a Mid-Split upstream can provide, it is important that the systems to upgrade a customer, whether online or through a service call, recognize the home's readiness state, as identified by iHAT. Alternatively, these tools can trigger an instant iHAT test for an updated result.

Biller – new CPE: When a customer changes CPE, possible iHAT variables that are affected are the device DOCSIS capabilities, the sensitivity to interference of a new video CPE, and the possibility of a wiring change in the home. It is prudent, given these potential changes to the iHAT state, to test (or re-test) the home.

XOC – Job Scheduler: When a home "fails" iHAT, it goes into a remediation queue, with a flag for what needs to be remediated (video or DOCSIS). For a Tech Ops plan based on proactive remediations, occurring routinely and not waiting for a house call to take care of iHAT-known issues, iHAT can report its findings per account to the local XOC tools that queue, prioritize, and schedule jobs.

Sales – Serviceability: Similar to Customer accounts, sales representatives should be able to quickly assess whether a customer is eligible for Mid-Split speeds by accessing iHAT status in existing sales tools.

Care – iHAT status, ITG Updates: When a care agent takes a customer call, after some amount of Interactive Troubleshooting Guide (ITG)-led questioning, the possibility of the issue being Mid-Split-related will be considered. A check on the iHAT status of that home, or an instantaneous iHAT test, can help the triage process.

Tech Tools – Tech360: Similar to care agents, when technicians are enroute or onsite at a customer home, part of the awareness they can have is the home readiness state, as determined by iHAT. More deeply in the tools, the sequence of steps to diagnose and fix a MS-related issue should also be available.

Inventory Management: As remediations are made at relatively large scale to remove old drop amps, procurement awareness to the deployment of alternative solutions can ensure that the supply pipeline is tracked and nurtured. This is even more important for proactive amplifier replacement plans, to ensure supply alignment with the plan for the alternative solutions – passive or active.

Data Sciences: As iHAT data is accumulated, new information about the home RF environment – isolation performance, trends over time, and correlations across neighborhoods – can be stored and processed for future optimizations, and to inform future process implications and costs.

Note that the MUSL flow leading into iHAT is from the perspective of a cutover to a Mid-Split-capable DAA node and network, from which flows notifications to activate the spectrum. This includes the instantiation of iHAT, to figure out who can use it at the RPD level. Once this cycle is complete and the Mid-Split node is in operation using the extra spectrum, several reasons were identified to check home readiness status via iHAT on an individual account basis. Noted at the bottom of **Figure 18,** these are referred to as "Asynchronous iHAT Triggers." They are options that can become part of new Mid-Split operations and maintenance practice, and include:

- New CPE device: XG STB or XB HSD gateway triggers new state-of-home update
- Buy-flow for new product offering that requires Mid-Split: Serviceability tools trigger up-to-date home state
- Premise Health Test (PHT): Tech in the home can trigger from available tools to assess state-of-home locally, as well as to assure that remediation work is completed properly
- Care (E360 tool) – Agent ability to see home state in real-time triage and possibly have access to reverting to Low Split and scheduling remediation
- (New) Home Metrics: Indications that imply a high likelihood that the equipment in the home has changed location or wiring has been changed, such as a persistent DS level change

Lastly, note the hourglass in the middle-right of **Figure 18**. As Mid-Split rolls out in scale, a determination will be made on whether a periodic update of all homes is warranted, and if so, how often. It will be based on empirical data that will reflect findings of just how dynamic the home environment is, and whether it is enough to warrant sweeping all devices on the RPD periodically, or spot checking if the asynchronous triggers do not provide enough off-cycle visibility. The tool will allow for periodic revisiting of each RPD. This eventually could place a lot of additional compute and overhead traffic on the network, storage (and associated cost), and state management resources. For an issue of small enough scale, this might not be warranted – experience and scale will tell.

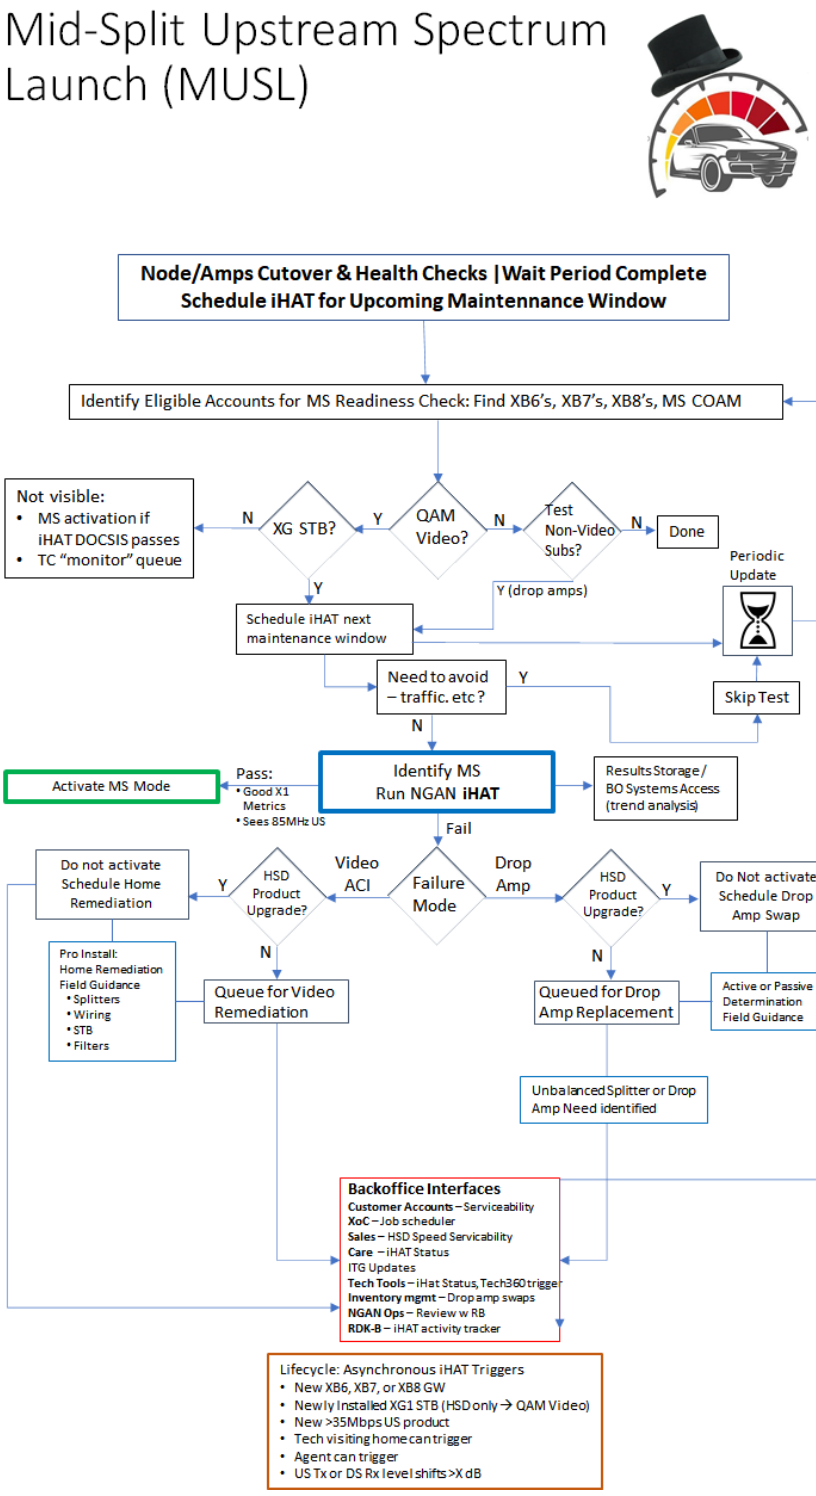

Figure 18 – iHAT as the Engine of the MUSL Framework

8.3. The Care and Feeding of Mid-Split

The iHAT tool described above prepares nodes and homes for the launch of Mid-Split. However, because the home environment can change, and is not under control of the operator, a particular state declared by iHAT is impermanent. New devices can and do come into the home, and customers do change wiring and add in-home passives and actives. Service changes, in particular a broadband speed upgrade for the upstream, increases the likelihood that video service interference could be observed, and exposes any blocking drop amplifiers.

In addition, the video interference potential is statistical in nature: There is an inherent (but small / <1.5%) probability that conditions in the end-to-end system, including OSP and home, shift in such a way that the threshold of interference for visual impairment observed in lab testing is breached.

Finally, the software tool itself will take time to mature, scale, and optimize, and should not be expected to operate perfectly to every potential negative use case and error condition it could encounter at scale.

Because there is a finite probability that a customer could experience video or HSD issues with newly activated OFDMA spectrum, the introduction of Mid-Split spectrum could lead to new inbound call types. As a result, there will need to be process updates such as for ITGs and Line-of-Questioning (LoQ) scripts to diagnose whether Mid-Split is the cause of these issues in the home.

By contrast, a DOCSIS failure is not a statistical phenomenon – either the upstream signal path is blocked by a drop amp, or it is not. As such, there is not very much nuance required around Care processes. The most intricate part of the practice of remediating a DOCSIS failure is two-fold:

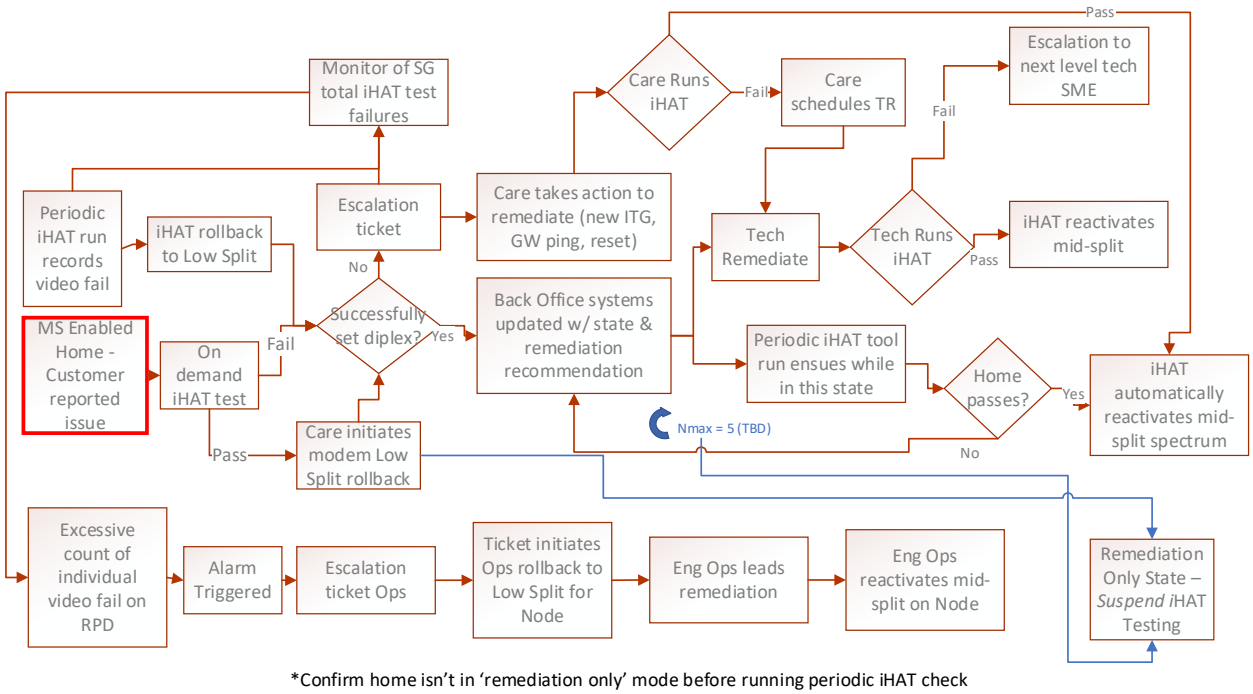
1) A home drop amp is replaced with what?
   The knee-jerk answer is another drop amp that supports the expanded frequency split. However, this places a new frequency barrier in place that is likely to be an obstacle in the future, such as for 10G FDX. Best practices and training are being built around a methodology that prioritizes a passive termination at the point of entry, if is not a DOCSIS termination itself (such as for DOCSIS 4.0, in an all-IP home configuration). If a typical splitter implementation is inadequate, a specialized unbalanced splitter may be possible to assure healthy levels at each.

2) Proactive Remediation
   Until HSD products are launched that require the Mid-Split spectrum (upstream speeds of 50+Mbps), the additional upstream spectrum is unlikely to affect the customer experience, one way or the other. To the extent that the added capacity reduces the average upstream utilization and provides a more uniform HSD experience, the customer experience should generally improve with the use of Mid-Split.

   Of course, as mentioned, one of the key benefits of Mid-Split spectrum is the launch of higher upstream speed tiers. As these become available, interested customers who live in a household with a Low-Split upstream limitation will require an additional step. Because faster upstream products are an inevitability, and their penetration will likely grow over time, it makes sense to consider a proactive plan to remove the amplifiers with transactional house calls made for other reasons, and eventually for the specific purpose of pulling the Low-Split drop amplifiers out of the system. This is a business balancing act of operations investment at the right time, to stay ahead of the trajectory of these speed tiers. The alternative is that a percentage of customers who want these speeds will have to await a scheduled truck roll to receive them. However, much can be

known in advance with the iHAT tool, so that messaging on the buy-flow front-end can be developed to make that outcome as smooth and efficient as possible for the customer.

For the potential video impact scenario, there is additional nuance and more options to ensure that a quality video experience is maintained. **Figure 19** charts this nuance.

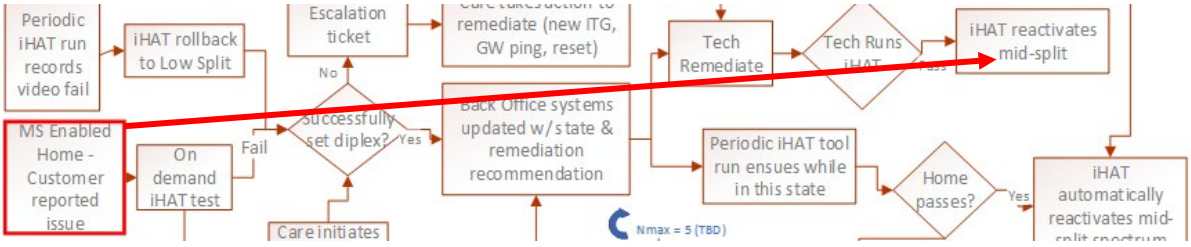


*Confirm home isn't in 'remediation only' mode before running periodic iHAT check

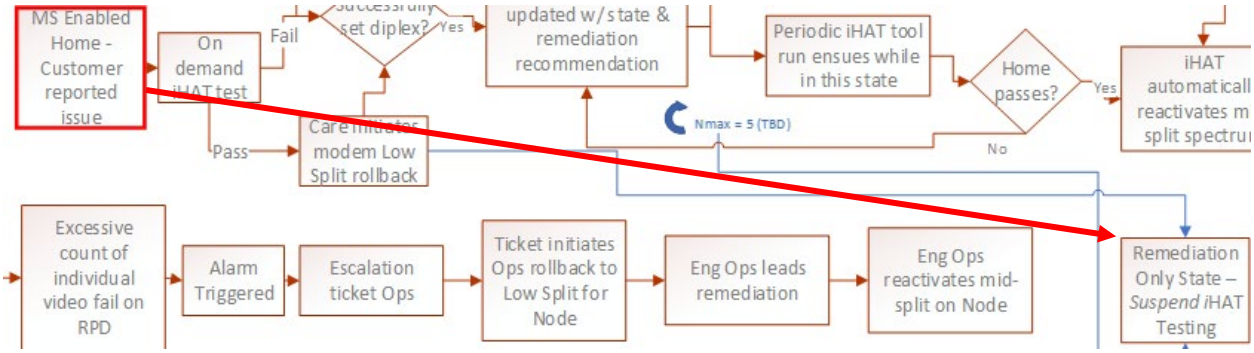
Figure 19 – Care Flow for Support of Mid-Split Related Service Impacts

The flow details are self-explanatory. The diagram assumes that the issue has been diagnosed as likely due to Mid-Split. All other possible causes more probable than Mid-Split have been checked, as they typically would have before reaching this branch of an overall triage flow. In summary form, the fundamental sequence of events in **Figure 19,** after a call to an agent leads to a potential MS diagnosis, are as follows:

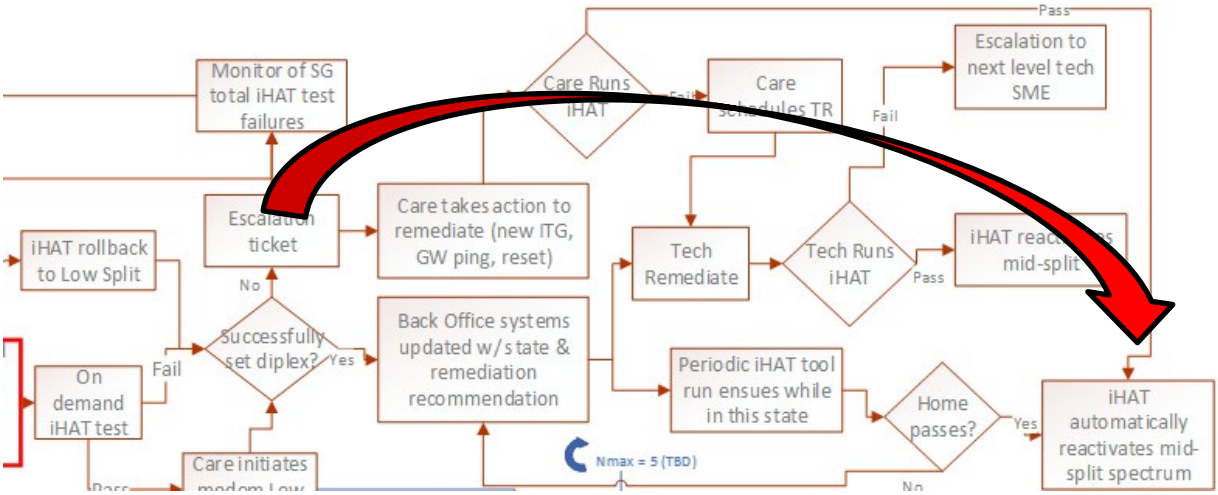
1) Run iHAT for an up-to-date state check and disposition of home, compared to prior state
2) Check if iHAT *before|after* state aligns with the TC (iHAT "fail" and device goes from Mid to Low Split). In Low-Split, the video issue will be eliminated, if it was indeed a Mid-Split-related issue. If so, leave the customer in Low-Split mode, schedule remediation, determine the root cause, and reactivate the Mid-Split region for that home, as charted below:



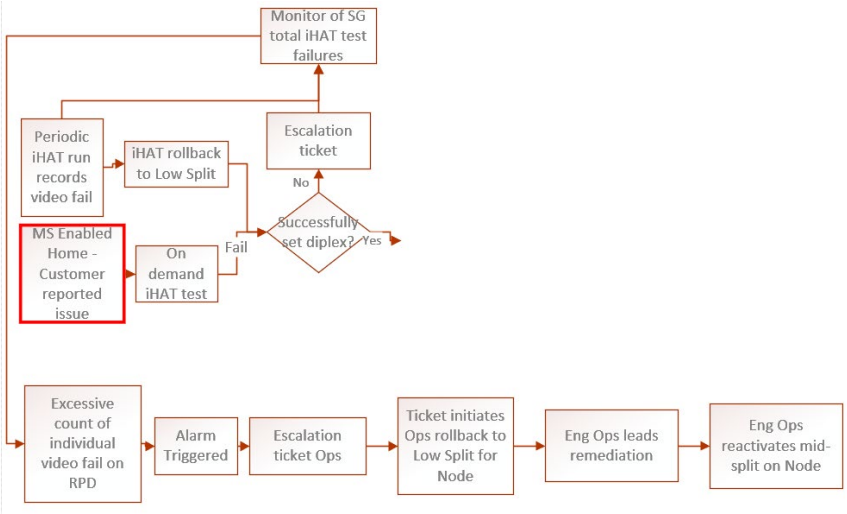
3) If iHAT *before|after* is Mid-Split → Mid-Split, then iHAT believes there should not be a video impairment and yet this is what the customer is experiencing. This does not mean it *is* definitely Mid-Split related. but making this determination on-site is the next step. First, however, the home is manually (via Care directly or via escalation to Operations) reverted to the Low-Split to eliminate the video issue. Again, if this does NOT eliminate the video issue, it is not related to Mid-Split. Assuming this step eliminates the video issue, the account is scheduled for remediation. It is also removed from any further iHAT updates – referred to as the "Remediation Only" queue – that would place it back in Mid-Split mode (because iHAT is giving an erroneous result of "pass" to begin with).



4) A next branch of the flow deals with the case where iHAT does diagnose that the device should be in Low-Split, but it does not properly revert the device to that state. Over time, with code maturity and optimization, we expect this scenario to get diminishingly small. The path first has Care or Eng Ops try to set the modem manually as above, or even factory resetting the modem. If unsuccessful, the path escalates into on-site remediation.



5) A final branch of interest is the scenario where, knowing "typical" metrics for iHAT DOCSIS and video test "fail," a certain threshold of "too many" is set that indicates the issues are probably not on a home-by-home basis, but more systemic. In this case, Engineering Operations is brought in to triage the situation immediately:



8.4. Scars? What Scars?

In summary, the seamless migration to Mid-Split, from a customer experience perspective, looks like this:

- The full 85 MHz upstream signal can exit the home intact and get onto the network – not blocked by drop amps, filters, or otherwise poor frequency response
- The full 85 MHz signal can be activated, and it causes no QAM video artifacts on any STB in the home
- Any video issues that are encountered by a customer and diagnosed as being caused by Mid-Split can be eliminated remotely and immediately
- Products (speeds) that need Mid-Split spectrum can be delivered to a customer who wants the speeds simply and effectively by any buy-flow means available

We have not detailed further, but these additional components fill out this list:

- In-Home filters are not required to launch Mid-Split spectrum
- Mid-Split can be activated using a self-install kit (SIK) model most of the time

9. Mid-Split → High Split and DOCSIS 4.0

9.1. High Split (5 MHz – 204 MHz)

While this paper focused on a Mid-Split migration scenario, operators are looking also to High-Split and, further out into the future, DOCSIS 4.0. Earlier in the paper we described some of the incremental challenges of operationalizing High-Split, compared to Mid-Split. We left one of these challenges out of that discussion until we were able to go into the Mid-Split details of RF isolation management. Of course, High Split has the overlapping band phenomenon with STBs, only worse. There is much more bandwidth for High-Split that extends into and thus overlaps the forward band. Because of this additional energy that will be launched into the spectrum between 54 MHz and 204 MHz, which currently overlaps the input bandwidth of a STB, there is an even greater chance of ACI interference. Therefore, a migration to a High-Split also includes a migration of the home that is receiving High Split-enabled HSD services (e.g., 1 Gbps symmetric service) to an all-IP configuration – i.e., no QAM video. Without a QAM STB, we can ensure that the video service in the home is not affected by the new service.

However, the relatively loud and wide upstream to 204 MHz has enough energy that this is not necessarily the end of the interference story. A phenomenon that has undergone much study is that of "Neighbor Interference," (NI) whereby the cable "Tap" neighbor of a High Split services user may be "close" enough in the dB sense to have services impacted on the adjacent STB or CM. This scenario is shown in **Figure 20**.

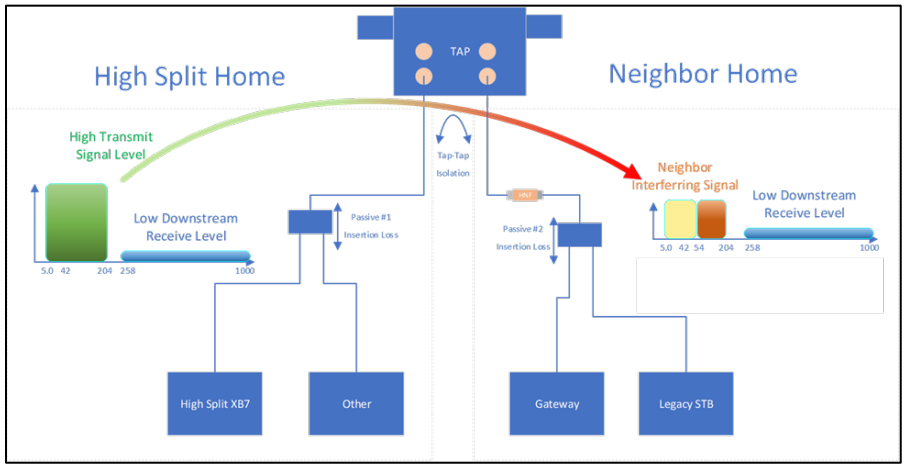


Figure 20 – The Neighbor Interference Phenomenon of High Split

As with the in-home scenario described for Mid-Split, it is also an RF port-to-port isolation and ACI phenomenon with Neighbor Interference, but it is instead the Tap ports that are of consequence. There has been substantial characterization of Tap isolation performance and STB and CM ACI sensitivity recently for this extended upstream band, and the likelihood of this issue has become very well quantified. The MUSL and iHAT tool kit can be applied to a High-Split upstream with these major differences:

1) The OUDP probe signal of interest needs to be modified to one that can be consistently correlated to an extrapolated equivalent of *High-Split* signal energy
2) The potentially at-risk" STB is in a neighboring home, and physical addresses and the relationship of CMs in the field, to Tap ports, is generally not easily known in an automatable way
3) The "victim" device can also now be a non-High-Split CM

Mitigation of NI involves different processes. Visiting a neighborhood home for remediation because a different neighbor on the block upgraded their HSD would be an awkward process on every conceivable level. Thus, the bias for NI would be towards blocking filters in the OSP at the "guilty" Tap port. Documenting filters installed would be an important way to simplify new customer adds going forward. Complete quantification of this phenomenon with respect to the customer experience is difficult until some correlation of High-Split transmissions to video and non-High Split HSD performance can be documented.

9.2. DOCSIS 4.0

Assuming the all-IP home policy that is anticipated for DOCSIS 4.0 homes, coexisting with QAM STBs and legacy CMs in the plant using DOCSIS 4.0 Extended Spectrum technology would take on the equivalent model as High-Split NI, but with the Ultra High-Split bandwidth as the spectrum limit, and STB sensitivity characterization work to be done.

It's worth noting that in DOCSIS 4.0, the very nature of the FDX technology at its core is an overlapping upstream and downstream. As such, it is inherent in the protocol to introduce new technology to manage this overlap. There are two ways this is done, as shown in **Figure 21**:

Echo Cancellation: "Self" cancellation at the PHY level, leveraging knowledge of the transmitted signal at the co-located receiver.

Sounding/Scheduling: Avoids having an FDX CM transmit upstream when it is known that a neighbor could be affected in the downstream that is receiving packets.

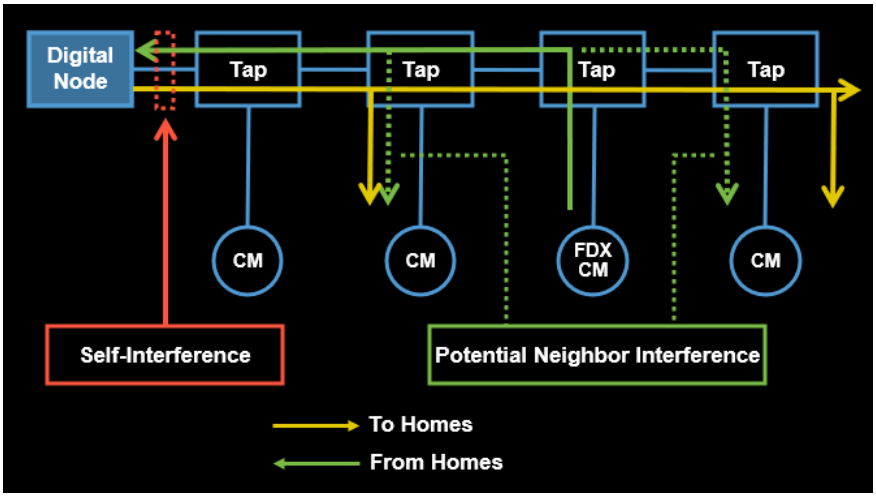

Figure 21 – The Two New Technology Features of DOCSIS 4.0 FDX

For the latter, FDX determines the RF dB isolation relationships among modems to form Transmission Groups (TGs). FDX "sounding" is effectively the built-in, standardized version of NI for the FDX band (108-684 MHz) in FDX systems.

For FDX, the limitation that arises is that these relationships can only be discovered in DOCSIS 4.0 CMs and DOCSIS 3.1 CMs with an FDX-L SW upgrade. FDX-L is a way to make DOCSIS 3.1 CMs aware that they are connected to a DOCSIS 4.0 system, and thereby have their traffic scheduled within the context of the TG assignments. DOCSIS 3.0 CMs cannot participate in sounding at all. The number of DOCSIS 3.0 CMs continues to decline rapidly in the field, but they will not be completely removed from the network before FDX is deployed.

There will be more to come on DOCSIS 4.0 migration challenges and solutions as the 10G technologies continue to be developed [1].

10. Conclusions

Operators are recognizing that, as good as the upstream has been to them since the launch of HSD services, it has given nearly all that it can at this point and needs a spectrum boost to continue to deliver value and support continually growing HSD services, capacity, and speeds. The next step is to add spectrum and launch the next long runway of capacity, with new speed expectations in mind. With the commitment to spectrum comes a commitment to managing it through an HFC lifetime of legacy equipment that is simply not built for it. Building the technology, tools, processes, and practices to enable this transition is a

challenge all operators are working through, with a seamless and non-disruptive experience for the customer as the top priority.

In addition, as in any network evolution that touches the outside plant, making sure that enough is done to the network for the longer term, once the commitment has been made to go out and touch it, is an important part of the upgrade. For access network engineers, the billiards analogy is that, as you are lining up the 6-ball at the side pocket, it is important you make sure that after sinking it you've left the cue ball lined up neatly behind the 12-ball at the corner pocket. With the right series of deft maneuvers, the 10G-ball will be lined up to finish out the game.

1. Introduction

Cable access networks and equipment has changed dramatically since the inception of high-speed data over hybrid fiber coaxial (HFC) networks. This evolution has enabled cable to become the dominant supplier of broadband access worldwide. The ongoing need for scale and operational efficiencies to maintain this lead is anticipated and will enable Multi-System Operators (MSOs) to meet subscribers' voracious appetite for bandwidth and internet-enabled devices while lowering the overall cost of ownership so that MSOs can stay competitive with alternate access providers.

A common element to cable access network evolution has been a focus on purpose-built hardware appliances, employing advances to information encoding (e.g., DOCSIS® 1.0, 1.1, 2.0, 3.0, 3.1, and 4.0), that operate on-premises at *carrier scale for a single service medium, DOCSIS*. These advances were complemented by the modularization and distribution of functionality to various portions of the operator's access network (inside and outside plant) using tightly coupled (industry standard) hardware appliances continuing to operate at carrier scale and including other service medium such as passive optical networks (PON). In recent years, the industry has acknowledged the utility and applicability of public (and private) cloud operator approaches to organizing, operating, and deploying massively scalable computational networks for the access network. These *cloud-native* architectures started by partitioning functions into software-based applications running on commercial off-the-shelf (COTS) servers and Ethernet switches to *virtualize* typical hardware-based network functions (VNFs). This approach to VNFs has evolved into the orchestration of *containerized* cloud-native functions (CNFs) that comprise a collection of disaggregated loosely coupled microservices that can operate in public, private and distributed portions of an operator's network to advance *carrier scale toward cloud scale*. Further evolution of these networks is now occurring along two dimensions to i) leverage elasticity of hyperscale cloud service providers' (CSPs) compute resources and ii) deep edge computing infrastructure to converge deployment and operations for a diverse collection of access technologies and services into a single multi-access, multi-service edge computing (MEC) platform. A paper presented last year focused on exploring the former aspect of access network evolution. This current paper focuses on the latter point — access service convergence.

This paper summarizes the role of CNFs and edge compute in access network convergence based on the practical experience of deploying distributed access architecture (DAA) DOCSIS networks and PON. This convergence is in a form of CNFs on a common cloud-native platform leveraging general purpose x86-based compute resources. Motivation and strategies for convergence, as well as its impact on network topology change and daily operations is considered. The concepts of cluster resource elasticity and horizontal scaling, along with the benefits of infrastructure resource sharing between access media (e.g., DOCSIS and PON) workloads in MEC deployments, are also analyzed. Finally, furthering DOCSIS and PON network convergence with other access technologies that provides a path for building CNF-based service agnostic networks will be described.

2. Terminology

The following interpretation of key industry terms is assumed throughout the paper.

Multi-access Edge Computing (MEC): applies to a system which provides an IT service environment and cloud-computing capabilities at the edge of an access network and contains one or more types of access technology that is within close proximity to its users [1].

Cloud-native Network Function (CNF): network functionality delivered in software via cloud-native development and delivery practices [2].

Cluster: a set of compute nodes that can be viewed as a single system. Cluster nodes are connected via a converged network (e.g., Ethernet-based) and managed by platform management software.

Multi-tenant cluster: sharing compute resources for infrastructure pods and workload pods serving different types of applications (e.g., DOCSIS, PON, wireless), while providing required levels of resources and components isolation.

Access network convergence: providing wireline and mobile services from a single flexible, programmable connectivity platform whose hardware, software and data storage resources spanning multiple geographic locations are shared across multiple access technologies. For operators, network convergence reduces the complexity and cost of providing multi-service offerings [3].

Pod: a group of one or more software containers, orchestrated by Kubernetes [4].

Container: an application that has its own file system, CPU, memory and process space. It is similar, but more lightweight compared to a virtual machine (VM), as containers have relaxed isolation properties to share the Operating System (OS) among the applications.

3. Historical Overview of Access Network Convergence and Virtualization in Cable

Historically, the telecommunication equipment market was dominated by hardware-based appliances tailored for a specific access layer technology, implementing one or more layers of the Open Systems Interconnection (OSI) model, from L1 to L7 [5]. Although such appliances employ industry standard protocols (e.g., SSH, Telnet, SNMP, NETCONF, etc.) each is built and managed using proprietary methods. The result has been economic and operational overhead that inevitably comes with the proliferation of disparate networking appliances on the same network.

The evolution of telecommunication equipment was (and remains) focused on the following.

1. Increased performance and capacity (e.g., throughput, network latency, and port density) facilitated by innovations in purpose-built, highly integrated application-specific integrated circuits (ASICs) and systems on a chip (SoCs).
2. Reduced construction cost and operations maintenance.
3. Increased availability, reliability, and security.
4. Improved network management and network operations.

Each of these advances has been mostly focused on individual network elements that each operate at *carrier scale and availability* rather than focus on the network as a converged system. Examples of these network improvements include the original Modular Cable Modem Termination System (M-CMTS) followed by the Converged Cable Access Platform (CCAP), later the Modular Headend and Distributed Access Architecture (MHAv2 and DAA), Remote PHY (R-PHY), and Flexible MAC Architecture (FMA) specifications; all of which were closely tied to advances in physical layer optimizations via the DOCSIS 2.0, 3.0, and 3.1 standards. Today, the cable industry recognizes challenges for taking networks to the next level, as described by CableLabs' vision of the 10G platform — a combination of technologies that will deliver symmetric multigigabit internet speeds [6].

As an alternative to optimizing individual network appliances, a new approach to meeting these challenges has emerged. This can be described by the following two points.

1. Network and service convergence.

2. Network and service virtualization.

Network convergence and network virtualization has presented a convenient approach to solving these challenges given exponential growth of computational efficiency available in general-purpose processors using common design patterns and leveraging open source software libraries, tools, and network operating systems. The increased performance of general-purpose compute has enabled telecommunication equipment vendors to develop solutions that run on generic, compute platforms that can implement virtual network functions (VNFs) in software. By using COTS server hardware, operators are reducing variations and consolidating vendor proprietary hardware appliances that were deployed in their network. The transition from purpose designed hardware appliances to similarly capable virtualized functions running on COTS servers is illustrated below.

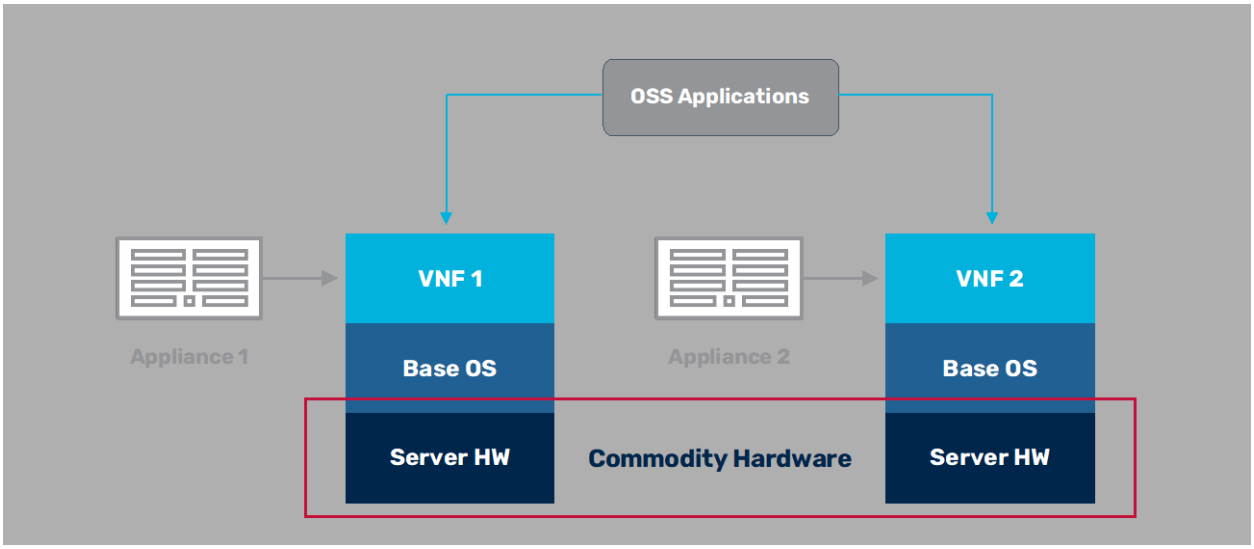

Figure 1 – Transition from Hardware-based Appliances to VNFs on Commodity Hardware

This first transition from hardware to VNFs remained *carrier scale and availability* of individual elements as it has been mostly focused on substituting network appliances with a better mouse trap [11].

Based on advances by the major hyperscalers, the next natural step in network convergence and virtualization has been the adoption of a new paradigm that operates at *cloud scale and availability*: the shift from VNFs to CNFs operating under the management and control of a container orchestration system (such as Kubernetes). This container orchestration system provides a time tested, scalable, de-facto standard for managing cluster resources (such as central processing unit (CPU), networking, memory, and storage), network function partitioning & abstraction, and operation of the network. Rather than managing individual appliances at carrier scale, this *cloud-native* paradigm creates an open environment where homogeneous general-purpose compute can be shared by networking applications from any vendor design deployed in the form of CNFs that is scalable and isolated from other vendor CNFs. The following diagram illustrates independent network functions (from one or more vendors or the operator themselves) operating as CNFs to provide an end-to-end network solution.

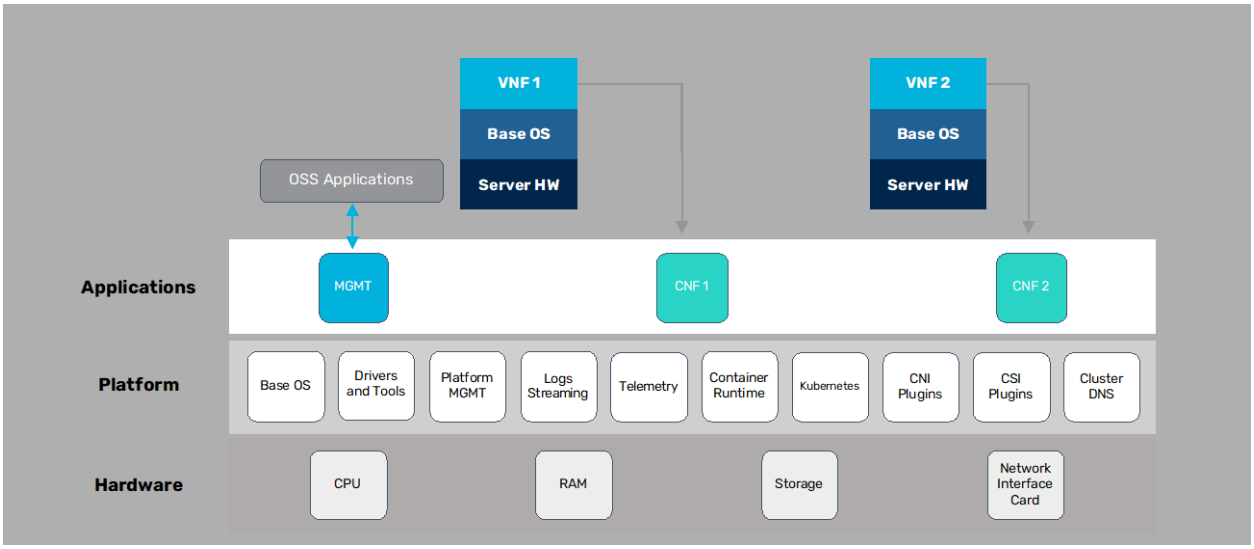

Figure 2 – Transition from VNFs to CNFs

To date, access network convergence and virtualization has helped cable operators to address the following challenges.

1. Sustaining ever-growing network performance requirements by leveraging a short and predictable cycle of increasing performance gains available in general-purpose compute.
2. Reducing network capex by riding economies of scale provided by commodity hardware.
3. Optimizing network opex by reducing the number of disparate devices deployed and maintained in the network.
4. Improving network reliability by employing native high availability (HA) facilities that come with the flexibility of network functions implementation in software, in general, and in particular with the use of Kubernetes-orchestrated CNFs.
5. Simplifying and unifying network management and operations by reducing the number of different systems to manage and leveraging service-based telemetry and logging for receiving and storing the information from different CNFs in a uniform way.
6. Advancing *carrier-scaled* applications that can grow or shrink both in terms of performance/capacity of an individual CNF (vertical scaling) and in terms of the number of deployed CNFs (horizontal scaling) at *cloud scale* one CNF and one server at a time.

In subsequent sections of the paper, we describe different aspects of the current state of cable access networks convergence and virtualization.

4. Access Networks Convergence in Cable: The Current State

Network convergence can be viewed by considering three different access technologies employed in cable. Looking at cable's HFC, it becomes clear that the same fiber carrying analog and digital wavelengths for video and data can be used for Ethernet and PON. In fact, DOCSIS, Ethernet, and PON are three edge technologies that have been used in cable networks for years. These access technologies are typically applied for different subscriber categories and managed by different personnel using unique operations. For example, it is often the case that DOCSIS is reserved for residential and small medium businesses (SMB), Ethernet is used for enterprise and mobile xHaul, and PON is used for managed property and multidwelling unit (MDU) subscribers. Although provisions were made for designing

hardware appliances with support for multiple edge access technologies in the CCAP specification, it is typically the case that DOCSIS, Ethernet, and PON are provided by different vendors using quite different approaches to managing and operating the network. The impact is a non-uniform and disparate collection of point products that must be managed by cable operators. The result is a lack of convergence and economies of scale that come from modern approaches to deploying and managing cloud-native networks. Alternatively, when considering access solutions based on virtualization, it becomes possible to consider workloads for two or more of these access technologies within the same converged platform.

Key factors that contribute to access networks virtualization include the following.

1. Growth in general-purpose CPU performance capable of software implementation of network functions in the form of CNFs with the same or better performance as of field-programmable gate array (FPGA)/ASIC-based hardware appliances.
2. Maturity of software frameworks that accelerate packet processing workloads running on a wide variety of CPU architectures [12].

The trigger for virtualization of the CMTS (vCMTS) was the release of the DOCSIS Remote PHY Specification [10], that partitions the DOCSIS PHY from components responsible for MAC and upper layer protocol functions. This separation of the lowest layer of the DOCSIS protocol enables the repartitioning of upper layer software-only implementations. In this way, virtualization of the CMTS was achieved and brought into operator's facilities [11]. Using general-purpose compute resources for running DOCSIS vCMTS workloads makes it possible to consider workloads for other access technologies on the same cluster of compute resources.

The following diagram illustrates an example of how access workloads, operating on general-purpose COTS servers, can be applied to DOCSIS and PON.

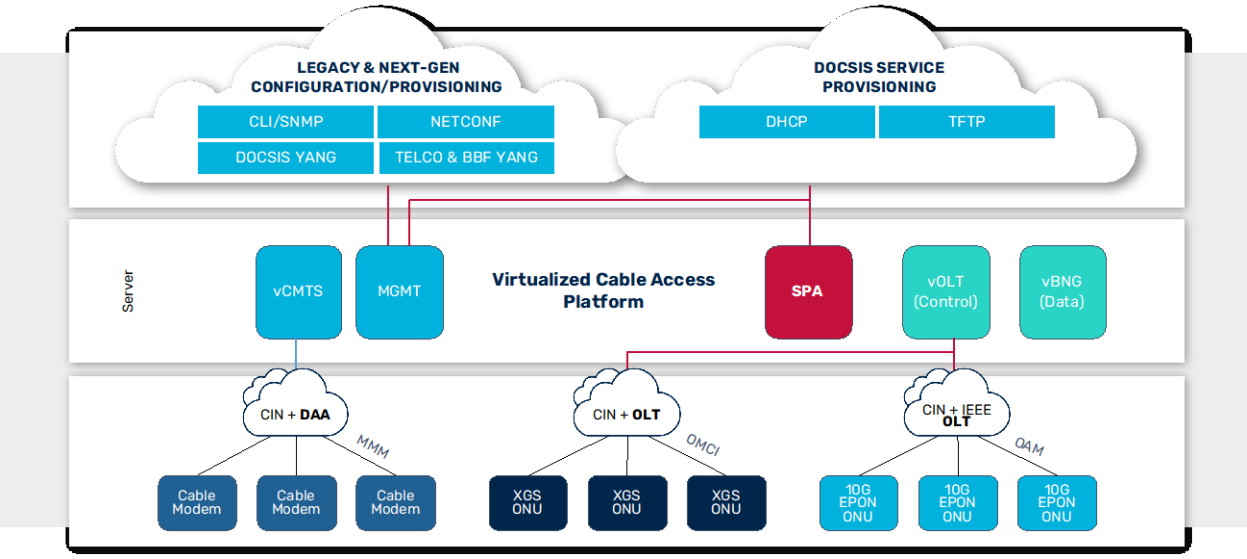

Figure 3 – Access Network Convergence and Uniform Service Provisioning for Any Access

This is explained by the following.

- vCMTS — DOCSIS workloads are provided by CNFs that virtualize the CMTS upper layers serving DAA-based PHY devices.
- vOLT— PON workloads are provided by CNFs that virtualize the control of external physical OLTs
- vBNG — upper layer functions typically provided by hardware appliances for PON are provided by CNFs performing subscriber management and user plane operations
- MGMT and SPA — OSS/BSS, fault, configuration, accounting, performance, security (FCAPS) is provided by Management and Service Provisioning Application CNFs to complete the convergence

In this way, not only are different access technologies and protocols converged on common COTS servers, but they are presented to the operator's network with a uniform and scalable platform that can share and load balance available resources.

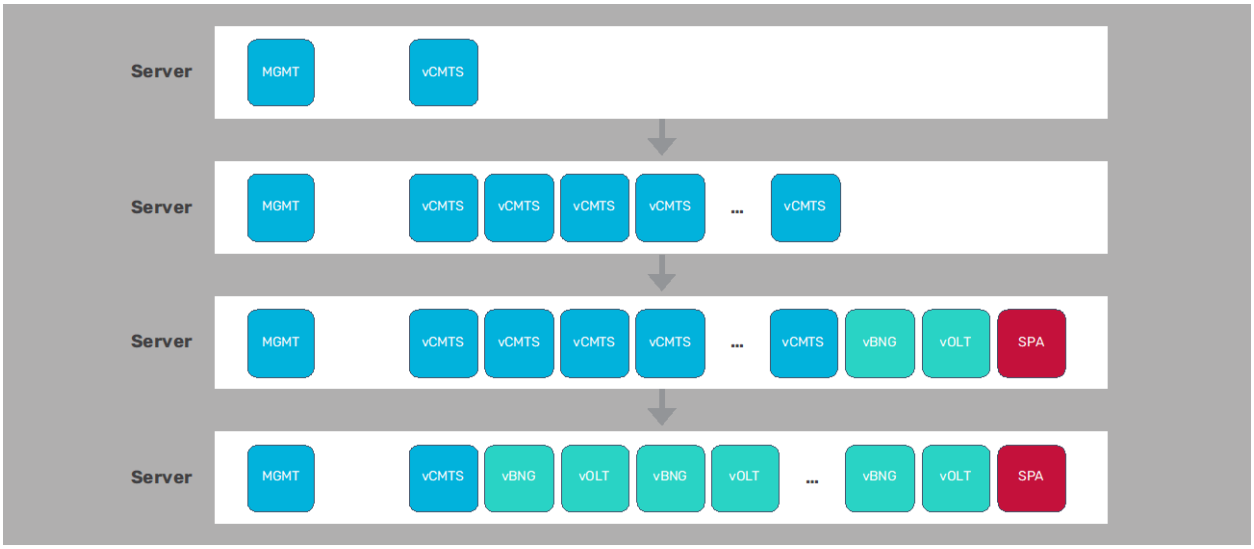

Figure 4 – Horizontal Scaling of CNFs on a Converged Access Platform

Figure 4 illustrates the example of horizontal workloads scaling on a converged access platform.

1. The deployment starts with a relatively small number of DOCSIS service groups (SGs) connected to one CNF instance that implements vCMTS functions.
2. As the number of connected DOCSIS SGs grows, the number of vCMTS workloads increases proportionally.
3. With the introduction of a new type of access technology (PON), CNFs implementing vBNG, vOLT, and SPA functions are instantiated on the same cluster resources.
4. Over time, the number of CNFs implementing different types of access technologies may change. For example, some of the DOCSIS SGs may be converted to PON SGs, which is reflected by the proportional change in the number of CNFs of a certain type running on the platform.

As a converged access platform, the solution now offers common interfaces for managing and operating the entire network. One example of this convergence is the presentation of traditional DOCSIS service provisioning.

Cable operators have long benefited from a simple and standard method of provisioning individual subscriber services. The utility of this basic approach for defining individual subscriber connections and

service level agreements (SLAs) was recognized and applied in the DOCSIS Provisioning of EPON (DPoE) standards [17]. While originally defined and qualified for 1 Gbps EPON, this same DOCSIS-based method for defining subscriber connections, when partitioned as a collection of CNFs, can be applied to any media, including ITU-T (GPON and xGPON), IEEE (10G, 25G, and 50G EPON), and Ethernet. Further, by separating provisioning and management CNFs from the media-specific CNFs, adoption of other methods becomes far more flexible and scalable. As an example, by applying cloud-native APIs within Management and Service Provisioning Applications, use of CLI, SNMP, NETCONF, and of course virtualized cable modem (vCM) methods specified in DPoE, are all available and of little consequence to the vCMTS, vOLT, and vBNG CNFs that they serve.

While this is one way of converging an access network, it is but one example. The point is that the impact of access network convergence in the cable industry results in the following benefits.

1. Increased service agility.
2. Reduced operational cost.
3. Simplified and uniform network operations.
4. Increased network reliability, availability and security.

Next, we will explore the connection of cable access network convergence with the MEC concept.

5. Multi-access Edge Computing in Cable

The ETSI definition for Multi-access Edge Computing enables the implementation of applications as software-only entities that run on top of a virtualization infrastructure, which is located in or close to the network edge [7]. The MEC framework represented in the diagram below shows the general entities involved. These can be grouped into system level, host level and network level entities.

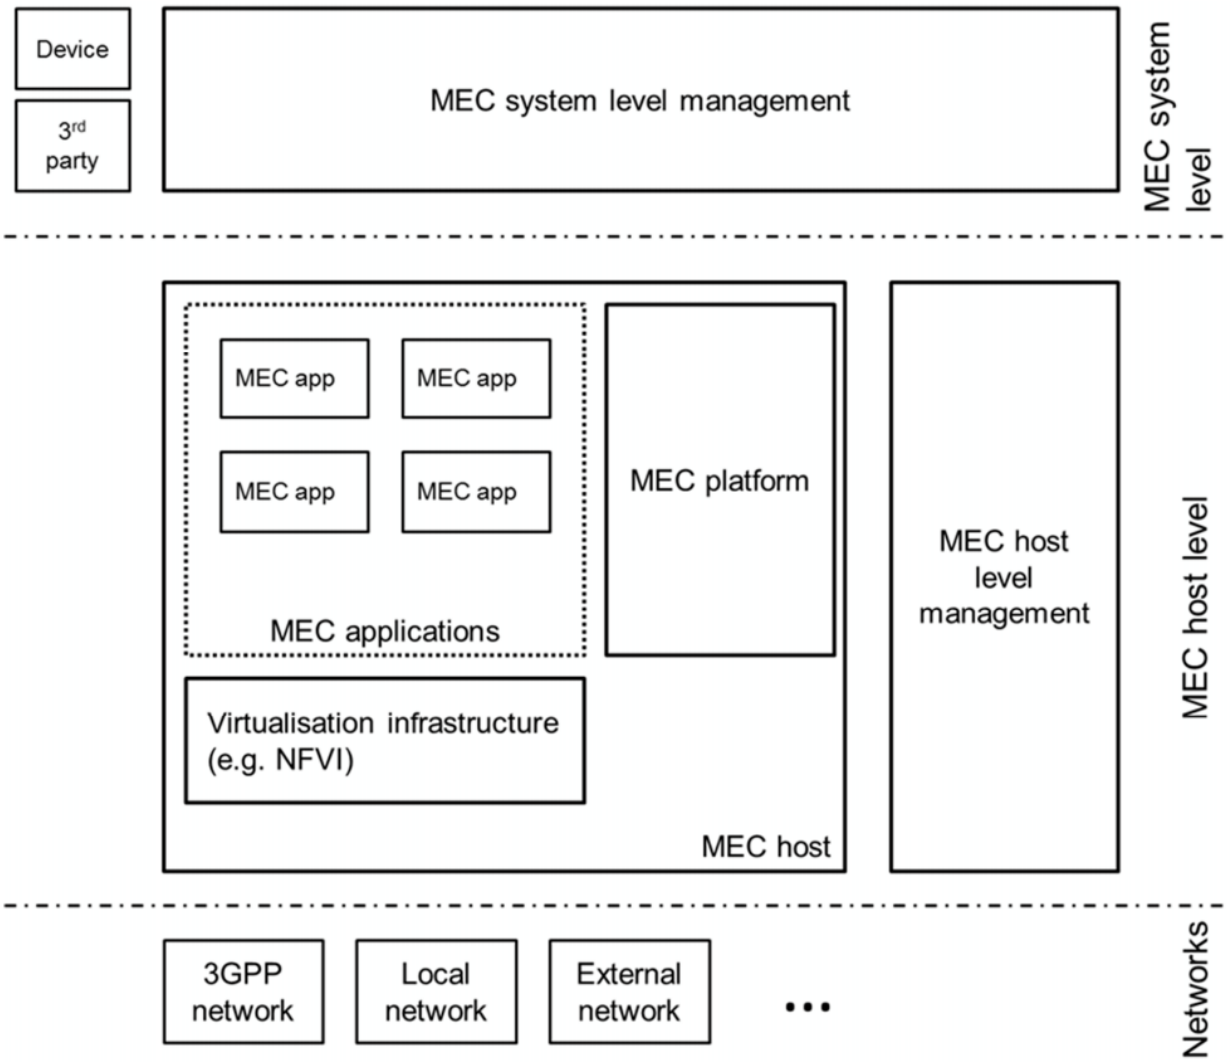

Figure 5 – ETSI Definition of Multi-access Edge Computing Framework [7]

The framework for Multi-access Edge Computing consists of the following entities.

1. **MEC host** – an entity that contains a MEC platform and a virtualization infrastructure that provides compute, storage, and network resources for the purpose of running MEC applications.
    a. **MEC platform** – the collection of essential functionalities required to run MEC applications on a particular **virtualization infrastructure** and enable them to provide and consume MEC services.
    b. **MEC applications,** instantiated on the virtualization infrastructure of the MEC host based on configuration or requests validated by the MEC management.
2. **MEC system level management** that includes the multi-access edge orchestrator as its core component. The orchestrator is responsible for the following functions.
    a. Maintaining an overall view of the MEC system.
    b. Application packages on-boarding.
    c. Selecting appropriate MEC host(s) for application instantiation based on constraints, such as latency, available resources, and available services.
    d. Triggering application instantiation, termination, and relocation.

3. **MEC host level management** which handles the management of the MEC-specific functionality of a particular MEC host and the applications running on it.

While the MEC concept originated in the context of mobile/wireless networks, the general definition of the MEC concept and framework has a lot in common with the real-world architecture of the current generation of the virtualized cable access platforms deployed today [8].

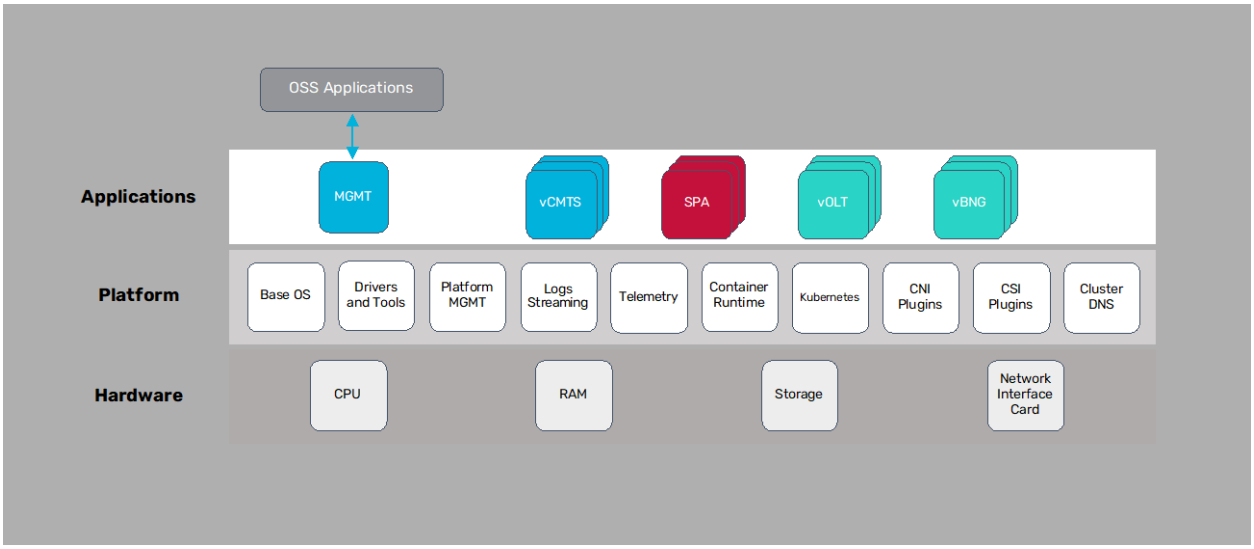

Figure 6 – A Host of a Virtualized Cable Access Platform

As can be seen from the figure above, the implementation of a virtualized cable access platform is like the generic ETSI definition of MEC compute framework. This includes the following similarities.

1. The role of the platform layer of the virtualized cable access platform is equivalent to those of the MEC platform and virtualization infrastructure entities.
2. Applications running on a virtualized cable access platform are equivalent to MEC applications. Examples of applications running on top of the virtualized cable access platform are:
    a. Virtual cable modem termination system (vCMTS).
    b. Virtual optical line terminal (vOLT).
    c. Virtual broadband network gateway (vBNG).
    d. Service provisioning application (SPA).
    e. Management (MGMT) applications implementing “northbound” interfaces toward operations support systems (OSS) as well as “southbound” API calls toward platform and CNFs.
3. MEC system level management in a virtualized cable access platform is partially covered by the OSS applications, and partially implemented by a set of tools for deployment automation and monitoring.

In fact, the cable industry has been leveraging the MEC concept for years [9] without calling it “MEC.” Future directions for the application of the MEC framework within cable may include the following.

1. Further network convergence and proliferation of the applications running on top of the virtualized cable access platform:

a. Adding new types of broadband access applications on the virtualized cable access platform.
b. Adding applications specific for the hospitality industry (e.g., digital signage and targeted advertising applications).
c. Converging applications implementing 5G CU/DU/cCore components with other broadband access applications.
d. Exploring new business models with healthcare applications. This use case also covers more generic list of applications dealing with sensitive customer data, where application data is not allowed to leave the perimeter of the organization.

2. Integration with hyperscalers and offloading certain types of workloads traditionally deployed in CSP infrastructure to the network edge.
3. Adopting CI/CD practices on the organizational level to accelerate the development and deployment of edge compute applications.

6. Dealing with Transport Matters in a MEC Era

As shown on Figure 5, the MEC framework is generally agnostic to the networks connecting MEC hosts. Luckily, the current state of the virtual access networks convergence doesn't leave many variations for networking technologies connecting applications running on the edge compute hosts with their consumers. To explain the concept and why it's perceived to be a positive way of network evolution, we need to take a step back and state the challenges attributed to the networks of the past.

Consider the following diagram showing a typical legacy DOCSIS network with analog fiber going from the hub to the field.

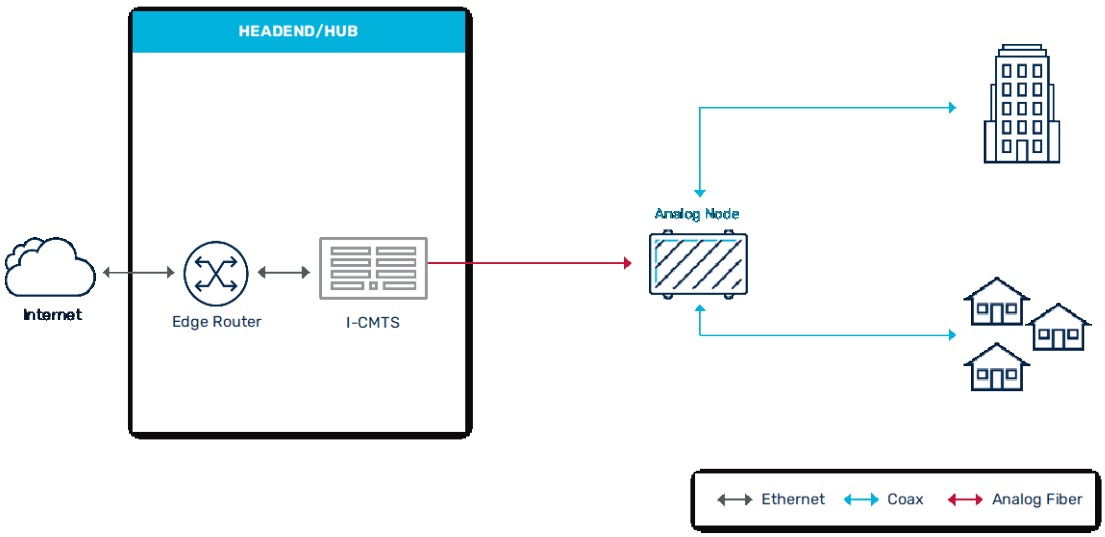

Figure 7 – Legacy DOCSIS Network

Analog connectivity between headend/hub and fiber node doesn't leave options for choosing the connectivity type for the end subscribers. If, for example, a business subscriber is looking for a speed tier that cannot be provided by a DOCSIS network, then it would require the cable operator to lay a dedicated optical fiber line from the headend/hub to the customer's facility. The cost of such work and the time it would take to do the construction makes the business case not economically viable. Similarly, delivering high-speed internet connectivity using Ethernet as a last mile technology would require adding more

physical appliances (e.g., access switch, BNG) to the operator's facility and integrating them with the service provisioning systems. The alternative, of course, is to use the same fiber with different digital wavelengths that can carry a variety of access protocols. This is a key concept of the DAA.

With DAA, Ethernet transport becomes a universal means of transporting broadband access applications running on top of the compute resources (wherever they are) to the devices implementing physical layer connectivity. The result is a converged multi-access network as shown below.

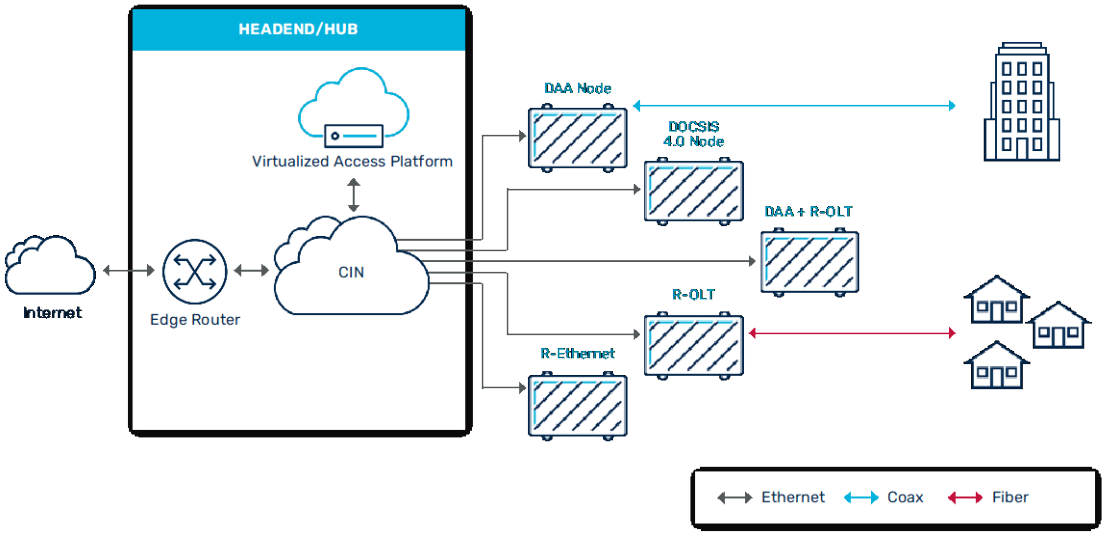

Figure 8 – Converged Multi-services Cable Access Network

The benefits of this converged multi-service cable access network include the following.

1. "Standardization" of the outdoor plant, with Ethernet links (via the converged interconnect network, CIN) connecting DAA nodes with headend/hub equipment that in turn may be connected to off-premises resources *in the cloud.*
2. *Stretching* the CIN closer to end users with outdoor digital fiber segments extending reach, aggregation, and overall network capacity.

It's worth mentioning that while current DAA deployments are based on 10G Ethernet connectivity between distributed access architecture switches (DAAS) and DAA nodes, the industry is looking into adopting higher rates (25G, 100G and higher speed Ethernet).

Using the same example of an enterprise business customer connected over a DOCSIS network looking for a higher speed tier, let's look at how a virtualized access platform enables instantiation of new services.

6.1. Use Case: Adding New Services On Virtualized Access Platform with DAA

6.1.1. Outside Plant Work

The scope of the outside plant work includes installation of a digital fiber from the DAA node closest to the customer's facility to enable 1G or 10G Ethernet or PON. Rather than the expense and complexity of

a headend/hub trunk connection, the scope of required construction to reach the customer's facility is far smaller.

6.1.2. CNF Instantiation

A vBNG CNF workload is deployed on the virtual cable access platform's compute resources that are closest to the customer's facilities. Generally speaking, the exact location of the compute resources serving a specific customer is flexible: location of the CNF can be anywhere in the network and can change over the time based on commercial and operational needs.

6.1.3. Topology Discovery

The logical connectivity (session) is established between CPE and the corresponding vBNG instance using automation tools or statically.

6.1.4. Services Provisioning and Activation

This step implies provisioning of the selected speed tier and SLA for the customer premises equipment (CPE) and applying the corresponding configuration to the vBNG application running on the virtual cable access platform. As noted earlier, using uniform MGMT and SPA CNFs permits common tools and workflows to be applied for services provisioning over different access networks.

6.1.5. Monitoring

At this point, services are up and running and an operator performs routine monitoring of the subscriber connectivity and availability using cloud-native telemetry and logging.

The advantage of this approach for adding a new subscriber or introducing a new type of access technology is that it does not require installation of any new equipment within the operator's facility or change in workflow and tools. Connecting a subscriber to the desired access technology (e.g., DOCSIS, Ethernet, PON) to the nearest DAA node becomes more plug-and-play. Such deployment flexibility and service agility are enabled by the introduction of the digital fiber all the way down to DAA nodes, on the one hand, and leveraging MEC for broadband access applications deployment, on the other.

7. Network Operations in a Converged World

The change in network operational practices for access networks convergence can be viewed through the prism of network virtualization. The move from hardware-based networking appliances towards CNFs running on a common virtualized access platform implies changes to the following network operations properties.

7.1. Separation of Platform Management from Applications Management

The virtualized access platform provides standard resource units, such as CPU cores, memory, storage, and network share, to applications (CNFs). The platform considers CNF resource needs, as well as other requirements, such as locality and high availability (HA) preferences. As a result, operators need only to operate a single Kubernetes-based platform that is responsible for multiple CNF workloads in a consistent way. In comparison, legacy access networks typically require at least one element management system (EMS) or network management system (NMS) dedicated to each class and vendor provided networking appliance. The result is oftentimes complex and expensive software systems that attempt to orchestrate this collection of appliances.

7.2. Ubiquitous Automation

CNF deployment automation provides a declarative configuration model and single configuration interface for managing the configuration of different CNFs. Automation in cable access networks leverages standard network management protocols, such as NETCONF, and data models, such as DOCSIS YANG [19].

1. Operator builds configuration template(s) using standard data model.
2. Operator applies configuration to a virtualized access platform via NETCONF.
3. CNFs are instantiated on a platform to accommodate services configuration provided by the operator.

Using services-oriented configuration data models allows an operator to focus on services requirements while corresponding CNFs instantiation and resources allocation are handled by the platform.

7.3. Deprecation of Legacy Monitoring Interfaces in Favor of Modern Telemetry-Based Protocols

In the current context, SNMP and IPDR fall into the category of legacy protocols providing data to external monitoring and billing systems.

In short term, the usage of service-based telemetry is not mutually exclusive to legacy protocols. In fact, the current state of access networks convergence is characterized by the simultaneous and compatible use of modern and legacy monitoring/billing interfaces and protocols. The long-term vision is that legacy protocols will be deprecated in favor of the scalability and deployment flexibility requirements available in virtualized converged access networks. Figure 9 provides an example of a telemetry streaming pipeline from CNFs running on top of a virtualized access platform. The pipeline is highly scalable, provides updates with short time intervals, and can be incorporated into operator's automated analytics and machine learning (ML) applications.

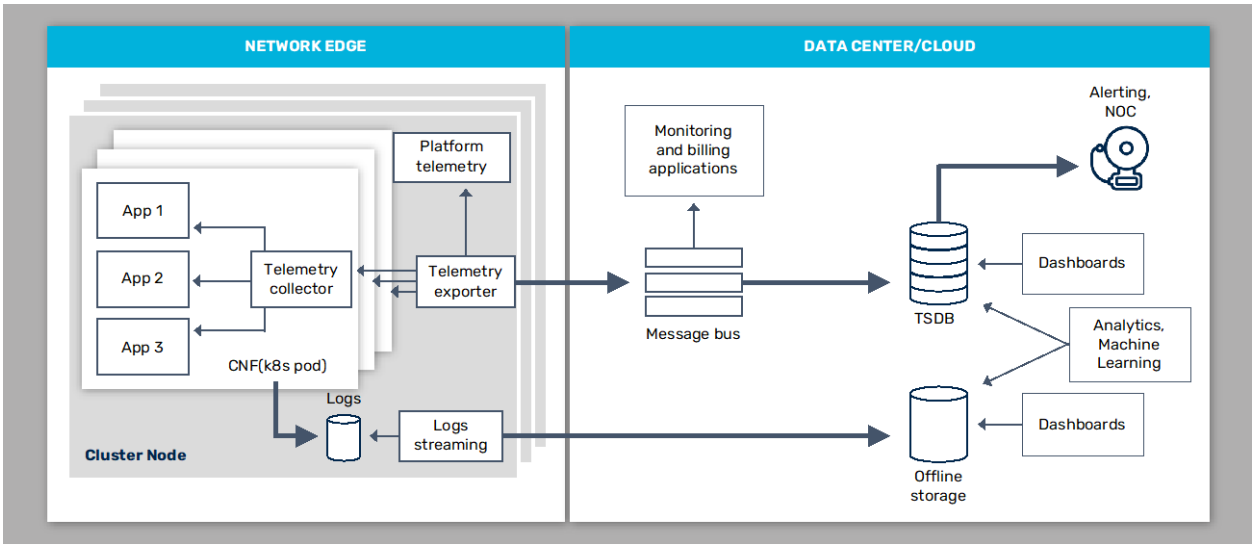

Figure 9 – Telemetry Streaming Pipeline

The result of telemetry data processing by automated analytics and ML applications can be then applied back to the access platform in a form of closed-loop automation.

7.4. Introduction of The New Software Distribution Models and Adoption of CI/CD Methodologies at The Organizational Level

In legacy networks, an upgrade of a networking device is typically executed in a form of transferring a software image file(s) to the target device and activating a new software version accompanied by the reboot of the device. In virtualized converged access networks, CNF software is released in the form of containerized images. This approach is characterized by the following.

a. The virtualized access platform is always connected to a container image registry, facilitating simultaneous software distribution and installation at *cloud scale*.
b. An upgrade of a CNF can be performed in a way seamless to the services provided to end users (in-service software upgrade, ISSU), with minimal service interruption. No host (server) reboot is required for a typical CNF upgrade cycle.
c. Individual CNFs running on a converged platform can be upgraded independent of each other.
d. The same virtualized access platform can host CNFs of the same type running different software versions. This enables *candidate or canary* upgrades and A/B testing on a per-service group basis for final field acceptance prior to networkwide updates.

8. Conclusion

Cable access network convergence and virtualization were developed as a general solution for the challenges and opportunities the cable industry has experienced over the years.

- Meeting and exceeding ever-growing network capacity and performance requirements.
- Network construction and operations cost reduction.
- Improving network reliability, availability and security.
- Managing the complexity of network operations to incorporate new services and access technologies.

The cable industry is taking advantage of concepts defined by MEC by applying hyperscale cloud methods to DAA with CNFs. These concepts help to accelerate the convergence of cable access networks. These innovations enable cable operators to take advantage of the following converged network benefits.

- Elasticity of cluster resources and infrastructure.
- Automation and service instantiation at high velocity.
- Horizontal scaling capabilities and ability to change capacity on demand.
- Visibility of the platform and service.
- Faster time to market for deployment of new applications and repair.

Standard Ethernet-based connectivity between MEC infrastructure and devices in the field becomes a key enabler for many access technologies.

Moving forward, future directions of MEC development in access networks may include the following.

1. Adding new types of broadband access technologies and services, with the end goal of deploying an access agnostic network.
2. Unifying service provisioning processes for multiple access network types.

3. Integration with hyperscalers, that may be executed in two directions:
    a. Moving certain types of CNFs from on-premises compute resources to hyperscaler infrastructure.
    b. Moving some of these workloads, traditionally operating in hyperscaler infrastructure to on-premises clusters or deep edge compute resources.
4. Adopting CI/CD practices and modern software distribution and management practices to further improve service agility.

Abbreviations

ASIC	application-specific integrated circuit
CAPEX	capital expenditures
CCAP	converged cable access platform
cCore	converged core
CD	continuous deployment
CI	continuous integration
CIN	converged interconnect network
CMTS	cable modem termination system
CNI	container network interface
CNF	cloud-native network function
COTS	commercial off-the-shelf
CPE	customer premises equipment
CPU	central processing unit
CSI	container storage interface
CSP	cloud service provider
CU	central unit
DAA	distributed access architecture
DNS	domain name server
DOCSIS	Data Over Cable Service Interface Specification

Cox's Distributed Access Architecture (DAA) standard calls for deployment of a Converged Cable Access Platform (CCAP) chassis acting as Remote PHY core in every metro edge facility. To support the deployment of these chassis, we need substantial amounts of rack space, power, and HVAC at these critical facilities. In locations that have severe constraints we need an alternative solution to enable Remote PHY while avoiding highly expensive facility augmentations. In this paper, we explore our network design options to deploy a CCAP chassis non-locally in a host facility and to utilize our Converged Interconnect Network (CIN) to reduce the footprint at the remote edge facility. We discuss how to prioritize these solutions by their impact to service availability. The reliability analysis provides further insights into the design/decision thresholds for selecting a host site in a successful application of the remote head-end Extended (E)-CIN solution. We further discuss the implementation, limitations, and challenges of the E-CIN solution and assess impact to the business in terms of capacity planning and cost in comparison to the full-CIN solution. The outcome from this comprehensive analysis is very useful in deciding favorability of a given site as an E-CIN candidate.

1. Introduction

The access network has continued to evolve by leveraging new technologies – the recent one being Remote PHY– to meet the ever-increasing demands for bandwidth. Remote PHY is a distributed architecture that encompasses moving the physical (PHY) component from the traditional Cable Modem Termination System (CMTS) out to the edge, thereby extending Ethernet closer to the customer and providing the capability to support greater bandwidth. This architecture will ultimately enable cable operators to deliver Gigabit service tiers at a fraction of the cost of replacing the existing Hybrid Fiber Coax plant with fiber. In this context, CIN is a flexible, resilient, and extensible network that interconnects the CCAP core with Remote PHY Devices (RPDs). It is essentially the infrastructure that supports the distributed access and fiber-deep architectures of Remote PHY.

Implementation of the traditional CIN network requires deploying the CCAP core within the service provider's critical facilities. These CCAP chassis have significant space and power requirements that would need to be accommodated at those facilities. An example of the CCAP core is the Cisco cBR-8 shown in Figure 1. It has the below chassis specifications:

- Weight: 429 lb. (195 kg) maximum fully loaded
- Height: 13 RU (22.75 in / 57.78 cm)
- Width: 17.45 in (44.32 cm) with no rack mounts, 17.65 in (44.83 cm) with rack mounts
- Overall Depth: 28.075 in (71.3 cm)
- Operating temperature (nominal): 32 to 104ºF (0 to 40ºC) Sea Level

The Cisco cBR-8 router can be either mounted on the rack at the front or in the middle. Also, the router can be either mounted on a standard 19-inch wide four-post equipment rack unit or a two-post rack unit. It is also power intensive with the below requirements:

- Cisco cBR-8 Lifetime Facility Power Requirement: 9000 W
- Hardware Facility Power Requirement (D3.0): 7300 W
- Hardware Facility Power Requirement (D3.1): 7900 W
- Average fully loaded chassis between 4500 and 5200 W

Figure 1 – Cisco cBR-8 CCAP, 13RU Height

To deploy the CCAP chassis and digitalize a facility that is constrained on space, power, and HVAC, we would need cost intensive facility expansions/augments which can run into millions of dollars. In certain cases, an expansion may not even be a feasible option, requiring office move and re-design of the outside plant with new fiber builds. In this paper, we explore the concept of Extended (E)-CIN, which essentially means the digital CCAP is hosted in a separate facility than the site that houses the Remote PHY Aggregation switches (RPAs). In other words, E-CIN involves the de-coupling of R-PHY core resources (i.e., cBR-8 data & video cores) from the edge of the CIN. This can enable digitalization of facilities with physical space constraints and thereby recover rack space from decommissioning obsolete analog equipment, thus avoiding the regrettable spend on expansions. Although physical space constraint is the primary driver, E-CIN can also optimize network efficiency by consolidating host resources and serve as a conceptual proof towards the adaptation of future designs like "centralized CCAP" and/or "virtual CCAP".

In the rest of the paper, we refer to the facility where the cBR-8 is located as the "host" site, and the facility where the RPA resides as the "remote" site. Inherently, in most cases, E-CIN will increase the optical distance between RPDs and the CCAP core, which can add unique challenges, primarily regarding latency performance and network reliability. In section 2, we first consider all the possible network topologies and perform a reliability analysis to derive insights on the best choice of the host site for a given remote site. In section 3, we discuss the implementation of the designed solution. In section 4, we discuss the latency and throughput performance of E-CIN. In section 5, we discuss the financial impact to business for capacity planning and finally conclude in section 6.

2. Network Design

Important design questions on hand for E-CIN are:

1) What are the possible topological solutions for E-CIN?

2) How does one choose the most optimal solution and host site for a given remote site?

In this section, we first explore the topological possibilities by considering both L3 Internet Protocol (IP) and L1 optical Dense Wavelength Division Multiplexing (DWDM) layers. Secondly, we present an approach based on the analysis of network reliability to draw insights on the choice of host site.

2.1. Network Topology

The illustration in Figure 2 is representative of the CIN implementation within the Cox network. HUBC0x are the Metro hub routers controlling metro traffic, and DSRJ0x are the Distributed Service Routers connecting to the backbone network. The Remote PHY Aggregation switches (RPAs) aggregate the Remote PHY Devices (RPDs), and the Digital Physical Interface Card (DPIC) Aggregation switches

(DPAs) aggregate the connections from DPIC providing an ethernet network between the CCAP core and the RPDs. Note that the Host Site could also be the Regional Data Center (RDC).

For the problem on hand, we need to establish communication between the RPDs at the remote site and the CCAP within the host site. There are a couple options to consider:

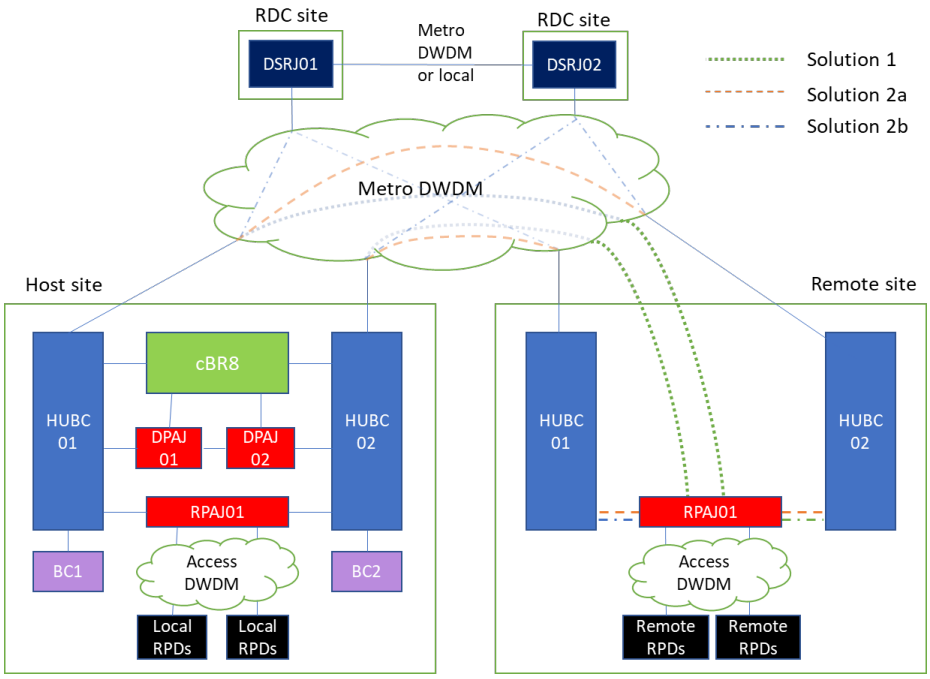

Figure 2 – Generalized Cox Metro Network Topology Showing Routing Options for E-CIN

Solution 1: One way to achieve this would be to leverage the DWDM metro optical network to transport traffic directly between the remote site RPA and the host site hub routers. In essence, the RPAs are re-homed manifesting as the expansion of the host site's access network.
Pros: This would be the least hop solution with low latency, and thus more reliable.
Cons: The solution is not scalable, as aggregation over the DWDM network is very expensive. Therefore, we do not discuss this solution any further in this paper.

Solution 2: The second possibility is to route the traffic via the hub routers. Traffic from the CCAP core hops via the hub routers in the host site before being transported over the metro optical DWDM network to the RPAs via the hub routers at the remote site.
Pros: Provides a scalable solution by aggregating traffic over the uplinks of the hub routers.
Cons: The solution has more hops, and consequently higher latency and lower reliability in comparison to the first solution.

- **Solution 2a**: The hub routers at the remote site can be directly connected to the hub routers at the host site over the metro DWDM network without passing traffic through the Distributed Service Routers (DSRs). This option creates a spur from the host site to the remote site, rather than utilizing the existing hub & spoke architecture. This is achieved by provisioning a primary wave and a secondary protecting wave between the hub routers at the two ends.
  Pros: Fewer hops in comparison to solution 2b.

Cons: Unless there is a pair of direct fiber between the two sites within the optical network topology, it results in a non-optimal aggregation over the DWDM network. Additionally, this alters the IP network topology from the standard (where uplinks connect back to the DSRs at RDC).

- **Solution 2b:** The hub routers at the remote site are not directly connected over to the hub routers at the host site, so the traffic instead hops via the DSRs over the metro DWDM network.
  Pros: Standardized metro topology in alignment with full CIN. Optimal aggregation of waves over the metro DWDM network.
  Cons: More hops and likely longer latency in comparison to solution 2a.

In summary, since scalability, DWDM aggregation and standardization are of top business priorities, our preferred solution is to reserve solution 2a for sites that have a direct fiber pair to another site. This implies we have a single node ring L1 optical network (L3 is secondary spur from primary set of hub routers), which would be the host in this case. For the more common multi-node ring topology of the L1 metro DWDM network (L3 topology is hub-and spoke from DSRs), solution 2b would be more preferential. Selection of host site in this case requires further analysis.

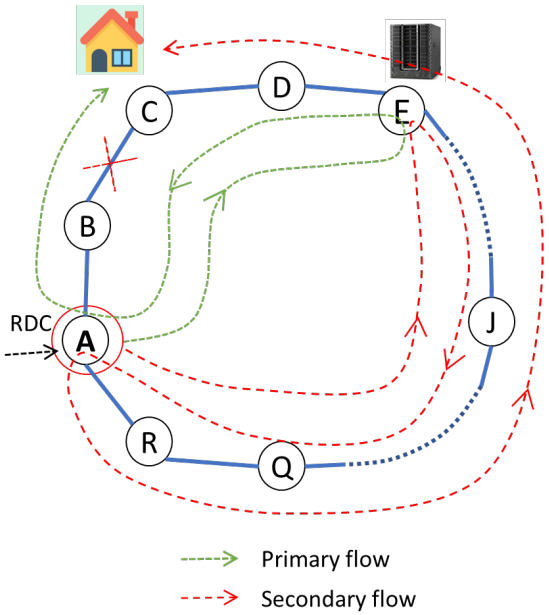
2.2. Reliability Analysis

Separating the CCAP core in one facility from the edge components in another facility increases the number of network elements, and specially fiber distance between the customer premise and the headend. This compels an evaluation of service availability to validate the Service Level Agreement (SLA) requirements, as well as draw insights into the impact of CCAP location on the network reliability.

2.2.1. Problem Definition

In a metro DWDM network, although mesh topologies exist, it is more common to have the ring topology to uplink the hub routers to the DSRs with a primary wave and a secondary protection wave. Considering the worst case - What is the impact on service availability as we vary the CCAP location?

Let's take a deeper look into the traffic path over the metro core in case of solution 2b. The traffic path over an optical ring is shown in Figure 3 for both the steady state and fail-over cases. Considered here is a ring with 18 sites (A to R) spanning over a total mileage of ≈1300km with a single RDC location, akin to one of the largest metro rings on the Cox network. In steady state, the traffic from backbone starting at the DSR in the RDC traverses the shorter side of the ring to the CCAP location, again on the shortest path, returns to the RDC before finally reaching the customer site where RPDs are located. The flow is similar during failover, except that it traverses the longer sides of the ring. In the example shown in the figure, A is the RDC site, E is the site where CCAP head end is located, and C is the customer site of interest. It shows the primary path of traffic flow, and the secondary path when a failover occurs, say on the event of a fiber cut between sites B and C. For this exercise we vary the CCAP and the customer site over the ring and perform a reliability analysis of the metro network.



Fiber between locations	Fiber (kms)	Metro Fiber (kms)	Longhall Fiber (kms)
A -> Rs	30.7	24.56	6.14
R -> Q	65.5	13.1	52.4
Q -> P	111.7	11.2	100.5
P -> O	91	9.1	81.9
O -> N	86	12.9	73.1
N -> M	67.9	13.6	54.3
M -> L	55.5	5.6	49.9
L -> K	93.5	14.1	79.4
K -> J	87.9	17.6	70.3
J -> I	111.2	83.4	27.8
I -> H	70.7	28.3	42.4
H -> G	124.4	24.9	99.5
G -> F	58.3	43.8	14.5
F -> E	31.5	4.8	26.7
E -> D	99.8	15	84.8
D -> C	66.3	10	56.3
C -> B	63.8	12.8	51
B -> A	53.5	21.4	32.1
Total	**1,369.20**	**366.2**	**1,003**

Figure 3 – Protected Traffic Paths on a Metro Ring with the Fiber Distances

2.2.2. Modeling and Simulation

For reliability analysis we used the ReliaSoft BlockSim package allowing the creation of reliability block diagram and discrete repairable system event simulation. The fiber distances between sites for the case study is shown in Figure 3. Outside plant fiber mileage is distinguished between metropolitan and long-haul by their urban density for analysis since optical impairments (disruption of signal in the fiber optical link) largely depends on human activities, and they have different failure rates. The failure rates are modeled with lognormal distribution computing the means and variance for long haul and each metro individually. The customer service availability is then modeled with the primary and secondary path elements in a parallel system with all intermediate routes and optical infrastructure at the module level with built in redundancies.

Disregarding the “last mile” OSP infrastructure within the access network, we have simulated the service availability for customers at different sites on the ring as we vary the CCAP locations over the ring as well. For this comparative analysis, the Mean Time to Repair (MTTR) is assumed constant and equal to 4 hours. The results are shown in Figure 4. It can be observed that for a given CCAP location, network reliability is highest when the headend is local and decreases as the CCAP is moved farther away. Secondly, for all sites, the network reliability when the CCAP is located at the RDC site A is almost as high as when it is local. This is apparent from the figure as the line plot for “CCAP in A” is an envelope for the rest. It is due to the nature of traffic flow - locating the CCAP at the RDC does not add any additional fiber distance to the traffic path. Hence, the RDC would be the second choice, next only to local, from the perspective of network reliability. Further, if the RDC cannot host the equipment, then the facility closest to it needs to be considered.

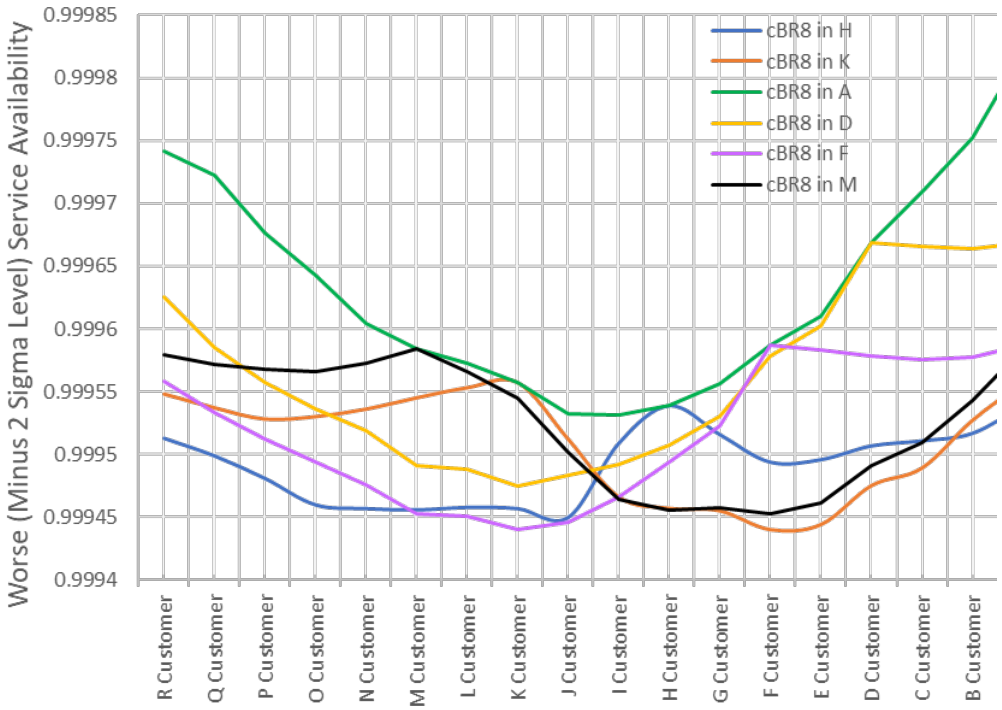


Figure 4 – Metro Core Service Availibity at Different Sites for Fixed CCAP Location

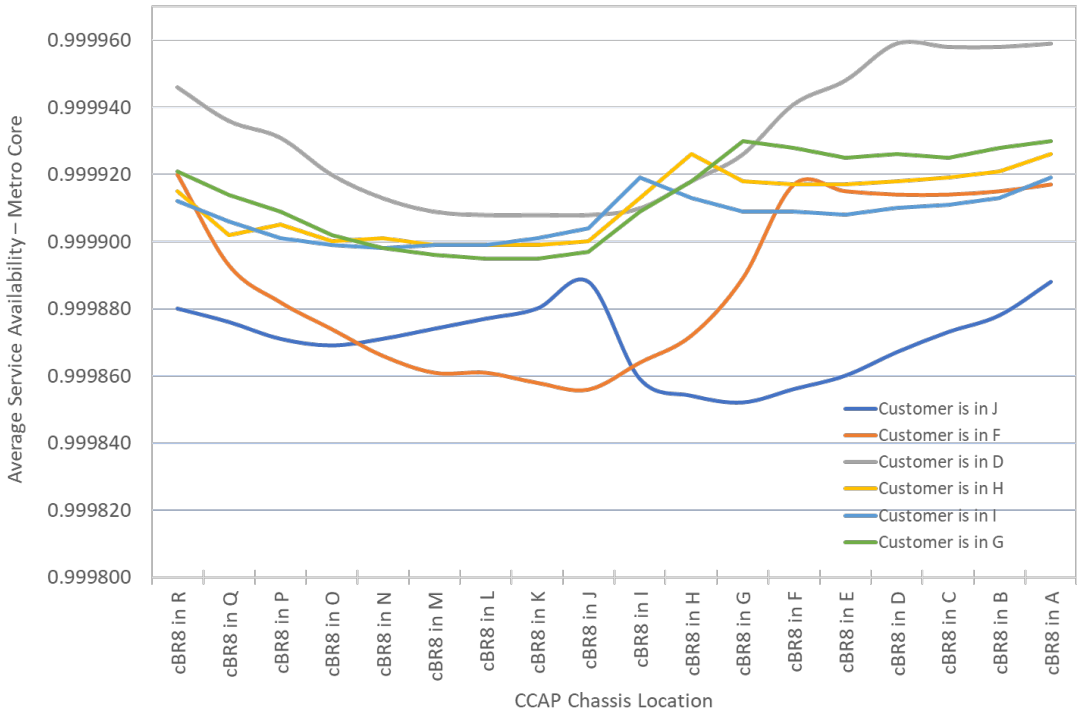

Figure 5 – Metro Core Service Availability at Specific Sites for Different CCAP Locations

In Figure 5, we can see that the inverse relation has a similar trend. It should be noted that the plots consider only the metro core network reliability and does not include the backbone and the Access OSP infrastructure. To qualify a host site, we need to verify that the absolute reliability for the entire network meets the SLA. Due to shape of the plot, it is possible for certain sites within the market to meet the requirements while certain others beyond a distance do not. In the above case study, we performed a detailed analysis including the "last-mile" R-PHY OSP infrastructure at Cox by considering the hardware, software, human factor, and commercial power outages. To be more accurate, we have modeled the MTTR with log-normal distributions with the log location $\mu = 3.3.4576$ and the log standard deviation $\sigma = 0.5287$. Similar distributions are used for RDC and hub site hardware with tailored parameters. This is a computationally very intensive model with over 1000 blocks simulating 5 years of operation and at least 5,000 iterations for acceptable convergence. For remote site F as example, the mean availability for CCAP location in RDC A resulted in 0.99964, and we can therefore qualify A as the host. We have observed a consistent drop in mean availability compared to Figure 5 by about 0.00028 for all host sites with the improved accuracy model.

2.3. Summary

In summary, directly linking the remote site RPA to the host hub routers (solution 1) is not scalable. To handle the RPD scale and to benefit from aggregation, the CIN traffic needs to hop via the remote site hub routers before passing through the DWDM network. Given the optical network topology, the remote site hub routers may have direct primary and secondary uplink to the hub routers at another site, if they have a pair of direct fibers between them. In this case, the second site would be the chosen host site. This is the "***Subtended hub-hosted***" solution. Generally, we have sites with optical nodes in the metro connected as a ring with one or two (split) RDC sites hosting the DSRs connecting over to backbone. In the standard metro IP topology with primary and secondary uplinks from the hub routers within the market to the corresponding DSRs, these uplinks are non-overlapping DWDM waves provisioned over the optical network on the primary and secondary fiber paths of the ring. Hence all traffic from a remote site hops over the RDCs before reaching the host site. Therefore, the RDC itself would be the primary choice for the host site in E-CIN. This not only maximizes reliability as shown in the above analysis, but also minimizes latency. This is referred to as the "***RDC hosted***" solution. In cases where the RDC facility does not meet the requirements for space, power, and HVAC, then the hub site closest to the RDC in fiber distance would be the next choice of preference for a host site. This is most generalized but least optimal, and it is called the "***Hub-hosted***" solution.

3. Implementation

In this section, we discuss the implementation of E-CIN and the necessary configurations specific to E-CIN deployment. Firstly, although general CIN routing guidelines apply, IP addressing needs to be tailored appropriately for successful operation. Secondly, supporting video service becomes more complex due to multiple channel lineups at the host core and requires additional configurations on the CCAP.

3.1. Networking

The host site will have the CCAP, Digital Physical Interface Card (DPIC) Aggregation switches (DPAs), and the Boundary Clocks (BCs). The remote site will have the "edge" CIN equipment: one or more RPAs, Remote PHY access DWDM equipment, and switches for local management/telemetry. However, remote sites will not have local boundary clocks for Precision Time Protocol (PTP); the boundary clocks at the host site serve the purpose instead.

In terms of routing, general CIN guidelines apply with appropriate updates to the IP space addressing and route advertisements to ensure reachability between the RPA, CCAP core and boundary clocks. Route advertisements specific to the Cox network is shown in Figure 6, and the same routing policy works for all solutions of E-CIN. In a typical Remote PHY network, a facility has two PTP boundary clocks and each is connected to a different router which in turn resides either on the "Hub1" or "Hub2" side of the network. BC1 is preferred by all RPDs on the CCAP, because the standard Remote DOCSIS Timing Interface (R-DTI) profile points to it. BC2 only comes into play if BC1 is unreachable. If the primary path between host and remote sites utilizes the Hub Router 1 path, then this standard CCAP configuration is used. If the optimal path between host site and remote sites uses the Hub Router 2 path, however, then BC2 is preferable because it is closer to the RPDs. In this case, a second R-DTI profile is configured on the CCAP and the RPDs in the remote site must use that profile instead of profile 1.

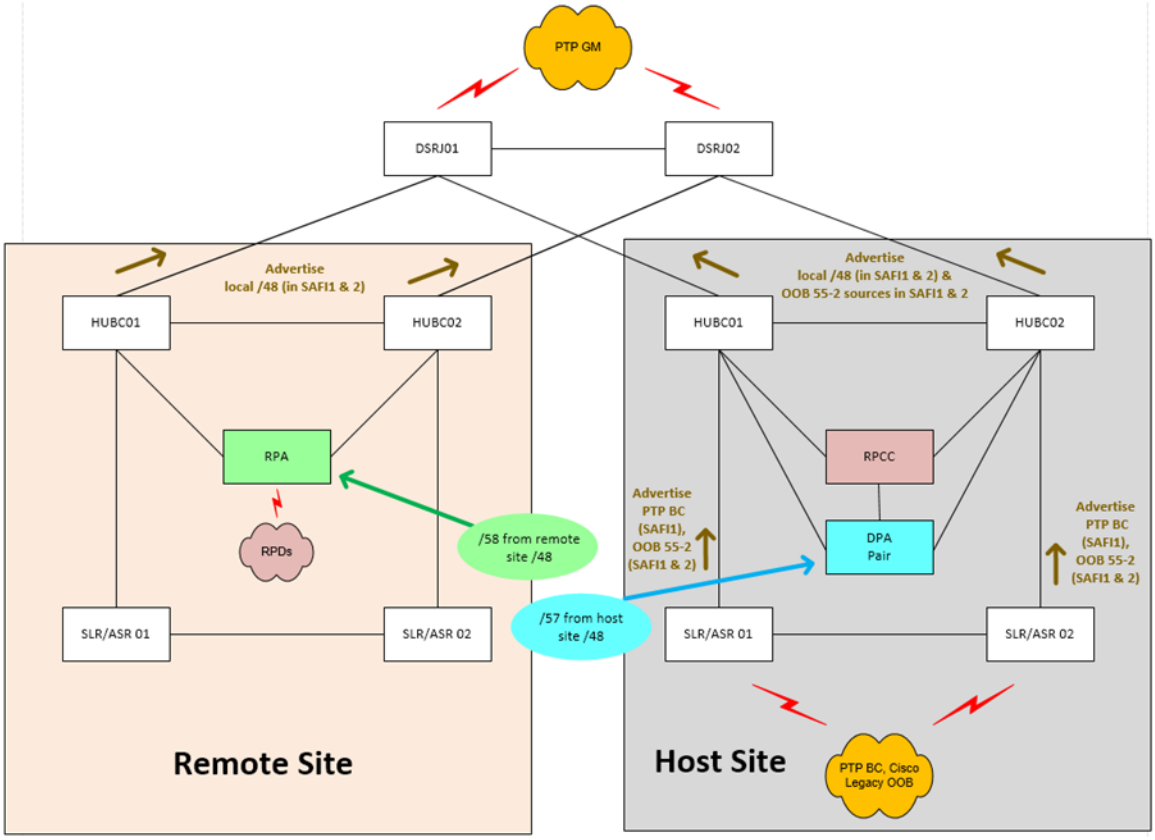

Figure 6 - Route Advertisements in the CIN Network

3.2. Video Support

One of the limitations to E-CIN is the increased operational complexity for supporting video services. In the case where the remote site has the same channel lineup, ad zones, DOCSIS Set-top Gateway (DSG) tunnels, legacy Out-Of-Band (OOB), and Public, Educational, and Government (PEG) channels as the host site, there may be no additional configurations required to support Quadrature Amplitude Modulation (QAM)-based video services including broadcast video and narrowcast video (Switched Digital Video (SDV) and Video on Demand (VOD)). However, if any of the above differ between the host and remote site, then care must be taken to configure the CCAP accordingly.

Consider a Synamedia PowerKey market as an example. Legacy OOB is a Narrowband Digital Forward (NDF) signal delivered via multicast from a Kronback NDX source to a set of destination RPDs. The legacy OOB is assigned to a Digital Hub on the Explorer Controller. It is imperative that both the legacy OOB NDF signal and the DSG multicast flows to the CCAP are assigned to the same Digital Hub on the controller. Failure to do so will render Basic DSG Tuning Adapters inoperable. A CCAP hosting an E-CIN will have to be evaluated to determine whether the remote site is serviced by a different Digital Hub. If so, the CCAP will require a matching NDF pseudo wire for each set of DSG multicast flows.

For any multicast video transport streams sourced at the extended facility, those services will need to be routed back to the host CCAP so they can be ingested and mapped to an output like any other video source. Additionally, care must be taken when supporting multiple Ad Zones in a single CCAP. Multiple Ad Zones means that not all narrowcast video service groups are equal. This calls for additional coordination and operational processes. Before a narrowcast service group is associated with its first RPD, it must be first determined to which Ad Zone the RPD belongs, and then the correct zone should be associated with the service group. Further, any other RPD that gets associated with that service group must also belong to that same Ad Zone.

Extended CIN is limited to environments contained within a single market. There are several reasons for this, but the primary factor is video support. Because all video in a R-PHY network is ingested by the CCAP and then re-generated toward the RPDs, it is not practical (or even possible, in many cases) to support channel lineups and video encryption from multiple markets on the same CCAP. Within a market, when the channel lineup in an extended site differs from the lineup in the host site, the CCAP must be configured to support both, which can add additional complexity. Sometimes, it may not be advantageous, or even possible, to group some sites together. In such a case, multiple CCAP chassis would be needed at the host site to support E-CIN.

Here are some of Cox's best practices on CCAP configuration. Some of these could be relaxed or eliminated if a standalone video core were used in place of a converged data/video CCAP:

- No more than 6 full broadcast service groups per CCAP.
- No more than 12 total broadcast service groups per CCAP including PEG service groups.
- Only 1 Conditional Access System per CCAP. Sites tied to different set-top box controllers cannot be supported on a single CCAP.
- Except for very specific circumstances, only 1 main SDV lineup should be supported on a CCAP. Within the CCAP video config, its linecards are pointed to a SDV session server. The session server is associated with a main lineup. While it is technically possible to point different linecards at different SDV session servers, this should only happen for very small sites whose total capacity needs can be satisfied with 1- or 2-linecards on a single CCAP.

When a host facility is planned to support one or more extended facilities, it is advisable to consider the following options:

1. Support for all extended sites on each CCAP in the host facility. This means that all CCAPs are essentially created equal, and RPDs from any extended site can be moved to any host CCAP. This option is the most flexible but comes at a cost of complexity on the CCAP, and potentially reduced Data Over Cable Service Interface Specification (DOCSIS) Service Group capacity.
2. Segregation of CCAPs by serving footprint. This option would involve setting aside one or more CCAPs as being "E-CIN" hosts and mapping the extended site(s) to certain CCAPs. Doing this would reduce the amount of waste involved in the universal configuration, but at the expense of having to keep track of RPD mappings.

3. Cox is also considering a third option to consolidate video onto a standalone dedicated video core. In this scenario, only the DSG tunnel configurations on the Data CCAPs would be needed to host multiple remote facilities. The CCAPs could therefore be fully utilized for DOCSIS.

4. Performance – Latency, Throughput, and Distances

There are many factors that contribute to a customer's perceived latency. Only the contribution of the access network (CCAP to cable modem) is considered here. Figure 7 illustrates the DOCSIS request/grant cycle and the impact of E-CIN on the same. It is critical to have symmetric latencies from core to RPD and vice versa for both PTP and DOCSIS traffic for Remote PHY operation. It can be observed that the optical distance between the RPD and the CCAP core is the primary factor influencing this latency performance.

The latency between core and RPD is higher in an E-CIN environment primarily because of the additional fiber distances from the metro DWDM network. In a lightly loaded system, where congestion is not a factor, customer ping times to the CCAP are generally 5-6 ms in the best case. Those times start to go up almost linearly as you add distance between the core and the RPD as shown in Figure 8. Typically, a non-Extended hub site can serve RPDs as far as 100km away with only minimal impact to ping times. With Extended CIN, that distance from hub to RPD must be added to the distance from host facility to remote site, which could be as high as 1200km. Because upstream scheduling is done in the core and not in the node, a customer's best-case ping time to the CCAP increases linearly by 4X the latency added by Extended CIN because of the DOCSIS request/grant cycle. For example, if 400km (2ms) is added to the distance between the host facility and the remote facility, the customer will see an increase of 8ms in their ping times (best case).

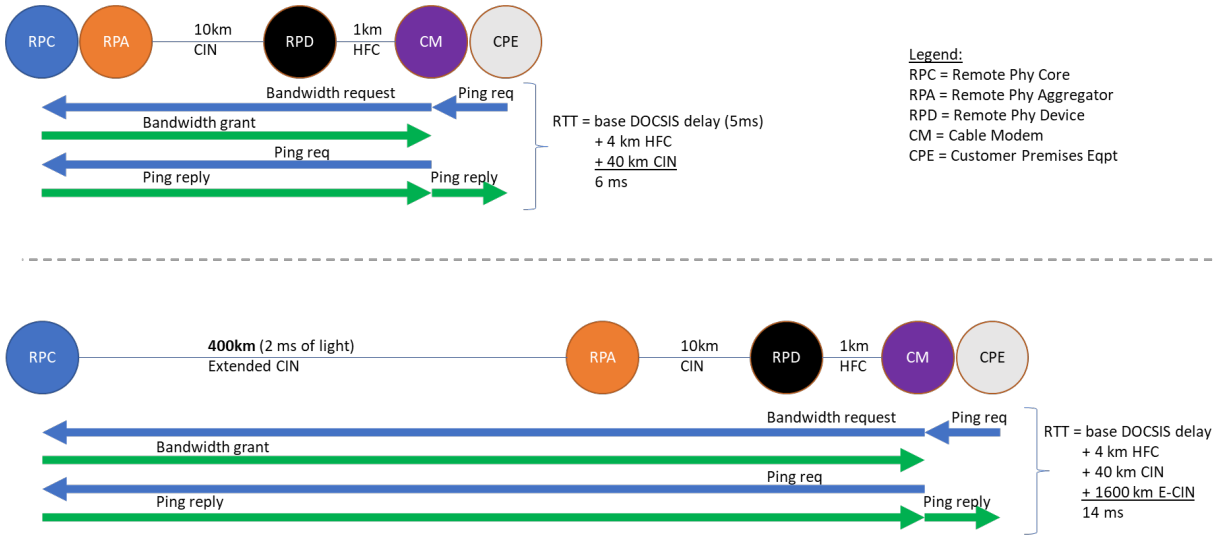

Figure 7 – DOCSIS Ping Time from CPE to CCAP in Regular vs Extended CIN

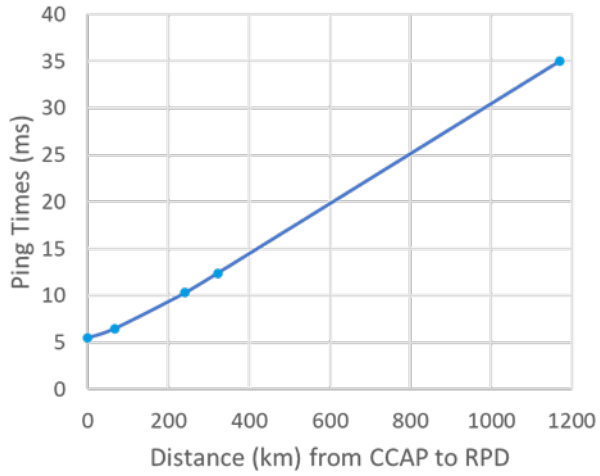

Figure 8 – Latency with Distance

Since DOCSIS is a timing-dependent technology, it is essential to maintain optimization, both in terms of preferring the shortest path (in steady state) and ensuring symmetrical (forward & return) traffic flow. The degradation in latency performance can be mitigated by ensuring that all Remote PHY traffic takes the optimal path from core to RPD, and from RPD back to core, without being load-balanced across multiple paths. This may require change in the Internet Gateway Protocol (IGP) metrics of the metro IP layer to default to the shortest path. Only during a failover should the suboptimal path come into play.

Field testing has shown that customers should be able to achieve full downstream and upstream throughput, even on the Gigabit tier, at distances up to 320km. Field experimentation is currently in progress to determine the exact distance limitation to preserve full Gigabit download. In the very worst-case scenario, which occurs during a path failover, at 1200km, downstream throughput was inconsistent and did not reach the usual gigabit-class downstream. The modems stayed online and continued providing service in a degraded state. However, use of secondary path needs to be minimized for achieving better throughput as well, in addition to latency. Limited field testing has shown that during a failover from short to long path, or from long to short, RPDs and cable modems generally stay online. Nevertheless, large scale testing would be needed to fully validate whether customers could see an interruption in service while their modems re-register.

5. Impact to Business

5.1. Capacity Planning

Depending on the E-CIN topology, the design may involve some “double-back” traffic across certain segments/links of the metro network. Therefore, bandwidth requirements need to be adjusted carefully. Let’s consider the generic hub hosted design for discussions in this section.

Traffic flow between Remote PHY core and the Extended CIN edge over metro core is unique in that it is deterministic and not load balanced. All the traffic – multicast, forward unicast, return unicast, and PTP – must always take the same path, for every RPD. This ensures traffic routes through the shortest path and there is symmetrical forward and return path latencies, which are necessary to meet the timing requirements for DOCSIS. Figure 9 shows how this can be achieved by designing the IGP metrics appropriately. The red path shows load balanced traffic, whereas the green path shows the L2TPv3 tunnel

with a preference on HUB1 side of the network. The optically shorter path, either via HUB1 or HUB2, needs to be engineered as the preferred default and the other as the failover.

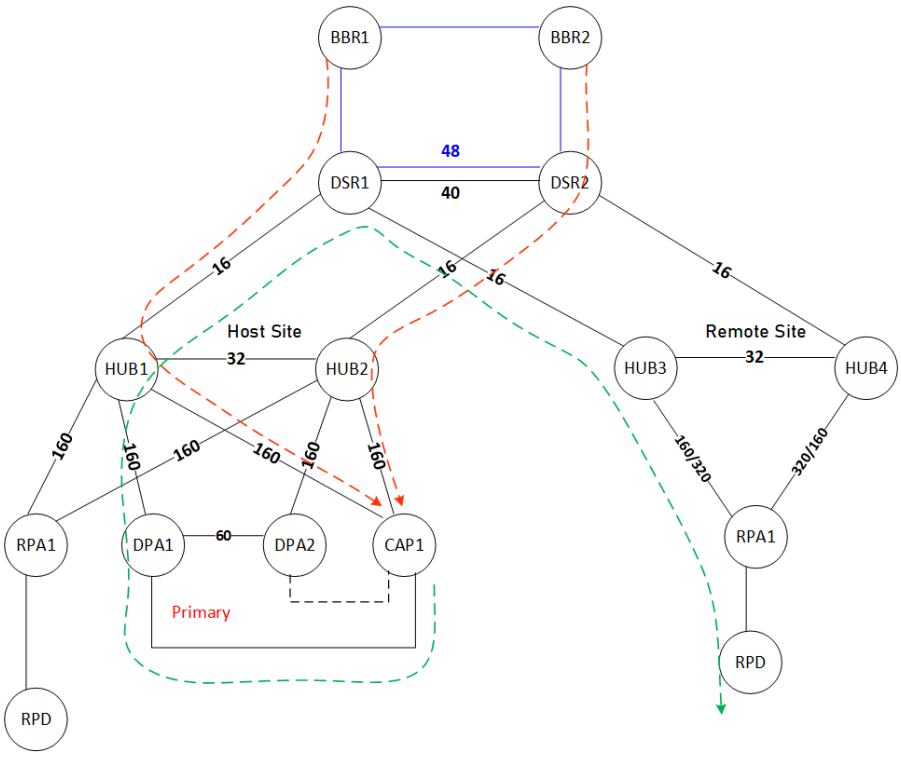

Figure 9 – Traffic Engineering with ISIS Metrics

In planning capacity for the metro network, the CIN component of the traffic needs to be monitored separately. For the metro-core links, we have the below capacity calculations (All traffic rates would be 95th percentiles in Gbps):

Host hub router to DSR uplink capacity = $\lceil max(Td_H + TCIN_R/2\ , M * (Tu_H/2 + TCIN_R/2)) \rceil$

Remote hub router cross bar capacity = $\lceil Td_H/2 + M * TCIN_R \rceil$

Remote hub router to DSR uplink capacity = $\lceil max(Td_R\ , \frac{M}{2} * (Td_R + TCIN_R)) \rceil$

Remote hub router cross bar capacity = $\lceil Td_R + TCIN_R \rceil$

Where Td_H is the total downstream traffic to the hub routers at the host site, Tu_H is the total upstream traffic from the hub routers at the host site, Td_R is the total downstream traffic to the hub routers at the remote site, $TCIN_R$ is the CIN component of the total downstream traffic to the hub routers at the remote site, and M is the bandwidth margin on the router uplinks. It is a good practice to set M=1.5, which means that the fill rate is below 66.66% in steady state operation. This margin is required to ensure healthy operation, since tunneled traffic - unlike load-balanced - would otherwise operate at 100% rather than 50% in steady sate unable to absorb temporary spikes.

Under special circumstances such as split-RDCs where DSRs in different locations, a single fiber cut could force traffic over the DSR crossbar, in which case, it needs to be augmented as well.

5.2. Cost Benefit

From a cost perspective, E-CIN has a wide range of possibilities. On one end, in cases where we could save expenses on facility expansion it could benefit the company, whereas, on the other end, where traffic rates are significantly large, E-CIN could be more expensive than regular CIN. Cost benefit is generally at best where facility augments can be avoided. Secondly, if resource sharing is maximized, remote site can share the CCAP chassis, its processor, and spare line cards; the boundary clocks; and the DPAs at the host. This could result in additional savings. However, depending on the video configuration, it may not be possible to fully leverage resource sharing, especially in cases where dedicated video core may be necessary.

E-CIN also comes with an additional expense – it needs more bandwidth capacity and hence growth expenditure on the metro core as discussed in the previous section. Bandwidth augments are not only necessary to address the double backing of CIN traffic, but also the tunneling effects viz., no load balancing, and operational margin. The main component here is the transport network cost, which depends on the traffic rates, optical network platform, transponder wave density, and its topology. Unless host and remote site traffic rates are very low, augments may be necessary on the uplinks of either one or both the hubs. We may need to typically add 2-4 wave augments on either end. Therefore, the financial impact for each remote and host site pair candidate needs to be assessed on a case-by-case basis to precisely estimate and compare costs.

6. Conclusion

Extended-CIN provides a novel technology to geographically decouple the Remote PHY core and the edge on already existing CIN infrastructure. It is useful reducing the footprint on a facility by consolidating core resources and therefore avoiding expensive augments. However, it can add unique challenges, primarily regarding network reliability, latency performance and operational complexity for video support. These risks should be minimized by optimally choosing the design and host sites with additional case specific analysis. It would be preferable to reserve E-CIN for cases where optical distances between the remote site's edge and the host site's core are relatively low and the cost benefit is high. As part of the future work, we will be evaluating the significant and applicability of E-CIN as newer technologies such as Remote MAC-PHY and virtual CCAP arise.

1. Introduction

The requirements of emerging interactive real-time services and changes in online usage patterns impose entirely different network challenges that Internet Service Providers need to overcome. Cable networks are going through a big transition to the next-generation 10G technologies with substantial speed increases, that can meet the online traffic volumes created by these services accumulatively. However, the new quality of experience judge will not praise or condemn the network operators only by their speed but also by their consistent support of low latency. Therefore, 10G technologies need to address a fundamental redesign of traffic classification and latency monitoring, prediction and optimization. Unprepared Internet Service Providers (ISPs) that design their architecture for mean and median values instead of peaks cannot support the interactivity of real-time services and cannot avoid the impact of these huge data volumes on other services.

In this paper, we will discuss the low latency services that are still evolving today, such as cloud gaming, video/voice conferencing and live video streaming, as well as emerging applications with progressively more interwoven human and machine interactions. We will first cover current network features and tools that can be used to measure, monitor and manage the latency of today's networks. We will then describe the next steps to support new Low Latency (LL) services by applying D3.1 features and a LL service differentiation framework. To support the LLD (Low Latency DOCSIS) features, traffic classification and monitoring must be redesigned and inherent rules may need to be replaced. Lastly, we will provide guidelines to deliver low latency services with the most efficient and future-proof investments.

2. Low Latency Services and Requirements

Not only do we experience continuous technological advancements and breakthroughs but we also observe faster democratization of technologies. Improved products and user experiences on interactive real-time services, IoT and sensor-based systems with big data learning, immersive applications, and autonomous systems altered the landscape of network traffic as consumers have easier access to these products and services. Mass production, digitization, software-defined, virtualized and cloud-based systems with open source software, platform models with partners and co-innovators have been key in the democratization of these technologies and building blocks of digital native companies. Legacy companies cannot survive if legacy chains are not broken for a digital transformation to meet the consumers' demands. Consumers are so immersed in the new technologies that they expect good quality, and nothing infuriates them more than if they don't work [1]. A technology that doesn't work for a consumer means bad Quality of Experience (QoE) [2].

Cable operators continue increasing connectivity speeds to improve the QoE of their subscribers through a series of new technologies and deployments, such as widening the upstream path via mid-split and high-split spectrum, and applying Full Duplex (FDX) architectures and distributed access networks. Speed as a performance metric has been regularly measured by MSOs, but speed is only one of the performance indicators. Different services and applications require different levels of Quality of Service (QoS) metrics, such as speed, latency, jitter, packet loss, reliability and security. Recently, many specifications and standardization documents from various networking technology organizations have been updated to include new traffic categories and QoS levels. Latency and latency variation (jitter) definitions and measurements are not as unified and standardized as speed (throughput) and packet loss. In the following sections, we will describe latency and jitter metrics that ISPs should monitor and improve for low latency services and thresholds, as defined in various standards and specifications.

2.1. Low Latency Services

For an efficient and future-proof design, cable operators must have a solid understanding of current and emerging services with reliable traffic forecasting. However, as we have seen during the pandemic, traffic forecasting and emerging services may not be always foreseeable. Therefore, it is crucial to design an agile system that can adapt to the changes faster and establish an accurate assessment of consumers' new QoE factors. Below we define the key points for current and emerging low latency services.

Real-time Gaming: Gaming lag means a delay between pressing a command button and the game responding on-screen. Network latency is one of the sources of gaming lag. Gamers are particularly sensitive to latency performance (a.k.a. jitter) when competing in multi-player online games, such as *League of Legends*, *Rocket League,* and *Fortnite*. A common complaint from gamers about latency is that the connection "lags out" during gameplay; even millisecond-level differences can make an impact for players competing in multiplayer online games. Latency variation (jitter) that lag-compensation algorithms cannot mitigate may reduce the gamer's QoE significantly. Additionally, the time difference of responses received by different multi-players causes unfairness [4]. Many game applications monitor and report measured latency and jitter, as shown in Figure 1, where players can compare the gaming performance to monitored latency.

Figure 1 – Ping Reports on the Gaming App

Cloud Gaming: Gamers send commands from a mobile device to cloud gaming platforms that execute those commands and then stream the results back to the gamer [6]. Network latency and jitter in the downstream affect the streaming and chat quality and while latency and jitter in the upstream affect the user input reception time and chat quality. Overall, high latency and jitter cause lag during play, choppy audio, poor video and distorted chat.

VideoConferencing: As more people have been working or studying from home, the quality of video and audio conferencing became essential in everyday life. High latency and jitter cause time lags, loss of lip synchronization and choppy or frozen video and audio [4]. Media and file sharing time can be also affected if the network quality is low.

Real-time interactive video streaming: While buffered streaming can be affected by high latency and jitter, the requirements for real-time interactive video streaming are stricter [3]. Services such as sports

betting, watch parties, shopping and synchronized second screen depend on an end-to-end platform with ultra-low latency and jitter. High latency and jitter can cause a subscriber to miss the hard cut-off times to place a bet before a game or a shopping window time. It can also cause spoiler issues during watch parties [8].

New services with web browsing are also sensitive to latencies on the order of hundreds of milliseconds [5]. Other emerging low latency services such as Holographic Type Communications, Multi-Sense Networks, Time Engineered Applications and Critical Infrastructure Services exposed several deficiencies in current network technologies that need to be addressed for future-proof deployments. [7]

2.1. Latency and Jitter Definition

Network latency (delay) is defined as the total time it takes for a data packet to travel between two networking points. One-way latency is the time required for a packet of data to travel from the sender to the receiver while Round trip time (RTT) is the time required for a packet of data to travel from the sender to the receiver and back again [5].

Network jitter or latency/delay variation refers to variation in the latency of arriving packets over time. Inter packet delay variation is the difference in latency of each received packet as compared to the previously received packet, while packet delay variation is the difference in latency of each received packet as compared to one reference value such as minimum or average latency [5].

The QoE depends on the end-to-end network latency and jitter while each network hop can be monitored and managed as discussed in [2].

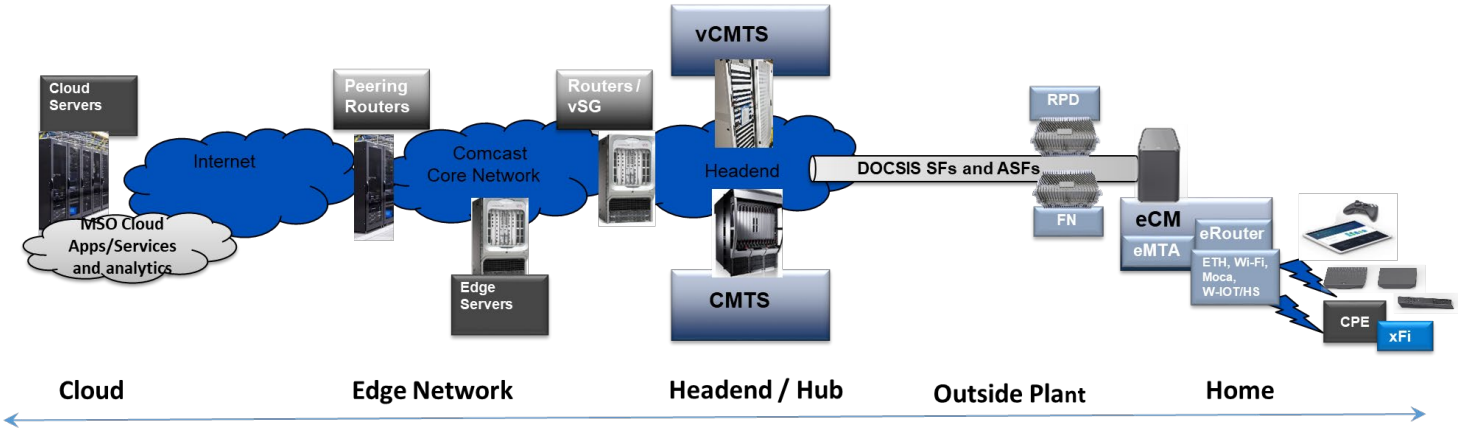

Figure 2 – Cable Network Segments

The low latency services in Section 2.1 require consistent latency, hence well-bounded jitter levels. It is important to assess the worst-case latency in the network while other latency and jitter measurements can help to analyze the latency sources and components. **Idle latency** measures responsiveness when a network connection is unused. It is mostly correlated to access network and distance of the path (round

trip time) e.g. fiber vs. Hybrid fiber-coaxial (HFC) vs. satellite. Many wireline network differences are insignificant. **Working latency (a.k.a. latency under load)** is the real-world measure of responsiveness when a network connection is actively used. Responsiveness of real-time applications during moderate usage of a network connection, whether upstream or downstream. When it gets really bad, it is often called “Buffer Bloat.”, e.g. when gaming or video conference is interrupted by large file download or many devices in homes. The worst-case latency can be measured by the maximum allowed load (e.g. speed tier rate).

A common property of low latency services is that packets are useless when they are received with latency higher than an acceptable level. Therefore, they benefit from fast transmissions over shallow queues. This traffic type is called **non-queue building traffic (NQB)**. They do not benefit from increasingly consuming resources beyond need. They perform well in idle network conditions and good link quality, but with larger queues or dynamic movement between Idle Latency and Working Latency QoE can be variable without the right technology [9].

On the other hand, large down/uploads, buffered video streaming, speed tests, email, etc. rely on protocols that fairly use as much of the network capacity as possible to transfer the data at a high rate. This traffic type is called **queue building traffic (QB)**. The applications often open many TCP sessions in parallel and they are not latency sensitive. When these applications traffic is present on the network, latency is Working Latency. Small network queues lower latency but can make high speed QB traffic not hit peak rates without the right technology.

An overview of QB and NQB traffic is displayed in Figure 3 [9]. Real-time gaming control data and some audio/videoconferencing data are low-data-rate NQB traffic while cloud gaming streaming, real-time streaming and some videoconferencing applications are being implemented by developing new scalable congestion control algorithms (e.g. defined in [9]) to conform to high-date-rate NQB traffic type.

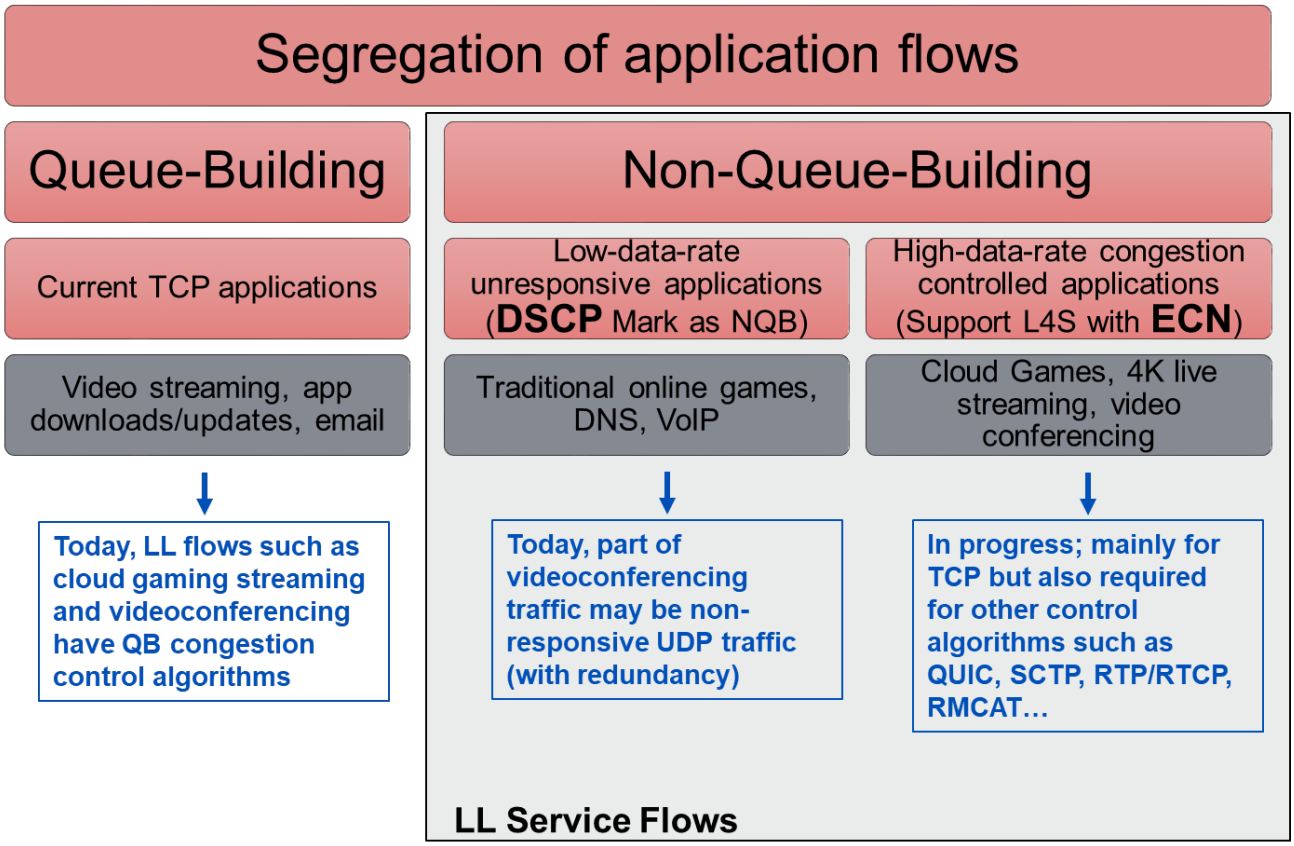

Figure 3 – QB vs NQB traffic

2.2. QoS requirements for Low Latency Services

DOCSIS 3.1 Specifications and Standards

DOCSIS 3.1 specifications include Low Latency Services support based on the coupled dual queue and proactive grant scheduling algorithms. The current target sets for applications such as real-time and cloud gaming and videoconferencing are <10ms RTT between the Cable Modem Termination System (CMTS) and Cable Modem (CM) for 99th percentile of packets. 1ms RTT can be achieved with proactive grant scheduling with the tradeoff of efficiency based on the currently available solutions. More details on the D3.1 low latency services support are provided in Section 4.1.

IEEE 802.11 Specifications and Standards

Time Sensitive Network support in 802.11 includes bounded 802.1Q traffic classification and stream reservation, low latency capabilities with 802.1Qbv over 802.11, scheduled operation with 802.11ax and 802.11be low latency channel access enhancements. Lower worst-case latency and jitter is a key feature for Wi-Fi 7 with multi-link and multi-AP operation and wider channels [10].

In [4], latency, jitter and packet loss requirements are proposed for several low latency services for the Wi-Fi networks (Table 1). Latency is defined as the RTT between the station (STA) and Access Point (AP), and jitter is defined as the standard deviation of latency. Since worst case latency is a key issue for these services, the definitions are based on the latency spikes that can also cause packet loss when certain

thresholds are exceeded, hence causing lagging and other issues. The document suggests new areas for further enhancement. Potential enhancements and new capabilities to address requirements of emerging real-time applications that can be grouped in the following categories:

Table 1 – Requirements Metrics of RTA Use Cases

Use cases		**Intra BSS latency/ms**	**Jitter variance/ ms**	**Packet loss**	**Data rate/ Mbps**
Real-time gaming		< 5	< 2	< 0.1 %	< 1
Cloud gaming		< 10	< 2	Near-lossless	< 0.1 (Reverse link) > 5 (Forward link)
Real-time video		< 3 ~ 10	< 1~ 2.5	Near-lossless	100 ~ 28,000
Robotics and industrial automation	Equipment control	< 1 ~ 10	< 0.2~2	Near-lossless	< 1
	Human safety	< 1~ 10	< 0.2 ~ 2	Near-lossless	< 1
	Haptic technology	<1~5	<0.2~2	Lossless	<1
	Drone control	<100	<10	Lossless	<1 >100 with video

3GPP Specifications

Technical specifications produced by the 3rd Generation Partnership Project (3GPP) and adopted by regional standards organizations use QoS class identifier (QCI) as a reference to a specific packet forwarding behavior (e.g. packet loss rate, packet delay budget) to be provided to a service data flow [3]. A subset of QCIs with a one-to-one mapping of standardized QCI values to standardized characteristics is shown in Table 2 for guaranteed and non-guaranteed bitrate resources (G/Non-GBR). A standardized QCI and corresponding characteristics are independent of the user's current access (3GPP or Non-3GPP). The characteristics describe the packet forwarding treatment that a service data flow aggregate receives edge-to-edge between the UE and the Policy and Charging Enforcement Function / Packet Data Network (PCEF/PDN) Gateway that is the interconnect point to the external network backbone.

Table 2 - A subset of 3GPP QoS Class Identifiers

QCI	Resource Type	Priority Level	Packet Delay Budget	Packet Error Loss Rate	Example Services
1	GBR	2	100 ms	10^{-2}	Conversational Voice
2		4	150 ms	10^{-3}	Conversational Video (Live Streaming)
3		3	50 ms	10^{-3}	Real Time Gaming, V2X messages Electricity distribution - medium voltage Process automation - monitoring
4		5	300 ms	10^{-6}	Non-Conversational Video (Buffered Streaming)
67		1.5	100 ms	10^{-3}	Mission Critical Video user plane
5	Non-GBR	1	100 ms	10^{-6}	IMS Signalling
6		6	300 ms	10^{-6}	Video (Buffered Streaming) TCP-based (e.g., www, e-mail, chat, ftp, p2p file sharing, progressive video, etc.)
7		7	100 ms	10^{-3}	Voice, Video (Live Streaming) Interactive Gaming
8		8	300 ms	10^{-6}	Video (Buffered Streaming) TCP-based (e.g., www, e-mail, chat, ftp, p2p file sharing, progressive video, etc.)

For instance, real-time gaming can be supported optimally if end-to-end latency is <60ms as working latency while <100ms latency can provide a good QoE [5, 6]. If Wi-Fi and DOCSIS networks can provide 15-20ms working latency as described above, 45-85ms latency can be allocated for the network segments outside of the ISP domain, encoding/decoding, rendering and/or cloud computing.

3. Current Latency Measurement, Monitoring and Management in the DOCSIS Networks

As discussed in a technical paper published at the 2020 SCTE Expo, and written by many of the same authors as this year's contribution [2], current DOCSIS features such as buffer control, Active Queue Management (AQM) along with better scheduling and efficiency implementations can help to reduce working latency and jitter for all High Speed Data services. Additionally, increasing speed tier rates through upcoming Mid-Split, High-Split and FDX technologies will help to improve the QoS support. However, these advancements alone are not adequate to provide bounded low jitter aimed for low latency services. QB applications can increase their traffic rates as speed tier rates increase and still cause high latency and jitter for NQBQ traffic. On the other hand, most NQB services do not require high speed, and network cost and operations can benefit from latency and jitter improvements to provide only the required

resources to each traffic type. To achieve better QoE for all services while creating an efficient and cost-effective network resource management, Cable Operators must have accurate and manageable latency measurement and monitoring tools.

We have been deploying with optimal configurations both D3.1 US AQM and DS AQM in our networks. The initial results have been captured in our 2020 latency paper [2]. Our internal measurement techniques for working latency (LUL) are similar to Samknows LUL data that is available as part of the FCC's Measuring Broadband (MBA) database [13]. We analyzed DS LUL results using FCC MBA data before and after our optimization. As displayed in Figure 4, DS working latency/LUL has been improved after optimal AQM deployments, which we were able to monitor and manage using our own platform.

As we extended our latency management platform, we optimized some of our methods and tools as we learned more with each deployment. In the following sections, we describe several parts of our platform by emphasizing key points that may be useful for other operators considering their latency strategies.

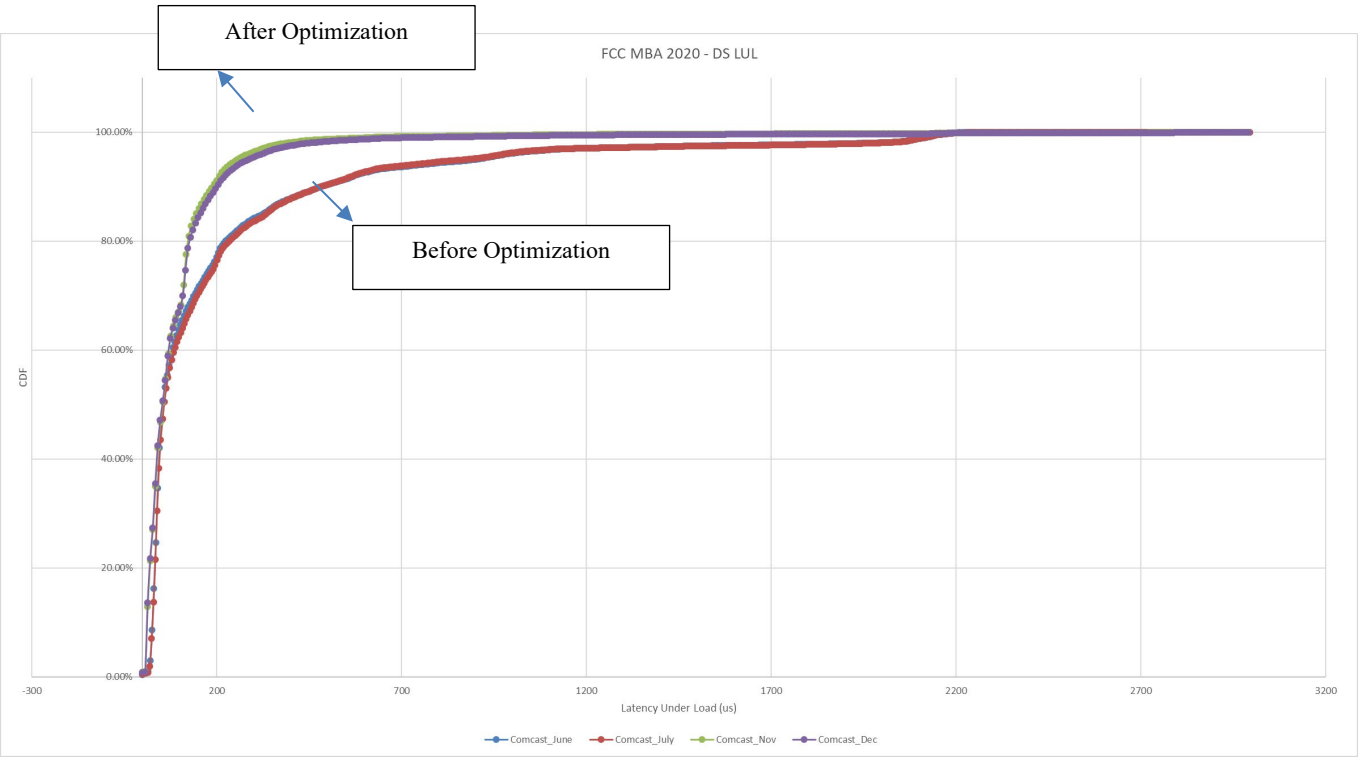

Figure 4 – FCC MBA 2020- Comcast LUL Results

3.1. Latency Measurement

As network operators focus more on the latency portion of the Quality of Experience, the challenge becomes how to measure the latency mitigation techniques being deployed on the network. Historically, the Internet Control Message Protocol (ICMP, RFC 792) has been used to perform a network layer latency check between two network endpoints. The limitation of ICMP is that it is a network layer check. Ideally, the latency check would be included as part of the application layer. Since that layer is predominantly outside the scope of the network operator, an alternate approach is to conduct the latency measurement at the transport layer. Further, most ICMP latency measurements are conducted in a

standalone instance, whereas the typical latency that impacts the customer QoE occurs while other users are accessing the network concurrently. Idle latency through ICMP pings can provide limited information.

Comcast has developed the Internet Measurement Platform (IMP) which provides a platform for measuring throughput and latency concurrently. Adapting the model used in other open source network measurement tools like Flent (https://flent.org), Comcast's IMP conducts both an "idle" latency measurement, meaning no other concurrent traffic from the test user, and a "latency under load (LUL)" measurement, meaning a latency measurement at the same time a throughput measurement is conducted, where the throughput measurement is trying to maximize its data consumption. Comparing the idle latency vs working latency (latency under load) measurements enables a clearer picture of the effectiveness of a deployed latency mitigation technique.

This new platform is implemented with an embedded agent on cable modems based on the Reference Design Kit/Broadband. The IMP agent interacts with the IMP control servers to process test requests using the specific IMP data plane test servers. The results are reported back from the client & server. By launching the tests from within the modem itself, the network operator is able to measure as closely as possible to the in-home devices that utilize the Internet service.

The idle latency portion of the measurement uses an HTTP CURL request / response, which uses TCP as its transport protocol. The latency under load portion of the measurement uses Netperf's request / response test, which uses UDP as its transport protocol. The throughput portion of the measurement uses the Iperf3 open source measurement tool, which uses TCP as its transport protocol. Both measurements are run concurrently. The TCP based data transfer will attempt to maximize its throughput up to the available provisioned capacity, potentially filling up node buffers along the network path while the UDP based request / response will attempt to complete its transaction competing against the load from the throughput measurement. In this fashion, the test is simulating the user's in-home experience where one user may be conducting a bulk data transfer (e.g. large file photo downloads) while another user is trying to complete quick request / responses (e.g. real-time gaming).

The latency reports can include min, mean, max, 50%, 75%, 95% and 99% and standard deviation values. Packet loss can be estimated by monitoring the successful transactions. Methods such as iRTT can be extended for more accurate packet loss and latency values, depending on an efficient implementation that can be supported by limited resources in the gateways.

The IMP platform has been audited by NetForecast, a 3rd party who independently reviewed the test results generated by the platform https://www.netforecast.com/netforecast-design-audit-report-of-comcasts-network-performance-measurement-system/

The IMP platform is currently in use on Comcast's production network, providing a comprehensive data set of latency measurements. Future enhancements to the platform include:

- Measuring the impact of different TCP congestion control algorithms
- As QUIC protocols are widely used, implementing UDP based data loading for speed test and working latency measurements
- Marking test data to measure latency for different services, such as low latency HSD flows.
- Exploring various control protocols to standardize test requests & results reporting

In addition to ping and working latency/LUL, there are other latency options that can be explored by the Cable Operators [5] such as actual customer traffic latency by monitoring TCP connections [2], monitoring queuing latency at DOCSIS with new D3.1 latency histogram recordings and Wi-Fi queuing metrics and two-way active measurement techniques.

The Two-Way Active Measurement Protocol (TWAMP), specified by IETF RFC 5357, provides a common protocol for measuring two-way or round-trip measurement between network devices. Today many routers used in Cable Operators' core network and CIN have TWAMP measurements capabilities. These capabilities may be extended to cover DOCSIS and other access networks and home networks as well [5]. The extensions can enable end-to-end latency profiling for QoE assessment of low latency services. A simplified version called Simple Two-way Active Measurement Protocol (STAMP) by IETF RFC 8762 can be used for one-way and round-trip latency, jitter and packet loss metrics.

As we measure the speed and latency for higher speeds, we see the shortcomings of certain measurement techniques. For example, when we measure symmetric 1Gbps DOCSIS network speed and latency for High-Split architectures, current TCP algorithms are not adequate. One key issue is that optimal test parameters that measure the speed tier vs working latency are not the same, depending on the protocol used for data load. Concurrent TCP flows may fill up the pipe but not the available buffer depending on the test parameters. When the goal is to measure the speed and working latency accurately and during a short time interval, other measurement options such as using UDP may be more efficient [11]. Cable operators can try these techniques by using Odroids connected to HS CMs as open source implementations (e.g. https://github.com/BroadbandForum/obudpst) are available before integrating them to their gateways for automated and stand-alone measurement capabilities.

3.1. Latency Visualization and Dashboarding

Visualization has always been a challenge for data. Of course, there are stated rules to follow also known as the graphic continuum. The challenge comes in telling a specific story that the data outlines in a readable form for the audience. Many can often make a scatter plot, bar chart, line chart etc., but readability becomes the challenge. Does your audience understand the story you portray?

For example, Figure 5 and Figure 6 can be used effectively to explain the difference between idle and working latency, to assess the best CM model and configuration for certain services. It is clear from the latency visualizations that, although idle latency performance does not vary significantly among the CM models, working latency is very different depending on the model and configuration. These visualizations can be used to compare the measured latency levels with the requirements given in Section 2.2.

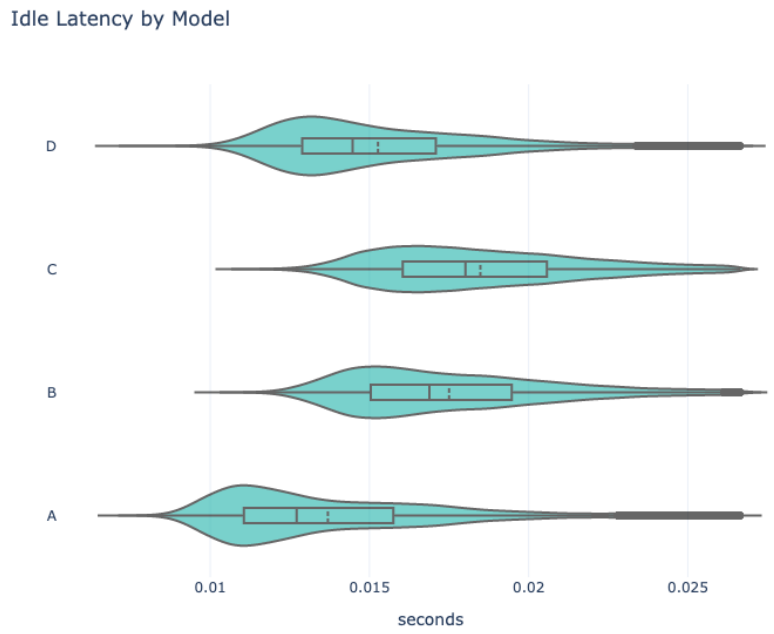

Figure 5 – US Idle Latency

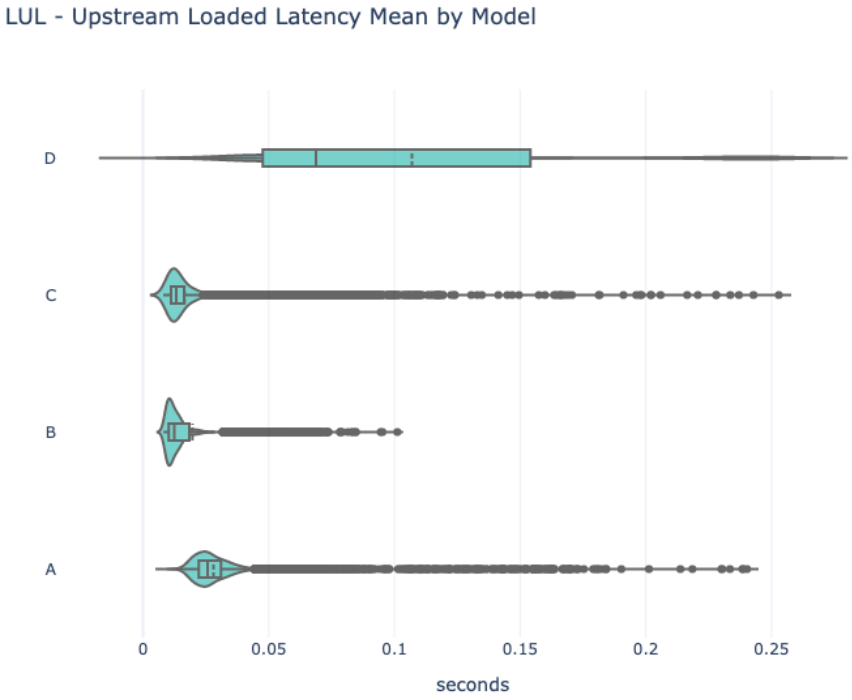

Figure 6 – US Working Latency (LUL)

Latency measurements over time as shown in Figure 7 can be used to monitor the latency improvements of a certain model that may have new FW or configurations, or of a new model that is deployed recently. Figure 8 is another example for DS working latency monitoring over time where new configurations are deployed to achieve a common improved latency range for all models.

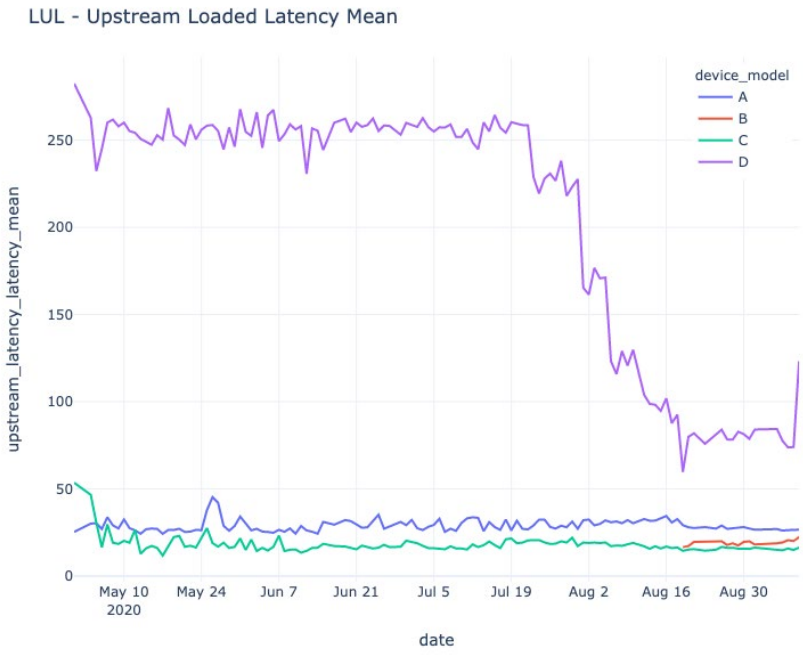

Figure 7 – US Working Latency (LUL) over time

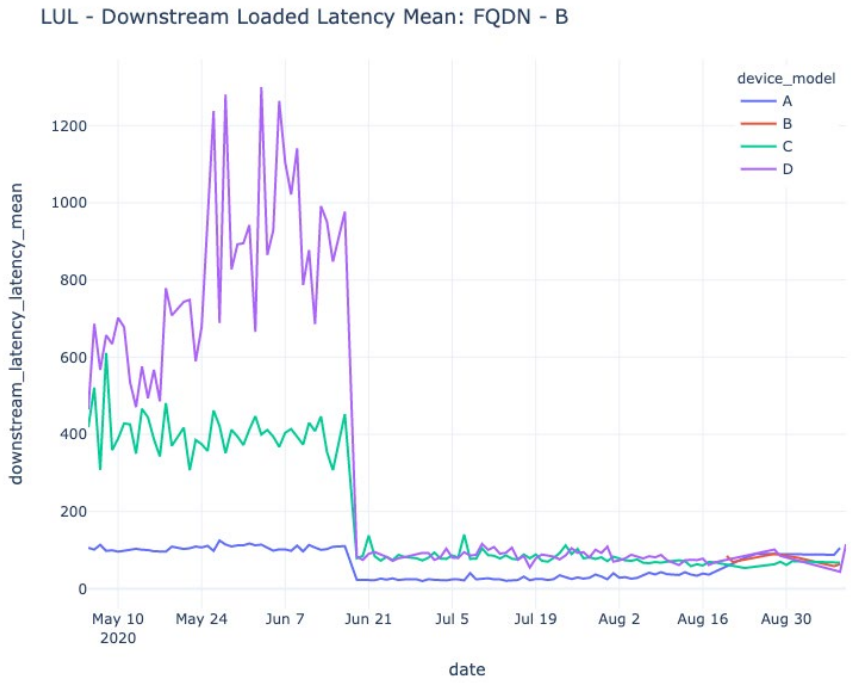

Figure 8 – DS Working Latency (LUL) over time

These initial visualizations are then used to create dashboards for continuous latency monitoring and management.

3.1.1. Current dashboards and data analysis

Figure 9 is an "executive" view of the latency data. Understanding your audience is what helped to shape the data into this view. The dashboard went through many iterations before becoming the high-level view shown above. The data shown is an aggregation of millions of rows of data that are processed daily. Breaking down the data with simplified thresholds allows an easy look into the performance. This also allows the end user to see spikes, anomalies, and trends from the data. This does not allow for a deep dive into the data and isolation of specific problems.

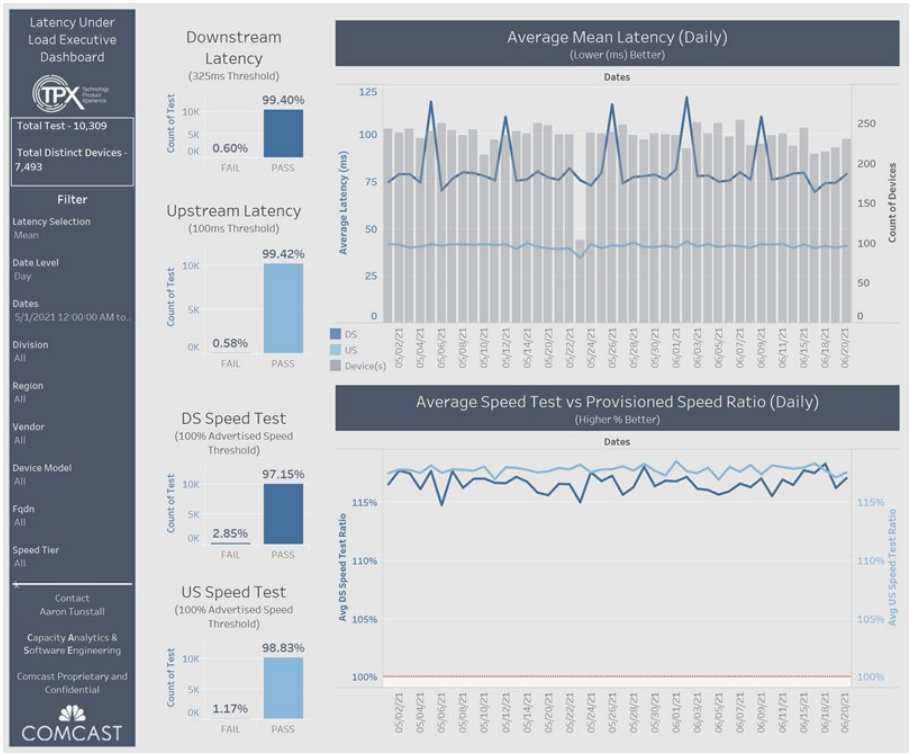

Figure 9 – Executive Dashboard for Latency & Speed test

To enable a more granular view of the performance we created a detailed version of the dashboard (shown in Figure 10). This version was the main source of truth for identifying latency performance and outliers. Each portion of the dashboard is interactive and allows the user a plethora of filters and customizations. Most users will never use all the functionalities included in this view, hence the "executive" view is the main view given to customers when they first load the dashboard. The main issue with data, especially latency, is that you have to balance what is readily available so all customers' needs are met and a proper analysis can be obtained.

Figure 10 – Latency Detailed Dashboard

3.2. Latency Management

3.2.1. Monitoring Latency

It is important to have a smart Business Intelligence (BI) tool when monitoring data. It must be dynamic enough to allow easy understanding and manipulation of the data. For latency we decided to use Tableau dashboards as they allow easy filtering and customization of views. The customer can easily click to change, aggregate or highlight specific data to find outliers and information.

3.2.2. Joint Analysis of latency and speed tests

Once latency data is processed and network configurations are set, the next analysis needed is to see if there are direct correlations between latency and network congestion (utilization). Correlation can be difficult when the measurements of latency can't be directly aligned with metrics that measure network congestion. This makes finding correlations difficult.

The easier method comes with comparing high latency to speed test results. When we compared "failed" speed tests (tests that don't achieve 100% of advertised speed), we found little correlation to high latency. The main reason is that latency is affected by small bursts of delay or packet loss that can be very challenging to detect in a granular way. When the utilization measurements are averaged between long measurement intervals compared to required granularity, the correlation cannot be seen. Therefore, we started a new trial where more granular utilization measurements are implemented to correlate their impact on the speed and latency tests.

3.2.3. Challenges and Guidance

When given the task to analyze data, the main challenge is balancing what is needed and what is not. It is an even harder challenge when you have data and no clear understanding on thresholds. What makes

latency good or bad? What is the expected customer experience? How can we isolate issues and outliers? Initially, when data was received, it was a small sample size and the dashboard was created with that in mind (Figure 11).

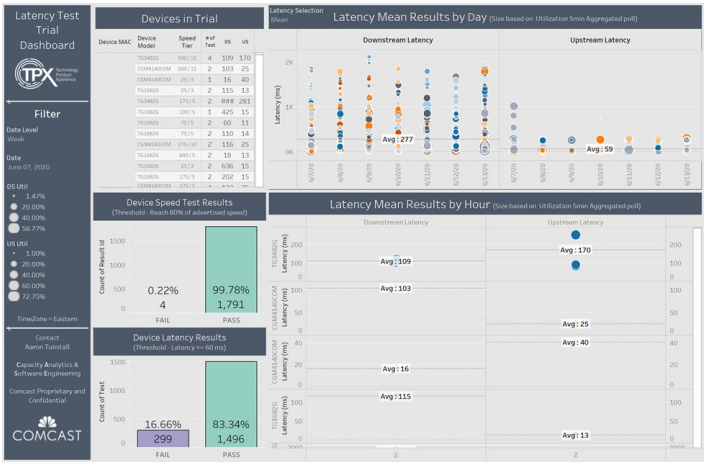

Figure 11 – Original dashboard for latency trial

At this point, there was no real threshold, just a small sample of test device data. We had an understanding that high latency is bad and lower latency is good. As the trial began and the scale of devices increased, the first version of the dashboard had to evolve. We created a detailed dashboard (Figure 10). This allowed a deep dive to analyze latency in multiple aspects. The dashboard showed how CMTS, device model, device firmware, vendor, and speed tier performed. This allowed us to isolate differences between all of the above, and how latency varied for each. The functionality made outlier identification a lot easier. This dashboard served its purpose, but when reporting findings it was not dynamic enough for presentation.

Newer temporary views were created, each to serve a different purpose for our Operations and Testing teams. These views were high-level comparisons of vendors, device types, and more. One of the lessons learned was to understand what your customer needs. This can be difficult when those needs are truly not yet understood. As time progressed, data became more readable, and thresholds started to be defined the needs of the customer become easier to define. What we learned allowed us to create the Executive dashboard (Figure 9) as well as easier views that tell the story the data shows. This allows a high level understanding of the overall customer experience.

In conclusion, data can be difficult to decipher when there is no clear understanding of how to read it. Understanding simple things, like high latency is bad and low latency is good, does not assist with telling the data's story. Sometimes it takes multiple views and analysis to find the needle in the haystack. As a data engineer, you have to understand that your initial idea or understanding may not be the final. Lastly, it is important to transform your data. As the analysis progressed the data sample grew, causing performance issues for customers viewing it. Summarizing data through aggregation is very important to giving the best customer experience when reviewing the data.

Another challenge is the storage, maintenance and query of the available data. We started getting LUL measurements from Elastic search production. The data was downloaded in Json format using Python script and stored it into the SQL server. The real-time data is visualized using Kibana - the data visualization dashboard software (open search dashboard) for Elasticsearch. The data download frequency was daily basis for the previous day. Due to ELK cluster workload maintenance, the LLD data is moved

to our internal streaming data platform, and Kinesis streaming for download [12]. The raw data download frequency is close to real-time. Scalability issues can arise later, as more data is collected and more queries are done by different teams. Therefore, the design must be flexible and extensible.

These large-scale measurement comparisons should provide additional data to justify the future deployment of AQM by ISPs and customer premise equipment manufacturers. This may be of interest to people working on the Low Latency, Low Loss Scalable Throughput (L4S) protocol or other TCP/UDP congestion controls. We believe, there is an opportunity to better standardize/define how working latency is measured. There is a need for open global internet measurement platforms to focus on working latency (or create new platforms & beyond access network segments) and/or sharing of such measurement data.

4. New Low Latency DOCSIS Features and Latency Management

As we discussed briefly in Section 1, broadband has historically differentiated based on download speed, however, customers are increasingly interested in additional characteristics when shopping for broadband. These emerging differentiators include faster upstream speeds, whole home WiFi coverage, and low latency.

Gamers are a large market and for serious gamers, latency influences ISP switching behavior and product selection. Gamers are also heavy streamers and in general, they tend to buy the best product that can support low latency services and high speed streaming. Beyond gamers, customers are generally interested in the concept of "no-lag broadband," suggesting that low latency DOCSIS could resonate with a larger audience. Specifically, broadband users that are employed and/or working from home have higher interest compared to other non-gamers, implying that the employed/work-from-home segment is another group to potentially target.

Enabling low latency DOCSIS would give cable providers an advantage over other ISPs that cannot compete with such consistently low levels of latency under load. Given the interest level in low latency among certain segments, go-to-market approaches could include incorporating low latency features across all internet households (where available), incorporating low latency features in premium speed tiers, or upselling low latency features within a separate premium data product.

To support these business cases, a new architecture that can differentiate low latency services and provide required QoS requirements must be defined and implemented. Although latency and jitter improvements described in Section 3 improve the overall QoE for several services, they are not adequate for current and emerging real-time interactive services.

Low latency will enable the creation of major new classes of applications where delay to local storage is equivalent to delay to a network-based resource. The cable industry is poised to take some leaps ahead of the competition as in the post-gigabit future, latency will be equally important to speed in marketing.

If we apply the same network resources with the same functionalities to each traffic with different QoS requirements (Section 2.2), then we provide equal resources but the outcome, which is the quality of experience, will be very different for each traffic type and unfair. AQM provides equitable performance because some traffic is managed (Figure 12 explains the difference between equality and equity nicely). Both large QB flows and smaller NQB flows perform better. LLD with L4s and dual queue promise even better. Early results show that we can hit the LLD target for working latency. As well, equity increases for all traffic because they are not having to share the same queue. This also helps to make sure that no app/service is harmed while, for example, providing different AQMs to low latency traffic groups because the equal quality of experience score is targeted.

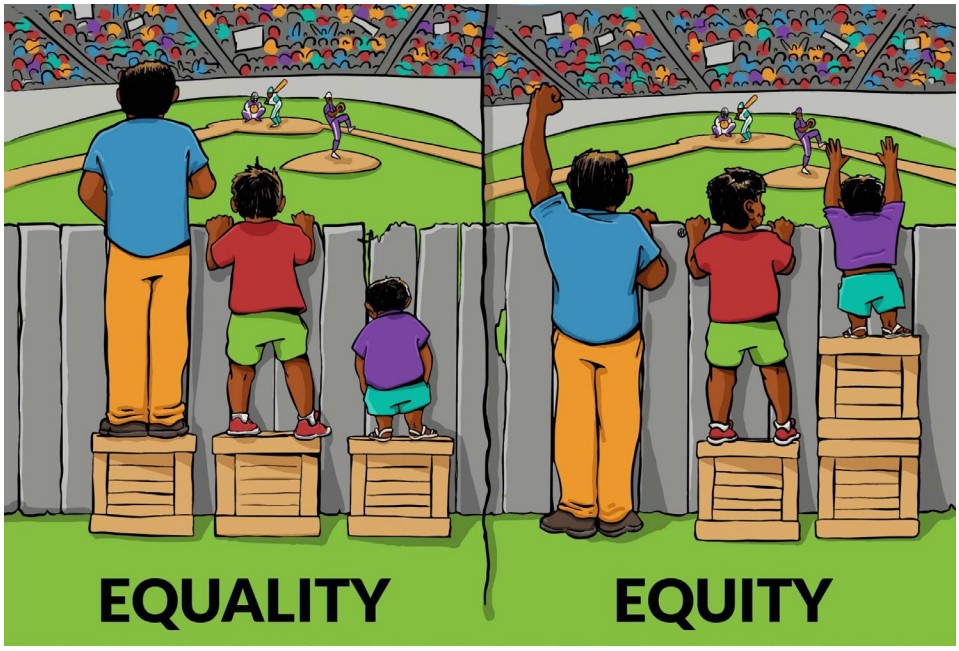

Figure 12 – Equality vs Equity

4.1. D3.1 LLD Features

New D3.1 LLD Dual Queue Features promise <10ms RTT between the CM and CMTS for 99th percentile of LL service packets. The main functionalities are described in Figure 13and Figure 14 [14].

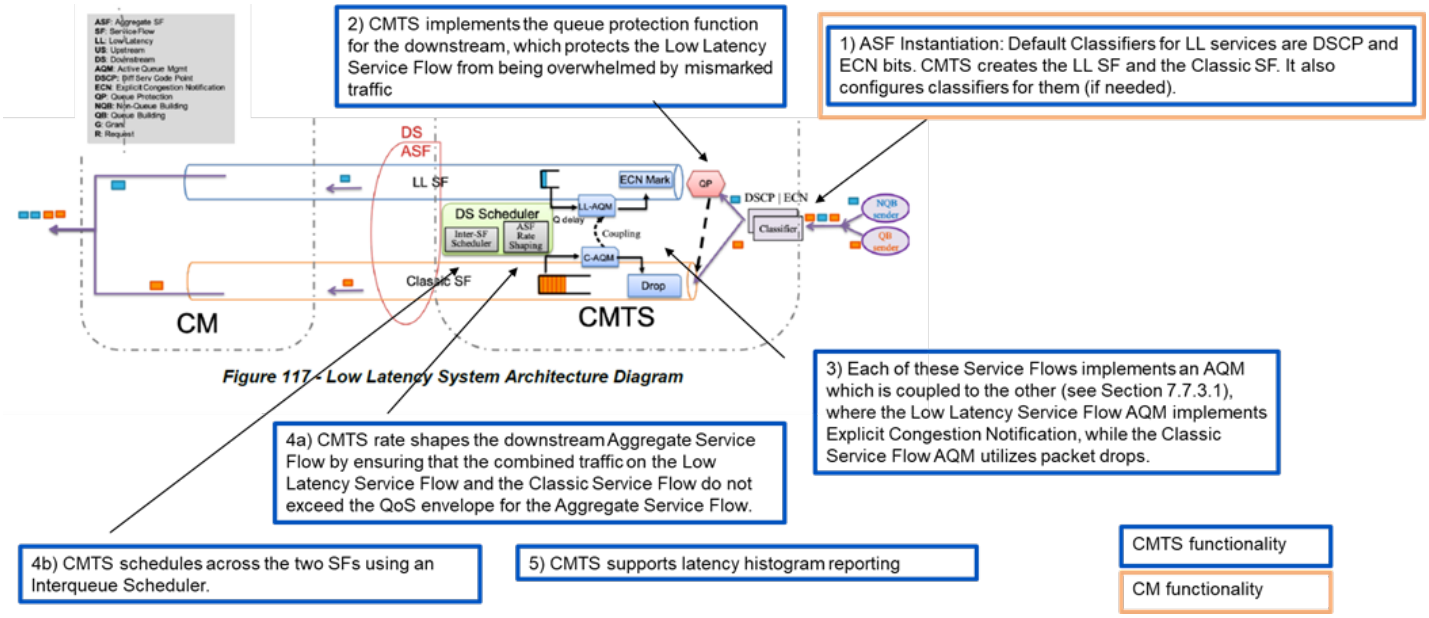

Figure 13 – D3.1 DS LLD Features

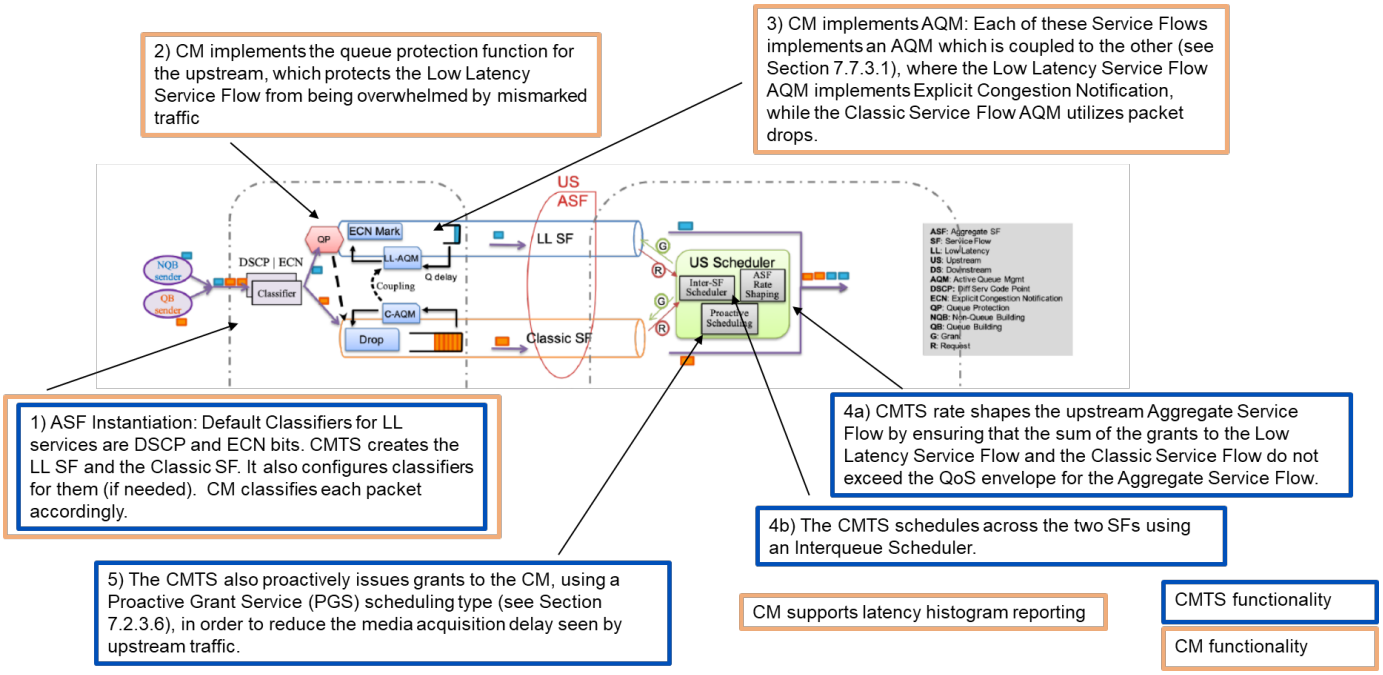

Figure 14 – D3.1 US LLD Features

We collaborate with Cablelabs closely for the new LLD features. The dual queue approach will enable us to support the latency and jitter requirements described in Section 2.2 for low latency services. In this section, we present an example scenario tested by Cablelabs[1] with dual queue approach and PGS.

Figure 15 shows the results for upstream LLD without PGS, with a mix of TCP upload file transfers as cross traffic. QB and NQB traffic packets are queued to classic and low latency queues respectively. In the latency distribution charts, both the raw latency distribution and the distribution of Inter-Packet Delay Variation are plotted. Latency distribution is plotted with solid lines, IPDV plotted with dot-dash lines. The 99.9th percentile of LL traffic latency is less than 10 ms.

Figure 16 shows upstream LLD with 2Mbps PGS, with the same cross traffic. The 99.9th percentile of LL traffic latency is less than 6 ms. The NQB traffic has different packet sizes while PGS grants for the selected settings are for 250 bytes. Therefore different latency values for different packet sizes are observed in this test.

We can conclude that the current DOCSIS network latency that may be in the order of 100 ms can be decreased to less than 10 ms for 99th percentile of LL service flow packets with the new LLD features.

[1] We would like to thank and acknowledge Greg White from Cablelabs for his LLD tests presented in this paper.

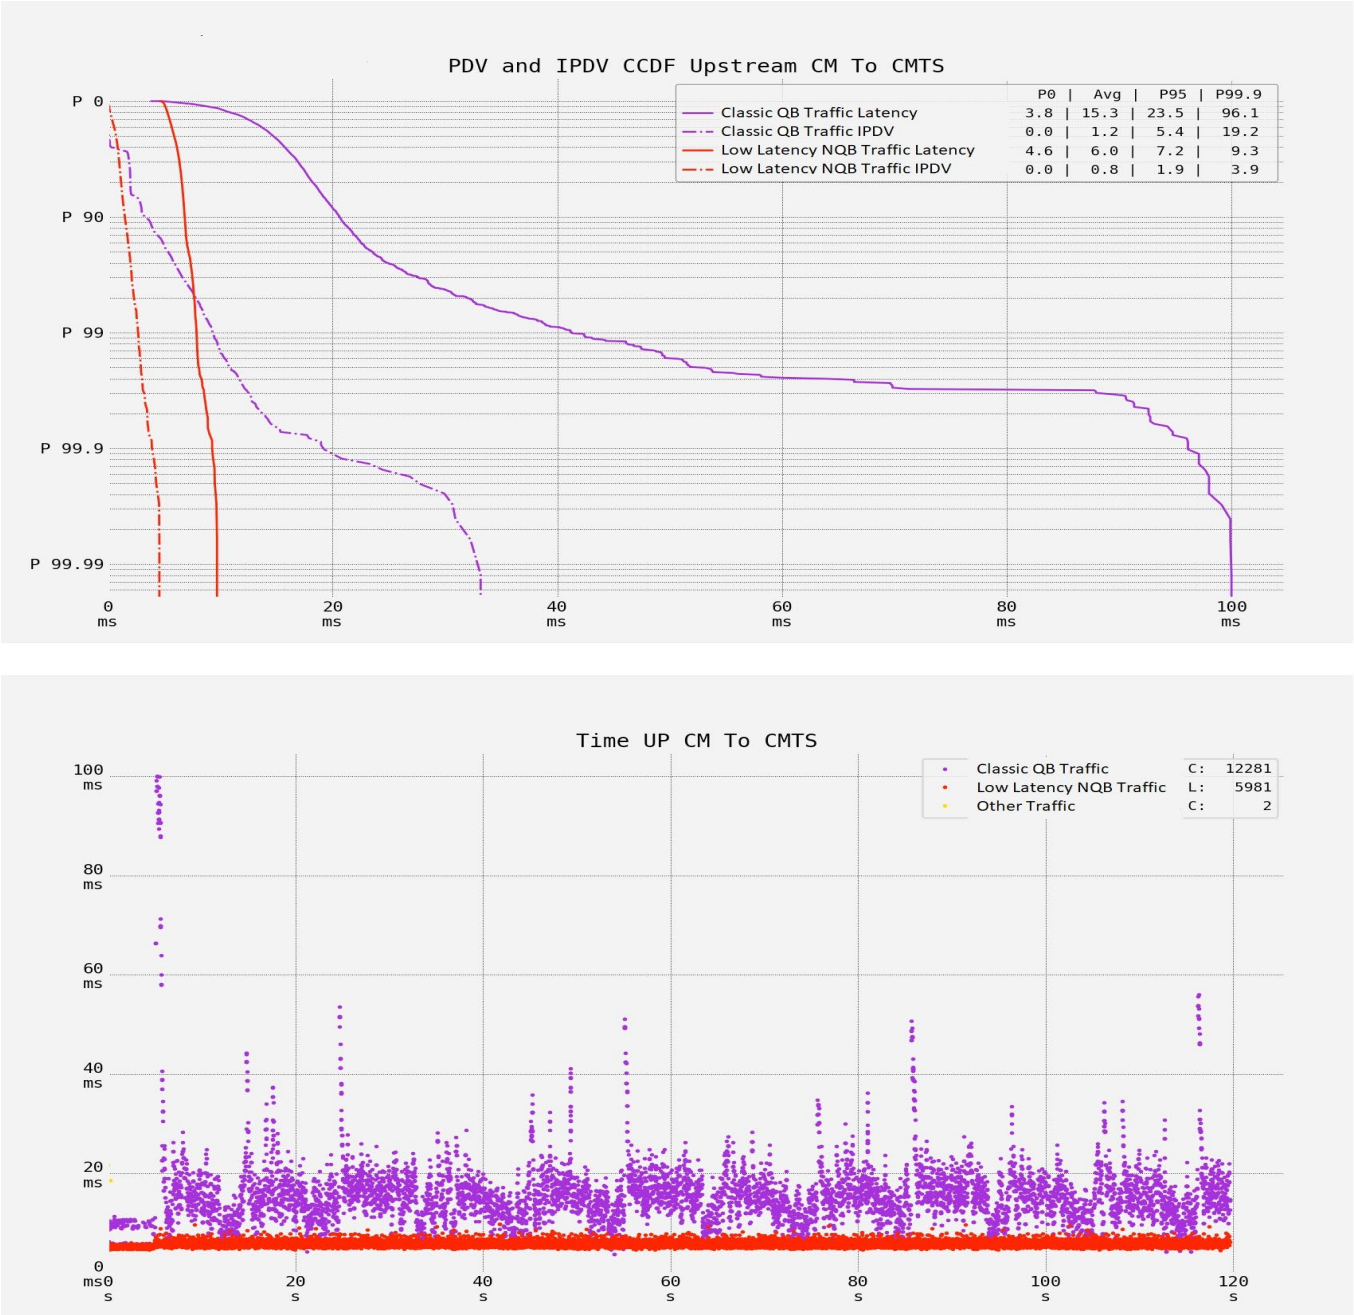

Figure 15 – US LLD With Dual Queue and no PGS

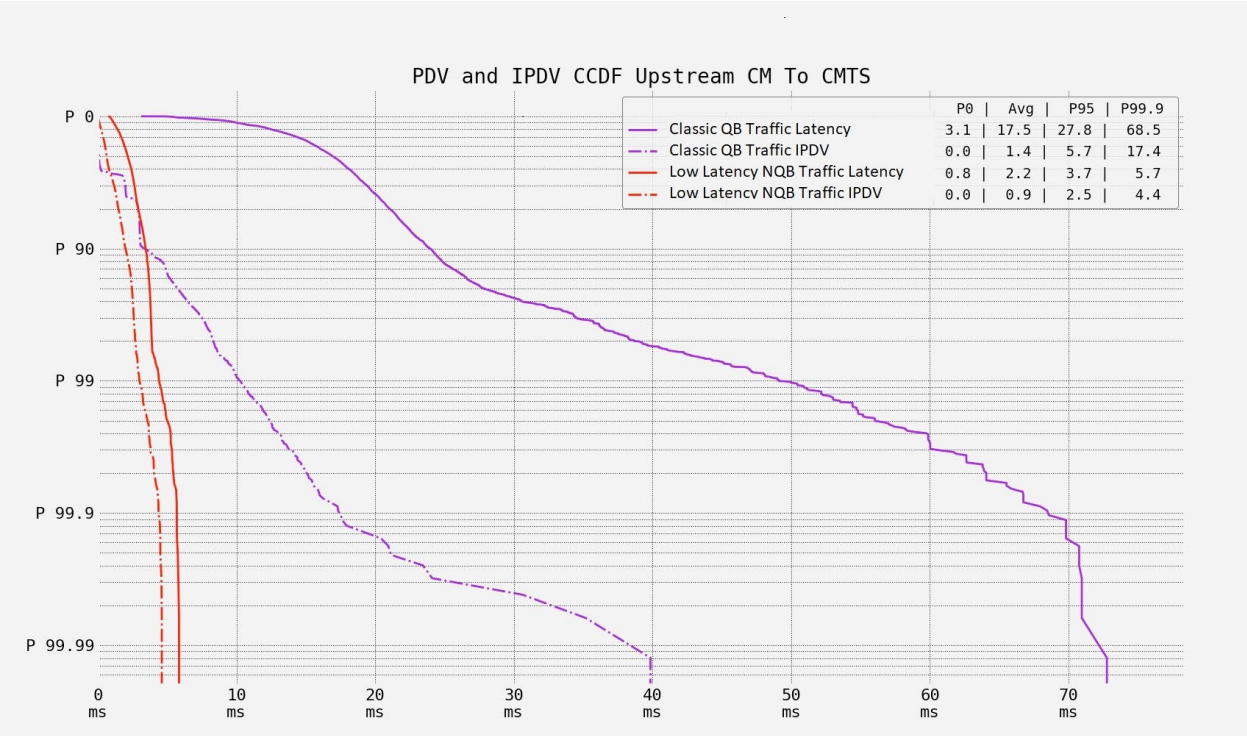

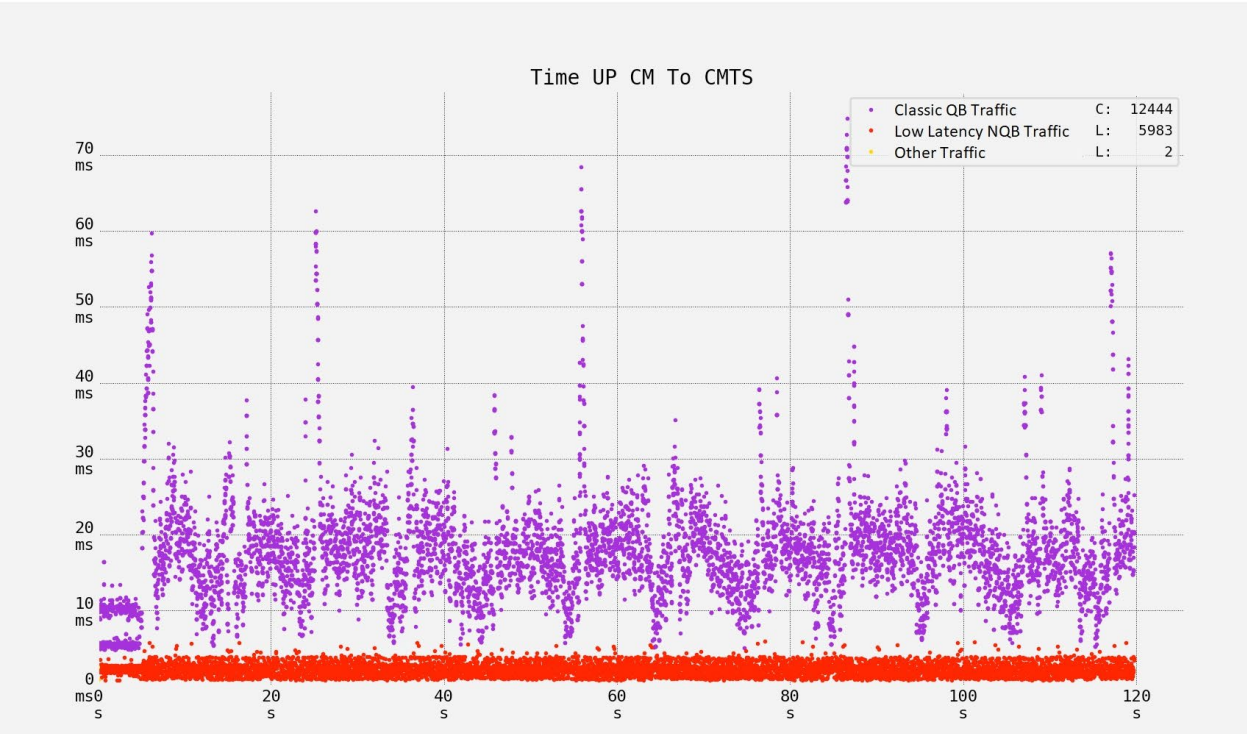

Figure 16 – US LLD With Dual Queue and PGS

These features can be enabled only if Low Latency services are differentiated. Traditionally, Cable Operators do not trust any marking from the user space due to security and operations challenges. The new framework suggests Differentiated Services Code Point (DSCP) marking for low-date-rate NQB traffic and ECN Capable Transport ECT(1) bit marking for high-data-rate NQB L4S traffic (Figure 3 and Figure 17). NQB-DSCP and L4S IETF documents address the challenges of this new framework.

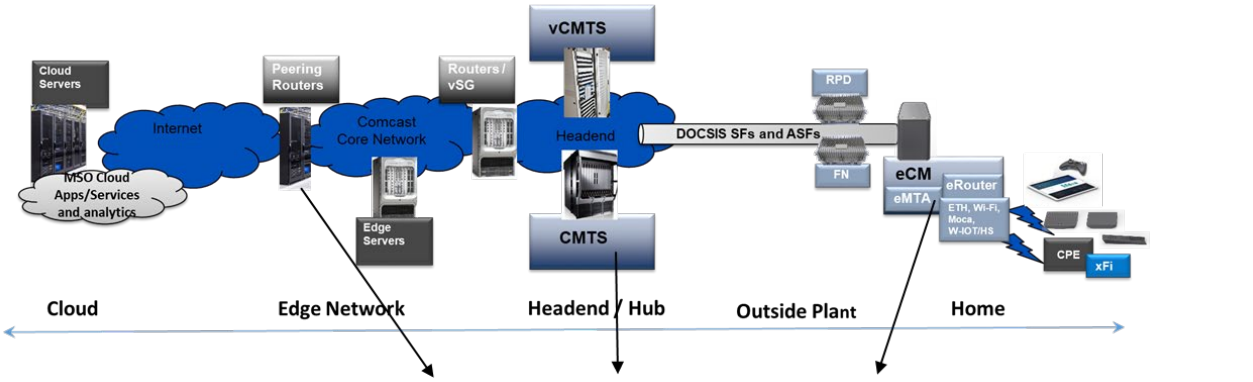

Figure 17 – Marking for LL Services

5. Conclusion

Current latency measurement, monitoring, and management frameworks are fundamental to support the next generation of Low Latency services. These platforms and network architectures must be extended to differentiate LL services to apply D3.1 LLD features, Wi-Fi and Core Network enhancements and to manage their performance. The faster democratization of technologies pushes ISPs to support new services at a faster pace. This can be enabled by achieving three main points within the industry:

1) Better standardize/define how latency, jitter, packet loss and other QoS metrics are measured and create open global internet measurement platforms to focus on end-to-end QoE assessment.
2) Start breaking legacy chains through digitization, software defined, virtualized and cloud based systems with open source software, platform models with partners and co-innovators to meet the consumers' demands in an agile way.
3) Apply an end-to-end approach for traffic differentiation and QoE management with new upcoming 10G technologies.

Abbreviations

AP	Access Point
AQM	Active Queue Management

1. Introduction

Broadband access is an essential utility to connect with each other and the cloud, from the convenience of our homes. Ultimately broadband evolution is about delivering a reliable and affordable user experience at gigabit speeds, but no single access technology can cover all use cases equally well. To connect everyone with the digital world we live in, requires a multi-access broadband strategy that combines an expanding range of wireline and wireless access technologies.

The paper discusses how cable operators may effectively leverage 5G fixed-wireless access (FWA) to complement and enhance their existing wireline broadband offer and deliver a converged multi-access broadband experience everywhere.

2. The case for fixed-wireless broadband access

Cable operators have done a remarkable job extending the life and utility of the existing coaxial access plant to bring the Internet to nearly every home. By pushing fiber ever closer to the home, they were able to speed up data transfer rates from kilobits to megabits per second and do so without breaking the bank. But demand for faster access continues unabated while the cost of extending fiber further to the home is increasingly steep. Fiber-to-the-home is typically the preferred and future safe way to go, but deployment can be costly and time consuming, even for new housing projects. Gradually and inevitably, a faster broadband experience may literally become out of reach for more and more consumers.

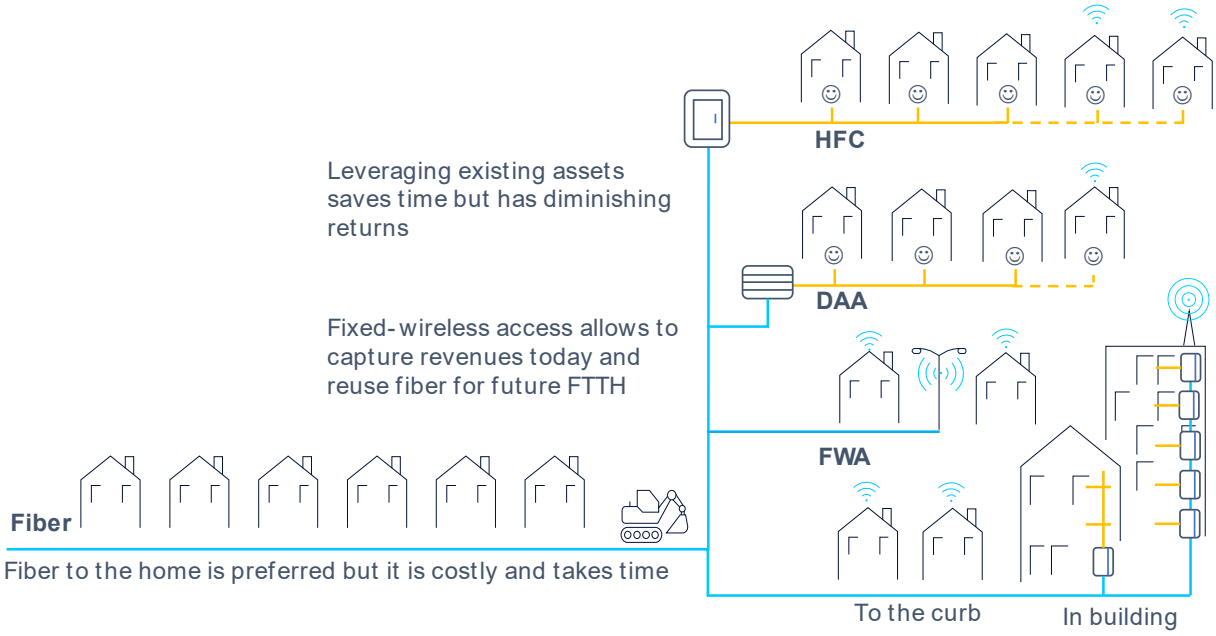

Figure 1. The case for fixed-wireless broadband access

Fixed-wireless access can address these last-mile broadband wireline coverage issues (

Figure 1). LTE/5G radio deployed in the sub 6 GHz frequency bands can rapidly cover large areas with access speeds that can sustain high definition video streaming. Small cells operating at mmWave

frequencies (24 to 39 GHz) can even deliver fiber-grade Gigabit broadband services. Besides licensed spectrum, many regulators have actively engaged to make shared and unlicensed spectrum available in various frequency bands. For example, the US Federal Communications Commission designated spectrum in the 3.5 GHz band for shared use (the "innovation band" of the Citizen's Broadband Radio Service or CBRS).

FWA perfectly complements wireline broadband deployments in the last mile:

- In brownfield it can be used in overlay to address capacity and coverage issues of underserved wireline broadband users.
- In greenfield, FWA can be an effective tactic to get quick service coverage and revenues and potentially support a phased fiber-to-the-home rollout.

The question is how to integrate FWA in a combined multi-access broadband infrastructure to create better cost synergies reduce operational complexity?

3. Multi-access broadband and edge convergence

Convergence in general aims to achieve operational simplification and better economies of scale by consolidating network requirements and pooling resources. The operational goal of fixed and wireless broadband convergence is a seamless and simplified multi-service user experience that is access agnostic. Although broadband consumers typically use only one wireline or wireless access method at a time, another objective is to leverage a common operational infrastructure to manage subscriber access and service policies. Converged operators that also offer mobile broadband services are keen to consolidate all their services on a more agile, cloud-native 5G Core (5GC), and reap the cost and performance synergies of fixed and mobile convergence (FMC).

The ultimate goal is to build an agile and cost optimized network that can deliver a ubiquitous and seamless service experience over any broadband access medium. Figure 2 summarizes the requirements in a multi-access broadband target infrastructure.

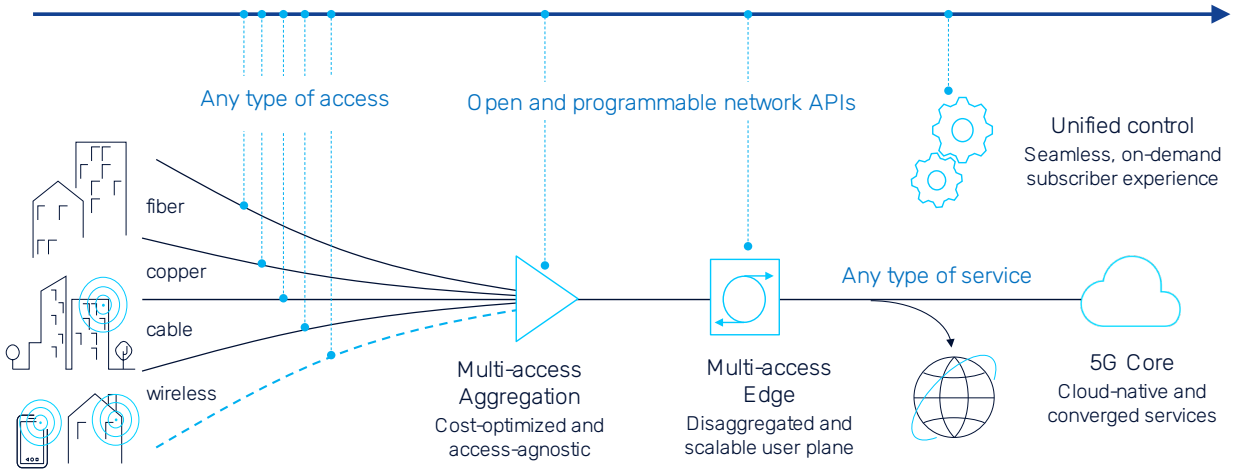

Figure 2. Multi-access broadband target architecture

Because all service traffic has converged on IP, all wireline and wireless broadband traffic can potentially be aggregated over a common multi-access backhaul network. However, current broadband access and aggregation networks may present an obstacle that hinders a smooth transition to this multi-access

broadband architecture. While most operators are moving towards access-agnostic IP/ethernet aggregation layer in the metro and regional network, they often maintain dedicated platforms that accommodate for different access network requirements. The inherent duplication of functions in a heterogenous aggregation network reduces becomes increasingly costly and complex as more access technologies are introduced and evolve in parallel.

Fortunately, the new generation of disaggregated wireline and 5G wireless access solutions enable access-agnostic IP/Ethernet transport aggregation on a converged interconnect network (CIN) by virtualizing technology-specific access network functions and moving them into the distributed edge cloud under a programmable software defined network (SDN) controller. Examples are virtualized converged cable access platform (vCCAP) for distributed access architectures, virtualized optical line terminal (vOLT) for XGS-PON, and virtualized baseband units (vBBU) for the 5G radio access networks.

The second obstacle is a broadband service edge that typically deploys dedicated edge gateways for each access network technology: A CCAP/CMTS for cable access, a Broadband Network Gateway (BNG) for fiber-to-the-home (FTTH) access and a Serving and Packet Data Network gateway (SPGW) for 4G/LTE mobile services. While such divide and conquer edge strategy separates concerns, it also reduces cost synergies while increasing complexity, both at the service edge and in operational back-end systems.

The broadband service edge is a critical network junction where subscribers and service policies are enforced. The inclusion of fixed-wireless access should at least add no further complications, and this is the main subject the rest of the paper will focus on.

4. Fixed-wireless access gateway requirements

A converged fixed-wireless edge can play an important role in delivering affordable, high-performance broadband services to every home. However, wireline and wireless access technologies come from very different worlds, so where does fixed-wireless access fit in? Wireline or wireless?
To answer this question, we must compare their service characteristics (Table 1).

Table 1. Comparing wireless and wireline service characteristics

Requirement	Mobile user	Wireline user
User devices	1 (typically)	>10 per home
Service type	Nomadic	Stationary
Session type	Dynamic	Always-on
Subscription type	Usage based	Unlimited (flat rate)
Monthly data usage	3-5 GB	100s of GB
Average speed	~10 Kilobit/s	~1 Megabit/s
Gateway location	Centralized	Distributed
Gateway functions	Virtualized (x86)	Physical (NPU)

To complement (or compete with!) wireline broadband, fixed-wireless access gateways must support the same residential broadband applications. There are no roaming requirements because all user devices are tethered to a single, stationary home gateway that serves up to a dozen user devices such as TVs, PCs, tablets and gaming consoles. Home broadband services are always on and must sustain high bandwidth usage for multi-cast IPTV and streaming ultra-high definition broadcast TV, binge-watching Netflix, Zoom video conferencing, and downloading software for PCs and game consoles. Sophisticated quality-of-service (QoS) techniques are needed for the delivery of multiple services over the same bearer.

Monthly data usage per home averages several hundreds of Gigabytes that are charged at a monthly flat rate, without usage caps for the highest service tiers.

In contrast, wireless broadband users typically connect a single device (smartphone) with short-lived dynamic user sessions. Although mobile devices can generate significantly more control plane traffic, mobile data volumes are orders of magnitude lower and charged by the Gigabyte. Mobile data rates are comparably high. One month of broadband usage charged at mobile data rates would easily cost a homeowner more than a one year wireline broadband subscription.

As a result of their different usage characteristics, mobile-wireless gateways are polar opposites of the wireline gateways used for residential broadband:

- Wireless gateways are optimized for dynamic, mobile user applications that yield a high revenue per bit. They are typically centralized and virtualized on x86 servers, which allows operators to cost-efficiently pool resources for roaming users and leverage cloud-native compute and storage to support dynamic user sessions with elastic scaling needs. They are not designed nor dimensioned to cost-efficiently support bandwidth-intensive internet or IPTV applications over extended periods of time.
- Wireline gateways are cost-optimized for delivering always-on Gigabit broadband services to homes and businesses. They are typically purpose-built network appliances that leverage custom routing silicon for granular bandwidth management and hierarchical QoS to ensure that available network resources are fairly and optimally shared among subscribers and user devices. Default residential broadband service features such as Internet access and IPTV multicast replication are far more economical to deploy and scale on wireline gateway platforms, compared to Internet offload (LIPA-SIPTO) and IP multicast (eMBMS) on mobile gateways.

In conclusion, the service requirements of fixed-wireless access are very similar to wireline broadband access. Because fixed-wireless access gateways and broadband wireline gateways share most requirements, there are potentially significant operational cost and performance synergies when leveraging the same type of edge platform for both.

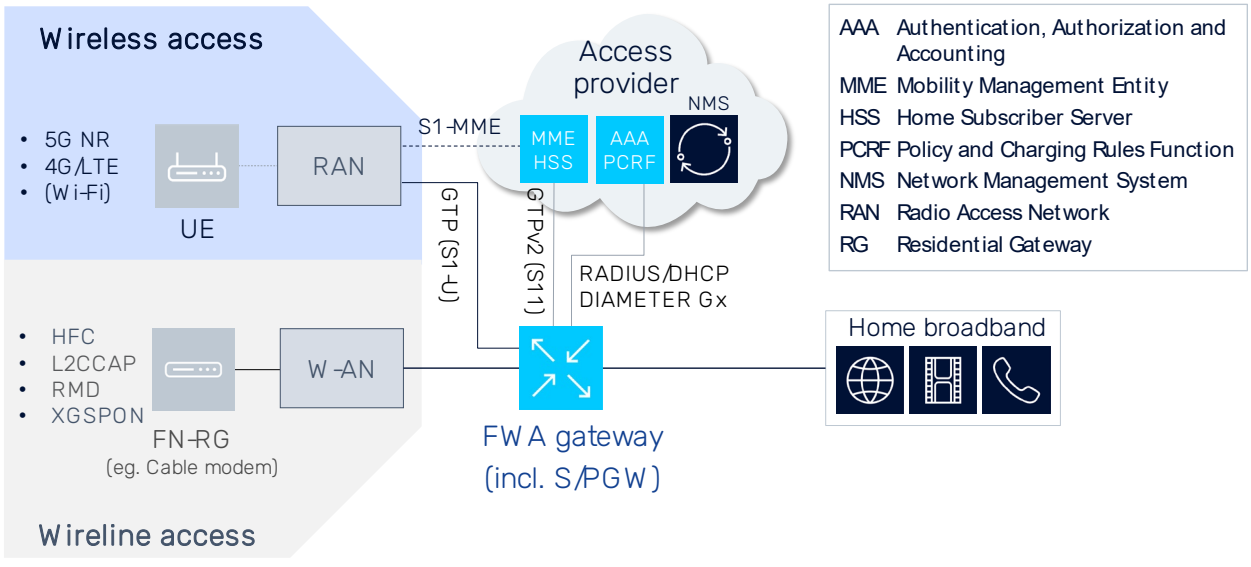

Figure 3. Fixed-wireless broadband access gateway

The addition of a Serving and PDN Gateway (S/PGW) function allows wireline operators to deploy FWA stand-alone or in conjunction with wireline access (see Figure 3). Broadband access providers deploying FWA will chiefly consider using shared, unlicensed or mmWave spectrum because licenses are more affordable. Because user devices are tethered to a stationary home gateway there is no need to provide blanket service coverage from multiple angles to support user roaming and only a subset of the MME and HSS mobility functions are needed to enable X2 handovers between adjacent base stations (eNB, gNB) within the tracking area. This significantly reduces the operational complexity of integrating FWA in a home broadband offer and enables access providers to essentially leverage the same operational backend as used for their existing wireline broadband service.

5. Disaggregated multi-access edge gateway

Converged operators may wish to interwork their wireline and fixed-wireless access services with their 5G packet core to enable fixed-mobile convergence. Most user traffic that is converging on the multi-access edge will originate from wireline broadband users (including 5G mobile users connected to Wi-Fi), followed by fixed-wireless access, and mobile roaming services. IPTV (live and on-demand) and Internet are the largest broadband consumers by far, and this traffic should be offloaded at the multi-access edge to distributed edge caches and peering points. The remaining (mobile) traffic is forwarded to an Evolved Packet Core (LTE and 5G non-standalone) or a 5G core and mainly consists of metered traffic from mobile voice, IMS and roaming data applications.

From an scaling perspective, a multi-access edge gateway needs to make a gymnastic split to combine the need for a distributed, high-performance user plane capable of processing massive data volumes, with the goal of operating a centralized, cloud-native management and control plane that can seamlessly integrate with a 5G Core. Control and User Plane Separation (CUPS) achieves this feat and is the key enabler for the wireline broadband evolution to fixed-wireless and fixed-mobile convergence.

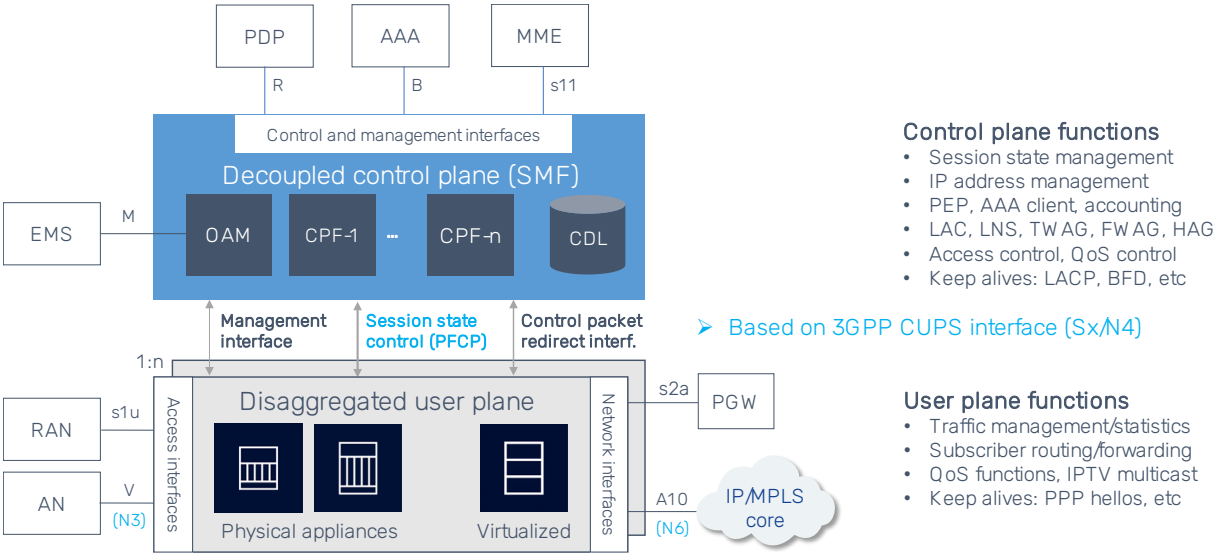

Figure 4. Disaggregated multi-access edge gateway with CUPS

A broad industry cooperation between the 3GPP, Broadband Forum and Cable Labs helped define the necessary standards (e.g., BBF TR-459) for a disaggregated multi-access edge gateway that can fully

integrate with the 5G ecosystem (Figure 4). The standards specify the functional separation of control and user plane functions and the interface protocols to be used for their subsequent interworking. The interworking protocols between the control and user plane are derived from the 3GPP CUPS standards with extensions for use in wireline access networks. They encompass the following:

- Model-driven management APIs allow for centralized management of multiple, distributed user plane functions as a single management entity.
- The Packet Forwarding Control Protocol (PFCP) is used by the control plane to manage subscriber session state. It leverages the 3GPP CUPS specification with wireline extensions.
- The Control Packet Redirect interface enables the User Plane to forward subscriber authentication messages from the CE to the centralized control plane over GTP tunnels.

The control plane (SMF) is typically cloud-native and deployed in a data center. Ideally, it uses a stateless compute model with a Common Data Layer to manage control plane state information. This model allows to easily scale out and load-balance control plane capacity, and quickly recover from failure situations that trigger a reboot of any virtualized control functions.

Control and User Plane Separation (CUPS) offers several operational benefits:
- Efficient operation, through a centralized control plane that can scale out in the cloud, while distributing physical user plane to optimize delivery cost and performance.
- Simplified maintenance, as decoupling control and user plane functions makes it easier to manage their different life cycles and minimizes the impact of hardware and software upgrades.
- Flexible scaling, by allowing control and user plane functions to be deployed on either physical or virtualized platforms and to scale their capacity independently.
- Fixed-mobile convergence and wireline broadband integration with a 5G Core by interfacing the UP via the Sx/N4 interface with a common 3GPP Session Management Function (SMF).

The last two bullets are essential for the evolution to a cost-optimized multi-access edge that seamlessly integrates wireline and wireless access with a 5G core.

6. Wireline and wireless convergence on a 5G Core

Let's now examine the evolution to a multi-access edge that interworks both wireline and fixed-wireless access networks with a 5G core. Although 5G is strongly oriented to new radio technology and mobile service evolution, wireline access networks can be integrated by supporting a set of well-defined 3GPP reference interfaces:

- **N1** between User Equipment (UE) and Access and Mobility Management Function (AMF) to exchange NAS (Non-Access Stratum) messages.
- **N2** between Wireline Access Nodes (W-AN) and AMF based on NGAP (Next Generation Application Part).
- **N3** between W-AN and multi-access User Plane Function (UPF) based on GTP-U (GPRS Tunneling Protocol User Plane).
- **N4** between Session Management Function (SMF) and multi-access UPF to manage data sessions at the user plane based on the Packet Forwarding Control Protocol (PFCP).
- **N6** between multi-access UPF and packet data networks to transport IP and Ethernet packets.

A 5G Access Gateway Function (W-5G-AGF) can be introduced to interwork legacy wireline access platforms that do not natively support the required N1, N2 and N3 reference interfaces (see Cable Labs

specification WR-TR-5WWC-ARCH). Through the W-5G-AGF, both the wireless and wireline access network can then be controlled by the 5G AMF.

The objective of delivering multi-access broadband access with 5G Core interworking is enabled by leveraging a common control plane (SMF) across both wireline and wireless user planes. The unified SMF operates on the same 3GPP N4/Sx CUPS interface and dynamically selects the proper UPF for fixed wireline/wireless or mobile access based on Access Point or Data Network Name, IP address range, subscriber profile, traffic load or configured resources and services. This allows efficient off-loading of broadband internet and video traffic from the 5G Core and allows independent scaling (and placing) of fixed/-wireless and mobile gateway functions (Figure 5).

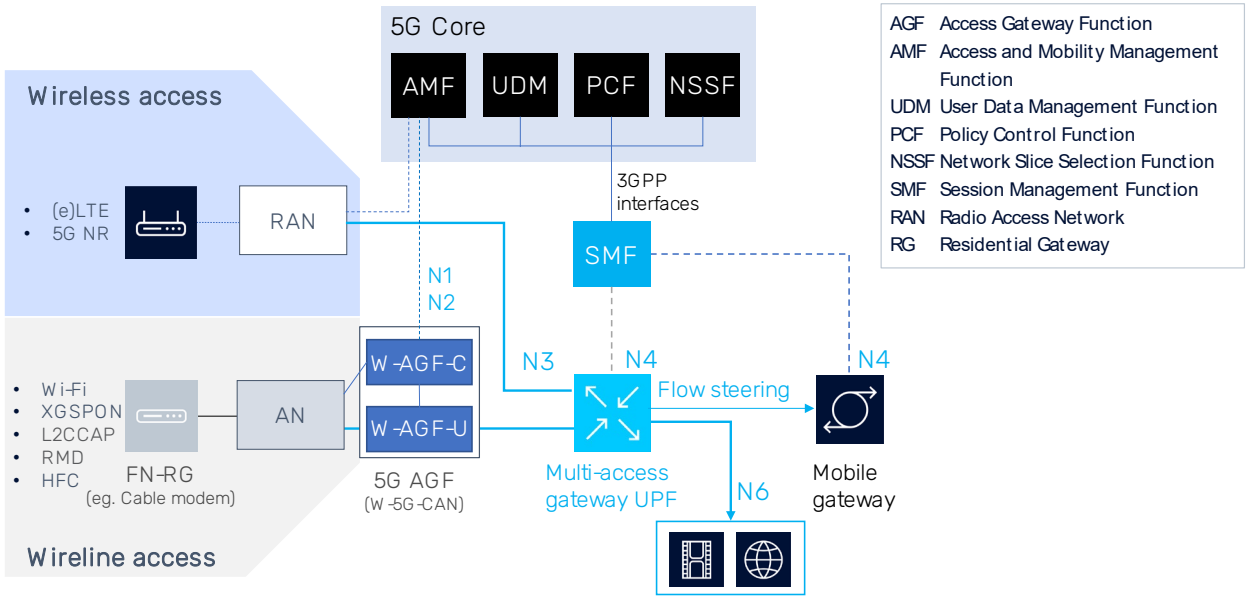

Figure 5. Wireline and wireless convergence on a 5G core

The multi-access edge gateway (UPF) handles all wireline and wireless broadband traffic. It offloads internet and video traffic to the IP/MPLS data network via the N6 interface and steers the remaining 5G user traffic to the more centralized cloud mobile gateway that control access to 5G Core services and applications.

To cost-efficiently manage high-volume/low-revenue broadband applications, the multi-access UPF is best performed by purpose-built edge router appliances that can be distributed in proximity of end users. The following requirements are typically supported by custom network processors and routing silicon:

- Highly scalable hierarchical QoS (HQoS) to enable thousands of subscribers on dozens of access nodes to fairly share the available broadband network capacity
- Granular shaping and policing of traffic flows to ensure that each subscriber receives the committed – and peak data bitrates according to their subscription policy
- Scalable and granular Access Control Lists (ACLs) to enforce security functions such as anti-spoofing to prevent service theft and denial of service (DDoS) attacks.
- IP multicast replication and IGMP snooping to facilitate premium broadcast TV streaming
- Streaming flow telemetry of subscriber flows to account for data usage and monitor quality of experience, and identify security threats,
- Flow mirroring to support lawful intercept and analyze potentially malicious traffic flows

The SMF provides a single access point for managing all distributed UPF instances and presents a common interface to the other 3GPP system functions (e.g., AMF, UDM, PCF, NSSF, etcetera).

7. Conclusion

5G fixed-wireless access is a new and promising technology that can be cost-effectively leveraged to expand the coverage and capacity for underserved broadband homes in wireline brownfield deployments, and to facilitate and accelerate the rollout of fiber-to-the-home in greenfield and out-of-region areas.

The introduction of a multi-access edge gateway with control user plane separation, enables converged service operators to combine wireline and wireless access in a seamless broadband experience, and to enable fixed-mobile convergence on a unified 5G Core.

Abbreviations

AGF	Access gateway function
AMF	Access and Mobility Management Function
CCAP	Converged cable access platform
CIN	Converged interconnect network
CPF	Control plane function
CUPS	Control user plane separation
DDA	Distributed access architecture
FWA	Fixed-wireless access
NSSF	Network slice selection function
PCF	Policy control function
SMF	Session management function
SPGW	Serving and Packet Data Network Gateway
UDM	User data management function
UPF	User plane function
XGS-PON	10 Gigabit/s symmetric passive optical network

1. Introduction

Over the last few years, and accelerated by COVID-19, the approach to corporate IT has fundamentally changed and companies are undergoing significant shifts in IT strategy and culture. The illusion of a "private, secure" network run by undersized IT teams has been shattered and companies are left grappling with the complexity and security of large, remote, organically grown networks.

Cloud as-a-service operators offer a reprieve: augment your team with our offerings. Their teams manage the day-to-day complexity and security of the services in a cost-effective way while your IT teams focus more on value-added services specific to the business. In some domains, that value-add is as simple as on-prem tech support. In other domains, the value-add can be a significant network unto itself.

The latter domain is our focus: MSOs operate significantly complex networks and domain-specific applications. MSO teams have specialized technical skills and experiences which allow operators to provide scalable and robust Internet connectivity to their end-users. Cloud offerings can augment existing investments by reducing time to deploy new services and enabling existing teams to focus on domain specific problems and solutions.

In this paper we look at a Flexible MAC Architecture (FMA) deployment following these principles. Some of the network is domain specific and managed by specialized in-house teams which are then augmented by resources and teams provided by 3rd party Cloud offerings. We examine the viability of a hybrid approach to FMA deployment through design, constraints, security, and costs using a prototype deployment.

2. FMA Overview

CableLabs®'s Flexible MAC Architecture defines an architecture for deploying a Remote MACPHY architecture, where the DOCSIS processing is done remotely in specialized hardware and the management is disaggregated into software components. The architecture is comprised of 3 primary components:

- MAC Manager (MM). A Management plane component that aggregates many RMDs into a single, unified controller. It provides a backwards compatible OSSI interface to legacy cable backoffice technologies.
- Remote MACPHY Device (RMD aka MAC-NE). A physical device containing a DOCSIS MAC and DOCSIS PHY expected, but not required, to be housed within an outside plant Node enclosure.
- PacketCable Aggregator (PAG). An aggregation component which bridges between existing PacketCable infrastructure and a population of deployed RMDs.

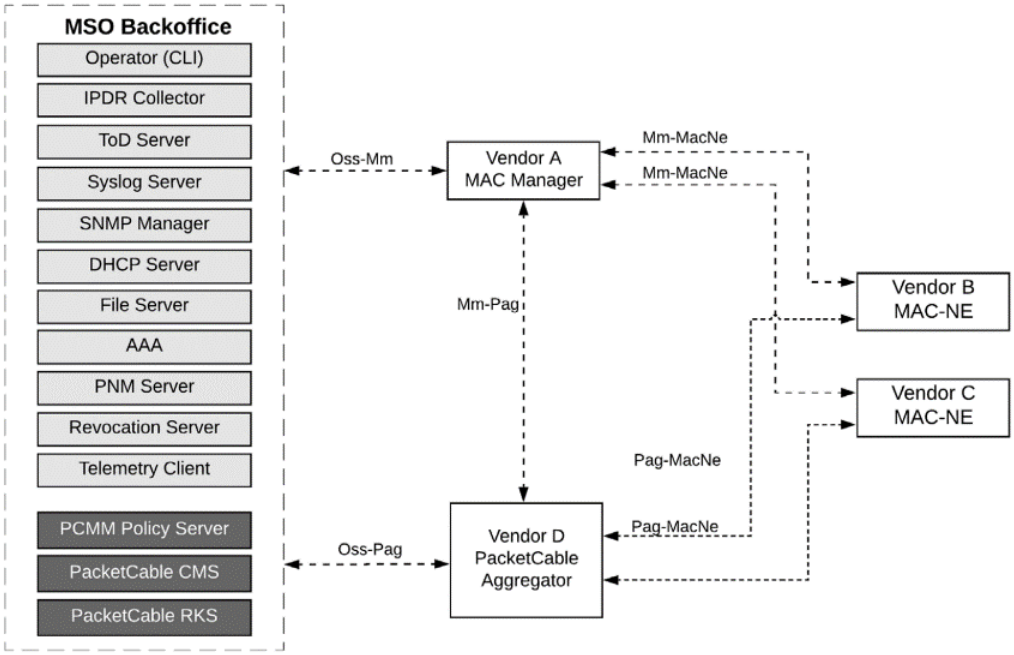

Figure 1 - CableLabs FMA

A key differentiation between FMA and Modular Headend Architecture v2 (MHAv2) Remote PHY Devices (RPDs) paired with (virtual) Cores is that the DOCSIS portion of the access network is terminated at the remote RMD and customer bearer traffic is readily available at the first-hop aggregation switches within an operators' network. FMA separates the data plane packet handling from the management components, placing data plane into the RMD and management plane concerns in the MAC Manager. This separation removes the need for the MAC Manager to handle high throughput packet processing and allows the MAC Manager to be more easily virtualized.

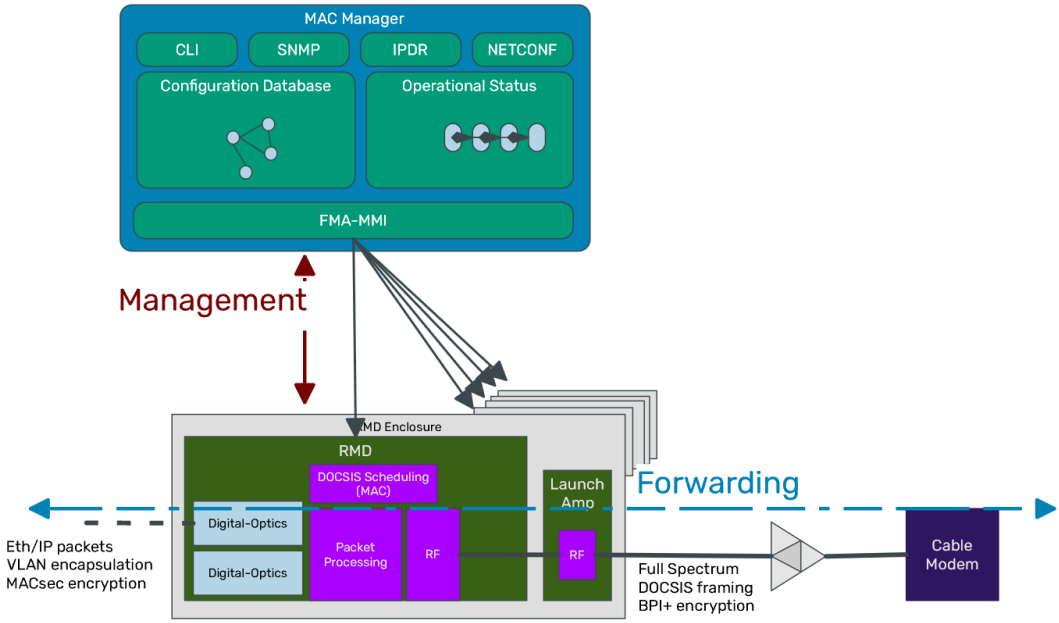

Figure 2 - FMA Management / Data Plane Separation

We take advantage of this property to build a best-of-breed hybrid network: domain specific networking concerns for bearer traffic are handled by in-house specialists while generic compute resources are augmented into the team by scaled cloud providers.

A cloud-based Flexible MAC Architecture can be readily designed in many ways, some of those options are explored within this paper as a thought-exercise. To explore a cloud-based solution more concretely, we deployed our solution for testing as follows:

- The MAC Manager was deployed into Amazon AWS, although any large cloud provider could be used.
- A VPN connection was established to a private lab network
- The MSO backoffice was on the private network
- The cable modem traffic was routed on the private network

This leads to a hybrid network where AWS was used as an extension or expansion of our private network. Customer traffic was not routed to or originated from an AWS address space.

3. Clouds

There are many options for cloud providers today, both large and small. The large cloud providers, such as Amazon, Google, and Microsoft, offer similar competitive portfolios and can be compelling partners when investigating cloud augmentation.

Cloud service offerings can be approached and purchased in different ways, and we categorize the offerings into the following from higher level to lower level. The service provided by the

cloud operator dictates the required software packaging, service model, and abstraction level for any application deployed into that service.

- **Software-as-a-Service (SaaS)**: Building an application on top of provider-specific applications services. SaaS applications can be augmented to other deployment technologies to address specific application requirements. SaaS offerings have the largest variance between cloud providers.
- **Containers**: Building an application as a set of containers deployed onto a cloud-managed Kubernetes or another container orchestration platform.
- **Virtual Machines**: Building an application bundled with an operating system and targeting an ideal hardware environment which would run on a hypervisor and be deployed as a unified whole.
- **Bare Metal**: Building an application bundled with an operating system targeting a specific hardware environment and running directly on the hardware resources.
- **Racking**: Renting rack-space, lab resources, and connectivity while purchasing and managing hardware life cycles and depreciation yourself.

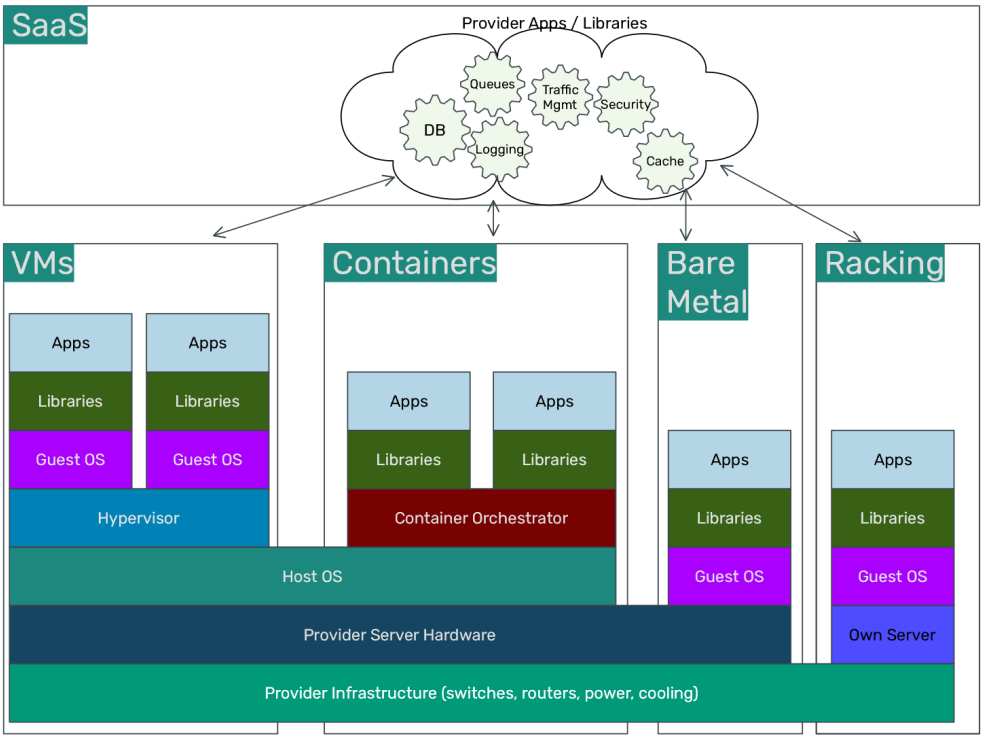

Figure 3 - Cloud offering types

The lowest level options, Bare Metal and Racking, are not as attractive to most operators because there is little value-added services added to an operator team; as such, they are not discussed in this paper.

The final 3 options of Virtual Machines, Containers, and SaaS each offer different advantages and disadvantages that need to be considered when investing in Cloud solution architecture.

4. Deployment Models

Virtual Machines, Containers, and SaaS augmentation are three ways to engage with cloud providers and each type of engagement has different strengths, weaknesses, and costs. In this section we provide an overview of these engagement models.

4.1. Virtual Machines

The most straightforward cloud-based deployment model is the placement of virtual machines (VMs) into a cloud provider network. A VM combines the application software with a bundled, often customized, operating system into a portable VM image which can be launched on a hypervisor.

Virtual machines are attractive, in part, due to their low coupling between the software application and the virtual infrastructure. This makes the VM easy to target as an application developer and easy to deploy into any cloud offering, reducing cloud vendor lock-in. Virtual machines can bridge gaps between defined hardware appliances and a fully virtualized world making it easy to work with internal teams and external vendors.

There are some inherent disadvantages to bundled virtual machine deployments. Given their agnostic attitude to their infrastructure and that they include their entire operating system, they can sometimes cost more than other options. In addition, all application dependencies are usually included directly in the virtual machine image, making it difficult to offload application features, such as database redundancy and resiliency, to the cloud operator.

A single MAC Manager is expected to manage many RMDs, so consideration must be given to redundancy, resiliency, and the impact of an outage (planned or unplanned) on customer services. In a similar way to the physical deployments that VMs emulate, high availability strategies come from the VM vendor implementation and are difficult to transparently offload to a cloud provider. When deploying redundant VMs, it's important to ensure cloud availability zones (AZs) are a part of the strategy which limits or restricts the use of layer 2 based high availability techniques. Most cloud providers offer some insight and monitoring into the health of VMs but do not have visibility into the health of the application(s) running in the VM.

The VM resources are analyzed in a similar fashion to physical deployments - in increments of CPU, memory, and storage. Evaluation and costing of compute resources in a VM model is straight-forward as the costs of a virtual machine are obvious from the cloud provider. Network traffic needs are more sensitive to the running application design and configuration, as certain parameters such as telemetry, logging frequency, and communication density may be adjustable in the application. However, between the two cost considerations of compute and traffic, network traffic costs will outpace those of the compute resources except in certain edge-cases, such as GPU compute.

There is significant parity among all the major cloud provider offerings regarding virtual machine deployments and compute resource offerings.

4.2. Containers

Containers offer a deployment option in which individual microservices can be launched and managed as discrete entities running on a virtual environment. Containers can be deployed manually but are more often paired with an orchestration service, such as Kubernetes, which performs the role of container lifecycle management, redundancy, storage virtualization, and load balancing functionality.

Containers decouple the applications into individual services, allowing each to be deployed independently. Where a VM commonly bundles "everything" into a single integrated deliverable, a container deployment provides a model to offload key functions to an operator or third parties. By discarding the Guest OS, containers reduce the virtualization overhead required to deploy applications and may reduce overall costs of a solution.

In a VM model, a hypervisor limits each VM to a specific set of resources and ensures two or more VMs operating on the same physical hardware do not interfere with each other. Containers run without a hypervisor and without a Guest OS, so resource constraints need to be considered on a per-container basis. Most container models allow for fine-grained tuning of resources and resource limits to give priority resources to the applications that need them most while ensuring that none overstep defined limits causing negative side effects to the broader system. Shared resources such as disk, memory, and network access can be defined on an individual basis that are best suited to the requirements of the application.

Orchestration systems, like Kubernetes, enable larger shared resource pools across many physical devices to be managed and container instances to be deployed automatically within the pools. Using load balancing or distribution strategies, individual containers managed by the orchestrator can have workloads distributed evenly (in, for example, a round-robin fashion) or as a redundancy strategy. Containers can exist as long-term entities for persistent, permanent operation or short-term entities for distributed workloads such as metrics processing or batch operations.

Container orchestration systems can be deployed in VMs or onto bare metal by an operator manually, however, most major cloud providers offer a Kubernetes container deployment target as a service. In these models, the operator doesn't think about or provision any virtual machines and can deploy containers directly into the cloud operator's container network. The underlying virtualization/HW is left to the cloud operator.

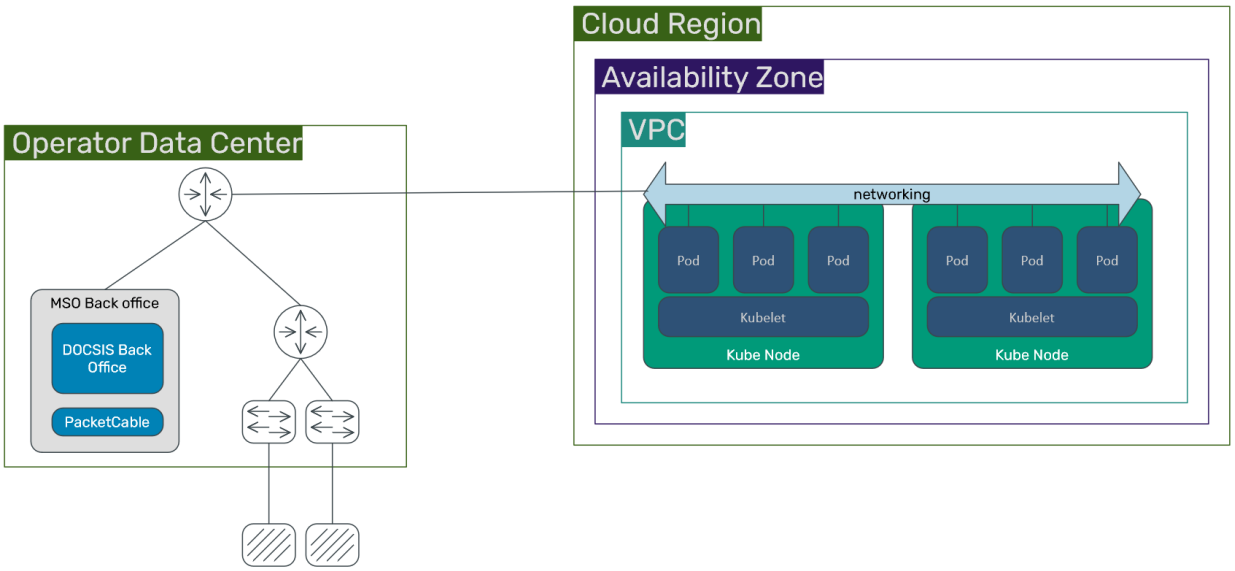

Figure 4 - Orchestrated Containers

A key principle of microservices and containers is the reduction of application-scope: A container will do one thing well and rely on other containers to provide any other services. For example, a container will often be stateless and rely on other containers or SaaS offerings to provide stateful storage, such as a database service. In some cases, the smaller container scope allows for best-of-breed application container choices and increases release velocity of individual container applications. The downside of this approach is the increase in the number of integration points an operator needs to manage. When a container needs to communicate with other containers to fulfill its responsibility, it does so with a protocol, protocol version, and specific API. These communication points need to be integration tested by the operator and vendor before confidence in the whole system can be established. These new integration tests can be empowering for an operator but also need to be understood and managed through life cycle and resource allocation.

4.3. Software-as-a-Service

Software as-a-Service (SaaS) can augment any other type of deployment, outsourcing critical generalized functionality to the cloud provider. SaaS functionality between cloud providers is the most specialized with different providers offering different SaaS products. In many cases it is also the most expensive but also the highest value functionality a cloud provider can offer. Databases, queues, traffic routers, and caches are all generic architectural components demanding high availability and reliability while also being complex to deploy and manage. SaaS offerings from cloud providers offload that complexity to their specialized teams to handle infrastructure, monitoring, security, and support infrastructure. This lowers the operator's burden and allows operator teams to focus on connectivity domain specific concerns.

Some SaaS offerings require little custom integration to gain the benefits. For example, most SaaS SQL databases are compatible with SQL client applications without any additional effort. However, in some cases, specialized high-value offerings, such as AWS Lambda, need specialized application logic and delivery mechanisms to integrate correctly.

While SaaS offerings can be cost-effective, reliable, and easy to use, they can cause an application to be locked into a specific cloud provider due to proprietary APIs or service offerings from a specific cloud provider.

Operators can compare SaaS offerings versus their own resources and areas of expertise and make individual evaluations for each of these categories of need. Ultimately, decisions will come down to costs and benefits. While maintenance of logging stacks, metrics stacks, or databases is possible independent of cloud providers, SaaS choices remain available, and these options are where distinctions between cloud providers are more evident. Furthermore, it becomes a matter of comfort, preference, or experience that may define more attractive choices to operators.

4.4. Cloud location & Connectivity

Operators will most often have, and want to take advantage of, the opportunity offered by major cloud service providers to geographically locate cloud-based deployments into areas that pair best with MSO datacenters. Latency tests indicate that even cross-continent, round trip times are low enough that RMD to MAC Manager communications are feasible without failures but reducing RMD to MAC Manager latency could improve the overall performance of interactive tasks.

A standard connection to a cloud provider would be over the public Internet with best-effort delivery. At a minimum, a VPN connection established between the cloud provider network and the operator network would be expected, but this is still delivered as best-effort over the Internet. The largest cloud operators offer additional services to reduce the latency of best-effort connectivity between an Operator core network and the cloud services. These additional services vary between the cloud operators, but we attempt to unify the concepts here.

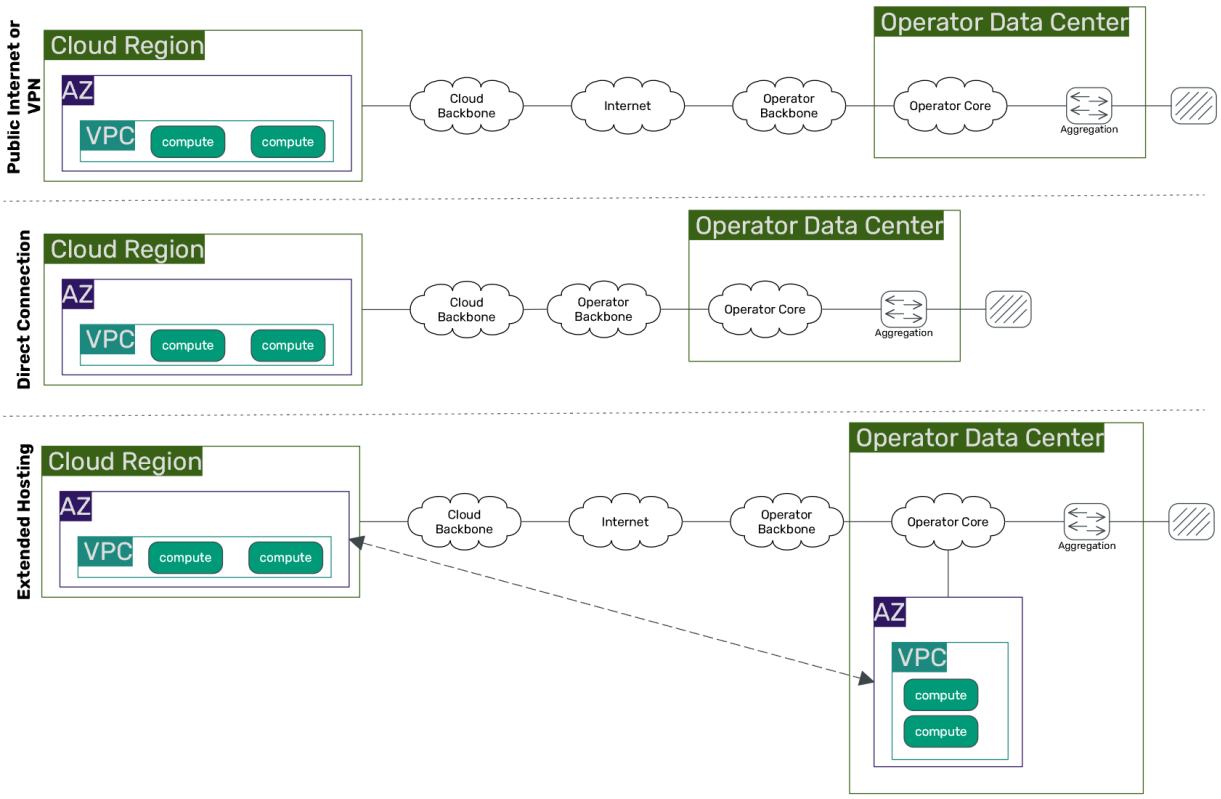

Figure 5 - Cloud Connection Types

One option is to use "accelerator" functions to attempt to route primarily on the cloud operator backbone and stay off the general Internet. This may be particularly attractive if the MSO already has peering established with the cloud operator. Another option is establishing a direct connection physically between two data centers; however, this requires presence in a common location and provisioning the connection. Another option for some cloud operators is to install their hardware directly into an MSO data center, which can then be provisioned through the cloud user interfaces.

With a diverse set of geographically located datacenters from cloud providers across North America, Europe, or Asia, operators should consider leveraging these locations for hosting their applications. It may also be required that cloud hosting be located in a specific region for legal, taxation, privacy, security, or other purposes. It's important to highlight that the MAC Manager will likely store and manipulate certain fields considered private identifying information in some jurisdictions and cloud data center geographic location will play a key role in complying with those regulations.

4.5. Backup and Retention

Depending on the nature of the cloud deployment, there are extensive options available for backup and retention of data. Virtual machines are often backed by block storage devices that can be snapshotted on a manual or scheduled interval. The same options are available for block storage devices attached to container images in an orchestrated containerized deployment. These

block backup techniques can be achieved transparently to the VM or containers, reducing integration cycles associated with backup and retention mechanisms.

The various SaaS options, such as SaaS databases, often manage and monetize their own retention models, where retention rules can be set by volume, time, or other configurable parameters.

Some cloud providers offer additional choices for backup operations, such as large-volume cold storage, where data can be retained at very low cost, but retrieval or restoration of the data often comes at a higher cost. In some offerings, physical export of the data is possible as well.

Beyond the options cloud providers offer, direct connection data links into the cloud would allow for more conventional, self-maintained backup and retention policies. In the case of certain SaaS offerings, manual export and retention of bulk data may not be fully compatible with the software offerings, or across cloud providers.

5. Cost Centers

Cost centers associated with cloud-based deployments of FMA architectures can vary greatly depending on methodology chosen and services deployed. There are some consistent elements across cloud providers that will affect cost independent of the chosen architecture:

- MAC Manager compute resource hosting/consumption (VM or container)
- MAC Manager runtime storage, with a focus on IOPS
- Bandwidth usage of FMA-MMI and FMA-OSSI traffic
- Fixed data links between MSO datacenter and cloud datacenter
- Backup and retention costs

In a resilient architecture, regardless of whether the MAC manager is situated as a monolithic software package or a microservices-based model, some measure of cost will exist. Virtual machines operated by cloud providers typically present two costing options: hourly or reserved (fixed cost by term). Hourly-costed instances offer more flexibility in terms of the actual runtime of the virtual machine. For example, operators could choose to have cold standby backup instances which may offer a cost savings approach. Similarly, in microservices models, instances could be launched or deprovisioned to support batching operations for processing data in bursts instead of instances running continuously.

Reserved instances are more cost effective outside of these types of operations. Reserved instances cost less than the equivalent hourly instance when run for the same amount of time but require a contractual lock-in over a monthly or yearly term. As a result, reserved instances require greater understanding of operational needs in advance of the actual deployment.

Storage access, particularly in IOPS, can represent a significant area of cost. Different implementations of MAC Managers may have very different IO profiles, Resilient data storage will play a key role in any MAC Manager implementation.

Bandwidth costs will vary based on several factors. Principal among them is the number of deployed RMD devices connected to MAC managers, as well as configuration on reporting thresholds and intervals of telemetry, IPDR, and logging data. As a general rule, when surveying major cloud providers, we found an asymmetric cost associated with data transfer: ingress data is cost-free and egress data is costed at total data transfer across tiered pricing intervals.

In FMA, outside of actual bearer traffic, there are two inherent modes of traffic, each bidirectional in nature but also asymmetric in the volume of data transfer. In a robust cloud-based deployment, recommended setup would have redundant or backup MAC managers distributed across availability zones to ensure impact of outage has a small footprint in terms of service impact, scope, and time of impact.

In general, bandwidth usage and anticipated cost is summarized by the following:

Table 1 - Bandwidth Usage Summary

	RMD to MAC Manager		**MAC Manager to RMD**	
FMA-MMI	High throughput	No cost	Low throughput	Costed
	MSO DC to MAC Manager		**MAC Manager to MSO DC**	
FMA-OSSI	Low throughput	No cost	Medium throughput	Costed
	MAC Manager inter-AZ communication			
MAC Manager HA	Medium throughput	Costed		

The final cost center is in bridging the MSO datacenter into the same network space as the cloud provider. The major cloud providers each offer their own variant on this high throughput, dedicated secure network link. Datacenters and links are regionally distributed, meaning that an MSO datacenter in the eastern region of the US could have a direct, non-public link into geographically matched cloud provider networks.

Similar to virtual machine costing options, these fixed and dedicated links can be found in hourly or fixed-term options, with the corresponding flexibility versus cost optimization consideration.

6. Experimental Cloud Architecture

By disaggregating the DOCSIS processing from management concerns, FMA has introduced flexibility and design choices in deployment strategies. Data plane concerns of throughput, latency, and cost-per-bit are left to be optimized by packet-processing silicon, while management plane concerns of flexibility, agility, and evolution are left to be optimized in the virtual, software-defined design space.

Shown below, we built a specific architecture to explore a Cloud FMA deployment, but other architectural choices are possible as well.

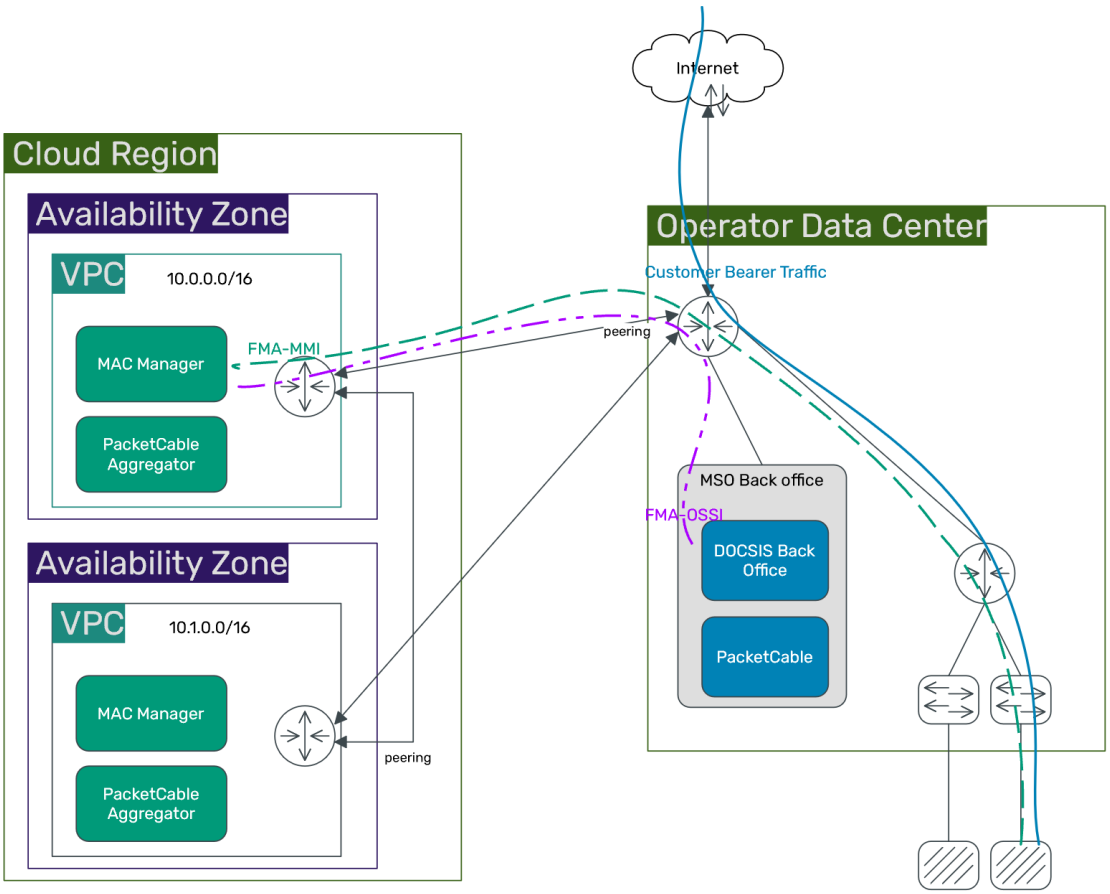

Figure 6 – Cloud-based FMA

A virtual private cloud (VPC) is an isolated network and set of cloud resources, such as compute servers, launched and configured in a cloud providers infrastructure. All resources within the VPC are private from other users, isolated from other networks including the Internet, and are assigned IP addresses from a private CIDR pool.

Resources launched within an Availability Zone (AZ) are on the same physical network, connectivity, and power infrastructure. Resources launched in two (or more) separate AZs are on unique physical infrastructure to provide redundancy and resilience, limiting the impact of an outage in one AZ. AZs are usually inter-connected with high-speed redundant links to allow for common data-replication techniques to be useable across AZs. To ensure high availability it's important to deploy applications across AZs.

Cloud providers offer different options when connecting an Operator data center to the cloud provider. Two common methods are, generically, a VPN and a direct connection. The VPN option is quick and easy to setup and provides an encrypted tunnel between the cloud and the operator network. While encrypted and secured, the VPN tunnel is routed over the open Internet and may have a variable performance profile and specific maximum throughput limitations. Another option is to directly connect from your own data center into the cloud providers data

center. This direct connection is not software controlled and involves people from both companies to install and provision physical connections between the sites.

A VPN connection can be 'upgraded' to a direct connection without impacting the logical architecture of the solution. This allows for initial deployment trials to be setup with a VPN and later, optimized into a direct connection. For our setup, we used a VPN based connection between our deployment and AWS.

Once a connection between a VPC and the MSO data center is established, routing rules need to be installed to allow communication into and out of the VPC. Routing to the cloud over either connectivity option can be done with static routes or dynamically using eBGP. Given the small network in our testing we used static routing, but larger deployments will likely want to make use of eBGP.

We placed the MAC Manager and PacketCable Aggregator into the VPC and setup a static route to our physical infrastructure. The VPC was isolated from the Internet. The RMD to MAC Manager control communication transited our aggregation network, through our traffic router, across the VPN peer connection, and to the MAC Manager in the VPC. The RMD customer bearer traffic transited our aggregation network, through our traffic router, and out to the Internet. This deployment did not make use of PacketCable. Our implementation hosted firmware files for software downloads for the RMDs in the MAC Manager component.

7. Bandwidth

Bandwidth consumption over the Cloud connection is a primary concern when moving to cloud deployments. In an FMA deployment, the management plane traffic is separated from the customer traffic and the MAC Manager is not doing per-packet data processing. This disaggregated architecture allows for hybrid network deployments by placing management components in virtualized Cloud networks and keeping customer bearer traffic within the operator core network.

Bandwidth consumption between the MAC Manager and RMD will vary between vendor implementations and services deployed. However, to attempt to understand possible real-world consumption of the cloud provider transit, we investigated bandwidth consumption of an implementation of a MAC Manager and RMD, deployed in a 2x2 configuration, with a modest number of Cable Modems.

Communication between a MAC Manager and RMD in FMA can fall into one of two traffic patterns: steady state and on-demand. Steady state traffic is a continuous exchange of data during normal operation and on-demand traffic is bursty and usually triggered by an external command, such as a software upgrade.

We then classified the different streams of communication into the following categories:

Table 2 - Communication Classifications

Category	Type	Description
Telemetry	**Steady State**	**Regular streaming of status, operational, and statistics which the MAC Manager uses to monitor RMD population.**
Configuration	**On-demand**	**MAC Manager actions to configure changes in the RMD.**
IPDR	**Steady State**	**Regular streaming of customer related statistics to fulfill IPDR interface north of the MAC Manager.**
Support Info	**On-demand**	**Extra support and trouble-shooting data gathered and stored for historical data during support cases.**
Logs	**Steady State**	**Streaming of system logs.**
Heartbeats	**Steady State**	**Regular heartbeat and RMD discovery processes.**
Firmware Upgrades	**On-Demand**	**Download of firmware to RMDs.**
SSH/CLI	**On-Demand**	**Direct SSH/CLI connections to RMDs if needed.**

We monitored the communication between the MAC Manager and the RMD over time and through regular use, classified all protocol connections into one of the above categories, and aggregated the consumed bandwidth into an average consumption rate. The values are specific to our implementation but can provide an "order of magnitude" value to allow us to understand cloud provider transit costs.

Table 3 – Bandwidth Consumption by Classification

Category	Size	Downstream Bandwidth	Upstream Bandwidth
Telemetry	**Constant**		**4.3 Mb/s**
IPDR	**Constant**		**1.0 Mb/s**
Support Info	**~ 30MB**		**76 Mb/s**
Configuration	**n/a**	**Negligible**	**Negligible**
Logs	**Constant**		**Negligible**
Heartbeats	**Constant**	**Negligible**	**Negligible**
Firmware Upgrade	**~ 131MB**	**116 Mb/s**	
SSH/CLI	**n/a**	**Negligible**	**Negligible**

The constant steady state traffic between each MAC Manager and RMD pair is about 6 Mb/s when communicating with a 2x2 RMD with a modest Cable Modem count. Telemetry and IPDR making up most of this traffic means that the consumption will vary with the number of services deployed within the RMD. To understand Cloud transit consumption, we need to take the steady state values and multiply them by the RMD population size served by the MAC Manager. So, with the experimental implementation, the MAC Manager deployed with 100 RMDs might constantly consume ~ 600 Mb/s (75 MB/s) of cloud transit. Some cloud providers also charge asymmetric rates, where "download" out of the Cloud is charged at a different rate than "upload" into the Cloud. Our investigation found most of the steady state traffic is "upload" from the RMDs to the MAC Manager.

The largest on-demand "download" operation was the software upgrade functionality. This function, managed by an operator, commands one to many RMDs to download their software upgrade file from the MAC Manager. The firmware file used in the test was about 131MB and the full download for a single RMD took about 10 seconds. While short lived, this consumption could be significant if an operator commanded an entire population of RMDs to download their firmware upgrade file concurrently. The FMA architecture does not require that the MAC Manager host SSD firmware files. If the cloud-based MAC Manager is aggregating many RMDs and an operator expects a high concurrent download demand, an attractive option is to host the SSD firmware files 'on premise' on a local HTTP server and simply issue the SSD command to download the firmware files from the locally hosted file server.

8. Latency

In an FMA deployment, the latency between the MAC Manager and the RMD can affect management plane traffic for configuration and status information but does not directly add to bearer traffic latency. This is due to FMA making the bearer traffic available at the first-hop aggregation switch rather than routing the bearer traffic through a core, such as the MAC Manager.

To better quantify the impact of latency between the MAC Manager and the RMD, we injected latency into our deployment and monitored the operational status of the deployment in the presence of latency. The latency was only injected between the MAC Manager and RMD connection and not in the data plane bearer traffic, which was separated at the first-hop aggregation switch and routed normally.

Typical Headend/Hub based MAC Manager to RMD one-way latencies we see in deployments are between 0.01ms and 8ms, inclusive of standard propagation delay and the overhead of switching elements.

The introduction of a routed network over a VPN into the cloud VPC adds latency to the MAC Manager to RMD connection. The amount of latency added by the cloud connection is highly variable and based on many factors, some of which are not within the operators control. We tested a connection to explore real-world latency values to ensure our latency tests would simulate a useful range of latency targets. The latency measurements were made from a single IP location in the US Southeast to load balancers in our cloud provider network (AWS in this setup). Values are round-trip time averages.

Table 4 - Cloud Latency Measurements

Zone (US Southeast to…)	Average RTT (ms)	Std Dev (ms)
US Northeast	30.37	9.16
US Central	64.79	13.52
US Northwest	85.99	17.43
US Southwest	79.26	14.82
Europe (Frankfurt)	132.08	17.31
Asia (Tokyo)	254.31	26.26

The overseas values were included as interesting data points but are not relevant to our testing and not discussed further due to their performance and the legal and regulatory implications of hosting a MAC Manager across international borders. Focusing only on the continental US results, we see significant result differences between the AWS regions from our RMD deployment in US southeast. It's expected that countrywide RMD deployments will likely want to be connected to MAC Managers deployed in cloud data centers with the best performance from the RMD location. In AWS, for example, we would want MAC Managers deployed in each of the 4 major regions and have RMDs connected within a single region.

For our testing, to ensure controlled injection of a range of latencies, we built a controlled network with as few switching elements as possible and used a network testing tool to inject the specific latency targets.

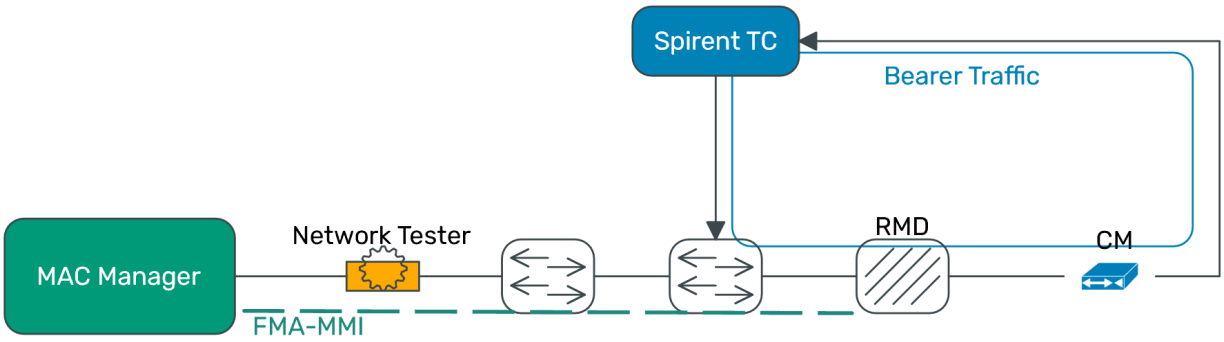

Figure 7 - Latency Test Setup

For our investigation, we choose a range of 1-way latencies between 10ms and 50ms, equivalent to 20ms - 100ms round-trip time (RTT). 10ms (20ms RTT) being worse than current on-premises, real-world deployment cases and 50ms (100ms RTT) being an upper range beyond latencies we saw with our real-world connections to our cloud provider.

When normalized to propagation distances, this results in a range as follows:

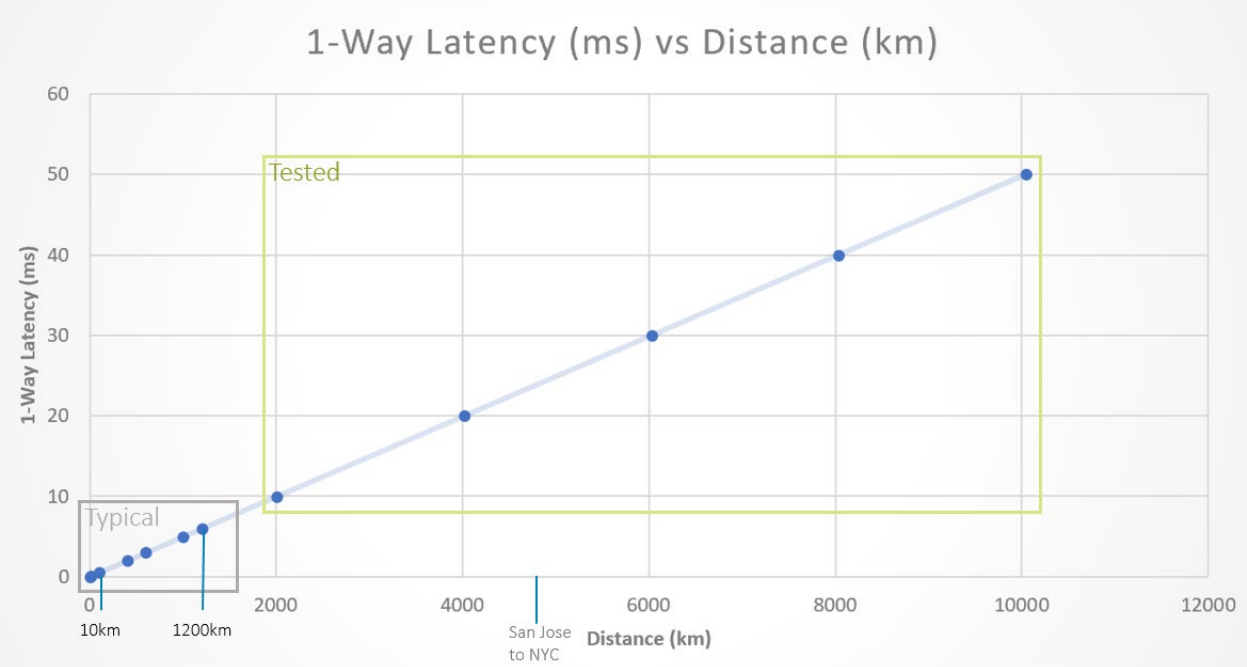

Figure 8 - Latency vs Distance (propagation)

We tested the same use cases as in the Bandwidth section, specifically:

- RMD Software Upgrade downloads
- RMD Support Info uploads
- MAC Manager to RMD Control connection
- MAC Manager IPDR (bulk data)

RMD Software Upgrade downloads represent the single largest bulk download operation from a MAC Manager to an RMD. These files are downloaded over a TCP connection to ensure reliable delivery of the upgrade file. Firmware image files sizes are highly variable between RMD implementations. In our test, the upgrade file was 131MB in size. Additionally, the specific RMD implementation we used in our test throttles firmware upgrade download speeds to 120Mb/s to ensure safe transport in the presence of other network traffic, which is visible in the baseline result:

Table 5 - Firmware Download

# of RMDs	Baseline	20ms	40ms	60ms	80ms	100ms
1	9s	10s	11s	13s	15s	19s
20	12s	32s	81s	101s	123s	144s

TCP connections used for bulk transfers are sensitive to latency due to TCP being a protocol that requires an acknowledgement from the receiver before more data is transferred. TCP utilizes a

window-size scaling algorithm that accommodates a progressive increase in the amount of data transferred per acknowledgement up to a threshold. When latency is present, a throttling effect can come into play ensuring that the data has been reliably transferred.

In the FMA model, firmware is downloaded and stored on the remote devices directly and is not downloaded during each reboot by a bootloader in the RMD. This means the firmware upgrades are only issued within the FMA system when new firmware is provided by the vendor and approved for distribution by the operator. We expect firmware upgrades to be somewhat infrequent and associated with a maintenance window. The additional impacts of latency to the firmware download within this context are minor.

The RMD Support Info files are on-demand uploads from an RMD to the MAC Manager used during support activities. The size and contents of these files are vendor-specific, but the transfer mechanisms are standardized in FMA. In our RMD implementation, these files are between 2-30MB, depending on RMD history data files, and we used a 17MB file size during the testing.

Table 6 - Support Info Upload

Measure	Baseline	20ms	40ms	60ms	80ms	100ms
Time	1.8s	1.8s	2.1s	2.6s	3.4s	4.2s
Bitrate	76 Mb/s	76 Mb/s	64 Mb/s	53 Mb/s	41 Mb/s	32 Mb/s

We also tested the operational behavior of the system under latency conditions. Latency plays a complex and not directly measurable role in the operational behavior of the other connection types, so we tested the impact of latency as to a user of the function.

Table 7 – Functionality Impacts

Function	20ms	40ms	60ms	80ms	100ms
MM to RMD Control Connection	No issues	No issues	No issues	No issues	No issues
IPDR	No issues	No issues	No issues	No issues	No issues
CM Remote Query	No noticeable delay	No noticeable delay	No noticeable delay	No noticeable delay	No noticeable delay

The MM to RMD Control connection is a TCP connection transporting YANG-based object models. The transported data is much smaller and more intermittent than the previous bulk transfer leading to negligible system impact, despite the latency introduced by the TCP Ack RTT. Another mitigating factor for the Control connection is that the DOCSIS MAC is housed

within the RMD itself, further reducing the systems impact of latency in the Control connection since there is no MAC signaling between the RMD and the MM.

The IPDR connection is between the IPDR collector and the MAC Manager and the IPDR protocol was not negatively affected by the latency injection. The MAC Manager has an internal cache for fulfilling IPDR data requests and a real-time TCP control connection round-trip for configuration and maintenance aspects of IPDR, which is where latency injection would impact IPDR operation. During each of the injected latency tests, our IPDR collector did not have any issues gathering required IPDR records from the MAC Manager.

The CM Remote Query function has the MAC Manager gather SNMP operational data from all subtended Cable Modems on regular intervals and cache the values within the MAC Manager. The SNMP protocol is "chatty" with many packet exchanges during SNMP operations which would be penalized by our injected latency. This test was to ensure that SNMP CM Remote Query would not have operational issues in the presence of high latency during the SNMP exchanges. We found from MAC Manager internal metrics and user tests that the additional latency did not impact the ability for the MAC Manager to provide the CM Remote Query functionality.

Our conclusion is that the FMA architecture is resilient and robust in the presence of latency between the MAC Manager and RMD components. The MAC Manager functions we found most impacted by the additional latency, bulk downloads/uploads, are still completed within acceptable ranges and, more importantly, are robust in the face of the additional latency.

9. Conclusion

The Flexible MAC Architecture decouples data plane and management plane concerns and provides a strong distributed access architecture in hybrid-network deployment models. With the MAC Manger control traffic decoupled from customer bearer traffic, the MAC Manager can be placed in a virtualized hybrid-cloud deployment without introducing latency on the bearer traffic. Furthermore, since customer bearer traffic is not routed through the MAC Manager, this traffic can be processed by high-throughput, low-latency specialized equipment designed specifically for Ethernet/IP packet processing.

We explored an implementation-specific MAC Manager to gather real-world tests to validate the FMA decoupling approach in variable-latency environments. We also gathered an implementation-specific baseline of bandwidth usage to validate relative or proportional utilization of the link bandwidth transit demand that could be seen in MAC Manager implementations.

For many operators, a hybrid-cloud approach utilizing AZs, VPCs, and compute engines to host FMA functionality may provide an agile framework to start small and pay-as-you grow into more advanced services provided by the major cloud operators. FMA is uniquely suited to agile approaches due to the separation of management and data plane traffic, allowing packet processing of data plane customer traffic to be managed separately and completely “on-premises”.

Abbreviations

API	Application Programmer Interface
AWS	Amazon Web Services
AZ	Availability Zone
BGP	Border Gateway Protocol
CIDR	Classless Inter-Domain Routing
DAA	Distributed Access Architecture
DOCSIS	Data Over Coax Service Interface Specification

1. Introduction

From the early days of cable data services back in the early to mid-1980s until today there has been a continued improvement in supported capabilities by pushing the limits of Hybrid Fiber Coax (HFC) technologies, both in terms of modulation orders and frequencies utilized. Each step has had its fair share of corporate antigens introduced to elicit the desired outcome, and fortunately for the industry an adequate supply of antibodies has generally resulted. Monolithic architectures served their purpose for DOCSIS® head-end equipment by getting equipment deployed and reducing risk associated with rolling out these new technologies.

A monolithic architecture has limitations, primarily in terms of rack space, powering, and environmental requirements. The first part of overcoming these limitations was decomposing the Cable Modem Termination System (CMTS) by adding the use of Edge QAMs as the PHY layer for all downstream spectrum, which also allowed a single device to provide video, voice, and data services. The second piece of the puzzle was moving toward a distributed access architecture (DAA) to push these capabilities closer to the customer and remove analog optics from the deployment equation. The third strategy is moving both the MAC and PHY into the field to simplify the scheduling and timing requirements necessary for services of the future and to eventually the eliminate rack space, powering, and environmental problems of the legacy monolithic architecture.

By moving to a DAA based on a Remote PHY Device (RPD) or a Remote MACPHY Device (RMD) to provide services there are several important considerations. First, the head-end is greatly simplified as a significant portion of the combining network is no longer needed with many services being provided over Ethernet and with the transformation to radio frequency (RF) occurring in the field at the RPD and RMD. Second, the rack space, power, and cooling requirements in the head-end are reduced and potentially eliminated. Third, an all-digital network means that higher order modulations may be used as the Ethernet to RF transition is now within no more than a few thousand feet from the customer.

Transitioning to new technologies is challenging, but we must consider why we should do other than just extending the life of the monolithic architecture as a primary means of service delivery to customers.

- When cost of entry is low, cost to exit is high. The easy technologies to deploy are typically the hardest to move away from when needed.
- Moving to the next generation of a technology is cheaper than trying to keep the previous generation meeting the needs of customers. There comes a point where it is clearly no longer cost effective to keep an existing technology working. When you finally realize that you can be years behind in getting a new technology deployed.
- Changing technology is easy; changing people is hard. Never forget it is the field staff who keep things running and they need to be ready when new things are deployed.
- Everyone has a nice paint job. Most competing technologies look nice and shiny but are mostly similar for 80%-85% of necessary functions.

In this paper we address how we can progress towards a DAA and minimize the risk along the way. Major upgrades are never easy, but with careful planning and training they can be accomplished. One of the biggest challenges in the brave new world of DAA is how to manage new devices without forcing significant changes to OSS/BSS/EMS/NMS software that has been used for decades. To stand up to the challenge, we have been working for the past 8+ years on Remote PHY and the 3+ years on the Flexible MAC Architecture (FMA), which includes Remote MACPHY. Remote PHY and FMA provide standard interfaces both north and southbound of their respective Core network functions to manage DAA devices, removing OSS/BSS/EMS/NMS roadblocks and allowing the journey to DAA to begin.

2. Deployment Motivations for DAA and FMA

With DAA, we're not in Kansas anymore. Getting there may seem as scary as the idea of riding a tornado to land a house on top of a wicked witch. Where we came from was the legacy CMTS and an Edge QAM, a Converged Cable Access Platform (CCAP) and an Edge QAM, and a fully integrated CCAP. Familiar things that will always be a part of us. Where we are going is a land where DAA thrives and where CCAP with Remote PHY support live. And most certainly lots and lots of Munchkins.

In the DAA Land of Oz the Emerald City is where FMA and Remote MACPHY reside, and we must not only get to Oz but journey through it if we want to get to the Emerald City. But first, we need to consider why we might want to go there. Then we need to take a good look around at where we are now. We must consider what we expect to find at our destination and plan for what we need to take with us when we go there. Only then can we start our journey in earnest.

Literally speaking, an operator wanting to get to FMA and Remote MACPHY from where they are today has a lot to consider. What can be reused, what needs to change, and how? What service evolution factors influence how FMA is implemented with Remote MACPHY? How can the legacy approaches co-exist with FMA in a gradual roll-out?

But let's first start with the motivations…

2.1. Why DAA?

Why should we want to go to the DAA Land of Oz in the first place? Let's focus on five areas of interest as illustrated in Figure 1:

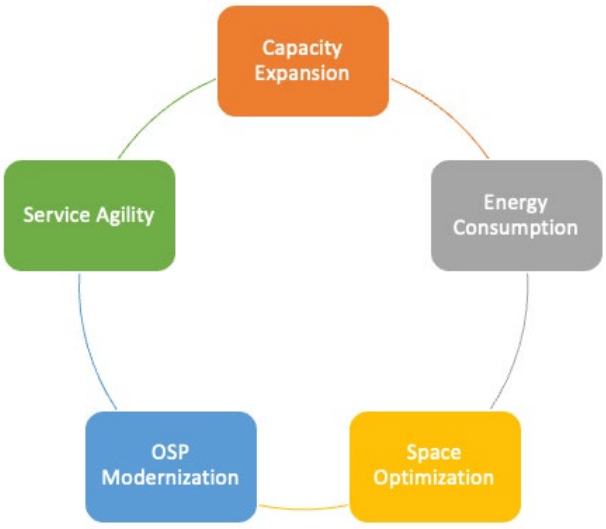

Figure 1 - Benefits of DAA

First, capacity expansion is a critical consideration. As shown in Figure 2, consumer speed tiers continue to scale on an exponential basis with consistent cumulative growth rates. Existing chassis-based CCAP devices that deliver the DOCSIS® and serve 50+ service groups cannot scale to the maximum throughputs needed while at the same time keeping all the RF circuitry within the platform. Hub space, power, and cooling requirements necessary to scale capacity of analog optical transmitters and receivers, the RF

combining networks to serve them, and the traditional CCAP devices themselves are too bulky if we continue to shrink service groups to deal with increased capacity needs.

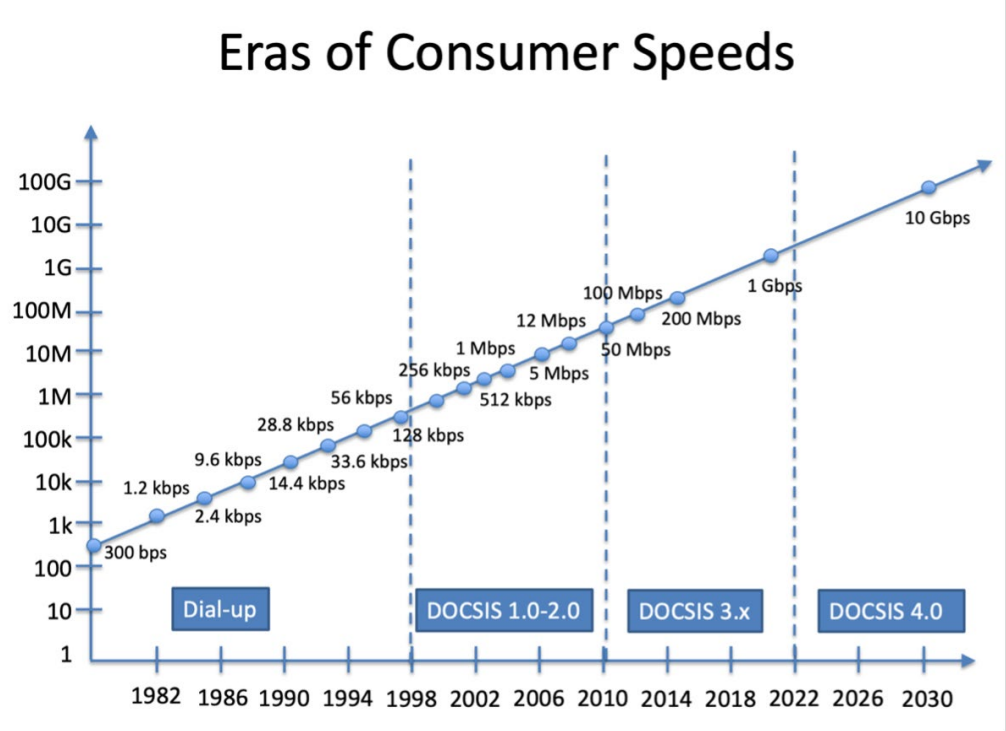

Figure 2 - Consumer Speeds over Time

To avoid regrettable spend on real estate rather than on network infrastructure to serve customer needs, we need to slow and eventually reverse hub space growth and associated increased power and cooling requirements. Remote PHY can help by removing the DOCSIS PHY and RF modulation/demodulation aspects from the CCAP and placing them in the outside plant (OSP). Remote MACPHY can go further by moving all DOCSIS functionality and RF modulation/demodulation to the OSP. Both alternatives can eliminate the need for a hub-based analog combining network and analog optical transmission equipment, replacing them with a Converged Interconnect Network (CIN) of compact Ethernet switches.

Modernizing the OSP by moving from analog optics to digital Ethernet optics increases optical reach, improves performance, and reduces the cost of fine-tuning in the OSP. Moving the RF modulation/ demodulation closer to the subscriber greatly improves RF performance. The combined effects of moving to digital optics and relocating the RF modulation/demodulation close to the subscriber also lead to a cleaner and easier to operate OSP. The movement to all-Ethernet in the OSP optics allows convergence of the network into a CIN with DOCSIS, passive optical networking (PON) for fiber-to-the-home, 4G and 5G wireless Xhaul, and business services all served from a common shared Layer 2/Layer 3 (L2/L3) network.

Finally, DAA is the only path to get to service levels beyond DOCSIS 3.1. DOCSIS 4.0 requires a DAA baseline, whether it be Remote PHY or FMA/Remote MACPHY. You can get to the DAA Land of Oz from Kansas, but you can’t get to DOCSIS 4.0 from Kansas without first taking a trip through Oz.

2.2. Why FMA? Why Remote MACPHY?

Once we're in the Land of Oz, why would we want to go all the way to the Emerald City? The answer is, that's where FMA and Remote MACPHY are.

FMA has standardized the Remote MACPHY architecture, which has been deployed globally in pre-standard implementations. Standardization allows RMDs from multiple vendors to work in the same operator network by interoperating with a single management entity and provides the operator with protection from the risks of being locked into single-vendor solutions.

The Remote MACPHY architecture is a step forward architecturally from Remote PHY. Eliminating the split DOCSIS architecture removes the tight coupling and synchronization requirements from the Core network element and the OSP devices. The "Core network element" in Remote MACPHY is a software management function that only needs to support device and subscriber management, not DOCSIS MAC and upper layer functions such as the DOCSIS upstream and downstream schedulers. It also does not need to deal with the DOCSIS data plane at all as FMA disaggregates the data plane and management planes into separate elements. With this disaggregation and decoupling comes several benefits:

- Simpler Interoperability – Interoperability for Remote MACPHY will be simpler relative to split DOCSIS Remote PHY interoperability, which has been and continues to be cumbersome due to the tight coupling of MAC and PHY between CCAP Core and RPD.
- Latency – DOCSIS latency of request/grant cycles between Cable Modem (CM) and DOCSIS MAC function is contained within the RF network between RMD and subscriber in Remote MACPHY. This provides optimal support by eliminating the delay between CCAP Core and RPD given the Remote MACPHY scheduler is co-located with the MAC and PHY layers in the same device.
- Simplified CIN – Remote MACPHY's CIN is simplified. Traffic engineering for DOCSIS data traffic can easily be provided in a native Ethernet/IP network, whereas it cannot in Remote PHY since data traffic is encapsulated in L2 tunnels. There is also no need to design the CIN to hairpin data traffic through a purpose-built Core element in Remote MACPHY and the need for precise phase and frequency synchronization between MAC and PHY from RPD using IEEE 1588 Precision Time Protocol (PTP) is not necessary for DOCSIS support as the MAC and PHY are co-located. Since long-term cable networks will likely run video over IP (i.e., DOCSIS) the Remote MACPHY approach can minimize or eliminate the need for PTP.
- Reduced hub space, cooling, power – Remote MACPHY enables the minimum requirements in hub space, cooling, and power of any of the DOCSIS alternatives. The "Core network elements" are COTS servers for management and control functions rather than chassis-based systems that pass hundreds of Gigabits of data plane traffic. These COTS servers can be located anywhere in the network and do not need to be near the OSP devices.
- Optimized virtualization of management/data plane – Remote MACPHY and FMA were designed to maximize virtualization opportunities for operators by cleanly separating the management and control functions from the data plane functions. The simplified CIN of Remote MACPHY plays nicely in a virtualized architecture by maximizing native transport virtualization opportunities as well.

There are plenty of reasons to want to go to the DAA Land of Oz, and there certainly are incentives enough to take a stroll toward the Emerald City once we are there.

3. Current Deployment Architectures

Before we can begin our trip to the Emerald City, it is important to understand where we are starting from so that we can plan our journey and know what to take with us. We first must document what is included and how the system functions are realized in existing centralized access architectures for DOCSIS and QAM video.

3.1. Pre-DAA

In Kansas we have a centralized access network with lots of splitting and combining and analog optics. We have legacy CMTS and an Edge QAM, a CCAP and an Edge QAM, and a fully integrated CCAP. The state-of-the-art in Kansas is the fully integrated CCAP.

The fully integrated CCAP includes a routing engine, cable control plane and subscriber management functionality. It also brings together DOCSIS and QAM video functionality and has the analog RF ports which connect to a splitting and combining network and then to analog optical transmission gear. In practice only narrowcast video is provided through the integrated CCAP. In many cases, broadcast video is processed external to the CCAP and needs to be combined in the combining network separately. Also not included in the integrated CCAP is video out-of-band processing, which is provided by special hub and head-end gear that connects over RF into the splitting and combining network. Figure 3 illustrates the fully integrated CCAP.

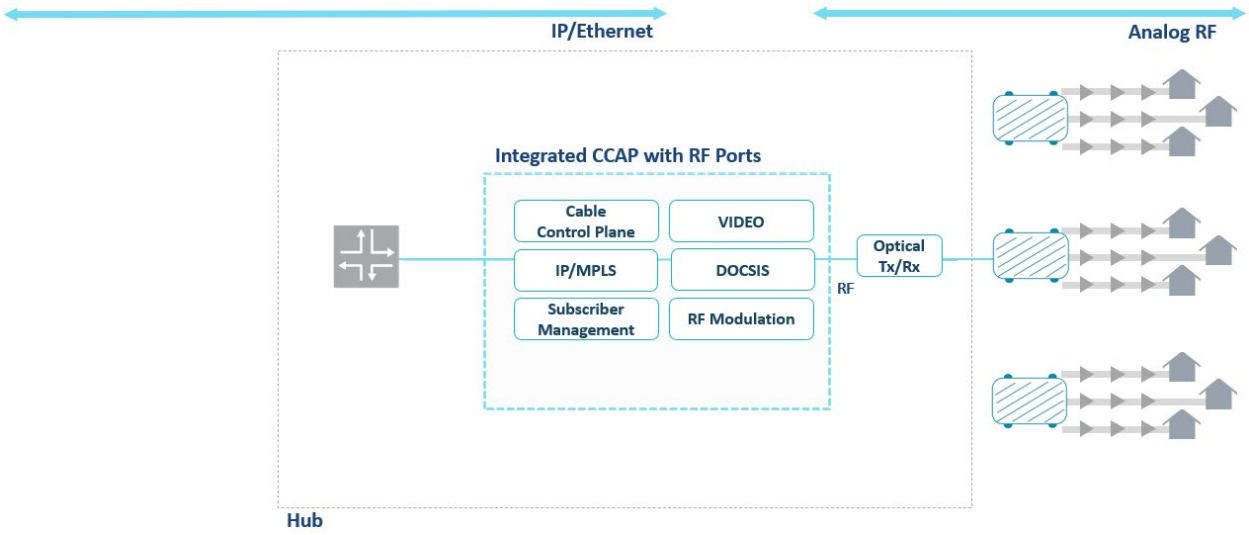

Figure 3 – Integrated CCAP

The RF access network in this environment starts in the hub. It includes the splitting and combining network and analog optical transmission gear. Analog fiber nodes are deployed in the OSP to perform RF optical/electrical conversion. The serious OSP operations maintenance activities begin back at the hub.

The difference between the integrated CCAP architecture and other RF-based hub equipment is typically in the video. A CMTS provides only DOCSIS functionality and is far less dense than a CCAP. A non-integrated CCAP is analogous to a dense CMTS. Narrowcast video is provided in both cases by a separate Edge QAM. Video out-of-band in all cases uses special gear which must be combined in the RF domain.

3.2. DAA with Remote PHY

In Oz we have a distributed access network, DAA, which provides us both Remote PHY and Remote MACPHY. Due to existence of legacy CCAP deployments a first DAA step for many operators was to convert their “big iron” chassis-based CCAPs to support Remote PHY.

In the chassis-based Remote PHY environment are most of the same things provided in the integrated CCAP. This includes a routing engine, cable control plane and subscriber management functionality. It also brings DOCSIS functionality but does not have analog RF ports, a splitting and combining network, or analog optical transmission gear. Those are replaced with Ethernet-based digital optics and a stack of Ethernet switches.

The RF line cards of the integrated CCAP are replaced with Ethernet-based Remote PHY line cards. These line cards perform upper layer DOCSIS and DOCSIS MAC functions. The DOCSIS PHY and RF modulation/demodulation are moved to the OSP in the RPD, typically in a fiber node form factor. This split DOCSIS is achieved via a complex set of Remote PHY requirement specifications provided by CableLabs®. Precision timing is required at both the Core network element and RPD to support DOCSIS.

Narrowcast video that was provided through the integrated CCAP cannot be supported as it was before. RF video of all types in DAA needs to be packetized and sent over the CIN. For this purpose, specialty elements called Video Cores and Traffic Engines are added to the architecture to provide packetized RF video which is then modulated at the RPD and delivered to the traditional video end devices. Legacy video out-of-band needs to be treated in a similar manner by what is dubbed an Out-of-band Core.

Figure 4 illustrates the integrated CCAP Remote PHY architecture.

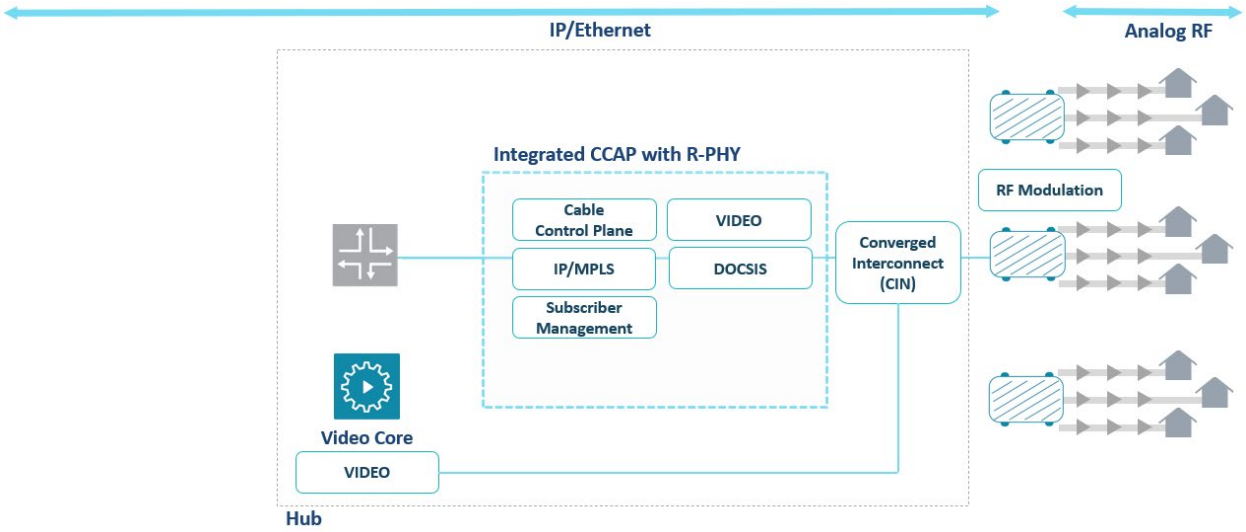

Figure 4 – Remote PHY Architecture

The RF access network in this environment starts in the Remote PHY node in the OSP. The serious OSP maintenance activities begin at the Remote PHY node, which is a significant DAA improvement versus the centralized access architecture.

4. Future Deployment Architecture – DAA with FMA

4.1. Overview

As much fun as the trip might be, getting to FMA does not literally require a tornado flight to the DAA Land of Oz nor a lengthy journey on foot to the Emerald City. Simply put, it is an evolutionary step that builds upon the successful foundation of DOCSIS, CMTS, integrated CCAP, and Remote PHY.

The key benefit of a DAA deployment is to converge the data plane packet interfaces across a range of access technologies on common and well-understood Ethernet/IP technologies. This allows operators to reap the benefits of DOCSIS and deep RF signal modulation/demodulation in their coax network, while also leveraging common high-volume packet-switching products on the fiber part of the access network.

FMA is a set of standards that further improves on DAA concepts by decoupling the management plane and data plane components of a traditional integrated CCAP, allowing each concern to be treated and deployed separately. The data plane can be optimized for throughput, latency, and uptime, while the management plane can be optimized for scale, agility, and velocity.

FMA defines three primary new components:

- MAC Manager (MM) – A management plane functional component that aggregates many MAC Network Elements into a single, unified controller. It provides backwards compatible OSSI interfaces to legacy Multiple System Operator (MSO) backoffice technologies.
- MAC Network Element (MAC-NE) – A physical device containing a DOCSIS MAC and DOCSIS PHY. It is expected, but not required, to be housed within an OSP Node enclosure. The MAC-NE embodied currently in FMA is the RMD. We refer to the FMA MAC-NE as an RMD throughout the paper.
- PacketCable Aggregator (PAG) – An aggregation functional component which bridges between existing PacketCable infrastructure and a population of deployed MAC-NE/RMDs.

FMA optionally reuses some Remote PHY components:

- Video Cores and Traffic Engines – FMA is compatible with the Remote PHY legacy video infrastructure.
- Out-of-Band – FMA is compatible with Remote PHY SCTE 55-1, 55-2, and Narrowband Digital Forward/Narrowband Digital Return (NDF/NDR) Remote Out-of-band (R-OOB) solutions.
- PTP – FMA is compatible with Remote PHY PTP profiles.

The FMA architecture is illustrated in Figure 5.

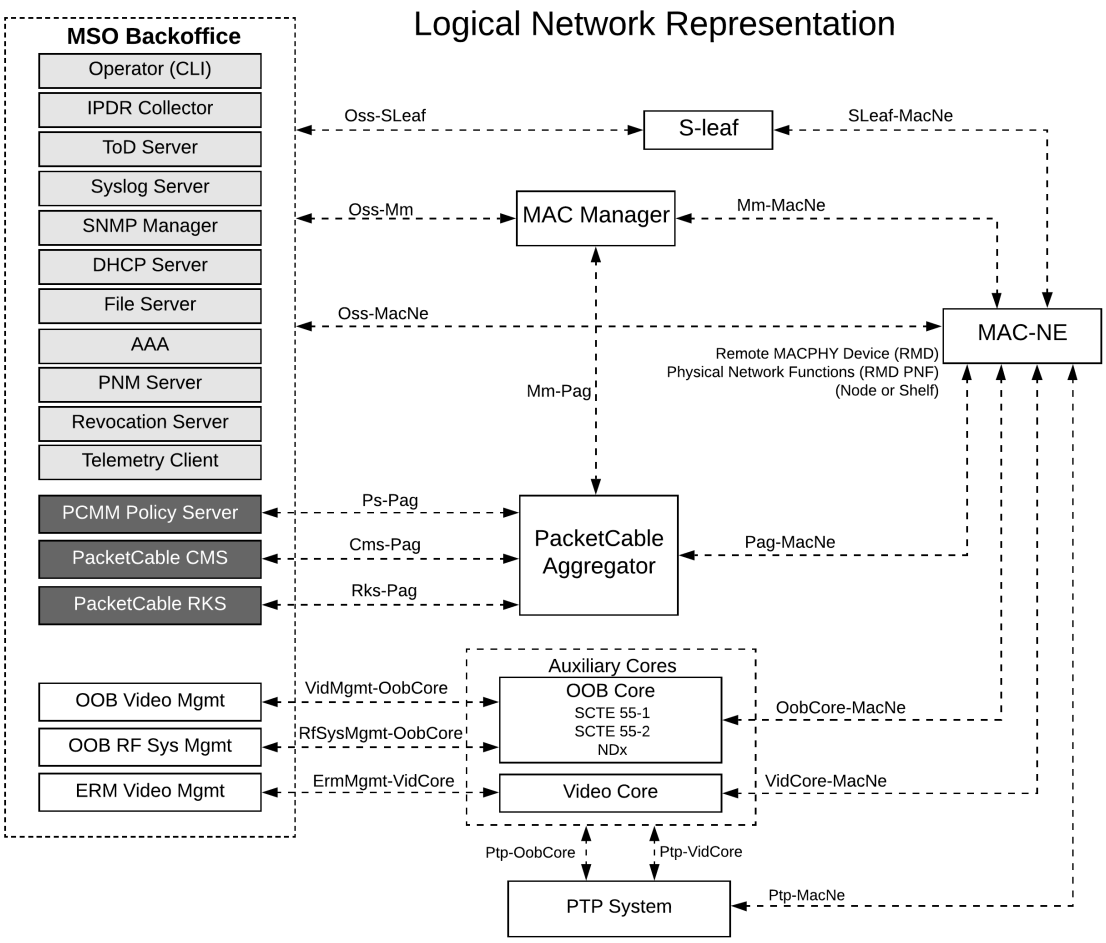

Figure 5 – CableLabs® Flexible MAC Architecture

In FMA, each interface is named by specifying both ends of the interface. A few key interfaces within the specification are:

- Oss-Mm – OSS to MAC Manager. A backwards compatible interface with existing MSO backoffice interfaces (e.g., SNMP), realized on the MAC Manager.
- Mm-MacNe – MAC Manager to MAC-NE. A new API, defined in YANG modules, between the MAC Manager and the MAC-NE to command, control, and monitor MAC-NEs. Mm-MacNe is commonly referred to as the MAC Management Interface (MMI).
- Pag-MacNe – PAG to MAC-NE. A new API, defined in Google Protocol Buffers, to command-and-control PacketCable functionality on the MAC-NE. Pag-MacNe is commonly referred to as the PacketCable Aggregator Interface (PAI).
- SLeaf-MacNe – CIN Secure Leaf to MAC-NE. A data plane interface between the first-hop aggregation points in the CIN and the MAC-NE.

Like Remote PHY, FMA places the full-spectrum RF generation and reception in a remote location, such as a node enclosure deployed in the OSP. This allows FMA to realize the same RF signal quality benefits as Remote PHY in improving Modulation Error Rate (MER) and allowing for higher modulation rates in channel plans. Unlike Remote PHY, which tunnels DOCSIS packets over IP to/from a packet-processing

CCAP/DOCSIS Core, FMA terminates DOCSIS in the remote device and provides raw customer bearer traffic directly in Ethernet/IP packets to the first-hop aggregation device. This removes the need for a CCAP/DOCSIS Core in the architecture and enables per-packet-processing and routing to occur in standard switch and router products. This allows operators to access the larger switching market and bundle switch and router cores into higher volume products. Further, because FMA provides standard Ethernet/IP packets at the SLeaf-MacNe interface, FMA is converging with other access technologies on common and proven packet interfaces.

4.2. Management Considerations

In FMA, the MAC Manager acts as the management plane entity which aggregates configuration and operational status of many individual RMDs into a single functional entity. The MAC Manager does not participate in data plane packet handling, a function that is housed completely within the RMD. However, the MAC Manager has larger-scope visibility and intelligence, and the ability to dynamically adjust the behavioral parameters of the distributed RMD packet-processing entities.

The MAC Manager provides an OSSI compatible interface to existing MSO backoffice systems. This enables a backwards compatible transition from CMTS/CCAP deployments into FMA deployments. SNMP, IPDR, and Command Line Interface (CLI) for the RMD population is all realized in the MAC Manager for all subtended RMDs. DHCP and TFTP snooping/intercept is implemented in the RMDs and learned services are provided to the MAC Manager for operational management over the MMI.

The FMA-OSSI specification extends the existing CCAP-OSSI with new object models to manage the subtended RMDs. Streaming telemetry is expected to be added in future phases to allow metrics to be streamed directly from the RMDs or from the MAC Manager to telemetry collectors in the cable operator backoffice.

From a management perspective, transitioning to FMA from an existing CMTS/CCAP with or without RPDs is straightforward. MAC Managers will likely be available as software-only deliverables (virtual machines or container clusters) or may be available in ready-to-deploy server appliances as well. After launching/installing the MAC Manager and giving it an IP address in a routable network, the MAC Manager would be ready to be used.

Like the approach used in the Remote PHY architecture, in FMA the MAC Manager requires L3 connectivity to any RMDs that it will be managing. Also like the approach used in Remote PHY, the RMD learns the network address of the MAC Manager via DHCP options. This discovery mechanism has the RMDs announce their presence to the MAC Manager using addresses provided over DHCP, either via IPv4 or IPv6, to the RMDs. RMDs support discovery of MAC Managers via DNS, IPv4, or IPv6 address. The DNS mechanism is new in FMA and is not supported in Remote PHY. It provides a clear path to virtualized MAC Manager solutions. When deploying container-based solutions into an orchestrator, such as Kuberenetes, the favored approach is through dynamic IPv6 addressing of container instances. Using MAC Manager discovery through DNS eases the deployment of container-based MAC Managers and helps bridge the dynamically orchestrated container environment to the statically deployed RMD environment.

Existing MSO backoffice implementations continue to operate when moving to a MAC Manager and RMD based deployment, while new functionality such as new FMA-OSSI object models, can be layered into existing operational tooling to gain better visibility to the RMD status directly.

4.3. Data Plane Considerations

4.3.1. DAA Advantages

In FMA full spectrum RF is generated at the RMD, just as is done in Remote PHY at the RPD. In CMTS and integrated CCAP, full spectrum RF is generated in the head-end/hub. This relocation of full spectrum RF generation has multiple benefits, including moving from analog modulation (AM) to digital-optics in the HFC fiber plant, improved fiber redundancy, and improved modulation orders in the HFC plant.

Converting the legacy HFC AM fiber to instead carry digital-optical signals represents one of the single most important aspects of moving to a DAA in both Remote PHY and Remote MACPHY deployments. Removing optical AM modulation of RF signals in HFC fiber removes the errors introduced by optical losses such as clipping and optical noise. Digital optics in SFP module form-factors are more robust, enable higher throughput, and make better use of optical wavelengths. Digital optics carry Ethernet/IP packets in a point-to-point connection between the CIN and the OSP Node enclosure housing the RPD and RMD modules. When deployed with DWDM the fiber cable is shared with other point-to-point SFP pairs at unique wavelengths.

In DAA, on one end of the SFP pair is an aggregation switch or router in a Hub or Headend aggregation point. On the other end is an individual RMD or RPD device. Redundancy of this point-to-point link can be handled passively at the optical/Layer 1 or actively at L2 by deploying two SFP pairs with unique fibers or wavelengths between the CIN and a single RPD/RMD, and then configuring active redundancy in the RPD/RMD software. In FMA, active redundancy is standardized using 802.3ad Link Aggregation Group (LAG) and Link Aggregation Control Protocol (LACP).

DAA moves full-spectrum RF generation into the OSP. This supports improved spectral density with higher modulation orders and better MER on the RF portion of the network, which no longer includes the AM optics. All that remains to impact modulation order and MER is the coaxial distance between the DAA node and the CM. This creates an opportunity to greatly improve modulation profile configurations in DAA versus legacy CMTS and integrated CCAP architectures.

The DAA data plane is clearly superior to legacy architectures for the reasons previously mentioned. Within DAA there is however a data plane divergence between Remote PHY and Remote MACPHY to consider. In Remote PHY the MAC continues to be based in a centralized component through integrated CCAP chassis line-card upgrades or transitioning to a virtual Core architecture. DOCSIS packets are opaquely tunneled across the CIN. In Remote MACPHY the MAC is deployed along with the PHY in the RMD. This makes subscriber bearer traffic more readily available at the first-hop Ethernet switch or router. The Remote PHY choice supports integrated CCAP chassis reuse through line-card upgrades. The Remote MACPHY choice enables early routing and maximizes CIN convergence with other applications such as PON, 4G and 5G wireless Xhaul, and business services.

4.3.2. Remote MACPHY Data Plane

Figure 6 illustrates the Remote MACPHY data plane logical architecture. Upstream, the RMD uses digital-optical modules to provide connectivity back to the aggregation network in a hub/headend location. Commonly, this link would be 10G SFP+ DWDM LR modules, though FMA isn't prescriptive on the digital backhaul. The optical interface of the RMD carries subscriber bearer traffic over Ethernet/IP which in the upstream direction has already been BPI+ decrypted and reassembled. FMA RMD uses MACsec L2 encryption technology between the first-hop aggregation device and the RMD to ensure subscriber traffic is encrypted while transiting the OSP fiber links.

Downstream, the RMD outputs RF which could be provided to a launch amplifier and further extended with line amplifiers in N+X or N+0 plant designs before reaching the taps and customer premise. FMA supports full spectrum up to 1.2 GHz DOCSIS 3.1 and 1.8 GHz DOCSIS 4.0, but plant upgrades from existing upper frequencies are not explicitly required by RMD deployments. The cable-plant coax/RF return is also terminated in the RMD with link processing and packet-reassembly occurring in the RMD.

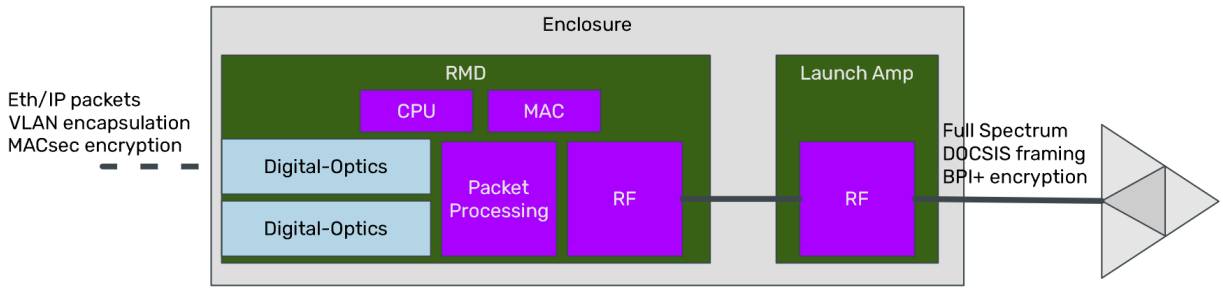

Figure 6 – Logical RMD Architecture

The RMD implements the DOCSIS MULPI and PHY specifications as a L2 CMTS. Remote MACPHY terminates the DOCSIS network in the RMD, a key difference compared to Remote PHY. The DOCSIS MAC is contained within the RMD and both downstream and upstream packet scheduling is managed within the RMD itself.

In Remote MACPHY no additional DOCSIS-specific packet-processing components, physical or virtual, exist in the network. All bearer traffic transiting into or out of the RMD are transparent native Ethernet/IP packets handled by standard switching and routing solutions. Hub and headend space are consequently significantly reduced since no additional compute equipment specific to DOCSIS packet processing is required. The amount of switching equipment needed in the CIN may also be reduced in FMA compared to Remote PHY because the DOCSIS traffic is no longer opaquely tunneled to a packet-processing entity for DOCSIS-specific processing, which can cause the bearer traffic to transit twice across the CIN due to hair pinning to reach the packet-processing entity.

When compared to an integrated CCAP deployment the FMA architecture decomposes the monolithic chassis into composite parts and places functionality into best-fit locations. Access-technology specific functionality moves to the edge closer to the customer and is contained in its optimal location. Packet aggregation at L2 is placed within first-hop aggregation switches and readily capable of horizontal scaling. L3 routing is decoupled from L2 aggregation to allow it to be more centrally deployed and managed.

This architecture can be seen to be very similar to a traditional Broadband Network Gateway (BNG) used with L2 PON devices or in telco copper access with digital subscriber line access multiplexers (DSLAM). Shifting routing to a BNG-like implementation with L2 in the RMD allows for easier convergence for operators deploying a mix of HFC and fiber-to-the-home.

The Remote MACPHY architecture functional decomposition between CIN functions and RMD functions is illustrated in Figure 7.

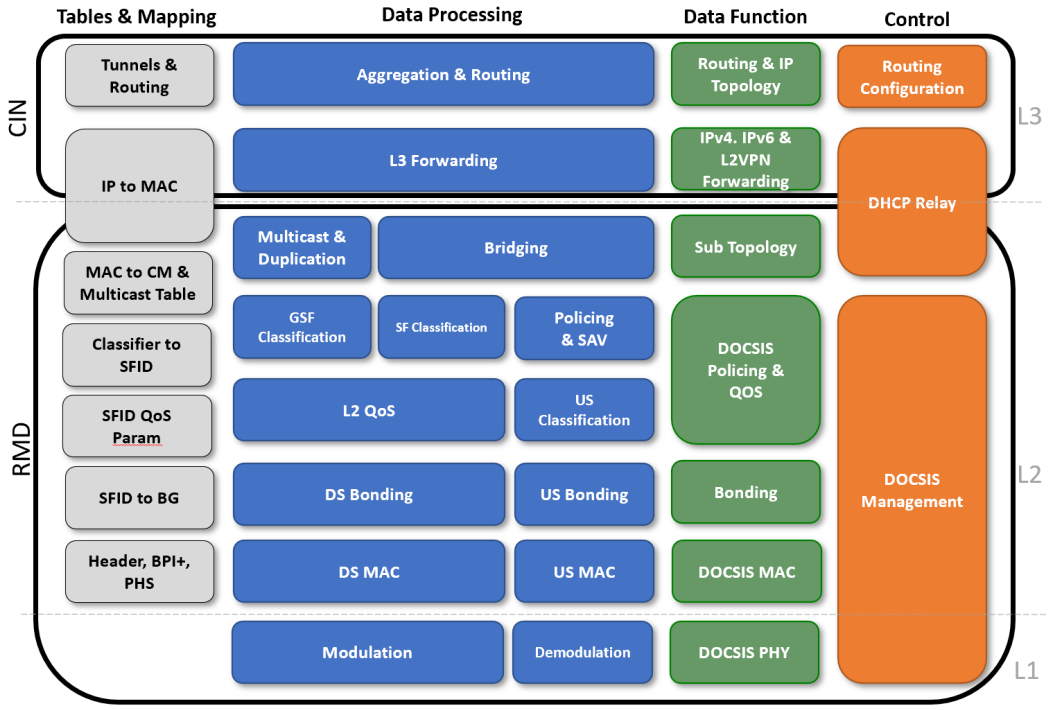

Figure 7 – Remote MACPHY Functional Decomposition

4.3.3. CIN Considerations

FMA outlines one example of CIN design, that of a Spine-and-Leaf illustrated in Figure 8, but does not mandate that type of network layout.

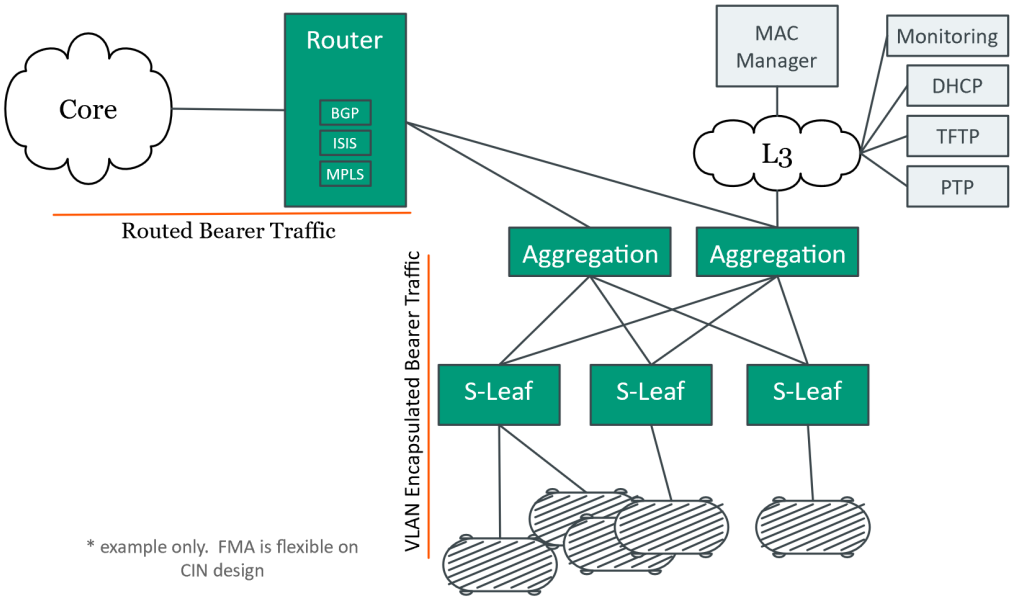

Figure 8 - Spine-and-Leaf CIN

An FMA based DAA does presuppose certain functions are handled within a CIN of any design though. MACsec, DHCP relay, and routing of both are required, as are separation of management and subscriber traffic are supported. The RMD handles certain DOCSIS-specific network functions: DHCP intercept (add/remove DHCP options), TFTP intercept, Source Address Verification (SAV), MAC learning, and cable bundles via VLANs. As such, routing at the first hop networking device is an equally valid topology for FMA.

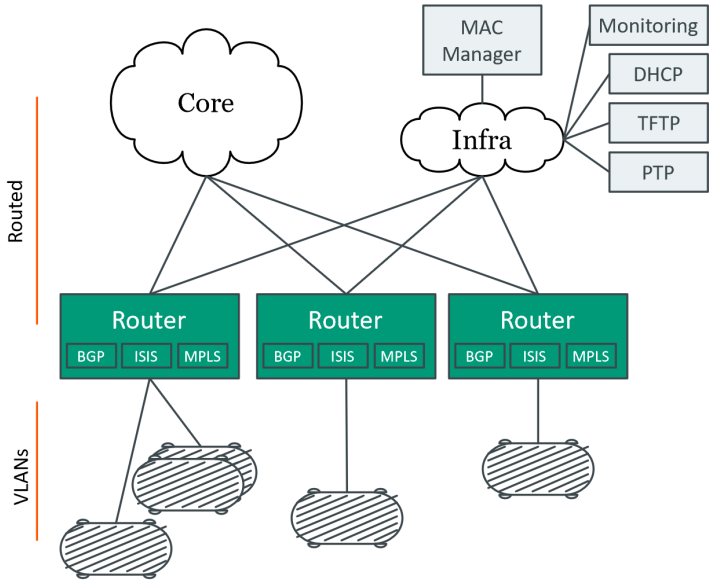

Figure 9 - Flat Network CIN

Spine-and-Leaf can be attractive in designs were high aggregation and oversubscription is expected, though FMA doesn't expect to see large east-west traffic patterns which mutes some of the benefits of this type of CIN. Flat designs are attractive to reduce VLAN stretching and in deployments with high north-south traffic patterns but may result in more routing entities to manage as the network horizontally scales. Operators may want to explore hybrid or other CIN topologies as well.

4.4. PacketCable

4.4.1. PacketCable Overview

PacketCable 1.5 Dynamic Quality of Service (DQoS), PacketCable Multimedia (PCMM) and PacketCable Event Messages (PCEM) are all supported transparently in FMA by the combination of the MAC Manager and PAG applications and the collection of RMDs within their scope. FMA makes the distributed access system appear to the legacy PacketCable backoffice systems as a CMTS or integrated CCAP, greatly simplifying the transition to FMA from legacy systems.

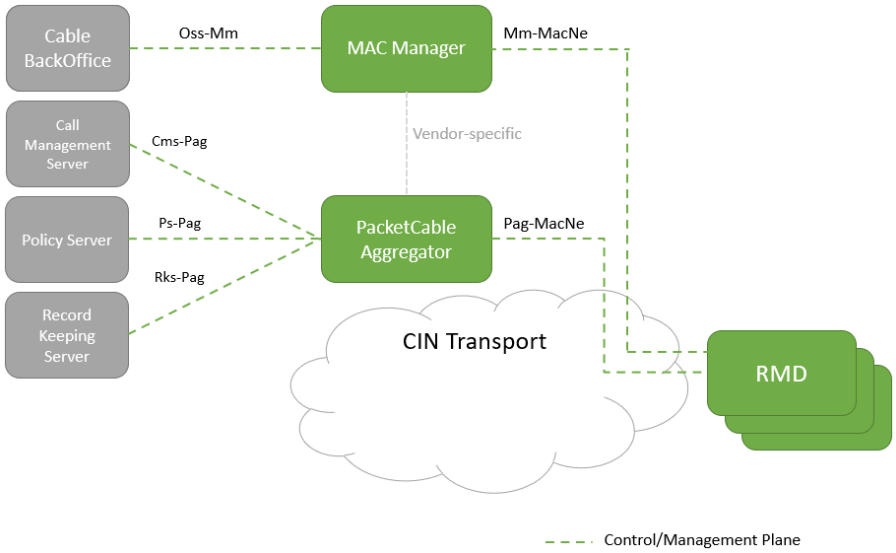

Figure 10 – FMA PacketCable Architecture

The MAC Manager supports MSO backoffice provisioning of PacketCable on the FMA System via the Oss-Mm interface. The PAG enables DQoS via Call Management Servers (CMS) for IP packet-based voice telephony and PCMM via Policy Servers for IP packet-based multimedia applications by providing the necessary COPS-based Cms-Pag control interfaces to these legacy functional entities. The PAG also supports PCEM delivery to Record Keeping Servers (RKS) for accounting purposes via the associated RADIUS-based Rks-Pag event reporting interfaces. The MAC Manager and PAG are software-based applications in the FMA System. They interact in a vendor implementation-specific manner.

The RMDs provide finite state machine operations required of the CMTS in PacketCable specifications. However, RMDs need only communicate with their PAG rather than connecting with one or more CMS, Policy Server and RKS functional entities. This simplifies RMD operations by moving most connectivity management to a central location, the PAG. It also efficiently scales the FMA System by keeping the number of legacy functional entity connections on par with a CMTS or CCAP sized system.

4.4.2. PacketCable Provisioning

Existing CCAP PacketCable provisioning parameters are available in FMA, as specified in CCAP-OSSI and FMA-OSSI. In FMA the Oss-Mm is implemented on the MAC Manager.

The MAC Manager is responsible for provisioning the PAG with its PacketCable parameters. After the PAG receives its PacketCable provisioning it connects to the legacy PacketCable backoffice functional entities. PacketCable DQoS specifies requirements for connecting the PAG with a CMS. PCMM specifies requirements for connecting the PAG with a Policy Server. Both PacketCable DQoS and PCMM specify COPS-based protocols which run over TCP connections. When it is provisioned for event message reporting, the PAG reports PCEM to the RKS via a RADIUS-based protocol which runs over UDP. The RKS destination is not provisioned by the MAC Manager but is signaled dynamically to the PAG in PacketCable DQoS and PCMM control signaling.

When new RMDs come online, they are configured and provisioned by the MAC Manager over the MMI (Mm-MacNe). The MAC Manager is responsible for provisioning the RMD with its PAG address and its PacketCable parameters. The RMD connects to its provisioned PAG over the PAI (Pag-MacNe), which

runs on top of TLS. The PAI supports the complete message set that is specified in PacketCable. It is based on messages defined using Google Protocol Buffers (GPB), which is supported by tooling and automatic source code generation that greatly enhances interoperability.

4.4.3. PacketCable 1.5 Operation

In PacketCable 1.5, the CMS is the call control entity responsible for enabling packet-based voice over IP telephony over a DOCSIS access network. A CMS signals end-to-end to CMs with embedded multimedia terminal adapters (E-MTAs) using the Network-based Call Signaling (NCS) protocol for call processing control. Functionality such as relaying on-hook and off-hook conditions, applying dial tone, collecting digits, and ringing phones are all communicated to and from the CMS via NCS signaling. The PAG and RMD do not participate in end-to-end NCS signaling.

The CMS also controls DOCSIS access network quality of service (QoS) via DQoS signaling. In legacy environments, DQoS runs between the CMS and CMTS or CCAP, opening and closing QoS "Gates" on the access network. In FMA, DQoS operates between the CMS and PAG, which translates COPS-based messages to and from the corresponding PAI messages sent and received over the PAI between the PAG and RMD. The Gate Control operations signaled by a CMS are implemented in the finite state machines of the RMD.

When PCEM is supported, the RMD will generate QoS-related events over the PAI to the PAG. The PAG relays the events to the RKS over the PCEM Rks-Pag RADIUS interface. The PAG does real time event message relay and controls batch processing of events as well. It also manages RKS redundancy with the Primary and Secondary RKS. Event message controls are provisioned on the PAG by the MAC Manager and provided by the CMS in its DQoS messages to the PAG.

4.4.4. PacketCable Multimedia Operation

In PCMM, the Policy Server is the QoS control entity responsible for enabling QoS for PacketCable 2.0 voice telephony and various multimedia applications over a DOCSIS access network. The Policy Server or Application Manager associated with the Policy Server signals end-to-end with end user CPE and applications in an application-specific manner. The PAG and RMD do not participate in end-to-end application-specific signaling.

The Policy Server also controls DOCSIS access network QoS for these applications using PCMM signaling. In legacy environments, PCMM runs between the Policy Server and CMTS or CCAP, opening and closing QoS "Gates" on the access network. In FMA, PCMM operates between the Policy Sever and PAG, which translates COPS-based messages to and from the corresponding PAI messages sent and received over the PAI between the PAG and RMD. The Gate Control operations signaled by a Policy Server are implemented in the finite state machines of the RMD.

When PCEM is supported, the RMD will generate QoS-related events over the PAI to the PAG. The PAG relays the events to the RKS over the PCEM Rks-Pag RADIUS interface. The PAG does real time event message relay and controls batch processing of events as well. It also manages RKS redundancy with the Primary and Secondary RKS. Event message controls are provisioned on the PAG by the MAC Manager and provided by the Policy Server in its PCMM messages to the PAG.

4.5. Lawful Intercept

4.5.1. Lawful Intercept Overview

FMA provides full support for Lawful Intercept. The MSO interface point to Law Enforcement Agencies (LEA) requiring intercept of traffic within the cable operator network is referred to as Mediation Device, or alternatively the Delivery Function. The Mediation Device touches several network entities in the cable operator network to provision Taps on those devices and to collect mirrored traffic and certain traffic-related metadata. The Mediation Device is not specific to FMA. It is inherited from the legacy CMTS and CCAP Lawful Intercept architectures.

The FMA architecture provides alternatives which operators can leverage based upon the functionality present in their networks and the desired method of delivering intercepted traffic to the Mediation Device.

- For PacketCable 1.5 Electronic Surveillance, which supports intercept of PacketCable 1.5 voice traffic, the combination of PAG and RMD enable the functionality that is provided by the CMTS and CCAP in legacy systems.
- For broadband High-Speed Data (HSD) intercepts, the combination of MAC Manager and RMD enable the functionality that is provided by the CMTS and CCAP in legacy systems.
- Alternatively, for broadband HSD intercepts the operator may choose a convergence strategy where routers located above the access networks serve as the focal point for intercepting traffic over disparate access technologies such as HFC, PON and wireless.

These mechanisms are all supported in FMA. The details of each mechanism are provided in the sections which follow.

4.5.2. PacketCable 1.5 Voice Lawful Intercept

In PacketCable 1.5, the CMS is the call control entity responsible for enabling packet-based voice over IP telephony over a DOCSIS access network. The CMS also controls DOCSIS access network QoS using PacketCable 1.5 DQoS signaling. In this environment, requirements for supporting Lawful Intercept have been specified in the PacketCable 1.5 Electronic Surveillance specification.

Intercept Taps are provisioned by the Mediation Device on the CMS. The CMS signals that intercepts are required on a call-by-call basis via electronic surveillance parameters in PacketCable 1.5 DQoS messages, which are sent to the RMD by way of the PAG. If PCEM event messages are to be reported as part of the intercept, the PAG makes note of this and serves as a mirroring point for these events when they are reported to it by the RMD. In this case the PAG mirrors the events toward the Mediation Device.

The RMD implements the voice traffic mirroring point. It mirrors intercepted voice traffic to the Mediation Device as indicated in the DQoS electronic surveillance parameters on a call-by-call basis.

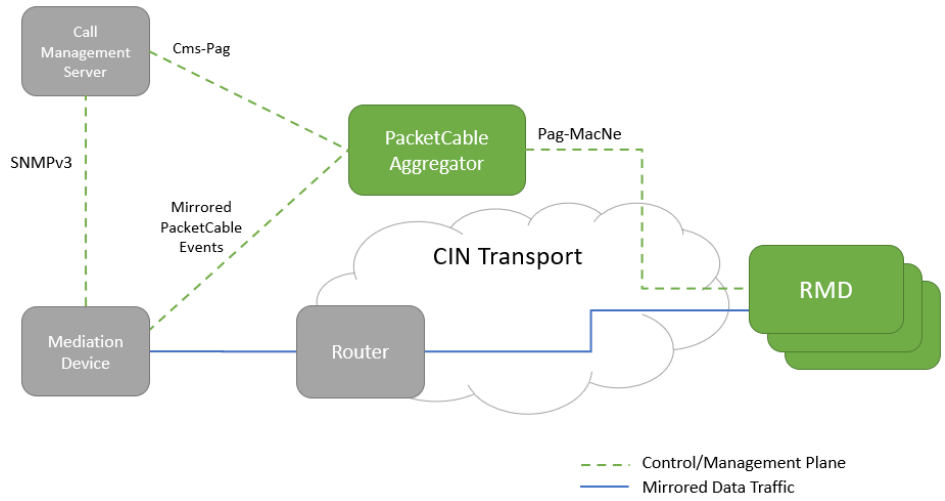

Figure 11 – FMA PacketCable Lawful Intercept Architecture

4.5.3. FMA-specific High Speed Data Lawful Intercept

Broadband HSD traffic on the cable network is also subject to Lawful Intercept. When an HSD Tap is provisioned, the traffic to be intercepted is specified in an FMA Tap MIB that unifies various Tap MIBS which exist in the industry to provision Taps on CMTS and CCAP devices. The FMA Tap MIB provides commonly used parameters and eliminates those parameters that the industry has not found to be relevant.

Intercept Taps are provisioned by the Mediation Device on the MAC Manager via SNMPv3 and the new FMA Tap MIB. The MAC Manager in turn provisions the Tap on the RMD over the MMI. These taps are persistent, unlike the call-by-call Taps used in PacketCable 1.5 Electronic Surveillance.

The RMD implements the HSD traffic mirroring point. It mirrors intercepted data traffic to the Mediation Device as configured by the MAC Manager over the MMI.

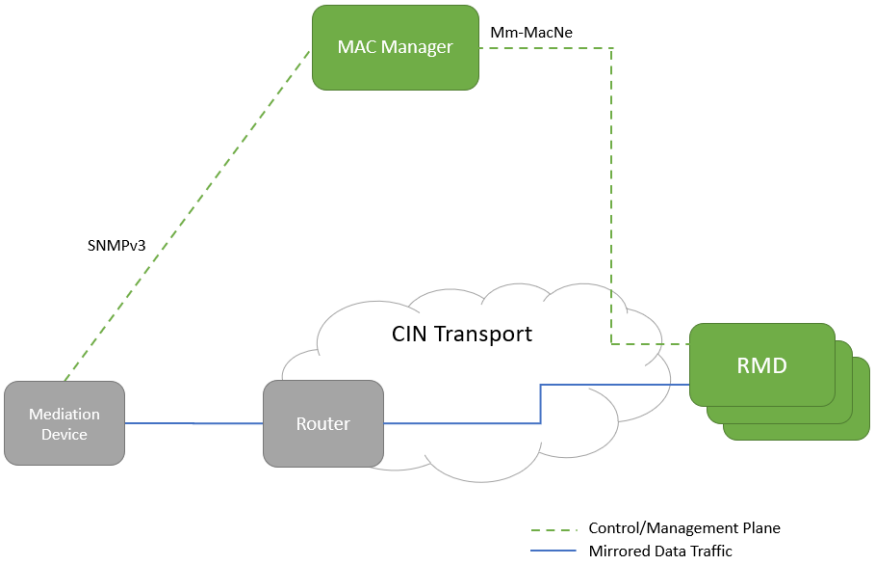

Figure 12 – FMA High Speed Data Lawful Intercept Architecture

4.5.4. Converged Access High Speed Data Lawful Intercept

Broadband HSD traffic is subject to Lawful Intercept regardless of the access technology. Operators with more than one access technology in their network may be wise to consider an architecture where Taps can be done at a common point in the network, such as in a router at a level above the access network. This is an architecture that is independent of access technology. Therefore, while such an architecture would also support FMA HSD traffic intercept, it does not impact the FMA System.

Intercept Taps are provisioned by the Mediation Device on the router via one of the industry-supported Tap MIBs. These taps are persistent.

The router implements the HSD traffic mirroring point. It mirrors data traffic to the Mediation Device as configured by the Mediation Device.

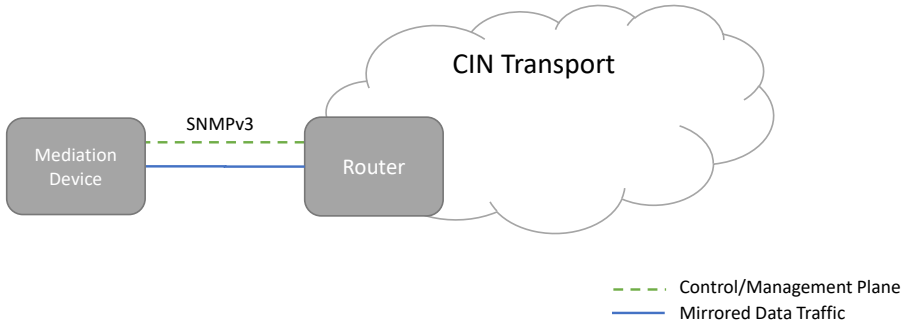

Figure 13 – Converged Access High Speed Data Lawful Intercept Architecture

4.6. Remote PHY Reuse – QAM Video, OOB, and Plant Maintenance

FMA specifications include the idea of eventually incorporating a mixture of flexible MAC (the "FM" in FMA) devices or MAC-NEs under a single umbrella architecture. This could possibly include a CCAP Core configured and monitored by a MAC Manager, or even a Remote MAC Core (RMC) that contains the DOCSIS MAC but feeds subtended RPDs.

There has also been focus on reusing components from the original Remote PHY specifications where possible so that these can be shared between different MAC-NE implementations, potentially in the same market area. This includes three main functions: QAM video operation, set-top box (STB) and other out-of-band (OOB) signals, and signals needed for plant maintenance.

In all cases the same protocols, Generic Control Plane (GCP), Remote Downstream External PHY Interface (R-DEPI), Remote Upstream External PHY Interface (R-UEPI), and Remote Out-of-Band (R-OOB) are used by FMA so the associated centralized components, the Auxiliary Cores, supporting these functions do not need modification to serve all forms of MAC-NE in an FMA System.

Auxiliary Core operation in FMA relies on the same mechanisms as Remote PHY, with the exception that the MAC Manager configures all the Auxiliary Core information on the RMD before the RMD can start GCP operation. The MAC Manager does not need to interact with Auxiliary Core except to be able to configure the core details in the RMD.

4.6.1. QAM Video

DAA QAM video implementations have evolved as Remote PHY systems have moved into scaled deployment and the unique needs of operators are being addressed. [QAMVideoDAA] provides an excellent summary of the options available and considerations in those Video Cores and Traffic Engines. Figure 14 summarizes options generally available and being deployed by operators for QAM video in any DAA environment, whether it be Remote PHY or Remote MACPHY.

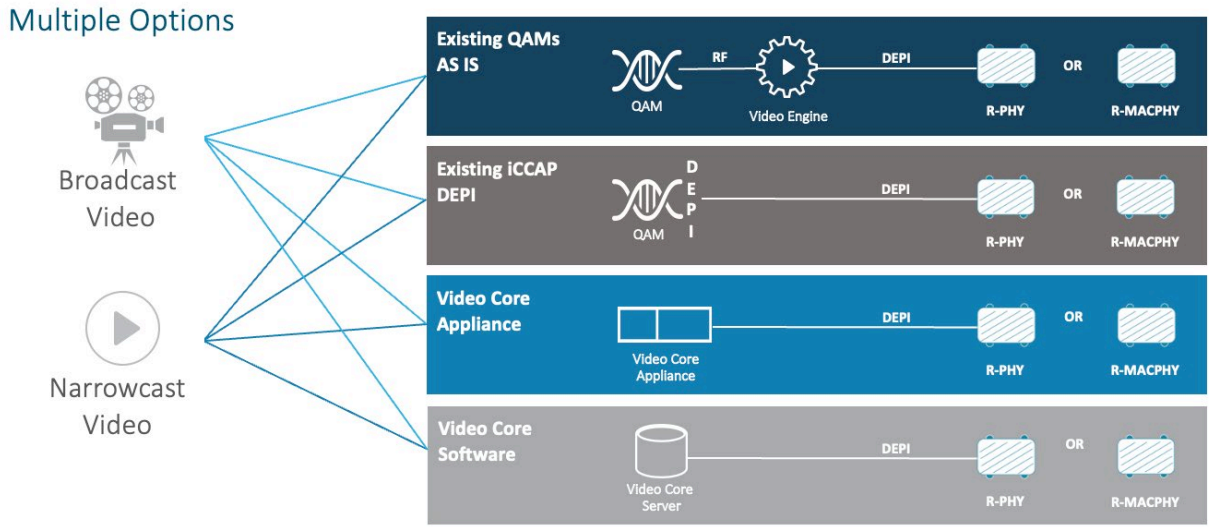

Figure 14 - QAM Video Implementation Options

4.6.1.1. Edge QAM and Traffic/Video Engine

Operators can leave existing Edge QAMs in place and deploy large scale QAM demodulators to convert pre-encrypted, full rate QAM, multi-program transport streams (MPTS) with NULL packets into R-DEPI format for transport to the RPD or RMD. This solution is also referred to as a Traffic Engine, which means a device that supports the QAM video data plane only, leaving Auxiliary Core operation to configure the video channels to other components. The MAC Manager can support video configuration of Traffic Engines on the RMD through the MMI as a static pseudowire.

4.6.1.2. Fully Integrated CCAP

Many operators have existing integrated CCAP solutions that support all their QAM video needs for analog node deployments. Some integrated CCAP solutions may also support R-DEPI out for Remote PHY operation and Auxiliary Core operation. These solutions can provide DAA QAM video for RPDs and RMDs alike.

4.6.1.3. Standalone Video Core

A third alternative is a Standalone Video Core appliance or software solution that contains both traditional Edge QAM functions (narrowcast video control plane, single program transport stream (SPTS) to MPTS multiplexing, encryption) and provides an R-DEPI output compatible with any RPD or RMD solution. These Video Cores may support both Traffic Engine for video data plane and Auxiliary Core for

GCP control or may just act as the Traffic Engine and support configuration using the MAC Manager with static pseudowire objects specified over the MMI.

4.6.2. Out-of-Band

QAM video deployments in HFC with traditional STBs require a way to provide authorization, encryption messaging, and software update capability for those STBs. Options for the transport of this traffic includes:

- DOCSIS 1.0-3.1 – No specific functionality is required in the FMA system to accommodate.
- DOCSIS Set-Top Gateway (DSG) – The RMD operates as a DSG Agent. An additional accommodation of adding NAT64 to the DSG Server in the network and a DSG Agent in the RMD is required if the operator chooses to deploy in an IPv6-only environment. This functionality is unique to FMA and not reused from Remote PHY.
- SCTE 55-1 – ALOHA protocol, typically used with Motorola conditional access.
- SCTE 55-2 – DAVIC protocol, typically used with Scientific Atlanta conditional access.

Similar to QAM video, SCTE 55-1 and SCTE 55-2 in FMA reuses implementations already supported in Remote PHY. Figure 15 illustrates these options – NDF/NDR or direct OOB operation using an OOB Core.

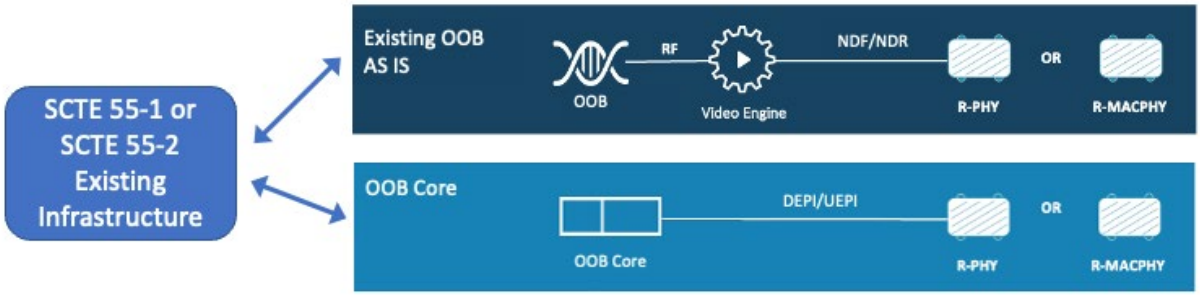

Figure 15 – Out-of-Band Implementation Options

4.6.2.1. NDF/NDR

NDF digitizes narrowband signals from the existing RF-based SCTE 55-1 and 55-2 systems with a centrally located Video Engine component which then transports the digitized signal using R-DEPI to the RPD/RMD where it is regenerated and transmitted to the STB.

NDR digitizes narrowband return signals from the STB in the RPD/RMD and transports them back to the Video Engine component using R-UEPI. The Video Engine regenerates those signals and transmits them back to the existing 55-1 or 55-2 RF systems.

SCTE 55-1 is tolerant to jitter and latency, so NDF/NDR operation is robust in many different deployment architectures.

The SCTE 55-2 protocol requires fast acknowledgements (under 3ms) of received STB transmissions. As a result, SCTE 55-2 operation using NDF/NDR requires shorter distances between the Video Engine and

RPD/RMD, as well as tight control of round-trip network latency. This general DAA constraint applies to both RPD and RMD systems.

4.6.2.2. Direct SCTE 55 Operation

In direct operation mode, centralized components are added which replace or augment the existing RF-based systems in place for SCTE 55-1 and SCTE 55-2.

For SCTE 55-1, downstream Moving Picture Experts Group (MPEG) transport packets from existing control components are R-DEPI encapsulated by a centralized 55-1 OOB Core function and subsequently decapsulated and modulated onto SCTE 55-1 OOB RF channel(s) at the RPD/RMD. Upstream ATM-like cells are R-UEPI encapsulated at the RPD/RMD and subsequently decapsulated at the 55-1 OOB Core, which groups together multiple RPD/RMDs to look like a single legacy RF component to minimize issues with scale of the existing control components.

The centralized 55-1 OOB Core function can be implemented as:

- Part of the CCAP Principal Core in Remote PHY – Extra functions are integrated within an Integrated CCAP Core already serving DOCSIS and QAM video.
- An Auxiliary Core in Remote PHY and FMA – A single element contains both data plane transport over R-DEPI and configuration of RMD/RPD using GCP.
- A Traffic Engine in Remote PHY and FMA – A data plane only element based on static pseudowires, with configuration coming from the Principal Core using GCP in Remote PHY or the MAC Manager using MMI in FMA.

For SCTE 55-2, existing centralized RF-based control components are replaced by functions in the RPD/RMD and a centralized 55-2 OOB Controller. The 55-2 OOB Controller acts as an Auxiliary Core, containing the full 55-2 MAC and connecting to the video backoffice. The 55-2 OOB Controller encapsulates downstream packets in R-DEPI format and transmits them to the RPD/RMD, which performs R-DEPI decapsulation and RF modulation. In the upstream the RPD/RMD demodulates RF, encapsulates as packets in R-UEPI format and transmits to the 55-2 OOB Controller. The RPD/RMD must also perform some lower layer MAC functions such as upstream acknowledgement insertion. Lower layer MAC functions for 55-2 are included in the RPD/RMD to ensure tight ACK turnaround times can be met with long distances and higher jitter between the OOB Controller and RPD/RMD.

4.6.3. Plant Maintenance

Reliable operation of the HFC system requires support of the operational tools used by field technicians to setup and monitor critical RF OSP conditions. Each of these tools for FMA RMD operation leverages the systems already deployed widely for Remote PHY:

- Downstream and upstream sweep – Sweep provides ongoing validation of proper signal levels across the entire downstream and upstream bands to detect excessive cable loss and impairments between the node (RPD/RMD), amplifier cascade, passives and CMs in the plant. Available options for sweep operation in Remote PHY are reused for FMA and are described in R-OOB Appendix III.
- Upstream spectrum capture – Capture of the upstream spectrum as part of overall proactive network maintenance (PNM) provides significant benefit to operators to understand sources of upstream packet errors due to persistent or intermittent noise and ingress. Upstream spectrum

capture operation for Remote PHY is reused for FMA and is described in R-UEPI sections 8.2.8 and 8.2.9.

- Leakage detection – Regulators mandate that cable operators ensure the cable plant does not "leak" RF energy into frequency bands that may be susceptible to interference (e.g., aeronautical communication frequencies or spectrum used by licensed mobile wireless systems). Identifying and repairing faults as part of PNM leakage detection activity also reduces errors due to ingress interference from those other uses. R-OOB Appendix IV and Section 9 describe operation of downstream leakage detection. In the future, High Split systems where upstream OFDMA signals will operate in the aeronautical frequency band on potentially licensed mobile wireless frequencies will require additional support, which has recently been added into CableLabs® DOCSIS specifications. See [LeakageHighSplit] for details on the specifications and High Split leakage detection solutions. It should be noted that all High Split leakage detection solutions in the specifications are applicable to both Remote PHY and FMA RMD deployments.

5. FMA Migration Considerations

As operators begin their journey toward the Emerald City to enable the deployment of FMA with RMD, it will be important to know what they should take with them. If their journey started with legacy systems in Kansas, a transition to DAA is required. If their journey began with Remote PHY, a DAA starting point is already in place. In either case it is important to understand the similarities between Remote PHY and FMA standards and components as well as where they diverge. Knowing this can help operators identify common operational benefits where Remote PHY and FMA may coexist and understand the changes required if transitioning deployments from Remote PHY to FMA with RMD.

Table 1 summarizes the reuse opportunities for each of the steps.

Table 1 - FMA Migration and Remote PHY Reuse

FMA Migration Step	Remote PHY Architecture and Component Reuse
Fiber node change	Yes
OSP analog to digital optics change	Yes
CIN - L2 RMD aggregation layer	Yes
CIN - 802.1X RMD port authentication	Yes
CIN – MACsec encryption	No – MACsec not used in Remote PHY with BPI+ applied at CCAP Core
CIN – DHCP for RMD	Yes
CIN - Synchronization (PTP/SyncE)	Yes, but PTP only needed in FMA for delivering precision time services such as Mobile Xhaul
CIN – L2/L3 termination	No – largest area of divergence
QAM video and STB OOB support	Yes
Plant maintenance tool updates	Yes
MAC Manager addition	No – Remote PHY pCore/vCore management possible with MAC Manager in future FMA phases

5.1. Migration Steps with Remote PHY Reuse

The FMA network migration steps listed below all have significant reuse of Remote PHY architecture and components.

5.1.1. Fiber Node Change

An analog fiber node is swapped for a Remote MACPHY node or a new Remote MACPHY node is deployed instead of splitting an existing analog node.

Remote MACPHY node installs in the OSP are effectively the same as Remote PHY conversions by migrating to nodes with digital Ethernet optics capability.

5.1.2. OSP Analog to Digital Optics Change

The traditional OSP analog fiber distribution and associated wavelength division multiplexing (WDM) equipment is converted to digital optics with appropriate pluggable Ethernet transceivers. Outdoor mux/demux are installed as needed to match the wavelength and fiber planning.

Remote MACPHY OSP digital-optical fiber conversion is the same as Remote PHY and, in fact, investments in digital conversion for Remote PHY can be reused for Remote MACPHY deployments.

5.1.3. CIN - L2 Remote MACPHY Aggregation Layer

The new digital Ethernet optics and associated Remote MACPHY node are connected into a L2 aggregation network as the node-facing part of the CIN.

The L2 aggregation CIN network is very similar between Remote PHY and Remote MACPHY with the exception of some considerations for segmenting offered services into VLANs that is available in Remote MACPHY.

5.1.4. CIN - 802.1X Remote MACPHY Node Port Authentication

The L2 CIN is provisioned to support 802.1X mutual authentication for network access control.

802.1X operation is very similar between Remote PHY and Remote MACPHY as a way to ensure there is no unauthorized access into the CIN L2 aggregation layer.

5.1.5. CIN – DHCP for Remote MACPHY

A DHCP server, IPv4 or IPv6, is configured to serve RMDs and provide the MAC Manager network location via IP address or DNS name.

RMD boot and DHCP mechanisms are based on the initialization and operation of RPDs.

5.1.6. CIN – Synchronization (PTP/SyncE)

As an optional step, IEEE 1588 PTP Grandmasters (GMs) are added and connected to the CIN if needed for precision time services such as Mobile xHaul. Network elements in the CIN between GM and RMD are provisioned as Boundary Clocks or Transparent Clocks as needed to meet precision timing performance requirements. SyncE network clock synchronization may also be added as needed to meet precision timing performance requirements.

In contrast with Remote MACPHY, Remote PHY networks cannot operate without PTP phase and frequency synchronization, which is required between the CCAP Core and RPD for DOCSIS scheduling. While Remote MACPHY does support R-DTI requirements from Remote PHY, PTP is only needed in

FMA for delivering precision time services such as synchronization for small cells or mobile Xhaul. Depending on implementation in any deployed Remote PHY equipment, coexistence of Remote MACPHY and Remote PHY in the same network may also require the use of PTP for frequency synchronization for synchronous QAM video or NDF/NDR solutions.

5.1.7. QAM Video and STB OOB Support

QAM video and STB OOB support are added in the network using Video Engine(s), Traffic Engines and Auxiliary Cores using whichever best fits the operator video backend and STB infrastructure. The MAC Manager directly configures static pseudowires on the RMD or directs the RMD towards the Auxiliary Core(s) for further configuration.

QAM video and Remote PHY R-OOB functions (55-1, 55-2, NDF/NDR) are all directly reused in FMA.

5.1.8. Plant Maintenance Tool Updates

Updated versions of plant maintenance operational tools for sweep, spectrum capture, and leakage detection are installed and configured, with the RMD provisioned for working with these tools through the MAC Manager as needed.

Plant maintenance tools used in the network are the same for Remote PHY or FMA.

5.2. Migration Steps Divergent from Remote PHY

The FMA network migration steps listed below all diverge from the Remote PHY architecture and do not reuse components from Remote PHY.

5.2.1. CIN – MACsec Encryption

FMA/Remote MACPHY adds configurable MACsec encryption in the L2 aggregation layer for operators who choose to encrypt all traffic in the OSP network segment(s).

Remote PHY encrypts user traffic with BPI+ from the CM through the RPD and CIN to the CCAP Core, so MACsec encryption is not required for bearer traffic. Remote PHY does not mandate encryption for non-bearer traffic such as management and control signaling between the Core and RPD, or for certain types of signaling between back-office and CM, such as DHCP and TFTP.

A CIN which converges PON access along with HFC will generally require MACsec for the same reasons as FMA with Remote MACPHY since the PON layer terminates at the OLT or Remote OLT.

5.2.2. CIN – L2/L3 Termination

A router is configured to route bearer traffic from the RMD to the Core network through the CIN.

The largest divergence between Remote PHY and FMA is the decoupling of L3 routing from DOCSIS packet processing. In FMA there is no centralized DOCSIS packet processing engine terminating an L2TPv3 tunnel containing DOCSIS frames and providing a L3 CMTS northbound router for the customer traffic. Rather, the RMD terminates the DOCSIS frames and acts as a L2 CMTS northbound toward the aggregation network. L2 packet flows are aggregated at a standard L3 router to provide routing into the operator core network. Customer bearer traffic is directly accessible for aggregation, switching, and routing at the first-hop switch or router which can be selected from a range of readily available switch and

router vendors. Traffic engineering of natively transported traffic in an FMA CIN is a considerable upside of the architecture.

5.2.3. MAC Manager Addition

A MAC Manager is deployed and configured with IP routable connectivity between the RMD network location and the MAC Manager, with provisioning for the associated RMD(s) configured on the MAC Manager.

No MAC Manager is present in current Remote PHY systems but the "Flexible MAC" part of FMA can be utilized to manage pCore/vCore MAC-NEs in future FMA phases once that operation is standardized. In this way, the Remote PHY portion of the network can eventually be brought under one FMA umbrella.

6. Other Architecture Considerations

There are several other important architecture considerations between traditional integrated CCAP, CCAP + Remote PHY, and FMA with Remote MACPHY deployments.

6.1. CIN Latency

Scheduling upstream traffic on a DOCSIS access network relies on a request and grant cycle between the CM requesting bandwidth and the entity scheduling minislots against those requests.

Both Remote MACPHY and traditional integrated CCAP co-locate the MAC and PHY components so there is no additional delay added to each request and grant in the protocol. No CIN impact on DOCSIS request/grant cycle latency is present in FMA with RMD. In addition, as shown in [FMACloud], latency between the MAC Manager and RMD is not a critical consideration for system operation since no data plane functions exist between MAC Manager and RMD.

In Remote PHY the MAC and PHY are in separate devices separated by a CIN of one or more hops. CIN latency and jitter between the CCAP Core MAC and RPD PHY add to request and grant cycle, thereby lengthening the time for CM bandwidth requests to be served and increasing upstream latency. The impact is dependent on the distance and delay within the CIN as well as the DOCSIS MAP interval. Centralization of the CCAP Core exacerbates the problem by extending the distance, delay and probability of jitter, so careful consideration of where CCAP Cores are placed is needed in Remote PHY systems.

6.2. Deployment Granularity

In traditional integrated CCAP and CCAP + Remote PHY deployments, space and power targets for hub-based equipment have resulted in high density chassis which serve tens to hundreds of service groups in a single element. This tends to result in a natural bundling and a deployment architecture where only the largest geographic areas get the latest high density chassis features and capabilities. CCAP + Remote PHY deployments can help with this by centralizing the CCAP Core to share over a large geographic area but then the CIN latency impacts of section 6.1 can result in degraded upstream latency.

In contrast, the latency tolerance of the disaggregated MAC Manager and RMD in FMA allows for service groups to be added one RMD at a time, with operational efficiency by using a centralized MAC Manager which can be deployed 1000s of kilometers away. This makes RMD with FMA well suited to rural and other low-density locations, or as a way to boost capacity in targeted locations within a larger urban center while continuing to use integrated CCAP or CCAP + Remote PHY.

7. Conclusion

We know why we want to go to the DAA Land of Oz and, once there, why we want to go to the Emerald City. There's a clear path to the Emerald City once in Oz, and that path as not as scary as it would seem since we can take along plenty of familiar friends for support.

This paper has presented a comprehensive discussion of the considerations for migration of HFC delivered services from traditional integrated CCAP or CCAP + Remote PHY architectures to FMA with Remote MACPHY. Significant reuse of architecture and network components between Remote PHY and FMA allows operators deploying FMA with Remote MACPHY to:

- Obtain the well understood and proven benefits of DAA
    - Converged digital Ethernet optics
    - Improved end of line RF performance for greater capacity
    - Improved field operations through intelligent nodes
- Apply the lessons learned by the industry during Remote PHY deployment in an FMA deployment
- Support coexistence of Remote PHY and FMA with Remote MACPHY within the operator network
- Support a graceful migration from Remote PHY to FMA with Remote MACPHY

Some areas will be different between Remote PHY and FMA for operators – this isn't Kansas anymore – but these offer a pathway to the future of cable operator access networks:

- Disaggregation of the management and data planes through the FMA MAC Manager
- Access network abstraction through the FMA MAC Manager
- A common L2 architecture similar to PON for convergence on the overall access network L2/L3 topology

The near future is sure to be very active in FMA with standards activities moving from specification writing to product implementation, interoperability events happening to demonstrate the multi-vendor capability of FMA, and the upcoming industry movement towards DOCSIS 4.0 which requires DAA nodes for deployment.

1. Introduction

Patent pools are increasingly well known as a mechanism to license patents essential to a technical standard. Pools have a variety of benefits, including relative ease in licensing for both licensors and implementers ("one-stop shop") and a lower aggregate royalty level. CableLabs had early experience when it launched in the mid-1990s the first modern day pool covering MPEG2-essential video codec patents. Since then, pools cover a variety of technologies, including video codecs that succeeded MPEG2. Other pools today encompass a wide range of standardized technologies implemented by cable operators or used in cable households. Over time, the fractured licensing environment for the video codec HEVC brought many industry players to look for greater clarity for licensing of the most recent ISO/IEC MPEG video codec, Versatile Video Coding (VVC). Earlier this year, the Media Coding Industry Forum (MC-IF) completed its fostering of pool formation covering VVC-essential patents.

When implementing a video codec in a cable network, SCTE and its members bear in mind not only the technical merits of the standard but also the overall costs, including royalties paid to patent owners by their vendors (e.g., set-top box manufacturers). Patent pool formation and licensing have a cost but provide certainty and other benefits that are attractive to the cable operator and to their vendors. Some of these benefits can be passed on to subscribers and other consumer households.

As undertaken by MC-IF, fostering is a pre-commercial activity that is intended to result in the selection of a single pool administrator that takes forward the work of pool facilitation. Once facilitation is completed (the licensors have agreed royalties and other terms, royalty split, the role of the administrator), the administrator manages the pool, including licensing, royalty collection and distribution to patent owners.

Pool formation takes time. For this reason, MC-IF recognised that it was important to launch the pooling effort soon after the adoption of the new VVC standard. This effort was based in part on the experience of the DVB Project in fostering pools essential to DVB standards. MC-IF scaled DVB's process to meet the challenges of the VVC patent environment: dozens of holders with diverse business models drawn from the audio-visual industry, but also widely divergent industries. Some based their revenues wholly on collection of royalties; some largely on sales of devices and services (while owning one or more VVC-essential patents). In this paper, Section 2 describes patent pooling and its growing use as a tool for licensing patents essential to the implementation of a standardised technology. Section 3 sets out the experience of DVB (and other standards bodies) in fostering the formation of pools covering their standard essential patents. Then Section 4 shows how MC-IF applied DVB's approach to pool fostering in its effort to foster a pool for VVC-essential patents, notably with the goal of the selection of a single pool administrator. Section 5 concludes, first by presenting some "lessons learned" from the VVC pool fostering activity. These lessons could inform future efforts at patent pooling. That section also offers a comparison of VVC Pool Fostering with the licensing frameworks for other next generation video codecs.

2. Patent pooling

Patent pools are increasingly well known as a mechanism to license patents essential to a technical standard. A patent pool is licensing program under which patents essential to a standardised technology are jointly administered by a licensing administrator. This model was introduced by a MPEG LA in the mid-1990s with its pool covering MPEG2-essential video codec patents. It has been adopted by other licensing administrators such as Sisvel and Via Licensing and the recent new entrant Access Advance. Very broadly, the formation of a patent pool is facilitated by a licensing administrator who calls for participation by holders of patents essential to the target technology; it manages the process for review, often by an independent expert, of patents claimed to be essential; and the administrator convenes meetings of holders to negotiate terms, for example, on the joint patent license and on distribution of royalty income among the pool participants. This first step, pool facilitation, can take well over a year to complete. When the participants have agreed on the terms, the licensing administrator launches the licensing program, encourages implementers to take up licenses, and collects and distributes royalties.

Patent pooling is an attractive alternative to other licensing models like bilateral licensing (licensing after negotiation between individual patent owner and individual implementer). Pooling offers a variety of benefits, including relative ease in licensing for both licensors and implementers ("one-stop shop"); a lower aggregate royalty level; and through its essentiality review process, greater certainty of patent quality. CableLabs had early experience when it launched in the mid-1990s the first modern day pool covering MPEG2-essential video codec patents. When CableLabs formed MPEG LA, it worked with the US Department of Justice in developing a number of safeguards to reduce the risk of anticompetitive practices. These included: only standard essential patents may be offered through the pool; the patents holders remain free to license bilaterally; the licensing administrator is independent; and sensitive market information is not communicated to the royalty recipients.[1] This well-settled regulatory framework that reduces exposure to claims of antitrust violation is another attractive feature of today's pooling environment.

Since the launch of the MPEG2 pool, pools cover a variety of technologies. In addition to the video codecs that succeeded MPEG2, these technologies include DVB and ATSC transmission standards; mobile telephony standards; differing audio formats; Wi-Fi (802.11) and more. The success of the MPEG2 pool, and of MPEG LA as pool administrator, has encouraged other commercial entities to offer pooling services, notably Sisvel (whose first pool indeed predates MPEG LA), Via Licensing, and more recently Access Advance and Avanci.[2]

[1] The regulatory framework is set out in a series of Business Review Letters issued by the US Department of Justice. MPEG LA's 1997 letter can be found at on the Department of Justice website here. The framework has evolved as reflected, for example, in a recent letter, *University Technology Licensing Program* (13 Jan 2021).

[2] A list of pools currently operational and under development can be found at the websites of the licensing administrators. See Further Resources below. Until recently Access Advance was known as HEVC Advance.

As a result of over two decades of commercial activity, it's possible to identify elements of the technology marketplace that are well-suited for an intermediary to provide patent pool license administrator services and to derive profits for such services.. A licensing administrator can be useful when

(a) ownership of standards-essential patents is widely diffused (ownership is not concentrated in few holders);

(b) manufacturers (implementers of the technology) are numerous,

(c) for the production of numerous implementations, notably interoperable devices (and corresponding services) for large consumer markets (for example, where the market can be measured in billions of implementing devices);

(d) the standardised technology will not be overtaken quickly by other technological developments; and, relatedly,

(e) the standardised technology will be a market success, ideally a blockbuster, government-mandated or otherwise compelling.[3]

Broadcast transmission standards have fit within the framework. For example, the ATSC pool had (at inception) some eight licensors, a number of manufacturers of ATSC-implementing devices and enjoyed a market primed by analog switch-off (replacement of analog broadcast services with digital broadcasting), mandated by government, and a government subsidy for household purchase of ATSC consumer equipment. Similar factors have influenced territories adopting DVB terrestrial transmission standards. And broadcasting has had in the past long technology development cycles, for example to reduce the risk of obsolescence of television receivers targeted by broadcasters under a public service mandate but constrained by terrestrial frequency scarcity.

Pooling can fail. Pools can fail during the facilitation phase: for example, the call for participation fails to attract the holders of a critical mass of patents, or significant holders representing the key commercial innovation for a standard remain outside the pool. Or holders may not agree on royalty split or other terms. After formal launch, the pool may not be commercially successful because implementers find the terms unattractive and they prefer to wait to see if anyone else takes a license (a form of holdout). The technology underlying the pooled patent may not be a commercial success if it's displaced by later innovation. Pooling can also fall short if there are multiple, competing pools for the same standardised

[3] These factors are drawn from an unpublished study prepared by one of the authors for a standards body then considering offering commercial licensing administration services.

technology. A pool administrator can also abandon a pool if it does not enjoy the anticipated commercial success and it finds that it's more lucrative to commit its resources elsewhere.

In the case of HEVC, competing pools, offering different licensing models and royalty rates, confused the landscape for obtaining licenses of HEVC-essential patents. The confusion arguably slowed market adoption of this video codec technology. As a result of this recent, indeed ongoing, experience, many industry players looked for greater clarity for licensing of the most recent ISO/IEC MPEG video codec, Versatile Video Coding (VVC). Earlier this year, the Media Coding Industry Forum (MC-IF) completed its fostering of pool formation covering VVC-essential patents. Its effort was based in part on the experience of the DVB Project in fostering poo ls essential to DVB standards. Section 3 of this paper sets out DVB's experience in pool fostering; section 4 discusses the application by MC-IF of this experience to its effort in VVC pool formation.

3. Pool Fostering

Pool fostering is generally the effort undertaken by a standards body to encourage the formation of a patent pool covering one of its standards. It is an extension of the work of the standards body after it completes development of the standard. As such it is a precommercial activity, preceding pool facilitation and administration. As a precommercial activity, it generally adheres to the antitrust rules governing standards bodies, including no exchange of market sensitive information, no anticompetitive collusion among participants, etc.[4]

Pool fostering is a response to the perceived risk of market failure of a recently adopted standard due to concern over onerous aggregate royalties or other difficulty in licensing the underlying patents. By and large, there's little need for fostering if the assessment of commercial pool administrators is that a pool is viable, and they independently take preliminary steps leading to pool facilitation. On the other hand, fostering is valuable when participants of a standards body consider that an early start in clarity in licensing for a new standard will be an advantage for market acceptance of its standard. For example, the contributors to the SDO's standard (often the holders of patents essential to these contributions) may have knowledge of the capabilities of the technology and its market potential superior to that of licensing administrators. The SDO participants are aware that a pool may enhance the attractiveness of the SDO's innovation, overcoming market "hesitation." [5]

[4] Pool fostering is discussed extensively in Eltzroth, *Fostering by Standards Bodies of the Formation of Patent Pools* (2018) available at SSRN.

[5] Other instances of "market hesitation" include: when modern pooling was relatively unknown (CableLabs fostering, leading to the MPEG LA pool); and when the commercial returns for otherwise "orphaned" standards are not evident. Fostering may be suitable as a first step to a pool to be sponsored by the standards body (AVS1 pool, sponsored by the Audio Visual coding Standard Workgroup of China; IEEE's similar activities in the 2010s).

Pool fostering can also be attractive to licensors to get an early start on pooling and to reaffirm early licensor interest in "one-stop shop" and the other benefits of pooling. This was the case for VVC pool fostering (discussed in Section 4) when many patent holders shared the market perception that confusion in HEVC licensing caused in part by multiple pools had slowed take-up of HEVC technology. Another feature of pool fostering is that it offers the opportunity for all licensing administrators, incumbents, and new entrants, to present their capabilities and expertise to licensors on a "level playing field." This would reduce the advantages of incumbency. In addition, those new to pool licensing (and indeed new to exploitation of their patents by licensing) can engage with colleagues to discuss pooling, within a framework virtually without enduring legal commitments.

DVB's experience with pool fostering started shortly after its inception in the mid-1990s, prompted by the provisions of the IPR policy in its Memorandum of Understanding.[6] The initial approaches to pool fostering were not the most efficient and through trial and error, across a number of fostering efforts, DVB has developed a "toolbox" to advance a pool fostering effort. Today these include early identification of probable holders of patents essential to a recently adopted DVB standard; after completion of standards development, prompt convening of these holders to an initial meeting of holders; as guided by these participants, exchanges of information between the participants and candidate pool facilitators; formal presentations by the candidates; selection by the participants of a facilitator to take forward the work of pool completion and ultimately pool administration.

Based also on close to three decades of fostering, DVB has a set of well-settled rules for the conduct of fostering, including the basis of participation by a holder of DVB-essential patents; confidentiality; decision by consensus; and equality of treatment. Each of these is geared to be "light-touch," that is not imposing undue burdens and costs on participants. These ground rules were largely adopted in VVC Pool Fostering (discussed in Section 4) with modifications to account for the larger number of participants and the need to hold meetings entirely remotely as a result of the COVID pandemic. In both DVB and VVC Pool Fostering, there was careful attention to adherence to antitrust rules: as with conduct within standards bodies, pool fostering is treated as a precommercial activity. In DVB's pool fostering, commercially sensitive information was not exchanged, and participants were reminded of the constraints on their jointly decided actions.[7]

[6] A discussion of how DVB was brought to include pool fostering in its IPR policy is included in Eltzroth, *IPR Policy of the DVB Project*, Int'l J IT Standards & Standardization Res (2008, 2009) available at dvb.org.

[7] DVB's toolbox is summarised in a DVB document promoting pool fostering, DVB Project, *DVB's Fostering of early Formation of Patent Pools: Note to DVB's Liaison Partners and to Standards Bodies that author Materials normatively referenced by DVB Standards.* See Further Resources.. DVB has other tools relating to pools, involving the use of its IPR Module as a sounding board for exchanges of views of possible licensing terms. (VVC Pool Fostering did not exclude a later meeting to discuss pool developments if circumstances warrant.) DVB also intervenes when a pool is failing. Eltzroth, *Fostering by Standards Bodies of the Formation of Patent Pools* (2018), available at SSRN.

4. Pool fostering for VVC

Media Coding Industry Forum was founded in 2018 with a goal to facilitate cross-industry discussions around the non-technical aspects of deployment of media coding standards, including patent licensing. MC-IF has become the focal point for discussions around deployment and licensing of the next-generation video coding standard, Versatile Video Coding (VVC).[8] At the time of MC-IF's formation. VVC was on a course to complete formal standardisation within ISO/IEC by summer 2020.

In common with other industry participants, MC-IF members noted the lack of clarity in licensing of patents essential to HEVC, the predecessor standard of VVC. In a nutshell, it was claimed that market adoption of HEVC was slowed by the multiplicity of pools covering essential HEVC patents; the competitive tension between the pools; other licensing structures formed by patent holders; and still other holderss that had made clear that they would license their HEVC-essential patents only bilaterally. In the face of this apparent confusion, some contributors to VVC standards development looked to MC-IF for a solution that would, for VVC, resolve the issues that have persisted for HEVC. The general view was that confusion could be reduced if a single licensing administrator for a VVC pool could be named early by the patent holders.

Several MC-IF members were familiar with DVB's model of pool fostering. In addition, DVB had recently begun "evangelising" its fostering model through contacts with sister standards bodies, including ISO/IEC.[9] Senior leadership of both DVB and MC-IF met at IBC in Amsterdam in September 2019 for a further discussion of pool fostering, its benefits and DVB's experience. By spring 2020, MC-IF had decided to launch a pool fostering effort and engaged a specialist in pool fostering to lead the effort.[10]

Several weeks after the VVC standard was adopted by ISO/IEC,[11] MC-IF's pool fostering issued a call for participants and set an initial meeting to occur on 1 September 2020. The activity was designated

[8] The website of MC-IF has further information on its activities and materials on its VVC pool fostering activity. www.mc-if.org Other next generation video coding standards include Low Complexity Enhancement Video Codec (LC-EVC) and Essential Video Codec. Together with VVC, both are standardised through ISO/IEC. Other recent video codecs, not developed through ISO/IEC, include AV1 (developed by the Alliance for Open Media) and AVS3 (Audio Visual coding Standard Workgroup of China). The licensing policies related to LC-EVC, EVC, AV1 and AVS3 are discussed in Section 5.

[9] See Further Resources for a link to DVB's Note addressed to other standards development organisation on DVB's Fostering of early Formation of Patent Pools.

[10] Both convenors were experienced in pool fostering. Carter Eltzroth, as DVB's Legal Director, had led its pool fostering across a range of DVB standards. He was named convenor. Co-convenor Judson Cary played an active role in pool formation for a technology for which standards were adopted by DVB and CableLabs. He was also President of MC-IF.

[11] The VVC standard was consented by ITU-T Study Group 16 on 3 July 2020, to be published as ITU-T Recommendation H.266. Concurrently, MPEG submitted the VVC standard for Final Draft International Standard ballot, to be published as ISO/IEC 23090-3.

"VVC Pool Fostering." While the activity was sponsored by MC-IF, the designation was intended to indicate that fostering was pursued independently of MC-IF. It would be for the participants in VVC Pool Fostering – the VVC-patent holders – and not the board and members of MC-IF, to take decisions on its direction and final decision. The initial meeting and later meetings were all held virtually because of the COVID pandemic. This presented disadvantages but at least one benefit: because there was no travel, meeting cycles could be significantly shortened.

In addition to the call for participants and other press releases, the co-convenors actively solicited for other participants. Ultimately 49 companies joined VVC Pool Fostering. By its participation each affirmed that it had a well-founded belief that it held one or more VVC-essential patents. Among these 49 companies were nine of the top 10 companies whose contributions were accepted during the course of VVC standards development. The 49 companies represented a mix of R&D companies and non-practising entities, together with implementers (with essential patents). There was broad geographic diversity: 15 companies were US-based; eight came from the EU and UK; and 26 from East Asia. The number of Chinese companies (10) represents their increased contribution to standardisation, including the VVC standard, and the recent emphasis on patent filing in China.

As in DVB's practice, the initial meeting of VVC Pool Fostering set out the operating rules governing participation, conduct and decision-making. The participants agreed that:

> Participation by each company was based on its well-founded belief that it holds one or more patents potentially essential to VVC; consistent with the DVB model, the company's "well-founded belief" was sufficient; there was no call for declarations of essential patents (or third-party determination of essentiality) that could have imposed unnecessary (and ultimately duplicative) costs on participants;
>
> Each participant agreed, by its presence in VVC Pool Fostering, to treat as confidential the contents of meetings and documents (notably presentations by candidate facilitators); no formal non-disclosure agreement was proposed; the sole exception to confidentiality covered public statements agreed by participants in VVC Pool Fostering, for example press releases reporting on progress or calling for additional participants;
>
> Any decision (including notably on candidate facilitators) was to be undertaken by consensus or, in the absence of consensus, a two-thirds supermajority; on consensus, VVC Pool Fostering followed the well-understood notion of this practice within standards bodies, including ISO/IEC;
>
> All participants were to be treated equally; there was no favorable treatment for MC-IF members and no separate "voting block" formed by MC-IF;
>
> There was to be strict adherence to antitrust rules and antitrust counsel was present at all meetings; and

In view of the varied business practices of participants and the need for virtual meetings, the participants adhered to a basic set of unexceptional netiquette guidelines.

The convenors also solicited the participation of licensing facilitators based on the convenors' knowledge of pooling and the suggestions of VVC Pool Fostering participants. Some eight were contacted; of these four agreed to participate as candidate facilitators. After the initial meeting, the participants drew on tools from the DVB toolbox: they solicited questions from potential candidate facilitators; once received the participants agreed on answers that were then, together with the underlying questions, circulated to all candidate facilitators. Conversely, the participants addressed questions to potential candidates. After these exchanges, VVC Pool Fostering held successive meetings to receive presentations from the candidate facilitators. As the meetings progressed, the field of candidate facilitators was narrowed progressively from four to two.

Over time, as VVC Pool Fostering continued its work, some additional process elements were added. One concern was that some participants may not fully express their views because of the difficulties in communicating in a remote setting and because of reticence (whether cultural or due to lack of familiarity with patent licensing). For this reason, the convenors redoubled their efforts at participant outreach. In addition, VVC Pool Fostering facilitated participant engagement by the use of confidential non-binding surveys, notably to solicit views on individual candidate facilitators. Anonymous comments were welcome (that is, delivered to, and anonymized by, the convenors). Moreover, an important process development was the use during meetings of the roll call, calling upon each company to express its views. This prompted colleagues to prepare a statement (but some would merely offer "not ready to express a view").

VVC Pool Fostering progressively narrowed the field of candidate facilitators from four to two. In each case of elimination, a secret ballot was taken. The result of the vote guided the decisions taken at the next meeting; a consensus of participants was found that a candidate was to be removed from contention. MPEG LA and Access Advance remained. By the seventh meeting, it was clear that the participants would not find consensus (as "consensus" was defined by participants at their initial meeting) around a single facilitator to take forward the work of pool formation. In addition, neither would achieve the two-thirds supermajority vote to make a definitive decision. Instead VVC Pool Fostering "identified two strong pool administrators."[12]

VVC Pool Fostering had set as its goal the selection of a single licensing administrator to form a pool of VVC-essential patents. A single facilitator was thought to be best suited to reduce the type of market confusion, recently encountered in HEVC licensing, caused by multiple licensing administrators offering patents in multiple pools. But the same contest between leading administrators of HEVC pools spilled over to the deliberations with VVC Pool Fostering and shaped the ultimate outcome. Each final candidate facilitator had a core group of participant supporters to vote and to advocate on its behalf. In

[12] The press release of VVC Pool Fostering announcing this result, together with other public statements during the course of pool fostering, are available on the MC-IF website. See Further Resources.

addition one candidate explicitly linked its existing HEVC program to its VVC proposal so that, for example, an implementer could obtain a license covering both video codecs.

VVC Pool Fostering was not writing on a clean slate; it was arguably inevitable that the turmoil of HEVC licensing would frustrate it from achieving its goal of one-stop shop for VVC licensing. On the other hand, some participants reflected that the outcome of VVC Pool Fostering had value because a "two-stop shop" was better than none at all. And the competing efforts in pool facilitation by the "two strong pool administrators" may (at the time of this writing) yet result in a single administrator.[13]

5. Conclusions

While its efforts did not result in the selection of a single licensing administrator to take forward the work on a VVC patent pool. VVC Pool Fostering was successful in bringing together more than a critical mass of VVC patent holders, drawn from a variety of industries and using diverse business models, to discuss VCC licensing arrangements in a precommercial setting. It provided a platform for presentations by several licensing administrators, including a new entrant. This was achieved in the midst of the pandemic when remote communications alone were available. Overall, the DVB model, grounded on a toolbox of arrangements for convening and advancing pool fostering, successfully scaled up to cover a standard with far more contributors.

At the same time, some lessons may be drawn from the experience of VVC Pool Fostering.

> *(Slightly) tightened participation test?* The basis for participation in a pool fostering effort is today established as "well-founded belief that the participant holds one or more patents essential to the standard". In VVC Pool Fostering this imposed a low threshold for those new to pooling (and indeed to patent licensing). This was welcome. At the same time, the cost for participation was low for interlopers or "peepers," those companies with essential patents that had no intention ultimately to join a pool.
>
> The test for participation could be changed by requiring the affirmation from the participant that it is "actively exploring joining a patent pool".

[13] By mid-August 2021, Access Advance had issued a press release announcing the launch of its VVC licensing program, *Access Advance Launches VVC/H.266 Video Patent Pool: includes innovative Multi-Codec Bridging Agreement that Provides Substantial Royalty Savings to Licensees in both the VVC and HEVC Advance Pools* (1 Jul 2021) and (earlier) a Royalty Rates Summary (1 Jun 2021). MPEG LA has announced development of a VVC pool license and called for submission of VVC-essential patents: *MPEG LA Announces Development of VVC (Versatile Video Coding) Pool License: VVC expected to improve video compression efficiency and functionality* (27 Jan 2021).

Confidentiality. Confidentiality was based on a "gentleperson's agreement" not to disclose. It worked well (at least the convenors were not aware of significant leaks of confidential information). At the same time it may be useful to consider, in a future pool fostering a "plain-vanilla" non-disclosure agreement, that could be adopted without significant negotiation (and without delay).

Confidentiality protected the deliberations and materials of VVC Pool Fostering. It may have negatively impacted its activities when some participants, when solicited by a candidate facilitator, entered into an NDA with that facilitator. It's possible that these participants felt constrained in their freedom to discuss the merits of the candidate facilitators. A further pooling effort could discourage participants from agreeing to arrangements with potential candidate facilitators that undercut the fostering process

Finding consensus. During its initial meeting, VVC Pool Fostering adopted a rule that, in the absence of consensus, decisions were to be taken by a two-thirds supermajority. It was essential to have adopted this rule at initial meeting! But the value of this rule could be reconsidered when a large number of participants refuses to vote, declaring themselves "not ready," with "no comment," choosing "to abstain." Other voting or tally mechanisms could be considered.

Affiliates in pooling. Participants and candidate facilitators in VVC Pool Fostering were not required to disclose any cross-ownership or other material affiliations. For example, several participants were shareholders in candidate facilitators. These links are well-known among licensing professionals, but participants new to licensing may be unaware. During meetings, they could have a sense that proceedings were gamed. For this reason, it may be suitable to require, in pool fosterings, disclosure by a participant if it has an affiliation with candidate facilitator and its pledge that it will not pass confidential information on to its affiliate.

RfP? In DVB's experience, during the presentation phase, each candidate facilitator largely shapes its own materials and chooses what to disclose. In VVC Pool Fostering, some participants already had extensive knowledge with the candidate facilitators and drew on this background when developing questions addressed to them. Their answers were worked into the presentations (or delivered separately). In pool fostering where there are several candidate facilitators (and many participants) it may be well to specify the structure of the presentations, and the items to be covered. This could be formalized in a request for proposals issued by the pool fostering participants. Setting a more formal framework for presentations could permit the participants more easily to compare competing proposals and the respective strengths (and weaknesses) of the licensing administrators.

As a result of VVC Pool Fostering, is VVC in an advantageous position compared to other next generation video codecs? It is hard to make a definitive assessment because of the range of licensing models offered by competing codecs. In addition to VVC, two other video codec standards have been recently approved by ISO/IEC. Essential Video Coding (EVC) is an open-source codec completed by MPEG in April 2020 where the development effort was led by Samsung, Huawei and Qualcomm. The

development process has been defensive against patent threats establishing a baseline with codec tools made public more than 20 years ago. There are a further 21 tools for the main profile to be available under separate royalty-bearing negotiated licenses. In a May 2020 press release, the three companies announced that they would be announcing their respective licensing terms for these further tools within two years.[14] In respect of Low Complexity Enhancement Video Codec (LC-EVC), the company responsible for its core technology foundation, V-Nova, announced licensing terms in May 2021: use of its essential patents are royalty-free for integration by device or chipset manufacturers, browsers, encoder / player vendors; but a fee is payable for usage by service operators based on service size (from $0.01/per user per year to a cap at $3.7 million/year).[15]

In addition to the codecs adopted by ISO/IEC, two other standards bodies have completed development work on competing technology solutions. The codecs previously adopted by the Audio Visual coding Standard Workgroup of China were each the subject of a patent pool characterised by a low royalty. For its AVS3, AVS has launched pool facilitation, calling for holders of AVS3-essential patents to submit declarations for an initial meeting of holders during autumn 2021. AVS has made clear that decisions on royalties and other licensing terms will be determined by the essential patent holders participating in AVS3 pool formation.[16] A further codec, AV1 has been developed by the Alliance for Open Media, which, for licensing has adopted the W3C IPR policy. Its form of patent license provides for a "no-charge, royalty free" license for implementation. But this license is not free of controversy because it also provides that the implementer / licensee must make its own essential patents available under the same royalty-free terms. While this creates a genuine "eco-system" for royalty-free licensing, it arguably places some implementers, looking for royalty revenues, at a disadvantage.[17]

The licensing terms for each of these alternatives are associated then with special factors: EVC, with a baseline of technology subject, if at all, to expired patents; LC-EVC, a single principal owner of the core technology; AVS3, a pool structure now seeking to extend beyond East Asia; and AV1, available on a royalty-free basis, provided the licensee agrees to reciprocal RF licensing. VVC can be based on a more classic model of licensing of standards-based technology, coupled with pooling, a well-established mechanism for easier licensing administration. It can follow the structure already adopted for a long line of video codecs, MPEG2, AVC and HEVC. Fostering is the means to encourage VVC holders to take on that structure again.

As cable operators define next-generation set-top boxes and streaming services, they will need to choose video codecs that meet their technical needs for compression, efficiency, and resolution. They will also

1. Introduction

Over the past two decades, the transformation of service delivery and use of social media and digital platforms have opened the flood gates for the threat landscape. When it comes to protecting ourselves from bad actors, are tips, tricks, and risk indicators enough?

In short, the answer is no. It is not enough in some cases. We see evidence of this every day in the news. Even though we see signs that bad actors are sometimes successful, security professionals often prevail. With a conscious effort to move from "information" and "education" to meaningful behavioral change, we are turning the tides.

Laws are being written and updated with new mandates on data protection and privacy. Corporations are taking strides, reacting to government mandates, and implementing initiatives such as shifting security left. Security professionals are stepping up their game on both user and device identity, reducing the blast radius of potential attacks, and making it harder for bad actors to breach networks and steal data. Protection is provided to consumers by building security into products and services, as well as account protection measures like strong authentication and alerts of new or suspicious activity.

But there is more to do. Security professionals must go beyond tips, hacks, and risk indicators and use all the tools in their arsenal to create plans that incorporate a blend of policy, process, and technology as a catalyst to change end-user and consumer behavior.

This paper demonstrates how security threats have shifted marketplace adaptation. Modern DevSecOps and security practices are discussed, along with how establishing cyber risk ratings to provide accurate and transparent cyber health can uplift security efforts. Adoption of these transformations can bring security out of the shadows and benefit corporations and consumers alike, making a siloed approach to security tenable.

2. Security Goes Mainstream

The 2010s can be labeled as the decade cybersecurity went mainstream. Data breaches started to make big headlines. Personal information was being stolen from big name retailers, popular gaming sites, and even the US government. Millions of people were affected, and corporations faced extensive downtime, costly damage, expensive fines, lawsuits, and a loss of consumer trust. Government secrets were exposed, threatening the safety and security of nations. The lives of everyday people were being affected by cybercriminals and it was being felt across the globe.

2.1. How Hackers Pushed Security Forward

Cybercriminals with no budget constraints or change control processes developed a level of sophistication that surpassed the outdated "point solution" security controls that were protecting our most valuable data. They were taking a multifaceted polymorphic approach that easily bypassed the mechanisms that were supposed to keep them at bay.

Amidst all the damage, society was awakened to just how much disruption and destruction could be done with surprisingly little effort. This changed the perception that security can be left as an afterthought. Cybersecurity budgets grew. Corporate board members started paying attention. Governments started paying attention. Consumers started paying attention. Security was getting its long overdue 15 minutes of fame.

While there is no industry that is safe from the threat of attack, the cable industry is one of the top 10 targets for hackers [1]. “Always-on” internet access and video streaming have changed consumer behavior. Consumers are moving away from watching linear channels to adopting streaming channels which require high-speed broadband. With this shift in demand, broadband security risks are being compounded. As the details and motivations of attacks continue to evolve, there are several popular methods attackers use, which are described next.

2.1.1. Compromised Accounts

A favorite weapon of choice when looking to gain unauthorized access to networks and wreak havoc on unsuspecting victims is compromised accounts. Companies can see from hundreds to thousands of attempts per day to penetrate both enterprise and consumer accounts on their networks via compromised credentials. Due to increased sophistication of password-related attacks, coupled with the slow adoption of methods to combat them, an astounding 61% of data breaches can be traced to compromised credentials. [2] There are several ways in which accounts are compromised. Some of the more common methods include phishing attacks, brute force password attacks, and credential stuffing.

Once an attacker retrieves a set of credentials, they are validated, and after a successful test, made available on the dark web for sale. Fraudsters then purchase these credentials and use them not only to access consumer broadband accounts and steal services, but also as a pivot point to identity theft. Additionally, the fraudsters can sometimes use the credentials to access consumer email. Once access to an email account is gained, they use scanning tools to find third party targets like bank information, financial transactions, credit card information or crypto currency accounts associated with the victim. The email credentials are used to reset passwords, and possibly as 2nd factor authorization to access the victim’s financial accounts. Sometimes fraudsters can even get as far as transferring money out of a victim’s account. The use of stolen credentials by fraudsters to gain access to consumer banking services creates a ripple effect to the financial sector. Though cable operators can implement more secure authentication mechanisms to protect their own subscriber accounts, a chain is only as strong as its weakest link. If authentication is weak on one account, all accounts that are linked are exposed to risk.

The use of video streaming services by consumers during the pandemic has increased many folds. Some consumers share their credentials with their family, but in some cases, these credentials are sold for commercial use. The identification of legal sharing of passwords within family or illegal sharing has become another threat to video streaming and account security.

2.1.2. Brand Phishing

“Lower your cable bill” is an example of a scam that has been around for many years and has hurt the brands of many cable companies. The scammers pose as ‘companies’ officially doing business, call customers, and trick them with better deals, getting monthly payments out of their pockets and impacting the company brand. Often, these scammers will request the account credentials to offer discounts, further exposing the subscriber to identify theft risks.

2.1.3. Ransomware

Ransomware attacks go beyond just stealing and exploiting data, with recent attacks impacting the daily lives of many in ways we have not experienced before, causing gas shortages, interruptions in public transit, and disrupting the food supply chain. Unfortunately, experts do not expect this onslaught of attacks to slow down anytime soon. It is projected that during 2021, ransomware attacks against business will occur every 11 seconds, with costs expected to exceed $20 billion globally. [3]

The concept of a ransomware attack is as follows: The hacker finds a way to install malicious software onto an unsuspecting network. Usually this occurs via malicious emails with malware, an unpatched vulnerability, or exposed ports or services with weak authentication for remote access. Once the ransomware is deployed, the data is encrypted, and the victim receives a ransom note demanding payment, usually with a cryptocurrency such as Bitcoin. The victim is then faced with the choice to either pay the fee or incur the untold damages of downtime, rebuilding, or declaring a total loss on the infected resource(s). When faced with these difficult options, more than half of the victims of ransomware attacks pay the ransom. This is not a favorable outcome, given that it fuels further ransomware attacks.

2.1.4. Voice Fraud

Voice technology has taken a strong position in customer interactions for businesses in recent years. It is the future of every service offering and still being adopted in the industry. The voice interactions are using artificial intelligence (AI) for chat bots to respond to customers. There are device apps which provide faster calling services. These new innovations in voice technology have invited scammers for voice phishing [4] [5]

Additionally, scammers make their way into unsuspecting victim's voice service accounts and place high volumes of expensive calls on the victim's dime. This practice is lucrative for criminals and expensive for voice service providers with an estimated cost of $12 billion dollars in damages annually.

2.1.5. Internet Facing Application Attacks

Business-centric interactive websites have become the new norm to do business and provide quick responses to customers. Although these on-line sites have tremendously

improved the user experience, they have also brought new cyber security threats. The most common threats are on web servers and databases for cross-site scripting and SQL injection. According to industry data, 90% of the applications have security flaws and it takes an average of 38 days to patch the application-related components. During the development process of these web applications, code analysis is done for less than 50% of applications. [6] A small rogue application, which is not on a company's radar, poses an even larger risk due to lesser controls and assessments. A vulnerability on a rogue application's web server with internet connectivity and unknown change control practices, can invite a threat actor with this ingress and allow lateral movement.

2.2. Turning the Tides

If there is one guiding principal security professionals should follow, it is this one: Assume you will be breached.

Most companies have started initiatives related to the overall cybersecurity uplift, to strengthen the ingress points, decentralize applications, implement, and govern the security frameworks with Zero Trust to reduce the blast radius -- to name a few. The use of Machine Learning (ML) for cybersecurity threat intelligence, multi-factor authentication to inform risk engines, for both users and devices, has contributed greatly to the understanding and reduction of risk within the threat landscape. The enterprise-side user education on threats, via ransomware readiness exercises, phishing exercises, and Zero Trust programs will help prepare the organizations for growing attacks. The implementation of MFA brought a positive change, and over last couple of years it reduced the number of threats for identities.

2.2.1. Zero Trust Security

If one were to make a list of most popular security buzzwords, Zero Trust would likely be close to the top. But while buzz words usually get a bad rap with security professionals for not living up to the hype, Zero Trust would be an exception. Maybe because Zero Trust is more than a "latest and greatest" product suite that you enable to solve all your security woes. In fact, it's not a product at all, but rather a philosophy or mindset of "never trust, always verify." [7] [8]

Traditional security models worked like a "castle and moat" system for accessing corporate resources. A perimeter was created around the company network and security efforts were focused on ensuring the perimeter was not breached. Everything within the perimeter was considered a safe and trusted resource. Everything external to the perimeter was not trusted. This model was more effective when corporate resources lived within the perimeter and were accessed from the confines of the corporate network using corporate owned devices. Today this is not the case. Corporate resources exist both within and external to the corporate network and can often be accessed from any device and/or location. The network perimeter, where security efforts were traditionally focused, has disappeared. [9]

In contrast, a zero-trust security model assumes every device, user, and application is a threat until verified. Every resource is treated as though it is an attack vector, and measures are taken to contain the damage of an attack. IP based access controls are replaced with identity-based controls and security is taken out of the shadows by shifting the focus to people, devices, and applications as the network perimeter.

While each organization will implement a zero-trust security model in its own way, there are common elements that one would expect to find including strong identity management for users, devices and applications, network segmentation, and advanced monitoring and logging. [10]

2.2.2. Improved Incident Detection and Response

To stay ahead of the constantly shifting threat landscape, corporations are building their own threat intelligence programs. These programs, focused solely on threat prevention and detection, use a combination of threat intel data collected from trusted sources and advanced SEIM technologies to alert organizations of potential and actual threats. They also focus on incident preparedness, using tools such as the MITRE ATT&CK framework.

The MITRE ATT&CT framework was designed to help organizations in assessing risk against common tactics used by attackers. The framework is defined as “a comprehensive matrix of tactics and techniques used by threat hunters, red teamers, and defenders to better classify attacks and assess an organization's risk” [11]. Using tools such as the MITRE ATT&CK framework can assist with mapping threats detected in a SEIM system to potential use cases for security automation.

Another instrumental tool in preparing for attacks is an exercise known as a purple team event. In these events, both a red team (made up of “attackers”), and a blue team (made up of “defenders”) get together in a controlled environment and use an “offensive defense” strategy to identify security gaps within an environment. These exercises, sometimes partnering with specialized third-party organizations, help to improve skills and techniques of the participants so they are ready to respond when a real incident occurs. They also bring visibility to security gaps that do exist, which helps prioritize the efforts of resources so they can focus on the biggest wins.

2.2.3. Multi Factor Authentication

We already know that one of the most common ways data breaches occur is compromised credentials. We have also looked at common ways accounts are compromised. The best defense against these kinds of attacks is the use of multi factor authentication (MFA).

The premise of MFA is that you prove you are who you say you are – aka authenticate yourself - by providing something you know – your password – with something you have

(token, one time passcode [OTP], approved sign-in request) and/or something you ARE (fingerprint, facial recognition).

Although some forms of MFA have been around for the better part of two decades, adoption has been slow, mostly due to cost, additional hardware requirements, and the cumbersome user experience. Prior to the abundance of data breaches that took place over the past decade, companies and consumers alike were not particularly interested in investing money or losing convenience by adding steps to access online resources. As companies grew better at detecting compromised accounts and realized how often and easily passwords were being compromised regardless of "best practice" password policies, it became widely recognized that the benefits of MFA far outweighed the drawbacks of cost and inconvenience.

Technical difficulties, conflicting priorities, and an endless list of ever-changing use cases are just a few of the very real challenges companies may face when deploying an MFA solution, especially when considering the vast differences between protecting enterprise and consumer accounts. However, there is no disputing its effectiveness at stopping password related attacks almost entirely, with a success rate of more than 99% [12].

When implementing MFA, there are a variety of different solutions from which to choose. Depending on the complexity of the environment, there may not be a single solution that meets all use cases. In situations such as this, multiple solutions may need to be deployed to ensure all resources and users are MFA protected. For many companies it is likely that MFA will be an ongoing journey that will continually be improved upon as new technologies emerge to combat the ever-constant threat of account takeovers.

2.2.4. Ransomware Readiness

With ransomware attacks on the rise, it is more important than ever to be prepared on how to respond to a ransomware attack. There is no one single strategy to combat ransomware attacks. To best prepare for a successful outcome, consider the below recommendations:

a) Address your known vulnerabilities and keep up to date on patches, especially on parameter assets.
b) Disable unused services and processes, specifically remote desktop protocol (RDP) and secure shell (SSH), on externally facing systems. If these services must be exposed, use access control lists (ACLs) and multi-factor authentication.
c) Use least privilege access models.
d) Reduce the blast radius of attacks with network micro segmentation
e) Use advanced security tooling for logging, monitoring, and alerting to bring visibility to what's happening within your environments
f) Back-up your systems regularly and encrypt backups
g) Have a response plan ready and practice recovery efforts, especially for critical resources.

2.2.5. Shifting Security Left

The concept of "shifting security left" is all about closing security gaps further upstream. To accomplish this, security feedback must be incorporated as part of the feedback loop throughout the entire software development lifecycle (SDLC). Adopting the mindset of addressing security concerns before any code is written saves teams considerable time and money and elevates the level of trust customers have in products and services. When a multifaced approach is taken that includes training, coaching, and automation to help prioritize the sometimes-overwhelming number of security tasks, application development teams can improve the chance of successful delivery for secure products without adding any additional time to their development cycles.

The software development cycle has many skip hops when trying to reduce cycle time and get products delivered faster into customer hands. To support shortened cycle times that incorporate security into the development process, many organizations are on a journey to transition from DevOps to DevSecOps deployments. This shift brings the demand for new tools, and specialized knowledge. This creates the need for organizations to determine how to support these new requirements. Some organizations have incorporated coaching programs, appointing experts in both security and the development process to guide their development teams through this transition.

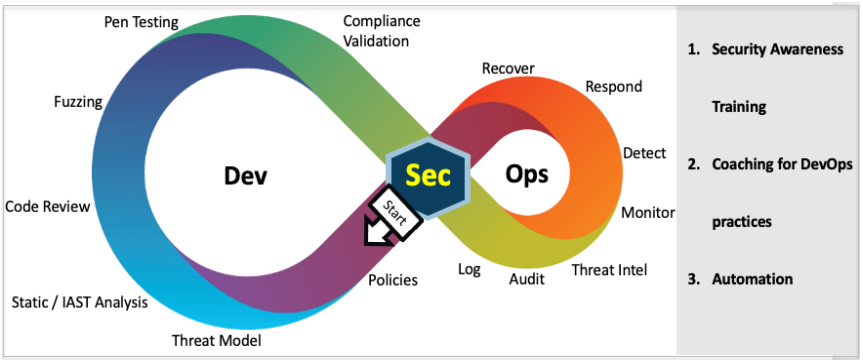

Figure 1 - Shifting Security Left in each phase of SDLC

2.2.5.1. Security awareness training

One aspect of creating a security focused development process is ensuring that all resources contributing to any part of the SDLC are well trained on security best practices and policies, including those in management roles. Ideally this training would be specifically tailored to the role(s) of each participant. Training material could be catered in a tiered level ranging from a base level of understanding all the way to expert. The ideal would be that, after training, participants are able to

demonstrate their knowledge of the security concepts covered before advancing to the next level.

2.2.5.2. Coaching for DevOps practices

With things evolving so fast, it may be hard for development teams to stay on top of emerging security threats and changing security priorities as well as stay focused on improving dev/ops practices to deliver quality products. This need creates an opportunity for security coaching. Security coaches can work with teams to align security practices to the phases in the development lifecycle. These individuals, with an expertise in both security and the software development lifecycle, guide development teams through onboarding new security requirements or shifting processes to incorporate better security practices by assimilating them into their team norms. Coaches can work with teams to understand their workload and constraints, and assist with prioritizing the security work, breaking it down to manageable deliverables.

2.2.5.3. Automation

Another helpful tactic is adding automation around security scans and other security required processes that have made their way into the continuous integration and continuous delivery (CI/CD) pipeline. By introducing automation around these new security requirements, teams are not bogged down with new requirements and things are able to run smoothly. Training the development teams and appointing developers as "security champions" can ensure that as developers built up their skills to handle the fallout of these new processes, the teams could still operate efficiently. [13]

3. Securing Your Customers

The defense strategy against attackers seeking to steal service, customer data, and video content is still evolving. It benefits broadband operators to collaborate both within the industry as well as with external partners to set guiding principles of basic security, communication to customers, and guidance on how to consume their services in secure ways. There are many efforts to secure web interfaces, user logins, and devices by broadband providers. Additionally, the following actions will help to improve the protection for consumers from email threats, account abuses, and device security.

3.1. Identity Protection Capabilities

Implement identity protection capabilities to combat the threats at scale by using AI to support consumers. Comprehensive detection of darknet market ads for account credentials provides the capability to measure the availability of account credentials. This is just an example of one measurement for identifying credentials available for sale in the darknet market. Some additional measures are listed below:

a. External credential spill monitoring and remediation can be built as a basic feature for standard security operations
b. Deep and dark web credential advertisement detection and remediation
c. Robot software agent (BOT) attack prevention at web, application programing interface (API), and mobile authentication interfaces
d. Use internet protocol (IP) information for "geo velocity" and to determine "geo location" to reduce credential theft
e. Implement 2FA or MFA support for consumers and disable less secure authentication methods
f. Detection capabilities using Machine Learning (ML) based tools for credential sharing and compromised accounts
g. Work with law enforcement and other enforcement bodies to identify and disrupt the distribution of unlicensed content

3.2. IoT Device Infection Prevention

In the connected world of customers, internet of things (IoT) devices pose a large threat [14] and have not received full attention. Customers usually do not focus on security measures for devices and forgo more secure devices for their less costly counterparts. On top of this, there is not enough standardization of security control requirements for device vendors. Also, vulnerabilities for these devices do not get addressed regularly. Bringing privacy awareness to device security features as well as how to keep devices up to date with the latest patches is the key to protect individuals from being attacked via their connected devices. Internet providers are offering internet security solutions which block access to compromised or malicious domains and protect customer devices from these threats.

IoT device infections have grown 100% during Covid. [15] This surge in the rate of device infections, directly matches the trajectory of the visibility of the devices on the internet. The cybercriminals probe these devices for security vulnerabilities and exploit them to control the device with unauthorized access, damage it, or penetrate to other devices on the same network. Antivirus software and intrusion detection capabilities are the first layer of security to protect these devices from infections. [16]

IoT is here to stay, and it will continue to grow tremendously, as will the attack surface. The industry demands security leaders to develop a comprehensive IoT lifecycle approach and an IoT security posture to protect and enable IoT devices from both existing and unknown threats. Also, consumer awareness for various precautions to protect the IoT devices is of utmost importance.

3.3. DDoS Attack Mitigation

The exposure of IoT vulnerabilities has dramatically changed the landscape of Distributed Denial of service (DDoS) attacks in recent years. These devices have enough compute power to launch any processes using BOTs and create an attack on other devices. Along with detection measures, effective preventive measures are important to combat the DDoS attacks. Many Threat Intelligence subscription services "Always-on DDoS Protection" are evolving

to help combat these threats and help the customers. [17] [18]. These capabilities include preventive, detective, and mitigation controls which automatically or on-demand mitigate the DDoS attacks.

3.4. Protect Customer Data

In today's data driven customer interactions, businesses rely on large amounts of data being available every second of the day without a blip. The Network Data Loss Prevention (DLP) solutions are relied upon by many organizations, but data breaches happen all the time. Hence there is more to do to protect the data. Privacy initiatives and recent Executive orders provide guidance on some controls around securing data for user identities. They also highlight a need for data-centric tools to build personally identifiable (PI) data inventory, creating data classification policies, performing data discovery, and other initiatives that address data privacy concerns around customer data. To safeguard the data, the use of data encryption and data de-identification practices provide protection but are still evolving. Another key factor in securing data is ensuring that there are strict policies around granting access to and removing access from sensitive data as needed.

3.5. Customer Education

A recent, sophisticated phishing scheme was uncovered in which consumers of unlicensed content were sent an email indicating their free trial was ending and their credit cards were about to be charged. They were directed to a fake website and informed that to cancel their subscription, they must download an Excel file, which contained a ransomware program commonly used by the REvil ransomware group. This is one of the many dangers consumers encounter in their daily lives. It is important to educate consumers of such risks and provide guidance on how to stay safe online.

The Cable and Telecommunications Association for Marketing (CTAM) has seen the need for educating consumers on various security topics and have created a website for sharing information on how to stay safe when streaming content on the internet (streamsafely.com). [19] The dangers of accessing television/streaming content through illegal pirate services and the risks involved in unauthorized password sharing are a few examples of the topics covered on customer education website. As the customer pattern changes and new services are offered, educating customers is essential in keeping the eco-system secure. Developing and sharing tools with industry partners, programmers, studio, and law enforcement, foster partnerships that create better protection for all connected consumers, not just service subscribers.

Figure 2 - Streamsafely.com educational articles

3.6. Industry Alliances required to combat the email Fraud

Customer communications have shifted significantly over the last decade to boost customer service, customer retention and engagement. Email communication is still heavily utilized for notifications or verification of identity during certain events for service changes. Email accounts are one the most sought-after types of credentials because they can be used as a pivot to identity theft. Some email clients on customer devices may be old and vulnerable to attacks due to flaws in email client protocols. An alliance is required between third party email providers to deprecate older email clients and encourage customers to deploy secure new clients.

Below are some actions which can be considered to secure email:

a. Disable unused 3rd party email clients
b. Modernize authentication for 3rd party email clients using oauth
c. Implement email platform anti-abuse capabilities (anti-spam, anti-malware, anti-phishing, anti-viral)

As an abundance of user interfaces are consumed for various user activities, account misuse (knowingly or unknowingly) is extremely high. This demands a defense in depth approach to all attack surfaces. The layering of intelligent defenses has shown a demonstratable impact and is recommended by various organizations. Advanced email authentication attack detection and mitigation development, partnering with vendors and dedicated teams of security professionals managing these platforms, help mature the security of email accounts.

4. Monitor Cyberhealth across your eco-system with CyberScores

The cable industry has been working hard over the last decade on security hygiene, regulatory compliance, and protecting themselves and their consumers from bad actors. Many companies have adopted one or multiple frameworks to evaluate, manage, and ultimately reduce risk over time. Some examples of frameworks that provide guidance on best practices are NIST Cybersecurity Framework, ISO 27000 series, SOC2, FISMA, and the Essential 8 Framework. Using frameworks such as these attest to mitigate 85% of cyber threats [20]. A few common best practices from these frameworks are to implement security controls around the following:

a. Patch Management
b. Application Controls for Workstations and Servers
c. Restrictive Admin Privileges
d. Backups
e. 3rd Party Risk Assessments
f. MFA

Businesses implement a variety of tools for assessing security controls based on framework adoption to better understand, manage, and reduce cybersecurity risk and help protect from various threats. These tools are used to collect metrics from possible sources of risk and present this information in dashboards. As security tools evolve, and new tools are added to the ecosystem, there are challenges around how to continuously measure the effectiveness of the security controls from these various tools and identify aggregated overall company risk.

To combine and analyze data from various security tools and frameworks, a robust risk assessment platform can be utilized to quantify and aggregate the risk and drive meaningful actions for the business.

A few products have emerged with the capability to collect data from various sources and quantify the overall performance of security controls and produce a meaningful cyber risk score dashboard or a Cyber Risk report [21] [22]. Some products also provide compliance assessment based on industry standards and even go beyond to simplify the scores by mapping them to risk ratings [23]. While the maturity of these products is in the early stages, businesses are looking for ways to develop their own centralized security metrics dashboards. According to Gartner, in the future, cybersecurity risk ratings will likely be utilized the same way credit ratings are used when assessing partners for business relationships [24]. The US department of Defense (DOD) now requires supply chain companies to report a cybersecurity maturity model compliance (CMMC) to the DOD if they provide services to them [25].

The enterprise eco-system is usually complex and the risks for each system are evaluated based on the rate of the issues and the severity. A cybersecurity rating platform enables continuous assessment of the tens of security criteria along with thousands of security checks [26]. Companies can either leverage cyber score tools or develop their own. The risks can be evaluated, assigned weightage, and aggregated for contributions to overall cyber risk score based on the company's risk appetite.

Starting small with just a few security controls and combining to one aggregated score may be a good first step toward a single platform. For example, combining the data from vulnerability assessment tools and 3rd party risk assessments into a single dashboard. Once this step is taken, team can be trained to understand the relevance of the combined have a clearer picture on the actions needed to secure their applications all in one place. As the cybersecurity rating program matures, the CyberScores can help drive the various decisions about cybersecurity risk posture from the application level all the way through to the organizational level.

5. Conclusion

The past decade has thrown security into the spotlight. It is no longer overlooked or addressed only after a damaging and expensive incident. Security is now a part of the conversation at every level of business and government. It is no longer bolted on but built into products and services with an expectation from consumers that those we trust are taking every precaution to protect us from the adversaries. Security professionals strive for the right level of protection to keep attackers out of systems and protect customers. Taking a multi-layered and proactive approach has created many successful outcomes. The industry alliances are also key in each sector to uplift the standards for common services and consumer education. The work cannot stop here. As long as there is value to be gained from their efforts, hackers will continue to create challenges. It is up to all of us to keep security part of the conversation, to learn from every attack, and grow our defenses to prevail.

Abbreviations

2FA	Two Factor Authentication
ACL	Access Control List
AI	Artificial Intelligence
AP	Access Point
API	Application Programming Interface
BOT	Robot Software Agent
bps	Bits per Second
CCPA	California passed the California Consumer Privacy Act
CI/CD	Continuous integration/continuous delivery
CMMC	Cybersecurity maturity model certification
CPNI	Customer Proprietary Network Information
CTAM	Cable and Telecommunications Association for Marketing
DOD	Department of Defense
DLP	Data Loss Prevention
FEC	Forward Error Correction
GDPR	General Data Protection Regulation
HD	High Definition
Hz	Hertz
IP	Internet Protocol
ISBE	International Society of Broadband Experts

K	Kelvin
MFA	Multi-Factor Authentication
ML	Machine Learning
NCTA	The Internet & Television Association
OTP	One Time Password
PI	Personally Identifiable
RDP	Remote Desktop Protocol
SCTE	Society of Cable Telecommunications Engineers
SDLC	Software Development Life Cycle
SEIM	Security Event Information Management
SSH	Secure Shell

1. Introduction

Passive Optical Networks (PON) have come a long way in the Cox network since our initial Gigabit PON (GPON) deployments over 12 years ago. A key milestone for Cox Communications was the launch of IP Video and Telephony products via GPON in mid-2020, which enabled the elimination of Radio Frequencies over Glass (RFoG) technology and presented an opportunity to re-consider the architecture. We took this opportunity to relook at our FTTx deployments through a fresh lens and explore opportunities to improve operational efficiencies, including 10G PON evolutions, optical transport, and distribution network architectures.

In particular, the Optical Distribution Network (ODN) approaches were tailored to "right size" the cost and deployment options for the individual application, which led to different approaches for Single Family Units (SFU), Multi-Dwelling Units (MDU) and Commercial Business customers. Each had their own unique ODN architectures, which drove variation and complexity for field teams to support. There was an opportunity to harmonize those approaches with the additional benefit of making them easier to deploy and maintain.

This paper will explore a variety of architectural considerations and logic which drove decision-making around Cox Communication's next generation Fiber-to-the-X (FTTx) deployments, with a focus on a new approach to optical distribution and splitting methodologies.

1.1. History of PON at Cox Communications, Inc

Our first deployments of PON were Broadband PON (BPON) in 2004, which were deployed to a very limited extent for commercial applications. As the PON technology matured, Cox began deploying GPON in 2008, again exclusively for commercial applications. Fast forward to 2014, we repurposed the GPON platform and offered a gigabit symmetrical product to our residential customers, deploying GPON in both brownfield and greenfield applications. The key difference being the type of network carrying legacy data, video, and telephony products. Like many other cable operators at the time, we chose to leverage an RFoG technology to support these legacy products in greenfield fiber only deployments. Supporting RFoG and PON drove some unique considerations to Fiber-to-the-Home (FTTH) deployments which do not apply to PON alone, including but not limited to, a smaller optical budget and Optical Beat Interference (OBI). RFoG was intended to bridge the gap to All IP over PON, it turns out that gap lasted about 6 years and went through many evolutions until we launched all of our products over PON for residential services in 2020.

The PON portion of the FTTH network also went through a series of evolutions in the 2014 to 2020 timeframe. Initial deployments of GPON Optical Line Terminals (OLT) were rack-mounted in large environmentally controlled cabinets feeding a 1:32 split ratio. While we still deploy large OLT cabinets to a limited extent, today we primarily deploy hardened passively cooled Remote-OLTs for smaller targeted areas. The transport architecture used up until recently for the GPON Remote-OLT was a routed (layer 3) multi-hop ring solution, allowing up to 8 Remote-OLTs per ring. Recently it was decided to leverage synergies from our Distributed Access Architecture (DAA) solution used for Remote-Phy node deployments and migrate OLT transport across a homegrown Dense Wave Division Multiplexing (DWDM) solution called the Optical Communication Module Link extender (OCML). Furthermore, in an effort to position ourselves to support the ever-growing bandwidth demands, we're in the process of launching 10 gigabit symmetrical PON (XGS-PON) OLT's, capable of supporting 10G symmetrical speeds.

The GPON distribution network architecture started at a 1:32 split ratio and increased to a fixed 1:64 split ratio a couple years in to optimize OLT port consumption efficiencies. In an effort to optimize fiber and labor efficiencies, the optical splitter array varied based on the application. SFU applications used a centralized splitting architecture, while MDU and commercial applications each used different distributed splitter approaches.

With the elimination of RFoG on our roadmap, it gave us an opportunity to relook improving operational efficiencies in the FTTx ODN. In 2019, we began investigating a distributed optical tap concept, using a combination of unbalanced and balanced couplers to control optical insertion loss in a more efficient manner (see Figure 1).

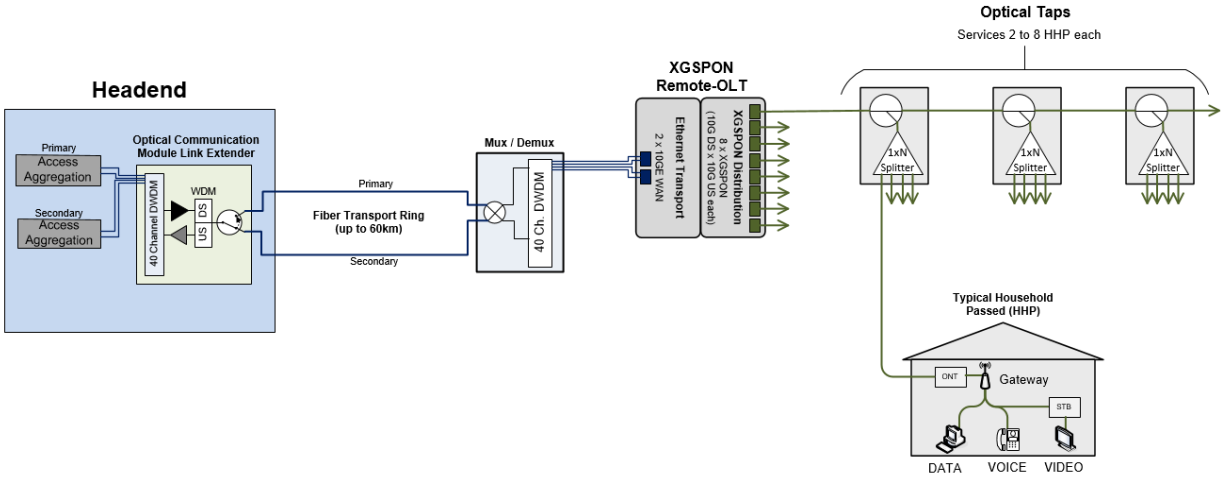

Figure 1 – Cox Communications FTTx Architecture

2. Optical Transport

Cox Communications current Optical FTTx Transport Network includes a pair of components called the Optical Communications Module Link extender (OCML) and Mux DeMux (MDM) which make up our standard DAA solution. The OCML is used to transport up to 40 DWDM wavelengths (20 channel pairs), redundantly up to 60km. The OCML is located in the headend and the MDM in the field. This same DAA solution is used by other deployments and is commonly shared with other network elements such as Remote-Phy nodes and Metro Ethernet links.

2.1. OLT Strategy

Up until this point, the vast majority of our FTTx deployments have been with GPON in alignment with ITU-T G.984.1, offering nearly 600,000 homes passed (HP) with gigabit symmetrical speed tiers today. In preparation to support 10G speeds in the future, we've recently started the process of transitioning all new PON deployments to XGS-PON exclusively in alignment with ITU-T G.9807.1.

While XGS-PON enables a path to 10G symmetrical speed tiers, long-term Next Generation PON 2 (NG-PON2) and/or Coherent PON (CPON) appear to be potential evolutions. Both NG-PON2 and CPON are still just being discussed and the picture isn't fully clear exactly how it will be operationalized, but future considerations are being made to support either option. It will be important for each PON iteration to operate at different wavelengths to allow co-existence through migration periods. NG-PON2 will operate

at 1530nm Downstream and 1600nm Upstream, but CPON wavelengths have yet to be determined. CPON is capable of speeds greater than 100G, and the calculated approach of the distributed optical tap system aligns well with the increased optical budget of the coherent optics allowing for extended optical reach and the potential for a truly passive plant without the need of remote OLT devices.

3. Optical Distribution Network

Up until recently, our PON distribution network was a conventional fixed 1:64 split ratio, which used a bank of optical splitters in an ODN cabinet. The two primary architecture types used were centralized splitters and distributed splitters. In a centralized splitter architecture, the entirety of the static split ratio is contained within the ODN cabinet. In this configuration each customer may get their own dedicated fiber spliced in parallel from the cabinet to customer premise. A distributed splitter architecture is also based on a pre-determined static split ratio, but a portion of that split ratio is distributed to a drop terminal (aka cross connect) within 400' of the customer premise (see Figure 2). For example, it may be common for an operator to distribute a 1x4 splitter near the customer and assume the first 1x16 of the total 1:64 split ratio is in the cabinet. The advantage of distributing splitters over centralized splitters is the reduction in fiber and splices required to build the network, which may result in cost savings. However, it can be wasteful because with any static split ratio it is uncommon to have exactly 64 customers to feed, so those additional ports may get stranded. Furthermore, in a static split ratio architecture, the more of the split ratio that is distributed, even more ports may be stranded. Considering MDU's typically have a higher density per demarcation Cox chose to distribute a 1x8 splitter. For commercial applications a distributed 1x4 was the right balance between splitter capacity and splicing labor considering the varying densities in commercial zones.

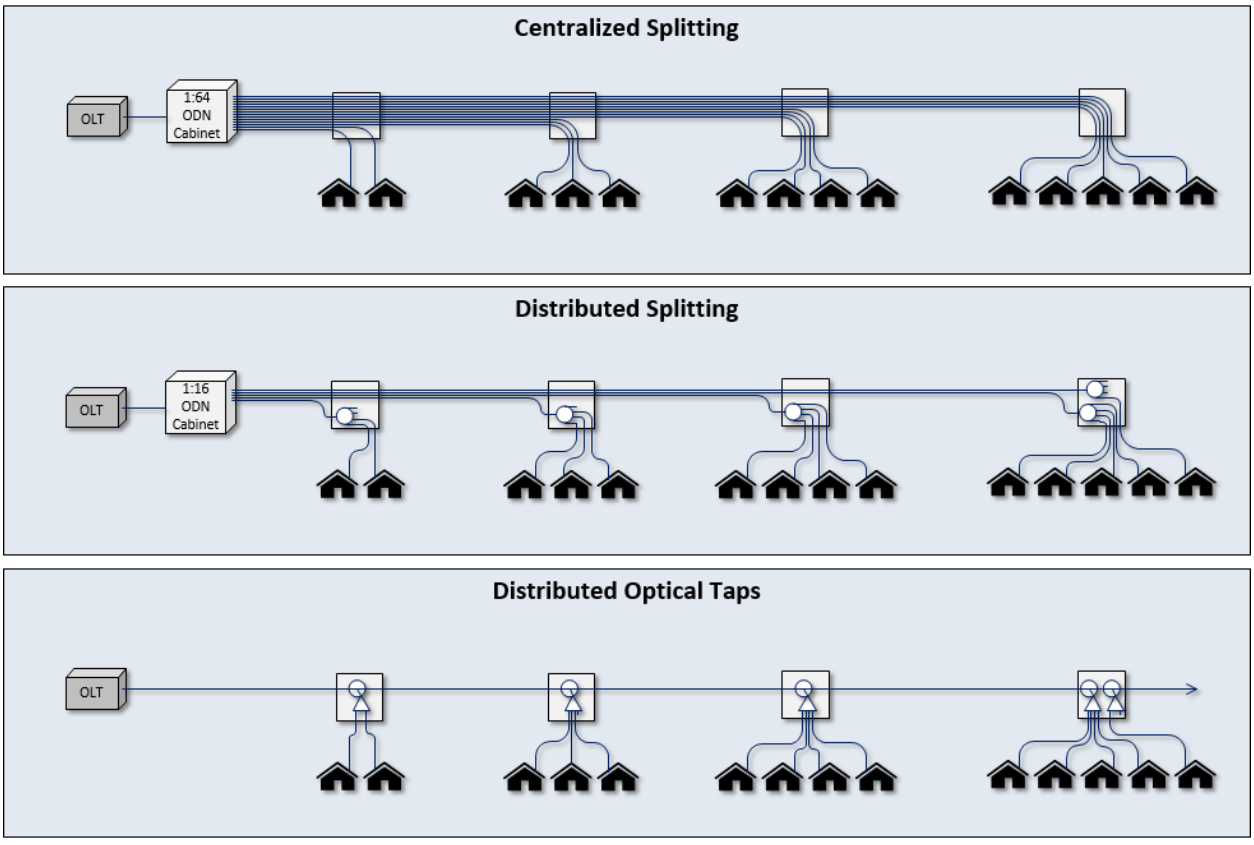

Figure 2 – FTTx ODN Architecture Concept Comparison

The insertion loss of the selected split ratio, fiber attenuation, and optical budget of each technology must be considered. Additional variables such as Co-Existence (CEx) WDM's, fusion splice and connector loss, may vary by operator, but also must be factored into optical reach calculations. Figure 3 below shows the relationship between split ratio and physical reach based on typical splitter loss characteristics. GPON assumes Class B+ optics, XGS-PON and NG-PON2 assume Class N1 optics, while the CPON specs are still being defined, but assumes worst case 35 dB optical budget operating in the C-Band. Both GPON and XGS-PON ITU standards assume a 20km physical reach limit; however, at Cox with standard 1:32 and 1:64 static split ratios, realistic operating ranges of GPON and XGS-PON are roughly 20km and 10km respectively, which include insertion loss characteristics of aforementioned variables.

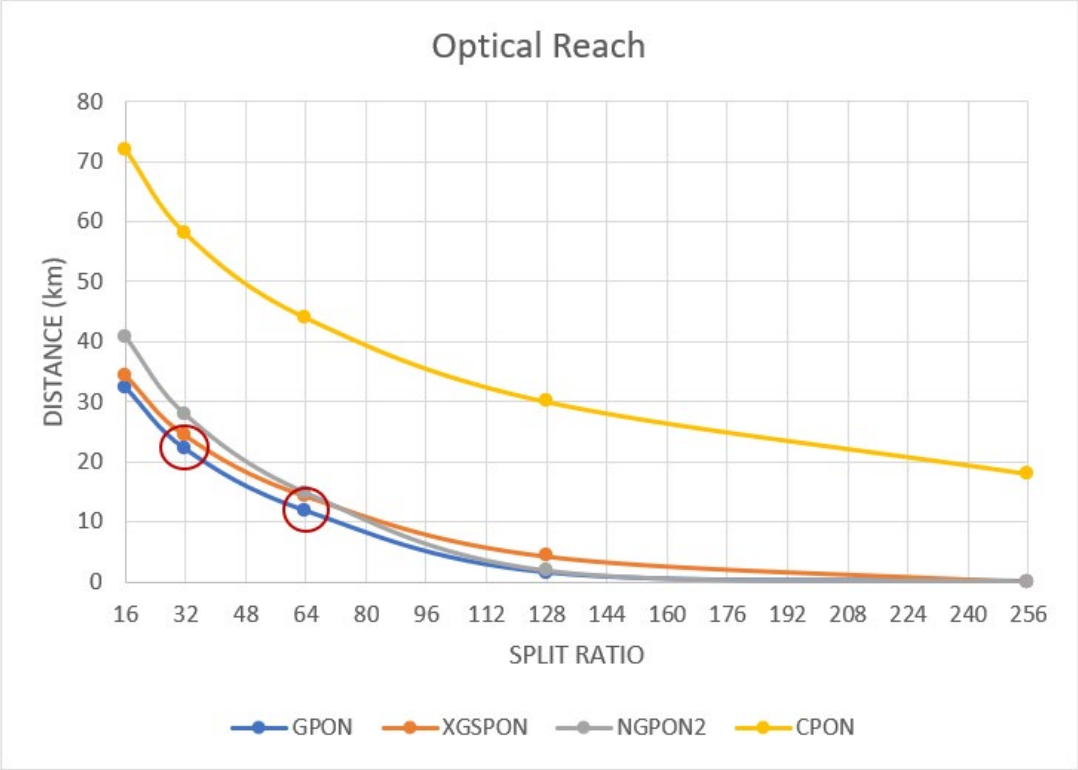

Figure 3 – Optical Reach with Static Split Ratios

3.1. Distributed Optical Tap Concept

Through the course of exploring all of these various splitting approaches it led us to a familiar concept, a tap (see Figure 4). The tap system is a controlled approach to managing signal levels to each customer throughout the network while optimizing fiber usage efficiencies and maximizing reach. A tap is characterized by a split-ratio, which is indicative of a percentage of signal received by the tap that continues through the tap to downstream devices versus a percentage of signal that is split off for creating network terminations at the customer premise.

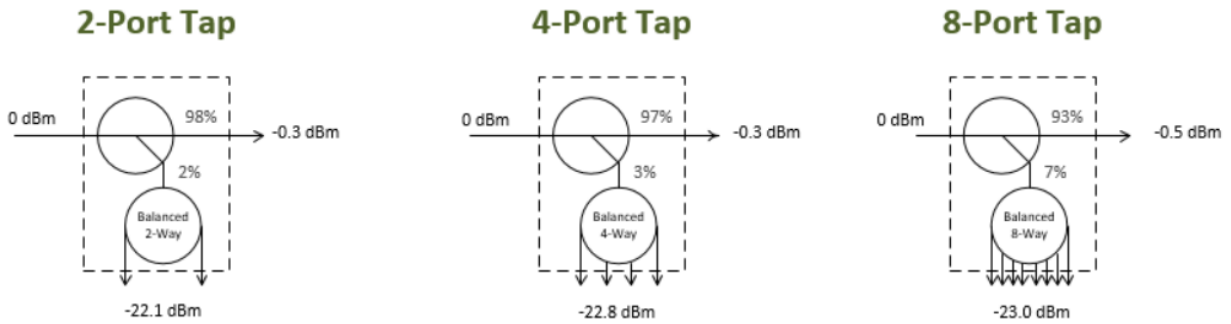

Figure 4 – Distributed Optical Tap Internal Scematics

The distributed optical tap solution takes the fiber efficiency concept a step further than a distributed splitter because much less fiber and fewer fusion splices are required than either conventional method described above. It also enables the user to control the 'size' (number of tap ports or legs) of the splitter included with the tap based on the number of legs needed and control the signal loss based on how much signal is received at a given location, and therefore is much less wasteful than the other approaches. The optical tap solution simplifies the application by pre-engineering combinations of a first stage coupler and a second stage splitter into a structured system of pre-integrated modular tap devices. A tap being "modular" refers to the fact that multiples of any tap type can be installed within any drop terminal. This contrasts with other solutions which integrate distributed splitters into a fiber enclosure, which does not allow for as much flexibility to add ports or control signal levels.

For example, if a user needs to add additional ports to a tap for new customers, they could replace a 2-port tap module with a 4-port tap module. As another example, if a technician needs more or less signal at a given location, they can simply replace the tap module with a different incremental value module. Both examples may trigger a network design change action in accordance with operational policies to maintain good record keeping, but the flexibility is feasible. In addition to the significant cost savings from minimizing fiber materials and fusion splice labor, this solution does not require a centralized cabinet for housing banks of splitters which may be expensive and challenging to get permission from municipalities to build in the right-of-way. The distributed optical tap solution also improves damage restoration time because a customer's service is dependent on fewer fibers and can be respliced quicker in the event of a damaged cable.

The distributed optical tap system intentionally mimics an HFC architecture, sharing many common principles (see Figure 5).

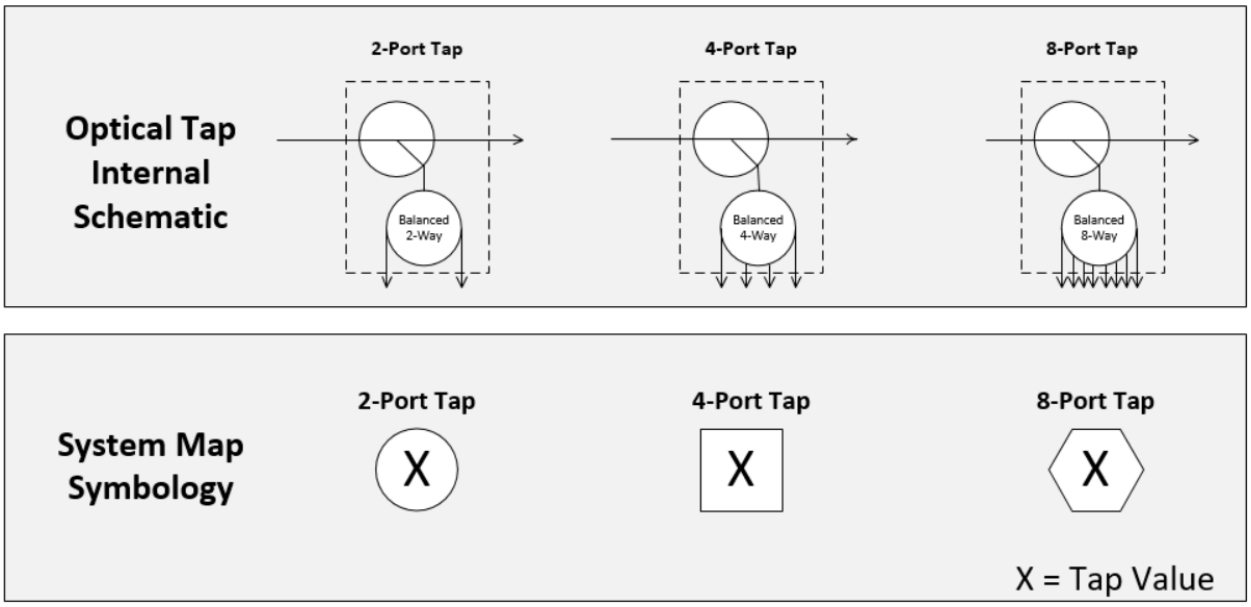

Figure 5 – Distributed Optical Tap Schematic and System Map Symbology

Optical tap devices will be installed into drop terminals (aka cross connects), which includes weather-tight fiber enclosures for pedestal, vault or aerial deployment, or PON wall-boxes for higher density MDU or commercial applications.

Additionally, more traditional optical splitters, such as a balanced splitters (2-Way & 4-Way) and asymmetrical directional couplers (DC) will be deployed into traditional splice enclosures to create additional branches as needed (see Figure 6). Similar to HFC, directional couplers will come in varying split ratios, like taps, the 'value' is representative of the down leg loss.

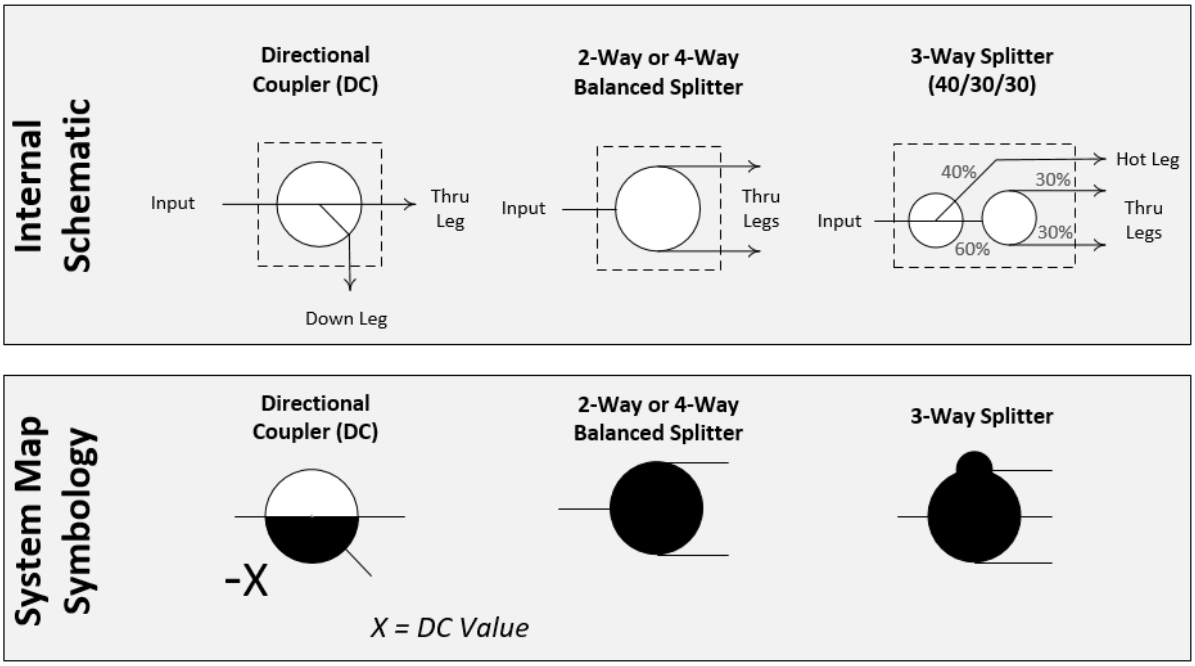

Figure 6 – Coupler/Splitter Internal Schematics and System Map Symbology

3.1.1. Optical Performance Characterization

Downstream, fiber splitter/couplers divide optical power from one common port to two or more split ports and upstream combine all optical power from the split ports to a common port (see Figure 7). 2-way optical splitter/couplers are often expressed in split ratio (SR), (e.g., 75:25).

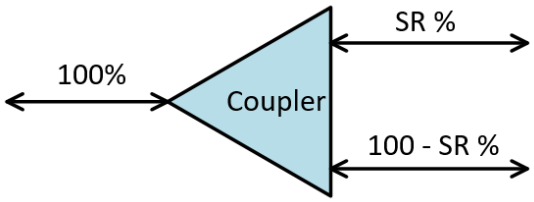

Figure 7 – Coupler Split Ratio Example

SR can be determined based on total optical power relative to the power passing through:

$$SR = \left(\frac{P_i}{P_T}\right) x\ 100$$

An industry standard formula was used to calculate insertion loss (IL):

$$IL\ = -10\ log\left(\frac{P_i}{P_T}\right)$$

Where:

IL = Splitter/coupler insertion loss for the split port, dB

P_i = Optical output power for a single port, mW or dBm

P_T = Total optical power output for all split ports, mW or dBm

Additionally, splitter/coupler excess-loss is a critical assumption that must be applied to factor in lost signal power due to imperfections in the manufacturing process and can range anywhere from 0.1 to 2.0 dB. Published insertion loss specifications from optical passive manufacturers often are expressed as "Typical" and/or "Maximum", but always factor in additional excess-loss. Based on lab testing and IL specifications from major optical passive manufacturers, we observed the higher calculated IL, the higher excess-loss variability, while the lower loss legs were more consistent. Lab testing data in Figure 8 below includes the average measured insertion loss of at least 3 samples of each type from each vendor.

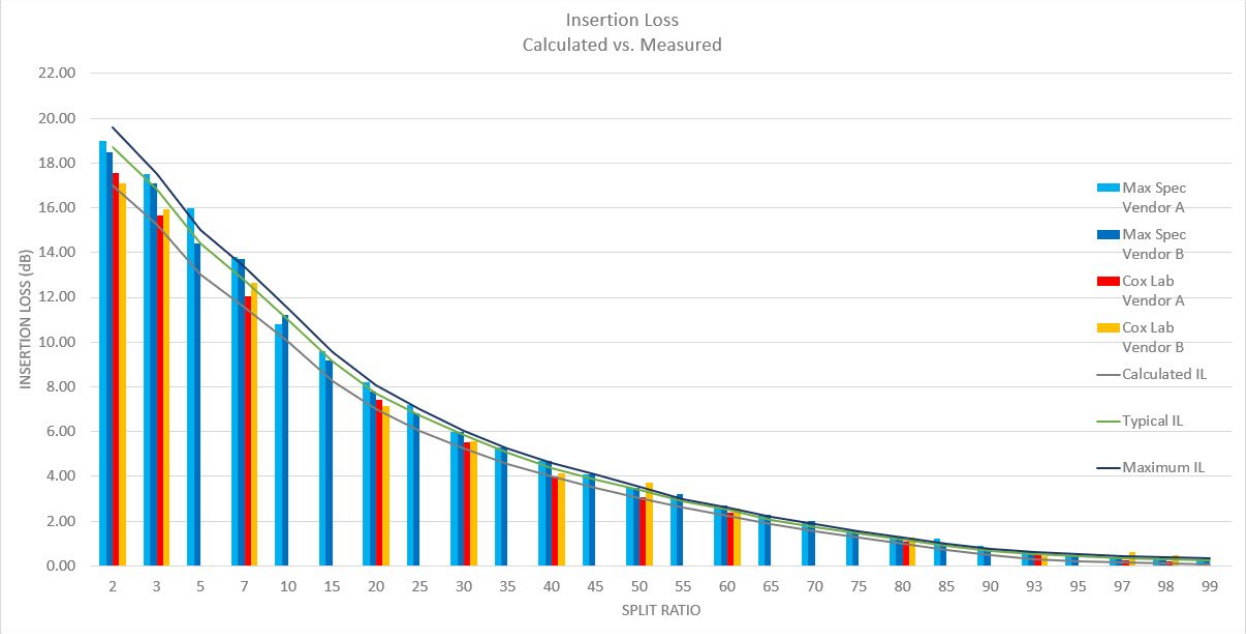

Figure 8 – Calculated Loss vs. Reported Loss

Based on these observations it was decided 'Typical' IL would include an additional 0.2 dB or 10% IL for typical excess loss. 'Maximum' IL would include an additional 0.3 dB or 15% of IL for maximum excess loss.

Both typical and maximum IL specifications are important for daily operations. It's important for field technicians to be mindful of maximum insertion loss while looking at individual events. However, if maximum loss were used for network design calculations of multiple taps spliced in series it would result in excessive amounts of cumulative loss margin. For this reason, it was decided to use typical insertion loss for network design calculations, which aligns closer to average measured loss.

3.2. Design Study

A design study was conducted to validate the optical tap concept in real-world network design scenarios against some of the aforementioned conventional methodologies. One of the many goals of the design study was to validate that we could repurpose some of the tools that we've been using for many years to design HFC networks. Additionally, we were seeking a larger sample size of network design data to help compare construction costs and network efficiencies against traditional splitting methods.

3.2.1. Design Parameters

Cox has been designing HFC networks via Lode Data Design Assistant to run RF calculations for many years. It turns out it is relatively easy to convert the core RF spec files to calculate optical levels instead. However, a significant amount of consideration was given to the core parameters that drive the design calculations to ensure a fair amount of margin for field variations without being overly conservative.

These are the key parameters and the assumptions we used (see Table 1 & Figure 9):

Table 1 – Key Network Design Parameters

Description	UOM	Parameter
Downstream OLT Transmit Power	dBm	+3.0
Downstream ONT Receive Power Minimum	dBm	-26.0
Downstream Tap Port Minimum	dBm	-23.0
Fiber Drop Loss (< 500') Maximum	dB	2.0
1490nm Attenuation (DS GPON)	dB/km	0.28
1310nm Attenuation (US GPON)	dB/km	0.34
1577nm Attenuation (DS XGSPON)	dB/km	0.25
1270nm Attenuation (US XGSPON)	dB/km	0.35
Maximum HP per OLT Port	HP	64

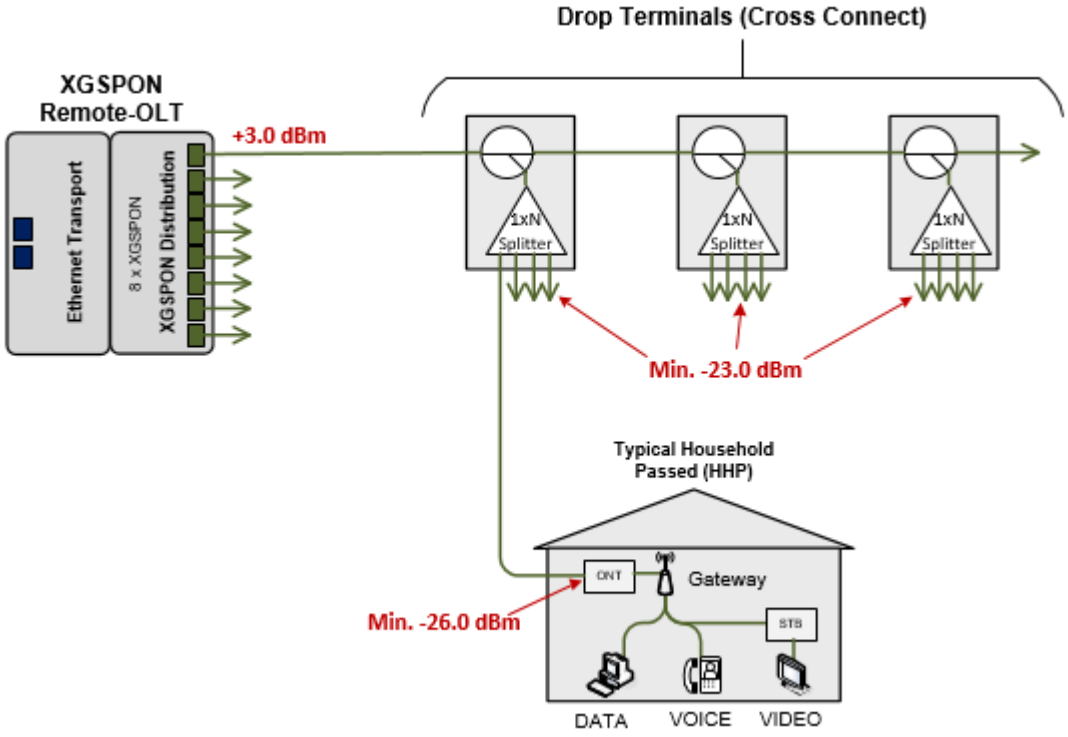

Figure 9 – ODN Diagram with Key Design Parameters

Considerations should be given to maximum versus typical, particularly when deciding what to design to, to balance performance and cost. In the case of the OLT launch power, per ITU-T G.984.1 the OLT transmit level can range from 1.5 to 5.0 dB, leading us to analyze the optical transmit power of over 17,000 OLT interfaces in our network to generate a histogram of OLT transmit power. Results found the OLT ports actually transmit at +3.63 dBm on average, with less than 1% of the population transmitting below +3.0 dBm (see Figure 10).

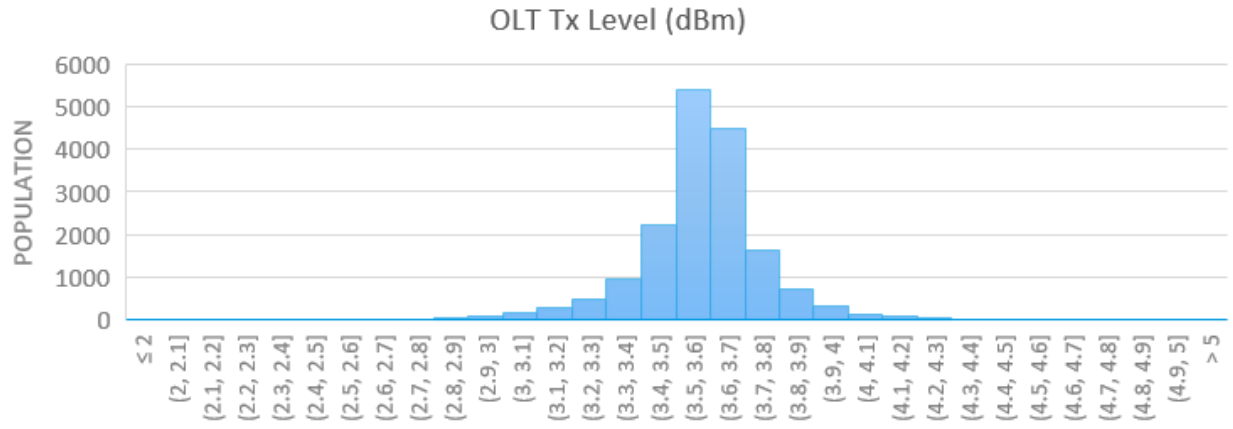

Figure 10 – OLT GPON Interface Population - Downstream Launch Power

Downstream tap port minimum (GPON & XGS-PON), for the sake of design calculations, was set at -23 dBm, but we allow -24 dBm acceptance criteria for field activations. This combined with OLT launch power margin provides 1 – 2 dB of margin for additional field variables, such as maximum insertion loss conditions, fusion splice loss, connector loss, etc. For the last 100' – 500', the drop network is given 2 dB of loss for the connectorized fiber drop from the tap port to the optical network terminal (ONT).

Also, considering this network type doesn't naturally control the number of HP per OLT port like a traditional fixed split ratio, we opted to implement a 64 HP limit policy which will be enforced at the individual design level. While there certainly is a healthy amount of optical budget in our current GPON and XGS-PON deployments to support many more than 64 HP, the spirit behind this policy was to mitigate potential network contention in the future. As technology and bandwidth demand changes this policy may be revisited.

3.2.2. Design Analysis

The actual design study included 5 SFU properties totaling 920 HP across 4 different markets, as well as 4 MDU properties totaling 799 HP across 4 different markets. Many data points were collected, but the two primary metrics being evaluated were fusion splicing requirements and OLT port optimization, because they have the most bearing on cost efficiency.

The SFU portion of the study considered standard centralized splits and distributed 1x4 or 1x8 splitters at a fixed 1:64 split ratio compared to the distributed optical tap concept (See Table 2).

Table 2 – SFU Design Study Results

SFU Properties		Centralized Splitters (Current)			Distributed Splitters			Distributed Optical Taps		
Market	HP	OLT Ports Used	HP per OLT port	Fusion Splices	OLT Ports Used	HP per OLT port	Fusion Splices	OLT Ports Used	HP per OLT port	Fusion Splices
Site 1	405	7	58	892	9	45	178	7	58	142
Site 2	85	2	43	178	2	43	39	2	43	29
Site 3	55	1	55	120	1	55	20	1	55	25
Site 4	240	4	60	526	5	48	86	4	60	91
Site 5	135	3	45	280	4	34	58	3	45	58
Averages:	***184***	***3.4***	***52***	***399***	***4.2***	***45***	***76***	***3.4***	***52***	***69***

When compared to centralized splitting in an SFU application, there was an 83% reduction in fusion splices required which is a significant labor cost driver. Furthermore, a centralized split is often considered the most efficient in regard to HP per OLT ports, but with distributed optical taps there was no change in OLT port efficiency. The distributed splitter model maintained the traditional fixed 1:64 split ratio but allowed the distributed splitter in the field to be either a 1x4 or 1x8 based on the number of passings at a given location. When looking at the distributed splitter solution versus centralized splitters it resulted in an 81% reduction in fusion splices, but costly OLT port usage requirements increased due to stranded capacity in the cross connect device at the curb.

For the MDU portion of the study, distributed 1x8 splitters at a fixed 1:64 split ratio were compared to the distributed optical tap concept. Centralized splits were not considered because previous cost modeling exercises in years past had already considered it and led to standardization of a distributed 1x8 for MDUs (see Table 3).

Table 3 – MDU Design Study Results

MDU Properties		Distributed 1x8 Splitter (Current)			Distributed Optical Taps		
Market	HP	OLT Ports Used	HP per OLT port	Fusion Splices	OLT Ports Used	HP per OLT port	Fusion Splices
Site 6	204	4	51	62	4	51	45
Site 7	287	6	48	106	5	57	75
Site 8	190	5	38	139	3	63	114
Site 9	118	3	39	48	2	59	31
Averages:	***200***	***4.5***	***44***	***89***	***3.5***	***58***	***66***

Distributed optical taps averaged 32% more efficient OLT port usage than our current distributed 1x8 splitter solution, which can be attributed to the flexibility allowed by the taps to choose the appropriate splitter size at each demarcation box. Furthermore, there was a 26% reduction in fusion splices required per property.

3.2.3. Cost Modeling

In addition to splicing and port efficiency improvements shown above, the ODN Cabinet was another important factor considered in the cost model. The distributed optical tap architecture solution assumes the ODN cabinet may be eliminated considering splitting will be distributed to the tap locations instead of a centralized bank of splitters in a cabinet or enclosure.

With the splicing and port efficiency improvements shown above, coupled with additional material and labor savings not directly tied to these drivers, we estimate approximately $65 and $40 per HP savings for SFU and MDU respectively, relative to our current architecture solution.

3.3. Product Development

As a cable operator with large groups of technical resources who are trained and educated on how to operationalize HFC, the goal of product development was to make it look and feel as much like HFC as possible. Small things like product naming and labeling were intentionally created to blend HFC terminology with fiber products for ease of knowledge transfer.

The physical form-factor of the devices was also carefully considered; it was important that the optical tap device was decoupled from the enclosure that it lives in. This provides the flexibility to deploy taps into any generic fiber terminal and deploy multiples of any combination of tap devices within the terminal based on the need of the given location. Generally speaking, our preference is fusion splicing whenever

possible, because hard splices are inherently more reliable than mated connectors. For this reason, we decided the standard tap modules would have standard 250µm bare fiber leads on the input and through-legs to allow fusion splicing the cascades of taps in series, while the tap legs would be connectorized for drop connections. Additionally, we specified a connectorized cassette with bulkhead connectors on all ports. Cassettes will primarily be used for wall-mount applications, where long strings of multiple taps are not spliced together in series.

3.3.1. Product Specifications

Tap modules and cassettes contain two integrated balanced and/or asymmetrical optical couplers designed to a series of fixed insertion loss values (See Figure 11) just as RF taps are designed today.

Definitions:

1st Stage Coupler: Either balanced or asymmetrical two-way optical coupler, with one of the output legs fusion spliced to the input of a second stage optical splitter.

2nd Stage Splitter: Balanced 2-way, 4-way, or 8-way optical splitter.

Input Leg: The input fiber of the first stage coupler will feed out of the tap module.

Thru Leg: The second output fiber of the first stage coupler will feed out of the tap module.

Tap Legs: Output fibers of the second stage splitter will feed out of the tap module.

Thru Loss: The insertion loss from input to thru leg.

Tap Loss: The combined insertion loss from input through drop legs

Tap Value: Numeric identifier indicating the loss structure of the tap, which is closely related to the tap loss.

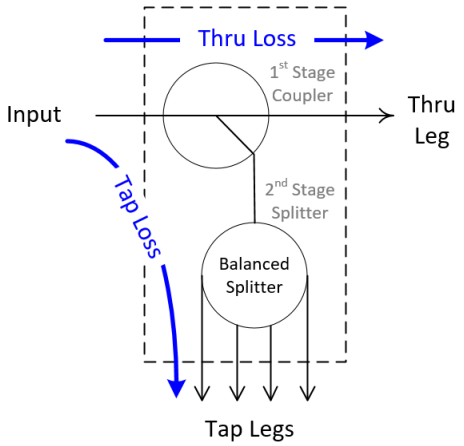

Figure 11 – Distributed Optical Tap Schematic

Insertion loss characteristics are expressed in both typical and maximum insertion loss characteristics of each tap variation across entirety of the passband (1260 – 1650 nm), not including connectors. Tap Loss Uniformity must be ≤ 1 dB.

Taps are available in 24 different size/value combinations and will be labeled with the following symbology (see Figure 12). Taps will be available in two form-factors: Outside Plant (OSP) Modules (see Figure 13) and Inside Plant (ISP) Cassettes (see Figure 14):

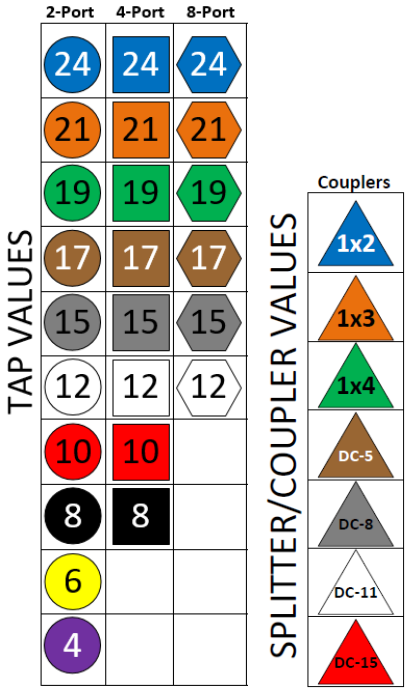

Figure 12 – Device Naming and Labeling

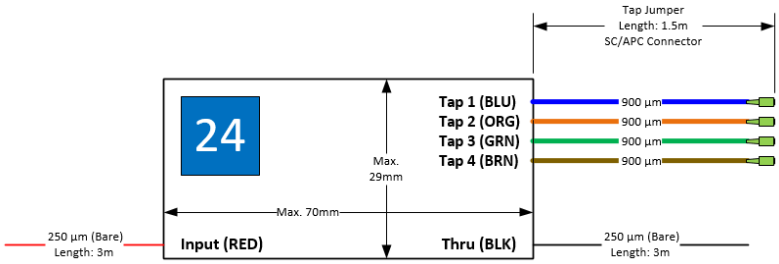

Figure 13 – Example of Tap Module Form-Factor

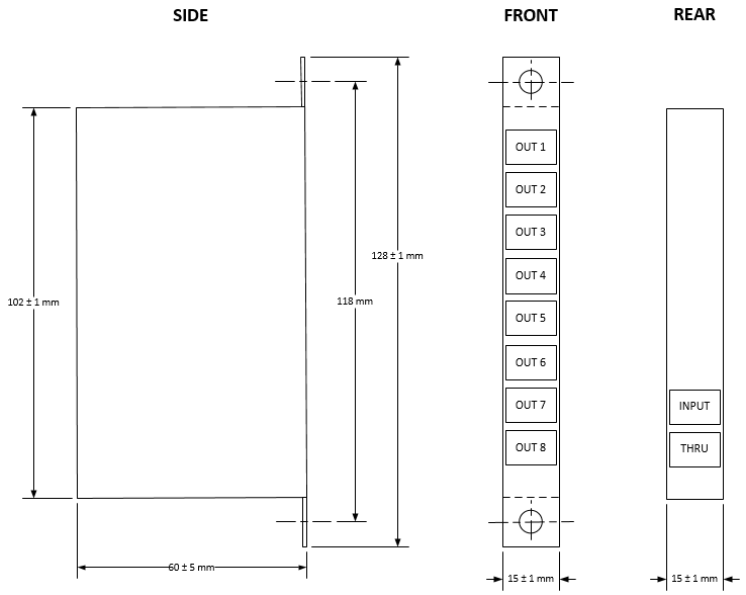

Figure 14 – Example of Tap Cassette Form-Factor

3.4. Field Trials

Prior to any customer facing deployments, full proof-of-concept networks were built in the lab with strings of couplers/splitters spliced together operating both GPON and XGS-PON networks successfully. As well as final product testing from multiple vendors, and mechanical form/fit/function testing within our standard fiber enclosures. Design tools such as our GIS database also needed further development to prepare for modeling of this type of network in digestible manner for field technicians. New object types were created, and fiber splicing documents were modified to support this type of network.

A reliability study was also conducted, which resulted favorably for a fusion-spliced distributed optical tap network with improvements in mean availability time, Mean Time Between Failure (MTBF), Mean Time to Restore (MTTR), and a reduction in annual maintenance truck rolls. While more customers are dependent on a single strand fiber in this type of network, there are fewer points of failure and in the event of a fiber impairment, services can be restored quicker.

The final step before full scale deployments was to gain some production experience to ensure processes are aligned and to identify any potential operational gaps. We conducted 5 field trials in 5 different Cox markets to demonstrate performance for the selected applications: greenfield, brownfield, SFU, MDU and commercial applications.

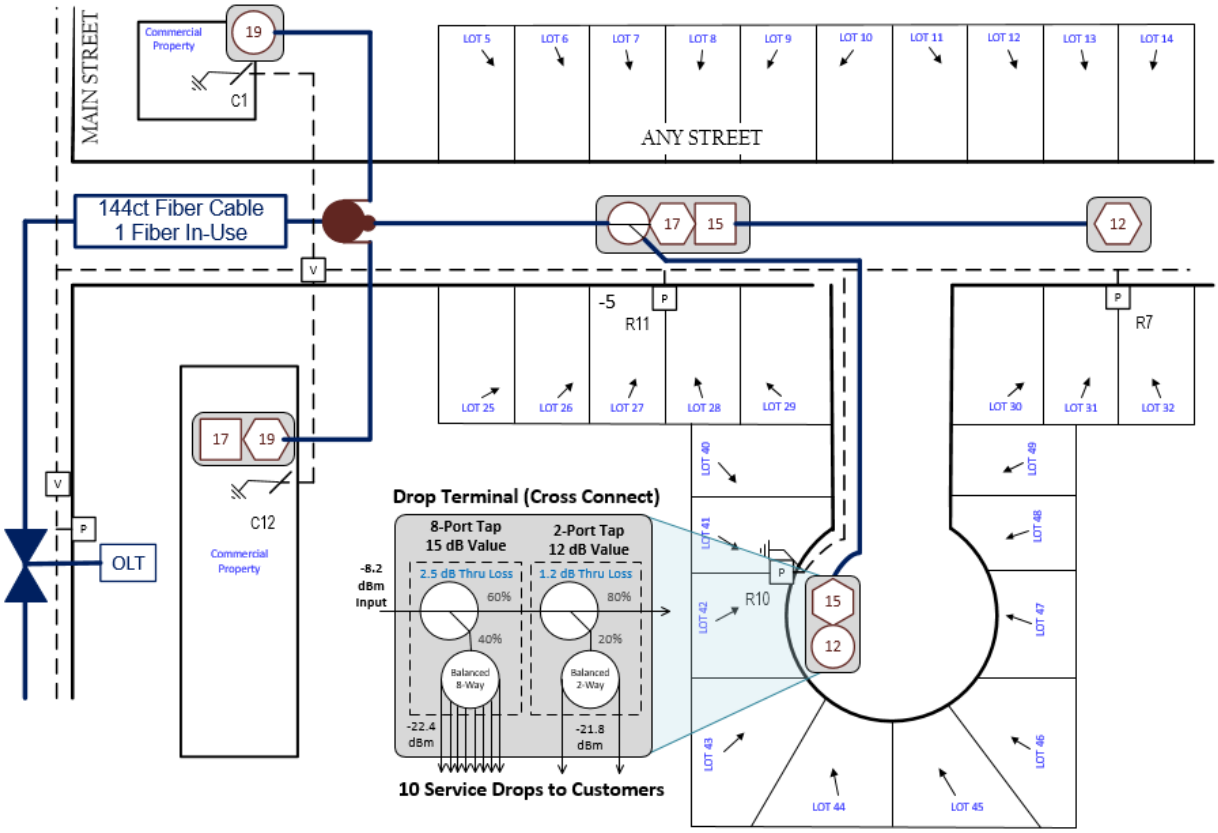

Figure 15 – Example of Field Trial Network Design

3.4.1. Lessons Learned

We successfully built and activated 5 different FTTx networks with the distributed optical tap solution and compared calculated design level versus actual measured levels. At the time the data was analyzed, levels had been collected from only 72 optical tap locations (see Figure 16).

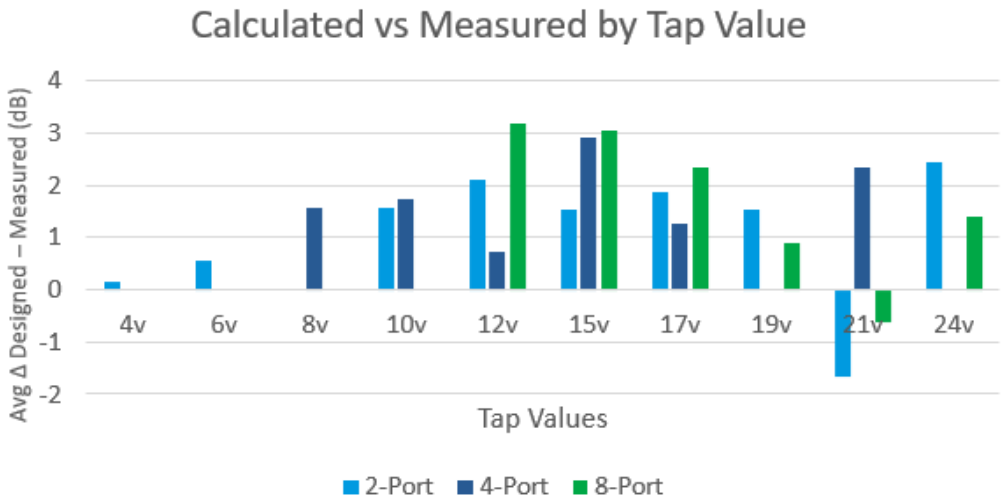

Figure 16 – Example of Field Trial Network Design

In most cases, measured levels were 1 - 3 dB better than calculated with few exceptions, which aligns with the built-in margin. In some cases, measured level was within the field acceptance criteria (-24 dBm), but lower than calculated, upon further investigation these were attributed to higher than typical splices but deemed acceptable. Considering all the variables involved and built-in margin we were comfortable with the results.

Be mindful of Optical Time Domain Reflectometer (OTDR) capabilities and limitations when designing turn up and troubleshooting processes. Characteristics of this type of network make obtaining OTDR shots particularly challenging due to relatively short distance links (< 2 km) with high insertion loss. We have observed good results when shooting 'in-line' into Thru Legs of taps but had very limited success shooting an OTDR into a tap leg. Tap legs, in particular of tap values greater than 17 dB, require a pulse width setting of at least 500ns, which decreases your resolution and creates lengthy dead-zones on the opposite side of the devices under test. This may be good enough to establish continuity back between two points, but events in between may not be visible. In contrast, in-line shots allow you to reduce pulse-width settings resulting in shortened dead-zones and with better resolution for the entirety of the link. We learned the addition of a connector on the last tap of the end-of-line circuit as an 'in-line' access point specifically for troubleshooting is valuable.

In the examples below (see Figure 17 & 18), OTDR shots are taken from the same 2-Port 12 dB value (2p12v) tap location into the tap leg versus the Thru leg; notice there is an additional ~10 dB of loss 400' from the test location which becomes much more difficult to discern with higher pulse width settings.

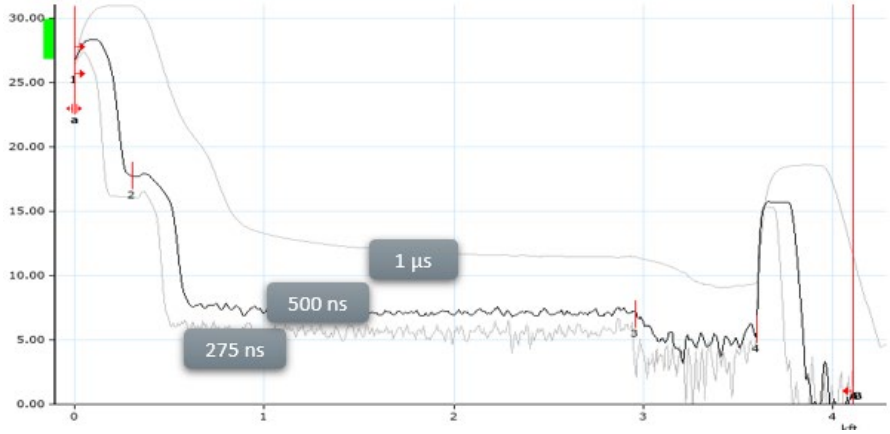

Figure 17 – Effects of Pulse Width Variation into Tap Leg of 12 dB Value Tap

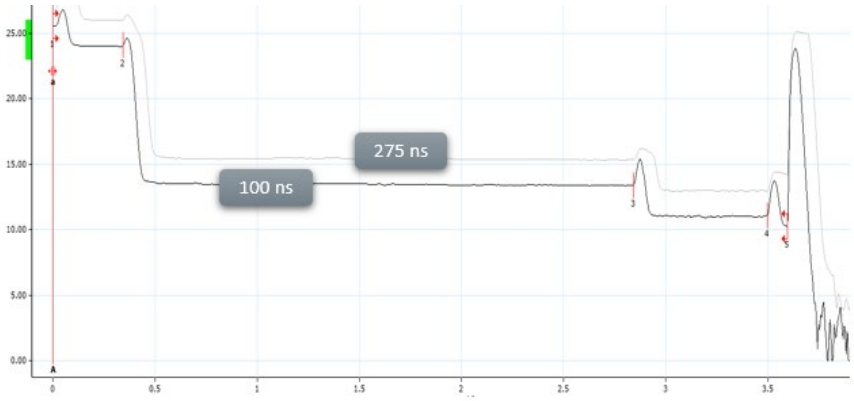

Figure 18 – Effects of Pulse Width Variation into Thru Leg of 12 dB Value Tap

Test equipment vendors are actively working to improve software profiles to make them more intuitive at identifying asymmetrical couplers and faults. In the interim, it takes a little more skill to read a traditional OTDR trace result and distinguish acceptable events from problematic events. We've found that the measured event loss of an OTDR can be very accurate (± 0.05 dB), the challenge is understanding the difference between a 'good' and 'bad' event. Historically any event greater than 0.5 dB was considered bad, in this type of network 5 dB of loss at one location could be 'bad' while the next is acceptable.

Figure 19 below is of a network with low levels (-27 dBm) at two locations, an OTDR was shot from end-of-line back toward the OLT. The technician must have a comprehensive view of the network design to compare anticipated loss to actual loss; in this case, the issue found was a bad splice on the input of the DC-8, which the anticipated loss was 1.5 dB, but the actual loss was ~7 dB.

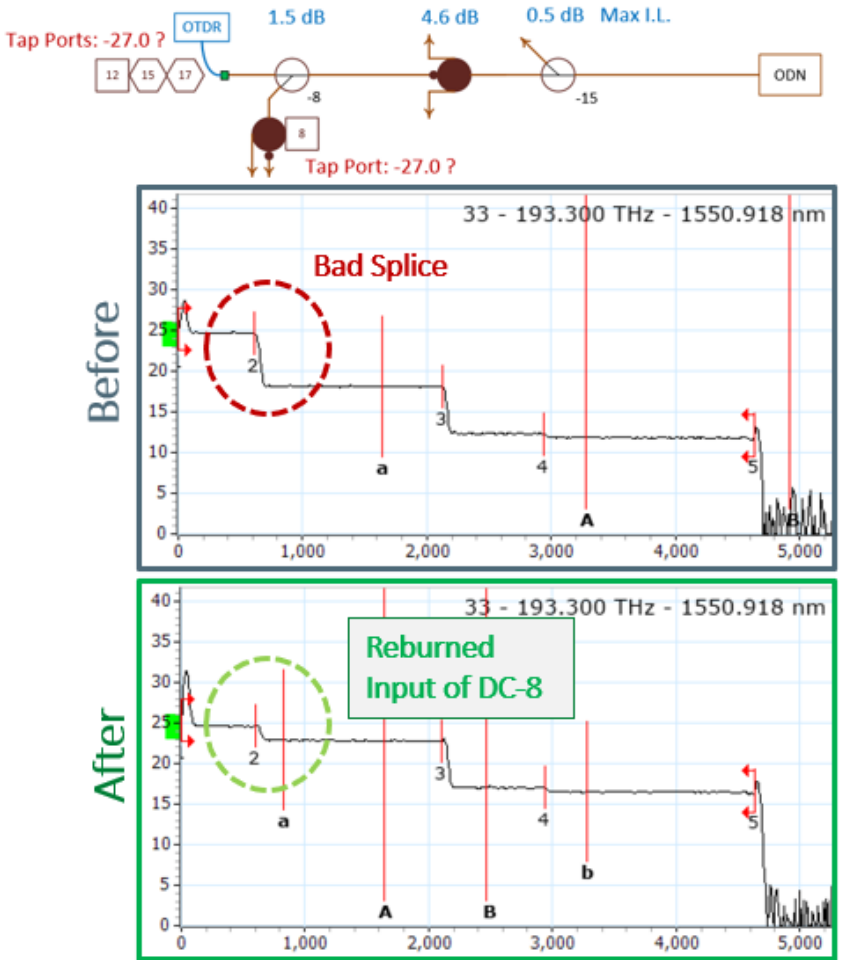

Figure 19 – OTDR Troubleshooting Example

4. Conclusion

Having completed lab testing, field trials and the early phases of production rollout, we feel confident in the distributed optical tap system serving as the standard optical distribution network for our PON deployments now and into the foreseeable future. Operationally, it fits well into many of our technicians existing skill sets and legacy RF design tools can be repurposed to model optical networks instead. This network is cost efficient, and more closely aligns network capacity with demand.

For network design parameters excess-loss must be factored in, but typical (as opposed to maximum) optical splitter insertion loss specifications from vendors is sufficient. Additional margin may be strategically applied to OLT launch power and/or drop loss instead.

An OTDR is a valuable tool for troubleshooting but must be performed in-line as opposed to a tap port. Consider fusion splicing versus optical connectors; well-placed connectors are valuable access points for troubleshooting purposes but can reduce optical reach and become future points of failure.

1. Introduction

Cable operators continue to expand the service offerings towards the end-users with wireless and cellular capabilities. Some of the operators already leverage Mobile Virtual Network Operators (MVNO) relationships with existing nationwide Mobile Network Operators (MNO) partners to offer mobile services on the macro cellular networks. This enables the Cable Operator to be able to offer a unified experience for the end users and able to tap into additional revenue by offering differentiated services.

However, depending on the markets and needs, the availability of spectrum or regulatory requirements Cable operators are considering deployment of new 4G and 5G networks from the ground up, which are a Greenfield network. Depending on the timing of the market in the region and the device ecosystem availability within the region, it may be possible that the Cable Operator would have to deploy a 4G radio but given the timing of the industry, we anticipate more 5G network deployments to ensure investments are directed towards the network of the future. In some cases, the operator may choose to leverage a 4G+5G Radio access network and terminating on a 4G Core. This architecture – widely known as 5G NSA would allow for the cable operators to leverage existing device ecosystem but also partially build towards the network of the future. However, more and more MSOs seem to be evaluating a 5G Standalone deployments and this paper tries to focus primarily on the 5G SA deployment models but also addresses ability to handle specific scenarios of 4G+5G deployments. In this paper, we consider any 3GPP standards based wireless network that is being built up for the first time by a provider without having the dependencies of legacy 3G network interworking or device support related to 2G/3G.

Additionally, we use the terminology Multiple Service /System Operator (MSO) to refer to cable operators who have decided to deploy Greenfield mobile networks. By contrast, Mobile Network Operators are the traditional mobile operators like AT&T, Verizon, T-Mobile, Vodafone, etc.

While architectures for deployment based on 3rd Generation Partnership Project (3GPP), Cable Labs and other industry standard development organizations (SDOs) are widely available and considered before finalizing deployment, it is also critical to consider some of the lessons learned by wireless network providers over the years ramping up the network capabilities.

Based on some lessons learnt in deploying 4G networks globally as well proven best practices in the industry for macro and microcellular networks, this document addresses and captures multiple key challenges to anticipate and plan for both the architecture and operational models. Given that 5G SA architecture leverages new capabilities like Service Based Architecture and some of the challenges related to 4G networks based on point-to-point interfaces using Diameter and GTP-C interfaces may not always be applicable, the authors believe that initial set of deployments will have some form of point-to-point capabilities – though leveraging new protocols defined in 3GPP. Hence, some of the lessons learnt in 4G networks would absolutely be applicable.

2. 5G – Architecture and Capabilties

There is significant amount of collateral and information related to 5G and the new capabilities that 5G network architectures bring to the table. Rather than reiterating the capabilities of 5G and cover the architecture options in detail, this section provides a very high-level view of 5G, and the nomenclatures used in the rest of the document.

Beyond just being an advancement in mobile generation – 5G was expected to lay a path for new capabilities and services that are yet to come. The underlying premise for the architecture enhancements was to enable capabilities that would allow Service Providers leveraging 5G to break through some of the constraints of legacy internet connectivity paradigms and enable a new set of differentiated services.

Within the scope of a 5G Network, we believe that the network must be flexible enough to deliver a wide range of new services but also be able to address existing legacy applications. Given the complexity of owning a brand new 5G network, the network needs to account for ease of deployment but also for ease of day-to-day operations and management.

The figure below takes a high-level representation of the various domains of an end-to-end 5G network.

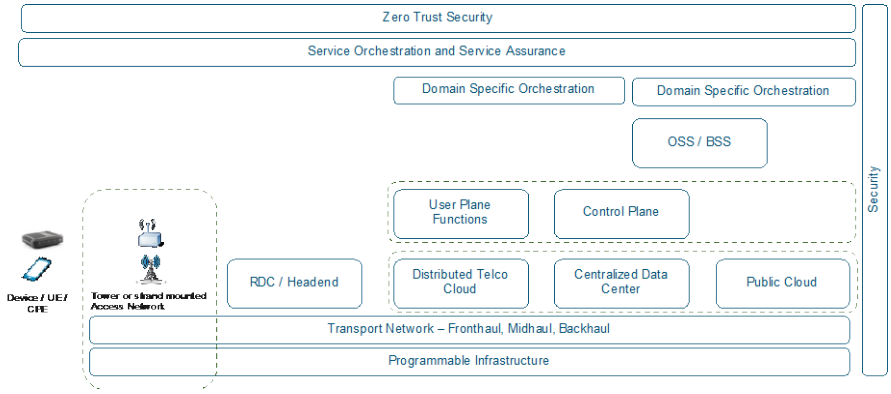

Figure 1: Different Domains of a typical 5G network

At a minimum, the following domains must be individually understood and designed for a successful deployment of 5G network.

- Radio Access Network
- Transport Network
- Packet Core
- Automation and Assurance
- Compute and Infrastructure
- Security

While this document does not go into each of these individual domains, care must be taken to ensure each area is tuned and enhanced to account for 5G network deployments for the specific MSO environment. For subsequent sections, capabilities and unique learnings and architecture options around packet core network are detailed.

A simplified representation of a 5G network architecture is shown below with the key capabilities described.

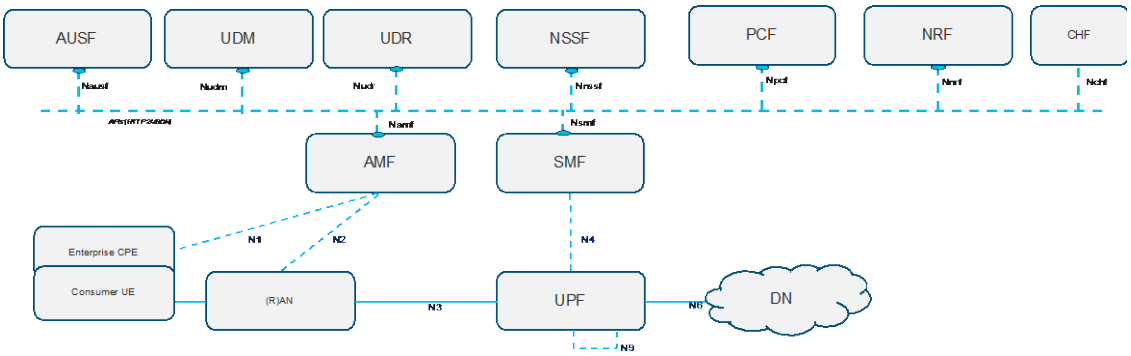

Figure 2: Simplified 5G network architecture with packet core focus

- **Consumer UE / Enterprise CPE**: The end user device that is connecting via the radio access network or in case of MSO environment, via the existing cable network back into the 5G Core network.
- **Radio Access Network (RAN)**: In the case of 5G wireless access technology, the Access Network typically consists of a 5G gNodeB which performs Radio resource management, radio bearer control, scheduling of packets over the air interface among other access management functionality. In MSO deployment scenario, based on 3GPP Release 16 or later specifications, Access Network could be existing access capabilities like Cable plant or WiFi technologies terminating via appropriate trusted or untrusted access.
- **Access and mobility management function (AMF)**: AMF is responsible for Registration management, access control and mobility management function for all accesses (incl. WLAN), Terminates NAS signaling for all accesses (single AMF per UE). AMF receives mobility related policies from PCF (e.g., mobility restrictions) and forwards mobility related policies to the UE (via N1)
- **Session management function (SMF)**: With 5G SA architecture, SMF provides a mechanism to deploy a common session management for all accesses (incl. WLAN) and wireline capabilities. SMF handles all session management signaling with UE (relayed by AMF), controls the user plane functions. SMF interfaces directly with UDM to receive subscription information (no need to go via AMF) along with policy information from PCF.
- **User plane function (UPF)**: UPF supports set of operations (forwarding to other functions, encapsulation/decapsulation, bitrate enforcement, application detection etc.) and acts as a primary anchor point of IP packets in the network. Within 5G SA architecture, SMF dynamically configures UPFs (activates/configures subset of the operations defined above) to provide the traffic handling functionality needed for a session. In addition, one or

multiple chained UP functions can be activated and configured by SMF per session as needed for a scenario. Within the MSO network architecture, UPF can also enable convergence capabilities by unifying access gateway capabilities when leveraging 3GPP Release 16 and additional SDO specifications.

- Policy control function (PCF): The PCF Provides QoS and charging rules to Session Management Function and interfaces with external Application function (e.g., IMS) when applicable. PCF also provides mobility related policies directly to AMF (e.g., mobility restrictions for stationary devices (FWA) and optionally provide policies to the UE e.g., on network discovery/selection. Additional support for network discovery/selection policies, while defined in 3GPP require UE/CPE capabilities to be deployed in the network.
- Unified Data Management (UDM): UDM uses subscription data (including authentication data) that may be stored in UDR and is responsible for generation of 3GPP AKA Authentication Credentials, identification Handling and Access authorization based on subscription data.
- Authentication Server function (AUSF): AUSF Supports authentication for 3GPP access and untrusted non-3GPP access and supports recover from synchronization failure in certain cases.
- Unified Data Repository (UDR): UDR carries the subscription data and offers services for UDM, PCF etc., to allow for retrieval of appropriate user data to be used for allowing the device onto the network and applying the corresponding policy. In MSO deployments, UDR could be a mechanism to unify the wireless and wireline subscription data in the future.
- Network Slice Selection Function (NSSF): Network Slice allows for a self-contained, logical portion of an E2E network resources within a service provider but to ensure the UE/CPE is allowed access to the appropriate slices defined, NSSF was introduced as a new capability within the 5G SA Architecture and helps selecting the set of Network Slice instances for the specific devices.
- Network Repository Function (NRF): With the introduction of Service Based Architecture, Service Providers have the ability of the steering away from somewhat of a point-to-point network architecture in 4G networks. NRF enables service registration from NFs and acts as a service discovery function – either for enable direct or indirect communication between various functions defined above.
- Charging Function (CHF): The charging function is responsible for generating charging data records (CDRs), based on usage information obtained from the UPF and SMF. The CHF interfaces to the operator's billing system.

Note that while this section captured some of the high-level capabilities of the critical network functions in the 5G architecture, 3GPP TS 23.501, Section 6.1 carries a comprehensive list of capabilities for the complete set of the network functions. Full set of functions as defined by 3GPP are listed in the Appendix A.

3. What could 5G be for MSO's

Cable operators get presented with more opportunities every day in different countries to expand the footprint and offerings to the end users by enhancing the service capabilities and enable new set of customer use cases and experiences. With more spectrum options being made available by regulatory bodies in different countries – example CBRS and C-band in US, Canada's 3.5 GHz auction and upcoming auctions in India as well as other countries - the ability for Cable operators to enhance their network to offer mobility solutions to their customers is more viable than ever.

Especially with 5G architecture capabilities defined in 3GPP specially to address the wireline and wireless convergence (5WWC Work Item in Release 16 of 3GPP specifications[1])and additional capabilities being addressed by Cablelabs[2] Cable operators are certainly closer to achieving the goal of becoming MSOs. Cable operators' interest for foraying into the mobility domain is being driven by a multitude of factors – some country specific and some globally applicable.

Offering a mobile service to the users could:

- Significantly increase revenues – new wireless service to existing customers or new standalone wireless customers
- Enhance customer experience by offering seamless service experience – extending the home experience to wider area
- Offer differentiated services that could not be offered on wireline alone – broadband services including voice

Depending on the country, regulatory requirements, and competitive positioning – Cable operators are typically presented with multiple options.

1. Tight partnership with an existing Mobile network provider
2. MVNO network agreements with one or more existing Mobile network provider
3. Build a standalone network with nationwide coverage
4. Build pockets of wireless network with MVNO or partnership with Mobile network provider for enhanced coverage by leveraging small cells or micro coverage

When it comes to a mobility network built from the ground up, some Cable operators have traditionally relied on unlicensed spectrum to offer mobility for the end users, leveraging capabilities of WiFi which is being enhanced every day with new capabilities as well. WiFi6 will continue to be a critical part of the MSO architecture it is critical to understand the capabilities of 3GPP to deploy 5G networks in the licensed bands as well as shared access and unlicensed access being leverage would be available. In addition to network capabilities, enhanced device capabilities also offer new potential options for MSOs that have traditionally not been present. As an example, being able to leverage eSIM capabilities will enable MSOs to migrate subscribers faster and more seamlessly onto the new MSO networks.

[1] https://portal.3gpp.org/desktopmodules/WorkItem/WorkItemDetails.aspx?workitemId=830050
[2] https://www.cablelabs.com/specifications/WR-TR-5WWC-ARCH

While some MSOs could have common requirements and the end use cases being similar, as captured in Cable and Mobile Convergence, A Vision from the Cable Communities Around the World[3] and Section 4, "A Survey of Mobile Deployment Plans by MSOs Around the World", the deployment models and the architecture options being considered vary per country and per MSO.

3GPP network architecture and the spectrum options could be classified into the following broad set of deployment architectures:

- Consumer Fixed Wireless Access
- Consumer Enhanced Mobile Broadband Access
- Enterprise focused wireless access – Private Networks or a Private access via public access

Deployment of RAN assets could vary as well – including but not limited to strand mount access nodes, small cells, dedicated base stations or shared resources access nodes. We believe there are 3 main architecture deployment models as listed below when the MSO chooses to deploy a wireless network based on 3GPP standards.

3.1. MNO Partnership

This is a scenario where the nationwide coverage is provided by the MSO with a tight partnership with an existing MNO. The MSO can build and deploy a selected set of markets or regions in the country to offload data via MSO network – which reduces cost of delivering the service and / or offers a more differentiated service compared to the MNO network. This can be achieved via roaming relationship with a single identity or DSDS capabilities[4].

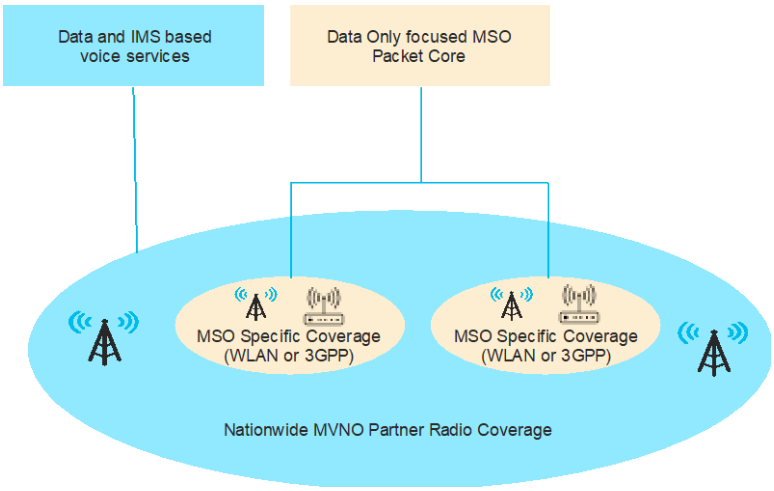

Figure 3: MNO Partnership for nationwide coverage with MSO pockets of coverage

[3] https://www.nctatechnicalpapers.com/Paper/2020/2020-cable-and-mobile-convergence
[4] DSDS details depicted in "Cable and Mobile Convergence, A Vision from the Cable Communities Around the World" section 4.1.5

3.2. Nationwide MSO

Ability to offer a nationwide coverage provided by the MSO on Day 1 leveraging existing WLAN assets and deploying new 3GPP RAN where applicable and available based on regulatory requirements. These scenarios would require the MSO offer full voice capabilities in the network and deliver regulatory compliance like Emergency calling from Day 1. In lieu of a tight MNO partnership, the MSO can leverage roaming partnerships but may be challenging to achieve roaming within the same country without a tight relationship with the MNO. While the network is being expanded and built out with 3GPP, the MSO may have some coverage gaps and impacting the subscriber experience.

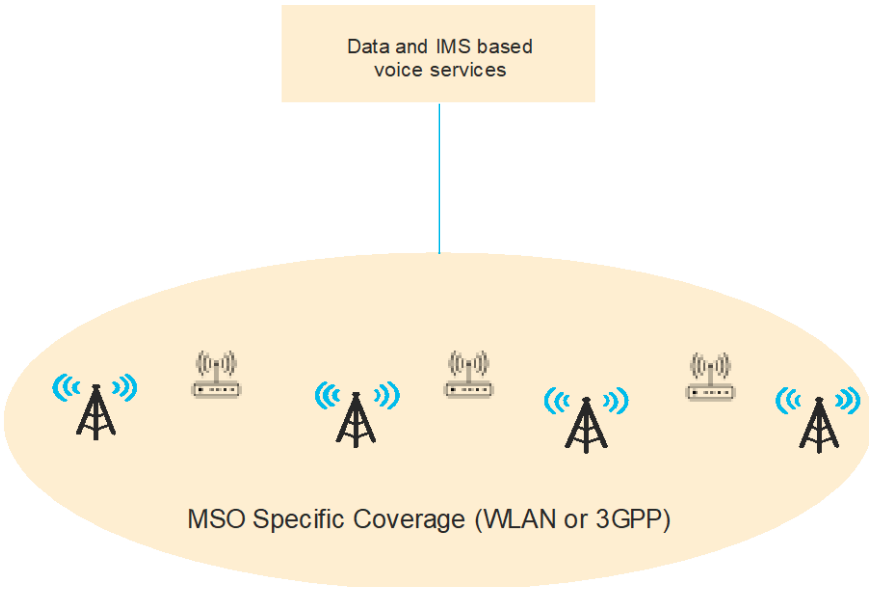

Figure 4: Nationwide MSO network without MNO partnership (except roaming)

3.3. Private Networks

A scenario where the MSO could choose to focus primarily on new opportunities only using the licensed spectrum and target the Enterprise Private Network markets. The MSO may choose to offer a consumer service only via a pure MVNO partnership as an option – however, the spectrum assets are leveraged only for the enterprise deployments to begin with. With this model, the MSO could always expand to nationwide MSO or MNO partnership models in the later phases. MSO may choose to deploy a dedicated or a multi-tenant core for enterprises

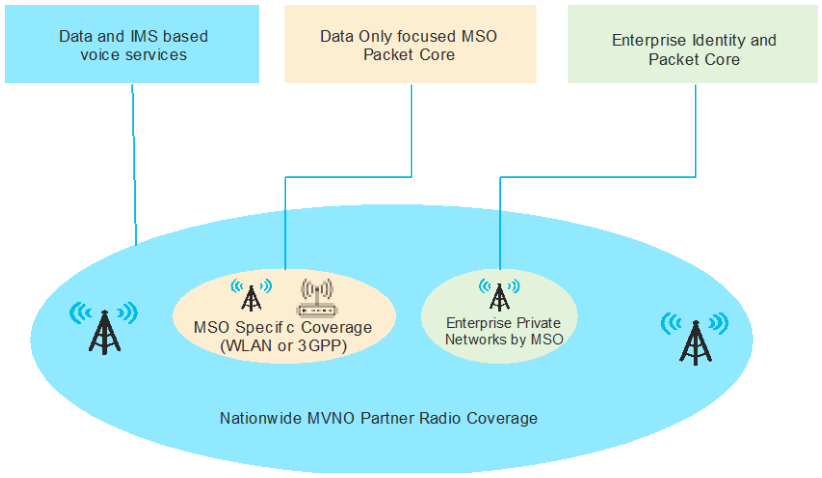

Figure 5: Focus on Private Networks and Limited MSO consumer coverage with nationwide MNO partnership

All these network options could exist by themselves as standalone or fully integrated. Introduction of additional capabilities could be in phases – as an example,

- 5G Fixed Wireless Access Network Deployment – Data offload only
- Voice Network introduction – migrate from MVNO Voice
- WiFi integration
- 5G Differentiator Features Deployment: Slicing; MEC; External APIs and Roaming supported
- 5G Core Advanced Features Deployment: Network Analytics (Artificial Intelligence (AI)/Machine Learning (ML)); Common Data Layer deployment

The sequence of the phases does not always have to be as depicted above but rather based on operator priorities.

While the 3GPP architecture seems simple on paper, what drives the deployment complexity is the service differentiation the operator chooses to provide towards the end user. As an example, a SMF/UPF combination depicted in the 3GPP architecture is supposed to deliver at a high level, the following base functionality for simple packet routing.

- Session Management and UE IP address allocation
- Configures traffic steering at UPF to route traffic
- Interfaces towards Policy control functions
- Lawful Interception and other regulatory requirements
- Policy rule enforcement, (e.g., Gating, Redirection, Traffic steering) and QoS handling
- DPI and application detection

In addition to the functionality defined above, due to operational requirements an operator will have:

- Local Redundancy in case of card or a process failure
- Geo-Redundancy in case of site failure or connectivity challenges
- Local Policy in case of temporary glitches in connectivity
- Local storage or accounting records and NAT Binding records

In certain scenarios, building out as a greenfield mobile network operator, the MSOs will be presented with choices to build a simplified network. However, it could end up being a competitive differentiation or a service parity with the MVNO network scenario which may end up forcing the MSOs to deploy an equivalent capability in the network.

As 5G network architectures evolve and deployment plans are formalized, the industry is driven not just by competitive pressures, but also based on evolving use cases which are heavily dependent on the availability of the device ecosystem that supports various 3GPP capabilities. The current expectation of the market trend as seen by the authors is depicted below.

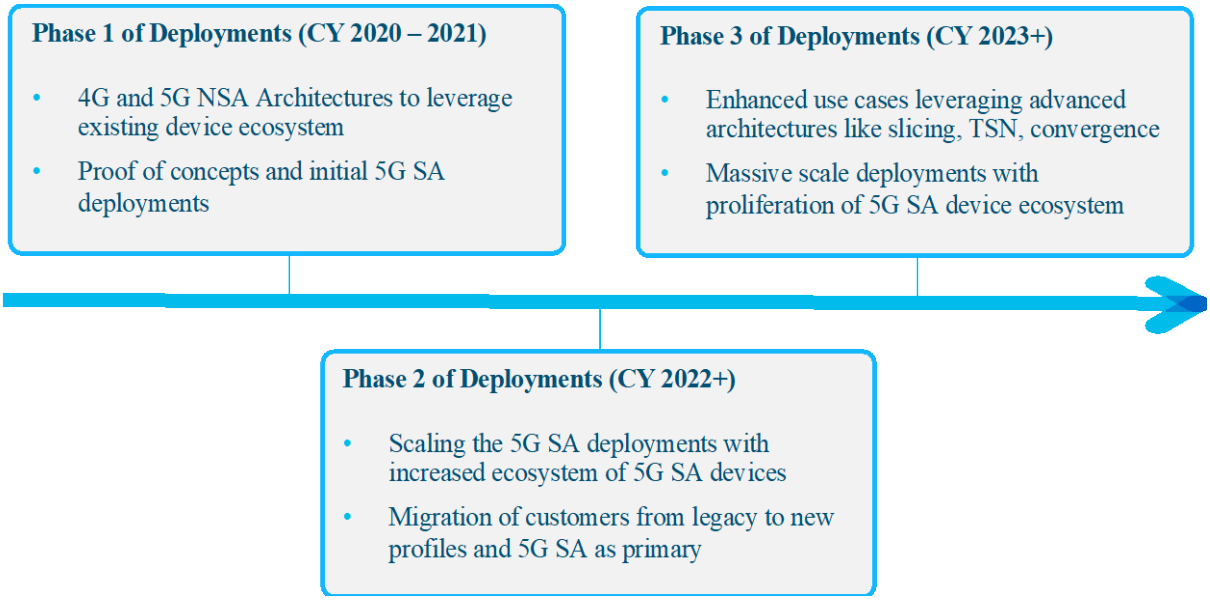

Figure 6: Likely timeline of deployments based on industry momentum

While there have been enough publications around what 3GPP network architectures in 5G offers for MSOs, technical capabilities, deployment models, this paper focuses on highlighting some of the key lessons learnt in existing Mobile network deployments – during 4G deployments and some initial 5G deployments. Intent of this paper is to offer solutions to common pit falls in mobile networks as it stands today – to account for these from the get-go and avoid any potential network issues and service interruptions. The authors believe that the lessons learnt during the initial 4G deployments, and the maturity achieved over the period of 10+ years in 4G networks should be leveraged as 5G networks are being built out.

4. Greenfield Network Considerations

4.1. Converged 4G+5G core Deployment

One of the important decisions an MSO faces would be to either deploy a 5G only RAN (also called as 5G Stand-alone (5G SA) or Option 2 RAN) or 4G 4G-and-5G non-standalone (5G NSA) or Option 3 RAN. The high-level architecture for the two options is shown in the Figure below.

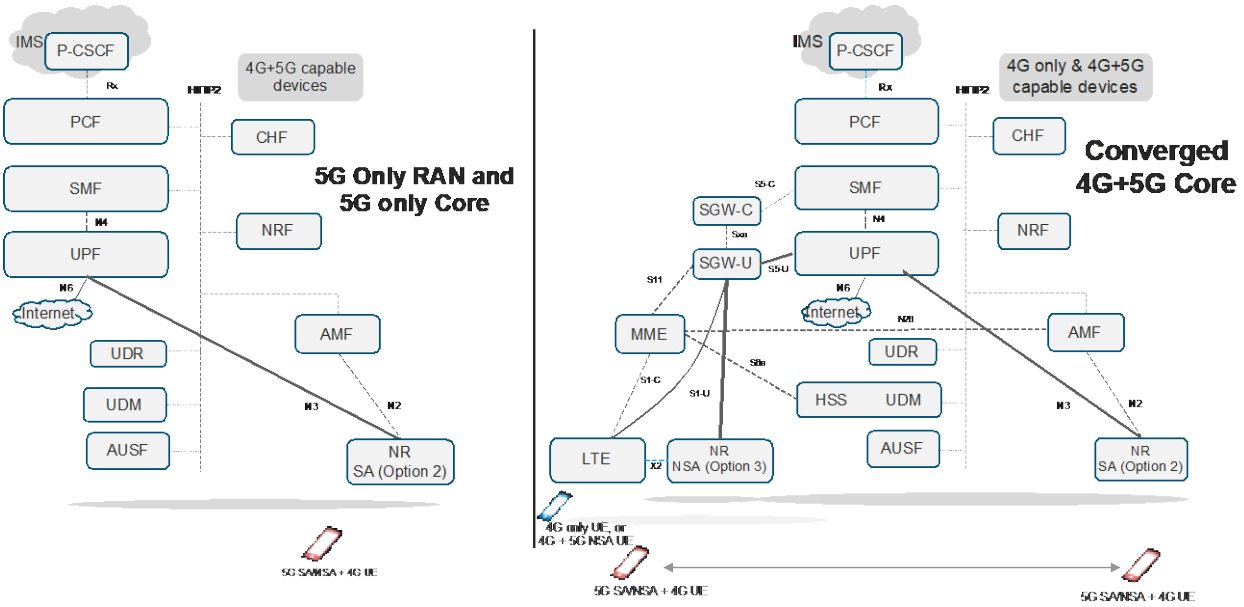

Figure 7: Converged 4G+5G Core architecture vs. 5G SA architecture

The left side of the Figure depicts the key network functions of 5GS system that only serves 5G RAN (NR) in a stand-alone mode. This would imply that in the gNB in NR band for the specific country is deployed and there is no 4G LTE deployment. Also, the mobile supports 5G SA mode of operations.

On the right side is a converged 4G and 5G core that also support 4G LTE radio and core network. The 4G related elements includes the MME and Serving Gateway (SGW). Also interworking interface between the MME and AMF (N26) is used to enable seamless mobility between NR and LTE. With this deployment the MSO can offer both LTE and NR in different frequency bands in the 150 MHz CBRS frequency spectrum, as an example. In addition, the mode where NR radio is added for additional downlink and uplink data rates with signaling going via the LTE cell. This configuration is called 5G NSA or Option 3. This requires the deployment of both LTE and NR i.e., eNB and gNB. The same NR radio can operate both in Option 3 and in Option 2 mode. With this deployment mode an operator can support legacy 4G UEs and the new 5G NSA and 5G SA UEs.

The main driving factor in such a decision is the availability of 5G SA capable devices. Though the number of devices that support 5G (NSA and/or SA) is increasing it is still very small compared to the 4G UEs (May 2021: approximately 800 device types that support 5G NSA or 5G SA compared to about 25,000 device types that support 4G technology[5]). Furthermore, the number of 5G devices that support 5G SA is a small fraction of the devices that support 5G (NSA or SA). Though the number of devices (phones and other form factors) that support 5G will increase, this number will still be smaller than those that support 4G. Depending on the timeline of deployment, it is possible for an MSO to deploy the converged 5G and 4G core. The operator should deploy this converged core also in comparison to deploying a separate 4G only EPC core (with PGW and PCRF instead of SMF+UPF and PCF), since EPC core cannot support 5G NR SA mobiles and EPC also is based on legacy telecom specific protocols like Diameter and GTP-C whereas the converged 5G and 4G core is based on protocols that have much wider deployment in the market, e.g., HTTP.

If the MSO chooses not to deploy 4G radio and no support for 4G only devices is required, the MSO can choose to deploy a SA core. However, given that MSO subscribers could potentially roam into a country that does not yet have 5G deployments or a partnership with a roaming provider with 4G only capabilities, it may be required to terminate the legacy GTP-C interfaces from the roaming partner. This would mean that the converged 4G+5G core will primarily be leveraged as a 5G SA Core when the device is on the MSO deployed RAN but when the device is connecting from a 4G only partner RAN, the converged core capabilities of exposing legacy GTP-C interfaces i.e., S8 interface could be leveraged. Note that in this case, N26 interface is not required unless a tight roaming relationship with handovers is planned.

4.2. MNO/MSO demarcation points

As stated in the previous sections, the most common deployment model mobile network deployment for an MSO could be one with partnership with an MNO, where the MNO provides nationwide coverage, and the MSO provides coverage in pockets (e.g., in urban dense areas). The network architecture diagram for such a deployment scenario is shown in the figure below where the MNO is providing 4G including 5G NSA coverage and the MSO has deployed 5G SA in NR bands in its pockets.

[5] https://gsacom.com/webinar/the-5g-story-so-far-5g-spectrum-networks-and-devices-in-1h-2021/

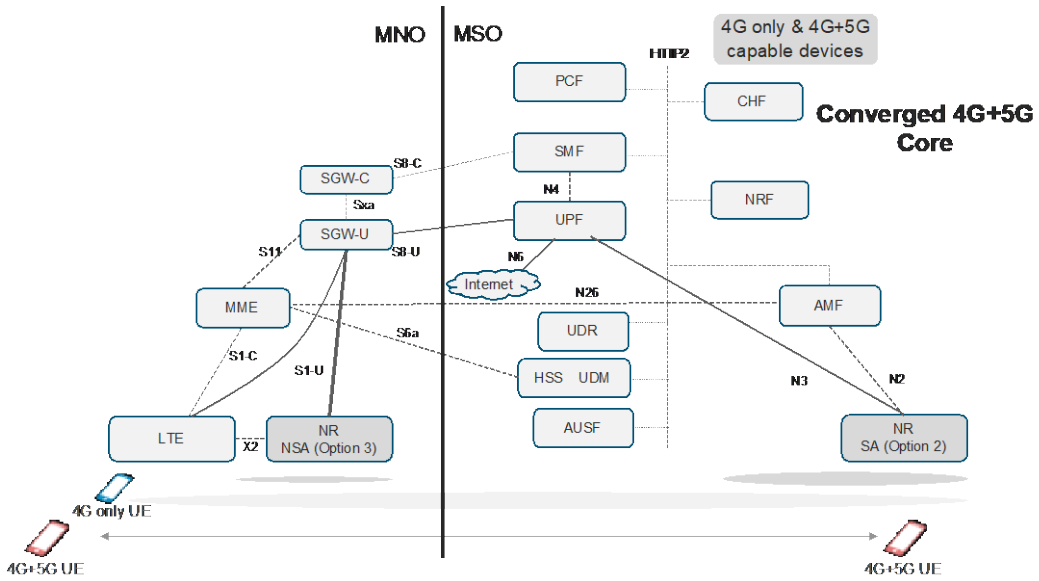

Figure 8: Demarcation of MNO and MSO networks in partnership when single-SIM is used.

The key interworking interfaces between the MNO and MSO are those that cross the thick black demarcation line between the MNO and MSO. The S6a interface between the MNO's MME and the UDM+HSS of the MSO is used to authenticate the MSO's UE when that UE is in MNO's coverage area. The S8-C and S8-U interfaces between the SGW-C and SMF and SGW-U and UPF respectively, are used to anchor the IP connection of the mobile in the MSO's SMF and UPF (this is also called home-routed scenario in 3GPP specifications). The reason for home-routing is that primary service policy and charging are provided by the SMF and PCF in the home-network of the UE, i.e., the MSO. The N26 interface between the MME and AMF is used to transfer contexts between the MNO and MSO network to enable seamless mobility.

Though 3GPP specifications exists that provides all the details of the call-flows to support the above architecture, the main challenge is in deployments of these inter-operator interfaces. The vendors providing the network functions on the two sides of the demarcation lines may be different and may require extensive inter-operability testing. Also, the interactions between the radio networks to handovers from the MNO network to the MSO network when a mobile is in the coverage of the MSO's radio network and vice-versa require quite a lot of radio planning (e.g., configuring neighboring cell information and updating these as the radio network of the MNO or MSO changes).

To mitigate some of these challenges, a DSDS based approach could be leveraged as described very well in Cable and Mobile Convergence, A Vision from the Cable Communities Around the World 6 and Section 4.1.5, “Dual-SIM”.

[6] https://www.nctatechnicalpapers.com/Paper/2020/2020-cable-and-mobile-convergence

4.3. Single vs. Multivendor strategy – Open Interfaces

While 3GPP provides a very well debated and industry vetted architecture with the operator, vendor and entire ecosystem contributing, it sometimes is unable to accommodate every single deployment scenario and use case. Especially, when it comes to requirements driven by MSOs, since the use case requirements and deployment models are not always aligned with established MNOs in the market, there could be a need to extend of enhance the capabilities for MSO deployments. Given that 3GPP and other SDOs have a set schedule for completing the documentation of specifications and priorities, it is likely that timelines for deployment of the operator may not align

This typically drives the MSOs to consider custom implementations. Take a scenario where an MSO would like to identify a customer not just via mobility identity but based on wireline identity or a cable identity. If leveraging 3GPP Release 15 specifications, this is not possible today without custom adaptation as 5WWC work item in Release 16 would add some of these capabilities. In these scenarios, an MSO may consider adding a Cable Line ID as a custom attribute across the nUDM service and on nChf service to identify the mobile user and tie into the Cable Service.

A similar capability was leveraged in 4G LTE networks extensively – especially on diameter interfaces. This was typically achieved via vendor defined AVPs or vendor specific AVPs. Additional details are captured in the Diameter RFC 3588, 5.3.3. Vendor-Id AVP. While this was a well understood mechanism, due to competitive scenarios, it is not always viable and possible to take this custom vendor defined AVPs to SDOs. In such scenarios, it may be required to continue supporting custom implementations which would require ensuring interoperability across vendor products.

Since 5G Service Based Interfaces support extensions or information elements that could added beyond the specifications, this could be leveraged by the MSO to achieve the use case and faster go to market option without having to wait for 3GPP or other SDO. Invariably, such custom behavior creates a challenge during software upgrades or interoperability across different vendor solutions.

We recommend that operators need to ensure that all deployment interfaces are open and compliant to 3GPP specifications. This is typically achieved via vendor-to-vendor interoperability testing either from a lab to lab or within the MSO labs. Any extensions or custom attributes implemented as described above by any vendor specific to the MSO network are recommended to be fully documented and more importantly, should be protected by a feature capability exchange and only utilized when the peer node indicates support.

- Option 1: Implement feature capability exchange: The recommended way is to ensure the initiator of the message that includes the custom information does so only once it has been established that the receiver can gracefully handle the custom information provided. This could be achieved in multiple ways in 5G network deployments.
    - In case a client / server relationship is established – leverage feature capability during initial connection establishment

- Leverage NRF capability exchange to communicate and register feature versions which include the custom attribute supports and only provide the producer information when the client specifically requests for this capability

- Option 2: Implement configuration options: This option provides an easy implementation choice by only including the custom attributes if specifically configured to do so. This removes the complexity of feature capability exchange or relying on NRF but poses an operational challenge of making sure every NF is appropriately configured and upgrades are sequenced and managed in a controlled manner
- Option 3: Ignoring uninterpreted attributes and default behavior: Alternate to a feature capability exchange or configuration is ensuring that the information passed through the custom attributes is ignored when a receiver is not able to interpret it and ignoring such information does not impact service. This is critical even if one of the additional options is implemented to avoid any service disruptions to minor changes in software releases or attribute parameters. The receiver should log an error so the issue could be debugged and addressed appropriately but while this is underway, network service is maintained without disruption, albeit with likely not all capabilities.

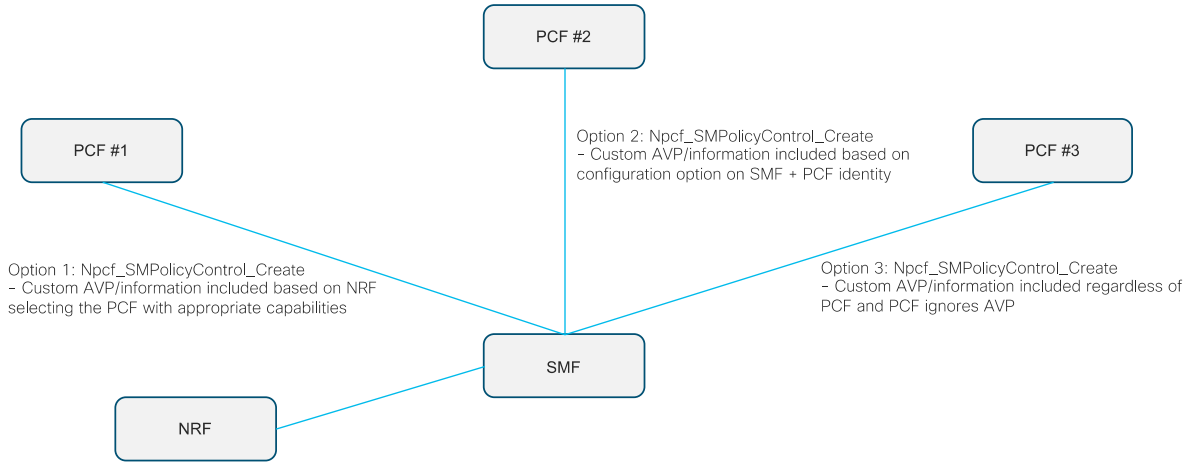

Figure 9: Options to achieve interoperability with custom implementation

We believe that at the end of the day – 3GPP compliant interfaces are the best way to deploy networks. The reason for recommending this is to ensure potential introduction of additional vendors in the mix. As an example, to achieve certain tracking area mapping capabilities, it was required in initial days of 4G LTE RAN ecosystem to implement custom behavior on the S1-AP interface between eNodeB and MME. However, it had eventually gone to a point where it was almost impossible to interwork an eNodeB from the RAN vendor with any other vendor's MME without impacts to service or capabilities which created a "lock in" problem for the operator and not being able to deploy best of breed network functions or a dependency on the operator introducing new services as the radio provider feature acceleration may not be at par with the operator requirements or a market specific mapping of RAN and MME i.e., tight dependencies cause operator to define a clear boundary of operation for radio and packet core

As an example, a radio vendor that has the radio infrastructure deployed in one region was able to only utilize MMEs from that vendor. During a system outage or migration or other similar scenarios, the operator is not able to leverage the additional capacity that is available from a peer market or region which is provided by another Radio vendor. Especially, the use of ASN.1 as a protocol between Radio and MME decreases the ability to interwork once custom attributes are introduced.

Similar rules apply to the non-radio deployment scenarios but due to the ability to extend diameter or GTP protocols without causing interoperability issues based on proposals above has resulted in somewhat of a manageable model within the packet core. Any deviations from common practices and not documenting could result in an interoperability issues and delay in service launch or disruption to existing services. Relying on open interfaces for scalable network architecture and debugging across network functions is critical for long term success of the solution.

4.4. Policy and charging architecture

The sheer number of different data-plans that are offered by MNOs is an evidence of the complicated policy and charging rules and traffic measurements that are performed in MNO networks. Specialized application charging rules, such as zero-rating of Netflix or Spotify traffic, require significant DPI and application detection capability in the network.

3GPP PCC architecture example for 5G System is depicted in the figure below and with all the options supported, the deployment could be daunting with ability to create policies across multiple service enablers in the network and ensuring policies do not contradict each other in this scenario. A well-defined PCC rule can help with detection of a service data flow and providing parameters for policy control and/or charging control and, for PGW enhanced with ADC, for application detection and control.

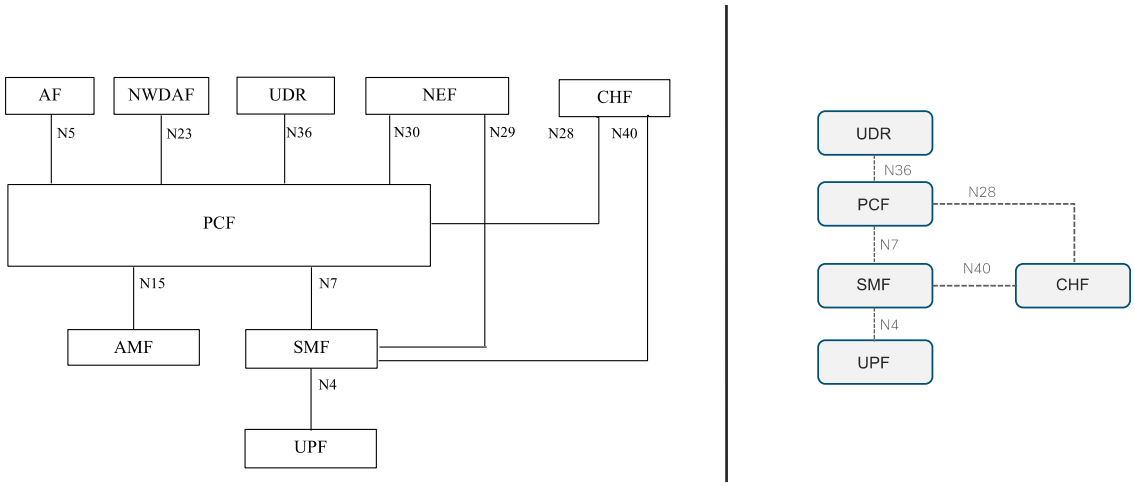

Figure 10: 3GPP PCC Architecture for 5G (left). Simplified PCC architecture for MSO (right).

There are two main drivers for the complex policy and charging infrastructure in MNO networks:

1. Requirement to support dynamic QoS, e.g., for providing periodic scheduling with low latency for voice traffic. (NOTE: This is not typically for charging perspective, since most MNOs are not monetizing voice traffic), and
2. Data caps and rate-enforcement required either for on-line charging (pay-as-you-go) or for offline charging (monthly payment) data-caps per month.

MSOs can simplify these by not supporting voice traffic natively. Not having to support voice or other traffic that requires dynamic signaling of filters and QoS rules at least does not require to support the N5 interface between the PCF and the application function (AF).

MSOs should look at only providing offline charging and not have to implement the more complicated on-line charging model. Typical MSO customers have at the minimum monthly subscriptions with them. Trying to support the more complicated on-line charging (pay-as-you-go) model will simplify the real-time requirements for policy and charging.

With the above simplifications, the only rules that an MSO needs to look at is enforcing are data-cap rules that are simpler to define and maintain. This design would align with similar billing and accounting capabilities offered within the Cable access for end users today in most networks. However, if the MSO chooses to offer more aligned capabilities as MNO, this will require similar PCC architecture and complex rule definition as done on the MNO network today.

Number of policies deployed could have impact on the overall performance of the system. When PCEF needs to perform Deep Packet Inspection or process policy while handling small packets, the overall system capacity could be impacted. Any DPI needs to be accounted for when deploying the static and predefined rules being installed on the gateways and only service / revenue impacting rules should be considered. Changes in policy based on specific locations require the PCF to be aware of the current location of the subscriber and in a mobility intensive environment, this could generate signaling all the way from the RAN, MME/AMF, SGW, PGW/SMF and eventually to the PCF causing massive signaling. Smart Phones tend to create Service Request in the network at an average of 2 mins and any location changes triggered during service request could generate unnecessary signaling.

Location based policy should be higher level granularity e.g., Presence Reporting Area or regional boundaries instead of individual RAN locations. Any rules installed by the PCF should be considered for the depth of the packet inspection required and impact to the system performance.

Designing for a simplified but robust policy, charging architecture and rule definition would ensure a seamless service experience for the end users and enabling new capabilities in the network with limited planning.

4.5. Device Behavior

When a network function or node is not able to handle the messages or is in maintenance mode, it is important that the downstream peer functions are aware of this. It is essential that the operators define a clear expected behavior within a client for error codes received from peer nodes and act in a graceful manner. As an example, if the PCF is unable to handle the message due to a session that is not found, the error code provided towards the SMF should provide enough information for the SMF to either initiate the session recovery procedures or gracefully disconnect the user and reestablish the session. While some of the network error behaviors could be gracefully handled or at least addressed with software updates, during the initial days of LTE launch, a critical lesson learnt was on the unexpected UE behavior.

As LTE networks were deployed, it became apparent that the error codes were not interpreted the same way, despite some documentation in 3GPP. This resulted in unpredictable behavior during error scenarios, but also resulted in non-uniform behavior in different markets or geographic regions of the same operator where different vendor solutions were deployed.

This was eventually addressed in LTE with much more prescriptive behavior expectations on error codes at the device (Reference: TS 24.301[13]) but also a massive effort to map error codes from every diameter interface to eventual error code mapping at the device. While some of these are based on lessons learnt from real deployments, some were mere clarifications of predefined behaviors in 3GPP.

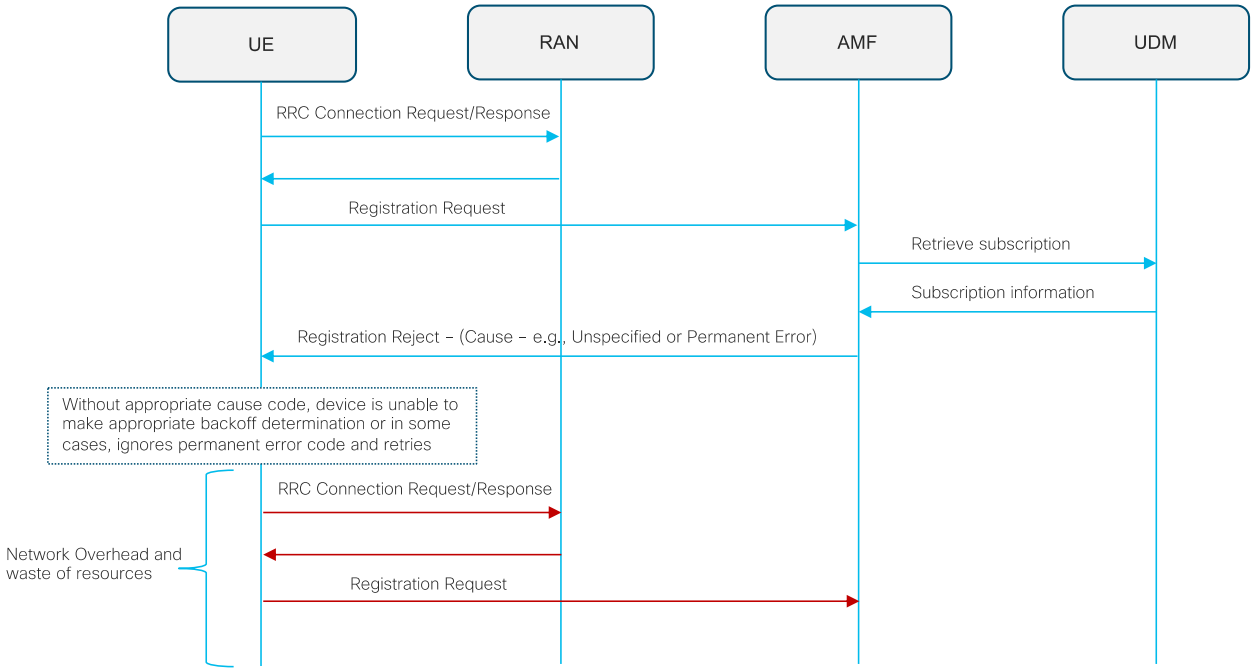

Figure 11: Call flow depicting UE errors and retries

Fortunately, most of this work has been forward ported into the 5G specifications already and similar capabilities as mature 4G networks exists already in 5G networks. However, it is imperative to plan for previously unseen behaviors in the network. Especially, new capabilities and interfaces in 5G defined around Service Based Architecture, slicing capabilities on devices and additional new functionality defined in 5G – it is very likely unforeseen scenarios will occur in the network.

It is critical to also note that the error scenarios are not just to be UE focused but rather a network focused approach as well. Some of these could be avoided by:

- Formal interoperability testing as described in previous sections or relying on statements of compliance to begin with
- Adding intelligence into the network to decommission or remove certain software functions in the network based on error trends
- Configurable error code behaviors

Accounting for unforeseen device behaviors and designing for graceful recovery mechanisms would help ensuring a reliable end use experience.

A couple of good examples of what has been achieved in 4G networks and positive outcomes of lessons learnt could be based on the overload scenarios or race conditions in the network.

Race conditions have typically occurred when the network and device are attempting conflicting procedures which are unfortunately not completely preventable but by adding message priorities and sequenced queues, the impact of these race conditions could be mitigated to a certain extend.

For overload scenarios, based on ecosystem and industry discussions, IETF work on overload control (Reference: https://datatracker.ietf.org/doc/html/rfc8582 [12]) or GTP-C load / overload control was introduced into 3GPP specifications. It should be noted that these are not widely leveraged today, partially due to the timing of availability of these capabilities in the specifications. By the time these specifications were available in 4G, there was an industry momentum within 5G and focus shifted towards 5G software development and implementation in the field. However, most of these capabilities have been made available with 5G specifications from day 1 and so could be leveraged as needed from initial deployments for MSOs.

One additionally way of ensuring device vs. network race conditions or duplicate messaging is avoided is by fine tuning the timers in the network and the message queues with validity timers / expiry tags for messages so that any messages stuck in queues are discarded after a certain time. In some rare scenarios, if a message from the queue is processed after the device internal timers have already expired and a procedure from the network is executed, this could result in out of band processing of the messages resulting in incorrect and unexpected behavior from the devices.

While there may be some reluctance to use some of these advanced capabilities in the specifications to begin with, we believe that having the capabilities planned in the network from the initial get go would be important.

5. Other topics for consideration

While not captured in detail in this document for brevity, it is critical for MSOs to take additional topics into consideration as listed below.

1. **Virtualization Stack**: Every MSO may choose to have a platform of choice – which may or may not be driven directly by the 5G deployment strategy. It is likely that some MSOs have already charted a path for virtualization of Network Functions in the existing deployment and service strategy. In some ways, the same platform could be the entry path for 5G Core cloud-native NF's or implementation of Open vRAN architectures that are critical for success of 5G. Depending on the capabilities of the MSO, operational focus within the company, a CaaS and PaaS capability may be under evaluation or already in deployment which could be leveraged or any existing investments on NFVI could be leveraged. Given that this is a choice for the MSO which could be influenced by other factors in the company – additional details are not discussed in this document.
2. **Convergence architectures**: 3GPP has defined the baseline architecture for convergence of wireline and wireless services as part of the 5WWC work item in Release 16 specifications. However, with additional dependencies being addressed in CableLabs and the detailed analysis and discussing in Cable and Mobile Convergence, A Vision from the Cable Communities Around the World[7], this document does not address convergence but could be a critical decision point for the MSOs before finalizing the 5G deployment architectures.
3. **Support of Voice Services:** Given the stringent performance and regulatory requirements for voice, in a deployment model where MSO partners with an MNO (see previous sections), it could be simpler for the MSO to have the MNO support voice services whereas the MSO provides internet connectivity as native voice support and client capabilities are made available specific to the MSO architecture. One challenge of achieving voice services delivered via the MNO partner with data services from the MSO native network is that either the device will have to support dual SIM capabilities or when the voice network of MNO is leveraged, the data is offloaded to the MNO partner network as well while the device is in a voice call
4. **Support for lawful interception**: Lawful interception is a required functionality by regulatory bodies in most countries where mobile networks are deployed. As cable operators consider their journey from MVNO to MSO, they will need to plan and deploy lawful interception. Most vendors who provide infrastructure equipment support lawful interception on their network function. Also, MSOs will need to create a system for handling lawful interception request from law enforcement agencies in their jurisdiction. Since information about targets of lawful interception needs to be guarded very closely in an operator's network, this involves only enabling a select few operation staff to have access to this information and for configuring and monitoring the system for lawful interception.

[7] https://www.nctatechnicalpapers.com/Paper/2020/2020-cable-and-mobile-convergence

5. **Roaming partnerships**: Roaming architectures are very well defined in 3GPP but most importantly a clear cross operator engagement model defined by GSMA to enable global roaming. It is recommended that MSOs leverage the existing guidelines of GSMA[8] for 5G being developed. One of the important considerations for the MSO as they finalize the deployment model is the any dependencies related to anchoring devices from 4G networks in countries where 5G is not yet available. Using a converged core architecture could simplify the operations and supporting different roaming models as described in Section 4.1
6. **RAN considerations**: This document does not cover RAN architectures in detail as there has been a significant amount of collateral and analysis on the various RAN deployment architectures. Please refer to Security Benefits of Open Virtualized RAN9 or additional standardization details as part of O-RAN alliance10. O-RAN could be discussed as a standalone document alone.
7. **SIM profiles and Device Management**: SIM profile development and device management capabilities could be driven by the operator choice of device partner ecosystem, compliance to OMA-DM specifications and partnerships with specific UICC provider itself. Given that the SIM profiles and UICC management are usually not disclosed publicly due to security concerns, this document does not specifically capture the lessons learnt from 4G deployments with respect to device management. However, this would be a critical area of investment for the MSO to ensure ability to configure new APNs/DNNs within the network and subsequently provisioning the device with the capabilities or being able to manage the MAPCON profiles on the device for WLAN vs. 3GPP selection. Note that with 5G, given the capabilities of ANDSF from 4G networks are now integrated with the PCF, we anticipate that once the devices start supporting the capability, network selection would become simpler to manage in 5G.
8. **Network Failures and Recovery**: Network failure scenarios are inherent in the regardless of the architecture and stability of the network functions and their underlying infrastructure. In the move to cloud infrastructure, this is even more prevalent as the virtualization infrastructure typically does not achieve more than 99.9% redundancy. To achieve a 5x9s service or greater, the redundancy of the network functions must be increased to support more common cloud infrastructure failures. Care needs to be taken to address:
    - Network Function Failures
    - Software Upgrades and Configuration Failures
    - Blast Radius of a Failure

6. Conclusion

We acknowledge and understand that every MSO has different reasons for investing in building a new Mobile Network. Whether it is to reduce the cost structure in offering mobile services by offloading as much traffic as possible from the MVNO partners network or to compete with differentiated services offering in the market, MSOs now have a unique opportunity to leverage new spectrum assets to do so. With 5G architecture defined in 3GPP and other SDOs enabling convergence capabilities in the future, investing in 5G to build a standalone network could be ideal in some cases but due to regulatory requirements or device ecosystem dependencies or roaming opportunities, there may be a need to support 4G / LTE networks as well.

As MSOs explore the option of natively building a greenfield network it is critical to ensure some of the lessons learned by MNOs while building the 4G networks or during the launch of VoLTE networks should be leveraged to ensure the new 5G networks by MSOs do not have the same challenges.

As described in the various sections, the following would be critical considerations, though not a comprehensive list.

1. Partnership scope with MNO partner or MVNO partner to ensure ability to influence policy across the network for seamless experience for the end user regardless of which network (MNO vs. MSO greenfield) the user device connects from
2. Augmenting voice and required regulatory compliance capabilities while the native coverage by MSOs is being expanded / built
3. Ensuring open interfaces across the network architecture and functions – to be able to leverage best of breed architecture vs. a single vendor strategy risking potential "lock in"
4. Reducing the complexity of policy and charging architecture but still being able to address inline service requirements to offer similar or same capabilities as the partner network
5. Expect that even with wide interoperability testing and device compliance, there will be a scenario where one device firmware/model may misbehave and with the volume of devices, this could quickly snowball into a massive network challenge. Preparing network with various mitigation capabilities when such device behavior is encountered could reduce subscriber impact and reduce operation costs
6. Design for various potential race conditions and network failure scenarios and fallback mechanisms from day 1 and ensure mobility is accounted for as devices connect from alternate access types or locations during a mass failure or pockets of failures in the access/core network

With the extensive knowledge that the MSOs have gathered over the years with existing networks and the interest to offer differentiated service to the end users, we believe that MSOs are at a cusp of changing the dynamics on wireless/wireline networks as a whole and the entire Service Provider model. Taking into consideration the variety of challenges that mobility and wireless pose and leveraging best practices will make this transition smoother and more successful.

7. Appendix A

A complete set of 3GPP network functions as defined in Release 15 and Release 16 specifications is listed below. The authors believe that while these capabilities are eventually required to be able to offer a wide set of use cases and completive solutions, not every function is required from day 1 of the deployment. It is possible to introduce most of the functions into an existing Greenfield network after launch without disruption of service or a major redesign. Some functions, like BSF or SCP may need some consideration before launch and planning for the future.

Table 1: Complete list of the 3GPP defined network functions

5G-EIR	5G-Equipment Identity Register
AF	Application Function
AMF	Access and Mobility Management Function
AUSF	Authentication Server Function
BSF	Binding Support Function
CAPIF	Common API Framework for 3GPP northbound APIs
CHF	Charging Function
ePDG	evolved Packet Data Gateway
GMLC	Gateway Mobile Location Centre
LMF	Location Management Function
LRF	Location Retrieval Function
N3IWF	Non-3GPP Interworking Function
NEF	Network Exposure Function
NR	New Radio
NRF	Network Repository Function
NSSF	Network Slice Selection Function
NWDAF	Network Data Analytics Function
PCF	Policy Control Function
(R)AN	(Radio) Access Network
SEAF	Security Anchor Functionality
SEPP	Security Edge Protection Proxy
SMF	Session Management Function
SMSF	Short Message Service Function
UDM	Unified Data Management
UDR	Unified Data Repository
UDSF	Unstructured Data Storage Function
UPF	User Plane Function

Abbreviations

3GPP	Third Generation Partnership Project
5GC	5G Core
5GS	5G System
AF	Application Function
AMF	Access and Mobility Management Function
AP	Access Point
APN	Access Point Name
AUSF	Authentication Server Function
CBRS	Citizen broadband radio service
CDR	Charging Detail Records
CHF	Charging Function
CPE	Customer premise equipment
CUPS	Control plane and user plane separation
DN	Data Network
DSDS	Dual-SIM Dual-Standby
eMBB	Enhanced mobile broadband
EPC	Evolved Packet Core
ePDG	Enhance Packet Data Gateway
EPS	Evolved Packet System
eSIM	embedded SIM
FWA	Fixed wireless access
LTE	Long Term Evolution
MCC	Mobile Country Code
MNC	Mobile Network Code
MNO	Mobile Network Operator
MSO	Multiple System Operator
MVNO	Mobile Virtual Network Operator
NEF	Network Exposure Function
NF	Network Function
NFV	Network Function Virtualization
NG-RAN	Next Generation RAN
NR	New Radio
NRF	Network Function Repository Function
NSA	Non-Stand Alone
NSSF	Network Slice Selection Function
NWDAF	Network Data Analytics Function
OCS	On-line Charging System
OfCS	Off-line Charging System
PCF	Policy Control Function
PCRF	Policy and Charging Function

PLMN	Public Land Mobile Network
SA	Stand Alone
SBA	Service Based Architecture
SBI	Service Based Interface
SMF	Session Management Function
SMSF	Short Message Service Function
SEPP	Security Edge Protection Proxy
RAN	Radio Access Network
UE	User Equipment
UPF	User Plane Function
UDM	Unified Data Management
UDR	Unified Data Repository
URLLC	Ultra-Reliable Low Latency Communication
VoLTE	Voice over LTE
VoNR	Voice over NR
vRAN	Virtual RAN
WWC	Wireless-Wireline Convergence

1. Introduction

This paper presents findings and insights from Mediacom Communications' application of automated design and optimization (ADO) technology to its access network strategy and planning activities, and to its business-as-usual network design and implementation efforts. Mediacom's decision to adopt ADO technology is discussed in the context of having to make decisions on major capital investments in an environment that requires considering multiple, evolving network technologies and architectures as well as serving a variety of markets ranging from urban to rural, while having too little time to perform the necessary analyses using traditional manual methods.

This paper further describes Mediacom's strategic approach to managing such challenges and how it sees the use of ADO technology being transformative to its operations. The benefits of having 'the whole company in a bag' are discussed in detail. Such benefits include having the ability to ask and answer billion-dollar, footprint-wide questions in hours, as well as the ability to quickly react to network utilization issues and implement solutions on a node-by-node basis that are consistent with Mediacom's network evolution plan. The distinction between the use of actual network designs, as opposed to costing models and rules-of-thumb, in generating bills-of-materials and capital cost estimates, is described in terms of concrete benefits to the capital planning and budgeting process, as well as to construction planning and execution activities.

This paper also describes a unique situation in which Mediacom entered into a competitive bidding process to serve a mid-size US city with symmetrical Gigabit service and, using ADO technology, was able to quickly and confidently evaluate multiple N+X network architectures in terms of technical feasibility and capital cost. Finally, this paper presents and discusses the technical and operational path taken by Mediacom in evaluating and deploying ADO technology.

2. Business and Operational Challenges

Mediacom's network engineering group is constantly working to answer the deceptively simple sounding question: What must we spend on improvements to the access network to ensure it consistently satisfies our customers? Coming up with an answer to that question is fraught with challenges including:

- New and forthcoming transmission technologies that simultaneously offer excellent performance but complicate the capital expenditure decision-making process
- A network footprint that comprises relatively dense urban, medium-density suburban, and low-density rural environments, each presenting unique service requirements and design considerations
- The need to design, budget, approve and deploy network improvements in the shortest possible time to maximize the return on capital and to avoid losing customers to competitors
- Making the highest and best use of the capital funding available for network improvements, regardless of the challenges noted above
- Very long lead times for delivery of equipment and materials which is causing, and is expected to continue to cause, painful delays in network deployments
- The requirement to regularly (semi-annually) review and modify the long-term (5-year) network technology and architecture strategy to keep up with evolving transmission technology, growing customer demand, and competitive threats.

Mediacom, as a profit-making business, also must satisfy its investors that capital investments in the access network have been well planned and accurately budgeted. Similarly, as a telecommunications service provider to the public, Mediacom must satisfy its respective franchising authorities that, in fact, the access network will continue to reliably meet the service requirements of its customers.

3. Adoption of Automated Design and Optimization Technology

3.1. Pilot Project

In early 2020, Mediacom embarked on a program to determine and, over several years, deploy a new network architecture across its entire footprint. At that time, it was expected that most of the network would be upgraded to an N+2 architecture, though N+0 and FTTH architectures would be considered where customer demand warrants. Since then, Mediacom has adopted a network architecture strategy, dubbed Fiber-Deep, that does not call for a fixed maximum cascade length of 2 active devices, instead specifies a range of homes-passed per CMTS port – or Fiber-Deep node – as the determining factor for cascade length.

At that time, Mediacom undertook an evaluation of an ADO technology to determine if that technology could deliver:

- preliminary designs for N+2 architecture access network in accordance with Mediacom's design rules and equipment specifications
- optimization of locations of all new nodes to minimize node count
- fully calculated, technically valid RF plant design
- optimal routing of new fiber cable as required to connect new nodes to the existing fiber plant
- integration with Mediacom's existing plant engineering platform
- amplification of the effectiveness and productivity of Mediacom's existing network planning team
- savings of time and cost relative to manual planning and design methods

The results of the pilot project demonstrated that all of Mediacom's requirements were, or could be, satisfied by the ADO technology under evaluation. Mediacom subsequently decided to implement the ADO technology, commencing in early 2021 and continuing through Q3 of 2021.

3.2. Overview of ADO Platform

The ADO environment comprises three main components and two primary results, as shown in Figure 1. The three main components and the two primary results are:

- Mediacom's existing geo-spatial information GIS/network engineering database containing a complete model of the as-built access network
- a set of network design rules, one for each network architecture that Mediacom wishes to consider, which are created and maintained within the ADO platform, and
- the ADO engine itself, which reads in the as-built access network from the GIS/network engineering database and applies the design rules for a selected new architecture to the as-built network, resulting in
- preliminary designs and cost estimates for the new network architecture.

Mediacom initially utilized ADO to apply network design rules for its 'Fiber-Deep' architecture to its entire network footprint, which resulted in Mediacom having 'The Whole Company in a Bag'.

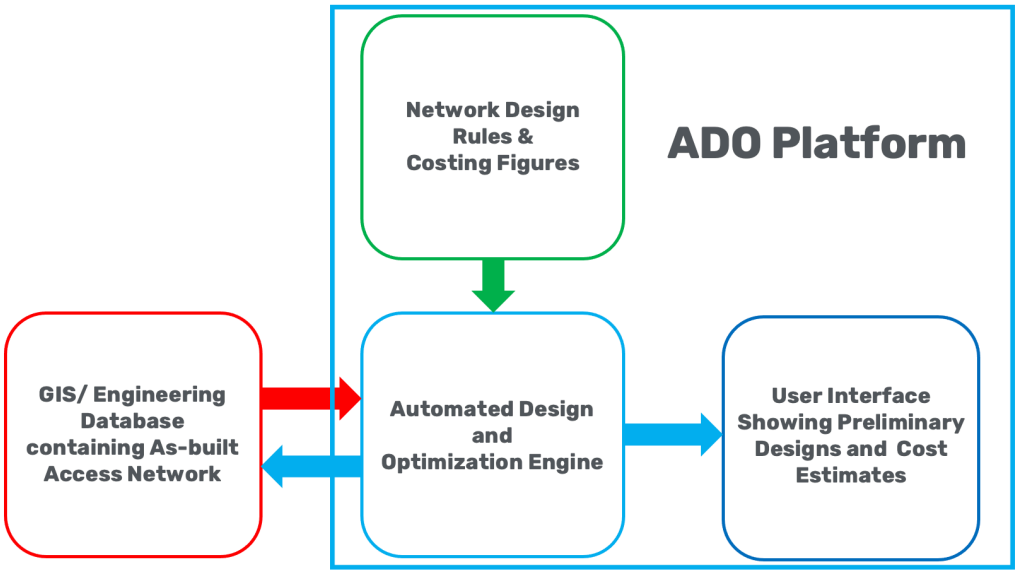

Figure 1 – Overview of ADO Environment and Platform

It is fundamental that the GIS/network engineering database be complete and accurate, otherwise the resulting preliminary designs and cost estimates will be incomplete and inaccurate. Mediacom, along with most major operators, has invested significant time and money in recent years in ensuring that its GIS/network engineering database is complete and accurate and, with the availability of ADO, is seeing a return on that investment beyond its previous expectations.

By serving as the repository for all of design rules for multiple network architectures, the ADO platform allows Mediacom to centrally develop, easily deploy and automatically enforce corporate design standards. This results in all preliminary designs and cost estimates being compliant with corporate standards, thus eliminating the typical variations that occur when multiple planners and network designers are each producing preliminary designs manually. The design rule sets in the ADO platform can be configured to allow the individual planner or designer to adjust certain design parameters, such as the use of express coaxial cable, and execute multiple designs runs to arrive at a preliminary network design that incorporates the insight of the planner or designer while remaining compliant with corporate standards.

The resulting preliminary designs can be viewed in the ADO user-interface in map view (geographically on a scaled land-base, including a satellite photo base) and schematically (in a simplified view that shows user-selected technical details, such as signal levels, active device cascade lengths, and cable lengths). The network designs are stored in the ADO platform's internal database for as long as required, which is typically until a new network architecture is decided upon and preliminary designs are then produced accordingly, or until a network deployment is decided upon and the preliminary designs are exported from the ADO platform to the GIS/network engineering database to be the basis for production of final design and construction drawings.

The cost estimates (and underlying bills-of-materials) are similarly stored in the ADO platform's internal database and are viewable in multiple formats via the user interface. They can also be exported for use by other software platforms within the network engineering group and within other groups in Mediacom.

3.3. Designs Versus Models

Traditionally, the operator's network planning personnel estimate access network deployment costs by manually producing a costing model whereby preliminary designs are developed for a relatively small portion of the network footprint in question, cost estimates are tabulated based on those few designs, then those cost estimates are extrapolated across the network footprint. Typically, the costing figures in the cost model are over-estimated by a significant amount to ensure that they do not prove to be unmanageably low. While this approach allows network planning personnel to provide information to support senior management in a timely manner, the cost model is necessarily subject to an undesirable degree of uncertainty, which in turn leaves the planners and senior management having to make major capital decisions with less-than-ideal information at hand.

The application of ADO technology offers the operator the opportunity to develop preliminary designs and cost estimates for multiple network architectures across the entire network footprint in the same, or less, time than required to manually develop sample designs and to extrapolate a cost estimate. By virtue of the speed of the ADO processing engine and of every single foot of the access network being processed to develop preliminary designs for a new architecture, there is no modelling required to develop the corresponding cost estimates. Rather, the ADO processing engine applies the operator's standard equipment, cable, and installation costing figures to the bills-of-materials for the preliminary designs to provide costing for every item of new equipment and cable, and for the construction labor to install same.

While it is understood that the preliminary designs, and resulting cost estimates, are subject to change during field validation and construction, that degree of change – or uncertainty – is much less and more easily managed than is the case with manually produced design and costing models.

Further, by having legitimate preliminary designs for the entirety of the network footprint in question, any questions as to the validity of the preliminary designs and the corresponding cost estimates can be very quickly addressed because all of the designs can be viewed on-demand both in map view (geographically on a scaled land-base) and schematically (in a simplified view that shows user-selected technical details, such as signal levels, active device cascade lengths, and cable lengths).

Ultimately, Mediacom expects that the application of ADO will simplify and expedite capital planning for access network upgrades by making better quality network planning information more accessible than previously possible.

4. Whole Company in a Bag and Why That's a Good Thing

Planning and budgeting for access network upgrades is more complex than ever before and has become a costly, full-time activity given the rate of development of new transmission technologies, competitive threats, and increasing customer demands. At Mediacom, the 5-year plan is updated semi-annually, which has required a significant allocation of personnel to carry out using traditional manual processes. The application of ADO to produce the Whole Company in a Bag, that is: A set of preliminary designs and cost estimates for Mediacom's current standard Fiber-Deep architecture, has given Mediacom a comprehensive and accurate baseline for use in planning and budgeting of access network upgrades - for the entire network footprint. Importantly, this capability obviates the need to invest time and money in manual production of preliminary designs which are often superseded by changes in technology by the time a given portion of the footprint is scheduled for upgrade.

Furthermore, by being able to produce, on demand, preliminary designs and cost estimates for alternative network architectures, Mediacom can quickly evaluate and compare each alternative network architecture in terms of equipment and cable quantities, and construction costs. This allows Mediacom to very quickly:

- update its long-term planning and budgeting by processing the entire footprint when needed, which satisfies the need of senior management for long-term planning information, and
- select and deploy the ideal network architecture for any portion the network footprint in question, which is particularly important given Mediacom's mix of urban and rural serving areas.

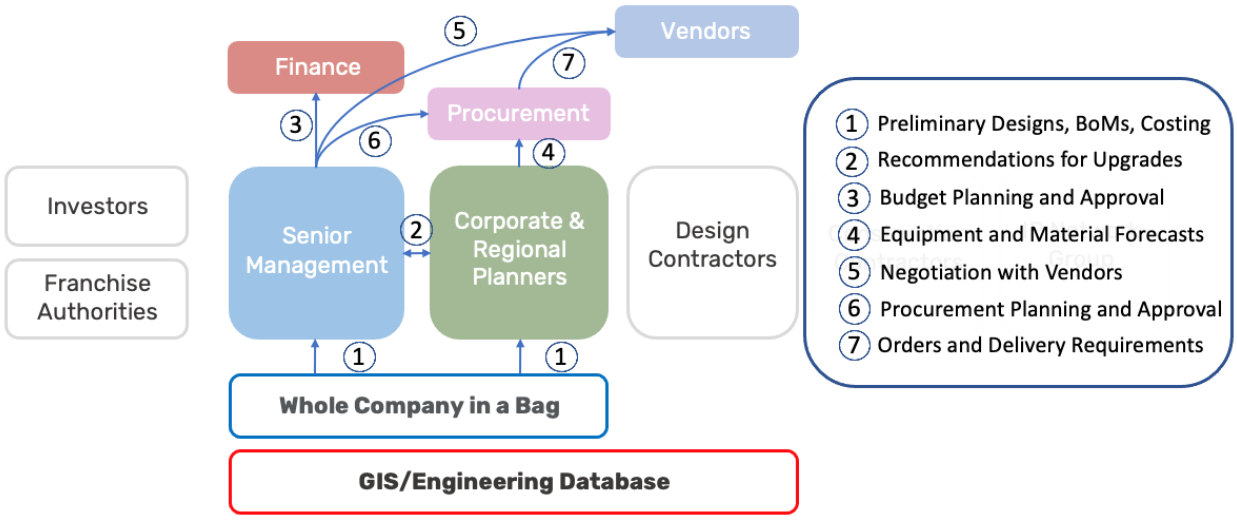

Figure 2 – Long Term Planning Activities

Traditionally, Mediacom has identified and upgraded single nodes to address congestion or other service issues. This approach has allowed Mediacom to keep up with customer demand but doesn't allow for any consideration of a more comprehensive and cost-effective approach to improving the surrounding larger portion of the network footprint.

The use of ADO allows Mediacom to do exactly that. For example, the entire serving area of a hub can be processed by the ADO platform practically as quickly as one or two nodes, allowing Mediacom to

identify opportunities to not only immediately upgrade problem areas, but to do so in a way that supports the eventual upgrade of the larger surrounding area and affords time and cost savings.

Mediacom expects this capability to become even more important when considered deployment of a Distributed Access Architecture (DAA) because the equipment complement in a hub will be reduced as DAA nodes are deployed in the access network. By using ADO to produce DAA preliminary designs for an entire hub serving area, Mediacom's access network planners can give their colleagues responsible for inside plant systems and technical facilities the information they need for their planning and deployment efforts. Similarly, Mediacom can then identify costs (and ideally overall cost savings) across its technical facilities, inside plant systems, and the access network when planning a DAA deployment.

An immediate benefit of having the Whole Company in a Bag is that serving areas that are well out of compliance with any current Mediacom network architectures can be easily identified when processed by the ADO platform against Mediacom's Fiber-Deep design rules (or, any other current architecture design rules) because the resulting cost estimates are higher than the average cost per node. This allows Mediacom to prioritize those network serving areas for upgrade or, if required, immediate maintenance work.

As noted in Section 3.2, the preliminary designs can be viewed in the ADO platform's user-interface in:

- map view, geographically on a scaled land-base, including a satellite photo base, and
- schematically, which is a simplified view that shows user-selected technical details, such as signal levels, active device cascade lengths, and cable lengths.

The various views allow Mediacom personnel to intuitively grasp the fundamental design characteristics of the proposed network itself and, by being able to see the network on a satellite photo base, assess its suitability to the physical topology of the serving area and distribution of the customer premises therein.

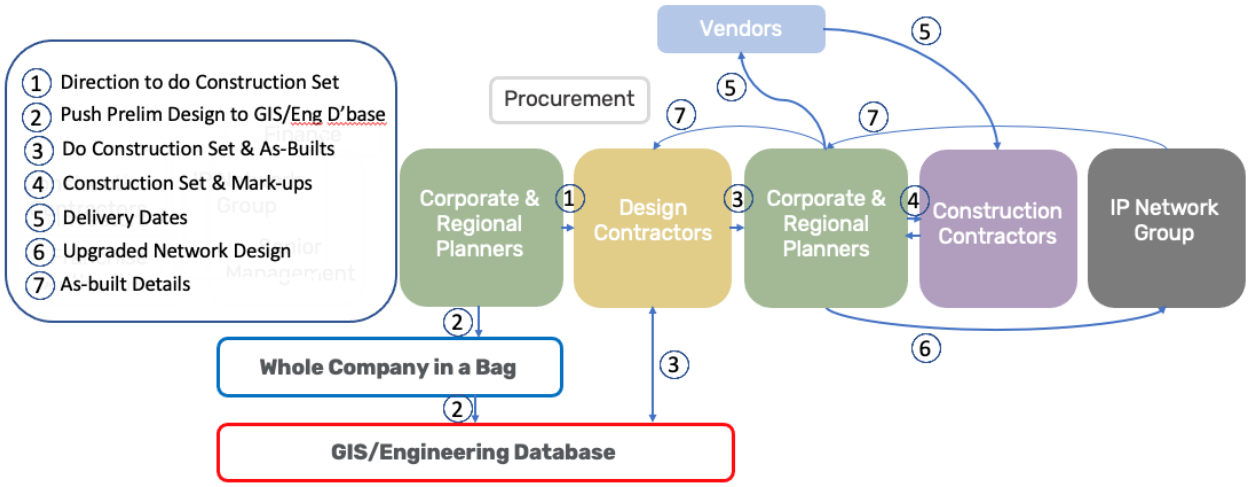

Figure 3 – Network Planning and Deployment Activities

Overall, Mediacom has seen a reduction in time for approval of network design for any area to be upgraded of two to four weeks. This is primarily due to having pre-approved preliminary designs for the entire footprint already 'in the bag'. Also, network planners at corporate and in the regions can see exactly the same designs at the same time, allowing them to collaborate very effectively to arrive at an agreement on exactly what network architecture to deploy by using the ADO platform.

It is noted that the aforementioned time savings do not include any time savings in the production of construction drawings expected by having the preliminary design from the ADO platform as an advanced starting point.

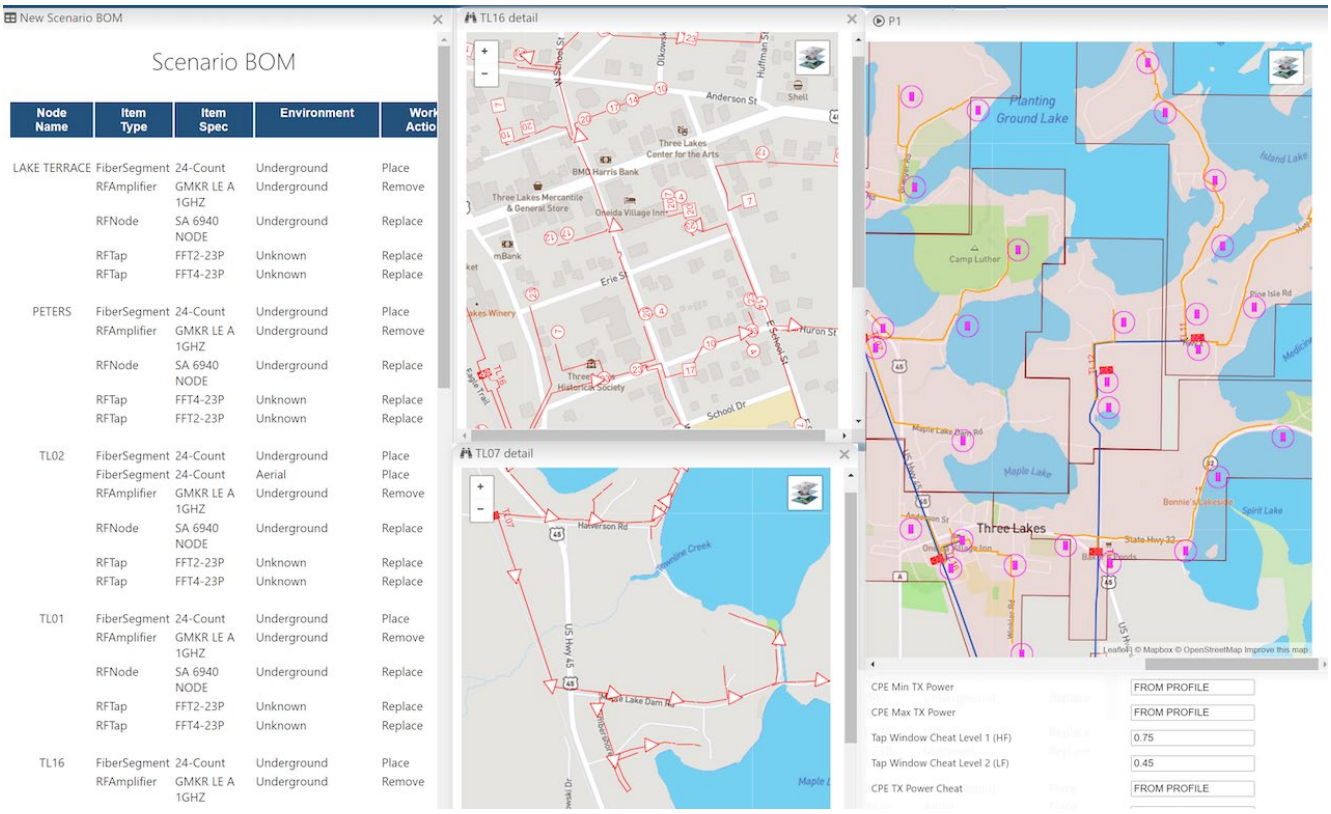

Figure 4 – Screenshot of User Interface – Network Map View

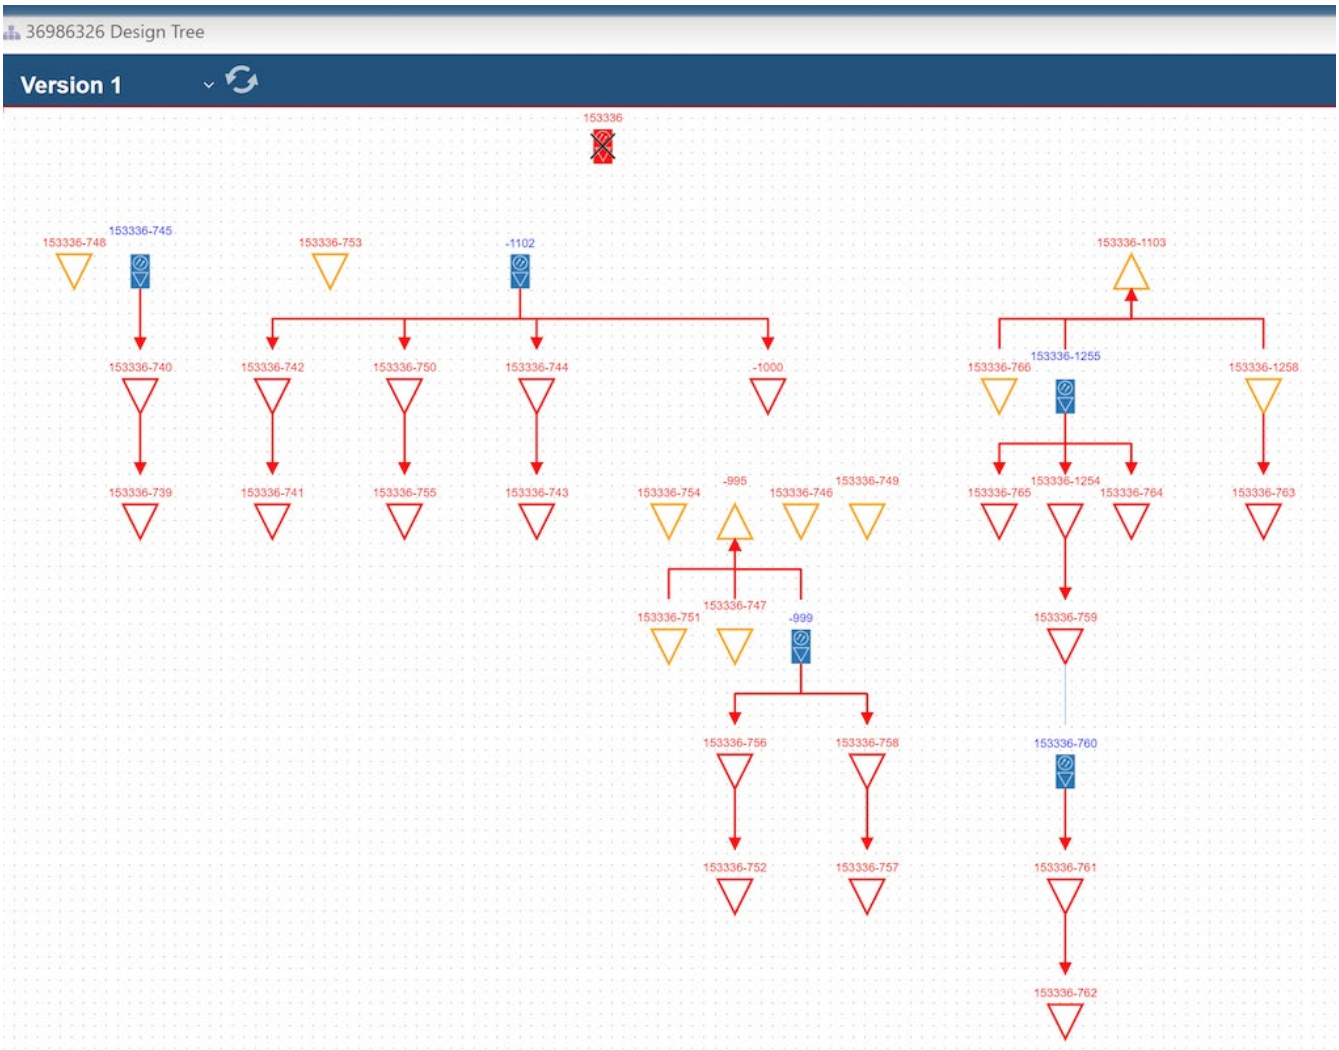

Figure 5 – Screenshot of User Interface – Network Schematic View

As much as Mediacom dedicates a great deal of time and money to ensuring its customers are very happy with their services, Mediacom must also ensure that its investors and its franchise authorities are confident that Mediacom is fulfilling the company's respective commitments.

By being able to provide investors with comprehensive insight into the company's capital expenditure and network upgrade plans, Mediacom can best maintain the confidence of the investor community, which is fundamental to ensuring access to capital funding.

Similarly, the franchise authorities must be confident that Mediacom is going to fulfill its obligations under the respective franchise agreements. Using ADO, Mediacom's ability to demonstrate (at an appropriate level of detail) its network upgrade plans and to, as a normal course of business, move increasingly quickly to maintain and improve the quality of the network.

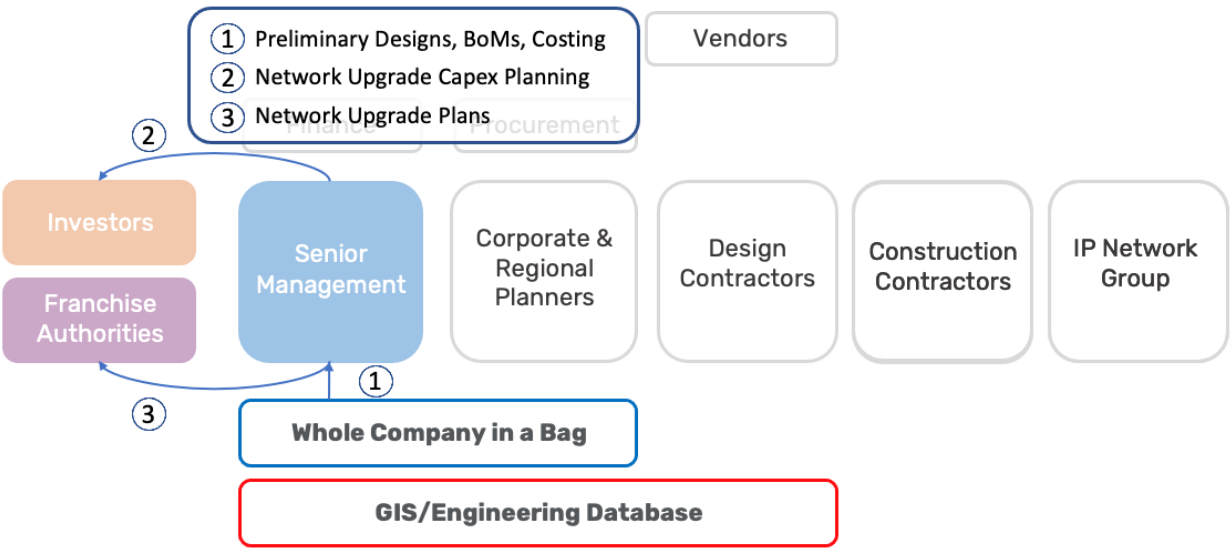

Figure 6 – Relations with Investors and Franchise Authorities

5. N+0 Planning – A Real World Example

In early 2021, Mediacom participated in a competitive bidding process that was set out by a mid-sized city wherein Mediacom is the incumbent service provider. The city solicited proposals from several service providers with regard to obtaining the highest possible bandwidth connectivity for all of the city's residents and businesses.

For the purposes of meeting the city's deadline for submitting its proposal, Mediacom utilized traditional network planning and cost estimation techniques for a N+0 network architecture. Subsequently, Mediacom utilized ADO to obtain more detailed and comprehensive designs and cost estimates in order to prepare for negotiations with the city. This was important given that the city was proposing to contribute funding to the network deployment effort. As a result, Mediacom was required to clearly demonstrate that its proposal would provide the most technically advanced service to its customers at the lowest possible cost.

In utilizing ADO, Mediacom was able to:

- quickly develop proposals for several different service levels, corresponding architectures, and respective costs thereby providing the city with a comprehensive range of options, instead of only one
- confidently compare (lower) capital costs of HFC upgrade options with the cost of building and FTTH network (as proposed by others)
- demonstrate that the deployment of its proposed network architectures would be much less physically disruptive to the community by virtue of maximizing the use of its existing access network
- be highly responsive to the city's requirements and strengthen the working relationship between itself and the responsible city officials.

Mediacom's application of ADO to the competitive proposal process demonstrated that having network designs and cost estimates for the entire access network footprint in the city, as opposed to only sample designs of parts of the footprint and costs extrapolated therefrom, allowed it to manage a significant competitive threat more effectively and confidently.

As noted previously, Mediacom operates under numerous franchises granted by the respective franchise authorities, which can prove challenging at times. In this situation, Mediacom was able to demonstrate a high degree of responsiveness to the franchise authority by providing a very detailed and well considered proposal which can only have a positive effect on Mediacom's working relationship with the franchise authority's personnel.

6. Deployment of ADO

Mediacom undertook a phased approach to the deployment of the ADO platform, with Phase 1 being to obtain 'the whole company in a bag' to support senior management in capital planning and other corporate-level activities, and Phase 2 being to implement ADO functionality for business-as-usual planning and design to support corporate and regional planning, design, and construction activities.

Phase 1 involved a number of activities including:

- development of Design Rules for Mediacom's Fiber-Deep architecture, which is Mediacom's default, or baseline, network architecture for purposes of corporate-wide capital planning and for considering any particular network area for upgrade,
- processing of Mediacom's by the ADO vendor of Mediacom's GIS/engineering database of the as-built network to produce Fiber-Deep preliminary designs and cost estimates for the entire network footprint, which were stored within the ADO platform's internal database,
- definition of Mediacom's requirements for querying the Fiber-Deep database, which were then implemented as functions within the user interface, and
- delivery of the user interface as a web-based portal into the Fiber-Deep database maintained on a server within the ADO vendor's IT infrastructure.

By pioneering the use of ADO technology, Mediacom was able to exert significant influence over the functionality and general design of the user interface and the Fiber-Deep database queries during the deployment process. This allowed Mediacom's senior management to obtain value from the ADO platform relatively early in the deployment process.

Phase 2, being focused on business-as-usual activities, involved:

- significant interaction with Mediacom's network planners at the corporate level and in the regions to ensure that the functionality provided by the ADO platform was truly useful in terms of time and cost savings in their day-to-day activities,
- implementation of an interface between the ADO platform and Mediacom's GIS/engineering platform so that the ADO platform
    - had on-demand access to the data therein describing the as-built access network configuration, thereby ensuring that any preliminary design produced in the ADO platform would be based on the best available information, and
    - can export selected preliminary designs to the GIS/engineering database so that network planners and design contractors could use those designs as the basis for completing detailed designs and construction drawing packages, thus saving a significant amount of time and effort in that process.

As with any major deployment of new technology, there were a few interesting, and some critical, factors to the successful implementation of the ADO platform, including:

- having to invest some time and expense to process the legacy computer-aided design (CAD) data within the existing GIS/engineering platform database into fully modelled data to ensure that the ADO platform could function optimally, which work was carried out in 2020 on the expectation that the ADO platform deployment would occur in 2021,
- working with the vendor of the GIS/engineering database to implement the interface between that system and the ADO platform so that the GIS/engineering database vendor could ensure that the ADO platform could read from and write to that database with no risk of data corruption,

- dedicating a reasonable amount of time on the part of a few senior Mediacom personnel on a weekly basis to working meetings and technical discussions to, most importantly, convey Mediacom's technical and operational requirements to the ADO platform vendor,
- revising the deployment plan at the kick-off meeting to include the N+0 planning work (christened Phase 0) described in Section 5 above, which involved developing N+0 Design Rules and applying them to the as-built network in the city in question to produce two sets of preliminary designs and cost estimates within 90 days
- engaging in regular discussion within Mediacom and with the ADO platform vendor to develop a working understanding of how Mediacom's internal processes will be improved, and
- communicating process changes to Mediacom personnel not originally involved in the deployment of the ADO platform but, nonetheless, affected by its deployment and adoption.

Phase 0, the N+0 planning work was executed in Q1 of 2021 while Phase 1 was executed in Q2/Q3 and Phase 2 in Q3.

Mediacom anticipates continued expansion of the ADO platform in terms of network design capability, e.g., FTTH, and supporting a broader group of users that would benefit by having access to the ADO platform. It will certainly take some time and effort to bring the broader user group onto the ADO platform, if only because people are naturally reticent to change the way they do their jobs, but the benefits to be gained by using ADO technology are expected to far outweigh the adoption costs.

7. Summary and Conclusions

Mediacom has found that the adoption of ADO technology does enable evaluation of the technical and capital costs characteristics of access network designs much more comprehensively and quickly than was previously possible.

While it was expected from the outset that ADO technology would immediately benefit those directly involved in network planning and engineering. It became increasingly apparent that the use of ADO technology – specifically, the data within the preliminary designs and cost estimates it produces so rapidly – has conferred benefits on practically every group within Mediacom involved in the funding, design, construction, and operation of the access network.

The increase in confidence and the saving of time afforded by having easy access to preliminary designs and cost estimates for multiple network architectures for network areas as small as a single node and as large as the entire footprint has allowed Mediacom to execute its access network upgrade strategy significantly more efficiently and effectively.

Interestingly, Mediacom's ability to work with external groups – investors, franchise authorities, and vendors – has also been enhanced by being able to provide clearly and consistently each of those groups with information they need to best understand and support Mediacom's access network upgrade strategy.

As Mediacom gains more experience with ADO technology, it is anticipating opportunities for automation of the design of power distribution for HFC networks and of FTTH networks.

Finally, it seems that, whereas 'having the whole company in a bag' was coined to refer to having at hand designs covering all of Mediacom's access network footprint, it more accurately means having designs for entire footprint in one place AND having everybody in the company who cares about the access network working together better than ever.

Abbreviations

ADO	automated design and optimization
CAD	Computer-aided design
CMTS	cable modem termination system
FTTH	fiber to the Home
GIS	geospatial information system
IP	internet protocol
IT	information technology
N+0	node plus zero active RF devices in cascade on a single coaxial cable leg of access network
N+2	node plus 2 or less active RF devices in cascade on a single coaxial cable leg of access network
N+X	node plus 0 or more active RF devices in cascade on a single coaxial cable leg of access network
RF	radio frequency
Q1	first quarter of calendar year
Q2	second quarter of calendar year
Q3	third quarter of calendar year
Q4	fourth quarter of calendar year

Helm: Self-Service Customer Data Platform

A Technical Paper prepared for SCTE by

Sriharsha Gangam
Principal Architect
Comcast Cable

sriharsha_gangam@comcast.com

1. Introduction

For any organization or business, the importance of good customer experience cannot be overstated. Capturing and understanding customer interactions with the business is the first step towards empathizing with customers. For large organizations and conglomerates with millions of customers and multiple domains or business areas, typically the data is scattered across several business units. It becomes challenging to understand the holistic customer experience. For example, the data from domains such as billing, customer care, audit, and operational interactions could be generated by siloed business units. To understand customer experiences, it is important have these data points stitched together -- particularly when there are multiple products and services available to a customer.

These challenges are industry-agnostic and apply to industries beyond cable and telecommunications. For example, in the retail industry, it is important to understand customer interactions for products and services across multiple channels (e.g., marketing, orders, billing, shipment and call-center interactions). A customer might purchase certain merchandise online, exchange it with another product at a retail store, and subscribe to a new monthly payment installment plan. It is expected that all these interactions are captured and linked together to serve and assist customers. Similarly, in healthcare, it becomes important to have a comprehensive view of health records for all patient interactions, even as the health data could originate from several independent health care providers.

To address these goals, organizations build customer data platforms (CDP). A CDP consolidates and integrates customer interaction data from multiple domains to build and present a unified profile around each customer. At the heart of every CDP is a metadata management system to enable ingestion, governance, and access to the data. Once the data is available, it enables one to gain insights into customer experiences, troubleshoot problems, and interact with customers to improve their experiences.

While it is important to be data-centric, the dynamic nature and increasing variety of customer interaction datasets introduces new challenges. It is ever more important to manage customer data in a safe, secure, and self-service manner. While rich applications can be built on a CDP, data governance and ownership responsibilities can be overwhelming if they are not democratized and decentralized.

In this paper, we will present Helm, which is the name of one of Comcast's CDPs that manages data ingestion, processing, and consumption of anonymized customer data for purposes of advanced issue resolution. We share our experiences to understand what it takes to effectively build and maintain a CDP. The Helm platform ingests hundreds of event datasets from multiple domains, such as customer care, audit, billing, device activations and operations. To put the scale in context, the platform captures tens of billions of customer interactions from millions of customers every month. Internally, it is directly used by tens of thousands of employees to serve several hundred thousand customers, every month. An important component, Helm application programming interfaces (API), play a crucial role across several products in Comcast, serving several billions of API requests every month.

The paper is organized as follows: we will begin by introducing some of the challenges in building, maintaining, and governing CDPs. We then present an overview of the Helm CDP and its impact on customer experiences. This is followed by the platform architecture and design principles. We conclude the paper with a look at Helm’s journey so far, and possible future states.

2. Helm Overview

Everything discussed in this paper as “Helm” dates back to the 2012 timeframe, when a group of Comcast employees developed a “Lab Week” project, called “Timeline,” to help us to better stay in touch with our

customers who experience service issues. During its conception and the early stages, Helm was composed of bespoke data engineering extract, transform and load (ETL) steps. Each dataset had separate plumbing (data pipelines and code) to extract data from external database systems and apply custom business logic to transform the data. This was hard to maintain, as the data evolved over time. The Helm organization was responsible for data ownership, management, and governance of these datasets. The lack of domain expertise made it challenging for consumers to leverage the data. As the number of datasets grew in terms of domains and variety, data onboarding was hard to scale up, due to limited team capacities. This approach became untenable.

Helm Self-Service was built to address these problems. It represents the control plane or management layer of the Helm CDP. With it, data originating teams can define metadata and configurations about the datasets they publish into Helm. Data producer teams tend to be data business owners, data managers, and domain experts; the platform enables a seamless communication between the domain experts and data consumers. Dataset onboarding and governance deliberately do not require engineering effort by the Helm team. Instead, they are consistent, decentralized and democratized across business domains. As of this writing, a few hundred datasets are onboarded and made available in Helm. Several datasets are modified or added every week. Helm Self-Service user interface (UI) and APIs made this possible.

The Helm team has been in pursuit of continuously improving the Helm Self-Service user experience. Helm is integrated with Matomo (*https://matomo.org/*), InMoment (*https://inmoment.com/*), and Intercom (*https://www.intercom.com/*) to capture usage metrics and product net promoter score (NPS). Data onboarding and metadata management can have several configuration steps and occasionally require additional support from Helm administrators. The Helm success team leverages tools such as Atlassian (*https://www.atlassian.com/*) service desk, Slack (*https://www.slack.com/*) and Intercom for assisting Helm users.

Data's value is only as good as its quality. With Self-Service, data quality control responsibilities are shared with data producers. Helm is integrated with DataDog (*https://www.datadoghq.com/*) to expose data and platform observability metrics. Data availability (e.g., missing data) and quality (e.g., unexpected, or missing attributes) metrics are captured, summarized, and saved for historical lookups. These metrics are sent back to the data owners to resolve any data quality and availability issues. In addition to data quality, a metadata completeness score is captured to ensure that the metadata (e.g., attribute level documentation, tags) is up-to-date and accurate (see Figure 1). This way, Helm users can browse, understand, and consume data correctly as it evolves. Helm as a CDP platform publishes its own platform metrics, logs, and traces into DataDog to enable operational support and expose Helm's service level objectives (SLO).

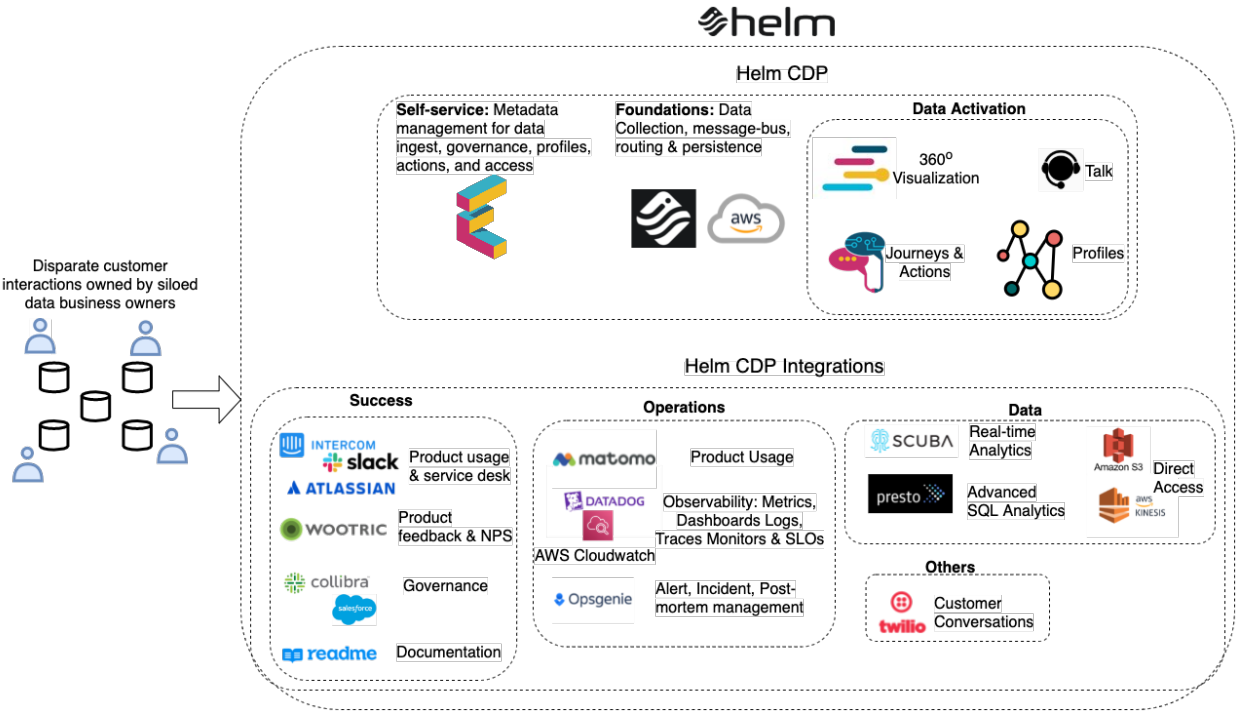

Figure 1 – Helm Overview

Once high-fidelity customer data is available, the next step is to enhance customer experiences and bring business value. Helm Applications is collection of packaged services that is included and integrated with the Helm CDP. The applications are a 360° Visualization application (timeseries visualization), Talk (customer conversations), and Analytics. They are designed to work together, draw out valuable data insights, and enable users (employees) to deliver the best customer experiences. To enable and support a variety of applications, data organization is foundational for CDPs. The next section introduces the Helm data model, which describes how data is stored within Helm. This is followed by an overview of Helm Self-Service for ingesting, managing, and governing the data.

Data Model

A profile (or entity) is the principal or thing around which timeseries event data is captured. For example, a "customer" profile is associated with a variety of customer interaction timeseries datasets such as product activations, billing data, or troubleshooting tickets. Such timeseries datasets could be originating in different business units within an organization. Each entry in these event datasets would have a unique customer identifier (the profile identifier) to link back to the customer profile, a timestamp to understand event chronology, and other attributes relevant to the specific dataset type. A product activation dataset could have additional attributes to capture a product activation experiences (e.g., attributes about the type product or service, lead time to activate the product, and activation failures).

The Helm data model supports different types profiles that may or may not have relationships with each other (see Figure 2). In addition to the customer profile, the "account" and "device" profiles are relevant in the cable and telecommunications domain. Every profile has a unique identifier and certain attributes. A customer's profile could have essential attributes to lookup, verify and assist a customer such as the name and contact information. An account profile could have attributes such the account activation date, service type, and a unique account number. If customers can open multiple accounts, this is represented by a one-to-many relationship between a customer profile and each opened account. Certain timeseries

event datasets, such as truck roll schedules, may apply to accounts rather than customers. For each account, multiple devices could be registered that generate device availability events. These datasets directly apply to devices (not customers or accounts). It is important to define and maintain profile relationships (*i.e.,* relationships between customers, accounts, and devices) to understand, navigate, and correlate events across datasets. These profile relationships are foundational in Helm and are represented by a graph – the profile graph. The profile graph along with timeseries datasets for each profile type constitute the Helm data model.

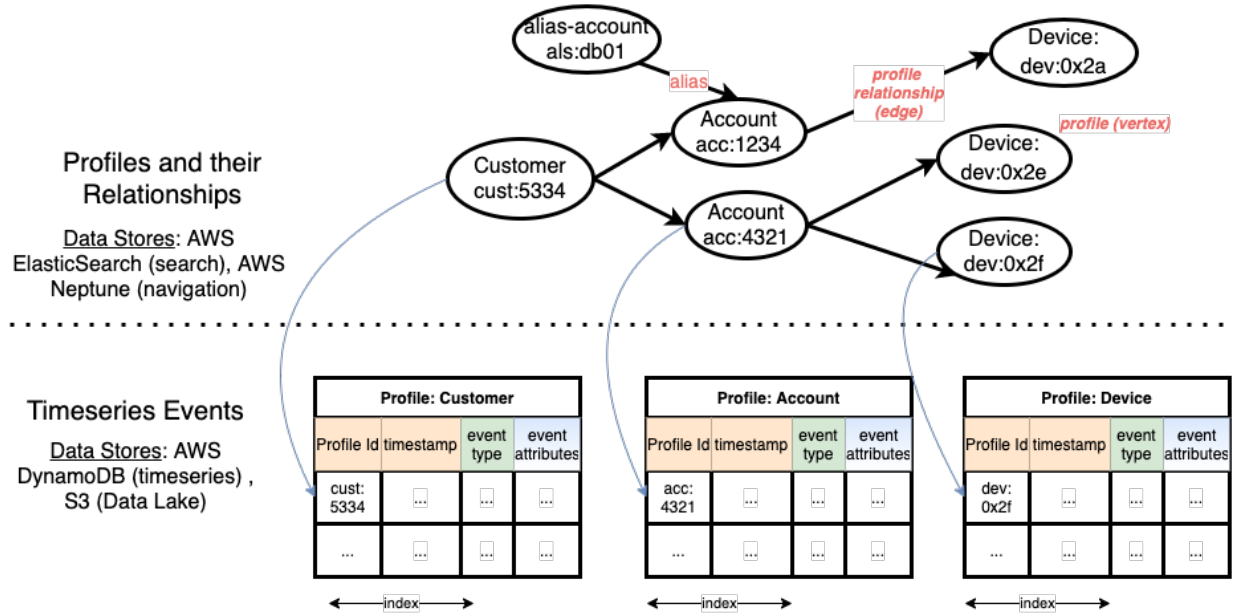

Figure 2 – Example Helm Data Model

2.1. Self-Service

First and foremost, a CDP needs to provide services to capture data effortlessly. Data owners across the organization should be able to publish data into Helm with minimal supervision. Data owners use Helm's Self-Service portal to define schema and other onboarding metadata. While the dataset schema is determined by the data producer and the business context, it must adhere to Helm's data model. It must have a timestamp (for timeseries data), a profile identifier, and additional attributes. Once a dataset is onboarded, the Helm platform will orchestrate the creation of specific infrastructure to enable data ingestion. Orchestration creates configurations to define and manage the data plane. For example, a dedicated hypertext transfer protocol secure (HTTPS) API endpoint is made available for the accepting the data. Additional application-specific orchestrations are executed when necessary.

As stated previously, Helm Self-Service represents the control plane or management layer of Helm CDP. In addition to incoming schema metadata, it enables metadata capture of transformations, routing, persistence, lifecycle, and access controls. The data producers configure the following metadata while onboarding a dataset (See figure 3):

Self-Service Metadata – Control Plane

- **Source Metadata**: Includes all the metadata relevant to a source dataset; e.g., security credentials, feed schema, and documentation. Security credentials ensure that only authorized users and applications produce data into the Helm platform. Data onboarding requires producers

to configure necessary credentials upfront. For real-time data ingest, Helm supports client authentication and authorization using OpenID connect (OIDC) and open authorization, version 2.0 (OAuth 2.0). The feed schema defines the structure of data published into Helm. It includes expected attribute names [JavaScript object notation (JSON) paths], expected data types, and expected values as per JSON schema specifications. The feed schema is used to validate ingested data and errors are communicated back to the data producer. The data producer will either need to fix the schema or the data being published. Every feed schema is accompanied by documentation that describes the dataset and attribute definitions with necessary business context. Documentation is important to build good data dictionaries. Helm users can search the dictionary to identify datasets of interest.

- **Transformation Metadata**: Includes all metadata definitions to transform the ingested data; e.g., normalization and encryption schemas. The encryption schema identifies sensitive attributes that require encryption. Helm encrypts these attributes while ingesting the data. Decryption of these attributes is restricted to privileged users and applications. The normalization schema defines naming and structural transformation specifications. It determines a target data schema that is persisted in Helm. Often times, data owners would like to change the name of an attribute or the structure of data stored in Helm without depending on the source dataset. This decouples data production from consumption and provides flexibility when data producers are unable to update their schemas. However, historical data processing can become tedious if the attribute names are updated over time. For example, analytical SQL queries would require multi-part queries, one part for each attribute name. Instead, the datasets flowing into the Helm data lake (for analytics use cases) are transformed. The transformation reverts attributes to their oldest (unique) registered names. This ensures consistent attribute names across historical data.
- **Routing, Persistence and Access Metadata**: The routing metadata for a dataset determines if one or more Helm applications (such as 360º Visualization, Analytics, or watchlists) are subscribed to the dataset. Not all datasets are suitable for every application and use case. The access metadata defines fine-grained access control policies for datasets and attributes based on their sensitivity levels. Persistence metadata defines the data lifecycle and retention goals for the dataset. These are influenced by an organization's data compliance and governance policies. Retention and lifecycle management features of underlying data stores are leveraged when applicable.
- **Application Metadata**: Helm is integrated with applications such as 360º Visualization, Talk, Watchlist, Profile Search & Navigation, and Analytics. Self-Service extends to these applications and enables users to configure them. For example, users can define icons for every data type in 360º Visualization. The profile schema metadata is applicable when the dataset is used to build a profile graph or used to define profile translations. It contains profile attributes, identifiers, and relationships between profile types. It also determines keyword-searchable attributes for a profile.

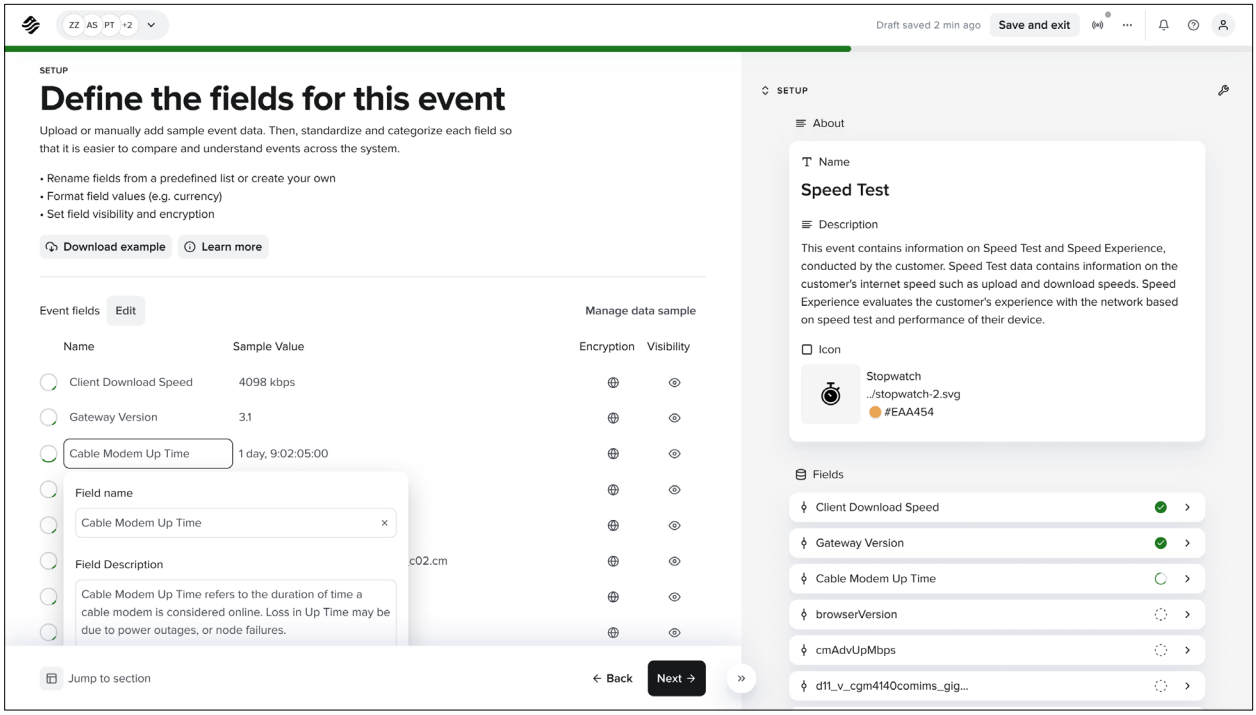

Figure 3 – Helm Self Service Data Onboarding

Ingestion & Persistence – Data Plane

After a dataset is registered in Helm Self-Service, the producer can publish the data into Helm. For ingesting real-time data into Helm, a dedicated HTTPS endpoint is created for each onboarded dataset. In this scenario, the ingested data is available for consumption in near real-time. For batch use cases (e.g., data is produced hourly or daily), data producers can directly push files to a dedicated Amazon Web Services (AWS) S3 bucket using temporary credentials generated by Helm's API. Unlike real-time ingestion, batch ingestion delays are less predictable due to their underlying nature (e.g., asynchronous and throughput-optimized).

For each event datum received from the producer, Helm performs a series of validation steps as per the security credentials and feed schema defined in Self-Service. The datum is then transformed in a sequence of steps such as normalization and encryption (if necessary). If any of these steps fail, the datum is rejected, and the data producer is notified. Helm provides live and historical observability of failures and rejected data. If all the steps execute successfully, the datum is accepted and is written to Helm's message bus for routing and consumption.

A datum's journey from the message bus is determined by the routing metadata configured in Self-Service. Helm applications consume this datum and may perform certain compute operations (e.g., sessionize, evaluate rules, aggregate, enrich, or store) specific to the application. Finally, the datum is persisted in datastores appropriate for the query use case. To enable profile keyword search and navigation based on profile attributes and relationships, the datum is stored in a modern graph database (AWS Neptune) and search database (AWS Elasticsearch). Similarly, to support real-time event lookups (timeseries data) for a profile, the datum is stored in a document store (AWS DynamoDB). For long term trends and aggregate analysis, the data is batched and written into the Helm data lake (AWS S3 and AWS Glue).

3. Data Activations

In the previous sections, we provided an overview of the Helm CDP and the importance of Self-Service in scaling the platform, and the underlying data model. In this section, we describe how employees engage with customers to enhance customer experience using Helm applications like Profile Search & Navigation, 360º Visualization, Talk, Journeys & Actions, and Analytics. Datasets that are onboarded once are reusable across these applications. This section describes how these applications complement each other and provide value that is more than the sum of its parts. Helm datasets are made available to non-Helm applications via data integrations and APIs.

3.1. Profile Search and Navigation

Once all the relevant datasets are onboarded and ingested into a CDP securely, the platform provides capabilities to query and serve this data. Helm's Profile Search & Navigation helps employees use search keywords to identify customers. For example, a care agent could use a customer's street address or a device's media access control (MAC) address to identify a customer profile. After identifying the correct profile, the account and device timeseries event data can be explored using 360º Visualization. A hypertext markup language (HTML) form accepts a keyword and returns all profiles that match the keyword. Auto-suggest results are provided for every keystroke, to enhance the search experience. The profile search application is served by APIs for programmatic integrations. The API accepts keyword requests to match with searchable profile attributes and returns a collection of matched profiles. It also accepts a profile identifier and allows one to navigate profile relationships and traverse to the profile graph.

The Profile API also aids in data ingestion, such as when a dataset does not have expected profile identifiers. For example, Comcast has several biller integrations. Depending on the services, customers could have multiple accounts, one for each biller. To serve customers effectively, it is important to transform biller-specific datasets to a common account identifier. Using profile relationships between biller accounts, the ingestion pipeline can transform the account identifiers of a dataset.

3.2. 360º Visualization

360º Visualization provides an intuitive and exploratory experience for understanding customer (profile) interactions. Customer interactions for a given customer's globally unique identifier (GUID) (i.e., profile identifier) occurring within a time range are presented in a single, chronological view. This "lifetime view" enables employees to serve customers more effectively, because they can see, sequentially, all current and previous interactions, without having to access disparate databases and systems. An employee can understand the customer's journey with historical data, as well as serve customers with real-time status and information. The visualization enables employees to seamlessly drill-down to a specific customer event of interest, from what can be many interactions associated with that customer. Figure 4 shows a screenshot of 360º Visualization, where events are represented by icons. In practice, clicking on these icons expands the event with necessary business context. The range-selector box (black) at the top of the screen helps users choose the timeframe of interest. The "swim lanes" and event filter selections enable one to hide irrelevant events. Visualization user preferences can be customized and saved.

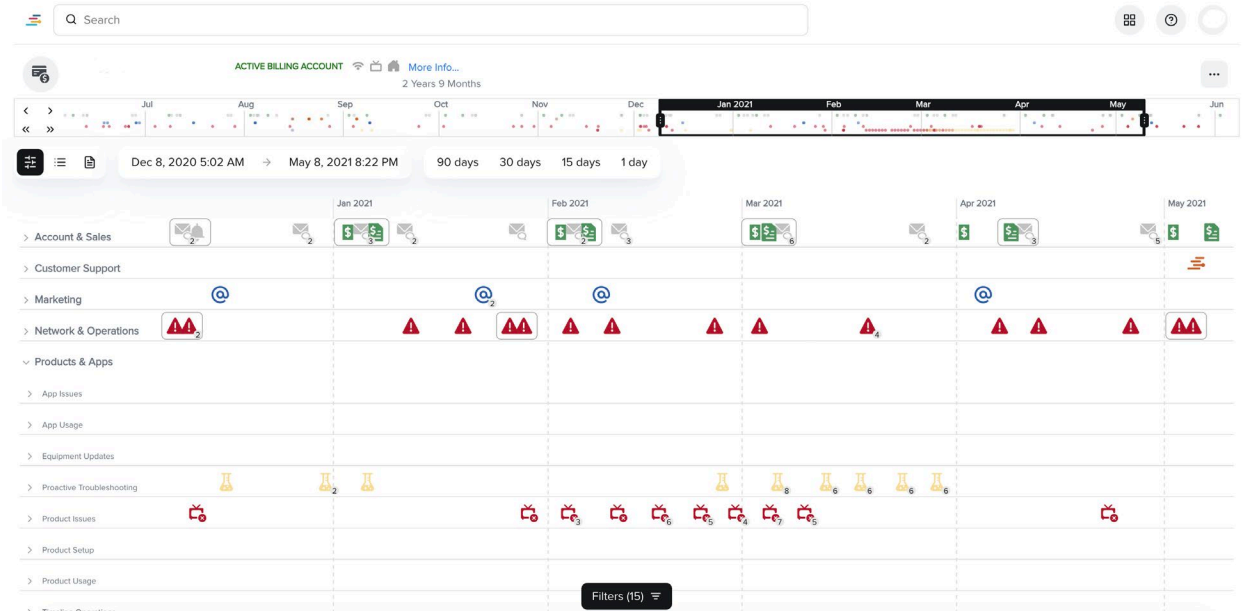

Figure 4 – 360º Visualization - Chronological View of Customer Interactions

Behind the scenes, the UI is backed by the Helm Events API. The Events API accepts a profile identifier, profile type, a collection of event types (optional), and a timestamp range (optional) and returns all events occurring within the time frame. These events are fetched from Helm's timeseries document store that is indexed on profile identifiers and timestamps. The Events API integrates and serves several critical Comcast applications external to Helm. At the time this paper was written, the Events API serves several billion API calls monthly, and the 360º Visualization UI serves several hundred thousand visits every month.

3.3. Talk

As employees troubleshoot customer concerns in 360º Visualization, they might want to reach out to the customer. Helm is integrated with "Talk", a collection of services that initiate short message service (SMS) messages, email, chat, or phone conversations with customers. This contact information is made available from Helm Profiles. No matter who or how many care agents communicate with a customer, all customer conversations are captured as events and ingested back into Helm. The 360º Visualization application allows one to review all these conversations in context of a customer's overall experience. Conversations with a shared context across channels and care agents are captured in a single place. Conversations are seamless, and care agents assisting the customer are literally all on the same page.

Helm Talk has played an important role with the NPS callback program at Comcast. Customer profiles with unsatisfactory NPS surveys are made available to certain employees (via Helm Analytics). The employees are required to proactively reach out to these customers to understand and address their concerns. With the integrated Helm Talk and 360º Visualization capabilities, employees can effortlessly review and initiate customer conversations.

Behind the scenes, Helm integrates with Twilio APIs (*https://www.twilio.com/*) to provide these communication capabilities. During the Covid-19 pandemic, Helm Talk capabilities were expanded to support video calls. This enabled our workforce to extend troubleshooting capabilities with audio and video communication without entering customer homes. This success story was feature in Comcast's corporate blog (*https://corporate.comcast.com/stories/digital-solutions-keeping-us-connected-covid-19*).

3.4. Journeys & Actions

Once customer troubleshooting is completed via the 360º Visualization and Talk applications, a care agent might wish to get notifications (triggered by specific events) about a customer, to ensure that there are no chronic issues. Similarly, care agents and customers might want to get notifications for planned network outages occurring within a certain neighborhood. These examples require configuration of event-driven rules and actions.

An event-driven rule defines the business criteria when a certain action (e.g., a customer notification) is performed. In the above example, the rule evaluation determines if an account belongs to a specific neighborhood and if the interaction type is a network outage. Information to evaluate a rule is typically available as attributes within the event and is enriched by external systems if necessary. In theory, actions could be defined to trigger any external service API call making them extensible.

The above examples do not consider a customer's historical events or prior context for evaluating event-driven rules. For example, a care agent might be interested in truck roll notifications that are re-scheduled more than twice. This requires information about a customer's journey or historical state to evaluate rules and execute actions. A "journey," in this context, is a snapshot of a customer's experience, built from a collection of seemingly disparate or distinct events occurring within a time period. A customer's truck roll journey state machine, for instance, could transition between the following states: Created, scheduled, completed, cancelled, or re-scheduled (see Figure 5). As individual events (e.g., "created," "scheduled") are observed, the workflow progresses, and the journey state is transitioned to a next one.

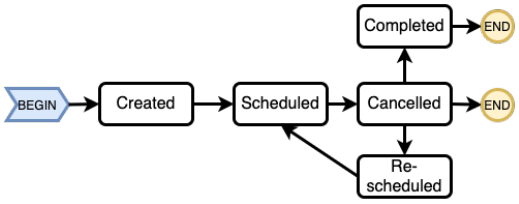

Figure 5 – An Example Truck Roll Journey

In 360º Visualization, care agents would need to mentally re-create a customer's journey by looking at individual historical events to understand the overall context. For complex workflows, this incurs a heavy cognitive load, every time. A journey state machine visualization aids this understanding and presents a customer's journey that could be understood with a single glance. The journey state machine is defined by business process flows and managed with workflow engines such as Flowable (*https://flowable.com/*). Each state transition creates an event in Helm representing the source and target states. By defining event-driven rules on journey state transition events, complex business rules and actions can be accommodated. Rule evaluation remains a stateless operation and is decoupled from journey state management.

Helm is integrated with 'Watchlist', an application that lets employees get notifications about customer events. This is achieved with a few clicks from the 360º Visualization experience. For example, a watchlist rule could be - "For new network outage events matching account numbers in the list [0003, 0004, 0005], trigger an SMS & email notification". The subscribed employees receive watchlist notifications via email or text (the action) along with the customer and event details that triggered the notification.

3.5. Analytics

It is valuable to review a single customer's experience in 360º Visualization or Journeys, but this can be hard to scale. With millions of customers, it becomes important to understand aggregated customer experiences across the population. This is accomplished with Helm Analytics, which provides both business insights and analytics capabilities. For example, it is useful to understand the population distributions at each step of a business workflow journey. This can be visualized with Sankey diagrams and infographics as shown in Figure 6. This helps business teams identify common problems across customers, and invest in areas that provide the most value. Product owners can understand the impact of their feature rollouts on customer journeys by correlating with product NPS. This fast feedback enables organizations to adapt and innovate with short lead times. Similar arguments apply for initiatives that aim to reduce an organization's budget expenses without impacting the customer experience.

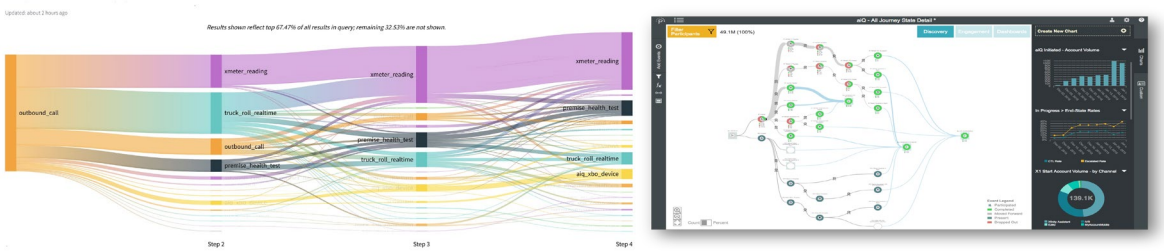

Figure 6 – Journey Analytics from Scuba and Pointillist

The NPS callback program at Comcast lets certain employees query Helm Analytics for customers with a low NPS. With a list of such customers, employees could review events in 360º Visualization, follow up with Talk, and query for customers with similar problems. These complementary applications provide the flexibility to switch context from an aggregate population view to individual customers and vice-versa, and demonstrate the immense value of Helm CDP at Comcast.

Datasets within Helm are processed and made available for analytical queries using modern data stores and analytical query engines. Users are exposed with a UI & API for interfacing with the underlying query engine. Like 360º Visualization, data access is managed using user groups and roles. At Comcast, Helm is integrated with Scuba (*https://www.scuba.io/*) and Pointillist (*https://www.pointillist.com/*) to provide near real-time analytical query capabilities. The platform serves tens of thousands of queries every month from thousands of users. The underlying datasets are partitioned and managed in Helm's data lake (backed by AWS S3andAWS Glue) to enable integration with other analytics products.

4. Helm Architecture & Design

In the previous sections, we provided an overview of Helm and showed how the applications activate data to improve customer experiences. In this section, we will present the building blocks of the Helm platform. This section details the design principles guiding the architecture, an architectural overview, and the platform's evolution over the years.

4.1. Design Principles

Below are some of the design principles that helped shape Helm's current architecture.

1. ***Metadata Driven, Domain Agnostic, and Multi-Tenant Capable***: Configurability was an essential architectural consideration, because it enables the re-use of functionality or services. Self-Service is intended to manage all metadata configurations per dataset. Observability metrics

are provided to understand the impact of configuration changes on the datasets. Platform configurability enables Helm to be domain- and industry-agnostic, and, as a result, to support multiple business verticals and industries. Profile types, their relationships, and associated time series datasets can be defined for each domain. Branding and user experiences (e.g., 360° Visualization swim-lanes) are configurable. Organization-specific integrations could be built with Helm SPIs (service provider interface), and as such support multi-tenancy by providing dedicated Helm instances in tenant namespaces. A Helm instance is created by cloning the infrastructure in a tenant namespace and applying tenant configurations. Helm is in the process of transforming into a shared-services, Software-as-a-Service (SaaS) model to reduce the time necessary to onboard new tenants.

2. ***Near Real-time Streaming with High-Fidelity***: Helm is designed for near real-time data ingestion and stream processing applications. Delays are unacceptable, from a usability standpoint, in applications like 360° Visualization and Watchlist (for troubleshooting and notifications). Certain other applications (e.g., Analytics) may be more delay-tolerant, especially if data efficiency is the priority, in which case data can be processed in batches. Data validation errors are immediately made available to the data producers. This enables data fidelity, creates a fast feedback loop with the data producer, and promotes dataset evolution.

3. ***Cloud Infrastructure and Performance Isolation***: Helm is designed to leverage cloud efficiencies, having been built using several managed and serverless AWS technologies (e.g., Beanstalk, Lambda, Kinesis, Firehose, S3, IAM, KMS, DynamoDB, Elasticsearch, Neptune, and RDS). Use of the public cloud as a technology choice is influenced by factors including corporate technology guidelines, Helm's business and strategic objectives, and personnel budgets.
Helm is designed to provide isolation and performance guarantees per dataset. For example, infrastructure orchestration (via Self-Service) creates a dedicated stream (AWS Kinesis) and compute infrastructure (AWS Lambda) for each dataset. The downside is the additional overhead for managing this infrastructure. The trade-off could be tuned by enabling shared infrastructure configurations. For example, a message bus with 's' streams could share 'd' datasets, where $1 \leq s \leq d$.

4. ***Delivery and Access Guarantees***: The Helm ingestion pipeline provides "at least once" delivery guarantee. "Exactly once" delivery requires every component in the data pipeline to guarantee it, and is generally hard to achieve. Assuming it is achievable, a data producer might still publish duplicate data into Helm. Instead, Helm provides "at least once" delivery guarantees and requires consumer applications to be idempotent. For 360° Visualization, the data store overwrites an event record if it receives another datum with the same idempotency key. The idempotency key uniquely identifies an event and is generated from a strong one-way hash function of event datum attributes. Similarly, for applications such as Journeys and Actions, the underlying state machines are designed to be idempotent. All aspects of Helm access, the product UIs, APIs, data, AWS services, and third-party integrations are secured by access controls with the principle of least privilege. All data is encrypted in transit and at rest. Additionally, sensitive attributes are encrypted at the application layer. Only authorized users and applications can decrypt these attributes.

4.2. Architecture Overview

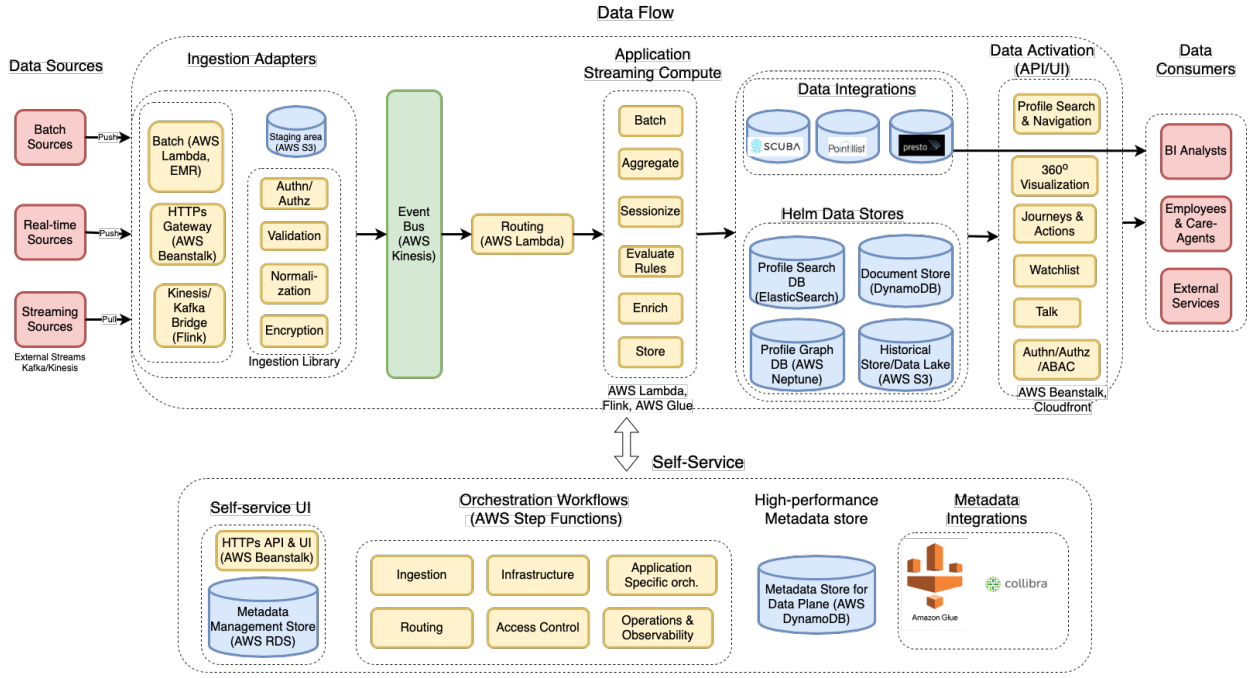

Figure 7 – Helm Architecture

Helm's high-level architecture, illustrated in Figure 7, starts with the foundational Self-Service control plane for metadata management. Self-Service is intended to manage datasets for all aspects of the data flow, from ingestion into Helm to consumption from Helm. Dataset registration in Self-Service triggers a workflow of orchestrations to enable ingestion, routing, infrastructure, persistence, access, and observability.

Ingestion adapters receive data from real-time, batch, and streaming sources. Data ingestion includes a sequence of steps such as authorization, normalization, encryption, and publishing to the Helm message bus. These steps are implemented as shared libraries and are reusable across different compute engines (AWS Beanstalk, EMR, Flink). A datum is said to be accepted in Helm only after it is written to the message bus.

Data from the message bus is consumed and written to Helm's historical data store (AWS S3). A dataset's routing configuration determines if it is consumed by one or more Helm applications. These applications and data integrations (e.g., Scuba, Pointillist) process, persist, and provide access to the data (via APIs and UIs). Applications consume the datasets independently using streaming compute (e.g., they transform, aggregate, batch, evaluate rules, sessionize, enrich, or store). For example, certain timeseries datasets are sessionized to reduce noise in 360° Visualization before persisting. For 'Watchlist', matching rules are evaluated to trigger notifications. Profile datasets are transformed into vertex and edge representations for storing in a graph database.

Occasionally, there are no data producers to publish profile datasets into Helm. In such cases, timeseries event data is processed to identify profiles missing in Helm. Profile-specific SPIs are used to fetch these profiles from source systems and ingest into Helm. These SPIs are also used to fetch profile updates from source systems. Similarly, certain timeseries datasets do not have data producers. Helm maintains a

collection of scheduled jobs to periodically fetch these datasets from source systems and ingest them into Helm.

4.3. Helm Evolution - Past and Future

Helm was initially conceptualized to support 360º Visualization. Back then, the platform was simply called "Customer Timeline". The Timeline web-application was originally built on Comcast's cloud infrastructure. It was designed to capture and visualize customer interaction (timeseries) data. Dataset onboarding required engineering new data pipelines to fetch data from source systems. It was time consuming to onboard new datasets. The 'Timeline API' enabled data access for external applications. Around this time, initiatives for migrating on-premise services to AWS public cloud had begun. Self-Service was introduced to catalog and manage datasets. Self-Service enabled dataset orchestrations and auto-created data pipeline infrastructure. Self-Service enabled the platform to scale using a shared responsibility model for datasets. However, day-to-day data operations were time consuming as the number of datasets scaled. Data producers could not get immediate feedback on the data quality. Customized dashboards were built for each dataset to monitor volume anomalies.

Helm was built to better understand customer journeys across every product and channel where they interact with Comcast. Data visualization tools and data APIs for sharing customer context with other applications are the cornerstone capabilities that enabled Helm to scale throughout Comcast. As high value datasets were onboarded, other applications such as Watchlist, Talk, Analytics, and messaging applications were introduced to leverage this data. Again, these applications had bespoke data pipes consuming from the Timeline's message bus. These applications required engineering work for every new onboarded dataset. Platform investments expanded Self-Service to support analytics and other applications. Dataset orchestrations that were originally intended for ingestion were expanded to support routing datasets to applications. At the same time, the applications evolved to consume these datasets and provide rich experiences. Eventually, the applications were integrated and managed with Self-Service and the platform was rebranded to Helm in 2019. Enhanced observability and process improvements enabled data producers to address the data quality and volume anomalies.

Over time, Self-Service and orchestrations expanded in complexity. Orchestrations were re-engineered to be modular, and workflow driven. Also, over time, Helm's operations, user onboarding, and Self-Service capabilities were hardened. Profiles were formally introduced to aid with domain-agnostic features. The platform was designed to scale, in terms of data variety and volume. With additional success, multi-tenancy had gained spotlight. Helm instances were spun up to support Comcast syndication partners and other tenants.

Current Challenges and Future Work: Spinning up new tenant and partner Helm instances demonstrates versatility. However, standing up a new Helm instance can take several hours. Our ongoing initiatives aim to reduce the time it takes to standup new instances. An end-goal is to host Helm in a SaaS model using a services-first approach. Additionally, certain aspects of Helm are not managed by Self-Service. For example, direct data access from Helm infrastructure (AWS Kinesis streams and S3 buckets) requires a code deployment. Similarly, observability dashboards are not externalizable, and teardown infrastructure orchestrations are yet to be integrated into Self-Service. With regards to data quality, statistical data quality checks over longer time ranges (days or months) are not managed in Helm. This is a future capability that can help identify data drift for analytics and machine learning use cases. We are also in the process of evaluating hot/warm storage techniques to optimize infrastructure costs.

5. Conclusion

In this paper, we introduced “Helm”, a CDP that enables employees to deliver best customer experiences by giving them a faster visual timeline of what’s going on, when our customers are experiencing service issues. We showed how CDPs like Helm provide value by consolidating customer experiences from siloed domains or organization verticals.

Data management and governance are the biggest challenges to any customer data platform. The paper highlights the importance of a Self-Service-oriented management layer to govern all aspects of data. As a direct result, the Helm CDP platform is modular and integrated with constituent applications, to enable data re-use. We demonstrated how these applications, including Analytics, 360º Visualization, and Journeys, work together to understand customer experiences and address concerns. We described the design principles that influenced Helm and described its architecture. Finally, we shared the architectural evolution of Helm and future work.

6. Acknowlegements

Neither Rome nor Helm was built in a day. Helm, as it stands today, has evolved several times since its inception as a “Lab Week” project at Comcast in 2012. It has come to fruition from the incredible work of a driven team of less than hundred members. I would like to thank and acknowledge all the engineers, managers, architects, and leaders who have made Helm successful over the years. I would like to particularly thank Leslie Ellis, Dave Torok, and Edward McLaughlin for their valuable inputs on the paper.

Disclaimer: All errors, viewpoints, and opinions in the paper are from the author. They do not necessarily represent the position of the author’s employer or affiliation.

1. Abstract

Software development across the industry relies on the use of open source components (OSCs). Because these components are open-sourced, there is an assumption that these components are tested for security by third party researchers or open source communities. A vulnerability in a popular component can have ripple effects across the ecosystem. Consequently, more popular components are more likely to attract the attention of third-party researchers or the community. Less popular components are thus often left unexamined and potentially vulnerable. In this paper we propose a model to identify OSCs that create the greatest attack surface. Specifically, we propose a metric called relative popularity ratio and use it to risk-rank a set of JavaScript OSCs. We further refine the ranking using observable properties of code, such as number of lines of code. We then validate the efficacy of this metric by engaging third party university researchers to find vulnerabilities. Our results conclude that the hidden risk from unpopular OSCs is concentrated and can thus be addressed by small investments in the security analyses of OSCs.

2. Introduction

Black Duck's audit of commercial codebases in 2017 found that 96% of scanned applications contain open-source components [1]. According to Veracode software security report [2], 7 out of 10 applications contain flaws in their open source libraries on initial scan. 3 in every 10 applications have more flaws in their open source libraries than in the primary code base. Unlike commercial software, open source relies on voluntary contributors to identify vulnerabilities, build patches, and provide updates. Security researchers may spend more time finding vulnerabilities in popular components rather than those used less frequently. Thus, unpopular and consequently underexamined components may pose a hidden risk for their users.

A vulnerability in just one OSC can potentially impact software across multiple products and even across multiple companies. Consider "prototype pollution" [10]. It allows an attacker to modify an object in JavaScript, and its implications can range from injection attacks to denial of service. While fewer than 25 prototype pollution vulnerabilities were reported in 2019, according to a report from Synk, they impacted over 115,000 projects scanned [3]. For example, one high severity prototype pollution vulnerability was discovered in Lodash open source library. This library was used by 4.35 million projects on Github alone.

Once a vulnerability is found, the resulting exposure can take a long time to mitigate. Veracode's software security report notes that only 1 in 4 flaws are fixed in the first 32 days; 2 in 4 are still open after the first 6 months [2]. Simultaneously, a newly discovered vulnerability can turn into active exploits within days, leaving organizations with scant time to respond. A notable example is the 2017 Equifax data breach that affected 143 million customers. A vulnerability in the Apache Struts2 package made it possible for a remote attacker to send a malicious request that allowed them to execute arbitrary commands. 72 days after disclosure, the Equifax breach happened [4].

Thus, the hidden security risk of unpopular open source components cannot be ignored. One solution is for organizations to limit their software developers to an approved set of OSCs. Mature organizations may use tens of thousands of OSCs. Finding a secure and functionally equal OSC for each component is in itself a difficult, if not impossible, proposition. Another solution is to conduct continuous assessment of all the OSCs being adopted in an organization's software supply chain. Unfortunately, an exhaustive analysis would likely be cost prohibitive.

How, then, should organizations and development shops address the potential hidden security risk of the open source libraries? In this paper, we present a three-step approach to address this question:

1. Define a framework to risk rank OSCs based on factors such as popularity
2. Apply the framework to OSCs to produce a list of OSCs and identify areas of concentrated risk
3. Conduct security analysis of the high risk OSCs to identify vulnerabilities

Section 3 starts off by introducing different indicators of security risk for OSCs. In section 4 we describe how these factors can be combined to operationalize a *relative popularity ratio* and then used to determine areas of concentrated risk. Section 5 presents a case study of the security analysis of the OSCs identified in Section 4. Section 6 concludes with a discussion of key findings.

3. Risk Indicators

There are many direct and indirect indicators of the security risk posed by OSCs. They can be categorized as: 1) security status, 2) code characteristics, and 3) OSC popularity. Table 1 provides a list of potential measures for each category. Different language or package managers collect different information and rank OSCs differently. Even the metadata and statistics available also differs. Even if an organization has a complete inventory of all the OSC it uses, the details may be incomplete. Thus, there may be no one size fits all solution to using these OSC security risk indicators. Instead, each organization may select the indicators that suit their development environment. Here, we discuss the three categories of OSC security risk in detail.

Table 1. Possible risk indicators.

Security Status	Code Characteristics	Popularity
▪ Reported vulnerabilities from CVE and NVD ▪ Severity of vulnerabilities based on CVSS ▪ Security of the language ▪ Typical time to remediation ▪ Number of open issues	▪ Lines of code ▪ Complexity of the code ▪ Number of versions ▪ Time of creation ▪ Number of libraries they use ▪ Where/how it is used	▪ Number of contributors ▪ Number of Github stars ▪ Number of forks and pull requests ▪ Number of subscribers ▪ Number of downloads ▪ Number of dependencies

3.1. Security Status

Indicators of security status can include the number of reported vulnerabilities from CVE and NVD databases as well as severity of reported vulnerabilities based on CVSS scores. However, not all flaws have CVEs. The percentage of flaws or vulnerabilites that have a CVE vs those that don't can vary widely depending on the language. In Veracode's analysis of open source, 61.8% of Javascript vulnerabilities don't have a CVE while it is only 10.5% for PHP [5].

Furthermore, different repositories may have distinct level of security exposure depending on how security conscious the owner is and how many independent researchers have analyzed the OSC. They may be captured by the number of open issues against a repository as well as the mean time to remediate.

The language in which the code is written may provide additional indicators. Some languages provide more in-built protection against specific security threat, such as type safe languages. Each language is also more susceptible to specific attacks and less vulnerable to others [11]. For example, JavaScript unlike Ruby is more susceptible to deserialization.

3.2. Code Characteristics

Characteristics of the OSC code can also be indicative of the probability of risk. Prior research has found that code complexity and code size both may correlate with the probability of finding a vulnerability [6] [7]. The coding language used also matters, since almost half of PHP packages contain vulnerabilities while the number is much smaller for other languages [2]. The number of libraries used by the OSC also matters. A report by Snyk found that 86% Node.js vulnerabilities are from indirect dependencies, 81% for Ruby and 74% for Java [3].

In addition to the characteristics of OSC itself, characteristics of the application using the OSC also matters. Depending on where and how it's used, a vulnerability in the OSC can have widespread impact that's difficult to fix or be easily fixed with a compensating control.

3.3. Popularity

Another way to evaluate the risk of open source is by looking at its health or popularity. If a project has low contributor attraction or retention, there's a high chance of it dying out and used by attackers in typosquatting or social engineering. However, the total number of contributors does not correlate to whether a project survives, experience level of the contributors matter as well for the quality of the project [8].

With that said, there are many smaller libraries with just a handful of total contributors and 1-2 active maintainers, so it's important to look at activity level as well instead of just contributors. Node package manager (npm), for example, has a popularity rating that takes into account the number of stars, forks, subscribers, contributors, dependents, downloads. They also have a maintenance score looking at ratio of open/total issues, time takes to close issues, most recent commit, commit frequency, release frequency [9]. While the popularity of the project is important, it is also important to account for the stability of the project as well as distinguish between a huge pull request vs. multiple smaller ones.

4. Risk concentration

Current security solutions aim to identify known vulnerabilities and corresponding patches for OSCs used within an organization's software development lifecycle (SDL). Discovery of new vulnerabilities and verification through exploits necessitates manual analysis. If the organization uses thousands of OSCs across different applications, an exhaustive analysis would likely be cost prohibitive.

It might be difficult to get information on some OSC security risk indicators due to scale or incomplete inventory. Furthermore, it may be difficult to compare these indicators as distinct package managers collect different types of information. Thus, each organization must begin with a set of indicators for which they have the most complete information. These indicators can be combined into a relative popularity ratio to address the bias introduced by one single metric.

Based on this ratio organizations can identify areas of concentrated risk. This allows prioritized security analyses of OSCs that have a greater probability of containing hidden risks as well as for whom

vulnerabilities will result in greater organizational impact. In this section we discuss this process with an example from Comcast.

4.1. Relative Popularity ratio

The goal of the relative popularity ratio is to identify OSCs that are more popular within the organization (high impact) than externally (under evaluated) and is calculated as:

$$Relative\ Popularity\ ratio\ = \frac{Internal\ popularity}{External\ popularity}$$

By using a ratio of two measures, rather than a single measure, we are able to reduce biases specific to a single dataset. Furthermore, relative popularity captures both the under evaluation of an OSC by third party security researchers, and therefore the hidden risk, and the possible impact for the concerned organization. Table 1 notes the various indicators of popularity, e.g. number of forks.

For Comcast, internal popularity was measured by the number of dependents, as this information is easily assessable through Software Component Analysis or SCA tools. External popularity was measured as an average of: 1) dependents (impact), 2) weekly downloads (current popularity), and 3) Github stars (long term popularity). These were selected based on the specific information available for npm, the specific repository that hosts the specific OSCs under analysis.

$$Popularity\ ratio = \frac{\%\ of\ Comcast\ dependents}{(\%\ of\ npm\ dependents + \%\ of\ github\ stars + \%\ of\ weekly\ downloads)/3}$$

4.2. Risk Concentration

While ranking OSCs according to their relative popularity can help prioritize the list of OSCs, there are still have thousands or tens of thousands of OSCs for each language. The next step then is to determine areas of concentrated risk. For example, consider the main languages used for development at an organization. At Comcast most of the development is limited to three: 1) C, 2) Java, and 3) JavaScript.

For each language, developers may use hundreds of OSCs. An individual library may be used just once or in up to thousands of applications. Figure 1 plots the OSCs for each language by percentage of dependents. Observe that the top 50 OSCs covers 26.2% of dependents for C, 37.7% of dependents for JavaScript and 25.9% of dependents for Java. In fact, top 200 OSCs provide more than 50% coverage for each language, i.e. 52.2% for C, 59.6% for Java, and 59.5% for JavaScript.

Figure 2 shows the number of dependents or applications using each OSC for the top 1000 JavaScript for 2019, 2020 and 2021. The top 50 OSCs cover 37.7%, 23.7% and 37.9% of the risk for 2019, 2020 and 2021 respectively. The top 200 OSCs covers 63%, 45% and 60% of the risk for 2019, 2020 and 2021 respectively. Thus, as more development teams adopt SCA tools and more OSCs are inventoried, the general trend continues to hold true from year to year.

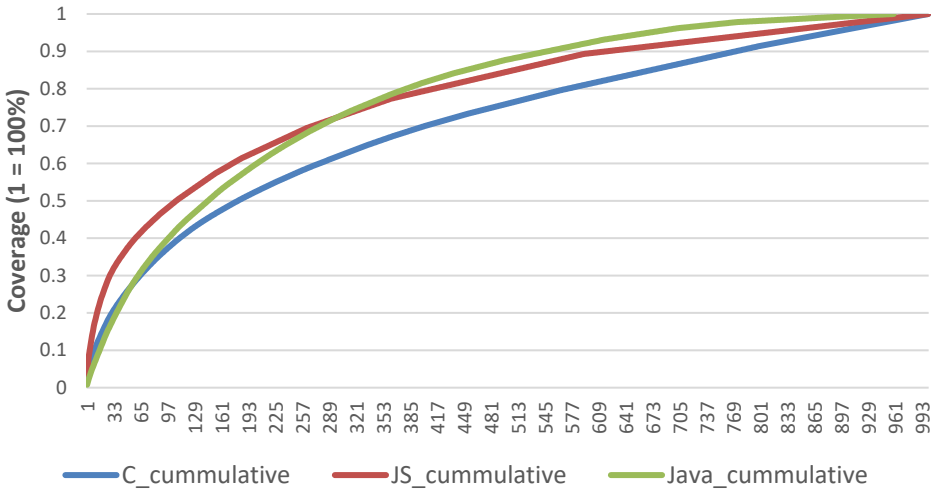

Figure 1. Percentage of dependents covered by the top 1000 OSC for C, JavaScript and Java

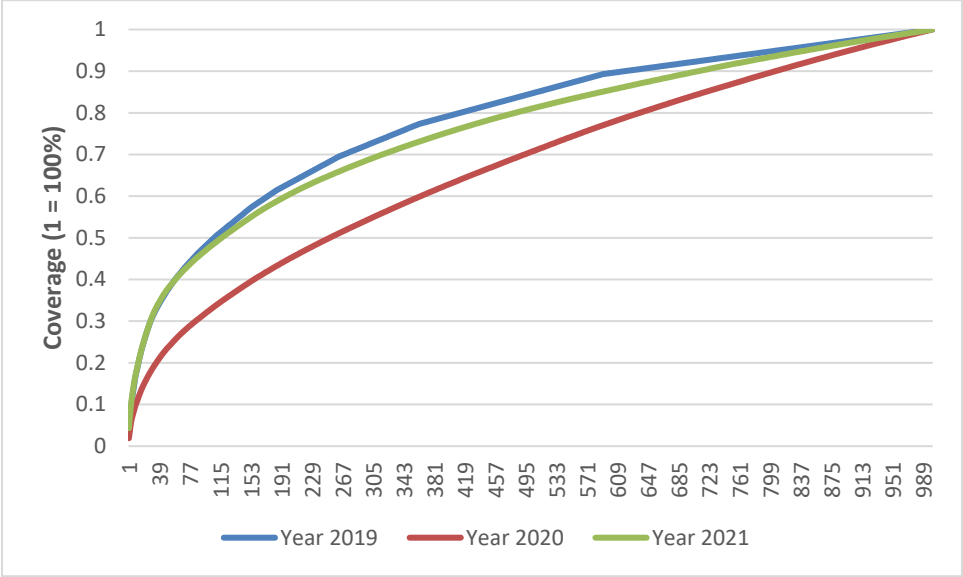

Figure 2. Number of Dependents for top 1000 JavaScript OSCs for 2019, 2020, and 2021.

Thus, the security risk from OSCs is concentrated. Analyzing the top 50-200 components will provide coverage for majority of the risk. There is then no need to conduct an exhaustive security assessment of all components. Instead, the organization can focus its resources on OSCs with greater number of dependents. Here we focus on the top 50 components in JavaScript, which covers approximately a third of the risk.

5. Case Study

As we note in Section 4, the security risk from OSCs is often concentrated. Thus, a detailed security assessment of a small set of OSCs provide coverage for much of the security risk. In this section we discuss an example of such an assessment. We began by selecting the OSCs. Based on the trajectory of usage of OSCs within Comcast, we decided to analyze top 50 JavaScript OSCs. We further narrowed our scope based on the relative popularity ratio.

In terms of manual analysis, there are many ways to attack and test the OSCs. OWASP top 10 and SANS top 25 are a good place to start. In addition, according to a report by Veracode [5], there are four categories of flaws that represent 75% of all flaws found in the open source libraries: access control, cross-site scripting, sensitive data exposure and injection. We decided to focus on the flaws within the source code rather than due to access control or other external factors, and those that are server side rather than client side.

5.1. Methodology

The first step of the analysis is to collect a list of OSCs. The information for OSCs used within Comcast are collected from WhiteSource, thus the list only includes OSCs used by applications of teams using WhiteSource. There is a limited amount of information available for all OSCs so the list only contains the name of the component, and the number of dependents (applications using it with all versions combined together). For this experiment we focused on JavaScript.

Once the internal list of popular OSC is collected, we ranked them according to the number of dependents, and external data is then collected for the top 50 OSCs that are used by most applications within Comcast. External data used for popularity ratio calculation such as number of dependents and weekly downloads are collected from npm repository. The number of stars is collected from the Github repository. The popularity ratio is then calculated for each OSC, where a higher number indicates it is more popular within Comcast than externally, while a lower number indicates that it is more popular outside of Comcast than internally.

The list of top 50 JavaScript OSCs was given to third party university researchers at Comcast Center of Excellence for Security Innovation at the University of Connecticut for security analysis. The analysis focused on identifying previously undiscovered code injection vulnerabilities and verifying that they are exploitable.

5.2. Results

Figures 3, 4, and 5 lists the 50 OSCs under analyses based on external popularity, internal popularity, and relative popularity ratio respectively. Security analyses found new code injection vulnerabilities in 3 of the 50 OSCs: jade, depot and prototype. These components are color coded red. The problems came from embedded dependencies; newer versions of the packages have fixed the vulnerabilities. Separately, one package was found to be deprecated, and colored grey.

When ranked according to either internal or external popularity, as seen in Figure 3 and 4, the vulnerable packages are scattered throughout the top 50 list. In Figure 5 however, when the top 50 OSCs are ranked according to the popularity ratio, where higher ratio indicates high popularity within Comcast but low popularity externally, we can see that the vulnerable components are concentrated in the top third of the list. It also makes sense that the deprecated OSC would rank high on the popularity ratio since there would

be almost no external usage (thus the external popularity is only from a few GitHub stars) while it was still used internally. The OSC has been phased out of use since then.

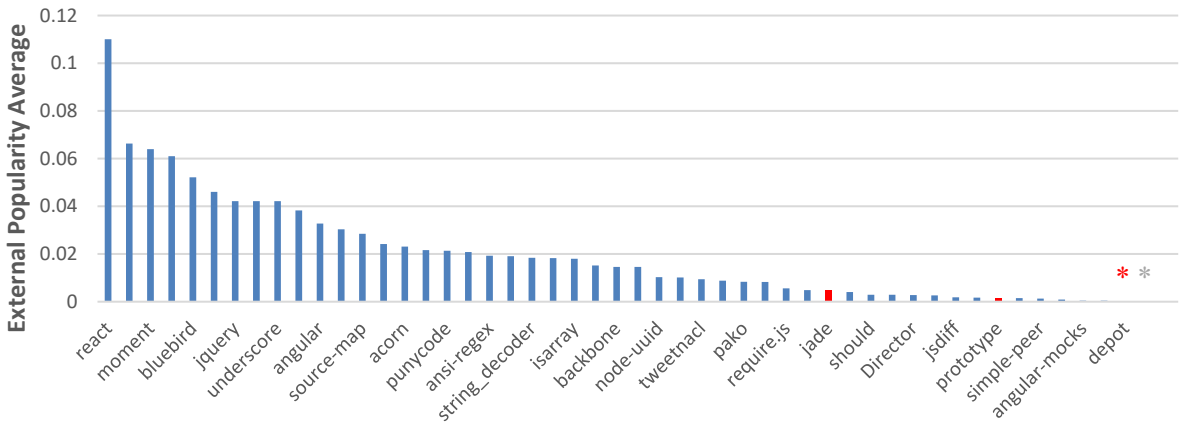

Figure 3. Top 50 OSCs ranked by external popularity. * denotes location of vulnerable/deprecated components difficult to see.

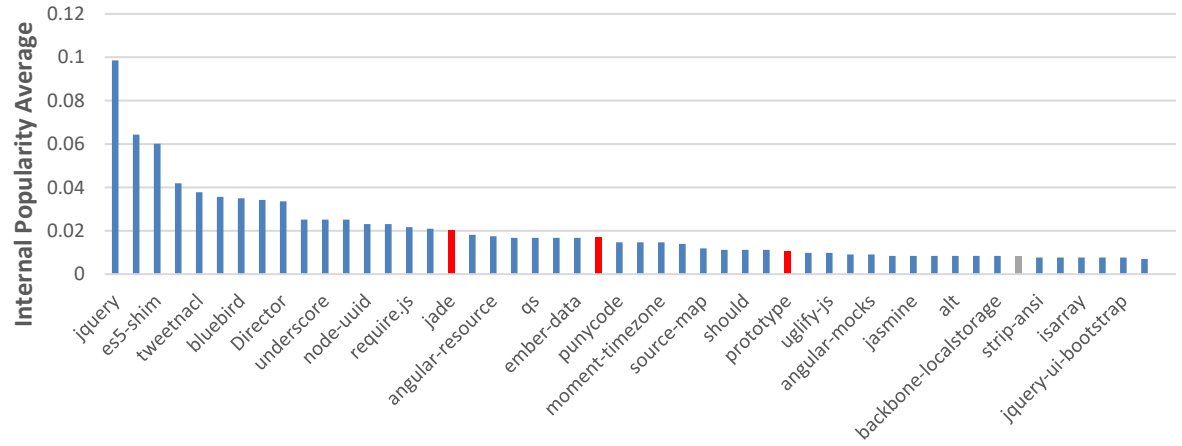

Figure 4. Top 50 OSCs ranked by internal popularity.

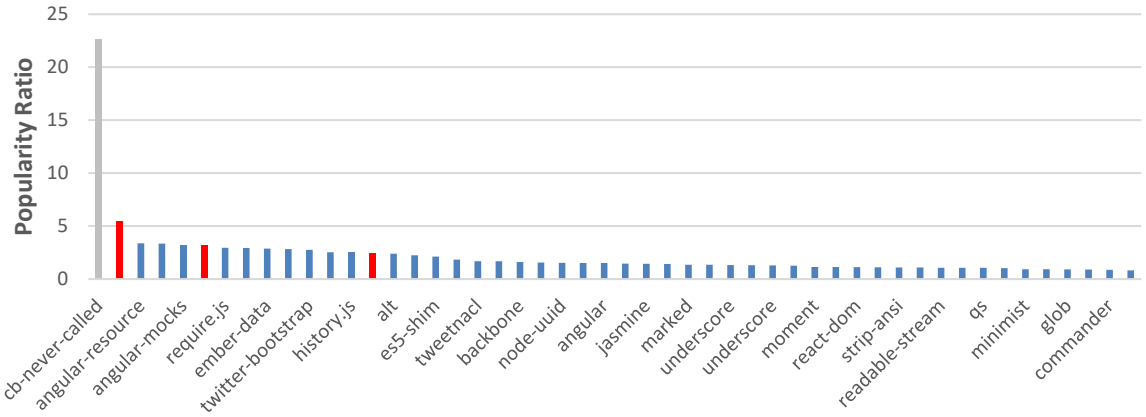

Figure 5. Top 50 OSCs ranked by popularity ratio.

The three vulnerable OSCs covers 1.78% of dependents or applications used by the teams in the list and the analysis was only done for code injection vulnerability. From this case study, we have verified our hypothesis that less popular OSCs contain hidden risk.

6. Conclusion

The first step toward managing the risk from open source is to identify the OSCs used across the organization. Using software composition analysis helps with both taking inventory of OSCs used and whether there are any existing vulnerabilities as well as corresponding patches available. It also automates the discovery of old or deprecated versions of an OSC being used. For many OSCs no significant vulnerabilities may be publicly known. This may be because these OSCs are secure. Alternatively, it is possible that these components are not popular enough for third party security researchers to analyze them. This creates a hidden security risk. As most organizations use hundreds, if not thousands, of OSCs an exhaustive security assessment would be both cost prohibitive and impractical.

In this paper we provide a roadmap to address the hidden security risk from such OSCs. First, we describe the various indicators that can be used to approximate the security status of an OSC. Then we provide a way to use these indicators to risk rank OSCs via a relative unpopularity ratio and identify areas of concentrated risk that can be prioritized for security assessments. We then present an example case study. Our results indicate that a majority of the hidden risk is concentrated in a minority of components. For us, the top 50-200 components cover 30-50% of the risk. Thus, small investments in security assessments of OSCs can address any potential unknown vulnerabilities.

This paper presents a specific instantiation of the relative popularity ratio. However, organizations may choose their own indicators based on their operational context, information sources, and data completeness. Furthermore, the relative unpopularity ratio is only intended to provide a way to prioritize security assessments. It is unlikely that there will be a quantitative correlation between the ratio and the number of vulnerabilities found. As the ratio can be constructed in different ways, the specific ranking of an OSC will differ in each distinct instantiation of the formula depending on the indicators used. Additionally, assessors (and assessments) themselves may be better at finding certain types of vulnerabilities over others. Regardless, as we show in this paper this qualitative approach is still effective at identifying areas of concentrated risk and addressing them. Thus, it is possible to shine a light on the hidden risk of unpopularity in OSCs.

1. Abstract

Quantum Key Distribution or QKD offers a quantum safe mechanism to establish an encrypted and authenticated communications channel. QKD is theoretically secure against a computationally unbounded adversary; this contrasts with classical key distribution systems where security is contingent on the assumptions made about the computational capacity of the adversary. These systems are being deployed in operational test environments across the globe. Most commercial systems require expensive proprietary technology, where the marginal cost of deployment is proportional to the capital investment. This means that the cost of adding an additional user is proportional to the cost of the original system. Thus, some experts have argued that the security assurance of QKD systems is not adequate to justify a transition from current approaches, other than for niche or otherwise narrow use cases. This paper provides an overview of current QKD systems, provides insight into the economics of deployment, and discusses the potential for commercial applications.

2. Introduction

The promised advent of quantum computers has focused on the negative impact of quantum technologies for security. Large quantum computers can void the security of current public key cryptosystems, necessitating a transition to Post Quantum Cryptography (PQC), i.e. cryptography that would be secure against know quantum cryptoanalysis. Less attention has been paid to security enabling solutions such as Quantum Key Distribution (QKD) [1]. These solutions, unlike quantum computers, are currently being tested in operational settings across the world. South Korea Telecom, which announced the first 5G smartphone enabled with Quantum Random Number Generator (QRNG), is now testing ID Quantique's QKD system in its 5G network [2]. British Telecom partnered with Toshiba Labs and is now testing a QKD-enabled link between two research sites in Bristol, United Kingdom [3]. Stateside, Verizon is piloting a QKD network in the Washington D.C. area [4].

The key security advantage of QKD systems is that they are theoretically secure against a computationally unbounded adversary [1]. Thus, unlike RSA or Elliptic Curve cryptography, the security of these systems is not based on the hardness of solving a mathematical problem. Simultaneously, unlike AES and post-quantum cryptography, their security is not based on the computational limits of the adversary. Instead, the security of QKD is based on the laws of quantum physics. This means that any communications secured using QKD can be recorded by an adversary and the communicating parties can be assured that, regardless of any future technological advances, the messages will be secure in perpetuity [5]. Critics, however, will point out that adversaries typically do not rely on cryptoanalysis or breaking the math. The easier solution is to find a vulnerability in the software [6].

In the United States, the NSA has supported the critics' view by stating that national security systems should not be secured with the use of quantum cryptography, including quantum key distribution [7]. Yet, the Bureau of Industry and Security continues to restrict the dissemination of QKD technology as part of export controls [8]. Internationally, ETSI [9], ITU [10], as well as ISO/IEC [11] have continued their standards efforts for QKD, advancing the view of supporters of QKD.

If you are new to QKD and all this confuses things, DON'T PANIC. This paper is an effort to provide a representative overview of QKD, the arguments for and against this technology, and the possible future implications. We begin with an introduction to QKD in Section 3. Section 4 provides an overview of the commercial landscape and deployment architectures. In Section 5, we discuss the benefits and limitations of various solutions as well as potential use cases. Section 6 concludes with a summary of key points.

3. An Introduction to QKD

QKD is a subset of quantum cryptography technologies [12]. These solutions are based in large part on the quantum physical property of *no cloning*, i.e. it is impossible to measure a quantum state without changing its properties [13]. This property has led to many quantum cryptography solutions, such as quantum coin tossing [14], quantum oblivious transfer [15], quantum zero knowledge proofs [16], quantum bit commitment [17], quantum secret sharing [18], and QRNGs [19]. While many of these solutions have been of theoretical interest to cryptographers, some, like QRNGs and QKD, have gotten significant commercial traction [1].

The first and perhaps the most well-known QKD protocol is BB84, which was designed by Charles Bennett and Giles Brassard in 1984 [20]. Every subsequent protocol is to a degree an adaptation for BB84 for a specific technical design under distinct constraints. BB84 has two main stages. In stage 1 Alice sends a series of quantum states to Bob over a quantum channel. These states are randomly constructed in either the X or Z basis by Alice and similarly arbitrarily measured in either basis by Bob. If the states are measured in the same basis as the one in which they are constructed, the outcome is deterministic, otherwise it is random and destructive.

In stage 2 Alice reveals her basis to Bob through a classical channel and Alice and Bob keep the states in which Bob chose the correct basis. The channel for classical communication is public but authenticated, i.e. Eve can eavesdrop on this channel, but not tamper with any message sent on it. Due to the no cloning theorem of quantum mechanics, Eve must actively attack the quantum signal (she cannot store the quantum data to attack at some future time). Finally, since Eve does not know the basis choice that Alice used, she cannot deterministically extract any information with certainty. In fact, any attempt by Eve to extract information from the quantum data will cause the quantum state to become disturbed, which may be detected by Alice and Bob.

The BB84 protocol was designed to be used with single photon emitters. However, these can be difficult to build and operate and thus add expense to the system. Researchers have addressed this by proposing decoy state BB84, which can be implemented using weak coherent lasers [21]. Others have proposed measurement device independent or MDI QKD protocols, which protect against side channel attacks [22]. Finally, a recent addition has been semi-quantum QKD protocols [23]. In these protocols, some of the participants need to be able to prepare or measure quantum states, whereas others can simply reflect them.

The cost of QKD systems is driven by the photon detectors, i.e. Single Photon Avalanche photoDiodes (SPADs). These may require special cooling equipment, resulting in higher capital costs, increased operational costs, greater operational complexity, as well as more cumbersome form factors. A good SPAD should always click when a photon hits it (quantum efficiency), should not click when a photon is not present (dark count), have a low reset time (dead time), should not result in multiple clicks for a single photon (afterpulsing), and be accurately able to ascertain when a photon was detected (timing jitter).

The physics of single-photon detection leads to fundamental trade-offs between the various desired characteristics. For example, an increase in quantum efficiency is achievable with a larger detector area. However, that leads to a greater uncertainty in the incident location of the photon which translates an increase in timing jitter. Similarly, it is desirable to lower detector temperature to reduce dark noise however that increase the probability of after-pulsing (as well as the cost).

QKD systems can operate over fiber or in free space. Systems that operate over fiber are typically limited to a range of 50-100kms. This is a fundamental difference between classical and quantum communication. One cannot use a traditional fiber amplifier on single-photons due to the *no cloning* theorem [13]. Thus,

QKD systems use trusted nodes to extend their range. This inherently limits the security guarantees offered by QKD, i.e. the overall security of the system becomes dependent on the trustworthiness of the trusted nodes. Another limitation is the hold-off period of SPADs applied to prevent after-pulsing after an avalanche breakdown, i.e. the detector needs a time gap between detecting two distinct photons. Without this gap, or hold-off period, the detector may click multiple times even though there is only one photon in the fiber. The hold-off period of Indium Gallium Arsenic or InGaAs SPADs, for example, is 1-10 μs. This limits communication speed to 100 kbps-1 Mbps.

Free space solutions, i.e. earth to space or space to space, may overcome the distance constraints of fiber-based systems. They are instead constrained by line of sight. Furthermore, their efficiency may be impaired by atmospheric conditions such as rain. In fact, QKD systems have a range of variations in implementations, each with distinct advantages and disadvantages. For example, QKD systems that form the base of quantum communication use entangled photons. Some QKD systems use discrete variable implementations, while others use continuous variable alternatives. An exhaustive discussion is beyond the scope of this paper and is covered elsewhere [1].

4. Systems in the Wild

QKD systems are increasingly being tested in a variety of operational setting for various use cases. Some of these are being deployed by the industry alone, others in collaboration with academia and government. There are a range of commercial solutions being offered by traditional technology companies as well as startups of varying levels of maturity. In this section we aim to provide a representative overview of these systems.

4.1. ID Quantique

ID Quantique's flagship product is the Cerberis XG QKD system [24]. The system is designed to be operated over 50km with a secret key rate of 1.4 kbps. The quantum channel can operate over dark fiber or via channel multiplexing with the quantum channel around 1310nm (O-band). The system can be integrated in a diversity of network topologies, including point-to-point, relay, and ring, as well as hub-and-spoke. The system complies with the Advanced Telecommunications Computing Architecture (ACTA) to allow for easy plug and play into existing physical infrastructure.

4.2. Toshiba

Toshiba systems use both proprietary detector, self-differencing single photon detectors, as well as a proprietary protocol, T12 [25, 26, 27]. This allows Toshiba to offer 1 Mbps key rates over 50km deployments, with the equipment operating at room temperature. Toshiba offers two commercial solutions. The first uses multiplexing to allow data and QKD on the fiber. The second operates on dark fiber for long-distance applications. Toshiba has been awarded the contract to deploy and manage the QKD infrastructure of the National Institute of Information and Communications Technology in Japan. The company has partnered with British Telecom to lead the first industry deployment of QKD in UK. In the U.S., it is partnered with Verizon and Quantum Xchange to pursue QKD demonstrations in operational environments.

4.3. Quantum Xchange

At the time of writing, Quantum Xchange does not produce its own QKD systems. Instead, it has partnered with other QKD vendors to provide a key management solution that works with and without QKD. Additionally, Quantum Xchange also has a proprietary trusted node technology developed in collaboration

with Battelle [28]. This is being used to build a QKD network from Boston to Washington, D.C., over which it plans to offer QKD as a service. Its systems operate over dark fiber to allow for better key rates and longer-range deployments [29]. The flagship product, known as Phio QK, is available standalone or as a managed service to allow for an easier transition. At the time of writing (summer 2021), the company's primary focus is the financial sector, although, as noted, it is conducting pilots with Verizon.

4.4. Qubitekk

Qubitekk's solution uses entanglement-based QKD rather than prepare and measure systems [30]. Its systems are specifically designed for industrial control systems, and run over standard optical fibers with an offering of 100kbps over 20 kms. Qubitekk's focus is on the energy sector, as a participant in the Department of Energy's Quantum Grid initiative. In one instance, it demonstrated trusted relay based QKD in collaboration with the Electric Power Board in Chattanooga, TN. The demonstration used three distinct QKD systems: 1) a COTS system with BBM92, 2) a research system with BB84, and 3) COTS systems with SARG04. The overall key generation rate was slower than the slowest QKD system [31].

4.5. Quintessence Labs

Quintessence systems are based on Continuous Variable QKD (CV-QKD) vs. Discrete Variable QKD (DV-QKD) [32]. The company's flagship product is qOptica™ 100. Quintessence is focusing on free-space QKD, where CV-QKD may offer additional advantages. The latter does not use SPADs, which are sensitive to atmospheric conditions. Instead, CV-QKD relies on homodyne detectors that may operate unimpeded under daylight conditions, without the need for spatial filters or spectral filters.

4.6. VeriQloud

VeriQloud's flagship product, QLine, takes a different approach to QKD architecture [33]. It does not require each client to both prepare and measure the state of a qubit. The product QLine then requires only one photon source and detector for a set of clients on a single linear fiber. These clients have neither the ability to measure nor prepare qubits. However, they can transform the state of the photon using optical modulators. Its architecture may be used with either DV-QKD or CV-QKD. At the time of writing (summer 2021), no commercial product is available.

5. The Case for QKD

The unconditional security of QKD comes at a cost, which impacts the availability of potential use cases. In this section we will discuss how the economics of QKD may change with technological evolution and thus open the technology to additional use cases.

5.1. Economics of Deployment

QKD systems often use specialized hardware, have more usable keys rates over dark fiber, and may also require special cooling equipment. Given these requirements, a QKD system connecting two nodes may cost on the order of ~$100,000. Simultaneously, as these systems are designed to operate point to point. Thus, the marginal cost of adding another node is the same as that of the initial capital investment. This does not account for the cost of adding a trusted relay, which can further impinge costs for deployments over longer distances. Fortunately, there are both academic as well as commercial solutions emerging that may redefine the economics of deployment.

Many commercial solutions are now ACTA-compliant to allow the use of existing chassis. Commercial products, such as IDQuantique's Gen 4 Cerberis, work in a variety of network topologies, e.g. star, spoke and hub, etc. New experiments from Toshiba have extended the range of fiber-based QKD from 50-100km to 600km [34]. This reduces the cost of long-range deployments by a factor of six (or perhaps even 12). The distance limitations of fiber-based QKD can also be compensated by satellite-based QKD. In Canada, Loft, in partnership with QEYSSat and the Canadian Space Agency, is looking to build small, inexpensive satellites for QKD [35]. Singapore-based startup Speqtral has already demonstrated entanglement in space with ira nano satellite SpooQy-1 CubeSat [36].

Another promising solution is the potential for auto-compensated QKD systems that use Faraday Mirrors in combination with semi-quantum protocols. These essentially act as mirrors for optical signals and simply reflect them back down the fiber. As early as 2002, IDQuantique conducted a demonstration of one such solution over 67km with a bit rate of 50bps at 1550nm [37]. This was followed up with another auto-compensated system as part of the SECOQC initiative where key rates were closer to 1Kbps [38]. VeriQloud's QLine requires but one set of sender and receiver for a set of clients. With these solutions the capital cost of deployment may be high, but the marginal cost of adding another client will likely be orders of magnitude lower. For example, Faraday Mirrors (FM) used in auto-compensated QKD are on the order of $100 (vs. a single detector which runs on the order of $25,000). The corresponding end point systems may be on the order of ~$1000 for Faraday Mirrors vs. ~$100,000 for detectors.

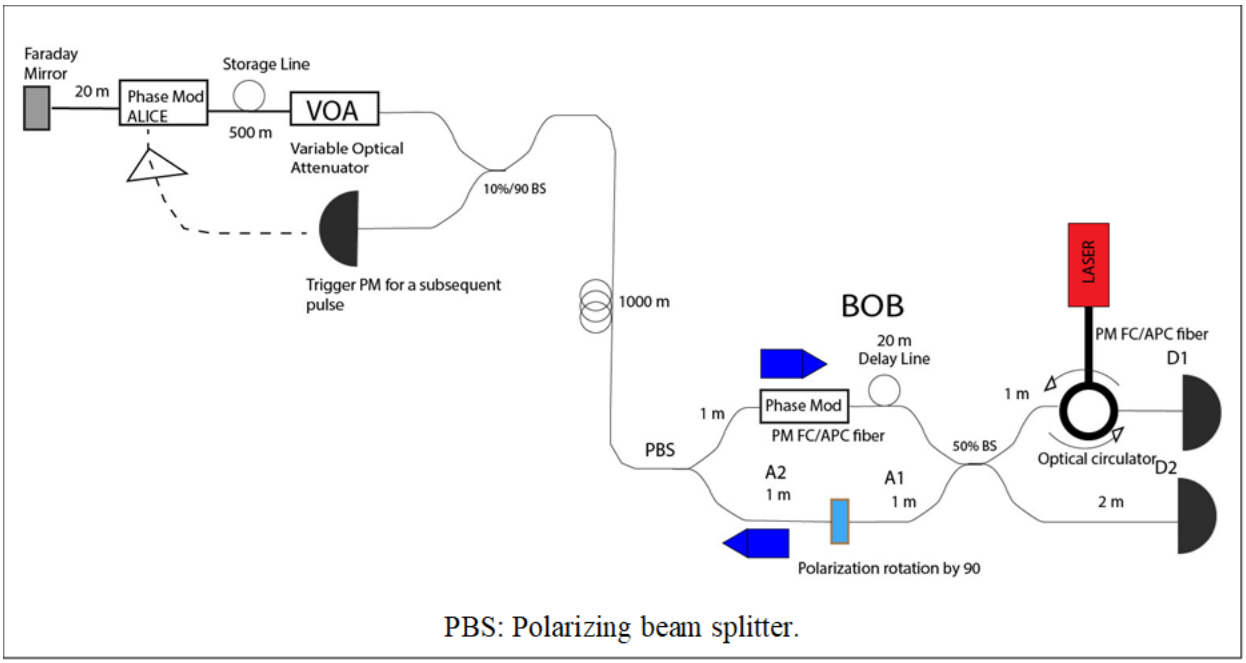

Figure 1 - Example Auto-Compensated DV-QKD System

At its core QKD is simply a mechanism for securely distributing keys. These keys can then be used in any of the various contexts that currently use PKI for key distribution. For example, as far back as 2010, ETSI published a white paper noting that the keys generated from QKD can be integrated in any part of the network stack from Data Link Layer to Application Layer [39]. On the Data Link Layer, QKD keys can be used be used to support the encryption component of Point-to-Point Protocol (PPP). They can be combined with a link encryptor to support a Virtual Private Network (VPN) [40]. Fortinet, for example, in partnership with IDQuantique ,will begin to offer a QKD-based VPN platform [41].

It has been argued that any protocol that requires a pre-shared secret can use QKD keying material instead [42]. Thus, the use of QKD keys can be extended to Network Layer protocols such as IPSec [43], Transport Layer Protocols such as TLS [44], and application layer protocols such as Kerberos [45] or Single Sign On [46]. For example, IPSec uses Internet Key Exchange (IKE) protocol for key management. A QKD key may be used in place of the Diffie-Hellman shared secret used by IKE. This can be done in conjunction with an agreed upon cipher suite, or alternatively, the QKD key may be used as an One Time Pad (OTP). The second option will ensure security in perpetuity, whereas the security of the first option will be contingent on the security of the cipher suites.

Thus, QKD keys can be integrated in any part of the infrastructure. The specific use cases will depend on the cost of the QKD end-points vs. the benefit of the security offered. There are many sectors, such as defense and health, where data may need to be protected for 100 years, and perhaps more, in the case of genetic data. However, at $100,000 per QKD-end point, the solution may be cost prohibitive. Over fiber, QKD requires trusted nodes over long distance, which impacts its security assurance.

One solution is to focus fiber use cases for smaller distances [33]. Smart buildings, smart campuses, data centers etc. all require key distribution over short distances. Furthermore, many current approaches assume that both the sender and the receiver need to be able to prepare and measure quantum states. Another alternative is to use auto-compensated systems, which require only the sender to have this capability [37]. The receiver need only manipulate the phase of the photon. The receiver then needs to have a phase modulator along with a Faraday Mirror.

The sender, Bob, can be treated as a central key distribution authority interacting with multiple Alices using polarization division multiplexing [47] (or wavelength division multiplexing [48]). Assuming a distance limit of 50km based on current commercial systems, this system on average can provide coverage for 7850 sq kms. (=3.14 x 50^2). An average U.S. city is 338 sq kms, whereas the average county is 2911.4 sq kms. Thus, many city-wide and metropolitan networks may also satisfy the distance constraints of current QKD systems without trusted repeaters [49].

This can be used to connect local government offices, to secure electronic voting, or even to offer highly secure VPN for remote workers. Advances in the use of QKD with drones may allow for secure key distribution in hard-to-reach areas, disaster zones, etc [50]. With an auto-compensated system using a Faraday Mirror + Phase Modulator, the receiver will offer a more usable form factor both in terms of size and weight for drones.

6. Conclusion

In the past two decades, QKD systems have gone from an academic pursuit to being commercially viable. Implemented correctly, their security is based on the laws of physics rather than the computation ability of the attacker. This guarantee comes at a cost that is partly driven by the need for specialized hardware. However, crypto has often required specialized hardware -- from Hardware Roots of Trust to Hardware Security Modules. Furthermore, there are certain classes of data, such as health data, that may need to be secured for long time, e.g. 100 years. There are no current crypto solutions, including PQC, which can guarantee this. The only solution for these classes of data is QKD, as it does not make assumptions about the computation capability of the attacker, which may evolve with time [51]. (Although it does require QKD key rates that allow for OTPs.)

Perhaps unsurprisingly, market analysts sized the QKD market in 2019 at $2472.4M, with expected growth to $8562.7M by 2026 [52]. Currently, the cost of deployment has limited use cases to high-risk environments such as defense. However, as technological evolution reduces the cost of deployment, it is

likely that new use cases will emerge to further increase the size of the market. This potential revenue stream is driving investments in both startups across the globe, and operational proofs of concepts (PoCs) in a range of sectors, from energy to communications.

Finally, entanglement-based QKD is critical to securing a Quantum Internet. QKD, then, is a technology that will increasingly become mainstream. While it will never be the answer to life, the universe, and everything cybersecurity, it will certainly have its use cases. This is reflected in the efforts to standardize architectures and interfaces to ensure interoperability [10,11]. QKD itself comes in many different flavors, i.e. CV-QKD vs. DV-QKD; entanglement vs. prepare and measure; fiber vs. free-space, etc. As with any emerging technology, it is unclear which solution will become the default option. It is possible that different versions may be applicable for distinct uses cases. Thus, this paper was intended to provide a representative overview of relevant technical, operational, and economic considerations, with an eye toward practical QKD.

How Cox Communications Implemented an Expert System for Service-First Autonomous Operations

A Technical Paper prepared for SCTE by

Dave Norris
Sr Director, Video Engineering
Cox Communications
6205-B Peachtree Dunwoody Rd
Atlanta GA, 30328
dave.norris@cox.com

1. Introduction

At the beginning of the current video evolution to deliver live IPTV streaming to subscribers, the Cox Video Engineering team recognized they were entering a period of unprecedented change and growth. There would be many challenges coming fast to high-capacity video delivery. We knew we'd need to absorb and incorporate new methods of compressing and delivering video without dropping the preexisting systems. At the same time, we were approaching end-of-life status on our national video compression systems. All these factors drove the need for and timing of deploying a new and more flexible video compression platform.

In 2017, the Cox Video Engineering team evolved our national video encoding systems into a virtual platform. For agility, flexibility, API controllability, and ultimately economy, we selected a software video encoder running on commodity servers in dense blade-center chassis. One of our chief concerns was that deploying a virtualized video encoder might be less reliable than the legacy hardware-based appliances. Any negative impact to video stream reliability would be highly visible, driving subscriber frustration, calls, and expense.

We decided to close any performance gaps by implementing a closed-loop Expert System solution to manage all system day-1 build and day-2 operational functions.

This paper will present some of the reasons that drove the evolution to software video encoding, some unexpected motivation that expanded our scope, a few details about the phases of the implementation, and the results.

2. Motivation and Drivers

At the end of 2015, we recognized that in the next 18-24 months we'd need to replace our aging national video encoders. We realized that Cox would be expanding our delivery of MPEG-4 to commercial and residential customers, as well as growing our offering in OTT-style IPTV live streaming for both in and out-of-home uses. We opened an RFP and began the search to find our new video encoders. At that point, no single vendor offered everything we were looking for.

It quickly became apparent that the software-based vendors had the most up-to-date feature sets, and the least disruptive pathway for upgrades. Our requirements included things like: time-aligned multi-bitrate ("MBR") encoding for adaptive ("ABR") playback; accepting HEVC contribution streams from content-providers and eventually outputting content compressed in HEVC; ATSC 3 features supporting new audio CODECs and metadata; etc. The hardware-based compression vendors could meet many of the requirements but were challenged when addressing the path and timing for incorporating new features. The software-based compression vendors provided a much faster and more efficient path for incorporating new technologies and features. Thanks to Moore's Law, CPUs (and GPUs) were closing the density gaps that had stifled software video encoding for years.

As our path to software-based compression became clear, we were increasingly intrigued by the prospect of leveraging APIs and scripting to provision both the environment and the video streams on the platform. While server stand-up automation is mature, automating video

compression software was new territory. Video compression devices, whether hardware or software based, traditionally use GUIs for configuration. The operator must manually enter a lot of parameters to define the inputs, outputs, customized filters and processing of the audio and video streams, ad-insertion messaging, and any other necessary metadata. This manual interface interaction is very repetitive and error-prone, particularly when done at a high volume. We recognized we needed to bring automation into the process.

3. Platform Evolution

With the decision to move to software-based encoding, it was time to select hardware for our new platform. We decided to purchase and host our own Cisco UCS blade server chassis and run them as bare metal for video encoding. Bare metal saved us CPU processing overhead vs VMs, and running warm spares enabled the fastest methods of video stream failover. We leveraged PXE boot and Spacewalk to take our hundreds of bare-metal servers from boot-up through the installation of CentOS.

4. Selecting an Automation Strategy

While it was expected that we would be scripting the API calls to load the video streams onto the encoders, we also decided to engage companies offering more advanced automation solutions. We spoke with a vendor offering an “Expert System” automation platform and quickly became motivated by the idea. Instead of just executing a script referencing a database that defines the systems configuration, the Expert System can be programmed with rules and exceptions. It’s also a form of a state machine and can take “expert” actions based on a pre-programmed understanding of the operational states of the components within its scope of authority.

To explain the differences in strategies, consider a self-driving car. It can be programmed to deliver its occupants and cargo to a destination. Scripting can do that in a closed and controlled environment like at a proving ground—just define the destination and route to move the car from here to there. But if you want that car to navigate on real roads, alongside the rest of us and arrive safely, advanced steps must be taken to adapt to the real-world issues it will encounter along the way. Advanced algorithms are necessary to account for the dynamic environment consisting of traffic, adverse road conditions, construction zones, weather, flat tires, etc. The Expert System self-driving car is programmed to adapt and react to each variable like a human expert would. Each of the many various task algorithms are employed as part of the autopilot system as needed to avoid that box in the road, stop for the school bus, or slow down over the rough roads, etc.

We saw a ton of potential in the Expert System approach. Properly designed, this could enable capabilities well beyond simply provisioning thousands of streams automatically. It could become an autonomous operator of the platform after that provisioning. We selected the StratOS Expert System from Sea Street Technologies, and partnered with them in the development process.

5. Development

We created a flat database file that included every parameter needed to build our hundreds of video streams into the encoders. For efficiency, we utilized look-up tables for the highly repetitive audio and video settings based on classes of outputs in MPEG-2 and 4 like SD, HD 1080i, HD 720P-60, single program AC3 audio, primary and AC3 audios, AAC audio, etc.

That database would be loaded into the Expert System to kick off the automatic build activities. Any future additions, changes, or deletions would be conducted in the same way. Once read into the Expert System, it automatically modifies whatever necessary to reflect any changes to the latest version of the database.

At Cox we use the TeleStream (formerly Tektronix) Sentry product family as video probes. The Sentries monitor and alert on issues that impact audio and video quality. These can be conditions like audio silence or excessive loudness, loss of stream, frozen video, tiling or blocky video artifacts, among many other conditions. When any Sentry sounds an alarm condition, SNMP traps are sent to collectors in the Network Operations Center and are then forwarded to the NOC personnel for triage and escalation to the correct fix agents.

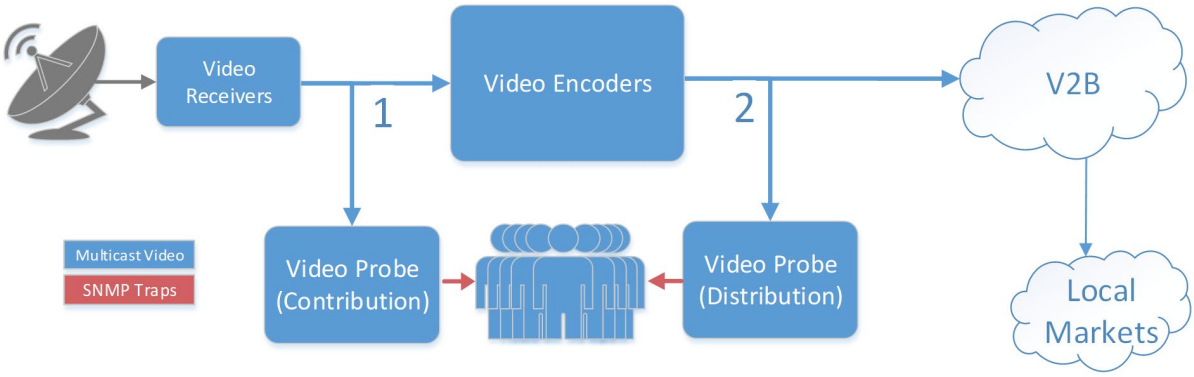

Figure 1 – Humans respond to SNMP traps from the Video Probes on the Contribution and Distribution sides of the video encoders

We integrated the Contribution and Distribution probes SNMP alerting capabilities into the Expert System by adding it as an additional destination for traps and then modeling how it should respond as they arrive. This allows the system to be aware of the health and status of the streams at both the input and output sides of the video encoders.

We also documented the steps a human expert fix agent would take based on the good or bad status reports from the video probes. The Expert System was programmed to monitor for traps on the distribution streams, and when an alarm condition exists, to check for the same traps on any

or all the available redundant contribution streams. With knowledge of stream health on both sides of the video encoders it's controlling, our Expert System automatically makes informed "expert" decisions on what to do, in sequenced steps, to restore from the outage or impaired condition.

To define the actions an expert human operator would take during break-fix activities, we created a decision matrix consisting probe-error feedback that defines the problem conditions, and the first few steps the expert would take under those circumstances to restore the stream. For example:

- Output bad, all inputs good→ restart the encoding service
  - If still bad→ mute the primary output and rebuild the stream in spare encoder pool, then remove the stream instance from the primary encoder
- Output bad, primary input bad, secondary input good→ toggle input
  - If still bad→ restart the encoding service
  - If still bad→ mute the primary output and rebuild the stream in spare encoder pool, then remove the stream from the primary encoder
- Output bad, all inputs bad→ do nothing, let the alarms flow to the NOC Operators

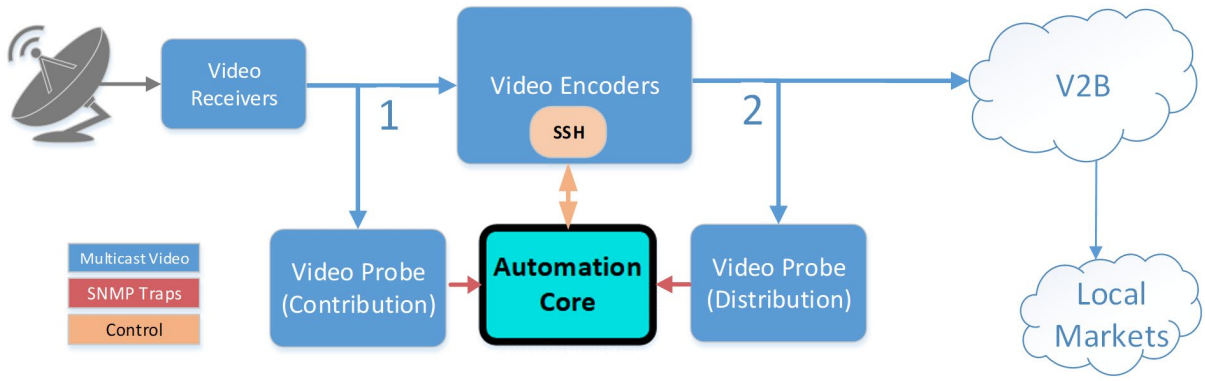

Figure 2 – The Expert System Automation Core Responds to SNMP Traps

6. "Service-First" Self-Assured Autonomous Operations Platform

A Service-First solution is one that focuses on the health of the service over the health of the individual elements. Frequently, automation platforms focus on ensuring each element is healthy but aren't aware of the health of the service itself end-to-end. Working with Sea Street Technologies, we used their StratOS platform to create an Expert System that focuses on the health and remediation of the service as the first priority, before it takes steps to fix the elements.

For example, in our solution when a fault is detected with a video stream, the Expert System will first focus on fixing it by restarting the encoder service or moving it to a spare encoder within seconds of the fault. Only after the stream is reported to be healthy again does the Expert System return to fix the faulted encoder.

The Expert System is designed to manage each video stream from initial creation to daily operations. When new video streams are brought online, the Expert System will autonomously create and configure each one and then start to monitor and independently operate each one indefinitely. This is done through "Objectives," which are continuously running objects that collect health data, execute business logic, and take actions. Instances of an Objective are created for every encoded stream and the instances all run in concert with each other, working to ensure the health of all streams and underlying elements. This method of self-assurance has enabled us to improve the reliability of our video streams, significantly improve MTTR, and reduce the need for additional staffing.

7. Launched!

In 2017, we launched our new software encoder platform under Expert System control. We entered the launch maintenance activity with all the servers online and provisioned only with CentOS. The platform-defining database was loaded into the StratOS Expert System. StratOS interpreted the database and took over the maintenance, loading and licensing the video encoding software before it began to automatically provision approximately 650 streams in the first data center.

The full configuration was completed in a less than an hour. A manual configuration of the same platform would have taken a few months of maintenance-window activities. Since launch, our Expert System autonomous operation platform has been routinely restoring errored streams in seconds with machine speed and accuracy, typically before the NOC is even alerted to the service impact.

8. Continous Improvement

The modular architecture of our Expert System makes the process more straightforward for adding features or modifying parameters. For example, we were able to easily add repair-retry logic to the system for use after extended contribution stream outages.

We've also added a second video encoder vendor's software to our Expert System. This has proven the operational environment to be independent of any single video encoding solution. Our preexisting business and operations logic was simply inherited by the new vendor-specific API resource driver module. Should Cox decide to modify our video encoding automation business rules or operations logic, those changes would immediately be applied to all the Objectives, regardless of the underlying software encoding platform.

9. How's it Working?

After years of successful operation, this has been a trailblazing and fantastic success! Bell Labs was hired to evaluate the state of automation in use at Cox and described our Expert System autonomous operation platform as the most advanced of its kind they had ever seen. They conducted an evaluation of some of the benefits and concluded the following:

- Reduced Eng effort: Fewer Maintenance Windows
  - **.4 Full Time Employee ("FTE") saved (efficiency) per year**
- Reduced Eng effort: Incident management
  - 100 in-scope incidents per week
    - **38 minutes saved per incident (T2)**
    - **15 Minutes saved per incident (T3)**
    - **2.2 FTE saved (avoidance) per year**
- Reduced Eng effort: Platform Process savings
  - **Cut time to process by 90%**
  - **1.9 FTE saved (efficiency) per year**
- Reduced Eng effort: Software release upgrade
  - **.5 FTE saved (efficiency) per year**
- Team avoided FTE growth
  - **5.0 FTE saved (avoidance) per year**

Per Bell Labs calculations, our Expert System has saved Cox over $10 Million, and continues to provide savings of $2 Million per year.

1. Introduction

We have recently embarked on a project with the aim of capturing all the building blocks of the access network, their relationships, and their properties in a graph representation encompassing vertices and edges. This representation is to be available in a high performance and scalable graph database that allows access to the data through application programming interface (API) endpoints and in batch. The graph database mirrors the dynamic nature of the network by getting updated as customers get connected & disconnected, optical nodes get segmented, network equipment gets commissioned & decommissioned, as well as the happening of any other impactful network change. Having all the relational information in one source, and combining the physical & logical elements in a single view allows analyzing the access network at any level of network topology (e.g., service group, fiber node, amplifier, tap, drop) on a use case basis. The graph database technology also allows enrichment of the data with ease by overlaying device telemetry, Cable Modem Termination System (CMTS) telemetry, and maintenance data on top in order to implement algorithms for business intelligence and troubleshooting (e.g., root cause analysis).

Building the graph database required combining and reconciling data across many different sources of the organization without identified primary keys (ids) and creating algorithms to automate inference of connections. In this paper, we share Comcast's journey into this process that is currently scaled to cover ~20% of our footprint. We present the very first use case of utilizing the network graph to study the effects of the amplifier cascade length on radio frequency (RF) performance in the upstream (US) and downstream (DS). The interest in this investigation falls within a broader question on the operational effort required to maintain nodes with large cascade of amplifiers (both in terms of depth and breadth). Our findings reveal that, predictably, longer amplifier cascade lengths exhibit degraded RF signal-to-noise ratio (SNR) -- yet with no significant impact on quality of service, likely due to the mitigating impact of the profile management application (PMA) system currently deployed in Comcast.

We acknowledge contributions to the project from former team members Doga Keresteciogl u, Matt Lord, and Athanasios Tsiaras.

2. Constructing the Graph

The Comcast access network data platform is an enterprise-scale graph data platform that maps the entire access network from the CMTS to the Customer Premise Equipment (CPE) while incorporating all of the physical and logical elements that form part of the network. At a very high level, the graph platform brings together site/headend topology, computer aided design (CAD) physical plans, telemetry, and billing systems together to construct the access network graph as one connected entity (see illustration in Figure 1).

While the individual data sources that form the building blocks of this graph data platform are highly mature with rich offerings, they have varied goals and are managed by various teams. There are no common keys that connect the boundaries between these data sources to form one connected access network graph. Hence, the need for such a graph data platform assumes significant importance to drive various data science applications and serve as a source of truth for deriving relationships between various access network components.

The platform supports a rich set of use cases from anomaly/network deterioration detection, triangulation, capacity planning [1] and various aggregation use cases. In addition, the platform uses several statistical

and data science techniques to bridge boundaries between individual data sources by inferring relationships and provides a single unified view of the access network.

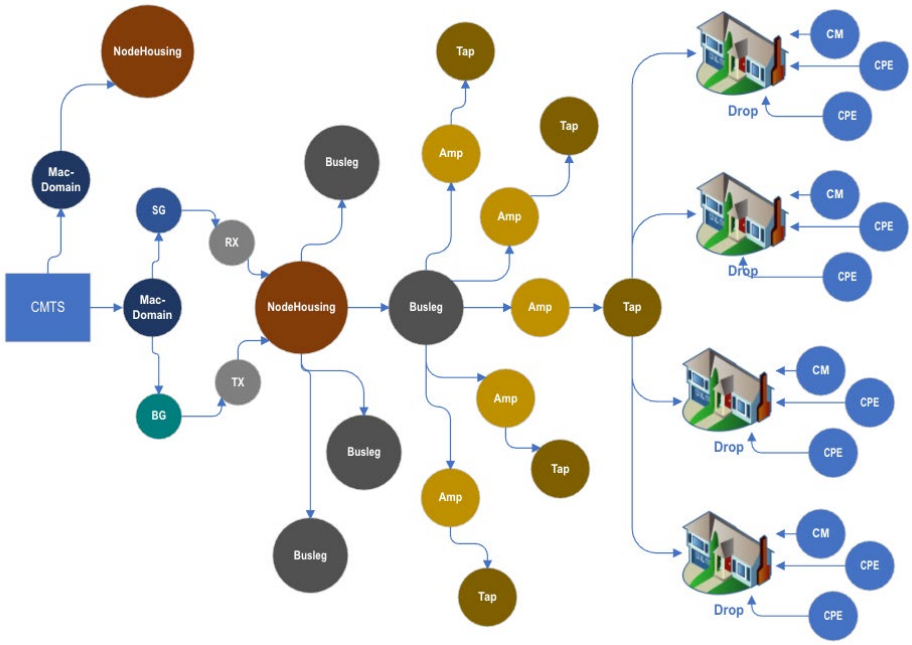

Figure 1 - Schematic representation of some of the main entities captured in the graph database.

By the virtue of being a scalable graph platform that is being purpose-built within the cloud, we're able to build multiple data pipelines to ingest various data sources and rapidly experiment and iterate through various algorithms, data processing, and refreshing techniques that feed into the end-product. The graph defines vertices and corresponding attributes for CMTS, nodes, RF equipment such as bus legs (port on a node), amplifiers, passives, taps, drops, and customer entities such as household, devices entitled, and so on. Each of these vertices are connected by edges, and in the case of equipment, these edges define the attributes of RF cables that form the connection (e.g., cable length). This graph platform allows us to query and traverse the network in either traffic direction and start at the most granular level (i.e., the CPE) and go all the way up to the CMTS or start at the CMTS and terminate at the CPE.

One of the many functions that the graph platform realizes is to diagrammatically connect physical address drops that are defined in CAD documents, to the appropriate households, which are logical elements defined in billing systems. Since there are no common keys connecting these 2 elements, the platform performs address standardization, further employs various Natural Language Processing (NLP) techniques and coordinate-based proximity to identify the right households and match them to the appropriate drops. The telemetry data set that consists of online cable modem inventory and CMTS configurations helps cross-validate these inferred relationships using reported MAC (Media Access Control) domain, bonding group, service groups, and so on.

A significant engineering challenge that was solved during the development of this platform is to account for graph refreshes. The access network consists of components that independently refresh at different rates. Hence, we needed a decoupled solution that independently refreshes various sub-graphs, even within the footprint of a single CMTS. We use property-graph architecture to implement our data model and use Apache Gremlin Tinkerpop to perform traversals, look ups, or aggregation queries. We often

notice that the depth of traversals for our queries is more than 40 layers deep, indicating the extent of cascading and density of our access network. These traversals would never be effective for any relational or NoSQL database. In contrast, through the use of large-scale data processing platforms, we're able to complete the required traversals or queries on the graph platform in a matter of minutes, for the entire footprint.

Figure 2 is a screen capture from a graphical interactive tool used to explore the graph database. It allows retrieval of attributes for vertices and edges by clicking through the graphical interface.

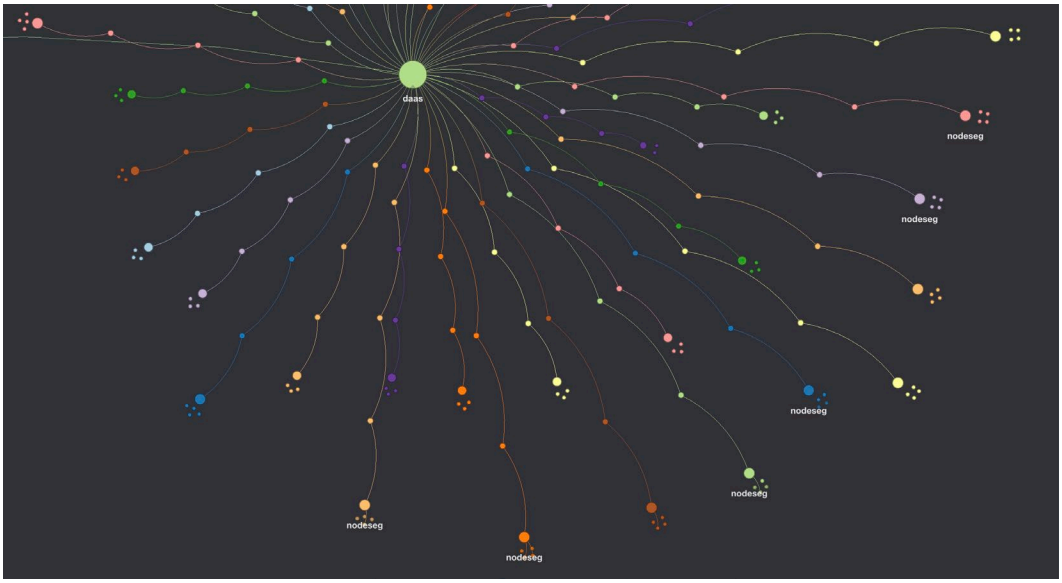

Figure 2 - Screen capture from Graphistry—an interactive graph map that allows browsing attributes of the different vertices and edges by hovering over the element with the mouse tip.

3. Visualizing the Graph

The ability to visualize the network in the form of a graph, which encompasses vertices and edges, serves a multitude of purposes. These include validating the graph construction algorithms by thorough visual inspection of the outcome, uncovering errors & inconsistencies where they may appear, and supporting use cases related to troubleshooting network issues by layering key telemetry data on top of the basic topological view. There exists a host of libraries for the purpose of graph visualization—both in the form of stand-alone proprietary software as well as open-source packages that integrate with Data Science programming language such as R and Python. For this analysis, the R packages *tidygraph* and *ggraph* were adopted for creating graph visuals. They both follow the data principles established by the popular *tidyverse* family of R packages used for data wrangling and visualization [2], thus, allowing enrichment of the graph data with ease.

The graph database at Comcast establishes relationships that span thousands of CMTSs, hundreds of thousands of optical nodes, and millions of households. For visualization purposes, the task is limited to producing a visual for a very small subset of the full network at a time and on demand. Typically, the interest is in plotting the tree-like structure that connects devices to the same fiber optics node (also referred to as a busleg/port on a node clamshell). The pathway from the device to the node includes elements such as amplifiers, passives, taps, and drops. This view is very relevant to troubleshooting of access network problems because issues originating in elements under a node may impact multiple

customers (this is especially true in the upstream direction in which noise is known to funnel). In contrast, customers connected to different nodes are usually isolated from each other. Figure 3 shows an example of a graph visual for a single node. The power of the graph is manifested in its ability to combine physical elements and logical elements in the same view. For example, the customer's billing address (shown as black square) is included in the graph and hierarchically positioned between the drop and the cable modem (tree leaf). Notice that some customers have multiple cable modems under the same billing address. These include the household internet gateway and one or multiple DOCSIS video set-top boxes.

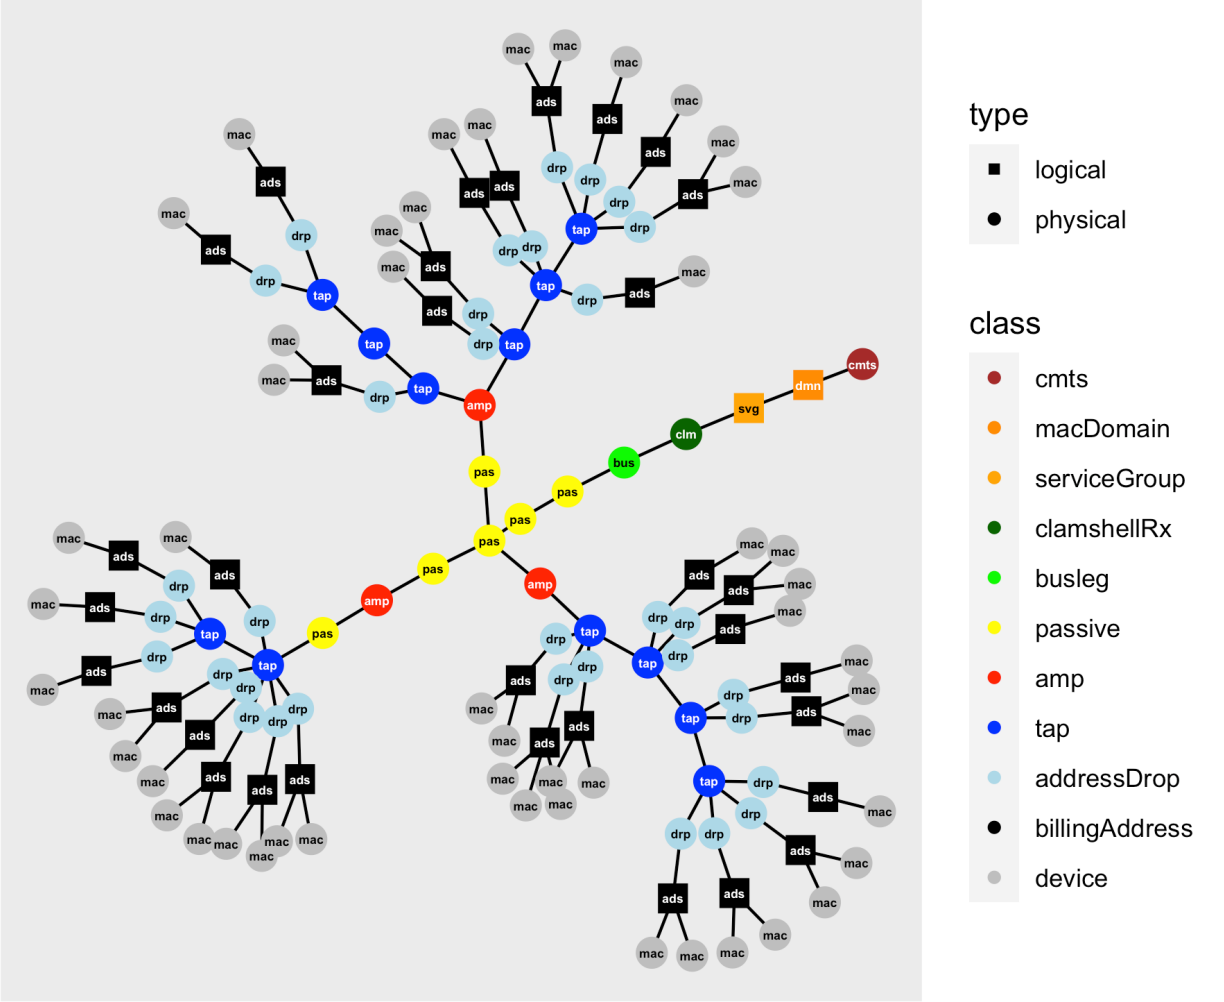

Figure 3 - Example of a basic graph visual for a relatively small size node. The tree trunk (brown circle) corresponds to the CMTS, and the leaves (gray circles) correspond to the cable modems/IP devices. The pathway connecting the two traverses multiple physical and logical elements as shown here.

Figure 3 represents a basic view of the graph that can be enriched in many ways. A few illustrative examples are considered henceforth. In the first example, shown in Figure 4, the thickness of the edge is utilized to designate the traffic volume as measured by the number of devices that transmit/receive traffic through that link. In the same figure, the number of devices is also annotated on the graph vertices. Alternatively, the weights can be easily adjusted to correspond to actual traffic volume rather than number of connected devices.

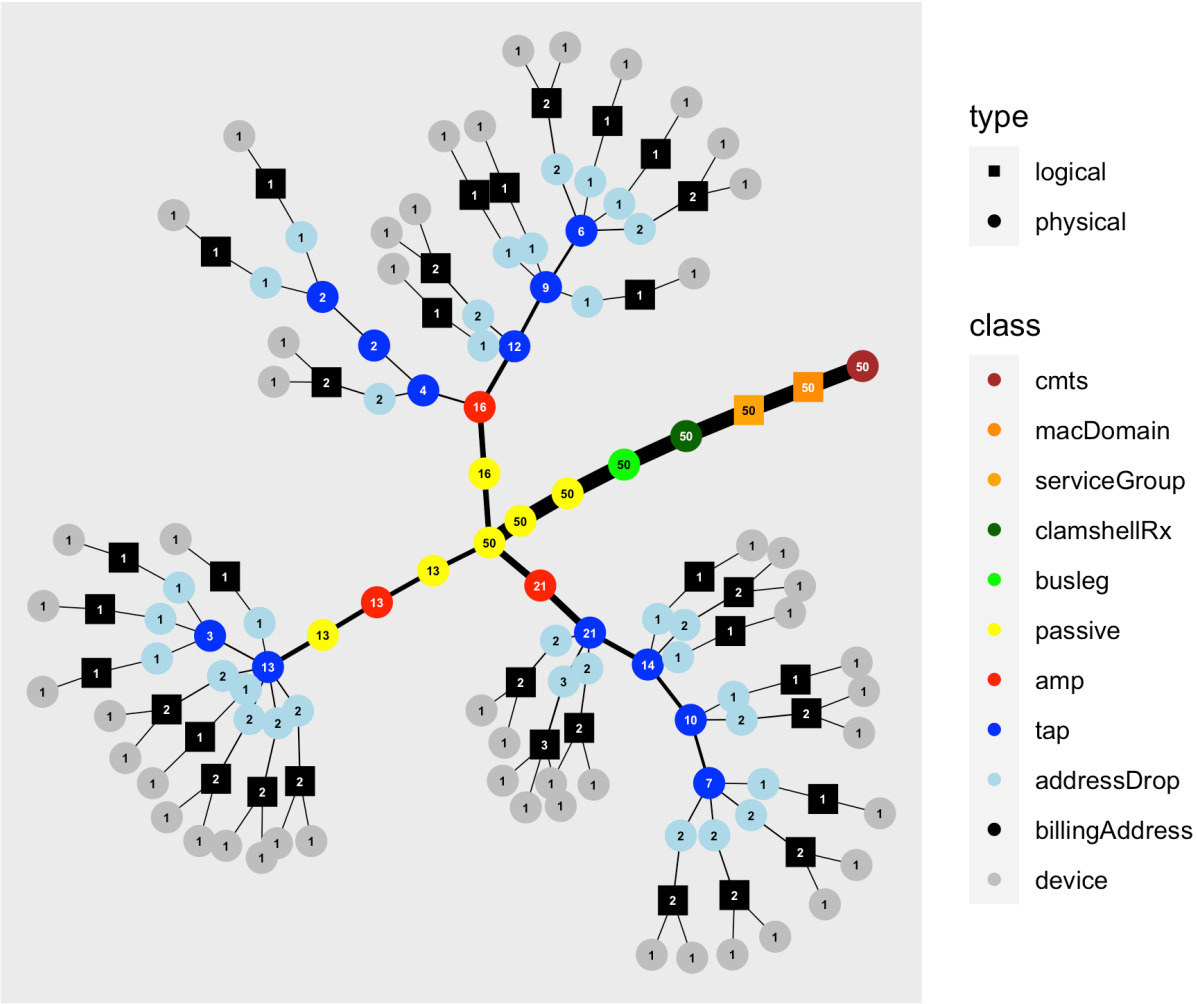

Figure 4 - Example of graph visual in which the thickness of the link (edge) is weighted by number of cable modems connected through the link. The label on each vertex represents the total number of cable modems that are hierarchically located underneath the vertex.

The example shown in Figure 5 overlays telemetry data onto the topological view. In this example, the US device-level SNR is coded as the color of the device symbol. Such view is useful for visual identification of "hot spots". These could be a cluster of devices suffering from the same impairment and in which the graph visual provides a clue to the problem root cause.

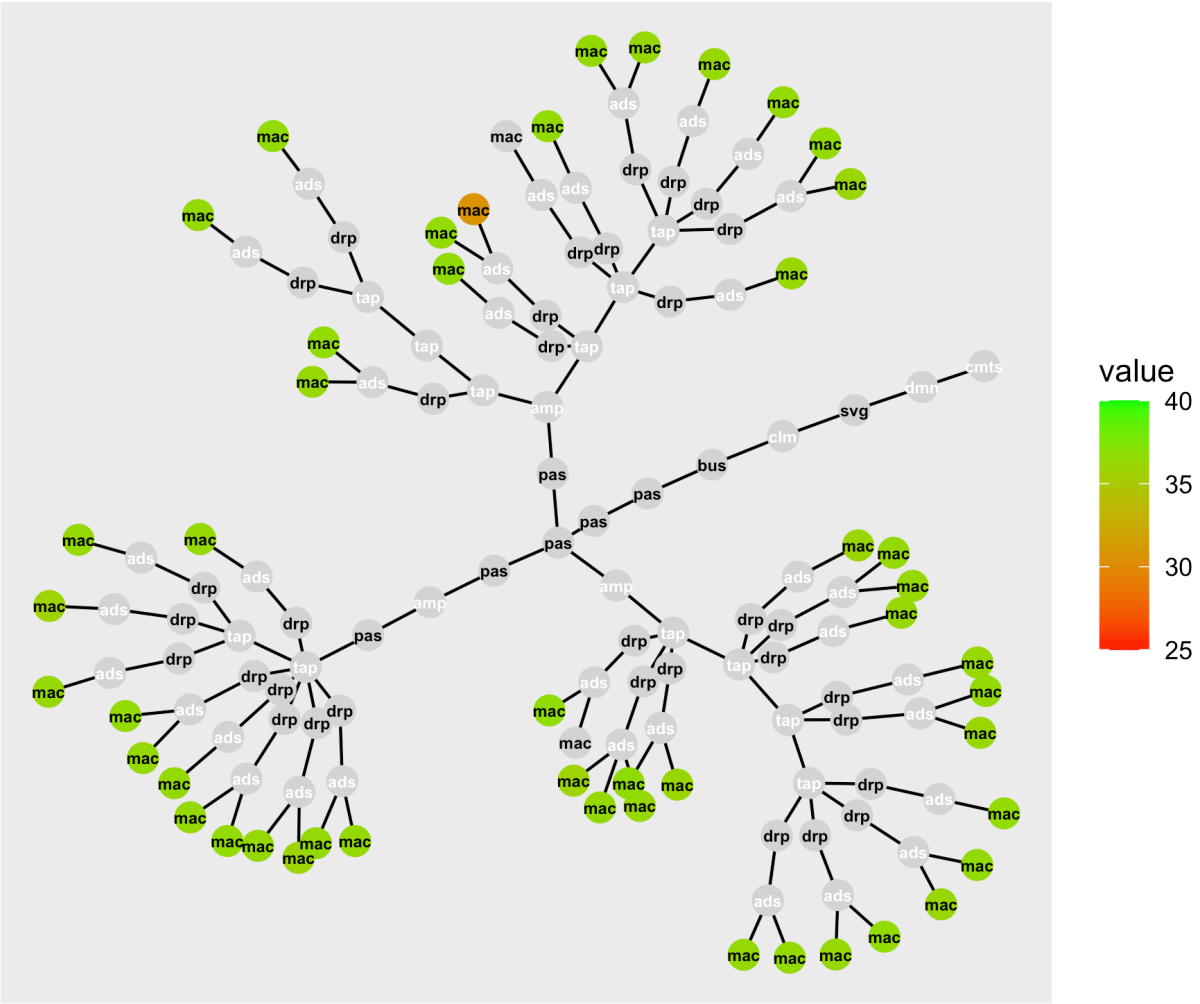

Figure 5 - Example of a graph visual in which the color of the cable modem symbol indicates the upstream SNR on the 25-to-40 dB scale shown in the adjacent color bar. The one cable modem colored gray had missing telemetry data for that polling time sample.

4. Amplifier Cascade Length Analysis

A question that arises frequently in discussions around network design best practices is the impact on the customer experience of a large cascade of amplifiers. From an RF design perspective, it is accepted that amplifiers introduce distortions to the signal—there is no such thing as an "ideal amplifier". Albeit there is an implicit assumption that distortions are tolerated if they are deemed to be within an acceptable design range. However, the reality is that network growth is dictated by customer demand and geography, and often deviates from original plans, causing limitations on node size to be exceeded. In this context, no hard written rule exists on the maximum allowable amplifier cascade length. Furthermore, there is no straightforward approach to quantifying the impact of the amplifier cascade length on customer experience. In fact, examining this question was the very first use case of the network graph database.

The analysis dataset contains the ~20% of our footprint's CMTSs that are fully captured in the graph database at the time of writing this paper (summer of 2021.) The basic idea behind the analysis is to correlate the node size with key telemetry data and explore this relationship in depth. The very first task within the analysis requires defining what is meant by "node size" in relation to the RF amplifiers. It was decided to explore the following two features:

- **Amplifier cascade length**: This is a device-level feature that represents the total number of amplifiers traversed in the path between a cable modem and the node (see Figure 6).
- **Total number of amplifiers**: This is a node-level feature that represents the count of all amplifiers within the node.

The rationale behind the choice of cascade length and total amplifier count was to accommodate the different noise accumulation behaviors between downstream and upstream paths. In the downstream, noise does not funnel between devices. Therefore, what matters from a distortion perspective is the number of amplifiers in a device's path. Whereas in the upstream, noise funneling causes all amplifiers to potentially contribute to the distortion for any given device in the node.

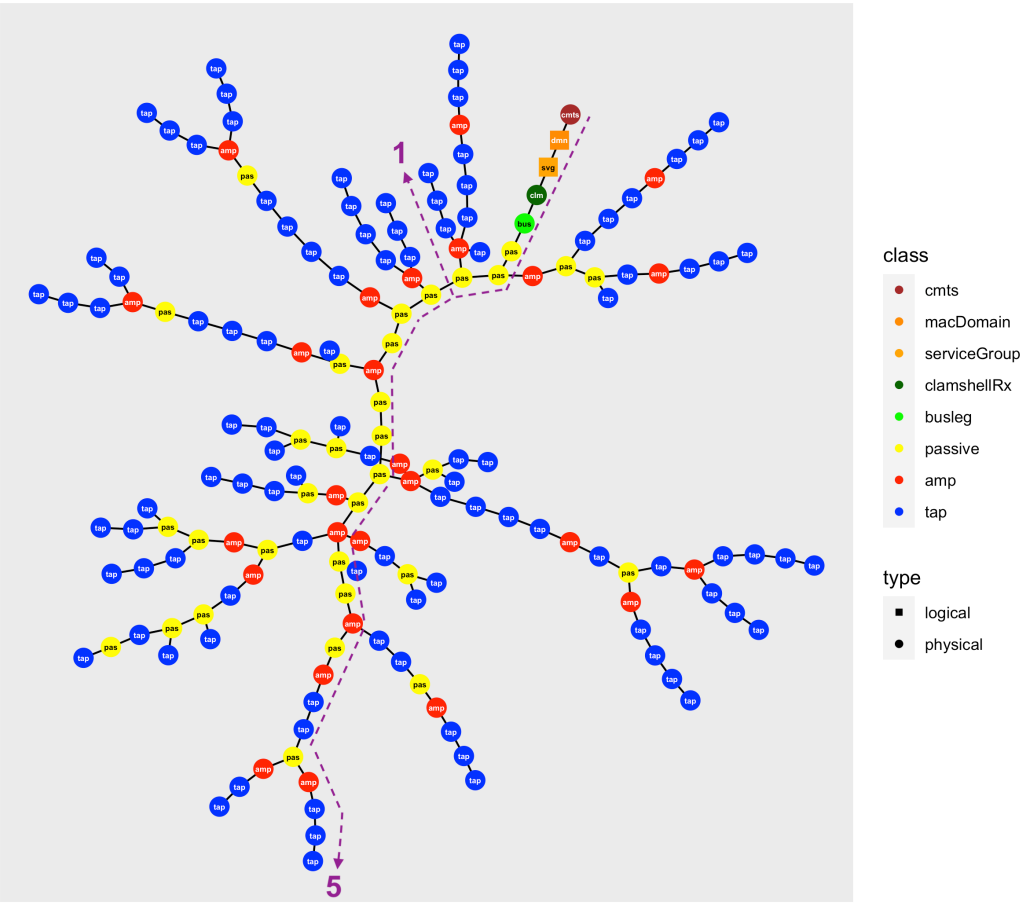

Figure 6 - Visual example of a large node in which devices, billing addresses, and drops were removed for clarity. Two paths from CMTS to tap are highlighted in purple. One path traverses a single amplifier and the other traverses 5 amplifiers. Devices attached to the latter are expected to experience larger amplifier distortions in the downstream path.

Figure 7 shows the distribution of the two features across the ~20% of CMTSs mapped in the graph database. The amplifier cascade length distribution is unimodal with a peak at 2, meaning that the majority of devices connect to the node via a cascade of 2 amplifiers. The distribution in the figure was intentionally cut off at 10, even though the data contains outliers with cascade lengths that exceed this value. The total amplifier distribution has a peak at 1 and gradually diminishes at ~40 amplifiers. It may be surprising to see ~3000 nodes served by a single amplifier. These are small size nodes in terms of either the number of customers or the geographical extent of the node (or both).

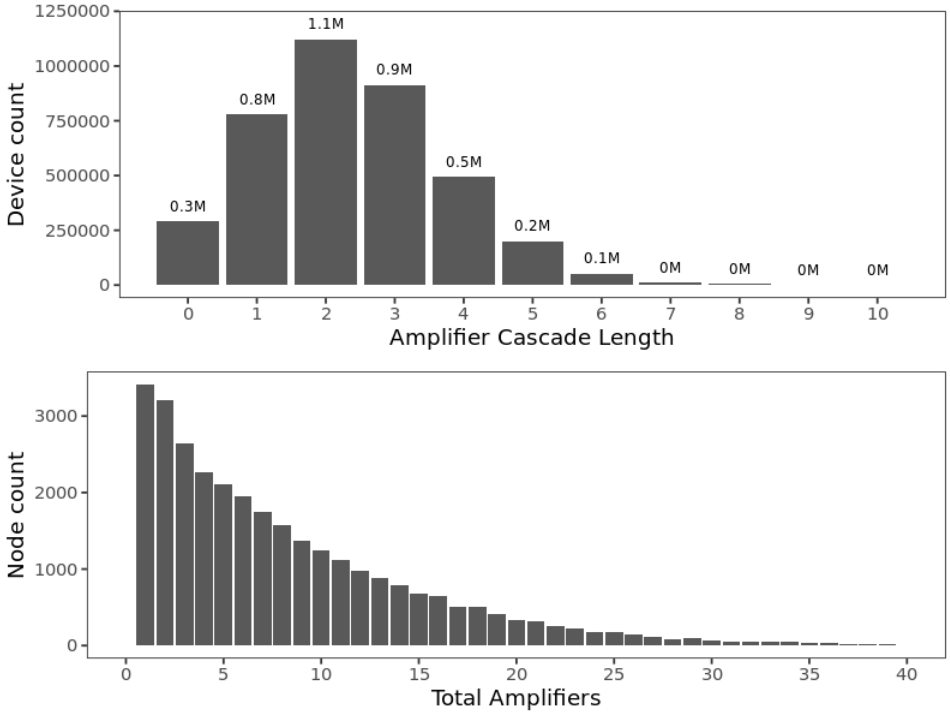

Figure 7 - Distribution of amplifier cascade length across devices (top panel) and distribution of total number of amplifiers across nodes (bottom panel). This data was generated by querying the graph database.

With the features derived from the graph database extracted, the next step involved identifying and examining telemetry data in relation to the graph features. The following variables were considered in the analysis:

- **Upstream Signal-to-Noise Ratio (US SNR)**: 10th percentile of a device's upstream SNR samples (i.e., data is collected from multiple time polls and aggregated)
- **Upstream Forward Error Correction (US FEC)**: The percentage of time a device polled when transmitting upstream experiences an uncorrectable codeword error rate > 0
- **Upstream Partial Service**: The percentage of time a polled device goes into partial service with respect to an US channel
- **Upstream Power**: mean device power level
- **Downstream Receive Modulation Error Ratio (RxMER)**: A device's OFDM channel RxMER samples (data resolution by 50 KHz subcarrier)

The correlations between graph features and the variables above were explored and are shown in Table 1. One glaring outcome was the lack of a correlation between graph features and the FEC metric. The

absence of correlation with FEC is attributed to the mitigating effect of Comcast's Profile Management Application (PMA). PMA was deployed for both DS D3.1 (OFDM) and US D3.0 since early 2020 [3,4]. Under PMA, channels that exhibit degraded spectrum get assigned a configuration that ensures that devices continue to use the spectrum without experiencing unacceptable levels of uncorrectable errors. While the algorithms are quite different between PMA for DS D3.1 vs. US D3.0, the result is the same: for those degraded channels, capacity is traded off for robustness. Hence, the lack of correlation is an assuring sign that PMA is doing its intended job.

Table 1 - Correlations between the node features and device telemetry.

	US SNR	**US Rx Power**	**US FEC**	**US Partial Service**	**DS OFDM MER**
Amplifier Cascade Length	-0.04	0.03	0.01	0.00	-0.12
Total Amplifiers	-0.05	0.04	0.02	0.01	-0.07

The strongest correlation exists between amplifier cascade length and OFDM RxMER. In Figure 8, two views supporting this trend are presented. The first shows different aggregating RxMER percentiles vs. amplifier cascade length. In all of these, there exists a trend of decreasing RxMER with increasing amplifier cascade length. Trend lines are included in the plot, which one can use to estimate an effect of ~2 dB for every 10 amplifiers added to the path (a more proper calculation, based on regression model, is presented below). The second view shows the distribution of modulation assigned to each subcarrier based on the standard D3.1 RxMER-to-modulation mapping for DS [5]. In this view, no aggregation is done as every subcarrier contributes to the distribution. Once again, there's a clear effect that is most visible in the diminishing proportion of 4096-QAM as the amplifier cascade length increases.

A question that remains is to quantify the effect of this relationship on customer experience. Given that PMA is mitigating the impact of low RxMER by dynamically managing OFDM profiles, we restrict the definition of "customer experience" to the "capacity" dimension. Below, a model is introduced that quantifies the impact of the amplifier cascade length on available capacity. In the first step, a linear regression model is fitted to that RxMER data as presented in Figure 9. The linear model yields a statistically significant relationship (with a p-value $< 2 \times 10^{-16}$) between RxMER and the amplifier cascade length. The relationship is outlined in the following equation:

$$\text{RxMER} = 37.7\ \text{dB} - 0.37 N_{Amps}\ , \tag{1}$$

in which N_{Amps} is the length of the cascade. In other words, every additional 10 amplifiers reduce RxMER, on average, by 3.7 dB.

An interesting feature of the overall distribution of RxMER is that the 38 dB line falls through the middle of the distribution (notice that the linear fit intercept is 37.7 dB). This level happens to be the PMA threshold for assigning a modulation of 4096-QAM, the highest possible under the current vendor implementation of D3.1. The threshold was deliberately set to be 3 dB lower than the recommended value under the D3.1 specification [5] (i.e., it is more aggressive). This means that for more than half the population (at and below this level), reduction in SNR due to increasing amplifier cascade length may

cause demotion to lower modulations. Indeed, this explanation agrees with the trend shown in the lower panel of Figure 8.

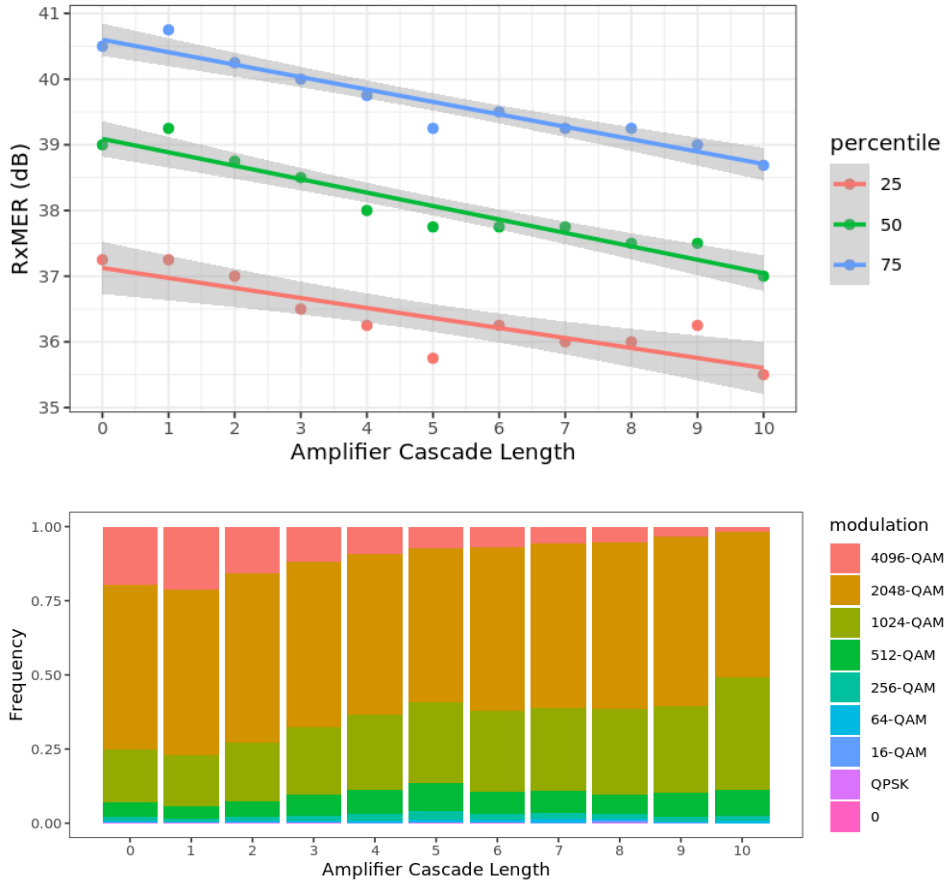

Figure 8 - The top panel shows the relationship between RxMER and amplifier cascade length for different aggregating percentiles (25th, 50th, and 75th). There's a clear downward trend, as highlighted by the linear best-of-fit lines. The bottom panel shows the corresponding modulation distribution. Once again, the trend is visible by the decreasing ratio of 4096-QAM as the amplifier cascade length increases.

To translate the results from the linear model into a capacity impact figure-of-merit, we turn to the Shannon capacity theorem [7]. In a previous SCTE contribution [3,4], we argued that D3.1, with its low-density parity check (LDPC) error correction algorithm, operates close to the Shannon limit. The Shannon theorem can be approximated in the large SNR regime as follows:

$$C \approx 0.332 \cdot B \cdot \mathrm{SNR(dB)}\,, \tag{2}$$

where C is capacity, B is bandwidth, and SNR is measured in dB. The derivative of the equation above yields:

$$\Delta C \approx 0.332 \cdot B \cdot \Delta\mathrm{SNR(dB)}\,, \tag{3}$$

which provides a recipe for translating small changes in SNR to changes in capacity. Based on the above, for a standard 96 MHz wide OFDM channel, the results from the linear model translate into ~118 Mbps reduction in capacity for every 10 amplifiers traversed in the node-to-device DS path.

As demonstrated in this analysis, the effect is measurable and statistically significant. However, it is not impactful in the context of DS capacity for several reasons. First, the 10 amplifiers represent the upper bound of the distribution, i.e., this is an extreme scenario, as the bulk of the population falls below a cascade length of 5 amplifiers. Second, the spread in RxMER values within each "bucket" is much wider than the effect of increasing cascade length. This implies that there are other pressing issues one can solve before turning attention to cascade lengths. Third, even with loss of ~100 Mbps of capacity, D3.1-capable devices have access to sufficient D3.0 and D3.1 spectrum to support our highest speed tiers.

The same analysis was conducted for the US, exploring the relationship between US SNR and the total number of amplifiers in the node. Once again, the linear regression model shown in Figure 10 reveals a statistically significant relationship. However, the effect of increasing the number of amplifiers is even less impactful on customers compared to the DS, because of the large safety net that is intrinsic to a D3.0 US: while the highest possible modulation under D3.0 US is 64-QAM, the distribution of SNR lies ~10 dB above that level.

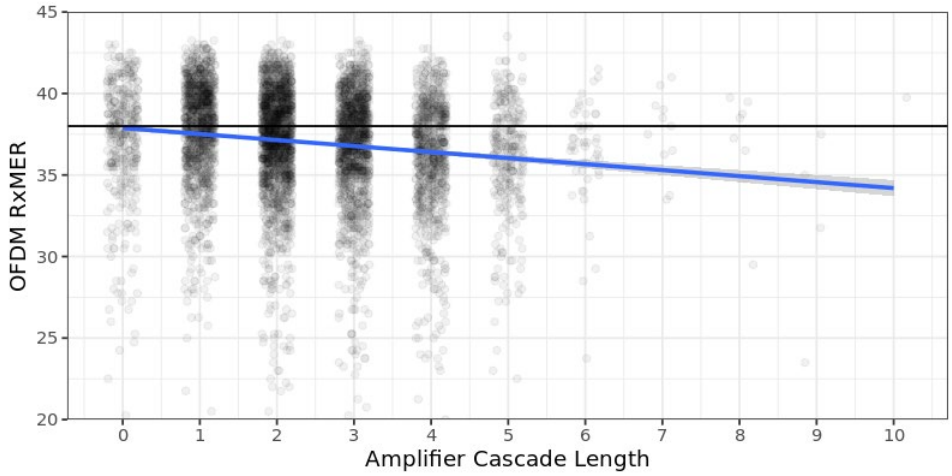

Figure 9 - Linear Fit to the RxMER vs. amplifier cascade length data (blue line with gray confidence band). The horizontal black line, at 38 dB, is the current threshold in PMA for assigning a 4096-QAM modulation.

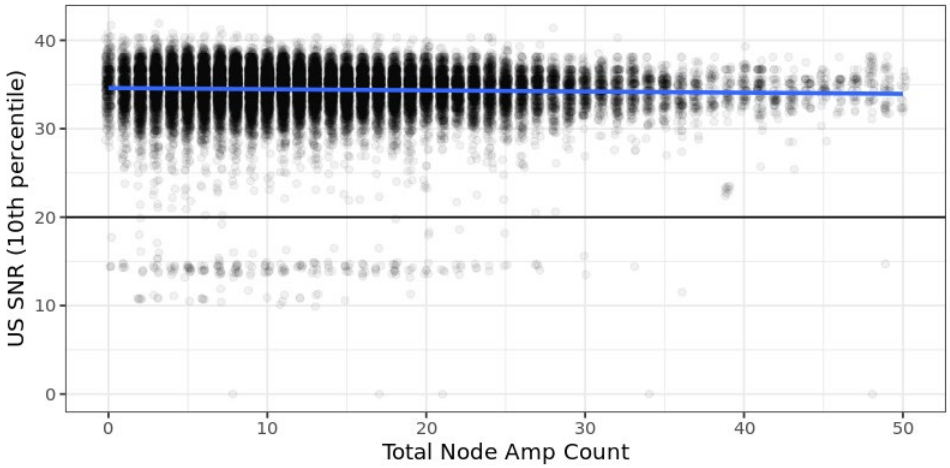

Figure 10 - Linear Fit to the US SNR vs. total number of amplifiers (blue line with gray confidence band). The horizontal black line at ~20 dB is the current threshold in PMA for assigning a 64-QAM modulation.

5. Conclusion

This paper highlights the power of the graph database in getting a better understanding of our network, and especially to track all physical and logical elements within the network. Using the relevant information, we were able to analyze and measure the impact of the amplifier cascade length on RF performance. The outcome was in the form of guidance on the effect of increased cascade length on capacity. While the impact on customers is assessed to be minimal today, future evolution of the network will bring service offerings that push the physical bandwidth to its limit (e.g., symmetrical Gbps service). These developments will make it critical to have a thorough understanding of the impact of network topology on customer experience—beyond the particular "amplifier cascade length" feature.

The graph database is being scaled up to cover our entire service footprint. In addition to the use case presented in this paper, there is much excitement about utilizing the graph database to build algorithms for root cause analysis and noise triangulation. These examples constitute a "holy grail" for us and the industry, as they promise to significantly cut down the labor-intensive troubleshooting processes involved in locating sources of noise/ingress. Given that machine learning techniques that utilize graph data representation exist today and are mature enough to support the intended use cases, the remaining bottleneck to conquer is to complete the construction and maintenance of the high-quality graph database presented in this paper.

How To Not Pop the Balloons —

Migrating The Analog Headend for The Digital Broadband Future Facility

A Technical Paper prepared for SCTE by

Benjamin Strunk
Senior Director – Power and Infrastructure
Comcast Cable – Northeast Division
1131 South Duke Street Lancaster Pa 17601

Benjamin_Strunk@comcast.com

1. Introduction

The transformation of the legacy broadband buildings into Broadband Digital Nexus (BDN) structures that enable the digital connections to millions of people and businesses daily, is at a crossroads. At a fast-approaching time horizon, all legacy analog sites will need to change from housing an analog-facing technology to a digital infrastructure. These structures will gain more useful life in the cable broadband ecosystem. This paper will show in detail the transformative steps achievable in hundreds of locations simultaneously or individually. All these steps can be accomplished while maintaining a limited or negative amount of critical infrastructure equipment. When comparing energy consumed in an analog facility versus a digital facility, the initial data is showing an energy reduction of 200%. Coupling these transformations to adopting sustainable building technics and energy reduction options, the space and power of Broadband Digital Nexus structures is presenting opportunities hidden within physical constrictions setting operators up for rapid growth and digital transformations in the field.

2. Pump up the Volume

To understand the start of the Community Cable Television Antenna (CCTA) systems, we should look back into the ways of the telephone. The switching phone equipment and operator system needed to be housed within a structure. It sounds obvious today, but think about what that required for the telephone and telegraph systems. Engineers needed to evaluate and string telephone wires along with the power conductors of the time. The brick and block buildings that housed this function made possible the birth of the telephony exchange or Central Office (CO). These simple repeatable structures also were built for vertical expansion. Countless buildings were built on a first floor and then an expansion to a second floor and upwards. The telephony buildings were, in fact, the beginnings of the world's internet.

As the usage of the Bell and ATT telephony systems grew, the physical network equipment in the COs were forced to accommodate these new switches. These digital exchange switches were classified as Class 5 switches. These switches came in a vast variety. There was the Bell Technology Lucent 5ESS. The General Telephone Equipment GTD5. Siemens even had their own version I called the Brown Monster. All these large main frame switches ushered in the dawn of the electronic switching age. With the scope, growth and size of these switches, many telephony buildings needed a way to provide energy backup and 24/7 operations. The solutions were the adoption and full usage of DC batteries and power conversion units provided by AC to DC conversion systems. This architecture enabled the telephone powered network. This powering system allowed for the uninterruptable services that society began to rely on for communication, comfort, and business.

As we follow the communication timeline to the 50s, we have the start of the satellite age with the launch of Sputnik and the broad licensing of over the air broadcast television. Amplified Modulation and Frequency Modulation. The world at this time was "wired" for power and telephone and "wireless" for entertainment/news. Communication infrastructure is poised to get another player into the content and via for eyeball time of the population. This brings us to the need for video infrastructure.

The video ingest of the time was via an antenna. The tower would have multiple antennas attached facing a tuned direction to pick up the broadcaster's signals. These signals were then received and attached to the coaxial cable within the building. Encoders and other devices allowed the RF signals to be embedded and modulated upon the coax and to leave the building. The stringing of the coax cables to the subscriber base enabled the community part of the cable systems to fledge. The

greater the height of the tower, the better the signal or more signals were able to be received. More receive signals means more channels and more equipment needing space in the buildings.

Figure 1: Image of CATV headend-image by author – circa 03/2016

3. Cup…..String….Cup

The available bandwidth on the coaxial cable was being utilized to its known capability. The MegaHertz signals were determined by the thickness of the coaxial cable, distance between amplifiers and pure decibel signal loss over the distance to the customers. The invention and applications for fiber optical cable allows for the manufacturing and production of radio frequency nodes to be connected into the field. These nodes allowed for the usage of Headend-located transmitters, situated into equipment cabinets. These transmitters received a RF signal over coax and converted the signals to analog optical light that would be transmitted along the glass until it landed at an RF node in the field. At the receiver housed within the field node, the receiver injected the optical analog signal and converted the light amplitudes back to a radio frequency to be embedded upon the RF coax cable to be run down past the homes it was going to serve. This "Cup-String-Cup" methodology allowed the distance of unpowered optical plant to stretch for kilometers. The longer the distance achievable by the lasers, the closer the node could be placed to the end customer.

The lasers began as large form factor units, sized at approximately 6 Rack Units (RUs) per transmitter or receiver. With a standard rack being 19" wide, that's a transmitter-to-receiver density of approx. 3500 cubic inches (19w x 10.5" tall X 18" deep). Given the usage of the transmitter, receivers and the adoption of combining on the RF forward and the RF return decombining… the spatial needs of the headend started to move into not just active equipment, but a new category of passive equipment. The need for passive equipment driven by cost savings, testing necessity, and optimization.

Cost savings on the transmitters happened with the adoption of service groups. Take 1 Transmitter and split it to feed 2 or 3 or 4 field nodes. This service group allows the cost (transmitter) to be distributed

into the field connecting to multiple nodes. In this application, the transmitters will still communicate, but their power output needs to be modified. These headend amps will take an input power level and increase it to optimize the dB receive signal in the field.

Every node still needs to transmit the upstream data and information to the headend. The new 2-way communication require new devices to be placed within the Headend. The receiver allows for the receipt of the signal, and new decombining equipment allows for the separation of the return signal. The receive signals are broken down for multiple applications: Conditional Access for video authentication; signal maintenance by the outside plant teams and communication to the cable modem termination station (CMTS). So, when we look at the new spatial needs for these analog touching devices, the Headend space is rapidly being consumed at only the third generation of Headend equipment -- generation 1 equipment being simple receiver and encoders; generation 2 equipment being 300 MHz systems operating with conditional access equipment that controlled the set top boxes, which ensured that only the video programming purchased was made available for consumption. Generation 3 equipment is true bi-directional communication between the Headend equipment and the customer premise equipment (CPE).

If you were keeping count so far, we have:

Table 1: Video Analog Equipment

Receivers	Encoders	Transmitters	Receivers
Signal testing equip	Controllers	Amplifiers	Signal Combining
Signal Decombining	Test ports	EAS equipment	

All the above equipment works as a homogeneous group of standalone equipment needed to send 1 defined signal down the coax line to the homes.

We are approaching a situation where power to these devices is critical. Two developments within the electronic space are driving to what is being called clean power and/or conditioned power. The electronics have more and more solid-state components needing a clean and uninterruptible sine wave to bridge the gaps on an alternating cycle. The original equipment handled the under-voltage section of the sine wave by embedded capacitors that would hold the electrical current charge to the device for the other ½ cycle. The adoption of the Alternating Current Uninterruptable Power System (UPS) would allow for not only the conditioned, clean power but also the opportunity for backup power. The UPS systems are currently a simple dual power conversion unit that takes AC power in. Rectifies the power and allows some of the energy to be stored within batteries. The System then takes the direct current energy and feeds it into an inverter system. The output of the converter system them passes out of the unit and feeds into the Headend electrical outlets to power the headend signal generating equipment. But everything comes at a cost. The space needs for the UPS would take up rack space or floor space. For a typical 22kva UPS, you could or would lose about 2 racks of space within the equipment 4 walls of the Headend.

With the wide usage of UPS systems taking hold within the industry, there is another push to protect the UPS system. This came with the adoption of on-site power generators and Automatic Transfer Switches (ATS). The ATS serves as a large power selector switch. During 99% of the operation of the building, the Utility power grid provides the power to the building. For the 1% of the time when the utility power company cannot provide power to the building, a signal is sent to the generator to start. The ATS then sees a reliable voltage on source 2 emergency input to the switch. The ATS will then select the generator

voltage over the lack or no voltage coming from the power utility. This transfer from utility failure to Generator start and transfer is usually less than 12 seconds.

The physical nature of the ATS is that it is a basic electrical component. It is placed within a UL listed enclosure based on its size and configuration. Typical for this time within the history of cable, the units are wall mounted and typically less than 12 inches in depth. Since these unit are not on the floor, we have some level of relief from losing rack space. However, since the access to the unit is front hinged door, we have the need to leave what is called a safe working border to the front of the unit. This will typically require 36” of free access space from a grounded location. The ATS can be placed outside the building on a concrete slab or a wall mount location at the desire of the engineering agent. This spatial offload allows for some space relief within the building but comes at a cost of reliability and capabilities. We want to always strive to keep this equipment within the conditioned space of a building.

4. Can I phone a Friend

Bidirectional communication between a customer and the communication facility begins to usher in the age of coaxial cable television voice or Voice over IP (VoIP). This meant that, unknown to the customer at the time, their experience at home was tied directly to the successful operation of the building supporting the services. The functionality of the legacy CO joined the video content delivery subscription services of the time: The voice over internet opportunity needed space in the Headend.

Voice over Internet Protocol was the third leg of the triple play stool pitched by many cable operators. The equipment in the headend was identical to the voice soft switches that began to replace the legacy Mainframe Class 5 switches of the CO. The advancements of the CPE equipment to be able to inject a common telephony phone input and ring service output connected the equipment platforms in the homes. The other end of the wire at the Headend removed the voice modulation signals from the RF carriers and sent the signals out to the world telephony network.

This advancement was not without difficulty. This new internet-based voice system was built commonly as a modernization effort for the big phone companies, that have been operating on a 48v platform of power for the network/telephony equipment for scores of years. This legacy power platform is rigid, hardened by years of OEM investments and backup systems that would cause a massive shift in facility architecture and mindsets of the Cable TV Facility Engineers. The video side of content was content with the platform being supported by only utility voltage (120v). With the onboarding of a UPS, the equipment was still predominantly AC powered. So emerged equipment co-habitation issues, with specifically different powering needs. Would the equipment be AC powered or DC powered?

Figure 2: An analog-only two-way Headend. Image by Author. Circa 12/2018

5. Rock, Paper, Scissors.

In that timeframe, the battle for power supremacy was fought on a square foot by square foot basis. The telephony camp was locked-in on the operation of the power input to the power supplies to be 48v nominal. This allowed for the most typical and standard power supplies available to be procured with the telephony devices. The uptime argument between the cable TV guys and the Telephony Central Office guys entered the regulated space in the Code of Federal Regulations (CFR)47. If the companies entering the telephony service provider space wanted to compete and market a reliable, capable, and cheaper service than the legacy land line carriers, they had to prove a reliable and available network. The answer: Cable companies would use the same equipment as the telephone carriers. DC powered equipment backed up by batteries for 4 hours and generators for 24 hours. The OEMs continued to provide DC power supplies to make the power delivery reliable and enable the headend to run under multiple failure conditions -- first, a failure of utility power; second, a failure of the utility generator. Operational survivability on batteries via direct current power to the network devices.

With the supportive adoption of the DC power input to critical network routers, optical transport nodes and by default the CMTSs that communicate with the cable modems in the home. With the supportive adoption of the DC power input to critical network equipment, the stage is set to run and operate (2) independent power delivery systems to the multiple devices within a headend space. The adoption of telecom grade 2 volt batteries would also drive a rapid consumption of network-required space allocation.

At the worst, I have seen where the power and batteries needed to deliver back up energy and distribution to the network consumed as much space as the network equipment. In completing over 8 years of planning for the space and power within the headend, indications are that spatial consumption distribution from a per sq foot perspective leaves only about 40% of the total under roof space available to the network engineers to populate revenue generating equipment. Chewing through more footprint for multiple power providing equipment would only continue to diminish the spatial ratio.

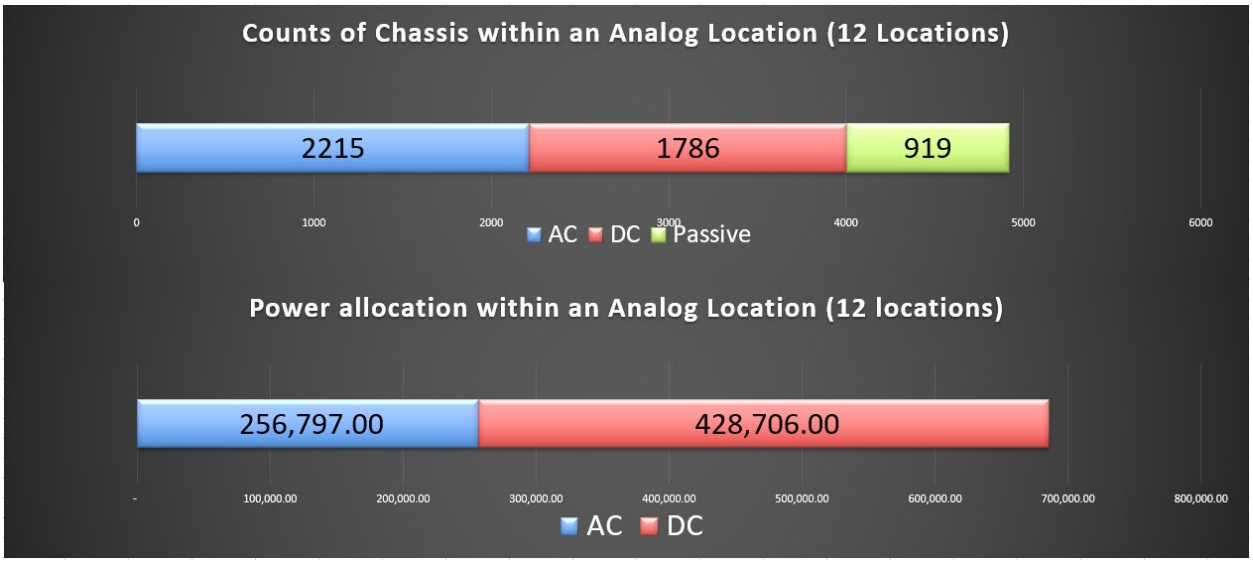

Figure 3: AC vs DC energy consumption relative to RUs consumed

6. "I Want It Now"

With the enhancements of the cable spectrum and capabilities, the industry was able to launch video on demand as a service. This service required the adoption of something within the headend not typically used… Servers. Servers allowed for the VOD content to be stored as close to the customer location as we could get based on needs and caching library. The server farms were typically located within the datacenters of the blossoming Internet world. The easiest ways to get a lot of content to the masses of people was to centralize the content and release the content when requested by the user. This would require massive transport builds from locations spread out across the nation. Over time and the adoption of Video on Demand (VOD), the scalability of the transport networks showed a level of weakness. This weakness was only resolved by placing local content caching as close to the packet build of the time. This location was called the headend. Eventually, the thoughts of putting servers everywhere were scaled back to placing it in a multi transport hop location so that multiple local edge sites can grab the content from 1 hop or two. Terabits of storage at this point was being located as close to the customer as possible to support VOD and the fledging over the stop streaming services content.

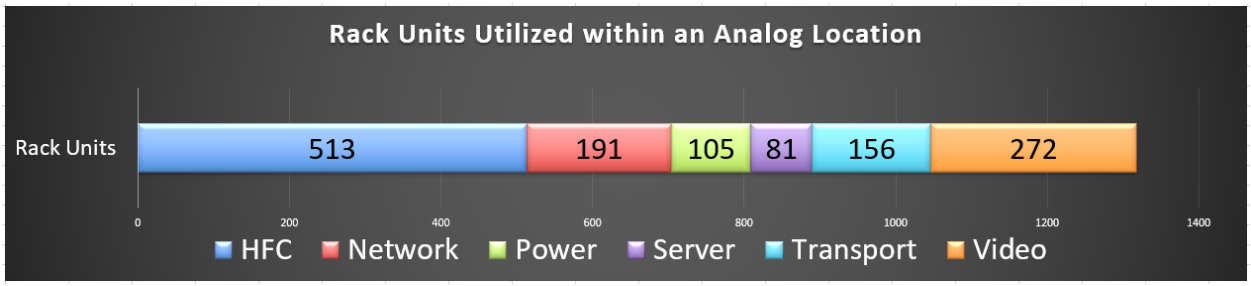

Figure 4: Rack unit allocation within 1 headend

The headend was almost at the peak of physical loading the in the early 2010s, but there was still a growing customer base needing fiber optic connections and speed tier offerings. Small, Medium and Enterprise businesses were growing rapidly. This rapid opportunity for revenue was based on the premise of providing a direct fiber connection to a place of business. This Metro-ethernet connection afforded customers the opportunity to choose a path of speed they could choose to fund. These full fiber connections required a multitude of new equipment to also be located within the Headend. These were also the most robust, largest, power hungry and feature rich devices companies could engineer and code. As more and more of these customers loaded up on the boxes, services and support needs also grew at the physical layer to supplement what was provided at the customer locations accompanying virtual command and control. These enterprise scale routers, with the drive for redundancy, stretched the footprint consumption within the smaller Headend to the point of costly expansions, utility upgrades hampered by abandoned technology not ready to go to the grave.

7. If The Shoe does not Fit…Stretch the Shoe

For those keeping track, we are now at the below list of items and services within the small cable TV building at the top of the hill:

Table 2: Active Equipment Groups in an Analog Headend

Receivers	Encoders	Transmitters	Servers
Signal testing equip	Controllers	Amplifiers	Signal Combining
Signal Decombining	Test ports/gear	EAS equipment	UPS
Routers	DC Power Plants	Batteries	Battery Distribution
Commercial Edge Gateways	MetroE Switch	OLT	VOD QAM chassis
Linear Video Edge Qams	Fiber Muxes	Optical Panels	Pilot Carrier equipment

The buildings were at a max capacity, providing most of all traffic via analog linear video spectrum, with a minor amount (one to two 6 MHz channels) of HSD digital spectrum.

The advent and adoption of the virtual cable modem termination station (vCMTS) and the potential to generate RF quadrature amplitude modulation (QAMs) at the node has opened a new world. This ability of sending 0s and 1s to the node and for the node to change digital into RF signals to extend the useable life of the existing RF plant will drive even more equipment into analog buildings as they move to be Digital Broadband Nexus structures.

The vCMTS is made up of many different components likened to the "medusa" boxes of the legacy VOD-connected CMTS. Eventually, the medusa boxes collapsed into a converged cable aggregation platform (CCAP). There are two key items to the new vCMTS. Routing and video…. Sounds like the entire buildings of the 1990s. The difference is that this new vCMTS platform is function built for the digital world. For the bargain price of servers, layer 1 switches, and a robust routing table and chip set, the first part of the vCMTS will allow the sites to send broadband digital traffic to and from the cable modems. The second part of the platform is the video generation units. This is a must carry due to the legacy needs of the existing customer base, the customers who are on a legacy RF only tuning set top boxes that are still on network. The adoption of an IP only set top was not universally given nor forced to the customers. The business decision to continue allowing analog devices in the home will maintain a legacy of analog equipment base operating withing the headend that would inevitably need to move to the RF strand or leave the home.

8. Now Boarding At Central Station

We have the base platform needed to accommodate the digital goodness in the HE and the nodes in the field with the capability of the remote physical layer conversion (RPHY). Where do we place all this equipment? This raises two additional questions that are repeatedly is addressed by CEOs and CTOs across the industry. Do we place all this equipment in one location, like a data center, or do we disperse it into the network like a neural feed to all the buildings, and keep the equipment at the edge?

Using the Centralization theory:

- Less infrastructure to maintain at a "five 9s or better" status
- Fewer locations to staff
- Fewer sites needing "big iron"
- Already probably exists with a heavy loading of fiber.

Using the Distributed theory:

- Smaller "blast radius"
- Shorter latency
- Cheaper Transport costs
- Already inhabited by legacy analog CMTSs

The platform architecture is the origination of the new digital packet train that transfers data from site A to Site K. In the physical layer, we have a laser or transmitter that will send a packet of information down the fiber pipe. This pipe has only 1 entrance and 1 exit. In the analog world, you could take a signal from the Master Headend and channelize the signal onto an analog transmitter. This allowed you to send this signal to multiple hubs. At these Hubs, more RF signals could be injected into the coax stream and allow for combining locally as needed. In the binary world of digital signals, packets need to be assembled at

the origin and be understood at the destination. The packet build can only occur at a vCMTS location. This will inevitably require a centralization effort of all legacy dispersed servers to cohabitate with the vCMTS. Pulling to a centralized location will eliminate the edge equipment located at the existing locations. This edge equipment we have identified above refers to mostly caching servers and edge VOD qam devices. These two items were needed in the legacy analog world to support the demand for less transport and more edge services. As the VOD QAMs also deprecate with the general adoption of IP content delivery, there is less need for edge linear video equipment. However, the product still needs to get to every customer. Pushing out would refer to the location and placement of the vCMTS into the edge locations. There are multiple benefits and detriments to address.

Pushing the vCMTS to the edge effects the operational efficiency of the vCMTS and the transport layer to support it. In the first assumption of decentralization, deployment and efficiency of equipment modernization will be key cost determining items. The assembly of the vCMTS is completed in a centralized location akin to an assembly line or production center. This assembled platform requires a level of assembly control through the physical build to configuration and onto deployment and original testing on network (OTON). Pre-configurations loaded for the end location will drive very tangible and cost savings opportunities. Speed to deployment, speed to growth, and value-added remote access from a centralized configuration support center. This will all require building to scale effectively with the nodes attached to the physical location. The existing and total node counts need to be reviewed before anyone can make a best utilization decision on vCMTS locations.

A vCMTS is connected to the node via a chip set on the server/ line card within the platform. A Hub may have 400 nodes. A HE may have 90 nodes. A master Headend may have 1000 nodes. We need to understand the math of the connections to validate the options for locational placement of the vCMTS. If your vCMTS is capable of 50 nodes to 200 nodes, the ideal location may be in the edge location. If the vCMTS is cable of supporting 200 to 500 nodes per cabinet, it would be better to centralize so the disbursement of compute would be efficient to the subtending Broadband Digital Structure (BDS)s.

9. The Slinky Effect

Do you remember as a child playing with a Slinky? Standing at the top of the stairs, starting a slinky, which by the forces of gravity and nature crawls down the stairs, much to our amazement. The other thing we did as young engineers, of course, was pull the slinky apart. Hopefully, you never pulled the slinky too far apart and then it would never compress back to original again. The effect of stretching a slinky too far is deformation. The spring never returns to an original dimension, and the original dimensions are never recovered. Stretching the cable network will have good and bad effects on the facilities. The optical limits of fiber and the effective usefulness of transmitters and receivers allow us to stretch digitally for 80 KM from the switch originating the packets to the node. This allows the facilities to range in homes served from a modest amount to a large amount based on the location and serving density.
