Space in a legacy analog site has (4) classifications: AC powered network equipment, DC powered network equipment, passive equipment, and non-functional units. In every facility, operators should understand the requirements and dependencies of these assets. AC powered equipment is anything that is powered from a UPS, inverter, or standard utility power. The power distribution to these locations typically is a power strip in the back of the cabinet or rack. No RUs within the cabinets are consumed by these power strips. DC powered equipment is from a fuse alarm panel (FAP)s/ Distribution Circuit Breaker Panel (DCBP) or direct feed from a power system. These FAPs and DCBPs are typically located in the top of equipment cabinets, taking space away from the active equipment. Passive equipment is anything that does not consume energy but has a purpose within the building. These are typically fiber

pre-terms and RF combining on the upstream or the downstream. Non-functional units are a great level of opportunity when we talk about the transition from analog to digital.

The power capabilities at a facility are among of the easiest to understand, trend, project and manage. The service entrance ampacity is the single energy gate and can measure what I have, what I have capacity to add, what will I have left after I add it. The Electrical service utility entrance is a single energy gate. This allows for an Engineer to measure what they have, what energy capacity they can consume, and project what is left after that decision is made. This measurement is typically in amps or in kilowatts. Simple meters and measuring tools have been exhaustively added to the buildings, allowing for the consistent trending and tracking of this metric. We would also look at the capacity of energy conversion at the DC plant level and UPS level. The final power draw component is the HVAC consumption measurements.

Cooling energy is a necessary evil, as it is called: Energy must be spent, in order to cool energy. Since most energy processes are consumable in nature, we traditionally see a 1 to 1.6 relationship on energy consumed, to energy needed to cool. These energy metrics and options generate our "Facility Spring". If we work within the facility spring, we can survive the transition to digital without a major influx of capital (the "deformation," in Slinky terms.)

10. I Think I can Fit One More Thing

The start of a journey begins with a plan. Our planning takes place with the kickoff called Blueprint-531. The B-531 is a planning assisting workflow that allows space planning managers and engineers to understand the destination. Once you decide where to go, it is easy to map your journey. The B-531 looks at the finite data available to be understood at the facility level. The physics around the transmitter/SFP distance limitations, lambda restrictions in a piece of glass and the availability to mux and demux optical paths are defined parameters we can engineer solutions from.

The other parameter feeding into the blueprint is the fiber density in and around the physical building. This fiber density looks at all services available to be rendered from a facility in way of commercial customers and SMB connections. Fiber consumption take rates for the embedded customer bases and designs the number of households passed (HHPs) per node split within the digital transformation end state. The equation is:

$$C = D_{nt}\,(@\text{Xhhp density}) + (O_n{*}d) + S^{2ch} + V + U + F_p$$

Equation 1: Cabinets needed = total digital nodes at "X" HHP density + Degrees of Optical transport nodes + number of redundant chassis needed per service + Video + utility + passive fiber terminations.

The above would indicate the total cabinet need of a site with 22,000 homes passed and commercial customers requiring PEG channel origination would equal 1+3+2+4+1+1 = 12 cabinets needing approximately 190 square feet for cabinets and aisle space walkways. With the average size of any BDS being 300 to 500 square feet, building additions based on space end state are very rare. At the time of this writing (summer 2021), after evaluating over 218 locations, only 9 sites would have no path to sustained footprints when a proper execution path is achieved.

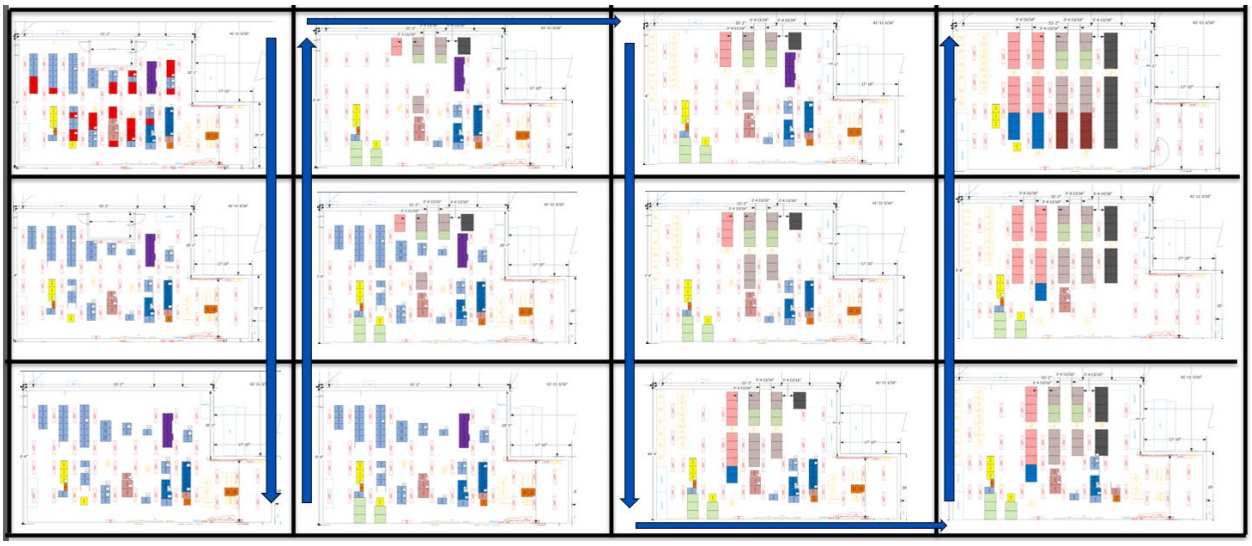

Figure 5: Facility Equipment location migration plan for a vCMTS location

What comes into the building first to facilitate a digital conversion is an effort of trial and error. Due to capital intensity, modernization efforts and customer needs consuming items at the port level, multiple B531 start points are to be "war gamed." The first most obvious path to free space is the conversion of the legacy analog CCAP cable CMTS to a vCMTS platform. As we evaluate the opportunities for space conversion, a decision of transition process needs to be understood. Original equipment Manufacturer (OEM) vendors have the hardware available to utilize a vCTMS Digital to analog shim called Shelf Physical (SPHY) Layer. This shim allows for the installation of multiple RF output ports to tie to existing transmitters and receivers allowing for the removal of all supporting analog hardware.

The method of deploying the SPHY equipment is a major decision point for energy and customer impacts. If the decision is made for equipment velocity, the result is a fragmented mess of analog abandoned equipment running in a very inefficient space and powering plan. Legacy best methods of collocating combining with TX/RX may leave the building with no recovered space until a defragmentation plan is enacted. This will impact the customer experience twice: One time to cut over to vCMTS, and the second time on the transmitter centralization plan to free up needed space. In the world of hardware modernization, velocity usually trumps efficiency.

Table 3: Dual Platform BDS - Analog and Digital

Receivers	Encoders	Transmitters	Servers
Signal testing equip	Controllers	Amplifiers	Signal Combining
Signal Decombining	Test ports/gear	EAS equipment	UPS
Routers	DC Power Plants	Batteries	Battery Distribution
Commercial Edge Gateways	MetroE Switch	OLT	VOD QAM chassis
Linear Video Edge Qams	Fiber Muxes	Optical Panels	Pilot Carrier equipment

Receivers	Encoders	Transmitters	Servers
DAAS Switch	SPHY chassis		

The sister step to the transition from CMTS to vCMTS involves the deployment of Distributed Access Architecture Switches (DAASs). The isolation of the DAAS to a separate cabinet may seem a gratuitous consumption of space, but it layers in a "forever rack". These forever racks allow for the long-term build and spatial reservation for nodes to terminate to mux shelves and switches. Existing density architecture allows for the build of over 554 nodes within 1 cabinet space consuming 15.83 sq feet. When addressing the legacy CMTS spatial consumption of over 285 sq foot via a spatial consumption of 95 for the same digital node, a savings of over 300% is realizable. But that requires taking the first step, which is installing the Digital DAAS cabinet.

The next parameter to understand is time. The time horizon to a location conversion to vCMTS and SPHY will drive the downstream part 2 conversion plans -- commercial chassis modernization and transport updates will inevitably conflict with the time horizon on the digital node conversions in large sites. The actual upgrade of transport chassis and routers to absorb the dedicated pipes running from the DAAS switches to the Broadband Digital Primary (BDP) centralization center will potentially drive more chassis before a hardware refresh can begin. The growth of the commercial side of the business may require separate routing networks that will scale differently than the routers for residential traffic. When the site has been converted to an entire SPHY connected DAAS, the beginning of the digital transition can begin and end. Within the table shown below, the highlighted equipment can at this point be removed from the edge locations.

Table 4: Analog Items to remove post vCMTS connectivity

Receivers	Encoders	Transmitters	Servers
Signal testing equip	Controllers	Amplifiers	Signal Combining
Signal Decombining	Test ports/gear	EAS equipment	UPS
Routers	DC Power Plants	Batteries	Battery Distribution
Commercial Edge Gateways	MetroE Switch	OLT	VOD QAM chassis
Linear Video Edge Qams	Fiber Muxes	Optical Panels	Pilot Carrier equipment
DAAS Switch	SPHY Chassis		

11. Do Not Stop At Go

As we reflect to where we are in this long process of removing the first round of analog equipment, we may have left a path of inefficiency in our wake. Leaving the existing Tx and RX in their existing locations will cause a level of effort that in some sites will be minor. In other sites, it will be immensely

difficult. On the level of easy, I have injected an image of a location that has left the analog world behind but still has the leftover equipment sparsely located with the HE:

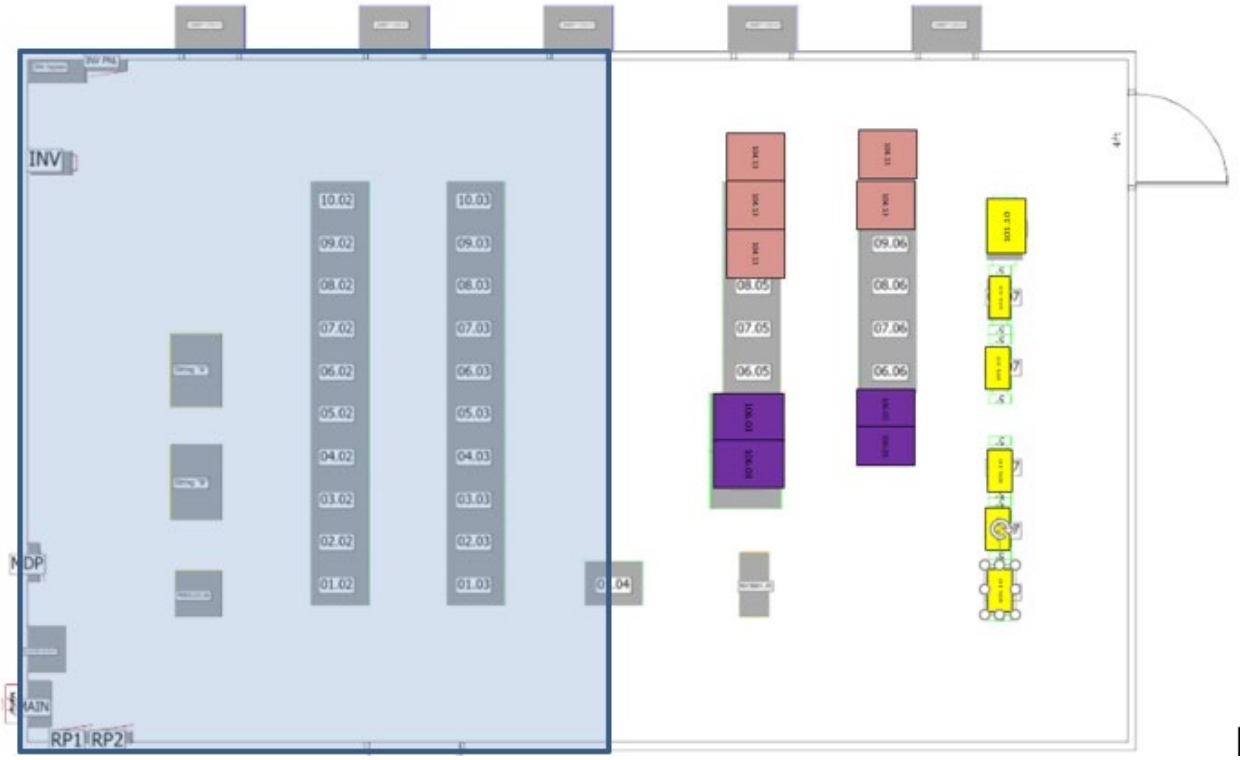

Figure 6: Active Digital Cabinet surrounded by legacy analog equipment

The leftover spare locations are inhibiting not only the ability to make the site as efficient as possible, but also leaves a complex legacy of old transmitters and receivers that no longer have a meaningful return in investment to be upgraded. At this point, a cost benefit analysis for the replacement of legacy RX and TX instead of a forced conversion to digital nodes in the field and connections to only the Digital DAAS. This will cause conflict and discussions and analysis and meetings and more conflict in priorities. As you see in figure 6, the blue highlighted area is capable of 100% vacancy. The SCTE champions the energy conservation of the MSO industry. Leaving so much analog active equipment burning through the HVAC airflow problems will be a counter argument to the reliability plans and limited touch operation that drives our strategic objectives. We as an industry need to understand there is a tradeoff between digital improvement opportunities, energy efficiencies and the customer experiences and that they all should be in balance.

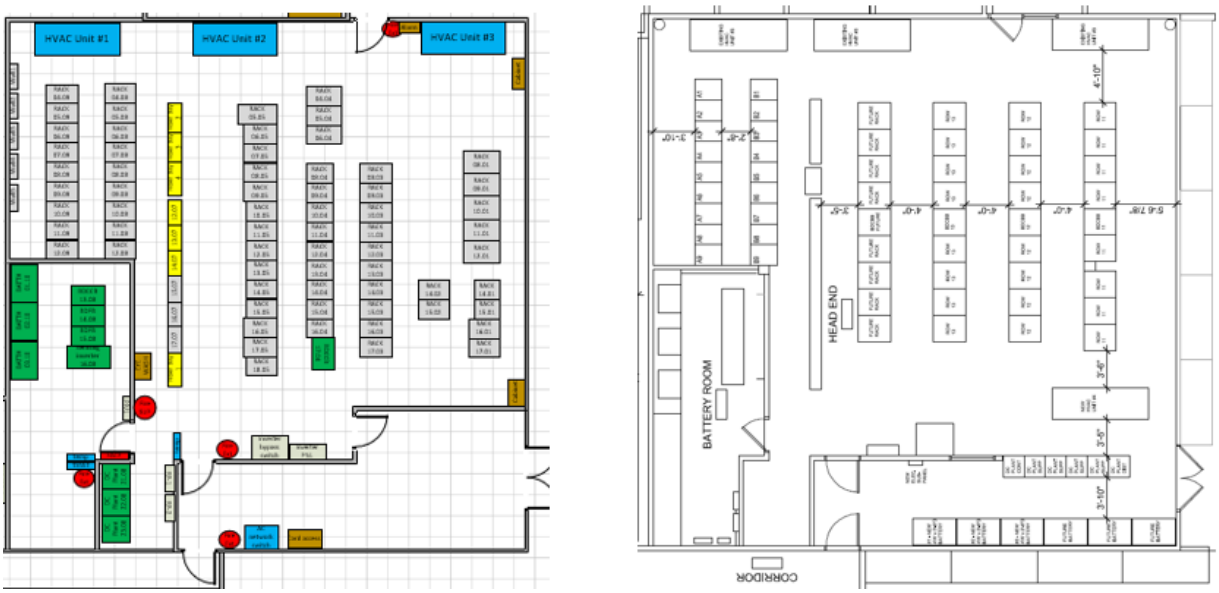

Figure 7: Before and after planning showing a path to all Digital

The final transition to digital will require the outside plant to do a significant amount of work to support the final transition. This may or may not require the replacement of actives downstream of the node by either replacing the amplifiers and or the nodes and split the service groups to a manageable amount of cable modems on each of the remote physical devices (RPDs). This activity and business cases need to take many items into consideration. The acceleration into a permanent standard cabinet and layout will accelerate the potential year over year growth opportunities. Speed to complete future activities can be achieved via this spatial and energy consolidation efforts. As efforts have been realized, the below items need to be understood as to the level of need for the final conversion to digital:

- Energy savings to be achieve by the digital conversion
- Recovery of energy capacity within the former edge sites
- Recovery of space within the former edge sites
- Operational improvements from the conversion to digital
- Additional bandwidth available due to the conversion to digital
- Elimination of OEM Analog equipment due to the conversion to digital
- Better OSP efficiency from operating digital nodes in the field
- Eliminating infrastructure equipment within the headends and hubs due to the conversion to digital equipment
- Right sizing of space needs within leased locations due to the conversion to digital operations
- Optional removals of underperforming sites within the networks due to the optic reach from digital small form factor pluggable (SFP)s to the nodes in the field
- Low-cost expansion into rural markets due to the range and options digital provides.

Table 5: BDS items left after analog leaves

Receivers	Encoders	Transmitters	Servers
Signal testing equip	Controllers	Amplifiers	Signal Combining
Signal Decombining	Test ports/gear	EAS equipment	UPS
Routers	DC Power Plants	Batteries	Battery Distribution
Commercial Edge Gateways	MetroE Switch	OLT	VOD QAM chassis
Linear Video Edge Qams	Fiber Muxes	Optical Panels	Pilot Carrier equipment
DAAS Switch	SPHY Chassis		

Within the above list of tangible improvements realized from the full conversion to digital, the 1 item that provides a meaningful tangible capability is the recovery of usable energy capacity at the edge locations. If we take a review of the imbedded energy opportunities within a former edge site, we can calculate the available energy and available space at a today cost to build the same surplus. In a presentation produced back in 2017, an MSO had the MW of embedded energy capacity at the edge locations of 73mw, of which only 44mw was being consumed. Since then, the overall capacity of energy has grown to approximately 87mw and a consumed amount of approx. 55mw. With the known advantages of a digital conversion to eliminate 80% of energy consumption at the edge locations, the asset value of unused and provisioned energy capacity can be measured in megawatts of network available energy for growth and new edge technology. When our industry looks back of the growth opportunity at the edge locations and the almost-free cost of connectivity to energy to serve customers, the low cost of expansion and opportunity will be plentiful, if digital realities are strategically aligned to the opportunities within the facilities we operate.

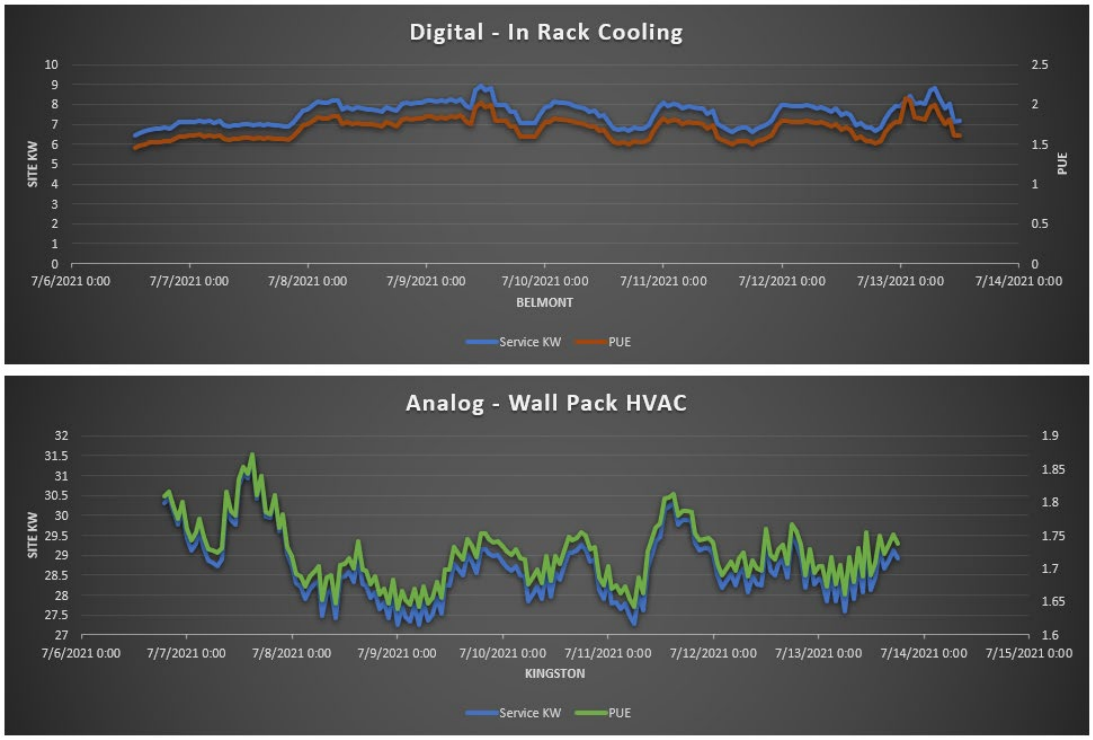

Figure 8: Digital vs Analog

12. Conclusion

The name "Cable TV" is becoming synonymous with antique, legacy, old and clunky. The names Headend, Master Facilities and Signal Buildings are becoming just as legacy. We are in the Information Age as a sea change event since 2003. The brick and mortar headend of the 60s, 70s, 80s and 90s have a long roadway available to them. Buildings we have built since 1963 to enable the analog age are still able to grow the Information Age and the upcoming Age of Digital Expansion. Innovations of the future will inevitably need to be connected to a physical layer; the cloud will always need the ground. This paper reviewed the opportunities to plan the layout and location of items within a building and how to phase plan for all activity. By following a pre-determined playbook of tech refresh, capacity augments and right sizing infrastructure, you also will achieve a building able to sustainably grow with the network that demands its support. The Age of Digital expansion will connect the future world within the bricks laid in the past.

Vice President of Video Strategy, Harmonic

1. Introduction

OTT delivery is increasingly becoming a primary solution for the consumption of live video content. With OTT, the QoE provided to users should be at the same level as traditional broadcast TV.

OTT has become so mainstream that even live content is now available from video streaming providers. In the U.S., between Sling, DirecTV Now, Hulu, YouTube and Sony Vue, there were more than 9 million OTT subscribers at the end of 2018, according to a Fierce Video report. Yet, quality is sometimes an issue, and that's a problem because consumers expect the same video QoE for OTT as they've experienced with broadcast TV.

While the experience is expected to be the same or better, there are many technical differences between OTT and broadcast delivery. OTT targets a variety of devices (i.e., smartphones, tablets, desktop computers, connected TVs, game consoles) and delivers the content over a variety of networks (i.e., xDSL, fiber, radio 4G and now 5G).

To address these issues, many efforts have been made to define technical solutions for OTT streaming. One example is lowering the latency for the most popular streaming protocols HLS[1] and DASH[2]. This was presented in the 2019 SMPTE conference paper "How OTT Services Can Match the Quality of Broadcast"[3], but there are still some problems to be tackled when it comes to achieving massive at scale viewing of live events.

This paper will examine the different solutions that can be deployed in an OTT environment, comparing the technical merit, the integration aspects in an open ecosystem, the need for standardization and the overall impact on total cost of ownership (TCO) and QoE. It will provide suggestions on how scalability can be achieved to deliver high-quality live video to millions of subscribers on every device at any time, even during peak hours.

2. Current State of the Art for the Video Streaming Industry

There have been a lot of new streaming protocols and formats popping up over the past decade, but when you observe the current OTT delivery landscape for video on demand (VOD) and live content, it's clear that a vast majority of content is distributed using either HLS or DASH formats. Both use HTTP[4] as the underlying transport protocol and are based on adaptive bitrate (ABR) technology, which makes it possible to deliver video over unmanaged networks with variable available access bandwidth. The other formats have either reached obsolescence (e.g., Microsoft Smooth Streaming) or should be reserved for more specific use cases (e.g., ultra-low latency) as they come with some additional constraints. For example, WebRTC[5] can provide low latency but relies on peer-to-peer and thus has some serious scalability issues.

Since the focus of this paper is on large-scale content delivery, it is not a debate that the streaming industry will rely on two dominant streaming technologies for the next few years: HLS and DASH both using CMAF[6] as a common format for the delivery segments.

While there's been a growing demand for live content over the past few years, the vast majority of OTT consumption has always been and is still VOD content. This brings some additional constraints to the delivery workflow.

Several content delivery optimizations have already been deployed but most, though not all, are dedicated to VOD asset distribution or suffer huge limitations:

- Several years ago, Netflix introduced its per-title encoding [7], then per-scene encoding to provide a better video quality at a given bitrate. It also included a new paradigm of adaptive ladder, removing the profile when it doesn't bring any value to the end user from a video quality standpoint. These innovations improve the viewing experience, but they have been implemented for VOD assets with no real-time constraints on the processing.
- During the BEITC 2019 conference, Brightcove presented [7] some techniques to dynamically adapt the profile ladder based on the network conditions. These are a promising path but not yet available for live content distribution.
- Storage of recorded assets (e.g., cDVR applications) can be optimized by an offline profile curation removing the nonessential rendition in the profile ladder. The criteria to remove the nonessential rendition is based on a perceived QoE by the end user. This approach can work to optimize the storage volume and therefore the costs but again this is not yet something that can operate in real time for live content.
- Current multi-CDN strategies are based on static cache allocation. For large-scale events like the Olympics or FIFA World Cup, a major CDN would need to book physical resources up to 12 months in advance.
- Finally, as required for any closed-loop optimization client/CDN analytics may be collected in real time (which sometimes occurs at the end of the viewing session) but are generally not processed in real time to build actionable insights to optimize QoE.

When a popular event must be delivered live over a variety of networks to a variety of devices, it is a lot of work to make sure everything goes smoothly. For such an event or for regular peak audience, most popular services experience some QoE issues like rebuffering and long start time, when it is not a total impossibility to connect to the service.

The next section will discuss how the scalability issues and generally how a service operator can improve the delivered QoE by moving from a fixed, non-optimal workflow to a much more flexible workflow that is adaptative to the external context.

3. Motivations to Move From Static Workflows to Dynamic Delivery of Content

Depending on the business model for the service provider, the most critical metrics it needs to monitor and improve are:

- The acquisition of new subscribers, at a reasonable cost
- The churn ratio (or the ratio of new subscribers) for a subscription-based model or the total viewing time for an ad-subsidized model
- The cost of service (that can be approximated by the TCO value).

The first bullet will not be addressed in this paper, as the acquisition of new subscribers is mostly linked to the content proposed and service feature package, more than to the quality of the delivery.

The metrics reflected in the second bullet are the result of multiple factors, technical and nontechnical (typically based on the content offering and service features). However, for the technical side, which is what the platform can offer, the metric that is prominent is the QoE perceived by the end user. The QoE metric itself is a combination of multiple factors, including the video startup time (VST), video start failures (VSF), rebuffering ratio (CIRR), end-to-end latency and the perceived video quality. This metric can be estimated by collecting telemetry directly on the user devices or by deducing from other telemetry collected on the network.

The TCO includes any costs needed to run the service. This can encompass hardware costs and the cost of operation in the case of an appliance-based service or the cost of service invoiced when operated in SaaS mode. In any case, this total cost covers the headend and delivery (e.g., CDNs).

Any evolution of the current workflows should therefore be considered keeping these two goals in mind: improving the QoE and reducing or keeping the TCO under control.

Looking at the whole delivery workflow from the content capture to the end device, there are several areas where the processing needs to be flexible to get the optimum use from resources (i.e., computation resources, bandwidth, storage, etc.). In the video compression space, it has been well known for decades that the codec engine should enable the most appropriate mode depending on the content nature. This is a supported capability in any video codec since fixed QP approaches have been enriched by many other techniques driven by the content nature. Video codecs have dynamically adapted to the content characteristics for years, providing compression improvements. But things are now getting more complex with ABR distribution. Content is now made available in several bitrates, several resolutions and several frame rates. Even if one can anticipate general rules linking these parameters (for example, when the bitrate is reduced, at some point, it becomes more efficient to reduce the resolution), these thresholds are highly dependent on the nature of the content. The same applies for the frame rate. It is commonly agreed on that for sports content a high frame rate will provide a better result at a given bitrate, which is not the case for other types of content.

The delivery side, compared with the "good old simple broadcast era," is also much more complex. Delivery is made via multiple types of networks, all of which have limited resources that should nevertheless cope with the unicast paradigm used in OTT. Moreover, the QoS of the delivery network is highly variable over time and locations (on the open internet QoS is not guaranteed as it is on a cable network, for example). Dealing with these variable parameters on the network side can be achieved by overprovisioning resources. For example, putting more edge caching in the CDN. But this approach carries a significant cost that might impact the profitability of the service. If considering the worst case in a static configuration is not a viable option, then the alternative is to adapt the delivery to the current condition in order to find the sweet spot that will, at any time, give the best compromise and maximize the end-user satisfaction. All this is even more complex when consumption is on mobile networks, meaning there are even less predictable network conditions.

There is a clear motivation for the service provider to maximize the perceived QoE and keep TCO under control in a fast-moving environment. This multi-variable equation cannot be solved efficiently in a rigid, static delivery workflow. Moving from a static to a more dynamic approach can greatly impact the entire delivery workflow.

4. Industry Trends and Research

On the content preparation side, compression technologies have evolved and become more complex. In the past few years a new paradigm called content-aware encoding (CAE) has emerged. CAE embraces different technologies that are highly dependent on the encoder vendor but overall the codec decisions are more driven by an on-the-flow content analysis. More recently, artificial intelligence (AI) and machine learning (ML) technologies were added to cloud-based solutions, making these tools economically viable. Thanks to a big push by industry leaders like Netflix, AI entered the game to propose per-title and then per-scene encoding. Here the video content is not only analyzed in real time to extract the relevant feature but, then, a prediction model is created offline using a large database of content to select the best codec configuration. More details can be found on this topic in the SMPTE 2019 conference paper [9]. All these techniques, from CAE to more advanced AI-based processing, were first used in production for VOD

assets but now are starting to be deployed for live content, with the even greater challenge of matching real-time operation. This is the next step the industry should take, introducing some new dimensions and new flexibilities to create an optimal profile ladder at any time. These new areas will be described in the following sections.

On the delivery side, the situation is a bit less mature, as this part of the global workflow has been a moving target in the past decade. Nevertheless, the global trend on the delivery network side is to transition to a more flexible software-based architecture. On the one side deploying new network elements (software based) according to demand is an option. On the other side, providing some hints to the end-user player so that it can make smarter requests to the network is also a possibility. There has been a significant amount of academic research on building some models of the various delivery networks. Much of the research is focused on the mobile network where data consumption (mainly driven by video content) explodes and will continue to grow in the coming years while QoS is still an issue, especially in crowded areas and at peak hours. Stanford University has done work on network optimization using deep reinforcement learning [10]. On the client side, MIT has developed research around an improved ABR algorithm using reinforcement learning to improve the player behavior in difficult network conditions [11].

As explained in Cassie Tolhurst's blog [12], deep learning algorithms can help secure highly demanding content like UHD delivered at a large scale. We are seeing AI spread more and more across the workflow from content preparation to network delivery to enhance the end-user experience. The different functions, part of these new dynamic workflows, are presented in the following sections.

5. Moving to More Dynamic Workflows

5.1. Introduction

Dynamicity of the workflows must be done in relation to external context, as explained above. Taking a holistic view of the global situation for live video streaming, we came to a conclusion about where it's important to build a new way to distribute video. This analysis leads, therefore, to the creation of adaptive workflows taking into account all possible contextual sets of information:

- **Content characteristics:** Live video is per nature changing over time. Encoding and packaging it with fixed configuration (i.e., bitrate, resolution, frame rate) as done today is not optimal to ensure the best QoE the delivery network can give at any time.
- **Content consumption:** Having the same encoding, same packaging (same profile ladder) for all live channels is sub-optimal. This should be dynamically adjusted over time using feedback from the network (i.e., player, CDN, access network).
- **Content importance:** Premium content with high value attached to it will have to be encoded with a higher quality than less valuable content. This should be dynamically adjusted over time according to the operator's preference.

Moving from the traditional static (set and forget) approach to a workflow where many configurations can change over the time, sometimes with a high dynamicity, is not a simple task. This covers many aspects summarized in Table 1.

Table 1 - OTT evolution from static to dynamic workflows

Static workflow	Dynamic workflow	QoE improvement	Cost improvement
All parameters are fixed	Variable parameters	✓	✓
Fixed resource allocation	Variable resource allocation	✓	✓
Fixed architecture/ maximum TCO	Usage-based architecture / Optimized TCO		✓
Siloed approach	End-to-end approach	✓	✓
Deterministic approach	AI-based approach	✓	✓

As illustrated in Table 1, the different areas moving from a static paradigm to a dynamic workflow may impact either the end-user QoE, the service provider costs or both.

The move to a dynamic approach implies that the decisions made should be driven by various criteria linked to the contextual sets of information mentioned above (i.e., content characteristics, content consumption and content importance).

The various dynamic actions across the delivery chain can be split into two categories:

- Actions and tools aimed at optimizing the production on the profile ladder, either for the purpose of improving the QoE or reducing the operation costs
- Actions or tools aimed at optimizing the delivery path to improve the QoE (mitigation of network congestion during peak audience)

The next sections give a description of the various tools, most being guided by AI, which are part of the Context Adaptive Delivery solution embracing the two categories of actions.

5.2. AI-based Encoding/Content Aware Encoding

One of the ways service providers are battling QoE issues for OTT is through advanced compression methods. Content Aware Encoding (CAE), a per-title encoding technique currently used by Netflix, is one such method that supports both VOD and live applications.

CAE assesses the video complexity in real time and adjusts the encoding parameters to provide the best picture quality. It works similarly to VBR for statistical multiplexing, except that only one program is encoded, and the video quality measurement is more refined since it is based on the Human Visual System (HVS) model. In order to have a more accurate video quality measurement, the CAE live system is trained offline using artificial intelligence technologies. For more details, see Harmonic's technical guide on EyeQ [13].

Over the past few years, CAE has made a real change in video compression and is now backed by Apple, Netflix, and the Ultra HD Forum, which has demonstrated a consistent savings of 40% vs. CBR for UHD ABR using CAE in 2018.

The next step of video compression improvement using AI is what Harmonic calls "Dynamic Encoding Style." We leveraged our first research in AI to embed prediction models in the encoding engines to feed the compression engines with the most appropriate set of parameters. As with many ML-based solutions, we train a prediction model offline using a large database of assets in order to find the best compromise among the huge set of encoding parameters that can be fine-tuned. Then, on the live system, the prediction model uses the video characteristics extracted in real time by the first blocks in the encoding

pipeline and matches it to the “optimum” set of encoding parameters. Dynamic Encoding Style is a natural complement to the CAE approach and shares a lot of common principles, including the video quality assessment technique used to build the prediction models in the Human Visual System Model.

Dynamic Encoding Style uses an AI based two-step approach, depicted in Figure 1.

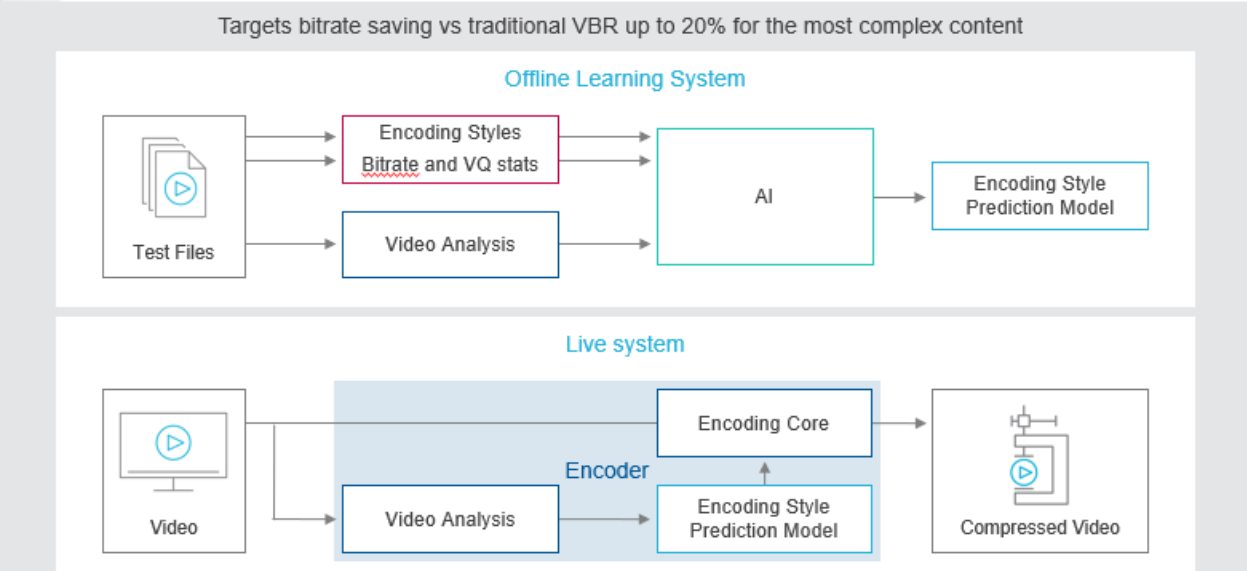

Figure 1 – AI-based Encoding

5.3. Elastic Encoding

Elastic encoding is the last tool mentioned in this paper that focuses on the compression core for live content distribution. The general approach is to use feedback from the network on the content popularity in order to allocate variable CPU resources for the transcoding. The new generation codecs have a very large toolbox that could, if they are all used for every content, have a huge impact on the solution density (number of transcoding instances that can run in parallel on a given cloud resource). All the live encoder vendors are therefore making compromises to find the sweet spot between quality, bitrate and CPU resources. This compromise can be different when the distributed content is very popular. Allocating more CPU cycles will lead to lowering the bitrate at a given video quality which, in turn, will reduce the CDN costs. This is very interesting when the CDN egress is high for popular content.

As it is sometimes difficult to predict which event will be very popular, having a flexible solution that can adapt dynamically when the live event is being distributed is very important.

5.4. Dynamic Resolution Encoding

This tool (and the next one) is different from the previous ones, as the AI is not used to modify the configuration of the compression algorithm but is used to select the optimal resolution of the encoded video. It is well known that there is a link between the representation bitrates and resolutions in an OTT profile ladder. For low bitrate representations, it is more efficient to reduce the content resolution before encoding to get the best QoE. As the threshold to change the resolution at a given bitrate is highly dependent on the content nature and evolves dynamically over time, a solution based on a ML prediction model is a good choice to estimate the best resolution before the encoding processes.

Like the previously mentioned tools, Dynamic Resolution Encoding uses an AI-based two-step approach, as depicted in Figure 2.

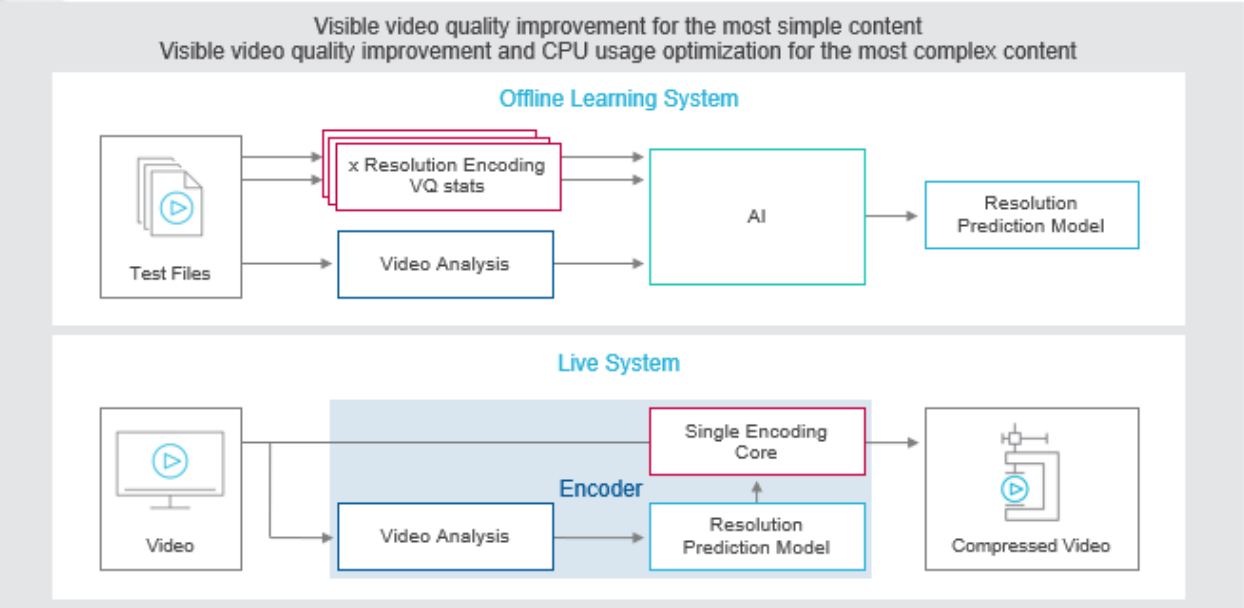

Figure 2 - Dynamic Resolution Encoding

Dynamic Resolution Encoding allows operators to improve the QoE by enhancing the picture quality perceived by the user. It also improves the density of the solution, thus the TCO, as less profiles need to be used for OTT.

5.5. Dynamic Frame Rate Encoding

Dynamic Frame Rate Encoding works on the temporal activity of the content. Relying on known properties in conjunction with what the user can perceive (all of this is described in the HVS model), this tool will determine the optimum frame rate for a given piece of content, making temporal decimation when a full frame rate is not required.

The value brought by this decimation is that the encoding core will not encode all the frames, therefore saving CPU cycles that can be used either to achieve a better bitrate or to improve the network reach (i.e., less stalling, less rebuffering when the content bitrate is lower). Another use for the CPU savings is to get a denser architecture and/or reduce power consumption, and this adds to the TCO for a service. Dynamic Frame Rate Encoding uses an AI-based two-step approach, as depicted in Figure 3.

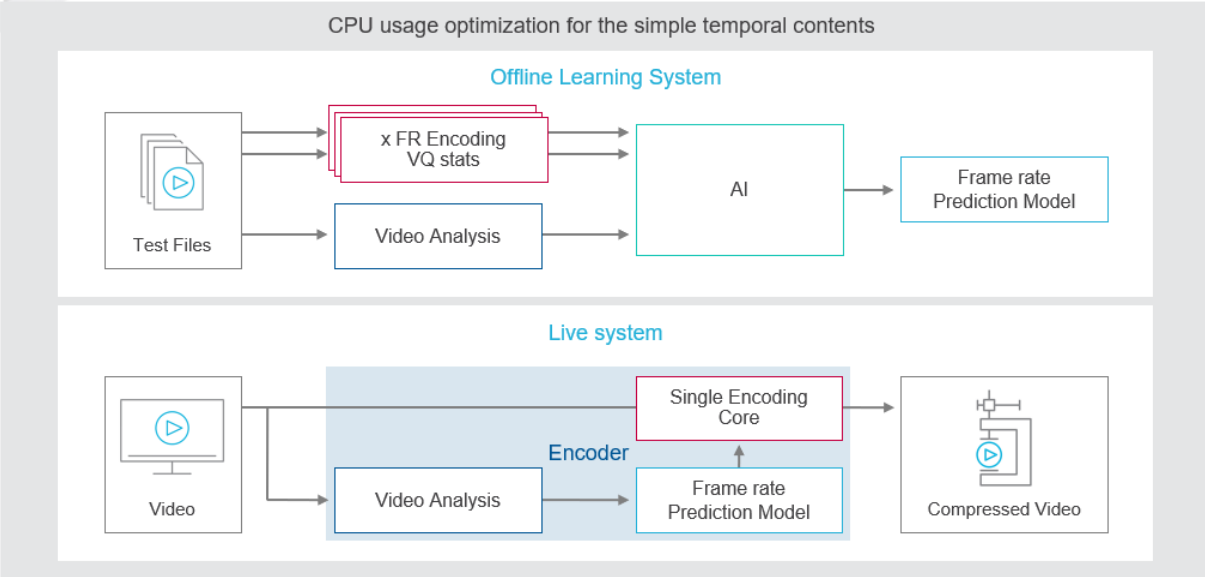

Figure 3 - Dynamic Frame Rate Encoding

5.6. Delivery Optimization

The different tools presented above are aimed at selecting the best encoding configuration depending on the content characteristics. Using these approaches, or a combination, one can create an adaptive content preparation workflow that should optimize the profile ladder based on the content itself or its popularity. But, at this point, another important aspect needs to be considered. The content will be sent over various networks from a core network to the edge and then to the delivery network with a lot of different situations depending on whether the user is on a fixed or radio network, and depending on if it is in a geographic area where this content is very popular compared with other areas (think about a sports match between team A and team B where the audience will be higher in regions A and B compared with the rest of the eligible territory).

With a traditional broadcast paradigm, the service provider delivers one single stream to all the users, making sure that the signal-to-noise ratio will be good enough to ensure a reliable reception on the covered geographic area. On the other hand, a modern OTT distribution platform needs to cope with multiple CDNs, multiple devices, and adapt to much different situations. It seems very ambitious or may be suboptimal to define one single strategy to dynamically adapt the delivery workflows to all these situations. Therefore, flexible architectures will be easily tunable to find the best configuration at a given time.

Whatever the strategy for this delivery optimization is, there are some basics that need to be met on the network. Collecting information from the different elements in the networks is necessary to understand, in real time, how the network is behaving and what the actual QoE is for end users.

A typical analytics collection architecture is illustrated in Figure 4.

In many deployed systems, analytics are collected for the purpose of offline marketing dashboarding but not for real-time usage on a feedback loop.

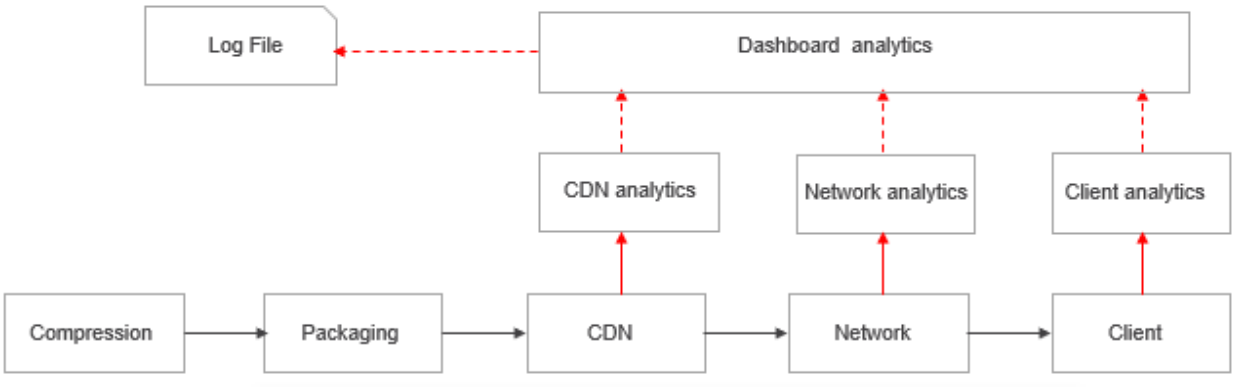

Figure 4 - Typical analytics collection architecture

As presented in the first category of tools that will dynamically adjust the profile ladder, all these decisions may be influenced by the current situation in the delivery network.

The generic architecture for a full Context Adaptive Delivery (CAD) workflow, including the profile ladder optimization and the network path optimization, is illustrated in Figure 5.

Many variants can exist, but the high-level idea is to use the raw data collected on the network to feed a decision engine that will trigger some actions on:

- The compression engine (tools mentioned in the previous sections)
- The packager/origin
- The network path controller

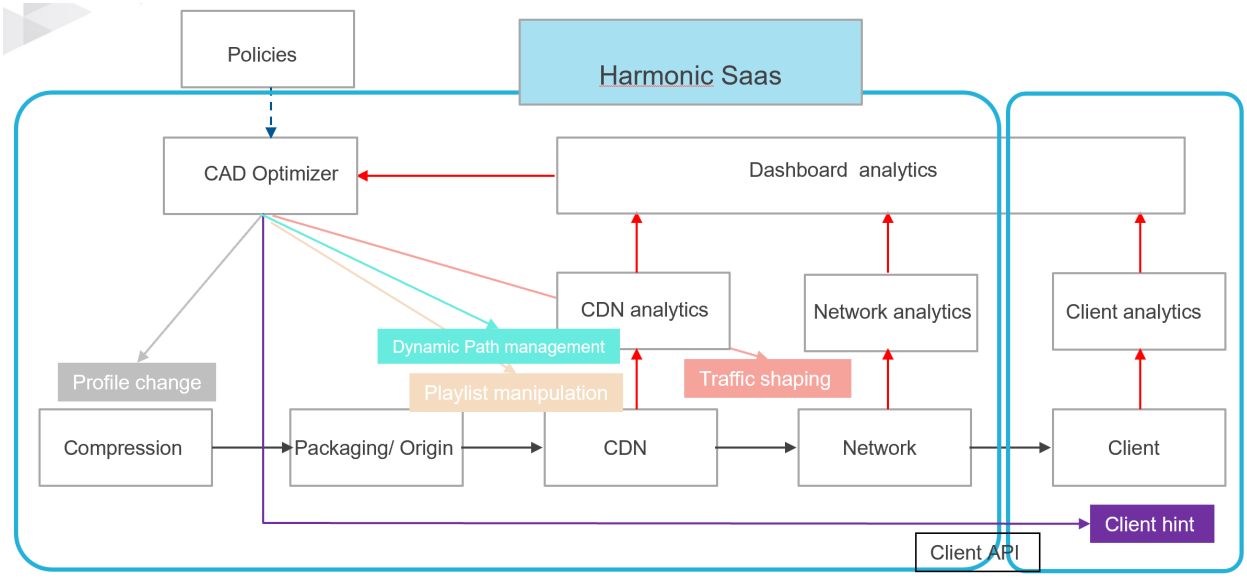

Figure 5 - Context Adaptive Delivery (CAD) generic architecture

The decision engine located in the "CAD optimizer" box above can be as simple as logical switches triggered on fixed thresholds of any of the raw data. But a more forward-looking architecture is to bring AI into this system to enable action before the network crash occurs. Building an accurate and reliable

model of the complete delivery network, from the core network to the last mile, is still a research topic but modern AI approaches look very promising. Because the network conditions are evolving over the time, the AI should adapt automatically based on the current network situation. To achieve this goal, reinforcement learning[14], an area of machine learning, provides some interesting tools. Through a rewarding mechanism, the decision engine gets instantaneous and continuous feedback from the network on the actions taken. It can then adjust the decisions to find, at any time, and under any conditions, the optimum configuration.

As mentioned above, different strategies or scenarios to optimize the delivery at scale for live events can be imagined using the raw information collected in the network. The aggressiveness of the scenario depends on the policy the service provider wants to use to prevent or reduce the breakdown in case of peak audience for a given event.

The global optimization scenario will therefore combine, with a holistic view, the optimization that can be made on the profile ladder and the class of actions to:

- propose a dedicated manifest to some category of player (through manifest manipulation approach),
- dynamically change the delivery path by selecting the most appropriate CDN or delivery nodes

As the second part of the contextual information that the CAD should use, the content consumption is translated into the network load that can be heterogenous, typically based on geographical distribution. To estimate this network load in real time, the system should collect information telemetry from different points in the delivery network. This includes client-side telemetry as well as CDN analytics and network traffic measurements. The collection and capability to perform real-time processing on this information is critical in order to have a timely answer (feedback loop) to any significant change in the content consumption.

Below are some possible scenarios that the CAD optimizer can implement using the network telemetries combined with the service provider policies:

- Based on the reported network load, either global or in some geographic areas, the Customer Management System (CMS) can decide, when a given threshold is reached, whether to prevent any new subscribers from connecting to the service.
- Based on reported network load, either global or in some geographic areas, the traffic can be routed to one CDN or another (when the problem doesn’t come from the last mile).
- Based on reported network load, either global or in some geographic areas, the manifest generator can be instructed, when a given threshold is reached, to remove one (the top one) or several high demanding representations in the manifest either to all or a subset of subscribers. This decision can also be influenced by some business rules to give higher privileges to premium customers.
- Some geographic areas can be isolated and treated with a particular scheme if the network indicates that something is wrong in this area.

These scenarios can be seen as a reaction to a given situation but should bring more value if, thanks to an accurate prediction model, the action anticipates and therefore avoids a future crash.

As depicted in Figure 5, the loop-back action can be directed to different elements in the delivery workflow:

- This can be on the encoder where an action can be decided based on content consumption information. This is the elastic encoding tool presented above.
- This can be at CMS level where new subscribers to the service are rejected when network capacity is exceeded.

- This can be on the packager/origin where playlist manipulation can be done to present the best profile ladder to all or a subset of end-user players.
- This can be on the path management system that can dynamically move the delivery from one CDN to another based on reported consumption or risk of overload on the delivery path.
- This can be on the player itself where some instruction or guidance can be delivered in real time to make sure it will request the most appropriate resource (this may include some hints to help the ABR decision algorithm, for example)

In summary, depending on the contextual set of information on the content characteristics, its consumption and its importance and on scenario choices, Table 2 gives an overview of the different actions triggered by the CAD optimizer. This comes together with the content characteristics-only related tools mentioned in the previous sections.

Table 2 - Delivery optimization summary

Tool category	Usage	QoE improvement	Cost improvement
Profile change	Adjustment of the profile ladder based on delivery network status	✓	
Playlist manipulation	Provide different playlist/manifest to groups of users based on network congestion, user category, device groups	✓	
Dynamic path management	Optimize the distribution between several CDNs or private delivery nodes based on reported consumptions and business rules	✓	✓
Traffic shaping	Set business rules to limit the traffic (enhanced zero rating approach)		✓

6. Conclusion

Context Adaptive Delivery is a new paradigm that takes the end-to-end video delivery workflow to the next level in order to address the two most important aspects for an OTT service provider: delivering better QoE to end users while reducing or keeping the TCO under control. Taking into consideration the dynamicity of the content's consumption over a variety of delivery networks is the next step now that OTT technologies are ready for the main screen. Moving from today's rigid configuration to much more adaptive workflows should be seen the same as the transition from hardware- to software-based solutions. With Content Adaptive Encoding, Dynamic Resolution Encoding, and Dynamic Frame Rate Encoding, the content preparation can be much more flexible and adapt to the content type itself as well at its popularity. All these tools should be used to prepare the optimum profile ladder at any time. Then, once the profile ladder is optimized, using network optimization in an adequate scenario allows one to provide the best delivery to users, no matter what their location, device or subscription is. This will quickly create opportunities to improve the user experience, leveraging the value that AI-based processing and cloud-native deployments bring into this landscape.

With more adaptive workflows for the delivery of large-scale live events, the end-user experience can be dramatically improved to reach the expected level and match broadcast services. In addition, service operator profitability can be improved. Even better, we can imagine the introduction of new services and new user experiences that are not possible today.

Abbreviations

ABR	Adaptive Bit Rate
AI	Artificial Intelligence
CAD	Context Adaptive Delivery
CAE	Content Aware Encoding
CDN	Content Delivery Network
cDVR	Cloud Digital Video Recorder
CIRR	Connection Induced Rebuffering Ratio

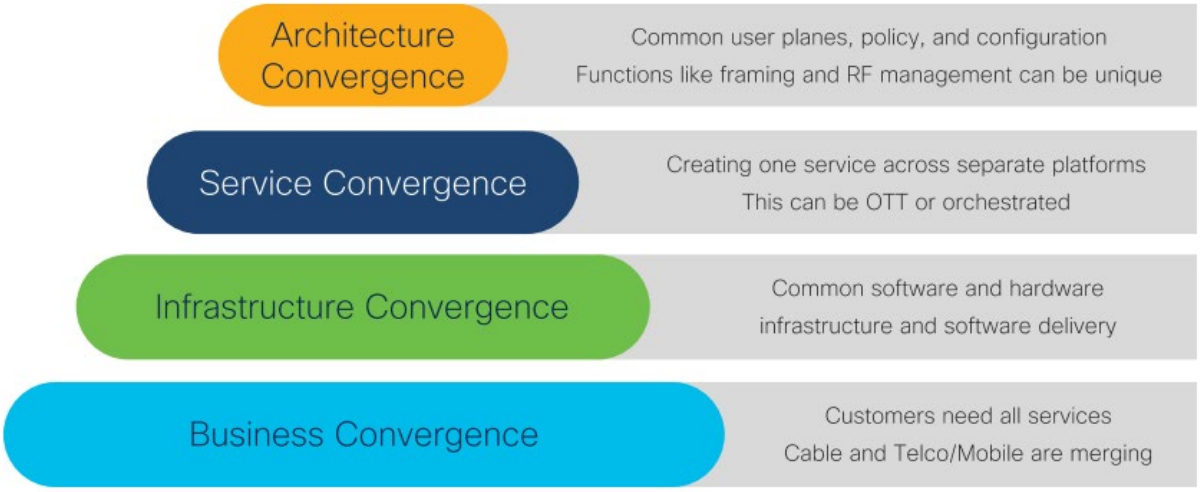
1. Introduction

Network convergence has been gaining a lot of attention in the telecoms industry recently with the architecture shift in both wireline and wireless communication networks to be more centralized in terms of core and baseband processing, and more distributed in terms of the analogue and RF functions.

This has also led to the disaggregation of the hardware and software functions of the network. Furthermore, the standardization of the interfaces in this network, for example the O-RAN, 3GPP wireless wireline convergence (WWC), Broadband Forum fixed mobile convergence (FMC), cable distributed access architecture (DAA) and the more recent flexible mobile architecture (FMA) initiatives enables wider participation of ecosystem vendors leading to competitive solutions for operators.

Centralized functions of the network such as 5G-Core for wireless and cable modem termination system (CMTS) for data over cable system infrastructure specifications (DOCSIS) are well suited to being implemented in software and to run on common off the shelf (COTS) hardware, giving better scalability over time and adaptability for different deployment scenarios.

There are many aspects of network convergence as shown below (from reference [1]), at business, infrastructure, service, and architecture level.



Source: Cisco & CableLabs, "Cable and Mobile Convergence, A Vision from the Cable Communities Around the World"

Figure 1 – Four Levels of Convergence

This paper will focus on infrastructure and architecture convergence and specifically, how the advent of 5G has created a great opportunity to leverage the existing DOCSIS network for two key purposes:-

- Xhaul of 5G small-cell traffic over DOCSIS
- Fixed mobile convergence (FMC) using the Cable access network

It will be shown how the flexibility of a software-based vCMTS makes it much easier to adapt the Cable access network for these new 5G use-cases and to evolve over time.

This paper will explore the rationale outlined above as to why Cable MSOs should prioritize vCMTS deployment in preparation for 5G xhaul and FMC, while identifying some gaps that need to be addressed by the Cable industry to prepare for 5G mobile convergence.

2. Cloud-native Infrastructure Convergence

Infrastructure convergence as shown in Figure 1 in the previous section is already happening in terms of common hardware platforms and software stacks being used to host wireless and wireline network functions as shown in Figure 2 below. Network function virtualization (NFV) and the subsequent progression to adoption of cloud technologies for communications network functions started in the Mobile core and is now gathering pace for central-office deployments of access network functions such as virtual broadband network gateway (vBNG), and the virtual cable modem termination system (vCMTS) in cable head-ends.

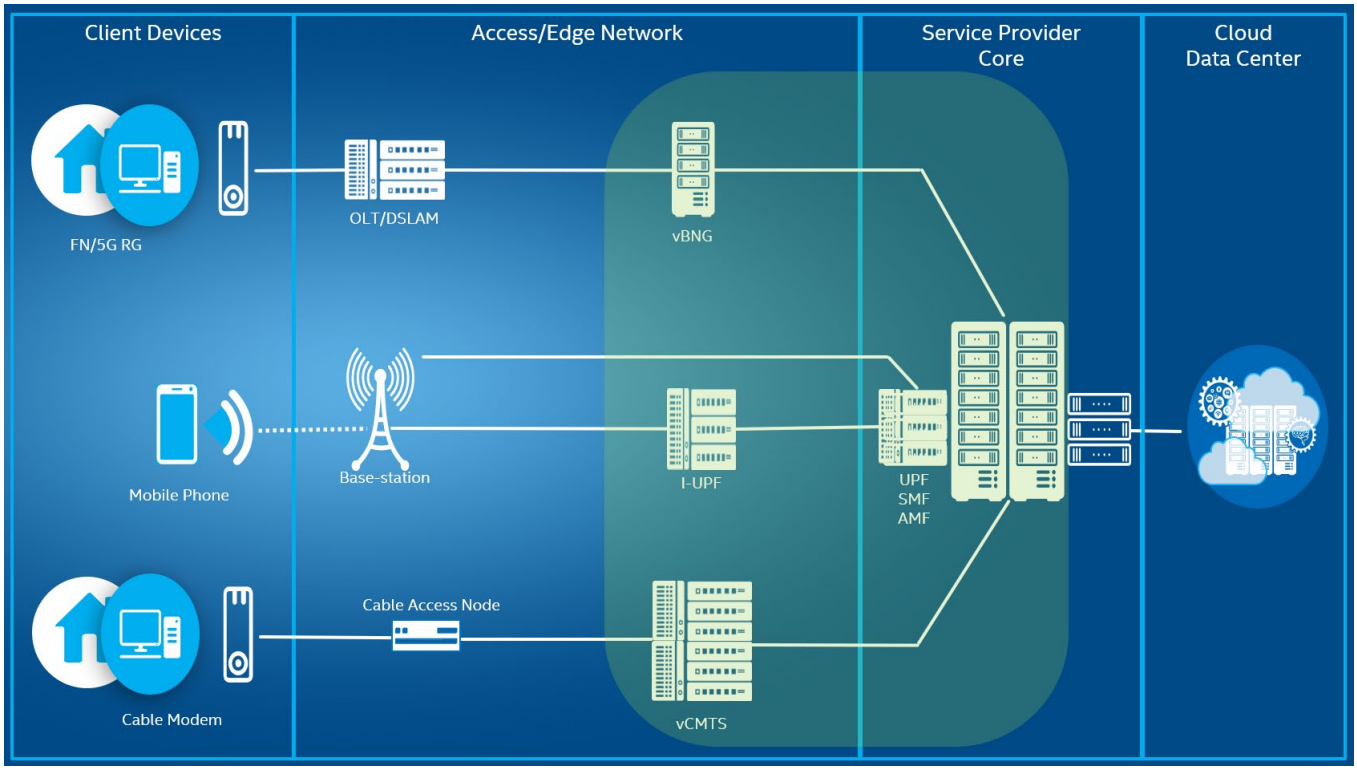


Figure 2 –Telecoms Network Infrastructure Convergence

Cloud-native is a term that has come to be used to describe the use of cloud technology for network function deployment on COTS hardware platforms. Significant work has been done in several mainstream open-source projects to enable high performance network function data-planes to be deployed on a cloud-native platform. Open-source packet-processing frameworks such as DPDK and FD.io/VPP (see references [2] and [3]) make the required data-plane performance possible in software while key features have also been added to open-source cloud computing platforms such as Kubernetes to enable network applications based on these packet-processing frameworks to be deployed with the scalability, flexibility, and observability of a cloud environment.

2.1. Cloud-native deployment of vCMTS

Significant effort has been invested in open-source projects to advance cloud-native network function virtualization by providing reference software which is highly optimized to run on general purpose COTS hardware platforms while also leveraging the benefits of cloud technology such as automation, scalability, flexibility and observability.

A Container Bare-metal Reference Architecture as shown in Figure 3 below (see reference [4] for details) is provided by Intel which combines general purpose hardware and open-source software components to provide a reference cloud-native platform which may be configured appropriately with Ansible playbooks to host network functions at various network locations - mobile core, central-office, access network edge and on-prem.

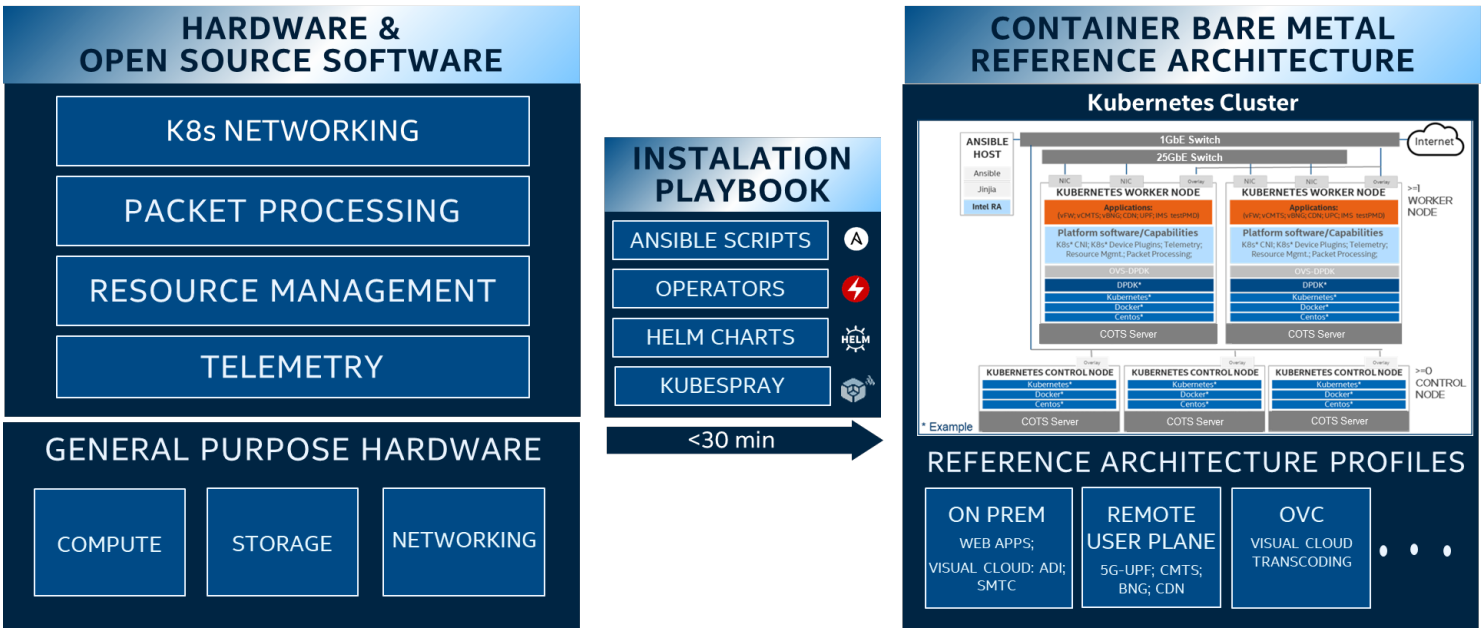

Figure 3 - Container Bare-metal Reference Architecture

A cloud-native software stack such as this is key to preparing the cable access network for mobile xhaul and FMC, as both require new functionality to be added. The network function adaption needed for these new DOCSIS use-cases are greatly simplified by having a modular extensible cloud-native vCMTS software architecture with rich telemetry and observability already in place.

A reference vCMTS data-plane implementation based on DPDK as shown in Figure 4 below has also been provided by Intel (see reference [6] for details). Such an implementation demonstrates the software performance capability of this key component of the cable access network on a cloud-native platform. DPDK forms the foundation for any high-speed packet processing software. And for this reference DOCSIS MAC data-plane, 80% of the code comes from DPDK, with each function in the DOCSIS MAC pipeline leveraging existing CPU-optimized DPDK library functions.

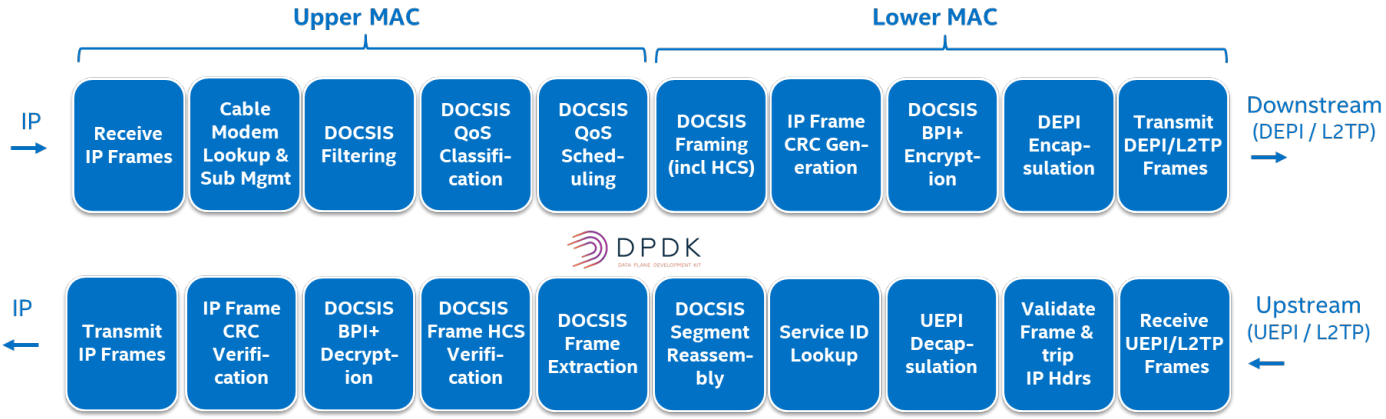

Figure 4 –vCMTS Data-plane based on DPDK

An example of a cloud-native software stack based on open-source components for deployment of vCMTS is shown below. Such a stack may be deployed in a lab environment for performance and TCO analysis using Intel's container BMRA (reference [4]) and vCMTS reference data-plane (reference [6]).

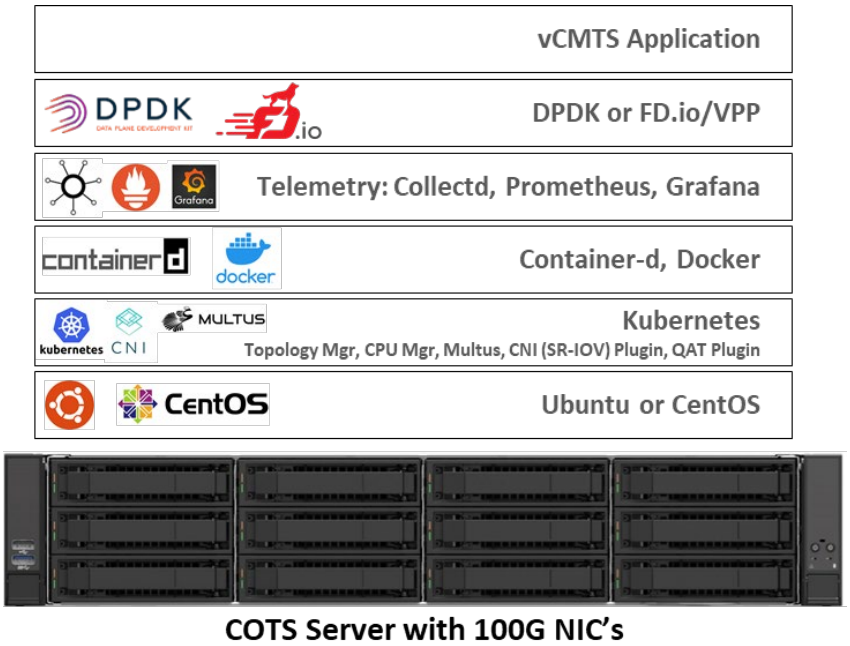

Figure 5 - Sample Software Stack for vCMTS Cloud-native Deployment

A cloud-native vCMTS runtime environment is shown in Figure 5 below. The vCMTS software architecture shown below is an example of how a monolithic CMTS may be decomposed into multiple Pod's (for example one per cable service-group) and each Pod decomposed into containers running distinct functional parts. This is based on the cloud concept of micro-services which enables optimum extensibility and resilience while simplifying the maintenance and upgradability of network function deployments.

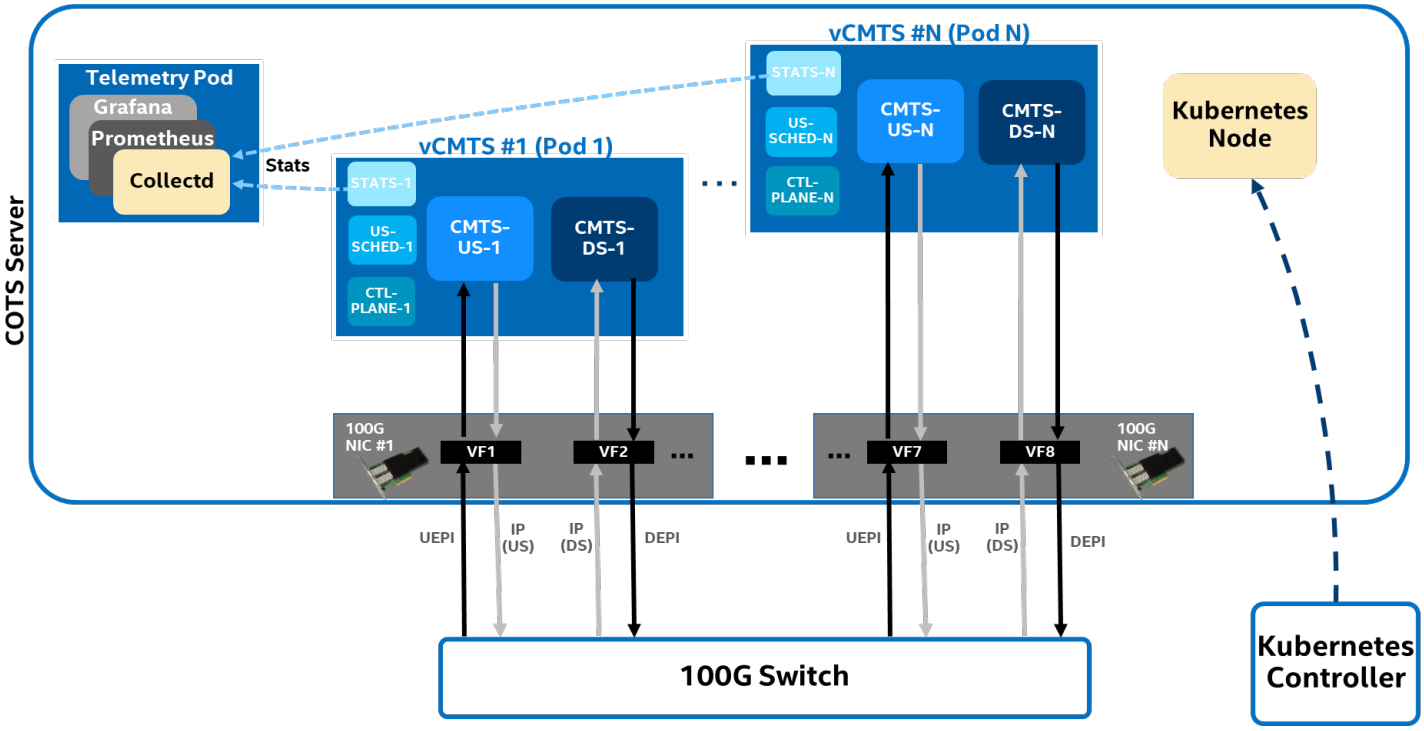

Figure 6 - Cloud-native vCMTS Simulation Environment

Reference [5] provides details of the performance capability of a cloud-native vCMTS data-plane. Empirical performance measurements such as shown in Figure 6, taken using the Intel vCMTS reference data-plane, prove that a cloud-native vCMTS is more than capable of achieving the throughput required for future DOCSIS 3.1 and 4.0 capabilities, and indeed to support transport of 5G small-cell traffic.

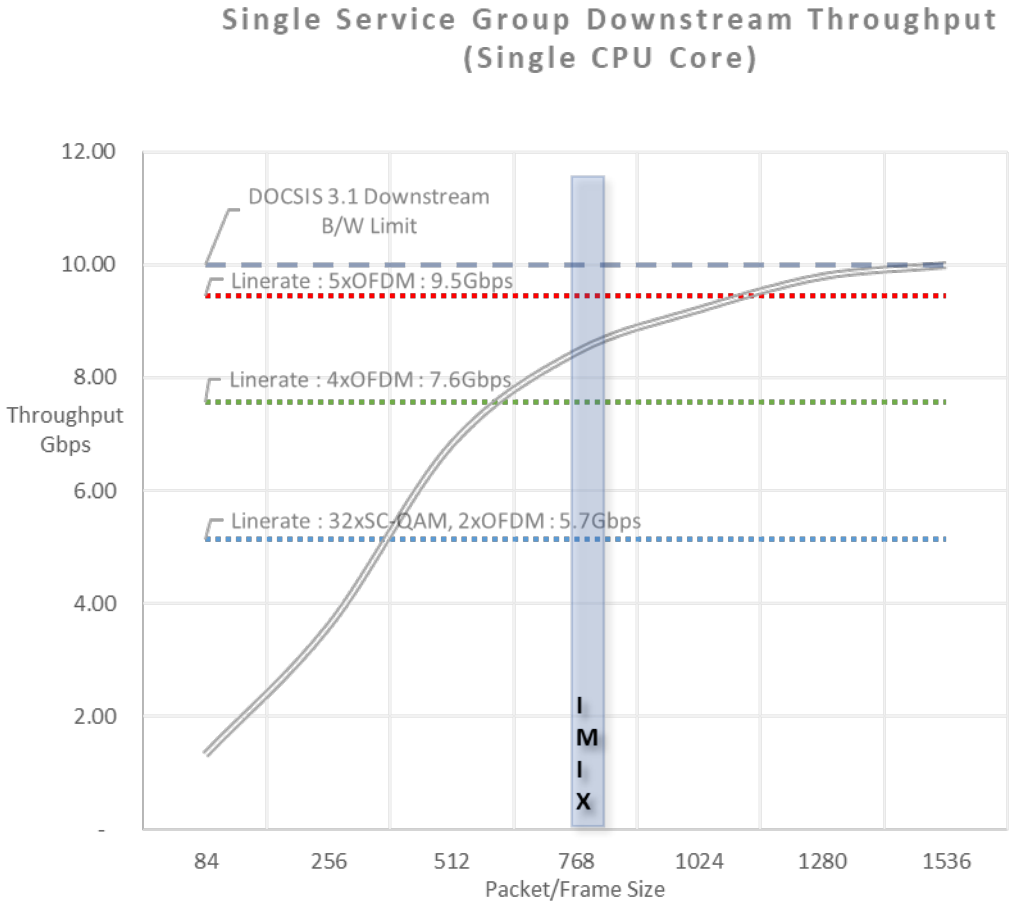

Figure 7 –vCMTS Data-plane throughput capability of a single CPU core

Scalable performance is a key aspect of vCMTS that directly paves the way for 5G xhaul and FMC use-cases. Each have their own particular performance requirements which will be covered in the respective sections that follow.

3. Extending vCMTS to support 5G Xhaul

Multiple systems operators (MSOs) are rolling out 5G deployments for a number of different business drivers and using a number of different convergence approaches. Operators like Shaw Communications and Videotron have acquired or built wireless assets to become mobile network operators (MNO). Charter, Comcast and Cox have entered into mobile virtual network operator (MVNO) agreements with MNOs such as Verizon and T-Mobile. In an MVNO agreement, the MVNO pays the MNO a fee to carry subscriber traffic over the MNO network. Still other operators like Vodafone began as an MNO and later acquired fixed network assets.

One common element across these operators is that there is a certain cost associated with carrying subscriber traffic and there is a goal to minimize that cost, thereby increasing operating margin. Minimizing cost to a large extent means leveraging existing assets to their full extent. A key existing asset in the cable industry of course is the hybrid fiber coax (HFC) network. Charter and Comcast plan to use the HFC network to build a network of 5G small cells to offload MVNO traffic, thereby reducing service cost. They and other operators will also market their HFC network to carry traffic for other operators planning to deploy their own small cell networks.

Three possible 5G functional split options are shown in Figure 7 below. Throughput and latency requirements placed on the HFC network will vary depending upon the split. These requirements are categorized as fronthaul, midhaul and backhaul with fronthaul having the most stringent bit-rate and latency constraints and backhaul the least.

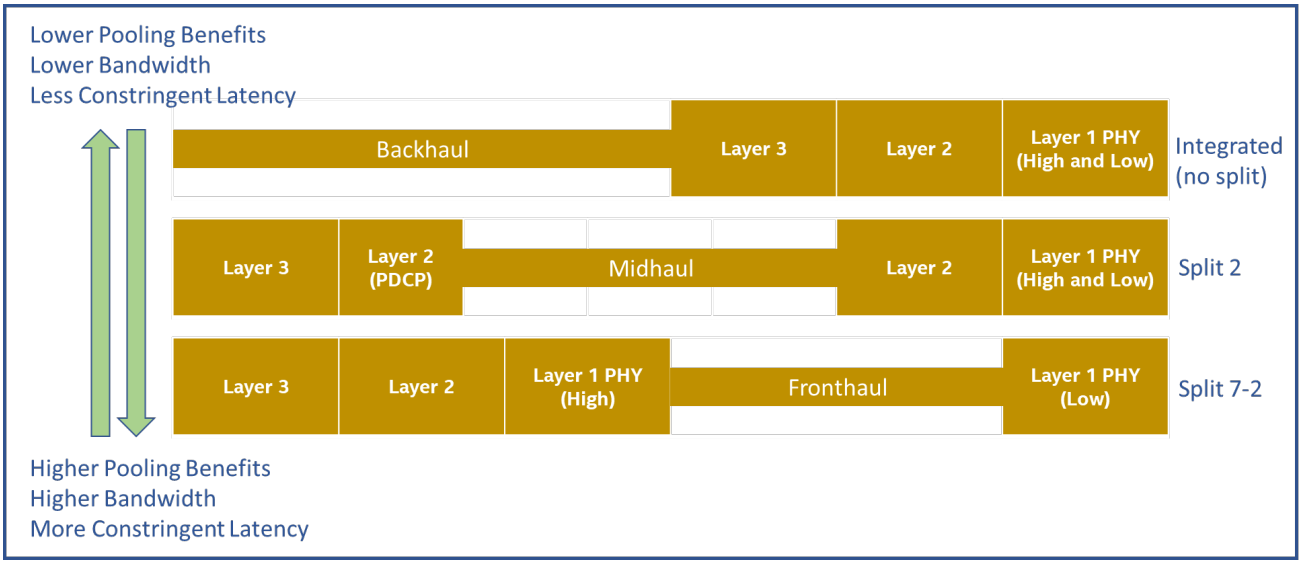

Figure 8 – Possible 5G Functional Split Options

Because HFC networks reach over 90% of North America and many parts of Europe, MSOs are uniquely positioned to quickly and cost-effectively roll out 5G if the HFC network can meet these latency and bit-rate requirements. Unfortunately, a 'plain vanilla' DOCSIS 3.1 network is hard pressed to meet all but basic mobile backhaul requirements.

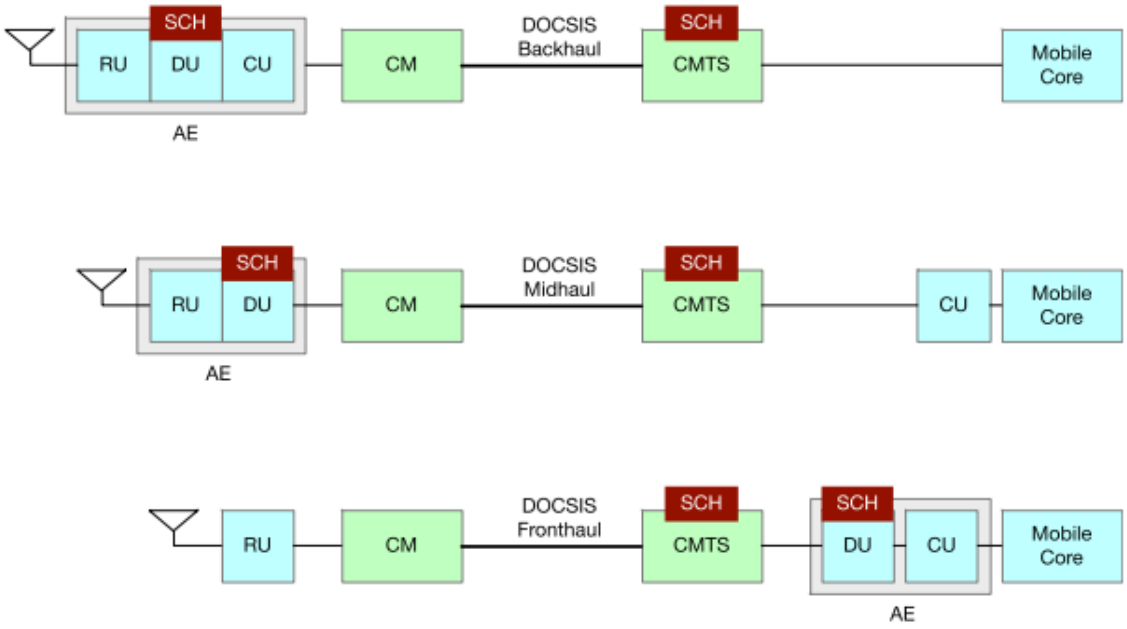
But several recent technology advancements will greatly enhance the ability of the HFC network to meet 5G xhaul requirements - namely:

- The recent release of the DOCSIS 4.0 standard enabling multi-gigabit capacity in both uplink and downlink
- Distributed access architecture (DAA) which enables a software-based DOCSIS MAC to be deployed at the Cable head-end or remote HFC node
- The development of flexible MAC architecture (FMA) which enables flexible deployment of DAA options
- Low latency DOCSIS (LLD) which provides latency-sensitive traffic management
- Low latency xHaul (LLX) which streamlines upstream scheduling across 5G and DOCSIS schedulers, further reducing latency
- Finalization of the generic access platform (GAP) hybrid fiber coax (HFC) node specification which enables operators to deploy modern CPUs in nodes to implement evolving access protocols and optimization techniques in software much more cost effectively

In the remainder of this section, we will focus on LLX and GAP to showcase how implementing DOCSIS in software (i.e. implementing vCMTS) paves the way for 5G xhaul.

3.1. How to achieve low latency for 5G xhaul over DOCSIS

Figure 8 below shows how a DOCSIS access network may be used as a transport for 5G backhaul, midhaul and fronthaul cases. This is an example of infrastructure convergence which includes the transport network as well as common hardware and software.

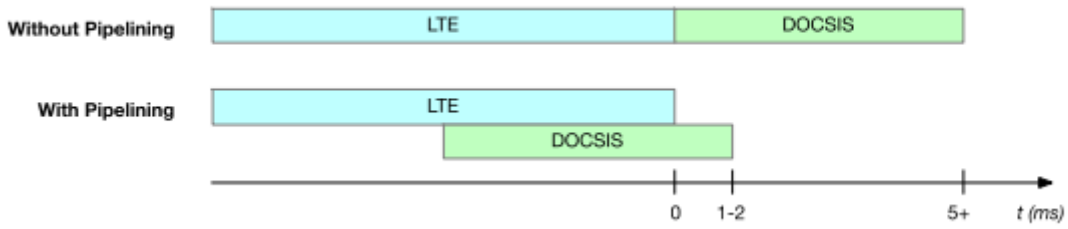


Source: CableLabs, "Low Latency Mobile xhaul over DOCSIS Technology"

Figure 9 – Access Entity Definition for Mobile Xhaul

As both DOCSIS and 5G are shared-medium networks, an upstream scheduler (SCH in the diagram above) must be present to ensure that traffic from subscribers does not collide. These respective schedulers introduce latency because a subscriber must ask and wait for permission to transmit through a request-grant message sequence. Without any optimization, the delay is compounded since each network has its own scheduler cycle.

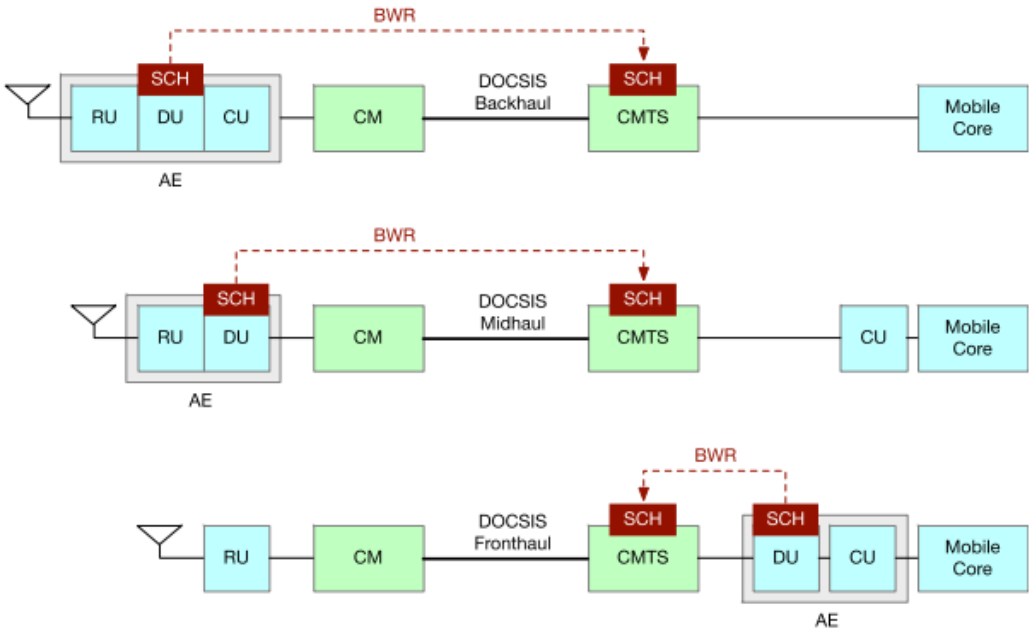
Through use of LLX (as specified in reference [8]) the DOCSIS upstream bandwidth grant request-response delay is hidden behind the equivalent upstream traffic scheduling function for wireless access as shown below (noting that while the diagram shows LTE, the same principles apply 5G)



Source: CableLabs, "Low Latency Mobile Xhaul over DOCSIS Technology"

Figure 10 – Hiding DOCSIS Upstream Sheduling Latency behind Mobile

This is achieved by adding the bandwidth report (BWR) capability to the 5G DU and the DOCSIS Upstream scheduler in order to pre-determine the upstream grants needed on the DOCSIS network for Mobile xhaul.



Source: CableLabs, "Low Latency Mobile Xhaul over DOCSIS Technology"

Figure 11 – BWR Transits Across Xhaul

As shown below, a cloud-native vCMTS software architecture can be relatively easily adapted to support the LLX BWR feature required for low-latency transport of 5G small-cell traffic. This is because the upstream scheduler is simply another algorithm implemented in software. As such, only software in the vCMTS system needs to be updated to implement LLX – and specifically only the software algorithm that implements the scheduler. Contrast that with a proprietary CMTS consisting of several sub-systems engineered to a specific set of requirements. Any change in the target requirements means that each sub-system needs to be carefully evaluated and re-tuned – which could include updates to proprietary hardware – a long and expensive undertaking.

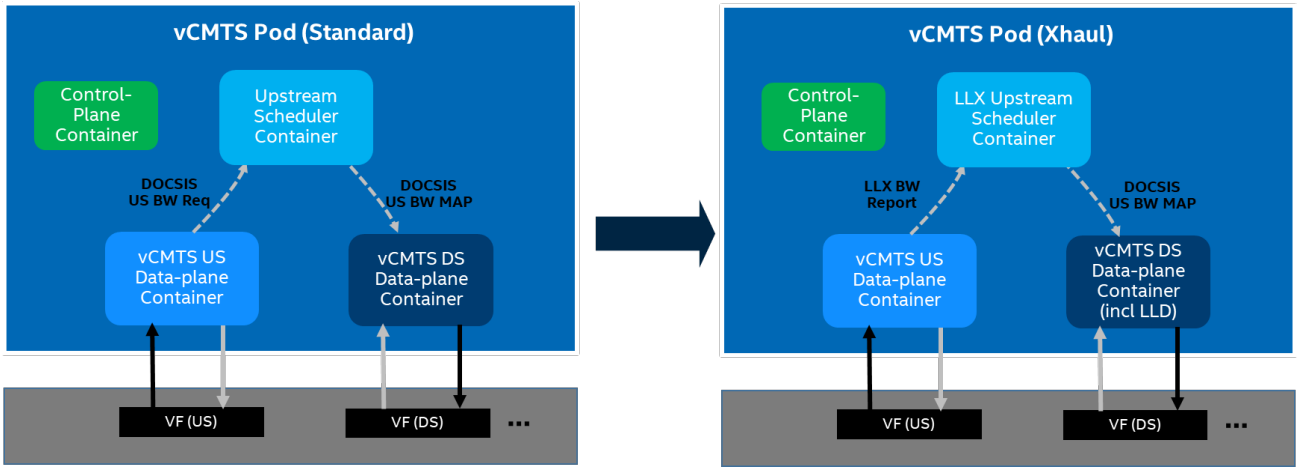


Figure 12 – Cloud-native Software Architectiture for LLX

But does implementing vCMTS (i.e. DOCSIS processing in software) actually introduce significant latency?

It can be seen in Figure 12 below from a CPU cycle count breakdown of the vCMTS upstream and downstream data-plane pipelines in software that it is possible to achieve ultra-low packet-processing latency in software with a single core run-to-completion pipeline based on a high-performance packet-processing frame-work such as DPDK or FD.io/VPP.

Considering average CPU cycles per packet for upstream and downstream vCMTS data-plane pipelines, based on measurement using the Intel vCMTS reference data-plane (reference [6]) with a 2.2 GHz CPU clock, software can perform DOCSIS MAC processing on upstream and downstream packets at an average of 615 nano-seconds and 967 nano-seconds respectively.

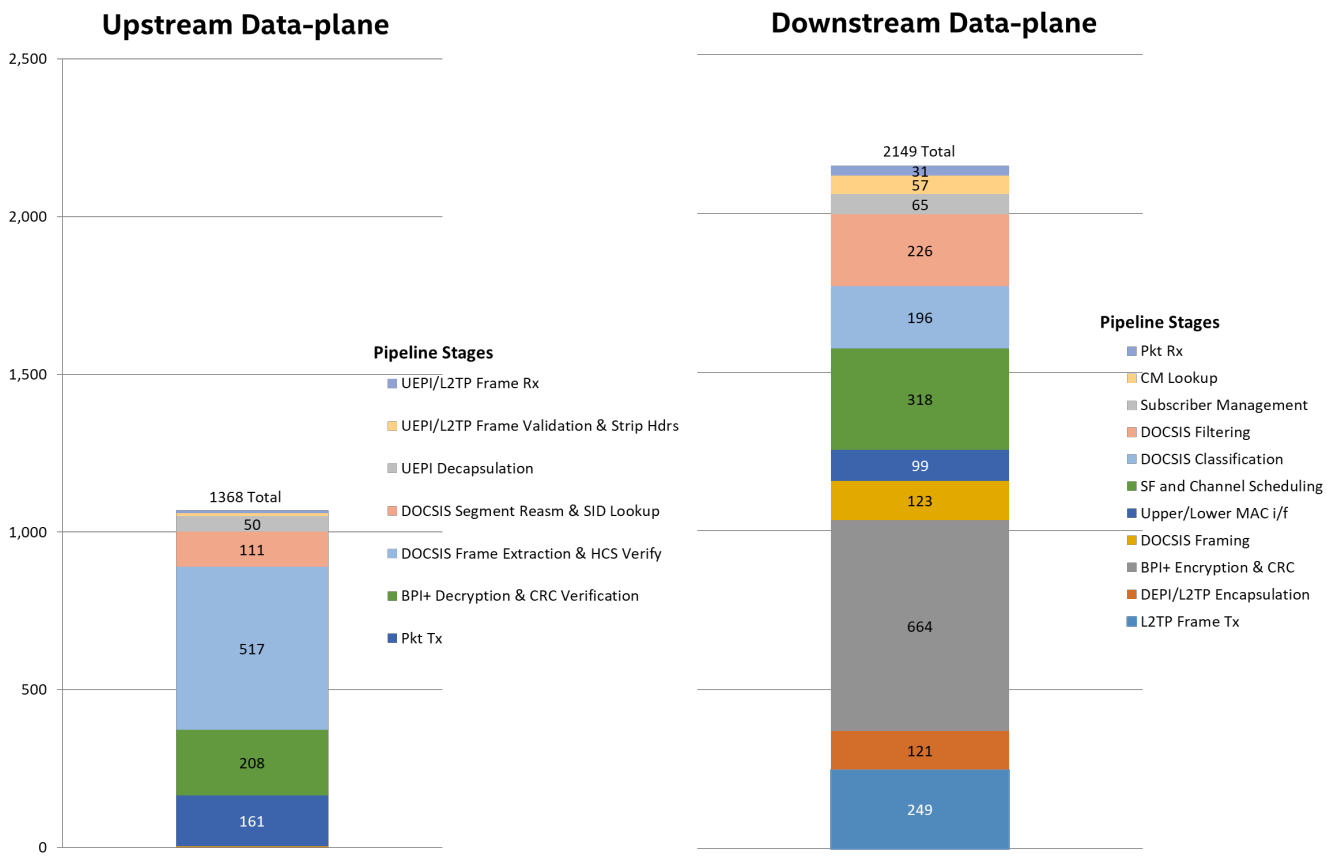

Figure 13 – vCMTS data-plane CPU cycle-count breakdown

However, latency is also added by packet buffering which occurs at three points in a DOCSIS MAC data-plane software pipeline - NIC Receive, Transmit and Downstream QoS scheduling. However, based on latency analysis using the Intel vCMTS reference data-plane, an optimally tuned system, can achieve sub 100 micro-second average latency per frame with a DOCSIS MAC data-plane implementation in software.

Low latency DOCSIS (LLD) functionality as described in a white-paper from CableLabs (reference [9]) may be used to reduce the impact of this by extending the standard Downstream Service-Flow QoS scheduling component to prioritize latency sensitive flows such as 5G signaling when vCMTS is being used for 5G xhaul over DOCSIS. LLD will most likely be needed to achieve the ultra low latency required for 5G fronthaul over DOCSIS.

The combination of an ultra-low-CPU-cycle software pipeline and the low-latency extensions to the DOCSIS standard described earlier should enable DOCSIS to meet the latency requirements for 5G backhaul and it should even be possible to meet the more stringent latency requirements for midhaul by combining LLX with proactive upstream scheduling.

Further work is needed to prove that DOCSIS is sufficient for 5G fronthaul, which has latency requirements in the order of hundreds of microseconds. At this low level of latency, even the PHY layer

latencies become critical and need addressing. As for the DOCSIS upstream schedular related latency, LLX could potentially be augmented with AI models for better traffic pattern prediction resulting in even smaller request-grant cycles and less grant waste. Perhaps the solution lies in a custom grant-request cycle just for small cells, or a combination. Whatever the future solution brings, vCMTS is just a software upgrade away from implementing that solution which makes vCMTS a logical first step in 5G over DOCSIS and network convergence.

Not only is vCMTS more easily adapted to new innovations, but it can be readily scaled down and distributed as needed.

3.2. How FMA and GAP can help with 5G xhaul scenarios

As shown below, the portability of software enables the same DOCSIS MAC software to be used for all three flexible MAC architecture (FMA) scenarios being specified by CableLabs (see reference [10]).

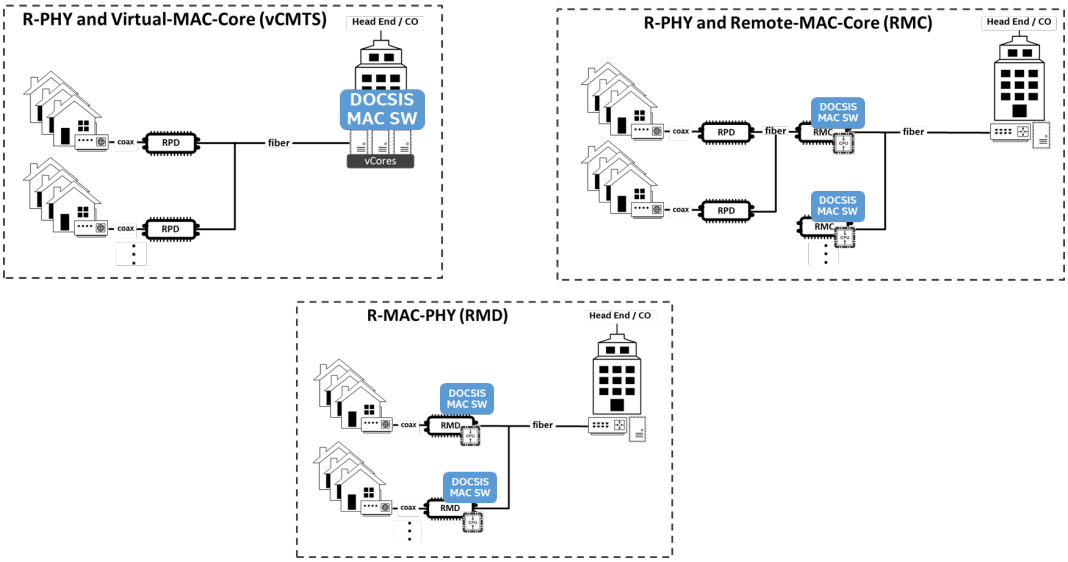

Figure 14 – Portability of Software for Flexible MAC Architecture Scenarios

Overlaying these three FMA options with the RU, DU, CU split options shown in Figure 7 produces a rather large matrix of deployment options for 5G over DOCSIS.

The industry is still in the process of evaluating these deployment options. While not all options ultimately will get deployed, it is most likely that at least several will get deployed because operators all have different assets and aspirations.

Analogous to the Intel vCMTS reference data-plane (see reference [6]), Intel has developed vRAN reference software (see reference [12]) for the upper PHY portion of a 5G base band unit (BBU). The industry eco-system adds layer 2 and layer 3 components to implement a full software based vRAN stack. This means both DOCSIS and RAN access implementations that are almost entirely software-based exist in the market today. In the case of vCMTS, the PHY is implemented in hardware and in the case of vRAN, the lower half of the PHY is implemented in hardware.

Because vCMTS and vRAN are both software based and can be scaled and moved as needed, implementing the matrix of FMA and RAN splits in combination becomes a much more tenable exercise. And as technology evolves both in the RAN and CMTS stacks to make them work better together, implementation of that new technology is a software upgrade away.

Of course, a suitable CPU host is required to run these software stacks. In the headend, the host will be a standard off the shelf rack mountable server with one or more x86 processors. But until recently a suitable CPU host in the HFC node did not exist.

The SCTE has recently released the generic access platform (GAP) specification. This specification defines the mechanical, electrical and thermal requirements of a modular, standardized strand mount HFC node enclosure. GAP includes the specification of a high speed PCIe/KR backplane which means that GAP is a suitable host for modern day x86 and other processors.

AOI, ATX, Charter, Cisco, Intel and Silicom demonstrated an early working prototype of a general purpose compute module at CableTec Expo in 2019 (see reference [13]). Coupled with an RPD module, the prototype was an early implementation of a software based RMD device. By adding the appropriate vRAN BBU components, a GAP RMD node becomes a key enabler for 5G over DOCSIS. While out of scope for this paper, by adding a pluggable PON SFP, a GAP node can similarly be used to drive 5G small cells over PON.

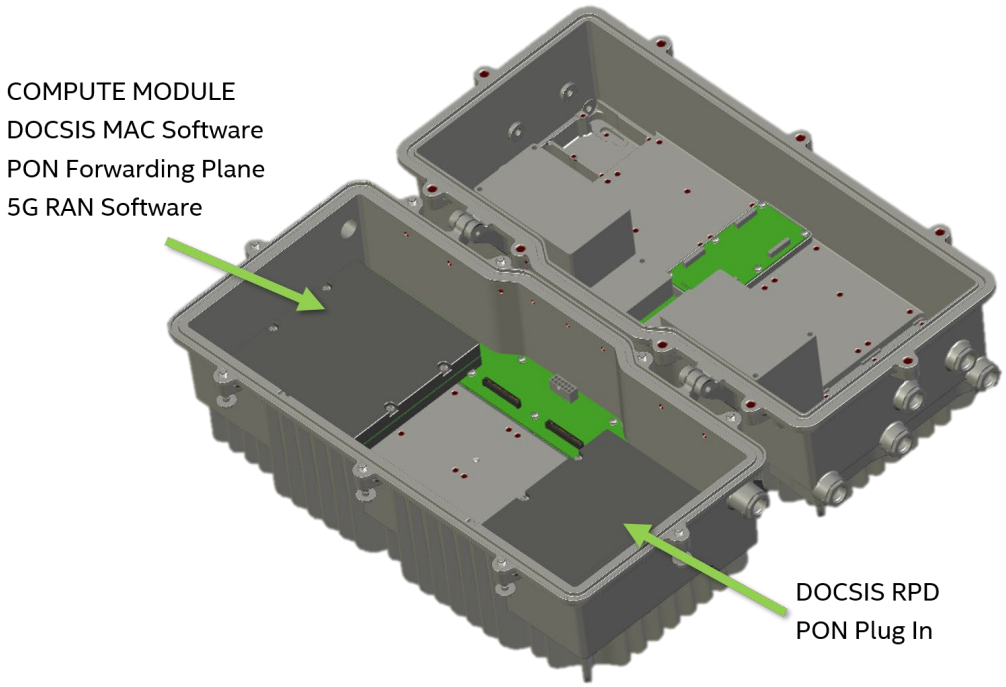

Figure 15 – GAP Configuration for RMD

Other Benefits of a software-based access network include enabling the highest degree of flexibility as it can be written once and re-targeted onto different platforms such as central-office servers or edge nodes.

But there are other more compelling reasons to move to software-based access that revolve around the availability of a tremendous amount of readily available software tools and packages.

Examples include:

- Telemetry frameworks and tools for faster fault detection and correction built around modern interfaces such as Yang models.
- Management and orchestration tools for easier and faster provisioning as well as 'self-service' customer provisioning.
- Network slicing applications to automate the creation of customer defined networks with customer specific characteristics around throughput, latency and quality of service.
- AI and Deep Learning frameworks to build sophisticated network optimization algorithms.

While it could be argued that all of the above are POSSIBLE to implement on networks with proprietary access nodes, software-based access nodes make the above much more PRACTICAL to implement. The reason is simple economics. Standard tools and utilities are developed for a broad range of markets and industries. This means that the cost of development is amortized over a much larger footprint and in the case of open source, that development cost is shared across several companies. Contrast that to a proprietary CMTS as an example where a single vendor historically had to develop 100% of these tools – including custom command line interface (CLI) protocols tasked with managing several internal sub systems such as ASIC based line cards. The latter is costly, time consuming to implement, costly to maintain and largely not re-usable.

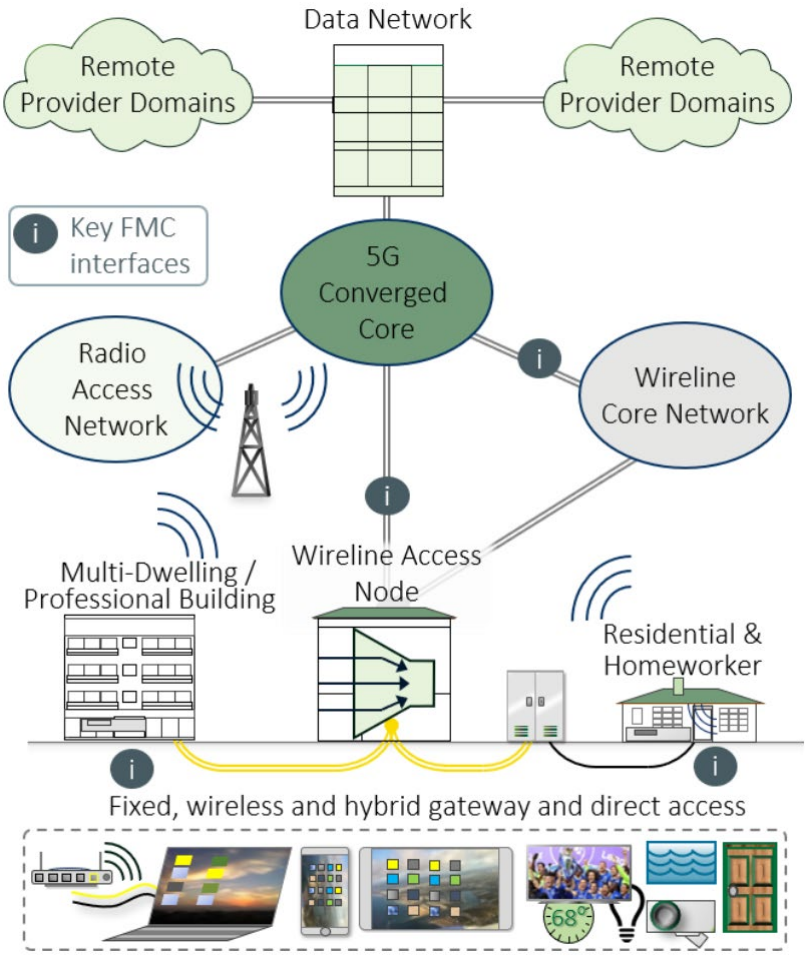
4. Adapting vCMTS for Cable FMC

The goal of fixed mobile convergence (FMC) is to have a common core across wireless and wireline access networks. The term wireless and wireline convergence (WWC) is used by 3GPP to describe this convergence which may also be applicable to Cable access; for the purpose of this paper FMC will be used to describe this, whether for Cable or BBF Wireline.

As described in reference[16], the drivers for this include:

- Seamless multi-access connectivity and simplified service experience for end-users
- More effective use fixed and mobile assets for service providers
- Opportunity for service providers to properly integrate emerging technologies such as Connected Home, Virtualization/Cloud and High-speed Broadband Access

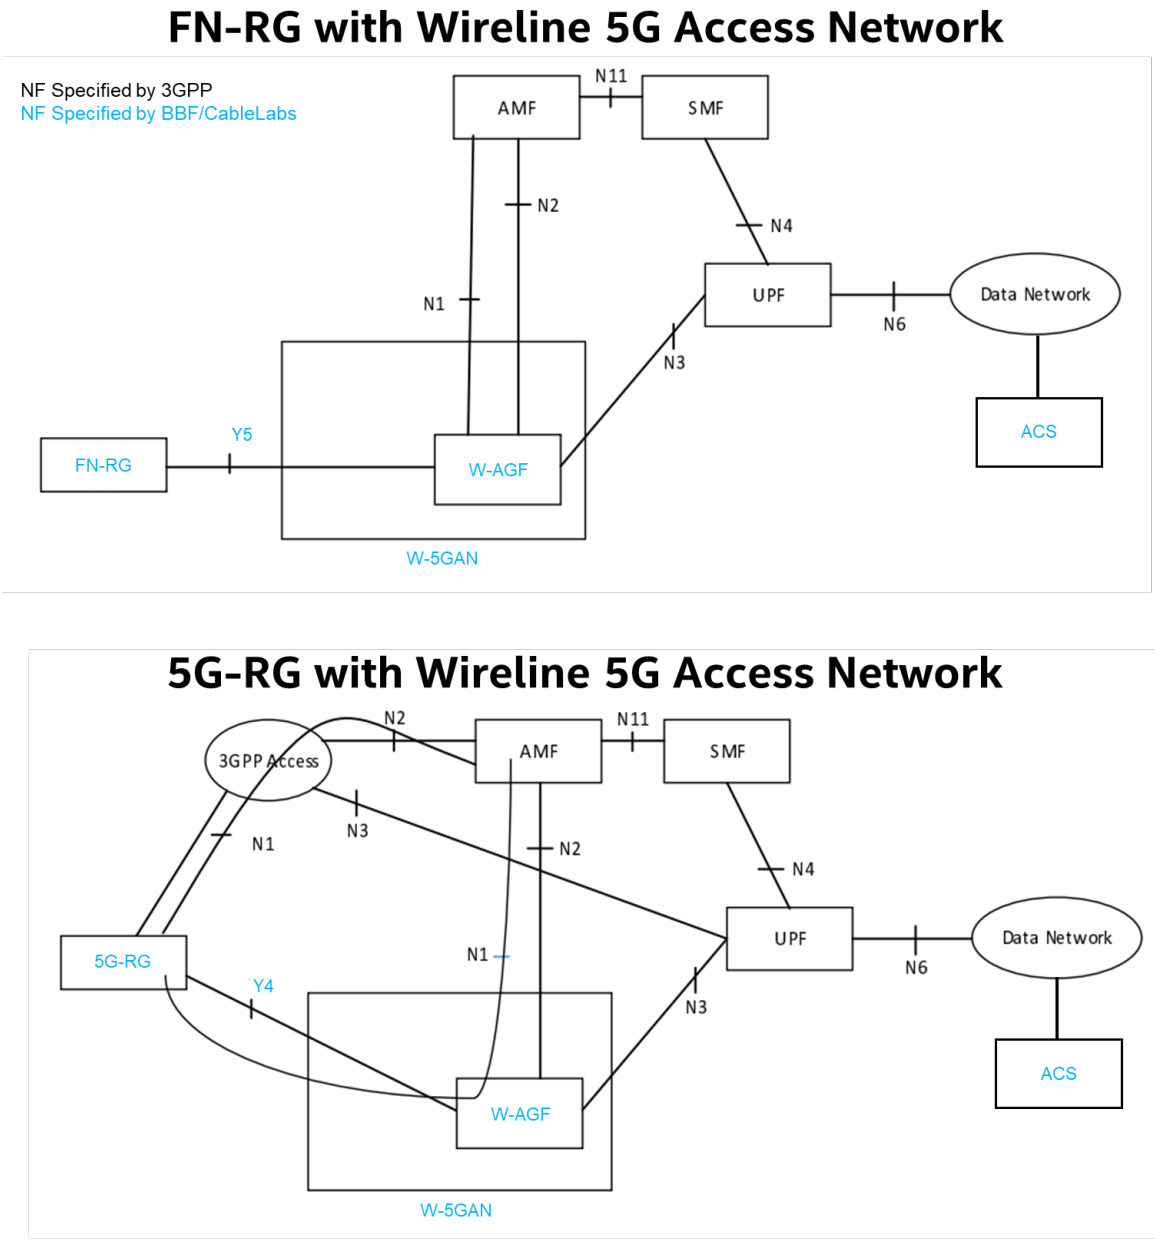
Figure 15 shows the desired end state for WWC/FMC – both wireline and wireless access served by a single 5G core.



Source: Broadband Forum, "5G Fixed-Mobile Convergence – Marketing Report"

Figure 16 – 5G Fixed-Mobile Convergence

As stated in the 3GPP TS 23.316 specification for wireless and wireline access support (reference [17]) the key network function required for convergence is the Wireline AGF (W-AGF). This is a network function that mediates between the wireline access network and the 5G Core Network. In addition to supporting existing residential gateways (RGs), it is assumed that a new residential gateway (5G RG) will be introduced which must also be supported in the future (through the AGF). Both scenarios are shown below.



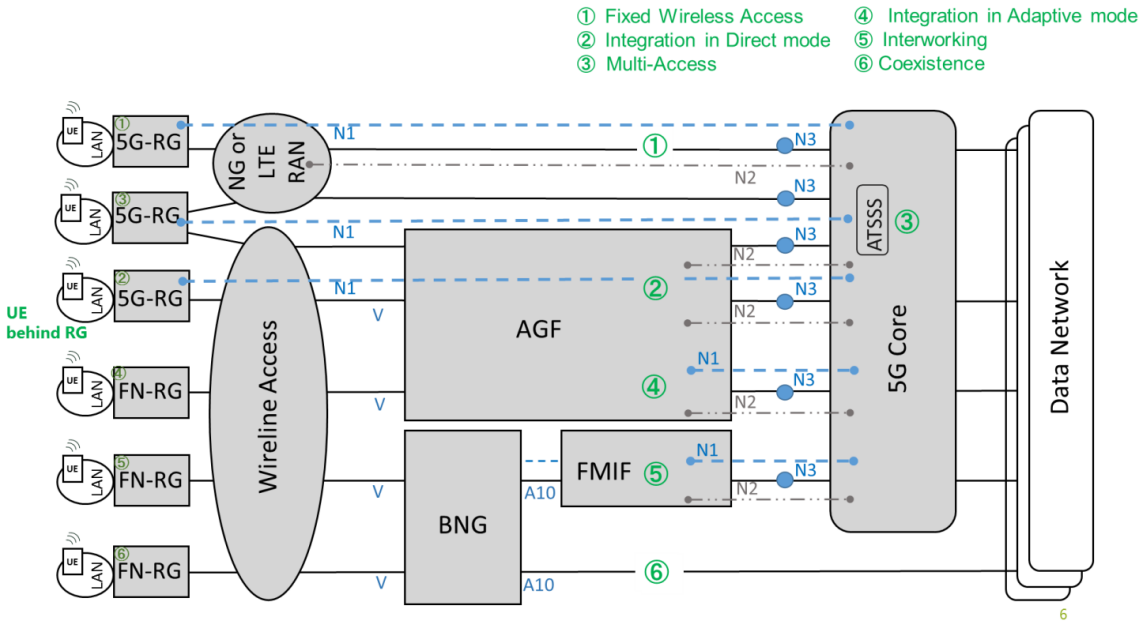
Source: 3GPP, "23.501 Rel 17: System architecture for the 5G System (5GS)"

Figure 17 – 5G Converged Core Architecture for FMC

While CableLabs was involved in the 3GPP Wireless Wireline Converged Core working group and published a technical report in relation to this (see reference [15]), the Broadband Forum (BBF) has made significantly more progress by providing FMC and AGF specifications for PON and DSL wireline access.

The requirements for initial convergence with existing RG's/Cable-modems should be similar to BBF: the integration of vCMTS functionality into a 5G-Core access gateway function (AGF) will be required to enable the use of the cable access network for FMC. At this point 5G and cable access networks become architecturally converged, the top level of convergence as shown in Figure 1.

Figure 17 below shows the five different FMC deployment scenarios/modes as defined by the BBF in TR-470.



Source: Broadband Forum, "TR-470: 5G Wireless Wireline Convergence Architecture"

Figure 18 – FMC Deployment Scenarios

The scenario most likely to be used for initial BBF convergence is **Integration in Adaptive Mode** with FN-RG (i.e. existing residential-gateways/modems). It is proposed that a similar approach also makes most sense for Cable FMC.

In this case the RG (aka modem) is connected over the wireline access network and the AGF mediates layer 2 traffic with the 5G core network based on N2 and N3 interfaces. However, FN-RG does not support N1, so the AGF acts as end point of N1 on behalf of the FN-RG. The AGF is said to integrate access sessions in "adaptive mode".

In the case of "adaptive mode" for cable access the AGF will perform the same functions as the vCMTS, on the Cable access network (aka CIN) side, while providing the following additional functionality to integrate with a 5G-Core on the other side:

- Control Plane function:
  - map wireline information into 5GC information
  - map 5GC information into wireline information

- proxy N1 and N2 on behalf of the FN-RG and generate all the relevant N1 / N2 signalling for an FN-RG that has been identified / connected via the wireline access network
- map data-plane L3 connections from the Cable access network to PDU sessions in the 5GC and provide relevant signalling on the N1, N2, N3 interfaces
- manage access specific resources based on 5G QoS profiles

- User Plane functions:
  - for Uplink: encapsulate incoming FN-RG traffic with a GTP-U Header (mapping to the appropriate GTP-U Session), apply an appropriate DSCP value to the outer packet and forward it to the UPF
  - for Downlink: decapsulate incoming UPF traffic by removing the GTP-U Header, mapping the incoming traffic to the appropriate RG service-flow (using the GTP-U header, QoS flow indicator (QFI) and DSCP value if provided) and forward the extracted packet to the target FN-RG

Below is a high-level view of an AGF for DOCSIS, with control and user plane split, connecting cable residential gateways to the 5G core through the cable access network.

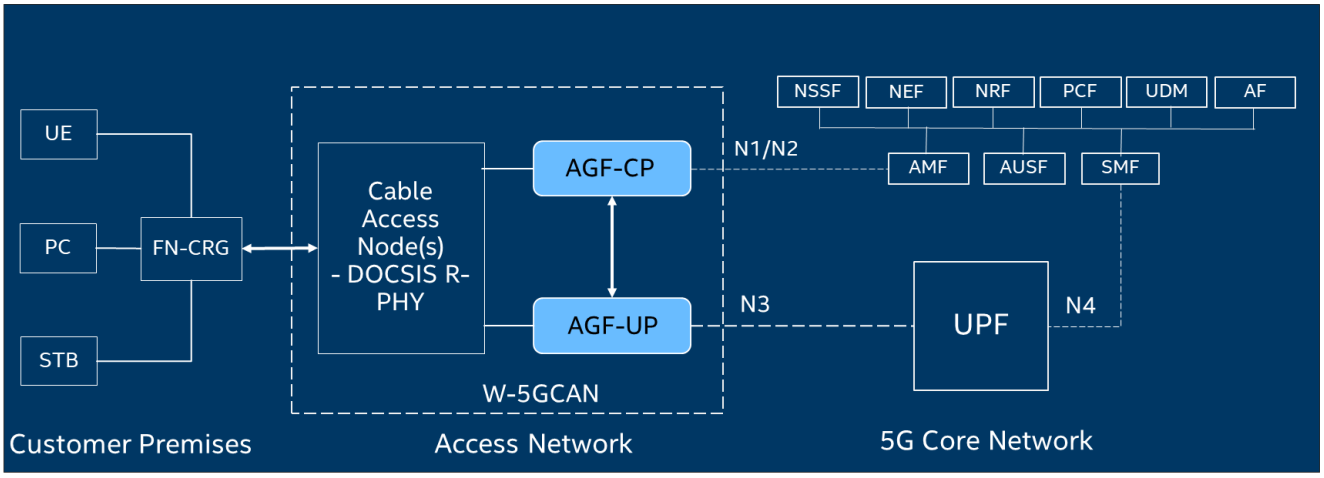


Figure 19 – Cable Residential Gateway Integration with 5G Core (in Adaptive Mode)

The existing software-based vCMTS network function will essentially need to re-purposed to become the vAGF network function as shown above. This will involve re-using vCMTS components such as DOCSIC MAC upstream and downstream data-planes, DOCSIS upstream scheduler and control-plane and integrating these with some new components for the 5G Core interface such as N2 control-plane, GTP-U encap/decap for 5G user-plane conversion and mapping of 5G QoS flows to DOCSIS service flows.

It is recommended that the Cable AGF adopt a control-plane/user-plane separation (CUPS) architecture which may require some re-architecting of an existing non-CUPS vCMTS architecture to deploy control-plane and data-plane functions in separate Kubernetes Pods on the same server or on separate servers in the same Kubernetes Cluster. Indeed, such an architecture has the added advantage of allowing control-plane and data-plane functions to be deployed at separate locations in the network. For example, it may be desirable to place the control-plane function in the cloud.

In terms of performance requirements for a Cable vAGF, data-plane throughput and latency are the critical KPI's that need to be considered. Upstream scheduling latency may be addressed in the same way

as for 5G xhaul as shown in the previous section. The impact of adding additional processing stages for 5G user-plane adaption to data-pane also needs to be considered for FMC.

Below are the additional packet processing stages that would be added to a standard vCMTS data-plane to re-purpose it to a Cable vAGF data-plane processing pipeline. The additional stages are highlighted.

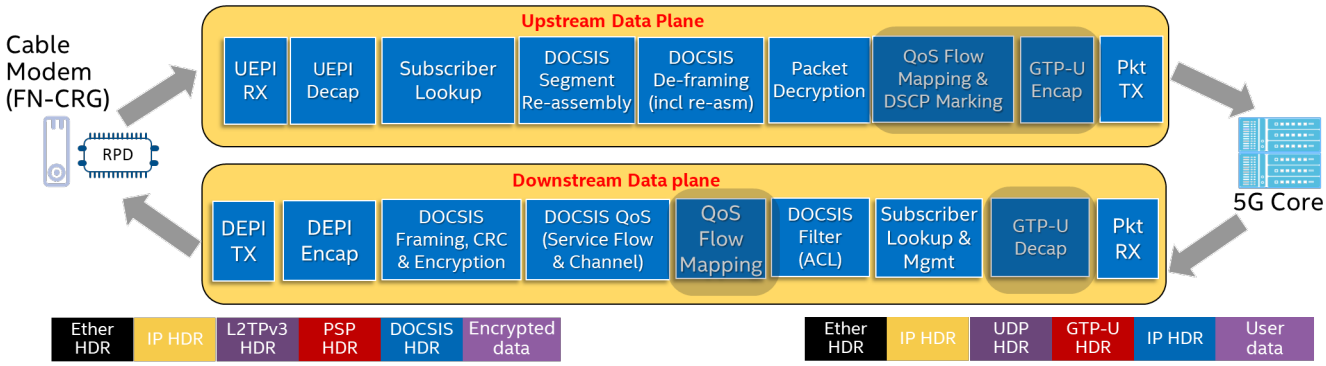

Figure 20 – Comparison of vCMTS and Cable vAGF data-pane processing pipeline

It is estimated that the additional processing shown above for 5G user-plane conversion adds 15 to 20% more CPU cycles per frame when compared to standard vCMTS data-plane processing. Given the performance capability of modern CPU architecture shown in Figure 6 and Figure 12 the required packet-processing performance for Cable access FMC is considered feasible in software.

It remains to be seen how broadly applicable AGF will be to cable operators; it may be a more desirable approach for mobile operators rather than cable operators. Furthermore, there are other viable approaches to fixed mobile convergence. For example, it could be said that MSOs such as Comcast have achieved this by deploying Wi-Fi Access Gateways in their cable network. This coupled with a high density of Wi-Fi hotspots allows subscribers to seamlessly switch between mobile and cable access networks.

However, it is clear that when starting with a cloud native vCMTS software architecture which is modular, extensible, and scalable, implementing FMC is greatly simplified versus starting with a proprietary hardware based solution.

As was shown for the xhaul case, software offers the flexibility to enable deployment at the pace of innovation and standardization of FMC while advancements in CPU architecture and the accompanying high-performance packet-processing frameworks ensure that throughput and latency requirements can also be satisfied. Such flexibility will be key to MSO's leveraging their Cable access networks to take advantage of advantage of such a major new use-case as 5G FMC.

5. Conclusion

As shown in this paper, the flexibility of a software based vCMTS makes it much easier to adapt for new 5G use-cases such as xhaul and FMC and to evolve over time.

It has also been shown that a software-based vCMTS is more than capable of meeting the throughput and latency requirements to transport 5G small-cell traffic by leveraging new low-latency DOCSIS methods. These should be used in conjunction with high-performance packet-processing frameworks such as DPDK and FD.io/VPP which are highly optimized for modern CPU architectures, which in turn are continuously improving gen-on-gen to meet ever-increasing network processing performance demands.

A software-centric architecture also has the benefit of leveraging open-source and the thousands of engineering person-hours of optimization and feature-development in mainstream projects such as Kubernetes, DPDK and FD.io/VPP. Additionally, there exist off the shelf tools for telemetry, management, orchestration, and AI which can be leveraged to improve network performance and resiliency.

Ultimately it is clear that starting with a modular, extensible, and scalable cloud-native software based vCMTS greatly reduces development effort and time-to-market for the two major new 5G use-cases of Xhaul and FMC as well as future-proofing for further standardization and innovation.

How Working and Schooling from Home has now Driven a Change in How we View Home Connectivity and Networking

What We Did During the Pandemic and How it Could Define New Products and Services

A Technical Paper prepared for SCTE by

Charles Cheevers
CTO Home Networks

Charles.Cheevers@CommScope.com

1. Introduction

During the last 18 months many things have changed for many people. One indelible change seems to be how important our home is for working, schooling, and staying connected. While we cannot fully predict what the real ramifications of virtual working from home , schooling from home are going to be – there are many predictions of significant changes in our workforce locations from new permanent at home work increases to flexible working being introduced more by employers. As well as the work from home changes there are likely to be other permanent changes in how we view and use connectivity and digital connection from our home.

- Our consumption and use of OTT and IP video services has increased and adoption of its use by even more 'traditional telly' focused consumers has increased
- The number of connected IoT devices we have has increased – because of more online consumer adoption. The current silicon shortages have been the result in this rapid change in consumer purchasing behavior of electronic devices for the home.
- The rapid acceleration of adoption of Telemedicine services including virtual doctor visits that is likely to change the way we engage with our medical resources.

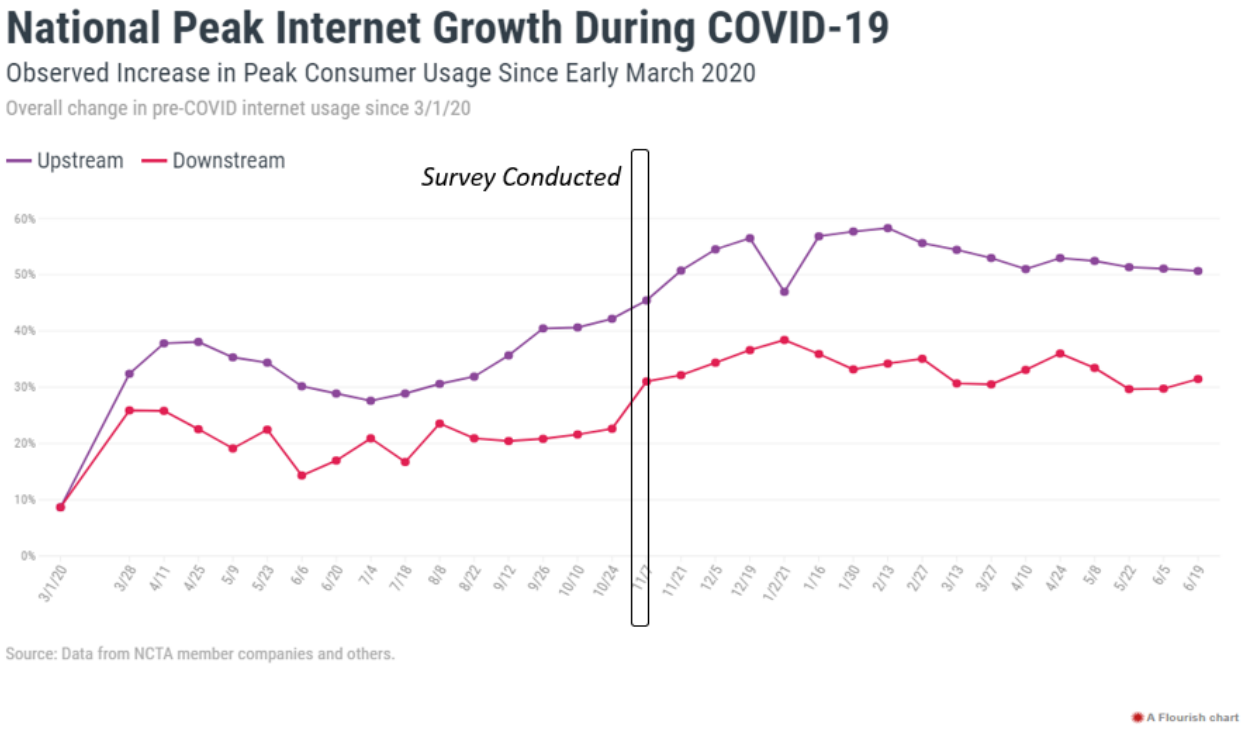
Because of this step function and acceleration in behavior change driven by being at home for 12-18 months there is now also likely potential for new and improved Service Provider services that offer to cater to raised awareness and desire from Consumers to improve elements of their connected digital home. In particular

- Reliability of home network connection
- Latency of home network connection
- Improved performance of Wi-Fi
- Separation of work environment at home from residential environments

And potential opportunity for Service providers to bring the Enterprise, School or Doctors office to the home via new services, devices, and technologies.

- WFH and Corporate services to the home
- Telemedicine and Aging in Place services
- Increased Privacy and Security
- Increased Reliability

This paper is the result of a poll of ~2,200 CommScope employees during the height of the pandemic last year in November 2020 when according to the NCTA Covid-19 dashboard – home downstream/upstream connectivity growth had not yet hit its peak (which seemed to happen during Christmas/Holiday Season end of December and early January 2021). The poll sought to understand the connectivity drivers and conditions of consumers during the pandemic and their robustness of connectivity and performance ratings. The paper will use some of this feedback to try and put the case forward that there are potentially new requirements for the Broadband delivered home. Based on the survey analysis it will then try and propose the potential for new pandemic home architecture and services potential and outline some of the new device and system elements that could play a new role for Cable Operators to continue to own the digital connectivity and services for their consumers.



2. November 2020 Survey of Working and Schooling at home

Given the drastic change in all our lives, 2020 presented a unique opportunity to survey people on their new environments of lockdown and working, schooling and effectively trying to do everything from home and on-line. This change of

- Number of end points on Broadband networks concurrently active
- Number of concurrent active devices in the home
- Frequency and time of use of Broadband
- Increase in upstream traffic from Video and Audio conferences
- Number of IP connected devices in the home
- Rooms and new locations in home being used for high value and high capacity services like laptop driven Video conferencing

has been described as almost 2 years of growth of capacity and services in a 6 month period. It did however accelerate how people create their home connectivity platform, resolve their niggling issues that were tolerable when they only had entertainment services primarily at home, improve range of connectivity as new rooms were occupied with WFH and Schooling activities.

Consumers views on reliability, camera resolutions, microphone quality and latency were all sensitized more because of the higher performance of being able to work effectively and to not be that person upsetting everyone else on Video conferences. Because of these changes in our home environment the thesis put forward was that the existing set of Broadband, Video and IoT services may

- Not be good enough to cope with the demands for service the pandemic has highlighted

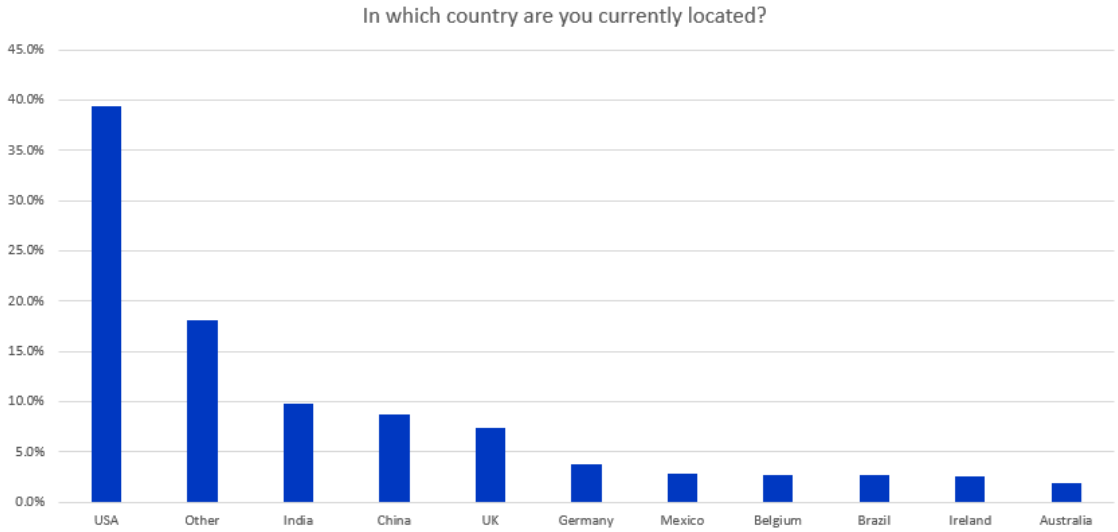
- Offer opportunity to improve services with new features that may either be sticky for consumer retention or drive new business opportunities
- Be driven by acceleration of new technologies like products developed using new 6GHz spectrum allocations, improvements in IoT like the new Matter solution.
- Be driven by price decreases in technologies like Cameras, Smart Assistants, Microphones, IoT devices which make them more accessible or potential for Operators to bundle into traditional broadband and Video services
- Be driven by acceleration of areas like Telemedicine which even as people resume some normality has reached a point in areas like Virtual Doctor visits where this has become more acceptable and the benefits of not having to wait in Doctors office for minor issues may move this faster to mass adoption
- Be driven by our adoption and acceptance of Video conferencing as a more normal and regular means of connecting with people generally and from the home
- Be driven by new niche areas that have been highlighted as capable of being addressed with technology solutions like Aging in Place – where during the pandemic innovative ways had to be created to keep elderly loved one's safe and connected

With the goal of trying to open up a discussion on new opportunities to capitalize on this technology acceleration and mind shift in consumers having changed habits pre-pandemic to more use of digital services this paper will first explore how over 2,000 consumers in different countries and with different

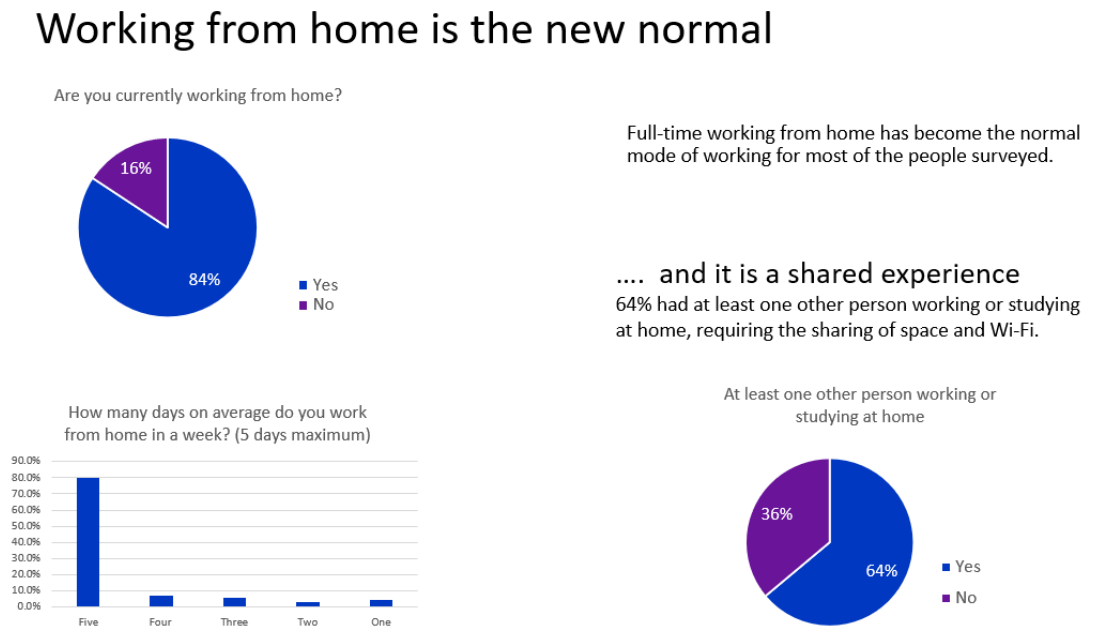
- Service Providers
- Home Sizes and constructions
- Home Family and occupancy differences
- Demographics

all coped and shared their insights to a series of questions that were asked to gage what they valued and what they will value going forward to ensure their homes are not just for after 5pm during the week for digital excellence.

Almost 40%/~1,000 of our respondents were from the US with the following spread of other non-domestic respondents in the table below. For the sake of this paper the answers to the questions are presented in a blended fashion as generally the differences created by the pandemic and the needs were similar in all countries.



The sample of respondents had 84% working from home. 80% of these were working full time (5 days) from home. Of course, the key issue with the working from home experience is that many homes during the pandemic had multiple people trying to work and school from home. In our sample 64% of respondents had others working or schooling with them while 36% were on their own.



Exploring the respondents working conditions in more detail, 23% of them had to share a working space in the home. Over 40% had 2 people in a room and 10% had 3 people trying to work and school in a

single room. While its is expected that many people will start moving back to their workplaces towards the end of 2021 many companies are now trying to find the best balance to

- Investment in Office real estate
- Creating collaboration face to face for innovation
- Maintaining flexibility for the employees to work more from home
- Allowing employees to work from home more permanently where it has made sense

To create and sell services to the needs of the height of the pandemic is the big question that is still hard to answer. However, there is a much more acute awareness of the reliability and performance of the home environment for connection to the internet and corporate office that is likely to remain, particularly for those employees who will remain working flexible conditions from home. As of the time writing this paper it does look like schooling will resume for the majority back in the classrooms at the start of the 2021/2022 school calendar. The worry about new developments in strains of the Covid-19 virus will keep consumers vigilant on their home connectivity performance but consumers will always balance their investment to their budget and additional performance/reliability features offered may not be invested in ahead of need.

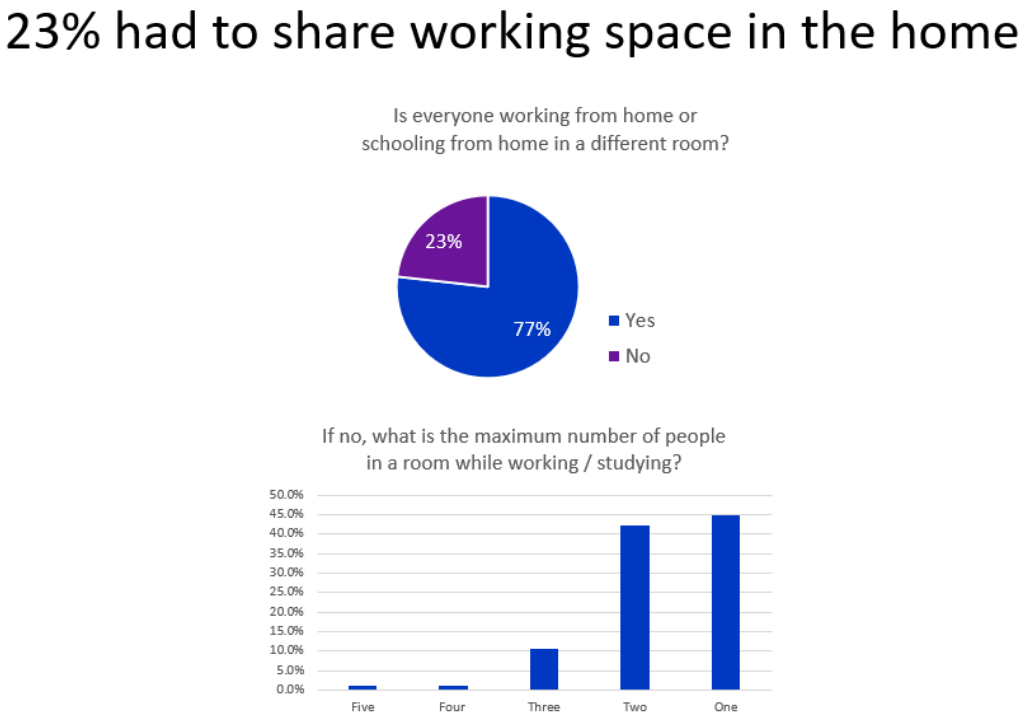


Figure 4 How many people had to share a room to work and school

Of those respondents working from home 42% of them had another person working with them and typically working 5 days per week. This has been a key stress point for both the psychological wellness of the workers from home as well as their connectivity performance.

Phycological wellness has been challenging for many households

- Parents working from home and schooling and minding children

- Multiple people trying to work simultaneously in small homes
- Audio and background interference during working and schooling sessions
- Problematic connectivity on important schooling or work video or audio conferences
- Additional group meetings to stay connected

Connectivity performance and its issues was also higher and more exacerbated in homes with multiple people working and schooling at the same time. The stress of problematic calls and connectivity would generate household questions like

- Was someone watching streamed video content while others where trying to work – and it is causing problems
- Could someone in the house drop their sessions to see would it help others
- Could someone having problems get closer to the Wi-Fi router and work in that room for a while
- Could everyone stop what they were doing so Gateway or Access Point could be rebooted to see does it resolve the problem
- Trying to resolve an outage with your Service Provider in time for that important call
- Giving schooling children priority during exams even at the expense of issues with Work tasks and meetings

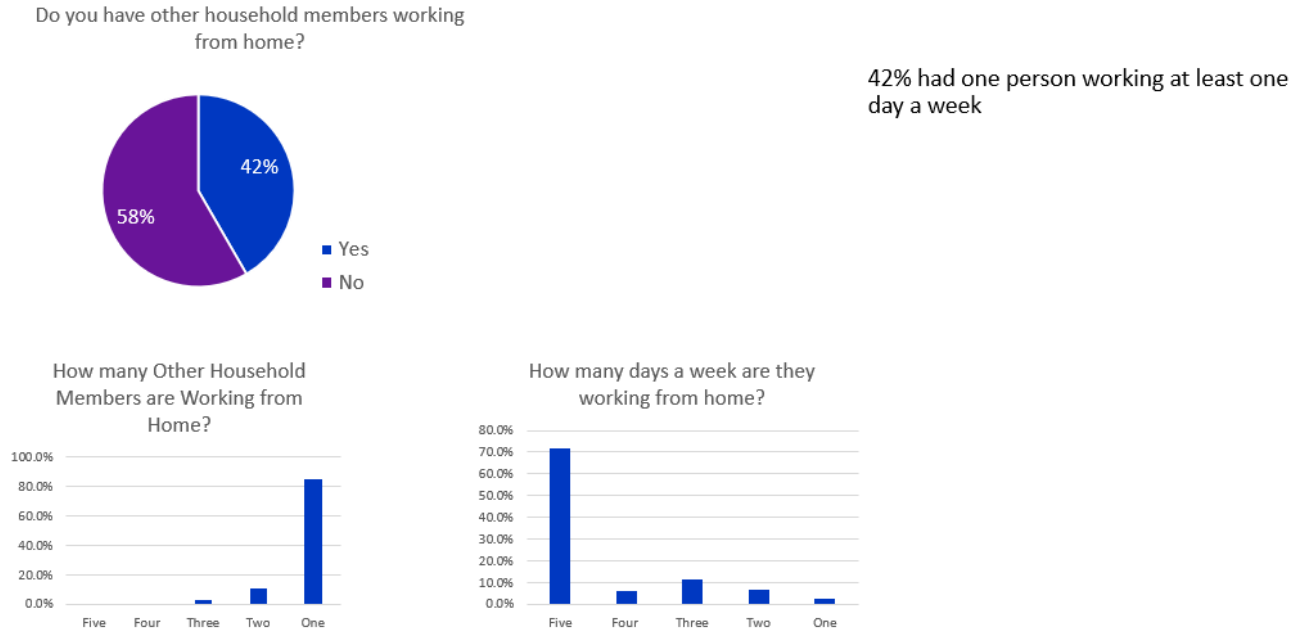

Figure 5 People working at home - did they have others working with them

Schooling from home was also important during the pandemic. In this survey 43% of the respondents had at least one child schooling at home with them. Over 50% of students were doing one day at home but most children were still attending school for the most part of the week. It is expected that most children or University students will go back to in school tuition in the coming 2021/2022 year. However, there is probably a marked rise in future homeschooling which in the US has typically been about 3% of children pre-pandemic but set to rise by potentially 5% based on effects of pandemic

(https://ifstudies.org/blog/homeschooling-is-up-thanks-to-covid-but-will-the-increase-last , https://www.census.gov/library/stories/2021/03/homeschooling-on-the-rise-during-covid-19-pandemic.html?utm_campaign=20210322msacos1ccstors&utm_medium=email&utm_source=govdelivery).

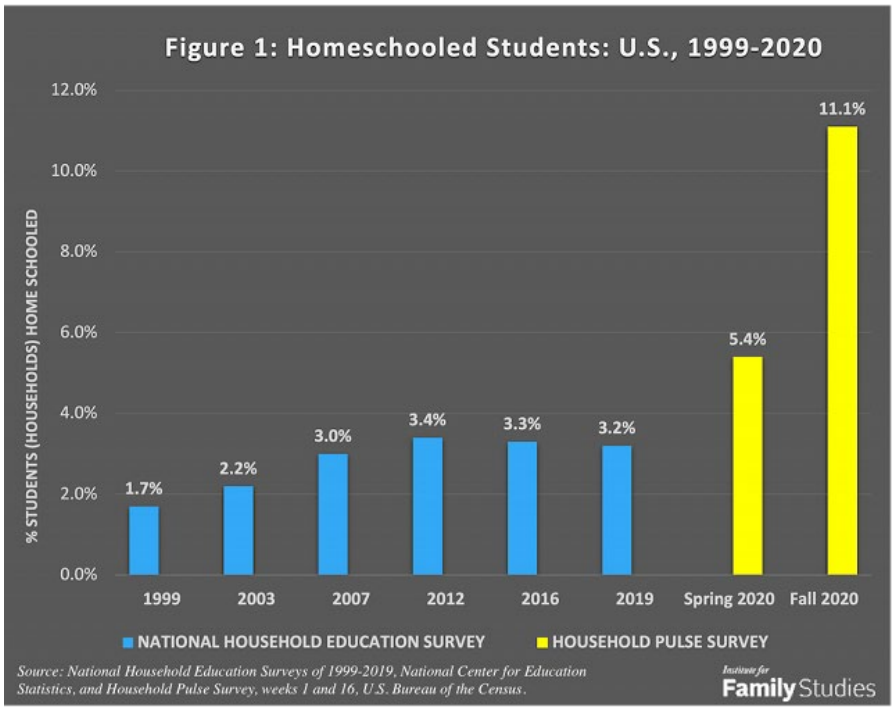

Figure 6 Homeschooled Students : US 1999-2020

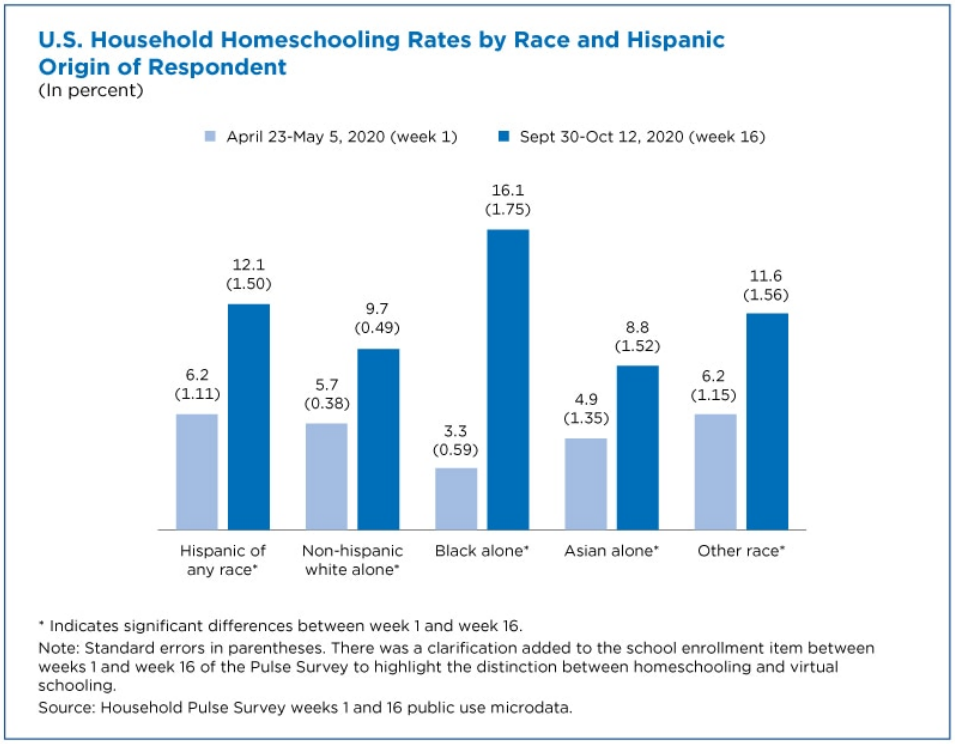

Figure 7 US Household Homeschooling rates

43% had children doing online schooling at home

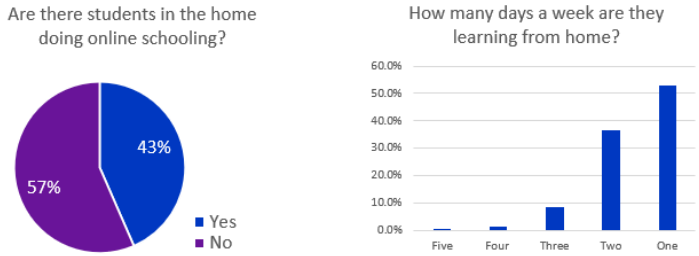

Figure 8 How many days were Children spending schooling at home

During this change in the home environment the importance of being able to work and school effectively raised in performance. There was pressure from several factors

- The ergonomics of a desk environment and replicating our office setup at home.
- Connectivity in particular Wi-Fi performance improvements
    - Bedrooms and every room being used for concurrent family member use exposing issues with Wi-Fi performance at range
- Audio performance – multiple people working in single room and generally trying not to allow the normal noises of home life interrupt work and school times.

- Introduction of Video Conferencing as the new pervasive tool to try and fill the gap for in person meetings and its performance affect on the upstream bandwidth from the home. Video conferencing applications were not as efficient in adaptive bit rate technologies and typically wanted to grab 1.5Mbps to 2.5Mbps to stream video upstream.

Looking at the way the survey respondents spent their money on to improve their new home environment, we see that it covered a number of areas in particular

- 55% of respondents bought desks.
- 40% of respondents improved their home monitors to augment their laptop screens
- Almost 30% of respondents bought separate microphone solutions to improve their audio performance
- Almost 20% of respondents bought new webcams to improve their Video Conference performance
- Over 40% of respondents bought Wi-Fi AP or Wi-Fi mesh solutions

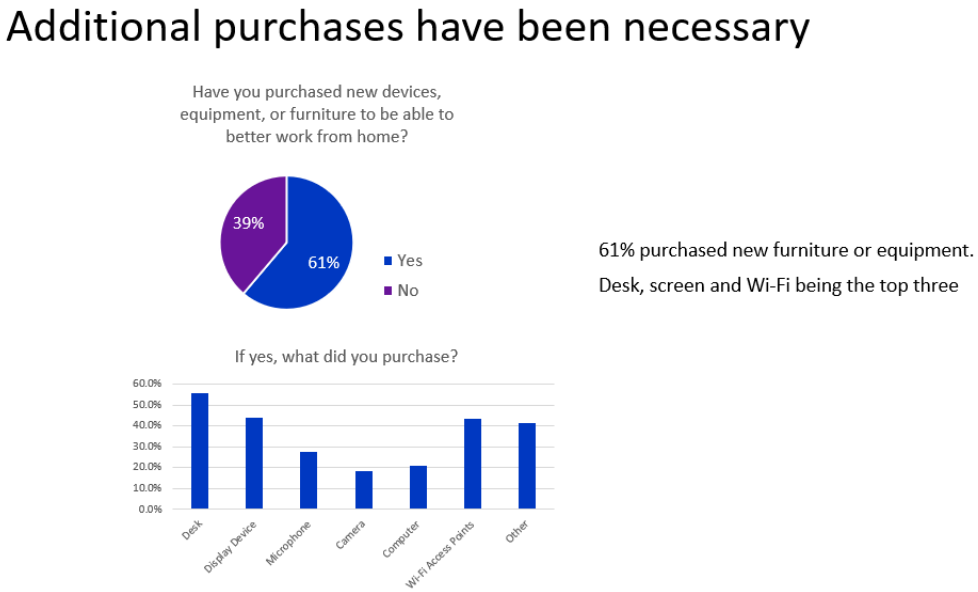

Figure 9 What items did WFH/SFH families purchase during the pandemic

With connectivity the main requirement of a stay at home solution the survey looked to see how respondent's connectivity performance catered to their work and school needs.

For Broadband speed generally 83% of respondents felt that the were on the right and acceptable broadband tier/speed for their requirements. The survey checked what access network the respondents were using with 30% of them on Cable, Fiber and FWA respectively. The ISP's the respondents were using was recorded and showed that 8 ISP's registered above 5% for our survey sample. Comcast, Charter, AT&T and Verizon served about 37% of our respondents. Internationally, China Telcom, Vodafone, Virgin Media, and Airtel also registered covering 5% of our respondents.

The survey also used the opportunity to see what percentage of homes had an MMP (Massive Multiplayer Gamer) in the house and 20% of respondents were gamer homes. As 10%+ of all downstream traffic now is gaming this is a growing segment of traffic that is important to understand for performance implications on home connectivity.

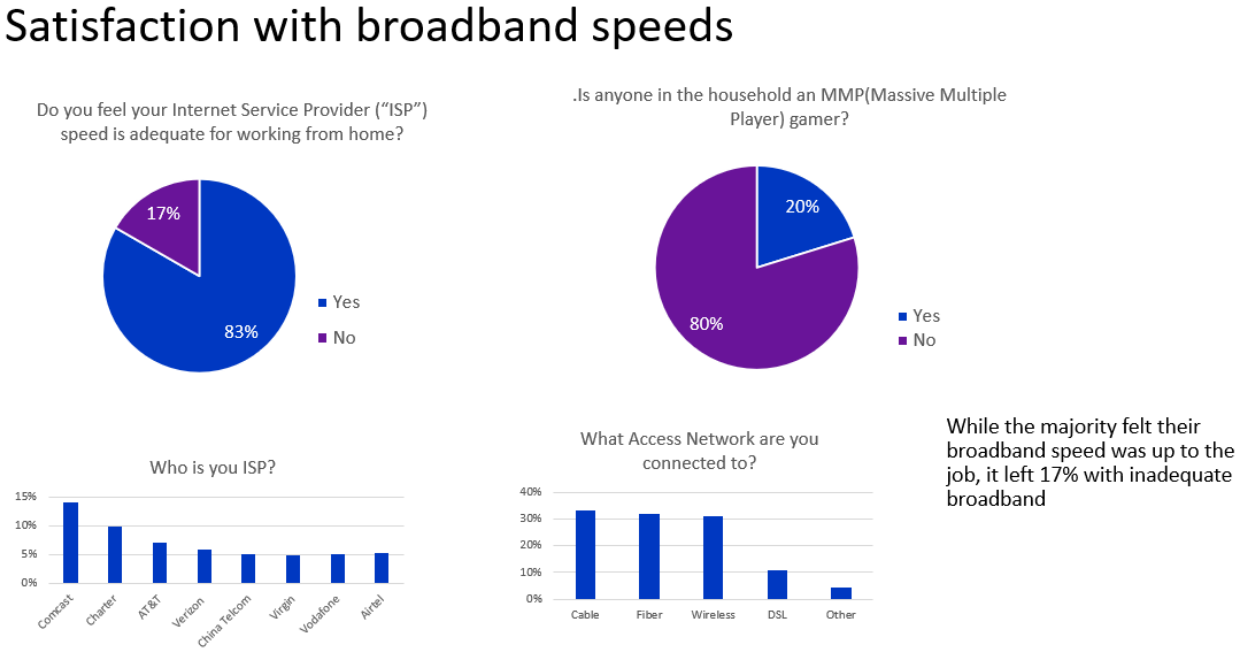

Figure 10 Consumer satisfaction with Broadband speed during pandemic

The survey further asked respondents to check their broadband speed both up and down and showed the following results.

Download speeds

- 25% of respondents were over 200Mbps
  - 7% of these said it was inadequate
- 17.5% of respondents were 100-200Mbps
  - 11% of these said it was inadequate
- 20% of respondents were 51-100Mbps
  - 19% of these said it was inadequate
- 21% of respondents were 21-50Mbps
  - 23% of these said it was inadequate
- And the remaining respondents 16.5% < 20Mbps
  - 40% of these said this was inadequate

Upload speed performance and robustness was the most important metric during the pandemic. The survey respondents answered for their homes that

- 4% of respondents had > 200Mbs Upstream performance (100% of these on Fiber networks)
  - 6% of these said this was inadequate
- 7% of respondents had > 101-200Mbps Upstream performance (100% of these on Fiber networks)
  - 4% of these said this was inadequate
- 10% of respondents had > 51-100Mbps Upstream performance
  - 10% of these said this was inadequate
- 30% of respondents had > 21-50Mbps Upstream performance
  - 10% of these said this was inadequate

- 16% of respondents had < 20Mbps Upstream performance
    - 70% of these said this was inadequate

Generally, it looks like respondents were happy with their broadband speed but room for improvement. It is the cost and hassle factors of upgrading or changing service provider for the return which will drive them to change. As the reader will see later in this paper the survey revisited this a few times as well as introduced reliability and latency questions to the overall view of Broadband performance.

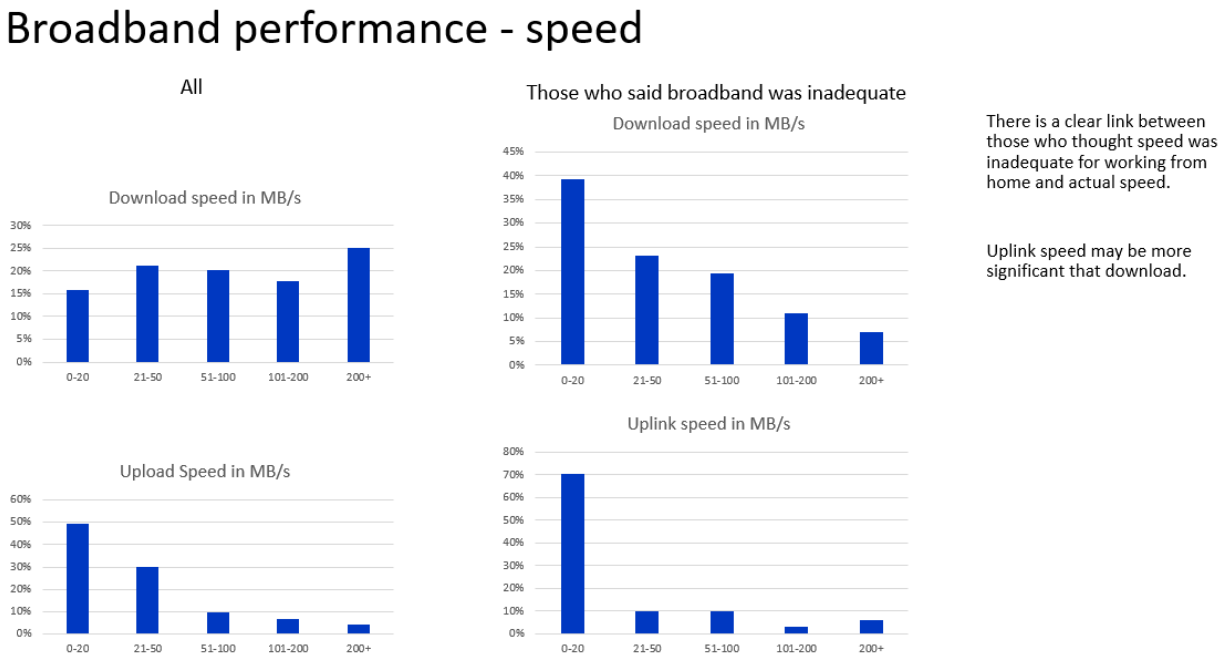

Figure 11 Consumers satisfaction with their Downstream and Upstream performance

As Latency is becoming more important as a performance metric for Audio and Video conferencing, Gaming, and more immersive video experiences like AR/VR – the survey also checked with respondents on their latency performance. Consumers are still not aware of what latency really is or what jitter is and still really view their Broadband quality as their overall speed. They are getting more cognizant of the difference between ISP WAN speed and their Wi-Fi speeds to devices, but latency is still something they don't fully understand. Homes that have gamers are more educated on the value of latency as there is a very specific correlation between latency (or probably more relevantly jitter) in the performance of gaming. With the pandemic consumers were introduced to more latency sensitive applications like Audio and Video Conferencing with echo and problematic video conferencing often related to issues with latency. The survey asked the respondents to use the Netflix fast.com web based speed test which ran loaded and unloaded latency tests (loaded have a traffic mix defined here https://netflixtechblog.com/building-fast-com-4857fe0f8adb). The difference between the 2 numbers is defined as buffer bloat and can certainly affect very latency sensitive applications.

A quick note on the importance of consistent jitter to a gamer versus latency. Gamers seems to be happy with any latency that is less than 55ms (55ping as it is referred to by gamers). What they really value then is having not more than 5ms of jitter within their latency value. This means that it is not good for a gamer

to have 50ms of latency with 10ms of jitter or reducing latency to 30ms but jitter inconsistent across packet arrivals.

The results were interesting with a diverse spread of latency

- 42.5% of respondents had unloaded latency < 20ms
    - 50% of these felt their broadband was inadequate
- 28% of respondents had unloaded latency between 21ms-50ms
    - 30% of these felt their broadband was inadequate
- 15% of respondents had unloaded latency between 51ms-100ms
    - 9.5% of these felt their broadband was inadequate
- 6% of respondents had unloaded latency between 101ms-200ms
    - 7% of these felt their broadband was inadequate
- 7.5% of respondents had unloaded latency > 200ms
    - 4% of these felt their broadband was inadequate

For loaded latency result

- 28% of respondents had loaded latency < 20ms
    - 28% of these felt their broadband was inadequate
- 18% of respondents had loaded latency between 21ms-50ms
    - 23% of these felt their broadband was inadequate
- 23% of respondents had loaded latency between 51ms-100ms
    - 20% of these felt their broadband was inadequate
- 12% of respondents had loaded latency between 101ms-200ms
    - 14% of these felt their broadband was inadequate
- 17% of respondents had loaded latency > 200ms
    - 12% of these felt their broadband was inadequate

These latency results and especially the correlation to broadband inadequacy is has some ambiguity as one would expect the higher latency issues to have increases in dissatisfaction. The comments on the respondent's survey seems to suggest that latency is not well understood by people generally. Those that are gamers or more technical understood latency well enough to in many cases still not be happy with 15ms latency results as they strove for higher performance. Those with > 100ms of latency seemed to also not really be interested in spending money on improving things.

There is also the reliability of the fast.com test and its repeatability and temporal performance levels based on how congested the networks were at time of test as well as what device the test was done.

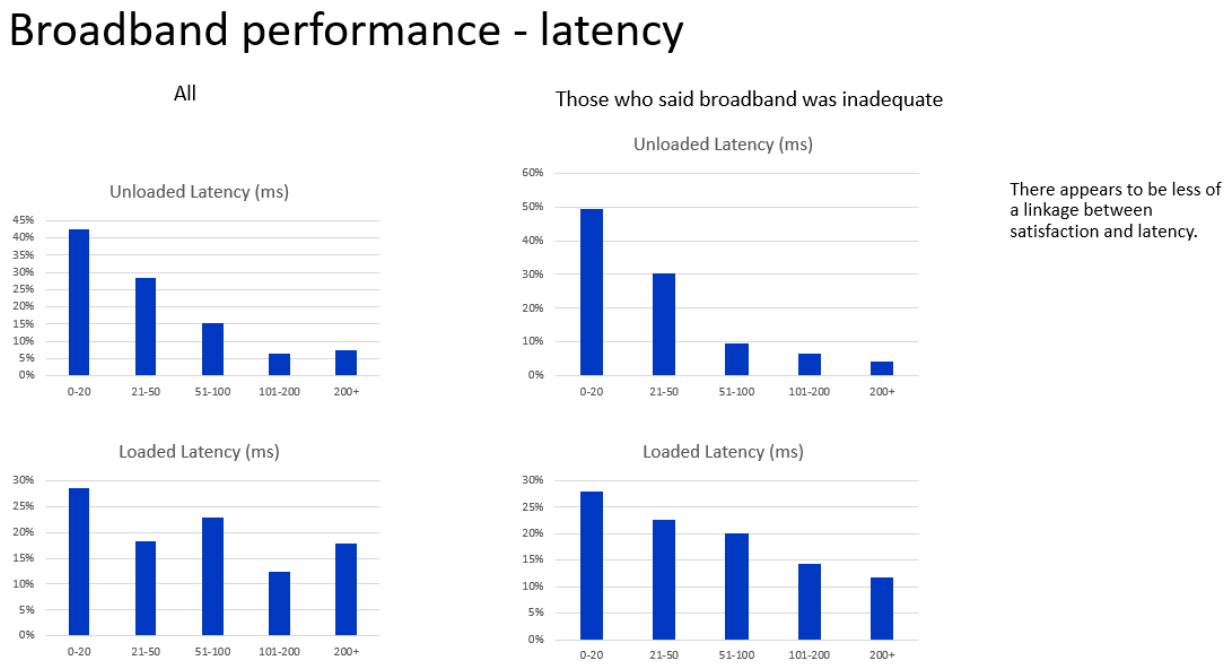

Figure 12 Latency performance of our respondents.

The respondents to rate their ISP and then this was correlated to each Network access type

- 85% of Cable ISP respondents were happy with performance
- 77% of DSL ISP respondents were happy with performance
- 90% of Fiber ISP respondents were happy with performance
- 76% of FWA ISP respondents were happy with performance

Network types

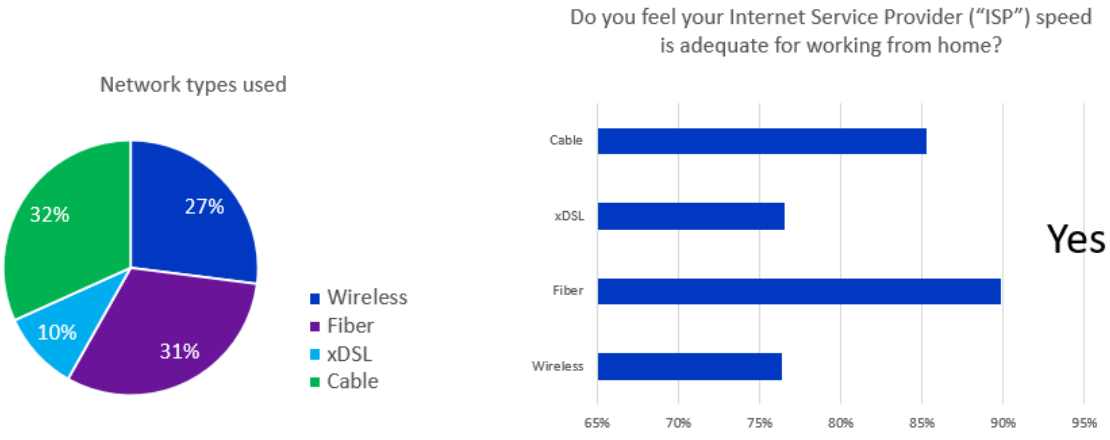

Figure 13 Respondent satisfaction with their ISP by Access Type

As Wi-Fi performance was so critical to everyone at home during 2020 the respondents were asked to explain their Wi-Fi solution and if they had added extenders.

It was interesting that

- 40% of respondents had an AP that was integrated into the SP's GW device
- 49% of respondents had bought their own retail Access Points
- 11% of respondents had an AP issued by their SP

Delving further into the Wi-Fi solution architecture of the respondents

- 31% of our respondents had a Wi-Fi extender/mesh solution with 69% relying in a single AP

Of the 31% of respondents with a Wi-Fi extender solution

- 50% of respondents had 1 extender
- 31% of respondents had 2 extenders
- 14% of respondents had 3 extenders
- 5% of respondents had > 3 extenders

This seemed to show clearly that respondents had to augment their Wi-Fi solution to cater with the increased demand of working and schooling from home at range. The survey may have some bias to more consumer owned devices versus using the supplied SP devices as it was based on employees from CommScope who do skew to more technically aware for a larger base of the sample. However, the majority of respondents were not engineers by job function.

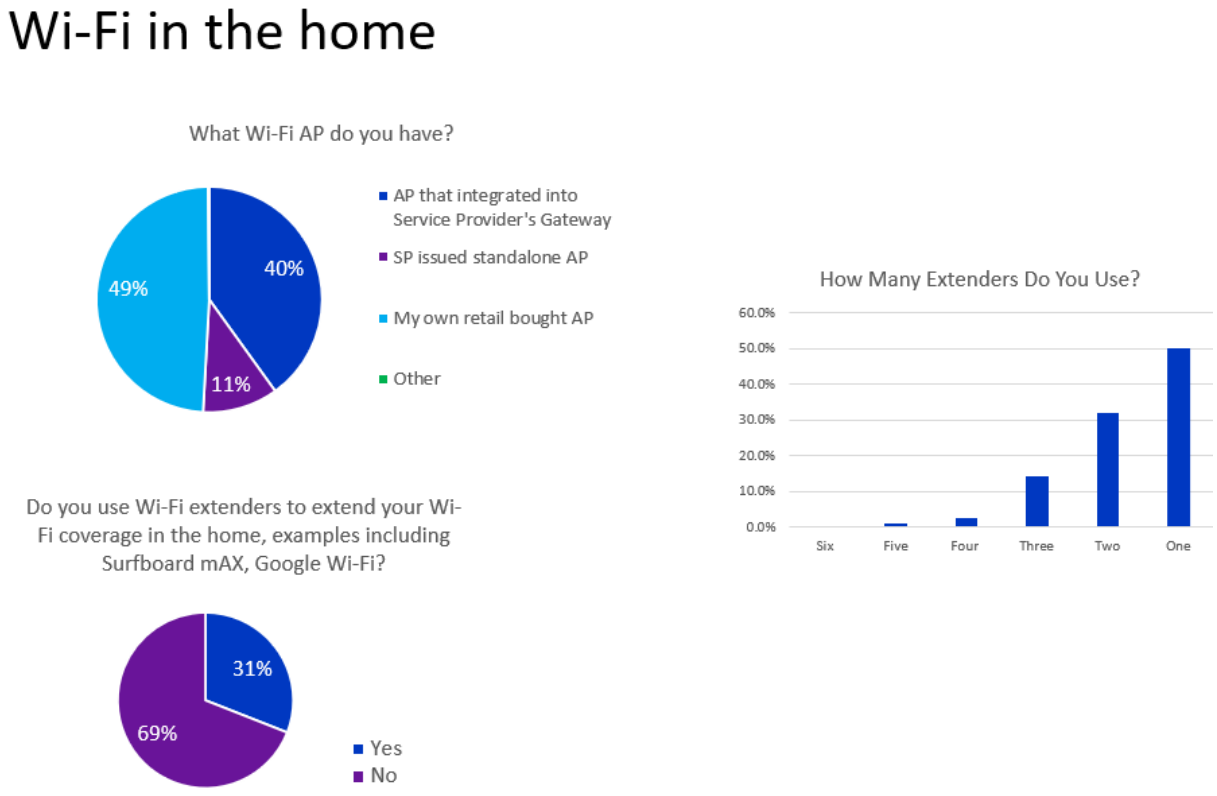

Figure 14 Wi-Fi device use and extenders in our survey

The survey respondents were asked what was their primary device for Working from home

- 95% of respondents said it was company issued laptop, tablet or phone
    - The remaining 5% used Home PC/Laptop or Apple Product

Of the additional devices that respondents used to work from home

- 66% of respondents used a second screen
- 42% of respondents used headset for audio/video conferencing
- 20% of respondents had a dedicated work printer
- 27% of respondents set up a separate webcam for video conferencing

This was to be expected as many consumers during pandemic tried to ensure their home was as comfortable as possible to work and school. Because of security requirements and that almost all of the respondents have office jobs that have company supplied laptop or desktop device – the company issued laptop was the dominant WFH device for the respondents surveyed.

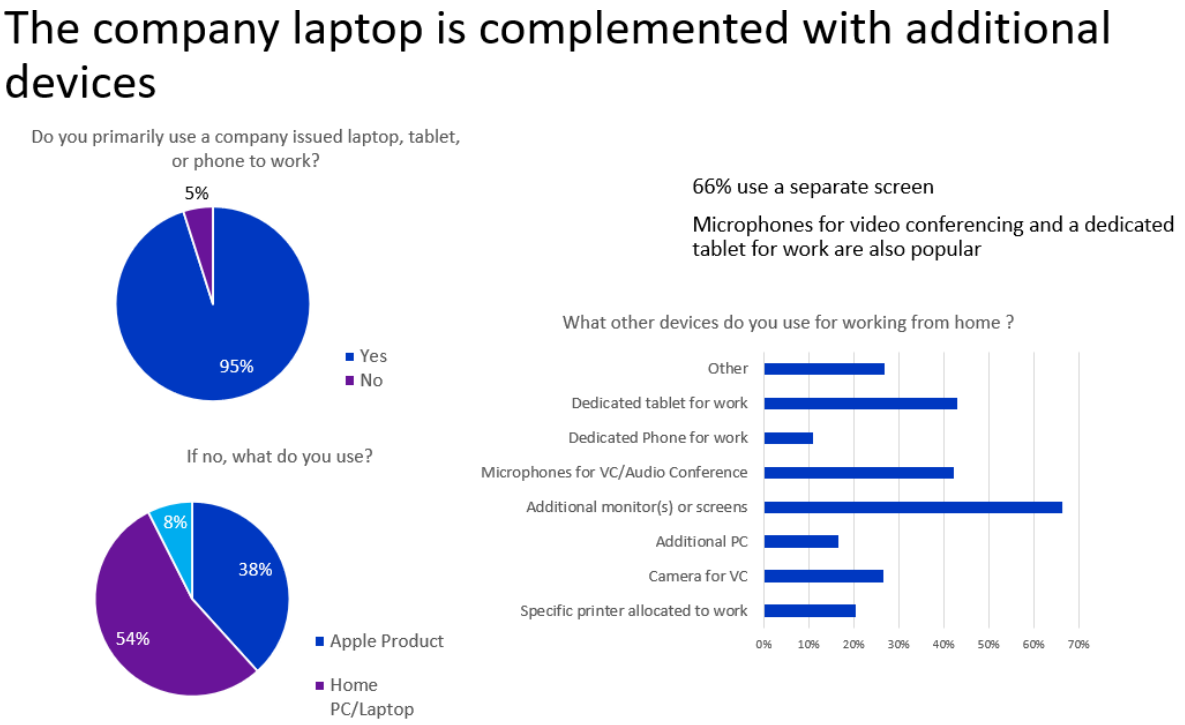

Figure 15 The devices people used at home to Work from Home

The survey asked the respondents if they used VPN to access work resources.

- 97% of respondents were using VPN for work related traffic. (There are some CommScope services that require VPN)

One of the issues at the outset of the global WFH change was the lack of VPN resources scaling and the overhead in speed/performance of VPN. In the survey we checked with the respondents the reliability as well as performance of the VPN

- 30% of the respondents answered they kept the VPN on all the time
    - 15% of respondents said they never turned it off
- 24% of the respondents frequently turned it off

- 30% of the respondents said they occasionally turned off the VPN

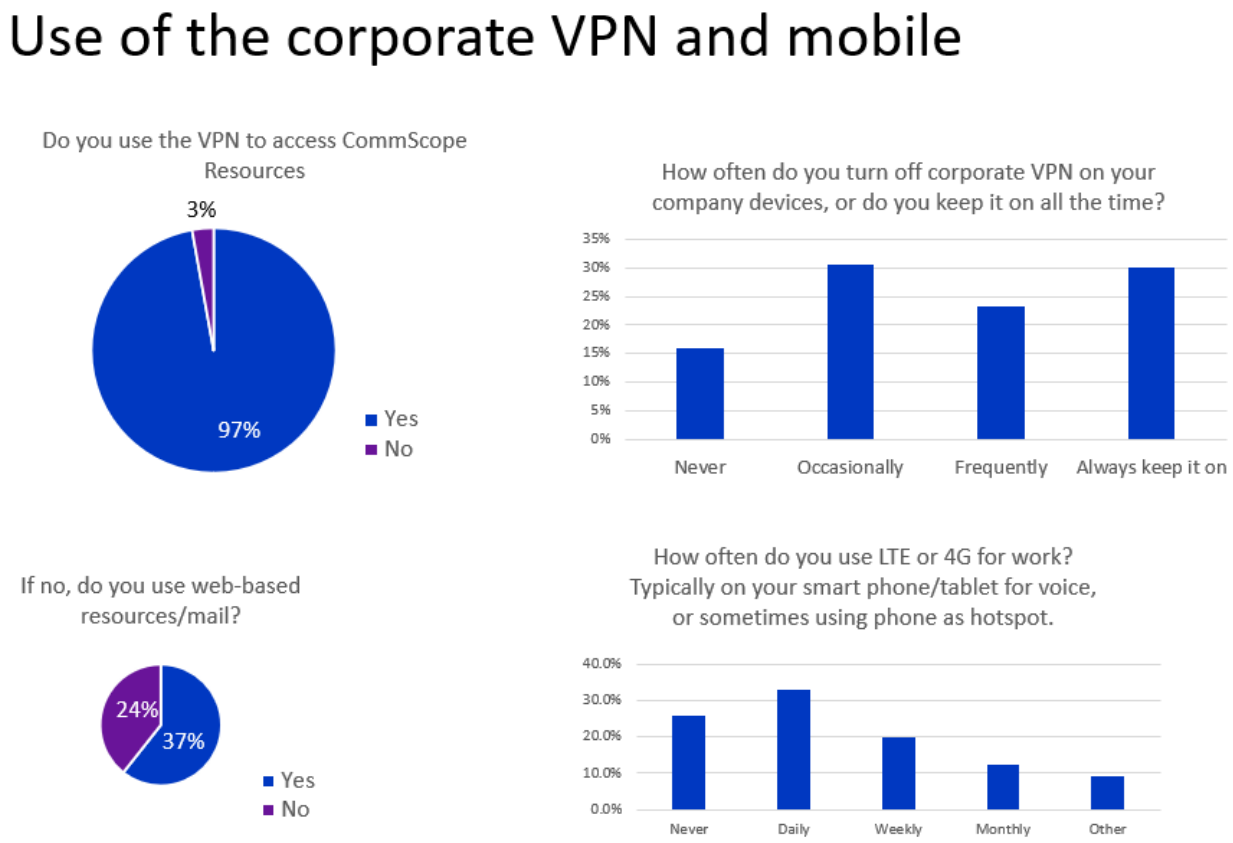

Figure 16 Use of corporate VPN and Mobile device

The survey asked the respondents the direct question of their view of their connectivity issues while working from home

- 31% of respondents said they had connectivity issues
- 28% of respondents identified issues related to using VPN services

The respondents identified the source of the connectivity issues they had

- 59% of respondents said their connectivity issues were the fault of the SP or speeds
- 48% of respondents said the issues were related to Wi-Fi performance
- 50% of respondents said issues were related to VPN performance and overheads
- 28% of respondents said issues were related to Video Conferencing application

Additionally the survey checked with the respondents how often the chose to call IT for support when they had issues

- 56% of respondents never called for help
- 42% of respondents called IT 1-4 times during first 7 months of working from home

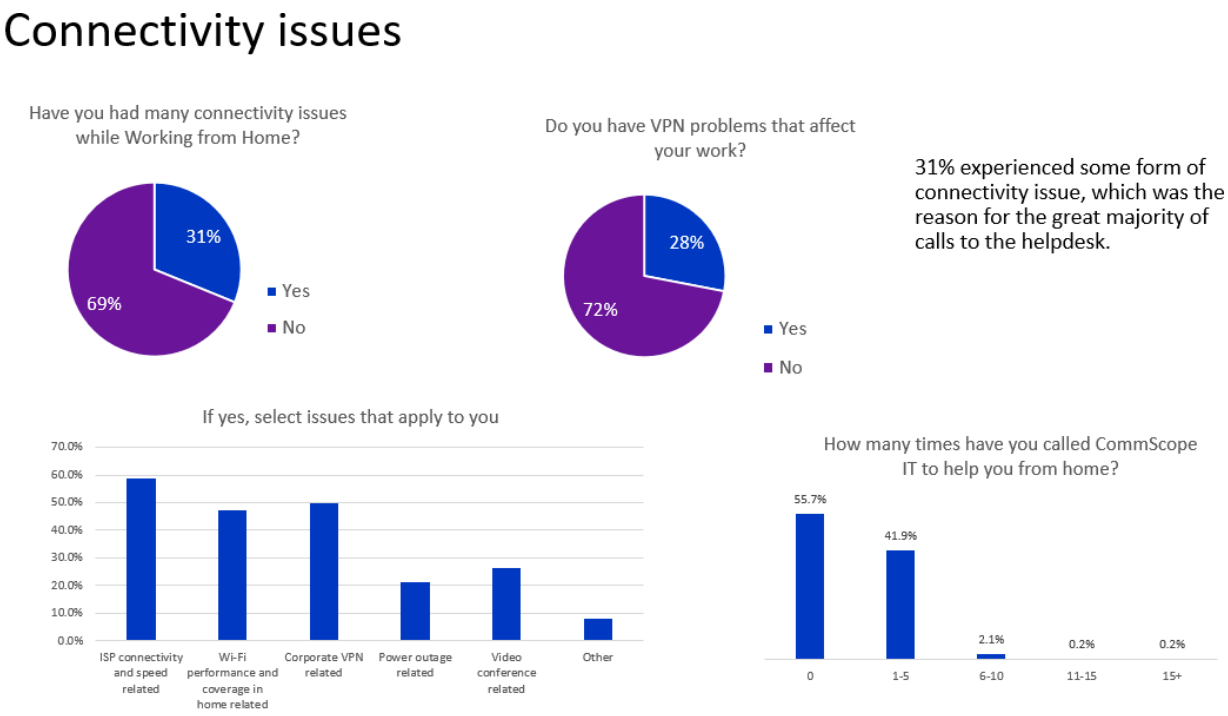

Figure 17 Frequency of Connectivity issues WFH

Being specific again on Low Latency the survey explicitly asked the respondents how they valued low latency

- 42% of respondents valued low latency working from home and for services like gaming

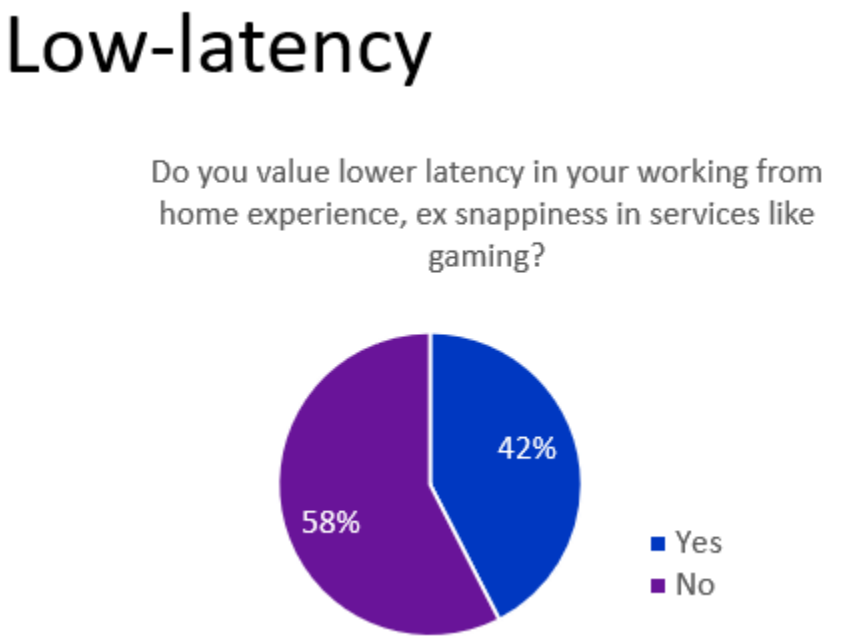

Figure 18 How do we value Latency working from home

Going a bit deeper on the Audio and Video Conferencing side of Working from Home the survey asked several questions

- 69% of respondents used a headset when doing Audio or Video conferencing
    - 40% were wireless; 60% were wired headphones
- 86% of respondents primarily used the camera in their laptop or PC for Video conferencing

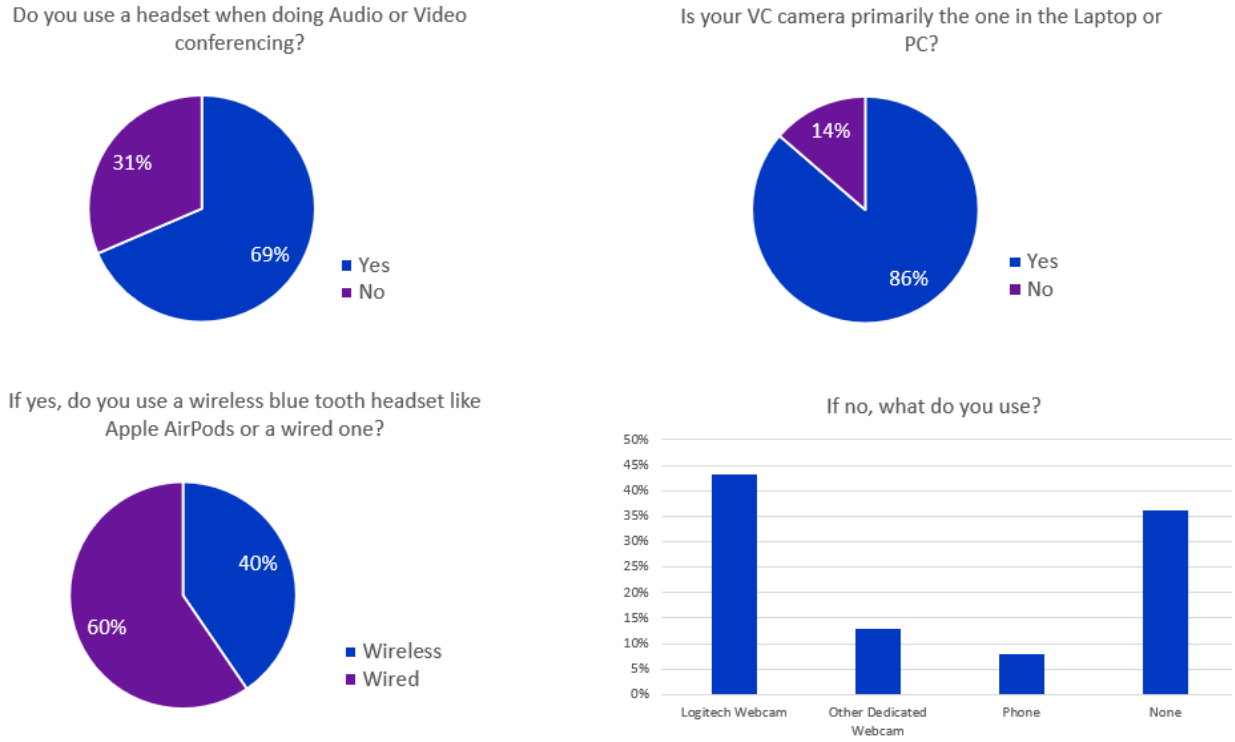

Figure 19 Audio and Video Conferencing for WFH

With the potential of using existing home screens like TV's to help with Working from home the survey asked respondents if they would value using the TV for work video conferencing – only 34% of people felt this was something they would use.

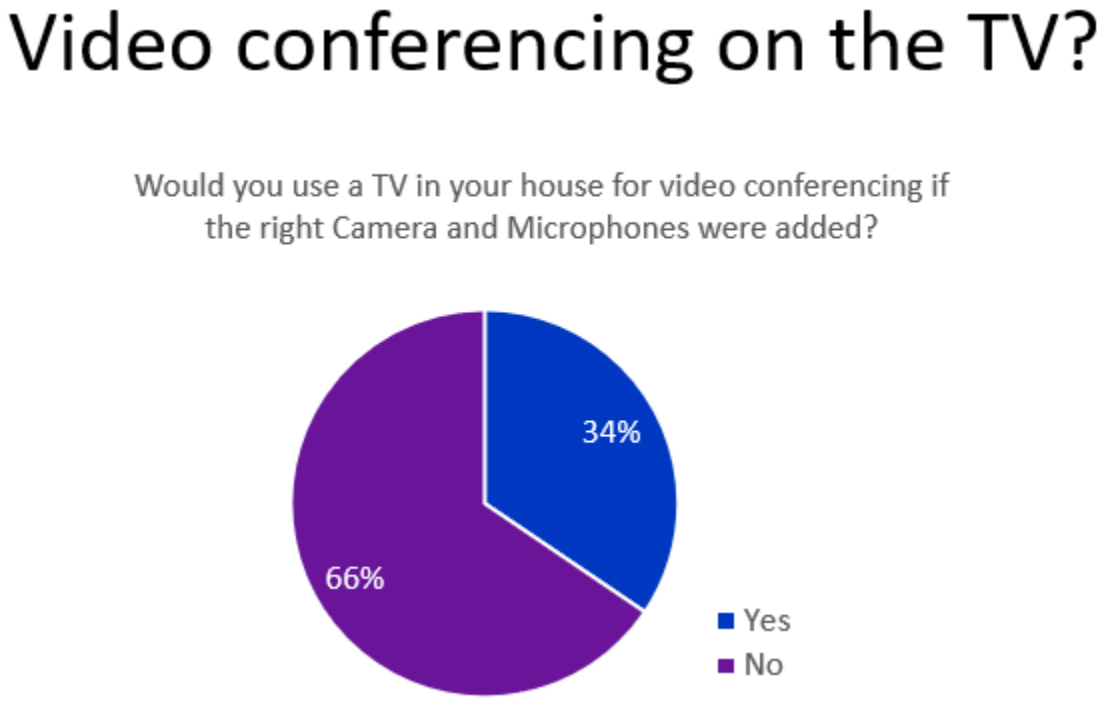

Figure 20 Would you use Video Conferencing on the TV ?

Trying to understand the impact of others Working and Schooling from home on each other the survey got the following responses

- 27% of respondents felt that other home members doing Video Conferencing or Video streaming was affecting their own connectivity
- 44% of respondents said that the had experienced Video Conferencing dropouts that had made doing their job more difficult

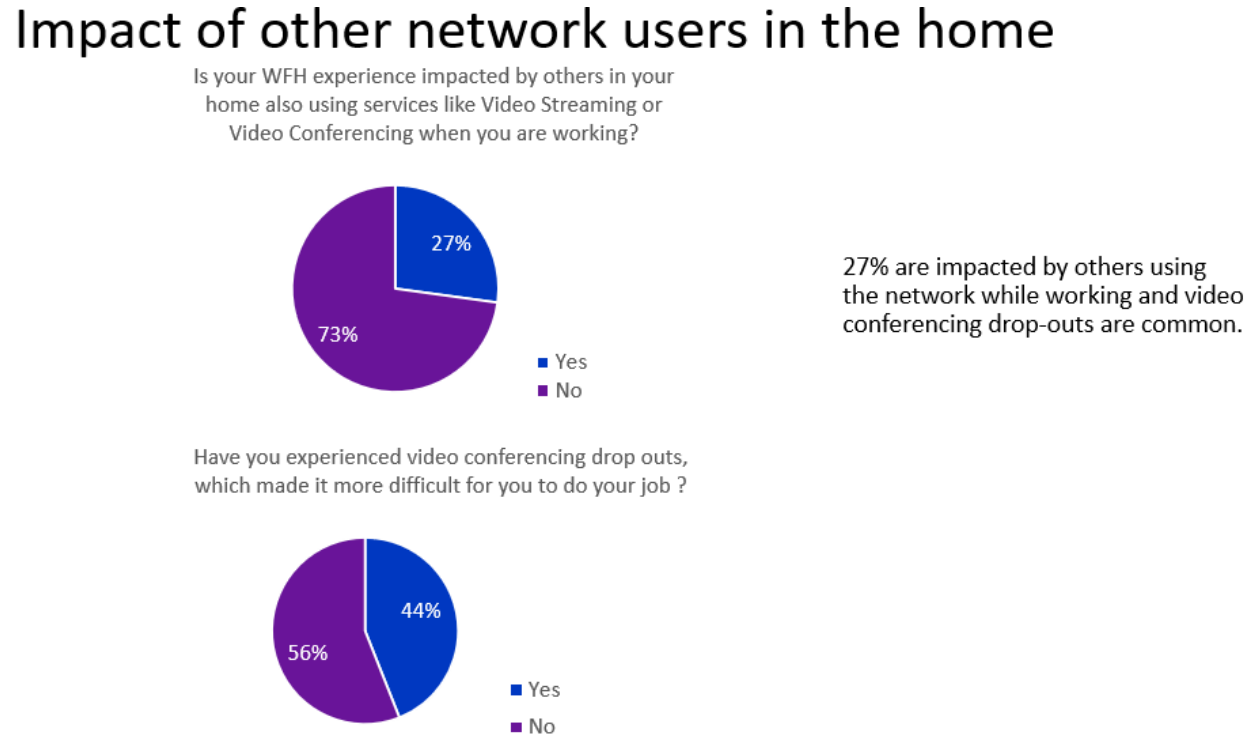

Figure 21 Impact of other home members on your Work connectivity

Going deeper and asking directly if respondents felt that their home working environment was adequate the survey got the following responses

- 45% of respondents felt they needed more reliability
- 37% of respondents felt they needed a better home office setup
- 52% of respondents felt they could benefit from lower latency broadband
- 28% of respondents felt they had Wi-Fi coverage and performance issues
- 22% of respondents felt they had inadequate broadband speeds

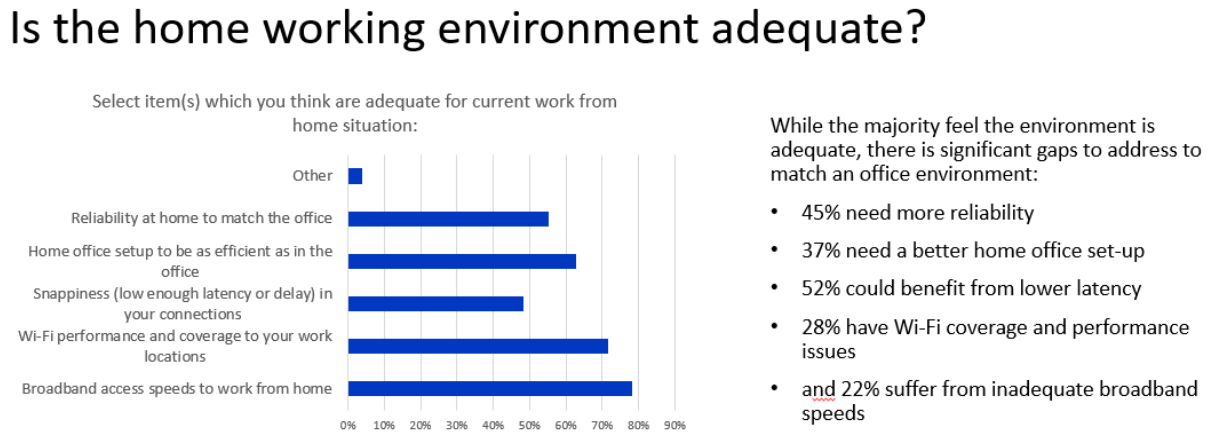

Figure 22 How adequate is your Working from Home environment

Now that we have learned the key issues and things that our respondents' value in their Work from Home lives the survey wanted to check their interest and value in improving the issues and adding new value services

The survey asked them to rank High, Medium and Low several items

- Use of additional screens at home
    - 57% of respondents ranked it high; 29% of respondents ranked it medium and 17% low
- Security on connection to the office
    - 46% of respondents ranked it high; 34% of respondents ranked it medium and 20% low
- Power Backup solution
    - 25% of respondents ranked it high; 36% of respondents ranked it medium and 39% low
- Separate Wi-Fi SSIDs for company work vs personal work
    - 24% of respondents ranked it high; 36% of respondents ranked it medium and 40% low
- Higher Reliability from ISP with backup WAN connection
    - 51% of respondents ranked it high; 33% of respondents ranked it medium and 16% low
- Better Hands-Free microphone solution
    - 42% of respondents ranked it high; 33% of respondents ranked it medium and 25% low
- Separate Corporate Network and Service to residence
    - 25% of respondents ranked it high; 38% of respondents ranked it medium and 37% low
- Better Cameras for Video Conferencing
    - 21% of respondents ranked it high; 36% of respondents ranked it medium and 43% low

This was somewhat different than some of the similar other responses asked in the survey but if we are looking for responses that show over 50% pull from the respondents from the cumulative High+Medium results, there seems to be some merit in number of areas below – in particular high reliability , security. Other teaser questions like the need for corporate SSID and network separation also seem to have some merit but may need to be driven more from the company side vs a pull from the consumer to really make them emerge as potential services a Cable Operator can sell back to corporations.

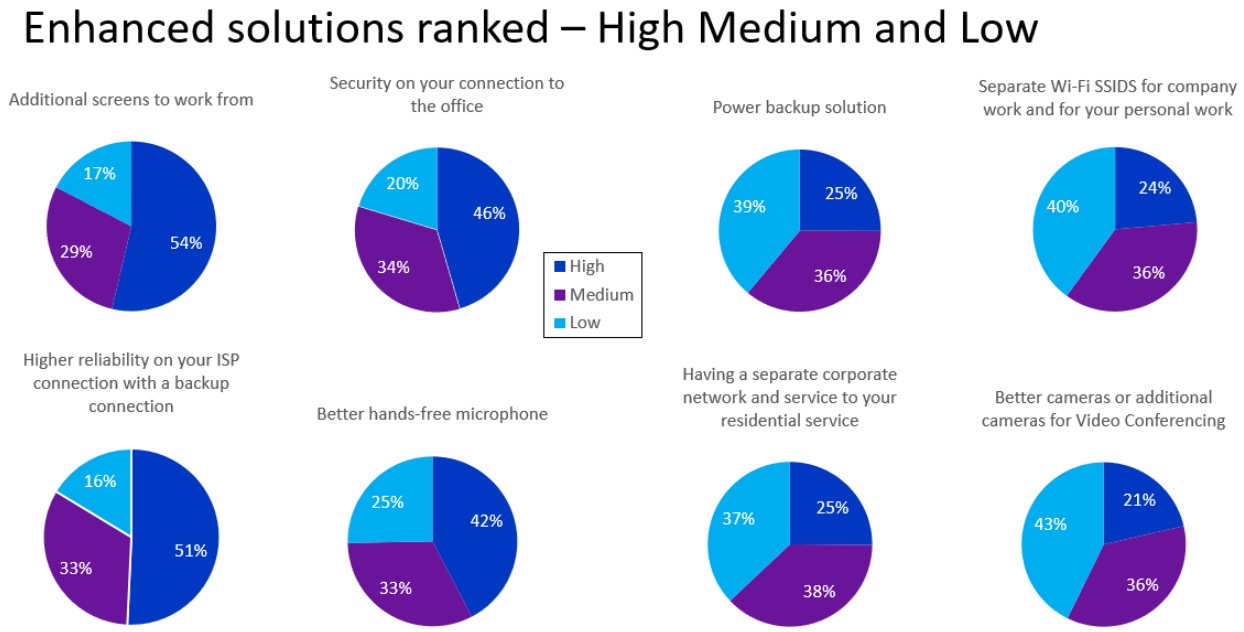

Figure 23 What additional Services and Features would WFH respondents value

Moving to the more social side of working from home the survey asked respondents how they would value more separation of Work and Home time through technology features

- 87% of respondents stayed in the same room while working
- 40% of respondents would like a technology or connectivity solution that separated Work time from Personal time
    - As you will see below when the question is posed as a summary set of questions with the specific use case of turning off corporate resources at certain times there was a higher interest level

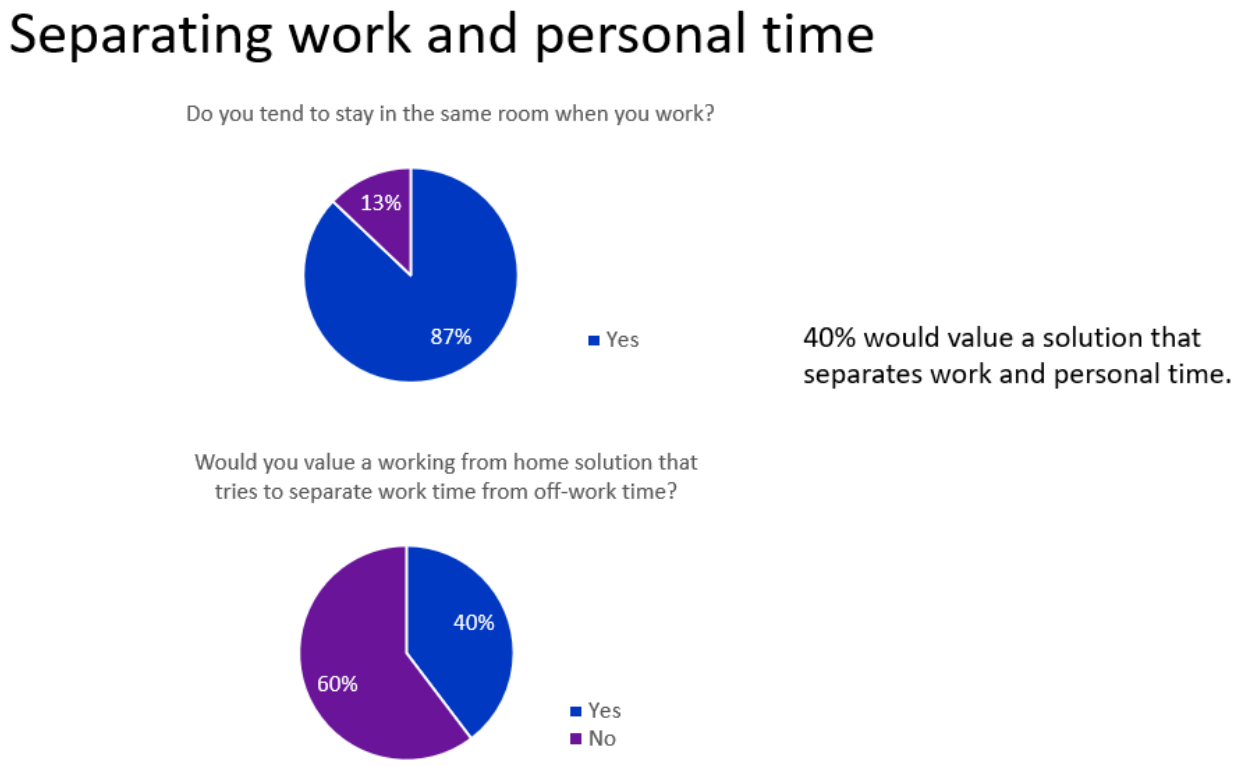

Figure 24 Value to our respondents of solutions to separate work and home life

Trying to analyze further some ideas that may benefit working from home the survey asked the respondents to give their view on some work life balance ideas

- 48% of respondents thought a timer that shut off WFH activities at defined time would be a worthwhile idea
- 73% of respondents thought that there were value in tools that analyzed your working habits to help you stand up from your chair, get some exercise and take breaks from balancing working and screen time
- 51% of respondents thought a dedicated work Wi-Fi, VPN solution may be something they valued
- 6% of respondents interestingly felt they wanted their company to pay for broadband service to the home. This question when followed up with respondents was interpreted as the company would pay for and own all broadband services to the home. There was some fear of privacy that came with this interpretation. When explained that it could be a completely separate service that was independent from residential broadband there was a much higher acceptance of company sponsored broadband and connectivity in the home.
- 68% of respondents felt that they valued physical separation of Work from home location with dedicated devices to home working.

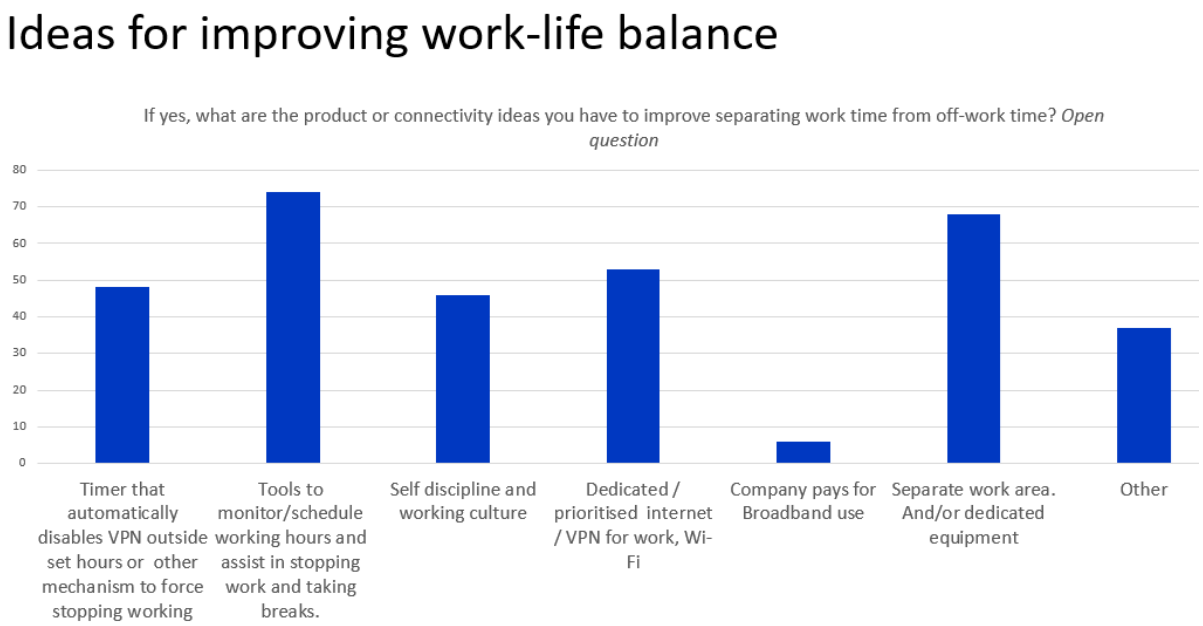

Figure 25 How do you value tools and features for work from home and life balance

As we now try and ascertain if there is a product, service, or market for a better working from home solution we delve a little deeper with the survey to ask some additional questions.

The survey directly asked the following

- Would you be interested if your SP offered a better WFH solution with higher downstream and upstream speed, better home Wi-Fi and more reliability – 75% of respondents said Yes. (For this initial analysis we did not push on how much the respondents would pay for this)
    - To further clarify some of the elements we asked
    - Are you likely to upgrade Wi-Fi because of issues – 43% of respondents said Yes
    - Are you likely to upgrade your WAN connection – 39% of respondents said Yes

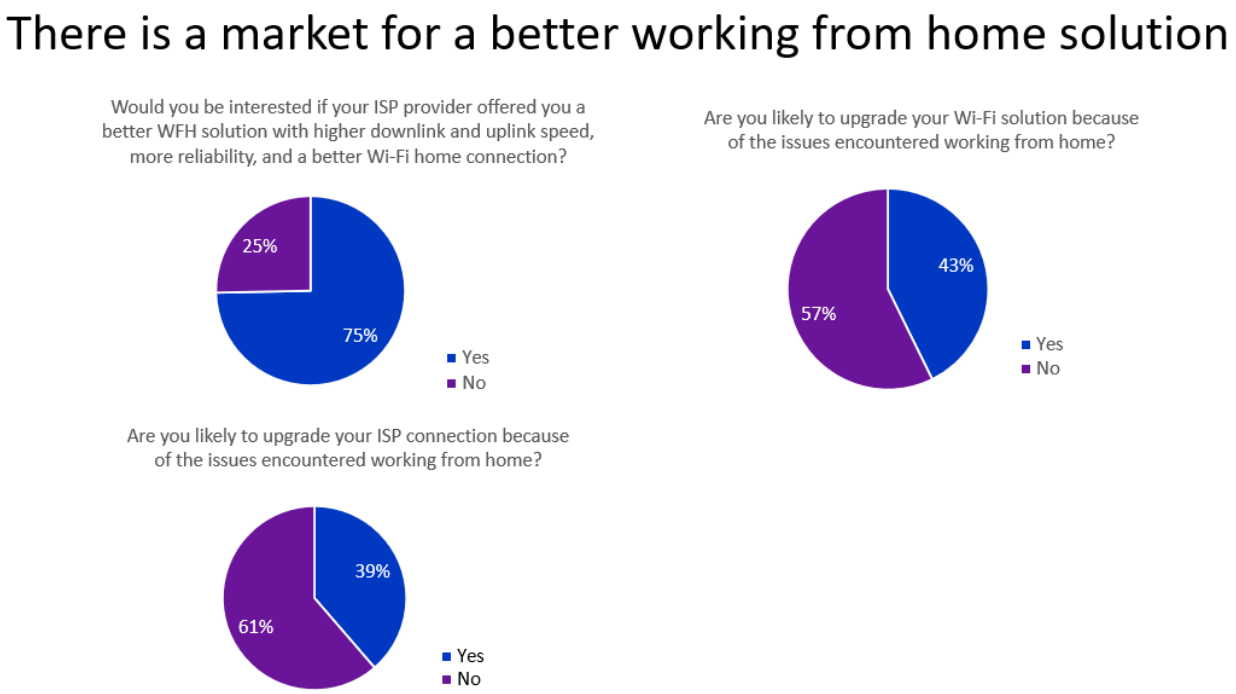

Figure 26 Would Homeowners want to upgrade their connectivity because of WFH

This survey result has some clear responses and leaves a number that are still ambiguous when trying to figure out the value of

- Reliability and backup – the results seem to show clear potential value here
- Security – the results seem to show clear potential but also highlight (with privacy) the importance for clear separation of any WFH sponsored services that they do not bleed into residential use.
- Separation of work and home life – the respondents were a little ambiguous in a couple of shaped questions but there seems merit in exploring this area. There are a number of separation areas from data, time and even Wi-Fi channels and frequencies. Additionally, even separate devices are also potentially something the respondents would value.
- Performance – its clear that consumers and the respondents in this survey vary on their understanding of the performance issues affecting their video conferencing and ability to work from home. Some just rely on their top line speed and maybe aware of their upstream speeds, others very cognizant and aware of Wi-Fi performance in the last 30ft and others who are also aware of latency derived issues.

So, let's move to the next section and explore the potential for the current stock issue of Cable Operator devices to change to reflect some of the new drivers for the home beyond supporting entertainment primarily.

3. Is there a better Home solution now for supporting Working and Schooling from home

Let us now explore the potential opportunity for the new home architectures that cater for

- Residential and Corporate services to a home
- Reliability of Service
- Extension of Corporate Office to the home
- Security and anti-theft of corporate information
- Separation of residential, schooling and working from home services
- Separation of work life and residential life from home

But before we do that lets baseline the simple service offered by Cable Operators today where there are predominantly

- 4 devices – Gateway (or EMTA and AP) , Extenders/Wi-Fi Mesh , STB and for a growing number of Cable Operators a Smart Phone MVNO play.

From a service perspective though there are the following assumptions and residential class of services that are offered

- For the majority of Cable Operators – a single Coax cable to the home with no backup solution for Coax side service failure.
- An ever-decreasing number of Gateways that provide battery backup of the VoIP service
- No solution for battery backup service for data services
- Typically, only 2 SSID in the home – the primary residential service and guest Id. Additional SSIDs can be Community Hotspot and for a few Cable Operators a Smart Home Wi-Fi network. Current networks on 2.4GHz and 5GHz frequencies.
- VoIP services using EMTA function in Gateway as part of DOCSIS network – which has been diminishing in use – in favor of smart phone calls at home and increasing use of FaceTime, WhatsApp and other popular video conferencing applications.

Figure 27 Current Cable Operator devices and services

Is there an opportunity to develop the following logical solution to create separate networks to the home and split the residential and corporate/schooling services for different SLA and policy management or possibly just increase all residential SLA to be able to support the same levels as Enterprise. There are several factors in consumer want and adoption of a solution like this

- Who pays for this uplift to Enterprise or Corporate level reliability and SLA's
- Privacy and separation of home and work life
- Can an Operator provide an SMB/Business like SLA and solution en-masse to consumers with or without subsidization of corporations?
- Will there be enough employees stay at home for work to have enough of a market and need for this solution
- Does the Cable Operator have the economics to be able to provide wireless backup solutions to wired services and without control of the wireless network in MVNO solutions can it work
- Will a consumer value having corporate IT control some of the elements of a home network or see it as invading their home privacy?
- Does the DOCSIS GW technology or indeed even standalone Access Points have low enough power draws to support meaningful holdup times for home data services off of backup wireless solutions. Indeed, can a HFC solution also work long enough for data in the event of a power failure in the home but HFC network still capable of passing data.
- Is it less complex when a consumer wants a WFH solution with higher reliability and performance SLA's to just offer a separate set of devices to separate the residential service/devices?

- Giving Corporations the Security, Performance and Reliability that they offer their employees in the Office
- Providing differential QoS and Separation for Residential and Corporate Svcs
- In HFC plant – even a separate eMTA

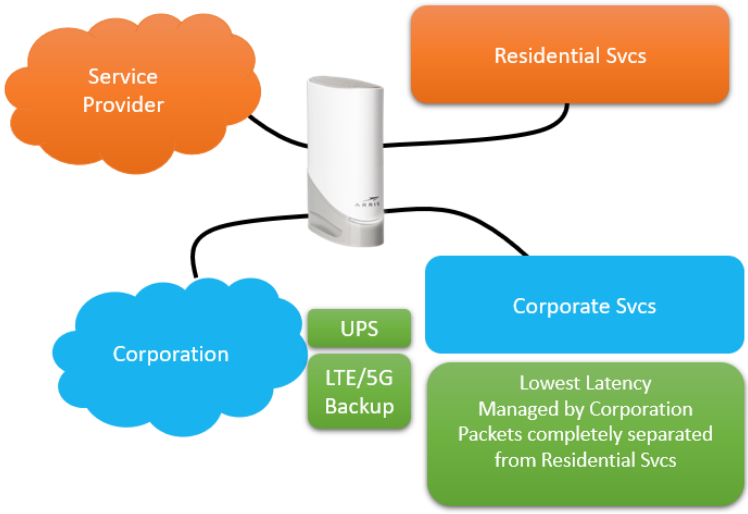

Figure 28 New Potential split Residential and Corporate services model

Expanding on this Gateway/Broadband/Wi-Fi architecture more could the following be a set of potential requirements and features for the better Gateway

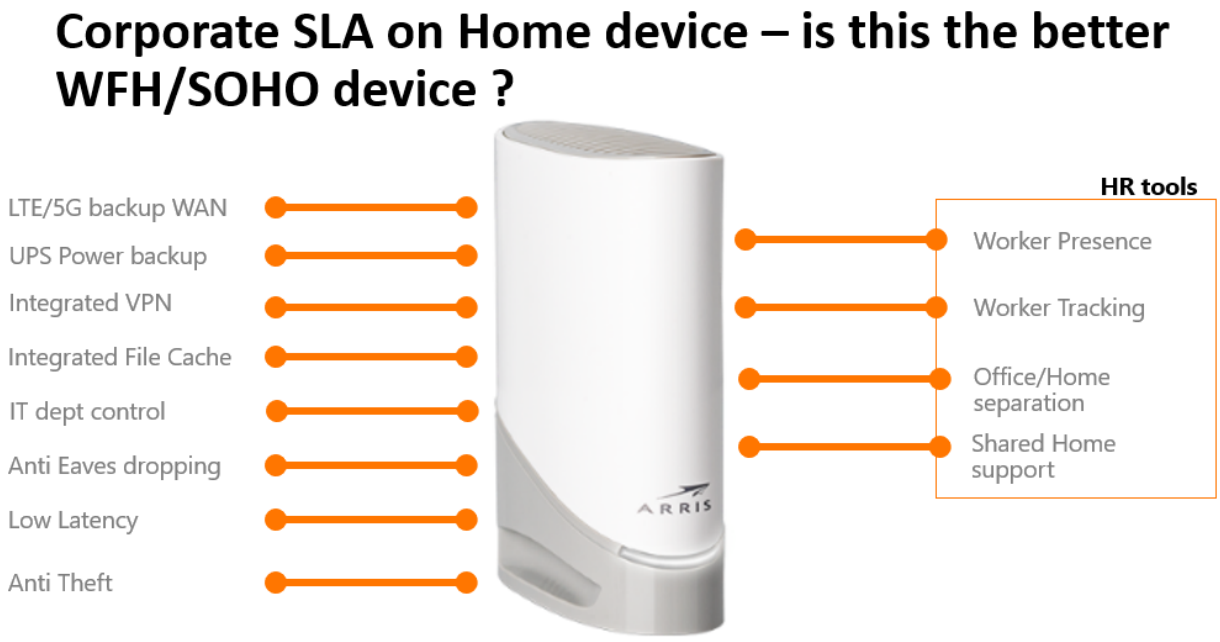

Figure 29 Potential additional features for the better WFH/SOHO Gateway

Some of the features we are defining are not new and have been always in the mix for inclusion in residential services but with the pandemic now really highlighting the stress points of reliable services and devices will these features like LTE backup and UPS/Battery backup now have a place for Operators to sell an improved service to consumers. These services cannot be free to the consumer as they have

additional capital and operational costs to provide them, so consumers must see value to their home requirements to increase their monthly payment to their service provider.

We could also look at the SMB and Enterprise market and apply some of the technology directions there to the home. For example with SD-WAN services and architectures squarely focused on Enterprise and SMB – would the solution above be better defined as an SD-WAN play and provide a Universal CPE (uCPE) component to the connectivity gateway (integrated or separate compute/storage device) and use SD-WAN software solutions for orchestration and management of WFH services independent of the residential services. Who would provide the uCPE device and is there a collaboration with Corporation and Operator to provide the SD-WAN services ? Corporations for example providing their own authorized VPNs but Operator providing other value add services.

Let's go through the services mentioned above to see their relevance to the consumer and if each one itself makes a difference or the combination of all these services is the 'killer application' for the consumer.

3.1. LTE/5G Backup WAN

Probably one of the most often discussed residential features over the years has been the potential of WAN backup to DOCSIS or xPON with LTE or now emerging 5G networks. This has been something that Telco/MNO's have offered more in the past given their ownership of LTE spectrum. Generally, because of the high availability of the wireline network it has not really been deployed at large scale. This paper does not contain any refence information on the number of outages or average yearly outage level on the HFC elements of the network. Residential services had not tended to be enterprise critical but now with increased WFH residential use WAN backup has now also become a potential service that consumers may now pay for the additional capex and cellular packet costs to have a convenient and ready to go backup service.

The increase in higher speed LTE services and more importantly the additional 5G capacity being developed for mobile and FWA applications makes a high function WAN backup feasible.

Some Cable Operators also offer their own MNO services and more and more Operators are moving to offer MVNO cellular services. In North America some Cable Operators have also purchased CBRS band 3.5GHz spectrum so have the potential to use that spectrum for WAN backup if they develop the network and CPE infrastructure to support

As well as a backup solution the addition of an LTE/5G module with a DOCSIS or Fiber WAN port also offers the potential for

- Carrier/Hybrid Aggregation – potentially combining at the cellular spectrum levels across different channels or potentially across wireless spectrum and wired service. This solution has been employed in some cases to augment low bandwidth xDSL networks with LTE and is less likely to be of high value to aggregate high bitrate DOCSIS 3.1 or xPON networks.
- Policy/Service based routing – the potential to be able to send packets over either of the WAN links based on achievement of SLA levels (latency) or congestion issues in either network.

The key issue in this solution particularly at the time of writing this paper is the overall cost of the addition of the wireless backup solution

- LTE UE modules of higher category performance and 5G UE modules are almost the same cost as a Wired Gateway so can the cost of supporting 2 high speed Access networks be covered in the service charge to consumer.
- MVNO costs for data make it less desirable to have wireless backup as the goal of the Operator is to minimize data traffic over LTE/5G or pass the cost of backup services to the consumer.
    - In an MVNO relationship packet priority for MVNO packets may also be constrained to create longer latency in congested areas of cell use.
- The speeds and latencies offered by the wireless backup solution also must be of sufficient enough speed and low enough latency to provide a WFH solution. This may be a lot lower than the Wired service but sufficiently high enough to support WFH service. A reliable 25Mbps/25Mbps could potentially support the majority of WFH workers for quality Video conferencing and low latency enough connectivity for the workers in the home. To make the lowest bitrate possible, software policies can be added to the WFH SLA to prioritize all WFH packets over any other residential devices to at least minimize latency for WFH traffic.
- Probably, most importantly consumer view on the reliability of Wired Broadband vs the investment in a backup solution for Wireless. Additionally, their views on power outage vs wired broadband outages and the downtime exclusively for wired outages. Its also a tougher sell from a wired Service Provider to provide a Wireless backup to their inability to maintain reliability on their wired network. However, consumers are becoming more aware of the environmental issues of fallen trees and storms affecting infrastructure outside the control of the operator so there is some sensitivities now in consumers to want to pay for this additional reliability. As we saw from our survey 51% of people felt it was a High value feature to them with a further 33% saying it was of medium value. Only 16% of respondents felt it was low in their home broadband requirements.

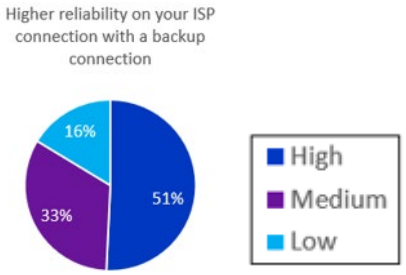

Figure 30 Respondents view on needing a backup higher reliable WAN service

So, for a multi wan backup solution there does seem to be a more heightened view by residential subscribers that it is a worthwhile option to have for their homes to keep them reliable for working and in the rare time outages occur.

3.2. UPS/Battery Backup

It's always an interesting question whether the HFC plant is inherently more reliable than the power grid. Certainly, in parts of the country with overhead power lines and HFC cables and with lots of trees, there tends to be correlated power and HFC outages when a tree takes down both power lines and HFC cables. The US Energy Information Agency reported https://www.eia.gov/todayinenergy/detail.php?id=45796 in November 2020 on the 2019 grid metrics. The average US power interruption was 4.7 hours or (284 minutes) per year (about 99.95% availability or 3 and a half 9's).

Including major events, the average interruption of 4.7 hours (284 minutes) in the United States during 2019 was nearly half the average interruptions experienced in 2017, a year with more hurricanes, wildfires, and severe storms. Excluding major events, the average duration of interruptions customers experienced was 1.5 hours (92 minutes), relatively consistent with previous years.

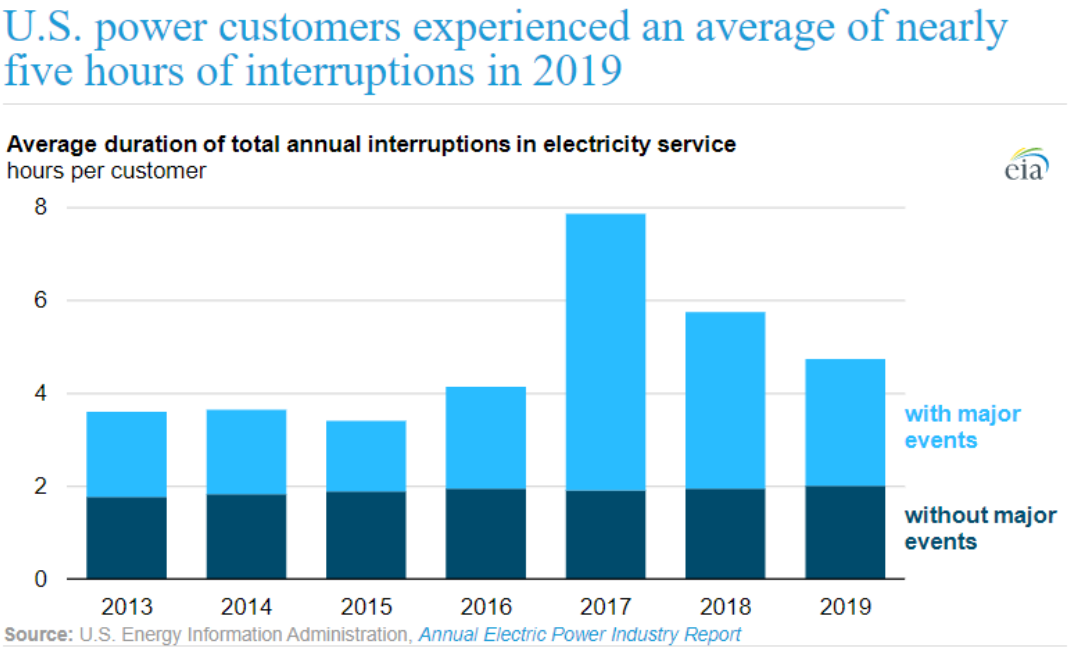

Figure 31 Average Duration of total annual Electricity interruptions in the US

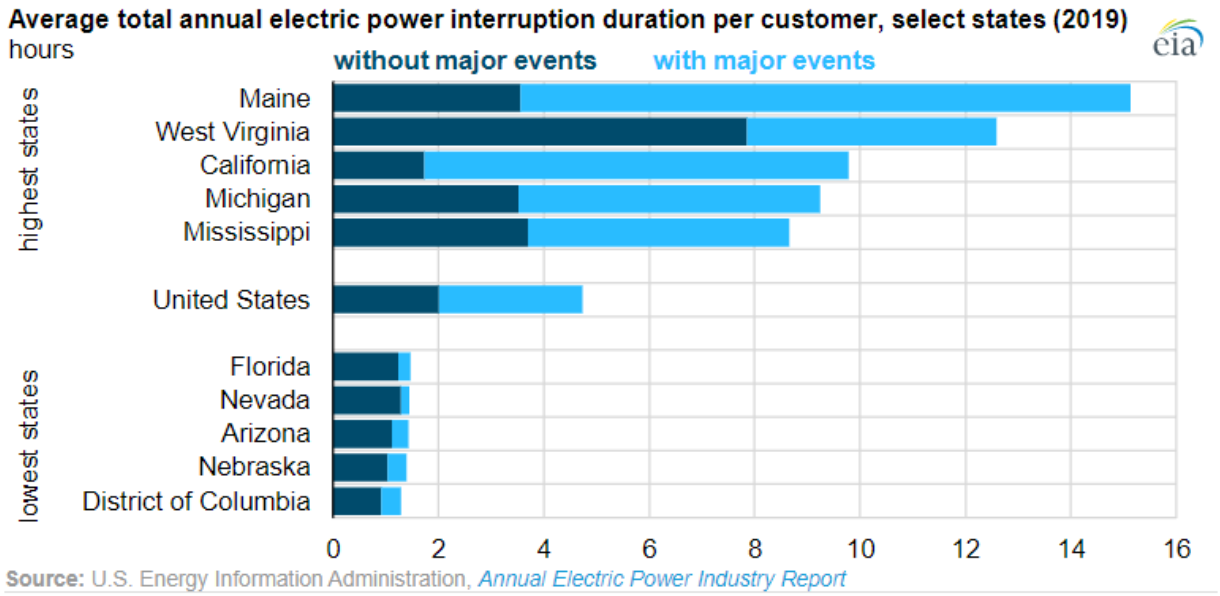

Figure 32 US Power interruption average duration per consumer - select States

So, how often does the power drop in the home really cause the consumer and the SP to want to invest in backup solutions. Certainly requirements for E911 calls still remain but smart phones and power backed up local base stations tend to be the main fall back for consumers now for critical communications and we

have seen a big drop in the use of battery back up in eTMA for VoIP calls on DOCSIS/Cable as consumers and Operators see less of a reliance on the main landline phone for critical or even comfort level services in a power outage.

The correlation of both a power and internet outage are also another interesting data point. As of writing this paper – we did not have correlation information of power vs internet outage. Certainly for major events like Hurricanes, flooding there is often a 1:1 correlation between both power and HFC infrastructure outages (Trees bringing down cables) that also diminish the value that a Power outage solution can bring to somebodies home.

All that said – given the right marketing and cost points WFH consumers who are in areas with higher rates of power outage may opt for a UPS system. Marketing departments in Operators could test the market for UPS to support up to 65W for a single GW device (not including Mesh Wi-Fi) from 600VA/330W at under an hour of hold up time and about $60 to 3000VA/850W solutions closer to $1,000 exceeding the total average power outage time in the US and far exceeding the typical spike fallout or non-major event outage. This UPS would be targeted to support the Wi-Fi GW only with scope for USB charging of phone devices and potential to keep a WFH laptop trickle charging as well.

Of course, homes that generally feel that they experience multiple outages also opt for home generators and typically place their refrigerators and lighting circuits on the generator but with more sensitivities around the importance of Wi-Fi connections in the home also tend to add the Residential Gateway to the Generator.

3.3. Integrated VPN

Many corporations still use VPN for their WFH security requirements. More and more corporations do provide non-VPN support for Applications like Office365 and some companies require specific USB keys like Yubikey to authenticate the use of laptops and devices outside the corporate network. Generally, there is continual work to improve the performance and security of VPN's – supporting context aware connections, zero trust networks and what is defined as Software Defined Perimeters (SDP) to improve security.

When a corporate VPN is used – it is typically run as a software application or extension on the Laptop, Tablet or Phone and in most cases is not application aware. Certainly, corporate VPN's may route all traffic from the corporate device through their VPN servers. In some cases, the VPN client can offer split VPN capability where corporate domain applications or servers/data are sent over VPN and other IP addresses are sent directly through the Gateway to their internet destinations. The Corporation itself will be the ultimate driver of this feature and will determine its viability from their IT policies

- Does the corporation want ALL traffic from a WFH device to go over the VPN for its security and employee application use policies?
- Putting a specific corporate VPN application into an ISP provided Gateway is something not supported currently. With the advent of new containerized Services Delivery Protocols, the feasibility of allowing a corporation to add their own VPN client to the GW runtime.
- Does the corporation favor a single VPN client in the GW supporting multiple WFH devices and having clear channel connections to the client only encrypted by Wi-Fi?
- For regular mobility use of VPN the end device like the laptop must support VPN client anyway so is a WFH solution worth it.

This last point is potentially the most interesting one from the WFH employee's perspective. Often while at home the employee may use their WFH device for non-work applications and typically drop their VPN

for these applications. Potentially, listening to music or watching videos during their lunch break or after hours. Bringing up and down the VPN client manually from the laptop device is an employee inconvenience that could be better accommodated with a GW based context/application aware split VPN. It depends totally on the IT policies on laptop and WFH device use and what is monitored from the company's perspective. Sometimes IT policies for workers while in the office will apply tools like WebSense to prohibit access to certain websites even general use of YouTube or Filesharing tools like Dropbox. If the device itself is not the restricted element but the work hours usage is – then some IT policies can reflect this with the ability to use laptop for personal uses when not on VPN or outside working hours. Ultimately if an IT department has a policy that a corporate issued device can only be used for company activity and all internet access is subject to the company's policies then split VPN tunnel at the GW itself may not be a useful feature.

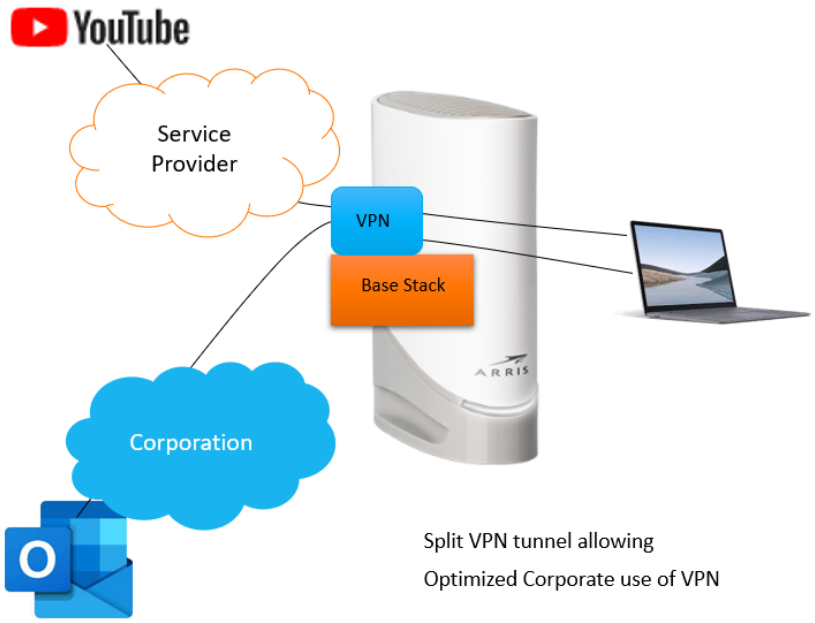

Figure 33 Integrated VPN and Split VPN solution

One additional comment on VPN from a Laptop vs VPN from a Gateway is the ability to provide quality of service to individual services like Corporate Video conferencing vs treating all VPN traffic as higher priority. When every service from a corporate laptop is encrypted in a VPN tunnel then differentiated service policies cannot be applied. While there are additional security implications with WPA3 encrypted traffic to a VPN in a Gateway – it does allow the GW to apply split VPN solutions easier and treat different services with different QoS policies better. A VPN client on the laptop applying split tunnels can also be used.

3.4. Integrated or Home File Cache

With much of the increase in upstream traffic in a WFH environment now starting to be file syncing to solutions like Microsoft onedrive – is there the potential to move that onedrive location to a local file cache in the home and then replicate it also in the corporate or Microsoft cloud? Depending on sync and user policies this could also help with Operator upstream bandwidth crunches where the syncing could be dependent on available bandwidth on the network vs currently more realtime and during office hours. It is

unlikely today that file syncing or local home storage solutions would be integrated in the Gateway (SSD technology making it at least easier from a size perspective) but could be something that is done in a Universal CPE device that offers local WFH processing and storage functions for SD-WAN like services to the residence

3.5. Corporate IT department control

Looking at the potential for the GW to be an extension of the corporate office and maintained as a virtual office end point by the IT department, what are the basic elements of a solution that may extend the office to the home.

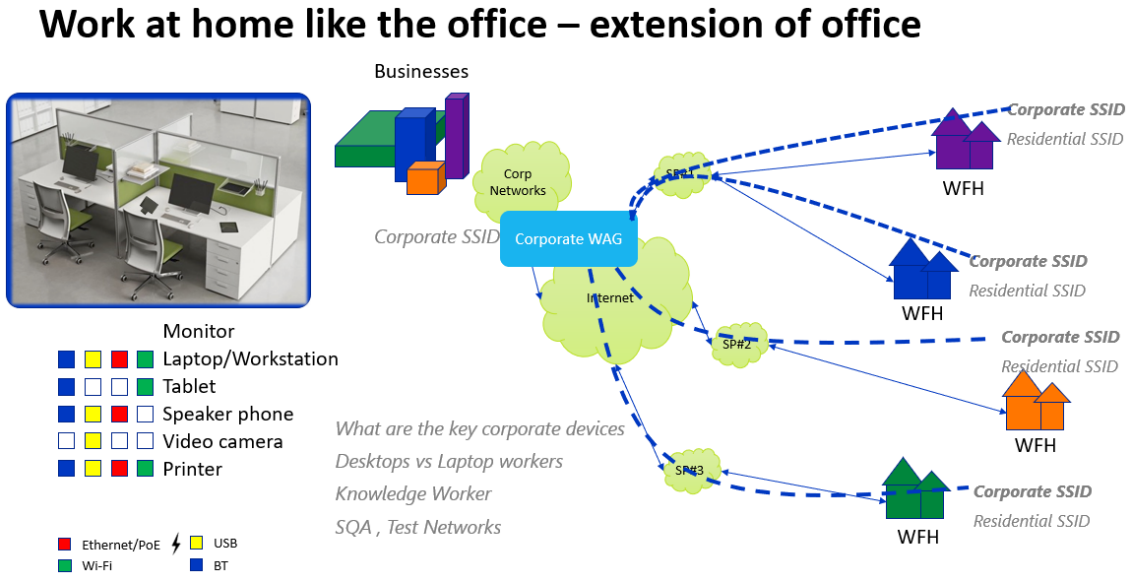

Figure 34 Extending Corporate IP Scope and SSID to the WFH GW

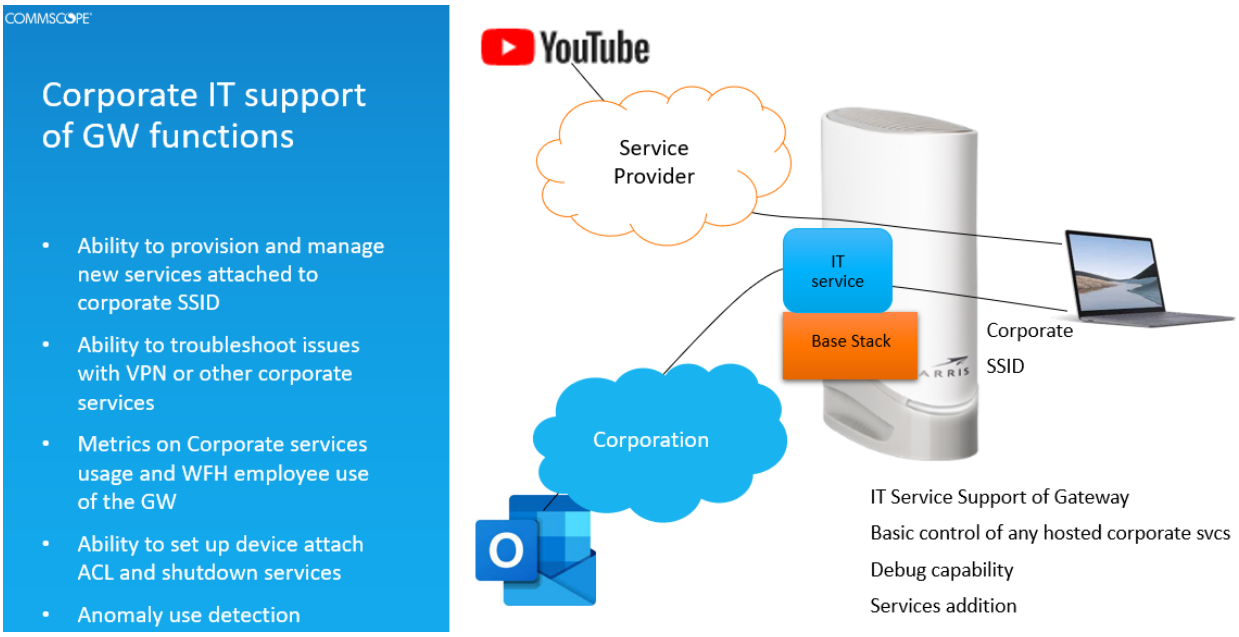
Consider the above approach of providing a dedicated Corporate SSID extending the typical office setup. Using both WPA3 encryption for the Wi-Fi SSID and VPN for all corporate bound traffic and services there is scope to have these residential GW's offer this service by downloading a specific containerized s/w solution on a per company basis. Allowing an Operator to charge to host this service and SSID for the separation of residential and WFH services. Creating containerized edge solution that can allow Corporations to apply their own security policies and ability to reset the service to the SSID when required. There could also be some options where the Operator provides telemetry information normally picked up by its own TR-181 pull and sends a subset of this to the IT department in the case of issues with the Broadband or Wi-Fi services in the home. Simple elements like – the broadband service speeds, wired broadband service is down and 5G/LTE backup is on and its usage statistics, Wi-Fi performance and any anomalies, VPN status, Security Status, CPU status, Memory status etc. An application and telemetry demarcation that (i) allows the Operator to pass the issues for any WFH service to the IT department to resolve (with special access to reset the Wi-Fi or even the Broadband Router device) and (ii) sells a service to Corporations that ties in with Employee presence and use on the Corporate connection could have a double benefit to the Operator.

Something more to consider as its realization is much easier to implement now as Gateways move towards containerized services models and away from monolithic images. Being able to add these services as well as protect the Operator/Consumer in residential mode from the Containerized memory

space and runtime and services that are exposed – enables these applications more to be able to be realized.



3.6. Anti-Eaves Dropping Solutions

With working from home now exposing corporate information outside the company office at huge scale and now having lots of endpoints distributed like leaves on a tree over a huge geography – the ability to steal corporate assets seems to have increased. Consider the following scenarios

- Shared GW and Wi-Fi networks by people working for different companies in the same house or apartment. More frequent and easier access to both Wi-Fi data from specific devices and even open laptops in the apartment. Will corporations pay to improve security in these more often and more frequent situations.
- Increased number of hours that someone is connecting to their corporate network. Everyone usually does work at home, but this can be intermittent vs WFH had day long corporate devices connected to corporate network.
- Higher probability of someone trying to get access to company information targeting a worker at home to steal passwords or create an intrusion to the corporate network. Still requires sitting outside someone's home or being in a neighboring apartment where Wi-Fi connection of the target is available.

One of the reasons why corporations favor running VPNs on the Laptop directly is that all passwords and traffic is VPN encrypted additional to the Wi-Fi encryption on the link to the corporate device. To provide VPN from the GW vs from the Laptop does leave a potential security hole between for example a corporate laptop and the GW it connects over Wi-Fi. Typically, this link will now be WPA3 encrypted but can be exposed with Man in the middle attacks and typically what is know as Evil Twin Access Points that masquerade as the users own Access Point and SSID. Solutions such as a **wireless intrusion prevention system** that monitors the radio spectrum within a wireless network's airspace for unauthorized or unexpected activity and frequencies could also be deployed and be part of a new improved WFH security solution.

Shared homes with different company employees in the same market are also now exposed more for theft of IPR/Assets with the increased frequency of WFH and the opportunity to target employees and corporations by sharing homes and apartments. Solutions that

- Separate traffic, networks, SSID's, encryption schemes as much as possible between co-habitants in a SFU or MDU are potentially desirable. Again, typically corporations require on VPN from the corporate issued laptops to provide security for their IPR. Would SSID separation and WPA3 encryption separation also be desirable?
- Minimize exposure to passwords employing two-factor authentication to a second issued corporate device like a smartphone/SIM is another solution that should be employed more for WFH as the location of the WFH employee and device could be easily spoofed.
- Provide Operator created schemes that are like 2FA using other associated home devices to help a corporation ensure their employee is located in a specific WFH location while working? For example, using other devices such as extenders and Wi-Fi STB to be present in Wi-Fi scans to correlate to an employee being in their home while working and using the specific corporate issued VPN or other connection.
- Track and manage large downloads – potentially requiring 2FA schemes to continue and or limiting the number of bytes that can be accessed in a day for WFH. While the corporation can track the capacity through the VPN client and concentrator the operator can potentially also provide some correlation numbers on this endpoint as well. This also highlights potential applications too of work and home separation (discussed later) to be able to provide billing information for WFH traffic vs residential traffic. This is particularly important given that many service providers operate traffic caps where overages cost the consumer. With WFH increasing both Downstream and Upstream traffic usage, there could very well be an offered solution from a Cable Operator to offer corporations a separate bill for any corporate traffic, identifying it from per instance VPN bandwidth and/or destination addresses, application use etc.

If WFH is set to be a high percentage consistent activity these eavesdropping security issues will only increase so there may very well be value to expand some of these ideas to provide the most secure WFH Wi-Fi or Ethernet connection with some of these ideas below – offered by Cable Operator to corporations as a potential chargeable service.

3.7. Low Latency Service

Latency is very topical now as people have experienced video conferencing issues, audio breakup while working from home as well as the rise of online gaming and general gaming during the pandemic. Is there an opportunity to apply low latency features like Low Latency DOCSIS and Low Latency Wi-Fi into the WFH application space? Is the following thesis potentially valid enough to create these new services and architectures?

- WFH traffic during working hours should be prioritized higher than residential traffic?
- Certain WFH applications like the audio from Video conferencing should be prioritized ahead of other traffic when those flows are detected. This can be impossible to do when Video Conferencing applications are always put into the VPN tunnel and hard to identify their service or destination address to apply QoS and priority policies.
- Being able to apply DSCP and TOS marking to WFH services with or without affecting residential priorities.

There is potentially other latency issues that occur in MDU environments with congestion on Wi-Fi networks in the 5GHz and 2.4GHz. Jitter and latency in congested Wi-Fi environments can affect Video conferencing and potentially in the future other work from home low latency sensitive solutions like

running visualization application on cloud servers but rendered in home devices – for example mechanical engineers running immersive video-based visualization tools and using hand gesture to move around objects in real time.

Enter the new 6GHz spectrum that has just been released in US and is rapidly being approved across the globe. Is 6GHz spectrum destined to be used as a WFH private network to optimize performance, separate service, improve security and create an extension of the office. One simple representation of a Wi-Fi 6E WFH application is illustrated below. Using additional corporate sponsored or supplied devices that connect to the Cable Operator Gateway using a private corporate supplied 2 box Wi-Fi 6E network could create the best blend of home Wi-Fi performance for WFH, total separation of residential and WFH traffic using not only VPN and IP separation but now channel and frequency and device separation. There could be also potential improvements for Wi-Fi RF eavesdropping as well using a solution where 25mW in room VLP is used to connect corporate devices to the first 6GHz AP and then VPN tunneled from their through 6GHz backhaul double protected with WPA3. VLP 6GHz propagation is highly unlikely to be sensed outside SFU and even in the majority of MDU environments so could provide a range limited but effective WFH Wi-Fi spectrum to use for both lowest latency and security.

From a latency perspective using Wi-Fi 6E and 6GHz spectrum provides access to Wi-Fi 6 scheduling of device transmission, clear spectrum for the most part, 160MHz (and 320MHz channels with Wi-Fi 7) all contributing to be able to provide deterministic latency and high probabilities of retaining a 1ms latency per AP hop. This would provide a WFH solution independent of congestion, contention, and latency to be able to power all WFH applications.

Figure 35 Is 6GHz the opportunity to create a private WFH low latency network

3.8. Anti-Theft of Service/Device solutions

Assuming that there are corporate software solutions added to Cable Operator Gateway or Corporate supplied home solutions like those defined above for a 6GHz VLP based in home office WFH solution –

then is it desirable by corporations or their employees alike to also have a solution that supports anti-theft of the device. Having the device only work in WFH environment for the specific corporation and in specific locations and with specific people and even specific applications.

Providing a series of checks to allow operation of the device could be done by several means

- Two or more factor authentication – using Cable Operator other Wi-Fi based devices that are defined to identify location and person requesting use of the WFH gateway
    - One or more STB need to be present
    - Bluetooth beacons need to be present from designated devices like Smartphones and STB
- Specific association of a corporate supplied device with a specific Cable Operator GW or Extender to allow WFH operations
- Nonoperation and boot of a GW if removed from its regular client environment. Regular client environment could be defined as simple as some mandatory presence of the devices in a persistent ARP table. (Note MAC randomization makes these simple associations more difficult and other schemes may have to be used).

There seems to be some merit in adding a feature like this to review with corporations if this level of anti-theft of service and device makes them feel more comfortable allowing employees to work from home.

3.9. HR Tools : Worker Presence & Tracking

A more sensitive or controversial set of features that may be relevant to employers and corporations as they move to completely virtual work solutions – is the application of presence and tracking technology for their workers. This all has to be done within HR guidelines as well as GDPR, CCPA, CCPR privacy regulations. Employers have been concerned that employees working from home, may not retain the same time and work diligence at home than in the office and can take opportunity to skip out from work to do home activity or other local activities during the day. There are simple technology ways to validate worker presence (presence not totally being indicative of the person working to any quantitative level) and a potential Realtime clocking in solution. Potential ways to do this are

- Traffic activity from the specific WFH device or on specific WFH VPN, SSID etc
- Connection of the WFH laptop or corporate issued phone on the Wi-Fi AP and correlating its frequency and potential type of traffic

Additionally, there could very well be some policies applied that an employee must have Bluetooth on in a corporate issued phone and this BLE beacon presence potentially also combined with Wi-Fi presence on the Operator or Corporate supplied GW/AP/IoT hub defines worker presence. This can obviously be spoofed by leaving home without the corporate issued phone but a somewhat restrictive solution to define trust that you are at home and working.

Other more intrusive but potentially allowable schemes are

- Using camera on issued laptop (Exam taking schemes now require the use of camera on the device exam is being taken on. Employers could also mandate something like this for their employees to work virtually).
- Radar and Wi-Fi motion solutions. Trying to signature a specific employee vs another home member is the key algorithmic requirement to make this solution offering viable.
- Remote clock in and clock out solutions – that are also aided by correlating to traffic and network usage

- Keyboard clicks, mouse usage are more invasive presence detection solutions but may not be qualitative of work or who is using computer or mouse.
- Turning on location services on corporate issued devices and company having agreements with employee to track their location during working hours or as a condition of being supplied corporate phone or even working from home.

And of course, a combination of all of the above may be able to reliably track the presence of an employee.

Of course, this may not be an appropriate or acceptable way to create a trust culture with employees and it may be better to trust the time-honored tradition of managers being responsible for the qualitative performance of their subordinates – so does presence or the metric pursuit of presence make any difference if any employee constantly excels at their tasks and role.

One security related use of presence that would be good to improve a WFH environment where multiple employees of companies in similar sectors are sharing an apartment. Having a local only presence solution between a smartphone and a GW/AP where the AP/GW or the WFH virtualized services running the GW are paused/blocked/not accessible unless the GW detects via BLE presence of the corporate phone and/or Wi-Fi attachment of same. A similar approach could be applied directly to the laptop or other corporate devices where they are logged out in the absence of another 2FA solution like BLE presence of smartphone.

A very sensitive and controversial area but there could be some happy medium of presence detection that is both beneficial to employee and employer.

3.10. HR Tools : Office/Home Separation

One of the more employee centric and mental health elements of working from home is the issue of separating Work and Life, This includes work and life from time and location perspective. Working in the place you also live can have issues on many levels. One of the simpler ones is to try and ensure that employees have the same natural triggers and events to start and end their day as well as take breaks for health purposes. For sure in a virtual world online meetings and meetings in general have now become scheduled rather than impromptu with a check of someone in their office. This has caused many people in WFH environment to say that they walk downstairs directly to their computer and surface late in the evening without the regular rhythm of commute to work, beating the traffic home and the odd call by to see can you do lunch.

Also, in certain countries there are very specific rules for time worked per week and the times that you can work. A virtual work environment makes it harder to enforce and check on this and there could be in the future WFH employees who have stress and mental issues that they blame on this WFH virtual working environment.

So, is there a technology way to separate Office and Home?

Separation can be defined in several ways

- For those fortunate enough to have a home office – it does provide some logical and physical separation of work and lifetime. When you enter the office – you are in the company domain even in your own home. When you step outside you are back into your residential environment. As we discussed above something like 6GHz VLP for example could actually separate Wi-Fi

connectivity from work and home and effectively only allow work devices to connect in a specific room of the house and not follow you to the kitchen.

- For time separation, policies can be applied to corporate issued devices or even in the case of a Cable Operator GW providing a WFH SSID for example – it be shut down at specific times to conform to companies working policies. The employee themselves may have to unlock things to complete certain critical tasks they deem necessary, but the company has complied with its or country working directives.

And of course, presence and tracking mechanisms coupled with solutions that have to comply to specific hours worked may be complete solution.

This may be something that could be applied to contractors in particular who understand their requirement to offer value typically billable on hourly basis.

Another potentially controversial topic but again in this new world of increasing virtual work and contracts based on virtual work stipulations giving HR tools to understand working patterns or even to shut down employees or throttle their work based on work directives that companies have to show compliance.

4. Conclusion

As we all wait to see what the permanent effect of the 2020/2021 pandemic is on the number of employees who work fulltime from the office, full time from their home or a flexible mix of both it does seem that there is opportunity to develop a better home connectivity and services solution that caters to the WFH elements and its new effect on the typical residential connectivity solutions. This paper tried to create a discussion on the development of this new mousetrap and see does it have merit for the employer, employee, the employee family or all of the above. Is there a business plan that can show who would pay for these improved services for productivity, security, anti-theft of IPR and even remote worker wellbeing? It does seem that most of the funding for these new services would have to come from corporations paying the Operator to allow these services to be dropped into their devices as containerized home services or easy onboarding of corporate supplied devices into a primary residential service provider solution. With the emergence of containerized service delivery and the arrival now of 6GHz spectrum this does also provide at least new technology elements that can offer path to be able to create some of the solution ideas discussed above. Is the better path to follow the SMB SD-WAN architecture and move this to manage a single WFH employee? Does it scale down to support that and does the new WFH solution also need a new rethink on the Universal CPE solution and role for split residential and WFH services. The authors conclusion from both the almost 2,500 WFH pandemic time employees and the wire brush of some of the ideas above is that there is an opportunity to extend the current residential only connectivity, security, and services model to add WFH as a service with feature additions like those above BUT this is dependent on the indelible change in the ratio of hours spent working in an office moving to the home environment. As of today in August of 2021 , the prediction is that an hours work ratio in 2019 pre pandemic of Office:Home ratio something like 90:10 is now going to be something like 70:30 or 60:40 is probably a big enough shift to make the better WFH GW and Solution mousetrap.

Humanoids Optional: Deploying vCMTS at Scale with Automation

A Technical Paper prepared for SCTE by

1. Introduction

For more than two decades, cable internet has provided the means to access the internet for hundreds of millions of people. The traditional cable modem termination system (CMTS) has played a key role in facilitating this access. The advent of cloud computing and containerization has caused a shift in access network solutions, with proposals to replace the traditional "integrated" CMTS (iCMTS) with a virtual CMTS (vCMTS), where the hardware-based iCMTS is replaced with an cloud native architecture that delivers the same functionality. By decoupling the CMTS implementation from the underlying hardware, vCMTS was proposed as a way of providing a modern, more flexible alternative to traditional models. For example, when deployed in a distributed access architecture, where the digital nodes can be placed closer to the homes they serve instead of in the headend, vCMTS can provide improved service with significantly increased density while also reducing headend infrastructure costs.

Broadly, vCMTS brings cloud-native approaches to bear on a problem that was traditionally solved through iCMTS hardware/appliances (Cloud Native Computing Foundation, 2020). At Comcast, vCMTS is comprised of a collection of servers running Kubernetes to orchestrate the containerized vCMTS microservices (The Kubernetes Authors, 2021). These micro services communicate with a remote physical device (RPD) through a networking layer composed of various switches in a leaf-spine architecture (see Figure 1). While cloud providers such as Amazon Web Services (AWS) offer services that can stand up Kubernetes clusters with a click of a button, latency and timing between vCMTS containers and the RPDs is a critical consideration for DOCSIS protocol application, making it impossible to use a public cloud for compute resources. As a result, the vCMTS cluster are typically deployed at the edge in the hub sites where their iCMTS counterparts were previously deployed.

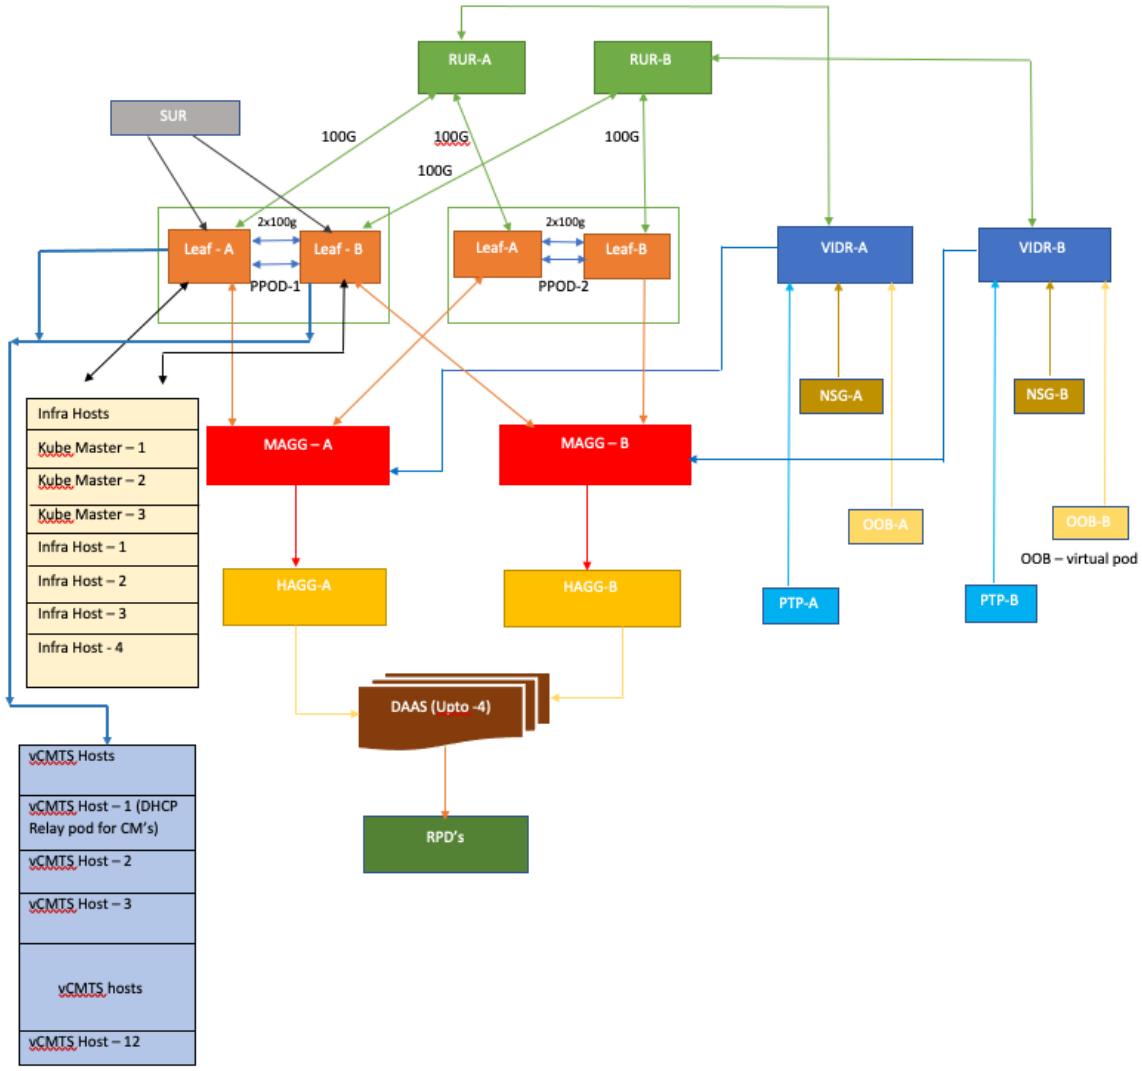

Figure 1- VCMTS Network In A Leaf/Spine Architecture, Where VCMTS Microservices Are Hosted In Servers On The Leafs And The Spine Facilitate Connectivity To The Rpds.

In 2018, Comcast deployed its first production vCMTS cluster. At that time, bringing the first customers online in vCMTS architecture was a major success, proving the feasibility and performance of the distributed access architecture (DAA) using vCMTS (Cable Television Laboratories, 2014). However, as Bob Gaydos, a Fellow at Comcast, remarked at the subsequent SCTE meeting, "Realistically, because Intel came in and helped us … make the vCMTS work on their platform, that's not the hard part. The hard part is actually the operations" (Robuck, 2018). Though the vCMTS architecture provided a huge improvement over iCMTS in terms of visibility through real-time telemetry and logging, operationalizing vCMTS proved challenging in several different ways: how the clusters were built; how changes were deployed to the clusters; how operations teams monitored the systems for issues and responded to incidents.

After our initial success, we started scaling out vCMTS across the Comcast footprint and quickly realized that our operational model would not scale. While each subsequent cluster was identical to the original in terms of hardware and software, each required unique configuration (e.g., IP addressing), making each new cluster build a significant effort. It was not uncommon for a cluster to take months to build from the time when the hardware arrived in the data center until we were ready to cut the first customers onto the new cluster. Because the clusters were painstakingly built by hand by different people, the vCMTS clusters were inevitably considered "pets" — each with their own slightly different personalities. While effort was made to keep the cluster definition in code, because the clusters were hand-configured from inception, it was a constant battle to prevent the clusters from "drifting" from their initial configuration over time.

The culture of customization proved particularly problematic when scheduled maintenances were performed. Since the clusters were built manually by humans, changes to the clusters generally also occurred by humans, often involving a long and complicated standard method of procedure (SMOPs) to both implement and validate the change. Though the SMOPs were scripted as much as possible, because the running configuration of a cluster could differ from the configuration stored in source code, the same change may go perfectly on one cluster but face an unexpected issue in another cluster. These issues could compound; when an unexpected issue was encountered, changes that should have been trivial to revert could snowball into outages that were difficult to resolve. Consequently, changes to software were approached with wariness and generally avoided, resulting in a delay or outright cancelation of feature deployment in this first generation of clusters.

Having proved the validity of the vCMTS model, it became clear that something needed to change if we were to deploy on a national scale. Staffing estimates predicted that we would require between 10-100 times the number of current operational resources to support the vCMTS clusters across the Comcast footprint; more importantly, root cause analyses of incidents indicated that a significant number of issues encountered were caused by human error. While DAA improves the fault tolerance of vCMTS, this comes at the cost of complexity. Fortunately, we were able to use much of the learnings from the DevOps movement to identify three key areas where we needed to improve: clusters must be identical, changes must become "boring" (i.e., frequent and predictable), and incident detection and mitigation must be automated (Kim, Humble, Debois, & Willis, 2016). Practically what this meant was that everything in the cluster lifecycle, from creation to maintenance to incident detection and mitigation, needed to be automated.

2. Infrastructure as Code: GitOps and a Beginning to the End of Customization

Even before the commitment to "automate everything", it was very clear that we were contributing to our own problems by requiring humans to deploy changes. After the first successful vCMTS customer trial, significant effort was invested in codifying the vCMTS deployment into an "infrastructure as code" (IaC). This idea, which has been central to the DevOps movement, is that the desired state of a system should be expressed as a versioned (e.g., Git) code that completely describes how to build that state. Therefore, any desired change to the running state should be achieved by altering the desired state.
A common variant of IaC is the "GitOps" model, where the infrastructure code is stored in Git and, upon commit to Git, the change conveyed in that commit is applied to the running system via a continuous integration/continuous deployment (CI/CD) pipeline. In our initial vCMTS systems (aka "Gen1") human operators were still required to implement changes; nonetheless, investing in IaC enabled us to rapidly rebuild systems, bringing us a step closer toward eliminating the culture of customization that made changes unpredictable.

3. Automating the vCMTS cluster stand up

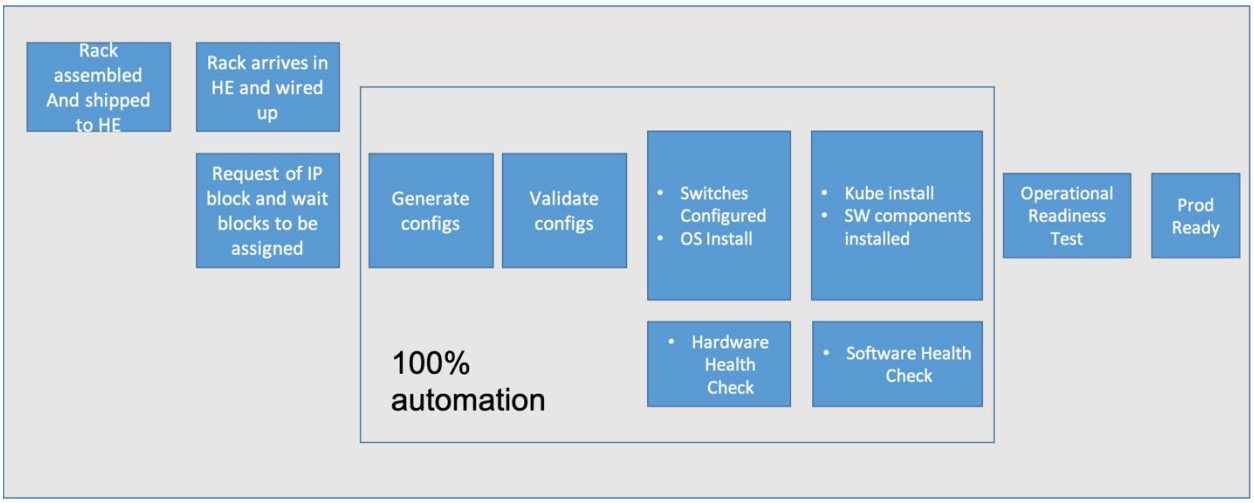

Figure 2 - Automated vCMTS cluster build process

As we were beginning the process of automating the vCMTS cluster build, an obvious but important step was identifying exactly what was required to build a cluster. A cluster build would typically occur over the course of many weeks. Eventually, we found that nearly a dozen teams or specific individuals were responsible for the various steps in a cluster build; this makes sense given that the original build was an "all hands" effort, different individuals or teams naturally became the subject matter experts on different aspects of the build. Since it evolved organically, the resulting build process resembled a web of dependencies as opposed to an assembly line. In the same way that the physical cluster assembly benefitted by consolidating within a team that "owned" the assembly process, as the dependencies were untangled and codified into a CI/CD process (Figure 2), the network and cluster build process was also recentralized around a dedicated team.

Recall that vCMTS consists of microservices (performing the DOCSIS scheduling and control functionality) and that communicate with RPDs via a networking layer. Having streamlined the issues in cluster builds, the remaining challenges can be grouped into two categories: network (switch OS and configuration) and vCMTS (cluster operating system, Kubernetes, configuration, and microservices). In both cases, the configuration (primarily related to IP assignments) is automatically generated based on the planned topology. Running a vendor-supplied network operating systems (NOS), the network primarily implements IS-IS to provide dynamic routing between the microservices and RPDs. When the cluster racks arrive in the local data center and are powered on, the first part to provision are the network devices. The switches automatically begin zero-touch provisioning (ZTP), download the latest OS (IaC, versioned in Git), and load the generated configuration (again, versioned in Git). When the switch becomes reachable, health checks are automatically performed to verify that the switch has the correct OS, configuration, and that the network is healthy.

Once the networking layer is functioning, a CI/CD pipeline brings the vCMTS online. This begins with the servers loading their base operating systems via ZTP. Subsequently, firmware is updated, Kubernetes is installed, and the vCMTS and supporting microservices are installed. A constant source of friction

during the original vCMTS deployments was integrating new clusters with external applications within Comcast (i.e., services that were not part of vCMTS itself, but that were required for a vCMTS cluster to function normally); this process was initially informal (e.g., an email), but by formalizing these dependencies as APIs, a constant stumbling point with external teams became a seamless integration. The CI/CD pipeline concludes by performing health checks for the application level, verifying that the vCMTS system is functionally working, and concludes by registering itself as a built cluster. By structing the build as a CI/CD process, we prevent an unhealthy cluster from accidentally being used to serve customers.

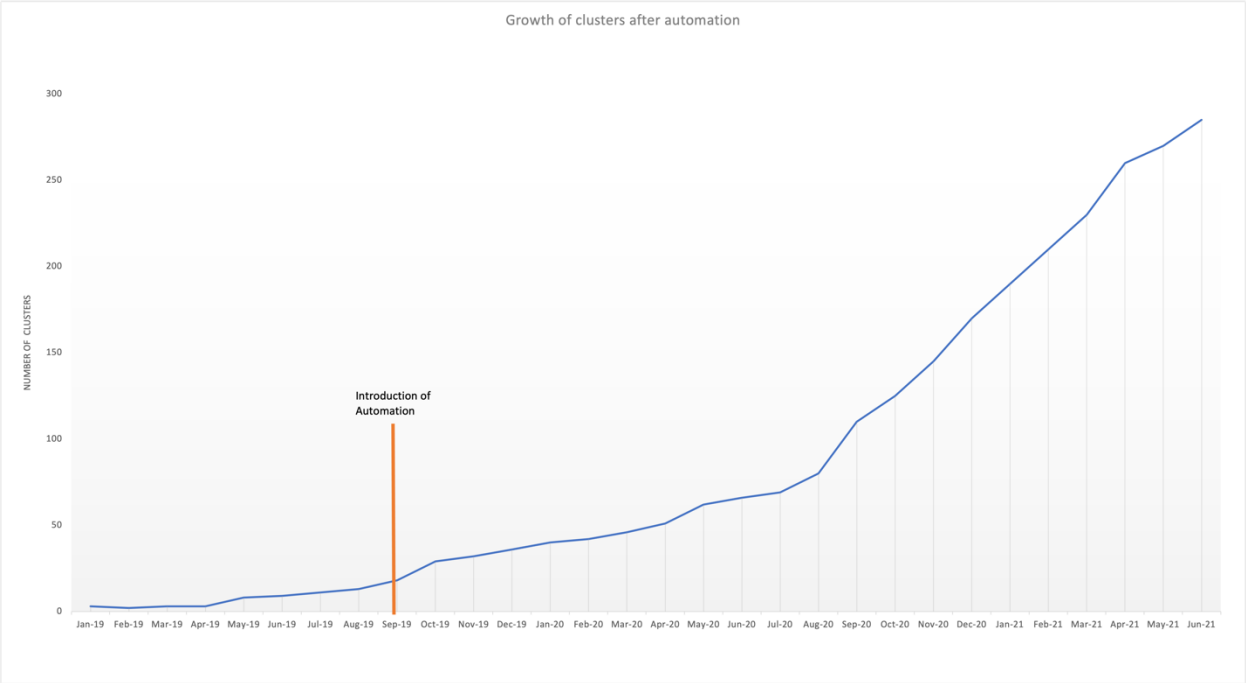

Figure 3 - Number Of VCMTS Clusters Versus Time. The Automated Build Process Began In September 2019, Significantly Accelerating The Cluster Build Process.

While the cluster could theoretically cut-over customers upon conclusion of the CI/CD pipeline, we have maintained a final step of human-driven manual testing (e.g., a cable modem is brought online, voice calls are performed, speed check, connectivity to backend tools, video channel lineup tests). This is consistent with our overall goal of automation—humans should: be removed from tedious and error-prone work that can be readily performed by machines, function as supervisors of machines by providing high-level instruction (e.g., "build a cluster with these parameters"), monitor for patterns and issues that are currently unknown and difficult to detect through automation.

Revisiting the overall build process, human involvement has been limited to 1) physically wiring the cluster/network, 2) some upstream network configuration into the core network (which currently cannot be automated), 3) final manual validation testing. This automated build process was released in September 2019 and as shown in Figure 3, has enabled us to grow the number of vCMTS clusters deployed across the Comcast footprint exponentially without a corresponding exponential growth in human resources as previously predicted. Concretely, provided that the clusters have been wired correctly, the automation has decreased the cluster build time from weeks to a few hours. The cluster

build process has become so predictable that all clusters which had been hand-built prior to automation were rebuilt in automation with essentially no customer impact. Now that the clusters were all identical and consistent with their IaC definitions, we were able to focus on the automation of changes.

4. Automating software and network changes

A critical issue we encountered in Gen1 was that, over time, the clusters drifted from their configuration defined in Git. This was primarily due to humans needing to deploy changes and address incidents, each which inevitably introduced small (unintentional) changes that compounded into significant drift. Thus, having spent considerable effort to ensure that the vCMTS clusters were built with no human involvement from a CI/CD pipeline using (automatically generated) configuration stored in Git, it was critical that any subsequent change to that git also be deployed to the cluster automatically.

While DevOps is often framed in terms of using tooling to achieve CI/CD, a mantra of the DevOps community is that a DevOps transformation is a cultural shift, not just a change in tooling. One of the first significant steps toward this was realized by Eric S, Principal Engineer at Comcast. A frequently encountered issue in Gen1 was that people tended to inadvertently work outside of version control. Whether it be by writing a SMOP and storing it in the change ticket (only to have the underlying cluster definition change in Git, rendering the SMOP "stale"), applying a script that was valid in a previous software version but invalid in the currently deployed one, or contaminating one site by accidentally using configuration from another, we constantly encountered issues with incorrect configuration being accidentally applied to clusters. By 1) breaking apart the deployment scripts for the various microservices into isolated and independently versioned bundles and 2) changing the workflow to require users to always import the current IaC into a local, containerized environment any time they wished to interact with the cluster, Eric was able push the organization toward that DevOps transformation by making it significantly more convenient to practice IaC.

A second step toward DevOps maturity was achieved through the CICD pipeline (Figure 4). Capitalizing on Eric's work to isolate cluster components into visioned collections of deployment scripts (in our case, Ansible roles), deployment pipelines were developed using the same IaC. Operating at the vCMTS cluster level, the pipelines were automatically triggered when a software component version was upgraded for that specific cluster. In Gen1, each change was required to have a series of pre-deployment and post-deployment checks; these were generally included in the change ticket so that if a deployment did not go as planned, the incident could be better triaged. As part of the Gen2 deployment pipeline, these pre-/post-check deployment snapshots were automatically captured and linked with the associated change ticket. By automating this tedious but important part of deployment process, we were able to further incentivize adoption of the CICD process.

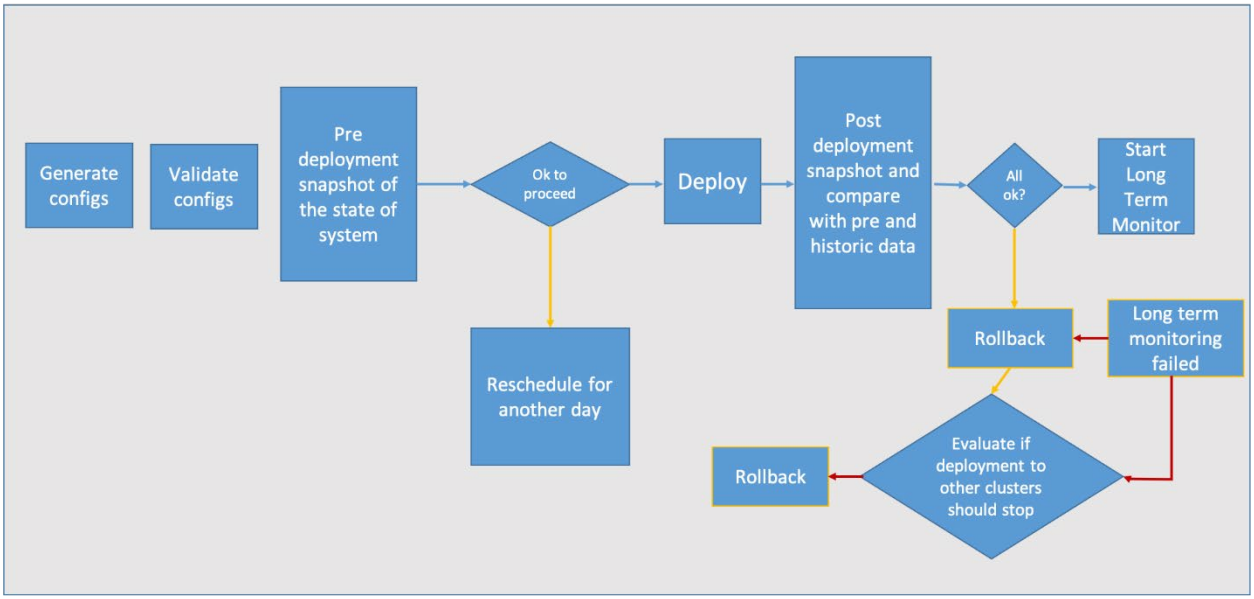

Figure 4 - Software And Network Change Deployment Pipeline

However, as both the number of clusters (due to stand up automation) and the number of changes (due to the cluster deployment automation) began to exponentially increase, we had an increasingly urgent need to orchestrate the deployment of changes across clusters. Since each cluster was identical, we were able to track changes as they were deployed and be confident that any issues encountered were due to the change, as opposed to unexpected differences in the clusters. Here, there are two competing interests. An important theme in DevOps is that developers should have the ability to easily introduce changes themselves and rapidly receive feedback about the success/failure of that change; however, the reality is that ISP operations are critical services, limiting the use of practices like A/B testing of potentially service impacting changes. Here, a compromise is achieved using canary testing, where each change is introduced gradually across the footprint. Changes are categorized by risk and deployed to minimize potential customer impact—first in QA, then staging environments (those without subscribers), and ultimately staggered into production environments.

In terms of changes to the network layer, the switches require both upgrades to their NOS as well as configuration changes. There is redundancy in the network so that if any given switch goes down, the redundant path is used with no impact to service. Our automation has taken advantage of this redundancy to turn maintenance into a zero-downtime event. Maintenance actions are first performed on one device (“A”) in the redundant pair (“A”, ”B”); traffic is then shifted to “A” side and only if everything behaves normally does the maintenance continue to patch the “B” side; if unexpected behavior occurs, the change is reverted. Through this entire process, the subscriber served by that network is unaware of any change being performed—their services continue uninterrupted.

Due to the large number of switches in the vCMTS access network (currently in the thousands), it was imperative that we fully automate the network operations and maintenance. To this end, configurations are generated purely through automation. Network operators are not generally allowed to make changes to the configuration on any given switch. Instead, network engineers edit the switch’s template file and commit it to version control where, consistent with the GitOps model, changes are detected and automatically scheduled for deployment across the entire network. Similar to the software

deployment automation, a network change will ripple across the Comcast footprint, with the engineer who performed the change having direct visibility into the impact and success/failure of their change through health checks. Consistent with the DevOps principles, providing this immediate feedback to engineers has significantly increase the overall quality of network changes and stability. Rather than the classic pattern of engineers "throwing a change over the wall" to operations to implement, the person who initiated the change is empowered to safely deploy a change across multitude of devices with a click of a button.

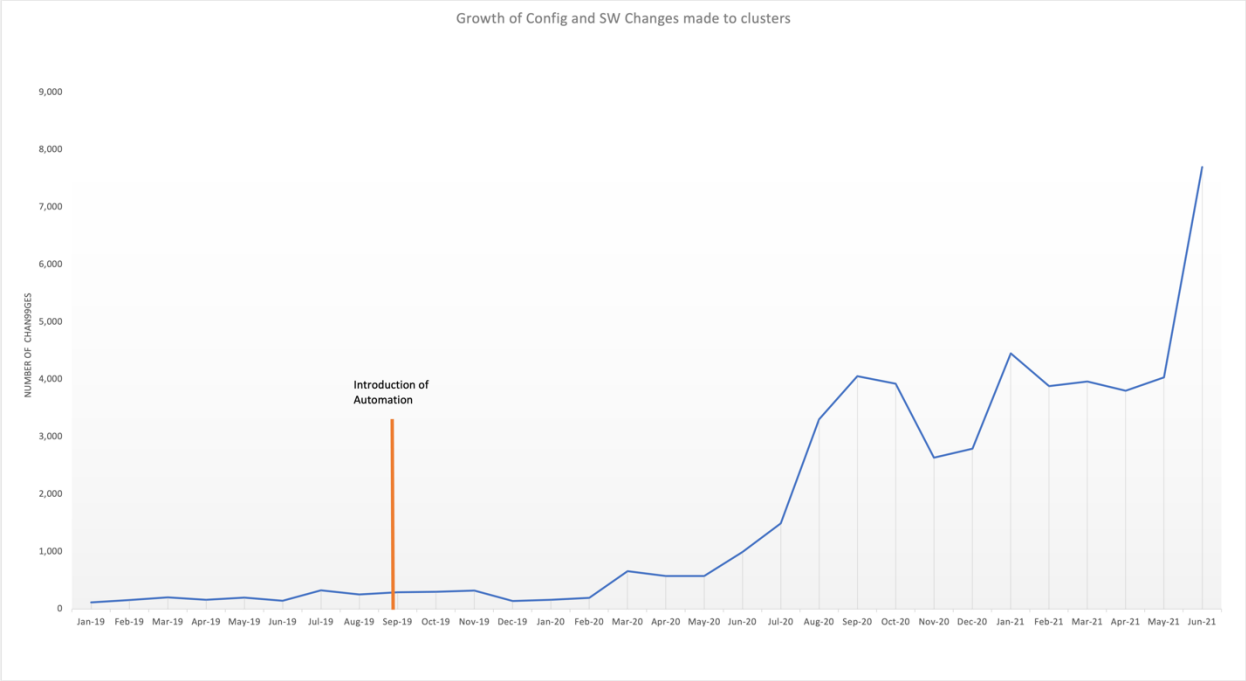

Figure 5 - Number Of Changes Versus Time. Automated Change Deployment Pipelines Were Introduced In September 2019

As is shown in Figure 5, automation was crucial in enabling our ability to deploy changes across the ever-expanding footprint of vCMTS devices. In Gen1, software and network changes were high-stress and high-risk events. Even though we had fewer than 25 Gen1 clusters, any given change would take several weeks to roll out since each change was manually performed by a human; furthermore, due to the high incidents of human error causing accidental outages, all changes (even to supporting applications that were not required for customer service) were typically performed in a scheduled maintenance window in the middle of the night out of a general fear of an unexpected issue escalating into a customer outage. As will be shown in the subsequent section, automation was crucial to our ability to scale out and rapidly deploy changes. Furthermore, the DevOps adage that "infrequent changes decrease service availability, frequent changes (e.g., continuous deployment) increases availability" was borne out; frequent deploys, including empowering the engineer who is making the code change to deploy the code, has significantly improved reliability and service availability, making changes "boring".

5. Automating incident detection and mitigation

After automating the VCMTS cluster build and change processes, our next focus was to automate the incident detection and mitigation. Because each cluster is identical and because no humans interact with the clusters directly during normal operations, our overall incidence of human induced errors dropped to zero essentially overnight. Correspondingly, the availability of the clusters across the

footprint has increased significantly (Figure 6). While issues certainly arise day-to-day (e.g., hardware failures), due to the built-in redundancy of the vCMTS clusters, these issues are typically not service impacting. Furthermore, because these issues are often routine, the response to them is known and can be codified in a script. For example, when a server in the Kubernetes cluster becomes NotReady, we automatically determine the cause of the Kube node being in NotReady state; if the problem is fixable and non-impacting (e.g., by rebooting the host or even reinstalling the host OS), it is done automatically and noted for subsequent analysis rather escalating to on-call operational support. If the issue does require human intervention (e.g., arranging an RMA with a vendor, re-seating an optical device in a maintenance window) steps like scheduling the maintenance are automated. By using machines for these routine and repetitive tasks, we significantly decrease the load on our ops team, enabling them to act as supervisors of the automation by codifying their responses into scripts and reserving them to troubleshoot non-trivial issues.

Figure 6 - System Availability Vs Time. Availability Is Plotted On The Right Side (Excluding Scheduled Maintenances) And The Number Of Incidents Per Month Caused By Human Error Is Plotted On The Left.

A hallmark of cloud native architectures is the improved visibility into the internal workings of the systems. Using a combination of open-source solutions, our vCMTS operators have visibility into everything ranging from network health to the performance of individual microservices. When an incident arises, this makes troubleshooting that cluster a much easier process because nearly everything that could go wrong is monitored. However, considering that we now operate more than hundreds of clusters, we cannot rely on humans having "eyes on glass" monitoring the clusters for potential issues. In a very real sense, we are simply inundated with data. Fortunately, in the age of data science and machine learning, being inundated with data is a great problem to have. A customer going offline could be caused by many sources: a fiber cut, power outage, network issues, backend unavailability, cluster software errors, etc. Troubleshooting the root cause can therefore be a lengthy process, resulting in a long mean time to repair (MTTR). Instead of immediately escalating to a human to investigate, our automated triage system can quickly probe various failure domains and rank likely root causes. This allows us to rapidly deploy the correct fix-agent.

During a deployment, variable usage patterns in the network can make immediately identifying issues difficult. While many changes are known to be non-service affecting in advance, some changes are intrinsically higher risk. Hence, long-term monitoring for anomalies is required. Using machine learning, external systems monitor telemetry for deviations from historical patterns. Since higher-risk changes are staggered across the footprint, this enables the automation system to detect anomalies and recommend that deployment be halted and already-deployed changes be reverted. This is integrated in our deployment orchestration system, allowing for the safe and hand-off deployment of changes.

6. Conclusion

In the past few years, vCMTS has evolved from a prototype to full-fledged production infrastructure providing cable services to a considerable portion of the Comcast footprint. While our initial Gen1 deployments proved the technology of vCMTS, the last three years have been devoted to scaling vCMTS operations. Often when we discuss our work with colleagues in other departments, a common response is that their work is automated too—via scripts. We want to make the distinction that, while Gen1 was fully scripted, the automation in Gen2 is neither a collection of scripts nor a simple CI/CD pipeline. Indeed, while one can write a CI/CD pipeline for a full stack application and deploy it in the public cloud in an hour, we have (somewhat painfully) learned that is not trivial to automate the operations of hundreds of bare-metal Kubernetes edge clusters running in hundreds of data centers across the US, in total comprising of thousands of switches and tens of thousands of servers. After our early work defining our infrastructure in code, we naively thought we had solved the difficult part of the problem. In fact, someone in our organization famously predicted it should take “a few weeks” to whip up the automation to allow us to manage vCMTS at scale. Instead, what began with a few engineers has evolved over the past three years into multiple teams comprised of 15 people. Building capabilities such as self-recovery, complex decision-making logic, risk-based scheduling to name a few took months of hard work by some of our highest performing engineers.

In a traditional ISP operations model, even our current footprint was projected to require hundreds of operational support engineers. Our goal ultimately is to reduce that to tens of engineers. While we released our initial automation almost two years ago, this work has grown over that time into a full-fledged product involving the collaboration of numerous teams at Comcast. Critically, this work has enabled us to achieve the exponential growth necessary to expand vCMTS across the Comcast footprint while also improving on the reliability and maintainability of iCMTS. As this work continues, we are further integrating our operational automation into the monitoring and core network infrastructure at Comcast, with the goal of achieving a zero-downtime and high-speed experience for our customers.

1 Introduction

Communications networks are at the heart of advancing society and bringing people and places closer together. The evolution of communications services will be central in transforming how we work, play, collaborate, and interact with the environment around us. Emerging collaboration technologies such as augmented and mixed reality (AR/MR) promise to offer highly immersive, multi-user, real-time and content rich experiences that will simplify business operations, improve productivity, and unlock new services and revenue sources across a wide range of verticals. This type of application relies on large amounts of bandwidth and extremely low network delay to do real-time processing of very large data sets and tracking user and virtual object movement, while enabling fine-grained interactions between remote users, the physical world, and holographic objects. This will be possible as network application intelligence and cloud platforms converge at the network edge in Multi-Access Edge Computing (MEC) locations.

Over the last decade, communication service providers (CSP) have invested in significant network modernization to keep up with a growing demand for bandwidth hungry applications and increasingly distributed service consumption patterns. The adoption of Telco Cloud architectures for virtualizing network services has improved the operational responsiveness of the network. However, despite advances in network automation, the traditional top-down BSS/OSS operating model has not adapted to the realities of delivering dynamic, cloud-native network services to meet the needs of distributed MEC applications. This new application delivery paradigm requires new operational tools that enable CSPs to maintain carrier-grade operations for virtual machine-based virtual network functions (VNF), while evolving to the on-demand and intent-based deployment of cloud-native containerized workloads for the next generation of network services and MEC applications.

MEC infrastructure and connectivity services are expected to be a growing revenue source for service providers who build a distributed edge compute network platform for application delivery from cloud to edge to the customer premise [11]. However, no single provider will be able to address this massive opportunity, thus, there will be a need to coordinate resources across multiple layers of the network infrastructure as well as the federation of services from different providers in the wide area network (WAN). This type of inter-provider coordination requires the flexibility to define a specific network topology for a given application and user endpoints as well as exposing Telco Edge Operator Platform capabilities [9]. Such a system must include a tighter coupling with application networking for optimal placement of MEC workloads given the specialized requirements for compute resources and proximity to endpoints.

As enterprises adopt hybrid, multi-cloud strategies to support their digital transformation initiatives, pressure is mounting on the traditional telco cloud environment to align with the same level of service agility and developer experience offered by the hyper-scaler cloud providers. This is driving the need to support multiple providers for different components of the application infrastructure. For example, a cloud provider could be responsible for portions of the application infrastructure while a network provider could be responsible for portions of the network infrastructure and latency-constrained application components. Additionally, the use of the same MEC environment to support components from multiple application providers will require different hard or soft isolation techniques at MEC locations. A service provider must also find

ways to align to a cloud provider's edge deployment and operations model with suitable hooks for tighter visibility and control of the service provider's network. Service providers will need tools to do this at scale with the likely need to manage 100s-1000s of highly distributed sites.

In this paper, we propose a Kubernetes-based control plane with built-in intent-driven automation to address these operational challenges and facilitate deployment of both virtual machine-based and container-based network functions (VNFs/CNFs) alongside MEC applications in a hybrid, multi-cloud architecture with a multi-layer connectivity network underlay.

This paper first describes the use of Kubernetes technologies and extensions to those technologies introduced as a solution to address the operational challenges implementing a MEC architecture (section 2). These technologies are then applied as the paper describes deploying a MEC architecture based on the Kubernetes system (section 3). Finally, the findings and recommendations based on the work completed are summarized (section 4).

2 Background and Technologies

The European Telecommunications Standards Institute (ETSI) [1] provides a reference architecture for the deployment of MEC hosts and applications. With the shift to containerized workloads in a cloud-native environment, ETSI [7, 8] work supports the use of container management systems such as Kubernetes for providing platform-as-a-service (PaaS) services. Additionally, the mapping of the ETSI management and orchestration (MANO) information model to the container workload deployment model enables an approach for implementation using a Kubernetes model. The MEC architecture can be deployed using a Kubernetes model and, with extensions, a more complete MEC model can be achieved with virtual machines (VM), VM to container service chaining, and constraint policy-based connectivity.

ETSI [Section 8 of reference 1] defines MEC service as a service provided and consumed either by the MEC platform or a MEC application. In the context of this paper, the term is inter-changeably used for both user application services, e.g., a MEC application like AR/VR rendering, as well as host or platform services, e.g., traffic management service or domain network service. As an example, some host level MEC services could be offered by a network provider while some application level MEC services could be offered by a cloud provider. Some of these MEC services may be part of the Kubernetes implementation.

2.1 Kubernetes In Brief

Kubernetes is a portable, extensible, open-source platform for managing containerized workloads and services, that facilitates declarative configuration and automation. It has a large, rapidly growing ecosystem. It provides a framework to run distributed systems resiliently, providing standard patterns for application deployment, scaling, failover, security, and load balancing. A full description of Kubernetes and its capabilities can be found at [10].

Since Kubernetes primarily operates at the container level rather than at the hardware level, it provides some general features common to PaaS offerings, such as deployment, scaling, load balancing, and lets users integrate their logging, monitoring, and alerting solutions. There are

also extensions to Kubernetes that allow it to manage VM based workloads which will be discussed later in this section of the document.

Kubernetes is not monolithic, and its default solutions are optional and pluggable. It provides the building blocks for building platforms but preserves user choice and flexibility where it is important.

A single Kubernetes deployment is known as a cluster and consists of a set of machines (physical or virtual) called nodes, which are utilized to host containerized applications. The nodes within a cluster can be classified as either a control-plane node, where workloads that implement the Kubernetes system are executed, or a worker node, where primarily application workloads deployed to the cluster are executed.

The Kubernetes control plane manages the worker nodes and the pods in the cluster, and it makes global decisions about the use of cluster resources. A Kubernetes pod is a schedulable entity that is comprised of one or more containers. The control plane components can be run on any machine(s) in the cluster, however, the usual practice is to run all control plane components on one or more machines and avoid running user containers on the same machines as the control plane components.

The following illustrates Kubernetes cluster elements described above [12].

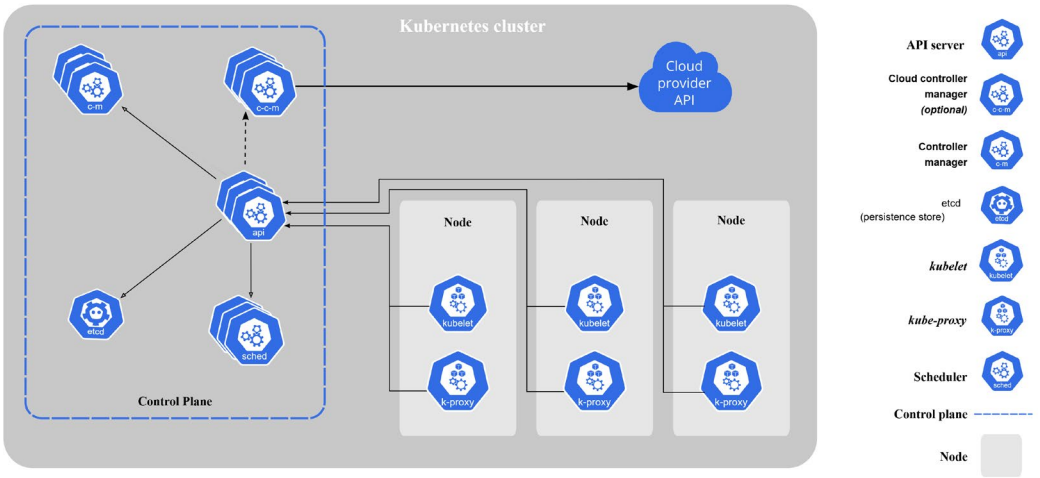

Figure 1 - Kubernetes cluster with all its components

As mentioned, Kubernetes is an extensible system and a key mechanism to extending Kubernetes is implementing a custom resource definition (CRD). A resource created through this feature can be used to store and manipulate information in the Kubernetes system. These custom resources are normally used in combination with a custom Kubernetes controller that interprets the data for the custom resource type contained in the Kubernetes store and then reacts to changes in the data (adds, deletes, modifications). This extensibility via CRDs highlights the fact that at its core, Kubernetes is a declarative based resource management system, and this can be leveraged when implementing a MEC architecture with Kubernetes.

2.2 Multi-cluster Strategies

Enterprises are adopting Kubernetes as a platform to enable application portability and agile deployment across public clouds, private environments, and more importantly on the network edge to optimize local service performance. This is critical for enterprises running retail, hospitality, and manufacturing operations with 100's if not 1000's of locations where application infrastructure is needed to support business to consumer (B2C) and business to business (B2B) applications, as discussed in section 2.8.

Kubernetes supports mechanisms such as pods and name spaces to isolate application components, and ensure resources are allocated optimally within a multi-tenant edge cluster. However, as Enterprise MEC applications proliferate at the network edge, industry trends are starting to emerge to define mechanisms to spread workloads across multiple clusters in different geographic areas. The chief technical reasons for multi-cluster deployments are:

- Lower latency by deploying applications closer to end users
- Service availability with fail-over support and geo-redundancy
- Workload scalability across distinct physical clusters with specialized resources
- Workload isolation & security with physical separation

The main two dimensions of these multi-cluster trends are the *distribution* of an application's resources and the *delegation* of lifecycle control of the distributed application resources, (see Figure 2).

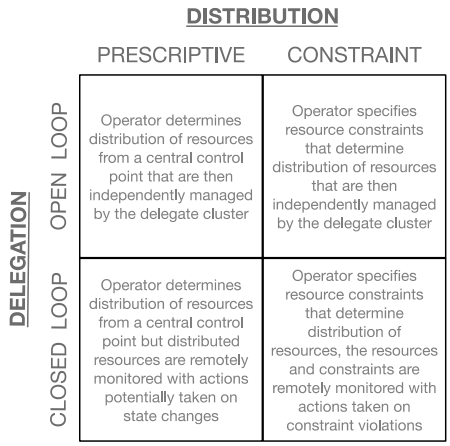

Figure 2 - Multi-Cluster Scheduling Strategies

Distribution of an application's resources refers to how an operator specifies the initial distribution of the resources across the available clusters. Distribution may also reference how an application's resources are redistributed based on a failure or other event. In a *prescriptive* system, the operator specifies the cardinality and location (Kubernetes cluster) for each

application resource. In a *constraint-based* system, the operator specifies the constraints for application resources, such as CPU, memory, network bandwidth, and network latency to an internal application resource or another external MEC application. These constraints are used by a scheduler to determine the optimum placement of the application resources.

Delegation of application resource lifecycle control refers to how the lifecycle of a resource is managed, including initial assignment to a member cluster, and any reassignment to a different cluster based on manual intervention or an event. In an *open-loop* system, once a resource is delegated to a participating cluster, the resource's lifecycle is completely managed by that cluster and will never be removed from that cluster except via an explicit action. In a *closed-loop* system, once the resource is delegated to a participating cluster, a feedback loop is used to monitor the resource and decisions about moving a resource would be based on a defined policy.

Both the distribution and delegation dimensions reflect the level of automation in a multi-cluster system. Systems that fall to the lower right quadrant (see Figure 2) tend to be more autonomous where systems that fall to the upper left quadrant tend to be configuration systems that strictly enact actions in the exact way the operator specifies without any remediation based on failures or resources violations.

2.3 Node/Cluster Capability Discovery

Applications are increasingly looking to leverage available hardware accelerators (GPUs, TPUs, etc.) and software data plane technologies (DPDK, VPP, etc.) to meet their performance requirements. This information is useful to a MEC control plane when placing MEC service components on inter-connected compute nodes. Leveraging Kubernetes and CNCF projects enables the deployment to self-discover a node's capabilities and report or expose those capabilities to a control-plane to be used during scheduling of workloads. Specifically, the CNCF node feature discovery project [55] provides this capability by discovering node features and labeling nodes in a standard format to allow features to be used as part of the standard Kubernetes scheduling capability. This is of critical importance in space & power constrained MEC environments, where full visibility of resource capabilities and programmability of the network infrastructure enable optimal allocation of premium resources.

2.4 Constraint Policy

Kubernetes provides a mechanism for a workload to specify resource constraints that can be used by the control-plane to influence the node selected when scheduling a workload. The existing mechanism is simplistic and predefines only the CPU and memory resource. Kubernetes does allow for other resources to be defined but limits the requested value of those resources to be an integer without a unit specification.

The system we have developed defines a constraint policy model that allows for arbitrary resource constraints to be specified and then leveraged by a custom scheduler as well as de-scheduler [6] extension.

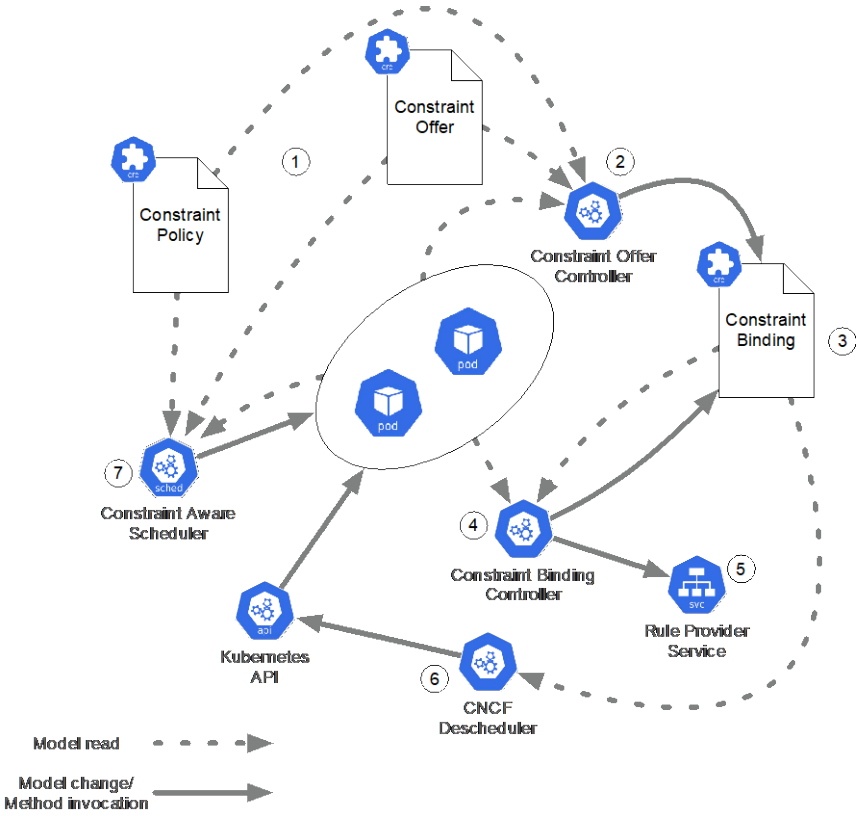

Figure 3 - Constraint Policy Overview

Figure 3 depicts the model and interaction of the constraint policy extension. A constraint policy is a set of constraint rules, where each rule is a tuple of constraint name, constraint request, and constraint limit. The constraint subsystem is designed to be dynamically extensible, and as such the constraint name is a moniker that is used to locate a constraint provider implementation at runtime. The implication is that the system does not pre-define any set of constraints. The constraint request and limit mirror the semantics of the existing resource constraints in Kubernetes in that a request is the preferred value, and the limit is the "worst" allowed value.

A Constraint offer ① is used to associate a constraint policy to one or more workloads (Pods, Services, or NSM network chains in the current implementation). The association is discovered by the Constraint Offer Controller ②, using a selector based on the tuple of Kubernetes ApiVersion, Kind, and Name. For each association discovered, a Constraint binding ③ is created to track the specific policy-workload association including its compliance status. Offers are periodically evaluated and the set of bindings is updated accordingly, deleting bindings that are no longer valid and creating those that now exist.

The Constraint Binding Controller ④ periodically evaluates the policies against the list of bindings leveraging the various provider services ⑤. A provider service is identified via a well-known label based on the constraint name. This allows providers, and thus constraint types, to be

dynamically managed. The compliance of a binding is updated as part of the status value for the binding.

This implementation extends the CNCF de-scheduler project ⑥ to monitor the status of the bindings and when a binding is found to be non-compliant, the de-scheduler may, based on a policy setting, evict the pod via the Kubernetes API ⑦.

2.4.1 Network Connectivity Constraints

Utilizing the constraint policy capability, this implementation defines a set of network connectivity-based constraint providers: bandwidth, latency, and jitter. Using these constraints, an operator can specify the requirements for connectivity between two or more workloads.

By implementing a declarative model for connectivity within Kubernetes, the network becomes part of the overall resource model within the environment, opening new automation use cases, including the ability to declaratively specify constraints that affect the underlay and overlay networks to meet the operator specified application requirements.

2.5 Scheduling Optimization

By default, the scheduling context for Kubernetes is a single pod. During scheduling, Kubernetes selects a node and assigns the pod to that node. Once a pod is assigned to a node, the containers defined within the pod are created and invoked. This can lead to sub-optimal scheduling when constraint policies (see Section 2.4.1) represent a binding between two or more pods as is the case with a connectivity constraint. For optimum scheduling, the entire set of connected pods to be scheduled should be known, and a "plan" should be created such that the pods can be scheduled according to the optimized plan.

To provide this capability, a scheduler extension was developed that operates as an optimized schedule plan builder, as well as a gating function to prevent pods from being scheduled until a trigger is detected. For the initial implementation, we are using a "quiet" timer, but this is easily extendable to support additional trigger types. The quiet timer simply fires when no new pods are defined over a specified period, thus the assumption being that all required pods have been defined and an optimal schedule can be produced.

Before the trigger fires, the scheduler is called repeatedly for each pod. When the planner is invoked, it queries the list of all unscheduled pods and creates a candidate plan, utilizing any specified constraints via the constraint policy resources. If the candidate plan is preferred over the existing plan, the existing plan is replaced by the candidate plan. In either case, an empty node list is returned indicating to Kubernetes that the pod cannot be placed at this time and the pod will remain in a "Pending" (non-assigned) state. After the trigger fires and the scheduler is called, the scheduler uses the plan to determine the node to which to assign the pod. As pods are assigned to nodes, they will be instantiated, and their containers will be created. At this time the connectivity-based constraint policy bindings will be created based on the scheduled pods.

2.6 Network Controller

As described in previous section, the scheduler extension developed as part of this work can leverage the connectivity-based constraints when scheduling workloads.

During development of the solution, while simulating network latency between two nodes, it was noticed that the connectivity-based constraints could not be met by the existing network configuration, causing workloads never to be scheduled, even though the underlying network had the capacity to meet those constraints. As these conditions could exist in a production deployment, especially a multi-cluster deployment, the concept of a network controller was introduced into the solution.

A network controller was represented by a defined interface and could be used by the scheduler to request network resources when the current network configuration could not meet the specified constraints. From the perspective of the scheduler, the network controller is an external entity located by a label on the Kubernetes service resource.

When invoked, the network controller has the flexibility to modify the underlay, overlay network, and/or network slicing to meet the resource request, returning to the scheduler enough information so that the pods that will be created can leverage the modified resources. This information can be used with the network service mesh project to ensure the connectivity to containers by creating the proper network interfaces and configuration on the containers. When the existing network does not meet the constraints and the network controller is not able to modify the network to meet the constraints, the pods will remain in the pending state until the constraints are modified, or the network comes into compliance.

The network controller was then integrated into the de-scheduler capability. When a connectivity-based constraint was found to be out of compliance, rather than immediately evicting the pod for rescheduling, a capability was added to the network controller to mediate this situation via network configuration. If the network controller is not able to bring the network back into compliance, then based on policy, pods may be evicted to be rescheduled or the violation can be ignored to prevent service disruption.

2.7 Common Application Function Model

Telco cloud implementations based on the ETSI network function virtualization (NFV) model have been in production for several years, delivering data and control plane network functions in a much more flexible and software-based format. These virtual machine-based VNFs evolved from the software applications delivered via dedicated hardware appliances for traditional switching, routing, firewall, and signaling services, among others. From a compute environment perspective, these network applications are no different than enterprise or consumer type applications that are delivered from cloud-native environments today, except for requiring specialized hardware assist for packet processing functions. These functions include protocol encapsulation and decapsulation, packet header classification, inspection and manipulation, wire-speed forwarding, encryption, and traffic protection, to name a few. These functions typically require traffic to be steered through multiple functional blocks that make up a network application service chain. The implication is that it is possible to describe a common model for

service function chaining of network application components independently of the specific software logic running within these components. This service function chaining specifies the communication patterns and processing policy for function chaining blocks.

2.7.1 Service Function Chaining

A network function is composed of one or more deployable components. These components can be inter-connected workloads to provide the overall features intended by the network service. The workloads form a chain with traffic flow sequence dependencies, and therefore, should be deployed as a unit on a single compute cluster node for optimal performance. In a hybrid virtualization configuration, a network function could potentially inter-connect hypervisor and container-based workloads on the same cluster node. For this reason, the MEC compliant platform should expose a common network function model to onboard and chain different workload formats.

Although sub-optimal, there may be cases where service function chains span multiple nodes within the same cluster or even multiple clusters separated by an edge network. This may result from constraints imposed on the service chain and the availability of specialized resources such as GPU or smart NICs required to support hardware accelerated functions. In such cases, constraints such as network latency, bandwidth, packet delivery guarantees, and traffic balancing must be taken into consideration when composing the end-to-end service chain through cluster federation mechanisms and network connectivity constraint policy.

2.7.2 Kubernetes Controllers for Function Chaining

When a purpose-built device and associated objects that consume compute resources are not directly modeled by Kubernetes, they can be represented through CRDs and the Kubernetes API can be extended to expose the configuration and capabilities of that new device. A custom controller can then be implemented to manage the lifecycle and translate the resource data into instructions that the target device may understand. Once CRDs and controllers are installed in a Kubernetes cluster, the orchestration of the device can be done through the Kubernetes control plane by abstracting the interactions through the custom device controller.

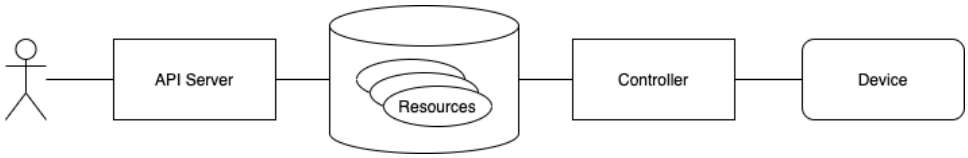

Figure 4 - Orchestrating Device Configuration via Kubernetes CRDs

We used this approach to support the orchestration of VM-based and container-based network functions (NF) on a common operational platform and service chained on a common network layer. This common orchestration framework was achieved by defining models to abstract the network function and chaining complexity. The models are then converted to Kubernetes custom resources with their corresponding controllers. The NF controllers are responsible for orchestrating a VM or container, based on the specified NF type. The chaining controller can

instruct the cluster to establish connectivity between the NFs on the underlying data plane, which may consist of software-based switching and hardware-based traffic processing.

This orchestration walkthrough for VMs and containers is a simplified and high-level view of what really needs to occur. Two scenarios can be considered to configure a system that supports virtualization for both VMs and containers.

1. System with hypervisor engine only with a VM instance running container native constructs, such as Kubernetes, to host containers.
2. System with both hypervisor and container engines to host VMs.

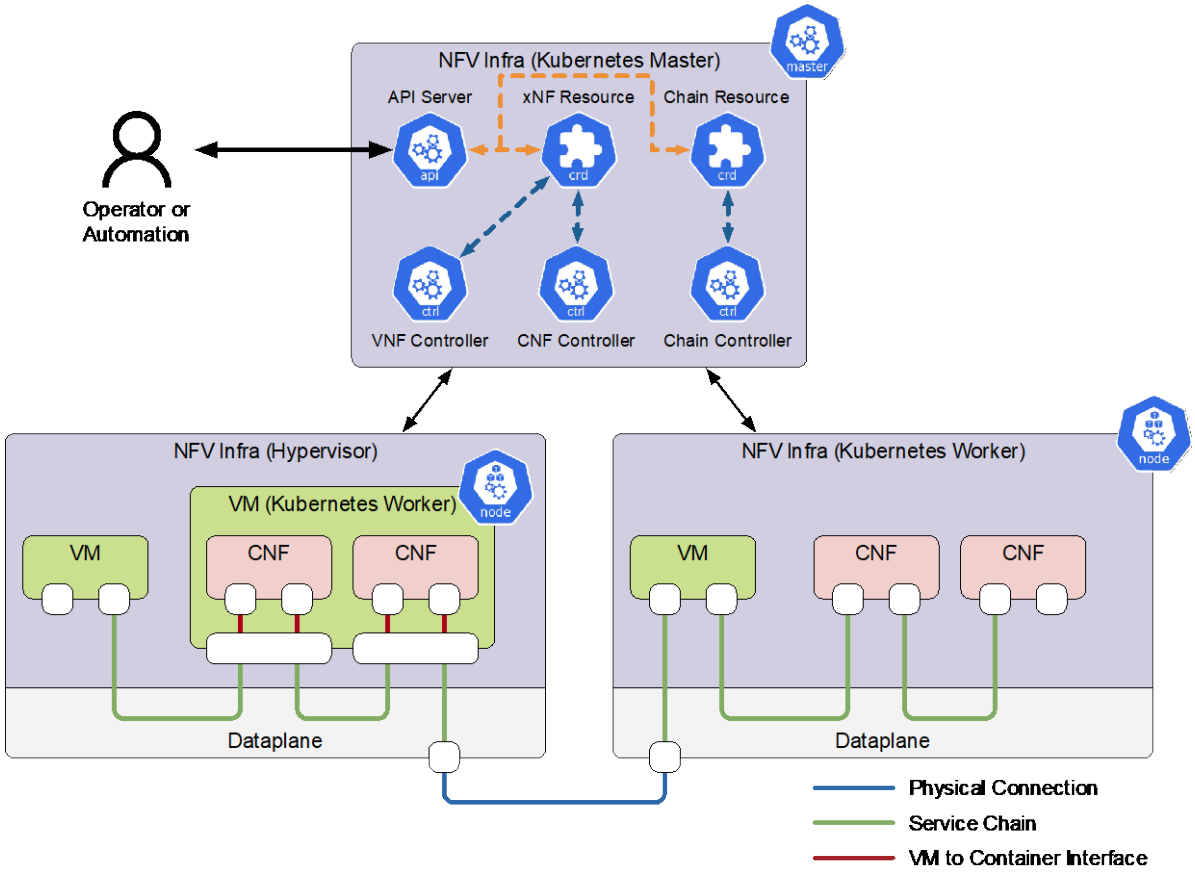

Figure 5 – CRD Driven Chaining

In the first scenario (Figure 5, left side), VMs are orchestrated through the system's hypervisor. A VM running Kubernetes is also used to deploy the container-based network functions. The connectivity between network functions is handled by service chaining the interfaces allocated to the VMs and then linking the containers with the Kubernetes VM interfaces using container networking interface (CNI) plug-ins (for example, Multus). In the second scenario, VMs and containers are orchestrated by their respective virtualization engines. The connectivity between the network functions is handled by service chaining the interfaces allocated to the VM and containers. In both cases, the interface allocation is provided by the data plane embedded in the NFV infrastructure.

In the second scenario (Figure 5, right side), the VM/Kubernetes capable infrastructure is used to create both the VMs and the containers. The connectivity between the network functions handled by using the infrastructure interfaces to chain the VM interfaces across the data-plane and then into the container-based NFs.

2.8 Public/Private Cloud Integration

When architecting a multi-cluster Kubernetes deployment, it is important to understand common industry deployment models. Currently, it is common that network operators and enterprises leverage both their private cloud resources and resources available from cloud hyper-scalers such as Google, Amazon, and Microsoft. Consider a scenario where an Enterprise customer with a large chain of retail stores is planning the introduction of new cloud native applications for inventory management, store security, advertising, and in-store customer engagement. This customer uses one of the major cloud providers to run their own DevOps environment and a national network operator to inter-connect all their stores to MEC locations, private data centers and cloud. A key requirement for the Enterprise IT operations team is to unify the management and delivery of containerized applications to 100's of locations (premise and edge) while maintaining a common network and security policy nationally. As Figure 6 illustrates, this leads to designing a fabric of Kubernetes clusters deployed at many locations, managed through a cloud provider's control-plane and interconnected by a network operator that hosts some of the clusters within the MEC locations.

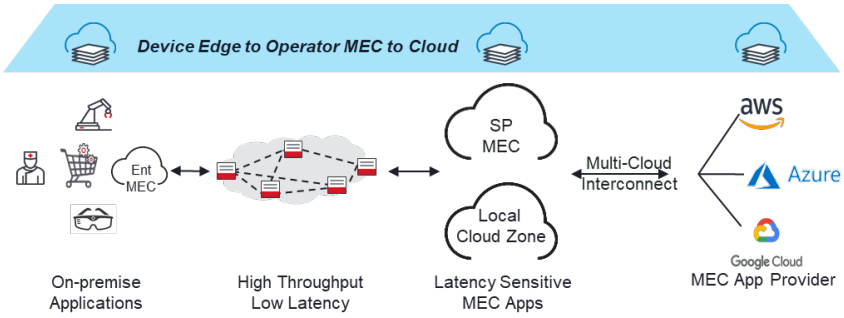

Figure 6 - Enterprise Multi-MEC Applications

While the capabilities described in the sections above can be deployed into Kubernetes clusters under the administrative control of the network operator, it is not always possible to deploy these capabilities on the Kubernetes clusters provided by the hyper-scalers. This is more obvious when it comes to the aggregation or federated level as each hyper-scaler typically provides a custom federation solution as one of multiple tightly integrated cloud-based services, i.e., Google Anthos, Amazon EKS, Microsoft Arc, Rancher, etc.

How these capabilities can be integrated with the various hyper-scalers' offering depends on the amount of customization each allows. In the case where a custom scheduler extension cannot be deployed, this can be "worked-around" by creatively assigning node affinity to resources before

allowing the hyper-scalers scheduler to be activated. Node affinity is a standard Kubernetes capability available on all distributions.

This can be implemented by shifting the capabilities described above, particularly scheduling and de-scheduling, from the Kubernetes domain to a DevOps domain, as depicted in Figure 7. In this situation, the DevOps pipeline would be leveraged such that when an application is pushed to storage ①, the pipeline would evaluate the scheduling needs of the workload and augment the resources with the node assignment encoded as a node affinity configuration ②. Additionally, the constraint aware scheduler may, depending on availability, contact a network controller provided by the network provider ③ to request network capabilities compliant with the constraints specified in the constraint policy. This in turn might trigger the network provider to reconfigure the underlay network ④. If a network controller is provided by the hyper-scaler, then the scheduler may also make requests via that interface which could affect both the overlay and underlay ⑤. After the scheduler updates the manifests and commits those back to storage, the DevOps pipeline receives the augmented manifests ⑥ and pushes the manifests to the hyper-scaler managers ⑦. The hyper-scaler managers process the manifests using their standard schedulers ⑧, adhering to the standard affinity rules, and enact the set node assignment ⑨.

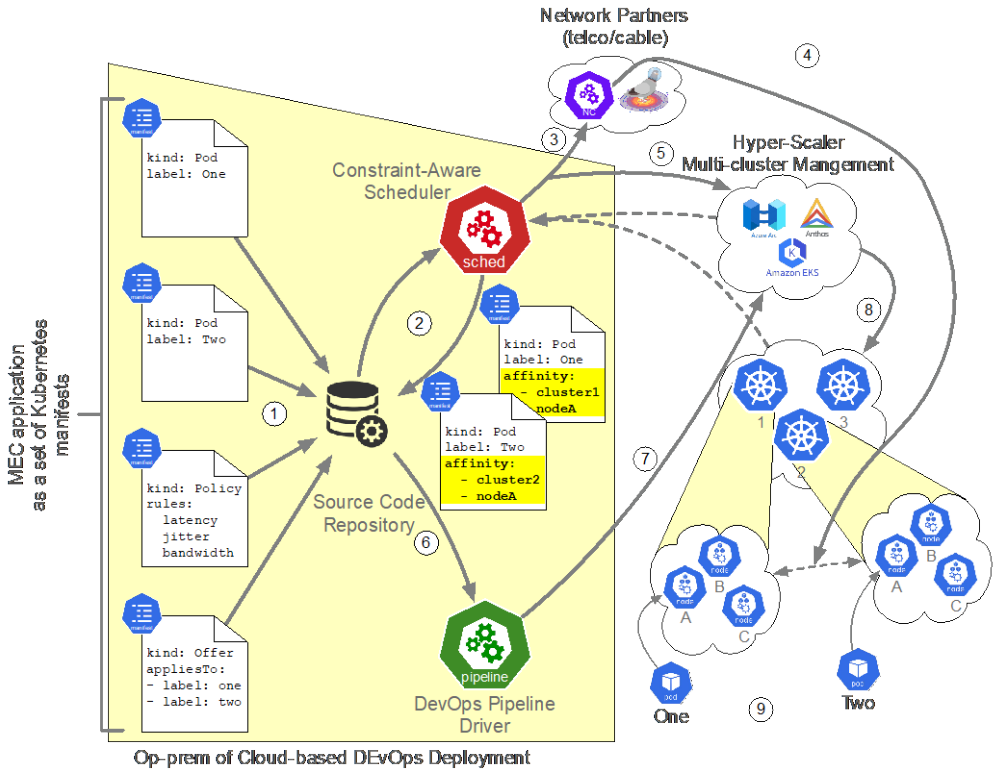

Figure 7 - Using Constraint-Base Scheduling with Public Clouds

Other than the scheduler extension, the described technologies should be able to be leveraged within a hyper-scaler's environment as the other technologies either are common user-based extensions (CRDs + controllers) or components that run outside the core Kubernetes control-

plane (de-scheduler). The one exception is the network controller, which may require support from the hyper-scalers to support underlay control, although it is possible to implement a network controller that only affects the overlay.

3 MEC Architecture on Kubernetes

In this section, we describe how the MEC architecture can be implemented using the de facto industry standard container orchestration system originally developed by Google, i.e., Kubernetes. Figure 8 depicts the standard MEC architecture on the left and on the right depicts that same architecture with an overlay that indicates the cloud native technologies that can be leveraged to implement the MEC architecture. The following sections will detail how each component of the MEC architecture can be implemented using specific cloud native technologies.

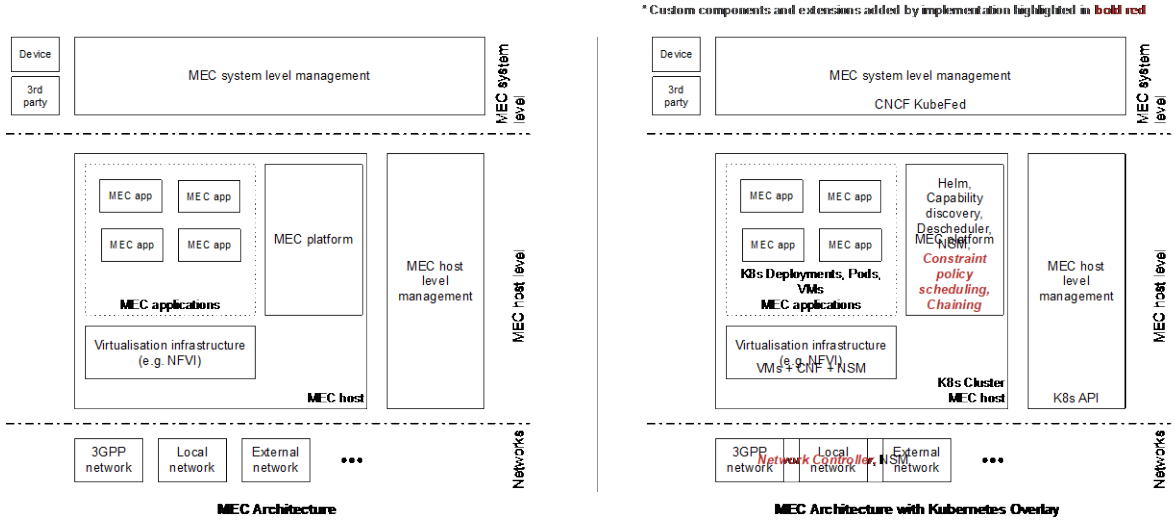

Figure 8 - MEC Architecture with Kubernetes Overlay

3.1 MEC Host

A MEC host is defined as “an entity that contains the MEC platform and a Virtualisation infrastructure which provides compute, storage and network resources for the MEC applications. The Virtualisation infrastructure includes a data plane that executes the traffic rules received by the MEC platform and routes the traffic among applications, services, DNS server/proxy, 3GPP network, other access networks, local networks and external networks.” [1]. By this definition the MEC Host is functionally equivalent to a Kubernetes cluster, which is defined as “A set of worker machines, called nodes, that run containerized applications” [2] The Kubernetes cluster provides the virtualisation infrastructure and data plane as required by the MEC definition. While Kubernetes’ original focus was orchestration of containers, several virtualizations extentions have been added to Kubernetes to provide a run-time for virtual machines and networking.

3.1.1 MEC Virtualization Infrastructure

The virtualization infrastructure of a MEC compliant system should have the ability to orchestrate hybrid service deployments where VMs and containers can coexist on the same platform. To achieve this hybrid configuration, there is a need to accommodate VM based network functions within Kubernetes. A system with such capabilities would have to share resources (compute, memory, storage, networking) to offer a seamless integration with the hosting platform. KubeVirt is one of several projects of the Kubernetes ecosystem that can manage the lifecycle of virtual machines within a Kubernetes cluster while also supporting container workloads.

Additional solutions and platforms exist that provide VM/container capability through the Kubernetes declarative model solution. Further, some of these solutions provide a tight integration with the network interfaces such that they are purpose built to support VM and container-based network functions.

Today the declarative models used to define VM based resources vary across the available solutions and most focus primarily on the detailed attributes for creating a VM and less on the concept of chaining NFs. The solution proposed in section 2.7 bridges this gap by allowing the specification of network services that can contain both VMs and container-based NFs, abstracting away the specific virtualization choice and focusing on the connectivity between those functions. Further, this approach can be extended in the future to support additional virtualization techniques and/or new infrastructure as it is released by vendors.

3.1.2 MEC Applications

A MEC application "runs a virtualized application … on the infrastructure provided by the MEC host" [1]. Within Kubernetes, the typical executable workload is known as a pod, which is a set of containers run on a single Kubernetes node that share storage and networking. As shown above, with the use of CRDs, Kubernetes can be extended such that a workload may be either a pod (container) or a VM.

Kubernetes provides several "higher" level resources constructs that help the operator group and deploy the basic building blocks of an application. These include a Deployment, which is a set of distinct pod definitions and the cardinality for each of the pod types, as well as a ReplicaSet, which maintains a stable set of pod instances for a single pod definition. In addition to pods and other deployment constructs, Kubernetes also provides mechanism to enable load-balancing and high availability for applications.

These basic building blocks provided by Kubernetes provides the basis on which MEC compliant applications can be built. Because an application typically requires more than a single Kubernetes resource, a higher-level application construct can be created using the CNCF Helm [3] tool. This abstraction allows a MEC application developer to specify any number of Kubernetes resources as a set and then deploys that set of resources under a single name, thus allowing a complete application to be deployed instead of dealing with the applications piecemeal.

At its core, Helm is a template engine that create instances of resources based on defined templates, parameterized Kubernetes resource definitions, substituting configurable values for the required parameters. Templates can be core Kubernetes resources as well as CRD defined resources, thus providing access to the full resource model.

3.1.3 MEC Host level management

As described above, the MEC virtualization infrastructure capability can be provided by Kubernetes with extensions to support VMs. Through the defined NF CRDs, both VM and container-based capability can be specified and deploy via a common abstraction. Once deployed, the Kubernetes control-plane will monitor the lifecycle of the resources accounting for scalability and high availability. Additionally, Kubernetes provides a security and network infrastructure to support application deployment.

With the additional of the connectivity-based constraints, scheduler extensions, de-scheduler, and network controller, Kubernetes provides the base capabilities required of MEC host level management.

3.1.4 MEC Host Level Scheduling

MEC host level scheduling is the equivalent of scheduling on a single Kubernetes cluster. The previously described technologies (constraint-based scheduler, optimized scheduler, de-scheduler, and network controller) work in concert to provide the scheduling of workloads to nodes.

3.1.5 MEC Host Level Networking

While a single Kubernetes host provides basic MEC host networking capabilities, through the use of add-on capabilities such as the network service mesh (NSM), additional MEC host (or Kubernetes intra-cluster) networking can be leveraged. A key consideration when deploying a NSM into a Kubernetes cluster is the ability to declaratively define the network connectivity such that there is a separation of concerns between the development of the application and the deployment of the application., i.e., the expected connectivity should not be “baked” into the application code and instead be left to deployment (declarative) configuration. This can be achieved with the NSM implementation.

A network function deployed within a MEC host must focus on serving its intended purpose and should remain unaware of any chaining requirements with other network functions. The Network Service Mesh framework (NSM) in the Kubernetes eco-system fills the role of creating chains and managing the assignment of a network function within a chain. It does so by augmenting orchestrated network functions with a sidecar container and controlling the interactions between the sidecars. The NSM manager can then implement the desired topology by establishing links between sidecars through the NSM data plane.

3.2 MEC System Level Management

The Cloud Native Computing Foundation (CNCF) has defined a special interest group, the Multi-cluster Special Interest Group (SIG), whose charter specifies that this SIG focuses on "solving common challenges related to the management of multiple Kubernetes clusters". [4] As indicated above, if a MEC Host represents a single Kubernetes cluster, then the MEC system level management is meant to manage multiple MEC Hosts and thus multiple Kubernetes clusters.

The CNCF Multi-cluster SIG facilitates the development of a solution for deploying workloads across multiple Kubernetes clusters known as "KubeFed". KubeFed allows an operator to specify the cardinality and location of workloads that are part of an application. Thus, an operator can deploy an application and prescriptively control which cluster a pod is deployed on and how many instances of that Pod are deployed to that cluster. While this is required, it is not sufficient for an autonomous MEC system that can deploy MEC services based on their compute, storage, network, and other resource constraints. Sections 2.4, 2.5, and 2.6 describe a constraint policy extension to Kubernetes that can be applied to a multicluster Kubernetes deployment to provide the capability to deploy MEC services across multiple MEC hosts based on operator specified constraints.

3.2.1 Why Multi-MEC Host is needed

In modern deployment architectures, a single MEC host is not always sufficient to meet the MEC service requirements for latency and/or performance. MEC services will be designed around network and performance bottlenecks, but these designs cannot always compensate for the limitations imposed by the constraints of a single MEC host.

To truly meet the requirements of modern and near future MEC services, deployments must take advantage of multiple MEC host deployments where some of the MEC hosts may be "network close" to the end client with lessor compute power, commonly called edge, and other hosts may be "network distant" with greater computer power.

It is important when deploying a MEC application across multiple MEC hosts that the MEC application is not "topology aware" in that it is not aware of the network location of the compute nor the network on which it is deployed. Instead the MEC applicaiton must specify the constraints it requires and allow the "MEC control-plane" to allocate resources to meet the specified constraints. Providing this separation of concerns between the MEC application and the MEC control-plane allows operators to better align their resources and provide the expected quality of service (QOS) to their clients.

3.2.2 MEC and Edge Computing

Edge computing is the delivery of computing capabilities to the logical extremes of a network to improve the performance, operating cost and reliability of applications and services to the user of the services.

As ETSI GS MEC 003 document [1] states, “Multi-access Edge Computing enables the implementation of MEC applications as software-only entities that run on top of a Virtualization infrastructure, which is located in or close to the network edge.”

While this means that MEC can define a network edge capability, it is also true that MEC can define a metro or central data center. In the context of MEC, any Kubernetes cluster is considered a MEC host regardless of the “nearness” to any given client. As such, at the system level, MEC hosts create a mesh of connectivity that can be leveraged by users that deploy MEC applications.

A MEC *location capability* is simply the MEC host that is “network near” the client of a given MEC application. Thus, any given MEC host may be *at the edge* to some client regardless of its actual location.

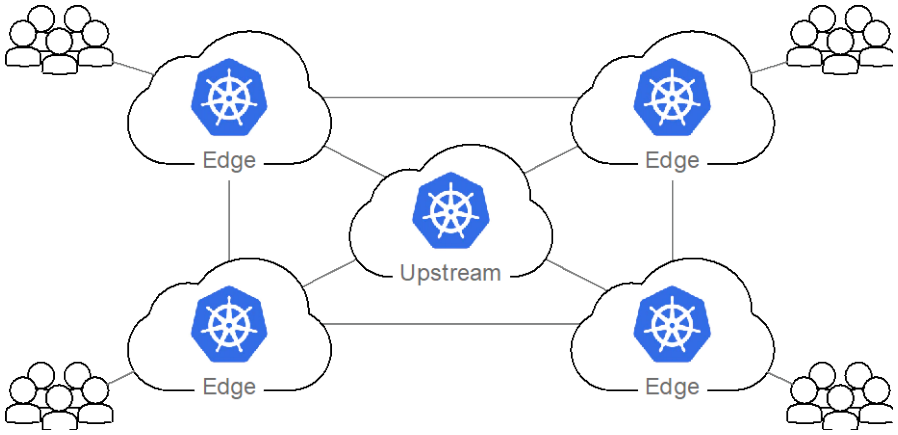

Figure 9 - Depiction of a Kubernetes Cluster Mesh

The illustration above shows an example of how Kubernetes clusters can be inter-connected to represent a MEC host mesh. While some of the clusters are labeled “Edge” or “Upstream” it is important to note that all clusters are functionally equivalent. Where the cluster may differ is in resource capacity or nearness to a given client, but these are operator deployment choices, and an “Edge” could have just as much or more capacity as an “Upstream” cluster.

Based on the above, it is possible to qualify existing or purpose-built MEC hosts as edge clouds for placement of services required by applications that use them.

This edge computing requirement driven optimization of network and compute resources also can be achieved by re-configuration of the underlay connecting MEC hosts.

3.2.3 MEC System Level Scheduling

At the Kubernetes multi-cluster (multi-MEC host level), scheduling is provided via the KubeFed project. At the federation level, the scheduling process changes from scheduling a single pod to a node to delegating or replicating Kubernetes resources to a cluster. The constraint-based

scheduling described above in the context of a single cluster can be applied at the system level with minor additions to the capabilities.

In KubeFed's existing implementation of scheduling, an operator specifies how a resource is federated across the set of member clusters. This includes the specification of the cluster as well as the cardinality of a resource assigned to that cluster. There is a capability to allow the federation to be ratio-based as opposed to completely explicit, but this still equates to a prescriptive federation.

By augmenting KubeFed's scheduling algorithm, as it does not provide the same extension mechanism that base Kubernetes provides, constraint-based scheduling, including connectivity-based constraints, can be achieved. Instead of specifying a cardinality and a cluster, the cardinality and connectivity constraints can be specified allowing the scheduler to place the workloads across the multiple clusters. After the workloads are placed, the constraints can be monitored and upon violation, the resources can be rescheduled within the currently assigned cluster or to another cluster.

3.2.4 MEC System Level Networking

Kubernetes does not provide inter-cluster networking capability natively nor as part of KubeFed project. CNCF provides multi-cluster DNS capability that can be used in a multi-cluster deployment.

Inter-cluster connectivity can be facilitated via the exposing of cluster services via a standard Kubernetes ingress controller or the NSM. Additionally, as part of the scheduling process, a network controller can be used to establish new network paths or modify existing paths.

When using an ingress controller, the services provided through a given cluster are exposed on a public IP address and port. This allows services from other clusters to access these services. The downside of this approach is that it only supports layer 3 (L3), and in some implementations only HTTP connections.

With an NSM implementation, inter-cluster networking can be established through peer to peer connections between NSM managers in each cluster. This allows the establishment of layer 2 (L2) and L3 connections. Further, using sidecars, this connectivity can be declarative, maintaining the SOC between application development and application deployment.

Where a network controller can be integrated, either through a scheduler extension or a DevOps pipeline, new network connections can be established that meet the connectivity-base constraints specified via the constraint policy system. Between the use of the network controller and the NSM complex, inter-cluster networking scenarios can be supported.

4 Summary

This document described extensions and additions to the standard Kubernetes deployment that provide constraint-base, specifically connectivity-based constraints, scheduling of Kubernetes workloads. Additionally, support for VM as well as container-based workloads was introduced,

including chaining of those workloads. How these capabilities can be applied to a single Kubernetes cluster and a federation of Kubernetes clusters was described. Additionally, how these technologies could be applied to non-operator cloud capabilities (i.e., hyper-scaler Kubernetes clusters) was described.

This document then showed how the Kubernetes-based technologies could be deployed to provide an architecture that is compliant with the MEC architecture and how the components of the Kubernetes deployment map to the MEC architecture.

In summary, this document has shown how a MEC compliant multi-host system can be deployed using existing CNCF projects with a few key extensions providing a declarative based, autonomous system for MEC service deployments.

Abbreviations and Definitions

API	application programming interface

SOC	separation of concern
VM	virtual machine
VNF	virtual network function

WAN	wide area network

Mixed Reality	Merging of physical and virtual worlds to produce new environments and visualizations, where physical and digital objects co-exist and interact in real time.
Augmented reality	Related to Mixed Reality term, and it takes place in the physical world, with information or objects added virtually.
Edge Computing	The delivery of computing capabilities to the logical extremes of a network in order to improve the performance, operating cost and reliability of applications and services. By shortening the distance between devices and the cloud resources that serve them, by reducing network hops, edge computing mitigates the latency and bandwidth constraints of today's Internet, ushering in new classes of applications. In practical terms, this means distributing new resources and software stacks along the path between today's centralized data centers and the increasingly large number of devices in the field, concentrated, in particular, but not exclusively, in close proximity to the last mile network, on both the infrastructure and device sides.
Edge Cloud	Cloud-like capabilities located at the infrastructure edge, including from the user perspective access to elastically-allocated compute, data storage and network resources. Often operated as a seamless extension of a centralized public or private cloud, constructed from micro data centers deployed at the infrastructure edge. Sometimes referred to as distributed edge cloud. Implementation of these capabilities with Kubernetes clusters is this paper's focus.

1. Abstract

Pedestrian fatalities are on the rise, with more than 6,000 pedestrians killed each year in the United States.[1] There are several technologies and use cases that can help cities make the roads and highways safer. The Smart Intersection proof of concept (POC) deployed by Spectrum is one such example that demonstrates how cities can use technology for protecting pedestrians.

The Smart Intersection proof of concept uses computer vision, edge and near-edge computing to detect and monitor the pedestrian and vehicle movement at the intersection. The anonymous pedestrian and vehicular traffic data is stored in the cloud for further analysis, planning and design of the components of the intersection, including stop signs, traffic/pedestrian light timing, crosswalks and sidewalks to improve pedestrian safety.

This paper discusses the Smart Intersection architecture, machine-learning (ML) model and computer vision technology. The paper also explains the collection, storage, visualization and analysis of metadata on pedestrian and vehicle movement at the intersection.

2. Introduction

As cities around the world grow at an unprecedented rate, there has been an uptick in traffic accidents. Pedestrians are the most vulnerable users of the roads. As per the National Highway Transport Safety Administration, “pedestrian fatalities in crashes increased 44 percent in the last decade (2009 to 2018), with the pedestrians’ share of traffic fatalities increasing 32 percent, from 13 to17 percent.” [2]

One initiative cities are working on is Vision Zero. The goal is to bring the number of fatalities or collisions in an intersection to zero. Data collected from road sensors and cameras can help cities better understand everything from crosswalk signal timing to traffic patterns that may lead to these collisions.

Data-driven decisions are essential for improving public safety. This paper discusses smart intersection use cases, technology, and the methodology used to collect and analyze a broad array of traffic data to draw actionable insights to make the intersection safer for pedestrians.

In the Smart Intersection POC, we are using several IoT sensors, edge computing, computer vision, wired and wireless connectivity, cloud services for data storage, analysis and visualization to help a city improve pedestrian safety.

3. Computer Vision

Computer Vision is a field of study that trains and enables computers to process images and extract information similar to the human visual system. Recent advancements in algorithms, computational power, and the availability of large datasets of digital images have helped improve computer vision capability.

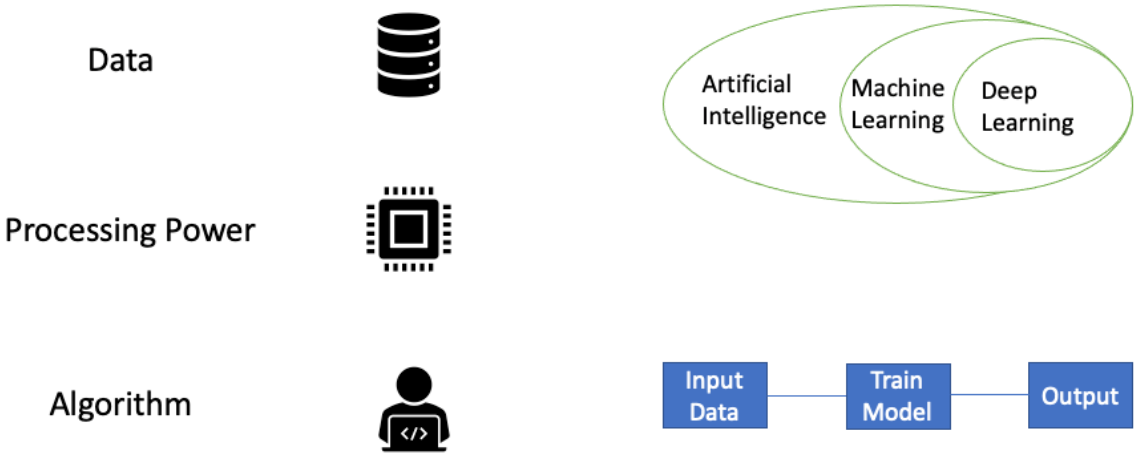

Figure 1 - Computer Vision Components

4. Architecture

The Smart Intersection POC uses cameras attached to the light poles and has the option to use fiber or wireless connectivity to backhaul the data. The switch inside the light pole has multiple Power over Ethernet (PoE) ports providing power to the cameras.

The cameras use edge computing technology with high computing power offered by the graphical processing unit (GPU) to process computer vision. A near-edge server with additional computational power is used for more advanced image processing and machine learning.

The traffic metadata is sent to the cloud for storage, analysis and visualization and can be accessed via a dashboard using a web browser.

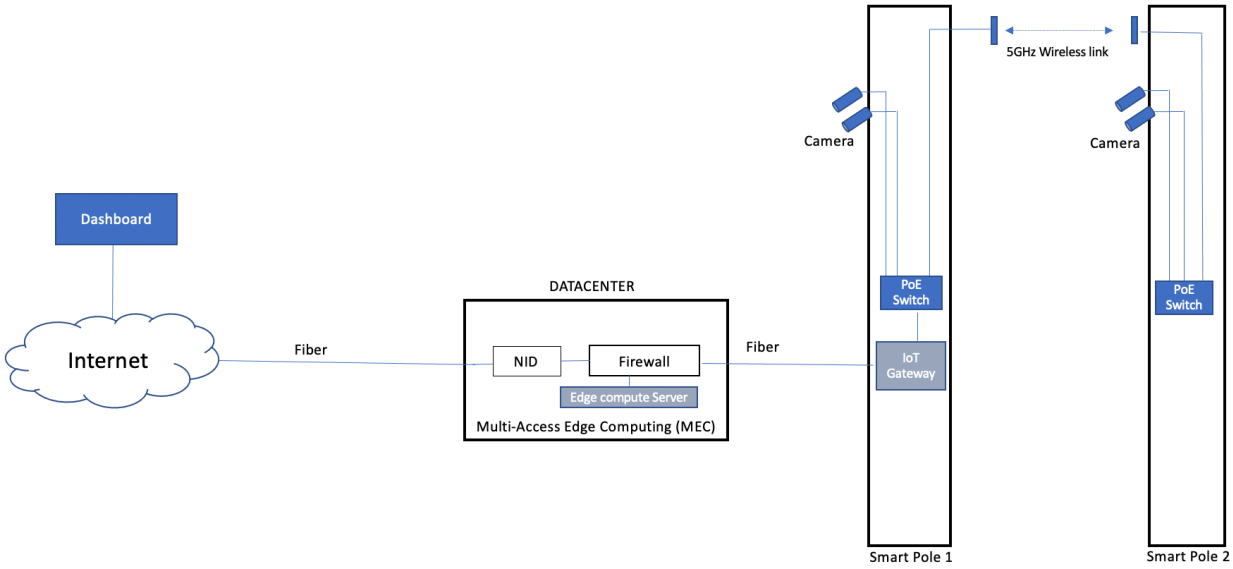

Figure 2 - Architecture

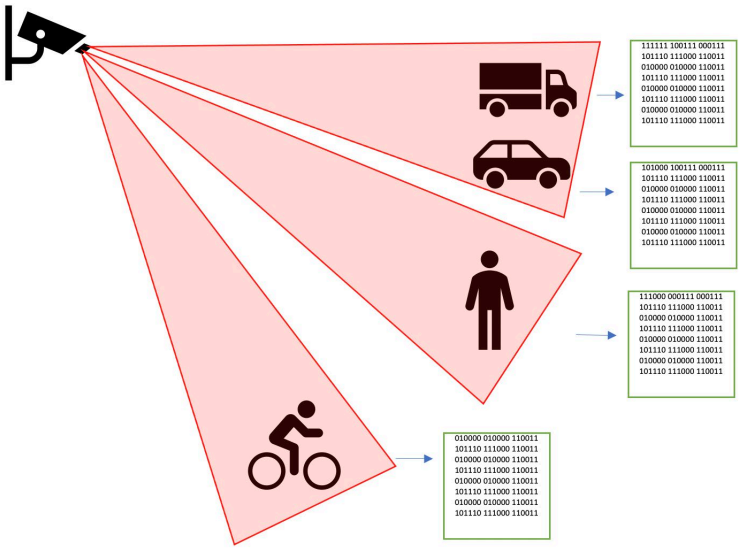

Figure 3 - Digital Image

The Smart Intersection proof of concept uses computer vision and edge computing to detect the presence of a pedestrian. The camera's technology can be used to set the zone within the view of the camera that needs to be monitored for pedestrian activity. The images are anonymized by deleting the image after extracting the metadata and only the metrics are leveraged for analysis. The anonymous pedestrian and vehicular traffic data is also stored in the cloud for further analysis, planning and design of components of the intersection, including stop signs, traffic/pedestrian light timing, crosswalks and sidewalks to improve pedestrian safety.

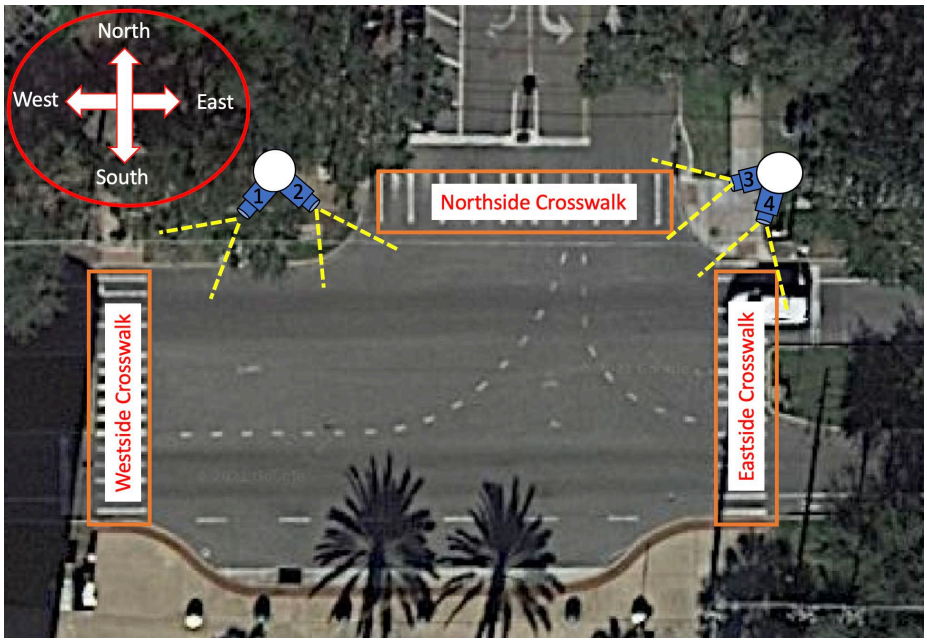

Figure 4 - Smart Intersection

Using computer vision, the cameras are able to detect the presence of pedestrians, bicycles and vehicles at the intersection and also determine the direction of travel.

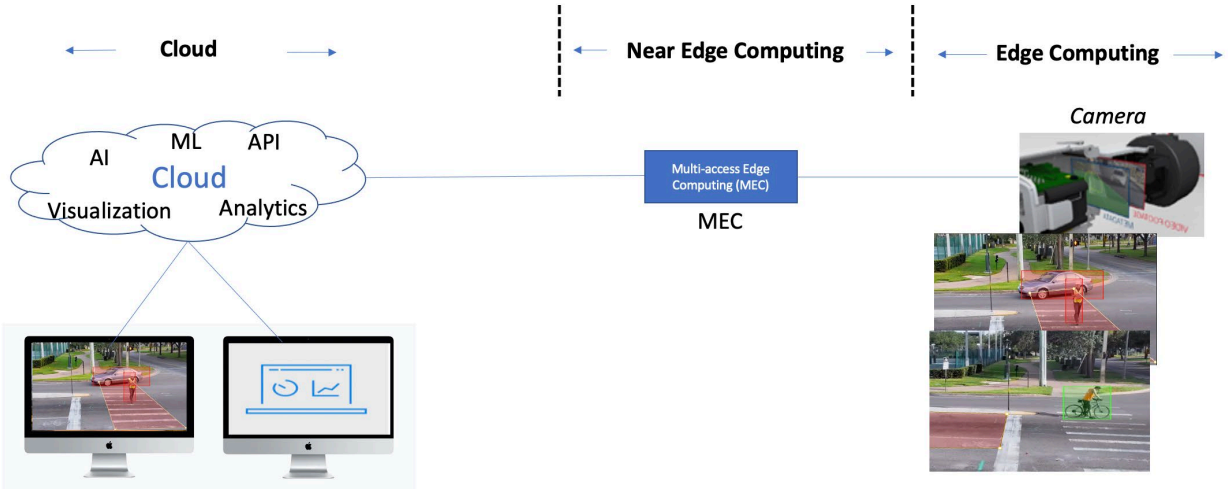

Figure 5 - Computer Vision

The Smart Intersection POC uses a computer vision machine-learning model to train the camera to process complex images such as pedestrians using a walking aid, pedestrians walking with pets or identify different types of vehicles.

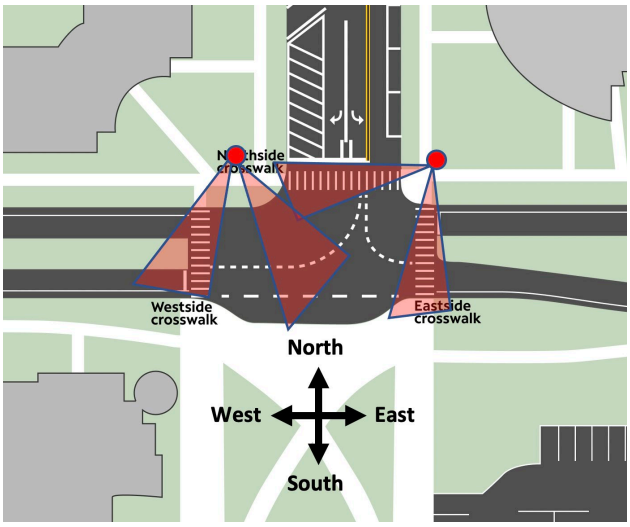

Figure 6 - Camera position

Computer Vision Model Training and Prediction

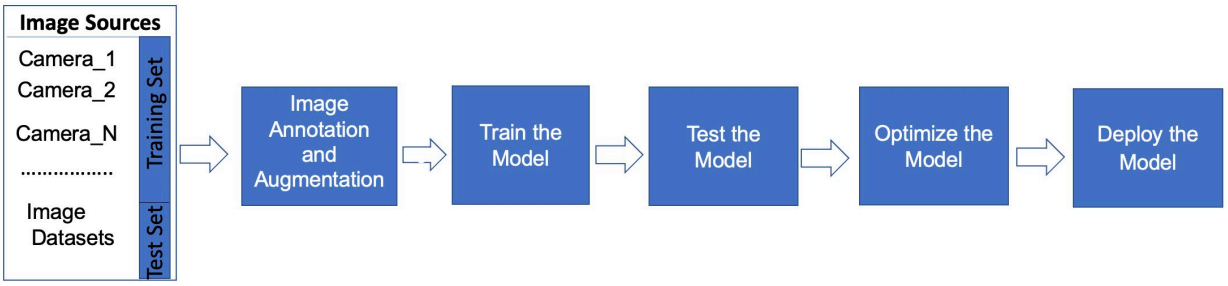

Figure 7 - Computer Vision Training Model

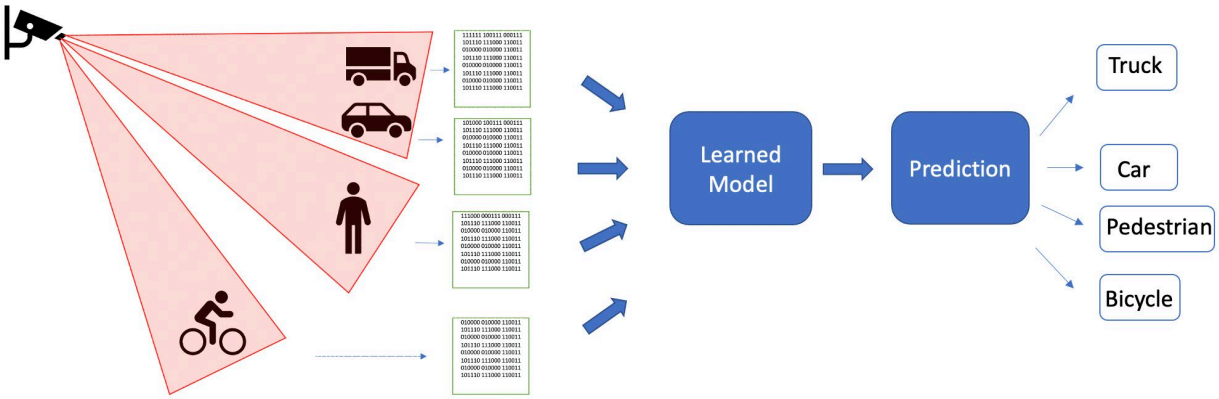

Figure 8 - Learned Model Prediction

5. Data collection and analysis

It is not just the collection of data through the deployment of sensor technology that makes a city smarter; it's also the ability to analyze, to draw insights and make informed decisions. In the Smart Intersection POC, only the metadata is sent to the cloud for storage and analysis. As discussed earlier, for privacy reasons, the image is deleted after extracting the metadata.

When it comes to data, privacy is, of course, very important, especially if the data collected has personally identifiable information (PII). Such data should be handled as per the agreement with the city, and it must also meet regulatory compliance.

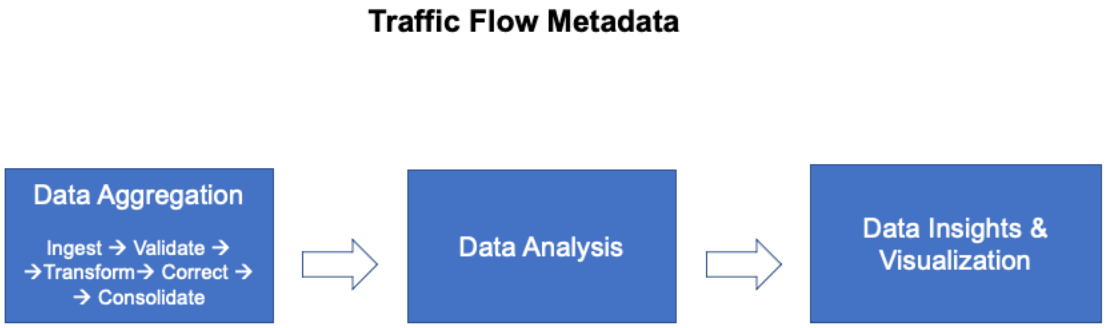

Figure 9 - Data Model

5.1. Pedestrian count data and direction of travel

The camera collects the following metadata on pedestrian movement:

- Number of pedestrians crossing the crosswalk
- Direction of pedestrian movement (e.g., north, south, east, west)
- Jaywalking

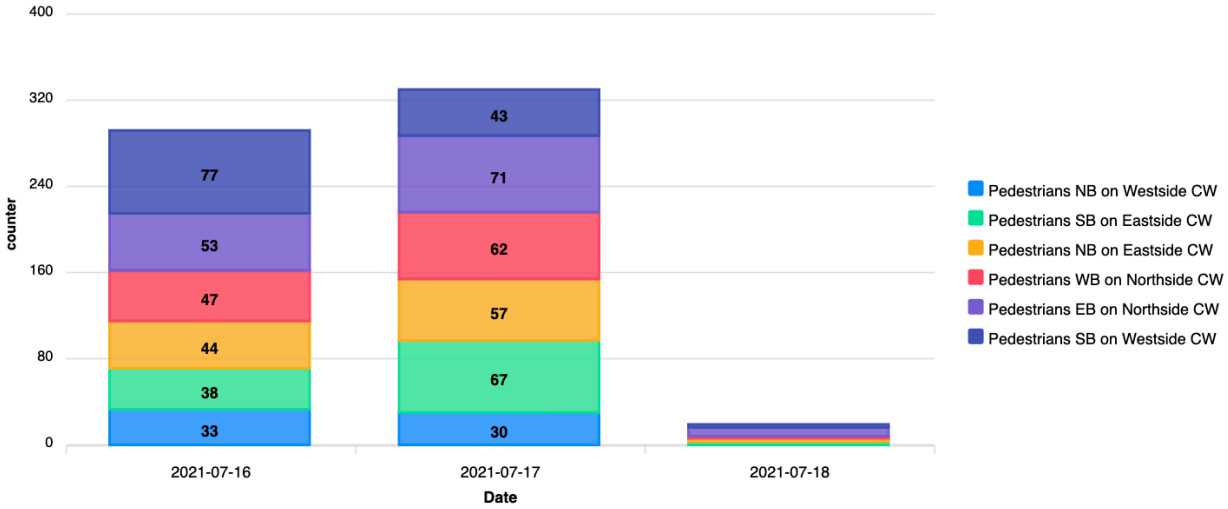

Figure 10 - Pedestrian Traffic Per Day

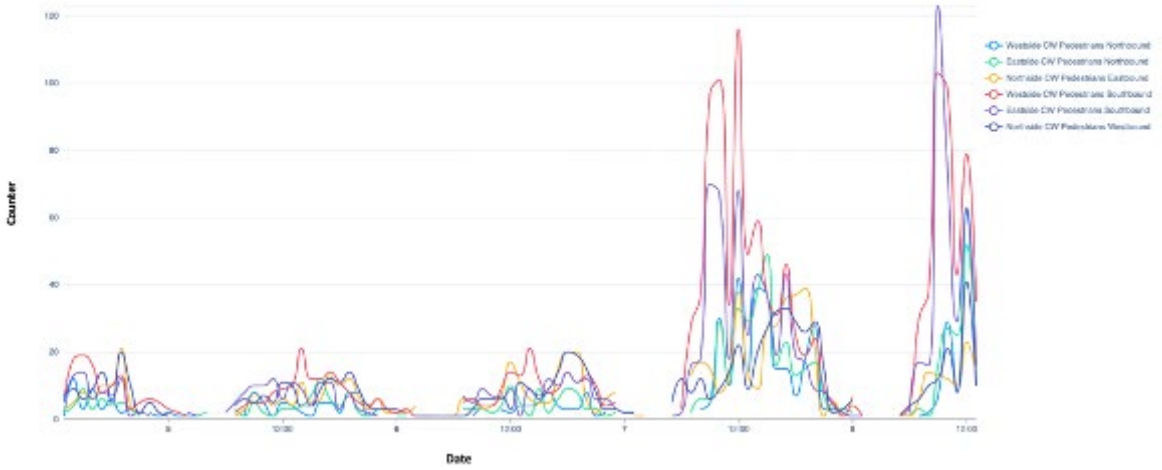

Figure 11 - Pedestrian Traffic Per Hour

The Smart Intersection POC picked up a high number of pedestrians avoiding the crosswalk and jaywalking at the intersection.

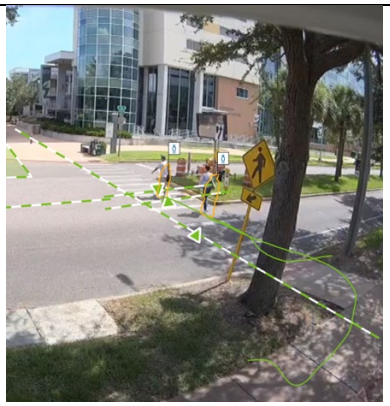

Figure 13 - Pedestrian Image

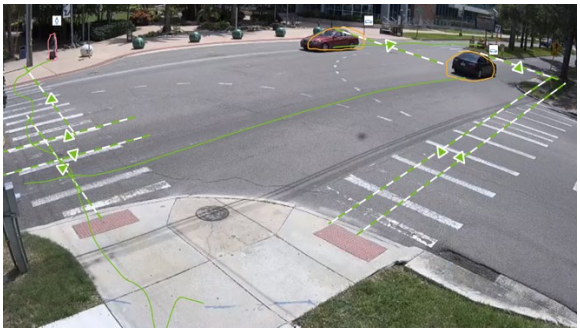
Figure 12 - Jaywalking

5.2. Vehicle count and direction of travel



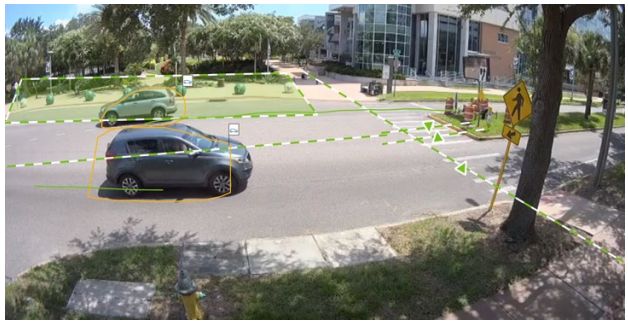


Figure 14 - Vehicle Image

The camera collects the following metadata on vehicle movement:

- Number of vehicles crossing the intersection

- Vehicle making turn at the intersection

- Vehicle making an illegal U-turn

The following data shows more westbound data.

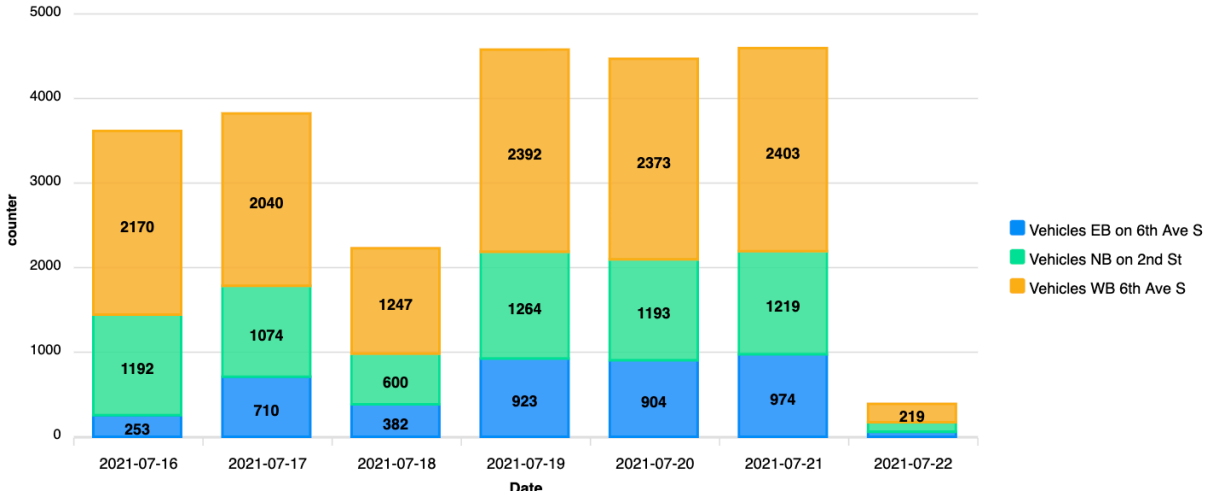

Figure 15 - Vehicle Traffic Per Day

The traffic flow at the intersection shows a consistent and predictable pattern, as shown in the image below. The traffic peaks during a specific time window during the day and shows minimum activity during the night.

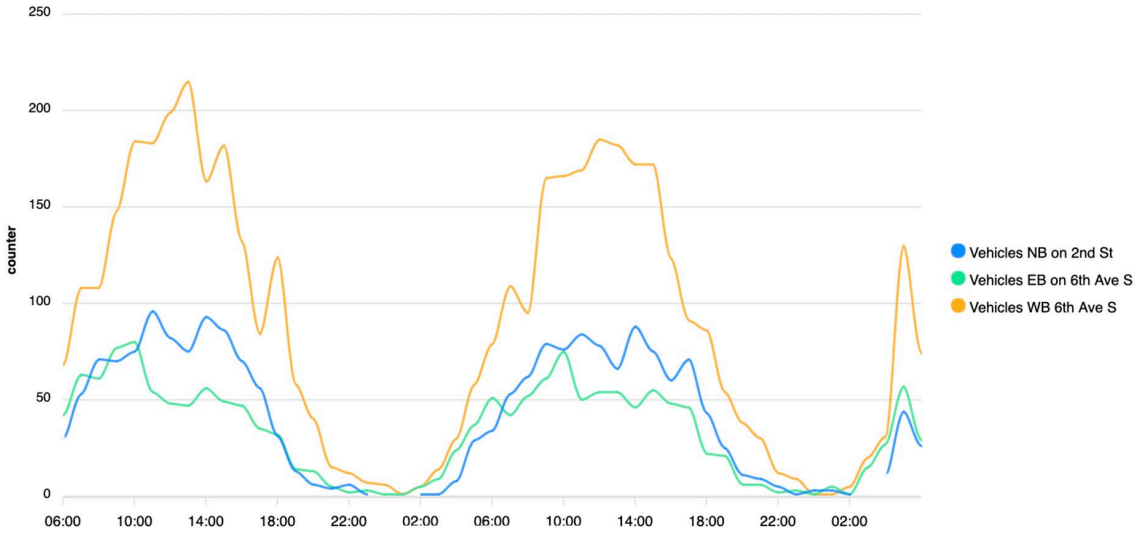

Figure 16 - Vehicle Traffic Per Hour

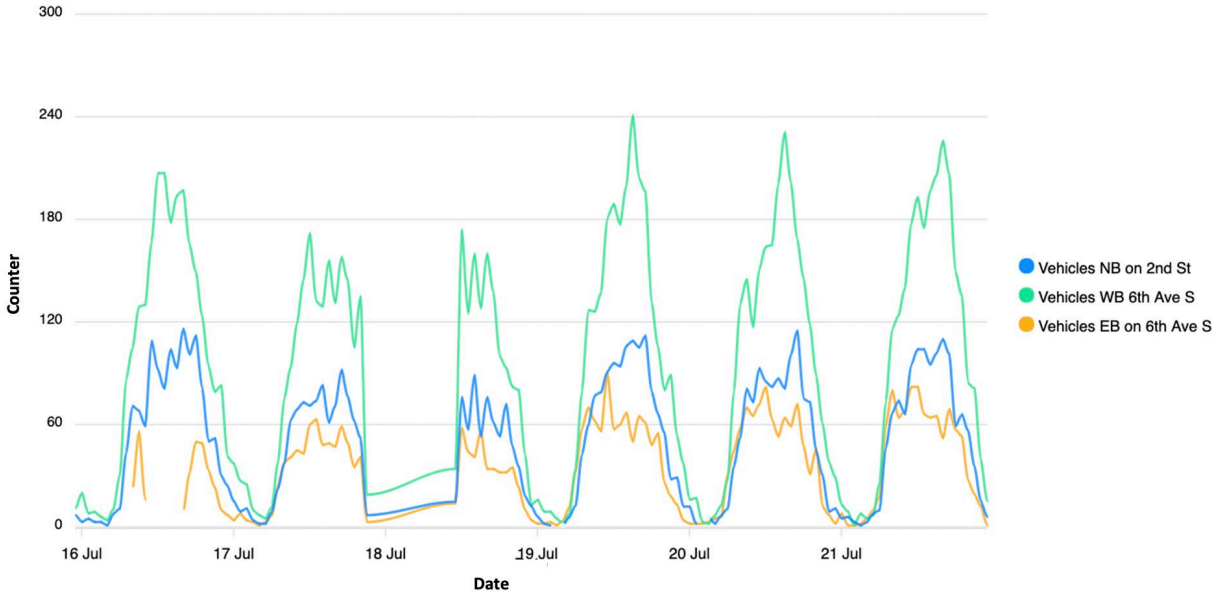

Figure 17 - Vehicle Traffic Per Direction

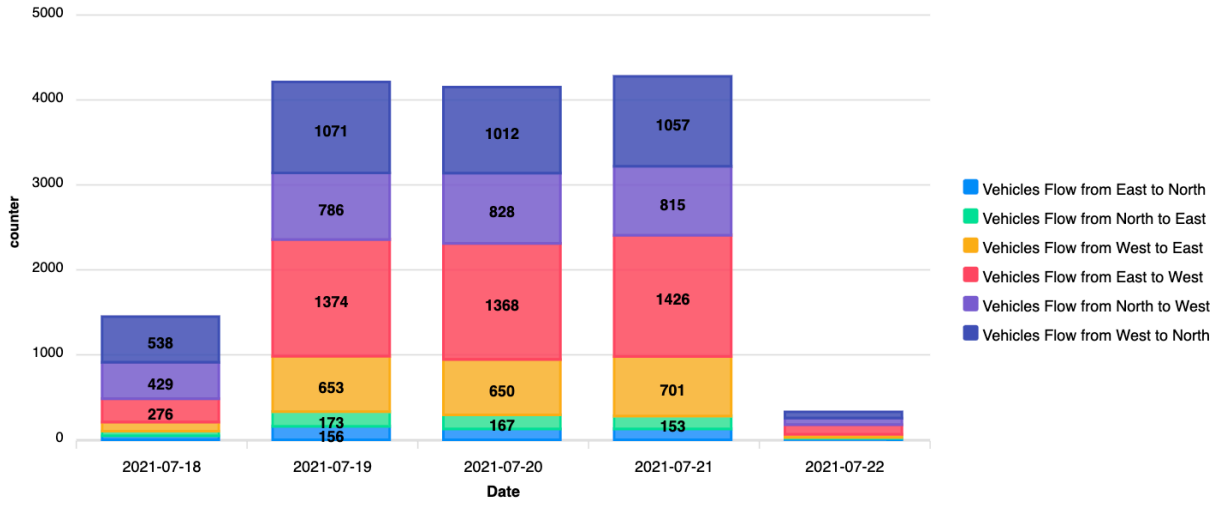

Figure 18 - Traffic Direction of Flow

The Smart Intersection POC even picked up illegal U-turns, putting pedestrians at risk.

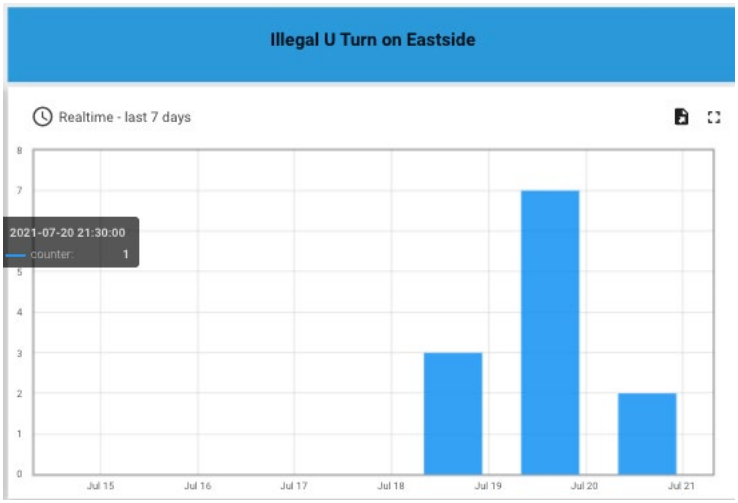

Figure 19 - Illegal U-Turn

5.3. Bicycle count and direction of travel

Figure 20 - Bicycle Image

The camera collects the following metadata on bicycle movement:

- Number of bicycles on the road and crosswalk
- Direction of bicycle movement on the road and crosswalk (e.g., north, south, east, west)

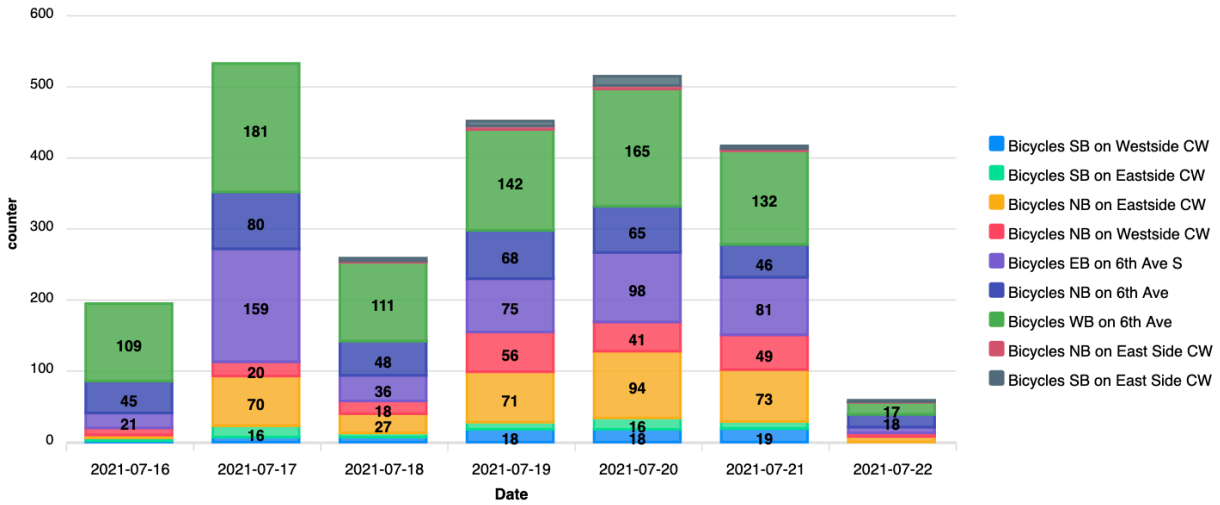

Figure 21 - Bicycle Traffic Per Day and Direction of Flow

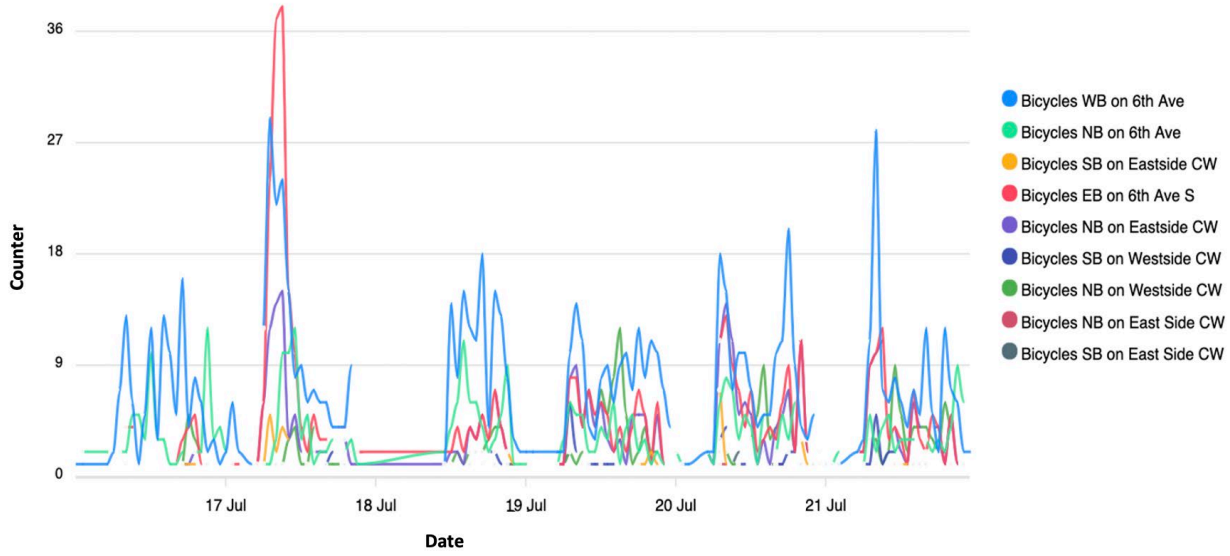

Figure 22 - Bicycle Traffic Per Direction

5.4. Data summary and forecast

This data is currently being used to train and develop a data model to forecast the traffic at the intersection.

P90: The true value is expected to be lower than the predicted value 90% of the time.

P50: The true value is expected to be lower than the predicted value 50% of the time.

P10: The true value is expected to be lower than the predicted value 10% of the time.

Figure 23 - Traffic Forecast

The city is using this anonymized pedestrian, bicyclist and vehicular traffic data to study all traffic activity at the intersection. Analyzing this information is helping the city to draw insights and help city planners redesign intersections to improve pedestrian safety.

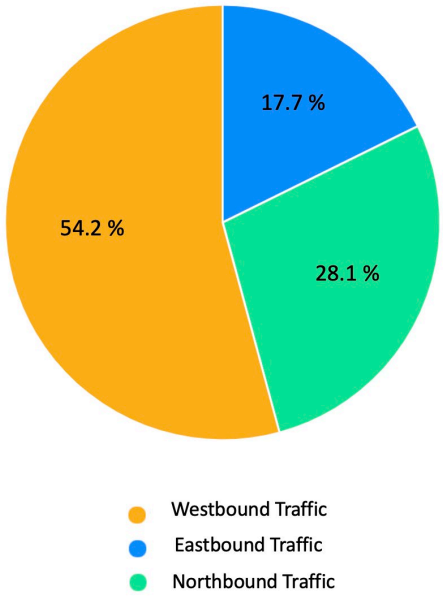

Figure 24 - Overall Traffic Flow by Direction

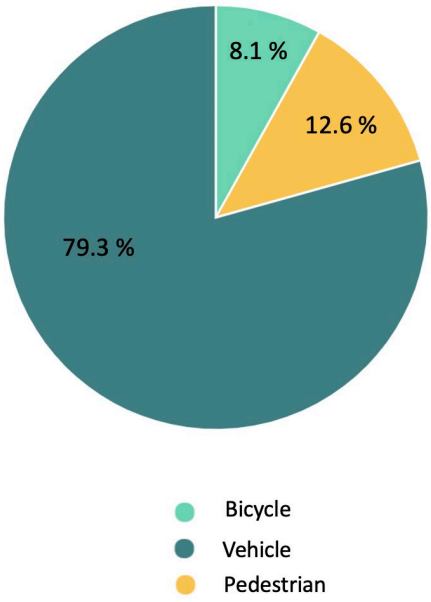

Figure 25 - Percent of Pedestrian, Bicycle and Vehicle Traffic

6. Conclusion

Designing an effective intersection requires an understanding of what activity actually happens within the intersection. The Spectrum Smart Intersection POC exponentially increases that level of understanding over manual methodologies that simply produce a count of pedestrians or vehicles. The POC is collecting, anonymizing, analyzing and visualizing data sets covering pedestrians, bicyclists, vehicles, direction of travel, time of day, counts of accidents and near-accidents and more.

The traffic activity data is helping the city to design and optimize intersections that focus on optimizing pedestrian safety while also streamlining traffic flow through intersections. These types of implementations allow a city to truly emerge and leverage technology on their path to becoming a smart city.

As we collect more data and datasets get richer over time, we expect to draw more insights and forecast traffic. Using the training data sets, we can train the computer vision model and capture additional metadata on the type of traffic at the intersection so that cities can have richer insights and move them closer to the goal of Vision Zero.

1. Introduction

Cable operators are facing an unprecedented increase in upstream traffic usage because of the shift to working/schooling from home, and the reliability, capacity, and efficiency of the upstream is top of mind for all operators. This paper is focused on improving the efficiency of the DOCSIS upstream (DOCSIS 3.0 SC-QAM and DOCSIS 3.1 OFDMA) channels. The paper will document some of the upstream engineering problems seen by operators and make robust recommendations on how improve those situations. There are thousands of upstream parameter settings and control knobs available to an operator and much of the time operators leave those settings at their default values. This paper will investigate areas (for SC-QAM & OFDMA) such as minislot size, FEC, Cyclic Prefix, FFT size, frame size, pilot patterns, channel size, guard bands, profile definition, CMTS settings for changing IUCs, etc., and make recommendations on each of those parameters and settings. This paper will also explore configuration file service parameters for a cable modem (CM) and make recommendations for better performance on the upstream. Ultimately, this paper will help operators understand optimized upstream configurations and settings for production deployments.

This paper assumes some background understanding of both DOCSIS 3.0 and DOCSIS 3.1 upstream technologies. Here we try to provide an understanding of different upstream channel parameters (which an operator can tweak) and then the pros and cons of choosing different values for that parameter. Based on these tradeoffs we make recommendations on optimal values for each of these channel parameters or network configurations.

2. DOCSIS 3.0 SC-QAM Upstream Recommendations

This section of the paper is a “how-to” on improving SC-QAM upstream efficiency. Access network, outside plant and system engineers would like to understand the benefits and how to realize those benefits as they continue to maintain the DOCSIS SC-QAM upstream technology.

2.1. Minislot Sizes

The DOCSIS bandwidth allocation MAP uses time units of "minislots." On SC-QAM channels, the size (duration) of the minislot is a multiple of the DOCSIS SYNC time ticks (6.25 us). A minislot is the unit of granularity for upstream transmission opportunities and represents the time allowed for CM transmission of a fixed number of symbols. Figure 1 shows the range of values of minislot sizes for an upstream SC-QAM channel, assuming 64 QAM as the modulation order.

To determine the best minislot sizes, one needs to understand how the network upstream traffic behaves and model it accurately. Based on the traffic patterns seen on the upstream one can optimize the DOCSIS minislot size for an upstream channel.

There are overheads involved with different settings of the minislot size. Setting minislot sizes to one of smaller settings can increase the scheduling granularity for the CMTS. Also, for larger grants, the overhead of bytes wasted in the grant will reduce. On the other hand, larger minislot sizes increases the largest grant that can be made to DOCSIS 2.0 modems (which support only one upstream SC-QAM channel). Prior to DOCSIS 3.0 technology modems requested bandwidth in minislots, whereas starting with DOCSIS 3.0 technology, modems (with support for channel bonding) request bandwidth in bytes using the queue-depth based requests. Also, a larger minislot size, may make the computations a bit simpler on the CMTS upstream scheduler and receiver though the benefits may vary by implementation.

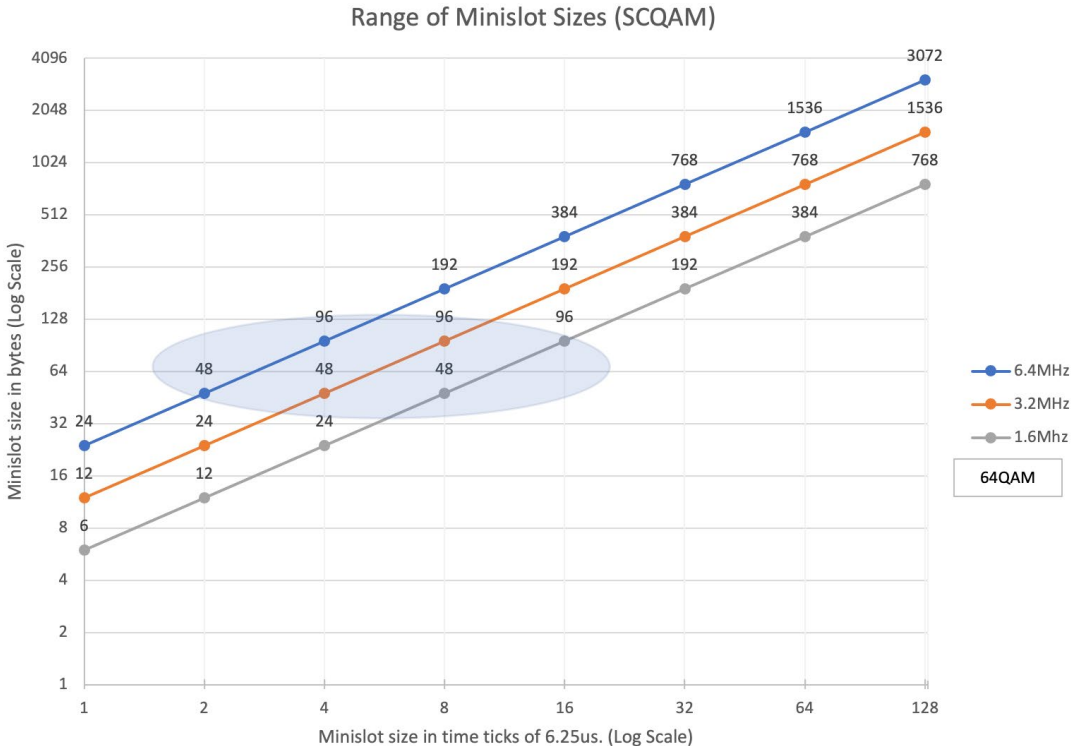

Figure 1 – SC-QAM Minislot Sizes Range

As seen in the graph above, for a 6.4 MHz channel (5.12 MSyms/sec) using 64 QAM modulation, a minislot size of 1 has a raw capacity of 24 bytes. The maximum grant size (a 255-minislot grant) will be 6120 bytes. A minislot size of 4 will have a raw capacity of 96 bytes and allows a maximum 255-minislot grant of 24480 bytes. Based on current patterns of upstream packet sizes, and the size of an Ethernet frame carrying a TCP ACK (64 bytes), the consensus is that minislot sizes in the range of 48 bytes to 96 bytes will enable an appropriate variance in grant capacity and efficiency for upstream scheduling. This translated to a minislot size configuration of 2 or 4 for a 6.4 MHz channel or a size of 4 or 8 for a 3.2 MHz channel.

2.2. FEC Settings

DOCSIS specifications allow for a range of FEC settings for an upstream SC-QAM channel. This is enabled by two settings in the upstream channel which have the following range restrictions:

- FEC codeword information bytes (k), 16 <= k <= 253
- FEC codeword correction setting (T), 0 <= T <= 16.
    - The number of parity bytes is 2T and ranges from 0 bytes to 32 bytes
    - Thus, the total codeword length (k+2T) would be in the range of 16 to 285 bytes

A short data grant may use FEC parameters that are appropriate to shorter packets while a long data grant may be able to take advantage of greater FEC coding efficiency. FEC codeword lengths for Request, Request/Data, and Ranging IUCs can be shorter while the codeword lengths should be longer for Short Data grant (IUC 5) and Long Data grant (IUC 6) and UGS grants (IUC 11).

The FEC parameter selection is a trade-off between channel utilization and robustness to noise. In practice a codeword efficiency of 75%-to-90% (i.e., 10%-25% FEC overhead) looks to be the optimum

for a DOCSIS upstream SC-QAM channel. An operator can use the lower end of that range for noisier channels (e.g., lower in the cable upstream spectrum) and the higher end of the FEC efficiency range for cleaner channels. Of all the possible values of k from 16 to 253, many k & 2T values lead to a codeword efficiency which fall outside this optimal range. The below graph (Figure 2) shows the zone (gray) of these optimal values.

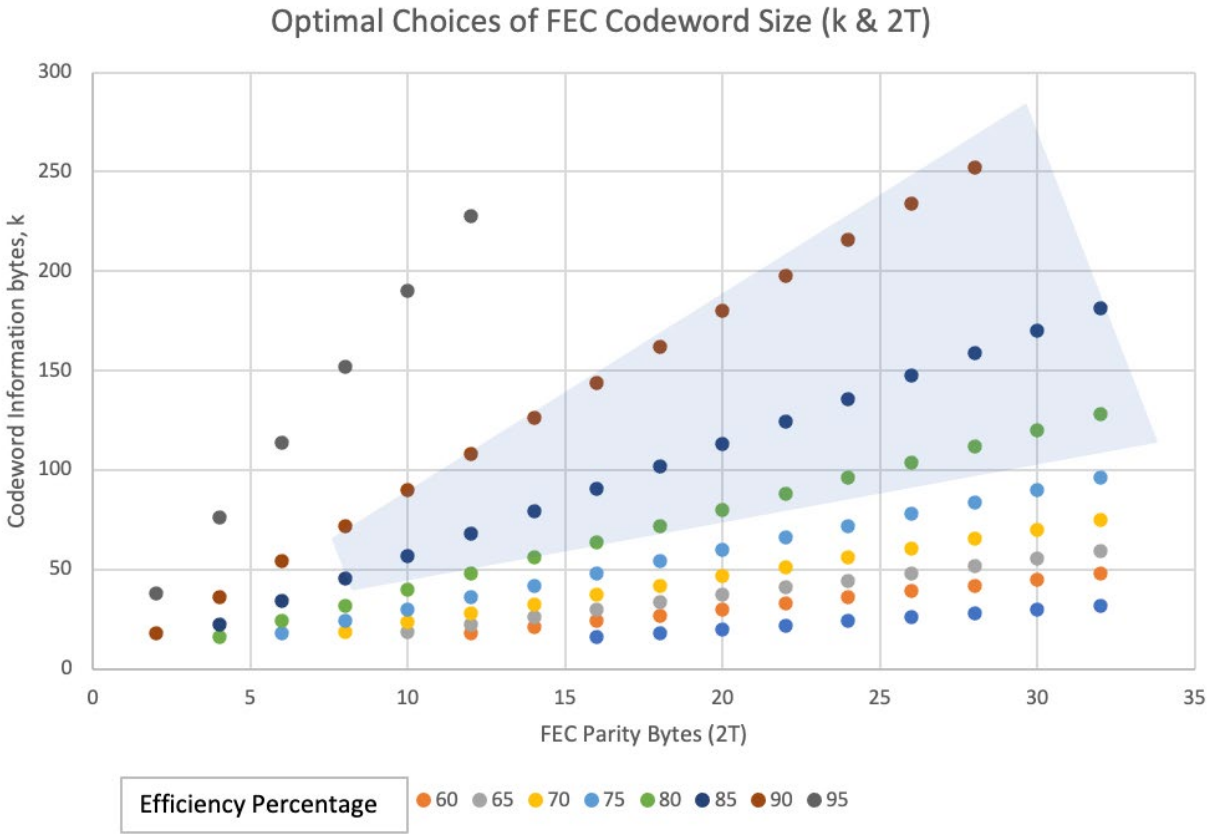

Figure 2 – SC-QAM FEC Sizes Range

Table 1 shows the range of k values (information bytes) for various choices of 2T (FEC Parity bytes). Combinations of k & 2T which give below 50% codeword efficiency are ignored, as they are not useful in the normal cable plant. Shown in green are the range of k values which fall in the 75-90% efficiency range and are the meaningful codeword sizes to choose for Data IUCs.

Ideally an operator would read the RxMER numbers for each of the CMs using the upstream channel and based on those would choose an appropriate FEC setting (k & 2T) and vary the modulation order for that IUC.

Table 1 – Choosing values of k and 2T for SCQAM FEC

Information bytes (k)	FEC bytes, 2T															
Codeword Efficiency	2	4	6	8	10	12	14	16	18	20	22	24	26	28	30	32
50								16	18	20	22	24	26	28	30	32
60						18	21	24	27	30	33	36	39	42	45	48
65					19	22	26	30	33	37	41	45	48	52	56	59
70				19	23	28	33	37	42	47	51	56	61	65	70	75

95	38	76	114	152	190	228										

2.3. Interleaver settings

The DOCSIS SC-QAM upstream interleaver supports two modes, one operating mode in which the block size is fixed, and a second dynamic mode in which the interleaver depth is determined based on the burst size. The FEC encoded data bytes of the packet are first divided into interleaver blocks. In the fixed mode, the interleaving depth of the last interleaving block of a packet can be small, resulting in low burst noise robustness for this block. In dynamic mode, the depths of the interleaver blocks are chosen such that all blocks have approximately the same depth to achieve nearly optimal burst noise robustness (for the given block size). The current point of view is to choose "dynamic mode" and let the system decide the appropriate interleaver settings. An MSO who uses data analytics on the channel performance metrics could potentially outperform the CMTS but until operators have such software systems built, the dynamic options look to be the best.

2.4. Upstream performance

This section provides guidance on the operational conditions and recommends which modulation orders are recommended for various levels of SNR to have an FEC error-free operation. The ability of the system to support a given QAM level depends on the RxMER values and the mappings to an appropriate QAM level when creating a profile. These mappings are used for DOCSIS 3.0 SC-QAM channels and are summarized in Table 2 below.

Table 2 – Upstream RxMER to QAM Level mapping

Upstream Constellation/ Bit Loading	Upstream MER (dB)
QPSK	10
8 QAM	14
16 QAM	16
32 QAM	19
64 QAM	22+

3. DOCSIS 3.1 OFDMA Upstream Recommendations

This section of the paper is a "how-to" on improving OFDMA efficiency. Access networks, outside plant and system engineers would like to understand the benefits and how to realize those benefits as they plan to deploy DOCSIS 3.1 OFDMA technology.

3.1. OFDMA Channel Location

Many operators have shared data indicating the spectrum below 20 MHz is burdened by the presence of ingress noise as shown in Figure 3. In some plants which are well maintained and cleaner, operators have successfully reported running SC-QAM channels down to 9 MHz. In some cases, if the plant is clean, the spectrum may be amenable to the presence of an OFDMA channel in those lower frequencies. In many cases if the spectrum contains bursty or impulsive noise ingress, then we do not recommend placing OFDMA channels in that region. A few operators have reported OFDMA codeword errors leading to system stability issues with the OFDMA channel in spectrum below 20 MHz, whereas these issues become non-existent when the channel is moved to higher portion of spectrum.

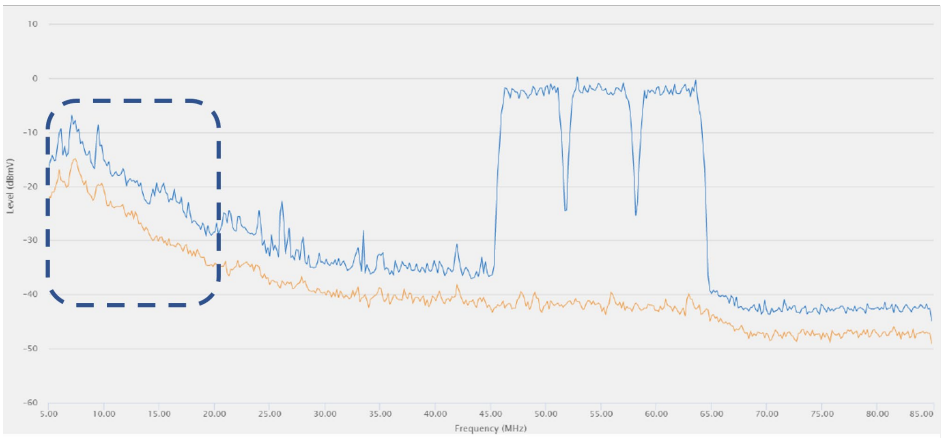

Figure 3 – Noisy Spectrum Below 20 MHz

When initially deploying OFDMA channels it would be prudent to initiate the OFDMA trial in a cleaner (higher) part of the spectrum. The idea is to work out the inevitable system issues and bugs and get the OFDMA channel working reliably first in a cleaner part of the spectrum and then evaluate OFDMA below 20 MHz.

3.2. Number of symbols in a frame (K)

The number of symbols in an OFDMA frame, K, is configurable between 6 (minimal value) and one of the following values:

- With 20 µs FFT duration (2K FFT)
  - Kmax = 18 for BW≥ 72 MHz
  - Kmax = 24 for 48 MHz ≤BW < 72 MHz
  - Kmax = 36 for BW < 48 MHz
- With 40 µs FFT duration (4K FFT)
  - Kmax = 9 for BW ≥ 72 MHz
  - Kmax = 12 for 48 MHz≤ BW < 72 MHz
  - Kmax = 18 for BW < 48 MHz

Figure 4 shows the layout of minislots within an OFDMA channel.

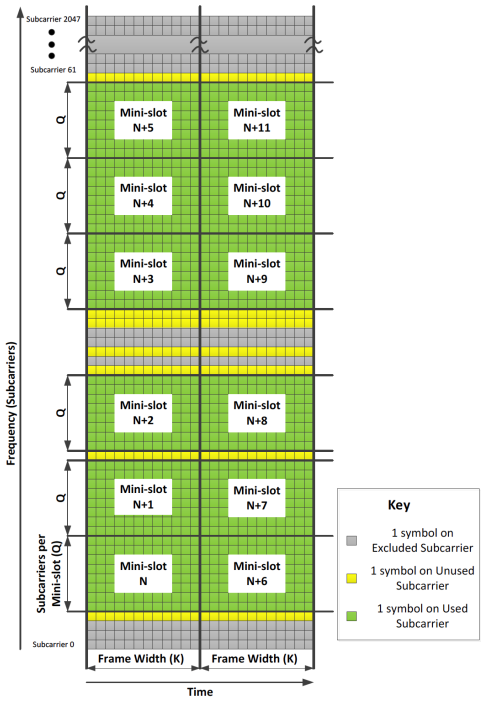

Figure 4 – Minislots in OFDMA

We performed various throughput tests in the lab with 32 MHz and 75 MHz channels, at 2K FFT and 4K FFT with different values of K. We consistently found a 3% to 5 % increase in data throughput across all CMTS platforms when the value of K is increased from 6 to 9/18 (for the larger 75MHz channels) or 6 to 18/36 (for smaller 32 MHz channels).

There are two minislot types, edge minislots and body minislots. Edge minislots have a bit more overhead and carry less data than body minislots. An edge minislot is the first minislot in a transmission burst and also used after an exclusion band or a set of skipped subcarriers. Body minislots are used for all other minislots in a burst. Hence it is advisable for an operator to avoid gaps in the OFDMA channel if possible.

3.3. FEC – Unreliable/Uncorrected Codewords

We tested various DOCSIS systems to verify the FEC performance under different noise level/ type (flat AWGN) to build expectations under different plant conditions. Figure 5, 6, and 7 show the FEC error rate (both correctable and uncorrectable) over different RxMER levels. The lab testing was run with traffic of 200- and 1500-byte packets and a combination of the two. The noise (AWGN) was introduced to reduce the RxMER levels across the OFDMA channel, and the levels of FEC statistics were captured at every level of increasing noise. We also tested with two different pilot patterns, the most dense pattern 4 and the least dense pattern 1.

Note that in most CMTS implementations when unreliable codewords are detected on an OFDMA channel, the upstream receiver discards the unreliable codewords considering them as uncorrectable. In other implementations they are sent to the MAC layer for additional processing using the MAC HCS and Ethernet CRC.

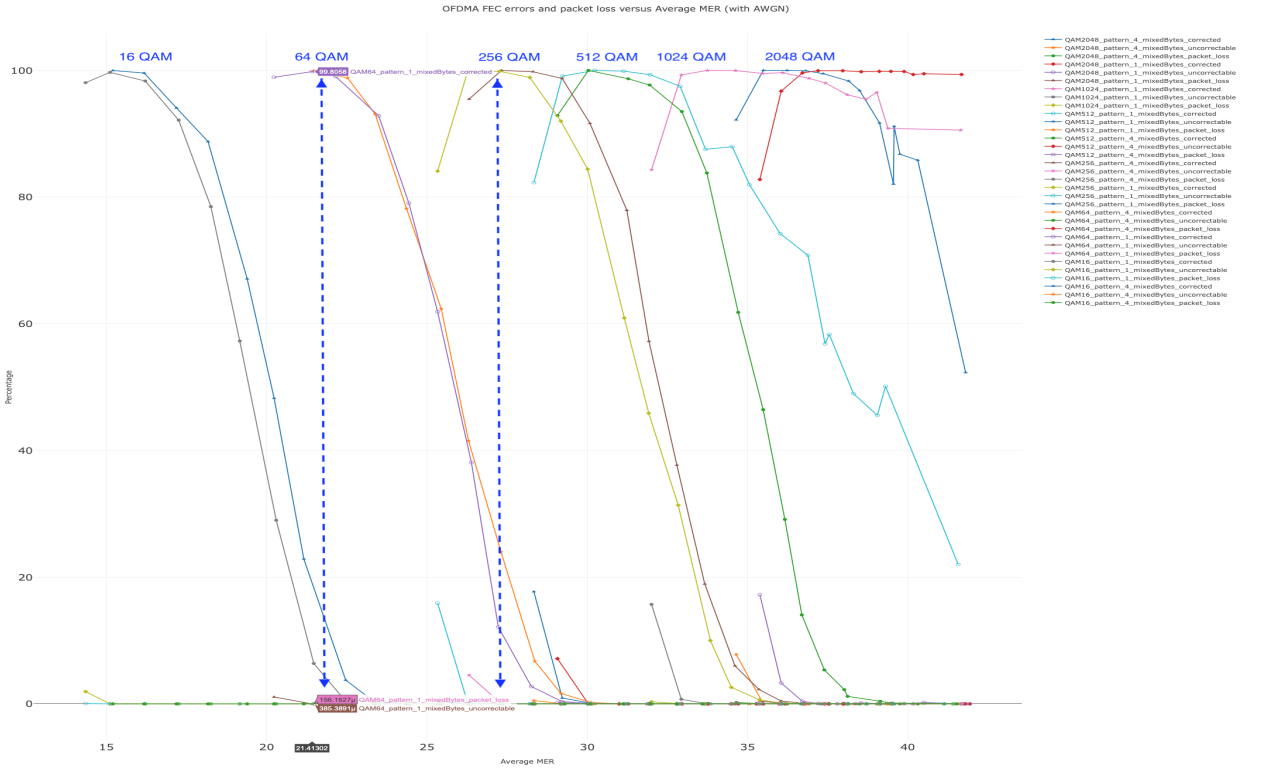

Figure 5 – OFDMA FEC Performance (mixed size packets, Pilot Pattern 1,4)

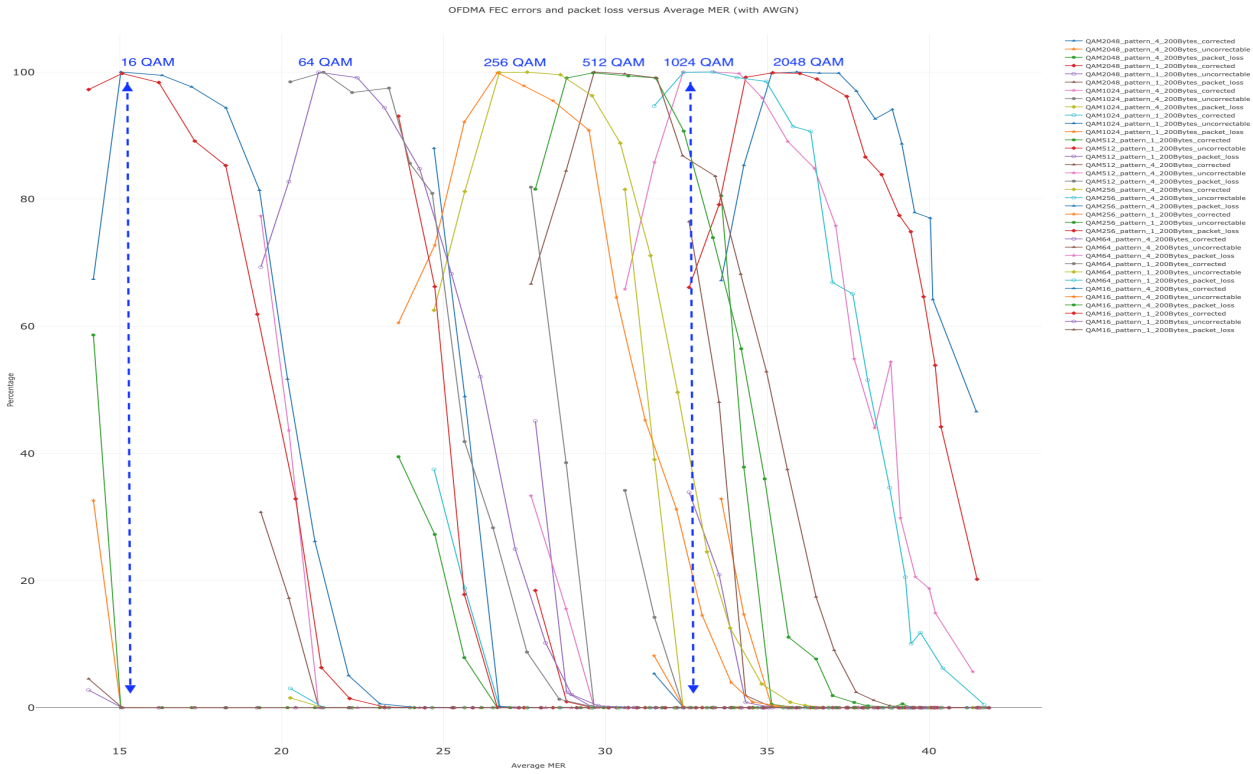

Figure 6 – OFDMA FEC Performance (200 byte packets)

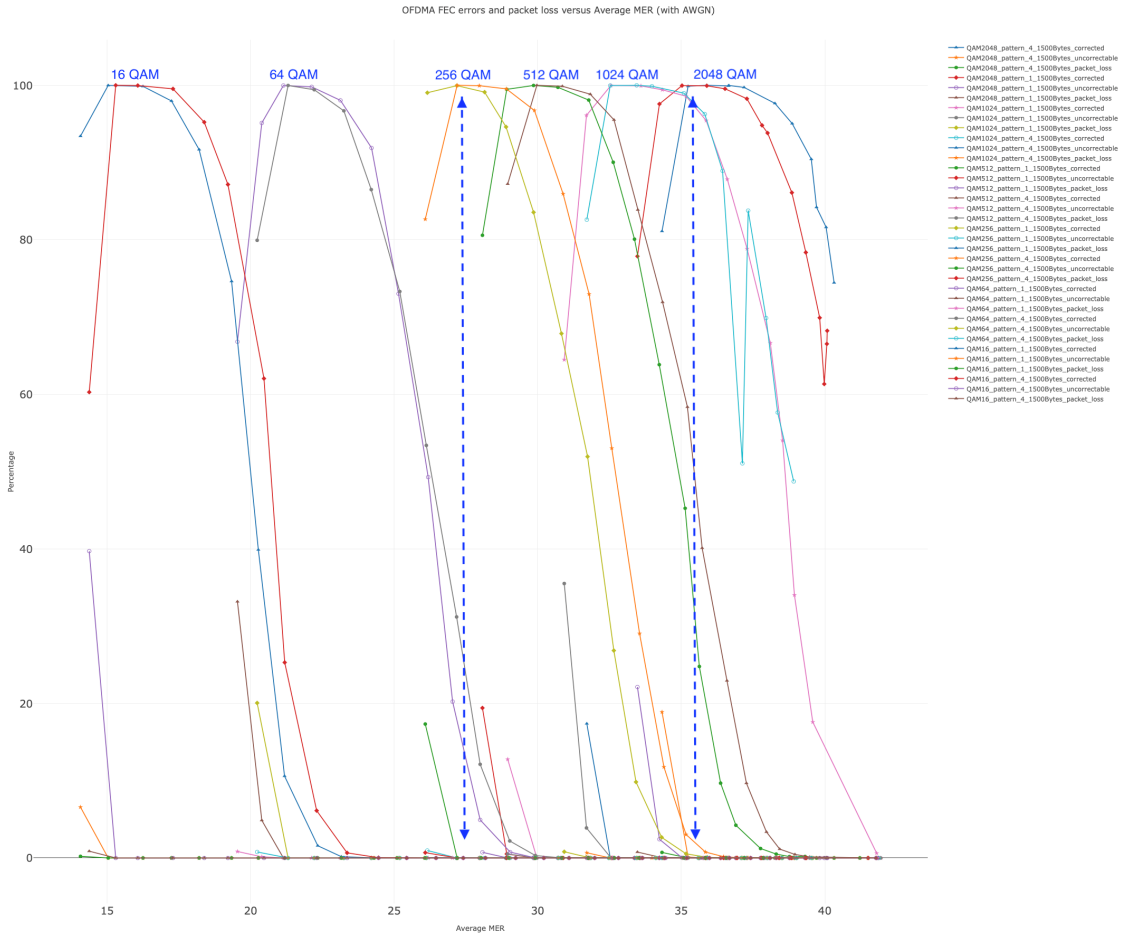

Figure 7 – OFDMA FEC Performance (1500 byte packets)

3.4. Cyclic Prefix (CP) and Roll-off Period (RP)

Two options exist for upstream OFDMA FFT size, either 2048 (2k FFT) or 4096 (4k FFT). A cyclic prefix (CP), which precedes an OFDMA symbol, should be slightly longer than a longest significant echo to be encountered in the channel, which normally is in the range of a few microseconds for coaxial cable. (See Figure below from [DOCSIS PHYv3.1]. The addition of a cyclic prefix enables the receiver to overcome the effects of inter-symbol-interference caused by micro-reflections in the channel.

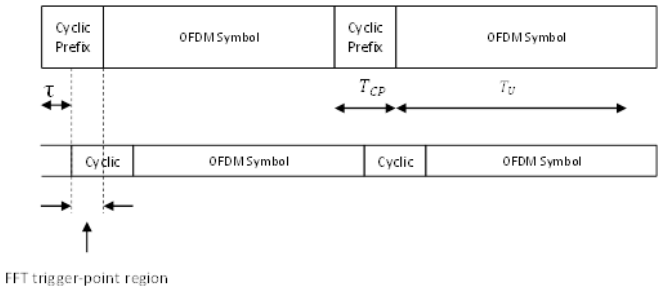

Figure 8 – CP and microreflections

The duration of the FFT useful symbol duration is 20 µsec for the 2k mode, or 40 µsec for the 4k mode. Therefore the percentage of overhead for a 2.5µsec CP can be either 12.5% (2k FFT) or 6.25% (4k FFT). CP sizes vary from 0.9375 µsec to 6.25 µsec, for which the overhead will vary from 4.6% to 31.25% for the 2k FFT, or 2.3% to 15.6%for the 4k FFT. Figure 1 shows the change in capacity for a 40 MHz channel, 2k FFT size, for the range of possible CP values.

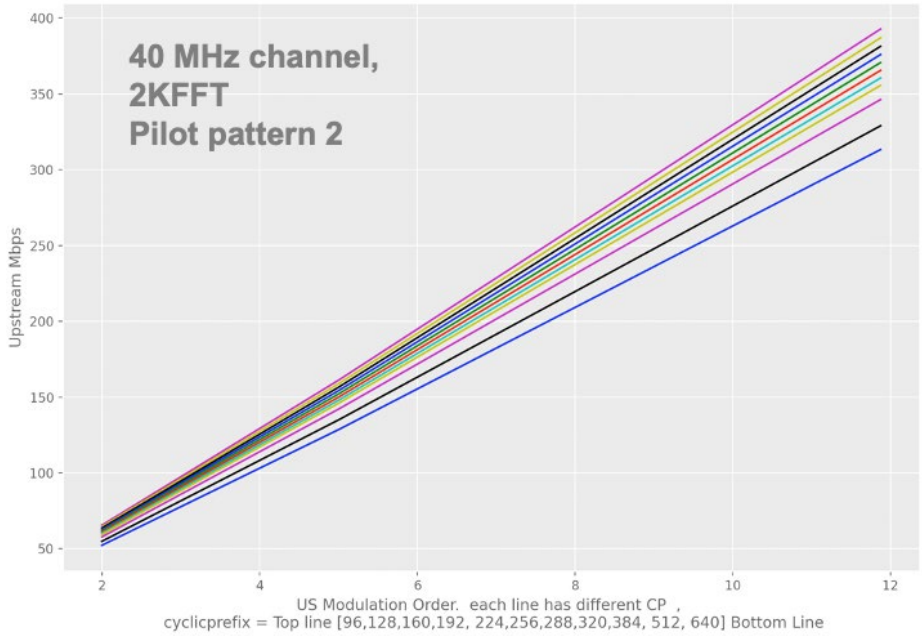

Figure 9 – OFDMA capacity change for different CP

Windowing maximizes channel capacity by sharpening the edges of the spectrum of the OFDMA signal (this applies to an OFDM downstream signal as well). Spectral edges occur at the two ends of the spectrum of the OFDMA symbol, as well as at the ends of internal exclusion band. The roll-off period (RP) setting is another OFDMA overhead. An RP is defined by a number of samples and essentially is a gradual rise or fall in energy and precedes or trails an OFDMA transmission. The purpose of the RP is to limit the spread of interference of an OFDMA transmission to adjacent single frequency carriers. See Figure 14. A longer duration RP produces less interference, and like the CP, decreases efficiency. Note that the effect of a RP is to decrease effective CP time, so if a long RP is chosen, the CP duration should be increased. The RP does nothing to protect an OFDMA channel from energy from adjacent SC-QAM channels.

3.5. 2K vs 4K FFT size or (subcarrier spacing)

The OFDMA upstream multicarrier system is composed of either 25 kHz or 50 kHz wide subcarriers. In the upstream, the subcarriers are grouped into independently configurable OFDMA channels each encompassing up to 95 MHz of spectrum, totaling 3800 25 kHz spaced subcarriers or 1900 50 kHz spaced active subcarriers. Figure 10 shows the possible size of the minislots with 4k FFT (25 kHz subcarriers) and with 2k FFT (50 kHz subcarriers)

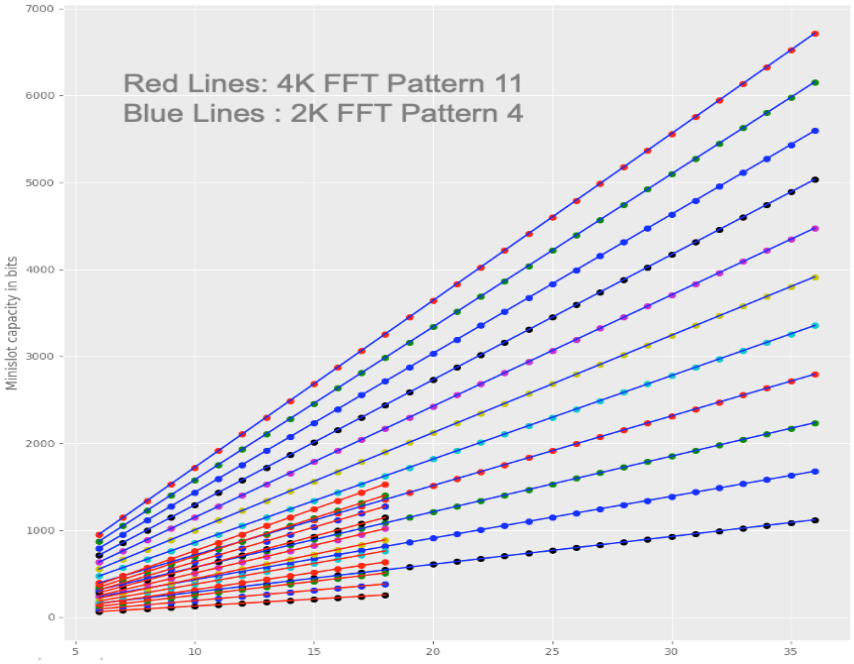

Figure 10 – OFDMA Minislot capacity change 2K vs 4K FFT

Figure 11 shows the capacity difference in OFDMA channels using either the 2K FFT or the 4K FFT, with different pilot patterns.

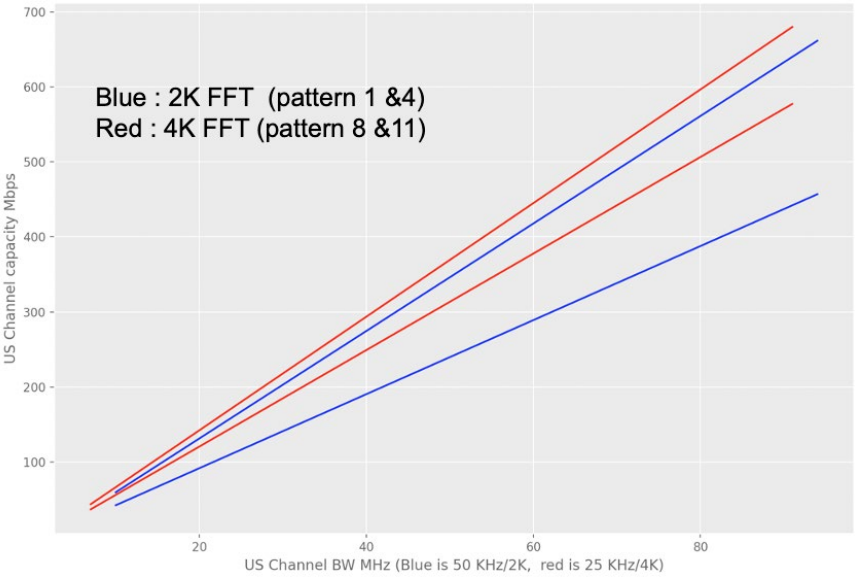

Figure 11 – OFDMA capacity change 2K vs 4K FFT

When processing an OFDM or OFDMA frame with CP, an exact integer number of symbols are chosen for processing by a FFT, either 2k or 4k. The abrupt truncation of symbols in the time domain creates a window in the frequency domain which has frequency domain sidelobes. See Figure 12. If spurious energy, such as a single carrier or a continuous wave (CW), lands on a sidelobe it will cause inter-symbol interference, generally affecting the subcarriers on the edges of the OFDM(A) band the most. One

solution is to provide vacant bandwidth adjacent to the OFDM(A) transmission to prevent sidelobe vulnerability. Another solution that has been used is to use a lower modulation order for subcarriers that are on the lower and upper portions of an OFDM block. Using lower order modulation, such as 256-QAM instead of 1024-QAM reduces the chance of symbol errors.

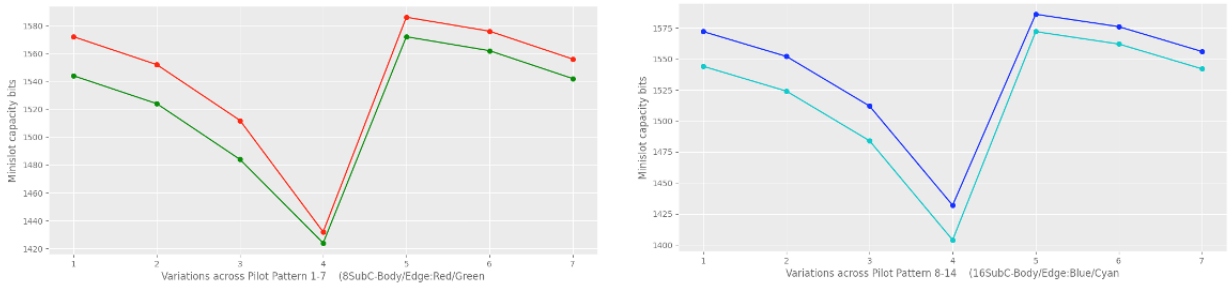
On sidelobe vulnerability, 2k is twice as susceptible because each sidelobe is twice as wide, relative to 4k. Note that this vulnerability affects upstream OFDMA as well as downstream OFDM.

An adjacent OFDMA channel will not cause harm to an OFDMA channel if the interfering frame timing is the same. This implies that both channels are using the same timing including FFT size, CP, and RP.

4k does have a vulnerability relative to 2k. It is more susceptible to phase noise. That is because any wander or movement of phase while an OFDM(A) frame is being captured is detrimental. Phase noise can be caused by a transmitter symbol clock, a receiver symbol clock, or any frequency conversion used in the OFDM(A) signal processing, such as block up and down conversion. Lab tests indicate this effect is a couple of dBs of MER worsening for 4k around the 35-40 dB level.

3.6. Upstream Pilot Patterns

Various pilot patterns are available for OFDMA transmissions. Not all CMTS vendors have implemented all pilot patterns, and different implementations support different default pilot patterns. Generally boosted pilots give a better channel characterization in the presence of noise, and denser pilot patterns improve estimates for signal time, frequency, phase, and amplitude offsets. But more pilots come at the expense of efficiency. The pilot pattern chosen should be sufficiently dense to characterize the ripples in the frequency response caused by echoes. If transmit pre-equalization is not used, less efficient pilot patterns should be used.



K= 20 symbols. 2K FFT
Patterns 1-7

K= 10 symbols. 4K FFT
Patterns 8-14

Figure 12 – OFDMA Minislot capacity change w Pilot Patterns

It is recommended that pre-equalization be turned on for both OFDMA and SC-QAM channels because not using pre-equalization requires a use of more dense pilot patterns, which are less efficient. Operators need to watch for this as in many cases pre-equalization, for OFDMA and SC-QAM channels, is off by default.

3.7. Efficiency of OFDMA channel

The throughput and efficiency (e.g., bits/Hz) of the OFDMA channel changes with respect to channel width and other configuration parameters, e.g., CP, RP, frame size, etc. The expected range has been detailed in a previous paper [D31 Capacity].

4. Upstream Interference Analysis

Generally, these technical discussions apply to both upstream and downstream single carrier (SC, such as SC-QAM) and multicarrier signals (MC signals, such as OFDMA and OFDM), although upstream efficiency is the general topic of this paper.

A problem arises when a single carrier signal and a multicarrier signal are located next to each other in adjacent frequencies. For this reason, when doing spectrum planning, for best efficiency it is generally best not to "mix up" single carrier and multi carrier signals but keep them separated as much as possible

On the upstream, as previously discussed, due to upstream noise funneling, the lower part of the spectrum, especially below 20 MHz, is hostile to all signals, and particularly hostile to OFDMA signals. This is due to impulsive energy spreading by an OFDMA receiver's FFT. This is particularly detrimental when there is switching regulator impulsive noise ingress in the upstream. This example of impulsive energy is created by poor switching power supply filtering combined with a loss of coaxial shield integrity (e.g., shield break). This allows both radiated and conducted energy from the power mains in homes to get onto the coax center conductors and travel upstream. Many switching regulated power supplies operate at frequencies close to the OFDM/A frame rates, such as 50 kHz, so there may be an impulse in every OFMDA FFT, with impulsive energy being transformed (spread) to each OFDMA symbol.

In the downstream both SC-QAM and OFDM signals are continuous, hence if there is adjacent channel interference, it is also continuous. In contrast, the upstream uses bursts of energy, so if a SC-QAM burst occurs when there is no adjacent OFDMA burst, no interference occurs. And if a OFDMA burst occurs when there are no adjacent SC-QAM bursts, again there is no interference. An interference problem only arises when the SC-QAM and OFDMA bursts occur at the same time(s) in adjacent frequency bands.

Interference needs to be evaluated in both directions, OFDMA into SC-QAM, and SC-QAM into OFDMA. Generally, an adjacent SC-QAM signal is more likely to damage an OFDMA signal than vice-versa.

4.1. OFDMA interference into SC-QAM

When an OFDM or OFDMA signal is created by a D-A converter and transmitted, out of band sidelobes are created. This is because, when transmitting data, the OFDMA signal abruptly transitions to different amplitude (voltage) levels. The sidelobes can be seen and measured on a conventional scalar spectrum analyzer and can cause interference with adjacent single carrier signals. Usually, time domain symbol damage is limited to just the one or two symbols that occur at the start and stop of the OFDM frame. The sidelobes interference can be reduced by using a roll-off period specified in the DOCSIS specification, along with providing a guard band between an OFDM(A) block and a single carrier signal. This causes inefficiency both in time for the roll-off period, and lost bandwidth.

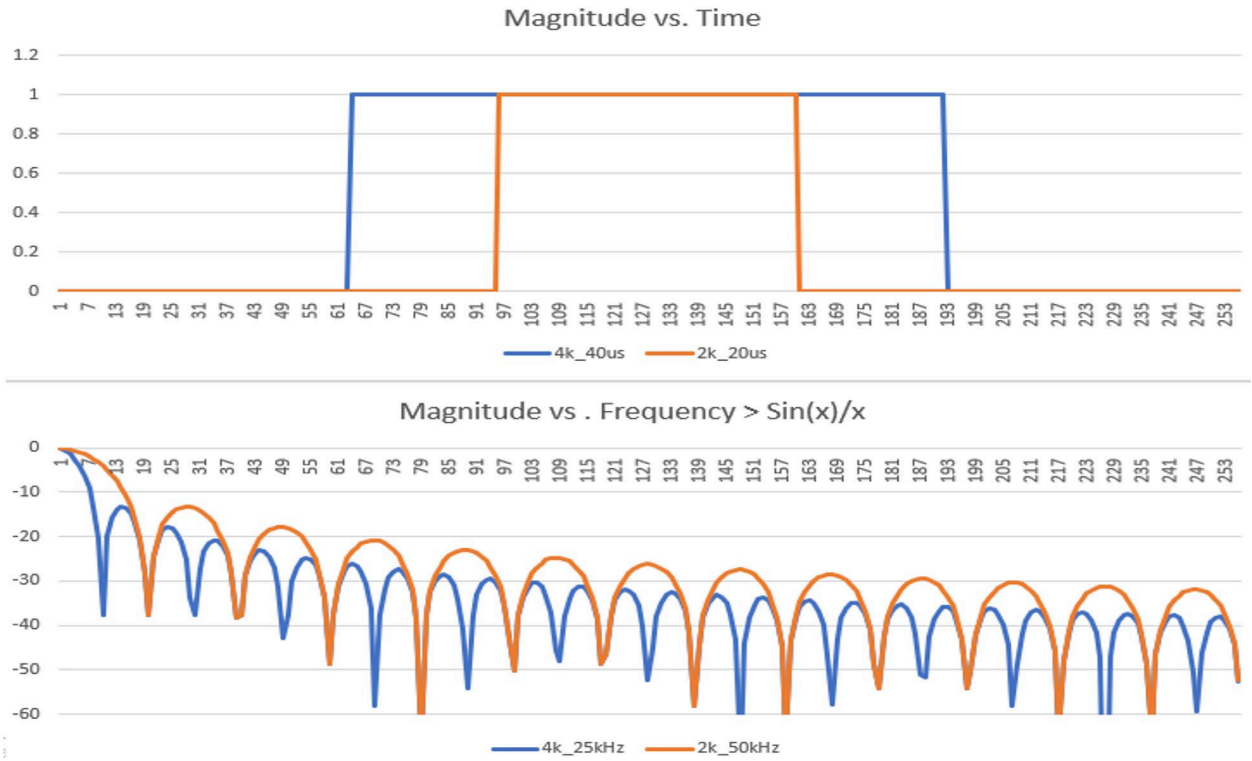


Figure 13 – OFDM/A Sidelobes created by rectangular time domain energy

In Figure 13, the upper plot is a rectangular pulse of magnitude voltage vs. time. The vertical axis is linear voltage, and the horizontal axis is time index. The rectangular pulses have a duration of either 20 µsec (2k mode) or 40 µsec (4k mode). If this waveform is transformed into the frequency domain with an FFT, the lower plots are obtained. The lower plot's vertical axis is dB, and the horizontal axis is frequency. The spectral shape consists of a DC term at 0 dB on the left, and then decreasing sidelobes over the rest of the plot. The sidelobes decrease as an absolute value of a sine(x)/x function. The separation between sidelobes is 50 kHz for 2k mode or 25 kHz for 4k mode. As you place more vacant spectrum between a SC-QAM signal and an OFDMA signal, the OFDMA interference to the SC-QAM signal is less.

The DOCSIS specifications provides another way to reduce interference besides vacant spectrum. The method is to shape OFDMA interference sidelobes and reduce their spectral reach over into the SC-QAM signal. That is done by employing a roll-off period (RP), which is tapering of the time domain envelope so that it gradually rises and falls, not with an abrupt transition, as illustrated in Figure 14. This is also referred to as a Tukey filter. Tapering is illustrated in Figure below (from the [DOCSIS PHY v3.1] specification). The roll-off period is subtracted from the cyclic prefix (CP) length, so CP length may need to be increased if a roll-off period is used. Unfortunately, employing a roll-off period and a CP is a time overhead penalty which decreases efficiency.

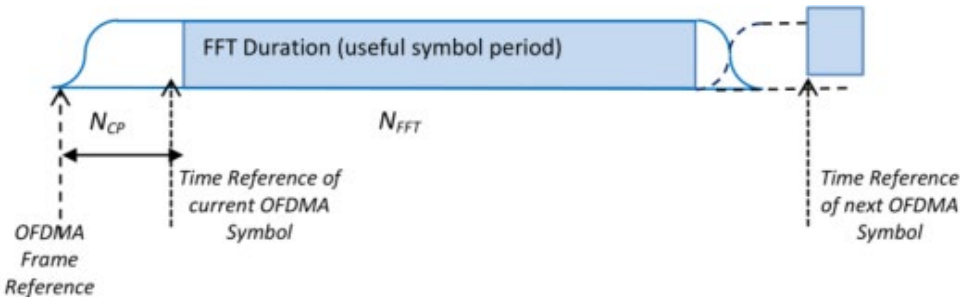

Figure 14 – OFDMA Signal, Useful symbol period and roll off

The above figure shows a time diagram of an OFDMA signal showing roll-off period and useful symbol period.

As mentioned above, for OFDM modulation, in general, there are spectral sidelobes beyond the edges of the modulated spectrum. This is a physical property of OFDM modulation and comes in the form of non-zero modulation energy beyond the edges of the configured modulated spectrum (i.e., below the lowest active subcarrier and above the highest active subcarrier). Figure 15 below, illustrates this modulated energy (sidelobes) and how it varies over different settings of the roll-off period (Nrp).

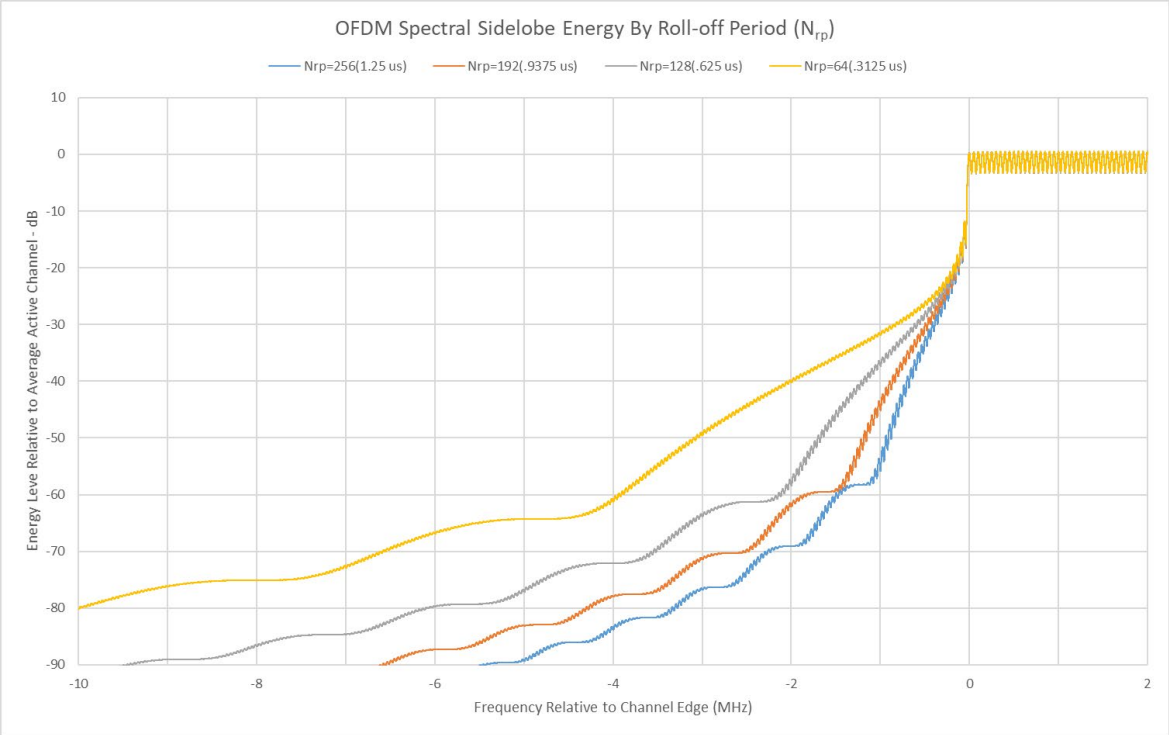

Figure 15 – OFDM/A Spectral Sidelobes (impact on Adj. SC-QAM)

** Figure 15: MATLAB simulation data provided courtesy of Roger Fish & Thomas Kolze, Broadcom*

Note that there is a trade-off between different Nrp settings. Smaller settings may offer more efficiency in the time-domain but have the cost of additional spectrum used by the OFDM channel modulation (larger spectral sidelobes/guard bands).

If you consider the top time plot of Figure 13 carefully, the interference to adjacent SC-QAM channels only occurs in time at the instant when the voltage is abruptly changing to or from zero, occurring every 20 or 40 us. So, if the SC-QAM bursts could be timed to "miss" those abrupt steps, no interference would occur. That could be an opportunity for a CMTS scheduler. Using 40 us (4k mode) generates half as many abrupt steps as 2k mode, so is half as harmful to an adjacent SC-QAM.

There is also a possibility that the damage to adjacent SC-QAM symbols can be eliminated by using good FEC settings on the SC-QAM bursts. The SC-QAM symbol rate is 5.12 MSymbols per second, and symbols occur every 195 ns. The abrupt transitions will damage one or two SC-QAM symbols out of every 256 symbols. Upstream FEC uses a Reed-Solomon block code, so setting the value of T to a large number (e.g., T= 16) can undo symbol damage. Furthermore, the increased FEC code overhead increases the robustness of the SC-QAM signal in general.

If two OFDM(A) signals are using the same exact timing, start time, stop time, cyclic prefix, and roll-off periods, they do not interfere with each other. So, no guard band or roll-off period needs to be used when signals are originating from the same slot/port on a CMTS and are using the same synchronous clock and the same OFDM & OFDMA frame timing. (The same CP etc. on the OFDMA frame)

4.2. SC-QAM interference into OFDMA

When receiving an OFDM(A) channel a comparable timing process occurs, where a first sample is taken continuously to the final sample. Unfortunately, time sampling is abrupt, not tapered. As a result, the same leakage phenomena that occurs with transmission occurs with reception, but this shows up as a susceptibility to interference from foreign energy at frequencies outside of the OFDM(A) channel. This energy can be a nearby SC-QAM and shows up as poor MER on subcarriers near the band edge as seen in the experimental results in Chapter 5.

Back a few years ago, it was observed in the field that the RxMER (receive modulation error rate) per subcarrier for lowest and highest subcarriers appeared worse than MER for subcarriers in the center of the OFDM or OFDMA band. It was determined that the presence of a SC-QAM above or below the OFDM or OFDMA spectrum was the culprit. Figure 17 and Figure 18 are plots of MER per subcarrier with an adjacent SC-QAM signal. Observe that subcarriers nearest the OFMDA band edges were automatically eliminated (not used) by the CMTS to avoid damage. Figure 19 is a MER per subcarrier plot with no adjacent SC-QAM signals. MER is uniformly good.

Why was this happening? An OFMDA receiver uses a rectangular sampling window in the time domain. The rectangular sampling window is illustrated in Figure 14 as the time interval with a blue shading. A resulting receive spectral window is not rectangular, but also extends into adjacent frequencies with sidelobes.

Figure 16 illustrates two receive spectral windows, one in red for 2k FFT and one in blue for 4k FFT. Because the sidelobes associated with the 4k FFT sidelobes decay more rapidly than the sidelobes associated with the 2k FFT, the 4k FFT has a narrower receive spectral window, and thus is more efficient than the 2k FFT. That is, the 4k FFT pulls in less energy from an adjacent SC-QAM signal relative to a 2k FFT.

Can using a roll off period on a transmitted signal improve efficiency by reducing interference? The answer is no, because the tapering is not inside the blue sampled region and is discarded (not used in the transform). Using a long cyclic prefix or a long roll-off period do not improve the problem of poor receive MER on OFMDA band edges. Choosing a 25 kHz (4k) subcarrier spacing over a 50kHz (2k) subcarrier spacing does make an improvement.

This advantage is illustrated in Figure 16. This narrower receive spectral window advantage for a larger transform size applies for both OFDMA and OFDM.

Figure 16 – Receive Windows 2k vs 4k

Receive spectral windows extend into the sidelobes and are wider for 2k (red) relative to 4k (blue) FFT.

4.3. Conclusions on Upstream Interference

The following are some conclusions reached based on the above discussion.

1. Generally OFDMA is harmed more by an adjacent SC-QAM than the SC-QAM is harmed by an adjacent OFDMA.

2. 4k is more efficient than 2k for reasons of narrower receive spectral window and required CP being half the symbol period. 4k also interferes with adjacent SC-QAM less, because of half as many abrupt voltage transitions.

3. Putting on more CP or RP on an OFDMA does not protect it from an adjacent SC-QAM signal. That is because its CP or RP do not modify the receive spectral window.

4. Adding a RP to an OFDMA channel does protect an adjacent SC-QAM channel from interference.

5. This discussion applies to upstream or downstream channel adjacencies.

5. OFDMA and SC-QAM Upstream Recommendations

5.1. Guard Bands

To examine the treatment of spectral guard bands in the DOCSIS specifications for OFDM/OFDMA channels and within different implementations, it is instructive to look at fundamental properties of OFDM modulation, in general, as well as a comparison between DS/OFDM and US/OFDMA specification requirements. As described in chapter 4, it is important to point out that the additional spectral sidelobe energy beyond the edges of the modulated spectrum is part of the channel and carries useful information. Therefore, another signal encroaching on this spectrum, such as a non-synchronous adjacent channel, has the potential to interfere with the OFDM channel and, vice-versa, the spectral sidelobe energy of the OFDM channel can also cause some interference on the adjacent channel.

5.1.1. DS/OFDM Requirements

We think of a full-width DS/OFDM channel as 192 MHz, although the maximum modulated spectrum width is only 190 MHz. This is convenient since, for downstream OFDM channels, the specifications require a minimum 1 MHz spectral guard band at the lower and upper channel edges. This guard band is required to accommodate the spectral sidelobe energy at the edges of the OFDM channel.

The nominal 192 MHz OFDM channel width includes 1 MHz (minimum) unmodulated spectrum at each edge as guard bands. It should be noted that more guard band could be needed, depending upon the setting for the roll-off period (N_{rp}). [DOCSIS PHYv3.1] spec (Appendix V) provides suggested additional guard band sizes (referred to as Taper Regions) for different N_{rp} settings. The MATLAB model used for the plot in Figure 15 was used to obtain the recommended guard bands (Taper Regions). Note that there is a trade-off between different N_{rp} settings. Smaller settings may offer more efficiency in the time-domain but have the cost of additional spectrum used by the OFDM channel modulation (larger spectral sidelobes/guard bands).

5.1.2. US/OFDMA Requirements

The physical properties of the OFDM modulation process still apply for bursted OFDMA upstream signals. Spectral sidelobe energy still occurs during bursts. Since the US/OFDMA channels are scheduled bursts of minislots, adjacent channel interference due to the spectral sidelobes of the OFDMA channel would only occur when these adjacent channels are scheduled and granted to burst simultaneously. Interference can be avoided through the scheduling and granting of these adjacent channels.

Based on our lab experiments, we found that CMTS implementations enforce some amount of guard band at the edges of OFDMA channels. Different CMTS implementations enforce OFDMA guard bands in different ways. In some cases, a minimum 0.5 MHz guard band is enforced by the CMTS at each edge of the OFDMA modulated spectrum. In other cases, 1 MHz or more guard bands are enforced by the CMTS implementation, either fixed or variable, depending upon the configuration parameters of the adjacent channels.

The important take-away here is that different CMTS implementations enforce different guard bands in different ways, even though the specs do not require enforcement of guard bands for US/OFDMA channels. It's important for the operator to examine and understand whether and/or how their specific CMTS implementation(s) enforce(s) guard bands at the edges of US/OFDMA channels.

This automatic enforcement of guard bands by the CMTS, which is not required by the spec, could result in part of the OFDMA channel not being used. For example, the CMTS might not grant a number of minislots at the edges of the channel so that its own minimum guard band requirements are met.

For the OFDMA channel, as an example, the interference comes in the form of reduced RxMER on the OFDMA subcarriers at the edge close to the adjacent channel whenever both channels are bursting simultaneously. Figure 17 shows the degraded RxMER per subcarrier at the edge of a 32 MHz OFDMA channel when an adjacent SC-QAM channel is bursting simultaneously (SC-QAM channel is to the left of the OFDMA channel). Note that, although the SC-QAM is configured immediately adjacent (guard band = 0 MHz), the CMTS in this case enforces a minimum 0.5 MHz guard band by leaving 2 minislots ungranted/unused at the edge of the channel.

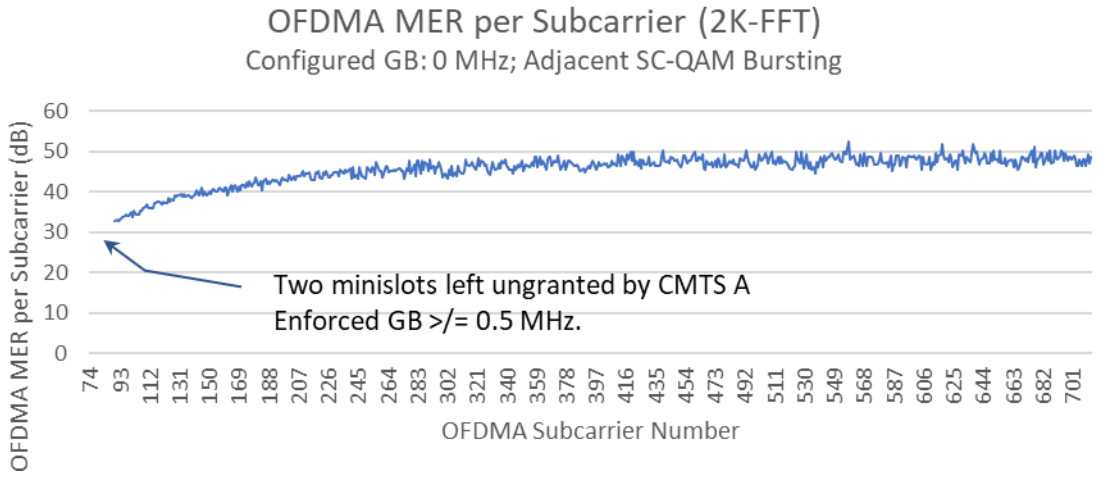

Figure 17 – RxMER : Non-synchronous Adj Channel Bursting Simultaneously (CMTS A)

In Figure 18, after further lab experiments using a different CMTS but with identical channel configuration, we observed that the first 10 minislots are left unused by this CMTS to automatically enforce its own guard band rules.

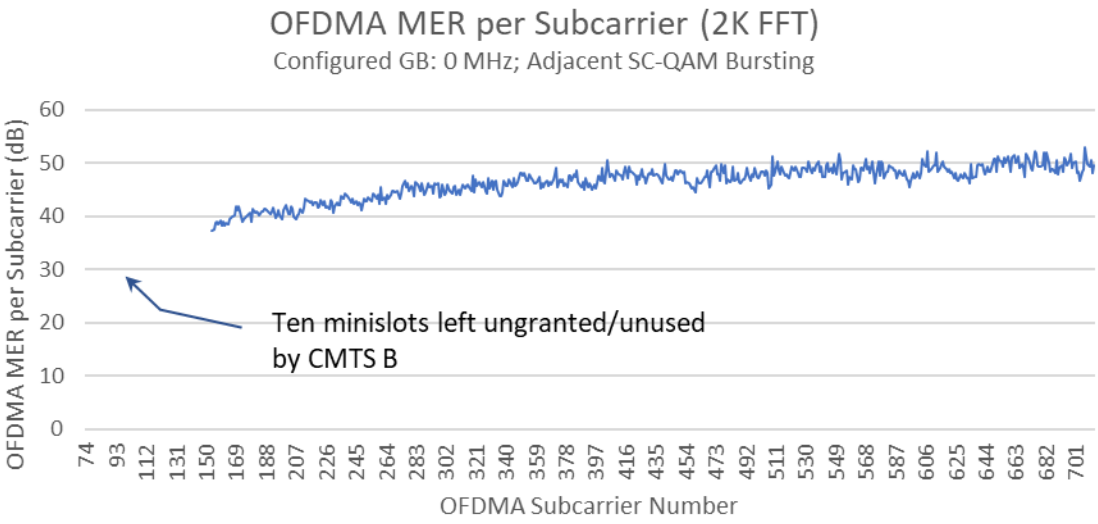

Figure 18 – RxMER : Non-synchronous Adj Channel Bursting Simultaneously (CMTS B)

It is important to remember that the interference affected RxMER and automatically enforced guard bands only occur when both adjacent channels are bursting simultaneously. When bursting alone as shown in Figure 19, there is no degraded RxMER at the edge and there are not automatically enforced guard bands.

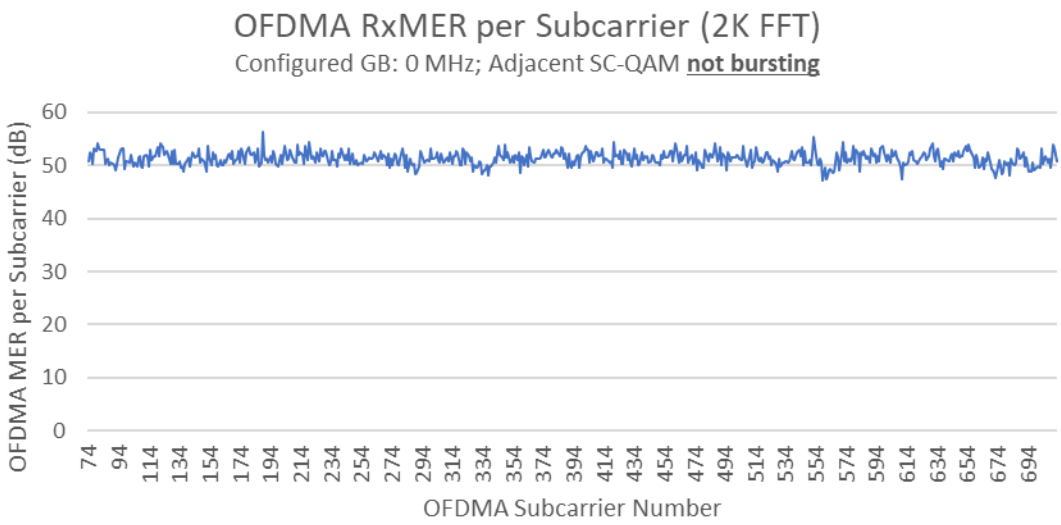

Figure 19 – OFDMA RxMER (OFDMA bursting alone)

5.1.3. Recommendations

It's important for the operator to know and understand how their specific CMTS systems treat adjacent channels with respect to their own enforcement of guard bands. If their own minimum guard band limits are not met by the spectral location of adjacent channels, parts of the OFDMA channel edges might be unused (minislots ungranted) by the CMTS scheduler.

An adjacent SC-QAM channels' interference on the OFDMA channel largely affects the subcarriers on the edge of the OFDMA channel, the impact is that the subcarriers on the edge of the OFDMA channel have worse RxMER than the rest of the channel. The OFDMA interference on SC-QAM can be remedied with a large guard band or moderate guard band with taper (Roll off period). Tapering/Roll-off period does not protect the OFDMA channel from an adjacent SC-QAM channel.

5.2. TaFDM (Time and Frequency Division Multiplexing)

It's useful to examine the use of TaFDM in the context of the discussion of guard bands (above). As previously noted, DOCSIS specifications do not mandate minimum guard bands for US/OFDMA channels. In fact, it follows that different non-synchronous channels may even occupy the same frequency spectrum. This is allowed by the specification and can be handled by the CMTS scheduling the use of overlapping spectrum by the included channels at separate times.

5.2.1. TaFDM and CMTS Guard Band "Rules"

In practice, we find that CMTS implementations tend to adhere to their own guard band enforcement processes, either partially or in whole, to implement TaFDM. In fact, we have seen that some CMTS implementations might automatically trigger their own TaFDM mode when adjacent channels are configured closer than their own expected minimum guard band. Even though the modulated spectrum may not overlap, it could be considered overlapping by the CMTS if a portion of their expected minimum guard band is overlapped.

Other CMTS implementations may extend their own guard band rules to zero out larger portions of the OFDMA channel that is also occupied by, for example, an overlapping SC-QAM channel. This could result in half or even more of the OFDMA channel being zeroed out (not granted for OFDMA bursts).

Like the examples above, Figure 20 shows the MER per subcarrier for the same 32 MHz OFDMA channel, but with a 6.4 MHz SC-QAM channel configured in TaFDM mode just above the center of the OFDMA channel.

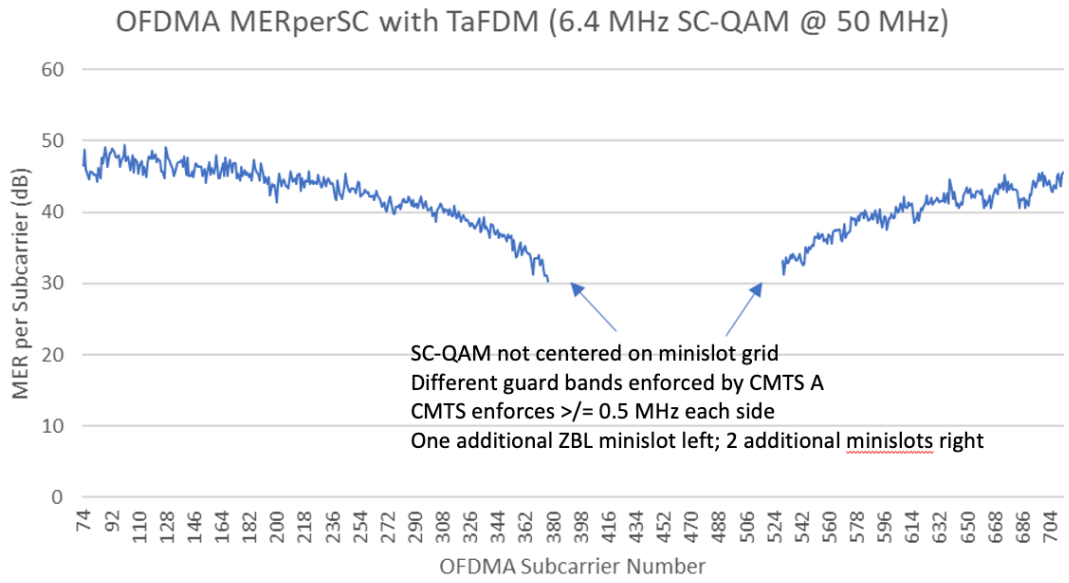

Figure 20 – OFDMA RxMER w TaFDM (SC-QAM bursting in center of OFDMA) (CMTS A)

As shown in Figure 21 when using a different CMTS, nearly half of the OFDMA channel is unused in order to enforce a combination of its own guard band and TaFDM rules.

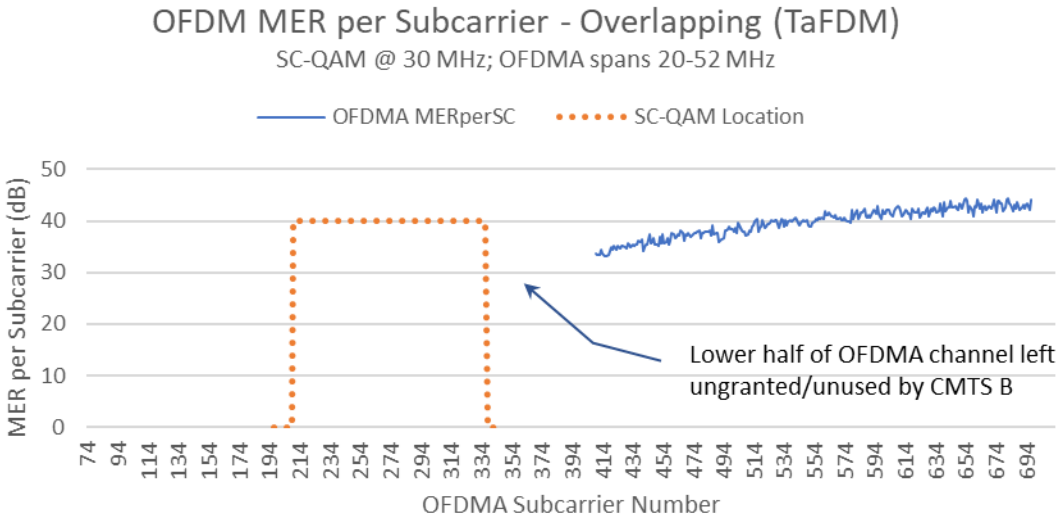

Figure 21 – OFDMA RxMER w TaFDM (SC-QAM bursting in center of OFDMA) (CMTS B)

It is worth mentioning again that when the OFDMA is bursting alone, the full width of the channel is used without MER degradation, as shown in Figure 19.

5.2.2. Recommendations

It is important to understand how a CMTS implementation handles TaFDM to judge whether the associated trade-offs are worthwhile. If a particular CMTS only enforces a small guard band at each end of a fully overlapping spectrum and, therefore, allows simultaneous bursting of overlapping channels using TaFDM, then there may be situations where fully overlapping channels are useful. Of course, it's possible that the use of TaFDM could zero out half or more of the useful modulated spectrum of an OFDMA channel, depending upon the location of the overlapping channel and the specific CMTS "rules" for handling guard bands and TaFDM, and in these cases may not be an efficient use of the spectrum.

6. DOCSIS Protocol and Configuration Efficiency Considerations

DOCSIS protocol relies on several processes for proper operation. These processes include initialization, request for data, the multiple aspects of ranging and the processes to assign CMs to the right channels and their configuration to the right profile. Most of these processes will have some impact on efficiency that are worth further analysis.

6.1. Initialization

The initialization of a CM consists of downstream scanning, upstream channel acquisition, ranging, IP connectivity, time of day acquisition, config file download in addition to registration verification and the establishment of connection privacy. These processes by themselves are part of the expected behavior, however efficiency problems arise when these initializing CMs take a longer time or struggle to complete any of these processes. There may be conditions in the plant, sub-optimal configuration or problems with the implementation that forces a CM to repeat one or more of these processes to recover normal operational state.

6.2. Initial Maintenance

DOCSIS 3.1 CMs use an initial maintenance region that is of significant size in frequency and time. This region is used to allow CMs to perform initial ranging which takes place in a broadcast mode and is used with a very coarse time adjustment as initially the CMs do not know what timing offset to apply to their transmissions. The design of this time and frequency resource area (ranging zone) must be done very carefully to minimize collisions that occur when that initial maintenance region is not big enough or to avoid wasting resources if it is too big. The frequency of occurrence of this initial maintenance region, which is called the insertion interval, must be carefully defined. In conjunction with the insertion interval, the back-off process is configured by adjusting the random range back-off parameter that is used after a collision occurred.

Above all the location of the ranging zone needs to be chosen in a higher part of the spectrum to minimize interference from the noise sources on the upstream. This has been a single point of failure in some early deployments of OFDMA, where the default ranging zone created by the CMTS was not in a robust region to allow all the CMs to range successfully.

Figure 22 depicts the initial ranging zone in a DOCSIS 3.1 OFDM channel, time and frequency map.

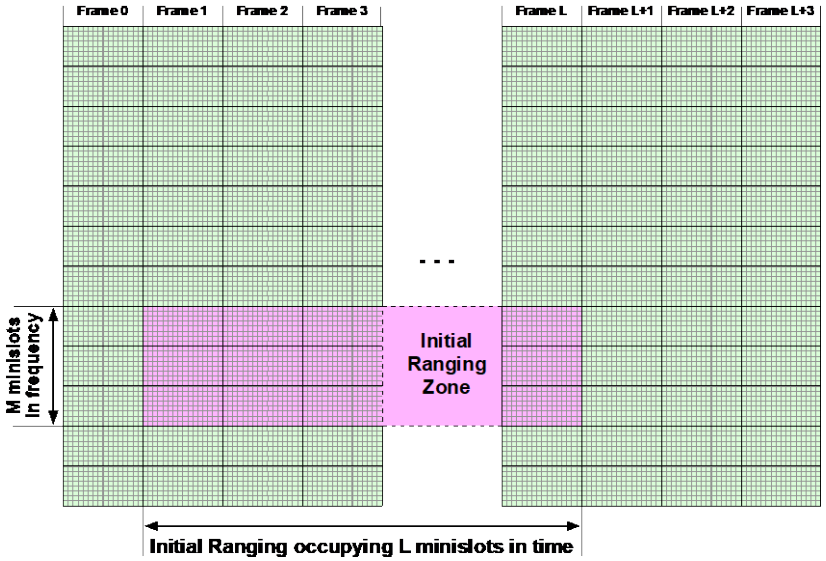

Figure 22 – Initial ranging zone in DOCSIS 3.1 in symbol versus frequency view

When ranging power levels, since initially the CM has no knowledge of what the right power level should be, it must go through many power levels before converging on a final value. The time this process lasts can be significant and any improvement mechanisms are worth implementing. One popular approach is to try the last good known state first. So, if a CM reboots it uses the last good known power and frequency configuration parameters that worked the last time the CM successfully initialized. Once the initial maintenance is successfully achieved, the CMTS and CM can communicate through unicast messages. Nevertheless, impaired channel conditions can force CMs into repeating this process.

6.3. Station Maintenance

The ranging response message is used to adjust transmit timing information, transmit power level information, transmit equalization information among other things. A CM that requires such an adjustment must wait until the CMTS acknowledges that the CM is ready to transmit by changing the ranging response messages from “RNG-RSP continue” to “RNG-RSP success”. The CMs cannot transmit data while still in “RNG-RSP continue”, a state which results in upstream inefficiency. These processes can extend for a while. Every time that a RNG-RSP message is not acknowledged, the T3 timeout counter is increased. After 16 successive T3 timeouts a T4 timeout occurs. The US channel is then deemed unusable, and the US channel enters in partial service mode or if it is the only channel, it forces re-initialization which represents an even greater impact on efficiency. In a good stable environment periodic maintenance is only used to conduct minor adjustment. Monitoring and quantifying the extend a CM spends beyond an uneventful ranging, helps you assess the impact on CM performance and efficiency.

6.4. Upstream Partial Service

The CMTS puts a CM in partial service mode when a CM is not able to range on a particular channel. This CM in partial service stops using the degraded channel. While station maintenance is the default mechanism to put CMs in partial service mode, alternative metrics can also be used to place a CM in partial service which include thresholds in SNR, as well as thresholds in uncorrectable as well as correctable codewords. This provides the operator with different tools to manage which CMs should have channels in partial service mode. These alternatives mechanisms also provide a hysteresis function so that

a CM does not waste time going in and out of partial mode. The CMTS periodically will have the CM attempt to range on the degraded channel and check if it is still impacted. Going into partial service not only has the impact of not having US channel available to a CM, but also these transitions to and from partial service impact efficiency. CMTS algorithms on resolving partial service is a big factor in how quickly a CM returns to full service.

If a system struggles to achieve operational stability due to constant adjustment of power levels, constant adjustment of timing offset and a lack of convergence of equalization coefficients, efficiency is significantly impacted. Proper maintenance of a healthy US and DS channel prevents such occurrences.

6.5. Contention and Piggybacking Bandwidth Requests

The process of requesting upstream bandwidth in DOCSIS systems could also introduce inefficiencies. To request bandwidth, (minislots is the upstream resource currency), the CM takes advantage of a contention period designed for that purpose. This contention period allows CMs to send a request message containing how much data is desired. The size and periodicity of this contention period must be configured carefully by the CMTS to limit the number of collisions. Like contention in initial maintenance, when request messages collide, a random back-off is used to reduce the probability of further collisions

In addition to the contention request messages, DOCSIS systems also leverages a piggybacking process to reduce the number of contention requests needed thereby having a side benefit of reduce the likelihood of collisions. In piggybacking a bandwidth request is appended behind the packet just transmitted thereby not requiring a contention request.

Monitoring the number of regular request messages sent and number of piggyback requests sent in addition to monitoring the number of bytes requested and bytes granted are ways of determining how efficiently bandwidth is being allocated.

6.6. Traffic Characteristics and Signatures

The amount of traffic as well as its characteristics such as packet rate, packet rate variability and packet size distribution, stream duration as well as resources available are useful in determining how many mini-slots and how often to allocate request message opportunities. Since the traffic characteristics are dynamic, the CMTS will likely react and adapt according to these changing traffic conditions. The intelligence and efficiency of the CMTS scheduling algorithms will result in lower or higher transport efficiencies.

In the upstream, in DOCSIS 3.1 technology there are short, medium, and long codewords, each with different efficiencies. Very short packets will have lower efficiency and longer packets will have higher efficiencies. Also, in SC-QAM upstream operation each packet is preceded by a preamble and a guard time. This represents a time overhead that is fixed and for short payloads the payload size could be comparable to the preamble and guard-time, while with longer payloads such as is the case of 1500 Bytes, the preamble and the guard-time is only a small fraction of the packet duration. This inefficiency is aggravated with higher order modulations as the payload is further reduced in time. Efficient concatenation reduces the percentage of shorter packets thereby resulting in higher efficiency.

In DOCSIS systems the CMTS measures consumption and allocates resources in minislots, not bytes. One can have an accurate estimate of the resources being used when we leverage the MIBs that provide minislot utilization. An operator needs to make sure that the system is not starving for minislots, simply tracking the bytes can be deceiving.

Figure 23 shows an example of packet size distribution characteristics for some applications and aggregate packet size distribution of CMs on a service tier to highlight the specific impact that packet size distribution could have on performance. Some other packet size studies have found that 80% of upstream packets have a size below 80 bytes, and 90% of upstream packets are below 160 bytes.

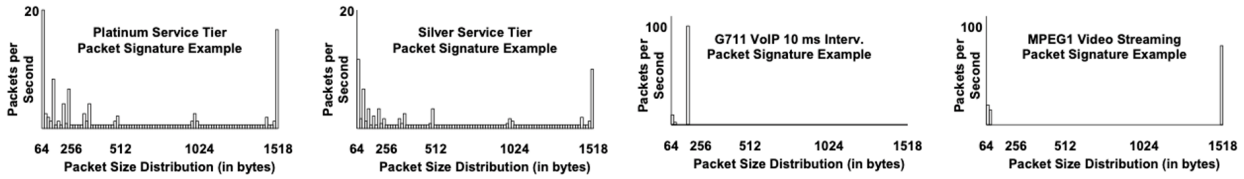

Figure 23 – Traffic Signatures for specific applications and for sample service tiers

In today's very high service tiers, bursty traffic is more prevalent. Tweaking the token bucket parameters is a tool that has been used in the past to optimize performance and can play well under bursty conditions, this could get large bursts of traffic out of the way to free up the channel for other transmissions.

6.7. Service Flow Configuration

The service flow configuration for the upstream directly affects the user experience. There are many Service flow parameters which an operator configures for an upstream service flow. These include CM Service Flow Parameters such as the Max sustained rate, Peak traffic rate, Max traffic burst, SF Priority, R/T Policy, Buffer control, AQM etc. Using the Buffer control setting (50 ms recommended) and enabling AQM will reduce the latencies observed by the user. The Max Sustained traffic rate for the service flow is set by the Service tiers offered by the operator.

One recommendation that will improve the user experience across all the service tiers is setting the Maximum Traffic Burst to something beyond the default of 3044 bytes, which is too small. The recommendation is to bump up the Max Traffic Burst (B) setting for a service flow to something in the range of 50 kBytes to 65 kBytes. Higher values of B can give users a boost in the initial data rate seen by the user, until the CM uses up the tokens allowed by the B value.

6.8. Profile Management / Upstream IUC management

DOCSIS 3.1 specifications introduced the concept of profiles so that performance of CMs could be optimized based on the SNR that they have available on the plant. DOCSIS systems have thereby evolved from the lowest common denominator conditions operation to a more dynamic opportunistic resource usage approach.

The CMTS assigns OFDMA IUCs (profiles) to the CMs based on the measured plant conditions. It is intended that the Data Profile IUC 13 is configured to be a robust OFDMA profile usable by any DOCSIS 3.1 CM served by that upstream channel and is used for all OFDMA data grants to modems which have not completed registration and for transport of MAC management messages and data grants after registration.

During or after modem registration, the CMTS has the option of assigning the CM to use any other configured data profile. Typically, the data profiles other than IUC 13 will be configured with higher modulation orders than IUC 13, although not all these profiles will be usable by all modems. The CMTS typically assigns IUC 13 and an additional data profile (one of IUC 5/6/9/10/11/12) to the CM for an OFDMA channel. The CMTS grants bandwidth on the OFDMA channel for data transmissions to a CM using this data profile (e.g., IUC 5). Now at some point the plant may have a noise ingress and interfere

with the upstream transmissions. If the CMTS detects codeword errors on the IUC/profile used for a CM, it will temporarily use IUC 13 for data transmission, and initiate a dynamic change process to swap out the errored data profile with lower modulation data profile (e.g., swap out IUC 5 with IUC 6). This process continues (and the CMTS may further downgrade profiles) until the CMTS can receive codewords from the CM without errors. At a later point in time when the noise ingress goes away, the CMTS based on US RxMER measurements (using probes) or OFDMA Upstream Data Profile (OUDP) testing bursts, can evaluate the CM performance on a higher modulation profile and then choose to assign those profiles to the CM if appropriate. (e.g., upgrade from IUC 6 to IUC 5)

On noisy upstream spectrum, ingress noise issues may interfere with the signal enough to cause FEC codeword errors, to initiate the whole process described above, where a CM's profile is continuously being upgraded or downgraded, or in the worst case where the CM goes into partial service and is unable to use that channel for periods of time. Intermittent noise will cause this profile flapping behavior in the upstream OFDMA channel, such instability may be triggered by plant conditions and ultimately ends up impacting CM performance. (Similar profile flapping has been observed in noisy downstream channels as well).

DOCSIS CMTS settings need to be configured correctly to minimize the profile flapping. This includes the thresholds for the number of FEC errors, the RxMER dB thresholds for a particular modulation order, the time for which a CMTS downgrades a CM before re-evaluating if a profile is appropriate for a CM, the choice of looking at RxMER vs FEC errors in the upgrade/downgrade decision.

A well-designed Profile Management application (PMA) or system can create a good set of profiles, adjusted to the noise characteristics of that node, and minimize the profile flapping for each CM. A lot of the profile management concepts, algorithms, field experiences and deployment lessons have been described in a previous paper [US PMA].

The ability of the system to support a given QAM level depends on the RxMER values and the mappings to an appropriate QAM level, when creating a profile. These mappings are defined in [PHYv3.1] and are summarized in the Table below.

Table 3 – Upstream RxMER to QAM Level mapping

Upstream Constellation / Bit Loading	Upstream MER (dB)
QPSK	11.0
8 QAM	14.0
16 QAM	17.0
32 QAM	20.0
64 QAM	23.0
128 QAM	26.0
256 QAM	29.0
512 QAM	32.5
1024 QAM	35.5
2048 QAM (optional on CMTS)	39.0
4096 QAM (optional on CMTS)	43.0

6.9. Channel Conditions and PNM

In the previous sections, we have seen how unstable operations of DOCSIS processes directly impacts transport efficiency. This change from a stable to an unstable DOCSIS operation may have been triggered by changes in channel conditions. The DOCSIS system configuration may not be robust enough to overcome the channel impairments. These impairments may be sporadic or time of day sensitive. Even though these conditions may be difficult to detect, there are different parameters that are worth monitoring, including:

RxMER on a per channel and per subcarrier basis, FEC statistics, transmit and receive power levels and the different PNM tools such as equalization coefficients/channel estimate, full band capture, upstream triggered spectrum analysis, quite probes and CM specific probes analysis.

The goal is to have a good understanding of the conditions of the plant, troubleshoot and correct problems that are performance impacting and/or verify performance and profile assignment is as expected.

Of the upstream PNM functions defined in the specifications, we have obtained and looked at the following data sets: upstream RxMER per subcarrier, upstream Equalizer Coefficients (CMTS), upstream Triggered Spectrum Capture Analysis, and upstream FEC Statistics (aggregated over the channel / all CMs). All of these have useful PNM applications in understanding the upstream performance. Upstream and downstream equalization coefficients contain valuable channel information, please refer to [PreEq Analysis] for further details.

So far, we have not been able to get access to data from CMTSs for the following PNM features: upstream Capture for Active and Quiet Probe, upstream Impulse Noise Statistics, upstream Histogram, upstream Channel Power. These upstream PNM functionality needs to be implemented on CMTS platforms and then further investigated and applications developed.

7. Upstream Split Migration Scenarios

There are a few different approaches for increasing the upstream bandwidth within the cable plant. The DOCSIS 3.1 system will have options of several split configurations that can be exercised based on traffic demand, services offered and the capability of the cable plant. These include the classic Low-split, the mid-split, and high-split frequency plans for DOCSIS 3.1 equipment and going to the ultra-high split options with DOCSIS 4.0 technology. To reach the target service goal in the upstream direction, plant changes on the upstream/downstream spectrum split are expected.

7.1. Adding Upstream Spectrum

Information theory says there are two ways to increase channel capacity:

- Add spectrum
- Increase the signal-to-noise ratio of the spectrum in use

In brief, doubling the upstream spectrum will double the upstream capacity; that is, a 100% increase in capacity. Staying in the same spectrum and increasing the Gaussian SNR by 6 dB to go from 256 QAM to 1024 QAM provides a 25% increase in capacity. Below 20MHz the noise is usually bursty, so a Gaussian noise assumption is not quite appropriate. Furthermore, the impulsive noise is spread to all frequency domain symbols by the FFT at the CMTS receiver. At some point, increasing the SNR has diminishing returns and the big gains will come from increasing the amount of spectrum allocated to the upstream.

Hence DOCSIS 3.1 technology includes both mid-split and a high-split options will be discussed in more detail. DOCSIS 4.0 technology includes ultra-high splits which provide additional upstream spectrum. Figure 24 shows the relative amounts of upstream spectrum with sub-split, mid-split, and high-split plant in DOCSIS 3.1 systems.

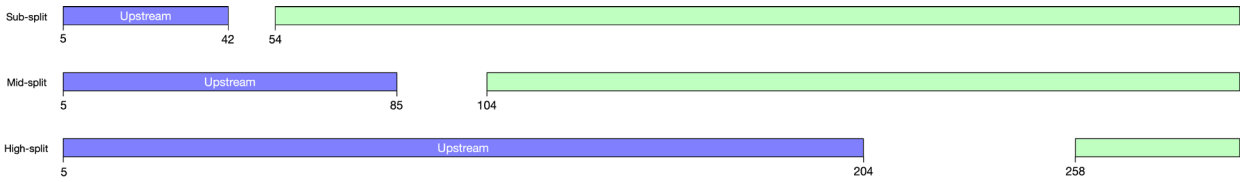

Figure 24 – Split Scenarios

7.1.1. Impact on Legacy Customer Premise Equipment

Existing cable modems deployed in the field may not support different splits, however, they will operate with the DOCSIS channels that reside in their existing upstream spectrum option. Set-top boxes (STBs) are limited to forward data channel (FDC) frequencies between 70 MHz and 130 MHz in the downstream direction as described in the SCTE 55-1 and 55-2 standards. As a result, these set-top boxes can continue to operate on a mid-split network but not a high-split network.

7.1.2. More Upstream spectrum and Downstream Spectrum

As more upstream spectrum is added, the downstream starts higher in the spectrum. For example, with a sub-split the downstream spectrum starts at 54 MHz. With a high-split network, the downstream starts at 258 MHz, and to maintain enough downstream spectrum the top end of the useful spectrum is usually increased, and the typical number is 1000 MHz or 1218 MHz.

As a summary, Table 4 shows the aggregate upstream throughput for the examples given in the following sections.

Table 4 – Upstream Throughput Examples

Case	Channels	Approximate Throughput
Sub-split Use Cases		
1	Four 3.2 MHz SC-QAM at 32 QAM	44 Mbps
2	Two 3.2 MHz SC-QAM at 32 QAM and Two 6.4 MHz SC-QAM at 64 QAM	72 Mbps
3	Four 6.4 MHz SC-QAM at 64 QAM	100 Mbps
4	Four 6.4 MHz SC-QAM at 64 QAM and One 3.2 MHz SC-QAM at 64 QAM and One 1.6 MHz SC-QAM at 64 QAM	115 Mbps
5	Two 6.4 MHz SC-QAM at 64 QAM and One 3.2 MHz SC-QAM at 64 QAM and 13 MHz OFDMA at 1024 QAM	160 Mbps
Mid-split Use Cases		
6	Ten 6.4 MHz SC-QAM at 64 QAM	250 Mbps
7	Four 6.4 MHz SC-QAM at 64 QAM and 40 MHz OFDMA at 1024 QAM	400 Mbps

8	70 MHz OFDMA at 1024 QAM	525 Mbps
High-split Use Cases		
9	Four 6.4 MHz SC-QAM at 64 QAM and One 66 MHz OFDMA at 1024 QAM and One 96 MHz OFDMA at 1024 QAM	1350 Mbps (1.3 Gbps)
10	Two 96 MHz OFDMA at 1024 QAM	1700 Mbps (1.7 Gbps)

7.2. Sub-split HFC network

A sub-split HFC network has a return path up to 42 MHz and has room to carry multiple upstream DOCSIS channels. In North America, sub-split is a hold-over from the days of analog television channels and cable-ready TV sets (both of which are rapidly going extinct, if not already there). Sub-split allowed the old Channel 2 to be carried on the coaxial cable starting at 54 MHz. The old analog Channel 2 has been replaced by digital TV carriers and IPTV, so the reasons for sticking to sub-split are diminishing. The following sections will show examples of how to get the most out of various configurations of an upstream channel.

The configurations in Cases 1-5 shown below will fit within the spectrum of a sub-split HFC network and as can be seen the upstream capacity can more than double by increasing both the amount of spectrum used for broadband and increasing the modulation order of the SC-QAM channels.

7.2.1. Making the most of Upstream SC-QAM Channels

For sub-split operation operators should experiment with various recommendations to get more upstream capacity. Strategies include:

7.2.1.1. Case 1: Remove Guard Bands

Removing large guard-band between upstream SC-QAM carriers; these guard bands are not needed. The DOCSIS specifications are written such that upstream SC-QAM channels can be directly adjacent to each other. Deployments exist where the upstream SC-QAM carriers have large guard-bands between them as shown in Figure 25 below.

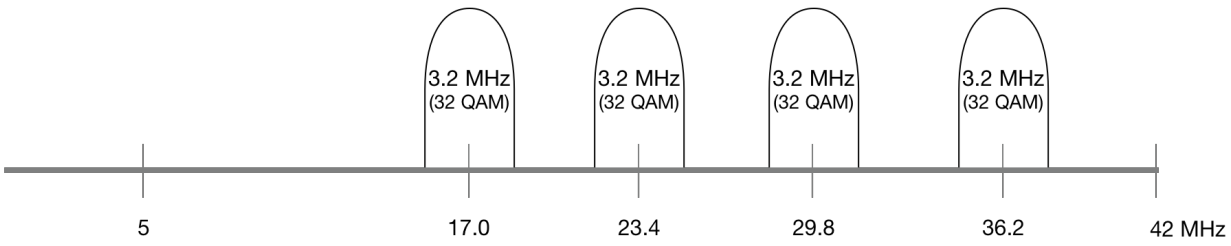

Figure 25 – Large Guard Bands Between Upstream Channels

With four 3.2 MHz wide channels, operating at 32 QAM, the aggregate throughput of this upstream channel is about 44 Mbps which leaves a lot of unused capacity on the table. The guard bands between upstream SC-QAM carriers are not needed; the carriers may be directly adjacent to each other on each side with no guard-band. However, as you place a carrier near the roll-off starting at 42 MHz it is best to

leave around a 500 kHz guard-band from 41.5 MHz to 42 MHz to avoid non-linearities related to amplifier cascades.

7.2.1.2. Case 2: Increase Modulation Orders

The next step for an operator would be to increase the modulation orders to 64 QAM for the upstream SC-QAM carriers. The DOCSIS SC-QAM technology is quite resilient, and the recommendation is to increase carriers to 64 QAM modulation, widen the carriers to use available spectrum, and remove the guard-band between the carriers. As shown in Figure 26 below, the moves should be done stepwise to confirm proper operation.

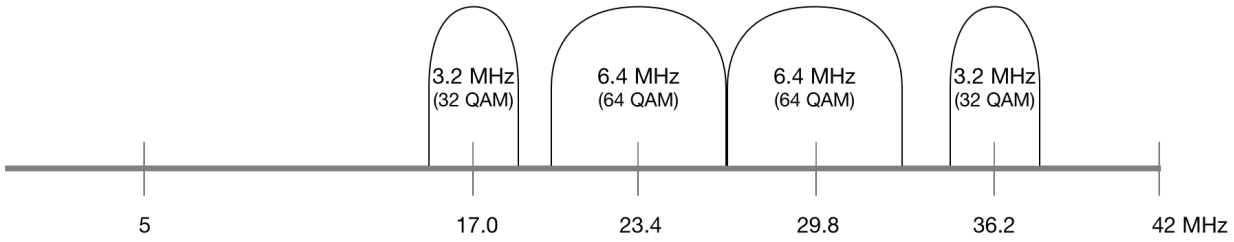

Figure 26 – Increasing Channel Width To Increase Upstream Capacity

With both two 3.2 MHz wide channels operating at 32 QAM and two 6.4 MHz wide channels operating at 64 QAM, the aggregate throughput of this upstream channel is about 72 Mbps.

7.2.1.3. Case 3: Use available spectrum

Another option for an operator would be to use all the available spectrum and using the widest channels. Figure 27 shows using all available spectrum, which could include widening all upstream carriers and abutting those carriers.

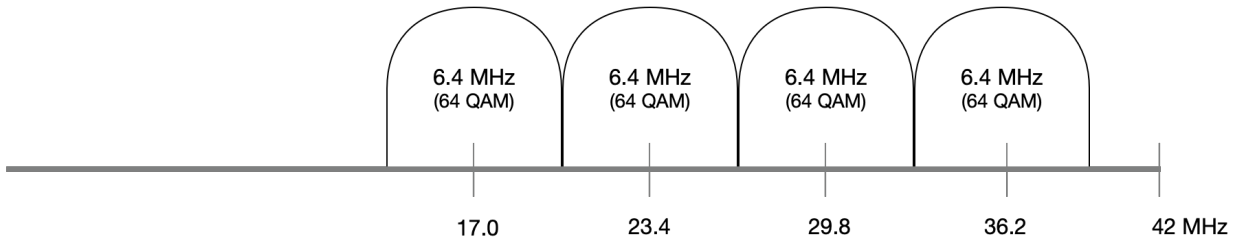

Figure 27 – Maximizing Upstream Capacity With Wide Upstream Channels and Small Guard Bands

With four 6.4 MHz wide channels operating at 64 QAM, the aggregate throughput of this upstream channel is about 100 Mbps.

7.2.1.4. Case 4: Squeeze in an additional carrier

As a final step for a sub-split network, operators could try adding one or more additional upstream SC-QAM carriers, up high or down low as shown in Figure 28 . The paper [Bandwidth Growth] draws the conclusion that even adding 10% additional upstream capacity can help alleviate upstream congestion.

Operators have been successful at adding new carriers, which is a testament to maintaining the plant more diligently over the last decade.

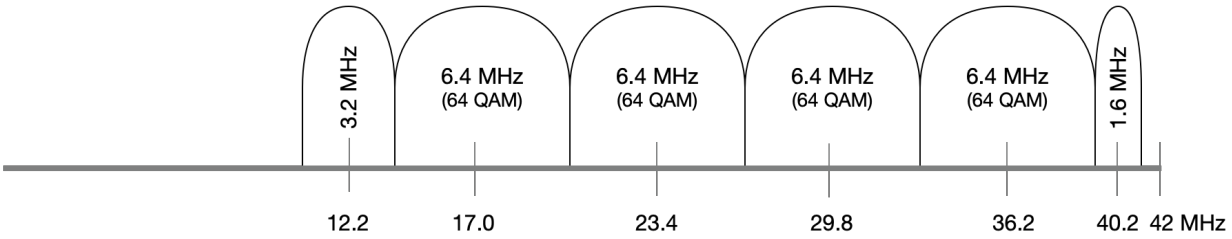

Figure 28 – Adding Additional Upstream Channels

This example adds both one 3.2 MHz wide channels operating at 64 QAM and one 1.6 MHz wide channels operating at 64 QAM, the aggregate throughput of this upstream channel is about 115 Mbps.

The DOCSIS technology has many options for optimizing channel layout and is different from even a decade ago. The digital transceivers have increased in sensitivity and capabilities to enable optionality not thought of even 5 years ago. Homes passed has decreased which lowers the effect of noise funneling at low frequencies. Cascades have shortened which lessens the impact of group delay close to the diplex filter cut-off frequency. Operators have been successfully running narrow carriers (typically with lower order modulation) both down to 10 MHz and closer to the diplex filter.

7.2.2. Sub-Split and OFDMA Channel

If the deployment must stay sub-split and there are enough DOCSIS 3.1 modems on the network, consider removing upstream SC-QAM channels and replacing them with an OFDMA channel. OFDMA technology makes better use of spectrum because it can operate nominally at 1024 QAM whereas an upstream SC-QAM channel is limited to 64 QAM.

An OFDMA channel low in the spectrum will be susceptible to impulse noise. Very strong noise impulses in the time domain might result in the loss of blocks of symbols at the receiver because that impulse noise is spread across multiple symbols.

7.2.2.1. Case 5: Add a small OFDMA Channel

The recommendation here is to put the OFDMA channel high in the spectrum where there is less impulse noise, (at least initially until the operators get comfortable with OFDMA) as shown in Figure 29.

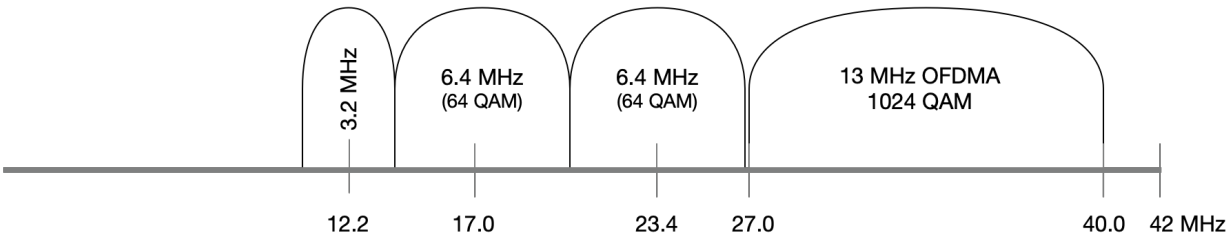

Figure 29 – Sub-split HFC Network with OFDMA Channel

The arrangement of channels shown above can provide an aggregate upstream capacity of 160 Mbps, showing the efficiency of the OFDMA spectrum as compared to SC-QAM spectrum. Note though that only DOCSIS 3.1 modems can take advantage of the OFDMA channel, therefore, there should be a large percentage of DOCSIS 3.1 modems on that plant segment.

Time and Frequency Division Multiplexing (TaFDM) is discussed in Section 5.2.

7.3. Mid-split HFC network

A mid-split network has a return path up to 85 MHz, or two times the spectrum of a sub-split network. With a mid-split, the forward path begins around 108 MHz so set-top box-based video services should be able to be maintained because the forward data channel can be up to as 130 MHz.

The additional upstream spectrum provided by a mid-split network can provide about 500 Mbps of capacity.

7.3.1.1. Case 6: Start with SCQAMs

In terms of additional upstream spectrum, a mid-split can be configured in several ways. As shown in Figure 30, a mid-split can fit ten traditional upstream SC-QAM carriers of 6.4 MHz width (for a total of 64 MHz of upstream spectrum allocated to broadband).

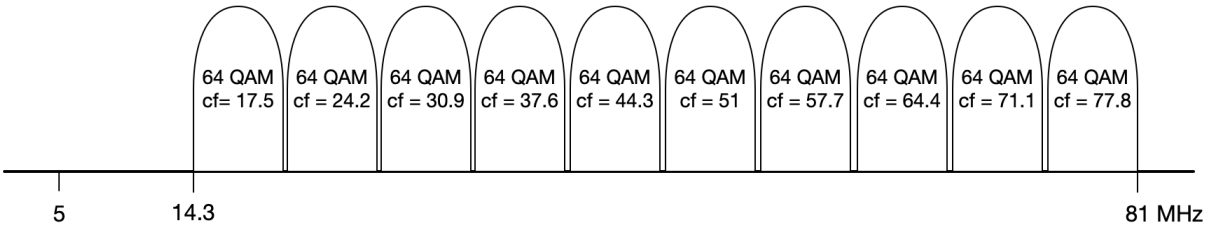

Figure 30 – Mid-split with 10 SC-QAM channels

This configuration can yield up to 250 Mbps of aggregate upstream capacity. Note that DOCSIS technology allows SC-QAM to be modulated up to 256 QAM and no higher. That is, with SC-QAM the options of 512 QAM and 1024 QAM are not available. However, the newer DOCSIS 3.1 technology does allow higher order QAM modulation.

7.3.1.2. Case 7: Add an OFDMA channel

As shown in Figure 31, another example is the traditional 4 upstream SC-QAMs up to 40 MHz, and then 40 MHz of OFDMA running at 1024 QAM from 42 MHz to 82 MHz.

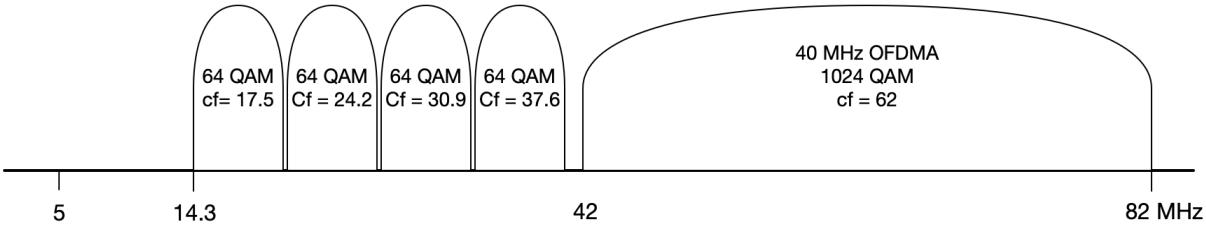

Figure 31 – Mid-split with Both SC-QAM and OFDMA channels

This configuration can yield up to 400 Mbps of aggregate upstream capacity and increase of 150 Mbps using the same spectrum because the OFDMA carrier can operate at a higher order of QAM modulation than the single-carrier QAMs.

7.3.1.3. Case 8: Replace with OFDMA

As shown in Figure 32, another example is shown using 70 MHz of OFDMA at 1024 QAM which can offer 525 Mbps of capacity.

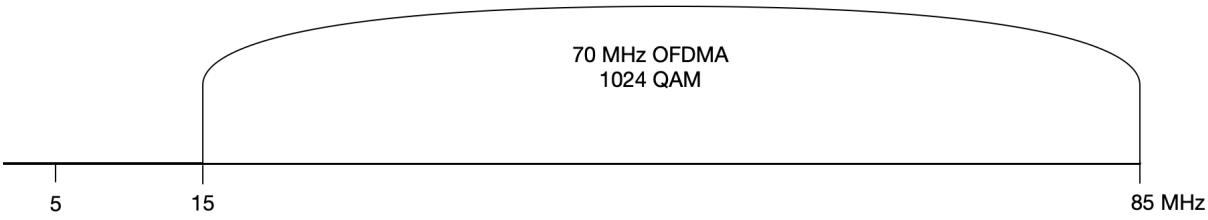

Figure 32 – Mid-split with All OFDMA channel

Though it may be necessary to retain a single SC-QAM upstream channel for DOCSIS 2.0 modems.

7.4. High-Split HFC Network

A high-split network has a return path up to 204 MHz, or four times the spectrum of a sub-split network. With a high-split, the forward path begins around 258 MHz hence set-top box-based video services cannot be maintained because the forward data channel (FDC) can only be moved as high as 130 MHz as described in the SCTE 55 standards.

However, the additional upstream spectrum provided by a high-split network can provide more than 1.5 Gbps of capacity.

7.4.1.1. Case 9: Add a second OFDMA

Figure 33 shows a configuration that retains the four SC-QAMs for DOCSIS 3.0 (and earlier) modems and uses the rest of the spectrum for OFDMA using up to 1024 QAM modulation.

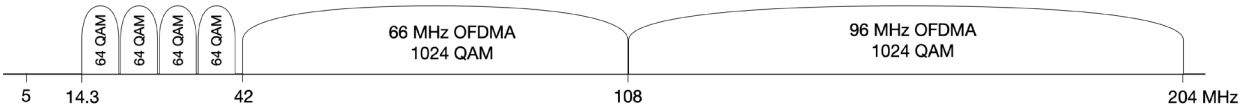

Figure 33 – High-split with Both SC-QAM and OFDMA Channels

This configuration can provide up to 1.3 Gbps of capacity while retaining backward compatibility for DOCSIS 3.0 and earlier modems.

7.4.1.2. Case 10: Full OFDMA

Figure 34 shows all the high-split spectrum using OFDMA and this configuration is capable of over 1.6 Gbps of capacity.

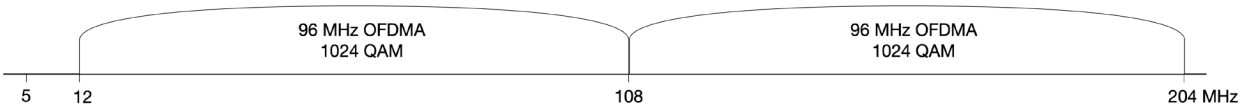

Figure 34 – High-split with All OFDMA Channels

7.5. Ultra-high split Networks

The DOCSIS 4.0 specification builds upon DOCSIS 3.1 OFDM and OFDMA technology with an extended Frequency Division Duplex (FDD) DOCSIS alternative. DOCSIS 4.0 FDD supports both mid-split and high-split and provides extended upstream splits up to 684 MHz in an operational band plan that is referred to as Ultra-high Split (UHS). DOCSIS 4.0 FDD also introduces expansion of usable downstream spectrum up to 1794 MHz to support the higher upstream splits.

8. Conclusion

For the past 20 years in most of the world, the DOCSIS upstream has included up to four SC-QAM channels. With DOCSIS 3.1 technology, OFDMA technology became available for the upstream. As compared to SC-QAM, OFDMA has more configuration options which can be used to optimize upstream efficiency.

As DOCSIS technologies evolve, so do the tools and understanding the operators need to ensure that their networks are running as efficiently as possible, while still maintaining robust service offerings. There is a fundamental trade-off between robustness and throughput. This paper analyzes those trade-offs and discusses methods to increase the efficiency of the DOCSIS upstream. Included are discussions on:

- SC-QAM technology,
- OFDMA technology,
- Interference considerations when combining SC-QAM and OFDMA on the same upstream,
- DOCSIS protocol efficiency,
- Adding more spectrum to the upstream.

A first step to increase upstream efficiency is to use as much of the available spectrum as possible with existing SC-QAM technology. SC-QAM technology has a well-established history and experience, though potentially less flexible when compared to OFDMA technology. There are still multiple parameters like minislot size or FEC size choices which when optimized will improve the upstream efficiency.

A second step includes consolidating SC-QAM technology and allocating spectrum to OFDMA technology. Mixing both SC-QAM and OFDMA technology on the same upstream allows support for older cable modems (DOCSIS 3.0 technology and earlier) as the penetration of DOCSIS 3.1 modems increases. Adding OFDMA allows the DOCSIS 3.1 modems to take advantage of the newer technology to increase the overall throughput of the upstream.

OFDMA technology can provide more flexibility for spectral efficiency but carries more configuration complexity to be considered across all networks as well as individual network conditions. A prerequisite for deploying OFDMA technology is working through the optimal configuration of the upstream parameters which include trade-offs for robustness and capacity. For example, an operator needs to understand how a CMTS enforces guard bands in the upstream and think through the implementations of TaFDM on the CMTS. The overhead of the cyclic prefix can gain robustness but at the cost of capacity. The 2K FFT is more robust and the 4K FFT provides more throughput. 4k is more efficient than 2k for reasons of narrower receive spectral window and required CP being half the symbol period, 4k also interferes with adjacent SC-QAM less. Designing profiles to match the channel conditions on a particular part of the plant, using a profile management application (for OFDMA and SCQAM channels) allows an operator to gain robust operation and extra capacity. OFDMA is worth the effort because it is the new foundation for upstream technology just as OFDM has become the new downstream technology.

Lastly, to get more out of the upstream consider adding new spectrum by changing the upstream split. Just continuing to segment the HFC network does not provide more speed, rather, segmentation replicates the existing spectrum and provides the same speeds for fewer users which does have benefit but does not enable the true capability of the HFC network. To get to both more upstream capacity and really fast speeds, more spectrum must be allocated to the upstream. This new spectrum should be allocated to OFDMA technology to make the best use of it.

Abbreviations

AP	access point
AWGN	average white gaussian noise
bps	bits per second
CM	cable modem
CMTS	cable modem termination system
CP	cyclic prefix
CW	continuous wave
dB	decibel
DOCSIS	data over cable service interface specifications
FDD	frequency division duplex
FDX	full duplex
FEC	forward error correction
FFT	fast Fourier transform
GB	guard band
Gbps	gigabits per second
HD	high definition
Hz	hertz
IUC	interval usage code
kHz	kilohertz
MAC	media access control
Mbps	megabits per second
MER	modulation error ratio
MERperSC	modulation error ratio per subcarrier
MHz	Mega hertz
MSyms/sec	Mega symbols per second
OFDM	orthogonal frequency division multiplexing
OFDMA	orthogonal frequency division multiple access
PMA	profile management application
PNM	proactive network maintenance
QAM	quadrature amplitude modulation
QPSK	quadrature phase shift keying
RNG-RSP	ranging response message
RP	roll-off period
RxMER	received modulation error ratio
SC-QAM	single carrier QAM
SCTE	Society of Cable Telecommunications Engineers
TaFDM	time and frequency division multiplexing
UHS	Ultra high split

1. Introduction

Last year's paper, titled "It's 10 PM: Do You Know Where Your Wavelengths Are?" provided an overview of Comcast's move into Distributed Access Architectures (DAA) and the need to reinvent how we manage and monitor fiber assets. The DAA architectures call for individual fiber nodes to be smaller and placed farther out into the network which leads to a significant increase in the number of fiber assets that are being installed. All this new fiber needs to be monitored and managed.

"It's 10 PM: Do You Know Where Your Wavelengths Are?" highlighted several innovations in fiber monitoring using a triad of tools. This includes a headend racked Optical Time Domain Reflectometer (OTDR) and Optical Spectrum Analyzer (OSA) monitoring device capable of continuous monitoring of 48 fiber links, a handheld optical meter, and cloud integration software and storage. With these tools it becomes possible to quickly identify fiber cuts and other service impacting fiber degradation events. The tools are used to accurately locate fiber cuts with closest address and cross streets and determine the service impact caused by these events.

But we still find ourselves with a tremendous amount of fiber unmonitored. DAA calls for a great deal of new construction of fiber, and that infrastructure gets much attention and focus. At the same time, we still maintain a huge legacy network. Existing analog fibers, commercial subscribers, and fiber to the premise products also have fiber assets to manage and monitor.

When any unmonitored fiber is cut, a human technician must identify the root cause of the damage. This can sometimes take hours of time -- just to isolate the location of the cut. Yet the goal is that our fibers will not be left alone or dark for long. Whether DAA or legacy infrastructure, digital or analog, residential or commercial services, all services can and will benefit from improved fiber monitoring tools.

"With the CPM (Continuous Pervasive Monitor), we provide infinite attention to individual fiber links with continuous and pervasive monitoring." -- Venk Mutalik, Executive Director / HFC Architecture, Comcast, 2021, in an interview for this paper

In this paper we will explore the steps being taken to expand coverage of our fiber monitoring capabilities. This includes process changes in our operational and development organizations, configuration optimizations and automation to help manage information on hundreds of thousands of fiber links and introduce a new optical passive hardware solution to address physical limitations such as bad optical test ports. We will also cover some of the latest features that have been built into these tools. Enhanced GIS mapping and location of fiber events. Network DVR and time averaging to play back data over time. Refined dispatch tools that combine information about our fiber optics with real time customer equipment status, commercial power outage impacts, and natural disaster events. And we have learned about specific event signatures that allow us to build workflows to automatically route alarms and instruct a fix agent on what to do in easy-to-follow steps, removing a lot of the human guesswork necessary to isolate root cause and required fix. Join us in our ongoing documentary as we improve our fiber monitoring capabilities.

2. DAA Systems

In a DAA system, a CMTS core is located at the Primary Headend (PHE) sending digital signals over fiber optic strands out to a Secondary Headend (SHE). The SHE contains a collection of equipment organized together into a DAA Switch Point of Deployment (DAAS POD).

In the POD, one of the components is the new Continuous Pervasive Monitor (CPM). The CPM is a 48-port rack-mounted device which includes a 1611nm OTDR and an OSA for monitoring individual fiber links. This monitoring unit is capable of continuously tracking fiber length with the OTDR, to isolate physical abnormalities within the fiber strand, while the OSA is full fledged spectrum analyzer on the C-Band and provides monitoring of all wavelengths of light present on the fiber. These monitoring capabilities allow us, in near real-time, to detect when a fiber length shortens, indicating a fiber cut. This monitoring unit also allows us to track when power levels on existing wavelengths go down, when specific wavelengths disappear, or when wavelengths show up that were previously not there.

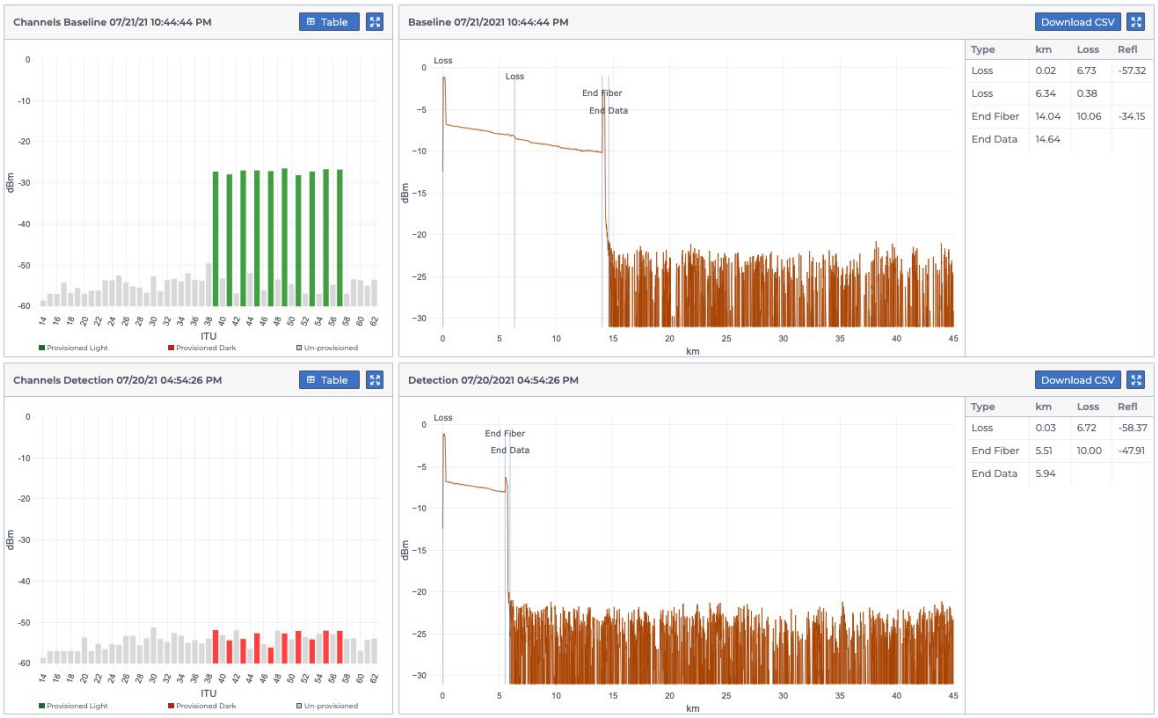

Figure 1 – Event View: Baseline vs Fiber Cut Side by Side

In a DAAS POD, each CPM port is connected to the Inside Plant Multiplexer (ISP MUX) test ports for monitoring of the fiber links and wavelengths served by this DAAS POD. The ISP MUX is a hardware component that takes many different wavelengths of light and combines them together onto a single fiber strand, enabling dozens of wavelengths to share transport on a single fiber. The ISP MUX is paired with an Outside Plant MUX (OSP MUX) in the field to separate those wavelengths back out and send them on to individual fiber nodes.

These new monitoring and troubleshooting tools provide next generation capabilities to pair with our next generation networks, allowing us to pinpoint root cause of a major outage event within minutes. Not only are we alarming on the outage in 90 seconds, on average, but also immediately identifying the root cause

of the outage and where the break in the network is located -- both as a distance from the headend, and with an estimated geo-location, including latitude and longitude, and a list of all impacted services. This detailed data combined with plant design data allows us to know where to drive to find the cut, what kind of fiber is installed there and if it's aerial or underground plant, and how many other fiber strands are in the same bundle as the fiber in alarm. 100% of new DAA installations are required to be installed with these next-generation tools.

3. Legacy Systems

Although DAA currently takes the spotlight and the most focus on fiber monitoring coverage, we still maintain a tremendous amount of legacy architecture with existing fiber links that serve millions of subscribers. They also need to be monitored better than we do today. The good news is the CPM monitoring tool is not specific to DAA architectures and can be deployed as a monitoring tool on legacy systems as well. That said, there are some specific hurdles to overcome for legacy-facing deployments.

For example, one advantage of DAA is that for new construction, we use all the latest technology, including ISP MUXes that have consolidated test ports. These consolidated test ports provide convenient access for monitoring fiber assets with the CPM, because a single test port can connect to a single monitoring port and provide monitoring capabilities for both OTDR and OSA features. Legacy architectures are not as consistent on what is available for test ports on older equipment. In many cases there are no functional test ports available at all, presenting challenges about how to connect the headend monitoring equipment.

For these cases where there are no available test ports for our monitoring equipment, there is a new rack-mounted device with inline optical test points that can be placed in-line between the ISP MUX and Outside Plant (OSP) MUX. This device samples a small amount of light from the fiber optic strands, for the CPM to monitor. Connecting this equipment in-line removes the dependency on available and functional test ports. This optical device only reduces the optical power levels by about 0.5dBm, which in practice has negligible effect on plant performance. The gains that we see in improved fiber monitoring are well worth the small loss of power.

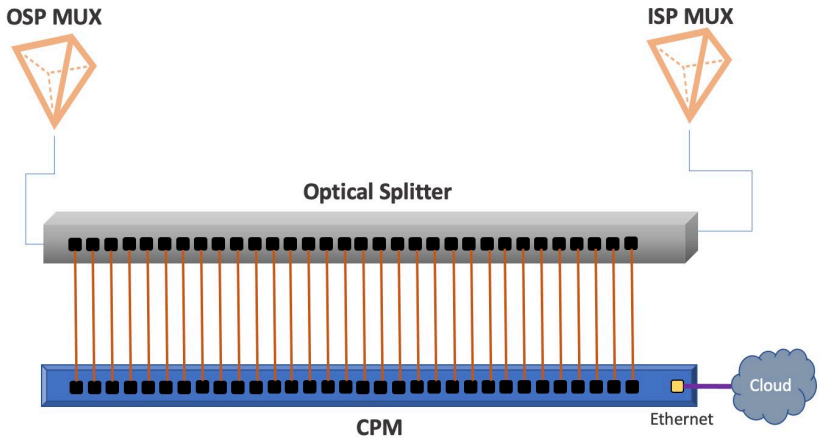

Figure 2 – Inline Optical Test Points Connected to CPM

In other situations, we do have functional test ports available, but they do not support consolidated OTDR and OSA measurements. In these cases, we have modified the CPM software to logically combine 2 physical ports for monitoring of a single fiber link. In this situation, we configure one port to perform the OTDR functions, and another port measures the OSA channels. The application then combines these two ports for monitoring and alarming purposes, so we represent them as a single fiber link to the end user.

Other legacy scenarios include the need to monitor analog optics, or to monitor fibers with wavelengths that are outside the range of the OSA. Both the OTDR and the OSA feature of the CPM are capable of operating independent of each other. The OTDR feature can monitor a fiber for length and physical abnormalities on its own in cases where we do not have visibility into the wavelength power measurements. And the OSA feature can be used independently to monitor wavelengths in places where the 1611nm laser is blocked from giving us monitoring visibility of the physical fiber attributes. We have many reasons to be optimistic about our legacy networks benefiting from these new innovative monitoring technologies.

4. Handheld Optical Multimeter & OTDR

This past year brought many new powerful features to the handheld unit. The home screen has new intuitive control bar and menu selection area for the technician. The control bar provides real-time status on both the handheld unit and the SFP connected to it. There is a real-time indicator for laser status, whether the SFP is programmable, the current ITU wavelength configured on the SFP, and a threshold warning if there is too much power coming into the OSA or OCC ports. There is now an SSO login, for technicians to connect their scans to their account in the cloud. The control bar also provides status on WIFI connection, power status, and battery levels.

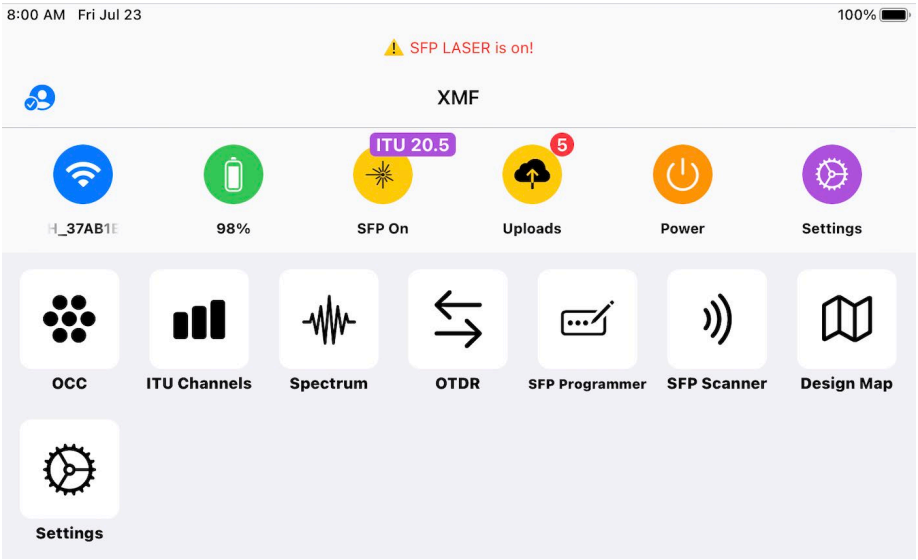

Figure 3 – Handheld Unit – Control Bar and Menu

With the SSO login integration and ability to upload scans to the cloud, we now can search and view those scans by technician, job ID, node, or geographical bounds drawn on a map. This allows the user to compare different scans taken at different times or locations, view progression of a particular job, and hand off information about a particular job from one technician to another.

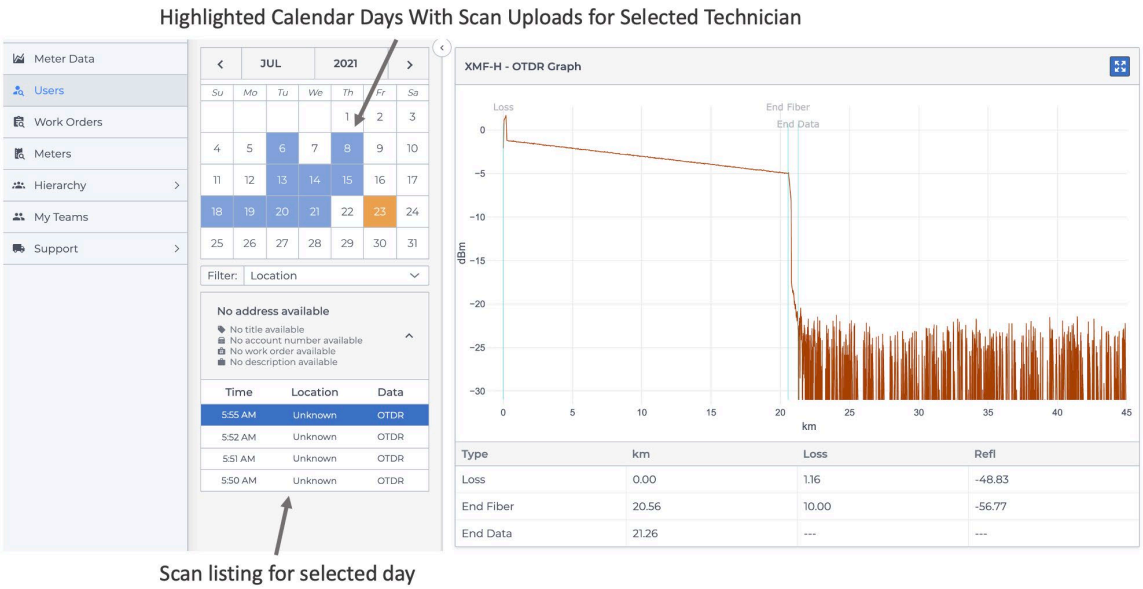

Figure 4 – Cloud Navigation for Uploaded Scans (Technician View)

The handheld device also includes an Optical Channel-band Checker (OCC) which is a quad-band power meter that can sense power levels on the fiber. The OCC provides power measurements across the entire usable spectrum. It measures and displays the detected power levels, grouping them into four bands:

- 10G EPON Downstream (L-Band 1577 mm)
- BAU DWDM (C-Band 1550 nm)
- 10G EPON Upstream (O-Band 1270 nm)
- All Other Bands not specified above

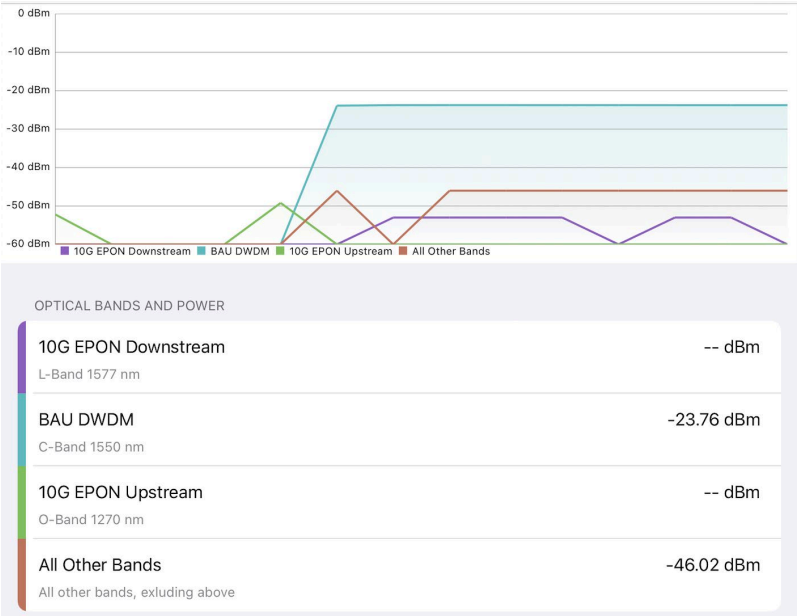

Figure 5 – Optical Channel Checker Application View

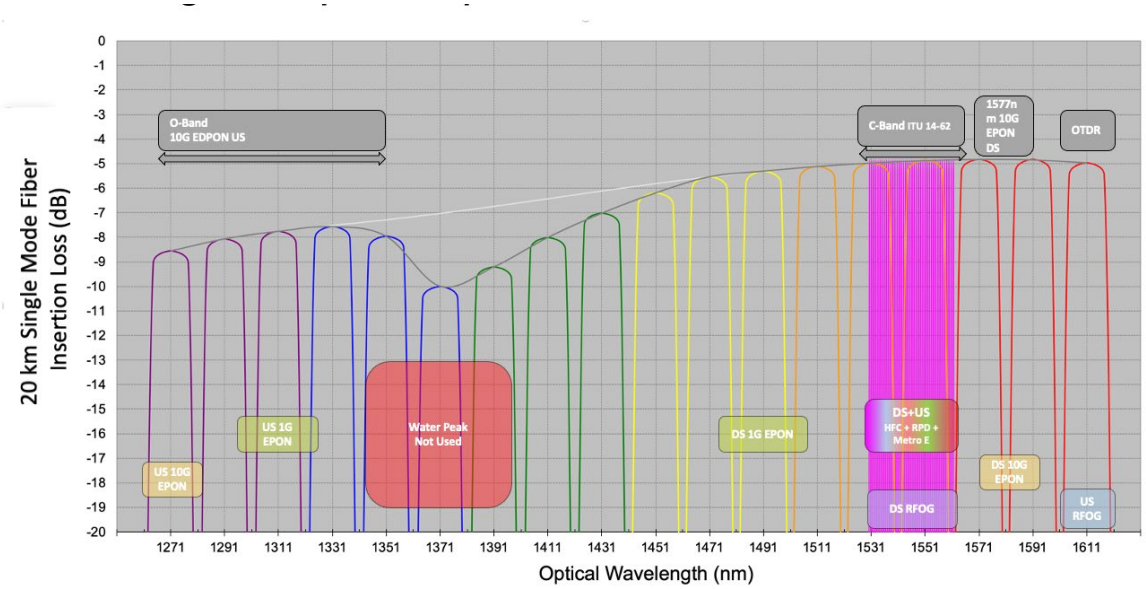

Figure 6 – OCC Wavelength Band Overview

Another powerful new feature on this platform is the integration of the handheld device with the headend rack-mounted CPM. With these technologies integrated with the cloud, a technician can be out in the field troubleshooting an outage. While physically located miles away from the headend, the technician can remotely search the system for the fiber being tested, and connect to the CPM that is monitoring the same fiber link. The technician can trigger an OTDR from the headend, down the fiber link, and within seconds shoot the fiber from their current location back towards the headend with their handheld device.

With cloud storage, all measurements are stored for future playback and analysis, and to provide visibility to other technicians who may need to assist with the same outage. The combination of headend and handheld equipment is designed with a similar look and feel, and with comparable features on both platforms. This helps to foster a common language and a shared platform used by both the headend and field technician, where the two disciplines now overlap in ways that were not previously possible.

While connected to the remote CPM in the headend, another benefit to the technician is the ability to be "virtually hands-on" with a fiber strand located miles out into the network, taking measurements of the fiber from the perspective of the headend CPM. For example, by creating a bend in a fiber strand, the technician can look for loss in the micro bend on the OTDR traces of the CPM, enabling validation of the fiber strand and where it connects. Changes to the network can be made instantly and verified by the changes in the receive power at the headend.

While troubleshooting the network and requesting live traces from the CPM, the software is also configured so that the continuous monitoring feature doesn't miss a beat. The CPM can quickly switch between ports as part of its ability to monitor 48 fibers with a single optical receiver. This switching capability allows a technician to request live data from the CPM, and this request is interleaved with the scans that are required for ongoing monitoring. The CPM creates a queue for any live requests coming in, and any live requests are processed in the order received. But no matter how many live requests are in queue, every other scan is still prioritized for continuous monitoring. This matters because we will never miss detecting the next major outage and creating a dispatch ticket with detailed information about that fiber cut, while in parallel we can still provide real-time troubleshooting capabilities to the technicians working in the field.

5. Installation and Configuration

With a target of 100% of DAA architecture including CPM monitoring on every fiber link, keeping up has proven challenging. The initial installation of the CPM requires power, network, and configuration for every wavelength being served. And BAU updates over time need to be updated on the device configurations.

Manual configuration of each fiber link and wavelength becomes a tedious and time-consuming process as the number of DAA installations increases. The hours required for manual configuration has been one of the roadblocks encountered in our efforts to get 100% adoption from the field. This led to one of the major new features enhancements this year, allowing configuration that scales and better acceptance from the user base managing these configurations. This new feature is bulk import capabilities from the fiber configuration spreadsheets used by each local headend.

Each headend is already required to maintain an up-to-date configuration of its fiber links, and the format of these configuration sheets is standardized across the various regions. By supporting bulk configuration of the data format already in place, this reduced the configuration time from a multi-hour effort to just a few minutes.

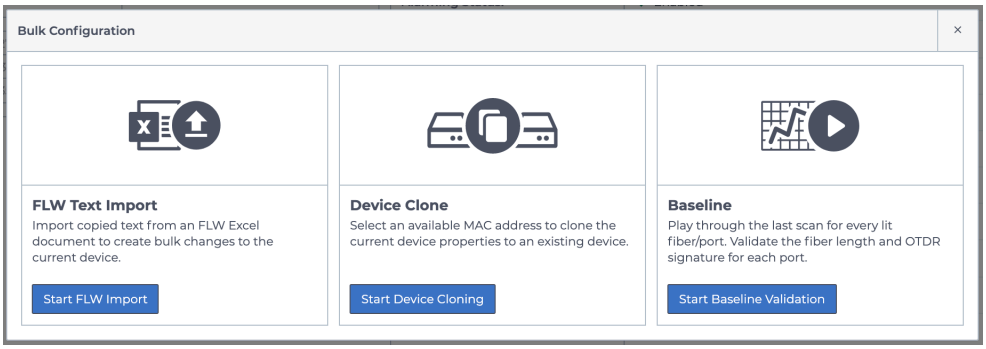

Figure 7 – Bulk Configuration Selection Screen

The next phase of configuration automation is to centralize all the local fiber configuration data into a database, with APIs the CPM can use to fully automate the configuration and relationships between ISP MUX, OSP MUX, CPM, wavelength, and fiber node. By centralizing and providing APIs to access all the fiber configuration data, the additional configuration required that is specific to the CPM becomes minimal, and the installation process for the CPM becomes scalable even for a busy field operations staff. By centralizing fiber configurations into a database, we also enable the CPM to receive real time updates as BAU configuration changes are made over time.

Another critical element of configuration is establishing a baseline of the expected fiber length, as well as the expected power of each wavelength at the receiver in the headend. The baseline is what allows us to determine if a fiber is short or if individual wavelengths are degraded from their normal operational state.

The initial plan was to manually certify each baseline by putting "eyes on glass," and allowing a person to identify flaws in the OTDR trace that may have "slipped through the cracks." This provides an opportunity to clean up bad splices or other physical flaws during the installation process and provides a better physical network that gets handed off to operations after installation and configuration.

Although manual verification was well-intentioned, as we started to deploy monitoring on what quickly became thousands of fiber links, it became a roadblock to field adoption of the tool and willingness to put in the time to configure. So, we pivoted to an automated baseline feature where the software looks for trends over time. When we have specific wavelengths that stay continuously lit for a specified period, this triggers that wavelength to become eligible for ongoing monitoring. And during this time, when we flip wavelengths from unmonitored to monitored, the automation software updates the baseline for that link with the current length of the fiber and the power levels of the wavelength. In addition to the automatic creation of fiber baselines, the automation software also must be aware of trends over time and watch for fibers that may have been decommissioned or changed monitoring ports.

Another installation and configuration feature that has been added is related to how we monitor various fibers with different physical attributes. For DAA, we see fiber lengths ranging from a few hundred meters to 50 km or more. We have variations in the amount of light coming into the headend receivers. And there are various kinds of glass strand and physical anomalies in the fiber link that lead to different attenuation and refraction patterns.

With the OTDR portion of the CPM we continuously monitor the length of fiber looking for when the fiber is cut or damaged. The challenge has been that an OTDR must be tuned to accurately analyze the fiber strand based on distance and other physical properties.

One of the tuning parameters is pulse width. A short pulse width provides a small "dead zone" at the beginning of the fiber, where this dead zone represents a blind spot where it is not possible to accurately measure the end of fiber or find anomalies. A short pulse width also provides the ability to detect distinct events that are stacked close together. However, a short pulse width also reduces the dynamic range of what we can measure, so in cases where there is a high amount of attenuation in the DAAS POD installation, the short pulse width can cause the signal to get lost in noise before being able to measure the end of fiber. Short pulse width also loses its energy over long distances, so the signal gets noisy at longer distances.

Long pulse widths provide better dynamic range, but we lose monitoring capabilities within the blind spot of a longer pulse width/ larger dead zone. And we lose granularity.

Averaging time is another tuning parameter available to us. In general, the greater the averaging time, the better the results on the OTDR trace. But the cost of higher averaging time is longer time to fiber cut detection. As the CPM loops through the 48 ports, it is looking for fiber cuts and other events in real time. If the averaging time is set too short on a particular port, we gain a quick measurement but lose to a noisy signal and inaccurate analysis of what is happening on that fiber. If the averaging time is too long, we gain accuracy but lose on the time it takes to detect a significant issue like a fiber cut.

IOR (Index of Refraction) is another parameter that is important to tune so as to achieve accurate distances on the OTDR analysis. IOR is a representation of how fast light travels through a particular medium. Set IOR too low, and all the distances measured will be too long. Set IOR too high and all the distances will be too short. Inaccurate distances cost the field technician time when trying to find a fiber cut. And inaccurate distances also can cause us to misidentify which sheath the fiber is contained in, which gives us access to what other fibers are bundled together, and then what other services are connected to all those fibers in the sheath -- which may all be down, if the entire sheath is cut.

To solve these different tuning requirements, we continue to look to automated configurations based on fiber design, combined with AI and machine learning using the data collected and stored in the cloud. This allows us to customize the settings for each individual fiber link.

6. Cloud Integration

One of the most empowering new features that these new tools have added is integration with the cloud and other internal tools, to enrich the data we gather and publish. In the handheld meter, one of these features is integration with node inventory and jobs. Field technicians are often troubleshooting fiber nodes, and one of the features in the handheld meter is the ability to search for a node to tag onto existing scans. By tagging scans with a fiber node (or other equipment), when the scan is stored in cloud this data is indexed on node name. This allows anyone to search the cloud for scans that have been taken on this node over time, which provides visibility into patterns and historical context. Another feature for the field technician is "job search," where a technician can tag handheld meter scans with a job currently assigned to them. The job association allows the work the technician is doing to be visible to others, which benefits other technicians if an issue is escalated to them, or it gives more visibility to all technicians working the same job in tandem.

On the CPM headend tool, another focus over the past year has been enhanced DVR functionality. The DVR is a tool that allows the user to view a particular fiber link over time, in a movie-like experience, where every scan taken over the selected period is played back in sequence at a selectable frame rate. As the user watches the playback, they can isolate changes in pattern and visualize how the OTDR trace changes over time.

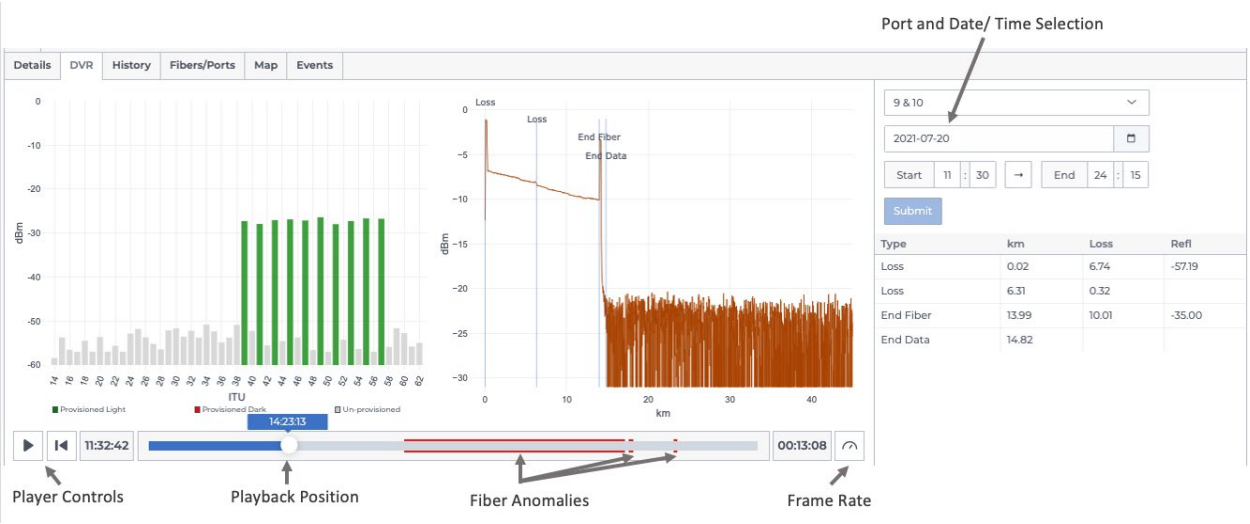

Figure 8 – DVR Playback View

An alternate tool to the DVR is the history tool, where the user can select a time window, but instead of playing frame by frame, they are presented with min, max, and average lines over the selected time.

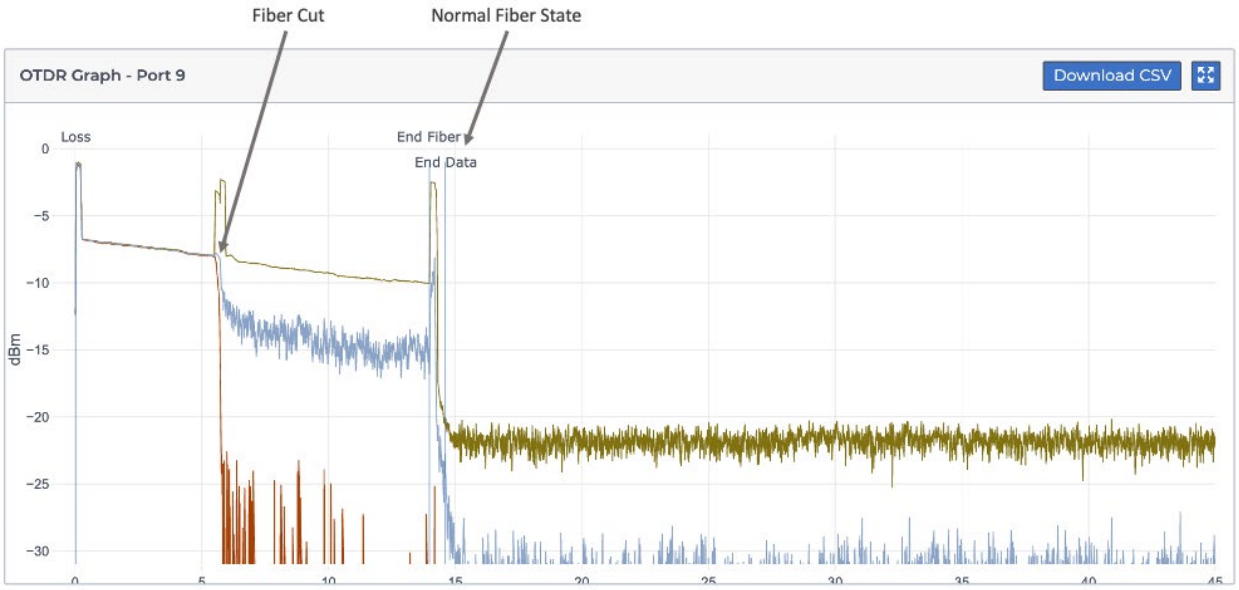

Figure 9 – Historical Averaging View

7. Validating Design Maps

One of the ongoing efforts is to validate the design data for our fiber assets. All our fiber assets are stored in a GIS asset database that includes the physical path where the fiber travels, the length of each fiber segment, and includes the helix factor, amount of sag, and amount of fiber contained in slack loops. By using the OTDR and measuring physical distance from the headend, we can audit the design data to validate distances and correct mistakes that are found. We can also store regional averages for helix, sag, and slack that let us better estimate fiber cut locations by adjusting the distance of the fiber to account for the regional helix, sag, and slack averages. One of the other benefits of our GIS asset database is that the entire fiber run is connected in the database from the fiber node to the headend. With this connectivity, we can trace from the fiber node to each splice, through MUX and various fiber sheaths, to the termination panel, OCEF, and ISP MUX in the headend. With access to all the physical connections being made along the fiber path, we can correlate specific events in the OTDR trace to specific equipment. We can also help audit the GIS asset database to flag fiber lengths that do not match the OTDR measurements and provide reports to the field that can be used to clean up bad or missing data.

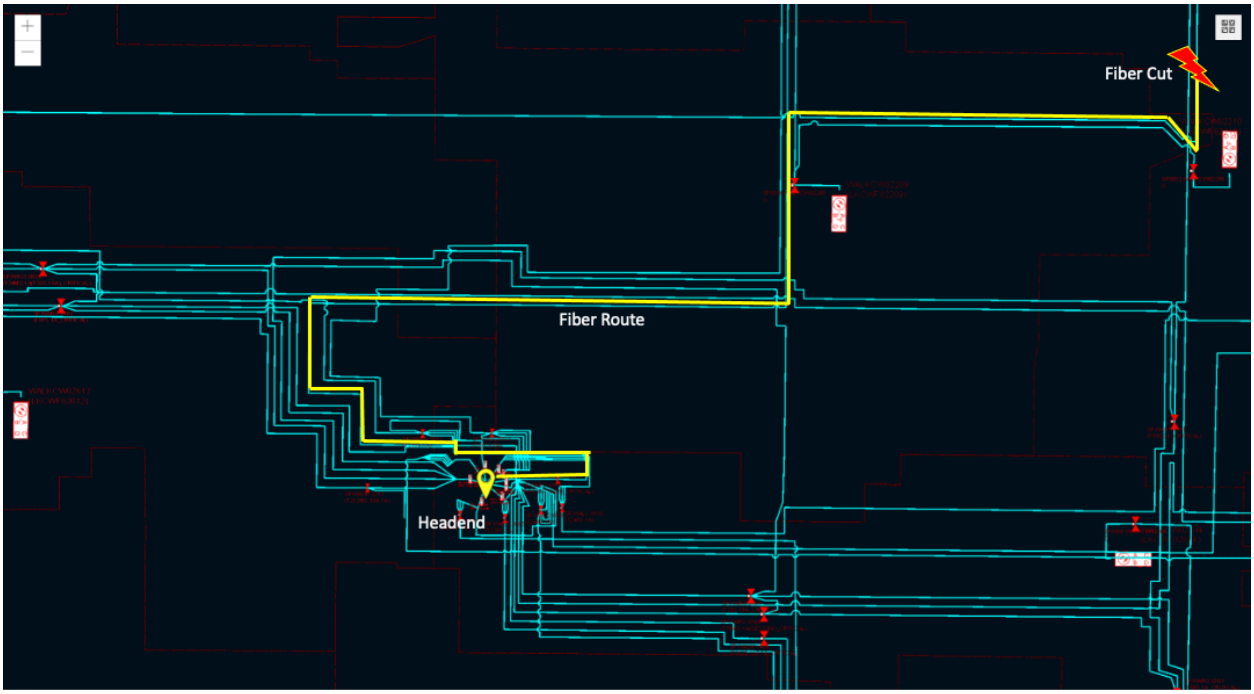

Figure 10 – GIS Asset Maps/ Route to Fiber Cut

8. Natural Disasters

Another opportunity for the CPM to provide unique value is for large scale natural disaster events. During these large events, there are an overwhelming number of alarms that are generated by all the different monitoring tools on the network. Trying to triage the alarms and work them in a prioritized order is not an easy task. The OTDR fiber cut detection capabilities of the CPM becomes an amazing tool to help with this prioritization process. With the OTDR functionality, identifying a fiber cut is highly accurate. Many of the other alarming tools deployed on our network are good at finding outages but require manual research to find the root cause of the outage. The CPM can immediately identify root cause for an outage

as a fiber cut. Combining the fiber cut with configuration data that tells us what is deployed on that fiber lets us identify the scope of impact of each fiber cut that is still active and helps the field better triage which cuts they want to fix, in what order.

Another reality with natural disasters is that during large scale events there are some outages that stay open for many days, or, in rare cases, many weeks. As the CPM tools get better about learning the network and setting baselines, we also need to program the tool with a method to anticipate these large-scale events, so the tool behaves in an appropriate way in context of all open alarms. For example, one of the asks of the CPM is the change the baseline length of a fiber in cases where there has been an intentional change to the fiber length. These scenarios happen in cases like node splits, or when the headend makes physical configuration changes. If the fiber monitored by the CPM does physically change, the baseline needs to change with it. One method to automate this change is to look for configuration changes applied in the fiber configuration data. But we do not always have visibility into those configuration changes. In these cases, we can look for trends on the physical characteristics of the OTDR trace and decide when to update the baseline using those trends. But then in a disaster scenario, we want to suspend those trend-based updates, so the algorithms do not make mistakes like setting a fiber to "inactive" in a case where we have a real and ongoing customer-impacting fiber cut.

9. Conclusion

As we reflect on the past year and look at lessons learned and the new development that has gone into this monitoring platform since we last convened to describe it, the value of this innovation continues to surpass what the development team had initially envisioned. Fiber optics are a critical part of the service delivery platform serving our customers, and our fiber assets continue to expand deeper into the network. Our customers rely on this network around the clock for video, internet, phone, home security, home automation, and emergency services. Our customers depend on our network in their everyday lives; therefore, reliability is of paramount importance. Fiber optic monitoring tools are one of many ways we are improving on that reliability. We began with DAA as the target for these tools, but over time we continue to uncover so many remarkable new opportunities to provide better insight into our fiber optic networks. So many legacy systems, analog optics, commercial services, and fiber to the premise products can benefit from these monitoring innovations. And in parallel to the technology development, working with the field and operational leadership to shape process changes and training around these new products. We look forward to new discoveries of what this platform can do for our company. We also embrace this technology as just a single part of a broad effort at Comcast to build a culture of reliability across all products. We are winning the battle against fiber dark forces, ensuring that we wake up in the morning knowing our fiber is light and watched over.

10. Acknowledgements

OTDR and Optical Spectrum Analyzer technologies have been around for decades and are common tools used for monitoring and managing long haul fiber networks. But it was not until 2019 that our own Venk Mutalik, Executive Director of HFC Architecture was inspired to take these technologies used in long haul environments and apply them to the local fiber optic networks serving our residential and commercial customers. It has been a privilege for the team to follow Mutalik's technical leadership in our journey -- to take his invention and build enterprise scalable applications and tools that provide real operational value to Comcast.

1. Introduction

System leakage monitoring and detection in a Low-Split and Mid-Split world involves detecting leakage of transmissions originating from a CMTS, CCAP, R-MACPHY node and R-PHY node. Legacy methods for accomplishing this have been in place for many years and are well-understood.

In Low and Mid-Split scenarios, the aeronautical band from 108 MHz to 137 MHz lies within the downstream spectral band. With DOCSIS® 3.1 High-Split and DOCSIS 4.0 Ultra-High Split, the aeronautical band will fall within the upstream spectral band. As a result, system leakage monitoring and detection in High-Split and Ultra-High Split scenarios involves detecting leakage of transmissions that originate from a cable modem (CM). This requires a completely new way of approaching the problem.

The cable industry has made significant recent progress analyzing the alternatives available to solve the High-Split and Ultra-High Split leakage detection problem, specifying the necessary support in industry standards, and validating in laboratory and controlled outdoor environments. This paper discusses the progress that has been made on the most promising of these alternatives which has now become part of the DOCSIS 3.1 specifications.

2. Basic Concepts of the Chosen Solution

A paper from Comcast and Arcom Digital [4] described the problem well and offered four possible solutions. It suggested that the most viable of these alternatives is one where the CM is granted opportunities to transmit OFDMA Upstream Data Profile (OUDP) test bursts under the control of the CMTS, CCAP, or R-MACPHY node (hereafter referred to simply as "CMTS"), in an operator-specified leakage detection test spectral region in or near the aeronautical band. Figure 1 illustrates an example of such a leakage detection test region that is placed between 138.1 MHz and 139.7 MHz in an OFDMA channel that spans 108 MHz to 204 MHz.

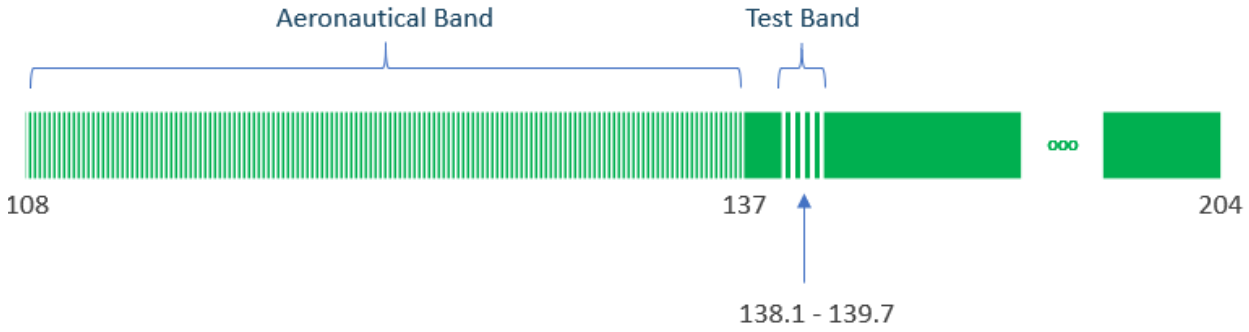

Figure 1 – Example Leakage Detection Test Region

DOCSIS 3.1 CMs are required to support transmission of OUDP test bursts on all OFDMA channels, as specified in [2]. An OUDP test burst has a specific MAC header and payload data format. It is transmitted by the CM using the modulation order and Pilot Pattern configured in a burst profile definition for the minislots granted to the CM for the test burst.

The CMTS is configured to make OUDP test burst grants covering the operator-configured leakage detection test spectral region. Field detectors tune to this spectral region and detect egress of the OUDP burst signal from the cable network by looking for the specific known Pilot Patterns from these test burst transmissions made within the region by CMs. The Pilot Patterns that are easiest to detect and

correspondingly provide the greatest detector sensitivity are those which are most densely populated with pilots. The two densest Pilot Patterns are illustrated in the [1] excerpts in Figure 2 and Figure 3. Pilot Pattern 4 is recommended for 2K FFT leakage detection test bursts. Pilot Pattern 11 is best for 4K FFT leakage detection test bursts.

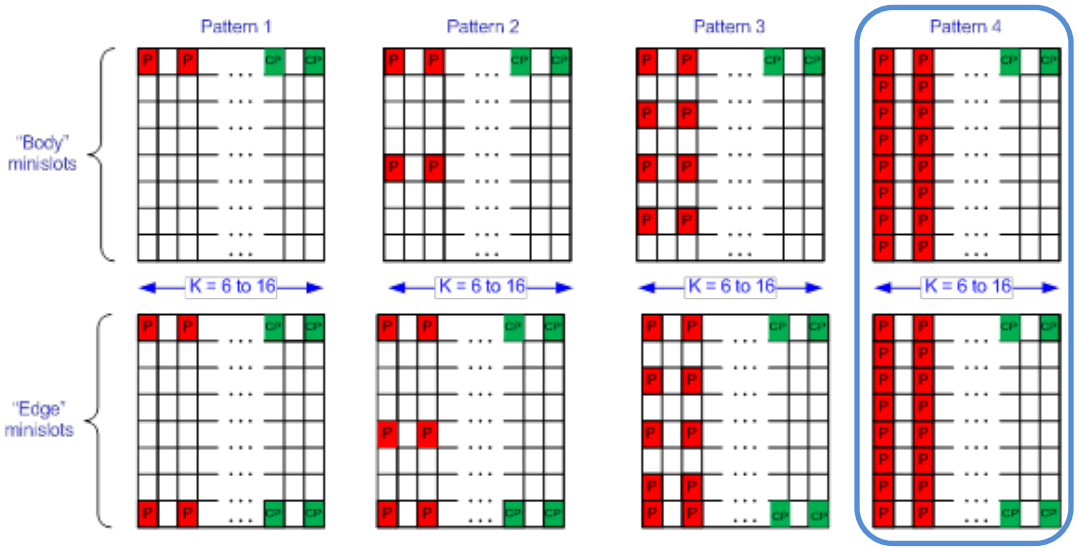

Figure 2 – Recommended 2K FFT Pilot Pattern for Leakage Detection Bursts

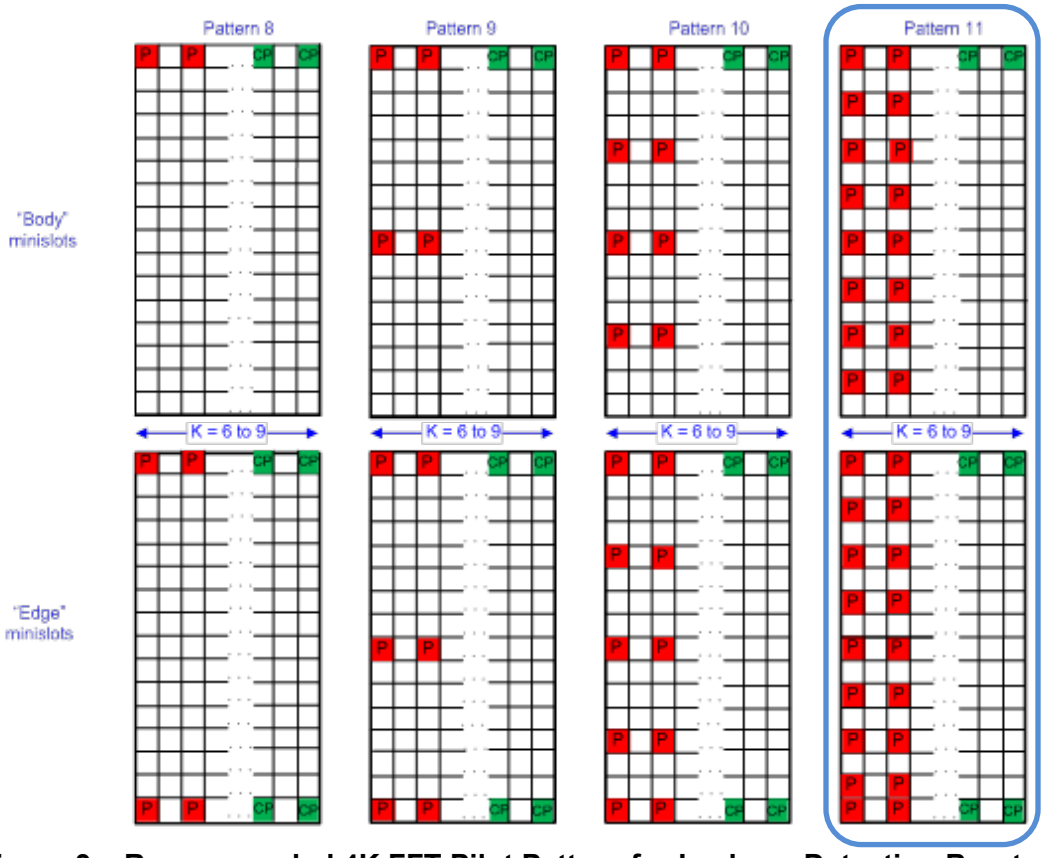

Figure 3 – Recommended 4K FFT Pilot Pattern for Leakage Detection Bursts

A user interface, Command Line Interface (CLI) and/or Application Programming Interface (API), is enabled at the CMTS to define the scope of leakage detection tests and to control scheduling of OUDP test bursts within the specified scope. For example, a CLI would specify which CM(s) to test, the frequency range of test region to use for grants, OUDP test burst duration, etc. An information model representing the configurable attributes for such a user interface has been specified in [3].

The user interface also supports reporting metrics that verify test performance. In a perfect world there will be no leakage detected. Without test metrics, there is no way for the operator to be certain that grants were made to CMs and that granted CMs responded with test burst transmissions. For this reason, a complete solution provides leakage detection test metrics per tested CM.

3. Leveraging the Solution

3.1. Leakage Detection Testing Use Cases

The DOCSIS 3.1 specifications support testing of a single CLI/API-specified CM, a CLI/API-specified ordered list of CMs, a CMTS-determined ordered list of CMs based on a CLI/API-specified upstream scheduling domain (e.g., OFDMA channel ID, MAC Domain), or CMTS-determined ordered lists of CMs created for every upstream scheduling domain in a CLI/API-specified scope, such as an entire CMTS or a specific R-PHY or R-MACPHY node.

The variety of use cases supported allows the operator to perform leakage testing according to their desired implementation. This facilitates lab testing of CMs for support of OUDP test burst capabilities and field detectors and applications for performance in various leakage scenarios. It enables both targeted (e.g., per CM, per upstream scheduling domain, per node) and sweep-based (e.g., per CMTS) testing and provides an opportunity to combine use cases to support maximum automation and intelligence in the leak identification process.

As one possible use case, consider a scenario with a theoretical Flexible MAC Architecture (FMA) MAC Manager which provides management functionality for three R-MACPHY nodes that are deployed in the same geographic area. Each of these R-MACPHY nodes has two Upstream Service Groups (i.e., upstream scheduling domains). A single leakage detection test session is configured at the MAC Manager to cover all three of these R-MACPHY nodes. All of the upstream scheduling domains in all of these R-MACPHY nodes will then simultaneously have leakage detection test sessions running. Each leakage detection test session automatically includes all DOCSIS 3.1 CMs which are currently using the specific OFDMA channel that is undergoing testing. This widespread sweep coverage approach, illustrated in Figure 4, is most suitable for operators that just want to set up leakage testing and leave it. It would also be appropriate at times when aeronautical flyovers are being performed for leakage detection. Leakage would be detected by field detectors encountering leaked signals from OUDP test bursts. Leakage can be isolated manually by monitoring detector strength-of-signal and detector proximity to the leak.

Automation can be introduced via field detectors equipped with GPS and associated leakage applications. Field detectors would transmit their current GPS locations to the application, and the application would communicate with the MAC Manager via an API to schedule testing, for example, only in those nodes which currently have field detectors operating in proximity to the node. Scheduling would need to be refreshed every few minutes to account for vehicle movement, but the process is easily automated. Since vehicles equipped with leakage detection equipment are only in a small percentage of nodes at any one time, this process could decrease the cumulative bandwidth required for leakage detection, allowing the test region to be scheduled for normal data transmission when there is no leakage detection occurring on the nodes where service vehicles are not nearby.

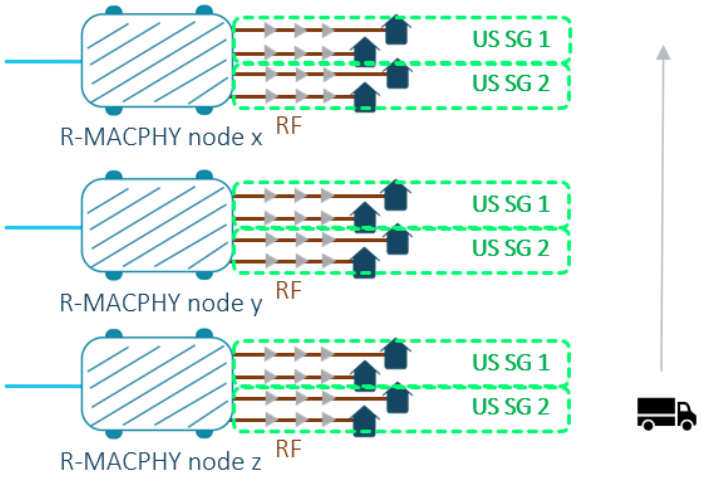

Figure 4 – Example FMA Leakage Detection "Sweep" Test

An alternative use case might be to configure test sessions using an ordered list of CMs. The list of CMs on-line and available to test could be provided by the MAC Manager to the leakage application using an API. The API then would instruct the MAC Manager as to the desired test burst sequence and the desired scheduler control parameters. Since CMs are generating OUDP bursts in a known order and the characteristics of the bursts are known, it is possible using intelligent detection algorithms to determine exactly which CM in the sequence was bursting when leakage was detected. This type of targeted leakage testing is illustrated in Figure 5.

The leakage application could then query a database that associates the MAC address of the CM causing leakage to the physical address of the leak such that repair can be scheduled. This could happen without the field technician leaving the vehicle. As such, utilizing ordered lists can potentially result in significant time savings in the last step leak identification process. The ordered list technique can also be useful in remotely determining whether the leak source is in the hardline (where multiple CMs could be detected as the leakage source) or the drop (where only one CM could be resolved as the leakage source).

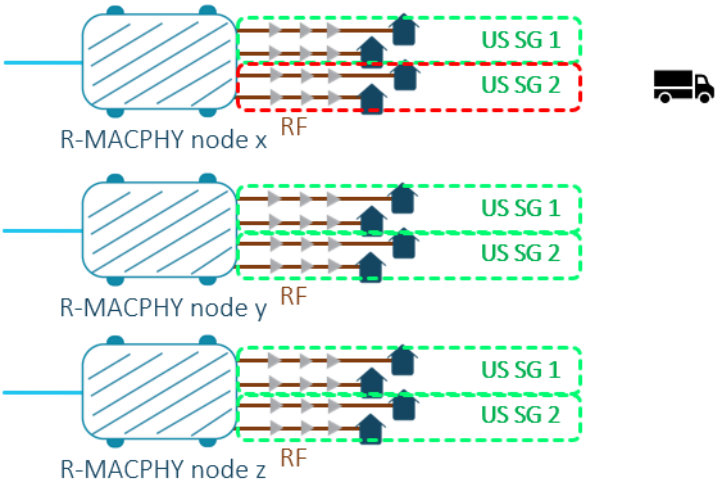

Figure 5 – Example FMA Leakage Detection Targeted Test

A similar process using an ordered list containing only one or a few CMs could also be used as technique to confirm that the CM whose transmissions are suspected to be source of the leak is in fact the exact source. In Figure 6, a single CM in an Upstream Service Group is specifically tested for leakage.

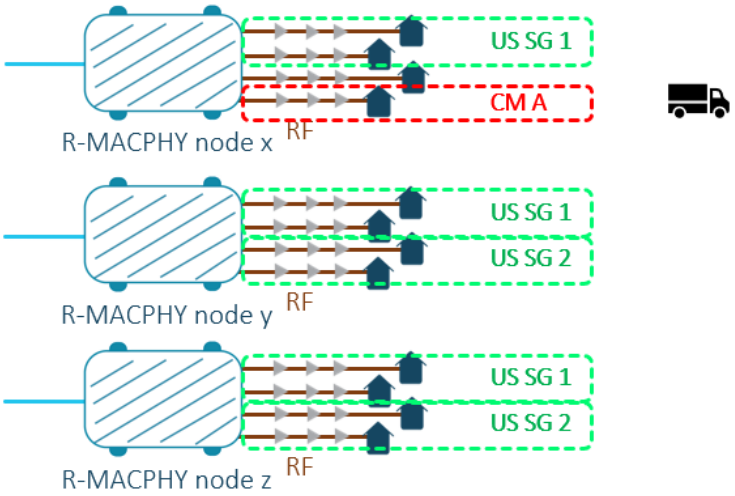

Figure 6 – Example FMA Leakage Detection CM Specific Test

3.2. Configuration of OFDMA Channels for Leakage Detection Testing

Operators are responsible for configuring their OFDMA channels to maximize data throughput. They are also responsible for OFDMA channel configuration aspects to enable leakage detection in High-Split and Ultra- High Split band plans. A leakage detection test region needs to be defined where OUDP test burst grants can be made to CMs by the CMTS. This test region can be in or near the aeronautical band, which lies between 108 MHz and 137 MHz. Ideally the test region is just above the aeronautical band so that leakage testing does not actually result in leakage into the aeronautical band.

A modulation profile, or Interval Usage Code (IUC), needs to be configured for leakage detection OUDP test burst granting into the test region. This profile must cover the minislots which fully span the leakage detection test region frequencies. The profile should also specify the densest Pilot Pattern available on the OFDMA channel for use in the test burst. As previously mentioned, Pilot Pattern 4 is recommended when the channel uses a 2K FFT and Pilot Pattern 11 is recommended when the channel uses a 4K FFT.

Since a DOCSIS 3.1 CM is only required to support two IUCs per OFDMA channel, it is recommended that the OUDP test burst configuration within the test region be assigned to IUC 13, which is generally the most robust profile. Another IUC can be defined to cover optimal data transmissions by the CM when the test region is not being used for leakage detection testing.

3.3. Configuration of Leakage Detection Testing Sessions

[3] specifies the configuration necessary for supporting a variety of leakage detection testing use cases. It defines a generalized information model that can be used for CLI-based or API-based implementations. The information model can be supported with CableLabs® standardized YANG code. A protocol for the API has not yet been specified by CableLabs®. Obvious alternatives are available such as NETCONF, which is a standard OSSI protocol, and gRPC/gNMI, which is becoming commonly used in Streaming Telemetry applications and in several FMA interfaces.

The configurable parameters provided by the information model are:

- Test region start and end frequencies
- Test scope:
    - Single CM MAC address or
    - Ordered list of CM MAC addresses in a single upstream scheduling domain or
    - Interface name of upstream scheduling domain (OFDMA channel ID, MAC Domain) or
    - Specific R-PHY or R-MACPHY node or
    - Full CMTS/CCAP/MAC Manager scope
- Scheduler control parameters:
    - Duration of test burst per CM, in number of frames
    - Duration of gap between CMs in a list, in number of frames
    - Duration of gap between cycles through a list of CMs, in number of frames
    - Scheduled start time of test (i.e., time of day; not precision timing)
    - Scheduled stop time of test (i.e., time of day; not precision timing)
    - Explicit immediate test enable/disable

Leakage detection tests are configured as independently controllable test sessions that focus on lists of CMs within a single upstream scheduling domain. Each session is identified by a session ID. When a leakage detection test session is created for CMTS, CCAP or MAC Manager scope, a master session ID is created as a control envelope for the independently controllable constituent test sessions in scope, each of which receives its own session ID.

3.4. Execution of Leakage Detection Tests

During a leakage detection test session, the CMTS upstream scheduler cycles through each list of CMs repeatedly and independently. Note that the single CM use case is a degenerate case of a list of CMs with only one CM in it. The rules followed by the CMTS upstream scheduler per configured test session are as follows:

- Grant OUDP test burst opportunities to each CM in the list over the entire test region spectrum and for the number of frames configured by burst duration
- Do not grant to multiple CMs in a given list in the same OFDMA frame
- Provide a gap between CM grants if one has been configured (intra-CM gap)
- Provide a gap between cycles through the list if one has been configured (inter-cycle gap)
- When a cycle through a list completes, including the intra-CM and inter-cycle gaps, start a new cycle through the list and continue this process until the test completes.

Intra-CM and inter-cycle gaps provide flexibility to support different scenarios. In one case it may be that the amount of time required to get through a full cycle is quite low and available time remains to transmit data. Gaps can provide the opportunity to do so. In addition, Probes need to be transmitted periodically by CMs as part of regular maintenance activities. Probes cover the entire spectrum of an OFDMA channel and cannot be scheduled if there is constant transmission of OUDP test bursts in the channel. As another example there several Proactive Network Maintenance (PNM) capabilities such as Active and Quiet Probe and Upstream Triggered Spectrum Capture where the entire OFDMA channel may be needed for other purposes for a specific period. Gaps in the leakage detection burst grant cycle can be leveraged for these activities as well.

Figure 7 illustrates a theoretical example of a 16 minislot OFDMA channel with a four minislot leakage test region. In practice the OFDMA channel will be much wider and there would be more data minislots relative to the test region. The test region in this example is being scheduled for four frames each to three CMs in the upstream scheduling domain. There is no intra-CM gap and there is a four frame inter-cycle

gap where the inter-cycle gap is being used for Probe transmissions and for data transmission. The CMTS scheduler inserted a P-MAP for the Probes and left the first two frames of MAP #3 for data transmission.

Figure 7 – Example Scheduler View with Leakage Detection Test Region

It should be noted that there are some differences in upstream scheduler processing rules for CLI/API-specified versus CMTS-determined lists of CMs. In CLI/API-specified list cases the cycle is not disrupted when CMs are not available to transmit (e.g., are offline). The unavailable CM is simply skipped in the cycle and its position is not granted at all. This preserves the timing of the cycle, which can be used algorithmically to determine when leakage is detected what CM was transmitting.

For CMTS-determined lists, the order of CMs is preserved but empty spots do not need to be maintained when a CM becomes unavailable. Conversely, if a CM becomes available during a test it can be inserted into the list by the CMTS. It is not expected that automatic determination of which CM transmission led to leakage is possible in this case. It is more likely that a manual detector strength-of-signal and proximity approach is used, or that the GPS location of the field detector at the time leakage is detected will be noted, and that further isolation will be required.

3.5. Leakage Detection Testing Metrics

In a perfect world there will be no leakage detected. Without test metrics, there is no way for the operator to be certain that grants were made to CMs and that granted CMs responded with test burst transmissions. For this purpose, the CableLabs specifications include metrics to count the number of OUDP test bursts granted per CM for leakage detection as well as the number of bytes received at the CMTS from the CM for these grants. There is also a “no burst received metric” available as an alternative to the bytes received metric. These metrics are shown in Table 1.

In combination with existing leakage detection verification mechanisms used for downstream leakage detection (e.g., service vehicle mileage and plant coverage records), these metrics can and will be used by operators in their reports to authorities, such as the FCC and CRTC, to prove the effectiveness and accuracy of their leakage testing operations.

Table 1 – Leakage Detection Test Metrics

Attribute Name	Units	Description
NumBurstsGranted	Grants	Count of grants made to a CM's OUDP Test SID during a leakage detection test session
NumBurstsNotReceived	Bursts	Count of bursts not received for bursts that were granted during a leakage detection test session
NumTestBytesReceived	Bytes	Count of bytes received for grants made to CM's OUDP Test SID during a leakage detection test session

3.6. Feature Interactions with Leakage Detection Testing

There are several feature interactions to consider with leakage detection testing. As previously mentioned, Probes need to be scheduled periodically for ranging-related functions such as determining CM transmit pre-equalizer coefficients, and for taking RxMER measurements. Probes consume minislots over the entire OFDMA channel and therefore cannot be granted when OUDP test bursts are taking place in the leakage detection test region of the channel at the same time. For this the CMTS implementation must either interrupt the leakage detection test session or make use of intra-CM and/or inter-cycle gaps. The decision is implementation specific. However, interrupting sessions where a CLI/API specifies the list of CMs to test can disrupt automatic determination of CMs causing leakage and is therefore not the best choice in such a scenario.

Similarly, the Active and Quiet Probe Proactive Network Maintenance (PNM) test relies on Probe grants to take measurements of underlying noise in an OFDMA channel at the CMTS. The same considerations as mentioned above apply to this PNM test.

OUDP test bursts were originally created to gather information on FEC performance or count CRC errors for a particular modulation profile. OUDP test bursts used for this purpose are generally to assign profiles to a CM for data transmission, which is typically done early in the lifetime of a CM's registration with the CMTS. In the same fashion as the Probe discussion, these bursts can either interrupt existing leakage detection tests or can be made to fit within intra-CM and/or inter-cycle gaps.

The DOCSIS specifications support a battery back-up mode for appropriately equipped CMs to transition into when they lose AC power. In battery back-up mode, CM functionality is taken down to a minimal viable subset of its full functionality to preserve battery life but at the same time keep the CM operational. It is implementation specific as to what the CMTS does in this case. On one hand, exempting the CM from leakage detection tests can save battery. On the other hand, if the CM transmissions are causing leakage it would be good to learn that.

Finally, DOCSIS Light Sleep and Energy Management Modes are supported in the specifications, even though not largely deployed. Having CMs that are otherwise idle transmitting OUDP test bursts as part of leakage detection testing clearly interacts with the CM's ability to sleep and conserve power. Once again, it is implementation specific how these features interact.

NOTE: Standards work on High-Split and Ultra-High Split leakage detection will continue as operators determine their strategies for deployment and field operations in the presence of these new capabilities.

4. Testing the Leakage Detection Solution

Significant progress has been made in demonstrating the viability of the OUDP test burst approach for leakage detection. Recently, successful radiated leakage detection was accomplished from an OUDP burst signal transmitted by a DOCSIS 3.1 CM. The test was significant and a milestone because the CM which generated the OUDP test burst was directed to do so by an R-MACPHY node using standard DOCSIS MAC Management signaling. This test was a natural progression from previous testing of the OUDP approach which was accomplished using test equipment which generated the OUDP test burst, or by using a diagnostic CMs instructed to burst directly via serial control.

4.1. Test Setup

The test setup is as shown in Figure 8. Using the R-MACPHY node's MAC Manager CLI, the OFDMA channel and test session configurations were input into the R-MACPHY node. The node then instructed the CM via DOCSIS MAC Management messages to generate OUDP test bursts according to the specified test session configuration. The coax output of the CM was connected to a reversed two-way splitter with one leg connected to node via the access network and the other leg connected to a transmit antenna to create a leaked RF signal over the air. The RF signal leakage was received by the field detector antenna – which measured the OUDP leakage signal level. The detector was configured and tested first in a lab and then vehicle mounted for drive-out testing.

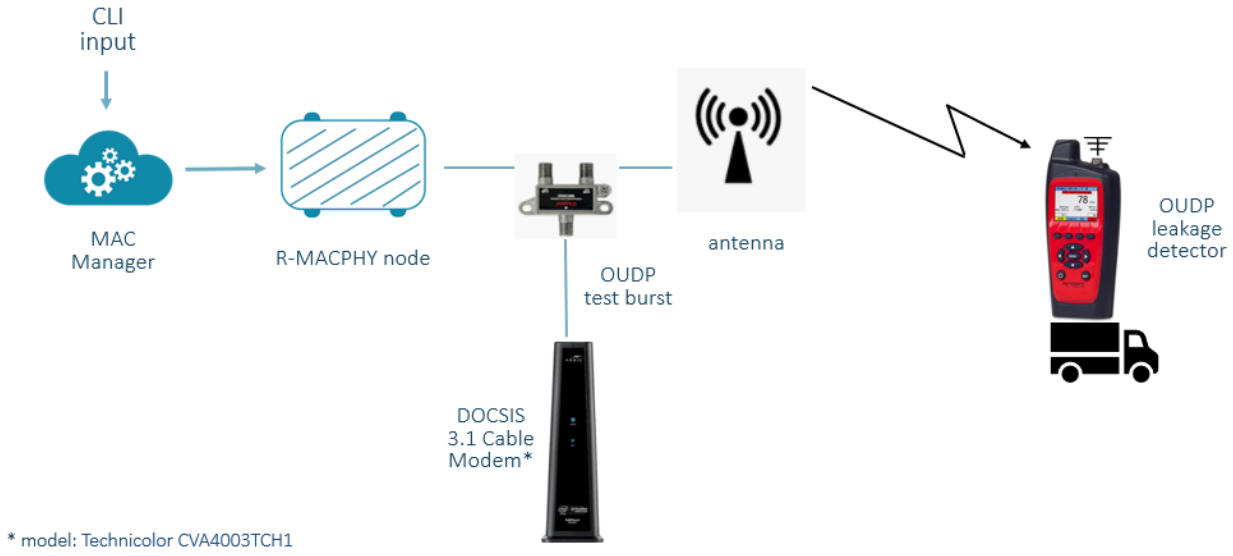

Figure 8 – Test Setup

4.2. Test Environment Configurations

In practice OFDMA channel and leakage detection test region configurations are an operational decision made by individual cable operators. We expect that common practice will be to define a narrow band test region of approximately 1.6 MHz located just above the aeronautical band in the OFDMA channel. Burst descriptors must be defined such that the desired burst characteristics will be used by the CMs when transmitting OUDP test bursts in the test region. These burst characteristics impact field detector sensitivity so must be chosen carefully. Field detectors must also be configured to match the test region frequencies and the expected OUDP burst characteristics used by CMs in the test region.

The OFDMA channel parameters of interest when configuring the OFDMA channel where the leakage detection test region resides are illustrated in Figure 9. Of these, the key variables are the size of the test region and Pilot Pattern configured in the burst descriptors defining the region, and number of symbols per frame and Cyclic Prefix of the OFDMA channel. It is desirable to use the least amount of spectrum needed for the test region. Our recommendation is to keep the test region to four minislots, or 1.6 MHz. The recommended Pilot Patterns for optimal field detector sensitivity are Pilot Pattern 4 for the 2K FFT and Pilot Pattern 11 for the 4K FFT. The number of symbols per frame needs to be balanced between optimal data throughput on the channel and field meter sensitivity. Fewer symbols per frame is better for field meter sensitivity. More symbols per frame may be better for data throughput. Cyclic Prefix length impacts the symbol duration and CMTS burst receiver accuracy. We show the values which are optimal for field detector sensitivity.

Parameter	2K FFT	4K FFT	Comments
Channel Start Frequency	108.50	108.50	Frequency of first active subcarrier in OFDMA channel (subcarrier# 74 | 148)
Channel Width	95	95	Range of active subcarriers within OFDMA channel (max 95 MHz)
Subcarrier Spacing (kHz)	50	25	
Symbols per Frame (K)	6	6	Range: 6-18 (2K FFT), 6-9 (4K FFT)
Cyclic Prefix	512	512	Value: 96, 128, 160, 192, 224, 256, 288, 320, 384, 512, 640
Pilot Pattern in Test Region	4	11	Configure in the Burst Descriptor for Test Region minislots (use IUC 13)
Test Region Start Frequency	138.10	138.10	Preferred frequency of first subcarrier of Test Region
Test Region Stop Frequency	139.70	139.70	Stop - Start should = multiple of 400 kHz (recommend 1.6 MHz, or 4 minislots)

Figure 9 – OFDMA Channel Configuration Key Parameters

Given an OFDMA channel with a configured leakage detection test region, the next step is to define the desired leakage detection test session configuration. When performing leakage detection testing on groups of CMs in a scheduling domain it is necessary to provide adequate burst durations per CM to achieve the desired field detector accuracy. It is also desired to use the minimum burst duration to enable a shorter overall time to cycle through the group of CMs. This is done to ensure that leaks can be detected by field detectors at vehicle speeds. The configurations shown in Figure 10 were selected such that sensitivity of the detection is sufficient to meet FCC signal leakage requirements when the CM is granted a minimal burst duration such that each CM within an Upstream Service Group can burst at least once every half second, as required for a robust confirmation of detection.

The CableLabs specification also specifies configuration for a gap between CM transmissions and between cycles through groups of CMs. These gaps are left to allow for data transmission when the number of CMs is low, and to allow for maintenance activities such as Probe transmissions.

Parameter	2K FFT	4K FFT	Comments
Burst Duration per CM (Frames)	8	4	
Gap Between Cable Modems (Frames)	0	0	
Gap Between Cycles Through List (Frames)	8	8	Leave for Probe processing; each CM gets a full symbol in Probe frames

Figure 10 – Leakage Detection Session Parameters

The OFDMA channel configuration and leakage detection test session configuration needs to be aligned with field detector configuration. Field detector configuration is vendor specific. Details of that are not provided here.

For the leakage detection test described in this paper we tested with a single CM which was granted a continuous stream of OUDP test burst opportunities by an R-MACPHY node. The OFDMA channel was from 108 MHz to 204 MHz with active subcarriers between 108.50 MHz and 203.50 MHz and 50 kHz

subcarrier spacing. The channel was configured with 18 symbols per frame, which was designed to test the worst sensitivity at the field meter. Cyclic Prefix was 512.

The test region was defined with burst descriptors to cover 135.025 MHz to 136.825 MHz. Pilot Pattern 4 was configured.

The spectrum of the OUDP test burst generated by the CM under test is shown in Figure 11.

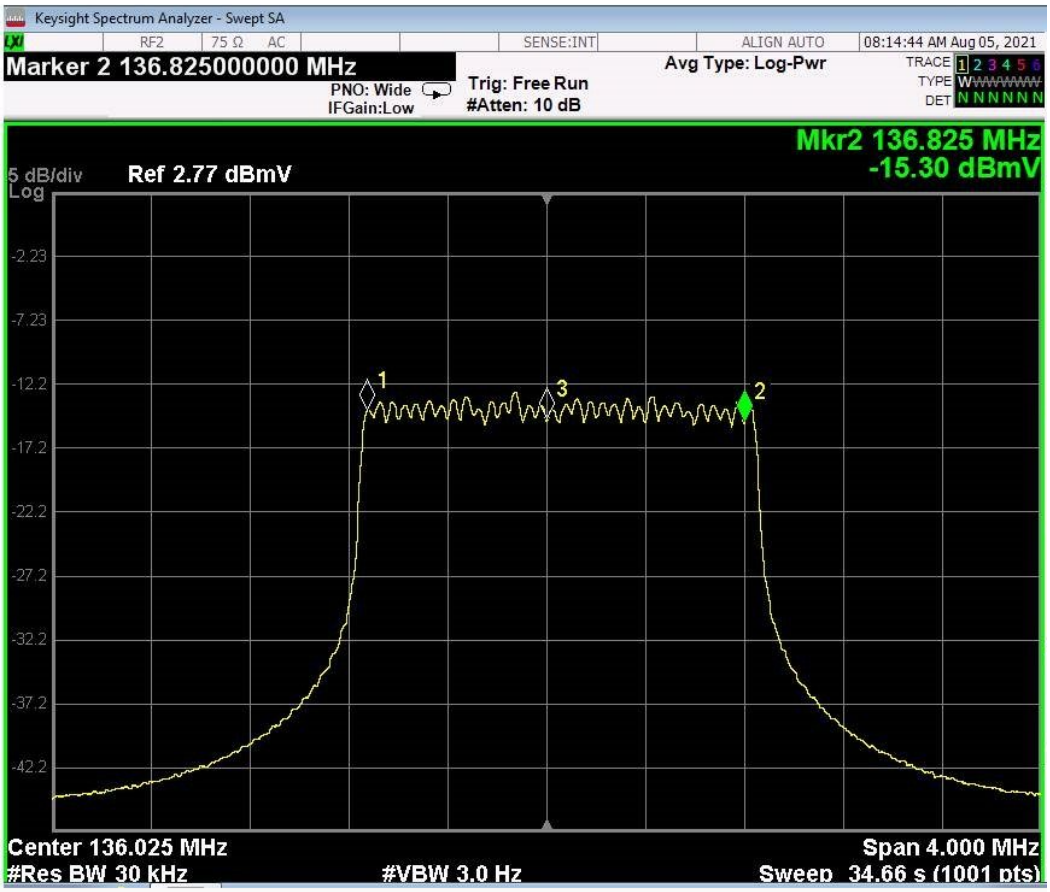

Figure 11 – Leakage Detection OUDP Test Burst Spectrum

After initial hard wired conducted tests were performed in the lab to confirm configuration alignment between the OFDMA channel, test region and field detector, a simple drive-out test was performed. A leak was generated outside of the building using an antenna tuned to the 136 MHz detection frequency. The antenna was connected to the CM output via a reversed two-way splitter as shown in the test setup. A vehicle was outfitted with a corresponding 136 MHz receive antenna, a GPS antenna, and an OUDP leakage detector. No leakage signal was detected until the OUDP burst command was entered into the R-MACPHY node's MAC Manager CLI. Once the CM began to burst, signal leakage was continuously detected, as illustrated in Figure 12.

Figure 12 – Leakage Detection in a Stationary Vehicle

The vehicle was then used to perform a short drive-out in the parking lot around the building, which is indicated in the bread-crumb trail on Figure 13. Each red dot shows a detection point in the one second leakage detection measurement interval. The test session was quite successful, and there was no trouble in detecting the OUDP test bursts. Since the transmitted signal level was a relatively large, leakage was recorded along the entire drive route. Detected signal leakage levels on the far side of the building were as expected, less than as compared to detection points in closer proximity to the leakage source.

Leak ID	Leak level, [µV/m]	Address	PSID	HUB	Node / device	Details	Manage	Ordered date
1	1000/-/-	185 Ainsley Drive, Syracuse, NY 13210	00000	OUDP Test Hub No.1	Not available	Info	Manage	
2	794/-/22	unnamed road, Duluth, GA 30097	00000	OUDP Test Hub No.2	Not available	Info	Manage	

Figure 13 – Leakage Detection in a Moving Vehicle

Future testing will be expanded to include multiple CMs in a group, along with the capabilities and use cases as described in this document. This type of testing will be enabled as vendors implement the functionality described in [3], and as operator plans for operationalizing leakage detection in their High-Split deployments become clear.

5. Conclusion

The OUDP test burst approach for detecting CM initiated signal leakage in DOCSIS 3.1 High-Split and DOCSIS 4.0 Ultra-High Split continues to look quite promising and viable. Excellent progress has been made with support of the OUDP test burst approach being specified in the [3] standard, which provides great flexibility to the operator community by enabling a variety of use cases such that the signal leakage process can be aligned with individual operator goals.

Significant progress has also been made with recent successful tests which prove that DOCSIS 3.1 CMs under the control of an R-MACPHY node can be instructed to and can in fact generate OUDP test bursts, and that the corresponding OUDP test burst (leakage signal) is able to be detected by an OUDP leakage detector installed in a vehicle while performing a drive-out.

As these advances morph into viable operations strategies the primary blocking factor for High-Split deployments in North America will be removed and operators will have at their fingertips the ability to offer 1 Gbps upstream services.

1. Introduction

Cable operators have been actively converging video and data services into a common converged cable access platform (CCAP) for many years now. This trend, which requires an evolution towards newer, more modern, and denser equipment, was intended to free up space in the headend.

However, as the success of high-speed data and on-demand services continues, the evolution of the access network progresses towards expanded capacity and/or ever-smaller service groups. For the former, the spectrum allocated to narrowcast services increases, driving operators to deploy Data-Over-Cable Service Interface Specifications (DOCSIS©) services including more SC-QAM (single carrier quadrature amplitude modulation) channels, more capacity for more or wider OFDM (orthogonal frequency division multiplexing) channels, as well as more narrowcast video services. For the latter, more CCAP ports are needed, which drives the deployment of more line cards and eventually more chassis. These expansion trends result in a continuous growth of headend equipment, which is already starting to exceed the capacity that headend facilities can support.

The above trends are now intractably linked to additional evolutions: distribution of components of the access network, implementing a distributed access architecture (DAA), and virtualization of the core network functions. By now, deployment of DAA devices, such as remote PHY (R-PHY) nodes, is accelerating to tens of thousands of remote PHY devices (RPDs), hosting millions of cable modems.

As a result of the experience, an agile approach to network and device management is now required to ensure that we can effectively monitor our networks, these distributed devices, and customer service status. Traditional proactive network maintenance (PNM) and operations support system (OSS) toolsets provide views into current system health, but unexpected behavior on the RPDs and the systems that work with them provide clear opportunities for new approaches to network and system monitoring and management.

This paper explores lessons learned the hard way, gaps discovered and filled, as well as processes developed to improve issue detection and lower mean time to repair (MTTR). The paper focuses upon factors to keep both maintenance technicians and customers happy, including:

- Whole system monitoring: Real-time telemetry, visual dashboarding tools, and error condition detection and alarming for not just RPDs, but the entire architecture, including R-PHY cores, engines, switches, and timing servers;
- Outside plant considerations, including plant powering;
- Provisioning management, including addressing challenges with having all required systems configured at time of node cutover;
- Hardware and software management, including how lab testing can lead to a better customer experience.

This paper begins by outlining the evolution of service provider networks, and then describes why and how the migration to a distributed access architecture is necessary and beneficial. The paper then expands into features that can be implemented with DAAs and discusses the topic of virtualization. Finally, the paper explores how the implementation of DOCSIS 4.0 could be implemented in DAA networks.

2. Cable Network Evolution

2.1. Typical HFC Networks Today

Most hybrid fiber/coax (HFC) networks have been designed with an upper frequency boundary of 750 MHz or 860 MHz, while some are designed to support 1 GHz and other newer networks are designed to support 1.2 GHz. For the more abundant 750 MHz or 860 MHz networks, if not already fully utilized, it is expected that use of their capacity will be increased to the point of exhaustion. This will happen as a result of 1) increased DOCSIS usage for even faster high-speed data (HSD) service tiers; 2) additional high-definition (HD) programs (for broadcast [BC] and especially narrowcast [NC] services, such as video on demand [VOD] and switched digital video [SDV]); and 3) new service additions such as Internet Protocol (IP) video and cloud-based digital video recorder (cDVR.)

In recent years the growth in, and demand for, HD programming has resulted in the need for allocation of large numbers of CTA (Consumer Technology Association) channels[1] for HD services, both for BC and NC, which has filled every available portion of the spectrum. This is especially true for BC, where large numbers of programs are offered in HD format, while simultaneously the need for distributing the standard definition (SD) version has persisted. This has resulted in the need for use of 3x to 5x the number of CTA channels than previously required. For example, a typical digital multiplex including 10 to 15 programs would require an additional three to five CTA channels for the HD-equivalent streams, even assuming the newer, more sophisticated multiplexing schemes available in the market. Of course not every program is available, or still sought by subscribers, in HD format. But very large numbers of them are, including 100 to 150 BC programs.

The above is also applicable to a great extent in systems utilizing SDV technology for content distribution. The difference is that the HD and SD versions of the program are not distributed unless a subscriber requests them, which reduces the marginal increase in capacity. Assuming that all programs are distributed in only one format, which is certainly a valid expectation for programs of low viewership, then the increase in capacity for a conversion from SD to HD would just be the increase in capacity required for the transmission of the HD program without requiring the simultaneous use of bandwidth for both formats.

Additionally, considerable spectrum is needed to deploy high-capacity narrowcast legacy video services, especially cDVR, and thousands of HD video-on-demand titles. For the former, initial observations suggest that network requirements for cDVR may be as high as 4x to 5x that of VOD, and that peak utilization overlaps, at least partially, with that of peak use for other narrowcast services, such as HSD.

Finally, the growth in HSD services continues. All network operators have offered increased service tiers and observed an increased use of broadband capacity for well over a decade now, as shown in Figure 1, which amounts to a constant year-over-year compounded growth. The applications have changed throughout this time, and the demand has continued to increase at the same relentless rate.

[1] 6 MHz-wide channel allocations used in North American and some other cable networks are defined in *CTA Standard "Cable Television Channel Identification Plan" CTA-542-D R-2018 (Formerly CTA-542-D), updated February 2019*.

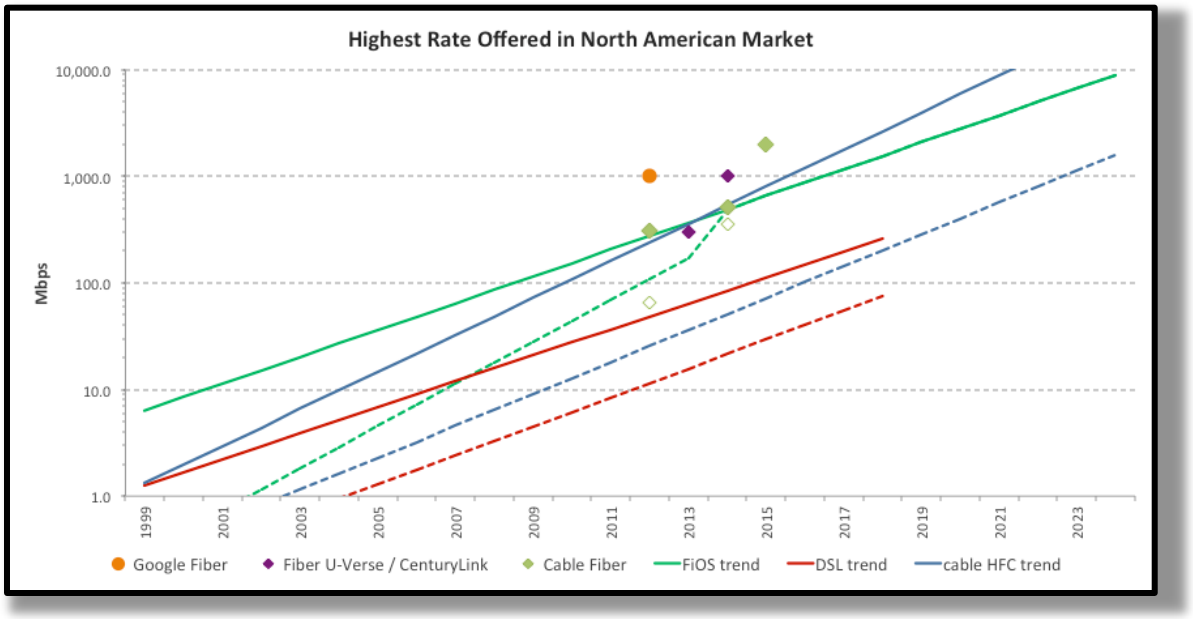

Figure 1 - Examples of HSD service tier capacity increase over time

How does this compare to other operators' data services and a longer period? Projecting an operator's HSD service growth back in time to when Internet services started 25+ years ago, services should have been about 100 bps. This coincides with the history of telephone modems from 110 and 300 baud modems from the mid-1980s, to 56 kbps/V.42, into ISDN (integrated services digital network) services.

This demonstrates that the growth seen in cable industry HSD services is typically over a much longer period of time, rather than an exception observed by operators in recent years.

2.2. Growth Projections

From all of the above, it follows that, should the usage growth pattern continue at the same rate as in the past, networks will be required to provide >1 Gbps HSD services within the next few years. This growth, coupled with the surge in HD video formats (8K TV sets are increasingly available, even as compatible content catches up), and more personalized narrowcast services, will result in a significant growth in narrowcast capacity, as shown in Figure 2.

To support this growth, cable operators have deployed bandwidth reclamation tools such as SDV for digital broadcast, digital transport adapters (DTAs) for analog service reclamation and the shift to all-IP, increased spectrum (1 GHz and above), or a combination of all. These tools have been extremely valuable to operators, and their operational complexity and cost remains well justified.

In the case of SDV, early predictions from industry analysts projected that the efficiency of SDV would reach 40% (e.g., programs requiring 10 CTA channels could be carried in 6). This has proven to be understated, since it was based on the use of SDV to reduce bandwidth required for existing services. As SDV's role in the network grew, the efficiencies have been even greater, especially as SDV expanded in scope to support niche service introductions with low initial viewership that would otherwise be difficult to deploy.

The benefit of DTAs has been just as, or perhaps even more striking. Cable operators deploying DTA devices are able to eliminate the need to distribute the analog channels in the network. Even if DTAs are distributed to top tier analog customers, such as only the traditional "expanded basic" subscribers, the move would reduce a channel line up from perhaps 50 6 MHz channels, or 300 MHz of capacity, dedicated to 50 analog programs to perhaps as little as four such 6 MHz channels (24 MHz) dedicated to transport the 50 programs in their digital-equivalent transport. Using the same comparison method as the above SDV case, this is a >90% efficiency. If extended to the entire analog tier, the efficiency gains are very significant.

Despite the availability of these tools, they are not universally applicable. With respect to SDV, in general it is not likely that all broadcast programs will be switched since experience shows that many broadcast programs are constantly viewed by someone in the service group during peak hours, which will leave a large portion of the spectrum still used for broadcast. Similarly, not all analog channels can be removed in the short term due to operational and/or cost constraints.

Additionally, while many cable operators will use some or all of the capacity tools, in general they won't be used by every operator for all applications because of a range of variables that are out of scope for this discussion.

Finally, there are also significant potential gains to be achieved from the use of advanced video compression standards (VCS), and variable bit rate (VBR) multiplexing. In the case of VCS, coding efficiencies of approximately 50%, depending on implementation and content type, can be obtained with H.264/MPEG-4 Part 10. Furthermore, with the release of the H.265 standard in April of 2013, it is possible to achieve a 50% improvement over H.264. The use of VBR promises to result in a capacity efficiency gain of as much as 70% versus constant bit rate (CBR) . The combined gains from using the above approaches for multiple services are even more significant.

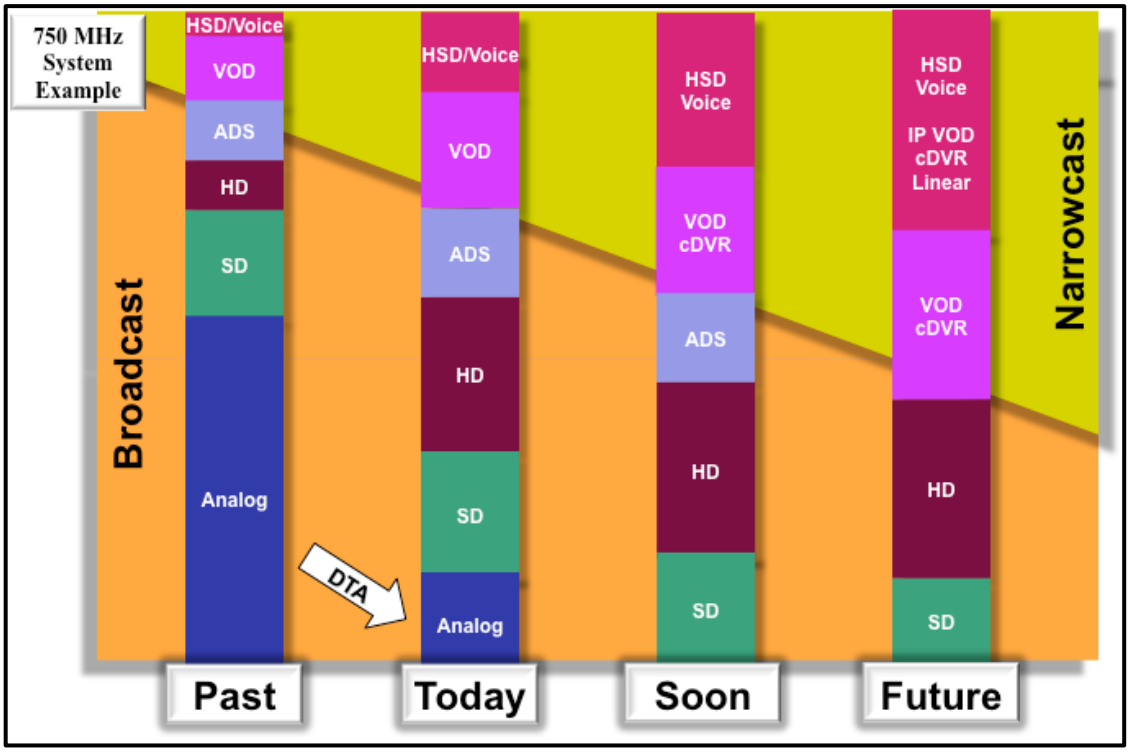

Figure 2 - Example of narrowcast service growth over time

However, these are difficult tools to take advantage of from a network perspective, because on a proportional basis, relatively few legacy set-tops will support all these technical advances, especially H.265. These tools are more likely to find significant support in equipment designed to handle newer, IP-video based services.

And, this approach will nonetheless require additional capacity from the network. This is especially true when considering that the deployment of these advanced video services will result in yet another simulcast of video programs, at least initially. This is because, realistically, advanced services will not, at least initially, replace the currently deployed service formats.

Furthermore, ubiquitous support for such devices would require considerable spectrum if the legacy services are maintained for an extended period – which is expected, given that legacy devices will continue to be deployed, for some amount of time. Moreover, this increase in simultaneous use of the more advanced IP video services while maintaining legacy services will be especially impactful over time, as the number of IP video services increases.

All of the above, coupled with the success experienced by operators in recent years with business services, homes security, etc., will likely require the deployment of IP capacity beyond what can be supported today. As well, it will require the development of tools for increased spectral efficiency and/or unleashing additional spectrum in the HFC network. The following sections of this paper enumerate some ways in which this can be achieved.

2.3. The Advent of DOCSIS 3.1

As it has been pretty well covered in the trade media, DOCSIS 3.1 deployment has been quite extensive. Most cable operators have deployed DOCSIS 3.1 across their markets, and several have even deployed DOCSIS 3.1 throughout their entire footprint.

The key motivation for the 3.1 version of DOCSIS technology is, in a nutshell, to scale DOCSIS more efficiently, both from cost and operations perspectives.

For the first 10 years of DOCSIS deployments, it was possible to offer Internet services and support its growth with just one downstream 6 MHz DOCSIS channel. Over the last five to 10 years, service speed demands increased to speeds of hundreds of Mbps, which require bonding of many 6 MHz channels. Therefore, the industry deployed multiple DOCSIS channels using DOCSIS 3.0, sometimes using 32 or more channels, and even requiring capacity beyond that supported by DOCSIS 3.0.

To that end, the three key goals and features of DOCSIS 3.1 were:

1. A much more efficient use of spectrum, with up to a 50% improvement in bandwidth efficiency (or bps/Hz). This is a result of more efficient forward error correction (i.e., replacing the older and less efficient Reed-Solomon approach with the far more efficient low density parity check [LDPC]), and the addition of the higher-order modulations1024- and 4096-QAM downstream, and 256- and 1024-QAM in the upstream.)

   These new modulation schemes provide two and four bits per second per hertz of improvement in both the upstream and downstream signal directions, while the use of the new forward error correction approach provides approximately 5 dB better RF performance. The end result is that networks are able to transport 1 Gbps of DOCSIS capacity in about 120 MHz of spectrum. For context, doing the same with DOCSIS 3.0, using SC-QAM requires about 180 MHz of spectrum.

2. Cost reduction, mainly by leveraging technologies commonly used in other transmission media. Specifically, the inclusion of OFDM, which is used extensively in wireless and wireline transmission media. The addition of OFDM for the downstream and OFDMA (orthogonal frequency division multiple access) for the upstream should enable operators to reduce costs by "packing" more bits in the HFC network more efficiently. As a result, these technologies will likely attract a larger supplier ecosystem, increasing innovation and fueling competition.

3. To enable a simple and orderly transition strategy. This applies doubly, in terms of compatibility with the previous generation of cable modem termination system (CMTS) and cable modem (CM) equipment, and simultaneously supporting an expanded spectrum capacity in the HFC network.

Specifically, DOCSIS 3.1 cable modems operate with DOCSIS 2.0 and 3.0 CMTS/CCAP equipment, enabling deployment of DOCSIS 3.1 CPE (customer premises equipment) as soon as it became available. Similarly, DOCSIS 3.1 CCAPs support DOCSIS 2.0 and 3.0 CPE, allowing operators to upgrade headend equipment without having to change any of the existing CPE. And, DOCSIS 3.1-based CM and CMTS equipment both support the currently required upstream and downstream spectrum, with expandability of the upstream to 85 MHz and beyond, and of the downstream up to 1.2 GHz.

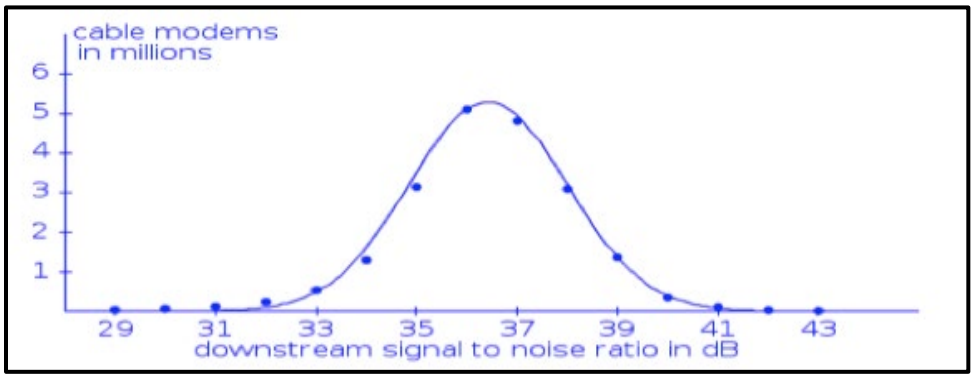

Figure 3 - Example of downstream SNR for a large population of cable modems

Figure 3 depicts the downstream signal-to-noise ratio (SNR) as reported by a very large population of cable modems. This data shows that many cable modems will be able to support the high-order modulation profiles included in DOCSIS 3.1.

Table 1 - SNR required for DOCSIS 3.1

Modulation	Signal-to-Noise Ratio
512-QAM	27 dB
1024-QAM	30 dB
2048-QAM	33 dB
4096-QAM	36 dB
8196-QAM[2]	39 dB
16384-QAM	42 dB

[2] 8196-QAM and 16384-QAM are included for future consideration in the DOCSIS 3.1 specifications.

Assuming an 8/9 LDPC coding ratio, Table 1 shows the required SNR for the modulation rates included in DOCSIS 3.1.

Applying the SNR requirements from Table 1 to the population of modems shown in Figure 3, we can see that a large population of cable modems would not achieve sufficient SNR to operate at 4096-QAM. Furthermore, if sufficient headroom is allowed to account for environmental fluctuations, the population of cable modems that would not receive signals with sufficient SNR to operate at 4096-QAM would be significant.

2.4. The Analog Intensity Modulated Forward Link in HFC Networks

As the name indicates, HFC networks use a fiber transport between the headend and the coaxial plant. This fiber link, intended to reduce the size of amplifier cascades, which improves performance, was originally developed with analog intensity modulated[3] lasers and compatible receivers in both signal directions, upstream and downstream.

Over time, the performance of the upstream link was improved by replacing the analog modulation with a digital transport. This improved performance significantly, and allowed for longer distances between the headend and the node. Different vendors implemented their own methods and technical capabilities to implement a digital transport, which resulted in incompatible systems and required the use of the same vendor's components for both the node and the headend.

However, the downstream link remained almost unchanged over time, with the only enhancements focused on improving distance and RF spectrum capacity. Performance has not really been an issue like it was in the upstream.

But more importantly, while the digital capacity of the upstream was limited to a few megabits per second, well under a gigabit of digital capacity which could easily be digitized and carried with Ethernet optics, the downstream digital capacity needed to transport the downstream spectrum has been considerably higher, reaching and even exceeding 10 gigabits per second.

Because of the above, analog forward links continue to be used. Even though headend equipment is currently capable of launching signals with >47 dB modulation error ratio (MER) performance, which is sufficient to generate and transport 16,384-QAM signals, analog lasers are limited to about 35 to 38 dB of MER performance, which would limit end-of-line performance to barely enough for 2,048-QAM or 4,096-QAM in short cascades in the best of the cases. In short, QAM density from headend equipment development outpaced the capabilities of the analog lasers we use.

2.5. Description of Options for Digital Forward Link

As time has gone by, technology evolution and certain developments as described below have enabled options for implementing a digital forward link. These include:

1. Evolution of edge-QAM modulators, which have gone from single and/or a few modulators to supporting 32, 64 or even more modulators,

2. Development of the CCAP, combining the functions of the video QAM modulator and DOCSIS into a single platform, and

[3] The majority of optical links deployed in HFC networks use linear fiber optic signal transmission, based upon analog intensity modulation. Many in the field use the term "AM fiber link" or similar.

3. Migration to digital video, either partially or completely.

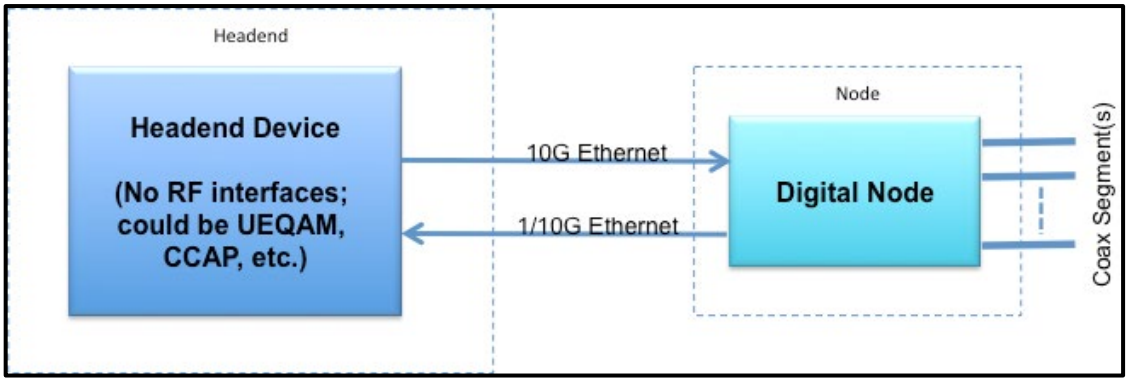

Figure 4 - Digital forward high-level architecture

With this technological evolution, it is conceivable to remove the RF combining network, and instead implement it digitally in the edge device, such as the CCAP. This evolution of the edge headend devices makes it possible to envision several options for digitizing the forward link.

Fundamentally, the migration to a digital forward includes the components included in Figure 4, and described as follows:

- The headend device, such as a CCAP, a high-density edge-QAM modulator supporting QAM for the entire spectrum,
- The node, which contains components normally implemented in the edge-QAM modulator or CCAP, to generate the RF signals,
- The link between the headend device and the node, comprising a digital interface, such as an Ethernet link.

There are the various approaches for how a digital forward link can be implemented to replace the currently used analog link. These approaches can be categorized into four groups, plus one option that would still leave RF generation at the headend device, as outlined in Table 2:

Table 2 - Categories of options for implementing a digital forward link

Option	Description and Approach
1. Maintain RF output in the headend	1.a Headend equipment remains unchanged 1.b Headend RF output is digitized, transported digitally, and RF is regenerated in the node
2. Remote the DAC from the PHY	2.a The DAC is removed from the headend 2.b Digital samples are transported digitally to the node where the DAC generates the RF signals
3. Partition the PHY and remote the lower portion of the PHY	3.a The PHY is split between the headend and the node 3.b The digital bit stream between upper and lower PHY is transported from headend to node
4. Remote the entire PHY	4.a The entire PHY modulation is moved to the node 4.b The MAC remains in the headend, and MAC frames are transmitted from the headend to modulator that resides in the node
5. Remote the entire PHY and MAC	5.a The entire PHY and MAC are removed from the headend device and placed in the node 5.b IP frames are transported from the headend to the node.

2.6. Comparison of Options for Digital Forward Link

There are pros and cons for each of the options. The following sections outline these tradeoffs.

2.6.1. Option 1: RF remains in the headend

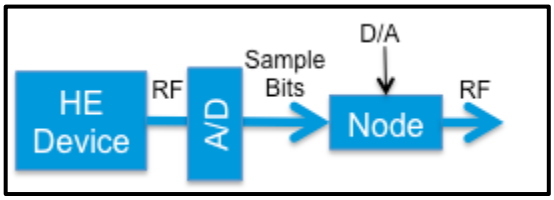

Figure 5 - Block diagram for Option 1

Equivalent to digital return, the RF output from the headend device is digitized, transported digitally, and converted back to RF in the node. This maintains HFC transparency. This option results in the highest bit rate over fiber; the capacity for multiple nodes would not fit into the available capacity of one 10 Gbps fiber. There is a loss of MER in the double conversion, so this option provides the least performance improvement. This option results in the least intelligence placed in the node, but an additional conversion stage is added in the headend.

2.6.2. Option 2: Digital-to-analog conversion is moved to the node

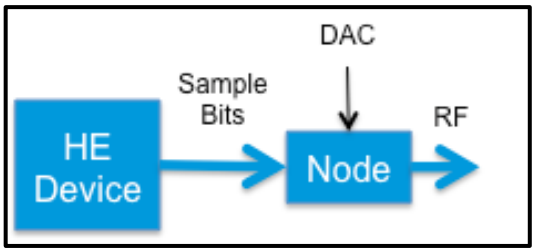

Figure 6 - Block diagram for Option 2

This option requires separation of the digital-to-analog conversion from the modulator. Together with Option 1, it results in the least intelligence in a node. It has a similarly high bit rate over fiber as Option 1; capacity for multiple nodes would not fit into the available capacity of one 10 Gbps fiber.

2.6.3. Option 3: Lower PHY is moved to the node

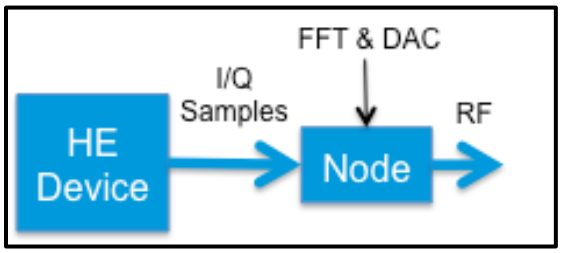

Figure 7 - Block diagram for Option 3

In this option, the PHY layer needs to be split into two components: upper and lower. This implements more node intelligence than in either of the previous options. Although it offers a lower bit rate over fiber than the previous options, it is still reasonably high. However, this option would require an industry proprietary point-to-point link between the headend port and the node, to transport the I and Q samples. Also, implementing this option would require the definition of interfaces which have never been defined in previous versions of the DOCSIS specifications, which in turn would result in modification of the silicon used and/or planned to date, and therefore results in the highest implementation complexity.

2.6.4. Option 4: Entire PHY is moved to the node

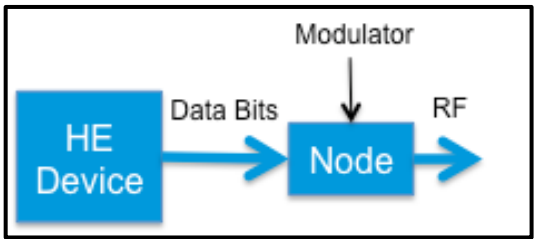

Figure 8 - Block diagram for Option 4

Moving the entire PHY layer into the node places more intelligence in it than with all previous options. This option results in the lowest bit rate over fiber; multiple nodes fit into the capacity of a 10 Gbps fiber. It enables a packet-based link between the headend and node, which results in significant benefits (which are outlined later in this paper.) It could use existing/planned silicon devices, and thus may be the easiest and quickest to implement. Lastly, this option offers the best MER performance improvement over analog.

2.6.5. Option 5: Move PHY and MAC to the node

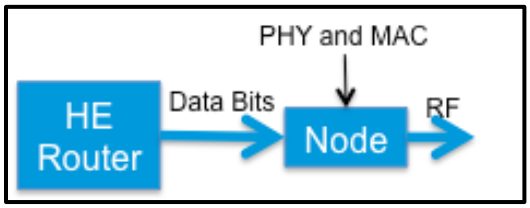

Figure 9 - Block diagram for Option 5

This option puts the most intelligence in the node. The data rate between the headend and the node is equivalent to the actual data transmitted, except for the addition of ancillary network data. It offers the same packet-based network benefits, and the same (highest) MER performance, as Option 4.

2.6.6. Comparison of Options and Implications

Any of the five options described above accomplish a migration away from the analog intensity modulated forward link and into a new era, where the link between the headend and the node becomes a digital link. And, while any of the above approaches accomplish a migration to a digital link, over the years, options 4 and 5 have received the most attention because of their relative implementation simplicity versus options 1, 2 and 3. We now call these options remote PHY and remote MAC-PHY, and we call the devices that implement them RPDs and RMDs (remote MAC-PHY devices), respectively.

As we migrated towards the implementation of a digital link, and separated either the physical layer in a remote PHY implementation, or also migrated the MAC in a remote MAC-PHY implementation, we stepped into the era of DAA. In these distributed access architectures, the remainder of the CCAP in the headend no longer needs to be implemented in an application-specific hardware design. Instead, the remainder of the CCAP in the headend can be implemented entirely as software running in general purpose compute platforms, which we now call a virtualized headend platform.

3. Benefits of Distributed Access Architectures

We will now focus on the benefits of a distributed access architecture, discuss some of the features of DAA, and outline network evolution strategies.

There are many benefits from the implementation of DAA. The following sections of this paper describe them.

3.1. Improved performance

Improvements on performance are achieved in multiple ways, including:

- Improved SNR (and MER) characteristics
- Longer link distances
- Higher reliability
- Better use of capacity

As described in the above sections of this paper, one key benefit of digital forward link is the improved performance resulting from the migration from an analog to a digital link. This gain varies depending on the characteristics of the analog link being replaced, but can be generalized as an improvement of 5 dB in SNR at the end of the line. This gain will result in higher capacity/Hz as it will be possible to run the higher order modulations as shown in Figure 3 and Table 1 for more of the cable modems in the network. This will enable significantly higher transport capacity for customers in the HFC network.

In addition, the digital forward link will enable longer distances between the headend and the node. This is because digital interfaces, such as an Ethernet link, are designed to operate over much longer distances while carrying the designated capacity. Extending the distance between the CCAP and the digital node would enable operators to move their CCAP devices back in the network to more centralized facilities, leaving the hub or OTN free of CCAP equipment. The benefit of such change could be very big for some operators, especially as segmentation of the network continues towards smaller service groups, for which additional CCAP equipment needs to be deployed.

A third benefit from the digital forward link is improved reliability of the optical link. It is well known that analog links require periodic maintenance and are subject to the effects of environmental changes. By contrast, Ethernet optical links are far more stable across a wider range of environmental conditions, and require little to no maintenance. The impact of this benefit could be very significant to operators.

Finally, the data transmitted through the link can be used more efficiently. One key example of such efficiency is the case where one link is used for multiple remote devices. As shown in Figure 10, one link from the headend CCAP device can be used to transport broadcast services once for multiple remote devices. This is achieved by using multicast addressing, whereby each of the remote devices uses the same lineup for each of the respective service groups. In doing so, a single link from the headend CCAP can be used for all the remote devices without exhausting the transport link capacity.

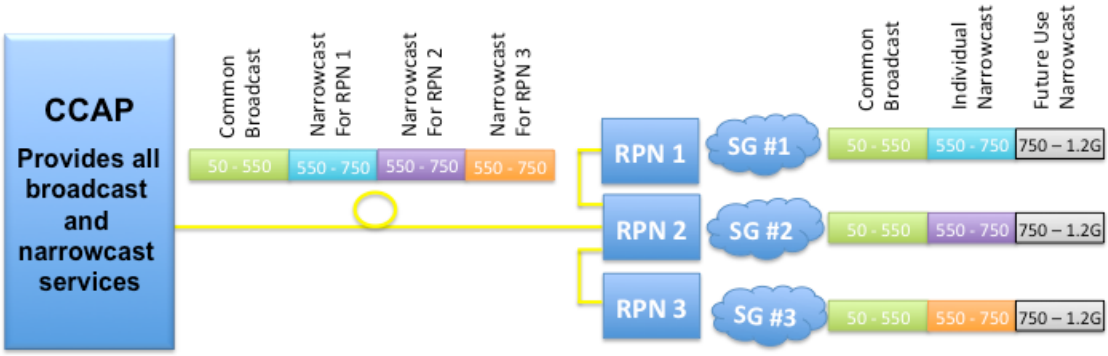

Figure 10 - Reuse of broadcast capacity across multiple RPNs

3.2. Increased Headend Equipment Density

The implementation of DAA makes it possible to improve the density of CCAP devices in several ways.

First, while CCAP devices are normally implemented via separate upstream and downstream line cards, a DAA line card could implement both upstream and downstream. This, in effect, doubles the capacity of a CCAP chassis.

In addition, a typical CCAP downstream line card will house eight or perhaps 12 RF ports, as defined by the printed circuit board space consumed by the components required for RF modulation, plus the sheer connector spacing required. However, Ethernet connectors can be placed considerably closer to one another, allowing a similar line card to easily house 16 to 24 ports. This additional density gain once again doubles the capacity of a CCAP chassis.

Finally, it is possible to consider "daisy chaining" remote PHY nodes (RPNs) off of a single CCAP Ethernet port. This is because, on the one hand, the capacity of a 10 Gbps Ethernet link would support the capacity needed for a single RPN. Plus, it is possible to generate an RPN "channel lineup" by transmitting the broadcast content once to multiple RPNs. As depicted in Figure 10, the data stream transmitted from the CCAP could contain a single "copy" of the broadcast line-up content, plus individual versions of the narrowcast content for each of the RPNs. The RPNs would then reuse the broadcast lineup content to recreate the individual RPN channel lineup. In this way, each service group served by the CCAP port would contain the same broadcast lineup while allowing for its own unique narrowcast line-up.

Then, as the narrowcast lineup capacity grows over time, CCAP ports would be segmented to support fewer RPNs, akin to the way service groups are split today to provide more narrowcast capacity as it is required.

As summarized in Table 3, the combined effect of the three factors described above is very significant, ranging from 8x to 18x of headend capacity gain. From a space and power perspective, this can facilitate huge savings.

Table 3 - DAA headend density gain

Density Factor	Density Gain
Combined US/DS line card	2x
Greater number of ports per line card	2x to 3x
Multiple RPNs per CCAP port	2x to 3x
Combined capacity gain	8x to 18x

But, just how meaningful is this headend density gain?

Consider: A migration from an HFC architecture with an average of N+5 (meaning an optical-to-RF node followed by five cascaded amplifiers) to N+0 would require about 10x the number of nodes, and the headend density benefits resulting from the DAA would neutralize the potential increase in CCAP equipment.

It is then quite clear that from a space and power savings, distributed access architectures take the benefit of CCAP to a whole new level.

3.3. Integration of HFC and Fiber Services

One of the largest areas of growth for operators is business services. Cable operators have deployed business services via both cable modems and fiber-based infrastructure. The fiber-based services are either point-to-point, using Ethernet and wavelength division multiplexing (WDM), or point-to-multipoint, using PON (passive optical network) technologies (either EPON [Ethernet passive optical network] or GPON [gigabit passive optical network]).

This duality results in the existence of two parallel networks. One of them, the HFC infrastructure, uses fiber from the headend to the node via an analog intensity modulated link for the forward direction and either analog or proprietary digital return, followed by coax infrastructure from the node to the home. The other consists of digital fiber from the headend to the customer, which is often used for commercial services.

Given the use of a digital fiber in both the forward and the return for the RPN, and especially because this digital fiber is based on Ethernet technology, it is possible to collapse both of these networks into a single infrastructure. Even without fully collapsing the Ethernet network better utilization of physical fiber can be enabled by the move to common DWDM wavelengths and multiplexers.

Therefore, the implementation of RPNs with an Ethernet interface between the CCAP and the RPN would make it possible to implement a PON interface at the RPN.

The benefits from this integration include:

- Reduction of the optical link for PON to the distance between the node to the customer premise
    - The typical distance from a node to a customer premise in an N+0 architecture is 1 to 2 kilometers. This would virtually eliminate any distance limitations for PON, making it possible to implement the largest possible densities.
    - In addition, this shortened distance would enable the use of lower power optics, which can translate into significant savings – especially for 10 Gbps optics, and for the upstream, which results in significant savings in the ONU.

- Leverage a single network for multiple services, which will reduce maintenance and increase operational efficiencies.

3.4. Migration Strategy

One of the more concerning issues to operators is the migration strategy when going to DAA.

Any migration that requires synchronized cutovers, or which requires changes in multiple locations to execute, is problematic, and usually results in a barrier to adoption. Therefore, it is very important that the migration to DAA allows for unsynchronized changes.

Ideally, the migration to DAA allows for opportunistic changes in the network. For example, one such change would be to migrate a single node, such as would be the case in a multiple dwelling unit (MDU) to increase capacity.

As it turns out, DAA enables such gradual, unsynchronized and opportunistic changes in the network. What follows is an overview of the steps and components involved in the migration to DAA.

Starting with the components of the network on both sides of the DAA, neither the back-office nor the various components in the customer premise need to be modified in any way. All back-office components are unaffected by the migration to DAA, and any additional MIBs (management information bases) for management and/or commands for configuration can be added well before the first CCAP line card or node is deployed. Customer premise devices are not affected in any way when deploying DAA, and any enhancements that are made possible through the introduction of DAA would be implemented in CPE that can be introduced before or after the migration to DAA.

The critical portion of the network where changes need to be made are in the headend and the plant.

To begin with, the changes required in the headend are primarily in the CCAP platform. The CCAP architecture was specifically designed to support multiple technologies simultaneously, which makes it possible to install regular RF upstream and downstream line cards and DAA line cards in the same chassis. While some operators may choose to deploy a separate CCAP platform for DAA, it is certainly possible to support both types of line cards in the same chassis. Of course, these DAA line cards can be installed at any time prior to beginning the migration in the plant, and any removal of RF upstream or downstream line cards can follow the deployment of any number of DAA line cards or nodes.

Turning our attention to the plant, it is similarly possible to migrate regular nodes to DAA nodes in any sequence. As an example, what follows is a sequence of steps where a single node is gradually converted from standard HFC to DAA.

Figure 11 depicts a single HFC node connected to a CCAP device.

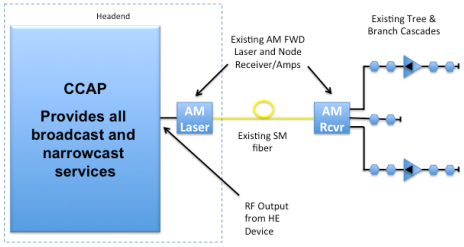

Figure 11 - Single traditional HFC node

Figure 12 shows how the HFC node would be converted to RPN while the rest of the HFC network remains unchanged. The DAA line card in the CCAP would have been deployed in the headend in a prior activity, and even the RPN could have been deployed before the day of the cutover. Then on the day of the change the fiber cable could be swung in the headend from one AM laser to the CCAP DAA card, and in the field from the HFC node to the RPN. Of course it is not necessary to perform the migration in such a fashion, but it would be possible if desired.

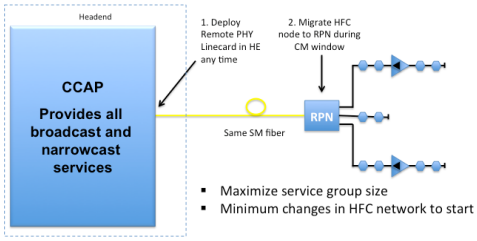

Figure 12 - RPN deployment step 1

Figure 13 depicts a possible step 2 in the process, whereby additional RPNs are installed to segment the original service group further. These additional RPNs could be daisy chained from the original RPN by taking advantage of the broadcast reuse feature, minimizing complexity in the deployment process.

NOTE: The example depicted is one in which fiber is run to every amplifier station. However, a more efficient segmentation scheme would include optimal placement of RPNs in an N+0 HFC architecture with some turnaround of passive components.

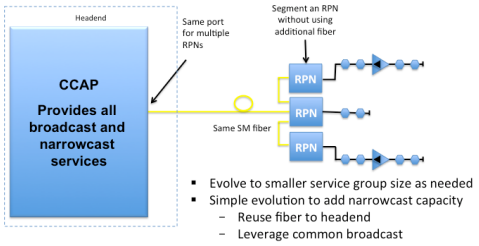

Figure 13 - RPN deployment step 2

Figure 14 shows how further segmentation could take place by replacing the remaining amplifiers in the network with RPNs.

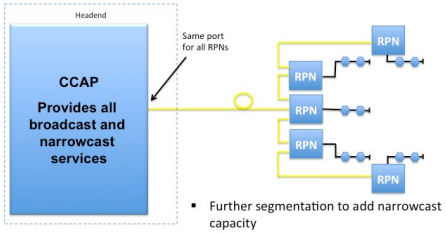

Figure 14 - RPN deployment step 3

Figure 15 shows that the RPN service group depicted above is segmented as additional narrowcast capacity is required. In this example, two of the RPNs from the DAA service group shown in Figure 14 are split into separate service groups using separate CCAP ports.

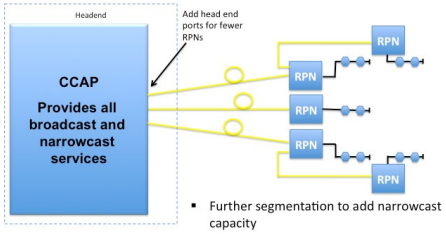

Figure 15 - RPN deployment step 4

Eventually each of the RPNs could be connected to an individual CCAP RPN port as shown in Figure 16. This would provide up to 10 Gbps of capacity to each RPN. This could, for example, be desirable to provide both RF and PON services from the RPN.

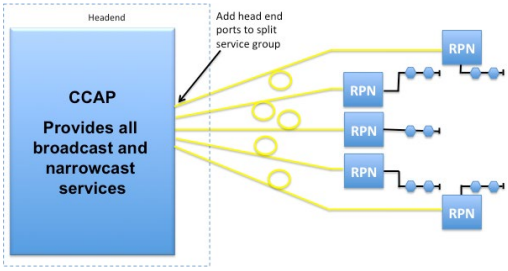

Figure 16 - RPN deployment step 5

Similarly, the DAA line card in the CCAP could be upgraded to support even more capacity as such capacity is needed and becomes cost effective. For example, the Ethernet link from the CCAP to the RPN could eventually be upgraded to 40 or 100 Gbps, both of which are already commercially available.

3.5. From Today to Virtual CCAP

As the network has to continue in operation through the transition, virtualizing the CCAP requires careful planning and a sensibly staged process. As with roads, where cars must be kept moving during any lengthy highway reconstruction, in the network customer traffic must continue flowing day after day. In a sense, while road work is visible to car drivers, in a network the modifications remain invisible to the end user.

One way to do so is to migrate individual functions, one at a time. So, one must develop a list of the functions that would be virtualized, and this list would be prioritized, such as on the basis of complexity of implementation and benefit. Those features with the lowest implementation complexity and the highest benefit would be prioritized higher in the list, and consequently implemented first.

In DOCSIS 3.1, one of the functions that would rise to the top of any such list is modulation profile management (MPM). This is because MPM will take time to be implemented by vendors in a CCAP chassis, but implementing externally via virtualization could be quite simple. In the process, its benefit to operators is quite significant since it would enable better efficiencies from DOCSIS 3.1.

Over time, implementing virtualization of the various functions of the CCAP would lead to a completely virtualized CCAP platform. Such a platform would be more easily scalable than CCAP

platforms are today, where segmentation of service groups requires the addition of more chassis in a linear relationship fashion.

In addition, and perhaps more importantly, virtualizing the CCAP will enable the development of additional functionality, and improvements to such functionality, to occur much more rapidly than it is possible to do today.

4. DAA Components, Use Cases and Generations

As operators move forward with the implementation of DAA, the evolution of DAA components, implications of the various use cases, and the generational aspects of DAA have become important to understand and track.

4.1. DAA Components

As the link from the headend to the node is converted from analog intensity modulated forward to digital, using Ethernet as the transport, several approaches can be taken for the implementation of the remaining headend components. In this section we examine one approach in some detail, for which a key goal is to convert all required components into functionally individual software pieces implemented independently.

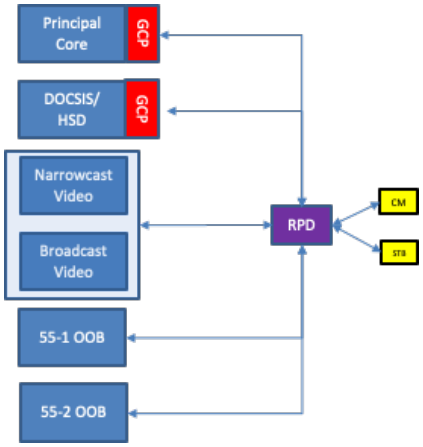

Figure 17 - DAA implementation components

4.1.1. Advantages and disadvantages of discrete components

As shown in Figure 17, an implementation approach for DAA is to develop discrete software (SW) components for each of the various DAA components. Some of the advantages for doing so include:

- The implementation can consist of a multi-vendor platform, where each component can be developed by a different party.
- By having smaller functional components, their implementation tends to be simpler.
- Time to market also tends to be reduced.

However, implementation of smaller discrete components has its downsides, such as:

- There is an implied requirement to more tightly specify the behavior of each component to ensure that the overall system will operate as intended.
- Interface specifications between the various components is required.
- Management of the various components, including their configuration and upgrade is generally more complicated, and requires more elaborate orchestration.

4.1.2. Key DAA discrete components

The key components depicted in Figure 17 include:

- The principal core, which is the first component that the RPD will contact after receiving an IP address.
    - The principal core is implemented such that it will configure all the RPD functions except DOCSIS channels and behavior, which will be implemented by the DOCSIS CMTS.
    - As depicted in Figure 17, the principal core communicates with the RPD using the GCP protocol, for which it is known as the Generic Control Protocol Principal, or GCPP for short.
    - Included in the GCP principal core are all the non-DOCSIS command and control functions for the RPD, including configuration, management and reporting.
- The DOCSIS core, which is the second component that the RPD will contact in the network.
    - The DOCSIS core also communicates with the RPD using GCP.
    - The DOCSIS core provides all configuration, command and control for DOCSIS channels, both downstream and upstream.
- Narrowcast and broadcast video engines
    - Implemented as separate components, the narrowcast and broadcast video engines provide all the content services for the various RPDs in the network.
    - Neither the narrowcast nor the broadcast video engines communicate with, nor have knowledge of, the RPDs.
    - Services are configured statically in the narrowcast and broadcast video engines upon their bring-up, and are multicasted to all RPDs, which listen for these services as configured by the GCPP.
    - The narrowcast and broadcast video engines could be implemented separately, but they could be operated together as a single functional system.
- Out-of-Band engines or cores
    - The OOB (out of band) functions are implemented separately from the video engines.

- Given that video systems are implemented using a single encryption and command/control technology, only one (i.e., either SCTE 55-1 or SCTE 55-2) of them is deployed in any one system.

- The OOB function may or may not implement GCP for communicating with the RPD. When GCP is implemented the OOB server is a core, and it will configure the OOB downstream and upstream OOB channels in the RPD. However, when GCP is not implemented the OOB server is an engine, and the GCPP will configure the downstream and upstream OOB channels.

- Finally, not depicted in Figure 17 is a very important component: the timing server.

  - The timing server, also known as the grandmaster, provides the critical timing synchronization for all the DAA components.

  - Each of the DAA components will include a timing client, which will communicate with the timing server to maintain timing synchronization.

  - While timing synchronization is not absolutely critical for video services, it is imperative for DOCSIS service to operate. Therefore, video services may be initiated before timing synchronization is achieved, but DOCSIS services will not.

4.2. Key aspects of DAA interoperability

The base implementation of a DAA system is generally simple. However, significant complexity is introduced when interoperability with different vendors' components is introduced.

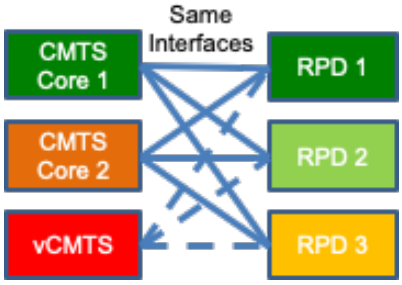

Figure 18 - Functional CMTS-RPD interoperability matrix

As depicted in Figure 18, the number of combinations of interoperable components increases geometrically as additional components are added on either side of the interoperability matrix. Having a single CMTS interoperate with multiple vendors' RPDs is complex and requires a lot of careful planning and implementation. If the number of CMTS implementations is increased to two or three, the interoperability complexity doubles and triples respectively.

When considering the overall CCAP system, the complexity to achieve multi-vendor interoperability is even larger. For example, if multiple GCPPs and/or multiple video engines and/or multiple OOB engines/cores are introduced into the mix, the amount of complexity and work required for testing and interoperability results in increases by orders of magnitude.

Therefore, a multi-vendor RPD deployment coupled with a single headend implementation is a sensible approach to an interoperable DAA ecosystem.

4.3. Use Cases

In the same way as there are different kinds of nodes for different HFC network applications, there are RPDs with different characteristics that are best suited for each of the specific HFC network use cases. Similarly, while there are use cases for RPDs in the outside plant, there are also applications for RPDs in headends, or the "inside plant" as it is frequently called, which will have different implementation characteristics. The following sections cover the key scenarios.

4.3.1. Outside plant

The environmental characteristics of RPDs developed for outside plant make the design of such devices very different than for RPDs developed for inside plant. The key characteristics for outside plant RPDs are as follows:

- Designs must conform to very tight space availability requirements inside of a node enclosure
- RPDs must support an environment where heat dissipation without the use of fans is critical
- Powered from quasi-square wave power supplies used in HFC networks
- Minimize power consumption to the extent possible given the limited amount of power during normal operation and especially during stand-by power mode

In addition, and perhaps more importantly, there are different kinds of nodes for different HFC network applications, which will drive varying designs for RPDs for outside plant, as follows:

- Traditional HFC networks include cascades of multiple amplifiers and cover a plant footprint of a few hundred homes. In such cases the network capacity offered by the RPD should be maximized, such as including multiple downstream and multiple upstream ports.
- Newer HFC networks are built with fewer, or even no amplifiers, and are targeted to cover smaller network footprints. In such cases it is not necessary for the RPD to support much more than a single downstream port, with either a single or dual upstream ports.
- Finally, given that scaling is needed as in any other network application, it should be possible to support greater capacity over time to the extent possible. For example, while initial deployment may only require a single downstream and/or upstream, over time service group segmentation may require additional downstream and/or upstream ports in a single node. For that purpose it is usually a design requirement that multiple individual RPDs fit into a single node enclosure.

Given the above, RPDs that are built with a single downstream and a single upstream (frequently called 1x1) or a single downstream with dual upstreams (1x2), such that operators can place a single one in the node or place additional units when capacity demands require it. Newer silicon designs include more capacity at lower power levels, making it possible to develop RPDs that

contain multiple downstream ports and multiple upstream ports, such as 2x2 and 2x4 designs in a single RPD.

4.3.2. Inside plant

In contrast to the outside plant environmental characteristics, RPDs developed for inside plant have other constraints that make the design of such devices very different than for RPDs developed for outside plant. The key differences in the design of RPDs for inside plant are as follows:

- Rather than the physical volume of the allocated space, the layout is a primary concern so that dense set-ups in a rack are possible, including cabling distribution in the front and/or back of the rack.
- Designs must support an environment where forced air is used for heat dissipation, requiring airflow from front-to-back or back-to-front, sometimes allowing airflow from side-to-side and/or in a vertical direction.
- Powering frequently requires DC power supplies, but AC power supplies are used in other cases.

In the case of inside plant RPDs, these are frequently implemented in one of two different form factors:

- Modular, where RPDs are individually removable in a chassis-based design, or
- Fixed, where the entire set of RPDs are part of a monolithic device

The modular design is generally used in larger headends where the ability to replace a defective individual unit is a paramount concern. The fixed design is targeted for a smaller facility, or even a cabinet, where space is the primary concern.

4.4. Generational considerations

One additional consideration is the evolution of the DAA to support new generations of equipment.

The initial implementation of DAA components included support for DOCSIS 3.1. The main component that is specifically developed and implemented for DOCSIS 3.1 is the RPD, which incorporates application specific integrated circuit (ASIC) devices which support up to DOCSIS 3.1, but will not support DOCSIS 4.0 functionality.

As newer parts of the DOCSIS 4.0 specifications are implemented, such as full duplex (FDX) DOCSIS, the RPDs will have to be swapped out in order to expand their support for DOCSIS 4.0. This process is akin to what had to be done with CCAP line cards in the past, where either upstream and/or downstream line cards are swapped over time as new versions become available. And, as part of this upgrade, the older equipment is reused in other locations where the newer equipment is not yet needed.

However, for the remaining DAA components, if these are implemented in software on general purpose compute platforms, these should be upgradeable to support newer DOCSIS specifications

such as DOCSIS 4.0 and/or other enhancements by simply expanding the functionality implemented in software and downloading it to the platforms in which they run.

In fact, the process for upgrading the DAA components to support changes in the functionality including enhancements to DOCSIS, becomes easier than ever before given the nature of the DAA platform, especially when the DAA implementation includes a minimalistic RPD at the edge of the HFC network and virtualized components for the remainder of the DAA components.

5. Deployment experiences and lessons learned

As operators move forward with broad deployment of DAA, including tens of thousands of RPDs in hundreds of locations, there are many useful lessons learned. The following sections of this paper describe findings in four key areas: monitoring system approaches, plant powering, provisioning processes and approaches, and hardware and software management techniques and experience.

5.1. Monitoring System Approaches

As the number of DAA sites and components increases rapidly, the use of tools such as Simple Network Management Protocol (SNMP) become exceedingly difficult to operate and scale. With just a few thousand RPDs, operators would have more end points from which to gather data than they have CMTS or CCAP systems in total. Having deployed multiple tens of thousands of RPDs, and projecting that deployments will pass the hundreds of thousands in just a few years, streaming telemetry approaches become much better suited for monitoring such vastly distributed systems, and perhaps the only viable approach.

Open source tools like Grafana can be very easily used to plot streaming data collected from network components. And, gathering data from various sources, such as those outlined in Section 4.1, allows for quicker correlation of issues in the network.

As an example, Figure 19 depicts the status of RPDs in a particular area of the network. The view in the figure shows the status of RPDs as seen by a vCMTS, including the number of active and inactive RPDs and the corresponding number of cable modems in those RPDs. The vCMTS is one of the network cores in the DAA, and similar views are available as seen by other network cores as outlined in Section 4.1.

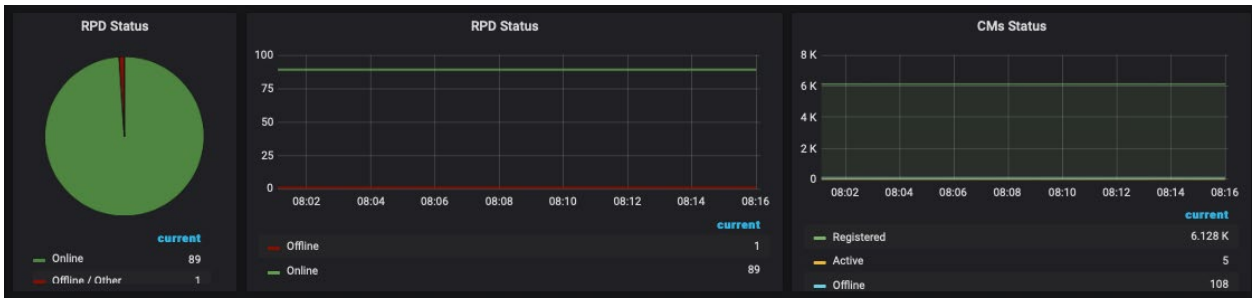

Figure 19 - RPDs and cable modems in a particular section of the network

Streaming telemetry can be easily obtained from modern compute resources, such as those used to virtualize the CMTS and other DAA components. However, streaming telemetry is not currently

available from RPDs. Instead, an RPD supports polling telemetry through protocols such as GCPP, which is used in the RPD for other purposes, including configuration.

To further expand on the use of streaming telemetry to RPDs, work is currently underway in an effort led by CableLabs, and supported by cable operators and suppliers alike, to incorporate streaming telemetry in the remote PHY specifications. This specification development effort includes a prototype being developed between CableLabs, Comcast and the support from vendors.

5.2. Plant powering

Plant powering of RPDs has become surprisingly challenging, and as a consequence represents a rich set of "lessons learned." This section provides some relevant background, describes the challenges encountered, and the solutions applied to date.

5.2.1. HFC network topology and component powering

Network power supplies have always provided power to multiple HFC plant devices. Historically this included nodes, amplifiers and line extenders. In addition to HFC plant devices, network power supplies provided power for any other device connected to the plant, such as Wi-Fi access points, cellular microcells, etc. In the past, the plant powered some individual CPE devices used for specific applications, such as telephony (which are largely removed from cable networks now).

The footprint covered by an individual network power supply, which we might refer to as the power serving group, depended on the specific characteristics of the HFC network, especially related to the density of the area in question. In areas where traditional N+x HFC architecture is deployed, an individual power supply may provide power to a single node and a collection of amplifiers and line extenders, plus whichever other devices may be present in that power serving group. In the case of passive HFC plants, such as fiber deep and/or N+0 plants, a single network power supply might power a number of nodes and any other devices that may be present in the power serving groups.

5.2.2. Traditional network maintenance activities

Before the introduction of DAA, the HFC plant devices became operational almost instantly upon receiving power from a network supply. By contrast, other devices that may be present in the power serving group, such as a Wi-Fi access point or microcells, would take several minutes to become operational once network power is supplied.

Over the years, the normal process of a maintenance technician included some interruptions of network power for troubleshooting purposes. This might include procedures intended to identify sources of signal interference or impairments, or replacement of HFC components that might be causing signal interference or impairments, such as taps, splitters, power inserters, and any other passive component, all of which could be done very quickly. In doing so, power would be interrupted for a matter of seconds, or even fractions of seconds, which would cause a very brief loss of power for an amplifier or line extender, which CPE devices would not perceive, and therefore not cause an interruption of service beyond the brief moment of the power interruption itself.

5.2.3. Impact on DAA network devices

As DAA components have been deployed, those nearly imperceptible power interruptions described above became much more impactful.

For example, while a traditional node, amplifier or line extended would recover from a power interruption nearly instantly when power was restored, the same does not apply to an RPD. Instead, the RPD, which has a processor (or multiple, actually), requires considerable time to boot (in the minutes range), and then go through a power-on self-test (POST) process, which takes additional time to complete. This was followed by processes such as time-synchronization, which take even more time to complete.

Therefore, while a second or sub-second power interruption would have been imperceptible to most users in a traditional HFC network, it now causes multiple minutes of interruption until an RPD becomes operational, and even longer until the CPE in the home becomes operational once again.

To make matters worse, in cases where a serving group power supply provides power to multiple RPDs, such as is the case in passive networks, the service interruption would affect an even larger footprint.

5.2.4. Solutions

Several actions can be taken to overcome these problems, including training, shortening the power cycle process, and using power holding devices.

The most immediately available solution to minimize power interruptions is training, to prevent unnecessary power interruptions. As all cable operators' maintenance team leaders well know, this is much easier said than done. Training requires time, practice and repetition, all of which takes months or years to implement. Furthermore, there are many cases when interrupting power becomes impossible to avoid, such as when component replacement is necessary for impairment resolution.

Shortening the power cycle process requires, in most cases, substantial changes in the SW running in an RPD and the related systems, and in their integration. For example, it is relatively easy to simplify the POST process and/or to shorten the bring-up time. It requires more effort to reduce the configuration time, such as by keeping and reusing configurations whenever possible. Other aspects of the power-up process are more difficult to shorten, such as the time synchronization, which can only be shortened, and even eliminated, with a reboot from active operation that did not follow a power cycle.

An additional approach for eliminating short power loss events is to implement power holding devices within the RPD or in the node housing the RPD. Such devices, which are based on hardware, take even more effort to implement and have a linearly increasing cost (i.e., each unit has a cost, and the cost does not decrease substantially with the deployment volume). In addition, power holding devices can't hold power for considerably long periods of time, so they only prevent short power interruptions (i.e., power holding devices only prevent power interruptions lasting a few seconds).

The combination of all of the above approaches is probably the most effective combination.

5.3. Provisioning process and approaches

The installation, configuration, bring-up and provisioning process for an RPD requires information related to all the services provided by cable operators, plant characteristics and operational requirements. The process is complex given the various sources of information, and requires automation and verification. The following paragraphs provide an overview of those topics.

5.3.1. RPD Installation

There are two fundamental types of RPDs: those that are installed in nodes and those installed in headends (shelf-based). While the two types are functionally the same, the use case is different, and therefore some aspects of the installation and configuration are different.

For example, for node-based RPDs, there is an individual RPD to identify, configure and verify (unless two RPDs are placed inside of the same node). In the case of shelf-based RPDs, the identifier label used is typically for the entire shelf instead of being specific for an individual RPD, and identifying the specific RPD that is being provisioned requires an understanding of the shelf architecture.

While RPD identification may seem trivial, actually identifying an RPD that is part of a shelf presents several complications. Finding the identifier label may be difficult, especially if the shelves are installed immediately above or below another shelf (i.e., without any space between them in the rack). Additionally, the media access control (MAC) address of the RPD, which is a fundamental component of the configuration process, may be derived from a base MAC address for the shelf, instead of included on the label as it would be for an individual RPD in the node. While these may seem inconsequential aspects of the installation process, they become significant complexities operationally, especially when speed of deployment is a key goal.

An additional twist to the installation process is the replacement process. When an RPD needs to be replaced, the process has to involve some form of removal plus an addition. Given that the RPD configuration is specific to the RPD, the MAC address of the RPD being replaced needs to be removed, and the MAC address of the new RPD needs to be used in its place.

Finally, the installation process needs to take into account the isolation of known defective RPDs, a return material authorization (RMA) and repair, and a manufacturing, purchase and installation identification for tracking devices with problems and defects, all of which has to be taken into account as part of the process.

5.3.2. Information and Sources

The information that is used in the configuration and provisioning process includes plant characteristics such as power levels, tilt, leakage detection tones, pilot tones, etc. It also includes service information, such as broadcast and narrowcast video services' frequencies and channels, DOCSIS channel frequencies and modulation characteristics, and OOB signals, to name the most common.

The above information comes from different sources within the operator's organization, and therefore various individuals determine what's the correct information and use various types of source data. This can naturally lead to conflicting information and configuration.

In addition, there is added complexity in having multiple configuration sources for an RPD. For example, in the DAA described in this paper (see Section 4.1), the RPD receives configuration information from two or three different sources within the network, which include the GCPP, followed by the vCMTS auxiliary core, and the OOB engine auxiliary core for 55-2 encryption networks. Having multiple sources of configuration information can easily lead to conflicts that are hard to identify.

Finally, parameters change over time for a multitude of reasons on a regional or per-node basis. Some of the changes will apply to a number of nodes simultaneously, such as changes in channel line-up and/or addition of DOCSIS channels. Other changes will be unique to a node, such as changes in channel configuration to optimize capacity usage through profile management application (PMA) tools.

Given the multitude of information sources and configuration components, it is almost inevitable that errors will occur. One example involves the specific frequency assignments for either of the configuration components which might be incorrectly captured or communicated, including frequency overlaps. Given that the RPD does not have the inherent intelligence to understand which overlaps are intended and which are errors, it is possible to create a configuration that will not work.

5.3.3. Configuration and Verification Tools

Resolution of configuration errors, such as overlaps and conflicts, could be considered to be relatively straightforward. Configuration tools can certainly be developed to capture the information, and automation can be implemented to minimize errors, and even prevent them in some cases.

However, there are factors that make the detection of errors more challenging, such as when the information arrives at a central configuration tool from different data sources. In that case, an additional tool would have to consolidate all the configuration information before the final configuration is created, which is especially the case if the configuration is created “on the fly.” In such cases, the change in the configuration could have been made a priori, perhaps hours or even days before the configuration is applied, and therefore the person or system that commanded the change would no longer be notified of the conflict.

Other information and/or changes are much harder to verify, such as configuration of pilot tones or leakage tones, either frequencies and/or signal magnitude. Only experts in the specific field might understand the information that is being entered, and therefore determine that a different value would have been appropriate.

Perhaps the ultimate approach to verify the configuration is to conduct a field configuration test. Tools have been developed for quite some time to measure RF characteristics of a channel line-up, including signal levels, channel content, etc. More recently, tools have been expanded to read an entire channel lineup, and compare it to a known, “good” lineup, to determine if there are any errors. Such tools are very useful because they verify the actual RF signals being generated by the RPD in their entirety. However, such testing does take resources, time and additional cost.

5.4. Software and hardware management

As with any device containing a processor, RPDs require software upgrades. While that is very much expected, how frequently changes are required may be surprising. In addition, hardware changes and

use cases have been even more frequent than anticipated. The following paragraphs provide an overview of some of these situations found through field experience.

5.4.1. Software upgrades

Everyone involved in access networks has experienced their fast-paced evolution. Changes not only include the expansion of capacity, which is, of course, a very big challenge, but also of functionality, uses, and most recently of configuration, including dynamic changes.

The most typical of such changes involves incorporating new or modified functionality. For example, almost all operators deployed downstream channel bonding before upstream channel bonding, or downstream OFDM channels before upstream OFDMA channels. Similarly, lots of functionality included in the DOCSIS specifications is deployed over time. As a result, equipment manufacturers implement such functionality progressively, as it becomes necessary and useful to the operator. Therefore, software upgrades are required to make such additional functionality available.

Less predictable are new or different use cases. For example, while initially an operator may deploy RPDs in passive networks, they may over time expand to using RPDs in a more traditional N+x HFC network. Therefore, while the operator may not have needed to support pilot tones initially, such functionality may be required later on in the deployment lifecycle. As with any other functionality that is not needed initially, it may not have been incorporated into the initial software load and then deployed over time, requiring software upgrades.

An additional type of software change involves making configurable information dynamically possible. For example, initial deployments of DOCSIS channels may not require that modulation profile configuration changes be made without rebooting the RPD, such changes may need to be made dynamically later on, without requiring the reboot of the RPD, and even without requiring cable modem reset or even re-ranging. As with the above cases, such changes in the RPD operation require software upgrades.

Finally, as with any other software, bugs are almost inevitable. Therefore, when bugs are found they have to be identified and fixed, which of course requires software upgrades.

Upgrading RPDs that have been deployed requires the use of software deployment tools. This is important when the number of RPDs that have been deployed is in the thousands, and it becomes especially important when the number of RPDs increases by one, two and possibly three orders of magnitude.

In addition, it is inevitable that RPDs are manufactured over time, bought over even longer periods of time, and then placed in warehouses until these are deployed. Therefore, RPDs are almost always upgraded upon initial deployment, which generates the need to manage multiple software versions and upgrade processes.

Moreover, RPDs become even more challenging when their variety increases, for example when multiple vendors are deployed in a network, and especially when multiple models from each vendor are deployed. Performing field tests becomes necessary, requiring handling of exceptions, and gradual or partial deployments are inevitably necessary to support operational requirements. All this makes the need for a sophisticated software management and deployment tool.

5.4.2. Hardware upgrades

Just like having to support multiple software versions, over time multiple hardware versions are also inevitable. This can happen because of product evolution by manufacturers, new use cases by the operator, and industry technology evolution. Let's examine a few examples of each.

Product evolution is probably the least appreciated, but the most real form of hardware evolution. Manufacturers will almost always evolve their products to reduce costs, resolve component obsolescence, or achieve better performance. Therefore, multiple hardware versions are almost always necessary and inevitable. In some cases, it might be necessary to keep track of different hardware versions for purchase tracking requirements, especially when costs change. But keeping track of hardware versions is also important for other reasons, such as for certain troubleshooting activities, and even to understand and support certain software differences, such as when certain newer versions support features not available to older hardware versions.

Less predictable is the evolution of use cases. For example, an operator may initially deploy RPDs with fewer downstream and/or upstream ports than may be required over time. While it may be possible to double the use of some RPDs on certain nodes (i.e., start with one RPD in the node and later move to two RPDs in the node), in other cases it may be necessary to deploy a different type of RPD (i.e., start with one model of RPD in the node and over time move to use a different model of RPD in the node). In most cases the evolution would require one to keep track of the number or modem of RPDs in each node. Yet another example of change in use case would be the initial need for node-based RPDs, which eventually changes to incorporate the use of shelf-based RPDs, or vice versa.

Finally, the almost certain hardware evolution scenario is that the technology used initially evolves over time. For example, initially RPDs were developed to support DOCSIS 3.1, but more recently their design has been modified to support FDX. Cable operators have dealt with the evolution of access network technology for decades, migrating from pre-standards to DOCSIS 1.0, then to DOCSIS 2.0, followed by DOCSIS 3.0 and eventually DOCSIS 3.1. Equipment management, including shifting equipment between locations, is a process that operators have mastered and will continue to apply to support technology evolution.

6. Conclusions

Demand for more narrowcast service capacity has driven many changes, allowing operators to reclaim spectrum. Splitting nodes to reduce the number of homes passed in an HFC node's footprint is one key method used to provide more narrowcast capacity. Enabling narrowcast services on this reclaimed and newly added spectrum requires more equipment in the headend. Given the trajectory of growth, using traditional equipment technology creates an increased demand for more headend space. Deploying DAA enables the required growth without expanding facility footprints.

The deployment of the highest modulation orders available with DOCSIS 3.1 required higher MER out of the node. Transitioning to a digital forward link, which became possible with the newer DAA, is a key enabler to achieve this demand. Moving the entire PHY layer to the node has become the standard method to implement a digital forward link.

Deploying DAA in the outside plant allows for more efficient infrastructure utilization between services. DAA and commercial services can share physical fiber due to commonly used DWDM wavelengths and spacing. There is also the possibility of a converged Ethernet switching network to serve both DAA

nodes and commercial customers. Having Ethernet inside of a DAA node allows for efficient PON deployments sourced from the same node.

Moving from specialized CCAP hardware to virtualized components leads to a more scalable system, where additional capacity can be added without the step function of adding new CCAP chassis. Furthermore, feature velocity can be improved on a virtualized system. DAA is implemented with discrete components that allow for a multi-vendor platform and includes smaller functional components.

On the flip side, implementing discrete components requires well behaved interfaces that adhere to a well-defined set of specifications. In the DAA implementation described in this paper, key functions include the GCPP core, the DOCSIS core, the narrowcast and broadcast video engine, the SCTE 55-1 OOB engine or SCTE 55-2 OOB core, PTP timing distribution, etc.

RPDs are available for both inside and outside plant applications, implemented as individual units or in shelves containing multiple RPDs, and including single or multiple services groups. Power level and segmentation capability/capacity are key attributes of outside plant RPDs. Density and serviceability are key attributes of inside plant RPDs.

Even though current generation RPDs lack support for FDX operation, other DAA components may have the ability to be upgraded for FDX operation using the current hardware. This enables an easier transition to FDX on an as-needed basis, by swapping hardware on desired nodes while utilizing the existing platform.

The experience acquired over the course of the last five years, especially the last two years, leads to several key lessons learned that are outlined in this paper. One such lesson is the need for flexible and scalable monitoring systems, using streaming telemetry and open source reporting tools. Another is the impact of plant powering considerations, which resulted in the development of software systems and hardware components to alleviate the effects of power interruptions during normal maintenance activities.

Having provisioned tens of thousands of RPDs already, a well thought out provisioning system process and approaches for configuration verification are very important to ensure smooth, rapid and correct deployment. It is especially important to consider the variety of information and the number of sources, and to create a process for gathering and applying the information that minimizes errors, some of which are easier to foresee than others.

Finally, given the need to deploy RPDs of multiple types and from multiple suppliers, software and hardware upgrade management becomes very important. Both foreseen and unforeseen changes require the use of flexible version management tools.

Abbreviations

A/D	analog-to-digital
AC	alternating current
AM	amplitude modulation
ASIC	application specific integrated circuit
BC	broadcast
CBR	constant bit rate
CCAP	converged cable access platform
cDVR	cloud digital video recorder

CM	cable modem
CMTS	cable modem termination system
CPE	customer premises equipment
CTA	Consumer Technology Association
DAA	distributed access architecture
DAC	digital-to-analog converter
dB	decibel
DC	direct current
DOCSIS	Data-Over-Cable Service Interface Specifications
DS	downstream
DTA	digital transport adapter
DWDM	dense wavelength division multiplexing
EPON	Ethernet passive optical network
FDX	full duplex [DOCSIS]
Gbps	gigabits per second
GCP	generic control plane
GCPP	Generic Control Protocol Principal
GHz	gigahertz
GPON	gigabit passive optical network
HD	high definition
HFC	hybrid fiber/coax
HSD	high speed data
Hz	hertz
I	in-phase
IP	Internet Protocol
ISDN	integrated services digital network
LDPC	low density parity check
kbps	kilobits per second
MAC	media access control
MDU	multiple dwelling unit
MER	modulation error ratio
MHz	megahertz
MIB	management information base
MPEG	Moving Picture Experts Group
MPM	modulation profile management
MTTR	mean time to repair (sometimes mean time to restore)
NC	narrowcast
OFDM	orthogonal frequency division multiplexing
OFDMA	orthogonal frequency division multiple access
ONU	optical network unit
OOB	out-of-band
OSS	operations support system
OTN	optical transport network
PHY	physical layer
PMA	profile management application
PNM	proactive network maintenance
PON	passive optical network
POST	power-on self-test

Q	quadrature
QAM	quadrature amplitude modulation
RF	radio frequency
RMA	return material authorization
RMD	remote MAC-PHY device
RPD	remote PHY device
R-PHY	remote PHY
RPN	remote PHY node
SC-QAM	single carrier quadrature amplitude modulation
SCTE	Society of Cable Telecommunications Engineers
SD	standard definition
SDV	switched digital video
SNMP	Simple Network Management Protocol
SNR	signal-to-noise ratio
SW	software
US	upstream
VBR	variable bit rate
vCMTS	virtualized cable modem termination system
VCS	video compression standards
VOD	video on demand
WDM	wavelength division multiplexing

Lessons Learned: Embedding AI in Cable Customer Experience to Better Serve Agents and Customers

An Operational Practice prepared for SCTE by

Rachel Knaster

1. Introduction

As we all know the last two years drove massive change and presented new challenges for people and business. From a technology standpoint there was a renewed focus on artificial intelligence (AI) and its application— particularly as call wait times skyrocketed and customer frustration grew. The cable and telecom industry adapted, as it has done during its long history, and there has been an incredible opportunity for business. So, I wanted to share some of the lessons learned and best practices around AI for the cable and telecom customer experience (CX) that can bring immense value, efficiency, productivity, scale and brand loyalty.

Digital transformation is underpinned by technologies such as artificial intelligence and 10G— fundamental technologies to scale productivity, operations and generate better financial returns. Large enterprise businesses have petabytes of data, but major systemic CX inefficiencies that technology has not been able to solve to date. How cable companies interact with their customers is changing. Customer expectations are changing, and contact center agents can't scale without a move to digital. This touches on a fundamental challenge of rules-based technology: it is systemically inefficient because it relies on people programming rules constantly. Managing these rules is not scalable. Machine intelligence can be far more efficient in significantly improving productivity gains, financial performance, along with the customer and employee experiences. If implemented well, artificial intelligence can take months, not years, to implement and deliver the outcomes desired by the business.

With that said, people play a key role in defining successful customer experience and driving organizational success. Despite what many technologists would have you believe; AI is simply not sophisticated enough to replace all people on the frontlines of customer service. There are myriad applications for AI to help drive successful customer experience. To merely equate AI to chatbots does the field of AI research and development a disservice.

Shifting how an organization views and adopts artificial intelligence technologies like machine learning, natural language processing and speech recognition should not be seen solely through a prism of automating people out of the equation. Don't get me wrong automation is a key component but putting people at the center of thoughtfully designed AI tools will radically increase directed and independent automation, efficiency, productivity and make agents better at their jobs. By automating a significant amount of repetitive day-to-day processes, AI-driven solutions help increase the cost savings a company is seeking while creating a stellar customer experience.

2. Determine the Business Goals

A focus on business outcomes is important from the outset. Artificial intelligence has the capability to transform an entire cable company and its operations. Thinking big and thinking different is key. Nonetheless, the size, scope and steps within a major AI project should not be so wide that it creates a generic and impersonal customer experience, or so narrow that it misses part of the audience. Once goals are established, it's critical that the data used to build bespoke AI models isn't skewed such that models end up with poor predictions.

Healthcare IT supplier, McKesson recognized that if you want to earn customers, you put their interests first. That meant reducing hospital expenses in non-labor areas, such as medical supplies, one of the highest costs outside of labor. Once the goal was determined, McKesson looked beyond the traditional challenges and visible symptoms inside their operations. They looked across the entire supply chain to uncover the true problems and bottlenecks —challenging existing people, processes, and technology

solutions[1]. Using data insights learned from its product, location and transport data from scanners and sensors, the company was able to cut inventory by $1 billion when needed and identified opportunities for cost reductions and time-savings. [2] Artificial intelligence, when applied smartly, is capable of (as one executive at the time put it) "making the invisible, visible."

For the cable and telecom industry, if we consider customer satisfaction (CSAT) as a business goal, the competition isn't other large enterprises, rather it's the most popular consumer apps such as Facebook, TikTok, Instagram, even Uber or Lyft that both agents and customers are experiencing frequently. These apps provide best in class software that offers versatility and an intuitively designed user experience.

3. Measure What Matters

Over 20 years ago, Bill and Melinda Gates put $20 billion into their foundation to tackle global health challenges, spending $1 billion each year. Former CEO Patti Stonesifer said: "*Sometimes… we were probably measuring the wrong thing. You have to pay close attention to whether your data is getting you to the ultimate goal. We were learning so fast that sometimes we had to change data sets midstream. Say you had a seed that would double production of yams, and you were focused on that number. But then it turned out that nobody would use the seed because the yams took four times longer to cook at night."* [3]

And this is one of the big challenges with measuring what matters—not only can it be difficult to determine the most actionable metrics to focus on, but it can also feel more instantly gratifying to track vanity metrics. "A vanity metric is like a distorting mirror– you might like what you see in it but it's not a true picture, it's just your vanity." [4] These vanity metrics can be thought of as those that don't cleanly map to business objectives.

Take the example of an e-commerce business: it's certainly tempting and fun to track page views and to keep seeing that graph of page views going up and to the right. However, if the goal is sales, then "page views" is not the most clear or efficient metric to drive the desired behavior. In this example, a team might be encouraged to create superfluous or "click bait" links to the site to keep driving up page views, rather than focusing on meaningful engagement that drives sales The same is true of all of us trying to solve different problems in the CX space and in the cable industry.

When you're evaluating using artificial intelligence in CX operations, this industry needs to consider evolving the way it thinks about measurement. Take containment or conversion rate as examples. These are industry standard measurements established with rules-based technology.

In the case of conversion, an overly simplistic view is also problematic. Take your retail sales team, telephone-based sales team, and your digital-based sales team. All these groups will have varying conversion rates. Operating by established approaches, a retail-based team will always have higher conversion rates than telephone or digital agents. Does that mean companies should go out and build more brick-and-mortar stores? No.

[4] Lean Startup Series: Vanity Metrics vs. Actionable Metrics (2018)

Shifts in buying habits, technological advancements and socio-economic changes are upending the way consumers engage with brands that have profound ramifications on how sales organizations capture, retain, and grow their customer base. This requires sales leaders to transform their organizations' approach for engaging consumers, particularly digital-first millennials, and Gen Zers who want to engage via digital.

So, it's important to review what you're measuring.

For example, contact center management has spent decades measuring average-handle time, concurrency, containment, and abandon rates among other measurements. But what about considering labor-per-hour, or revenue-per-labor hour as a new metric? Measuring conversion rate might not be the best metric, especially when a company wants to scale customer services. Take sales conversion rate in digital. If it's lower than retail, does that mean you abandon digital? No, it means we need to look at things differently to better understand the throughput of an organization.

Consider agent efficiency as throughput of customer issues: the number of issues handled per agent per unit of time. The industry can improve throughput both by decreasing agent handle time (AHT) for single issues and by increasing concurrency as well as by automating more conversations. As agents' use of AI expands, handle time decreases – and agents can manage more concurrent conversations, leading to higher throughput.

To encourage a shift to digital, cable companies need to encourage customers with awesome and intuitive experiences, reimagined with the help of AI-driven tools. Further, a rethinking of service level agreements for all channels is likely needed. Long term, digital provides better analytics and automation rates with a more convenient customer experience that is staffed more cost effectively with people who are operating more asynchronously.

Another example I see a lot is focusing on containment, meaning keeping conversations "contained" by automated systems that don't require reaching an agent. In the case of containment, it can only be treated as a proxy for success in limited situations because complex issues can rarely be handled effectively without human involvement. So, tracking containment as a "success" metric doesn't account for the significant number of customers who still require an agent to solve their problem. But what if the conversation wasn't successful? What if the automation did half of the work for the interaction so the agent no longer needed to do that half of the work? Under a metric like containment, any agent involvement is considered failure, but if we take a more holistic view of total throughput, we'd discover that we're significantly increasing the number of conversations that an agent can handle in the day.

The cable industry's CX operations have an opportunity to look more holistically at measurements and understand their organizational throughput, which requires a degree of change management to follow.

It's critical for organizations to measure what matters and update thinking by looking at what new metrics will deliver. Looking at the right measures can deliver results that will truly represent the customer experience overall.

4. Evolve Workforce Management Practices

Several years ago, the Associated Press announced that the majority of U.S. corporate earnings stories for its business news report would be produced using automation technology. In a relatively short amount of time, AP increased its earning coverage 14-fold delivering over 4,000 more public company earnings

quarterly, because of AI. [5] It altered the way their 248 bureaus globally reported news. The technology didn't replace journalists, rather it freed them up to tackle more work and interpretative reporting of earnings.

When cable companies want to use AI to maximize automation, productivity, and scale in its business, it's critical to understand where changes in the workforce management processes and operations will be required. With a change in how a company measures success of contact center operations, there needs to be an accompanying change in the way the contact center operates. To start it's important that you have the right people on the team. For example, it's important to have people who know and think about your customers and the accompanying journey mapping, operations, integrations, or the professional services that support a company.

There's a very interesting paradigm shift that needs to happen within the groups responsible for implementing or overseeing AI systems—the best results with AI are born out of allowing the systems to do their own work in processing vast amounts of data, not from configuring all the rules. Configuring rules gives a sense of control without allowing teams to achieve scale. I've observed across many use cases and many industries a learning curve in adapting to that flexibility of AI systems coming from the configuration mindset.

A specific example comes up with call routing. There's an urge to optimize by defining specific and narrow groups of queues, classifying calls into those queues, and setting up granular rules for when a queue is full or when it has availability. A downside of this is that defining rigid rules with such specificity can result in an imbalance of distribution—yes, if there's no constraints for equal availability and equal demand everywhere, then it can work, but the reality is often much messier. Depending on what is happening, which agents are staffed, how many customers have one question vs another, these types of policies can backfire. If instead we preserve larger groups of agents—but allow the models to learn about which agents do well with which types of customers, which types of intents, at which points in the day—AI can bring higher levels of global optimization vs sub-optimization of more distinct areas. [6]

Training for agents and how applications are permissioned for agents will need to evolve. Some agents will be able to handle two, three or more customers at a time asynchronously depending on their skill and experience level.

With the introduction of AI, an organization must be willing to invest in evolving the way it operates and willing to react flexibly as it encounters new challenges on the frontier of chartering a modernized customer experience and redefining its KPIs.

To drive digital adoption new SLAs will need to be designed, which could impact non-digital efforts like voice to succeed. When customers use a digital channel, they are retrained on how to approach the company in the future. This will in turn require an organization to look at intentional staffing, that might require labor sourcing or retraining existing agents that have good typing skills and response speed.

Attrition rates of digital agents are lower than attrition rates of voice agents so hiring practices could also change because of AI.

5. Cooperate, not Compete with Other Departments

Large companies often have competing departments, which can undermine each other's efforts and create contradictory visions. If these challenges aren't addressed, it can lead to a demotivated and siloed workforce that loses sight of the common goal and how they can contribute.

While it's difficult to accurately measure the impact of one department vs another, a company can measure output such as revenues, ROI and speed-to-market. Measuring behavior doesn't work but measuring results and considering the degree of cooperation will help departments to continually shape workflows to nurture better cooperation. Therefore, not only defining the best business goals and measuring the right things is important, but also ensuring those goals permeate through different teams, aligning incentives for different departments.

Take for example: A digital self-service sales team that competes with a chat-supported sales team. One group is trying to lock customers into the self-service model, while the other team is proactively getting consumers to talk with agents to sell cable packages. Both groups should be working together, rather than operating in silos or competing for customers – having people be integrators between both teams is essential, as well as ensuring both teams KPIs and incentives are directed at the same overarching goal.

Additionally, consider how often different groups have ownership over different channels, some own the website, another the mobile app, another social channels, another asynchronous channels, and a completely different department owns the voice stack. While there are different skills necessary for some channels, and the goals may be slightly different, customers don't ultimately care—they are contacting a company and expect consistency regardless of the channel. Ensuring that all the different teams are tying back the customer experience to a holistic goal vs. to individual channel goals is crucial.

6. Know Your Tech Stack

Many large customer service organizations are dependent on a frankenstack of technologies and tools that have been layered on top of each other—sometimes as a result of mergers, acquisitions, or years of accumulation. These digital towers of Babel were built as sources of data for rules-based programming and are often a patchwork of incompatible systems and data formats. Achieving personalization and productivity gains within the constraints of rules-based technology is a challenge, so it's critical to ensure that the technology stack is the right one for a digital transformation.

For AI to work well with a technology stack, the APIs need to be ready. Far too often bad APIs or poor API documentation is a major tripping hazard for the success of AI. The more systems you glue in the more difficult it becomes to untangle and experiment. However, when more integrations are built and established, AI-Native technology can simplify workflows and the tech stack, while caching customer details to feed routing, autosuggest and multiple parts of the conversational experience for a more impactful, personalized experience.

Not allowing silos due to organizational structure or vendor strategy to seep into the user experience is critical. As companies look towards using AI-powered solutions to users, the need to simplify the stack in order to simplify the experience is increasingly important.

7. Design AI For People

As Martin LeBlanc famously said, “A user interface is like a joke, if you have to explain it, it’s not that good.” And this becomes ever more critical with AI. Artificial intelligence alone won’t solve the challenges of cable without human agents who are key to delivering a successful customer experience. For the industry to reap the benefits of AI, companies need to think about the various users from agents through to customers—each has different goals, expectations, and metrics for success.

When AI is designed to be a part of the business process, and a thoughtfully designed product that specifically caters to its users, it makes for more productive and efficient agents in their day-to-day operations. It can make agents better at what they do more rapidly than any other technology.

AI designed for the end customer experience can provide a smooth, simple engagement that meets customers where they are—whether it’s a digital or voice interaction. The design of AI can empower cable companies to have real-time insights and reporting on every single customer interaction.

When AI is designed for agents, you have significantly more visibility into how agents are solving issues in their journey. For example, with auto pilot greetings and data inserts in autosuggest, AI can speed up and improve quality of the greetings while allowing the agent to focus on getting up to speed with the customer’s account and queries.

Customer conversations can be a mix of automation and conversation. For example, when a customer is having a service issue that can only be resolved with an onsite cable technician, AI can take over for the agent and automate the appointment scheduling, freeing up the agent to troubleshoot other more complex issues. Automation can summarize the conversation and confirm everything with the customer. If the customer ends up needing more help, the agent can seamlessly jump back into the conversation where a human touch will make the difference. AI can provide the flexibility to leverage automation without leaving the customer stuck if the conversation veers off track.

Customers and agents, like all of us, are used to using the absolute best consumer software every day such as Uber, or Facebook. That’s the competition, not other enterprise software providers. If you, as a consumer, downloaded an app that required you to switch through multiple applications and web pages to complete a payment, would you do that? Or look for the product you were attempting to purchase from another source with a more streamlined checkout flow. The interface of AI is crucial to make users feel supported in their jobs, to making your customers enjoy interacting with the company. Treat all your users like consumers, the agents, the supervisors, the data analysts-- build tools that make them want to do more work and better work, this can only be done if they are at the center of the research and development process.

8. Conclusion

With customer agents working from home, a lot of the infrastructure around management, service and quality that previously relied on in-person interaction need to adapt quite significantly. With access to peers and management limited in some instances, artificial intelligence can be a major enabling tool for employees to improve their efficiency and productivity wherever they are. When AI is designed for people, the AI models learn what works well for agents, to improve future actions and automations—and most importantly business outcomes, even in this new environment. The right AI models can help supervisors and managers adapt, allowing them to see what’s happening on an agent’s journey in real time, provide real-time coaching and support where it’s needed to deliver the best customer experience.

Designed well, AI should make an agent's job better. It can identify where agents are getting stuck, or when a customer's mood is shifting in a conversation in a good, or bad way, so that in the future AI can help move those conversations along in a positive way where the agents feel supported.

Think big. Think different and the cable industry's CX operations can lead the way artificial intelligence transforms business operations in customer experience.

Machine Learning and Proactive Network Maintenance: Transforming Today's Plant Operations

A Technical Paper prepared for SCTE by

Brady Volpe

0. Introduction

Proactive Network Maintenance (PNM) aims to proactively determine issues in a network so higher quality service can be provided and service impairments can be fixed before subscriber's experience issues. PNM can leverage updates in Data Over Cable Service Interface Specification (DOCSIS), an international telecommunications standard that enables high-bandwidth data transfer through existing cable television systems. The introduction of many PNM related test metrics has made it possible to pinpoint the root causes of issues in an HFC network. Full band capture (FBC) data allows operators to have visibility into all downstream RF signals anywhere DOCSIS 3.0 or 3.1 modems are deployed. This eliminates the need to bring spectrum analyzers to customer homes and perform inspection. Through PNM, downstream RF signals can be monitored 24x7x365 just using the subscriber's cable modem, which leads to better performance and impairment resolution. Issues can be identified and located faster, leading to greater cost savings and improved subscriber experience.

A challenge for operators is manually analyzing the FBC data from thousands or millions of modems. Further, the cable operator must be able to determine if RF impairments in FBC data are associated with a single home or multiple homes. When an impairment impacts a single home one can usually assume sending a technician to the individual home is the correct action. However, when multiple homes see the same impairment, sending a technician to a single home is almost always the wrong answer as the impairment is in the outside plant. In this scenario, rolling a truck to a single home for an outside plant impairment wastes time, money, extends MTR and annoys the subscriber.

This is where the power of machine learning and PNM shine. Machine learning can quickly analyze the data of thousands or millions of modems in just minutes. Then it will lead the end user to determine if there are impairments and if so, where the impairments are located.

This paper will discuss the type of RF impairments observable by PNM. Next it will discuss how machine learning is used to analyze impairments using an unsupervised model. Then it will look at how machine learning is combined with CableLab's spectral impairment detector (SID) to substantially improve on SID's impairment classifiers. Finally, the paper will look at how the author is using gamification to use feedback from end users to migrate to a supervised learning model.

Enjoy.

1. Types of Impairments

It is important to provide a brief understanding of the typical types of impairments that are generally found using FBC. Rather than using the standard impairment chart kindly produced by Larry Wolcott of Comcast, this document will demonstrate the same impairments, but with new charts. These charts are taken from live cable operator plants using a PNM application.

In the next sections, we will be focusing on the following impairments: adjacencies, suckouts, resonant peaks, rolloff, standing waves, and tilt.

1.2.1 Adjacencies

Adjacencies are essentially misalignments of radio frequency (RF) channels where adjacent channels have a large delta in channel power. This can result in packet loss, video tilting, freezing, and black screens. These impairments can often affect multiple cable modems (CMs) downstream, meaning that

clustering and especially localized clustering could find common impairments to better be able to identify the root cause of an adjacency [7].

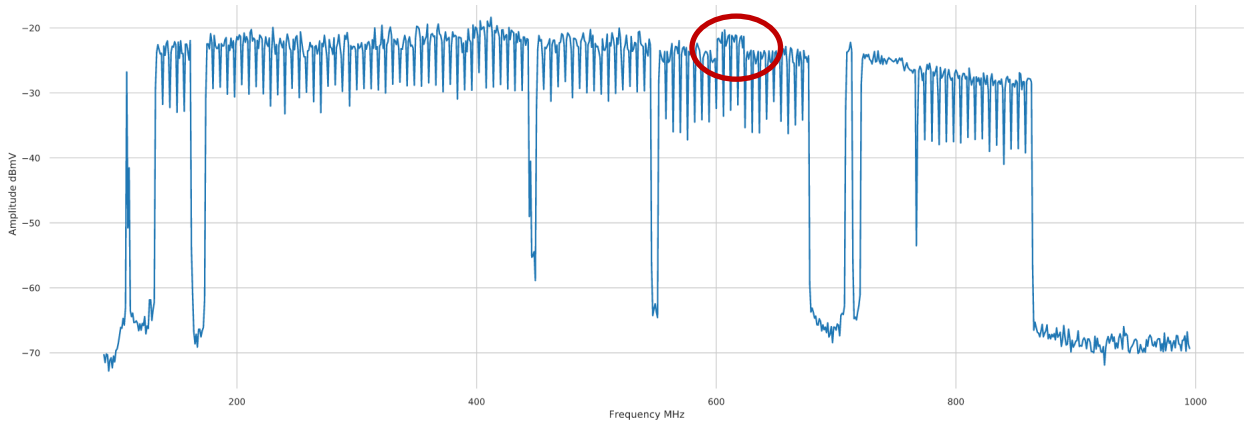

Figure 1.1 Example of Adjacency at around 600 MHz

1.2.2 Suckouts

Suckouts are another type of RF impairment that span multiple channels. They dip down to a certain depth to make a V-shape in the signal. The depth and width of these impairments determine the severity and effect and may often not have any significant impact on customer performance [7].

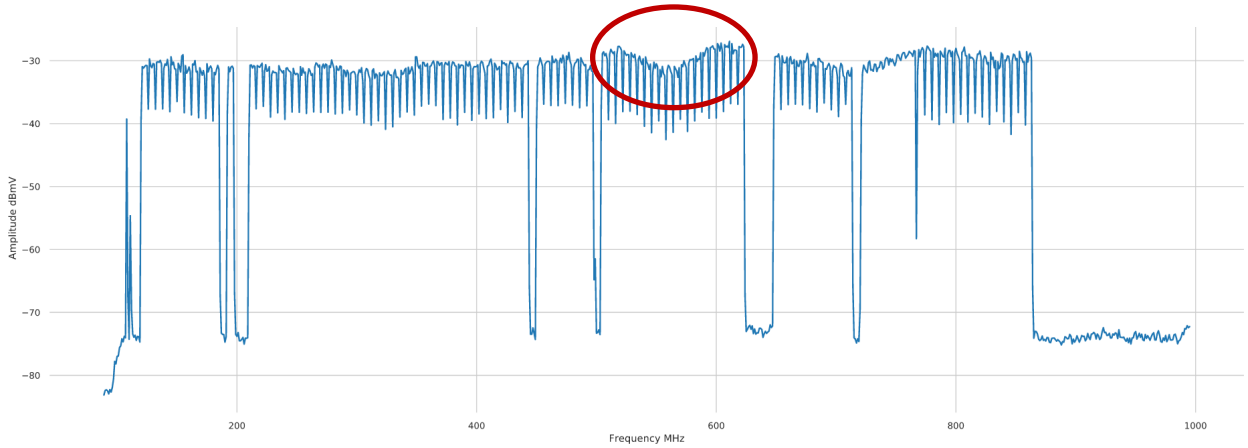

Figure 1.2 Example of a Suckout at around 550 MHz

1.2.3 Resonant Peaks

Resonant peaks are another impairment that usually spans multiple RF channels. They look like inverse suckouts, forming mountain-like peaks in the signal. They can be quite sporadic, forming and disappearing quickly, due to factors such as temperature and can have a wide range of performance impacts including packet loss, tiling, and freezing [7].

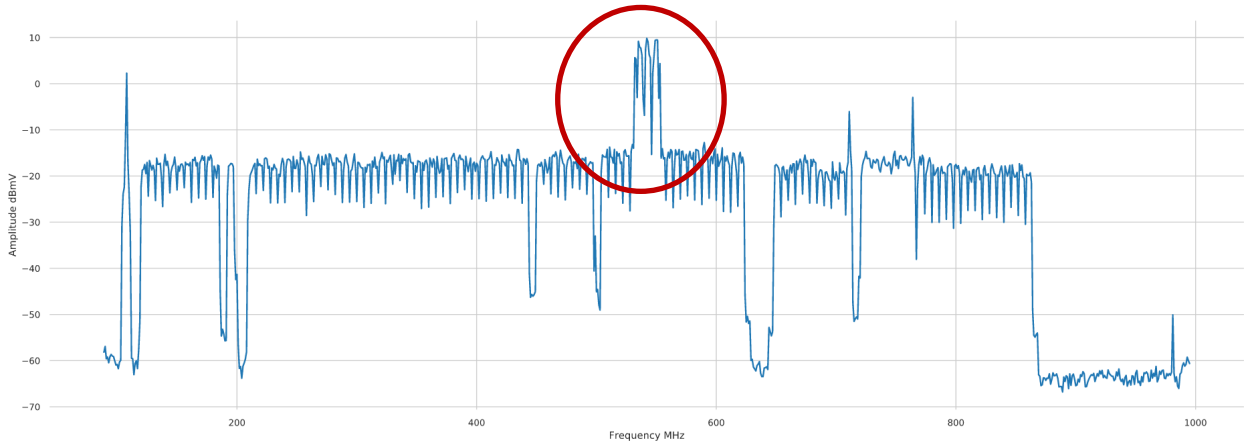

Figure 1.3 Example of a Resonant Peak at around 520 MHz

1.2.4 Roll Off

Roll off is an impairment characterized by a gradual, non-linear, exponential looking decrease in amplitude and power. Roll off can have many causes including old cables being used or individual elements in the network being configured incorrectly. It can cause freezing or tiling of video channels and is, unfortunately, one of the more common RF impairments [7].

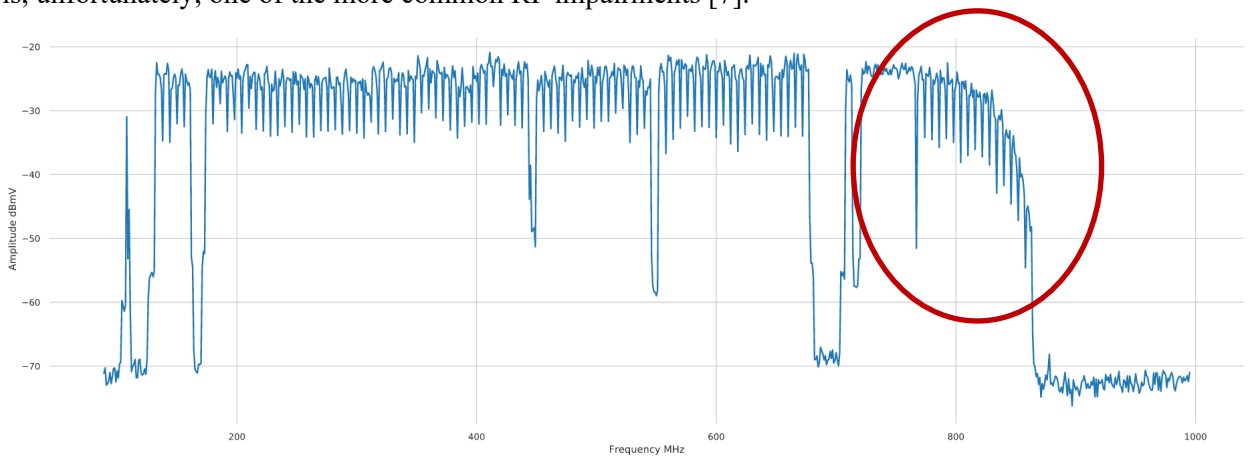

Figure 1.4 Example of Roll Off at around 820 MHz

1.2.5 Standing Waves

Standing waves are RF impairments which affect the entire spectrum. They are usually caused by an impedance mismatch in the signal and appear as waves seen at the peaks of the signals [7].

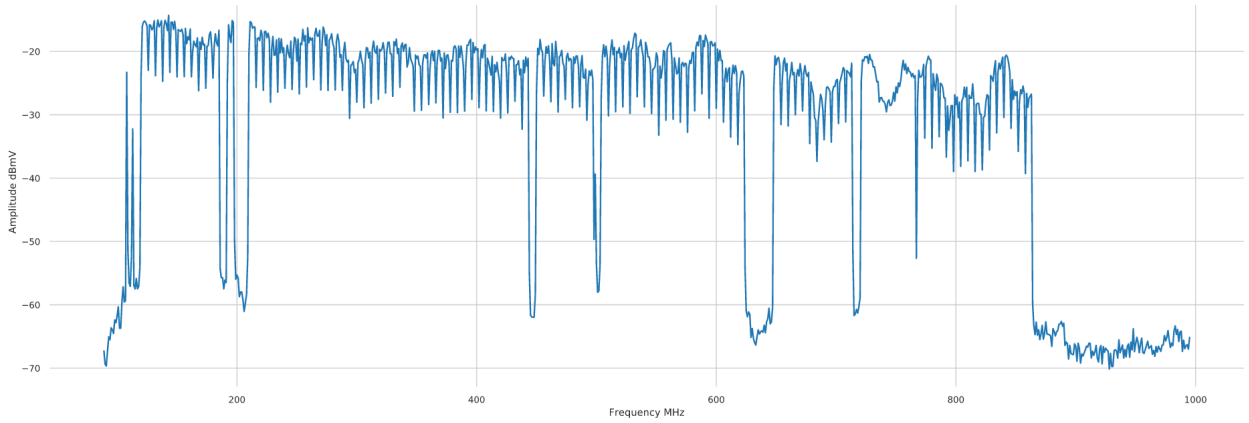

Figure 1.5 Example of a Standing Wave

1.2.6 Tilt

Finally, tilt is an impairment that is characterized by amplitude differences between higher and lower frequencies. There can be a positive or negative slope to a CM. This impairment does not always cause issues for customers [7].

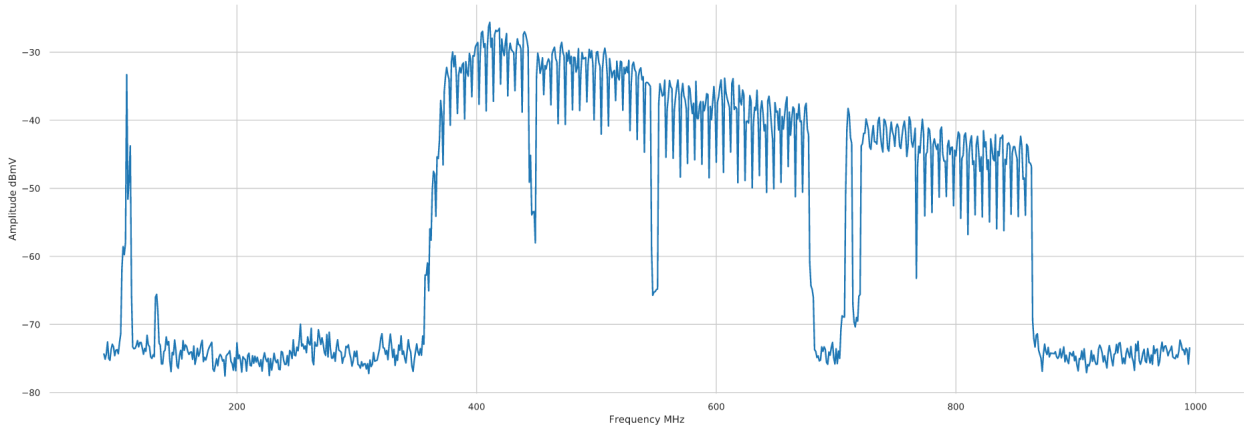

Figure 1.6 Example of Tilt

1.3 Purpose of Clustering

The purpose of clustering is to be able to find shared impairments between CMs in an automated method. This allows us to determine if an impairment affects one cable modem (CM) or if it affects multiple CMs so that cable operators can better pinpoint issues in their systems. As mentioned previously, the focus on clustering is to determine; do we roll a truck to the subscriber's home or to the outside plant. Getting this right results in immediate time and cost savings.

The objective is to find both global and local clusters of impaired modems. Global clusters are clusters where the entire signature of cable modems matches tightly while local clusters have similar signatures or

impairments in localized regions. Examples of localized clusters may be things such as a shared suckout between multiple cable modems.

1.4 Purpose of SID Overlays

The final step is to overlay CableLabs spectral impairment detection (SID) impairment labels to validate SID outputs and generalize SID predictions to more CMs. SID is software that can identify and localize common RF impairments in FBC data. It was created by the CableLabs PNM working group and has many thresholds that must be tuned to optimize performance. This does mean however that it often makes mistakes in correctly identifying impairments such as suckouts, standing waves, etc.

By overlaying SID detections on existing clusters, it is possible to validate the SID impairment labels and generalize them to the rest of the CMs in the cluster. Further, if a certain percentage of CMs in a cluster share a common SID label, then these SID overlays can be applied to both global and local clusters. Once the ML model has identified a high correlation of modems having impairments detected by the ML engine and by the SID engine, it is possible to label the impairment to the end user with a high degree of confidence.

2. Technical Approach

It is assumed that the reader has some knowledge of machine learning from previous SCTE or other papers on this topic related to ML and FBC. For this reason, topics such as unsupervised learning, supervised learning, features, and general machine learning terminology will not be covered. It will be up to the reader to review currently available documents as referenced at the end of this document.[1][5][11]

The next sections discuss how FBC data must be manipulated prior to any machine learning analysis. From a development standpoint, this is where the most work occurs in a machine learning exercise. It is often said that machine learning is easy, but it's the preparation of the data that is hard. Meaning bad data in means bad data out. To get to a good machine learning model means lots of pre-work.

While the following sections may initially appear a bit intimidating, it is important to note that the work being shown is fully automated in a PNM application. The user need not know any of the mechanics behind the machine learning. From the end user's perspective, the result is displayed data which is easily actionable because now meaningful data is being presented. Machine learning just did the hard work of sifting through piles of data for the user.

Now, let's look at the technical approach for giving the end user a meaningful experience.

2.1 Pre Processing

Preprocessing steps are necessary to manipulate FBC data to have an optimal performance with clustering.

2.1.1 Downscale Data

The raw FBC data has a varied sample rate and a varied number of data points per cable modem. The clustering algorithms that were used however require all the data to have the same dimensions. Also, it makes the code simpler and faster since it allows for NumPy arrays to be used for many operations [8]. The data is downscaled to one datapoint per integer frequency from 89 to 996 MHz. Simply put, the

corresponding amplitude for the sampled frequency closest to each integer frequency is kept and stored to end up with 907 data points per cable modem.

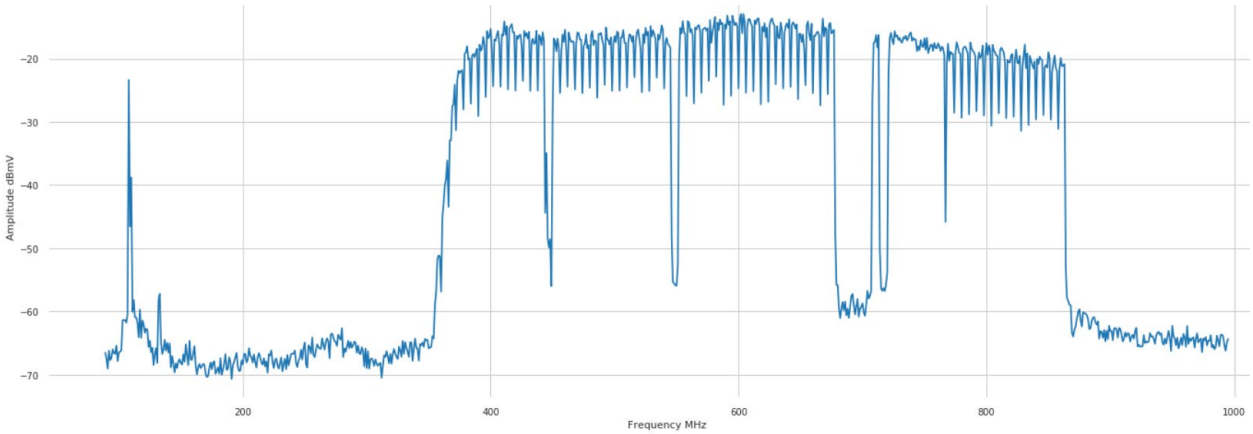

Figure 2.1 FBC Data Scaled Down

Additional downscaling was tested by using the data points closest to every other frequency from 89 to 996 MHz since most impairments did not lose any resolution and instead only some noise in the signal was eliminated.

2.1.2 Rolling Median

A rolling median is simply a median calculated for a certain window size passed over an entire signal [6]. This can remove very small and unimportant variations in the signal which would otherwise introduce unnecessary noise and produce incorrect clusters. Additionally, the advantage of a rolling median over something like a rolling mean is that it can filter out the gaps between channels. A rolling mean is not resistant to outliers meaning those dips would have a large impact on the surrounding regions. The median was calculated from the center meaning that n number of data points on the left and n number of data points on the right were used to find the median for the center point.

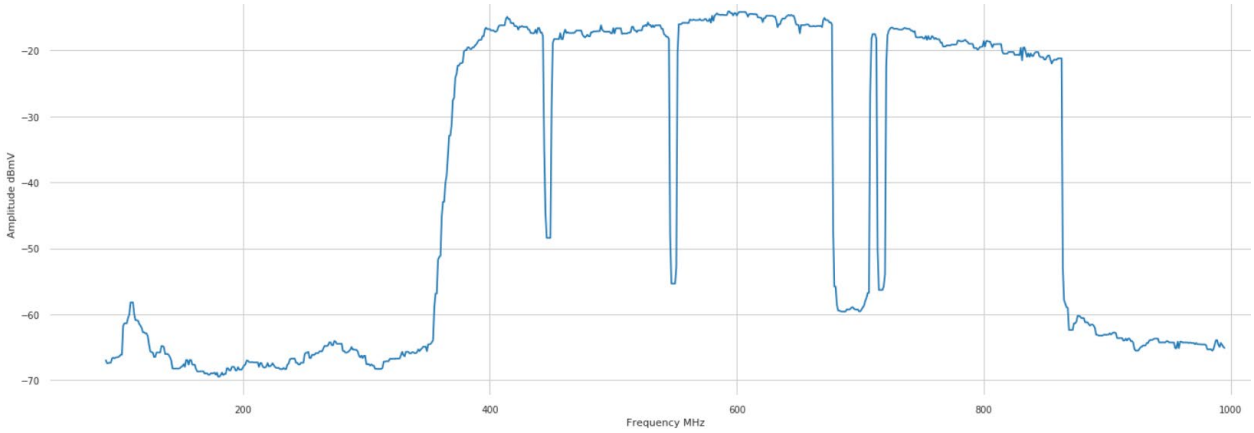

Figure 2.2 FBC Data Scaled Down with Rolling Median

2.1.3 Transforming to a New Center

When creating clusters, the power of a CM is irrelevant because impairments come from the deviations in a signal. Therefore, the signal was transformed up to 0 dBmV for the average of a certain region of the signal. The area of the signal was chosen to be 820-850 MHz because this results in transforming modems with rolloff much higher than other modems and therefore easily filtering them out (as seen with the blue CM in figure 2.3). Note that this arbitrary center frequency must be adaptive. For example, some plants may not have any signals between 820-850 MHz or there may be large impairments in this band. The transformation to a new center is used to find a clean and flat center where machine learning can be achieved. Finally, it was determined that rejecting the FM band (88-108 MHz) improved results because in nearly all cases FM ingress occurred in or near the subscriber home.

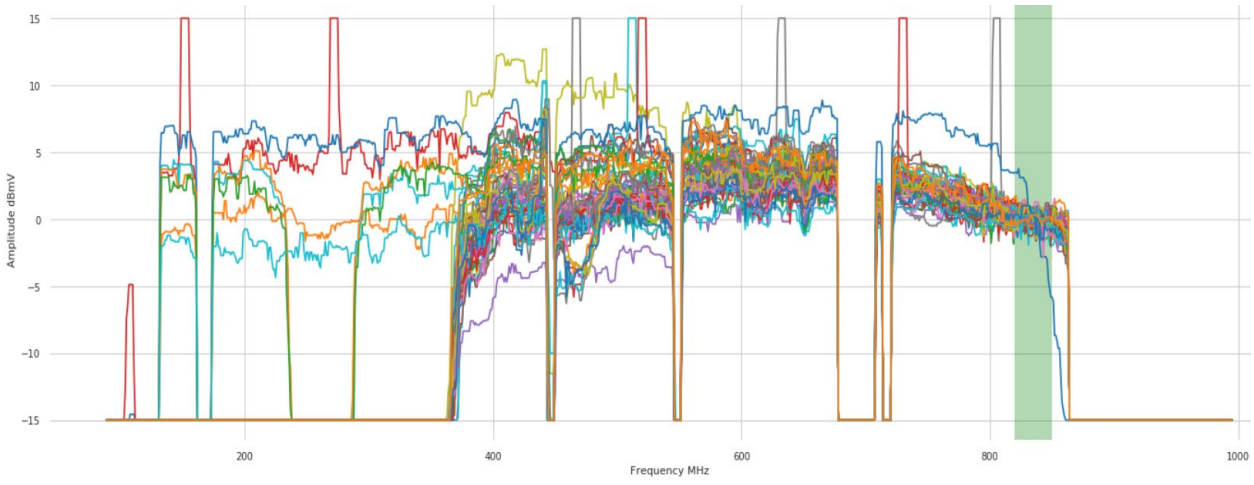

Figure 2.3 FBC Data Scaled Down with Rolling Median and Transformed and Clipped

2.1.4 Normalize Data

Data is normalized from -1 to 1 before any machine learning is performed. Since all data that is clustered on is clipped before clustering, all the data is simply divided by the clipping amplitude maintaining the

same shape of the data but reducing the amplitude range to -1 to 1. The purpose of normalization is to have a standard range of the data so that any predetermined parameters work optimally [5]. Data normalization is a very common machine learning practice.

2.2 Modem Health Classifier

The first step in clustering aims to classify each modem in a node as impaired or not impaired. These classifications are done in an unsupervised manner as no accurate ground truths currently exist on which to create a supervised learning model. For this system to work properly, an assumption is made that the majority of CMs in a node are healthy. This is a bold assumption, but one which must be taken until 1) proven otherwise by inspection or 2) a supervised machine learning model is available. Note that as discussed later in this document, by using SID data, it is possible to overcome 1) above with the use of SID data. This is because SID data will provide the necessary information that all modems in a node have some type of impairment. Once a cluster is created, if all modems in the "healthy" cluster are shown to have SID impairments, then by inspection of the SID data it can be determined that the cluster is not healthy.

2.2.1 Region Identification

The first step of classifying modems as healthy or not was to identify the sections of RF spectrum that occupied by video or QAM channels. For the purpose of this document, occupied spectrum are named regions. Identifying regions is a necessary step because otherwise, classification could be made on modems with varying sections of used and unused spectrum which would be more quickly classified as an outlier and impaired than any modem which has an actual impairment. In Figure 2.5, an example of unused spectrum is the spectrum below about 375 MHz, where the blue line drops to -1.0. For someone familiar with the industry, it is apparent that a data only filter is in use in Figure 2.5. The data only trap causes all signals below 375 MHz to be attenuated. The signals that are still present below 200 MHz are FM ingress signals (88-108 MHz). As previously mentioned, the FM band is omitted from machine learning in the current model, so these low frequency signals will be ignored.

The process starts by roughly identifying all the used frequencies of every modem in a node (see figure 2.5 and 2.6).

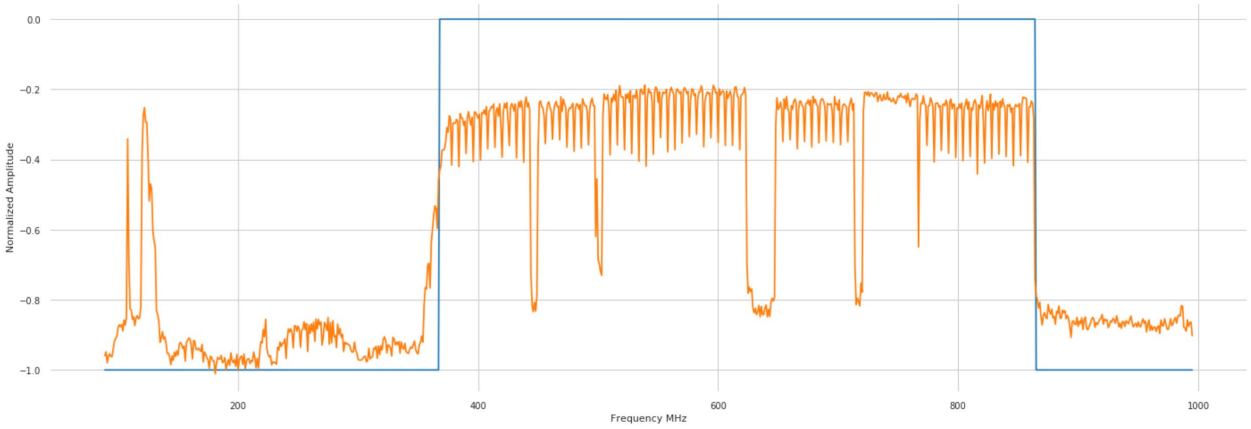

Figure 2.5 Used Frequencies Identified on Modem

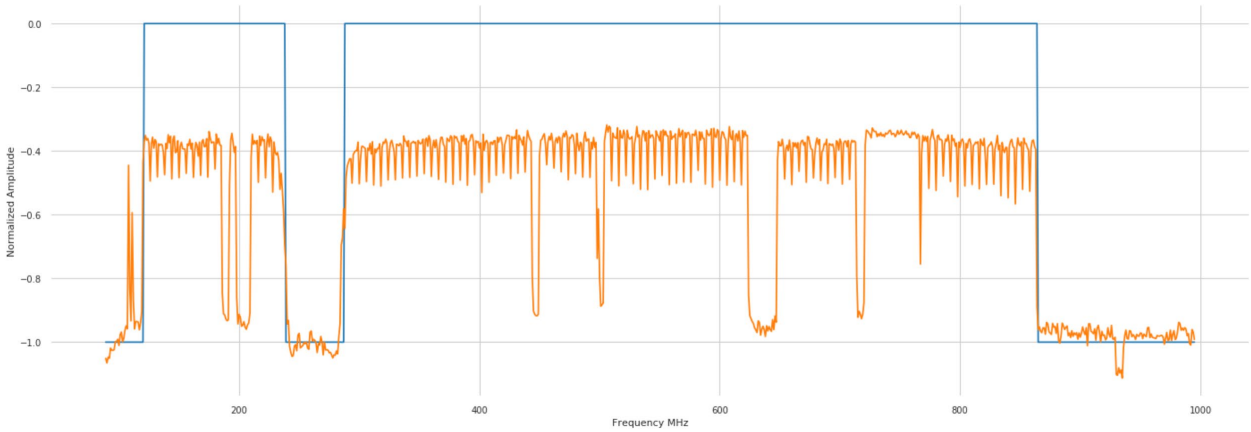

Figure 2.6 Used Frequencies Identified on Modem with Band Stop Filter

In Figure 2.6, it is evident that the pre-processing can identify unused frequencies, but this time it is not due to the presence of a data only filter. In this case, there are channels missing between 275-300 MHz. The blue line indicates pre-processing is eliminating these frequencies from the model. While there are unused frequencies higher in the band around 625 MHz, these do not the minimum width for the classification engine to exclude the band.

The used spectrum is found by first passing a rolling median with a large window size over the normalized, transformed, and clipped signals from section 2.1.3 (see figure 2.7). Then, at any frequencies where the normalized amplitude is greater than -1, those regions are labeled as used (blue line at 0) and any frequencies where the normalized amplitude is -1, those regions are labeled as unused (blue line at -1).

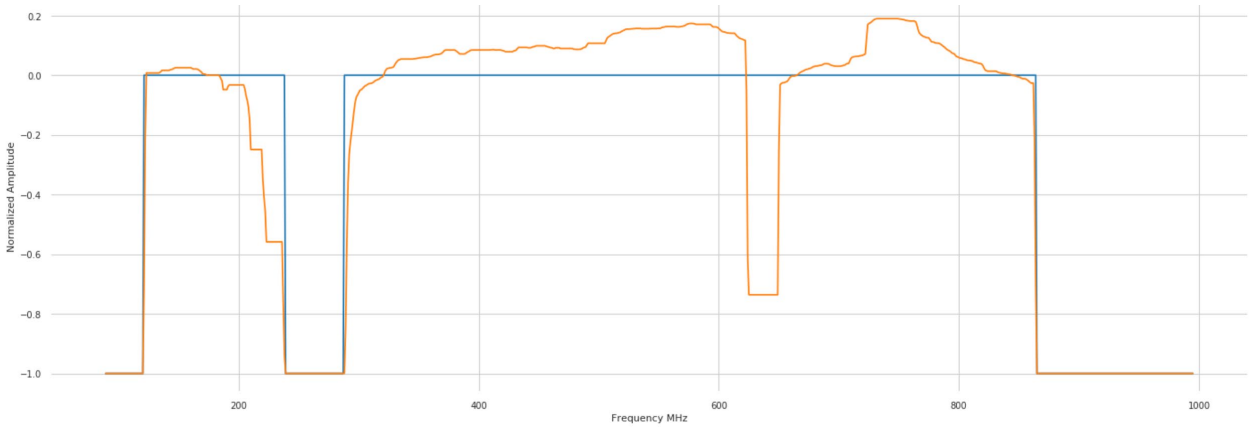

Figure 2.7 Used Frequencies Identified on Smoothed Modem with Band Stop Filter

Once all the modems have their used regions extracted, regions can be extracted representing the various regions of commonly used frequencies between modems. This works by first identifying the regions with the most used spectrum of all modems (see figure 2.8 for used spectrum of all modems). In the case of this node, that region is from around 380-850 MHz. Then, health classification is done on this region as described in region 2.2.2. Following this, all modems will be identified as impaired or not impaired for that region. This region is then removed as being a used spectrum from all modems which have used spectrum in that region. Following this, the process repeats for the next region with the highest number of commonly used frequencies by classifying and then removing that region from the used regions as well. This process is repeated until there are no more used regions in the spectrum. At this point all modems have been classified as impaired or not impaired based on regions where modems have the same used and/or unused spectrum.

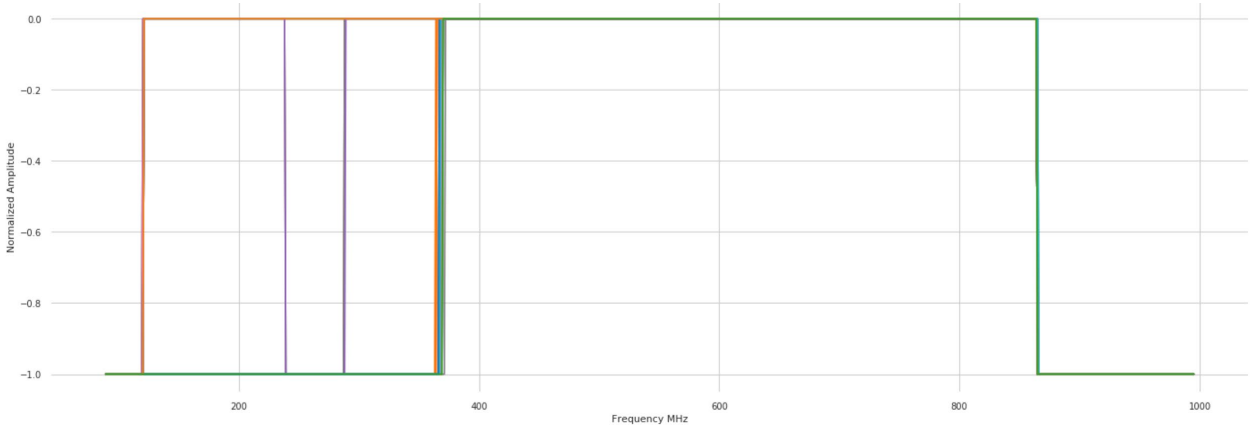

Figure 2.8 Overlapped Used Frequency Regions

2.2.2 Health Classification on Extracted Regions using Local Outlier Factor

Once common regions of used frequencies are extracted, outlier detection is done on modems which have the regions. This outlier detection utilized the local outlier factor (LOF). LOF is an unsupervised (well, semi-supervised) machine learning algorithm that uses the density of data points in the distribution as a key factor to detect outliers, LOF roughly works by calculating a standardized distance to n number of

neighbors and labeling data points with a large distance as outliers [1]. In turn, this can filter out modems which deviate from the rest of the modems due to impairments.

2.3 Global Clustering

The next part of the clustering is to cluster together the impaired modems (outliers from clustering) to determine if there are any similar global impairments between cable modems. Global clustering requires that signatures of CMs match throughout the entire frequency range, meaning that it cannot cluster together smaller local clusters, but it can find modems with common signatures.

Global clustering is useful in finding modems that have large impairments such as standing waves or tilt, which impact the entire spectrum.

2.3.1 DBSCAN Clustering

In machine learning there are many algorithms for grouping or clustering common sets of data together. One of the most used is K-Means. K-Means clustering works very well, however it is non-optimal for noisy data, such as FBC data. The current implementation in this paper is using a model called DBSCAN.

DBSCAN stands for density-based spatial clustering of applications with noise. The algorithm works by first selecting a random point in the data. Then, if there are minimum points (a specified parameter) number of data points within the radius of Epsilon (EPS, a specified parameter) distance or the Euclidean distance, straight-line distance to the original point, it is labeled as a cluster. Then this process repeats for every point that was in the original cluster, if the points have at least minimum points number of points within their EPS distance, then the points are labeled as core points. However, if a data point does not have the minimum points number of data points, it is labeled an outlier, unless it is within the EPS of a core point. If there are no more data points nearby, then a new random point is chosen until all the data has been clustered [3].

2.3.1 Global Impairment Clustering

Global impairment clustering was implemented purely using DBSCAN. The minimum points parameter is lowered to two to allow for very small clusters and the EPS is slightly lowered also to ensure clusters are tight. Figure 2.8 demonstrates the use of global clustering but also highlights some of the weaknesses.

Global clustering can cluster these modems and conclude that they are all impaired and have both a common impairment and rest of signature. What the impairment is or where the impairment is located cannot be determined purely using global impairment clustering (this is where SID overlays are needed).

The issues that arise from this approach is that if that same suckout were to be seen around 470 MHz on a different modem with used spectrum below 350 MHz, then they would not be clustered together. This is when local clustering is effective.

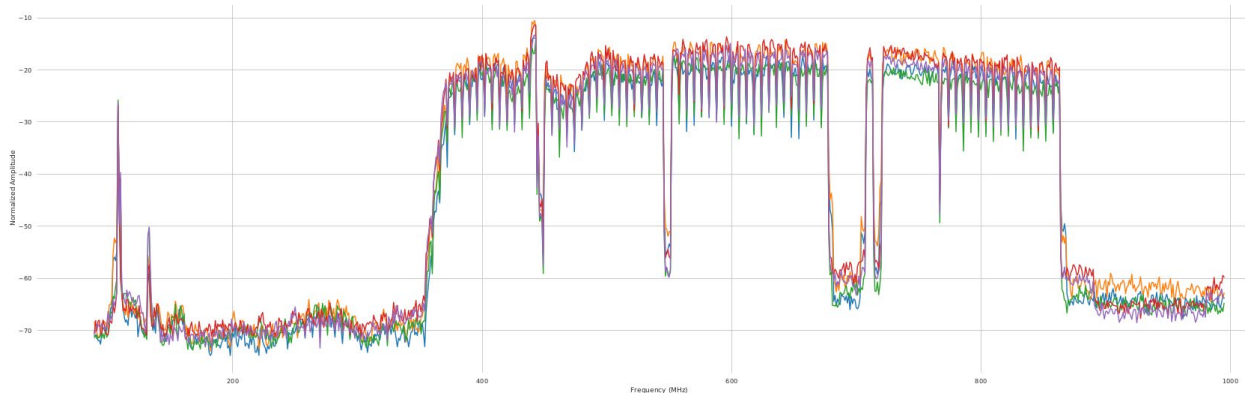

Figure 2.9 Global Cluster on Impaired Modems

2.3.2 Global Impairment SID Overlay

SID labels are overlain on global clusters to determine the location and type of impairments seen in a cluster. If a certain percentage of modems have an impairment, then that impairment can be generalized to the rest of the modems. Additionally, if that impairment is found in a local region for multiple CMs, then it can be generalized that those modems all have that impairment at that specific location. This is beneficial for two reasons:

1. The data being used is unsupervised data, which means it is not known if the FBC data is impaired or not impaired, but overlaying SID data, it is now possible to determine not only if the FBC data is impaired, but also the type of impairment (i.e., suckout, standing wave, etc.).
2. SID impairments are often inaccurate. For example, suckouts and adjacencies are often mis-labeled by the SID engine. By classifying many modems with the same SID overlay, it is possible to improve the accuracy of SID classifications through scale. If many modems show the same SID impairment at the same frequency, then the probability that SID is accurate is high.

SID overlays also allow the algorithm to discard SID impairments that are rarely found in the cluster. In figure 2.10 it is apparent that only 20% of the CMs in the cluster were labeled as having a resonant peak by SID. From this one can conclude that the modems in the cluster most likely do not have a resonant peak at around 620 MHz.

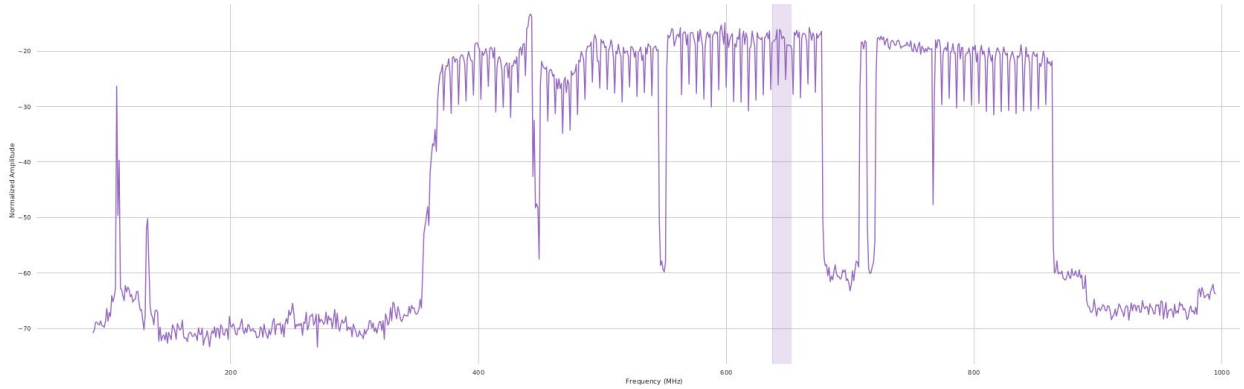

Figure 2.10 Resonant Peak Identified at 20% in Global Cluster shown by vertical purple bar

On the other hand, SID labels can be verified based on the percentages that they occur at and if the location that they occur at overlap. In Figure 2.11, it is visible that 100% of modems are labeled as having a standing wave from around 100-900 MHz. Therefore, one can accept this label as being most likely true. This can also apply to other labels which are not seen in 100% of modems however such as the adjacency labeled in 40% of modems for this cluster around 650 MHz. This can be generalized to all modems in the cluster if the threshold of the percentage of modems in a cluster that need to have a SID label for a certain region is met.

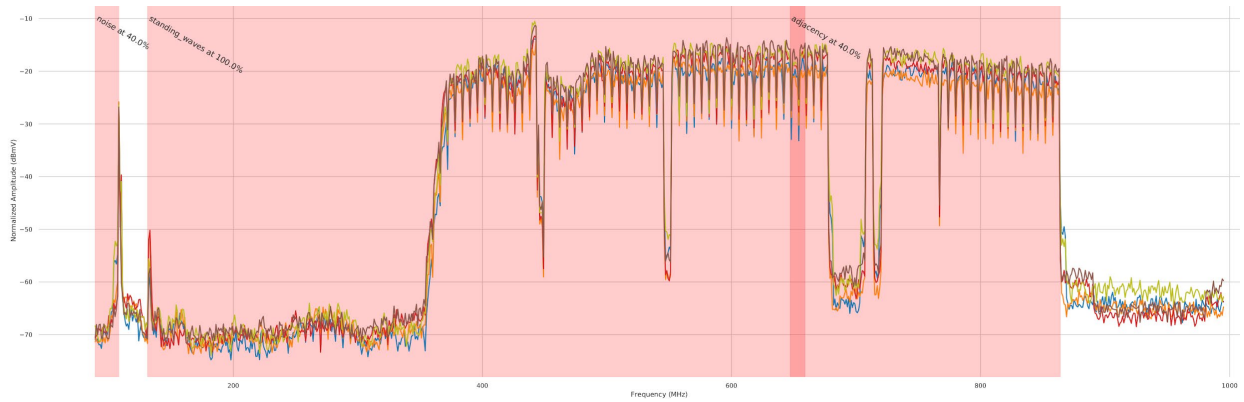

Figure 2.11 SID overlay with 40% Threshold

2.4 Local Clustering

To cluster together similar local impairments, different clustering techniques need to be used which only look at local regions. This is because CMs may share one common impairment, while not sharing a whole separate range of impairments and signatures which result in them being placed in different global clusters. Again, this is very important for narrow impairments such as suckouts and adjacencies.

2.4.1 Local Impairment Clustering

To find local impairments, clustering was done using DBSCAN on a certain window throughout the spectrum. This window slid over the entire FBC spectrum with a certain step size and clustered together

all the modems in the node using DBSCAN [10]. The FBC spectrum was preprocessed the same way as with variability-based outlier removal (section 2.3.2) so that the FBC data was straightened and centered at 0. This was important because DBSCAN would not work properly unless the data was in the same shape and located at the same amplitude because that is the only way for the Euclidean distance between sections of the FBC data to be small and therefore clustered together.

Then if one of the clusters formed only contains impaired modems, it is a localized impaired cluster in that region. If a cluster contains modems that are not impaired, it means that the cluster found similarities that are not an impairment, and the cluster is therefore not considered a localized impairment cluster. Additionally, if a cluster contains more than a certain percentage of the modems in a node, it was removed from the local impairment clusters because it most likely is clustering on something that is not an impairment.

In figure 2.11 we can see that the localized impairment clustering was able to find local clusters due to the preprocessing steps taken. Preprocessing manipulated the data to be in the shape seen in figure 2.12. Here DBSCAN can easily find clusters in certain windows even though the orange modem has many used channels under 400 MHz that the blue modem doesn't and that the blue CM has tilt but the orange one doesn't. This resulted in a important breakthrough, which was the ability to detect similar impairments on modems with radically different spectrum usage due to bandpass and band stop filters.

Figure 2.12 Localized Impairment Clusters on Impairment Modems

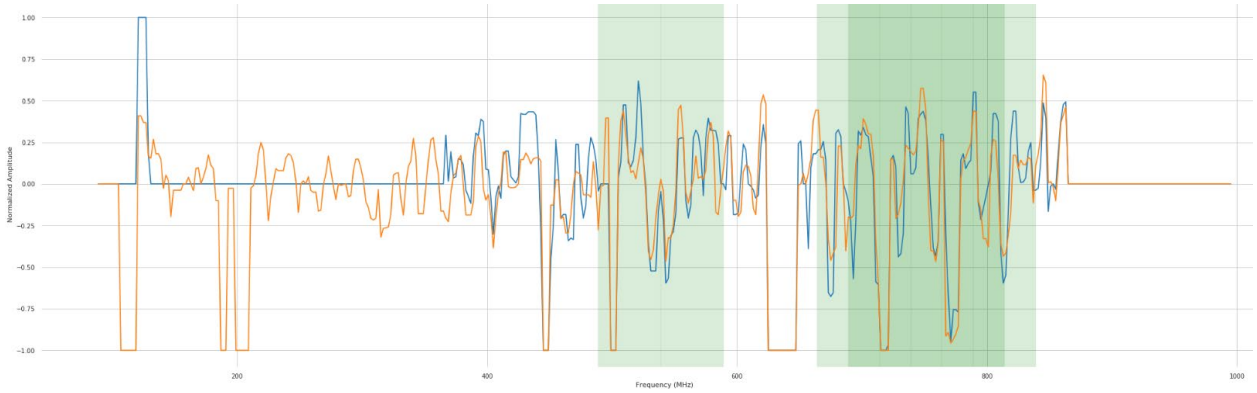

Figure 2.13 Localized Impairment Clusters on Impairment Modems Pre-Processed

2.4.2 Local Impairment SID Overlay

The last step with the localized clustering was to overlay the SID impairment labels for localized impairments (i.e., suckouts and adjacencies). This allowed us to draw conclusions about the accuracy of the SID labels and see if the labels intersected with the local cluster regions. In all the figures below, the green highlights indicate local cluster regions while the red indicates the global cluster regions.

In figure 2.13, we can see that SID labeled that both modems in the same local cluster had standing waves and that the labels intersected with regions of local clusters, meaning that we can conclude that both these modems have standing waves in the regions of overlap between the SID label and local cluster regions. We cannot generalize and say that both modems have standing waves on all regions from 100-850 MHz however because since this is local clustering, the regions could have nothing to do with each other.

As seen in figure 2.13, local impairment clustering can also be used to generalize impairments that are not detected in all modems such as the resonant peak around 530 MHz. Even though only 50% of the modems in the cluster had this label, it can be generalized to apply to both modems because it falls under a local clustering region. Figure 2.14 contains more visuals of a different local impairment cluster.

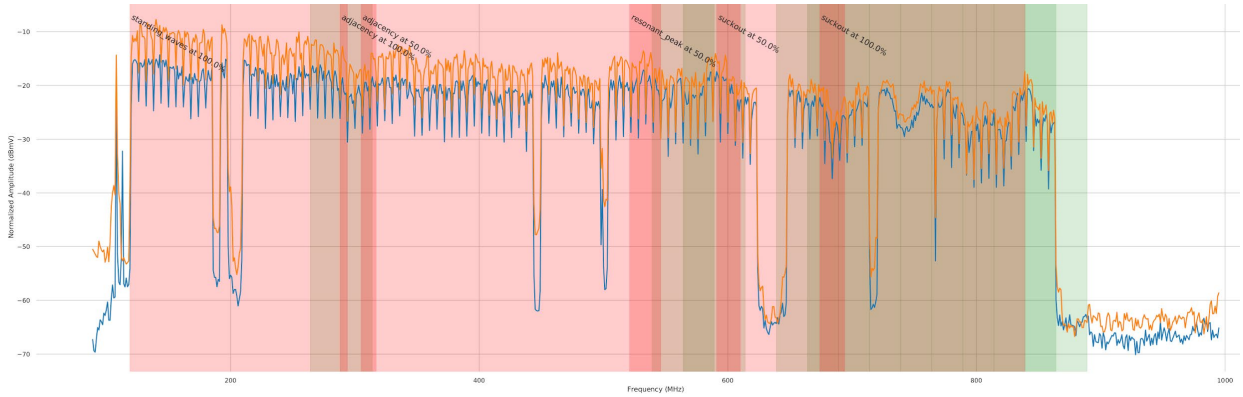

Figure 2.14 SID Overlay on a Local Cluster with Threshold of 40%

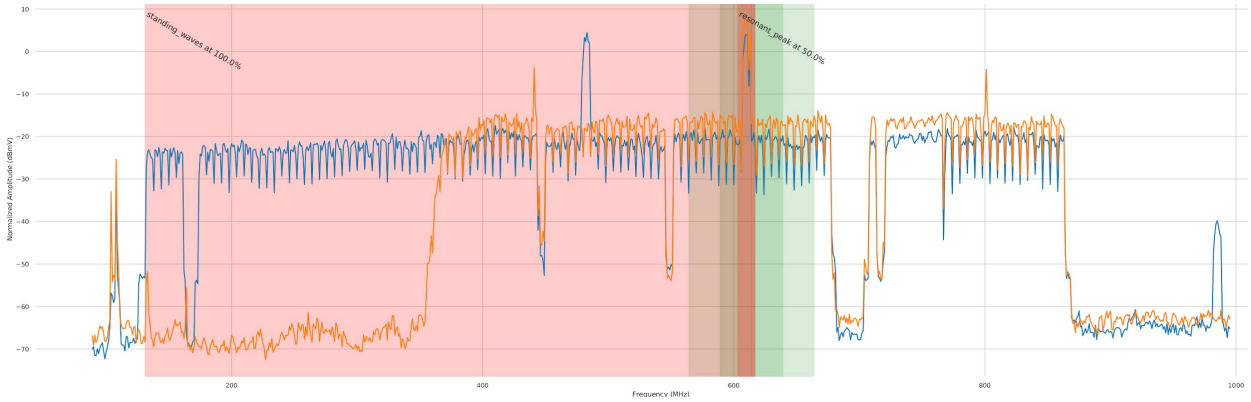

Figure 2.15 Resonant Peak SID Overlay

3. Results and Discussion

This section will analyze some of the performance, nuances, optimizes and observations identified during the use of machine with full band capture data. As this technology is continuously being improved upon but not only the author of this paper, but others in the industry, it is the hope that some of the findings in this paper will be used by others to build upon this and a collaboratively shared for the betterment of the industry.

3.1 Modem Health Classifier

3.1.1 Pre Processing Performance

The preprocessing steps were vital to the clustering. By clipping and centering the signals, small local impairments such as resonant peaks and suckouts become much more influential in the data and are therefore easily labeled as outliers only using DBSCAN.

Preprocessing does occasionally run into issues, however. Occasionally, minor impairments such as the red spike around 600 MHz in figure 3.1 are run over in preprocessing as seen in figure 3.2. This is most likely a result of the spike being very thin and the rolling median, therefore, discarding it. The spike is most likely the result of RF interference that could impact customers and was missed.

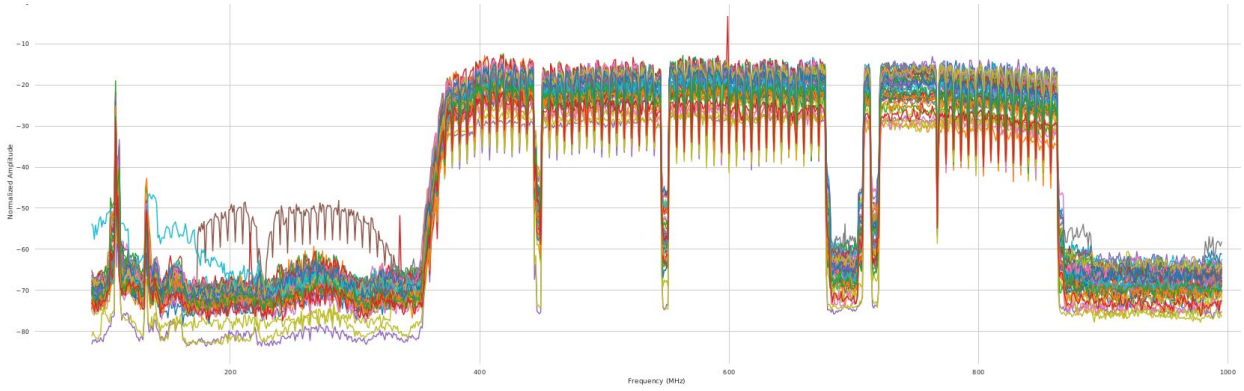

Figure 3.1 Raw FBC Cluster

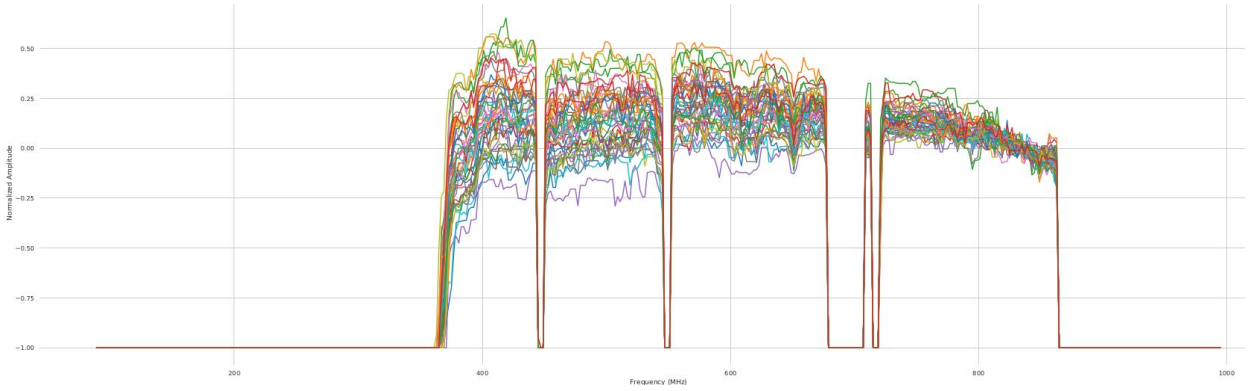

Figure 3.2 Pre-Processed FBC Cluster

3.1.2 LOF Performance

LOF proved to be optimal for this use case because it accurately and efficiently was able to identify outliers with impairments. Finding the optimal number of neighbors was a difficult task and will continue to be a difficult task when applying this software to various CMTSs and cable operators. Figure 2.14 shows LOF finding outliers on the highlighted regions while figure 2.15 shows the modems not labeled as having outliers.

Figure 3.3 shows a cluster of modems which has been continuously showing up across cable operator systems since this algorithm has deployed. Notice the spikes appearing roughly 20 dB above nominal RF spectrum. When examined more closely, these spikes are roughly 8 MHz in bandwidth. The author of this paper has visited several subscriber locations where the signal is present. The signal was not observable using traditional swept-spectrum analyzers. Further, once the subscriber modem was replaced the modem was replaced, the signals were no longer present. Suspect modems were collected and are under current evaluation.

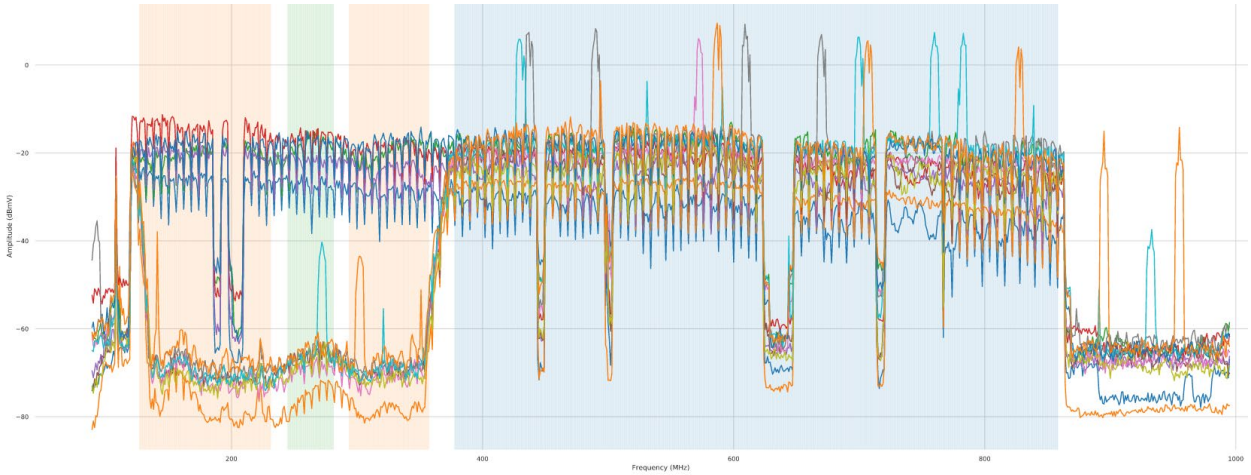

Figure 3.3 Impaired Modems with Used Regions Indicated

Figure 3.4 shows what is expected for a healthy cluster of modems on the same node. Here we see many cable modems not showing the spike in figure 3.3. The point of this example is that although root cause is not yet determined, machine learning combined with PNM was successful in identifying anonymous activity in modems which were customer impacting. Each customer with spurious activity had open tickets for downstream video or DOCSIS issues which where un-resolved.

Figure 3.4 Healthy Modems with Used Regions Indicated

3.1.3 Fixes for Band Stop Filters

Band stop filters filter out ranges of frequencies in a signal [2]. They are used by cable operators to restrict certain channels from customers. In the data we used for this paper, band stop filters were occasionally found in CMs as seen in figure 3.3. By using the different regions with commonly used frequencies, modems with Band Stop filters were not automatically classified as impaired, but instead accurately classified based on the rest of the used frequencies and how they related to the rest.

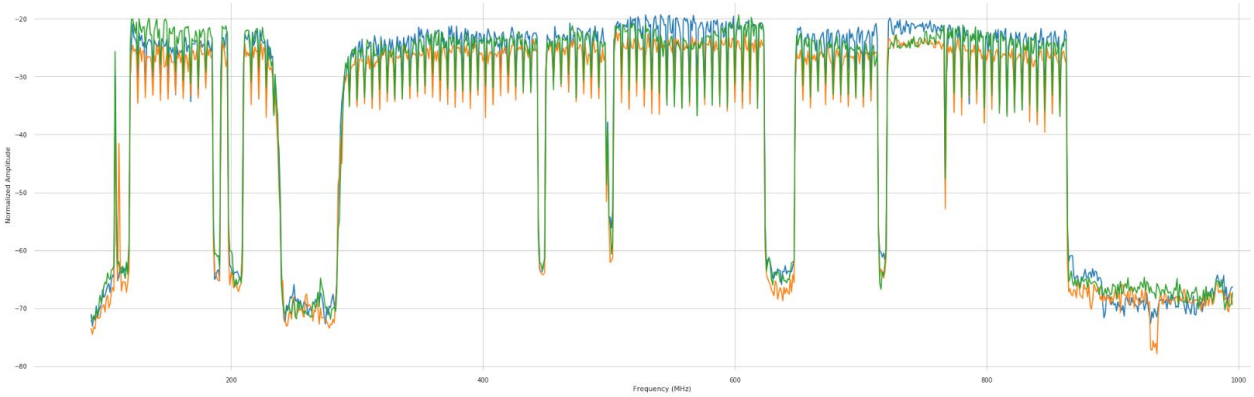

Figure 3.5 Modems with Band Stop Filters

3.2 Global Clustering

Global clustering was effective for its purpose of finding impaired modems with similar global signatures.

3.2.1 Global Clustering Shortcomings

One issue seen with both global and local clustering is when validating SID impairments when there are few modems in a cluster. If there are only 2 CMs in a cluster and one has an incorrect SID label, if the threshold for the correct SID label to be generalized is 50% then the incorrect impairment is accepted. However, if the threshold is at over 50%, correct SID labels may also be overlooked.

3.3 Local Clustering

Local clustering was effective in finding local regions with similar signatures. Occasionally regions that just happen to only be found in impaired CMs are labeled as local clusters when they are completely healthy regions of the spectrum that just have signatures not found in the rest of the healthy CMs.

3.3.1 Local Clustering Shortcomings

Shortcomings include times local clusters were identified but no SID labels were to be found in those regions and when common SID labels were found in regions and no local clusters were identified. Using both the clusters and SID labels, however, allows one to build greater confidence in the SID labels even if the system is not 100% accurate.

Local clustering also has the same issue when there are few cable modems in a cluster as seen with global clustering in section 3.2.1.

3.4 Optimization of Parameters

One factor seen across the board is that there are many parameters with this approach. Optimizing parameters also takes lots of processing and lots of time. Every cable operator with different hardware and different severities may need different parameters and perhaps even different CMTSs. There is no numerical way to find the optimal parameters as this is an unsupervised setting with no ground truths, meaning that someone must look through as much data as possible and look through many variations of parameters to find which fits the given data the best while not overfitting.

There are also many parameters that impact each other such as the window size parameter for local clustering. If the window size is changed, the EPS parameter in DBSCAN must also be changed to adjust. This makes optimization even more complex.

For this reason, real-time optimization parameters are added to the application which enable the end user to modify DBSCSAN parameters. These optimizations on performed on the cable operators' network to ensure DBSCAN is optimized based on the system's channel lineup.

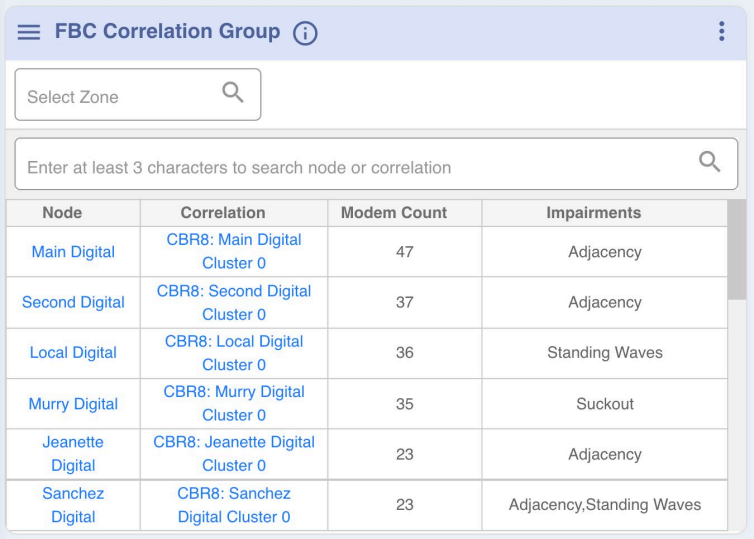
4. Conclusion

This project is effectively able to identify common impairments between CMs and is also a step towards replacing SID with a more intelligent system. Extensive preprocessing and clustering on FBC signatures were able to reveal shared impairments between CMs in a node. Additionally, SID labels were then overlaid to clusters to verify the accuracy of SID labels. This model was further modified and applied to RxMER data of OFDM channels in DOCSIS 3.1 downstreams. This had value in identifying outside plant impairments impacting multiple subscribers with DOCSIS 3.1 modems.

4.0 Operationalizing the Plant Maintenance

PNM and machine learning begin to show their complimentary value when it comes to operationalizing plant maintenance. Before applying machine learning, it would be up to the end user to manually view many fullband capture images and attempt to make mental correlations. This was a tedious process and relied on human to first do the work and second be effective at doing the job. The job being to determine if an impairment was impacting one home or many. Machine learning will automate this task by automatically clustering FBC data. It is up to the application programmer to make the data available to the end user.

One example can be seen in Figure 4.1 where a widget is made available to the end user with a list of FBC correlation groups (i.e. cluster groups), the node each correlation group, the number of subscribers impacted by the impairment and the impairment type. Clicking on the blue hyperlink takes the user to a visual representation of the impairments (shown in Figure 4.2) on a map, where action can be taken.



Node	Correlation	Modem Count	Impairments
Main Digital	CBR8: Main Digital Cluster 0	47	Adjacency
Second Digital	CBR8: Second Digital Cluster 0	37	Adjacency
Local Digital	CBR8: Local Digital Cluster 0	36	Standing Waves
Murry Digital	CBR8: Murry Digital Cluster 0	35	Suckout
Jeanette Digital	CBR8: Jeanette Digital Cluster 0	23	Adjacency
Sanchez Digital	CBR8: Sanchez Digital Cluster 0	23	Adjacency,Standing Waves

Figure 4.1: FBC Correlation Widget Groups by Node, Modem Count, and Impairment Type
(Image Courtesy: NimbleThis)

Figure 4.2 the machine learning-based results of FBC correlated modems as plotted on a map. The blue modems on the map are associated with the FBC data on the right-hand side. A user may select a modem on the left, a MAC address on the right, or a trace bottom right to interact with the data. The actionable data for the end user is that this section of coax plant has a system-wide standing wave. Fixing the standing wave by visiting a subscriber's home is not a good choice. This is an outside plant problem which must be addressed as such.

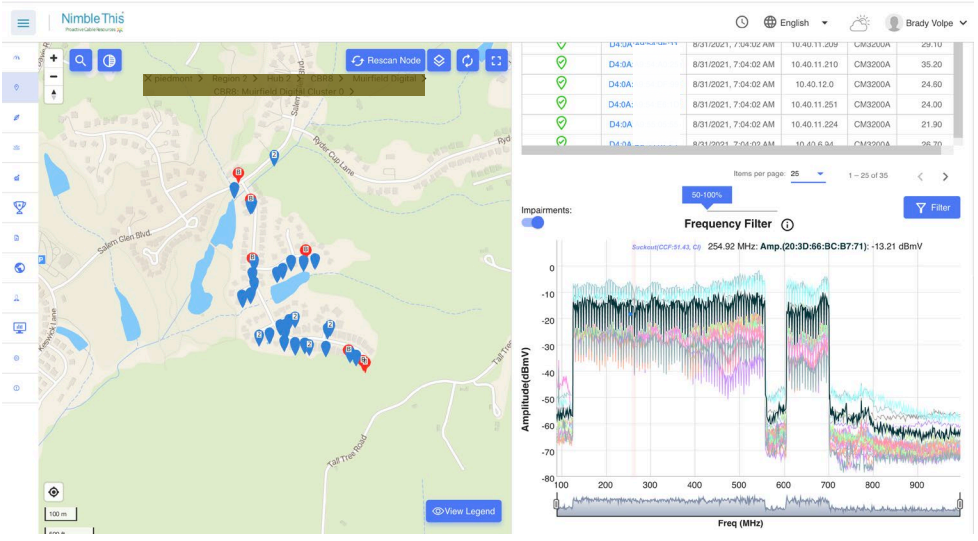


Figure 4.2: Representation of FBC correlation group on map (left) with respective FBC impairments (right)
Image courtesy: NimbleThis

As indicated, this same algorithm is easily adapted for RxMER data in DOCSIS 3.1 OFDM channels. As with FBC data, it is useful to present data at a high-level first as a widget, shown in Figure 4.3.

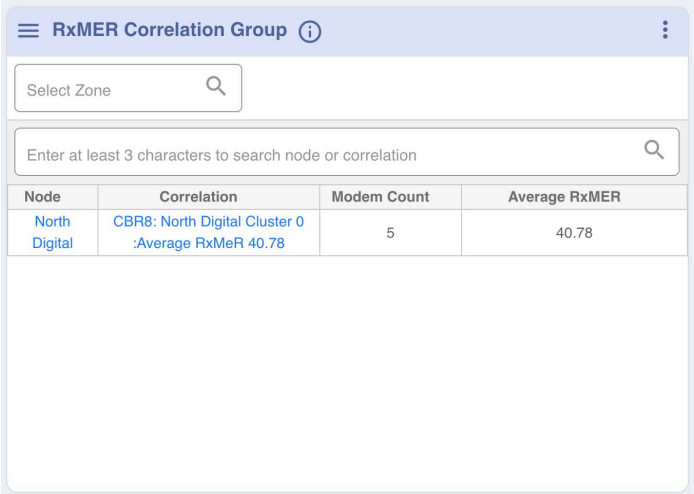

Figure 4.3: RxMER Correlation Widget Groups by Node, Modem Count, and Average RxMER

(Image Courtesy: NimbleThis)

The operational value of the RxMER correlation widget is that an end user can quickly identify clusters with low RxMER. Clusters with low RxMER will operate at a low OFDM modulation resulting in low or no data speed to subscribers. The low RxMER in a cluster is a result of outside plant impairments, so these can be addressed by outside plant techs.

Figure 4.4 shows the mapping of the clustered data. This view results when clicking on the correlation group in the widget of Figure 4.3.

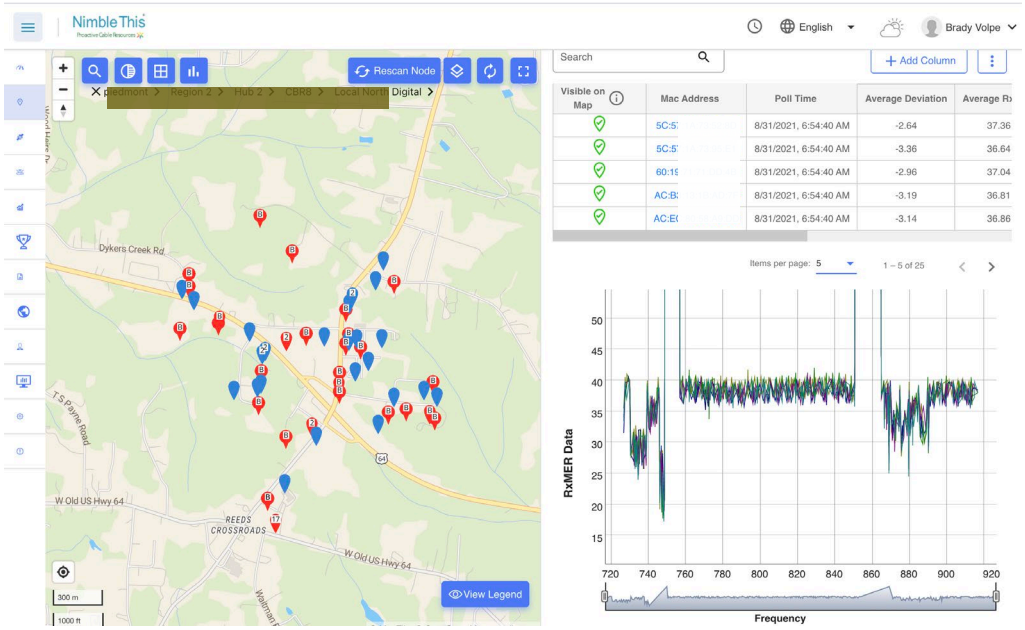

Figure 4.4: RxMER Clustered data on map (left) with clustered RxMER data (right)
(Image Courtesy: NimbleThis)

Figure 4.4 shows the actual RxMER clustered data on the right-hand side. As can be observed, there are many locations in the RxMER data where the MER drops below 35 dB. An ideal OFDM channel would have its RxMER data above 39 dB across every data point to support 4096-QAM.

On the left-hand side of Figure 4.4, the blue modems indicate which DOCSIS 3.1 modems are part of the cluster group and are impacted by low RxMER. In many networks today there is not 100% penetration of DOCSIS 3.1 modems, so it is quite common to have many DOCSIS 3.0 and DOCSIS 2.0 modems that are around the cluster but are not impacted because they do not use the OFDM channel.

Again, the value of Figure 4.4 is that a technician can quickly observe that the downstream impairments in the OFDM channel are common to every subscriber. Visiting an individual subscriber home will not fix the impairment. This is an outside plant problem which must be addressed in the outside plant.

4.1 Future Research

4.1.1 Supervised Learning

The current implementation, while very powerful, uses unsupervised machine learning. This means the ML engine has no knowledge if the FBC data is impaired or not impaired nor does it know the impairment type once it is classified as impaired. The classification comes from SID data, which is only somewhat accurate. The next level is to achieve supervised learning, which is a machine learning engine whereby the engine already has knowledge about FBC impairment types. This requires a lot of work from end users to label these existing impairments and build a database through which the ML engine can be trained.

There are two approaches in process to do this. First, a built-in gaming feature that encourages its users to label impairments when fixing problems has been applied. Fix a problem and label an impairment and get points. Users with the most points get on the leader board. This is used by cable operators as an incentive program for their technicians. An example of this is shown in Figure 4.5.

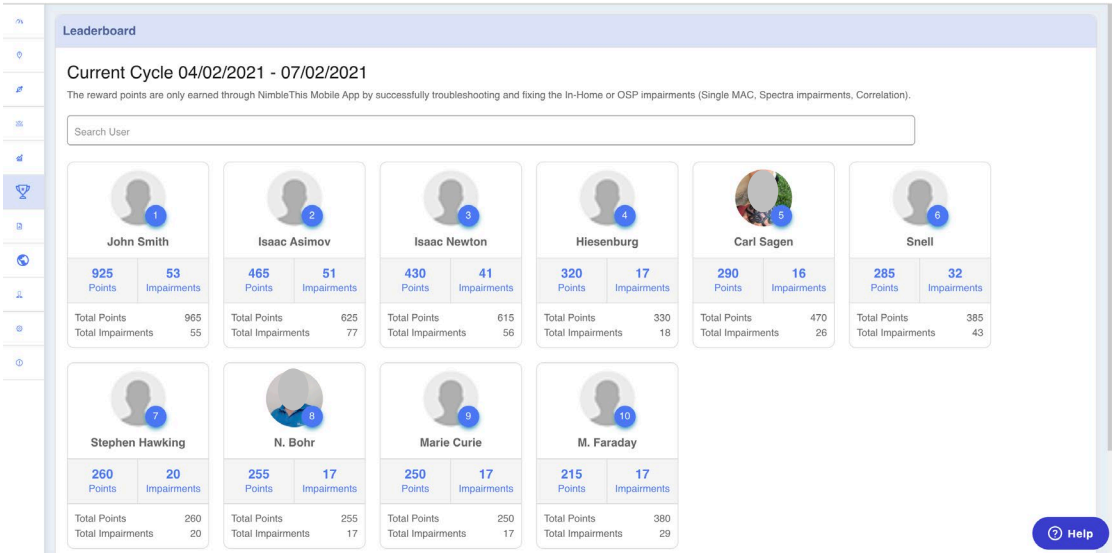

Figure 4.5: Leaderboard used for incentivizing users and collecting labeled data
(Image Courtesy: NimbleThis)

Second, CableLabs is working to have several expert users, including the author of this paper, to label a set of FBC data. It is hopeful that either or both two methods will generate a large enough dataset to be used for a true supervised learning model which can further improve upon the existing model.

4.1.2 New Impairment Detector

In the future, one could analyze ways to create a reliable way of identifying and localizing impairments to bypass the need for SID and clustering in the first place. Analysis/clustering on accurate labels of impairments would be able to find the same impairment in multiple modems but do so with greater confidence and accuracy. To be able to identify and localize all these impairments there needs to be large datasets of labeled data which are currently not accessible. Models for prediction could be made for each impairment or one large model could be made to make predictions about all impairments. Possible avenues to investigate include Convolutional Neural Networks (CNNs), perhaps some like ones seen in computer vision such as YOLO (You Only Look Once) to both classify and localize impairments [4, 9].

This starts to move into the arena of artificial intelligence (AI). Which the author of this paper chooses to use with great care. Today machine learning is being used and often times AI is used as a marketing gimmick. However, given enough data, a true AI model can be developed with the help of technicians. Lots of technicians feeding accurate data into PNM applications. Once this level is achieved, ML and/or AI models can be developed which will look at a single or multiple FBC images and not only inform the user of what the impairment is (i.e., suckout or standing wave), but further it can make very accurate suggestions of what the most probably repair for the impairment may, such as “85% probability of a bad drop cable”. This technology is not years away, but something we expect to realize within the next 1-2 years and will change the technicians interact with PNM technology.

Abbreviations

CM	Cable Modem
CMTS	Cable Modem Termination System
CNN	Convolutional Neural Network
DBSCAN	Density-Based Spatial Clustering of Applications with Noise

1. Introduction

As wireline subscriber demand for increased broadband speed grows, cable operators will have to upgrade their networks to accommodate. Cisco estimates that the average fixed broadband speed in North America will increase 2.5-fold from 2018-2023 [1]. In Canada, strong competition from telco fibre-to-the-premises (FTTP) networks adds to the need for upgrades. Shaw Communications is in the fourth year of a five-year upgrade cycle of its hybrid-fibre coax (HFC) network. This upgrade has allowed Shaw to offer a 1.5Gbps downstream by 100Mbps upstream service tier to most of its footprint and has driven congestion to near zero, all during a global pandemic that has seen network utilization spike by 30% in the downstream and 60% in the upstream. Despite its strong position, Shaw is already planning the next upgrade cycle, which will follow quickly on the heels of the current upgrade. This paper will discuss a strategy to manage network congestion and tier offerings, leveraging available HFC network architectures.

2. HFC Network Status

HFC networks traditionally operate in a frequency division duplex (FDD) mode with upstream spectrum carried below downstream spectrum, separated by a cross-over region. The Data over Cable Service Interface Specification (DOCSIS) supports several different upstream spectrum splits, including 5-42MHz, 5-85MHz, 5-204MHz, and higher, otherwise known as sub-split, mid-split, high-split, and ultra-high-split respectively. Each subsequent version of DOCSIS expands its support of upstream frequencies, always with backwards compatibility as depicted below.

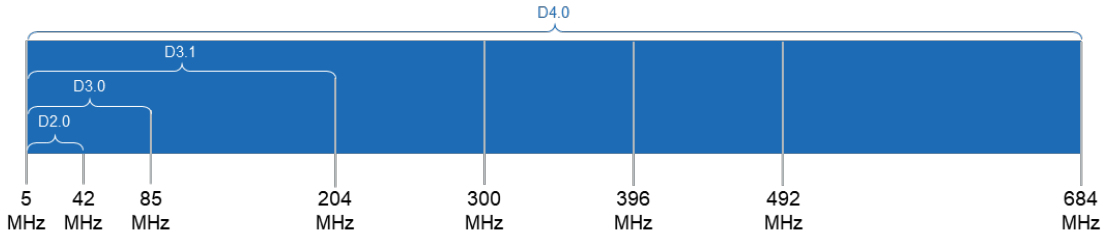

Figure 1 – Upstream Spectrum Band Plans

In the downstream, DOCSIS supports up to 857MHz for DOCSIS 2.0, 1002MHz for DOCSIS 3.0, 1218MHz for DOCSIS 3.1, and 1794MHz for DOCSIS 4.0 FDD [2] – [5]. For simplicity, plant types will be referred to as mid-split, high-split, and DOCSIS 4.0 FDD, describing band plans of 1002/85MHz, 1218/204MHz, and 1794 with an ultra-high-split upstream option.

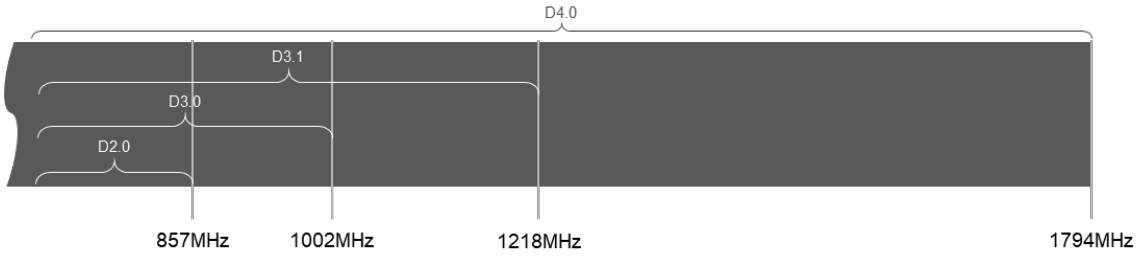

Figure 2 – Downstream Spectrum High Frequencies

Shaw operates an HFC network, that at the time of writing was over 90% mid-split with upstream signals carried from 5-85MHz and downstream signals carried from 108-1002MHz. The approximate spectrum breakdown is shown in Figure 3.

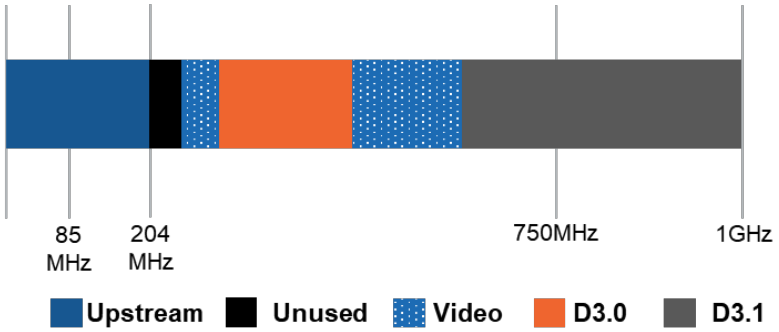

Figure 3 – Shaw Mid-split Spectrum

The HFC network uses analog optical transport from the hub site to the optical node where the transition to coax happens. Plant architectures are measured both by the allowable number of amplifiers in cascade as well as the link budget or spacing between amplifiers. The cascade length is referred to as N+X where N refers to the optical node and the X to the maximum cascade depth. Amplifier spacing refers to the maximum designed frequency, as in 750MHz or 1GHz plant. Shaw's outside plant contains a mixture of architectures, but the average cascade depth is N+4 and, with some exceptions, is designed to 1GHz. A high-level depiction of an HFC network is shown in Figure 4.

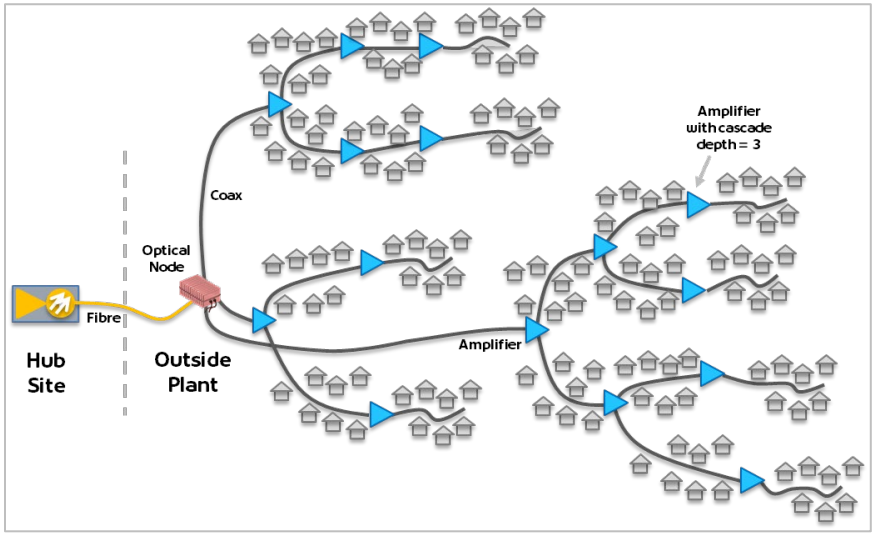

Figure 4 – Hybrid-Fibre Coax Network

2.1. COVID-19 Impact

The COVID-19 pandemic caused a shift in subscriber behaviour unlike anything previously experienced by broadband providers (Figure 5). Restrictions on movement increased subscriber usage of their in-home broadband services in a short time span. In the downstream, this growth was quickly mitigated through a reduction in video bitrates by streaming video providers such as Netflix [6].

Figure 5 – Relative Downstream Traffic During COVID-19

The growth of specific categories of traffic can be analyzed using deep-packet inspection (DPI) systems. In Figure 6, the height of the bars represents the relative amount of added consumption with traffic categories on the left adding the most consumption and categories on the right adding the least consumption. The percentage on top of each bar represents the increase in consumption of that traffic category compared to pre-COVID-19 levels. As can be observed, streaming media, which includes Netflix and YouTube, grew by 30%, which was lower than some of the other traffic categories but accounted for the bulk of increased consumption.

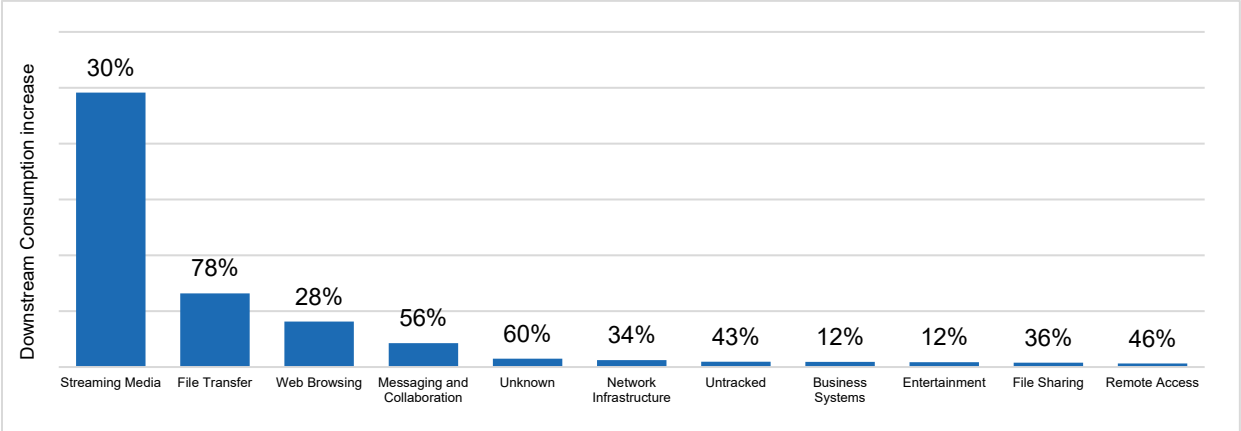

Figure 6 – Downstream Consumption Increase by Application

In the upstream, the shift to remote learning, working from home and the increased use of video calling applications kept upstream traffic higher for a longer period compared to downstream traffic (Figure 7).

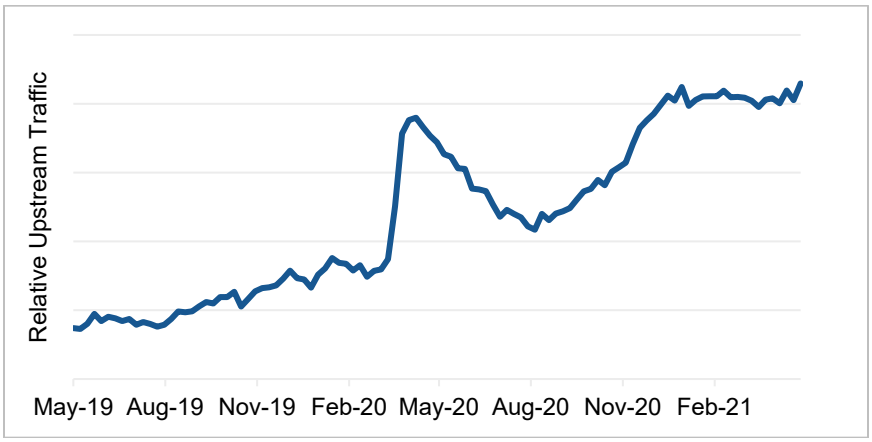

Figure 7 – Relative Upstream Traffic During COVID-19

The largest amount of added consumption, as well as the largest percent increase, came from the messaging and collaboration category, which includes FaceTime and Skype (Figure 8).

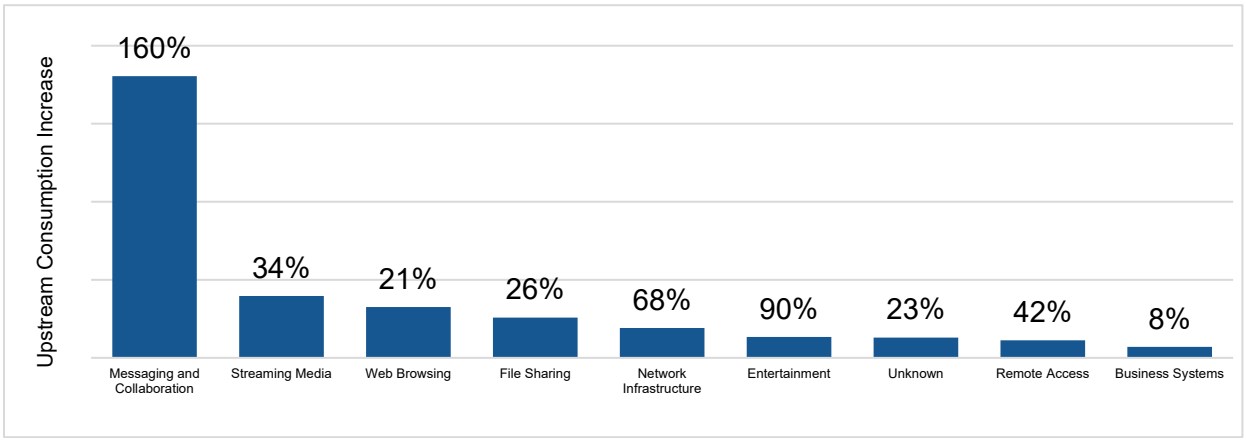

Figure 8 – Upstream Consumption Increase by Application

2.2. Mid-split Journey

Prior to the mid-split upgrade, Shaw's HFC network operated to a high frequency of 750MHz with a sub-split band plan. Increasing demand for broadband services had driven the transition from analog video to the more efficient digital video, freeing up spectrum for DOCSIS carriers. While this provided more spectrum to allocate to the downstream, it did not increase the spectrum allotted to the upstream.

At the time, the downstream-to-upstream ratio was much lower than it is today and there was a concern that upstream congestion would become unmanageable. The decision was made to reserve the downstream spectrum from 54-108MHz for a mid-split upgrade—a decision that was not easy at the time given that downstream spectrum was highly desired for additional broadcast video services.

Mid-split testing began in earnest to ascertain the level of effort required to upgrade the network to 85MHz in the upstream and 1GHz in the downstream. Video set top boxes that used out-of-band communication in the 72.75MHz range had to be re-tuned to a new frequency where possible or retired from the network if necessary. Interference testing was undertaken to see if upstream transmissions in the 54-85MHz range would harm the function of customer premises equipment (CPE) in the same or

neighbouring house, and performance of optical transmitters was measured to ensure proper functionality. Lastly, research was undertaken to understand whether the upgrade could be done on a drop-in basis, or whether amplifier respacing was required.

In 2013 the first upgrade of a production node was completed and used to conduct further testing. In the meantime, the network was experiencing unprecedented growth in both the upstream and downstream, driven by increased demand for broadband services. In 2012 upstream year-over-year growth reached a high of 55%, while in 2013 downstream year-over-year growth reached a high of 85%. This demand created increased levels of network congestion, for which a solution was required.

Analysis was undertaken to explore network levers which could be pulled to increase network capacity. Potential solutions included a digital-to-IP video transition to make room for more downstream DOCSIS carriers, node splits in congested areas, an HFC upgrade to N+0 or N+few, and a mid-split upgrade. In comparison to the first three options, a mid-split upgrade was found to be cost effective and could be executed in a relatively short timeframe.

3. Competitive Environment

Canadian telcos are aggressively upgrading their Digital Subscriber Line (DSL) networks to FTTP. As of the end of 2020, Bell's network was 57% FTTP and Telus' network was 81% FTTP [7], [8].

Telus, which operates in much of the same footprint as Shaw, offers a max tier of 1.5Gbps downstream by 940Mbps upstream in its FTTP footprint using Gigabit Passive Optical Network (GPON) technology, as shown in Figure 9. This technology operates at a physical layer (PHY) rate of 2.488Gbps downstream and 1.244Gbps upstream [9].

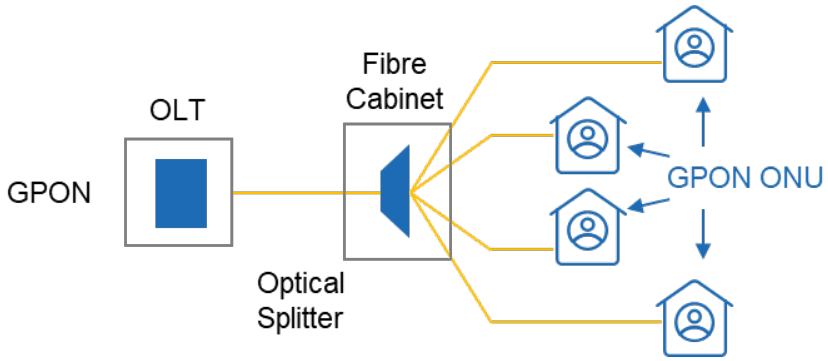

Figure 9 – Gigabit Passive Optical Network

As shown in Figure 10, this Passive Optical Network (PON) architecture allows for the coexistence of GPON and Ten-Gigabit Symmetric PON (XGS-PON) with the addition of Optical Line Termination (OLT) line-cards and additional splitters.

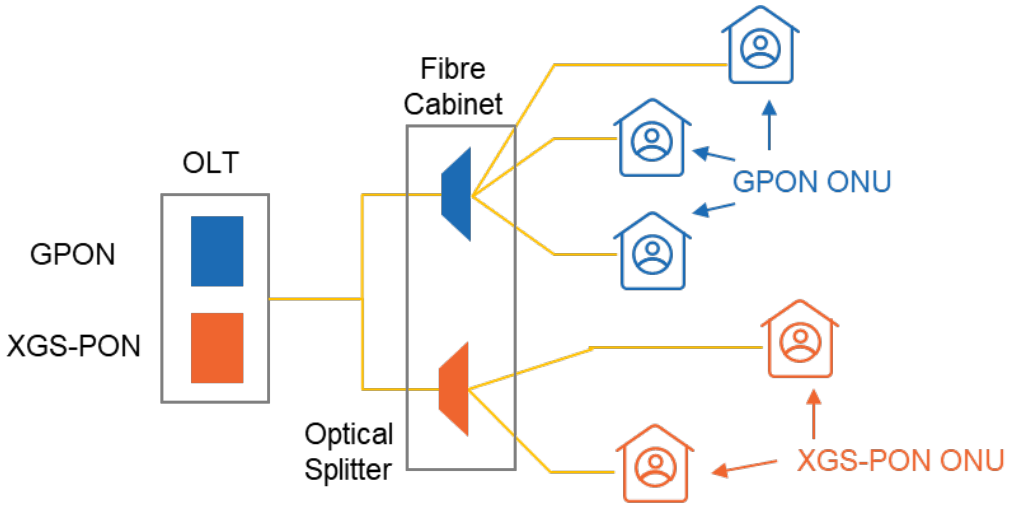

Figure 10 – Passive Optical Network Coexistence

XGS-PON is 10Gbps capable [10] and the max tier supported will depend on the split ratio and how aggressive the operator chooses to be. At the time of writing, Telus launched new 2.5Gbps symmetric services, giving an indication of initial XGS-PON tier offerings. It is important that any upgrade strategy have a roadmap for supporting similar tiers.

4. Upgrade Needs

A mid-split HFC network has similar or greater capacity when compared to a GPON network in the downstream, which allows Shaw to offer a 1.5Gbps downstream tier with options for higher tiers in the future. In the upstream however, a mid-split network has a lower capacity compared to GPON. An HFC network upgrade would be required in order to match the upstream tier.

When network traffic is observed, it is highly asymmetric, with downstream-to-upstream ratios above 15:1 for residential consumers and in the range of 5:1 for business subscribers (Figure 11), even during the COVID-19 pandemic that saw a disproportionate increase in upstream usage, as discussed earlier.

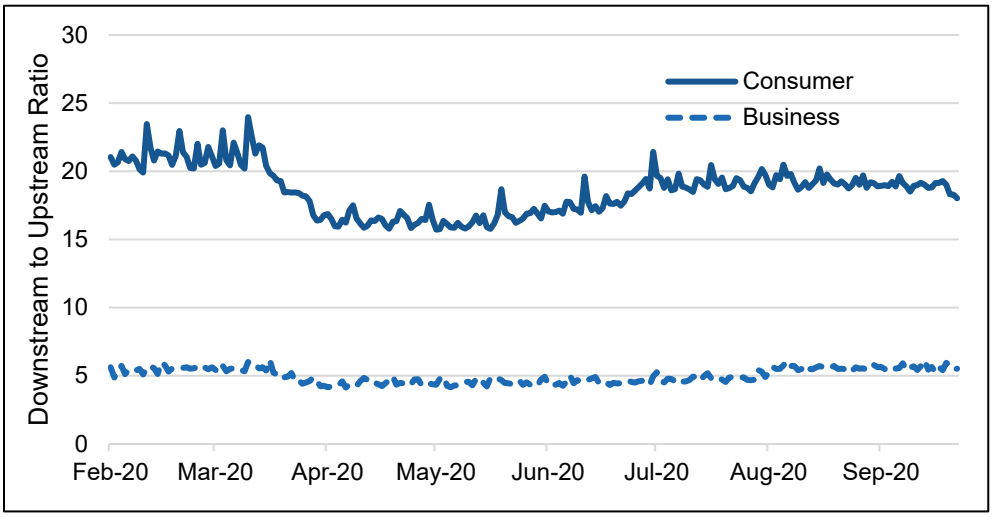

Figure 11 – Downstream-to-Upstream Ratio

Given this relationship, there is a question as to whether subscribers can fully utilize gigabit upstream services, and if so, whether their experience is improved. In looking at the 1Gbps downstream by 100Mbps upstream tier, two interesting phenomena can be observed. Using DPI systems, the max speeds a subscriber is able to reach over the span of a month can be measured. As seen in Figure 12, a significant number of subscribers, likely connected over Ethernet, use their full 1Gbps tier. Many subscribers, however, have a max speed in the 400-500Mbps range due to in-home Wi-Fi limitations.

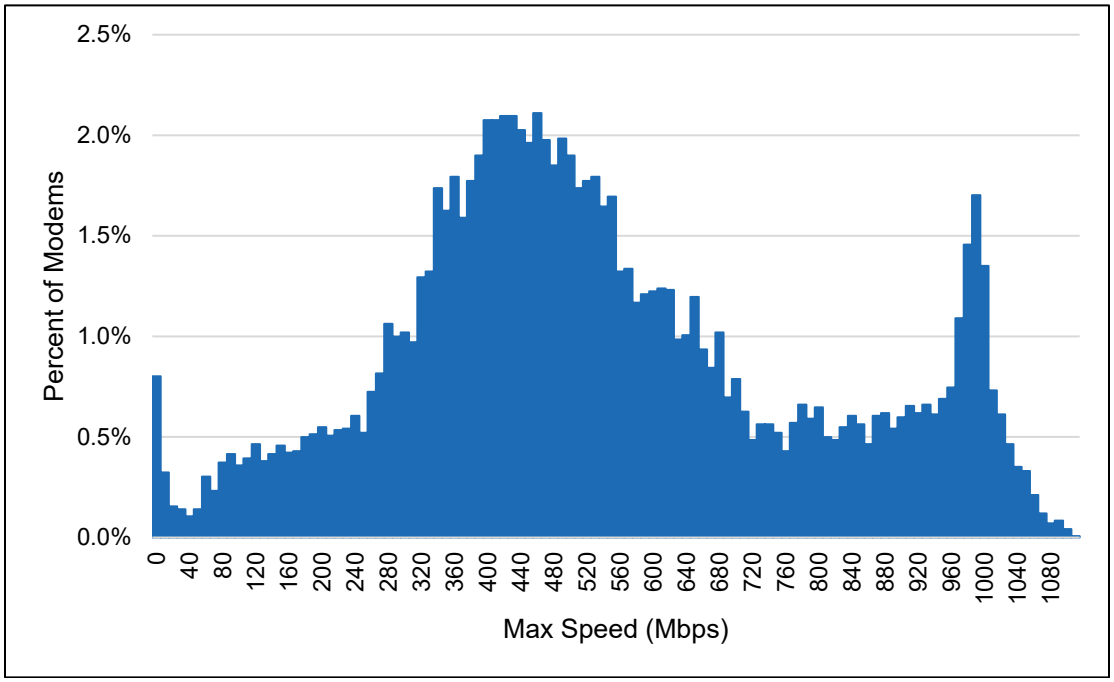

Figure 12 – Downstream Max Speed Distribution (1Gbps Tier)

Wi-Fi 6E will remove current limitations as it introduces new spectrum that will enable gigabit speeds [11]. However, the process to upgrade CPE and end-user devices to Wi-Fi 6E compatible equipment will take time.

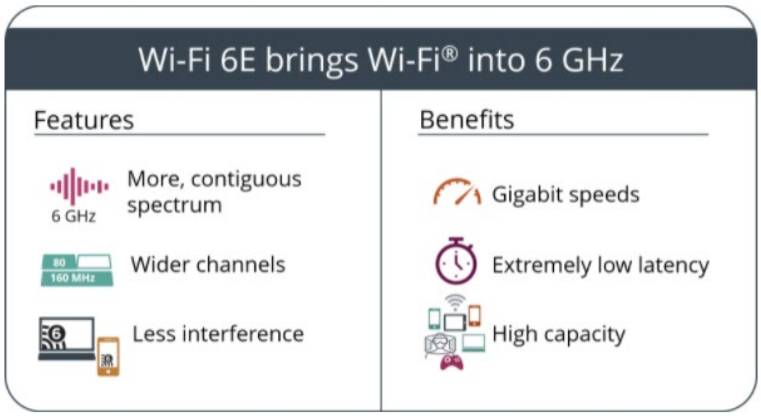

Figure 13 – Wi-Fi 6E Benefits (Source: Wi-Fi Alliance)

The types of applications used during high-speed upstream bursts can be observed using DPI systems. The data shows that the higher the speed, the more the traffic is dominated by backup applications operating in the background, not necessarily noticed by the user (Figure 14).

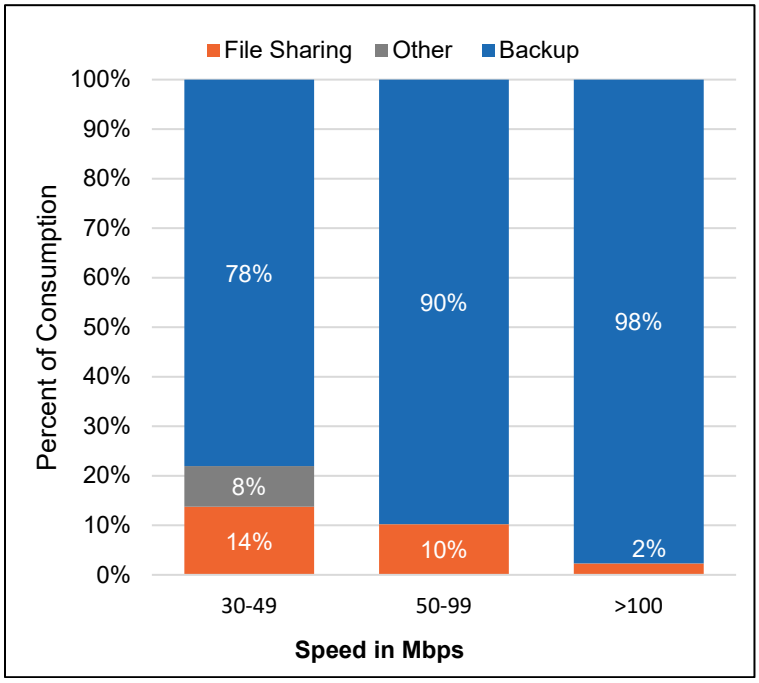

Figure 14 – Median Upstream Consumption by Speed

As mentioned earlier, Shaw is experiencing near zero congestion as the mid-split upgrade cycle approaches completion. Congestion forecasts were produced to estimate when a subsequent upgrade will be required for capacity reasons. Forecasts assume 15% downstream compound annual growth rate (CAGR) in addition to increased IPTV traffic due to customers migrating from older quadrature amplitude modulation (QAM) video hardware to new IPTV video solutions. In the upstream 25% CAGR is assumed. These numbers are in line with recent growth.

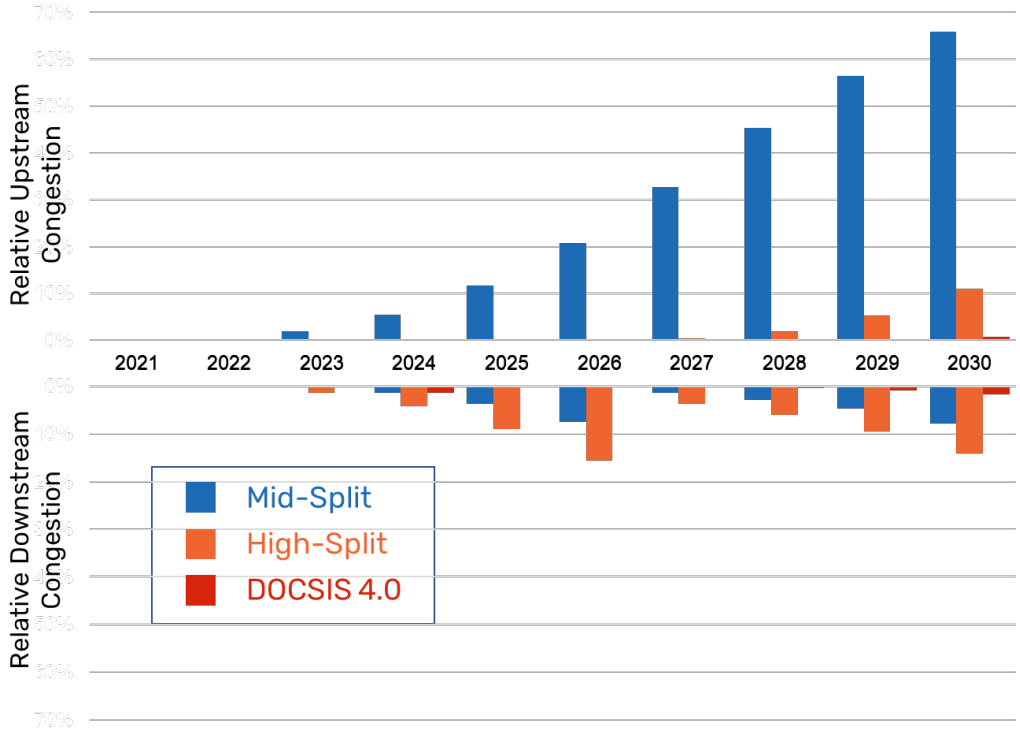

Figure 15 – Congestion Forecast

In Figure 15, congestion is plotted for mid-split, high-split, and DOCSIS 4.0 FDD networks, with upstream in the upper half and downstream the lower half. Low levels of congestion can be resolved with targeted node splits, while higher levels require network-wide solutions. As can be observed, concerns do not arise with mid-split capacity until the latter half of the decade.

In the downstream it is assumed that a high-split plant is operated only to 1GHz, resulting in a net decrease in downstream capacity when compared to mid-split. Downstream congestion grows in 2025 and 2026 but is reduced in 2027 when the transition from QAM to IP video is expected to be complete and more spectrum allocated to DOCSIS traffic. These two topics are discussed further in the following sections. In contrast to the congestion forecasts for mid-split and high-split, a DOCSIS 4.0 FDD upgrade provides enough capacity for the network to run nearly congestion-free through 2030 and beyond.

5. Upgrade Options

With our mid-split upgrade nearly complete, the next network upgrade is being planned. The options currently available are high-split, DOCSIS 4.0 FDD, DOCSIS 4.0 Full-Duplex DOCSIS (FDX), and FTTP.

5.1. High-split

An upgrade of the HFC plant to high-split, with upstream spectrum from 5-204MHz and downstream spectrum from 258-1218MHz (Figure 16), represents a modest increase in spectrum but has the advantage of the required equipment being available now.

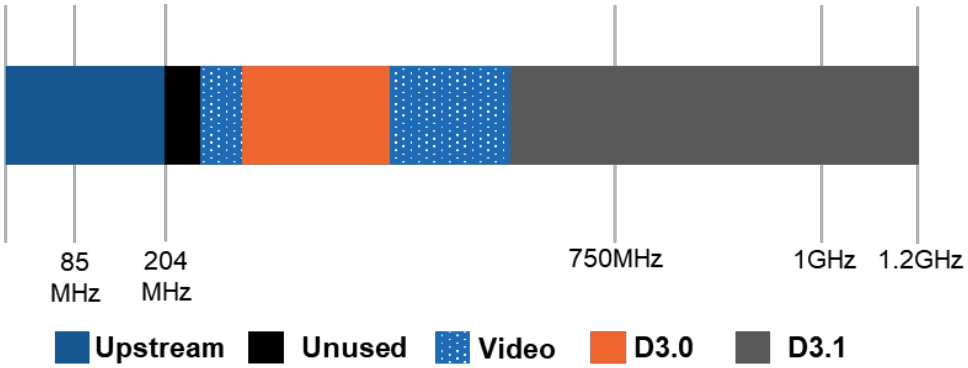

Figure 16 – High-split Spectrum

As displayed in the table below, the increase in spectrum is heavily weighted toward the upstream with 149% additional spectrum, while the spectrum allocated to downstream increases by 7%.

Table 1 – High-split Spectrum Allocation

	Mid-split	High-split	Percent Increase
Upstream Spectrum (MHz)	80	199	149%
Downstream Spectrum (MHz)	894	960	7%

As discussed earlier, the strategic reason to upgrade to high-split is to match the tier capability of GPON, which requires additional upstream spectrum. Another advantage of a high-split upgrade is that the technical considerations are similar to those recently explored with a mid-split upgrade.

Shaw set top boxes that do not have DOCSIS modems use the ANSI/SCTE 55-1 standard for communication. The downstream out-of-band (OOB) transmission frequency range is 70-130MHz [12] in spectrum that transitions to upstream when upgrading to a high-split network. While there are options available to continue OOB operation [13], the decision was made to remove the OOB and all video equipment reliant on ANSI/SCTE 55-1 in the case of a high-split upgrade. Operationally, this means that this equipment must be removed from a service area before upgrade but does not require all equipment to be removed at the system level.

Industry Canada mandates that cable distribution networks do not interfere with international emergency frequencies and that they are monitored for compliance [14]. Monitoring is done by measuring the signal level of an analog television channel chosen by Industry Canada. In a high-split plant these frequencies switch from downstream to upstream and a new method for monitoring is required. There are options available for leakage monitoring in a high-split plant [13], but until commercial solutions are available that range of spectrum will be left unused.

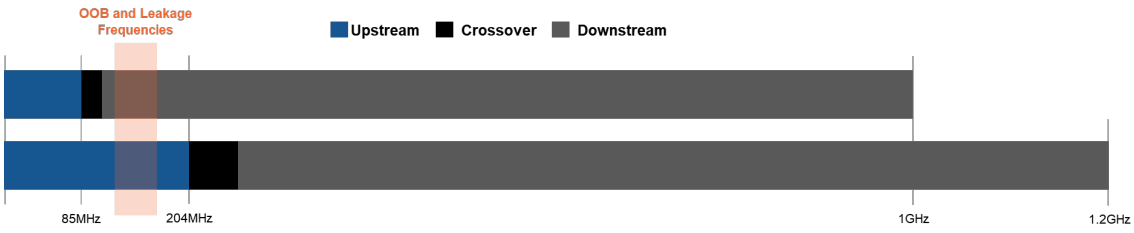

Figure 17 – Out-of-Band and Leakage Frequencies

Another issue to consider in the implementation of high-split is the in-home coexistence of DOCSIS and Multimedia over Coax Alliance (MoCA) signals above 1GHz. MoCA devices use in-home coax wiring for transport of multimedia content, as seen in Figure 18. At Shaw, MoCA is used with whole-home video solutions, allowing a single MoCA gateway to transport video content to MoCA portals over the in-home coax network.

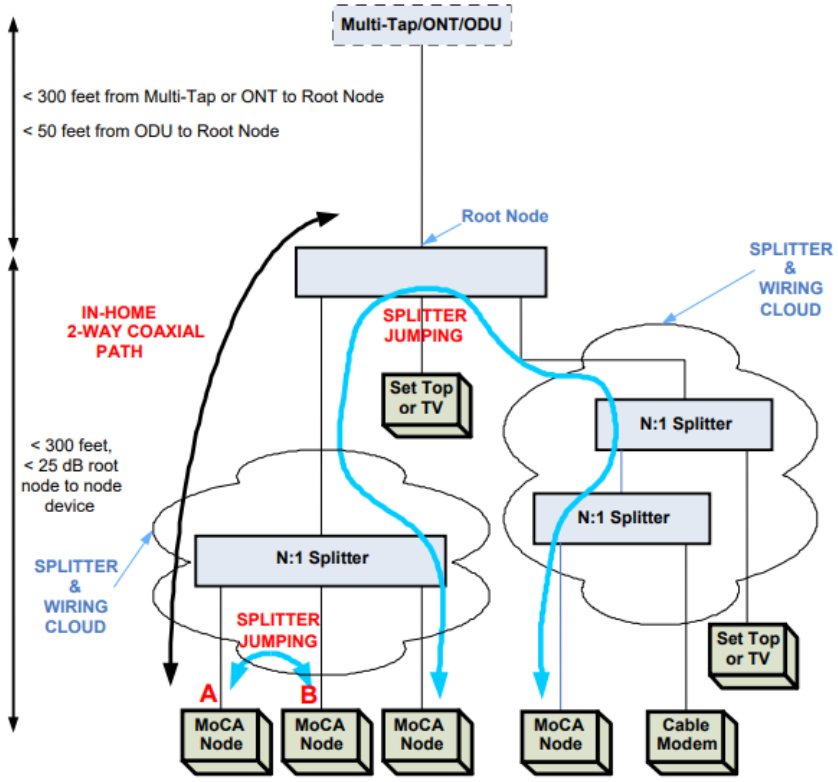

Figure 18 – MoCA Network (Source: MoCA Alliance)

MoCA 1.1 devices operating in an HFC network use 50MHz wide channels in the D-band which is located from 1125MHz to 1525MHz [15], as illustrated in Figure 19. Devices will move to a different channel if received signal strength is not adequate at the current channel.

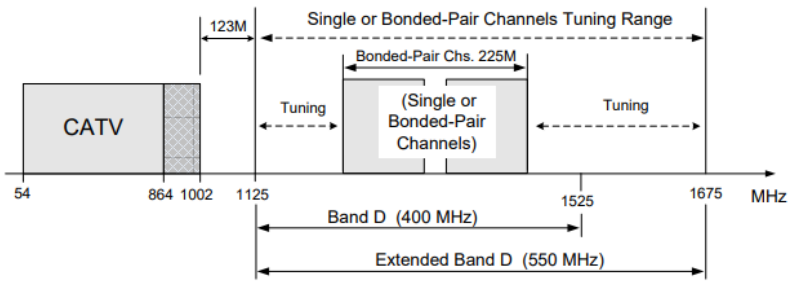

Figure 19 – MoCA Spectrum Use (Source: MoCA Alliance)

A sample of MoCA devices were polled to see what channel they were using. As shown in Figure 20, 46% of devices were using the lowest channel with a centre frequency of 1150MHz, but a significant percentage of MoCA devices had moved to higher spectrum.

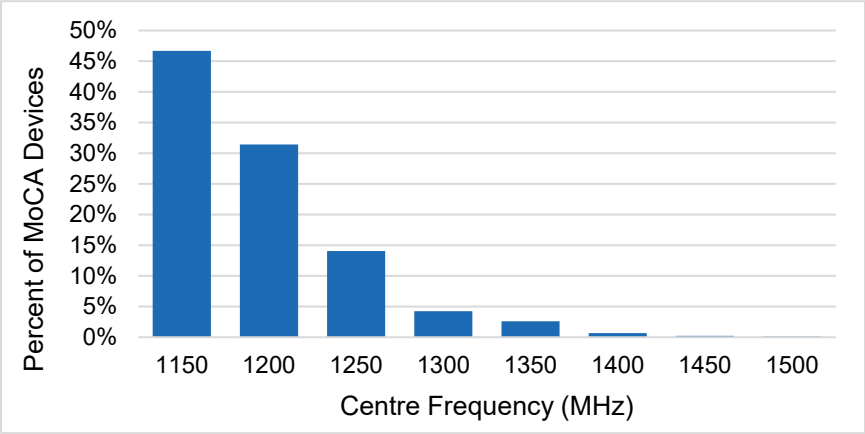

Figure 20 – MoCA Centre Frequencies

Research is required to determine whether MoCA devices can be forced to higher frequencies either through back-office commands or by occupying spectrum to 1218MHz with DOCSIS carriers. If this is not possible, then MoCA spectrum would have to be left unutilized until MoCA devices are removed from the network. In a worst-case scenario, if high-split frequencies are limited to 258-1002MHz downstream, the high-split upgrade would result in 17% less downstream spectrum when compared to mid-split (Table 2). While this is not a preferred outcome, downstream spectrum can also be freed up by the more efficient transmission of video content, or by removing a portion of that content altogether.

Table 2 – High-split Spectrum Allocation when Limited to 1GHz

	Mid-split	High-split (MoCA)	Percent Change
Upstream Spectrum (MHz)	80	199	149%
Downstream Spectrum (MHz)	894	744	-17%

As previously mentioned, a decision was made to remove set top boxes reliant on the OOB for communication. These boxes also happen to be the only ones in the network that do not support MPEG4 video and thus their removal allows for MPEG2 video signals to be carried more efficiently via MPEG4. The amount of spectrum that can be freed up is sufficient to prevent downstream DOCSIS capacity loss during a high-split upgrade.

A high-split upgrade provides the opportunity to move to a Distributed Access Architecture (DAA), although it is not strictly required. DAA allows for scalability and preserves space in hub sites as the number of optical nodes increases. This eliminates the analog optical link as well as any testing that would otherwise have been required to ensure upstream signals could be carried at high modulation rates over the 5-204MHz range. The difference in performance between DAA and analog nodes can be observed by comparing signal-to-noise ratio (SNR) data. A group of approximately ten thousand modems in each type of plant were polled for SNR. As shown in Figure 21, the average downstream SNR of modems in analog nodes was 38.8 decibels (dB) versus 41.4dB in DAA nodes, a difference of 2.6dB.

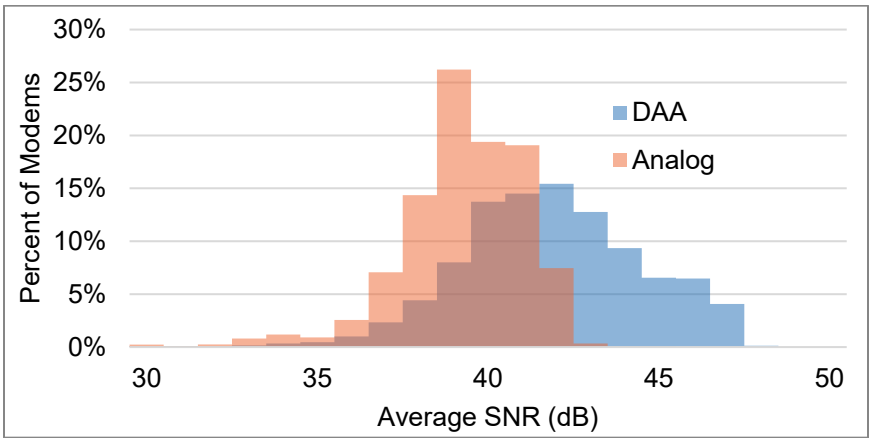

Figure 21 – Downstream SNR DAA vs Analog

As depicted in Figure 22, the average upstream SNR of modems in analog nodes was 33.1dB versus 37.3dB in DAA nodes, a difference of 4.2dB. By using DAA nodes, more modems will be able to make use of the highest modulation profiles, thus increasing capacity.

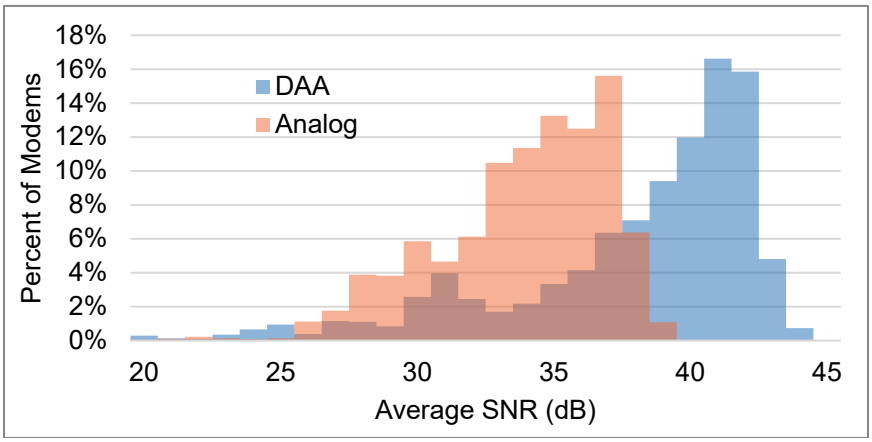

Figure 22 – Upstream SNR DAA vs Analog

As with mid-split, the preferred method for a high-split upgrade is to replace amplifiers in a drop-in fashion. This eliminates the need for plant redesign and amplifier respacing, which would complicate the upgrade. The risk with this method is that signal quality degrades with each additional amplifier in cascade. While adding fibre to the network to reduce cascades to a chosen maximum depth would solve this problem, the time and capital required for such an upgrade is substantial. DOCSIS technology can help in this regard as DOCSIS 3.1 changed the way we think about node capacity. DOCSIS 3.1 introduced the concept of profiles used by orthogonal frequency division multiplexing (OFDM) and orthogonal frequency division multiple access (OFDMA) signals. These profiles allow cable modems with higher signal quality to transmit and receive at higher data rates compared to cable modems with lower signal quality. While the data rate of a cable modem located at the end of line may be lower than other cable modems on the node, there is no issue so long as the data rate is sufficient to enable the service tier. In the case where cable modems at the end of line cannot support service tiers, either tier offerings in that location can be reevaluated, or fibre optics can be deployed to reduce cascade lengths.

During Shaw's mid-split upgrade all passives that were sub-1GHz were upgraded. 1GHz passives could be retained in a high-split upgrade as the top frequency for DOCSIS 3.1 was chosen with 1GHz passives

in mind because they were found to continue operation beyond 1GHz. Optionally 1GHz passives could be replaced with 1.8GHz or 3GHz models, which would provide decreased loss from 1-1.2GHz for high-split plant and pave the way for DOCSIS 4.0 FDD.

5.2. DOCSIS 4.0 FDD

Upgrading the HFC plant to DOCSIS 4.0 FDD with a high frequency of 1794MHz represents a large increase in spectrum that comes with several options for upstream frequency range (Table 3). As upstream spectrum increases, downstream spectrum decreases. In deciding which band plan is optimal it is important to look at the downstream-to-upstream ratio and the maximum service tier that can be offered in both directions. DOCSIS 4.0 FDD can materially outperform GPON and compete effectively with XGS-PON, which is capable of 10Gbps symmetric speeds. Depending on which band split is selected, DOCSIS 4.0 FDD can have greater capacity than XGS-PON in the downstream but remains lower in the upstream.

Table 3 – DOCSIS 4.0 FDD Spectrum Allocation

	Mid-split	High-split	UHS-300	UHS-396	UHS-492	UHS-684
Upstream Spectrum (MHz)	80	199	295	391	487	679
Downstream Spectrum (MHz)	894	960	1422	1302	1188	960
DS:US Spectrum Ratio	11.2	4.8	4.8	3.3	2.4	1.4

For capacity planning purposes it is beneficial to have a downstream-to-upstream capacity ratio similar to the downstream-to-upstream demand ratio, which as discussed earlier, is greater than 15:1 for residential subscribers. For competitive purposes however, it may be beneficial to offer symmetric or near symmetric tiers.

Another consideration is the high frequency of current DOCSIS cable modems and video set top boxes. In Shaw's network 100% of CPE currently has a maximum high frequency of 1002MHz. As shown in Figure 23, ultra-high-split options would reduce the available spectrum to current CPE.

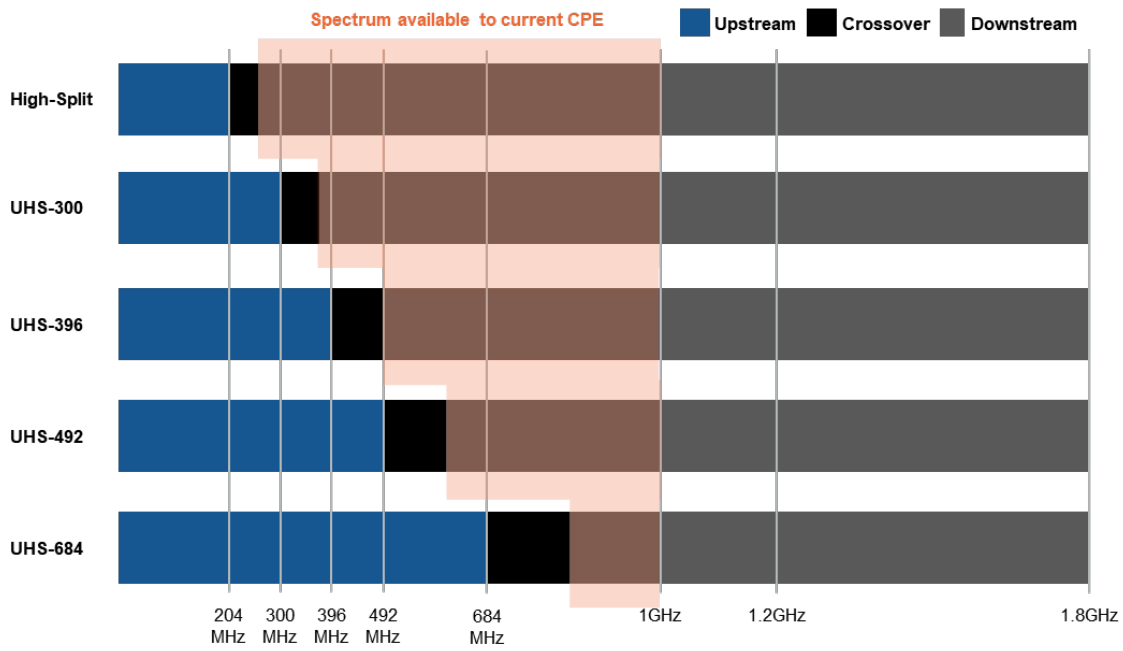

Figure 23 – Spectrum Available to Current CPE

Reducing the capacity available to the installed base of CPE could create congestion until such time as either enough DOCSIS 4.0 FDD cable modems are in the network or QAM video can be retired. One potential strategy is to initially run DOCSIS 4.0 FDD with a high-split band plan and switch to an ultra-high-split band plan in the future, perhaps when the transition to IPTV is complete. UHS-396 is a potential band plan that balances traffic engineering with the need for competitive service tiers.

The mid-split upgrade process at Shaw involved replacing amplifier modules when possible, and the entire amplifier with housing only when necessary. Amplifiers that were 1GHz/42MHz were bench upgraded to 1GHz/85MHz in a properly controlled lab environment as it was not found to be practical to swap diplex filters in the field. DOCSIS 4.0 FDD was designed with multiple band plans in mind, and it is important that new amplifiers have a practical method of changing between them. There are many options for accomplishing this change, ranging from field-swappable diplex filter boards to centrally controlled and dynamic systems that remotely switch band plans depending on instantaneous demand.

As with a high-split upgrade, issues with ANSI/SCTE55-1, leakage detection, and MoCA coexistence arise with a DOCSIS 4.0 FDD upgrade. MoCA coexistence issues are more acute as the overlapping spectrum is greater. The MoCA D-band is 400MHz and the extended D-band used by MoCA 2.0 is 550MHz, which is too much spectrum to forego for long.

Initial tests have been performed on plant segments to confirm operation to 1.8GHz, but as with all HFC networks, signal performance will degrade with increased cascade length. Similar to high-split, the desired upgrade path for DOCSIS 4.0 FDD is a drop-in upgrade. It is expected that a drop-in upgrade will operate in current plant cascades and spacings with performance gains realized as fibre is deployed deeper into the network. Unlike with high-split, all passive devices will require upgrading to 1.8GHz or greater. If available, swapping passives or their housings to 3GHz could future-proof those devices and make any future upgrade easier.

5.3. DOCSIS 4.0 FDX

FDX allows spectrum to be used in both upstream and downstream directions simultaneously, effectively doubling the spectral efficiency for those frequencies (Figure 24).

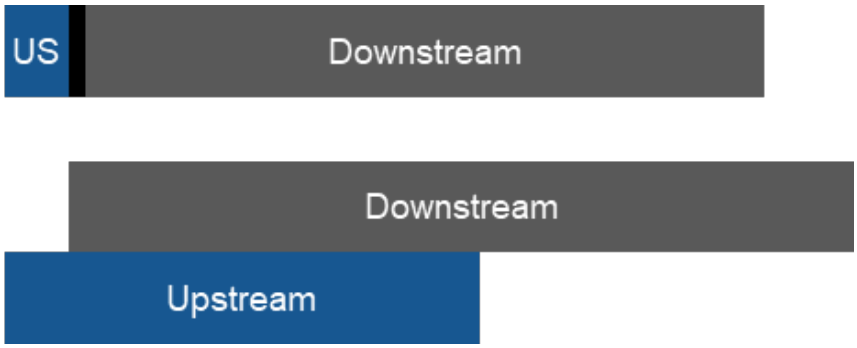

Figure 24 – FDX Spectrum Overlap

The FDX specification supports a high frequency of 1218MHz, and the frequency range from 108-684MHz may be used bidirectionally, leading to a large increase in spectrum (Figure 25).

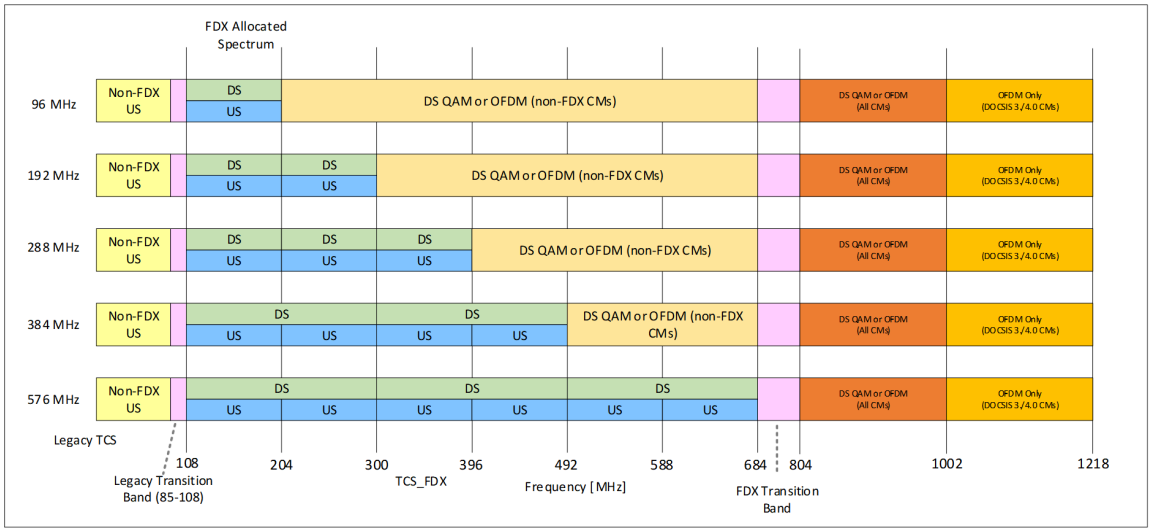

Figure 25 – FDX Band Plans (Source: CableLabs)

The amount of spectrum allocated to upstream and downstream can be delineated by the amount of bidirectional spectrum, as shown in Table 4.

Table 4 – FDX Spectrum Allocation

	Mid-split	96MHz	192MHz	288MHz	384MHz	576MHz
Upstream Spectrum (MHz)	80	176	272	368	464	656
Downstream Spectrum (MHz)	894	1098	1098	1098	1098	1098
DS:US Spectrum Ratio	11.2	6.2	4.0	3.8	2.4	1.7

The quantity of downstream spectrum remains the same for different amounts of bidirectional spectrum. The frequency range between 108-684MHz not used bidirectionally, however, is only available to non-FDX Cable Modems (CMs), as shown in Figure 25.

FDX is designed to be operated in passive, or N+0, plant. This requires the removal of all amplifiers and fibre deployed deep into the network (Figure 26).

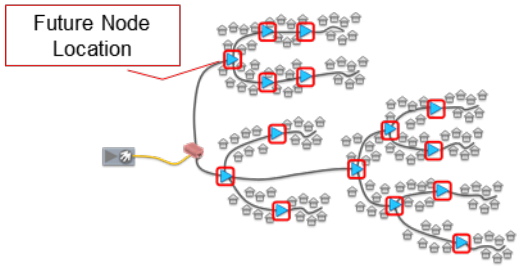

Figure 26 – N+0 Build

In Shaw's network, N+0 represents a small fraction of homes passed, generally in newer areas or especially in Multiple Dwelling Units (MDUs). In these areas, a deployment of FDX is a matter of swapping out the node. In networks with amplifier cascades, however, fibre deployment is required.

The cost and time required to upgrade to N+0 is heavily influenced by the type and ownership of the infrastructure. Owned aerial infrastructure is the easiest to upgrade, with un-owned underground infrastructure the most difficult, with estimates showing upwards of ten times the difference in cost and build time between the two. The mix present in an operator's network will dictate the average cost per home passed as well as the time required to complete the upgrade.

5.4. FTTP

As with FDX, an upgrade to FTTP is heavily impacted by the infrastructure and has the additional requirement to deploy fibre drops, either at the time of upgrade or in a success-based fashion at a later time. One important consideration in moving to FTTP is the lack of backwards compatibility, requiring CPE to be replaced. Depending on infrastructure access agreements there may not be the option to overbuild and transition customers slowly. In a worst-case scenario, the HFC network is removed, a PON network deployed, and all subscribers transitioned within a short period of time. The logistics of such an upgrade would have to be managed diligently.

6. No Regrets Investments

Deploying fibre into the HFC network to decrease coax cable distances and amplifier cascade depths is a no regrets investment beneficial for each upgrade option. Additional capacity is achieved both by decreasing the number of subscribers per serving area and by increasing the spectrum and signal quality available to that group of subscribers.

Outside plant networks can be differentiated by what percentage of the network is fibre optics, with FTTP on one end and N+X on the other. Upgrade strategies that deploy fibre all the way to the subscriber or deep into the network have the advantage of creating a large surplus of capacity. A pragmatic upgrade strategy would be to deploy just as much fibre as is necessary to relieve current network deficits. There are also strategies to reduce the maximum cascade depth in the network, or deploy fibre to an intermediate depth, in areas where congestion is expected. There are reasons to pursue all the above

strategies depending on network context. The benefit of a deep fibre strategy is that when work is completed in an area, no network augmentations will be required for a significant amount of time. Any permitting or approval process is done only once, and logistics are concentrated. The drawback of this strategy is that in an environment where capital and time are constrained, the time delay between the first and last subscriber upgrade is significant. A broad fibre strategy, which reduces amplifier cascades to a set depth, would allow capital and time to be spread more evenly throughout the network, increasing the capacity to all subscribers. This approach can be useful in upgrading the network to compete with FTTP offerings in a relatively short time frame.

As shown in Figure 27, upgrade strategies can be placed on a plot of capacity versus fibre depth. Capacity is considered as the sum of upstream and downstream, while fibre depth is subjectively defined, with current HFC networks considered low fibre depth and FTTP considered high. This is a relative judgement as a very high percentage of current HFC networks are fibre.

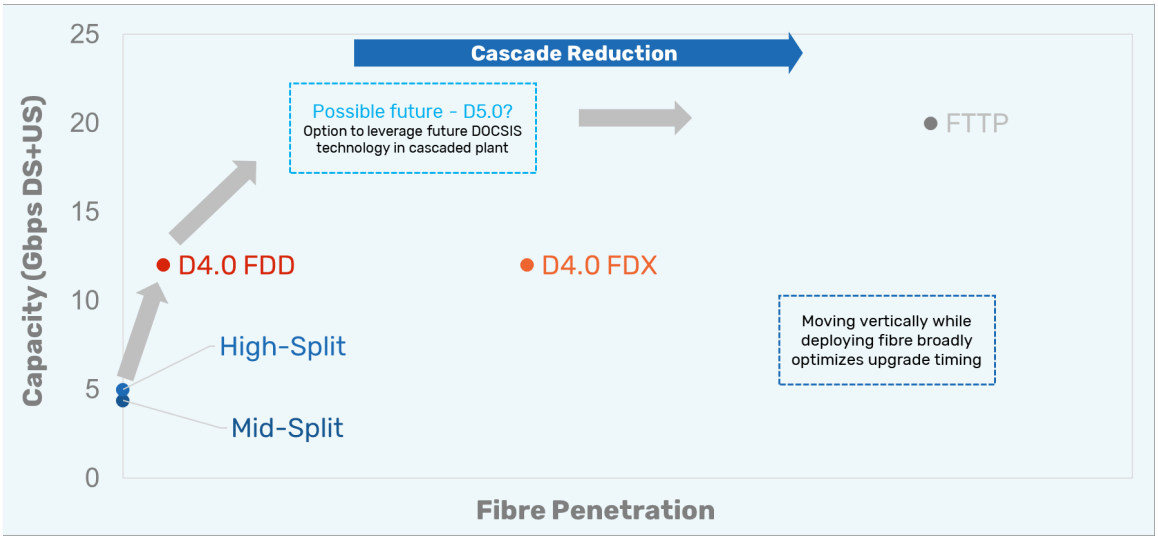

Figure 27 – Capacity vs Fibre Penetration

A deep fibre strategy moves diagonally to the top right on this plot, enabling FDX or FTTP by increasing capacity and fibre depth. A broad fibre approach moves in a near-vertical fashion, reducing cascades over time while using drop-in upgrades to create more capacity. The strategic direction will be influenced by future predictions of the direction of technology, fibre deployment costs, and subscriber demand.

A broad fibre strategy benefits if DOCSIS versions beyond DOCSIS 4.0 FDD are created that continue to operate in cascaded plant. If the direction moves toward passive operation, the deep fibre strategy is optimal. It is best to deploy fibre as quickly as possible if future fibre deployment costs, which are heavily weighted toward labor, increase significantly. An advantage of the broad fibre strategy is that capacity growth can more closely match demand growth, moderating or accelerating as needed.

Another no-regrets investment is the transition of video from QAM to IP delivery. As serving group sizes get smaller, a QAM broadcast video model becomes less and less efficient and the capacity increase achieved by moving to IPTV more compelling.

Lastly, pre-seeding the network with future-proof CPE will ensure that new capacity is available to subscribers as soon as an upgrade is complete. Switchable diplex filters can be used to ensure there is no interference from new CPE.

7. Potential Path

One potential path is to begin upgrading the plant to high-split as soon as the mid-split upgrade is complete. This upgrade would not be undertaken to reduce congestion as mid-split capacity is forecasted to satisfy customer demands for the next few years. Instead, a high-split upgrade would demonstrate HFC's ability to achieve gigabit upstream tiers and could be used to match or exceed an FTTP competitor's high service tier of 1.5Gbps downstream and 940Mbps upstream. A high-split upgrade can also pave the way for future DOCSIS 4.0 upgrades through the development of leakage detection, DAA, QAM reclaim, and other foundational components required for both solutions.

As soon as DOCSIS 4.0 FDD equipment is commercially available, the switch can be made from a high-split upgrade to a DOCSIS 4.0 FDD upgrade but operated with a high-split band plan. In parallel, programs to reduce cascade lengths and retire QAM video hardware will increase the capacity available to subscribers. When QAM video is retired a significant amount of spectrum will be freed up, which can be used for additional downstream capacity or to increase upstream capacity via a change to one of the ultra-high-split band options.

In new developments, FTTP will be the technology of choice, slowly becoming a larger fraction of the overall network. As fibre is deployed into the network to reduce cascades, the amount of work required to upgrade to N+0 or FTTP will be reduced, making such a move more practical in the future.

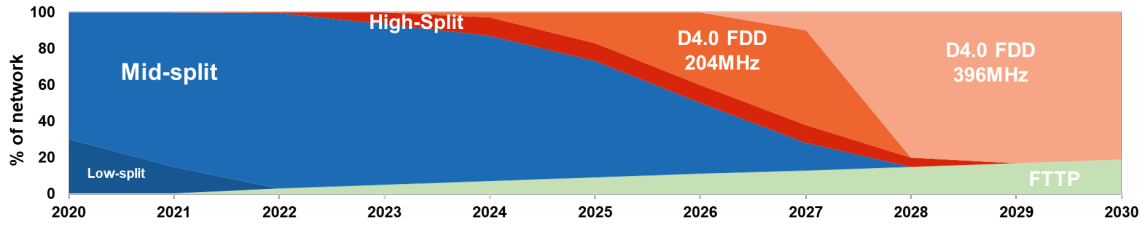

Figure 28 – Potential Network Path

8. Conclusion

Broadband subscriber demand continues to grow, as does competitive pressure, obliging network providers to upgrade their networks. The upgrade strategy network providers choose will impact capital intensity and competitive position. One strategy is to upgrade the HFC network in a drop-in fashion, allowing for a broad increase in capacity while minimizing time and capital spent. This allows time for a measured fibre deployment, slowly bringing the network toward N+0 or FTTP.

While DOCSIS 4.0 FDD is not currently available, starting an upgrade with high-split allows for gigabit symmetric tiers and requires operators to tackle some key issues such as leakage, DAA, QAM reclaim and MoCA coexistence. Once DOCSIS 4.0 FDD is available, focus can shift, initially to a DOCSIS 4.0 FDD upgrade with a high-split band plan and eventually to an ultra-high-split band plan. This strategy maximizes return on investment while efficiently competing with FTTP challengers.

1. Introduction

In the late 1990s, when the only number after the DOCSIS (Data Over Cable Service Specification) acronym was "1.0," measuring capacity and throughput, i.e., speeds, was a straightforward matter, limited to one channel in each direction: 40 Mbps Downstream and 10 Mbps Upstream. Now, with DOCSIS 3.1 and 4.0, we can bond multiple channels to support amazing multi-gigabit upstream and downstream speeds – enabling network capabilities that will benefit broadband consumption categories spanning the Internet of Things (IoT) and virtual reality, interactive video conferencing, health care and remote learning, among others.

However, with advanced performance comes advanced complexity, and that's especially true with respect to how we measure broadband capacity and throughput. This is especially noteworthy as underlying technologies become more deliberately dynamic, able to shift from one carrier or subcarrier to another, when connectivity becomes impaired or is more optimal in an adjacent or nearby spectral location. Measuring capacity and throughput in today's advanced stages of DOCSIS is trickier and more complicated because each bonded channel's frequency and modulation type can vary, based on spectrum availability and HFC network reliability.

This paper will address the new challenges in capacity and throughput measurements. It will examine how one operator measures capacity now, versus how those measurements are made or will be made, in more dynamic spectral configurations. It will also explore the capacity measurement methods and requirements for Full Duplex (FDX) and Extended Spectrum DOCSIS (ESD) techniques.

2. The Increasing Complexity of Capacity Management

2.1. Spectrum Range and Capabilities

Coaxial Cable lives on spectrum frequencies (measured in Hertz) located between 5 MHz and a range of upper boundaries (750 MHz, 1 GHz, 1.2 GHz, and future 3 GHz configurations are envisioned.) Figure 1 shows a capacity and services timeline for the cable industry, dating from the pioneering systems of the late 1940s, to today's growing service mix of voice, video, data and beyond. Capacity-wise, in the 1960s, the maximum frequency reached on coax was 240 MHz; now, cable systems operate at 1218 MHz (1.2 GHz) and beyond. The spectrum is traditionally divided into 6 MHz channels, a now-vestigial segmentation associated with analog television signals. In the beginning, there were three networks carried on three channels: ABC, CBS and NBC. After that, the name of the game was capacity expansion, to transmit dozens of analog TV channels one way, downstream, to homes.

In the 1990s, and coincident with return path / reverse spectrum activation, cable modems were introduced, in part to replace dial–up telephone connections to what was then a very new world wide web. It was those cable modems, and the broadband connections they enabled, that gave rise to so many "broadband native" video streaming, online shopping, and all things done over Internet Protocol (IP) connections. In the 2018 timeframe, for instance, over-the-top (OTT) video, social media services and online gaming drove substantial growth in broadband consumption and catalyzed our industry of connectivity providers to advance our capacity, throughput, and latency. Now, DOCSIS 3.1 enables multi-gigabit broadband speeds over cable spectrum upto 5 Gbps and can combine multiple 6 MHz channels into one large bond, which is what enables multi-Gig services. DOCSIS 4.0 further increases the downstream RF frequency range by using two methods: Full Duplex DOCSIS (FDX) and Expanded Spectrum DOCSIS (ESD). Newer Orthogonal Frequency Division Multiple Access (OFDMA) techniques

designed to accompany the rollout of FDX, ESD and DOCSIS 4.0-based components will provide additional bandwidth up to 10 Gbps. OFDMA will also advance how we measure overall throughput and capacity, which will be discussed later.

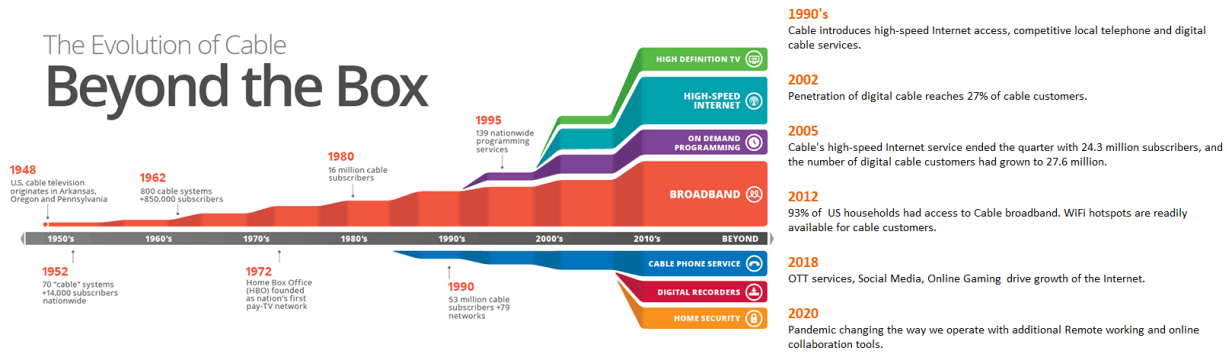

Figure 1 – Evolution of Cable (CCTA)

2.1.1. Coaxial Cable and the Frequency Landscape

Even though fiber is faster than cable capacity wise, coaxial cable is the faraway winner, in terms of capacity to cost ratio – the fire hose to the drinking straw, relative to telco twisted-pair. That said, coaxial does carry its own nuances. The upstream signal path in particular is perpetually nuanced by signal/noise that can overlap with downstream frequencies -- especially as the upstream path is eventually widened to accommodate mid-split, high-split and other upper spectral boundaries beyond the traditional top of 42 MHz.

Expanding the upstream band also allows a buffer for noise reduction and allocates more spectrum for higher speeds -- with frequencies ranging between 5 MHz - 396 MHz (from between 5 MHz – 42 MHz), while the downstream could reach up to 1.8 GHz or 3 GHz, depending on the use of Full Duplex DOCSIS (FDX) or Extended Spectrum DOCSIS (ESD.) Current industry plans to increase the upper boundary of the downstream spectrum to 1.2 GHz allows FDX to play a major role in simultaneous bidirectional transmissions on a signal carrier.

One view of a spectrum progression is shown in Figure 2, below. The top line illustrates a traditional 750 MHz configuration, with a 5-42 MHz return path. Below it, in yellow, the downstream spectrum above 750 MHz is illustrated as potentially usable for downstream transmissions, and the upstream is widened to a mid-split from 5 MHz – 85 MHz. The third line illustrates a high-split return path, from 5 MHz – 204 MHz, guard band between 204-258 MHz, and a combination of video, VOD, DOCSIS 3.0, DOCSIS 3.1, and reserved/unused bandwidth above 1 GHz. The fourth line, with the cutout detail below it, shows an ultimate spectral allocation with simultaneous bidirectional traffic moving between 300 MHz and 644 MHz. In that zone, traditional digital video, VOD and some DOCSIS traffic moves over the same carriers at the same time as FDX and DOCSIS 4.0 traffic. Clearly, as spectral configurations grow and shift to accommodate the ceaseless growth of broadband consumption, our mechanisms for measuring capacity must adapt and grow as well.

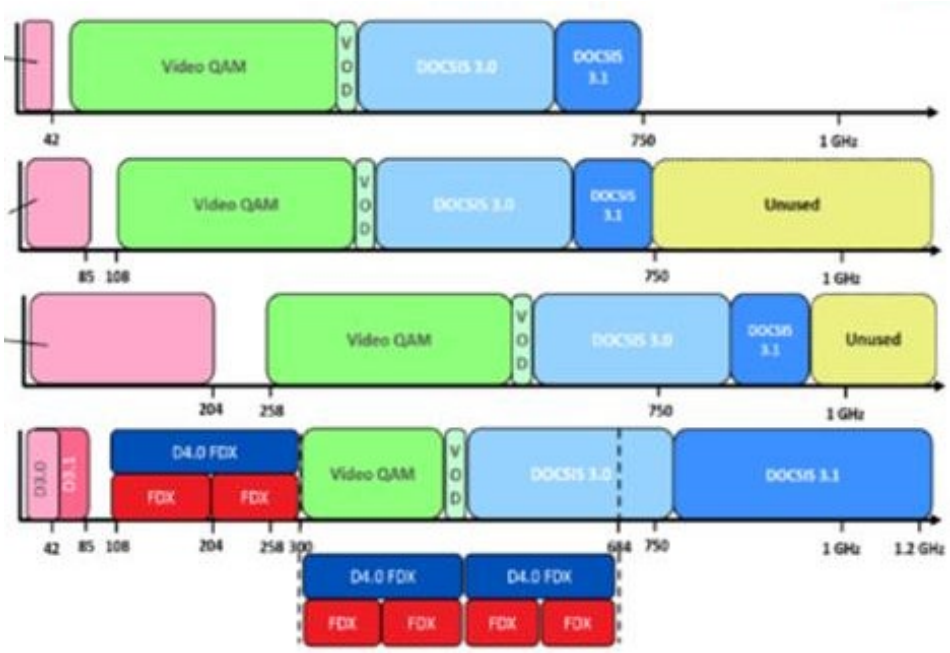

Figure 2 – HFC Spectrum

2.1.2. Hybrid Fiber Coax (HFC) Plant Issues

Attenuation, or the loss of signal strength, is a factor when measuring network capacity. The outside hardline coaxial cables typically attenuate at a rate of 2.4 dB/100 ft at 1.8 GHz, and 3 dB/100 ft at 3 GHz. By contrast, drop cables connecting to homes, and in-home RJ-6 cables, can attenuate at a rate of 12 dB/100 ft at 3 GHz. In general, the older the cable, the less it can carry, in terms of higher frequencies and long distances. In some cases, taps, amplifiers and nodes will need to be replaced to support an upper spectral boundary of 1.8 GHz. In other cases, the amplifiers could be replaced with fiber deeper nodes (such as to achieve N+1 or N+0 amplifier configurations).

2.2. Upstream and Downstream Frequencies

2.2.1. Upstream Boundaries

The upstream frequency band from 5 MHz to 42 MHz typically carries 4 Single-Carrier Quadrature Amplitude Modulators (SC-QAMs) that can deliver an aggregate 100 Mbps. Implementing an upstream mid-split to 85 MHz increases the aggregate capacity to 8 SC-QAM channels, which can deliver up to 200 Mbps that are usable by D3.1 modems.

2.2.2. MAC Layer vs. Physical Layer Capacity

One measurable difference between the Media Access Control (MAC) Layer and the Physical (PHY) Layer is the DOCSIS overhead. The Profile Management Application (PMA), which was developed by Comcast in 2019, and consequently shared with the industry, is vital for generating the D3.1 profiles for OFDM channels. In a capacity measurement context, PMA enhances part of the overhead efficiency to increase the usable bandwidth by ~15%, on average, based on a mix of modem types. The dynamic changes in the profile range between 10% to 25% in improvement. Table 1 is a PMA example using 6.4 MHz channels, where profile 271, when dynamically experiencing changes such as improved plant conditions/reduced noise, or a reduction of the number of connected modems, will proactively shift to profile 251, thus gaining an additional 5 Mbps of capacity.

Table 1 – Profile Management Application (PMA) example

Profile Template for 6.4 MHz Channels

251	256	261	266	271
25.6 Mbps 64-QAM short: 97/2, burst=5 long: 247/4 snr at 1% uccw = 22.8 dB	24.5 Mbps 64-QAM short: 91/5, burst=5 long: 239/8 snr at 1% uccw = 22.1 dB	23.3 Mbps 64-QAM short: 105/10, burst=6 long: 229/13 snr at 1% uccw = 21.2 dB	22.5 Mbps 64-QAM short: 99/13, burst=6 long: 223/16 snr at 1% uccw = 20.5 dB	20.7 Mbps 64-QAM short: 99/13, burst=6 long: 121/16 snr at 1% uccw = 20.3 dB

Based on the table 1 we observe ~9% improvement for Profile 266, ~12.5% for Profile 261, ~18% for Profile 256 and up to ~24% improvement for profile 251. In actual deployments we have observed ~15% improvement on average when PMA has been deployed in the field.

2.2.3. Frequency Bands, Modulation and Spectrum Allocation

One current approach in capacity is to increase the HFC spectrum to 1.2 GHz, allowing FDX combined with D3.0 and D3.1channels to achieve a D4.0 bandwidth supply of up to 4.2 Gbps for the US and 7.6 Gbps for the DS. The modulation and spectrum enhancements intrinsic to FDX and ESD will allow even higher Multi-Gig services. This is depicted in Figure 3.

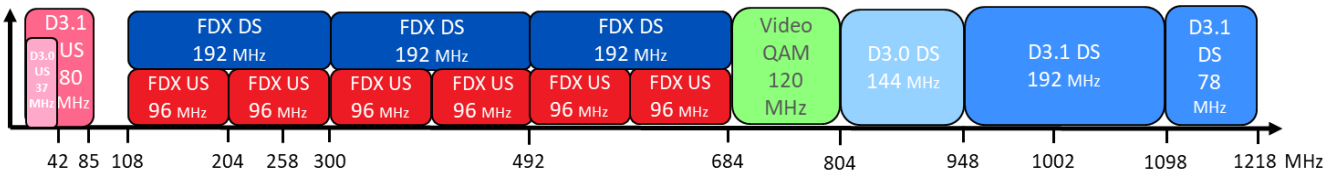

Figure 3 – D4.0 FDX HFC Spectrum

2.3. Multi-Gig Services That Will Likely Impact Capacity Measurements

Demand for higher speeds is increasing, as it has since the very onset of cable modems and broadband connections, in the mid-1990s. The current amount of bandwidth consumed per device is continuously

on the rise. Many applications and services are likely to require multi-Gig speeds, such as those within the Internet of Things (IoT), Virtual Reality (VR), Augmented Realty (AR), cloud gaming and streaming. Further discussion of these anticipated growth engines is out of scope for this paper, other than to note that anything that impacts the demand for network capacity must be considered and modeled, to the extent possible, when measuring throughput and capacity.

Downstream speed tiers reaching 1 Gbps using D3.1 are expected to expand to 10 Gbps with D4.0, which will yield ample bandwidth that can be applied to both foreseen and unforeseen applications.

2.4. Capacity Measurement Methods

As mentioned previously, in the "good old days" of early DOCSIS networks, with static channel widths and fixed modulation mechanisms (variations on QAM, from 64-QAM to 256 QAM in the downstream, and QPSK in the upstream), it was reasonably straightforward to predict capacity readings: The modulation rate on a particular channel width yielded a specific number of bits/Megabits per second.

As our broadband networks continued to advance and were deliberately engineered to stay ahead of consumer and business demand, the "simple math" of capacity measurement became part of a far more complex assessment. Now, multiple channel widths and a wider range of advanced modulation makes capacity measurement a trickier proposition.

2.4.1. Capacity Measurement Methods for OFDM Carriers

Currently, and because OFDM channels are primarily available on the downstream signal path, we have been collecting the percent utilization values reported by the CMTS based on demand. For SC-QAM, D3.1 modems can access both SC-QAM channels and OFDM, so they benefit from measurably higher throughput.

When high speeds are required for certain applications, or to run a speed test, the DOCSIS 3.1 modem can utilize both SC-QAM and OFDM spectrum. Since there is no means to determine the combined throughput between the two metrics, the actual available capacity can be determined based on the available capacity -- after deducting the 98th percentile SC-QAM used bandwidth from the total capacity, to remove anomalies, as well as the 98th percentile OFDM utilization. This is achieved by converting it to bandwidth based on the most prevalent profile used during a designated polling hour, then deducting that amount from the capacity of that profile. The sum of these two provides the available bandwidth during peak hours – in a sense, an erlang for broadband capacity. This matters to ensure that we plan for augments and have enough capacity to support our advertised speeds. This will be discussed later.

2.4.2. Orthogonal Frequency-Division Multiplexing (OFDM)

Combining multiple 6 MHz channels into one larger band (192 MHz) avoids Inter-Symbol Interference (ISI) and improves Signal-to-Noise ratio (SNR), which impacts capacity measurement in a beneficial (to capacity) way. OFDM traffic combined within SC-QAM channels provides an ample amount of BW to allow multi-Gig transmissions.

2.4.3. Orthogonal Frequency-Division Multiple Access (OFDMA)

OFDMA uses time slot and frequency allocation for D3.1 modems and higher. Each modem will be given a time slot or group of subcarriers to send the data. Excellent coverage of the topic of OFDMA for

upstream capacity gains can be found in the 2020 SCTE Expo paper titled "Field Experiences with US OFDMA and Using US Profile Management." As well, substantial detail about improvements to the upstream signal path are expected as part of this year's Fall Technical Program. For those reasons, we will say only that from a capacity management perspective, the inclusion of OFDMA adds another layer of complexity to the capacity measurement task.

It represents an active area of exploration.

2.5. Tools and Methods to Measure Utilization

Currently, we measure capacity by regularly polling the CMTS for network activity from channels modulated with SC-QAM, as well as channels or bonded channels modulated with OFDM. In the case of the upstream signal path, the four SC-QAM channels are polled every five minutes, and the results aggregated. The total value for those four channels is then adapted from a daily or weekly view, depending on report type, and the last two percent removed, to get to a 98th percentile reading. The top 2% is removed as a countermeasure against network anomalies.

2.5.1. Cable Modem Consumption

Measuring hourly consumption in bytes per service flow at the cable modem level helps in identifying "top talkers" and the contribution during peak hours. Peak hours are based on the highest consumption of the averaged top 20 hours per month. Figure 4 shows the US and DS speed tier consumption at peak hours by service type. Modem consumption by speed tier is crucial to evaluate the growth and projection for multi-Gig speeds.

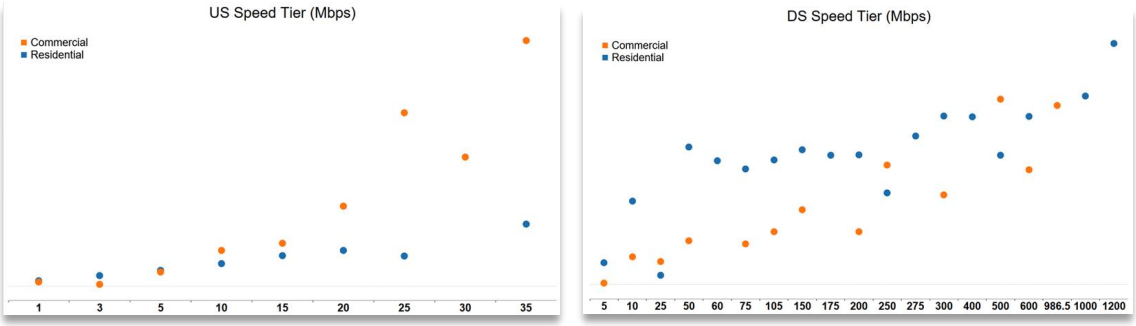

Figure 4 – BW Consumption During Peak Hours by Speed Tier

2.5.2. Traffic Aggregation and Concurrency

Aggregating hourly consumption during the top-twenty hours per month, per modem, at the CMTS Service Group (SG) and CMTS Bonding Group (BG), provides the behavior by demographics and shows any heavy usage by SG and BG. This method helps in better augmentation approaches and predictive analysis. It also aids in capacity measurements.

2.5.3. Reporting Frequencies and Metrics Needed

We use the iCMTS/vCMTS pollers to collect the average 5-minute polls, daily, over a month period, to calculate the 98th percentile values. The reported values are based on daily, weekly, and Monthly periods at a SG/BG level.

The metrics collected are as follows:

- In-bps, out-bps converted into percent utilization
- Up-channel utilization
- OFDM percent utilization
- OFDMA percent utilization
- PMA profiles and capacity
- Interfaces' speeds

Cable modem pollers provide the following metrics:

- Cable modem type
- Bootfile specifications
- CMTS mapping
- SNR, MER

Additional metrics collected are:

- HHP per node, per zip code
- Node-to-CMTS mapping

The combination of these metrics is utilized to address network augmentations, forecasting, and DOCSIS 4.0 capacity.

2.5.4. Future of Measurements

More trials and higher D4.0 penetration will be needed, in addition to methods to report on FDX. Profile types by interface are necessary to collect 5 minutes utilization for OFDM/A.

2.6. DOCSIS 4.0, Full Duplex DOCSIS (FDX) and Extended Spectrum DOCSIS (ESD)

2.6.1. Boundaries of D3.1

DOCSIS 3.1 modems max out at 1.2 GHz, where one (relatively large) OFDM channel could be utilized. This sets the downstream speed at 2 Gbps and the upstream speed at 300 Mbps (and potentially 600 Mbps where OFDM/A is applicable.)

2.6.2. Bandwidth Boundaries and CM Populations (D2, D3,…)

Currently, our network, like that of most operators, operates a range of cable modems, some based on DOCSIS 3.0 and others on DOCSIS 3.1. Currently, most of our footprint uses D3.0-based CMs, with the rollout of D3.1-based modems poised to shift the balance in a reasonably swift fashion. To fully and efficiently utilize an advanced, future-state network. outfitted with OFDM/A and FDX/ESD, and to benefit from the additional BW, that same trajectory will be required, to shift the balance again, from D3.1-based CMs to D4.0-based CPE.

Plus, because the maximum capacity of D2.0 is limited to 40 Mbps DS and 30 Mbps US, modems based on that DOCSIS version will ultimately need to be replaced.

For D3.0-based modems, the number of DS SC-QAM channels varies from 8 to 32, resulting in a capacity range from 320Mbps to 1.2 Gbps. Similarly, US capacity ranges from 30 Mbps to 120 Mbps. This is summarized in Table 4, below.

Table 2 – Modem Types and Bandwidth

Modem Type	Max. Speed	SC-QAM Bonding	OFDM/A Capable?
D2.0	40 Mbps DS 30 Mbps US	1 DS 1 US	NO
D3.0	1 Gbps DS 120 Mbps US	8 DS 4 US	NO
D3.1	10 Gbps DS 1 Gbps US	32 DS 8 US	YES
D4.0	10 Gbps DS 6 Gbps US	44 DS 8 US	YES

2.6.3. Differences between D3.1 and D4.0

A very important reason why measuring broadband capacity is sometimes an "It Hertz" proposition can be seen in Figure 5, below, which shows spectrum ranges and modem capabilities. The expansion of spectrum frequency is the only means to obtain additional throughput:

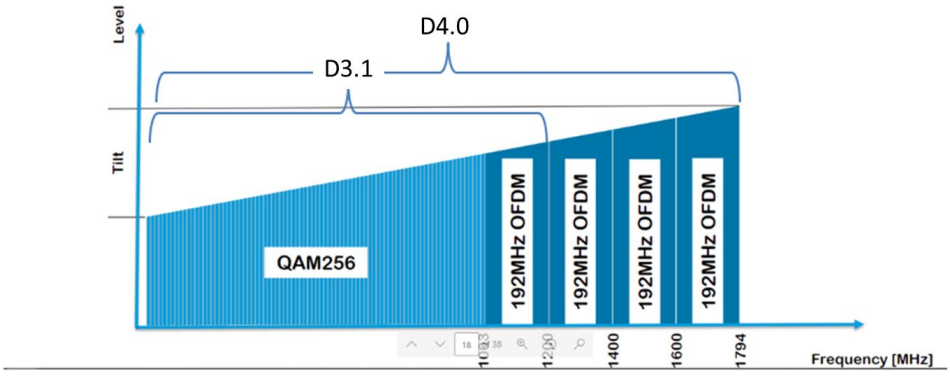

Figure 5 – Frequency Expansion

DOCSIS 3.1 can function at a maximum frequency of 1.2 GHz, with OFDM channels, while DOCSIS 4.0 can utilize higher spectrum up to 1.8 GHz, thus combining multiple OFDM channels to reach multi-Gig speeds.

2.6.4. Why is D4.0 needed?

Higher speeds, like 10 Gbps downstream and 6 Gbps upstream, are only possible with DOCSIS 4.0, also known as Full Duplex DOCSIS (FDX). This will coincide with plans by operators to drive optical fiber deeper into their networks, go higher spectrally, and/or to provide sufficient capacity to the Remote PHY Devices (RPDs).

Although this paper didn't go into substantial detail, it is worth repeating that more bandwidth, wider spectrum, and higher efficiency (lower latency and faster speeds) will be required to meet the demand for known and unknown broadband services and service categories (e.g. IoT, the "metaverse," and so on.)

3. Conclusion

Measuring network capacity is an activity that is vital to strategic planning, especially as broadband consumption continues to steadily grow. In the earliest days of broadband, such calculations were a relatively straightforward matter related to modulation type and channel width. As network capabilities advanced, however, the very technologies that enabled the advancements simultaneously increased the complexity for capacity planners.

DOCSIS 4.0 traffic, for instance, is especially convoluted – so, from a complexity standpoint, "it Hertz". In addition, the dynamic nature of the Profile Management Application (PMA) introduces additional challenges, in that it is vastly more challenging to count when channel widths and modulation types are hopping around, on the fly, in pursuit of optimal transmission paths. While many of the DOCSIS 3.1 techniques of measuring traffic apply, an aggregation of the OFDM interface metrics is required for DOCSIS 4.0.

Upgrading the network to 1.2 GHz and 1.8 GHz by replacing taps, amplifiers and nodes is a major effort, as is stairstepping D2.0 and D3.0 modems with D3.1 and D4.0 gear. With FDX and ESD on the near-term horizon to further increase the capacity of the access network, it is paramount that we make sure our capacity measurement techniques keep pace.

The good news is, over time, these network improvements will facilitate the periodic measurement of a balanced demand at SC-QAM, and OFDM/A levels combined. Tracking Latency/Jitter and SNR/MER proactively will further eliminate network issues. Along the way, we will need to also consider how to blend WAN, CPU, Memory, and other metrics beyond DOCSIS into the capacity monitoring mix, as all are or will be essential to the overall capacity planner's work.

Abbreviations

AP	Access Point
AR	Augmented Reality
bps	bits per second
BW	Bandwidth
CMTS	Cable Modem Termination System
CPU	Central Processing Unit
D2.0	DOCSIS 2.0
D3.0	DOCSIS 3.0
D3.1	DOCSIS 3.1
D4.0	DOCSIS 4.0
dB	Decibels
DOCSIS	Data Over Cable Service Interface Specification
DS	Downstream
EoHFC	Ethernet over HFC
ESD	Extended Spectrum DOCSIS

1. Introduction

Message Queuing Telemetry Transport (MQTT) is a well-designed, lightweight messaging protocol that can be used for communication between mobile clients, microservices, and IoT devices. Unlike HTTP (Hypertext Transfer Protocol) and other messaging protocols, MQTT is a low bandwidth, low latency alternative for IoT device transmissions, which is far more suitable because these devices may operate within tiny bandwidth, power, and transmission footprints. MQTT uses publish/subscribe operations to exchange data between client and server -- meaning an IoT device (or any other client) "subscribes" to a topic and asynchronously receives messages when data is published on that topic.

Also, unlike HTTP, this method saves a substantial amount of time previously spent on polling, which makes updates occur more quickly and smoothly. The lightweight nature of MQTT helps the end user – or customer - receive messages even when they are in low bandwidth situations, such as when traveling in areas with limited connectivity. Quality of Service (QoS) features supported by MQTT help clients opt into the level of service based on network reliability.

In this paper, attendees will learn how and why Comcast opted to adopt the MQTT protocol in customer-facing applications such as the Xfinity Application when connecting and bridging communications with IoT devices such as Philips Hue, LIFX, Ecobee, August door looks, and other Zigbee devices (via a Residential Gateway) using the AWS IoT Core as the MQTT message broker.

2. History of MQTT

MQTT was created in 1999 by Andy Standford-Clark (IBM) and Alen Nipper (Arcom, now Eurotech) as part of the IBM MQ series of products. The goal was to invent a new protocol for connecting oil pipelines over unreliable satellite networks. In 2011, IBM and Eurotech donated MQTT to the proposed Eclipse project called Paho. In 2013, MQTT version 3.1 was submitted to OASIS (Organization for the Advancement of Structured Information Standards). On October 29, 2014, MQTT 3.1 was approved. Since then, MQTT 3.1.1, currently the most supported version, was ratified in 2016, and MQTT 5.0, which supersedes MQTT 3.1.1, was ratified in 2019. MQTT is also published as an ISO/IEC 20922 standard reference.

A frequent question concerning MQTT that arises is, "What does the acronym stand for?" The answer is debatable. Given its source, the "MQ" in "MQTT" is historically based on the name of the IBM "MQ" Series product line. Others say "MQ" means message queueing - but this is a misnomer, as MQTT is not a message queue, but *can* queue messages for clients. Unfortunately, the OASIS technical committee named itself "OASIS Message Queuing Telemetry Transport Technical Committee". This is likely the source of the acronym's more common definition. In any case, the messaging protocol is no longer really an acronym, but is simply recognized by the letters "MQTT."

Given the maturity and design of MQTT as a lightweight messaging protocol, it has been widely adopted for MTM (machine to machine) communications for industrial, messenger, and IoT applications. MQTT's ability to keep bandwidth requirements to a minimum -- while dealing with high latency, unreliable networks, small footprint devices, and low power consumption -- has made it an excellent choice for communications over a variety of networks between clients and/or devices with high cardinality to cloud-based platforms.

Other protocols, such as, HyperText Transfer Protocol (HTTP), Advance Message Queuing Protocol (AMQP), eXtensible Messaging and Presence Protocol (XMPP), or Websockets, while often considered as potential solutions, have fallen short of meeting some of the basic selection criteria. MQTT continues to edge out other options because of its nature as a lightweight, asynchronous, bi-directional, secure, efficient, reliable, publish/subscribe, and data-agnostic messaging protocol.

3. Advantages of MQTT

3.1. Asynchronous bi-directional communication

Asynchronous APIs matter in that they can provide significant performance and responsiveness in client-server communications. This mechanism is inherently *non-blocking,* which means that an application does not need to wait for a response in order to proceed. In the context of an application showing the status of IoT devices, a list of devices can be shown – and updates to their status will be received as devices report them, rather than pausing to wait for all devices to respond.

Messages can also be pushed directly to the client without an explicit request. Downstream microservices can choose to directly send updates to a client application – an ability they may not have had if they communicate only to an upstream synchronous API. This is useful for status reporting, user messaging, and more.

For asynchronous APIs to work, the client must maintain a persistent connection with the server.

3.2. MQTT Features that make it an ideal protocol for async messaging

3.2.1. Publish/Subscribe

MQTT uses a publisher / subscriber messaging pattern to provide a framework for exchanging messages between publishers (producers) and subscribers (consumer clients). A publisher can send a message and it will automatically be routed – via the MQTT message broker – to any client subscribed to that topic.

3.2.2. Topic structure

MQTT uses a topic hierarchy to send and receive messages. This can be thought of as the equivalent of a path or route in a HTTP API, except that they do not have to be pre-defined.

MQTT topics can consist of wildcards and topic separators. An example topic may be:

platform / customerId4 / house1 / lights / lamp4

MQTT topic levels are separated by a forward slash (/) and subscribers can use two different types of wildcards when subscribing:

+ A plus represents a single topic level wildcard.

A hash is a multi-level wildcard that can only be at the end of a topic subscription.

If a client wants to subscribe to all of customerId4's devices located in house1, they will subscribe to:

platform / customerId4 / house1 / #

If a client wants to subscribe to all of customerId4's lights in ANY of their houses, they will subscribe to the topic:

platform / customerId4 / + / lights / #

These patterns allow for significant flexibility across many types of services.

The MQTT protocol has no limits on the number of subscriptions for a given connection.

3.2.3. QoS

Quality of Service (QoS) is a key feature of MQTT. An MQTT Client gets an option to select the level of service that works for their application, based on network reliability. MQTT manages the re-transmission of messages and guarantees delivery, even when the underlying transport is not reliable. QoS makes communication in unreliable networks a lot easier. There are 3 different levels of QoS:

QoS 0 is also known as "Fire and Forget service". An MQTT client sends the message to an MQTT broker and doesn't wait for an acknowledgement, so there is no confirmation if the message is received by the end client. However, this is considered the fastest message delivery service.

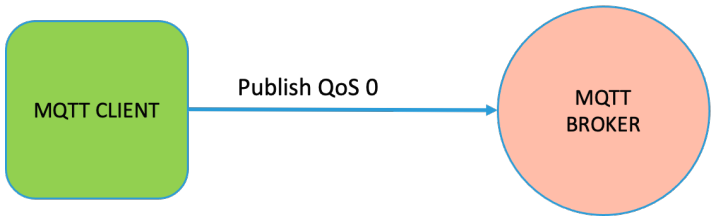

Figure 1 – Quality of Service 0(QoS 0)

QoS 1 makes sure that the MQTT message is delivered at least once to the end client. The publisher sends the message to MQTT broker and waits for an acknowledgement. If the publisher doesn't receive the acknowledgement within the given time, it publishes the message again with a duplicate flag (DUP). The MQTT broker sends the message to end clients and responds back with PUBACK packet to the publisher. The only drawback of this service is the possibility of end clients receiving the same message more than once.

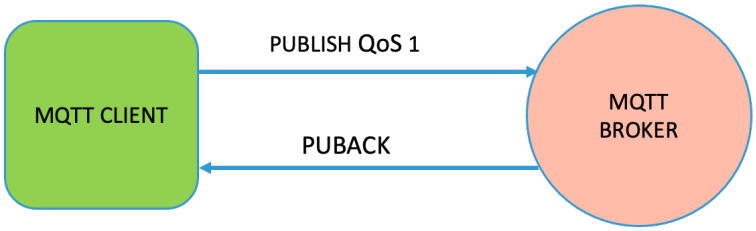

Figure 2 – Quality of Service 1 (QoS 1)

QoS 2 is also known as the safest and slowest message service. The publisher (MQTT Client) sends a QoS2 message to an MQTT broker and waits for acknowledgment. Once the publisher receives an acknowledgement (PUBREC) from the MQTT broker, it sends a PUBREL message

to the MQTT broker. The MQTT broker only sends the message to the end clients after it receives the acknowledgment (PUBREL) from publisher and sends back PUBCOMP to the publisher. Simply put, there is a four-way handshake that happens between a publisher and an MQTT broker to make sure the end client receives the message only once.

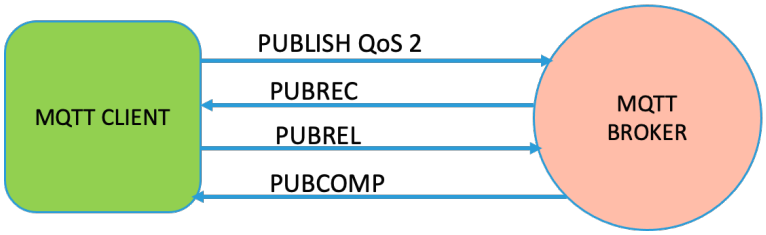

Figure 3 – Quality of Service 2(QoS 2)

The AWS IoT Core (MQTT broker) only supports QoS0 and QoS1 but not QoS2.

3.2.4. Last Will and Testament

Last Will and Testament (LWT) is a feature of MQTT that can notify other clients about a client that is disconnected without notice, often due to a lost network connection.

During the connect phase, a client registers the LWT with the broker. The broker then stores the LWT and publishes it if the client disconnects ungracefully.

LWT contains several parameters:

1. Last Will Topic (topic that the LWT message will be published to)
2. Last Will QoS (QoS of the LWT message)
3. Last Will Message (LWT message itself)
4. Last Will Retained (boolean) (whether the last lost connection information will be retained)

One example of usage in IoT devices is a *connected* flag. Immediately after connecting to a broker, an IoT device could send a *connected: true* message **and** set a LWT message that contains *connected: false*. If the IoT device's network connection is lost, the MQTT broker would send *connected: fals*e on the device's behalf, giving other clients real-time information as to whether it can expect a device to receive a command or update its status.

4. How to use MQTT for mobile or web application client

The MQTT message broker acts as medium for communication between the clients. Clients can be mobile or web application or an IoT device or microservice. Let's take a look at how a mobile application client can use MQTT for communication with IoT devices. Key actions include connect, disconnect, subscribe, unsubscribe, and publish. Key components include the MQTT broker, client(s) and topic(s).

Clients connect to the IoT services and devices through the MQTT broker using the connect method. Next, the client subscribes to topic(s) to receive messages. When a message is published to a topic, all clients that are subscribed to the topic will receive the message asynchronously, as depicted in Figure 4, below:

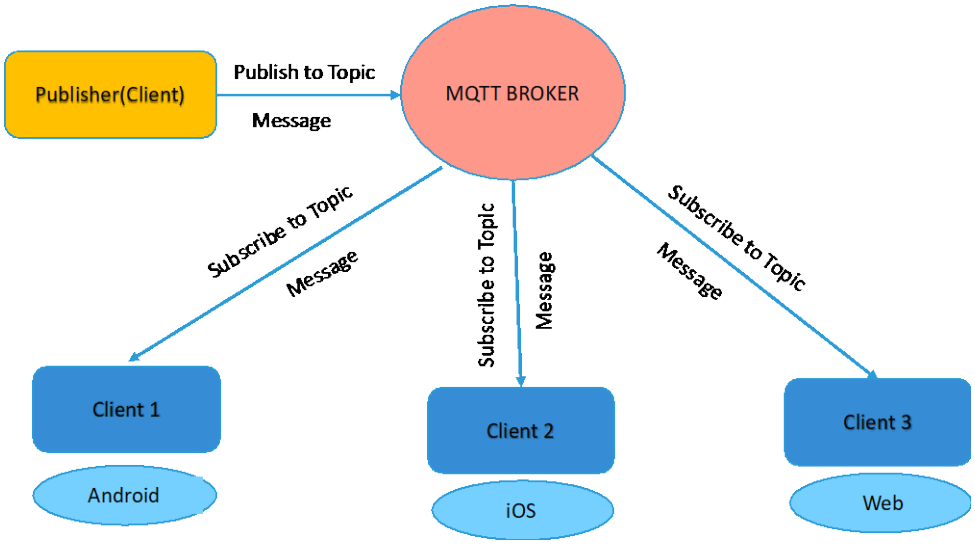

Figure 4 – High level diagram of MQTT

4.1. MQTT Connect

Application clients can establish a secure, persistent connection with an MQTT broker. Let's take a look at one of the MQTT brokers (used in Xfinity app) within AWS's IoT Core. IoT Core provides an open source SDK which can be used by the mobile client to integrate and consume the MQTT broker. AWSIotMqttManager, which is part of the SDK, provides an interface to make an MQTT connection. The AWSIotMqttManager requires the region, ClientID, and account endpoint, to which it uniquely establishes an MQTT connection.

The client ID provided by the application client is a unique identifier that represents the connection (one example could be a concatenation of a client account ID and app installation ID). "Region" is the AWS region identifier to which to connect (such as us-east-1 or us-west-2). The topic namespace is limited to an AWS account and namespace. The string accountEndpointPrefix indicates the specific customer endpoint. Example:
[prefix].iot.[region].amazonaws.com

AWS IoT Core allows a client to connect to the MQTT broker in four different ways:

1. Connect with keystore (secure location for storing cryptographic keys) and port number
2. Connect with AWS credentials provider
3. Connect with proxy host and proxy port.
4. Connect using custom authorizer. The IoT client of Xfinity Application uses custom authorizer to connect with MQTT broker. This custom authorizer is used to validate the customer against an internal identity provider.

The AWSIotMqttClientStatusCallback provides the status of the connection. Here is a sample of status call back details from a mobile client:

Connecting -> Trying to establish the connection Connected -> Successfully connection is established Reconnecting -> Trying to reconnect after a connection error ConnectionLost -> No longer client is connected to MQTT broker ConnectionError -> Error in the connection due to network or attempting to connect to a invalid topic

The attributes set as defaults can be altered by the application client. By default, the autoReconnect attribute is set to TRUE, which indicates that a reconnect attempt will be established when there is a connection error reported by the MQTT broker. A client can set the minimum and maximum reconnect time in seconds and maximum reconnect attempts. Another key attribute used is *clean session*. By default, clean session is set to TRUE, which means a non-persistent connection is established, which will not store any subscription information or undelivered messages for the client. By setting clean session to FALSE, a client can establish a persistent connection which will store subscription information and undelivered messages are delivered with QoS 1.

Table 1 – Clean Session with QoS

CleanSession Flag	QoS	Message received after Reconnect
TRUE	0	NO
TRUE	1	NO
FALSE	0	NO
FALSE	1	YES

4.2. Publish and Subscribe to Topic

Clients who subscribe to a topic will receive messages published to the topic, after a secure connection is established through MQTT broker. QoS level can be set to subscribe and publish topics. A client can also unsubscribe to topics before they disconnect. Using the AWS IoT Core, a client can publish messages as a JSON string or simple string.

4.3. MQTT and AWS Shadow State

The AWS Shadow State service, provided by the AWS IoT Core, is a persistent cache that can be used to store IoT device state. Reserved MQTT topics are provided to update this cache and to receive notification of create, update, and delete events. The two types of state in shadow state messages are *desired state* and *reported state*. Desired state lets the client send a request through an MQTT broker to the Shadow State service, where the Shadow State service calculates a *delta state*

(difference between desired and reported) and forwards the request to a device via an AWS IoT Core Rule. The device then attempts to honor the request, resets the desired state, and updates the reported state accordingly. The reported state is in turn returned via the device's MQTT topic to which the client is subscribed.

Here is a sample json payload that demonstrates desired and reported shadow state messages:

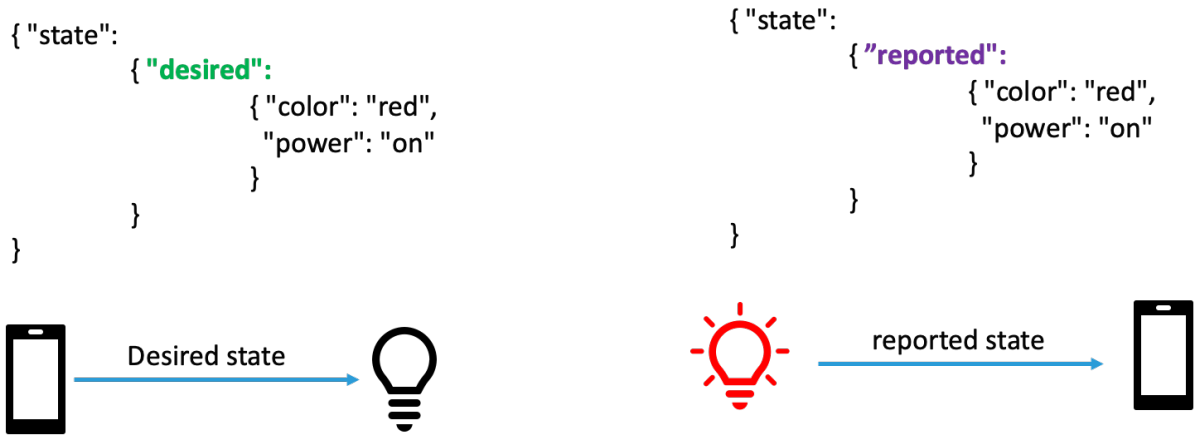

Figure 5 – desired and reported state messages

4.4. Message payload

Since MQTT is a lightweight protocol, the message payloads cannot extend in size. AWS's IoT Core supports a maximum payload of 128kb. In the Xfinity Application, the client receives the payload of one device at a time. MQTT messages also have no guaranteed ordering. Due to these limitations, we included s*equence number* and *total messages expected* to our MQTT message payloads to ensure all messages are received and ordered properly.

Shadow Reported state message payloads contain a property named *version*, which gets incremented with each change in shadow state. If the client receives a payload with version 5 and then a payload with version 4, the client can ignore the payload with version 4 as it is considered stale. Also, the desired state payload request sent by the client either needs to be same or higher version than the reported state, otherwise the AWS IoT Core MQTT broker rejects the desired state message with a *409 version conflict*. This feature, called optimistic locking, ensures that the client has the latest device status prior to trying to update the state.

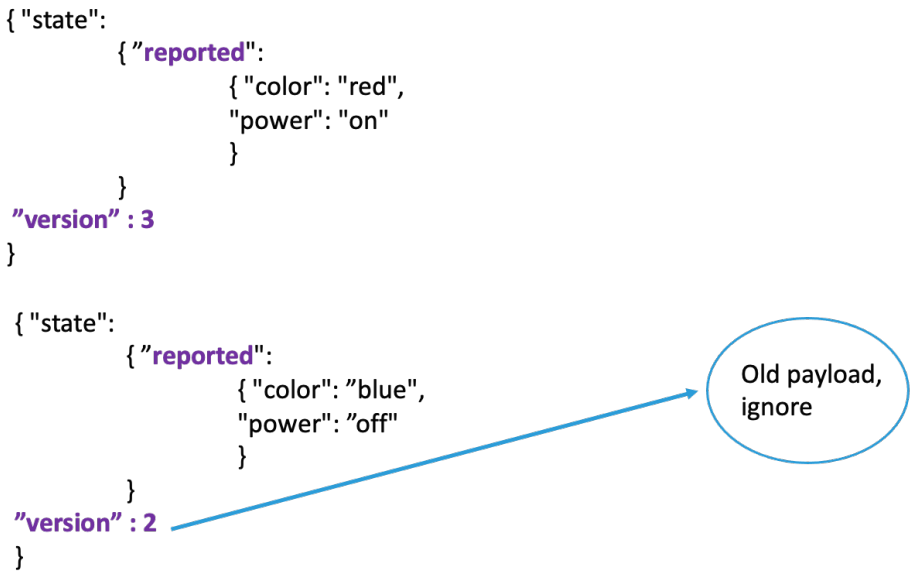

Figure 6 – reported state with old payload

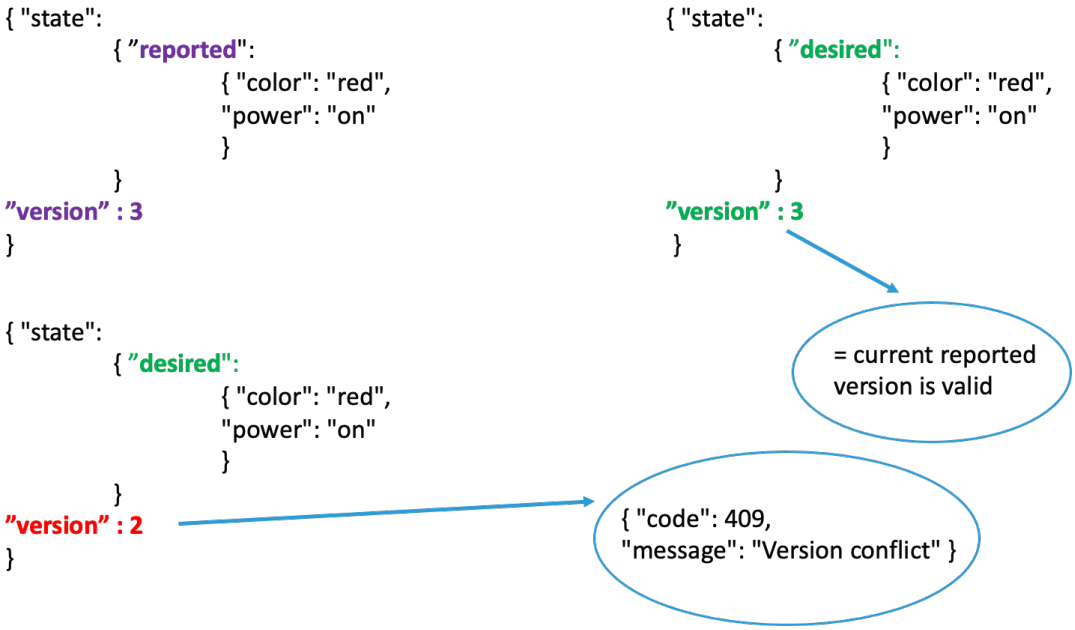

Figure 7 – desired state with previous version number

5. Security

The security of MQTT connections for a given subscriber (using mobile/web clients and residential gateways) is of the highest importance. To achieve fine-grained security controls and minimize blast radius (total impact of a security event), Xfinity leverages the capabilities provided by the AWS IoT Core MQTT Message Broker and its support for custom authorization using Java Web Token (JWT) and Just in Time Registration (JITR) with x509 Certificates. The authorizers generate AWS IoT Core Policies that allow MQTT connect, publish, subscribe and receive actions at the finest level of granularity - the MQTT topic.

5.1. Mobile Client

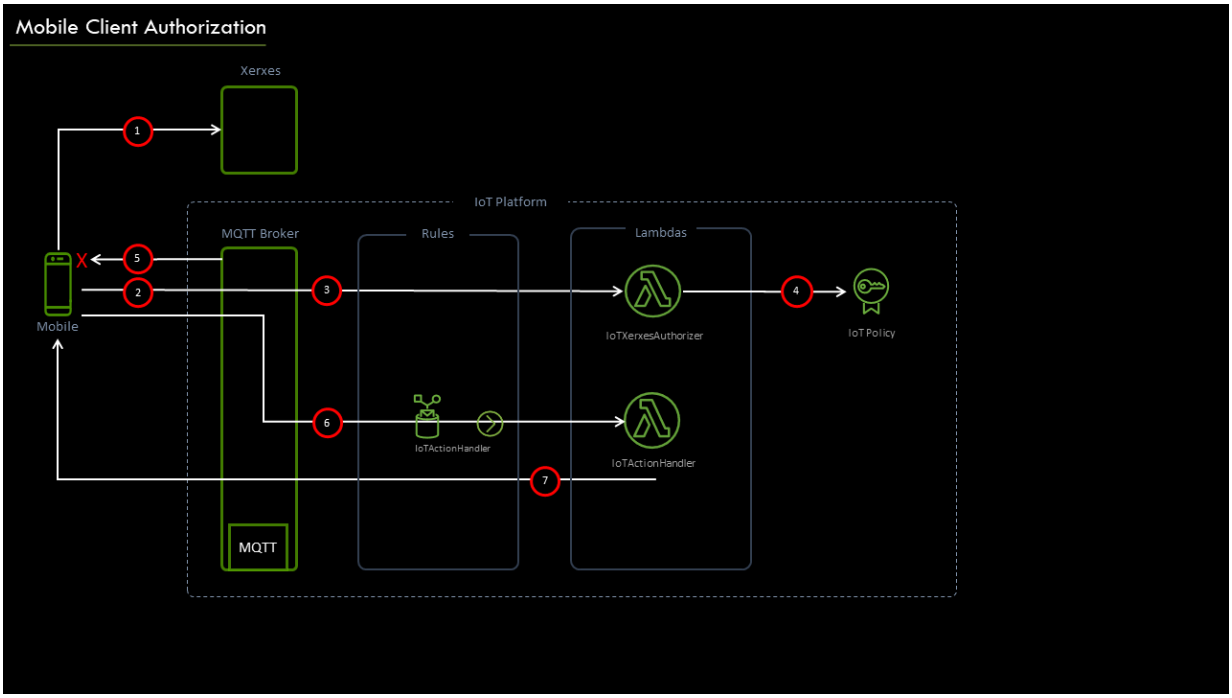

Figure 8 – Mobile Client Authorization Flow Diagram

The Xfinity Application uses an Enterprise Federated Identity Management system, known as Xerxes, to integrate with syndicated partner IdPs (Identity Providers). This system provides authentication and authorization via a Java Web Token (JWT) based Identity Token. Within the JWT there are principal attributes critical in supporting a fine-grained security model. These attributes are:

- Partner Identifier (PID) – Syndicated partner identifier for the Multi System Operator (MSO).
- Account Identifier (AID) – Identifies the subscriber's account id
- JTI – Java Token Identifier (JTI) attribute

The AWS IoT Core MQTT message broker provides a custom authorization capability which is used to verify the JWT and authorize the Mobile Client MQTT connect operation. The JWT is verified via Signature, audience attribute (aud), and issuer attribute (iss) match. Once

verified, the JWT principal identity attributes are used to generate an AWS IoT Policy that allows the MQTT Mobile Client to:

- Connect – allow the MQTT connection with a unique MQTT Client ID (CID) generated from the principle information within the JWT. This information includes the PID, AID, and the Java Token Identifier (JTI). An MQTT Client ID must be unique amongst all connected MQTT clients or the prior MQTT Client is disconnected. An example MQTT Mobile Client ID is as follows:

  ```
  xfi:[PID]_[AID]:clt:[JTI]
  ```

  This authorizes only the MQTT client matching the validated JWT to establish a connection to the MQTT Message Broker. An MQTT client with a JWT that is expired or is invalid is denied connection.

- Publish – allows the MQTT client to publish messages to MQTT topics which are name spaced based on the PID, AID and JTI. An example service request message topic is as follows:

  ```
  c/xfi/[PID]_[Account ID]/[SID]/[CID] /[RID]
  ```

  where,

  c is the root of the MQTT topic

  xfi represents the Xfinity Application part of the MQTT topic

  [PID] represents the Syndicated Partner

  [SID] represents a unique Service Identifier as the destination of the request

  [CID] represents the MQTT Client Identifier as the source of the request

  [RID] represent the type of request. This limits the ability of the MQTT Client to publish only to topics containing its principle identity and to services to which it has been granted permission to send action request messages.

- Subscribe/receive – allows the MQTT client to subscribe/receive messages to/from MQTT topic(s) which are name spaced based on the PID, AID and JTI. An example service request response topic is as follows:

  ```
  c/xfi/[PID]_[AID]/[CID]/[SID]/[RID]/[success|failure]
  ```

  where,

  c is the root of the MQTT topic

  xfi represents the Xfinity Application part of the MQTT topic

  [PID] represents the Syndicated Partner

[SID] represents a unique Service Identifier as the destination of the request

[CID] represents the MQTT Client Identifier as the source of the request

[RID] represent the Response Identifier or type of response. This limits the ability of the MQTT Client to subscribe and receive action response messages only on topics containing its principle identity and from services to which it has been granted permission to receive action response messages.

5.2. Residential Gateway

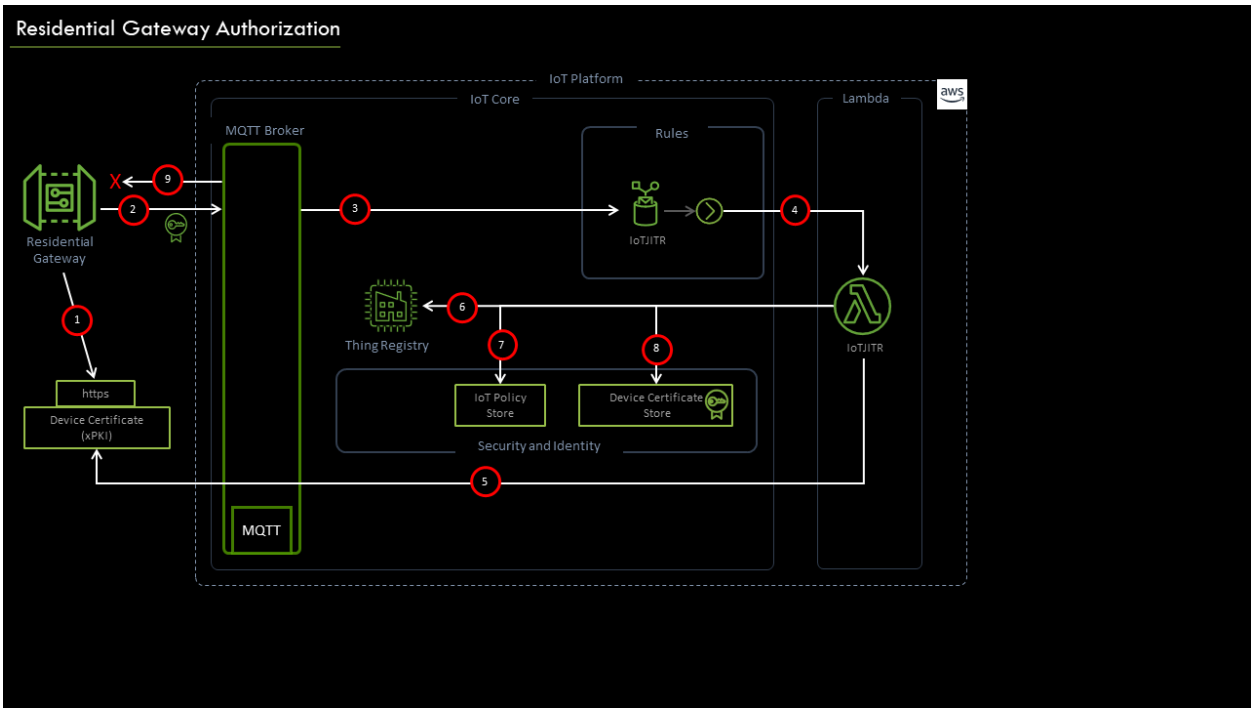

Figure 9 – Residential Gateway Authorization Flow Diagram

The Xfinity Residential Gateway enables advanced IoT Bridge capabilities for Zigbee, Thread, and WiFi-based devices. To provide a secure MQTT connection to the IoT Platform, the Residential Gateway performs a CSR (Certificate Signing Request) and is issued a device certificate by Xfinity Public Key Infrastructure (xPKI). Within the Certificate there are critical principle attributes that provide for a fine-grained security model. These attributes are:

- Partner IDentifier - syndicated partner identifier for the Multi System Operator (MSO). Stored in the SAN (Subject Alternative Name) -> Dir Name (DirName) -> Org Name (O) attribute.
- Account Identifier (AID) - identifies the subscriber's opaque account id; Stored in the SAN (Subject Alternative Name) -> Dir Name (DirName) -> Common Name (CN) attribute.
- Installation Identifier – the device identifier as a UUID (Universal Unique Identifier); Stored in the Subject -> UID attribute as the fourth part of the form [Model]:[Serial Number]:[AID]:[Installation ID]

- Mac Address – Device CMAC address. Stored in the SAN -> URI of form *urn:dev:mac:[CMAC]*. CMAC is of valid EUI-64 format.

The MQTT message broker provides certificate-based authorization support. The AWS IoT Core exposes this capability as part of the Just In Time Registration (JITR) feature, which is used to verify a pending device certificate and authorize the MQTT connect operation. The certificate issuer chain is verified and an OCSP check is performed. Once verified, the certificate's principal identity attributes are used to generate an AWS IoT Policy that allows the MQTT Residential Gateway to:

- Connect – allow the MQTT client to connect with a unique MQTT Client ID (CID) generated from the principle information within the Certificate. This information includes the PID, AID, and IID. An MQTT Client ID must be unique amongst all connected MQTT clients. An example MQTT Residential Gateway Client ID is as follows:

iot:[PID]_[AID]:adp:xhf:[IID]

  This authorizes only the Residential Gateway MQTT client matching the validated Certificate to establish a connection to the MQTT Message Broker. An MQTT client with a certificate that has expired or has been revoked is denied the connection.

- Publish– allow the MQTT client to publish messages to MQTT topics which are namespaced based on the PID, AID and IID. An example service request message topic is a follows:

c/iot/[PID]_[Account ID]/[SID]/[CID] /[RID]

  where,

  c is the root of the MQTT topic

  iot represents the IoT Device part of the MQTT topic

  [PID] represents the Syndicated Partner

  [SID] represents a unique Service Identifier as the destination of the request

  [CID] represents the MQTT Client Identifier as the source of the request

  [RID] represents the type of request. This limits the ability of the MQTT Client to publish action request messages only on topics containing its principle identity and to services to which it has been granted permission to send action response messages.

  This limits the ability of the MQTT Client to publish only to topics containing its principle identity and to services to which it has been granted permission to send action request messages.

- Subscribe/receive – allow the MQTT client to subscribe/receive actions to/from MQTT topics which are name spaced based on the PID, AID and CID. An example service request response topic is as follows:

c/iot/[PID]_[AID]/[CID]/[SID]/[RID]/[success|failure]

where,

c is the root of the MQTT topic

iot represents the IoT Device part of the MQTT topic

[PID] represents the Syndicated Partner

[SID] represents a unique Service Identifier as the destination of the request

[CID] represents the MQTT Client Identifier as the source of the request

[RID] represents the type of response. This limits the ability of the MQTT Client to subscribe and receive action response messages only on topics conatining its principle identity and from services to which it has been granted permission to receive action response messages.

This limits the ability of the MQTT Client to subscribe and receive action response messages only on topics that contain its principle identity and from services to which it has been granted permission to subscribe/receive action response messages.

6. MQTT versus other messaging protocols for client-platform communication

How does MQTT stack up against other messaging protocols? This section seeks to answer that question by first defining the key criterion upon which the messaging protocols can be fairly evaluated. This criteria can then be weighed upon each messaging protocol. These messaging protocols include HTTP, Websocket, AMQP, XMPP, and MQTT. The pros and cons of each messaging protocol is then considered, and finally this evidence can be used to inform a decision.

6.1. Evaluation Criteria

It is important to first define the evaluation criteria used to determine how the messaging protocols fit the needs of an IoT-based messaging system.

Asynchronous bi-directional messaging is necessary to provide support for enhanced Message Exchange Patterns (MEP). This includes asynchronous request/response messages and events using a publish/subscribe messaging pattern. Support for either UDP/IP or TCP/IP bi-directional communication is required.

The ability to support different type of data models for message exchange, whether binary, XML, JSON, etc, provides the flexibility to choose the data type most appropriate to publish a message specification, and enable message validation using client libraries and tooling that is widely available and adopted by the industry. JSON Schema support is required given its wide adoption and support within our organization.

Given the heterogenous nature of program languages and platforms across mobile clients, web clients, devices and services, wide support for client libraries must be available. At a minimum, client libraries must be supported from the likes ofAndroid (Kotlin), IOS (Swift), web clients (Javascript), devices (C/C++), and services (Java/Golang) ..

The security of an IoT system is of upmost importance. It is absolutely necessary to provide a secure communication channel between the mobile/web application clients, devices, and services of the IoT Platform. To this end, TLS 1.2 is required for inflight encryption, support for port 443 to avoid router/firewall traversal issues, and support for token-based auth for mobile/web clients and certificatebased auth for devices.

The performance and efficiency of the messaging protocol and overhead of the client/device libraries must be considered. The solution must offer minimum resource overhead, given factors including the negotiation of the initial connection and connection keep-alive, and the need for efficient messaging (small size on the wire), reduced power consumption for all devices and lightweight implementation (i.e code footprint, memory, etc). The solution must minimize latency related to network protocol negotiation and message broker and router traversal.

The reliability of the communication protocol is important as it offers a way to mitigate errors that may arise from unreliable mobile and/or home networks. The ability for the messaging protocol to deliver in-order messages, to acknowledge receipt of messages, and retransmit messages, if necessary, is required to build a reliable IoT system.

The solution should be cost-sensitive. Some of the key factors to consider that drive cost are the number of mobile clients and devices connected over a period of time (i.e. one day), the size and frequency of the messaging payloads, and the cost of vertical/horizontal scalability of the solution. Note that the extent to which the mobile and web clients are typically connected is a fraction of the time that the gateways are connected, which is to say 24x7.

6.2. HTTP (HyperText Transfer Protocol)

HTTP semantics has dealt quite well with brokering synchronous request/response messaging between the client and backend services, via URL paths. But HTTP has fallen short of satisfying the need to support asynchronous notifications across the convergence of application clients, gateways, and backend service(s). The use of multiple HTTPS long or short polling mechanisms, which mimic support for asynchronous responses, requires the mobile and web clients to connect and poll numerous backend services simultaneously. A better mechanism is required, and hence the need to extend the HTTP API semantics to include asynchronous notifications, using a publish/subscribe MEP. HTTP simply does not support publish/subscribe.

Also, it is not always easy to provide a single secure HTTP API connection endpoint for HTTPS client(s). Different services, within a vast organization, typically expose their own HTTPS endpoints. This necessitates a common strategy to expose a single endpoint across an HTTP API Gateway deployment. and in turn. fan-out the requests across the backend services. Horizontal scaling and high availability of this solution is required. Sections 6.2.1 and 6.2.2 detail the pros and cons of HTTP.

6.2.1. Pros

- Supports primary request/response but can lend itself to pub/sub with some work using PUSH_PROMISE vs. Long-polling, but please no short-polling!
- Reasonably small with HPACK for header compression required
- IETF standards are preferred by some vendors
- An HTTP API gateway supports millions of connected clients
- Rsed in mobile applications and most web applications that do not require pub/sub
- Support for many programming languages

6.2.2. Cons

- No guaranteed delivery (retry required
- No “last will & testament” feature for IoT devices that suddenly lose connectivity
- Slightly larger message size due to headers
- Primarily a pull technology:
    - short polling is not real-time (request timer driven) and if the time between requests is short, it can be server resource-intensive; most recommend never to use
    - long polling is immediate but is more complex and server resource-intensive; typically used for responses to requests for information in cases where a server is doing work in the background
- Server push requires work to implement pub/sub and asynchronous responses via PUSH_PROMISE

6.3. Websockets

Websockets provide an extension to application clients and web browser support of HTTPS. Where HTTPS offers only a request/response message pattern, websockets offer a very raw form of bi-

directional packet-based communication. It is the lack of built-in MEP and the number of potential connections that is the primary distractor of using websockets directly. Sections 6.3.1 and 6.3.2 detail the pros and cons of websockets.

6.3.1. Pros

- Works over port 443
- Supported by numerous mobile clients and web browsers (implementation on modern browsers is less of a concern)
- Supported by many web servers such as NGINX and Apache

6.3.2. Cons

- Client reconnection implementation on top of websockets is required
- A bit too raw even though it supports two-way asynchronous client/server communication. There is no built-in support for asynchronous request/response and pub/sub message exchange patterns. This would require additional work.
- Using raw websockets would still suffer from having to maintain a connection per client and potentially backend services. This approach would be very resource inefficient from both a client and backend perspective. It would lead to having to scale the web servers to meet the needs of all client/service connection needs, especially when websocket endpoints are not shared across services.

6.4. AMQP (Advanced Message Queueing Protocol)

AMQP is a great protocol for communicating between applications. It meets many of the needs of an asynchronous publish/subscribe and guaranteed message delivery system which supports numerous programming languages. But, as a message-oriented, middleware-based solution, it has not really found its home in the IoT space. Sections 6.4.1 and 6.4.2 detail the pros and cons of AMQP.

6.4.1. Pros

- Richest set of message scenarios (patterns)
- Asynchronous
- Supports queuing
- Mobile client support; web browser support via web sockets

6.4.2. Cons

- Uses port 5672 (not 443), which would lead to potential router and firewall issues
- Requires RabbitMQ on AWS EC2 instances; not a managed AWS service
- Larger protocol
- Used in IoT space by very few vendors

6.5. XMPP (eXtensible Messaging and Presence Protocol)

Extensible Messaging and Presence Protocol is an open communication protocol designed for instant messaging, presence information, and contact list maintenance. Based on XML, it enables the near-real-time exchange of structured data between two or more network entities.

6.5.1. Pros

- Support for message read, write, and consume
- Extended messaging and presence protocols
- Used for two-way chat and push notifications

6.5.2. Cons

- Uses port 5222 (not 443) which would lead to potential router and firewall issues
- Requires an XMPP/Jabber server on EC2 instances; not a managed AWS service
- It's XML-based, not JSON

6.6. MQTT

MQTT, as described in this paper, is a mature, stable, and feature rich messaging transport system. It delivers on all the key evaluation criteria. Sections 6.6.1 and 6.6.2 detail the pros and cons of MQTT.

6.6.1. Pros

- Provides a backend service the ability to publish notifications without the added complexity of implementing a long polling or websocket mechanism, as well as message routing within the context of each individual service. Aggregating and pushing the responsibility to the MQTT Message Broker decouples this problem from the client and underlying services. Note: MQTT also handles session persistence by delivering missed messages to the client.
- Provides a means to multiplex notifications across 1 or more topics grouped by backend service responsibility; the MQTT Message broker inherently supports message routing via topics.
- Only one secure client connection to the MQTT Message broker is required, allowing for simpler configurations for clients, load balancers, security policies, etc
- JWT and X.509 certificate-based authorization support
- Support for port 443
- Supports asynchronous message patterns (i.e. pub/sub)
- Assured delivery (3 QoS levels) and retained messages which provide flexible options for Client/Server.
- Supports the “last will & testament” feature that notifies other clients of an ungraceful disconnected of gateway-based devices
- Multiple subscriptions are ‘multiplexed’ over one connection
- Smaller size on the wire - minimum compressed header
- Great for a resource-constrained device, low bandwidth conditions, and high latency networks
- Brokers support millions of connected devices
- Easy to route messages to topic subscriber(s)
- Used in mobile applications, web clients, and devices for numerous IoT-based applications

- Lightweight implementation for embedded clients
- Power-efficient due to no-polling, shorter messages
- Less resources consumed compared to long polls on server.
- Support for many programming languages

6.6.2. Cons

- MQTT is based on the OASIS standard (OASIS-open.org), which is not preferred by some vendors
- Fixed headers and options apply if extensibility is required

6.7. Decision

In the end, after numerous discussions, careful consideration, and weighing the options based on the selection criteria, MQTT was the clear choice. Our Mobile/Web Client and Gateway teams decided that MQTT was the preferred communication protocol for messaging to/from the IoT Platform.

7. Conclusion

The Xfinity Mobile and Platform teams worked together to implement data models and topic structures for MQTT communications that are standardized and extensible across any device type and payload size. Its robust security, enabled by custom authorizers, ensures that mobile/web clients and devices can only publish and subscribe to topics relevant for the operator and subscriber's account.

By contrast, API semantics based on HTTP and other communication protocols have fallen short when it comes to satisfying the need to support secure, asynchronous notifications across the convergence of application clients, gateways, and backend service(s). The use of MQTT, in addition to the use of HTTP API semantics, fulfills the need to extend the API semantics to include asynchronous notifications using a Publish/Subscribe MEP.

We chose MQTT as a protocol for mobile-to-platform communications as well as Residential Gateway-to-platform communications. Its maturity as a lightweight, scalable, and robust protocol has proven itself in our production deployment of millions of clients.

1. Executive summary

The delivery of healthcare is undergoing seismic shifts. From remote consultations to remote patient monitoring, the healthcare of tomorrow will look and feel different than it does today. Numerous technological advancements have enabled these transformations, but each comes with a series of challenges to solve. These challenges include issues such as connecting devices to a local network, guaranteeing optimal bandwidth and latency, ensuring that services are being properly delivered by providers, and ensuring that patients are adhering to treatment plans. Cable operators are well-positioned to assist in developing standards to address these obstacles.

In this paper, we describe at a high level some of the services that tomorrow's healthcare will offer, the stakeholders that interact with these services, and the needs of each stakeholder according to the service. We then define four types of data categories and how they address the series of challenges that tomorrow's healthcare services face. We also provide recommendations on how cable operators can support these data needs and high-level architecture of a potential implementation for data collection, access, and analysis.

2. Introduction

The Healthcare industry is going through a major transformation to modernize the infrastructure, reduce the cost and increase the quality of care. In a series of articles, we have suggested how the Telecom industry can assist the Healthcare industry [1][2][3]. We call this inter-industry collaboration Telecom for Healthcare (T4H). Even though the T4H opportunity is not limited to these two major intersection points, we focus on Aging in Place (AIP) and Telehealth use cases to illustrate our thoughts on the end-to-end T4H architecture. (Refer to [4] for six different opportunities that a Telecom operator can address through the T4H architecture covered in this paper.) The SCTE Data Standards Subcommittee, in which the authors are members, is actively working on T4H solutions for the AIP and Telehealth areas in working groups three [5] and four [6]. The current paper on telemetry and metadata can be reviewed with the companion paper on the end-to-end T4H architecture published in the 2021 SCTE Expo [7] for a detailed understanding of the solution.

Figure 1 provides an intuition for the data needed from a T4H solution from per platform users (including the payor, who are not extensively considered in this paper) per type of services point of view. These data needs are categorized into four groups in the following section for further detailed purpose-driven analysis from telemetry and metadata points of view.

The players involved in the T4H solutions include the users (for AIP these are the elders, and for Telehealth[1], these are the patients who want to use the platform being developed in [5][6]), the service providers (such as the doctors, caregivers, etc.), and the other stakeholders (such as the family, legal guardians, trusted circle, etc.). These players use the platform for the following services:

- Use the platform for **communicating with different T4H players** (unified collaboration and communication (UCC)), and **communicate different information** relevant for the success of

[1] The US Department of Health and Human Services (HHS) defines telehealth as “the use of electronic information and telecommunications technology to support and promote long-distance clinical health care, patient and professional health-related education, and public health and health administration”. It encompasses everything from video calling to text messaging. In the realm of reimbursement, insurances may cover different levels of telehealth. The level of reimbursement has also changed after changes that came with COVID. Within telehealth here are four other broad categories: Synchronous, Asynchronous (store-and-forward), Remote Patient Monitoring, and Other Services such as mobile health (mHealth).

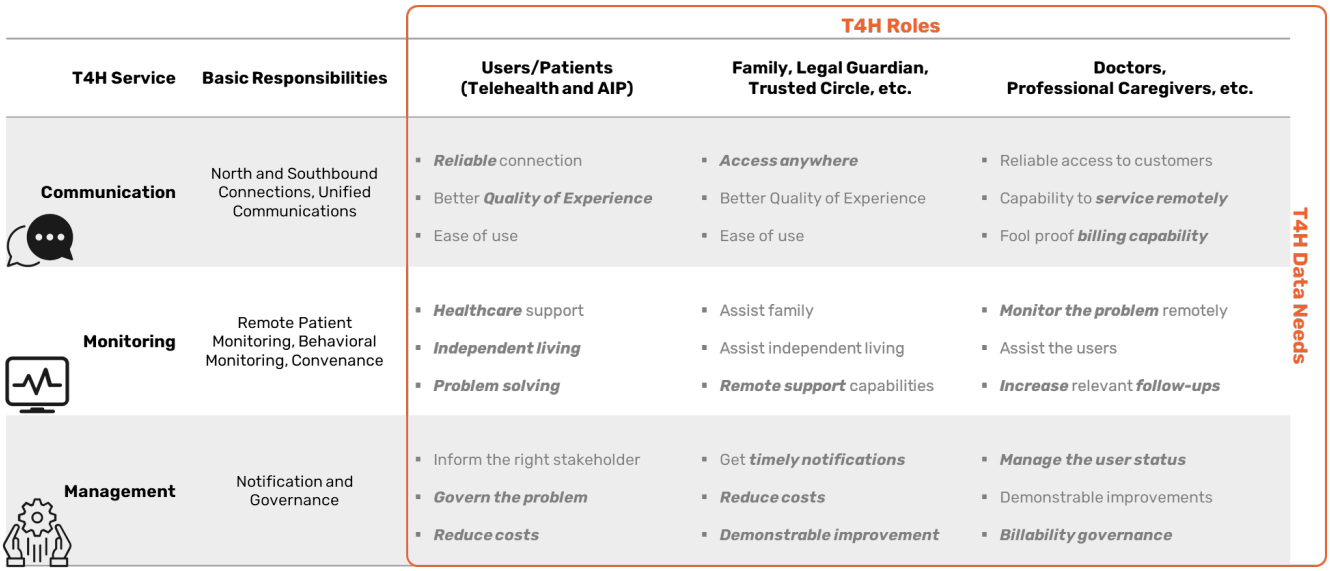

Figure 1 Understanding the T4H services, different roles, and their data needs

T4H services. For the users to adopt these services, they need to have a reliable connection with quality of experience and that is easy to use. For the stakeholders, in addition to the needs of the users, they should be able to access the services from anywhere. For the providers, the platform shall provide reliable remote service to the customer and an accountable billing capability.

- The players in the T4H space are very interested in **the monitoring capabilities** of the platform. The users are interested in healthcare and non-healthcare (independent living) needs. The incentive for them to use this platform is its problem-solving capabilities using the data that they assemble from different sources. The stakeholders, in addition to supporting their loved ones with their needs, have to provide these monitoring services remotely. The service providers shall be able to effectively monitor the problems remotely, improve the quality of care and reduce the overall cost of care.
- Use the platform to **manage timely notifications** and **govern the condition** of the user. To enable such functionality, the user depends on the timely assessment of the problem and reduces the cost through the management infrastructure. The stakeholders depend on timely notification, cost reduction, and most importantly the demonstrable improvement. The providers, on the other hand, in addition to the user status management, shall be able to claim the billability of the services.

In the next sections, we elaborate on T4H data categories based on the high-level incentives that we discussed in this section, expand on each of these categories in the following section, summarize the findings and propose the next steps.

3. Telecom for healthcare data categories

By analyzing the T4H users, stakeholders, and service providers, we categorize the metadata or telemetry data collected from the T4H platform, as shown in Figure 2, into four categories. (Note that the data collected in the metadata and telemetry cases are the main data streams provided by the devices, but are the supplemental information provided to assist the T4H players). They are:

- **Quality of Experience (QoE)**: The questions to be answered by the T4H platform include - are T4H services meeting stakeholder experience needs and are users engaging with services? The data collected here such as bandwidth availability, latency behavior, platform experience for back-office, and individual connections represents the customer adoption.
- **Monitoring**: The goal of this set of data is to evaluate if we are providing useful T4H services? The types of data collected here are healthcare and non-healthcare related streams, sensor and UCC flow information, network and device status, etc.
- **Connectivity**: As opposed to the quality of the service, reliable and highly available communication infrastructure is essential for providing these emotionally sensitive AIP and Telehealth services. The connectivity metrics offer these parameters. They are measured using platform availability, SLA (Service Level Agreement) guarantees, service up times, zero-touch provisioning, etc.
- **Accountability**: Are the service providers delivering expected results? Are the users adhering to the treatment plan? Is the provider's billing in line with the services they offered? These accountability metrics include – Quality of Care, timely resolutions, problem resolution rate, timely status notifications, etc.

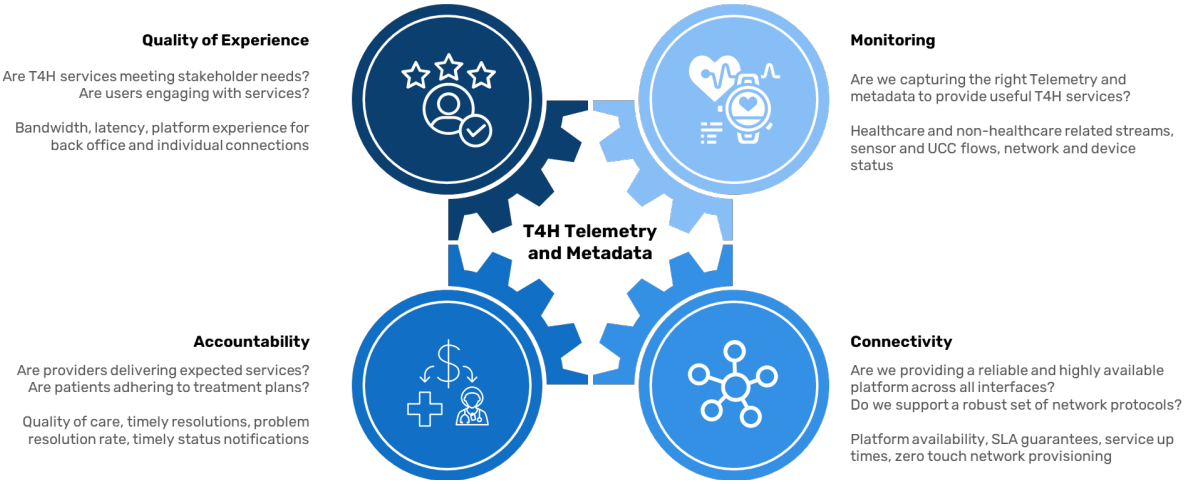

Figure 2 T4H telemetry and metadata categories

4. Metadata details

Figure 2 provides an end-to-end T4H architecture based on the framework proposed in [4][7]. There are multiple locations, as shown in the figure, where the T4H related metadata and telemetry information can be gathered. These data collection points include:

- In-home device interface: This interface is used to monitor the in-home T4H sensor and interactive devices. The QoE metadata can be monitored from this data collection point.
- In-home network interface: The north-bound interface of the sensor network gateway can be used for the aggregated in-home information such as broadband connectivity-related data and per session-related monitoring.
- T4H sensor network interface: The reliability and availability metrics can be monitored from the T4H sensor network infrastructure.
- T4H service back-office interface: This interface provides the overall service level QoE metrics, aggregate service level information, Quality of Care analysis metrics, governance metrics, etc.

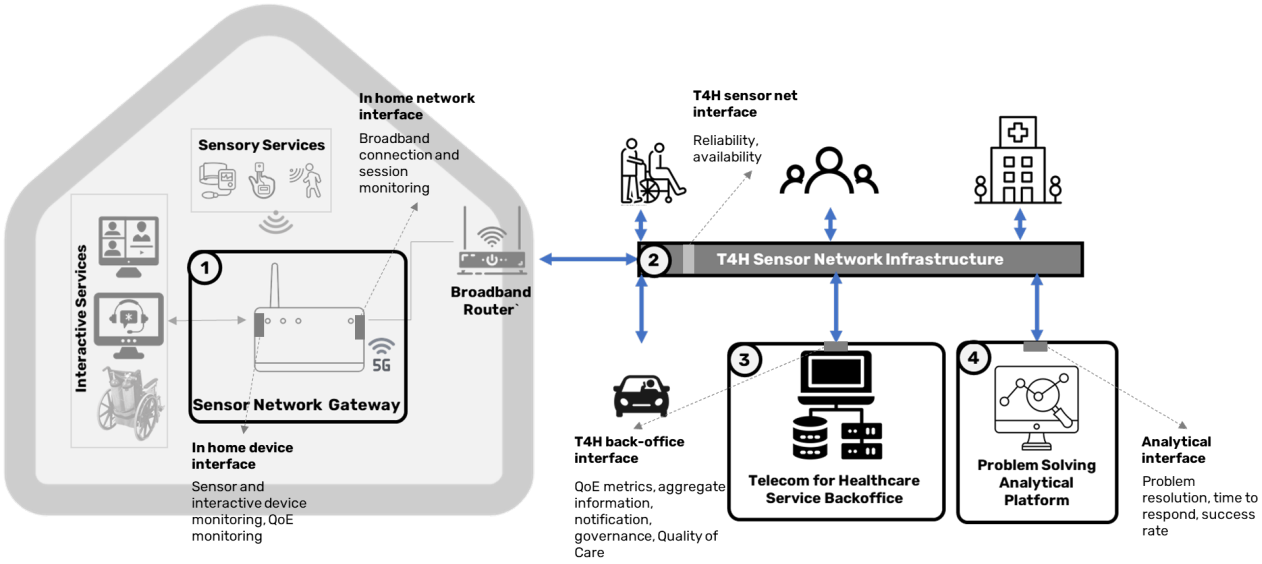

Figure 3 Different monitoring points in Telecom for Healthcare architecture

- T4H analytical interface: This interface provides the responsiveness, accuracy, and success rates of the problem-solving analytical infrastructure.

The information collected from the above interface must be securely collected and shall follow HIPAA privacy compliance [10]. We will not elaborate on these requirements in this document. In the following sections, we will highlight some of the details behind the proposed metadata and telemetry classes of information.

4.1. Quality of Experience related data

Understanding the QoE needs of different applications [8] and measuring them to see if the platform is meeting the needs, is essential for the adoption of T4H services. The applications used in the T4H environment are sensor and interactive applications. These application's QoE is measured at in-home for individual usage and at back-office service infrastructure that hosts the applications for aggregate usage.

Class of applications*	Throughput sensitive	Loss sensitive	Delay sensitive
Onetime measurements	X	X	
Video monitoring	X		X
Sensor monitoring	X	X	
Video communications	X		X

Figure 4 Quality of Experience needs of T4H applications

Generic metadata required to support QoE metrics:

- Sensor instrument-related metadata: Sensor id, type, group, priority (critical, high, medium, low), location in the house, vendor information, etc.
- Interactive applications-related metadata: UCC id, UCC type, application location (home, caregiver, provider, family), UCC vendor information, application experience (e.g., 5-star scale), etc.

QoE specific metadata: As discussed in [8], and as shown in Figure 4, the application QoE can be grouped into throughput, loss, and delay sensitivity.

- Throughput sensitivity data: This includes bits per second (Peak, Min, Average) metric. The monitoring locations include sensor hub and back-office hosting. The level granularity of this metric should be per session and per aggregated (per sensor or UCC id) stream.
- Latency sensitivity data: This includes one-way delay (Peak, Min, Average) metric. The monitoring location should be at the back-office hosting at a granularity of per session. To analyze latency the relevant communicated information should be timestamped.
- Loss sensitivity data: The data points lost per minute (Peak, Min, Average) will give the performance of the underlying communication infrastructure. This data needs to be monitored at the back-office hosting location at the granularity of per session. To measure the loss statistics the data needs to be time sequenced.
- Experience-related data: As an overall experience metric for the application, the user experience rating (from 1 to 5) per usage may be monitored. This can be tracked at different aggregation points based on the scope.

4.2. Monitoring related data

As shown in Figure 5, the applications that are offered and hence are monitored are the sensor and interactive applications. They can support both healthcare and non-healthcare applications. The idea of these data needs does not include the core data streams such as the temperature from a thermometer, but the additional metadata/telemetry that supports the players.

Generic metadata required to support monitoring data:

- Additional sensory applications metadata to support monitoring capabilities: Status (up or down), start time, healthcare or non-healthcare related, etc.
  Additional interactive applications metadata to support monitoring capabilities: Start and end times of the sessions, type of interactive application use (video, audio, video +audio), number of sessions, etc.

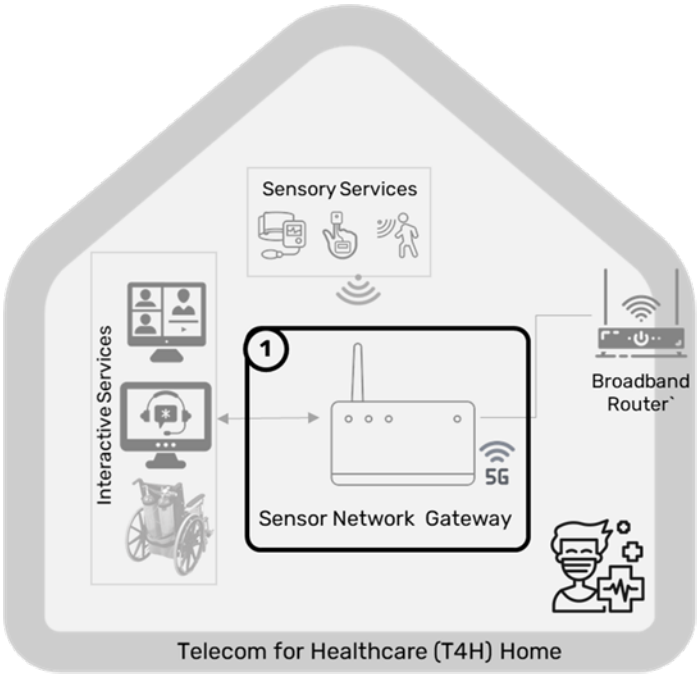

Figure 5 T4H monitoring services

Monitoring specific metadata: To provide a responsive platform to different healthcare and non-healthcare needs, we need to capture different metadata from the monitoring streams. The data can be monitored at the aggregation point in the home (sensor network gateway, as discussed in [7]) or at the hosted service back office. These metadata
include:

- Senor monitoring data: Priority of the
  sensor, privacy level of the data (generic, provider-specific, stakeholder, the user alone, etc.), urgency level of the notification (such as threshold crossing alarms)
- Interactive services monitoring data: Session related (number of legs, number of streams, etc.), stream related (QoE measures, transcriptions, metadata, etc.)

4.3. Connectivity related data

Connectivity focuses on providing a highly available service platform with five 9s reliability. These measures are very important to support highly emotional and sensitive subjects of healthcare and elderly care. In addition, providing ease of configuration (zero-touch configuration) is essential for T4H adoption. The reliability is measured reliability of the devices, connections, and the platform. The availability of the end-to-end services is the uptime and Service Level Agreement (SLA) guarantees for these time-sensitive T4H services. Also, due to the number of devices and solutions that will be integrated with the T4H services, we include the ease of configuration as part of connectivity.

Generic metadata required for connectivity data:

- Additional sensor metadata to support connectivity services: Sensor uptime, sensor loss of connectivity, sensor reliability

Connectivity-specific metadata: Providing a reliable platform to demonstrate the capabilities of T4H services as a differentiator is essential for cable operators to enter this market. These metrics depend on both the device and the platform's reliability and availability.

- Reliability data: Device reliability metrics, service reliability metrics
- Availability data: User device uptime (primary connection, secondary connection), server uptime, percentage availability, service availability
- Zero-touch configuration assessment: Number of service calls during installation, failed self-installs, in-home installation percentage, and average installation duration per service offering
- Other connectivity data: Availability SLA adherence

4.4. Accountability related data

The accountability of the T4H environment is used to evaluate the Quality of Care provided by the service providers and platform providers. These assess the improvement, the timely notifications that can be provided by the platform, and the billability of the services offered by the platform (and hence the provider). In this hyper-competitive and very expensive T4H environment, demonstrating the value of the service is a critical differentiator. Also, the healthcare industry is moving towards a pay-per-performance model, which constantly checks on the accountability of the providers. Hence cable operators need to showcase how they can provide a platform to assist providers with their accountability goals (such as improve notifications to different stakeholders). Providing corroborative information to bill appropriately is an essential service that cable operator T4H should offer to make their solutions attractive.

Generic metadata to support accountability data:

- Analytical platform metadata: Efficacy of the algorithms (problem resolutions rate), speed of analysis
- Notification infrastructure metadata: Notification statistics, notifications per type of problem

Accountability specific metadata:

- Quality of care data: Time to resolve the issue, condition improvement, reduce the number of missed appointments, cost reduction (for user, stakeholder, provider)
- Notifications related data: Response time (average, peak, minimum), per problem, per provider,
- Billability related data: Session context (duration, reason, parties involved, provider information, etc.), stream context (devices, device performance, potential transcription, additional notes)
- Other related data: Other stakeholder accountability, a payor accountability measure

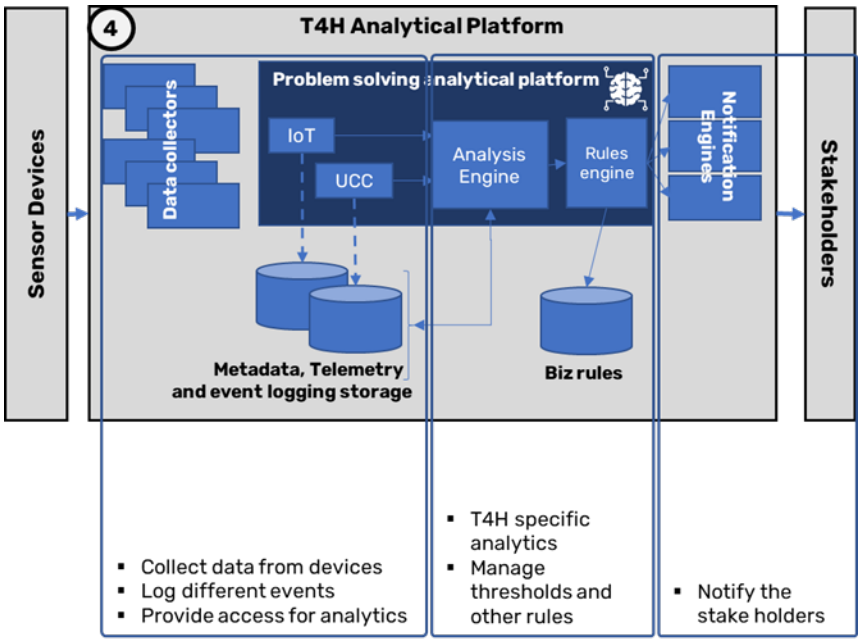

Figure 6 Using metadata to solve T4H analytical problems

5. Interaction of metadata with the analytics framework

The topic of metadata is not complete without understanding how the data is used. In [7], we explain the end-to-end T4H architecture including the analytical platform, as shown in Figure 6. The four categories of data, as discussed in the previous sections, are stored and used in the problem-solving analytical platform. The analytical platform provides the interface to different metrics as discussed in the previous sections, and assists in providing timely notifications to the stakeholders. These analytical functions that are presented in Figure 6 can be centralized or distributed in or closer to the home for availability purposes. These discussions are not in the scope of this paper.

Component	Status in MSO	Comments
Data collectors	Existing for IoT and other service info.	Need to repurpose for T4H data
Analysis engine	Existing for IoT engines	Need additional development for T4H
Rules engine	Potentially new function	Need solutioning
Notification engines	Existing with service assurance tools	Need to extend to T4H
Data privacy	Existing for PII	Need to extend to PHI
Performance	**Status in MSO**	**Comments**
Scalability	Device level alarms	Need to extend to per sub per stream
Security	SNMPv3 based	Need to validate if this is enough
Privacy	PII after collection	Need to validate if we need to anonymize at the collection points
Reliability	Reliable communication	No additional changes in our opinion
Responsiveness	Good for current use	Crucial for the success

Figure 7 Understanding the gaps in the end-to-end analytical platform

As presented in Figure 7, many of the analytical components relevant for the T4H solutions are already developed for the current Cable operator solutions. As provided in the comments section, these solutions need to be extended for the T4H requirements. Also note that the performance of the platform, which is currently tuned for the network device level needs to be scaled to per-stream level information gathering. The current Telecom solution data security and privacy constructs shall be validated against the needs of T4H needs. Although the responsiveness of the current solutions is good for the Telecom needs, using this platform for the time-critical and highly responsive T4H solutions calls for a fresh look at the data architectures. Further analysis on these architectural constructs will be conducted in the SCTE working groups [5][6].

6. Conclusion and next steps

In this paper, we have highlighted the transformations taking place in healthcare delivery and some of the challenges they pose. We have described the different needs of the various stakeholders and how they can be met with additional data and analytics. These needs include metrics to assess the quality of experience; monitoring applications; reliable, highly available, and easily configurable connectivity services; and notification and billing accountability systems. Many of these data sources and services already exist and simply need to be exposed to authorized third parties. In other instances, new infrastructure and standards are needed.

Cable operators have a unique opportunity to play a foundational role in the transformations taking place in the healthcare industry. We can take the lead in establishing standards for data transit, storage, access, security, and analysis. We can assemble a coalition of device manufacturers, inter-industry partners, and healthcare providers to ensure wide adoption. Regardless of what cable operators choose to do, these changes are coming to healthcare. By capitalizing on this opportunity cable operators can design a suite of new products to keep them relevant into the future. Failure to capitalize ensures that over-the-top solutions will emerge and eventually render them a dumb pipe.

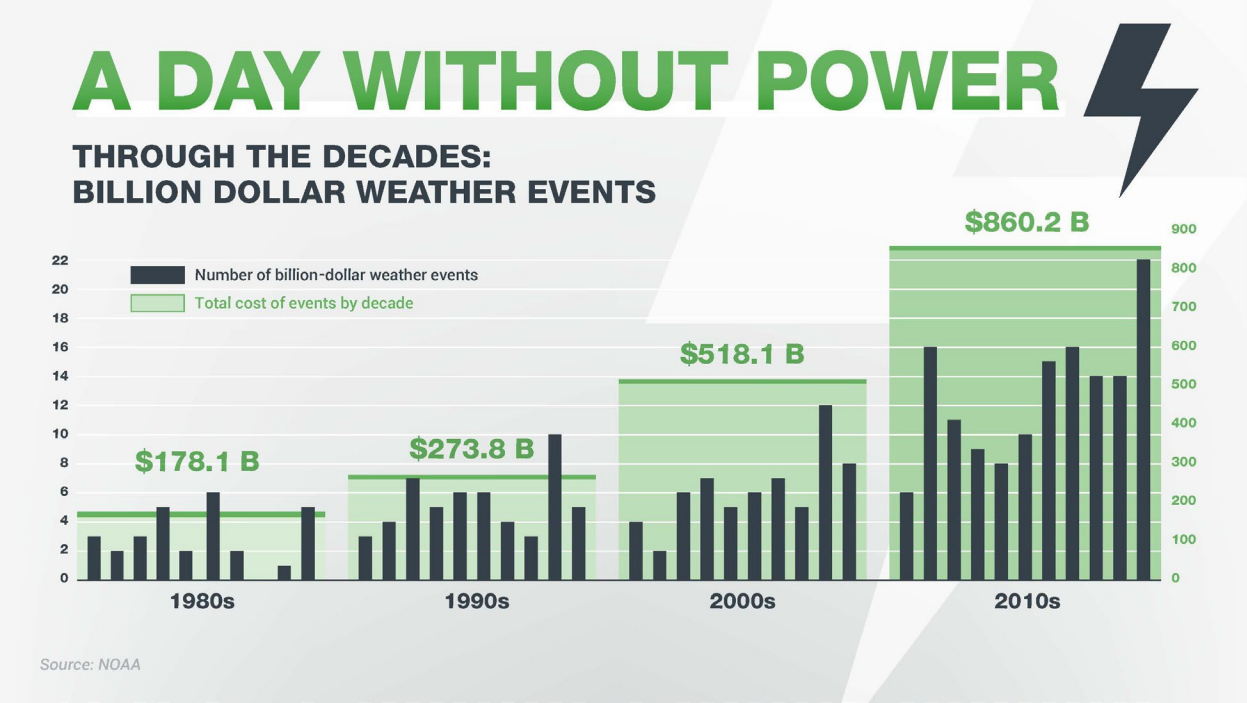
1. Introduction

A day without power is hard to imagine. Electricity has become a basic necessity, powering everything from our homes, to our businesses, to our transportation systems. But in a post-climate change world, extreme weather events are happening more frequently and becoming increasingly severe, threatening our access to the 24 x 7 power so integral to our everyday lives. This has caused a shift in thinking from, "the cost of power" to "the cost of not having power."

Demands of our digital economy coupled with the escalating consequences of our changing climate have created an unprecedented risk landscape. Energy challenges are on the rise and pressure is mounting for our electric system to get cleaner, faster. The sheer financial cost of climate impact is nearly outpacing the billions of dollars utilities are spending to improve the electric delivery system.



During 2020, there were 22 separate billion-dollar weather and climate disaster events across the United States, breaking the previous annual record of 16 events that occurred in 2017 and 2011.

This is the risk landscape for all of us, but without proper safeguards in place, the consequences of those risks are higher for those whose power choices are directly tied and vital to the functioning of their organizations. Mitigation requires a highly strategic approach to energy management.

Fortunately, we are now in a time where there are multiple options for sourcing and delivering electricity. Distributed generation has completely shifted the energy paradigm, providing a clear path forward for those seeking to gain more control of their electricity supply.

This paper explores this crucial paradigm shift. Its objective is to educate and mobilize individuals, businesses, communities, and policymakers around the importance of resilient power – the challenges we

face, the risks we can mitigate, and how leaders can gain control of their energy future through distributed generation and microgrid solutions.

2. Centralized Present, Distributed Future

Over the course of the 20th century, the U.S. electric grid was built as a one-way value chain from fuel supply to end-user consumption. Such infrastructure design created cascading vulnerabilities whereby a failure of any one component can result in disruption of service to end users. Grid hardening programs are underway in every region, but upgrading such a complex system is expensive, and takes years to properly execute.

Some might say it's too little too late – that these complexities have left society too heavily reliant on an electric delivery system that has simply not kept pace with the evolution of its surrounding environment. This aging centralized power grid that is inherently prone to failure, now faces heightened demands of digitization, a rising frequency and intensity of natural disasters and a dangerous cyber-threat landscape.

As a result, companies with mission critical facility requirements must invest heavily in back-up and conditioning devices to ensure a constantly available, high-quality energy stream to power their equipment. However, the few traditional solutions available are prone to their own failures.

But consider the implications of developments in the energy space that have come from the rapid digital transformation over the last few decades. The conventional way of delivering electricity is experiencing a fundamental and promising shift – we are moving away from our centralized present towards a distributed future.

3. Energy as a Keystone Metric

Depending on the industry, energy can be a large component of a company's cost structure and a complicated operational issue. It touches every piece of a business' value chain.

Companies are increasingly opening the aperture on their energy strategies to meet their corporate objectives, with each company's approach reflecting critical business needs. These critical business needs may be substantially different depending on industry and facility requirements.

Retailers face different challenges than data centers or manufacturers. In some cases, business needs primarily reflect rising energy costs and their impact on other operating margins. In other cases, business needs may be more closely tied to reliability of critical infrastructure and ensuring that the business can continue to operate effectively during a prolonged grid outage.

The critical challenge for businesses in building a cohesive energy strategy is identifying their full scope of electricity-related risk factors. Recognizing risk is one thing. Having a strategy to mitigate it is another. Doing so requires a deeper understanding of the issues and how to address them from the top down.

4. The Reliability Spectrum

Every building has a distinct energy "fingerprint" based on the needs and requirements of its routine operations. When drilling down to the facility level, understanding the difference between demand and consumption is key to defining its energy characteristics. Fluctuation of demand and the usage that results from that demand make up one's load profile.

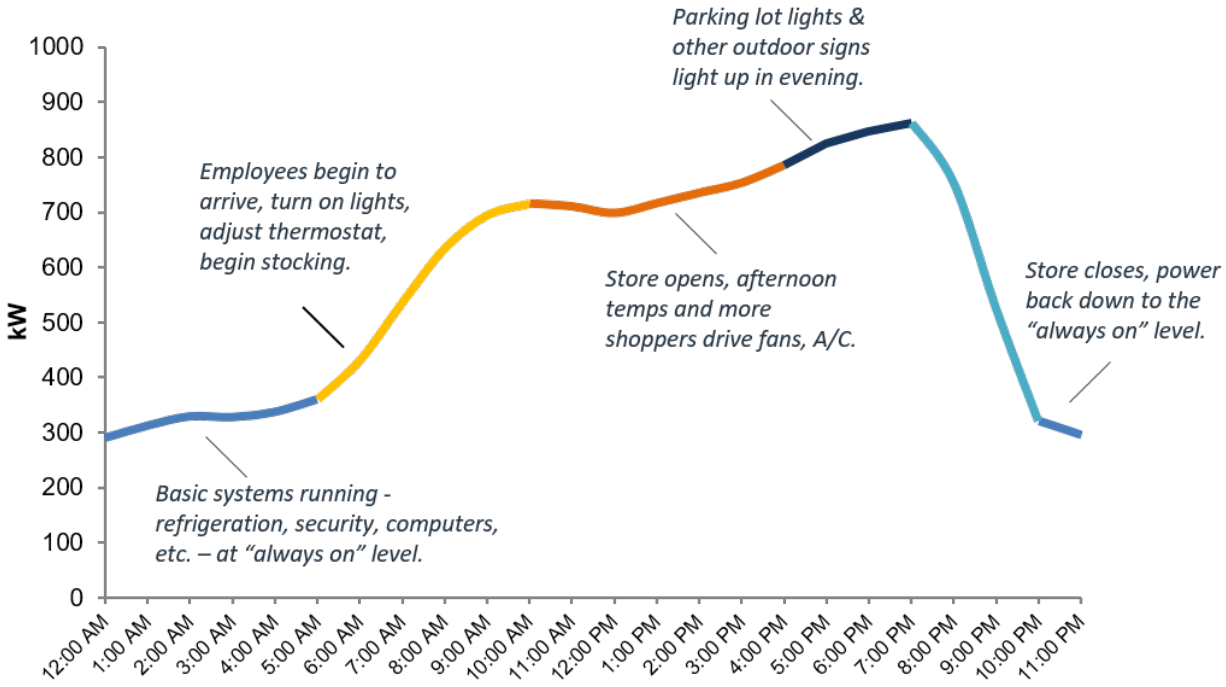


Figure 2: Snapshot representation of energy use for a typical day of business

A 'critical load' is a portion of electricity supply that powers infrastructure directly related to an organization's ability to operate. Infrastructure that warrants this status must either be kept running when main power supply fails or be powered down in an orderly manner to prevent system crashes, data loss or corruption, and life shortening hardware damage.

The term 'mission critical' is defined as something that is vital to the functioning of an organization. Operating under these conditions necessitates stronger emphasis on criteria that ties directly into the structural elements of a building's design.

Figure 3: Key considerations when operating a mission critical facility

Special focus must be placed on meeting minimum requirements across several key energy components – utility power supply, back-up generation, uninterruptible power systems (UPS), and cooling systems – which can come at great cost. Emerging technologies and business models represent a key opportunity to manage costs and mitigate risks. However, they also present an optimization challenge in terms of structuring those options to maximize the economic, reliability, and sustainability benefits.

5. The Resiliency Challenge: Eliminating Tradeoffs

As businesses look to address their critical resiliency needs, growing ambitions of a clean energy future and impacts of rising energy costs have elevated the importance of choice when it comes to power.

Most distributed energy resources (DER) are self-sufficient, but they are not one-size-fits all. Resiliency is just one benefit among many that microgrids provide, but resiliency decisions should not be made at the expense of environmental concerns and sustainability decisions should not ignore the importance of reliable energy supply. Diesel generators have been the status quo solution for power disruptions for decades. However, they are monolithic machines without inherent redundancy and they produce over 40 toxic air contaminants, including a variety of carcinogenic compounds during operation. What's more, since they are idle assets, they needlessly consume fuel while testing to ensure they can be available when needed. Further, the availability of diesel fuel during an extended outage and the reliability of diesel engines to operate continuously for long periods of time are both risks to the traditional design.

Technologies like solar and wind are great for their renewable profile but due to their inherent intermittency, cannot practically solve resiliency challenges. Their very nature requires some sort of energy storage and today's technology does not cost effectively support the massive load shifts from day to night, and certainly not from summer to winter. Further, the majority of solar (66%) and wind (~100%) are utility scale projects, meaning they still rely on the vulnerable, above ground, transmission and distribution system.

Fuel cell distributed generation projects are uniquely positioned to help eliminate tradeoffs and solve these compounding challenges. A fuel cell microgrid provides a distributed solution that is onsite and

always on. It is not a UPS or generator sitting idle waiting for an outage event – it's an active asset that produces clean, highly reliable power 24 x 7 without particulate emissions.

6. Fuel Cell Building Blocks

Fuel cells provide a critical foundation for microgrids of varying complexity and can provide significant benefits to the communities, businesses, and utilities they are part of. This type of technology targets a customer's 24 x 7 energy usage whereas technologies like solar or battery storage are intermittent. Fuel cells were invented over a century ago and have been used in practically every NASA mission since the 1960's, but until now, they have not gained widespread adoption because of their inherently high costs – a challenge that once plagued a developing solar industry decades earlier.

There is a range of fuel cell technologies that exist today, however solid oxide fuel cells (SOFCs) are the market's most efficient and practical form. SOFC's provide an electrochemical pathway to convert fuel directly to electricity without combustion. The cell itself consists of three parts: an electrolyte, an anode (-), and a cathode (+). The electrolyte itself is a solid ceramic material and the anode and cathode are made from special inks that coat the electrolyte. As oxygen ions interact with fuel in the cell, the resulting electrochemical reaction is able to produce electricity without combustion. Because of its extremely high conversion efficiencies, they are able to produce twice as much electricity as conventional combustion generators using the same amount of fuel.

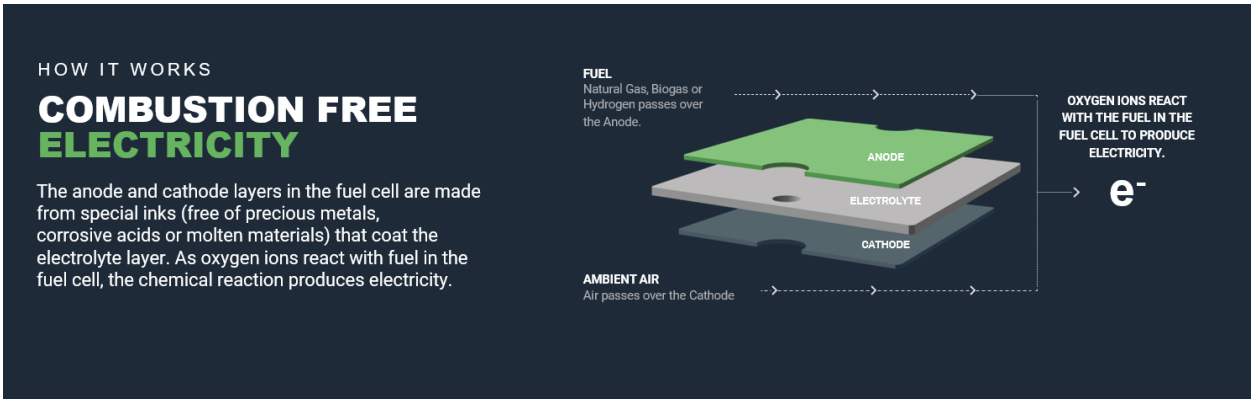

Figure 4: How a solid oxide fuel cell works

7. Microgrid System Architecture

Fuel cells are extremely versatile when comprised within a larger system. The process starts with a single cell which produces 25W, roughly enough to power a light bulb. The cells are then stacked within the system and assembled into 50 kW power modules – modules that can function independently from each other. This modular flexible architecture design allows for any number of modules to be clustered together, in various configurations, to form solutions from hundreds of kilowatts to many tens of megawatts.

The standard system architecture design interconnects with your facility in a grid parallel configuration. This means the system leverages a current mode inverter replicating the frequency and voltage of the grid and will not impact site power quality. Load changes by the site will similarly not impact output; the site will essentially have two utility feeds and anything needed above the fuel cell output will be supplied by the electric grid. A grid parallel interconnection is subject to IEEE-1547, similar to solar, such that when

the grid is unavailable or out of IEEE-1547 specifications, the system is required by code to stop exporting power until the grid returns.

A mission critical design topology allows the fuel cell system to continue operating during an electric grid outage. The design requires a segmented load to be wired directly into a second set of voltage mode inverters that will be added to the system's architecture.

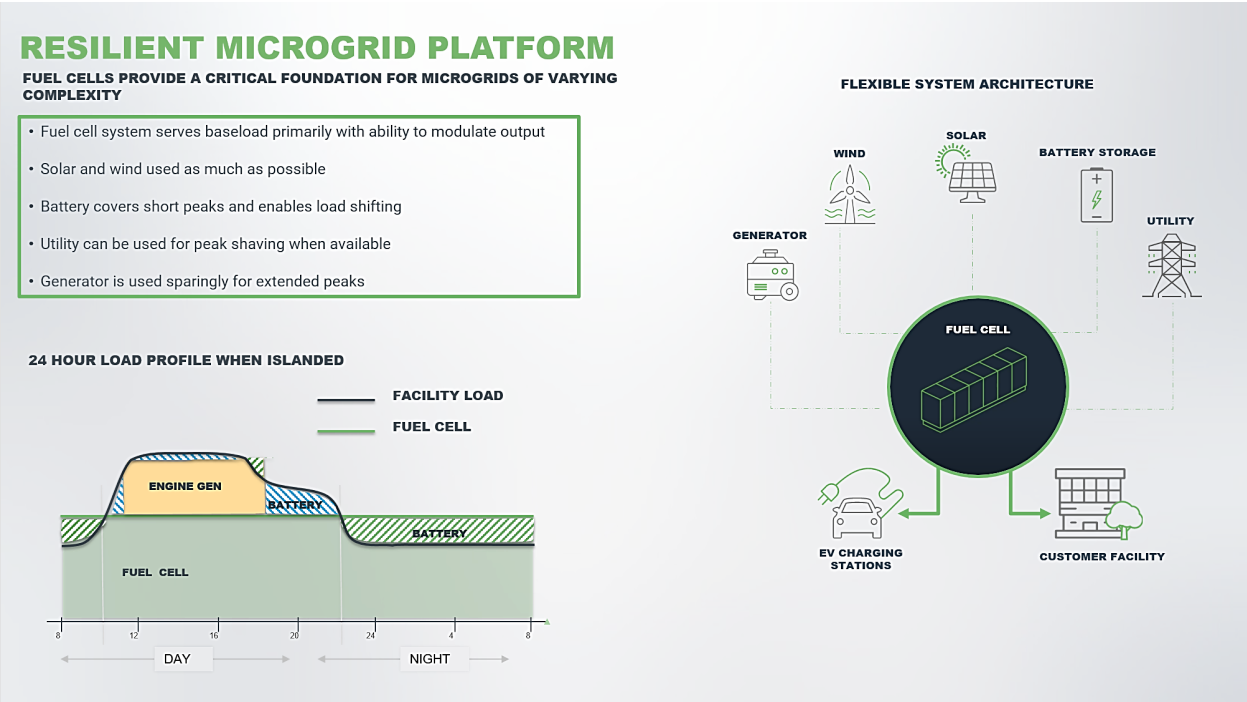

Figure 5: Illustrative view of fuel cell microgrid system architecture

8. Key Differentiators for Mission Critical Support

Power Quality

The power quality delivered by SOFC systems is comparable to best-in-class UPS systems deployed in data centers and other mission critical facilities. They are able to utilize state-of-the-art PWM (pulse-width modulation) inverter technology for conversion of fuel cell DC power to 480V AC power. The waveform of the current supplied to the customer is generated by a sophisticated multi-level current-source inverter control scheme. The high inverter switching frequency supplemented by a high-performance filter in each inverter module means that harmonics are virtually eliminated.

These systems are designed to meet or exceed power quality requirements of standards relevant to distributed power generation and distribution such as:

- UL-1741
- IEEE-1547
- IEEE-519
- Other utility grid interconnection requirements in the USA and other countries around the world.

Density

Fuel cells provide significant power generation in a small footprint which makes it an ideal power solution for smarter space utilization. Unlike large, multi-megawatt generating combustion engines, SOFC systems can be deployed in increments as small as 200 kW, enabling power sources to be distributed and land to be used for critical business applications. Due to this minimal onsite footprint compared to other generation technologies, facilities can utilize available land for higher value uses – such as data centers expanding their facility to accommodate more server racks, or a hospital adding a new wing to accommodate more patients.

Redundancy

The modular, redundant architecture makes it such that a solid oxide fuel cell system can continue powering facilities while operation and maintenance activities occur on individual modules. Each power module independently connects and feeds power to a DC bus. When a power module needs maintenance, that module will be safely ramped down and shut off while the remaining modules continue producing consistent electrical output. The power module will then be repaired or replaced, and then ramped up to full power, ensuring consistent output from the fuel cells without disruption to a customer's business operations.

Reliability

SOFC systems deliver 24 x 7 x 365 baseload power, with mission critical reliability and grid independent capabilities. They can be easily configured to eliminate the need for traditional backup power equipment such as diesel generators, batteries and uninterruptible power systems.

What's more, by generating power at the point of consumption, the system is able to avoid the vulnerabilities and line losses of conventional transmission and distribution. It draws from two continuously operating independent sources – existing gas infrastructure, which is a redundant underground mesh network, and the utility grid. The probability of both failing simultaneously is extremely low. Modularity and combined with this fault-tolerant design means that SOFC systems are able to reliably operate at very high availability around the clock.

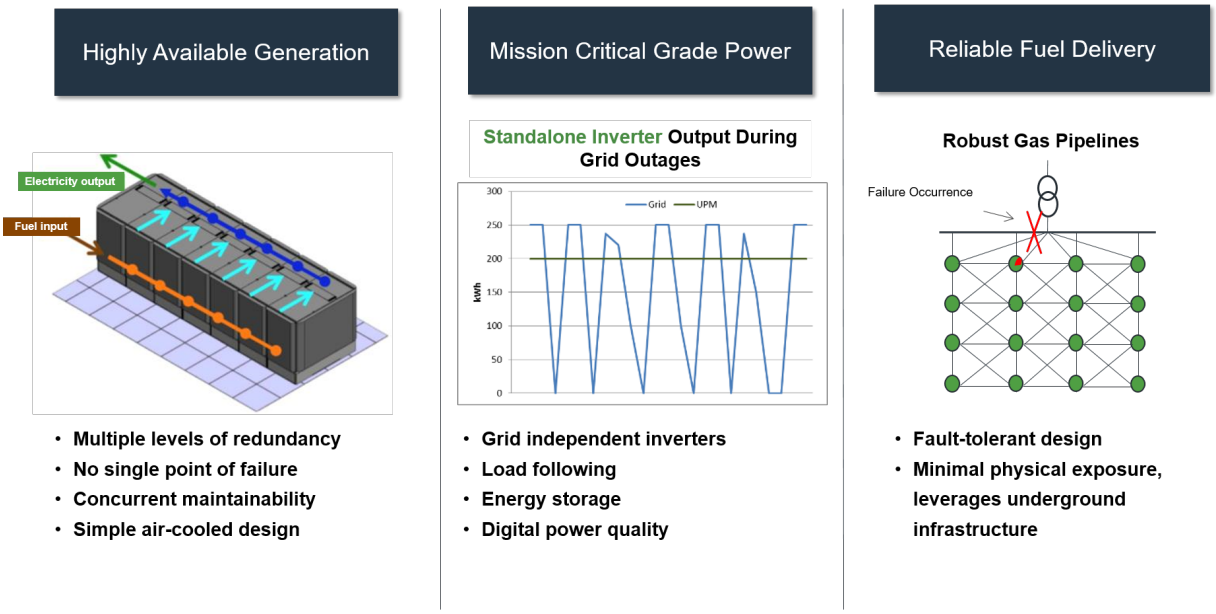

Figure 6: Key differentiators of SOFC for mission critical support

Resiliency

Fuel cell microgrids can provide critical resilience from power instability, driven increasingly by climate-related extreme weather events. The following case study highlights a technology manufacturing company who deployed Bloom Energy's AlwaysON solution to secure their operations and mitigate the negative impacts associated with escalating climate risks.

Case Study: Spotlight Save

A large technology company manufactures electronic test and measurement equipment and software that supports the larger digital ecosystem of e-mobility, network monitoring, 5G, LTE, and IOT. Their business needs are closely tied to the reliability of critical systems in operation at their HQ campus, located in a high-risk wildfire zone in Northern California.

The numerous unplanned outages they were experiencing throughout the year were costly and damaging to highly sensitive manufacturing equipment. With backup infrastructure reaching the end of its useful life, they were seeking new solution with mission critical capability that could power the whole campus independent of the grid.

In the wake of a growing number of outages and elevated risk to its operations, the company implemented an AlwaysON Microgrid, which enabled 2.8 MW of mission critical systems to operate independently when disruption to the electric grid occurs.

In the summer of 2019, California utilities began implementing transmission-level Public Safety Power Shutoffs (PSPS) to mitigate wildfire risk. Faced with one instance that left millions of customers without grid power for multiple days, Bloom's AlwaysON microgrid kept their campus online and operational throughout, reinforcing the technology's proven resiliency in the field.

9. Conclusion

In the last two decades, diverse groups across the energy sector has been working hard to create and commercialize innovative alternatives to centralized energy generation and delivery. Widespread decarbonization is occurring quickly through policy changes, technology innovation, and the willingness to adapt. However, it's becoming increasingly clear that alongside decarbonization sits an equally critical resiliency challenge. Hardening of our modern energy system will be a major focus for utilities going forward but businesses can support these efforts by helping break off smaller challenges through with distributed generation.

Fuel cell microgrids have changed the way businesses look at their critical power infrastructure, serving as a viable alternative source of primary power. The versatility of solid oxide technology operating at the core of a microgrid creates distinct advantages that will enable applications across the entire energy value chain for years to come. Its core efficiency advantages and ability to scale within a rapidly evolving energy landscape makes it the ideal distributed generation solution – one that delivers the greatest value now and provides the clear path needed to propel us all towards a better energy future.

Modernizing Cox Communication's Access and Aggregation Network Infrastructure for Remote PHY Deployment

A Technical Paper prepared for SCTE by

Deependra Malla
Lead Network Design Engineer
Cox Communications Inc.
6305 Peachtree Dunwoody Road
Atlanta, GA 30328
602-694-4429
deependra.malla@cox.com

1. Introduction

Like other Multi System Operators (MSOs) and Internet Service Provider (ISPs), Cox Communications needed to transform its access and aggregation network infrastructure to meet increased bandwidth demands and support next generations of multi-services. The evolution of Internet of Things (IOTs), increased usage of social media and video sharing platforms have drastically increased traffic volume putting lot of stress in the existing legacy outside plants and related access network infrastructures. The legacy cable plant relies on RF technologies and analog optics that are difficult to scale, expensive to maintain and not suited to meet demands for new and emerging digital technologies. This required Cox to modernize its access network infrastructures by implementing Distributed Access Architecture (DAA) and going fiber deep to expand customer serviceability, increase bandwidth, and improve efficiency and performance of the access network. To enable the deployment of Distributed Access Architecture and related new technologies, Cox introduced a new packet switched access aggregation network called Converged Interconnect Networks (CIN) based on IPv6 routed technology to connect its headend with new access network.

Cox Communication has one of the largest deployments of Converged Interconnect Networks, Distributed Access Architecture and Remote PHY in North America that covers almost 40% of Cox's footprint. Cox's vision to design a standardized, elastically scalable, and future proof IPv6 routed network has enabled Cox to meet its immediate and future evolution of modern access network paving its path for Next Generation of DOCSIS technology.

2. Legacy Access Networks in Cox and its Limitation

Most Multiple Services Operators (MSOs) use linear point-to-point optical fiber on their access fiber network between headend and primary optical node. However, Cox communication access fiber network, as shown in figure 1, is unique in that it uses a single SMF fiber in a diverse ring topology to add a level of protection from the fiber cuts. The access network fiber topology uses a passive optical architecture to select the shortest path as a primary path between headend and primary optical node. The primary optical node can be located anywhere along the fiber route, resulting in a short path and long path that must be managed optically. The access fiber path can range in overall distance up to 60KM and meets at the primary optical node into an optical bypass switch. The optical bypass switch is responsible for selecting the primary and backup path and provide an optical failover associated with loss of light on the primary path during a fiber cut event. A typical primary optical node in Cox HFC network services 500 household passed (HHP).

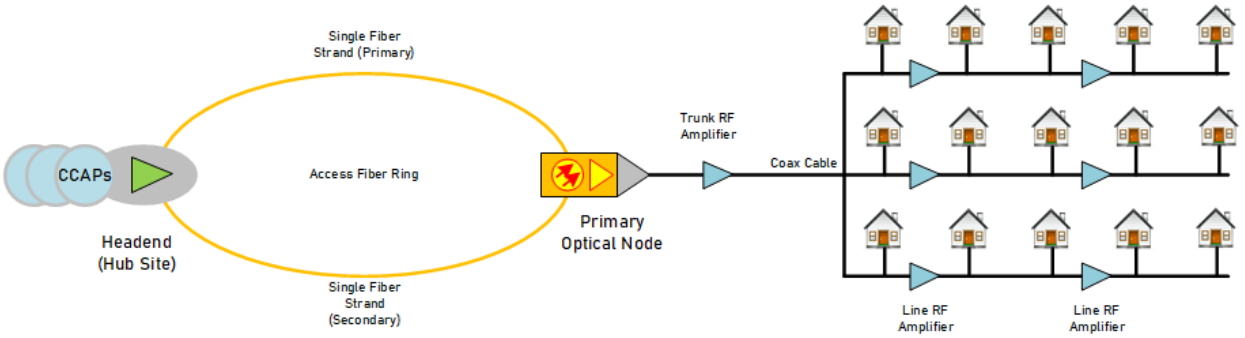

Figure 1 – Cox Communication Hybrid Fiber Coaxial (HFC) Network Architecture

Figure 2 shows the current access network infrastructure of Cox which includes several analog technologies embedded deep into the cable network. The Legacy cable networks have served customers well for a long time. However, with the increase bandwidth demand and new service requirements, these legacy networks

are stretched to their capacity limits. Also, the analog nature of the infrastructure possesses several limitations to the expansion of the network and provisioning of new services. Today's legacy cable plants are prone to signal noise and signal quality degradation because of lots of RF amplifiers between customers and headend equipment. The analog technology also has distance limitation and capacity constraints. We are required to install new CMTS and related auxiliary equipment to provide services to communities that fall just beyond the boundary of the existing headend. Such analog infrastructure is also expensive to maintain and operate and are susceptible to environmental factors.

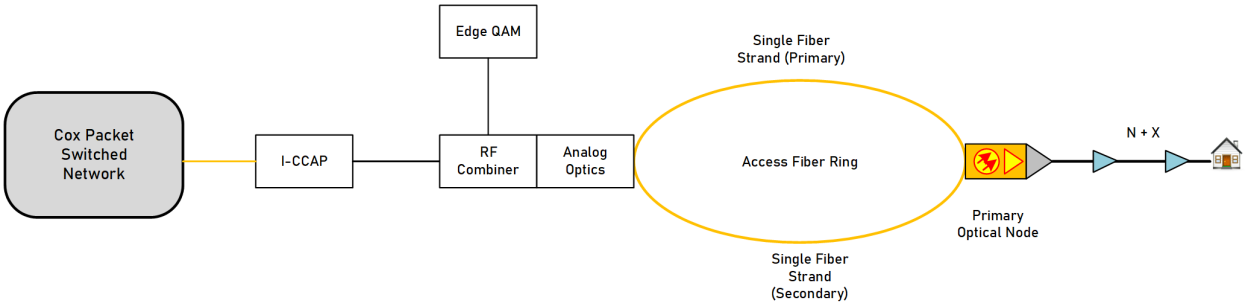

Figure 2 – Cox Communication Legacy Cable Network Infrastructure

As the demand for new and emerging digital technologies grew, the legacy analog architecture was not suited to meet the future requirement of digital communication services. To leverage and benefit from future access technologies like DOCSIS 4.0, R-OLT and beyond, it was imperative for Cox to modernize its analog access infrastructure that would meet customer demands and business requirements of current as well as future services. That is why Cox decided to implement the new access architecture to unlock new possibilities of future network capabilities. However, in doing so Cox needed to carefully integrate the current fiber and network assets to the new access network to maximize the utilization of existing infrastructure and reduce overall capital expenses.

3. Access and Aggregation Network Evolution in Cox

When we discuss the access network evolution in Cox network, it is relevant to know about the overall network architecture of Cox and various segments of Cox network. Like other ISP, Cox network is also a layered network as shown in Figure 3. Cox core backbone is a mesh of backbone routers that connect all its markets, data centers and peering centers. Each market constitutes a network called Regional Data Center (RDC) network that serves as an aggregation layer for that market's metro network. The metro network in each market is a collection of hubs/headends network that is based on hub and spoke architecture. Each headend network is also a hub and spoke network with a pair of hub aggregation routers that aggregates several access, business, and service routers.

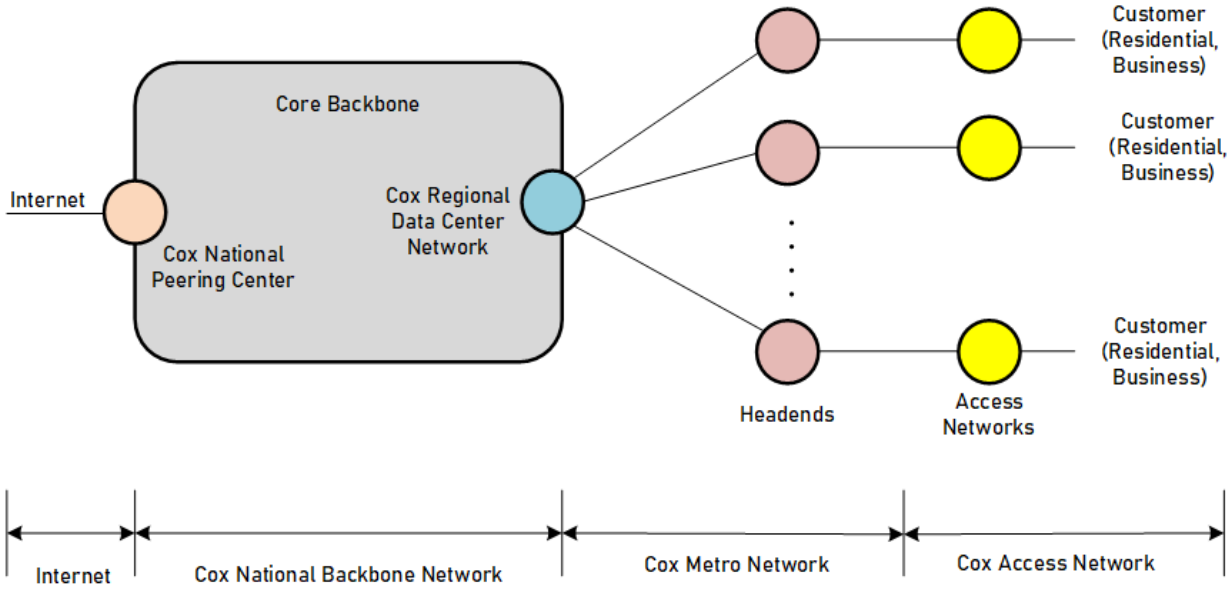

Figure 3 – Cox Communication High Level Network Architecture

As Cox faced continued pressure of increased bandwidth demand and scalability challenges in its legacy access network, it needed to evolve and transform its analog access network to modern digital access network. Distributed Access Architecture (DAA), a fiber deep technology developed by CableLabs was adopted to replace the current access network in Cox.

3.1. Distributed Access Architecture (DAA)

Cox has significant number of fibers and coax network infrastructure in its serving areas. It was important to utilize those existing fibers and network assets to save capital expenditure while continuing to provide higher capacity and reliable services to customers. CableLab's DAA technology was the right access architecture that would fully utilize Cox's existing access network infrastructure and transform it to modern digital access network.

DAA technology allows cable operators to disaggregate traditional I-CCAP into several key network components and functions and move them closer to the subscribers. It helps in reducing power and space requirement in already constrained headend and improve signal quality from customers to headend. The digital transformation also enables operators to automate and virtualize various aspects of new access network infrastructure.

DAA can be broadly classified into two technological variants:

a. **Remote PHY Architecture:** This architecture relocates PHY component of Integrated CCAP closer to the subscriber. A Remote PHY Devices (RPDs) replaces the existing fiber node or a primary optical node in Cox case. Given the maturity of RPHY specifications from CableLabs and availability of RPHY devices from various vendors, Cox has chosen RPHY technology as its DAA architecture. RPDs in Cox are deployed in N+0 as well as N+X model. Currently, Cox has successfully deployed 11,000+ RPDs covering 3.27 million HHP and 2.13 million subscribers.

b. **Remote MacPHY Architecture:** Another variant of DAA is Remote MAC PHY technology where the PHY as well as MAC domains are relocated close to the subscriber. The new access and aggregation network need to support seamless transition from RPD to RMD solution where the control plane and data plane are truly separated. These RMD devices eventually will replace the primary optical node and co-exists along with RPDs for sometime.

Deployment of large-scale Distributed Access Architecture in Cox had to overcome several challenges. Migrating from legacy access architecture to DAA required significant amount of planning, investment, and coordination among several departments in Cox. Deployment of DAA in Cox network was a paradigm shift from design, implementation, operation, and support perspective. The introduction of Layer 3 IP network in the form of Converged Interconnect Network between Digital CCAP and RPD has changed the operational and support modality of Cox metro and access network.

3.2. High – Level Cox Distributed Access Architecture (DAA) Topology

Figure 4 shows the high-level architecture of Cox DAA network deployment. As mentioned in section 1 of this paper, Cox access fiber network is unique in that it is a diverse ring topology from headend to primary optical node instead of linear point to point fiber. To preserve the ring topology of the access fiber, Cox designed and deployed Optical Communication Module Link (OCML) Extender as a DWDM component that would transport multi-wavelength optical signal over the existing ring fiber infrastructure. OCML amplifies and multiplexes 20 unique 10G DWDM wavelengths onto a single fiber. It also demultiplexes all DWDM wavelengths in the reverse direction.

Similarly, Mux/Demux Module (MDM) is a passive device that is located at the point where the legacy primary optical node exists today. MDM demultiplex all the unique DWDM wavelengths coming from OCML and separate them out to ports where RPDs are connected. MDM also multiplexes all the DWDM wavelengths coming from several RPDs onto a single fiber towards the OCML.

Cox utilizes ITU channel #18 through channel #37 for all downstream wavelength mapping whereas ITU channels from channel #42 to channel #61 are utilized for all upstream wavelength mapping. The concept of OCML and MDM has helped Cox to rapidly deploy DAA over existing access fiber infrastructure while preserving it unique ring topology. The use of standard ITU complaint wavelength in OCML/MDM also allows Cox to deploy 100G wavelength solutions in future.

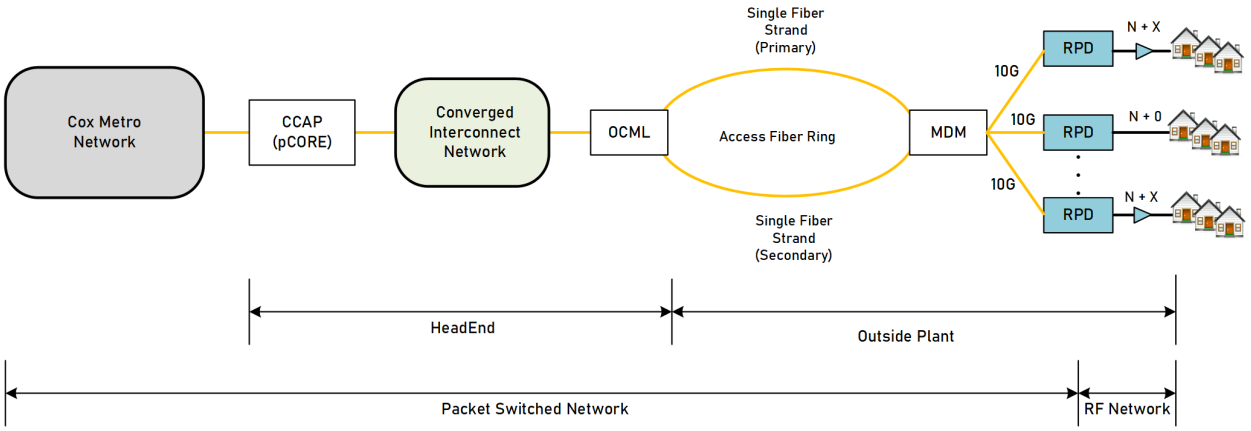

Figure 4 – Cox Communication High Level DAA Network Topology

3.3. Cox Converged Interconnect Network (CIN) Architecture

To enable the deployment of Distributed Access Architecture, Cox introduced a new packet switch network called Converged Interconnect Network (CIN) that connects Cox's headend with new digital access network. Cox's CIN infrastructure is Layer 3 based and is built on native IPv6 only that leverages loop-free communication using industry-standard routing protocols like IS-IS and BGP in control-plane and uses Zero Touch Provisioning (ZTP) to deploy massive number of aggregation switches needed to support the growing CIN deployment. Cox's CIN network is true IPv6 fabric that provides non-blocking, highly elastic, extensible network, and support any-to-any connectivity between RPDs and CCAP cores. This enables Cox to quickly move RPDs between CCAP cores without any physical work needed, and also enables Cox to deploy an "Extended CIN" technology for space-constrained head-ends. The CIN architecture solution deployed at Cox is also able meet the future requirement of regionalized controller based FMA architecture that is separate from the data plane for DOCSIS technology.

CIN Design Principles

As CIN was adopted to interconnect RPDs and various CCAP cores at headend, it blurred the line between several technologies and departments inside Cox. To maintain the CIN network, the collaboration between various teams and departments was integral. Although the CIN network primarily connects RPDs with digital CCAP's cores, it is capable of supporting future access network termination need like RMDs and R-OLTs. Following are few of several design principles Cox adhered to while designing the CIN architecture.

- Effectively and efficiently utilize existing network assets and architectures
- Standard deployment using one common architecture for different size hub sites/head ends
- Provide any – to – any reachability between RPDs and CCAP cores in the market
- Routed L3 only network based on industry standard and proven protocols like BGP, IS-IS and PIM
- IPv6 only network to conserve scarce IPv4 network and avoid complex architecture
- Efficiently utilize existing access fiber topology
- Automation friendly and ZTP capable

CIN Spine-and-Leaf Network Architecture

The implementation of Converged Interconnect Network required an extensive network architecture analysis, testing and meticulous planning. Several design architectures were considered for Converged Interconnect Network. Cox's desire to create Next Generation Access Aggregation Network that is elastic, resilient, fast, and easy to manage led to the implementation of already proven spine – and – leaf architecture in its CIN layer that is popular in Data Center Network today. By using the spine and leaf architecture in CIN, Cox was able to create a highly scalable and hierarchical network that can aggregate extremely large volume of physical connections at every headend.

Several possible combinations of spine – and – leaf architectures were considered for CIN in Cox metro network. Based on Cox's current metro design architecture and design requirement for new access aggregation network, Cox deployed independent RPD aggregation and DPIC aggregation at leaf layer and utilized existing hub aggregation routers as spine layer. Leaf routers that aggregate RPDs are called RPD Aggregation (RPA) routers and routers that aggregate Digital PIC interfaces of digital CCAP are called DPIC Aggregation (DPA) routers. Both RPAs and DPAs are connected to spine layer HUB routers. The overall CIN network as deployed in Cox metro network is show in figure 5.

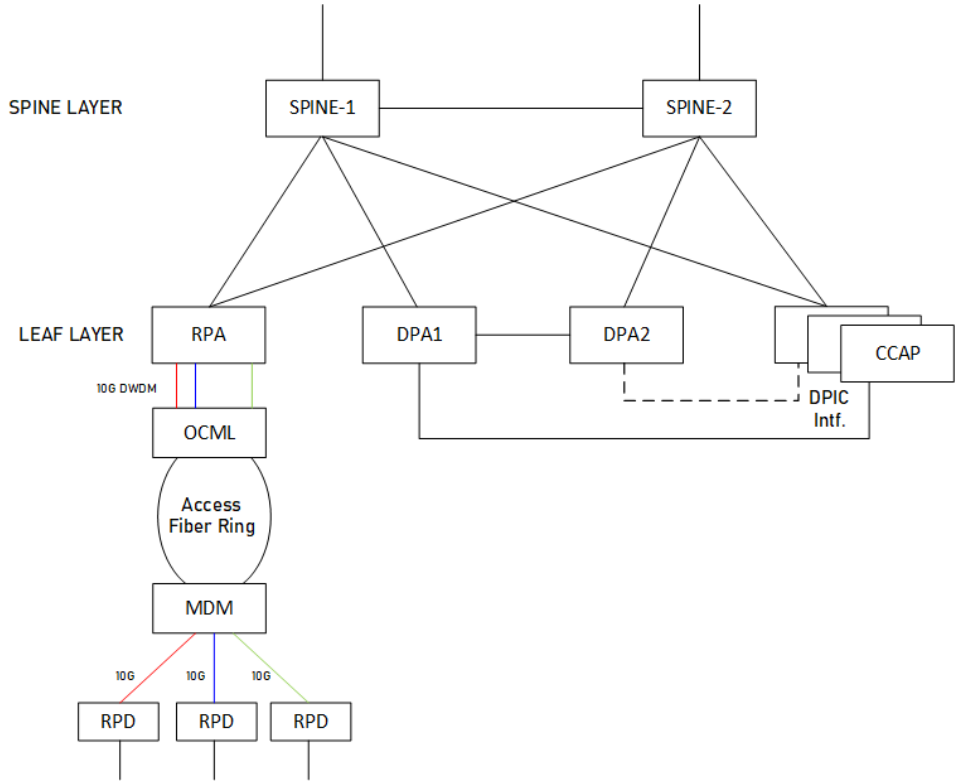

Figure 5 – Cox Communication CIN Topology

The new Converged Interconnect Network consists of following three segments:

- **Leaf Layer – DPIC Aggregation (DPA) Routers:** DPA routers aggregate DPIC interfaces from digital CCAP and are deployed in pair to provide High Availability feature.
- **Leaf Layer – RPA Aggregation (RPA) Routers:** RPA routers aggregate RPDs from outside plants and supports 10G DWDM Bidi optics
- **Spine Layer – Hub Aggregation (HUB) Routers:** A pair of P routers that aggregates RPAs, DPAs and CCAPs.

CIN Routing Design

The routing architecture of new access aggregation network needed to seamlessly integrate with existing metro routing architecture. To achieve all the design and business requirement of new access network, Cox deploys following routing protocols and services in CIN network.

- **Routed IPv6 only Layer 3 network:** To eliminate the dependency on IPv4 address and simplify the network architecture, Cox uses IPv6 only routed network in CIN. The IPv6 routed network allows for globally unique addresses thereby eliminating the need for complex network architecture.

- **IS – IS as an IGP:** Intermediate System – to – Intermediate System (IS – IS) Multi Topology in level – 1 is used as Interior Gateway Protocol in CIN to announce infrastructure prefixes like loopback and point – to – point interfaces of CIN devices.

- **MP – BGP:** Multi-Protocol BGP (MP – BGP) with unicast and multicast address families is used to advertise non-infrastructures prefixes. Spine routers are route reflectors to all leaf routers. BGP traffic engineering, like manipulation of local – preferences and route – aggregation, are used to enable deterministic routing and predictable traffic flows in CIN.

- **PIM:** As 99% of traffic in CIN is IPv6 multicast, PIM SSM is deployed as multicast routing protocol. MDLv2 is enabled on RPD Aggregation routers so that multicast listeners are automatically discovered on all MLD enabled interfaces.

- **Quality of Service:** To prioritize various types of traffic (control, user data, voice, video), class of service is configured with proper classification, mapping, and queuing.

- **802.1x:** To authenticate RPDs, RPD aggregation routers are configured with 802.1x authentication.

- **Other protocols and service**s: As a standard practice, all CIN layer routers are configured with other necessary protocols and services like LLDP, DHCPv6 relay, TACACS, NTP, SNMP etc.

3.4. Cox Extended CIN (E-CIN) Architecture

One of the main design features of CIN was to accommodate any – to – any connectivity between RPDs and CCAP cores in the market. The architecture, called Extended CIN, allows RPDs to connect to any CCAP cores that are not co-located at same headend. In E-CIN architecture, CCAP cores are located on a separate headend (called host site) than the RPD aggregation routers (called the E-CIN site). The high-level architecture for E – CIN is show in figure 6.

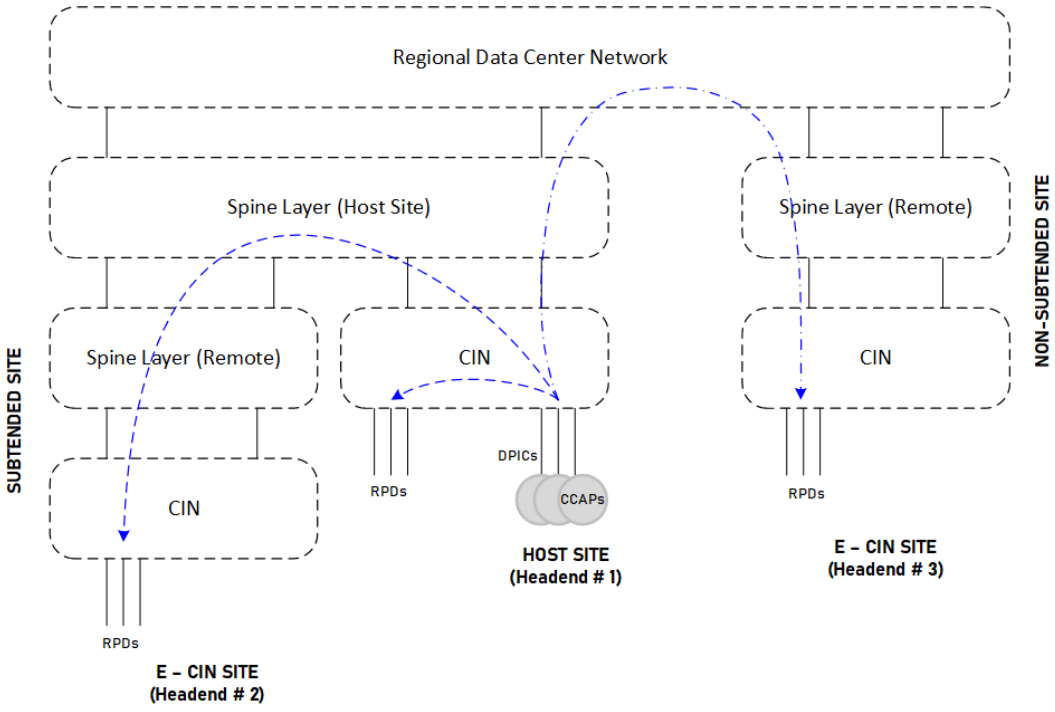

Figure 6 – Cox Communication High-level E – CIN Topology

In the E – CIN architecture of figure 6, host site's (Headend #1) CCAP cores serve headend # 2 (Subtended Headend to Headend #1) and headend # 3 (Non-subtended headend). Extended CIN, in some cases increases optical distance and introduces more hops in the routing path between host site and E – CIN sites which might add challenges to sensitive control plane and real time traffic. To address such issues, Cox has implemented some design features and specified the optical fiber distance for which E – CIN architecture can be implemented without sacrificing any traffic quality. Cox also implements IGP traffic engineering to keep E – CIN site traffic in optically shortest path. Also, proactive bandwidth capacity planning and augmentation ensures that there is enough capacity between host site and extended CIN sites all the time.

3.5. PTP Architecture

For proper DOCSIS operation, the timing synchronization between CCAP and RPDs is extremely important. To maintain such timing synchronization, Cox utilizes IEEE 1588/PTP protocols in hierarchical architecture. A pair of Grandmaster clock at the RDC level are master for all boundary clocks deployed at each headend. These boundary clocks provide timing for CCAP cores and RPD devices. Given the sensitive nature of timing synchronization between RPDs and CCAP, PTP traffic is symmetrically routed in CIN and metro network to eliminate packet delay variation. It is also treated as priority traffic in network to minimize queuing delay.

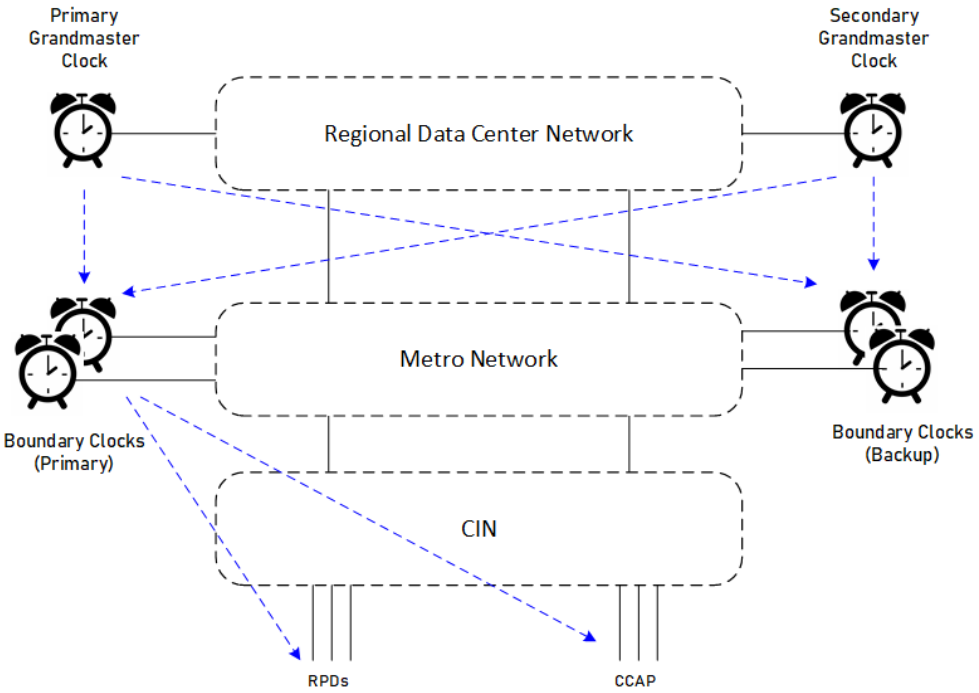

Figure 7 – Cox Communication High-level PTP Architecture

4. Access Aggregation Network Standardization and Automation

For the large-scale deployment like access aggregation network/CIN, it is extremely important to standardize the network deployment to minimize misconfigurations and enforce predictable network performance. A CIN playbook was created to document all protocols, services and configuration standards related to CIN deployment. To make the network automation easy, configurations on routers are done in such a way that they are user friendly and easily parse by any choice of programming languages. Configuration compliance are strictly enforced by compliance tools.

Network modeling and scale analysis showed that Cox will be deploying huge numbers of RPD and DPIC aggregation routers. As manual deployment of these devices is operationally expensive and consume lots of time and resources, Zero Touch Provisioning (ZTP) has been utilized to turn up these devices. ZTP engine is responsible to create configurations and apply them to all corresponding devices during new device turn up.

5. Conclusion

The tremendous growth in demand for bandwidth is pushing the legacy analog infrastructure to its capacity limits opening the opportunity to deploy modern network infrastructure in the access side of the network. Building upon this momentum of increased demand, Cox is deploying a new DAA and CIN architecture to push fiber deep into its serving areas. Cox started with Remote Phy (RPHY) as its preferred DAA technology. The foundation laid during the modernization of access and access aggregation network has far reaching impacts in Cox network. The access agnostic nature of new aggregation network allows Cox to deploy several IP and non-IP services over the same converged network. Pushing ubiquitous digital transmission technology as close to the subscriber as possible has helped Cox in delivering better services with improved quality to its valued customers. The real time performance monitoring of network assets deep into the network has also helped Cox to proactively address impending issues before it gets service impacting.

As Cox embarks on a path to the next generation of DOCSIS technologies like RMD/FMA, R-OLTs and business services, the new access and access aggregation network will offer the new and improved digital capabilities and versatilities as demanded by new and emerging technologies.

Abbreviations

DAA	Distributed Access Architecture
CIN	Converged Interconnect Network
CCAP	Converged Cable Access Platform
OCML	Optical Communication Module Link Extender
MDM	Mux/Demux Module
DWDM	Dense Wave Division Multiplexing

1. Introduction

Access systems such as Cable Modem Termination Systems (CMTS) have traditionally been monitored using tools that leverage CLI and SNMP interfaces. These same interfaces are also used to gather live information while troubleshooting issues in the field. The data exposed by these interfaces are limited by the standard set of commands and MIBs supported by the system. With the move to a distributed access architecture (DAA), deployments can support much higher scale, and their software-centric designs make available richer data useful for vendors in operating, debugging, and optimizing the systems, but access to this increased amount of data is bottlenecked by the limited performance and limited extensibility of CLI and SNMP interfaces. Newer system designs support streaming logs and telemetry to overcome these limitations, and this paper looks at how these features not only overcome the limitations of traditional interfaces but also enable more efficient monitoring and troubleshooting workflows. We will show the building blocks of a system that implements streaming logs and telemetry. The performance and security improvements offered by such a system will be noted. We will illustrate some monitoring features and describe something we call "time-travel debugging" — using the streamed data for easier troubleshooting. Finally, we will give an overview of using the data for advanced analytics and machine learning, specifically for faster root cause analysis of field issues.

2. Monitoring and Troubleshooting at Scale with Advanced Analytics

Monitoring and troubleshooting traditional CMTS deployments can be a labor-intensive activity. Deployment health is monitored via SNMP or CLI scripts using metrics such as modem registration status or call volumes to customer support. Basic troubleshooting of common issues can be done by operations or vendor support personnel logging into each platform remotely to run monitoring commands and look at locally stored logs. Complicated issues may require direct involvement of development engineers to analyze logs and perform further troubleshooting steps. Some issues with significant service impact may occur only intermittently and may not be easily reproducible. Fault monitoring and resolution is mostly a manual process.

Compared with traditional architectures, the DAA allows deployments to be launched quickly, and operators can provide increased bandwidth to more subscribers. The troubleshooting load will grow with the scale of deployment, with a corresponding increase in operational overhead.

Monitoring and troubleshooting workflows can be augmented with tools that enable operators to handle the increased scale while keeping operational overhead under control. There are non-obvious but nevertheless important implications to vendors and operators, which will be explored in subsequent sections.

3. Troubleshooting

Let's look at some of the challenges with troubleshooting production deployments at scale and explore some of the solutions possible with new tools and workflows.

3.1. Challenges

As deployments scale to handle increases in bandwidth and number of subscribers, there's a corresponding increase in issues that occur and need to be debugged. Issues having significant operational impact can be quite complex to root-cause. Here is a list of potential issues:

- Transient cable plant problems

- Vendor-specific interpretation of DOCSIS specifications
- Non-compliant cable modems (sometimes with different firmware versions exhibiting different behavior on the same model)
- Incorrect handling of new DOCSIS features by older equipment
- Intermittently malfunctioning equipment
- Complicated interactions between specific configurations and plant population
- Combination of multiple issues

3.1.1. Limited Storage

With limited onboard storage on the CMTS, only a reduced number of data samples are stored for a short time span, severely hampering analytics and troubleshooting efforts that require a longer history of data. The logs pertaining to the issue may no longer be available, and troubleshooting efforts can be delayed until the issue occurs again, or effort is made to actively reproduce the issue. Because storage capacity is limited, only limited logging is enabled by default, and this means that logs are not as information-rich as they could be for some root-cause analysis.

3.1.2. Availability of Expertise

When logs are available, there may be only a limited number of engineers with the knowledge required to interpret the logs and correlate them with the observed issues. Thus, troubleshooting can be limited by availability of skilled personnel to handle the increased workload.

3.1.3. Security Considerations

Scale operations involve software running across many IP hosts, and this necessitates maintaining a list of IPs for support personnel to log in to. Login accounts need to be set up and/or passwords shared for debugging efforts. Managing access to these accounts and hosts need to be done carefully to avoid security issues. For example, the integrity of a deployment can be compromised by a single compromised account, or by a compromised host accessing a jump host.

3.1.4. Complexity of Issues

A DAA deployment has many hardware and software components. Problems can occur in any of these components, and some issues will be due to complex interactions between these components.

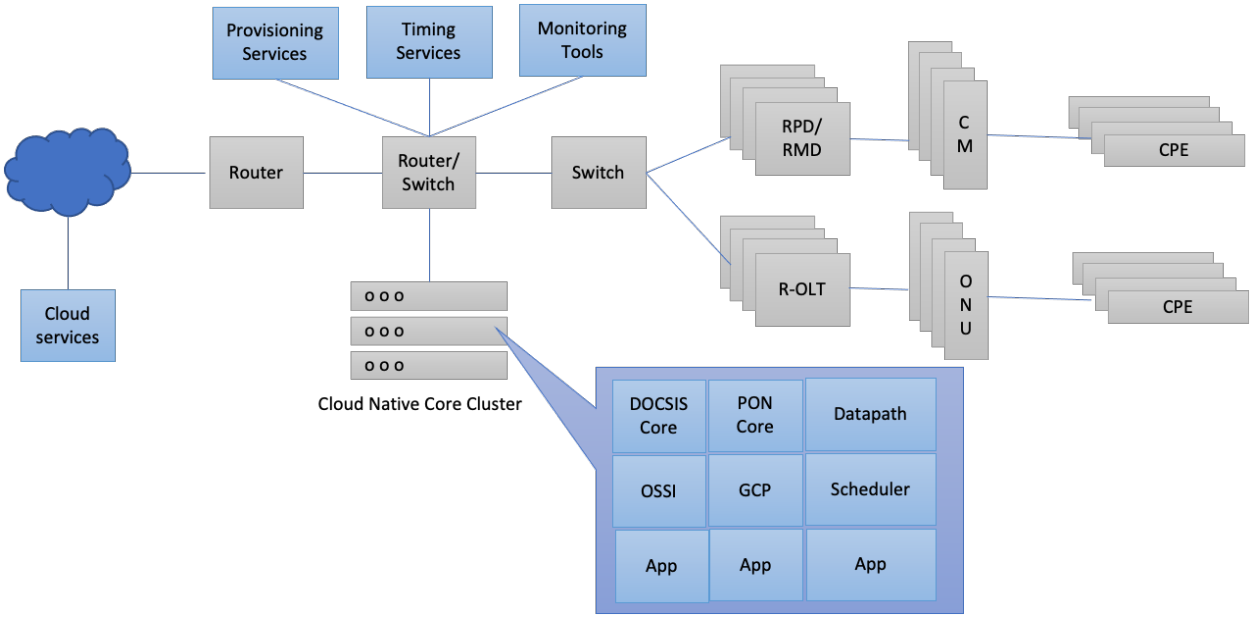

Figure 1 - A deployment has many possible fault sources

Logs and monitoring data from multiple sources must be analyzed to pinpoint the cause of a failure. Traditional troubleshooting processes can be overwhelmed by the volume of logs and metrics generated by the many software components of a modern cloud native solution. For instance, logs from multiple sources might need to be examined to troubleshoot a modem bandwidth problem. Generating a timeline of events across multiple system components will be challenging without new tools.

3.1.5. Legacy Monitoring Tools

Traditionally, the monitoring interface of a CMTS is defined by the DOCSIS OSSI standard, and tools such as CLI and SNMP are used to query the system to gather performance monitoring metrics. The OSSI standard does not specify data objects for all metrics that can be exposed by modern software designs, and CLI and SNMP tools do not scale well to handle vast amounts of fast-updating data. With increasing scale, using CLI for manual real-time analysis becomes impractical. A data pipeline constrained by these legacy tools limits the richness of data available for analysis and increases latency in detecting critical changes in key metrics.

3.2. Cloud Native Solutions

Cloud native, software-based solutions are now the popular field-proven choice for cost-effective, high-scale CMTS deployments. Service is provided by loosely coupled microservices deployed in containers running in a compute cluster. Each microservice exposes its own metrics and logs that provide highly granular insights into their operation to aid with advanced monitoring and troubleshooting. A vast amount of data is generated by the software components, and new tools are needed to process and consume the data.

3.2.1. Streaming Logs

Logs are streamed out to an external (cloud-based) service such as Elasticsearch. Analysis tools automatically monitor logs for known patterns and can generate alerts on critical events. Dashboards summarize log statistics and visualize events in time-series graphs, making it easier for operations

personnel to monitor and troubleshoot systems. Search capabilities allow complex log patterns to be easily searched across multiple log sources.

3.2.2. Streaming Telemetry

Each software component exposes performance and state metrics that are continuously streamed to external services for monitoring, analysis, and visualization. Threshold-based alerting indicate when metric values are outside expected bounds, allowing operations personnel to investigate potential issues before they lead to failure. Dashboards help visualize the state of the system, and visual indicators draw attention to potentially problematic states.

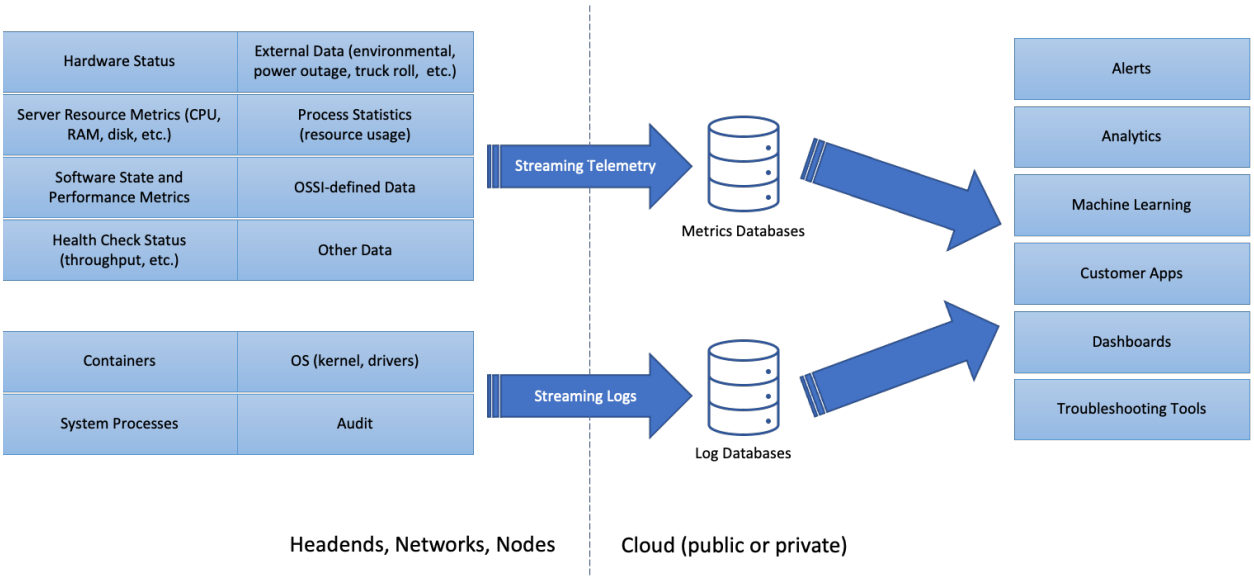

Figure 2 - Logs and metrics are streamed out and used for various applications

Streaming logs and telemetry mitigate the challenges with troubleshooting mentioned previously. The next sections will discuss how.

3.2.3. Scalability

The scalability of compute and storage resources in the cloud allows vast amounts of logs and metrics to be stored and analyzed. Since the data is continuously streamed off the system, local storage no longer limits availability of the data. Also, DAA deployments consist of many software components running across many servers, and tracking which server runs what software component while also figuring out which components are contributing to a field issue quickly becomes a problem if troubleshooting requires direct access to the server. With logs and metrics streamed out to accessible and external cloud-based services, such considerations are no longer an issue.

3.2.4. Automation and Analysis Tools

Logs and metrics are automatically analyzed for indicators of failure or violations of SLA guarantees. Alerts are automatically generated to draw attention of operations personnel to problematic areas. Data is visualized in dashboards and reports generated to ease understanding of system state without manually digging through logs or running debug commands. Search interfaces and interactive data exploration tools allow filtering out data irrelevant to a troubleshooting activity and drilling down to additional details in

areas of interest. The data pipeline is continuously augmented with new analysis algorithms, dashboards, alerts, and other features based on experience and input from operations and domain experts so that troubleshooting activities are continuously being simplified. Since most of this runs in the cloud, adding new features to the pipeline do not generally require changes on core servers that might introduce risks such as increased CPU usage and core software bugs.

3.2.5. Security

Access to logs and metrics no longer require logging into a deployment instance since all debug and system state information are streamed out and made available in secure and globally accessible external systems. There may be many deployments streaming data to a few external entities. Managing access to these external entities is much simpler than managing direct access to deployments. Since logs and metrics are pushed out to the external systems, there are no incoming connections into the deployments, further enhancing security and simplifying firewall rules.

3.3. "Time Travel" Debugging

"Time Travel" here refers to being able to look at the state of the system at a point in time in the past while troubleshooting a problem.

In many cases, the failure that needs to be diagnosed occurred in the recent past, and operations personnel might have already executed recovery procedures to restore service before support engineers have had a chance to access the system to gather information needed to root cause the failure. Without streaming logs and telemetry, most of the information needed to diagnose problems would be stored on the system itself. As previously mentioned, the amount of data stored is limited because of onboard storage capacity limitations. By the time someone is able to access the system, the logs relevant to the failure might have already been flushed from the system. Further, default logging levels might not have all the information needed to debug the problem. Since recovery procedures were executed, the system is no longer in a problematic state, and state information critical to determining the root cause of the failure has been lost.

Such situations lead to prolonged troubleshooting and root cause analysis efforts. Lack of system state and logs relevant to the failure would require waiting for the failure to occur again and being able to capture logs and system state leading up to the failure. Recording system state leading up to the failure can be challenging if that state is not captured in logs or by OSSI tools such as SNMP. Initial analysis might determine that additional logs or debug features need to be turned on, requiring further reproduction of the failure. Additionally, if live debugging is needed (requiring access to the system in the failed state), there could be prolonged service outages while the failure is being analyzed. Debugging under time pressures can result in erroneous analysis.

Streaming logs and telemetry mitigate these issues. Onboard capacity constraints are no longer a limiting factor, so logs are available in an external log database for extended time periods, and richer information can be logged by default (although there are cost implications; see later section). This means that the logs pertaining to a failure can be looked at, long after the failure occurred. Streaming telemetry makes periodic (many times a minute) state snapshots available in external databases, enabling the state of the system at any point in time to be analyzed. Operations personnel can execute recovery procedures without worrying about losing critical historical debug information.

In a sense, operations and support personnel and development engineers can "travel through time" to observe the state of the system at any point in the past. This can be done simply by using database query interfaces to search for information pertaining to the system at any time. Tools can show how various

state metrics change over time leading up to a failure. This means that failures can be analyzed without having to wait for multiple reproductions of the issue.

The state information streamed out is comprehensive and not constrained by the limited time resolution and information richness of CLI or SNMP data models, so almost any information needed to analyze the system at any point in time is always available. During root-cause analysis, various subsystems might need to be analyzed as the analysis progresses. Various domain experts will need to be brought in at different points of time. Since the streamed-out state is rich with information across all subsystems, there is seldom a situation where additional reproduction efforts are needed because information in some specific domains are lacking. Separate subsystems can be analyzed independently — each stage of the analysis can use the tools to explore system state across various subsystems over various periods of time. The result is faster root-cause analysis and minimal downtime.

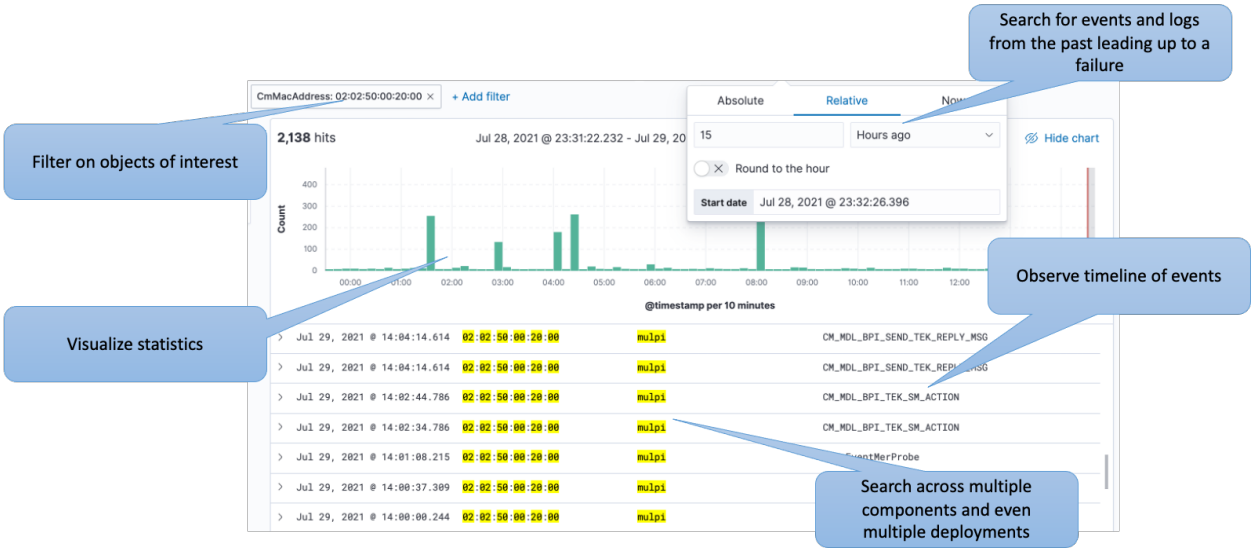

Figure 3 – Search and analysis of logs using tools such as Elasticsearch and Kibana

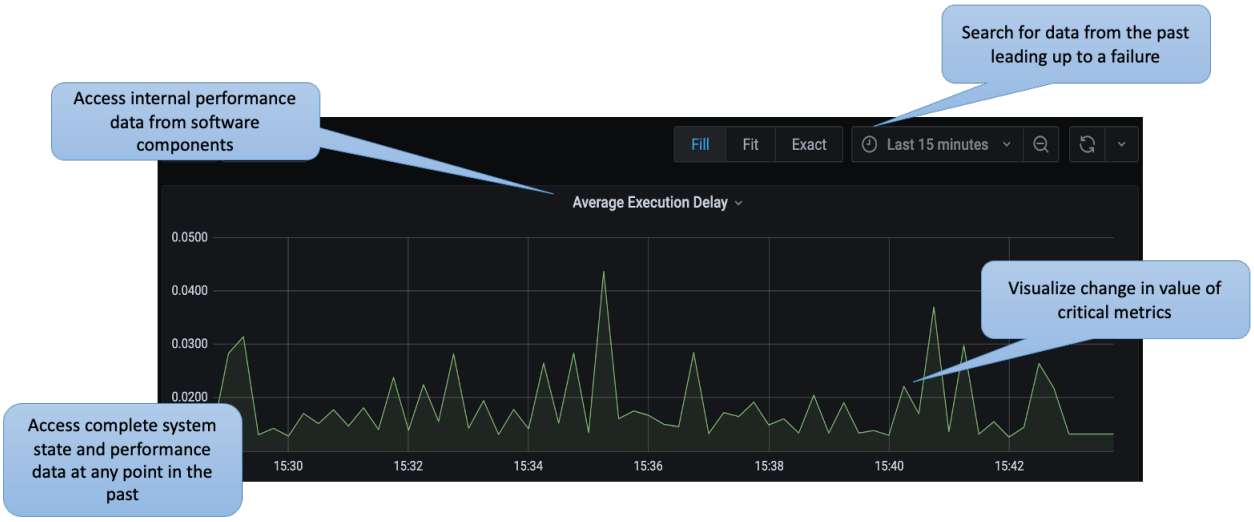

Figure 4 - Data visualized and analyzed using tools such as Prometheus and Grafana

Looking into data from the past can help determine the reason of a current system fault. Current symptoms and logs and telemetry data can be compared with analysis from previous investigations and corresponding logs and telemetry signatures. For help with future investigations, a database of failure events and their corresponding logs and telemetry snapshots may be created. Frequency of each event can be tracked to generate correlations between the events and certain logs and metrics, and this can be used to isolate root causes to specific system components.

4. Advanced Analytics

The data available in the cloud can be used for other data-driven apps such as billing and analytics. Data from the past can be used to train predictive algorithms and fed into machine learning pipelines. Closed-loop controls can be implemented where external applications analyze the streamed data and call back into system configuration interfaces to make performance-optimizing adjustments. In this section, we will take a brief look at some of these applications.

4.1. Auto Observability

Observability of systems must scale with the number of deployments. Manually monitoring systems and taking manual corrective actions impede the ability to expand service footprint and operate at scale while maintaining SLAs. A robust data analytics pipeline can help with this.

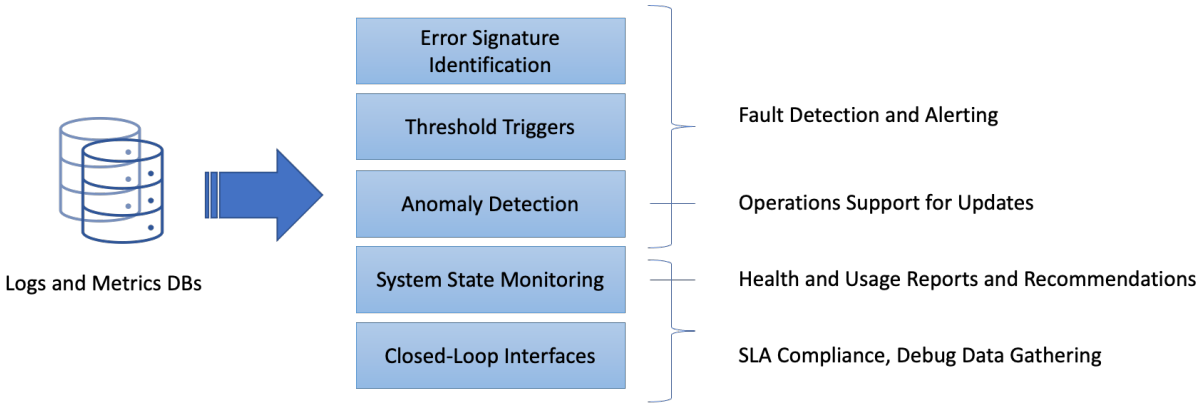

Figure 5 - Observability tasks are automated using data processing pipelines

4.1.1. Identify Failures

Comprehensive system state information is available in streamed telemetry and logs. Failures can be identified using basic data analytics (such as by identifying log signatures and metrics thresholds corresponding to failures) or by advanced approaches such as machine learning.

4.1.2. Rapidly Root-Cause Issues

At scale, failures must be analyzed quickly before they propagate and affect a large population of users. Failures detected during upgrades or operational updates must be diagnosed immediately to prevent stalling of planned operational procedures and rollouts. Potential issues introduced by an update can be identified by anomaly detection algorithms analyzing streamed logs and telemetry.

4.1.3. Proactive Debug Data Collection

Some investigations require more debug data than what's provided by logs and telemetry (such data might incur too much overhead to be streamed in logs and telemetry). For instance, an issue with specific kinds of data traffic might require analyzing a packet capture. Such data may be collected automatically when a potential issue is identified. This can be done by triggering advanced data collection when certain thresholds are exceeded. For example, a set threshold of subscriber-reported traffic problems can automatically trigger a traffic recording process for more advanced investigation.

4.1.4. Maintain SLAs

Performance metrics must be monitored across all deployments to ensure service quality. Monitoring tools must analyze streamed data to identify, report, and potentially correct problems as soon as they occur. Reports can identify subscribers who may benefit from moving to a different service tier. Closed-loop pipelines can observe streamed data and call into system configuration interfaces to take corrective action or adjust configuration to maintain SLA targets. For example, OFDM RxMER data from cable modems can be monitored to dynamically create and apply OFDM profiles optimized for current plant conditions. Having such closed-loop pipelines run in the cloud enables the associated algorithms to be easily updated and the performance of the algorithms themselves be monitored.

4.1.5. Characterize System Health

Data provided by streaming telemetry and logs must be analyzed to characterize system state and usage over time. The knowledge of system behavior provided by such analysis will aid in optimizing existing deployments and forecasting and planning for future needs. Automated reports can give an overview of system usage, and analysis pipelines can provide recommendations on managing deployments (such as recommending node splits based on bandwidth data or enabling features such as dynamic load balancing and equalization).

4.2. Multi-Variable KPI

Key Performance Indicators (KPIs) tracking customer satisfaction can be optimized for using data analysis and machine learning. As an example, bandwidth utilization could be a KPI, and optimizing it can involve tuning multiple parameters. RF parameters (modulation profile), subscriber density, cable modem configuration, and connectivity bandwidth, are just some of the things that contribute to optimal bandwidth usage. However, these parameters can also have adverse influence on some other metrics. Let's look at a couple of these parameters.

4.2.1. Modulation Profile

More robust modulation profiles may be configured when RF plant conditions deteriorate. Streaming telemetry includes RF metrics such as counts of uncorrectable and corrected FEC codewords, and this can be monitored to determine an appropriate modulation profile. A single-variable optimization would be to maintain the counts below a certain threshold. However, the more robust modulation profiles usually reduce available bandwidth as well. If the optimization is based on just optimizing the FEC-related counts, bandwidth utilization is adversely affected.

4.2.2. Subscriber Density

More per-user bandwidth can be made available by reducing the number of users sharing the RF spectrum. This involves a node-split. Bandwidth utilization is reported via telemetry, and peak bandwidth

can be used as a threshold to decide on splitting a node. Additional nodes imply additional cost; therefore, optimizing on just the peak bandwidth can adversely affect cost.

Thus, monitoring and optimizing a single parameter can adversely affect other KPIs. What's needed is optimization across multiple variables: configuration must be dynamically adjusted to maximize utility over multiple metrics such as FEC, bandwidth utilization, and cost. One method of achieving this is by using a machine learning pipeline based on reinforcement learning.

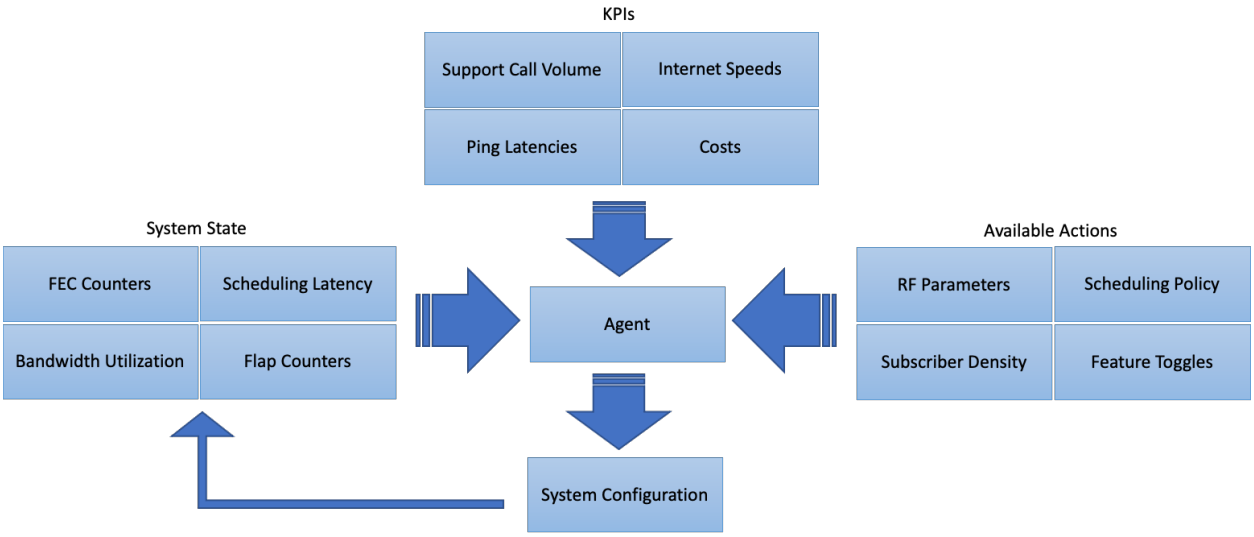

Figure 6 - Machine learning pipelines optimize key performance indicators

4.3. Fault Isolation

A DAA deployment contains many hardware elements (RPD, core servers, RF plant components, network switches and routers, etc.) and software components (RPD software, core software, software on network elements, OSSI tools, etc.). Each of these components are further composed of many subsystems, and many components are duplicated for redundancy. The overall system can be quite complex, with many potential points of failure. When a problem occurs, it can be challenging to pinpoint the source.

As an example, consider a case where some cable modems go offline. The root cause could be plant RF issues, a power outage event, a transient failure on a node or RPD or RF chassis, a network issue, a software crash, a hardware resource issue, or any number of other possibilities. A first step in analyzing the failure would be to identify the point in the topology where the failure originated. If the root cause is a power failure, then the metrics for multiple components would show a problem depending on the affected outage area. Identifying the cause of failure is not easily done just by looking at system dashboards. However, an analytics pipeline that is fed all the relevant data, including data from power supplies and third-party data sources such as utility companies, can correlate failures to the observed events, and combined with topology information, indicate the origin of the failure.

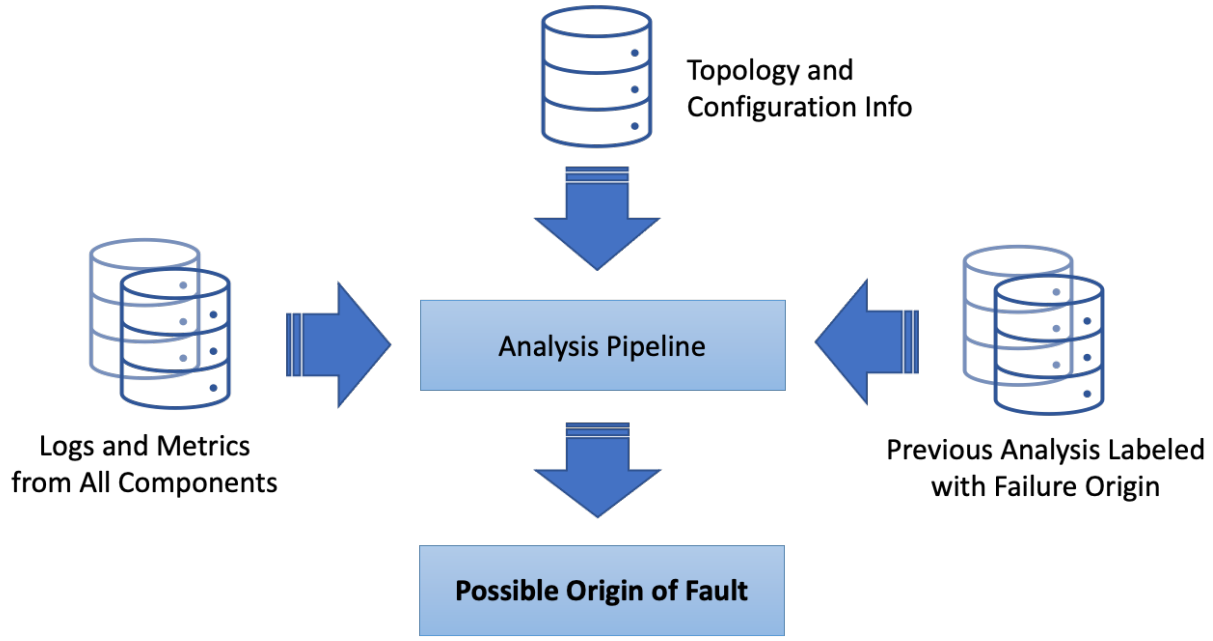

Figure 7 - Logs and metrics signatures indicate fault origin

Past analysis efforts can be used to automate future identification of root causes. Streamed data is continuously analyzed for patterns and anomalies, and problems identified in the past can be used to label the data and used to train machine learning algorithms. The algorithms can then automatically identify failures and indicate the root cause in future occurrences.

5. Other Considerations

Data analysis and machine learning enable tools that provide powerful new capabilities. There are some potential issues that need to be considered when deploying these tools at scale. This section will examine a couple of them.

5.1. Data Privacy

Logs and telemetry data can contain privacy-sensitive data. Information such as cable modem registration attempts, subscriber data usage, subscriber data activity, IP and MAC addresses, and other identifiers can potentially be combined with external data sources to gather information about subscribers. It is best to not collect such data in logs and telemetry. Identifiers must be sanitized, and any data collected must be anonymous. Data collection practices must be guided by both moral and legal (such as GDPR) considerations.

5.2. Infrastructure Cost

The most convenient and scalable method for running the components of the analytics pipeline discussed in this paper involves use of public cloud infrastructure. The associated cost can be significant if not managed well. It can be challenging to assign a dollar amount to the value provided by the pipeline so that a budget can be allocated for the public cloud services. For instance, the value is close to nil for the troubleshooting use case when everything works and there are no problems to be debugged. However, the services provided by the pipeline can be invaluable when a complex issue occurs that would have

otherwise required the operator's or vendor's most experienced engineers to spend significant chunks of time analyzing and root causing the issue. The cost analysis is further complicated by the fact that this time spent troubleshooting takes away valuable time from those engineers.

The features provided by the pipeline, such as smart alerting and usage reports with data analysis, can significantly improve the operator's customer satisfaction metrics. The value provided by such features also needs to be considered when assessing the cost.

Regardless of the challenges assigning a value to the services, there are some knobs that may be used to control the costs.

5.2.1. Compute vs. Storage

The most expensive cost component is cloud compute resources. The data streamed to the cloud needs to be processed for analysis and display. For instance, compute resources are needed to index logs to enable fast searches. On the other hand, storing the data is relatively inexpensive. The pipeline can be tweaked to store raw data and use compute resources only on demand. The main drawback of this strategy is increased latency in accessing the data.

5.2.2. On-Prem vs. Public Cloud

Running the services on-premises instead of using a public cloud provider can reduce operational expenditure (depending on how the cost associated with operating the on-prem infrastructure is accounted for), with the caveat that additional overhead is incurred maintaining the on-prem hardware and software. Service expense is traded for capital expenditure. Drawbacks of this approach include additional difficulty in aggregating and analyzing data across multiple deployments, and more challenging upgrade processes and infrastructure scalability. In general, on-prem infrastructure might be a good option if all use cases are well-defined and already implemented and scale of operations is known in advance. Machine learning and advanced data applications are still evolving and use of public cloud infrastructure can provide flexibility in accommodating the changing use cases.

5.2.3. Data Retention

Storage costs can be managed by limiting the amount of data that is retained. For example, data older than a certain age can be discarded. Some architectures support a warm or cold storage option where older data is stored in cheaper (but higher latency) storage mediums. Discarding older data has the disadvantage that longer-term seasonal patterns may be missed by data analysis tools; this may be mitigated by feature generation capturing traits of the data and storing that longer term.

6. Conclusion

In this paper, we looked at how modern data analysis and machine learning tools help with operating critical infrastructure at scale. We examined the challenges posed by legacy tools and systems and how those challenges are mitigated by software-centric solutions that support streaming logs and telemetry. We explored how data and tools can be used as a framework for powerful troubleshooting capabilities that simplify analysis of failures. We looked at some of the applications made possible by using automated data analysis and machine learning algorithms. We also looked at some potential issues that need to be considered when deploying these applications at scale.

The applications and use cases presented in this paper are just a sample of what's made possible by rich data sets and advanced data analytics. As deployments scale to support more subscribers and bandwidth,

such applications will be an essential component of successful operations and critical to ensuring customer satisfaction.

1. Introduction

Quantum computing is an emerging technology that can dramatically change the security landscape. Unlike traditional computation that processes information in binary bits, 0 or 1, the information in quantum computing is stored in a particle in a quantum state called a "qubit." Qubits exist in a superposition, which means they can be 0 or 1 or everything in between, until measured. This allows quantum computers to simultaneously perform computations for a range of inputs. In practice, this reduces the computational complexity of certain algorithms from exponential to polynomial time -- from $O(e^n)$ to $O(n)$. This means that to solve certain classes of problems that would take classical computers hundreds of years, quantum computers may only take days or even hours.

For example, Grover's algorithm provides a quadratic speedup on unstructured search problems [1], whereas Shor's algorithm can be used to factor the product of two large prime numbers in polynomial time [2]. This has an impact on the security of current crypto systems. Grover's algorithm halves the security of current symmetric keys and Shor renders all public key cryptosystems insecure [3]. These classical public key algorithms are used ubiquitously in security protocols for digital signatures, authentications, key transport and authorization. These algorithms secure cyber infrastructure, from software distributions to virtual private networks. Thus, the construction of a large enough quantum computer will require a transition to quantum-safe alternatives to ensure the continued security of these systems.

It is unclear whether such computing capacity will be available in the near future -- but it's a matter of when, not if. Many experts posit that there is a substantial probability of this happening in the next 20 years [4]. This may create the impression that the threats associated with quantum computing have a long-time horizon. However, it is important to consider the challenges in crypto transitions. For example, the transition from Secure Hash Algorithm 1 (SHA1) to Secure Hash Algorithm 2 (SHA2) took over 10 years and cost organizations $5M on average [5]. In that light, a transition across all cryptography can seem overwhelming. However, there is much cause to keep calm and carry on.

In the U.S., the National Institute of Standards and Technology (NIST) has a process underway to determine a list of post-quantum cryptography (PQC) algorithms to replace current public-key cryptography [6]. Open Quantum Safe has open-source implementations of many PQCs for benchmarking and exploration [7]. Additional support is available from European Union projects PQCrypto and SAFEcrypto, as well as CREST Crypto-Math project in Japan [41]. Cloud computing providers, such as Amazon Web Services (AWS), already provide the option of using hybrid cryptography, which combines PQC within a classical cryptography wrapper [8].

There are three components of a quantum transition. First is the choice of crypto algorithms themselves. Second is the implementations of these algorithms in core technologies such as FPGAs. The third component is the evolution of supporting infrastructure to support PQC. For best results, these three components get combined in a broader crypto agility strategy. This sets the stage for a smoother transition, within a time period commensurate with an organization's risk tolerance.

In this paper we help you navigate a transition to the post-quantum world. We begin by providing an overview of post-quantum cryptography, including the various standardization efforts. Next, we introduce the different implementations that currently exist for incorporating PQC algorithms into your infrastructure. Then we discuss the state of complementary solutions -- specifically certificates, protocols, and cloud computing. We also describe crypto agility frameworks that can be used to develop a transition strategy and identify potential gaps. Finally, we close with a roadmap to help you move forward efficiently according to your organizational needs.

2. Post-Quantum Cryptography

All current public-key crypto-systems assume that certain mathematical problems are hard to solve, i.e. the time to solve them on classical computers increases exponentially in proportion to the size of the input. For example, RSA assumes that factoring the product of two very large prime numbers is difficult to do with current computing technology. Thus, the security of RSA is predicated on this assumption staying true. A large enough quantum computer may render these assumptions false [3]. For example, Shor's algorithm can factor RSA keys in polynomial time [2]. Consequently, any transition to a quantum safe future requires new classes of algorithms with hardness assumptions that will not be impinged upon by quantum computers [13].

The impact of quantum computing will be different based on the type of algorithms. According to NIST [41], larger key sizes for symmetric key and larger output for hash functions may be needed to ensure security in the post-quantum world, while public key cryptography such as RSA (Rivest Shamir Adelman), ECDSA (Elliptic Curve Digital Signal Algorithm), ECDH (Elliptic Curve Diffie-Hellman) and DSA will no longer be secure. Thus, the development of new classes of crypto algorithms focuses on public key cryptography used for key exchange and digital signature schemes. In this section we provide an overview of these efforts.

2.1. Quantum-Safe Algorithms

Quantum-resistant cryptography is primarily based on one of six different mathematical problems. Each problem has distinct hardness assumptions as well as pros and cons in terms of performance. These are listed below:

1) **Lattice-based cryptography** is based on the hardness of well-studied lattice problems in the construction itself or in the security proof. Two popular sub-categories of it are NTRU signature and ring-LWE (Learning With Errors.) These algorithms are simple, efficient, and parallelizable. However, they have larger public key sizes than RSA. Additionally, it is difficult to give precise estimates of the security using known cryptanalysis techniques [14].
2) **Code-based cryptography** relies on error-correcting codes. Examples include McEliece encryption algorithm and CFS (Courtois-Finiasz-Sendrier) signatures. They have large key sizes and attempts to reduce them so far all resulted in compromised security. There has been more
3) with implementing it for encryption than for signatures [4].
4) **Hash-based signatures** are digital signatures constructed using hash functions such as Merkle signature scheme and XMSS (Extended Merkle Signature Schemes.) The security of hash functions is well studied. However, corresponding schemes can only produce a limited number of signatures, and many require a secure record of the exact number of previously signed messages. Together with the much larger signature, the drawbacks make it tricky to implement for large-scale environments [43].
5) **Multivariate cryptography** is based on the difficulty of solving systems of multivariate polynomial equations over a single finite field. The multivariate encryption schemes are not very efficient, due to large public keys and long decryption times. However, they are more successful for building signature schemes because they provide some of the shortest signatures among the post-quantum algorithms [4].
6) **Isogeny** uses mathematics of super-singular elliptic curves and super-singular isogeny graphs to create a Diffie-Hellman-like key exchange. This mathematical problem is the most recent basis for any post-quantum candidates and is therefore less studied. However, it has one of the smallest key sizes [48].

7) **Zero knowledge proof (ZKP)** proves validity without revealing underlying information. It is currently only used by one PQC, Picnic, where it was made non-interactive and turned into a signature scheme using the traditional Fiat-Shamir transform [15].

The mathematical structure for different PQC algorithms varies widely. A detailed discussion is beyond the scope of this paper and is available elsewhere [16].

2.2. NIST PQC Standardization

In 2017, NIST started a post-quantum cryptography standardization effort to select algorithms that will supplement or replace existing public key cryptography. There were 82 submissions received in the 1st round, and 69 accepted, with a focus on the security analysis. Round 2 was started in 2019 with 26 candidate algorithms, and a focus on the hardware and software performance as well as security. To keep the diversity but reduce the numbers, NIST encouraged mergers of similar submissions. In July 2020, NIST announced the candidates for the third round, which included 7 primary and 8 alternate candidates. At the time of this writing (summer 2021), the finalists are still being reviewed for standardization at what is the conclusion of the third round. Algorithms with structured lattice schemes appear to be the most promising general-purpose algorithms for public key encryption and digital signature schemes. Several of the alternate candidates have worse performance than the finalists but might be selected for standardization if there's high confidence in their security. Others have acceptable performance but require additional analysis to inspire sufficient confidence in their security [6]. NIST will select which alternates to keep studying in a 4th round and expect the finalized standard to be ready around 2024 [40].

NIST's standardization effort focuses on two categories of PQC algorithms: 1) public key encryption/key establishment and 2) digital signatures. The current candidates all offer a range of security based on the parameter set, that range from two to eighteen. The key sizes and ciphertext sizes differ based on the parameter set selected, as shown in Table I and Table II. The * denotes an alternate candidate.

Table 1. NIST Finalists: Public-key Encryption

Name	Type	Public Key (bytes)	Private Key (bytes)	Ciphertext Size (bytes)
Classic McEliece [9]	Code-based	261120 - 1357824	6492 - 14120	128 - 240
Crystals-Kyber [10]	Lattice	800 - 1568	1632 - 3168	768 - 1568
NTRU [11]	Lattice	699 - 1230	935 - 1590	699 - 1230
Saber [11]	Lattice	672 - 1312	1568 - 3040	736 - 1472
*BIKE [11]	Code-based	2542 - 6206	3110 - 13236	2542 - 6206
*FrodoKEM [11]	Lattice	9616 - 21520	19888 - 43088	9729 - 21632
*HQC [11]	Code-based	2249 - 7245	2289 - 7285	4481 - 14469
*NTRU Prime [11]	Lattice	897 - 1322	1125 - 1999	1025 - 1184
*SIKE [11]	Isogeny	197 - 564	28 - 644	197 - 596

Table 2. NIST Finalists: Digital Signature Algorithms

Name	Type	Public Key	Private Key	Signature
Crystals-Dilithium [11]	Lattice	1312 - 2592	2544 - 4880	2420 - 4595
Falcon [11]	Lattice	897 - 1793	1281 - 2305	690 - 1330
Rainbow [11]	Multivariate	60192 - 1930600	64 - 1408736	66 - 212
*GeMSS [12]	Multivariate	352000 - 10400000	13100 - 12300	240000 - 600000
*Picnic [11]	ZKP	33 - 65	49 - 97	14612 - 209510
*SPHINCS+ [11]	Hash based	32-64	64-128	8080 - 49216

The appropriate PQC algorithm may depend both on the security and the asset constraints. Consider the public key encryption candidates. Lattice-based algorithms such as NTRU and Saber have a much smaller public/private key size than the code-based Classic McEliece. However, Classic McEliece has a smaller ciphertext size than the lattice-based algorithms. Similarly for digital signature algorithms multivariate-based Rainbow has a much larger key size, but much smaller signature size, than the lattice-based Falcon and Crystals-Dilithium.

PQC generally has larger key sizes, but some algorithms at lower security levels have a comparable size to classical algorithms at a higher security level. The five security levels are denoted as:

- Level 1: At least as hard to break as AES-128 using exhaustive key search.
- Level 2: At least as hard to break as SHA-256 using collision search.
- Level 3: At least as hard to break as AES-192 using exhaustive key search
- Level 4: At least as hard to break as SHA-384 using collision search.
- Level 5: At least as hard to break as AES-256 using exhaustive key search.

The focus of NIST competition is on security level 1, 2, and 3. Take the key exchange algorithms, for example, as shown in Figure 1. SIKE, SABER, Crystal-Kyber and NTRU all have comparable key and ciphertext sizes with RSA/DH. For the digital signature candidates, shown in Figure 2, Falcon and Crystals-Dilithium have similar signature and public key sizes as RSA.

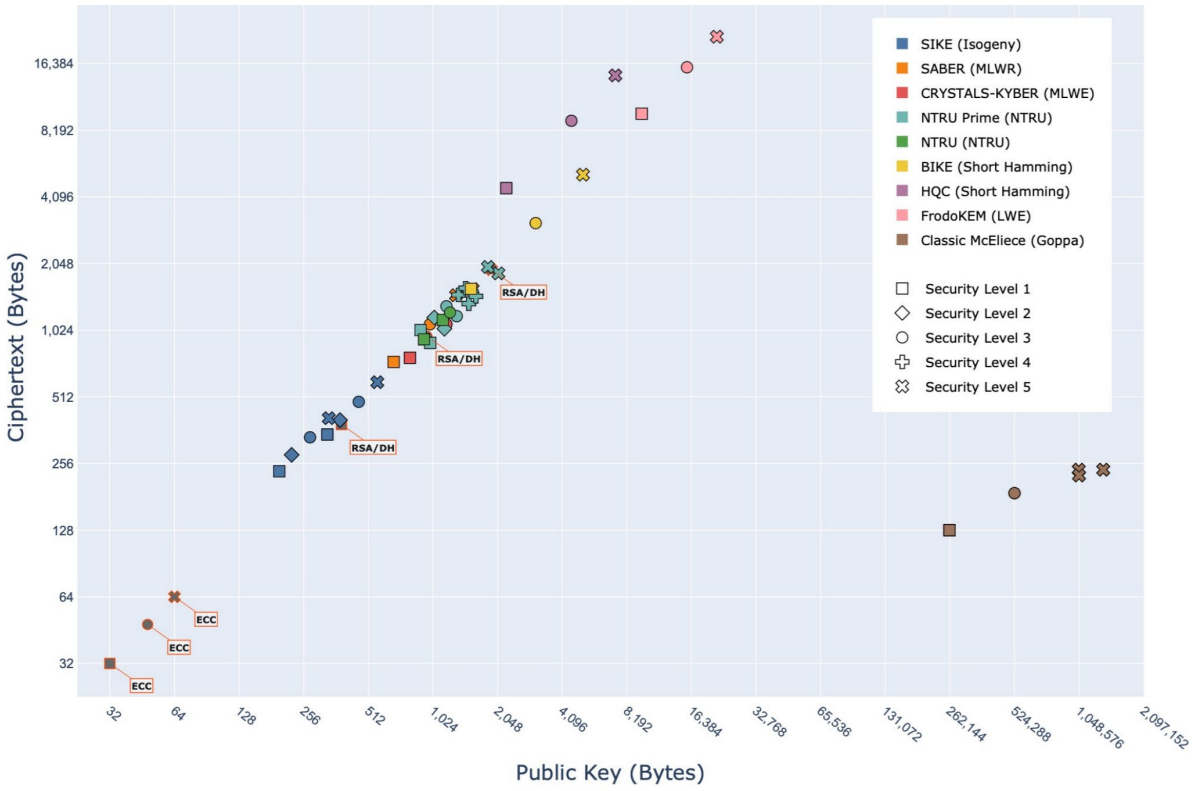

Figure 1. Ciphertext and public key sizes for NIST 3rd round key exchange + classical PKE [20]

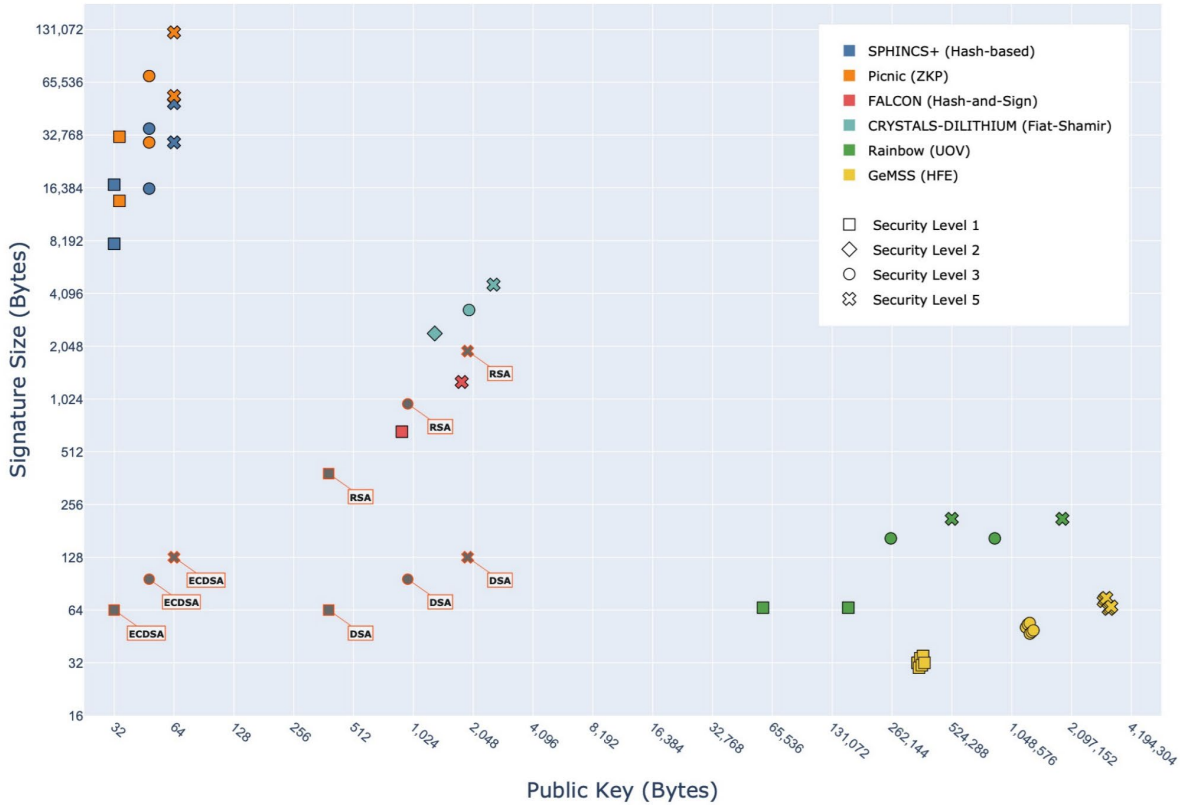

Figure 2. Signature and public key sizes for NIST 3rd round and classical digital signature [20]

2.3. CACR Competition

Aside from NIST, China also held their own post-quantum cryptography competition. The Chinese Association for Cryptologic Research (CACR) issued a notice of algorithm competition in August of 2018. The competition focused on functionalities, security, and performance. While NIST separated the competition into two tracks (digital signature and public key crypto/key encapsulation), China separated the competition into three tracks: digital signature, public key cryptography and key exchange. The first round received 36 submissions, with the majority being lattice-based algorithms. Unlike NIST, which included multiple rounds, the CACR competition only had one round and concluded in December 2019. The results of round 1 contained 14 finalists with 1st, 2nd, and 3rd place winners across the three categories [21]. The list of finalists is provided in Table III and the details are from the Announcement of the Results of the National Cryptographic Algorithm Design Competition Algorithm Selection, a technical report published by the CACR in 2020 [22].

Table 3. CACR Competition Finalists

Rank	Name	Category	Type
1st place	Aigis-sig	Signatures	Lattice
1st place	LAC.PKE	KEM	Lattice
1st place	Aigis-enc	KEM	Lattice
2nd place	LAC.KEX	KEX	Lattice
2nd place	SIAKE	KEX	Isogeny
2nd place	SCloud	KEM	Lattice
2nd place	AKCN	KEM	Lattice
3rd place	OKCN (SKCN-MLWE)	KEX	Lattice
3rd place	Fatseal	Signature	Lattice
3rd place	Mulan	Signatures	Lattice
3rd place	AKCN-E8	KEM	Lattice
3rd place	TALE	KEM	Lattice
3rd place	PKP-DSS	Signature	PKP
3rd place	Piglet-1	KEM	Code-based

2.4. Europe

While Europe did not hold its own post-quantum competition, there have been multiple initiatives exploring the current solutions. The European Technology and Standards Institute (ETSI) is a recognized regional standards body dealing with telecommunications, broadcasting, and other networks and services. It recognized that cryptanalysis and the standardization of algorithms require significant time and effort for their security to be trusted by governments and industry. Thus, ETSI is taking a proactive approach and formed the Cyber Quantum Safe Cryptography (QSC) Working Group to assess and make recommendations for quantum-safe cryptographic primitives, protocols, and implementation considerations. The focus is on practical implementation with consideration of performance, capabilities, benchmarking, architecture, and protocols, instead of development of the cryptographic primitives [14]. The European Union Agency for Cybersecurity (ENISA) also published a study that provides an overview of NIST finalists as well as proposals that system owners can implement now in order to protect the confidentiality of their data against a quantum-capable attacker [4].

3. PQC Implementations

The performance of PQC algorithms will depend on their implementation and deployment environments. Most of the published benchmarks are based on algorithms from round 2 of NIST's competition. They include benchmarking of seven lattice-based algorithms [17]; benchmarking of algorithms in hardware [18]; benchmarking using FPGA [20] and benchmarking in TLS [19]. Because these algorithms are currently evolving, their actual performance may differ from published benchmarks, which is also informed by implementation platforms. The most comprehensive benchmarking of the round 3 algorithms, as of this publication, is from the Open Quantum Source (OQS) profiling project and includes runtime, memory use and performance on x86 [44]. The code for OQS profiling is open source and geared toward collecting information across the algorithms at different levels of the software and network stack. It does not provide testing at the raw algorithm level, which can be done using SUPERCOP, a

toolkit that measures crypto primitives according to length of the key/message and time to generate, encrypt or authenticate [45]. Because each PQC algorithm has its own limitations and might be appropriate for distinct platform or assets, it's best to test and explore the implementation challenges on your target device.

3.1. Libraries

There are several libraries that implement PQC for distinct systems and corresponding requirements. One of the earliest is libpqcrypto, a cryptographic software library produced by the PQCRYPTO project that includes software for 77 cryptographic systems. It includes AES-256 and Salsa20 for symmetric/secret-key cryptography, McBits for public-key cryptography and SPHINCS+ for signatures. PQCRYPTO can be used with OpenSSH and OpenIKED. The project includes a benchmarking and testing framework as well as libraries for ARM Cortex-M4 and FPGAs. However, the library is research-oriented and not ready for use in production environments [23].

Another library that is more widely used is liboqs from Open Quantum Safe (OQS) [7]. It is an open-source library written in C and has well developed support for many platform and languages. The library can run on Linux, Mac and Windows. It supports x86 and ARM architectures, as well as compilers from Clang, GCC (GNU Compiler Collection) and Microsoft. It also contains language wrappers for C++, Go, Java, .Net, Python and Rust. OQS provides code for integration into TLS, SSH, x.509, CMS and S/MIME via OpenSSL and OpenSSH. The library has been used by many external projects, including Microsoft Post-Quantum Cryptography VPN, Mullvad VPN, Thales eSecurity Go wrapper, Liesware Coherence Cryptographic Server, IBM Cloud and others [39]. However, it is built as a library for testing and not commercial deployment, so some components are more mature than others. Some algorithms implemented have large stack usage and may cause failures when run on threads or in constrained environments [11].

In addition to general libraries, Cloudflare released the source code of CIRCL, a cryptographic library written in Go, in 2019. It contains a package that combines an implementation of Diffie-Hellman with SIKE (Super-singular Isogeny Key Encapsulation), allowing developers to experiment with post-quantum key exchange schemes for TLS 1.3. They are currently looking to add lattice-based algorithms such as NTRU and Crystals-Kyber, and post-quantum signature algorithms to CIRCL [24].

Aside from open-source libraries, there are commercial alternatives. ISARA's Radiate Quantum Safe Toolkit supports system Android, iOS, Linux, macOS, Windows 10 and FreeBSD Crypto library and integration tools. It also includes a hybrid mode that has PQC but is backward compatible and maintains the current security measures [25]. Then there's also PQshield, which helps customer transition to quantum-secure standards with a post-quantum cryptography library, hardware for embedded devices, an SDK for mobile and server, as well as a solution for messaging platforms and apps [26].

Other efforts in post-quantum cryptography are happening within the United Arab Emirates. The Technology Innovation Institute (TII), part of Abu Dhabi's Advanced Technology Research Council (ATRC), made available its first PQC software library for the nation in early 2021. Not much is known about the algorithms used, but the library is written in C and supports a wide variety of architectures and OS. A hardware (FPGA-based) implementation has also been developed. The first release of the library has already been integrated in several secure communication products [27].

3.2. Hybrid

There are currently two options to implement post-quantum cryptography, either by replacing current public key algorithms such as RSA and ECDHE, or as part of hybrid cryptosystems. Post-quantum cryptography

has not yet been tested with a real quantum computer, so there is a risk of security or implementation flaws. Thus, many current solutions are exploring the option of hybrid cryptography.

Hybrid cryptosystems combine two or more different cryptographic techniques to perform the same function. There are three different types of hybrids: classical/quantum-safe hybrids, which secure against classical attacks at least; quantum-safe/quantum-safe hybrids, which are good for future attacks, but the security of quantum-safe algorithms remain uncertain; and classical/QKD hybrids, which combine the security of classical algorithms with the only one known quantum-safe method. Hybrid cryptosystems will in theory remain secure if at least one of the underlying cryptographic schemes remains unbroken. However, they can be slower, have a larger footprint for key storage, and be less efficient [8].

4. PQC Infrastructure

The first step to a PQC transition is to identify which algorithm is appropriate for your asset and explore the implementations of these algorithms in core technology. However, because these algorithms are drastically different from classical algorithms, from mathematical foundation to key sizes to performance overhead, there may be changes needed in the infrastructure to support both them and the transition to them. The infrastructures most affected are those that use public-key cryptography, such as certificates and PKI, protocols and cloud solutions. In this section we'll explore some of the changes needed in the infrastructures when transitioning to PQC.

4.1. Certificates and PKIs

The most common certificate sizes on the internet today vary between 500-1500 bytes. Most of the proposed post-quantum schemes have public key and signature sizes of 10-200 kilobytes (kb), which is significantly bigger and can pose challenges for the infrastructures that would use them in X.509 certificates. These challenges include transmission overhead, IP fragmentation and wasted bandwidth for connections. To support new proposed post-quantum signature schemes in X.509, new algorithm identifiers that correspond to certain post-quantum signature scheme parameters and structures will need to be defined [28]. While the x.509 data format allows for long public keys and signatures, some applications may put size limits on the x.509 fields. Also, the cost and performance overhead will differ depending on the implementation and usage of the certificates. Some devices or system may or may not be fully upgradeable due to software or hardware limitations.

The transition to PQC can be a huge undertaking that takes a long time. To ensure a smooth transition, there will be a need for a certificate that can work with both PQC-enabled systems and non-upgraded systems, or hybrid certificate. A hybrid certificate is an X.509 certificate with additional quantum safe components, so you only need to support one certificate instead of two no matter the system. The hybrid certificate would contain extra X.509 certificate fields for quantum-safe keys and signatures as well as encoding for a quantum safe algorithm. NIST has updated the guidance on transition in SP800-56C Rev. 2 to permit the use of hybrid mode. In hybrid mode, an unapproved (i.e. PQC) algorithm can be combined with a NIST-approved algorithm and still receive FIPS validation [42].

One way to implement a hybrid certificate is to offer the option of choosing to use the classical or post-quantum algorithm. This allows the relying parties that cannot update their cryptographic suites to be in the same infrastructure as other relying parties that use a stronger validation algorithm. Another way is to implement the certificate such that it encrypts/decrypts using both classical and post-quantum algorithms. Instead of choosing one or the other, the server/client now needs to use both. This way the certificate is

protected against classical and quantum attacks. However, this does present an implementation challenge, because you need to upgrade the PKI system, and maybe the servers and the clients as well. The signing and validation might also need to be upgraded [29]. There are currently multiple collaborative efforts on new digital certificate formats that can work with both classic and post-quantum algorithms from ISARA, Cisco, CableLabs, DigiCert and Entrust. For more details, refer to [46] for a method of embedding alternative sets of cryptographic materials into digital certificates as well as how creation, verification, signing and revocation would work in such cases.

4.2. Protocols

Once successfully adopted, security protocols tend to be long lived in products and networks. Thus, protocols typically allow for some elements of flexibility in changes to the key sizes and cryptographic parameters in case of algorithm degradation. However, protection against quantum attacks may require more drastic changes, where the cryptographic primitives may need to be replaced entirely or protocol-level changes may be needed. This can be an easy or difficult process depending on how crypto-agile the protocols are. An overview is provided here, and more details can be found in the white paper from ETSI [14].

Internet Key Exchange (IKEv2) is a protocol used mainly for setting up VPNs, using three exchanges to set up a security association. First, a common key is derived using the Diffie-Hellman key agreement algorithm. Second, the key is authenticated using certified digital signatures or pre-shared authentication key. Thirdly, the key agreement is conducted again to generate new ephemeral keys for the IP packet. The protocol standard is rigid and only offers a small set of cryptographic algorithms. Making IKE quantum-safe will require replacing the algorithms used in all three exchanges.

The Transport Layer Security (TLS) protocol, previously SSL, establishes a protected tunnel between a client and server for transmission of application data. It starts with a handshake sub-protocol that authenticates server and client, then establishes shared secret keys for transmission of application data. The shared secret keys are then used in the record layer subprotocol to encrypt and authenticate application data. The handshake uses public key cryptography and will have to be replaced with quantum-safe alternatives. The subsequent record sub-protocol uses symmetric key cryptography and just needs to increase the key sizes. The design of TLS is largely independent of cryptographic algorithms and allows the parties to negotiate the cipher suites to be used. While quantum-safe algorithms with large public keys or signatures may require additional changes to the standard, there are currently libraries available to help test the post-quantum algorithm implementations and identify implementation challenges.

Secure/Multipurpose Internet Mail Extension (S/MIME) is used to securely send email messages. It allows email to remain encrypted during the entire path from sender to recipient, preserving end-to-end confidentiality and data integrity. Content encryption in S/MIME relies upon symmetric ciphers and is believed to be quantum-safe. However, the digital signatures for authentication and integrity use DSA or RSA, which will need to be replaced with quantum-safe alternatives. S/MIME does support extended key size and encryption methods, so it is possible to upgrade signature and key-establishment algorithms without replacing the entire protocol.

Secure Shell (SSH) is used to encrypt information sent over an insecure network and allows remote login, file transfer or operations without compromising data integrity or confidentiality. The SSH protocol involves three major sub-protocols: 1) The transport layer protocol that creates a secure channel and runs over top of TCP/IP; 2) The user authentication protocol that authenticates the client to the server; and 3) The connection protocol that takes the encrypted tunnel generated by transport layer and multiplexes it into

several channels for login, proxy forwarding and accessing secure subsystems etc. The SSH protocol includes a high level of cryptographic agility and allows servers and clients to negotiate the algorithms, so the addition of quantum-safe controls should not require significant changes to the base SSH protocol.

4.3. Cloud Solutions

At its most basic level, quantum-safe solutions involve using quantum-safe cryptography, supported by certificates and protocols that accept the quantum-safe option. At a higher level, quantum-safe cloud computing means quantum-safe server, endpoint, and network infrastructure. The Cloud Security Alliance has published a note on cryptanalytic and mathematical research that builds meaningful confidence in the algorithms' security [30]. It's not an analysis on implementation, performance or application to protocol. However, many companies have already taken steps to explore performances and integrate some post-quantum cryptography into their offerings.

Google took a first step towards post-quantum cryptography by researching and prototyping lattice-based public-key cryptography. In 2016, Google launched an experiment to incorporate the lattice-based algorithm into its Chrome browser in developer mode. It is implemented for OpenSSL and designed to provide post-quantum security for TLS [31]. They also explored the performance of Apache HTTP server using post-quantum key exchange algorithms BCNS, NewHope, NTRU and Frodo (only NTRU and FrodoKEM remained as finalists in NIST's competition.) By looking at throughput, connection time and handshake size, they have concluded that the additional overhead in serving typical webpages (between 10KB and 100KB) with a post-quantum cipher suite will only decrease server throughput by less than a factor of two [32].

IBM researchers developed lattice cryptography suites which include the NIST finalists crystals-Kyber and Crystals-Dilithium, and is working with open-source community to develop open standards implementations as part of Open Quantum Safe. Currently, Kyber has been integrated as part of IBM Key Protect for IBM Cloud, a full-service encryption solution that leverages cloud-based hardware security modules. The algorithm performance may be affected by network profile, CPU speed and API call rates. The quantum-safe TLS is currently supported through the Key Protect software development kit and available both in hybrid mode and quantum-safe mode. It is currently only available in Linux, but support for additional operating systems is anticipated [33].

AWS started incorporating PQC since round 2 and now supports post-quantum TLS in AWS KMS. It supports ECDHE with BIKE and ECDHE with SIKE [8]. For the two hybrid algorithms tested, ECDHE with BIKE have a larger size than ECDHE with SIKE. However, ECDHE with SIKE is slower than ECDHE with BIKE. Which algorithm to use would depend on the constraints of the asset, and whether memory or computational speed is more of a priority.

Microsoft is working with academia and industry on four candidates for cryptography systems: Rooke, SIKE, Picnic and qTESLA. Each algorithm may be appropriate for different scenarios where different trade-offs regarding performance and key size are preferred. In addition to working with Open Quantum Safe to develop a post-quantum branch of TLS and SSH, Microsoft also worked on a fork of OpenVPN integrated with post-quantum cryptography to enable testing and experimentation [34].

5. Crypto Agility

According to NIST, "continued progress in the development of quantum computing foreshadows a particularly disruptive cryptographic transition." Once quantum computers and exploitation of such attacks becomes practical, protecting stored keys and data will require re-encrypting them with a quantum-resistant

algorithm and deleting or physically securing backups. The integrity and sources of information will become unreliable unless they are processed or encapsulated with quantum-resistant mechanisms. In the best case, 5-15 or more years will elapse after the publication of the standards before a full implementation of those standards is complete. Without proper planning, it may take decades to replace most of the vulnerable public-key systems currently in use. Thus, NIST encourages enterprises to identify where and for what it is employing public-key cryptography and all the use characteristics, as well as developing a playbook for crypto agility [13].

While there are many libraries and solutions available to help with the quantum transition, many information systems are not designed to encourage support of rapid adaptations of new cryptographic primitives and algorithms. Cryptographic algorithms cannot be replaced until all components of a system are prepared to process the replacement. This may require not only the replacement of cryptographic algorithms, but also updates to the protocols, hardware, dependent operating systems and procedures, especially in the case of post-quantum cryptography where the parameter and structures can be very different. In addition to replacing algorithms, other non-security issues, such as adoption rates, backward compatibility and performance must also be considered. The Crypto Agility Risk Assessment Framework (CARAF) can be used to combine all the factors into a broader crypto agility strategy that allows for a smoother transition within a time period commensurate with an organization's risk tolerance [36]. The risk framework consists of five phases:

1. **Identify threat** – the threat in this case is security risk attributable to quantum computing, and more specifically the challenges and risk of migrating to PQC. The assets that will be phased out before quantum computers become practical, or NIST publishes a definitive standard for PQC, can be eliminated from the risk assessment. Meanwhile, NIST has published transition guidance on the recommended algorithms and key lengths [35].
2. **Inventory of assets** - will give an overview of how crypto-agile assets are and help in identifying which assets should be prioritized in any migration. In this case, we need to identify where, how and for what public-key cryptography is employed, as well as use characteristics. NIST has published a draft on how to identify and what information should be recorded for post-quantum migration based on 5 scenarios: FIPS-140 validated hardware and software modules, cryptographic libraries, cryptographic applications, embedded code in computing platforms and communication protocols [47].
3. **Estimate risk** – given the lack of information on attack vectors, the risk estimation for crypto agility is based on a combination of timeline, to realize the threat, and cost to mitigate.
4. **Secure asset** - based on an evaluation of the risk and the resources available, the organization may prioritize the assets and decide to accept the risk, mitigate it, or phase out the asset. While it is important to assess how crypto-agile your assets are when assessing the risk, it's also important to keep crypto agility in mind when choosing a new solution to implement, especially since PQC has not been tested against quantum computers and may still undergo changes in the future. Some of the properties to keep in mind for the new solutions are extensibility, removability, interoperability, compatibility, flexibility, and updatability [37].
5. **Create roadmap** - the solutions will likely go through a few iterations and will affect different assets differently. In addition to performing benchmark testing to evaluate the performance and impact on your assets, it's important to make sure that all teams and vendors are on the same page and take future changes into account in policies and guidelines. What the roadmap should consists of depends on the mitigation methods and the organization. Security standards, best practice documentations, installation and administration documentations may all need to be changed or replaced.

The transition to PQC and making assets crypto-agile requires cooperation and collaboration between different teams and vendors. It can be overwhelming at first, but the more elements of crypto agility are implemented, the easier the next step will be. By preparing now for the upcoming transition, we can ensure a more orderly, less costly, and minimally disruptive changeover [38]. Because many of the PQC solutions have not been rigorously tested yet, they may have systemic weakness and go through several iterations before they become secure. Crypto agility will provide a practical framework to address updates to crypto threats in a quick and efficient manner.

6. Conclusion

Transitioning to post-quantum algorithms is a big undertaking. Different algorithms have different key lengths, performance, and operational constraints. There is no one size fits all solution. Benchmarking of the algorithm and crypto agility assessment of the target assets will help determine what algorithm is appropriate, as well as the potential overhead. Even if your asset implements post-quantum cryptography, there will be backward compatibility problems if others don't. Thus, it is important to plan and create a roadmap for your PQC transition.

The first step in transitioning to a post-quantum world is assessing which assets are capable of post-quantum transition using a crypto agility risk assessment. The more elements of crypto agility your assets implement, the easier the transition will be. Based on the risk assessment, action plan options range from phasing out the asset before quantum computing becomes available, accepting the risk, or securing it.

The true security of post-quantum cryptography won't be testable or tested until a practical quantum computer becomes available. For that reason, and in the meantime, a more proactive approach is to focus on the implementation and performance of hybrid cryptography.

Picking the appropriate quantum algorithms is a decision that is tied to security requirements and asset/system constraints. As with all new technological environments, testing how post-quantum algorithms work with your assets will be informative; different implementations may provide distinct benefits. Also important: Transitioning to support a quantum-based crypto environment, and the identifying which phases happen when, based on existing or desired risk tolerance levels.

1. Introduction

The Network In A Box (NIB) definition started with a 4G network that is operating the core network and base-station in a single box that is portable and self-organizing, which provides seamless connectivity to a group of mobile users, offering services such as internet connectivity and closed group communication (Push To Talk/Video/Text). The NIB setup expands cellular network coverage in various environments and different use cases, such as terrestrial disaster relief, private networks in-flight, at sea and in other scenarios and environments where an ad-hoc cellular network is required. The NIB concept is a miniature evolution of the traditional cell on the wheel (COW) concept that has been widely used for cellular mobile voice communication.

In this paper, the NIB cellular network architecture in a CBRS (Citizen Broadband Radio System) environment is described, and the background of combining an 'off the shelf' 4G eNB with a software-based open-source core network and a 'Zero Touch' system bring-up and control SW implementation will be presented. Finally, the testbed implementation of the 4G core network and eNB will be installed in a bare-metal environment with MEC (Mobile Edge Compute) demonstration application environment. The paper will conclude with lessons learned, and outlook to migrate to a 5G and container-based NIB.

2. Cellular Network CBRS Architecture

The network architecture in Figure 1 shows the traditional 4G network architecture with a CBRS environment. The RAN (Radio Access Network) and CN (Core Network) architecture in the NIB setup is very much like the traditional LTE network in commercial solutions; main difference is the small-scale nature of the setup. Since the use of the frequency band B48 (3550 MHz – 3700 MHz) is ideal for the NIB approach – shared spectrum/no spectrum needs to be owned – the connectivity of the NIB setup to a SAS (Spectrum Access System) is mandatory.

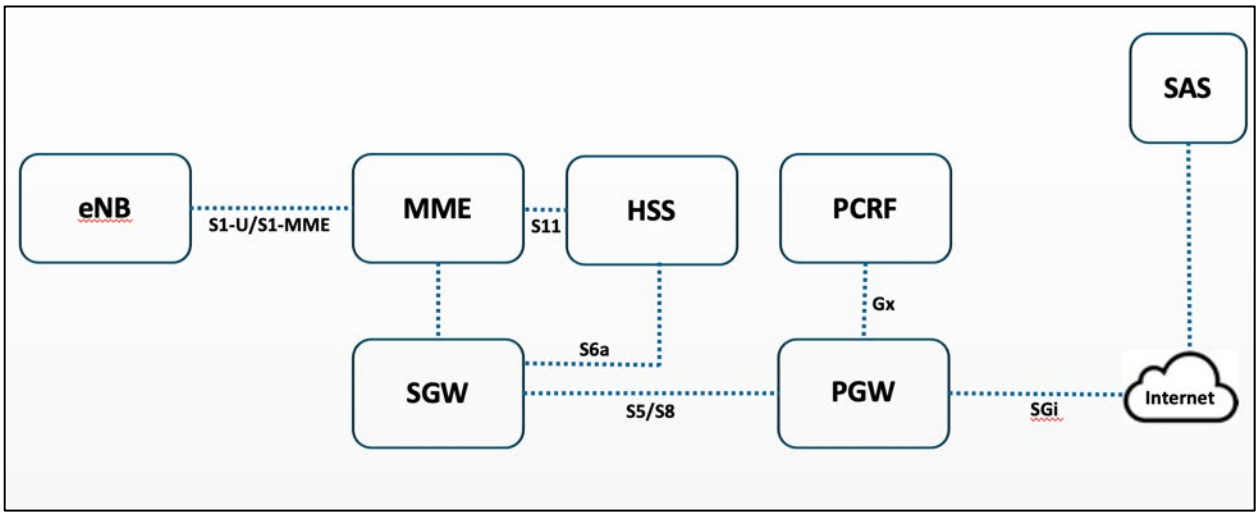

Figure 1 - Network architecture

2.1. Radio Access Network (eNB)

For the eNodeB, a commercial small cell Pico eNB is used. The output power was limited to 14 dBm/25mW per antenna port but can be increased to 24 dBm/250mW if required for respective use case.

Table 1 – LTE eNB Equipment Specifications

Specification	Value
Product	LTE Pico eNB
Band Support	B48 (3.55 – 3.7 GHz)
Carrier Aggregation	Up to 3 CA (only 1 Carrier used in NIB setup)
MIMO	2x2
Frame Configuration	TDD Frame Configuration 2 Special Sub Frame 7
IBW/OBW	150 MHz / 60 MHz
Output Power	2 x 10 W
Antenna	Built-in average 0 dBi
Modulation QAM DL/UL	256 / 64
BF Capability	No
CBRS Classification	CBSD CAT B

2.2. Core Network (EPC/HSS/PCRF)

The Core Network functions are established by utilizing an open-source application suite running on a bare-metal industrial small scale PC with a Linux-based operating system.

There are nowadays many options of open-source EPC/HSS solutions, see below for a list (not conclusive) of most popular open source core network:

- Open5Gs - Formerly NextEPC
- OpenAI Core Network - Related to / branched from OMEC
- Magma - Based on OMEC, with a focus on Fixed Wireless more than mobile
- OMEC – Open Evolved Mobile Core
- OpenMME – MME
- OpenCORD
- srsEPC

3. End To End NIB integration and setup

To be able to easily deploy the NIB, all the components are installed in a Pelican case for easy transportation. Additionally an embedded screen and wireless keyboard/mouse are included in the setup.

Figure 2 - Fully-integrated NIB setup

Figure 2 is showing the industrial type PC, running the EPC/HSS and O&M functionalities, on the left side in the case. The right component in the case is the commercial Pico eNB.

3.1. Physical connectivity

The eNodeB is physically interconnected to the industrial PC via 2 * RJ45 Ethernet cables. One connection is for the S1-MME&S1-MME LTE connectivity, the other one is for O&M administration purposes. The O&M link is utilized to automatically control the bring-up and maintain the system. A third Ethernet interface on the industrial PC is for the Backhaul connectivity to the Internet (user traffic and SAS connectivity). The same function can also be established via an internal WiFi or (Commercial) Cellular module. In the future, NIB versions and other BH connectivity options will be explored, e.g. MANET in unlicensed spectrum.

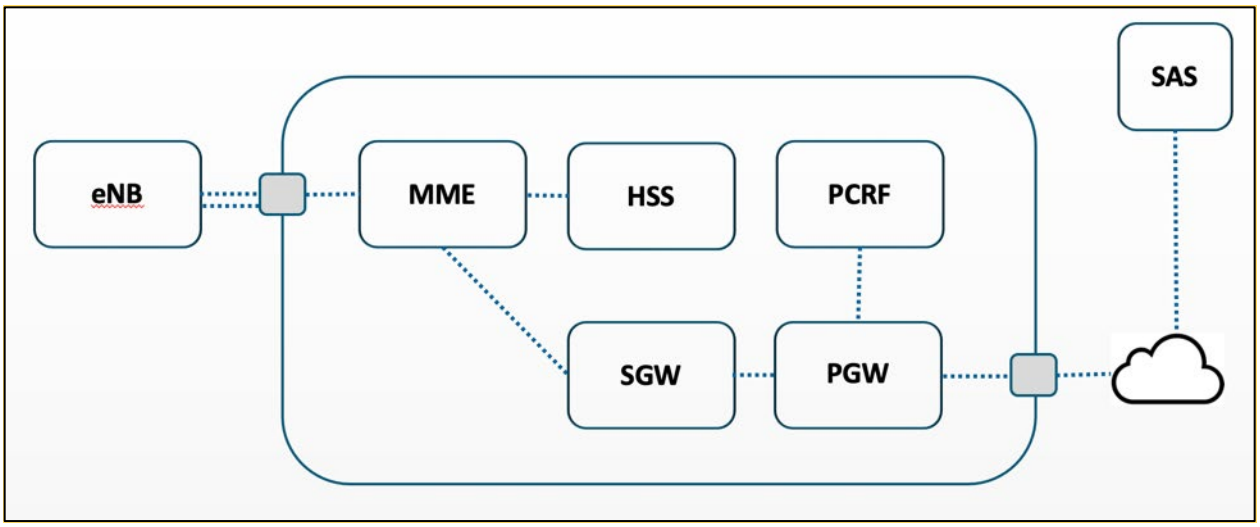

Figure 3 - Logical and physical connectivity

3.2. Automated system bring-up and device monitoring – "Zero Touch"

3.2.1. Introduction

For the purpose of a 'zero touch' and controlled system boot-up, a software application suite was developed to overcome any possible grace conditions and system malfunctions while the NIB setup is coming in service. The application starts automatically after power-up of the NIB and observing the physical and functional status of all components. If a delay or intervention during the boot-up process is necessary, the application will do so. Once the system in completely in service and the Radio is On-Air, the user will be notified and the power-on of the end-user devices can begin.

The requirement was to automate all manual processes to start the private wireless network, known as Network in a Box. Therefore, the start mechanism has to follow the new concept of Zero Touch.

In order to implement a Zero-Touch start mechanism for the Network in a Box, a three-tier software solution has to be developed.

The most common software architecture for typical client-server applications is three-tier architecture, which divides applications into three logical and physical computer tiers, as shown in Figure 4.

The presentation tier, or user interface; the application tier, where data is processed; and the data tier, where the data associated with the application is stored and managed, is a well-established software application architecture that organizes applications into three logical and physical computing tiers.

For many years, the three-tier design was the standard for client-server applications. Most three-tier programs are now candidates for modernization and cloud migration using cloud-native technologies like containers and microservices.

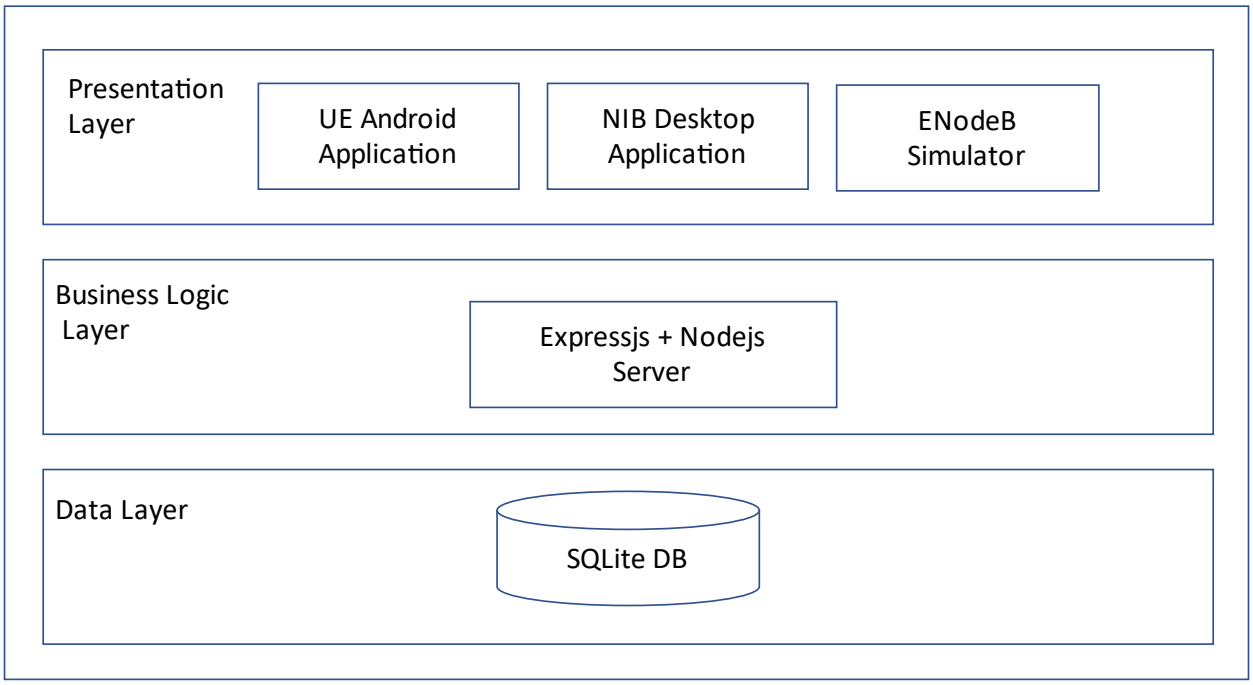

Figure 4 - NIB 'Zero Touch' portal architecture

3.2.2. Presentation Layer

The idea here is to have two applications, the first one is a desktop application, and the second one is an android application.

The desktop application runs on the ubuntu server, and it starts automatically once the server starts. The desktop application automatically starts the private LTE components (MME, SGW, PGW, PCRF, and HSS). It checks the log file for all of these components to ensure that each component starts correctly. It displays a block diagram to represent the elements of the network and it uses the color scheme to represent the status of each element as shown in the screenshots below.

The software used to build this layer are Reactjs and Electronjs and can be located in referenced links 1 and 2.

The desktop application has to communicate with the operating system and it executes a number of the commands in the command-level. In order to do that, the JavaScript child_process package had to be used.

The child_process module creates new child processes of our primary Node.js process. We can execute shell commands with these child processes.

Using external processes can improve the performance of an application if used correctly. For example, if a feature of a Node.js application is CPU intensive, as Node.js is single-threaded, it would block the other tasks from executing while it is running.

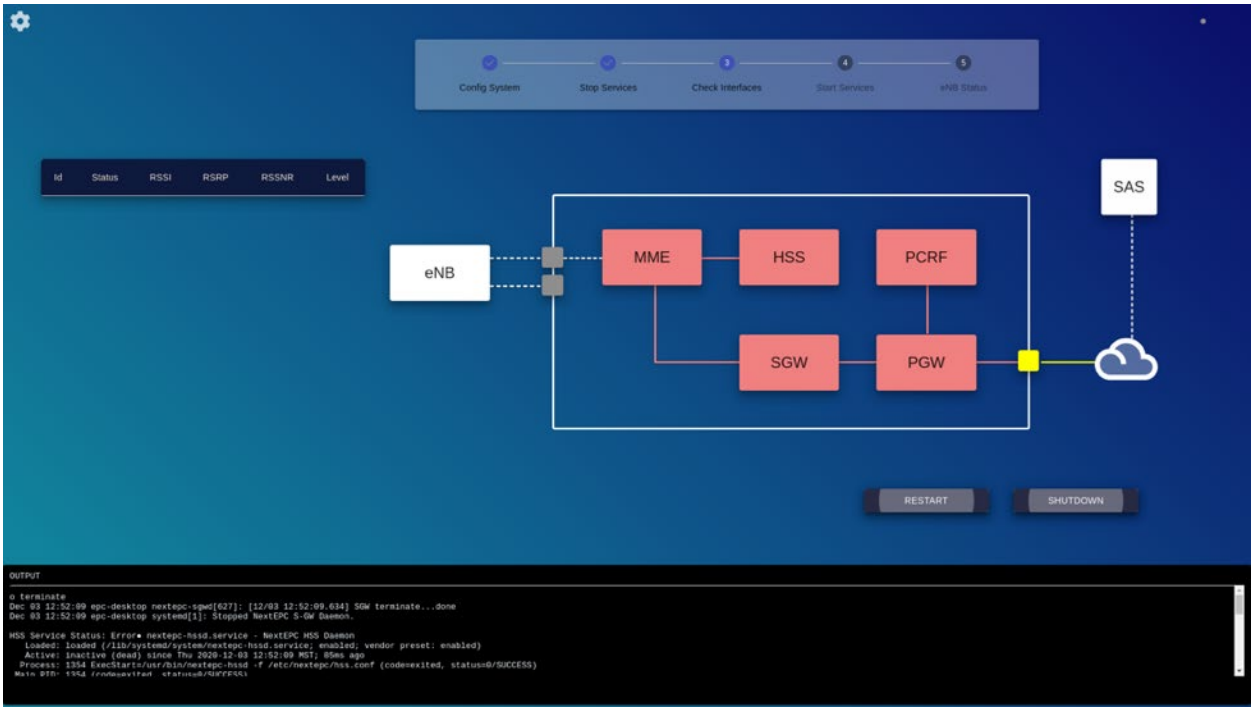

Figure 5 - Initial status after power-up - next step wait for physical interfaces to come in service

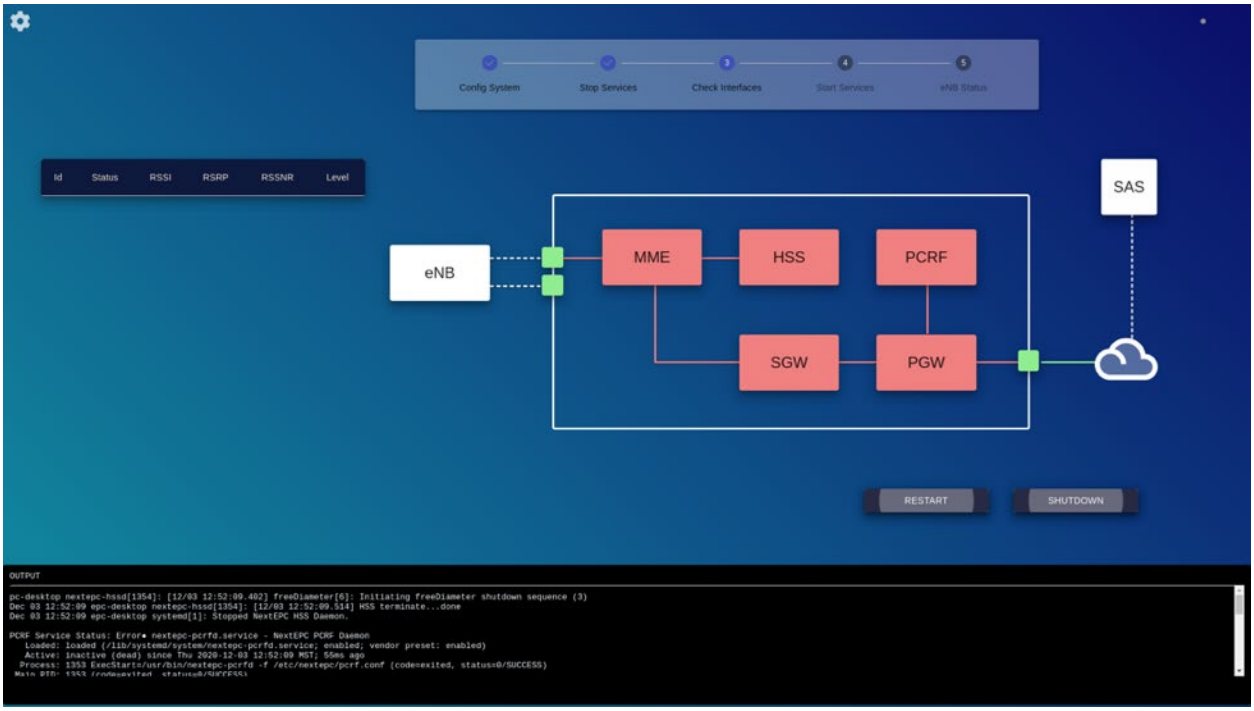

Figure 6 - All Ethernet interfaces are in service – next step start of EPC/HSS services

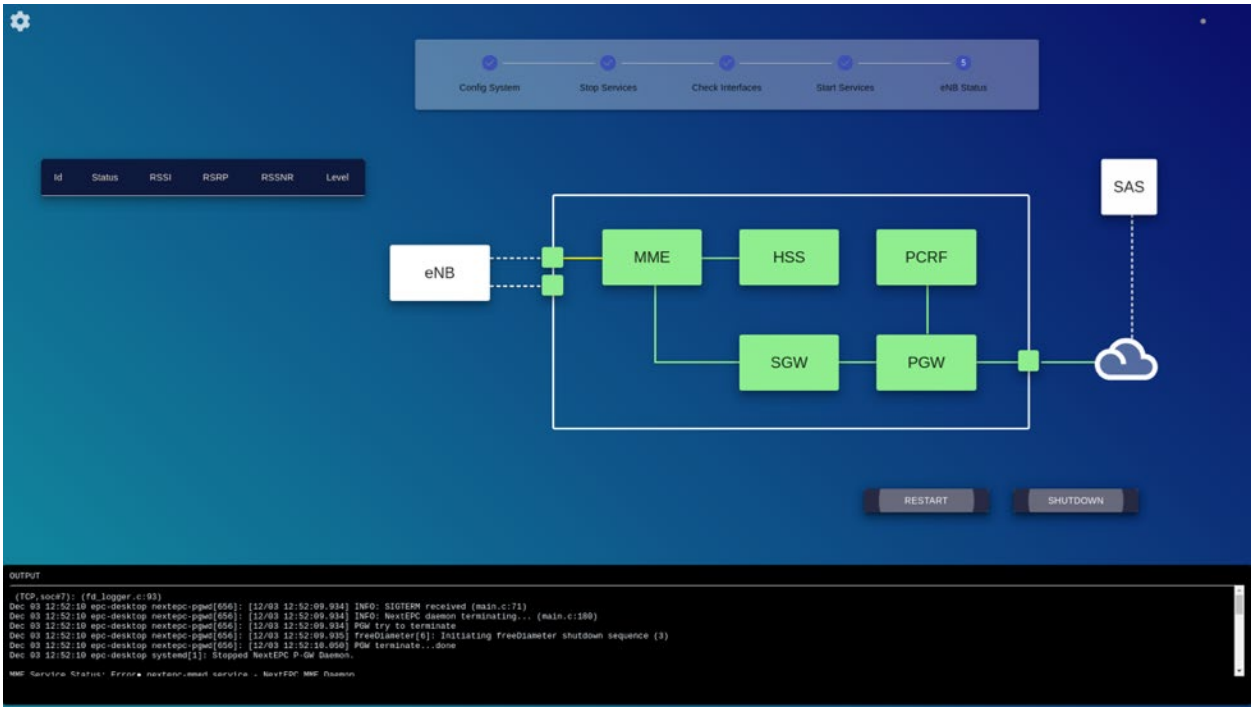

Figure 7 - EPC/HSS services started – next step activation of S1 link

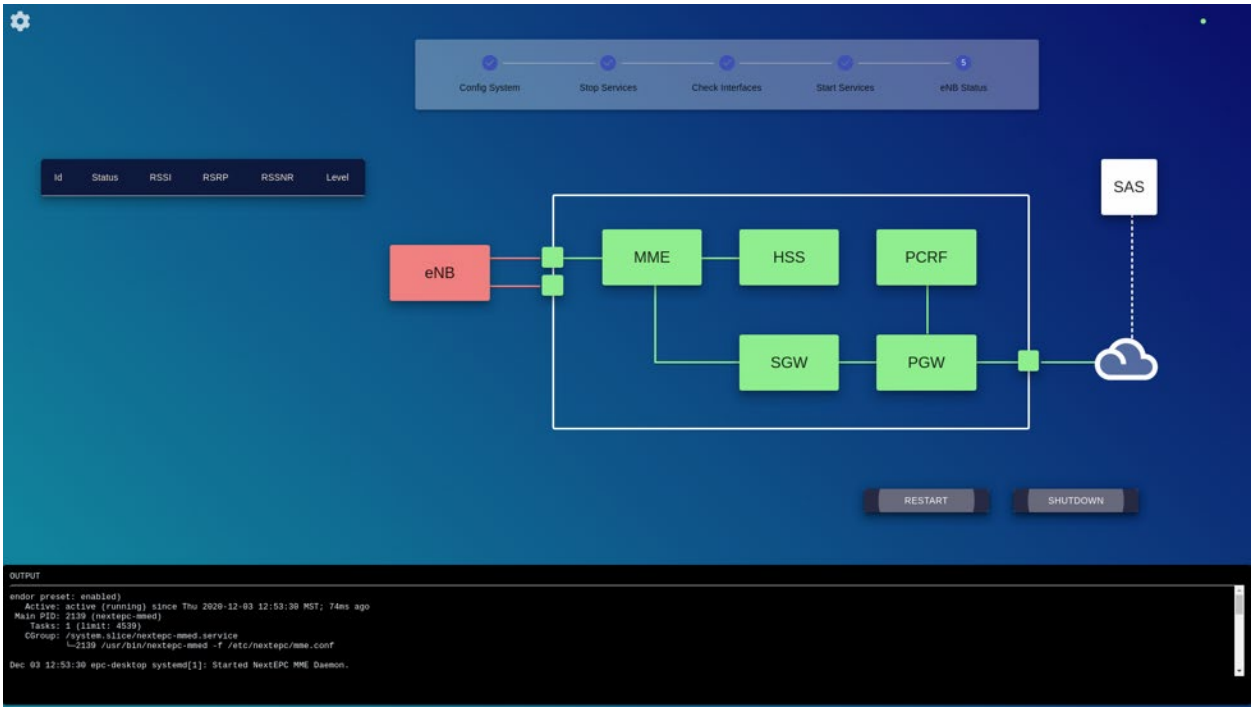

Figure 8 - S1 link is activated – next step wait for positive SAS communication and eNB to come On-Air

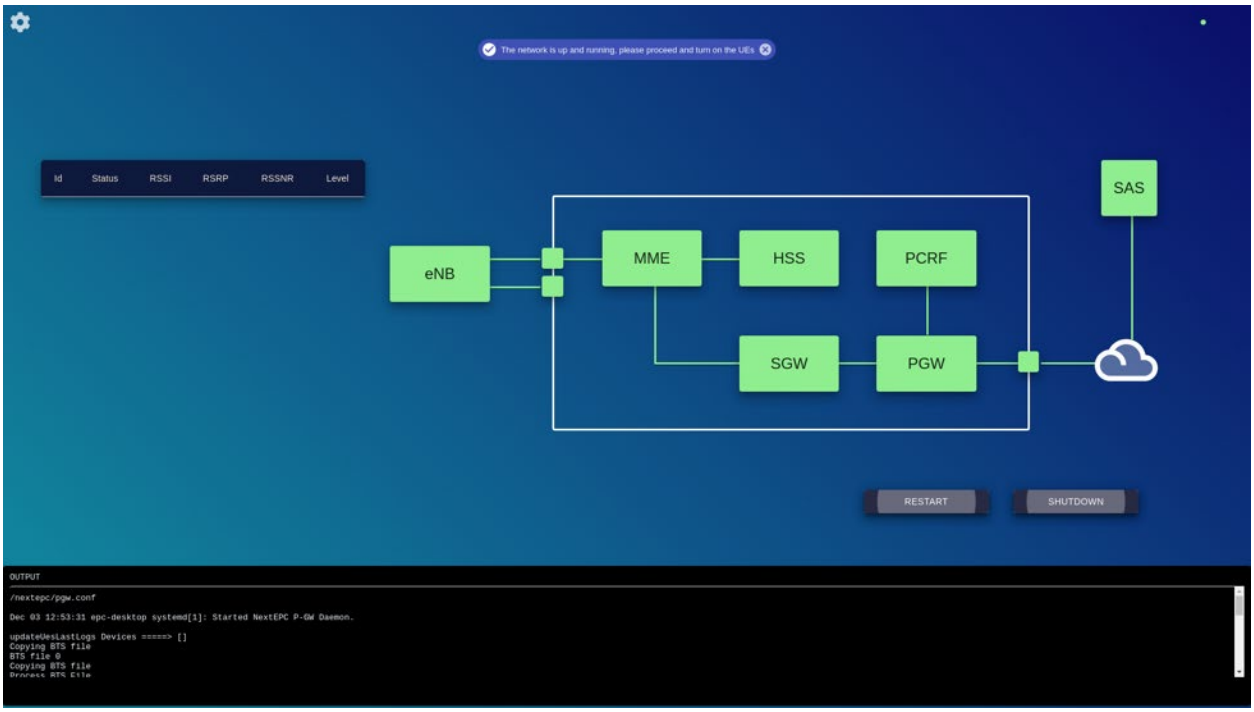

Figure 9 - The system is fully in service and eNB On-Air – user is notified that devices can be powered-on

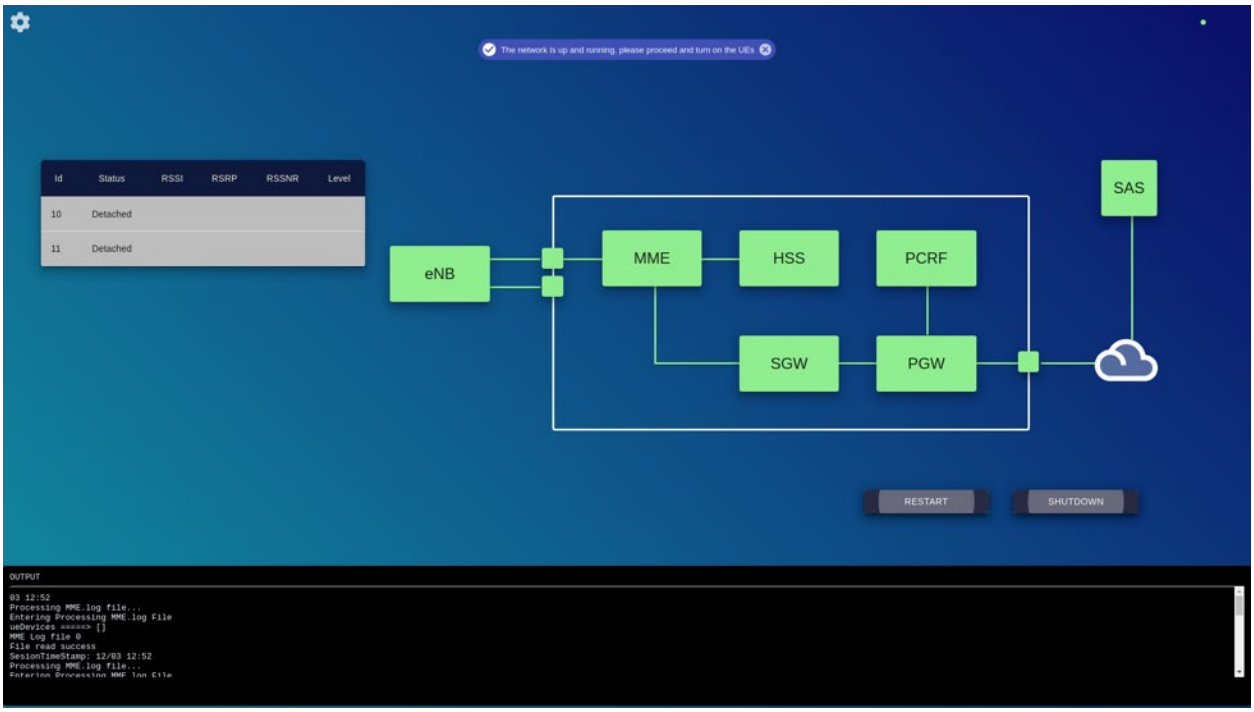

Figure 10 - After devices are powered-on, the device table is activated and device status monitored

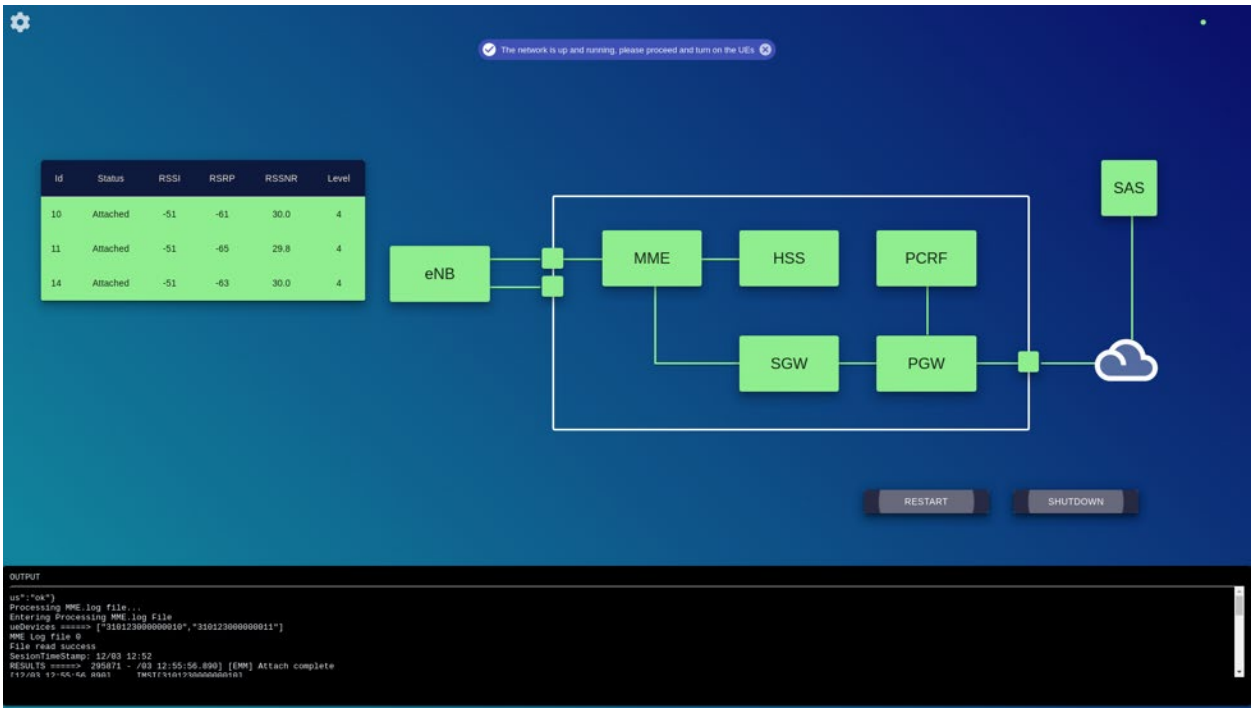

Figure 11 - The devices are successfully attached to the NIB network and the RF conditions reported and presented in the NIB portal

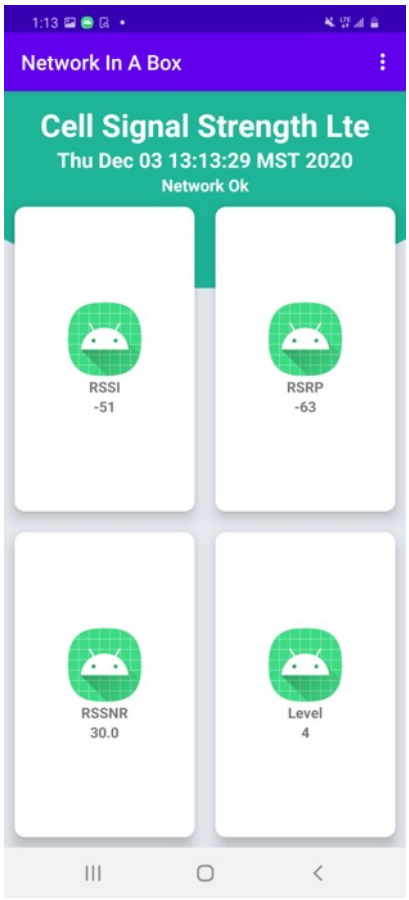

Figure 12 - Corresponding device NIB application

3.2.3. Business Logic

Three software components had to be used in this layer. The software list is ExpressJS, NodeJS and Puppetee,r and can be located into the following referenced links 3-5.

The ExpressJS was used to build a Rest API interface to serve all the HTTP requests from the Desktop Application.

Express is a Node.js web application framework that offers a comprehensive range of functionality for both web and mobile apps.

Express adds a thin layer of basic web application functionality without obscuring the Node.js capabilities users already know and appreciate.

Node.js is a scalable network application builder that uses an asynchronous event-driven JavaScript engine. Many connections can be handled at the same time in the "hello world" example below. The callback is invoked with each connection, but if there is no work to be done, Node.js will sleep.

Puppeteer is a Node library that provides a high-level API to control headless Chrome or Chromium over the DevTools Protocol. It can also be configured to use full (non-headless) Chrome or Chromium.

A headless browser is a great tool for automated testing and server environments where one does not need a visible UI shell. For example, one can run some tests against an actual web page, create a PDF of it, or inspect how the browser renders an URL.

The Chrome DevTools Protocol allows for tools to instrument, inspect, debug and profile Chromium.

3.2.4. Data Layer

The database which was used to store the data is SQLite and it can be found in the referenced link 6.

The SQLite file format is stable, cross-platform, and backwards compatible
The following information is stored in the database:

UeID: User Entity Identification
RSSI: Received Signal Strength Indicator
RSRP: Reference Signal Received Power
RSSNR: Reference Signal Signal to Noise Ratio
CQI: Channel Quality Indicator
level: Battery Level
timeStamp: Time Stamp

3.2.5. Development Strategy

It was not possible to have an environment for each developer who designs with the application.

The strategy was to create a simulator for the ENodeB as shown in Figure 13.
The ENodeB simulator was built using the ReactJS and NodeJS in the referenced links 1-2.

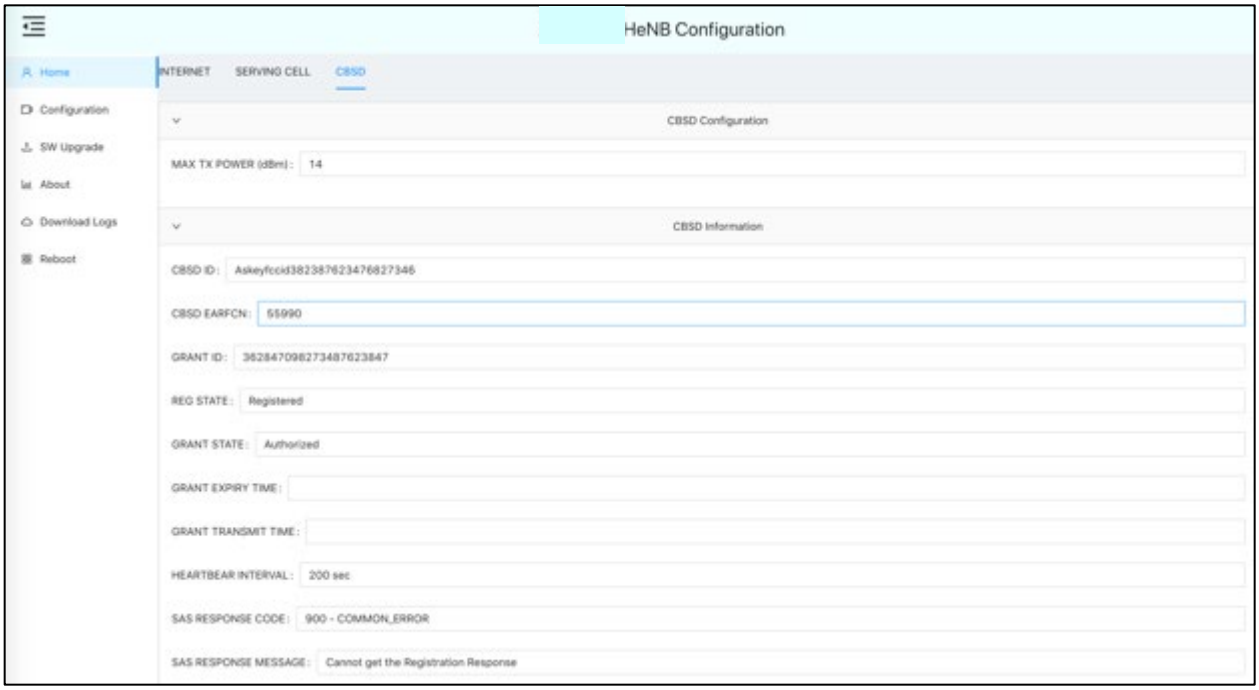

Figure 13 - eNodeB Simulator

3.2.6. Configuration Management

A Configuration had to be added for the user to be able to choose between which ENodeB is connected to the PLTE Core Network, as shown in Figure 14.

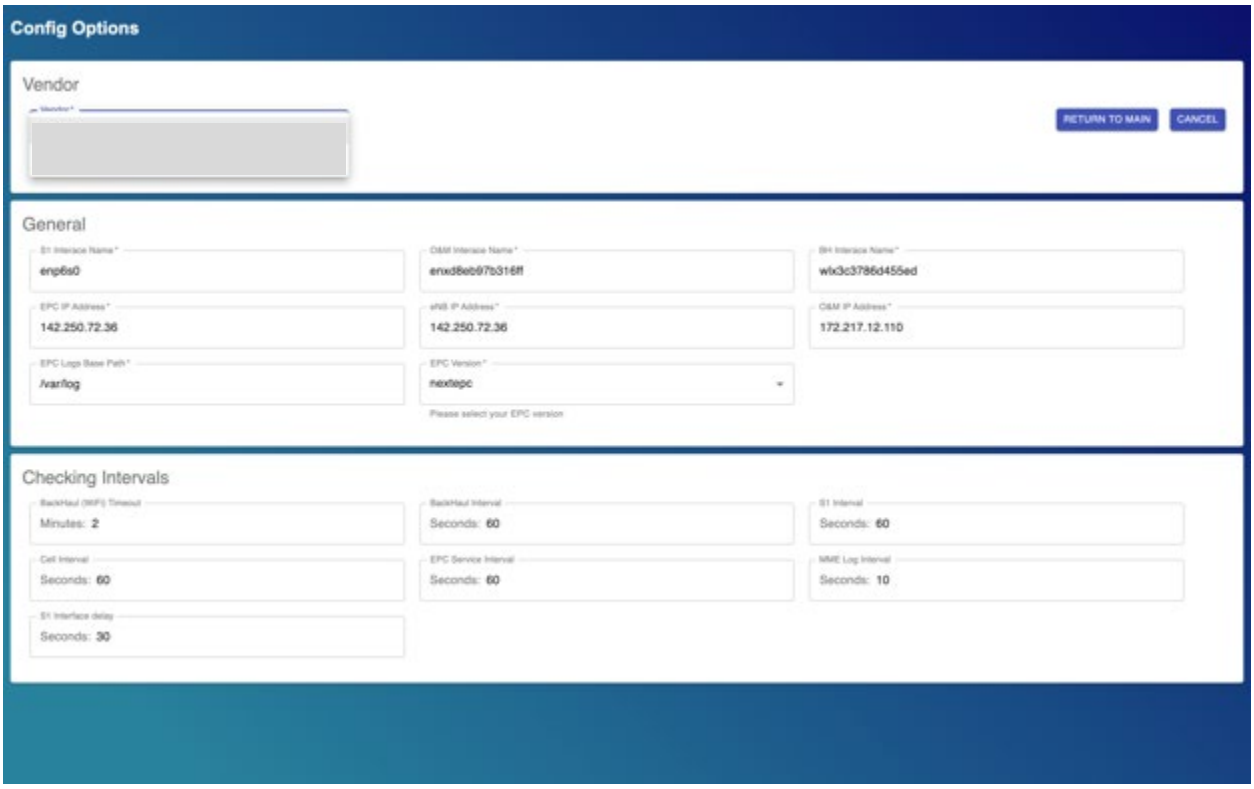

Figure 14 - Desktop Configuration

4. Mobile Edge Compute Use Case Examples

Beside generic end-user internet access, different options for MEC-based use cases were explored. The following lists two examples:

Closed Group Communication

Closed Group Communication aka 'Push To Talk/Video/Text' is an ideal communication method in an enterprise private wireless environment, e.g. factory, hotel etc... End users can be easily communicating with their respective groups (all or some at once or one-to-one), or a local PTx network dispatcher, by a push of a button. In our NIB solution, we installed a demo version the PTx server and dispatch applications in the MEC and respective PTx client application on the end-user devices.

VR (Virtual Reality) low latency applications

VR Workplace: Teleport to virtual office floor, Interact virtually with lab - machines and sensors

VR smart light control: Able the city workers to access Smart light for control and data retrieval using VR

VR Healthcare: Control instruments remotely, read patient charts

VR Industrial: Troubleshoot and analyze machine performance

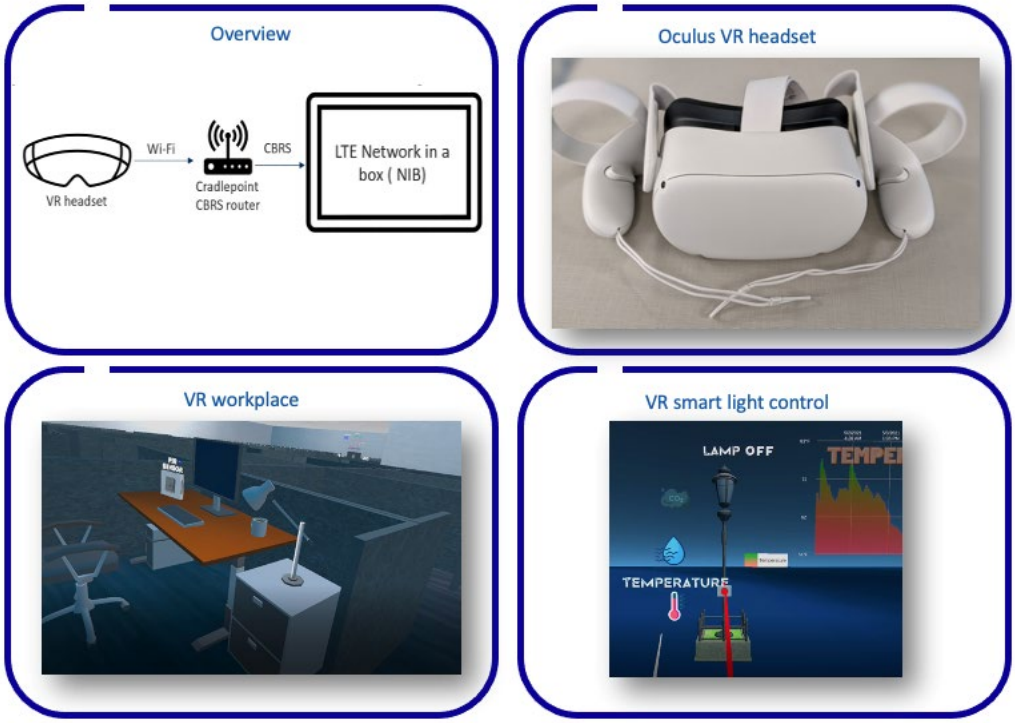

Figure 15 - VR over NIB with low latency

5. Conclusions

Network In A Box has a well-deserved reputation in the cellular industry. With the addition of 'zero touch' control and MEC in the same compute platform, the use for any users and many applications domains is opened up.

- Research and further development of NIB will continue which includes:
  - Evolve to a 5G system, e.g. 5G n48 Pico eNB and a 5G SA Core Network
  - Expand on the list of supported RAN vendors in the NIB 'zero touch' portal
  - Migrate the CN to a virtualized/containerized implementation

Abbreviations

CBRS	Citizen Broadband Radio System
CN	Core Network
COW	cell on the wheel
MEC	Mobile Edge Compute
NIB	Network In A Box
RAN	Radio Access Network
SAS	Spectrum Access System
VR	virtual reality

1. Introduction

Traditionally, a universal subscriber identity module (USIM) and roaming agreement between the serving network (visited public land mobile network (PLMN)) and home network (home PLMN) is needed in order for the user equipment (UE) to gain access to normal services (i.e., data/voice) when roaming. This type of "control" has been a long tradition used within the mobile network operators (MNO) to control which roaming network that their subscribers are authorized to gain services using 3GPP radio access technologies (RAT). With the ongoing development of 5G private network in the 3GPP ecosystem, a new service paradigm with 5G standalone architecture (5G SA) and 3GPP RAT is being created. USIM (or eSIM) are no longer the only storage mechanism for credentials when using 3GPP RAT. Onboarding can be performed locally for non-initialized UE to access the network. UE credential storage at the network side can be separated from the network that is providing the access to the users. And overall, the 5G private network can take advantage of the native support for edge computing to allow service hosting environment to be locally deployed for services with ultra-low latency and better quality of experience (QoE).

This paper first describes in a high level on how a UE obtains services with the current 4G cellular networks to contrast with the new capabilities offered with 5G private networks (also known as Stand-alone non-public network (SNPN)[1] [2]). These new capabilities defined by 3GPP 5G system architecture standards for SNPN set a course for a new service paradigm possibility for 5G private networks.

2. Services Provided By The Current Cellular Networks

Nowadays, a typical service provided by the cellular networks is mainly a best effort bit pipe connecting the UE to the external data networks (i.e., the Internet). When the bit pipe is characterized as best effort or non-guaranteed bit rate, it means that everyone shares the available bandwidth within the network and in some cases the user may exhibit congestion where the QoE became unsatisfactory.

Some services like real-time voice or public safety related services can be tailored by the network by setting the quality of service (QoS) parameters for that the bit pipe. This requires the network to be aware of at least two properties: 1) who is using the network, and 2) the type of QoS for which the user is eligible.

[1] SNPN is defined by 3GPP. Another type of 5G private network called public network integrated non-public network which is not described in this paper.

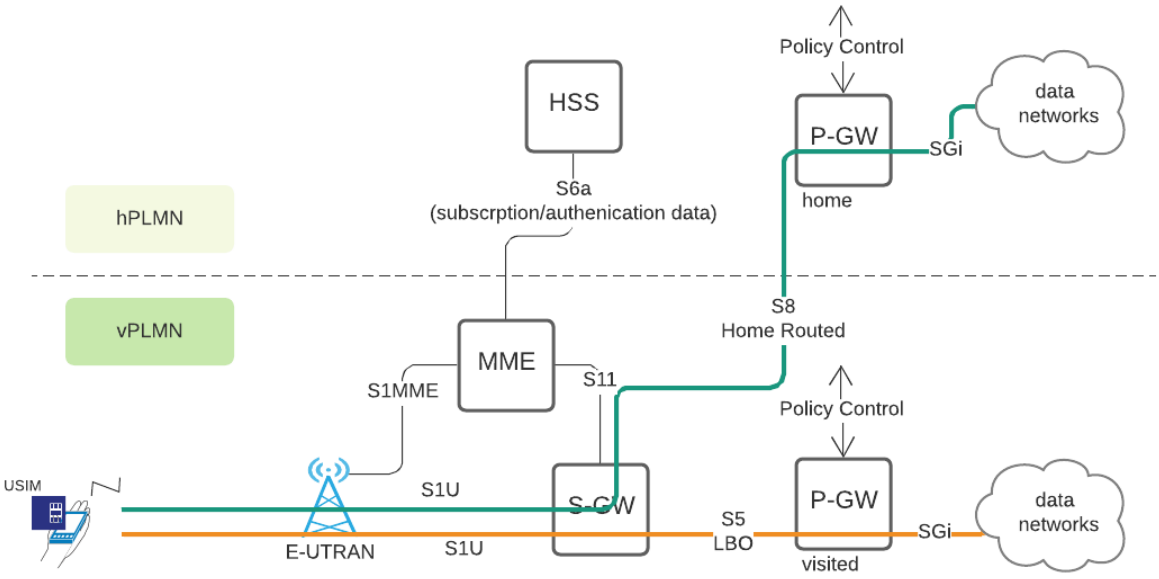

Figure 1 – Simplied EPS Architecture With Roaming Interfaces Illustrated

To determine who is using the network, a USIM with mutual authentications is used between the UE and the vPLMN. This requires the vPLMN to obtain the authentication vectors from the user's home (i.e., hPLMN) in order to perform mutual authentications with the USIM. With this requirement, a user must somehow obtain a USIM from a hPLMN before a cellular service can be rendered. In addition, a business relation (i.e., roaming relation) between vPLMN and hPLMN is needed in order to fetch the authentication vectors from hPLMN.

In the roaming example shown in figure 1, the UE has two protocol data network (PDN) connectivity services established from the vPLMN. The user's subscription in the home subscriber server (HSS) indicates that S8 home routed for internet traffic is used and local breakout (LBO) is used for e.g., voice media with IP-multimedia subsystem (IMS). Effectively, this means one user plane tunnel is breaking out locally at the vPLMN while the other is routed back to hPLMN.

The type of PDN connectivity service allowed (and their associated QoS profile) is based on user subscription data from hPLMN (but can be modified by the vPLMN if dynamic policy control is used).

The following list shows the QoS parameters related to each PDN connection:

- QoS class identifier (QCI) – a scalar that points to a set bearer level packet forwarding treatment (delay budget, packet loss, scheduling priority, etc.).
- Allocation and retention priority (ARP) – for admission related criteria during congestion with priority level (scalar), the pre-emption capability (flag) and the pre-emption vulnerability (flag).
- Guaranteed bit rate (GBR) (as oppose to the best effort).
- Maximum bit rate (MBR) – the upper limit of the bit rate that is expected to be provided by a bearer.
- Access Point Name Aggregate Maximum Bit Rate (APN-AMBR) – to limit the aggregate bit rate that can be expected to be provided across all non-GBR bearers and across all PDN connections of the APN.

- UE Aggregate Maximum Bit Rate (UE-AMBR) – to limit the aggregate bit rate that can be expected to be provided across all non-GBR bearers of a UE.

3. Why 5G Private Network Is Different?

As described in the previous section, a user who is able to obtain connectivity service in a vPLMN must first have a prior relationship with a hPLMN and that both vPLMN and hPLMN must have roaming relationship with each other in order to allow the vPLMN to authenticate the user and to obtain the subscription information for QoS settings and for user plane routing between the UE and the networks.

For 5G private networks – namely SNPN, it is neither necessary to use USIM to gain access to local access network using 3GPP RAT nor that a roaming interface is required from the SNPN in order to reach hPLMN.

3GPP SNPN [2] offers the following new capabilities which are different from technologies used for prior cellular services described in the early section.

- Subscriber identifier (SUPI) is no longer restricted to IMSI. Network access identifier (NAI) using the NAI RFC 7542 based user identification (e.g., lux_luther@phantom.zone) can be defined and used.
- Mutual authentication is no longer restricted with the shared secret stored in the USIM. Extensible authentication protocol (EAP) with TLS/TTLS can be used (e.g., certificate, username/password) as well. The credentials can be stored in the device itself as well.
- SNPN is identified with the addition of NID (Network identifier) – i.e., PLMN ID + NID. PLMN ID is not required to be unique. It the traditional cellular network, PLMN ID (i.e., MCC and MNC pair) is assigned by either ITU or regional organization like ATIS IOC (IMSI Oversight Council) and is globally unique. For SNPN using MCC with 999 [1] any MNC and also any NID can be used. Operator can also choose to use its own dedicated PLMN ID plus any self-managed NID value as deployment choice. In addition, 3GPP allows the option of using a globally unique NID value independent of the PLMN ID.
- NG-RAN may also broadcast a human-readable network name to ease the user to select SNPN. This is mainly used for manual selection based on network name awareness of the user.
- Onboarding service allows a UE without any prior relationship (i.e., no credential to access the network) to obtain the necessary authorization and credentials on demand from a local SNPN.
- Authentication vectors can be stored externally from SNPN (e.g., in an external AAA server, other UDM from 3rd party) to allow neutral hosts type of deployment.
- Accessing to hPLMN service via SNPN is also possible with untrusted access procedure over 3GPP RAT.

Please note that real time voice communication and emergency session can also be supported with SNPN toward the local PSTN.

The following figure illustrates an example of a simplified SNPN architecture.

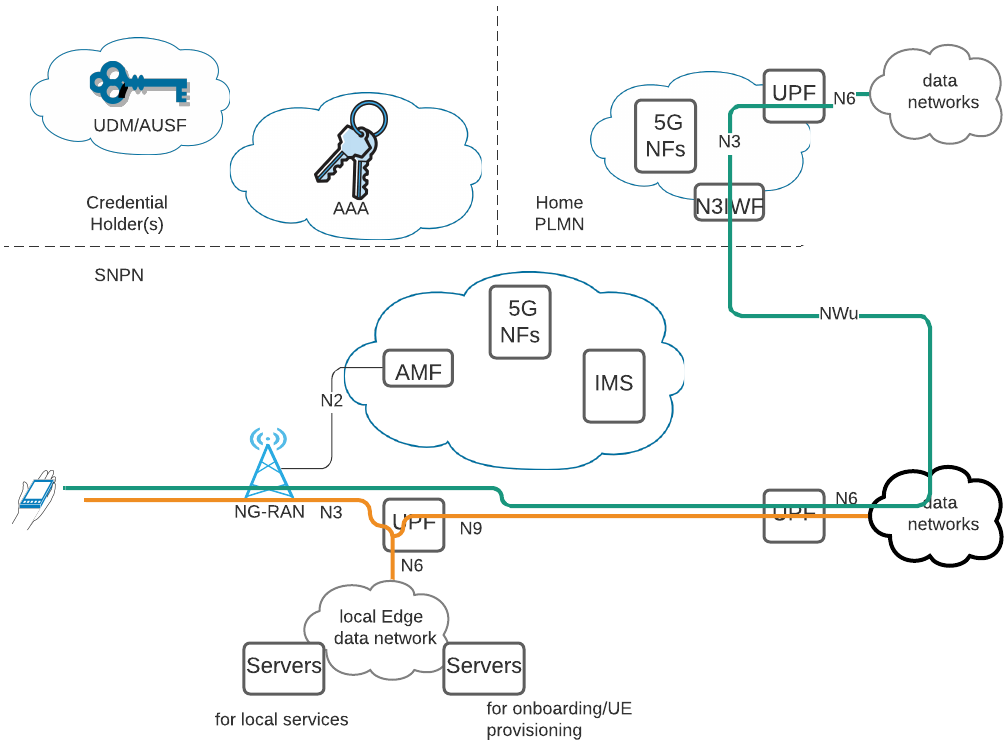

Figure 2 – Simplied SNPN Architecture With User Plane Routing For Different Services

The following section describes some of the key capabilities [2] [3] with more details using SNPN that is differed from PLMN.

3.1. UE Onboarding

Onboarding is the service to allow a non-provisioned UE to obtain SNPN credentials in order to get connectivity service from the SNPN.

The following figure shows a simplified view on how a non-initialized UE is provisioned with SNPN credentials.

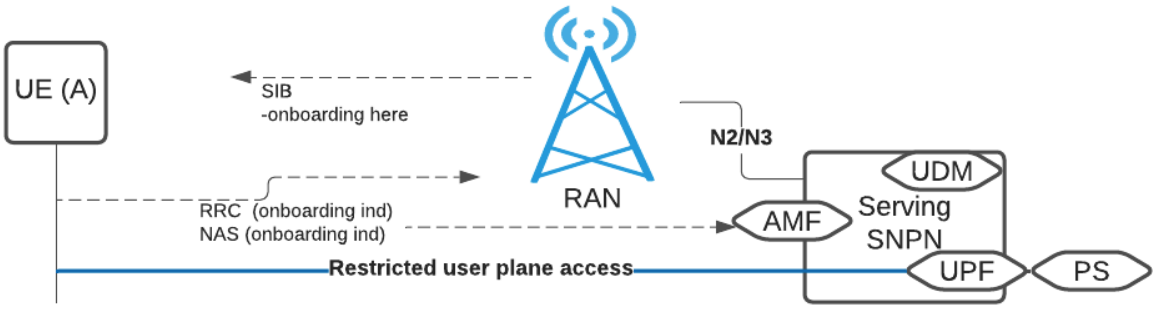

Figure 3 – Onboarding Process For A Non-initialized UE.

The SNPN which allows onboarding process will broadcast an indication at the cell level that onboarding is supported. UE, which wants to be provisioned with SNPN credentials for connectivity service from the SNPN, will signal to the network with onboarding indication in both radio resource control signaling (RRC) and non-access stratum signaling (NAS). This allows the RAN to forward this request from the UE to a dedicated onboarding access and mobility management function (AMF). AMF uses the NAS level indication to select a session management function (SMF) used for remote provisioning and to setup a restricted user data plane between the UE and the provisioning server (PS). The SMF may send the PS fully qualified domain name (FQDN) to the UE as part of protocol configuration options (PCO) in the PDU session establishment response. After PDU session is set up, the application in the UE is then interacting with the PS to obtain the SNPN credentials. The PS may request certain information from the UE/user (e.g., name, type of connectivity services requested, credit card, etc.) prior to sending the SNPN credentials to the UE. The PS may also provision the UDM with corresponding SNPN subscription data if it has not been prefilled already. The applications in the UE for handling provisioning task is out of scope of 3GPP standards and is left for OEM implementation.

Once the UE has received the SNPN credentials from the PS, it will restart and use the downloaded SNPN credential to access the network.

3.2. Access to SNPN With Credentials Owned By An Entity Separate From The SNPN

Credentials holder is defined in 3GPP [2] as an entity which authenticates and authorizes access to an SNPN separate from the credentials holder. It means that the serving SNPN does not store the credentials that can be used to authenticate/authorize the UE. This is also commonly known as neutral host offering as it allows the SNPN to provide connectivity service to the users using credentials from 3rd party.

The following simplified figure shows how a serving SNPN interacts with credential holders.

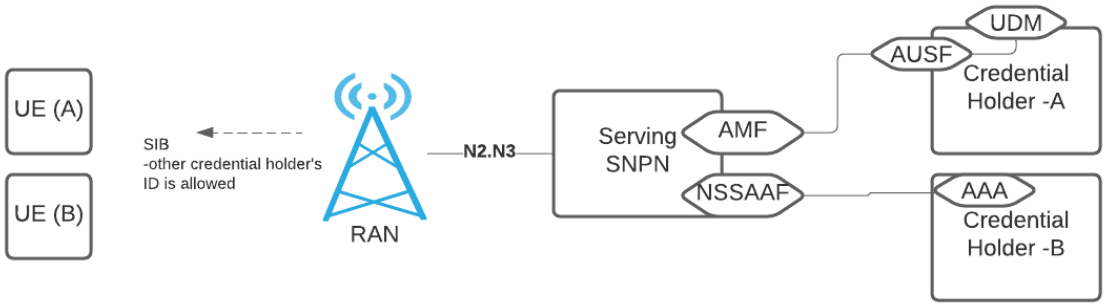

Figure 4 – SNPN Interacting With Credential Holders

The following figure shows two 5G architecture views from 3GPP TS 23.501 [2] with credentials holder and SNPN.

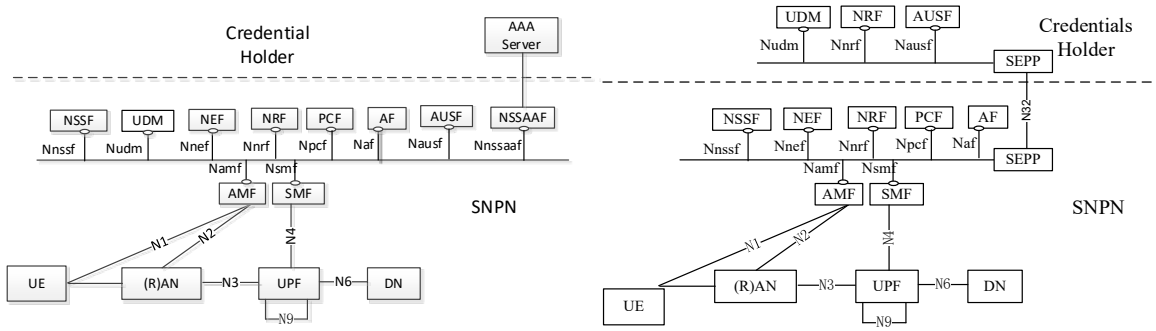

Figure 5 – SNPN and Credential Holder From 3GPP TS 23.501

Please note that from 3GPP's point of view, the architecture for SNPN and credentials holder is always depicted as a non-roaming reference architecture even though a roaming reference point (i.e., N32) is used. In this sense, the 3GPP does not support roaming for UE between SNPN and MNO.

When accessing a SNPN with credentials from 3rd party (credential holder), the UE must first check the system information block (SIB) broadcast message from the RAN to determine which 3rd party (credential holder) is supported by this SNPN. This could be in the form of a list of PLMN ID + NID or group ID (GIN) for network selection. GIN represents a group of 3rd parties using a common Network ID to minimize the broadcast list in the SIB. If the UE has been configured with a credential from one of those 3rd parties that is shown in the SIB then the UE may proceed to register to the SNPN using the 3rd party credential.

RAN may also broadcast an additional indication in the SIB to indicate that UE with any 3rd party (credential holder) information can try to access this SNPN. This type of uncontrolled access may be useful for general public usage (e.g., public access at the park, public library, etc.).

Credential holder can be from another SNPN or PLMN or from enterprise domain in the case of AAA.

If the credential information is stored in 3rd party UDM, AMF in SNPN forwards the EAP message to the AUSF of the 3rd party based on PLMN ID + NID received from the UE.

If the credential information is stored in an AAA Server in the credential holder, the authentication function (AUSF) in SNPN selects a network slice-specific and SNPN authentication and authorization function (NSSAAF) to handle the related EAP messages from the UE. The NSSAAF selects AAA server based on the domain name to the realm part of the SUPI, relays EAP messages between AUSF and AAA server (or AAA proxy) and performs related protocol conversion. The AAA server acts as the EAP server for the purpose of primary authentication. UDM is still used for storing subscription information and to decide that the primary authentication is performed by AAA or AUSF.

3.3. Accessing PLMN Services From SNPN

Interesting enough that even when 3GPP does not support roaming between SNPN and PLMN, the specification does allow a UE with dual credentials (e.g., similar to dual SIM dual standby (DSDS) or dual SIM dual active (DSDA)) to access both SNPN and PLMN services at the same time. This is particularly useful when a user wants to separate their usage between enterprise and personal domains or when the user is in a remote SNPN environments like caves or shielded factory where PLMN coverage is not available or accessible.

3GPP defines the following terms to cover this usage:

- Overlay network: When UE is accessing SNPN service via NWu using user plane established in PLMN, SNPN is the overlay network. When UE is accessing PLMN services via NWu using user plane established in SNPN, PLMN is the overlay network.
- Underlay network: When UE is accessing SNPN service via NWu using user plane established in PLMN, PLMN is the underlay network. When UE is accessing PLMN services via NWu using user plane established in SNPN, SNPN is the underlay network.

The following figure illustrate this architecture setup using hPLMN as overlay as an example. Please note that the other direction is also valid (i.e., accessing SNPN via PLMN's 3GPP RAT) but is not used here for illustration.

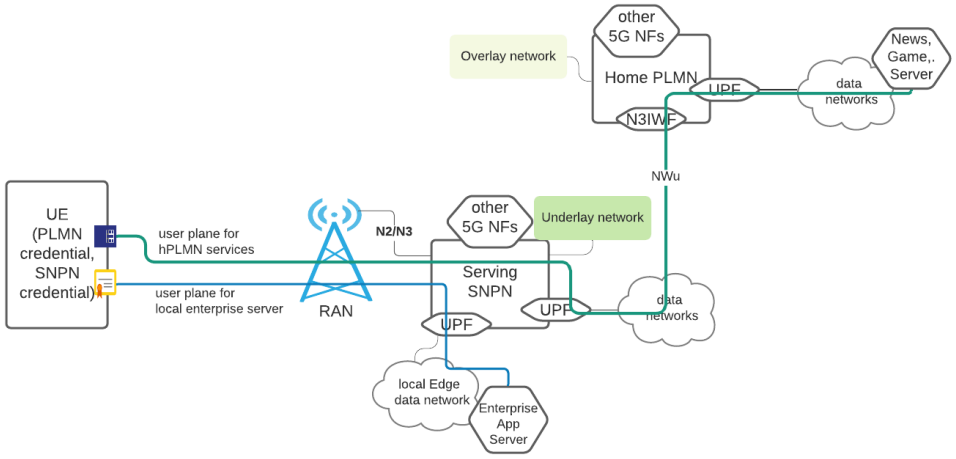

Figure 6 – Accessing HPLMN Services Via SNPN

The UE has both the SNPN credential and the PLMN credential. The enabler here is that the UE is able to use the untrusted non-3GPP access procedure over the 3GPP RAT of the SNPN in order to create a NWu

tunnel toward the hPLMN. The SNPN credential is needed in order to get access to the data network via SNPN. The PLMN credential is needed in order to access the hPLMN via the NWu tunnel.

On the SNPN side, UE maintains at least one PDU session in the network that can reach the N3IWF of the hPLMN, and UE keeps its state in CM-CONNECTED state as if the UE is using WiFi access.

From hPLMN's perspective, UE is accessing the hPLMN as if the UE is using any WiFi access even though the UE is actually using 3GPP RAT from SNPN.

When UE is moving out of the SNPN coverage and into the 3GPP radio coverage of the hPLMN, the user data session can also be transferred from SNPN to hPLMN using non-3GPP to 3GPP handover procedures as described in 3GPP specifications. In other words, when UE has detected that the radio coverage of the PLMN is sufficient, it can initiate a registration procedure to the hPLMN with an indication that an existing user plane session from NWu needs to be moved over to this 3GPP radio interface. In the figure below, the data carried via green path will be moved to blue path after this handover procedure is completed.

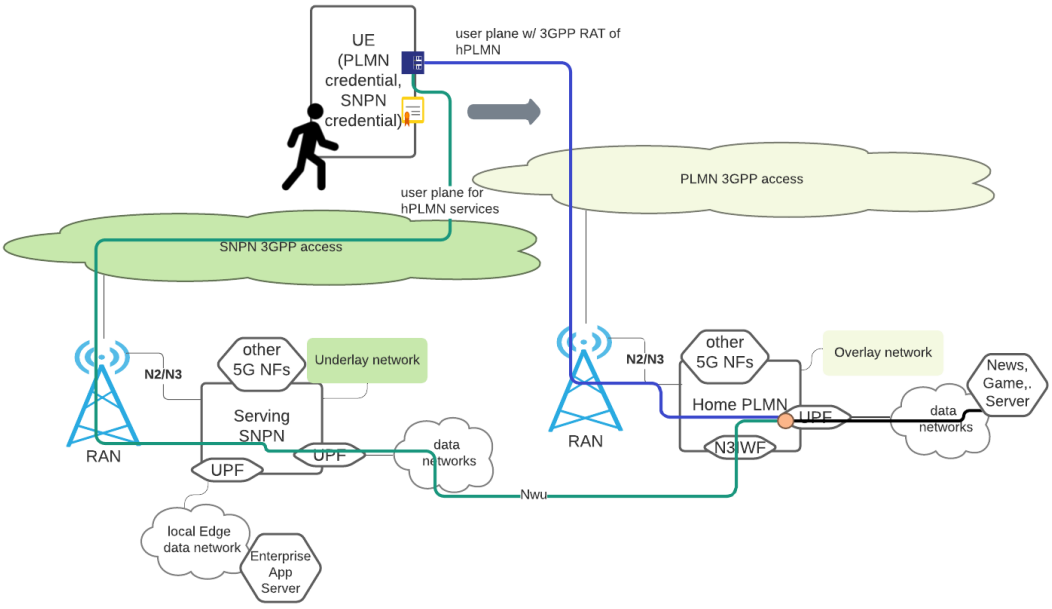

Figure 7 – Mobility Into PLMN's 3GPP RAT Coverage From SNPN

With the network based non-3GPP to 3GPP handover procedure, the data path is switched from one tunnel to another (i.e., from blue to green in the above figure). This means that even if the UE is able to maintain Rx/Tx connections to both 3GPP RATs at the same time, the UE must decide which tunnel is used for data transfer.

If the UE is bouncing between both networks then the tunnel switching will also happen each time the UE is switching between the networks. This may induce excessive network signaling procedure with the hPLMN. To minimize the signaling induced by tunnel switching with HPLMN, and to allow mobility procedure between SNPN and PLMN, a 3GPP feature called access traffic steering, switching, splitting (ATSSS) can be used. ATSSS allows the UE and the network to transfer user plane data via one or more data paths using MPTCP and/or ATSSS low-layer (ATSSS-LL). MPTCP is a protocol defined by IETF

and has been widely used in the industry already for reliable delivery via different data paths for TCP traffic. For UDP, 3GPP develops its own ATSSS-LL as IETF MP-QUIC is not yet finalized. Overall, ATSSS defines the following different steering modes to steer the traffics between two paths:

- Active-standby: One path is denoted as primary access and is always used even when the other path is available.
- Smallest delay: The path with the smallest round-trip time (RTT) is used.
- Load-balancing: Traffic is split across different paths.
- Priority-based: The primary path is used until it reaches certain congestion level in which case the other path is used.

4. Services That Can Be Offered With 5G Private Networks

3GPP in Release 18 has been studying new use cases for 5G networks providing access to localized services and identifying relevant requirements. The study takes a number of relevant aspects into consideration as depicted in a business model in Figure 8 [5]:

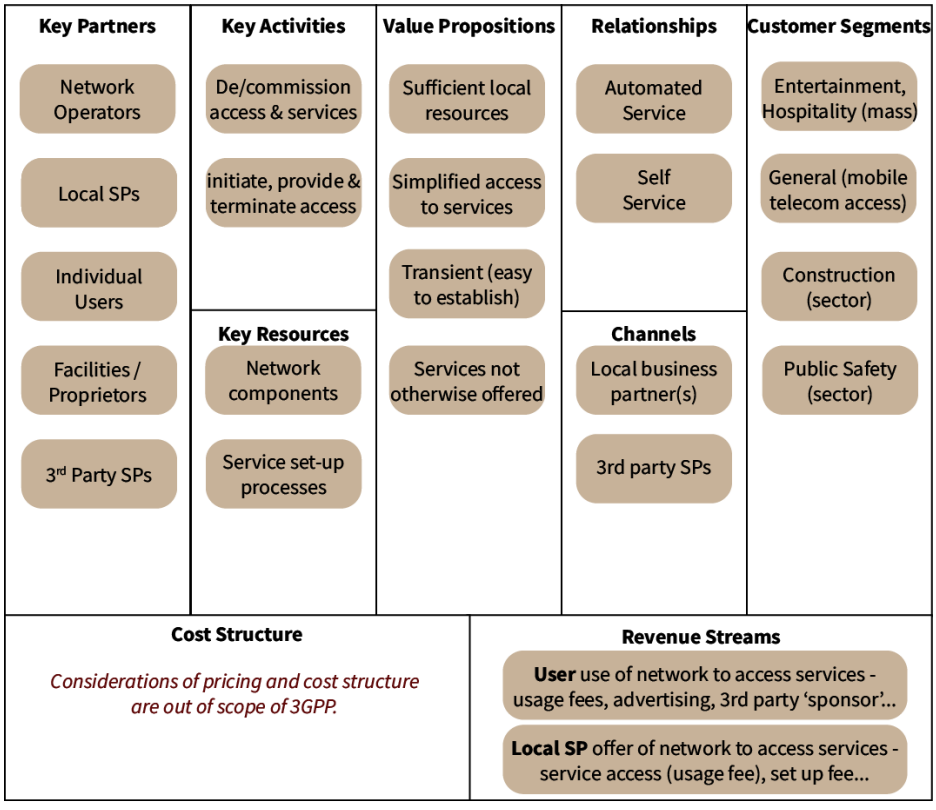

Figure 8 – Business Model For Providing Access To Localized Services

- *Key partners* may include network operators (MNOs, private network operators, MSOs, etc.), local service providers, individuals (users), owners of facilities or proprietors of businesses in which the local access network will be available, and 3rd party service providers. These stakeholders need to work together to provide local access to services.
- *Key activities* may involve how to commission/decommission access to local network and a localized services offered by any of the key partners using the local network. Since the access is local and may

be bounded in time and space, the effort to commission/decommission accesses and services needs to be aimed to be requiring short lead-time and low complexity, etc. From a user perspective, the user needs to become aware of access and local services to choose and access them. The process for the user and his/her equipment to gain access to the network, to use and terminate access and services needs to be efficient, simple and convenient. The offered resources and services cannot be accessed by any other way.

- *Value proposition* perspective providing access to local services can result in some distinct opportunities for users and service providers.
    - The access can be provided that is sufficient in areas that otherwise would lack them, for example, on a fairground established far from other infrastructure.
    - The access to local services can be simpler than access would be without this service. For example, obtaining network access may result in associated local service configuration and effortless presentation to the user.
    - The access and local services operation can be established as needed, without the need for long term business relationships such as facilities, permanently installed equipment, etc.
- In order to establish the set of business *relationships* and arrangements from the perspective of all involved key partners that could be very complex, business processes need to be automated, or at the very least available for self-service.
- *Customer segments* for localized services can be broad. The ones listed in the figure are just some sample ones.
- Two kinds of key *resources* are needed to provide access to local services:
    - Network components: The network operator needs to have or be able to make use of other operators' network infrastructure, both for mobile access and for configuration of services, authorization and other aspects.
    - Service set-up processes: A set of service set-up processes need to be in place such that the service providers (local service providers, 3rd party service providers and the network operator provided services) are able to arrange for their services to be offered via the local access.
- These local service access can be promoted and arranged through different *channels*. Principally the local service operators, such as an entertainment venue, can provide and promote information to potential users so that they can seek to access the local services. Third party service provider, such as a sports club, can also inform, motivate and prepare their users to expect local access to services in a particular place and at a particular time.
- *Cost* and *revenue* due to offering and usage of localized services can vary such that the key partners need to make necessary business agreements to get their proper share. The cost of using some localized services to users may be free-of-charge or usage-based. Some offered localized services may be sponsored, for example, by any of the key partners, advertisers, or 3rd party sponsors.

In the light of the aspects listed above, as an example for providing access to localized services, an SNPN deployed at a sporting venue may offer various services to their customers visiting the venue for a game: The offered services may be like the Internet access, real-time video or AR/3D services from various camera angles of the field (e.g., the perspective of the referee or a favorite player) that are only available to visitors at the venue. Any services in the venue may be offered by one or more key partners such as the sporting venue owner, infrastructure network provider, broadcasting agency like a TV station, 3rd party sponsor or one of the athletic clubs, etc. The visitors can be made aware of the offered services and how to get onboarded to the local access network and the localized services before or when they come the venue by one or more of the key partners. The offered services can be broadcasted by the local access network and compatible UEs can show the available services to the users; and guide the interested users for easy onboarding and then start using the services. When new services or an update to the previously

offered services become available, the visitors can be made aware via various means such as updating service broadcast at access network or via a venue application, etc. While some or all services offered might be free-of-charge or usage-based to the users. The service provider may generate advertising revenue by offering advertising services to 3rd party companies while users rendering localized services.

5. Standards Development For 5G Private Networks

Standardization work for 5G private networks (i.e., SNPN) was started from 3GPP Rel 16 using 5G standalone architecture as the baseline. The development has continued in Rel 17 [3] with more capabilities and features. Currently, the industries are discussing further possible enhancements in Rel 18 [4] [5] [6].

Rel 16 was frozen at June 2020. Rel 17 is currently under development and is scheduled to be frozen by March 2022. R18 has already been started with new requirements gathering by 3GPP SA1 since the end of 2020 and most likely that the freeze date for Rel 18 will be by the end of 2023 or early 2024.

The following figure shows some of the key features related to 5G private networks per 3GPP release cycle under the umbrella of the system architecture group (3GPP SA). Rel 18 content is only at the initial phase of the development; hence, it is a best guess from the authors of this paper.

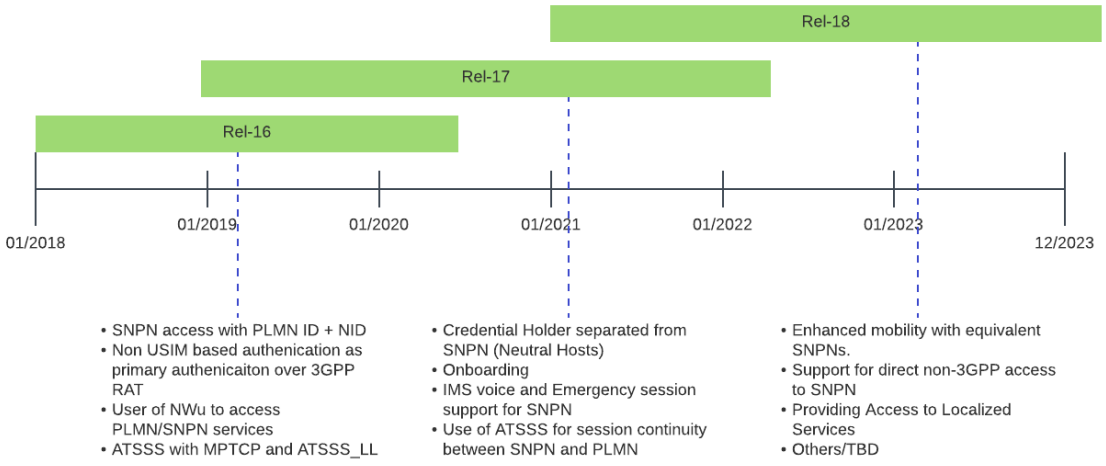

Figure 9 – SNPN Related Feature Per 3GPP Release

In 3GPP Release 18, in addition to providing access to localized services studied in [5], other potential Rel 18 features are aiming for better mobility experience. Enhanced mobility with equivalent SNPNs, allows a UE with subscription for one of the SNPNs has access to its all equivalent SNPN(s), similar to how equivalent (h)PLMNs work today. 5G system architecture can already support non 3GPP access like Wi-Fi or fixed broadband access. The SNPN feature has so far been focusing on using 3GPP RAT due to time pressure, however documenting the support for SNPN for non-3GPP access will make the standards specifications to be more holistic.

6. Conclusion

The new capabilities available for 5G private networks (i.e., SNPN) open a new realm of service possibilities that was previously not available with 4G systems based on evolved packet core (EPC). The on-demand credential provisioning with onboarding feature, the adoption of using network access identifier (NAI) for user identity and EAP with TLS/TTLS, flexible network ID assignment (PLMN ID + NID), and neutral host offering are some of the features that make 5G private network unique from any of the previous 3GPP systems, and this allows much wider applicability of using 3GPP eco-system with 3GPP RAT and non-3GPP RATs (WiFi, fixed-broadband access) for new service creation.

Abbreviations

3GPP	3rd Generation Partnership Project
AAA	authentication, authorization, accounting
AMF	access and mobility management function
ATIS	Alliance for Telecommunication Industry Solutions
ATSSS	access traffic steering, switching and splitting
ATSSS-LL	ATSSS low-layer
AUSF	authentication server function
CH	credentials holder

Node Health Within Cox ACOE's Service Health Framework

Improve the Health and Quality of HFC Services through Predictive Analytics

1. Introduction

The Service Health framework is a suite of analytic models designed to predict and prevent customer impacting issues, while improving overall service quality. While this framework includes a multitude of Network, Customer, Premise, etc. focused components, this project and abstract are focused on Node Health and improving the effectiveness of the workforce that operates the HFC network, the Field Network Technician (FNT).

The FNT group is responsible for responding to all network impacting events, restoring customers' services, and performing proactive network maintenance to prevent issues before they occur. Previously, this work was created through a combination of rules-based telemetry processing and manually generated events. While this approach provided insight into clear rules violations regarding customer service availability, performance, and utilization, it was both limited in its ability to find novel patterns impacting customers and in its effectiveness with prioritizing work based on the potential impact to customers.

However, through the Node Health Framework, Cox can analyze thousands of combinations and permutations of RF patterns that may impact customer's services now and into the future. Additionally, this framework uses the predicted impact to prioritize work, both daily at a macro-level and hourly at a micro-level. As a result, FNTs have increased the volume of proactive network maintenance, prevented thousands of customer impacting events, reduced transactions to record low levels (note: Cox has attributed a 10%-15% reduction in transactions from the Node Health initiatives), and radically improved customer service quality.

2. History

Network Health is an initiative with roots going back to 2015 within Cox Communications. This started as a KPI-driven initiative to measure the health of the HFC network. The ultimate output of the early initiative was a measurement system called OSP7 (pictured below).

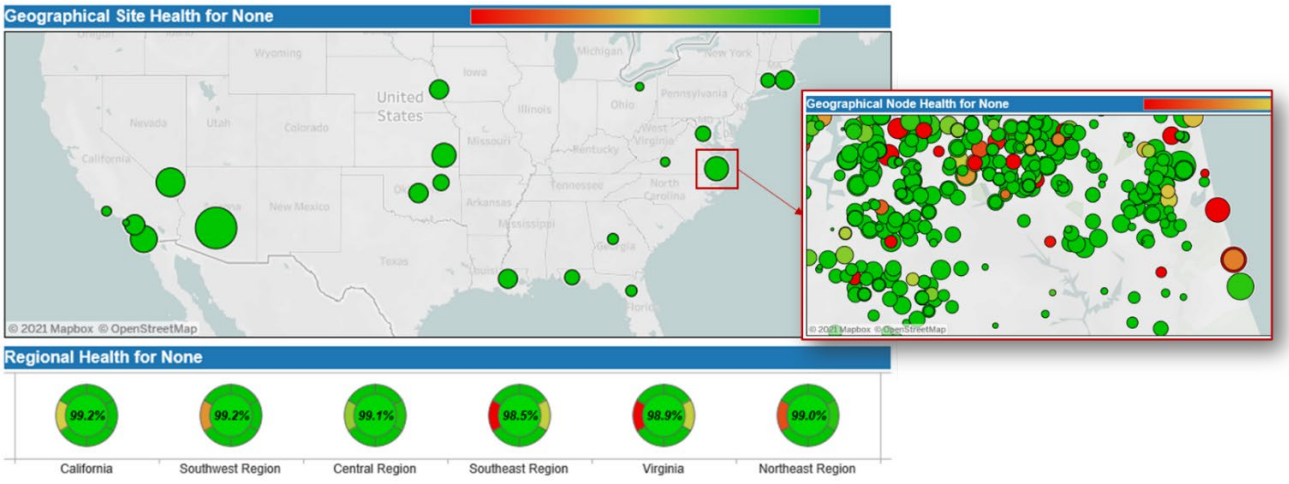

Figure 1 – OSP7 Measurement System

This measurement system began as a preliminary set of KPIs that measured a wide array of metrics, 35 to be specific, which ranged from operational performance to technician throughput/effectiveness.

However, the analytics team believed there was room for improvement, so they put these KPIs through the two-factor test below:

1. Does this metric correlate with operational processes and practices? Or to put this more simply, can the Field Network Technician (FNT) organization successfully influence the metric either positively or negatively?
2. Does the metric correlate with business and financial objectives?

As a result of this two-factor test they created the OSP7 (or Outside Plant 7), which contained the 7 metrics represented below that correlated best with both FNT labor processes and business/financial objectives. The table below represents the first draft of the OSP7 program:

Table 1 – OSP7 Program Metrics

	Metric	Description	Spec
1	**DS RX (Downstream Receive)**	Downstream Power-level at the Customer modem within Docsis Spec	-12dB to +15
2	**US TX (Upstream Transmit)**	Upstream Power-level at the Customer modem within Docsis Spec	+30dB to +52
3	**DS SNR (Downstream Signal to Noise)**	Downstream SNR ration at the Customer modem within Docsis Spec	>+32 dB
4	**US SNR (Upstream Signal to Noise)**	Upstream SNR ration at the Customer modem within Docsis Spec	>+30 dB
5	**DS FEC (Downstream Forward Error Correction)**	Downstream packet loss at the Customer modem	<1% packet loss
6	**US FEC (Upstream Forward Error Correction)**	Upstream packet loss at the Customer modem	<1% packet loss
7	**Aggregate Health**	The combined score between all metrics	n/a

Within this program, the magic was not derived from the KPIs themselves, but rather from the user's ability to navigate the map (pictured above) and quickly identify problematic areas that required more focus from the FNT team. The FNT was now able to make decisions based on analytical modeling (i.e. what is healthy in green and unhealthy in red) provided to them using simple visualization principles. As a result, Cox experienced a substantial improvement in overall network performance (~1% improvement to OSP7 over 2 years associated with this work) and a corresponding drop in transactions (~5% reduction to Tech Support calls and UHT truck rolls). This reduction was calculated using several controlled experiments, where we measured improvements at the node, headend, and market/site level vs. control groups to validate and quantify the effect with precision.

3. Service Health Framework

As the organization matured, there was a clear need to evolve the space of analytics. As a result, Cox announced the formation of the Analytics Center of Excellence (ACOE) in 2017, which centralized all analytics teams across Cox's Technology and Operations organizations. With the formation of this new team, the ACOE launched new advanced analytical capabilities focused on the health and quality of the customers' services. This led to the creation of the Service Health Framework.

The Service Health Framework is based on three principles:

1. Most customer-impacting events can be predicted
2. Customer-impacting events are complex but unique and identifiable
3. We can shift from the customer as a diagnostic to prediction as a diagnostic

Additionally, there are four key focus areas that shape the framework:

1. Deep understanding of data that describes quality and use of service by our customers
2. Ability to predict future service impacts and mitigate or prevent them
3. Machines executing the right actions to take, at scale
4. Continuous learning capabilities to improve over time

From the intersection of these principles and focus areas, the ACOE designed the following structure to define the Service Health framework:

- **Node Health**: Predict, isolate, and prevent any customer experience issues at the node level
- **Location Health**: Predict home/business wiring, device, Wi-Fi customer experience issues
- **Usage Health**: Understand customer experience impact based on individual customer usage and behavior
- **Interaction Health**: Link human conversation to Service Health root cause

4. Node Health

As the Service Health framework launched, the previous foundations of network health, outlined in the history above, were used to quickly advance the overall framework. In particular, the lessons learned from using the OSP7 methodology/dashboard on how to direct labor, became an essential component for how Cox's ACOE developed the Node Health component of the Service Health framework. To help frame this up, the ACOE developed three pillars as the core to the Node Health concept:

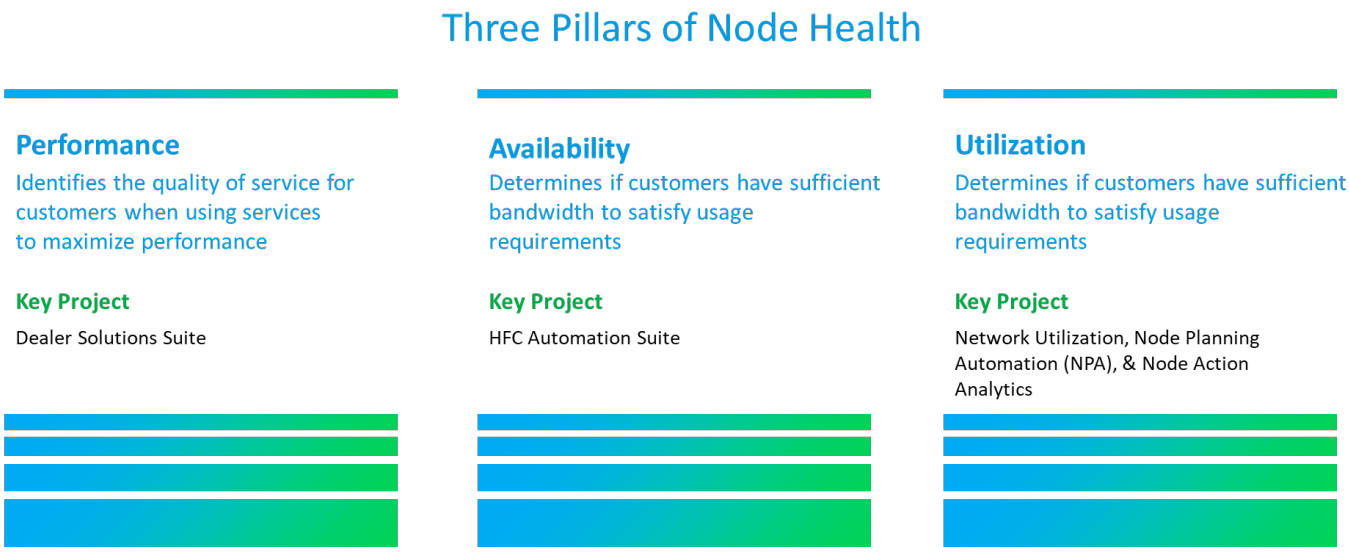

Figure 2 – Three Pillars of Node Health

These three pillars are the backbone of the Node Health framework and contain a suite of projects that seek to predict problems before customers recognize issues and prevent unnecessary transactions. Projects within these pillars span from predictive analytics, proactive customer resolution, and real-time root cause analysis. To dig a little deeper, there are six overarching projects that will deliver the core of the value within the Node Health framework.

These projects are described in the diagram below:

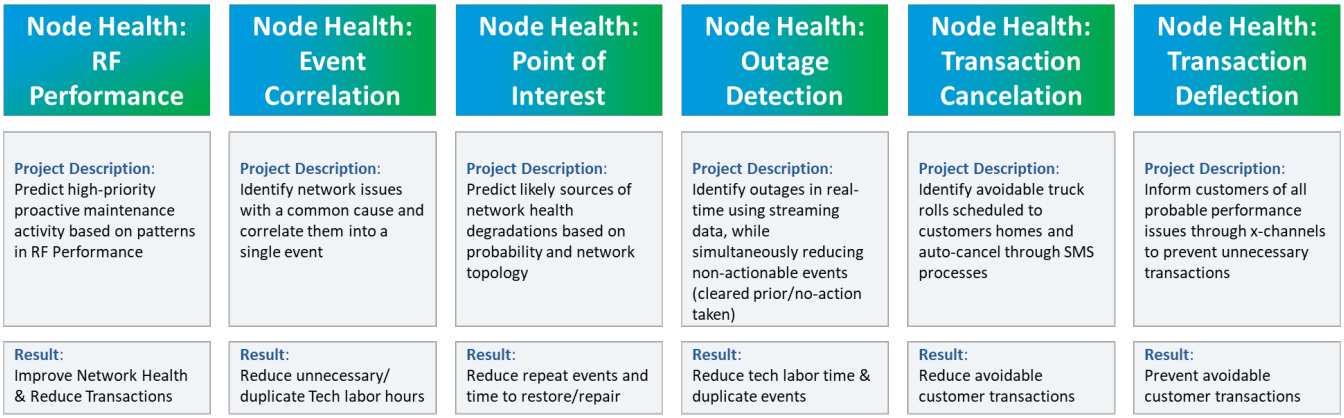

Figure 3 – Node Health Projects

The first program, titled "Node Health: RF Performance", is a proactive network maintenance model that takes in data from a multitude of sources and makes a prediction about the most impactful work that a technician can perform. Specifically, the model makes a prediction about the impact/value of performing work in every HFC node by creating patters based on historical node performance and the response/improvement those patterns recognized following proactive maintenance. Following this

prediction, the model then stack ranks those nodes based on the calculated value and routes the work according to priority to ensure the most impactful work is driven to the top priority. To make these predictions, we use the following suite of models listed below. One component left out of the diagram below is the continuous learning component of the model, which continues to learn how RF impairment patterns are impacted by proactive network maintenance activity to retrain and optimize the model.:

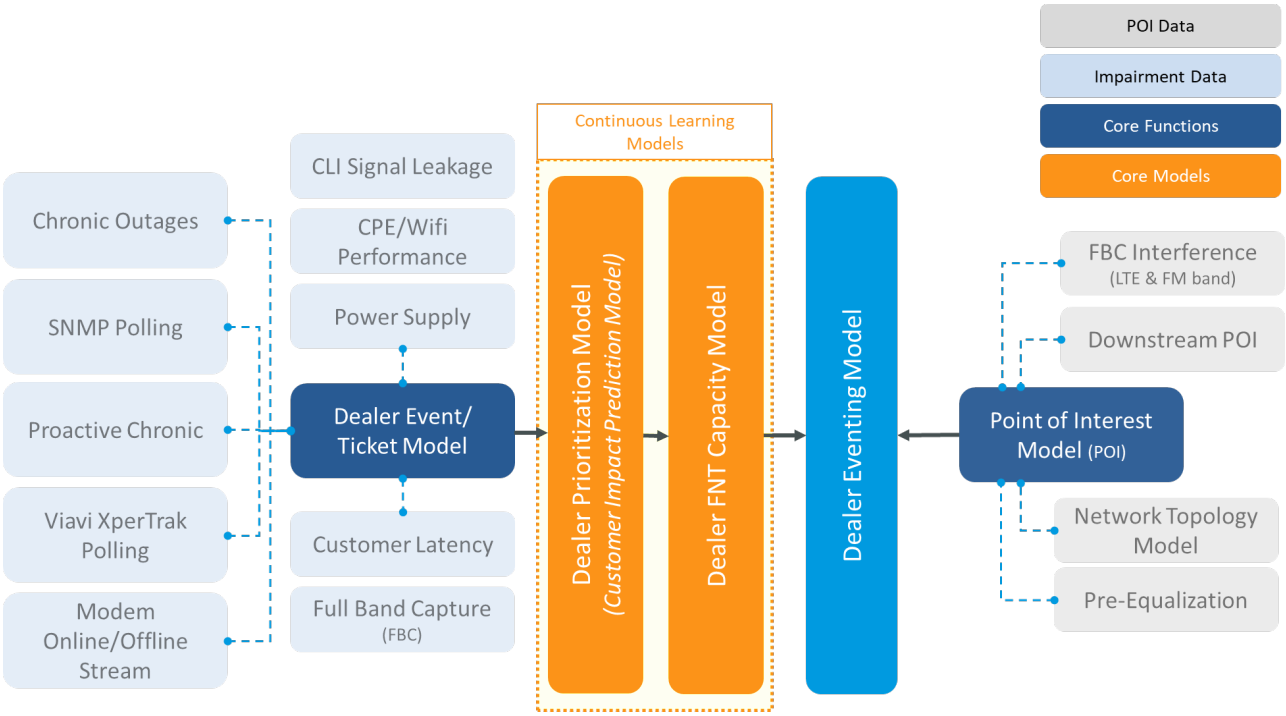

Figure 4 – Node Health Models

5. How Does Node Health RF Work?

5.1. Overview

Node Health RF Performance is a proactive platform for identifying areas of the network with recurring, intermittent and service affecting issues in order to optimize the use of Field Network Technicians' (FNT) time and labor before customers recognize an issue. With the introduction of Node Health RF Performance, Cox moves away from leveraging our customers as a primary diagnostic to leveraging machine learning models and their predictions as a primary diagnostic.

5.2. BAU Process (Previous Approach)

Before Node Health, our journey started with a customer calling in an issue. The customer in this case is uninformed throughout the entire process. Painfully, our technicians and care agents also have no visibility into the status of the issue. As a result of this reactive process, most operators have a difficult time enabling technicians or leveraging enhanced tooling to monitor and respond to the network events. Furthermore, managing customer interactions during the process is quite challenging as none of the various channels (web, app, phone, etc.) have visibility to these impairments. Below is a diagram outlining a recent example:

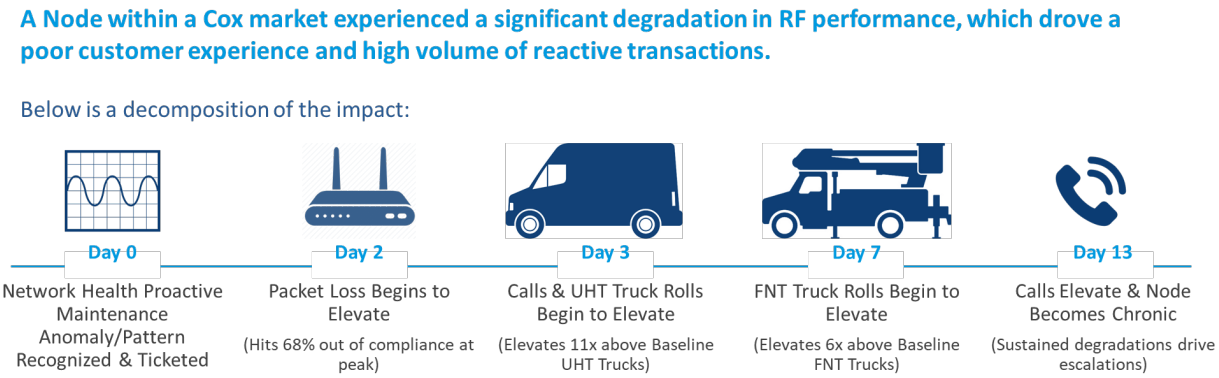

Figure 5 – Decomposition of the Impact of a Degradation RF performance Node

5.3. Problem Statement

Data shows a strong correlation between the amount of labor devoted to proactive maintenance event and the overall improvement in the health of the network (see diagram below, which depicts the correlation between proactive maintenance and network health). When network health is low, we see more outages, which leads to additional reactive work. However, the key challenge is how to prioritize this maintenance activity in a way that it can prevent the most transactions and can best improve customer experience. There are more proactive impairments to troubleshoot than there are technician labor hours in each week/month. As a result, much of the existing reactive work, both multi-customer outages and single-customer escalations, could be prevented if Cox successfully predicts which ***X*** impairments were the most critical and demanded work within ***Y*** days/hours.

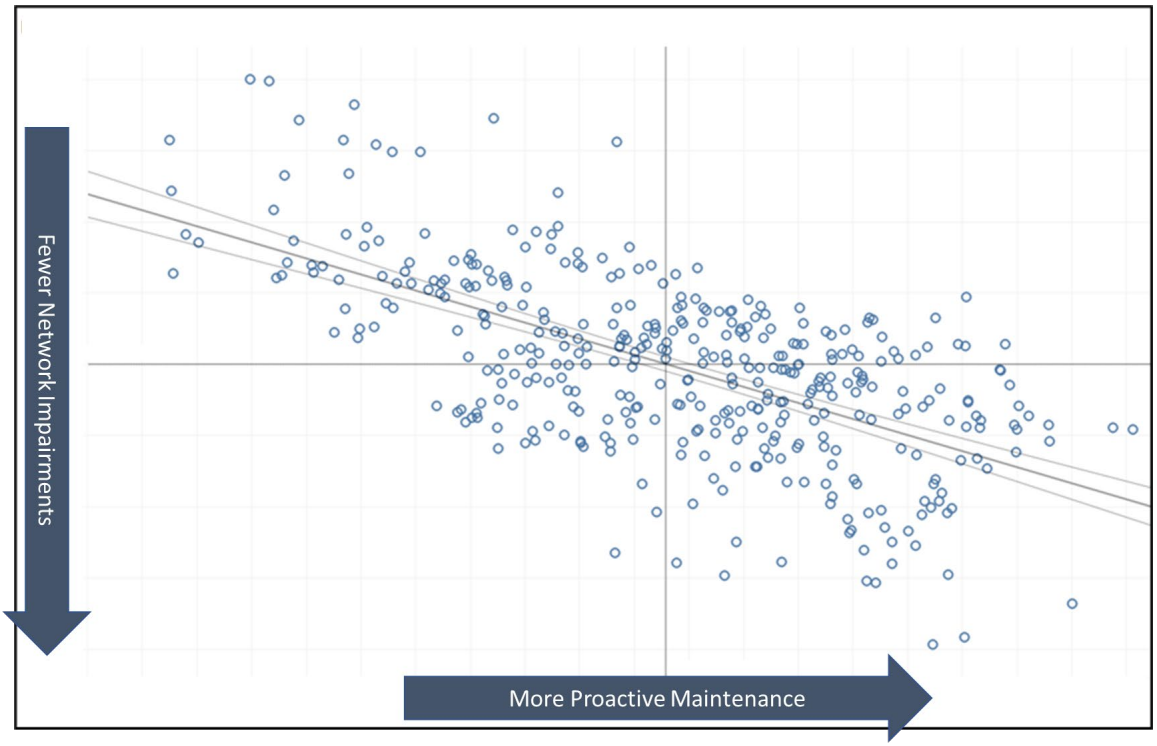

Figure 6 – Correlation Study betweeen Proactive Maintenance and Node Health

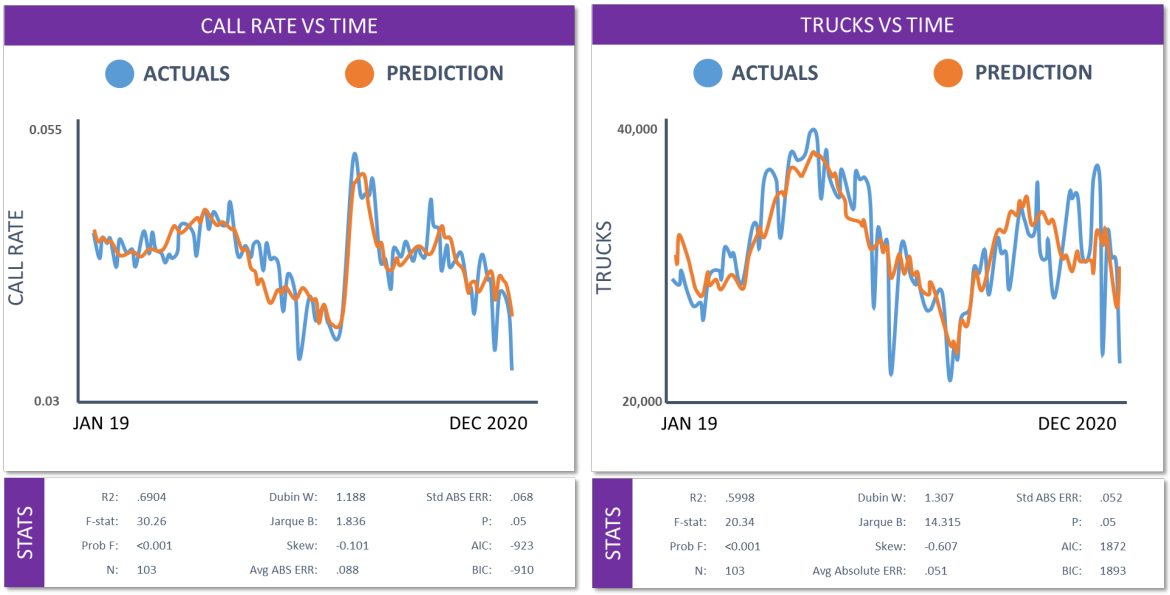

Figure 7 – Correlation with Node Health and Transactions

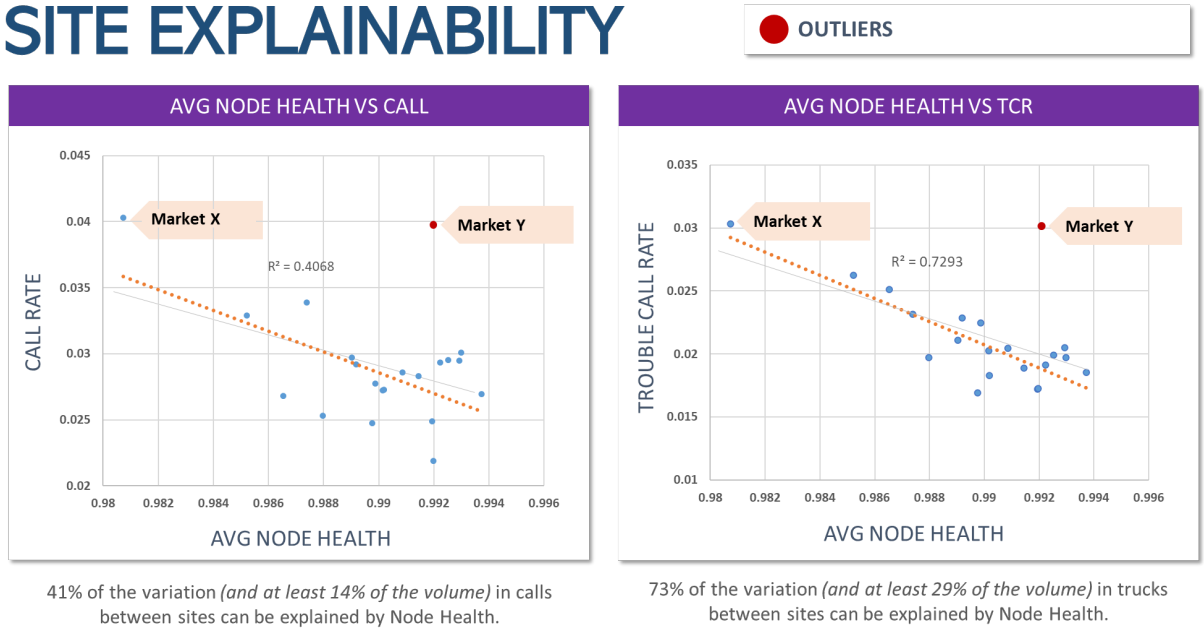

Figure 8 – Relationship between Node Health and market-level transaction level/variation

5.4. Solution Proposal

Cox uses a multitude of network and customer premise equipment (CPE) telemetry when identifying an issue. Specifically, they use the combination of sources highlighted in the diagram above, which retrieves the RF (Radio Frequency Signal data) and impairment metrics for multiple customer and network devices. By leveraging RF signal data and impairment data, devices with statistically similar patterns can be grouped together to act as an indicator of an issue on the network. Also, by leveraging real-time signal level and the frequency of occurrence of rapidly changing patterns, we can predict a time of day when the issue is present, which allows a technician to isolate the issue and find regular/irregular patterns in signal.

As a part of the capacity model, Cox also predicts the daily volume of reactive tickets to identify the volume of available labor hours/technicians grouped by their skills and schedules. Specifically, this model allows the Field Network Technician (FNT) team to receive a volume of proactive network maintenance work that meet the available capacity.

Finally, Node Health RF Performance ensemble models proactively creates a prioritized list of events/tickets that identify nodes with recurring/intermittent issue or continuous issue. This list of events/tickets is then routed based on priority and available technician capacity, which is performed daily (note: this process can run every 15 minutes but is currently running daily in accordance with existing processes). As a result, we can recast the diagram above with the following remediation and response:

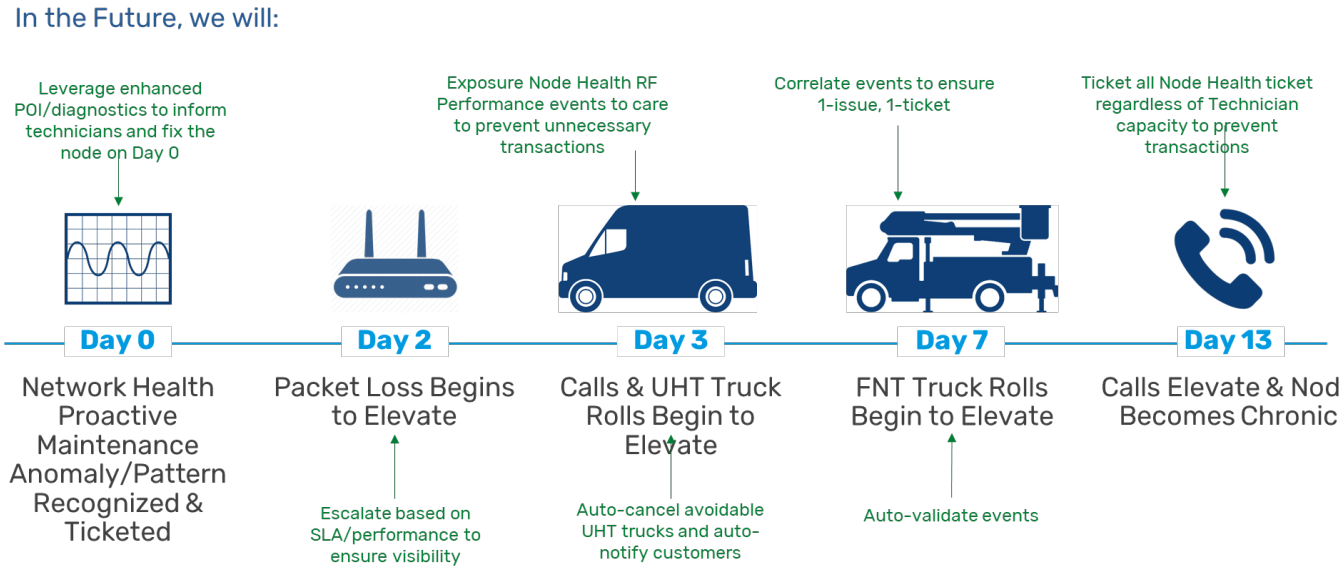

Figure 9 – Model of improved customer interactions post-Node Health models

5.5. Conclusion and Business Impact

The Node Health RF Performance application has been a significant driver in reducing the number of service-affecting events, multi-customer disruptions, and single-customer escalations. This has reduced unnecessary transactions, prevented customer service disruptions, and improved customer experience. Additionally, these capabilities have not only made technicians more efficient and effective, but they have also enabled next-generation communication with customers, allowing Cox to inform on potential issues and preemptively perform maintenance on parts of the network that are predicted to degrade. As a result of these ensemble models, Cox has experienced a ***5%*** reduction to Tech Support calls and in-home technician Service Call Truck Rolls.

6. Putting the Model into Action: AWS Cloud Architecture

The ACOE team used Amazon Web Services (AWS) as the primary cloud vendor for hosting this new technology. The following architecture diagram shows, generally, the services used by the Node Health RF Performance program.

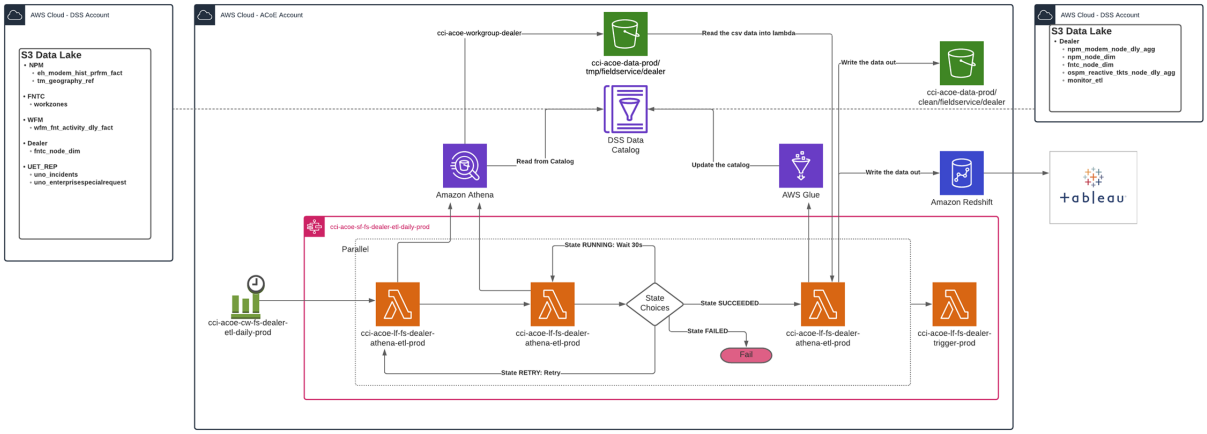

Figure 10 – Cloud-based Node Health architecture

When selecting to use a cloud partner, the ACOE had five primary considerations:

1. Scale: How do we scale our infrastructure easily when new projects/programs are approved?
2. Rapid Development: How do we get from ideation to production more quickly?
3. Next-Generation Capabilities: What platform gives Cox's ACOE capabilities that are multiple generations beyond existing tools?
4. Talent: What platform allows Cox's AOCE team to recruit and retain the best talent in the marketplace?
5. Future-Proof: What platform hardens our environment to ensure it is not obsolete in 2-5 years?

Moreover, the above architecture, which leverages Lamda, Athena, S3, Redshift, and Glue were selected for the following reasons:

- The overall cost of this pattern was the most cost effective model at the time
    - We don't need always-on database service since Node Health runs in batches periodically during the day rather than all of the time
    - The primary data sources were already in an S3 data lake
    - The tables are partitioned well such that we don't incur unnecessary cost when using the Athena service which charges by the GB scanned
- This pattern does not require ongoing maintenance of a database cluster
- The skills and experience required to create and manage Lambda functions are better aligned with the skills of our Data Scientists and Analysts over management of an EC2 instance.
- The Dealer application ETLs run (at the most frequent) once per hour and we did not want to incur the added time and money cost of turning up and down an EMR cluster (or EC2 Instance) or leaving one active
- Athena is a very fast service for its cost

7. Further Discussion

While this white paper focused on components of Node Health within the Cox ACOE Service Health framework, in future sessions we can focus on additional components of both Node Health and Service

Health. Areas of further discussion on Node Health that may be of interest and that are only briefly touched on in this whitepaper include:

- **Advanced event correlation**: How to improve grouping and correlation of related events based on predictive models and real-time root-cause analysis (RCA)
- **Point of interest (POI)**: How to predict potential drivers of problems within the node to reduce technician time to restore services and prevent repeat/unnecessary transactions
- **Outage detection**: How to reduce non-actionable events (i.e. often coded off as no-problem found/cleared prior), improve detection of true outages, and reduce the time to restore customers services using predictive analytics
- **Transaction cancelation**: How to cancel and prevent in-flight transactions using multiple models making predictions about customers' services and creating a dynamic interaction with the customer through SMS messaging
- **Transaction deflection**: How to improve predictions about service issues impacting customers and enrich the interaction through multiple channels to inform and educate the customer regarding restore/repair

These additional five projects augment the Node Health RF Performance project and add additional features that further improve the health of the network, reduce operating expense, and improve customer experience. Notably, these additional programs will reduce Tech Support calls and Service Call Truck Rolls (i.e. in-home technicians) by an incremental ***5%-10%***.

1. Introduction

Upstream DOCSIS® carriers use predistortion data to cancel linear distortion. Equalization is a required step in a digital transmission system to remove linear distortion. In continuous DOCSIS downstream transmissions the equalization is done in the cable modem (CM) receiver, but in DOCSIS upstream the burst transmissions are pre-distorted by the CM so that they arrive at the cable modem termination system (CMTS) receiver with linear distortion removed. The predistortion is adjusted during a periodic process called ranging, which occurs about every 20 to 30 seconds.

An analogy for predistortion is corrective eyeglasses, which custom pre-distort an image so that it arrives on a wearer's retina in focus. An optometrist can measure lenses and determine what visual impairments are being corrected, such as myopia or astigmatism. Likewise, upstream predistortion can be analyzed to determine what linear distortion impairments are being cancelled, such as echoes, group delay, tilt, suck-outs, filters, etc.

DOCSIS 3.0 single carrier upstream equalization data has been mined for over 10 years to provide troubleshooting information about plant impairments. Now both DOCSIS 3.1 upstream orthogonal frequency division multiple access (OFDMA) multicarrier equalization and downstream orthogonal frequency division multiplexing (OFDM) multicarrier channel estimation data are available from CMs using management information base (MIB) objects. OFDMA is being used mostly in mid- and high-split cable plant because of spectrum availability. OFDM and OFDMA multicarrier data should be more valuable than single frequency carrier data because of a much wider potential bandwidth relative to narrowband DOCSIS 3.0 single carrier coefficients. This wider bandwidth provides high resolution time responses, enabling cable problems to be identified with high accuracy.

Two application categories have been used to date: examination of a single response for impairments and comparing multiple responses to form groups with common impairments.

OFDM and OFDMA data obtained to date needs to be pre-processed before analysis due to the addition of delay and phase from the CM-CMTS interaction during ranging. This paper discusses the processing steps, provides field and lab data, and discusses new applications which are now feasible.

Just as full band capture (FBC) came to be described as a "free spectrum analyzer in every CM," OFDM and OFMDA coefficients can be viewed as a "free pair of network analyzers in every CM." The OFDM & OFDMA equalization data are compelling because there are many millions of deployed DOCSIS 3.1 CMs, and the data have both high time resolution and large dynamic range.

2. Background

As mentioned above, predistortion analysis has been used operationally on cable upstream single-carrier transmissions for a while, and readers are directed to the bibliography for publications on this common operational practice, done under the CableLabs® umbrella of proactive network maintenance (PNM). DOCSIS version 1.1 upstream used an 8-tap finite impulse response (FIR) filter which was upgraded to a 24-tap FIR filter for DOCSIS upstream versions 2.0 and 3.0.

There is also a possibility of reading coefficients for downstream single carrier signals which are modulated with 64 or 256 QAM. Decision feedback equalization (DFE) is used for downstream equalization. Unfortunately, this practice has not been highly successful due to the large number of configurations of feed forward and feedback taps, plus inconsistent coefficient reporting. This was caused in part by an incomplete and confusing MIB description.

A common limitation for both upstream and downstream single carrier signals has been the relatively narrow bandwidth, which is 6.0 MHz in the USA for downstream and frequently 6.4 MHz in the upstream. The narrow analysis bandwidth results in a limited time accuracy resolution. The limited time accuracy implies limited distance accuracy, resulting in an imprecise location of plant damage. This limitation makes locating a point of damage on cable plant harder to identify, which can be particularly annoying when locating damage in buried cable.

In DOCSIS 3.1 specifications, both OFDM and OFDMA were standardized. Pre-distortion for upstream OFDMA carriers was continued, although made optional. On both modulation types, MIBs were specified to reveal the frequency domain (FD) complex coefficients associated with each of the potentially thousands of active subcarriers. A MIB object request is sent to the CM, and the CM performs a trivial file transfer protocol (TFTP) transfer of a file containing the requested in-phase (I) and quadrature (Q) coefficients. Note that the upstream coefficients returned are for the corrections to remove impairments, not for the impairments themselves. The two responses are inverses of each other. In the downstream, the CM can report channel estimation coefficients for OFDM, which are also complex coefficients.

With both upstream and downstream single carrier (SC) signals, the returned complex coefficients are in the time domain (TD). Alternately, the returned coefficients in the multi-carrier (MC) systems, both OFDM and OFDMA, are FD coefficients. The discrete fast Fourier transform (FFT) and inverse fast Fourier transform (IFFT) may be used to convert between time and frequency domains.

3. Past and New Applications for Equalization Data

In the past, two main application categories were developed from analysis of the SC coefficients. The first was a stand-alone path analysis. At a CM this analysis revealed echo tunnels created by two or more impedance mismatches along with other problems such as excessive (GD) group delay, suck-outs, peaking, and tilt. The second application was a matching path analysis, indicating that a group of CMs share a common impairment. This information, along with a strand map of the plant, reveals likely locations of plant damage. Figure 1 illustrates upstream single carrier groupings done within a node, revealing homes with common impairments, which are color coded on the map and spectral plots.

Figure 1 - Upstream SC groupings showing common plant impairments.

Applications for equalization data previously mentioned are single response analysis for impairments and matching common impaired responses to assist in the location of line damage. This second application can be expanded to a third application where matching nonimpaired (normal) responses are compared to determine if subscribers are neighbors sharing a common cable line. This can be done to validate records, or as a source of information for locating CMs in the network when location data are not available.

Another application for equalization data is for plant stability analysis. Intermittent connections will cause re-adaption of coefficients to the new echoes. Connections may change infrequently, such as daily in the case of thermal-caused intermittent problems, or several times per second if intermittent connections are experiencing wind or traffic vibrations. Comparing responses with earlier stored coefficients reveals the presence of intermittent connections. If the changes are large, or frequent, the problem may be severe.

Equalization can also be affected by interference, such as band-limited ingress LTE signals or wider bandwidth interference such as common path distortion (CPD) interference or passive inter-modulation (PIM). An examination of the "smoothness" of an equalization solution can reveal noise causing a poor equalization setting. These data can be complementary to MER-per-subcarrier data available on both OFDM and OFDMA. Figure 2 shows a lab equalization response with a poor equalization solution in an LTE band.

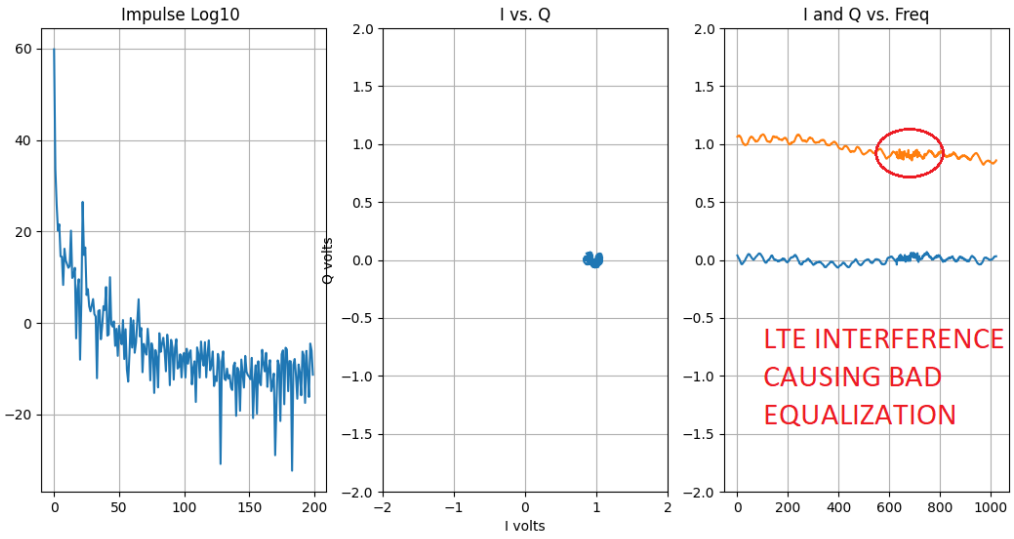

Figure 2 - LTE interference causing poor equalization shows up in the right pre-equalization plot.

Another application is determining if a selected cyclic prefix (CP) is sufficiently long to accommodate the longest significant echoes that are being corrected. Figure 3 shows an example of the strength of echoes vs. delay time. The longer a signal travels in a cable, the greater the attenuation. Knowing the cable type allows this attenuation vs. time curve to be corrected down to near the noise floor. Another application is determining if the programmed cyclic prefix length is long enough for the longest expected echo, which is shown in green in Figure 3. Any echo longer than the CP must be sufficiently weak to cause no harm.

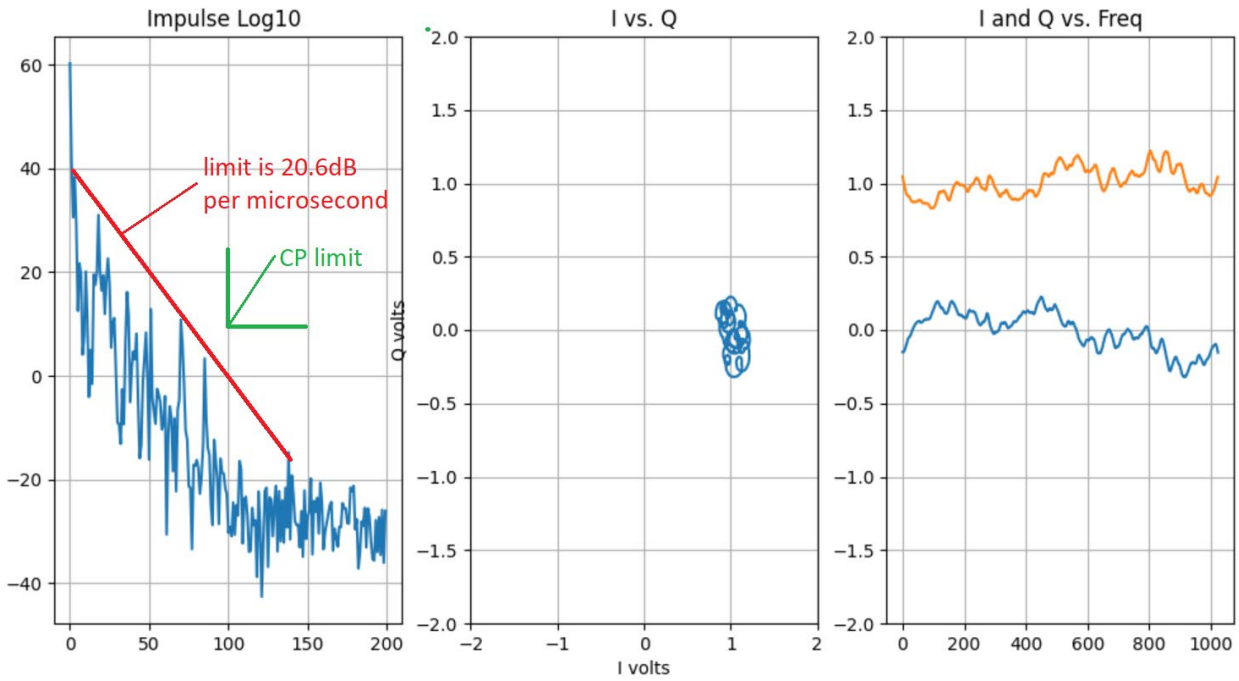

Figure 3 - See the impulse response on the left with the added red limit of 20.6 dB per microsecond, showing no unexpected echo tunnels as peaks above the line. Also no echoes appear over the green corner threshold, indicating sufficient CP is being allocated.

4. Pre-Processing OFDM and OFDMA Coefficients

Presented next are the processing steps for correcting raw (direct from CM) phase so we can make use of it for the described use cases. The basic idea to correct a frequency response is to remove added uniform time delay, which manifests itself in the frequency domain as phase rotating linearly with frequency. We assume that there is a direct current (DC) component to the frequency response, and it can be used as a single "pilot" subcarrier. In this method, there is a coarse delay removal step done in the frequency domain followed by a phase rotation done in the time domain. The phase rotation is done to make the DC term real-only, so the imaginary component of the DC term is forced to zero. In other words, the DC "pilot" is calibrated. With this assumption, the remaining signal reflects the plant condition, which allows us to process these data for our described use cases.

At a high level, the steps are as follows.

1. Import the complex FD data.
2. Estimate linear delay ($d\varphi/d\omega$) – calculate ω using arc tangent to get phase angle.
3. Coarse delay removal – Flatten the angle vs. frequency plot for the middle portion of the band. Using only the middle portion of the band prevents group delay (GD) from effecting the calculation.
4. Convert corrected response to time domain using IFFT, and measure phase on the DC term.
5. Correct phase on all time samples so Im[0]=0 by a time-domain rotation
6. View response in FD by a FFT calculation.
7. Optionally normalize coefficients. For example, make the total power in all coefficients equal to unity, or make the DC term 1.0.

8. (Optional) compare with another response using FD division

The next few figures show the transformation of the processing steps. Appendix 1 contains C++ computer code to remove the undesired (random, linear) time delay and Python code to plot the results as a set of 3 graphs per CM.

As mentioned above, I and Q coefficients for both upstream OFDMA and downstream OFDM arrive raw from a CM with a random time delay inserted that must be removed before processing the coefficients for estimating the channel-plant. In the TD, a delay manifests itself as the main tap being moved from its desired position, which is ideally the 0th or DC term. In the FD, the time delay appears as a constant rotation of phase angle with frequency. Figure 4 illustrates a raw downstream FD polar response with rotation, and Figure 5 illustrates that same response as I and Q plots vs. frequency.

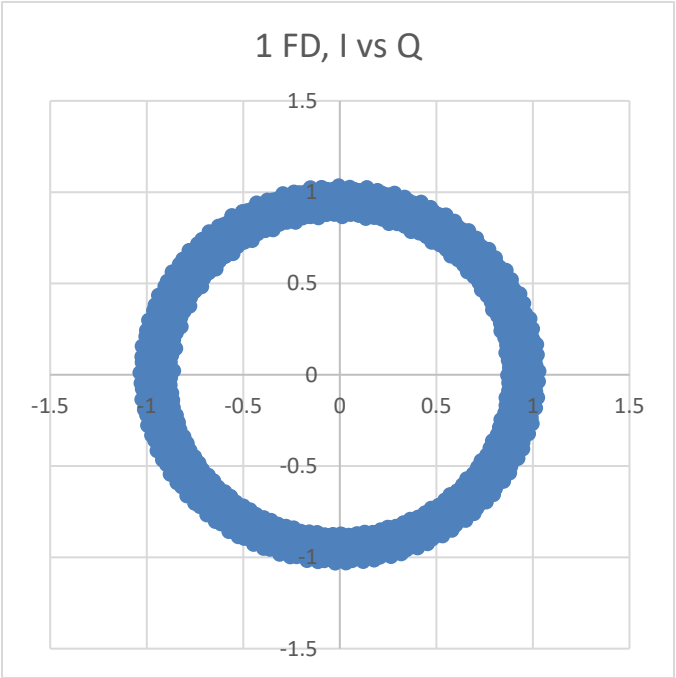

Figure 4 - Raw downstream equalization coefficients, no echo or other impairment.

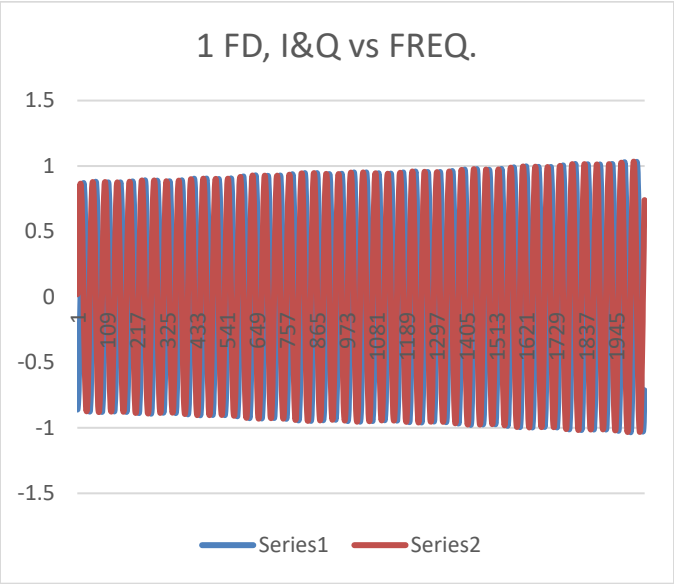

Figure 5 - Raw downstream equalization coefficients versus frequency, no echo or other impairment.

To heuristically explain and demonstrate the removal of delay in the frequency domain, an Excel spreadsheet program was made with two slide controls. It is available from CableLabs. The first slide bars adds or subtracts linear delay, and the second slide bar adjusts the phase angle. The pre-equalization data in the example was obtained from upstream lab testing.
The slide bars operate in the frequency domain. One slide bar changes the rate of change of phase vs. frequency:

$$\Theta = \Theta_0 + k_1\omega$$

where Θ is the new phase angle in radians for every frequency, Θ_0 is the starting phase, and ω in the angular rate of change in radians per second. The value of k_1 is determined by a first slide bar position. Magnitude values for each frequency are not altered; only the phase angle is adjusted.

The second slide bar rotates the response phase equally for all frequencies:

$$\Theta = \Theta_0 + k_2$$

The value of k_2 is determined by a second slide bar position.

See Figure 6 through Figure 12. Fig. 6 is a raw I-Q upstream response in FD polar form, having approximately 450 degrees of unwanted rotation before delay removal. Figure 7 is a plot of angle versus frequency associated with Figure 6. The angle in radians is obtained by taking the arctangent of the Q coefficient value divided by the I coefficient value. The object of the slide processing is to remove delay by adjusting the phase response to be flat in the middle of the spectrum, and then adjust phase angle of the DC term in the time domain to be real-only with an imaginary value of zero. Figure 8 is the angle versus frequency plot with delay (rotation in FD) removed. Observe that the middle of the band has been flattened, but there is still movement at the low and high frequencies. This is caused by group delay associated with upstream high-pass filtering on the low end, and upstream low-pass filtering on the high end.

Figure 9 is an I-Q polar plot showing the removal of rotation. Observe that the plot still has some residual rotation due to group delay, which is not uniform with frequency.

Figure 10 is a plot of group delay vs. frequency. Group delay is the derivative of the slope of phase vs. frequency.

$$GD = -\frac{d\varphi}{d\omega}$$

If the frequency steps are 50 kHz, a group delay value of 0.035 from the graph would be 111ns = 0.035/(2*π*50,000).

Figure 11 is corrected real and imaginary responses vs. frequency. Finally, Figure 12 shows the TD impulse response which is obtained by taking the IFFT of the coefficients in Figure 10. Phase angle has been adjusted to produce a maximum DC real value and zero DC imaginary value.

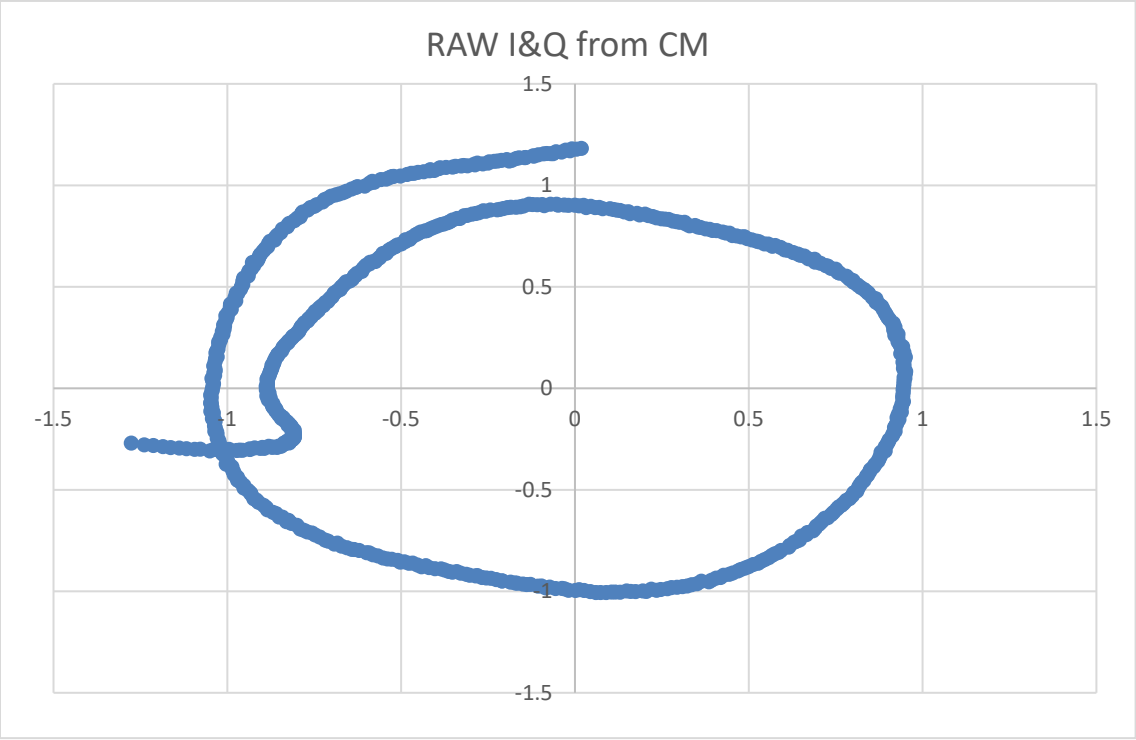

Figure 6 - In-phase (I) versus quadrature (Q) coefficients as supplied by a CM, contaminated with a time delay, which manifests itself as a uniform rate of phase rotation with frequency.

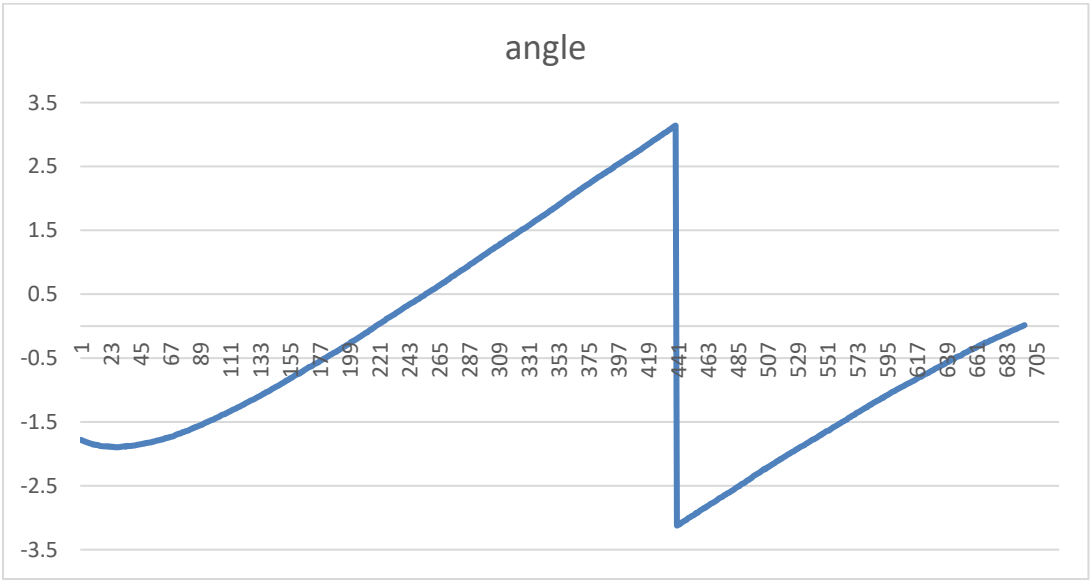

Figure 7 - Angle plot of the data from Figure 6. The rate of change of angle (in radians) versus frequency is delay.

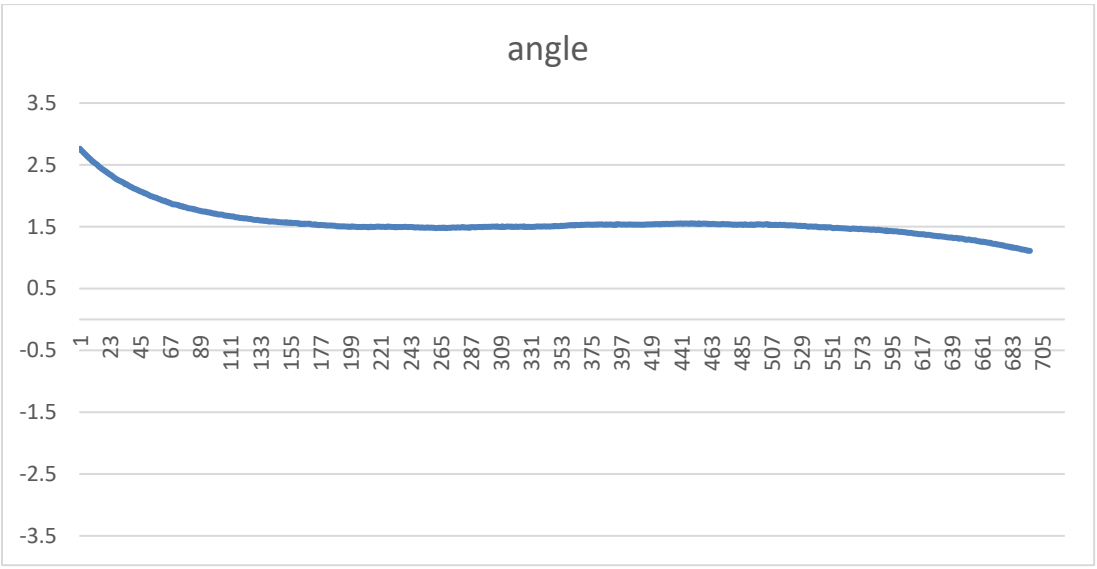

Figure 8 - Phase angle of I and Q coefficients after delay removal. Phase is adjusted to be flat in spectral band without excessive group delay.

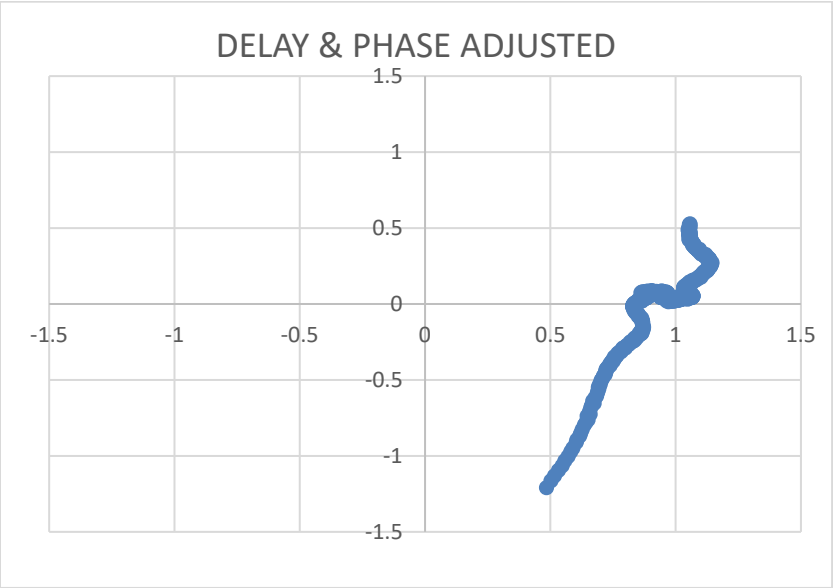

Figure 9 - I and Q coefficients as a polar plot, after delay removal.

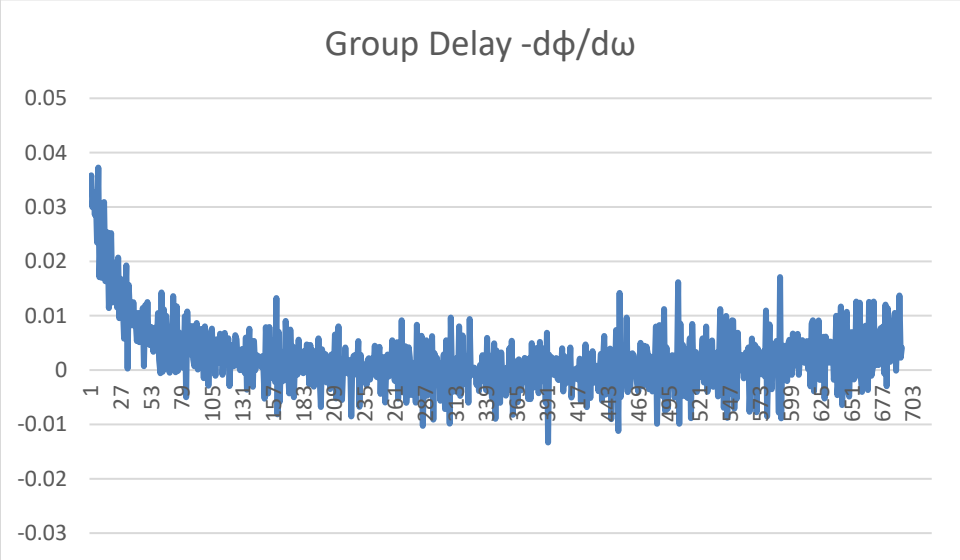

Figure 10 - Group delay, created by taking the derivative of the phase response with respect to frequency. Group delay is a "bending" of the phase response, and is caused by a high-pass filter at 5 MHz.

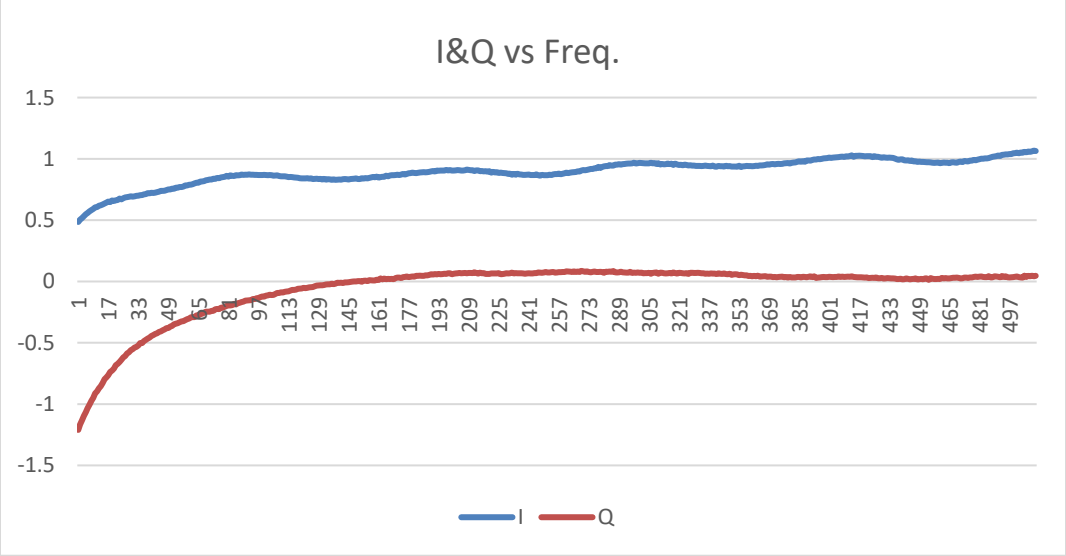

Figure 11 - De-rotated I and Q values.

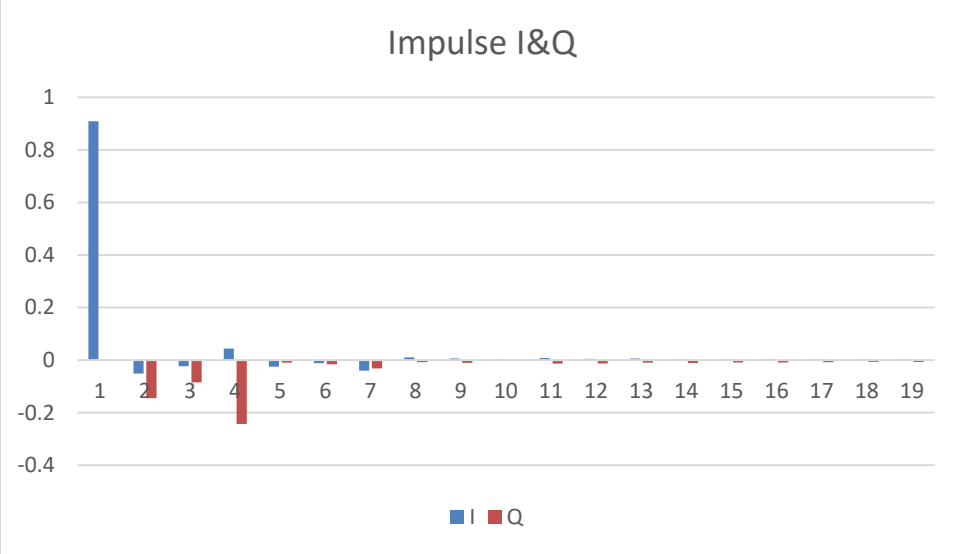

Figure 12 - Impulse (time domain) response that was obtained by taking the IFFT of the re-rotated response. It shows a maximum DC real value (I) and zero DC imaginary (Q) value.

Because of group delay at the low end of the frequency band, only the middle portion of the band was flattened. As mentioned above, computer code has been written to automate delay removal and angle adjustment with a target of maximum energy in the real DC coefficient and zero energy in the DC imaginary coefficient. The code for executing that process is in Appendix 1 of this paper.

A question arises: why is there a time delay (same as FD rotation) addition added to the frequency domain coefficients? A best guess is that delay is an adjustment method that allows an optimal selection of time domain samples on which to perform an FFT. Symbols selected for FFT processing come from an OFDM frame preceded by a CP (or cyclic extension, or guard interval). Lab vector network analyzers (VNA) also add delay to responses as a result delay from connecting cables.

5. Downstream Lab Results

In the lab, tests were performed to compare transmission (S21) on a Keysight VNA with a CM's downstream equalization coefficients after passing through a created echo. 1800 complex coefficients were analyzed with a subcarrier spacing of 50 kHz, starting at 612 MHz.

A plot of raw VNA downstream I and Q values with an echo and accompanying delay is illustrated in Figure 13. The same delay-corrected data are shown in Figure 14, which illustrates a downstream single-recursion echo created with a pair of splitters and a long 100' cable with a 12dB attenuator, and a short 1' cable with no attenuator (see Appendix 2 on types of echoes). These data are shown as I and Q coefficients plotted versus frequency. On the left of Figure 14 is a response from the VNA and on the right is a response from a CM. Figure 15 shows a time plot showing the magnitude impulse response after both responses were transformed with IFFTs. Note that the delayed echo was about 16.5 dB due to an additional 4.5 dB of cable loss.

An interesting VNA test result is that the coefficients were produced by the instrument with an accompanying electrical delay, which needed to be removed for analysis and comparison. The delay in S21 in Figure 13 was caused by cable length.

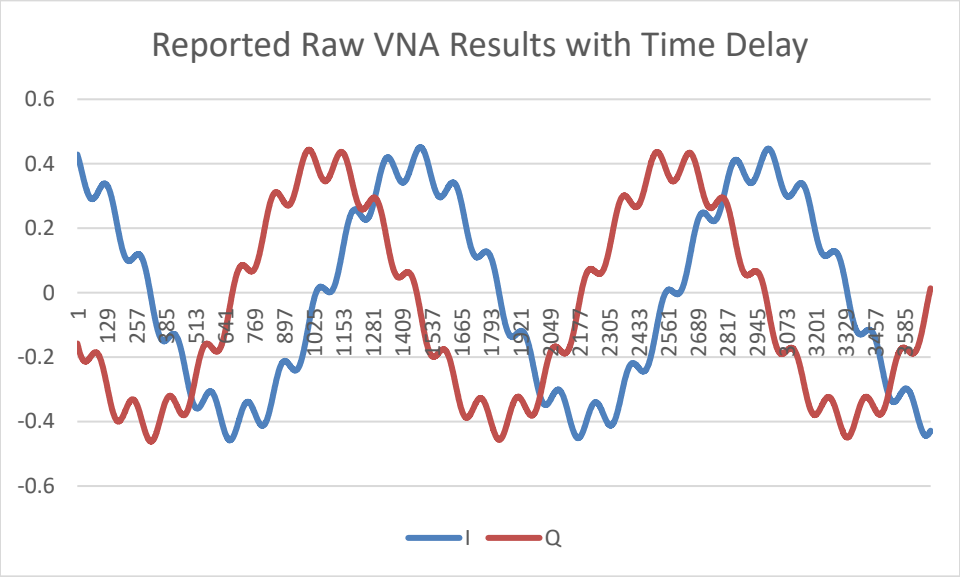

Figure 13 - Raw VNA data showing echo (fine ripple) and time delay (large coarse ripple).

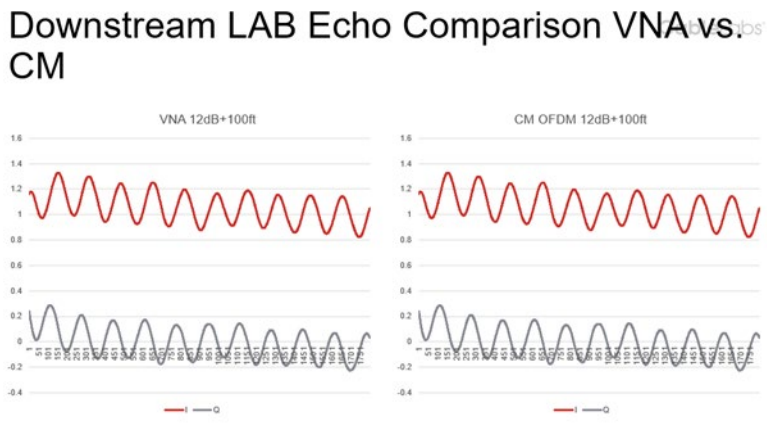

Figure 14 - A downstream single-recursion echo created with a pair of splitters and a long 100' cable with a 12dB attenuator, and a short 1' cable with no attenuator, as I and Q coefficients plotted versus frequency.

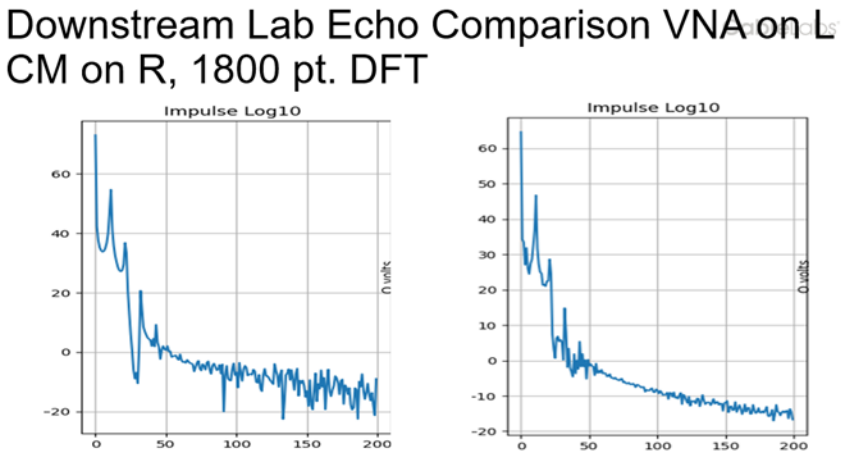

Figure 15 - Time plots showing the magnitude impulse responses of the VNA (left) and CM (right) after both responses were transformed with IFFTs.

Another experiment that was done in the lab was to measure reflection (S11) using a CM and then compare test results with those obtained by the VNA. See Figure 16 for test plant wiring. It illustrates a fiber node feeding signals to a string of taps. The output cable of a fiber node was tapped with a high impedance -20dB probe, and a cable modem (CM METER) connected to the probe was allowed to range and register on a downstream OFDM channel. The standing wave of the OFDM received signal was captured in the complex frequency domain as coefficients, and then inverse Fourier transformed. The red lines show one path the reflections can take to make a standing wave. The green graph in Figure 16 shows an expected impulse response with tap reflections. There should have been an impulse response returned from each tap, and possibly an indication of plant damage, if there was any. Figure 17 shows the OFDM's transformed coefficients (impulse response) from the lab string of taps, and Figure 18 shows the impulse response from a Keysight vector network analyzer. Other than the VNA having more dynamic range than a CM, the results are comparable.

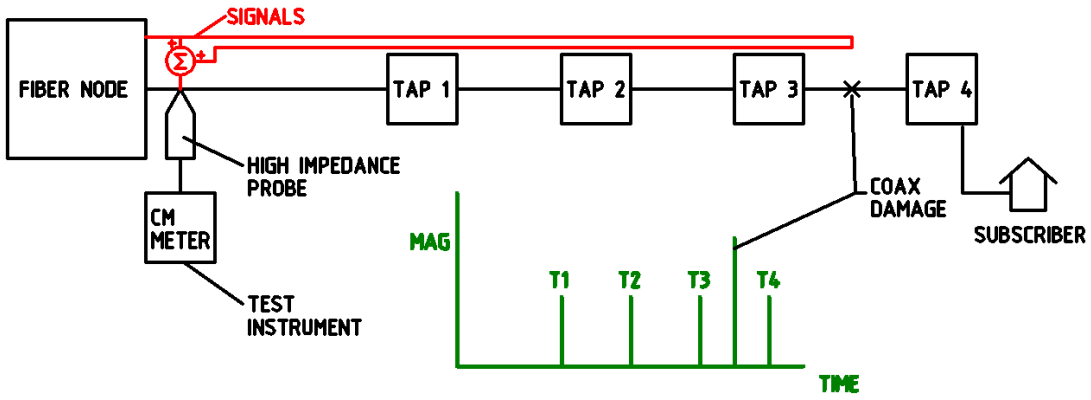

Figure 16 - Test wiring for the second experiment.

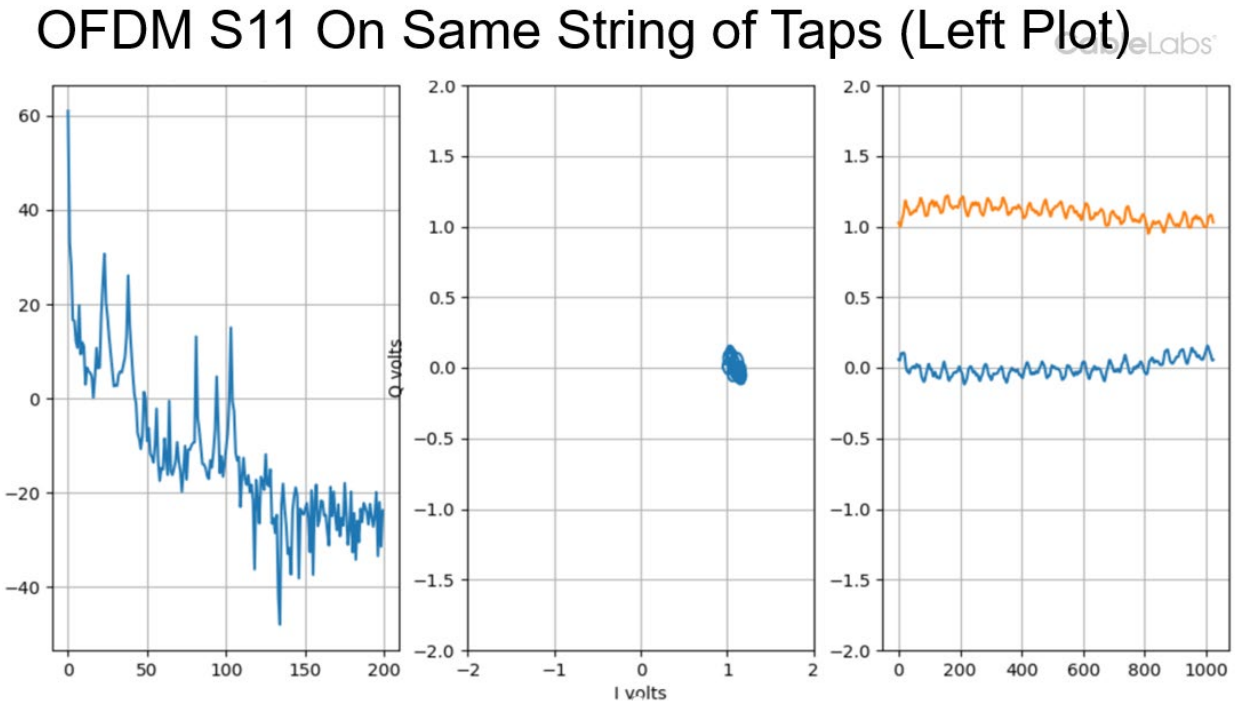

Figure 17 - Impulse response from the lab string of taps in Figure 16, obtained using a CM.

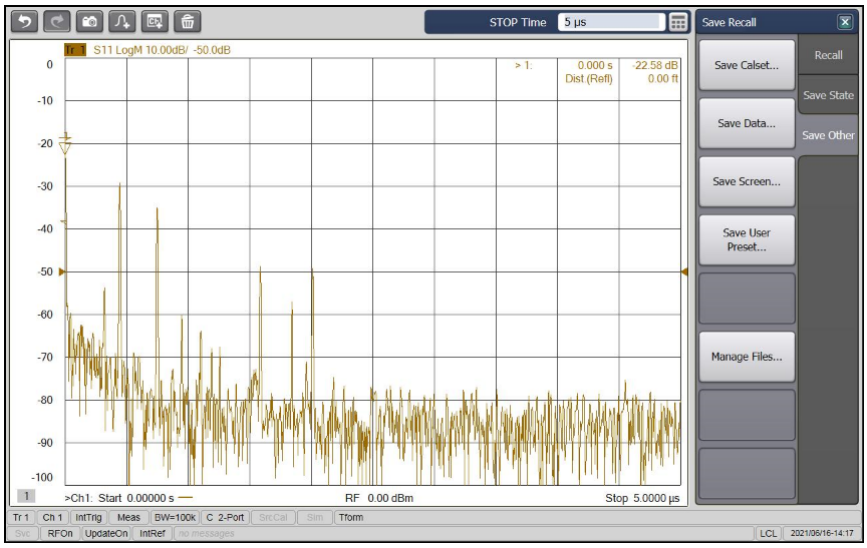

Figure 18 - Impulse response from the lab string of taps in Figure 16, obtained using a Keysight VNA.

Generally, the downstream responses contain much more uniform delay relative to upstream responses.

Lab testing has revealed that if a CM is rebooted, the delay value in the coefficients will probably change to a new value. Likewise, a different CM will likely obtain new delay values when it comes online.

Another observation that has been made is that if there is an exclusion band programmed into the OFDM(A) spectrum, the delay values "jump" over the vacant band. That is, different delay values are applied on occupied bands on either side of an exclusion band. Authors are not sure why. But this does complicate the correction work.

A lab confirmation was that, while OFDMA coefficients are commonly reported as the applied correction (demonstrated in the next section), CMs report OFDM coefficients as the channel's actual response, as expected from the specifications. The channel's correction and its response are frequency domain reciprocals of each other.

The horizontal axes of spectral data are index units, which for these tests were 50 kHz frequency steps.

On the horizontal axes of impulse responses, the units are also indices, which can be converted to time. For example, assume the downstream FFT size is 4096 and symbol rate is 204.8 Mega symbols per second. That results in a symbol period of 4.88 ns per symbol. OFDM frame time is 20 µsec. But because 4096 coefficients are not available, the FFT transform size used is reduced to 1024 (time and frequency symbols). This increases the time per symbol by a factor of 4. Therefore, there are 19.53 ns per index number.

6. Upstream Lab Results

The downstream comparison tests were repeated on the upstream OFDMA channel, which ran 10-85 MHz and used 50kHz channel spacing. This gave a 1500 point discrete Fourier transform. The network analyzer results on the echo are shown in Figure 19, and the CM results are shown in Figure 20. Note

that the VNA is showing an echo, but the CM coefficients are showing the channel's correction, which is the inverse, and infinitely recursive as described in Appendix 2. In the frequency domain, if the ripple goes up for the VNA at some frequency, it is reported as going down from the CM to make a correction. In the frequency domain the inverse solution is infinitely recursive, but in the time domain the measurement is a single recursion.

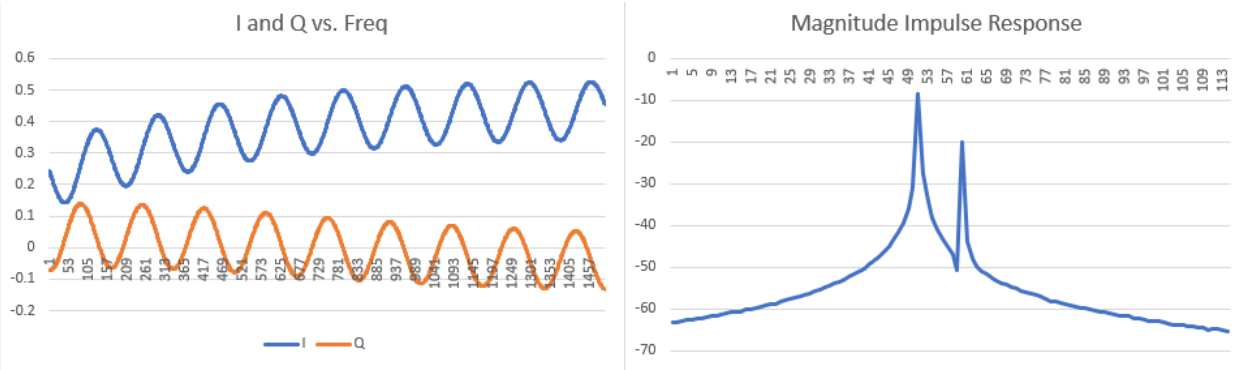

Figure 19 - Network analyzer upstream results in time and frequency.

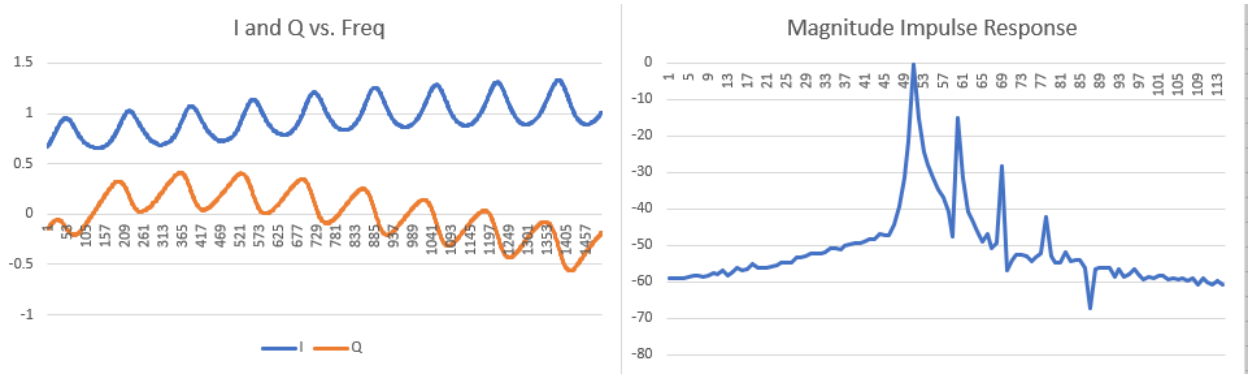

Figure 20 - Cable Modem upstream results in time and frequency. Notice the results are the inverse of the network analyzer results because the CM is returning the correction, not the channel response.

7. Field Data

A browsing tool was created in Python to display equalization coefficients. It is included in Appendix 1. The data are preprocessed for removal of the added delay. Two example plots are illustrated in Figure 21 and Figure 22. The center plot is FD linear I vs. Q. The right plot is FD linear I and Q vs frequency. The left plot is TD magnitude log impulse response. The time scale is IFFT index numbers and is 19.53125 ns per point. On the impulse response, echoes appear to the right of the main tap (delayed) and group delay effects will appear to the left of the main tap.

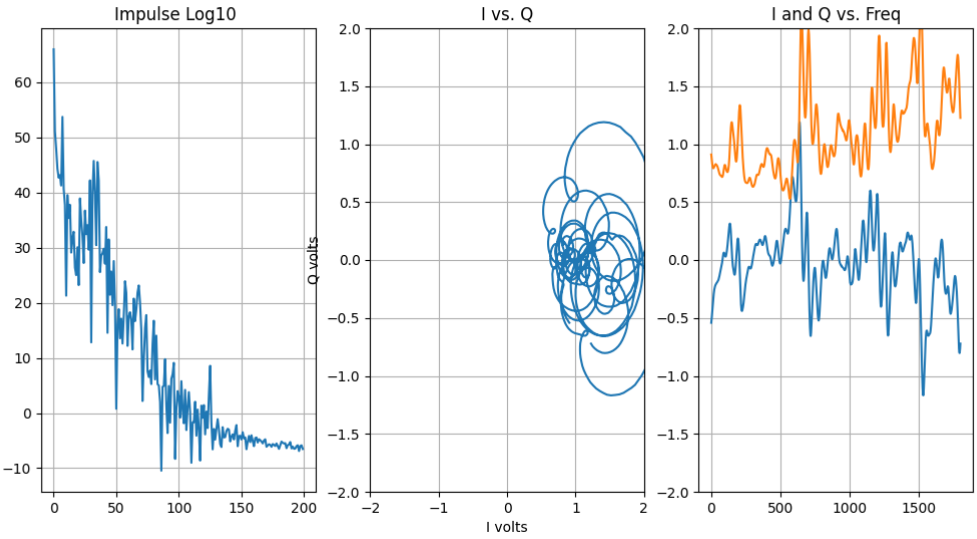

Figure 21 – Downstream example shows an unknown big problem, maybe water in coax.

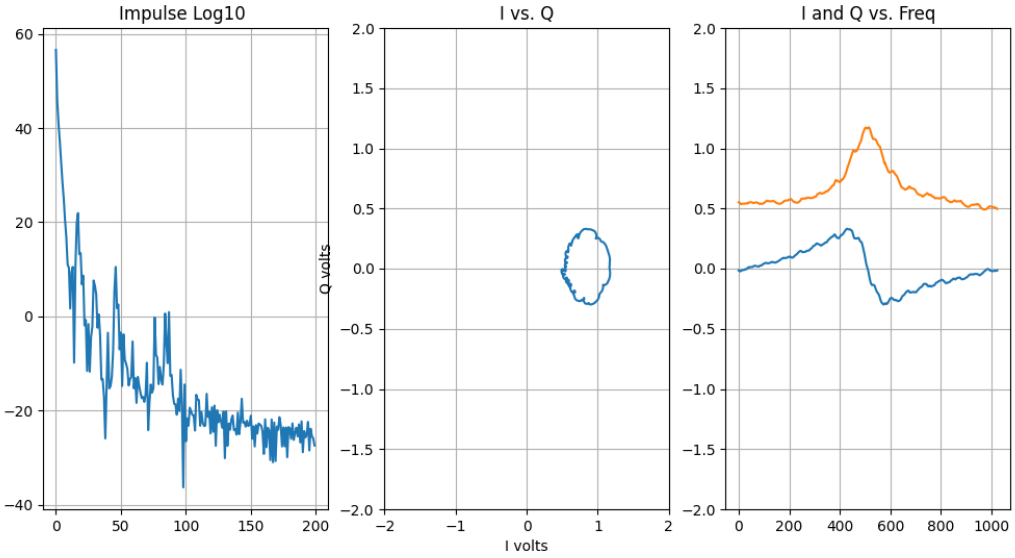

Figure 22 – Second downstream response showing resonant peaking response.

The most common impairment observed was a standing wave created by an echo tunnel. Taps, amplifiers, and other network components generally have a return loss around 16-18dB. This implies, if the coaxial cable was lossless, the strongest observed echo would be 32dB from two reflections between any two components. Of course, cable is not lossless, but has predictable loss as a function of diameter and frequency. For every nanosecond a reflected signal travels in the coax predicted attenuation should occur given by:

dB/ns = A dB/meter * VoP * 0.3meters/ns

Example: 0.5 cable at 750MHz has 7.09dB per 100m, or 0.079dB/1m

The speed of light is 3e8m/sec, and the velocity of propagation (VoP) is 87%.

So, every nanosecond an echo is attenuated by 0.0206dB, or 20.6dB per microsecond.

This allows a mask to be applied to an impulse response, as illustrated in Fig. xx. Any impulse crossing a threshold signifies an out of spec. component. This simple test allows cable damage producing less than a 16dB discrete reflection to pass undetected unless echo timing is considered.

Figure 23 is a similar plot to Figure 3. It shows a CM downstream response with an added threshold red line of some number of dB of attenuation per microsecond slope. Because the cable diameter (loss) was not known, the line's correct slope is a guess. This line can be used as a limit for finding any echo that peaks above the line, indicating of a potential plant problem. A problem is shown where the echo limit is crossed. The far-right FD plot indicates echoes (ripple) that align with the peaks in the left plot. The green CP limit line shows that the selected CP length is sufficient.

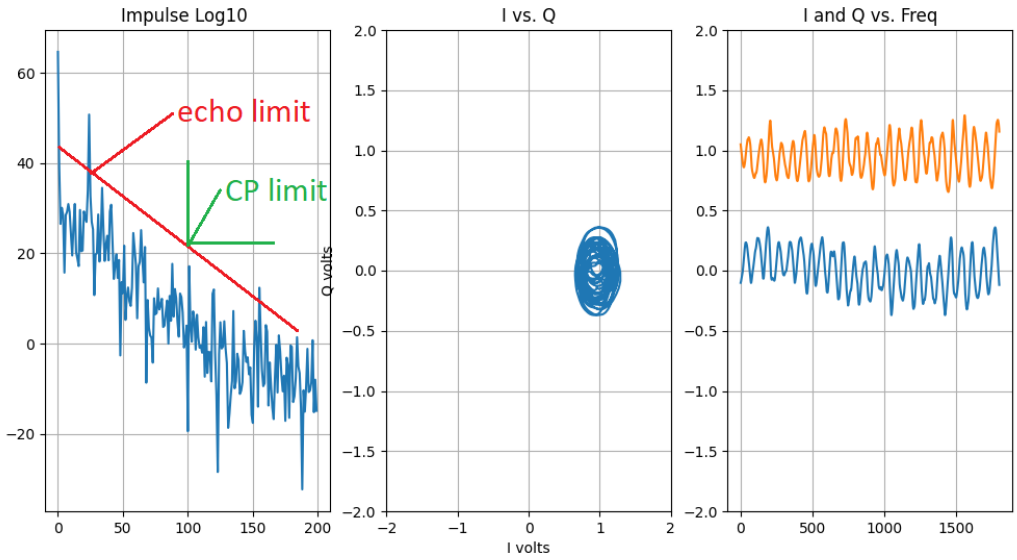

Figure 23 – Adding a line that reflects the CP, so that any peak above the line indicates a signal problem.

Appendix 4 holds a gallery of interesting downstream and upstream data plots from field data with comments in the figure captions.

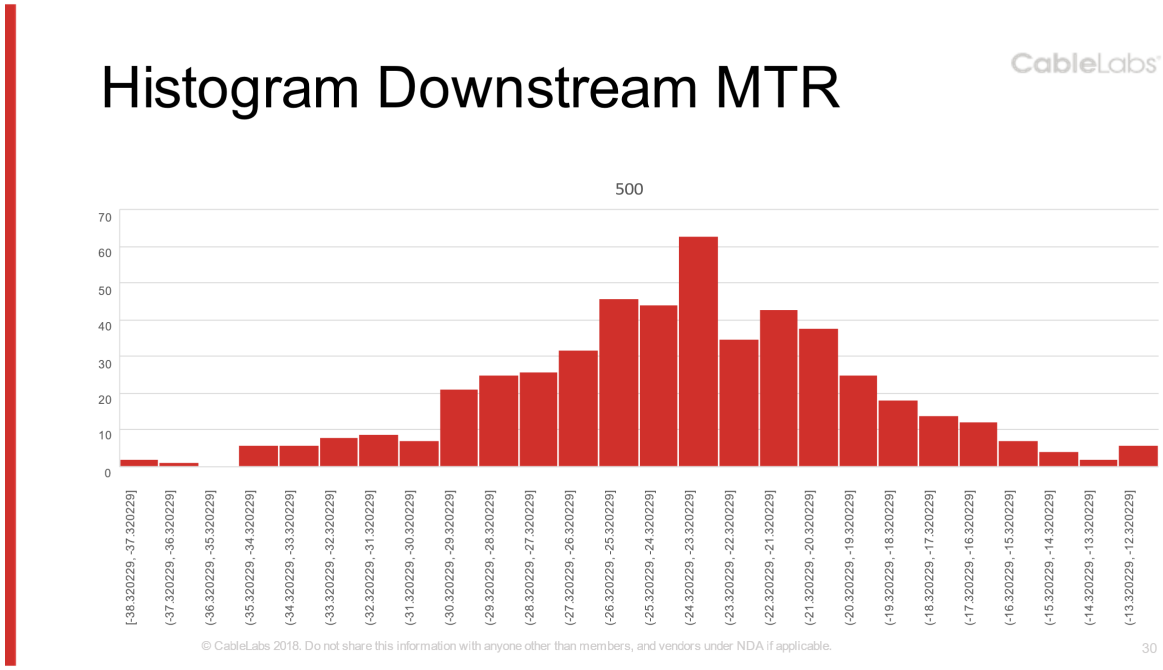

Figure 24 - A histogram of DS main tap ratio values from about 500 CMs from the field.

Fig. 24 is a histogram of downstream main tap ratio (MTR) values for a field population of about 500 CMs. The values range between 12dB and 37dB with a peak around 24db. MTR is the measure of the energy in the main tap to the energy in all other taps combined. If residual delay is not removed, the MTR values will be lowered.

8. Response Matching Algorithms

For many years PNM engineers have been discovering which field responses are similar by using frequency domain division, followed by an IFFT. Similar responses may indicate that modems share a common plant impairment, as illustrated in Figure 1. This makes for easier and quicker plant troubleshooting when a strand map is available. More recently, unimpaired normal responses are being matched, allowing discovery of which common cable lines are used, indicating CMs are in the same neighborhood. More details on this in Appendix 3.

In this matching process, a set of coefficients from one cable modem is divided into another CM's coefficients at each subcarrier frequency using complex frequency domain division. The result is a set of quotients which will be all 1.0 at 0 degrees, if responses are identical. This set of quotients is processed with an IFFT to make a time response. A temporal power measurement can be made of the DC term (coefficient zero) relative to the power in all other coefficients combined. A large ratio of main tap to all other taps combined indicates a good complex response match. This is illustrated in Figure 25, where two I-Q polar responses look very similar. Their quotient is illustrated in Figure 26 as both I and Q vs. frequency and I vs. Q. When this spectral response is transformed with an IFFT, almost all of the transform's power will be in the temporal DC term.

To form clusters, processing is generally only done on CM data from inside a fiber node. Each CM's response is used as a reference and compared with each other CM response, and all matches are noted and formed into groups.

In the past this has been done on 24 coefficient single carrier upstream responses. Now it can be done on both upstream OFDMA and downstream OFDM responses with hundreds of coefficients. Trials on downstream field data show it works well. Furthermore, the effects of different house wiring can be masked by eliminating (zeroing) low value time domain coefficients when performing the power calculation.

Using complex coefficient matching generally produces noticeably better results than using magnitude-only coefficient response matching.

Figure 25 - Two CM's responses, one used in a numerator and the other (reference) used in the denominator.

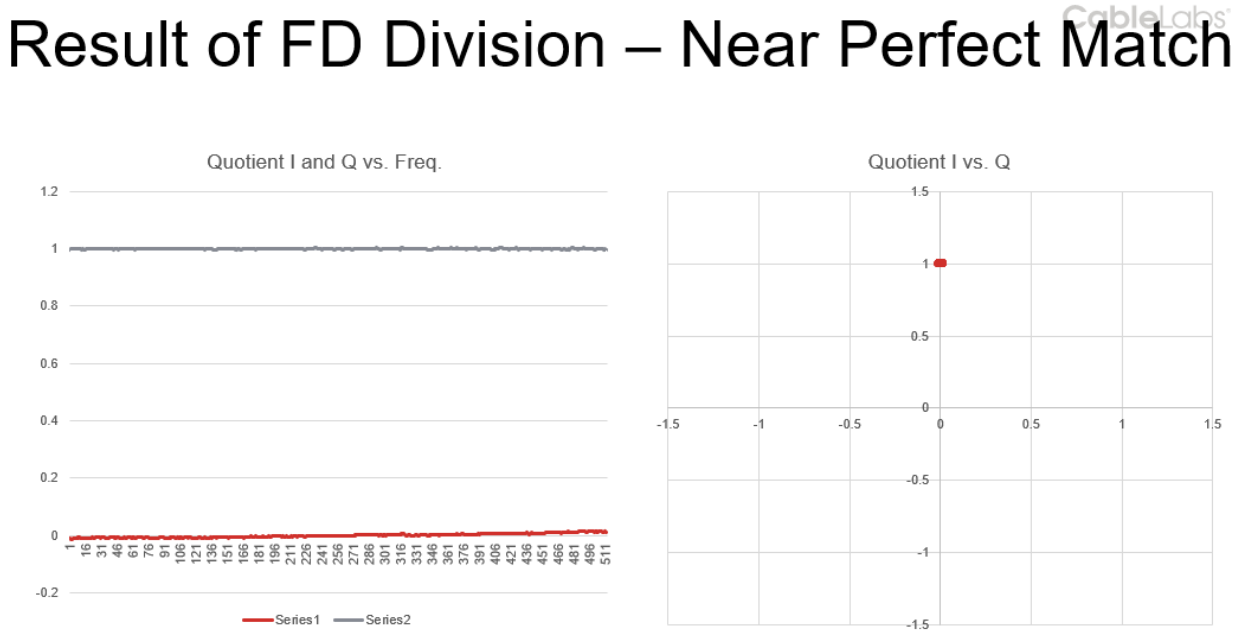

Figure 26 - Two nearly identical responses produce quotient coefficients of 1.0 at an angle of 0 degrees. Nearly all the energy is in the DC term.

9. New Applications for Wideband Equalization Data

Existing applications of impaired response matching and individual response matching work better with multicarrier than single carrier because the equalization data has more dynamic range, in part due to using elevated pilots. The wider bandwidth of the signals also provided for more accurate time resolution.

New possible applications are:

1. Wideband downstream and upstream response matching.
2. Investigation of correct sizing of OFDM(A) CP length.
3. Intermittent detection from unstable equalization responses.
4. Interference or ingress causing band-limited wrong equalization values.
5. In-house wiring problems, such as broken coaxial shields, identified by energy in low index coefficients.
6. Water detection in coaxial cable.
7. Locating subscribers connected to the same coaxial line by matching responses or identifying amplifiers in a cascade.
8. Field test gear, including time domain reflectometer (TDR) functionality.

Experience from using PNM objects has taught us that operational value is gained by learning what physical problems are manifested in observed channel responses. Unfortunately, we have not been provided feedback from our operators on what problems have created the unusual responses, partially due to time and distance, and partially due to the global pandemic.

An operational disservice occurs when time and resources are wasted on chasing non-problems. An impairment that is time-variable in nature is more suspicious than one that is static. Likewise, an impairment that increases with time, such as water slowly entering a cable, should be flagged for inspection and possible repair.

DOCSIS equalization is powerful, and many impairments can be tolerated. For example, if a tap's return loss drops from a specified 18dB to 15dB, the equalizers can normally fix that issue.

10. Conclusions

OFDM and OFDMA equalization coefficients both contain useful complex frequency response data, but the data need to be pre-processed to remove added random, linear delay which is phase rotation. Code to do this processing is in the CableLabs PNM GIT repository C3, and a verbose version is provided in the first appendix of this paper. The first appendix also has Python code for plotting results. This equalization analysis should work for water wave detection and have field test equipment applications. The wide measurement bandwidth obtainable from OFDM and OFDMA provides detail in the time domain, which allows more precise distance measurements. The impulse response can show if your CP (or Guard Interval) is the correct length or if echoes are above expected limits.

While spectrum data, which is magnitude only, has been proven to be very valuable for impairment detection, the complex data from pre-equalization and channel estimation data may be more useful for determining more precisely the location and cause of the issue, better informing maintenance decisions.

Many thanks to the members who contributed data for this analysis.

Appendix

1. Removing the delay in the TD, which is rotation in FD.

The computer code explained in Section 4 of the paper is provided in this Appendix 1. First, we provide C++ code for delay removal from raw responses, followed by Python browsing code which plots responses in 3 graphs.

1.1. C++ code

The following code is meant to be copied and pasted into your software editor for direct use.

```
//PaperCodeR3.cpp a program to process OFDM equalization coefficients

//R3 added choosing a freq band where to flatten angle, s1 to s2

//R2added normalization, group delay

2. Upstream Cable Echoes Come In Two Flavors

A first type of echo can be compared to a person standing within two walls of a canyon and yelling "hello". They hear their call repeated several times, each time getting weaker. The signals are bouncing off the 2 walls.

A second type of echo can be compared to a person standing in front of a big single wall and yelling "hello". They hear their call repeated only once.

Cable systems have both types, although the first type is by far more common. The first type, "infinitely recursive", is created by a pair of impedance discontinuities created on a cable line. It is of interest as the impedance mismatch may be caused by cable line damage.

The second type, "single recursive", may be caused by a signal finding two paths upstream. This condition was discovered from upstream transmissions that took the easy upstream path from a home through a high value tap port to the fiber node, and a slightly harder and longer path from a home, through the tap port to the tap's output port, and then off an impedance mismatch downstream to head upstream to the fiber node.

Figure A1 shows the first type of channel (top left) and how it is canceled with the top right impulse response. Essentially, each time an echo is canceled, a tap makes another smaller echo that also needs to be canceled until it is too weak to matter. The infinitely recursive solution impulse response is shown on the upper right.

Figure A2 shows the second type of channel (top left) and how it is canceled with the top right single recursion impulse response. Essentially, each time a multi-recursive echo is encountered, a second tap makes an inverse echo to cancel the next recursion. The solution impulse response is shown on the upper right.

Thus, the solution to an infinitely recursive echo is single recursion set of tap coefficients.

The solution to a single recursive echo is an infinitively recursive set of taps, up to the point when you run out of taps. Hopefully at that point the echo has died out.

This same principle works when observed in the frequency domain for both types of echoes because of time-frequency duality. In the frequency domain, when a frequency response ripple goes up, its inverse response ripple goes down.

OFDM/OFDMA does not employ time domain taps per se but multiplies each frequency domain subcarrier with a complex coefficient for correction. An IFFT can reveal the associated impulse response.

The Math

A single recursion echo can be modeled by: 1 + a where 1.0 is the main signal amplitude and 'a' is the echo's amplitude in linear terms. That is, for a -3dB echo a = 0.707. In a baseband channel 'a' is real, but in an RF channel 'a' may be complex. To be more precise,

$$a = Ae^{j2\pi fT}$$

where A is the amplitude of the echo, f is carrier frequency (MHz) and T is the delay of the echo (usec). However, the equations are easier to present if we simply use 'a'.

The equalizer solution is for a single recursion echo is:

$\frac{1}{1+a} = 1 - a + a^2 - a^3 + a^4 -$ So, the result is what was expected: infinitely recursive. The first term '1' represents the main tap of the equalizer. The second term '-a' acts to cancel the echo by subtracting it. However, in doing so, it causes another, smaller echo in the response. This smaller echo requires the third term to cancel it. This produces another, yet smaller echo, which requires the 4th term to cancel it, and so on until we reach the end of the equalizer delay line. After that, any remaining echo energy (hopefully very small) is not canceled and shows up as reduced RxMER (received modulation error ratio), essentially a noise floor, in the receiver.

If 'a' is a relatively big number such as 0.707 (-3 dB), and the delay T of the echo is several symbol periods, we might run out of taps in the pre-equalizer before we get an accurate solution. DOCSIS 2.0 and later pre-equalizers have 24 taps, with 7 taps normally assigned ahead of the main tap, leaving 16 taps to cancel the echo. For a small value of 'a' such as 0.1 (-20 dB), with a short echo delay, 16 taps is normally sufficient to cancel the echo with minimal residual energy.

Note that the recursions in the above equation have alternating signs. To check for this effect, we can examine the real and imaginary parts of the equalizer taps. If the response is alternating in sign, it is a hint that this type of solution may be present.

A multiple recursion echo may be modeled as:

$$1 + a + a^2 + a^3 + a^4 - .....$$

So its solution can be computed as:

$$\frac{1}{1+a+a^2+a^3+a^4-....} = 1-a$$

Which shows that an infinitely recursive echo can be canceled by a single recursion. So, you should be able to cancel a multiple recursion echo with an adaptive equalizer with only two taps – one for the main signal and one for the echo. To be precise, this example applies to an ideal case where the echo delay T equals a multiple of the symbol period, which for a 5.12 Msps DOCSIS upstream symbol rate is T_s = 195 ns. So, the pre-equalizer can exactly cancel the echo with a single tap if the single echo has delay T = 195 ns, 390 ns, or 585 ns, etc. If the echo lies between these multiples, the equalizer will activate additional taps to provide interpolation. In that case it will be more difficult to see the pattern of a single main recursion.

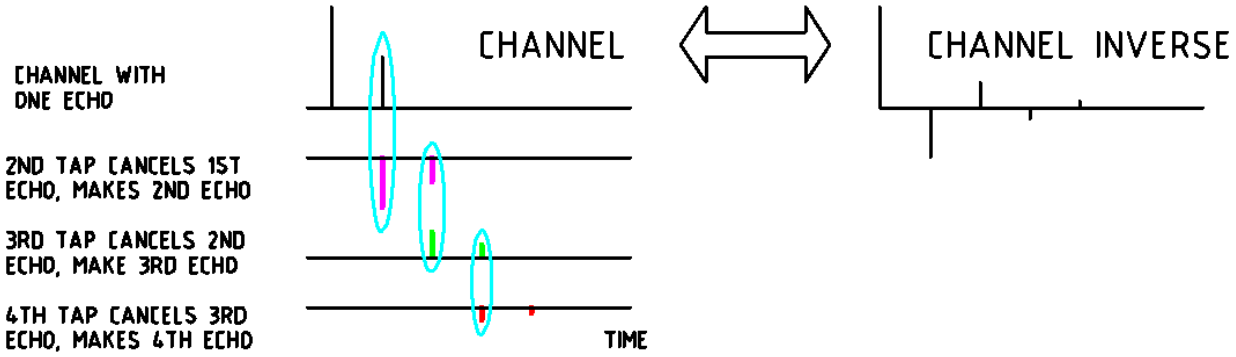

Figure 27 – A single recursive echo needs an infinite number of taps for cancelation. Plots are linear voltage vs time. Blue ovals show cancelation.

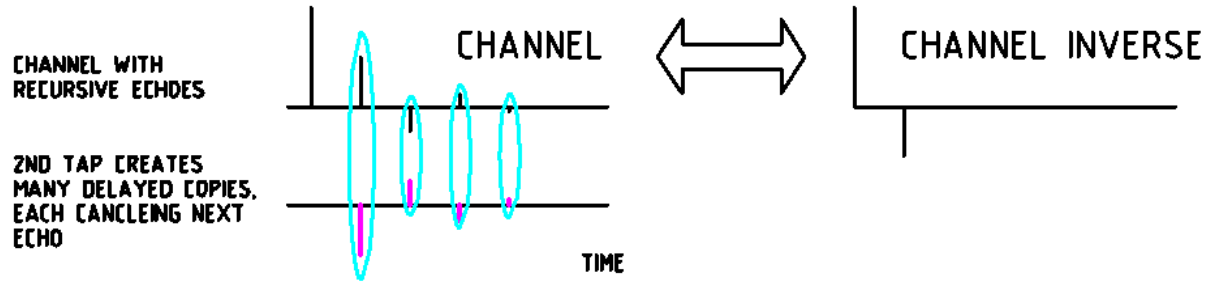

Figure 28 – An infinitely recursive echo is candeled with a two-tap equalizer. Each echo encountered cancels the next echo with a single tap.

3. Linear Distortion Analysis and Network Discovery

Since early days of PNM, we found that by analyzing the characteristics of equalization coefficients, we were able to identify characteristics and features of our HFC network. Many times, these characteristics are apparent when accompanied by a noticeable impairment or condition in the plant such as an impedance mismatch due to a loose connector or an amplifier malfunction. Prior to the DOCSIS 3.1 spec version, we relied on 6.4 MHz or narrower channels in the upstream leveraging up to 24 pre-equalization coefficients. In the downstream direction, although number of coefficients have not been specified, we have seen implementations using 32, 48 or higher number of equalization coefficients to compensate for distortion within the 6 MHz downstream channel. The upstream uses the ranging process to iteratively adjust the coefficients until they converge to a value that compensates channel distortion. In the downstream there is no handshaking with the CMTS so the CM has the sole responsibility in distortion compensation. We have introduced techniques to correlate common impairments within these narrow channels and figure out which CMs share the same impairment and infer the portion of the network that is common to them. One technique consisted of performing complex division of the FFTs of time domain equalization coefficients of the two CMs under comparison. High correlation results in the complex division approaching 1, while if uncorrelated values the division would be much different than 1.

The same approach is valid in DOCSIS 3.1 systems except that the coefficients are already in the frequency domain so one just has to divide the coefficients of CMs under comparison. The normalized equation is shown below.

$$DistortionMatchingMetric = \frac{\sum_{i=1}^{N} \left| \frac{Coef_i CM_k}{Coef_i CM_l} \right|}{N}$$

Where each of the i equalization coefficients of CM_k and CM_l, are complex divided with N being the total number of subcarriers.

Because in DOCSIS 3.1 systems, we are talking about thousands of coefficients rather than tens of coefficients, a much higher resolution is expected. The fact that you are leveraging a complex division process, the likelihood of false matches is much smaller compared to an amplitude only comparison operation. This greater sensitivity enables grouping of cable modems that have more subtle conditions in common, thereby enabling network discovery even on healthy portions of the network.

Another useful tool leveraging complex equalization coefficients analysis is group delay distortion. In DOCSIS 3.0 and earlier versions of the specifications, by analyzing the energy in the pre-main tap coefficients, we had a good indication of the amount of group delay distortion present, and we could infer whether the CMs where sitting behind 0, 1, 2 or higher numbers of amplifiers in cascade. One challenge was that very short micro-reflections would also cause pre-main tap energy to rise, so careful analysis is needed. Figure 32 shows the tap values from an example DOCSIS 3.0 CM.

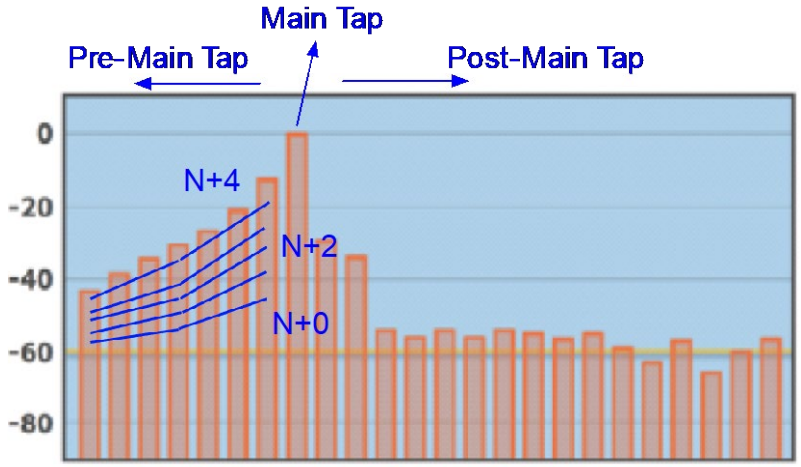

Figure 29 - DOCSIS 3.0 Pre-main tap coefficients and group delay.

In DOCSIS 3.1 systems, we have a view of not just 6 .4 MHz but we can cover the entire US and by obtaining group delay from phase response we can have an accurate view of how group delay changes at the band edges as the number of actives in cascade changes; see Figure 33.

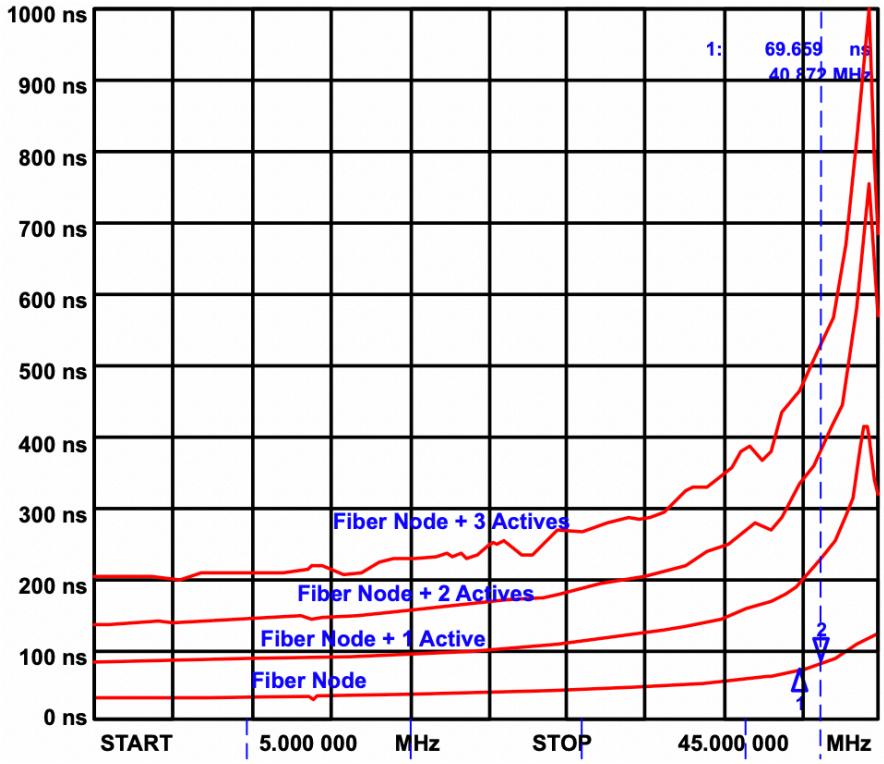

Figure 30 - Group delay and cascade value.

When reflections occurred at tap-coax interfaces, we have been able to deduce coaxial lengths between taps and amplifiers or between taps. This has been useful in determining plant characteristics. As DOCSIS 3.1 specifications came along, the channel became much wider, up to 192 MHz in the downstream and 96 MHz in the upstream. DOCSIS 3.1 specifications evolved from single carrier QAM to multiple subcarriers using either 50KHz or 25KHz, resulting respectively in up to 3800 or 7600 subcarriers in the downstream. In DOCSIS 3.1 specifications, the approach to distortion compensation is the same as with DOCSIS 3.0 and earlier specification versions, in the upstream pre-equalization leverages the ranging handshaking process between CMTS and CM and in the downstream only CM equalization takes place.

A change between DOCSIS 3.0 SC-QAM and DOCSIS 3.1 multicarrier OFDM/OFDMA is that while in DOCSIS 3.0 and earlier versions we had equalization coefficients represented in the time domain across several symbols, in DOCSIS 3.1 we are dealing with a frequency domain equalization representation with one coefficient per subcarrier. This difference is easily overcome through a translation from time to frequency domain using Fourier transformation.

A key difference is that instead of 24/32/48 coefficients in DOCSIS 3.0 and earlier specifications you have up to 3800 or 7600 coefficients in DOCSIS 3.1 specifications. The level of granularity that is possible is more than two orders of magnitude. The techniques discussed here enable the use of equalization coefficients' magnitude and phase for all processes.

Knowing magnitude and phase allows us to determine whether the reflection due to an open a short or a specific complex impedance. This becomes very useful to discriminate whether the distortion impacting CMs is the same or not and will play a key role in grouping devices with common features with high level of sensitivity. The goal is to correlate and group CMs not only when there is a noticeable event or change in channel conditions but also to detect subtle changes even when the network is not impaired, thereby making the HFC network discovery process not just impairment driven but feasible on a healthy network.

Regarding the wider bandwidth coverage, it is worth mentioning that the band-edges in the narrow SC-QAM channels introduce uncertainties as the nature of the FFT requires same values at both edges. The much wider DOCSIS 3.1 channel and frequency equalization operation circumvents that issue. The wider channel view allows us to better describe the group delay distortion in the upstream that is indicative of cascade value.

4. Several upstream (first operator, OFDMA Pre Equalization) and downstream (second operator, OFDM Channel Estimation) results in figures.

For this appendix section, we provide several field data examples in plots. The data come in as I-Q coefficients, one per subcarrier, and typically every 50kHz. The plotted spectral coefficients have linear delay removed before viewing. The FFT size is typically 1024 points for downstream, while the DFT size is 224 points for upstream. In each figure in this section, the center plot is polar I vs. Q, the right plot is I and Q vs. frequency, and the left plot is magnitude of time (impulse response) in dB vs. time. The horizontal scale is the index number. For downstream the time is 19.53ns. per index (4/204.8e6) with a 1024 sample FFT. The bandwidth is 50 kHz times the index, or about 11.2 MHz for upstream and 51.2 MHz for downstream. Note: not all the downstream data provided were plotted.

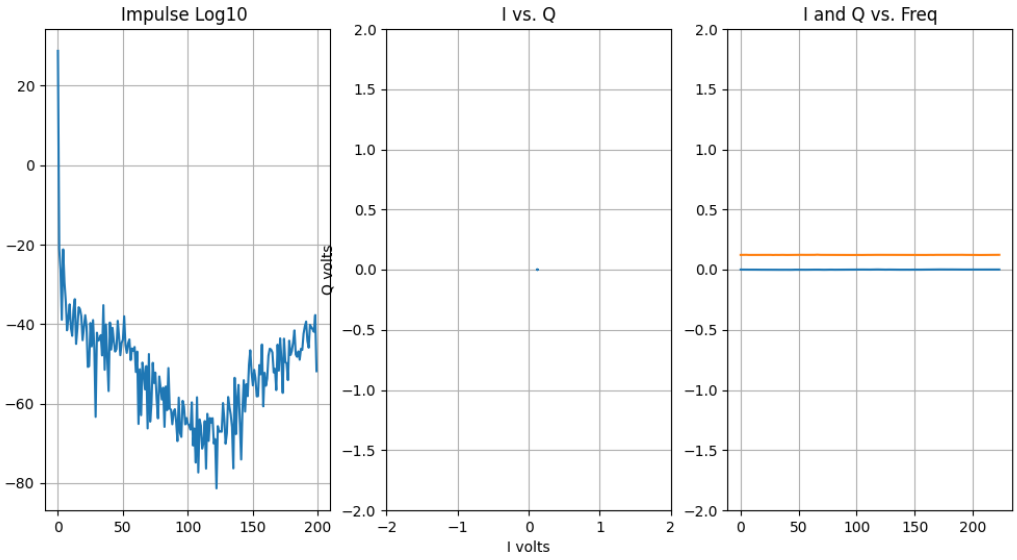

Figure 31 - Pre-equalization data that appears too clean to be cored.

Figure 34 above, shows an upstream response that is too good to be real. Half of the CMs in the data set we received have this response. We guess the result is possibly related to having pre-distortion turned off.

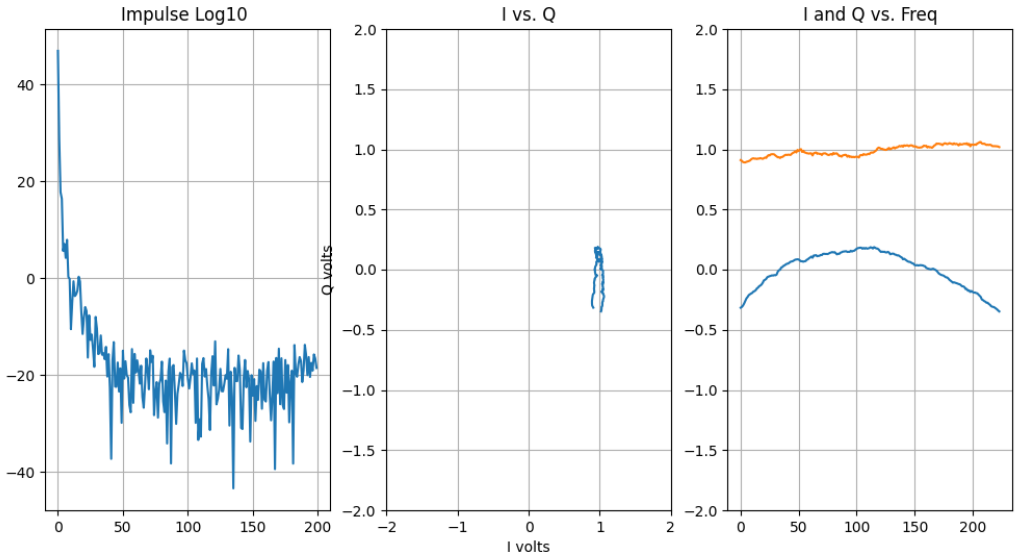

Figure 32 - A typically good pre-equalization result.

Figure 35 above shows a more believable upstream response. A typical upstream good response. Most CMs in our data set look similar to this one. Group delay variation is shown at the top and bottom of the band.

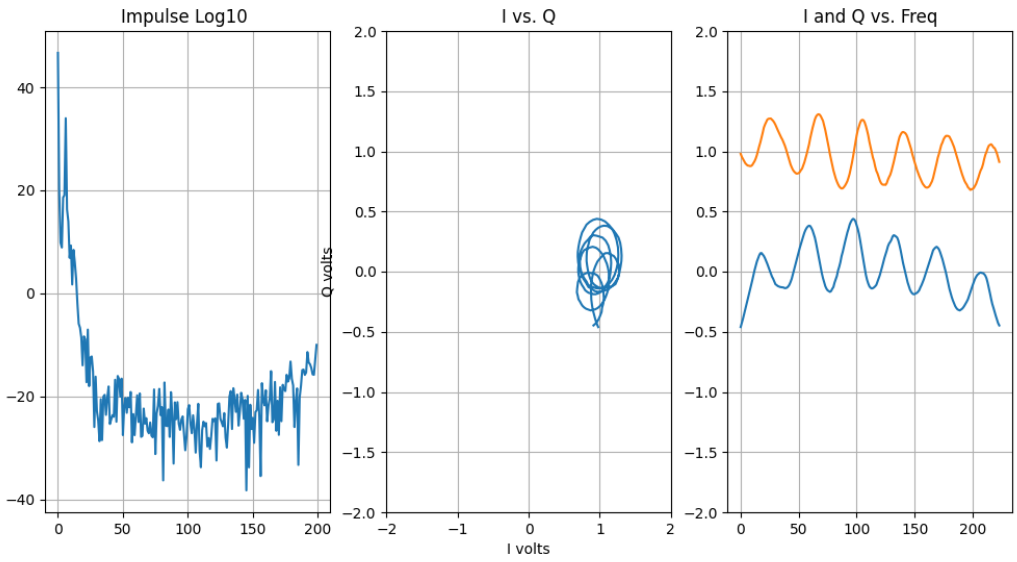

Figure 33 - Pre-equalization showing a standing wave.

Figure 36 above shows an upstream response with a standing wave caused by an infinite recursion echo, which we know because the solution appears as a single recursion.

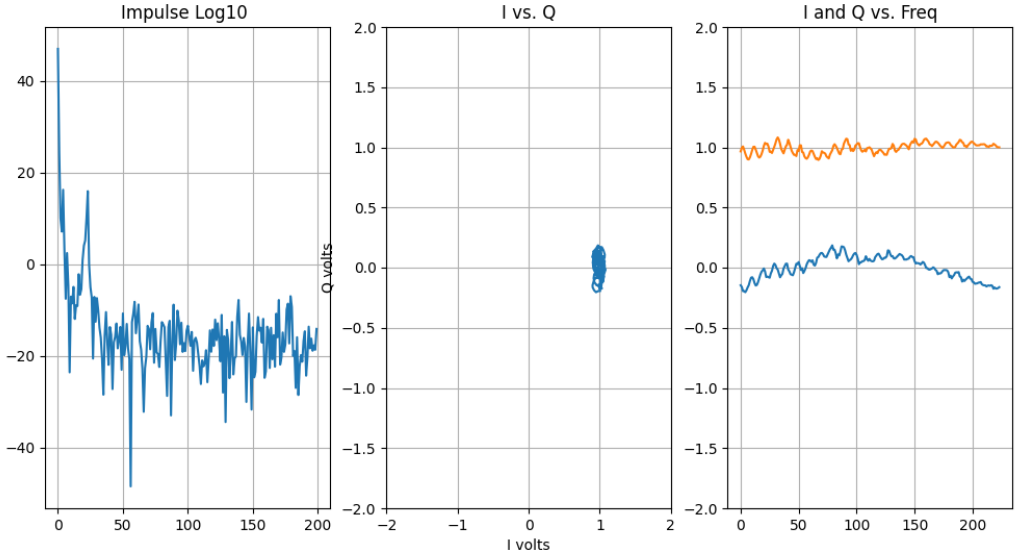

Figure 34 - Upstream pre-equalization data showing a relatively long echo.

Figure 37 above shows an example of an upstream response with a long echo. Note the tight ripple response in the far-right graph.

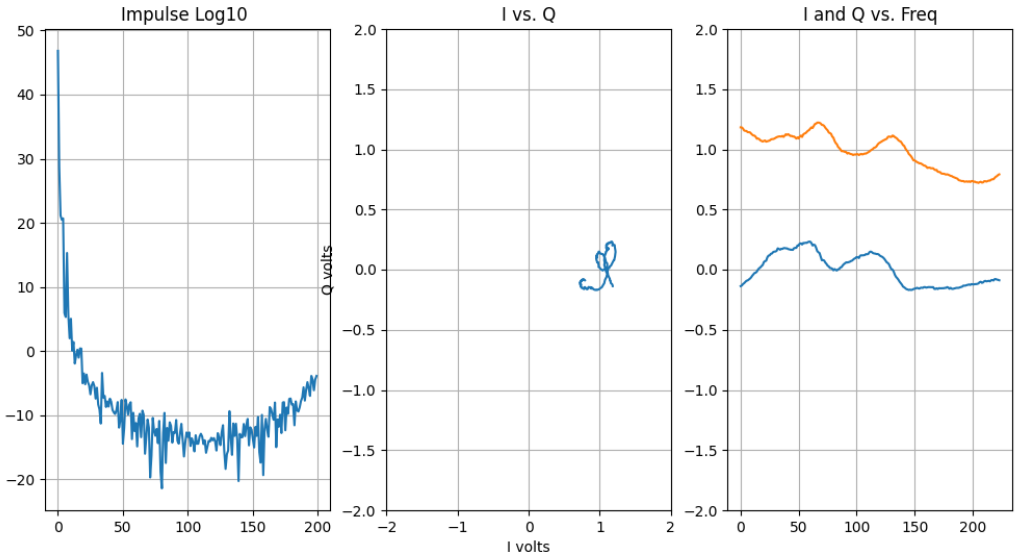

Figure 35 - Upstream pre-equalization, problem probably in house.

Figure 38 shows an upstream data plot of a close-in echo which is probably in the home.

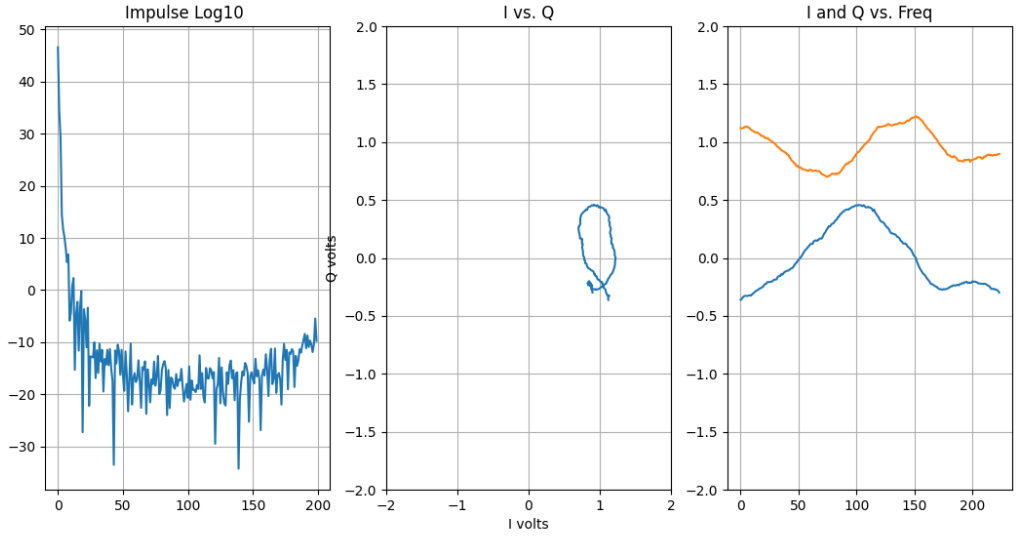

Figure 36 - Upstream pre-equalization data, in-home wiring, maybe open coax shield.

Figure 39 shows pre-equalization data from a CM where there is likely an open shield or other in-home wiring problem.

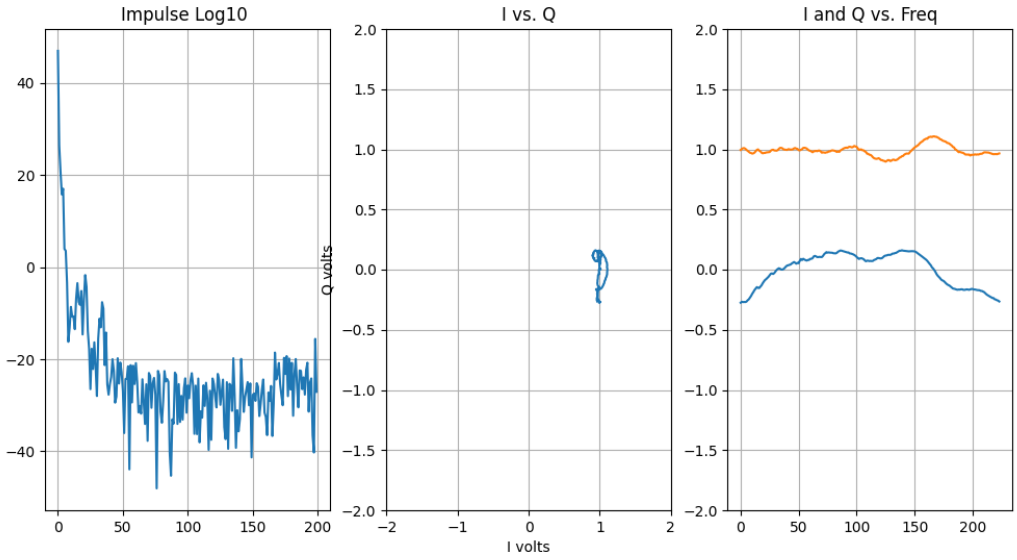

Figure 37 - Upstream pre-equalization, echo only in low frequency bands, so defect probably in home.

Figure 40 above shows an echo but only in the lower part of the band, which suggests an echo cavity, likely in the home.

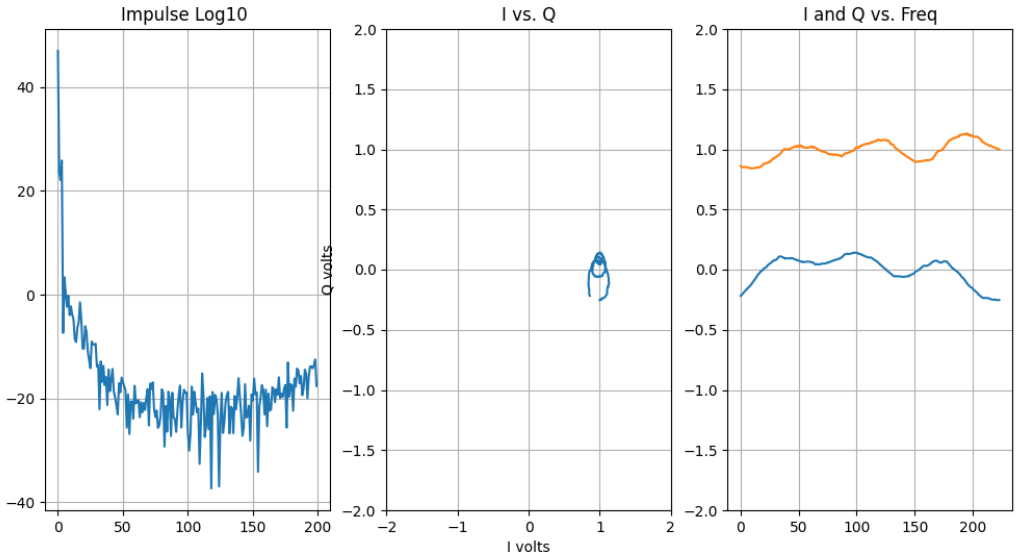

Figure 38 - Upstream pre-equalization data, standing wave.

Figure 41 above shows an example of a small standing wave. Echo is again probably in the house.

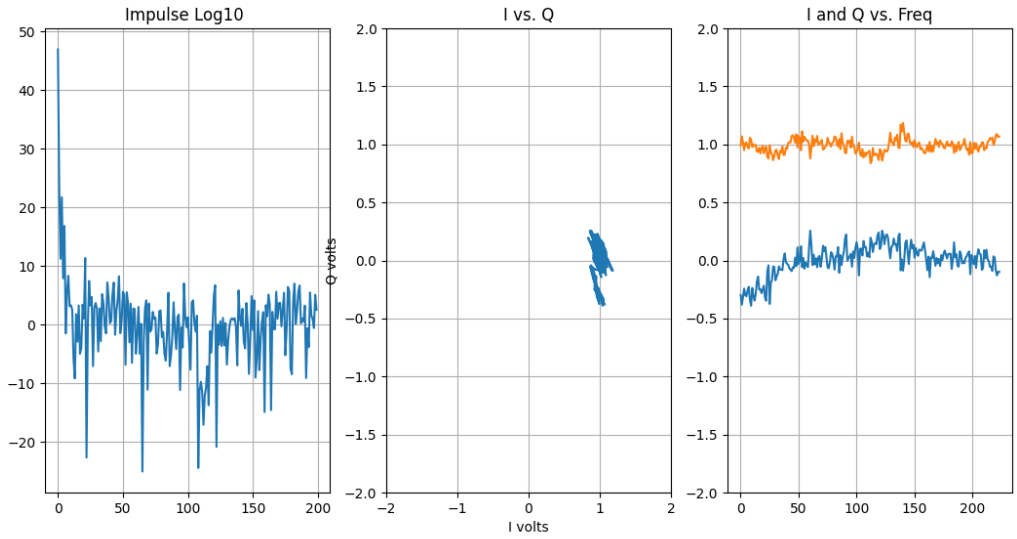

Figure 39 - Upstream pre-equalization, guessed to be water in coax.

Figure 42 above is rather rare in the data set we received. A guess is that it is water in the coax cable from the jagged frequency response. No field tests confirmed this conjecture.

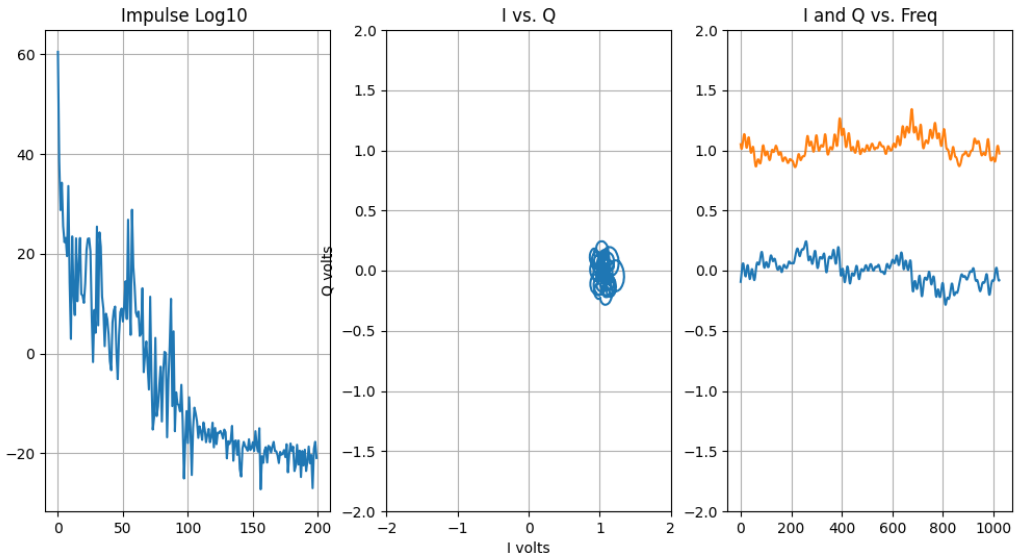

Figure 40 - Downstream, guessed to be water in coax.

Moving now to downstream data, in Figure 43 we see our first example which is guessed again be a case of water in the coax plant. Note the jagged plot on the right, and echo energy close in time on the far-left impulse response plot.

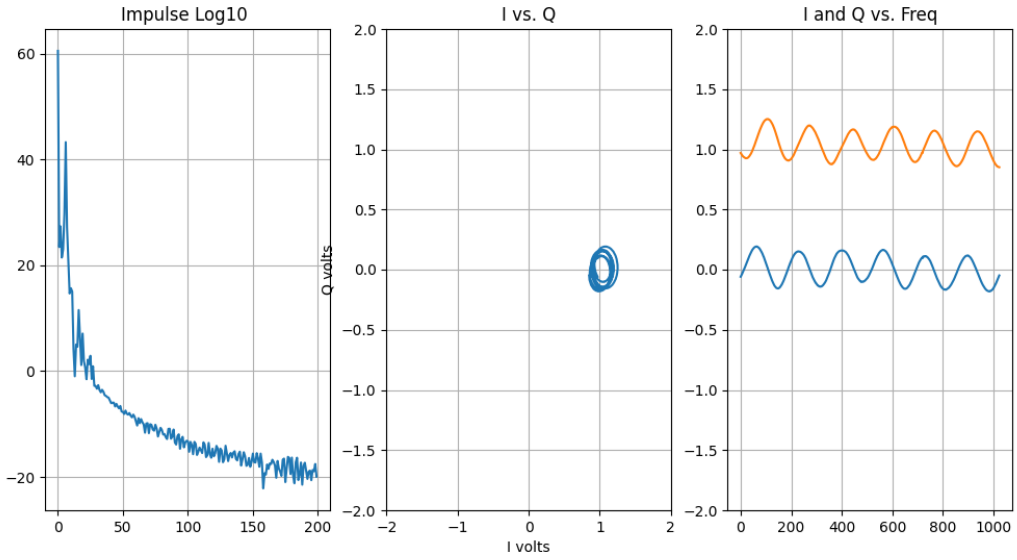

Figure 41 - Downstream lab test. CM is reporting channel response.

Figure 44 shows a confirming lab test, which we used to prove that the CM here was providing channel estimation data in the downstream, clearly showing the echo we inserted.

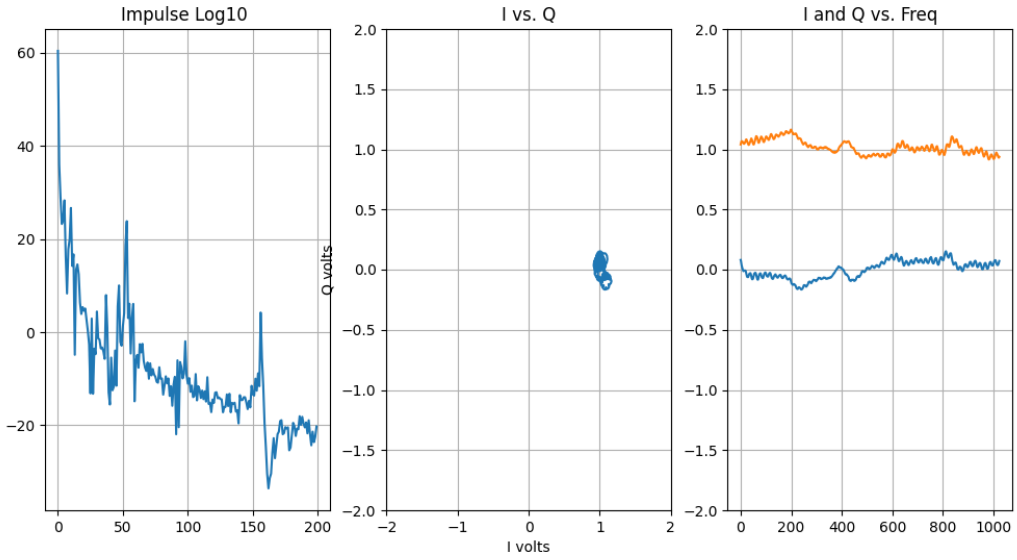

Figure 42 - Downstream, long echo tunnel so echo was weak. Source unknown.

Figure 45 is a channel estimation data plot of a long echo tunnel, which shows a weak response.

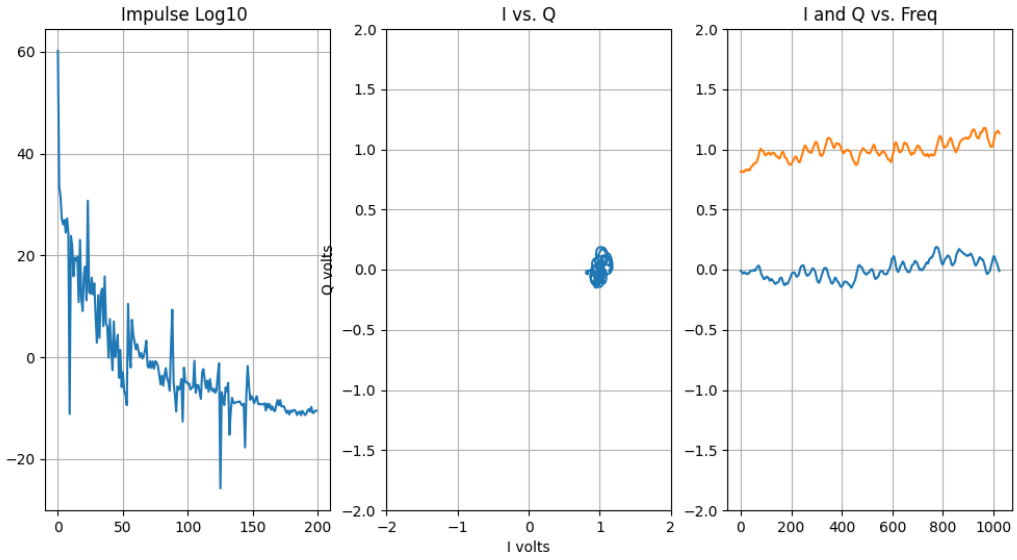

Figure 43 - Downstream, pair of long echoes.

Figure 46 shows a pair of long echoes in the channel estimation data.

On the Road to 10G - Converged Access Platform for HFC & Ultra Long (60+ km) NGPON2

1. Introduction

As the Cable industry investigates solutions for 10 Gigabits per second (Gbps) subscriber bandwidths and beyond, the convergence of the two main Multiple System Operator (MSO) network topologies in use today, Hybrid Fiber Coax (HFC) and Passive Optical Network (PON), becomes highly desirable. COX's current access platform, the Optical Communications Module Link Extender (OCML)[1], supports protected bi-directional transport of 10G Dense Wavelength Division Multiplexing (DWDM) optics over dual 5 to 60 km fiber links for Remote PHY Devices (RPDs), remote Optical Line Terminal (OLT) uplinks and business services. This paper describes COX's next generation converged access platform, the ROCML (Raman OCML), that is targeted for 10 Gbps subscriber bandwidth utilizing Data over Cable Service Interface Specification (DOCSIS 4.0) and/or long distance (60+ km) multi-wavelength 10 Gbps Next-Generation Passive Optical Network 2 (NGPON2). Extended Spectrum DOCSIS 4.0 (ESD) usage of a full 1.8GHz Radio Frequency (RF) spectrum requires 25 Gbps optical interfaces at the Remote PHY Device/Remote MAC-PHY Device (RPD/RMD). The ROCML's innovative combination of Raman, semiconductor and erbium doped fiber amplification (EDFA) transports both multi-wavelength NGPON2 and 25G DWDM optics over 60+ km optical links from the same integrated platform. It provides scalability to meet future bandwidth requirements such as multiwavelength 25G PON and Distributed Access Architectures (DAA) requiring >25G optical signals to RPDs/RMDs. The solution stays in line with COX's preferred methodology of keeping the outside plant passive. Hitherto, deploying PON over optical links >20 km has been a challenge requiring COX to deploy outside plant remote OLTs, either in cabinets or in clamshell enclosures.

The ROCML's long distance NGPON2 capability allows OLTs to remain in centralized indoor hub locations, creating a truly passive long distance PON, vastly improving reliability while reducing Op Ex and capital equipment costs. The ROCML's scalability to multi-wavelength 25G PON ensures a path to a future all Fiber to the home (FTTH network); it also allows for the transport of high capacity Coherent 100G - 400G optical signals, providing a powerful multi-purpose optical access platform for today's networks and tomorrow's requirements.

2. Data Projections

Figure 1 provides the twenty-year downstream data projections based on a 25 to 30% YoY CAGR. It shows the aggregate link usage for both DOCSIS 4.0 (D4.0) and 10G PON. Current COX RPD node size is approximately 350 homes passed, which with a 60% penetration rate gives approximately 200 subscribers per RPD. 10 Gigabit Symmetrical (XGS) PON deployments utilize 1:64 split (64 homes passed) per PON port, which using an average 60% penetration rates gives approximately 40 subscribers per link. For D4.0 to meet future data growth, node sizes can be reduced, or spectrum added such as in a 2x2 RPD, both requiring upgrades to the plant. 10G PON can meet projected data demand well into the future, with 25G PON meeting demand for the next twenty years. The maximum speed available to subscribers on either D4.0 or PON will be limited to half the link capacity, so with current D4.0 at 200 subscribers per link, maximum available speed will be 5 Gbps till 2027 and beyond that node sizes can be reduced, or spectrum added (2x2 RPD). On the other hand, 10G PON can support 5 Gbps till 2032 and beyond that a transition to 25G PON can be implemented to meet capacity requirements.

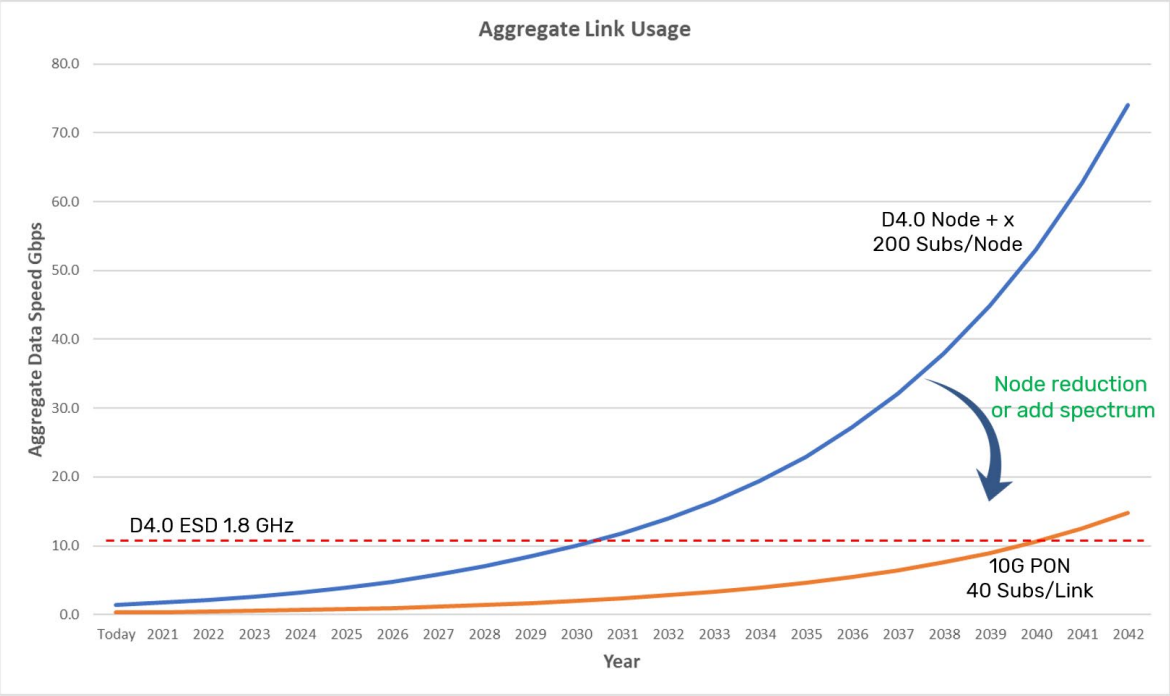

Figure 1 - Twenty Year Downstream Data Projections

3. ROCML Drivers

Some of the main drivers in developing the ROCML concept are given below:

- Long distance 60+ km 10G NGPON2, scalable to 25G PON
- 25 Gbps DWDM optical link for ESD 1.8GHz
- Optical transport over dual fiber links, switchable from primary to a backup fiber
- High system OSNR platform
- Coherent Capability 100G - 400G

The main challenge was in developing a solution which would provide long reach PON capability over 60 km and the inherent OSNR required to enable this. Since 25G DWDM was also an important requirement, dispersion management became an important factor given the inherent increased dispersion at high data rates. A move from 10 Gbps to 25 Gbps in Distributed Access Architectures (DAA) will be required in the next few years to meet projected subscriber demand. DOCSIS 4.0 ESD 1.8 GHz allows HFC networks to provide much higher bandwidths than current DOCSIS 3.1 which supports only 10 Gbps downstream and 1.5 Gbps upstream. ESD usage up to 1.8 GHz in DOCSIS 4.0 shows downstream rates exceeding 12 Gbps for a 1x1 node and 24 Gbps for a 2x2 node, hence a 25 Gbps optical input to RPDs will be needed. Next generation RMDs supporting ESD 1.8/3 GHz and 25 Gbps optical interfaces could meet projected bandwidth demand for the next decade. 25 Gbps DWDM direct detect Non-return-to-zero (NRZ) is planned to be used over 70 km links in the COX access network with the ROCML, with the assumption that RMDs will be able to support 25 Gbps optical interfaces. Figure 2 provides a breakdown of optical bandwidth requirements for DOCSIS 4.0 ESD 1.8 GHz.

Description	Data Gbps
Legacy 258 MHz – 1002 MHz	
2 OFDM Blocks @ 4096 QAM at 1.8Gbps	3.6
24 Ch DOCSIS 3.0	0.93
ESD 1002 MHz – 1794 MHz	
4 OFDM Blocks @ 1024 QAM	6
Total Data Payload	10.53
Total Data Payload (2x10.53)	21.06
Total Video Payload	1.4
IPv6 + L2TPv3 Overhead (5.3%)	1.19
TOTAL OPTICAL LOAD	**23.65**

Figure 2 - Optical Bandwidth Requirements For a 2x2 ESD RMD

4. Raman Optical Communications Module (ROCML) Overview

Figure 3 shows a block diagram of the ROCML which is intended to support ethernet bi-directional DWDM signals in the C-band over a single fiber and 10G PON transport utilizing the NGPON2 wavelength designation in a Point to Point (PtP) configuration. The ethernet transport can be 10G/25G NRZ direct detect signals or high capacity 100G-400G coherent transport. Dispersion compensation allows the 25G NRZ signals to be transported over longer distances. The ROCML provides switching capability to a secondary fiber in case of a fiber cut. Most COX access links are below 40 km, but a few links exist up to 65 km. Downstream amplification is provided by C and L-band EDFAs for the ethernet and PON signals respectively, while Raman pumps at the two output ports provide upstream amplification in the C band which is shared between the NGPON2 and ethernet signals. The Raman Mux DeMux (RMDM) is a passive integrated Mux/DeMux located in the outside plant and enables connectivity to either PON or remote MACPHY devices (RMDs). Eight PON ports allow 512 PON homes to be supported while twenty ethernet ports can be used to support RMDs or business services. The ROCML also incorporates Optical Time Domain Reflectometer (OTDR) ports for in-service (continuous) OTDR monitoring which enables instantaneous location of fiber cuts that drastically reducing time to repair.

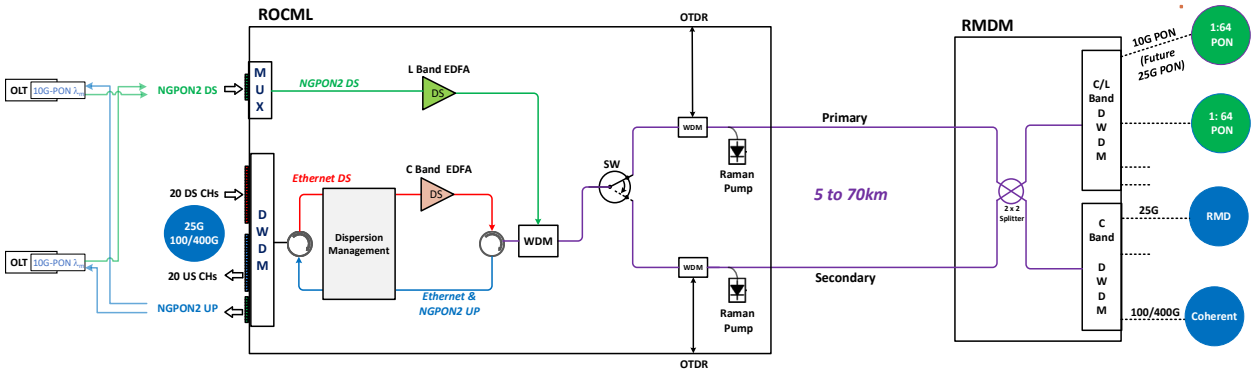

Figure 3 - ROCML Block Diagram

4.1. Optical Wavelengths

The ROCML - RMDM is designed for bi-directional transport over a single fiber and the wavelengths utilized are given in Figure 2 below. C-band DWDM is utilized for ethernet transport in both the downstream (DS) and upstream (UP) directions. For the NGPON2 signals, L-band is used in the DS and C-band for the UP signals.

ETHERNET					NGPON2				
	Downstream		Upstream			Downstream		Upstream	
Pair	ITU	Wavelength	ITU	Wavelength	Pair	ITU	Wavelength	ITU	Wavelength
1	14	1566.31	38	1546.92					
2	15	1565.5	39	1546.12					
3	16	1564.68	40	1545.32

Figure 2 - ROCML Optical Wavelengths

4.2. ROCML – RMDM Loss Budget

The ROCML - RMDM loss budget given in Figure 3 shows a 37 dB and 50 dB loss budget for the ethernet and PON signals respectively. The system goal was to provide minimum optical receive power levels in both downstream and upstream signals of -18dBm for the ethernet signals and -25dBm for the PON signals. 25G NRZ transport requires higher optical levels than 10G NRZ which can operate down to -22 dBm, hence the design ensures at least -18 dBm optical levels. 10G PON will work down to -28.5 dBm but since the ROCML will have to support 25G PON at a future date, it was decided to ensure at least -25dBm optical receive power levels for the PON signals.

PARAMETER	LOSS/GAIN			
	Ethernet		PON	
	DS C Band	UP C Band	DS - L Band	UP - C Band
Transmit Power (dBm)	1	1	7.2	6
ROCML	14.4	14.4	4	8.9
Fiber (65km)	14.3	14.3	15.6	14.3
RMDM	6.5	6.5	5.4	5.4
PON Splitter (1:64)			21	21
Margin	2	2	2	2
Total System Loss Budget (dB)	**37.2**	**37.2**	**48**	**51.6**
Gains (EDFA + Raman)	18	18	15	21
Optical Rx Power (dBm)	-18.2	-18.2	-25.8	-24.6

Figure 3 - ROCML RMDM Loss Budget

4.2.1. Optical Amplification

The ROCML uses conventional C and L-band EDFAs for the downstream ethernet and PON signals respectively. Upstream amplification is provided by Raman pumps located at both the primary and secondary output ports of the ROCML. The Raman pumps' power and wavelength are selected to provide sufficient amplification in the upstream C band used by the ethernet and PON signals. The Raman pumps also provide some gain in the downstream for both the PON and ethernet signals. The Raman pump powers/wavelengths are optimized to provide maximum gain for the PON signals and the Raman gain

profile for a 70 km link is given in Figure 4. This shows 21 dB upstream gain for the PON signals which is required to increase the PON loss budget from a typical 29 dB to 50 dB. An 18 dB gain for the upstream ethernet is sufficient to meet the loss budgets given in Figure 3. The Raman pumps also provide downstream gains of 7.5 dB and 5 dB for the ethernet and PON signals respectively.

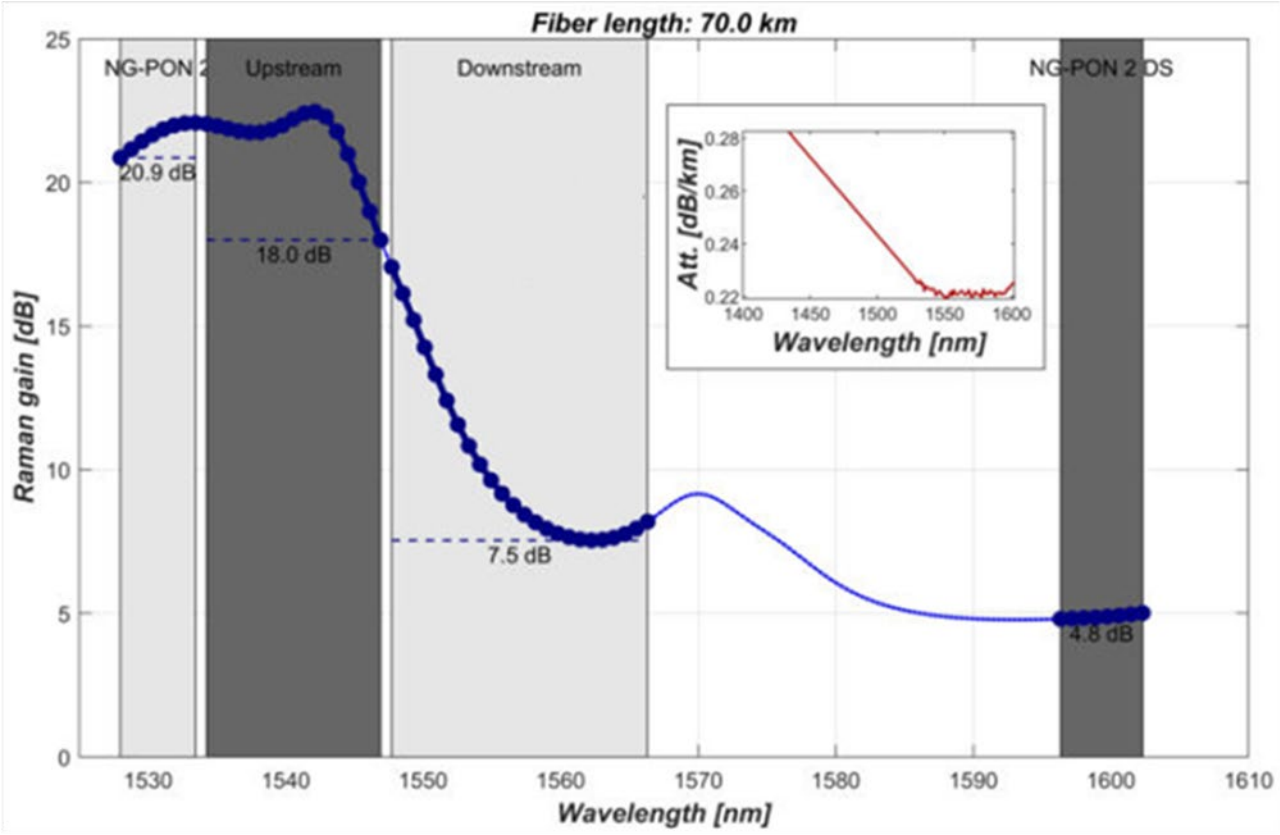

Figure 4 - Raman Gain Profile

4.3. Dispersion Management

Chromatic dispersion (CD) can cause laser pulses traveling down fibers to spread until they become unrecognizable as depicted in Figure 5. It occurs because different optical wavelengths/frequencies launched from the Tx light source travel at different velocities in a propagating dispersive medium, with the longer wavelengths traveling faster. Chromatic dispersion degrades the transmission quality and limits link distance and hence Dispersion Compensation Modules (DCMs) are added for Intensity Modulated Direct Detect (IM-DD) systems.

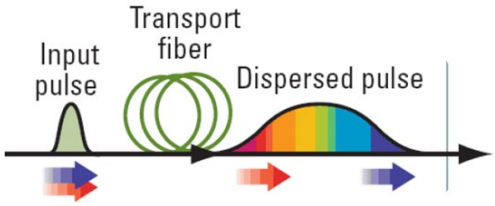

Figure 5 - Pulse Broadening Due to Dispersion

Maximum fiber link (L) due to chromatic dispersion CD is given by equation 1 below:

$Equation1:\ L = \frac{104{,}000}{CD*B^2}$

where

L: Distance in km
CD: Dispersion in ps/(nm*km)
B: Bit rate in Gbps

The maximum fiber links which can be transported for direct detect systems are tabulated in Figure 6 below using equation1. For 25G NRZ direct detect signals, links are limited to 10 km, so dispersion compensation modules (DCM) are employed in the ROCML to extend these links up to 70 km. The DCM can be made from Dispersion Compensating Fiber (DCF-DCM) or Fiber Bragg Grating (FBG-DCM). There are pros and cons with both dispersion compensation technologies. The DCF-DCM has a fixed amount of dispersion compensation but is bi-directional, so a single DCM can be used for DS and UP. The FBG-DCM can be tuned to the specific fiber length but are uni-directional and hence separate FBG-DCMs are needed for the DS and UP signals.

Data Rate Gbps	Maximum Fiber Link (km)
10	61.2
25	9.8
40	3.8
100	0.6

Figure 6 - Max link vs Data Rate

5. COX PON Architecture

COX current PON deployments utilize XGS-PON which is limited to fiber links of 20 km. XGS-PON utilizes L band downstream (1575-1580 nm) and O-band upstream (1260-1280 nm). The upstream wavelengths used have a minimum dispersion which is required since the Optical Network Unit (ONU) uses low-cost direct modulation and the resulting chirp combined with fiber dispersion fiber would cause performance degradation. The ROCML's innovative design manages fiber dispersion in the upstream, hence C band transmission as defined in the NGPON2 standard can be utilized over longer distances.

5.1. Current COX PON network

The current COX PON architecture (Figure 7) utilizes 10G ethernet uplinks from the current COX access platform OCML[1] to feed remote OLTs which are environmentally hardened, passively cooled, strand-mount devices. The OLTs can be mounted in a pedestal or on aerial strand and must be provided with plant power. A distribution split ratio of 1:64 is used which can be dropped to 1:32 to reduce contention.

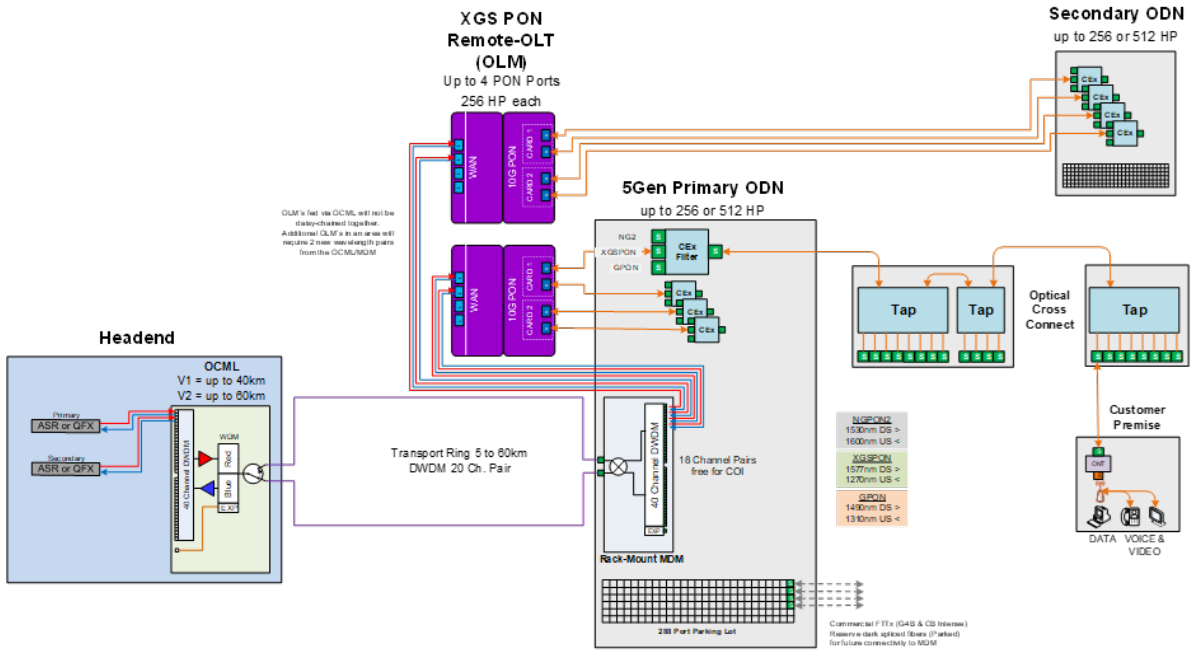

Figure 7 - COX XGS-PON Network

5.2. Proposed COX Next Gen PON network

The proposed PON network with the ROCML is shown in Figure 8, which shows centralized OLTs transported over a primary and back up secondary fiber which could be up to 70 km. Eight C/L band ports on the passive Mux/DeMux (RMDM) located in the outside plant can each support 64 subscribers for a total of 512. Larger split ratio of 1:128 can also be used over shorter links of 40 km (most COX networks) for a total of 1024 subscribers. This network creates a true passive optical network with all active components inside the headend, vastly improving reliability, network downtime and reducing OPEx.

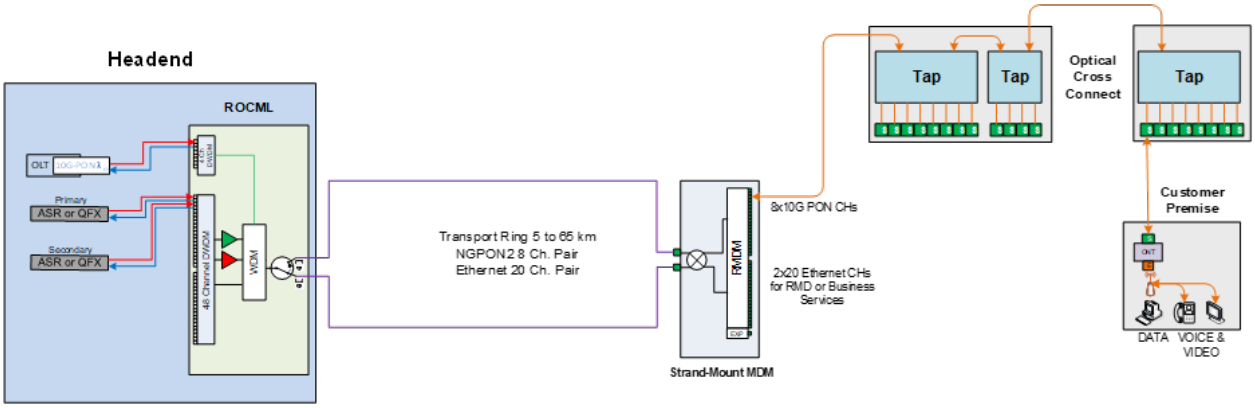

Figure 8 - ROCML 10G PON Network

6. 25G PON

25G PON is the next step in PON evolution driven by concrete demand and use cases, including 5th generation mobile network (5G), advanced enterprise applications, and wholesaling services. As shown in Figure 1, COX would need to move to 25 Gbps PON, possibly within this decade to meet projected data demand, especially if 10 Gbps were to be offered to subscribers. 25G PON Delivers a 250% increase in capacity over today's 10 Gbps XGS-PON and can deliver true 10 Gbps symmetrical services. It leverages mature, high-volume data center optical technology.

6.1. 25 Gigabit Symmetric Passive Optical Network (25GS-PON)

25-Gigabit-capable symmetric passive optical network (25GS-PON) is an optical access network for residential, business, mobile back/mid-haul, and other applications, operating over a point-to-multipoint infrastructure at 25 Gbps downstream and 10 or 25 Gbps upstream. The main features of the 25G PON network shown in Figure 9 are:

- 29 dB loss budget
- 20 km maximum fiber link
- O-band single wavelength
- NRZ transmission
- Low cost Directly Modulated Laser diode (DML) in ONUs
- No dispersion compensation
- No optical amplification

This solution would require remote OLTs as in the current COX XGS-PON deployments with high capacity ethernet uplinks.

Figure 9 - 25GS-PON Network

6.2. 25G PON Over ROCML

One of the drivers of the ROCML was to create a scalable long-distance 60+ km PON solution which could seamlessly migrate from 10G PON to 25G PON. To enable low-cost direct modulation NRZ to be utilized at the ONU, it was critical to be able to manage dispersion at the higher 25Gbps data rates and to have a high system OSNR. It is envisaged that the same NGPON2 wavelengths (L-band DS and C-band UP) could be utilized to transport multiwavelength 25G PON over the ROCML-RMDM system and extend the loss budget to 50 dB. The main features of the 25G PON "ROCML" network shown in Figure 10 are:

- 50 dB Loss budget
- 60+ km
- L/C-Band multiwavelength, 8 X 25G
- NRZ transmission
- Low cost DML lasers in ONUs
- Dispersion compensation
- Optical amplification (EDFAs and Raman)
- 512 subscribers over 60+ km, 1024 subscribers over 40 km
- Less hardware
- Increased reliability with no field actives
- Reduced OpEx

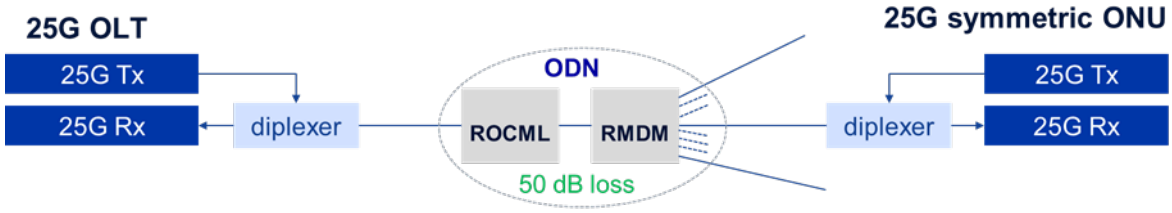

Figure 10 - 25G PON Over ROCML Network

7. Access Network Topology

The ROCML-RMDM is the optical access physical layer that connects the spine/leaf network located in the hubs/headends to the metro and backbone networks. It provides optical amplification to provide appropriate signal levels to the Remote PHY nodes for COX's HFC network. The current OCML is essentially a 10G DWDM optical physical layer which provides 10Gsignals to RPDs and remote OLTs.

The ROCML will transport 25G DWDM signals to Remote MACPHY nodes in a DOCSIS 4.0 ESD 1.8 GHz network and multi-wavelength 10G PON signals which can be transported over extended fiber links of 60+ km, obviating the need for remote OLTs in the outside plant.

7.1. DOCSIS 4.0 ESD 1.8 GHz Network

Figure 11 depicts a high level DOCSIS 4.0 ESD (1.8 GHz) network in the COX access networks in a node + x environment. Many devices will need to be upgraded and Figure 11 provides approximate numbers. To get further to an all-Internet Protocol (IP), DOCSIS4.0 10G network, the following need to be upgraded:

- Converged Cable Access Platform (CCAP) to Virtual Controller (or v mac manager)
- Converged Interconnect Network (CIN) to 25 Gbps network aggregation (via ROCML)
- Nodes need to be upgraded to Remote MAC Devices (RMDs).
- Nodes and amps need upgrades to ultra-high-split 1.8 GHz
- Taps need to be upgraded to 1.8 GHz (or better)
- D4.0 cable modems and gateways capable of ultra-high-split and 1.8 GHz

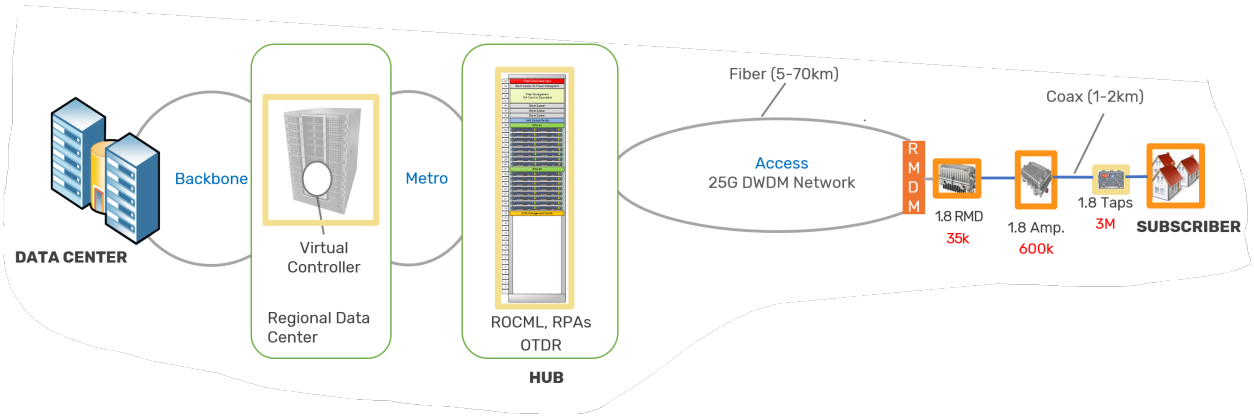

Figure 11 - DOCSIS 4.0 ESD 1.8 GHz Network

7.2. Fiber To The Home (FTTH) Network

Figure 12 shows how the ROCML - MDM can be utilized to create a true passive PON network and transport 10G signals to subscribers. The biggest Capex in a FTTH network will be trenching fiber to subscriber homes and some upgrades such as:

- CIN needs upgrade to ROCML
- Centralized OLTs
- ONUs at the subscriber

However, this is a one-time cost and future upgrades such as higher capacity 25G PON will only require changing equipment at the access fiber end points such as OLTs in the headends and ONUs at the subscriber homes. Such a true FTTH network requires less hardware, has no field actives, significantly improves reliability while reducing OPEx.

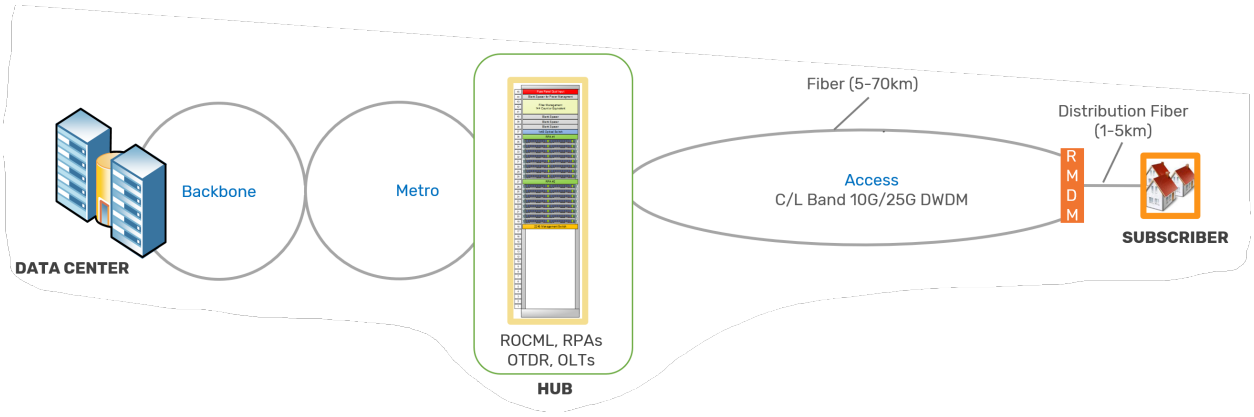

Figure 12 - FTTH ROCML PON Network

8. Conclusion

The ROCML - RMDM is a true universal access platform for the foreseeable future. It's a single integrated optical communication module which can be used for DOCSIS 4.0, long distance symmetrical 10G PON (scalable to 25G PON), 5G and enterprise services. Its innovative design allows for a 10G/25G DWDM direct detect transport over 60+ km fiber links to support RPDs or RMDs and its long-distance 60+ km PON capability creates a true passive optical network. The ROCML will allow COX to seamlessly transition from a DOCSIS 4.0 ESD 1.8 GHz network to an eventual FTTH network.

1. Introduction

In 2020, Comcast deployed a Profile Management Application (PMA) system (1) for optimizing the DOCSIS 3.0 (D3.0) configuration across upstream channels in the network to achieve the proper balance between efficiency and robustness (fault tolerance). The established PMA system strengthens organizational objectives to increase network capacity, proactively respond to impairments, and support robust service optimizations for customers. At its core, the current system adopts a rules-based approach, in which a static policy (in the form of defined thresholds) for the different telemetry features (e.g., signal-to-noise ratio and codeword error rates) govern the choice of channel configuration.

Limitations within PMA exist when shaping telemetry thresholds to adapt to a wider range of environmental conditions. Currently, configurations are assigned to channels starting with conservative profiles and progressively moving toward efficient, yet less robust profiles. Further innovations within Comcast's PMA implementation focus on the delicate balance of applying intelligent, dynamic decision-making policies while preserving proper configurations for the diverse set of network devices.

A reinforcement learning (RL) approach for PMA allows, through experience, learning an optimal policy and therefore, enhancing the criteria used at various decision points. Simultaneously, RL simplifies policy management by consolidating permutations of telemetry boundaries into a single entity, called a 'state'. PMA efficacy improves with RL by reducing the latency of transitioning into optimal, efficient profiles, and doing so with increased confidence across varying network conditions (4). Inherent in this implementation is the risk reduction for operators to deploy more profile changes that maximize capacity without crossing the boundary that introduces disruption in service. This paper introduces a proof-of-concept RL-based PMA system along with performance study based on initial experimentation conducted in our laboratory.

2. Reinforcement Learning Design for PMA Systems

The purpose for implementing RL on upstream PMA is twofold: to manage PMA using a dynamic policy that continuously learns and to select optimal profile configurations with increased efficiency. An RL-based system provides the framework to facilitate these two objectives. A dynamic policy that is updated over each time step is more attuned to fluid network conditions than a static policy with fixed global thresholds. When a dynamic policy is updated, the decision criteria for choosing the optimal profile configuration under the current network conditions represents the best-known policy discovered by the system (2).

2.1. RL Concepts for US PMA

The RL sequence consists of an *agent*, selecting *actions* to take from a given *state*, and calculating the *value* of the action taken with respect to a *reward* system as the resulting state interacts with the *environment*. Figure 1 represents the sequence of interactions in a feedback loop. As the agent collects the rewards, it updates the policy using the *value function* (Equation 2) that satisfies the Bellman Equation (2) to continually refine the values for states-action pairs encountered. This process is called *value iteration* and is the basis of the dynamic policy.

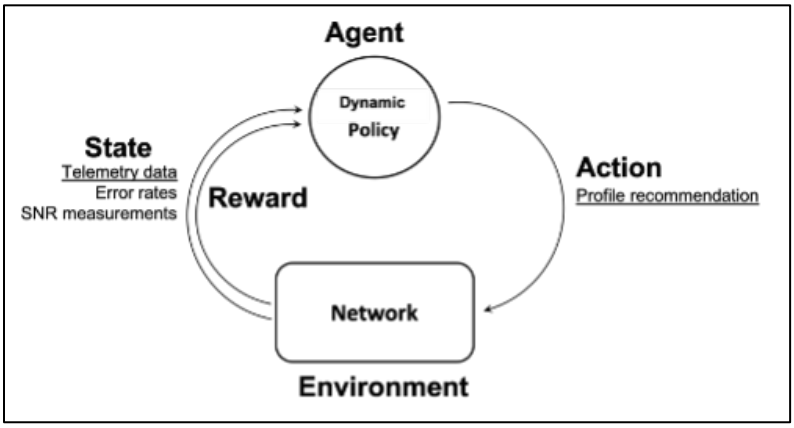

Figure 1 - RL Framework of the PMA System.

State-action values are numeric representations describing how valuable it is to take a given action from any state. They are calculated with respect to the next state-action pair, establishing the update process for sequential decision-making as Markov Decision Process (MDP). As the system builds experience, convergence occurs in the policy whereby updates to state-action pairs change the values over time in progressively smaller increments. The calculations of state-action values are based on the acronym SARSA. S, A, and R respectively denote State, Action, and Reward. With a subscript referring to the time step, SARSA can be represented with the following trajectory:

$$S_0, A_0, R_1, S_1, A_1, R_2, S_2, A_2, R_3, \ldots \quad (1)$$

In an MDP, the consequences of an action taken within the current state do not depend on maintaining the entire history of the trajectory; instead, just updating the state-action pair encountered maintains the legacy of experience already gained. The nature of the update considers how rewards are weighed, which influences how the policy is learned. For the proof of concept described in this paper, the Temporal Difference (TD) SARSA equation, $Q_\pi(s, a)$ in Equation 2 for online policy improvement is used to update the policy. The hyperparameters, α and γ, influence the learning rate and value of the future reward, respectively.

$$Q(S_t, A_t) = Q(S_t, A_t) + \alpha[R_{t+1} + \gamma Q\big(S_{t+1}, A_{(t+1)}\big) - Q(S_t, A_t)] \quad (2)$$

The α and γ terms are both floating point values between zero and one. α is a fixed learning rate where a value close to zero slows the learning and closer to one increases the learning rate. γ is a discount rate that determines how much to weigh immediate rewards and potential future rewards. As γ approaches one, the value of potential future returns influences the state-action pair estimates just as much as the immediate return; whereas a value closer to zero treats near-term rewards with more emphasis than future rewards. With respect to the US PMA effort, responding quickly to poor telemetry is critical in reducing customer impact. Finding an appropriate combination of these hyperparameters is an important objective for the problem at hand.

A dynamic policy is interesting to the PMA problem for its adaptive behavior that adjusts state-action pair values, and then uses those new values in real-time. With a dynamic policy in place, the RL system can adjust decision criteria under clean or adverse conditions. Consider a scenario where network impairments are causing high Uncorrectable Codeword error ratio (UCCW) rates and low signal-to-noise ratio (SNR). The RL policy, already having been exposed to this state, will recommend a profile change toward alleviating the side-effects of the larger problem (UCCW rate). If the issues persist, it is possible

for the RL policy to learn to take more aggressive action. The negative reward associated with the more conservative step will reduce its state-action value. Once an acceptable profile is reached, the state-action value is positively updated. At a point, if the cycle continues, the value of taking the aggressive action will become higher than the conservative action. Thus, the agent will then choose the aggressive action next time the poor telemetry is encountered.

In terms of α and γ, having parameters that reflect values associated with learning quickly is an intuitively logical approach. When an impairment occurs, the quicker the policy can adapt within the environment, the better decisions it will make. An example would be to set α to 0.8 and γ to 0.3. In this paper, multiple variations of the policy parameters are explored to inform of system short-term and long-term behavior implications associated with different policies.

2.2. RL Applied to US PMA System

Within the scope of an upstream PMA system, the states, actions, and a reward system were defined to represent characteristics of the current telemetry and configuration data to choose the optimal profile configuration for the present conditions (4). A state represents a distinct set of channel configurations and their associated network metrics. Each defined action is available for each state. The reward system is the mechanism used to influence how valuable it is to take an action from a state. As the system iterates over the timesteps, rewards are used to update the policy for the current action.

One key principle in RL systems is the trade-off between exploration and exploitation. Exploitation occurs when the highest-valued action previously encountered is taken from a state. However, that may not be the absolute best action to take for that state. To find the optimal action, the algorithm could select a random action to evaluate. When operating in production systems, random exploration is a risky endeavor because the policy could choose a transition that either introduces elevated UCCW rates, or transition to a slower profile when it is completely unnecessary to do so. In this POC, the evaluation of dynamic policies omits the exploration step and uses only exploitation to select the best actions available.

2.2.1. State

In the RL system for this paper, a state is considered a collection of telemetry metrics and configurations that are represented by discrete bins, with each state being unique. Continuous variables, like telemetry, were categorized by value ranges. Categorical variables fell naturally into their associated bins. Table 1 provides a breakdown of attributes to bins. In reality, only a small portion of the possible states will be encountered. As an example, not all CMTSs may be configured with six upstream channels and will never encounter any state where a fifth or sixth channel is represented.

A unique state is represented as a concatenated string of the bins as shown in Figure 2. In this example, the state of the channel on Remote PHY Device (RPD) HN1 is interpreted as a sub-optimal profile configuration that is experiencing a poor UCCW rate and needs to be downgraded to a more robust profile configuration.

Table 1 - Attributes of a State

Category	Attribute	# Bins
Telemetry	Uncorrectable Codewords (UCCW)	3
	Correctable Codewords (CCW)	3
	Signal to Noise Ratio (SNR)	6
Channel Configuration	Channel Width	3
	Modulation	5
	Profile Type	5
	Traffic Volume	2
	Channel Frequency	6
	CMTS	5
Total # Possible States		243,000

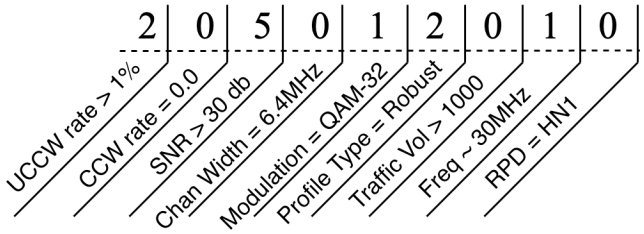

Figure 2 - Example of a Unique State ID

2.2.2. Actions

For each defined state, the complete set of actions is available to choose from when making profile recommendations. Like the states, many actions will never be encountered for certain states. For example, if the upstream channel was running on the optimal profile, there is no ability to move to a more efficient profile. Therefore, the state-action values for upgrades would all remain at zero.

In this RL system, three categories of actions were defined:

1. Upgrade or downgrade
2. Remain in the same configuration
3. Transition onto and off the most robust configurations, referred to as 'transient' profiles (these are designed to deal to dynamic impulse or burst noise)

Actions were limited to a maximum of four steps to restrict the dynamic policies from taking large action steps which would increase the likelihood of entering a poor state.

2.2.3. Reward System

The reward function serves to describe to the agent how it ought to behave. The key attribute to direct the agent in the simplest way is the UCCW rate. In this implementation, the reward system is boiled down to an evaluation of a Boolean condition that answers the question, "Is the UCCW rate greater than 1%?". If it is, a large negative reward (punishment) of -10 is given to the agent. Otherwise, the reward is $1 + profile\ speed\ gain$. A negative reward can still be observed if the UCCW rate is below 1%. For example, if a channel is in an optimal profile and the algorithm moves it to a transient profile, the loss of

speed is greater than the static bonus of +1 for keeping the UCCW rate low. This simple approach is designed to encourage upgrades in good conditions, and downgrades in poor conditions.

2.2.4. Policy Updates

The heart of the dynamic policy is the process of value iteration. Value iteration using TD SARSA from Equation 2 is the update algorithm that continues to adjust the state-action values until convergence (2). For each iteration, and each state and action encountered, the Bellman equation (2) is applied as an update rule in the form of Equation 2 and the profile recommendation logic uses the freshly updated policy in the same iteration.

3. System Architecture

3.1. Lab System

The lab system architecture was built off the existing Profile Management Application (PMA) Lab design. The primary functional groups consist of:

1. Impairment generation
2. RF switching matrix
3. Diplexing/combining components
4. Cable modem racks
5. Traffic generation
6. RPD nodes under test
7. vCORE and backoffice

The automation controller randomizes impairment profiles on the generator via an SCPI interface. It is also used to run GNURadio to create bespoke waveforms played back through a software-defined radio. The impairment sources are connected to an 8 x 16 port RF switch to steer or distribute the impairments to the appropriate devices under test. The impairments are combined into the appropriate points to feed either the RPD upstream burst receiver or the cable modems' downstream receivers. For the traffic generation loop, the network side interface is connected to the Distributed Access Architecture Switch (DAAS) and the CPE ports are VLAN'ed and connected to each cable modem on a high-density, mobile rack.

Five RPDs, with an average of 8 cable modems (CM), made up the population of devices for the trial. Each RPD contains a bonding group of either four or six D3.0 upstream channels, with a total of 24 upstream channels across the RPDs. Random impairments (none to severe) were introduced to evaluate the policies under both clean and adverse telemetry.

Table 2 - Lab Devices

RPD Name	Number of Channels	Number of CMs	Vendor
AS2	6	6	CMTS X
AN1	4	8	CMTS X
CN1	4	7	CMTS Y
HN1	4	12	CMTS Z
HS3	6	8	CMTS Z

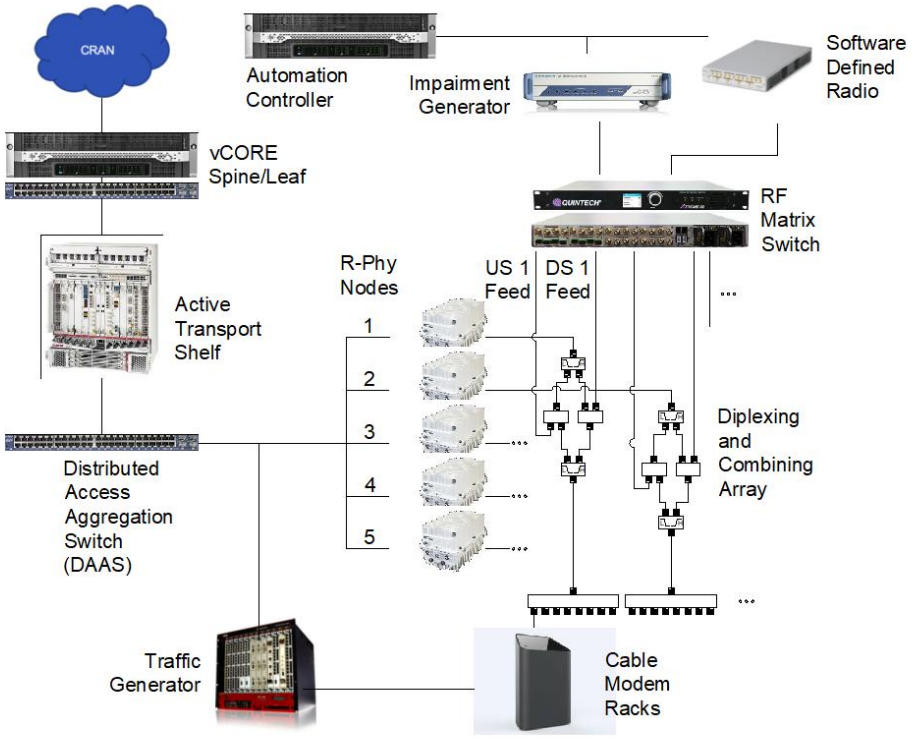

Figure 3 - Lab System Architecture

3.2. Data Pipeline

Each section of the pipeline is decoupled from the other sections to accommodate for experimentation and manipulation of policy parameters, states, actions, or other logic that would benefit from incremental changes. The sequence of the pipeline is shown in Figure 4:

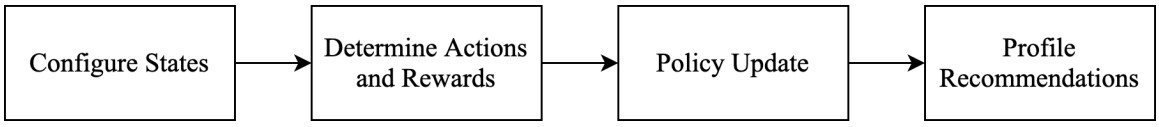

Figure 4 - Data Pipeline Sequence

The primary inputs are the attributes that make up a unique state (described in Section 2). Once collected, the current state can be assigned for each channel on the RPD. The data is associated with a timestamp that can be used, if necessary, to retrain a policy through the sequence of actions taken using historical data.

Arranging the data points by timestep for each upstream channel, the sequence of actions taken, and states encountered in order can be observed and rewards assigned. Being an independent step in the pipeline, this gives the opportunity to update the reward function or actions, and to be able to run the updates over the complete set of historical data or just the latest data points that need updated. In this pipeline, acquiring the action taken is not solely dependent upon the profile recommendation from the previous step, which makes determining the action taken delayed. A separate transaction manager must apply the recommendations first, and that function may or may not have succeeded.

In the policy update step, the latest timestep that needs to run through the SARSA equation with the full suite of the current state, action, reward, next state, and next action data is collected. The collection of all updated state-action pair values is preserved for use in recommending profiles.

Making profile recommendations is relatively trivial after the policy has just been updated; however, there are special cases to account for to either prevent abnormal behavior or change the degree of exploration desired. In most cases, the agent simply looks for the highest-valued action for the current state, also known as exploitation. Exploration is the selection of a random action a specified percentage of the time. In a production environment, either the exploration is very limited or not used at all. The profile recommendations in this paper for RL-based policies were all derived using exploitation – selecting the highest-valued action in all cases.

It is possible for the RL system to encounter states not seen before. When this happens, conventional logic is to select a random action. This could be detrimental to the channel's capacity on live CMTSs. In this described RL system, logic was added to directionally influence the profile recommendation based on the UCCW rate for the channel if a state is encountered for the first time. There is no need to downgrade a channel's profile if the telemetry is obviously adequate for consideration of upgrading.

3.3. Closed Loop

The closed loop system consists of the lab architecture and operation, the data pipeline, and the profile transaction manager. The lab generates telemetry and maintains configurations, which is processed through the pipeline, and the profile recommendations are applied onto the systems. Pipeline cycles are scheduled to complement the noise transition schedule in the lab by executing just prior to the noise transitions, ensuring that the next profile recommendations are based on the most current telemetry.

4. Building Dynamic Policies

Training a dynamic RL policy from an absolute baseline in this problem space would require more iterations over the pipeline than is realistically feasible to allow for adequate exploration of the state-action space in a live feedback loop. An approach to priming the state-action pair values in the policy is to leverage historical actions from the existing static policy. Starting from this point enables the policy tuning to occur in less timesteps, while also allowing for liberal exploration of the state-action space.

4.1. Initial Policy from Historical Data

The approach in using historical data for initially creating a RL policy follows concepts from imitation learning (IL) and inverse reinforcement learning (IRL). Both disciplines use a demonstration - a replication of behavior sequences in the problem space – to acquire experience and learn a policy. "The inverse reinforcement learning problem is to find a reward function that can explain observed behavior" (3). With a reward system in place, determining the right policy is a matter of exploring values of α and γ for the TD SARSA equation.

The static policy represents the human-generated data, taking directionally accurate (not necessarily optimal) actions under various network conditions. Doing so approximates state-action pair values toward their true values, which are refined over future value improvement iterations. The historical data is transformed into an ordered set of actions associated to states, as in Figure 5.

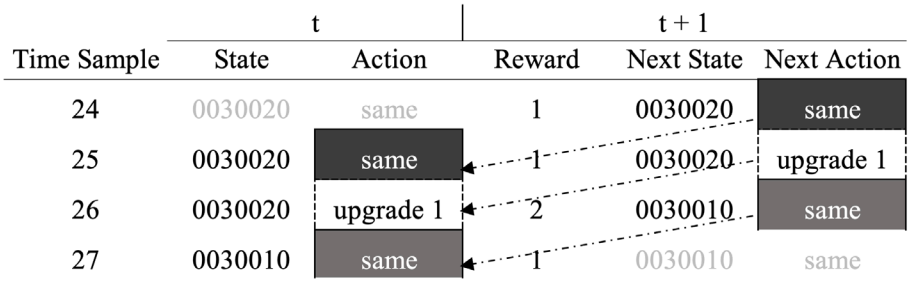

Figure 5 - Ordering Historical Data for Learning RL Policy

For each row, the $S_0, A_0, R_{t+1}, S_{t+1}, A_{t+1}$ observations needed to update the policy are arranged by windowing over the data and observing the sequence of profile transitions. This arrangement of historical data is the model used in future cycles when training RL policies using any decision-making policy. With the de-coupled implementation of the data pipeline, each step of data collections and transformations can be re-processed in their entirety. This becomes useful when adjusting a reward function or making any changes to the state or actions.

4.2. Tuning the Initial Policy

To build a true RL policy from the static policy's historical data, the RL policy itself is used to make profile recommendations and receive the resulting state condition through tens of thousands of state encounters. Over the iterations, the policy learns the highest-valued actions to take for many common situations using progressively restrictive variations in the trade-off between exploration and exploitation.

Initially, the policy was allowed to explore 100% of the time with the goal of starting to refine the state-action values. The exploration variable was decreased incrementally over time to the point where no exploration occurred to allow for the policy evaluation.

4.3. Multiple Policies

For each iteration, variations of policies can be trained on the actions taken by another policy. Values of α and γ are permuted to build multiple policies simultaneously. Since the parameters influence learning rate and reward weighting, the permutations of the parameters build policies that behave differently from one another, but still directionally appropriate.

5. Performance Study

The performance study focuses on comparing the static policy and the dynamic policies; specifically, evaluating profile speeds, profile sequences used, and policy responses to impairments. The objective is to identify a dynamic policy that can match or exceed the performance of the static policy.

5.1. Design

Every policy in the study will manage the profiles for five RPDs having either four or six upstream channels between 10.4MHz – 40.5 MHz along the spectrum. A minimum of 25 iterations for all five RPDs through the data pipeline will provide opportunities for the system to experience impairments from the randomized noise transitions from the lab. The dynamic policies are configured to not conduct any random exploration; they will behave in a similar manner as the static policy by always taking the best-

known action from a given state – even if the best-known action dynamically changes during policy updates.

Prior to each iteration, the profiles on all upstream channels are set to a baseline that mimics the configuration on a CMTS / RPD when it is onboarded into the PMA system. The channels lower on the spectrum begin in a transient profile configuration, while the upper 6.4MHz channels (above 27MHz) begin in sub-optimal profiles configured at modulation QAM-64. If the system has a sixth channel, it starts in a transient profile as well. For each dynamic policy pipeline run, updating the policy includes updating the other policies in consideration by applying the actions taken to different values for α and γ. In a sense, the decision-making policy is demonstrating actions to take for the other policies that get updated by evaluating decision-making policy's actions.

The four-channel configurations are all 6.4MHz wide, while the six-channel configuration adds a 3.2MHz channel below and a 1.6MHz channel above the four-channel configuration.

5.2. Policy Behavioral Expectations

Under good network conditions, the policies are expected to upgrade profiles for more efficiency and capacity until the most efficient profile is reached. The channel would ideally remain in the optimal profile if conditions are supportive. As UCCW rates climb over the 1% threshold, the policies are expected to downgrade the profiles to those more suited to handle noisy conditions. By doing so, the UCCW rate may recover at a point in the downgrade process, whereby the policy is expected to attempt periodic upgrades to check if the issue has been cleared. Otherwise, the policies are expected to learn to remain at a lower profile over time. This study was not designed to observe policy changes for long-running impairments, mostly due to time and resource constraints.

5.3. Performance Evaluation

Profile speed is a heuristic that can be used to represent the overall health of a bonding group (the collection of each upstream channels on each RPD). As the bonding group approaches the maximum profile speed, it is representative of the policy taking appropriate actions under good telemetry conditions. The maximum possible speeds are calculated by summing the optimal profile speeds for each upstream channel per system. Observing instances where maximum profile speed is not reached, determination of the cause falls into three categories: network impairments, poor decision by the policy, or an error external of the data pipeline (RPD channel error, transaction manager failure, etc).

UCCW rates are indicators where policies are expected to upgrade or downgrade profiles, if possible. Policies are expected to begin upgrading the profiles as conditions improve, downgrading under poor conditions, and remain in the best profile possible.

Achieving the best possible profile, as quickly as possible, is measurable by the number of timesteps it takes to achieve the optimal profile in a clean environment. To ensure a fair side-by-side comparison, the dynamic policies were limited to the largest transition step allowed in the static policy. The trajectory while transitioning off the baseline profiles is indicative of how assertive the policy is with respect to reaching the best-available profile.

5.3.1. Static Policy

The static policy has deterministic behavior, albeit through a combination of several thresholds. It was designed to reach optimal profiles by making transitions that are proportional to multiple telemetry metric

thresholds. Conservative decision criteria were purposefully built into the logic to greatly reduce introducing negative impact for customers.

5.3.1.1. Profile Speed Analysis

Observing the transaction history for each of the 25 timesteps, the static policy's ability to reach and maintain a steady state for the majority of RPDs indicates only few impairments were encountered. This allowed the policy to continue to use optimal profiles on many of the individual channels.

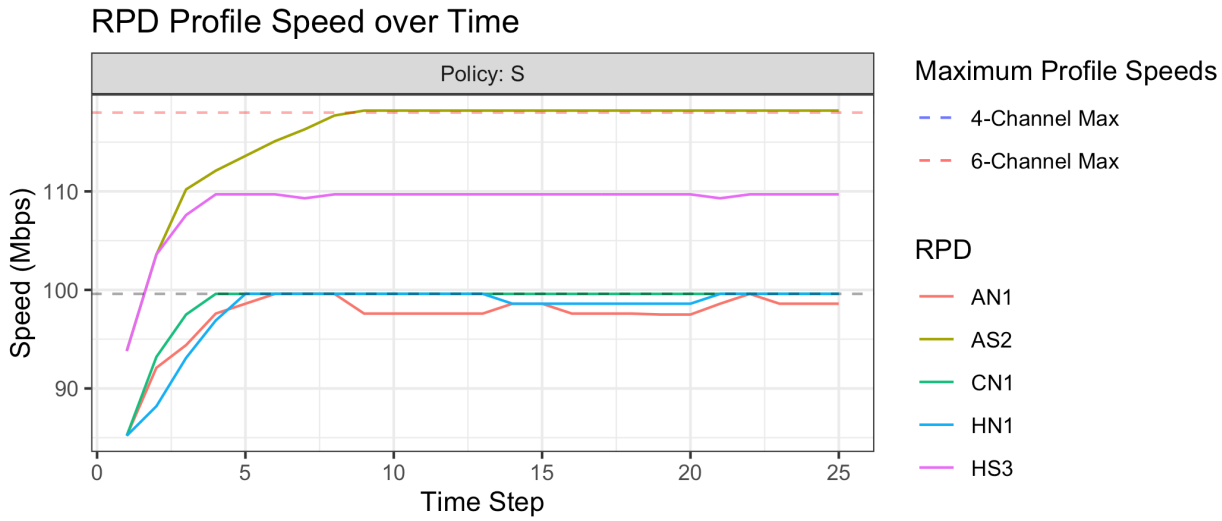

Figure 6 - Static Policy Profile Transitions in Terms of Speed

Under the static policy, the distribution of profile speed values is correlated to the UCCW rate values above and below 1%. Figure 7 affirms the behavior of the static policy achieving a steady state with mostly optimal profiles under the network conditions experienced in the iterations. AS2, CN1, and HN1 achieved the maximum possible speed for the bonding group and maintained during a significant portion of the study. A channel error occurred on HS3 that prevented the policy from achieving full speed for the bonding group. For that purpose, the policy achieved the maximum speed possible for the remaining five channels.

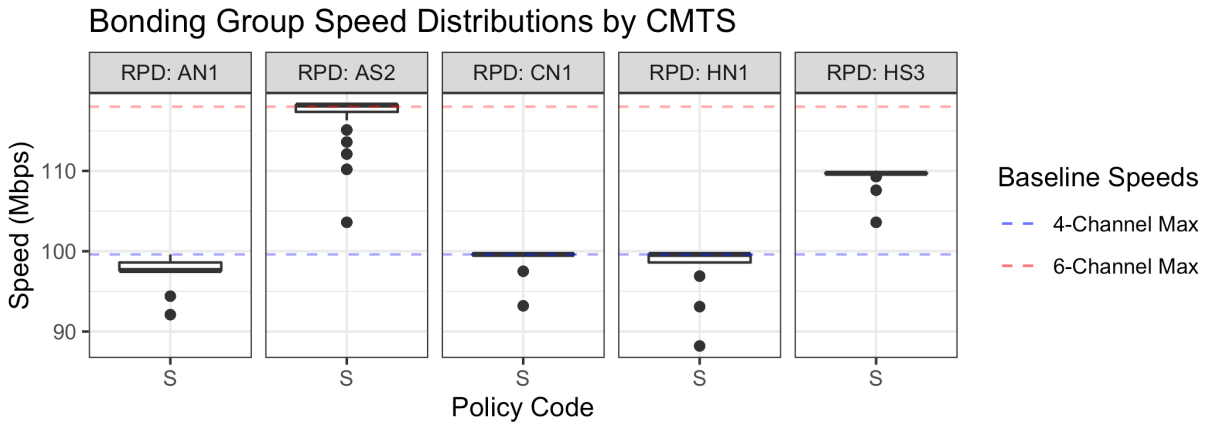

Figure 7 - Bonding Group Speed Distribution

Figure 8 illustrates how the RPDs were unaffected by the random noise generation from the lab. Despite experiencing majority clean UCCW rates, not all RPDs reached optimal profiles for all channels. A single channel on AN1 fluctuated between the top two profiles relating to reported SNR values and thresholds associated with SNR in the policy. Otherwise, the static policy behaved as expected, and under the conditions of the test environment, achieved the optimal profile available for the channel given the telemetry feedback.

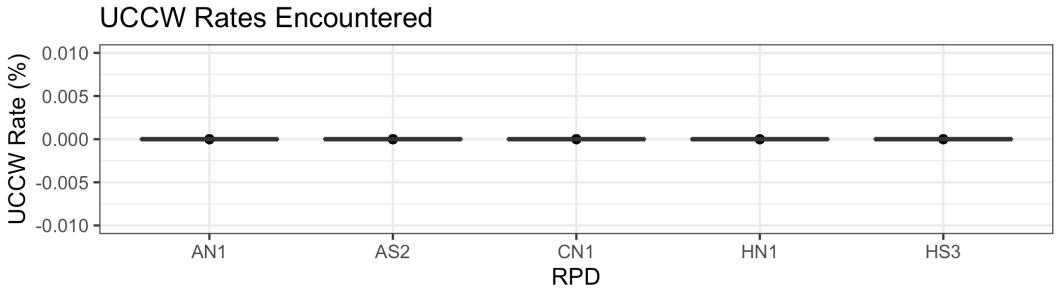

Figure 8 - UCCW Rates Encountered (Static Policy)

5.3.1.2. Latency to Optimal Profiles from Baseline

The number of timesteps the static policy took to reach a steady state operating on mostly optimal profiles for four-channel RPDs is represented in Figure 9. Omitting step zero, it took an average of four timesteps to get all three systems to a steady state on optimal profiles. Each RPD was upgraded at a slightly different rate, indicating a factor besides UCCW rate was affecting how large of a transition to make for each channel (SNR or CCW rates). The average SNR for RPDs CN1 and HN1 was below 30 dB for four of the six timesteps, while AN1 enjoyed an average SNR above 40 dB for the same timesteps. In spite of this, AN1 was the last to reach a steady state on optimal profiles.

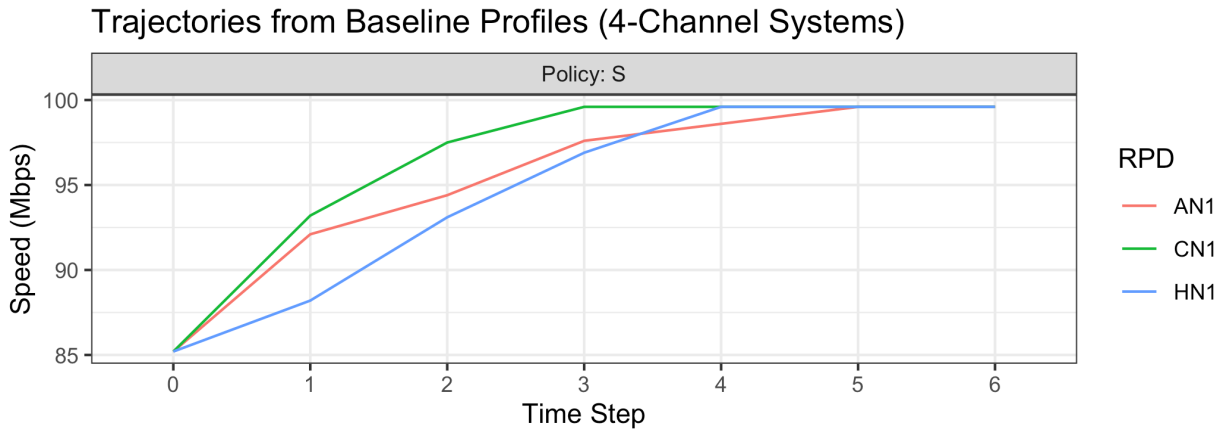

Figure 9 - 4-Channel Upgrade Trajectory from Baseline (Static Policy)

The six-channel RPDs demonstrated a wider disparity in terms of steps to reach a steady state. HS3 took two steps before leveling off, albeit notably by not upgrading the single channel that incurred reporting errors during the trial. AS2 reached a plateau after eight timesteps. This is attributed to the number of upgrades that had to occur for the upstream channel at 10.4MHz. Since it starts at the lowest possible profile, and limits upgrades to a maximum of four steps, this channel takes the longest to reach an optimal profile.

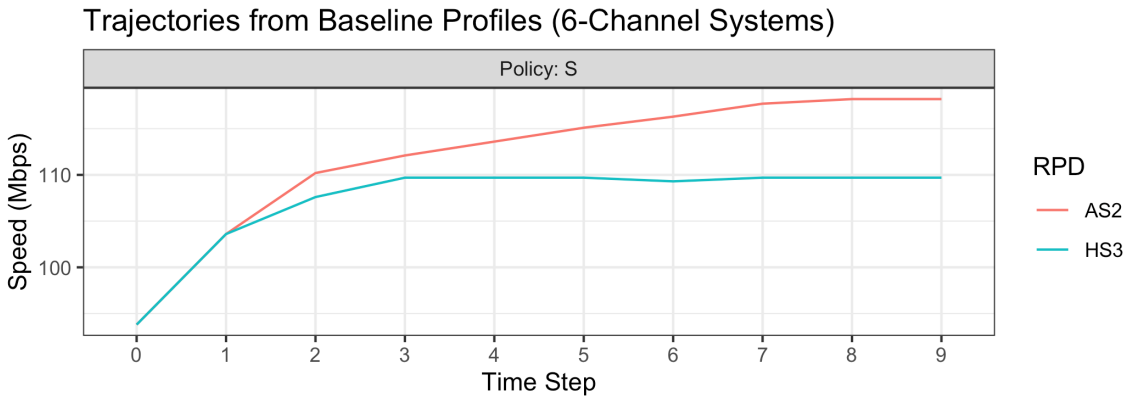

Figure 10 - 6-Channel Upgrade Trajectory from Baseline (Static Policy)

5.3.1.3. Summary Statistics

Over 25 iterations, the static policy achieved an average speed of 522 Mbps per iteration (all five RPDs), for an average bonding group (RPD) speed of 104.3 Mbps per iteration. Table 3 has the breakdown of profile usage:

Table 3 - Static Policy Profile Speed Metrics

Profile Type	% of Total Speed	% Profile Occurrences
Optimal	88.95%	85.15%
Sub-optimal	8.83%	8.44%
Transient	1.37%	2.24%
Below QAM-64	0.84%	4.17%

Also of interest is the relationship between which profiles were used in which locations along the spectrum during the trial. The transient profiles exist largely on the low end of the spectrum, as expected with clean telemetry throughout. Optimal profiles occurred often on the 6.4MHz channels from approximately 16MHz – 36MHz.

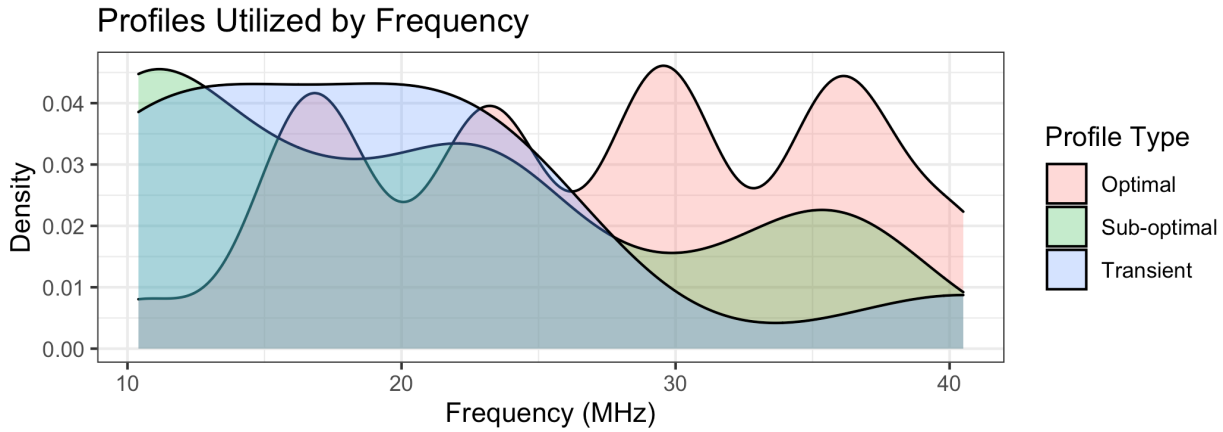

Figure 11 - Profile Type Utilization by Frequency (MHz) on Static Policy

5.3.2. Dynamic Policies

The four dynamic policies chosen for illustration in this paper were selected considering the values of α and γ that affect the learning rate and the weight placed on future rewards, respectively. Table 4 describes which values were used per policy, along with a high-level summary for how the policy generally behaved.

Table 4 - Dynamic Policy Information

Policy	α	γ	Policy Behavior
A	0.9	0.2	Achieved optimal profiles on 4 out of 5 RPDs
B	0.8	0.8	Indecisive, did not reach steady state, fluctuated profiles
C	0.3	0.8	Not as assertive as policy A, fluctuated profiles
D	0.8	0.2	Similar to policy A, optimal profiles on 3 out of 5 RPDs

5.3.2.1. Profile Speed Analysis

The dynamic policies experienced elevated UCCW rates on RPD HS3 during the trial. This prevented any of the policies from achieving optimal profiles in a steady form on that system. Policy A exhibited the most similar behavior as the static policy, maximizing the four-channel systems and reaching optimal speed on one of the six-channel bonding groups. Policies B and C have the most severe 'indecisiveness', fluctuating between profiles and largely not showing the ability to maintain a steady speed.

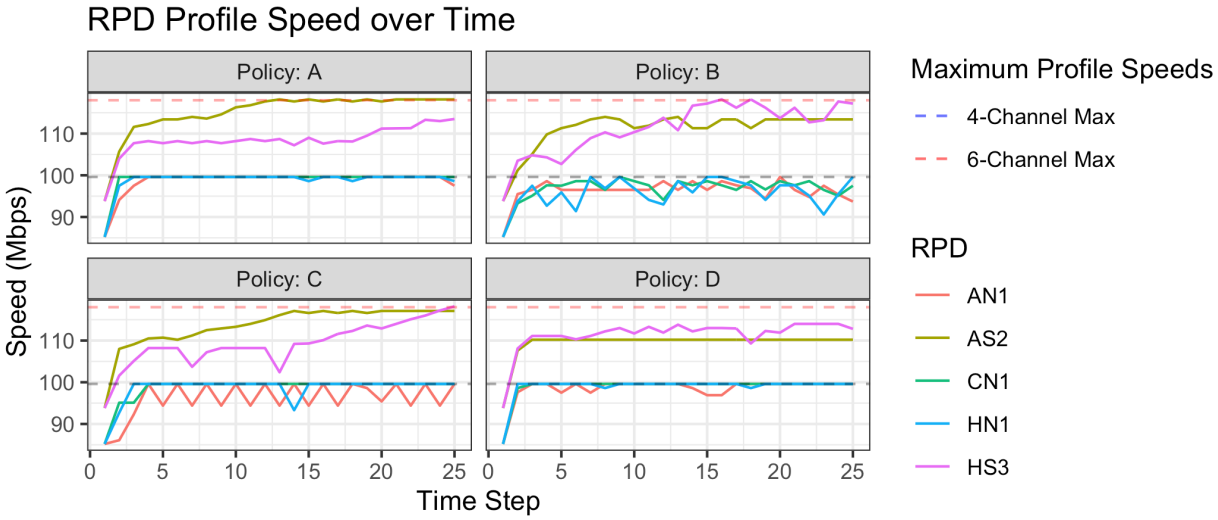

Figure 12 – RPD Profile Speed over Time (Dynamic Policies)

Figure 13 illustrates how the dynamic policies performed over the 25 iterations with respect to profile speeds distributions for each CMTS. The tight distributions observed on systems AN1, CN1, and HN1 indicate a lack of impairments over the iterations and affirm the observations in Figure 12. Certain policies quickly achieved optimal profiles and maintained throughout. The larger distributions are found in the six-channel systems, AS2 and HS3. Almost all the dynamic policies struggled to achieve consistent optimality on the two RPDs. Policy A had the most success and tended to be the most assertive of the policies.

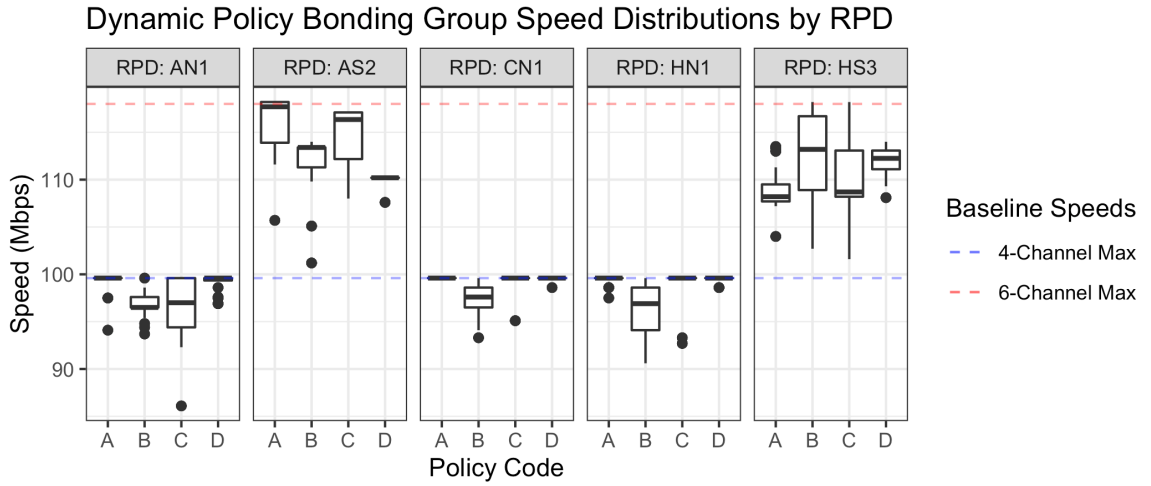

Figure 13 - Profile Speed Distributions by Dynamic Policy

UCCW rates did have an impact on system HS3 over the course of the trial for each of the dynamic policies. At one point, policy D experienced a channel with a severe UCCW rate of 100% (Figure 14). Since channels with severe impairments will not achieve the best profile, RL policies adapted to reaching profiles suitable for the impairment event.

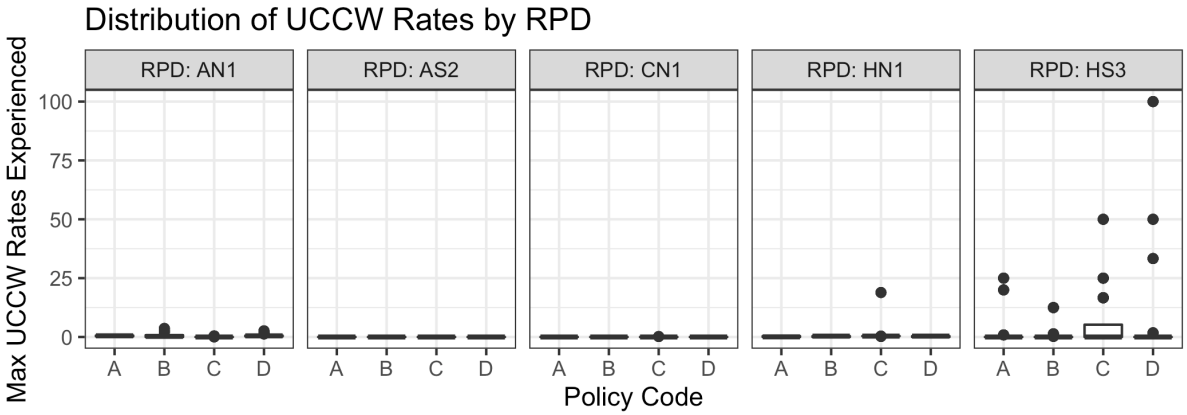

Figure 14 - UCCW Rates of RPDs by Dynamic Policy

Figure 15 highlights the UCCW rates observed on each iteration for each policy in relation to the overall profile speeds for each timestep on system HS3. In almost all cases, as a UCCW rate above 1% was detected, a decrease in profile speed for the bonding group indicates one or more channels downgraded to a slower, more robust profile. This is the expected behavior from both the static and dynamic policies. The change can be subtle for the channels less that 6.4MHz wide since those have less capacity to begin with, and the speed difference between profiles is a tighter distribution.

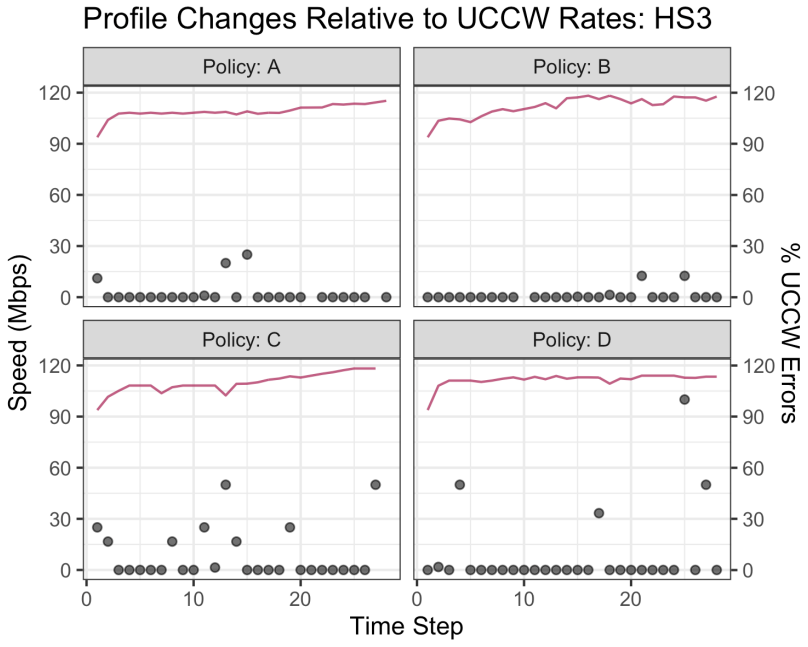

Figure 15 - Changes in Profiles with UCCW Rates on RPD HS3

As shown by policies A, B, and C, as UCCW rates improved, the policies continued to upgrade the profile configurations for more capacity. Observing the trends both with and without noise demonstrates the RL policies' ability to make directionally accurate decisions.

5.3.2.2. Latency to Optimal Profiles from Baseline

The dynamic policies took varying paths on the four-channel systems from the baseline profiles. Policy D took the most efficient route of the policies, reaching a steady state on optimal profiles in an average of two steps (actual = 1.7). Similarly, policy A averaged two steps, however, took a slightly less efficient route. Also notable, as policy D reached the optimal profile, a channel began fluctuating between the optimal profile and a two-step downgrade. This is a flaw within the policy. The same fluctuation activity is observed on policies B and C – both of which had more difficulty achieving and maintaining optimal profiles.

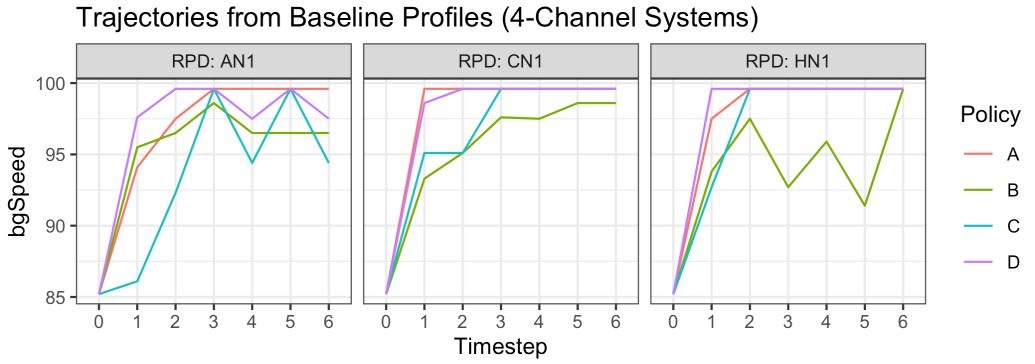

Figure 16 - 4-Channel Upgrade Trajectory from Baseline (Dynamic Policies)

The six-channel systems (AS2, HS3) had a more difficult path toward achieving optimal configurations. With the impairments on HS3, reaching the optimal profiles is not expected; however, reaching the best profile available is expected. The consistency between policies on HS3 indicates that impairments had a strong influence in keeping the profiles sub-optimal. The channels were influenced to use lower profiles to reduce the poor telemetry responses from the network in reaction to the chosen profiles. None of the policies on AS2 achieved optimal profiles, but the speeds were higher, indicating clearer telemetry. Policy D settled early after two timesteps, but at a sub-optimal overall speed. This indicates that the wrong action was valued highest for a particular state. The policy needs to explore different actions to overcome this.

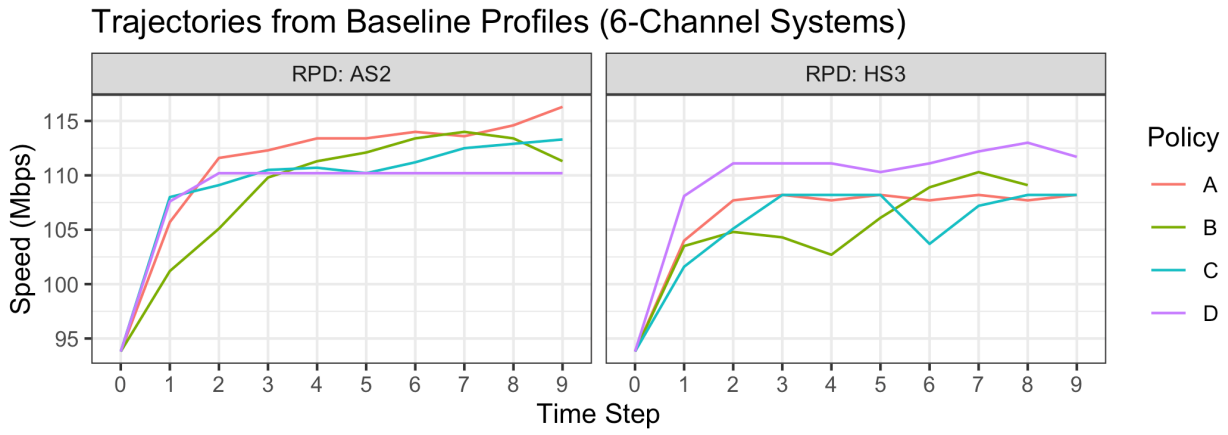

Figure 17 - 6-Channel Upgrade Trajectories from Baseline (Dynamic Policies)

5.3.2.3. Summary Statistics

Over 25 iterations, the dynamic policies achieved varying average bonding group speeds, as shown in Table 5 as an average speed per bonding group.

Table 5 - Dynamic Policy Raw Profile Speed Totals

Policy	Average per Bonding Group
A	104.0 Mbps
B	99.5 Mbps
C	103.2 Mbps
D	103.7 Mbps

Despite none of the dynamic policies achieving the 104.3 Mbps average, the measurement from the static policy, each of the dynamic policies experienced adverse UCCW rates that prevented the policies from upgrading into optimal profiles and remaining there. Yet, Policy A fell just short of attaining the static policy's benchmark.

Figure 18 has the breakdown of profile usage by profile type as it pertains to contributions to the overall speed values. Viewing the results by profile type is useful in understanding how the profiles were utilized across the iterations.

Notable in the profile density plot is the use of optimal profiles for policies A, C, and D in relation to the other profile types. Policies A and D exhibit the best consistency of optimal configurations.

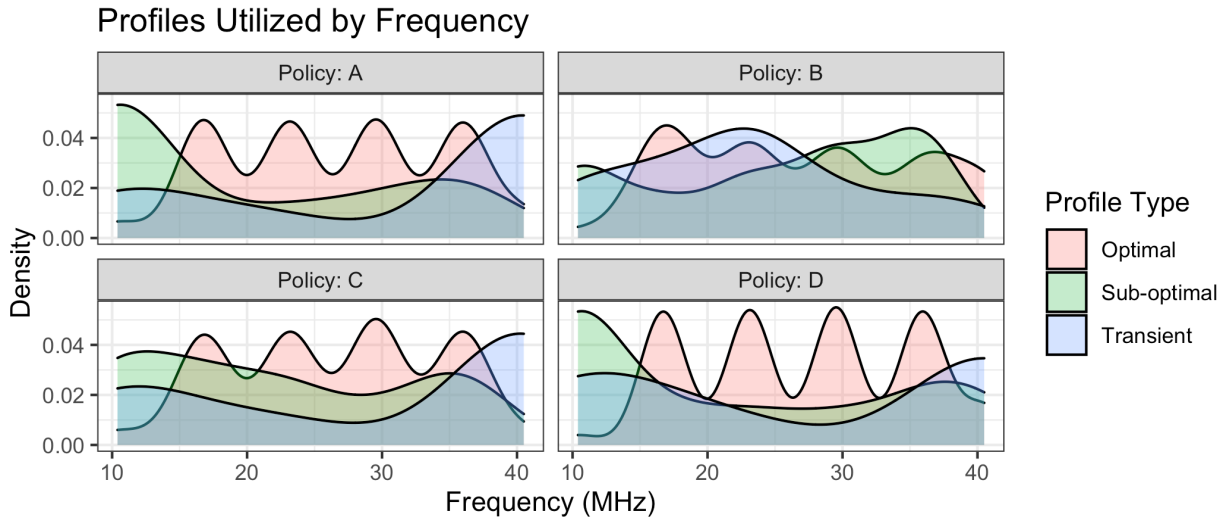

Figure 18 - Profile Type Utilization by Frequency (MHz) for Dynamic Policies

5.3.3. Summary Evaluation

Overall, policy A outperformed the other dynamic policies and will be the subject of a final extended study with respect to the static policy. Both policies ran for a total of 40 timesteps to provide additional insight into whether an RL based policy is definitively capable of being more performant than the static policy. Figure 19 shows the profile speed results comparing the two policies together over time.

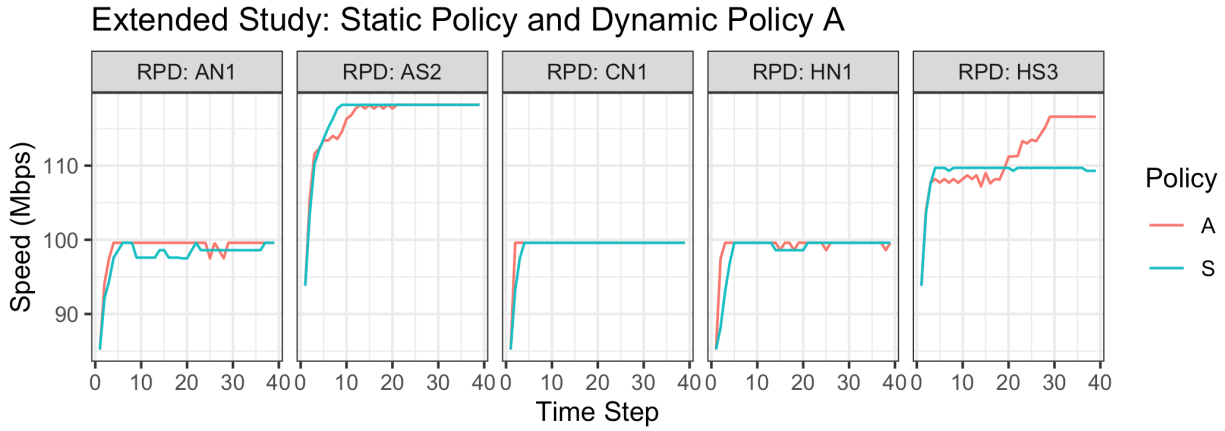

Figure 19 - Profile Speed over Time, Static vs Dynamic

A notable difference is on RPD HS3 when dynamic policy A runs were no longer encountering poor UCCW rates and saw a total increase of approximately 10Mbps from step 20 to step 30. The policy maintained that speed approaching the end of the study. The discrepancy of speed between the two polices is due to a channel reporting erroneous telemetry in the static policy iterations. It is unknown whether the static policy would have encountered poor telemetry or not as it upgraded, therefore it cannot be definitively proven by profile speed alone which is the better policy. Policy A increased to an average of 104.2 Mbps per bonding group of raw profile speed, while the static policy maintained an average of 104.6 Mbps. The high UCCW rates incurred on the systems during the trial runs for policy A explains much of the difference.

One other interesting point related to RL specifically occurred on RPD AS2. Figure 20 shows a zoomed in view of the change that took place. As policy A reached the optimal profile speed, a single channel had learned the highest valued action in that state was to downgrade by one step. Over four total cycles of fluctuating between the optimal profile and the sub-optimal one, the policy was getting updated by being penalized for moving down and rewarded positively by moving up. After those four cycles, the best action from the optimal profile for that channel changed to the action of remaining in the optimal profile under good telemetry conditions.

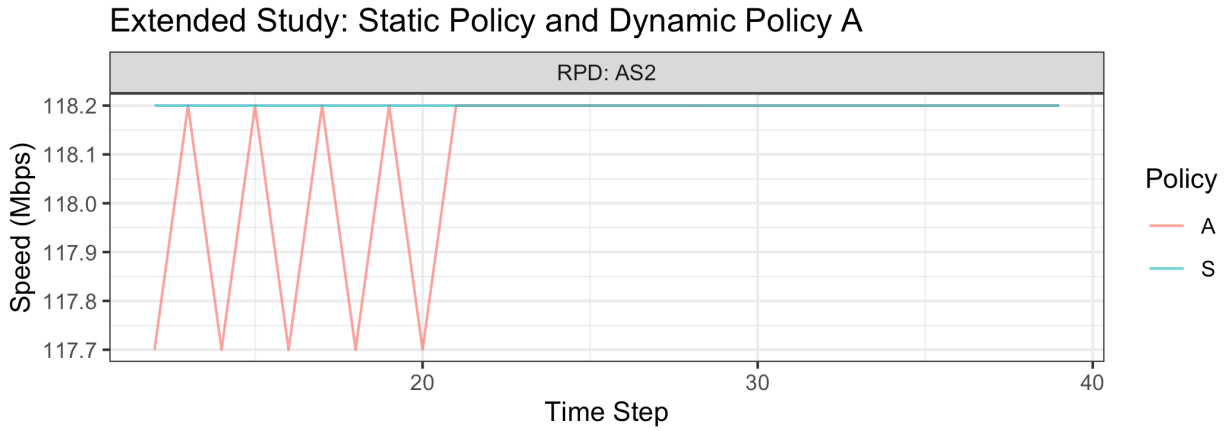

Figure 20 - Dynamic Policy Learning Better Action

Optimal profile configurations on policy A trials account for more of the overall aggregated speed than for the static policy. The static policy spent less time on transient profiles, however that is due to the differences in telemetry between the policy trials. Sub-optimal profiles – those that are between the optimal and transient profiles – accounted for almost twice as much of the total speed on the static policy than on dynamic policy A.

Table 6 - Profile Speed Metrics, Static vs Dynamic

	Policy A		Static Policy	
Profile Type	**% of Total Speed**	**% Profile Occurrences**	**% of Total Speed**	**% Profile Occurrences**
Optimal	91.67%	84.69%	88.95%	85.15%
Sub-optimal	5.11%	5.78%	8.83%	8.44%
Transient	2.42%	6.8%	1.37%	2.24%
Below QAM-64	0.79%	2.72%	0.84%	4.17%

Both policies have proven to behave very similarly in the interest of managing a US PMA system. Dynamic policy A only slightly edges out the static policy based on the following criteria:

- Policy A achieved optimal profiles on the four-channel systems from the baseline in an average of two steps, whereas the static policy took an average of four steps.
- Policy A utilized the optimal profile configurations more often than the static policy.
- Static policy achieved higher overall profile speed over the 40 iterations, with the caveat that the RPDs using policy A experienced more noise from the lab.

A key advantage the dynamic policy has over the static policy is the ability to learn on the fly. These policies are capable of correcting for changing conditions and adapting to what is normal for each RPD

system. As was demonstrated, policy A changed behaviors in the middle of the trial toward the more optimal action – this after experiencing several timesteps with poor telemetry.

While policy A, at a minimum, matches the behavior of the static policy, it also introduces the ability to build customized policies for individual RPD or CMTSs. Geography, weather, ingress, and other external factors impact network service to varying degrees – making a one-size fits all policy advantageous for many systems, but not applicable to all. Changes in one policy will not affect all systems, just the system for which it manages.

Balancing the many permutations of telemetry and configuration values using RL states removes complexities involved with tuning thresholds and applying the conditional logic in the algorithm for all thresholds.

5.4. Opportunities for Enhancement / Potential Future Steps

The proof of concept described in this paper is a promising step toward building more intelligent PMA systems. Below is a list of opportunities to improve the current policy building process and suggestions for future steps that would move this work forward.

- Training a dynamic policy from scratch – given enough time and resources, a policy trained from scratch would not be influenced by the initial historical data used in this POC.
- Synchronize noise settings from the lab such that each RPD and policy experiences the same sequence of impairments. Measuring responses of devices at each transition would provide a clearer picture of policy behavior differences.
- Improve the policy training process using n-step TD prediction methods, whereby more steps in the sequence and the rewards from those steps is used to estimate state-action values. This POC used the current state/action and next state/action to calculate values. Additional states and actions in the sequence can be bootstrapped for learning.
- Adaptation for scalability – architect solution capable of managing tens of thousands of RPDs. This may sound daunting at initial glance, however, the state-action space to maintain is significantly smaller than the collective set of possible states. In this study, .007% of the 243K possible states were encountered.

6. Conclusion

An upstream PMA system operating through a static policy is a proven effective strategy for configuring D3.0 channels across an entire network. By taking a cautious approach, the single policy caters more to the adversely impacted RPDs and CMTSs as the lowest common denominator when establishing thresholds that need to apply to a wide range of devices and conditions.

To improve profile configuration management, RPDs and CMTSs would benefit from a policy that best suits the individual operational environments. In fact, through the current implementation, a primary static policy manages the majority of Comcast's footprint, and a secondary policy manages a small set of devices with special requirements. Following a path of creating multiple static policies that manage different sets of devices would become difficult to manage.

One option for establishing self-managed dynamic policies is to apply an RL-based decision-making process that updates in real-time and is flexible enough to tune for either groups of devices or individual devices. The finer-grained management leads to confidently bolder profile transitions to reach steady state operations in less time than the static implementation. While both policies performed similarly in the trial,

the advantages a PMA system gets with an RL implementation may make the RL approach more appealing for large networks.

Optimizing Value from Service Provider Wi-Fi in a Converged World

A Technical Paper prepared for SCTE by

Mike Darling
Principal Engineer
Shaw Communications
2728 Hopewell Place NE, Calgary AB T1Y 7J7
mike.darling@sjrb.ca

1. Introduction

Increasingly, subscribers want access to their broadband services at home, on the go and at their destinations. The value proposition of service provider Wi-Fi is to give subscribers access to their services when they are away from home at all types of destinations. In the absence of service provider Wi-Fi, subscribers must deal with authenticating to destination Wi-Fi on a case-by-case basis by asking for authentication codes, using their mobile data plans, or foregoing the use of their applications. Cisco estimates that the number of public Wi-Fi hotspots globally will quadruple from 2018-2023 [1]. Shaw operates a service provider Wi-Fi network in its cable footprint that is available free of charge to broadband wireline and wireless subscribers. This paper examines how subscribers use the service provider Wi-Fi network and seeks to answer some key questions around the value of the network, both to subscribers and to service providers.

2. Service Provider Wi-Fi Network

Shaw's service provider Wi-Fi network is made up of three types of access points (APs)—service provider APs expressly installed for service provider Wi-Fi connectivity, business Wi-Fi APs that are installed in business customer premises, and home hotspot APs installed in subscriber premises. Service provider Wi-Fi traffic is backhauled over fibre or coax to a wireless access gateway and into the core network.

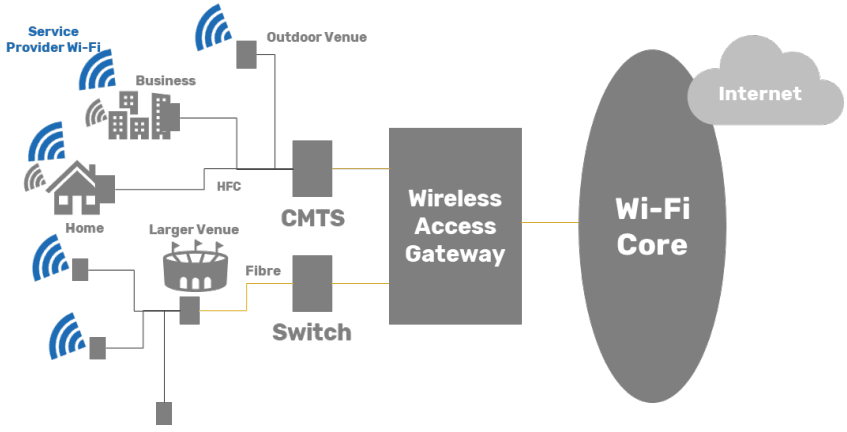

Figure 1 – Service Provider Wi-Fi Network

2.1. Types of Access Points

Service provider APs come in indoor and outdoor units with different backhaul options. The service provider network initially targeted the install of outdoor units that could be mounted on aerial infrastructure with power and backhaul provided via the hybrid-fibre coax (HFC) network. These APs are used to cover public areas such as parks or shopping districts. Indoor units were targeted at public spaces such as community centres and shopping malls and were backhauled via the HFC network or fibre optics, depending on the existing network infrastructure.

Figure 2 – Service Provider Wi-Fi Access Points

Business Wi-Fi APs are used for business Wi-Fi services, and secondarily used for service provider Wi-Fi. One or more SSIDs are set up for the business' use and service provider SSIDs are also broadcast for service provider subscriber use. These APs are used to allow clients of Shaw Business customers to use service provider Wi-Fi without needing to ask the business for authentication codes.

Home hotspot describes residential subscriber modems used for service provider Wi-Fi. In this case one or more SSIDs are set up for the subscriber and additional SSIDs are broadcast for service provider subscriber use. Similarly to business Wi-Fi, these APs allow service provider Wi-Fi users access to Wi-Fi in residential homes without needing to ask for authentication codes.

2.2. Network Access

Access to the service provider network is granted to all broadband and wireless subscribers. In terms of access, one difference is that the home hotspot network is only available to wireless subscribers. There are various methods of authenticating onto the network. Broadband subscribers can connect to the service provider network at an AP and enter their credentials into a splash page. Additionally, subscribers can add the MAC addresses of devices via a web portal, a feature that allows devices to be registered without being in range of the network. Wireless subscribers are automatically authenticated through their SIM cards. Once a device is authenticated it will automatically attach to the network when the device is in range. Broadband subscribers are allocated a 30Mbps downstream and 5Mbps upstream Wi-Fi speed tier, while wireless users have a 100Mbps downstream and 10Mbps upstream Wi-Fi speed tier.

2.3. Reporting Platforms

Shaw collects reporting data from several sources. Data is anonymized and aggregated to gauge performance of the Wi-Fi network.

Both APs and wireless access gateways send RADIUS accounting records with session data. The RADIUS accounting functions allow records to be sent at the start and end of sessions indicating the resources used during the session [2]. This analysis specifically looks at stop records, which are only sent at the end of a session.

To gather application-level statistics a deep-packet inspection (DPI) system was used. This system has a catalog of application signatures to which user traffic is mapped. The DPI system was also used to gauge bitrate statistics at the modem level for Wi-Fi APs backhauled over DOCSIS. This system takes 256ms data consumption samples and summarizes them into one-minute bitrate statistics. These statistics include average, mean, median, 95th percentile and peak throughput.

2.4. Subscriber Feedback

Shaw has undertaken consumer surveys of broadband and mobile subscribers to gauge the sentiment towards service provider Wi-Fi and to verify whether subscriber perceptions match the intended value.

81% of broadband subscribers and 86% of dual broadband and wireless subscribers who responded were aware that they had access to service provider Wi-Fi. Service provider Wi-Fi was ranked third in terms of factors impacting a subscriber's decision to keep their broadband services with Shaw, with 80% responding that it was impactful.

57% of respondents noted that they frequently or occasionally use service provider Wi-Fi, which ranked higher than other sources of Wi-Fi such as restaurants, coffee shops, and retail stores. Given the same options for connecting to Wi-Fi, 81% rated the quality of service provider Wi-Fi as good or very good, a higher percentage than all other options.

Overall, 86% of broadband subscribers and 95% of wireless subscribers who responded to the survey answered that they find value in service provider Wi-Fi.

3. Network Usage

Service provider Wi-Fi is meant to provide subscriber value. Anecdotally however, there had been reports that subscribers authenticating to the Wi-Fi network were unable to connect to the Internet. Additionally, there was a concern that individuals not subscribed to Shaw services were accessing the network. This section explores these issues, general network usage and performance and whether the network was being used as intended. The data presented in the following sections was gathered in 2019 and 2020, before the start of the COVID-19 pandemic.

3.1. Monthly Consumption

Average monthly Wi-Fi consumption was calculated per device for both wireline and wireless subscribers. As shown in Figure 3, average monthly Wi-Fi consumption was nearly identical for the two groups at approximately one gigabyte per month. One gigabyte is a small amount when compared to wireline monthly consumption but is comparable to wireless monthly consumption.

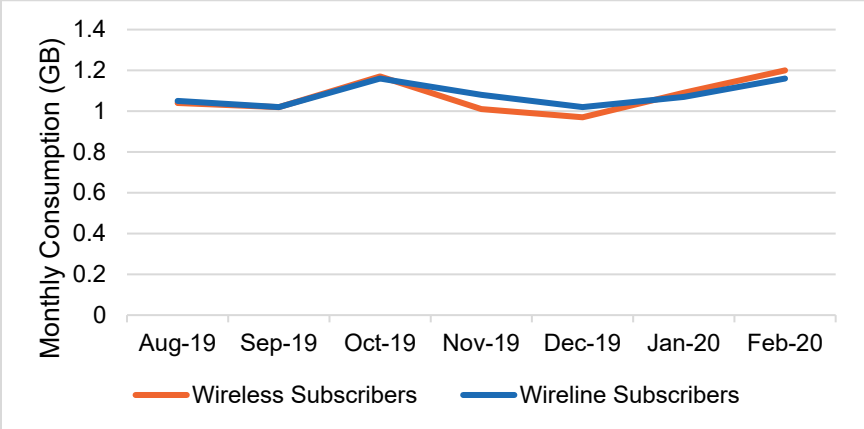

Figure 3 – Average Monthly Wi-Fi Consumption

Monthly Wi-Fi consumption averages hide the large disparities between subscribers. Although these disparities are observed in the wireline network, they are more pronounced in the Wi-Fi network, as shown in Figure 4.

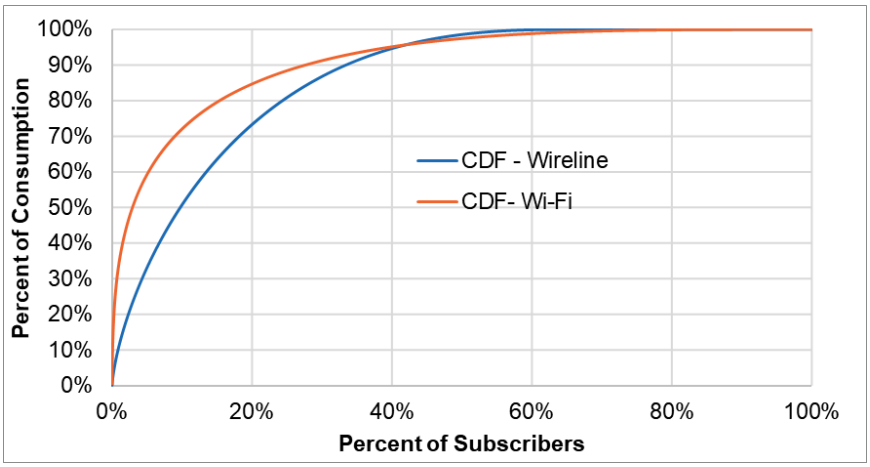

Figure 4 – Wi-Fi and Wireline Consumption Cumulative Distribution Function

This chart shows the cumulative distribution function (CDF) of Wi-Fi and wireline consumption. It can be observed that 20% of subscribers on the wireline network account for approximately 75% of consumption, while 20% of subscribers on the Wi-Fi network account for approximately 85% of consumption. There is no pronounced difference in the number of subscribers who account for little or no consumption, which would be expected if users were authenticating but not connecting to the Internet.

Figure 5 shows that there is an even spread in the percent of devices using Wi-Fi for a specific number of days per month. The data shows that 4.5% of devices access the network only a single day per month, while 4% of devices access the network every day of the month. This pattern fits with destination use because the number of days a subscriber visits destinations, such as restaurants, varies person to person. In contrast, subscribers access the wireline and wireless networks all or most days of the month.

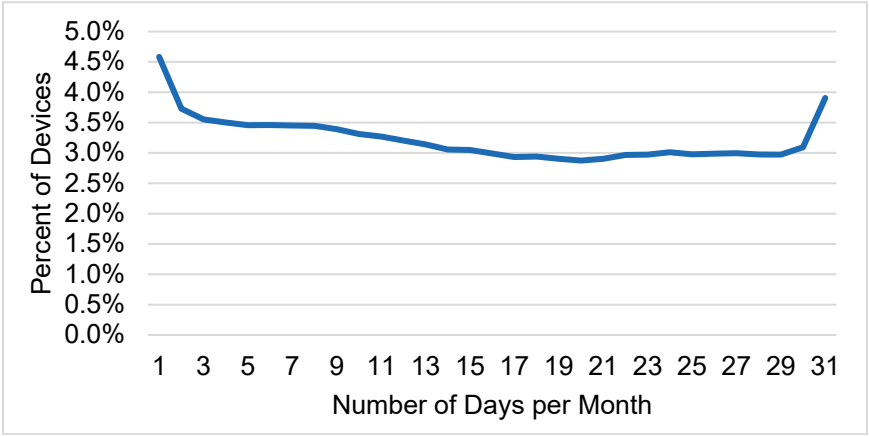

Figure 5 – Wi-Fi Days of Use per Month

Wi-Fi consumption was also compared to wireline and wireless consumption for individual subscribers. While wireline consumption is much higher, there is a correlation between high wireline consumption and high Wi-Fi consumption, as demonstrated by Figure 6. Wireline consumption is shown on the Y-axis in

gigabytes while Wi-Fi consumption is shown on the X-axis in megabytes. Note the logarithmic scales on both axes. The size of the bubbles indicates number of subscribers.

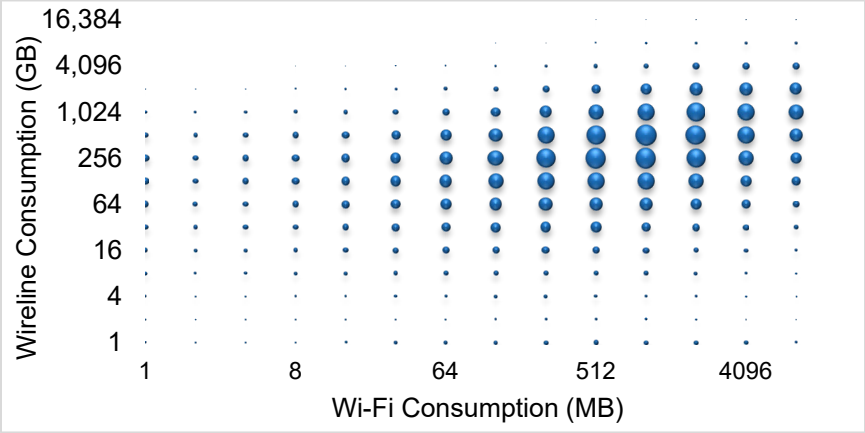

Figure 6 – Wi-Fi vs Wireline Consumption

This result points to Wi-Fi consumption being complementary to—rather than a substitute for—wireline consumption. There is not a significant number of subscribers with heavy Wi-Fi consumption and low wireline consumption.

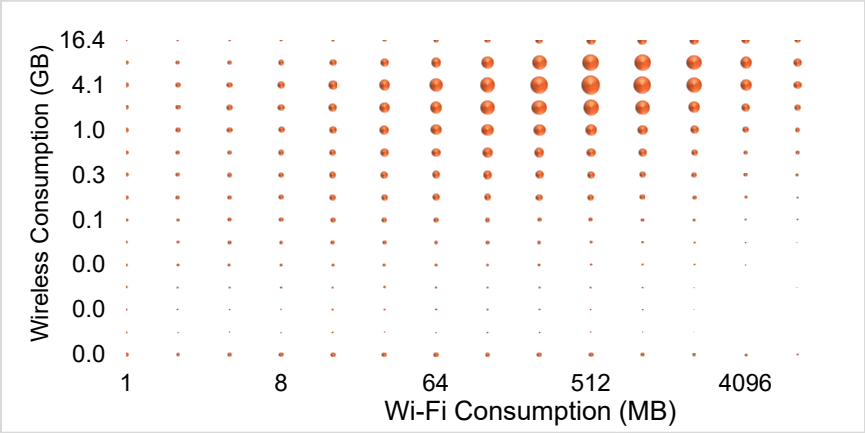

Figure 7 – Wi-Fi vs Wireless Consumption

Monthly consumption for wireless subscribers who used the service provider Wi-Fi network was also analyzed. The result showed a similar correlation to the wireline/Wi-Fi comparison in that subscribers who had high monthly wireless consumption tended to also have high monthly Wi-Fi consumption.

Wireline subscribers can register multiple devices on the Wi-Fi network, with limits set depending on which broadband tier they are subscribed to. Although there is potential for subscribers to allow people outside their household to access the network, this is not seen in the data. 70% of accounts have only one or two registered devices, which roughly matches the number of people per household.

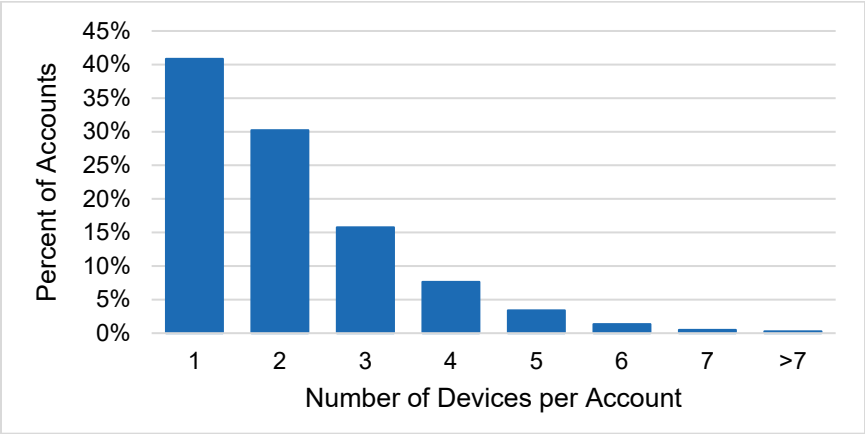

Figure 8 – Number of Devices Registered per Account

3.2. Bitrate Statistics

Average and 95th percentile bitrate is measured in the downstream and upstream every minute for a month for each DOCSIS backhaul modem. From those measurements the monthly 95th percentile bitrate is taken and graphed.

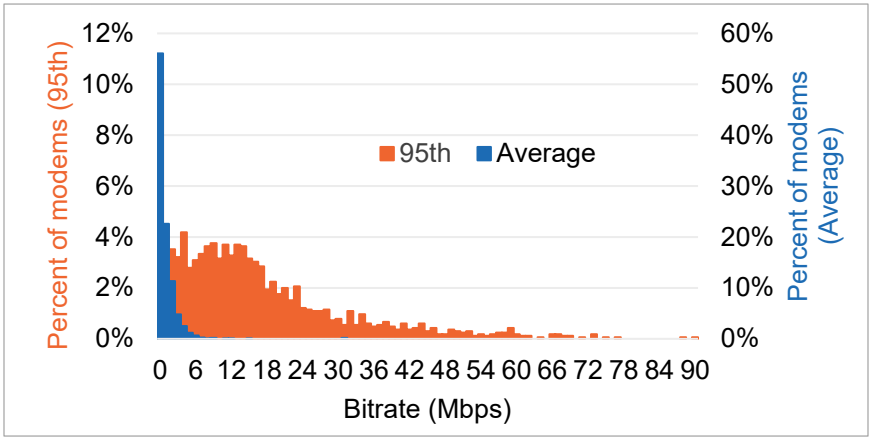

Figure 9 – Downstream Average and 95th Percentile Bitrate

On average, downstream backhaul modem bitrates are below 5Mbps, while the 95th percentile bitrate is more distributed.

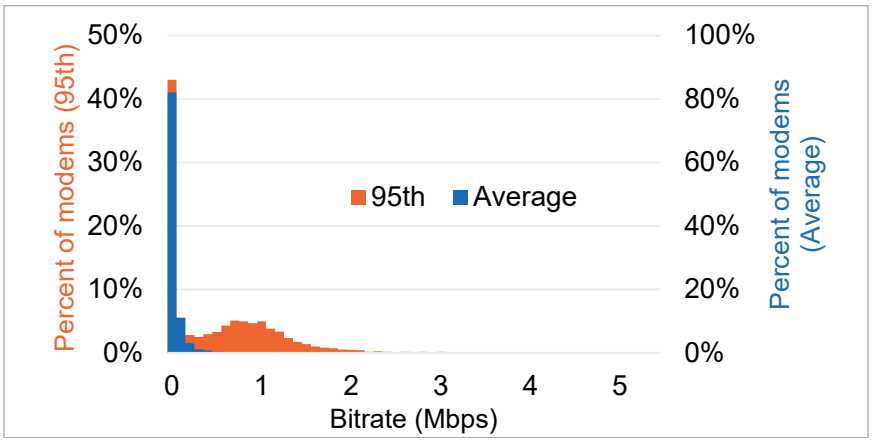

Figure 10 – Upstream Average and 95th Percentile Bitrate

The average upstream bitrate of the backhaul modem is below 1Mbps with the distribution of 95th percentile bitrates centered at approximately 1Mbps. These graphs show that the bitrate limitations placed on subscribers do not hinder their use.

3.3. Application View

The top applications ranked by consumption on the Wi-Fi network can be observed and contrasted with those on the wireline network using DPI systems.

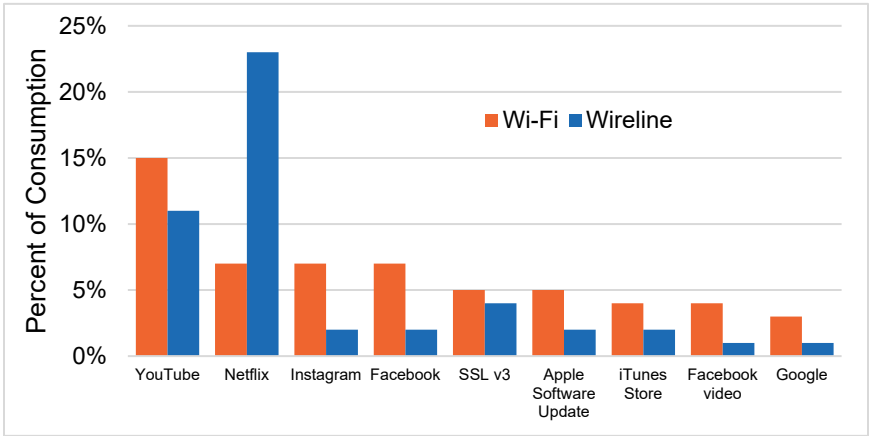

Figure 11 – Wi-Fi and Wireline Application Usage

Streaming media dominates data consumption for both wireline and Wi-Fi. In both cases, the top two applications are YouTube and Netflix. However, the order of these two applications is reversed for wireline and Wi-Fi, likely due to the nature of these applications. YouTube videos are generally shorter and can be more easily watched on a small screen at a destination connected to Wi-Fi, whereas Netflix is geared toward longer programming and is more commonly watched on a larger screen at home. Social media applications also account for a higher percentage of Wi-Fi consumption than wireline consumption as demonstrated by Instagram and Facebook.

As illustrated in Figure 12, while video dominates consumption, social media—specifically Facebook and Instagram—is used by a higher percentage of subscribers.

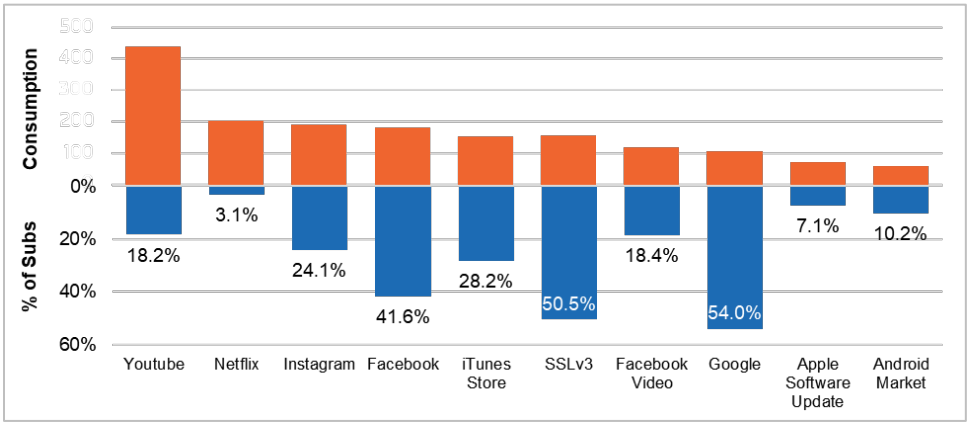

Figure 12 – Application Penetration and Consumption

When organized by application type and ranked by consumption, the top three categories are streaming media, web browsing, and messaging and collaboration (Figure 13).

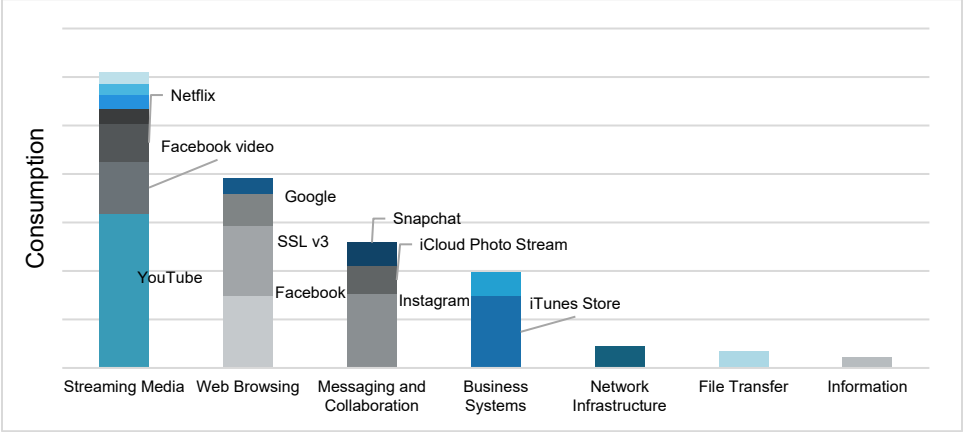

Figure 13 – Consumption by Application Type

3.4. Time of Day Trends

Wireline and wireless services have very different consumption patterns over the day. Wireline consumption peaks in the evening when subscribers are at home, while wireless consumption peaks in the late afternoon. Figure 14 shows that Wi-Fi time of day statistics are similar to wireless, but slightly delayed in time. This delay is likely to allow subscribers to get from home to their destinations where Wi-Fi is present.

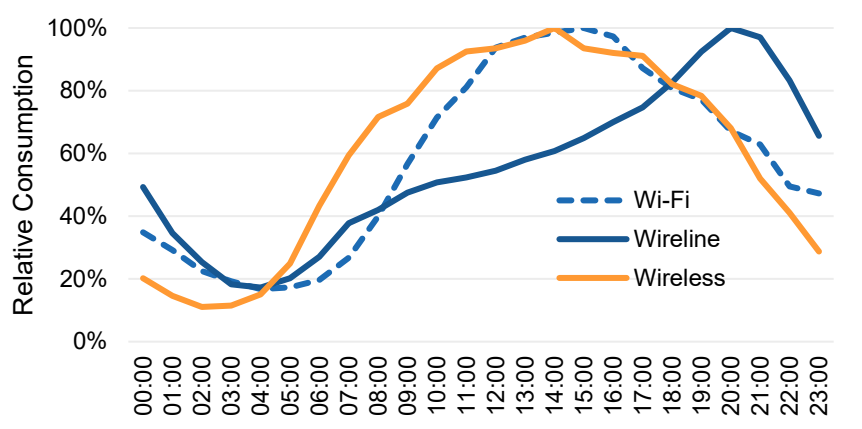

Figure 14 – Wi-Fi, Wireline and Wireless Network Time of Day Trends

Aggregate network consumption analysis points to subscribers deriving value from the Wi-Fi network and the network being used as intended. Per-device consumption, as well as time-of-day and monthly usage patterns, point to the Wi-Fi network being used to offload wireless data at destinations. The distribution of monthly Wi-Fi consumption per user was similar to the distribution of monthly wireline consumption per user. The correlations between Wi-Fi and wireless or wireline consumption demonstrates that subscribers have high consumption on both networks. Bitrate statistics and application usage suggest that devices connecting to the Wi-Fi network are mostly small-screen portable units. The number of devices per account roughly matches the number of people per household, indicating that there was no wide-spread sharing of access to non-subscribers.

After researching aggregate network usage, specific users and venues were analyzed for a more in-depth perspective.

3.5. Venue Examples

Wi-Fi APs are installed at many different types of venues, as shown in Figure 15. While most venues were similar in terms of consumption, transportation (transit platforms and similar venues), hotels and Shaw Wi-Fi Zones have higher consumption per AP.

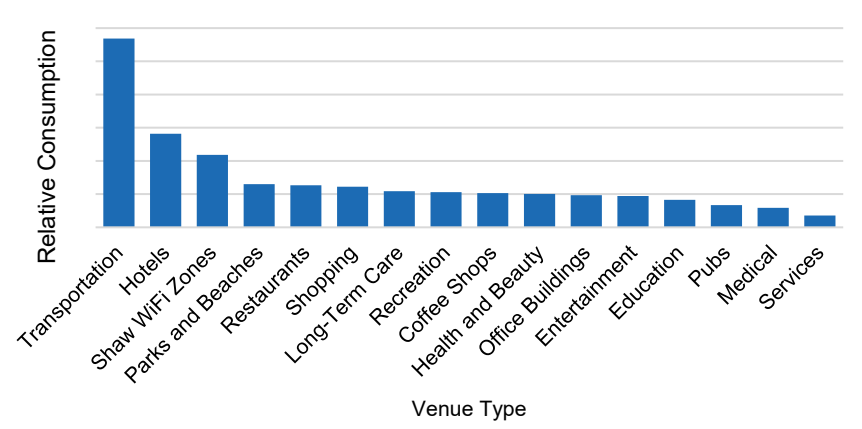

Figure 15 – Wi-Fi AP Consumption for Different Venue Types

One of the Shaw Wi-Fi Zones has previously been identified as potentially having poor performance, so an in-depth analysis was undertaken for that venue. Specifically, this venue is located close to a main thoroughfare and there is anecdotal evidence that subscribers in their cars would connect to Wi-Fi as they passed by or stopped at a stop light, disrupting any wireless session they may have had. Monthly consumption and unique device count were collected for each AP in the venue.

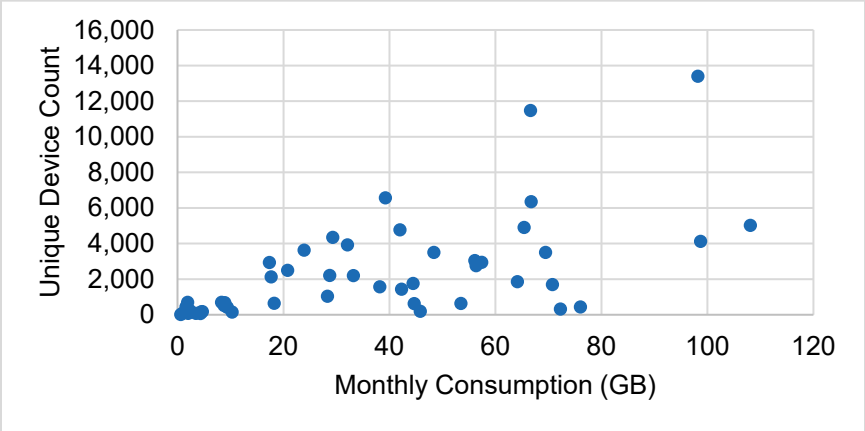

Figure 16 – Unique Device Counts vs Consumption for One Venue

As can be observed, there are large differences in consumption and unique device count between APs. APs with a high number of unique devices also have a high monthly consumption, as opposed to low monthly consumption, as might be expected with APs close to traffic lights. The correlation appears to be that APs close to popular locations such as restaurants and coffee shops have more unique devices and higher monthly consumption, while APs close to more lightly visited locations have fewer unique devices and lower monthly consumption.

One specific AP with a high number of unique devices and a large amount of consumption close to a popular restaurant and busy intersection was further analyzed. The device with the highest monthly consumption for that AP was 4GB, pointing to casual usage.

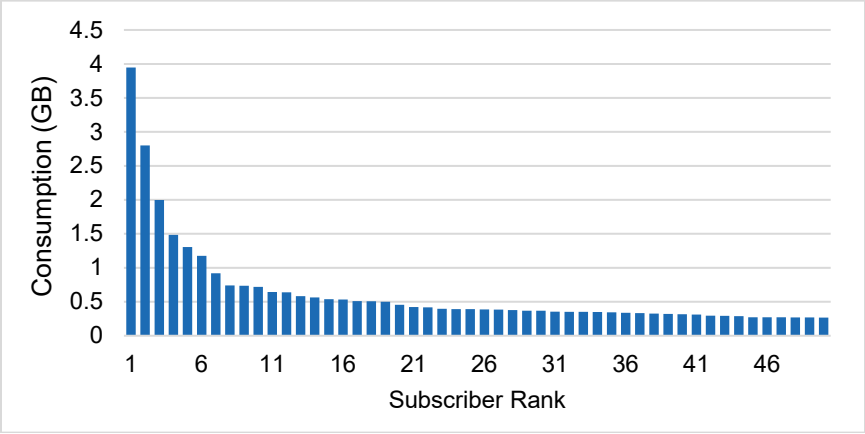

Figure 17 – Consumption of Top 50 Devices for One AP

As shown in Figure 18, the application distribution of this particular AP differed from the aggregate statistics. Video represented less consumption, with YouTube ranking tenth and Netflix ranking outside of the top ten applications. However, similarly to the aggregate statistics, social media ranked high on the

list. The top application by consumption for this AP was SSLv3, which is likely encrypted web browsing. The application mix points to short duration usage, as might be expected in a restaurant.

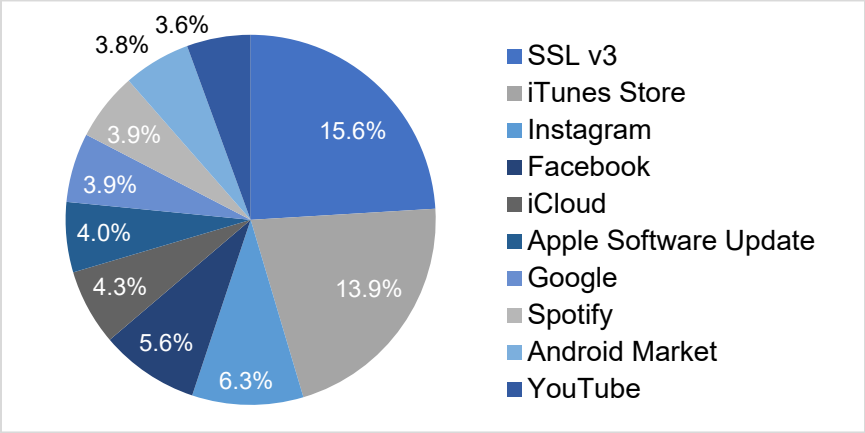

Figure 18 – Top 10 Applications for one Access Point

Five-minute throughput samples can be used to estimate bitrate over a longer duration. Max bitrates over five-minute durations tend to be low, indicating that few devices are being used to transfer large files or watch high quality video.

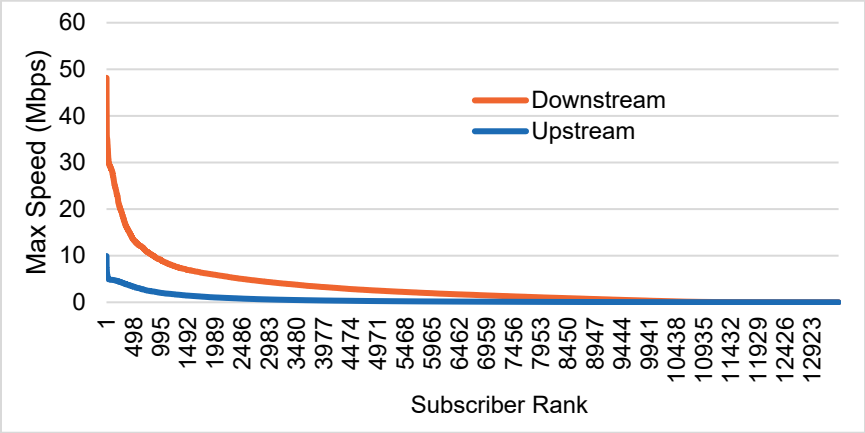

Figure 19 – Max Speed for All Users on one Access Point

While no evidence of a poor subscriber experience was found based on the data collected, it was determined that venue data can be used to prioritize the addition of new sites and potentially to reposition or remove APs that are being underutilized in their current locations.

3.6. Heavy Users

A dashboard was created to focus on a small number of heavy users whose monthly Wi-Fi consumption was greater than 100GB. In Figure 21, Wi-Fi consumption is plotted on the Y-axis and wireline consumption on the X-axis. The size of the circles denotes how many devices are linked to the account. Available data include device level statistics, as well as location and application-level information. Circles in pink have greater Wi-Fi consumption than wireline consumption and vice versa for circles in blue.

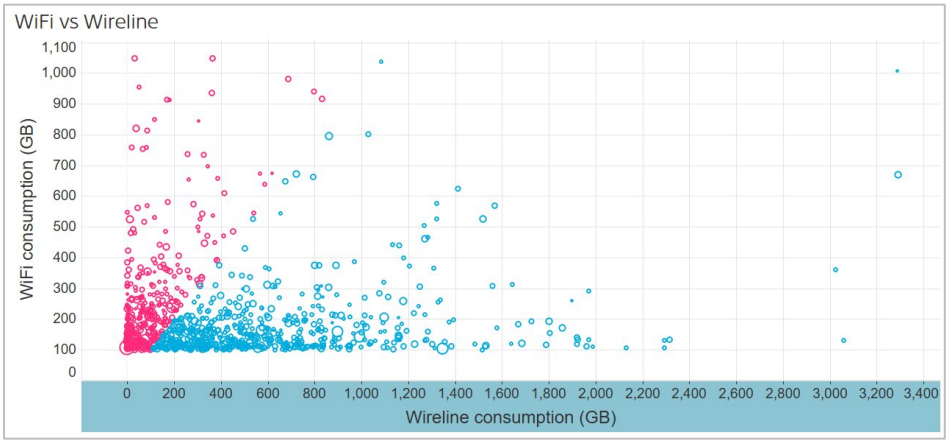

Figure 20 – Wi-Fi vs Wireline Consumption for Heavy Users

It was found that most consumption came from one or two connected devices, even for accounts with many connected devices. For most cases, consumption came from one or a small number of locations. This points to heavy but normal use of the Wi-Fi network, analogous to what is seen in the wireline network.

4. Network Optimization

Earlier in the year, a network optimization initiative was undertaken to reduce the occurrence of devices connecting to the 2.4GHz network at low signal strength. The intent was to reduce the 2.4GHz coverage to match the 5GHz coverage in order to decrease instances of devices authenticating but not connecting to the Internet and allow more devices to see the 5GHz network sooner as they approached an AP.

Figure 21 – 2.4GHz Coverage Optimization

When looking at the data for a single market, a large reduction in the number of devices connecting to the 2.4GHz network can be observed after the optimization was made. Importantly, there was no drop in consumption for the 2.4GHz network, meaning that the optimization was performing as intended and not preventing subscribers from accessing the network. At the same time there was an increase in consumption on the 5GHz network, pointing to more usage of the network.

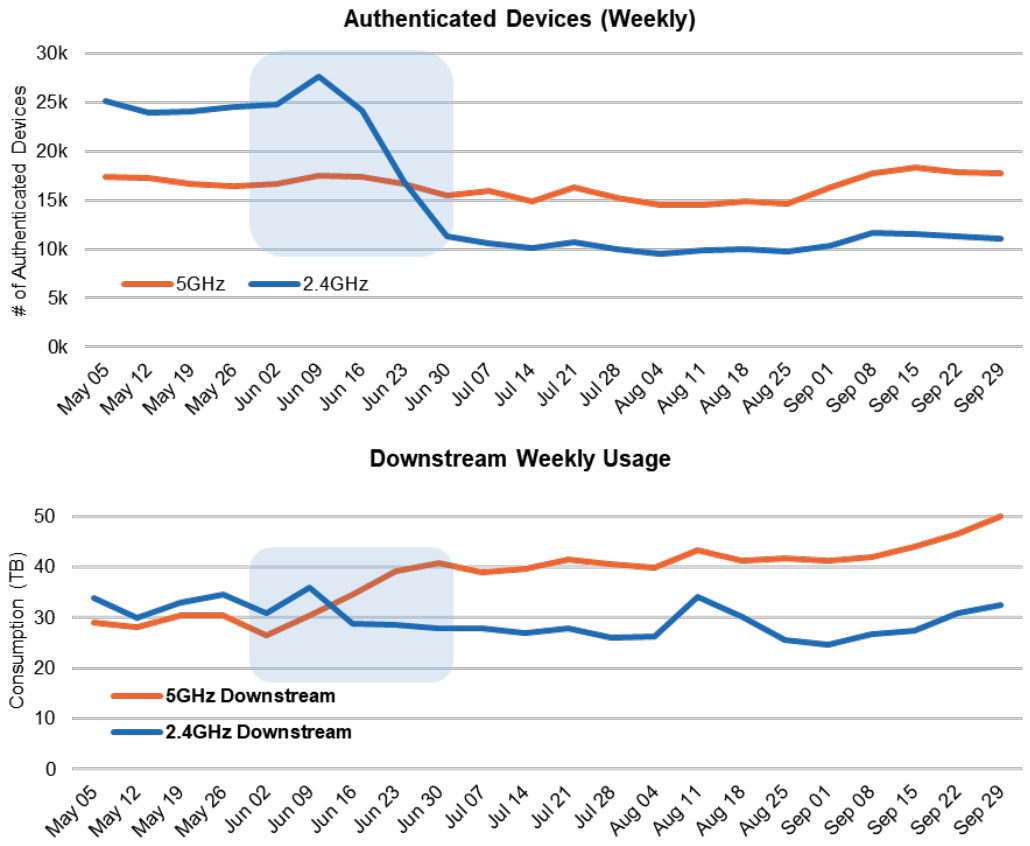

Figure 22 – Impact of 2.4GHz Optimization on Device Counts and Consumption

This optimization covered the area investigated and prevented users from authenticating but not connecting to the Internet. Given its effectiveness, it was eventually rolled out across the entire service provider Wi-Fi network.

4.1. Upgrade Strategy

Initial service provider Wi-Fi APs were Wi-Fi 5 and were reaching their end-of-life, which raised the question of if and how these APs should be upgraded. Wi-Fi 6 provides several new features (Figure 24) which combine to deliver greater capacity and a better performance with a high density of users [3].

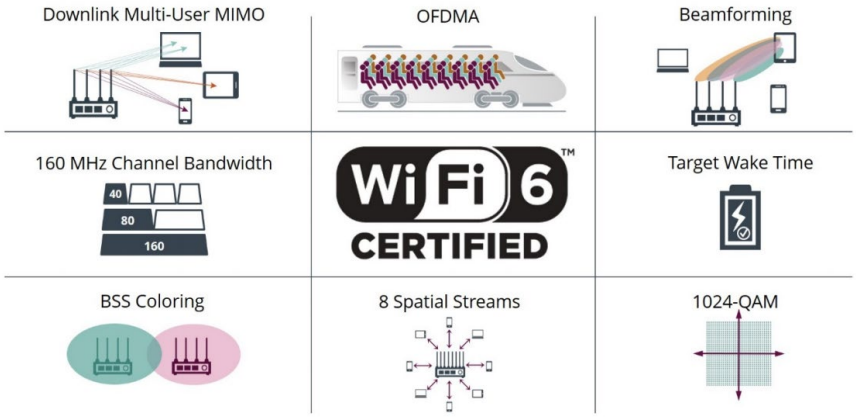

Figure 23 – Wi-Fi 6 Benefits (Source: Wi-Fi Alliance)

The experience analyzing venues revealed that there was significant differences between APs in terms of unique devices and monthly consumption. A methodology was created to separate APs into three different categories—Priority Upgrade, Maintain, and Minimize Support. The categorization was made based on the number of unique devices connected to the AP that consumed over 50MB of data in a month. 50MB was used because it provides tangible data offload and is likely to be above the data threshold that would cause a subscriber to seek out Wi-Fi.

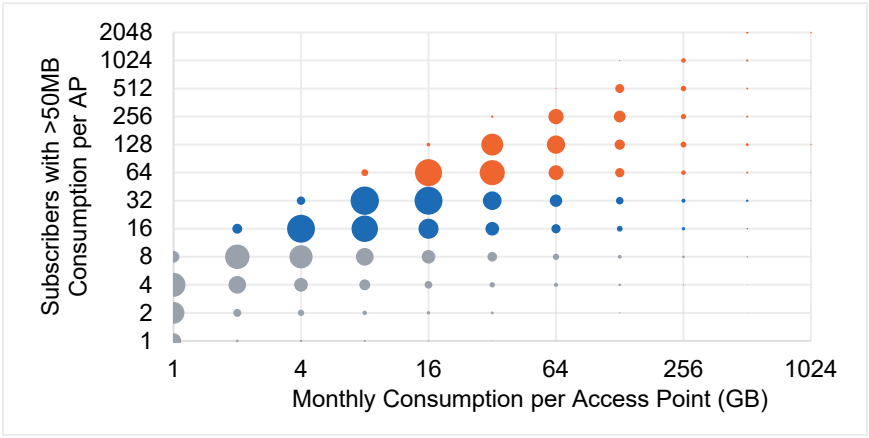

Figure 24 – Devices with >50MB of Consumption per AP

Service provider Wi-Fi APs with more than 64 subscribers with greater than 50MB of consumption were put on the list to upgrade to Wi-Fi 6 as they came to end of life. APs with between 16 and 64 subscribers were to be maintained, while APs below 16 were to have operational support minimized. This upgrade strategy allows investments to be focused where subscribers get the most value while reducing operational costs elsewhere. A simple strategy that uses the total consumption per device could prioritize APs where a single device consumes a large amount of data. Similarly, a strategy that uses total unique devices could prioritize APs where many devices connect but do not consume data.

4.2. Small Cell

Small cells can be used to increase wireless capacity and coverage in localized areas [4]. The coverage area is small compared to a macro cell, as shown in Figure 26.

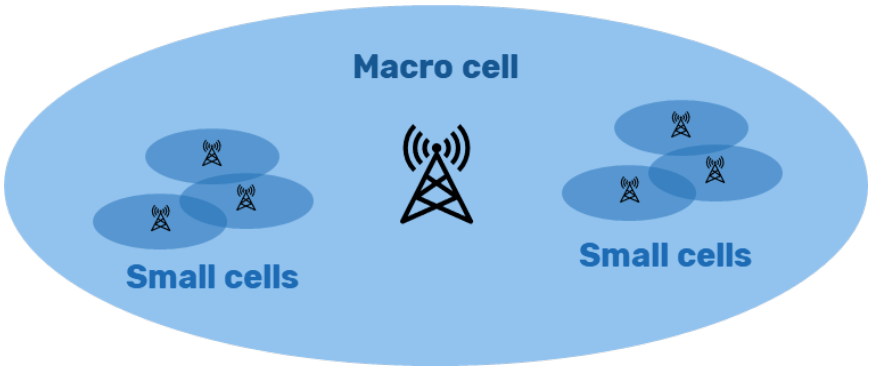

Figure 25 – Small Cell vs Macro Cell Coverage

The coverage area of a small cell will depend on the spectrum used. New mmWave spectrum used for 5G will have RF coverage areas similar to Wi-Fi. mmWave spectrum, or high-bands, represent a large capacity over small coverage areas [5], as shown in Figure 27.

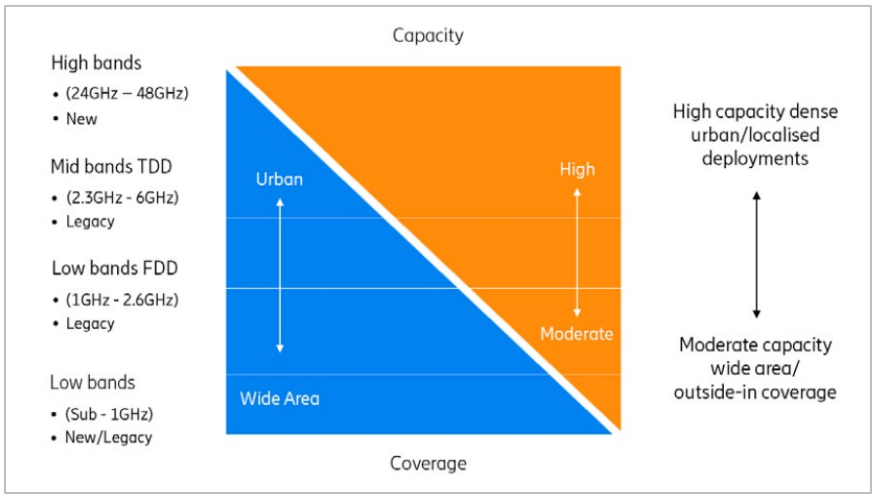

Figure 26 – Capacity vs Coverage for Different Spectrum Types (Source: Ericsson)

These new networks will require space, power, and backhaul. The service provider Wi-Fi network has all of these resources and in the future may be augmented or replaced with 5G small cells.

Shaw has deployed small cells in its wireless network, initially for trials and in advantageous locations. One such location had both service provider Wi-Fi and small cells deployed. The networks were installed separately from each other and individual coverage planning was done. The location of Wi-Fi APs and small cells were similar, however, allowing for a direct comparison. There were 26 Wi-Fi APs and 23 small cells in the facility. It was found that wireless subscribers had four times as much consumption on the Wi-Fi network compared to the small cell network. Figure 28 includes all Wi-Fi traffic and shows consumption per AP or small cell.

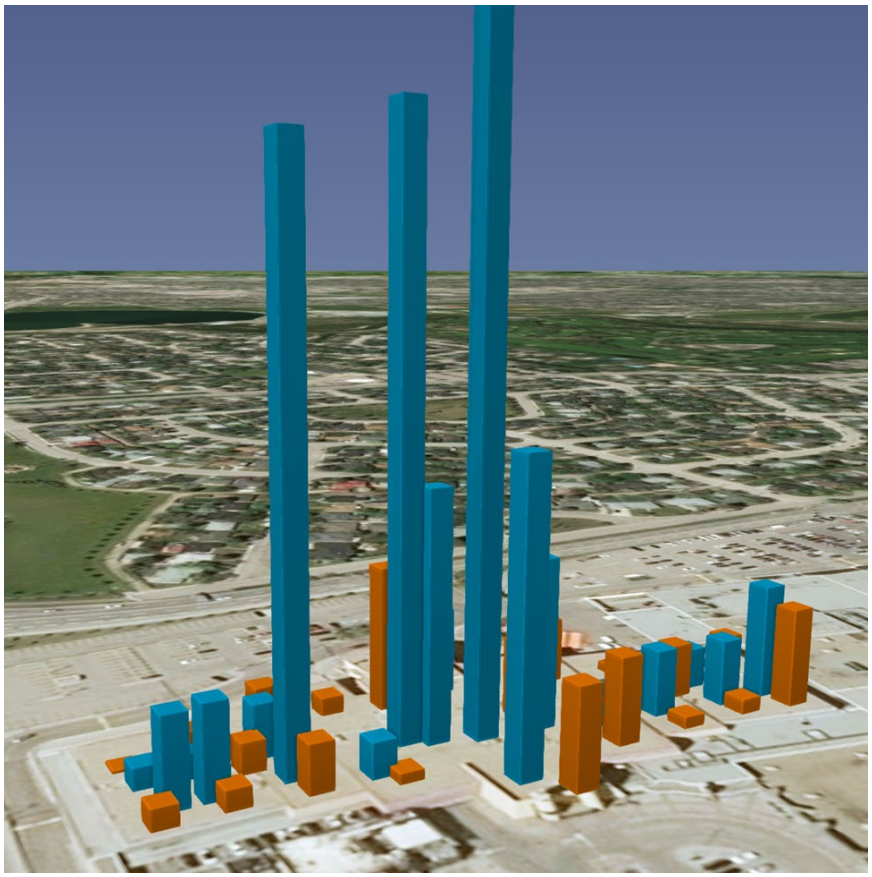

Figure 27 – Consumption for Wi-Fi APs and Small Cells

Wi-Fi consumption is shown in blue and small cell consumption in orange. The venue is a cinema with consumption highly centered in the lobby and the highest consumption at the AP near the entrance. The consumption for this AP was much higher than the others and the representative bar was cut off in the figure to allow the consumption of the other APs to be observed. The low small cell use raises the question of whether it makes sense to deploy both service provider Wi-Fi and small cells in the same locations for offload. However, wireless coverage is still a strong justification for placing small cells, especially for legacy devices that require 3G connectivity for voice.

Technology advancement, as well as business strategies, will dictate whether these networks will be replaced with 5G or whether Wi-Fi will continue to operate in parallel. Licensed-Assisted Access (LAA) is an LTE feature that allows mobile devices to use the unlicensed 5GHz band without having to switch to Wi-Fi. This relieves devices of the burden of deciding which network to prefer and under what conditions to switch from one network to the other. However, Wi-Fi may be the only option for devices without SIM cards such as laptops, or the preferred network in situations where LAA traffic is counted toward a subscriber's data usage. In scenarios where both networks exist, efforts such as CableLabs' Intelligent Wireless Network Steering (IWiNS) project aim to improve the user experience by steering traffic to the most appropriate network given the specific context.

5. COVID-19 Update

As with all networks, the service provider Wi-Fi network was heavily impacted by the COVID-19 pandemic. While wireline networks saw large increases in consumption, wireless networks saw

reductions, owing to stay-at-home orders or similar limitations on movement. Daily consumption on the Wi-Fi network fell approximately 50% in March of 2020 at the start of the pandemic, slowly climbing back to pre-COVID-19 levels over the summer (Figure 29).

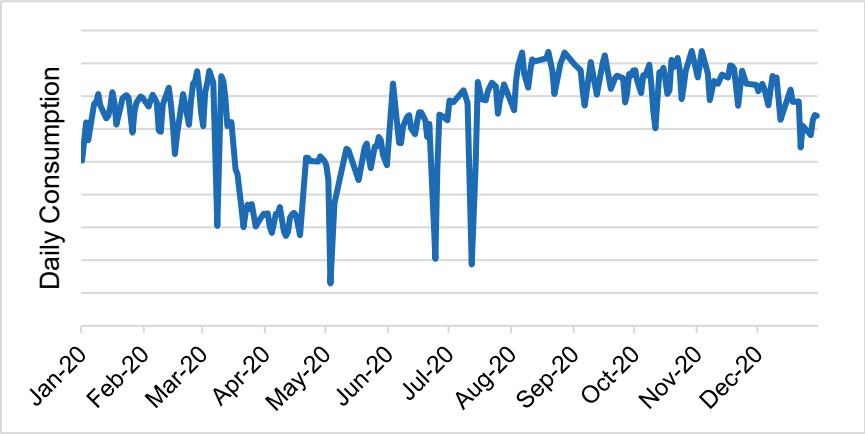

Figure 28 – Daily Consumption During COVID-19

Relative application use did not change significantly, with the notable exception of increased Facebook and decreased Instagram consumption (Figure 30). This makes sense as Instagram is used to document experiences, which are rarer during stay-at-home orders, while Facebook is used to search for news and check in with social networks.

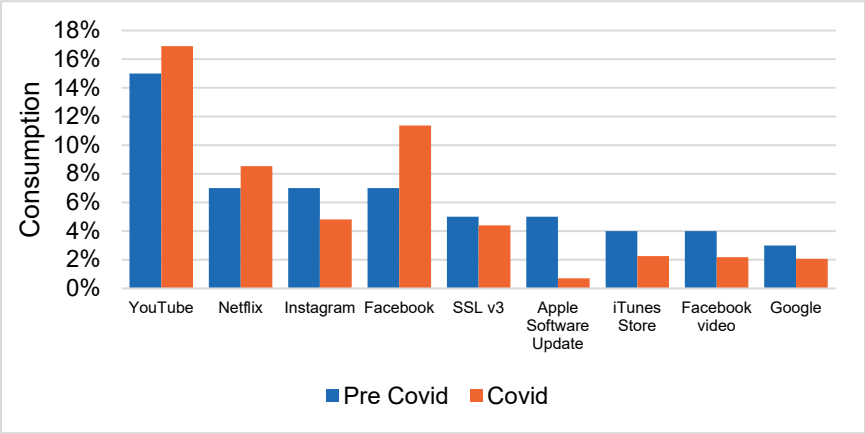

Figure 29 – Application Use During COVID-19

Home hotspot APs saw slightly increased consumption at the beginning of the COVID-19 pandemic in opposition to other Wi-Fi APs (Figure 31). This also makes sense as people stayed home or in their neighbourhoods where home hotspots are more common.

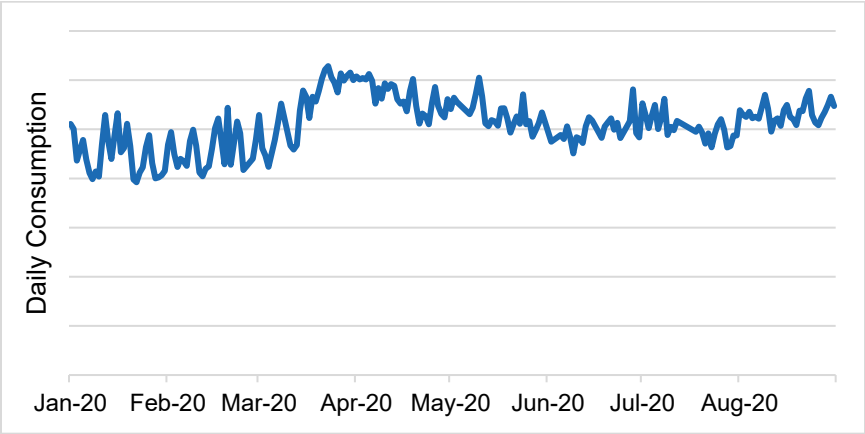

Figure 30 – Home Hotspot Consumption During COVID-19

6. Conclusion

As networks converge and become ubiquitous, consumers will expect to be able to access their broadband services at all times, wherever they are. Service provider Wi-Fi can deliver an important piece of this puzzle, extending subscribers a quality connection at their destinations. In general, service provider Wi-Fi is used as an extension of the in-home wireline network, geared towards shorter durations and smaller devices. The implementation of the service provider Wi-Fi network will have implications on the customer experience. In particular, it was found that devices could authenticate to the 2.4GHz network at low signal levels, but not be able to connect to the Internet. This can cause mobile sessions to end, resulting in frustrated subscribers turning off their Wi-Fi. Matching 2.4GHz and 5GHz coverage reduces this occurrence, leading to a better customer experience. The wealth of AP usage data can inform a network upgrade strategy, but care must be taken to choose metrics that optimize subscriber value. A strategy that uses the number of unique devices that consume 50MB or greater allows for AP upgrades to be targeted where subscribers find the most value. In the future, as small cells and 5G are deployed, the service provider Wi-Fi network will offer a wealth of data to optimize deployments and provide readily available space, power and backhaul.

Abbreviations

5G	Fifth Generation Wireless Standard
AP	Access Point

1. Introduction

Traditionally, electric utilities forecast electricity consumption, aka load, and then generate enough power to supply demand at any point in time. But the world is changing, and this model is becoming tenuous at best, and perhaps will be wholly insufficient to meet our needs for low-cost reliable power. The grid is aging and becoming less reliable as evidenced by recent years' California wildfires and the February 2021 Texas Power Crisis. As the need to reduce carbon emissions is becoming more urgent, significant amounts of distributed power generation from solar and wind are coming online, and demand is increasing with the penetration of electric vehicles (EVs).

These changes present opportunities for innovation, and one area of activity attempts to shift the demand for energy (via load shaping) to the most efficient, cheapest, and cleanest sources of energy supply during the daily cycle. As significant consumers of electricity, cable companies have much to gain by adopting load shaping strategies for facilities, fleets, customers, and the outside plant.

Several working groups within the SCTE have been exploring technologies that could aid in actively shaping electrical loads. A specific use case is the battery-backed EV charging station. Cable fleets of tens of thousands vehicles will become electrified and there is ample motivation to drive down the anticipated costs of EV charging. Using utility-provided Optimum Load Shaping (OLS) signals—based on pricing, low carbon generation, and weather—each charger may be controlled to time its charging periods to ensure the least cost.

Other examples of load shaping include the orchestration of loads within a micro-grid that powers a cable facility. In this scenario, a micro-grid controller may obtain OLS signals and other data to drive algorithms that optimize the load within its domain, using solar, battery, fuel cell, and building management assets.

The outside plant consumes most of the electricity in a cable operation, and there are interesting concepts to leverage batteries, renewable generation, and consume energy in proportion to RF bandwidth powering.

2. Limits to Supply

Since electricity became available in 1882, the grid was simply assumed to grow to meet demand. The one-way model of energy generation, transmission, and distribution has generally been taken for granted, and as cities and towns grew—and more and more appliances and devices were powered up—electricity suppliers simply worked to satisfy all new demands. There are natural limits to this approach, and we've hit them.

2.1. Diverse Generation

The Public Utility Regulatory Policies Act of 1978 complicated the traditional one-way model of the grid by allowing non-utility generators to market their power to utilities. Energy supplies and pricing became more dynamic, and the sourcing and movement of electricity became more complex and less reliably predictable.

More recently, Distributed Energy Resources (DER), such as industrial, community, and household solar, wind, and emerging battery systems add vastly more energy generation sources, deeper into the distribution system, further complicating pricing and management systems. Repurposing the same infrastructure developed for stable one-way generation and transmission to a highly dynamic bi-directional system has worked remarkably well, it reminds one of how cable networks were fortuitously able to accommodate Data traffic overlaid upon infrastructure developed for broadcast TV. However, the grid was not designed for the uses its being asked to serve. Renewable generation fluctuates with the weather, complicating forecasting of fossil fuel generation. Regulations, financing models, distribution systems, management and maintenance systems, and infrastructure—all struggle to adapt without the benefit of a modern intentional design or purpose-built systems.

2.2. Carbon Pollution

Politics aside, carbon pollution appears to be a present and growing threat that communities and governments around the globe are reacting to. Utilities are adopting external or internal mandates to de-carbonize and, in many regions, vigorous efforts are currently underway to replace fossil fuel generation with less carbon-intensive alternatives.

While energy suppliers strive to replace and surpass current fossil fuel capacity, we consider ways to shape and blunt the growth of demand. If the rate of demand growth slows, then the rate of replacement of carbon intensive fuels by renewables accelerates, helping suppliers reach carbon targets more quickly.

2.3. Inefficiencies

As engineers, we might feel offended by how inefficient we've been with fossil generation. As shown in Figure 1, fully 2/3 of the energy released from burning fossil fuels is wasted as heat! Simply put, 2/3 of the carbon we've released into the atmosphere by electrical generation has served humanity not one bit of good. We can—and of course should—do better.

In Figure 1, line widths are proportional to flows. Given total usage of 100 quadrillion BTUs, all numbers on the chart denote approximate percentages, e.g., at left, solar power provided for 1% of U.S. Energy use, and at right, 33% of all energy provided for useful work and 67% was rejected as waste heat—via smokestacks, heat exchangers, and tailpipes.

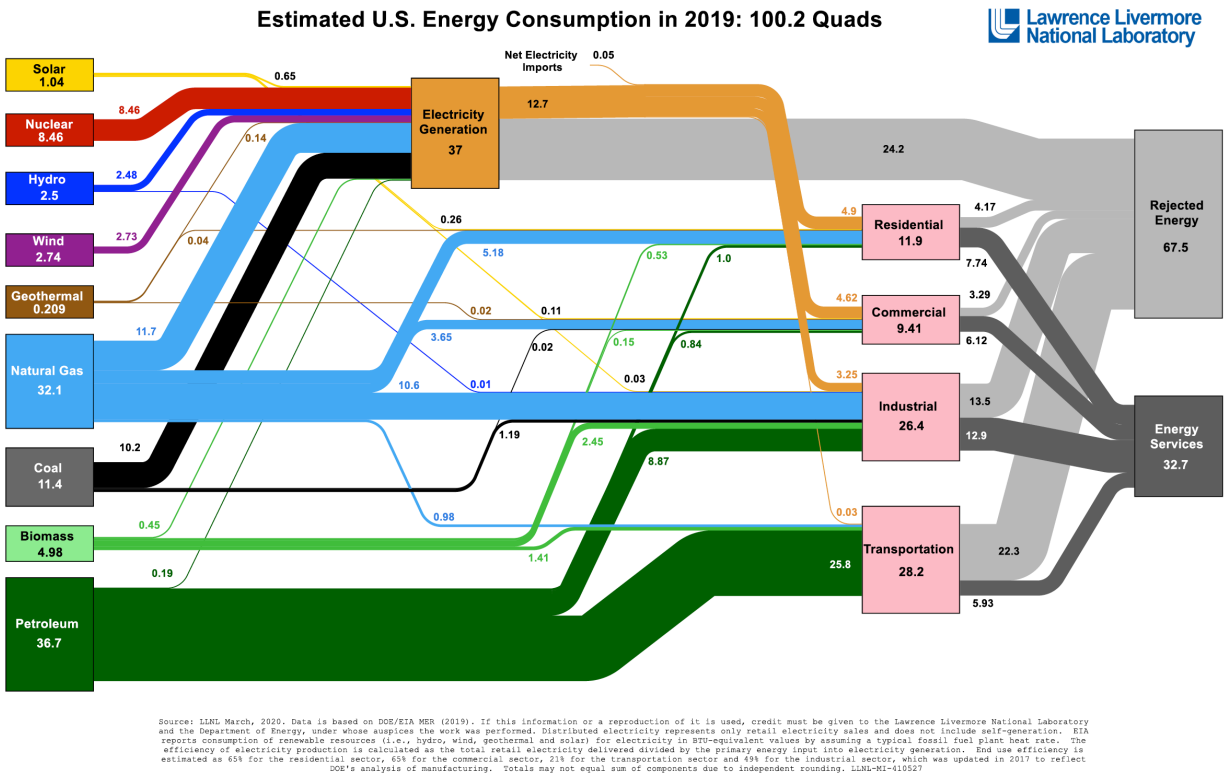

Figure 1 - U.S. Energy Consumption

2.4. Aging Infrastructure

A failed C hook, purchased circa WWII for half a dollar, caused the Camp Fire in California in 2018, the most destructive fire in the state's history to that point, causing $16.8B in damages and 85 lost lives. Images illustrative of Pacific Gas and Electric's failing infrastructure, responsible for starting the fire, are shown in Figure 2.

Figure 2 - PG&E Failing Infrastructure

The mean life expectancy of grid equipment is 65 years, yet, on average, equipment is in service in the field 68 years, with components as old as 108 years!

This leads to an inherently fragile and costly grid that will require time and money to rebuild and repair. Diminishing the maximum capacity that the grid is meant to support will lessen the overall costs and time required to retrofit.

2.5. Severe Weather

Recent history and unexpected trends indicate more frequent and severe weather events that can overwhelm the grid. The unprecedented cold in Texas earlier this year led to catastrophic grid failures. Increasing drought and heat, especially along the West coast is spiking demand for air conditioning.

A cruel irony of higher temperatures is that it makes fossil generation less efficient—the necessary cooling and condensation of water vapor is less effective leading to a higher ratio of fuel to kilowatt-hours (kWh) generated.

2.6. Electrification

Most car manufacturers have by now made it clear that Internal Combustion Engine (ICE) vehicles will be as quaint as horse drawn buggies in a few decades. Electric Vehicles (EV) alone will cause an estimated 25% surge in electricity demand, growth that today's infrastructure is simply incapable of handling.

Other factors will lead to increased electrical demand, for example rising temps will induce increased use of air conditioning. Continued efforts to reach carbon neutrality will necessitate transitions to electric heating, cooling, and cooking.

Figure 3 reminds us of the many of today's sources of fossil fuel consumption by transportation and buildings; these all will transition to electricity over time.

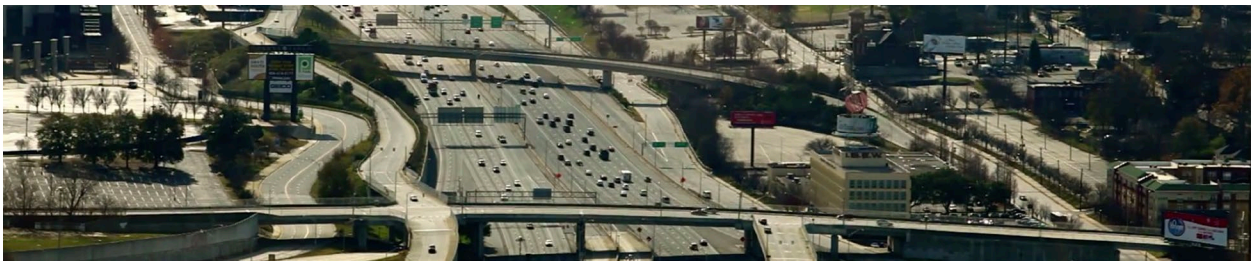

Figure 3 - Energy Consumers

2.7. Cyber threats

Increasingly, various elements of our national infrastructure, such as recently publicized ransomware attacks on fuel lines and meat processors, are under attack via software hacks. There are known instances of successful infiltrations of energy grids. While it appears intruders have to date not exploited such attacks to great effect, there is risk that that they could by activating current breaches or introducing others. Our ability to more fully monitor our energy infrastructure, effectively distribute generation, and dynamically respond to adverse conditions, whether natural or man-made, are signature elements of future grids. Mitigation strategies include shifting or curtailing loads by switching to local generation or postponing demand when the grid is attacked or otherwise failing.

3. Limit Demand

All of the stressors on supply described above require tremendous costs and years of effort to address, and fortuitously all of them can be mitigated to some extent by controlling the amount and timing of demand.

As noted, the general paradigm in electricity services has been that supply chases demand that grows unconstrained by any overt controls—and that electricity costs are so low that it presents very little impediment to growth in demand. The obvious upside of low costs and reliable access is accelerated economic growth and minimally constrained personal use. The obvious downsides are waste, pollution, and over-investment in fuel and infrastructure.

We consider here ways to diminish the rate of growth of electrical consumption, if not one day decreasing the absolute amount of electricity consumed.

There are two categories of demand side control:

- Lowering absolute consumption
- Time-shifting consumption

3.1. Frugality

There will always be people who are sensitive to wasteful consumption and don't particularly mind trimming their own use by turning down the thermostat in winter and hanging their laundry out to dry—but let's face it, most folks will opt first for convenience and comfort. Making it easy for people to lead more efficient lives will probably require seamless technologies and higher prices.

We mention this simply to acknowledge that we all might become more energy aware but concede that this will not likely be sufficient to eliminate all supply issues.

3.2. Pricing

Electricity has been relatively inexpensive since it was first made available 140 years ago. Most homeowners are not enthusiastic about seeking reduction in their consumption as it represents such a small percentage of monthly budget. Renewables are proving to be less expensive than coal and natural gas, and we may find ourselves paying even less for electricity over the long term. In the short term however, a carbon tax or other price signal might be introduced to spur transition to a net carbon neutral economy.

3.3. Building and Device Efficiency

Energy Star appliances, LED light bulbs, strict building codes, improved materials, better batteries, and many other improvements in all of the thousands of technologies we rely upon have had significant impacts on our overall energy footprint. Recall the cable voluntary agreement to deploy energy efficient set-top boxes. Many fossil fuel generation plants have not been build as the result of inexorable improvements in our material culture.

But these gains are significantly offset by other energy-hungry advancements. The growth of mobile and other personal devices, crypto-mining, expanding air-conditioning, and many other factors erode the gains produced by efficiencies.

3.4. Utility Incentives

For some time, various mechanisms have been developed to help utilities avoid brownouts and blackouts by encouraging customers—typically large facilities such as factories—to reduce or avoid consumption during times of expected peak load. Imagine a heat wave during which a utility forecasts a supply deficit in the late afternoon, as some businesses are still operating but many people are coming home and cranking up the AC. This utility may have pricing agreements with energy consumers to encourage strategies such as peak-shaving and load shedding to help avoid grid failures.

Time of use pricing seeks to encourage consumption in periods during the day when prices are low. To succeed, accurate and timely accounting of energy consumption must be collected and reported. This is a form of time-shifting demand, as opposed to lowering absolute demand.

Time-of-use pricing leads us to consider Transactive Energy models. Such systems promise to create highly efficient markets as producers and consumers use real-time and dynamic pricing to balance supplies and demand. Such systems are technically and operationally complex and have yet to be widely deployed.

While certainly valuable, given the scale of supply challenges, these strategies have not proven to be entirely sufficient to mitigate supply shortages or disruptions.

3.5. Direct Controls

A number of strategies have been developed to allow utilities to directly control system loads. You might have seen or even enrolled in a program that allows your electricity provider to manage your home's thermostat. Such programs are bespoke to address specific targets for a specific provider.

The Automated Demand Response (ADR) protocol has been standardized to spur adoption of such systems by enabling interoperability between utilities that issue control messages and the devices and management systems that respond to them. While this lowers technological barriers it doesn't necessarily lead to mass scalability. Business and product development of ADR programs remain time consuming and costly in order to meet specific goals of specific utilities.

4. Optimum Load Shaping

A close cousin to ADR, Optimum Load Shaping (OLS) provides a mechanism that may encourage time-shifting of energy consumption on a massive scale. The control signal is not a specific on/off command or a retail price signal, but simply a table of values that represent the optimal percentage of a day's electrical load that should be consumed within a given period, typically an hour. The set of values describe a curvilinear shape, and are intended to accordingly shape the load on the system.

The Optimum Load Shape protocol has been standardized by SCTE and published as ANSI SCTE 267 2021. The specification was developed within the SCTE micro-grid working group and specifically addresses the cable industry's emerging EV fleet and battery charging systems, however, the protocol can be applied to any flexible load.

4.1. Theoretical background

The economic value of flexible load shaping has been studied, using various data sets and modeling strategies. A study of related literature and a description of a simulation of the Texas ERCOT system, using historical data, is provided by [Cruickshank].

A key element of the simulation methodology is the Unit Commitment Model, used within the Generic Algebraic Modeling System (GAMS), and expressed in Figure 4.

The mathematical formulation of the Unit Commitment model constructed in GAMS consisted of a cost-optimization objective function based on production costs:

$$\min \left\{ \sum_{t=1}^{n} \left\{ \sum_{i=1}^{N} v_i c_i(p_i) \right\} \right\}, v_i \in \{0,1\} \qquad (11)$$

which was constrained by the need to match supply and demand in each time period:

$$\sum_{i=1}^{N} p_i = d \qquad (12)$$

where:

n was the number of time intervals in each optimization step

N was the total number of generators

v_i was the binary variable indicating whether a generator is committed (1) or not (0)

c_i was the operating cost of generator i ($US/MW)

p_i was the power generation of generator i (MW)

d was the system demand (MW)

Figure 4 - Unit Commit Model [Cruickshank]

Simulations were run to 1) calculate the cost and carbon emissions of meeting all load through traditional fossil-fueled generation, 2) calculate the cost and carbon of an optimally flat fossil-fueled generation scenario, and 3) to overlay renewable generation onto the flat fossil-fueled

scenario. Flat constant-output fossil-fueled generation is more efficient than variable output, as it eliminates the inefficiencies of starting and stopping generators, ramping generators up and down, and running at less than ideal capacity, i.e. less than maximum efficiency. Flat fossil-fueled generation does not, however, meet demand that exceeds that static supply, hence renewables and storage are overlaid onto that scenario to create an Optimum Load Shape.

The result of the third simulation indicates that costs and carbon emissions can be significantly reduced if fossil-fueled generation is held flat and load follows the shape produced by overlaying renewables.

4.2. Architecture

The OLS system follows the common client-server pattern, using the term Producer instead of server, and Consumer instead of client; an OLS producer makes available OLS signals, and any number of consumers may acquire the signals as shown in Figure 5.

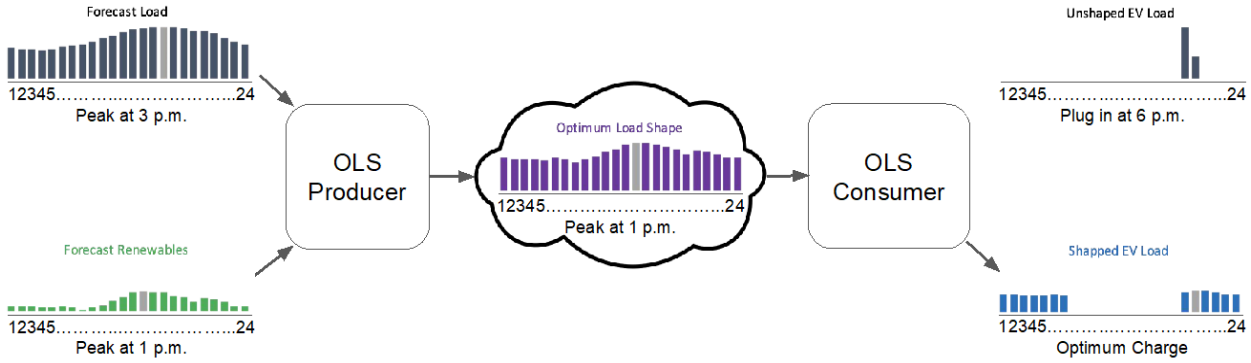

Figure 5 - OLS Architecture

An OLS signal is a datagram that simply contains a table of timestamped values. Timestamps represent the start of a period sometime in the future, typically the top of an hour of the day following the generation of the signal, and as mentioned above, the values represent the percentage of daily use that should ideally be consumed for that period.

The producer of the signal may use any algorithm to create the signal, incorporating input such as fossil fuel generation costs, availability of renewables with weather forecast, machine learning inputs from historical usage data and anything else those crafty nerds can make use of. In its simplest form, the signal can be made available to everyone within a service area—since the shape applies to the supply-side and does not target specific users.

The left side of the diagram in Figure 5 illustrates a strategy to optimize the use of renewables by flattening fossil fuel generation and overlaying the forecast renewable generation. The closer the aggregate load matches this shape, the more efficiently the mix of renewable and fossil fuel generation will be.

Consumers of OLS are not concerned about why the signal takes the shape it takes; they simply respond as best they can to the signal. Some electrical consumers, say the lighting of a retail store, cannot time-shift, but many others, say a battery or thermostat, often have flexibility to determine the times at which to pull power from the grid.

Each consumer autonomously decides how best to respond to OLS signals, if at all. For example, an EV charging system may define flexibility constraints, such as blocking certain hours during the day in which a car will be in use and not available for charging—and a specific hour, say 7 am, by which the car must be fully charged. Given these constraints, the OLS consumer can strive to match the OLS shape as best it can. This still can produce dramatical results, for example, avoiding load spikes at the close of the workday by smoothing the load across a population of EVs.

The right side of the diagram in Figure 5 illustrates examples of unshaped load (at top) and shaped load (at bottom). Figure 6 provides a more detailed analysis of the concepts in Figure 5 and depicts ~20% savings at far right.

	Supply-side: Two forecasts [GWh] feed Optimum Load Shape (OLS) Producer							Demand-side: OLS Consumers modulate load			Forecast Load	Electricity Price and Cost

Assumptions & notes:													per/day	per/year

The vehicle is in use and unavailable for charging from 0700 - 1800 hours.

The charger takes unavailability into consideration and autonomously adjusts the Optimum Load Shape that it received from the supply-side.

1. Data are illustrative of load for the serving area of the Electric Reliability Council of Texas, and represent ~10% of U.S. nationwide electricity usage on a hot peak summer day.
2. Model can be similarly applied to any vertically integrated serving area, e.g., for micro and nanogrids. Modeling wholesale markets and on-site combined heat & power (CHP) is TBD.
3. In power systems, generation = load. In optimization, loads from electric vehicles (EVs), facility batteries, and smart devices are modulated , i.e., shifted forward & backward in time.
4. The OLS is normalized between zero and one by dividing the generation at each time step by the sum of generation over the simulation horizon, in this case 1-day.
5. The unshaped EV Level 2 charger draws 7 kW for 1.43 hours = ~10 kWh of energy for ~100 miles of travel. No opt-in or two-way communications is required; OLS can be broadcast.

Figure 6 - EV Charging Example Detail

4.3. Protocol

The ANSI SCTE 267 2021 standard defines the Data Model for an OLS signal in YANG format. YANG is a human and machine-readable schema language designed to model hierarchical data structures. YANG can be converted via software tools, or by hand, into various transport and encoding formats, such as REST and Protobuf.

The standard provides an HTTP REST OpenAPI specification of an API based on the Data Model. REST is arguably the most common protocol in use today to support client-server architectures.

Human and machine-readable assets are available on Github at:
https://github.com/cablelabs/scte-ols

There could be many non-exclusive paradigms for communicating OLS signals, including pull, push, and notifications.

The lightweight specification of the payload and non-normative guidance on transport/encoding formats is intentional and encourages innovation. Both OLS producers and consumers are expected to iteratively develop and improve algorithms to generate and respond to signals, based on learnings in the field.

4.4. Monitoring

The OLS specification currently provides no definitions for how OLS consumers expose their behavior in response to OLS signals. This greatly simplifies the entire platform, compared for instance to Transactive Energy models. While one might expect that OLS consumers will more aggressively adopt OLS if given new incentives, which be performance based, these business issues are not explicitly addressed in the current standard.

Additional definitions could be developed and standardized to support monitoring of OLS consumers. For now, we expect the market to innovate and discover where then real needs lie. In the meantime, when OLS is used with increasingly popular dynamic electricity rates and existing back office, interval metering, and billing infrastructures— lower cost of operations electricity bills are the result.

4.5. Use Case: Cable EV Fleet Charging

The initial use cases that led to the development of OLS within the SCTE micro-grid working group are concerned with lowering costs, increasing network reliability, and enhancing operations during the transition of cable fleets from internal combustion engines to EVs. In the absence of load controls, local load spikes may occur when numbers of EVs stop service for the day and attempt to recharge at the same time. Such spikes can easily overwhelm a local grid endpoint, such as a transformer, leading to expensive and time-consuming upgrades to the distribution grid. Such software-based mitigations are called ‘non-wired solutions’ in the utility industry and are highly prized as they avoid capital outlays.

With OLS, the EV charging load can be shaped to follow renewables and smoothed out over several hours, as described above. This provides cable operators more flexibility in when to recharge fleets and could lower overall costs where Time-of-Use dynamic pricing or other incentives are provided by utilities.

Figure 5 illustrates an example where pricing follows expected load. In this particular example, load shifting can reduce OLS consumer costs by approximately 20%.

The effort to create the OLS standard benefited from having specific use cases identified, but the resulting standard has applicability to any scenario in which a load can be shifted in time.

The authors have built a web-based API that provides SCTE-compliant OLS signals for nearly 22,000 grid transmission interconnection regions across the US. The OLS signals reduce the cost of purchasing electricity. Broadband providers may consume an OLS and further target and optimize to specific sub-regions or consumers. For example, a micro-grid controller might consume a regional OLS and subsequently pass further-optimized OLS signals to sub-components like battery walls, EV charging systems, building management systems, thermostats, and other flexible loads.

5. Conclusion

ANSI/SCTE 267 2021, Optimum Load Shaping, is intended to benefit the cable industry in lowering energy costs and improving operations. It's meant to directly address the transition of the fleet of service vehicles to EV and can also provide value by being applied in many other use cases, including many beyond the cable industry.

Besides cost reductions and operations improvements for cable operators the benefits of OLS include:

- Reduce fossil fuel utilization
  - Improve efficiency by reducing peaks, starts/stops, up/down ramping
  - Reduce fuel costs, water consumption, pollution
- Accelerate transition to low-carbon economy
- Reduce investments in electrical infrastructure
  - Provide non-wires solutions to local congestion
- Lower costs to electrical consumers where time of use or other incentives are offered
- Improve Service Continuity for cable operators as grid failures are reduced

Abbreviations

ADR	automated demand response
EV	electric vehicle
HTTP	Hypertext Transfer Protocol
ICE	internal combustion engine
kWh	kilowatt hour
OLS	Optimum Load Shape
Protobuf	protocol buffer
REST	representational state transfer

ORAN, The Future Of Wireless Architectures

A Technical Paper prepared for SCTE by

Bill Beesley, Principal Solutions Architect, Fujitsu

1. Abstract

As MSOs continue to transform their networks to be more wireless centric, many are considering the architectural map provided by the Telecom Infrastructure Project's Open Radio Access Network or ORAN project. ORAN has defined a set of open interface specifications that allow vendor neutral disaggregation of the radio access network software and hardware that delivers increased flexibility, via best of breed vendor options and eliminates the issues of vendor lock in that currently burden the wireless infrastructure ecosystem. This paper will outline what ORAN is and how it can be implemented in an operationally sustainable fashion sharing examples from existing operator implementations. The paper will provide how MSOs can and should use an ORAN architecture to increase flexibility in vendor selection, take advantage of virtualization and containerization of software, provide innovation via adoption of new technologies and maximize supply chain diversity

2. Introduction

When Alexander Graham Bell (or Elisha Gray depending on which side of the historical fence you stand) created the first telephone in 1876, it took another 75 years for the telephone to reach 50 million users. Television, which started broadcasting in 1929 took 33 years to reach 50 million users. The World Wide Web took only 4 years, and the popular app Pokemon Go only took 19 days to reach 50 million users. What we've seen happen over the last 100 years is that the pace at which people adopt technologies has accelerated astronomically. Much of this increased pace is arguably because of the Internet, which hit 50 million users in 7 years, itself a technology evolved on the telephone lines created by Bell. It is hard to imagine what Bell would think of what his invention has evolved into and even harder to imagine he would have believed that most of that evolution has happened in the last ten years.

Transport networks have also had to evolve to keep up with the expectations of users. Network function virtualization has increased the agility of networks, made them more programable and adaptable, and ultimately made them less expensive to own and operate. Open optics, open line systems, open ROADM, DOCSIS, and other open standards work has further allowed innovations in networks. Globally, ORAN is beginning to bring these same evolutions to the wireless mobility ecosystem. ORAN is allowing operators to evolve their networks to be more flexible, capable and agile. But here in the US, there is still much skepticism on the viability of ORAN, even among operators who are currently creating greenfield networks and are not constrained with having to own and operate an existing closed ecosystem.

3. What is ORAN

Generally speaking, ORAN represents efforts to standardize the radio access network by disaggregating the hardware from the control software and defining standard interfaces to allow a multi-vendor network ecosystem. For the purposes of this paper, the author is intentionally conflating the work being led by two groups into a single term, "ORAN. The first is the O-RAN Alliance and the Telecom Infrastructure Project's OpenRAN working group. O-RAN with the hyphen is an alliance founded in 2018 by AT&T, China Mobile, Deutsche Telekom, NTT DOCOMO, and Orange with a mission to reshape the RAN industry towards more open and competitive ecosystem. Next is TIP's OpenRAN program comprised of both suppliers and operators who collaborate to create open, multi-vendor interoperable products. Traditionally, radio access networks or RANs were closed ecosystems, often with all the necessary equipment and management and control software coming from a single vendor.

The most recent version O-RAN architecture specifications divide the RAN into the radio side, and the management side. On the management side, there is the service management and orchestration components as well as the Non-Real time RAN Intelligent Controller (RIC) which is primarily responsible for high level intent-based control and optimization of RAN resources. The non-real time RIC is analogous to a traditional element management system providing element visibility, high level management and reporting. On the radio side, the near-real time RIC is responsible for supporting more granular control and data, generally via microapps delivering functions such as anomaly detection and mitigation The radio side also defines the radio unit (RU) providing RF interfaces and protocols, the centralized unit (CU) supporting higher layers of the stack (eg SDAP, PDCP, and RRC) and the distributed unit (DU) supporting the lower layers (eg RLC, MAC, and PHY). These abstracted elements can be delivered by either a single supplier or the operator can select to obtain these from multiple suppliers.

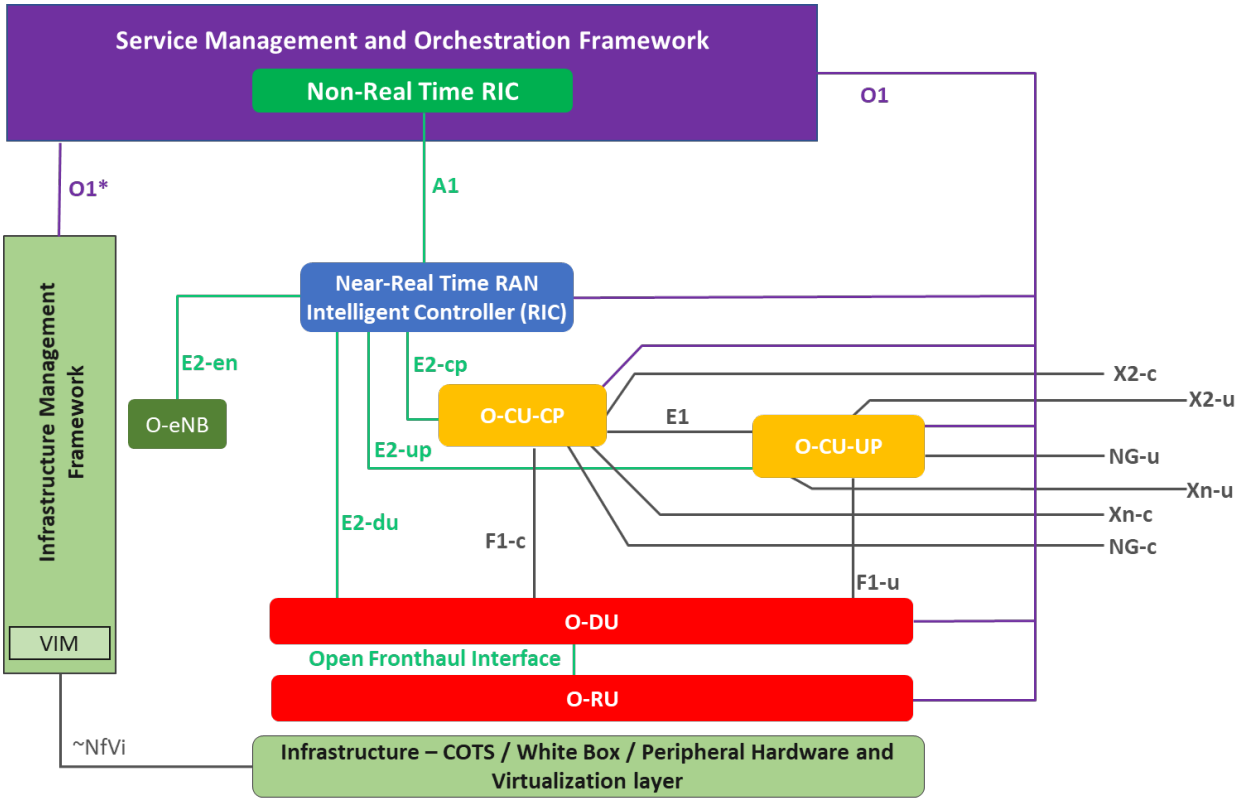

Figure 1 - O-RAN Alliance Logical Architecture

4. Arguments against ORAN

Historically, open systems such as the original IBM PC, DOCSIS, Open ROADM, and others have driven down costs to own and operate their respective technologies, but more importantly they spurred innovations in those industries that allowed the original use cases to grow. So, why would anyone be resistant to ORAN? Frankly, there are very valid concerns about how ORAN changes how wireless networks are built and operated. The current 4G and 5G technology that allows us to have near ubiquitous access to communications and information are very complex systems with a lot of moving parts that must operate in a consistent and coordinated manner. Operators who are skeptical of ORAN

generally have two reasons as to why they are resistant to the new paradigm. The first is supply chain simplicity. We often hear this phrased as “one throat to choke”. By having a single vendor ecosystem, there are fewer components to manage in the network. There is one company to call on for support, technicians have fewer systems to be trained for, and warehousing of equipment for deployments or spares is simpler. The second argument builds upon the first, closed ecosystems are more fully integrated whereas ORAN aside from TIPs interop lab work has little integration. There is a valid concern among operators that they will be left with total responsibility to integrate systems from multiple vendors and if problems arise, will be left in between suppliers who are pointing their fingers at each other. There is also the obvious concern that integration in a network does not happen just one time. Over the life of the network, as elements are updated and patched, this integration may have to happen multiple times. Thus, they take what is perceived as the less risky approach of selecting a vendor to supply most if not all the components necessary to build their radio network on the premise that vendor will be the “only throat to choke” to ensure systems are fully integrated, secure and operate as envisioned. Most of these operators are taking a “wait and see” attitude towards ORAN and opting to continue deploying traditional closed ecosystem networks. Recognizing the very valid concerns of operators who must manage and maintain networks at scale, the remainder of this paper will show how these concerns can be managed as well as a number of reasons why the risk in moving to the new paradigm is worth the benefits gained.

5. Supply chain advantages

The counter argument to the supply chain simplicity argument is one of supply chain integrity. Diversity of suppliers lowers the risk to your operations and gives you more flexibility. The current pandemic has brought us far too many stories of multiple supply chain disruptions. Historically events like natural disasters, disease, and even industrial accidents have caused supply disruptions of one kind or another. The telecommunications industry is currently experiencing supply shortages that are creating component lead times that may have traditionally been days or weeks to currently running into years. To mitigate this and ensure their networks can continue to grow and maintain the pace of demand mentioned earlier in this paper, operators are having to risk buy equipment that they won’t receive until months or a year or more later or risk disrupting business growth. ORAN allows for vendor diversity that de-risks supply chain disruptions by allowing the operator to select alternate vendors should their primary supplier not be able to deliver.

Selecting a single vendor for your network also constrains your ability to deliver new features or capabilities as they become available in the market. With a single supplier you are limited by their roadmap and their view of what technologies are important to bring to market and when. With an open ecosystem of suppliers, you are not locked into a single vendor’s vision of the network. When innovations become available, if another supplier brings them to market first you can take advantage of the innovation because you are not locked in. Open systems allow innovations to come to market and begin delivering value to your network and your customers faster.

Lastly, it is very difficult to imagine that any single vendor is going to be the best at everything that makes up a network as complex as the modern RAN. Having an open ecosystem allows you to select best of breed suppliers and make fewer compromises in your network.

6. Systems integration

While it is generally true that ORAN presents new integration challenges, it is not entirely true to suggest that if an operator elects to go with an open network, they are forced to take on all the integration

challenges themselves. First, there is nothing stopping an operator from deploying an open ecosystem in partnership with a single supplier who takes on all the integration responsibilities. This is a bit like the old adage, eating your cake and having it too. By having a single supplier responsible for the final solution, the operator takes on less effort and risk themselves while still allowing them to add in alternative technologies and products in the future should they decide to shift. Having the flexibility to pivot at some point in the future in this way is extremely difficult with vendor specific systems.

Operators can also take advantage of the work that TIP has been doing to create the OpenRAN Exchange which is designed to accelerate the creation of an ORAN ecosystem. The marketplace has a wide list of suppliers of RU, CU/DU, transport, software, consulting services and other components that have been demonstrated to provide best of breed technology and interoperability that is the promise of ORAN. More information can be found on their website listed in the references at the end of this paper.

Much of the concern of solutions integration for ORAN are essentially based on the fear of the unknown and operators are apprehensive about being able to not just deploy a service once, but ensuring the ability to consistently deliver a service in a repeatable manner thousands of times. Fortunately, wide industry support for deploying ORAN is available and growing daily.

7. ORAN and Security

There is a lot of back and forth over whether closed or open ecosystems are more or less secure. Generally speaking, the most adopted and popular systems, closed or open will tend to get the most attention of bad actors attempting to exploit flaws and gain access. It is also important to remember that if you are depending on a closed system being more secure because the internals are less widely known, there is an old adage that obscurity is not security. The advantage that open systems have over closed is the sharing of information about faults and exploits is much faster and much more transparent. Issues tend to be identified and brought to community awareness more quickly. There is also much more flexibility in developing workarounds more quickly and the operator often does not need to wait for one to be delivered as they have the option of implementing their own. Lastly, bugs and other security issues tend to get resolved faster in open systems because there are more developers contributing. A community of five thousand developers can outpace a company who may have as few as five developers working on a project.

8. Network Agility

As mentioned earlier in the paper, modern telecommunication networks must consistently evolve to meet the ever-increasing demands users bring. What Bell started as a communications network has evolved to become an information and content delivery system that even just a few short years ago was unimaginable. Emerging use cases for the RAN such as Industry 4.0, IoT, gaming, autonomous vehicles, AI/ML, augmented reality and others require not only increased bandwidth and lower latency, they also require networks that are adaptable and agile. The modern radio network will need to be envisioned as software that can be automated and programmable.

In addition to this, to achieve the latency and bandwidth promises of 5G, orders of magnitude more radios will need to be deployed so that the serving groups can have smaller numbers of users. Much like fiber deep technologies like Remote PHY are delivering making more bandwidth available per subscriber, highly distributed antenna architectures will soon become the norm. One major MSO has publicly

shared at trade conferences a vision of a radio network that is not the traditional large macro cell towers but thousands upon thousands of small strand-mounted radios deployed deep into the neighborhoods.

While closed ecosystem networks can support all of the above 5G features, having the most flexible, agile network will become a competitive necessity to support them. Open systems are much more adaptable, agile and flexible.

9. Opportunities for new revenue

Admittedly, the concerns raised over migrating to an ORAN architecture are valid even if they use appeal to possibility or fear of the unknown as their basis. We can't blame operations executives and their teams for being hesitant to dive into the unknown, especially when they are the ones held accountable should the network or systems not operate in a consistent and reliable manner. As a NOC expert friend of mine used to quip, "there are no optimists in Operations".

But the industry has successfully implemented open architectures in other areas of the network – DOCSIS is one example that comes to mind – and these implementations not only saved the industry both expense in purchasing the network and operating it, they drover further innovations that created new revenue streams.

Ultimately this is where ORAN will provide the biggest benefit to our industry. It supports an open and agile network that allows for innovations to bring new revenue opportunities to the network more quickly.

One of the most intriguing new service offerings that operators are expressing interest in is E5G or enterprise 5G. This is the delivery of private 5G networks, primarily to large enterprise and heavy industry to support use cases such as deterministic band for IoT and sensors in manufacturing, deterministic low latency/high bandwidth networks to support autonomous vehicles for industries such as mining, and the ability to slice out private networks so that mobility devices can access local network resources in a secure and reliable manner. Again, as stated 5G deployments can be accomplished with closed ecosystem networks but to provide competitive offerings that take advantage of 5G technologies such as network slicing, function virtualization and programmability, ORAN provides a clear differentiator. To be competitive in the emerging E5G space, operators will need to offer highly flexible and tailored offerings as no two enterprise networks have the same internal requirements. By selecting an open architecture, operators will be able to create offerings that appeal to the small to medium enterprise sweet spot that makes up 92% of the businesses in the United States and where the MSOs have been wildly successful in the past. ORAN will allow the operator to create highly adaptable offerings while minimizing capital and operating costs, especially for the edge radio and EPC functions as there will be more down-scalable products that minimize the cost to deploy.

Finally, it seems appropriate to give a mention to another upcoming open specification known as SCTE GAP. GAP is a working group that has created a standard set of mechanical specifications for outdoor equipment that allows for component reuse and the creation of a supplier ecosystem that will drive down costs and increase innovation much like the IBM PC standard did. As of the time of the writing of this paper, the final draft of the GAP spec is undergoing the final voting and comment process at the SCTE and should be finalized by the time this paper is published. What is innovative about GAP is that the service delivery modules can be mixed and matched to support multiple use cases at the edge. This means a GAP deployment could contain a cable modem module for transport, a CBRS small cell module and a compute module to push virtualized compute resources right to the subscriber edge. This opens up a number of use cases such as the aforementioned E5G. IoT for smart cities, edge gaming, or even

offering real-time access to the radio network through slicing and virtualization. This would allow the MSOs to offer access to highly distributed radio and compute resources to provide something similar to an MVNO offering but with a much higher degree of granularity and flexibility. It is not hard to imagine that given enough time to deploy thousands and thousands of distributed radios in the MSO network, which already has space, power and transport to the edge, that at some point in the future a cable operator could become a dominant wireless provider in the areas they serve. But using legacy closed systems won't create the next generation network that can support this vision.

10. Conclusions

As previously stated, ORAN doesn't mean that the operator has to become the wireless system integrator managing multiple supplier relationships and taking on all the risk for issues that arise. MSOs can select single suppliers to either provide a fully integrated ORAN solution or they can work with ecosystem suppliers that are emerging via working bodies such as TIP to build, deploy and maintain their infrastructure. What is important to remember is that ORAN means flexibility. Flexibility in defining what capabilities you want to have in your network. Flexibility to select best of breed suppliers, whether now or at some point in the future. And ultimately, ORAN provides the type of agile and programmable network that will be a competitive differentiator in our 5G IoT world

11. Abbreviations and Definitions

11.1. Abbreviations

5G	Fifth generation
AI/ML	Artificial intelligence/machine learning
CU	Central unit
DOCSIS	Data over cable service interface specifications
DU	Distributed unit
E5G	Enterprise 5G
GAP	Generic Access Platform
IoT	Internet of things
MSO	Multi service operator
MVNO	Mobile virtual network operator
NOC	Network operations center
ORAN	Open Radio Access Network
PC	Personal computer
PHY	Physical layer
RAN	Radio access network
ROADM	Reconfigurable optical add drop multiplexer
RU	Radio unit
SCTE	Society of Cable Telecommunications Engineers

1. Introduction

Cable 10G and Wireless 5G may seem to be at odds. However, when combined, they offer an evolutionary strategy with much synergy.

5G uses a collection of different frequency bands, each with unique characteristics. Recent developments in C-band, CBRS (Citizens Broadband Radio Service) and Wi-Fi provides some new mid-band spectrum (i.e. 3 - 6 GHz) that is offering a middle ground that may be the future wireless workhorse. Its reach covers a significant number of mobile users with substantial data rates. But its deployments may need many more densely packed cell sites than current 4G LTE macro-cells. This presents an opportunity for MSOs to leverage their existing HFC infrastructure for providing both backhaul and power to those new cell sites.

The paper presents a basic tutorial on mid-band wireless technologies in the 3-6 GHz range that includes C-band, CBRS and Wi-Fi 6E. It covers MIMO antenna systems from 2T2R to 64T64R and when and where each is appropriate. ORAN (Open Radio Access Network) standards help to virtualize the 5G infrastructure, identifying backhaul, midhaul and fronthaul interface options.

The many choices for the mid-band wireless system can vary bandwidth requirements from 100's Mbps to many 10's Gbps. The paper shows which configurations can easily be supported on DOCSIS 3.1 while others might require DOCSIS 4.0 and some may need direct fiber connect.

Some case studies are provided where potential mid-band small cells are mapped to actual HFC networks. Results from a CBRS design show its potential reach. This data is used to map cells to several existing HFC nodes. The nodes under study vary from dense urban nodes (i.e. >250 HP/mile) down to sparse rural nodes (i.e. <40 HP/mile). Various trade-offs are considered in cell site placement on the HFC.

HFC appears to be ideally suited to support this Mid-band xHaul infrastructure. A strategy is laid out for cable plants of varying densities. D3.1 midhaul can be leveraged extensively in the early days to get wide coverage quickly. Very dense urban areas will eventually require complex antenna/MIMO systems with fiber fronthaul. This integrates nicely with an N+2 fiber deep strategy. But even then, cells with DOCSIS xHaul will be needed to fill the holes and hotspots. D4.0 then enables even higher capacities at these cable cell sites.

In the end, Cable and Mid-band wireless (C-Band, CBRS, Wi-Fi 6E) are much stronger together and are at the core of a next gen converged network evolution.

2. 5G Midband and Wireless for Cable Dummies

For many cable operators, wireless in general and 5G in particular is a brand new, if not foreign, technology. This section provides a tutorial to help educate cable technologists in this area.

Mobile Wireless Services have been deployed since the mid-1980s through a succession of generations:

- **1G**: 1980s – Analog signals, typically 1 Tx port and 1-2 Rx ports on the radio (diversity improved signal reception). Frequency bands were 850 MHz in US and 900 MHz RoW (rest of world). Voice only
- **2G**: early 1990s – Digital signals, typically 2 ports on radio one for Rx, one for Tx/Rx. Initially Voice only but later technologies such as GPRS and EDGE allowed data to be encoded as if it were voice for early data transmission. First introduction of mid-band spectrum 1900 MHz in the US, 1800 MHz RoW. Fairly quickly all existing 1G services were converted to 2G.
- **3G**: 2000 – Digital signals, designed for data transmission, again 2 ports on the radio, only one doing Tx. New frequency bands were added, specifically at 2100 MHz (slightly different bands in US and RoW)
- **4G**: 2009 – (a.k.a. LTE, Long Term Evolution) Digital signals, designed for data transmission. MIMO introduced (Multiple Input Multiple Output) which improved data capacity by using multiple transmitters and receivers. In general, radios had 2 or 4 ports with all ports capable of Rx and at least 2 Tx ports. New frequency bands including 700 MHz and 2600 MHz in the US, 800 MHz, 2300 MHz and 2600 MHz RoW. VoLTE (Voice over LTE) encoded voice as data (similar to VoIP) to allow 4G systems to handle voice traffic. This allowed the decommissioning of 2G and 3G networks to commence.
- **5G**: ~2020 – Digital. Improved efficiency compared to 4G. In addition, 5G is meant to be more flexible, so that it could in theory replace not only existing mobile wireless communications standards (e.g. 4G) but also those for fixed wireless, vehicle anti-collision radar, Wi-Fi, Bluetooth, etc. To date 5G has really only been applied to achieve faster mobile wireless, but other Use Cases remain to be explored.

There are several aspects in which mobile wireless networks differ from fixed wireless networks such as Wi-Fi. Mobile wireless networks are designed such that a service area is broken up into a collection of cells and the network transitions the user from one cell to the next automatically and seamlessly as the user moves geographically. Therefore, mobile wireless is often referred to as cellular service. With Wi-Fi this transition is handled manually.

Another key difference is that Wi-Fi uses shared spectrum. This results in limits in terms of both antenna gain and maximum transmitted power, as well as their sum EIRP (Effective Isotropic Radiated Power). EIRP is connected to coverage – higher EIRP means that the signal strength will be adequate for data transmission over a wider area.

Most mobile wireless spectrum is licensed within geographic regions and within the region the license holder has exclusive use of the spectrum. This means that the license holder does not need to worry about interfering with other users. This enables them to achieve much higher EIRP levels. For example the UNII bands (which includes the 5 GHz spectrum that Wi-Fi uses) has a maximum allowed EIRP of 36dBm while most mobile wireless networks deploy radio and antenna systems with maximum output in the range of 65-75dBm (so a factor of 1,000 to 10,000 higher EIRP). The new CBRS band is a unique case. The spectrum is shared, but the power levels are higher, with a maximum of 47dBm EIRP per 10 MHz channel.

2.1. 5G Midband – What is all the hype?

5G is a collection of different frequency bands, each with unique characteristics. Recent developments in C-band, CBRS & Wi-Fi provides some new mid-band spectrum (i.e. 3 - 6 GHz) that is offering a middle ground that may be the future wireless workhorse. Its reach covers a significant number of mobile users with substantial data rates. But its deployments may need many more cell sites then current LTE macro-cells.

Citizens Broadband Radio Service (CBRS) is a first-of-its-kind effort to get maximum utilization out of spectrum. It refers to 150 MHz of spectrum in the 3550 MHz to 3700 MHz range that the FCC has designated for sharing among different tiers of users. The 3.5 GHz band has been identified as a critical band for wireless mobility. This frequency is low enough to have good propagation characteristics, particularly in comparison to extremely high frequency millimeter waves (mmWave). But it is also high enough so that advanced antennas using M-MIMO (massive multiple input multiple output) technology are small enough to meet zoning restrictions and be deployed.

However, once 3.5 GHz was proposed for usage for mobile wireless, the US found itself with a problem. The spectrum right around 3.5 GHz was already being used, by the US military in coastal regions and by incumbent Wireless Internet Service Providers (WISPs) inland. Most countries would have given up on this spectrum, but the FCC came up with a clever plan to maximize usage involving a 3-tier hierarchy.

The highest priority tier goes to US military applications and (for now) other legacy incumbents. SAS (Spectrum Access System) serves as a traffic cop, telling other users to shut down when the US military is using the spectrum. However, since the US military application is primarily ship-borne radar, the usage is mostly confined to coastal regions, particularly a few spots where US naval ships are based and even in those regions the usage is sporadic.

The second priority tier goes to PAL (Priority Access License) license holders who have paid to have exclusive use of 10 MHz channels within a specific geographic region (for CBRS these regions are counties). In any county, a single entity can own up to 4 PAL licenses which guarantees 40 MHz out of the 70 MHz available for PAL license holders.

The lowest level priority tier is General Authorized Access, GAA. GAA users have free access to the spectrum on a first-come, first-served basis. Since no more than 70 of the 150 MHz can be licensed under PAL, GAA users are assured that at least some spectrum will always be available for GAA use.

Since GAA usage is free, this allows end users to build and run mobile wireless networks for a fraction of the cost that would be required if licensed spectrum were being used. This puts CBRS into the same category as other free spectrum services such as Wi-Fi or Bluetooth. However, since CBRS has a EIRP cap of 47dBm instead of 36dBm, individual sites can cover a much larger area then Wi-Fi. This can be very advantageous in a campus or office park setting. And since CBRS typically is deployed with mobile wireless technology (usually 4G or 5G, though some radios use proprietary systems), true mobile wireless service is available, and handoffs can be managed automatically. This gives CBRS a further advantage over Wi-Fi.

In 2020, several mobile network operators (MNOs), primarily Verizon, AT&T and T-Mobile, spent over $80 billion purchasing C-Band spectrum (3.7 – 3.98 GHz) at the U.S. Federal Communications Commission (FCC) auction. Based on an accelerated clearing schedule, 100 megahertz of the auctioned spectrum will be cleared in 46 of the top U.S. markets by December 2021. Verizon and AT&T won 60 MHz and 40 MHz, respectively, of the earliest available C-band “A” blocks. Verizon’s deployment plans initially call for turning up spectrum at existing macro sites focused on 46 markets. Rural fill-ins, small

cells and in-building are part of the picture down the line. By December 2023, the remaining 180 megahertz in these same 46 markets, as well as the full 280 megahertz in the other markets, will be cleared for use by 5G services.

Comparing C-Band with CBRS, the C-Band EIRP limits are much higher – the combined antenna and radio may generate 76dBm. But none of the spectrum is free and in fact the licenses for C-band were much more expensive on average than CBRS PAL licenses.

Meanwhile in the United States and other countries, 1.2 GHz of spectrum from 5.9 to 7.1 GHz has been set aside as unlicensed spectrum that is being used in Wi-Fi 6E. However, the higher 6 GHz frequency band and lower transmit powers will limit the outdoor range for Wi-Fi 6E.

2.2. Antenna 101 – Success starts with the Antenna

Outdoor wireless network success starts with the antenna. It is the equivalent of the speaker/headphones for an audio system. Specifically, the antenna transforms the guided RF (Radio Frequency) energy generated by the radio and carried by transmission lines into free space electromagnetic waves that propagate through the atmosphere.

It should be noted that base station antennas (BSAs) are not intended for point-to-point communications. The goal of a base station antenna is to provide relatively uniform coverage in an area where coverage is desired (inside the cell area) with a minimum of excess energy going outside the cell area.

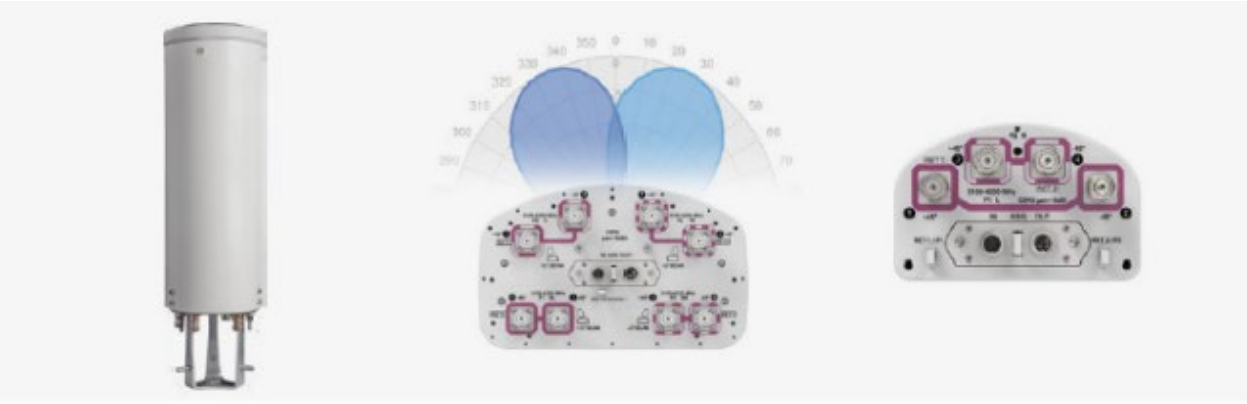
2.2.1. Omni vs. Sectored Antenna

There are different types of cell arrangements from the perspective of the base station equipment. In the 1G systems and even today in rural areas or for small cell applications, the site where the base station equipment is located will provide wireless coverage in all directions around the site using an omni-directional antenna. This is considered a single-sector site.

Note that in the wireless field, “omni-directional” refers only to the pattern in the azimuth plane. This is in contrast to academia where “omni-directional” is often thought of as identical to “isotropic” which indicates that energy is uniformly radiated throughout the 4π steradians of space. So in mobile wireless, one common antenna type is a “high gain omni” which marries an omni-directional azimuth pattern with a narrow, highly-directive elevation pattern.

The most common cell configuration today is a 3-sectored site (Figure 2). In this case the area surrounding the base station tower is divided into 3 120-degree sectors, each with its own set of radios and antennas. Typically, the antennas used will have a HPBW (half power beamwidth) of roughly half the sector size, so in this case 65° azimuth HPBW antennas are usually used. Since modern cellular systems have 100% frequency re-use, a 3-sectored site offers 3 times the data capacity of a 1-sectored site for the same geographic area.

Finally, in cases where very high capacity is required, a commonly chosen option is a 6-sectored site (Figure 2), which can offer up to twice the capacity of a 3-sectored site. For these sites, typically antennas are used with a 35° azimuth HPBW. In many cases operators will use special “twin-beam” antennas, where a single antenna is designed to provide coverage for two of the 60-degree wide sectors. This minimizes the amount of clutter at the top of the tower. Images of antennas for 1-sector, 6-sector and 3-sector sites are shown in Figure 1.



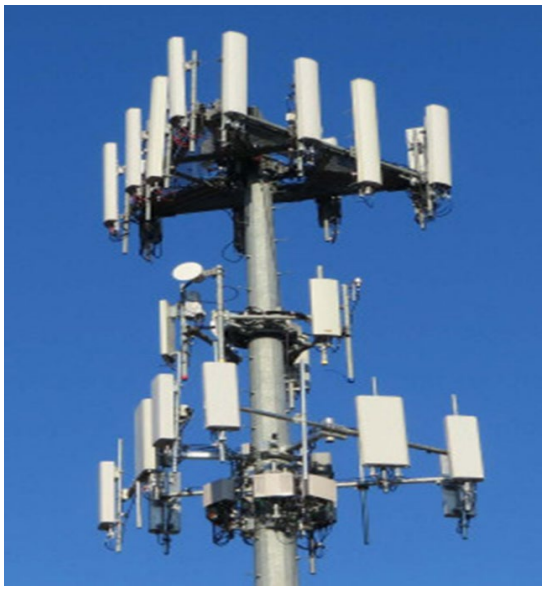


Figure 1 – Antenna technologies

Figure 2 – Sector antennas – Three to Six Sectors

Note that the full theoretical capacity may not be realized due to the overlap of radiated energy between sectors causing interference. In a cellular network there is always a balance that must be maintained between coverage and capacity. If there is too little overlap in coverage of the individual sectors, then holes in coverage may appear. But if there is too much overlap then interference builds to a level where capacity is reduced. Capacity generally is a function of SINR (Signal to Interference and Noise Ratio) which measures this level of interference relative to the primary signal strength. So, a goal of antenna designers is to make antennas that maximize the amount of energy that goes into the sector relative to energy going outside the sector. And the goal of an RF planner (network designer) is to deploy the antennas in such a way to further improve focusing of energy into the sectors.

2.2.2. EIRP considerations

A unique feature of CBRS is the medium level EIRP cap of 47 dBm. In Wi-Fi systems with a 36 dBm cap, it is typically assumed that the antenna gain will be quite low as well as the transmitted power. In other licensed bands, such as C-band, the EIRP cap is so high that it is effectively never reached, and both passive and active antenna systems are designed without any concern for the EIRP cap. The only limit on gain is the fact that the antenna must cover a certain region and so a very narrow fixed beam might not be appropriate.

For macro cell applications, C-band radios can offer up to 320W RF power and 21-25 dBi antenna gain, implying EIRP in the 78 dBm range. In a small cell or strand mount application, the radio power might be 40W (i.e. 4 channels @ 10W) with a 10-12 dBi antenna, so more like 58 dBm EIRP. This makes CBRS competitive for small cell applications, especially since the CBRS cap is per 10 MHz channel. Therefore, if 40 MHz of spectrum is available, the actual cap is 53dBm, not 47dBm.

EIRP equals the sum of transmitted RF power and antenna gain. It describes the energy density level of transmitted signals and is distance agnostic. However, given EIRP, one can calculate energy density at a specific distance from the site.

For wireless communications, one often talks about the link budget, which is the calculation of energy that makes it from the transmitter to the receiver. Per Figure 3, the link budget is positively influenced by transmitter power P_{TX}, transmit antenna gain G_{TX}, and receive antenna gain G_{RX}. It is negatively affected by path loss L_{FS} and other system losses L_{OTHER}. The first two terms P_{TX} and G_{TX} make up the definition of EIRP. Given that EIRP is limited, one can only improve the link budget further by increasing the receive antenna gain G_{RX} or reducing path loss (e.g. install antennas at a taller height to help eliminate blockages).

Let us digress for a moment to discuss antenna gain. Gain is a measure of an antenna's ability to focus the radiated energy in a particular direction. Typically, this is measured in dBi, dB relative to an isotropic radiator, which uniformly radiates energy in every direction. Since the antenna may radiate different amounts of energy in each direction, this is expressed as a bi-variate function Directive Gain = $D(\theta,\varphi)$ where θ and φ are variables describing one's angular position relative to the antenna. Since this relative to an isotropic radiator if the antenna has high Directive Gain at some values of (θ,φ) then it must have low values (< 0dBi) in many other directions. The maximum value of Directive Gain is called Directivity. Finally, antenna gain = Directivity – Antenna Losses. Examples of antenna patterns with low gain and high gain are shown in Figure 4.

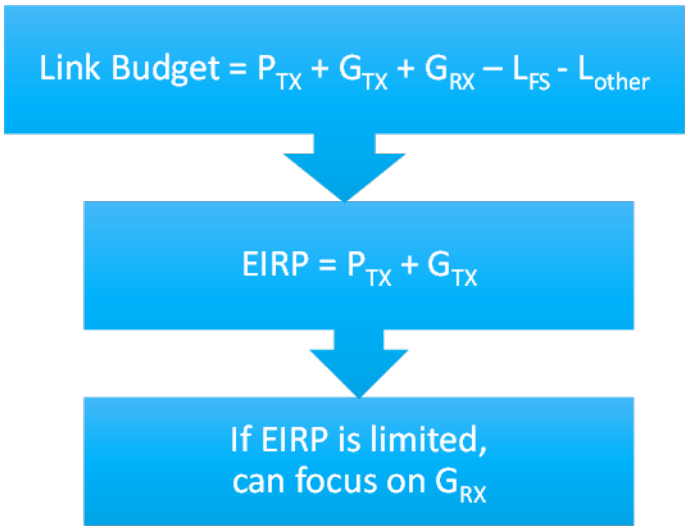

Figure 3 – Link budget vs EIRP

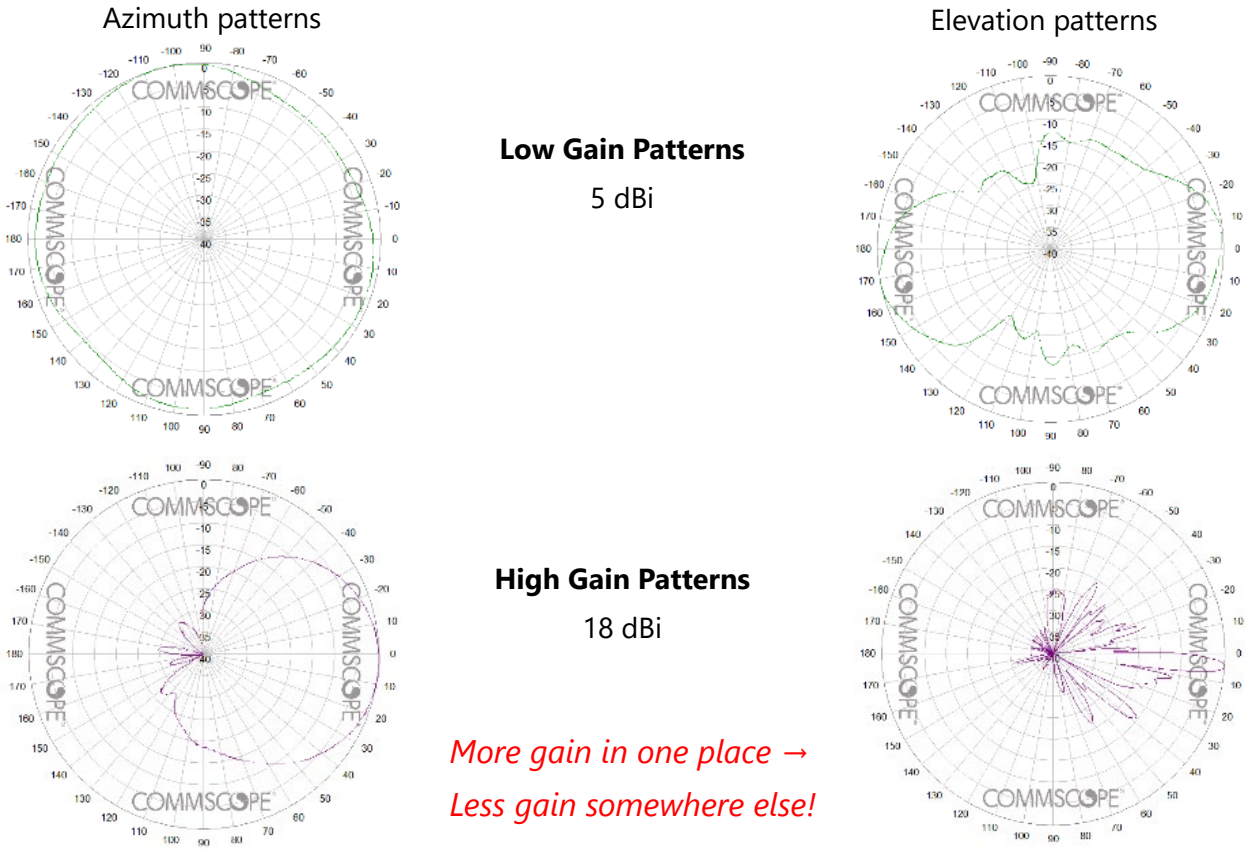

Figure 4 – Antenna Gain

The link budget equation is normally applied to point-to-point antennas which are aimed so that each has its maximum directive gain pointed at the other antenna. But as mentioned earlier, base station antennas cover an area and at the various points in the area the link budget between the base station antenna and the User Equipment (UE) antenna is better described by

$$P_{TX} + D(\theta,\varphi)_{TX} + D(\theta,\varphi)_{RX} - L_{FS} - L_{other}$$

Since antennas with high gain by necessity must have low values of $D(\theta,\varphi)$ at many angles, one can see that it is not necessarily a good thing for the antenna gain to be high.

From the perspective of the downlink, it is better to have higher input power and lower antenna gain since this implies that the energy is more evenly spread across the sector of coverage. However, from the perspective of the Uplink, both the UE transmit power and the UE gain are quite limited. So, the only way to improve the link budget is by increasing G_{RX}, the gain of the receive antenna, which for the uplink is the base station antenna. Thus, the optimal antenna design depends on whether CBRS is used only for the downlink, or for both downlink and uplink. Note – if the CBRS band is only used for the downlink, then the UE is most likely using a low band for the uplink. The low band has less path loss L_{FS} which helps the UE link budget with lower P_{TX} and G_{TX}.

2.2.3. Antenna arrays

The word antenna can refer to a single radiating element or a collection of radiating elements, called an array that are fed from a common input. Antenna arrays can be one dimensional (e.g. a single column of radiating elements) or two dimensional (e.g. a rectangular array with M rows and N columns). Most MIMO base station antennas use a single column as the array.

The size of these arrays can vary substantially, for example from 2T2R to 64T64R. The larger arrays tend to be used at macro towers and in conjunction with massive MIMO (M-MIMO). The technology enables features such as beam forming in 3-dimensions (e.g. vertical for tall office buildings). Small cells, such as strand-mount and streetlight locations, will tend to have much smaller antenna arrays due to their location restrictions.

2.3. Pattern impact on capacity

To verify the above, CommScope ran some RF simulations. Three different antennas with varying levels of gain were examined for a 3-sector grid.

1. 17.3 dBi gain, 5.4° EL HPBW, 4° tilt
2. 16.7 dBi gain, 9.0° EL HPBW, 6° tilt
3. 13.8 dBi gain, 17.0° EL HPBW, 8° tilt

The simulation was repeated for inter site distances (ISD) of 1 mile and 0.5 mile and for three different rad center heights (the height of the antenna above ground) of 45, 100 and 150 feet. The antennas were sited at the far corners of the 3 sectors and pointed towards the center of the area so that the impact of interference between cells could be taken into account. The layout for the 1-mile cell radius case is shown in Figure 5.

For this layout, each sector covers 5 square kilometers. The environment of the three sectors can be described as follows:

- Sector 3 (top): moderate/high density, residential/light industrial

- Sector 4 (right): open, flat, rangeland/airport
- Sector 5 (left): sparse/moderate density, industrial

Figure 5 – One-mile cell radius suburban scenario

The small triangles represent the locations of the sites. In particular, consider the case with 1-mile ISD and 45-foot rad center height. The simulation looked at three parameters:

- Downlink coverage (RSRP)
- Downlink capacity (RS-CINR)
- Uplink capacity (UL Allocated bandwidth throughput)

Since the results vary depending on the placement of the User Equipment (UE) in the sector, they are typically portrayed statistically via a Cumulative Distribution Function (CDF). The 3 CDF curves are shown in Figure 6. Note that for all 3 graphs, better performance is indicated by data points that are higher (same level of performance over a larger area in the sector) and further to the right (higher level of performance over the same area in the sector).

From a downlink coverage perspective, the best results come from the antenna with the lowest gain (the green curve). This is because the EIRP is capped. The lowest gain antenna G_{TX} can use higher transmit power P_{TX} and overall provides more even coverage across the sectors. The middle gain antenna provides the next best coverage (red curve) and the highest gain antenna provides the worst overall coverage (the blue curve).

For downlink capacity, the order is the same, with the lowest gain antenna performing the best and the highest gain antenna performing the worst. However, the results change for uplink capacity. Now the mid-gain antenna performs the best, the highest gain antenna performs nearly as well, and there is a large gap separating the performance of the low gain antenna from the other two antennas. The key difference is that for the downlink the transmit power could be increased to compensate for the 3.5dB difference in gain. But for the uplink capacity case the UE transmit power will be unchanged, so the higher gain becomes more important. Note that for mobile wireless systems, the Uplink path is always the weaker one because the base station radio can transmit at much higher power levels than the UE.

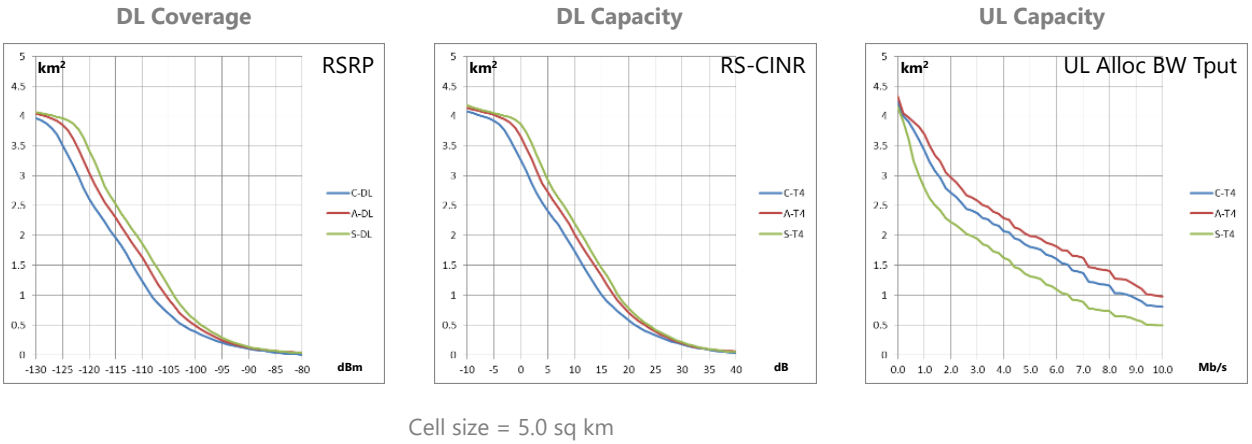

Figure 6 – One-mile cell radius suburban scenario - 45' Height Antenna

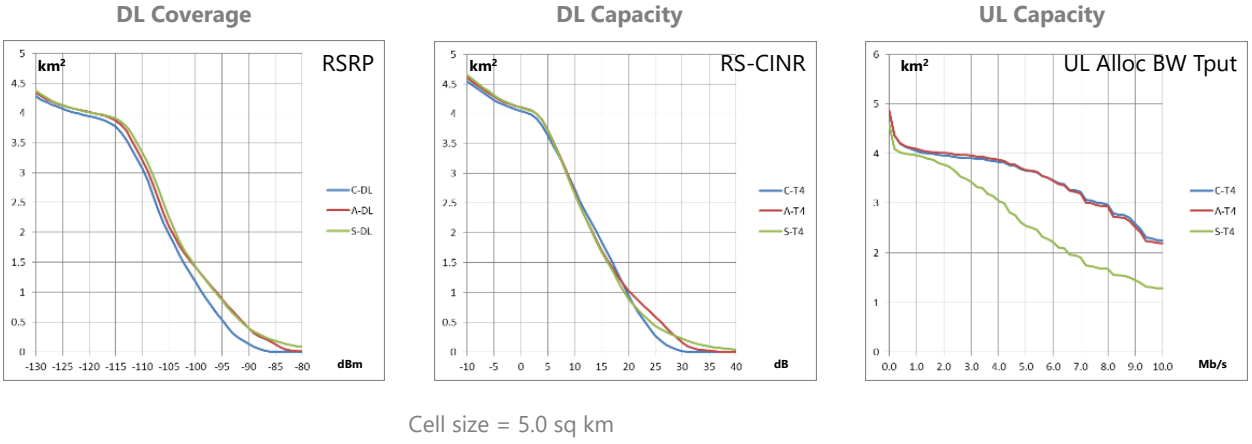

Figure 7 – One-mile cell radius suburban scenario - 150' Height Antenna

In Figure 7, the same 3 CDF plots are shown for the 1-mile ISD with a 150 foot rad center height. The results are generally the same except that the performance gap for DL coverage and DL capacity. The mid-gain and high-gain antennas perform identically for UL capacity, but there is a huge gap in performance between those two antennas and the low gain antenna.

Summarizing these results lead to the following conclusions:

If using CBRS for supplemental downlink:

- Meet the EIRP limit by using more radio power with lower gain antenna
- More even coverage due to fatter elevation pattern → higher RSRP and SINR
- **Depending on site specifics, optimal EL HPBW ~ 15–20°, optimal gain 12–14 dBi**

If using CBRS for uplink and downlink:

- Uplink thruput increased with higher gain BSA
- **Elevation HPBW 5–10° brings improved performance, optimal gain 15–18 dBi**
- Assumes 3 sectors, 65° Az HPBW
- Can get increased gain/capacity via sectorization

2.4. Small Cell Coverage

For cable operators, the most enticing use case that takes advantage of their HFC infrastructure is the small cell deployment. Perhaps the two most obvious applications will be strand mounted small cells on aerial coaxial plant and small cells mounted on streetlights. Streetlights may be the best/only option for underground plants. Streetlights also have an advantage over strand mount as they are at a higher elevation (e.g. 45' vs. 30') which enhances the reach of the antenna.

Table 1 provides some small cell range estimates for C-Band, CBRS and Wi-Fi 6E. As shown previously, the coverage is also impacted by the transmit power which varies quite a bit between technologies. Wi-Fi 6E is also at a disadvantage as it is using the 6GHz which has higher path losses than the 3.5 to 4.0 GHz bands used by CBRS and C-Band.

Table 1 – Small Cell & Strand-mount Coverage Range Estimates

Mid-band Small Cell Ranges	EIRP	Mounting Location	Reasonable Range (more Urban)	Stretch Range (more Rural)
C-Band	52-58	Streetlight	600m (~2000')	900m (~3000')
		Strand	425m (~1400')	640m (~2100')
CBRS	47-53	Streetlight	340m (~1150')	500m (~1650')
		Strand	240m (~800')	360m (~1200')
6GHz Wi-Fi 6E	36	Streetlight	70m (~240')	100m (~325')
		Strand	50m (~175')	70m (~240')

Note that the above table contains several assumptions:

1) The C-band radios are 4 x 20W and the antennas are about 12dBi gain. Some variation in EIRP is allowed given that the antenna gain may vary.
2) Note that the actual antenna gain depends on whether an omni or directional antenna is used and the height of the antenna
3) Directional antennas normally have a higher gain than omni antennas, but you need 3 of them to cover a site for 360 degrees. So nominally the directional antennas take a 5dB hit in terms of coverage.
4) CBRS EIRP is shown as a range since the cap is per 10 MHz channel, so a user with more channels can increase their EIRP.
5) Small cell array length can be as high as 24" (600mm) for a streetlight antenna, but strand-mount arrays are normally under 8" (200mm) in height. Thus, assumed that in general the strand mount system would have 3dB less EIRP than a streetlight system. The difference in height might have a slight difference in propagation, but we assumed that this was negligible.
6) Propagation loss goes as the square of distance. So, assume that a 6dB increase in EIRP corresponds to a doubling of the range.
7) The range is for outdoor UE. There can be significant additional path loss when trying to penetrate inside buildings depending on building materials.

2.5. Backhaul, Midhaul, Fronthaul RAN Interfaces

Given the many diverse requirements that 5G networks must support such as high data rates, low latency and high reliability, the implementation of the Radio Access Network (RAN) has been under constant debate. Early proposals focused on the idea of Cloud-RAN with a dense network of cells. However, the 3GPP's 5G-R RAN2 specification included eight different functional split options. A discussion on these different interface options are detailed in [LARSEN_2018] and [ORAN_2020].

The functional splits for the different interface options from [ORAN_2020] are shown in the lower half of Figure 8. The industry has evolved to supporting a distributed RAN architecture that includes a Central Unit (CU), a Distributed Unit (DU) and a Radio Unit (RU) that might also be called a Remote Radio Unit (RRU). This architecture is shown in the top half of Figure 8. The term fronthaul refers to the interface between the DU and the RU/RRU. Midhaul refers to the interface between the CU and the DU.

Today, most 5G industry focus is on one of two options:

- Option 2: a high-level centralized unit (CU) and a distributed unit (DU) split which is essentially a separated control and user plane. In this implementation the DU and remote radio unit (RRU) are often combined into a single entity as a self-contained access point.

- Option 7.2 Cat A: a low-level split that allows for high reliability and low latency communications and near-edge deployment. This split takes place between the Hi-PHY (Physical Layer) and Low-PHY. In this split, only the Low-PHY and RF functions are in the access point.

With more complex antenna arrays (e.g. 64T64R) and massive MIMO (M-MIMO), the processing requirements for the DU increase significantly. Using Option 7.2x allows the DU to be moved to a more optimum location and it reduces the size and power requirements at the antenna site.

With simpler antenna arrays and reduced MIMO levels, the DU becomes simpler and can be more easily integrated with the RU/RRU. Small cells are a perfect example of this.

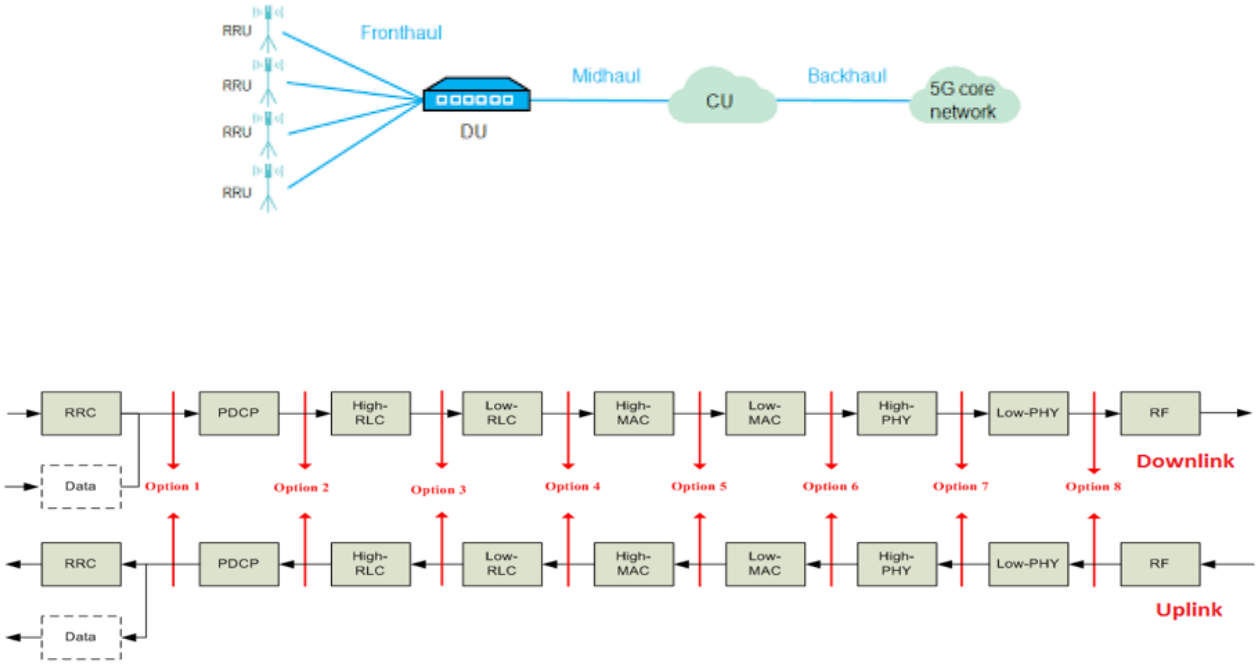

Figure 8 – Backhaul, Midhaul, Fronthaul RAN Interfaces

3. Capacity Planning for Midhaul or Fronthaul Cells

3.1. Midband Backhaul & Fronthaul Interface Capacity Requirements

The amount of capacity required for wireless xHaul varies significantly based on several factors. It becomes a function of the number of antennas, MIMO level, channel bandwidth, number of sectors per cell and the RAN interface used (e.g. Midhaul or Fronthaul). Table 2 shows some capacity examples for various configurations that could be seen from HFC-based small cells to Macro tower base stations.

Table 2 – xHaul Capacity Estimates for various Antenna configurations

Antenna	MIMO	Location	Channel Bandwidth	Sectors per cell	Midhaul DL	Midhaul UL	Fronthaul DL	Fronthaul UL
2T2R	2x2	Strand or Streetlight	40MHz, DL only	1	525 Mbps	-	1.9 Gbps	-
			40MHz	1	420 Mbps	62 Mbps	1.9 Gbps	2.0 Gbps
4T4R	4x4	Strand or Streetlight	40MHz, DL only	1	1050 Mbps	-	3.8 Gbps	-
			40MHz	1	840 Mbps	125 Mbps	3.8 Gbps	4.1 Gbps
			100MHz	1	2.2 Gbps	320 Mbps	9.7 Gbps	10.6 Gbps
8T8R	BF 2x2		40MHz	3	0.6 – 1.1 Gbps	90 – 165 Mbps	2.8 – 5.0 Gbps	3.1 – 5.5 Gbps
	4x4	Mini-Macro	40MHz	3	1.3 – 2.2 Gbps	180 – 333 Mbps	5.7 – 10 Gbps	6.2 – 11 Gbps
	4x4		100MHz	3	3.3 – 5.8 Gbps	500 – 850 Mbps	15 – 26 Gbps	16 – 28 Gbps
64T64R	8x4	Macro	100MHz	6	10 – 23 Gbps	0.7 – 1.7 Gbps	44 –104 Gbps	24 – 56 Gbps

The above table assumes that the downlink (DL) is operating at its best modulation of 256-QAM. This may be generous given real-world conditions, but wanted to show a worst case capacity estimate. The uplink (UL) is assumed to be operating at 64-QAM modulation. For NR-TDD, it is possible to configure the mix between DL and UL. Most of the rows use a DL:UL ratio of 80:20. Two of the small cell rows are configured for 100% DL operation only. In these scenarios, it is assumed that the weaker UL signal is using more robust Low-band frequencies (e.g. <1 GHz).

As can be seen by this table, the Option 2 Midhaul interface has significantly lower bandwidth capacity requirements then the Option 7.2 Cat A Fronthaul interface. Capacity requirements also increases with the channel bandwidth and the number of sectors per cell. As added data point, using an IPv6 backhaul with IPSec would consume about 10% more capacity than the midhaul; while actual UE data consumption would be about 89% of the midhaul capacity.

3.2. CBRS RF Simulation Case Study

A recent case study performed a CBRS RF simulation analysis for a North American metro area. This analysis covered a region with approximately 40K addresses, and roughly 800 radios.

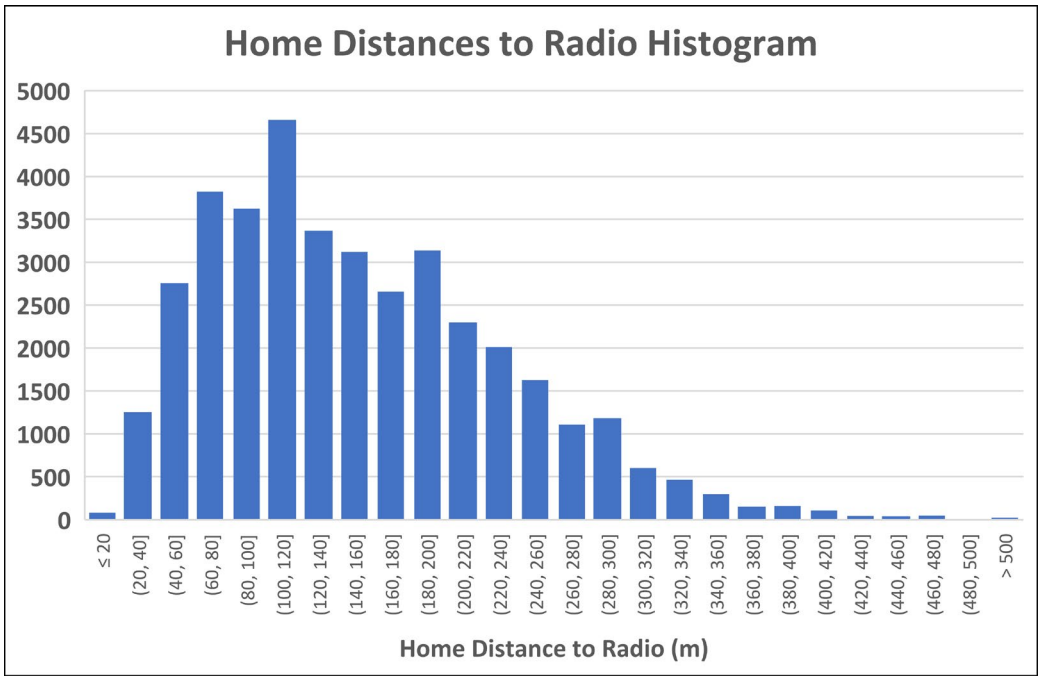

Figure 9 – CBRS Metro area Study – Home Distances to Radio histogram

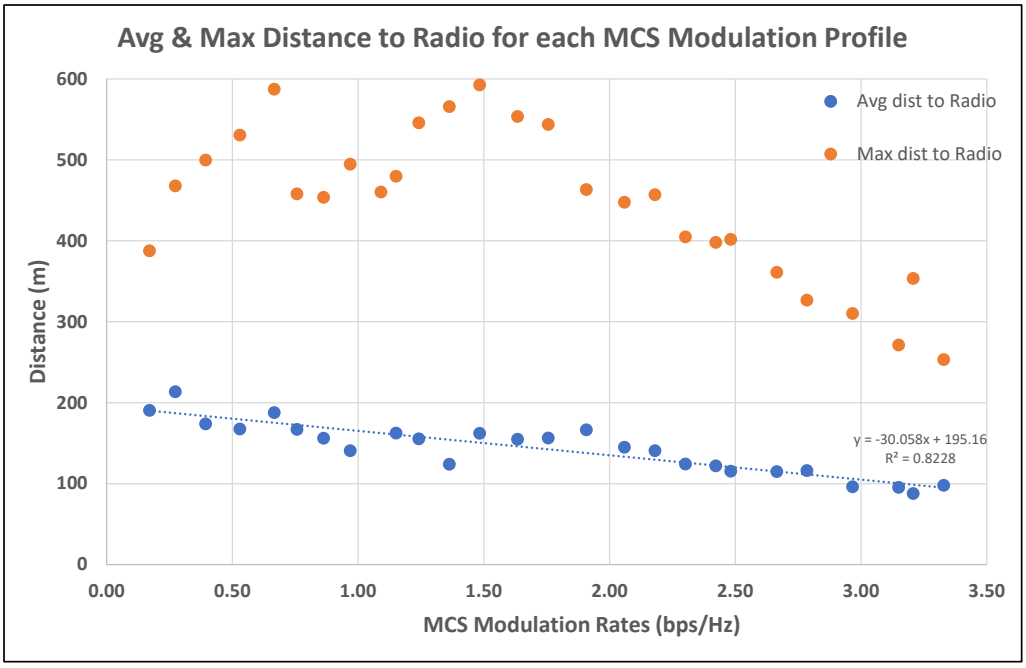

Figure 10 – Average & Max Distance to Radio for each MCS Modulation profile

Some of the key statistics from the study around the distribution of home addresses to the radio include:

Address Distances to Radio:

- Average = 153m
- Maximum = 592m
- Median = 140m
- 95% ≤ 300m
- 99% ≤ 385m

Figure 9 shows that most home addresses are within 200m of a radio and 95% are within 300m. However, there are still several addresses that could be up to 600m away.

Figure 10 shows the average and maximum distance to the radio as a function of the Modulation Coding Scheme (MCS) modulation rate. As the MCS modulation rate increases, there is a linear drop in the average distance to radio and an even more substantial in the maximum distance. For the best MCS rates, the max distance tends to be less than 300m.

Figure 11 is the inverse of Figure 10 where the average and maximum MCS rates are mapped as a function of the distance to the radio. The Max Distance for a given profile is stable up until ~1.5 bps/Hz but drops quickly above that. For distances up to 300m, average modulation (bps/Hz) drops with distance while max stays to MCS 27. Above 300m, average MCS rates stay flat while maximum MCS rates decline quickly with distance.

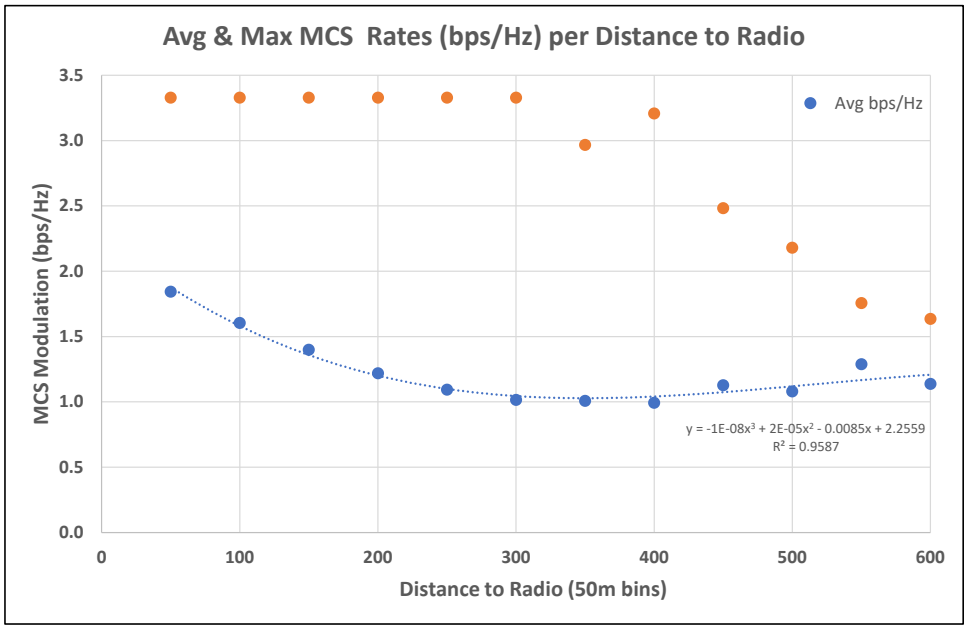

Figure 11 – Average & Max MCS Rates per Distance to Radio

Another observation from the CBRS case study was that in dense areas with >200 home addresses per radio, maximum distance was mostly <300m. Meanwhile, serving radios with fewer addresses (e.g. <60) have a wide range of max distances, even to 600m. Most Radios have fewer than two dozen addresses >300m, while a handful of radios (i.e. <1%) have 40-80 addresses >300m.

In general, the results from this case study reenforce the CBRS range estimates as shown in Table 1.

3.3. HFC Network Capacity Planning

3.3.1. DOCSIS 3.1 Capacities

DOCSIS 3.1 introduced OFDM/OFDMA technologies and increased frequency spectrum of up to 1218 MHz downstream and 204 MHz upstream. This means that the maximum capacity of an DOCSIS 3.1 HFC network could reach 9 Gbps downstream and 1.5 Gbps upstream. This assumes that the operator has retired most or all of its legacy video spectrum (i.e. converted to IPTV or SDV) and replaced most 2.0/3.0 modems with the newer D3.1 modem technology.

From an HFC perspective, the streetlight and strand-mount small cells with an Option 2 midhaul interface shown in Table 1 can be supported by a DOCSIS 3.1 system with an 85MHz mid-split. A 40 MHz DL could fit within 96 MHz OFDM channel or even multiplexed with the residential downstream data. And by accounting for some statistical multiplexing gains, it might even be possible to put a couple midhaul based small cells on a single DOCSIS 3.1 service group (SG). A 100 MHz DL:UL small cell with 2.2 Gbps DL and 325 Mbps UL capacity might fit better on a 1218/204 MHz HFC plant.

Implementing a fronthaul interface on the small cell is much more challenging. A 40 MHz DL-only 2x2 small cell could consume an entire 192 MHz OFDM channel. A 40 MHz DL-only 4x4 small cell then requires two 192 MHz OFDM channel. Turning on the UL will require multiple Gbps upstream capacity. This would require DOCSIS 4.0 as discussed in the next section.

3.3.2. 10G™ Capacities

10G was first announced in 2019 as a vision, or lighthouse beacon, to guide our industry roadmaps towards 10 Gbps services. Much progress has been made in the last 2-3 years. 10G includes multiple technologies including enhanced fiber optics as well as DOCSIS 4.0 technologies.

Figure 12 from [CableLabs_10G] shows the 10G vision for DAA services operating over cable, FTTP and wireless technologies while sharing a common converged fiber optical network through an aggregation node. [CableLabs_10G] states:

> *"The 10G optical network is the backbone of the distributed access architecture and will provide the industry with opportunities for true service convergence that leverages the flexibility and tremendous capacity provided by fiber optics. This year, CableLabs released an update to the 100 Gbps point-to-point coherent optics specification and released a new 200 Gbps specification – both intended to support the aggregation requirements of the distributed access architecture. While operators currently deploy 10G passive optical network technology (PON) where fiber to the premise is preferred, the IEEE standard for next-generation 25G-PON and 50G-PON technology remains on track for mid-2020 completion."*

As can be seen in the figure, 10G has the vision of supporting Mobile Backhaul/Fronthaul and Fixed Wireless Access (FWA) over the service provider's optical infrastructure. The P2P Coherent optics has the reach (up to 80km) and the capacity (to 200 Gbps) to support these applications. It even supports the fronthaul capacity requirements for the Macro cell shown in Table 2.

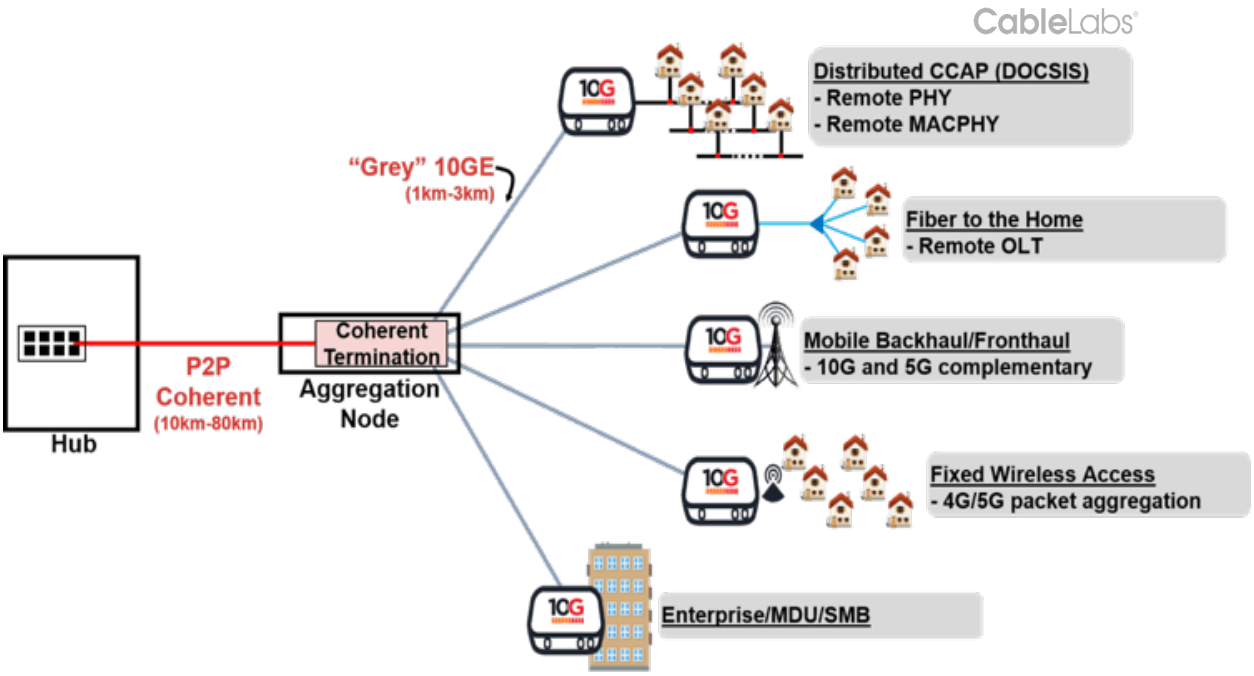

Figure 12 – 10G™ Converged Optical Network – Distributed Access Architecture vision

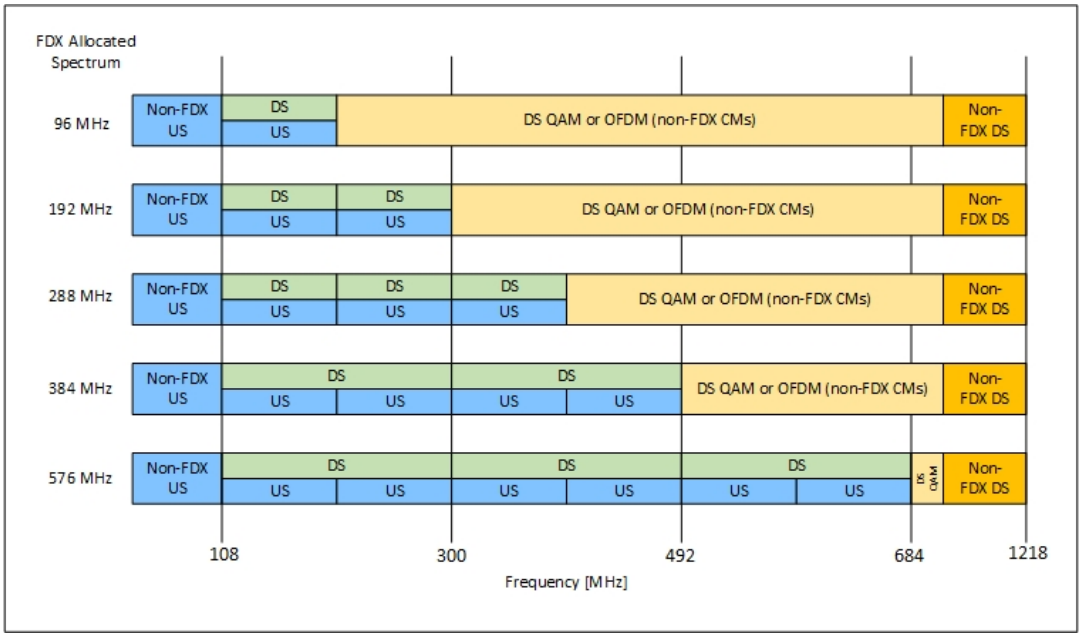

Figure 13 – Full Duplex DOCSIS (FDX) Spectrum Band Options

However, it may not always be possible to co-locate the small cell or mini-macro cell adjacent to the HFC fiber node or along the fiber path. This might result in the cells being connected to the coax portion of the HFC. For small cell RRU with fronthaul interfaces, this might necessitate the use of DOCSIS 4.0. [ULM_2019-1] discusses the capacities that DOCSIS 4.0 can enable and the migration path to 10G.

One area of focus at CableLabs is a technology called Full Duplex DOCSIS (FDX). FDX leverages echo canceller technology to allow simultaneous upstream and downstream operation in the FDX band. FDX is targeted at a fiber deep Node+0 DAA environment. FDX is now part of the new DOCSIS 4.0 specification [FDX_PHY].

The FDX capability offers a fundamental benefit that permits upstream spectrum expansions to occur without causing reductions in downstream spectrum. FDX proposes to have downstream and upstream transmissions occurring in the same frequency band at the same time. In the FDX specification, the overlapping frequency bands are shown in Figure 13.

On a fiber deep Node+0 plant, the upstream OFDMA channel might net capacity of as much as 8-10 Mbps per MHz. This means that a full spectrum 108-684 MHz FDX system might support ~5 Gbps US.

With the Node+0 architecture, the fiber node is now within 300m to 500m of every home. This means the need for using FDX over coax may be minimized.

The other facet of DOCSIS 4.0 is Extended Spectrum DOCSIS (ESD) which supports 1.8 GHz plant with different potential upstream splits in a Node+X plant. In this scenario, the fiber node may be a couple kilometers from the furthest home so it may become necessary to put small cells on the coax.

The extended 1.8 GHz downstream adds much needed DL capacity that could be used for fronthaul RRU devices. The upstream split can then be adjusted based on the desired UL capacity.

So, fronthaul RRU small cells might make a good early use case for DOCSIS 4.0, especially ESD.

4. Using Outside HFC Plant for 5G – considerations and logistics

[ULM_2019-2] took an in-depth look into supporting High band mmWave cells over HFC. At these high frequencies, the wireless cell is limited to very short distances on the order of <100m to 200m which creates coverage issues. The following sections highlight some of the HFC findings from that paper.

Across all the various wireless options, there is a driving need for much smaller cell sizes. To make this happen requires an infrastructure that supports both *the power and the backhaul* to the small cells. The cable industry Hybrid Fiber Coax (HFC) networks are ideally positioned to support this. The HFC networks might support the addition of attached in-line small cells at various demarcation points on the HFC plant. These cells can be added to the DOCSIS network to support 5G, Wi-Fi and/or CBRS/LTE over the HFC.

Figure 14 shows the additional level of density variability that must be considered in cell placement. This example is from a suburban city in New England. In Figure 14, lot sizes vary from 1 acre on the left, ½ acre lots in the middle to <¼ of acre on the right. Cell placement must also account for open spaces and office campus space too.

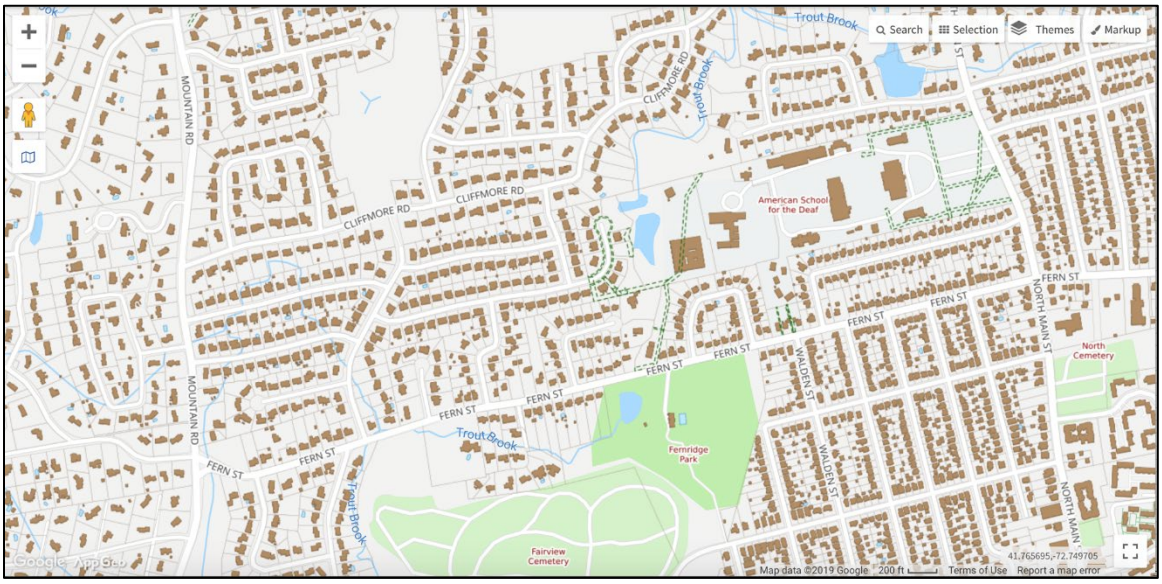

Figure 14 - New England suburb, illustration for variability of lot sizes within

5. HFC Case Study for N+3 nodes of varying Homes Passed densities

The HFC case study in [ULM_2019-2] considered 5 node examples that varied from low homes passed density in a rural area to a high urban node with many homes. Table 3 provides the key statistics for each of the five nodes. In general, these are N+3 nodes, except the highest density node being N+2. The homes passed per coaxial mile (HP/mile) ranges from 37 to 274. This paper now investigates the implications of mid-band small cells overlaid onto these same HFC nodes.

5.1. Mapping Mid-band Small Cells to N+3 HFC Plant

This section looks at mapping mid-band small cells to HFC N+3 nodes of various densities. The first step is to co-locate the small cell with the fiber node to ensure that the small cell has fiber backhaul. This gives the operator the flexibility to choose whether to implement Option 2 midhaul interface or the Option 7.2x fronthaul interface. If the operator is also implementing a DAA strategy with either a Remote PHY Device (RPD) or Remote MACPHY Device (RMD) in the node, then the small cell can potentially share the 10G long haul Ethernet link as well. After that, additional scenarios may be shown by adding other small cells located on the coax segment adjacent to one of the HFC plant active components.

For High and Med-High density nodes, a cell radius in 250m to 350m range is used. For Low and Med-Low density nodes, a cell radius can stretch to 500m range for handful of homes. This aligns with the CBRS small cell ranges from Table 1. Note that C-band small cells would have an even bigger coverage area due to their increased power budget.

Table 3 – Statistics of 5 HFC N+3 nodes of various densities

N+3 NODE Case Study:	Low	Med-Low	Medium	Med-High	High
Coax Plant Mileage	4.17	6.16	3.54	2.51	1.90
Aerial	0.82	4.72	3.44	2.18	1.72
Underground	3.35	1.44	0.10	0.33	0.18
Total Actives	21	30	21	19	14
Actives/Mile	5.0	4.9	5.9	7.6	7.4
Cascade	N+3	N+3	N+3	N+3	N+2
Total Passings	153	352	398	469	520
Aerial Passings	27	269	383	200	500
UG Passings	120	83	0	0	0
Comm/MDU passings	6	0	15	269	20
HP/Mile	37	57	112	187	274

5.1.1. High Density Node Example

The high-density node example shown in Figure 15 is N+2 with 520 total homes passed (HP) with a density of 274 HP/mile. The fiber node is located on the top side of the area. But even with that, most of the homes are easily within the 250m inner radius.

In this example with the node at one edge of the area, it may make sense to use a 180-degree directional antenna rather than an omni-directional antenna. This can provide some added gain for reaching the outer fringes of the node area.

In Figure 16, the CBRS small cell is placed on the coax adjacent to the first level amplifier. This provides a very central location for an omni-directional amplifier. Almost all of the homes are within 200m of the small cell. The only drawback might be that this limits the small cell to use an Option 2 midhaul interface.

5.1.2. Med-High Density Node Example

The medium-high density node in Figure 17 is N+3 with 469 total HP and 187 HP/mile. While most of the homes are within the 250m radius of the small cell, there are still a good number of homes that are in the 250m to 350m range. This means that the CBRS small cell might better be streetlight mounted for the extra elevation and coverage rather than strand-mount.

So again, it appears that this density node can be serviced by a single CBRS small cell that is co-located with the fiber node.

5.1.3. Medium Density Node

The medium density suburban node in Figure 18 is N+3 with 398 total HP and 112 HP/mile. This is an oddly shaped node, unlike the nicely packed previous two examples. Because it is so stretched, it cannot be covered by a single CBRS small cell. We do use this example to show how an operator might place four small cells scattered within this node to give coverage to both this node and neighboring nodes. One small cell is co-located with the fiber node and the other three are on the coax.

Note – if this node also implements a 2x2 RMD/RPD, then it is possible to arrange the CMTS service groups such that there are no more than two small cells on any given DOCSIS network.

This node shows why an operator needs to look holistically across a multi-node region when deciding on small cell placements.

5.1.4. Med-Low Density Node Example

The medium-low density node in Figure 19 is in a residential development and has N+3 with 352 total HP and 57 HP/mile. Because this is a more rural setting, the figure also now includes a 500m radius for the enhanced range for a streetlight mounted CBRS small cell.

The 500m radius appears to cover a majority of the homes in the node. This may be acceptable if the goal is to off-load as much traffic as possible without the requirement for 100% coverage. If the operator has partnered with a C-band MNO to deploy C-band small cells, a single cell should cover this entire node area.

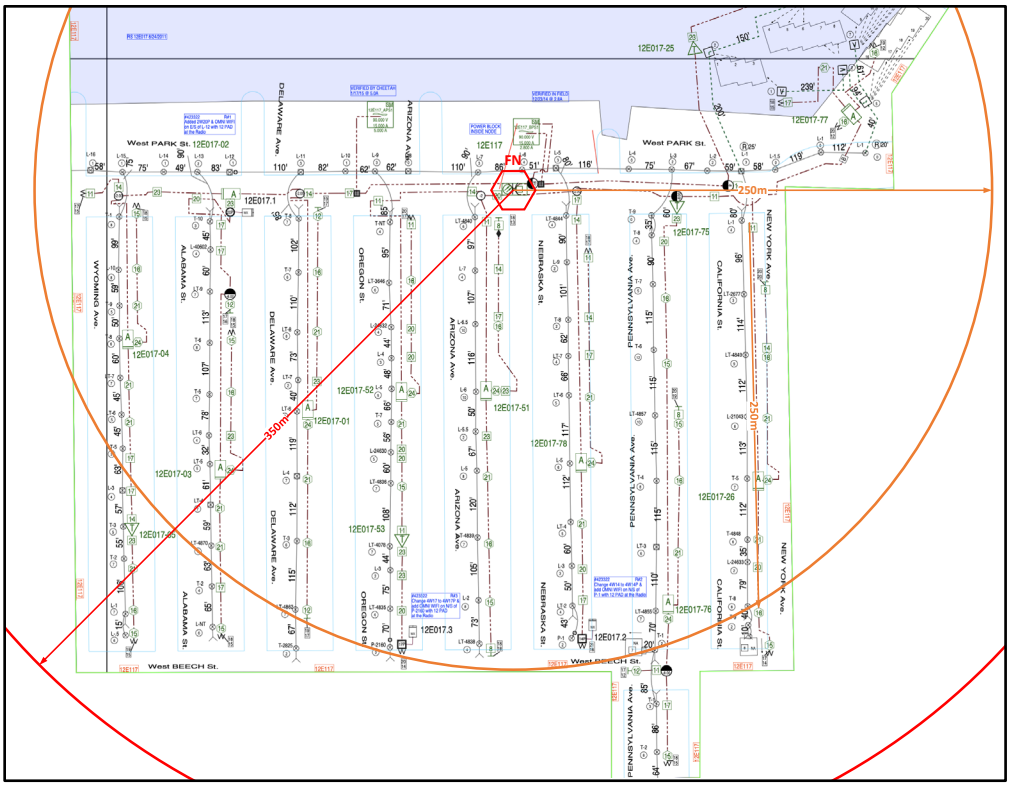

Figure 15 – High Density Node (274 HP/mile) with Small cell at Fiber Node

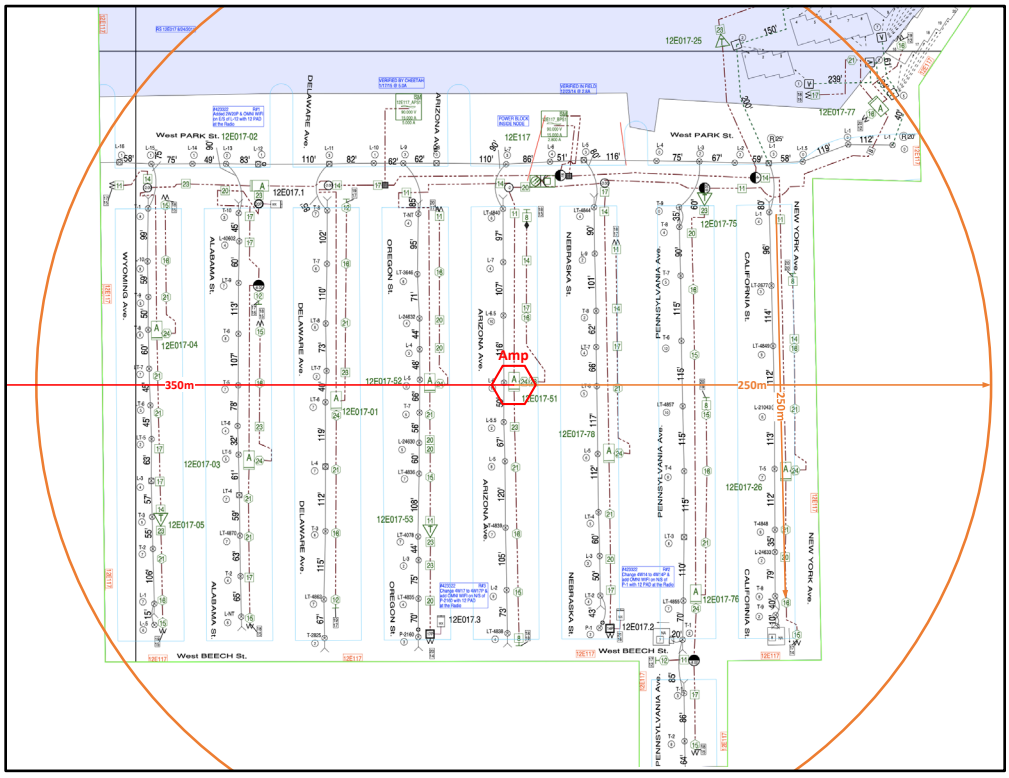

Figure 16 – High Density Node (274 HP/mile) with Small cell at HFC Amp location

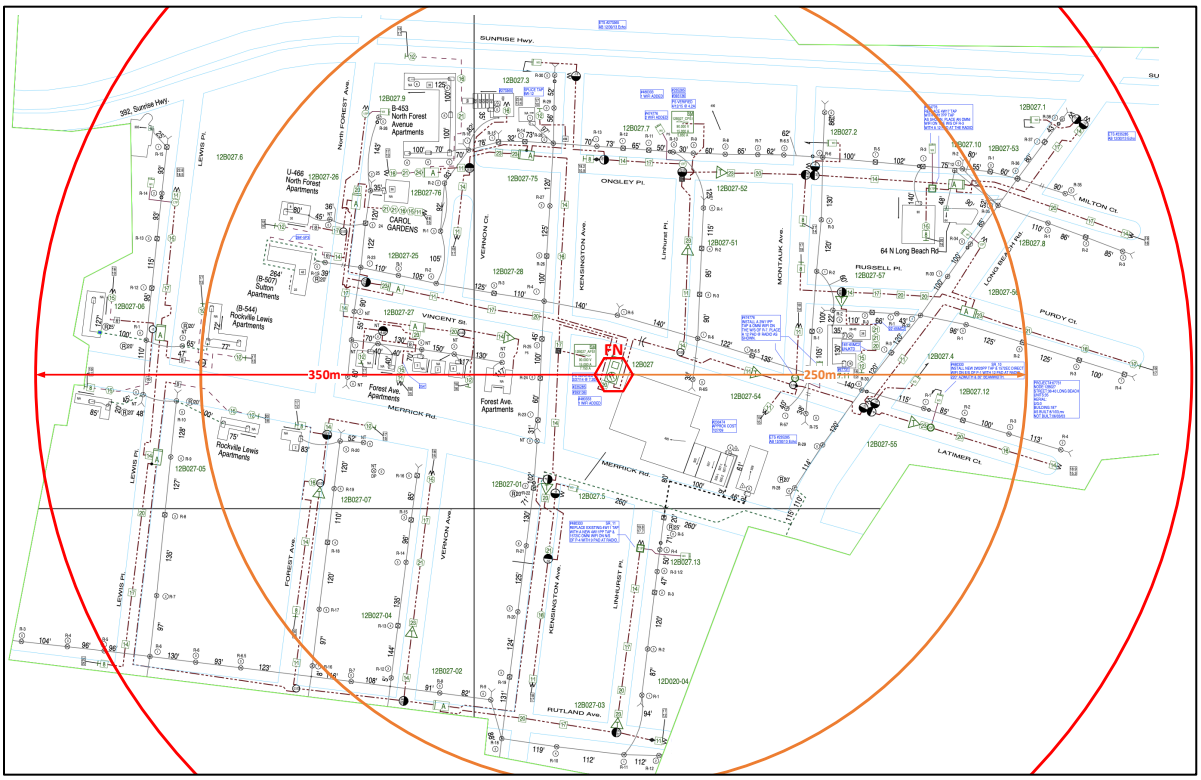

Figure 17 – Med-High Density Node (187 HP/mile) with Small cell at Fiber Node

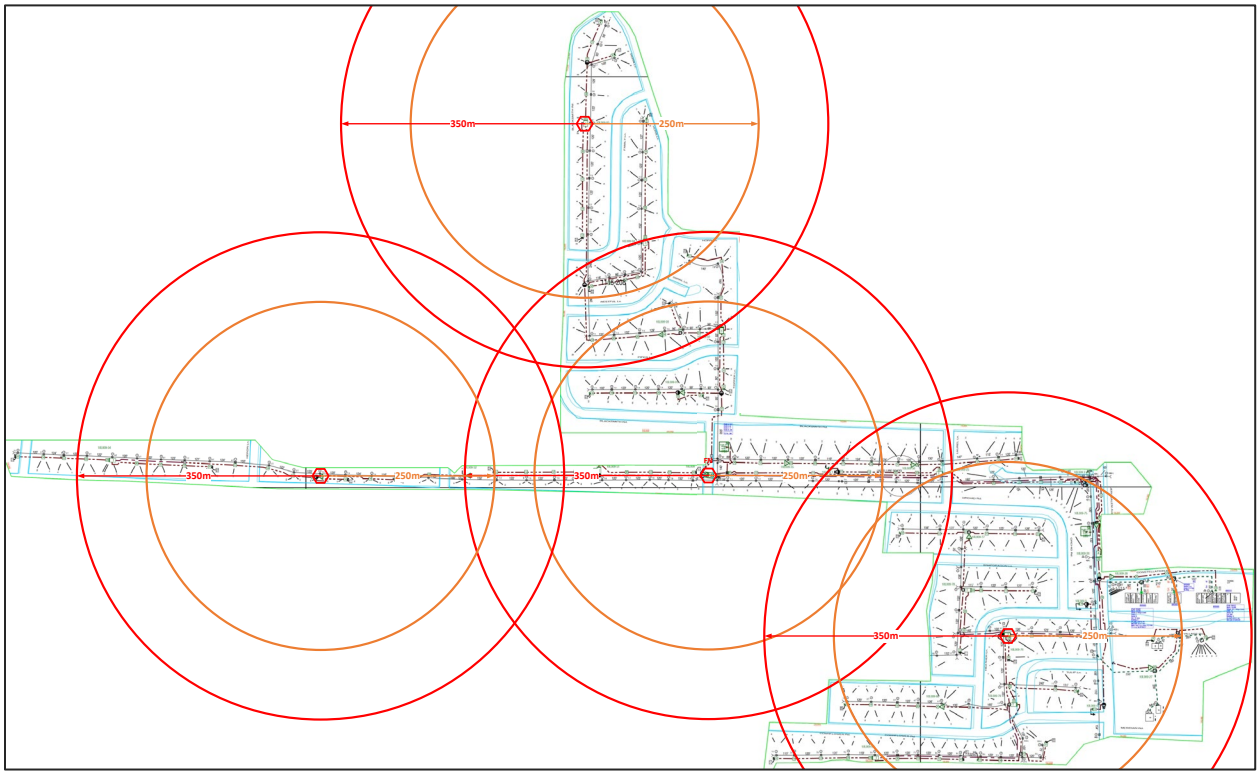

Figure 18 – Medium Density Node (112 HP/mile) with Small cell at Node + HFC Amps

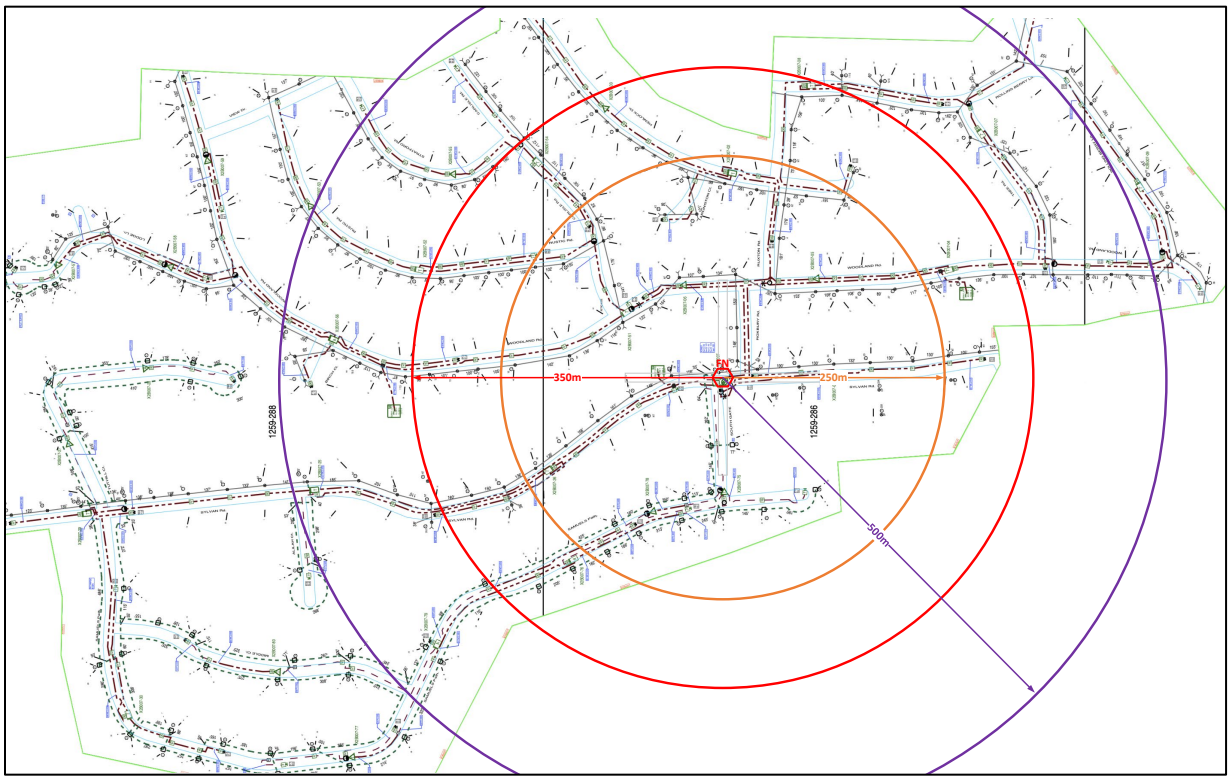

Figure 19 - Med-Low Density Node (57 HP/mile) with Small cell at Fiber Node

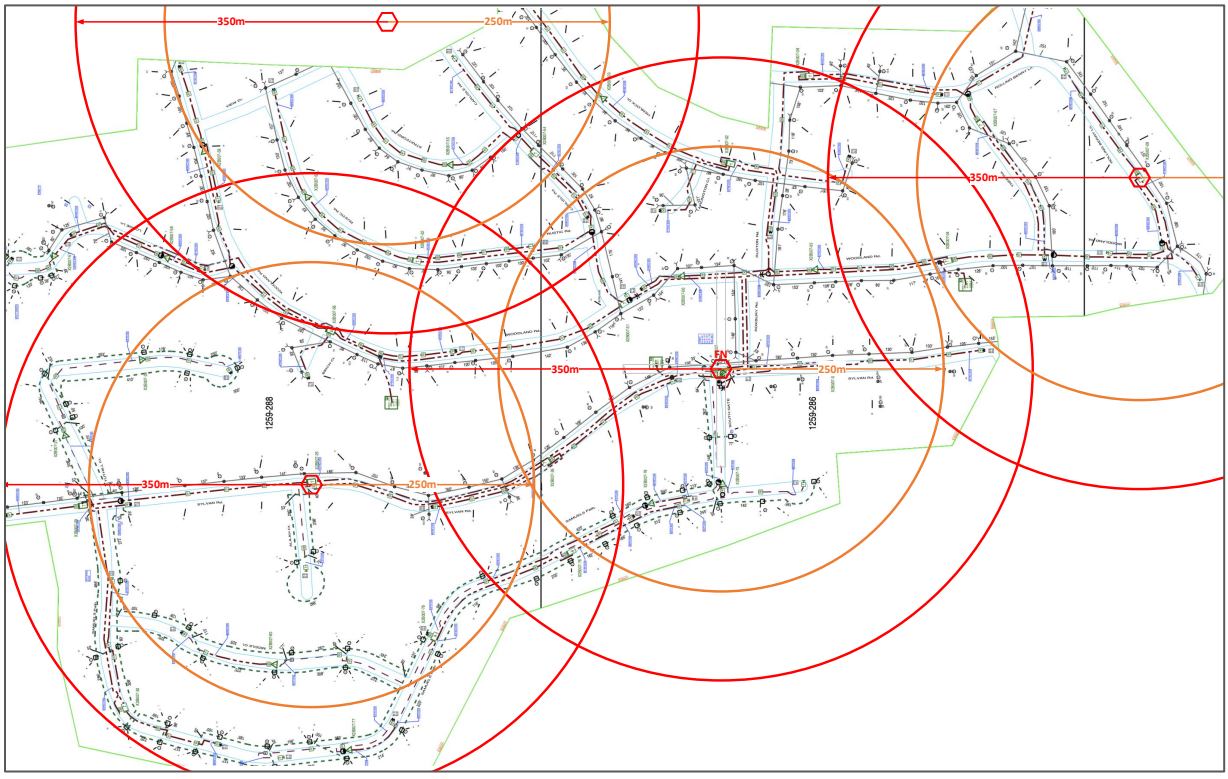

Figure 20 - Med-Low Density Node (57 HP/mile) with Small cells at Node + HFC Amps

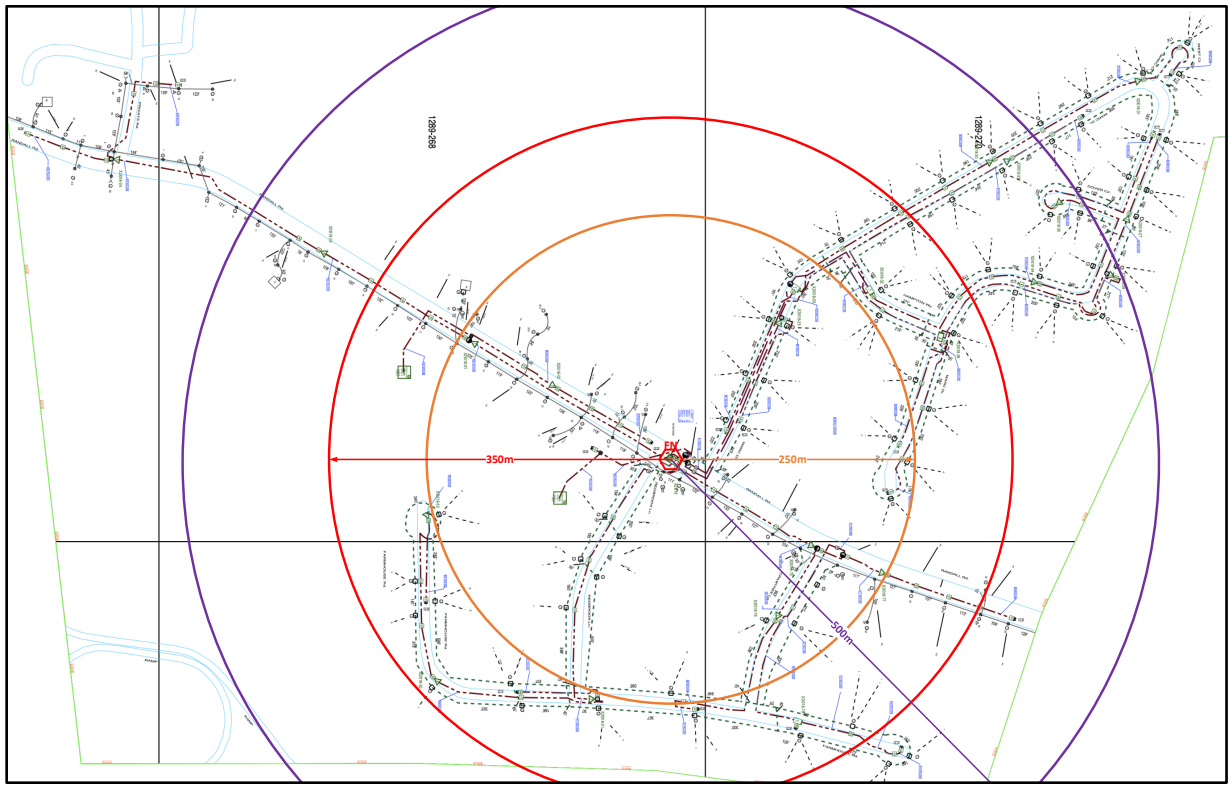

Figure 21 – Low Density Node (37 HP/mile) with stretched Small cell at Fiber Node

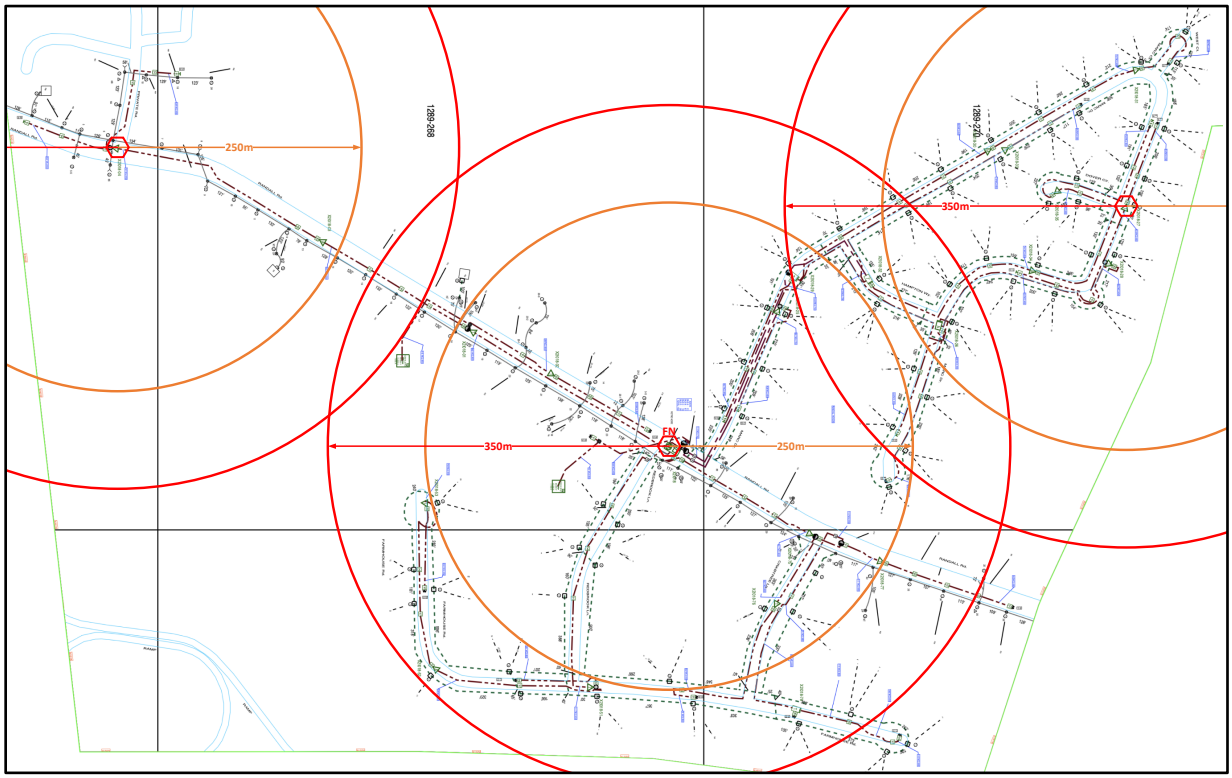

Figure 22 – Low Density Node (37 HP/mile) with Small cells at Fiber Node + HFC Amps

Figure 20 shows a couple of additional CBRS small cells added to the node. If these are all strand-mounted, then maybe their reach will be limited to the 250m to 350m range. In this example, one small cell has fiber access while the other two have coax backhaul. With a 2x2 RMD/RPD, they could be on separate DOCSIS networks.

5.1.5. Low Density Node Example

The low-density rural node in Figure 21 is N+3 with 153 total HP and 37 HP/mile. A streetlight mounted CBRS small cell with ~500m radius does a good job of covering most of the node area, but it still needs some help at the fringes. A C-band small cell should cover this node area without any problem.

Figure 22 shows some strand mounted CBRS small cells with 250m to 350m range. One is co-located with the fiber node while the other two or on the coax in opposite directions (i.e. probably separate RF legs and potentially separate DOCSIS networks.

5.2. Summary – Mapping Mid-band Small Cells to N+3 HFC Plant

After looking across an extremely wide range of homes passed densities (i.e. from 37 to 274 HP/mile), a single CBRS small cell that is co-located with the fiber node is sufficient to cover most of the homes in N+3 plant. For those nodes that need some additional small cells to achieve full coverage, this could be accomplished with only one or two small cells per DOCSIS networks.

Operators with larger HFC cascades (e.g. N+5, N+6) will obviously need additional small cells to achieve their coverage. But this case study shows that N+2/N+3 might be an optimal HFC design target for operators thinking of 5G mid-band convergence. As time progresses and bandwidth needs continue to rise, an operator might want to migrate from a DOCSIS based backhaul to a fiber backhaul. So, the operator might consider how they will eventually pull fiber to these small cells on the HFC coax plant as part of their overall fiber deeper strategy.

6. Mapping Mid-band Small Cells across multiple N+6 Fiber Nodes

6.1. Multi-node N+6 case study

The previous case study had certain limitations. First, many plants have longer amplifier cascades such as N+5/N+6 with fiber not as deep as the N+3 case study. Second, the expanded range with the mid-band small cells now potentially covers parts of multiple nodes at a time. The previous N+3 study gave us a wide range of densities, but only viewed a single node at a time. The next case study expands this to look at a much larger area from a North American metro suburban area to measure the impact across a multitude of nodes with varying densities.

Table 4 shows statistics for a ~3.5 square mile area consisting of 9 adjacent nodes. In addition to the statistics for the entire area in column one, the next four columns show the statistics for some select nodes: i.e. the highest and lowest density ones, as measured by number of homes passed per mile.

Table 4 – Statistics of Metro-suburban HFC N+6 nodes of various densities

N+6 Case Study:	Overall Area (9 nodes)	Node #1 Low Density	Node #2 Low Density	Node #3 High Density	Node #4 High Density
Coax Plant Mileage	**59.6**	9.56	6.58	4.3	2.24
Aerial	**36.1**	3.87	5.39	3.34	1.59
Underground	**23.5**	5.69	1.19	0.96	0.65
Total Actives	**381**	61	45	32	13
Actives/Mile	**6.4**	6.4	6.8	7.4	5.8
Cascade	**N+3 – N+6**	N+6	N+5	N+4	N+3
Total Passings	**5,740**	724	502	628	370
HP/Mile	**96**	76	76	146	165

Figure 23 displays the entire area. The node boundaries are shown on the map with magenta lines. The green lines show the HFC fiber routes. In addition to connecting the nine nodes to the hub site, the fiber backhaul also connects to two Macro tower base stations in the upper quadrant.

6.1.1. CBRS Small Cells at Fiber Nodes Only

Figure 23 also displays nine CBRS small cells located next to or near a fiber node. This location provides access to power and fiber backhaul in case the operator wants to use the Option 7.2x fronthaul interface. The small cell range is roughly shown as concentric circles of 250m and 350m coverage radius. This corresponds roughly to the coverage area of strand-mount and streetlight mount respectively.

Note that two of the fiber nodes were within 250m of each other. Putting a small cell at each node site would have resulted in too much overlap and interference. Rather than eliminating a small cell, we chose to move them a short distance away from the node (i.e. 500’ and 860’). The small cells are still on the fiber backbone and hardline coax to get access to power plus fiber backhaul. Again, the fiber backhaul allows for a fronthaul option 7.2 Cat A interface to be used if desired.

Figure 23 – N+6 Suburban area with Small cells at Fiber Node

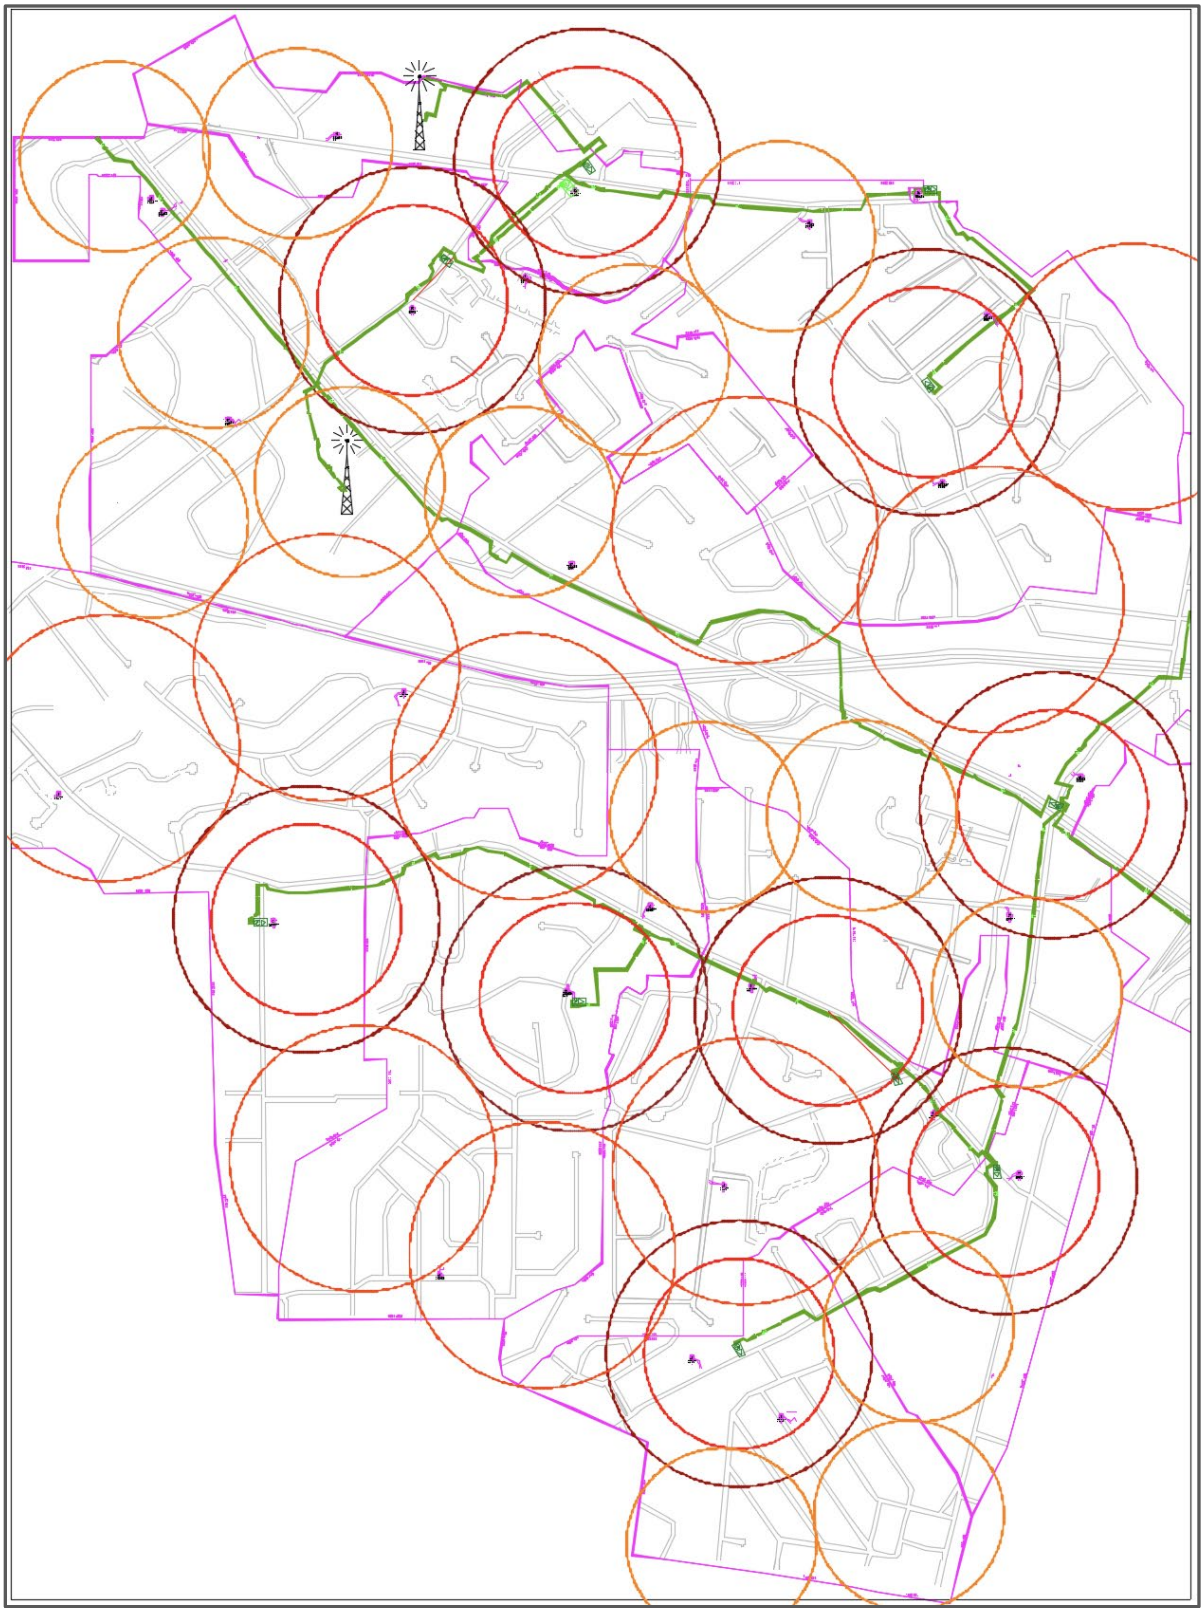

Figure 24 – N+6 Suburban area with Small cells at Fiber Node + HFC coax

The rectangle captured in Figure 23 and Figure 24 is about 1.9 x 2.6 miles (~ 5 square miles), while the actual area covered by our 9 nodes is ~3.5 square miles. As can be seen in Figure 23, less than half of the area has coverage, even with the extended 350m streetlight range. If the operator's goal is just to off-load some mobile data onto their network, this might be good enough. Also note how this coverage on N+6 plant is significantly less than the coverage seen on N+3 plant in the previous section.

6.1.2. CBRS Small Cells at Fiber Nodes and Coax locations

The next step is to fill in the area coverage with strand-mount CBRS small cells with ~250m to ~350m range. This is shown in Figure 24. These small cells would use a DOCSIS backhaul. For this analysis, any lower density nodes with <85 HP/mile were assumed to support ~350m cell range, while higher densities >85 HP/mile would only get ~250m range.

This requires 23 additional small cells to get reasonably complete coverage with a small number of residences just outside the cell radius. Care is taken that these small cells are centered either on the hardline coax strand or on a pole. Note that using streetlight mounting increases the coverage area to 350m to 500m and might eliminate a third of these coax-connected cells.

Overall, there are roughly three to four small cells for every fiber node in this N+6 HFC example. But this can vary quite a bit from node to node. Some nodes only have a single coax-based small cells while others need four more coax-based cells. It turns out that this is a function of the node's homes passed density.

Figure 25 – A zoom-in into one of the high-density nodes

Figure 25 zooms in into the two highest density nodes (i.e. Node #3 and #4 from Table 4). These are located in the lower-right corner of Figure 24 and have densities of 146 – 164 HP/mile. The high-density nodes tend to have shorter cascade lengths and only need one coax-based small cell in addition to the one at the fiber node to cover their area. It took a total of 4-5 cells total to cover this two-node area.

Figure 26 zooms into the lowest density nodes (i.e. Node #1 and #2 from Table 4) in the middle-left of Figure 24. These nodes have a density of 76 HP/mile. These low-density nodes need five coax-based small cells (with expanded 350m coverage) in addition to the two at the fiber node cells to complete the coverage of the 2 nodes' area. Even though there are many more small cells on the DOCSIS network, it should not stress the capacity of the system. The five DOCSIS small cells on low density nodes covers roughly the same number of homes passed as the two DOCSIS small cells on the high-density nodes. So, it is expected that the total DOCSIS load would be similar between both scenarios.

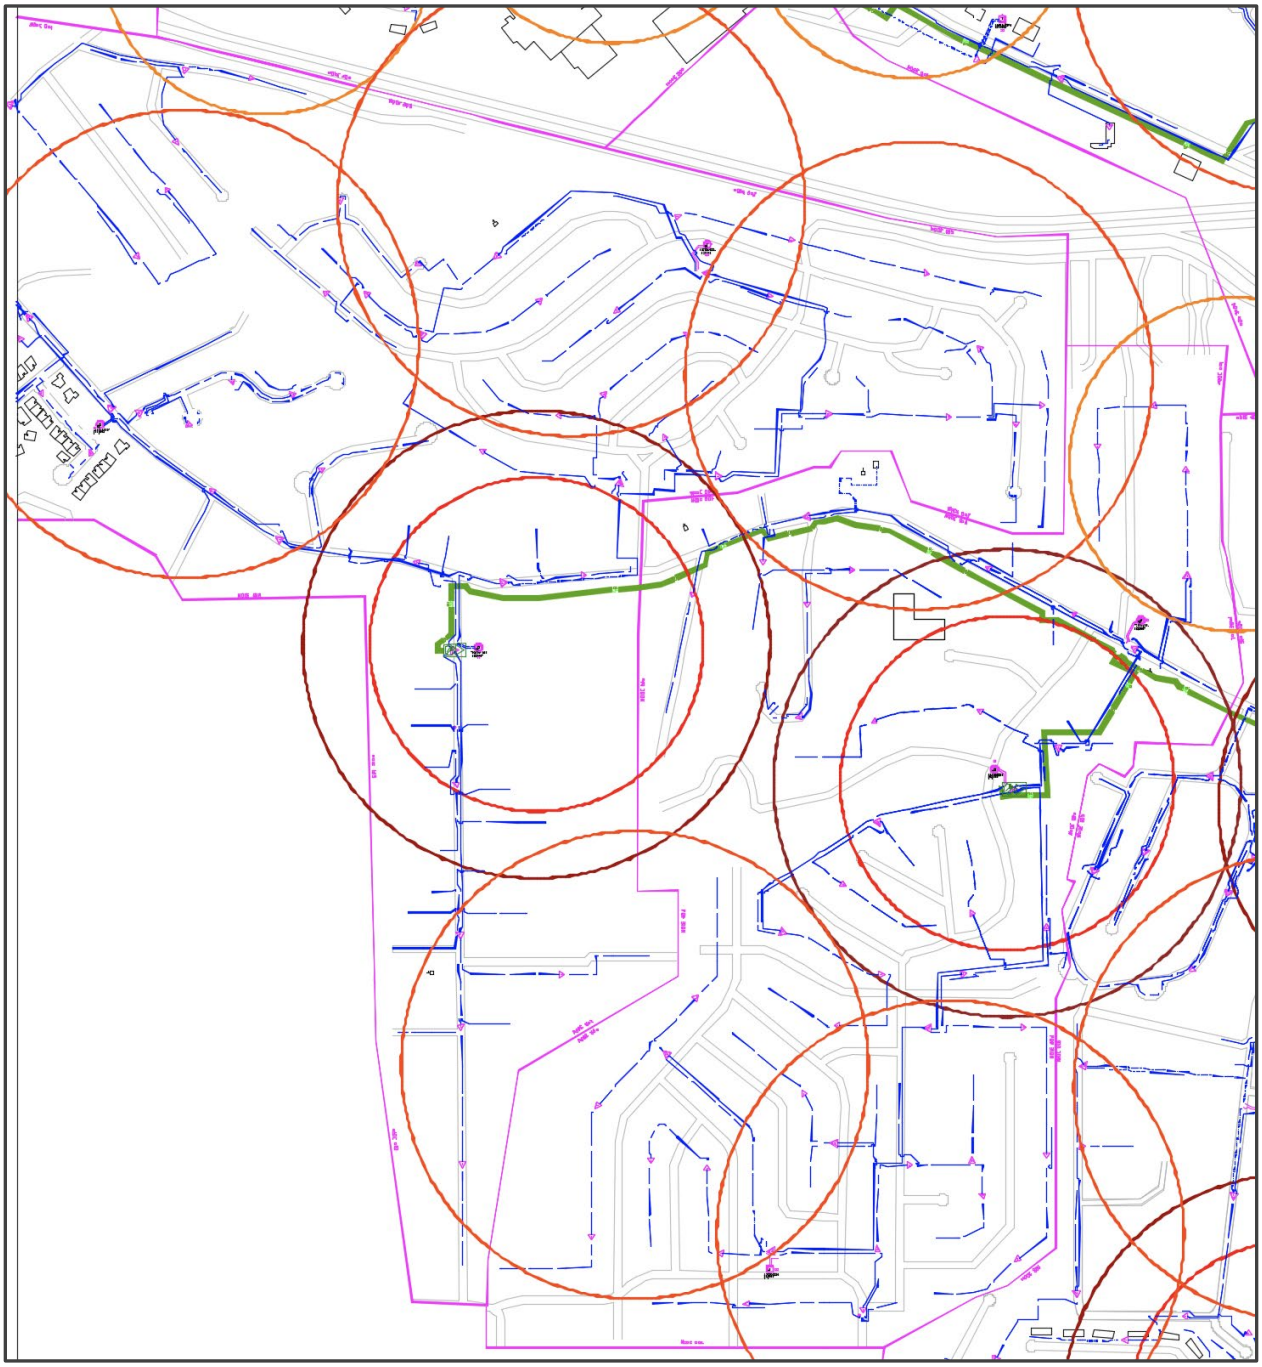

Figure 26 – A zoom-in into one of the lower-density nodes

One strategy that an operator might consider is to go to a lower 2x2 MIMO (instead of 4x4) to extend the cell reach and reduce the total number of small cells needed. The operator is effectively trading off coverage versus user capacity.

Note – In Figure 25 and Figure 26, hardline coax is shown in blue; and actives are visible as well.

6.2. N+0 Upgrade case study

The CommScope HFC design team did a N+0 upgrade design for this case study area. Table 5 shows the statistics for the N+0 upgrade compared to the original N+6 HFC plant. This upgrade pushes fiber much deeper into each node area. Total fiber mileage for this area would increase from 8.55 miles to 24.8 miles.

Figure 27 shows an update to the small cell placement from Figure 24. Note the additional fiber runs shown in green. As it turns out, fiber now passes next to 17 of the original 23 coax-based small cells. The remaining 6 cells are now within 100m – 150m of fiber. With a little additional effort, every CBRS small cell could eventually have a direct fiber connection. Note in the N+0 design that there are now 110 fiber nodes compared to a total of 32 small cells for this area.

In general, N+0 upgrades tend to be relatively expensive because of the amount of fiber being pulled. As shown, N+0 designs also push the fiber much deeper than is needed for CBRS small cell coverage. Our estimates are that an N+2 upgrade might have fiber node placements that align nicely with CBRS small cell placements. An interesting future study would be to look at a more economical N+2 upgrade to see how it aligns with the CBRS small cells.

Table 5 – Statistics of Metro-suburban HFC N+6 nodes vs. N+0 Upgrade

N+6/N+0 Case Study:	N+6 (original area)	N+0 (upgraded area)
Total Fiber Nodes	9	110
Total Fiber Mileage	8.55	24.8
Coax Plant Mileage	59.6	
Aerial	36.1	
Underground	23.5	
Total Actives	381	110
Actives/Mile	6.4	1.85
Cascade	N+3 – N+6	N+0
Total Passings	5,740	5,740
HP/Mile	96	96

7. Summary

Combining Cable 10G and Wireless 5G can offer an evolutionary strategy with much synergy. Recent 5G developments in C-band and CBRS provides some new mid-band spectrum (i.e. 3.5 – 4 GHz) that is offering a middle ground that may be the future wireless workhorse.

The paper presented a basic tutorial on mid-band wireless technologies; looks at the 5G mid-band capacity requirements; and then showed several case studies on how CBRS small cells might overlay various HFC nodes of varying homes passed densities.

The many choices for the mid-band wireless system can vary bandwidth requirements from 100's Mbps to many 10's Gbps. The paper shows which configurations can easily be supported on DOCSIS 3.1 while others might require DOCSIS 4.0 and some need direct fiber connect.

Two case studies are provided where potential mid-band cells are mapped to actual HFC networks. The nodes under study vary from dense urban nodes (i.e. >250 HP/mile) down to sparse rural nodes (i.e. <40 HP/mile). Various trade-offs are considered in cell site placement on the HFC.

7.1. Lessons Learned

Here is a collection of key takeaways from this paper:

7.1.1. Mid-Band Small Cell Coverage Range

- Small cells will most likely have a 2T2R or 4T4R omni-directional antennas supporting either 2x2 or 4x4 MIMO.
- CBRS strand-mount small cells might have approximately 240m reach in an urban setting with a greater reach (e.g. 360m) in a more rural setting.
- CBRS small cells on top of a streetlight have increased reach, perhaps up to 340m reach in an urban setting with a greater reach (e.g. 500m) in a more rural setting.
- C-Band small cells have even further reach then CBRS small cells thanks to its higher EIRP.
- Wi-Fi 6E range will be hampered to less than 100m reach due to its higher 6 GHz frequency and lower transmit powers. However, it is still expected to rule inside the home as the Mid-Band frequencies may struggle getting inside buildings.
- Some 5G small cells might be downlink (DL) only, using more robust Low-Band frequencies for the weaker uplink (UL) signals

7.1.2. Small cell Midhaul/Fronthaul capacity requirements

- Option 2 Midhaul interface substantially reduces bandwidth capacity requirements compared to Option 7.2 Cat A Fronthaul interface.
    - Option 2 requires more electronics at the radio site (i.e. DU + RU combined)
    - Option 7.2x allows for more sophisticated algorithms (e.g. beam forming) to be done in the edge cloud.
- In general, Option 7.2 Cat A interface would need a direct fiber connection
    - TBD whether DOCSIS 4.0 could meet all of the capacity and strict timing requirements for the Fronthaul interface
- DOCSIS 3.1 capacity appears to comfortably handle Mid-Band small cells with Option 2 Midhaul interface
    - 100 MHz of Mid-Band spectrum might need 1218/204 MHz HFC

7.1.3. Mapping Mid-band Cells to HFC – Key Takeaways

- Locate first small cell at or near the fiber node to leverage both power and fiber backhaul.
    - Maximum flexibility, including the choice of using Option 7.2x Fronthaul interface
- Add additional small cells with Option 2 Midhaul interface as needed along the HFC coax to access power plus DOCSIS network.
    - Over time, can pull fiber to any small cells whose capacity outgrows DOCSIS
- N+2 HFC appears to align nicely with CBRS small cells at fiber node location
- Higher density areas (in HP/mile) tend to require fewer coax-based small cells
- Lower density areas (in HP/mile) tend to require several more coax-based small cells
    - But capacity requirements are also lower due to smaller HP/mile
    - Optionally could support a lower 2x2 MIMO (instead of 4x4) to extend cell reach and reduce number of small cells needed.

7.2. DAA Synergies

- Small cells near fiber node can share 10G Ethernet connection with RMD/RPD.
- A distributed DU in the field that aggregates 6-12 small cells with Option 7.2x interfaces fits nicely into the CableLabs 10G DAA architecture
    - DU in the field greatly reduces the long range backhaul bandwidth capacity requirements (e.g. from 100's of Gbps down to 10's of Gbps)
    - Aggregation node with CableLabs coherent optics provides plenty of bandwidth capacity for the Mid-Band wireless network distribution.
- RMD works best for distributed DU in the field
    - RPD would require DOCSIS MAC core to be located near DU, not in the cloud

7.3. Potential Mid-Band Business Opportunities for Cable Operators

Considering these lessons, what makes sense for HFC service providers? CBRS/C-Band small cell reach covers a significant number of mobile users with substantial data rates. But its deployments need many more cell sites then current LTE macro-cells. This presents an opportunity for MSOs to leverage their existing HFC infrastructure for both backhaul and power.

First considering rural locations, MNOs have typically used Low-Band frequencies to maximize the distances between their macro tower base stations. This spacing may not be suitable for C-Band delivery from the tower to reach the entire community. As 5G bandwidth needs increase, MNOs may decide that deploying C-Band small cells is more economical than building more macro towers. The cable operator can provide the location (i.e. strand-mount) along with power and backhaul as a service to the MNO that owns the C-Band spectrum.

Alternatively, the cable operators might want to deploy their own 5G mobile network leveraging CBRS over their own infrastructure. In rural locations, there is a good probability that the cable operator can get access to a decent chunk of the 150 MHz CBRS spectrum via GAA.

If the cable operator is also acting as a virtual MNO (vMNO) by partnering with one of the leading MNOs, it might choose to place a handful of CBRS small cells in the busiest locations as an off-load strategy. Or the cable operator might build out the CBRS small cells across its HFC for more complete

coverage of the area. Note that 100 MHz of spectrum can enable UE data rates of 2 Gbps down by 300 Mbps up. Very impressive.

In urban settings, 4G capacity needs have already forced the MNOs to locate macro towers much closer together. So, they will be in a much better position to offer C-Band from macro towers leveraging sophisticated antenna arrays (e.g. 64T64R) and beam forming algorithms. The need for C-Band small cells will be much smaller; but it may still be needed in hot spots to help reduce congestion.

Therefore, the CBRS small cell will be key for cable operators in urban settings. But there will potentially be many others competing to get CBRS spectrum in these settings. Comcast, Charter and Verizon have all been active in acquiring CBRS PAL licensing so they can be guaranteed their share of the 150 MHz spectrum. Remember that PAL license holders can only consume up to 70 MHz total (up to 40 MHz per single PAL license holder), so at least 80 MHz will still be available for GAA users.

7.4. Conclusion

In conclusion, HFC is ideally suited to support this Mid-band xHaul infrastructure. A strategy is laid out for cable plants of varying densities. D3.1 midhaul can be leveraged extensively in the early days to get wide coverage quickly. Very dense urban areas may eventually require complex antenna/MIMO systems with fiber fronthaul, which integrates nicely with an N+2 fiber deep strategy. But even then, cells with DOCSIS xHaul will be needed to fill the holes and hotspots. D4.0 then enables even higher capacities at these cable cell sites.

In the end, Cable and Mid-band wireless (C-Band, CBRS, Wi-Fi 6E) are much stronger together and are at the core of a next gen converged network evolution.

1. Introduction

Speed. We never seem to get enough of it. This is certainly true when it comes to high-speed data. Over the past 20 years the data over cable system interface specification (DOCSIS®) publications have undergone several iterations to accommodate more and more speed. DOCSIS 3.1 introduced new technologies specifically to support even more speed improvements. Specifically, DOCSIS 3.1 introduced orthogonal frequency division multiplexing (OFDM) in the downstream and orthogonal frequency division multiple access (OFDMA) in the upstream. OFDM and OFDMA are unique in their implementation of frequency allocation because they use very narrow slices of bandwidth in the RF spectrum to transmit data, called sub-carriers. A single OFDM channel is made of many sub-carriers. For example, a single 192 MHz OFDM block can contain 7600 subcarriers. These subcarriers are only 25 kHz or 50 kHz in bandwidth. Contrast this to our traditional single-carrier quadrature amplitude modulated (SC-QAM) channel which is typical 6 MHz (or 8 MHz for some non-North American systems).

Each subcarrier can have its own modulation from 16-QAM up to 4096-QAM (even high order modulations may be supported. Again, we can contrast modulation to legacy SC-QAM, which are limited to 64-QAM or 256-QAM. In the comparison of SC-QAM to OFDM we see a drastic difference between bandwidth (6 MHz vs 25 kHz) and modulation (256-QAM vs 4096-QAM).

As previously mentioned, in OFDM each subcarrier can have its own modulation. This means one subcarrier can be running at 4096-QAM while its adjacent subcarrier could be running at 16-QAM. This is a very power feature when impairments are present because each subcarrier can be optimized to ensure modems can receive data from each subcarrier no matter how bad the impairment. But how could one possibly know how to configure 8000 subcarriers? It's not possible. This falls into software called the profile management application or PMA coupled with proactive network maintenance (PNM).

This paper will explain how PNM and PMA work together to optimize the OFDM downstream and later the OFDMA upstream to maximize the data throughput in the presence of downstream and upstream impairments.

2. What is PNM?

Proactive network maintenance (PNM) has been steadily growing in acceptance and popularity over the past several years with adoption amongst cable operators from Tier 1 such as Comcast all the way to the smallest Tier 4 operators — both in the U.S. and internationally — as a tool for optimizing their work force and improving subscriber quality of experience (QoE). No longer is it seen as a shiny gimmick or a novelty to detect the poltergeist in the network before it goes bump in the night. It is a go-to network maintenance tool with the added benefits of workforce optimization.

PNM DOCSIS Overview

PNM in DOCSIS collects several key metrics including equalization data from cable modems, downstream spectrum captures from modems and upstream spectrum capture from the cable modem termination system (CMTS). Along with traditional SNMP metrics, this data is used to identify physical layer impairments often not identifiable with legacy monitoring systems and meters. Two key takeaways with a properly orchestrated PNM system are that it provides visibility into impairments most operators have lacked visibility into, and it provides clear, visible, and actionable insights, such as whether the impairment is in the subscriber's home or in the outside plant. This alone drives key decisions as to which resource to send (and where to send it!) to resolve a problem; intelligent problem-solving leads to resource optimization.

Types of Problems Proactively Found

Proactive tools are rapidly seen as must-have tools as the need for nearly every industry to resolve issues before they occur is increasingly under demand. DOCSIS PNM specifically focuses on the physical RF plant. This means coax cable, connectors, and passive & active devices. Everything from the CMTS to the cable modem (CM).

Interestingly, the CMTS and CM are rarely the sources of problems. In fact, systems that use PNM see a rapid decrease in unnecessary modem replacements — the modem was never bad in the first place. The most frequently found problem is typically bad or improperly installed F connectors, such as the one in Figure 1.

Figure 1 - F-connector not flush with the cable's dielectric

When connectors are not properly installed, this can create several problems:

- Micro-reflections
- Intermittent connections
- Signal ingress
- Signal egress

The problems are difficult to detect with a traditional signal level meter (SLM) but can cause intermittent issues with cable modems and set top boxes resulting in repeat calls to the subscriber's home. Further, improperly installed connectors allow signal egress, causing possible regulatory issues with FCC Part 76

leakage regulations, as well as upstream and downstream ingress, potentially impacting many (or all!) subscribers on the same fiber node.

Figure 2 - Trunk line outer shielding cut by technician when coring cable for connector, illustrates another common issue identified with PNM — outside plant impairments.

In **Figure 2** we see that the outer shield on a hardline coax has been cut the entire way around when a technician was overzealous during coring. When the shielding is compromised, the coaxial cable's impedance is no longer 75 ohms. This results in a major impedance mismatch, or micro-reflection. Further, ingress and egress will result from this exposed section of coax.

In the examples of **Figures 1 and 2**, these impairments may or may not be immediately obvious to the technician depending on the severity of the damage. However, one fact we know is that cable does not get better over time. Water ingress will create more corrosion and these impairments will result in eventual outages of either single modems or clusters of modems. The impact will be dissatisfied subscribers, and technicians in firefighting mode to find and fix the root cause.

What if there were a better method? A way that we could find these impairments before the customer was impacted. There is. It's **PNM**.

Impact to Home Techs

PNM starts with home installation technicians. They are the front line, installing new modems every day or visiting subscribers who are calling about issues with their modems. Having worked with PNM since 2012 I can tell you two facts: 1) the majority of return path ingress comes from individual subscribers'

homes, and 2) most hard-to-find impairments causing repeat truck rolls to come from subscribers' homes. And this is where the home techs spend most of their time.

Given the new visibility into micro-reflections and group delay, home techs can now see impairments previously hidden to them. Micro-reflections are typically the dominant issue in subscribers' homes due to bad wiring, such as the example shown in **Figure 3.**

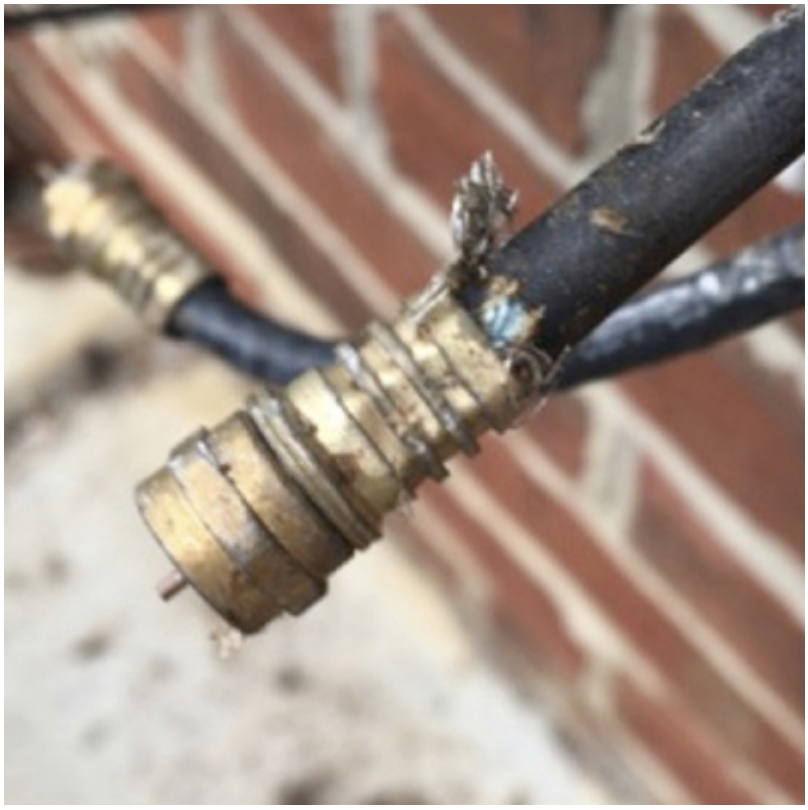

Figure 3 - Crimp-on connector showing poor grounding and corrosion on shielding.

The example shown in **Figure 3** is often difficult to find, especially when it exists under crawl spaces or trailers. However, the impacts can be maddening for technicians trying to resolve modem issues for frustrated or unhappy subscribers. Modems will report T3 timeouts, slow speeds, uncorrectable codeword errors and intermittently drop offline. Often the modem will be replaced by the tech in futility because traditional SLMs will not show micro-reflections. PNM will quickly show the micro-reflection and even estimate the distance to the micro-reflection, quickly showing the tech that there is a problem and where to look for the problem.

Every time a field tech installs a new modem or has an opportunity to gain access to a customer premise, this is an opportunity to be proactive. PNM gives the home tech the ability to test the subscribers' homes for several typical performance parameters, such as power levels and modulation error ratio (MER). And even more importantly they can test PNM metrics such as group delay, micro-reflections, and full band capture. These additional metrics go far to ensure every modem installed will perform well for the subscriber and will not allow ingress into the plant provided the tests pass. If the tests fail, the home technician should resolve the issues or escalate them to a more senior technician.

Impact to Maintenance Technicians

Maintenance technicians face the same issues as field technicians: impairments that are invisible with traditional tools. PNM provides visibility. Maintenance techs can now also see micro-reflections, damage to the outside plant, and group delay.

By identifying groups of modems affected by the same outside plant damage, we can form a Correlation Group. A Correlation Group is a cluster of modems seeing the same impairment. This cluster of modems can help triangulate and localize the outside plant impairment, thus identifying its location. Now maintenance technicians know there is an outside plant impairment, how severe it is, where it is located, and how many subscribers are impacted.

Frequently, outside plant impairments are made visible before subscribers notice the plant impairment. This is key to being proactive. The plant damage can be fixed on a schedule convenient to the operator or can be ignored until it degrades to the point that subscribers start to call CSRs. This becomes a company decision as to how they handle proactive activities.

PNM, DOCSIS 3.1 and RxMER

DOCSIS added many more PNM tests with the release of DOCSIS 3.1. One very power test added for OFDM and OFDMA is called RxMER. RxMER per subcarrier provides a modulation error ratio (MER) measurement for each subcarrier in the OFDM or OFMA channel. This means if an OFDM channel has 7600 subcarriers, the tester will receive 7600 MER results, one corresponding to each subcarrier. When plotted, it looks like a spectrum analyzer chart, but has different meanings. See Figure 4 for an example plot of OFDM RxMER per subcarrier data.

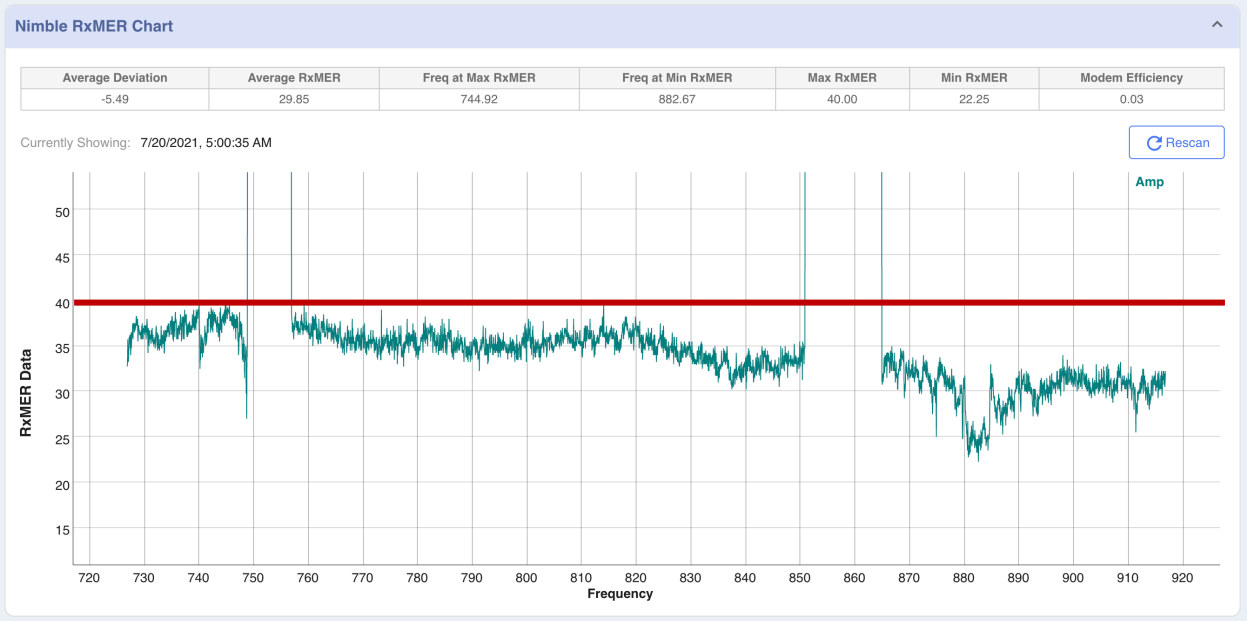

Figure 4 - RxMER per subcarrier plot of OFDM channel from live plant.

In **Figure 4** there are some unique observations one can make. First, the average RxMER is 29.85, as shown in the top of the chart. A red line is added at 39 dB MER, which is the threshold for which 4096-QAM is required. Ideally, all RxMER datapoints should be above the red line to provide the highest level of data speed to the subscriber. If the CMTS was configured to provide 4096-QAM, this modem would not be able to receive any data. See Table 1 for the mapping of RxMER to OFDMA modulation. Finally, there are two

sections of the RxMER plot where the chart goes above 50 dB. One between 749 and 757 MHz, and another between 851 and 865 MHz. These are called exclusion bands. Exclusion bands are configured in the CMTS to disable subcarriers where the cable operator knows high levels of RF ingress exists, such as LTE interference. Exclusion bands are helpful to disable subcarriers which we know will be severely impacted no matter how hard we work to clean up the HFC plant.

RxMER can be directly mapped to the modulation level which can be supported by a receiving cable modem. These mappings are defined in [PHYv3.1] (*see Table 46 - CM Minimum CNR Performance in AWGN Channel*) and the [CM- OSSIv3.1] (*see Table 72 - CmDsOfdmRequiredQamMer Object*). Table 1 shows these mappings up to 16384-QAM, but field testing has indicated that these mappings are conservative. As indicated in Figure 4, 39 dB is often used as the limit for 4096-QAM rather than the CableLabs recommendation of 41 dB for 4096-QAM.

Table 1 - Mapping of Downstream RxMER to supported QAM Level [1].

Constellation/ Bit Loading	CNR/MER (dB)
16 QAM	15.0
64 QAM	21.0
128 QAM	24.0
256 QAM	27.0
512 QAM	30.5
1024 QAM	34.0
2048 QAM	37.0
4096 QAM	41.0
8192 QAM	*46.0*
16384 QAM	*52.0*

3. What is PMA?

The profile management application (PMA) ingests RxMER data from a given node, analyses the RxMER per subcarrier data, and outputs the following:

- A modulation profile which can be applied to the CMTS which is optimized for all modems in the presence of RF impairments. This single profile is used across the entire OFDM / OFDMA channel, but does not account for frequency specific impairments, such as band roll-off or LTE interference, as an example,
- A modulation profile per subcarrier, which can then be used to create segmented profiles on the CMTS. This is a more refined method that allows the cable operator to optimize their profiles based on frequency specific impairments and is particularly useful where impairments are not consistent

across the spectrum. There are many use cases for this, but some obvious ones are high frequency roll-off, LTE ingress, suckouts, and low frequency noise,

- A per-modem profile which can be applied to each modem by MAC address. This is an aggressive method of profile management, which is not supported by all CMTS vendors at the time of writing of this document. However, future support is expected. In this method, each cable modem can have a specific profile applied specific to the modems' RF impairments, thus optimizing the end users experience and ensuring every subscriber has maximum data throughput in the presence of changing RF impairments.

The objective of the above process is to not only increase network capacity, but to also prevent outages. If a subscriber's modems is offered a profile higher than what the modem can sustain in the presence of RF impairments, little or no data will flow over the OFDM channel to the modem. In most CMTS implementations, the OFDM channel is set to the "primary" or "preferred" channel. When the primary channel is down, the subscriber experiences no data or from their perspective, an outage. This results in customer service representative (CSR) calls and likely truck rolls. This is costly to the cable operator. The PMA can function in a similar way to pre-equalization in the upstream, by changing the CMTS profiles to prevent unnecessary CSR and truck rolls, thus saving the cable operator money. Further, the PMA saves the subscriber preventable outages and makes for happier subscribers.

Today's CMTSs support only a few profiles, which does vary from vendor to vendor. Let's look at an example vendor that supports four profiles, which can be called profiles 0, 1, 2, and 3.

A CMTS engineer may configure profile 0 to operate with every subcarrier at 256-QAM. Then profile 1 to operator at 1024-QAM, profile 2 to operate at 2048-QAM and profile 3 to operate at 4096-QAM. On the CMTS, these profiles would look something as follows:

- ofdm ds-profile 0 default-modulation 256qam
- ofdm ds-profile 1 default-modulation 1024qam
- ofdm ds-profile 2 default-modulation 2048qam
- ofdm ds-profile 3 default-modulation 4096qam
- ofdm frequency low-edge 834000000 high-edge 1026000000 plc-block 842000000

Every subcarrier in the above profiles is assigned the default-modulation. For example, for ds-profile 0, every subcarrier is configured for 256-QAM; and for ds-profile 3, every subcarrier is assigned 4096-QAM. A subscriber's cable modem can dynamically choose which profile to use based on the impairments between the CMTS and the cable modem. High modulations will allow higher data speeds and lower modulation will allow lower data speeds.

Finally, notice the very last line. This indicates the OFDM start frequency of 834 MHz and stop frequency of 1026 MHz. It also shows a physical layer link channel (PLC) frequency of 842 MHz. The PLC is a special narrow channel of 400 kHz wide that carries signaling and boot-strapping information (e.g., OFDM channel parameters and MAC management messages). This PLC can be easily recognized: it lies in the middle of a specially defined 6 MHz wide range containing 8 pilot subcarriers [2]. See Figure 5 for an example of the PLC in an OFDM channel.

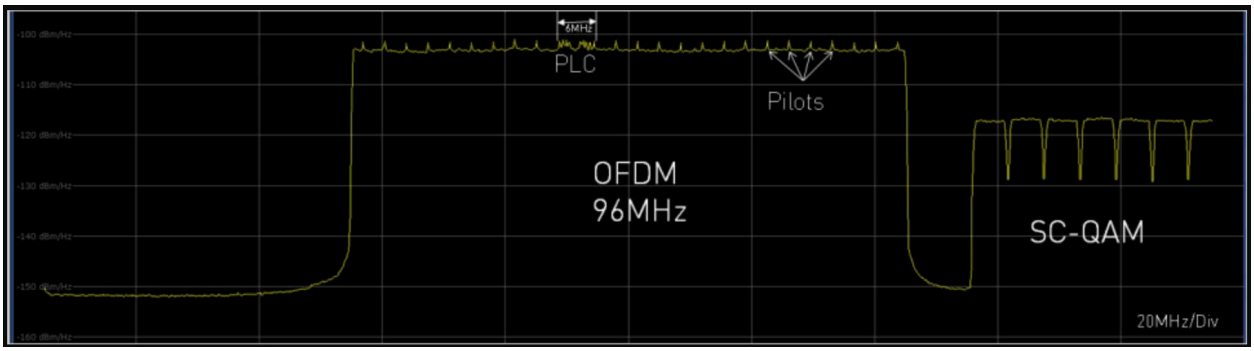

Figure 5 - Example OFDM channel highlighting the PLC [2].

The PLC is of critical importance because it delivers signaling and MAC management messages to all cable modems. If the PLC is impaired, it will cause all cable modems to go offline. We will discuss more on this in the next section.

Some of today's CMTSs permit only four modulation profiles as shown in the example above, while others support more. But what happens if RF impairments exist which are non-optimal for the configured modulations? As an example, what happens if there are significant impairments which permit modems from using 1024-QAM, but 512-QAM would be sufficient? Because 512-QAM is not an option in our selected set of profiles, modems must drop down to 256-QAM. Thus, we are leaving bandwidth on the table. Further, impairments vary over time. So even if we re-programmed the CMTS to support 512-QAM to regain our bandwidth, we may find a day later it needs a new update for different modulations. What's more is that most operators program their CMTSs with a flat profile, such as 4096-QAM across the entire OFDM channel. Considering that OFDM channels can be 192 MHz wide, one can imagine that impairments such as roll-off at high frequencies would make 4096-QAM unusable at high frequencies. It is possible to program mixed modulations in segments. An example of this would be where lower frequencies that have high RxMER are configured for 4096-QAM. Similarly, higher frequencies in the roll-off band with low RxMER are configured with lower modulations such as 512-QAM or lower. But again, how do we even know any of this information such as what frequency bands should get which modulations?

On top of this, how do we know the ideal location for the PLC on every node on every CMTS in the network? This can become a substantial amount of work when dealing with hundreds or thousands of nodes and a network that is constantly changing. We need a solution, and the solution exists – it's called PMA.

PMA is processing engine which analysis the RxMER data from every cable modem in each node. After analyzing the RxMER data, the PMA engine will provide the optimal modulation for each subcarrier and the optimal frequency location for the PLC. This takes the guess work out of determining which profiles and PLC location each node requires. Further, PMA can be fully automated so that every node can be optimized multiple times per day to compensate for the ever-changing RF impairments.

Figure 6 shows a high-level concept of the PMA architecture as it is implemented in multiple MSO systems. It generally has four components as described next.

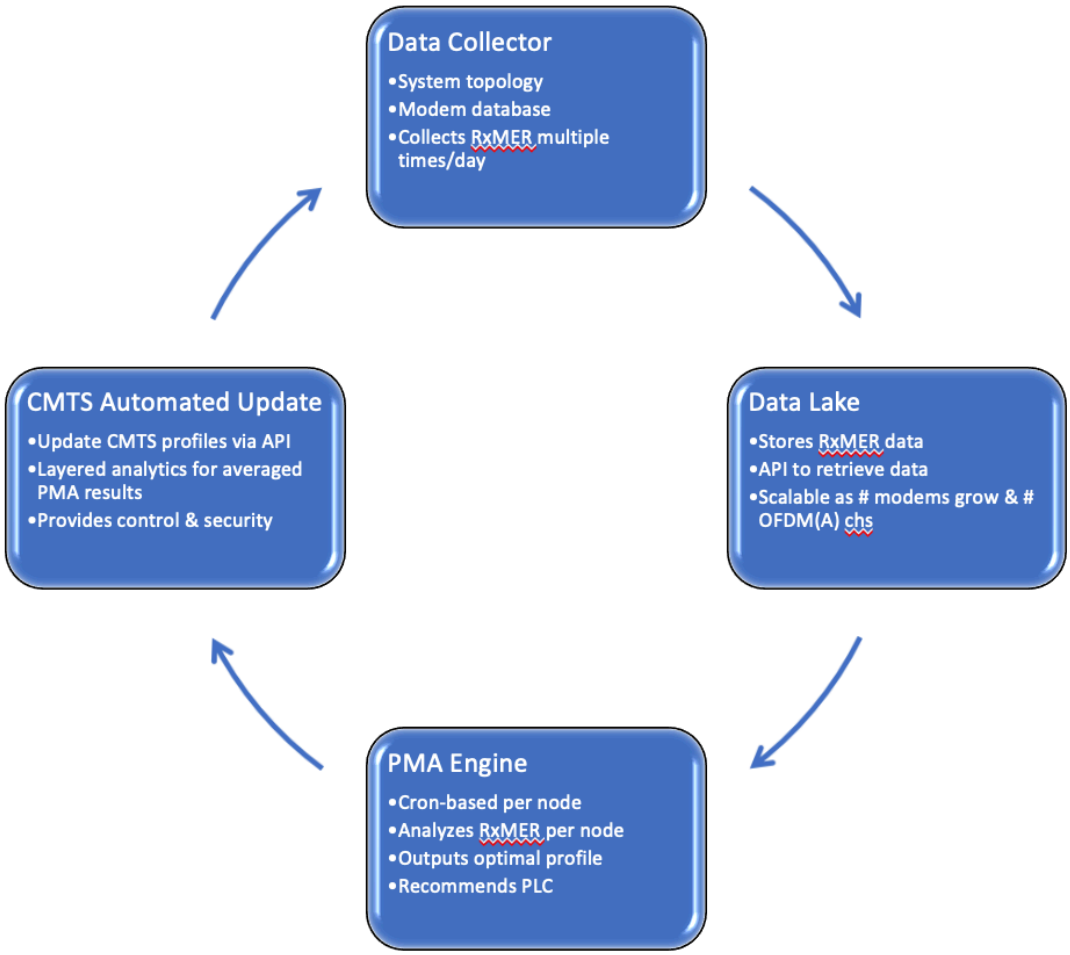

Figure 6 - PMA System Architecture.

Data Collector: The PMA process begins with the collection of RxMER data. To do this, the collector must first communicate with the CMTS to obtain a list of all cable modems and obtain topology awareness. Topology awareness simply means a mapping of each cable modem to its respective fiber node. The data collector then communicates with each cable modem to obtain the OFDM RxMER file. It also obtains additional telemetry information from the modem and CMTS to perform downstream and upstream PMA.

Data Lake: PMA can be performed on the fly; however, it is much more beneficial to make analysis on averaged data. Therefore, the data collector stores its data in a large database. Application programming interfaces (APIs) are implemented to easily retrieve data from the database.

PMA Engine: The PMA engine runs on a routine basis to pull the latest data from the Data Lake and process the data. It does so using an API to retrieve RxMER per subcarrier and other data for each fiber node in the network. Once done processing, the PMA engine outputs a file that contains the optimal profile set and PLC placement for the given node, along with the CM to profile assignments.

CMTS Automated Update: The CMTS automated update is responsible for pulling the output files created by the PMA engine and applying the profiles to the CMTS and CMs. This procedure ensures the cable

operator has full control of when and how profiles are applied. Further, profiles can by modified by the cable operator via analytics so that they are further optimized according to the limitations of the cable operator's CMTS equipment.

In the next section we will see the benefits than can be achieved through the PMA.

4. What are the benefits of the PMA?

The PMA has several benefits, which are immediately realizable as follows.

- The PMA will provide the optimal profile for a fiber node:
    - The bandwidth gains in running a well-designed set of profiles can be anywhere from 15% to 40% capacity increase on a channel, compared with running the whole channel at 256-QAM. This can translate to a solid 200 to 400 Mbps extra capacity on each OFDM channel! [3]
- The PMA will reduce individual subscriber and likely entire node outages:
    - When running the PMA on each node on a regular basis, profiles are continuously being optimized for new impairments. Profiles are downgraded and upgraded, similar to how upstream dynamic modulation profiles are used for SC-QAM channels to accommodate dynamic changes in the upstream. But the PMA will do the same for the downstream and the upstream. This helps ensure subscriber traffic continues to flow over the OFDM and OFDMA channels during dynamic impairment changes.
- PMA will provide PLC placement recommendations to ensure the PLC is not operating in an area with impairments:
    - This is often overlooked as a critical feature of PMA. If the PLC is placed in a region where impairments (think about a suckout or LTE ingress) exists, this will result in an outage. PMA will aid in preventing such instances from occurring. Again, the PMA can help prevent critical fiber node outages resulting in significant cost savings from truck rolls and subscriber grief.

The PMA is not only beneficial in increasing extra capacity in the DOCSIS network, but also in reducing CAPEX expenditures through increased network reliability.

These immediate benefits may seem obvious and exciting, but they have a bottom-line impact to total system capacity, which results to OPEX savings and preventative CAPEX investment.

In 2019, Comcast developed a PMA system for generating and transacting D3.1 downstream profiles tailored to the conditions of each OFDM channel in its network. Some point-in-time metrics from Comcast's deployment of PMA indicate its realized value [4]:

- 34.3% capacity gain in OFDM profiles (Division A),
- Raw gain of 6020 Gbps for Division A,
- 91.0% CM success rate (percent of CMTSs that were successfully configured with updated profiles).

Comcast considered the PMA a huge success and subsequently released public press releases [5].

5. PMA in Action

To see a PMA engine in action, it is first important to understand the relationship between modulation efficiency, which is the bits per MHz, and required MER to support the given modulation. This relationship can be developed by adding the modulation efficiency to Table 1, which results in Table 2.

Table 2 - Modulation Efficiency vs Bit Loading vs MER

Modulation	RxMER per Subcarrier	Modulation Efficiency
No Data	<12	0
QPSK	12.0	2
16 QAM	15.0	4
64 QAM	21.0	6
128 QAM	24.0	7
256 QAM	27.0	8
512 QAM	30.5	9
1024 QAM	34.0	10
2048 QAM	37.0	11
4096 QAM	41.0	12
8192 QAM	46.0	13
16384 QAM	52.0	14

The PMA outputs both modulation and modulation efficiency (also called bit loading) when RxMER per subcarrier data are provided to it. Modulation efficiency is easier to plot and manipulate than modulation. An easy lookup table can be generated to reference modulation efficiency to RxMER per subcarrier. This allows one to compare the RxMER per subcarrier data to the recommended MER profile for a given modulation.

Example RxMER per subcarrier data from all modems in a fiber node is shown in Figure 7. As is typical with RxMER data of many fiber nodes, a portion of modems are showing very high level RxMER (>40 dB). These modems will be capable of supporting 4096-QAM across the entire spectrum. However, as can be seen in Figure 7, more than 75% of the modems fall below 41 dB MER with many modems falling below 30 dB MER. In fact, 25% of the modems on this fiber node fall below the 30 dB MER threshold across the entire spectrum. Modems falling below the 30 dB spectrum will only support 256-QAM or less! Keep in mind that legacy SC-QAM had a maximum modulation profile of 256-QAM.

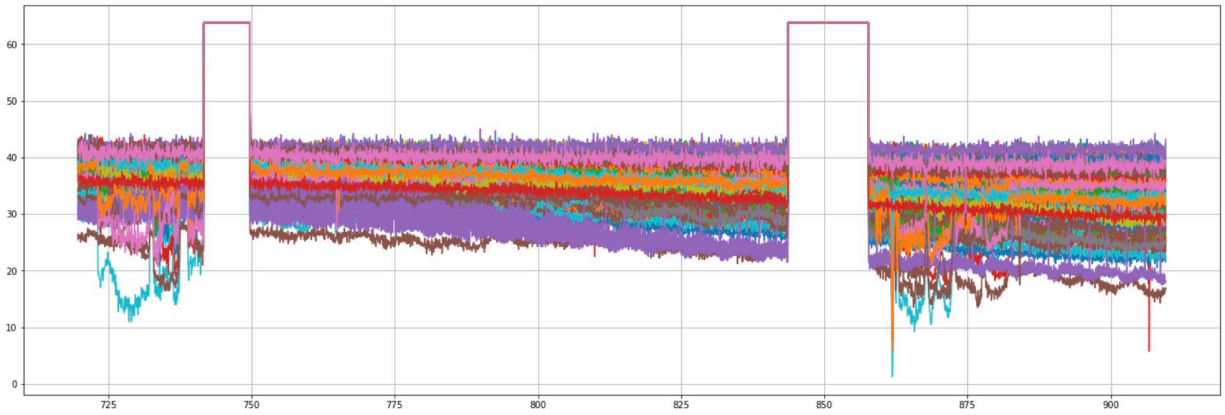

Figure 7 - Sample set from a typical fiber node with varied impairments.

This presents a challenge for cable operators to determine what modulation profiles should be assigned to this node. Without a PMA it is a guessing game. With a PMA, very inciteful information can be gathered which will allow the cable operator to configure the CMTS with the most optimal profiles to ensure all cable modems are well supported with a finite number of profiles that are supported in the CMTS.

Figure 8 shows a typical recommendation from the PMA output given the RxMER input of Figure 7. The blue dotted line in Figure 8 indicates the absolute MER for each subcarrier, which translates to the respective modulation in Table 2. The red line indicates the maximum and minimum recommended modulation profiles from a PMA based on the RxMER per subcarrier input. The red lines are broken into segments which can be applied to a CMTS that support mixed modulations in a segmented method. Additionally, the suggested profiles in this section are examples only and should not be considered as recommendations for any production system without prior testing.

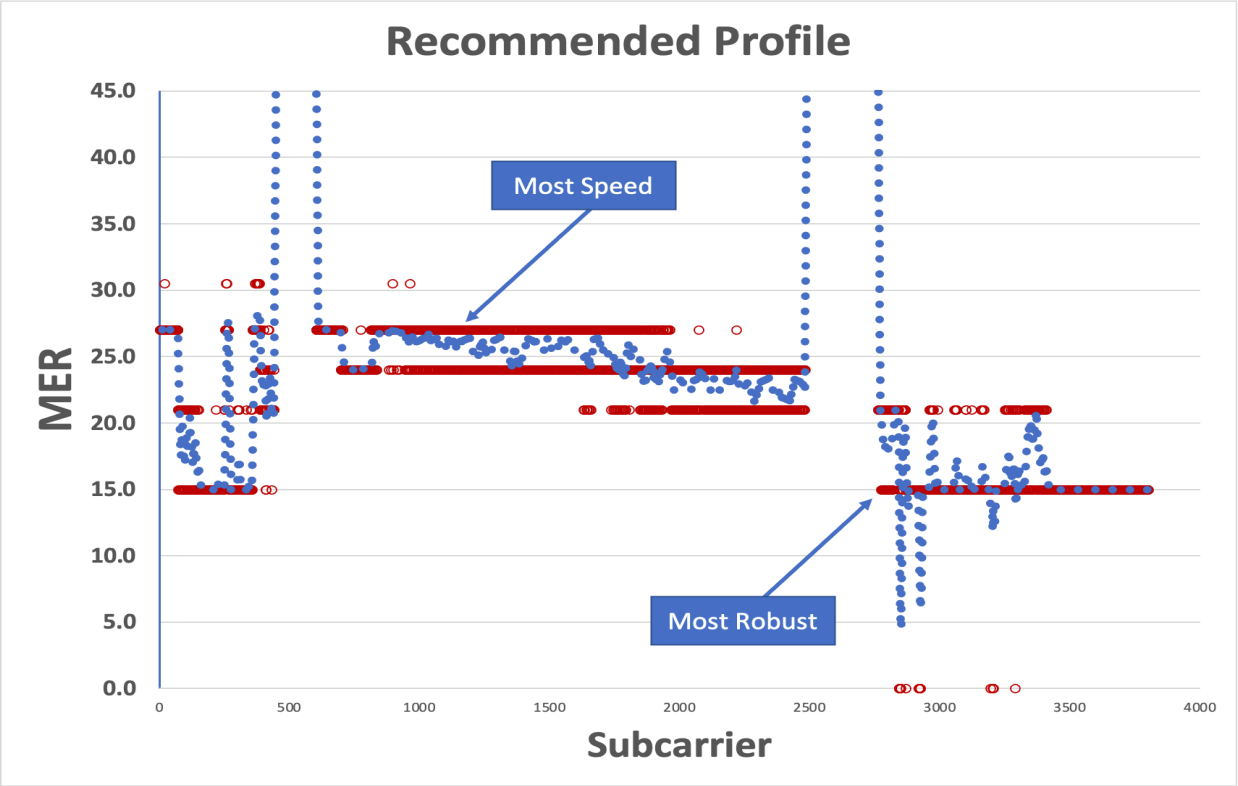

Figure 8 - PMA profile recommendations for fiber node in Figure 7.

In Figure 8, the upper limit red line is indicated as the "most speed" line. This means if the cable operator were to choose the upper end of the recommended profile, cable modems would likely achieve high data throughput, but would suffer more uncorrectable codeword errors. On the other hand, the "most robust" line indicates that choosing the lower modulation will ensure cable modems will have lower data speed but will likely have very few if any uncorrectable errors because the modulation is set low and therefore resilient to errors in the presence of impairments.

Ultimately, the data that is being presented are minimum and maximum profiles which can be updated in the CMTS to support all impaired modems in the fiber node and still maintain maximum data throughput.

Let's consider the original configuration on the CMTS as follows.

- ofdm ds-profile 0 default-modulation 256qam
- ofdm ds-profile 1 default-modulation 1024qam
- ofdm ds-profile 2 default-modulation 2048qam
- ofdm ds-profile 3 default-modulation 4096qam

First, we know that keeping ds-profile 3 is a good idea, because there are modems that support >40 dB RxMER across the band. These modems will be able to use ds-profile 3 and obtain the maximum throughput of the OFDM channel.

Next, there are some very impaired modems. To these modems always can transmit data profile 0 will be downgraded to 64-QAM, which is a very robust profile. Profile 1 will also be downgraded to 256-QAM for slightly less impaired modems. Profile 2 will be modified to a segmented profile to align the PMA profile output shown in Figure 8. There are three segments aligning with the three primary tiers in Figure 8 of 64-QAM, followed by 512-QAM and then back to 64-QAM. The segmented modulation in profile 2 represent the optimal profile from the PMA output that will give the maximum data throughput for modems. Finally, profile 3 of 4096-QAM is enabled for modems not experiencing impairments. Modems not experiencing impairments will be able to use profile 3 and will see the maximum data throughput the OFDM channel can support.

- ofdm frequency low-edge 807000000 high-edge 903000000 plc-block 850000000
- ofdm ds-profile 0 default-modulation 64qam
- ofdm ds-profile 1 default-modulation 256qam
- ofdm ds-profile 2 low-freq-edge 807000000 high-freq-edge 817000000 64qam
- ofdm ds-profile 2 low-freq-edge 817000000 high-freq-edge 877000000 512qam
- ofdm ds-profile 2 low-freq-edge 877000000 high-freq-edge 903000000 64qam
- ofdm ds-profile 3 default-modulation 4096qam

This updated profile provides an example of how one can update a CMTS profile based on PMA output to ensure that modems at the high RxMER will be able to support very fast data speeds. At the same time, the modems experiencing RF impairments will be able to toggle between the segmented profile 2 or drop to even lower modulations supported in profile 1 or 0. This will result a good quality of experience for every subscriber on the fiber node. In essence, the CMTS has been modified for this fiber node to provide maximum data speed when possible and maximum robustness when required. Every subscriber should be able to continuously receive downstream data regardless of outside plant impairments or bad in-home wiring thanks to the PMA output results.

The profiles above can be updated in an automated method each time the PMA is run on a given node to update profiles based on changing plant conditions.

6. Future Considerations

Obtaining RxMER data from modems is time consuming. It requires the use of simple network management protocol (SNMP) to configure the modems to send RxMER data back to a centralized collector. Once configured, the modems send a file using the trivial file transfer protocol (TFTP) to a TFTP server. Because plant impairments vary, it is important to gather RxMER data multiple times per day from each modem and update the CMTS accordingly. Taking multiple RxMER samples per cable modem and averaging these samples together for a single modem can make the PMA engine even more accurate. This is because a single RxMER sample from a modem could be impacted from an impairment, but multiple samples will provide a more concise data sample. However, doing so takes tremendous effort to gather RxMER data rapidly. A future implementation on the cable modem side would enable the modems to stream RxMER data back to the collector or to perform the averaging on the modem itself. As a side note, full band capture averaging is performed by most cable modem vendors today, so RxMER averaging should be doable capability. This would enable the collection of RxMER data more frequently without the addition of costly and energy hungry servers. Today, cable operators rely on servers in their data centers to collect RxMER data, which as previously mentioned, this is a CPU intensive process and

not green for the environment. As the industry focuses on optimizing data throughput, it must also focus on green initiatives. These initiatives start with pushing computations at edge devices such as cable modems rather than server farms collecting data from modems.

As shown in this paper, today it is possible to create segments in profiles. This is very effective for addressing frequency specific impairments to optimize throughput and help ensure subscribers do not experience outages. There is a limitation with this, however. Segmented profiles will often not address specific in-home wiring issues where an individual subscriber's modem is severely impacted. For this, CMTS vendors must support modem-based profiles. The PMA will output a profile for each modem. At least one CMTS vendor currently supports this functionality. As an industry it is important that achieving per modem-profile support in the CMTS is adopted. This will further improve capacity gains and the reduction of CSR calls and truck rolls for subscribers with bad in-home wiring. Like upstream pre-equalization, the PMA will output a profile to temporarily address subscribers with in-home wiring issues and ensure that their modems remain online until such a time that their wiring issues can be addressed. From this standpoint, the PMA can be considered a proactive application as it can flag individual subscriber issues having low, but still working modulation profiles.

7. Conclusion

In conclusion, a PMA is a useful add-on to PNM and DOCSIS 3.1 with OFDM. No cable plant is without RF impairments. Whether the impairments are in the outside plant or in subscriber homes, these impairments change over time. To provide reliable high-speed service over an OFDM channel it is important to configure the CMTS with the optimal profiles to maximize data throughput. A PMA provides operators the necessary visibility to ensure they are deploying appropriate profiles for each node. Further, it is evident that the PMA can be quite effective at reducing CSR calls and truck rolls via its inherent ability at improving the robustness of OFDM and OFDMA channels. This results in a cost savings for cable operators as well as keeping subscribers happy and online.

A properly developed PMA engine will create profiles for each node every time RxMER per subcarrier data are polled from DOCSIS 3.1 modems in each node. Keeping in mind the architecture diagram of Figure 6, one can understand the closed loop process of a PMA and how this plays out. Data collection, data storage, PMA analysis, and finally profile updates on the CMTS. Rinse and repeat. This process should be repeated at least four times per day for every node in the network, and more frequently if possible. Why? Because RF impairments change during the day and maximizing data throughput and customer quality of experience (QoE) are critical in today's world where people work, learn, and play at home with a high dependency on data provided over DOCSIS networks.

While this paper primarily focused on the PMA in the downstream, a PMA can work equally well, if not better, in the upstream. The upstream is the Achilles heel of the HFC network, having even more RF impairments than the downstream. As cable operators roll-out more OFDMA channels in the upstream, it is anticipated that a PMA will become a critical component to maximizing upstream data throughput and subscriber QoE.

1. Introduction

DOCSIS® 4.0 technology was created as a part of the 10G roadmap to increase capacity in both upstream (US) and downstream (DS). As we prepare to deploy this technology, the attention is rapidly shifting towards upstream, which was accelerated due to COVID-19. Last year, a noticeable jump in upstream utilization was realized by almost all multiple service operators (MSOs) worldwide, emphasizing the need for higher throughputs in the upstream. The shift to working remotely, learning from home, video conferencing and increased gaming activity demonstrated the need to increase bandwidth in the upstream to meet evolving consumer appetites.

Currently, many multiple system operators (MSOs) operate in 42, 65 or 85 MHz plant. The smaller bandwidth benefits the modems and amplifiers operating in the return spectrum. The same operators are planning on expanding the upstream spectrum bandwidth to 396 or 492 MHz in the near future, with 204 MHz as an intermediate step. Many operators are also planning on deploying DOCSIS 4.0 capable equipment in existing plant without re-spacing, which means there are a few key challenges to be considered.

In this paper, we will evaluate the DOCSIS 4.0 plant models by addressing these key challenges, including modem transmit capabilities, upstream amplifier performances and potential upstream performance expectations for various node and serving group architectures. The goal is to highlight the main areas that should be prioritized to ensure optimal DOCSIS 4.0 upstream performance in the access network.

Furthermore, this paper primarily aims to shed light on areas of the US that we need to focus on, along with providing new insights into performance of nodes and serving groups based on their characteristics and properties. The DOCSIS specifications define what can be expected from the cable modem (CM) and the cable modem termination system (CMTS). However, it does not specify what performance MSOs can expect in various plant architectures. This paper outlines the most important areas of focus for the optimal approach to deploying DOCSIS 4.0 technology in the US and sets expectations for performance in the access network.

2. Baselines and Assumptions

2.1. Distributed Access Architecture (DAA)

One of the main assumptions made in this paper is that DOCSIS 4.0 technology will be deployed in a DAA environment. There are many benefits to upgrading nodes to DAA that will not be discussed here, such as power savings in head-ends and hub-sites. In this paper the baseline assumption for required power levels and signal quality relies on DAA nodes being deployed as a part of DOCSIS 4.0 upgrades.

2.2. CM Transmit Capability

In order to find any potential shortfalls for the access network from the CM transmit channel set (TCS) back to the amplifier and DAA node port(s), the following table has been considered. In the DOCSIS 4.0 specification for modem transmit (Tx) power there are three different tilt options provided (8 dB, 10 dB and 12 dB). For the purpose of this paper only the 10 dB tilt option will be addressed.

Table 1 – DOCSIS 4.0 CM Tx /1.6 MHz

Upstream Centre Frequency	108 MHz	684 MHz	Spectral tilt (dB)
Upstream Reference Power Spectral Density (PSD) (dBmV/1.6MHz)	33	43	10

Converting the power levels above from 1.6 MHz reference power spectral density (PSD) to 6.4 MHz equivalent levels, the modem Tx power is shown below.

Table 2 – DOCSIS 4.0 CM Tx /6.4 MHz

Upstream Centre Frequency	108 MHz	684 MHz	Spectral tilt (dB)
Upstream Reference PSD (dBmV/6.4MHz)	39	49	10

Table 2 has been illustrated in the graph below:

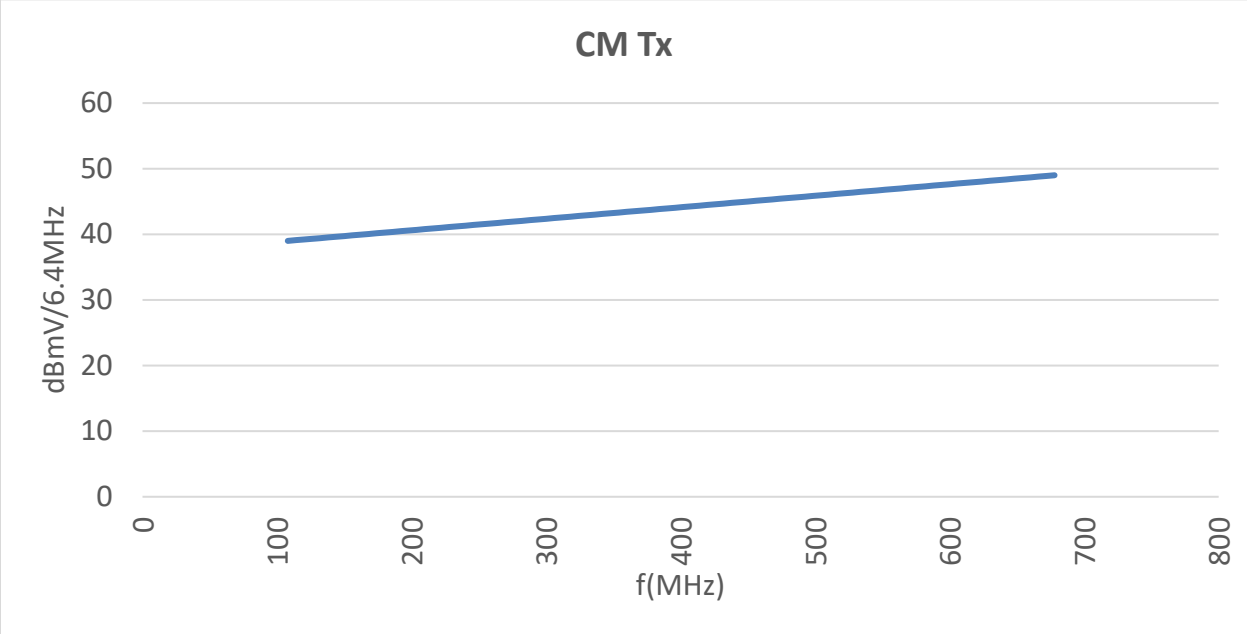

Figure 1 – DOCSIS 4.0 CM Tx Levels

2.3. CM Tx Modulation Error Rate (MER)

According to DOCSIS 4.0 CM PHY specifications, the following CM MER can be assumed:

Table 3 – DOCSIS 4.0 CM Tx MER

Grant	Tx MER
100% Grant (all OFDMA Mini Slots Used)	Each mini-slot MER ≥ 42 dB
Under-Grant Hold Bandwidth (UGHB)	Each mini-slot MER ≥ 47 dB

2.4. Modulation Order vs. Power and Carrier to noise

In order to have a baseline for achievable modulation orders throughout the plant in the US, Table 39 from the DOCSIS 4.0 PHY specification has been utilized. DOCSIS 4.0 PHY Table 39 outlines the performance that can be expected based on carrier to noise ratio (CNR) and power level received at the DAA node. Throughout this paper, power levels and CNR have been addressed to determine if one (or both) are limiting factors in performance.

The DOCSIS 4.0 PHY Table 39 does not account for the internal loss of the DAA node. For this reason, the required power levels for each modulation order have been increased by 3 dB to account for the additional insertion loss from the port of the amplifier to the remote-PHY-device (RPD) and/or remote-MAC/PHY-device (RMD) module, demonstrated in Table 4.

Table 4 – Constellation vs. Power vs. CNR

Constellation	CNR (dB)	Set Point (dBmV/6.4 MHz)
QPSK	11.0	-1
8-QAM	14.0	-1
16-QAM	17.0	-1
32-QAM	20.0	-1
64-QAM	23.0	-1
128-QAM	26.0	3
256-QAM	29.0	3
512-QAM	32.5	3
1024-QAM	35.5	3
2048-QAM	39.0	10
4096-QAM	43.0	13

CNR in the table above is otherwise referred to as signal to noise ratio (SNR) or MER.

SNR and MER have been used interchangeably throughout this paper. In Section 2.10 carrier to composite noise (CCN) has also been used as a method to estimate SNR/MER.

Section 5 explores expected performance in various plant architectures.

2.5. Amplifier Noise Figures

In order to determine the capability and performance in a cascade line, the noise figure of the return path amplifiers should be specified. The table below demonstrates this.

Table 5 – Return Path Amplifier Noise Figure

Return Path (US) Amplifier NF	6 dB

2.6. DOCSIS 4.0 Plant Models

The following plant models were created as a part of the DOCSIS 4.0 project:

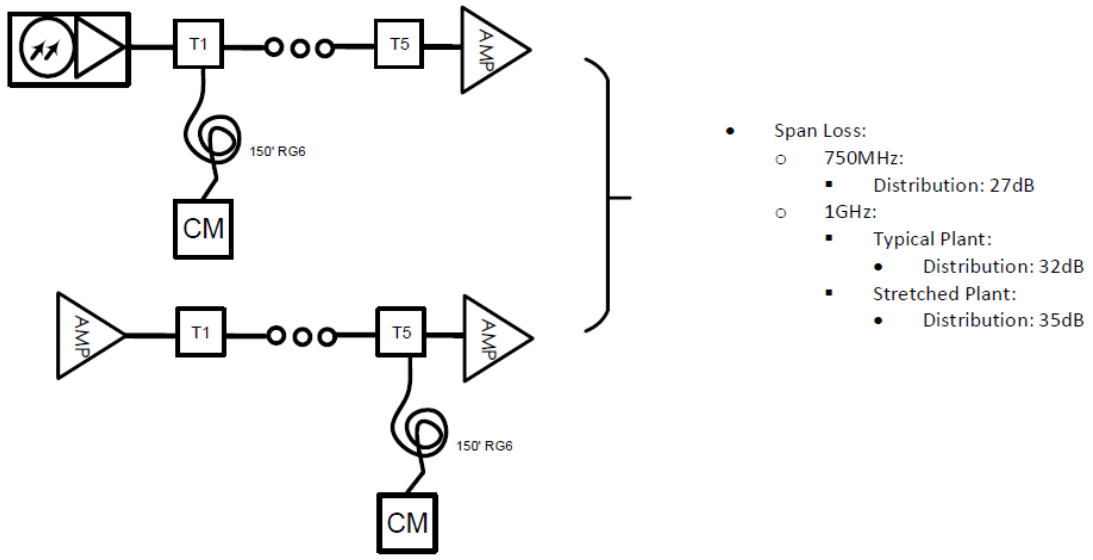

Figure 2 – DOCSIS Plant Models

In order to create a 'reasonable worst-case scenario' plant to analyze which essentially covers a higher percentile of the architectures MSOs might encounter in the outside plant (OSP), a distribution plant with 35 dB of span loss at 1 GHz has been considered. Refer to Section 3 for further details.

2.7. Noise

Designing a cascaded system for optimal CNR is always a top priority for an operator. One of the biggest contributors in network design is the receive (Rx) power at the amplifier, given that it is one of the primary drivers for achieving higher CNR throughout the distribution plant.

The minimum thermal noise power can be calculated using the following formula:

$$n_p = kTB$$

Where:

- n_p = noise power in watts
- k = Boltzmann's constant (1.34×10^{-23} joules/K)
- T = absolute temperature in K
- B = bandwidth of the measurement in Hz

The thermal noise in ~16.7 °c expressed in dBmV/6.4MHz is:

$$N_p = 57.1\ dBmV$$

The conversion of bandwidth from 6 MHz to 6.4 MHz has been rounded up from 0.28 dB to 0.3 dB.

From the equations above, carrier to noise can be calculated using the following formula:

$$C/N\,(dB) = \ C_i(dBmV) + 57.1 - NF(dB)$$

Where:

- C_i = input signal
- NF = noise figure of the amplifier

The equation above shows the significance of the Rx power versus noise figure of the amplifier, in network design.

The overall cascade C/N for amplifiers operating at different output levels can be derived from the following equation:

$$C/N_{total}\,(dB) = -10log\left\{10^{\frac{-C/N1}{10}} + 10^{\frac{-C/N2}{10}} + \cdots + 10^{\frac{-C/Nn}{10}}\right\}$$

Where, C/N_x is the carrier to noise of each amplifier calculated independently.

When cascading identical amplifiers operating at the same output level, the following approximation is typically used:

$$C/N_{total}\,(dB) = C/N_x - 10log_n$$

Where:

- C/N_x = the carrier to noise of a single amplifier
- $n =$ the number of identical amplifiers in cascade

2.8. Distortion

Distortion products from an amplifier or cascade of amplifiers have historically been characterized by measuring second order (CSO) and composite triple beat (CTB) on analog carriers. These distortion products are harmonics of the primary signal. Today, however, MSOs primarily use digital carriers. Digital carriers' distortion products do not appear similar to those of analog carriers. Instead, they appear very similar to a raised noise floor. For this reason, composite intermodulation noise (CIN) is the best way to characterize the distortion performance of amplifiers today.

The rate of accumulation of CIN products is dependent on many factors but two primary factors in how fast CIN accumulates are the amount of total composite power (TCP) utilized in the gain chip and the output level. In this paper, it is assumed that CIN products will accumulate at a 10*log rate.

2.9. Carrier to Composite Noise (CCN)

In this paper, CCN has been used as the primary method of determining signal quality. Although SNR and MER can be measured using meters and measurement equipment, there are inconsistencies in these types of measurements, especially when using different measuring equipment [4]. Some of these are:

- Equalized vs. unequalized MER measurements
- Measuring device noise floor (NF)
- Input level to the measuring equipment
- Temperature

In order to remove these inconsistencies, this paper aims to calculate CCN as a more consistent representation of signal quality based on input power levels, carrier to thermal noise (CTN), and CIN from each equipment. The formula used for calculating CCN is outlined below:

$$CCN(dB) = -10log\left\{10^{\frac{-Starting\ CCN/SNR/MER}{10}} + 10^{\frac{-CTN_{Total}}{10}} + 10^{\frac{-CIN_{Total}}{10}}\right\}$$

3. Plant Model Created

Based on the assumptions made for DOCSIS 4.0 plant models in Section 2.7, the plant model below has been created as a 'reasonable worst-case scenario' for analysis. This plant model results in roughly 35 dB of span loss at 1 GHz, which can be considered 'stretched' for today's standards of deployment, as per Section 2.6. Consideration that the following plant model encompasses a higher percentage of the scenarios that one might encounter in the outside plant has been covered.

Figure 3 – Analyzed Plant Mode – 35 dB Span Loss

As demonstrated above, a 26 dB tap value has been considered for an ultra-high-split (396 and 492 MHz) scenario and a 23 dB tap has been considered for a high-split scenario, both of which are analyzed further in this paper.

4. Analysis

4.1. Upstream Spectrum Bandwidth

Further to Section 2.11, in order to accurately set a baseline for the input power to the return path amplifier, the noise-power ratio (NPR) of the amplifiers must be studied. Due to lack of availability of NPR data at the time of writing, the following assumption has been made:

$$P_i(new) = P_i(legacy) - 10 * \log\left({}^{new\ BW}/_{legacy\ BW}\right)$$

Where:

- $P_i(new)$ = the new input power /6.4 MHz into the return path amplifier
- $P_i(legacy)$ = the current input power /6.4 MHz into the return path amplifier

An assumption has been made that the current input level to the return path amplifiers in an 85 MHz plant is 16 dBmV/6.4MHz. In this case the following table can be calculated using the formula above.

Table 6 – Return Path Expected Levels for US Splits

Return Path BW	Input Power to Return Path Amp. (dBmV/6.4MHz)
85 MHz	16
204 MHz	12
396 MHz	9
492 MHz	8

Historically MSOs have tried keep CM Tx levels as high as possible to keep carrier-to-ingress-noise as high as possible, but at the same time may have exhausted the transmit capability of the CM TCS. With that said, reducing Rx power levels into the return path amplifiers should not be a significant concern, assuming that regular plant maintenance and plant hardening practices are carried out.

Moreover, high transmit levels out of the modem can potentially increase the risk for interference between adjacent homes, as demonstrated in Section 4.3.

4.2. CM TCS's

DOCSIS 4.0 CMs will have two TCS's, one of which is capable of transmitting up to 204 MHz and the other from 108 MHz up to 684 MHz. It should be noted that there is an overlap region between the two TCS frequency bands.

The overlap region between the two TCS's can be used to the operator's advantage for near-term high-split deployment and long-term ultra-high-split deployment. MSOs have always tried to keep CM Tx levels as high as possible, both for achieving high SNRs and high carrier-to-ingress-noise. As discussed in the previous section, although the input to the return path amplifier has to be reduced by roughly 4 dB when expanding the return spectrum from 85 MHz to 204 MHz, that does not necessarily mean that modem transmit levels have to be reduced.

Amplifiers have the ability to pad the signal prior to the return (and forward) path amplifiers. Additionally, many MSOs condition their taps in the distribution line to 'force' CMs to transmit with high levels, increasing their source SNR/MER. In other words, CM transmit power, source (CM) MER and input to the return path amplifier chips have to be balanced by the MSO. Therefore, MSOs should try to optimize the amount of TCP available in the CM TCS without leaving 'unused power', which can help increase the CM Tx MER.

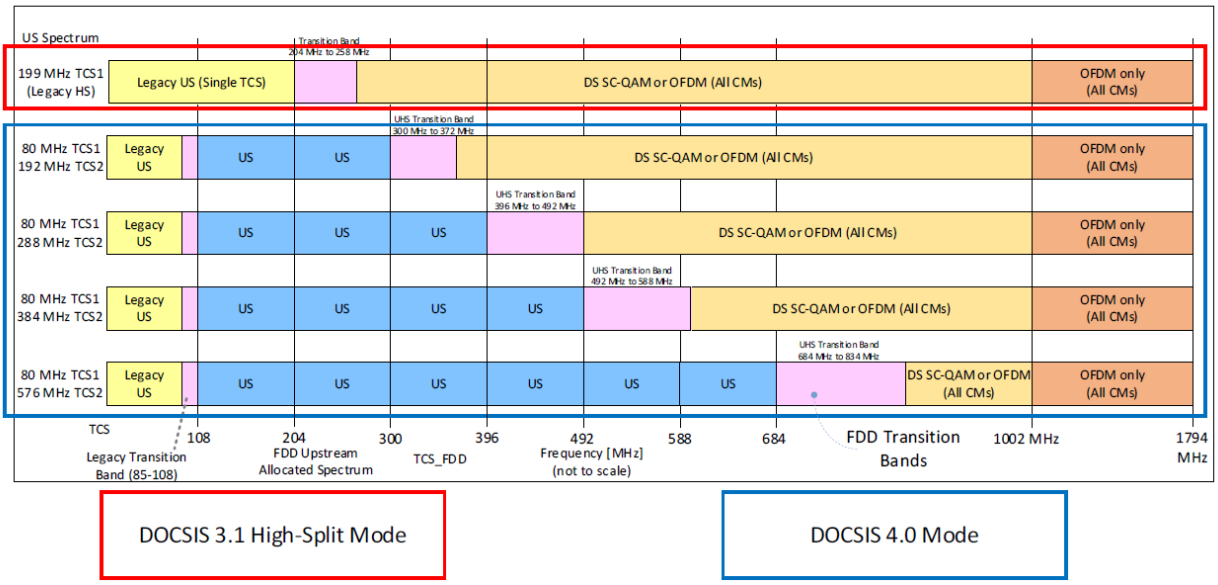

Figure 4 – Configurable FDD Upstream Allocated Spectrum Bandwidths

4.3. 204MHz Analysis

Based on the plant model discussed in Section 3, the following loss values can be calculated from the CM at the end of a 150' RG6 drop, installed as a point of entry device (PoE) to the amplifier or node port:

Table 7 – Plant Model Loss Values

Loss from each CM to Amp Port:					
Freq. (MHz)	**Tap 1 (23)**	**Tap 2 (23)**	**Tap 3 (17)**	**Tap 4 (14)**	**Tap 5 (11)**
5	23.87	22.39	20.91	19.83	19.55
30	24.77	23.78	22.79	22.20	22.40
50	25.29	24.54	23.80	23.45	23.90
83	25.93	25.48	25.03	24.98	25.71
108	26.34	26.07	25.82	25.95	26.87
150	26.91	26.96	27.03	27.47	28.70
204	27.54	27.96	28.38	29.19	30.76

Referring to Table 6, although the input to the 204 MHz return path amplifier needs to be reduced by 4 dB, the receive levels at the port of the amplifier is kept at 16 dBmV/6.4 MHz to determine if the CM has enough power to transmit to the amplifier port in this plant model. This is shown in Table 8.

Table 8 – CM Tx Levels to Amplifier or Node Port

CM Tx/6.4MHz to Port – 16 dBmV/6.4MHz Rx Level					
Freq. (MHz)	**Tap 1 (23)**	**Tap 2 (23)**	**Tap 3 (17)**	**Tap 4 (14)**	**Tap 5 (11)**
5	39.87	38.39	36.91	35.83	35.55
30	40.77	39.78	38.79	38.20	38.40
50	41.29	40.54	39.80	39.45	39.90
83	41.93	41.48	41.03	40.98	41.71
108	42.34	42.07	41.82	41.95	42.87
150	42.91	42.96	43.03	43.47	44.70
204	43.54	43.96	44.38	45.19	46.76

Knowing that the TCS is capable of 65 dBmV of TCP means that the modem can transmit 50 dBmV/6.4 MHz from 5 MHz to 204 MHz. As can be seen in the table above, the transmit levels are well below the TCP limit of the CM TCS. This can help the operator keep CM transmit levels 'consistent' with mid-split levels.

This is only true if the MSO is operating in 204 MHz return plant. If the return path spectrum is expanded to any frequency higher than 204 MHz, the first TCS will be limited to 108 MHz.

Another item to note is that the modem can in fact transmit with an 'up-tilt' (Table 9). This will be used in Section 4.4 for evaluating adjacent channel interference (ACI).

It can also be seen that we are now operating closer to the CM dynamic range window (DRW). Although many operators will not deploy any carriers below 15 MHz due to noise concerns, the modem can still transmit with up-tilt, as high as ~9 dB of tilt. This can cause concerns with the DRW of the CM, given that the current CMs have a maximum DRW of 12 dB.

4.4. Near Term Risk Analysis

In [3], a method for estimating the level of risk for ACI is outlined. Figure 5 demonstrates this method. It can be seen that with higher modem transmit levels—up to 204 MHz and beyond—the potential for energy leakage between adjacent tap ports increases. This additional energy in the adjacent home, assumed to be a 'legacy' mid-split home, can interfere with set top boxes (STB) and CMs. When the delta between the interferer and the downstream received signal for the legacy device goes above a certain threshold, depending on the front-end design of each device, it can cause degraded service.

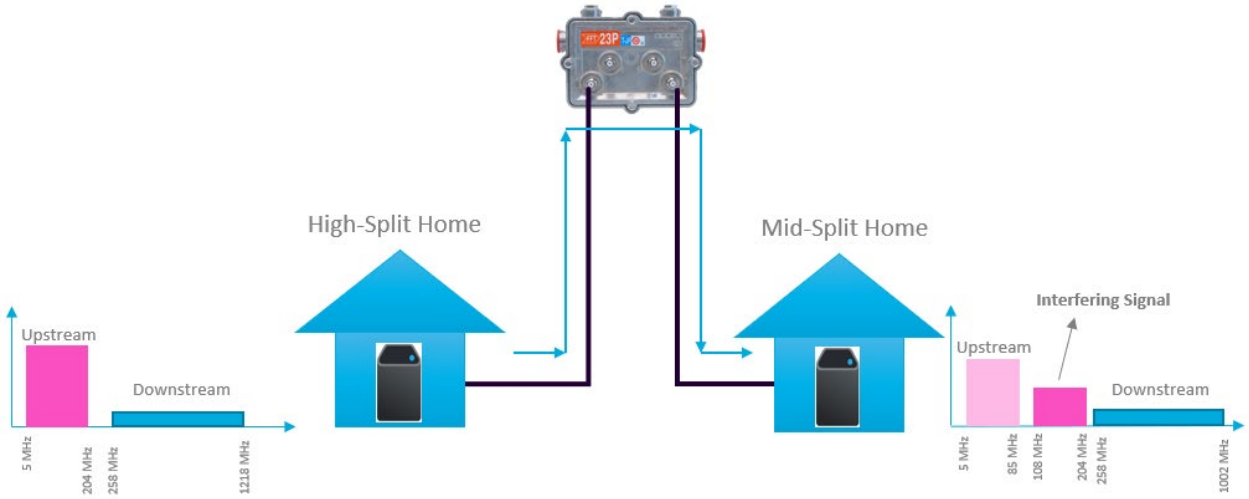

Figure 5 – Adjacent Home Interference – 204 MHz

A few modifications have been made to the methodology used in Dr. Prodan's paper to better outline the level of risk when an operator moves to high-split and ultra-high-split.

Prior to the analysis, the following should be noted:

- Based on Table 9 (below), the CM can transmit with 3 dB higher power per measured BW.
  - This has been determined by averaging the transmit levels from Table 9 from 85 MHz to 204 MHz.
- Tx levels close to 85 MHz have been gathered from the mid-split capable modems in the field.
- Rx levels close to 258 MHz have been gathered from the mid-split capable modems in the field.
- The high-split and mid-split devices are installed behind two-way splitters.

With that in mind, the following formulas can be used to evaluate the level of risk:

$$P_{loss} = (tap\ port\ to\ port\ isolation) + 2 * (drop\ cable\ attenuation + in\ home\ splitter\ loss)$$

$$Adjacent\ Channel\ Interferene\ (ACI) = CM\ Tx\ Level + 3(dB) - P_{loss}$$

$$Carrier\ to\ Adjacent\ Channel\ Interference\ Ratio\ (CACIR) = CM\ Rx\ Level - ACI$$

Along with the assumptions above, let us also assume that the tap port-to-port isolations can be any of the following:

- 20 dB
- 25 dB
- 30 dB

Table 9 outlines the assumed loss values for this analysis.

Table 9 – Averaged Loss Values

Loss Value Table	Drop (100' RG6)	Splitter	Port-to-Port Iso
	4 dB (Averaged from 108 – 204MHz)	3.5 dB (2-way splitter insertion loss)	20, 25, 30 dB

Tap port-to-port isolations are dependent on the frequency in which they are measured, along with the internal splitting formation of the tap ports. The values in the table above are assumed to be averaged across the spectrum.

Based on these numbers, the following figure was produced by sorting the calculated carrier to adjacent channel interference ratio (CACIR) value for each modem in an ascending order:

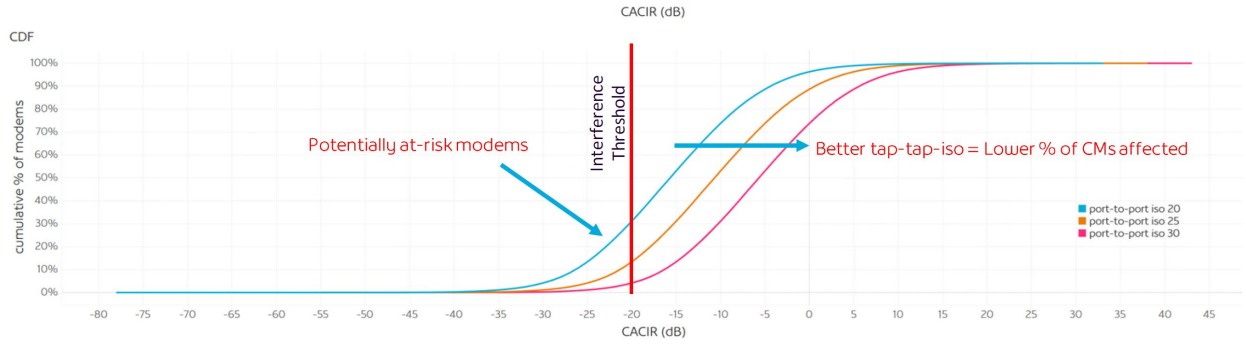

Figure 6 – CACIR Cumulitive Density Function

As seen in the figure above, the tap-to-tap isolation values of 20-, 25- or 30-dB result in vastly different levels of risks for interference in the field.

The CACIR threshold of -20 dB is set as a baseline for this study. Various devices in the field, including CMs with different front ends, can change this threshold and by extension the level of risk.

4.5. Ultra High-split Analysis

To determine shortfalls in the upstream with regards to the modem transmit power, it is assumed that all of the modems in the analyzed plant model are transmitting with their maximum capability (see Figure 1). Note that the focus of this analysis is on ultra-high-split TCS in the DOCSIS 4.0 CM. Refer to Section 4.2 for further information.

Figure 7 on Receive Power /6.4 MHz at the node and amplifier ports was created based on the required levels in Table 6, along with CM Tx capabilities and the assumed plant model, in Sections 2.2 and 3 respectively.

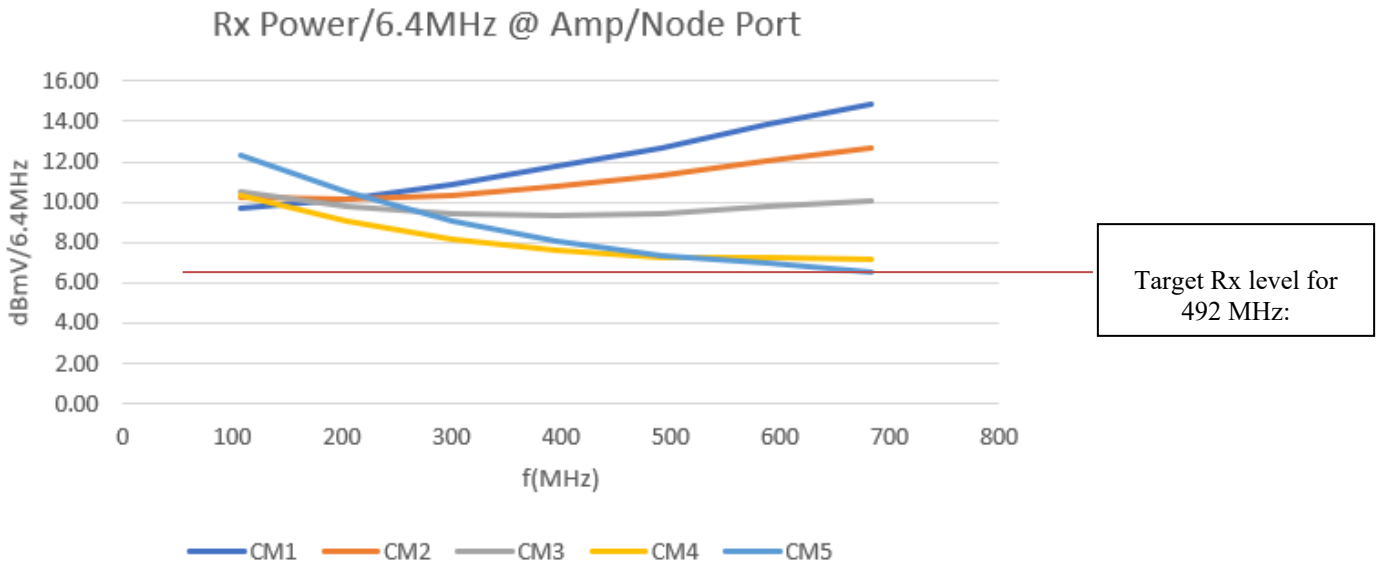

Figure 7 – Receive Power /6.4 MHz at Node and Amplifier Port

It can be observed that the modems installed at the end of the drop from Taps 1-3 have plenty of headroom in comparison to the target levels assumed at the port. It can also be seen that 'lower' receive levels at the amplifier port are only a concern for higher frequencies in modems that are in lower value taps (farther away from the node and amplifiers).

Figure 7 shows that frequency allocations (frequency stacking) appear to be an appealing approach for CMs. Essentially, although the DOCSIS 4.0 CMs will bond to all the Orthogonal Frequency Division Multiple Access (OFDMA) channels available in the spectrum, the CMs that are closer to the node/amplifier can use higher frequencies more efficiently given the 'headroom' available to them. Consequently, CMs that are farther away from the node and amplifiers can use lower portions of the spectrum.

As data usage patterns today outline, CMs will rarely use all the channels that they have bonded to. They will only do so in instances when large files are being uploaded or a speed test is being performed. For a majority of the usage cases, frequency stacking seems to be an appealing option for MSOs to optimize their return path, assuming the CMs do not do this automatically.

4.5.1. Splitter Added to the Plant Model

In this section the effect of additional flat losses such as splitters in the mainline will be discussed. When designing the plant, all additional insertion losses must be taken into account. This means that if a two-way splitter was to be added to the plant model, the 5 dB additional insertion loss must be deducted from the overall span loss, equaling to 30 dB of overall loss. As a result, the total span length of the original plant model could be reduced by roughly 200 feet. Figure 8 demonstrates this concept.

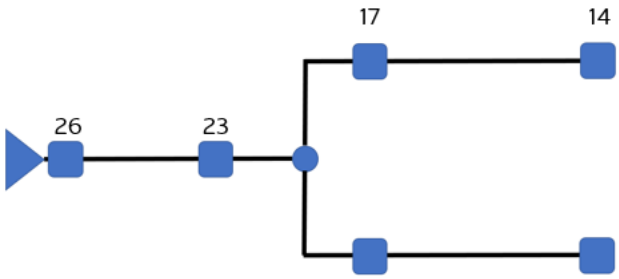

Figure 8 – Plant Model with Added Two-Way Splitter

Based on the new plant model, the receive levels at the port can be revised, as illustrated in Figure 9.

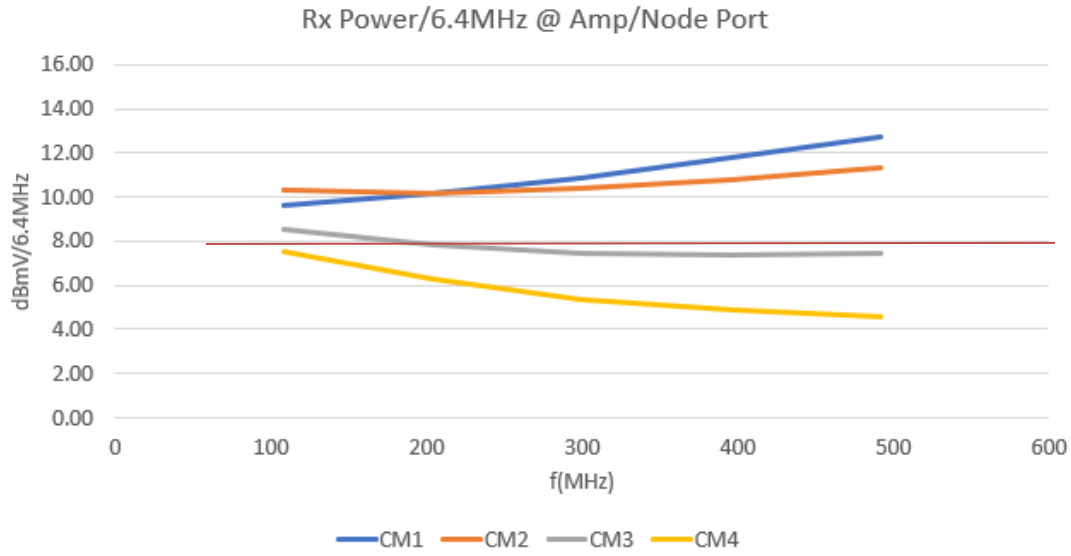

Figure 9 – Receive Power /6.4 MHz at Node and Amplifier Port

It can be observed that the upstream signals from CMs behind the mainline two-way splitter are received with less power than the target level of 8 dBmV/6.4 MHz for 492 MHz of return bandwidth (BW), based on Table 7. This may seem concerning at first but knowing that many MSOs will not be utilizing the entire 684 MHz of return BW, the CM can theoretically allocate the unused TCP from the higher portion of the spectrum to lower parts. For the purpose of this example, an assumption has been made that a maximum return BW of 492 MHz has been planned as a part of DOCSIS 4.0 upgrades. With most of the TCP concentrated at the higher frequencies, the CM can theoretically 'raise' the original transmit power by roughly 4 dB. However, in order to avoid concerns with spurious emissions, this paper assumes that the modem has 3 dB of additional power per channel, shown in the figure below.

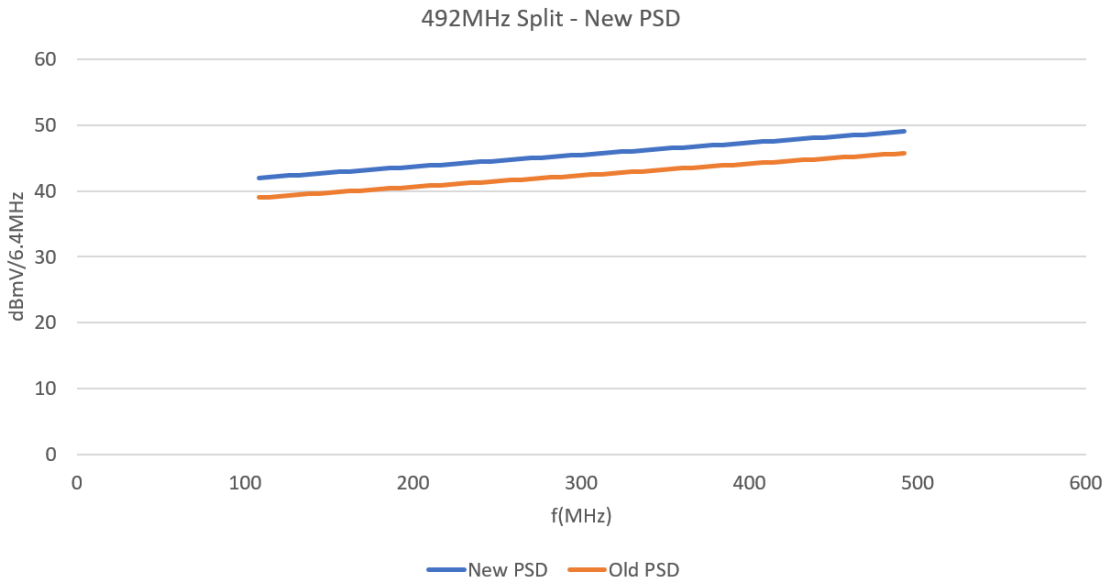

Figure 10 – CM Tx Level with 3 dB Boost for 492 MHz Split

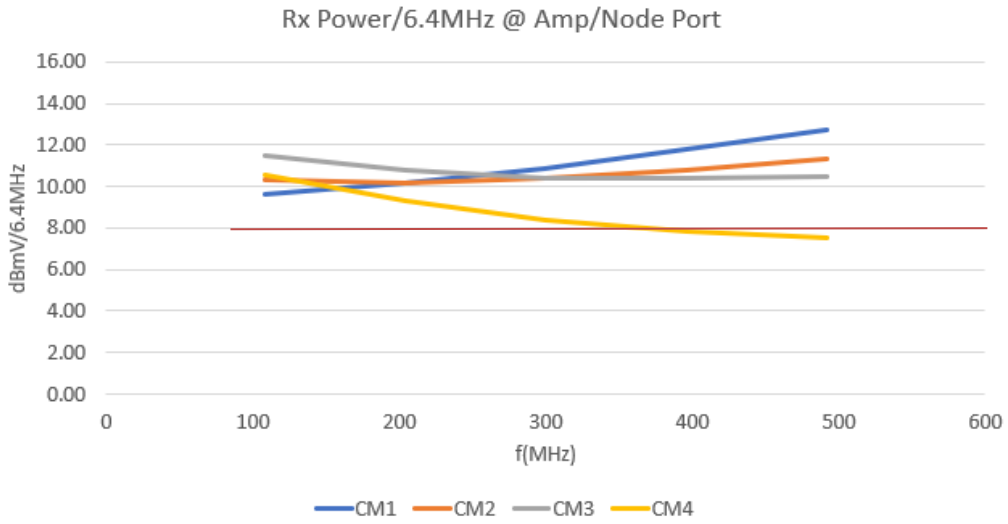
Applying the new CM PSD to the same plant model, the following receive levels can be expected at the port of the node and amplifiers:



Target Rx level for 492 MHz:

Figure 11 – Receive Power /6.4 MHz at Node and Amplifier Port

The raised CM PSD and increased power levels from the CM can increase the risk for ACI. Close examination of this option in various plant models and scenarios prior to deployment is encouraged.

It should be noted that receiving below the rated level for each upstream split (outlined in Table 7) will not always result in a noticeable MER degradation. CCN and MER are highly dependent on the source MER and the NF of each amplifier in the return path, along with the cumulative noise and distortion products from each amplifier. This will be explored more in Section 5 of this paper.

4.5.2. Flat Losses – The Limiting Factor

One of the most significant results from the studies done in Section 4.5, and particularly in Section 4.5.1 when a two-way splitter was added to the plant model, is that high flat losses appear to be the most limiting factor in the upstream.

The plant model analyzed was 35 dB of span loss at 1 GHz, which can be considered quite 'stretched' for today's OSP span losses. It was observed that CMs in the plant model at the end of 150 feet of RG6 cable should be able to make it back to the amplifier and node ports, approximately within the range of 396 or 492 MHz, which are being considered by many MSOs. In other words, coaxial loss is something that has been taken into consideration in the CM design with the ultra-high-split TCS.

Flat losses can be somewhat challenging to overcome, especially in the upstream. Flat losses, as the name suggests, affect the entire spectrum in the same way, meaning that it cannot be overcome by tilt. It should be noted that this analysis was undertaken with only a two-way splitter. There are other types of OSP equipment currently deployed by MSOs that have much higher amounts of flat loss across the spectrum, namely, couplers and multi-dwelling-unit (MDU) style indoor splitters. The additional flat loss can cause concerns due to the modem having to transmit at close to maximum across the entire spectrum for the carriers to be received at the target level. This can potentially cause the CM to go into partial service mode due to insufficient Tx power. The overall upstream performance will be discussed further in Section 5.

5. Signal Quality and Noise Funneling

In order to quantify performance in the network both signal quality and power must be taken into consideration. Thus far, this paper has analyzed signal power in the plant models created for DOCSIS 4.0 networks. We discussed how the CM is able to overcome coaxial loss due to its increased TCP, output power level and tilt in the upstream. However, that does not indicate the signal quality that can be expected in the upstream. In this section, we analyze the possible upstream MER and outline limiting factors.

SNR and MER modeling in the upstream can be quite challenging due to the funneling effect. To define it broadly, noise funneling is the summation of all the unwanted noise and distortions in the return path. There can be many different sources of noise funneling, such as impulse noise, ingress noise and common path distortion (CPD). Generally, it is accepted that if the plant is free of physical impairments such as cuts in cable or unterminated taps, the funneling effects from the sources mentioned above can be minimized, if not resolved. For this paper, we focus instead on the amplifiers in the field and how they contribute to thermal noise (CTN) and distortion (CIN) accumulations in the upstream.

DOCSIS 4.0 technology is designed to be deployed in a cascaded environment. Although the number of amplifiers in cascade (series) is one of the most important factors in the downstream, for upstream, as it currently stands today, it is the total number of amplifiers. As an example, an N+6 plant with no splitters can have up to 24 amplifiers, assuming four outputs from the node. This number can increase dramatically with the addition of splitters in the topology.

In reality MSOs will deploy different amplifier types for their gain capabilities and the number of output ports, such as multi-port amplifiers and line extenders. However, this will not have a significant impact on overall performance, as will be demonstrated further in this section. In this paper, all amplifiers are assumed to be identical with the same NF mentioned in Section 2.5.

In order to quantify performance and determine the most important factor, the following has been assumed:

- Amplifier NF: 6 dB
- Amplifier CIN: 56 dB
- Input level to each amplifier in the return path: 6 dB flat across the spectrum
- Number of ports utilized in the node: 4
- CTN: All amplifiers on either the entire node or each leg that would contribute to signal degradation
- CIN: Only the amplifiers in series on each leg of the node that would contribute to signal degradation

Following the assumptions above, we need to consider the number of amplifiers that exist both in series and in total. On the one hand, the total number of amplifiers is what is considered for the cumulative effect of thermal noise funneling from each individual amplifier in the node, assuming that each leg of the node cannot be isolated and they all funnel into a single port in the return. The amplifiers in series, on the other hand, would be contributing to total CIN in each leg of the node along with the total CTN, assuming that port of the node has been isolated. Utilizing the formulas outline in Sections 2.8, 2.9 and 2.10, Tables 10 and 11 can be calculated.

Table 10 – Upstream Peformance – All Ports Funneled

Total Number of Amplifiers	CTN	CIN	Source MER (38 dB)	Source MER (40 dB)	Source MER (47 dB)
16	45.36	49.98	37.04	38.56	42.28
32	42.35	48.22	36.35	37.61	40.3
44	40.97	47.55	35.92	37.04	39.3
56	39.92	46.97	35.52	36.54	38.48
68	39.07	46.00	35.12	36.04	37.73

Table 11 – Upstream Performance – Single Amplifier Leg

Total Amps in Series	CTN	CIN	Source MER (38 dB)	Source MER (40 dB)	Source MER (47 dB)
4	51.38	49.98	37.55	39.31	44.29
6	48.37	48.22	37.26	38.87	43.05
7	46.99	47.55	37.08	38.61	42.4
8	45.94	46.97	36.9	38.37	41.84
10	45.1	46.00	36.68	38.07	41.19

To better compare the results, the MER values for each table have been plotted in Figures 12 and 13.

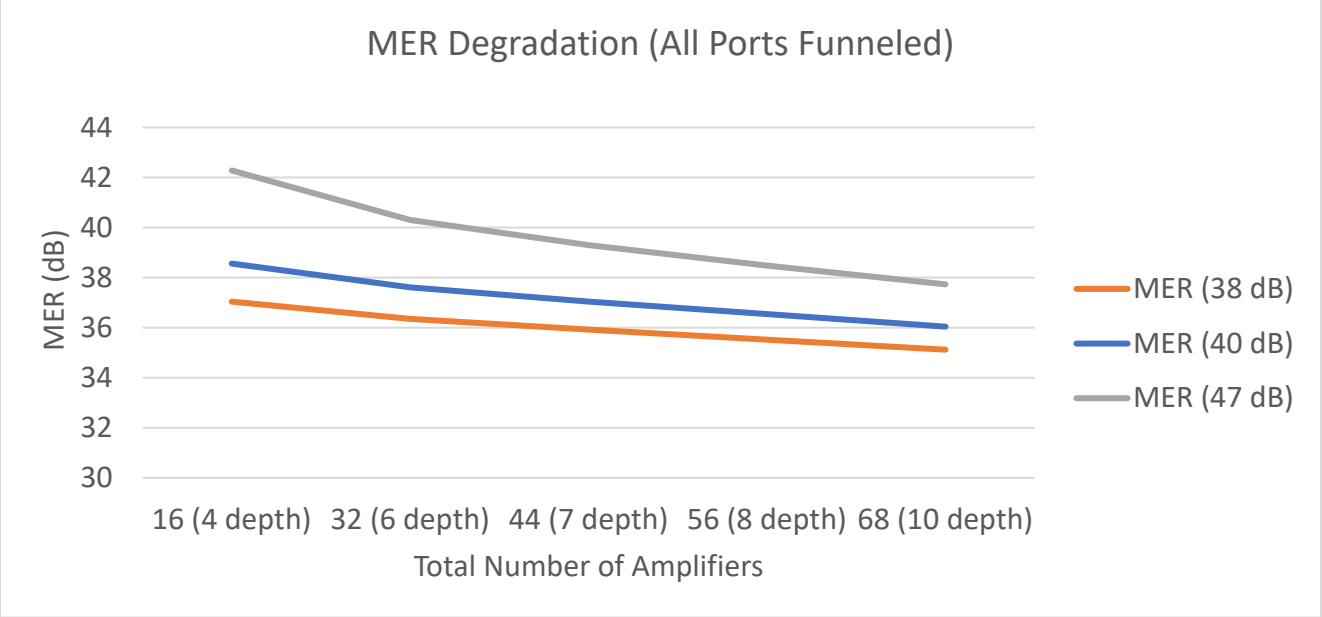


Figure 12 – MER vs. Total Number of Amplifiers – All Ports Funneled

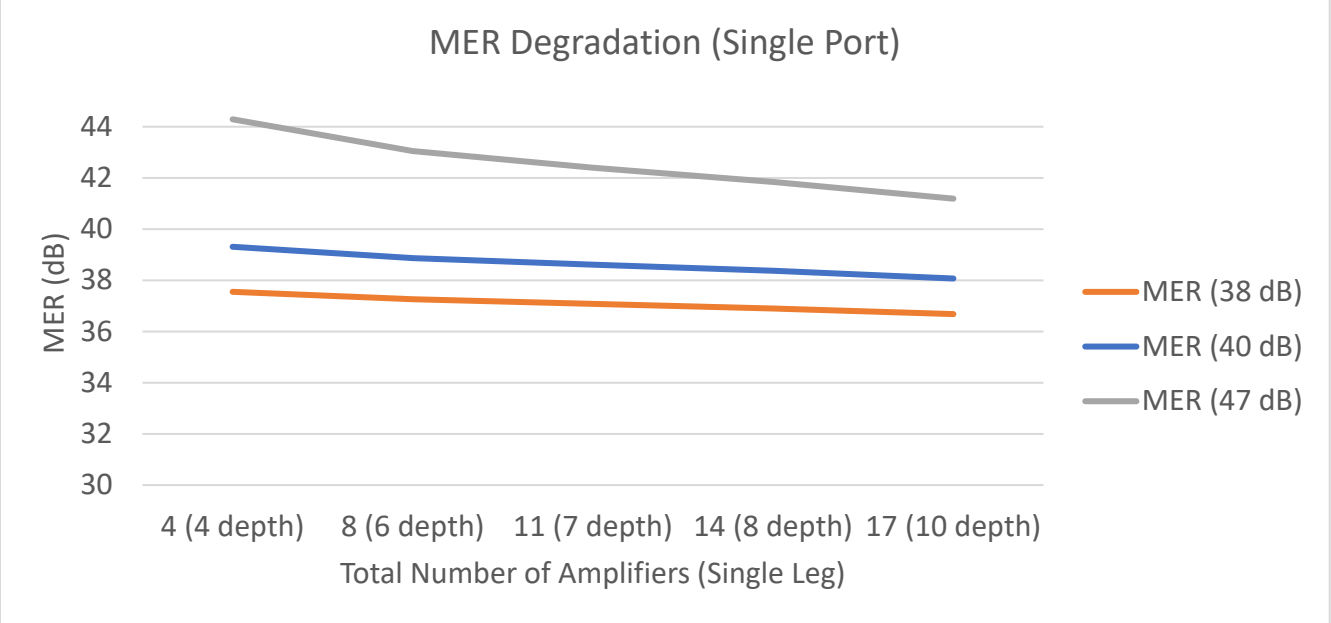

Figure 13 – MER vs. Total Number of Amplifiers – Single Amplifier Leg

When considering Tables 11 and 12, as well as Figures 12 and 13, a few interesting observations can be made. First and foremost, it can be observed that higher starting MERs such as 47 dB are more subject to degradation when exposed to noise and distortions. Figure 13 demonstrates that even with the addition of four amplifiers a ~3 dB MER reduction is realized. This reduction is then somewhat 'flattened' with further additions to noise and distortion products.

The most interesting observation from the figures above is that the 'starting MER' is arguably the most important factor in achieving higher orders of modulation. As an example, let's focus on a source MER of

40 dB as per Figure 12. There is only ~2.5 dB of additional MER reduction when the total number of amplifiers is increased from 16 to 68. Expanding on that further, focusing on the 38 dB MER graph in Figure 12, it can be seen that by reducing the number of amplifiers from 56 to 32 by performing a node split, the MER is increased by roughly1 dB. Alternatively, if the starting MER was increased by 2 dB to 40 dB, the same results can be achieved. Conversely, the total number of amplifiers or reduction of the cascade depth does not yield substantial MER increases in the upstream.

Lastly, it can be observed that isolating each leg of the node will yield more noticeable increases in MER for higher MER values. This is also true for reducing the total number of amplifiers.

It is very important to note that the results above do not tell the whole story of why it is important to be able to isolate each leg of the node from one another. Although this will have a direct positive impact on upstream performance, it also isolates noise from other sources (ingress noise) to one leg of the node. Additionally, node splits have many other benefits such as reducing the number of customers sharing the same data pipe and pushing fibre deeper into the HFC networks. These benefits are extremely important but have not been quantified in this paper.

6. Conclusion

DOCSIS 4.0 technology has been developed to enable HFC networks to provide multi-gigabit services. In this paper, a reasonable worst-case scenario plant was analyzed to estimate the capability of current HFC networks, with no amplifier re-spacing. It should be noted that the 35 dB span loss model was considered a ‘stretched’ plant by many MSOs during the development of DOCSIS 4.0 sets of specifications and plant models.

This study observed that achieving higher orders of modulation such as 1024 QAM is possible for the majority of cases. The only areas of concern for legacy plant design are areas where high flat losses are incurred in the upstream, namely due to splitters and couplers. This is only an issue in ‘stretched’ plant areas where there is already a higher amount of insertion loss from the modems installed at the end of drops and the end of line taps. How a modem can overcome the higher insertion loss with higher transmit powers was also discussed, assuming the operator does not utilize the entire 684 MHz band capability of the CM in the upstream. This should be balanced in conjunction with neighbour interference, since higher transmit levels from the CM can lead to additional neighbour interference cases between DOCSIS 4.0 devices and ‘legacy’ devices. MSOs will have to balance many moving parts, especially CM transmit powers, in order to optimize performance in the upstream to achieve higher source MER and high carrier-to-ingress noise ratio.

MSOs should optimize the TCP and power available in the modem to ensure sufficiently high transmit powers for higher transmit MER. This can assist with achieving higher orders of modulation in the upstream, along with a higher carrier to interference noise ratio. We also noted that funneling and the total number of amplifiers play a part in the overall signal quality in the upstream. Further, isolating each leg of the node from one another in the upstream results in a better overall signal quality. It can also help with isolating ingress noise to a particular leg, rather than it funneling to all ports in the return path. Finally, the source MER from the CM is one of the most—if not *the* most—important factor in the overall signal quality in the upstream. This can help MSOs prioritize efforts for increasing upstream capacity in the most efficient manner.

Abbreviations

ACI	adjacent channel interference
CACIR	carrier to adjacent channel interference ratio
CCN	carrier to composite noise ratio
C/N	carrier to noise ratio
CIN	carrier to intermodulation noise
CINR	carrier to interface noise ratio
CM	cable modem
CMTS	cable modem termination system
CNR	carrier to noise ratio
CPD	common path distortion
CSO	composite second order distortion
CTB	composite triple beat distortion
CTN	carrier to thermal noise
DAA	distributed access architecture
dB	decibels
dBmV	decibels relative to one millivolt
DAA	distributed access architecture
DRW	dynamic range window
DOCSIS	data over cable service interface specification
DS	downstream
ESD	extended spectrum DOCSIS

1. Introduction

Enterprises are looking for dedicated wireless networks that offer better control, which can be used to solve operational challenges. Private LTE and 5G networks offer reliability, ubiquitous coverage, high user capacity, and built-in security. Private networks combined with multi-access edge computing (MEC) also give the ability for enterprises to keep data on premises and implement use cases that require low latency.

Over the last year, Charter Communications has continued to work with CBRS spectrum in the private networks space. Charter has evaluated various vendor solutions for private LTE/5G networks. In addition, we have also deployed a private LTE network in a large manufacturing plant in Michigan and have plans to work with customers in other verticals. In this paper, we explain the main motivation behind deploying a private LTE/5G network and how it can be implemented. Second, we present different use cases that can be served by this network in the industrial, healthcare, and education verticals. Third, we show the criteria for vendor selection in our lab evaluation. Fourth, we illustrate the deployment of our first private LTE network in a factory.

1.1. Citizens Broadband Radio Services (CBRS) overview

In April 2015, The Federal Communications Commission (FCC) made the decision to establish Citizens Broadband Radio Services spectrum in the United States. This is a section of 150 MHz spectrum between 3.55 GHz and 3.70 GHz, which was originally used by the government for the military or by wireless internet service providers (WISPS). This decision by the FCC opened up CBRS spectrum to be shared on a dynamic basis depending on the user priority [1].

One of the key components of CBRS is the tiered sharing structure. This is achieved by establishing three different tiers of users, each allowed to use the band at any given time. Below is a brief description of some of the key components of this sharing structure in CBRS.

Spectrum Access System (SAS): The spectrum access system was set up to coordinate between the different users using CBRS spectrum. All Citizens Broadband Service Devices (CBSD) must register with the SAS before being allowed to transmit.

Tiers of users

- Incumbents – These are federal government, fixed satellite users and any grandfathered wireless internet service providers. They are granted interference protection from the other tiers below (PAL and GAA)
- Priority Access License (PAL) – These are licensed users who have access to 70 MHz of spectrum and up to a maximum of 40 MHz per licensee. They are protected from interference from the lower tiers but must cease transmitting to protect the incumbents if determined by SAS.
- General authorized access (GAA): These users can use the entire 150 MHz of spectrum as long as there is no one else using the spectrum within the area. They do not receive interference protection from any of the other tiers of users.

CBSD: CBSDs are defined as fixed radiating antennas and could be small cells, remote radio heads, DAS systems or a combination of all. There are two different kinds of CBSDs:

Table 1 - CBSD categories

CBSD category	EIRP limits	Comments
Category A CBSD	30 dBm / 10 MHz	Limited to indoor deployments. Outdoor deployment maximum height is 6 meters height above average terrain (HAAT)
Category B CBSD	47 dBm / 10 MHz	Limited to outdoor deployments and must be installed by CPIs

Certified professional installers (CPI): All CBSDs must be registered with the SAS by a certified professional installer. CPIs are authorized to give detailed information about each CBSD to the SAS before it is allowed to transmit.

End user device (EUD): End user devices are generally user devices like LTE or 5G capable smart phones, tablets, or routers, which communicate via CBSDs to the network. They are limited to a maximum of 23 dBm EIRP.

1.2. Motivation and benefits of private LTE/5G networks

Current connectivity options for enterprises are limited to either public cellular networks or enterprise Wi-Fi. Commercial networks from mobile network operators (MNOs) are designed for public use and do not cater to the specific use cases for enterprises. The advantages described below are a key reason for enterprises to deploy their own private LTE/5G networks.

One of the key benefits of private LTE networks is its ability to cover larger areas as compared to Wi-Fi. Private LTE/5G networks can provide superior coverage in challenging environments like factories with a lot of metallic structures, or in outdoor campus-style environments like universities. They can be used to complement existing Wi-Fi so that end users can benefit from the best of both networks.

Mobility is another use case where private LTE/5G networks can offer a lot of benefit. Seamless handovers and access point neighbor relations are built into LTE/5G networks. This mobility is ideal for use cases like asset tracking, autonomous vehicles, remote guided vehicles, and critical communications.

Private networks also offer a level of customization for the specific use cases for enterprises. Overall bandwidth in a LTE or 5G network can be customized depending on the requirements. The uplink and downlink ratios in the channel can be modified using different TDD frame configurations. For example, a frame configuration of one makes more sense in uplink heavy applications like video streaming while a frame configuration of two can be used for downlink heavy uses. The bandwidth can further be modified by combining channels together using features like carrier aggregation. Frequency re-use can further be used to control interference between different sectors in a venue. Customization can further be achieved by varying Quality of Service (QoS) parameters and assigning them to different groups of end user devices. For example, devices that require high bandwidth can be assigned a QoS that allows for higher throughput and guaranteed bit rates.

Private LTE/5G networks can also be leveraged to bring the benefits of MEC environments. MEC, as defined by ETSI (European Telecommunications Standards Institute,), “offers application developers and content providers cloud-computing capabilities and an IT service environment at the edge of the network” [4]. Thus, this allows for high bandwidth and low latency applications like video analytics, augmented reality (AR), and other use cases, which benefit from edge processing.

2. Private networks architecture

2.1. Components of a CBRS private wireless network

A private wireless network consists of many components which are either managed by the operator, a third-party system integrator or the end user. A CBRS specific private wireless network consists of the following key components:

A. Wireless spectrum
A private wireless network can be deployed on licensed, unlicensed, or shared spectrum like CBRS. This is granted by a governing body such as the FCC in the United States.

B. Spectrum Access System
The FCC has authorized several spectrum access systems for CBRS. These are deployed in the cloud and CBSDs or the domain proxy must have continuous access to this for regular heartbeats.

C. Radio Access Network (RAN)
Deployed on premises for a private LTE network, the RAN consists of the radios, antennas and baseband functions.

D. 4G or 5G core network
The EPC or 5G core can be located on premises, partially on-premises or entirely on the cloud. This is discussed in more detail in the architecture section of this paper.

E. Multi Access Edge Compute (MEC)
Located on premises to handle data analytics, caching, and other processing functions that would otherwise be deployed in the cloud. This allows for a host of low latency and high bandwidth applications.

F. User devices
The end user devices can be smart phones, tablets, cameras, LTE/5G routers, sensors, etc. and can vary depending on the use case.

G. Management systems
These consist of the portal(s) that help manage the RAN, network core, devices, and orchestration.

2.2. Architecture

The architecture for private networks depends on the deployment venue, use case, and technology (LTE or 5G). Presented below are some common deployments for private LTE, with their respective pros, cons, and usage.

2.2.1. Cloud-based core network

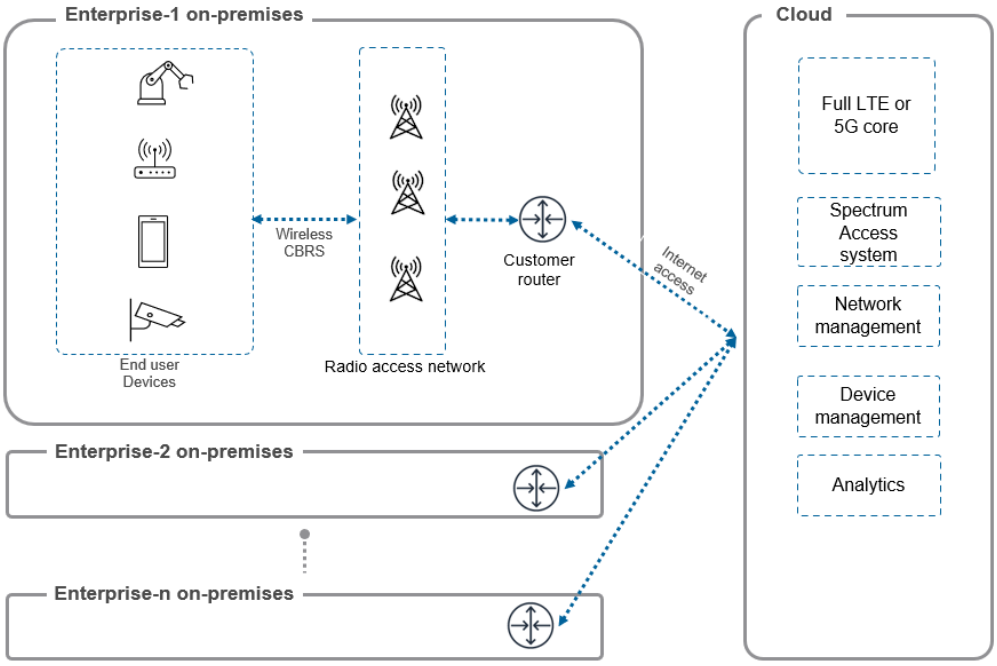

Figure 1 - Network core hosted on cloud

In this deployment, all the network core functions are hosted on the cloud with a dedicated radio access network on premises. This implementation is easy to deploy since there is little infrastructure needed on premises to host the core functions. Further, it can support multiple geographically distant enterprises if they have connectivity to the core.

However, this implementation does not support applications which require low latency since the data has to traverse multiple hops over the internet and back. It is also not efficient for higher bandwidth applications like high-definition video processing or real time streaming. For cameras and video, the backhaul requirements scale very quickly since all processing is done on the cloud. The enterprise still gains the benefit of having dedicated coverage in their venue, which is better than using a public commercial network.

2.2.2. Full network on premises

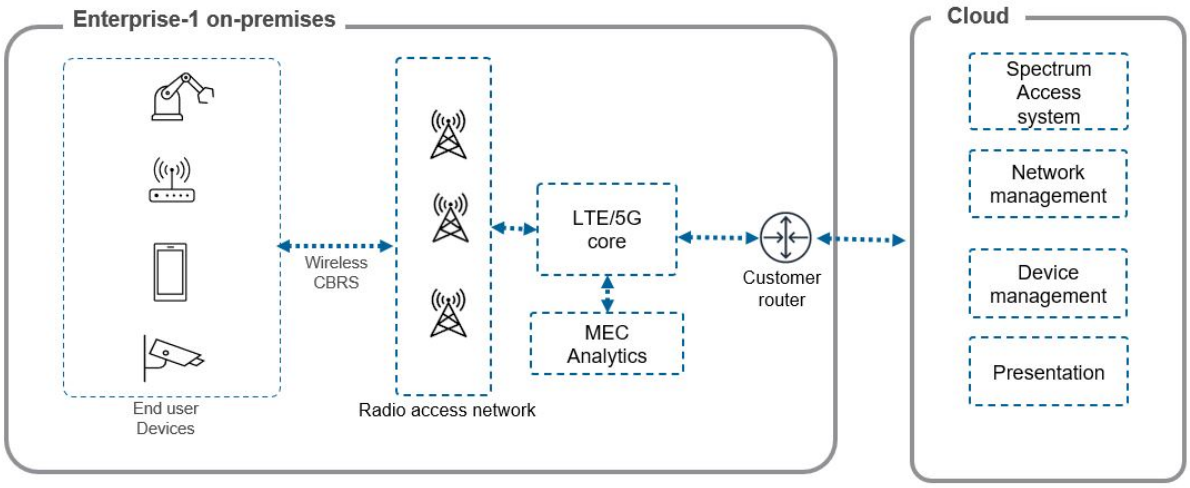

Figure 2 - Full network on premises

In this implementation, all the network core functions are located on premises. This is ideal for low latency applications or applications that require real time processing and high bandwidth like video streaming. For example, this would support a worker safety use case where life feeds from cameras are sent to the edge for further processing and analytics on the edge. While this offers advantages to the enterprise with a dedicated core on premise, it does not scale that well for an operator since separate infrastructure is required on premise for every enterprise.

The management functions can be hosted in the cloud for network operations and orchestration. As in all deployments, the SAS is also hosted separately in the cloud.

2.2.3. Network core at edge data center

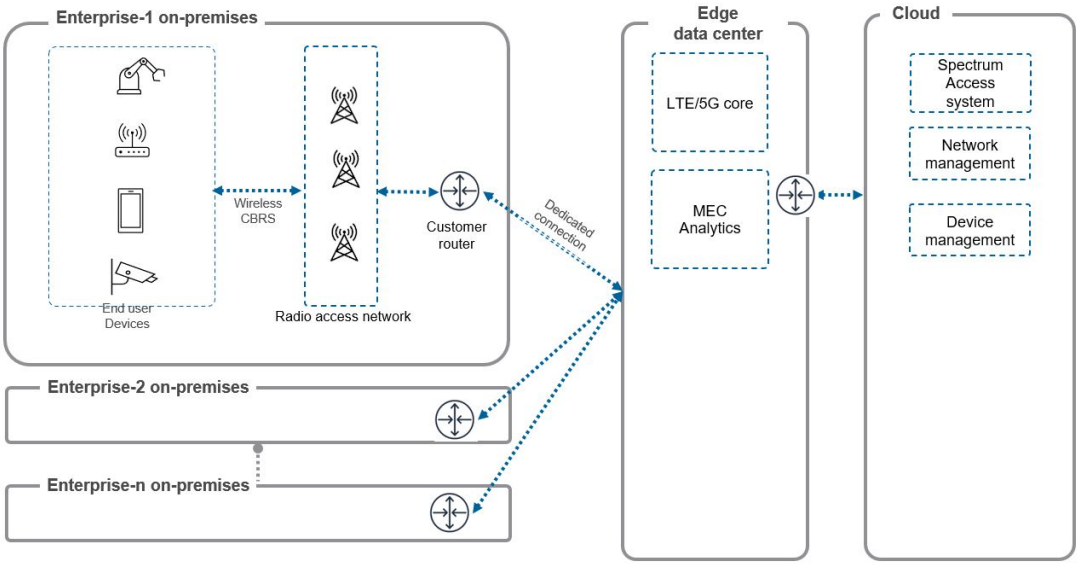

Figure 3 - Network core at edge data center

An edge data center is defined here as a data center with a dedicated connection to the enterprise. This can be owned by either the operator or managed by a cloud service provider as part of their edge offering. This implementation offers a balance between the full cloud and on-premises deployments, while still offering the ability to serve lower latency and high bandwidth applications.

2.2.4. Hybrid architecture

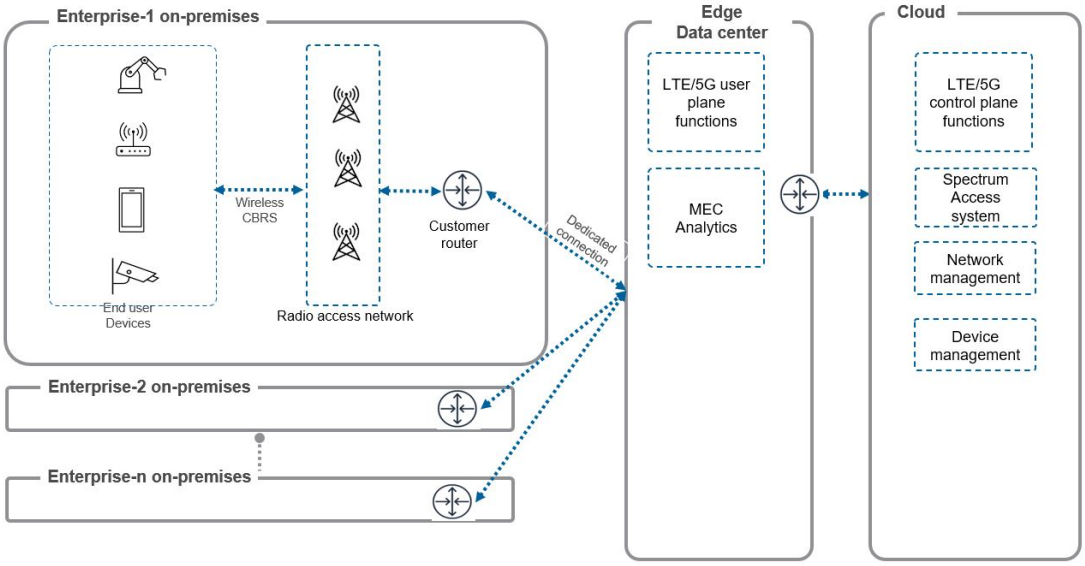

Figure 4 - Hybrid deployment

In this implementation, the use plane functions are located at the edge data center with the rest of the functions hosted in the cloud. For 5G, this means the user plane function (UPF) is hosted at the edge, while the access management functions (AMF), session management function (SMF), policy control function(PCF), network slice selection function(NSSF), authentication server function(AUSF) and unified data management(UDM) functions are hosted in the cloud. This architecture allows multiple enterprises within proximity of the edge data center to be served, while still leveraging the cloud for management.

3. Use cases in different industry verticals

As discussed earlier, private LTE/5G allows for a variety of different applications. Presented below are some of them split by vertical, illustrating how a private LTE network enables them.

3.1. Industrial

a. Worker safety

Safe and accident-free environments are a priority for plant managers in a factory. This can be done is two ways – by enforcing safety standards and then tracking compliance of those standards. Charter, along with its partners, has demonstrated a video analytics worker safety use case. A camera was used to capture video of workers operating a machine in the factory, and sent to the MEC on premises. An algorithm identifies whether the workers are wearing safety gloves, helmets, jackets, and other equipment required for safe operation of the machines. The data is anonymized and recorded for compliance purposes, and automatic notification is sent out if a particular worker is not wearing safety equipment.

b. Autonomous guided vehicles (AGV) and remote-controlled robots

For large warehouses or factories, there is a constant need to move large items from one area to another. Boxes, finished products, and other items must be loaded onto pallets and moved manually by employees dedicated for this task. This uses valuable employee time and resources. Remote controlled robots or AGVs can be used to transport materials within and around the factory to save time. A private LTE network provides this reliable coverage, mobility, and edge processing to realize this use case

c. Push to talk and push to video

In large industrial environments, cellular service is poor because of high penetration loss due to many large metallic structures. In the absence of good public cellular service, private LTE/5G networks can fill the gap. Charter has demonstrated this application to its pilot customer. The push-to-talk server is hosted on premises along with the network core, and factory employees can install a push to talk application on their existing smart phones if it supports CBRS.

d. Predictive maintenance

Factories and warehouses can collect valuable data from their machines with wireless connected sensors. Most mechanical systems have a vibration signature when operating correctly. Sensors can be used to detect any irregular vibrations, which would otherwise go unnoticed. The data is used to train algorithms, which can then predict an upcoming failure. The result is minimizing downtime and gaining insights into machine behavior [3]. Private LTE networks provide the connectivity and reliability to connect hundreds of sensors and process the data at the edge.

3.2. Healthcare

a. Secure communications

Healthcare workers in hospitals and other medical facilities require secure communication with high reliability. Additionally, they may require sensitive patient information to remain on premise. Indoor coverage in hospitals can vary depending on the building material and various medical equipment located indoors. A private LTE network can solve both these problems by providing reliable connectivity with a dedicated RAN, and edge compute to process the data on premises.

b. Augmented reality (AR) applications

Medical personnel equipped with AR headsets can have instructions and information overlaid on medical devices to understand how to properly use them. AR can also be used in a training setting for healthcare professionals to learn to use equipment.

3.3. Education

a. Remote learning

The worldwide pandemic has shown us the importance of having good connectivity at work, universities/schools, and at home. Private networks can be used to extend school connectivity to residential locations around it. Students can access school resources securely and safely from their homes.

b. Campus connectivity

Universities and other campus environments are ideal for private LTE networks since they provide seamless coverage both indoor and outdoor. Students can have access to local applications securely anywhere on the campus. The network can be further used to serve other

use cases like providing connectivity for security personnel, faculty communication and interactive learning via VR or AR headsets.

4. Charter Communications lab evaluation

Charter Communications has conducted an evaluation of private network offerings from several vendors to assess the best fit for its customers. The vendor selection depends on customer, type of use case, cost sensitivity and other factors. Our evaluation attempted to take a holistic look at the different criteria that are important for private networks for enterprises.

4.1. Selection criteria

4.1.1. Network

Private LTE and 5G networks can have varying deployment scenarios - indoor industrial, outdoor/indoor campus, hospitals, schools etc.). Selection of the radio access network determines which of these environments can be served efficiently. Some of the different types of RAN options are:

a. Indoor Pico or Femto radios varying in output power from less than 20 dBm to 30 dBm (maximum allowed power for indoor CBRS deployment)
b. Outdoor rated radios with integrated antennas
c. Outdoor rated radios with an option for external antennas
d. Remote radio head which connects to a central baseband

We chose to go with a vendor that has a wide variety of radio options to serve the different deployment scenarios of private LTE/5G. For example, in a factory which has existing Ethernet cabling, we would choose to go with the indoor small cells which backhaul via copper. However, in another scenario for outdoor campus coverage where the antennas are deployed on a tower, we would go with a RRH and external antenna connected via fiber to a central baseband.

To serve the varying bandwidth requirements within a private network, LTE provides the flexibility to modify different TDD frame configurations. For example, a TDD frame configuration of 2 allows for a 3:1 downlink to uplink ratio. Alternatively, a frame configuration of 0 allows for a 1:3 downlink to uplink ratio. The latter could be used in primarily uplink use cases like video security or worker safety based on video analytics. Another factor we looked at was the total aggregated bandwidth. This could range from 10 MHz to the entire 150 MHz with carrier aggregation. This has a big effect on throughput so was an important consideration in selection of RAN.

The total capacity of the system depends on the number of eNodeBs supported by the baseband and the total capacity of the EPC i.e. how many S1 links it supported. Our evaluation looked at how many of each link the network could support, and if there was room for scaling. Lastly, we looked at the network core configuration from the different vendors. For LTE, the evolved packet core (EPC) could either come in different configurations (small, medium, large) each with a different number of supported. Other vendors did not have an upper limit and scaled the core as the network grew.

4.1.2. Management systems

In a traditional network, there are different user interfaces to manage the different functions from RAN and core. There can be a network management system (NMS) for RAN, a separate command line interface (CLI) or graphical user interface (GUI) for the core, another portal for home subscriber server

(HSS) function, etc. For a private network, it is important to have a single pane to manage most functions. Table 2 describes some of these functions and the intended end user.

Table 2 - Functions of management portals and primary user

Function	Primary user
Adding and removing eNodeB	Operator
Modifying cell frequencies	Operator
Modifying / optimizing network parameters	Operator
Creating different QoS groups	Operator
Viewing network status and alarms	Operator / Enterprise
Adding / removing UEs and sims	Operator / Enterprise
Changing aggregate maximum bit rates	Operator / Enterprise
Creating IMSI groups	Operator / Enterprise

4.1.3. Ease of deployment and operations

Private wireless networks need to be easy to deploy and manage for enterprises. The complexity of LTE and 5G networks needs to be abstracted so that the enterprise can easily integrate the private LTE network into their existing infrastructure. In our evaluation we looked at several aspects of the ease of deployment

a. Ease of physical installation: use of existing IT infrastructure in venues is ideal because of obvious cost benefits. In an industrial environment, the wiring must be done either after hours or between shifts. Moreover, exact location of antennas depends on specific venue restrictions.
b. Ease of operations: after deployment, the private network must be managed remotely, with roles split between the operator and the enterprise customer. This is discussed in more detail in section 4.1.2
c. Support: Vendors need to have 24/7 support teams for any troubleshooting or escalations if needed, depending on the specific service level agreements. Our evaluation also considered this level of support from the network vendors.

4.2. Overview of results

Table 3 - Summary of network evaluation

Category	Vendor 1	Vendor 2	Vendor 3	Vendor 3
RAN – available options	a. 17 dBm Indoor radio b. Outdoor CAT-B radio with integrated antenna	a. 24 dBm small cell b. 24 dBm small cell with option for external antenna c. Outdoor radio with option for external antenna d. Outdoor radio with integrated omni antenna e. Baseband with RRH + external antenna	One radio with adjustable power for both indoor and outdoor. Option for external antenna	a. 24 dBm indoor radio b. 30 dBm indoor radio c. 30 dBm outdoor radio

TDD frame configuration options	1 & 2	0,1,2	0-7	1 & 2
Evolve packet core (EPC)	Full on-premises EPC with redundancy	Full on-premises EPC with redundancy	3rd Party EPC on premises with HSS on cloud	Cloud EPC only. Option for on-premises EPC with 3PP
Max allowable bandwidth (depends on SAS grant)	4 carriers 80 MHZ (40+40 MHZ)	3 carriers. 60 MHz (20+20+20)	8 carriers 150 MHz	2 carriers 40 MHz (20 + 20)
Max modulation	256 QAM	256 QAM	256 QAM	256 QAM
MIMO	2x2 or 4x4	2x2	2x2 or 4x4 (extra radio)	2x2
Maximum capacity	Maximum 24 radios	Scalable	Scalable	Depending on 3rd party EPC provider

5. Private LTE deployment in factory

Charter Communications has deployed a private LTE network in a 600,000 sq. km manufacturing plant in Michigan, USA. The following sections describe the planning, design, deployment, and lessons learned from this pilot.

5.1. Planning and design

Like with any network deployment, our deployment started with customer inputs and a discussion of how they would use the network i.e. primary use cases.

a. Size of the factory: The coverage area is important since exclusion zones need to be defined when doing the RF propagation study. In our scenario, the factory was a little over 600,000 sq. km. The main operations of the factory were on the first floor, while the IT and certain other offices were on the second floor.
b. Interior of the factory: We requested a map of all the equipment in the factory (machines, racks, pallets etc.). This is not always available, so site surveys are valuable when mapping out the venue and any design considerations that need to be made
c. Material properties: Industrial environments have a range of different items which affect the overall propagation. In our factory, the walls were concrete, most of the machines were metallic, there were large wooden structures, and 15–20-foot storage racks in many areas. In addition, there were large aluminum ventilation ducts and metal rails along the ceiling. These may be missing on the drawings, but they do affect coverage so should be accounted in the design as best as possible.
d. Acceptable locations to mount antennas: the factory had restrictions on where we could mount the radios and antennas. This was due to either some high equipment, fans on the ceilings, ventilation ducts, or existing antennas and access points from other technologies. We had to make a tradeoff between desired locations for coverage and these customer restrictions.

e. Networking requirements: IT personnel needed to specify what firewalls they have in place, what IP addressing scheme they have, whether they use a public or private domain name server (DNS), switch configuration, and anything else to integrate the private LTE network into their system.

Considering the customer requirements, we performed a RF design of the factory. Figure 5 shows the coverage, while figure six shows the best server plot.

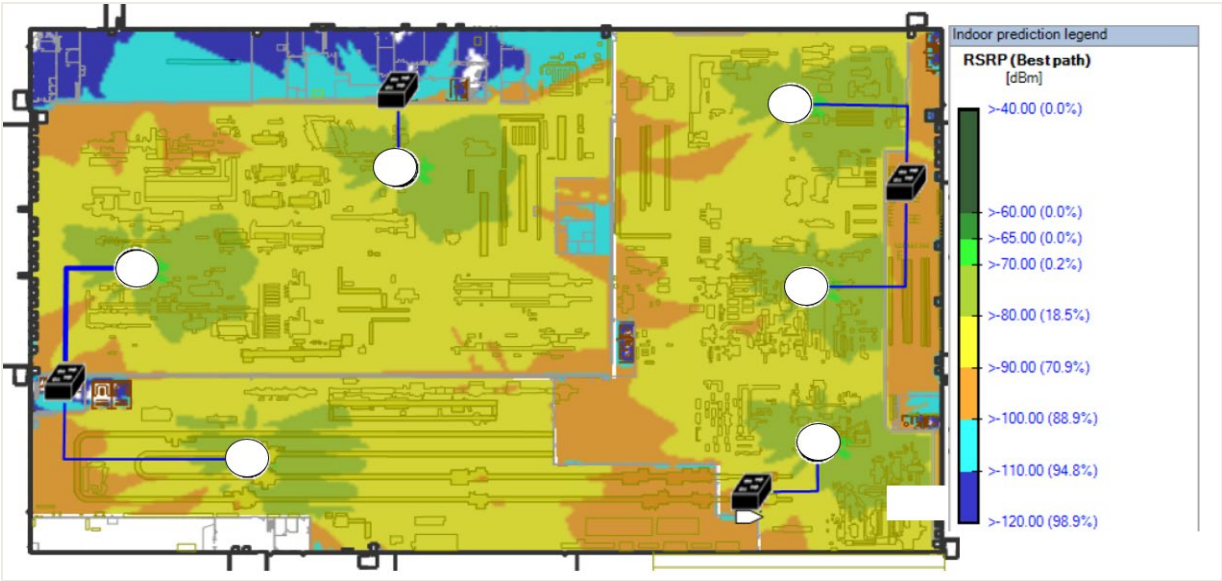

Figure 5 - RSRP plot from RF design

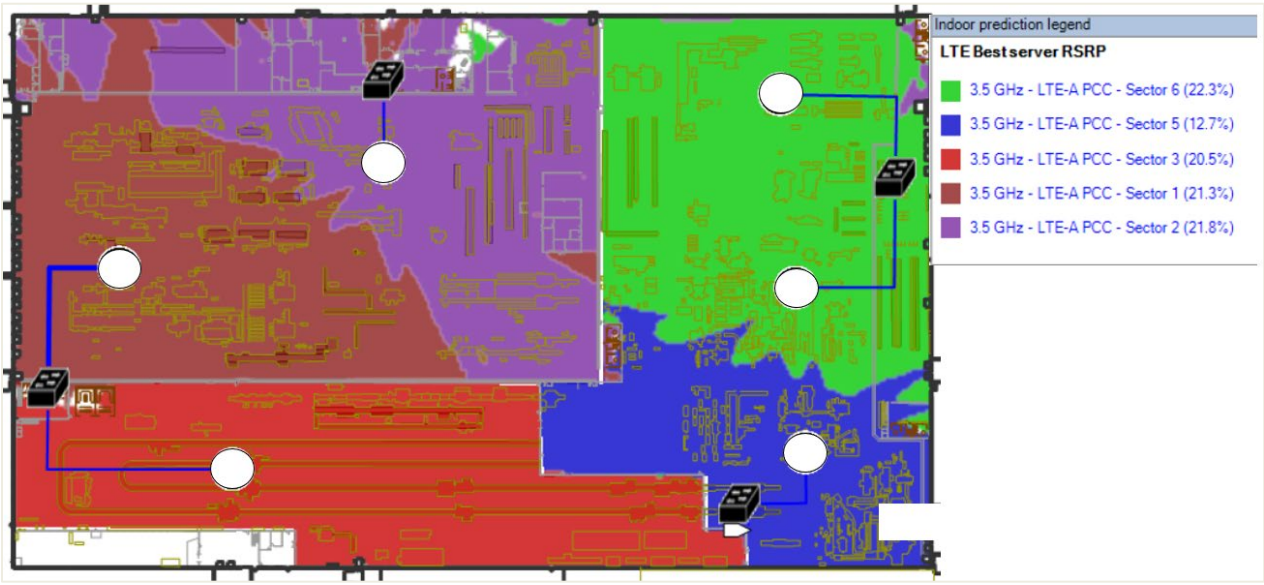

Figure 6 - Best server plot from RF design

The design shows 95% of the plant is covered by a signal level of -110 dBm or better. The intent of the design was to cover the entire factory, and we had to balance between desired coverage and interference between neighboring sectors. While the areas to the north of the factory (cafeteria and copy rooms) had

limited coverage, we can add additional radios there if required. We also implemented frequency re-use to limit inter-cell interference.

5.2. Deployment

The installation was done by the factory's approved installers who were familiar with the specific limitations and approvals needed to install. Custom mounts were created to mount the radios and antennas, which were then hung from vertical rails on the factory ceiling. The EPC and MEC servers were in the factory main distribution frame (MDF) room. Figure 7 shows the deployment architecture.

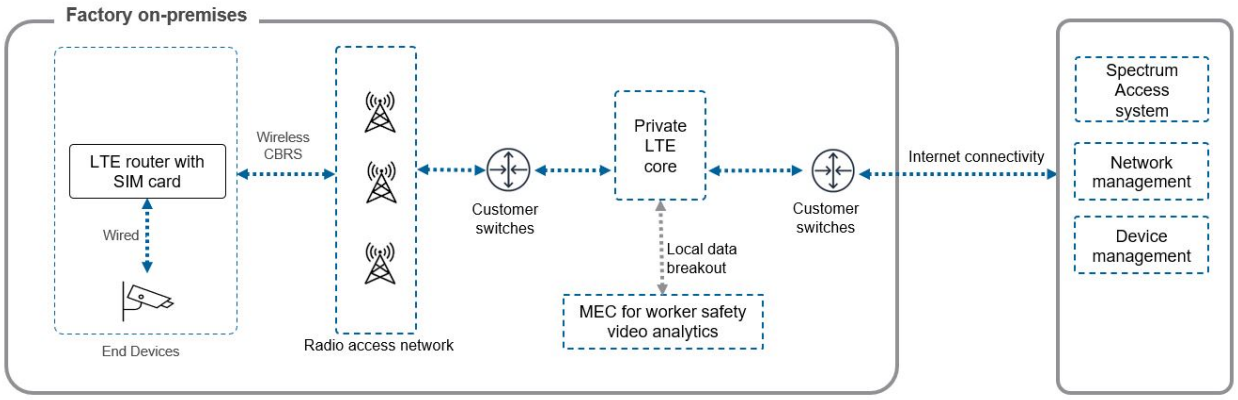

Figure 7 - Deployment architecture

5.3. Post launch testing

After the network was live, Charter conducted performance testing at pre-determined test points to assess coverage, quality, and throughput across the factory. The table below has the results of the testing, and comments where the results deviated from the expected performance.

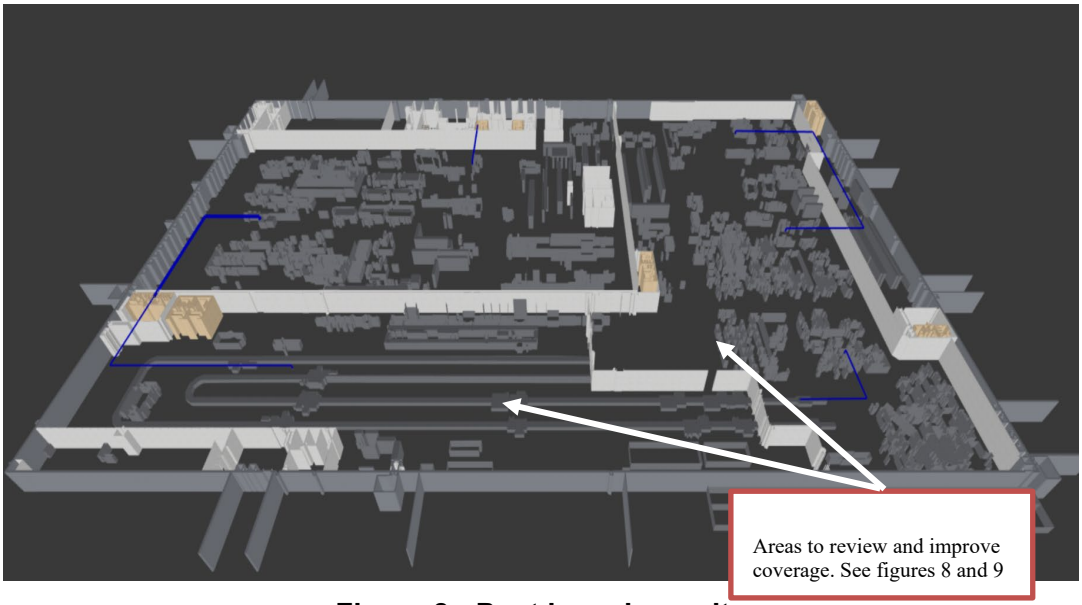

Figure 8 - Post launch results

Table 4 - Performance measurements from live network

	Measured Values				
Test point ID	**RSRP**	**SINR**	**DL Throughput (Mbps)**	**UL Throughput (Mbps)**	**Comments**
1	-81.9	29			
2	-78.9	30	170	22	
3	-97.5	24	105	17.6	
4	-104	20.1	90	17	Marked as exclusion in design
5	-105	18	70	5.8	Marked as exclusion in design
6	-75	30	172	17.6	
7	-94	25	100.5	17	
8	-94.5	28	115	17.5	
9	-95		114	17.1	
10	-110	24	95	17	See figure 7
11	-75	30	170	22	
12	-105	15	75	11.2	See figure 7
13	-96	25.9	80	17.5	
14	-108		40	12	
15	-82	27.9	170	17	
16	-95	23	105	17	
17	-72	30/30	170	17	
18	-108	12	90	11	
19	-80	29	125	22	
20	-107	19	105	17	See figure 7
21	-110	10	70	11	See figure 7
22	-102	19	105	17	See figure 8 - Antenna mount needs to be lower or moved
23	-106	23	120	17	See figure 8 - Antenna mount needs to be lower or moved
24	-87	30	123	17	
25	-95	27	112	17	

Based on the results, we assessed where the network performance could be improved and reasons for lower-than-expected performance. Figure 8 shows an example of an area within the factory. Large metallic structures like this can cause fluctuations in signal strength due to diffraction and are difficult to account for in the design. Directional antennas can better accommodate hard to reach areas or can be excluded altogether if the customer does not wish to cover them.

Figure 9 - Metallic and large structures effect coverage

Figure 9 shows the effect of antenna placement on coverage. The antenna in the picture had to be moved because of factory restrictions. However, it is not located between a metal duct and a rail which limits coverage in one direction. Our solution here is to either lower it to avoid the blocking, or to relocate it to a different area.

Figure 10 - Antenna blocked by metal duct and rail

5.4. Use case

Charter has demonstrated a worker safety use case based on video analytics. Cameras were set up to stream video over CBRS to the MEC located in the factory MDF. An algorithm was trained to detect if employees were wearing helmets, safety gloves, jackets, and boots. The plant manager then collected metrics for compliance purposes, to see if there were any areas of the factory which needed better safety protocols or signs in place.

5.5. Lessons and best practices from deployment

First, the operator needs to have a detailed discussion of the existing network, firewalls, and any other policies that the IT team has in place. We faced some initial issues with default DNS being blocked, but were able to overcome them by working with IT. This can be resolved by including networking requirements in the initial customer information questionnaire.

Second, the RF designer should factor in movable structures in the design, especially in an industrial environment where this can happen often. This could be accomplished by running several scenarios of propagation with equipment located at different areas. At the same time, defining exclusion zones is important since not every area can be covered. Third, the network installers and designers need to work closely to ensure proper installation. A ten foot change in antenna location may not make a big difference in an office or outdoor environment, but in a factory this could potentially impact coverage if the new location is behind obstructions. Fourth, there should be a discussion on the primary use cases so that coverage and capacity can be targeted to serve those regions as best as possible.

6. Conclusion

In this paper, we presented an overview of CBRS and the motivation for private wireless networks on CBRS. Second, we presented the main use cases in different verticals and how a private LTE/5G network enables those use cases. Third, we presented the evaluation of different network vendors in Charter's lab in Denver, Colorado. Fourth, we presented the planning and results from an actual deployment in a large factory in Michigan.

Private LTE and 5G networks have the potential to streamline operations, provide greater insight into operations and help solve critical challenges for enterprises across many different verticals. Charter communications is committed to investing in private LTE/5G networks and serving the needs of enterprises across the nation.

Abbreviations

AP	access point
bps	bits per second
FEC	forward error correction
HD	high definition
Hz	hertz
SCTE	Society of Cable Telecommunications Engineers
5G	5th generation Cellular technology
LTE	Long Term Evolution
MEC	Multi access Edge compute
CBRS	Citizen Broadband Radio Services
SAS	Spectrum Access System

Proactive Asset Decommissioning in Critical Facilities to Accelerate Energy Management and Sustainability on the Road to 10G

A Case Study of How Comcast is Embracing Sustainable Asset Lifecycle Management to Power the "Future of Awesome"

A Technical Paper prepared for SCTE by

Comcast Cable
Sikander_Chatha@cable.comcast.com

1. Introduction

In-rack assets in datacenters and other critical facilities continue to contribute significantly to the energy usage at cable companies. SCTE•ISBE has championed Energy 2020 as an Energy Management Program to provide cable system operators with the new standards, technology innovation, organizational solutions, and training desired to drive continued cable telecommunications network growth, availability, and reliability. While there is a lot of excitement for a new product/application launch and deployment of assets, decommissioning has been an afterthought for many organizations. Instead, companies have been focused on delivery of new projects to optimize service delivery and revenue. With advancements in technology many compute, storage, and networking assets are able to increase their useful lifespan to 5-10 years for certain non-demanding or legacy workloads. This results in little desire or incentive for the planning of asset retirement. New assets and infrastructure have always been priority, and organizations have been squeezing every last drop of productivity out of their assets, extending the asset lifecycle well beyond the manufacturer's End of Service Life (EOSL) dates.

Cable system operators can significantly and immediately impact their bottom lines by deploying solutions that can reduce data center power needs and increase energy efficiency, according to a presentation at the Smart Energy Management Initiative (SEMI) forum by the Society of Cable Telecommunications Engineers (SCTE).

At Comcast NBCUniversal, teams hold themselves accountable to be environmentally responsible. Kicking off a proactive asset decommissioning program was a step in the right direction to help achieve our asset retirement and sustainability goals. This technical paper will highlight how we were able to apply a renewed focus on asset retirement and how this helped with keeping our utility bill flat in 2019/2020.

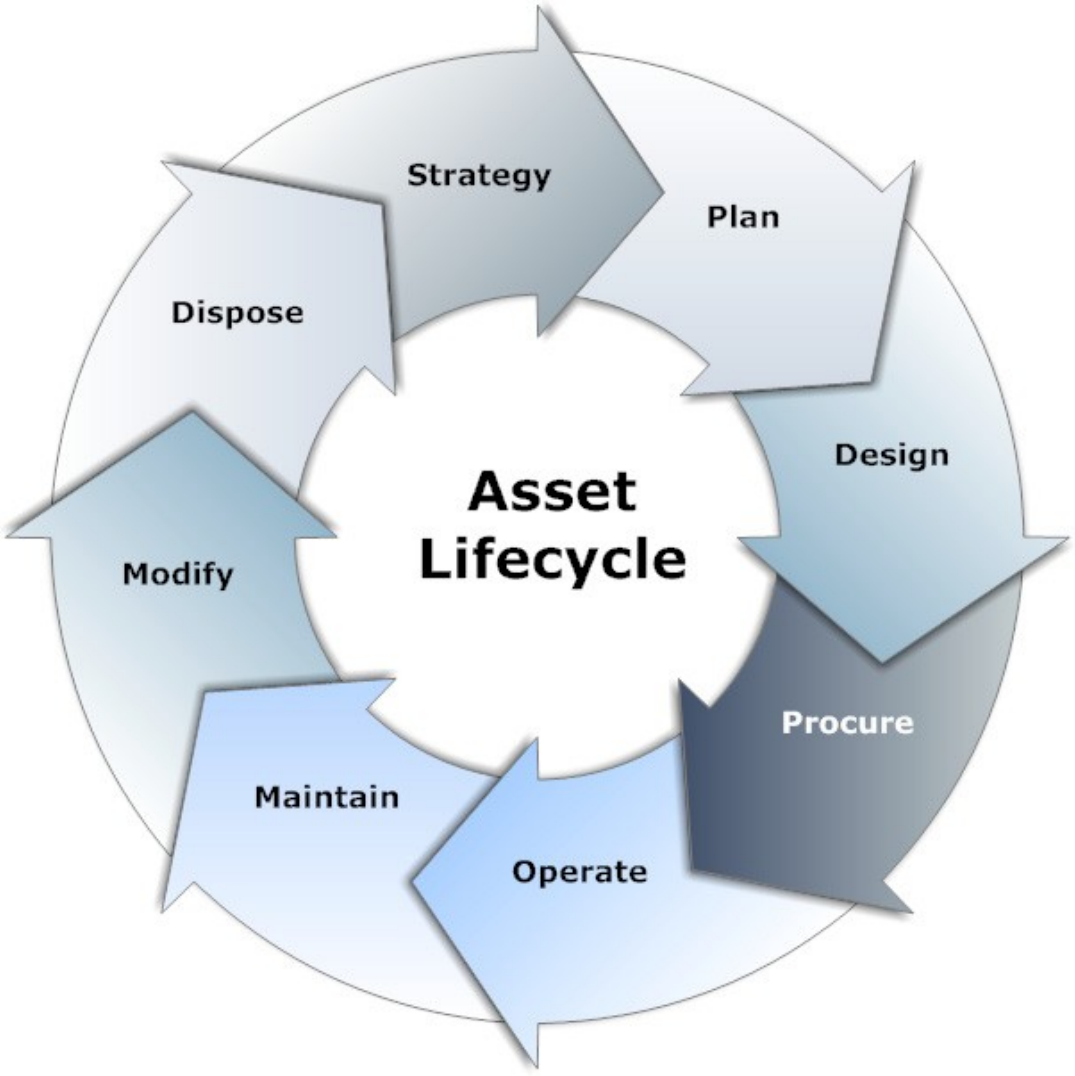

Figure 1 - Typical Asset Lifecycle (NIST SP 1800-5)

2. Benefits

The benefits of proactively running a Decom Program are numerous and include energy savings, reducing security risks, better inventory management, sustainability, reduced capital, and software spend. These are described below:

Energy Savings – Getting unused devices off your raised floor can have a significant impact on your organization's energy bill. Furthermore, newer servers are usually more energy efficient which should be an incentive to get aged devices out the door to help with your organization's goals for overall energy conservation.

Security Risk mitigation – Unused equipment and other aged devices may not be able to receive the latest patches and updates, and this can be cause for major concern due to lack of awareness of these vulnerable systems. Unpatched servers lead to persistent backdoors for hackers and increasingly unpatched servers are becoming a target for cyber-attacks, exploiting vulnerabilities in our organization. Keeping up and patching these systems when we know the ownership and applications being hosted on them is hard enough for any organization. The added burden of patching older abandoned and unused servers can turn into an impossible task.The benefits of retiring these systems early not only reduce risk but also reduce potential business intrusions caused by downtime. This is where a Decom Program can assist and get these unused vulnerable systems off your organization's network and help reduce unnecessary risk.

Help institute better Inventory Management – Getting your organization on board to focus resources on the proactive planning and retirement of unused and aged servers also has a direct impact on your organizations ability to track and inventory assets. Performing a book to floor and floor to book audit of all facilities housing your company's assets is step one of standing up a decom program. Knowing where all your assets are and who owns them is critical to success and this will force your organization to not only get a better understanding of what you own but will also open up the opportunity to better the process in managing these assets going forward. According to a recent Mercer report, the average employee turnover rate was 22% in 2018 which is a nightmare for asset management and keeping application ownership aligned. Getting ahead of the next re-org by understanding who owns and supports your organization's business applications and underlying assets and putting in a process to maintain this information will save your IT department countless hours down the road. This exercise will also help identify orphaned assets which would be ideal decommission candidates and lead the way to costing savings.

Sustainability – As your organization's compute and storage requirements grow, you will want to find ways to not only find alternative sources to power your data centers but also figure out ways to reduce the overall energy footprint. This is where retiring older assets and buying more energy efficient devices combined with the ability to do more with less will empower your organization to meet your individual sustainability goals.

Reduced Capital Spend – Many legacy systems are not cloud-ready, which emphasizes the need to stay lean and avoid the need to expand your physical footprint as eventually most if not all of your organization's workloads will be headed to the private or public cloud. Removing unused and aged devices and leveraging capabilities to optimize workload efficiency will ensure your organization is on the right side of change with shrinking and not growing their physical footprint.

Optimized Software Licensing – Software assets are a major cost in an organization's overall IT spend. The first step in optimizing these costs is knowing what you are consuming and then identifying opportunities to reduce your footprint. Reduction in software licensing and maintenance costs will be an indirect benefit your organization will receive by proactively decommissioning your physical assets. Not only will this result in huge savings, but this may also help your organization stay on side with your licensing obligations to your vendors.

Optimize overall Costs of IT - With the rising cost of IT including capital and operational spend, organizations are trying to find creative ways to avoid costs and save money. According to Gartner, worldwide IT spending will grow 4% in 2021. A major part of this increase and overall spend is associated with Data Center Systems and Enterprise Software. Standing up an Asset Decommissioning Program will directly attack both of these costs contributors and lead your organization not only into substantial cost savings but also provide an optimal setup for your organization to start optimizing IT

spend through virtualization and consolidation of workloads. Knowing what you own and what is and is not being used is step one to any organization's journey into standing up a Decom Program.

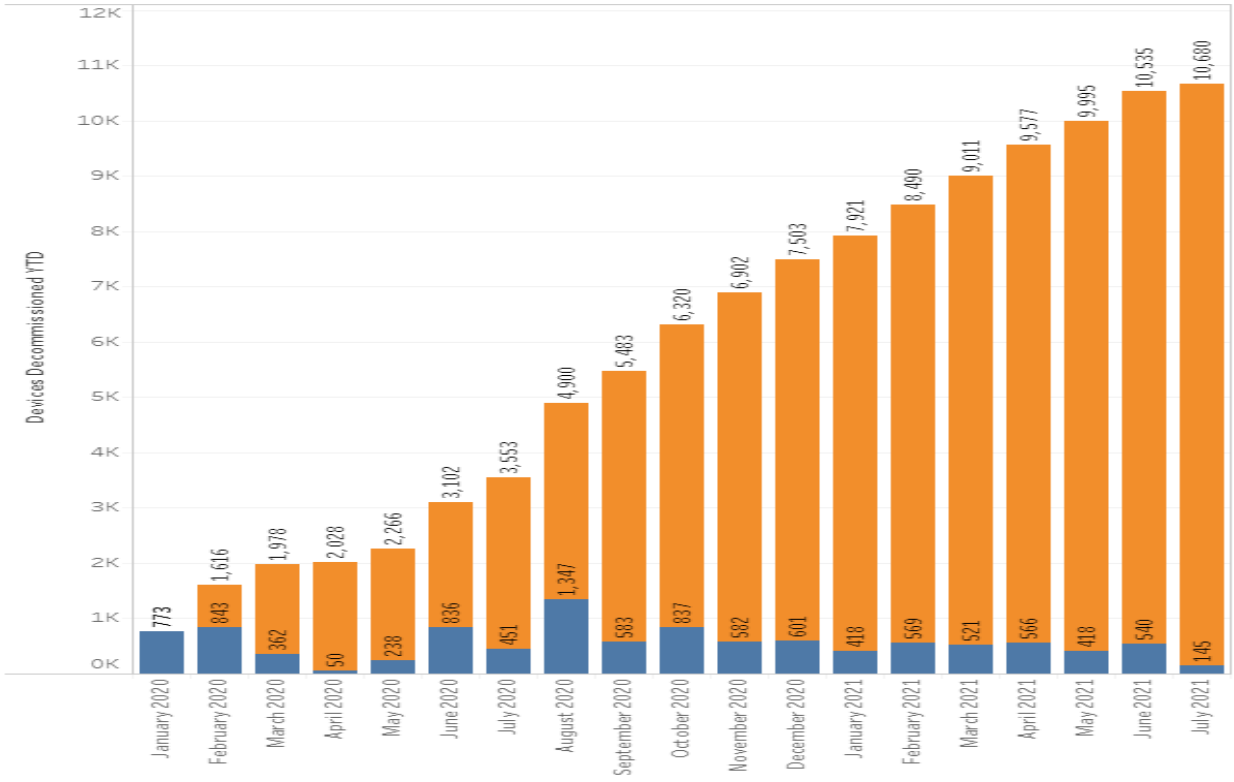

Figure 2 - Decommissions 2020-2021 (YTD)

3. Why is this not already a priority at many organizations?

Focus on new deployments – Generally speaking, there is a lot of excitement and related prioritization for effort involving new product launch and related new asset deployment. There is not as much focus on decommissioning those applications and assets as time passes.

Silos and reorganizations – The life of in-rack assets could be as long as 5-7 years. Many large companies go through multiple reorganizations of teams in such timeframes. This causes lack of ownership of these assets for the new teams. Also, organizational silos impact the ability to see an application retirement, asset decommissioning, and its sustainable disposal end-to-end.

Lack of proper inventory management – A well-maintained inventory with right CDEs (Critical Data Elements) and ownership is a necessary ingredient for a successful decommissioning program. Many companies are not able to create or manage this inventory as new assets come in and teams are reorganized.

4. Comcast Case Study

Why we did it?

Historically, the decommissioning of data center assets has been an afterthought for most organizations. This often results in abandoned physical workloads sitting collecting dust in critical facilities. These abandoned assets not only consume valuable resources but also pose a security threat to the organization. Our journey at Comcast begun in late 2018 as we started to cleanup and get a better handle on our assets. We worked to proactively optimize our decommissioning process to avoid the common pitfalls that a lot of organizations find themselves in, where unused assets are left in the racks, collecting dust, consuming power, and occupying space.

After realizing these potential impacts, Comcast embarked on the journey to shift from a reactive state to proactively managing decoms, similar to how assets are planned for and deployed during project delivery. The need for this was long overdue and some of the sure tell-tale signs were:

- Finding powered off or non-functional assets in our data centers during Data Center audits.
- Finding mismatches in asset status in various asset inventories.
- Finding sudden power drop offs in devices through our DCIM system.
- Finding gaps in our current Decom process, resulting in failed asset decoms.

Inventory Management

With the focus on physical device decommissions, it was very important that we did a floor-to-book and book-to-floor inventory of all our physical devices across all sites. This inventory was updated in our DCIM tool and reconciled with our CMDB to help identify ownership for each device. The team assessed various sources of inventory that can help identify the Critical Data Elements needed for each asset that would drive the identification of the initial assets to target:

Table 1 - List of Critical Data Elements needed for each asset to smoothly run through Decom process

Critical Data Element (CDE)	Note
Make/ Manufacturer	E.g. Hp/Dell/Cisco/Juniper to identify the OEM
Model Number	E.g. DL-360 to match up with EOSL list
Serial Number	E.g. 1234567 to uniquely identify each asset
FQDN/IP Address	E.g. billing-server1@comcast.com to identify network name and IP address
Application	E.g. Billing System
Application Owner	E.g. Consumer_Billing_Ops_team@comcast.com to work with for decommissioning process

Gaining buy-in from all stakeholders

The ability to proactively stand up a program around an area that has been historically ignored for years was an easy sell once the business case was developed and presented to leadership. The opportunities as discussed earlier were a clear and the thought of not moving forward with this was highlighted as a risk our organization was not willing to take.

Besides gaining senior leadership buy in, it was critical that we communicated the importance of this to all stakeholders, including both those submitting request to decommission and those fulfilling the downstream process to get decommissioned assets powered down and unracked. This was especially important because, like most organizations, the resources doing the deployments were the same resources that would be helping with the decommissioning of assets.

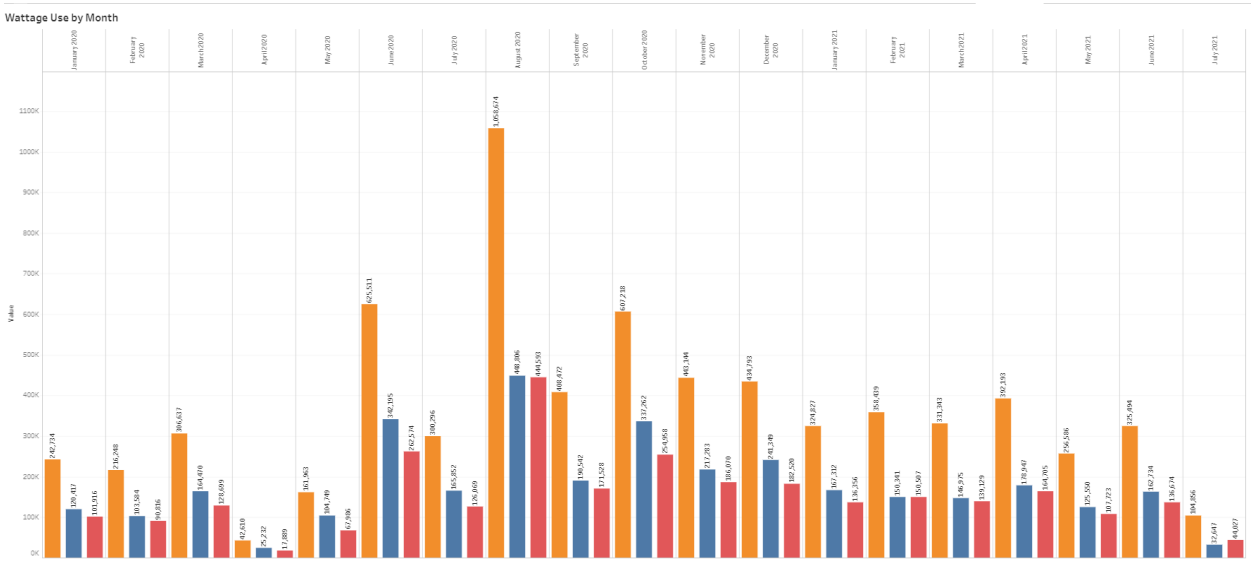

Figure 3: Power watts saving per month 2020-2021 (YTD)

4.3 Evolving the process

Evolving the process involved reviewing the current process and looking for ways to optimize. Looking for opportunities to streamline the process across different areas of the organization and cover various decom scenarios was a critical part of getting started. This involved removing unnecessary steps and introducing critical controls and checks and balances to avoid potential fallout.

4.3.1 Decom request submission

Without having the time or development resources to overhaul the current process, we put checks and balances in place to be notified of any decommission request that was being submitted. This simple step gave our team the power to see decoms through to the end, catching any fallout from decom rejections and potential failed changes.

4.3.2 Decom Governance & Control

The addition of governance tasks along with critical controls, really helped give us get a good handle on our decommissioned assets while we refined the existing process.

A few examples are listed below:

- We made sure new deployment projects highlighted hardware slated for decommissioning upfront so it could be flagged in our CMDB as a potential decom candidate. This really gave us a good handle on decoms associated with tech refreshes and data center migrations.
- We implemented a tool change that no longer allowed teams to diassociate their devices from their respective applications in the CMDB without a valid request to decommission the device. This ensured that we had a valid owner group associated with all devices until they were successfully decommissioned.Along with the above, we also ensured that the device state could not be updated to "decommissioned" without a valid change request to decommission the system. This would help address the concern we found where states were being flipped to "decommissioned," but the actual devices never got decommissioned from our critical facilities.
- Lastly, it was very important to align our decom program with our hardware maintenance process for our physical compute and storage devices. This helped us to identify potential decom candidates when devices are taken off maintenance and vice-versa.

4.3.3 Decom Fulfillment

The decom program showed early signs that the workload was putting a strain on fulfiller teams, and as they tried to balance the challenging task of giving decoms the same prioritization as new deployments, the queue backlogs showed that something was clearly not working.

The backlog of queues showed that tasks near the backend of the process, including port and IP reclamations, firewall entry removal, and unracking of the devices, were getting squeezed for resources, as these activities were involved the most risk and time to execute.

To address this issue head on we met with the teams to find alternative solution for these risky and time-consuming steps as the benefits of this program were much less appealing if assets just sat awaiting decom for months, especially when one use case we were trying to address was to minimize security threats.

After meeting with the teams, we were quickly able to enhance the current process by removing some of the more time-consuming steps that did not need to be in the actual decom flow. The teams flagged their work through the tasks and executed the work through a pre-approved change outside of the current decom process.

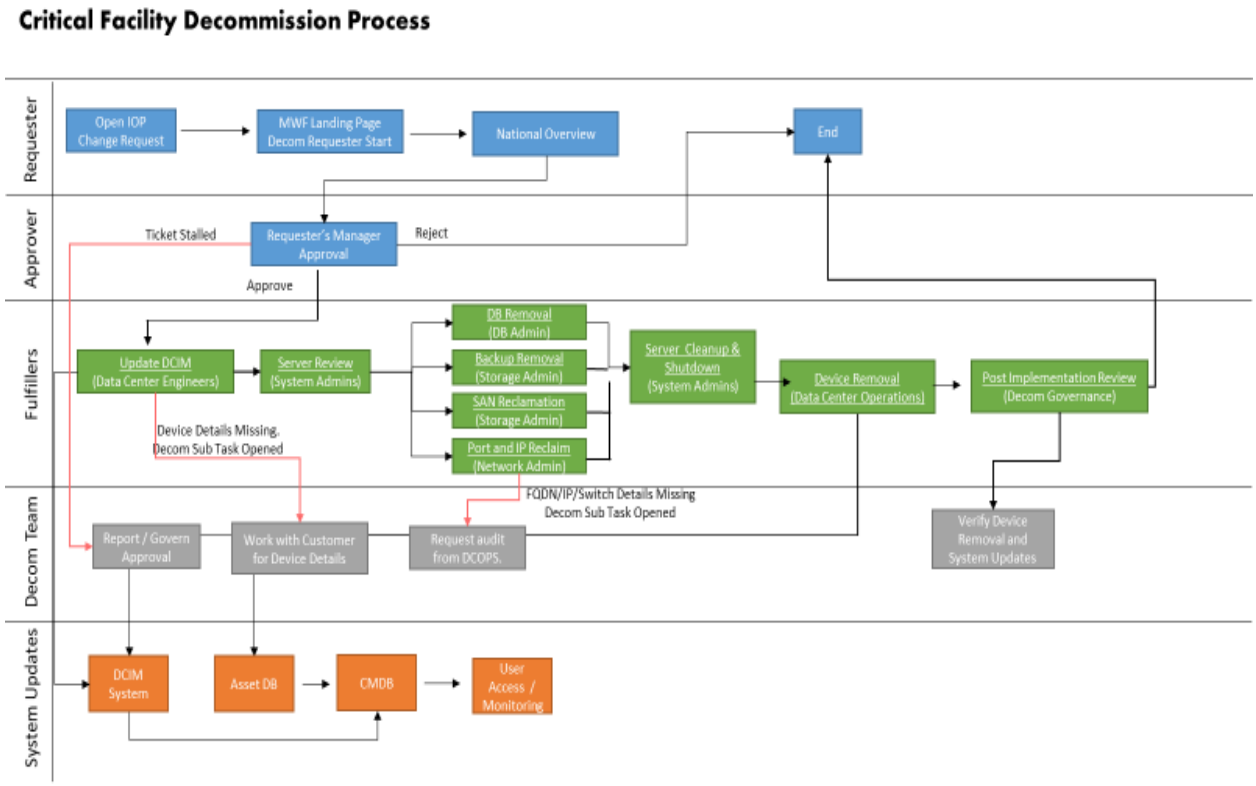

Figure 4 - Example Decommissioning Process

4.3.4 Orphaned Devices

Shortly after standing up the decom program and aligning with our CMDB as the source for ownership relating information, we launched our "Abandoned Server Decom Process" to address devices without ownership or other critical data elements. A few identifiers that we used to determine potential abandoned devices were:

- No ownership in our CMDB - This was the primary indicator.
- State mis-matches between our data sources.
- Powered down or off-network devices.
- Aging devices that were in service longer than 10 years or off maintenance.

In a very controlled manner we went through a 7 step process to turn down orphaned devices and ultimately decommission them if no one raised their hand within 30 days of shutdown. The steps were:

- Try to identify ownership through various sources and resources.
- Perform a physical audit to see if anything can be determined from the device itself. Check if it's even still racked, plugged in or on the network.
- Check for patterns in power usages and network traffic.
- Open a Change Ticket and get approvel for disconnecting or diabling the network port.
- Send out mass communication to Change Management ditro and all hardware service desks and monitoring teams.

- Disconnect or disable the network port.
- Wait 30 days and un-rack the physical device.

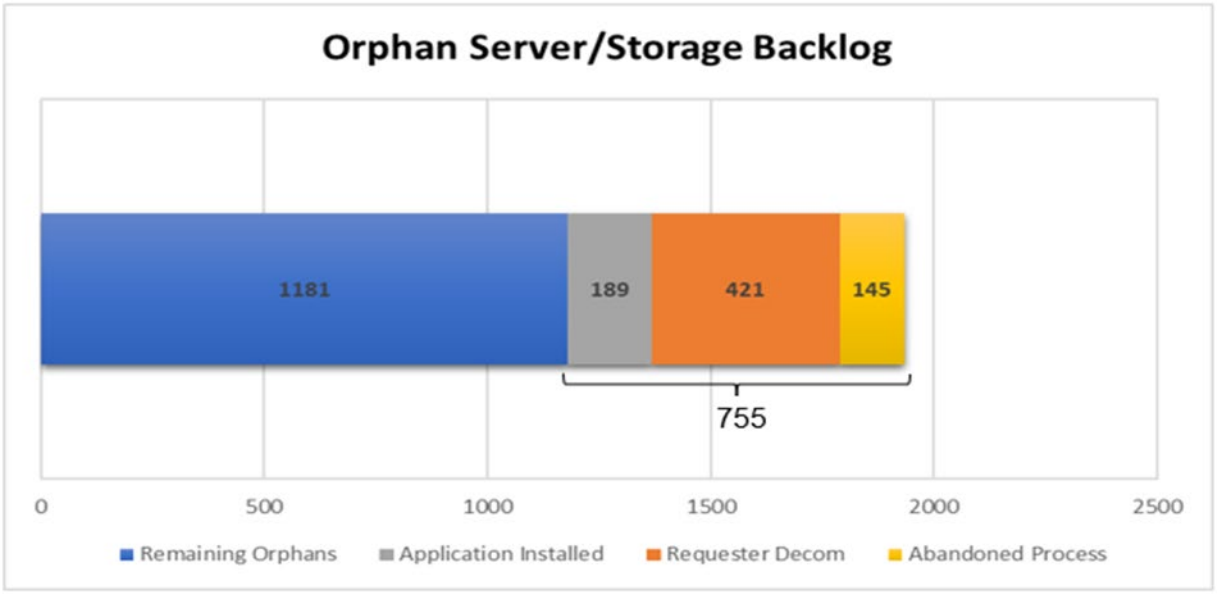

Figure 5 - Orphaned Device Progress Tracking

4.3.5 Remote Sites

The more labor-intensive tasks related to decommissioning of physical servers were still having trouble prioritizing the decom of the physical devices, especially at our non-staffed remote sites. To address this, we were able to generate dashboards and reports highlighting and grouping server decoms by site. This helped our data center teams prioritize and group deployments and decommissions at our remote sites, avoiding additional operating expenses that would have resulted in separate visits to our sites by our vendors

Since inception, we have successfully identified and decommissioned over 12,000 servers, including hundreds of abandoned servers.

5. Next Steps

Building on the success of the program, the team has further evolved the process to manage end-of-life/end-of-service makes/models to drive them thru the decommissioning process with advanced planning. The team is also enhancing the portfolio of the assets to include other appliance-like devices to help expand the scope. Teams are also discussing expanding the portfolio to other sites not in the program scope at this time, including all critical-facilities types, like our Headend & Hubs.

The evolution of the decom program will align with the One Network Program and will require partnership and collaboration across the entire organization. As we move forward we will continue to onboard teams and rationalize tools and processes so that the benefits of this program can be realized across the company.

6. Conclusion

If your organization has not already shifted from a reactive to a proactive approach to handle asset decommissioning, you may find that obsolete assets are taking up valuable resources and possibly draining your IT budget.

Since inception, Comcast has successfully identified and decommissioned over 12K servers including hundreds of abandoned servers and realizing a significant amount of power savings. This would not have been possible without the great work and prioritization given to this program from our Data Center partners and other fullfilment teams at Comcast.

1. Introduction

Enabling the upstream portion of the access network for Mid-Split or High-Split takes more effort than just configuring the cable modem termination system (CMTS) to activate new DOCSIS carriers. Without considering the potential consequences of in-home networks and their effects on DOCSIS and video services, it may not be as seamless to customers or field operations. Most of the characterization required can be remotely measured and observed through telemetry available in the network. Operators can use algorithms to predetermine if there is work to be done in the field or home to enable new spectrum.

While today's tools are helpful in keeping technicians out of homes to make measurements, they were designed for raising flags, enabling swivel chair dashboards, or troubleshooting specific cases. By contrast, turn-up of network spectrum must initiate action instantaneously at large scale, through multiple scenario permutations, and publish essential data and actions cross-functionally to stakeholder organizations such as Sales, Technical Operations, Care, and even Warehouse Ops.

Instead of reacting to consequences or relying on manual vetting of homes, software running on modernized cloud infrastructure can proactively identify blockers, on an individual customer basis, but in massive scale with machine robustness that is immune to human error. The cloud software creates connective tissue between the upgraded network infrastructure and the incumbent suite of tools currently used by operations. This approach facilitates seamless interaction with the customer experience by maximally enabling new services and identifying blockers to frontline teams to optimize efficiency of support.

The work and development in upgrading the plant and services to mid-split is directly related to future upstream expansion including High-Split. Many of the workstreams will continue and will build off the mid-split effort. Moving the downstream spectrum to allow room for the extended upstream spectrum, the process of upgrading the physical plant with nodes and amplifiers that support different frequency splits, the deployment of Orthogonal Frequency Division Multiple Access (OFDMA) and adjacent channel interference (ACI) -- all correlate to high split deployments. The tools and processes to validate mid-split in-home ACI can be used to evaluate neighbor interference in a high split system. ACI is dependent on in-home splitter isolation and neighbor interference is dependent on tap-to-tap isolation. In both cases, the tools and processes are similar. The mid or high split device can be exercised and the level of interference or effect on the adjacent or neighbor device can be measured prior to permanently moving the customer's device into mid or high split operation. In both cases methods have been developed which are non-service and non-customer impacting.

This paper will introduce the reader to Comcast's cloud software architecture, the high-level algorithms used to "score" a home, and the downstream systems fed by the system that will enable valuable upstream services in scale while minimizing impact to customers and maximizing efficiency of its delivery for the operator.

2. Background

Options for upstream capacity enhancements arrived in DOCSIS 3.0 around the 2006 timeframe [1]. The 42 MHz to 85 MHz or mid-split band could become the first step toward supporting new upstream DOCSIS channels for U.S.-based operators. Since then, new DOCSIS 3.1 and 4.0 standards have been developed to support even more channels, in even larger return bands, like high-split, up to 204 MHz, and Full Duplex DOCSIS (FDX), up to 684 MHz. Those new upstream channels would become part of the larger channel set, enabling operators to increase upstream service capacity appreciably beyond what has been historically constrained to 5 – 42 MHz, known as the standard-split or low-split operating band. During the mid-split introduction, diplexer switching within the cable modem (CM) would also be introduced, to remotely control a new and more flexible diplexer function and thus, the channels over which a CM could communicate. Switchable diplexer functionality enabled operators to seed their network footprint with mid-split-capable CPE, while the rest of the network's technology could catch up to support the activation of enhanced upstream services. What wasn't well understood at that time was the new work needed to enable new upstream spectrum activation -- a topic that will be introduced in this section.

Managing the outside plant to support mid-split has become well understood through ongoing upgrade activities. For example, preparations including vacating downstream spectrum, and relocating the downstream out-of-band (OOB) signal to a higher frequency have become standard operating procedures. Because these outside plant pieces were easily implemented, many operators have activated or at least tested mid-split services, and that experience has proven to be appreciably more challenging for some operators. Two of the challenges, standard-split drop amplifiers (SSDAs) and ACI susceptibility, were recently documented in [4] as home network-based challenges that will block the successful activation of mid-split services.

Mid-split tests at Comcast have helped us learn how to remediate these challenges. SSDAs are ideally removed from the home network for many reasons including that they are a more costly, higher-rate point-of-failure than their passive splitter counterparts. Furthermore, SSDAs used in a home network will have to be removed because of its standard-split diplexer, to make way for mid-split upstream services. Therefore, limiting drop amplifier use, wherever possible, may emerge as one of the preferred remediation approaches.

Remediating ACI susceptibility is accomplished by increasing isolation between the mid-split CPE (MS-CPE) and standard-split (SS-CPE) [4]. The following recommendations have emerged based on our learnings during early mid-split testing, to ensure mid-split connectivity between the home network and the outside plant, while minimizing ACI:

1. If there are few (≤ 4) devices within the home requiring outside plant connectivity, receiving video and/or DOCSIS quadrature amplitude modulation (QAM) signaling, use a higher isolation splitter
2. If there are many (> 4) devices within the home requiring outside plant (DOCSIS) connectivity, use a higher isolation passive network (POE DOCSIS-MOCA Passive or PDMP)
3. If 1 and 2 are not feasible due to severe drop loss, consider the following

a. Reduce devices requiring outside plant (DOCSIS) connectivity, and subsequent drop loss, by replacing them with Wi-Fi capable devices
b. Use a drop amplifier sparingly, which actively adds gain to overcome drop loss

4. If 1 through 3 still do not provide adequate isolation for ACI susceptible devices, use a notch filter

The remediation strategy above can be distilled down to the practice of removing drop amplifiers and swapping splitters --something installers are well-versed in dealing with in their day-to-day. The new work is focusing on when and where to perform the above remediation tasks, since we've already learned that doing them for 100% of the mid-split customers at the time of spectrum activation may not be feasible for some operators [4]. Even though it wasn't called this at the time of publication, in-home Health Assessment Tool (iHAT), as it has since become known, has demonstrated that Remote Feature Control (RFC) and Remote Health Monitoring (RHM) can be used to orchestrate remote identifications of mid-split-capable devices that can be activated without remediation. That's opposed to those that need remediation, which can be placed in a queue for activation when that work completes at some point in the future [4]. Activating mid-split upstream will include performing iHAT tests, and distributing results to teams, including installers, who can perform the remediation tasks described above.

3. New Mid-split Activation Tools

3.1. Mid and High split spectrum activation launch (MUSL/HUSL)

As described, the innovative iHAT tool provides a relatively non-intrusive view into a customer's home and, on a home-by-home basis, making basically a Go-No Go declaration with respect to activating spectrum in the Mid-Split band for that customer's device. The iHAT results score a home's DOCSIS readiness for passing spectrum to 85 MHz, and/or its likelihood of creating video interference.

Of course, the home cannot be assessed, nor the spectrum activated efficiently on a home-by-home basis, by relying on manual processes. The information iHAT needs to run, and the information needed by other systems to act on the iHAT outcome, must be automated and the interfaces to these other functions built for production scale.

On the input side, iHAT needs information from external systems to identify if a house is eligible for Mid-Split from an equipment standpoint, and thereby worth running iHAT at all. It needs the inventory of Mid-Split capable CPE on a per node basis identified so that it can target those devices to run the test. The output of iHAT – the scoring of a home's DOCSIS readiness or risk of degrading the video experience – is information that multiple other external systems need. For example, technicians in the home need to know what to fix if a problem related to Mid-Split is identified. Care agents need to know how to diagnose a possible Mid-Split related issue, guide a trouble call, and dispatch the proper support. Salespersons need to know if an upstream speed that requires Mid-Split capability is possible. Data sciences team need iHAT results to populate databases to analyze trends to adjust and optimize roll-out processes and operation support. We will look at these in more detail in a subsequent section.

3.2. Manual vs. Automation Processes – Cloud Infrastructure Choices

It is undeniable that a successful business must find ways to scale in order to stay relevant. This is extremely true when applied to the telecommunications industry. The bandwidth requirements of people and businesses, especially in the upstream, have been increasing dramatically year over year due to advancements in technology. To keep up with the high demand for broadband services, innovation is required. There are some problems that can be solved by throwing people at the problem; however, when you have customer devices in the tens and hundreds of millions, this becomes untenable.

In the field of software, the most basic reasons to build an automated solution have always been the need for smart investment on resources, and finding budget efficiencies, instead of spending to do manual work year after year. The manual method is undeniably easy and quicker to build but has its own downfall. Questions raised are 1) What can be automated? 2) What kind of automated solution would work? 3) What defines the "right" solution? 4) What platform is optimal to architect the solution? 5)What factors play a part in choosing and creating the solution? 6) What are the dependencies and integrations? 7) Perhaps the most important question of all is, how much of an automated solution can sustain the business growth year after year, without re-investing and redoing a lot of the work? A companion question: What about component usability, for other parts of the business?

The downside of the automated solution is that its machines must be built and trained in a way that mimics the thought processes for human troubleshooting skills. Outcome planning involves thinking through as many of the business's use cases as possible, considering regulations and validating as many inputs and outputs as possible. Also, implementing ways to listen and respond back to alerts, and handling notifications to support the operations and avoid potentially impacting customers.

Let's talk about what factors will make automation an answer for any business, which include but aren't limited to: Scalability, availability, maintainability, reusability and budget. It is imperative that incoming data feeds are well sanitized before entering an automation solution, so the data that comes out has integrity for better analysis and reporting. Effective automated solutions have a proven record of reducing the cost overtime -- emphasis is on "effective automation solution."

Taking some time to answer the questions raised above will help to decide upon the right solution. In fact, that's what led us to choose the solution for iHAT. Like any other software solution, we started with the version 1.0 build, described in [4], to research, implement, test and analyze. This pushed us to build iHAT version 2.0 from the lessons learned. Some of the downfalls of version 1.0 included:

- Manual process
- Scalability
- Speed test failures
- SNMP V3 key reset after every reboot made manual process difficult
- Availability of system depended on human resources
- Time consuming and not easily maintainable
- Handling unexpected exceptions
- Automatic rollbacks
- Having to wait until next day to see the runs, if resources are not available

That list of "cons," along with other elements we learned with the manual implementation of version 1.0, gave us clarity on next steps. It also elicited a new list of questions and requirements, including: 1) Developing a list of features to be automated 2) Cloud-based automated solution is the preferred option 3) Reduce human dependencies 4) Ensure that the platform is highly available 5) Automation, manageability, high availability, scalability, cost effective 6) Not possible to reduce dependencies, which will make the solution to be focused on understanding data collection and distribution and build reliable integration to pull right data from source of truth (SOT) and be the most reliable source of distribution (SOD). By taking these lessons learned into consideration, and after answering all the questions, a solution can be envisioned and built that encompasses the qualities that sustainably support business.

3.3. In-Home Health Assessment (iHAT) 2.0

iHAT is a method, or in programming terms, a script, whose inputs must include the Mid-Split-capable devices and any set top boxes (STBs) that share a home network connection with them [4] on an operator's Mid-Split-capable network. iHAT outputs provide operators with results indicating which Mid-Split-capable devices have successfully switched over to Mid-Split and which will require remediation to do so [4]. Remediation associated with Mid-Split was discussed in Section 2. The iHAT PoC from [4] has proven it will work well for small tests with up to 1,000 devices per instance. Performing iHAT for a larger population (millions of devices) revealed challenges in three key areas:

- Automation – Automation of iHAT, specifically input gathering and output distribution wasn't described in [4] but is a critical step at the beginning and ending of such a test. Taking steps to ensure the accuracy of the deployment data, which is constantly changing due to business as usual (BAU) activities, including device swaps, can prevent aborted iHAT tests attributable to incorrect device information. Minimizing the time between gathering inputs and executing iHAT will ensure integrity of the inputs and is best accomplished via automated process.
- Service Impact – [4] described the importance of the speed test application for iHAT testing, essentially behaving as a catalyst for determining whether a mid-split based service is going to degrade other customer services, like video. Using a speed test application in this manner is service affecting because it blocks a customer's use of their CM during speed testing, and therefore is limited to maintenance window activities. Another example of an iHAT service affecting feature is associated with rebooting a CM, which is required when CM switchable diplexer is changed from standard-split to mid-split. Eliminating service affecting components from iHAT process, like the speed test application and reboots, could enable iHAT testing to coexist with customer use.
- Application Dependencies – for many operators, RFC and RHM described in [4] likely translates to multiple application interactions. A sunny day scenario is that all the applications used to support iHAT are responsive, meaning they complete their function in a timely manner. When the sunny day scenario doesn't occur, iHAT is forced to retry, perhaps multiple times, and ultimately abort a test when dependent application functions fail. One example is when RHM doesn't return STB signal-to-noise (SNR) data necessary to perform a pass or fail decision on ACI susceptibility. Other examples of application dependencies include the speed test application in [4] and the associated class of service (COS) change application to test at the higher mid-split service rate. Most standard-split COS rates support up to 35 Mbps, but to fully utilize a DOCSIS 3.1 upstream [2], a new COS supporting a much higher rate, like ~300 Mbps, would have to be available for use during iHAT testing. Hardening iHAT for scale operation

requires a careful review of the function calls it makes, an assessment of their ability to fulfill their function in a timely manner, and a consolidation of all functions wherever possible.

As it turns out, there was an opportunity to consolidate application dependencies of the iHAT process involving the assessment of ACI susceptibility. The original version of iHAT described in [4] was successful in testing during worst-case conditions experienced on a home network, which were simultaneous occurrences of (1) fully utilized mid-split upstream and (2) ACI susceptible service, including a customer watching video. There were at least five dependent functions in the original version of iHAT that were required to assess ACI susceptibility:

1. CM COS change to support higher mid-split rate
2. Switchable diplexer state change from standard-split to mid-split
3. CM reset associated with both (1) and (2)
4. Speed testing application to simulate customer activity
5. Telemetry polls to assess against pass/fail criteria

Upstream carriers energized by an upstream speed test can be replaced with a OFDMA Upstream Data Profile (OUDP) burst signal. An OUDP request and response are shown in Figure 1. Using OUDP bursts can be facilitated without originally required COS changes of (1) but more importantly they give greater flexibility than speed test applications for estimating ACI susceptibility. OUDP bursts can be quicker, managed via CMTS scheduling functions, and more benign because their total transmission power can be reduced appreciably using smaller bandwidth, for example 1.6 MHz. This change may set iHAT up for no longer being restricted to maintenance window activities, especially if other service affecting aspects of iHAT, like reboots associated with switchable diplexer changes, are also eliminated.

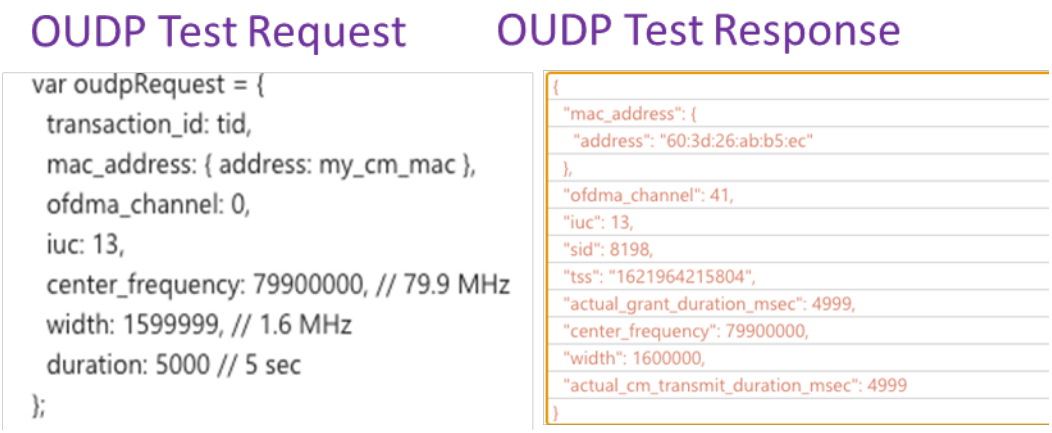

Figure 1 - OUDP Burst Request and Response Parameter Set

With these changes, iHAT will produce a different view of the ACI susceptibility problem, which will become a spectrum-based view from the SS-CPE point of view. While the OUDP signal is bursting in Figure 2, spectrum captures are performed by the SS-CPE at the highest rate possible, providing a multiple-sample spectral view of both the desired downstream signals and the upstream OUDP signal leakage into the SS-CPE, per Figure 3. From Figure 3, ACI assessment becomes more about visualizing OUDP signal leakage into the SS-CPE receiver, than about driving the SS-CPE into a failure state, like the original iHAT v1.0 using the upstream speed test application in [4].

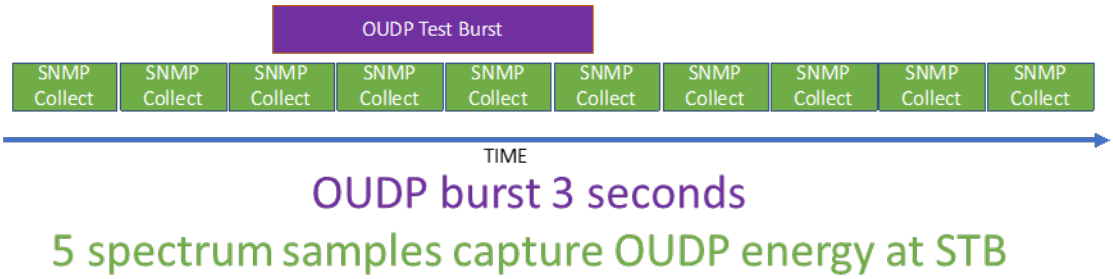

Figure 2 - Simultaneous MS-CPE OUDP Burst and SS-CPE SNMP Data Collection (incl. spectrum capture)

From this new spectrum view, two new parameters can be estimated: MS-CPE to SS-CPE (1) isolation, in decibel units (dB) and (2) interference level, in decibels relative carrier (dBc). When combined with the original metric collection described in [4], the isolation is a simple calculation based upon the telemetry polling of the MS-CPE transmit power in dBmV and the SS-CPE receive power in dBmV. Equation 1 shows this simple relationship, based on decibels relative to one millivolt (dBmV) per 1.6 MHz channels.

$$Isolation\ (dB) = P_{MS-CPE\ OUDP\ TX} - P_{SS-CPE\ DS\ RX} \qquad \text{Equation 1}$$

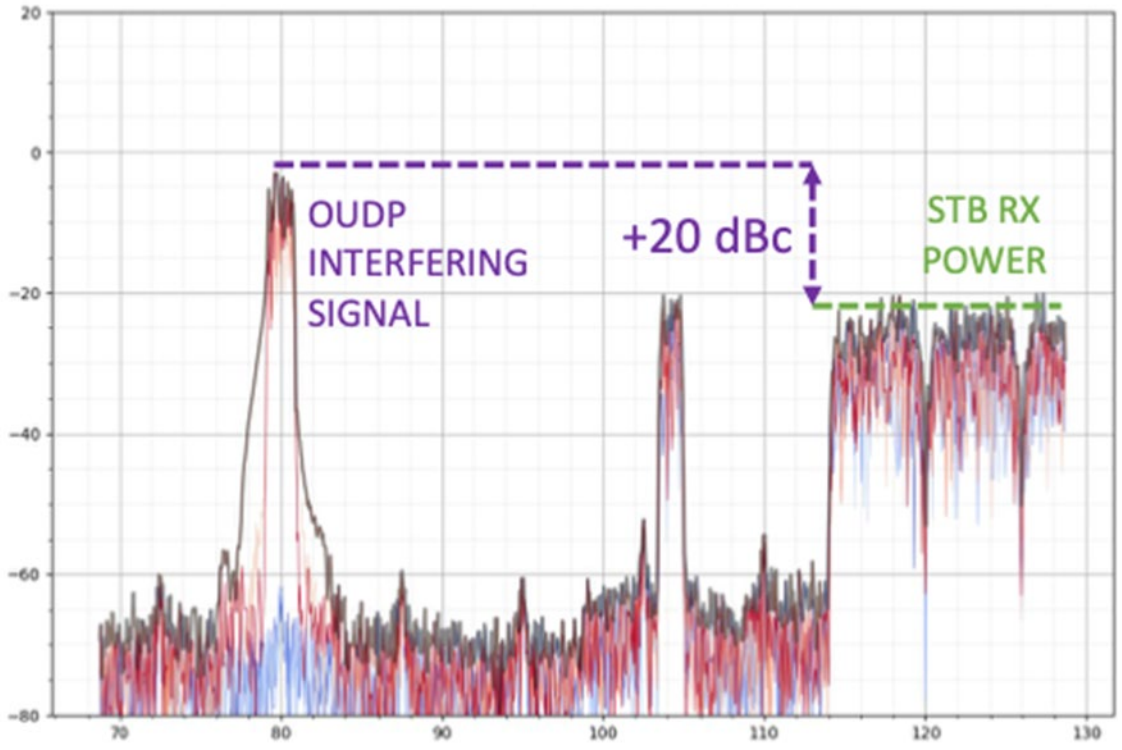

Figure 3 - Spectral View of MS-CPE OUDP Burst, and SS-CPE OOB and Low Frequency Downstream Signals

Adding SS-CPE spectrum data to dependent function 5, "telemetry polls" above and coordinating their capture to occur during the scheduled MS-CPE OUDP burst transmission will enable the estimation of interference level in dBc. Interference level can be estimated via spectrum capture of the SS-CPE per

Equation 2. Multiple captures are required to ensure good estimates can be made for both the OUDP burst and the downstream signal powers. Therefore, the power levels will be a statistical representation of multiple spectrum samples. In particular, the maximum hold, black trace of Figure 3, of the available traces is used to estimate channel power on a 1.6 MHz basis.

$$Interference\ (dBc) = P_{SS-CPE\ OUDP\ RX}\left(\frac{dBmV}{1.6MHz}\right) - P_{SS-CPE\ DS\ RX}\left(\frac{dBmV}{1.6MHz}\right) \qquad \text{Equation 2}$$

Deciding pass or fail will be different than what was originally shared in [4], where failure assessments were made when SS-CPE MER became worse than a threshold value of 28 dB for example, a point past which degraded video would likely be observed for most STBs. New thresholds targets, like 25 dB for isolation and 20 dBc for interference levels, would be revised as data is aggregated from many iHAT tests. Interference targets are based upon laboratory and other investigations, where greater than 20 dBc interference power would result in a degraded MER and FEC metrics. In other words, the undesired OUDP leakage is 20 dB higher than the desired downstream power observed at the SS-CPE input. This level of interference would put certain makes, models, and vintages of SS-CPE at risk of failure due to ACI susceptibility issues, based on internal testing performed in Comcast labs. Interference thresholds would also consider total power level differences of the OUDP signal (1.6 MHz) versus the overlapping mid-split power of OFDMA transmission in the SS-CPE receive window, see Figure 4. Lastly, process accuracy would be proven over full range of SS-CPE downstream receive and MS-CPE upstream transmit power. The 25 dB isolation target is based upon minimum output-port-to-output-port (OP2OP) isolation requirements specified for Comcast passive components.

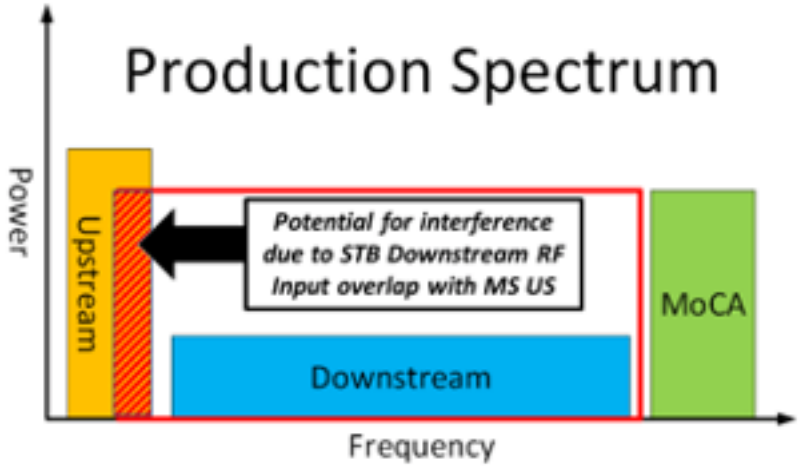

Figure 4 - 30 MHz MS-CPE, SS-CPE Receive Window Overlap

The last piece of scaling mid-split involves configuration of the MS-CPE switchable diplexer and as it turns out, the SNMP set approach discussed in [4] is works well for network utilization improvements and optimizing serving group capacity. Another way operators can manage the MS-CPE's switchable diplexer is using bootfiles. However, if there are no COS changes then redundant bootfiles would need to be deployed to have individualized control over a MS-CPE diplexer state. This could be challenging if there are many mid-split-capable platforms with many different COSs. For operators wanting to introduce a higher service tier, like within their commercial service markets, then co-managing the diplexer state with the COS should coexist nicely, and make more operational sense.

3.4. iHAT as the Engine for Mid-Split Upstream Spectrum Launch (MUSL)

As described, the innovative iHAT tool provides a relatively non-intrusive view into a customer's home and, on a home-by-home basis, will make a Go-No Go declaration with respect to activating spectrum in the Mid-Split band. iHAT scores a home's DOCSIS readiness for passing spectrum to 85 MHz, and its likelihood of creating video interference.

Of course, the home cannot be assessed, nor the spectrum activated efficiently on a home-by-home basis via human interaction. The information iHAT needs to run and the information needed by other systems to act on the iHAT outcome must be automated, and the interfaces to these other functions built for production scale. A logical flow diagram for the overarching Mid-Split Upstream Spectrum Launch (MUSL) ecosystem is shown in Figure 5. As shown, within the MUSL framework, iHAT is the engine. Note that "Tier 1" and "Tier 2" are arbitrary labels meant to represent individualized operator upgrade strategies and illustrate these how these new processes can fit together.

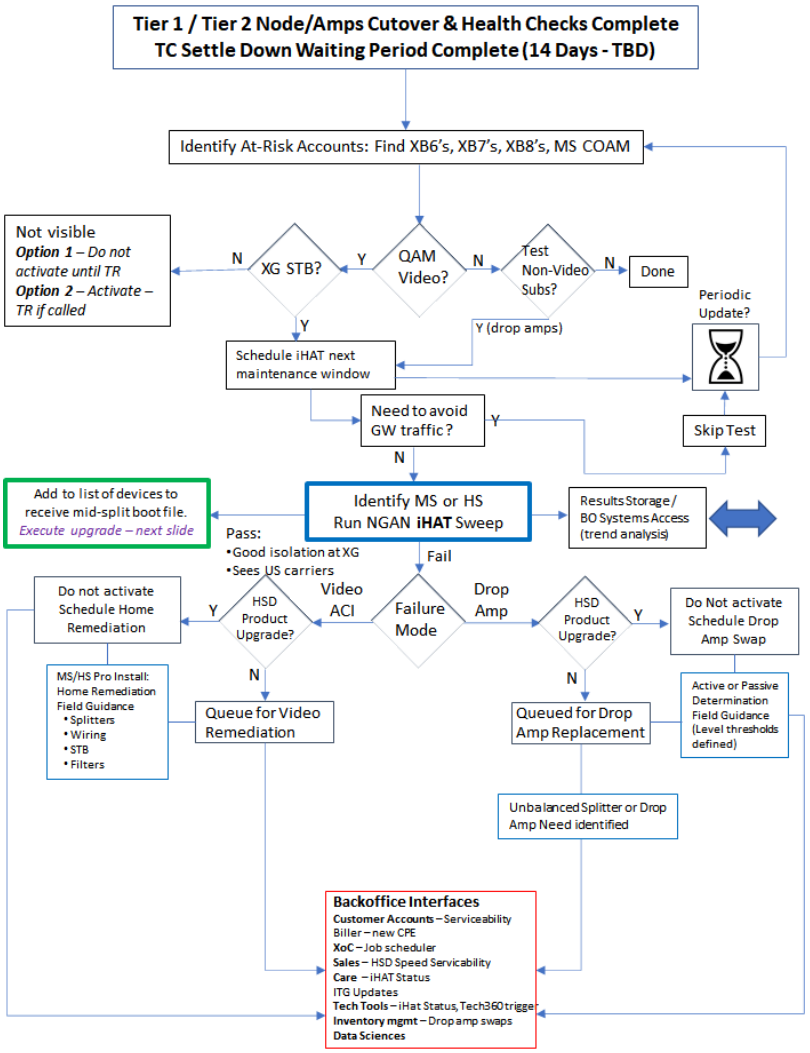

Figure 5 - iHAT is the Engine of the Mid-Split Upstream Spectrum Launch (MUSL) Framework

The interfaces for iHAT for its use in production are highlighted in the red box at the bottom of Figure 5 and briefly described below. These represent interfaces to consider for MUSL to distribute this important information to stakeholders in the success of Mid-Split activation.

Customer Accounts – Serviceability: It is important when there are new upstream speeds that only Mid-Split can provide that the systems to upgrade a customer, whether online or through a service call, recognize if the iHAT status of the home verifies this can be done safely and meet the service speed the customer expects. Alternatively, these tools can trigger an instant iHAT test for an updated result.

Biller – new CPE: When a customer changes CPE, possible iHAT variables that are affected are the device's DOCSIS capabilities, the sensitivity to interference of a new video CPE, and the possibility of a wiring change in the home. It is prudent given these potential risks to the iHAT state as recorded to test (or re-test) the home.

Operations – Job Scheduler: When a home "fails" iHAT, it goes into a remediation queue, with a flag for what needs to be remediated (video or HSD). This allows Tech Ops to plan proactive remediations, occurring routinely and not waiting for a house call to take care of iHAT-known issues.

Sales – Serviceability – Similar to Customer accounts, sales representatives should be able to quickly assess whether a customer, such as an MDU property, is eligible for MS speeds by accessing iHAT status in existing sales tools

Care – iHAT status, ITG Updates: When a TC arrives at an agent, after some amount of ITG-led questioning, the possibility of the issue being MS-related should be considered. A check on the iHAT status of that home, or an instant iHAT test, can help the triage process.

Tech Tools – Tech360: Like Care, when a tech is enroute or onsite to a customer home, part of the awareness the Tech should have is the MS status of the node, and the iHAT status of the customer. Further in the tools, the sequence of steps to diagnose and fix a MS-related issue should also be available.

Inventory Management – Drop Amp swaps: As remediations are made at relatively large scale to remove old drop amps, procurement awareness to the deployment of alternative solutions can ensure the supply pipeline is tracked and cared for

Data Sciences – As iHAT data is accumulated, new information about the home RF environment in dB performance, trends over time, and correlations across neighborhoods can be stored and processed for future optimizations and to estimate future process implications and costs.

3.4.1. Applying MUSL End-to-End

Referring to Figure 6, we can show how iHAT fits within the broader perspective operationally, going from the trigger of a distributed access architecture (DAA) node cutover on the far left to the completion of activation on the far right.

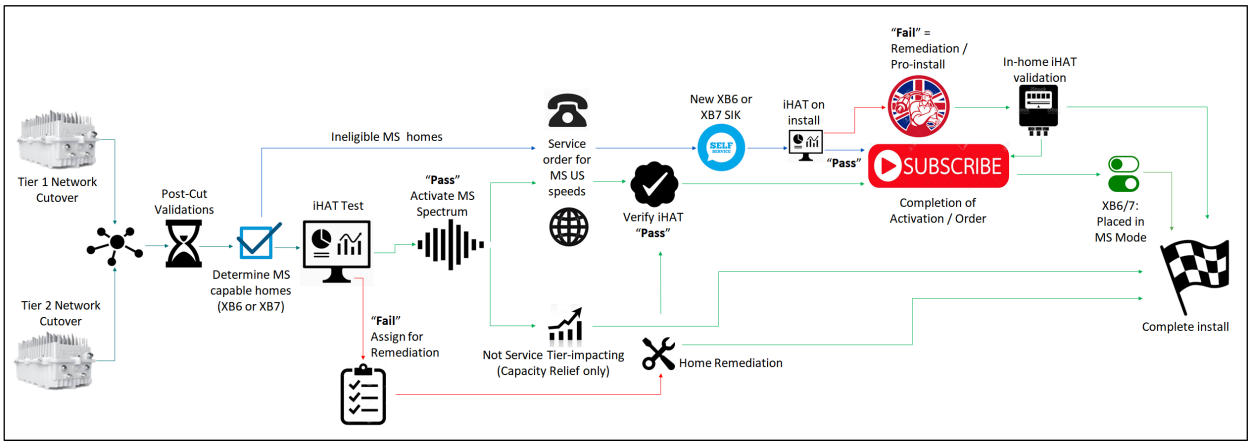

Figure 6 - Simplified Mid-Split Activation Flow: Cutover through to Activation

Beginning on the left, when a mid-split network upgrade occurs, the arbitrarily labeled "Tier 1" or "Tier 2" network cutovers can trigger internal tools, which can notify systems when construction is complete, and the cutover officially closed out. This can then trigger the spectrum activation process. Two things must happen prior to letting iHAT sweep across the node an validate homes where Mid-Split can be turned on. These are

1) *Post-Cut Validation* – Make sure that the network has settled to BAU metrics after the cutover. It is not uncommon to have a short period of elevated trouble calls shortly after a cutover, and it is desired to have any residual cutover issues resolved prior to moving to Mid-Split. This can be time-based, or it can be directly associated with trouble call metrics pre-cut vs post cut.

2) *Determine which homes are eligible for activation* – This boils down to whether the DOCSIS CPE is capable of Mid-Split. At present in Comcast, all DOCSIS 3.1 Gateways are Mid-Split capable.

On item 2) above, if a home is ineligible, then iHAT does not run. Following this arrow to the top path in Figure 6, there is no immediate required step to get that customer a Mid-Split capable modem. There is an effective loss of capacity for every CM that cannot access the DOCSIS 3.1 spectrum, because it forces utilization in the Low-Split band, rather than access the more efficient OFDMA spectrum above 40 MHz.

There is guidance in the field on what triggers a DOCSIS 3.1 upgrade for a customer – a particular speed tier for example. Over time, DOCSIS 3.0 CMs will organically disappear from the field, and it is likely at some point there will need to be a proactive effort to remove the stragglers still in the network to maximize the DOCSIS 3.1 capacity.

Now, as shown in Figure 6, if the customer decides to upgrade their speed tier to one that requires Mid-Split, then of course getting them a gateway capable of that becomes a priority. Also, of course, this customer's home needs to be evaluated for its ability to be placed in Mid-Split mode. So, as a new Mid-Split capable gateway is brought onboard, one of the first things it needs to do is call on iHAT and determine the state of the home for Mid-Split. If iHAT "PASS" is recorded, then the activation process continues, and iHAT sets the device into Mid-Split mode and it becomes capable of using the OFDMA

spectrum, in this case between approximately 40-85 MHz. If iHAT records a "FAIL," then the customer is notified that a technician must come to the home to complete their install, and that their new speed tier will not be available until this "Pro Install" step happens (nor will they be billed for it!). When the remediation is complete, the technician will validate onsite with iHAT triggered locally from the Performance health test (PHT) application.

If the eligibility conditions are in place – Mid-Split capable CM, and a STB model with the necessary Telemetry capability – we move to the right of the blue checkmark of Figure 6: "iHAT Test." Let's now follow the lower path – "iHAT FAIL."

3.4.2. The Remediation Queue

As noted, unless there is a speed upgrade required by a customer, there is not necessarily an immediate need to provide them with a Mid-Split capable gateway. However, it is still important that the iHAT score be logged, and the fact that the home needs to be remediated is documented and populated into tools used by agents and technicians. Homes in this category are placed into a Remediation Queue. iHAT will identify what the failure mode is so that Technicians know what needs to be done. In general, remediation tasks are well-understood and known tasks to technicians – changing out home amplifiers for alternative devices, checking the splitter configuration, model, and wiring to Comcast compliance. After remediation is performed, the iHAT test is run to validate readiness for Mid-Split spectrum, and the activation then completed.

When a home is scheduled for remediation, assuming there is no speed tier ask requiring it, is a business decision with a number of variables having to do with capacity, efficiency, and proactive expense. Ultimately, however, all homes in the remediation queue will need to get serviced to extract the full DOCSIS 3.1 capacity and maximize the upstream runway these architectures are made to deliver.

Also note that a customer's iHAT "score" is not necessarily static. Changes to the coaxial network in the home made by the customer, or new CPE brought into the home can both affect the iHAT score. These events are "On demand triggers" that will force iHAT to run off-cycle even after the initial iHAT sweep of the node at cutover.

3.4.3. iHAT PASS

The most straightforward flow in Figure 6 is right now the center, left to right. Both branches are logical and easily understood. An iHAT "PASS" means that the DOCSIS signals up to 85 MHz are ably received at vCMTS receiver, indicating that there is no home amplifier or filter blocking this transmission. AND it means that the home has been checked for RF isolation between the CM and the STB and determined not to be at risk.

Going to the lower green flow down the center of Figure 6, this is the case where there is no speed upgrade involved. The spectrum is being turned on to maximize efficient use of upstream capacity. The mid split plant upgrade plans, arbitrarily labeled as "Tier 1" and "Tier 2", are counting on use of this capacity to defer any future network augmentation by many years. So, while it may not be noticeably service impacting to a customer, it is network impacting and indirectly service impacting by lowering the congestion on that node overall.

The upper green flow is the case when a speed tier upgrade request is made, and there is already a Mid-Split capable device present. Because of the fact that an iHAT score is not static, a new iHAT score may make sense to obtain prior to upgrading the customer. The customer expectations for the new service will

be higher, and the awareness acute to service impacting issues, so it is prudent to be certain that the home is still in a "ready" condition. In addition, because the customer now has, for example, a speed tier of 200 Mbps, they will have bursts of energy more likely to utilize a wide chunk of the mid-split band at once, a condition that more aggressively exposes the STB to energy that can cause video degradation. If this "updated" iHAT result is still "PASS," then activation is completed. If not (this is not shown), this home reverts to a Remediation state, and because of the desire for a new service tier, it is a Remediation Queue with a higher priority.

3.5 iHAT Software Solution Implementation

An overview of the innovative iHAT tool process flow is described above. This section contains a detailed deep dive into the automated software solution that was built for iHAT version 2.0. The new version of iHAT has been built exclusively for the devices that exist on a distributed access architecture (DAA) platform only.

There are several aspects of the software that have been prioritized when upgrading to version 2 from version 1.

Invasiveness

The major purpose of iHAT is to test whether a customer can successfully be switched to mid split without impacting their service. To do so, some service test must be initiated and compared to a baseline. Previously, in iHAT version 1, a speed test was run on the customer device. While this provided impressive results and proved to be a robust option, it left something to be desired in terms of efficiency.

The end goal of iHAT, and really any type of automated software that has the possibility of impacting the customer experience, is to lessen that impact as much as possible. To this end, iHAT version 2 has switched to a lightweight OUDP burst in lieu of the more heavy-handed speed test that version 1 relied upon. While running a speed test on customer hardware during peak hours would be out of the question, scheduling a short OUDP burst is not. This opens the possibility of running iHAT tests outside of maintenance windows without impacting the customer experience. The only current barrier to a truly unobtrusive experience is the need for a device reset after the split type has changed on the gateway's diplexer – a limitation that will hopefully be lifted with a future software upgrade.

Scale

To properly scale out software improvements that can cover the entire network footprint, agile software is needed. Historically, network configurations and optimizations were carried out in an ad-hoc method by network technicians. While there may always be a need for humans to make tough decisions about how to go about solving some problems, there are other problems that are easily solved by simple logical automation.

One case study of this can be seen in the Octave project, where cable modem level data was gathered by the genome service and used to regularly optimize the DOCSIS configurations of CMTSs [6] [7]. Comcast as a company is striving to upgrade the network at a pace that cannot be matched by cherry picking small parts of the network one at a time. Therefore, the system that facilitates such sweeping network changes must be able to operate in a seamless manner.

In the case of iHAT, this automation comes at several stages. Version 1 had to manually run; this type of model can only be tenable for a handful of node segments/accounts/devices. In Version 2, node segments on the DAA will be automatically registered for the iHAT test pool when they become capable candidates based on network software and hardware criteria. Once a node segment is flagged as capable, automation is set in motion to filter the CPE devices that are serviced by the node segment to those that are iHAT eligible and testing will commence. MUSL will then periodically run iHAT as necessary based on network and account level changes.

Version 2 of iHAT is built to be flat and scalable. All tests are run at a gateway device level leveraging Amazon Web Services (AWS) step functions and lambdas. This type of architecture should theoretically make the iHAT service scale as needed until it can encompass the entirety of the network footprint. The only bottleneck comes from a DOCSIS limitation that only allows one OUDP burst to be scheduled at a time on a remote PHY device (RPD) level basis. This means that the theoretical maximum number of gateways that can be run per RPD is defined by the (maintenance window time)/(OUDP burst duration) with some padding on either end given for device resets.

Speed

The actual test only takes a few seconds of gathering empirical data and a second or so of computing. The bulk of the time during any given maintenance window is taken up by waiting for device resets, which will ideally be eliminated with hitless split changes sometime in the future.

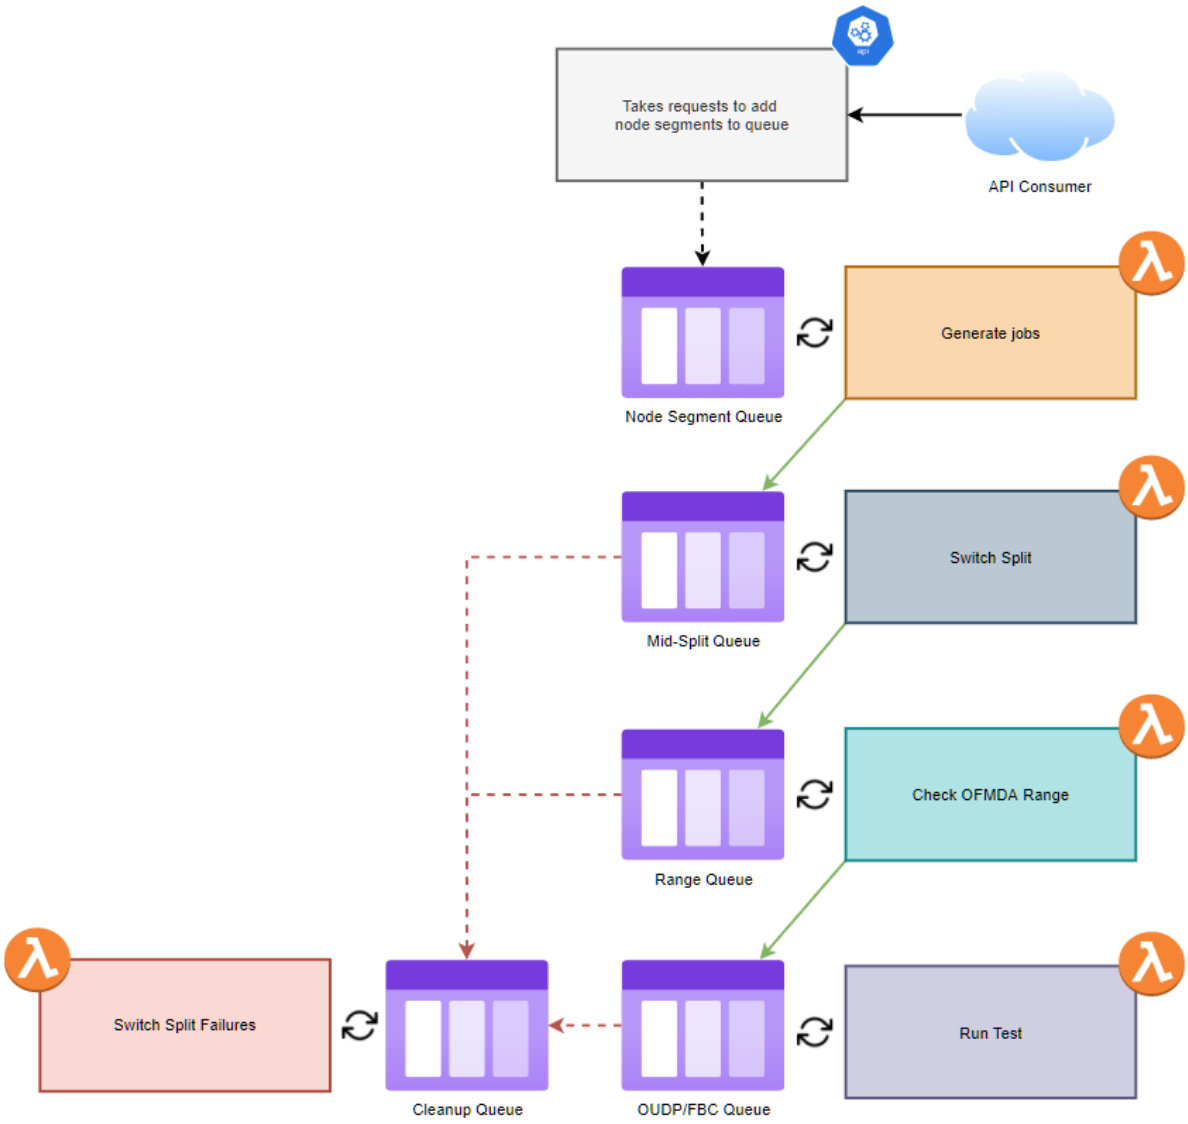

Figure 7 - High-Level iHAT Architecture

Error! Reference source not found. illustrates the high-level architecture that iHATV2 employs to orchestrate mid-split testing at scale. There are 6 distinct phases that are shown here.

Phase 1

Phase 1 is the acceptance phase. This is facilitated by having an application program interface (API) layer that accepts requests for node segment/RPD pairs to be added into the iHAT testing queue to be run in the next maintenance window. This API's sole purpose is to provide an authentication/authorization abstraction layer that wraps the node segment queue.

Phase 2

Phase 2 is the prep phase. This phase starts with spinning up lambda functions using CloudWatch events at the beginning on a maintenance window. Two integrations come into play in this phase. First, the federated data service (FDS) API is called with each node segment name. Node segment names are swapped for MAC addresses that are grouped by service location. At this point, the MAC addresses are opaque, and the genome service must be queried for each MAC address to get device metadata. Genome provides important data such as the model number and current diplexer switch type. The starting switch type is stored so that each device can be placed back in its original state in the case of inconclusive test results.

The model number is then used to classify device types and group devices on an account. Accounts can then be further classified as mid-split eligible based on the kinds and configurations of the devices. Each eligible gateway on an account will generate one "device-level" job. Each device-level job will include one gateway and all set-top-box devices on the account that can produce full band captures (FBCs). Jobs are placed in the switch-split queue for further processing.

Phase 3

Phase 3 is the switch split phase. The phase 3 lambda is responsible for making sure that all modems are switched to mid split mode prior to data collection. If the gateway is already in mid-split mode, then the lambda is responsible for moving the job from the switch-split queue to the range queue, so the cable modem can be immediately processed. If, however, the gateway is not in mid-split mode, then the lambda is responsible for first calling genome to initiate the switch-split into mid-split, and then calling genome again to initiate a modem reset. Once the modem reset has been initiated, the job can be moved from the switch-split queue into the range queue with a 2-minute message timer. This message timer will ensure that minimal resources are spent on waiting for the modem to reset. It is important to note that the rest and delay portion of this lambda may still be required when iHAT switches to a hitless mode of operation.

Phase 4

Phase 4 is the ranging phase. It imperative that the modem is in the correct state before iHAT data collection begins. The range queue that serves phase 4 is the only queue that is not a first-in, first-out (FIFO) queue as it must house two different types of messages. The first type of message represents cable modems that were already in mid split and did not need a modem reset. These messages should appear immediately in the queue as they have no message timer associated with them. The second type of message represents those cable modems that required a modem reset. These messages will only appear after the 2-minute message timer has elapsed. Once a lambda consumes either type of message, it polls genome for a device online status. Once the device is online, then the lambda confirms that the device can range on OFDMA. If the device fails to range, then the modem is sent to the cleanup queue, where it can be switched back into sub-split mode. This type of failure is most likely due to blockage by a drop amp. If, however, everything looks good at the device, --it's online and ranging, the job can be moved to the OUDP/FBC queue with a message ID corresponding to the RPD that the customer gateway is connected to.

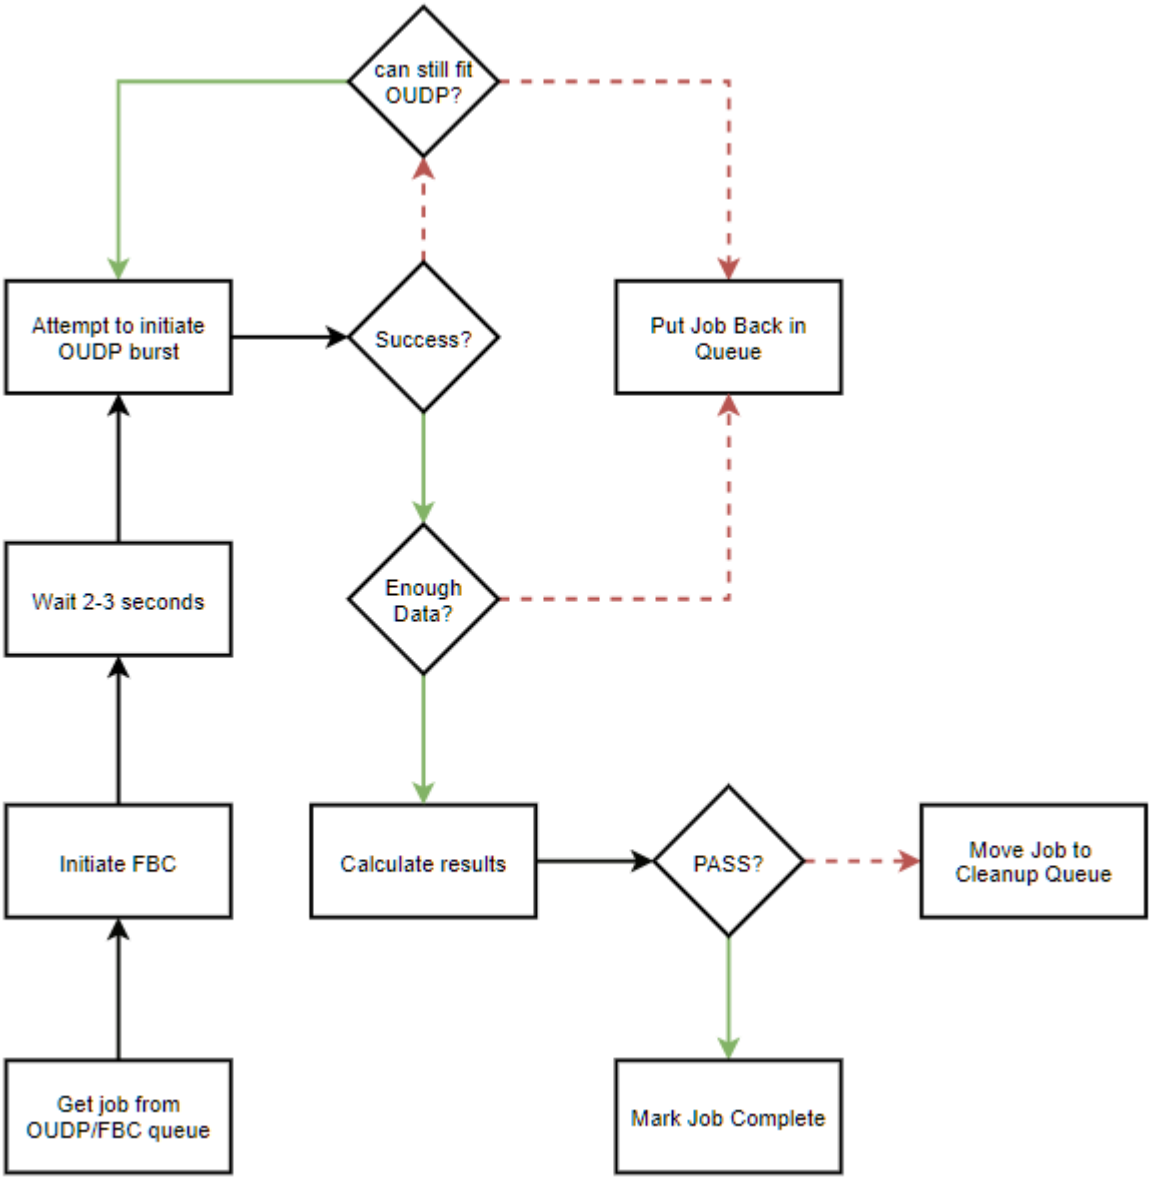

Figure 8 – OUDP/FBC Orchestration Workflow

Phase 5

Phase 5 is where the meat of the iHAT test is performed. A visualization of the workflow is depicted in Figure 8. This phase is slightly more involved than the rest of the phases because careful orchestration of the OUDP burst resource is required. As per the DOCSIS spec, only one OUDP burst on a certain frequency range can occur on a given RPD at one time. This means that one must be very careful when attempting to scale a process that heavily depends on the availability of the OUDP burst service.

The concurrency of this process is controlled by making sure that RPD names are used as message group IDs in the OUDP/FBC queue. In all other queues that exist in the iHAT V2 workflow, the message group ID is the unique value given by the job ID. Amazon simple queue service (SQS) enforces that only one message from a given message group ID is consumed at a given time if the message batch is set to 1. This

means that if all jobs that are associated with a given RPD are associated with the same message group ID, they should execute in serial.

The maximum theoretical concurrency for the data collection process is equal to the number of unique RPDs. Earlier iterations of the architecture tended towards forcing a concurrency equal to the number of unique RPDs in the maintenance window. The fact that a full range of scaling options is available is important, as the iHAT workflow relies on the availability and scale of many other systems to function properly. Being able to calibrate scale to successfully integrate with other systems is a must.

The workflow begins with a lambda firing from the SQS event trigger. First, genome is called to initiate FBC on each associated set top box in the job. This takes 2-3 seconds to initiate, so the lambda sleeps for 3 seconds before attempting to initiate the OUDP burst through the gateway. If the OUDP burst fails, then it is attempted up to 2-3 additional times depending on the FBC duration that was chosen. If it still fails, or if the FBC process does not capture enough data for any of the set top boxes, then the lambda places the job at the end of the queue to be retried later.

If the FBC and OUDP burst orchestration is a success, then the iHAT calculation can commence. This part of the code only takes on the order of a second to complete. If the calculation yields a success, then the OUDP/FBC job is marked complete, and the job has reached the end of the iHAT workflow. If the calculation yields a failure, then the job is moved to the cleanup queue.

Phase 6

Phase 6's purpose is to clean up all failed jobs. It used as the dead letter queue for all queues except the node segment queue. It can also accept jobs from the phase 5 lambda function in the case that a successful test is run, but a failure is noted by the telemetry indicating video service degradation. Categorized failures include, but are not limited to: failure of the device to switch split types, failure of the device to reset properly, failure of the device to range on OFDMA, failure of the OUDP burst to execute properly, and failure due to video noise. It is also possible that the iHAT workflow fails due to underlying software issues, which could be due to network failures or failures of external systems to provide required data.

There are three outcomes of the iHAT workflow. Case 1 is the case where everything is green and the iHAT calculations yield a PASS. In this case, the customer gateway is left in mid-split. Case 2 is the case where the iHAT calculations yield a clear FAIL. In this case, the customer gateway is switched back to sub-split. Case 3 is the case where the iHAT workflow failed and is inconclusive. In this case, the customer device is switched back to its original setting that was recorded in phase 2, whether that is mid or sub-split. Case 2 and 3 may require manual remediation.

The workflow outlined above serves the BAU process of moving customer devices in bulk to mid split and routinely testing them in bulk to ensure network health. There is, however, a separate use case for on-demand testing for customers with a technician in the home. Since the above workflow uses highly modularized components, serving this case is trivial as the individual lambdas can be exposed via API and used by customer care tools. The current use cases are for a technician to move a customer modem from mid to sub-split or vice versa and for an on-demand OUDP/FBC data collection and calculation to yield a score.

The iHAT project requires several integrations with external systems. The one that is used most heavily is the integration with the genome service. The iHAT tool would be much more complicated if it had to deal with authentication and SNMP, but the genome service abstracts those technical details away, allowing for a much cleaner and elegant solution. The next section describes in detail how the genome service achieves this level of abstraction at scale.

3.5.1 Data Collection & Device Interface Platform (Genome)

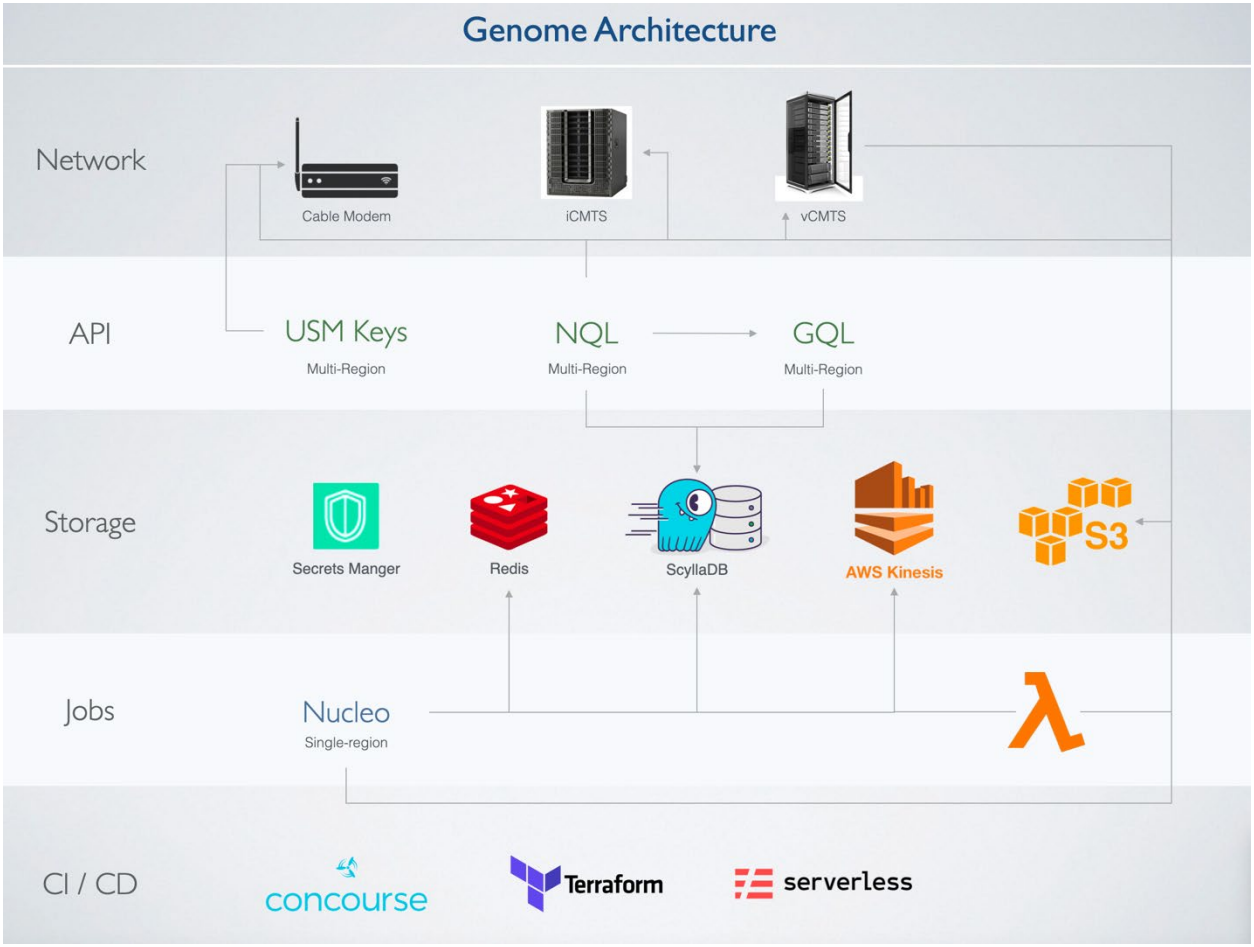

Figure 9 – Genome Architecture

The Genome platform in Figure 9 was originally built to serve the Octave Profile Management Application (PMA) initiative but has grown into a platform of its own since inception [6] [7]. The main purpose of Genome is to actively poll and cache data from devices such as cable modems and CMTSs in a scalable and configurable way while offering consumers the ability to analyze the cached data or get live data in a seamless fashion (on-demand data polling). This positions Genome to be the sole data provider, SNMPV3 secure key collection, data validator and device interface layer for cable modem and CMTS data, eliminating inefficiencies around oversaturating CMTSs or cable modems with multiple connections and over fetching duplicative data. In the context of iHAT, Genome is responsible for verification of eligible accounts and the devices that has been provided by business and their current status, running spectrum analysis while the OUDP has been triggered.

Genome is made up of two layers, the poller layer, and the query layer. A "poller" is simply a piece of software that is responsible for scheduling, collecting, and standardizing a set of data from devices. Pollers are built to be lean, modular, and extensible. The query layer for Genome is called Network Query Language (NQL), which exposes a declarative API service through which consumers request live or cached data. All pollers are primary consumers of NQL to collect live data, while also offering external consumers to do the same. NQL's goal is to offer a declarative abstraction layer for edge network devices, allowing

consumers to query using standard hypertext transfer protocol secure (HTTPS) instead of simple network management protocol (SNMP), trivial file transfer protocol (TFTP), and various other network communication protocols.

Genome requires a list of eligible devices to poll the necessary data for iHAT. iHAT integration layer works as the mediator between business system which holds the list of eligible Nodes/Accounts and verifies the OFDMA being active, along with mid-split capability and eligibility, then feeds Genome with this eligible device list to check the device status to make sure they are in the right state to run iHAT. The polling could be done at any configured frequency or on-demand.

In addition, Genome must ensure that data collection can scale when devices are added over time such that data collection and aggregation can be achieved in a given polling window. It must also ensure that the ingested data is validated and cleaned before it is cached. As the amount of data is large, especially in the case of cable modem data, Genome must also manage data retention policies in order to reduce cost.

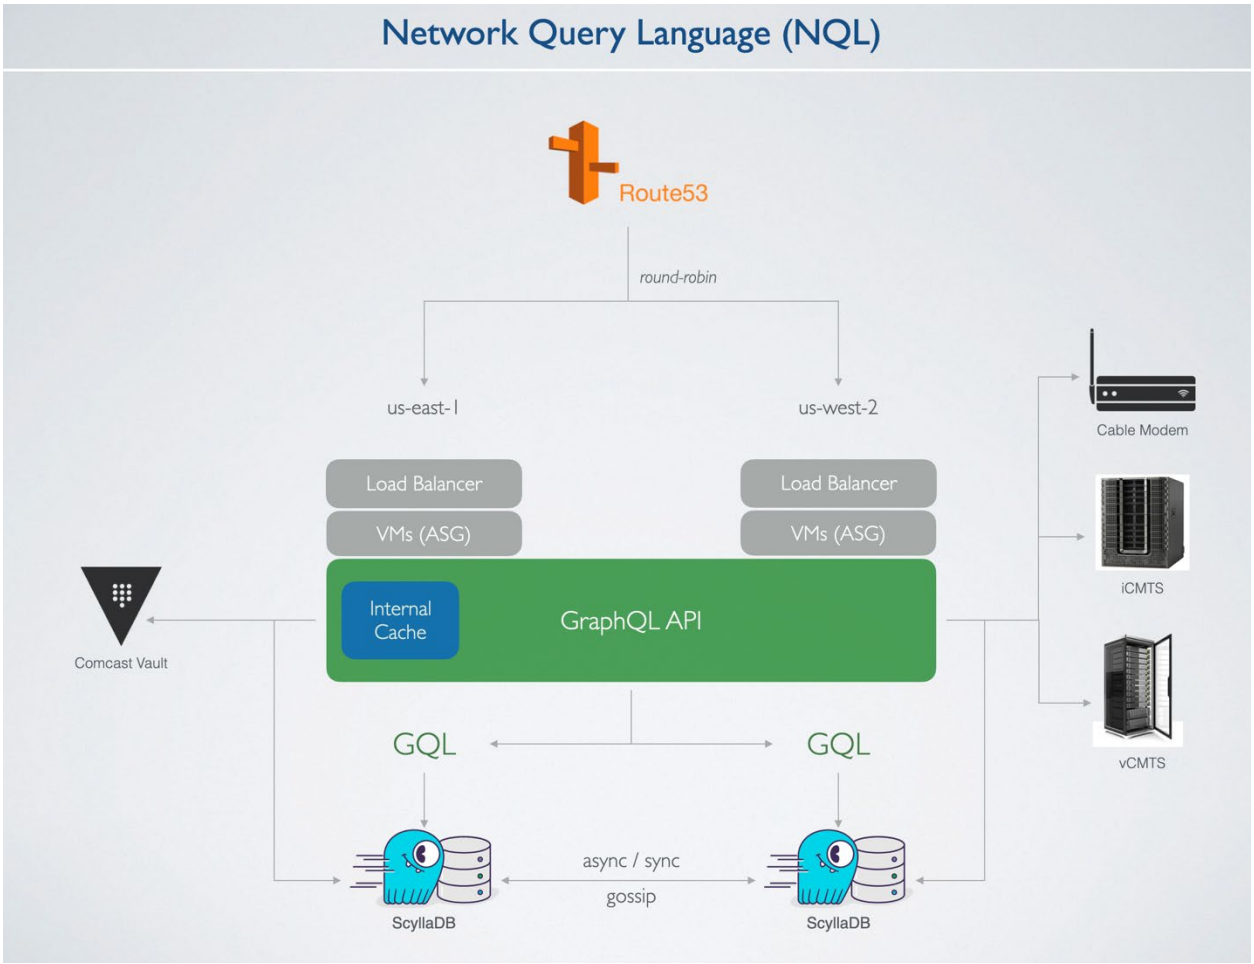

Figure 10 – Genome API – NQL Architecture

NQL's journey began in the early days of Octave development as well. The goal was to create an API service which abstracts away all different protocols around networking and let end users interact through HTTPS. The first iteration came in the form of a representational state transfer (REST) API which accepted object identifier (OIDs) parameters and returned the output through HTTPS. While this iteration ran in

production for several months, several shortcomings were brought to light. For example, use cases involving many data points per CMTS or CMs, necessitated making multiple requests to the API. Each request would connect to the CMTS, which resulted in opening and closing sockets many times over multiple requests. Furthermore, the work of encoding and decoding large amounts of javascript object notation (JSON) data was repeated for each request, degrading the overall performance of the service through repetition of work. Graph query language (GraphQL) was a natural option that allows data schemas to easily evolve and can handle complex relationships between data sets. NQL architecture in Figure 10 was born.

As NQL offers an abstraction layer for connectivity to both cable modems and CMTSs, it must therefore manage all writes as well as reads to each network device. In order to accomplish such a feat, it supports both IPv4 and IPv6 communication protocols. NQL is built primarily using the GraphQL specification and has been optimized at node level. In some cases, consumers may require a request-response type handshake, where the consumer keeps a socket open until the requested data is returned. However, many queries may be long running, and it may not be practical or possible for a consumer to keep a connection open for the duration of the process.

Historically, the team used Nodejs as a declarative jack-of-all languages. However, in this use case, performance is king. As Golang is routinely touted as a performance-oriented language geared towards networking applications, it was a simple choice after orchestrating some internal benchmarking. Genome as of today supports 3+ billion transactions a day with ability to scale up as we need. Simple GraphQL APIs were built in both languages to test a small fraction of our total scale.

NQL's secure shell (SSH) feature allows consumers to log into a supported remote device through HTTPS rather than SSH. This allows NQL to abstract away details around authentication, authorization, and managing the underlying SSH connection. Users are able to connect to a host, run multiple commands, and get output back for each command. NQL uses GraphQL to define the API, which allows developers to develop powerful features and evolve our API without breaking the world. NQLs SSH is a simple layer around SSH, all the logic around what commands to run in what order and what to do with the output is handled by the client itself. For example, configuration management can apply configurations to a CMTS and then analyze the output to see if everything went well. All this is done through HTTPS using NQL. NQL has evolved from a standalone service running on an elastic compute cloud (EC2) virtual machine (VM) to where it could be leveraged anywhere within our codebase and able to run in any container or lambda alongside our codebase.

SNMP v2/v3 capability and the user-based security model (USM) are shown in Figure 11. Genome by default uses SNMP V3, and if the device is not V3 enabled, the fallback option is V2. The role of USM is as follows:

- Get public and manager key from cable modem
- Use manager key and V3 security name as input to get vault secret
- Use cryptographic hash function on vault secret and public key and compute auth priv keys.

With authentication in place, collection of the SNMP data can be performed on an as needed basis and streamed to Kinesis, which will be used by Analytical Engine from PMA and other consumers of the data including iHAT. iHAT uses NQL layer as the interface to do the SNMP set for moving the device from sub to mid-split.

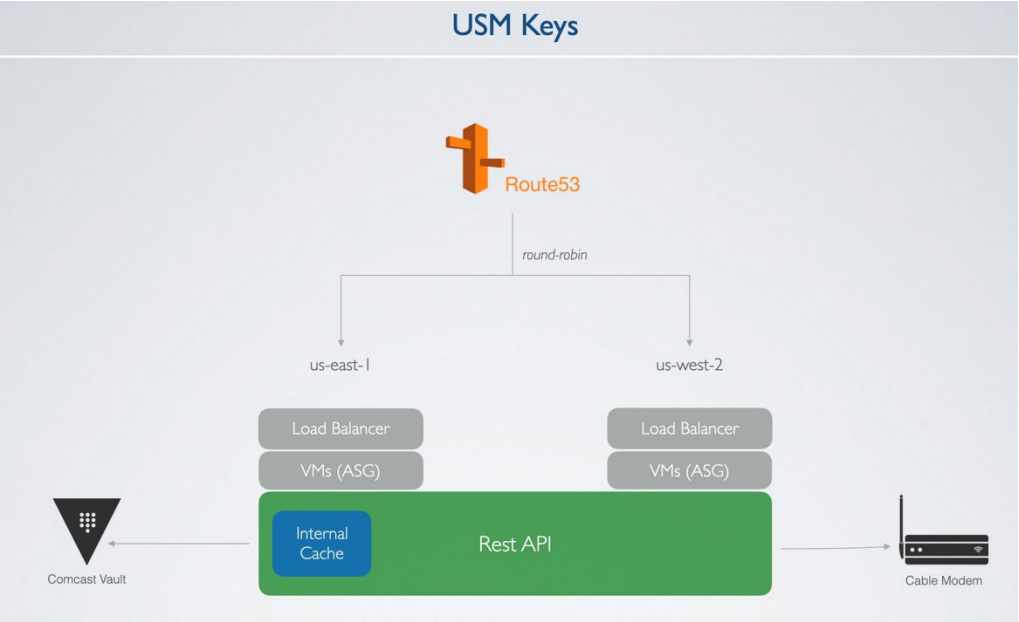

Figure 11 – SNMPv3 USM key architecture

This section has provided a detailed view of the iHAT software architecture covering genome, NQL and USM. Overall, the architecture is like previously presented PMA architecture [6] [7], with many software components being reused to support iHAT functionality. With an understanding of the iHAT operation for mid-split, we would like to now discuss future enhancement considerations for expanding upstream path to high-split and what new functionality would need to be considered for future generations of iHAT software.

4. High-split Future

Plant upgrades with mid-split are just the beginning of extending the upstream spectrum and increasing the upstream throughput capability. Mid-split spectrum activation adds needed capacity in the upstream and extends the life of node splits. To achieve 1 Gbps symmetrical services significantly more upstream spectrum is needed. High-split development and deployments are in process and FDX is right around the corner to achieve one Gbps and greater symmetrical services.

Throughout the development of mid-split, there were many aspects of the access network which were evaluated and many challenges which were overcome. Many of the workstreams and lessons learned in mid-split extend to high-split development and deployment.

OFDMA activation, node and amplifier upgrades, the shift of the downstream spectrum to allow room for the extended upstream spectrum, adjacent channel interference, plant design levels, CPE devices, in home amplifiers and splitting networks were all extensively evaluated and validated for mid-split deployments. The learnings from the development were and continue to be used for high split.

Comcast's network upgrades have predominately been N+0 and recently include amplifiers (N+X) for mid-split deployments. The process of splitting and upgrading a standard-split analog node to mid-split digital nodes is well understood and completed many times a day throughout our networks. Creation and push of the downstream channel map, upstream channel configuration and upgrade of plant equipment; nodes and amplifiers all happen simultaneously and with minimal disruption to our customers. This same

process can be used for mid to high split upgrades. Mid split nodes amplifiers are 1.2 GHz, so there's plenty of spectrum available to move the downstream spectrum above 258 MHz prior to high split equipment installation. Tools, like Comcast's Scout Monitoring, have been developed to monitor and validate many physical layer parameters, including OFDMA in the upstream, and these have been extended to 204 MHz in the upstream. Examples of these tools are shown below. Figure 12 and Figure 13 show the upstream DOCSIS 3.0 and 3.1 channel status via Scout.

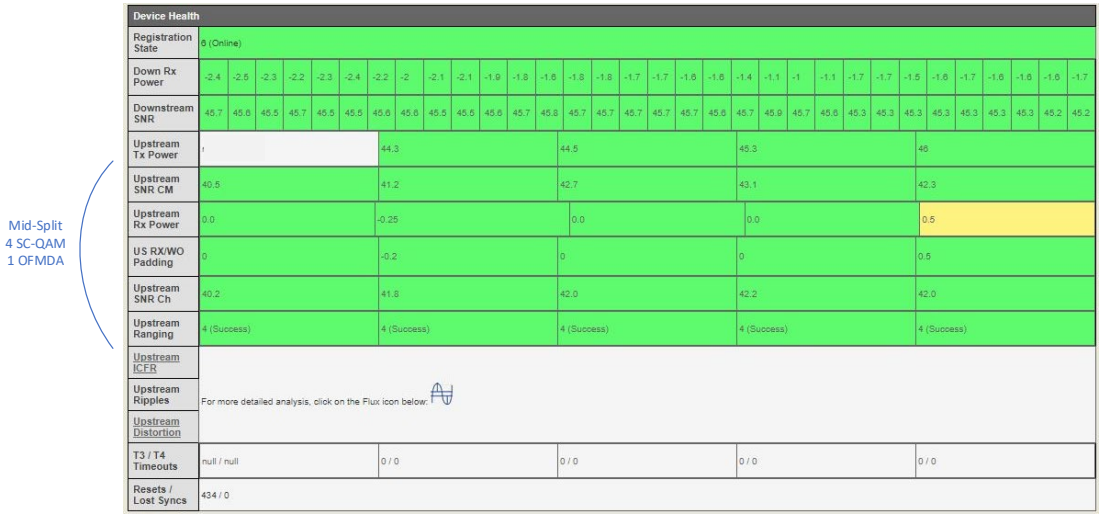

Figure 12 - Mid Split Scout Screen Capture with 4 SC-QAMs and 1 OFDMA

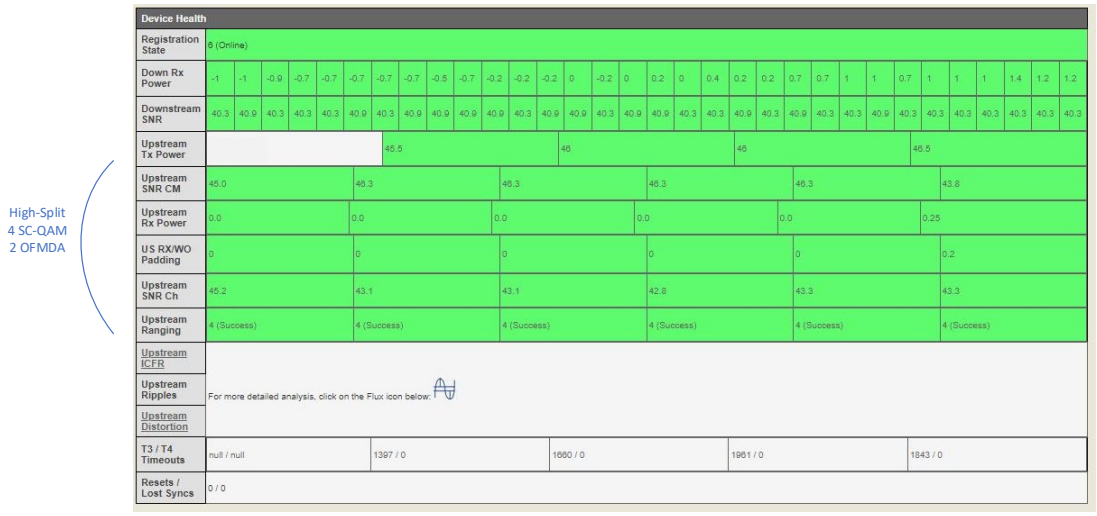

Figure 13 - High Split Scout Screen Capture with 4 SC-QAMs and 1 OFDMA

Figure 14 and Figure 15 show the upstream spectrum as received at the RPD via Yeti for mid split systems to 85 MHz and high split systems to 204 MHz. Yeti is a "real time" upstream spectrum analyzer tool used to evaluate the upstream channels and also the underlying upstream noise.

Figure 14 - High Split Yeti Screen Capture at RPD with 4 SC-QAMs and 1 OFDMA Channels

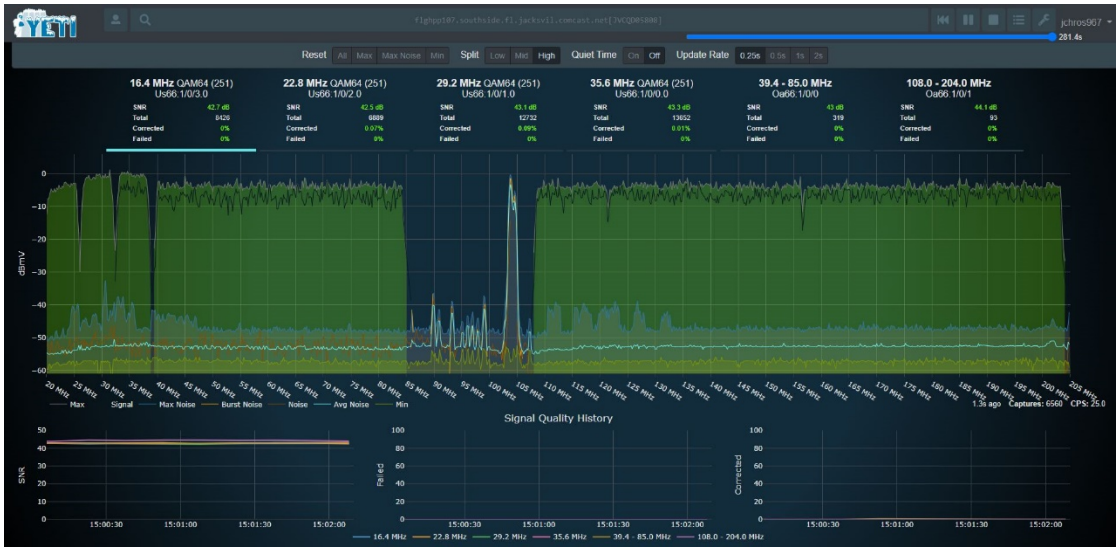

Figure 15 - High Split Yeti Screen Capture showing 2 OFDMA Channels

Note that the lower spectrum edge starts at 20 MHz due to current FFT limitations

4.1. Extending iHAT for Neighbor Interference Case

ACI has been studied extensively for mid-split plants. Thresholds of interference for our set-top boxes are well understood and as discussed iHAT development is well under way for mid-split deployment to analyze ACI with no customer impact. iHAT first started out exercising the full mid-split upstream band with a speed test and the adjacent in-home set-top box performance was monitored during the speed test. This was a very effective way to measure the impact of the mid-split spectrum on the adjacent in-home set-top boxes. The speed test could interfere with customer high speed data usage and interference was possible on the set-top box, if the in-home isolation between the gateway and set-top box was inadequate.

During the development of high-split, a method of evaluating leakage was needed where the high split gateway in the home creates a leakage tone. DOCSIS 3.1 supports OUDP signals and APIs have been developed to have the vCMTS command a cable modem to create an OUDP burst to be used for leakage detection. These same OUDP bursts are being used to evaluate adjacent channel interference. The OUDP burst is created by the mid-split gateway and a simultaneous full-band capture is taken on the adjacent in-home set-top box. Through extensive testing the thresholds for the set-top boxes for interference are well known and the measurement of the delta between the OUDP burst as measured on the adjacent set-top box and the downstream signal is measured to evaluate the potential for ACI. If the delta is less than the threshold the account can support mid-split spectrum activation. If the delta is more than the threshold, the account is targeted for remediation.

This same process can be used for high split systems to evaluate the potential for high split neighbor interference. In the mid-split plant, there is enough tap-to-tap isolation and the interfering bandwidth is smaller, so neighbor interference is not a concern. In a high-split system, the extended upstream bandwidth coupled with lower tap-to-tap isolation with higher frequencies creates the potential for neighbor interference. See Figure 16.

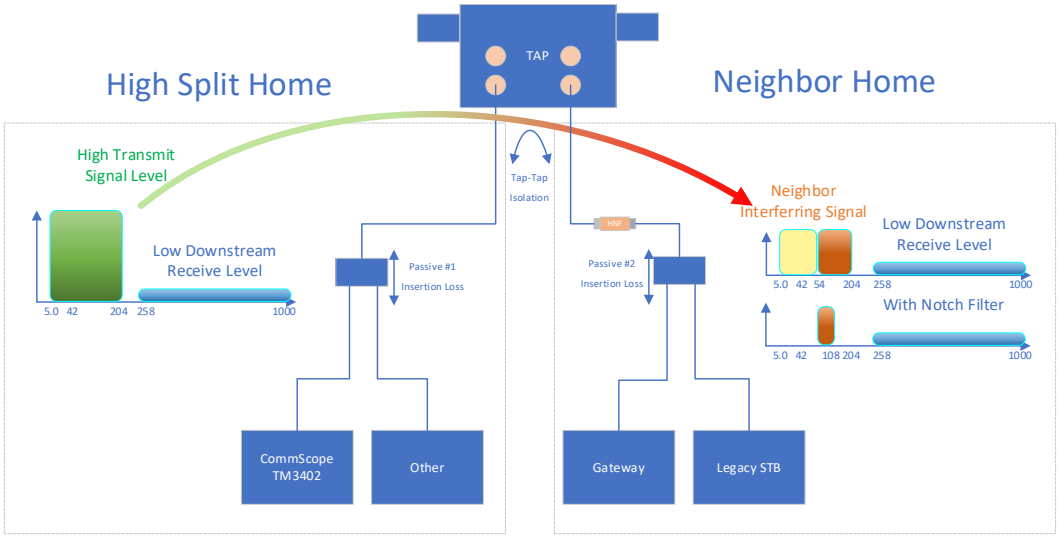

Figure 16 - Neighbor Interference in a High-Split System

The same process the iHAT tool uses with the OUDP burst can be used to evaluate high-split neighbor interference. When high split modems are first deployed and before service is activated, iHAT can be used to create the OUDP burst on the high split device and the neighboring standard and mid-split devices can be evaluated using the same full band capture technique used for mid-split ACI. Additional system and plant information is used to determine which devices are connected to the same tap as the high split device and these devices are monitored.

In a Mid-Split system, ACI and iHAT are focused on adjacent set-top boxes in the same home as the mid-split gateway or cable modem. In a high-split system, neighbor interference can occur both on neighboring set-top boxes and neighboring gateways and cable modems. As in the mid-split case, extensive testing has been completed to understand the interference and threshold levels for high split interference both on the set-tops and gateways.

Testing was completed on both set-tops and gateways with a “Neighbor” high split cable modem passing traffic under various upstream throughput scenarios. This setup for neighbor interference testing is shown in Figure 17.

For neighbor video interference testing there are two main test scenarios

1. Video: system connected to DAC for the STB testing
2. Data: connected to CMTS for CM testing

The same set-up was used for testing both Data and Video (QAM) CPEs. The first vCMTS is connected to the HS node to generate the upstream load to the HS modem is configured for interference as follows

- 4 x 6.4MHz SC-QAM channels (for the SS CMs only)
- 48 MHz OFDMA (up to 85MHz, MS)
- 96 MHz OFDMA (108-204MHz, HS)
- US Traffic and Level adjusted to produce the desired interference signal

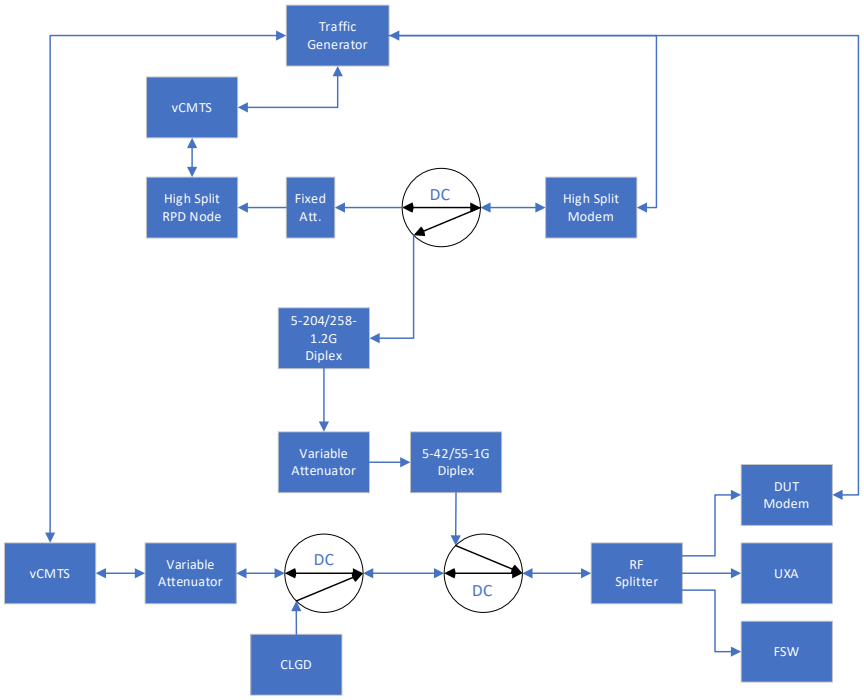

Figure 17 - Neighbor Interference for STB Test Configuration

The DUT modems are configured as follows:

- CM DS Load (258 – 1002MHz):
- OFDM (96MHz, 792 to 888 MHz)
- SC-QAM (603 to 789 MHz, Symbol Rate: 5.360537MSym/s, 256QAM)
- SC-QAM above and below those frequency ranges from CLGD
- Add noise to the DS to decrease the received MER to 38 dB
- A traffic generator is used to produce a fixed DS traffic for the DUT (300Mbps data rate) while the HS data rate was varied from 1 to 980 Mbps

- STB DS Load (258 – 1002MHz)

The Interference Level is defined as the ratio of the high-split Interference power spectral density (PSD) (dBmV/6MHz) with respect to the device under test (DUT) downstream PSD (dBmV/6MHz). It is important to note that the high-split Interference ratio takes in consideration the occupied bandwidth for each high-split interfering traffic rate which is CMTS scheduler dependent. The methodology for determining the High-Split threshold interference was based on a measured DUT DS codeword error rate (CER) above a threshold of $1e^{-6}$ for the Data scenario while an observer noticing video artifacts was used for the Video scenario. The variable attenuator controlling the high-split Interference level applied to the DUT is adjusted for each particular interference high split traffic rate until the CER threshold is reached or video artifacts are observed.

When testing interference low upstream throughputs correspond to low OFDMA utilization and/or a low duty cycle for the OFDMA channels occupying the band from 39.4-204 MHz. As upstream traffic rates are increased, the OFDMA channels are utilized more and the duty cycle is reduced, up until the point that the full spectrum from 39.4-204 MHz is being utilized 100% of the time. The threshold of interference under this testing shows that under very low utilization the interfering threshold is high. As traffic increases, there is a point where the interference threshold is very low and then as the traffic is maximum, the upstream spectrum is at a steady state and the interference threshold rises. This can be seen in both the interference of set-tops and in gateways, as shows in Figure 18.

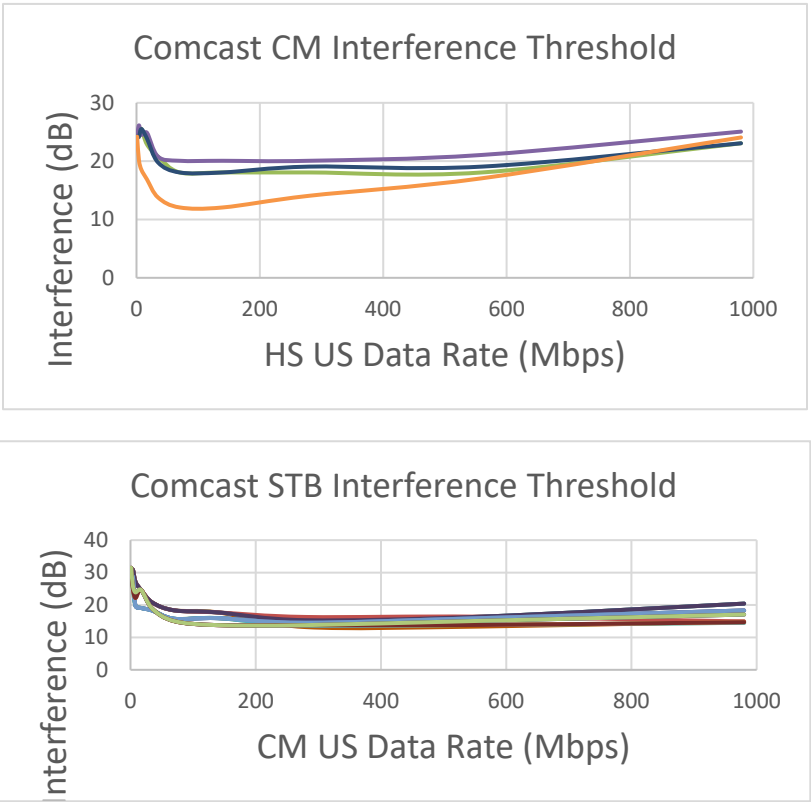

Figure 18 - Cable-Modem & Set-top Box Interference: Threshold vs Neighboring High Split Throughput for Several Different Models of Set-tops

A mathematical model has been developed to better understand the DUT front-end behavior and identify opportunities to improve the CM/STB performance. The goal is to capture the impact on the CM front end including front end overhead, automatic gain control (AGC) behavior, Downstream/Upstream power ratio, high-split upstream occupied bandwidth, and duty cycle. A typical CM front-end behavior is well described in reference [5].

Figure 19 shows the comparison of the model with data measured for a Comcast CM. It also shows the main regions of a typical CM or STB behavior.

- Low Energy Region: range with low interfering signal utilization (occupied BW and duty cycle) requiring higher levels of interference signal to impact the victim CM front end
- Maximum Interference Region: range where the increased occupied BW and duty cycle produces the highest levels of interference and corresponds to minimum interference thresholds
- Quasi Steady-State Region: range where the high interfering signal utilization gets close to a continuous mode requiring higher levels of interference signal to impact the DUT CM front end

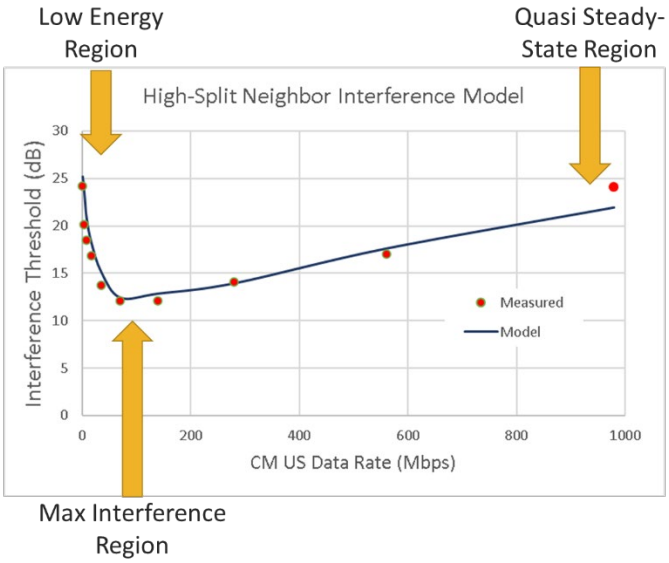

Figure 19 - High Split Threshold vs Neighboring High Split Throughput Model

It is important to note that the maximum interference frequency range is dependent of the CM front-end and CMTS scheduler characteristics. In the case of the CMTS scheduler, grant allocation implementation, which translates into a certain upstream occupied bandwidth and duty cycle, defines the interaction with the CPE front end.

Additionally, for system design purposes, the minimum threshold level is used since the upstream data demand varies all the time. Comcast measurements have indicated a minimum threshold levels in the order of 12 dB which is a little better than the “Maximum average power of carrier input to CM, within any 6 MHz channel from 54 MHz up to 1002 MHz” and “256-QAM Image Rejection Performance” PHYv3.0 DOCSIS specs, which limit the interference level to 10 dB. New case scenarios could be developed and proposed to the CPE chip-set manufacturers to further improve the CPE performance, particularly as the industry starts to get ready for FDX. However, tools like iHAT are critical for a smoother transition.

If high OUDP signal to downstream levels are measured and potential neighbor interference is identified, several remediation techniques can be implemented. One of the potential solutions is the use of notch filters that can be added to neighbor drops and suppress the interfering signal. Although not operationally desirable, these filters can be designed to notch out the complete spectrum from 54 to 204 MHz or to be compatible with mid-split systems, notch filters have also been designed and tested to pass up to 85 MHz and notch the spectrum between 85 and 204 MHz. Figure 20 shows the frequency response of a notch filter used to prevent the impact of the High-Split neighbor interference. Filter suppression higher than 20 dB would suffice for most case scenarios.

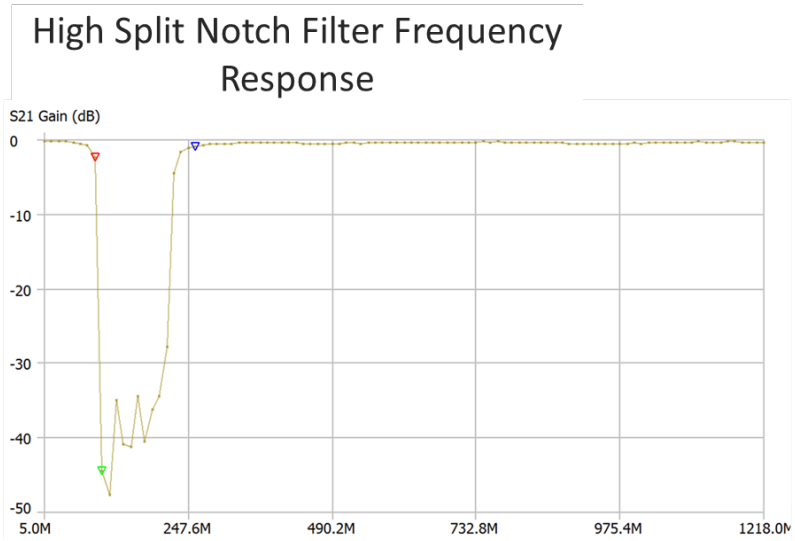

Figure 20 - Neighbor Interference Notch Filter 85-204 MHz)

This allows mid-split and high split devices to co-exist and minimizes device types deployed in the field. New tap plates can also be installed. Newer taps are specified with better tap to tap port isolation to help minimize neighbor interference.

With minor updates to the existing iHAT tools for ACI, iHAT can be adapted to solve the high-split neighbor interference. The threshold of the OUDP to downstream signal can be adjusted to match the measured interference levels for high-split interference, and the back-office tools modified to run/measure OUDP on different accounts. The frequency of the OUDP burst and duration can be optimized for certain areas of the band based on the isolation measurements and the duration may also be optimized.

iHAT and OUDP measurements are an ideal tool to validate the high-split system prior to activation to optimize the customer experience.

5. Conclusion

New work and learning have continued since the introduction and subsequent rebranding to iHAT this past year. Aside from the cool name, improvements upon the process of evaluating ACI using spectrum-based methods have been made that will one day enable OUPD leakage detection to occur in a non-service affecting manner, harmoniously with regularly scheduled traffic. As we work toward scaling iHAT, our intent is to focus on making this tool work as quickly as possible, while offering robustness of carrier grade software at scale using proven tools readily available in the marketplace. A well-defined

object model acting as the glue between iHAT process and downstream APIs can lead to the scale operations needed at Comcast, and reliable distribution of results into the hands of frontline teams who can act in a more proactive manner to address remediation issues. With an eye on the future, including high-split, iHAT has room to grow into a toolset that will one day make it easier for operators to operationalize 1 Gbps upstream speeds. It is our hope that these steps in upstream evolution will help us to embrace new DOCSIS 4.0 FDX sounding technology when the time is ready, and work to harmonize new technologies while always maintaining support for legacy service.

1. Introduction

This paper describes three visionary approaches to reduce the amount of network telemetry. The problem we discuss is that internet protocol (IP) network monitoring requires collection and storage of a large volume of data. This is a big issue for service providers (SPs), but the solution is usually not thought of outside of conventional approaches. With the advent of artificial intelligence (AI) approaches, especially in estimation, interpolation and imputation, new solution avenues are becoming available.

IP network monitoring often implies the use of NetFlow or Internet Protocol Flow Information Export (IPFIX). However, as we show shortly the two alone are not enough to cover all use cases. NetFlow and IPFIX can be used to turn the network into a large collection of sensors collecting information about IP traffic, which can be used to monitor network usage, identify misconfigured network elements, identify compromised network end points and detect network attacks (Santos, 2016). However, high fidelity network monitoring with technologies such as IPFIX comes with many challenges due to the amount of data that is collected by network elements, then transmitted to where it can be stored and finally processed to get the insights that the operator is looking for. IPFIX also only gives a partial view of the network state and additional technologies are needed to build a complete view of the network.

1.1. Overview of IP Network Monitoring

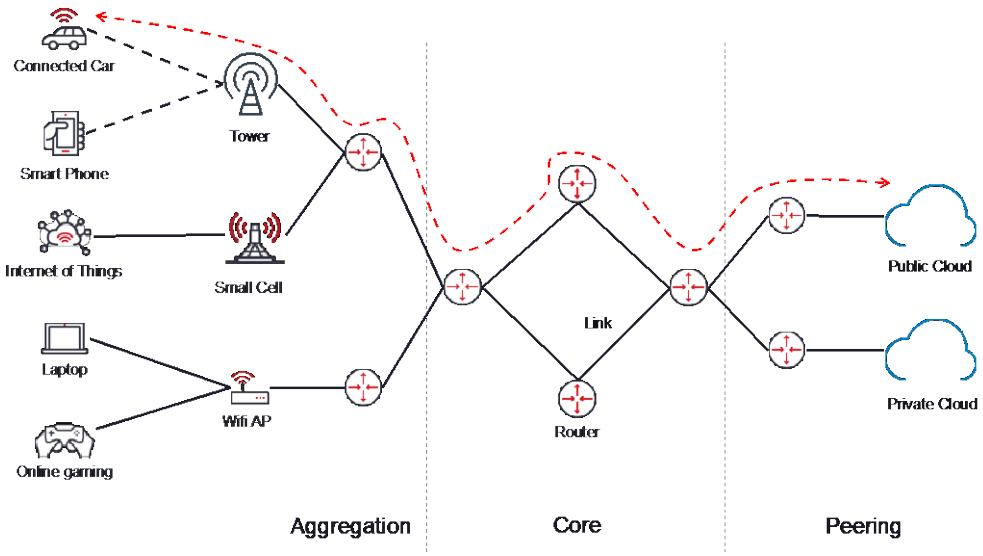

Figure 1 - IP Network

Figure 1 shows a simplified monitored IP network architecture. An IP flow is shown in red and refers to a distinct set of packets occurring in the same period that share a 5-tuple IP header (destination IP address, destination port, source IP address, source port and type-of-service). Aggregate flows, which combine traffic between points in the network may be used in core networks where there are too many flows to track individually. Flows traverse many network

elements, but as the focus of this paper is the IP domain, routers and links are the important part of the figure. Routers and links are both physical elements, however they can have appropriate "digital twins" in network monitoring/inventory software, which is used to create a logical network topology.

There two types of network monitoring: active and passive (Network monitoring, n.d.). In this paper, we are considering passive approaches, which are based on measuring network information without disturbing existing network traffic. Passive IP monitoring can be done at an IP flow level, link level, network level or router level. Active approaches include injecting network packets to probe the network. Some of the approaches for network probing are MTR (Wikipedia, n.d.), based on Internet Control Message Protocol (ICMP) (Wikipedia, n.d.), Iperf (Wikipedia, n.d.), based on a proprietary packet generation and application level protocols, or others, based on RFC 2544 (Wikipedia, n.d.). Active network monitoring can benefit from the applications of AI shown here, but due to space and time limitations these are not discussed.

The goal of IP network monitoring is to get an accurate enough picture of the network state, so that network operators can implement their operational use cases (Quittek, Zseby, Claise, & Zander, 2004). IP network monitoring addresses many use cases:

- *Usage-based accounting* is a business model for selling IP services. A user or a user group is charged based on how much traffic was transmitted. For example, this traffic usage model is used by Amazon Web Services (AWS) to charge for transmitting data out of the cloud. To enable it, very accurate packet counts for the user are required at an ingress/egress point.
- *Traffic profiling* uses information collected about an IP flow to describe it succinctly so that its statistical profile can be used inside of a traffic model. The model of the IP flow can be used in network planning or network dimensioning. For example, the profile may have the average or peak traffic volume and does not require very precise measurements. Depending on how traffic profiling is used flows may be individual or aggregated.
- *Traffic engineering* uses the information collected about IP flows to control the network with the goal of optimizing network resources and traffic performance. Typical measurements are link utilization, traffic volumes between network nodes and routing information. While precise information may be required about flow routing, the information about link utilization and traffic volumes can be approximate. For example, it may be sufficient to know the largest flow on a "hot" link to initiate its route transfer to another part of the network.
- *Attack/Intrusion detection* uses the information about IP flows to detect unusual situations and suspicious flows and then monitors attacking flows. This use case may require stateful packet flow analysis, which requires deep packet inspection. However, to analyse traffic for anomalies all that may be required is a statistical model of the traffic, which can be learned with machine learning.
- *QoS monitoring* uses quality measurements of IP flows to validate QoS parameters negotiated during service level specification (packet loss, latency). QoS monitoring requires correlation of data from multiple observation points, which requires proper clock synchronization. As QoS monitoring is often specified in statistical terms, precisely

collected information is not required to enforce SLAs, rather it is important to build up a statistical profile of the observed QoS experienced by flows.

Each use case has its own requirements on the veracity and type of data required, meaning that there may be multiple protocols and software required to collect the information for any one of the use cases. We note that while some require precise collection and storage of data (usage-based accounting), others may only require precise data collection, while the stored data does not have to be prices (attack/intrusion detection), and some do not require precise collection or storage of data (traffic profiling, traffic engineering, QoS monitoring).

2. Data Collection for IP Network Monitoring

IP network observation is done by collecting information about the infrastructure (routers and their physical connections), information about IP flows traversing the infrastructure and information about how IP packets are routed through the network (routes). This paper implicitly talks about the network observations of the core network (shown in the middle of Figure 1), but the content of this paper also applies to the aggregation and peering parts of the network.

There is no one standardized method to collect all the information required for each of the network monitoring use cases. Typically, a combination of network monitoring protocols is used, and the information is collected by a software tool, provided by vendor specializing in this. Most networks are multi-vendor networks, presenting a commercial and technical challenges to equipment vendors to collect network information from other vendors' equipment. A third-party vendor would resolve those challenges and provide a data collection software. Collected information can be grouped into device, routing, link and flow information. The monitoring software tool correlates the information and presents it in a "single pane of glass". Users can then get subsets of data required for their use case.

2.1. Router information

Router information can be obtained with direct queries using their command-line interface (CLI) (Wikipedia, n.d.). CLI commands typically provide network element information (infrastructure information), which is not otherwise available through other means. For example, configuration, CPU utilization, or debug logs can be obtained in this way. Other information such as routing tables and link utilization are also available, however routers are typically not optimized to access this information through their CLI interfaces and that should be avoided. CLIs can change at the whim of the network device vendor, making it difficult to track changes for a 3rd party vendor providing the monitoring solution.

While not strictly required for IP flow monitoring, some of the information collected directly from the routers can be used for root cause analysis (RCA) of undesirable network behaviours. Particularly, system logs may be useful for this purpose.

2.1.1. Route information

IP routing information can be collected with routing protocol sniffing. Interior gateway protocols (IGPs) such as Open Shortest Path First (OSPF) (Wikipedia, n.d.) and Intermediate System to

Intermediate System (IS-IS) (Wikipedia, n.d.) are used by routers to exchange topology information in an autonomous system (AS), which enables calculation of forwarding tables on routers. A monitoring system sniffs the inter-router traffic for route update packets and builds the known network topology as a router would.

Using the sniffed network topology and shortest path routing, the monitoring system can in real-time build the routing matrix for the network, which is a "digital twin" representation of the network forwarding tables. The routing matrix relates flows to the paths they traverse in the network. Note that since IP uses dynamically changing hop-by-hop routing, the routing matrix is a delayed version of the real-time routing matrix and is only a close approximation of how packets traverse the network.

2.1.2. Link Information

Link information includes volume of packets carried on a link and link utilization. This information can be obtained by subscribing or polling Simple Network Management Protocol (SNMP) (Wikipedia, n.d.) or Network Configuration Protocol (NETCONF) (Wikipedia, n.d.) router's management interfaces. SNMP is an older protocol with many limitations. For example, it has a polling interval of 5-10 minutes, while NETCONF can be configured to stream messages, which are sent on change detected by the router. NETCONF can use the Yet Another Next Generation (YANG) (Wikipedia, n.d.) format to collect information from the network devices. Internet Engineering Task Force (IETF) is actively working on defining new data sources and formatting of their data across router equipment (IETF).

2.1.3. Flow information

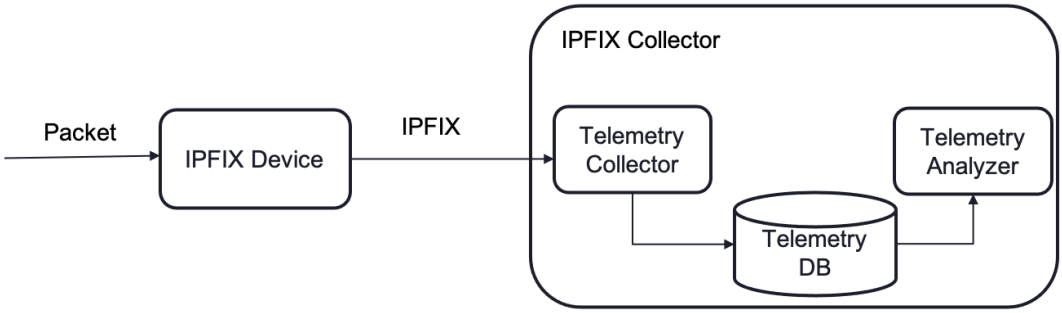

Figure 2 IPFIX Measurement Architecture

Flow information can be collected with NetFlow or IPFIX (Wikipedia), which are equivalent in functionality. IPFIX is the standardized method of doing it and we will limit our discussion to it, keeping in mind that problems with IPFIX also exist in NetFlow. Figure 2 illustrates key components of the IPFIX traffic measurement architecture. IPFIX device and IPFIX collector are two major components of the protocol.

- An IPFIX device is typically a part of routers or switches. It reports information about flows. A dedicated IPFIX device could also be installed to capture packets from the fiber

tap or the mirrored port at a switch. The IPFIX device could be hardware based, or virtualized, so it could also be software installed on a datacenter server.

- The IPFIX collector gathers and analyzes IPFIX flows from multiple IPFIX devices through reliable transport protocols. A typical IPFIX telemetry data record consists of 5-tuple of IP/TCP/UDP header fields, the number of bytes, the number of packets, the flow start time, and the flow end time. In IPFIX, communication between the IPFIX device and the flow collector is done through reliable transport protocols such as Stream Control Transport Protocol (SCTP) or TCP2.

As we just showed, IPFIX way of collecting flow information requires installation of a specialized monitoring system with intermediate collectors, large volume data storage and an enormous number of computational resources to analyze the collected data. The data volume problems start at the network element where the software and hardware are typically not able to track all flows passing the element. Still, the aggregate volume of information may be such that the multiple collectors, distributed across the network, may have to be used. Finally, the volume of collected data makes it impractical to keep IPFIX collected data for long periods of time.

Due to hardware limitations, the monitoring system is usually unable to track a majority of the traffic. One practical approach to mitigate the collection overhead in IPFIX is a technique called threshold compression. In this technique the router reports only flows above a threshold to the collection station. The main disadvantage of this method is that the information of flows below the threshold are not sent. It is quite possible that up to 90% of the flows don't cross the threshold and are not reported.

An alternative method of measuring traffic is use direct counters on traffic tunnels (aggregated flows). However, here we focus on standardized solutions such as IPFIX.

2.2. Overview of the paper

The rest of the paper is organized as follows. We start with a short description of how AI is implemented using deep neural networks (DNNs). Then we describe three ways to use DNNs to decrease the volume of telemetry and stored data, while keeping the fidelity of the data above what is required by traffic monitoring use cases. These are solutions to the problems with IPFIX that we just outlined.

Throughout the paper we cite Wikipedia and AI blogs for various AI concepts. While this may appear to not be the most scientifically sound, we found these articles easy to follow and they always link to the more complete computer science papers for the keen reader. There is much DNN jargon used in the paper. We introduce DNN-specific terms in quotes "" to emphasize their jargon origin.

3. Foundations of AI technologies

This section is intended as a general overview of AI technologies. Readers familiar with concepts of deep neural networks (DNNs) and machine learning (ML) can skip it. More information about DNNs can be found in (Goodfellow, Bengio, & Courville, 2016).

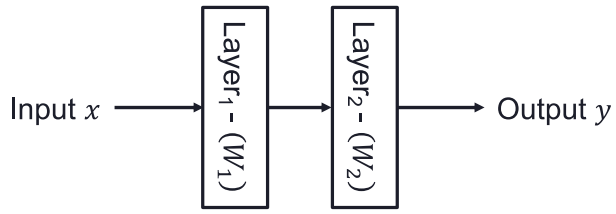
AI technologies are based on the use deep neural networks for machine learning. Machine learning is a computer science concept in which functional software blocks are created by showing the computer examples of correct outputs from inputs, instead of explicitly writing functions that instruct the computer on how to produce outputs from inputs in structured programming (Wikipedia, n.d.). Instead of coding the algorithm, a generic machine learning algorithm is "trained" with examples of what the correct outputs are for given inputs. In recent years, DNN technology has elevated machine learning to the level of human capability in some cognitive tasks. For example, it is now possible to train a DNN-based machine learning algorithm to read a paragraph of text and answer questions about more accurately than humans, or to categorize X-ray images better than a radiologist (Zhang, et al.).

DNN technology is based on basic linear algebra components – matrix multiplication and addition and basic calculus – derivatives. Most of the knowledge required for DNNs has been around for hundreds of years since the time of Carl Friedrich Gauss (Wikipedia, n.d.) and Issac Newton (Wikipedia, n.d.). What is new at this time is that the advances in parallel computing have made it possible to deal effectively with large matrices and train very large DNNs. The most common computing platform are the Graphic Processing Units (GPUs) (Wikipedia, n.d.), which can be used even beyond DNNs, and they are now being complemented with Tensor Processing Units (TPUs) (Wikipedia, n.d.), which are specialized computing units for DNNs. AI accelerators such as TPUs are now found almost anywhere from being embedded in laptops, cellphones, and dedicated data center servers.

For completeness and interest of the reader we now give a simplified overview if how DNNs make predictions and how they are trained.

3.1. How DNNs make prediction

A DNN is a set of algebraic equations that describes how outputs are determined from inputs using matrix operations. A graphical version of the DNN representation is shown Figure 3a, which shows the most basic type of building block for DNNs, known as "dense blocks". The 2-layer DNN shown in the figure is shallow. A typical may have dozens of layers (blocks).



a) Graphical Description of a 2-layer neural network

$$y = \max(0, W_2 \times \max(0, W_1 \times x + b_1) + b_2)$$

b) Mathematical Description of the 2-layer neural network

Figure 3 An example 2-layer DNN

The network in Figure 3a evaluates an equation involving linear algebra shown in Figure 3b. In this example equation, $W_1 \times x$ is a matrix multiplication (Wikipedia, n.d.) and the max function ensures that the result of all operations is positive. Terms b_1 and b_2 are called bias for the layer. The input to the network is x, while the output is y, so the equation describes the functional blocks used in the DNN. The output y is also called a prediction. The input x is a mathematical vector whose components is called a "features". Each feature is a separate input variable contributing to the output of the DNN.

The simple set of algebraic transformations in this example is very powerful as it can be shown mathematically that a neural network with enough layers – depth – can approximate any function. For this reason, DNNs are known as "universal approximators" (Hanin & Sellke, 2018).

A pictorial description of a DNN shown in Figure 3a can be translated into the above equation in Figure 3b by an AI engineer and then made into a software program that performs the set of algebraic equations. In practice, the software piece is simple to write using libraries such as TensorFlow (Abadi, et al., 2015) and PyTorch (Paszke, et al., 2019). The DNN can also be exported into the Open Neural Network Exchange (ONNX) (Open Neural Network Exchange, n.d.), which describes the equations and can be loaded into many DNN software frameworks.

3.2. How DNNs learn

So far, we have described the prediction or inference part of a DNN. If we know the weights of the DNN (e.g. matrices W_1 and W_2 in Figure 3) then upon receiving the inputs, the set of matrix calculations described by the DNN is performed to determine the outputs. The outputs of the DNN are called the "predictions". This process of making prediction is sometimes called "inference". Weights are determined during a process of training.

For example, if we have the function

$$y = 2x^2 + 3x,$$

we can generate a dataset of training samples shown in Table 1 in the two left-most columns. With the dataset, we can use a training function provided in open-source software such as TensorFlow (Abadi, et al., 2015) to determine a set of matrices W_1 and W_2 that result in the best approximation of the function. The training function is called "fit" as it fits the weights of the DNN to the dataset during the training. The fitting function minimizes the error of the predictions $\hat{y}$ for the dataset compared to actual values in the dataset y. The error can be measured with the Mean Absolute Percentage Error (MAPE) shown in the right-most column of Table 1.

Table 1 Example training dataset for $y = 2x^2 + 3x$

Input x	Actual output y	Predicted output $\hat{y}$	MAPE $\frac{\|\hat{y}-y\|}{y}$
1	5	4.5	10 %
2	14	15.6	11.5 %
3	27	25.4	5.9 %

The great DNN research achievement in recent years has been to devise an efficient training procedure that finds the set of internal weights W to minimize the error of the DNN. The training procedure uses "stochastic optimization" who's understanding essentially requires a PhD in mathematics or computer sciences. However, this understanding is not necessary to use DNNs as almost anyone who understands software development can write approximately 10 lines of code to create the DNN and train the function.

The training procedure is iterative and takes in a set of examples of inputs and outputs in batches. For each batch, the training procedure takes in the inputs and generates predictions using the current weights. The predictions from the DNN are compared with the known outputs to find the error in the predictions (the "loss" function) and this error is used to calculate the adjustment to the current weights. The adjustment is usually done using a gradient descent that takes a "learning rate" as an input and calculates the error of the predictions from the weights and number of predictions. The learning rate determines how quickly the descent happens and how closely to the best fit the training gets. The gradient of the whole DNN is calculated using "backpropagation" (Wikipedia, n.d.), which is an algorithm applied backwards through the DNN to differentiate it. Backpropagation is an example of automatic differentiation using the chain rule (Wikipedia, n.d.).

3.3. DNN Models

A DNN model is a trained DNN. A single DNN may have multiple models for different versions of the training data, or different versions of the training algorithms. Each version may have the same structure (number of matrices, size of matrices, and flow through the matrices), but the values in the internal matrices may be different. In a parallel to software development, DNN models have different versions, which presumably improve with higher version numbers. Unlike software, a DNN model is not guaranteed to work well over time, as the inputs may have significant changes in their statistical properties. An example would be traffic demands changing if a new data center peering point is added to the network.

Automating re-training of DNNs due to changes in input data is beyond the scope of this paper.

4. Reducing network monitoring data with AI

Now, we take a deep dive into three approaches for reducing network monitoring data volumes collected with IPFIX. Currently, this problem is resolved in unsatisfying ways. For example, IPFIX may not be active in the network at all, so end-to-end flow information is not collected. If IPFIX is turned on, it may not monitor all the flows – to reduce the pressure on the routers, some flows are simply reported. The collected data is often stored temporarily, or if it stored for longer time, it is reduced by averaging across days, weeks, or months.

We propose three new approaches to deal with the volume of data in the context of IPFIX. First, we consider how to reduce the volume of IPFIX measurements by using link volume information, without a substantial loss of end-to-end flow data quality. Second, we consider how to actively reduce the volume of IPFIX telemetry by taking advantage of correlations in the data. Third, we show how to use AI to compress stored network measurements without major loss of fidelity.

4.1. Reducing the amount of collected information

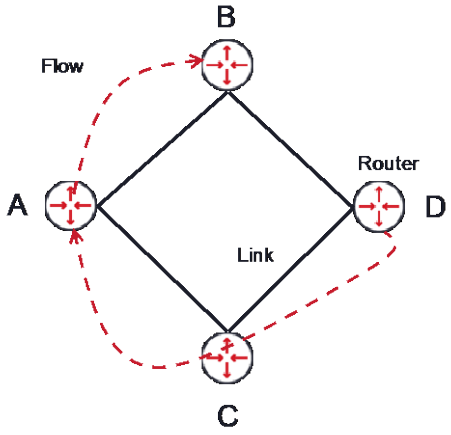


Figure 4 Relationship between links and end-to-end flows

Traffic profiling and traffic engineering are two major use cases for IP network monitoring. Each requires an estimate of the Origin-Destination (OD) traffic matrix, which describes the amount of traffic between each OD pair in the network. Figure 4 shows the relationship between OD pairs (end-to-end flows) and links. In the figure we have 4 routers A, B, C, D and 4 links AB, AC, BD and CD. In case of a core network, we would want to know the aggregate traffic between each OD pair. There are 12 relevant OD pairs, for example for router A there are AB, AC, AD. The premise of the idea in this section is that if we can deduce OD flows from link measurements, we can limit data collection to links. In the case of Figure 4, the amount of reduction would be 75 % (instead of collecting information on 12 OD pairs, we can collect information on 4 links).

Currently, IPFIX is a go to method to obtain OD pair information. IPFIX samples packets transiting through a given router and infers their origin and destination from packet headers. We now show that finding the entire traffic matrix can also be done by utilizing the available link counts and routing information.

Obtaining end-to-end traffic volumes from link measurements is a mathematical problem, which requires a matrix inversion. The instantaneous traffic matrix can be related to link measurements and the routing matrix with

$$\boldsymbol{y} \approx R\boldsymbol{x}$$

where $\boldsymbol{y}$ is the vector of measured link loads over links in the network, R is the routing matrix, and $\boldsymbol{x}$ is OD traffic matrix with one row corresponding to the demand of each OD pair. A flow in the matrix is denoted with row $x_i \in \boldsymbol{x}$ in the OD matrix x. The routing matrix is structured in a way that the link measurements $\boldsymbol{y}$ correspond to the sum of OD flows that traverse the link. Due to packet latencies and the random nature of OD pair traffic, the equation is approximate.

For the mathematically inclined, it may be obvious that the instantaneous traffic matrix can be estimated with

$$\boldsymbol{x} \approx R^{-1}\boldsymbol{y}$$

where R^{-1} is the "inverse" of the routing matrix. Alas, the routing matrix undetermined and is typically not invertible, so this solution is not possible.

One way to solve the undetermined equation is to find the OD traffic matrix $\hat{\boldsymbol{x}}$, which minimizes a distance between the true end-to-end flow measurements and their estimate:

$$\hat{\boldsymbol{x}} = \underset{\boldsymbol{x}}{\operatorname{argmin}} \|R\boldsymbol{x} - \boldsymbol{y}\|.$$

which is a problem solvable using AI technology. The equation reads: find an approximation of end-to-end flow volume, $\hat{\boldsymbol{x}}$, which has the smallest error, compared to the true matrix $\boldsymbol{x}$. If we have many link measurements taken during different times of the day, the estimate becomes the maximum likelihood estimate of the end-to-end flows.

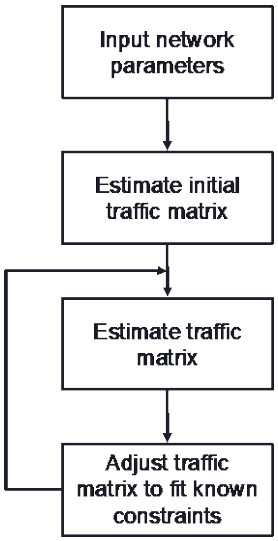

Figure 5 Iterative estimation of the traffic matrix

The optimization approach alone does not provide the best results. We have found it necessary to also combine that approach with stochastic approaches to deal with the randomness in network measurements. The details of how that is done go beyond the scope of this paper due to the volume of mathematics involved.

The approach used above ignores many of the known network constraints since it is defined as an unconstrained optimization. To get around this, the AI method can be incorporated in an iterative procedure shown in Figure 5. The method takes an initial traffic matrix estimate and then uses an estimation procedure followed by an adjustment procedure. As the procedure goes on, it produces a sequence of the traffic matrix estimates $\hat{\boldsymbol{x}}_0, \ldots, \hat{\boldsymbol{x}}_n$, each of which is expected to be closer to the true traffic matrix $\boldsymbol{x}$. As the initial traffic matrix estimate and the estimate in the iterative step may produce a traffic matrix which may not match information known about the traffic (e.g. ingress/egress aggregate counts), an adjustment procedure that projects the estimate into the known constraints is used to fix this.

We evaluate the performance our methodology using real traffic traces from a backbone network. Our source of data is the IP-level traffic flow measurements collected form every point of presence (PoP) in the Abilene Internet2 back bone network (Roughan). Abilene is the major backbone network, connecting over 200 universities in the US, and peering with other research networks in Europe and Asia. At the time the data was collected, the Abilene network had 11 routers resulting in 121 origin–destination flows; there were 15 links in the network. We note that Abilene was collecting OD pair information using flow sampling technology and it was also simultaneously collecting link information, which allows us to estimate OD flows from link measurements and then use true flow measurements to evaluate the performance of the AI-based approach.

Table 2 summarizes the results we obtained on the Abilene dataset. We make several observations. First, the AI approach reduces the error in the estimate significantly (by 42%).

Second, the estimates are now in the range of what is acceptable for the traffic engineering task. Third, the amount of data collection has been reduced by 78%, as we only need packet counters from links.

Table 2 Summary of OD flow estimation from link data performance results

	MAPE	Reduction in MAPE
Non-AI approach	29.6%	-
AI Approach	17 %	42%

We think that this may be a promising approach to reduce operator dependence on IPFIX in estimating OD pair demands for the purposes of network planning and traffic engineering.

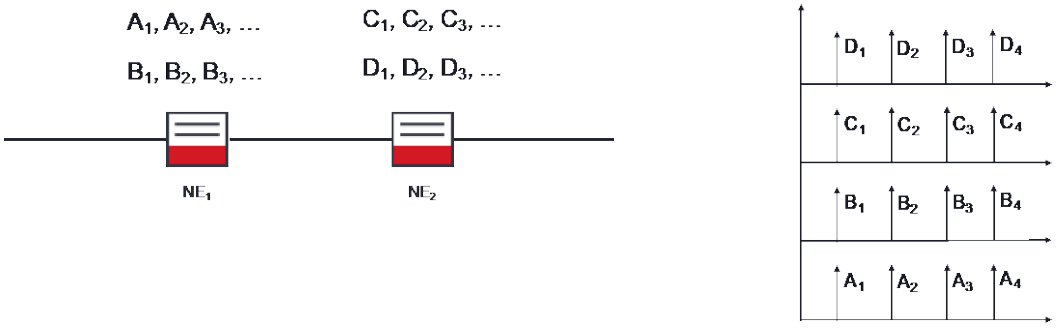
4.2. Reducing the amount of telemetry

Another way to reduce the amount of IPFIX data is in network telemetry. Here we look at ways to reduce number of samples of the collected data. Unlike the previous method, which reduces the number of data sources, where the data is collected, this method reduces the amount of data collected by each data source.

The main idea is to reduce collection of data by decreasing the amount of information collected about some flow, and then to use the information collected from other sources (flows) and AI to infer what data that was not collect would be.

There are two uses for the method described in this section. First, it could be used to reduce the amount of telemetry data. Second, it could be used to increase the frequency of some measurements, while keeping the volume of telemetry about the same. The way this works is that we increase the frequency of measurements on some of the sources, while reducing the frequency of measurements of other sources. We then use AI to impute (estimate) the missing values in the sources with reduced measurement interval.

Network data samples are taken at a prescribed measurement interval (typically in the order of minutes). When picking the sampling interval, the network operator is typically not concerned about sampling interval from the point of view of the Nyquist criterion (Wikipedia), which is required to reconstruct the sampled data without the loss of information. The operators are not trying to reconstruct the data at the point of the collection and processing; data is typically collected for other purposes (forecasting, anomaly detection), so the precise reconstruction of the underlying random process is not important.



Spatially correlated time-series Reported time-series

Figure 6 Spatially and time correlated multi-variate time-series

As an example of time-series collection, we show two network elements and 4 time-series in Figure 6. NE_1 collects time-series A and B, while network element NE_2 collects time-series C and D. Time-series are on the same element are correlated, which means that information of both flows exists in either flow. For example, A(C) could be link utilization and packet latency could be series B(D). If link utilization is high, packet latency is also high, meaning that the two are correlated. Similarly, time-series on the same path are correlated. So, if A is link utilization on NE_1 and C is link utilization on NE_2, they are correlated due to the shared flows on those links. For example, if link utilization is A is high, this could be due to a large flow traversing NE_1, which is also traversing NE_2, so C is also high.

Data pruning

To reduce the information generated and transmitted by NEs we drop (prune) some of the samples. This is called "measurement sampling". Measurement sampling is a well-known technique used in both packet and flow-based measurement to reduce the data volumes required to report. The main idea in this technique is to take only a subset of packets or flows out of all packets or flows to obtain reasonable result for the measurement. For example, we could prune every k^{th} sample of each time-series. This is called subsampling and can be undone for each time-series using a low-pass filter, if the Nyquist criteria is satisfied for the subsampled time-series. *However, this is not what we do.*

Given measurement sampling, we propose a system architecture shown in Figure 7. In the network element, (1) the data pruning module receives the data from the data gathering module and removes some portion of the data before (2) transmitting it to the network analytics. In the network analytics module, a data recovery module (3) reconstructs (imputes) the data and passes it to the recovery evaluation module to (4) determine if the recovery was of high enough quality. Finally, the pruning logic module (5) instructs the data pruning module on how to prune data to improve performance.

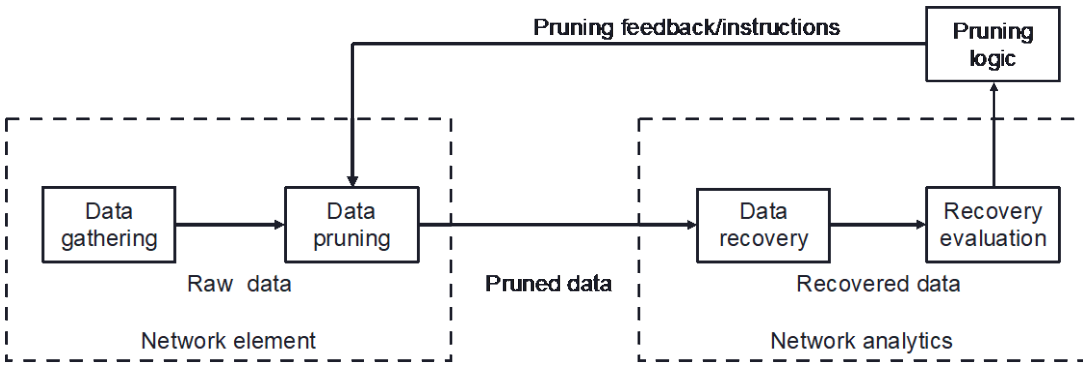


Figure 7 Pruning and reconstruction architecture

Correlation means that information about one time-series is available in another time-series. This is the fact we use when pruning and imputing missing information. We remove parts of a time-series so that some information is always available in another, correlated time-series. The information can be removed in many ways, but the easiest is to use an offset between the time-series when the k^{th} sample is removed. For the example in Figure 6, the samples can be reduced by only sending A_1, A_3, B_2, B_4, and C_1, C_3, D_2, D_4.

Data reconstruction

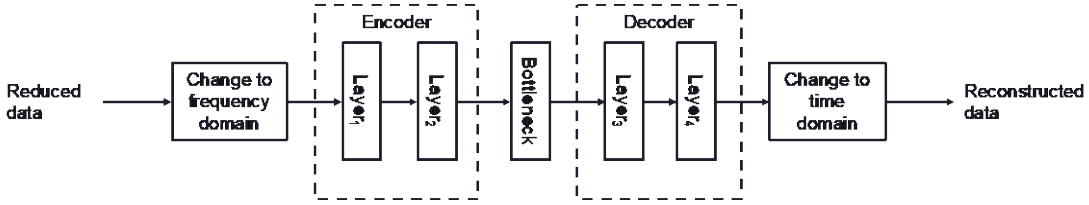

Figure 8 Reconstruction architecture

There are many ways of imputing the missing values received from the network elements. Here we discuss one way of doing it as a way of an example. The DNN treats the missing values as noise in the data and can work with any pruning strategy - the method does not require any information about how the data was pruned.

The AI reconstruction is shown in Figure 8. We use a multistage DNN. The pruned data is used as the input, while the reconstructed data is determined as the output. The method treats missing values as noise, so it is using a denoising method using an autoencoder (Wikipedia) (shown as the encode-bottleneck-decoder architecture). As the values are missing, the reduced data is first transformed in the frequency domain (using inverse Fourier transform or wavelet domain using wavelet transform). The transform into the frequency domain interlaces the missing and present values and so the structure of the data is pronounced even if some of the values are missing. The autoencoder structure denoises the frequency representation of the data thus emphasizing the structures in the data. The inverse Fourier transform then returns the denoised frequency domain data into the time domain.

Table 3 Summary of pruning/reconstruction performance results

Data reduction	5%	10%	20%
MAPE	4%	5%	9%

To evaluate this approach, we use the Abilene backbone dataset, which was discussed earlier. This is a relatively small dataset for this purpose, so learning to reconstruct the data is harder. Nevertheless, our analysis shows that data reduction is possible. For example, if we can tolerate a 10% reduction in data precision in data sources, which are being pruned, we can reduce the amount of transmitted data by 20%.

We think that this may be a promising approach to reduce the amount of telemetry used in IPFIX at a small loss of data precision.

4.3. Reducing the amount of stored information

Useful network data is high in volume, making it difficult to store for extended periods. Here we discuss compression of the data to make storage cheaper. For example, a network with a million data sources may generate 46Gb of 1-minute sampled data in one day, which translates to 16Tb of data per year. While the number of data sources may seem high, even in a traditional IP network this number would be inside the realm of possibility when considering each flow to be a data source. The number of data sources would be much higher when considering cloud services, IoT networks with billions of devices, multiple network layers, or high sampling network measurements (e.g., state of polarization, or wireless SNR measurements).

Using the example of 16Tb of data per year, the Amazon Web Services (AWS) S3 (AWS) cost to store it would be around $5000 in the first year and accumulating to $25,000 in year 5 of storing this data (AWS). Here, we describe a DNN-based lossy compression scheme to compress network data, which has a compression ratio of 100x-200x (Wikipedia). The one-time cost of compressing 16Tb using this compression scheme would be approximately $2.50 and the cost of storing the data for a year would be approximately $150-$250 for the one-year period, depending on the compression ratio. Over a 5-year period, the savings from compressing the data would be around $24,000, or 96%. These are significant savings that could be used in other business areas, instead of for simply storing data in the cloud.

Today's solution is not to store the data, reducing the operator's ability to make data-based decisions. Due to cost, network measurement data is not stored for extended periods, or it is aggregated in larger periods of time (daily, weekly, monthly, yearly), thus losing fidelity in an important historical record of what has happened in the network. The process of aggregation/averaging is a very crude way of lossy compression for time-series. For example, averaging represents a time-series with a single number over a period, so its accuracy is not good. The compression of averaging is not that good either - compressing 15-minute into a daily bin only has a compression ratio of 96, which we show is easily attained with neural networks.

Time-series compression with DNNs

We propose a method of storing network data in a deep-neural network, which greatly reduces the volume of information that needs to be stored. Figure 9 shows an example architecture for a network using the compression scheme. Data is collected from network elements (NEs), stored in temporary storage, compressed, and deployed as a deep neural network. Data is deleted after compression. Instead of using a database to store the data we use a server which hosts the DNN and allows querying of it to retrieve the data.

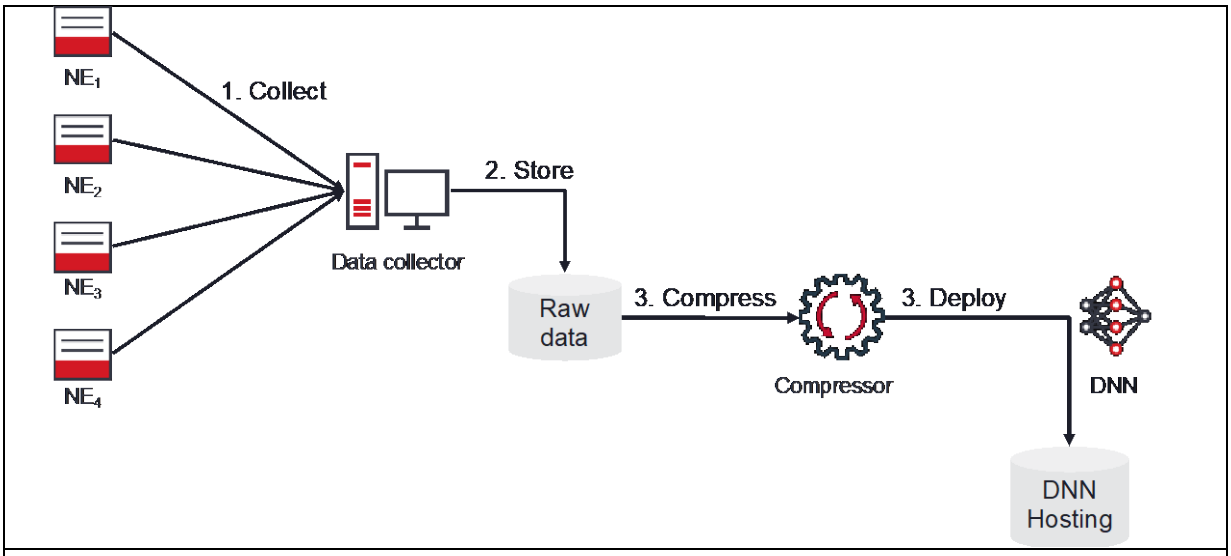

Figure 9 Network data collection infrastructure

The compression of the time-series is accomplished by using the ability of DNNs to memorize the mapping for any function. For example, we can train a DNN to memorize a relationship between a random index and a sequence of measurements. Suppose that the network data consists of sampled samples $\mathrm{ts}_1, \ldots, \mathrm{ts}_n$. The samples are windowed into fragments $\mathrm{w}_i = (x_1, \ldots, x_p)$ of p samples. Each fragment is associated with an index i.

Now we have a dataset where the features are the bits of the index i and the labels are the values in the fragment. We use a DNN to learn a function which maps a 32-bit integer into a p sample long fragment of a time-series. As an example, a 3-layer DNN is shown in Figure 10. Input to the DNN is the index of the bucket i and the output calculated by the DNN is the approximation of the time-series window $\widehat{\mathrm{w}}_i$

$$\widehat{\mathrm{w}}_i = W_3 \max\{0, W_2 \max\{0, W_1 i + b_1\} + b_2\} + b_3.$$

We note that due to lossy compression $\widehat{\mathrm{w}}_i \neq \mathrm{w}_i$, but their difference can be made arbitrarily small.

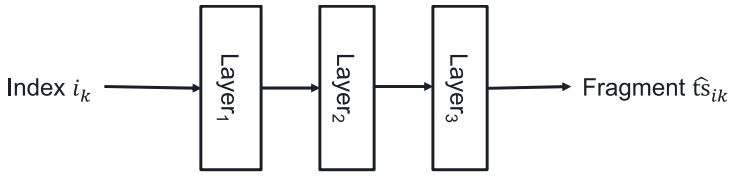

Figure 10 Decompression

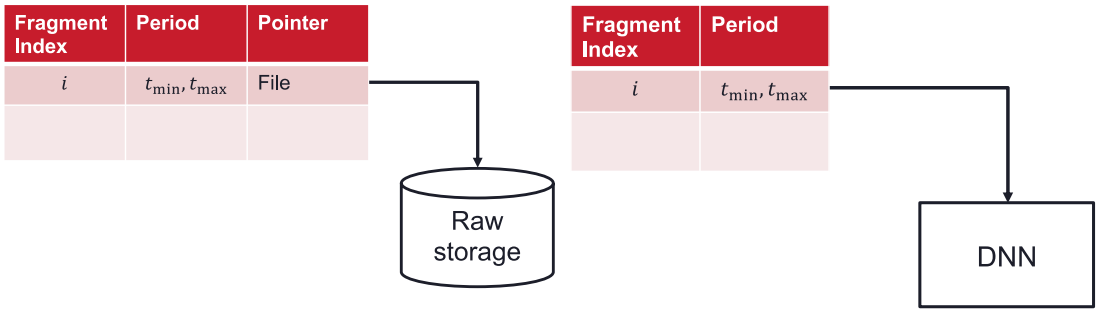
Figure 11a compares the DNN approach to how data is stored today. Raw time-series are stored as fragments on disk and a table is used to relate times-series, periods, and the files on disk. Figure 11b shows how data is stored into a DNN. A table is utilized to relate the time-series, periods, and fragments with *indices*. The DNN contains the relationship between the index and the stored time-series. When an index is presented to the DNN, the DNN reconstructs the time-series bucket for that index.



a) Raw storage b) Compressed storage

Figure 11 Time-series storage

Achievable compression

The level of compression is strongly related to the level of achievable precision. In general, the stronger the compression, the less achievable precision is possible. This means that the compression can be used judiciously to save on space and time to train the DNNs. When comparing compression algorithms, an important metric is the compression ratio (Wikipedia). The compression ratio is the ratio of the size of the uncompressed data to the size of its compressed form. For example, if the original size of a dataset is 16 MB and its compressed size (size of the DNN) is 4 MB, the compression ratio would be 4x.

In many cases, the size of values in a time-series may vary significantly. Consider the case of "mice" and "elephant" flows in an IP network. There may be several orders of magnitude difference in the size of these flows. In the case of traffic engineering, it is much more important to know the size of large flows precisely than the size of small flows precisely. For example, if there are 100 small flows that can be compressed at 100x compression ratio and 1 large flow that can be compressed at compression ratio of 10x, to maintain its acceptably high precision for each

set of flows, the average compression ratio compression could be 91x[1]. This should be compared to compressing all flows at the compression ratio of 10x, which the minimum required by elephant flows.

Table 4 Summary of compression performance results

Compression ratio	10x (XOR)	20x	40x	80x	128x	200x
MAPE	0%	0.5%	1%	2%	5%	10%

Table 4 show the compression achievable by DNNs. We used an IP-like dataset that we generated with a simulation. We use this dataset since we can control the size of the time-series, which makes it easier to see the performance of the compression scheme across different sizes. We also tried this on an IP dataset with similar results. The first column is for the XOR compression (Time-series compression algorithms, explained, n.d.), which is a lossless algorithm designed specifically for time-series. The MAPE for this algorithm is 0% since it is lossless. Next columns in the table use the compression we just showed. The compression varies from 20x to 200x, depending on the error in the estimates. We note that at 5% MAPE, which is very reasonable across a range of use cases the compression ratio is well over 100x.

We think that this may be a promising approach to reduce the disk space required to store IPFIX data at a small loss of data precision.

5. Summary

This paper has talked about various methods to reduce the amount of transmitted and stored telemetry data in IP network monitoring. We have described why network monitoring is important in relation to the monetization strategies used by network service providers. In most network monitoring use cases, the precision of the data is less important than the cost of collecting and storing the data. This introduces opportunities to trade off precision in the collected and stored IP telemetry with the cost of collection and storage.

We have reviewed 3 approaches that can reduce network telemetry 20% to 75% and the amount of stored IPFIX data by orders of magnitude. These are visionary applications of DNNs in network monitoring and the authors would appreciate feedback on their potential usefulness to service providers.

[1] We get this by calculating the compression ratio of large flows and small flows and then averaging out across all flows.

Reliable Power Monitoring is Critical to Successful 10G Deployment

A Technical Paper prepared for SCTE by

Tim Cooke
Director of Product Management
Amphenol Broadband Solutions
Chatham, VA
434-489-4713
tcooke@abs-go.com

1. Introduction

As network speeds increase, and their elements move ever closer to end users, the need for good, reliable and steady power has never been greater. With the changing architectures of networks – copper, fiber, wireless, small cells, etc. it is equally important that power solutions be scalable and intelligent.

It is important, therefore, that modern power solutions provide usable data that not only tracks their own health, but also can collect and transmit information that allows an operations team to make better informed decisions on how to best manage the entire network. Voltage, amperage and temperature monitoring, for example, can provide actionable insight in the following ways:

1. Within a co-location facility – understand the actual power usage when access to the metering device or monthly power usage invoice is not available. Such information will prove useful for contract negotiations related to power consumption.
2. Provisioning analytics can determine at what time of day the highest power consumption takes place and offers the ability to tailor tasks for periods when power is less expensive and places a lesser demand on the grid.
3. Mitigation – with advanced monitoring, the ability to avoid disruption of services exists by enabling the ability to recognize and identify issues before a failure occurs.

Each of these areas, and more, may be improved through the effective use of power monitoring.

2. Technology Driving a Shift in Network Architecture

As technology, media, and other sectors push an ever-increasing number of modern applications in such diverse markets as residential, healthcare, entertainment, manufacturing, farming, transportation and hundreds of others, the speed and latency of traditional networks simply cannot keep up. There is a need for all forms of broadband networks – fiber, copper, wireless, etc. – to work together seamlessly to carry the information needed to allow the continued advancement of the promise of the IoT, autonomous vehicles, and hundreds of other applications yet to come.

With the accelerating complexity of available “connected” products, and even those that are only imagined now, it is important to find a common denominator that can bring some level of order or commonality. This may well be the fact that all of the parts, from the tiniest sensor inside a suburban home’s washing machine, to the complex computers that run statewide networks must be powered. This fact provides engineers with a methodology to monitor much of the energy health of 10G networks.

Meanwhile, in the increasingly automated and connected homes of today, power reliability and quality become ever more critical as IoT and connectivity demands increase. According to a recent analysis by Emergen Research, “The global power monitoring market size is expected to reach $5.86 Billion in 2028 and register a steady CAGR over the forecast period.”

Power monitoring equipment is now available for the homeowner to monitor and troubleshoot incoming power and power usage throughout the day. As solar and alternative energy sources become more affordable and utilized, the ability to monitor and ensure the requirements are being met, increases. As power monitoring capabilities move to the level of the homeowner, how much more critical is the system intelligence for the network power, whether HFC, DOCSIS 4.0, PON, EPON, etc. All of these levels related to power availability and quality are essential for post pandemic workers to stay connected and ensure network QoS for the rapidly changing work force.

With advanced monitoring, the ability to avoid disruption of services exists by enabling the ability to recognize and identify issues before a failure occurs. Through constant measurement and comparison against expected power thresholds, deteriorating power or other conditions can trigger the necessary actions to avoid intermittent, or even total loss of power. Such mitigation ensures reliable network service and the highest level of customer satisfaction.

3. 10G Speeds Demand Distributed Architecture

With remote work becoming the norm since the pandemic, the 10G initiative is being brought to the forefront quicker than originally anticipated and along with it, the need for clean, reliable power to service the network and the end-use products in the residence and elsewhere.

Distributed Access Architecture (DAA) migrates the intelligence and functionality that had once existed in head ends and data centers out much nearer to where these things are actually applied. In other words, the data remains closer to where it will actually be needed, decreasing the delay of making a round trip to the head end. (Figure 1)

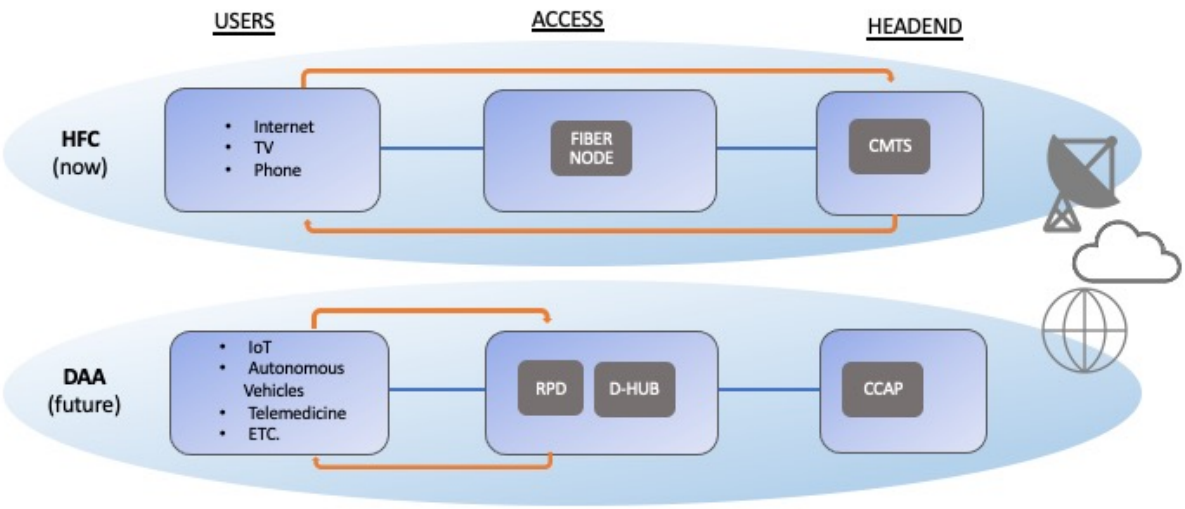

Figure 1 – DAA Migrates Intelligence & Functionality Closer to User

Consider autonomous vehicles. In this example, a future vehicle designed to operate at Level 5 (true driverless) will not only need to rely on the information available on-board the vehicle, but also such data as what traffic may be approaching from around a blind corner. This information is very location-specific,

and therefore it would be inefficient to forward all of this to a central data repository at a head end merely to push it back to the vehicle.

With distributed access “local” information can stay local, lessening the burden on networks to carry every bit of information to and from a central hub. Thus, speed is increased, and latency reduced.

Moving nodes closer to end users will result in a network that is more complex. Equipment with the intelligence to move data within the node, as well as beyond, will be deployed. To support these intelligent nodes, basic infrastructure such as secure shelter, health monitoring, and intelligent power sources must be available.

As equipment is deployed deeper in networks, exponential growth of equipment locations naturally occurs. Each network element must have the ability to sense possible problems, and to transmit the need for support before a failure occurs. Imagine the possible problems in our autonomous vehicle scenario should a network failure occur. Like all other critical equipment, power panels should have such intelligence and capability.

4. Power Panel Design is Evolving

The main function of power panels, of course, is to provide the power needed by each piece of network equipment in a given site. Whether using fuses, circuit breakers, high-, medium, or low-current options, connectorized or lug outputs, or any of dozens of other technology options, the basic functionality of these panels is the provision of power to each piece of equipment that needs it.

The latest generation of power panels makes the integration of power management directly in the power platform easier than ever before. While power panels have provided the ability to monitor their own health in the past through simple alarm closures, the intelligence to report and, more importantly predict problems is now available within the panel itself.

Within the latest generation of power panels, power monitoring has been isolated from the provision of power itself, meaning that, depending on the design of the actual panel, monitoring devices, such as “hot swappable” cards, may go “bad” without interrupting the flow of power to critical equipment. Thus, the card may be removed for service or replacement without affecting services.

Power panels have had the ability to deliver simple alarm information via output contacts for some time. These output contacts have been tied into a network’s alarm systems for decades. With the critical nature of traffic within every distributed node however, intelligent information that serves to predict problems before they occur is imperative.

Within a node, depending on its size, multiple panels may be required to supply the power necessary for all equipment to function at peak performance. In this case, the ability to “daisy chain” multiple panels over a serial cabling scheme which then use a single network connection to transmit critical data back to an operations center will simplify monitoring of multiple bays of equipment.

Intelligent power panels should monitor current at the individual circuit level, providing detailed information that is simply not available with feed-level monitoring or threshold alarming. By measuring parameters such as current per individual circuit, total input bus current, panel input voltage, temperature, and data from external probes, personnel now have access to a much more complete data picture, allowing operations to determine actual current usage, perform trend analysis, and gain critical insight

into equipment performance. This data facilitates proactive action to avert disruptions to service as related to power and power quality.

5. From Alarm Closures to Predictive Analysis

Simple Network Management Protocol (SNMP) is a way to monitor network devices that are on an IP network. Information is requested by an SNMP Manager about the device and connected equipment and status. With baseline measurements and continuous updates, equipment performance can be tracked and controlled. Additionally, SNMP traps sends alerts instantly whenever an event occurs.

The SNMP manager interacts with a network device and its connected equipment. Through the local area network (LAN), an SNMP manager routinely requests information, such as power provisioning, remote site management and circuit threshold data from network devices. This information is recorded and stored via the SNMP manager and can be viewed in a user-friendly table or graph. The data collected can often be displayed by equipment type and location, performance and power usage, and typically monitors threshold levels which allows proactive maintenance with equipment, mitigating downtime by allowing maintenance to be scheduled on a routine basis.

SNMP Traps send instant alerts from the network device when an event occurs. The network device sends these messages without being prompted by a request from the SNMP manager. As soon as an event occurs an alarm is triggered indicating where the event occurred. Immediate access to equipment alarms can prevent unnecessary downtime. During an event, an SNMP manager promptly notifies the local technician who can then make repairs or prevent equipment damage

6. Using data to drive energy improvement in the network

Troubleshooting and prevention alone is a compelling reason for intelligently monitoring power supplies throughout the network. Still, with a growing emphasis on energy efficiency and cost savings, a compelling argument can be made to use data as a way to drive continuous improvement in energy usage in each individual location, as well as across entire networks. Consider each of these scenarios:

Within a co-location facility the ability to understand the actual power usage as measured by the service provider’s own equipment, allowing comparison to readings from the metering device or monthly power usage invoice as provided by the power company. Such information will, along with confirming usage, prove useful for future contract negotiations related to power consumption.

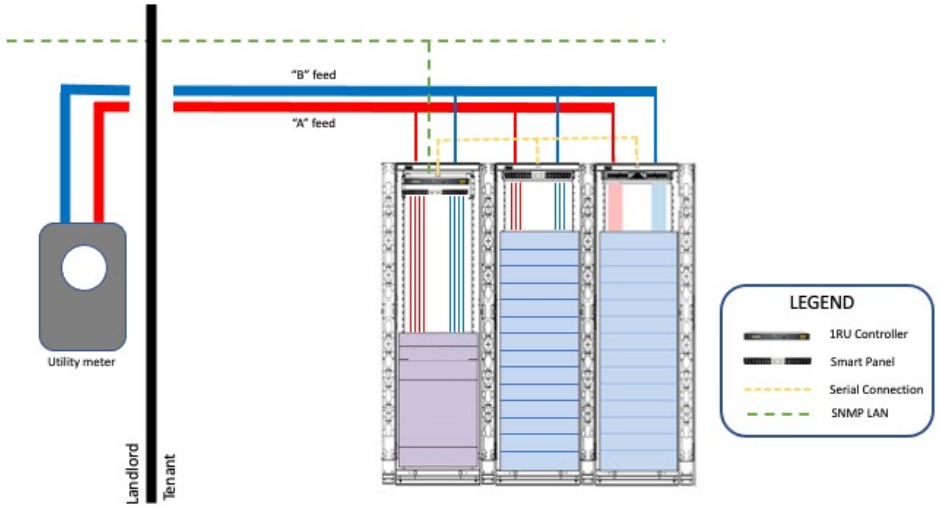

Figure 2 – Co-location Power Scenario

Perhaps even more critically, provisioning analytics will help determine the time of day or even day of the week when the highest power consumption takes place. This knowledge will contribute to better planning and cost savings by offering the ability to tailor tasks to occur during periods when power is less expensive. Further, the network provider will place a lesser demand on the power grid based on this information and planning.

7. Conclusion

With network speeds increasing exponentially, the need for good, reliable and steady power has never been greater, while changing network architectures indicate that it is equally important that power solutions be scalable and intelligent.

Modern power solutions must provide usable data that not only tracks their own health, but also can collect and transmit information that allows an operations team to make better informed decisions on how to best manage the entire network. Voltage, amperage and temperature monitoring can provide actionable insight in both the inside plant (ISP) and the outside plant (OSP), allowing engineers to determine key information such as time of day power consumption or, more importantly the ability to avoid disruption of services due to power loss.

Abbreviations

CAGR	compound annual growth rate
CCAP	converged cable access platform
CMTS	cable modem termination system
DAA	distributed access architecture
EPON	Ethernet passive optical network
HFC	hybrid fiber coaxial
IoT	internet of things
ISP	inside plant
LAN	local area network
OSP	outside plant
PON	passive optical network
QoS	quality of service
RPD	remote PHY device
SNMP	simple network management protocol

1. Introduction

When a customer encounters a service problem that cannot be resolved by regular triage with a call or chat agent, a fulfillment truck roll is scheduled. A standard technician, who specializes in repair issues located inside the premise and/or related to the service drop, performs onsite troubleshooting. If they discover an issue within the broader service network typically impacting multiple customers, they escalate the problem to a line technician. Line technicians expertise is in repairing and maintaining the Outside Plant (OSP) network, such as the nodes, amplifiers, passives, and hardline cables that provide service to multiple customers. This two-step troubleshooting practice incurs the cost of dispatching both types of technicians when an OSP network maintenance impairment is determined to be the root cause of a customer's service issue. More importantly, the follow-up escalation often delays the problem resolution for the customer.

In this paper, we will show that resolution efficiency can be improved by harnessing machine learning (ML) to predict when a customer's service issue has a high likelihood to be escalated to the line technician. Our approach leans on network and device telemetry as well as monitoring processes that assess the integrity of our service network (such as checking for outages, impairments, and performing problem segmentation). A key component of our ML modeling is the integration of graph features derived from network topology, that help identify issues related to equipment within the network that serves multiple customers. This model is in the trial stage and is being tested by selected regions. We also discuss how we can evaluate model precision to incur savings for implementing the model. Finally, we describe how the model will be integrated into the internal troubleshooting software.

2. Acknowledgements

We would like to acknowledge contributions of several Comcast colleagues. Michael Kreisel, who has since left Comcast, developed the initial RTM (Refer to Maintenance) model and the topology data. The extended Applied AI engineering team contributed to the setting up and maintaining of the data pipelines supporting the model. We would like to thank Kevin Bohinski, Ryan March, Likhitha Thebatni, Pat Dwyer, Nick Pinckernell, and Koundinya Venkata Sai Ravulapati for supporting the data structure for the model. We thank Applied AI researchers Yonatan Vaizman, Tianwen Chen, Fan Liu, Navdeep Jain, Scott Rome, Joshua Jackson, and Zhipeng Liu and director of Machine Learning Hongcheng Wang for their expertise and advice on the model development. We are grateful to our intern Vishnu Sharma who has supported model operations and contributed to the feature development. We thank Garret Beatty for his work during the Fall of Code program. We thank our product owners Dave Monnerat and Jason Stevens for being champions of the model among stakeholders. Background on plant operations and tools was obtained from interviews with many Comcast leaders and experts. We want to thank Larry Wolcott, James Sayer, Scott Johnston, Gary Ventriglia, Reid Downey, Scott Shrader, Andreas Lebaudy, Hari Palaiyanur, and Rich Aleong. We thank our field operations colleagues Ray Stewart, Mark Bosteder, Josh Halbrook, Nicole Atherholt, Jason Fletcher, Ed Reece, Brandon Yawn, Karen Washington, Robert Millis, Marcellis Price, Mike Mahaney, Andrew Herr, and Marc Tucker for their support during the model trial. We are grateful to Leslie Ellis, Larry Wolcott, and Jan Neumann for their edits and revisions.

3. Plant Operations

If recent global experiences have taught us anything, it is that connectivity to communications, information and entertainment are essential to modern life. There are many different technologies available to consumers for these needs, with cable TV / broadband networks being among the most common and widely available service delivery network types. During the pandemic of 2020, many service delivery providers, ourselves, and others, experienced significantly increased demand for data, as

well as increased expectations for reliability and availability. Energy is still being invested in building scalable solutions to meet the increasing demand for bandwidth to the end user. For the purposes of this paper, we are going to examine and define a typical system, dividing the network into several segments, primarily the ISP (Inside Plant), OSP (Outside Plant), and Customer Premise.

The ISP, also commonly referred to as the Headend, is the facility where signals are generated, received, and processed from content providers, as well as from Customer Premise Equipment (CPE), like broadband gateways and set-tops. It is typically a climate-controlled facility where the equipment is housed to manage the routing of video, data, voice, and other signals to their intended destinations. The Headend also houses CMTS (Cable Modem Termination System) devices for broadband connectivity.

The actual customer premise – the household, multiple dwelling unit (MDU) or business -- can have slight variations in definition, primarily around where the demarcation point exists between the premise wiring and the Outside Plant. In some cases, the outside drop cable that connects the hardline cable tap to the premise is considered to be customer premise wiring, and in other instances, the customer premise wiring is defined as the customer side of the grounding or bonding block. In the context of the Refer to Maintenance process, this demarcation is an important distinction. For this paper, we will define the premise as any and all wiring from the hardline cable tap port to the Customer Premise equipment (cable modems, WiFi gateway, video set top boxes, etc.), including all coaxial cables, amplifiers and splitters in the customer premise wiring.

We can now define the Outside Plant as the transmission medium(s) transporting signals between the Headend or Hub and the hardline cable tap port. This would include the fiber and coaxial cables, as well as the active components (nodes and amplifiers) and passive components (splitters, couplers, and taps) between the Headend and the customer premise.

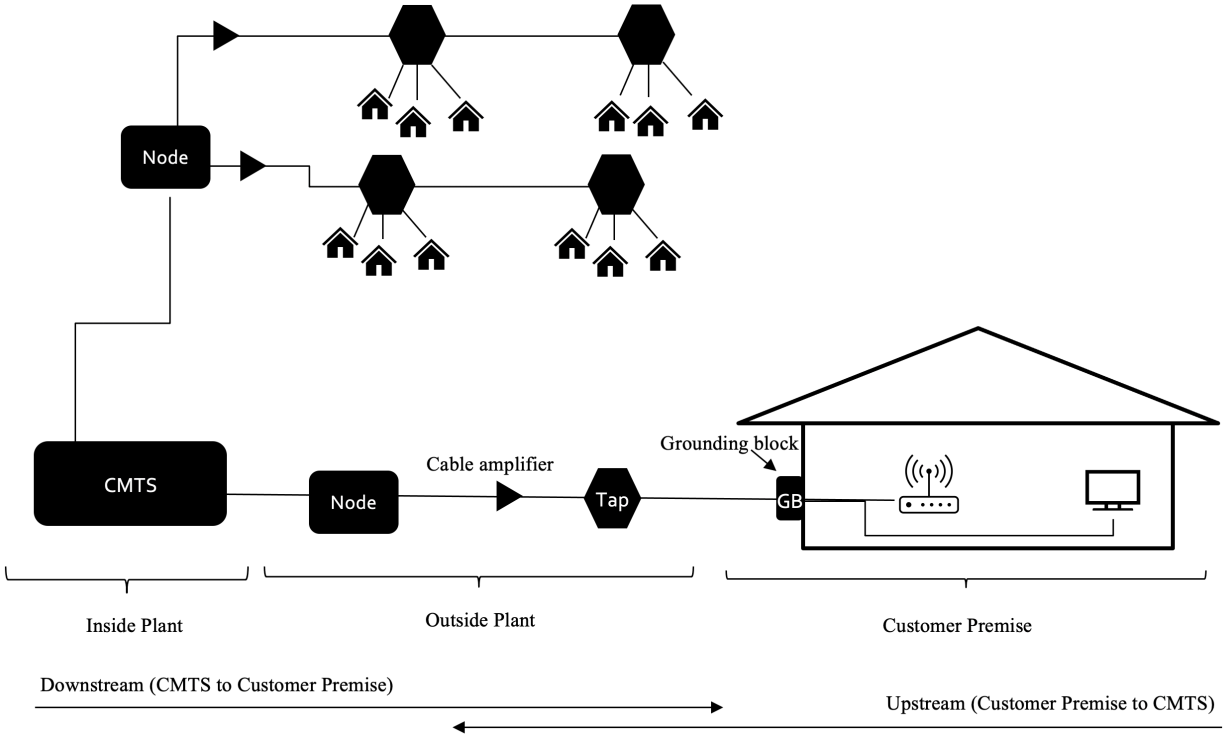

Figure 1 – Plant Diagram

As mentioned previously, this portion of the network is evolving rapidly to meet the increasing demand for bandwidth by the broadband consumers. The Hybrid Fiber Coax (HFC) portion of the network is becoming increasingly diverse as new technologies are developed and deployed, while previous generations of hardware are continually optimized to meet the signal quality and bandwidth needs of the customers. HFC networks built in the late 1990s can still reliably provide service to customers today. Even so, the components that make up the HFC section of the network have remained largely unchanged. To that end, we need to consider the failure points that are common to all generations of HFC networks.

The headend or hub locations that we mentioned have also undergone technology evolutions, but fundamentally, their purpose is to aggregate all the signals designated for a service area, and then modulate them into an optical format for transmission over a fiber optic transport network to a fiber optic node. The node translates that optical signal into an electrical signal and directs that signal into coaxial cable through a series of mechanical connections. The coaxial cable then transports those signals toward the target customer population through another series of mechanical connections via coaxial cable, connectors, couplers, splitters, and finally to the cable tap. The cable tap diverts a portion of that electrical signal to the customer service drop through another mechanical connection at the tap port. The service drop then transports the signal through yet another series of mechanical connections such as bonding or grounding blocks, splitters, amplifiers, connectors, and wall plates, until the intended signals arrive at a cable modem, set top box, or other customer premise equipment. In this example, we outlined many of the connection points that a signal must traverse in a single direction to reach the customer premise equipment, but this example did not include any active devices (amplifiers). This example of a single fiber node feeding a node service area without requiring any amplifiers is often referred to as a Node + Zero (or N+0) architecture, meaning there is a node, but no amplifiers to “boost” the signal to send it further into the network. Amplifiers allow operators to serve a larger area without adding more fiber cables or nodes. It is not uncommon for operators to still maintain HFC networks with N+6, or fiber optic nodes trailed by as many as 6 additional amplifiers, in cascade, required to reach all customers in the node service area.

Thus far we have only discussed the service delivery of signals to the customer in a single, or one-way direction. That is, signals are delivered from the headend or hub to all the customers in the node service area, or “broadcast”. The reality, of course, is that there are signals flowing in both directions, from the headend to the premises, and conversely, from the premises back to the headend, aggregated via the HFC network components. However, all signals, whether upstream or downstream, can be adversely affected by impairments at any point in the HFC network. The degradation of the signal level or quality can be experienced very differently by the customers and our intelligence tools, depending on which component in the transmission medium is damaged or compromised.

The HFC network is a complex yet robust asset. It is arguably one of the most important assets for any operator, and as such, much effort and energy is invested in keeping it healthy and performing at an optimal level. As we described at a very high level, there are a very large number of components that must individually be uncompromised, and collectively maintained to ensure the physical, mechanical, and electrical integrity of the overall network.

Fortunately, the maintenance of these networks has gotten much more efficient over the years. While many of the troubleshooting practices have changed very little, the telemetry we are able to collect from CPE and other assets in the HFC infrastructure have allowed us to better identify those areas which are exhibiting symptoms of impairment. From that additional telemetry data, we can prioritize our response by customer impact potential, and dispatch our Line Maintenance teams to the right area to repair the network and remove the impairments. Previously, plant maintenance was either 100 percent preventative, meaning we would sweep or inspect the network on a scheduled basis, or it was reactive, meaning we

responded to an area when our customers reported an issue. Using the data points that will be discussed later in this paper, we are able to collect metric data points from devices located in different points of the network and infer when those symptoms are caused by an impairment in the physical transmission medium.

4. Remote Network Telemetry Measurements

DOCSIS (Data Over Cable Service Interface Specification) technology is supported by comprehensive data collection systems that offer insights into the state of the access network remotely. Comcast has developed and operates several intelligence tools supported by DOCSIS specifications to help identify network impairments and prioritize repairs. Wolcott et al [1] wrote about the role of the network remote telemetry in the Proactive Network Maintenance (PNM) systems:

… [with] the capability of nearly all CPE [Customer Premise Equipment] to report some level of intelligence back to the tool sets, and [we] have a comprehensive view of all corners of the network. No longer is plant performance informed by a small quantity of DOCSIS channels on a relatively small number of devices. The ability to construct, analyze and match full downstream signatures in multiple portions of each individual premise within a node, in addition to the traditional DOCSIS frequencies, means that an operator can develop an accurate map of all the impairments in the upstream and downstream at virtually every component level within that node. Individual premise issues can be isolated and identified, and with the integration of system design prints, network level impairments can be correlated to active or passive components with a fairly high degree of certainty. This allows for impact scaling, and prioritization of impairment resolution with greater precision, as well as improved task management. Since causality can be attributed to the component level with greater accuracy, dispatch of the proper fix agent is more effective and efficient.

4.1. PNM Software Poller

As the DOCSIS specifications have evolved, so has our ability to poll CPE for meaningful data to analyze the performance of the network. Multiple pollers and polling frequencies can be aggregated to form a comprehensive picture of the performance of the network and premises. Using multiple pollers, or polling timing sequences can be useful in managing the demand on the systems by spreading the requests across time, while optimizing which data points are required at specific intervals. For instance, one PNM software programs could poll devices 3 times per day to report raw measurements describing connectivity between the modem and the CMTS, while others collect different data sets like Full Band Capture (FBC) energy in the FM band at more frequent intervals. We describe some of that data collected by the various pollers in the tables below.

Table 1 – Measures Collected by the PNM Poller

Telemetry	Description
Downstream Receive Power	Power (decibels relative to one millivolt, dBmV) received by the cable modem on the downstream DOCSIS channel. For a DOCSIS cable modem to work within the specification, the downstream power level needs to be in the -15 dBmV to + 15 dBmV range.
Upstream Receive Power	Power (in dBmV) received by the CMTS from a specific modem.
Downstream SNR	Signal to Noise Ratio (SNR) refers to the strength of the signal being received relative to the noise on the line. For the cable modem to

	work within the specification, the SNR needs to be at least 23.5dB; a desirable ratio is 30 dB or higher.
Upstream SNR Individual Modem	Similar to Downstream SNR (see above) but for signal sent upstream
Upstream SNR Channel Average	Similar to Downstream SNR (see above) but for the upstream channel average
Upstream Transmit Power	The strength of signal transmitted by the cable modem. Target levels could be between 42 and 50dB.
T3 Timeouts	Number of instances of T3 Timeout (i.e. ranging request retries exhausted). The cable modem has sent 16 Ranging Request (RNG-REQ) messages without receiving a Ranging Response (RNG-RSP) message in reply from the CMTS within 200ms. The cable modem is therefore resetting its cable interface and restarting the registration process. A T3 timeout is typically associated with an upstream impairment.
T4 Timeouts	Number of instances of T4 Timeout (i.e. when the cable modem did not receive a station maintenance opportunity to transmit a Ranging Request (RNG-REQ) message within the T4 timeout period (30 to 35 seconds) after receiving the previous RNG-RSP). The CMTS must provide each CM a periodic ranging opportunity at least once every T4 (30 to 35) seconds. A T4 timeout usually initiates a reboot of the CPE due to lack of communication: the cable modem resets its cable interface and restarts the registration process, reinitializes its mac after T4 seconds have elapsed without receiving a periodic ranging opportunity. This typically indicates an occasional, temporary loss of service, however, if the problem persists, it may indicate possible service outages or maintenance activity on the CMTS. A T4 timeout is typically a downstream problem; if many modems are affected by T4 errors it may indicate a section of the HFC network being affected. T4 timeouts can also be associated with a CMTS that has extremely high usage (e.g. > 95 percent capacity).
Lost Syncs	Number of times the CM lost synchronization with the downstream channel. Discontinuities in the value of this counter can occur at reinitialization of the managed system.
Resets	Total number of resets happened on the CM
System Uptime	Time in seconds (s) that the device has been ‘up’ and running.
FEC (Forward Error Correction)	Data does not always transmit through cables perfectly, there are often some errors in the bits (1s and 0s); a 0 might be flipped to a 1 or vice versa. To correct those errors, some extra data must be attached to every codeword that goes out (a codeword is just a fixed chunk of data). If it can fix the error, then all is well. However,

	sometimes codewords have too many incorrect bits and the error correction algorithm cannot fix it. If more than 1 percent of the codewords are uncorrectable, we may start to encounter some issues. FECBlks—The total number of FEC blocks (both good and bad) received by all the upstream ports associated with a given downstream. FEC is generally measured using codewords. A codeword is 16 bits with 2 bits for error correction.
Upstream FEC Unerrored	Total number of code word blocks received without any errors. In ideal scenarios it should be equal to total FECBlks
Upstream FEC Corrected	The total number of FEC blocks received by all the upstream ports associated with a given downstream that were slightly corrupted by noise or ingress and that could be corrected and recovered by the FEC algorithm. Number of code words detected as errored, and which have been corrected.
Upstream FEC Uncorrectable	The total number of FEC blocks received by all the upstream ports associated with a given downstream that were so corrupted by noise or ingress that they could not be corrected or recovered by the FEC algorithm. High values imply presence of data loss; this can happen if there is lot of noise in the signal.
Downstream FEC Unerrored	Similar to Upstream FEC (see above)
Downstream FEC Corrected	Similar to Upstream FEC (see above)
Downstream FEC Uncorrectable	Similar to Upstream FEC (see above)
Upstream | Downstream Interface ID	Generally, a device will be connected to the same interface ID over a period of N days; a change to another interface can be an indicator of network-related issues
Upstream ICFR	In-Channel Frequency Response: the max-min variation peak to valley of the response represented in dB. Minimal to no variations are ideal; large variations indicate network integrity issues.
Upstream Ripples	The number of amplitude variations within a 0.75dB threshold.
Upstream TTE	Total Tap Energy upstream from CM expressed in dB
Upstream PMT	Post Main Tap – the Adaptive Equalization (EQ) determined tap that is expending the most energy beyond the main tap. (In the absence of RF impairments, all signals will traverse through the main tap which will have the highest value.)
Upstream PMTE	Post Main Tap Energy – The PMT amplitude expressed in dB. Energy observed in these PMTs is indicative of RF impairments such as micro-reflections being present and the CMTS is activating the equalization gain states in its attempt to compensate for impairments. Energy level is positively correlated to the degree of impairment.
Upstream ETAP1, ETAP2	The EQ tap information for echoes or impedance mismatches beyond the PMT greater than the established threshold. ETAPs provide approximate ‘distance’ to issue (fault/echo). “Distance to issue” can be inferred as the ETAP number post “main”

	tap (outside premise that serves a cluster of residences) with highest 'energy' multiplied by approximately 85 ft per ETAP increment) [2]
CM Phase	Cable modem signal's measured phase angle deviation before adaptive equalization; frequency carrier wave's phase information is a key component in Quadrature Amplitude Modulation (QAM) technique for transmitting digital data as an analog signal.

4.2. PNM Account and Device Network Analysis Degradations Tool

Comcast has a PNM tool that seeks out account and network degradations. The tool consumes data from multiple pollers and runs the impairment algorithms to examine devices six times per day, to report account and device level degradation issues related to disturbances in the RF spectrum. Using comparative analyses, the tool attempts to isolate impairments related to network, drop, in-home wiring, loose connections, and whole home concerns. The table below lists selected metrics used in the impairment detection.

Table 2 – Measures Analyzed by the Algorithmic Impairment Analysis Tool

Metric	Definition
In-Channel Frequency Response (ICFR)	ICFR is the peak to valley measurement of the amplitude flatness. Ideal ICFR is flat and high ICFR can be caused by impedance mismatches due to loose connectors or other cable integrity issues. The algorithmic tool checks for matches between the ICFR signatures and PMT (Post Main Tap) values to identify a common impairment across neighbors.
Carrier to Interference + Noise Ratio (CINR)	CINR is defined is the range between highest and lowest Modulation Error Ratio (MER). CINR help us capture ingress on non-FBC-capable devices.
Full Band Capture (FBC) FM Noise	Full Band Capture -capable devices can identify if there are FM signals present at the RF input. Loose connectors and other cable integrity issues cause FM signal ingress.

Table 3 – Impairment Locations Identified by the Algorithmic Impairment Analysis Tool

Impairment Location	Description
Solo	The tool cannot isolate the fault to specific location in the home or drop but have checked neighbors and excluded a potential network issue. Fault can be at the device, ground block, drop but is not isolated to that single outlet or device.
Outlet	The tool isolated the fault to the specific outlet that feeds a single device.
Home	The tool isolates the fault to a common point in the home that feeds multiple devices but does not impact all devices in the home.

Drop	The fault is isolated to a common point that feeds all devices in the home and is not a network issue.
Network	The tool has correlated at least one other near neighbor with the same impairment on the same channel(s) indicating an Outside Plant impairment.

4.3. PNM Node-Level Network Degradation Impairment Analysis Tool

Alongside the account- and device-level impairments, there is a tool that consumes both account-level data as well as node-level data. This algorithmic tool that scans the network for RF impairments and reports them continuously and creates event logs indicating a problem and a list of accounts impacted. Events move from soaking to confirmed stages and vary by severity. Events include outages, service call alerts, plant faults, spectrum power analysis events, and upstream CMTS port analysis events.

Table 4 – Node-Level Impairments Identified by the Algorithmic Analysis Tool

Event Type	Description
Outage	Event generated when 4 or more devices that share a common problem are offline. Criteria area adjusted for multi-dwelling units.
Power outage	Event is declared if 4 or more devices appear to be a part of a commercial power outage, identified by devices on battery backup.
Service call event alert	Event is generated if the percentage of customers with a scheduled trouble call on the node exceeds a threshold
Plant Fault	Events are generated when a proportion of customers within the node violate the thresholds for the RF Levels. Problems include out of range upstream transmit power, upstream or downstream SNR/MER, downstream receive power.
Spectrum Power Analysis Events	Events are generated by looking for a cluster account matching a specific RF spectrum signature. Signatures include suckouts (a frequency-specific collapse in the RF energy caused by a short distance and high energy reflection), waves (a sinusoidal pattern detecting multiple peaks to nulls in the spectrum 4.5 dB or greater), and tilts (a delta threshold between upstream transmit level in the highest and lowest frequency channels that exceeds 3dB)
Upstream CMTS Port Events	Events are generated by monitoring utilization of upstream channels, failed and correctable FEC errored rate, number of upstream channels in use, and channel width and modulation.

We discuss how the inputs from the remote network telemetry are transformed into the model features in section 6.1.

5. Refer to Maintenace (RTM) Field Operations

When customers encounter service issues, they can reach out for help through various channels, like IVR (Interactive Voice Response), call or chat agents and the Xfinity Assistant interactive chat application. If a chatbot application detects issues that cannot be solved by system refresh or restart, it will route subscribers to a chat or a call agent. Call and chat agents use Interactive Troubleshooting Guides (ITGs) to localize the problem and offer the most effective solution. If an agent identifies an impairment in the network, they will schedule a service technician to visit customer's home and continue troubleshooting on site.

Ventriglia et al [3] describe a workflow for on-site troubleshooting. On site, technicians use field tools to take measurements at different points in the drop network. A technician might start with taking measurements at the ground block closest to the customers' premise. If these measurements are within acceptable specs, the technician will move to investigate impairments inside the customers' home. If a fault is found in the grounding block, the technician will continue to investigate issues at the tap. If no issues are found at the tap, the technician will do the work to replace the drop and perform a premise health test to confirm that customers' issues are resolved. If an impairment is found at the tap, the technician will escalate the problem to the line tech team by creating an RTM request. Issues are triaged by field operations teams and if they are confirmed as a plant impairment, a line technician job is scheduled. Field operations teams monitor non-severe issues, identify neighborhood impact, and send a line technician once a neighborhood impact is confirmed. When the standard technician finds a network issue, a cost is incurred to send both a standard technician and a line technician. Moreover, we estimate that a subscriber might wait up to two days for a standard technician appointment and then possibly another day for the line technician appointment. This historically has been the repair model when a single customer reports a service issue that is ultimately attributed to an impairment in the outside plant network.

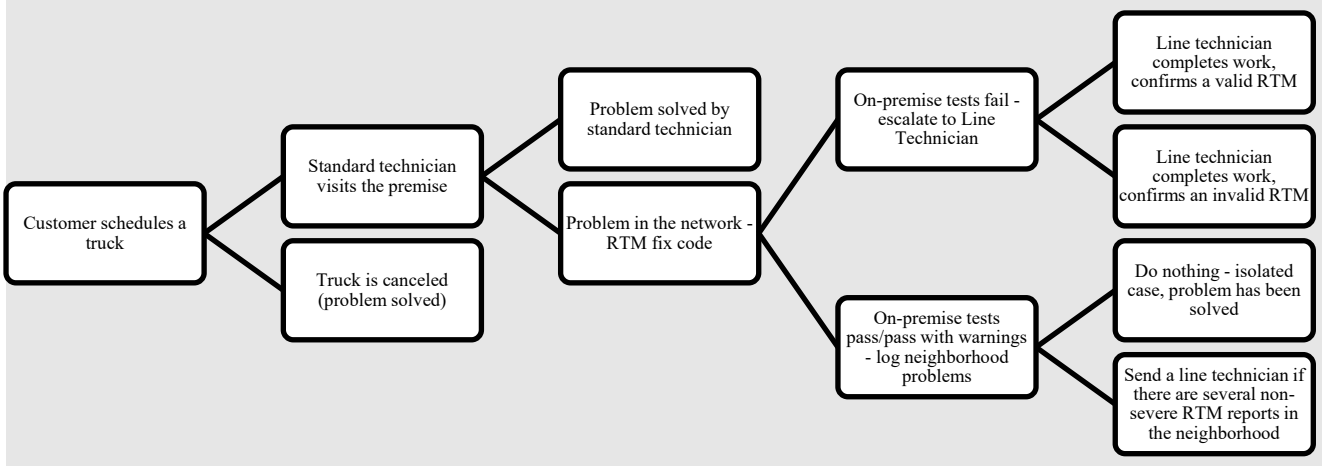

Figure 2 – Refer to Maintenance Field Operations

6. Refer to Maintenance Machine Learning Model

We propose a workflow where a predictive model will recognize that the issue will be an RTM problem, with high probability. In this case, we will not send a standard technician, but schedule a line technician instead. If the model predicts a low RTM probability, we might message the standard technician that the issue is an unlikely RTM.

We have developed a machine learning classification model to identify standard technician visits that will result in the RTM escalation that is also confirmed as "valid". The model is trained on the set of data comprised of standard technician visits. The model learns the target labels derived from the line technicians the "valid RTM" label, whereas all other codes are included as negative labels. We exclude trouble calls where technician could not access the premise, or no one was home.

The model has access to two sets of features: telemetry collected by pollers for all subscribers in the company footprint and information collected ad-hoc for subscribers who reported issues during the call with an agent.

We used a two-step modeling approach, which we refer to as *tier 1* and *tier 2*, to make the final prediction. Our *tier 1* model is trained on all the available telemetry information to determine the probability of RTM among the subscribers' neighbors. This is then used to evaluate the probability of RTM for the subscriber during the day prior to the day of call. Subsequently, our *tier 2* model uses features collected ad hoc during the call with an agent, archived telemetry features, including the *tier 1* derived probability of RTM during the previous days as well as the probability of RTM among neighbors.

Following sections offer details of model development within each stage.

6.1. Feature Engineering

6.1.1. DOCSIS Telemetry Features

The model uses features from PNM telemetry sources that collect and aggregate DOCSIS measurements. These sources poll and analyze the state of the network, looking for outages and impairments. Other systems collect network data and do the fault segmentation analysis.

We batch-process features from the PNM sources once per day. Each source has a varying aggregation window. Data from the pollers reporting connectivity between modem and CMTS and account degradation algorithm tools arrive 3 to 6 times per device per day.

For the tool reporting account-level degradation, we used a one-day lookback window and aggregated the data across devices and polls reporting the proportion of polls with a certain impairment. Aggregated features include a potential filter indicator, number of correlated accounts found by the algorithm, FBC FM Noise and ICFR impairments.

The PNM tool reporting on connectivity between the model and CMTS offers measurement and count data. Devices report cumulative counts of T3 and T4 timeouts, lost syncs, resets, FEC corrected, uncorrectable, and total codewords until they are rebooted. We transform count features to get the incremental increase since the last poll unless there has been a reset, otherwise, we take the feature value as is. Measurement features include receive and transmit power, SNR, TTE, PMT, PMTE, CM phase, upstream ripples, and ETAP1 and ETAP2 measures. We further transform FEC errored and corrected codeword counts as percentage of total errored and corrected codewords. Then, we proceed with data aggregations: we take averages for features across all polls for all devices attached to the account during the day prior to the model evaluation. Finally, we examine data across four days prior to the model evaluation to estimate standard deviations for the features.

We collect data from the node network impairment algorithm for all events created one day prior to the model evaluation tied to the subscriber who requested the truck. We estimate the number of accounts

impacted by the same events and identify events by type: plant issues (ICPF plant faults, upstream and downstream FEC), wave, and suckout events. We count the number of events reported for each account.

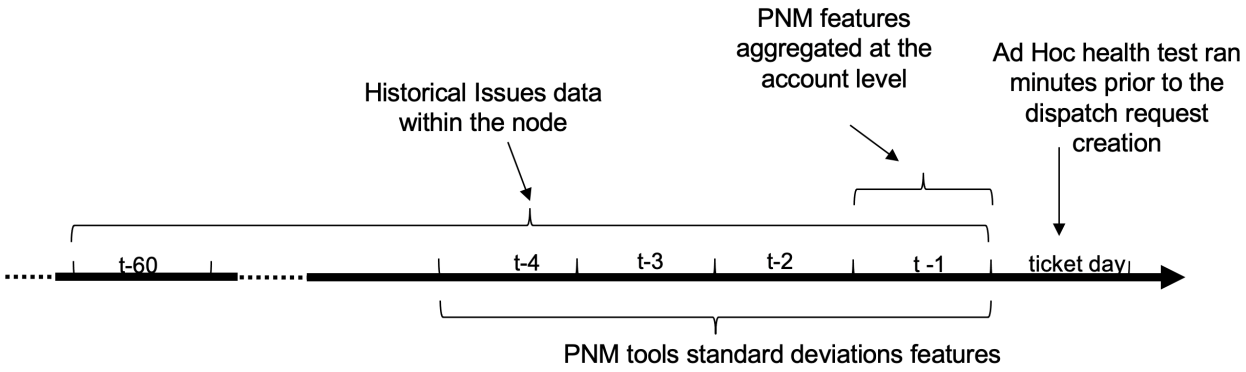

Figure 3 – Feature Extraction Timeline

6.1.2. Historical Issues Reported by Technicians

Another data source added to the model are historical rates of different types of issues reported by the technicians in the same nodes in the previous 60 days. Issues include construction and underground crew escalations, drop, ground block, and prior RTM escalations. We include these features as rolling aggregations for problems 60 days prior to the model evaluation.

6.1.3. Ad Hoc Remote Telemetry Health Checks

Agents use the remote Application Programming Interface (API) to run ad hoc telemetry checks using the capabilities of polling tools to collect the most recent data about the customers' network. Data from PNM pollers are collected 3 to 6 times per day and lag in time due to processing and data availability delays. Ad hoc telemetry health tests offer data from the same pollers but are retrieved on demand. In addition to the raw data, the tests also report pass/fail/pass-with-warnings analysis and offer heuristics for interpreting the raw data ranges (such as labels for failures in each DOCSIS analysis section). We transform raw data with similar aggregations described for PNM tools earlier and add labels and heuristics data as one-hot-encoded or ordinal (based on severity levels) features.

6.1.4. Topology Aggregations

Node topology was instrumental in creating features that detect network impairments. Node topology maps describe how equipment such as amps, taps, splitters, and cables are connected from the node to customers' homes. Data are collected by calling on the geographic information system API with a backend database to execute spatial intersect queries to identify equipment related to the locations supported by the Comcast footprint. Data are stored as a directional graph representing paths from the node to the tap, along with coordinate and equipment details.

Node topology maps were used to aggregate and average measurements, to provide a wider view of the network events surrounding a customer when the service call was being scheduled. One type of aggregation is at the parent level, which averages the telemetry over all customers who are immediate neighbors in the graph. Another aggregation is a comparison of parent measurements to those of parent's

neighbors. The idea is that if a single piece of network equipment is broken, we can observe the impact of this by comparing all the customers who depend on it (and thus have impaired service) with customers who do not depend on it but are otherwise similar because they share the same upstream network components. We also identified locations on the graph where amplifiers are located and estimated the average and standard deviation of measures across amplifiers on the path from customers' home to the node.

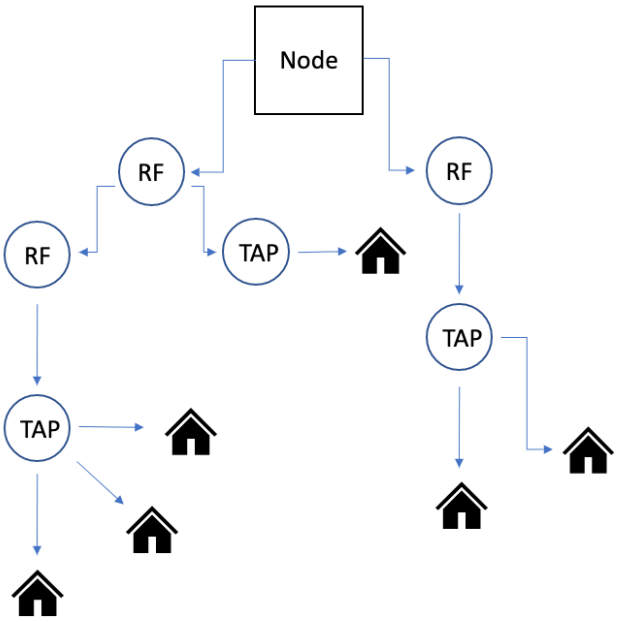

Figure 4 – Node Topology Diagram

Figure 5 provides an overview of the data, feature engineering and integration in our two-step modeling approach.

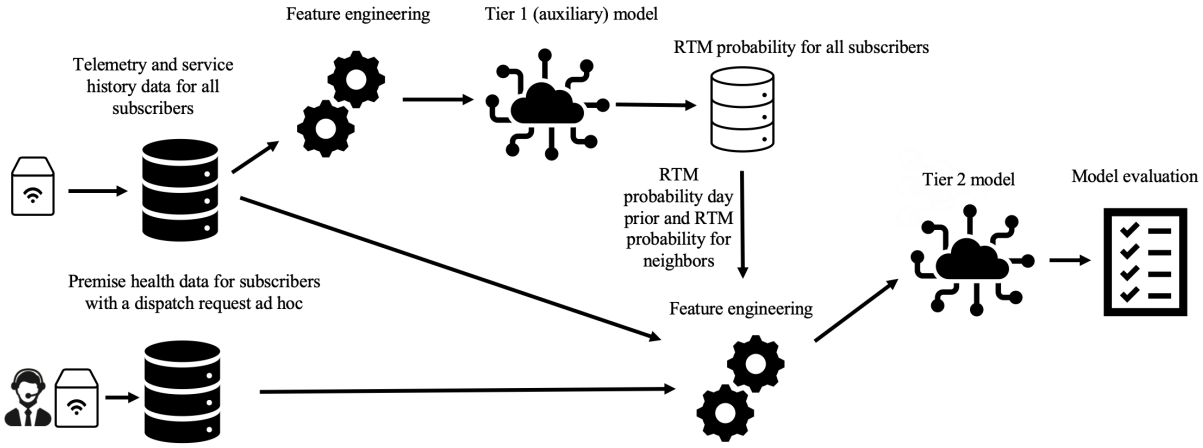

Figure 5 – Model Training Process

6.2. Model Evaluation

6.2.1. Model Performance

Our best-performing models is trained with an open-source XGBoost classifier (Tianqi and Carlos, 2016 [4]). The classifier has been calibrated for best hyper-parameters and uses 500 estimators to build trees with maximum depth 2. 239 features are used as model inputs in *tier 1* model and 375 features are used as model inputs in *tier 2* model. Our target label has a very small prevalence, resulting in the class imbalance problem. To assist the models to learn from a data set with class imbalance, we used the class-weighted version of the model to help remediate the class imbalance.

During the training stage, we separated data into training and testing sets, using the time of ticket creation to separate testing set of observations. Further, *tier 1* and *tier 2* models are trained on separate sets of data. In the latest iteration, tier 1 model was trained on 2,231,591 observations collected during December 2020 through March 2021.Tier 2 model was trained on 1,021,398 observations collected during April through June. During evaluation, tier 1 model is tested on full available out-of-sample data (April through August 2021), however, here we quote performance numbers for both models tested on the same data with 587,975 observations, collected during July through August 2021.

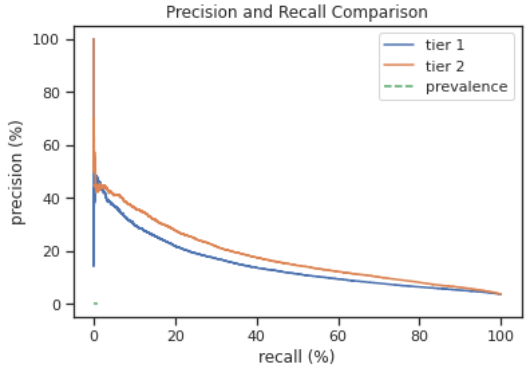

Figure 6 – Precision Recall Curve on Testing Data

The *tier 1* model is trained with telemetry data available for all subscribers. Calibrated at 5 percent recall, the model achieves 37.2 percent precision. Model performs 10 times better compared to the random guess.

The *tier 2* model is trained with combined telemetry, RTM probability of neighbors and subscriber prior day RTM probability, and ad-hoc health test features. Calibrated at 5 percent recall, the model achieves 41 percent precision: this means that the model calibrated to return at least 5 percent of true RTM trucks, can accurately identify 41 percent of cases. Model performs 11.2 times better compared to the average prevalence (random guess).

While Model stacking increases complexity of the model training process, it helps us to increase model precision by 3.5%. Figure below shows the precision and recall curve for the *tier* 1 and tier 2 models evaluated on the test data.

6.2.2. *Exploring Feature Importance*

We used normalized model weight to explore top features contributing to the model importance. Following graphs show features ranked and identified by source.

In *tier 1* model, features extracted from the account degradation analysis tool make up the majority of top features. Many of the features contributing to the model are based on the topology estimates – you can identify them by "parent" (tap aggregations) or "AMP" (amplifier aggregations) flags.

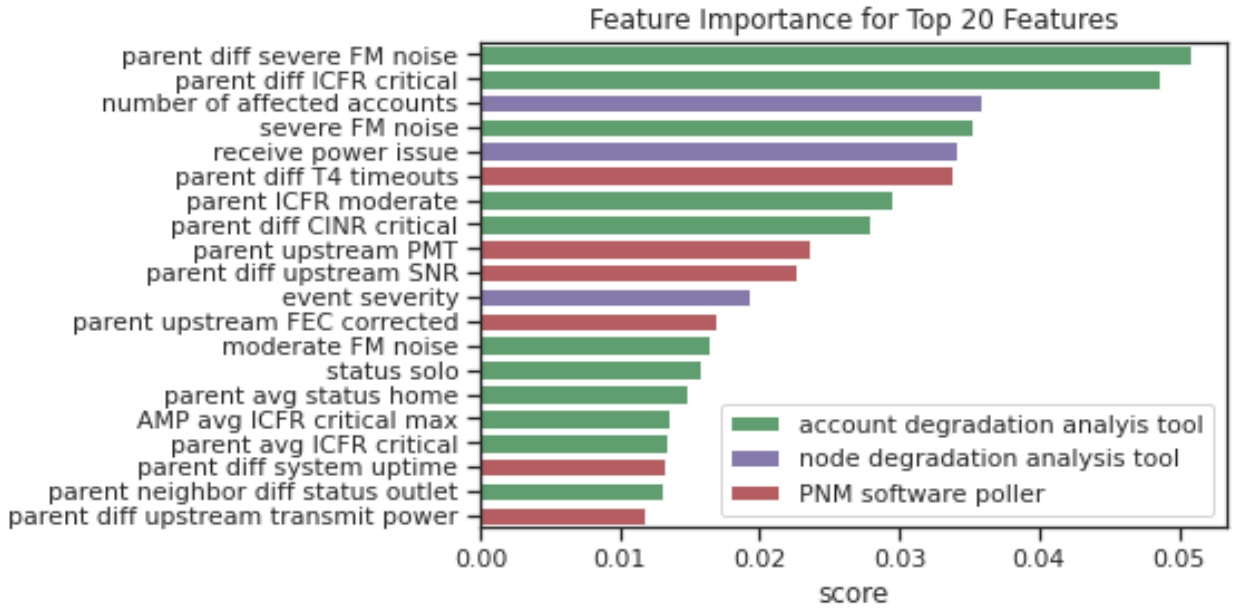

Figure 7 – Feature Importance for Tier 1 Model

In *tier 2* model, features extracted from the premise health check tool make up the majority of top features – it is expected as these features are extracted during the call with the agent and represent the most recent state of the device performance. The top 2 features contributing to the model come from the auxiliary tier one model and indicate probability of RTM 3 days prior to the call. The importance of these features leads us to believe that network problems might impact customers in a matter of days prior to the call. We also explore the directionality of features for *tier 2* model.

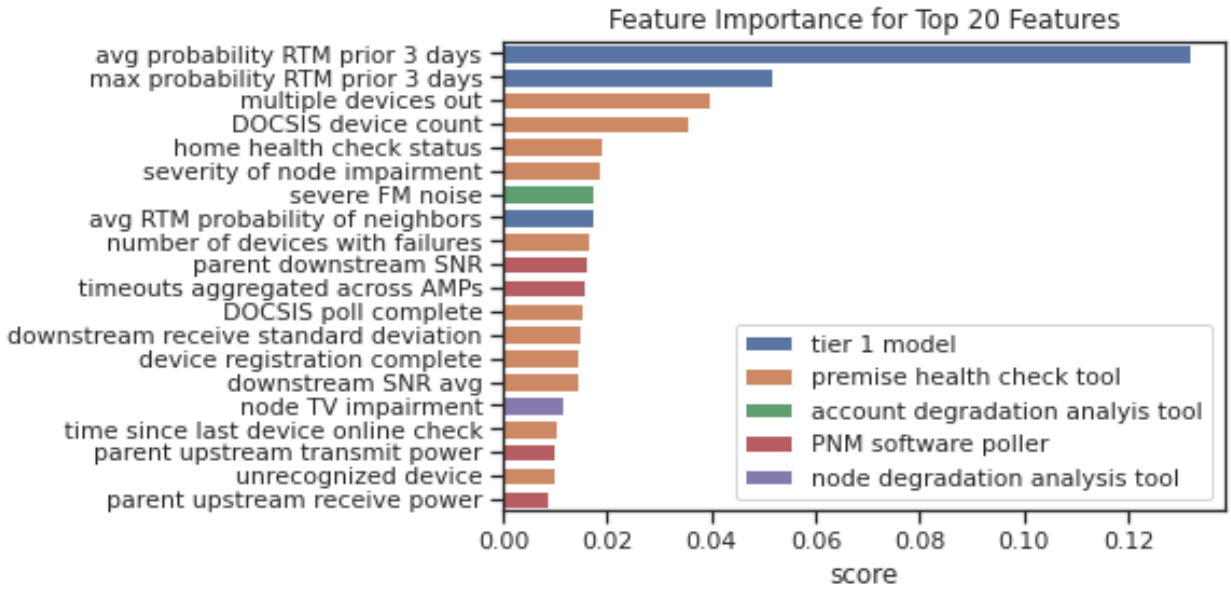

Figure 8 – Feature Importance for Tier 2 Model

Features positively correlated with the RTM outcome are number of device failures identified by health check, probability of RTM days prior, high downstream receive standard deviation, failed (high value of) home health check status, multiple devices out/offline, number of events with a TV-related impairment evident in the node, severity of node impairment, severe FM noise event incidence, and timeouts aggregated across amplifiers. For these features, higher values indicate a higher chance of RTM.

Features negatively correlated with RTM probability are time since last device online check/registration, parent upstream receive power, complete DOCSIS polls, found unrecognized devices, DOCSIS devices on account, complete registrations, downstream SNR, and parent downstream SNR. For these features, lower values indicate a higher chance of RTM.

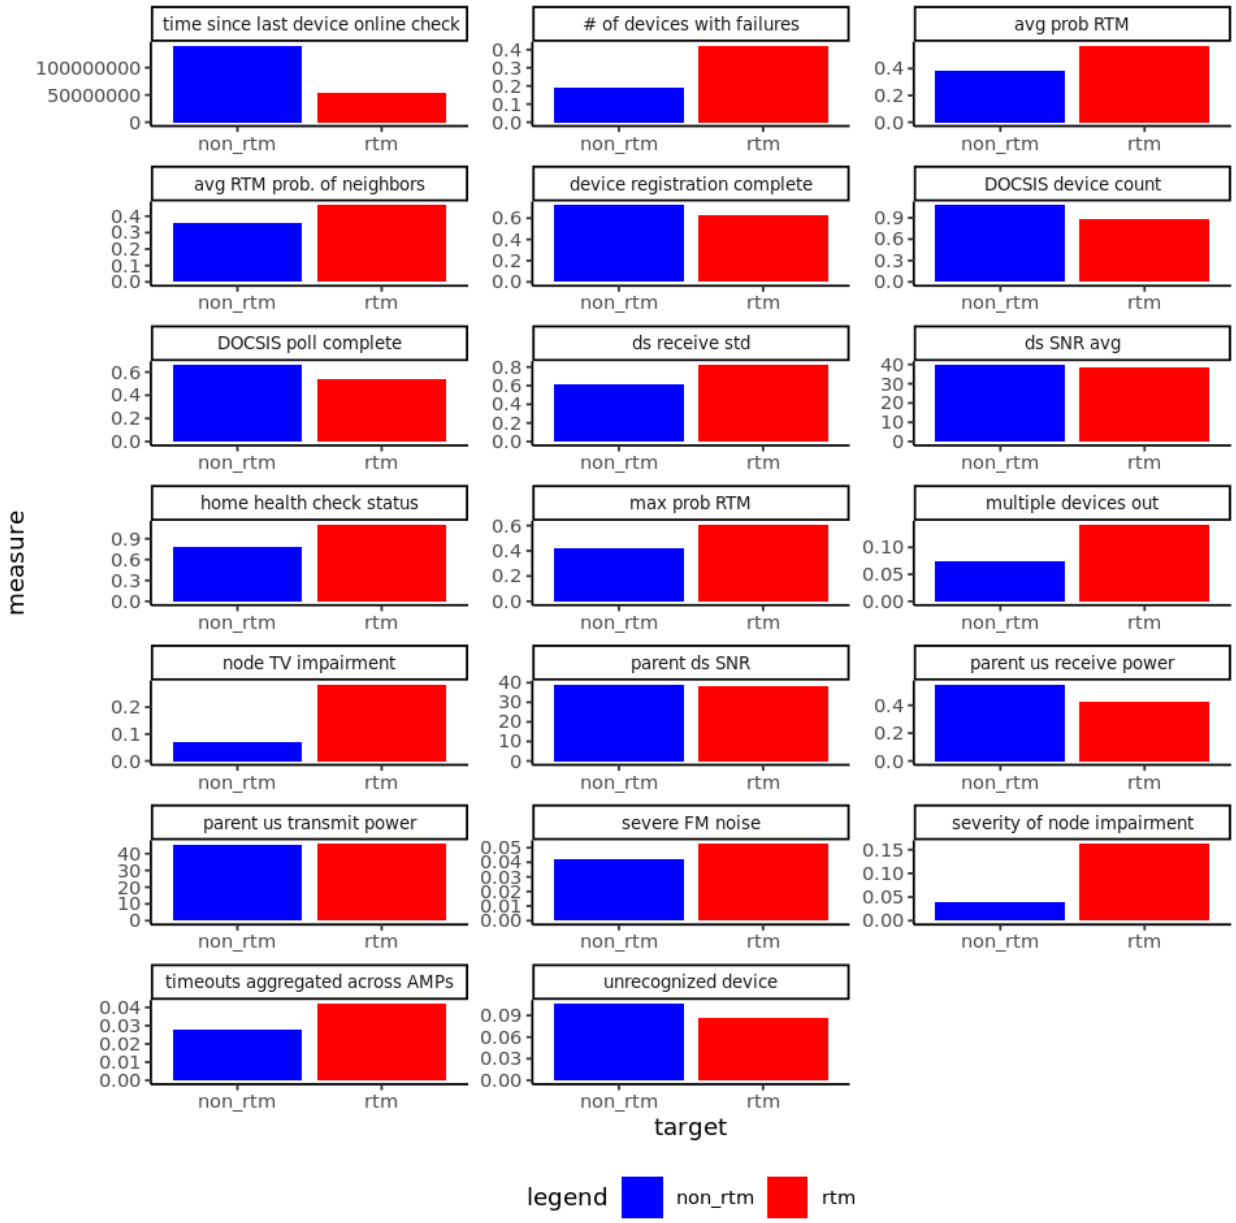

Figure 9 – Feature Exploration for Tier 2 Model

6.3. Cost Calculation

To assess the financial impact of the RTM model, we constructed a cost analysis comparing the business as usual (BAU) process to our model (RTM). The goal of this analysis is to identify the minimum precision required by the model to incur a net zero savings relative to BAU. This allows us to know when our model precision exceeds the break-even point before deploying in a live environment.

We assess the net savings relative to BAU when the RTM model makes a positive prediction (i.e. when the model recommends sending a line technician instead of a fulfillment truck). Note that the net savings for a negative prediction is effectively zero since a negative prediction defaults to the BAU protocol.

The cost analysis presented here also assumes that the model will make recommendations without any subject matter expert (SME) interventions. Asking SMEs to review model predictions, thereby utilizing the "human-in-the-loop" framework, improves the model precision but its impact to the overall cost is yet to be estimated.

Running a machine learning model incurs a fixed cost of computing, data storage, and engineering resources. Additional costs might include if we use a human-in-the loop model and each prediction is reviewed by an expert. The cost to run a model would be a fixed cost per prediction.

There are two approaches we used to assess the net savings incurred by our model. First, we describe in more detail the simpler of the two approaches. *Customer-level approach* estimates the net savings by taking into consideration only the customer with the model prediction in question. The latter approach, referred to as the *neighborhood approach*, additionally takes into consideration the impact of sending a line technician to the customer's neighborhood. Sending out technicians early and preventing more fulfillment trucks from going out into the neighborhood can generate additional savings. Let's first denote the following costs:

Table 5 – Cost Model Definitions

Cost of fulfillment truck	F
Cost of line truck	L, where L > F
Operations and research cost per prediction	R

6.3.1. Customer-Level Cost Calculation

In a true positive scenario where the RTM model correctly predicts that a line technician is required, the RTM model incurs a cost of L and the BAU model incurs a cost of sending both trucks, $L + F$. Therefore, the net savings for a true positive is

$$(L + F) - L - R = F - R$$

In a false positive, the RTM model incorrectly recommends a line technician and we will assume that in this case, we would need to send a fulfillment truck after incorrectly sending a line technician, costing the company $L + F$. We note here that this is a very conservative estimate as we can expect that sometimes a line technician can resolve issues that normally require a fulfillment truck (e.g. when an issue exists outside the home). For a false positive, the BAU's cost would simply be F. Let's also assume that sometimes customers cancel their scheduled trucks, and we will denote this cancellation rate as Y. Then, the net savings for a false positive is

$$F * (1 - Y) - (L + F) * (1 - Y) - R = -L(1 - Y) - R$$

We define precision as the proportion of predictions the model made correctly. Using these two estimates, the net savings, S_{net}, of the RTM model with precision P is given by

$$((F - R) * P) - (L * (1 - Y) - R) * (1 - P) \; = \; S_{net}$$

By setting $S_{net} \; = 0$, we can solve for precision P to get the precision required to break even with BAU's costs, which we denote as P_{even}. In customer-level approach,

$$P_{even} \; = \frac{L(1 - Y) - R}{F - 2R + L(1 - Y)}$$

Graph below illustrates the relationship between savings and the model precision. Actual estimates are omitted to comply with our company's data reporting policies. We offer the direction of the positive savings and show the precision required to achieve the break-even point.

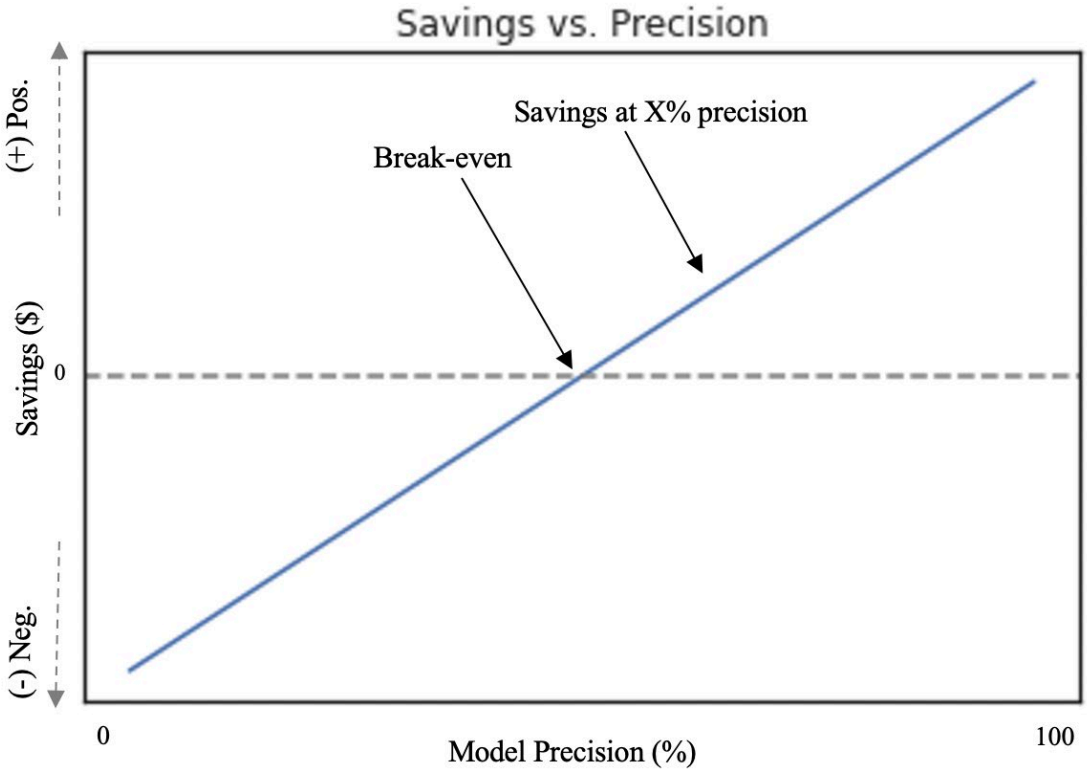

Figure 10 – Precision vs. Savings Curve Illustration

6.3.2. Neighborhood-Level Cost Calculation

In the neighborhood-level analysis we also consider the RTM model's impact to the neighborhood. By sending out line technicians early, there is a positive impact to other customers in the neighborhood suffering from internet issues that are predicted to also be RTM issues. In this scenario, if there exists a customer C_A with an RTM prediction, then we will delay sending out a fulfillment truck to C_A's neighbor, C_B, if the model also recommends a line technician for customer C_B within 2 days of C_A's prediction. In this analysis, we define two people as neighbors if they not only share the same CMTS node but also all the devices between the CMTS node and their respective homes.

In this case, we consider the true positive and false positive costs from customer-level calculation for the original customer C_A and we *additionally* consider the cost of a true positive and false positive to a neighbor C_B. A true positive for neighbor C_B occurs when the model correctly predicts an RTM for the original customer C_A *and* correctly predicts an RTM for customer C_B. In this case the true positive net savings for customer C_B is the cost of sending out a fulfillment truck needlessly, F.

A false positive for customer C_B occurs when we delay the customer from receiving a fulfillment truck when we incorrectly predict an RTM for C_A *or* C_B. The cost here is much less severe than only customer-level approach, as it is mostly a delayed response and possibly a second call to an agent made by the neighbor. If we denote the cost of contacting an agent as A and we assume that Z percent of the time, customer C_B will opt to call an agent instead of using an automated scheduling service, then the cost the model incurs for being wrong with customer C_B is $A * Z$. Because both the neighborhood sizes vary and the number of trouble calls made in a neighborhood vary across customers/regions, we used the test data to generate the net savings of our model as a function of the model's precision. We found that this neighborhood analysis decreases the required precision to break even, suggesting that implementing this delay service will have an additional positive financial impact.

6.4. Model Deployment

6.4.1. Model Deployment for Proof of Concept (POC)

We explored a "soft" deployment of the model for selected markets during our POC stage of development. Our goal was to obtain buy-in from our colleagues and test the model validity without incurring negative costs to the business or impacts to the customer experience.

During the POC we worked with the "human-in-the-loop" strategy. In this process, our program evaluated dispatch requests created by agents every hour and flagged "highly predictive" RTM candidates identified by the model. We then sent emails with the predictions to the regional subject matter experts (SMEs) for triage using AWS SES (Simple Email Service) email automation and posted in the Microsoft Teams channel. Emails were sent right after we received dispatch request logs to simulate a near real-time processing and prevent SMEs access to the truck outcomes (so that their judgement won't be "poisoned" by the truck outcome knowledge).

One of the participating markets explored dispatching a line technician the day a prediction was deemed valid by the SME, with the intent of remediating any customer pain from plant impairments prior to the standard technician visit. The majority of the market SME's evaluated network telemetry via desk top tools, logged notes and then validated the label (whether RTM is needed or not). Of note: the markets opted not to cancel the standard technician visit and schedule a line technician in their place until the predictions provided a higher degree of confidence. We have collected over 4,500 observations from the POC stage. SMEs evaluation of the model predictions resulted in 48 percent model precision. One of reasons for higher precision during the trial could be that evaluations were made on the dispatch request and not on the confirmed service calls. On average, 35 percent of scheduled service calls are canceled.

A debrief with the involved SMEs helped us to discover additional data sources, improve our feature engineering process, and identify false positive cases.

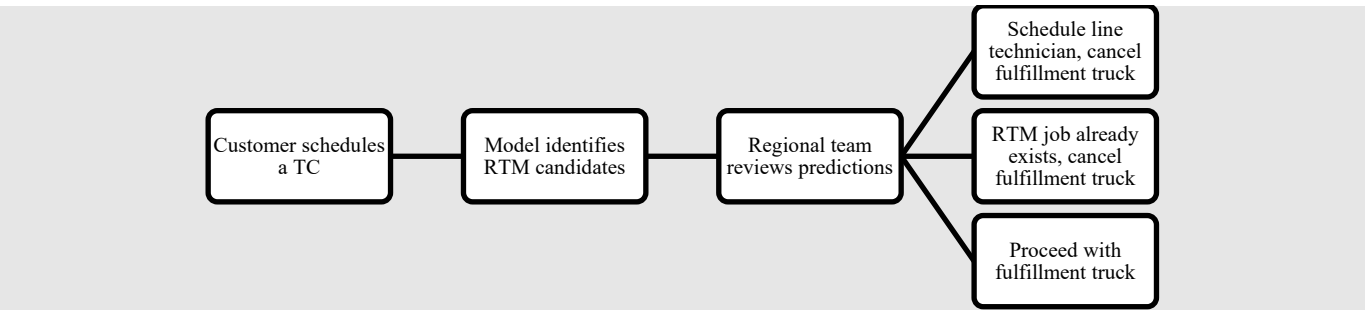

Figure 11 – POC Stage Model Deployment Workflow

6.4.2. Production Model Deployment

Figure 10, below, illustrates how we plan to deploy the RTM model into production. We will rely on the Redis (Remote Dictionary Server) [5], a fast, in-memory, open-source key-value data store to host the data. Our internal platform will host the model API. Model will consume two sets of features described earlier: payload from the ad-hoc premise health check passed by the agent making the API call, and features derived from the archived telemetry and *tier 1* model input stored in Redis feature store. Model engine will process features and output predictions to pass to the call agent. Subsequently features used and model result will be logged in AWS S3 (Amazon Web Services Simple Storage Service).

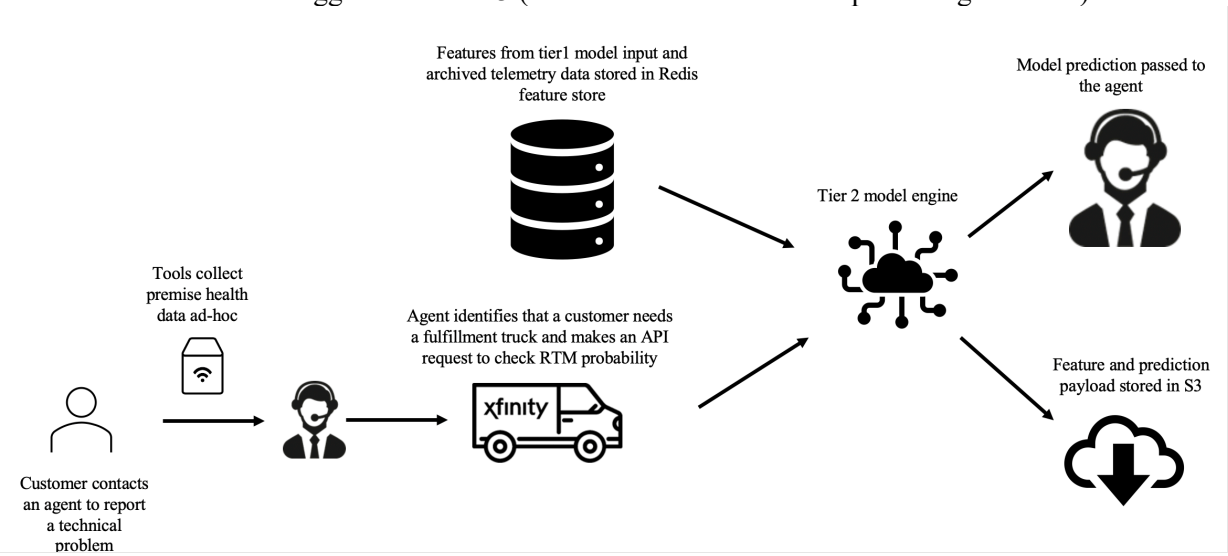

Figure 12 – Model Deployment Diagram

7. History of Model Development and Future Work

Network telemetry and topology features are used across multiple use-cases across the organizations. Originally, a set of features derived from the network telemetry was developed and applied to the classification problem predicting whether technician will only need to do work outside of the home. This model was implemented during COVID-19 business operations and helped us reduce the interactions between customers and technicians. We discuss this model in the Vengriglia et al [2] paper mentioned earlier.

The RTM model has been developed based on the telemetry features and benefited from RTM-specific features derived from topology and RTM probability of neighbors. During the development of the model, we have received feedback from the field operations colleagues and redefined the target label for the model. Originally, we trained our model to recognize the RTM fix code entered by the standard technicians. We then learned that regional teams put the requests through a triage process and only send a line technician for severe service disruptions only, taking other steps to help customers with non-severe service disruptions. Receiving this feedback, we have redefined our target label and updated the model to learn that the standard technician recommended an RTM, field operations triaged the case to send a line technician, and the line technician confirmed that the referral vas valid.

Our model development process does not stop with this paper or the model deployment, which is an early marker in the overall trajectory of ML and network operations. We have worked and will continue to work with experts to identify several telemetry sources that can help us improve model precision. First, we have learned that upstream interface problems can help us detect issues impacting multiple customers. Second, we have also acquired and plan to integrate packet data, hoping that this source can help us detect intermittent issues better.

8. Conclusions

In our paper, we described the complexity of the HFC network and the intelligent systems that collect measurements to monitor the health of the plant. While the telemetry measurements collected from the plant help us detect the symptoms of impairments, the machine learning approach is a predictive approach to plant maintenance and can enable us to dispatch line technicians to the right area in the network and remove problems more efficiently. The implementation of the Refer to Maintenance (RTM) with Machine Learning model would help us move from a reactive to a predictive maintenance approach. In addition, an ML approach can identify and uncover intermittent issues that are not always prioritized (or able to be prioritized) for line technician work, and can deteriorate the customer experience.

Adopting a machine learning approach will help us to continuously deliver an improved customer experience and streamline efficiencies across the service pipeline. Instead of multiple visits by different technicians, our customers could have their issues resolved faster with a single visit by the right technician. Further, we expect that a corrected network issue will have a positive impact on the whole neighborhood, delivering an improved experience to all customers in the area and thus reducing contact rates and unnecessary truck rolls.

We have described how cost analysis can help determine the appropriate model precision to achieve before deployment. Using this approach, we can deploy the model that is tuned to achieve an outcome beneficial to the business. In summary, the Machine Learning approach is a game changer that will help us to achieve continuous operational transformation. By identifying and prioritizing network issues, we can deliver the right technician at the right time and improve customer experience.

SD-WAN Security and SASE

How to Secure SD-WAN and Role Of SASE

A Technical Paper prepared for SCTE by

Charuhas Ghatge

Charuhas.ghatge@nokia.com

1. Introduction

Software-defined wide area networks (SD-WAN), a software approach managing wide-area networks, offer ease of deployment, central manageability, and reduced costs, and can improve connectivity to branch offices and cloud. End users are excited about SD-WAN because it enables them to manage and add network functionality using a cloud-first strategy for application access and delivery.

Compute resources and associated cloud services are exploding, and traditional enterprise network boundaries have expanded into the public cloud, branch locations, and intelligent edges. So, what does this all mean to the branch security?

Cloud computing has created several challenges since networking and security are incompatible with the cloud-centric and mobile-first business models. The network is rigid and static. Security is heavily centered around the data center, fragmented across multiple domains of physical locations, cloud resources, and mobile users. Networking and security have created silos that were built and implemented decades ago, and new functionalities are added and patched in as needed in a haphazard way. Secure Access Service Edge (SASE) is a new paradigm defined by Gartner that combines network and security into a single cloud-based service.

In this whitepaper, we will discuss SD-WAN security features and explain SASE – what is SASE, why is it needed, what does it comprise of and its deployment considerations.

2. SD-WAN Security

Existing security models cannot effectively address the new security requirements driven by move to cloud and the evolving threat landscape.

First, due to SD-WAN allowing the use of broadband internet as a transport mechanism, the internet, which is traditionally not a guaranteed secured link, the access to it needs to be made secure.

Second, current protection model in Enterprise branch is basic and not enough to secure local internet breakout to cloud as all traffic is steered over Multiprotocol Label Switching (MPLS) to Data Center (DC) sites where security is applied. Also, there is not much end to end micro-segmentation between branch and DC/cloud applications across the enterprise.

Third, with the increasing attack sophistication and evolving threat landscape we cannot assume that all attacks can be prevented by protective controls. Currently there is not much visibility to branch user traffic. Visibility and security analytics are key to help detect attacks.

Last, but not least, the current security provisioning model for applications is largely manual and device-centric.

Major security functions for a secure SD-WAN are discussed in the subsections below.

2.1. Securing broadband internet access

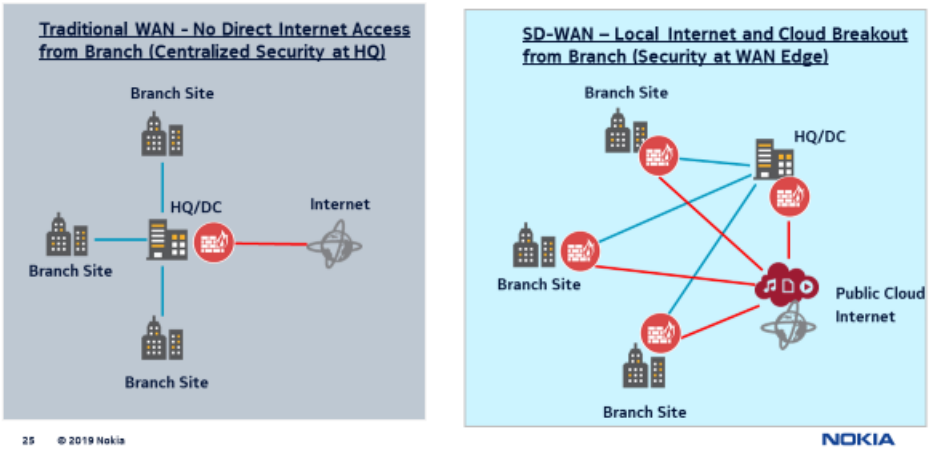

Figure 1 - Local Internet breakout

The Internet is not very secure for enterprise WAN requirements. Hence cloud-based application traffic is often backhauled from the branch to the enterprise Headquarters (HQ) before being handed off to the Internet. This introduces delay and jitter and hence application performance is often compromised because of WAN bandwidth constraints at the branch and added latency from backhauling connections.

The solution is to use direct internet connectivity to the cloud and web applications from the branch. The SD-WAN solution needs to make these internet connections secure and reliable by creating encrypted tunnels between every site in the SD-WAN, while taking advantage of Secure Socket Layer (SSL) security provided by the Software as a Service (SaaS) application for traffic going from the branch to the application directly using the Internet. This makes the Internet access more secure. With such encrypted links and a stateful firewall, an SD-WAN solution can prevent unauthorized outside traffic from entering the branch. The stateful firewall is usually implemented directly on the Customer Premise Equipment (CPE) device of the SD-WAN and no external security hardware or software should be needed for the stateful firewall functionality.

2.2. Threat prevention using IDS and IPS

Intrusion Detection System (IDS) and Intrusion Prevention System (IPS) are important to detect and prevent the known attacks by recognizing the virus signatures. Threat prevention component prevents malware from penetrating the network, regardless of application traffic in which they are hiding. It is important that the IDS/IPS functionality should be implemented natively on the CPE of the SD-WAN.

It uses signatures of known attacks to match traffic that passes through the CPE to prevent attacks and these signatures have been divided into groups of relevant signatures. IPS/IDS policies can be defined and managed centrally via the SD-WAN GUI or APIs. It is recommended that signatures be updated dynamically from cloud and applied on the local CPE device of the SD-WAN. The SD-WAN GUI should display statistics and generate reports of intrusion event details rule hit counts etc.

2.3. Stateful Firewall

A stateful Firewall filters packets based on the state and context of network connections and provides full protocol inspection considering the STATE+ CONTEXT of the flow, thereby eliminating additional attacks surface.

A stateful firewall understands the network flow and can identify data packets of a flow. Since a stateful firewall can look deeper into packet payloads, it can support DDoS (TCP/UDP/ICMP Flood), Port-scans etc.

Step one is to secure the branch within the SD-WAN network and to secure the links for the internet breakout. This is done by implementing a stateful firewall right on the CPE device without any additional external equipment or implementing any third-party solution. This way local branch users can safely access the corporate resources and SaaS applications in the cloud while being protected from both, inside and outside threats.

Enterprises can define access rules and policies to allow or deny traffic to/from the application – for example the administrator can define a policy to deny access to cloud storage app that is not in the corporate IT's management domain. There could be a policy allowing access to an application like say, Office365.

Note that, Stateful Firewall should preferably be validated by 3rd party for PCI-DSS network firewall requirements.

2.4. Threat Intelligenece based on IP Reputation

Threat Intelligence feature detects branch device communication to risky IP addresses and sites. It also generates reports on access to risky IP and sites from SD-WAN branch user devices. Threat Intelligence uses IP reputation database that is updated daily from cloud.

2.5. Web/URL Filtering

URL filtering limits access by comparing web traffic against a database to prevent employees from accessing harmful sites such as phishing pages. Users spend increasing time on the web, surfing their favorite sites, clicking on email links, or utilizing a variety of web-based SaaS applications for both personal and business use. While incredibly useful to drive business productivity, this kind of unfettered web activity exposes organizations to a range of security and business risks, such as propagation of threats, possible data loss, and potential lack of compliance.

2.6. L7 and SaaS Application Control

One of the prime benefits of SD-WAN is its ability to allow a direct access for a branch user to the cloud and SaaS applications. A good secure SD-WAN must have the ability to restrict user access to a specific

application, be able to set application-based policies and monitor and log application usage. For this, it needs to have a layer-7 Deep Packet Inspection (DPI) engine to recognize thousands of application types and pre-defined SaaS services - Office365, WebEx, Salesforce, GitHub, JIRA, Azure, AWS, Google among others for easy access as well as monitoring.

2.7. Automated and rapid response to threats

A rapid and efficient incident response continues to be the biggest challenge facing security teams today. The sheer volume of these signals means that a lot of critical alerts miss getting the timely attention. Security teams need help to scale better, be more efficient, focus on the right issues, and deal with incidents in a timely manner.

By defining automated response action, the users can prevent malware from infected branch device from entering corporate network. For example, leverage network security analytics to identify suspect end-points based on threshold alerts and use service chaining to dynamically insert services (such as NGFW or IPS) for suspect traffic. The suspect traffic could be diverted to cloud-hosted security service.

2.8. Realtime security analytics and automation

Some threats can be quite sophisticated and cannot be prevented by the protective methods. Real time traffic monitoring and security analytics provide fine granular visibility to locate the cause and reprogram the security response. Automated action reduces the time to react to the anomalies and reduce the impact.

With end to end visibility and control for each application, the operator can detect, protect resources at a very granular level, and use automation to respond in real-time to threats. SD-WAN security monitoring should allow you to do a contextual flow visibility of each flow.

Realtime security analytics helps in Threat hunting, Network Forensics as well as troubleshooting. The forensic reports can be used for compliance and security audits – both internal audits as well as external agency audits.

Realtime network security monitoring allows you to generate alerts based on security events - port scan detection, port sweep detection, security policy violations and volumetric DDoS attacks.

3. Third-party Security Technology Ecosystem

Third-party security products should be a part of the overall effective security functionality for an SD-WAN solution. Third-party security solutions should be incorporated in a couple of ways:

Most enterprises have an existing set of security infrastructure and solutions they use. SD-WAN vendor should partner with the best of breed security appliances already present in the IT infrastructure.

Secondly, for a tighter alignment with the security vendors' advanced functionality, the security VNFs (Virtual Network Functions) from those vendors should be integrated onboard the CPE. Both these options are described below.

3.1. Security partners and Cloud Security services

When it comes to security, it's simply not feasible for a single SD-WAN vendor to provide every security functionality on its own. The scope of threats, risks, and corresponding technologies is simply too great. SD-WAN vendor should establish technology partnerships covering several security domains, such as industry-leading next-generation firewalls and secure web gateway and Cloud Security services.

The integration with a Cloud Security vendor allows you to route local branch Internet-destined traffic directly to the security cloud to enable a fast and secure experience This eliminates the need to backhaul local traffic to the internet gateway.

You can route specific traffic to the Cloud Security vendor's security cloud through IPSec tunnels for further security. For example, you can define an action to route the traffic to Cloud Security vendor's cloud as part of the response to a threat.

3.2. Hosted VNF on CPE and Service Chaining

The CPE of the SD-WAN solution also acts as a powerful platform to host VNFs. SD-WAN implantation should have the service chaining functionality. By service chaining the VNFs (many a times, on-demand), a dynamic and advanced security features are provided.

4. Secured Access Service Edge (SASE)

4.1. Overview – What problem is being solved by SASE

As cloud becomes pervasive and driven by digital transformation of enterprises, the networking and security needs of an enterprise are evolving. Traditional enterprise network and security paradigm was centered around applications in private data centers. Although networking was complex, the security risk profile was well defined. Migration of applications to the cloud has redefined the networking and security. Many companies use SD-WAN to securely connect branch offices to their corporate networks instead of relying on traditional and expensive MPLS links. SD-WAN also facilitates direct access by corporate branch offices to the public clouds and SaaS applications. This creates stringent security requirements from the branch to the cloud.

Gartner observed this trend of security and networking requirements and has recently defined a new framework that converges network (SD-WAN) and security into a single cloud-based service: Secure Access Service Edge (SASE).

This section discusses what is SASE, it's advantages, key components, deployment options and recommendations for a successful SASE implementation.

4.2. What is SASE and its key components

SASE is a framework that brings together networking and security services in one unified solution designed to deliver strong security from edge to edge, delivered as a service. It is not an RFC or a static architecture, but rather a recommendation and a framework.

SASE has two major functional blocks – Networking (SD-WAN) and Security, as shown in figure x. SD-WAN is the foundation of SASE and security features are offered on and beyond SD-WAN.

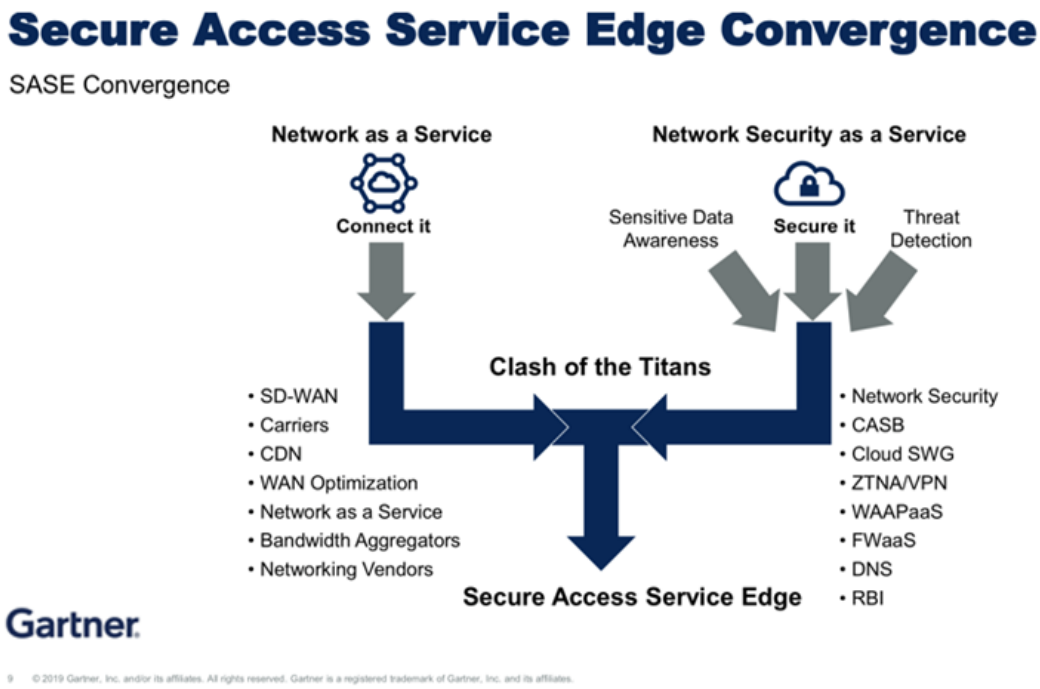

Figure 2 - SASE Components

4.3. SASE Networking (SD-WAN) – features and benefits

SASE networking capabilities offers the following benefits and capabilities:

- Network Agility – Flexibility and choice of MPLS, broadband or LTE.
- Multi-Cloud and SaaS Connectivity without the need for backhauling.
- Network Management and Automation - Real-time network monitoring, analytics, and reports.
- Application Performance Assurance – Business-policy based application prioritization.

Table 1 - SD-WAN Features and descriptions

Feature	Description
Comprehensive Routing capabilities	Full stack of routing protocols to support switching and routing personalities
Access and Connectivity to and from Anywhere	Seamless connectivity and policy management across fixed (internet, L2 and L3) and mobile WANs
Performance based POP selection	Support for multiple paths and POPs and performance-based selection ability
Application aware routing and traffic steering	Providing optimal application experience based on application types

Feature	Description
Hybrid WAN support (Full MPLS/Ethernet) for legacy Datacenter access	Seamless integration of existing networking to access data center and apps
Multi-Cloud & Hybrid Cloud connectivity	Policy based access to and across applications in private cloud and multiple public clouds
Connectivity Security – VPN, IPSec	Embedded encryption and end point security
SD-WAN Service Portal	Multi-tenant SD-WAN portal hosted by CSP for the visibility and control the CSP service and operations teams need to manage multiple SD-WAN services.
WAN Optimization & Bandwidth Aggregation	Optimizing the use of available network for availability and performance

4.4. SASE security components

Table 2 - SASE Components

Component	Description
IPS	Intrusion Prevention system
IDS	Intrusion Detection System
Firewall	Stateful Firewall
Realtime Security Analytics and Automation	With end-to-end visibility and control for each application, the operator can detect, protect resources at a very granular level, and use automation to respond in real-time to threats.
SWG and DNS Filtering	Secure Web Gateway is used to protect users and devices from online security threats by enforcing internet security and compliance policies and filtering out malicious internet traffic
ZTNA	Zero Trust Network Access
CASB	Cloud Access Security Broker - According to Gartner, a cloud access security broker (CASB) is an on-premises or cloud-based security policy enforcement point that is placed between cloud service consumers and cloud service providers to combine and interject enterprise security policies as cloud-based resources are accessed.
DLP	Data Loss Prevention - DLP provides visibility across all sensitive information, everywhere and always, enabling strong protective actions to safeguard data from threats and violations of corporate policies.
FWaaS	Firewall as a Service

4.5. Deployment considerations for SASE

SD-WAN, although a new technology, has been maturing in recent times and the number of deployments is growing rapidly. The security technology including cloud-delivered security is mature and most enterprises have deployed security in some form or other. Given this, a SASE deployment of rip-and-replace is not practical because of the existing investments. The most pragmatic solution will consist of utilizing existing security, especially cloud-delivered security to offer SASE. SD-WAN's flexibility to integrate with existing security vendors is very important. A complete SASE solution from a single vendor would compromise completeness due to vendor's technology limitations, it will reduce flexibility in a very dynamic space of enterprise security, and it will also risk the vendor lock-in. It should also be noted that MEF has specified SD-WAN standards, however, the security architecture is and likely will continuously evolve.

So, a good SASE solution should have the flexibility of:

- Scalable, high performance SD-WAN because SD-WAN forms the foundation of SASE.
- Exhaustive natively embedded security functions within SD-WAN itself.
- Integration with cloud security vendors for advanced security functions, as well as, evolving capabilities in this space.
- Ability to deliver SD-WAN as well as security features via Managed Service Provider or MSP partners' cloud and POPs.

This flexibility will allow the Managed Service Provider to offer cost effective SASE solutions based on its enterprise customer's specific needs rather than one size fits all expensive approach. It will enable MSP to differentiate its offer from other cookie-cutter (me too) solutions.

5. Conclusion

Since, SASE is a framework, rather than a standard, each vendor's implementation is unique to that vendor, depending on their expertise. Also noteworthy is that, like any new technology, there is a hype cycle and then there is reality. Currently, SASE is at the peak of its hype cycle. We believe, and Gartner agrees, that SASE is a 5-10-year journey versus a defined destination.

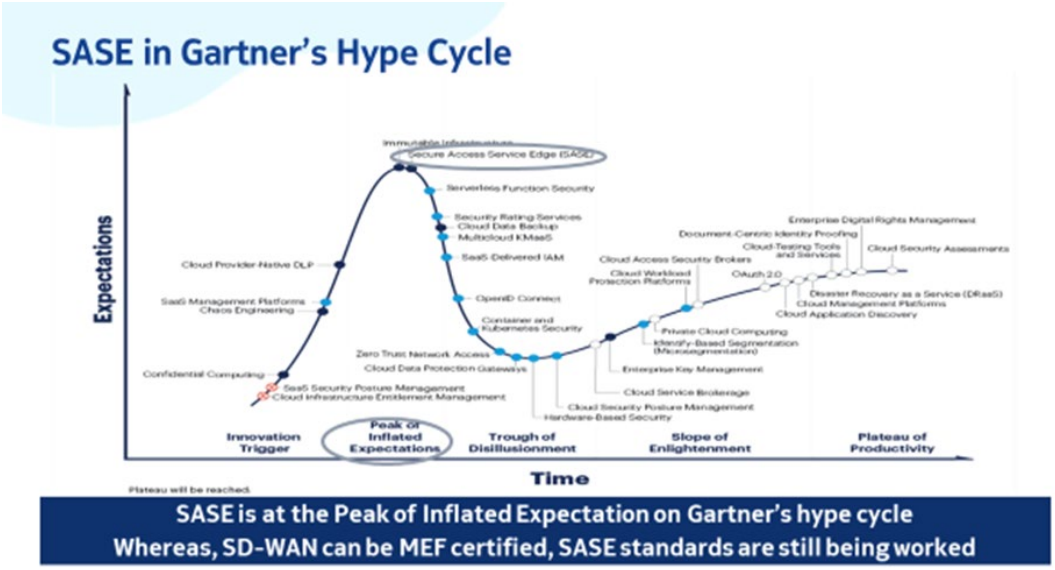

Figure 3 - Gartner Hype Cycle

Considering this, an MSP should opt for a solution that provides strong foundational capabilities and at the same time provides flexibility to evolve the solution in a vendor agnostic manner.

SD-WAN is being widely adopted by enterprises, greatly simplifying the branch network environment by integrating multiple functions (Internet and hybrid WAN connectivity, Advanced Security & NGFW, Cloud on-ramp, Application Experience, Wi-Fi, etc.). The SASE platform provides another strategic advantage for MSPs to offer SASE, a comprehensive networking and security solution, as a Service. With its foundational SD-WAN capabilities, advanced security embedded within the platform, and open vendor-agnostic platform affords MSP a future-proof SASE solution.

Abbreviations

AWS	Amazon Web Service
CASB	Cloud Access Security Broker
CDN	Content Delivery Network
CPE	Customer Premise Equipment
CSP	Communications Service Provider
DC	Data Centre
DLP	Data Loss Prevention
DNS	Domain Name System
E2E	End to End
FWaaS	Firewall as a Service
GCP	Google Cloud Platform
IDS	Intrusion Detection System
IPS	Intrusion Prevention System
IPSec	Internet Protocol Secure
MEF	Metro Ethernet Forum – An Industry consortium defining SD-WAN standard
MPLS	Multi-Protocol Label Switching
POP	Point of Presence
SASE	Secure Access Service Edge
SD-WAN	Software Defined Wide Area Networking
SWG	Secure Web Gateway
WAAPaaS	Web Application and API Protection as a Service
WAN	Wide Area Network
ZTNA/VPN	Zero Trust Network Access / Virtual Private Network

1. Introduction

Over the past decade, private businesses have increasingly been the victim of nation-state cyberattacks, which are defined as attacks carried out by a hacker, or a group of hackers, working with adversarial government to commit cybercrime against another country. Notably, there has been an 100% increase in nation-state incidents from 2017-2020. Specifically, nation-state attacks rose from 17% of all known attacks to over 40% during the last 3 years [3].

In this paper, we will highlight some of the issues with nation-state attacks and provide some guidance on how to defend against these attacks on a regular basis. There is no one way to defend against attackers, but there are strategies that can be implemented to prevent an attack from being catastrophic.

2. Nation-State Attack Background

The Cybersecurity and Infrastructure Security Agency (CISA), the Federal Bureau of Investigation (FBI) and the National Security Agency (NSA) and other government agencies continue to post warnings about nation-state attackers and their techniques to attack as they continue to advance. Many of these attacks could be applied to the cable industry. The cable industry has evolved significantly in the past 20 years with the rise of Internet and connected services to become a prized attack surface for nation-state actors.

Who are these nation-state attackers? Often these are known as Advanced Persistent Threats (APTs) because they are constantly working to come up with new attacks and they never go away. The largest groups of APTs come from Russia, China, North Korea, Iran and the U.S. [4]. The attacks are becoming more impactful, with posturing around government influence and even threats of physical war. Additionally, economic damage caused by nation-state attacks impact its citizens. The pipeline attack earlier this year in the U.S. caused fuel shortages for cars in the impacted areas which impacted people getting to work and school [10].

Just like all hackers, nation-states take advantage of known issues. Unlike the general hacking community, nation-states have political goals as well as financial goals. These nation-state attacks include theft of political or military data, advancing foreign policy, disinformation campaigns, or financial motivation. The nation-state attackers profile includes larger targets, more financially rewarding targets, and targets that will bring damage to other countries [4].

And most importantly, nation-states are well organized, funded, and very patient. It is not always directly obvious that a nation-state is sponsoring a cyber-attack, and many attacks do not have confirmation on their origin yet are heavily suspected to be a nation-state attack. If nation-states are going to make their goals, they will be persistent. Once attackers get into systems, they try to stay in them. A key activity for nation-states is to perform reconnaissance once in a system and prior to striking, so they have a good inventory of all the attack methods and damage they can cause before they strike. However, some attacks are very much predicated on timing of new zero-day attacks being found. Zero-day attacks are serious software vulnerability exploits, which the developer or vendor may not be aware of. It is always a race to exploit a new zero-day attack before a patch can be applied to fix the issue [5].

To make matters worse, on July 14, 2021, SecurityWeek reported that China has passed a new law that any zero-day vulnerability discovered by anyone in China is required to be shared with the CCP, and is prohibited from being shared with anyone, or any government outside of China. Product manufacturers may learn of vulnerabilities in their products, but this is not completely clear. This will make it more

difficult to gather information. Until then, security researchers around the world shared information about zero-day vulnerabilities they found.

As we look at how to best secure access from people and software to software resources storing and using sensitive data on various types of devices, we need to understand how to best apply our time and resources to protect against these nation-state attacks. Nation-state attacks have evolved from political statements to other types of attacks such as military intelligence, election interference, resource interference and ransomware. Protections include doubling down on security overall, and especially ensuring there are strong authentication, access management and authorization systems to protect against attacks like phishing, and escalated privileges.

There are many exploitable attack surfaces and nation-states understand how to take best advantage of many of these. One well known path is using supply chain weaknesses to plant malware which may propagate into other systems or provide access and visibility once implanted within a company. There have been cases of malware being included in devices or software specifically in products destined for the country they desire to attack. Therefore, when a device is powered on, software is now running inside the country and company they are trying to attack, and it does not appear to be an attack from the outside. Some security experts recommend not to buy devices or software from countries in question.

3. Past and Current Cyberattacks

Analysis of past and current cyberattacks is among the best tools when it comes to understanding where to apply more security to defend your systems. Knowing what occurs in those successful exploits can shape updated guidelines on what to consider when defending your own systems. Often, security requirements present as clinical, general statements and theories that take effort to apply to systems. And while those statements and theories are critical to system security, they fall into the category of security hygiene and overall best practices. Ensuring that data is using NIST-approved encryption mechanisms is a best practice, since any deprecated encryption practices could be broken by attackers, if they were able to breach the data in the first place. Best practices come from the assumption that attackers are already present. And zero trust principles require continuously questioning trust, aligning with the thinking that attackers are already present in systems. That doesn't mean every system has an attacker in it, it just means that we must assume that attackers can break past the first layer of security and are able to gain access to systems.

As was introduced earlier in this paper, nation-state attackers take advantage of undiscovered zero-day software vulnerabilities. Many of us receive notifications daily which ask us to update software. Outdated software is where exploitable vulnerabilities lay, and without updating software often and consistently, systems are more vulnerable to common attacks. When systems choose to release software patches, they often release patch notes on what was changed. Attackers often use these patch notes to create exploits for systems running the vulnerable version and will use these exploits to target unpatched systems. Possibly the most notable ransomware, WannaCry, originated from outdated software. Attackers used the exploit on the SMB protocol to create WannaCry, a ransomware that successfully attacked over 300,000 devices [9]. Ransomware has affected everything from gas prices to meat production and it is expected that it will continue to grow [10].

A recent attack that occurred using zero-day vulnerabilities was to a popular email, calendar, and collaboration tool [2]. In this situation, attackers had discovered four zero-day vulnerabilities within this server. Patches for this vulnerability were released about a month and a half later. The four vulnerabilities, when used in tandem, can lead to remote code execution (RCE). Remote code execution is

how attackers can hijack servers, create backdoors, steal data, and further any malicious code deployment. This attack was traced back to an APT group from China. APT groups, or Advanced Persistent Threats, are threats that originate from nation-state attackers, and often consist of an attacker gaining entry to a system and lying dormant for an amount of time. Although an update and security patch have been released to remediate these vulnerabilities, that does not mean the threat is gone. Anyone using the affected software versions is vulnerable to future attempts of the exploit. Furthermore, current systems may have been compromised even with the patch, and techniques such as an undetected backdoor or a time bomb file that will execute on a certain date may still exist on the patched server. This attack demonstrates the capability of nation-state attackers.

Another malware attack that occurred in 2020 offers insight into how nation-state hackers operate. In this situation, attackers were able to use forged tokens to obtain privileged access in a system used for IT administration throughout many organizations. Attackers then used this elevated privilege to access whatever software they wanted to within the organization by using the forged token. Forged tokens can only work if they are not cryptographically secure tokens, if the keys to secure the tokens were stolen or the applications validating the tokens are susceptible to replay attacks and do not validate the signatures with unique data for each transaction. These types of compromises provide unauthorized access to data and software.

In the past two years, we've seen an increase in ransomware, effectively making some systems completely unusable. From 2019 to 2020, ransomware attacks rose 62% worldwide, and an incredible 158% in North America [10]. Ransomware infects a system and encrypts the system data against the user's will. Then, the user is presented with an option to pay a ransom, which will hypothetically decrypt the user's data. Ransomware is complicated to resolve. In the past, ransomware victims were warned not to pay the ransom, as that would encourage other attackers to go down the ransomware route. There is also never a guarantee that paying the ransom will unlock your system. In some ransomware, it was easier for the program to wipe the system instead of encrypting it, so that by the time the ransom was paid, the data was already gone. Many of the new ransomware infections require multiple payments, the first to unlock your encrypted data, the next to avoid selling data to others. There may be a third payment set up as a monthly fee, to avoid any re-locking of data. In most cases of ransomware, it is unlikely that the targeted system will be able to recover normally, or that the organization will recover financially.

Nation-state attackers, as well as individual hackers, are seeing the current landscape of how organizations respond to ransomware attacks. The popularity of ransomware is partly due to how many organizations are paying out the ransoms. Statista surveyed over more than 600 IT organizations found that most of them had been infected with ransomware in 2020, and 68% of those infected paid the ransom [6].

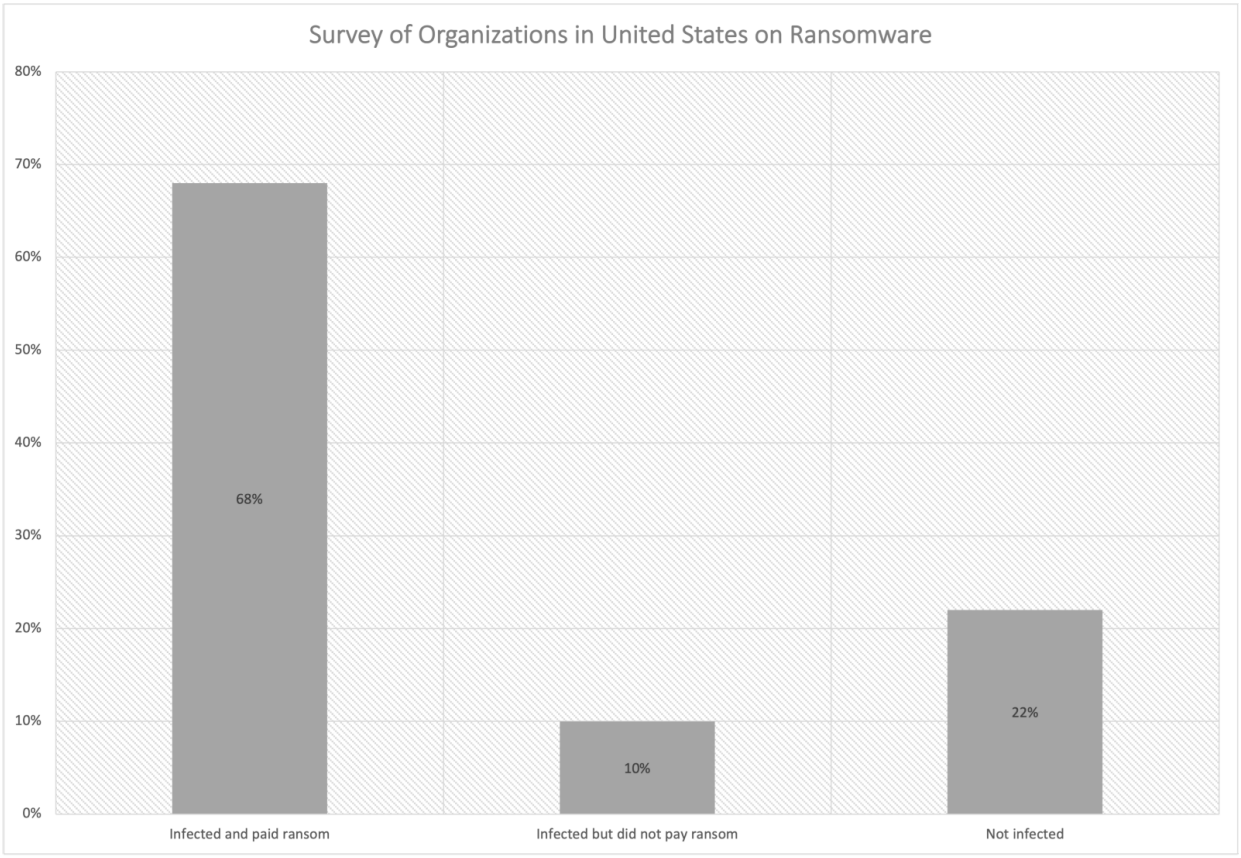

Figure 1 - Organizations on ransomware response in 2020

The effect of ransomware is two-fold. First, the ransom itself generates financial gain for the attackers. Second, the ransomware takes the system offline. Other attacks for taking systems offline include denial-of-service attacks, where a system is flooded with requests, too many to handle. Ransomware can take a system offline, as well as generate significant money for the attackers, which a typical denial-of-service attack cannot do. As more organizations continue to pay out the ransom, more ransomware attacks will happen. Instead of waiting for a ransomware attack to hit a system, it's better to plan.

The best defense against ransomware is to ensure that your system can be re-built, and re-instated, without touching the infected portion of the system. Often, this is done by building a disaster recovery (DR) environment, that replicates the production environment of the system. However, if a disaster recovery system is on the same network, or attached to the production environment in some way, it is useless. The disaster recovery environment should be geographically and logically separated from the production environment. The DR plan needs to include a back-up copy of any needed data, that is located off-site and stored in a separate way than other data. Many ransomware systems attempt to discover automated backup systems first, then ensure to lock both the original and the backup. Ensure your business-critical systems are equipped to deal with ransomware appropriately, to avoid unwanted payments and unwanted outages for your business.

4. IoT Device Security

Nation-state attacks can use any possible method to achieve its goals. One area that has been overlooked in the nation-state conversations, but could become an issue, is IoT devices. According to Juniper

Research, over 46 billion IoT devices will be attached to networks around the world by the end of 2021. That is a lot of potential attack surfaces.

IoT devices, even though small in processing power, can still propagate malware or overwhelm a network with traffic, especially if tens of millions start to chat all at once. Additionally, many IoT devices openly communicate with various back-office systems for software updates, configuration changes and service level monitoring. Many IoT device manufacturers have yet to appropriately implement security, because of resource constraints on the device, yet the device is able to connect to networks using various protocols. If an attacker could compromise the "right" (unprotected) IoT devices, they could be used to deny service, lock or steal data, and more. Some of the connectivity challenges are not only issues with specific protocols, but, just like software, which version of protocol is supported on the devices. Some more popular protocols include WiFi, Bluetooth, Bluetooth Low Energy (BLE), LoRa, RF, NF, Zigbee and others. Each protocol is created by a different organization at different times over the last 10+ years to help connect devices to a network. Even the protocols that start out with some security have a difficult time keeping up with new versions that are secure since IoT software stacks are difficult to update.

The Zigbee organization has changed its name to the Connectivity Standards Alliance (CSA) and now includes Matter (its newest secured protocol), Zigbee, Green Power, Smart Energy, JupiterMesh, RF4CE and Dotdot. We are happy to see the newer protocols evolve security protections. The Professional Service Association (PSA) organization certifies security principles for IoT devices for a unique identifier, security lifecycle, PKI certification, secure boot, secure updates, anti-rollback, secure storage and trusted cryptographic services. Earlier in 2021, they had certified 30 chips/SOCs, 14 software platforms and 10 OEM devices to date. Wi-Fi improved security with WPA3 which includes a QR code with a public key you can scan with your phone instead of using a password and has stronger cryptographic algorithms with forward secrecy and updated keys.

While we are making progress, it is not enough to rely on external organizations to provide all the necessary security for devices attaching to our networks. One thing we can do is participate more in setting standards and enforcing compliance from manufacturers. We can learn, from the many security standards on other products and services that have emerged from International Standards Organization (ISO), National Institute of Standards and Technology (NIST), Payment Card Industry (PCI), Health Insurance Portability and Accountability Ace (HIPAA), various privacy laws (GDPR, CCPA & CPRA, and many others), Financial Industry Regulatory Authority (FINRA) and others to help mold where we are today. We can certainly take many lessons learned from across the spectrum and apply as many as possible. Then where there are gaps, we need to step-up and lead innovative solutions.

To help understand how to best mitigate issues, study and understand past and present attacks. A good source of attack information is available from the U.S. CERT vulnerability advisory, which provides information on discovered vulnerabilities every day. A surprising number of vulnerabilities are published on a regular basis. As you learn about new security vulnerabilities, you can assess your environment, applications, devices, services and resources for issues. Some issues can be mitigated with workarounds or additional protections applied to help protect your company and your customers before formal patches can be released.

For IoT devices, let's apply the normal baseline security practices for larger devices. There are 5 major areas to ensure device security. Most of these are currently inadequate, which means they do not exist at all or are highly immature:

1. Standards to which IoT devices should comply
2. Designs which allow for improvements in features, including security updates over time -- which is more difficult to implement but necessary to resolve

3. Testing and compliance measures to ensure implementations meet laws and standards
4. Ongoing operational support for scanning and patching.

The real trick with an IoT device is to ensure it can be as secure as a server, but with very little resources. Many manufacturers' margins are thin because of tough competition and rising costs for resources and labor. Manufacturers have little incentive to increase spending on security unless other manufacturers are investing as well. Most people do not understand security well enough to know what look for, and have no influence on manufacturers of IoT devices. After all, if an IoT device breaks due to a security issue, the consumer must buy another appliance. That seems counter to the cycle we'd like to see created, where manufacturers are required to build security in to keep devices, people, and networks secure.

Part of a secure IoT device architecture could depend upon being behind a secure gateway in the home, however not all ISP connections and gateway products will be at the same level of security. Additionally, IoT devices may respond to a myriad of protocol announcements to join a network or be discovered and accessible and may never traverse on a path that is secure to the Internet. And then there are exploits which could take advantage of these devices that may not be able to discriminate against the signals from a secured gateway vs a rogue device.

Some basic tenants for device security include but are not limited to having secrets encrypted in storage, and obfuscated when in use. These secrets include a hardened identity that cannot be spoofed. One way to do this is to only put identity into hardware and secure it with an x.509 certificate, where the private key is also only available in hardware. Having a hardened identity prevents spoofing and evil twin attacks as well as serving as the basis for strong authentication against a trusted identity.

Devices also need to include secure boot up sequences and operational status to ensure integrity and authenticity of the hardware and software. Secure boot needs to include an unbroken chain of trust between the different layers of components and software, to ensure hackers cannot introduce new software between layers of different authentication keys that are not tied to a root of trust or authentication processes. Authentication is best when it is a cryptographic series of functions that cannot be interrupted when software is first being loaded for use during the boot process.

Devices must include a way to receive secure configuration updates as well as secure software updates. When devices do not include security on configuration interfaces, this leaves security entirely to the environment in which the device is run to ensure that only authorized configurations are allowed. The device must include protections against malware, which include automated software updates, without customer intervention.

Devices must ensure that unnecessary hardware and software ports are not available, which could be an open hole for attackers to exploit. Having open ports and unnecessary protocols or APIs is a common issue. Attackers will learn how to reach devices using these protocols and open ports. Additionally, ensuring security is turned on for the necessary open ports is critical. Using common or global secrets to protect ports is no longer an acceptable practice. Each port needs to use unit-unique public key cryptography to ensure access only comes from legitimate users in the ecosystem and is only destined for that specific device.

One of the most common issues is the inclusion of a default password in devices. This should be prohibited. Many people do not change default passwords. Attackers count on getting into devices this way. Additionally, passwords are easy to crack and should never be used without including multifactor authentication. People needing access can use mobile apps to manage multifactor authentication, or

a QR code with public key cryptography. Logins could use common sign-in systems such as Google, Microsoft or Apple. These are trusted authentication systems.

With the increased use of zero-trust principles which include micro segmentation, the blast radius for compromises can be reduced. Micro segmentation ensures that each resource should only be reachable by other authorized resources, and is accomplished by isolating network access. Authentication of resources is required, in addition to authorization as will be discussed. Another best security practice is to ensure that only things that need to reach the Internet, do. Many people accidentally configure public cloud accounts to be publicly accessible. Additionally, IPv6 addresses can be a source for common access mistakes, such as when people use a public address rather than a private address for internal applications.

One common question that comes up in security is how to assess if a device is healthy, meaning, not currently compromised. We not only need to know if a device is heathy as a part of normal monitoring, but also whether it is healthy upon first configuration for service – a clean start. For IoT devices today, we generally don't know. For IoT devices in the future, without overburdening the necessary hardware and software for an IoT device, it should be mandatory to have device security state, software versioning and file integrity. Creating a virtual device architecture for monitoring device health could improve our ability to contain attacks.

Using common security frameworks, such as the NIST Cybersecurity Framework, to map out all the components of IoT devices for its entire lifecycle is a good way to cover the necessary security protections. The NIST Cybersecurity Framework provides guidance on identification, protection, detection, response and recovery. For example, identification includes visibility into where and what systems or devices are in your ecosystem and how they are lifecycle-managed and governed. How will you able to respond to an attack if you don't know where or how to reach devices, systems or applications? In conjunction with traditional security frameworks, technological maturation processes need also to be assessed and anticipated. Consistency in security processes and operational monitoring need to be applied with good ways to measure against risk for your company.

Continuous scanning and immediate patching are both critical to keeping down the number of vulnerabilities on your devices and in your software. There are great scanning tools available for things like Windows servers, but when it comes to homegrown applications, IoT devices and industry-unique solutions, scanning leaves much to be desired. Each team responsible for building and operating devices and software can keep up their operational excellence metrics with weekly reporting on any known issues and remediation status. Operational excellence is a requirement to ensure there are no outages. Too often, software teams are focused exclusively on new release cycles at the cost of spending cycles to lower technical debt -- which includes security vulnerabilities.

Additional scanning techniques can look for static passwords, which should be immediately replaced with strong authentication mechanisms, managed by automation where possible. Also very important is scanning for certificate expiration dates and replacing certificates before they expire. For example, if a certificate is expired that is used for TLS authentication, TLS leaves a wide-open security hole by failing the connection open with no security. Be sure to configure TLS sessions to prohibit failing open, and monitor and replace certificates before they expire.

Monitoring for the previously mentioned device health, as well as activity such as communications paths are important to understand. If communication should only be happening with a back office system on your corporate network, but you can see communication messaging over APIs exiting your corporate network, that is an alert. It may represent a security issue related to data that may be leaking; access may

be compromised; malware may be propagating, etc. Monitoring should also include using data analytics and machine learning to access patterns for people as well as applications. Understanding what the normal operating model looks like can be key to blocking lateral movement, if access or device software is compromised.

Monitoring file integrity and approved configurations matters. If an attacker changes configurations and plants malware, you want to be able to detect and respond right away. Having a way to roll back or rebuild clean code quickly to remove malware is very important. Often the difference between a small incident and a large compromise is time. If good monitoring techniques are not in place, small issues can go undetected for a long time. Combinations of small issues may fall under the radar of detection and then can be executed together to perform a larger exfiltration, such as a "golden" pile of data being moved, or denying access to services or devices.

Concentrating on all points of network access is also important. That said, monitoring can only be as good as the data it is getting. If unauthorized access is happening in a vendor network or off-shore facilities, is there anything monitoring the network that will trigger unusual activity? This activity could appear to come from a legitimate vendor connection, but the fact that the traffic came at an unusual hour could be a tipoff.

Examining source IP addresses (if you can get them) can tell you if there are connections coming from geolocations that are unacceptable. Collecting context-rich data, containing information such as source IP address, can enable a system to separate legitimate traffic from unacceptable traffic. More systems and services are using location, connecting to compromised data sets for comparison and getting information from government agencies to help identify issues, such as known malicious source IP addresses. Also, security level protections for connections with outside businesses or facilities should be verified to ensure malware protections are in place before accepting traffic from that new connection. DDOS and malware-sourced verification is common.

Using good Secure Development Lifecycle (SDL) management practices is also mandatory. Ensuring every device make and model has gone through a threat model to identify attack surfaces and identify how to best protect them is important to do as a part of the design phase. When threat modeling, review not only the architecture, features and functionality of the product, but also the code build pipeline. Additionally, ensure all APIs and protocols are being designed for secure use. Data encryption and privacy also need to be reviewed as a part of a good threat model. Then ensure pen testing is conducted, in an environment like where the device will actually operate, to provide the right level of operation security configurations. There are many other aspects to the SDL, including scanning for bugs in code, and the previously mentioned monitoring aspects.

5. Authentication and Authorization

So how can we secure access? By using strong authentication, access controls and authorization for users, software, and devices. Authentication and authorization are often confused with one another, but in the scope of system security, it is critical for the two to be implemented and assessed separately but designed together to ensure no security gaps. Authentication is the process of confirming a subject's identity, and authorization is only allowing that identity access to information and systems they are allowed to access. Authentication and authorization are most associated with human users, but modern practices include authentication and authorization of machine access as well.

Secure your front and back doors as well as your windows into your systems, applications, resources, devices and services. Secure your workforce users, workforce admin accounts, workforce

service accounts, guest and vendor accounts, and all customer accounts. If nation-state attackers get their hands on any kind of credentials, they will use them. Work within the zero-trust model, to create checkpoints throughout the system to ensure users, and machines, are not only who they say they are, but that they also have the correct access. Following this model can prevent attackers from taking advantage of authentication and authorization in a system.

Evaluating the system's environment is the first step in considering authentication and authorization. A common solution to insecure connections is to require the use of a VPN, or a Virtual Private Network. The use of a VPN verifies that the user is on a private, usually encrypted, connection. However, before the connection to a VPN can be established, a user must authenticate to the VPN and prove their identity. Access to the VPN may be needed to access sensitive or confidential data, so it is important to use a strong method of authenticating users to the VPN. VPNs generally don't take care of any authorizations beyond hooking into authentication systems such as SSO to ensure they have active user credentials that are authenticated.

Ten years ago, a simple username and password combination would be enough to access sensitive data and critical systems. Today, multi-factor authentication is the industry standard. In fact, multi-factor authentication has a 99.9% success rate in protecting against compromised credentials [5]. The purpose of multi-factor authentication (MFA) is to first, enter your username and password, but as a second step, to prove user presence through a second device.

However, MFA is not invincible, and as it becomes widely adopted, we will see more and more attacks on systems protected by multi-factor. Older MFA solutions such as SMS-based MFA have shown to be easily hacked, which is why SMS-based MFA is becoming less popular and is being replaced by multi-factor that depends on an authenticator application, such as Duo Mobile or Microsoft Authenticator. These authenticator applications provide another level of security that SMS-based MFA does not. The difference between SMS-based MFA and application-based MFA is that it is easier for an attacker to compromise a user's text messages, but a significantly more difficult task at hand if they need to get to an application in the user's device and compromise secure APIs. However, there are even potential vulnerabilities with these authenticator apps, such as user error. If a user gets too comfortable accepting authenticator requests, they have the chance of accepting a false authentication request and approving an attacker's request. Therefore, many authenticator apps have begun implementing multi-factor requests that force the user to engage with the request, and in process, confirming that they are the one who made the actual request.

Passwordless authentication is making its way through the technology world [5]. At the root of authentication, there are three ways a user can prove their identity: something they know, something they have, or something they are. Something they know would be a password, or a security question. Basing user authentication on something they know is no longer considered secure. Multi-factor authentication, as well as SMS-based two factor authentication, depends on something the user has. This is usually a phone but can also be a hardware token. With multi-factor authentication, the first step of authenticating is to enter a username and password combination, and then approve a request on another device. The password is still in use during this authentication mechanism. With something that the user is, however, passwordless authentication is making a rise. This is authentication that is based on user presence, as well as user validation in the form of biometrics.

Passwordless authentication does not only consist of user biometrics. In fact, there are a handful of ways that users can authenticate into a system without using a password. However, biometrics have become one of the most popular ways a user can authenticate, without a password. The different technologies

behind passwordless authentication include, but are not limited to: FIDO2, Windows Hello, and Microsoft Authenticator passwordless authentication.

These forms of multi-factor authentication, app-based or passwordless, are acceptable options for gaining access to a network. However, once a user is authenticated through single sign-on using a specific device, that authentication can carry over to more resources, including other applications, without requesting to sign back in. This is accomplished by using technologies like OpenIDConnect (OIDC), SAML, and OAuth. These technologies rely on cryptographic tokens and keys to be passed from machine to machine. These technologies can be used to identify and authenticate human users as well.
Creating a secured identity for machine access may not be an obvious solution, but attackers have been able to use machine identities to gain entry to a system. How do we prevent attackers from spoofing machine identities? One solution is PKI, with a signature over unique data in the transaction which shows current proof of possession of the private key associated with the public key inside the certificate. The certificate contains the device identity, and the certificate is also signed by the trusted certificate authority.

Authorization ultimately arises from the principles of least privilege, which essentially states that users should have access only to the resources they need, and no more. Authorization is often overlooked, as it requires specifying explicit access to specific resources and tasks as named in an attribute or role-based access control policy. However, it is critical for access to be defined per user, such as a general user role with least permissions and then only giving specific users elevated privileges. Abusing excess privileges is an integral part of how attackers navigate through a network, and access control is how one can prevent an attacker from leveraging them.

While an attacker can certainly leverage excess privileges, an employee can as well. Insider threats are a real concern and make up a significant portion of privileged access attacks. This is especially concerning if an individual has unfiltered access to systems, and their credentials are not revoked after termination. Real-time ability to revoke credentials is crucial in preventing abuse and compromises. If an individual leaves the organization, or does not need access to a resource anymore, the immediate revocation of their credentials or access is critical. This includes not only employees, but also contractors and business partners. Vendor access is another area of user access that often is overlooked. Vendor access must follow the same policies as regular users within the environment, potentially with less access to base resources.

Following a zero-trust model, as well as authenticating and authorizing users for resources by using modern technologies will assist in preventing stolen, forged, or abused credentials from causing a catastrophic incident. Nation-state attackers are resourceful and will take what they can. Minimizing their blast radius from compromised credentials is essential.

6. Conclusion

There is no guaranteed way to prevent attackers from exploiting your systems. However, best practices can be applied, as can a bit of innovativeness about how to thwart unauthorized access into systems, and prevent unwanted events. As described in this paper, nation-state attackers will try any method possible to circumvent system security. Defending against potential attackers requires time, energy, and money. However, it is no longer possible to ignore security when building systems and networks. Using the methods outlined in this paper can help prepare a system to defend against attackers.

Attackers, especially those representing nation-states, will continue to evolve their attack methods as technology evolves. Underestimating these attackers will result in a security posture unprepared to deal

with evolving attacks. As we know, there is no one magic fix for defending against hackers. They are resourceful, unpredictable, and relentless. Instead of a one-time fix, system security involves an ongoing process of evaluating, building, testing, re-evaluating, re-building, re-testing, and repeating. The purpose of this continuous evaluation is to keep up with the attackers, as they are continually and constantly attempting to gain access to cable provider systems. Following the practices in this paper will help create a security posture for cable providers in the modern age.

1. Introduction

Operators are facing disruptive change to their networks driven by technological and business forces. The business seeks to increase innovation, reduce costs, and manage risk while network technologies including virtualization, software defined networking, streaming telemetry, and automation drive additional complexity into the network. Typically, an operator's functional disciplines such as engineering, operations, analytics, and planning each have separate, uncoordinated views of the network with sometimes overlapping, sometimes disjoint, data, leading to inefficiencies and uncertainty. Network Digital Twin provides a comprehensive view of the network, combining disparate data sources such as telemetry, monitoring, inventory, provisioning, analytics, planning, and network automation with variable-fidelity models of equipment, network functions, network services, network operations, and analytics, creating a separate digital representation of the live network. The network digital twin is an integrated, consistent, comprehensive, lively, and accurate model of the network and its constituents, connected to and representing the state and behaviors of the actual entities of the operating network. Operators use the network digital twin through the accompanying dynamic views and visualizations to better understand the state and behaviors of the network and, through manipulation of the digital twin, affect changes in the actual network. Functional disciplines within the operator's organization use the network digital twin to break down data silos and leverage the consistent model of the network as the basis for their individual missions. The paper addresses the formation, concepts, and implications of digital twins and their application to the operator's network, including an example from Cox's application of aspects of digital twin to our data center network.

2. System Architecture

The three top-level functional building blocks of the network digital twin functional ecosystem are depicted in Figure 1. The functional building blocks have significant internal composition (other functional blocks) and form an enduring basis for multiple logical and physical architectures. This architecture description, therefore, provides discussion, primarily, of key aspects of a functional architecture for network digital twin.

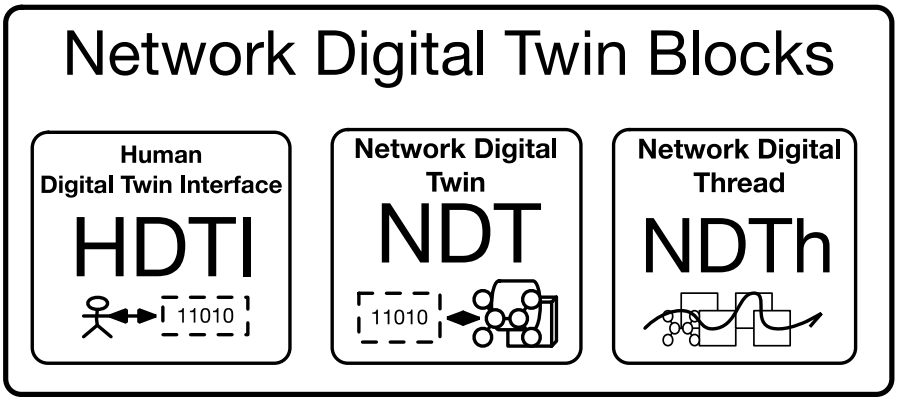

Figure 1 – Top Level Functional Blocks of the NDTE

The top-level functional building blocks of the Network Digital Twin Ecosystem (NDTE) are the Network Digital Thread (NDTh), the Network Digital Twin (NDT) itself, and the Human Digital Twin Interface (HDTI). These three top level building blocks work in concert to provide a transformative approach to the creation and operation of the network.

Network Digital Thread: The network digital thread contains engineering models for the network and its constituent subsystems and interfaces. Also included are any document-based information, specifications, drawings, images, and non-operational data relevant for the network that are created across the system development life cycle (SDLC), such as design and planning information.

Network Digital Twin: A network digital twin is a unified executing engineering model of an operating network entity coupled with normalized data pertaining to the actual operating network entity with which it is associated. The network digital twin can be queried and manipulated separately from the actual operating network entity, with the option for those manipulations to affect changes at the operating network entity. Network digital twins can be created to represent network entities at the logical, virtual, or service layer, as well as composites of any of these (including an entire network).

Human Digital Twin Interface: The human digital twin interface is a human-machine interface (HMI) providing the capability for a person to interact with one or more digital twin instances. It provides dynamic visualization of the digital twin instance and related data and supports human-driven query and intent-based manipulation.

2.1. Theory of Operation

The prototypical top-level functional connections and information flow between the network digital twin functional building blocks and the operating network entity are shown in Figure 2, adding an additional functional block to the mix: the Actual Twin (AT).

Actual Twin: The actual twin is the physical, virtual, or logical instance that is a counterpart to a digital twin instance. Examples of actual twins for the network include a network router appliance, a router network function in a virtual machine or container, and a layer 3 virtual private network (VPN) service.

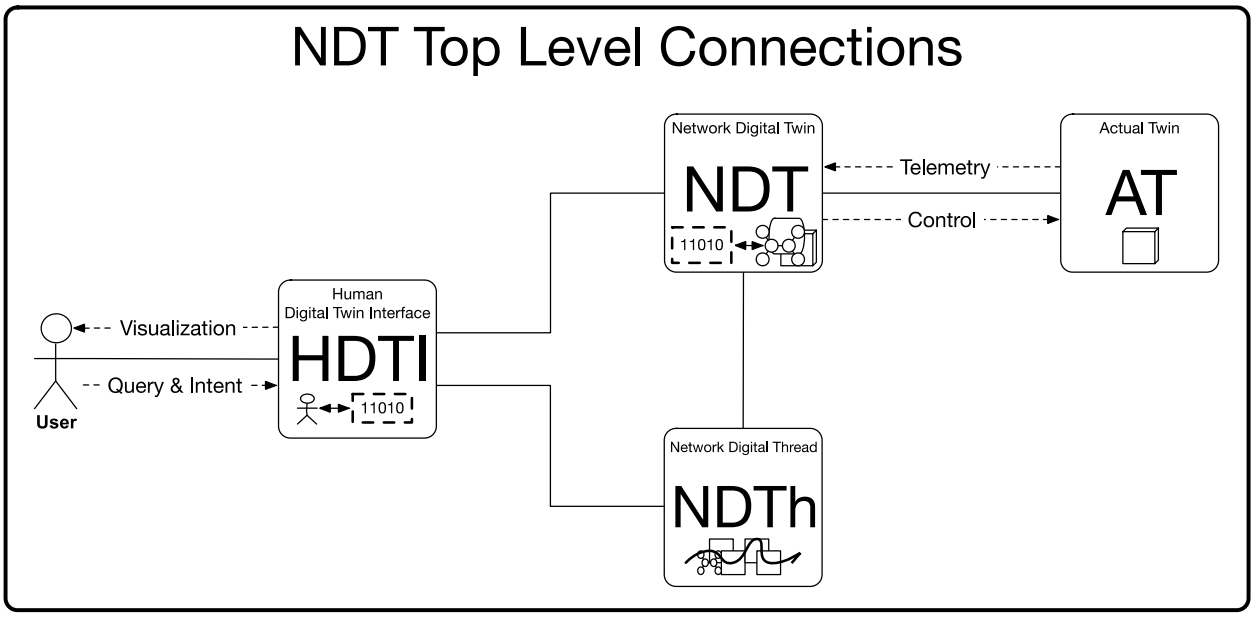

Figure 2 Top Level Functional Blocks and Connections

An overview of the theory of operation for a prototypical network operations situation using network digital twin is as follows.

An executable NDT instance is created with an integrated set of models pertaining to a specific type of network entity, e.g., the type of AT, in a given role in the operating network. The models are drawn from the Network Digital Thread, which is the authoritative source for this information. The NDT is also pre-initialized with data pertaining to operational intent for the instance.

The NDT instance is associated with an actual entity instance in the operating network, e.g. the AT. Telemetry data pertaining to the AT flows from the AT and other systems into the NDT. The telemetry data could be from streaming telemetry, monitoring systems, element managers, and other such intermediaries. The telemetry data is used to update the state of the NDT, causing the dynamic executing model to be evaluated, updated, and to react to the changing conditions of the AT. For example, the NDT may detect model constraint violations, a variance between operational intent and current state, or other such issues.

If the NDT models are constructed to provide control capabilities for the AT, then control signals are sent as needed toward the AT. The control signals could take many forms, depending on the specific implementation. The control signals could be of types such as configuration changes, commands, signals to intervening systems, and events. Incorporating this kind of model into the NDT provides intent-based closed loop control for the network.

The HDTI provides the user/operator experience for the NDT and the Network Digital Thread. It allows the user to see various static and dynamic views of various kinds pertaining to the network digital twin that are updated during operations. It also enables queries to be performed and the ability to express operational intent and other control input from the user perspective.

Ideally, any technical information from the Network Digital Thread is linked with the NDT and can be discovered and viewed using the HDTI environment.

2.2. Network Digital Thread

Network Digital Thread encompasses the engineering and analytical models for the network created across the entire system development life cycle (SDLC). The network digital thread building block is the digital thread created through digital engineering, with the subject being the operator's network.

The INCOSE Systems Engineering Body of Knowledge (SEBoK) states, in part, that digital engineering "…is the creation of computer readable models to represent all aspects of the system and to support all the activities for the design, development, manufacture, and operation of the system throughout its lifecycle. These computer models would have to be based on shared data schemata so that in effect a digital thread integrates all the diverse stakeholders involved…"; and further, "Everything from documenting requirements, technical reviews, architecture design, and so forth would be based on the models in a digital engineering environment (Vaneman and Carlson, 2019). The digital thread would be the authoritative source of truth concerning the system data." - [SEBoK/Digital Engineering].

The network digital thread contains engineering models for the network and its constituent subsystems, properties, interfaces, protocols, behaviors, and data. These models range across multiple disciplines, including network engineering, facilities engineering, reliability engineering, systems security engineering, software engineering, network planning, and operations engineering, to name but a few. The various discipline-specific models are all aligned and connected through the common context and consistency established and maintained in systems engineering models.

Within the engineering disciplines, a major class of model in the network digital thread are those models addressing forward engineering concerns. These models capture the "as-specified", and "as-designed" aspects for the network, addressing, for example, structural, behavioral, functional, non-functional, and operational concerns. In addition to the models that capture specifications and design decisions, this class of model also includes the accompanying engineering analysis models and engineering/test data sets.

Models of the forward engineering class are necessary to establish a correct model of the network as it is intended to be. They establish the interfaces, protocols, behaviors, data formats, and other characteristics of the network and its constituent subsystems, separate and independent of any hardware and software implementation. They are integral to the simulation, emulation, operational characterization, and operational control capabilities of NDT, forming the rational basis with which the live operational data is normalized and paired with the NDT.

One example of a forward engineering model relevant to NDT is a network engineering model for network layer 2-4 network functions, connections, configurations, and behaviors. A formal model is prepared for the functionality, interfaces, and behaviors of a give type of network function (ex. router forwarding), with the model providing state variable and state transition definitions, configuration parameter definitions, and the effect of configuration on those

behaviors. Other instance-independent characteristics of the network function can be included in the model. Given a sufficiently elaborated model, the designed layer 2-4 behavior of the network function can be determined given any set of internal state and external stimulus, as can an arbitrary network of many interconnected network function instances.

Another example of a forward engineering model relevant to NDT is a systems engineering model for a state machine-based autonomous operations closed loop controller. This type of controller is used at the network resource level (ex. device) or multi-resource network service level (ex. layer 3 VPN) to actively establish and maintain the operational state of the controlled entity according to operational intent. A formal model is prepared to specify the intent & configuration parameter definitions, states, state transitions, triggers, and actions of the controller, along with the input and output signals (ex. telemetry/events, control, configuration). Given a sufficiently elaborated model, the designed behavior of a closed loop controller can be determined given any set of internal state and external stimulus, as can an arbitrary set of many interconnected closed loop controller instances in communication with one another. Taken together, this type of model provides a key part of the executable specification for closed-loop controllers for network autonomous operations.

A third example of a model type relevant to NDT is a reliability engineering model for a manufacturer's network equipment model (in the last usage "model" means the manufacturer's model identifier rather than a formal engineering model of the equipment). A type of reliability engineering model is the Failure Mode and Effects Analysis (FMEA) model. The FMEA model identifies the inherent reliability characteristics of the equipment design, including the tree of relationships between possible failure modes and the resulting system performance degradation or failure. Given an FMEA model and a set of one or more fault conditions, the effect of the components failure modes to the system performance or safety can be determined and characterized. With relevant equipment test results and measurements from the population of a given equipment model in operation in the field, a predictive model for fault and failure probabilities can be created to live alongside the FMEA model. With a sufficiently elaborated predictive model of this type and the relevant time series state measurements for an instance of equipment, the probability of failure of the equipment can be predicted, indicating a need for proactive maintenance ahead of the failure. This second type of model may be developed using machine learning techniques and is closely associated with the area of predictive network maintenance.

Network digital thread entails more than models. For example, any document-based information or drawings and images relevant for the network created across the SDLC are part of the network digital thread. These non-model-based artifacts can be linked with the models, but do not play an active part in the executable network digital twin.

The preceding examples are but a few of the many types of models that are associated with network digital thread. Other examples include models for system security, network planning, network design (physical and virtual), and mechanical/physical design, among others. Some of these models are design models specifying correct characteristics of the described atomic or composite entities; others are analytical models of the resulting emergent characteristics of those

designs (ex. fault tree) or are predictive in nature based on the combination of the prior models with aggregated data from tests and measurements from the field.

All model types described above can be used for the purposes of engineering analysis. Some can be used for engineering discipline-specific model execution and/or simulation. Multi-discipline model execution and simulation is possible when coordinated through appropriate systems engineering models and co-simulation environments. As networks and network operations complexity rises, these techniques become more important to employ for the design and analysis of networks, their data, and their operation, even without the full capabilities of network digital twin.. They are used to support exploration of the network and operations design space and trade studies, for example, without connection to an AT.

2.3. Network Digital Twin

The models of the network digital thread designed for execution and simulation in the context of engineering design and analysis, along with the model execution platforms, can be developed beyond the scope identified in the previous section. Doing so enables a spectrum of model execution capabilities directly associated with an actual operating network and its constituent parts. A key characteristic of the approach is that the disparate models are linked together, coordinated, and updated with identical, or at least consistent, normalized, data during their execution.

For example, executable models from the network digital thread (at the needed level of fidelity and from the necessary engineering disciplines) pertaining to an instance of network equipment are brought together, connected, and co-executed in a coordinated fashion on a platform environment designed for that purpose. These executing models are then provided with data from and about the network equipment instance, forming a kind of digital copy of the equipment instance and its state. The digital copy consisting of these models bound with the network equipment instance's data forms the basis of an instance of a network digital twin for the actual network equipment instance.

The dynamic behavior, state changes, and other characteristics of the actual network equipment instance can be simulated, emulated, analyzed, represented, and predicted based on the network digital twin instance. The network digital twin execution platform provides additional data, from or about the actual network equipment instance, to the network digital twin instance as it becomes available.

The data pertaining to the actual network equipment falls into categories that include operational intent, target configuration and operational state, actual operational configuration and state, sensor readings (ex. temperature), network function-specific data (ex. firewall state, traffic counters, routing tables, etc.), and alarm conditions. Additional data about the actual network equipment instance can also include historical information, time-series data, failure data, scheduled maintenance actions, and other instance-related data.

The above data may be obtained for the network digital twin from a variety of sources, including telemetry and monitoring systems, element management systems, operations analytics systems, service provider data systems, or directly from the network equipment instance. The rate and

latency at which changing data from and about the actual network equipment is provided to the network digital twin will affect the extent to which the network digital twin instance reflects its twin's state.

Binding multiple, coordinated, executable models with a consistent set of instance data from an actual network equipment instance into the network digital twin instance enables the ability to achieve useful analytical and operational objectives.

The functional/behavioral models in the network digital twin instance combine with the actual twin data to enable analysis and simulation. For example, given a specification of network traffic arriving at one of the interfaces, the resulting forwarding plane and packet transformation functions and behaviors can be determined and/or simulated without further interaction with the actual network equipment instance. The case study later in this paper employs this type of network digital twin analytical model.

Anomalous or incorrect behavior or conditions in network equipment in the operational environment can be identified through the network digital twin's explicit and automatic checking of invariant conditions, constraints, policies, and state encoded in its models. Examples include the presence of disallowed configurations, variance between intent and operational configuration or operational configuration and relevant established policies, detectable functional behavior variances, and fault conditions.

With a network digital twin approach, the often-brittle workflow-oriented techniques using "golden config" templates and scripts for pre-checks and post-checks are eliminated in favor of an approach whereby the multi-discipline specification of correctness in context is expressed in the network digital twin models with continuous evaluation during model execution, and whenever new data is available from the operating environment.

Further, by employing state machine-based closed loop controller models as a part of network digital twins, the entire operational lifecycle of each actual twin in the operating network can be addressed, achieving intent-based network management with autonomous operations.

2.4. Human Digital Twin Interface

The human digital twin interface is a human-machine interface (HMI) providing the capability for a person to interact with one or more digital twin instances. It provides dynamic visualization of the digital twin instance and related data, and supports human-driven query and intent-based manipulation.

The HTDI is separate from the other functional blocks of the NTDE for several reasons. First, the pace of innovation between the NDT execution environments and HMI variety and innovation pace will be different; de-coupling these two facilitates the ability to take advantage of the pace of each independently. Second, the type of HDTI used for the same NDT is dependent on specific goals for the interaction, roles of the user, and so forth. Multiple HDTI experiences may be in simultaneous operation connected to the same NDT instance.

For example, an HDTI based on web technologies with user access via a web browser matches the typical network operations scenario of today. Static and dynamic views, queries, and controls appropriate to the user role and web browser environment are provided.

An application running on a mobile device in the field can also be created as an HDTI implementation, providing field technicians a new and improved way to view and interact with the autonomously operated network.

Another example of an HDTI is that provided by the class of tools, either web-based or native applications, classified as engineering design, simulation, and analysis tools. These tools are not used for operations but benefit from connection to simulation-only NDT instances, or connection to hybrid test environments containing a mix of simulation-only NDT instances and NDT instances associated to AT instances.

A final example with exciting promise for both operations environments and engineering exploration is that of virtual reality HDTI implementations. These will have a transformative effect on network operations centers enabling users to see and interact with the operating network in significantly new and effective ways.

In the operations environment, it may seem that HDTI is just another typical support portal, but that is not the case. The HDTI approach does not present an order/workflow-based view of the operating network, and user-initiated changes for the NDT are not user-initiated by manipulating orders. Rather, HDTI presents an active, intent-based way for the user to manipulate the NDT in a manner that is more natural and direct. With closed loop autonomous operations at work in the NDT layer, the user wields the HDTI to see the live state of the network and directly express intent for changes to the NDT, seeing those changes progressing and taking effect in the same view of the NDT. The overall approach embraces autonomous operations while hiding the complexities of its implementation, and, at the same time, provides improved visibility and control to the user.

2.5. Observations and Implications for Network Digital Twin

Applying network digital twin in the service provider network operations environment can take several forms ranging from passive uses for visibility, analytics, and verification/constraint checking on one end of the spectrum, to a full-up intent-based network with closed loop autonomous operations on the other.

The types and fidelity of models used in the NDT should be tailored to the specific purposes for which NDT is being used. An ideal network digital twin ecosystem should facilitate the flexible mixing, matching, coordination, and harmonization of the various models and uses.

Employing network digital twin effectively for many useful purposes does not require direct use of AI/ML at all. This is particularly true when using network digital twin for autonomous operations. Intent based network operation built upon executable models for state machine-based closed loop control, policy and constraint checking, service-to-resource configuration mapping, and other autonomous operations capabilities, along with integrated, consistent, and improved visibility, are achievable and valuable without direct reliance on AI/ML. It is preferable for the

automated operation of the network to be explicitly designed, implemented, and verified for desired characteristics through forward engineering disciplines. This approach ensures autonomous network operations remain consistent, explainable, and predictable.

On the other hand, AI/ML plays a vital role for the network digital twin ecosystem. It has already been discussed how machine learning plays an important role in engineering analysis and the formation of predictive models, playing a key role in the design of the executable models of the NDT. In connection with autonomous operations, machine learning has a key role to play in operations analytics (OA) within the network digital twin ecosystem, providing informational/advisory signals back into the closed-loop controller portion of the NDT. For example, the employment of OA functions based on machine learning and connected to the NDT used for evolving intrusion detection, identifying unusual network operational patterns, predicting equipment failure, and providing other operational recommendations. These OA advisory signals flow into the autonomous operations closed-loop controller layer of NDT; the controller layer is designed and configured to have a predictable and tested response, including the option of ensuring any appropriate human-in-the-loop decision making.

Of particular importance for success, and a challenge to be overcome, is the standardization of information across the NDT models and the normalization of network data (ex. from the AT) presented to those models. One of the benefits of moving to a network digital twin approach to network autonomous operations is that it will be a nexus forcing function to that normalization. It is a systems engineering challenge that begins early in the SDLC and affects multiple operator systems and organizational silos.

The network digital twin approach will transform the way provider networks are designed and operated, but it will not arrive overnight and all at once. Organizational inertia of existing tools, techniques, skills, and processes across the SDLC will need to be overcome. Here, too, it will take years to fully realize the complete architecture described in this first section.

However, network digital twin implementation has begun. The next section provides a case study of how one group at Cox has embarked on the journey employing a network digital twin operations analytics model for the data center network.

3. Case Study: Network Digital Twin in Cox's Data Center Network

With the goal of promoting the long-term health of Data Center Network operations within Cox Communications, Inc. (CCI), the Data Center Network Engineering (DCNE) team has embraced Intent-Based Networking (IBN) as outlined in "Intent-Based Networking – Concepts and Definitions (draft-irtf-nmrg-ibn-concepts-definitions-02), A. Clemm, *et. al.*" and in "Intent-Based Networking – Concepts and Overview (draft-clemm-nmrg-dist-intent-03), A. Clemm, *et. al.*", as a guiding framework in the implementation of a holistic automation strategy within CCI data centers. These documents, taken together, do not constitute a detailed blueprint for IBN, rather they define IBN and the structural components necessary to implement an autonomic network at a conceptual level. While investigating the promise and feasibility of IBN, it became

readily apparent that implementing automated change would require a high degree of visibility into the configuration and operation of network devices.

3.1. Background and Discussion of IBN Strategy

In the summer of 2020, the CCI Data Center network team began work developing an Intent-Based Networking strategy that could be implemented in successive stages with each stage providing value on its own and subsequent stages building upon the value of previous stages. Six stages were identified:

1. Visibility
2. Validation
3. Change Automation
4. Event Management
5. Auto-Remediation
6. Autonomic Network Operation

Visibility – Raw data about the network needs to be accessible at a *human* level. Considering the massive amount of network data that can be collected on a tier-3 Internet service provider network, it is important to distill that data into a digestible source usable by both humans and machines. This data must include both device and topology data as well as statistical traffic data. The refinement and analysis of this data into a usable, published dataset is the goal of this stage.

Validation – Testing using the data collected during the visibility stage provides a basis to ensure that the network is operating according to designed intent. In this stage, suites of tests are built to validate configurations, topologies, traffic flows, etc. These tests can then be used to ensure that changes to the network do not violate the original design intent of the engineer.

Change Automation – The risk in performing automated changes to the network is less stressful with a high degree of visibility into the operation of the network and the ability to validate that those changes had the desired result and did not break any existing network functions. This stage is often built in parallel to the previous two with the goal of automating simple, repetitive tasks. As Visibility and Validation mature, Change Automation can be trusted with riskier changes. Part of this stage is the identification of component configurations (config snippets) used to implement specific functions, i.e., implementing an access control list (ACL) to control access to the routing engine.

Event Management – Leveraging Visibility and Validation, AI and Machine Learning can be employed to detect anomalies in expected behavior. Analysis of these anomalies leads to the identification of events, which can be investigated, and appropriate action taken through human interaction.

Auto-Remediation – As the Change Automation and Event Management stages mature, trust in allowing the network to heal itself grows. Once a specific course of action has proven to resolve

an event that commonly occurs, Change Automation can be used to automatically fix or handle those events.

Autonomic Network Operation – This final stage requires significant investment in the previous five stages to the point where AI and Machine Learning algorithms can review high-level intents provided by engineers, validate them against the operating network, review the component configuration libraries of the Change Management stage to make determinations regarding how the network should be configured to realize the intended design of the network and finally schedule and implement the changes identified.

With this strategy in mind, the Data Center Network Design team began developing use cases focused on developing the Visibility and Validation stages.

3.2. Definition of Use Cases

Like most traditional network teams, the Data Center Network team at CCI is staffed primarily with engineers trained mainly on networking and security disciplines with a smaller number of individuals that have cross-training in programming and automation. Staff are comfortable working in a device command line interface (CLI), but less so writing code or leveraging tools like Ansible to make inquiries or changes to devices. To encourage the adoption of a 'NetDevOps mindset', the DC Network team began investigating various tools to facilitate movement *away from the CLI*.

A set of use cases was identified, and various network tools were researched for their feasibility in meeting those uses cases, as well as the part they could play within the broader context of the team's IBN strategy.

3.2.1. Functional validation of the network intent.

As discussed regarding Visibility and Validation, a fundamental component of our IBN Strategy is the ability to collect network data and test it based on an expected outcome. While many might consider it sufficient to validate that device configurations were matching some pre-defined standard template, it is also important to validate those devices were operating as expected and were implementing the intent of the design. The latter validation capability required a considerably more sophisticated testing framework to enable validating the output of various commands.

Examples of intents identified for the proof-of-concept testing were:

1. Route Propagation
2. Expected Path Analysis
3. FWs blocking/passing traffic as expected
4. VLAN Propagation within the Data Center
5. EVPN Functionality
6. Physical link connectivity and bi-directional traffic validation

3.2.2. Network database – searchable codex of devices and linkages.

Another aspect of visibility that was researched is the ability to perform a search and find various conceptual entities and where they might exist within the network. The goal was to quickly locate and isolate things like:

1. Devices and Device Interfaces
2. MAC and IP Addresses
3. VLANs
4. Routes
5. ACLs
6. L3VPNs
7. Text within a device's configuration, such as a neighbor hostname in a physical interface description.

3.2.3. Reporting – Automated Querying of Network Database

A final identified use case is the ability to perform ad-hoc queries on network data for the purpose of reporting. This use case could in turn facilitate other use cases by giving users direct access to search device data, create reports for management, or use search results as inputs to some other process.

3.3. Decision to implement a PoC with a Specific Vendor

Based on research and the use cases identified, an application was selected for implementation in a POC environment. One of the key factors in this decision was the fact that the application chosen builds a mathematical model of the network based on the transformations made to a packet as it passes through the network. Because the data center network at CCI implements EVPN with L3VPNs, it can be confusing to troubleshoot packets from the CLI. The application gives CCI engineers the ability to visualize how complex network configurations affect the path an IP packet takes through the network on a hop-by-hop basis.

3.3.1. Discussion of Implementation

After reviewing the possible security issues with the CCI internal security team, it was decided to implement the application in a SaaS model. In this model, an internal *collector* is installed within the security perimeter of the organization with the ability to make SSH connections to all devices participating in the network model. The collector logs into each device, runs a battery of commands and collects the resultant data generated by those commands. It then bundles up the data and encrypts it for shipping to the cloud environment, which processes the data, builds a mathematical model of the network, and provides a searchable map through the cloud-based GUI.

Depending on the number of devices requiring collection, the sizing of resources dedicated to the collector may vary. Appropriate sizing for the collector is something that needs to be determined

as part of the implementation process. It is important to note that the function of the collector is solely as a means of gathering information, not processing it. If the 'on-prem' application model is used, resource requirements are significantly higher.

Management of the collector is handled through automation provided by the vendor and upgrades to the cloud environment are all managed internally by the vendor.

The ease with which the application can be managed within CCI was an important factor in the decision to eventually move forward with purchasing the fully licensed version of the application.

3.3.2. Discussion of adoption and usage

The CCI DCNE team manages network connectivity for multiple data centers with the organization. There are two primary data centers, one in Alpharetta, GA and one in Phoenix, AZ as well as a disaster recovery data center in the Metro Atlanta area. In addition, there are distributed regional data centers servicing edge applications in the various CCI markets. To quickly gain benefit from the application, maps of each data center were built to assess if there were possible issues at those locations by running basic checks to validate connectivity between devices. After this initial stage and discovery process, a full map of the network including the network backbone was created. This map allows for the analysis of path data between the various data centers and ensures that traffic follows the expected paths based on where it originates and where it is destined.

Adoption of the new application has not happened as quickly as hoped. The initial collection of data in the primary data center included many devices. Because of this, the first maps which were drawn by the application were highly complex and difficult to understand. Though the search features worked as expected and gave accurate results, the complicated nature of the maps discouraged some users from engaging with the tool. To counteract this complexity, the application allows devices to be aggregated into 'clusters' represented by a single node on the map. This has been effective at making the map more digestible but requires a significant investment in effort to curate the maps. Leveraging the application's API, automated tools for map curation are being developed.

3.3.2.1. Device selection and curation of map

As previously discussed, having an accurate map is vital to developing trust in the tool by network personnel. While it may seem obvious on the surface for highly complex networks, determining the set of devices to collect requires some forethought. While the process of collecting and mapping the network can provide significant insights, a haphazard approach to adding devices can lead to a map that requires significant effort to curate. Built within the tool itself are the capabilities to automatically curate connectivity between devices, but this requires LLDP/CDP on devices interfaces, something that for security reasons is not viable on all devices (such as FWs and some LBs). Consequently, manually linking those devices together can become a time-consuming part of the curation process.

A recommendation to make the process smoother is to start from a central point or 'core' network device and then expand the collection of devices towards the edge of the network. By doing this, devices can be added to the network in a manageable way and the location and placement on the map more easily be curated.

3.3.2.2. Usage/adoption among front line staff

A key aspect of adoption is the use of the application as a troubleshooting tool. The search capability allows users to do things like locate hosts within the network or search paths through the network to ensure that end-to-end traffic is following the expected path. During the information gathering phase of the troubleshooting process, being able to quickly collect this data can have a significant positive impact on MTTI (mean time to innocence) and MTTR (mean time to resolution).

While the application has shown significant promise, there has been some difficulty in getting some network staff to adopt a 'new' tool when they are used to using other tools or using the CLI. A four-session training course was presented to show the efficacy of the tool as a troubleshooting resource. Three sessions were presented by internal staff and a fourth was presented by the vendor. Sessions were recorded and made available for the broader network community at CCI. Although this did increase the user base slightly, it did not reach the expected goal for number of users in the allocated time frame.

While some staff have seen value right away and have begun adopting the tool, these staff tend to be higher-level engineers. We are seeking further engagement and feedback from the potential user community to increase future adoption.

3.3.2.3. Expected growth in adoption

Recognizing the need to integrate this new application into the typical troubleshooting workflow for front line network support, we have undertaken to analyze the typical use cases seen by operations staff. More training on how to solve specific troubleshooting problems will be developed. During this process, operations staff will be engaged to provide feedback to the development process.

Another point of attack in growing adoption is the development of network queries to provide value to users by using the application's query engine to gather data, generate reports, etc. Queries that provide detailed validation of proper device configuration, for example, proper MTU sizing on an interface, can be adopted as part of a workflow process to remediate devices that are out of standards compliance. While this may initially be implemented as a manual process, the application provides a facility to make testing an reporting an automated process on all collections.

3.4. Discussion of PoC Results

Based on the use cases described above, the POC was very successful. In fact, very early on in the POC, issues with the network topology requiring immediate attention to prevent possible outages were discovered.

3.4.1. Efficacy of network entity searches.

One of the most useful toolsets is the ability to search the network for various network elements, such as IP addresses, MAC addresses or VLANs. This search capability has proved very useful and provided great insight into how VLANs are distributed in the various data centers. After searches are entered valid results are shown both as tabular data and as graphical representations on the map. When searching for a VLAN, all points that the VLAN is distributed to are shown on the map.

3.4.2. Efficacy of network path searches

Probably the most powerful of all the tools in the application's arsenal is the network path search: given two IP addresses on the network a graphical representation of the path traffic takes between those points is given. That path information includes detailed information from each device in the flow, including how the packet changes from entry to exit as it moves in and out of the device. The detailed information provided is extremely useful because it allows us to view the relationship between underlay and overlay parts of the EVPN configuration.

3.4.3. Use of network queries to identify misconfigured network devices

Another useful tool of the application is the query engine. This tool allows us to generate queries against all the devices in a map, extract data from those queries, and run tests against that data. During the POC we used this facility to validate the configuration of MTU size on device interfaces. Manually validating the MTU size on thousands of device interfaces is a tedious and error prone process. By writing a properly formed query, we can ensure that all device interfaces that are administratively and operationally 'UP' have an MTU of a certain size or greater. This function works very quickly and gives us the information needed to hand off to our operations teams in csv-formatted report so that the incorrect interfaces can be remediated.

3.5. Realities of Digital Twin maintenance

As described in this case study, the digital twin shows great promise in helping validate the proper operation of the network based on the intent of the network design. There are, however, some considerations that affect the construction of a network digital twin as it is being created and managed.

3.5.1. Time requirements for staff to manage.

The initial time commitment for building a digital twin is very high but should taper off as the number of devices in the collection reaches the full set of devices in the network. This is especially true if accommodations can be made to device configurations that make automated mapping of the network easier, such as the implementation of low-level device discovery protocols is enabled, such as LLDP or CDP. While the application was able to infer connections between devices without direct LLDP/CDP data by analyzing MAC addresses and ARP tables on the device, inference of connections can only work if the application can collect the data necessary to make those inferences. In some cases, network configuration can prevent the collection of that data.

Once the topology of the network is reviewed, and any curation of the twin required is completed, the application will maintain an accurate assessment of the topology unless some change requires an update to the map. It is important to note that the time needed to manage map curation at this point relates to arranging the placement of devices/cluster nodes on the map in such a way that it is readily understandable by all network staff.

3.5.2. Assigning overall responsibility/technical advocacy for map(s)

It is important that a RACI matrix be developed for ownership and management of digital twins. Responsibility and accountability for the accuracy of each map must be vested in individuals who have an interest in the value provided by the map. In a highly complex data center environment, especially a service provider environment, it is likely there is no one person who has a full understanding of the entire data center network. Being able to ensure that the map is accurate is an effort that should be shared between design and operations staff and should enlist enough staff to ensure expertise throughout the environment.

An example of the need for this effort would be the case where a connection between two devices was not properly discovered, requiring manual configuration in the digital twin model. In this case, path searches may not resolve as expected, which would be an obvious indication of an issue to someone familiar with the expected path that traffic should take.

3.5.3. Cost/Benefit discussion.

While a full ROI analysis has not been performed on the application, there have already been several instances where the manpower required to analyze and remediate issues in the network discovered by the tool would have been orders of magnitude greater if done manually (if they would have been identified and fixed at all). It is important to note though, that fully realizing the value of the tool requires investment in manpower to customize the tool to the specific environment within which it is deployed, which is something that must be done on case-by-case basis. In addition, a fair accounting of the fully realized ROI would require a significant analysis in time savings for network staff.

4. Conclusion

We hope that the paper has provided a blended view of network digital twin, including both a forward-looking glimpse of the long-term landscape with some of the exciting transformative possibilities, and a practical account of how one such possibility is being realized today.

In the words of Lao-tzu, “A journey of a thousand miles must begin with a single step.” The introduction, development, and wielding of network digital twin is a journey worth taking. We welcome fellow travelers on this journey as we all take the first steps!

Small Cell Deployment Strategies for Cable Broadband

A Technical Paper prepared for SCTE by

Toby Peck
Sr Director Product Management
EnerSys
Toby.Peck@enersys.com

Greg Laughlin
Strategic Marketing Manager
EnerSys
Greg.Laughlin@enersys.com

1. Introduction

Cable broadband and wireless operators are working together to create new revenue-generating partnerships and service offerings. While some cable operators are reselling wireless mobility as part of their bundled service offerings, others are selling mobile operators access to their infrastructure for cost-effective small cell connectivity.

Many broadband operators also plan to deploy their own small cell networks, leveraging recent acquisitions of CBRS spectrum and their existing Hybrid Fiber-Coax (HFC) infrastructure. Regardless of the reason, introducing small cells to the HFC network presents many challenges, from making a workable business case, to product design and development as well as operational practices.

Reliable power and quality backhaul are essential for small cells, and radios must be strategically located across a wide geographical footprint. You must also maintain a tightly coordinated schedule while working with a limited budget. The HFC network is a smart choice for distributed connectivity—it alleviates the cost of building a small cell network from the ground up, providing reliable, cost-effective infrastructure through most populated areas.

When HFC is not available to support small cell devices, alternative powering approaches may be more cost-effective. Remote Line Power (RLP) uses high-voltage DC power to distribute longer distances using copper with fiber, often in a hybrid fiber/copper composite cable. Local utility power can also be used, but often requires expensive construction, permitting and metering for new service to cell site installations. All three powering options have advantages and disadvantages.

This paper will evaluate HFC for small cell power and backhaul capabilities and explore different methods of deployment. We'll also look at local utility power as well as remote DC power solutions for small cell powering. Small cell deployment requirements and challenges will be explored with guidance on selecting connectivity solutions based on the situation and environment.

2. Small Cell Radio Deployment Challenges

In a perfect world, operators would be free to place small cell radios wherever they want, and every location would have a power outlet with reliable backup power and fiber for backhaul. The realities of small cell deployment are different, and it can be quite expensive and can take months to bring power and communications to the radio. Local siting restrictions and costly permits can add even more barriers.

2.1. Cost-Effective Infrastructure Availability

Unlike tower-based cellular radios which can provide several square miles of coverage, mid-band small cell radios output much less power with coverage areas of a few hundred feet maximum. This means radios must be close to the coverage target, and a large quantity is needed to cover a sizeable area. Small Cell Forum recommended best practice is to install small cells within 20-40m of heavy traffic locations.[1] In other words, a good deployment solution needs scalability and precise radio placement.

Getting permission to install a small cell can be a challenging process, with hurdles around zoning, securing siting, permitting and regulations. Jay Brown, Crown Castle CEO reported it can take up to 2

[1] SCF 2021 Market Forecast document 050.10.5; http://smallcellforum.org/scf-market-forecast; viewed 7/28/21

years to deploy a small cell on a wall or pole, due to wading through siting and construction issues.[2] That same deployment model can cost $25,000 or more.[3]

2.2. Reliable Power

More than ever, keeping the mobile network running at full capacity without interruption is essential. Networks must withstand daily power anomalies that plague the United States utility grids and cause damage to sensitive network equipment.

Extreme weather events are becoming more prevalent, resulting in more frequent, longer duration power outages. United States utility customers experienced 1.33 billion outage hours in 2020, up 73% from 2019's 770 million outage hours.[4]

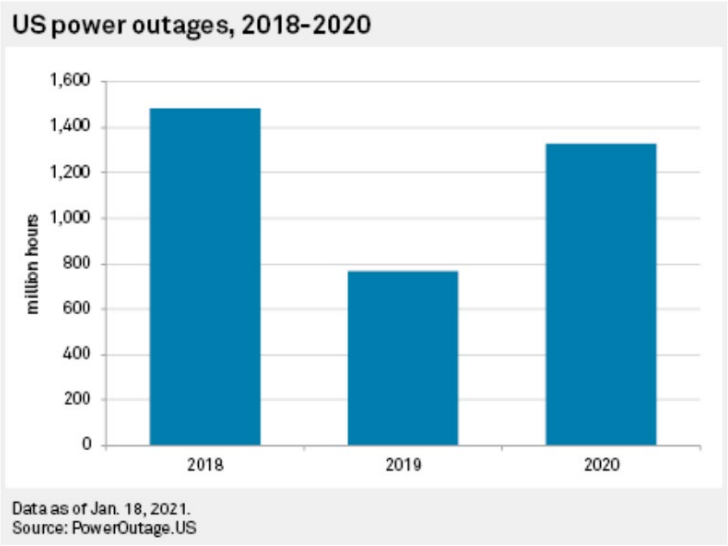

Figure 1 - US Utility Outages 2018 to 2020

A reliable small cell network requires clean conditioned power and, where econmically viable, energy reserves for backup during utility outages.

2.3. High Bandwidth, Low Latency, Reliable Backhaul Connectivity

Cellular networks have traditionally relied on fiber optic backhaul communications due to superior performance in bandwidth and latency. Next generation 5G design parameters specify delivery of up to 10Gbps throughput with less than 1ms latency[5]. These are essential factors for real-time use cases like gaming, video streaming and remote healthcare, where the experience requires seamless communications.

[5] 5G Low Latency Requirements, McLaughlin, 2019, https://broadbandlibrary.com/5g-low-latency-requirements/

While fiber may be preferred, it is not always cost-effective when construction is needed to bring the fiber to the location where the small cell is installed.

Meeting the goals of cable broadband small cell deployments will require operators to find financially viable ways to provide the fundamental elements for high quality small cell radio connectivity, while maintaining reliability of their existing network. Long term plans should consider product lifecycles and how to stay ahead of evolving radio technologies.

3. HFC as an Advantage for Small Cell Deployment

3.1. Advantage: Ubiquitous Broadband and Power Grid

For many years, the core mission of the cable broadband network has been to deliver fast, reliable and high-quality wired connectivity. What started out as a scattering of coax cable networks intended to provide community access television in the late 1940s[6], has evolved into a vast network of fiber optic and copper coaxial cables delivering not only television, but Internet and phone service around the globe.

In the United States alone, cable broadband networks have over 1.7 million total miles of deployed fiber and coax to make up the HFC network. This vast expanse of physical infrastructure passes 96% of the homes in the U.S., providing service to 78 million customers[7].

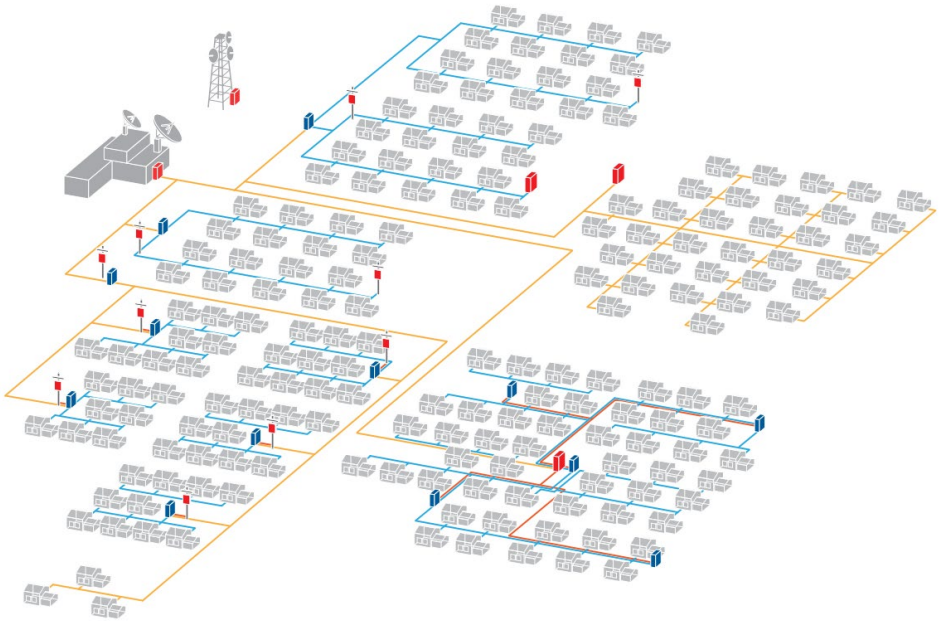

Figure 2 - HFC Network

In the HFC network, fiber optic cables are primarily used as an efficient delivery mechanism to bring long haul network traffic into neighborhood nodes; and in some new construction to end users directly using Fiber to the Home (FTTx). These nodes convert light signals to electrical signals for transmission over coax. The coaxial cable then delivers data for the "last mile" to each subscriber's home through a cable

modem. Remote PHY (CCAP) nodes, traditional fiberoptic nodes, and amplifiers require power, so the practice of using the network coax to carry power is still widely used as illustrated in Figure 3.

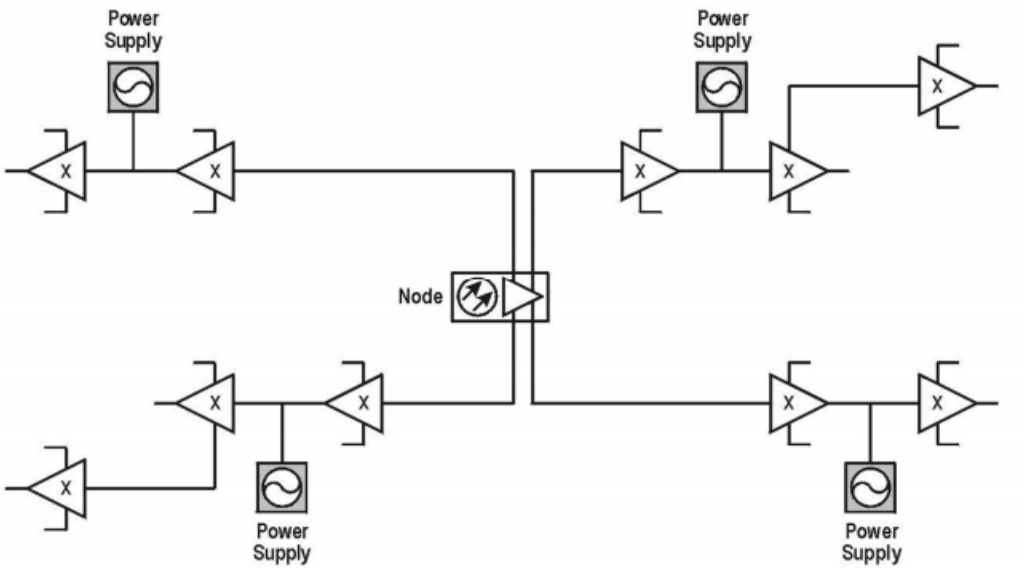

Figure 3 - Typical HFC Network Powering Diagram[8]

Coaxial cable accounts for 20% of the HFC network. This coaxial network can be looked at as 340 thousand miles of existing, accessible and available power lines running through most populated areas.[9] While utility power lines often span the same poles, there are other aspects of the HFC network that make it much more suitable for small cell deployments.

3.2. Advantage: Accessibility and Scalability

The HFC network architecture is built on a distributed access model that is extremely efficient and flexible, enabling Internet connectivity at any point in the network. According to a recent publication from iGR, it is estimated that the cable broadband aerial strand could support small cell installations for over 203 million people in the United States, about a quarter of the total addressable market.[10]

NCTA identifies the flexibility and continuous management as key value props of the HFC network:

> *"The beauty of HFC architecture is it marries the power of gigabit capable networks with an architecture that is extremely efficient and flexible…network engineers don't just plan for today, they build networks that accommodate future growth in consumer demand. That planning allows cable's networks to stay ready and robust in the face of events that may cause internet traffic surges."* [11]

[11] *"Why Cable's Broadband Network Is Handling the Pandemic and Ready for the Future", NCTA; 4/29/2020; https://www.ncta.com/whats-new/why-cables-broadband-network-is-handling-the-pandemic-and-ready-for-the-future*

The coax portion of the network is used for broadband delivery, with physical 'taps' cut into the hardline coax to provide individual connections to the broadband network through smaller, more flexible and manageable premise coax. While most taps used for residential customer broadband connectivity prevent power from travelling to the home, a special style of 'power-passing tap' allows for both power and broadband to be extracted. These power-passing taps were initially introduced to support telephony systems and more recently re-introduced to provide power and backhaul communications for Multiple Service Operator (MSO) strand-mount, Wi-Fi access points. With hundreds of thousands of HFC-enabled Wi-Fi access points deployed worldwide, broadband operators have proven the effectivity HFC can play for scalable wireless access.

3.3. Advantage: Reliable Source of Power

HFC power supplies take power from a utility connection and energize the coax, enabling nodes and amplifiers to power directly from the coax, removing the need for utility connections to each device. Since the cable operator's communications channel radio signals (RF content) and alternating current both propagate using sinusoidal waves at different frequencies and can simultaneously travel over the same coaxial cable. This combination of power and communication is unique to cable broadband and a differentiator for small cells.

HFC power supplies utilize ferroresonant transformers to provide a very robust and quality powering platform, ideal for sensitive network equipment. Ferroresonant transformers by nature provide excellent line isolation; 1000:1 ratio for HFC power supplies. This means that any change to the input, small or large will have little effect on the output. A high voltage surge or spike from the utility will be minimized at the power supply before it can affect the HFC network.

Most broadband cable operators co-locate their HFC power supplies in cabinets with batteries to maximize network power availability when utility power fails. Today's HFC power supplies can switch to battery mode within a half duty power cycle, preventing the nodes, amplifiers and radios from dropping power and resetting during the power transfer.

3.4. Advantage: Physical Placement

Furthermore, most cable operators enter into franchise agreements with their local municipality which allows them to connect any network equipment to the HFC without requiring additional site approvals or permits.

New Street research analyst Spencer Kurn noted the value the broadband cable strand played in Sprint's recent 20,000+ small cell deployment in Long Island. "Cable companies already have the public right of way with poles and strands of aerial cables… Historically, cable companies have been reluctant to open their infrastructure to wireless carriers to deploy small cells… Altice is unique in that they did this for Sprint in return for a really attractive wireless Mobile Virtual Network Operator (MVNO)."[12]

Moffet Research estimates that an MSO can install a CBRS small cell for around $2,500 by avoiding the siting costs that are applied to pole and wall installations.[13]

[12] L Hardesty, 2019, Altice's 19,000 small cells in Long Island don't help Sprint's network much, say analysts, Fierce Wireless, Viewed 3/1/2021, https://www.fiercewireless.com/wireless/altice-s-19-000-small-cells-long-island-don-t-help-sprint-s-network-much-say-analysts

[13] "Cable's wireless biz 'ready for its star turn' – analyst"; LightReading; J Baumgartner; 6/17/21; https://www.lightreading.com/cable-tech/cables-wireless-biz-ready-for-its-star-turn---analyst-/d/d-id/770301

3.5. Advantage: High-Capacity Low-Latency Backhaul

MSOs are pushing fiber optics deeper into neighborhoods and moving much of their core network processing from regional headends out to the edge of their network. This "edge computing" application greatly improves processing time, enabling higher capacity with lower latency. A recent CableLabs® analysis showed >50% reduction in total cost of ownership (TCO) for an outdoor use case of backhauling small cells when served by DOCSIS® networks compared to a more traditional deployment served by fiber.[14]

DOCSIS® 3.1 is currently deployed globally in millions of homes and businesses. Today's DOCSIS® 3.1 introduces support for low-latency DOCSIS (LLD), and provides an option to increase upstream spectrum from the traditional 5 to 45MHz range to 5 to 205MHz. This adds significant upstream capacity improvements and sets the groundwork for future improvements coming with DOCSIS® 4.0.

Through DOCSIS® enhancements known as low latency X-Haul over DOCSIS®, 5G backhaul latency can be reduced to approximately 1ms, surpassing 5G vRan targets of 5ms.[15]

Extended frequency division duplex spectrum DOCSIS® 4.0 will take advantage of the extended 1.8GHz of spectrum as well as full duplex to maximize throughput. DOCSIS® technology leaders expect throughput target speeds of 10Gbps downlink and 5Gbps uplink.

3.6. Advantage: Existing Well-Maintained Resource

One major advantage of the broadband HFC network is it's the lifeblood of cable companies and warrants significant, continuous investments and routine maintenance. Cable operators in North America invested $17B in 2020 alone, on infrastructure and networks[16], with total investments of $290 Billion since the year 2020[17]. NCTA credits these cable broadband commitments to investing in their network as key factors leading to industry's ability to meet added demands from the COVID-19 pandemic work-from-home impact.

> *"…hundreds of billions of dollars in investment in infrastructure and technology, smart and responsive network engineering, and a flexible network foundation that is being constantly upgraded with hardware, software and other technical modifications* (NCTA, 2020)[18]*."*

And in addition to capital investments, cable broadband's smart architecture and commitment to localized management provides a very resilient and reliable infrastructure. *"By having eyes on every aspect of network performance, engineers are able to diagnose localized issues and often troubleshoot them quickly."*[19]

4. Connecting Small Cells to HFC

4.1. Design and Integration Considerations

The cable broadband HFC network brings a unique set of connectivity considerations for small cell radios. Creating HFC-compatible small cell radios require integration of HFC components and elements into radio design allowing them to mount and receive power from HFC coax, backhaul via DOCSIS® and enable remote system management and reporting.

4.1.1. Housing Size Limitations

Cable broadband operators typically enter into franchise agreements with local municipalities that include rights-of-way. These agreements provide cable operators with the freedom to hang outside network equipment from the steel messenger cable, or "strand" that spans between utility poles and lashes the coaxial network cables. The terms of the agreements typically allow the operator to deploy their networks in this fashion without requiring new permits for each piece of equipment deployed. The equipment deployed on the strand, however, must meet size, weight and power restrictions.

Starting with form-factor, any device designed needs to fit into what the National Electric Safety Code (NESC) defines as the Communications Space. NESC specifies a minimum 12" clearance between cable TV and telephone lines as shown in Figure 4, but some jurisdictions lower that to 11in or even 9in in some cases.

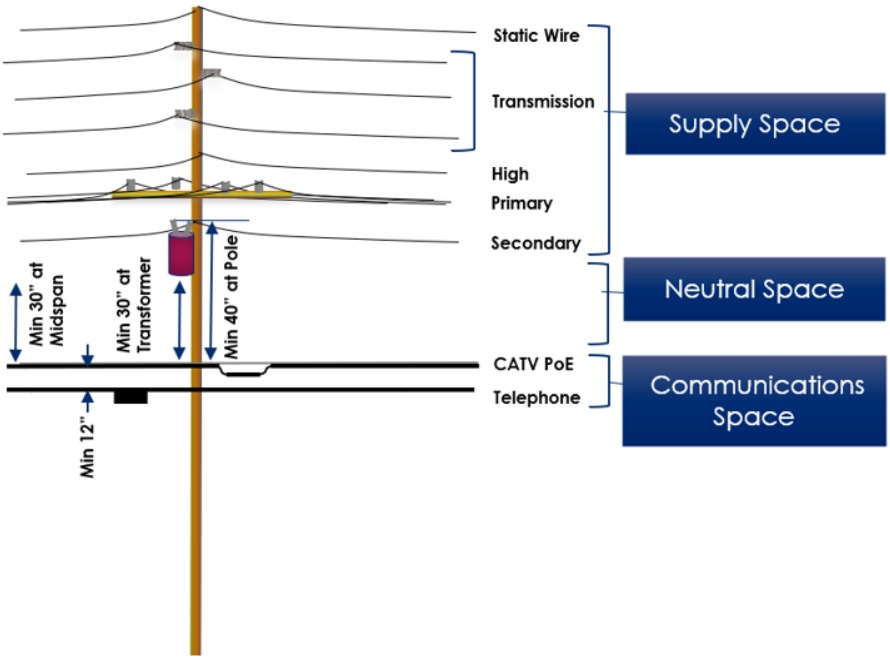

Figure 4 - Communications Space

The coax itself must be accounted for in this space as well which can reduce this space by 2 to 3in, and some broadband operators have individualized stringent space requirements. This means small cell radios should be no taller than 9in (including integrated antennas).

Figure 5 - Small Cell Radio within Communications Space[20]

4.1.2. Physical (Outside) Connections

The main connection points for the HFC small cell are the mounting connections to the strand, the grounding connection, and most importantly the connection to the HFC coax.

There is no industry specification for strand-mount brackets but there are basic guidelines to consider. Messenger strands are typically 0.25in or 0.375in in diameter, so useful designs would include flexibility to support either size. A potentially large cable bundle, up to a 3in diameter may be tethered to the strand, creating an obstacle between the strand and radio. Most strand brackets are designed with a "C" shape to accommodate the coax bundle. Another important consideration for the strand bracket is to check that materials are galvanically compatible with radio housing and the galvanized steel strand. Metals with dissimilar galvanic properties can lead to unwanted corrosion.

Figure 6 - Strand Bracket

The strand messenger, in addition to mounting, also provides the electrical grounding for strand-mounted equipment. While many radio designs use the mounting bracket as the ground connection, a ground lug on the radio housing can facilitate a dedicated cable to secure a ground connection between the radio and strand.

Perhaps the most important physical connector is the HFC coax connection. The coax cable delivers power to the radio, provides the network backhaul and is a potential source of water intrusion and radio noise ingress. There are two standard connection types used for HFC equipment, typically selected based on the size of coax cable connecting the equipment, which is determined by the cable operator based on

[20] Image taken from Airspan website; 8/1/2021; https://www.airspan.com/cbrs/

the amount of power that the equipment draws from the HFC coax. Most strand-mount HFC equipment like nodes and amplifiers connect directly to distribution “hardline” coax, which is much heavier and less flexible than the smaller coax “drop” cable that run from the HFC to a residence. Smaller drop coax, which is more flexible and less expensive than hardline can be used to connect smaller loads like Wi-Fi access points. While the decision is made by each cable operator, general guidelines limit the smaller drop coax for loads under 90W, with hardline coax is suitable for any loads. Smaller coax cables use F-style connectors, the same as home modems and set top boxes specified by ANSI_SCTE_124_2021[21]. Hardline coax uses a standard 0.625in x 24 threaded connector as specified by ANSI_SCTE_91_2015[22]. It is important to follow SCTE 91 specifications closely as there are essential elements like shrink sleeve ridge and galvanic considerations.

Figure 7 - Hardline ‘KS’ connectors

Designing small cell radios around SCTE 91 specifications (hardline connection) provides the cable operator with flexibility to connect using either hardline distribution cable or drop cable by installing a ‘KS male to F’, or “pin-to-F” adapter. The pin-to-F has the standard 0.625in x 24 threads to connect into the radio, with the other end having F-type threads for drop cable.

Figure 8 - Pin-to-F connector

4.1.3. Power

An HFC small cell radio must be able to power from the HFC coax, which delivers an alternating current (AC), quasi-square wave in the range of 45-90VAC, depending on resistive losses created by distance from the local HFC utility power supply. Cable networks work similarly to wireless networks, sending digital data over radio frequency (RF) waves, only the waves are sent within coaxial cables and fiber optical cables instead of openly through the air. A unique and important feature of the HFC network is the

[21] https://www.scte.org/standards-development/library/standards-catalog/ansiscte-124-2011/

[22] https://www.scte.org/standards-development/library/standards-catalog/ansiscte-91-2015/

use of Alternating Current (AC) for power, both power and data can travel through the same coaxial cable at the same time.

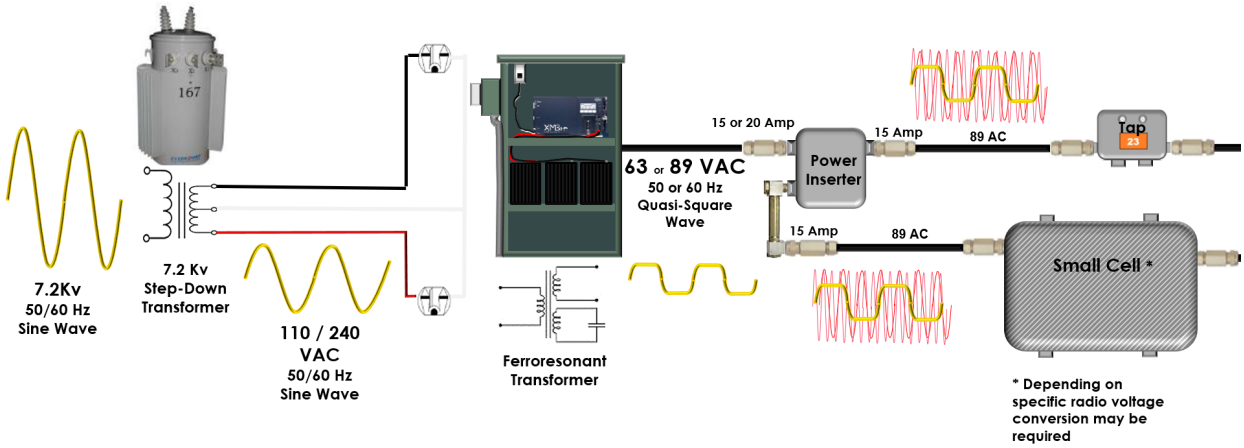

Figure 9 - HFC Power System

The device being powered by the coaxial network, be it a node, amplifier or in this case a small cell radio, will use RF filters to separate the power and DOCSIS® RF. At this point, the device can convert the voltage from AC to DC to power the device, and RF can be used for DOCSIS® backhaul with the integration of a cable modem.

Voltage levels drop over distances per Joule's I2R law, meaning voltage at the small cell will be lower than at the cable power supply. Most cable operators dictate that devices powered by HFC automatically shut down at lower voltages in the 35 to 45VAC range protecting the device from drawing too much current [Current (I) = Power (P)/Voltage(V), therefore a 100W radio will typically draw twice the current at 45VAC compared to 90VAC]. Many cable operators also require the powered-device (small cell radio in this case) sustain operation over a full duty-cycle of sustained power loss, requiring additional capacity in the power circuit.

Another consideration around small cell power is the advantage of using watchdogs and remote power control to reduce outages and costly truck rolls. Most end users have had experiences with home networking equipment locking up, requiring a power cycle to bring the device back online. This is simple when the device is in a home, office, or headend, but problems on the HFC strand require expensive truck rolls to perform the most basic tasks, like pushing a reset button. A good watchdog system should catch any problems with routine operation of the device and will auto-reset or trigger a power cycle to the system without human intervention. It's also valuable to provide remote power control of the radio element independently of the overall radio system. This can be very useful if the radio element gets stuck or if the operator wants to shut down the radio transmitter for a local service call. This value-added feature however requires communications and power control between the DOCSIS® modem and onboard AC/DC power supply.

4.1.4. Backhaul

One of the primary benefits of deploying small cell radios over HFC is the ability to use DOCSIS® for data backhaul. DOCSIS® 3.1 has incorporated features useful for small cells including: low-latency DOCSIS®, mid-split and high-split spectrum options to increase throughput, and additional tools like

business services over DOCSIS® for added management and security. Cable operators deploy millions of DOCSIS® modems to their home and business subscribers. Managing a cable modem inside of a small cell radio should not be much different.

However, there is a significant difference between a home or office modem and an outdoor hardened modem, especially when it resides inside an enclosed housing with an RF transmitter. Outdoor small cell radios are designed to operate in outdoor climates and be exposed to extreme hot and cold temperatures where modems must be built with more expensive, rugged components. In addition to harsh environmental conditions, outdoor HFC modems carry more stringent requirements to withstand power disturbances like surges, line cross and electrical static shock. They are expected to self-recover from network and power outages and can require operator-specific firmware for remote system management.

4.1.5. Safety

Electrical shock hazards and RF radiation are the top safety concerns for strand-mount small cells. The NESC limits products residing within communications spaces to 90VAC which is considered 'low voltage' and safe for technicians to work around without requiring electrician licensing. This however does not mean that HFC power is not dangerous. While it is important for technicians to use safety procedures when working on or near HFC, the products using HFC for power must meet rigorous standards for electrical shock and be proven through agency testing.

Small cell radios fall under the category of 'Information Technology Equipment' for Underwriter Laboratories[23] (UL) and CSA Group[24] (CSA – formerly Canada Safety Agency), the two primary safety certification agencies in North America for cable broadband equipment. Both UL and CSA are Nationally Recognized Testing Laboratories (NRTL) that test to the same harmonized Canadian Electrical Code (CEC) and National Electrical Code (NEC) standards, making their certifications virtually interchangeable.

4.1.6. Environmental

Outdoor small cell radios are subjected to harsh weather conditions, including extreme temperatures, ice, rain and wind. Installations in coastal areas add the element of salt, an enemy to steel and electrical circuitry. Aluminum housings coated with salt-resistant paint, along with designing around dissimilar metals, will go a long way to preserve equipment integrity.

4.1.7. Network Integrity

A challenging but important element of the small cell radio, especially when connected to the cable broadband network, is the mitigation or prevention of electromagnetic interference (EMI) between the cable and wireless networks. Both wired and wireless networks use radio signals for communications, often in the same frequency range. It is essential these networks are isolated from each other and radio signals from one medium do not bleed into the other.

Damaged or improperly installed coaxial cable can act like an antenna and is more susceptible to conducted interference, where RF noise or signals are propagated through the coax. This interference can impact the RF signals from the cable headend, resulting in poor or lost communications for customers

[23] https://www.ul.com/

[24] https://www.csagroup.org/

across the network. Conducted noise can also come from crystal oscillators in tuner circuits, or from AC/DC power supplies within the small cell.

Wireless networks are more susceptible to radiated interference, where RF signals leaking from the cable network via an enclosure or poor connector affect the wireless signal of the radio. The effects are similar to those on a wired network, impacting overall performance and integrity of the wireless network.

A sealed, aluminum small cell housing acts as a Farady cage and provides most of the protection needed to mitigate interference between networks. However, RF inside the sealed housing, especially when housing a cable modem and wireless radio can be exceedingly difficult to overcome. Shielding, grounding, internal wiring, EMI filters and a lot of testing are required to truly protect the cable network.

4.2. HFC Connectivity Methods: Integration and Demarcation

This section will discuss two methods of deploying small cells over the HFC network and provide advantages and disadvantages to both.

4.2.1. Small Cell with Integrated HFC Elements

A DOCSIS® small cell radio is one that has been designed specifically for strand-mount and connecting directly to HFC coax for power and backhaul. The radio manufacturer will design a housing to meet the industry requirements, including but not limited to:

- Strand mounting connections
- Coax connection including seizure screw
- Status indicators (modem, radio)
- Water intrusion
- UV
- Wind loading
- Antennas
- EMI
- Communications space limitations
- Electrical grounding
- RF Protection from external impairments
- Corrosion (water, salt water, dissimilar metals)
- Vibration
- Labelling
- Internal circuitry including RF protection
- Electrical surge

HFC-specific internal components must be designed or purchased to include:

- Coax interface
- RF/Power Filter
- Outdoor hardened DOCSIS® modem including all firmware for management, MSO-specific features

A single box system minimizes the number of cables, connectors and external components. This reduces the number of potential failure points and makes for simple system installation, troubleshooting and management verses a solution with multiple elements for power and backhaul.

The procurement process is also simplified by having a single manufacturer to coordinate with for purchasing if any problems arise. Instead of spending time to understand which part of the system is causing problems, the radio can be replaced, returning the defective unit to a single vendor.

However, creating a small cell radio specifically for HFC has its own drawbacks. The biggest challenge is with small cell radio manufacturers and their need for a business case to justify the investment needed to bring an HFC-specific radio to market.

Like any manufactured product, one goal is to create products serving multiple markets without additional SKUs, allowing manufacturers to leverage economies of scale to lower their overall component and operational costs.

HFC deployment historically has been a small niche sub-market for outdoor small cells, and outdoor small cell deployments are a fraction of indoor enterprise. For example, according to Small Cell forum around 468,000 outdoor small cells were deployed in 2019, approximately 20% of the total deployments.[25] In that same year Sprint deployed ~20,000 strand mount small cells over Altice's HFC, which would have accounted for ~4% of the total outdoor small cell deployments.

The outdoor small cell market share is expected to increase to 35% by 2026 to over 2 million radios installed, but it is too early to say how many of those radios will be targeted for HFC deployments.

	2019	2020	2021	2022	2023	2024	2025	2026
Rural and remote	55	62	76	110	145	156	170	185
Urban	468	556	680	950	1,345	1,670	1,850	2,210
Enterprise	2,228	2,455	2,643	2,890	3,465	3,680	3,810	3,890

Figure 10 - Small Cell Deployments by Segment 2020 - 2026[26]

Other large MSOs are planning their small cell programs with help from recent allocations of licensed and unlicensed CBRS spectrum by the FCC, and their deployment numbers will likely reach over 100,000, but this is not a proven market and any forecasted numbers must be met with caution. Without solid commitments, radio manufacturers are faced with high-risk investments which pull resources away from other revenue-generating opportunities.

[25] SCF 2021 Market Forecast document 050.10.5; http://smallcellforum.org/scf-market-forecast; viewed 7/28/21

[26] Ibid

Another challenge for the integrated small cell radio is each vendor must go through steep learning curves with regards to cable networks and nuances involved with HFC power, RF mitigation and industry practices. This can add significant delays in development schedules and require radio vendors to become experts in technologies outside of their core competencies. Vendors must invest in costly CMTS and HFC power equipment and may need to build their own cable networks for development and testing.

Certification is another pain point for radio manufacturers. Small cell radios must be FCC certified for each radio band they serve and may require additional certifications for each country where the radio will be deployed. The addition of a cable modem to the radio requires CableLabs DOCSIS® certification at costs intended for high-volume amortization seen in the residential modem market.

Each MSO will further qualify and verify the hardware for operation in their networks. These tests include functional, RF emissions and operational test as well as environmental tests. Test and certification cycles are lengthy and expensive, requiring heavy investments in specialized equipment and expertise. In a best-case scenario, the radio passes all tests on the first attempt but this is rarely seen if ever. Multiply this by several vendors and it can have a significant impact on complexity and schedule.

4.2.2. HFC Demarcations for Small Cell Radios

Another approach to bringing small cell radios to HFC is to create demarcations allowing radio vendors to use off-shelf products with minimal changes. Cable broadband already uses demarcations in the form of taps used to deliver DOCSIS® to residential customers. It is widespread practice within the industry for MSOs to establish standardized RF levels at their taps so technicians can deploy a set length of drop cable knowing it can provide the optimal signal at the user's cable modem.

An HFC demarcation device for small cells would perform the power and media conversions and provide the radio the power and network connections.

Figure 11 - Small Cell with Demarcation Gateway (Author's Photo)

Demarcations allow small cell radio manufacturers to use radios for multiple purposes, eliminating the need for them to design low-volume niche products for HFC. Radio certifications and SKUs are reduced, proving additional economies of scale for the radio vendor. The MSO can then leverage competition between radio vendors which can result in additional cost reductions.

Demarcation gateways are not radio vendor -specific, so operators can source from one or two manufacturers directly, leveraging volume pricing.

Demarcation also provides additional reliability to the HFC network by acting as an isolator between the wired and wireless networks, protecting both from RF ingress. It gives the MSO better control of the cable modem which interfaces directly with the core network. Demarcation gateway manufacturers have expertise in outside HFC plant and DOCSIS® modems, providing additional quality assurance to the operators.

Finally, the overall TCO of the radio network will continue to stay low as next-generation radio products come to market. Wireless products tend to evolve faster than DOCSIS®, and demarcations provide the ability to upgrade your forward-facing technologies without sacrificing the entire system. MSO lab qualification and testing time is also greatly reduced for even better financial results.

A downside of using demarcations is the burden of extra inter-connecting cables between the demarcation device and radio. Extra cables and connectors do add some cost, but more importantly add points of failure to the system. It adds complexity to installations and potential problems when troubleshooting in the field.

When an unexpected problem occurs in a 2-box system (demarcation + radio), a technician must isolate the problem and work with the vendor to troubleshoot. Having two vendors to coordinate with can drag out repairs, adding cost and potential network downtime to resolve. However, that ability to troubleshoot from the demarcation point can provide additional information to speed the troubleshooting process.

Another disadvantage to the demarcation concept is aesthetics. More cities and municipalities are requiring outdoor equipment to be more aesthetically pleasing. Fewer devices hanging from the strand looks better than a multiple boxes with cables in between.

One concept addressing the problem of multiple connected products is a direct connection where the radio and demarcation are physically attached to each other with virtually unseen power and network connections. This model still isolates the radio from the demarcation, providing the benefits stated previously, but provides the benefits of a single-box solution.

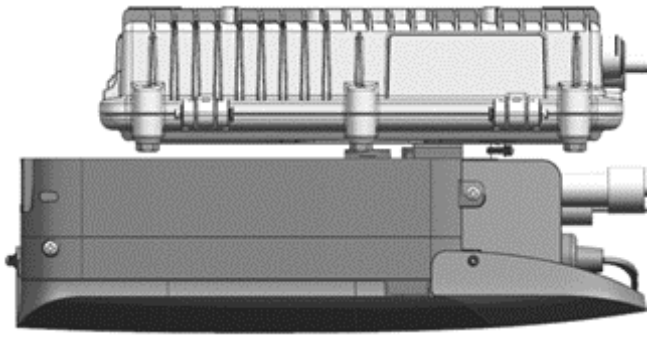

Figure 12 - Demarcation with Radio Attached

5. Local AC Utility Power for Small Cells

While this paper focuses primarily on HFC for small cell power, there are other options broadband operators can leverage.

In rare situations where rooftop power is available from a building where power distribution is managed by an operator, local AC utility power may be the ideal powering solution for small cells if it is the only source available, and if the small cell radio is designed to operate from AC voltage. The benefits are apparent: No time constraints for permits or meter installations, and only incremental monthly power consumption costs. However, the limitations of direct utility power for small cells include limitations around power quality and reliability.

If the availability of the radio is a high priority, or if the radio is designed for DC power, a local power supply should be installed between the utility and radio. A local power supply can condition utility power to remove noise and voltage spikes, and if the radio requires it, convert utility AC voltage to useable DC power. Batteries can also be added to the local solution to facilitate radio availability during utility outages and power disturbance events.

Using local utility power can become a disadvantage if that power is not readily available at or near the radio location.

6. Remote DC Line Power for Small Cells

RLP uses a centralized power hub to deliver DC power long distances over copper pairs to remote locations. The basic design involves converting local utility power to DC, elevating the DC to high voltage for distribution, then lowering the voltage at the delivery point.

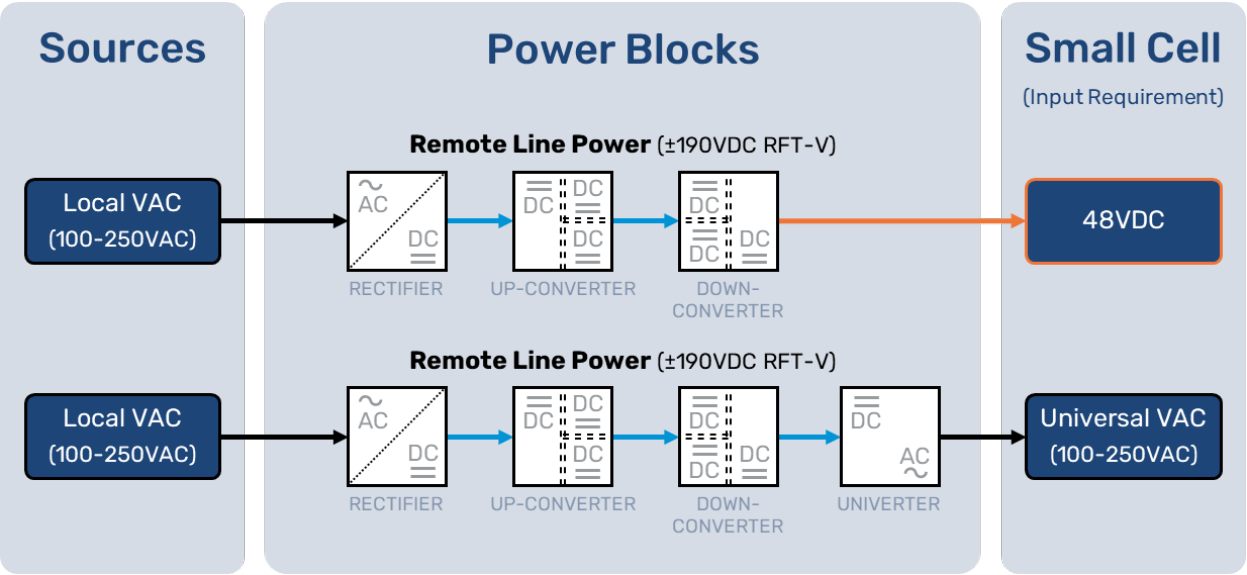

Figure 13 - Remote Line Power for AC or DC Delivery

RLP is a good solution for small cells, especially in green field or locations where other power sources are unavailable. RLP is popular with neutral host providers as it allows them to use existing telephony copper pairs to deliver power in high density areas, eliminating the need for costly construction or meter installations. Advances in this technology supports higher power using fiber and copper pairs, significantly more appealing in cost per node than local AC utility power. The time savings alone can more than justify the use of RLP.

While remote line power is an excellent solution for many use cases there are some limitations and drawbacks. Systems that use existing twisted copper pair may be limited to 100W per circuit. Multiple circuits can be used in parallel but must be aggregated at the small cell site. This aggregation can add more components on the strand for undesirable aesthetics as shown in the figure below.

Figure 14 - Remote Line-Powered Small Cell

7. Conclusion

It's time to bring awareness and identify different solutions to fulfill the objectives around network reliability, wireless connectivity, and corporate management. By highlighting the pain points in deploying small cells we explored three solutions to power small cells: utility power, HFC power and remote line power. We highlighted the benefits of using the HFC infrastructure for low-cost high value connectivity and discussed two methods of deploying small cells over HFC.

HFC certainly provides the cable broadband market with significant advantages in infrastructure availability, not only for small cells, but for any network-enabled product:

- Ubiquitous Broadband & Power Grid
- Accessibility and Scalability
- Reliable source of power
- Physical placement
- High-capacity low-latency backhaul
- Existing well-maintained resource

Hundreds of thousands of outdoor small cells will need to be deployed in the next 5 years to meet 5G demands. Upcoming smart cities, autonomous vehicles and drones will create even more demand for reliable network infrastructure for scaled deployments. Cable broadband operators are well situated to capitalize on these emerging markets.

Software Reliability Engineering

Scaling the Cloud with Automation

A Technical Paper prepared for SCTE by

Brian Gray
Sr. Manager, Software Engineering
Comcast Cable
1800 Arch St., Philadelphia, PA 19103
267.634.5540
Brian_gray@comcast.com

Sriram Ramakrishnan, Principal Architect, Comcast Cable

Fei Wan, Sr. Principal Architect, Comcast Cable

1. Introduction

Operations teams have long functioned under a primary mandate of assuring customers the most solid and uninterrupted experience possible. The recent advent of software reliability engineering (SRE) introduced engineers to the formalized automation of toil, leaving more time for creative problem solving of service interruptions. However, twin issues remain: how to automate a virtualized cloud environment in practice, and how to measure and prioritize repeated tasks to be automated for the greatest impact. In this paper, we offer a case study of the evolution of a complex cloud infrastructure from a state of manual deployment, scaling, failover, and upgrading, to one of push-button control and automated self-management. Driving this evolution is a pair of mathematical tools developed in Comcast's Core Application Platforms (CAP) group that use the financial concepts of "net present value"/NPV and "internal rate of return"/IRR to organize and value automation opportunities simply and objectively.

2. A Look Inside the Elements Deployment Architecture (A Starting Point)

Elements is the internal name of an asynchronous, fast, flexible push notification service which supports both individual and fan-out notifications across such diverse network destinations as outbound web hooks and mobile push notifications. The service is built as a publisher/subscriber (pub-sub) service, in which the senders of the messages, also known as 'Publishers/Producers' are decoupled from the receivers of the messages, called the 'Subscribers/Consumers'.

High Level Architecture

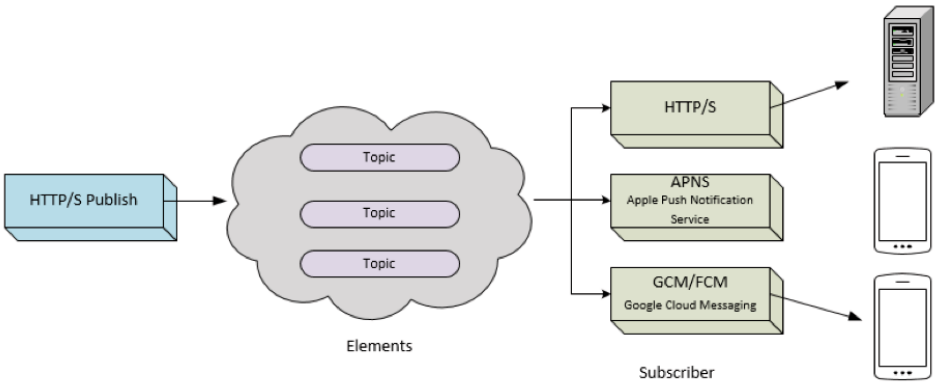

Figure 1 – Elements Architecture Layers

Complicating the equation is the complex requirement to operate across many layers of Comcast's internal network – or the "plant" – to reach destinations such as an X1 set-top box with notifications. Because we need deep access to underlying plant details, we lose out on the option of hosting this particular system in a public cloud like AWS with convenient, high-level facilities to assist our operations. Such a thing would technically be possible in a split-architecture design, using public cloud for pub-sub management, configuration, and global logic, and DirectConnect-ing into a private space that

hosts intelligent routing gateways. That solution, however, introduces many more points of failure, some of which actually lose the ability to report back that a failure happened. To compensate, you would then need **more** complexity to implement a run-time approach on a distributed trace algorithm.

2.1. Challenges

The infrastructure for the solution we maintain therefore runs entirely in our legacy private cloud environment and has many components, including Mesosphere DC/OS for container orchestration, Consul for service discovery, Couchbase for database persistence, and HAProxy for load balancing. Besides these, the system integrates with external Comcast systems for authentication, authorization, secrets management, and observability. As you can see given the complexity of this system, we see immense leverage from following the best practices for SRE. Unfortunately, when we started, we didn't have any such best practices. We were more operations-focused, which is reactive and time intensive, and not following many SRE guidelines.

To give an example, let's suppose we find out that HAProxy CPU usage is ridiculously high and that it's affecting the performance of our application. The extant tools we have available are Ansible – a simple IT automation facility – configured via "playbooks", and the HAProxy configuration schema. One option, then, is to check the config and verify if the value for nbproc is set > 1, where nbproc is an HAProxy configuration key that allows the proxy to spin up multiple processes. To change this config, since it's an emergency, we would create a one-time playbook with this HAProxy config and push the changes to our proxy servers. Once the change has been pushed, we would do a manual rolling restart of our proxy servers.

Obviously, there are multiple things wrong here. This change leads to inconsistent configuration, having no testing or automation. Also, this one-time run causes changes not to be source-controlled in GitHub, team-members might not be aware of this change, and there is no source-of-truth for the configuration. Beyond all these issues, time is critical: time we did spend on manual changes or figuring out who made the change. For all teams, but especially small teams like ours, time is the most valuable resource, and we really need to perform efficiently.

Another instance is a routine scaling of the database processing instances in our Couchbase infrastructure. If we wanted to increase the size of our cluster, we used Terraform (TF) to create the virtual machines (VMs) from the legacy cloud console and performed the configuration for adding this new Couchbase node to the cluster. Obviously, many things are wrong here, as well: No automation, lots of opportunities for failures, and no consistent way to scale the infrastructure.

In summary, these are the challenges we faced, which ultimately affected us as a team, and applications we maintain:

- Lack of automation
- Lack of Testing
- Inconsistent Configuration
- One-Off runs with Ansible
- No continuous integration & continuous deployment (CI/CD)

3. The Elements End State

3.1. Improved Configuration Management

The Elements end state continues to leverage Ansible as the configuration management tool. It's a useful tool that allows the declarative specification of your Infrastructure as Code (IaC), and having Ansible enables us to make changes to the configuration in a more consistent fashion. But we still run into the issue of one-time runs. Teams were making changes to the infrastructure by making one-time runs through Ansible. There are couple of issues with this approach:

- Changes are not shared with the other team members, and others might not know what has changed in the infrastructure.
- There is no single source of truth.

We really wanted to avoid this scenario and the only way to achieve that was to ensure teams follow the guidelines in making Ansible changes:

- All Ansible playbook changes needs to be in source control.
- Changes to playbooks must be done through Pull Requests (PRs) and can be merged only once review is completed by peers.

The obvious downside is changes might take time to be deployed, and reviews might take longer. We tried to reduce review times by pairing once a week (preferably after scrum) and approving the PR's. Remember, this process takes time and discipline among team members. But, in the long term, this helped us to have a predictable and consistent infrastructure that's easier to maintain.

3.2. Infrastructure Testing

Consider our scenario where we need to scale our Couchbase cluster. We don't have any consistent way to test our infrastructure, and we need one to test our Terraform, Packer and Ansible playbooks. Terratest is a Golang library that provides patterns and functions for testing the infrastructure built through Terraform. We baked Couchbase and all other standard tools into an image, which we created using Packer. Terratest can test the build of this image as well. Once the image has been built, Terraform will use those image IDs to build the Couchbase infrastructure. Ansible can be used to configure additional changes. Inspec is used to Test Ansible playbooks. Inspec is an open-source auditing and automated testing framework to describe and test for regulatory concerns, recommendations, or requirements. See Figure 1 – Elements Architecture Layers

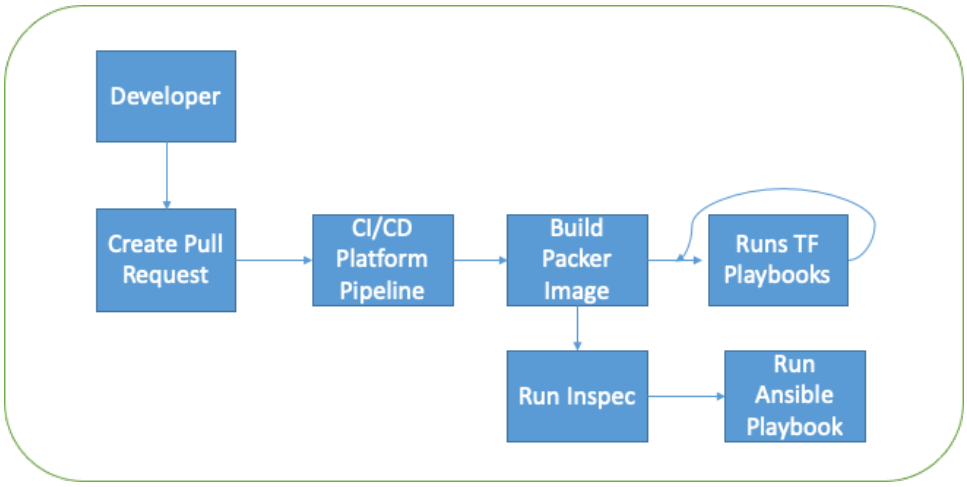

Figure 2 – PR -> Pipeline -> Playbook Process

Developing Terraform tests using Terratest requires Golang skills. This is not an insurmountable barrier, but some learning is needed. Inspec is more human-readable and might be easier for teams to learn.

Software infrastructure testing takes process, organization, and discipline, but will pay-off in long-term.

Just having testing is not enough, however; we needed an automated way to trigger these tests. That's where we decided to follow CI/CD guidelines for our infrastructure playbooks.

3.3. Continuous Integration and Deployment

This is where we really dig into the application of software development best practices to infrastructure code. These follow a couple of simple guidelines:

- All infrastructure code, including Terraform, Packer and Ansible playbooks, is in our source-control GitHub Enterprise repository.
- Any changes to the playbooks go through a PR process and, we have branch protection enabled to avoid direct merging into main. All PRs require at least 1 approving review.

It's good practice to have custom, application-specific templates for creating issues and PRs. For every PR that gets created, we have our CI pipeline that validates the syntactical correctness of the playbook, validates the format (using Terraform fmt for Terraform playbooks and Ansible lint for Ansible playbooks), and runs the test. We run automated tests in an environment that's totally separate from production for Terraform playbooks. We create all the resources (servers, load balancers, machine images) using namespaces with a unique name, to ensure that we don't accidentally overwrite any "production" resources in that environment and accidentally clash with other tests running in parallel. We ensure the tests always clean up after themselves, so we don't leave a series of zombie resources lying around untracked. Most times, we can anticipate the time taken for our tests and will stay within the default limits. But on occasion we might have to increase those timeouts.

Once PR builds are successful and review is complete, PRs can be merged into the main branch. In our case of scaling the Couchbase cluster, it's as simple as modifying the Terraform playbook to increase the number of instances. All changes get propagated or deployed to a lower environment automatically as they merge to main. But we don't do automatic deployment to production environments. We follow a

release-based, gated model to ensure we validate the infrastructure job was successful before we proceed to production.

4. Lessons Learned from the End State and the Path Forward

Configuration management, automated testing, and continuous integration are the key building blocks of a SRE approach to software reliability. The operations tasks required to ensure optimal uptime, performance, scalability, redundancy, and observability can overwhelm any team, but also can often be reduced to logical procedures: the very things where programming shines as a solution!

By leveraging a team's abilities as programmers, they can analyze a process (for example adding nodes to a database cluster), reduce that process to a task in the form of code, and have a pipeline trigger that task either in response to identified and alerted criteria, or else on demand, when a human merges a PR that changes the configuration. Thus do we address the primary culprit costing the team time and resources: toil.

5. SRE, and the Plight Thereof

As an SRE team, we spend a great deal of our capacity on automation of toil (in a rather circular definition, toil can be thought of as work that can be automated). You could say it's this very thing that most distinguishes an SRE team from a DevOps team. We see an opportunity, where we're doing work by hand, over and over, and look for ways to write code to do that work for us. Then we iterate to find the next most insistent itch to scratch.

This kind of ad-hoc, subjective process works well enough and can be great for morale. I mean, who wouldn't want to throw themself into automating away their personal bugaboo? So, let's assume we allow engineers to retain that flexibility. What else can we do to optimize our selection and evaluation of automation opportunities? Turns out we can get some help with tools invented for use in evaluating financial investments. Not only do these tools assist us in decision-making, but they can also act as indicators to report the real leading and lagging value of the SRE team to its parent organization.

6. The Financial Side

You know that thing you're an expert in? And then they make a movie about that thing, and you complain about all the ways they get it wrong? That's what this section will read like to financial experts. The situation here is simply that an engineering team with a need to formalize and quantify the priority of the automation work described above found a useful tool for doing exactly that, so – disclaimer provided – let's just dive in without checking the depth…

6.1. What Is Net Present Value?

Put simply, Net Present Value (NPV) is the amount a potential investment is worth today, including all outgoing costs, all incoming returns, and discounting each number to account for the time value of money.

What is the time value of money then? It's a formalization of the concept that money now is worth more than the same amount of money later. Sure, $100 is literally worth more now than $100 will be in ten years, because of inflation. But in addition to that, $100 in 2021 dollars is worth more now than $100 in 2021 dollars will be in 2031, in part because the ten years in the middle give you more options for what to do with the money.

To calculate the NPV of a proposal, you first need to decide what rate to assign to this time value. This is called the discount rate. When a person wins the lottery and is given the option of taking $X now or $Y/year for 30 years, the "now" value is calculated by applying the discount rate – for Powerball, 4% – to each payment's amounts and summing them to yield an NPV.

How is the discount rate figured? The simplest way is to determine the best low-risk investment available as an alternative to whatever else you may be thinking of doing with the money. For regular people, maybe this is a high-yield money market or bond fund. For a business that tracks metrics, it could be the return on marginal advertising dollars or scaling up workforce to accommodate more service delivery. Something you have control over and could throw money at. For the purposes of this discussion, we're conflating discount rate and "cost of capital" here. For a full treatment of the difference between them, review Cost of Capital vs. Discount Rate: What's the Difference?, but very briefly and inexactly, we can imagine that cost of capital is the real-world stuff above (advertising ROI, etc.), and discount rate is what it's called when it assumes the form of a number used in a mathematical formula.

Anyway, each time money changes hands, the present value of that transaction is calculated as:

$$\frac{R_t}{(1+i)^t}$$

Figure 3 – Present Value of a Single Event

…in which R_t is the cash flow (positive or negative) at the time of the event, i is the assigned discount rate, and t is the amount of time in the future the event takes place. To get the NPV of an entire series of events including the initial expenditure, we simply sum up all discrete events:

$$\mathrm{NPV}(i, N) = \sum_{t=0}^{N} \frac{R_t}{(1+i)^t}$$

Figure 4 – Net Present Value of a Series of Events

This result is a scalar value, in dollars, representing the magnitude of value that the project will net in excess of the discount rate over its lifetime. In other words, how much better or worse this investment is than going the risk-free route.

In the case of the lottery? Look into long-term equity or debt investments and see if you can find anything that beats 4%. It is for this reason that winners are advised to take the lump sum and invest initially in an index fund while figuring out better options. Historically, the average of the market as a whole has generated ~10% returns over the long term, minus inflation. The lump sum is far greater than the true NPV of the long-term payments because the discount rate applied to the winnings is so low.

6.2. What Is Internal Rate of Return?

Internal rate of return (IRR) is a fascinating inversion of NPV, which manages to factor out the discount rate. Thus, you're not concerning yourself with inflation, the risk-free investment alternatives, or cost of capital, only the factors internal to the investment. It does this by taking the NPV formula, setting the answer to 0, and solving for the discount rate:

$$\mathrm{NPV} = \sum_{n=0}^{N} \frac{C_n}{(1+r)^n} = 0$$

Figure 5 – Internal Rate of Return Formula

The mechanics of how to solve this are not at all easy or straightforward, so we'll gloss over them in favor of just using built-in Excel formulae. For a treatment of numerical methods to solve for IRR, start here.

The result is the discount rate at which this investment would yield no NPV. How is this useful? By itself, it is not. That is to say, in order to make use of the discount rate in an NPV calculation, it needs to have a real-world investment to compare against or you're just guessing. On the other hand, when you compare the IRR to other potential investments, it makes for a wonderful way to rank them by pure return percentage internal to the investment itself. So, to start, you can say, "Who cares what my cost of capital is? Investment #5 shows the highest IRR of all my options."

When combined with cost of capital though, you can first prune out those non-starters whose IRRs do not exceed it.

6.3. Which One Is Better?

The attempt to answer this question is effectively an attempt to decrease the number of tools you have at your disposal. It can be comforting to have and know your hammer and treat everything like a nail, but you become more effective when you learn about screwdrivers as well. As for IRR and NPV, they both have their place because they both describe very different viewpoints on your investment options:

- IRR gives you the rate of return but says nothing about the scale of the investment.
- NPV gives you the total value of the investment but gives no perspective on how quickly you recoup your initial layout.

An easy example is a pair of investments, one of which gives you an IRR of 25% over 2 years, returning $50,000 NPV. Another sustains a 20% IRR over 10 years and yields $200,000 NPV. The first option is a higher rate of return and gives control of your original investment back sooner, allowing reinvestment in year 3. The other locks in a $200,000 NPV investment and allows you to be hands off for 10 years. Are you sure you're going to have a >20% IRR option 2 years from now? What would a likely 10-year portfolio starting with the 25% investment look like, and would it compare favorably or unfavorably with a static 20%?

So, it pays to calculate both and use your own judgement to decide which investments to fund, depending on your risk acceptance, your demand for flexibility, and your list of known options.

7. Factoring out Dollars

Now that we've covered the financials, let's throw away the dollar signs. These calculations are great mathematical tools to leverage, but we're not here to talk about money. We're here to talk about time, so what happens when we change all our units to units of time?

I don't know if you noticed, but the IRR calculation placed $0 on the left, canceling out the R_t (expressed in dollars) on the right. The resulting percentage rate is unitless, indicating that we could use anything as the original units: potatoes, rainbows… or time. If you invest 40 hours of work automating a task, so that now there are 4 hours of work per month you don't have to do anymore, the formula works exactly as if you were investing money.

IRR doesn't care about units. Time works identically to money and gives you useful, sortable results.

Bam, done. We can go home now.

7.1. What about NPV?

Now this value does have units, namely dollars. And because it does, we must re-assess the validity of one of our concepts: the time value of money. If we're to switch our units to time, what does it mean to refer to the "time value of time"? Conceptually, we need to resolve the premise that time now is more valuable than time later. Is it?

This could be argued both ways. Let's say you have 2 weeks of vacation, and further that these weeks can rollover year over year until whenever you wish to use them. Maybe there is more value in using them now; after all, you could be dead in a year. But then Universal keeps opening exciting new theme parks. What if in 2 years they add a Jurassic Park Cruise where the room stewards dress as raptors and you have a port of call on Isla Sorna, and you could have gone had you not used the 2 weeks on Orlando? Decisions, decisions.

This 100% sounds like the kind of thing I'd have written a thesis on in school, and they'd have been all, "this is interesting, but it's not economics until it's quantified", but I'm not going to do that here. All that we need to recognize here is that you're going to have to make your own decision and assign your own value to the NPV discount rate (and it's ok for that value to be negative). Just take the time to think through your situation and come up with a value that makes sense for the priorities of your organization.

Ask your executives, and you'll likely hear that they'd rather realize a return on time sooner than later, because executives tend to keep an eye on mitigating risk. A project that completes sooner decreases risk because it represents a shippable, (possibly) revenue generating asset. If it succeeds, those revenues kick in sooner, leading to them literally being worth more due to the time value of money concepts discussed above. If it fails, the company takes the loss but has stopped pouring money into development sooner. Either way, there is a strategic net benefit to software leaders to apply a positive time value of time in calculating the NPV of potential automation efforts.

Once you've decided on a reasonable discount rate, NPV can work just fine using time as its unit of measurement. Exercise care assuming this extends to rainbows.

8. The Evaluation Process

The process is quite straightforward, given a step #0: create a spreadsheet that calculates IRR and NPV based on initial investment, with slots to input expected hours returned at various dates in the next 3

years. Why 3 years? That's arbitrary. You can extend it to 5 or 8 or whatever, but in CAP's technical sphere, rare is the infrastructure script that can be expected to survive more than 3 years of re-architecture. Once you've replaced your EC2 cluster with Fargate, or started managing Kubernetes with GKE, your carefully written scripts to resize, rehydrate, or redeploy are of no use. So, given you have a spreadsheet, the process is:

1. Do a task the first time, and remember you did it
2. Notice that a task is toil, by virtue of having to do it a second time
3. Record how long it takes to do it by hand
4. Mentally break down the process into automatable chunks
5. Estimate how many dev-hours would go into coding the automation, along with how often and when this toil would have to be done in the future
6. Enter #5 into the spreadsheet (as a negative value), and #3 whenever you expect to have toil replaced by automation in the future (accounting for the fact that until the automation is complete, you'll still have to do it by hand)

That's all you need to document the opportunity, which you will do in the "Data" tab as illustrated below in Figure 7. Then whenever you get capacity to do some automating, pull up the spreadsheet, sort by IRR, NPV, and Breakeven time, and compare the top few of each to find a combination you like. Maybe you only have a couple weeks until a larger project hits, so you take a smaller automation task with a high IRR. Maybe you've got a lull and a lot of time to do something big, so you shoot for high NPV.

Let's look at a sample spreadsheet. Here's what tab 1 – "Dashboard" – looks like:

Opportunity Name	IRR	NPV (hrs)	Breakeven	Idx
OpenStack Usage Accounting	-49.40%	(37.57)	Never	1
xCloud Usage Accounting	56.24%	69.35	Jan 2022	2
Big Good Project	35.71%	590.14	May 2022	3
Small Borderline Project	11.23%	0.75	Mar 2023	4
Medium Good Project	23.38%	58.42	Mar 2023	5
Big Bad Project	1.39%	(426.32)	Never	6
Doesn't Even Make Back Investment	-19.40%	(197.74)	Never	7

Figure 6 – Example IRR/NPV Dashboard

These values are calculated based on data entered in a second tab (named "Data") along the guidelines listed above. The first thing to note in the top left corner of tab 2 is the discount rate. We set this to 10% as a first guess as to how much our "time value of time" is, well… valued, and over time and experience we have had no reason to change it. It turned out our instincts about the time value of money for our team were good enough to be useful to our prioritization efforts. Notice also how the larger a project is, the greater the number of empty cells at the start to account for elapsed time spent in implementation:

Discount Rate: 10.00%	Development	Hours of Toil Avoided																			
Opportunity Name	Hours (Month 0)	Year 1												Year 2							
		1	2	3	4	5	6	7	8	9	10	11	12	1	2	3	4	5	6	7	8
OpenStack Usage Accounting	-100		6	6	6	6	6	6	6	6	6	6	6								
xCloud Usage Accounting	-100				6	6	6	6	6	6	6	6	6	6	6	6	6	6	6	6	6
Big Good Project	-1600			75	75	75	75	75	75	75	75	75	75	75	75	75	75	75	75	75	75
Small Borderline Project	-40						8						8						8		
Medium Good Project	-240												120								
Big Bad Project	-2800													120	120	120	120	120	120	120	120
Doesn't Even Make Back Investment	-480				10	10	10	10	10	10	10	10	10	10	10	10	10	10	10	10	10

Figure 7 – Example IRR/NPV Data Input Tab

Something to think about here is the difference between "Big Good Project" and "Big Bad Project". The returns (120h/mo vs 75h/mo) basically scale with the investment (2800h vs 1600h), and so if one is good, it stands to reason so is the other. The difference here that sets them apart is calendar time to complete. Big Good Project completes in 2 months, whereas Big Bad Project – at less than twice the number of required hours – takes a year. In real-world terms, what we're looking at here is the difference between a team of specialists, and a team that has cross-trained. Big Good Project is done by a full team made up of engineers all qualified to work this particular effort, and so can break it up and work in parallel. Big Bad Project is executed by a team in which only one or two engineers is qualified for this work, so it takes longer. But in each case, the applicability of the technology is still valid for only 3 years from inception, so the time to develop eats into the return.

To convert the raw data entered in tab 2 into the easily readable and sortable dashboard in tab 1, we need some Excel magic. We mentioned above that Excel offers built-in IRR and NPV formulae, which means we can skip the numerical methods for calculation and do this is a way that is accessible to the average engineer. Take a look at the formula for IRR in the first row of the dashboard:

```
=IF(Data!C4 <> "", XIRR(Data!C4:AM4, Months!$A$1:$A$37), "")
```

A sharp eye will notice that there is a third tab we have not yet mentioned. This 3rd tab, named "Months", is a simple, static list by row of dates representing the first day of each of the next 36 months. This allows us to drive our calculations by date. The XIRR function supplied by Excel takes the data from the "Data" tab, applies the dates from the "Months" tab, and calculates all the discounted values, sums them up, and solves for 0. The final piece to the formula is that "IF" at the beginning that simply allows us to show an empty cell if the data is not found, rather than a confusing internal error message.

The NPV cell is extremely similar in its formula:

```
=IF(Data!C4 <> "", XNPV(Data!$B$1, IF(ISNUMBER(Data!C4:AM4),Data!C4:AM4, 0),
Months!$A$1:$A$37), "")
```

Within the same basic structure, we now use the XNPV function, which requires the discount rate (from Data!$B$1), our effort data, and the months, plus the requisite embedded IFs to account for any possible missing information.

Getting back to the dashboard as a holistic entity, the first two rows (sorted by "Index" order, the order entered in the Data tab) represent a real case documented by the process above. We had to audit our usage of cloud resources and would have had to every month for the foreseeable future. We recorded time during the task, and it came out to 6 hours. A rough estimate of the time needed to automate the task came to 2½ weeks of work for one person.

Another bit of information that must be considered is that cloud teams sometimes migrate from one private cloud platform to another. The old system gets named after the legacy software on which it is based. The new system uses an internally branded codename, in our case "xCloud", and with a phased "go live" schedule that deprecates the old platform as hardware is shifted over.

Now at first glance that seems like a big investment: 2½ weeks to code something that only saves 6 hours a month. Which is exactly why we do this mathematically. This example, when applied to xCloud usage happens to provide the largest return on the sheet, at an IRR of 56.24%! By anyone's standards that would be a great candidate for a project to undertake. On the other hand, if we use the same effort to automate

legacy cloud usage, we see that it's a non-starter due to the limited lifespan of the solution. Because we will only (generously) get a year of use out of the automation attributable to migrating off of the platform, we never make back the time investment.

At other places in the sheet, you can see examples of good projects, projects right on the border with NPV near 0, and a couple that are negative, but that highlight the difference between IRR and NPV. "Big Bad Project" has a positive IRR – though less than the discount rate – but a hugely negative NPV. We'd technically end up saving time on it, but at the cost of missing out on a whole lot of better options along the way. "Doesn't Even Make Back Investment" is a loser from the start with a negative IRR, though overall it loses far less than "Big Bad Project".

9. Example

Taking as an example the case of xCloud Usage Accounting, we can walk through this process:

1. The team's VP has requested an accounting of how much we are spending in operational expenses for the cloud resources we use in the Elements project. We need to break this down into categories for compute, storage, network, etc. The work is manual but assisted by an internal web interface.
2. For the second consecutive month, the same request arrives to collect usage data. The work is done manually again but flagged for automation.
3. We record that the task required 6 hours of work to complete manually.
4. The internal tool has an application programming interface (API) that provides programmatic access to the categories we need to create this monthly report. We determine that we can write a script that queries each category we need information on, merge for each component by category, and assemble the data into a simple report of use at an executive level.
5. The work is estimated to require 100 developer-hours, which we can schedule over the course of 3 months based on our capacity as a team.
6. We open the spreadsheet to the "Data" tab. -100 is entered in the column for "Development Hours" to account for the time to automate. 3 months are skipped to account for elapsed calendar time spent developing, and 6 is entered in each month thereafter to realize returns on our investment from month 4 to the end of year 3.

Flipping back to the "Dashboard" tab, the information has been instantly calculated to yield an IRR of 56.24% and a NPV of 69.35 hours.

10. Conclusion

The basic concept of using data to support business decision making is hardly groundbreaking. We use various graphs and equations in the preparation of business cases, project performance reports, and managerial accounting as just a few examples. The higher levels of corporations are filled with Masters of Business Administration (MBAs) and other people comfortable speaking in finance as a second language, but often this perspective does not filter down to those closer to everyday decision making.

This paper presented a complicated, manually-operated system of interconnected dependencies and walked through a breakdown of the automation it took to render it into a self-managing entity. We also discussed one method of leveraging established financial models, at the individual task level, to yield a simple, plug-and-play tool for prioritizing toil automation.

It could be argued that the most valuable part of all of this is establishing a pattern of discipline to collect and organize the data (steps #1-5 of "The Evaluation Process"). Go ahead and edit your user story template to add pre-filled acceptance criteria with entries for:

1. Elapsed time spent on the task
2. The automation effort estimate

…and you're most of the way there.

Abbreviations

API	Application Programming Interface
CAP	Core Application Platforms
CI/CD	Continuous Integration / Continuous Deployment
CPU	Central Processing Unit
DC/OS	Distributed Cloud Operating System
IaC	Infrastructure as Code
IRR	Internal Rate of Return
MBA	Master of Business Administration
NPV	Net Present Value
PR	Pull Request
Pub-sub	publish/subscribe
SRE	Service Reliability Engineering
TF	Terraform
VM	Virtual Machine

Solving The Mysteries of the Distributed Access Architecture

A Technical Paper prepared for SCTE by

Matthew Stehman

Robert_Gaydos@comcast.com

As the benefits of a distributed access architecture (DAA) continue to be seen from real world applications, Comcast is continuing to convert its analog cable modem termination systems (CMTSs) to virtualized CMTSs (vCMTS). The new technology of DAA not only allows for increased performance of the network with the switch to all-digital components, but also increased visibility with more sophisticated real-time telemetry. The DAA framework emits high fidelity telemetry data from many components, from the primary headend to the customer premises equipment (CPE). The scale of our DAA footprint is growing rapidly, and it is no longer feasible for humans to monitor all of the raw telemetry data and identify patterns of interest and issues. This paper introduces a computational framework and analysis methodology for automated monitoring and alerting for events of interest.

With analog CMTSs, telemetry data is acquired via polling MIBs from the CMTS OS, typically hourly and even down to five-minute intervals in some cases. Our vCMTS implementation has a dedicated telemetry core that constantly emits and writes all telemetry data at 15 second intervals to a time series database, so the real-time data can easily be acquired and analyzed by the DAA team. Each vCMTS captures thousands of telemetry streams, comprising over 1 billion samples per day from a single physical server, which houses many vCMTS cores. With this volume of data, we needed a telemetry analysis tool that could make sense of the data in its current form and continue scale up with DAA in the coming years. Comcast is currently developing a tool for this purpose, internally named “Sherlock.”

The name isn’t entirely coincidental. As the title of this paper implies, the very act of distributing an access architecture tends to uncover many infrastructural mysteries that could benefit from a sleuth. Some relate to the huge amount of data that flows in every 15 seconds from the thousands of broadband-foundational components within our physical infrastructure. The upstream signal path in particular is a trove of noise-related anomalies, as one example referenced within this paper illustrates. It represents an excellent network segment to expose to machine learning (ML) – which thrives on large amounts of data.

While the DAA telemetry covers most of the active components in the network, there are external tools and data that can significantly enhance the capabilities of Sherlock. As such, Sherlock interfaces with other systems such as: customer contact, automated support tickets, existing performance metric tools, etc. The core component of Sherlock is its ability to interface with a wide variety of data sources and create a single, time-aligned view of the entire system for analysis.

Once the single, time-aligned view of DAA is created, event identification and alerting can be implemented. Initially, logic-based event tagging is implemented based on common thresholds for events like partial service, plant-based noise as well as system statuses such as DAA cores offline, remote PHY device (RPD) reboots, and CPE connectivity. Once these events are determined, analytics can be performed to evaluate the frequency and severity of events. Using the event statistics, rankings are created to support the DAA team in prioritizing issues to address as well as keep track of persistent issues. The analysis and rankings are performed at different levels of aggregation: RPD, physical server, site and even division and national.

Future research utilizing the core functionality of the tool includes advanced ML techniques to find patterns/events outside of the standard events identified from traditional logic-based checks. This paper introduces several active research areas in ML in the DAA space. An overview of the architecture is introduced, and an example is discussed.

The development of this tool has had a large impact on the successful deployment of DAA in Comcast's footprint. A sample of example findings from Sherlock is discussed as well.

1. Overview of DAA Telemetry

Remote PHY (R-PHY) has taken hold as the technology of choice for deployment of DAA solutions. The concept of a distributed architecture decreases the amount of equipment that traditionally sits in a cable headend and then connects via hybrid fiber/coax (HFC) to neighborhoods and eventually to customer homes. DAA moves the PHY, or physical RF layer, closer to the user by deploying RPD-equipped R-PHY nodes that sit on the access edge of the network. DAA allows for higher speeds to the end-user because it uses digital fiber optics in place of legacy analog optics. Digital fiber links improve signal quality and support higher modulation orders. DAA also offers operational savings related to the cost of headend equipment, power and more, as small hub sites or curbside equipment act as the PHY layer of the network.

vCMTS technology enables us to shift to a DAA by disaggregating the CMTS. It also allows us to move to IP-based connectivity and converge voice and data services with video and other legacy services, with an added benefit of no longer needing to manage and maintain traditional, bulky CMTS gear.

The transition from legacy hardware to a distributed server-based architecture that can run external software applications allows Comcast extreme visibility into the DAA platform. The scalability and openness of DAA means the platform can now support applications such as real time telemetry streaming that would have been too demanding to run on legacy CMTSs. The DAA system is rich in telemetry, where individual components within the network transmit data as frequently as every 15 seconds to indicate the health of system/network. Mining DAA telemetry data to identify and detect issues in the network that could potentially lead to bad customer service is not only challenging but also involves combing through a lot of existing tools and data sets to build a smart access network.

1.1. Problem Statement

As we scale our DAA deployment to thousands of digital nodes and hundreds of vCMTSs and sites in the next few years, we anticipate operational challenges. Among them, monitoring and going through all telemetry data points to determine system health, and correlating the impact of one component in the architecture to the other key components, while identifying impairments proactively, before customers are affected.

Sherlock is a tool designed to address those challenges by looking at all the relevant metrics, creating a time-aligned view at the most granular level, scoring the health of the system, and identifying root cause of issues. It also proactively identifies anomalous patterns that lead to poor system performance. The goal of Sherlock is to analyze and identify patterns of impairments and rank them based on several criteria, that are outlined in Section 4.

1.2. DAA Topology and Telemetry

As mentioned previously, the DAA architecture offers rich telemetry, from the headend all the way to the CPE. A simplified representation of the telemetry coverage across the DAA topology is show in Figure 1. A variety of telemetry metrics are reported across the topology, ranging from system statuses to traffic and even HW/SW versions of the RPDs.

In our topology, the primary headend houses the core servers and provides statuses of the principal and auxiliary cores for global system health. The primary headend comprises multiple PPODs, or physical

point of deployments. A PPOD is a cluster of servers running the necessary services to operate the connected RPDs. The PPOD the connects to a set of DAAS (distributed access architecture switches) that transfer data to and from the RPDs. The primary core or GCPP, for Generic Control Protocol Principal, provides containerized services for automating deployments, managing applications, the initial authentication of the RPDs, and configuring RPD features and video services. The principal core does not provide any services (video or data).

The GCPP core performs the following three primary functions:

- Initial authentication of the RPD.
- Initial configuration of the RPD, including the list of cores to which it connects and the resources that those other cores will configure.
- Configuration of the multicast sources that the RPD uses to populate QAM video (broadcast and narrowcast) channels. The GCPP allows integrating videos on a standardized, single video platform.

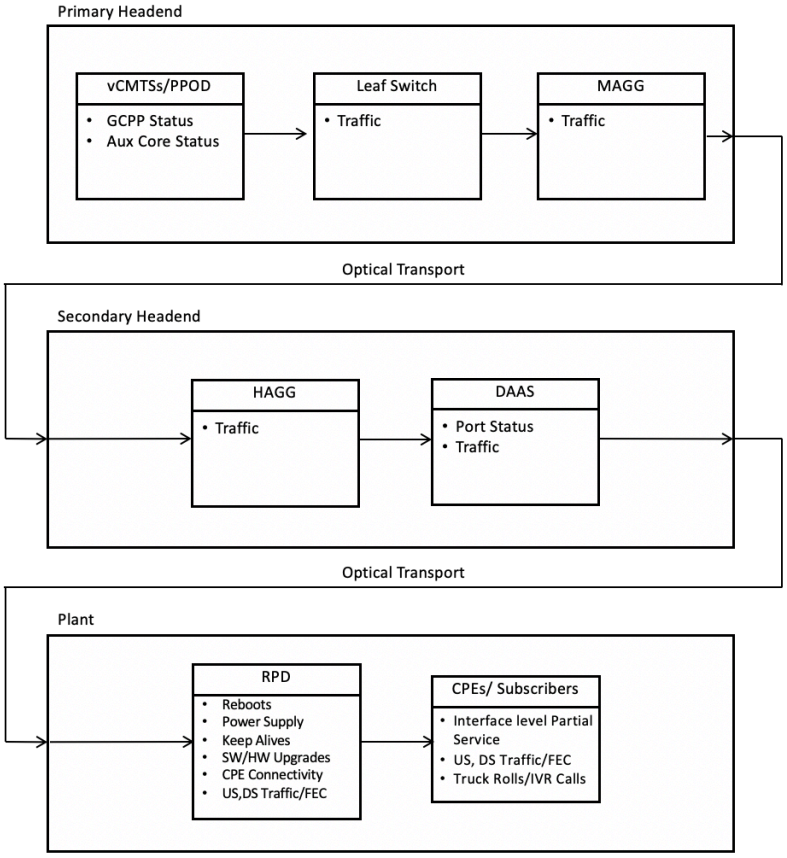

Figure 1 - DAA Topology Metrics Overview

The auxiliary core or GCP (generic control plane) is the second of the two main control planes within DAA architecture: The GCP, which sets up a control plane tunnel over a generic transport protocol such as TCP or UDP. GCP is used to program the R-PHY system upstream and downstream parameters from

the CMTS. It is also used to control the R-PHY system, thus if the AUX core is offline, no data can flow to/from the RPDs.

The secondary headend houses a variety of switches that prepare and breakout the signals prior to sending/receiving data from the RPDs. The main switch type of interest is the DAAS (distributed access architecture switch), which aggregates 10 Gbps connections to remote nodes. The DAAS switches report connection statuses which show the heath of the connection from the fiber port on the switch to the RPD.

In the plant region of the DAA topology, RPD metrics include RPD meta information, interface traffic and even CPE-level information. Having telemetry in different regions of the network topology allows for easier identification of where in the topology an issue may have originated. Table 1 includes more detail of the main metrics that are collected from the DAA network. These metrics were chosen through discussions with DAA experts as well as iterative exploratory data analyses during the initial development phases. These metrics, while not exhaustive, cover the key aspects of system/network health as well as customer experience. The list of metrics is continuing to grow as Sherlock is used in the development and deployment of DAA.

Table 1 - List of Metrics

Metric Type	Metric	Description
Platform Status	GCPP Status	GCPP Status captures the state of the Global Control Primary Plane and indicates if it is operational, offline or initializing
	Aux/GCP Core Status	The Aux Core Provides HSD services and the status indicates if it is online, offline or being configured
Network Status	Keep Alives	Keep Alives track the status of the TCP network connection between the principal cores and the switch interfaces
Hardware	RPD Reboots	Details about RPD reboots such as a reason for reboot, type and recovery time
	DAAS Port Status	DAAS port status captures the status of the DAAS switches located in the secondary headend
Traffic	Device, RPD, Routers-US and DS Traffic	Upstream and Downstream traffic is collected from various components from PPOD to CPE
Device Status	CPE Registration	Registration status captures the CPE devices attempts to pair with the vCMTS that must happened every 30s as dictated by the DOCSIS specifications
	US/DS Bonding Status	Bonding Status for each US/DS interface per CPE device is captured
FEC	Corrected and Uncorrected Codewords	CCW and UCCW are collected at device and interface levels. These can be an indicator of impairments within the plant/faulty modems that need to be proactively identified and addressed
Customer Contact	Truck Rolls, IVR Calls	Truck Rolls and IVR Calls capture customer contacts and are key metrics used within Comcast to measure operational efficiency

Originally, we were focused on finding metrics that correlated with trouble calls/truck rolls, since customer-facing technician appointments were thought to be a good indicator of system health issues.

However, it was found that trouble calls were highly sporadic, because of inherent human aspects, e.g., different tolerances to service interruptions and when calls happen relative to an issue. After exploring the customer-facing aspects, it was determined that Sherlock should focus on the engineering side of the DAA data and let the data drive the insights. Customer contact and technician visits are still evaluated, since those are valid indicators of issues, albeit not as straightforward to identify as data that comes directly from the system data itself.

1.3. Need for Data Aggregation

DAA telemetry has several dimensions, such as frequency of data, type of data (event-based and telemetry-based), the level at which telemetry is captured (device, RPD, PPOD, etc.), and traffic direction (downstream and upstream). This makes it challenging for a tool to thoroughly mine, to provide views at different levels in the network that help identify the health of the system, or identify areas of problem spots in the network.

In addition to the multi-dimensionality, data is transmitted and stored at different locations, which creates the need for a central data repository. As well, standardization of the data elements across different time intervals is needed, so as to have the data accessible for analysis and modeling while minimizing data transfer and storage costs.

To solve the problems stated in Section 2.1 as efficiently as possible, identification of the common components across DAA and outside data logs would enable the aggregation of information in either signal direction and still get the desired visibility of network health and customer experience. Considering the current DAA architecture, aggregating telemetry data points at the RPD level would enable us to focus on a specific RPD and its associated cable modems, or aggregate it to PPOD/site/vendor level. Aggregating at a device level, by contrast, would create millions of rows of data per metric, which would be computationally intensive and would not provide a view that would help operations or the DAA engineering team in understanding network/platform health. Aggregating data at a PPOD level would mask the issues encountered at an RPD level, given the mix of device types, software versions running on the RPD or vendor type.

2. Implementing Sherlock: a Big Data Analysis Architecture for DAA

As discussed, our DAA data is generated from many different components and are stored in a variety of different specialty database systems. The individual systems are customized specifically for the applications. While having compartmentalized data storage solutions for each type of data is simpler from a development and maintenance standpoint, it can make analysis tasks that require several data sources quite cumbersome.

To allow for efficient analysis of all relevant DAA data with minimal manual operations to join, clean and analyze the data, Sherlock was built using a big data analysis architecture. Sherlock has the ability to interface with a variety of existing cloud and on-premise data storage solutions (APIs, SQL databases, Prometheus, AWS), and combine all the relevant data for efficient analysis.

Building a centralized framework to combine all the different data sources, however, is only half the battle. This task is even more challenging considering the growing scale of the DAA data streams. Consider: A typical RPD has thousands of metrics that are stored at 15 second intervals, and each PPOD can link hundreds of RPDs, so, in total, a single PPOD will generate billions of data points a day. Given that we are continuously deploying new vCMTSs, Sherlock needs to be able to scale with the growing DAA footprint and require minimal maintenance. It is easy to see why this operation must be automated,

since it is not feasible to expect a team to manually process data at this scale and frequency. This section discusses the requirements, implementation, and core features of Sherlock.

2.1. Requirements

Sherlock is meant to be used by the DAA deployment and operations teams to actively monitor and address any DAA deployment and operational issues. Thus, the tool must meet the following requirements:

- Full footprint coverage
- Scheduled analysis reports
- Ad hoc analysis abilities
- Fast computation

Those requirements ultimately allow for ML to discover hidden trends and patterns in the data. An overview of the requirements is presented below.

Since the vCMTS deployments are occurring nationwide, Sherlock must be able to analyze data at different levels of aggregation, from a single RPD to a headend and all the way up to the national level. The varying levels of analysis allow experts to not only understand issues with a single RPD but understand if that same issue exists elsewhere and to what extent.

Sherlock should be able to perform automated analyses and generate reports on a schedule so the deployment team can consistently monitor performance. The scheduled runs can be weekly or even daily if needed. The automated runs should produce a concise and consistent output to enable efficient tracking of performance metrics.

Even though scheduled analysis runs are great for consistent summaries of deployment statuses over a known time window, there will inevitably be ad hoc analysis tasks that require a specialized analysis and output. Therefore, Sherlock should also have a manual interface to easily interact with the core data structures and perform a specialized analysis if needed.

Finally, Sherlock must be computationally efficient when performing operations. There is no specific metric for this requirement, but the general motivation is that the computational framework should support the frequency of the scheduled runs in the above requirement. In addition, ad hoc analyses should be able to be completed in a reasonable time frame. That is, if it takes 10 hours to compile the data and prepare an analysis, the tool would not be useful. To allow for efficient interactions and analyses, computational operations should take only a few minutes in general, such that the analyst can stay engaged while working with the data.

2.2. Implementation

Given the requirements listed in Section 3.1, significant effort went into developing Sherlock's implementation, such that all requirements would be met, while still allowing future scaling as DAA continues to grow. The initial stage of development was to become familiar with the data sources, and in this stage, it became very apparent that an advanced solution would be required.

The first implementation attempt was to load the DAA telemetry data with basic Python packages directly via API requests to the DAA time series database. While this was quickest way to start accessing the data and start developing a plan for how the data should be compiled, cleaned, represented, and analyzed, it was not performant enough to meet the design requirements. Using this approach along with standard

Python parallel processing packages, it was taking hours to load a week's worth of data from just a handful of RPDs (representing a very small fraction of Comcast's RPD footprint). It became evident that a more computationally-efficient and robust solution would be required. At this stage, the first implementation was deliberately done at very small scale for exploratory analysis (for determining useful telemetry metrics and experimenting with different processing/visualization methodologies).

Once it was clear what data was important and how it was going to be analyzed, the team designed a production system to meet all the requirements. The diagram of the implementation is shown in Figure 2. The chosen implementation solution utilizes Amazon EC2 (Elastic Compute Cloud) computing resources, which can scale to the meet the needs of a specific task. The source code is written in Apache Spark, which is an open source distributed processing framework specifically for big data. Databricks is used as the resource management system that manages Spark sessions and coordinates the EC2 instances to complete the computation tasks. The raw data is processed and stored in Delta Lakes[1] that are optimized for efficient reading and writing of big data on the distributed Spark framework.

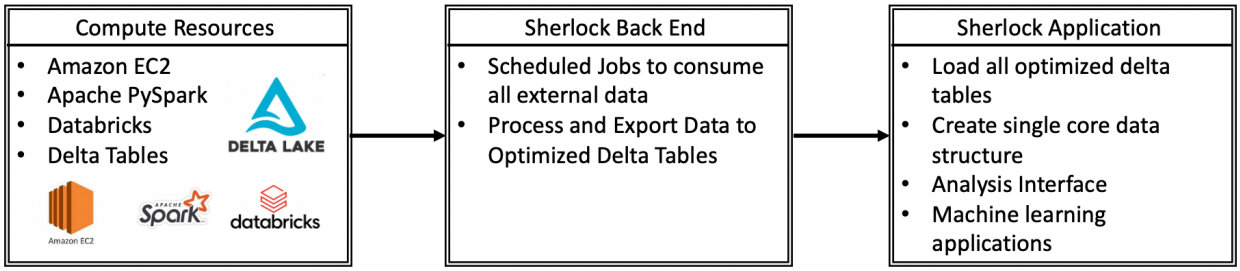

Figure 2 - Sherlock Implementation Diagram

Once the computing and storage frameworks were stood up for use, the data engineering team built the Sherlock backend. It consists of a pipeline of scheduled jobs that consistently read in the raw DAA data from the variety of sources previously discussed, to process them into efficient formats. The resulting data structures are saved to Delta Lakes for efficient access from the main Sherlock application. With the backend responsible for acquiring the data and pre-processing it, the main Sherlock application can then just reference these extremely efficient tables at analysis run time. The main application then uses this centralized data structure to perform a variety of analyses, which are discussed in later sections, as well as to provide the base data set for ML applications. An in-depth discussion about the main features/modules of the Sherlock application can be found in Section 3.3.

Once the end-to-end architecture was developed, the performance against two of the main requirements (full footprint coverage and fast computation) were evaluated. An analysis pipeline, including data loading, processing, event detection and plotting, was run for the entire DAA footprint (representing thousands of RPDs) for a one-week duration. This pipeline finished in less than one hour – the same amount of time it took to merely load 20 RPDs worth with standard Python processes. Similar analyses on subsets of the footprint take less than 20 minutes, and in the future the aim would be to build specialized pseudo-real-time operations that can be performed much quicker (such as real-time event detection with ML). These performance metrics surpass the design requirements discussed earlier. Scalability with the DAA framework also doesn't seem to be a concern at this point, either, due to the scalable and distributed computing framework provided by Databricks and Spark.

[1] Delta Lake "…is an open-source project that enables building what is called a Lakehouse architecture on top of existing storage systems such as S3, ADLS, GCS, and HDFS." For more information, see https://delta.io/

2.3. Features

Sherlock has five modules that handle different aspects of the analysis functionality: core, visualization, event classification, ranking and ML. The breakdown of module responsibilities is shown in Figure 3.

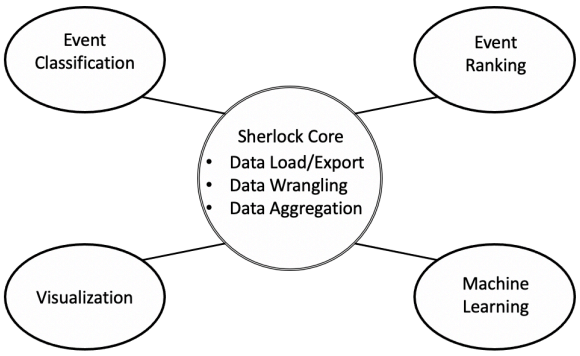

Figure 3 - Diagram of Sherlock Modules

The core module handles most of the data integration, such as loading the data from all the supported sources and converting to a time aligned view for each RPD. The core data structure in Sherlock is a Spark DataFrame with rows for each five-minute timestamp, for every RPD of interest, and columns for all the available metrics. Having the lowest level of aggregation at the RPD level was chosen since this allows for easy aggregation up in higher levels like sites, divisions, vendors, etc., while still being able to meaningfully aggregate CPE-level metrics (for example, upstream transmit and receive power). This core data structure is the foundation for the other modules.

Once the single time aligned view is created, the event classification module identifies events of interest. This module has a fully configurable pipeline that runs through a variety of event detection algorithms and combines the results into a summary table with the event type, start/end times and any other useful metadata about the event. The specifics of the event classification pipeline and logic are discussed in detail in Section 4.1. At this stage, any events identified for individual RPDs are available for use by other modules to support in-depth analyses.

The ranking module uses the events identified from the event classification module to rank the RPDs/sites, from worst to best, and prioritize any issues on the network. The ranking is performed at the RPD level and can thus be aggregated up to other levels as desired. Weights are assigned to each event based on several factors, and the final RPD ranking is the weighted sum over the events for each RPD. The ranking algorithm is discussed in further detail in Section 4.2.

The RPD/site-level rankings are then used to filter down the raw data to regions where there are a lot of interesting characteristics requiring investigation. The visualization module is then used to create charts that highlight the specific areas where the issues occurred. Currently, Sherlock generates plot files on request, given that the project is still in development at this writing (summer 2021). However, once the concept views are finalized, a dashboarding solution with all the views will be stood up to allow for easier access to plots. The two main plot types are RPD timeline and site timeline. An example RPD timeline plot is shown in Figure 6.

The RPD timeline views combine a wide variety of data. Although these plots are currently stand-alone files, they are fully interactive HTML plots. Even though Sherlock is in the development stage and production dashboards are not implemented yet, users of the output significantly benefit from the ability

to zoom/pan on events of interest. Having this ability allows for more productive interactions with the visualizations and serves as a proof of concept (PoC) for production visualization, to gather feedback for the production views. Figure 6a contains the AUX and GCPP core statuses. Figure 6b shows the battery level for the backup power supplies feeding the RPD. Figure 6c displays the CPE status information including counts of devices online/offline, and in different partial service states across the RPD. Figure 6d shows US/DS traffic in the form of total octets transferred, as well as US forward error correction (FEC) percentages (including unerrored codewords [UECWs], corrected codewords [CCWs] and uncorrected codewords [UCCWs]) across all interfaces on the RPD. Figure 6e contains all event-based information, including customer calls, automated alerts, technician repair tickets, and RPD SW/HW updates. Figure 6f contains the DAAS switch status between the RPD and vCMTS core.

Sherlock is the first tool in Comcast to make all this data readily available and digestible in a concise visualization. It is easy to see how powerful this timeline view is, as it allows clear visibility into events across the entire architecture, from vCMTS statuses in the headend all the way to customer experience and contact.

While the RPD view is very useful for deep-diving into specific events affecting areas of the DAA network, it doesn't easily allow for accessing the scale of the event. For example, power outages would likely affect multiple RPDs at time, whereas other issues, like noise ingress, are likely to be very localized. To help visualize and assess the scale of the events across the footprint for a given time window, Sherlock produces event heatmap plots, as shown in Figure 4. This view aggregates the individual RPD levels to the site level. The time dimension is hourly and the heatmap shows the count of RPDs that experienced a specific event in each hour. This type of view allows for a very quick review and determination of how widespread specific issues are across a given aggregation level.

The final module in Sherlock is the ML module, which can utilize the results of the other modules. The ML portion of Sherlock is talked about in detail in Section 6. The main goal of this module is to use all the core data generated through Sherlock's operations as training data for ML algorithms. Given the obvious richness in the DAA data set, there is a clear benefit to applying novel ML applications to mine the dataset and uncover complex patterns. The immediate use cases are:

1. Finding similar events via clustering.
2. Using pattern recognition to discover complex patterns and relationships across the vast dimensions of the data set.
3. Prediction of future issues based on current data.

These applications, if successful, have the potential to completely transform the DAA space. More discussion on the ML aspect of Sherlock is presented in Section 6.

3. DAA Event Classification and Rankings

As part of building a reliable and robust access network to deliver fast speeds to customers, we need to ensure our plant, network and platform health are constantly monitored to proactively detect and mitigate issues and reduce impact to customers.

There are cable industry standards and specifications which are widely used within Comcast to characterize the health of the HFC plant, CMTS and the connection to cable modems. Some of the more common metrics that are tracked are signal-to-noise ratio (SNR), modulation error ratio (MER), transmit power, receive power, and FEC, to and from CMTS. Each of these metrics has acceptable ranges. When telemetry data point goes above or below those ranges, the variance and the duration could indicate

different issues within the network. Comcast tooling currently classifies and captures those anomalies and alerts are sent out. Sherlock leverages those existing alerts to measure DAA plant health.

As stated previously, it becomes an operational challenge to mine through all the data using Grafana or existing dashboards, to pinpoint where and when things go wrong. Thus, Sherlock implements a scalable event detection pipeline to automatically detect events of interest. Sherlock can then leverage the detection of events to rank sites, PPODs and RPDs, based on the occurrence of said events, and help prioritize teams to address issues.

3.1. Event Classification

Sherlock makes use of the centralized core data structure with the telemetry metrics discussed in Section 2.2 to implement an automated event detection pipeline at several levels of aggregation. The lowest level of aggregation is currently the RPD level, while events can also be detected at PPOD level and above. The individual event criteria are specified as objects in the pipeline, and then the pipeline executes each object on the raw data to detect events.

Currently, the events are logical/threshold-based, because that is a great starting point to easily identify any known types of events. The types of events include offline status, anomalous trends in each metric, RPD reboots, SW/HW upgrades and even customer contact. While a single event only looks at specific metrics, the pipeline groups multiple events into a single event to infer when a more complex event is happening. This is especially useful in cases of known maintenance, such has RPD SW/HW upgrades, since these events will undoubtably cause outages and anomalous traffic patterns. This ability allows us to connect any maintenance/upgrade events to corresponding outages so they can be scored differently than unplanned outages.

The event pipeline is typically run on a weekly basis, which allows for analytics and tracking to be performed to document the type and frequency of events across the footprint. The event findings are summarized and automatically distributed to the DAA team to evaluate.

A brief description of the currently implemented events for the RPD level are presented in Table 2. As we continue to add new telemetry metrics and develop the existing list of events, this area will be constantly fine-tuned.

Once these events are identified in the RPD data, they can be aggregated up to higher levels to determine whether events are local, or more widespread. As previously mentioned, Figure 4 displays a visualization known as an event heatmap, which shows the number of RPDs in each site exhibiting a given event at a given time throughout a week. In this example, most events are a spread across a few RPDs, however, there are pockets of “no event found” flags that occur daily at the same time. These specific events were determined to be nominal nightly CPE reboots where the DAA system is healthy, but most CPE devices are offline performing scheduled updates. These types of dense views provide an extremely useful view of the network at a glance and easily display any major issues on the network that would require further investigation.

Table 2 - Description of event classifications

Event Name	Event Description
auxOfflineEvent	Aux core is offline
DAASOfflineEvent	DAAS port is offline
datagapEvent	Telemetry drop outs
gcppOfflineEvent	GCPP core is offline
keepAlivesEvent	RPD keep alive counter is non zero
noEventFound	No other event is flagged
rpdBatteryDrainEvent	RPD is on backup battery power
rpdHealthyEvent	RPD is online with expected CPE connectivity
rpdIopEvent	Automated ticket assigned to RPD
rpdIvrEvent	Customer support call
rpdMacUpdateEvent	RPD hardware was changed
rpdRebootEvent	RPD rebooted
rpdSWUpdateEvent	RPD software was changed
rpdTcEvent	Technician dispatched
usFecEvent	US FEC UCCW exceeded threshold
usOctetsEvent	US RPD traffic out of family
usPartialServiceEvent	Number of CPEs in US partial service above threshold
usPerfEvent	OpTek US System Alert

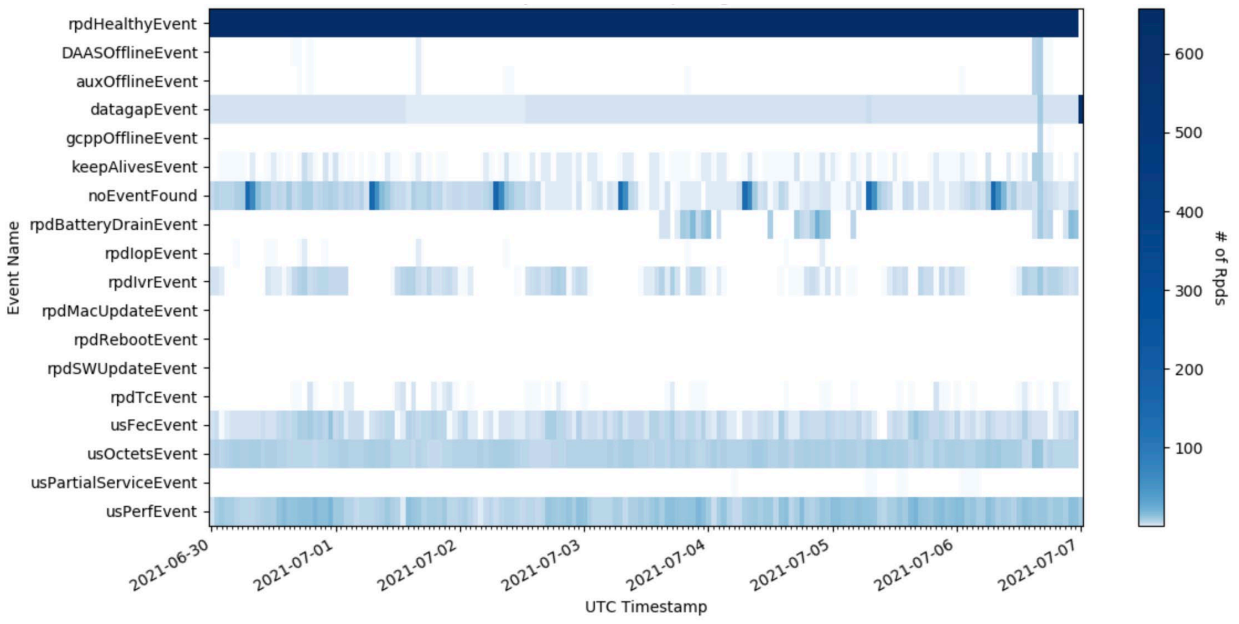

Figure 4 - Event Heatmap for a Single Site Over a Week

3.2. Ranking Methodology

Based on the events mentioned in the previous section, Sherlock ranks sites, PPODs or RPDs with events that are impacting customers for any given duration the most, and assigns them the highest rank. Ranking is aimed to identify sites, PPODs or RPDs with widespread events or events that occur frequently, causing service disruption to customers.

Individual events are assigned weights based on severity, duration, and customer impact. The final ranking is thus the weighted sum of the event coefficients to determine the most impaired sites/PPODs/RPDs. There are some nuances that go into ranking, where events that occur during a nightly maintenance window are ranked lower than events during non-maintenance windows for the same duration and frequency. Additionally, most of the events that occur immediately after RPD HW/SW changes are assigned a lower rank or aren't counted, as the entire system resets to clear current configurations and make the assigned changes. While customer contact events are not directly used in the weighted sum, because of the reasons discussed in Section 2.2, they can be used to break ties when two items have the same score.

Figure 5 shows the workflow that takes the telemetry data through event classification and ultimately to the final rankings. Once the rankings are complete, they are sent to the DAA team for evaluation. Section 4.3 discusses how the rankings are used.

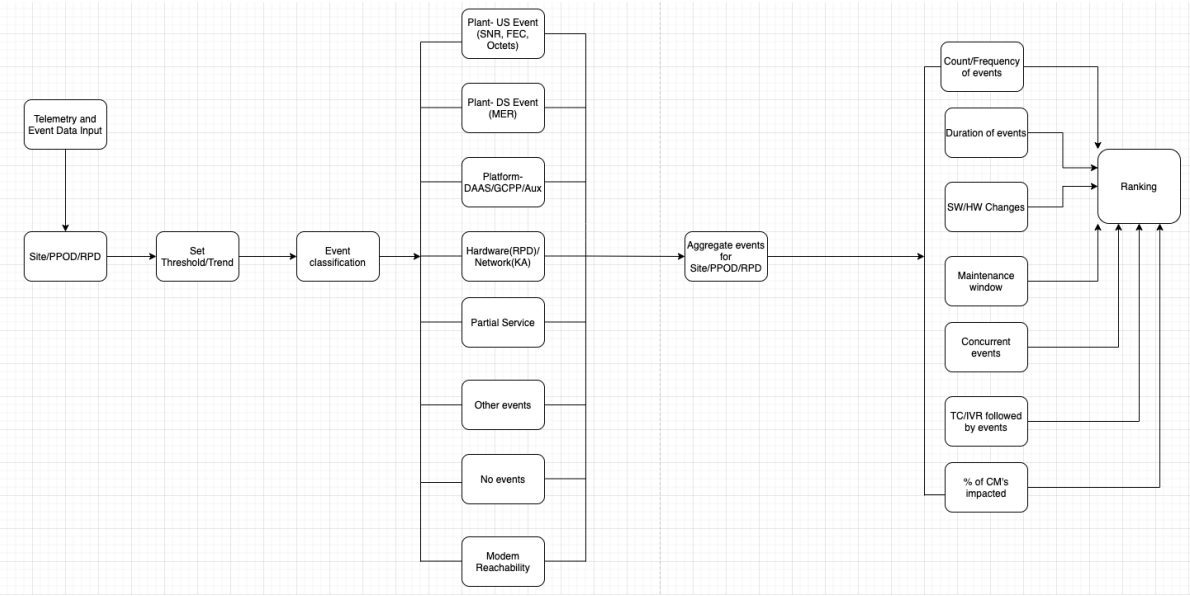

Figure 5 - Sherlock Workflow for Event Classification and Ranking

3.3. Ranking Usage

Once Sherlock generates weekly rankings for the entire footprint, or ad hoc rankings based on business needs, reports and views are stored within AWS. Reports capture highest ranked sites and RPDs based on events listed in Section 4.1, and list all the different events that were captured for that time period. This report serves as a starting point for engineering and operations teams to pinpoint any potential issues within the vCMTS architecture.

Using the ranking report, the heat map views at the site and PPOD are used to quickly see if the issue is widespread or isolated, and if there are specific events that occurred more frequently than the other events. The next layer analyzes the time series view at the RPD level and compares all the metrics that feed into Sherlock to ascertain end-to-end system health. RPD-level views also provide an events summary, with event duration and type, with the functionality to zoom into those events. Each event is assigned a unique ID, which helps in further analysis. This way we can quickly identify events at various levels in the network, and interdependencies between events as well as impact on customers. Ranking and views generated by Sherlock also help in flagging changes made to the system, such as hardware or software upgrades that caused a specific set of events and customer impairments.

Sherlock reports provide week-over-week trending, which helps in highlighting chronic vs. transient issues. Since homes-passed-per-RPD are relatively small in DAA, compared to analog nodes, some of our existing tools can prioritize the number of customers affected by events that would otherwise under-rank DAA issues. As such, Sherlock reports are specifically designed to better understand the DAA network and highlight problem spots in digital nodes, regardless of the number of homes passed.

Sherlock has an integration point with our internal messaging service where reports and visualizations are posted. Plans are underway to migrated to a web-based UI to provide enhanced analysis functionalities to DAA teams.

4. Practical Use Cases and Example Findings

In this section we illustrate the power of Sherlock with examples of specific events and views that highlight the health of the system.

4.1. Noise/Ingress

Table 3 and Figure 6 indicate an upstream noise event which is seen in the form of elevated UCCW. During the upstream noise event, plant and hardware elements (Figure 6a, b, c, e and f) appear to be functioning normally, whereas Figure 6d shows a drop in CCW and a corresponding increase in UCCW. In a DOCSIS plant, transient noise is a normal upstream event and the impact to customer service is minimal. Several tools already exist to sends alert on such events. Table 3 shows a sample of events determined by Sherlock during a portion of this noise ingress example. Most notably, Sherlock identifies usFecEvents as well as usPerfEvents (OpTek) events, indicating that our existing upstream performance monitoring tools are catching these events as well. The exact details of the OpTek events could be overlayed to determine more specific information, such as number of interfaces affected, etc.

Table 3 - Sample Event List for a Single RPD During US Noise Event

Event Type	Event Start Time (UTC)	Event End Time (UTC)
usFecEvent	6/25/21 9:35	6/25/21 9:35
usPerfEvent	6/25/21 16:35	6/25/21 22:35
usPerfEvent	6/25/21 22:50	6/26/21 2:15
usFecEvent	6/25/21 23:50	6/25/21 23:50
usFecEvent	6/26/21 1:05	6/26/21 2:00
usPerfEvent	6/26/21 2:35	6/26/21 3:10
usPerfEvent	6/26/21 4:40	6/27/21 0:35

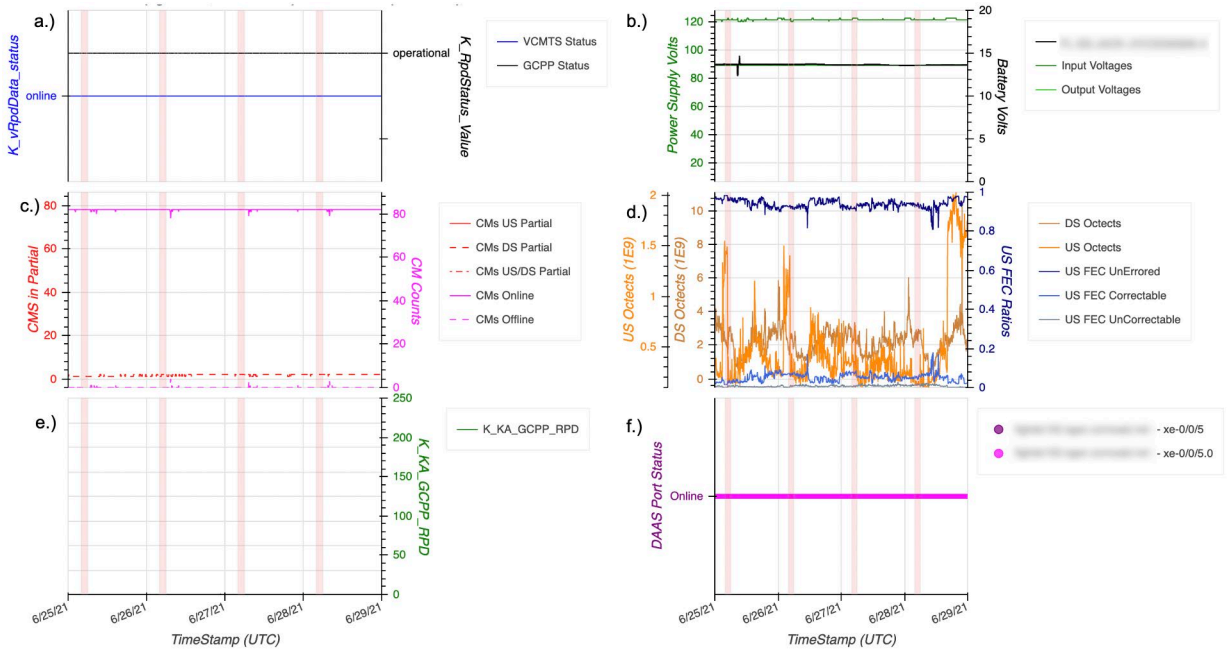

Figure 6 - Time Series View of RPD Noise/Ingress Event: a.) vCMTS/GCPP Statuses, b.) RPD Power Supply, c.) CPE Counts, d.) Traffic and US FEC e.) System Events (Customer Calls, Automated Alerts, RPD SW/HW Changes and f.) RPD Switch Status

4.2. SW/HW Upgrades

Table 4 and Figure 7 show a planned software update. This event is marked in Figure 7e with the initiation of the event as the RPD reboot/reset. Then corresponding dynamics across the other telemetry metrics are shown in Figure 7a, c, d and f. When the RPD software is updated, the AUX core goes offline, the CMs go offline (with some partial service along the way), traffic dips below nominal levels and the DAAS port also goes offline. Having the context of a software upgrade is key, since under other circumstances these types of system responses would be not ideal. However, software upgrades are performed during maintenance windows to minimize customer impact.

A sample of the event list is given in Table 4 showing a subset of the events identified in this time frame. It is worth noting that since the RPD reports its SW version at any given time, software upgrades like these can be determined directly from the data without relying on a ticketing system or external dependencies.

Table 4 - Sample Event List for a Single RPD During SW Update

Event Type	Event Start Time (UTC)	Event End Time (UTC)
auxOfflineEvent	6/17/21 14:50	6/17/21 14:50

5. Machine Learning Applications

As discussed earlier, the data aggregations and processing done by Sherlock represent an ideal setup for ML applications. The DAA data spans many dimensions, and ML/data mining techniques should be used to extract as much useful information as possible to optimize deployments and, ultimately, customer experiences. While the Sherlock ML module is nascent, three immediate use cases are currently being explored.

Clustering: The first application of ML is clustering. Clustering attempts to find smaller groups of similar samples in the raw data. This is especially useful when trying to determine if certain populations of data are more impacted than others, as well as understanding if there are subgroups of data inside major groups. An example of how this could be applied in the DAA space would be taking an RPD event classified via the methods in Section 4.1 and attempting to see if there are sub-populations of RPDs that experienced a given event for different reasons to help triage the event. Specifically, if partial service events are identified, clustering would be able to determine if some RPDs have CPEs in partial service mode because of noise ingress, platform-related issues, configuration issues, scheduled maintenance or even CPE-specific issues. This information could then be used to address the root cause of the individualized partial service issues. A simplified example of this is shown in Section 6.1.

Pattern Recognition: The next application of ML is advanced pattern recognition. As discussed earlier and as per industry standards, events on the network are typically identified via logic-based threshold exceedances, where an event is identified when a certain metric exceeds a predetermined value. While this is useful is many cases, it is limited when it comes to multi-dimensional events with complex relations, because completing a comprehensive detection algorithm with nested if/then logic becomes very cumbersome and hard to maintain. This is where ML shines: If example patterns in the data can be labeled by experts, models could be trained to find the important relationships across many different metrics to identify more complicated patterns than traditional logic-based approaches. An example use case of this in DAA could be identifying RPD backup battery degradation by looking at current and voltage drain during power outages. This application is in development.

Prediction: The third initial application of ML in DAA is the prediction of future issues given real-time data. At Comcast, customer experience is paramount and the ability to forecast and address issues before customers are aware of them is groundbreaking. Given the expansive coverage and real time nature of DAA telemetry, it is possible to use ML methods to find leading indicators of customer impacting events that are classified by the methods discussed earlier. An example of this for DAA could be forecasting when core server load will be too high, to the point of potentially shutting down.
This can be proactively addressed to obviate an outage. This application is also in development.

5.1. Clustering Example

This section presents a real-world use case for clustering DAA data. The example used here is trying to identify clusters of issues that cause partial service events at the RPD level. Using the Sherlock event classification module, partial service events were identified across all RPDs, where an event is classified as 25% or more of CPEs are in US partial service mode for at least 15 consecutive minutes.

Since the Sherlock data is very high dimensional and time-based, the first action is to perform a dimensionality reduction, to help the model focus on important features of the data. Several methods are possible here: traditional feature extraction/engineering, principal component analysis and even auto-encoding neural networks. This compresses the data into a smaller feature domain for the model to learn patterns. The architecture for clustering is shown in Figure 8.

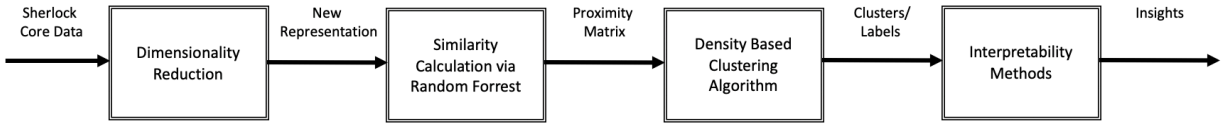

Figure 8 - Clustering Architecture

Clustering algorithms require a distance/proximity matrix that contains the distance between every pair of points in the sample data. This is often an area that requires a significant amount of tuning, because the choice of distance metric used has a huge impact on results. In most cases, Euclidean distance is used. However, in cases where the data set contains mixed continuous and categorical data, Euclidean distance hardly makes sense and typically custom distance metrics are derived for the specific problem at hand. Developing custom distance metrics can be extremely time consuming. For this reason, Sherlock is using a relatively novel distance calculation that relies on a type of ML method called "random forests," which can handle continuous and categorical data simultaneously with minimal pre-processing. The random forest is run on the data with training mode off, which essentially splits the data based on inherent similarity (typically entropy or Gini index.) The result can be turned into a proximity matrix as the number of times pairs of samples ended up in the same leaf node across all the trees in the forest.

The proximity matrix is then passed to a clustering algorithm to attempt to find clusters. Since the underlying structure of the data is not known a priori, representation-based clustering algorithms such as K Means are likely not a good fit. Instead, density-based methods such as density-based spatial clustering of applications with noise (DBSCAN) are utilized, since they make no assumptions about the shape/structure of the clusters. DBSCAN is also a good choice, since it does not require the desired number of clusters to be specified and instead attempts to identify the ideal number of clusters as well as any outliers. Once the clusters are identified, interpretability techniques should be employed to identify what clusters represent in the real world.

Once the cluster labels for each sample are determined, the data can then be passed to an interpretable ML classification algorithm. Essentially, the raw data and the corresponding cluster labels are used to train a classification model. In this case, the model is a single decision tree, to determine the path a sample takes to its classification target. Once the model is trained, it can be investigated to understand if the cluster labels have any real-world meaning.

In the example of US partial service clustering, the event pipeline discussed in Section 4.1 was run on the full footprint of DAA for three weeks, during which 897 partial service events were identified. The features for the clustering algorithm are a wide data table with Boolean flags for other events that occurred in proximity to the USPartialServiceEvents. In this example, the only other events considered were usFecEvents and rpdRebootEvents (to simplify the analysis); all events would be considered in a full analysis. The clustering algorithm was able to identify four clusters. Those four clusters were then passed as labels in addition to data as training samples to a decision tree. The resulting decision tree is shown in Figure 9.

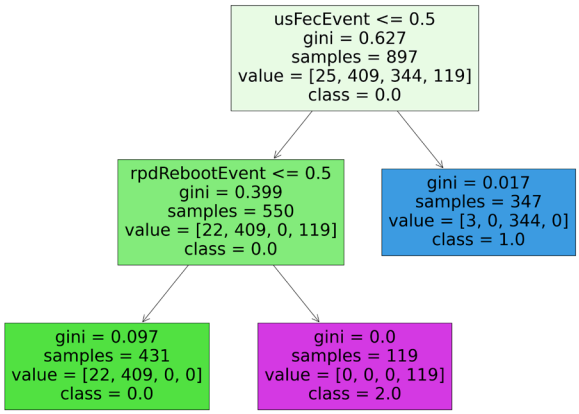

Figure 9 - Interpreting Cluster Results via a Decision Tree

From Figure 9, one can see the learned set of rules the tree uses to assign the cluster labels to a given US partial service sample. A tabular summary of the tree paths for each class is given in Table 5. From here it is easy to see that the decision tree can learn the cluster meanings relatively well. It is worth mentioning that the cluster label -1 is provided from the DBSCAN algorithm as outlier points that don't fit in to particular clusters, thus the decision tree has no path to correctly label those samples.

Table 5 - Decision Tree Paths for Clusters

Cluster Label	Number of Samples	Decision Tree Path	Decision Tree Label Accuracy
0	409	(usFecEvent <= 0.5) and (rpdRebootEvent <= 0.5)	95%
1	344	(usFecEvent > 0.5)	99%
2	119	(usFecEvent <= 0.5) and (rpdRebootEvent > 0.5)	100%
-1	25	N/A	N/A

The results from the above clustering example can be used to identify why RPDs experience widespread partial service events and lead to further mitigation-related enhancements to try in the future. In this case, partial service seems to be driven by usFecEvents and rpdRebootEvents. Further work could be done to understand the samples that had no usFecEvent and no rpdRebootEvent. While the results from this analysis are not too surprising, the architecture is a springboard for correlating different types of events and trying to identify where to dig deeper in understanding non-trivial issues. It is easy to see how this type of analysis could be expanding to more complex issues like understanding sporadic auxOfflineEvents, provided the correct data was fed to the ML architecture.

6. Conclusion

When Comcast began deploying DAA, the need for an automated big data analysis framework was immediately apparent. The DAA framework enables extremely rich telemetry with high frequency sampling rates, making two things true: 1) manual data analysis was infeasible, and 2) exposing the large amounts of data that is perfect for ML-based analysis. Our solution, internally called Sherlock, combines high fidelity data from a variety of sources across our physical infrastructure into a single centralized data structure that can be easily accessed for an assortment of analyses. Creating a centralized data structure with relevant DAA data proved to be instrumental in providing actionable insights from Sherlock analyses.

Sherlock was implemented using state-of-the-art technology that will allow for future scaling as we continue to grow our DAA footprint. Sherlock's core data structure allows for a multitude of analysis implications including event detection, event ranking, visualization, as well as ML advancements. These features allow us to identify and prioritize system issues at a glance, whereas such analyses were previously much more involved and required many manual operations. These analyses are currently being used by our internal teams to monitor DAA deployments and overall system stability.

While Sherlock is a relatively new tool, it is already starting to expand with applications to enhance the power of the insights provided to the DAA teams. As part of this work, we are exploring ML applications to find important trends in the complex DAA data. The immediate ML applications include clustering, pattern recognition and future event prediction. We are also working to integrate Sherlock into our expanding network topology graph, which will also open up new possibilities for advanced insights on the DAA network. The goal was and is to build a platform that can identify issues and recommend preventive maintenance before customers are impacted. Sherlock has proven to be extremely powerful in

its present state and is expected to become even more useful as the next generations of features are developed.

Strategies for Continuous Integration and Continuous Deployment at Scale at the Network Edge

…a.k.a. The Pursuit of the Zero-Downtime Headend…

A Technical Paper prepared for SCTE by

Quincy Iheme
Engineering Manager
Comcast TPX
Philadelphia
267.260.2923
Quincy_Iheme@Comcast.com

1. Introduction

The next several years will go down as the time when an astounding amount of work happened at the edges of the network, in part to get to the coveted "zero downtime headend." A perpetually-up headend matters because it sets the stage for edge compute services. Much of that work at the edge of the network is benefitting from the role of software, and in particular, the branch of software engineering that is Continuous Integration / Continuous Deployment (CI/CD).

This paper discusses how operators can take advantage of the new flexibility that comes with the deployment of software at the network edge, more quickly and securely. It will provide an overview of CI/CD, with a specific focus on how it is being applied at the edges of the network, in virtual Cable Modem Termination System (vCMTS) deployments and related efforts.

Software engineering is unquestionably infiltrating many aspects of the physical infrastructure that historically were hardware-only. As a result, the establishment of and adherence to a common CI/CD platform can set the stage for the anticipated increase in software deployment at the network's edges, especially for services or activities that require very low latency and/or wider throughput.

This paper will describe how Comcast arrived at a common CI/CD platform, then put it to work at the network edge to maintain network uptime and increase upstream throughput – such as blue/green and automated deployments, as well as Distributed Access Architecture (DAA) components like vCMTS and edge switching, to enable continuous configuration and deployment at scale. It will also discuss tools and automation, and how to configure and push software to the edge to enable customers to experience faster broadband speeds.

2. A Brief History of the Edge of the Network

The so-called "edge of the network" is both a moving target and a destination that carries different actual locations, depending on who's describing it. It's a moving target largely because of 60+ decades of technological advancement – what was "the edge" changed with each new chapter in capacity expansion, from microwave to coaxial tree-and-branch to modern HFC (Hybrid Fiber-Coax) topologies. Generally speaking, as capacity increases, the "edge of the network" moves closer and closer to consumers.

Network engineers tend to define "the edge" as being somewhere near where optical signals hand off to RF, or, near the output of optical nodes. Other disciplines define the "edge" as being at the output of the set-top box or broadband gateway. From a competitive perspective, there are still only three physical wires – three edges – that reach directly into U.S. households: The power line, the phone line, and the "cable" line. The power utility industry, despite commendable effort, has yet to successfully provide broadband connectivity. The telephone industry is showing, through its heavy investments in wireless 5G, what it knows to be true about the throughput potential of twisted-pair copper wires. Our network edge really is the only one that can consistently deliver high-bandwidth services, over a wire (or not), to IP/connected devices.

For the purposes of this paper, the "edge of the network" is located at the headend, where headend is defined as where we are actively transforming traditional CMTS devices, with integrated QAM modulator, into virtual CMTSs, where the modulation function is relocated into Remote PHY Devices, or RPDs.

The network edge is a high-stakes place, coveted by all in the broadband ecosystem, from cloud purveyors to networked gamers to any of a dozen adjacent industries that wish to be as close as possible to end consumers. As engineers, it is our responsibility to make sure our network edges are as healthy, fortified and ready as they can be, for whatever is coming. A big part of being healthy, fortified and ready is applying the principles of Continuous Integration and Continuous Deployment.

3. Why Continuous Integration/Continuous Deployment Matters

Continuous Deployment (CD) is a software engineering methodology that takes any code change that is deemed stable and (normally through parallel methods of Continuous Integration, or CI) and makes it available in production. This usually includes automated building, testing, and deployment, without human intervention.

Our CI/CD progression began as it often does within hardware-centric industries that began long before software engineering principles emerged: Organically, within certain parts of the company responsible for software delivery. In the beginning, many of the commercially available and/or open-source CI/CD systems were used throughout the organization (see Figure 1 as an example of the vast CI/CD landscape).

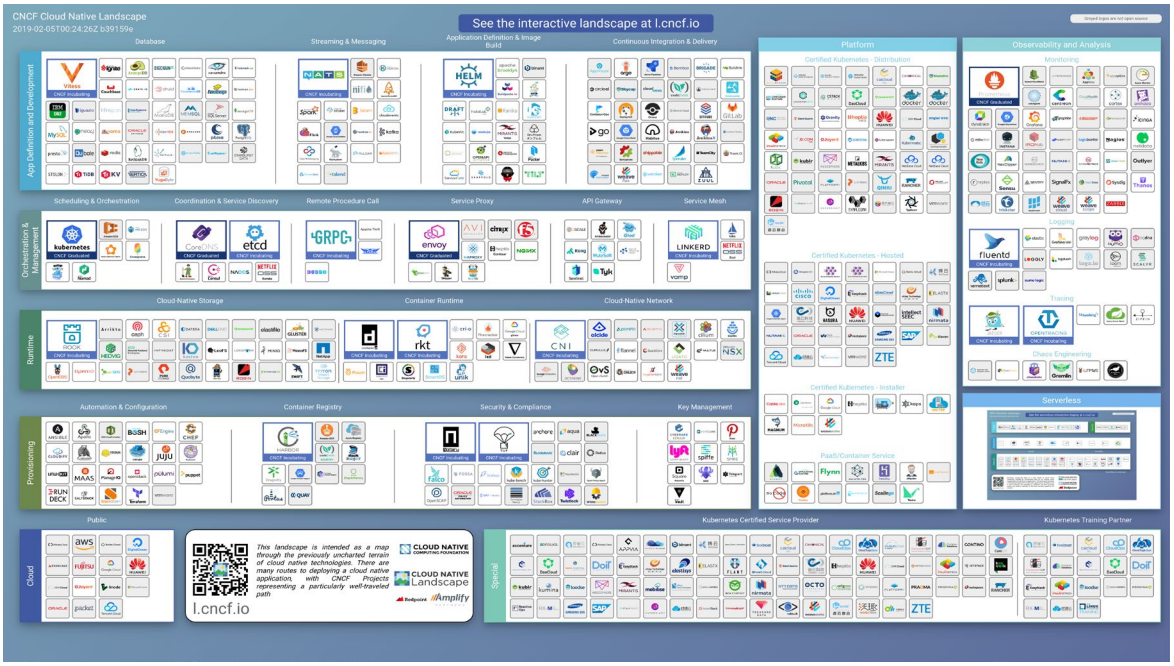

Figure 1 - CNCF Cloud Native Interactive Landscape

The practice of automating software delivery was one that was developed and documented outside the company, by the software industry at large. As more internal software teams began individually doing CI/CD themselves – including maintaining the cost of their own infrastructure to do so. Jenkins [1] (another common choice for implementing CI/CD within the engineering lifecycle) was one of the most popular options, as was Concourse, and a few others.

As more teams adopted CI/CD and related tooling, a need arose for a reasonably standardized pipeline tool. The main driver: Eliminating the technical debt associated with maintaining multiple infrastructures necessary to host different CI/CD tools, while creating a unified language that could be leveraged by all (or most.) By adopting a configuration-based CI/CD platform, component re-use can be applied to share many of the patterns and implementations that are very similar from one team to the next team. By establishing a shared platform and community around one tool, teams spend less time "reinventing wheels," among them code onboarding, because they can leverage already-public configurations.

As the reach of CI/CD platforms widened, a need arose to take stock of everything that was being done, in software, within Comcast's Technology, Product and Experience (TPX) organization. (Answer: A lot!) The CI/CD survey and its results happened within the construct of an internal TPX Architecture Guild, which consists of a group of engineers and technologists who were brought together to help guide technological decisions for the broader TPX organization.

The Architecture Guild uncovered a large amount of duplicate effort: Most teams were running their own instances of CI/CD software. The guild also identified varying degrees of implementation inconsistency: Teams were either as far along as deploying code into production every day (continuously deploying/integrating), or as far back as manually dropping compiled artifacts onto a web server.

Therefore, the guild recommended to Comcast TPX leadership that there be a dedicated team for maintaining CI/CD infrastructure, and that a single platform be chosen as the solution of choice. The recommendation was made with the idea that if you can get to a common platform and community, it would be easier to learn and onboard new teams, because they would only need to learn about a new CI/CD tool once. Questions like "has anyone done _____ with this platform?" could be answered by the more advanced users, further reducing the maintenance burden. The Architecture Guild was the ideal spot for a discussion as it was somewhat removed from the already formed opinions of specific teams. Asking team members to relinquish favored software tools, in favor of a different tool, is never easy; for more on this, see "The Tooling Abyss" by Joann Schuman, in this year's Fall Technical Forum papers.

Our then-Chief Software Architect and Senior Fellow, Jon Moore, was the main facilitator of the CI/CD unification discussions. As he describes it, in an interview conducted specifically to inform this paper, finding consensus on a unified CI/CD tool involved reconciling a couple of key points, including concerns around items like security and team separation. "The idea was that if we could get to a common CI/CD platform, with a community, it would be easier to learn and to on-board new teams, hand over ownership, because it wouldn't involve learning a new CI/CD tool," Moore explained [2].

4. The Architecture Decision Record (ADR)

With a few options then being proposed, an Architecture Decision Record (ADR) was formed to begin to track updates, offer reviews and other general comments. An ADR is a document that

captures decisions, including context (why was the decision made?) and consequences (what will adopting this decision impact?).

Since the ADR was in source control, interested/involved parties offered comments via pull requests and subsequent reviews. After a short period of proposals and reviews, a couple of options remained. Technically, any of the final options would have worked; as such, the goal was to pick the CI/CD tool that would cause the least amount of unhealthy friction, especially for those who would have to move over from another platform.

Instead of an outright vote, the guild proposed the use of a confidence poll, where each CI/CD software platform was ranked on a scale of 1-5, with a 5 representing, essentially, "the best," and 1 signaling "this would be a mistake." After rating the options on that scale, the scores closest to a 5 were interpreted as "acceptable to a majority of people." Ultimately, and instead of a straight-up vote for the "right" platform, Moore made the decision, based on the results of the CI/CD review process and confidence poll. As a result, the company now uses an open-source CI/CD tool called "Concourse" [3] to build CI/CD into various engineering lifecycles.

5. CI/CD at the Network Edge with vCMTS

With a tool of choice in place, teams could begin to implement an automation-driven software lifecycle to further increase the speed at which we could roll out changes. Such an effort was leveraged by several teams; in particular, and as it relates to this paper, a team that manage the Virtualized Cable Modem Termination System (vCMTS). Of course, there is a good deal of manual work to be completed beforehand. The racks that support the vCMTS need to be built. All the servers and switches that are part of the rack are shipped to headends. In the headend, wires are connected, to the RUs, power, and the GPS antenna. At that point, all the manual work needed for the connection is complete.

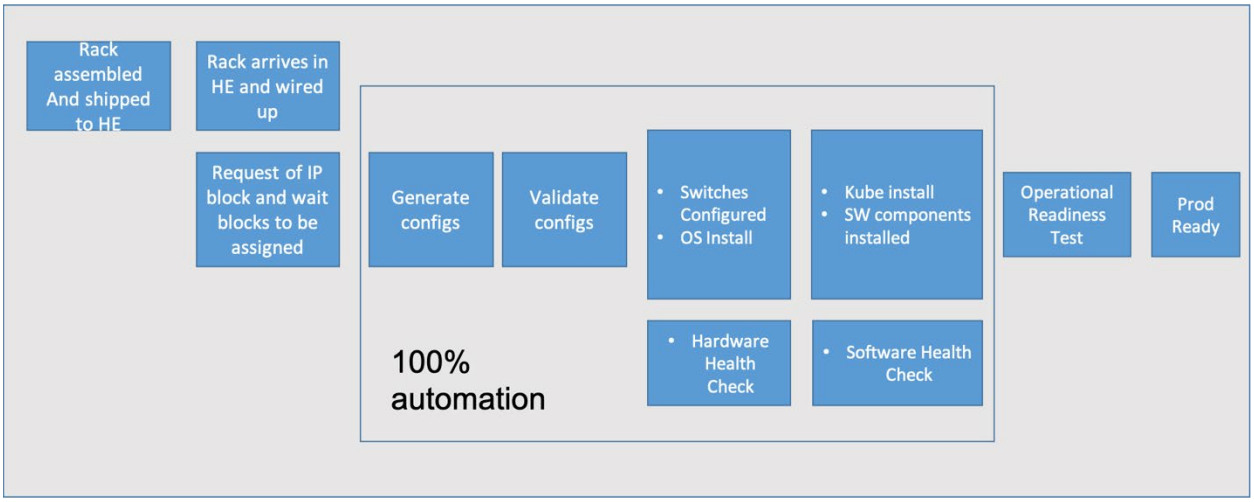

Figure 2 - Automated vCMTS Cluster Build Process

At this point, automation of the switch configuration is possible. Previously, if provisioning was needed, a ticket would need to be filed and a technician dispatched, to make the change onsite. An IP block would have to be requested and used to perform the requested provision. With automation, the IP block and configuration is known beforehand so the requested provision can be generated automatically. All of that now happens in Concourse, using a template to input the IP addresses, and to generate the configuration. Every cluster includes at least 2 switches and around 42 servers; up to 24 clusters can serve a headend. Looking at each pipeline (a set of tasks that run pre-defined operations), there is one pipeline per cluster. Each can have up to 192 vCMTSs. In that sense, each service group is a tiny vCMTS.

Every time there is a need to trigger a pipeline, a set of questions is asked: What am I deploying, and is it service-affecting or not? What kind of tests do I need to perform? The config, generated by Concourse, is then pushed to all the devices (servers and switches, numbering in the tens of thousands.) Afterwards, the OS (Operating System) is installed, and then software is installed. After automated hardware and software health checks are performed, the clusters are deemed production ready.

One thing to remember is all these different processes are resources. Concourse is a resource, running on servers. It needs a good amount of hardware to perform the operations being requested of it. One of the consequences of a shared CI/CD ecosystem is the sharing of resources. More resources could be allocated to speed up deployments to the vCMTS, but that would risk less availability of resources for other teams to use. This project in particular limits itself to 30 processes at a time.

For every change that needs to be made, a plan needs to be built to map out its journey to production. That mapping is fronted by a couple of questions, starting with reach: Changes are not rolled out to every single cluster at once. The focus is usually on new clusters that do not have new software yet. After clusters with older software are prioritized, the rest of the software updates are planned out. Based on the deployment type, and the service-affecting level, the deployment plan is calculated.

Once the deployment plan is approved, it is automatically rolled out during a maintenance window. First, a “pre” snapshot is taken of the current state of the systems in production. Health checks are performed, to make sure current systems are working as expected. Every change is made inside of a maintenance window. During that period, alarms are silenced because of the need to take systems down. After alarms are paused, the change is deployed to production. After the deployment, multiple post-deployment checks are run, with the aid of machine learning (ML). If there is a failure, there are 3 retries to access the systems and to ensure that the any change-related activity has settled down. Any failure that happens is logged, to let us know exactly what happened.

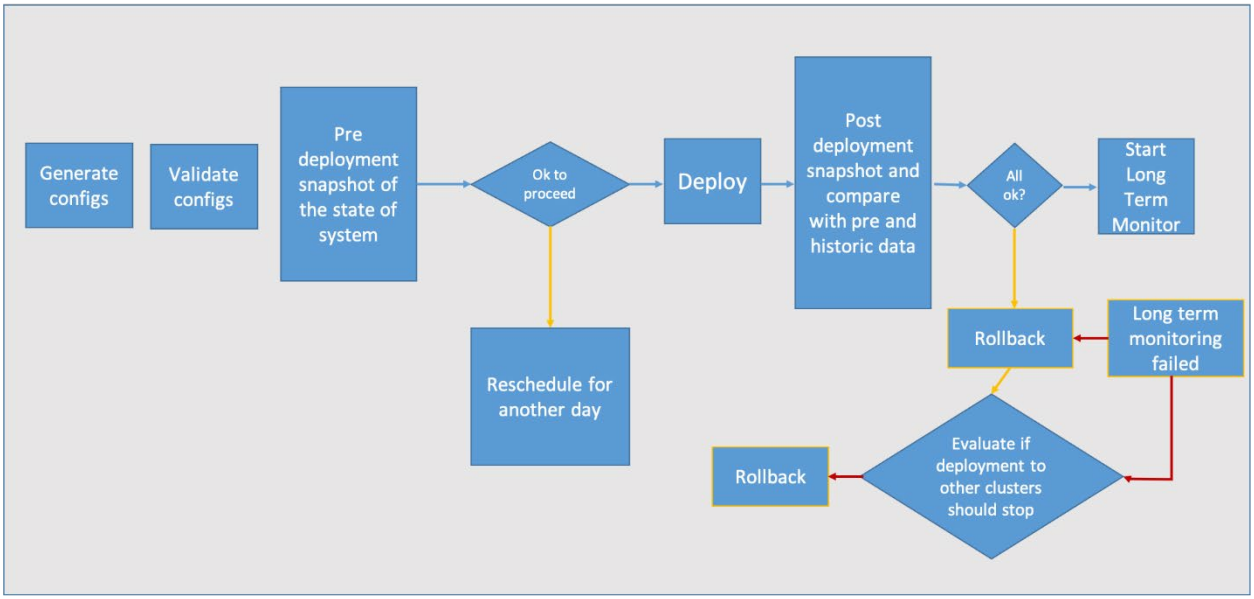

Figure 3 - Software and Network Change Deployment Pipeline

The process of connecting the RPDs ("Remote PHY Devices" / QAM modulators) can then begin. On a daily basis, and during the transition from integrated (which is to say, "traditional") CMTSs to their virtual counterparts, around 20 to 30 new clusters are being built in various places. Given common errors that can occur during config generation, or when scripts are run in a different order, or when switches malfunction, this process would traditionally take about three to four days. With the process of automating vCMTS deployments through Concourse, changes like these take anywhere from 2-4 hours. The variability of time depends on the platform, how many other jobs are running, platform health, etc. The beauty of automation is that there is a single source of truth from which configurations are read.

In the case that a rollback is needed for an upgrade that was deployed, for instance, checks exist to ensure that the rollback instances are healthy and ready to receive traffic. If there needs to be a change to the vCMTS core software, there's a check to see if it supports all CPEs (Customer Premise Equipment / set-tops and gateways). With a CI/CD methodology in place, you would expect any rollback to be done as quickly as (if not faster than) the roll out to production. In this case, rolling back is a progressive process. There is sampling of all kinds of data (with the aid of machine learning) that gives visibility around what specific failures there were and whether a rollback is needed in a certain area.

A zero-downtime headend necessarily means removing changes that can cause stoppages, and removing elements that can become points of failure. The iCMTS, with integrated RF modulators, was an example: From the analog node, you connected all the RFs. With vCMTS, the RF portions are removed from the CMTS, and put into RPDs. The physical component – the PHY, is in the RPDs; the nodes, in fiber-deep configurations, could be on a pole, in a pedestal, or underground. Upgrading them should be non "hitful" – which is to say, not service impacting.

At the headend, where the CMTS servers run, the intent is to complete upgrades with minimal scheduled downtime, on the order of 3 minutes. With a traditional iCMTS, the downtime tied to a scheduled upgrade is typically around 2 hours; so far, with the vCMTS, scheduled downtime related to upgrades is 15 minutes.

Our ultimate goal is to reduce headend downtime to close to or exactly zero. If there a catastrophic failure occurs with a small "blast radius," can take 15 minutes to redeploy software to a vCMTS, rather than take the risk of a lengthy time to diagnose and fix.

We are currently (summer 2021) also working on an in-service upgrade functionality. The intent is to get to 15 minutes or less of downtime for 2 components: The RPD, and the vCMTS, to simultaneously address the service-affecting route.

6. Conclusion

The journey into adopting a culture of Continuous Innovation and Continuous Deployment has been one that mirrors the actual process of continuously iterating and deploying: Problems are defined by processes or issues in progress. Updates and improvements are added frequently, without sacrificing stability. Changes are rolled out while ensuring reliability and adequate steps to rollback. Rolling out CI/CD (along with a unified platform and growing community) was done without jeopardizing the customer experience. What would've once been considered a phenomenon is now common practice in software engineering. Those lessons are now able to be transferred into the hardware side of engineering, to help drive improvements at a wider scale and without the need of constant manual intervention.

I would like to take the time to thank those who lent their time and expertise into the completion of this paper and presentation. Frankyln Athias, Sherita Ceasar, Leslie Ellis, Jon Moore, Max Knee and Bhanu Krishnamurthy.

Successful Wi-Fi 6 Deployment to Customer Homes

A Service Provider's Guide to Intelligently Controlling and Optimizing the Wi-Fi 6 Home Network

A Technical Paper prepared for SCTE by

Bill McFarland
Chief Technology Officer
Plume Design, Inc.
290 California Ace. #200
Palo Alto, CA 94306
1-844-69-75863
bill@plume.com

1. Introduction

Hailed as a new era for Wi-Fi connectivity, 802.11ax—known better as Wi-Fi 6—has created much excitement and anticipation. Capable of more than doubling the speeds of its predecessor, 802.11ac (or Wi-Fi 5), Wi-Fi 6 promises to transform the home network.

As well as boosting throughputs, this new technology improves overall system capacity, security, and even power consumption and battery life. And the timing couldn't be better. Not only are consumers relying on home Wi-Fi more than ever, but the smart home is also evolving to include more connected devices, immersive experiences, and bandwidth-hungry applications.

The Wi-Fi Alliance anticipates nearly 2 billion Wi-Fi 6 devices to be shipped in 2021 to consumers and organizations.1 Wi-Fi 6 products entering the market will spark renewed consumer interest in Wi-Fi upgrades, including deployments of Wi-Fi 6 home networks. It's an exciting opportunity for Communications Service Providers (CSPs) to elevate their offerings to subscribers.

There's no doubt that the new capabilities of Wi-Fi 6 will improve the user experience in all connected spaces. But maximizing its full potential means optimizing Wi-Fi networks in ways that are both more critical and more complex.

Wi-Fi 6 connectivity in any space is only as good as the system controlling it. To deliver on the promise of this new technology for their customers, CSPs must understand the limitations of Wi-Fi 6 home deployments and the requirements for intelligently managing the networks.

2. The State Of The Wi-Fi 6 Industry And The Market

Wi-Fi has become as ubiquitous as the internet itself. Considering that Wi-Fi 6 brings the first major improvement to 2.4 GHz band in a decade, the buzz surrounding it is understandable.

And a lot has changed in that decade. The home network is much more complicated and customers are increasingly relying on that Wi-Fi connectivity for work, school, and entertainment:

- The average US household served by Plume has 14.5 connected devices.
- 28% of consumers use smart home devices such as cameras and thermostats. (Deloitte)
- The number of global shipments of smart devices is expected to grow 71% between 2019 and 2023 (from 814.8 million to 1.4 billion). (eMarketer)

The excitement about Wi-Fi 6 can be best summarized in the words of Federal Communication Commission (FCC) Chairman Ajit Pai, who said, "The American consumer's wireless experience is about to be transformed for the better."

The Wi-Fi 6 market is just emerging. But the technology's potential to transform the home network is tremendous, especially as the smart home and work-from-home (WFH) trends gain momentum. Research firm Strategy Analytics sees the wireless home becoming "one of the leading technology trends of the early 21st century."

Here's just a glimpse of what the industry forecasts:

- 17 billion home devices will be in use by 2030 globally, with Wi-Fi 6 accounting for a third of device sales by 2023. (ABI Research)

- Wi-Fi 6 will become the predominant Wi-Fi standard both for consumers and enterprises by 2023. (Cisco)
- On the public Wi-Fi front, Wi-Fi 6 hotspots will grow 13-fold between 2020 and 2023, comprising 11% of public Wi-Fi hotspots by 2023. (Wi-Fi Alliance)
- 2 billion Wi-Fi 6 devices will be shipped in 2021 to consumers, enterprises, and public agencies. (Data aggregated from the Wi-Fi Alliance Product Finder, last accessed February 2, 2021.)

2.1. Market Developments

Rapid growth of the Wi-Fi 6 market began when the Wi-Fi Alliance launched its Wi-Fi CERTIFIED 6™ certification program, based on the IEEE 802.11ax standards, in September 2019. Even before that, some industry players—including networking vendors—began building the next-generation Wi-Fi infrastructure.

By February 2021, the Wi-Fi Alliance had certified nearly 1,400 different Wi-Fi 6 products. More than a third of those were in the router category, including home gateways. While the smart home category included only a few certified devices initially, some smart TVs, tablets, and even a couple of gaming systems were already available. It's only a matter of time before the consumer market explodes.

Momentum was also built in 2020 for Wi-Fi 6E (the E stands for Extended). Wi-Fi 6E is simply Wi-Fi 6 operating in the 6 GHz frequency band. The 6 GHz band has recently been allocated for Wi-Fi in the US, EU, and other geos. While this band promises more spectrum, better availability of 160 MHz wide channels, and lower interference levels, it requires more sophisticated management.

Notable Wi-Fi 6E events include:

- Broadcom announced a portfolio of residential and enterprise access point (AP) solutions for 6 GHz WLAN in January 2020, followed by a February announcement of a Wi-Fi 6E chipset.
- In April 2020, the United States became the first country to open the 6 GHz spectrum, and some have called the decision by the FCC historic and monumental.
- In December 2020, FCC authorized the first Wi-Fi 6E device, a Broadcom low-power indoor transmitter. In his statement, FCC Chairman Ajit Pai said this was "an exciting glimpse of America's Wi-Fi future."
- In early January 2021, the Wi-Fi Alliance introduced Wi-Fi 6E certifications, which will use enhanced, WPA3 security. The Alliance has certified more than a dozen products, including routers, from vendors such as Intel, Qualcomm, and Samsung, as of February.

2.1.1. Wi-Fi 6 Vs. 6E Devices

Wi-Fi 6E devices will be backward compatible with Wi-Fi 6 and previous Wi-Fi standards. But to take advantage of those new 6 GHz channels in Wi-Fi 6E, you'll need to be using devices that support it. In other words, you'll only be using Wi-Fi 6E once you pair a 6E-enabled client device (like a laptop or smartphone) and a 6E-enabled access point. Wi-Fi 6 devices paired with a 6E-enabled router will still be using the typical 5 GHz or 2.4 GHz channels.

3. Key Wi-Fi 6 Features And Benefits

In the home environment, the network is becoming more congested as a larger number of devices connect to Wi-Fi and customers run more bandwidth-heavy applications such as 4K video streaming, virtual reality (VR) gaming, and video conferencing. Wi-Fi 6 brings key changes to several areas, including:

- 2x higher throughput in low-congested environments
- Improved power efficiency
- 2x more devices that can be supported efficiently (to 8)

The new features are designed to better handle different types of traffic simultaneously from multiple users, as well as improve coverage for overlapping networks and dense environments. In practice, however, many of the new capabilities have limitations and drawbacks. Mitigating the issues will require advanced tools that manage and optimize the home networks.

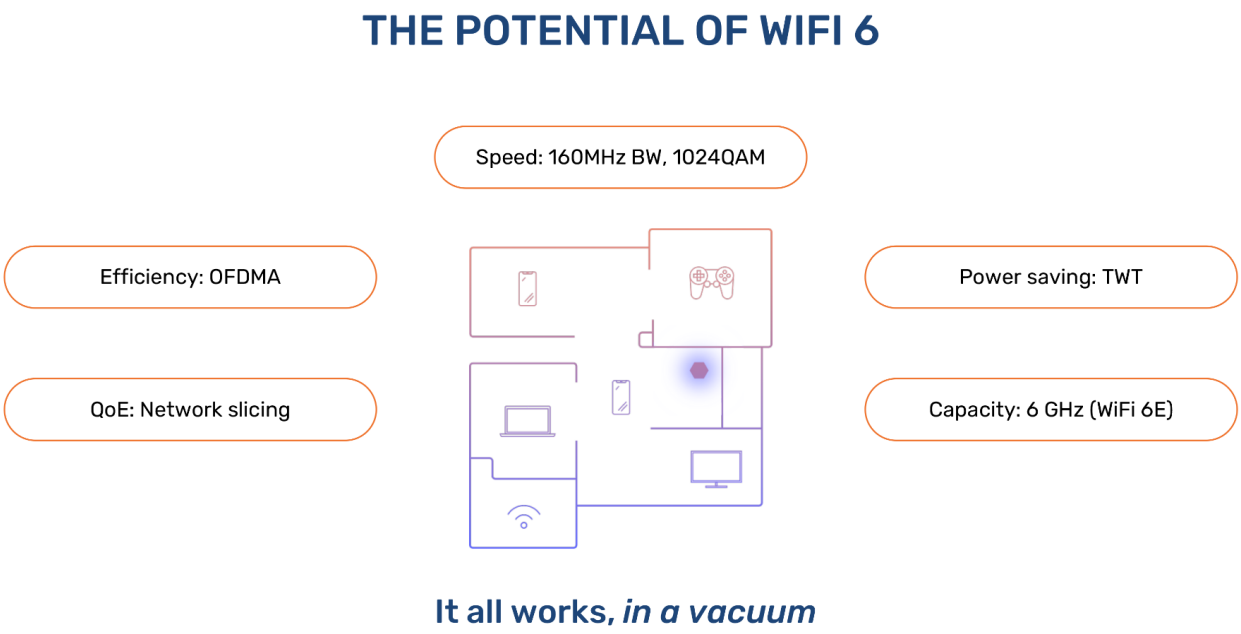

Figure 1 - The Main Advantages of Wi-Fi 6

3.1. An Overview Of New Wi-Fi 6 Features

3.1.1. 160 MHz Channel Bandwidth

The wider the channel used, the higher the data rate. While the Wi-Fi 5 technology officially supported 160 MHz capabilities, few devices actually offered channel bandwidths greater than 80 MHz. Although this is technically not a new feature, the expectation is for most Wi-Fi 6 devices coming to the market to support 160 MHz channel bandwidths.

3.1.2. 1024-QAM

Wi-Fi 6 goes from 256 quadrature amplitude modulation (256-QAM) to 1024-QAM, increasing the physical layer data rate by 25% at short range. Essentially, this modulation brings a more dense packing of bits into the signal, thereby boosting the network speed by increasing the data rate for the channel.

3.1.3. OFDMA

Uplink and downlink orthogonal frequency-division multiple access, or OFDMA, is a marquee feature of Wi-Fi 6, which allows for a single transmission to communicate with a large number of devices. It greatly improves efficiency and capacity by subdividing the channel into smaller frequency allocations (resource units) that are transmitted from one AP in parallel.

3.1.4. Resource Unit Reservations

The resource units, or smaller frequency slices, that OFDMA operates with can get allocated to particular clients. This allocation changes dynamically over time, which is what allows a single, wide, efficient transmission to serve multiple clients at once. Reserving resource units for particular clients or data flows provides guaranteed Quality of Service (QoS) to those clients or flows because a fixed amount of bandwidth within the network is allocated specifically for that traffic.

3.1.5. Target Wake Time

First developed for 802.11 ah (900 MHz Wi-Fi, branded "Wi-Fi HaLow" by the Wi-Fi Alliance), target wake time (TWT) is expected to be deployed widely with Wi-Fi 6. This mechanism improves battery life for devices that are transmitting only occasionally or at a low-duty cycle. The AP creates a schedule with specific times for each client to be awake and reserves that time so no other devices can transmit during that window, giving the waking devices clear airwaves to quickly communicate and return to sleep.

3.1.6. UL-MU-MIMO

The Uplink Multi-User Multiple Input Multiple Output (UL-MU-MIMO) is the companion to Downlink (DL) MU-MIMO that was standardized and implemented in Wi-Fi 5. UL-MU-MIMO allows multiple devices to be transmitting at the same time to the same AP, improving efficiency and uplink capacity. With OFDMA, the different devices transmitting at the same time use different parts of the frequency spectrum. In the MU-MIMO case, the devices involved rely on multiple antennas to separate the traffic by spatial means, so the AP can independently receive signals coming from clients in different directions.

3.1.7. BSS Color

Basic Service Set (BSS) color added with Wi-Fi 6 allows more efficient airtime usage between overlapping networks that are on the same frequency channel. This technique marks (or "color-codes") shared frequencies at the very beginning of the packet to indicate which network the packet belongs to and enables devices to make a very quick assessment if they are safe to transmit or must defer to traffic coming from a network with a different color.

3.1.8. 6 GHz Frequency

Wi-Fi 6E extends Wi-Fi 6 capabilities to the 6 GHz spectrum, previously only available to licensed users. This is considered a big step, as the need has become more urgent to prevent congestion on existing frequencies. The industry has been advocating for some time for the allocation of more bandwidth for

unlicensed use. The new spectrum makes available up to seven superwide 160 MHz channels that can support high-bandwidth applications such as unified communications and industrial IoT. For home networks, use cases that can benefit from the low-latency, higher-speed Wi-Fi include augmented reality and virtual reality.

4. Wi-Fi 6 Network Optimization And Controls

As highlighted earlier, the new or enhanced Wi-Fi 6 capabilities are not without issues. To ensure these features work to their full potential and truly benefit customers, CSPs need to implement sophisticated controls and optimize the network. These controls are especially critical in today's congested home Wi-Fi environments and in dense areas where issues such as interference arise.

4.1. 160 MHz Channel Bandwidth

Doubling the channel width from 80 MHz to 160 MHz should double throughput. So, in theory, customers would see twice-as-fast downloads, double resolution, and so forth, with the double data rate. The problem is that, in most countries, only two independent 160 MHz channels are available. In a dense environment, such as an apartment complex or even suburban homes on small lots, two different customers are likely to use an overlapping channel, leading to significant interference.

This issue can be mitigated with proper network configuration, which requires three factors:

- Intelligent sensing and prediction of the interference on 80 MHz subchannels of the 160 MHz transmissions.
- Intelligent channel allocation and bandwidth selection.
- Consideration of the complete interference picture in an environment, optimizing channel allocation across entire apartment complexes or neighboring homes.

Simple, locally managed networks can't achieve these factors. CSPs will need to handle them centrally through the cloud. For example, cloud-based interference analysis factors, loads, and device types. When considering what channel bandwidth to assign to each AP, the platform knows the history and current set of clients and loads that are present in the network at each access point. The system can then apply 160 MHz bandwidth channels where they are most needed and avoid them where they are not. Central cloud management also allows the optimal selection of channel bandwidths and frequency channels across an entire apartment building. Frequency channels can be “tiled" across the apartments, minimizing the conflicts between neighboring apartments. In cases where re-use of the same channel is unavoidable, the cloud-based optimization system can select apartments that are most able to share frequency channels based on their historical activity.

4.2. OFDMA

This signature Wi-Fi 6 feature stemmed from observing the poor efficiency of the small packets typically emanating from Internet of Things (IoT) and other low-data-rate devices. Each 802.11 packet has significant overhead, and to avoid collision with other transmitters, each transmitter must listen first to the medium for some time. Even if each transmission sends a modest amount of data, the overhead consumes a lot of airtime.

OFDMA allows transmission to multiple users simultaneously in one packet, eliminating overhead and wasted time. This capability only improves efficiency when a significant number of IoT devices are on

the same AP, each device sending or receiving a modest amount of data. But, modern Wi-Fi networks in smart homes will not always end up with a significant number of IoT devices on the same AP.

Here's why: Home networks have migrated to multi-AP topologies using mesh networks, repeaters, or multiple gateways. If the IoT devices in the home were to simply connect to the nearest AP, each AP would have few devices appropriate for grouping into OFDMA transmissions. On the other hand, forcing devices to connect to an AP that is too distant will force the data rates of these connections to drop, compromising efficiency in a different way.

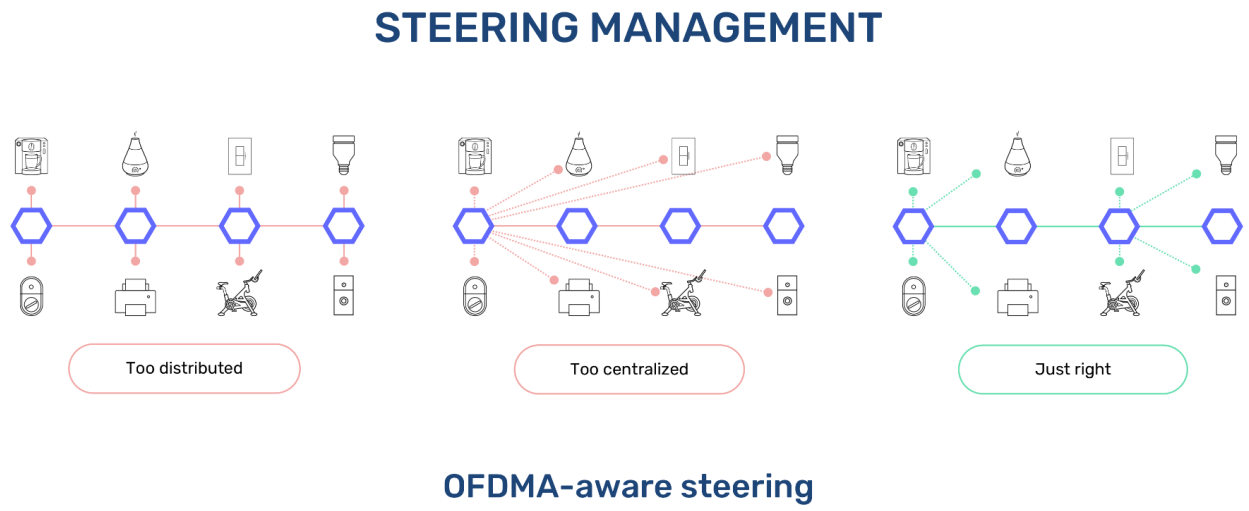

Figure 2 - OFDMA-Aware Steering

Consequently, OFDMA operation requires OFDMA-aware client steering. To make complex decisions, a centralized, intelligent network controller would need:

- Knowledge of which APs and clients are Wi-Fi 6 capable.
- Historical observation and forward prediction of the data needs of each device in the home.
- The ability to make intelligent, optimized choices about which of the multiple APs each device in the home should connect to considering the capabilities, traffic load, signal strength, and data rate each device can achieve.
- The ability to steer and hold devices on the correct AP.

For all the APs and clients to work efficiently, the best arrangement must be created through rigorous optimization. This should include the ability to steer clients to APs and hold them there, even if those aren't the closest APs. The steering mechanism must be specific to each type of device because different devices behave differently to various steering mechanisms.

4.3. Target Wake Time

Oftentimes, the home network has several APs operating on the same frequency channel. This creates potential overlap when multiple APs try to schedule the TWT for different devices. To avoid conflict, a central scheduler can ensure that TWT periods at the co-channel APs do not overlap.

The scheduler must know:

- The transmission requirements of all the TWT clients
- The shared channels among APs
- The clients connecting to each AP
- The signal strength between the APs and clients in the home

With this data, the system can create an optimized arrangement of TWTs at each AP, covering all clients across the home network.

In a multi-dwelling unit (MDU), the optimizer could go a step further, looking across overlapping networks that it controls in the MDU and plan TWT assignments and groups across the entire building. The system would factor the cloud-based controller's knowledge of which apartments interfere with one another, and the client capabilities and load requirements in each apartment.

4.4. Network Slicing

A QoS mechanism, network slicing is another way of allocating frequencies and time among different clients. This is essentially a time-division, multiple access (TDMA) method (where transmissions occur at reserved times) but has the added overlay of a divided frequency spectrum. In a home with multiple APs or in an MDU, network slicing can lead to high collision rates when both networks schedule the same time periods. The result is poor QoS, defeating the point of the time/frequency reservations. Centralized, intelligent controls can mitigate this issue by coordinating among the multiple APs.

4.5. 6 GHz Frequency Band

To protect point-to-point microwave systems that operate on the same 6 GHz spectrum, Wi-Fi 6E devices must use one of two modes:

- A low power (18dBm/63mW) that uses the low-power spectrum rules: This mode can't transmit as far or at as high a data rate because the signal is not very strong.
- Under the command of an AP that has an automated frequency control (AFC) system (30dBm/1 Watt allowed): In the US, for example, the AFC systems must check the data in an FCC database to ensure there are no microwave systems in the vicinity of the AP. There are currently around 100,000 microwave links in the US used by mobile carriers, industrial and business entities, and public safety agencies. By avoiding a frequency channel used by nearby microwave systems, the AP and its clients can operate at the high-power level, enjoying full range and data rates.

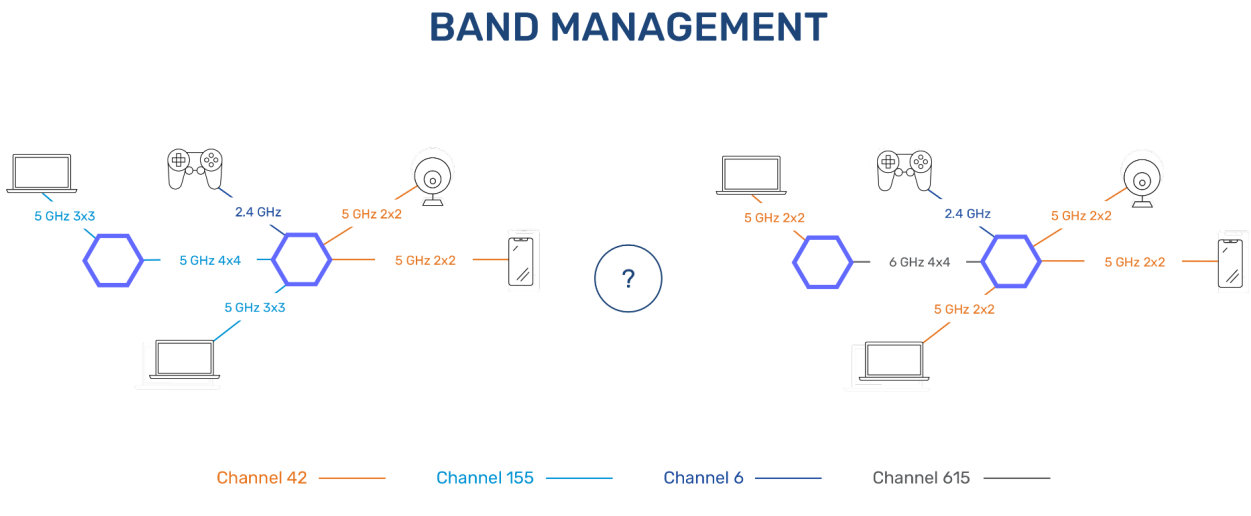

Figure 3 - Planning Band Management

These operating modes will require different types of controls:

- For the low-power transmission, more complicated, multi-AP configurations will be required for an optimization system to select the appropriate network topologies, frequency assignments, and client-steering options.
- For the AFC systems, the AP will need to communicate with a smart controller that can look up the FCC database, factor in the geodata, calculate interference levels, then deliver instructions back to the AP.

For either mode, the control system needs to take into account the client types, loads, and capabilities to decide how to allocate the network's radio resources. Depending on the capabilities of the clients in the network, it is not always optimal to put one of the AP's radios in the 6 GHz band. For example, using a 6 GHz channel for the backhaul connection may help the backhaul, but it may take away the high-performance radio in the AP from the 5 GHz band. High-performance clients that do not have a 6 GHz capability may therefore connect at lower speeds, actually degrading the experience in the home.

5. Intelligent Management Imperative For CSPs

Wi-Fi 6 brings long-anticipated improvements to a technology that's now 20 years old. The new features will solve many challenges created by the ever-expanding, increasingly more congested home network. It's undisputed that this technology takes the home network to a new level. However, Wi-Fi 6 brings additional complexities, such that simple controls can no longer satisfy the requirements of this evolved ecosystem.

To maintain the Quality of Experience (QoE) for their customers, CSPs will need to adopt an intelligent management approach. With centralized controls, ideally based in the cloud, CSPs can ensure that they're achieving the performance potential of Wi-Fi 6. More sophisticated controls, coordination, and

optimization will become especially critical as smart home adoption picks up the pace, putting further pressure on connectivity and performance.

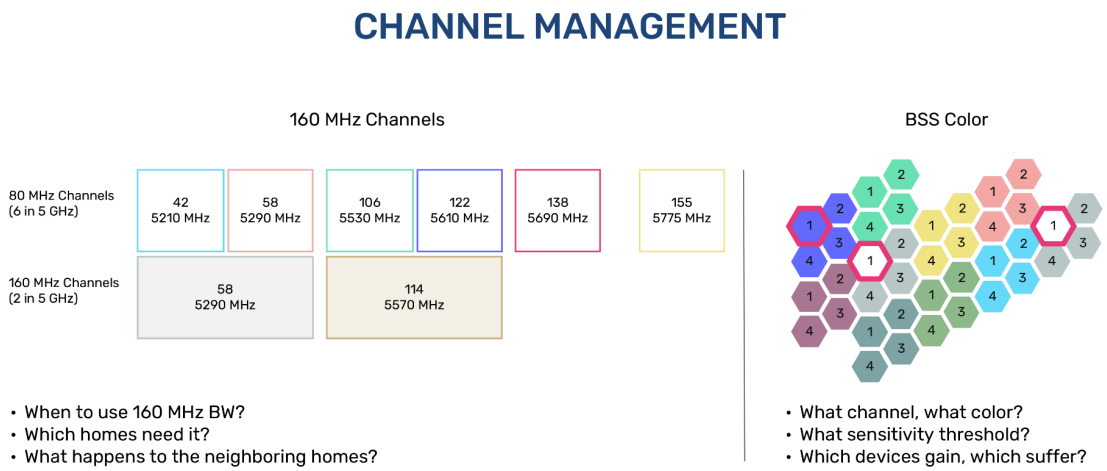

Figure 4 - Planning Channel Management

CSPs should harness the power of the cloud and artificial intelligence (AI) to make sure their subscriber's home networks are ready to support the exciting capabilities of Wi-Fi 6. The cloud offers practically infinite memory and computing power, supporting AI-driven innovation.

6. Measured Results

The previous sections outline the need for centralized cloud management in a Wi-Fi system, particularly when Wi-Fi 6 capabilities are being exploited. This section presents measured results of what can be achieved when centralized management is applied to real-world networks.

6.1. Selection Of 80 Vs. 160 MHz Channels

As described earlier, Wi-Fi 6 devices include the option to operate in 160 MHz channels, but this may not result in optimum performance. The optimization system measures the interference in homes and chooses the optimum channel bandwidth to maximize the throughput in that home. The chart below shows the percentage of homes that the system configures into 160, 80, 40, or 20 MHz. This study was conducted across a sampling of households in the United States.

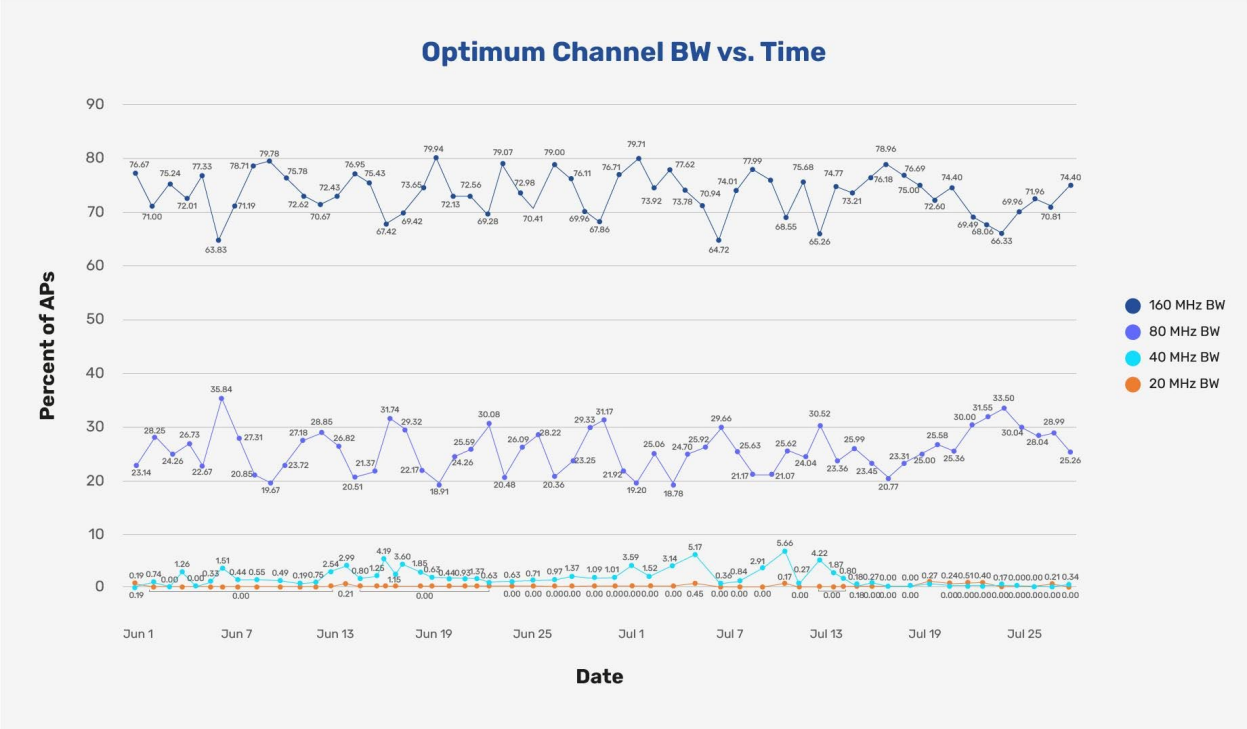

Figure 5 - Channel Bandwidth: SuperPod_AX to SuperPod_AX links

Several interesting observations can be made. First, roughly 25% of homes will achieve better throughput in 80MHz mode than in 160 MHz mode. Second, the exact distribution varies on a day-by-day basis due to variance in network usage and therefore neighbor interference. Finally, there are a small number of locations that achieve the best throughput in 40 MHz mode.

Clearly, a system that sets all networks into 160 MHz mode, or one which makes a one-time selection of 160 vs. 80 MHz will result in sub-optimal performance in a significant percentage of homes.

6.2. DFS Impact On 160MHz

Much of the 5 GHz frequency band is shared with radar systems. Wi-Fi networks must search for the presence of radar signals, and vacate the channel if they are observed. These radar events cause significant disruption to users as the entire network switches to different frequency channels to avoid the signal that looks like radar. Often these signals are not coming from a real radar system, but are generated by other types of devices operating in the 5 GHz band, or unusual signals generated by the collision of Wi-Fi packets from multiple networks. Therefore, these radar effects can be seen anywhere in the country, but are more common where radars are present, such as near airports.

Theoretically, doubling the channel bandwidth roughly doubles the odds that a radar event will happen within the channel, requiring the system to suspend operation and switch to a different channel. However, we have studied these radar events extensively and find that they are not at all evenly distributed by location, or by frequency channel at a given location. The table below shows the measured radar event rates reported by APs in a series of locations, some with multiple APs, some with a single AP. The rates are expressed as the number of radar events per hour of operation (0.04 = one radar event per day on average). The color-coding in the diagram highlights the location, AP, and frequency channel triplets that have high (orange), medium (yellow), and low (gray radar event frequency. Note that in this diagram each

numbered channel is 20 MHz wide. Therefore an 80 MHz channel will span 4 of these channels, while a 160 MHz would span 8.

Long Term Radar Rate Per DFS Channel Per AP (Aggregate Learning from July-2021)

SUM (Long Term Radar Rate)

0.0000 0.10000

Figure 6 - Long Term Radar Rate For DFS Backoff

Looking at the chart, it is easy to see that some locations can use 160MHz channels without concern, while others would be hit by radars at a high rate, frustrating users with frequent channel changes. However, many of the homes that could not support a 160 MHz channel can support an 80 MHz channel if it is properly positioned.

To minimize service interruptions, the system should monitor and record the radar rates that occur at each individual AP, and use that to intelligently avoid channel usage that would result in frequent radar events.

6.3. Clustering

Interference can occur in any type of environment, degrading or eliminating the benefits of Wi-Fi 6. However, the most likely location for high interference is in apartment complexes, or MDUs. Interference in these types of environments can be minimized using optimizations that consider MDUs in a holistic way, optimizing across the entire MDU. Because it would be impossible to jointly optimize the entire planet, the first step is to identify the MDUs, or sets of locations that present strong interference to each other.

Unfortunately, there is no simple database for knowing which locations will interfere with other locations. While conceptually this would be aligned along MDUs, actual interference patterns are complicated by any number of factors. The necessary grouping is accomplished through a clustering step. Each AP reports the neighbors that it can see, including the neighbors that it can see on different frequency channels using off-channel scanning. This database is then used to group the locations into clusters that should be optimized together because the locations have a high degree of interaction.

Community network machine learning algorithms can be used to accomplish this task. The diagram below shows a conceptual picture of how this works. Tightly intertwined locations are grouped together (e.g. locations in the same apartment complex), while only mildly connected groups (e.g. neighboring apartment complexes) are segmented.

Figure 7 - Tightly Intertwined Locations Are Grouped Together (Left) While Only Mildly Connected Groups Are Segmented

The following table summarizes the results when clustering algorithms were applied to two large service providers' customer bases. Keep in mind that the system clusters only the locations that have an AP that is managed by the cloud system. Because the cloud system cannot control neighbors that are not part of the system, there is no reason to cluster them together.

Table 1 - Cluster Identification For Community Network Machine Learning Based On Two Large Service Providers

Parameter	Service Provider A	Service Provider B
Number Of Plume-Managed Locations	12,527,567	5,017,865
Total Number Of Clusters	2,012,417	928,133
Size Of Largest Cluster	1,173	412
No. Of Clusters With >100	8,367	7,049
No. Of Clusters With 50-100 Locations	21,633	85,036
No. Of Clusters With 10-50 Locations	195,747	74,748
No. Of Clusters With 1-10 Locations	1,786,670	760,277

With the clusters identified, a joint optimization of all APs within the cluster can be performed, optimally assigning frequency channels and channel bandwidths across each of the clusters.

6.4. Interference Improvement

Studies of the improvement that can be achieved when optimization is applied across complete clusters as opposed to optimizing at each location individually were performed. These studies were done in a selection of individual MDUs, which were identified by our service provider partners.

The following diagram shows a histogram of the number of locations in the set of MDUs vs. the "pain" metric coming from interference. The pain metric is a function of the interference seen in a certain home times the load that devices in that home place on their own network. The pain metric does a better job of

estimating the true customer QoE than just the interference. For example, a home that is completely idle (no traffic flowing), is not impacted by a high level of interference from a neighbor. On the other hand, a home that has a very high load, consuming nearly 100% of the airtime, can be degraded with only minor interference from a neighbor. At a pain index of ~0.5 consumers experience occasional interruptions in real-time services such as voice and video.

In the diagram, the "Before" distribution represents the histogram of the homes in the MDUs prior to joint clustered optimization, and the "After" distribution represents the histogram of the same set of homes after joint clustered optimization.

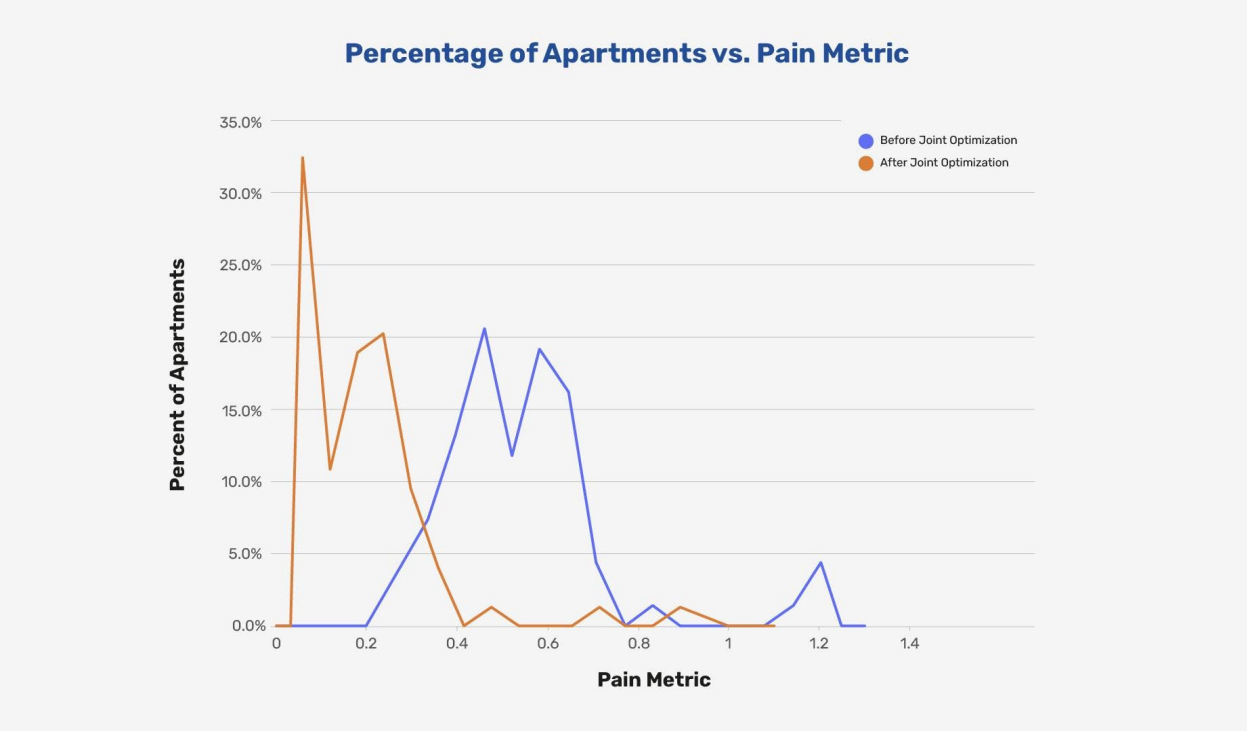

Figure 8 - No. Of Locations In The Set Of MDUs Vs. The Interference "Pain" Metric

The histogram shows that the number of homes at high levels of pain (exceeding the threshold at which real-time services are impacted) can be significantly reduced by the clustered optimization process.

7. Conclusion

As with most new technologies, it will take a few years for Wi-Fi 6 to become ubiquitous. But the possibilities are thrilling once the technology is fully developed and implemented. The greatly enhanced speed and performance of Wi-Fi 6 will open new doors for emerging technologies such as IoT and AR/VR. It's not only a new era for consumers but also an opportunity for CSPs to take advantage of the technology to enhance and expand services.

Wi-Fi 6 is, indeed, powerful. But it doesn't eliminate the need to optimize the network—on the contrary, the complexity of this technology creates an even greater demand for intelligent management. CSPs should take advantage of the advanced management solutions that future-proof their customer deployments while meeting customer demand and maintaining QoE.

1. Introduction

Synchronous Ethernet (SyncE) is used mainly in telecom networks to provide physical layer clock delivery for frequency synchronization (a.k.a syntonization). The cable industry has not yet adopted SyncE as a common supported functionality as IEEE1588 is more commonly used for time synchronization (mainly for DAA use cases).

Adopting SyncE in conjunction or in addition to IEEE1588 may add advantages both from a performance perspective, and from a simplicity and cost perspectives as well.

This paper will describe different use cases for both DAA RPHY/RMACPHY and mobile backhaul (LTE and 5G) where SyncE can add a true value. Analysis of performance compared to traditional IEEE1588 usage will be shown and the benefits in simplicity will be discussed.

2. The Need for Synchronization

Traditional network synchronization has been based on the accurate distribution of frequency. Wireless networks have evolved to require the distribution of accurate time and phase information. In order to deliver this information, network operators have to distribute a reference timing signal of suitable quality to the network elements processing the application.

There are two basic approaches for distributing synchronization information. The first is to follow a distributed primary reference time clock (PRTC) approach, implementing a global navigation satellite system (GNSS) receiver in the end application, and the second is based on a master-slave hierarchical strategy.

Master-slave synchronization uses a hierarchy of clocks in which each level of the hierarchy is synchronized with reference to a higher level, the highest level being the Primary Reference Clock (PRC). Clock reference signals are distributed between levels of the hierarchy via a distribution network which may use the facilities of the network. The hierarchical strategy can be used for physical layer frequency distribution as well as higher layer packet-based frequency, phase, and time distribution.

Packet-based methods for distribution of frequency, phase, and time have been developed using precision timing protocol (PTP) and network time protocol (NTP). PTP is typically used instead of NTP in applications with stricter phase and time synchronization requirements. The improved accuracy for PTP is a result of its hardware-based timestamping.

2.1. Synchronous Ethernet (SyncE) Overview

The ITU has defined mechanisms to use the Ethernet physical layer to distribute frequency information across a network that are similar to the physical layer methods used with synchronous digital hierarchy (SDH)-based network synchronization. ITU-T G.8261 provides the network limits for transferring timing across a packet network. G.8262 defines the timing characteristics of an Ethernet Equipment Clock, while G.8262.1. defines improvements for the Enhanced Ethernet Equipment Clock.

Synchronous Ethernet (SyncE) uses the edges in the Ethernet data signal to define the timing content of the signal and distribute a physical layer clock across a packet network. Each system recovers and forwards the network timing through the distribution path. A reference timing signal traceable to a PRC provides a reference timing signal to an external timing port (e.g., BITS, GPS) on the first Ethernet switch in the path. The system clock function of the switch synchronizes its Ethernet transmit bit stream to the

reference timing signal. Each subsequent Ethernet switch in the path recovers the timing from the incoming Ethernet bit stream on a designated port, and synchronizes its Ethernet transmit bit stream to the recovered timing signal via its system clock function. Like all physical layer frequency synchronization techniques, all network elements between network segments need to be capable of recovering and passing the frequency downstream.

A system clock function that supports SyncE timing contains an Ethernet Equipment Clock (EEC) or a physical layer clock. The EEC provides filtering of noise on the external reference or recovered timing signals. A holdover function is also provided to allow continued operation in the event of a failure in the distribution path.

ITU-T G.8264 adds support for an Ethernet Synchronization Message Channel (ESMC) based on the IEEE 802.3, Organization Specific Slow Protocol (OSSP). This message is used to communicate the clock quality levels (via a Synchronization Status Message, SSM) of the PRC to all EECs in the network. The EEC may use this received information to determine the appropriate actions to take, such as failover to a different SyncE port or enter holdover mode, when network failures occur. As an example, if an EEC loses its connection to the PRC and transitions to a holdover state, it will replace the Quality Level (QL) of the PRC in its outgoing SSMs with the QL of its internal oscillator.

The higher information rate and lower noise of SyncE enables a higher clock bandwidth than for a packet-based clock. The bandwidth of the clock PLL in an EEC as defined in G.8262 is in the range of 1 - 10 Hz. The clock bandwidth for an enhanced EEC as defined in G.8262.1 is in the range of 1 - 3 Hz. The higher bandwidth generally allows for a faster convergence.

The filtering associated with an EEC defined in G.8262 is sufficient for the cable network use cases identified and do not require the tighter filtering associated with enhanced EEC in G.8262.1.

2.2. Precision Timing Protocol (PTP) Overview

IEEE 1588, Precision Timing Protocol (PTP) is a standard for enabling precise synchronization of real-time clocks for devices in communications networks with system-wide synchronization accuracy in the sub-microsecond to micro-second range.

PTP relies on the transmission of dedicated packets that form the significant instants of a packet timing signal. The timing of these significant instants is precisely measured relative to a master time source, encoded in the form of a time stamp, and distributed to a packet slave clock.

PTP timing synchronization starts with a Grandmaster Clock which typically derives its time from a Primary Reference Clock (PRC) such as a GPS Receiver. Timing synchronization then propagates across the network through the exchange of PTP messages between each Master and Slave, allowing each Slave node to synchronize to the PTP timing reference provided by its Master.

There are three 1588 profiles defined by the ITU-T. G.8265.1 supports frequency synchronization, while G.8275.1 and G.8275.2 both support both frequency and phase synchronization.

G.8275.1 profile is defined with full timing support from the network, so all network elements are PTP aware and participating in the protocol. The message rate for this profile is fixed at 16 messages per second. Only two-way communication is supported in this profile. The current version of the specification requires the use of a physical layer clock, like SyncE. A version of the profile that does not include SyncE is considered for further study. R-DTI mentions this as an alternate PTP network profile based on full

timing support in the network. G.8273.2 defines the performance parameters for boundary clocks supporting this profile. The PTP clock in a T-BC defined in G.8273.2 has a bandwidth of 0.05 - 0.1 Hz.

G.8275.2 is defined with only partial timing support from the network, so not all network elements need to be aware and participating in the PTP protocol. PTP messages that transit a non-participating network element are subject to the additional delay variation associated with queuing of traffic before transmission. This can degrade performance. The profile provides flexibility in PTP message rates, from 1 message per second to 128 messages per second. The higher message rates allow support for applications that require higher accuracy and lower rates can be used for less demanding applications. Slower message rates also reduce the load on the processor on the master clock. Only two-way communication is supported in this profile. Because [R-DTI] adopted G.8275.2 as the profile to be used for R-PHY, it may be used for the RMD as well, assuming only frequency information is used. G.8273.4 defines the performance parameters for boundary clocks supporting this profile.

A PTP clock hierarchy consists of multiple devices that are synchronized within the same Time Domain. PTP timing synchronization starts with a Grandmaster Clock (GMC) which derives its time from a Primary Reference Clock (PRC) such as a GPS Receiver. Timing synchronization then propagates across the network through the exchange of PTP messages between each Master and Slave, allowing each Slave node to synchronize to the PTP timing reference provided by its Master.

PTP defines classifications for clock functionality, including Ordinary Clocks and Boundary Clocks. An Ordinary Clock (OC) is a PTP clock with a single PTP port. An OC may be either a Master Clock or a Slave Clock. An Ordinary Master clock cannot be slaved to another PTP clock. A Boundary Clock (BC) refers to a PTP clock with multiple PTP ports. A BC can synchronize to a Master clock via its Slave PTP port and serve as a Master via its Master PTP port to one or more Slave clocks.

2.3. Hybrid Mode

A node that uses SyncE with an EEC in combination with a timing protocol such as PTP or NTP with a Packet Equipment Clock (PEC) may be referred to as a hybrid EEC/PEC clock. The source of SyncE within a network should be generated from same source as the PTP domain (e.g., GPS or PRTC) to avoid frequency drift.

When SyncE, with its higher level of frequency accuracy and lower level of noise, is used with a timing protocol such as IEEE 1588, a higher level of timing accuracy is achievable across a packet network. Since SyncE is a physical layer clock, it is not subject to packet delay variation as the signal transits the network.

G.8273.2 provides the functional requirements for a telecom boundary clock or telecom time slave clock when used with full timing support from the network. The following figure from G.8273.2 provides an illustration of the clock function in a hybrid EEC/PEC clock.

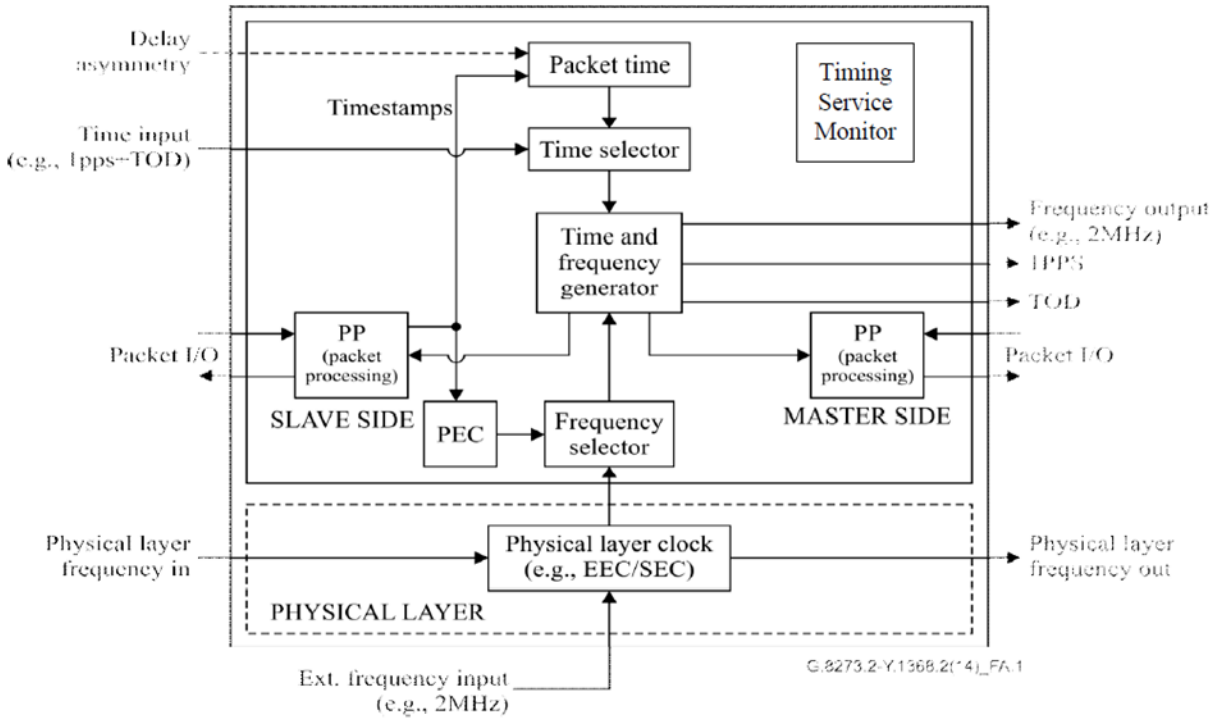

Figure 1 – Telecom Boundary Clock Model [G.8273.2]

The time information carried in the timestamps is used to establish the local time scales. The frequency information carried in the timestamps is used in the PEC to generate the local frequency.

The frequency selector block may select either the frequency information recovered from the timestamps, or the frequency recovered from a physical layer clock (e.g., Synchronous Ethernet).

3. Cable Network Timing

Timing and synchronization requirements for cable networks come from areas including existing DOCSIS specification requirements, Modular Headend Architecture v2 system requirements, and support of precision timing services, like Mobile Backhaul and other Mobile X-haul use cases.

In the MHAv2 architecture, the CMTS Core and the R-PHY are two entities located in separate locations. The DS PHY and US PHY are located in the R-PHY Device, and the DOCSIS MAC is located at the CMTS Core. Frequency and phase synchronization are required between the CMTS Core and the R-PHY Device so that they have a common knowledge of the DOCSIS time and to allow correct burst reception and to align the MAC scheduler with the PHY timestamping at the R-PHY. DOCSIS services require both frequency and phase synchronization while other services only require frequency synchronization, including Video (Sync mode), OOB (55-2 Sync mode), NDF/NDR, or Leakage Detection Signal Generation.

Certain MAC-NE (RMD) services do not require any external timing synchronization. These services can include DOCSIS services, Video (Async mode), or OOB (55-1 and/or 55-2 Async mode). Other services require frequency synchronization of the MAC-NE (RMD to an external frequency source. These services can include Video (Sync mode), OOB (55-2 Sync mode), NDF/NDR, or Leakage Detection Signal Generation.

The Mobile Backhaul application connects the mobile switching core (i.e., evolved packet core, EPC, for LTE or next-generation core, NGC, for 5G) and the radio access network (RAN) node. Long-Term Evolution (LTE) Frequency-Division Duplex (FDD) requires frequency synchronization between neighboring cells. Long-Term Evolution (LTE) Time-Division Duplex (TDD) requires additional phase synchronization between neighboring cells.

3.1. RPD Use Case

Remote PHY Device (RPD) is one type of a Distributed Access Architecture (DAA) that separates the Integrated CCAP into a CCAP Core that remains in the operator's headend and an RPD that resides in a remote fiber node or remote shelf. The RPD provides all PHY-related circuitry needed for HFC high-speed data and video services, including DOCSIS packet timestamping. The CCAP Core contains the DOCSIS MAC and the upper layer DOCSIS protocols, including all signaling functions, downstream and upstream bandwidth scheduling, and DOCSIS framing. It also contains all the video processing functions that an EQAM provides.

The CCAP Core and RPD synchronize their DOCSIS clocks in both frequency and phase so that they have a common view of DOCSIS time. This common view is enabled by Remote DOCSIS Timing Interface (R-DTI), which requires support for IEEE 1588v2 precision timing protocol (PTP). R-DTI further requires G.8275.2 with G.8275.1 and SyncE identified as being optionally supported.

The RPD also provides timing synchronization to subtended cable modems. Frequency synchronization between the RPD and the cable modems is achieved through the DOCSIS symbol rate, and DOCSIS time stamping [via Sync messages in DOCSIS 3.0 or OFDM preamble in DOCSIS 3.1] used to provide relative clock phase synchronization.

[R-DTI] identifies the timing architecture where the Core and the RPD are slaved to an external timing master.

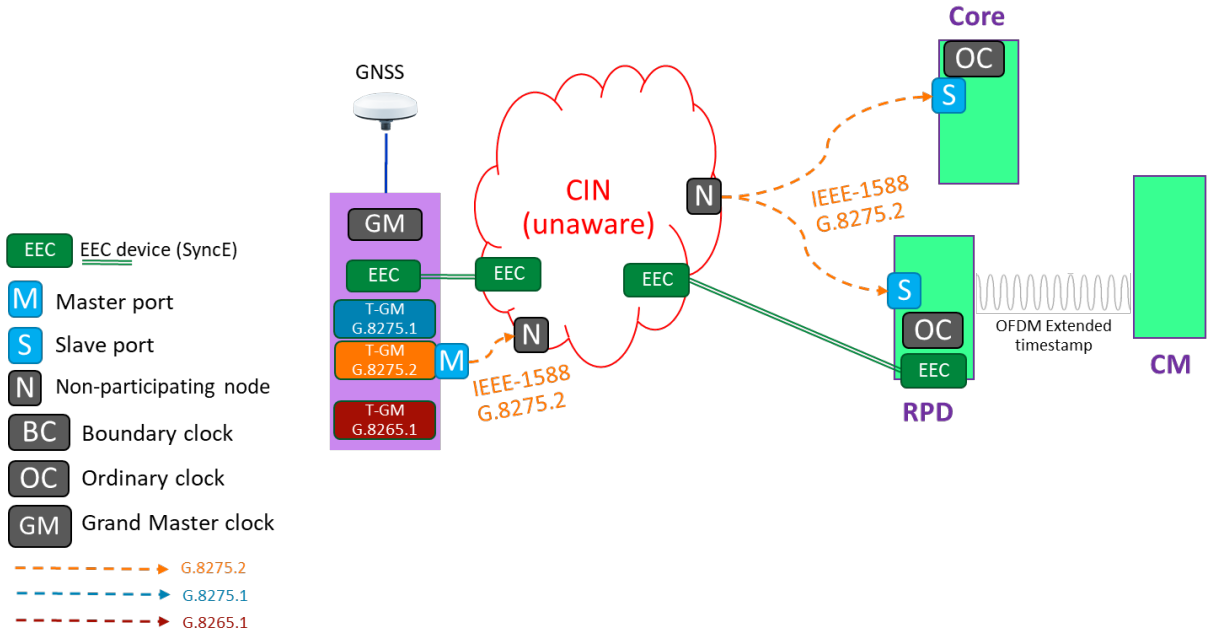

Figure 2 – RPD Use Case

External timing support is needed by the R-PHY application for the following features:

- DOCSIS services (phase and frequency sync)
- Video sync mode (frequency sync)
- Signal leakage detection (frequency sync)
- 55-2 sync mode (frequency sync)
- NDF/NDR (frequency sync)

Frequency synchronization for video sync mode avoids the need to support MPEG PCR restamping.

A summary of timing requirements from [R-DTI] for an RPD in R-PHY mode are listed below.

- The RPD MUST support 1588 OC slave
- The RPD MUST meet time/phase synchronization accuracy of ± 1 ms in reference to the 1588 GM.
- The RPD MUST comply with the T-TSC-P requirements of [G.8275.2].
- The RPD SHOULD syntonize the frequency of the local NDF/NDR clock with the assistance of the frequency recovered from Ethernet.
- The RPD MUST meet the frequency accuracy requirements (≤ ±530 ppb) specified by [R-OOB] when supporting signal leakage detection.
- The RPD SHOULD support Synchronous Ethernet for Precision Timing Services.
  Note: Precision Timing Services is a term used in [R-DTI] to describe Mobile BackHaul for wireless applications. Synchronous Ethernet is not required and is not even classified as a "truly optional" feature in [R-DTI] for other services, including DOCSIS services.

A summary of timing requirements in [D-RFI] are listed below.

- The 10.24 MHz Master Clock MUST have:
  - Frequency accuracy ≤ ±5 ppm
  - Maximum drift ≤ 10-8 per second (≤ ±.01 ppm)
  - An edge jitter of <=10 ns peak-to-peak (±5 ns)
  - DOCSIS timestamp jitter < 500 ns p-p.

The system clock in an RPD with SyncE support will typically consist of two components, a physical layer clock or EEC that uses SyncE as its timing reference and a packet equipment clock or PEC that uses PTP as its timing reference. The two timing references are normally traceable to a common frequency source since in DOCSIS the frequency and phase are coupled together. The output of the EEC portion may be used to assist and accelerate the PEC portion in achieving lock to the PTP timing reference. A node that uses SyncE with an EEC in combination with a timing protocol such as PTP with a PEC may be referred to as a hybrid EEC/PEC clock.

There are three timing related performance issues that exist in typical RPD implementations that can be improved by the use of a hybrid EEC/PEC clock system. The first is that CIN networks may introduce large PDV that can affect the frequency and phase servo algorithm convergence and accuracy of the RPD. The second is that typical RPD holdover performance is limited while there isn't a holdover specification defined for an RPD in R-DTI. The third is that services can take a while to be restored during initialization of an RPD since they rely on timing lock notification from the RPD which can last a non-negligible amount of time.

Another optional benefit of using SyncE is the ability to use NTP as the time of day (TOD) source instead of PTP for the RPD. Using NTP will eliminate the need to install a pricier PTP GM, since the frequency is already locked via SyncE. This is a subject for more detailed further study.

3.1.1. Benefit #1: Time accuracy can be improved

R-DTI defines the time/phase synchronization accuracy of an RPD to be within ±1 ms when referenced to the 1588 GM for DOCSIS Timing. R-DTI also requires support for the PTP network profile defined in G.8275.2. This profile is defined with partial timing support from the network. Since not all network elements need to be PTP aware, packet delay variation will be imposed on the PTP messages in both directions by each non-participating network element in the timing distribution chain. Long chains of non-participating elements accumulate the packet delay variation and degrade the time accuracy. The more stable and accurate frequency associated with the SyncE timing distribution and the physical layer clock assisting the packet equipment clock can result in lower output frequency and phase noise on the output signals from network element and enable improved time accuracy over using PTP alone.

Assuming SyncE and PTP are traceable to the same PRC, the servo algorithm for PTP could be simplified to lock to phase while frequency is already locked.

3.1.2. Benefit #2: Improved holdover performance

A TCXO is normally be used in RPD applications to meet the timing requirements defined in R-DTI without the increased power and cost associated with other technologies, like OCXOs. When the packet timing reference from the 1588 GM is interrupted, the RPD's clock will transition into holdover and the RPD's clock output will drift according to the characteristics of the TCXO and the quality of the timing reference frequency estimate prior to the holdover event. While R-DTI does not have an explicit holdover specification, an implied specification can be derived from the time/phase synchronization accuracy of ±1 ms and the most restrictive frequency accuracy requirements in [R-DTI] which is ±530 ppb. Currently, the holdover-out-of-specification notification is a vendor-specific implementation which relies on estimates of worst case frequency drift scenarios. The phase drift of a clock x(S) can be calculated using the following equation.

$$|\Delta x(S)| \leq \{(a_1 + a_2)S + 0.5bS^2 + c\}[ns]$$

Where:

a_1 represents an initial frequency offset during the entry into holdover

a_2 accounts for temperature variations after the clock went into holdover

b corresponds to the frequency drift caused by aging

c accounts for any additional phase shift during the entry into holdover

The following table provides some representative values for the phase drift coefficients for the equation above for a clock using TCXO technology and a clock using OCXO technology.

Table 1 – Representative Phase Drift Coefficient Values for a Clock

	Units	TCXO-based	OCXO-based
a_1	ns/s	10	10

	Units	TCXO-based	OCXO-based
a_2	ns/s	200	20
b	ns/s^2	5×10^{-5}	2×10^{-5}
c	ns	10	10

A TCXO meeting the holdover specifications in G.8262 or G.8262.1 will remain within this ±1 ms level for roughly an hour and 20 minutes. Replacing the TCXO with an OCXO extends the time the RPD would remain within the ±1 ms accuracy to roughly 1 day (25 hours), but it does come with additional cost and power associated with the OCXO. By using SyncE and a physical layer clock to enhance the performance of the RPD's packet equipment clock and providing a stable frequency reference that is traceable to the 1588 GM, the time output from the RPD will continue at the correct rate and maintain the correct time for an almost indefinite amount of time. This period of time is primarily limited by failures in the SyncE timing distribution network that interrupt the traceability to the PRC. These values are shown in the following diagram.

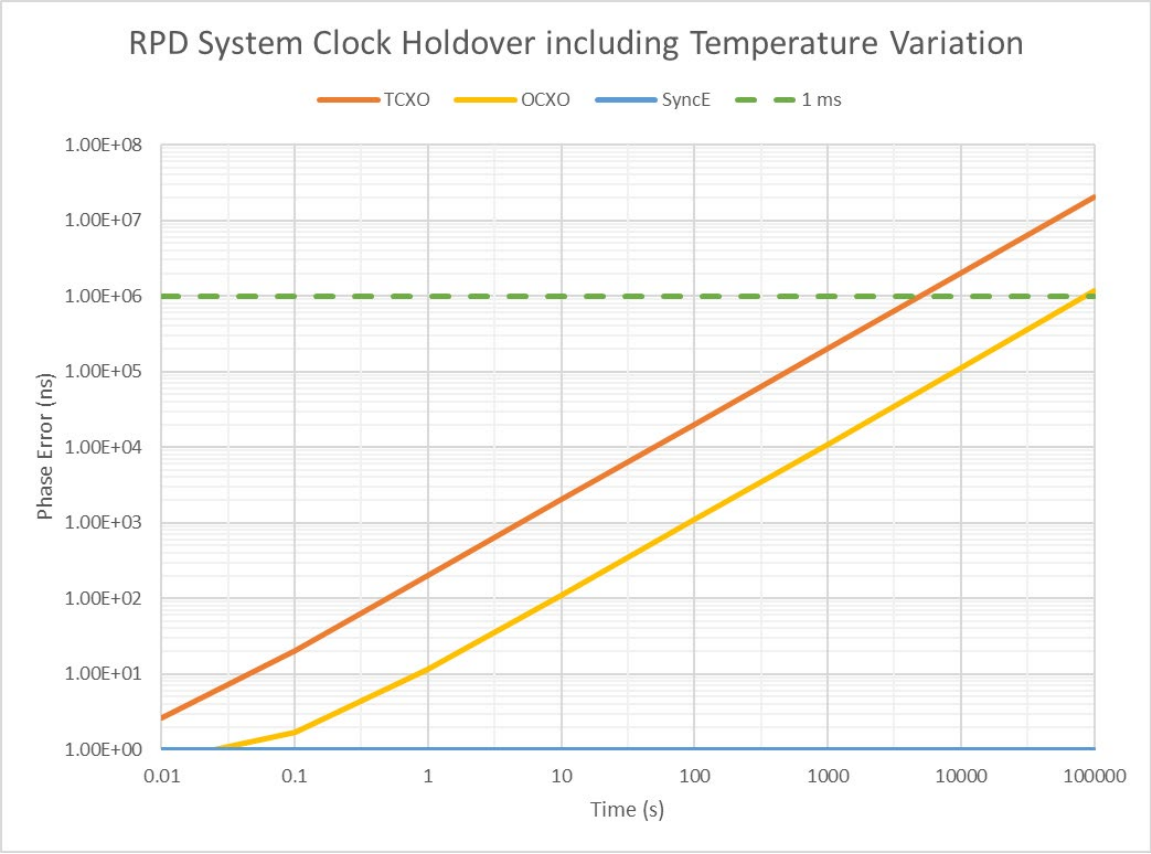

Figure 3 – RPD System Clock Holdover with No Initial Frequency Offset

Since R-DTI contains a frequency accuracy requirement of ±530 ppb, an RPD which is in frequency locked state might go into holdover with an additional initial frequency offset of ±530 ppb. This will cause the RPD to cross the ±1 ms threshold much faster. RPDs with either a TCXO or an OCXO will remain within this threshold for roughly 25-35 minutes. By using SyncE and a physical layer clock, the time output from the RPD will continue at the correct rate and maintain the correct time for an almost indefinite amount of time. These values are shown in the following diagram.

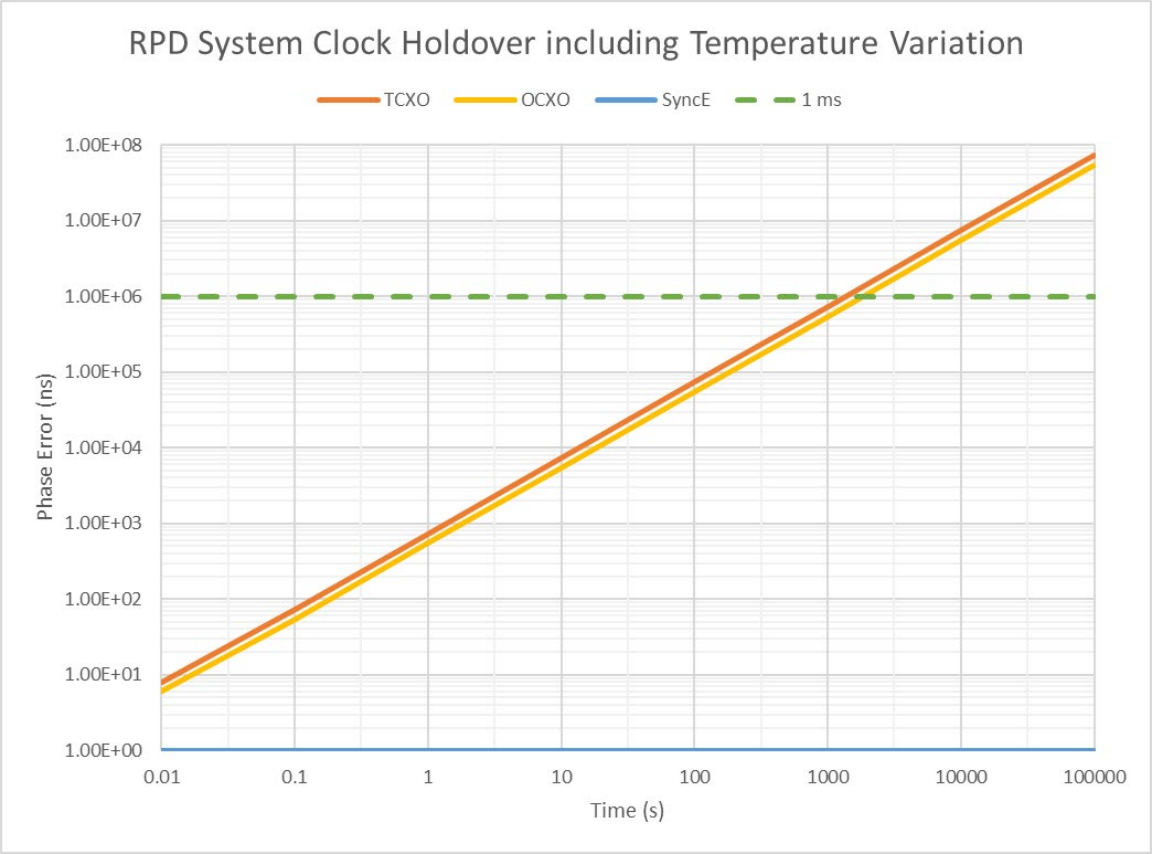

Figure 4 – RPD System Clock Holdover with 530 ppb Frequency Offset

3.1.3. Benefit #3: Reduced time to lock and recover after reset

SyncE as a timing reference to the physical layer clock that assists the packet equipment clock in the RPD's system clock can shorten the time for certain services to be available following an RPD reset.

As required in [D-RFI], an RPD receives its timing reference via PTP. The packet equipment clock is the source for all downstream timing. When exiting reset, the RPD must wait until the packet equipment clock achieves frequency lock and phase lock before it can begin to provide services, even services that only require frequency synchronization, like video and OOB services. Frequency lock can be achieved in a shorter amount of time than the time required to achieve phase and frequency lock. Phase and frequency lock with the ±1 ms specified in R-DTI can take multiple minutes.

Techniques can speed the acquisition of phase and frequency lock for the RPD's packet equipment clock after a reset. A soft reset with warm start relies on frequency information about the operating conditions of the RPD's packet equipment clock prior to the reset. Warm start is most effective if the reset time is brief and network conditions are stable during the reset time. If the conditions are not suitable, then a hard reset will be required. A hard reset is similar to a power-up reset in that it does not rely on information about the packet equipment clock's prior operating and can take longer to achieve lock. [R-PHY] provides an overview of soft reset and warm start functionality.

Reducing the time-to-lock for an RPD system clock using SyncE assistance is partially due to the difference in PLL bandwidths between the two portions of the system clock. The bandwidth of the SyncE physical layer clock PLL is in the range of 1 - 10 Hz for the non-enhanced case defined in G.8262 and in the range of 1 - 3 Hz for the enhanced case defined in G.8262.1. In contrast, the PTP clock in a T-BC defined in G.8273.2 has a bandwidth of 0.05 - 0.1 Hz. While the frequency locking process is non-linear, the difference in bandwidths between the SyncE physical layer clock and PTP clock should result in the SyncE clock obtaining frequency lock at least ten times faster than the PTP clock. Additionally, since the frequency lock is dependent on the SyncE timing reference, a larger amount of PDV can be tolerated on the PTP timing reference without significantly increasing the lock time. Frequency-based services using an RPD clock with SyncE assistance should be available in less than one tenth of the time for the same services to be available for an RPD using only a packet timing clock.

The following table shows some representative time frames for achieving frequency lock after exiting reset. The simplifying assumption is that the time to obtain phase lock after frequency lock is achieved is constant for each of the three cases.

Table 2 – Frequency Lock

	Hard Reset	Soft Reset / Warm Start	Hard Reset with SyncE Assist
Frequency lock achieved	minutes, depends on network PDV	within a minute	within seconds

Because of the faster frequency lock that results from the physical layer clock assistance, the RPD can begin to deliver video services while phase lock is still being acquired by the packet equipment clock portion of the RPD system clock. DOCSIS services may be delayed until phase lock is achieved by the packet equipment clock portion.

3.2. RMD Use Case

The Remote MACPHY Device (RMD) is a Distributed Access Architecture (DAA) device that contains all PHY-related circuitry needed for HFC high-speed data and video services as well as the DOCSIS MAC and the upper layer protocol support. This includes all DOCSIS signaling functions, downstream and upstream bandwidth scheduling, and DOCSIS framing. It also provides the digital interface to an Auxiliary Core for MPEG video and OOB signals as well as the analog interface for transmission over RF or linear optics.

Since the DOCSIS MAC and the PHY are collocated within the device, the RMD application does not have the complexity associated with frequency or phase synchronization between two devices for DOCSIS operation that the RPD requires. Non-DOCSIS functions, including some video and OOB functions, require the RMD to be frequency synchronized to the Auxiliary Cores that provide those functions. The Auxiliary Cores could be free running with an internal clock that meets the frequency accuracy specification for the specific application (e.g. ±30 ppm for video) or be synchronized to the PRC using technologies including SyncE, PTP, NTP, GNSS, BITS, etc. This allows the timing synchronization requirements of the RMD to be less strict than the requirements for the RPD.

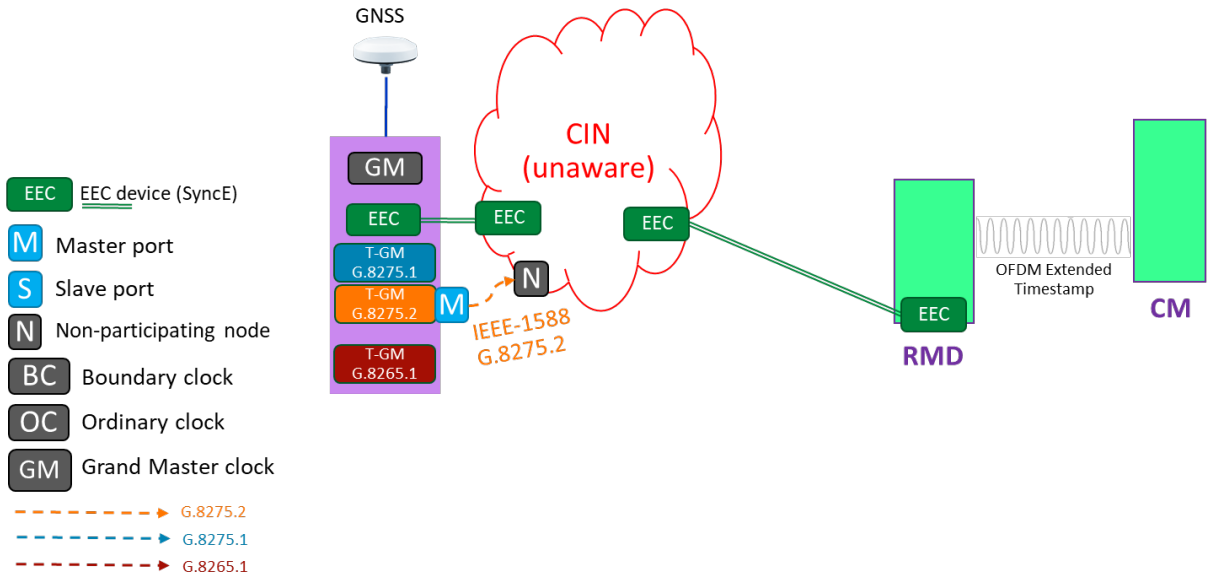

Figure 5 – RMD Use Case

Without a requirement for phase synchronization in the RMD application, there are four options for timing the RMD: free-run, frequency synchronized using the PTP profile defined in G.8265.1, frequency synchronized using SyncE, and frequency and phase synchronized using the PTP profile defined in G.8275.2. Using G.8275.2 is consistent with the requirements for an RPD in [R-DTI].

External timing support is needed by the RMD application for the following features:

- Video sync mode (frequency sync)
- Signal leakage detection (frequency sync)
- 55-2 sync mode (frequency sync)
- NDF/NDR (frequency sync)

For RMD applications that require external timing, frequency synchronization may be provided via SyncE, or by PTP. The timing reference signal in the two PTP options will have a higher amount of noise as a result of the packet delay variation on the PTP messages in the timing distribution network. The higher rate of significant instants in the SyncE timing reference and the lower amount of noise in the SyncE timing distribution network allow for a wider bandwidth of the physical layer clock in the RMD system clock function. This enables a faster lock time and faster restoral of service after a reset for a SyncE-based or SyncE-assisted RMD system clock over a PTP-only timing approach. In contrast to the RPD application, the faster restoral of service when using SyncE for frequency synchronization applies to both DOCSIS and non-DOCSIS services.

An RMD typically provides multiple Ethernet interfaces. The interfaces provide redundant SyncE timing references from the PRC to the RMD and allow the physical layer clock function to monitor the quality of the signal on the interfaces and select the better quality one, if appropriate.

The less complicated filtering and monitoring functions associated with SyncE timing references for the physical layer clock allows functions to be implemented in hardware and reduces the number of functions that need to be implemented in the CPU of the RMD. This reduces the load for timing functions on the

RMD's CPU and allows additional non-timing functions to be implemented in the same class of RMD's CPU.

3.3. MBH Use Case

A mobile backhaul (MBH) network connects the mobile switching core (i.e., evolved packet core, EPC, for LTE or the 5G core) and the radio access network (RAN) node. The SYNC specification [SYNC] describes the architecture and requirements to enable cable operators to use DOCSIS technology to carry precision frequency and phase synchronization signals over the hybrid fiber-coax (HFC) plant. This allows cable operators to take advantage of their rich infrastructural assets to provide backhaul services comparable to fiber for their own mobile traffic.

Although many wireless networks previously required only frequency synchronization, including LTE Frequency-Division Duplex (FDD), other networks require time and phase synchronization. Long-Term Evolution (LTE) Time-Division Duplex (TDD) is an example of a technology that requires frequency and phase synchronization.

3.3.1. Frequency Synchronization

From [SYNC], networks that require only frequency synchronization have a target performance for frequency accuracy of ±16 ppb [G.8261.1]. This is based on the requirement of a ±50 ppb radio frequency accuracy.

3.3.2. Time Error budget

[SYNC] provides a comprehensive view of the end-to-end performance budget of 1.5 µs for maximum time error for networks that require frequency synchronization and phase synchronization. One section covers the DOCSIS portion of the network, and specifically the portion of the budget allocated to CMTS and DAA equipment. The performance target for constant time error of the CMTS, RPD, or RMD is ±200 ns for class A equipment and ±100 ns for class B equipment. The jitter value in the CMTS, RPD, RMD component is been reduced to 5-10 ns (1/204.8 MHz plus phase noise jitter) as a result of using OFDM-based DOCSIS systems.

DOCSIS Time Protocol (DTP) allows IEEE 1588 protocol information to be passed over the DOCSIS network with high frequency and phase accuracy by eliminating the jitter resulting from network buffering in the DOCSIS network. DTP takes advantage of the fact that DOCSIS is a synchronous system and distributes a physical layer clock to distribute frequency information to the cable modems. It also uses the DOCSIS 3.1 timestamp to distribute time information. A signaling path determines the downstream timing offset, which is used as a correction factor for PTP.

3.3.3. Mobile Backhaul Use Cases

Four synchronization use cases for mobile backhaul are identified in [SYNC].

- Physical Layer Timing Support for Frequency Synchronization
- Full Timing Support for Phase Synchronization
- Partial Timing Support for Phase Synchronization
- Partial Timing Support for Frequency Synchronization

The current version of [SYNC] identifies requirements associated with Physical Layer Timing Support for Frequency Synchronization and Full Timing Support for Phase Synchronization. The other two use cases will be addressed in a future version of the document.

3.3.4. Physical Layer Timing Support for Frequency Synchronization

For Physical Layer Timing Support for Frequency Synchronization, the RPD or RMD is synchronized to the PRC using SyncE, and the cable modem provides the frequency reference to the end application using SyncE.

The RPD uses PTP to align its frequency and phase for R-PHY operation and generates the downstream DOCSIS frequency and timestamp traceable to the PTP clock domain. For the downstream clock to be SyncE-traceable, the input SyncE and PTP should be generated from the same source. The RPD operates in Hybrid mode so that SyncE may be used to assist the PTP clock for functions like holdover and fast-lock. The frequency source of SyncE should share a common frequency source with the PTP domain (e.g., GPS or PRTC) since DOCSIS couples the frequency and phase together and to avoid frequency drift between the two domains. Cores usually only support G.8275.2 as defined in [R-PHY]. Supporting different profiles for RPD and Core will require different GMs.

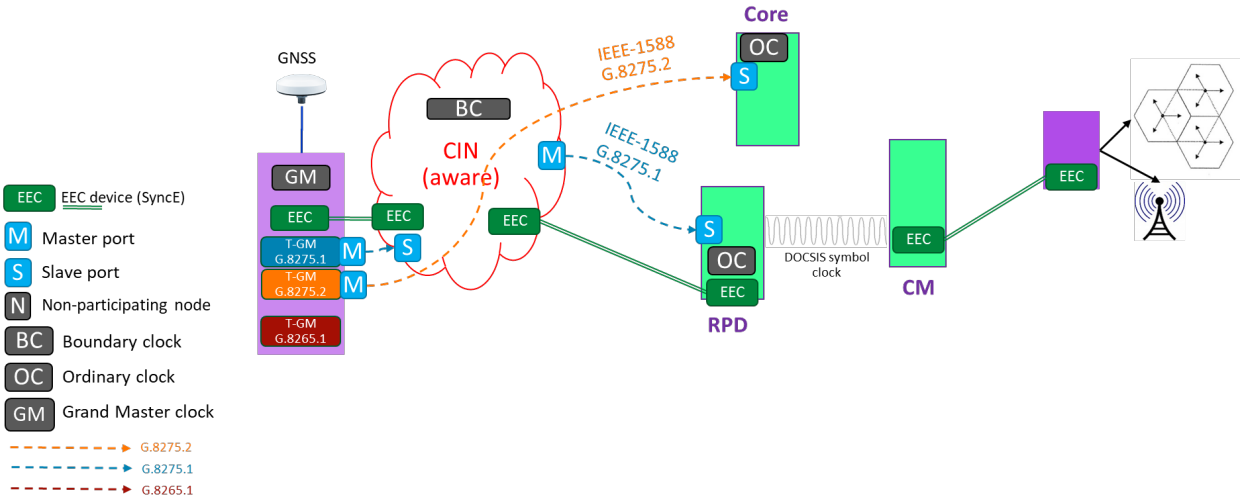

Figure 6 – RPD Physical Layer Timing Support for Frequency Synchronization Use Case

The RMD's system clock is locked in frequency via SyncE. Without a requirement for phase synchronization in this application, the RMD may use an arbitrary time of day or use NTP to establish the system's time of day. The lower amount of noise on the SyncE timing reference allow for a wider bandwidth of the physical layer clock in the RMD system clock function. This enables a faster lock time, faster restoral of service after a reset and more accurate holdover for a SyncE-based RMD system clock over a PTP-only timing approach.

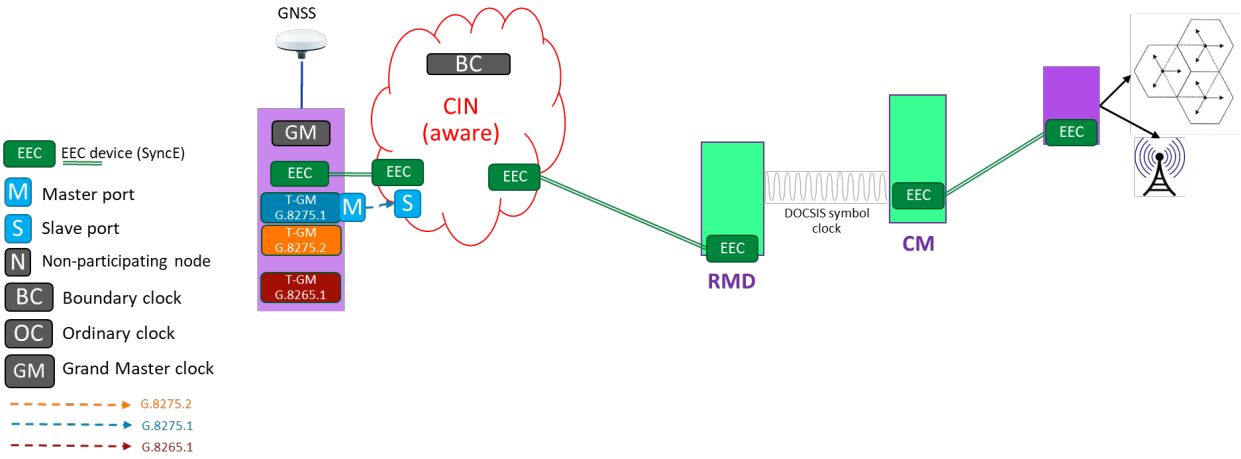

Figure 7 – RMD Physical Layer Timing Support for Frequency Synchronization Use Case

3.3.5. Full Timing Support for Phase Synchronization

Full Timing Support for Phase Synchronization in [SYNC] requires the DOCSIS interworking function to support the network profile defined in G.8275.1 with each switch in the network having PTP awareness (such as Ordinary Clock or Boundary Clock). It also requires the use of a physical layer clock, like SyncE, at each element in the network.

R-PHY has timing requirements specified in [R-DTI] that are different from the timing requirements for MBH support, i.e., the timing accuracy requirements (for frequency and phase) and the timing delivery requirements (profile, 1588/SyncE, etc.). The challenge is to have the R-PHY Device (RPD) clock support the requirements for two timing applications when the set of requirements for one application is not a superset of the other.

The following table from [SYNC] contrasts the requirements for an RPD operating in a MBH application and an R-PHY application.

Table 3 – R-PHY Requirements vs. MBH "Full Timing Support for Phase"

Item	R-PHY	MBH	R-PHY requirements when supporting MBH precision timing services
Lock threshold	1 ms	50 ns	See Section C.2.1 of [SYNC]
Phase lock time	Few minutes	Not defined (should be short)	See Section C.2.2 of [SYNC]
Profile	[G.8275.2]	[G.8275.1]	See Section C.2.3 of [SYNC]
SyncE	Recommended	Required	See Section C.2.4 of [SYNC]
Holdover requirements and duration	Not specified	[G.8273.2]	See Section C.2.5 of [SYNC]
Phase steps	Not allowed when locked	Not specified	See Section C.2.6 of [SYNC]

Item	R-PHY	MBH	R-PHY requirements when supporting MBH precision timing services
Frequency change rate	10 ppb/s	Not specified	See Section C.2.6 of [SYNC]
Precision timing frequency and phase budget	Table based on old DTP section	Specified in Section 8 of [SYNC]	See Section C.2.7 of [SYNC]
"soft reset" support	The RPD holds in holdover for <1 min during a soft reset in order to have a quick reset using a warm start. The RPD goes operational even before it re-locks to the GM.	Convergence after soft reset is for further study	See Section C.2.8 of [SYNC]
BC functionality	Allowable	Required on every Ethernet hop	See Section C.2.9 of [SYNC]

The RPD uses PTP to align its frequency and phase and generates the downstream DOCSIS frequency and timestamp traceable to the PTP clock domain. For the downstream clock to be SyncE-traceable, the input SyncE and PTP should be generated from the same source. The RPD operates in Hybrid clock mode so that SyncE may be used to assist the PTP clock for functions like holdover and fast-lock. The frequency source of SyncE should share a common frequency source with the PTP domain (e.g., GPS or PRTC) to avoid frequency drift between the two domains.

DTP functions are distributed between the RPD and the Core. Cores usually only support G.8275.2 as defined in [R-PHY]. Supporting different profiles for RPD and Core will require different GMs. PTP announce message delivery is from the RPD to Core via UEPI to forward to the CMs. Core needs to encapsulate the PTP announce messages on the UEPI PW from the RPD and forward to all CMs on relevant DSIDs.

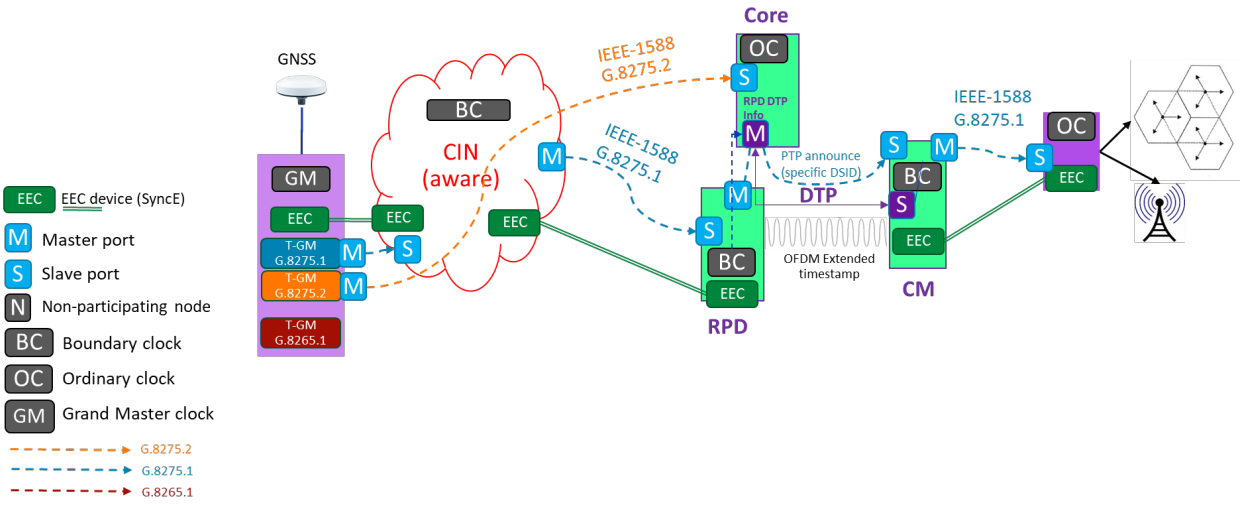

Figure 8 – RPD Full Timing Support for Phase Synchronization Use Case

The RMD's system clock is locked in frequency and phase via PTP using G.8275.1 with SyncE assistance. The lower amount of noise on the SyncE timing reference allow for a wider bandwidth of the physical layer clock in the RMD system clock function. This enables a faster lock time, faster restoral of service after a reset and more accurate holdover for a SyncE-based RMD system clock over a PTP-only timing approach. The lower noise on the system clock as a result of the SyncE assistance allows for lower noise and better accuracy of the timestamps.

All DTP functions are co-located in the RMD so there isn't the complexity associated with coordinating and synchronizing between two devices.

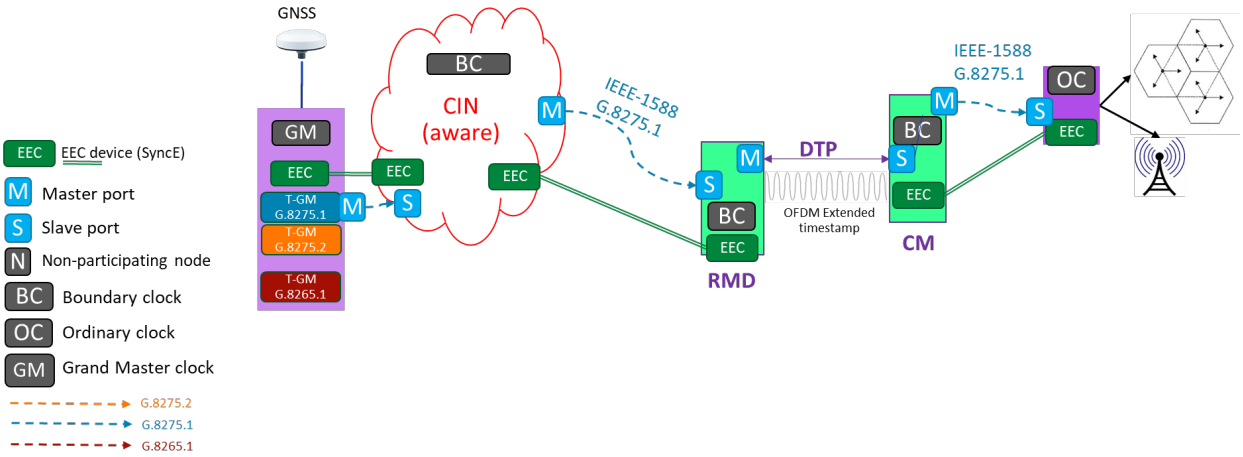

Figure 9 – RMD Full Timing Support for Phase Synchronization Use Case

4. Conclusion

Synchronous Ethernet (SyncE) is used mainly in telecom networks to provide physical layer clock delivery for frequency synchronization (aka syntonization). The cable industry has not yet adopted SyncE as a common supported functionality while IEEE1588 is more commonly used for time synchronization (mainly for DAA use cases).

The paper investigated the impact of providing SyncE support in DAA R-PHY and R-MACPHY applications as well as two use cases for mobile backhaul (LTE and 5G) applications. The RMD implementations provided additional benefits over the RPD implementations for each use case due to the integrated DOCSIS MAC and PHY functions in a single system and simplified timing interface. SyncE provided multiple benefits over the traditional PTP-only based implementations in these applications including:

- Improved timestamp accuracy
- Improved holdover performance
- Reduced time to lock and reduced time to recover services after reset

These improvements are realized without additional complexity. As a result, it is clear that SyncE is a valuable functional addition to the cable network.

Since converged interconnect networks (CINs) are generally new networks, requiring SyncE support for equipment in the CIN is a reasonable requirement. Even in case where a portion of the network does not support SyncE, there are reasonably priced boundary clocks that can be plugged into the CIN equipment to provide SyncE support.

Abbreviations

BC	Boundary Clock
BITS	Building Integrated Timing Supply
CCAP	Converged Cable Access Platform
CIN	Converged Interconnect Network
CMTS	Cable Modem Termination System
DAA	Distributed Access Architecture

1. Introduction

The way we create, share and consume information has led to a tremendous increase in wireless data traffic. The demand for wireless data continues to grow exponentially and that puts extreme requirements on the future communications systems. Each generation of mobile technology, from the first to the fifth (5G), has been designed to meet the new needs of end users and network operators. While the number of mobile connected devices is increasing rapidly, from 8.8 billion in 2018 to a predicted 13.1 billion by 2023, at the same, as anticipated by Edholm's law of bandwidth, the achievable data-rate is scaling new heights, from 20 Gigabits per second (Gbps) of peak data rate in 5G to expectedly 1 Terabit per second (Tbps) within the next few years. Figure-1 shows the roadmap for the wireless data rates up to year 2035 and is a good indicator of the past and anticipated growth in data rates.

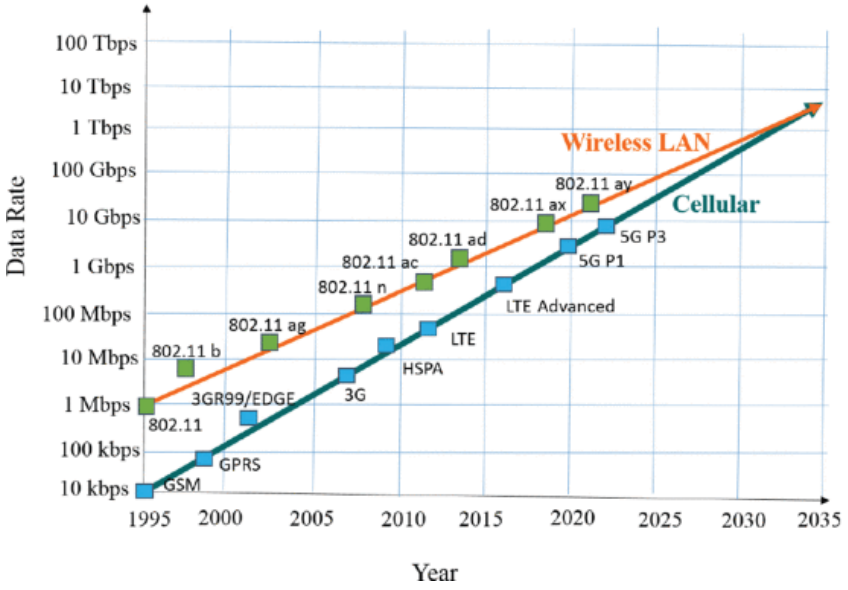

Figure 1 – Wireless Roadmap Outlook

Societies continue to become more and more intelligent, data-centric, data-dependent, and automated. Autonomous systems are hitting our roads, oceans, and air space. Millions of sensors will be embedded into cities, homes, and production environments, and new systems operated by artificial intelligence residing in local cloud and fog environments will enable a plethora of new applications. To glue this all together, communication networks will provide the nervous system for these new smart system paradigms. The demands, however, will be daunting. Networks will need to transfer much greater amounts of data at much higher speeds and lower latencies. Furthering a trend already started in 4G and 5G, sixth generation (6G) connections will move beyond personalized communication toward the full realization of the Internet of Things (IoT) paradigm, connecting not just people, but also computing resources, vehicles, devices, wearables, sensors, and even robotic agents. Beyond improving existing communication and signal processing solutions, there is a need to explore untapped frequency bands for communications. In order to enable the transmission of very high data rates (10s of Gbps), two approaches are possible. The first one is to improve spectral efficiencies beyond 10 bit/s/Hz for the systems operating at moderate bandwidths, which will be very challenging. The second

approach requires ultra-high bandwidths beyond 20 GHz while operating at moderate spectral efficiencies. But, such a large amount of spectrum is only available in the Terahertz (THz) frequency range, i.e., beyond 300 GHz.

THz band communications is being projected as a key enabling technology for next-generation wireless systems that promises to integrate a wide range of data-demanding and delay-sensitive applications. As more and more data move to the edge, the last meter solutions are getting more and more attention. The higher bandwidth and contention free data communication promised by terahertz spectrum is expected to be an important part of ITU (International Telecommunication Union) Network-2030 vision. As the wireless world moves toward 6G, radio layer Terabit per second (Tbit/s) communications and the supporting access and backhaul network infrastructures are expected to become a predominant technology trend. However, with the current approach, certain severe limitations affect the capability of future wireless communications systems to meet the combined requirements of high data rate, near-zero latency, and high spectral and energy efficiency. In this context, utilizing THz frequency bands for wireless transmissions, as an extension to optical fiber, is a promising enabler to bridge this gap and provide ubiquitous high-speed Internet access beyond 5G.

Since most of the traffic is generated indoors, the future wireless systems are also expected to rely on a significant number of indoor solutions to massively offload cellular networks. To enable this, the focus has been millimeter wave (mmWave) frequencies such as 28, 39 and 60 GHz. However, the use of mmWave solutions still leads to certain limitations as the shared throughputs will only approach a few Gbit/s. As an intermediate step between millimeter-wave and optical wireless communication systems, the THz band offers unique trade-offs between channel bandwidth and propagation properties that make it a key player in future wireless communication systems, including 6G. The THz band has sufficient resources not only to satisfy the 5G requirements of 10 Gbit/s peak data rate but to enable a number of new tempting high data rate applications.

However, the THz band brings a few novel challenges in terms of propagation (THz wall) and device availability (THz gap). To achieve wireless throughput of 100 Gbps and beyond, THz spectrum seems like a logical solution due to the availability of large bandwidths. The global community have been putting a lot of effort in developing THz band-based solutions and has shown some promising early development, but still have a long way to go before we see commercial solutions available.

As the THz band continue to gain noticeable attention within the global community. Seamless data transfer, unlimited bandwidth, microsecond latency, and ultra-fast download are all features of the THz technology that is anticipated to revolutionize the telecommunications landscape and change the way people communicate and access information. Motivated by the potential of THz technologies to shape the future of wireless communications, this paper seeks to identify the unique characteristics of THz waves, the critical technology gaps in system design, recent developments and some potential use cases/applications.

2. Terahertz (THz) Spectrum Overview

The Terahertz spectrum region of electromagnetic radiation lies between the microwave and infrared portions of the spectrum. Basically, THz range extends from the highest frequency radio waves to the lowest frequency infrared light. Theoretically, THz band should start at 1000 GHz, but for all practical purposes spectrum beyond 100 GHz is considered a part of THz band as shown in figure-2.

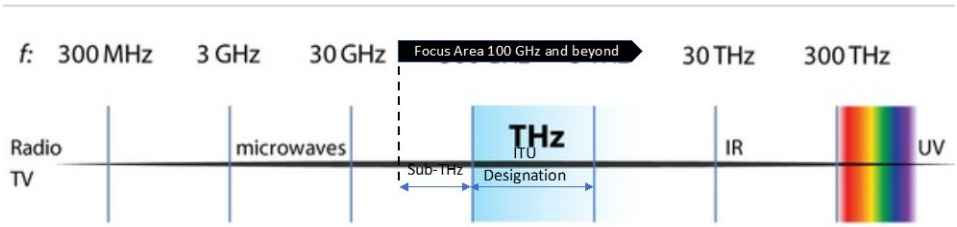

Figure 2 – Terahertz Spectrum

THz waves, also known as T-waves, T-rays, sub-millimeter waves or micrometer waves, are the electromagnetic waves in the frequency band of about 0.1 to 10 THz. ITU (International Telecommunications Union) has designated 300 GHz to 3 THz as the THz band. The spectrum between 100 GHz to 300 GHz is known as sub-THz band.

3. Terahertz Wall - THz Waves Propagation and Other Characteristics

The THz link suffers from several path loss mechanisms, the free space path-loss (FSPL) due to signal spreading, the effective antenna aperture, and the molecular absorption. The latter is a distinguishing feature of the millimeter and sub-millimeter bands. The main difference between the mmWave and the THz band is the progressively increasing molecular absorption loss.

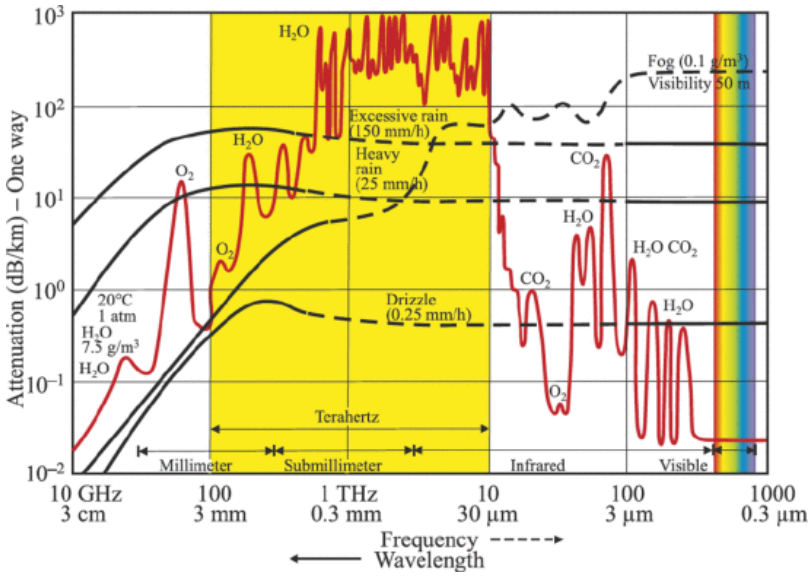

Figure 3 – Terahertz Propagation

At terahertz frequencies the propagation losses are very high, meaning the signal die down very fast. The impact of atmospheric attenuation for THz links is shown in figure-3. Although propagation losses are very high, a closer look indicates that not all frequencies suffer the same amount of propagation loss and the losses are not linear as we move towards high frequency region. Despite the existence of absorption peaks centered at specific frequencies, the availability of transmission windows allows for viable communication in the THz frequency band. These windows of opportunity (low absorption windows) for transmission at 94, 140 and 220 GHz are shown in figure 4 below.

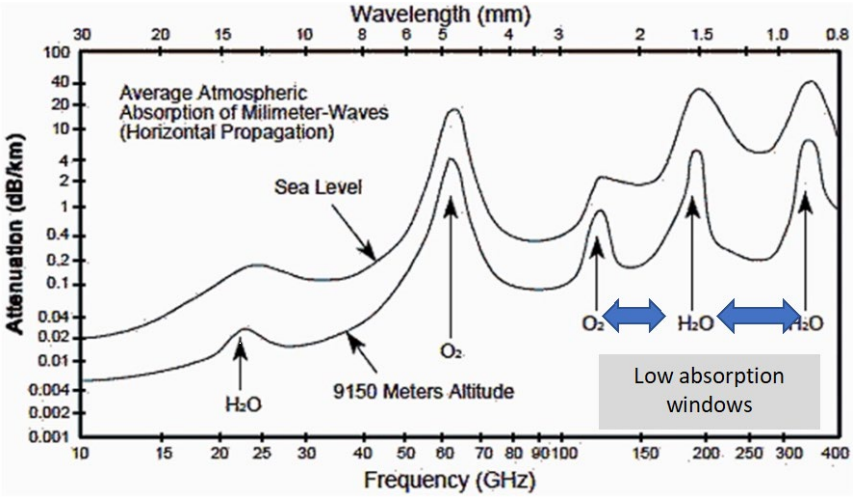

Figure 4 – Terahertz Propagation: Low Absorption Windows

The propagation distance of THz waves is significantly impacted by very high atmospheric loss. Based on the propagation studies, table-1 below shows the anticipated loss at a certain frequency using a specific bandwidth. Since water and oxygen are seen as the strongest absorber of the THz waves. For designing a THz link, it is very important to estimate the weather impact on high-capacity data links. As the THz band channel is considered highly frequency selective, the transmission distance is limited by attenuation and the appropriate carrier frequency should be determined according to the application.

Table 1 – Terahertz Ranges For Fixed Links

Frequency Range (GHz)	Contiguous Bandwidth (GHz)	Loss (dB/km)
275-320	45	<10
335-360	25	<10
275-370	95	<100
380-445	65	<100
455-525	70	<100
625-725	100	<100
780-910	130	<100

At terahertz frequencies the propagation takes the form of narrow a beam (similar to laser) and not a broadcast, which makes them more suitable for the point-to-point links. As shown in the

figure-5, THz waves quickly achieves a point where further power increase does not make any improvement in the link distance. This phenomenon is also known as terahertz wall. Figure-5 shows a comparison of different scenarios for horizontal transmission at sea level during good weather, bad weather, a range of distances (from 1 meter up to 6 kilometers), and specific frequencies between 35 gigahertz and 3 terahertz, to determine how much the signal strength degrades as conditions vary. The higher losses with rain and fog can be clearly seen as represented by dotted lines.

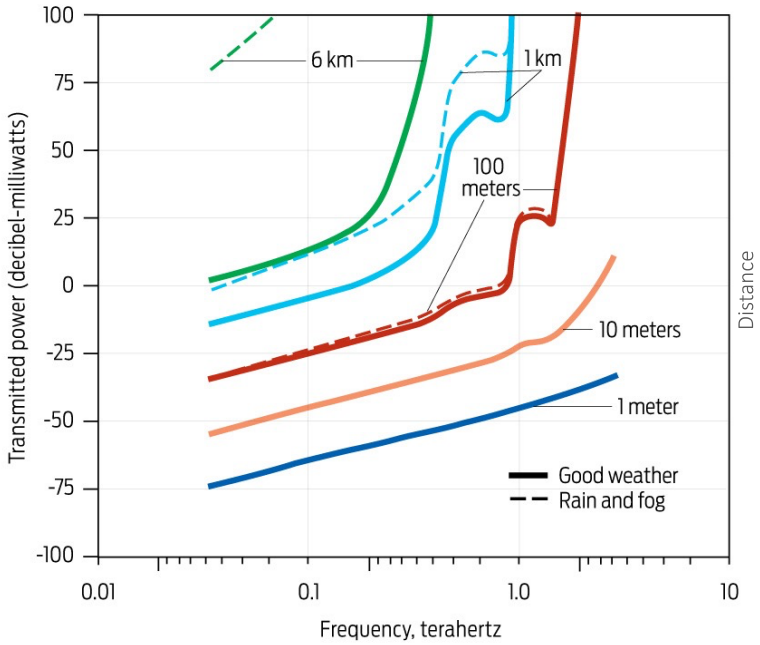

Figure 5 – Terahertz Wall: Frequency, Power versus Distance

For short-range operation, for example, signals traveling 10 meters or less—the effects of the atmosphere and bad weather don't really come into play. Any effort to send anything farther than that will quickly hit the terahertz wall. No matter how much the signal is boosted, essentially nothing gets through. A 1 watt signal with a frequency of 1 THz, for instance, will dwindle to nothing after traveling just 1 km, it only retains about 10-30 percent of its original strength. Even if transmit signal power is increased to the ridiculously high levels say a petawatt, it would get attenuated to a mere femtowatts by the time it reached its destination. Currently there are no terahertz sources capable of producing anything approaching a petawatt; the closest is a free-electron laser, which has an output in the low tens of megawatts and isn't exactly a field-deployable device. Basically, the extreme attenuation or propagation loss rules out using the terahertz region for long range terrestrial communications.

Some of the other unique properties of the terahertz waves are being harmless to the tissue and ability to pass through opaque materials. These properties make them promising candidate for use in noninvasive imaging in industry, medicine, and security. Unlike X-rays, terahertz waves are too low in energy (0.004 electron volt) to knock electrons off atoms, which could damage living tissue. Also, because of their shorter wavelength, they can produce pictures that are far sharper than those made with microwaves, the current safe imaging alternative. Terahertz waves also occupy a unique window of the electromagnetic spectrum where a large

number of molecules emit and absorb radiation. The signals produced when a molecule jumps among rotational modes form a unique and highly distinctive chemical fingerprint. Terahertz waves also passes thru most dielectrics, opaque materials for example textile, paper, plastics, cardboard etc. Since water absorption is high, terahertz waves can be used to monitor water content in food and chemicals. How these properties can be used for imaging and spectroscopy applications are briefly covered in the section 5.2 and 5.3 of this document.

4. Terahertz Gap – THz Technology Development Challenges

Terahertz region sits between the microwave (electronics) and far infrared optical (photonics) regimes. To make something as simple as a terahertz transceiver, a device that's capable of both emitting and detecting terahertz radiation, a few adjustments to a conventional electronic or photonic transceiver should have been possible. But neither technology is really suitable for the task. For example, trying to adjust a radio transceiver so that it operates at terahertz frequencies, fundamental physical limitations are quickly encountered. The rapidly flipping voltage of a high-frequency alternating current can have strong electromagnetic effects on the transistors in a transceiver, giving rise to parasitic resistances and capacitances that take power away from the devices. More fundamentally, there is a speed limit on how fast electrons can move. Beyond a few tenths of a terahertz, the frequency of oscillations becomes so high that an electron can't cross a transistor channel from the source to the drain before the voltage flips its polarity, forcing the electron to reverse direction and causing transistor power to drop precipitously. As shown in figure-6 below, the current devices exhibit very poor power-frequency scaling in THz range.

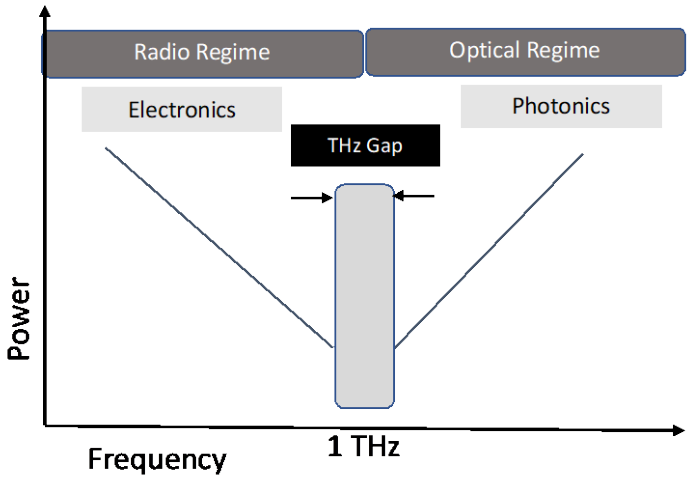

Figure 6 – Terahertz Gap: Power versus Frequency

This poor power versus frequency response exhibited by the current technologies have resulted in the device unavailability. This lack of devices in the terahertz spectrum as shown in figure-7 below is known as THz gap - a region in electromagnetic spectrum that does not have devices available for generation and detection. THz gap results from the lack of compact, energy-efficient device technologies. Most of the currently available devices are bulky, expensive and energy inefficient with power efficiencies in a single digit. At higher frequencies due to small antenna, device sizes create a lot of fabrication challenges, for example difficulty in ensuring

noise and inter-component interference suppression. In fact, integrated electronics are becoming large in comparison to the size of the corresponding antennas. Also, the high power and current density requires adequate cooling to prevent the device from disintegration.

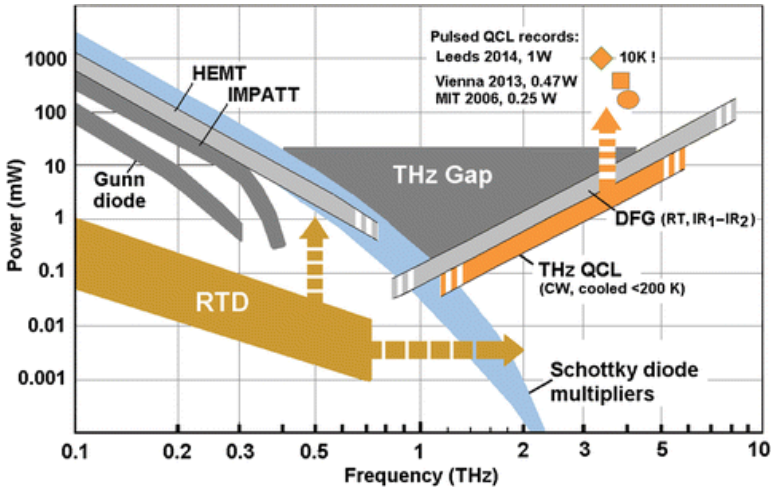

Figure 7 – Terahertz Gap: Current Device Technologies

These limitations are driving the invention of new materials. Progresses in electronic, photonic, and innovative plasmonic device technologies is continuously bridging the THz gap. Some of the promising technologies to achieve good output power and efficiency are Gallium Arsenide (GaAs), Gallium Nitride (GaN), Indium Phosphide (InP), complementary metal oxide semiconductor (CMOS), Silicon Germanium (SiGe), and fully depleted silicon on insulator (FD-SOI) CMOS. Figure-8 provides a high-level view of capabilities being offered by current technologies in terms of supported frequency and power output with still a long road ahead.

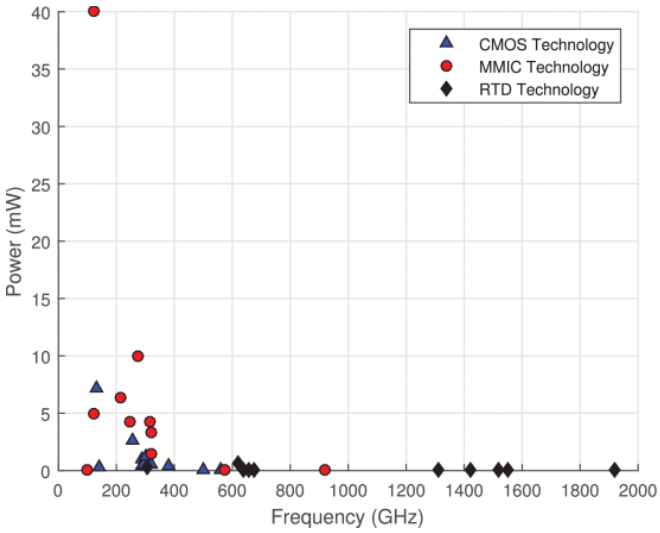

Figure 8 – Solid State Electronics: Frequency of versus power

Although today's technology has scarce high-power THz transmitters, it is expected that signal generators with high power can be created in the near future considering ongoing studies on graphene and InGaAs (Indium Gallium Arsenide) mHEMT (Metamorphic High Electron Mobility Transistor) monolithic microwave integrated circuits (MMICs). In the electronics approach, frequency multiplying and mixing chains enabled by transistor and diode technologies, resonant tunneling diodes, and traveling wave tubes are some of the major players. In a photonics approach, the beating of two lasers or frequency-difference generation, photoconductive antennas and quantum cascade lasers are examples of THz technologies aimed at closing the gap coming from the other end of the spectrum.

In addition to the device availability some of the other major areas that require a lot of work include radio frequency frontend and antenna design, propagation and channel modeling, waveforms, signals, and coding, beamforming and (ultra-massive) MIMO as well as resource management and medium access control schemes. All of these challenges demand for higher processing powers thus driving the need for new advanced processing devices.

THz spectrum offer the potential for breakthrough high data throughput applications. However, there are four key considerations for optimizing the performance of sub-terahertz systems operating over wide or extreme bandwidths: optimizing signal to noise ratio (SNR), minimizing phase noise, addressing linear and nonlinear impairments and making a waveform selection. In order to optimize SNR to achieve the best Error Vector Magnitude (EVM) performance, maximizing signal power (S) can achieve the highest SNR, but reducing the signal power becomes necessary to avoid harming any components along the signal chain. The noise contributions for SNR can be problematic for wideband applications since the noise power is integrated over wide signal bandwidths. For example, 10 GHz bandwidth signal will have 1,000 times more integrated noise than a 10 MHz signal. Basically, due to power level and high bandwidth contributing to poor SNR, basically SNR is effectively "squeezed" both on the high end and the low end. This is a key consideration in moving to extreme bandwidth test systems, and the SNR can often translate into what residual EVM is achievable. Also, up conversion from an intermediate frequency (IF) to sub-terahertz frequencies involves frequency translation with a local oscillator (LO) signal source(s) and frequency converter(s). A frequency multiplier will increase the phase noise by 20 * Log (N), where N is the multiplication factor. Furthermore, the multiplier can introduce additive phase noise that will further degrade the multiplied LO phase noise, dependent on the quality of the multiplier used. Low residual EVM test system performance at sub-terahertz frequencies requires high-quality, low-phase-noise LO signal sources.

To make the most out of the very large bandwidth provided by the THz band channel, new communication and signal processing techniques are needed. These include, among others, time, frequency and phase synchronization techniques, when transmitting at Tbps and in the presence of phase noise, real time channel estimation and equalization of tens to hundreds of GHz-wide bandwidths; and modulation strategies that can make the most out of the distance-dependent bandwidth of the THz channel. All these techniques need to be realized while keeping in mind that the sampling frequency of the fastest digital to analog and analog to digital converters is far below the required Nyquist frequency, which motivates the exploration of heavily parallelized systems as well as analog signal processing solutions. As opposed to traditional wireless networking paradigms, where the channel bandwidth is the scarcest resource that needs to be efficiently shared, the vast spectral resources in the THz band flip the script and change the focus to effectively everything else. Innovation is required in the higher layers of the

protocol stack, including dynamic power and bandwidth multi-hop relaying strategies that efficiently leverage the THz channel and real-time buffer-less routing protocols able to overcome the traditional delays associated with store-and-forward policies at the network layer; or innovative end-to-end transport layer solutions, which can accommodate frequent lack of connectivity between highly directional nodes.

Though the list of challenges in designing ultra-high frequency large bandwidth systems is very large, but the research community is continuously working on bridging this gap with new materials, processes and techniques.

5. Terahertz (THz) - Use Cases/Applications

Based on their properties discussed in the section 3, the applications of the THz waves can be broadly divided into three areas:

- Wireless Data Communications - THz can support high bandwidth (GHz), high data rates (Tbps) in the short range
- Imaging – THz waves are non-ionizing and harmless to tissues, can pass through opaque surfaces
- Spectroscopy - THz wave rotational and vibrational frequency matches those of molecules resulting in the creation of unique spectral fingerprint

Since the focus of this paper is wireless data communication, therefore communication related use cases will be discussed in more details, while imaging and spectroscopy will be covered at a very high level.

5.1. THz based Wireless communication applications

This section outlines some of the applications/use cases that will require ultra-broadband connectivity to work effectively. Due to high atmospheric losses the long-range communications (a few kilometers) with THz is not possible, but still there is a huge potential in using THz waves in the short range. At a high level the communication uses cases can be divided into three categories: Nanoscale (nano to centimeter), Microscale (centimeter to meter) and Macroscale (a few meters).

5.1.1. Terahertz Nanoscale Applications

Very small size of THz transceivers and antenna is driving a lot of application at a nanoscale. Over a very short distance referred to as nanoscale, the THz waves can be used to support intra-chip, inter-chip or intra-device communications. Chip-to-chip communications means wireless links inside computers or any other electronic devices. It is of high relevance because wired connectors and micro strip lines on printed circuit boards potentially become a bottleneck of upcoming bus systems and inter chip connections.

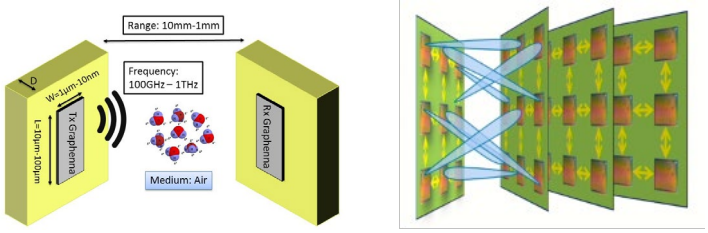

Figure 9 – Terahertz: On chip or chip to chip communications

Since transmission ranges are a few cm and the fully static environment allows for a fixed alignment during design process with automatic beam steering as an option for sequential multipoint operation between more than just two chips. Energy and chip real estate are two scarce resources in devices (e.g., smartphones, tablets, laptops). With the new advances in the coding and modulation used in the physical layer (PHY), chip to chip communications can be used to reduce the area and energy overheads of a given interconnect. Thus, terahertz waves can be used to implement simple and energy efficient on chip or inter-chip communications. The THz wireless communication is quickly evolving into a key enabler of applications involving operations inside computers and devices for a typical range of a few centimeters which includes chip-to-chip, board-to-board and device-to-device communications.

Additionally, nano-antennas enable wireless interconnection amongst nano-sensors deployed inside and over the human body resulting in many bio-nano-sensing applications.

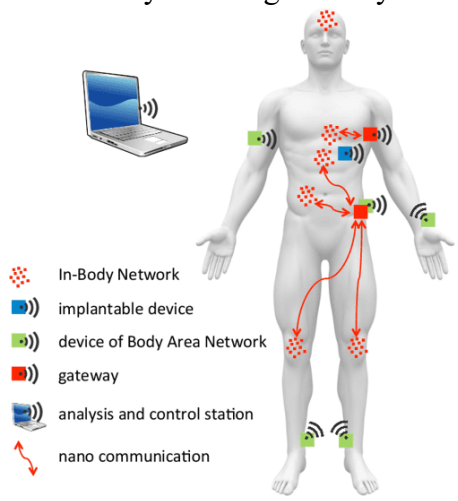

Figure 10 – Terahertz: Body area network (BAN)

As shown in figure-10 above, THz sensors can be planted inside and outside body to gather and transmit data to the wireless gateway connected to the diagnostic application.

5.1.2. Terahertz Microscale Applications

Wireless local area network (WLAN) and wireless personal area network (WPAN) form the basis of microscale applications which include high-definition television (HDTV) in home distribution, wireless displays, seamless transfer of files, and THz access points in the areas with device congestion. The THz band provides small cell communication for mobile cellular networks, where ultra-high data rate can be provided to mobile users within transmission range up to 20 m. As shown in figure-11 below, wireless personal area networks can be used for ultra-high-speed ad-hoc connections between devices over short distances, for example between a printer and a laptop. The typical THz deployment will be indoors and the alignment of high gain antennas should be ideally done by automatic beam steering, but rough manual alignment may be thinkable in case of less directive antennas.

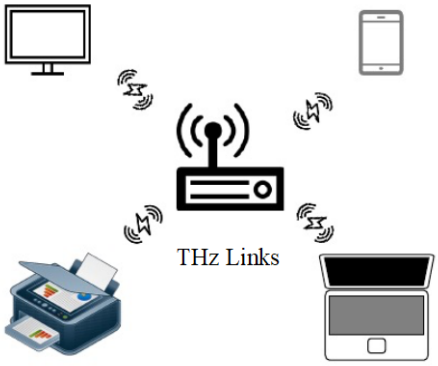

Figure 11 – Terahertz: Wireless Personal area network (WPAN)

THz frequencies can be used to provide transmission solutions in ad-hoc networks and for nomadic users by facilitating connection to access points for example at railway, stations, public buildings, shopping malls, etc. Microscale wireless communication at the THz band can also be used to transmit uncompressed high definition (HD) videos for education, entertainment, telemedicine, as well as security purposes. Kiosk downloading is another example of microscale application at THz frequencies, which offers ultra-high downloads of digital information to users' handheld devices. For instance, advertisement posters in metros, trains or streets can be the front interface for downloading pre-fixed contents such as newly released movie trailers, CDs, books, and magazines.

Wireless data centers are considered another promising application at the microscale. THz links in data centers can be deployed as a parallel technology to cabling, whereas the THz links can be used for the rack to rack or inter-cluster connectivity as shown in figure-12 below.

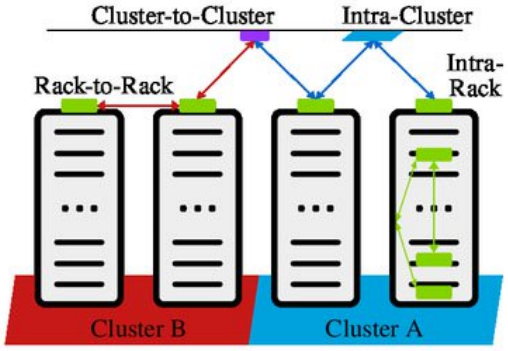

Figure 12 – Terahertz: Data Center Networks (DCN)

Such deployment in data centers results in an enhanced performance experience along with immense savings in cabling and time to deploy. For the optimization of capacity within data centers, a frequent and dynamic reconfiguration of the architecture is required, which is extremely difficult to achieve with fully wired systems. This introduction of ultra-high data rate wireless hops shown in figure-12 above, are considered as an attractive alternative. For wireless hops in a data center, racks are equipped with highly directive steerable antennas on top of the

racks. Connections between different racks are realized by aligning the beams of the corresponding antennas.

5.1.3. Terahertz Macroscale Applications

On a macroscale, THz wireless communication facilitates potential outdoor applications which range from few meters up to kilometers. For example, wireless backhauling/fronthauling is one of the envisioned applications for the standard 100 Gbps transmission solutions. THz links can be used for backhaul for base stations of macro cells especially in the areas where optical fiber is not available. For fronthaul THz point-to-point links can be used to connect the radio controller of a base station and the remote radio head (radio unit). An example of fronthaul application is shown in figure-13 below. The increasing number of mobile and fixed users in both the private, industrial and service sectors will eventually require hundreds of Gbps to be carried either to or between cell towers (backhaul) or between cell towers and remote radio heads (fronthaul).

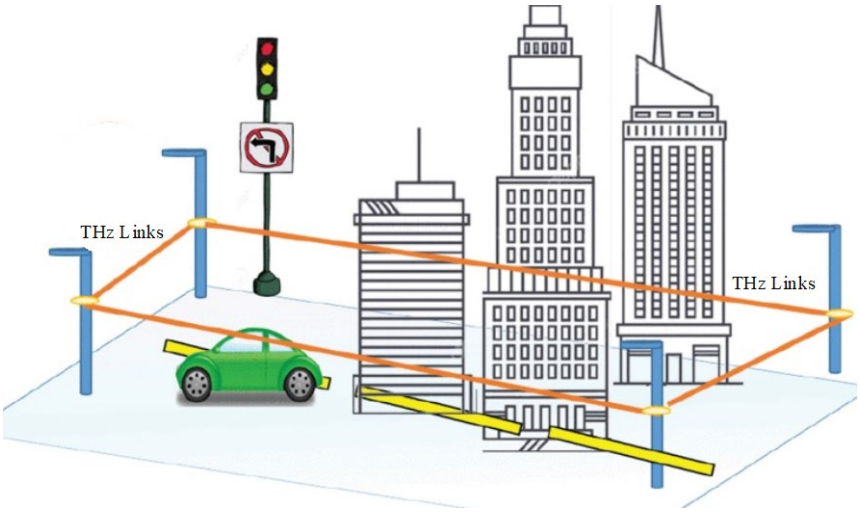

Figure 13 – Terahertz based fronthaul

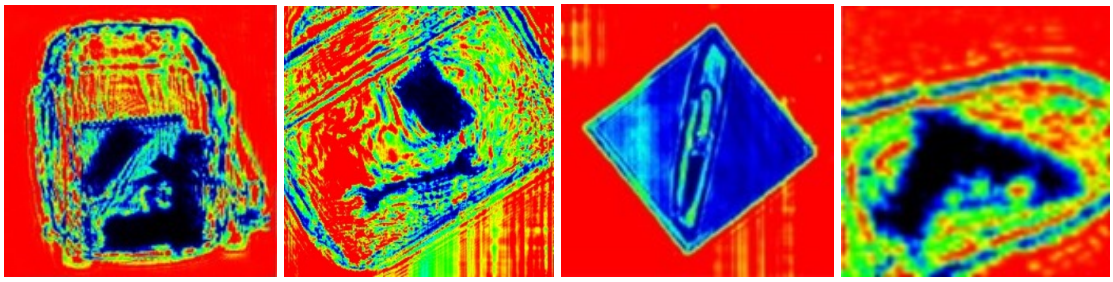
Future advancements which include massive deployment of small cells, implementation of cooperative multipoint transmission and Cloud Radio Access Networks (C-RAN) may increase the required data rates for either fronthauling or backhauling or both. Therefore, fixed links with ultra-high data rates can be utilized for the wireless extension of backbone networks, for the aggregation of multiple backhaul links with lower data rates as well as for the wireless backhaul of future cellular base stations with very high overall throughputs.

Even though the path loss increases with frequency, the antenna gain is related to the square of the operating frequency. Therefore, high gain antennas can cope with the extreme path loss in the THz band. As known, antennas with high operating frequency have relatively narrow beams compared to lower frequencies; hence, THz antennas can be utilized in point-to-point links to backhaul small cells. Moreover, since the antenna size decreases with frequency, it is possible to place a massive number of antennas on small surfaces. For example, it is possible to cover a 1 mm2 area with four antennas at 300 GHz. Beyond massive multiple-input multiple-output (mMIMO), namely ultra-massive (UM-MIMO), can be employed to increase the communication distance as well as the data rate enhancement.

5.2. Terahertz Imaging

Terahertz waves are nonionizing, meaning its photons are not energetic enough to knock electrons off atoms and molecules in human tissue, which could trigger harmful chemical reactions. THz waves can also penetrate a variety of non-conducting, amorphous, and dielectric materials, such as glass, plastic, and wood. These see through and non-ionizing properties makes them a good candidate for imaging application. Due to shorter wavelength compared to microwave radiation, THz waves create higher resolution images as well. Absorption and reflection of terahertz waves are highly material-dependent, and helps in providing the contrast in the images. Some examples of terahertz imaging with see-through capability are shown in figure-14 below. The images demonstrate THz imaging ability to reveal hidden objects.



Hidden Objects (Notebook/gun in a bag, wrench in a bag, knife in a book, gun in a box)

Figure 14 – Terahertz see-through imaging

The applications of THz imaging are endless and have been the key focus of research community. A lot of commercial products are available for industrial inspection, quality control, security scanning, medical imaging etc., for example, to screen for skin cancer and tooth decay. In the future, imaging capability in a reflection mode could be incorporated in smartphones for seeing through packages to detect what is inside without opening them, walls to locate wires and pipes, or decorative pieces to detect air voids and cracks another application for 3D THz imaging is to use it for providing accurate position determination and object detection capability. Terahertz radiation also offers a safe, non-ionizing solution to the problem of screening travelers passing through airports and crossing national borders.

5.3. Terahertz Spectroscopy

Terahertz waves also occupy a unique window of the electromagnetic spectrum where a large number of molecules emit and absorb radiation. The signals produced when a molecule jumps among rotational modes form a unique and highly distinctive chemical fingerprint. These unique fingerprints at terahertz radiation can be used for chemical detectors. As an example, in figure-15 below, unique fingerprints for a drug and explosive are shown.

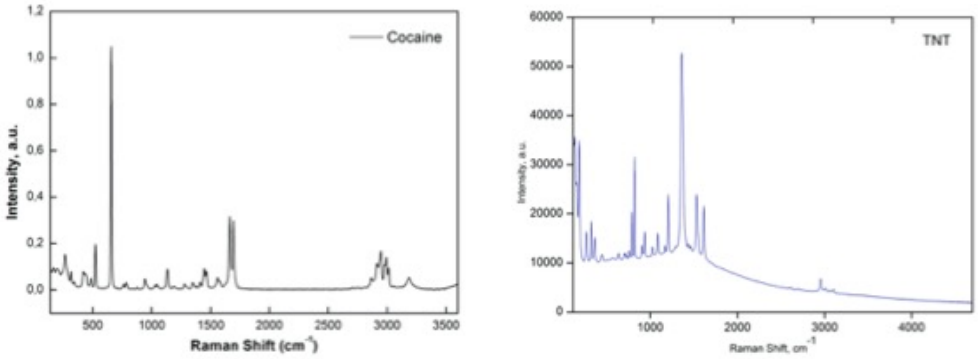


Figure 15 – Terahertz unique chemical fingerprints

Unique chemical fingerprints at THz waves makes them a good candidate for material and gas sensing, for example, environmental monitoring includes detection of pollutants and contaminants to meet the requirements of health and safety, monitoring of atmospheric components for weather and climate observation. Analyzing gases exhaled in human breath is a highly promising application, with the potential for early detection of disease biomarkers. Such detection would be fast and non-invasive, facilitating early diagnosis and state-of-health monitoring. Potential detectable diseases include lung cancer, diabetes, some neurological disorders, and smoking and alcohol consumption. In biochemistry, THz applications have been developed to explore the bioactivity of chemical compounds and identify protein structures.

For security and public safety applications, many explosives (for example, C-4, HMX, RDX and TNT) and illegal drugs (for example, methamphetamine and heroin) have characteristic features in the THz range. In an example (source RIKEN, Japan) below use of THz spectroscopy to inspect a package containing different chemicals has been demonstrated.

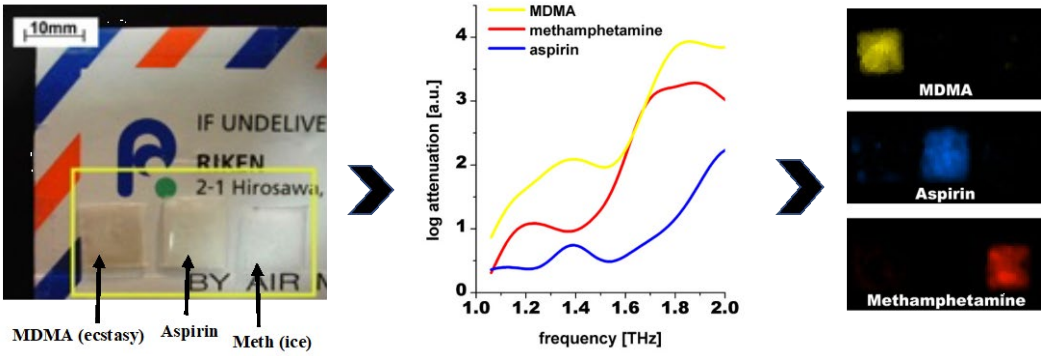

Figure 16 – THz spectroscopy for substance detection

As shown in figure-16, three different substances produce a unique fingerprint which can be used to detect the substance without opening the package. The combination of terahertz imaging and spectroscopy has resulted in a lot of commercially available products for non-destructive testing and new applications are growing every day.

6. Terahertz (THz) Development status

Seamless data transfer, unlimited bandwidth, microsecond latency, and ultra-fast download are all features of the THz technology that is anticipated to revolutionize the telecommunications landscape. These features have resulted in the terahertz band gaining noticeable attention in the global research community. The enthusiasm of the research community is reflected in the increased number of publications issued in the recent years on IEEE, SPIE etc. The potential associated with THz technology has attracted the broader research community. The combined efforts of active research groups are resulting in new designs, materials and fabrication methods that demonstrate endless opportunities for THz development. In table-2 below are some examples of various groups conducting THz research. The list below is a testimony of the focused research in this area being conducted in the laboratories across the globe.

Table 2 – Research Groups Working on Terahertz

Research Group/Lab	Location	R&D Activities
Mittleman Lab at Brown University	USA	THz PHY layer, spectroscopy, THz probes
Broadband Wireless Networking Lab at Georgia Tech	USA	THz PHY and MAC layer, THz Nano-communications, THz devices
NaNoNetworking Center in Catalunya	Spain	THz Nano-communications
Ultra-broadband Nano-Communications Lab at Univ. of Buffalo	USA	THz PHY and MAC layer, THz Nano-communications, THz devices
THz Electronics Lab at UCLA	USA	THz devices, reconfigurable meta-films, spectroscopy
MIT Terahertz Integrated Electronics Group	USA	Sensing, Metrology, security and communication.
Fraunhofer Institute for Applied Solid State Physics	Germany	THz PHY and MAC layer, THz electronics
Terahertz Communication Lab	Germany	Channel investigation and THz reflectors
Core Technology Lab Group NTT Corp	Japan	Terahertz IC and modularization technology
Texas Instrument Kilby Lab	USA	Ultra-Low Power sub-THz CMOS systems
Tonouchi Lab at Osaka Univ.	Japan	THz Nanoscience, THz bio-science, THz bio-sensing and industrial applications
THz Electronics Systems Lab at Korea Univ.	Korea	THz PHY and MAC layer, THz electronics
Nano-communications Center at Tampere Univ. of Technology	Finland	THz PHY layer, THz Nano-communications

Various regulatory and funding agencies have been supporting THz projects and opening up new horizons in communications and devices for deployment beyond 5G technology. The regulatory framework for spectrum above 100 GHz is beginning to take shape, as discussed in the subsequent sections.

6.1. International Telecommunications Union (ITU)

In November World Radiocommunication Conference 2019 (WRC-19) which meets every four years to discuss international radio rules (RRs) and other topics, made 190 GHz (252 to 356 GHz) of spectrum available for THz communication with no specific EESS (Earth Exploration Satellite Services) protection requirements. Before WRC 2019, there were no allocations above 275 GHz. Allocations were made for fixed and mobile communications for in 275-296 GHz, 306-313 GHz, 318-333 GHz and 356-450 GHz bands. Resolution was also made for a study plan for ITU-R for increased sharing above 71 GHz. Bands of interest include 100 - 102 GHz, 116 - 122.25 GHz, 148.5 - 151.5 GHz, 174.8 - 191.8 GHz, 226 - 231.5 GHz and 235 - 238 GHz. This came as a very encouraging news for the worldwide research community focused on THz research.

6.2. Federal Communications Commission (FCC)

The United States, through the Federal Communications Commission's (FCC) Spectrum Horizons First Report and Order, is taking a leadership role in the future of 5G and beyond. As a result of this initiative, the FCC is making more spectrum available. On March 21, 2019, the FCC adopted new rules to encourage development of new communication technologies and expedite the deployment of new services above 95 GHz. As a part FCC 19-19, the FCC opened 95 GHz- 3 THz band for unlicensed and experimental communications under "Spectrum Horizons" program. The FCC made the entire band available for experimental authorizations. In addition, the FCC made a total of 21.2 GHz spectrum available for unlicensed use. As shown in figure-17 below the unlicensed spectrum would span several band segments (116-123 GHz, 174.8-182 GHz, 185- 190 GHz, and 244-246 GHz).

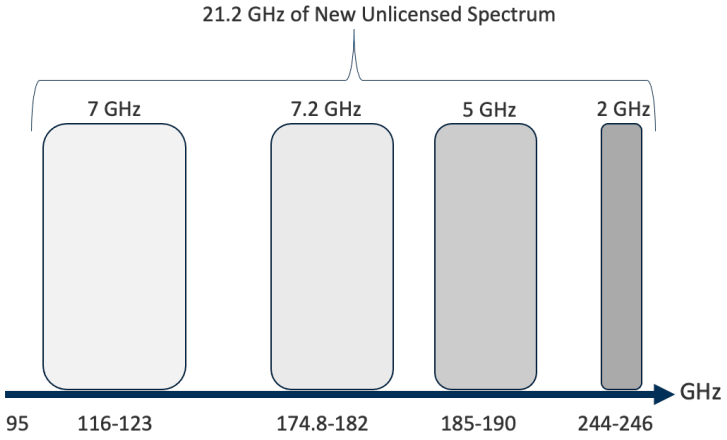

Figure 17 – FCC Spectrum Horizons Initiative: Unlicensed Spectrum

21.2 GHz of new unlicensed spectrum between 95 GHz and 3 THz can be used by devices that do not interfere with existing governmental and scientific operations and that operate within a maximum threshold of average EIRP (Effective Isotropic Radiated Power) of 40 dBm, as stated in the FCC order. This initiative gives researchers, innovators, and entrepreneurs the flexibility to conduct experiments blocks between 95 GHz and 3 THz through experimental licenses lasting up to 10 years. Researchers may also more easily market and demo equipment during the trial period. This will encourage the development of communication technologies and services above

95 GHz, such as data-intensive high-bandwidth applications; wireless cognition; and imaging, positioning, and sensing operations.

6.3. IEEE (Institute of Electrical and Electronics Engineering)

In 2008, the IEEE 802.15 established the 802.15.3d Task Group (Terahertz Interest Group) as a milestone towards investigating the operation in the so called “no man’s land” and specifically for frequency bands up to 3 THz. The new group was tasked to identify THz band communications as a feasible wireless technology for extremely high access rates of up to 100 Gbit/s. The group has worked closely with the International Telecommunication Union (ITU) and the International Radio Amateur Union (IARU) regarding the description of the frequency bands higher than 275 GHz.

The ratification of the IEEE 802.15.3d amendment to 802.15.3, was a significant step towards standardization consumer wireless communications in the sub-THz frequency band. IEEE 802.15.3d offers switched point-to-point connectivity with data rates of 100 Gb/s and higher at distances ranging from tens of centimeters up to a few hundred meters. IEEE approval of channelization standard is considered a major milestone towards THz wireless communication.

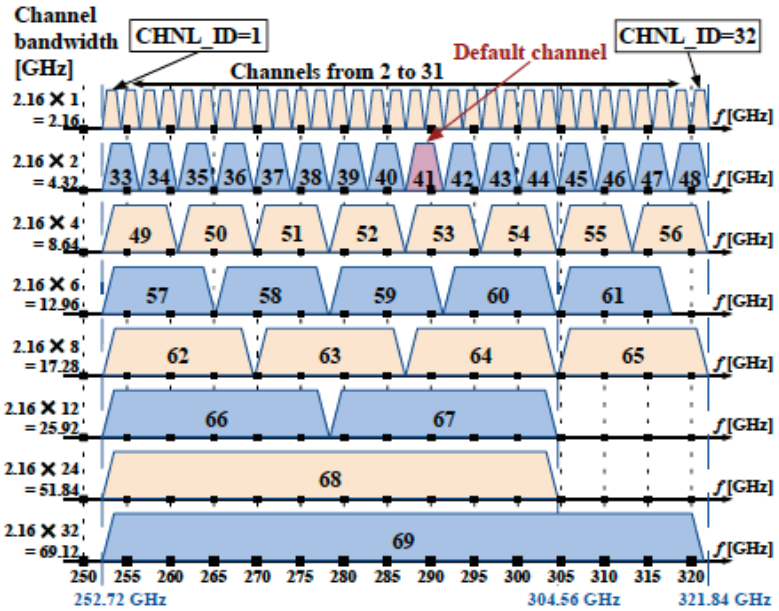

Figure 18 – Bandwidth and channels for IEEE 802.15.3d standard

The major highlights of IEEE 802.15.3d standard are:

- 8 different channel bandwidths (as multiples of 2.16 GHz)
- 2 PHY-modes (THz-SC PHY, THz-OOK-PHY) with 7 modulation schemes: BPSK, QPSK, 8-PSK, 8-APSK, 16-QAM, 64 QAM, OOK
- 3 channel coding schemes: 14/15-rate LDPC (1440,1344), 11/15-rate LDPC (1440,1056), 11/15-rate RS(240,224)-code.

As shown in figure-18 above, IEEE 802.15.3d may operate over the sub-THz frequencies between 252.72 GHz and 321.84 GHz. In total, there are 69 overlapping channels. There are 8 supported channel bandwidths ranging from 2.16 GHz (same as in mmWave IEEE 802.11ad 2012) up to massive 69 GHz channel bandwidth. Depending on the use case and the hardware capabilities, either the entire frequency range can be allocated for a single 69.12-GHz-wide channel (CHNL_ID = 69) or can be shared between several smaller channels. The bandwidths of the channels are integer multiples of 2.16 GHz. The channel number 41 with the bandwidth of 4.32 GHz (2x2.16 GHz) is the default channel.

Following the decision at World Radio Conference 2019 (WRC-2019), all the bands depicted in Figure-18 are available for THz communications globally if specific conditions to protect radio astronomy and earth exploration satellite service (EESS) are met. These conditions do not explicitly specify any transmit power limits and are applicable, in practice, primarily to the narrow areas surrounding the ground radio astronomy stations.

6.4. European Union ICT (Information and Communication Technologies)

There is a sharp increase in recent years in the research funding by European Union, body like Horizon 2020 (H2020). This funding ranges from enhancing research on the device technology to communication aspects including channel, physical, MAC and network layer characterization. The THz band related projects currently funded by H2020 are summarized in the table-3 below. Some of the projects are based on establishing the feasibility of communication windows within Terahertz Gap, for example Ultrawave, Dream, EPIC, and WORTECS.

Table 3 – EU Horizon 2020 Terahertz Related Projects

Project Name	Band	Target Speed	Focus
iBrow	60 GHz-1 THz	10 Gbps	Innovative ultra-broadband ubiquitous wireless communications through THz. Low cost and simple wireless transceiver architecture. Integrated semiconductors emitters and detectors with seamless fiber-wireless links
TERRANOVA	300 GHz	100 Gbps	Tbps wireless connectivity by THz innovative technologies to deliver optical network quality of experience in systems beyond 5G
TERAPOD	300 GHz	100 Gbps	Terahertz based ultra-high bandwidth wireless access networks for data centers
ULTRAWAVE	300 GHz	100 Gbps	High capacity backhaul links to enable 5G cell densification by exploiting bands beyond 100 GHz.
EPIC	-	1 Tbps	Enabling practical wireless Tbps communication with next generation of coding. Develop new FEC (forward error correction) codes for Tbps rates.
DREAM	D-band	100 Gbps	D-band reconfigurable meshed radio solution at 100 Gbps by exploiting radio spectrum bands like 130-174.8 GHz with beam steering functionality to reach optical systems speed.
WORTECS	90 GHz	10 Gbps	Wireless optical radio terabit communication system. Use 90 GHz for proof of concept with Gbps rates.

Project Name	Band	Target Speed	Focus
ThoR	300 GHz	100 Gbps	Front and backhaul solutions at 300 GHz for data rates beyond 5G.
TERAPAN	300 GHz	100 Gbps	Adaptive wireless point-to-point terahertz communication systems for indoor environments for distances of up to 10 m at data rates of up to 100 Gbps
ROOTHz	THz	-	Development of solid state nanodevices at room temperature of THz communications

The project which involves the research on advancing the communication methodologies while considering the MAC layer issues and challenges are TERAPOD, TERANOVA, and ThoR. Their aims and objectives include the device, channel and antenna characterization. They are also focusing on designing a simple and efficient MAC protocol for point to point and multipoint scenarios. However, each project is looking at a specific scenario. For example, the TERAPOD project is aiming to design a communication methodology for a data center environment, which involves potentially the channel, antenna and Physical layer considerations for an indoor environment only. The TERRANOVA on the other hand focuses on the backhaul point to point scenario for outdoor long range environment including small cells. Each scenario requires a different modelling approach for antenna, channel and propagation model and therefore requires different strategies to access the channel to establish communications. Similarly, ThoR is also looking at high speed link upto 100 Gbps over 300 GHz band for backhaul with partial involvement of point to point scenario for MAC layer channel access. These projects have helped creation of new THz devices, communication techniques which will lay new foundations for the rapid development of practical systems.

7. Conclusion

The paper has presented the current status in research, spectrum regulations and standardization activities in the field of THz communications. Though there are challenges developing terahertz products i.e., closing the THz gap by discovering new devices and the THz wall, the inherent high propagation loss caused by atmospheric absorption. Still, the field of THz communications has drastically changed in the last ten years and, what used to be a relatively niche discipline, is now identified as one of the key enablers of the future ultra-broadband networks, 6G and beyond. Major progress has occurred worldwide in the last decade both in terms of materials and devices as well as communication techniques. With these advances, wireless Tbit/s communications and the supporting backhaul network infrastructure are expected to become the main technology trend within the next ten years and beyond. To facilitate this, an unprecedented amount of 160 GHz of the spectrum was recently opened for THz communications after WRC 2019. Moving forward, besides addressing the technical open challenges, the adoption of the THz spectrum for communications needs to be accompanied by supporting spectrum policies that ensure an efficient, fair and secure use of the spectrum by both active (communications) and passive (sensing) users. Based on the recent progress, the commercial introduction of THz communications can be expected in the not-too-distant future and will help coping with the ongoing tremendously increasing demand for wireless data rates.

Abbreviations

5G	5th Generation
BAN	body area network
bps	bits per second
BPSK	binary phase shift keying
C-4	composition-4
CD	compact disc
CMOS	complementary metal oxide semiconductor
C-RAN	Cloud Radio Access Networks
DCN	Data Center Network
EVM	Error Vector Magnitude
FCC	Federal Communications Commission
FD-SOI	fully depleted silicon on insulator
FEC	forward error correction
FSPL	free space path loss
GaAs	Gallium Arsenide
GaN	Gallium Nitride
Gbps	giga bits per second
GHz	gigahertz
HDTV	high-definition television
H2O	chemical formula for water
HMX	high melting explosive
ICT	Information and Communication Technologies
IEEE	Institute of Electrical and Electronics Engineers
ITU	International Telecommunications Union
InP	Indium Phosphide
LO	local oscillator
MAC	medium access control
mHEMT	metamorphic high electron mobility transistor
MMIC	monolithic microwave integrated circuit
mMIMO	massive multiple-input multiple-output
O2	chemical formula for oxygen
OOK	on off keying
QAM	quadrature amplitude modulation
QPSK	quadrature phase shift keying
RDX	royal demolition explosive
RTD	resonant tunneling diode
SCTE	Society of Cable Telecommunications Engineers
SiGe	Silicon Germanium
SNR	signal to noise ratio
SPIE	Society of Photographic Instrumentation Engineers
THz	terahertz
TNT	trinitrotoluene
UM-MIMO	ultra-massive multiple-input multiple-output
WLAN	wireless local area network
WPAN	wireless personal area network
Tbps	terabit per second

The Dennis Botman Story

A Tale of Next-Level Chatops

A Technical Paper prepared for SCTE by

Michael Winslow
Senior Director, Software Development and Engineering
Comcast Corporation
michael_winslow@comcast.com

Ryan Emerle
Senior Principal Engineer
Comcast Corporation
ryan_emerle@comcast.com

Mia Kuang
Software Engineer
Comcast Corporation
mia_kuang@comcast.com

1. Introduction

What do you do when you have an amazing team and you want to make them even better? The 1995 Chicago Bulls added Dennis Rodman. Well, our team at Comcast created Dennis BOT-man: An automated Chatops bot that helped us re-imagine how we support our internal engineering teams.

1.1. What is Chatops?

ChatOps is a collaboration model that connects people, tools, process, and automation into a transparent workflow (see Figure 1). With our Chatbot, Dennis Botman, we've taken an iterative approach to add functionality over time. As we will get into later in the paper, our primary objective is to connect people with knowledge resources like frequently asked questions FAQs and how-to documentation.

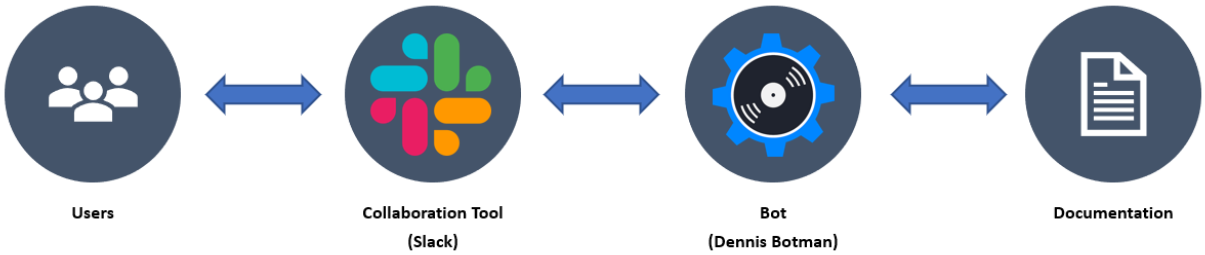

Figure 1 - Typical Chatops flow for Dennis Botman

1.2. Why do we need Chatops?

To understand why we needed this level of automation, it helps to know the scale of the application we support.

Comcast's open-source domain name system (DNS) management tool, VinylDNS, allows millions of DNS entries to be controlled by hundreds of individual groups throughout the company (Cleary, 2020). This decentralized governance model is a marvel on its own. One software developer, Stephanie Hingtgen, described her team's usage of VinylDNS in the following way:

> *"We leverage the VinylDNS system to instantly provision A and AAAA records for all new VIPs in our zone, as well as giving the user the ability to provision CNAME records. This was crucial for rolling out IPv6 VIPs in RDEI (Rapidly Deployed Elastic Infrastructure) so that users would have an easy way of remembering their VIP name."*

To ensure the reliability of this critical application, our group adopted a DevOps[1] model where our software engineers rotated to support the product. The primary means by which to engage our support team was by asking questions in our Slack support channel.

Before long, our support channel was filled with questions from our users; many of which were already answered in our support documentation. Valuable time that our engineers could have been spending developing new software and features were instead spent repeatedly answering the same basic questions. Something had to be done.

[1] DevOps is the combination of cultural philosophies, practices, and tools that increases an organization's ability to deliver applications and services at high velocity

In this paper, we'll tell the story of how we coded and delivered Dennis Botman to be a true member of the support team. We'll explain how Dennis Botman was able to answer over 35% of the questions being asked in our support channel. We will show how adding powerful tooling within the bot allowed engineers all over the company to solve DNS issues instantly. And perhaps most fascinating, we will use metrics to demonstrate how our support bot empowered our users by arming them with a self-service mindset.

After reading this paper, if your team would like to take advantage of the features we developed in Dennis Botman, feel free to visit our open-source project on Github: https://github.com/vinyldns/vinyldns-bot

2. Problem Statement

2.1. Small Team Supporting a Large Organization

The world of DNS is massive. Everything that is on the internet, from servers to automated teller machines (ATM) machines to your smartphone, are all addressable by internet protocol (IP) addresses which are often mapped to DNS records.

When tasked with managing millions of these records, which service hundreds of teams throughout Comcast, we set out to build a service to enable users to manage their own records. Born out of the necessity to reduce time-to-market, VinylDNS is the user-facing service we created that enables self-service for DNS.

What happens when thousands of users across hundreds of organizations suddenly have access to DNS records and the inherent complexity therein? They're going to have questions and they're going to need answers.

Suddenly, what was once a utopian dream of a self-sufficient, self-service, tool becomes a conduit to an influx of support requests. This deluge of questions simply shifted the burden and complexity of DNS management from the DNS engineering team to the VinylDNS service team.

Quickly we were scrambling to extricate ourselves from the critical path of thousands of users. To do so, we needed to find ways to offload our support personnel while still getting answers to the users and getting DNS records provisioned.

2.2. Customers Do Not Read Documentation

One of the quickest and easiest ways to get answers for users was to thoroughly document the service. With VinylDNS, the service and its corresponding APIs and tooling were all thoroughly documented before even being released to users.

Documentation of every aspect of the system was written. Reams of documentation detailed every nuance of the service and its corresponding user interface. Months of writing and revising lead to a thorough reference of the system and its behavior.

The problem? Users unfortunately do not tend to read documentation. This isn't because users are lazy, or unwilling; they simply have more important problems to solve. As authors of a user-facing service, we cannot assume that we are the center of our users' universe. Our service is likely a small part of the

overall problem being solved, and as such we cannot expect thousands of users to take several hours to pore over reams of documentation.

2.3. Providing Real-Time Support

In order to overcome this tendency to ignore the documentation, we needed to provide a means by which users could be directed to the subset of documentation that addresses their questions.

A logical next step was to provide real-time support. This entailed creating a channel in Slack where users could come and ask questions. The channel would be staffed by VinylDNS engineers who would help users get to their answers.

Upon establishing real-time support, the support personnel were inundated with questions. Among these were a set of questions that kept appearing. As such, the natural next step was to distill some of the documentation down into FAQs. The FAQs provided more direct answers and saved the users and support personnel time sifting through documentation.

While creating FAQs helped to reduce the influx of support questions, a pattern started to emerge. Users would come to the support channel, ask a question, and then a support person would find the relevant FAQ, copy the link, and paste it into the support channel as a response.

During this period, there were three to four engineers spending upwards of thirty percent of their time answering questions, searching the documentation on behalf of users, and pasting FAQ links into the support channel.

2.4. Providing After-Hours Support

Our team monitored our Slack support channel for one week and discovered that 13% of the questions from our customers happened after hours. There is no guarantee that a chatbot would solve their problems, but our customers would have more options when our engineers are not available. A simple reminder of our on-call hours is better than no response at all.

2.5. Is Automation the Answer?

It soon became clear that the repetitive nature of the real-time support that was being offered was untenable. We had engineers whose time is better spent improving the product than acting as glorified search engines.

When faced with repetitive tasks, there is a tendency toward automation. As engineers, we evaluated the landscape and began to consider how we might automate the repetitive task of searching documentation, copying links, and pasting them into the support channel.

The cost of automation is not free, however, so we needed to estimate the return-on-investment (ROI) for the automation.

The general formula for ROI *(Fernando, 2021)* is:

$$ROI = \frac{Net\ Value\ of\ Investment}{Cost\ of\ Investment} \times 100\%$$

In the case of automation, our value and cost parameters are in units of time. As such, we can restructure the equation as follows:

$$ROI = \frac{Time\ Saved - Time\ Spent}{Time\ Spent} \times 100\%$$

This simple formula can be a bit deceiving, as Time Spent needs to include the initial time to build the automation plus all future time spent maintaining it. Similarly, Time Saved is also cumulative. Further, determining, or predicting, Time Saved can be challenging. In this case, we're focused on the estimated time saved by the predicted reduction in time spent on support duties. Time saved by reduction in human error, training personnel and other factors are not being considered.

For the purposes of calculating a value, we can limit the ROI projections and calculation to a discrete time period. For the following example, we limit the calculation to one year.

Assume we have three engineers spending 30% of their time supporting users. Given a 40-hour work week, we can calculate the support cost, in time, for a single week:

$$Support\ Cost_{week} = 3\ engineers \times (40\ hours\ \times 30\%)$$
$$Support\ Cost_{week} = 3\ engineers \times\ 12\ hours$$
$$Support\ Cost_{week} = 36\ hours$$

Let's assume that we can implement some automation in four weeks at 40 hours per week.

$$Automation\ Cost_{total} = 4\ weeks\ \times 40\ hours$$
$$Automation\ Cost_{total} = 160\ hours$$

Let's further assume that our analysis indicates that the automation is projected to save 25% of our support personnel's total time.

$$Automation\ Savings_{week} = Support\ Cost_{week} \times 25\%$$
$$Automation\ Savings_{week} = 36\ hours \times 25\%$$
$$Automation\ Savings_{week} = 9\ hours$$

If our cost of automation is a total of 160 hours, then we can calculate the ROI for a year:

$$ROI_{year} = \frac{(Automation\ Savings_{week} \times 52\ weeks) - Automation\ Cost_{total}}{Automation\ Cost_{total}} \times 100\%$$

$$ROI_{year} = \frac{(9\ hours\ \times 52\ weeks) - 160\ hours}{160\ hours} \times 100\%$$

$$ROI_{year} = \frac{468\ hours - 160\ hours}{160\ hours} \times 100\%$$

$$ROI_{year} = \frac{308\ hours}{160\ hours} \times 100\%$$

$$ROI_{year} \approx 192\%$$

The resulting calculation shows that if we invest 160 hours in automation to recover 25% of the time spent performing support activities, we'll see a projected return of 192%. For every hour spent automating, 192% of that time is returned as time saved over a one-year period.

3. Getting Started Getting Started

3.1. To Build or to Buy

With an estimated ROI of 192%, we were confident that we were going to take steps toward automation. But before deciding to invest our engineering time to creating a custom chatbot for our internal customer base, we did some initial research on the costs of purchasing a solution. We found that adopting a chatbot service can possibly get quite costly.

According to mobilemonkey.com (MobileMonkey, 2021), once you factor in the cost of the platform along with the salary related costs for setup, development, and maintenance, you could be paying over $60k in the first year alone.

Table 1 - Estimated cost for a chatbot paid solution

	In-House Chatbot Costs	Agency Chatbot Fees
Chatbot Software Platform	$50-$500/month	$50-$500/month
Chatbot Setup and Development	Salaries (5-100 hours of work)	$500-$2,500
Ongoing chatbot support and maintenance	Salaries (0-10 hours of work per week)	$50-$5000/month

We decided it would be better to develop our own bot using opensource solutions and allowing our engineers to solve our specific problems. We chose to start with the Github's Hubot Framework (Metz, 2015) which is written in CoffeeScript and node.js. Hubot handles basic chat communication, which saved us a lot of time. But we required much more intelligence built into our bot if it was going to be useful. We would need to extend the functionality of Hubot, but by how much?

3.2. The "Big Ideas" Phase

During our initial brainstorming sessions, one thing that the team insisted was that the bot should be conversational rather than a glorified command line interface (CLI). This aspect did cause some team members to really think BIG:

- "We need to learn natural language processing / understanding (NLP/NLU)."
- "We cannot do this without artificial intelligence."
- "Machine learning is essential."

After several meetings that appeared to get us no closer to a starting point, the team began to lose interest. It was starting to feel like this task was simply too large an undertaking. As discussed in section 2.5 (Is Automation the Answer?), there just did not seem to be enough value to justify this level of effort.

Our problem was that we were trying to design the perfect system right from the planning phase. The sheer size and complexity of the solution we were proposing was putting us in a state of analysis paralysis. We would either need to narrow our scope or scrap the idea all-together.

3.3. Perfect is the Enemy of Good

Anyone who has ever read Stephen R. Covey's best-selling book **7** Habits of Highly Effective People (Covey, 1989) will tell you that to "begin with the end in mind" is critical. But be careful not to misconstrue this message with the idea that everything must be known and understood before beginning work on a software project. There are so many benefits to be had by taking an iterative approach.

In a 2019 article published by Forbes on the topic of Machine Learning projects, they state that "87% of projects do not get past the experiment phase and so never make it into production" (Dans, 2019). This is because software development teams far too often attempt to "boil the ocean" rather than identifying bite-sized chunks of functionality to deliver fast. It is better to have a product mindset and get users to begin interacting with your software in order to give valuable feedback.

If we wanted to be a part of the 13% of projects that actually see production, we were going to have to focus on the core problem we are trying to solve. We decided to clearly state our purpose and simplify our initial feature set. Once we were able to agree on a small set of essential requirements, Dennis Botman was ready to come to life!

4. Dennis Botman is Born / How it works

4.1. Initial Feature Set

We decided on the following technical requirements:

- The bot will be available in 0..n Slack support channels
- The bot can accept free text "interactions" as well as exact-match "commands"
- The bot can respond with answers to FAQs
- The bot can respond with links to support documentation and real-time dashboards
- Users can have direct message (DM) conversations with the bot
- The bot MUST log all interactions with the bot (to improve support)

A high-level design of our implementation is shown in Figure 2.

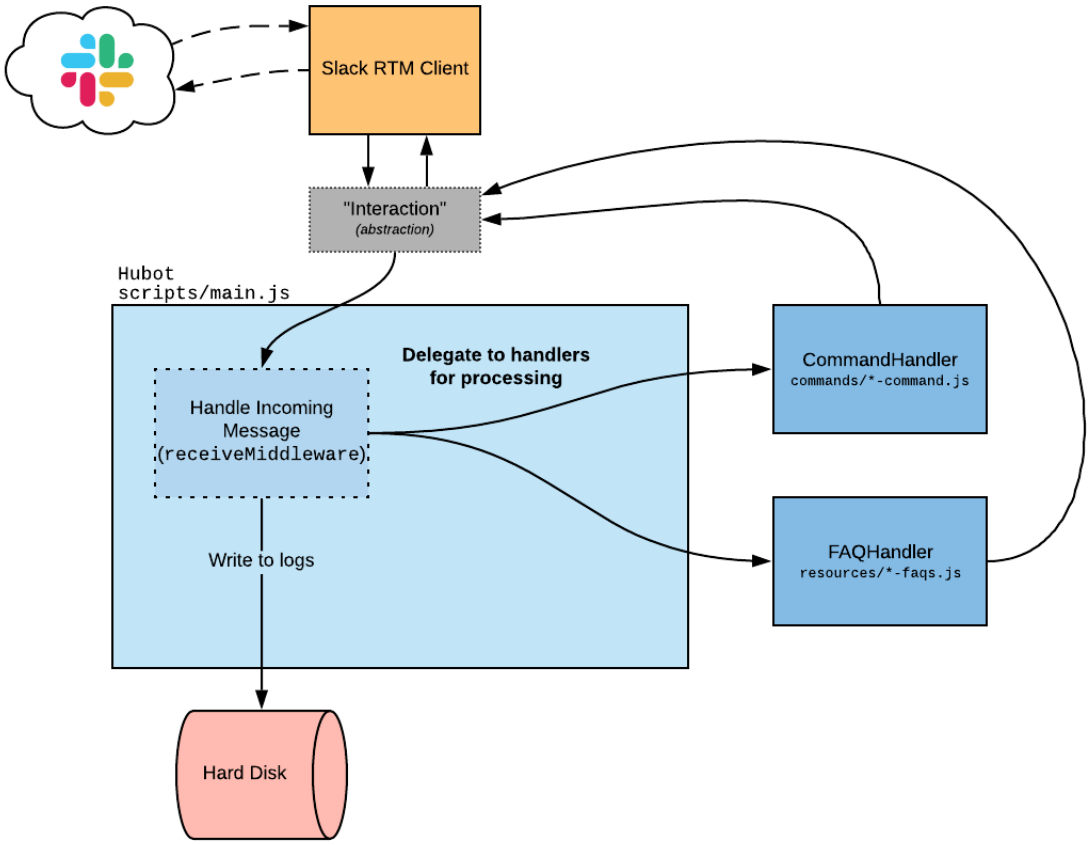

Figure 2 - Vinyldns-bot high level design

4.2. Basic Interaction (FAQs)

Figure 3 shows a common example of a user interacting with Dennis Botman.

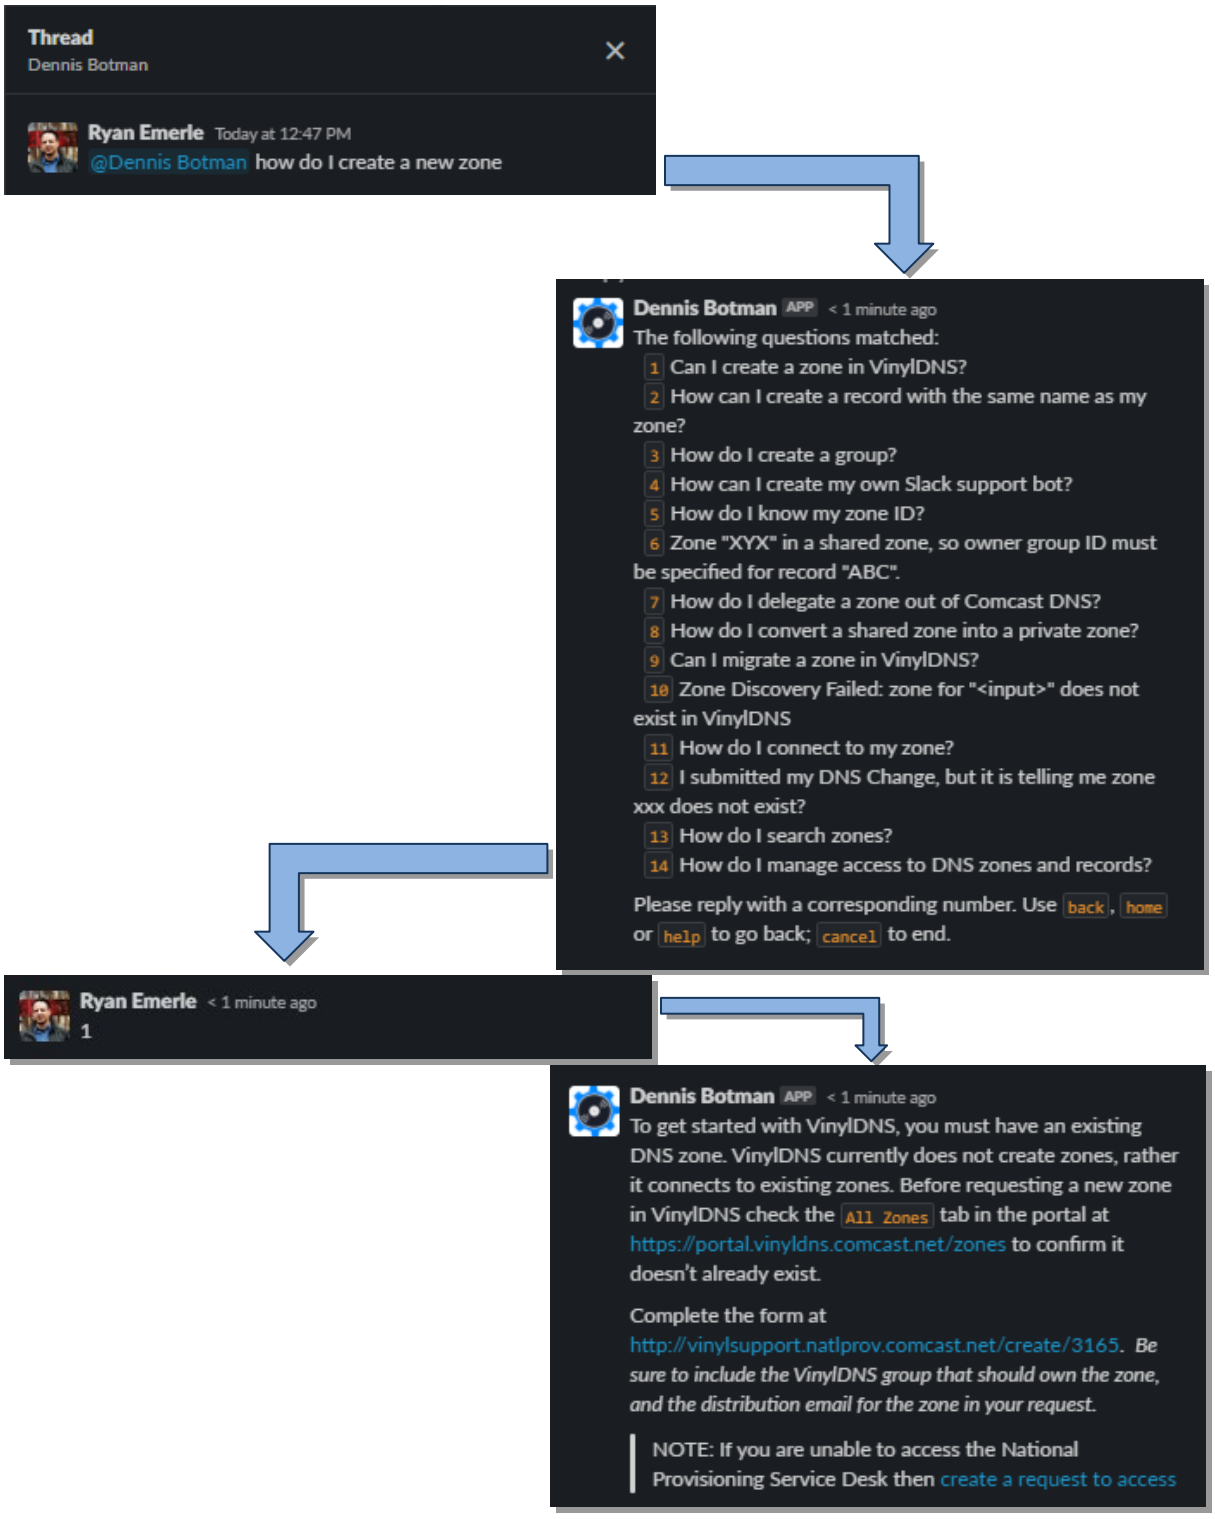

Figure 3 - Basic Dennis Botman conversation

4.3. Pre-Processing Text/Questions From Users

Users can interact with Dennis Botman by asking any question via direct messaging or in a Slack channel. Dennis Botman can process a user's question by searching through a set of FAQs files and return a subset of matched questions.

While the Hubot Framework handles the directing of traffic between the user and the bot, we still had to program the logic in determining how the incoming questions were processed. To do this, we utilized some common techniques around "Text Cleaning" and "Pre-Processing."

The bot pre-processes a user's input and extracts meaningful words. Then it performs the search for matching words from all the FAQs in the repository. Any FAQ that has one word or more matched is a candidate. Each FAQ is presented as a question form itself, with hidden extra terms that can be used to match with user input, and exclusion terms to be removed from the search. Depending on the number of matched questions, the number of matched meaningful words in each question, and the configured limit for number of results, the search will return a list of FAQs in a specific ranked order. If there is only a single match, the response to that FAQ will be provided directly. If there are multiple possible matches, the user will be prompted to choose from them using an enumerated response.

Using the example question from above, let's step through how Dennis Botman interprets the input:

Starting String:

"How do I create a new zone?"

Step 1: Convert text to lowercase

Converting all the incoming request text to lowercase allows us to do exact string comparisons against our library of FAQs given that we also convert the library to lowercase strings.

- result: *"how do i create a new zone?"*

Step 2: Remove unwanted characters

Special characters and punctuation can cause our results to be inaccurate. It helps to scrub the incoming text of any characters that may be troublesome.

- result: *"how do i create a new zone"*

Step 3: Remove stop words

Stop words are words which are filtered out before or after processing of natural language data (text). Words like "a", "do", and "is" are considered "stop words." We maintain our own list of stop words to increase our chances of getting a high-confidence result to our text search.

- result: *"create new zone"*

Step 4: Tokenization

Tokenization (in lexical analysis) is the process of demarcating and possibly classifying sections of a string of input characters. In other words, we separate each word in our string so that they may be used individually. This will help create the word match count needed for the final step.

- result: [*"create", "new", "zone"*]

Step 5: Ranking

By counting the number of matches that we have of our tokenized words within our library of FAQs, we can rank the confidence of our results. You can clearly see why the most relevant results appear highest in our list.

- "Can I **create** a **zone** in vinyldns?" – (2 matches)
- "How can I **create** a record with the same name as my **zone**?" – (2 matches)
- "How do I **create** a group?" – (1 match)

5. Increasing the Usage of the Bot

5.1. Roadshows and Reminders

In order to realize the benefit of our investment of time into creating a bot to automate support of the VinylDNS service, we need our users to engage with the bot. Not only must users engage with the bot, but they must also be able to get the answers they're looking for, so that they do not require human intervention.

The first step in increasing engagement is a logical one – tell the users that the bot exists. After initial development of the bot, the VinylDNS team found opportunities to speak at internal conferences in order to raise awareness across organizations. Through technical conferences and demonstrations, we were able to promote the existence of the bot and its many benefits.

While we evangelized the bot across multiple organizations, we also needed to bring attention to the bot where support was happening – in our Slack channel. To do so, we tackled the low-hanging fruit first. We simply added details about the bot in the channel topic. The channel topic is the place where users can find information about the channel and the various resources offered.

While include the bot in the channel topic was essential, it did not draw immediate attention to the bot. So, in order to supplement this, we added a daily "message of the day." This is a message that is posted to the support channel every morning. The message is posted by the bot itself and it details the existence of the bot, how to use it, and other details about the support channel.

With the addition of the "message of the day" we saw a marked increase in bot interaction. However, on occasion, the message of the day would be scrolled out of view by support discussions. As such, we also added a notification for all users who first join the support channel. Upon joining, new users receive a message detailing the existence of the bot and how to interact with it to get answers.

5.2. One-on-One Conversations with the Bot

After making a concerted effort to promote the existence of the bot, we needed to find ways to encourage users to interact with it.

First, we wanted to reduce the anxiety of users experimenting with a bot in a Slack channel with over 1,000 users. As such, one of the first features we added was the ability to DM the bot. This allowed users to interact with the bot in a private channel, independent of the main support channel. All the functionality remains the same; the only difference is that the experimentation is not broadcast to the wider community.

5.3. Using the Bot as a Proxy

As Albert Einstein once said, "[E]xample isn't another way to teach, it is the only way to teach." With that in mind, we wanted to encourage usage of the bot by interacting with it ourselves. To do this, instead of copy-and-pasting links to FAQs on our documentation website, we issued commands to the bot on behalf of the user.

To further extend this concept, we added a special command: "for <user>". This allows support personnel to issue commands on behalf of another user but establish a dialog between the bot and that user (see Figure 4).

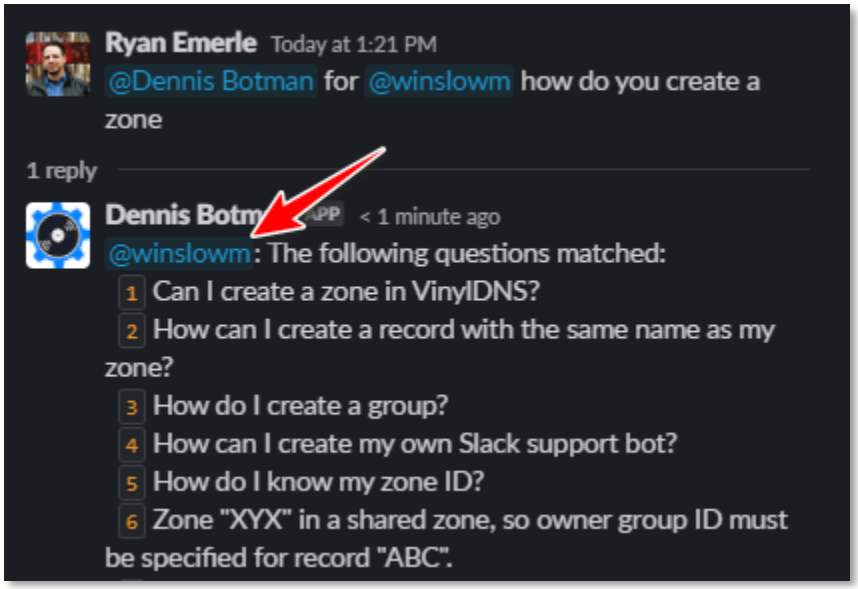

Figure 4 - Creating a dialog between Dennis Botman and a third party

5.4. Letting the Bot be the Bad Guy (Unsolicited Responses)

This feature was the result of collaboration with engineers in other groups, namely the groups that manage the DNS servers. One issue that they identified is that users would often create a support ticket for some DNS change, then immediately go to the real-time support channel and ask about the status.

In order to reduce the need for human intervention when a ticket was already created, we introduced the concept of "unsolicited messages". Unsolicited messages are messages sent by the bot that are not the result of a user interaction with the bot. As an example, a user might come to the support channel and say, "I created a ticket XYZ-123, can someone take a look?" The bot uses pattern matching to detect the presence of a ticket number, and automatically responds to the requestor with a message letting them

know that the ticket will be addressed in the order in which it was received and no further action is required on their part.

5.5. Keeping Our Engineers Involved

Once user engagement began to increase, we found additional opportunities to add functionality. Instead of simply providing answers to questions, the bot could also retrieve data from external sources in order to answers questions.

Keeping engineers involved in the automation of support activities was the key to making the bot more useful and, as a result, better equipped to resolve user questions without human intervention.

An example is the addition of a “lookup” command. This command queries the DNS backend servers to return record resolution details back to the user (see Figure 5). This is in lieu of asking the user to use cryptic command line utilities to query DNS resolvers. In the case of “lookup,” the user could simply message the bot “lookup <FQDN>” (where FQDN is a fully qualified domain name; e.g., “lookup www.comcast.com”). The result is a human-readable DNS lookup.

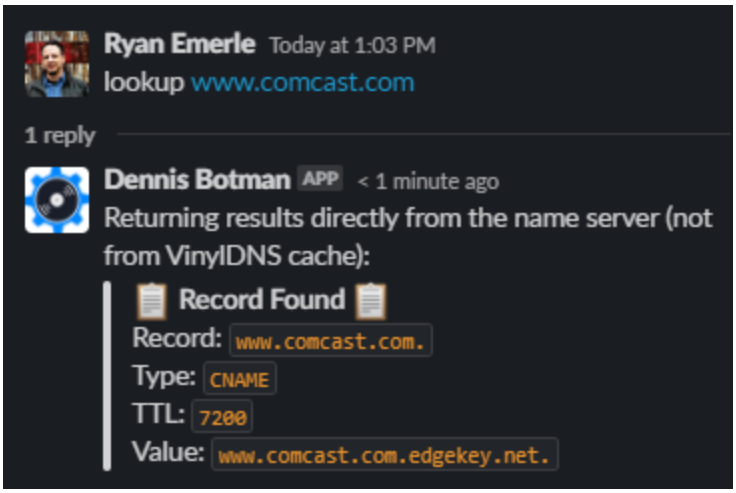

Figure 5 - An example of the “lookup” command

Similar types of commands were added that increased the utility of the bot and reduced the prerequisites required of users trying to interact the DNS services.

Engagement with a wider community proved to be invaluable. Through collaboration with engineers across multiple organizations we were able to significantly increase the ability for users to get to answers more quickly.

Seeing the power of collaboration in action, and given that VinylDNS is an open-source project, we open-sourced the VinylDNS bot code as well. Through greater exposure we hope to evolve the project to meet the needs of larger and more diverse audiences.

6. Observing the Lasting Effects

6.1. Overview of the Data

Determining the impact of our conversational chatbot would require us to log every interaction. This enables us to compare the number of times our internal customers were able to get the answers they needed without requiring human involvement. In addition to being able to put these results into buckets of human versus bot support, we were also able to determine exactly how our customer prefer to interact with the bot (see Figure 6).

The following results were over a 30-day period:

- 711 total interactions
- 347 interactions with the bot
- 260 of those were direct messages
- **7** of those were unsolicited

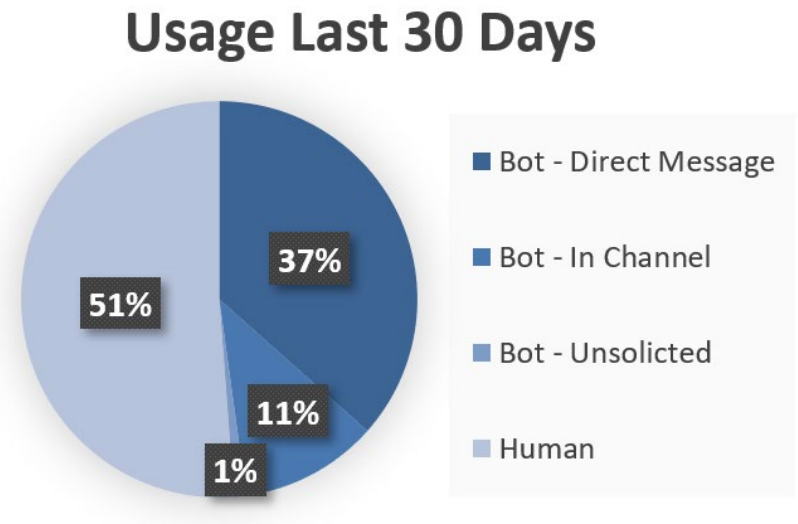

Figure 6 - VinylDNS Support Channel Interactions

According to our findings, total bot interaction was at 49% as opposed to 51% interactions with humans. This number alone does not tell us if our users were able to get to the answers they were looking for with each bot interaction. So we did a little more research.

By reviewing the users and time stamps associated with the 347 interactions with the bot, we investigated how many times those users subsequently returned to the support channel to get answers from a human. We found that 271 (78%) of those interactions required no human follow-up.

6.2. Re-calculating ROI based on real numbers

Automation Cost: Our initial time spent to develop Dennis Botman was approximately three weeks of one full-time engineer and one part-time engineer. It should be noted that we do spend small amounts of time on a continual basis to maintain the bot, but our initial time invested was less than a month.

1.5 engineers x 40 hours x 3 weeks = 180 hours of initial Automation Cost

Automation Saving: Using the statistics we gathered from the logs, we can replace our assumed time savings (25%) with the actual time savings we've observed from actual interactions with Dennis Botman.

271 bot handled requests (no human) / 711 total interactions = 38% Automation Saving

If our Support Cost remains constant at 36 hours and we multiply that by 38% instead of 25%, we get the following:

$$Automation\ Savings_{week} = 36\ hours \times 38\%$$
$$Automation\ Savings_{week} = 14\ hours$$

If our cost of automation is a total of 180 hours, then we can calculate the ROI for a year:

$$ROI_{year} = \frac{(Automation\ Savings_{week} \times 52\ weeks) - Automation\ Cost_{total}}{Automation\ Cost_{total}} \times 100\%$$

$$ROI_{year} = \frac{(14\ hours\ \times 52\ weeks) - 180\ hours}{180\ hours} \times 100\%$$

$$ROI_{year} = \frac{728\ hours - 180\ hours}{180\ hours} \times 100\%$$

$$ROI_{year} = \frac{548\ hours}{180\ hours} \times 100\%$$

$$ROI_{year} \approx 304\%$$

7. Conclusion

Software engineers solve some of the most complex problems for our customers every day to improve their product experience. Far too often, we do not use those same skills to solve our own problems to make our engineering experience more enjoyable and productive. We simply accept that tasks like on-call support, status reporting, deployments, and testing are things that have to be done manually in addition to our development tasks.
